A. Small vessels only
1. Erythema multiforme 2. Pityriasis lichenoides et varioliformis acuta (PLEVA) 3. Pigmented purpuric eruptions (especially pigmented purpuric lichenoid dermatitis of Gougerot and Blum) 4. Hypergammaglobulinemic purpura of Waldenström (although some lesions have histologic evidence of leukocytoclastic vasculitis)
Classic target lesion (usually erythema multiforme, but can be small vessel vasculitis, especially IgA-associated)

Table 22.4 Palpable purpura: inflammatory purpura with prominent early erythema. HSP, Henoch–Schönlein purpura; LE, lupus erythematosus; RA, rheumatoid arthritis.

DIFFERENTIAL DIAGNOSIS OF NON-INFLAMMATORY RETIFORM PURPURA
PATHOPHYSIOLOGY: OCCLUSION PRIMARILY DUE TO MICROVASCULAR PLATELET PLUGS
Major etiologies*
1. Heparin necrosis 2. Thrombocytosis secondary to myeloproliferative disorders 3. Paroxysmal nocturnal hemoglobinuria 4. Thrombotic thrombocytopenic purpura (though platelet plugs form primarily in visceral vessels, and skin hemorrhage is due more often to thrombocytopenia)
PATHOPHYSIOLOGY: COLD-RELATED GELLING OR AGGLUTINATION
Major etiologies*
1. Cryoglobulinemia, monoclonal (early lesions of mixed cryoglobulinemia are often inflammatory and leukocytoclastic due to immune complex deposition) 2. Cryofibrinogenemia (though most cryofibrinogens are incidental findings in hospitalized patients) 3. Cold agglutinins (rarely cause occlusion; usually cause hemolysis or are asymptomatic)
PATHOPHYSIOLOGY: OCCLUSION DUE TO ORGANISMS GROWING IN VESSELS
Major etiologies*
1. Vessel-invasive fungi (e.g. *Mucor* spp., *Aspergillus* spp.; usually in immunocompromised patients) 2. Ecthyma gangrenosum (often *Pseudomonas* spp. or other Gram-negative bacilli proliferating in adventitia of subcutaneous arterioles) 3. Disseminated strongyloidiasis
PATHOPHYSIOLOGY: SYSTEMIC ALTERATION IN CONTROL OF COAGULATION
Major etiologies*
1. Protein C- and S-related a. Homozygous protein C or protein S deficiency b. Acquired protein C deficiency (some patients with sepsis-associated DIC) c. Coumadin®/warfarin necrosis (protein C dysfunction) d. Post-infectious purpura fulminans (protein S dysfunction) 2. Antiphospholipid antibody, lupus anticoagulant
PATHOPHYSIOLOGY: VASCULAR COAGULOPATHY
1. Livedoid vasculopathy/atrophie blanche (may also have a systemic prothrombotic component) 2. Malignant atrophic papulosis/Degos' disease (antiphospholipid antibody syndrome can mimic this disease) 3. Sneddon syndrome (in most patients it is related to antiphospholipid antibody syndrome)
PATHOPHYSIOLOGY: EMBOLIZATION OR CRYSTAL DEPOSITION
Major etiologies*
1. Cholesterol emboli 2. Oxalate crystal deposition (rare) 3. Marantic endocarditis, atrial myxoma, crystal globulins, hypereosinophilic syndrome (all rare)
PATHOPHYSIOLOGY: RETICULOCYTE, RED BLOOD CELL OCCLUSION
High reticulocyte states
1. Sickle cell disease; occlusion worsened by red cell sickling 2. Other severe hemolytic anemias 3. Severe malaria (vWF strands, platelets, RBCs)
PATHOPHYSIOLOGY: MISCELLANEOUS
1. Cutaneous calciphylaxis 2. Brown recluse (*Loxosceles*) spider bite reaction 3. Intravascular B-cell lymphoma (see Ch. 23)
*Partial list.

Table 22.5 Differential diagnosis of non-inflammatory retiform purpura. DIC, disseminated intravascular coagulation; RBC, red blood cell; vWF, von Willebrand factor.

DIFFERENTIAL DIAGNOSIS OF INFLAMMATORY RETIFORM PURPURA
VASCULITIS
A. Primarily dermal vessels 1. IgA vasculitis B. Dermal and subcutaneous vessels usually involved 1. Mixed cryoglobulinemia 2. Rheumatic vasculitides (LE, RA) 3. Polyarteritis nodosa 4. Microscopic polyangiitis 5. Wegener's granulomatosis 6. Churg–Strauss syndrome
DERMAL VESSEL INFLAMMATION/OCCLUSION/CONSTRICTION
A. Livedoid vasculopathy B. Septic vasculitis C. Chilblains (pernio) D. Pyoderma gangrenosum

Table 22.6 Differential diagnosis of inflammatory retiform purpura. LE, lupus erythematosus; RA, rheumatoid arthritis.

neutralize thrombin as well as factors IXa, Xa and XIIa; this process is greatly enhanced by heparin sulfate or heparin binding to ATIII. However, the factor IXa produced during initiation is not inhibited by TFPI and is only slowly bound by ATIII.

The *thrombomodulin/protein C/protein S* system is the other major natural anticoagulant pathway. While both ATIII and protein C pathways are important in large vessels, the protein C system seems to be more critical for normal function of the microvasculature. Thrombin that escapes the clot site can bind to thrombomodulin on the endothelial cell surface. Once bound to thrombomodulin, thrombin loses its ability to activate procoagulant factors, and instead avidly binds and activates protein C, a vitamin K-dependent anticoagulant protein. The anticoagulant function of activated protein C is enhanced by its binding to a phospholipid surface as well as a high-density lipoprotein (HDL) and protein S (another vitamin K-dependent anticoagulant). This complex then inactivates factors Va and VIIIa. The factor V Leiden mutation results in a single amino acid change at the site of cleavage by activated protein C, and this change renders it much more resistant to inactivation.

The prothrombin 20210A mutation is a polymorphism located at the polyadenylation site in the 3′ untranslated region of the prothrombin gene that does not affect the final structure of prothrombin. However, it increases the levels of prothrombin, leading to a prothrombotic tendency in some patients.

Overlap of Coagulation and Inflammatory Vessel Disease

Hemostasis is one aspect of the host response to injury. It is clear that inflammatory injury can lead to fibrin deposition in vessels, as exemplified by fibrinoid necrosis in vasculitis (see Fig. 22.3). Conversely, coagulation factors may play an important role in inflammatory responses and wound healing[2,6]. It can be argued that the vertebrate coagulation system is an extension of the innate immune response system observed in the living fossil the horseshoe crab[7]. In this arthropod, 99% of the circulating cells are hematocytes that express pathogen-recognition receptors; upon activation, these cells release multiple proteins with both clotting and complement-like functions which localize and immobilize invading pathogens. The serine proteases involved in blood clotting in vertebrates appear to have diverged from primitive complement precursors, providing a link between the inflammatory and coagulant pathways.

Thrombin not only is a procoagulant factor, but it also can act to promote monocyte, fibroblast and endothelial cell migration into an area of recent injury in order to begin removal of damaged tissue and wound repair. Thrombin bound to thrombomodulin activates protein C, which (in addition to its potent anticoagulant action) also appears to have important anti-inflammatory properties. Of note, administration of activated protein C has been shown in some, but not all, studies to decrease mortality and improve organ function in patients with severe sepsis. In addition, the anti-inflammatory and antithrombotic effects of the protein C pathway may play a role in multiple disorders, from inflammatory bowel disease and rheumatoid arthritis to asthma and atherosclerosis[6].

Platelets release many growth factors and cytokines that affect wound healing (e.g. platelet-derived growth factor, transforming growth

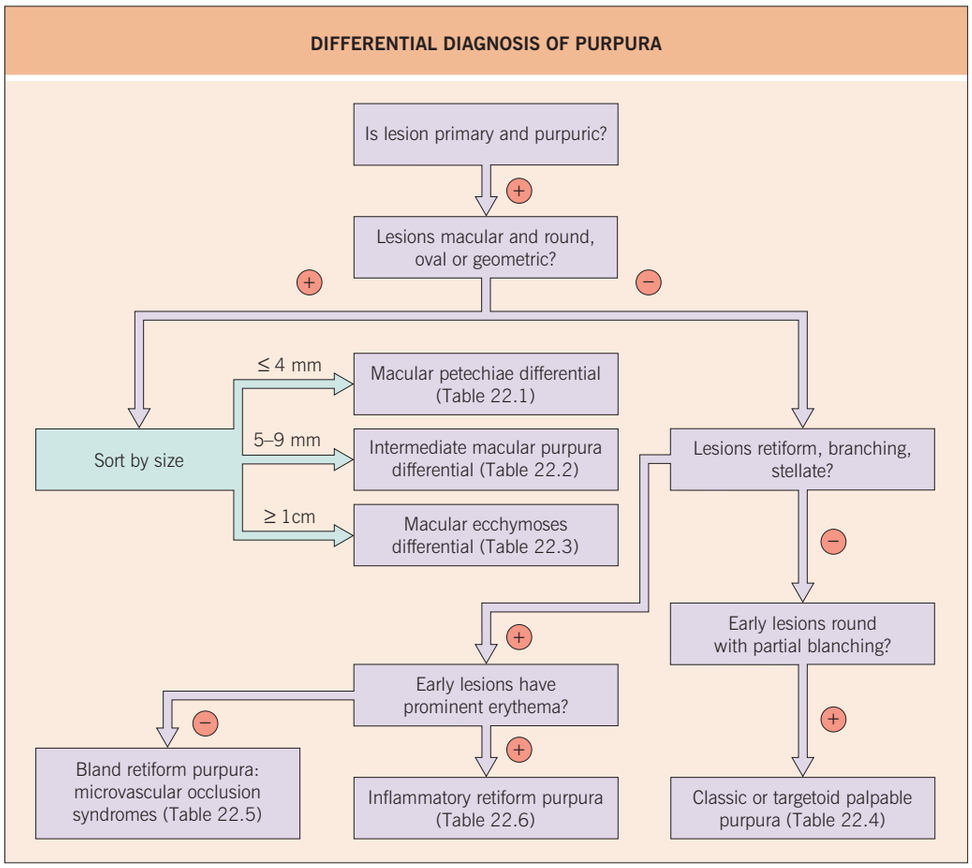

Fig. 22.2 Differential diagnosis of purpura.

factor-β)[7]. Also, a powerful angiogenesis inhibitor, angiostatin, is a cleavage product of plasminogen. These and many other findings suggest that coagulation, inflammation and wound healing pathways are richly and importantly integrated.

Tests for Coagulation

A thorough history (including family history) and physical examination are crucial in the proper selection and interpretation of tests measuring coagulation and anticoagulation parameters. A basic laboratory assessment of clotting includes a platelet count, prothrombin time (PT) and APTT. A prolonged PT with a normal APTT suggests a factor VII deficiency or the use of an oral anticoagulant (at a relatively low dose)[8]. A prolonged APTT with a normal PT can result from the use of heparin, a lupus anticoagulant, an acquired factor VIII inhibitor, von Willebrand disease (which results in a functional deficiency of factor VIII as well as defective platelet adhesion) or a significant deficiency of one of the following: factor VIII, IX, XI, or XII, high-molecular-weight kininogen (HMWK) or prekallikrein (PK). If both the PT and the APTT are prolonged, there may be a deficiency (or inhibitor) of fibrinogen, prothrombin, factor V or factor X or a combined deficiency of multiple procoagulant factors (e.g. due to severe vitamin K deficiency or high doses of an oral anticoagulant). Platelet function tests (e.g. bleeding time, ristocetin-induced platelet aggregation studies) are performed in settings suggesting platelet function defects unexplained by medications (e.g. aspirin, nonsteroidal anti-inflammatory drugs [NSAIDs]) or metabolic disorders such as renal failure. An example would be the platelet dysfunction observed in patients with Hermansky–Pudlak syndrome.

If the PT or APTT is prolonged, repeating the test using a 1:1 mixture of the patient's plasma and normal plasma can be helpful in distinguishing between a deficiency state and the effects of an inhibitor. A 1:1 dilution will usually normalize the time if there is a factor deficiency, but the time will remain prolonged if an inhibitor is present. Other tests, such as the dilute Russell viper venom time, may be helpful in confirming the presence of lupus anticoagulant activity.

Laboratory tests that are useful in the evaluation of a patient suspected to have a hypercoagulable state are presented in Table 105.10.

New Anticoagulant Agents

Over the past decade, a number of agents have joined heparin, low-molecular-weight heparins, and warfarin (Coumadin®) as useful anticoagulant medications, and more are undergoing clinical evaluation (Table 22.7)[9–11]. While offering advantages over warfarin such as reduced drug–drug interactions, the newer agents listed in Table 22.7 all require parenteral administration. However, several oral anticoagulants have recently been approved by the FDA that do not require monitoring of the international normalized ratio (INR), i.e. prothrombin ratio (Table 22.8)[12].

SELECTED PURPURA SYNDROMES

Some syndromes that are not traditionally discussed in chapters on microvascular occlusion (see Ch. 23) or vasculitis (see Ch. 24) will be addressed here.

Pigmented Purpuric Eruptions

Synonyms: ■ Capillaritis ■ Purpura pigmentosa chronica ■ Purpura simplex ■ Majocchi–Schamberg disease

Variants:
- Schamberg's disease: Schamberg's purpura, progressive pigmentary dermatosis of Schamberg, purpura pigmentosa progressiva
- Purpura annularis telangiectodes of Majocchi: Majocchi's disease
- Pigmented purpuric lichenoid dermatitis of Gougerot and Blum
- Eczematid-like purpura of Doucas and Kapetanakis: itching purpura
- Lichen aureus: lichen purpuricus

Key features

- Clustered petechial hemorrhage
- Often a background of yellow–brown discoloration due to hemosiderin deposition
- The location and pattern depends on the particular variant

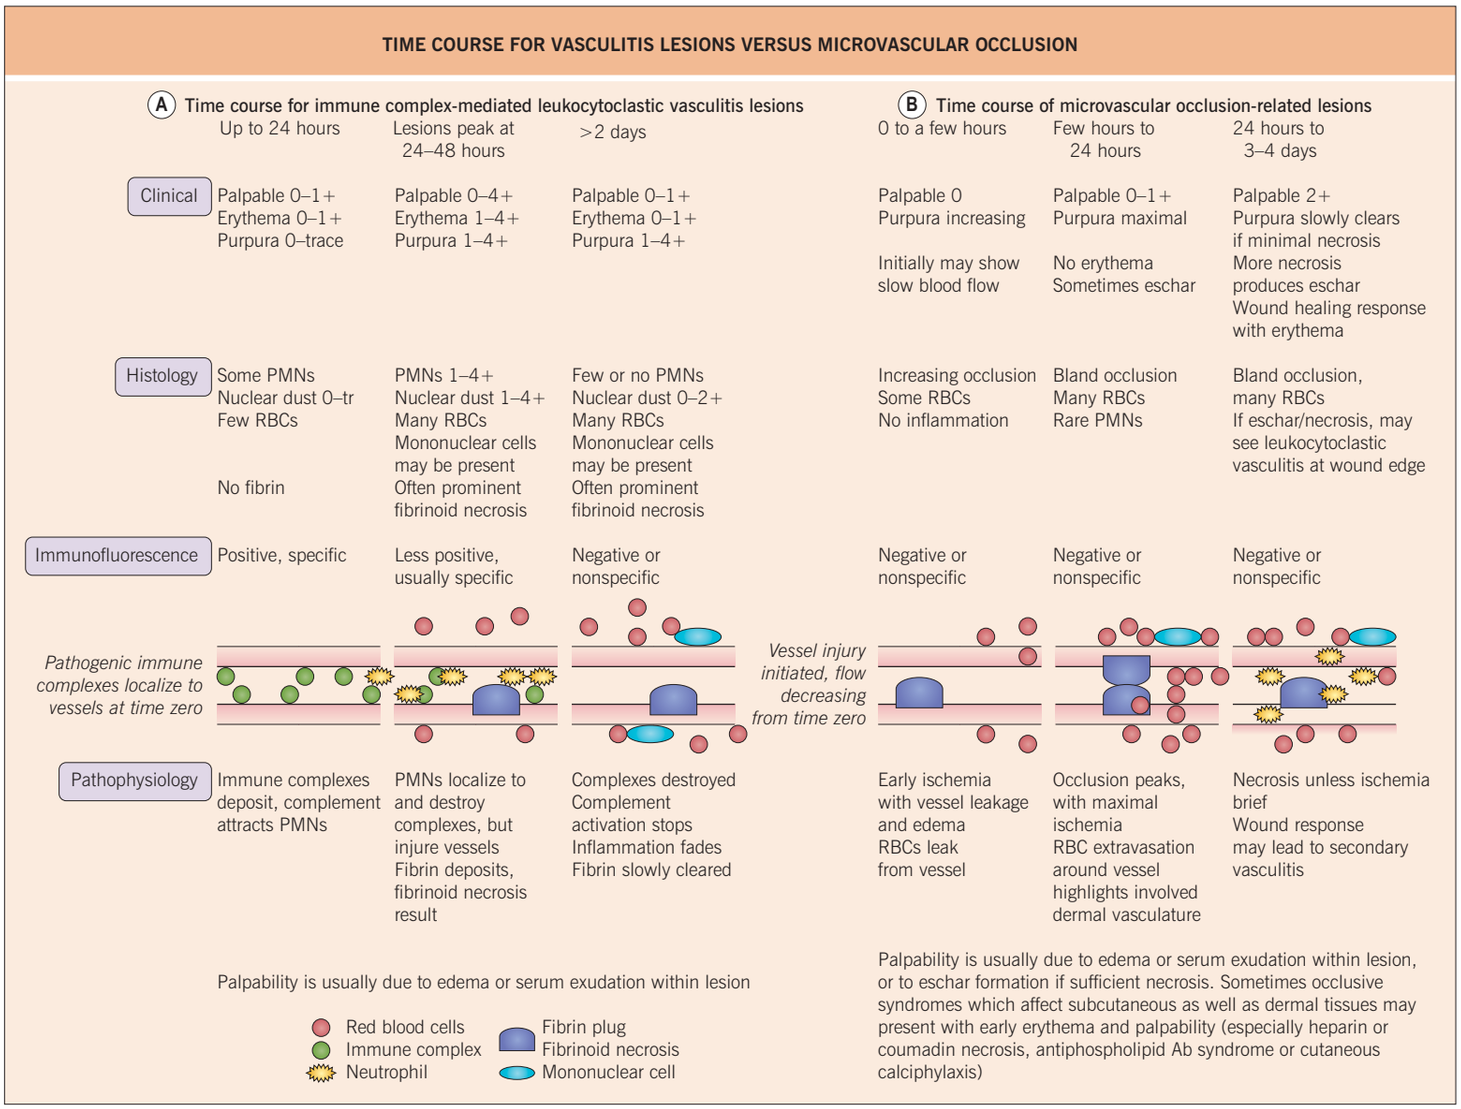

Fig. 22.3 Time course for vasculitis lesions versus microvascular occlusion. A Time course for immune complex-mediated leukocytoclastic vasculitis lesions. **B** Time course of microvascular occlusion-related lesions. Ab, antibody; tr, trace.

Introduction

Pigmented purpuric eruptions represent a group of diseases characterized by petechial hemorrhage thought to be secondary to capillaritis[13]. These diseases have no systemic findings, but they occasionally lead to a patient evaluation to exclude thrombocytopenia or vasculitis because of the purpuric (usually petechial) nature of the lesions and clinical misdiagnosis, especially of the rarer forms.

Pathogenesis

These diseases all result from minimal inflammation and hemorrhage of superficial papillary dermal vessels, usually capillaries. The reason for the inflammation is unknown. This group of chronic inflammatory disorders is not associated with any abnormality of coagulation.

Clinical features

The characteristics of the various forms of pigmented purpuric eruptions are outlined in Table 22.9.

Pathology

Histopathologic features include red cell extravasation, endothelial cell swelling, a perivascular lymphocytic infiltrate and hemosiderin-containing macrophages (Fig. 22.8). The lichen aureus and Gougerot–Blum variants are characterized by a lichenoid infiltrate, and epidermal spongiosis with patchy parakeratosis is often observed in the latter as well as in eczematid-like purpura of Doucas and Kapetanakis.

Differential diagnosis

The clinical picture is often sufficient for diagnosis, but a biopsy specimen may be required to distinguish the lichenoid variant from cutaneous small vessel vasculitis. Although usually on one extremity, angioma serpiginosum may occasionally be misdiagnosed as pigmented purpura. Lesions resembling capillaritis have been reported in patients with mycosis fungoides, allergic contact dermatitis (e.g. due to rubber or azo dyes such as Disperse Blue), non-allergic reactions to topical medications (e.g. fluorouracil or eutectic mixture of local anesthetics [EMLA]), drug eruptions (e.g. carbromal, meprobamate, acetaminophen, infliximab, pseudoephedrine), suction-induced purpura (e.g. cupping or pressing the back against a bathtub) and hypergammaglobulinemic purpura of Waldenström. Pigmented purpuric eruptions on the legs must be differentiated from dermal hemorrhage secondary to venous hypertension, which presents with petechiae superimposed on diffuse hemosiderosis (Fig. 22.5B) rather than the discrete yellow–brown patches that characterize Schamberg's disease.

Treatment

Topical corticosteroid therapy is occasionally helpful, especially in patients who report pruritus or have more evident erythema. Effective treatment of more extensive pigmented purpuric eruptions with PUVA and narrowband UVB has been described[14–16]. Successful therapy with ascorbic acid (500 mg twice daily) plus rutoside (50 mg twice daily) has also been reported.

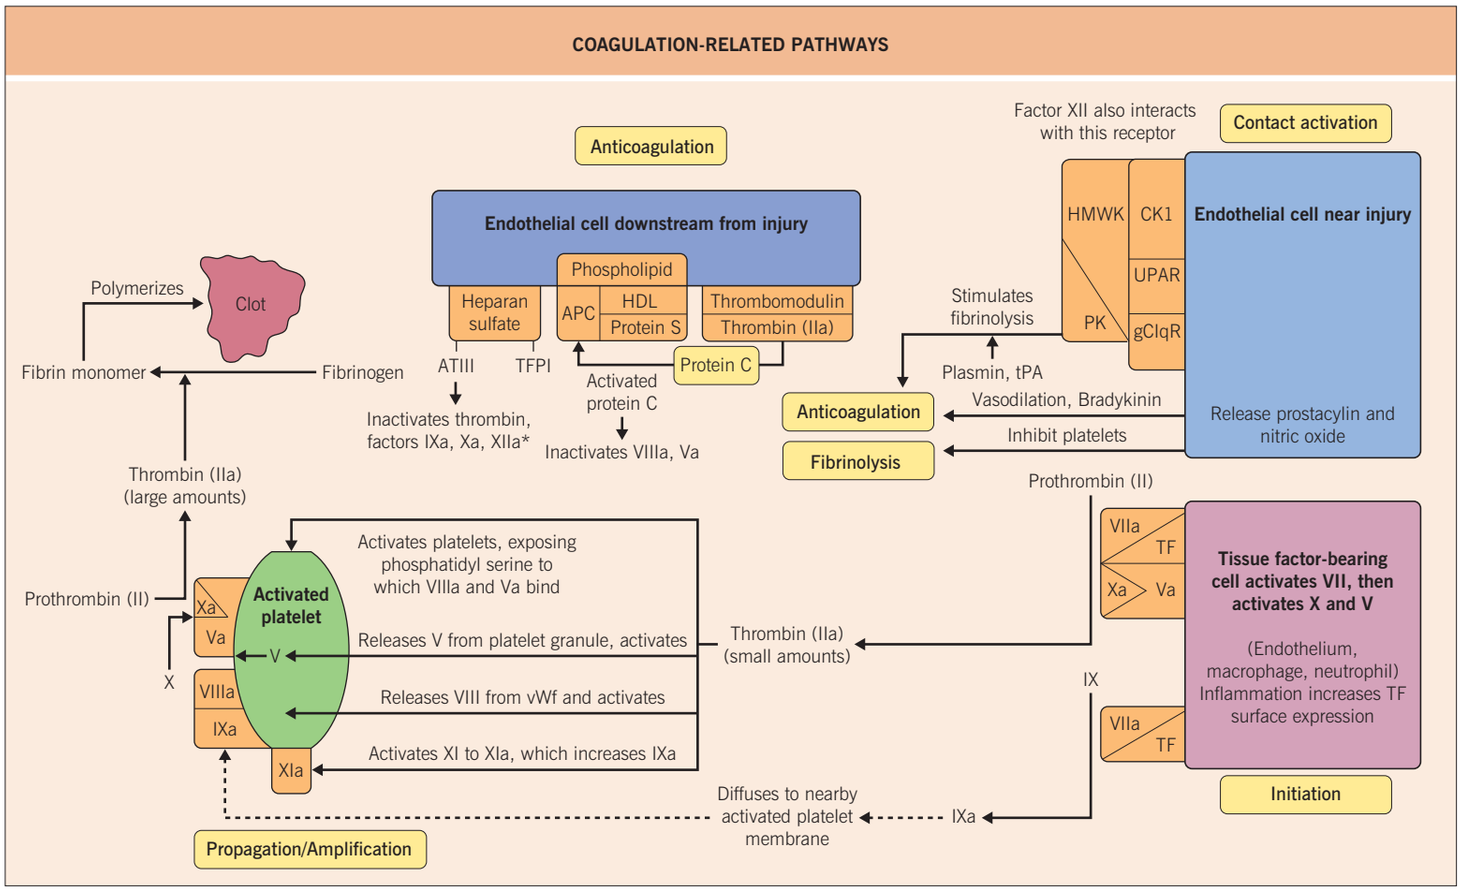

Fig. 22.4 Coagulation-related pathways. TFPI can inactivate factor Xa, and the TFPI–factor Xa complex can inhibit VIIa. *Enhanced by binding of heparin to ATIII. APC, activated protein C; ATIII, antithrombin III; CK1, cytokeratin 1; gC1qR, globular head of the C1q receptor; HDL, high-density lipoprotein; HMWK, high-molecular-weight kininogen; PK, prekallikrein; TF, tissue factor; TFPI, tissue factor pathway inhibitor; tPA, tissue plasminogen activator; UPAR, urokinase plasminogen activator receptor; vWF, von Willebrand factor.

Hypergammaglobulinemic Purpura of Waldenström

Synonym: ▪ Benign hypergammaglobulinemic purpura

Key features

- Usually affects women
- Recurrent crops of petechiae and larger purpuric macules on the lower extremities, which often burn or sting
- Patients typically have a polyclonal hypergammaglobulinemia and high titers of IgG or IgA rheumatoid factor
- An autoimmune connective tissue disease, most often Sjögren's syndrome, develops in a subset of patients

Introduction

This syndrome was first described in 1943 by Waldenström, who reported three women with chronic relapsing purpura, hypergammaglobulinemia, an elevated ESR, and mild anemia. Hypergammaglobulinemic purpura of Waldenström is often associated with an autoimmune connective tissue disease, especially Sjögren's syndrome.

Pathogenesis

Although associated with hypergammaglobulinemia, a strong argument can be made that a more specific feature of this condition is the presence of small circulating immune complexes containing IgG or IgA rheumatoid factor (RF). Such complexes of this size have been identified in individuals with a clinical presentation that fits this syndrome but who lacked polyclonal hypergammaglobulinemia[17,18]. IgG and IgA RFs are highly soluble, which might explain the rapidity with which lesions appear and resolve. The presence of monoclonal RF early in the disease in some patients as well as the tendency of affected individuals to develop autoimmune and (less often) lymphoproliferative disorders supports the presence of a mild immune dysregulation syndrome.

Clinical features

The purpura is often preceded by a slight itch, mild tingling or burning, and it may be aggravated by tight-fitting garments, prolonged standing and heat. Macular hemorrhage (e.g. petechiae or larger purpuric macules) on the lower extremities represents the most common presentation, but the lesions may be fleeting. Some patients have palpable purpura with histologic evidence of vasculitis (see below), which has led many authors to classify hypergammaglobulinemic purpura of Waldenström as a subset of cutaneous small vessel vasculitis.

Hypergammaglobulinemic purpura of Waldenström can be primary or secondary[19]. In younger patients it is usually primary, but over time some patients develop evidence of an autoimmune connective tissue disease, most frequently Sjögren's syndrome and occasionally rheumatoid arthritis or lupus erythematosus. Much less often, a monoclonal gammopathy or, very rarely, a lymphoma or multiple myeloma develops.

Laboratory evaluation typically reveals polyclonal hypergammaglobulinemia and an elevated ESR. Standard RF assays identify only IgM RF, so they will not detect the IgG and IgA RFs that are frequently found in this syndrome (although specific tests for IgG and IgA RF can be performed). Anti-Ro (SS-A) and -La (SS-B) antibodies are commonly present and may predict a higher likelihood of developing an associated autoimmune connective tissue disease.

ANTICOAGULANTS			
Agent	**Action**	**Origin/current form**	**Half-life (T1/2), Comments**
		CLASSIC ANTICOAGULANTS	
Heparin	Binds to AT (ATIII) to enhance 1000-fold the AT inhibition of thrombin and Xa Heparin/AT complex also inhibits IXa, Xa and XIIa of the intrinsic and VIIa–TF (tissue factor) of the extrinsic pathways, respectively	Biologic extract from bovine and swine lung and intestine that consists of multiply-sized glycosaminoglycan polymers	• T1/2 = 30 min–2.5 h iv; 2 h delay but 10 h effect sc
Warfarin (coumarin; Coumadin®)	Impairs γ-carboxylation of vitamin K-dependent clotting factors (VII, X, IX, II [prothrombin]) and anticoagulants (proteins C and S), with reduced levels of functional factors	Synthetic	• T1/2 = 35–45 h orally, but effect depends on impaired synthesis of proteins • Usually 5–6 days of stable dose required to reach maximum effect • Effect inhibited by vitamin K • Multiple drug–drug interactions*
		EXTRINSIC PATHWAY INHIBITORS	
Tissue factor pathway inhibitor (TFPI)	Binds, inactivates Xa, then inhibits VIIa	Plasma, platelet α-granules, endothelial cell surface/recombinant	• Clinical trials (iv)
Nematode anticoagulant peptide (NAPc2)	Binds X or Xa, then inhibits VIIa	Canine hookworm/recombinant	• T1/2 = 50 h sc • Clinical trials
Active-site blocked factor VIIa (factor VIIai)	Inhibits by competing with VIIa for tissue factor binding		• T1/2 = 45 min in plasma, but acts up to 6 h after single sc injection • Animal studies
		FACTOR Xa INHIBITORS: INDIRECT (VIa ATIII)	
Low-molecular-weight heparins (LMWH), including ardeparin, dalteparin, enoxaparin, nadroparin, tinzaparin	Like heparin, bind to AT (ATIII) to inhibit thrombin, Xa and other serine protease clotting factors (unlike heparin, inhibit Xa > thrombin)	Chemical or enzymatic treatment of native heparin to produce molecules that are 4000–5000 daltons (native heparin 5000–30 000 daltons)	• T1/2s allow once- or twice-daily sc administration • Adjust dose if renal insufficiency • Multiple prophylactic and therapeutic anticoagulant regimens
Danaparoid	ATIII-dependent anti-Xa inhibition	Mixture of 84% heparan sulfate, 12% dermatan sulfate, 4% chondroitin sulfate	• T1/2 = 24 h; daily or twice-daily sc administration • Renal clearance • Used to treat HIT
Fondaparinux	ATIII-dependent Xa inhibition; dissociates to bind additional ATIII molecules	Synthetic analogue of pentasaccharide sequence of heparin that interacts with ATIII	• T1/2 = 17 h sc; once-daily administration • Contraindicated in patients with crt cl <30 ml/min • Unlike heparin, no antidote • Does not bind to Plt factor 4, so should not cause HIT
Idraparinux	As above (fondaparinux)	As above (fondaparinux)	• T1/2 = 80–130 h sc; once-weekly administration
		FACTOR Xa INHIBITORS: DIRECT	
DX-9065a	Binds to active site of Xa	Non-peptide arginine derivative	• Continuous iv infusion
Razaxaban	Binds to active site of Xa	Imidazole derivative	• Oral; twice-daily administration
		INHIBITORS OF FACTORS Va & VIIIa	
Activated protein C	Inactivates Va, VIIIa	Recombinant	• Infusion over 96 h • Non-coagulant properties may play a role in sepsis therapy
Soluble thrombomodulin	Binds thrombin, activates protein C	Recombinant	• sc administration, every 2–3 days
		THROMBIN INHIBITORS (UNLIKE HEPARIN, INACTIVATE FIBRIN-BOUND AS WELL AS FLUID-PHASE THROMBIN)	
Hirudin	Irreversible bivalent binding to two sites on thrombin	Leech salivary gland	• T1/2 = 60 min iv, 120 min sc • Adjust dose if renal function decreased • No antidote
Lepirudin	65-amino acid analogue of hirudin	Biosynthetic peptide closely related to hirudin	• T1/2 = 1–3 h sc, longer if renal function decreased • No antidote • Approved for use in HIT
Bivalirudin	20-amino acid analogue of hirudin	Recombinant	• T1/2 = 25 min iv • Minimal renal excretion • No antidote
Argatroban	Reversible complex with active site of thrombin	Synthetic small molecule that is arginine derivative	• T1/2 = 45 min iv • Metabolized in liver • Approved for treatment of HIT

*Includes antibiotics, lipid-lowering agents, antiplatelet agents (see Ch. 131).

Table 22.7 Anticoagulants[9–11]. This list does not include the antiplatelet agents that block platelet ADP receptors (e.g. clopidogrel, prasugrel). AT (ATIII), antithrombin (antithrombin III); crt cl, creatinine clearance; HIT, heparin-induced thrombocytopenia; iv, intravenous; Plt, platelet; sc, subcutaneous.

NEWER ORAL ANTICOAGULANTS				
Agent	**Action**	**Oral bioavailability**	**Half-life (T1/2) and metabolism**	**Comments**
Apixaban	Directly inhibits factor Xa (both within and outside the prothrombinase complex)	50%, with peak plasma level 3–4 h post-ingestion	• T1/2 = 10–14 h • Partially metabolized by CYP3A4 and by CYP-independent hepatic mechanisms • Partially eliminated via kidneys (25%)	Neither induces nor inhibits CYP enzymes
Dabigatran	Directly inhibits thrombin (both free and clot-bound)	• 7%, with peak plasma level 1.5 h post-ingestion • Pro-drug dabigatran etexilate converted in the liver to dabigatran	• T1/2 = 14–17 h • Primarily fecal excretion, but up to 80% of active drug may be eliminated via kidneys	• Significant renal dysfunction a contraindication • Drug–drug interactions with quinine, quinidine and verapamil
Rivaroxaban	Directly inhibits factor Xa (both free and complex-bound)	>80%, with peak plasma level 3 h post-ingestion	• T1/2 = 4–9 h* • 66% excreted via kidneys	Contraindicated in patients with crt cl <30 ml/min

*Up to 12 h in patients >75 years of age.

Table 22.8 Newer oral anticoagulants. From ref. 12. crt cl, creatinine clearance; CYP, cytochrome P450.

TYPES OF PIGMENTED PURPURIC DERMATOSES			
Type	**Age/Sex**	**Morphology**	**Location**
Schamberg's disease	• Most common form • Can occur in children • Peak frequency in middle-aged to older men	• Yellow–brown patches with an oval to irregular outline (Fig. 22.5A) • Pinpoint petechiae within patches – likened to "cayenne pepper" • Successive crops	• Favors lower legs • Can also involve thighs, buttocks, trunk and arms
Purpura annularis telangiectodes of Majocchi	• Uncommon • Adolescents and young adults, especially women	• 1–3 cm annular plaques that may slowly expand • Punctate telangiectasias and petechiae within the border (Fig. 22.6)	Trunk, proximal lower extremities
Pigmented purpuric lichenoid dermatitis of Gougerot and Blum	• Rare • Middle-aged to older men	• Admixture of two types of lesions: 1) Schamberg-like 2) Purpuric red–brown lichenoid papules • Chronic • Occasionally pruritic	On lower extremity, may be confused with small vessel vasculitis
Eczematid-like purpura of Doucas and Kapetanakis	• Rare • Middle-aged to older men	• Scaly petechial or purpuric macules, papules and patches • Pruritic	Primarily lower extremities
Lichen aureus	• Rare	• Solitary patch • Color varies from golden to rust to purple–brown	Usually lower extremity, often over a perforator vein
Linear pigmented purpura	• Rare • Can occur in children and adolescents	• Linear array, usually unilateral (Fig. 22.7) • Individual lesions similar in appearance to lichen aureus or Schamberg's disease	Often a single extremity
Granulomatous pigmented purpura	• Very rare	• Brown patches with superimposed hemorrhagic papules*	Lower legs

*Histologically, hemorrhagic granulomatous inflammation in upper dermis.

Table 22.9 Types of pigmented purpuric dermatoses. Rarely, the first two types are familial.

Pathology

Simple hemorrhage, a mild perivascular lymphocytic infiltrate or leukocytoclastic vasculitis can characterize these lesions.

Differential diagnosis

The clinical picture is often characteristic. Some patients develop palpable purpura mimicking classic cutaneous small vessel vasculitis syndromes, but most patients present with recurring crops of burning or stinging macular hemorrhage.

Treatment

Some agents used to treat this syndrome, such as aspirin or support stockings, have also been reported to exacerbate the condition. Avoidance of precipitating factors such as alcohol and prolonged standing may be helpful. In secondary cases, treatment is aimed at the underlying disease.

Gardner–Diamond Syndrome

Synonyms: ■ Psychogenic purpura ■ Autoerythrocyte sensitization

Key features

- Factitial disorder that typically affects women with an underlying psychiatric illness
- Painful, swollen ecchymoses are observed at sites of trauma

Introduction

In 1955, Gardner and Diamond described four women with an abnormal response to bruising characterized by the development of painful ecchymoses at sites of trauma followed by progressive erythema and edema[20]. The largest series (71 patients) to date of Gardner–Diamond syndrome was reported by Ratnoff[21] in 1989.

Fig. 22.5 Schamberg's disease versus petechiae and hemosiderin secondary to venous hypertension. A Discrete yellow–pink patches with superimposed petechiae in Schamberg's disease. **B** Petechiae superimposed on more diffuse hemosiderin deposits in venous hypertension, referred to as "stasis purpura". *B, Courtesy, Jean L Bolognia, MD.*

Fig. 22.6 Purpura annularis telangiectodes of Majocchi. Annular plaques with cayenne pepper petechiae in the border.

Fig. 22.7 Linear pigmented purpuric dermatosis. Linear array of yellow–brown macules and patches with superimposed petechiae and small, red–brown purpuric papules on the arm of a child. The eruption had been present for several months and was limited to this segment of skin.

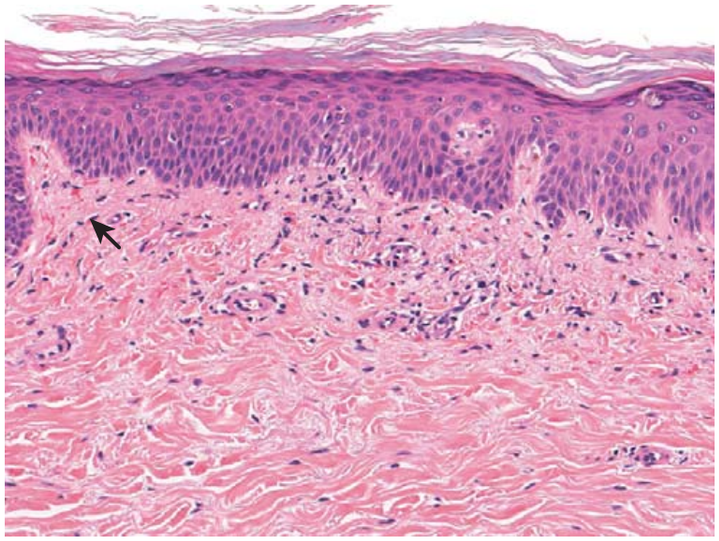

Fig. 22.8 Pigmented purpuric eruption – histologic features. Minimal perivascular lymphocytic infiltrate with extravasation of red blood cells (arrow) and hemosiderin deposits. *Courtesy, Lorenzo Cerroni, MD.*

Clinical features

This condition is seen predominantly in women, and has been associated with psychiatric illness in the majority of patients: depression, anxiety, difficulties in handling aggression and hostility, hypochondriasis, sexual maladjustments, masochism, hysterical and borderline personality disorders, and obsessive–compulsive behavior.

Lesions are characterized by the sudden onset of painful, swollen bruises of variable size in any area of the body. They usually resolve within a 2-week period and then typically recur. Original reports described appearance of these atypical purpuric lesions at sites of injection of a patient's own blood or other agents. However, later studies showed that in some patients, lesions were reproduced at injection sites that the investigator suggested were "test" sites but not at those suggested to be "control" sites (but injected with the same agent). Patients were observed to induce the lesions traumatically (i.e. factitial disease).

Pathology

The histologic features of early lesions consist of edema, a minimal perivascular mononuclear infiltrate and extravasated red blood cells in the upper dermis.

Differential diagnosis and treatment

The lesions in this syndrome are usually suggestive of a factitial origin, with atypical locations, geometric or peculiar morphologies, and a lack of clearcut precipitating factors. However, proving a factitial origin is generally difficult, and it is usually not helpful to confront the patient. Gentle probing for an underlying and potentially treatable psychiatric

condition may be beneficial. Effective management of this syndrome can prove to be very difficult.

Mondor's Syndrome of Superficial Thrombophlebitis

Synonym: ■ Mondor's disease

Key features

- Superficial thrombophlebitis affecting the anterolateral thoracoabdominal wall
- Pathogenic factors include trauma, surgical procedures, infections and cancer of the breast
- Presents with the sudden onset of chest pain and subsequent appearance of a cord-like thrombosed vein

Introduction

Mondor's syndrome is characterized by superficial thrombophlebitis of subcutaneous veins within the anterolateral thoracoabdominal wall (e.g. lateral thoracic, thoracoepigastric and superior epigastric veins). Though previously reported by others, Henry Mondor provided a very detailed description of this condition in 1939[22]. A similar cord-like superficial thrombophlebitis can occur in other sites (e.g. the upper and lower extremities, abdomen, groin and penis).

Pathogenesis

Common pathogenic factors in chest wall thrombophlebitis include trauma, excessive physical activity, a surgical procedure on the breast, mastitis, a breast abscess and pendulous breasts[22–24]. Up to 10% of patients with Mondor's syndrome have an underlying breast carcinoma. The condition is also occasionally associated with rheumatoid arthritis, filariasis, pregnancy, oral contraceptive use, intravenous drug use, intravenous catheters, a non-breast malignancy or a hypercoagulable state (e.g. hereditary protein C deficiency, anticardiolipin antibodies).

Clinical features

Sudden onset of chest pain followed by the appearance of one or more visible or palpable cords (representing thrombophlebitic veins) typify this syndrome. Associated findings include tenderness, a sensation of tension, erythema, ecchymosis, pruritus, arthralgia and, rarely, fever. Symptoms worsen on pulling the skin or elevating the breast and the ipsilateral upper extremity. The condition is usually unilateral and is three times more common in women than in men.

Pathology

A biopsy is rarely required. The process may involve arteries and lymphatic vessels as well as veins. Sclerosing endophlebitis with complete or partial obliteration of the lumen by thrombus and inflammatory cells is typical. The time period between the onset of the condition and ultimate recanalization of the affected vessels varies from 2 weeks to more than 6 months.

Differential diagnosis

The clinical presentation is unique, and etiologic factors should be identified. Recurrent superficial thrombophlebitis (migratory thrombophlebitis) is frequently associated with an underlying malignancy (Trousseau's syndrome; most often pancreatic or lung carcinoma), a hypercoagulable state (inherited or acquired) or an inflammatory condition (e.g. Behçet's disease).

Treatment

The disease is usually benign and self-limited, except when associated with breast cancer. Aching pain typically ends within 10 days, but the cord often persists for weeks to months and may be tender. Local heat, rest of the arm, and breast support can improve symptoms. The rate of recurrence is approximately 5%.

Superficial venous thrombophlebitis may occur in other locations (e.g. lower extremities), but is not considered Mondor's syndrome. In a Cochrane review of treatment options for superficial thrombophlebitis of the lower extremity, NSAIDs and low-molecular-weight heparin reduced extension or recurrences by ~70% (compared to placebo)[25]. Superficial venous thrombosis involving the main trunk of the saphenous vein has the strongest association with venous thromboembolism, and when the thrombosis is at or near the sapheno-femoral or saphenopopliteal junction, it should probably be removed, followed by venous ligation/stripping and possibly three months of low-molecular-weight heparin.

Disorders of vascular coagulopathies with cutaneous manifestations 380
Disorders of cellular vascular occlusion 382

INTRODUCTION

The differential diagnosis of microvascular syndromes involving the skin is extensive, and the evaluation can be confusing, but it is critical to distinguish between inflammatory injury and non-inflammatory occlusive injury to vessels. The diagnosis of occlusive syndromes in the skin is greatly facilitated by finding the telltale lesions of retiform purpura (see Ch. 22). Recognition of retiform purpura allows one to focus on the clues from the history and the remaining physical examination which may favor or exclude major subsets of cutaneous occlusive disease.

Diseases that produce skin lesions secondary to microvascular occlusion have often been lumped with cutaneous vasculitic syndromes, or discussed primarily as systemic diseases with little attention paid to cutaneous findings. While there is some overlap in the pathogenesis of deep venous thrombosis and pulmonary emboli and the pathogenesis of cutaneous microvascular occlusion syndromes, the two differ substantially with respect to disease etiology and treatment (see Ch. 22).

The differential diagnosis for occlusive syndromes is best approached through major pathophysiologic categories (Table 23.1). These major pathophysiologic categories frequently have sufficiently distinctive clinical settings that even a minimal history and physical examination plus laboratory findings can usually allow an efficient sorting of diagnostic possibilities (Fig. 23.1). This is especially important in life-threatening situations where making timely decisions is crucial. A reasonable panel of initial laboratory tests plus comments on their relevance are listed in Table 23.2.

It must be emphasized that some inflammatory syndromes capable of producing retiform purpura may occasionally present with lesions that have minimal inflammation (see Ch. 22). In particular, this may occur with the ANCA-positive syndromes of Wegener's granulomatosis and microscopic polyangiitis, as well as ANCA-negative cutaneous polyarteritis nodosa. Therefore, it is reasonable to order an ANCA test, even in a setting where occlusion is believed to be the most likely diagnosis.

Because treatment depends directly on pathogenesis, accurate diagnosis is critical to appropriate therapy. Therapies for inflammatory disease differ greatly from therapies for occlusive disease. The use of anti-inflammatory therapy for occlusive disease may not only be useless but also harmful, and the same may be true for anticoagulant therapy in most vasculitides.

DISORDERS OF PLATELET PLUGGING

Heparin Necrosis

Synonyms: ■ Heparin-induced thrombocytopenia (HIT) syndrome – platelet activation stage ■ Heparin-associated thrombocytopenia with thrombosis (HATT) syndrome – includes patients who develop thrombosis

Key features

- Exposure to heparin
- Retiform, branching purpura or non-inflammatory necrosis
- Lesions may be distant or at sites of heparin infusion or injection

Introduction

Heparin necrosis is an unusual but important iatrogenic syndrome first recognized in the early 1970s. Necrosis may occur with heparin exposure after subcutaneous or intravenous administration, including the trace amounts of heparin used to keep infusion lines open.

Heparin-induced thrombocytopenia occurs in 1–5% of adults exposed to heparin, with 30–90% of these patients developing thrombosis. However, the latter figures are primarily from retrospective series where the diagnosis of heparin-induced thrombocytopenia was made following a thrombotic episode; as a result, it is likely that the true incidence of thrombosis is ≤30%. In one study of 612 pediatric Intensive Care Unit patients who received heparin, the associated incidence of thrombosis was reported at 2.3%[1].

Pathogenesis

Heparin necrosis is caused by an antibody which binds not to heparin alone, but to complexes of heparin plus platelet factor 4, a protein expressed on the platelet surface. Antibodies which bind simultaneously to antigens on both these molecules appear to activate the platelet by Fc binding to platelet Fc receptors. Platelet aggregation and consumption follows. Vascular occlusion, involving veins, arteries or the cutaneous microvasculature, may result, leading to such complications as stroke, digital or limb necrosis, or cutaneous necrosis.

Clinical features

Heparin necrosis usually occurs between days 5 and 10 of heparin therapy, although it may develop much earlier in patients previously sensitized to heparin. In a study examining the timing of its onset in 243 patients who developed this syndrome, 70% developed thrombocytopenia 4 or more days (usually 5 to 10) after starting therapy, with or without a previous history of heparin therapy. In the remaining 30% of patients, a rapid onset was seen (median time 10.5 hours after start of heparin), which was dependent on exposure to heparin within the previous 100 days[2]. There is also a delayed-onset form of heparin necrosis, in which lesions can occur up to 3 weeks after exposure to heparin[3]. Heparin-dependent antibodies do not invariably reappear with subsequent heparin use *after* 100 days. Most patients with heparin-related thrombocytopenia do not develop clinically evident thrombosis, but heparin necrosis may occur without thrombocytopenia.

Lesions are usually tender, sharply demarcated, non-inflammatory (erythema unusual), and typically purpuric or necrotic with a retiform

DIAGNOSIS OF CUTANEOUS MICROVASCULAR OCCLUSION BASED ON PATHOPHYSIOLOGY	
PLATELET PLUGGING	
• Heparin necrosis*	
• Thrombocytosis secondary to myeloproliferative disorders	
• Paroxysmal nocturnal hemoglobinuria	
• Thrombotic thrombocytopenic purpura (rare)	
COLD-RELATED GELLING OR AGGLUTINATION	
• Cryoglobulinemia	
• Cryofibrinogenemia	
• Cold agglutinins	
VESSEL-INVASIVE ORGANISMS	
• Ecthyma gangrenosum (primarily Gram-negative bacteria)	
• Opportunistic fungi (e.g. *Aspergillus* spp., *Rhizopus* spp.)	
• Disseminated strongyloidiasis	
• Lucio's phenomenon of leprosy	
EMBOLIZATION	
• Cholesterol embolus	
• Oxalate embolus	
• Atrial myxoma	
• Marantic endocarditis	
• Libman–Sacks endocarditis (lupus, often in association with antiphospholipid antibodies)	
• Infective endocarditis (acute, fungal) (rare)†	
• Crystalglobulin vasculopathy	
• Hypereosinophilic syndrome	
SYSTEMIC COAGULOPATHIES	
• Neonatal purpura fulminans	
• Warfarin (Coumadin®) necrosis	
• Purpura fulminans of sepsis/DIC	
• Postinfectious purpura fulminans	
• Antiphospholipid antibody/lupus anticoagulant syndrome	
VASCULAR COAGULOPATHIES	
• Sneddon syndrome	
• Livedoid vasculopathy	
• "Malignant" atrophic papulosis	
CELL OCCLUSION SYNDROMES	
• Stress reticulocyte adhesion with major hemolytic anemias and/or sickling	
• Intravascular lymphoma	
MISCELLANEOUS/UNKNOWN MECHANISM	
• Cutaneous calciphylaxis	• Local interferon injection reaction
• Hydroxyurea-induced ulcers	• Large hematoma occlusion syndrome
• Brown recluse *(Loxosceles)* spider bite	
*Encompasses heparin-induced thrombocytopenia (HIT)/heparin-associated thrombocytopenia and thrombosis (HATT).	
†Usually inflammatory.	

Table 23.1 Differential diagnosis of cutaneous microvascular occlusion based on pathophysiology. DIC, disseminated intravascular coagulation.

morphology; large necrotic areas with irregular branching margins can also be seen. Lesions may occur at the site of subcutaneous injections (Fig. 23.2) or may develop at sites distant to the heparin infusion. Although consumption of platelets is part of this syndrome, and thrombocytopenia is often cited as a feature of the syndrome, absolute thrombocytopenia is often not present in patients with significant vascular occlusion. Without knowing the platelet count immediately prior to starting heparin, it is impossible to know when a platelet count of 200 000/μl, for example, may in fact represent a decrease by half from a pretreatment reactive thrombocytosis of 400 000/μl. Any organ or limb is potentially at risk for vascular occlusion, including the CNS.

Pathology

Heparin necrosis usually leads to non-inflammatory occlusion of vessels, including microvascular, venous or arterial occlusion. Although platelet plugs are traditionally referred to as white clots, even a skilled pathologist may have difficulty reliably distinguishing "white clot" platelet plugs from the usual "red clot" of fibrin thrombi.

Differential diagnosis

A recent history of heparin administration should prompt consideration of this diagnosis in any patient who develops retiform purpura or bland necrosis, whether or not the patient is thrombocytopenic. Of note, a drop in the platelet count is common in patients on heparin as an incidental finding, unrelated to the development of this syndrome. Conversely, a normal platelet count does not exclude the diagnosis, especially if the pretreatment platelet count is unknown. Other cutaneous occlusion syndromes likely to be associated with thrombocytopenia include antiphospholipid antibody syndrome, purpura fulminans secondary to sepsis, and thrombotic thrombocytopenic purpura (although lesions of cutaneous necrosis secondary to platelet plugging are rare in this last syndrome). Specialized antibody testing can confirm the presence of heparin–platelet factor 4 antibodies in patients, but clinical decisions usually have to be made before the results of these tests are known.

Treatment

Treatment requires cessation of heparin therapy. Although most heparin necrosis has occurred with unfractionated heparin, low-molecular-weight heparin appears to have a much lower, but still real, risk of inducing or supporting this reaction[4,5]. For a patient with heparin-induced thrombocytopenia or heparin-associated thrombocytopenia with thrombosis syndrome in need of acute anticoagulation, selection of an alternate anticoagulant strategy can be challenging, requiring expertise in anticoagulant options and assessment of risk of discontinuing therapy. Argatroban, danaparoid or lepirudin may be useful in this setting (see Table 22.7)[6]. Of note, if warfarin (Coumadin®) monotherapy is instituted during acute heparin-induced thrombocytopenia, the resulting decline in protein C activity may lead to progression of thrombosis and necrosis (see below, Warfarin necrosis).

Thrombocytosis Secondary to Myeloproliferative Disorders

Key features

- Retiform purpura
- Thrombocytosis due to myeloproliferative disorders
- Platelet plugs within dermal vessels or subcutaneous arterioles
- Some patients may develop secondary erythromelalgia

Introduction

Reactive or postsplenectomy thrombocytosis is not believed to be a risk factor for platelet occlusion syndromes, but thrombocytosis due to myeloproliferative (and, rarely, myelodysplastic [e.g. due to 5q deletion]) disorders clearly is. Essential thrombocythemia (thrombocytosis) is the most likely myeloproliferative disorder to result in cutaneous lesions of platelet plug occlusion, and polycythemia vera the second. Both of these syndromes, though rare, are more common in young people and in women.

Pathogenesis

Platelets in myeloproliferative and some myelodysplastic disorders can function abnormally, leading to hemorrhage or occlusion. Whether the platelet dysfunction in myeloproliferative disorders can lead to occlusive phenomena when the platelet count is within the normal range has not been proven.

Clinical features

The exact molecular or physiologic defects of platelets in myeloproliferative disorders have been poorly characterized, so it is not yet possible to predict the risk of bleeding or thrombosis in patients with these hematologic diseases. Cutaneous lesions have been reported in approximately 20% of patients with essential thrombocythemia, including purpura, hematomas, livedo reticularis, erythromelalgia, Raynaud's phenomenon, urticaria, cutaneous small vessel vasculitis, leg ulcers, gangrene and recurrent superficial thrombophlebitis[7]. Lesions of

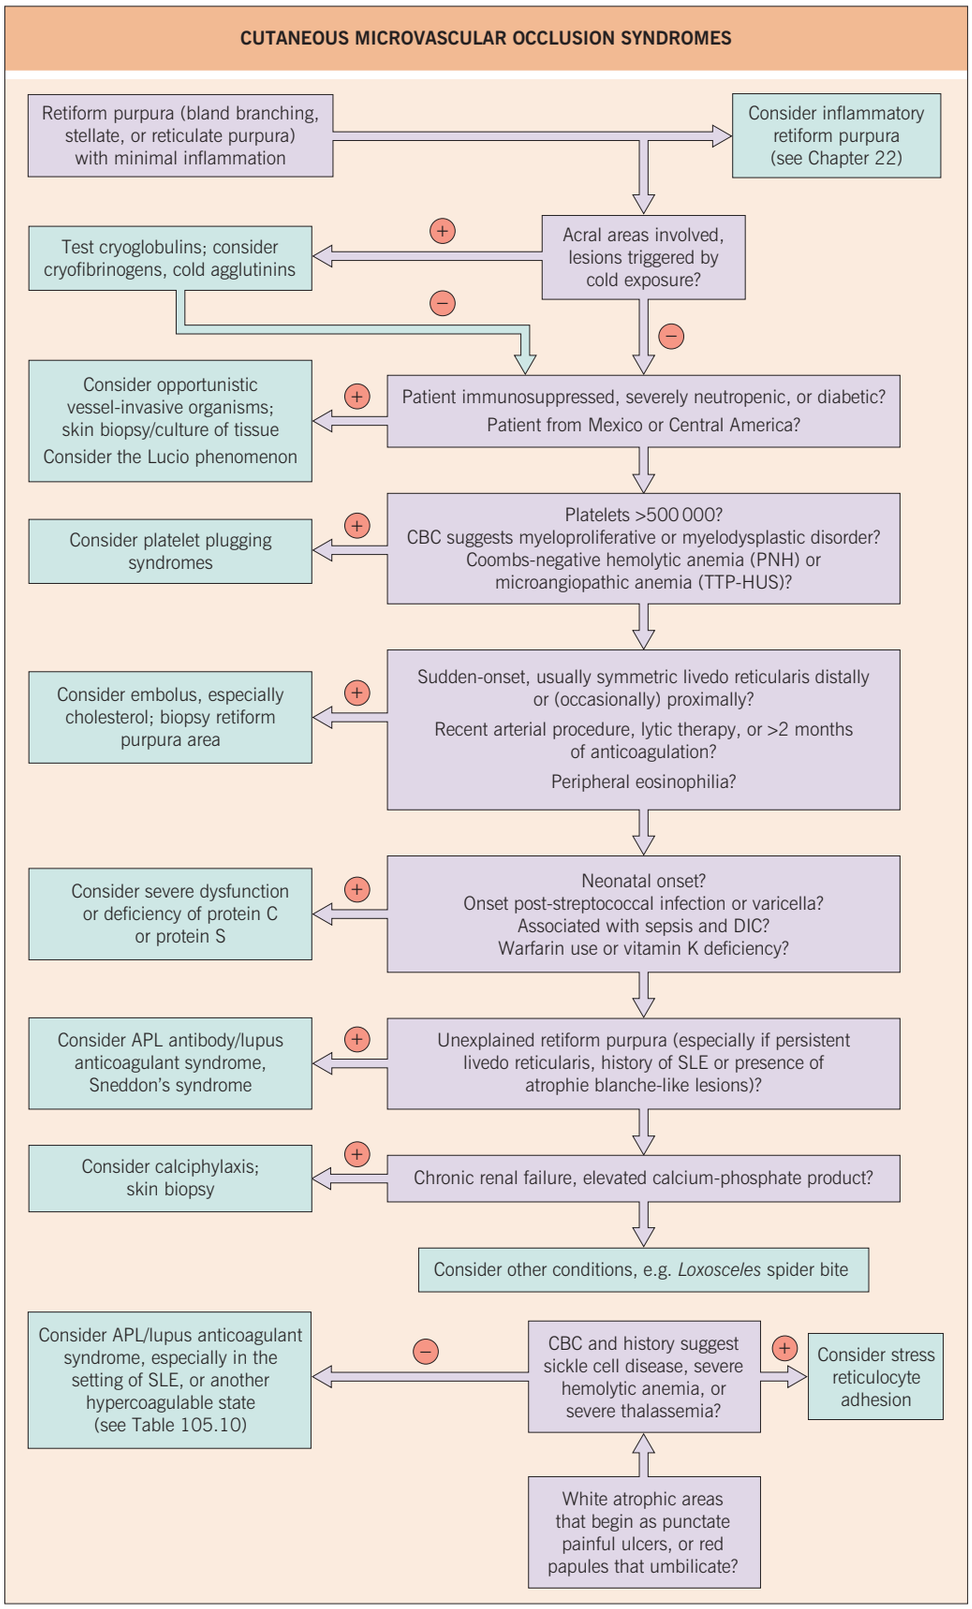

Fig. 23.1 Cutaneous microvascular occlusion syndromes. APL, antiphospholipid; DIC, disseminated intravascular coagulation; PNH, paroxysmal nocturnal hemoglobinuria; TTP-HUS, thrombotic thrombocytopenic purpura–hemolytic uremic syndrome.

microvascular occlusion are an important subset of these cutaneous lesions. Sometimes, the cutaneous lesion of platelet plugging can be the clue to an underlying myeloproliferative disorder[8].

Erythromelalgia is a syndrome that can occur as a primary (idiopathic) or a secondary phenomenon (see Ch. 106). It is characterized by intensely burning and uncomfortable paroxysmal bright erythema of the distal extremities. Most closely associated with essential thrombocythemia, and less often with polycythemia vera, this syndrome can occur in association with any myeloproliferative or myelodysplastic disorder if the platelet counts are sufficiently elevated[9]. This particular form of secondary erythromelalgia is caused by platelet-mediated acral vasodilation, inflammation, and microvascular occlusion. With abnormal platelets, but not in other erythromelalgia syndromes, one may also see discrete areas of purpura or necrosis, often retiform, that represent microvascular occlusion by platelet plugs. This version of erythromelalgia is typically dramatically responsive to aspirin administration, while idiopathic or other secondary forms typically show minimal to no benefit with aspirin.

BASIC SCREENING TESTS FOR OCCLUSIVE SYNDROMES
COMPLETE BLOOD COUNT WITH DIFFERENTIAL, PLATELET COUNT AND BLOOD SMEAR
• Polycythemia or anemia, granulocytosis, thrombocytosis, poikilocytosis – May be sign of myeloproliferative or myelodysplastic diseases • Evidence of red cell fragmentation (schistocytes) and microangiopathy, consider: – TTP-hemolytic uremic syndrome – Purpura fulminans with DIC, occasionally – Antiphospholipid antibody syndrome, occasionally • Thrombocytopenia, consider: – Heparin necrosis, some patients – Purpura fulminans with DIC – TTP-hemolytic uremic syndrome – Antiphospholipid antibody syndrome, some patients • Severe neutropenia – Immunocompromised; opportunistic infections very likely • Eosinophilia – Cholesterol emboli
PARTIAL THROMBOPLASTIN TIME (PTT)
• Minimally prolonged in TTP-hemolytic uremic syndrome • Prolonged in purpura fulminans and DIC • Prolonged if lupus anticoagulant activity present and assay sensitive
CRYOGLOBULINS (OCCASIONALLY CRYOFIBRINOGEN AND COLD AGGLUTININS) WHEN LOCATION AND HISTORY SUGGEST COLD OCCLUSION SYNDROME
BIOPSY
• Confirms occlusion versus other mechanisms of vessel injury • May suggest platelet plugs instead of fibrin thrombi • May suggest cryoglobulin gelling • May diagnose calciphylaxis • May suggest cholesterol, oxalate or crystal globulin occlusion • Special stains for organisms in immunocompromised hosts, when appropriate
BASIC HEPATIC AND RENAL FUNCTION SCREENS
• Hepatic function can affect vitamin K-dependent factors and warfarin (Coumadin®) metabolism • Renal disease moves cutaneous calciphylaxis higher in the differential diagnosis
ANCA
• To reduce the likelihood of the uncommon non-inflammatory retiform purpura presentation of Wegener's granulomatosis or microscopic polyangiitis. • ANCA may be available before permanent histologic sections

Table 23.2 Basic screening tests for occlusive syndromes. Elevated levels of fibrin degradation products, including D-dimers, are seen in purpura fulminans with DIC. DIC, disseminated intravascular coagulation; TTP, thrombotic thrombocytopenic purpura.

Fig. 23.2 Heparin necrosis at site of subcutaneous heparin injection. Note branching or retiform pattern of intense hemorrhage and necrosis in the center of lesion. *From Robson K, Piette W. Adv Dermatol. 1999;15:153–82, used with permission.*

Other clinical features of patients with myeloproliferative disorders depend on the diagnosis. All patients may develop splenomegaly. Polycythemia patients may have a ruddy cyanosis. Chronic myelogenous leukemia patients have elevated neutrophil counts and, frequently, elevated eosinophil or basophil counts. Patients with essential thrombocythemia may present initially with an isolated elevation in their platelet count or with thrombotic complications. Anemia and altered red cell morphology may occur in several of these disorders over time, sometimes culminating in leukemia or myelofibrosis with severe anemia and dyspoiesis.

Pathology

Microvascular platelet-plug occlusion of dermal vessels or subcutaneous arterioles is expected in biopsy specimens from retiform purpura/necrotic lesions in patients with these disorders, and may sometimes present as "white clot" on histologic examination.

Differential diagnosis

Useful findings which suggest platelet occlusive disease in the setting of a myeloproliferative disorder include anemia or an elevated hematocrit, abnormal white count or differential, and abnormal platelet count or platelet morphology. The differential diagnosis of reactive thrombocytosis, especially due to iron deficiency, infection or malignancy, must be considered when assessing the significance of an elevated platelet count. The presence of mutation in *JAK-2* (which encodes a protein kinase) can be confirmatory, as 90–95% of patients with polycythemia vera and 50–70% of those with essential thrombocythemia have such a mutation.

Treatment

Patients with essential thrombocythemia and polycythemia vera are more likely than patients with other myeloproliferative disorders to present with platelet counts of one million or greater, to have a good prognosis, and also to be young and female[10]. However, compared to the general population, these patients have an increased risk of morbidity from thrombotic complications, as well as from transformation into myelofibrosis with myeloid metaplasia or acute myelogenous leukemia. The cytostatic drug anagrelide has become an important therapeutic agent for thrombocytosis, as it is capable of substantially decreasing the platelet count at doses lower than those required to inhibit platelet activity[11].

Low-dose aspirin is often used for prophylaxis of thrombosis in patients with myeloproliferative thrombocytosis, but, despite widespread acceptance, its efficacy still awaits conclusive proof. Hydroxyurea may also be effective, alone or in combination with aspirin or anagrelide. The prompt and lasting relief of burning pain by low-dose aspirin is a characteristic finding in thrombocythemic erythromelalgia.

Paroxysmal Nocturnal Hemoglobinuria

Key features

- Retiform purpura
- Coombs-negative intravascular hemolytic anemia due to mutations in *PIG-A*

Introduction

Although considered to be a hemolytic anemia, paroxysmal nocturnal hemoglobinuria (PNH) is actually a rare hematopoietic stem cell disorder, probably first reported as overnight hemoglobinuria in 1882[12].

Pathogenesis

This disease is due to a somatic mutation in hematopoietic stem cells that affects the X-linked phosphatidyl inositol glycan class A (*PIG-A*) gene. This gene encodes a glycosyl phosphatidyl inositol (GPI) anchor required for the cell membrane attachment of several important membrane proteins. Some of these proteins are responsible for protecting blood cells and platelets from complement-mediated injury (e.g. CD55,

CD59). This relative lack of protection leads to red cell lysis and activation of platelets[13].

Clinical features

This acquired clonal hematologic disorder presents with intravascular hemolysis, deficient hematopoiesis, and a thrombotic tendency, with venous thrombosis affecting up to 40% of patients[14]. Venous thrombosis, including an increased incidence of Budd–Chiari syndrome with hepatic vein thrombosis, is likely multifactorial, but is due in part to microparticle formation from platelets and other blood component membranes. A variety of cutaneous findings have been reported in PNH, including hemorrhagic bullae, petechiae, leg ulcers, and lesions consistent with non-inflammatory retiform purpura[15,16]. Cytopenia of any or all blood elements is expected. Prior to 1990, red cell sucrose hemolysis was used as a screening test[12]. However, currently, a proaerolysin-based flow cytometry assay is utilized that is more specific, more sensitive, and quantitative (proaerolysin is a toxin that binds to GPI-anchored proteins).

Pathology

Biopsy specimens reveal findings consistent with microvascular occlusion secondary to platelet plugs.

Differential diagnosis

The differential diagnosis of the various skin lesions possible in this syndrome is quite diverse. However, the presence of hemolytic anemia, often with pancytopenia, should suggest the diagnosis.

Treatment

Both corticosteroid therapy and anticoagulants may be useful in the treatment of thrombotic episodes[12]; the role of antiplatelet therapy is unclear and there have been case reports of the successful use of thrombolytic therapy. Eculizumab (Soliris™), which inhibits the terminal phase of the complement cascade at the C5 stage, can reduce intravascular hemolysis and venous thrombosis[17]. Because eculizumab can increase the risk of meningococcemia via C5 inhibition, patients should receive the meningococcal vaccine at least 2 weeks before instituting therapy.

Thrombotic Thrombocytopenic Purpura–Hemolytic Uremic Syndrome

Key features

- Skin lesions of thrombotic thrombocytopenic purpura are usually macular, round petechiae due to simple hemorrhage
- Skin lesions are not part of the hemolytic uremic syndrome
- Fever, renal dysfunction (more severe in hemolytic uremic syndrome) and CNS involvement
- Microangiopathy, with red blood cell fragmentation and thrombocytopenia
- Prothrombin and partial thromboplastin times are usually normal

Introduction

Classic primary thrombotic thrombocytopenic purpura (TTP) was first described in 1925, but less classic syndromes are now included under the term TTP–hemolytic uremic syndrome (HUS). However, only TTP includes purpura in its clinical presentation. There is a consistent female predominance of 60–70% for TTP-HUS[18].

Pathogenesis

It is useful to distinguish between primary (idiopathic) TTP and secondary forms of TTP-HUS. Precipitants of secondary disease include hemorrhagic colitis and other infections (in the elderly, this can have a very high mortality rate), pregnancy, systemic drugs (particularly cyclosporine, mitomycin C, gemcitabine, tacrolimus, ticlopidine, quinine), metastatic carcinoma, autoimmune connective tissue disease (e.g. systemic lupus erythematosus), and the antiphospholipid antibody syndrome[19].

In primary acquired TTP, autoantibodies against ADAMTS13 are present, which lead to decreased activity of this metalloprotease, whose function is to cleave von Willebrand factor (vWF). As a result, large multimers of vWF are allowed to persist within the plasma and this leads to platelet aggregation and the formation of microthrombi. In the rare inherited form of TTP, there is reduced activity of ADAMSTS13 due to genetic mutations (as opposed to autoantibodies). In secondary TTP-HUS, the pathophysiology is less well understood, but is not thought to be related to dysfunction of ADAMTS13 (with the possible exception of drug-induced disease).

HUS in childhood epidemic form is usually secondary to hemorrhagic colitis with Shiga toxin-producing organisms (*Escherichia coli* 0157:H7 infection, less commonly other *E. coli* or *Shigella dysenteriae* serotypes).

Clinical features

Purpuric skin or mucous membrane lesions of TTP are most likely due to thrombocytopenia with simple petechiae formation, but rarely may be due to platelet plugging. The complete syndrome is characterized by fever, petechiae, thrombocytopenia, microangiopathic hemolytic anemia (schistocytes or fragmented red cells prominent on peripheral smear), renal disease and neurologic symptoms (most commonly headache and confusion).

Pathology

Microvascular occlusion of visceral terminal arterioles and capillaries is expected, but is rare in the cutaneous microvasculature; petechial (cutaneous) hemorrhage in TTP is most likely secondary to thrombocytopenia.

Differential diagnosis

Fever, CNS findings, renal disease, microangiopathic findings in the blood smear (red cell fragmentation), and thrombocytopenia can be seen in sepsis syndromes with disseminated intravascular coagulation (DIC), and rarely in the antiphospholipid antibody syndrome. A normal or minimally elevated prothrombin time plus profound thrombocytopenia strongly favors TTP-HUS over DIC in adults[20]. Sepsis with purpura fulminans and DIC is characterized by elevation of the prothrombin time and partial thromboplastin time.

Treatment

Treatment of primary acquired TTP includes plasmapheresis (to remove the autoantibodies) plus either plasma exchange or administration of fresh frozen plasma. It is also important to review medications for possible drug-induced variants of TTP-HUS. If plasma exchange is ineffective, rituximab has led to improvement in some TTP-HUS syndromes, including idiopathic and gemcitabine-associated[21].

DISORDERS OF CRYOGELLING OR CRYOAGGLUTINATION

Key features

- Retiform purpura in an acral location
- Due to type I cryoglobulins, cryofibrinogen or, rarely, cold agglutinins
- In acute lesions, hyaline plugs within vessels

Introduction

Cryoglobulins are immunoglobulins that reversibly precipitate or gel on cold exposure, and they are present in both serum and plasma. Cryofibrinogens are fibrinogens which gel in the cold, are consumed in clotting, and are therefore detectable only in plasma samples. Cold agglutinins are antibodies which promote agglutination of red cells on exposure to cold. All three groups can cause occlusive syndromes in the skin triggered by cold exposure. While cryofibrinogens and cold

agglutinins can be detected in many patients in association with a variety of illnesses, they are only rarely the cause of cold-related occlusion syndromes[22]. Clinical syndromes due directly to cryogelling or cryoagglutination are uncommon to rare.

Pathogenesis

Cryoglobulins, by definition, gel in the cold, but many of these proteins gel only at refrigerator temperatures, not at skin temperatures typically seen with cold exposure of acral areas. Cryoglobulins can cause disease through two mechanisms: occlusion or immune complex-mediated vasculitis. Simple occlusion with minimal early inflammation and often retiform purpura/necrosis develops when cryoproteins gel on cold exposure, and this is primarily a reflection of monoclonal immunoglobulins (IgG, IgM >> IgA, light chains), i.e. type I cryoglobulinemia, that is due to an underlying plasma cell dyscrasia or lymphoproliferative disorder. Immune complex disease leads to inflammatory purpura that is palpable, and this is a reflection of mixed cryoglobulinemia (types II or III) that is often due to hepatitis C viral infection (see Table 24.6).

Cryofibrinogen precipitate is composed of fibrinogen, fibrin, fibronectin, and, occasionally, small amounts of immunoglobulins or other plasma proteins. Cold agglutinins bind to red cells in the cold, often triggering complement activation and red cell lysis. Only IgM antibodies have enough binding sites to hold multiple red cells together.

Clinical features

Purpuric or necrotic lesions, often retiform, at acral sites of cold exposure, are cardinal signs (Fig. 23.3). Other cutaneous findings include acral cyanosis, Raynaud's phenomenon and livedo reticularis. Though some reports describe cutaneous small vessel vasculitis in patients with type I cryoglobulins, it is likely that this finding is a secondary form of leukocytoclastic vasculitis that occurs following occlusive necrosis or ulceration (see Fig. 22.3). Mixed (types II and III) cryoglobulins may cause occlusion by cryogelling if they are unstable at close to body temperature, but more frequently they induce lesions by immune complex mechanisms, with clustering in dependent areas of lesions of classic palpable purpura.

Fig. 23.3 Type I cryoglobulinemia in a patient with multiple myeloma (IgG type). Note the retiform purpura (**A**) and the areas of necrosis within the purpuric areas (**B**). Patients also have purpuric lesions on the helices of the ear and the nose. *Courtesy, Jean L Bolognia, MD.*

Since cryofibrinogenemia may be present in up to 3% of hospitalized patients, clinicopathologic correlation is critical in judging the significance of the finding of cryofibrinogenemia[23,24]. Cutaneous findings are the same as those induced by cryogelling of cryoglobulin. In a single hospital study, 22% (515/2312) of patients had cryofibrinogenemia[25], and of these, 88% also had cryoglobulinemia. Of the remaining 12% who only had cryofibrinogenemia (60 patients), 47% developed purpura, 37% skin necrosis, and 40% a thrombotic event, suggesting that cryofibrinogenemia may have greater morbidity than currently acknowledged.

Cold agglutinins are frequently asymptomatic, incidental findings, as with mycoplasmal infections. When symptomatic, cold agglutinins are usually responsible for post cold exposure hemolysis, which can be severe. Very rarely, cold exposure in patients with cold agglutinins can induce red cell agglutination, sludging and vascular occlusion in cold-exposed sites. Cold exposure includes infusion of cold blood products, with lesions at infusion sites[26]. Skin lesions are rare and include acrocyanosis, livedo reticularis, Raynaud's phenomenon or necrosis.

Pathology

Characterization of cryoglobulins by types has been discussed (see above). Histologic examination of new lesions of cold occlusion syndromes should reveal bland hyaline or red cell occlusion of vessels (Fig. 23.4). Biopsy specimens of lesions due to cryofibrinogen can demonstrate eosinophilic thrombi within small dermal vessels and necrosis.

Differential diagnosis

A sudden onset of acral disease with cold exposure should suggest this group of disorders. Occasionally, syndromes of distal occlusion, e.g. cholesterol emboli or acral antiphospholipid antibody syndrome, may have a similar appearance, but without the history of cold exposure and with sparing of the nose and ears. Chilblains (pernio) must also be considered, but lesions are usually slow in onset and seldom have significant acute purpura or necrosis.

Treatment

Therapy for cryogelling is primarily directed at minimizing cold exposure and controlling the underlying plasma cell dyscrasia or lymphoproliferative disorder (when possible) to reduce the titer of monoclonal cryoglobulin. Treatment of cryofibrinogen cryogelling is again aimed primarily at keeping acral areas warm. Stanozolol and other androgenic steroids with fibrinolysis-enhancing effects are sometimes useful adjuncts.

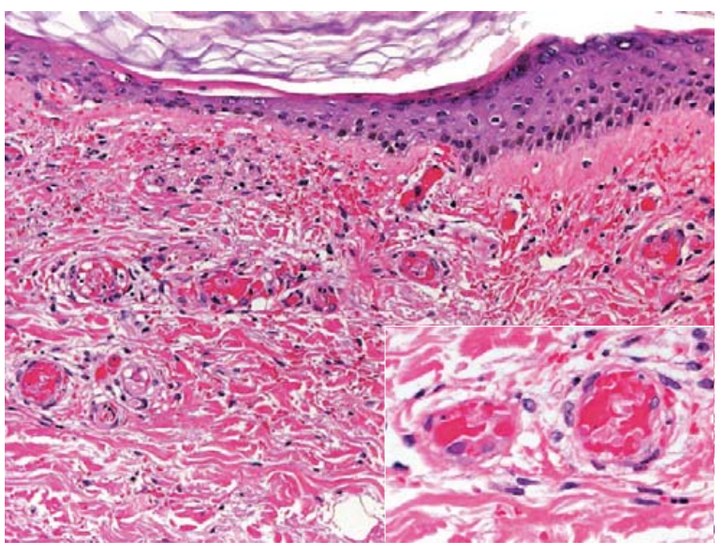

Fig. 23.4 Thrombotic vasculopathy due to type I cryoglobulinemia. In the dermis, there are fibrin thrombi within several blood vessels (insert) with hemorrhage and only a minimal inflammatory infiltrate. *Courtesy, Lorenzo Cerroni, MD.*

DISORDERS OF OCCLUSION BY OPPORTUNISTIC ORGANISMS PROLIFERATING WITHIN VESSELS

Key features

- Retiform purpura or non-inflammatory necrosis
- Often associated with administration of immunosuppressive agents or severe neutropenia
- Poorly controlled diabetes mellitus is a risk factor for mucormycosis

Introduction/pathogenesis

These syndromes share the feature of vessel invasion by organisms (see Chs 74 & 77), and they usually occur in severely immunocompromised patients. All but disseminated strongyloidiasis share the features of organism growth within the endothelium or vascular wall, usually in severely immunocompromised patients. Immunocompromise is usually due to severe neutropenia and/or to the administration of multiple potent immunosuppressive agents, but may be due to chronic disease or malnutrition.

Clinical features/pathology

Ecthyma gangrenosum is the syndrome of occlusion by organisms (usually bacterial) proliferating in the adventitia of subcutaneous blood vessels. The classic organism is *Pseudomonas aeruginosa*, but ecthyma gangrenosum-like skin lesions have also been described with other organisms, including other *Pseudomonas* spp. (*P. cepacia, P. maltophilia), Serratia marcescens, Aeromonas hydrophila, Klebsiella pneumoniae, Vibrio vulnificus, Moraxella* spp., *Morganella morganii, Escherichia coli* and *Staphylococcus aureus*; these lesions may also be due to fungal organisms, e.g. *Candida albicans, Mucor* spp., *Aspergillus fumigatus, Fusarium* spp. and *Scytalidium dimidiatum*[22].

Ecthyma gangrenosum begins as erythematous, painless macules, but typically progresses to purpuric or escharotic lesions which may be bullous or pustular, and frequently show retiform or branching features. There is extensive bacillary infiltration of the adventitia, media and perivascular regions of blood vessels, typically with sparing of the lumen and intima. As the bacteria proliferate, gradual compression of the vessel wall narrows and then ultimately occludes the lumen of a subcutaneous arteriole that supplies an overlying cone of skin. This is followed by clot formation within many blood vessels in that skin zone. Immediate antibiotic therapy is crucial, although the prognosis is poor if the neutropenia persists, if the antimicrobial agents are ineffective, or if the disease process is advanced. Of note, many authors include cutaneous lesions and histopathologic findings in this category which might more properly be classified as septic vasculitis due to bacteremia from Gram-negative rods, when sufficient neutrophils exist to provide a local response.

In severely immunocompromised patients, *vessel-invasive fungi* can result in necrotic lesions secondary to vessel invasion and thrombosis[22]. The most common opportunistic fungi in this group are *Aspergillus, Mucor, Absidia* and *Rhizopus* spp. The latter three are causes of mucormycosis. In diabetic patients, mucormycosis may present in the central face with cutaneous necrosis, presumably originating from a sinus cavity infection. Opportunistic fungi that produce retiform purpura tend to proliferate and invade from within the lumen into the vessel wall and into vascular branches. Thrombus develops around the hyphal elements within the vessels and presumably also on the altered endothelium.

Disseminated strongyloidiasis can occur in patients infected with the human nematode *Strongyloides stercoralis*. Reticulated purpuric lesions, especially in the periumbilical region, have been described with dissemination, though such lesions are rare[27]; their appearance has been likened to thumbprints (see Ch. 83). Histologically, the purpuric lesions demonstrate extravasated erythrocytes and larvae within capillaries and between collagen bundles. The mortality rate in disseminated disease is high.

Lucio's phenomenon is common in Mexico and Central America, but rare in other areas. The associated thrombotic lesions are distinguished from erythema nodosum leprosum (an immune complex-mediated neutrophilic vasculitis with variable involvement of the panniculus) by an absence of fever, leukocytosis and tenderness; being less responsive to thalidomide; and restriction to patients with diffuse non-nodular lepromatous leprosy. Acute lesions, described as having arcuate borders, seem to correspond to retiform purpura[28]. These lesions frequently progress to chronic ulcers. The histology of acute lesions shows extensive endothelial proliferation and thrombus formation in dermal and some subcutaneous vessels, with a sparse lymphocytic inflammatory infiltrate. There are a few reports of the presence histologically of leukocytoclastic vasculitis in early lesions. Acid-fast stains show aggregates of bacilli within the proliferating endothelial cells[28,29].

Differential diagnosis

Vessel-invasive organisms should be suspected in patients who are immunosuppressed or have severe neutropenia. Central facial necrotic lesions are typical of mucormycosis. Lucio's phenomenon is seen primarily in patients with diffuse lepromatous leprosy from Mexico and Central America.

Treatment

Treatment is directed at mitigating the immunocompromised state where possible, and by selecting appropriate antimicrobial therapy based on identification of the invading organism. Oral thiabendazole is the treatment of choice for disseminated strongyloidiasis, but the treatment period may be quite protracted due to the difficulty in eradicating disease in immunocompromised individuals.

DISORDERS OF OCCLUSION BY EMBOLI

Cholesterol Embolus

Synonym: ■ Warfarin blue toe syndrome

Key features

- Usually abrupt onset
- Livedo reticularis is usually much more prominent than retiform purpura
- Distal extremities, especially the legs, are the most likely site of cutaneous involvement

Introduction

Cholesterol embolus is primarily a disease of men 50 years of age or older[30]. In autopsy studies, cholesterol embolism was observed in 15–20% of patients older than 60 who had histories of atherosclerotic disease[31]. Given the relatively low frequency rate of the clinical diagnosis of cholesterol embolus, this figure suggests that cholesterol emboli are frequently undiagnosed.

Pathogenesis

Since fragmentation of ulcerated atheromatous plaques is the cause of cholesterol embolus, affected patients usually have severe (but sometimes unknown) atherosclerotic disease. Although spontaneous fragmentation of plaques with distal embolization may occur, there are three clinical settings in particular that are known to prompt embolization. The first is *arterial or coronary catheterization*, which may disrupt a plaque, leading to emboli within hours to days of catheterization. The second is *prolonged anticoagulation*, which slowly lyses the clot which reinforces a friable plaque, leaving exposed areas of the plaque subject to the shear stress of arterial flow. The anticoagulant-induced syndrome of cholesterol embolus typically occurs after 1 to 2 months of therapy. This "warfarin blue toe syndrome" is not restricted to warfarin anticoagulation and should not be confused with warfarin necrosis (see below). The third setting for cholesterol embolus is *acute thrombolytic therapy* given for myocardial infarction or stroke. Embolization may occur within hours to days of lytic therapy.

Clinical features

Clinical findings include fever, weight loss, myalgias, altered mental status and a sudden onset of arterial hypertension. Transient ischemic attacks, strokes, renal failure, gastrointestinal ulcerations and hemorrhagic pancreatitis can also occur. Patients with multisystem involvement can have significant morbidity, and occasionally they may die from complications of their emboli.

Cutaneous findings are frequent, reported in 35% of patients with cholesterol embolization[30]. Findings in these patients included: livedo reticularis (49%), multiple sites of peripheral gangrene (35%), cyanosis (28%), ulceration (17%), nodules (10%) and purpura (9%) (Fig. 23.5). Because these figures come from a review that included patients in whom the diagnosis was not made premortem (41%), it may have underestimated the incidence of cutaneous findings in cholesterol embolus patients. This point is emphasized by a study of eight patients with acute renal insufficiency of unknown cause, whose history suggested cholesterol embolus. On careful examination, all eight were found to have previously unrecognized livedo reticularis, which on biopsy confirmed the diagnosis of cholesterol embolus[32]. In two patients, the livedo reticularis was visible only in the upright, not the supine, position. Personal experience suggests that retiform purpura occurs frequently in cholesterol embolus patients with livedo reticularis, rather than in only 9% of patients. Retiform purpura is usually a purpuric accentuation of the livedo reticularis pattern, and therefore may be included as livedo reticularis in some reports. Upper extremity lesions may occur if the plaque is in the aortic arch.

Peripheral blood eosinophilia is common, occurring in up to 80% of recognized cases, and may be related to generation of the complement component C5[31]. Other reported laboratory findings include decreased complement levels, leukocytosis, pyuria, eosinophiluria, elevations in the ESR, serum creatinine, BUN and amylase, and heme-positive urine or stool[30,31].

Pathology

Biopsy specimens of the livedo reticularis generally need to be obtained by elliptical incisions centered on the blanched portion of the livedo reticularis and deep enough to include fat (see Ch. 106). Areas of retiform purpura usually provide diagnostic findings in punch biopsy specimens and should be the first choice for biopsy when present.

Histologically, cholesterol emboli produce elongated clefts within lumina of small vessels (Fig. 23.5E), often in association with thrombi[33]. The clefts are created by dissolution of cholesterol crystals during the fixation process. The affected arteriole is usually at the dermal–subcutaneous junction. Neutrophils, eosinophils and mononuclear cells may be seen in arterial walls within 24–48 hours in an experimentally produced cholesterol embolus, followed by multinucleated histiocytes within 3 to 6 days, and sometimes intimal fibrosis. Lesions of different ages may be found in the same patient, consistent with recurrent showers of emboli.

Differential diagnosis

The abrupt onset of distal livedo reticularis should prompt consideration of cholesterol or oxalate embolism. Retiform purpura, especially when it occurs distally in concert with more extensive distal livedo reticularis, is especially suggestive of this diagnosis. Acral cold occlusion syndromes (see above) need to be considered when only distal lesions are present, as well as antiphospholipid antibody syndrome.

Fig. 23.5 Cholesterol emboli. A Livedo reticularis is seen proximally on the thigh; **B** both livedo reticularis and retiform purpura are seen distally. **C** Purpura of the digits in warfarin blue toe syndrome. **D** Several irregularly shaped ulcers with eschars surrounded by retiform purpura. **E** Histologically, intravascular clefts are seen which are due to dissolution of cholesterol crystals during fixation. *A,B,E, Courtesy, Norbert Sepp, MD. D, Courtesy, Kalman Watsky, MD.*

Treatment

Treatment is mainly supportive, unless surgical bypass or endarterectomy can eliminate the source of embolism. Aspirin or other antiplatelet agents, HMG-CoA reductase inhibitors ("statins"), discontinuation of anticoagulation, initiation of anticoagulation in patients with severe renal damage, systemic corticosteroids, and infusion of the prostacyclin analogue iloprost have all been advocated as effective in occasional patients, but no therapeutic standard exists[31,33,34].

Oxalate Embolus

Introduction

Oxalate embolism is a rare event, usually occurring in association with primary hyperoxaluria. Primary hyperoxaluria results from rare metabolic disorders of increased oxalic acid production or increased intestinal absorption, leading to hyperoxalemia and calcium oxalate deposition in tissues[35,36].

Clinical features

Primary hyperoxaluria usually presents during childhood with recurrent urolithiasis. The kidney is the major site of oxalate deposition until progressive renal insufficiency develops, then clinical signs of deposition in other organs become evident. Therefore, oxalate embolus typically occurs after the development of renal failure. Death by the age of 20 years is not unusual in patients with a childhood onset. Secondary or acquired oxalosis may result from excessive intake of oxalate precursors, increased dietary absorption of oxalate, pyridoxine deficiency, impaired renal excretion, or bowel diseases such as Crohn's disease.

Cutaneous findings in systemic oxalosis include acrocyanosis, Raynaud's phenomenon, peripheral gangrene, acral cutaneous necrosis, livedo reticularis, erythematous ulcerated nodules, miliary calcified deposits, and a cutaneous calciphylaxis-like presentation[35]. The calciphylaxis-like presentation can be misleading, not only because of lesional similarity, but also because both oxalate embolus and calciphylaxis typically occur in a patient with renal failure.

Pathology

Skin biopsy specimens demonstrate findings that are characteristic, with yellow–brown, birefringent crystal deposition in rectangular or radial patterns within and around vessels in the deep dermis and subcutaneous tissue. Crystals are yellow to golden-brown in routinely stained sections and birefringent under polarized light[36]; they also stain with alizarin red S at pH 7.0 but not at pH 4.2. Although clinical lesions may mimic those of cutaneous calciphylaxis, calcium deposition in vessels is not a characteristic finding in cutaneous oxalate emboli.

Differential diagnosis

This disorder is most likely to be confused with cholesterol embolus or cutaneous calciphylaxis in a patient with renal failure, but the differential diagnosis includes all the causes of retiform purpura or livedo reticularis. The history of renal stones in a patient with sudden-onset livedo reticularis or retiform purpura suggests hyperoxaluria as a prime diagnostic possibility.

Treatment

Renal transplantation is contraindicated without correction of the underlying abnormality, since the transplanted kidney will be destroyed by the same oxalate deposition. Hepatic transplantation may reverse the metabolic effect in some patients, and in those patients renal transplantation would then be possible[36]. Simple measures include hydration and alkalinization of the urine.

Other Embolus-Associated Syndromes

In addition to emboli from acute bacterial or fungal endocarditis (which are usually inflammatory in nature), cutaneous emboli or thrombi have been rarely described in patients with atrial myxomas, marantic endocarditis, crystalglobulins and hypereosinophilic syndrome. Emboli from these disorders may produce retiform purpura, but cutaneous findings are diverse.

Atrial myxomas are rare, typically present between the third and sixth decades of life, and may be associated with constitutional symptoms of fever, malaise, arthralgias, weight loss, obstruction of blood flow mimicking valvular disease, or embolic phenomena[22]. Cutaneous findings of myxomatous emboli include acral papules (with claudication), purpuric, serpiginous or annular violaceous fingertip lesions, splinter hemorrhages, livedo reticularis, Raynaud's phenomenon, toe necrosis, a red-violet malar flush, and distal petechiae. The hereditary syndromes (Carney complex/NAME/LAMB) associated with cardiac myxomas may have other cutaneous findings such as lentigines and blue nevi, unrelated to the emboli. Treatment of atrial myxoma consists of surgical removal.

Marantic endocarditis results in focal deposits of fibrin and other blood elements on heart valves, similar to those with Libman–Sacks (antiphospholipid antibody-related) or acute rheumatic endocarditis. Portions of these loose sterile deposits may occasionally embolize. Vegetations of *infective endocarditis* may also embolize. Emboli are more likely to occur with acute bacterial endocarditis, whereas cutaneous lesions in subacute bacterial endocarditis are more likely to be the result of immune complex disease, not embolization, despite frequent localization to hands.

Crystalglobulin vasculopathy is a rare syndrome of usually IgG or light chain paraproteins which spontaneously crystallize intravascularly. The crystalglobulinemia syndrome presents with rapidly progressive renal failure, polyarthropathy, peripheral neuropathy and skin lesions. Cutaneous findings include ulcerations, petechiae and ecchymoses. Skin biopsies show intravascular crystalline deposits and thrombosis.

In the *hypereosinophilic syndrome*, intracardiac mural thrombus formation often occurs, and thrombi in smaller vessels are not uncommon at autopsy in patients with this syndrome[37,38]. However, there are very few reports of documented thrombotic or embolic skin lesions[38–40]. Clinical presentations described to date include splinter hemorrhages, "non-blanching livedoid discoloration", and necrotic, blistering or purpuric lesions. The more frequently observed cutaneous lesions in hypereosinophilic syndrome (e.g. pink plaques) are a reflection of infiltrates of eosinophils (and lymphocytes) (see Ch. 25).

SYSTEMIC COAGULOPATHIES WITH CUTANEOUS MANIFESTATIONS

While understanding of the exact mechanisms remains incomplete, it is clear that disorders of the thrombomodulin, protein C and protein S pathways are important causes of sometimes fulminant microvascular occlusion syndromes. Antiphospholipid antibodies and lupus anticoagulants are also a major known cause of microvascular occlusion, including the catastrophic antiphospholipid antibody syndrome. Many different pathways of antiphospholipid antibody-enhanced coagulation are known or suspected; some include interference with protein C or S function.

Protein C and S Disorders, Congenital and Acquired

Relevant associations: ■ Neonatal purpura fulminans – congenital severe protein C or S deficiency ■ Warfarin necrosis – acquired protein C dysfunction ■ Purpura fulminans of sepsis – probable acquired severe protein C deficiency or dysfunction ■ Purpura fulminans in children during recovery from streptococcal or varicella infections – severe acquired protein S dysfunction, probably antibody-mediated

Key feature

■ Retiform, branching or stellate purpura in one of the above clinical settings

Introduction

Warfarin necrosis has been recognized since the mid-1950s[41]. The term "purpura fulminans" was first used in the late 1800s to describe a syndrome of extensive purpura in severely ill patients, usually children, in the setting of an acute or convalescent infection. Nowadays, this term includes at least three different syndromes (see below), and is typically applied to septic patients with widespread purpura of any type (petechiae, ecchymoses, palpable purpura or retiform purpura). It would be more helpful in choosing or assessing therapy to restrict the term purpura fulminans to the subset of septic patients with clinical features of occlusion, including retiform, branching or necrotic purpura, and/or bland thrombi as the primary histologic finding.

Pathogenesis/clinical features

Despite some overlap in pathophysiologies, the differential diagnosis for cutaneous microvascular occlusion is quite different from that of deep venous thrombosis (DVT) or pulmonary embolus (PE), as discussed in Chapter 22. With respect to skin, the protein C–protein S–thrombomodulin pathway is critically important (see Fig. 22.4).

Neonatal purpura fulminans

While severe congenital deficiency of antithrombin III may result in repeated DVT or PE, the only cutaneous finding is venous stasis ulcers from DVT-induced valve destruction. In contrast, however, homozygous (or compound heterozygous) deficiency or severe dysfunction of either protein C or protein S leads invariably to neonatal purpura fulminans within a few hours to 5 days after birth; the latter is fatal unless treated. Lesions of neonatal purpura fulminans are those of non-inflammatory retiform purpura (until confluence results in large-scale cutaneous and limb necrosis) and, ultimately, visceral organ involvement. In addition, such infants are often born with cerebral thrombosis or retinal vessel occlusion with congenital blindness.

For protein C-deficient individuals, intravenous protein C concentrate is used as initial therapy and then warfarin is begun, followed by tapering of the concentrate. The warfarin is continued for life, and, occasionally, patients require chronic subcutaneous administration of protein C concentrate. Otherwise, initial anticoagulation with heparin is followed by lifelong warfarin therapy.

Warfarin (Coumadin®) necrosis

Warfarin therapy results in abnormal γ-carboxylation by the liver of the vitamin K-sensitive factors; presumably, severe vitamin K deficiency results in a similar dysfunction. The vitamin K-sensitive factors are II, VII, IX, X, protein C and protein S. Of these factors, the two with the shortest half-life are factor VII and protein C. As discussed in Chapter 22, factor VII is needed primarily to switch the idling coagulation system into progressive amplification of clotting, and there is considerable redundancy of the procoagulant cascade. Protein C, however, is critical in preventing the distal spread of clot from the initial point of coagulant activation. In warfarin necrosis, the *pro*coagulant system takes significantly longer to reach its low-point equilibrium than does the protein C-dependent *anti*coagulant activity (i.e. protein C function can drop dramatically within days).

Warfarin necrosis usually develops within 2–5 days of starting warfarin in the absence of heparin, and it is much more likely to occur if loading doses of warfarin are used[22,41]. This would coincide with the expected early drop of protein C function. In addition, reversal of warfarin necrosis via replacement with protein C concentrates and confirmation of very low functional levels of protein C support this proposed pathophysiology. The incidence of warfarin necrosis is four times higher in women, with a peak incidence in the sixth and seventh decades of life. Although up to one-third of cases of warfarin necrosis may involve inherited partial deficiency of protein C, the disorder occurs more commonly in individuals without inherited defects in protein C.

Affected sites usually overlie abundant subcutaneous fat, such as the breast, hip, buttock or thigh. Pain is often the first sign, followed by well-demarcated erythema, which rapidly becomes hemorrhagic and then necrotic (Fig. 23.6). Partial retiform or branching purpura typically can be seen within or at the margin of the cutaneous lesions. Biopsy specimens reveal bland (non-inflammatory) thrombosis of most of the dermal vessels. Treatment begins with discontinuing the warfarin; administration of vitamin K and heparin at therapeutic doses is recommended. Use of protein C concentrate should also be strongly considered.

Fig. 23.6 Warfarin (Coumadin®) necrosis. Striking areas of purpura and ischemia on the scrotum (**A**) and pannus (**B**). Note the branching outline of the purpura and central necrosis in the lesions on the abdomen. *A, Courtesy, Kenneth Greer, MD. B, Courtesy, Jean L Bolognia, MD.*

Purpura fulminans with sepsis

Recognition of the importance of the protein C–thrombomodulin pathway in maintaining cutaneous microvascular integrity suggested that careful examination of patients with DIC in the setting of sepsis might detect morphologic differences (amongst associated purpuric lesions) that were reflective of differences in pathophysiology. In a small study, the presence of retiform palpable purpura (non-inflammatory and irregular in a branching or retiform pattern) in patients with sepsis and DIC correlated with a severe protein C deficiency or dysfunction (approximately ≤20%) and it correlated histologically with extensive dermal vessel occlusion with bland thrombi[42]. This study suggests that careful assessment of physical findings could provide evidence crucial to guiding the acute care of such patients. While acquired purpura fulminans is most famously associated with meningococcal infection (see Ch. 74), it can occur in association with sepsis syndromes from a variety of bacteria, including *S. aureus*, groups A and B β-hemolytic streptococci, *S. pneumoniae, Haemophilus influenzae* and *H. aegyptius*[22].

Purpura fulminans postinfection

While protein C abnormalities seem to correlate with acquired purpura fulminans in the setting of sepsis in both children and adults, a second clinical presentation has been recognized in children which occurs during the recovery period from either group A streptococcal or varicella–zoster viral infections. These patients do not have deficient protein C activity; instead, they have an acquired antibody which interferes with protein S function[43,44]. The development of postinfectious purpura fulminans roughly 2 weeks after the onset of the initial infection would correlate well with the production of infection-triggered antibodies which interfere with protein S function. It is known that protein S requires phospholipid binding for full activity. One study has shown that transient antibodies to phospholipids or coagulation proteins are common in children with varicella–zoster viral infections, but are not predictive of thrombotic complications[45].

Treatment of this syndrome is even more challenging than treating protein C deficiency, because currently there is no commercially available protein S concentrate. In addition, it is significantly more difficult to overcome antibody-mediated inhibition of protein S than to restore

a deficiency of protein S. A combination of plasma exchange and prednisone is recommended as well as heparin anticoagulation.

Antiphospholipid Antibody/Lupus Anticoagulant Syndrome

Key features

- Livedo reticularis, retiform purpura or atrophie blanche-like lesions are typical
- The definite diagnosis of antiphospholipid antibody syndrome requires at least one clinical and one laboratory criterion (Table 23.3)

Introduction

Antiphospholipid antibody was first detected in patients with syphilis in 1906. A false-positive serologic test for syphilis in patients with lupus was recognized in 1952. This lupus anticoagulant activity was first thought to cause bleeding, but was soon associated with thrombosis. In the early 1990s, investigators recognized that clinically significant antiphospholipid/anticardiolipin antibodies often require the presence of an additional phospholipid-binding protein (e.g. β_2-glycoprotein I) in order to bind to cardiolipin[46,46a].

Epidemiology

In a 1000-patient cohort of individuals with antiphospholipid antibody syndrome (APLS), there was a strong female predominance (82% women, 18% men) and the mean age was 42 ± 14 years at study entry. Fifty-three percent of the patients had primary APLS; secondary APLS was associated with lupus in 36%, with lupus-like syndromes in 5%, and with other diseases in the remaining 6%[47]. Catastrophic APLS occurred in 0.8% of the cohort. In contrast to primary cases, patients with lupus and APLS had more episodes of arthritis, livedo reticularis, thrombocytopenia and leukopenia. Female patients had a higher frequency of arthritis, livedo reticularis and migraine, while male patients had a higher incidence of myocardial infarction, epilepsy and arterial thrombosis in the lower legs and feet. The onset of symptoms occurred most often in young to middle-aged individuals (2.8% before age 15 years, 12.7% after age 50 years).

INTERNATIONAL CONSENSUS STATEMENT – PRELIMINARY CRITERIA FOR ANTIPHOSPHOLIPID ANTIBODY SYNDROME
CLINICAL CRITERIA
1. Vascular thrombosis • One or more clinical episodes of arterial, venous or small vessel thrombosis
2. Complications of pregnancy • One or more unexplained deaths of morphologically normal fetuses at or after the 10th week of pregnancy; or • One or more premature births of morphologically normal neonates at or before the 34th week of gestation; or • Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation
LABORATORY CRITERIA
1. Anticardiolipin antibodies*, IgG or IgM, present at moderate or high levels† on two or more occasions at least 12 weeks apart
2. Lupus anticoagulant antibodies on two or more occasions at least 12 weeks apart
3. Anti-β_2-glycoprotein I antibodies, IgG or IgM (in titer >99th percentile) on two or more occasions at least 12 weeks apart
*β_2-glycoprotein I-dependent. †Several thresholds exist for low versus moderate-to-high: (1) >40 international "phospholipid" units; (2) 2–2.5× the median level of anticardiolipin antibodies (ACA); and (3) 99th percentile for ACA in the normal population.

Table 23.3 International Consensus Statement – preliminary criteria for antiphospholipid antibody syndrome[46]. Definite diagnosis requires at least one clinical and one laboratory criterion.

Pathogenesis

Antiphospholipid antibodies/lupus anticoagulants are a very important cause of purpuric cutaneous lesions and microvascular occlusion. Platelet activation leads to exposure of negatively charged platelet membrane phospholipids, followed by the sequential membrane-bound assembly of procoagulant enzyme–cofactor–substrate complexes, thrombin generation, and enzymatic conversion of fibrinogen to fibrin clot[46,48]. Thrombin, which escapes downstream from clot formation, may bind to an endothelial surface protein, thrombomodulin (see Fig. 22.4). Thrombin–thrombomodulin binding converts thrombin activity from procoagulant to anticoagulant with high-affinity activation of protein C. Disturbance of the platelet or endothelial membrane may lead to exposure of neoantigens coexpressed with negatively charged phospholipids which localize to these enzyme assembly sites. It is likely that some physiologically relevant antiphospholipid or lupus anticoagulant antibodies are directed at these altered sites, and may subsequently interfere either with normal surface protection against procoagulant enzyme assembly, or with the normal anticoagulant function of the thrombomodulin–protein C pathway.

Evidence suggests multiple mechanisms for antiphospholipid antibody-mediated thrombosis, including interference with production and release of prostacyclin by endothelial cells, interference with protein C and S pathways, activation of platelets by interaction with platelet membrane phospholipids, interference with antithrombin III activity, interference with prekallikrein activation to kallikrein, interference with endothelial plasminogen activator release, or interference with possible protective functions of proteins such as β_2-glycoprotein I or annexin V[46,48].

Clinical features

Cutaneous findings in patients with the APLS are listed in Table 23.4. In one large study, the incidences of cutaneous findings were: livedo reticularis, 24%; leg ulcers, 5.5%; pseudovasculitic lesions, 3.9%; digital gangrene, 3.3%; cutaneous necrosis, 2.1%; and splinter hemorrhages, 0.7%[47] (Fig. 23.7). Cutaneous lesions may also develop indirectly, i.e. by embolization from heart valve vegetations (see embolus section).

In addition to the skin, many other organ systems may be involved, although deep vein thrombosis/pulmonary embolus and CNS disease are the most common extracutaneous manifestations. Catastrophic APLS is an uncommon variant. Precipitating factors include surgical procedures, drugs (e.g. sulfur-containing diuretics, captopril, oral contraceptives), discontinuation of anticoagulant therapy, and especially infections. These patients often present with multi-organ failure; the majority present with renal involvement as well as evidence of acute respiratory distress syndrome.

Pathology

Antiphospholipid antibodies and lupus anticoagulants are detected by different assays. Patients positive for one type of antibody may also be

CUTANEOUS FINDINGS IN PATIENTS WITH THE ANTIPHOSPHOLIPID ANTIBODY SYNDROME
• Livedo reticularis, with or without retiform purpura
• Cholesterol embolus-like proximal livedo reticularis with distal retiform purpura
• Acral livedo reticularis
• Sneddon syndrome
• Livedoid vasculopathy or Degos-like lesions
• Anetoderma-like lesions with microthrombosis
• Raynaud's phenomenon
• Vasculitis-like lesions
• Behçet's-like lesions
• Pyoderma gangrenosum-like ulcers
• Nailfold ulcers
• Splinter hemorrhages
• Widespread cutaneous necrosis, typically as part of catastrophic APL antibody syndrome
• Pseudo-Kaposi sarcoma
• Superficial thrombophlebitis migrans

Table 23.4 Cutaneous findings in patients with the antiphospholipid (APL) antibody syndrome.

Fig. 23.7 Antiphospholipid antibody syndrome. Purpura and ischemia of the distal portion of the foot. The purpuric lesions have irregular borders (marked with ink). *Courtesy, Jean L Bolognia, MD.*

Fig. 23.8 Antiphospholipid antibody syndrome (APLS). Atrophie blanche-like scarring in a lupus patient with APLS. The lesions can also resemble those seen in malignant atrophic papulosis (Degos' disease).

positive for another, but usually because both subsets of antibodies are present rather than because of cross-reactivity between the antibodies responsible for anticardiolipin and lupus anticoagulant positivity. Screening for *antiphospholipid antibodies* is most often performed by anticardiolipin antibody testing, which detects antibodies that have an affinity for negatively charged membrane phospholipids. However, screening for anti-β_2-glycoprotein I (β_2-GPI) antibody may be more specific than that for anticardiolipin antibody, and this test is increasingly available. The *lupus anticoagulant* is an antibody which interferes with procoagulant assembly in the test tube measurement of the partial thromboplastin time, the dilute Russell viper venom test, and, uncommonly, the prothrombin time. Despite prolonging coagulation assays *in vitro* (due to the interference of the antiphospholipid antibodies with the assembly of the procoagulant complex), *in vivo* (i.e. in patients) the lupus anticoagulant antibody usually interferes with anticoagulant activity, leading to thrombosis.

Anticardiolipin antibodies are positive much more often than lupus anticoagulant antibodies, but their specificity for clinically significant disease is lower. Despite the lower specificity, clinical disease secondary to anticardiolipin antibody-positive APLS is roughly five times more common than lupus anticoagulant-positive APLS[49]. Clinically relevant antiphospholipid antibodies usually do not bind to phospholipid directly, but require a cofactor (usually a protein) before binding. The first recognized cofactor, β_2-GPI, may function *in vivo* to protect binding sites for procoagulant molecular assembly. An antibody which binds to this site might disrupt this protection, leading to thrombosis. Of note, the antibodies in patients with syphilis react directly with cardiolipin.

Other known cofactors include bound prothrombin, annexin V or components of the thrombomodulin–protein C system. Some antiphospholipid antibodies may interfere with prostacyclin production by the endothelium, leading to decreased endothelial cell anticoagulant properties. Still other antibodies may bind to platelets in a way that stimulates aggregation. Unfortunately, cofactor-dependent anticardiolipin antibodies (to β_2-GPI, annexin V or other suspected targets) or lupus anticoagulants are present often enough in patients who do not develop thromboses that they are poor predictors of thrombosis risk in asymptomatic patients without previous thromboses.

Histologic features of early lesions typically reveal non-inflammatory thrombosis of small dermal vessels; later lesions may show inflammation following necrosis or with wound healing.

Differential diagnosis

The differential diagnosis of APLS, beyond those syndromes discussed in this chapter, includes the diseases or syndromes associated with the findings in Table 23.4. In lupus patients, APLS is particularly likely to present as persistent moderate to extensive livedo reticularis or as livedoid vasculopathy (atrophie blanche; Fig. 23.8). Catastrophic APLS may mimic TTP or DIC.

Treatment

Treatment of the APLS is unfortunately empiric. Better understanding of the mechanism of thrombosis in an individual patient should lead to a better determination of prognosis and risk for future thrombosis, as well as a more specific therapy. Anticoagulation and antiplatelet agents are currently the mainstay of therapy, and are associated with variable success. In lupus patients with this syndrome, antimalarial therapy may be helpful in treating the atrophie blanche-type lesions and may be protective against arterial or venous thromboses[46]. Based upon case reports, rituximab has been used to treat severe disease[49a].

DISORDERS OF VASCULAR COAGULOPATHIES WITH CUTANEOUS MANIFESTATIONS

Sneddon Syndrome

Synonym: ■ Idiopathic livedo reticularis with cerebrovascular accidents

Key features

- Usually affects young women
- Persistent livedo reticularis or livedo racemosa
- Labile hypertension
- Recurrent neurologic symptoms due to cerebrovascular disease

Introduction

This uncommon syndrome was first described in 1965[50]. An estimated four new cases of Sneddon syndrome occur per million inhabitants per year[51,52].

Pathogenesis

Sneddon syndrome is, in a number of patients, a manifestation of the APLS (see the previous section), while in other patients it apparently represents a distinctive vasculopathy or vascular coagulopathy affecting smaller arteries and larger arterioles, especially in the skin and the brain.

Clinical features

Sneddon syndrome is characterized by persistent and usually widespread livedo reticularis, labile hypertension and CNS disease (usually transient ischemic attacks, strokes or dementia). There is a female

predominance, with onset in the third or fourth decade of life. A history of fetal loss and Raynaud's phenomenon are other features. The livedo reticularis may precede neurologic symptoms by several years.

In one comparative study, the antiphospholipid antibody-negative group was *less likely* than the antiphospholipid antibody-positive group to have seizures, mitral regurgitation by echocardiography, clinically audible mitral regurgitation, and thrombocytopenia (<150 000/μl), and *more likely* to have larger-pattern livedo reticularis with rings >1 cm in diameter[50].

Pathology

A 1–2 cm biopsy specimen from normal-appearing skin in the center of a livedo ring has been reported to have a sensitivity of 27% with one biopsy, 53% with two biopsies, and 80% with three biopsies. The characteristic, but not diagnostic, changes reported include endothelial inflammation, followed by subendothelial myointimal hyperplasia, with partial and complete occlusion of the involved arterioles[53].

Differential diagnosis

With livedo reticularis or livedo racemosa ("broken" livedo) as the characteristic cutaneous finding of this syndrome, other syndromes with persistent livedo reticularis should be considered (see Ch 106). In a group of 32 patients with generalized broken ("racemose") livedo and cerebrovascular accidents, 16 had an autoimmune disorder, thrombophilia, atherosclerosis or an atrial myxoma[54].

Screening for the presence of antiphospholipid antibodies should be part of the initial evaluation in patients with signs and symptoms of Sneddon syndrome. If, in addition to the traditional screens for antiphospholipid antibody and lupus anticoagulant activity, screening for antiprothrombin antibody is included, as many as 78% of the patients can have associated antiphospholipid antibodies[55].

Treatment

The primary treatment for Sneddon syndrome is warfarin, although this is not routinely effective[47]. Certainly, in patients with antiphospholipid antibodies or lupus anticoagulants, maintenance of anticoagulation at an international normalized ratio (INR) of 2–3 seems warranted. Corticosteroid therapy or immunosuppressive agents do not appear to prevent cerebrovascular disease.

Livedoid Vasculopathy

Synonyms: ■ Atrophie blanche ■ Livedo reticularis with summer ulceration ■ Segmental hyalinizing vasculitis ■ Livedoid vasculitis

Key features

- Favors the distal lower extremities, especially the ankles
- Female predominance
- Painful, punched-out ulcers
- White, round or stellate scars with peripheral telangiectasias
- Reticulated violaceous erythema may extend from ulcer

Introduction

This is a chronic cutaneous disease seen predominantly in young to middle-aged women. It can be divided into a primary (or idiopathic) form and a secondary form; the latter has been associated with a number of diseases, including chronic venous hypertension and varicosities as well as hypercoagulable states[56]. It would seem important in trying to understand this syndrome to exclude or separate cases of atrophie blanche-like scarring without a history of the characteristic ulcerations or surrounding livedo reticularis seen in the primary form.

Pathogenesis

The pathogenesis of livedoid vasculopathy is unknown, but it is believed to involve an alteration in local or systemic control of coagulation with formation of fibrin thrombi focally within superficial dermal blood vessels.

Clinical features

Painful, persistent and often punched-out ulcerations on the legs, especially over the malleoli and in women, should suggest this diagnosis (Fig. 23.9A)[22]. Some patients, particularly those with prominent livedo reticularis surrounding these ulcers, may develop retiform or stellate purpura or ulcer extension. Lesions tend to heal as white atrophic scars with peripheral papular telangiectasias. Some patients appear to have identifiable reasons for an occlusive proclivity, such as factor V Leiden, hyperhomocysteinemia, antiphospholipid antibodies, altered fibrinolysis or platelet activation (see Ch. 105)[56–58]. Lesions which mimic livedoid vasculopathy can be seen in patients with idiopathic and lupus-associated APLS (see above).

Pathology

The characteristic histologic findings in livedoid vasculopathy are mild perivascular lymphocytic infiltrates and extravasated red cells surrounding superficial dermal vessels with hyalinized walls and luminal fibrin deposition[22,56] (Fig. 23.9B). Although immunofluorescence findings are nonspecific, a recent study reported homogenous deposits of IgM, C3 and fibrinogen in the superficial and deep vascular plexus as supportive findings[59].

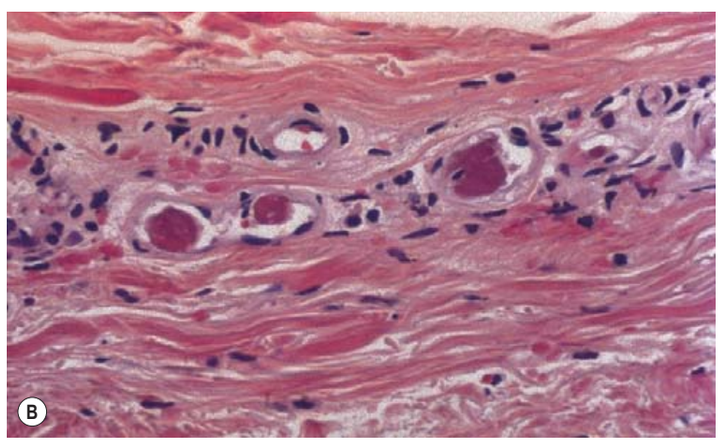

Fig. 23.9 Livedoid vasculopathy.
A Punched-out ulcers are seen on the ankle as well as multiple stellate purpuric macules.
B Thrombi are seen in the dermal blood vessels as well as a mild perivascular lymphocytic infiltrate.

Differential diagnosis

The clinical presentation of this syndrome must be distinguished from other disorders that can cause inflammatory retiform purpura (see Ch. 22). Atrophie blanche-like lesions are not specific for this syndrome, so a history of the characteristic ulcers should be used to distinguish this form of skin injury from other disorders that can lead to atrophic scarring, such as the APLS, cutaneous small vessel vasculitis, sickle cell anemia- and hydroxyurea-related leg ulcers, and, especially, venous stasis with varicosities.

Treatment

Anecdotally, successful treatment of this syndrome has been observed with antiplatelet, anticoagulant and fibrinolytic therapies[57]. Anabolic agents such as danazol and stanozolol have been helpful in some instances, as has PUVA therapy[60]. In patients with atrophie blanche-like lesions and lupus, antimalarial drugs may be helpful. Patients on hydroxyurea with atrophie blanche-like lesions may need a trial off the drug, since hydroxyurea may mimic this syndrome through unknown mechanisms.

Malignant Atrophic Papulosis

Synonym: ■ Degos' disease

Introduction

Malignant atrophic papulosis typically occurs between the second and fourth decades of life. The incidences in men and women appear to be roughly equal.

Pathogenesis

The pathogenesis of malignant atrophic papulosis is unknown, though a vasculopathy would seem to be a leading possibility.

Clinical features

Malignant atrophic papulosis is a rare vaso-occlusive disorder that predominantly affects the skin, gastrointestinal tract and CNS[22]. Cutaneous lesions begin as crops of small (2 to 5 mm) erythematous papules on the trunk or extremities. These evolve over 2 to 4 weeks, with the development of central depression and ultimately a porcelain white scar, often with a rim of telangiectasias and an appearance similar to atrophie blanche. Cutaneous findings typically precede systemic manifestations. Gastrointestinal lesions can lead to bowel perforation, and, along with CNS manifestations (e.g. cerebrovascular accidents), are the leading causes of death.

Pathology

Skin lesions are characterized histologically by a wedge-shaped area of altered dermis with a sparse perivascular lymphocytic infiltrate and an atrophic but slightly hyperkeratotic overlying epidermis. The dermis is usually altered by edema, mucin deposition and slight sclerosis, but occasionally it may be necrotic. The base of the lesion shows vascular damage with thrombosis[61].

Differential diagnosis

There are reports of a benign form with skin-limited disease, which may have a different underlying pathogenesis[62]. In addition, lesions mimicking those of malignant atrophic papulosis, i.e. Degos-like lesions, have been seen in patients with autoimmune connective tissue diseases (e.g. systemic lupus)[63]. Recognition that the APLS can produce similar lesions suggests that this entity should be excluded, particularly in patients with lupus and other autoimmune connective tissue disorders.

Treatment

There is still no proven treatment for idiopathic malignant atrophic papulosis, though occasional patients appear to respond to aspirin with or without pentoxifylline[64]. It is unclear how often those who are responsive have antiphospholipid antibodies.

DISORDERS OF CELLULAR VASCULAR OCCLUSION

Stress Reticulocyte Adhesion/Occlusion and Sickling Disorders

Just as endothelial cells are recognized to play an active role in the pathogenesis of adhesion and occlusion disorders, so too are red blood cells – specifically, stress reticulocytes – now recognized as active participants in some microvascular occlusion syndromes. The first evidence for this concept accrued from studies of cerebral malaria, where brain dysfunction and injury was shown to be related in part to adhesion by the large and sticky early reticulocytes that are released in settings of severe anemic stress. More recently, in sickle cell disease, the progressive vascular occlusion syndromes caused by ischemia-related cell sickling may be triggered by microvascular adhesion of these same stress reticulocytes. Once the vessel is occluded by these large red cells, perfusion of tissue drops, hypoxia ensues, and sickling of red cells follows, which may lead to expression of more adhesion molecules. The red cell adhesion has been attributed to thrombospondin-mediated adhesion to receptors on endothelium and on red blood cells, or by phosphatidylserine exposure on red cell membranes[65]. This binding can be blocked by coating the cells with annexin V. Interestingly, antibody interference with annexin V function on endothelial and platelet membranes has also been implicated as a mechanism for thrombosis in some patients with the APLS.

Intravascular Lymphoma

While chronic lymphocytic leukemia is the most common cause of a marked elevation of circulating atypical leukocytes, these cells are fragile and do not lead to vascular occlusion syndromes. Reduced perfusion of various organ systems may accompany high blast counts, nearly always of myelogenous origin. Cutaneous bland leukemic occlusion syndromes have not been reported, although repeated arterial occlusion from myeloblasts has been described (e.g. the retinal artery)[66]. Leukemic vasculitis in the skin has also been reported[67].

Intravascular lymphoma (B cell > T cell) is a very rare syndrome which is typically diagnosed post mortem, usually because of vague clinical findings. CNS involvement is often the most severe clinical manifestation. Skin lesions are commonly observed (40% of patients) but nonspecific and include erythematous, sometimes painful plaques or nodules and macular or telangiectatic lesions[68]. The lower extremities are the most common location (often in association with edema), followed by the trunk. Occasionally, it may present as retiform purpura (Fig. 23.10). The histopathologic finding of intraluminal occlusion by atypical lymphocytes can be missed on initial interpretation.

Fig. 23.10 Intravascular B-cell lymphoma. The clinical presentation in this patient was retiform purpura and necrosis with livedo. *Courtesy, Lucinda Buescher, MD.*

DISORDERS OF OCCLUSION, MISCELLANEOUS

Cutaneous Calciphylaxis

Synonyms: ■ Calcific arteriolopathy ■ Calcific uremic arteriolopathy

This syndrome of progressive cutaneous purpura and necrosis is most typically seen in patients with chronic renal failure (see Ch. 50). Vascular occlusion likely accounts for these cutaneous findings in most, if not all, cases, but the mechanism is controversial.

Brown Recluse Spider (*Loxosceles*) Bite

A *Loxosceles* envenomation may induce lesions of retiform purpura along with a systemic coagulopathy. While the cutaneous necrosis is undoubtedly multifactorial, the absence of bleeding during surgical debridement, a retiform morphology and extensive necrosis argue for a local microvascular occlusion syndrome in at least some of these patients.

Hydroxyurea-Associated Vascular Occlusion

By unknown mechanisms, patients with myeloproliferative diseases treated with hydroxyurea may develop painful ulcers, usually in the perimalleolar region. Some ulcers resemble those of livedoid vasculopathy, while others are larger and more shallow. Histologically, vessel findings range from inflammatory to thrombotic occlusion[69,70].

Interferon-Associated Cutaneous Necrosis

A number of cutaneous findings have been reported at β-interferon injection sites, with cutaneous microvascular occlusion and evidence of necrosis or necrotic panniculitis clinically[71,72]. While some blood vessels may have prominent perivascular inflammation, the thromboses are typically noted in the deep dermis or fat, often without inflammation.

Hematoma-Associated Retiform Purpura

Retiform purpura with necrosis, best explained by compression of subcutaneous arterioles by large trauma-induced hematomas, has been observed in multiple patients, including those with hemophilia[73].

Key features

- Cutaneous signs of vasculitis are a reflection of the size of the vessels involved
- Vasculitis can be limited to the small vessels of the skin or it can be a sign of life-threatening internal organ involvement
- The clinical diagnosis of cutaneous vasculitis requires histopathologic confirmation and multiple biopsies may be required

INTRODUCTION

Vasculitis represents a specific pattern of inflammation of the blood vessel wall and it can occur in any organ system of the body. Cutaneous vasculitis may be: (1) a skin-limited disease; (2) a primary cutaneous vasculitis with secondary systemic involvement; or (3) a cutaneous manifestation of a systemic vasculitis.

Vasculitis can affect small, medium-sized or large vessels of the arterial and/or venous systems (Table 24.1). Small vessels include arterioles, capillaries and postcapillary venules, which are found in the superficial and mid dermis of the skin. Medium-sized vessels refer to the small arteries and veins that reside within the deep dermis or subcutis. Large vessels include the aorta and named arteries. Cutaneous involvement occurs almost exclusively with vasculitis of small and medium-sized vessels; therefore, the large vessel vasculitides are discussed briefly or mentioned in Table 24.1.

In this chapter, cutaneous vasculitis refers to vasculitis with any underlying etiology and affecting any sized vessel where the clinical manifestations affect the skin. Cutaneous small vessel vasculitis (CSVV) is synonymous with cutaneous leukocytoclastic vasculitis (LCV) and refers to involvement of the postcapillary venules of the dermis by intense neutrophilic vascular inflammation.

CLASSIFICATION

The current classification scheme for cutaneous vasculitis is based upon the *predominant* size of the vessel involved (see Table 24.1).

CUTANEOUS VASCULITIS CLASSIFICATION SCHEME

Caliber of the predominantly affected vessel	Classification	Subclassification or etiologies	Morphology of cutaneous lesions
Small	Cutaneous small vessel vasculitis (CSVV)	Henoch–Schönlein purpura Acute hemorrhagic edema of infancy Urticarial vasculitis Erythema elevatum diutinum Secondary causes of CSVV (see Table 24.3): – Drug exposure – Infections – Malignancies, most often hematologic	Palpable purpura (most common) Petechiae Macular purpura Urticarial papules Vesicles Pustules Targetoid papules and plaques
Small and medium-sized ("mixed")	Cryoglobulinemia	Types II and III	Petechiae Palpable purpura Livedo racemosa Retiform purpura Ulcers Subcutaneous nodules Digital necrosis
	ANCA-associated	Microscopic polyangiitis Wegener's granulomatosis Churg–Strauss syndrome	
	Secondary causes	Infections Inflammatory disorders (e.g. AI-CTD)	
Medium-sized	Polyarteritis nodosa (PAN)	Classic (systemic) PAN	Livedo racemosa Retiform purpura Ulcers Subcutaneous nodules Digital necrosis
		Cutaneous PAN	
Large*	Temporal arteritis		Early – erythematous or cyanotic skin, alopecia, purpura, tender nodules on frontotemporal scalp Late – Ulceration and/or gangrene of frontotemporal scalp or tongue

*Cutaneous manifestations are rare.

Table 24.1 Cutaneous vasculitis classification scheme. AI-CTD, autoimmune connective tissue diseases.

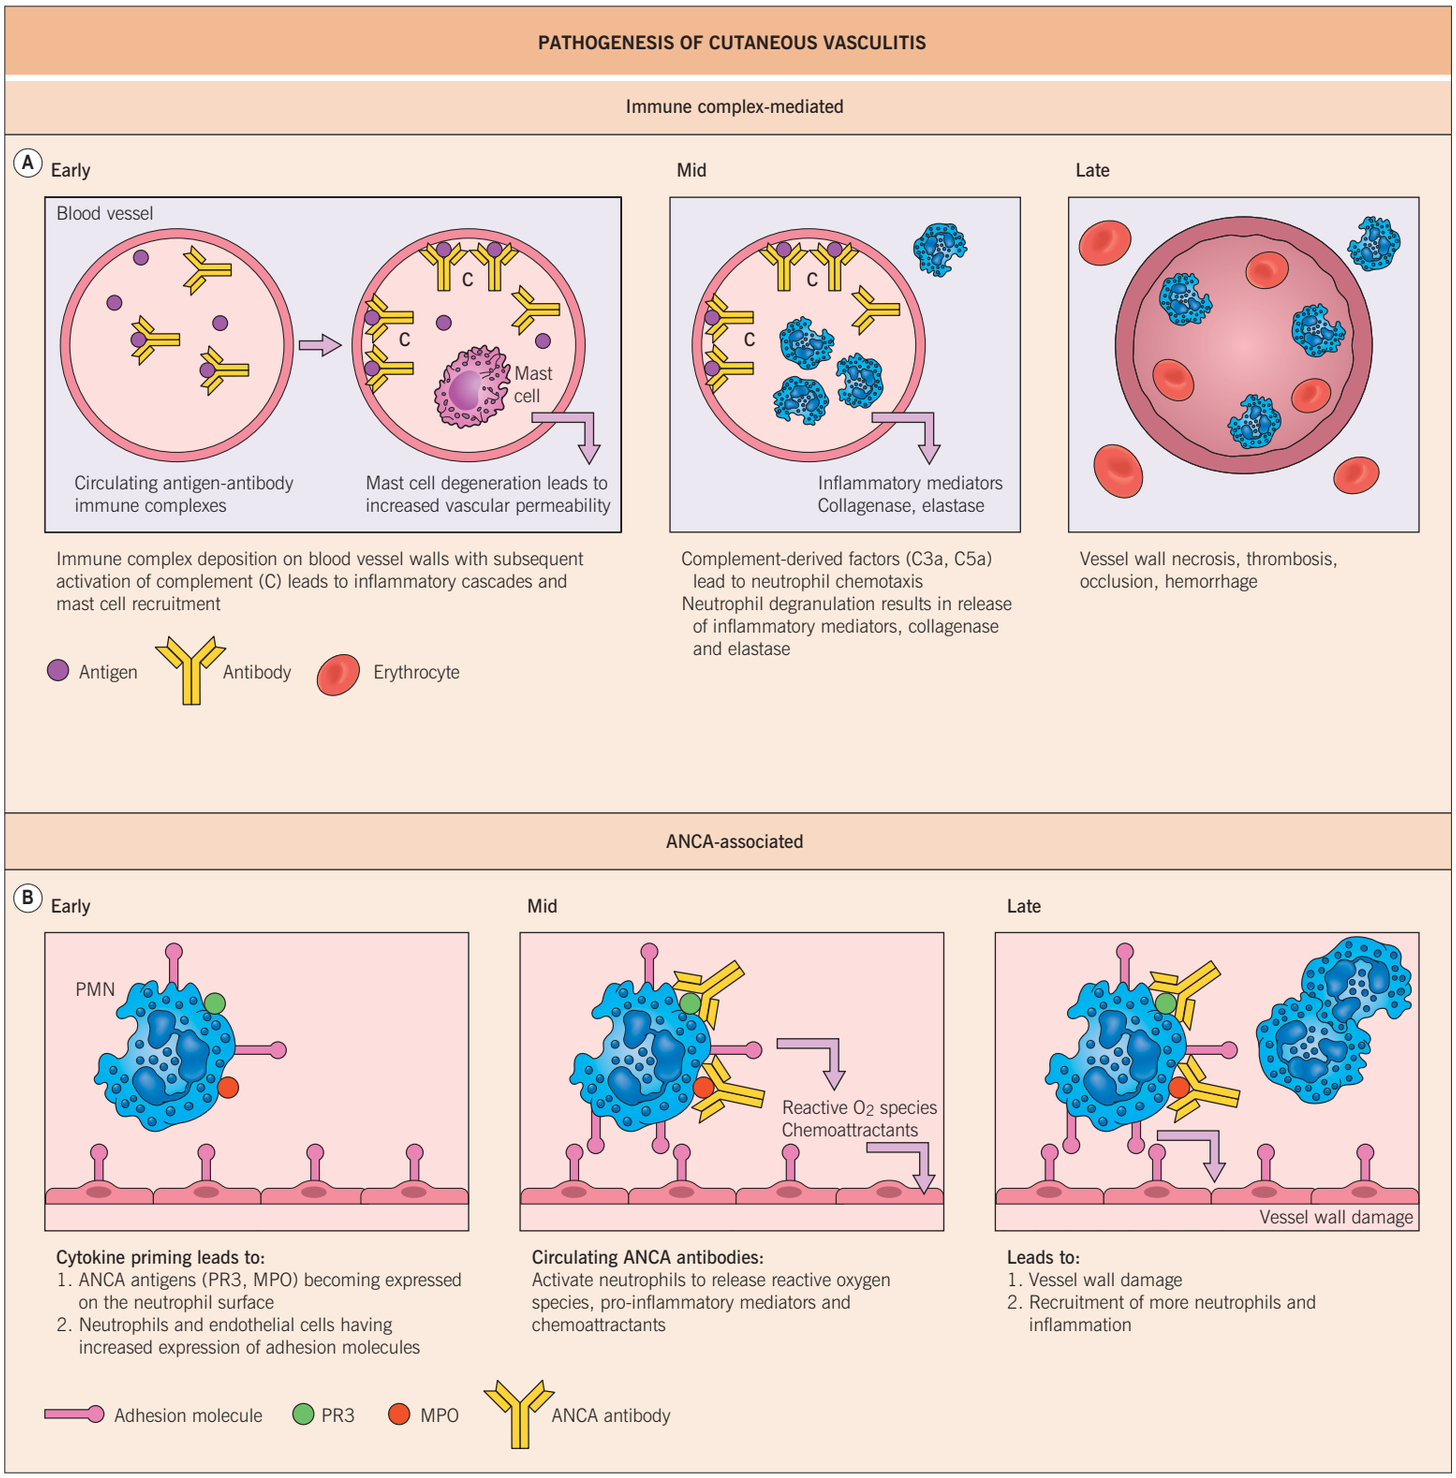

Fig. 24.1 Pathogenesis of cutaneous vasculitis – immune complex- versus ANCA-mediated. A In immune complex-mediated vasculitis, circulating antigens (e.g. infectious agents, medications, neoplasms) induce antibody formation. Binding of antibodies to circulating antigens creates immune complexes. Immune complex deposition within postcapillary venules activates complement and subsequently leads to an increase in adhesion molecule expression on the endothelium. Complement split products (C3a and C5a) induce mast cell degranulation and neutrophil chemotaxis. Mast cell degranulation leads to increased vascular dilation and permeability, enhancing immune complex deposition and leukocyte tethering to endothelium. Increased adhesion between inflammatory cells (especially neutrophils) and the endothelium is mediated by elevated expression of selectins (E-selectin, P-selectin) and members of the immunoglobulin superfamily (ICAM-1, VCAM-1, PECAM-1) on endothelial cells in concert with the upregulation of their corresponding ligands and receptors/adhesion molecules on leukocytes (e.g. P-selectin glycoprotein ligand-1, LFA-1, Mac-1) (see Ch. 102 for details). Neutrophils release proteolytic enzymes (such as collagenases and elastases) and free oxygen radicals that damage the vessel wall. In addition, formation of the membrane attack complex (C5–C9) on the endothelium leads to the activation of the clotting cascade and the release of cytokines and growth factors with ensuing thrombosis, inflammation and angiogenesis. **B** In ANCA-mediated vasculitis, intracellular proteins from neutrophils (e.g. proteinase 3 [PR3], myeloperoxidase [MPO]) become expressed on the cell surface. After formation of ANCA that recognize these antigens, binding of the autoantibodies to neutrophils leads to increased neutrophil adhesion to vessel walls and subsequent cellular activation. Neutrophils then release reactive oxygen species and other toxic mediators that result in vessel wall damage (see **A**). Because the vessel damage in ANCA-positive vasculitides is directly mediated by neutrophils rather than by immune complexes, they are referred to as "pauci-immune" vasculitides.

This then determines the clinical presentation and the corresponding histologic findings. Additional features that aid in classifying cutaneous vasculitis are systemic manifestations, direct immunofluorescence findings, and the presence or absence of antineutrophil cytoplasmic antibodies (ANCA). Despite descriptions of distinct vasculitic syndromes, there are no unique diagnostic criteria and clinicopathologic correlation is always required.

EPIDEMIOLOGY

The incidence of biopsy-proven cutaneous vasculitis of all types is 15–60 patients per million per year[1]. Cutaneous vasculitis occurs in all age groups (mean age in adults, 47 years; mean age in children, 7 years), has a slight female predominance[1,2], and is much more common in adults than in children. The majority of children have Henoch–Schönlein purpura.

PATHOGENESIS

All forms of CSVV and some forms of mixed and medium-sized vessel vasculitides (e.g. cryoglobulinemic vasculitis, polyarteritis nodosa) are mediated by immune complexes that form in the presence of antigen excess. Immune complex deposition in postcapillary venules activates complement, which, in turn, induces mast cell degranulation and neutrophil chemotaxis. Neutrophils release proteolytic enzymes and free oxygen radicals, leading to damage of the vessel wall (Fig. 24.1A). Increased adhesiveness between inflammatory cells and the endothelium, due to enhanced expression of adhesion molecules (e.g. selectins, LFA-1), also plays a role in the pathogenesis of cutaneous vasculitis (see Ch. 102).

ANCA are primarily directed against intracellular neutrophilic proteins (e.g. proteinase-3, myeloperoxidase), which can translocate to the neutrophil's cell surface following primary activation by cytokines such as tumor necrosis factor (TNF)-α. Binding to the surface of neutrophils results in neutrophil-mediated vessel damage (Fig. 24.1B). Because the vessel damage in ANCA-positive vasculitides is directly mediated by neutrophils rather than by immune complex deposition, they are referred to as "pauci-immune" vasculitides. Formation of ANCA may be related to an impairment in neutrophil apoptosis which results in a prolonged opportunity for autoantibody development.

GENERAL CLINICAL FEATURES

The skin lesions of CSVV usually appear 7–10 days after the triggering event. In systemic vasculitic syndromes, signs of systemic involvement often precede the appearance of associated cutaneous lesions (average, 6 months), but the interval can be as short as days or as long as years[1]. As noted previously, the cutaneous findings of vasculitis depend upon the predominant size of the vessels that are involved. CSVV typically presents with palpable or macular purpura, but urticarial papules, pustules, vesicles, petechiae or targetoid lesions can be seen (Figs 24.2 & 24.3). The lesions favor dependent sites, as well as areas under tight-fitting clothing, reflecting the influence of hydrostatic pressure and stasis on the pathophysiology. In general, the lesions are asymptomatic, but they may itch, burn or sting.

In medium-sized vessel vasculitis, the affected blood vessels reside within the reticular dermis or subcutis. As a result, the latter typically presents with livedo racemosa, retiform purpura, ulcers, subcutaneous nodules and/or digital necrosis. In general, the presence of ulcers or necrosis suggests deeper arterial involvement. The combination of palpable purpura (or other signs of CSVV) plus signs of medium-sized vessel disease points to a "mixed" pattern of vasculitis (see Table 24.1), as is seen in ANCA-associated vasculitides, mixed cryoglobulinemia, or autoimmune connective tissue disease-associated vasculitis. Since polyarteritis nodosa affects only medium-sized vessels, it rarely presents with cutaneous signs of small vessel involvement.

Arthralgias and arthritis as well as constitutional symptoms such as fever, weight loss and malaise can be manifestations of vasculitis of any size vessel[2]. For patients with systemic involvement, presenting symptoms and signs (e.g. abdominal pain, paresthesias, hematuria) will vary according to the affected organs.

PATHOLOGY

Timing and appropriate sampling of the most likely involved vessel increase the diagnostic yield of a skin biopsy. Ideally, lesions should be biopsied within the first 24 to 48 hours of appearance. When CSVV is suspected, a biopsy specimen for direct immunofluorescence should be obtained, as the presence of certain immunoglobulins (e.g. IgA) may suggest a particular diagnosis and influence prognosis. In general, punch biopsies are adequate for the diagnosis of CSVV while an incisional or excisional biopsy may be required to diagnose vasculitis of larger vessels.

In cutaneous vasculitis, the histologic findings vary depending upon the type and age of the sampled lesion in addition to the size of the affected vessel. The classic histopathologic features of CSVV are referred to as leukocytoclastic vasculitis and consist of transmural infiltration of the walls of small vessels (primarily postcapillary venules) by neutrophils undergoing karyorrhexis of their nuclei, as well as fibrinoid necrosis of the damaged vessel walls (Fig. 24.4). Other findings include leukocytoclasia (degranulation and fragmentation of neutrophils, leading to the production of nuclear dust), extravasated erythrocytes, and signs of endothelial cell damage. However, lesions present for greater than 48 to 72 hours may have a predominantly mononuclear rather than neutrophilic infiltrate. Palpable purpura, the most common clinical lesion of CSVV, can be explained by the infiltrate of leukocytes (palpability) and the resulting extravasation of RBCs from the damaged blood vessel (purpura).

Vasculitis of medium-sized blood vessels is characterized by similar changes involving the vessels (e.g. small arteries) of the deep reticular dermis and subcutaneous fat. Neovascularization of the adventitia, in the form of small capillaries, is commonly seen in older lesions of medium-sized vessel vasculitis.

In ~80% of cases of CSVV, direct immunofluorescence (DIF) demonstrates deposition of C3, IgM, IgA and/or IgG (generally in that order of frequency) in a granular pattern within the vessel walls[1]. Immunoglobulin deposition is highest (up to 100%) in skin lesions present for ≤48 hours[1]. On the other hand, in 30% of samples obtained 48–72 hours after lesion onset, DIF will be negative for immunoglobulins, and only C3 will be detected in lesions present for >72 hours[1]. In patients with an ANCA-positive vasculitis, the DIF of lesional skin is usually negative.

DIFFERENTIAL DIAGNOSIS

Several disorders can present with skin lesions that resemble the various cutaneous manifestations of vasculitis and they are listed in Table 24.2.

CLINICAL DIFFERENTIAL DIAGNOSIS OF CUTANEOUS VASCULITIS

Clinical presentation	Differential diagnosis
Palpable purpuric papules/plaques	Arthropod bites Morbilliform drug eruptions with hemorrhage in dependent sites Erythema multiforme Pityriasis lichenoides et varioliformis acuta Infectious emboli (septic vasculitis) due to bacteria (e.g. *Neisseria meningococcus* [acute meningococcemia]), rickettsiae, fungi (e.g. *Rhizopus)* Lichenoid capillaritis (pigmented purpura) Cellulitis
Purpuric macules/patches	**Hemorrhage** – Trauma – Solar (actinic) purpura* – Medication-related (i.e. aspirin, topical or systemic corticosteroids)* – Thrombocytopenia and platelet dysfunction – Coagulopathies* – Viral exanthems (e.g. enterovirus, parvovirus B19) – Scurvy – Primary systemic amyloidosis **Thromboses** – Hypercoagulable state (e.g. antiphospholipid antibody; see Table 105.9) – Livedoid vasculopathy – Purpura fulminans (e.g. due to sepsis/DIC) – Heparin necrosis – Coumadin necrosis – Thrombotic thrombocytopenic purpura – Hemolytic uremic syndrome – Paroxysmal nocturnal hemoglobinuria **Emboli** – Cholesterol – Cardiac (infective endocarditis >> myxomatous or marantic) – Fat – Air **Cold-related gelling** – Cryoglobulins (primarily type I) **Inflammation** – Pigmented purpura (capillaritis) – Hypergammaglobulinemic purpura of Waldenström **Infection** – Lucio's phenomenon (leprosy) – Strongyloidiasis
Urticarial lesions	Urticaria (including neutrophilic urticaria) Arthropod bites and papular urticaria Urticaria multiforme Serum sickness-like reaction Autoinflammatory diseases (e.g. periodic fevers; see Table 45.2) Still's disease Schnitzler's syndrome Viral exanthems Kawasaki disease Sweet's syndrome Urticarial phase of bullous pemphigoid
Ulcers ± atrophie blanche	Venous or arterial disease Pyoderma gangrenosum Livedoid vasculopathy Hypercoagulable state (e.g. antiphospholipid antibodies; see Table 105.9) Hemoglobinopathies Calciphylaxis Infections (e.g. bacterial, mycobacterial, dimorphic or opportunistic fungal, protozoal) Factitial Halogenodermas Degos' disease See Fig. 105.1 for additional entities
Nodules	Panniculitis Superficial migratory thrombophlebitis Dermal neoplasms Infections (e.g. bacterial, mycobacterial, dimorphic or opportunistic fungal)
Livedo reticularis	See Chapter 106
Digital gangrene	Arterial occlusive disease (atherosclerosis, etc.) Diabetes mellitus Thromboangiitis obliterans (Buerger's disease) Systemic sclerosis Emboli (e.g. cholesterol, septic) Cryoglobulinemia (type I) > cryofibrinogenemia or cold agglutinin disease Thrombosis (e.g. antiphospholipid syndrome, purpura fulminans, myeloproliferative thrombocytosis) Calciphylaxis Hypereosinophilic syndrome Paraneoplastic acral vascular syndrome (e.g. with lung or ovarian carcinoma)

*Element of trauma.

CUTANEOUS SMALL VESSEL VASCULITIS

Synonyms: ■ Cutaneous leukocytoclastic vasculitis ■ Cutaneous leukocytoclastic angiitis ■ Hypersensitivity angiitis ■ Cutaneous necrotizing venulitis

Key features

- Palpable purpura, urticarial lesions, hemorrhagic macules or vesicles
- Lesions favor the lower extremities (especially the ankles), dependent areas or pressure points
- Only involves small vessels (primarily postcapillary venules)
- Histopathologically, leukocytoclastic vasculitis is seen
- Extracutaneous involvement occurs, but it is uncommon and usually mild

Introduction

CSVV is a vasculitic process that involves primarily the dermal postcapillary venules and is characterized histologically by leukocytoclastic vasculitis (LCV). Although CSVV with LCV can be seen in the setting of mixed (small and medium-sized vessel) vasculitides (see Table 24.1), the term *CSVV* is generally reserved for small vessel vasculitis of the skin without medium-sized vessel involvement, irrespective of the clinical severity of the skin disease or the underlying etiology. CSVV is often idiopathic in nature, but may be secondary to an underlying cause such as an infection or medication (Table 24.3). Within the spectrum of CSVV are several subtypes whose rather unique epidemiologic and clinical features warrant subclassification (see Table 24.1) and separate discussion.

Epidemiology

CSVV occurs in both sexes and at all ages[3], but is more common in the adult population. It is estimated that ~10% of those affected are children. The incidence of CSVV is ~15 cases per million[1].

Pathogenesis

As depicted in Figure 24.1A, CSVV is mediated by immune complex deposition (see General Pathogenesis for details).

UNDERLYING CAUSES OF SECONDARY CUTANEOUS VASCULITIS				
Association	**Incidence**	**Agent/Disease**		
		Common	**Uncommon**	**Rare**
Idiopathic	50%			
Infection	15–20%	**Bacterial**		
		Beta-hemolytic streptococci, especially group A *Mycobacterium leprae*	*Neisseria meningococcus* (in chronic meningococcemia) *Mycobacterium tuberculosis* Atypical mycobacteria	*Mycoplasma pneumoniae* *Chlamydophila pneumoniae, Chlamydia trachomatis* *Brucella* *Bartonella henselae* *Salmonella* *Campylobacter* *Yersinia enterocolitica* *Treponema pallidum*
		Septic vasculitis*		
		Infective endocarditis	*Neisseria meningitidis* (acute) *Neisseria gonorrhea* *Staphylococcus aureus* Rickettsiae Gram-negative rods *Escherichia coli* *Klebsiella* *Pseudomonas* Disseminated fungal infections (immunocompromised hosts) *Candida* *Aspergillus* *Fusarium* *Mucor*	*Francisella tularensis*
		Viral		
		Upper respiratory tract infection Hepatitis C > B >> A, including vaccines	HIV Parvovirus B19	Cytomegalovirus Varicella zoster virus Influenza virus, including vaccine
Inflammatory disorders	15–20%	Autoimmune connective tissue diseases – Rheumatoid arthritis – SLE – Sjögren's syndrome	Inflammatory bowel disease Behçet's disease Hypergammaglobulinemic purpura of Waldenström Seronegative spondyloarthropathies	Sarcoidosis Cystic fibrosis‡ Primary biliary cirrhosis Bowel-associated dermatosis–arthritis syndrome Gluten enteropathy (adult HSP)
Drug-exposure†	10–15%	Allopurinol Bortezomib Cephalosporins, esp. cefaclor D-penicillamine G-CSF Hydralazine‡ Methotrexate Minocycline‡ NSAIDs Oral contraceptives Penicillins Phenytoin Propylthiouracil/other antithyroid agents‡ Quinidine Quinolones Serum (e.g. ATG) Streptokinase Sulfonamides Thiazides	ACE inhibitors TNF-α inhibitors Beta-blockers Cocaine adulterated with levamisole‡ COX-2 inhibitors Furosemide Interferons Leukotriene inhibitors‡,§ Macrolide antibiotics Quinine Retinoids Sirolimus Sulfonylureas Vancomycin Warfarin	Amiodarone Aspirin Atypical antipsychotics Gabapentin Insulin Leflunomide Mefloquine Metformin Methamphetamine 3,4-methylenedioxymethamphetamine Phenothiazines Radiographic contrast media Rituximab SSRIs Tocolytics (e.g. ritodrine, terbutaline) Vitamins Food/drug additives SSKI
Neoplasms	2–5%	Plasma cell dyscrasias – Monoclonal gammopathies – Multiple myeloma Myelodysplasia Myeloproliferative disorders Lymphoproliferative disorders Hairy cell leukemia	Solid organ carcinomas (adults with IgA-positive vasculitis)	
Genetic disorders	Rare			Immunodeficiency syndromes (see Table 60.1) Familial Mediterranean fever and other periodic fever syndromes (see Table 45.2)

*Histopathology varies and includes leukocytoclastic vasculitis, organisms within the vessel wall and non-inflammatory thrombotic purpura.
†Peripheral blood eosinophilia may be present in up to 80% and 20% of patients with systemic and skin-limited diseases, respectively[7a,7b].
‡May be associated with antineutrophil cytoplasmic antibodies (ANCA).
§Associated with Churg–Strauss syndrome.

Adapted from refs 3 & 4.

Clinical features

CSVV typically presents 7 to 10 days after exposure to an inciting agent with a single crop of lesions consisting of palpable purpura, erythematous papules, urticarial lesions or vesicles that range in size from 1 mm to several centimeters (see Fig. 24.2). Lesions often begin as a purpuric macule or partially blanching urticarial papule. Occasionally, pustules and targetoid lesions are seen (see Fig. 24.3). CSVV favors dependent areas, as well as areas affected by trauma (Koebner phenomenon) or under tight-fitting clothing. Although they are usually asymptomatic, the lesions can be associated with burning, pain or pruritus. Residual postinflammatory hyperpigmentation may persist for months after the primary process resolves.

Constitutional symptoms, such as fevers, weight loss and myalgias, may accompany flares of CSVV. Systemic symptoms develop in 5–25% of patients with CSVV, with arthralgias and arthritis occurring most commonly (15–65%), followed by genitourinary (3–7%) signs or symptoms and gastrointestinal involvement (3–5%)[5]. In general, signs or symptoms of gastrointestinal, renal or neurologic involvement should increase the clinical suspicion for a systemic vasculitis. In one study, the presence of paresthesias or fever and the absence of painful lesions were identified as risk factors for an associated systemic disease[6].

While the prognosis of patients with CSVV depends upon the severity of systemic involvement, approximately 90% of patients will have spontaneous resolution of cutaneous lesions within several weeks or a few months, while another 10% will have chronic or recurrent disease at intervals of months to years[7]. In the latter, the average duration of disease activity is 28 months[1]. The presence of arthralgias or cryoglobulinemia and an absence of fever may portend chronicity[6]. An underlying cause for the CSVV, such as an autoimmune connective tissue disease or neoplasm, will also affect prognosis.

Differential diagnosis

In addition to determining if the patient has a particular subtype of CSVV (see Table 24.1) or has CSVV as a manifestation of cryoglobulinemic vasculitis or a systemic vasculitic syndrome, causes of secondary cutaneous vasculitis also need to be considered (Table 24.3; Figs 24.5 & 24.6). Entities listed in Table 24.2, especially the first three categories, need to be included in the clinical differential diagnosis as well.

Treatment

The initial intervention in CSVV consists of supportive care and identifying possible triggers. The need for and choice of additional treatments depends on the severity of the cutaneous involvement, chronicity and whether or not systemic involvement is present. Specific therapeutic options are outlined in Table 24.10.

CSVV often resolves without any treatment other than avoidance of the inciting trigger. For mild skin-limited disease, supportive measures (e.g. leg elevation, avoiding tight clothing, rest) or symptomatic therapy (e.g. antihistamines, NSAIDs) may be all that is necessary.

Chronic (>4 weeks' duration) or more severe cutaneous disease may require more aggressive systemic therapy. Colchicine and dapsone may be used either alone or in combination. Oral colchicine (0.6 mg two to three times daily) is helpful for both skin and joint manifestations. However, gastrointestinal side effects are fairly common, even at low doses. Oral dapsone (50–200 mg/day) can lead to improvement of mild to moderate chronic lesions.

Patients with severe, ulcerating or progressive cutaneous disease who require rapid control of symptoms can be treated with a short course of high-dose oral corticosteroids (e.g. up to 1 mg/kg/day of prednisone). Because of the multiple adverse effects of long-term oral corticosteroids, a taper over 4 to 6 weeks should be attempted. If the patient develops recurrent CSVV as the dosage is decreased, addition of a steroid-sparing agent is warranted. Immunosuppressive agents such as azathioprine

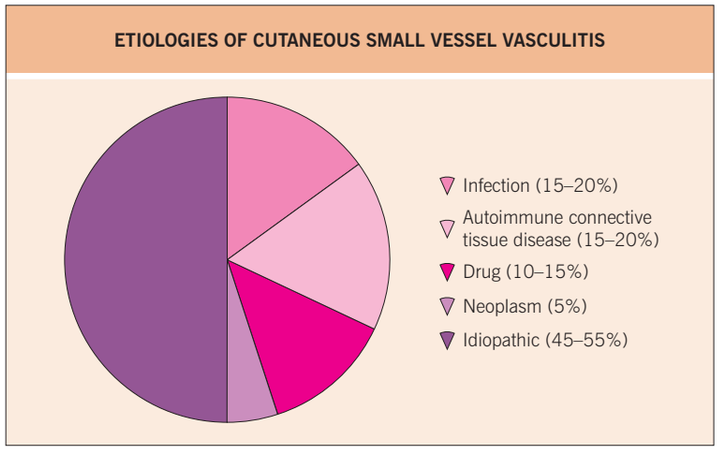

Fig. 24.5 Etiologies of cutaneous small vessel vasculitis.

Fig. 24.6 Cutaneous small vessel vasculitis associated with systemic disorders. The underlying diseases were Sjögren's syndrome (**A**), rheumatoid arthritis (**B**), and relapsing polychondritis with myelodysplasia (**C**). Note the Koebner phenomenon in **A** and rheumatoid nodules in **B**. *C, Courtesy, Jean L Bolognia, MD.*

(2 mg/kg/day) and methotrexate (<25 mg weekly) have been reported to be useful in recalcitrant CSVV.

Henoch–Schönlein Purpura

Synonyms: ■ Schönlein–Henoch purpura ■ Anaphylactoid purpura ■ Purpura rheumatica ■ Cutaneous small vessel vasculitis secondary to circulating IgA immune complexes

Key features

- Most commonly occurs in children <10 years of age and in association with a preceding respiratory infection, but may also be seen in adults
- Intermittent palpable purpura on extensor extremities and buttocks
- IgA-dominant immune deposits in walls of small blood vessels
- Arthralgias and arthritis
- Abdominal pain and/or melena
- Renal vasculitis often mild but can be chronic
- May be associated with an underlying malignancy in adults

Introduction

Henoch–Schönlein purpura (HSP) is a specific form of CSVV with vascular IgA deposition that typically affects children following a respiratory tract infection, but may also occur in adults. The classic tetrad consists of palpable purpura, arthritis, abdominal pain and hematuria. Although the relationship between HSP and other forms of vasculitis in which vascular IgA deposition is present remains controversial, the presence of IgA deposition within the walls of small blood vessels has clinical and prognostic implications in both children and adults.

Epidemiology

HSP is the most common form of vasculitis in children, with an incidence of 10 to 20 cases per 100 000 children per year. The average age of onset is 6 years and 90% of cases occur in children <10 years of age[8,9]. In adults, the incidence of HSP is 3 to 14 cases per million[10]. The disorder follows a seasonal pattern, with a peak occurrence during the winter. HSP has a slight male predominance in both children and adults.

Pathogenesis

HSP frequently presents 1 to 2 weeks following an upper respiratory tract infection, especially in children. Although several studies have reported that 20–50% of HSP patients have positive antistreptolysin O titers[8], no causal role for group A β-hemolytic streptococci has been demonstrated.

IgA (specifically IgA1) is thought to play a significant role in the pathogenesis of HSP, as IgA deposits in the postcapillary venules of the skin and mesangium, and, less commonly, circulating IgA-containing immune complexes and increased serum levels of IgA, have been demonstrated in patients with HSP[9]. Lack of glycosylation of the hinge region of IgA1 may promote the formation of macromolecular complexes that lodge within the mesangium and activate the alternate complement pathway[8].

Certain genetic polymorphisms may predispose to more severe disease in HSP, including polymorphisms in genes whose protein products are involved in the regulation of inflammation (Table 24.4). HLA-B35 positivity may predispose to renal disease, while patients who do not have the ICAM-1 469 K/E variant have less severe gastrointestinal involvement[9].

Clinical features

HSP classically presents with purpura (100% of patients) in association with arthritis, abdominal pain and/or nephritis[8]. Fever occurs in approximately 20% of adults and 40% of children[11]. Cutaneous lesions begin as erythematous macules or urticarial papules (Fig. 24.7) that evolve into palpable purpura ranging in size from pinpoint to several millimeters. Urticaria, vesicles, bullae, and foci of necrosis can also be seen.

GENETIC POLYMORPHISMS OR MUTATIONS THAT PREDISPOSE TO HENOCH–SCHÖNLEIN PURPURA OR WEGENER'S GRANULOMATOSIS	
HENOCH–SCHÖNLEIN PURPURA	
Protein product	
Mannose-binding lectin (MBL)	
MBL-associated serine protease

Vascular endothelial growth factor	
α_1-antitrypsin (deficiency)	
Gene	
Paired box gene 2	
Inducible nitric oxide synthetase 2A promoter	
MEFV (familial Mediterranean fever gene)	
Other	
HLA-B35 positivity – predisposes to renal disease	
ICAM-1 469 K/E negative genotype – less severe gastrointestinal involvement	
WEGENER'S GRANULOMATOSIS	
PTPN22 (PR3 antibodies)	
MHC (HLA-DPB1*0401)	
CTLA4	
Protease inhibitors	
Fc gamma	
PR3 promoter	

Table 24.4 Genetic polymorphisms or mutations that predispose to Henoch–Schönlein purpura or Wegener's granulomatosis. Either the gene or the protein product is listed. PR, proteinase.

Typically, lesions are symmetrically distributed on the buttocks and lower extremities, but may also involve the trunk, upper extremities and face. Individual lesions usually regress within 10 to 14 days, with resolution of skin involvement over a period of several weeks to months. Recurrences of skin disease are observed in 5–10% of patients[7].

Extracutaneous manifestations of HSP are common. Arthritis occurs in up to 75% of patients with HSP and most commonly affects the joints of the lower extremities (knees and ankles). Gastrointestinal involvement (50–75% of patients) may precede the purpura and presents with colicky abdominal pain (65%), gastrointestinal bleeding (30%) and/or vomiting. Intussusception and bowel perforation are rare complications. Renal involvement occurs in 40–50% of patients and typically presents with microscopic hematuria (40%), often accompanied by proteinuria (25%). Although the appearance of cutaneous lesions often precedes the development of nephritis, the latter is clinically evident within 3 months. Persistent renal disease (requiring longitudinal monitoring until all abnormalities resolve), is present in 30–50% of patients, but only 1–3% of children will develop long-term renal impairment[8]. Orchitis is a rare form of involvement in young boys. Poor prognostic factors include renal failure at the time of onset, nephrotic syndrome, hypertension and decreased factor XIII activity[1].

IgA small vessel vasculitis in adults, termed adult HSP by some authors, should be considered separately, as the clinical presentation and prognosis differ from that in children. For example, necrotic skin lesions are present in 60% of adults while cutaneous necrosis is observed in <5% of children[12,13]. Adults with IgA vasculitis are also more likely than children to develop chronic renal insufficiency (up to 30%)[13], especially if they have purpura above the waist, fever and an elevated ESR[12]. In addition, when CSVV is due to an underlying neoplasm, the latter is usually a hematologic malignancy (see Table 121.6). However, 60–90% of adult patients with neoplasm-associated IgA vasculitis will have cancer of a solid organ, in particular lung[14,15]. Adults are also more likely than children to have diarrhea and leukocytosis, to require more aggressive therapy, and to have a longer hospital stay[16].

Pathology

Leukocytoclastic vasculitis of the small dermal blood vessels is seen. DIF demonstrates perivascular IgA, C3 and fibrin deposits. Other immunoglobulins may be seen, but are generally not as prominent as IgA. By indirect immunofluorescence, IgA ANCA may be present in some patients.

Fig. 24.7 Henoch–Schönlein purpura. A Multiple pink papules on the lower extremities that are becoming purpuric. **B** More developed lesions with central necrosis.

Differential diagnosis

The clinical differential diagnosis includes any of the vasculitides involving small vessels (see Table 24.1) as well as several of the entities in Table 24.2. Of the several proposals for diagnostic criteria, the one developed by the European League against Rheumatism/Pediatric Rheumatology European Society (EULAR/PReS), may be the most clinically relevant to the dermatologist[17]. In addition to palpable purpura (a required criterion), at least one of the following must be present:

- arthritis (acute, any joint) or arthralgia
- diffuse abdominal pain
- any biopsy demonstrating predominant IgA deposition
- renal involvement (hematuria and/or proteinuria).

Because up to 80% of all adults with CSVV may demonstrate some vascular IgA deposition[18] and IgA deposition can be seen in other diseases (e.g. drug hypersensitivity), a diagnosis of HSP is supported by IgA *predominance* in the correct clinical setting. Evidence of medium-sized vessel disease or widespread lesions (including the face) may indicate an underlying IgA paraproteinemia.

Treatment

Because HSP is generally self-limited and resolves over the course of weeks to months, treatment is mainly supportive. Dapsone and colchicine may decrease the duration of cutaneous lesions (see Table 24.10)[19]. Systemic corticosteroids are effective in treating the arthritis and abdominal pain associated with HSP, as well as reducing the duration of skin lesions, but do not prevent recurrences of purpura[20]. Referral to a nephrologist is appropriate for patients with evidence of renal involvement. Because IgA vasculitis in adults is a more recently recognized disorder, most studies, including those discussed here, typically reflect treatment outcomes in children.

Considerable controversy surrounds the use of corticosteroids and/or immunosuppressive medications for the treatment of severe renal disease and for preventing renal sequelae in individuals who have severe renal involvement. In one study, the use of prednisone was associated with a more rapid resolution of renal disease during the 4-week treatment period (in addition to improvement of abdominal pain, arthritis and purpuric skin lesions)[20]. However, a Cochrane review of interventions for preventing and treating the renal disease of HSP found no difference in the risk of persistent kidney disease (at 6–12 months) in those children treated with prednisone (2–4 weeks) at the time of presentation as compared to placebo or supportive therapy[21]. This review also found no difference in the risk of persistent renal disease in patients with severe kidney disease who were treated with cyclophosphamide versus supportive care. A meta-analysis that examined the use of systemic corticosteroids at the time of diagnosis versus supportive care found a decrease in the mean (but not the median) time to resolution of abdominal pain, while the odds of developing persistent renal disease were decreased[22]. In sum, the current consensus appears to be that corticosteroids do not prevent renal disease but could be used to treat severe nephritis[9].

Acute Hemorrhagic Edema of Infancy

Synonyms: ■ Acute hemorrhagic edema of childhood ■ Infantile acute hemorrhagic edema ■ Finkelstein's disease ■ Seidlmayer syndrome ■ Finkelstein–Seidlmayer disease ■ Purpura en cocarde avec edema ■ Postinfectious cockade purpura

Key features

- The child is well-appearing
- Seen primarily in children between 4 and 24 months of age
- Annular, circular or targetoid purpuric plaques on the face and extremities
- Tender, non-pitting edema of acral sites
- Extracutaneous involvement rare
- Benign clinical course with spontaneous resolution within 1 to 3 weeks

Introduction

Acute hemorrhagic edema of infancy (AHEI) is a rare form of CSVV that usually affects children 4 to 24 months of age. Cutaneous lesions typically begin as plaques with variable degrees of hemorrhage which favor the head and extremities. They subsequently become edematous and targetoid in appearance. Previously considered a benign form of HSP, acute hemorrhagic edema of infancy is now recognized as its own clinical entity.

Epidemiology

AHEI is a relatively rare disorder, with approximately 300 cases reported to date in the world literature. It affects children <2 years of age, with

~70% of cases occurring in boys[23]. A seasonal variation is observed, with a peak incidence during the winter months.

Pathogenesis

Although the etiology of AHEI is unknown, 75% of patients have an associated infection, drug exposure or immunization[24]. An infectious prodrome is observed in two-thirds of patients, most commonly a respiratory tract infection (80%), diarrheal illness (12%), or urinary tract infection (6%)[23]. There are multiple reported triggers and they are listed in Table 24.5. As with other forms of CSVV, the pathogenesis of AHEI is thought to involve immune complex deposition in response to an antigenic trigger[25].

Clinical features

Children typically do not appear ill, although fever is present in ~45% of patients. The typical interval between the inciting event (see above) and the onset of disease is 1–2 weeks[26]. Cutaneous involvement presents abruptly with large erythematous patches or urticarial plaques that then evolve into medallion, annular, iris or targetoid purpuric plaques. The latter favor the cheeks, ears and extremities (Fig. 24.8), but truncal involvement may also occur. Lesions may be asymptomatic, painful, or, less commonly, pruritic. Arcuate, polycyclic, scalloped or rosette-shaped lesions and vesicobullae occur less commonly, as does healing with atrophic scars[26]. Tender, non-pitting edema of the face, ears, extremities (including the hands and feet) and scrotum is characteristic. Although mucosal and visceral involvement is rare, oral petechiae, conjunctival injection, abdominal pain, arthralgias, glomerulonephritis and intussusception (<1%) may occur[23]. The course is benign, with spontaneous and complete resolution without sequelae within 1 to 3 weeks. Although exacerbations may occur, once a remission has lasted 2 weeks, relapses as a rule are not observed[23].

Pathology

Leukocytoclastic vasculitis involving the capillaries and postcapillary venules of the upper and mid dermis is observed. By DIF, IgA deposits in a vascular pattern are seen in one-quarter to one-third of cases[23,25].

Differential diagnosis

Patients with features of both AHEI and HSP have been reported[25]. An age of onset <2 years, disease confined to the skin, and a briefer duration are characteristic of AHEI. In young children with urticarial lesions and acrofacial edema, urticaria multiforme should be considered[27]. The differential diagnosis also includes erythema multiforme, urticaria, urticarial drug eruptions, serum sickness-like reactions, Kawasaki disease, urticarial vasculitis and Sweet's syndrome. Given the significant cutaneous hemorrhage, trauma, acute meningococcemia and purpura fulminans are sometimes considered. Routine laboratory tests are nonspecific, and the diagnosis is based on appropriate clinicopathologic correlation.

Treatment

Treatment is supportive (see Table 24.10). Antibiotics should be given to treat concurrent bacterial infections. Antihistamines may be useful

for symptomatic relief. Systemic corticosteroids have not been shown to alter the course of the disease[24].

Urticarial Vasculitis

Synonyms: ■ Chronic urticaria as a manifestation of venulitis ■ Urticaria and arthralgia with necrotizing angiitis
If hypocomplementemia:
■ Hypocomplementemic vasculitis ■ Hypocomplementemia with cutaneous vasculitis and arthritis

Key features

- Recurrent episodes of painful, persistent urticarial lesions that last >24 hours and often resolve with residual hyperpigmentation
- May occur with or without angioedema
- May be associated with constitutional symptoms and arthritis
- Patients with hypocomplementemia are more likely to have systemic involvement
- Associated disorders include autoimmune connective tissue diseases (especially systemic lupus erythematosus, Sjögren's syndrome) and viral infections

Introduction

Urticarial vasculitis is a clinicopathologic entity consisting of persistent urticarial lesions that demonstrate the histopathologic features of leukocytoclastic vasculitis. Its association with autoimmune connective tissue diseases and potential overlap with systemic lupus erythematosus (SLE) distinguishes this disorder from typical CSVV. Although the relationship between urticarial vasculitis and neutrophilic urticaria is an area of debate, in this chapter, the definition of urticarial vasculitis is as follows: urticarial lesions that histopathologically demonstrate vasculitis as defined by a minimum of leukocytoclasia with vessel wall necrosis, but with or without fibrinoid deposits, perivascular inflammation or red blood cell extravasation[28].

Epidemiology

In patients with chronic urticaria in whom a strict definition of urticarial vasculitis (see above) is applied, the prevalence of urticarial vasculitis is approximately 5%[28], although this may be an overestimation. The peak incidence is during the fifth decade, and 60–80% of patients with urticarial vasculitis are female. The hypocomplementemic form occurs almost exclusively in women[29]. From 70% to 80% of cases of urticarial vasculitis are normocomplementemic and they follow a benign course with an average duration of 3 years.

Pathogenesis

The pathogenesis of urticarial vasculitis is similar to that of typical CSVV. In urticarial vasculitis, it is thought that complement activation triggers mast cell release of inflammatory mediators such as TNF-α that in turn increase the expression of ICAM on mast cells (important for eosinophil transmigration) and E-selectin on endothelial cells[28].

Although urticarial vasculitis is most often idiopathic, it can be associated with autoimmune connective tissue diseases (especially Sjögren's syndrome and SLE), serum sickness, cryoglobulinemia, infections, medications, and hematologic malignancies (Table 24.5)

Clinical features

Lesions of urticarial vasculitis consist of erythematous, indurated wheals (Fig. 24.9), with or without angioedema, that favor the trunk and proximal extremities. Urticarial vasculitis is distinguished from chronic urticaria by individual lesions that persist beyond 24 hours, are associated with burning and pain rather than pruritus, and resolve with postinflammatory hyperpigmentation. With diascopy or as residua, hemorrhage can be observed. However, these features are not always present. Rarely, bullae, erythema multiforme-like lesions, livedo reticularis, Raynaud's phenomenon and laryngeal edema are clinical manifestations of urticarial vasculitis[28].

When faced with urticarial lesions that histopathologically demonstrate features of LCV, the most important prognostic feature is the presence or absence of hypocomplementemia. Patients with normal complement levels tend to have skin-limited disease, whereas those with hypocomplementemia are much more likely to have systemic manifestations. The hypocomplementemic urticarial vasculitis syndrome (HUVS) is a more severe syndrome defined by specific diagnostic criteria[28]. They are as follows:

two major criteria: (1) urticaria for 6 months and (2) hypocomplementemia – plus –

two or more minor criteria: (1) vasculitis on skin biopsy; (2) arthralgia or arthritis; (3) uveitis or episcleritis; (4) glomerulonephritis; (5) recurrent abdominal pain; or (6) positive C1q precipitin test with a low C1q level.

Patients with hypocomplementemia who do not meet the criteria for HUVS are considered to have hypocomplementemic urticarial vasculitis (but not HUVS). While these disorders exist on a spectrum, they are not thought to transition from one to another.

Musculoskeletal involvement is the most common extracutaneous manifestation of urticarial vasculitis. Arthralgias of the hands, elbows, knees, ankles and feet occur in half of all patients with urticarial vasculitis, but up to 50% of patients with HUVS have frank arthritis[28]. Up to 20% of patients have pulmonary symptoms (cough, laryngeal edema, hemoptysis, dyspnea, asthma, chronic obstructive pulmonary disease [COPD])[7]. COPD is especially severe in smokers with urticarial vasculitis, and it is worse than would be expected due to smoking alone. Renal involvement, manifesting as proteinuria or microscopic hematuria, occurs in 5–10% of patients with HUVS[28]. Gastrointestinal manifestations (abdominal pain, nausea, vomiting, diarrhea) occur in up to 30% of patients; cardiac and central nervous system involvement are rare, but reported. HUVS shares features with SLE, but distinctive clinical findings in HUVS include ocular inflammation (30%; conjunctivitis, episcleritis, iritis, uveitis), angioedema (>50%), and COPD-like symptoms (50%)[28].

In patients with urticarial vasculitis, the most common abnormal laboratory studies are an elevated ESR, low serum C3 and C4 levels, and a positive ANA. HUVS is marked by low serum complement levels (which may vary, however, from non-detectable to normal, even during attacks) plus the presence of anti-C1q precipitin and depressed C1q levels. Although up to a third of patients with SLE have circulating anti-C1q antibodies and up to half of patients with HUVS have a positive ANA, patients with HUVS, rarely have anti-dsDNA or anti-Sm antibodies[28].

Pathology

Histopathologically, urticarial vasculitis is defined as a minimum of leukocytoclasia with vessel wall necrosis, with or without fibrinoid deposits, perivascular inflammation or red blood cell extravasation[28]. Although findings may be subtle and consist only of interstitial neutrophils or perivascular lymphocytes with extravasated erythrocytes (especially in older lesions), these findings alone do not fulfill the histologic criteria for the diagnosis of urticarial vasculitis.

Fig. 24.9 Urticarial vasculitis. Several erythematous urticarial plaques on the foot and ankle. *Courtesy, Cora Whitney Hannon, MD, and Robert Swerlick, MD.*

Eosinophils may also be noted. By DIF, 70% of lesions demonstrate deposits of immunoglobulin, C3 or fibrin around blood vessels[28]. A granular pattern of immunoreactants along the basement membrane zone occurs in ~80% of lesions and, when accompanied by hypocomplementemia, suggests the diagnosis of SLE[28]. Basement membrane immunoreactants have also been associated with renal disease[28].

Differential diagnosis

The main entity in the differential diagnosis is urticaria (including delayed pressure urticaria, in which lesions can last longer than 24 hours). Urticarial vasculitis should also be distinguished from neutrophilic urticaria, which, although considered by some to be within the spectrum of urticarial vasculitis, is not associated with hypocomplementemia or autoimmune disease and is better thought of as a subset of urticaria that histologically demonstrates a neutrophilic infiltrate without vasculitis. The differential diagnosis also includes disorders that clinicopathologically present with urticarial lesions and an interstitial neutrophilic infiltrate, including Schnitzler's syndrome, erythema marginatum (of rheumatic fever), adult-onset Still's disease, and cryopyrin-associated periodic syndromes (see Ch. 45). Additional entities to consider are the urticarial phase of bullous pemphigoid, atypical erythema multiforme, urticaria multiforme[30], Sweet's syndrome, tumid lupus erythematosus, SLE (see above), and rheumatoid neutrophilic dermatitis. For lesions of angioedema, the differential diagnosis includes acquired and inherited forms of angioedema (see Ch. 18).

Treatment

No randomized clinical trials have been performed to date to evaluate possible therapeutic options. Antihistamines may reduce the swelling and pain associated with cutaneous lesions, but do not alter the course of the disease. Oral corticosteroids are effective, but the duration of use should be kept to a minimum (see Ch. 125). Indomethacin, dapsone (with or without pentoxifylline), colchicine, hydroxychloroquine and mycophenolate mofetil have all been reported to be beneficial (see Table 24.10). Rituximab[31] or intravenous immunoglobulin[32,33] may also be a useful therapy for recalcitrant hypocomplementemic urticarial vasculitis.

Erythema Elevatum Diutinum

Key features

- Symmetric red–violet to red–brown papules and plaques
- Persistent lesions that develop on extensor surfaces
- Fibrosing leukocytoclastic vasculitis

Introduction

Erythema elevatum diutinum (EED) is a rare, chronic dermatosis, characterized by red–violet to red–brown papules, plaques and nodules that favor extensor surfaces. Histopathologic features consist of LCV in early lesions, followed by fibrotic replacement of the dermis in older lesions.

Epidemiology

Erythema elevatum diutinum is rare, with descriptions of several hundred cases in the literature. The disease can develop at any age, but is more common in middle-aged and older adults (ages 30–60 years). An earlier onset occurs more often in the setting of HIV infection[34]. The male-to-female ratio is approximately equal, and no racial predilection has been observed[35].

Pathogenesis

Although the etiology of EED is unknown, circulating immune complexes, with repeated deposition, associated inflammation and partial healing, are thought to represent the underlying pathogenesis[34]. Immune complex deposition results in complement activation, neutrophilic infiltration, and the release of destructive enzymes. The latter results in fibrin deposition in and around small dermal vessels during the later stages of the disease.

EED has been described in association with a number of systemic diseases, including infections, autoimmune diseases, and both benign and malignant hematologic disorders, especially an IgA paraproteinemia. Associated infections include β-hemolytic streptococci, HBV, HIV, tuberculosis, and syphilis[34]. Lesions identical to EED, both clinically and histologically, have been reproduced by the intradermal injection of streptococcal antigen into non-lesional skin of patients with EED[35]. In patients with HIV infection, EED may be due to either HIV-related antigen–antibody complexes directly damaging small blood vessels or HIV-induced immunosuppression allowing other infectious agents to serve as an antigenic stimulus. The observation that in patients with HIV infection EED responds to antiretroviral therapy supports an etiologic role for HIV[34].

Autoimmune or inflammatory conditions associated with EED include Wegener's granulomatosis, inflammatory bowel disease, celiac disease, relapsing polychondritis, SLE and rheumatoid arthritis. In addition to plasma cell dyscrasias (especially IgA monoclonal gammopathies), associated hematologic disorders include myelodysplasia, myeloproliferative disorders and hairy cell leukemia.

Clinical features

The typical cutaneous lesions of EED are violaceous, red–brown or yellowish papules, plaques or nodules that are symmetrically distributed. They favor acral and periarticular sites, in particular the extensor surfaces of the elbows, knees, ankles, hands and fingers (Fig. 24.10). Additional sites of involvement include the face, retroauricular area,

Fig. 24.10 Erythema elevatum diutinum. **A** Erythematous papulonodules on the knee (acute lesions) admixed with resolving lesions. **B** Firm nodule on the dorsum of the hand in a patient with HIV infection (late-stage lesion). *A, Courtesy, Kenneth Greer, MD. B, Courtesy, Rachel Moore, MD.*

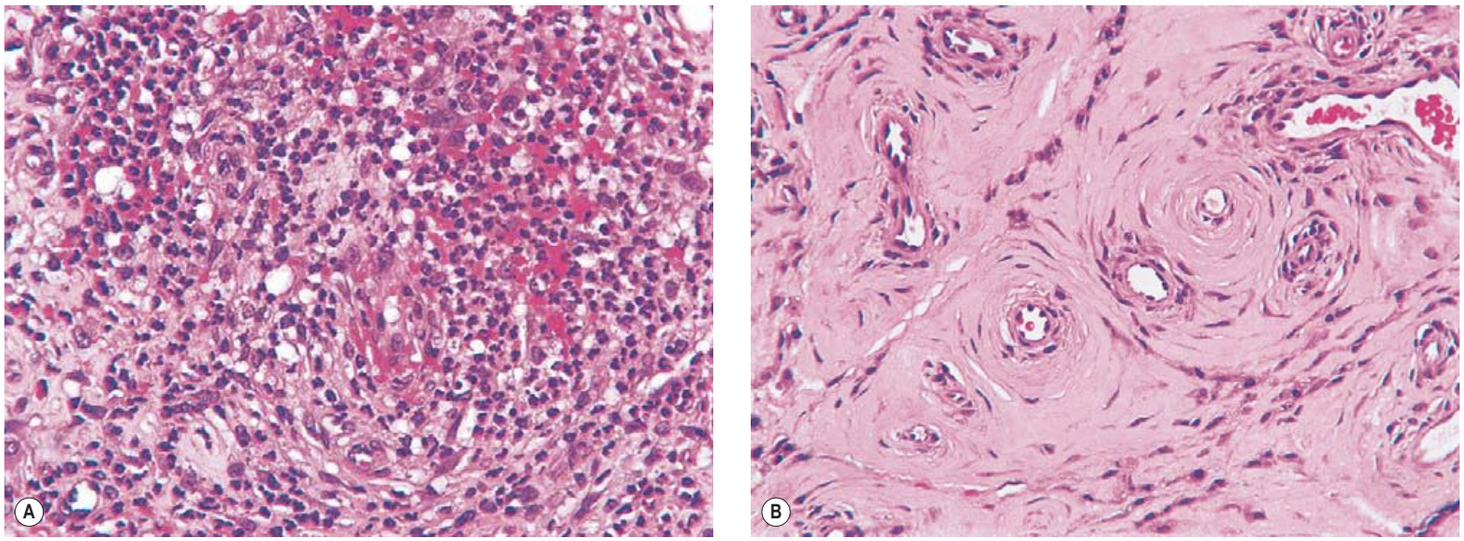

Fig. 24.11 Erythema elevatum diutinum – histologic features. A An early-stage lesion, demonstrating a dense perivascular infiltrate of neutrophils admixed with lymphocytes and histiocytes. trunk, axillae, buttocks and genitalia[36]. Initially, the lesions are erythematous and soft, but with time become red–brown or violaceous in color and doughy or firm to palpation due to fibrosis.

In general, the lesions are asymptomatic, but they can be associated with a burning sensation or pruritus, especially early on[34]. Annular plaques with a raised border[36] and verrucous plaques on the soles[37] have also been described. Nodular lesions, primarily palmoplantar, that progress to form bulky masses are characteristic of EED in the setting of HIV infection[34]. Arthralgias may develop in underlying joints[35], but extracutaneous involvement, with the exception of ocular disease, is extremely rare. There has been an increasing number of reports of associated peripheral keratitis, nodular scleritis, panuveitis and blindness[38,39]. The disease is chronic and has a relapsing and remitting course; the majority of cases resolve spontaneously over a period of 5 to 10 years, but the disease can last up to 40 years[35].

In patients presenting with EED, evaluation for an associated infection (e.g. streptococcal, viral hepatitis, HIV, syphilis), monoclonal gammopathy (serum immunofixation electrophoresis) or autoimmune disorder (see above) should be considered, based upon the clinical context.

Pathology

Early lesions of EED demonstrate the changes of LCV, with a neutrophilic infiltrate within the upper and mid dermis (Fig. 24.11A), admixed with some eosinophils. Involvement of the papillary and perifollicular adventitial dermis (without a grenz zone) is observed in more mature lesions[40]. The latter are also characterized by granulation tissue and perivascular, concentric or storiform fibrosis with mixed inflammation that is composed predominantly of neutrophils. In the late stage, capillary walls may have fibrinoid necrosis or fibrosis (Fig. 24.11B); vertically oriented capillaries can also be seen and it may be difficult to discern the features of vasculitis. Intracellular lipidosis, previously termed "extracellular cholesterolosis", is a classic finding in late-stage lesions[41].

Differential diagnosis

The clinical differential diagnosis depends upon the stage of the lesion. For earlier lesions, one needs to consider neutrophilic dermatoses (e.g. pustular vasculitis of the dorsal hands, Sweet's syndrome, rheumatoid neutrophilic dermatitis) and palisaded neutrophilic and granulomatous dermatitis. Late-stage lesions may be confused primarily with tuberous xanthomas, granuloma annulare, rheumatoid nodules, fibroid nodules of *Borrelia* and multicentric reticulohistiocytosis. Other granulomatous disorders (e.g. sarcoidosis, leprosy, necrobiotic xanthogranuloma) are sometimes in the differential diagnosis, and for an isolated lesion, dermatofibroma or dermatofibrosarcoma protuberans (DFSP). Occasionally, lesions with a prominent vascular component, especially in an HIV-infected patient, might be mistaken for Kaposi sarcoma or bacillary angiomatosis.

Histopathologically, the earliest lesions may share features with the neutrophilic dermatoses, but foci of LCV help to distinguish EED. Granuloma faciale may also be considered, but a predominance of eosinophils and plasma cells and the presence of a grenz zone are distinguishing features, as is the localization of lesions to the face. The differential diagnosis of later lesions includes tuberous xanthomas, fibrotic disorders or tumors (e.g. DFSP; see Chs 98 &, 116), and, occasionally, fibroid nodules of *Borrelia*, Kaposi sarcoma and bacillary angiomatosis[34].

Treatment

Dapsone induces dramatic improvement[42], but relapses frequently occur upon discontinuation. Other therapies include NSAIDs, niacinamide, tetracyclines, chloroquine, colchicine and plasmapheresis (see Table 24.10). Intralesional corticosteroids may be helpful for mild cases, but systemic corticosteroids are rarely indicated.

PREDOMINANTLY SMALL AND MEDIUM-SIZED VESSEL VASCULITIDES

Cryoglobulinemic Vasculitis

Synonyms: ■ Type II or III cryoglobulinemia ■ Idiopathic mixed cryoglobulinemia ■ Cryoglobulinemic purpura ■ Essential cryoglobulinemic vasculitis

Key features

- Palpable purpura, typically on the lower extremities
- Myalgias and arthralgias
- Associated with mixed serum cryoglobulins (IgM and IgG), most commonly in the setting of HCV infection
- Peripheral neuropathy and glomerulonephritis can develop

Introduction

Cryoglobulins are cold-precipitable immunoglobulins that can be divided into three subtypes, all of which have cutaneous manifestations (Table 24.6). Type I cryoglobulinemia, composed primarily of monoclonal IgM (and less frequently IgG > IgA), results in microvascular occlusion without vasculitis (see Ch. 23). In contrast, vasculitis is only seen with types II and III ("mixed cryoglobulins", composed of monoclonal and polyclonal components). This form of vasculitis may involve both small and medium-sized vessels (see Table 24.1), but preferentially

CLASSIFICATION OF CRYOGLOBULINS				
Subtype	**Molecular composition**	**Associations**	**Pathophysiology**	**Clinical manifestations**
I	Monoclonal IgM > IgG[¶]	Plasma cell dyscrasias, lymphoproliferative disorders	Vascular occlusion	Raynaud's phenomenon, retiform purpura, gangrene, acrocyanosis
II*	Monoclonal IgM[†] (>IgG[†]) against polyclonal IgG	HCV, HIV, autoimmune connective tissue diseases, lymphoproliferative disorders	Vasculitis	Palpable purpura, arthralgias, peripheral neuropathy, glomerulonephritis
III*	Polyclonal IgM[†] against polyclonal IgG			

*Referred to as "mixed" cryoglobulins because either monoclonal or polyclonal immunoglobulins bind to polyclonal immunoglobulins.
[†]Typically have rheumatoid factor activity (i.e. are directed against the Fc portion of IgG).
[¶]Rarely IgA.

Table 24.6 Classification of cryoglobulins. HCV, hepatitis C virus; HIV, human immunodeficiency virus.

involves small vessels. Approximately 15% of patients with circulating mixed cryoglobulins present with symptoms due to cryoglobulinemic vasculitis[7]. Cryoglobulinemic vasculitis typically affects the skin, peripheral nervous system and kidneys.

Epidemiology

The frequency of mixed cryoglobulinemia varies according to geographic location, e.g. there is a higher prevalence in Southern Europe than in Northern Europe or North America[43]. In northwest Spain, the annual incidence was determined to be 4.8 cases per million. Geographic variations in the frequency of mixed cryoglobulinemia likely reflect differences in the prevalence of HCV infection. While greater than 50% of patients with HCV infection have cryoglobulinemia, overt cryoglobulinemic vasculitis develops in approximately 5% of these individuals.

Pathogenesis

Mixed cryoglobulinemia occurs in the setting of specific infections, autoimmune connective tissue diseases, and hematologic malignancies[44] (see Table 24.6). When the association between HCV infection and mixed cryoglobulinemia was discovered in 1989, a cause for 70–90% of "essential" cryoglobulinemia became apparent. Only 5% of cases are associated with HBV infection, and, occasionally, EBV, cytomegalovirus, *Leishmania* and *Treponema* spp. have been implicated. In a minority of patients, mixed cryoglobulinemia has been associated with autoimmune connective tissue diseases, in particular rheumatoid arthritis, followed by Sjögren's syndrome and systemic sclerosis. Approximately 5% of the patients with mixed cryoglobulinemia have a lymphoproliferative disorder (e.g. B-cell non-Hodgkin lymphoma, chronic lymphocytic leukemia, macroglobulinemia).

It is poorly understood why mixed cryoglobulins are produced in these clinical settings. In the case of HCV and HBV infections, their production is thought to be related, at least in some patients, to the associated liver disease, e.g. patients with end-stage liver disease are at higher risk of developing mixed cryoglobulins. A significant percentage of lymphocytes in HCV-infected individuals possess a t(14;18) translocation that results in a rearrangement of *bcl-2*, whose protein product has an antiapoptotic function; this can lead to B-lymphocyte proliferation and may contribute to production of cryoglobulins. In HCV-infected patients who do not possess this *bcl-2* rearrangement, B-cell activation and subsequent cryoglobulin and autoantibody production is believed to result from chronic immune stimulation (e.g. by the virus)[43].

Cryoglobulinemic vasculitis occurs when immune complexes form from circulating cryoglobulins and then deposit within the walls of small and medium-sized vessels, but preferentially small vessels. As with other forms of cutaneous vasculitis, this immune complex deposition is believed to initiate complement activation and vascular inflammation. The presence of hepatitis C virion (in association with IgM and IgG antibodies) within vessel walls raises the possibility that viral particles are a component of the cryoprecipitate[44].

Clinical features

Cutaneous involvement occurs in up to 90% of patients with cryoglobulinemic vasculitis, most commonly manifesting as palpable purpura of the lower extremities (Fig. 24.12). Other cutaneous findings include erythematous papules, ecchymoses and dermal nodules; rarely, urticaria, livedo reticularis, necrosis, ulcerations and bullae are observed. The disease usually has a chronic course[7], and the types of lesions can reflect the size of the involved vessel (see Table 24.1). They are not typically cold-induced (as opposed to vascular occlusive lesions seen in type I cryoglobulinemia).

Common extracutaneous findings include arthritis or arthralgias (70%), peripheral (typically sensory) neuropathy (40%), gastrointestinal disease or hepatitis (30%), and membranoproliferative glomerulonephritis (25%)[7]. The hepatitis may reflect the underlying viral infection or an associated autoimmune hepatitis, or it may be a direct result of the cryoglobulinemia. Occasionally, patients have

Fig. 24.12 Cutaneous small vessel vasculitis due to mixed cryoglobulinemia. **A** The most common cause is hepatitis C viral infection. **B** Macular purpura mimicking Cullen's sign in a patient with hepatitis C infection.

xerostomia or xerophthalmia and endocrinologic disorders, e.g. thyroid, gonadal.

The most commonly associated infections, autoimmune connective tissue diseases and hematologic disorders are listed in the Pathogenesis section. Non-Hodgkin B-cell lymphoma is the most common associated malignancy. Rarely, solid tumors such as hepatocellular carcinoma and papillary thyroid carcinoma have been reported to have a relationship to cryoglobulinemic vasculitis.

With regard to the laboratory evaluation, tests for cryoglobulins can be falsely negative and need to be assayed during clinical flares on more than one occasion. In addition, the blood sample should be kept at 37°C while being transported to the laboratory. Approximately 70% of patients have circulating rheumatoid factor activity, while 20% have antinuclear antibodies. Up to 15% of patients with mixed cryoglobulinemia have a monoclonal gammopathy as detected by serum protein electrophoresis and/or immunofixation electrophoresis[7]. HBV, HCV and HIV serologies should be evaluated, followed by a determination of viral load if there is evidence of infection. Patients typically have low serum complement levels, often with low or undetectable C4 levels; however, complement levels do not necessarily correlate with the severity of the disease[43].

Pathology

Histopathologically, papular lesions show LCV, while necrotic or ulcerated lesions may demonstrate medium-sized vessel vasculitis. By DIF, granular deposits consisting predominantly of IgM and C3 in a vascular pattern are observed in the papillary dermis[1].

Differential diagnosis

The differential diagnosis of cryoglobulinemic vasculitis includes all forms of small and medium-sized vessel vasculitis (see Table 24.1). Cryoglobulinemic vasculitis can be differentiated from these disorders by the detection of circulating mixed cryoglobulins. Patients with Sjögren's syndrome can also have arthralgias, arthritis, xerostomia/xerophthalmia, and the presence of rheumatoid factor and/or mixed cryoglobulins; however, they are typically SSA (Ro)/SSB(La)-positive, have distinct histopathologic findings in salivary gland biopsies, and less frequently are found to have hepatitis, glomerulonephritis or hypocomplementemia[43].

Treatment

The treatment of mixed cryoglobulinemia should first be directed toward any underlying disease. All patients with HCV-associated mixed cryoglobulinemia should be treated with interferon-α plus ribavirin (see Table 24.10), which can lead to resolution of the cutaneous (100% of patients), renal (50%), and neurologic (25–75%) manifestations[44]. Interferon-α alone may improve the cutaneous vasculitis (50–100% of patients), but is less effective in reversing the neurologic or renal involvement. In rare cases, interferon may trigger or worsen the peripheral neuropathy. The role of newer antiviral medications such as telaprevir remains to be determined.

Plasma exchange or cytotoxic agents, such as cyclophosphamide, are often used for severe neurologic or renal involvement[43]. Corticosteroids in conjunction with cytotoxic agents may be necessary to control organ-threatening disease. Interestingly, cytotoxic drugs do not seem to affect the progression of the HCV infection and/or liver damage. More recently, use of rituximab has been shown to benefit patients with refractory HCV-associated cryoglobulinemic vasculitis as well as those with recalcitrant HCV-negative mixed cryoglobulinemia, and it has not been reported to worsen the underlying HCV infection. Sequential therapy, i.e. rituximab followed by interferon-α and ribavirin, has also been proposed for the treatment of cryoglobulinemic vasculitis[43].

ANCA-Associated Vasculitides

Introduction

The ANCA-associated vasculitides are characterized by involvement of small to medium-sized vessels, the presence of antineutrophil cytoplasmic antibodies (ANCA), and an overlapping spectrum of organ involvement, but with each having distinguishing clinical and laboratory features. The three ANCA-associated vasculitides discussed here are microscopic polyangiitis (MPA), Wegener's granulomatosis and Churg–Strauss syndrome.

ANCA are predominantly IgG autoantibodies directed against components of both primary granules of neutrophils and monocyte lysosomes and likely have an important role in the pathogenesis of ANCA-associated vasculitides[45]. By immunofluorescent staining, there are two vasculitis-relevant patterns: (1) cytoplasmic (c)-ANCA – directed against the antigen proteinase 3 (PR3); and (2) perinuclear (p)-ANCA – directed against the antigen myeloperoxidase (MPO), with other antigens (e.g. lactoferrin, cathepsin G, elastase) serving as targets in the setting of nonspecific inflammation. ANCA are detected in 85–95% of patients with Wegener's granulomatosis and MPA, and they are useful diagnostically and for monitoring disease activity[46]. These autoantibodies are also found in patients receiving certain medications and who have underlying chronic infections, rheumatologic or inflammatory disorders, and malignancies (see Table 40.6)[47].

In order to improve specificity with regard to ANCA-associated vasculitides, the indirect immunofluorescence (IIF) test should be used as a screening evaluation (detects perinuclear versus cytoplasmic staining), followed by an ELISA that specifically detects anti-PR3 and anti-MPO antibodies. However, up to 5% of serum samples are positive by ELISA only, so when there is a high index of suspicion for an ANCA-associated vasculitis, an ELISA should be performed even if the IIF screening test is negative. Anti-PR3 ANCA occur in up to 90% of patients with Wegener's granulomatosis and 30% of patients with MPA, while anti-MPO ANCA are seen in up to 60% of patients with MPA and Churg–Strauss syndrome[47]. Semi-quantitative analysis may allow for disease monitoring and response to treatment. Of note, the presence of ANCA within the first year following remission has been associated with disease relapse.

Pathogenesis

ANCA are primarily directed against intracellular neutrophilic proteins (e.g. PR3, MPO) which can translocate to the neutrophil's cell surface following primary activation by cytokines such as TNF-α. Binding to surface antigens on neutrophils results in enhanced adhesion of neutrophils to vessel endothelium and release of inflammatory mediators, with subsequent vessel damage and recruitment of additional inflammatory cells (see Fig. 24.1B). As ANCA are pathogenic, the ANCA-associated vasculitides are classically characterized by a lack of immune complex deposition in and around vessel walls ("pauci-immune").

Natural history

The morbidity and mortality of ANCA-associated vasculitides are relatively high, stemming from both systemic manifestations and complications of immunosuppressive therapy[48]. Delay in diagnosis, renal impairment, propensity for relapse, the presence of ANCA, and an older age group are risk factors for a reduction in the survival rate.

Microscopic polyangiitis

Synonyms: ■ Microscopic polyarteritis ■ Microscopic polyarteritis nodosa

Key features

- Vasculitis of capillaries, venules and medium-sized arteries
- Palpable purpura, erythematous macules and patches, splinter hemorrhages and ulcers
- Constitutional symptoms, crescentic necrotizing glomerulonephritis and alveolar hemorrhage
- Presence of p-ANCA
- Absence of granuloma formation

Introduction

Microscopic polyangiitis (MPA) is a systemic vasculitis that involves small and medium-sized arteries, with cutaneous, pulmonary and renal involvement most commonly observed. Although MPA is often recognized as a distinct clinical entity, it can have varying presentations such that some, but not all, of the characteristic clinical and laboratory findings are present in an individual patient. For example, patients may be diagnosed as having polyarteritis nodosa (PAN) if there is no evidence of

small vessel vasculitis (e.g. glomerulonephritis) or ANCA. In an attempt to allow distinction from PAN and Wegener's granulomatosis, clinical criteria for MPA have been proposed and are undergoing validation[49].

Epidemiology

Determining a precise incidence of MPA is complicated due to the lack of consensus regarding diagnostic criteria, but the estimated incidence is 3 to 24 cases per million. Men are more commonly affected than women and the reported mean age of onset is 57 years, with a peak incidence between the ages of 65 and 75 years. More severe renal vasculitis favors older patients[50].

Pathogenesis

The etiology of MPA is unknown. Unlike PAN, MPA is not associated with HBV infection; however, it may be associated with infectious endocarditis[50]. Medications or malignancy may play a role in triggering the disease[52]. ANCA are thought to play a role in the pathogenesis of MPA (see General Pathogenesis).

Clinical features

Most patients with MPA initially experience constitutional symptoms, such as fever, weight loss, arthralgias and myalgias, for months to years before other symptoms occur. Depending upon the series, from 20% to 70% of patients will have cutaneous involvement, most commonly palpable purpura (Fig. 24.13). In one study, additional skin findings, in decreasing order of frequency, were erythematous patches (50% of patients), livedo racemosa (17%), and splinter hemorrhages, urticarial plaques and ulcers (each 6%)[51]. These skin lesions developed after the renal and/or pulmonary involvement in three-quarters of patients. In another series, acral erythematous macules were described as the most common cutaneous manifestation[52]. Skin manifestations are associated with an increased incidence of arthralgias, ocular disease and mononeuritis multiplex[53].

Renal involvement occurs in nearly all patients with MPA (>90%), and a pauci-immune, crescentic, necrotizing glomerulonephritis is the primary pathology in MPA (almost identical to that observed in Wegener's granulomatosis). Pulmonary capillaritis (with dyspnea and pulmonary infiltrates) occurs in 30–50% of patients, which can result in diffuse alveolar hemorrhage (10%). Neurologic involvement is also common, usually presenting as a peripheral neuropathy or mononeuritis multiplex in up to a third of patients. However, upper respiratory tract involvement that resembles Wegener's granulomatosis develops at a much lower frequency than in the other ANCA-associated vasculitides. The progressive clinical course of MPA typically leads to renal failure and/or pulmonary hemorrhage.

Anti-MPO antibodies occur in 60% of patients, while anti-PR3 antibodies can be seen in 30% of patients with MPA in European and American series. Of note, in Chinese and Japanese patients, anti-PR3 antibodies are rarely observed[47,50]. Rare patients without renal involvement are typically ANCA-negative[48]. Additional diagnostic testing for systemic involvement is outlined in Tables 24.7 and 24.8.

Pathology

The characteristic histologic findings in microscopic polyangiitis include a segmental necrotizing vasculitis of the smallest blood vessels (capillaries, venules and arterioles) and, less often, a vasculitis of small and/or medium-sized arteries. There is no evidence of granulomatous inflammation.

Differential diagnosis

MPA frequently presents with palpable purpura and constitutional symptoms. If no additional internal organ involvement is evident at initial presentation, it may be difficult to distinguish MPA from CSSV. The differential diagnosis includes PAN, other ANCA-associated vas-

BASIC LABORATORY EVALUATION FOR PATIENTS WITH CONFIRMED CUTANEOUS VASCULITIS	
Organ system/ Suspected association	**Laboratory tests**
Hematologic	**Complete blood count with differential, platelets***; **ESR**; C-reactive protein; serum and urine protein electrophoresis, serum immunofixation electrophoresis; cryoglobulins
Gastrointestinal	**Liver function tests*; stool guaiac***
Renal	**Blood urea nitrogen***, **creatinine***; **urinalysis***; electrolytes
Infectious	Anti-hepatitis C antibody, hepatitis B surface antigen; antistreptolysin O/anti-DNase B titer; HIV antibody; urine, blood or throat culture
Immunologic	Rheumatoid factor; C3, C4, CH50; ANA; anti-dsDNA and -ENA antibodies, ANCA†
Neoplasms	CT chest/abdomen/pelvis, bone marrow biopsy, age-appropriate screening for solid tumors

*Repeated with flares of disease activity.
†Indirect immunofluorescence (IIF) should be done for screening, followed by ELISA as a confirmatory test because 5% of negative IIF test results are false-negative.

Table 24.7 Basic laboratory evaluation for patients with confirmed cutaneous vasculitis. Initial recommended tests (performed even when drug-induced vasculitis is suspected in a healthy-appearing patient) are in bold. Additional tests are done based upon suspicion of an underlying disorder or signs and symptoms of internal organ involvement. ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibodies; CT, computerized tomography; ds, double-stranded; ENA, extractable nuclear antigen (includes Sm, SSA/Ro, SSB/La).

POSSIBLE ADDITIONAL DIAGNOSTIC TESTING FOR PATIENTS WITH SUSPECTED ANCA-ASSOCIATED VASCULITIDES								
	Chest X-ray and/or chest CT scan	Electromyogram/ nerve conduction studies	Lung, nerve or kidney biopsy	Upper respiratory tract or muscle biopsy	ECG, echocardiogram	CT scan of sinuses	Serum IgE level	Consider GI and ophthalmologic examination
Microscopic polyangiitis	√	√	√					
Wegener's granulomatosis	√	√	√*	√*	√	√		√
Churg–Strauss syndrome	√	√	√		√	√	√	√
*Depends upon signs and symptoms.								

Table 24.8 Possible additional diagnostic testing for patients with suspected ANCA-associated vasculitides. This is in addition to the evaluation outlined in Table 24.7. CT, computerized tomography; ECG, electrocardiogram; GI, gastrointestinal.

KEY DISORDERS IN THE DIFFERENTIAL DIAGNOSIS OF ANCA-ASSOCIATED VASCULITIDES AND THEIR DISTINGUISHING FEATURES		
ANCA-positive vasculitic syndrome	**Disorder in differential diagnosis**	**Distinguishing features of the disorder in the differential diagnosis**
Microscopic polyangiitis	Churg–Strauss syndrome	• Eosinophilia • Asthma and sinus disease • Increased incidence of cardiac involvement
	Wegener's granulomatosis	• Granulomatous inflammation • Increased incidence of ocular and severe upper respiratory tract involvement
	Polyarteritis nodosa	• Absence of glomerulonephritis • Lower incidence of pulmonary involvement • Vasculitis of renal arteries rather than small vessel vasculitis • Renovascular hypertension • ANCA-negative
	Goodpasture syndrome	• Kidney-bound or circulating anti-glomerular basement membrane antibodies
	SLE or rheumatoid vasculitis	• Distinct rheumatologic serologies • In SLE, develops in individuals with longstanding disease
Wegener's granulomatosis	Churg–Strauss syndrome	• Eosinophilia • Asthma • Lower incidence of severe renal disease
	Microscopic polyangiitis	• Absence of granulomatous inflammation
	NK/T-cell lymphoma	• Destructive nasal midline lesion (see Table 45.3) • Characteristic histology
	Tuberculosis (lupus vulgaris), leprosy	• Destructive nasal midline lesion • Characteristic histologic features and laboratory findings
	Cocaine-induced destructive nasal midline lesion	• By ELISA, ANCA is positive for both human neutrophil elastase and proteinase 3
	Goodpasture syndrome, SLE, rheumatoid arthritis	• See above
Churg–Strauss syndrome	Microscopic polyangiitis	• No granulomatous inflammation • No history of asthma • No hypereosinophilia
	Wegener's granulomatosis	• Increased incidence of glomerulonephritis • Lower incidence of cardiac or peripheral nerve involvement
	Hypereosinophilia, secondary	• Due to medications, parasitic infections, allergic disease, malignancy
	Hypereosinophilic syndrome	• Pruritus, eczematous or urticarial eruptions, oral ulcerations and angioedema

Table 24.9 Key disorders in the differential diagnosis of ANCA-associated vasculitides and their distinguishing features. ANCA, antineutrophil cytoplasmic antibodies; ELISA, enzyme-linked immunosorbent assay.

culitides (see below), Goodpasture syndrome, SLE and rheumatoid vasculitis (Table 24.9).

Treatment

Treatment of MPA is divided into two phases: induction of remission and maintenance therapy. To induce remission, corticosteroids (e.g. 1 mg/kg/day of prednisone) are initially used, with addition of cyclophosphamide for patients with significant organ involvement (e.g. renal, pulmonary or neurologic) (see Table 24.10)[54]. Cyclophosphamide may be given for 6 months, either orally (2 mg/kg/day) or as intravenous pulses (0.5–1.0 g/m^2/month); pulse therapy reduces the total drug dose and incidence of side effects such as bladder carcinoma. Recent data suggest that corticosteroids plus rituximab may be equally effective as corticosteroids plus cyclophosphamide[55,56]. Methotrexate, azathioprine, mycophenolate mofetil and IVIg may be useful as corticosteroid-sparing agents, particularly in maintenance of remission[57]. Plasma exchange has proved beneficial in ANCA-positive patients. Targeted systemic immunomodulators ("biologics") such as infliximab show promise, but further evidence is required[50]. Patients with MPA have a higher rate of relapse compared to patients with classic PAN (regardless of disease severity)[54], but a lower rate than those with Wegener's granulomatosis. Persistence of ANCA despite induction of a remission is associated with an increased risk of relapse.

THERAPEUTIC LADDER FOR PATIENTS WITH VASCULITIS

Wegener's granulomatosis

Synonyms: ■ Granulomatosis with polyangiitis (Wegener's)

Key features

- Necrotizing granulomatous inflammation of the upper and lower respiratory tracts
- Pauci-immune glomerulonephritis
- Systemic vasculitis that can involve the skin and oral mucosa

Introduction

Wegener's granulomatosis is classically described as the triad of granulomatous inflammation of the upper and lower respiratory tracts, systemic necrotizing small vessel vasculitis, and pauci-immune glomerulonephritis. Patients with Wegener's granulomatosis exist along a spectrum of severity, from localized to systemic involvement. Patients with systemic disease typically have multi-organ involvement with (generalized disease) or without (limited or early systemic disease) functional impairment, and they have a high mortality rate if left untreated. On the other hand, patients with localized forms of Wegener's granulomatosis have primarily airway disease without constitutional symptoms or systemic vasculitis. The initial evaluation of patients with Wegener's granulomatosis should establish the extent of organ involvement, as recent evidence supports distinct treatment approaches for localized versus generalized forms of the disease[45,48].

Epidemiology

The incidence of Wegener's granulomatosis is estimated to be 5 to 12 cases per million, with a slight female predominance. The disease occurs most often in Caucasians, with a peak age of onset of 45–65 years. Wegener's granulomatosis is one of the more common systemic vasculitides of children, with an incidence of 0.03 to 3.2 per 100 000 children per year[58].

Pathogenesis

The pathophysiology of Wegener's granulomatosis is reflected in two clinicopathologic hallmarks of the disease – granuloma formation and small to medium-sized vessel vasculitis. ANCA, environmental factors and genetic polymorphisms (see Table 24.4) all contribute to immune dysregulation. Although the specific pathogenic roles of PR3 or anti-PR3 antibodies remain unclear, surface expression of PR3 on apoptotic and/or activated neutrophils may stimulate dendritic cell maturation and proinflammatory cytokine release by antigen-presenting cells, thereby favoring development of Th1-mediated granuloma formation (termed "neutrophil priming"). Expression of PR3 on the cell surface of neutrophils may impede phagocytosis by macrophages, thus prolonging the opportunity for autoantibody development. In turn, ANCA binding to PR3 on neutrophils results in vessel damage (e.g. pauci-immune or nonimmune complex-mediated vasculitis; see Fig. 24.1B)[46,59]. Neutrophil priming may occur as a result of certain infections, such as *Staphylococcus aureus*. Of note, nasal carriage of *S. aureus* is associated with relapse of Wegener's granulomatosis and treatment of nasal carriage with antibiotics improves outcome.

Clinical features

Several groups have defined clinical criteria for Wegener's granulomatosis, having reached some consensus[58]. Existing criteria consist of: nasal and sinus or oral inflammation; typical radiologic features on chest radiograph or chest CT scan; abnormal urinalysis; biopsy-proven granulomatous inflammation; airway stenosis; and serologic findings (e.g. anti-PR3 ANCA). Mucocutaneous involvement occurs in ~40% of patients, and it can be the presenting sign in 10%[7]. The most common lesions are palpable purpura, followed by oral ulcers (Fig. 24.14). The gingival tissue is often red, friable and hyperplastic ("strawberry gums"). Painful subcutaneous nodules and ulcers that resemble

Fig. 24.14 Wegener's granulomatosis. A Sharply demarcated ulcer on the distal lower extremity, sometimes misdiagnosed as pyoderma gangrenosum. **B** Ulceration of the tongue. **C** Subungual digital infarcts resembling splinter hemorrhages. **D** Palpable purpura of the distal lower extremity due to small vessel vasculitis (leukocytoclastic vasculitis). *A, Courtesy, Irwin Braverman, MD.*

pyoderma gangrenosum can also be seen. Papulonecrotic lesions are common and usually occur on the extremities (particularly the elbows), but can also affect the face and scalp.

The upper or lower respiratory tracts are involved in up to 90% of patients with Wegener's granulomatosis. Nasal, sinus, tracheal and ear involvement represent the presenting complaints in >70% of patients. Suggestive symptoms and signs include recurrent epistaxis, mucosal ulcerations, nasal septal perforation and saddle nose deformity. Patients with pulmonary involvement typically present with dyspnea, cough, hemoptysis or pleuritis, and chest X-rays demonstrate irregular infiltrates or nodules. Renal disease is present in only 20% of patients at presentation, but approximately 75% of patients eventually develop glomerulonephritis[60]. Other organ systems commonly affected by necrotizing vasculitis in Wegener's granulomatosis include musculoskeletal (70%), ocular (30–60%), neurologic (20–50%), gastrointestinal (5–10%) and cardiac (5–40%).

Laboratory findings are consistent with an inflammatory process, including elevated acute phase reactants (ESR, C-reactive protein), anemia and leukocytosis. Up to 50% of patients have a positive rheumatoid factor. C-ANCA with anti-PR3 specificity occurs in approximately 80–90% of patients with generalized Wegener's granulomatosis, but only 60% of patients with localized disease. Anti-MPO antibodies occur in approximately 10% of patients. Patients with renal involvement have active urine sediments with proteinuria, hematuria and red blood cell casts as well as progressive renal failure. Additional diagnostic testing for systemic involvement is outlined in Table 24.8.

Pathology

Although the majority of skin biopsy specimens show nonspecific histopathologic changes (e.g. perivascular lymphocytic infiltrates), up to 50% demonstrate leukocytoclastic vasculitis and/or granulomatous inflammation. Biopsies of papulonecrotic lesions show a palisading neutrophilic dermatitis with areas of granulomatous inflammation that surround foci of basophilic necrobiosis (see Ch. 45).

Differential diagnosis

The primary differential diagnosis for Wegener's granulomatosis includes the other ANCA-associated vasculitides, in particular Churg–Strauss syndrome, as both diseases are characterized by necrotizing, granulomatous vasculitis. Additional disorders and their distinguishing features are outlined in Table 24.9.

Treatment

The standard treatment for patients with generalized Wegener's granulomatosis is systemic corticosteroids (e.g. 1 mg/kg/day of prednisone) in conjunction with oral daily cyclophosphamide (see Table 24.10), resulting in a remission in up to 75% of patients and an 87% survival rate (in one study that followed patients for 6 months to 2 years after treatment)[45,60]. Pulsed intravenous cyclophosphamide also induces remissions and is associated with less toxicity, but a prolonged regimen of less frequent, reduced-dose pulses may be required to prevent relapses (occur in up to half of patients within 5 years)[46]. Cyclophosphamide-related side effects are observed in ~40% of patients, including cystitis, infertility, infection and malignancy; they occur in up to half of patients within five years.

Recent data suggest that corticosteroids plus rituximab may be equally effective as corticosteroids plus cyclophosphamide[55,56]. Remission was induced while the B lymphocytes (and the associated ANCA) were depleted, but the effect of rituximab on the granulomatous manifestations of Wegener's granulomatosis is less clear. Targeted systemic immunomodulators ("biologics") are also being studied for the treatment of Wegener's granulomatosis[45,61]. A large randomized controlled trial found that etanercept was not effective for the maintenance of remission and was associated with treatment-related complications including malignancy[45]. In contrast, limited studies of infliximab plus conventional therapy suggested an accelerated remission and a steroid-sparing effect[62]. However, the addition of infliximab may result in more infectious complications. Azathioprine can maintain a remission following induction with cyclophosphamide[63], but it is associated with a higher relapse rate in patients who are PR3-positive at the time of the switch to azathioprine.

Patients with localized forms of Wegener's granulomatosis may be treated with trimethoprim–sulfamethoxazole (TMP-SMZ), alone or in combination with corticosteroids[45]. Of note, TMP-SMZ is a component of the treatment regimen for all patients with Wegener's granulomatosis, as relapses can be associated with *S. aureus* infections and nasal carriage (see above). Methotrexate is typically used in combination with corticosteroids to treat limited systemic disease[45].

Additional alternative treatment regimens are summarized in Table 24.10.

Churg–Strauss syndrome

Synonyms: ■ Granulomatous vasculitis of Churg–Straus ■ Churg–Strauss vasculitis ■ Allergic angiitis and granulomatosis

Key features

- Asthma and allergic rhinitis typically precede vasculitic phase
- Peak peripheral blood eosinophil count >10^9/l
- Cutaneous vasculitis in approximately half of patients
- Histologic features consist of eosinophils, extravascular granulomas and vasculitis

Introduction

Churg–Strauss syndrome is characterized by an ANCA-associated vasculitis with vascular and extravascular granulomas, eosinophil-rich pulmonary infiltrates, and necrotizing vasculitis that involves small to medium-sized vessels within multiple organ systems. It is distinguished by an association with asthma and eosinophilia.

Epidemiology

Churg–Strauss syndrome is the rarest of the necrotizing vasculitides, with an incidence ranging from 0.5 to 2.7 cases per million[64]. The mean age at diagnosis is 48 years and it has no gender predominance. The incidence of Churg–Strauss syndrome in patients with asthma ranges from 35 to 65 per million.

Pathogenesis

The onset of symptoms has been associated with various triggering factors, including vaccination, desensitization therapy, leukotriene inhibitors and rapid discontinuation of corticosteroids. T lymphocytes, eosinophils and ANCA all play a role in the pathogenesis of this syndrome. Tissue infiltration and then degranulation of eosinophils can lead to tissue injury while T cells, especially Th2 cells, are postulated to contribute to granuloma formation. ANCA-dependent activation of neutrophils results in vasculitis (see above). The pathogenesis of vasculitis in patients who are ANCA-negative may be distinct and is an area of active research.

Clinical features

The clinical presentation can be divided into three successive phases: (1) first phase – symptoms of allergic rhinitis, nasal polyps and asthma, which may persist for years; (2) second phase – peripheral eosinophilia, respiratory tract infections and gastrointestinal symptoms; and (3) third phase – systemic necrotizing vasculitis with granulomatous inflammation, which can occur several years to decades after the initial symptoms. Asthma, frequently severe, affects almost all patients and often precedes the onset of additional systemic manifestations by a decade or more[65]. Cutaneous findings occur in 40–75% of patients, typically during the third phase of the disease. Palpable purpura is seen most commonly, typically on the lower extremities and often with necrosis. Subcutaneous nodules may be seen on the scalp or extremities[66], and, less often, urticaria, livedo racemosa, retiform purpura and papulonecrotic lesions are present (Fig. 24.15).

In addition to the respiratory tract, patients with Churg–Strauss syndrome often have neurologic and cardiac involvement, presenting as mononeuritis multiplex and cardiomyopathy or pericarditis. The cardiac manifestations are due to granulomatous inflammation, occur in up to half of patients, and are the leading cause of death[67]. Necrotizing glomerulonephritis and pulmonary capillaritis resulting in diffuse

Fig. 24.15 Churg–Strauss syndrome. **A** Palpable purpura of the buttocks due to small vessel vasculitis (leukocytoclastic vasculitis). **B** Purpuric dermal plaques of the palm that histologically demonstrated vasculitis of a small muscular artery. **C** Crusted, firm papules of the elbow. *C, Courtesy, Kalman Watsky, MD.*

alveolar hemorrhage occur less commonly than in the other ANCA-associated vasculitides, affecting ~35% of patients. Musculoskeletal, gastrointestinal and ocular involvement can also occur.

Laboratory findings are similar to those in patients with Wegener's granulomatosis, with the additional findings of peripheral eosinophilia (>10^9/l) and elevated serum IgE levels. The majority of ANCA in Churg–Strauss syndrome are directed against MPO (55–60% of patients); fewer patients have anti-PR3 ANCA[47]. The presence or absence of ANCA may be clinically relevant, with creation of two subsets of patients[67]. ANCA positivity has been associated with a higher risk of cardiac involvement, pleural effusions, fever and livedo reticularis, while their absence was associated with cutaneous purpura as well as renal, sinus and neurologic complications. Histologic evidence of vasculitis was observed in 80% of ANCA-positive patients versus 40% of ANCA-negative patients, with no difference in granulomatous inflammation[67].

Pathology

The histopathologic hallmarks are infiltrates of eosinophils, formation of extravascular granulomas, and necrotizing vasculitis of small to medium-sized vessels; both arteries and veins are affected. Biopsy specimens obtained from papulonecrotic lesions demonstrate a palisading dermatitis with eosinophil infiltration, granuloma formation and eosinophilic necrobiosis.

Differential diagnosis

Other ANCA-associated vasculitides can mimic Churg–Strauss syndrome (see Table 24.9). Secondary hypereosinophilia and hypereosinophilic syndrome (HES; see Ch. 25) must also be differentiated from Churg–Strauss syndrome[65]. Superficial thrombophlebitis and rarely purpura, splinter hemorrhages and/or digital necrosis develop in patients with HES, mimicking Churg–Strauss syndrome.

Treatment

Over 80% of patients respond to treatment with corticosteroids alone, although relapses may occur in up to a quarter of patients achieving remission[68]. Of note, asthma persists in the majority of patients. Individuals with severe internal organ involvement (CNS or myocardial disease, glomerulonephritis, gastrointestinal ischemia) or who are refractory to corticosteroids are treated with concurrent cytotoxic agents, similar to patients with Wegener's granulomatosis or MPA. Pulsed intravenous cyclophosphamide is considered to be first-line therapy for inducing a remission, with azathioprine, IVIg or interferon-α as alternatives (see Table 24.10)[65].

Because interleukin-5 (IL-5) is a critical eosinophil differentiation factor, chemokine and growth factor, there has been recent interest in IL-5 blockade as a therapeutic strategy. Rituximab can reduce both levels of IL-5 and eosinophil counts, and it has demonstrated efficacy in refractory cases[64]. The anti-IL-5 antibody mepolizumab, which has been used to treat hypereosinophilic syndrome, is being investigated[67,69], and it shows early promise in reducing eosinophil counts and enabling corticosteroids to be tapered, but relapses frequently follow its discontinuation[69a,69b,69c]. Omalizumab, an anti-IgE antibody, is also being investigated. Of note, there is one report of a patient who developed Churg–Strauss syndrome following the administration of omalizumab[64].

PREDOMINANTLY MEDIUM-SIZED VESSEL VASCULITIS

Polyarteritis Nodosa

Synonyms: ■ Periarteritis nodosa ■ Panarteritis nodosa

Key features

- Segmental vasculitis of predominantly medium-sized arteries
- Systemic and cutaneous variants both can present with palpable purpura, livedo racemosa, retiform purpura, ulcers, subcutaneous nodules or peripheral gangrene
- Extracutaneous manifestations of the systemic variant include fever, arthralgias, myalgias, paresthesias, abdominal pain, orchitis and renovascular hypertension
- The cutaneous variant has a chronic, more benign course; it may be accompanied by mild systemic symptoms (fever, myalgias, arthralgias and peripheral neuropathy)

Introduction

Polyarteritis nodosa (PAN) is a multisystem vasculitis characterized by segmental necrotizing vasculitis that involves predominantly medium-sized blood vessels. Cutaneous PAN is a "skin-limited" variant which typically follows a benign yet chronic course.

Epidemiology

The incidence of classic PAN ranges from 4 to 16 cases per million, with a male:female ratio of 4:1. PAN can occur at any age, but typically affects middle-aged adults (40–60 years). Cutaneous PAN represents approximately 10% of all cases of PAN, and it is the most common form of PAN in children.

Pathogenesis

PAN has been associated with infections, inflammatory diseases, malignancies (especially hairy cell leukemia), and medications. Concurrent HBV infection is present in approximately 7% of patients with classic PAN, and this may represent a distinct clinical subtype with a higher risk of gastrointestinal, neurologic and renal involvement, as well as a lower 1-year survival rate (82% for HBV-associated PAN compared to 91% for non-HBV PAN)[70]. HCV infection is also associated with classic PAN. Cutaneous PAN has been associated with other infections, including streptococcal (especially in children), parvovirus B19, and HIV, as well as administration of minocycline. Inflammatory conditions associated with both classic and cutaneous PAN include inflammatory bowel disease, SLE and familial Mediterranean fever. Hairy cell leukemia has also been observed in association with classic PAN.

Clinical features

Approximately 25% of patients with classic (systemic) PAN have cutaneous involvement[71]. The most common findings are palpable purpura, livedo racemosa, retiform purpura and "punched-out" ulcers (Fig. 24.16). The palpable purpura may be pustular and/or ulcerative. Painful subcutaneous nodules and digital infarcts occur less commonly in classic PAN. In a study that compared the cutaneous manifestations of systemic PAN and MPA, palpable purpura was the most common skin finding in both diseases – 19% and 26% of patients, respectively; urticarial lesions were more frequent in PAN (6%) than in MPA (1–2%). Overall, however, the cutaneous findings alone did not allow distinction of the two entities[53]. As with Wegener's granulomatosis, cutaneous involvement in PAN and MPA is associated with arthralgias and ocular disease.

Extracutaneous disease is the rule in classic PAN, and patients present with constitutional symptoms, such as weight loss and fever, as well as multiple organ involvement. The lungs are often spared. Common symptoms include arthralgias, paresthesias (mononeuritis multiplex), myalgias (due to myopathy), abdominal pain, and shortness of breath (due to congestive heart failure). Involvement of the kidneys occurs at the level of the interlobar renal arteries, resulting in renovascular hypertension and renal failure, but not glomerulonephritis. In male patients, orchitis frequently occurs, especially in association with HBV infection. Cerebral infarcts are a rare complication of classic PAN and may result from thrombotic microangiopathy or vasculitic arterial occlusion. Gastrointestinal involvement, specifically mesenteric ischemia, heralds a poor prognosis, with a 1-year survival rate of <50%[70].

In classic PAN, laboratory evaluation demonstrates nonspecific inflammation with leukocytosis, an elevated ESR, and thrombocytosis. ANCA are rare in systemic PAN. Microscopic hematuria can be seen, but evidence of glomerulonephritis is absent. Microaneurysms of the renal, mesenteric and/or celiac arteries that are detected by traditional or magnetic resonance angiography are highly suggestive of classic PAN.

Cutaneous PAN, a "skin-limited" form of the disease, represents about 10% of PAN cases. Painful or tender subcutaneous nodules on the lower extremities, livedo racemosa, cutaneous necrosis and ulcers are commonly seen (Fig. 24.16B,C). Occasionally, the subcutaneous nodules develop elsewhere on the body. Lesions may resolve with persistent hyperpigmentation, sometimes in a retiform pattern. Patients may have mild systemic symptoms, consisting of fever, myalgias, arthralgias and peripheral neuropathy. Cutaneous PAN is the most common form in children, and it is often associated with streptococcal infections. A chronic, relapsing clinical course is typical, but progression to systemic PAN is rare. P-ANCA may be present in 10–20%

patients with cutaneous PAN, in contrast to systemic PAN, in which ANCA are almost never present.

Pathology

The histology of PAN is characterized by a segmental necrotizing vasculitis of medium-sized arteries (Fig. 24.17). Vessels located within the upper dermis may only demonstrate nonspecific perivascular inflammation. Cutaneous PAN often involves the arteries of the deeper dermis and subcutaneous fat[71]. Focal areas of involvement result in vessel wall weakening and necrosis, leading to aneurysmal dilation and/or stenosis. DIF may show deposits of C3, IgM and fibrin within or around vessel walls.

Differential diagnosis

The diagnosis of classic PAN requires either a tissue biopsy of an involved organ (e.g. skin, muscle, nerve, kidney, testicle) with demonstration of characteristic findings or the detection of microaneurysms via angiography (usually renal, celiac and/or mesenteric).

The differential diagnosis of classic PAN is broad and includes cryoglobulinemic vasculitis, autoimmune connective tissue disease, MPA, Wegener's granulomatosis and Churg–Strauss syndrome (see Table 24.9). In general, the latter three disorders can be distinguished from PAN by the presence of glomerulonephritis and pulmonary involvement in association with circulating ANCA. There are several non-vasculitic diseases where aneurysmal dilations can be seen by angiography, including fibromuscular dysplasia, atherosclerosis, SLE, cholesterol emboli, neurofibromatosis, Ehlers–Danlos syndrome, and emboli from infective endocarditis and left atrial myxoma.

Cutaneous ulcers superimposed on a background of livedo reticularis could be due to cutaneous PAN, but the differential diagnosis includes cholesterol emboli, antiphospholipid syndrome and vasculopathies (see Ch. 105). Nodular tuberculid may mimic the cutaneous lesions of PAN, both clinically and histologically, so its exclusion prior to instituting immunosuppressive therapy is recommended.

Treatment

Patients with *classic* PAN should be treated with systemic corticosteroids (e.g. 1 mg/kg/day of prednisone) with the dose tapered over 6 months. Approximately one-half of patients will achieve remission or cure with corticosteroids alone[54]. For patients who are refractory to corticosteroids or who have significant internal organ involvement, cyclophosphamide should be added to their regimen for up to 12 months (see dosages in MPA section)[54]. Treatment of HBV-associated PAN is aimed at eradication of the virus; currently, interferon-2α and lamivudine are employed and may improve overall mortality[70]. Therapeutic alternatives are listed in Table 24.10[72].

Although it is often chronic with relapses, cutaneous PAN follows a benign clinical course. Topical or intralesional corticosteroids may resolve localized areas of cutaneous involvement, but progressive or extensive disease may warrant systemic corticosteroids. Based upon case reports and series, there are therapeutic alternatives and these are listed in Table 24.10. Symptomatic relief may be achieved with NSAIDs alone. Digital necrosis has been reported to improve with intravenous prostaglandins or calcium channel blockers (see Ch. 43).

TEMPORAL ARTERITIS

Occasionally, in this form of large vessel vasculitis, cutaneous ulcers, primarily of the frontolateral scalp and tongue, can develop (Fig. 24.18). However, earlier in the course of the disease, purpuric lesions and tender nodules may also be seen (see Table 24.1). Patients may have a history of tenderness along the course of the temporal artery, visual disturbances and the muscle weakness of polymyalgia rheumatica.

DIAGNOSTIC APPROACH TO PATIENTS WITH VASCULITIS

In Figures 24.19 and 24.20, a morphologic approach and a diagnostic algorithm are presented, respectively, for the patient with signs and symptoms suggestive of cutaneous vasculitis. Proper management includes diagnosis, determination of associated conditions, investigation for systemic involvement, and treatment.

History and Physical Examination

The clinician should assess the duration and acuity of symptoms and inquire about antecedent illnesses or exposures (e.g. medications). A history of autoimmune connective tissue disease or malignancy may be evident, but patients can present with cutaneous vasculitis as the initial symptom of these diseases. The presence of systemic involvement (suggested by fever, weight loss or focal symptoms) should be assessed via a thorough review of systems.

The cutaneous examination may be helpful in identifying the predominant vessel size affected (see Table 24.1 and Fig. 24.19). A complete head and neck, cardiopulmonary, abdominal, musculoskeletal and neurologic examination should be performed in any patient in whom systemic vasculitis is suspected.

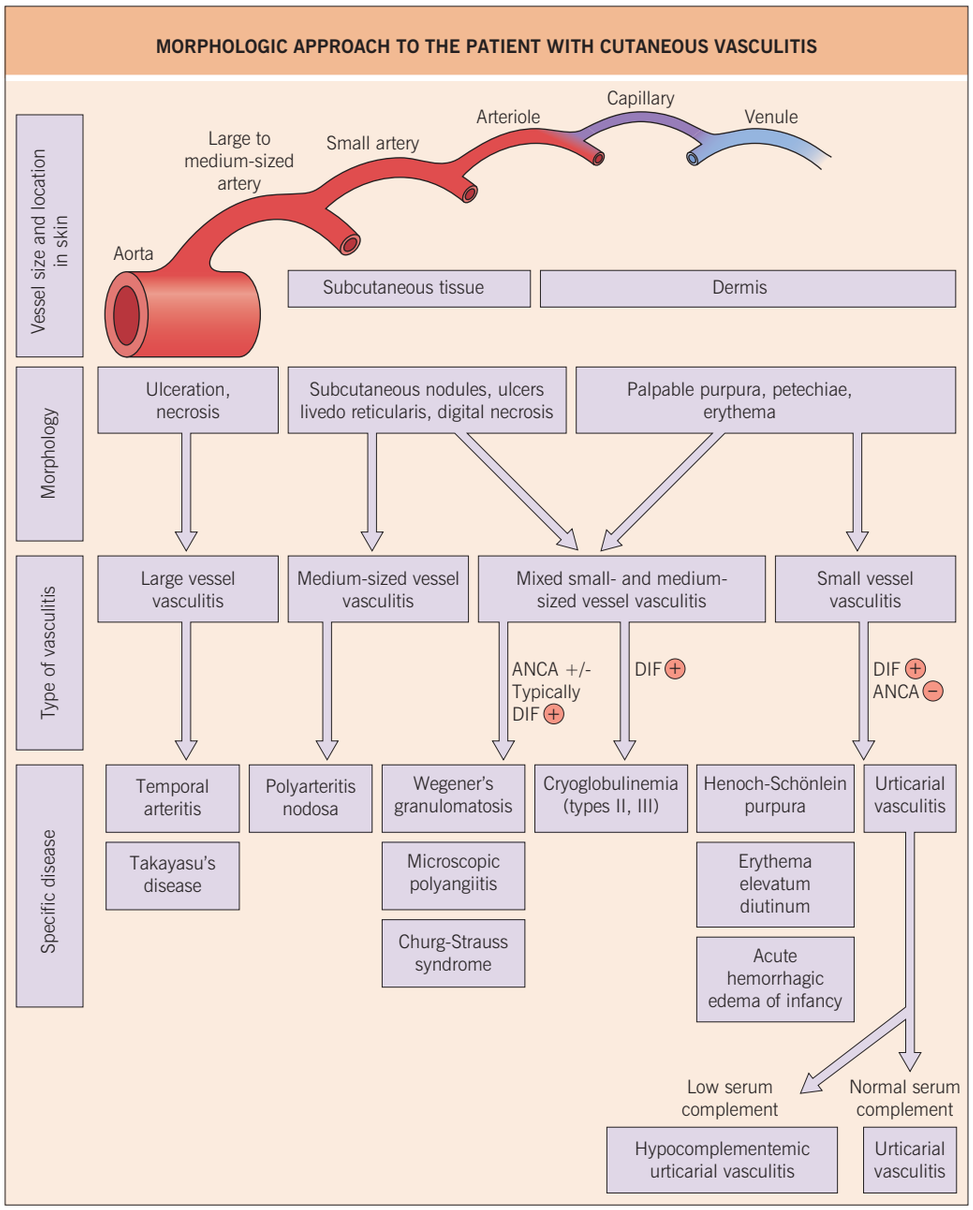

Fig. 24.19 Morphologic approach to the patient with suspected cutaneous vasculitis. ANCA, antineutrophil cytoplasmic antibodies; DIF, direct immunofluorescence.

Laboratory Evaluation

The laboratory diagnostic process begins with a skin biopsy in order both to exclude entities that can mimic cutaneous vasculitis (see Table 24.2) and to identify the size of vessel involved. If medium-sized vessel involvement is suspected, a deep incisional or excisional biopsy that includes subcutaneous tissue should be performed. Biopsies obtained from nodules tend to have a higher diagnostic yield for medium-sized vessel vasculitis than those taken from an ulcer edge or livedo racemosa. Ulcers should be biopsied at their edge and include the peripheral rim of inflammation (if present), as incidental vasculitis can often be found underlying ulcers and is not a diagnostic finding. DIF is best performed on the earliest lesion.

The initial evaluation of a patient with cutaneous vasculitis is outlined in Table 24.7. Additional tests can be performed based upon the suspected associated disease or the suspected vasculitic syndrome (Table 24.8). Laboratory tests to determine extent of disease should be repeated with each subsequent episode of vasculitis. Tests for associated disease are performed at baseline and only repeated if dictated by new information (e.g. screening for HCV infection).

Treatment

The first step in the treatment of patients with cutaneous vasculitis is to determine whether the disease is either primary or secondary to an underlying condition (e.g. infection, drug exposure) that can be treated (or, in the case of medications, discontinued). Treatment is then based on the extent and severity of systemic involvement. Specific and detailed therapeutic approaches are discussed in conjunction with each disease and are outlined in Table 24.10.

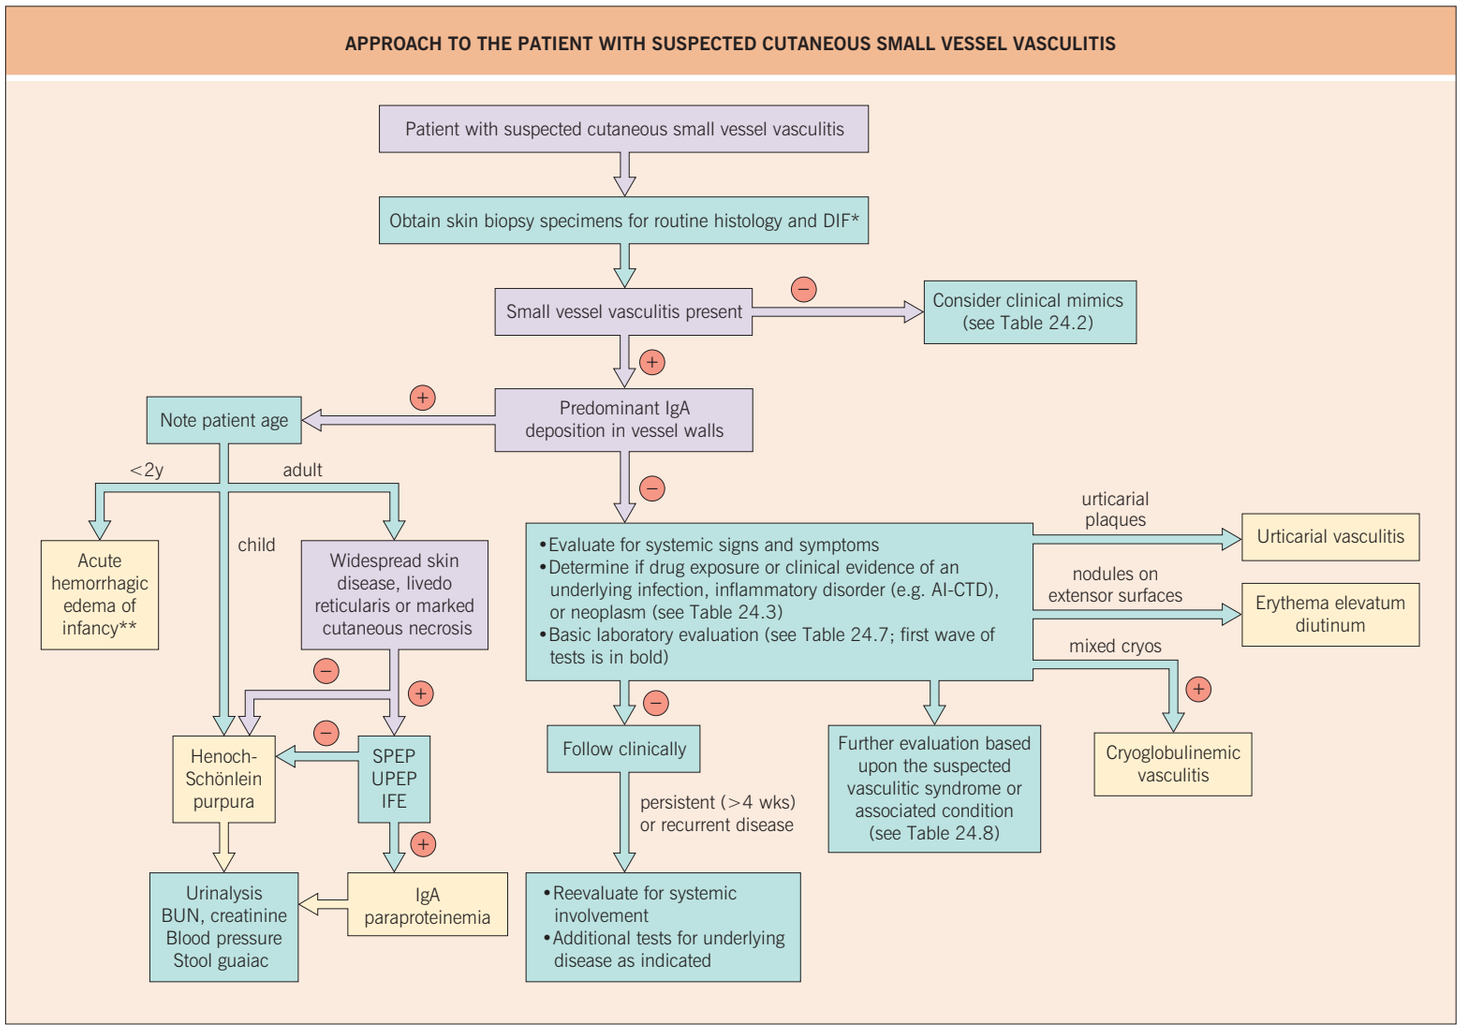

Fig. 24.20 Approach to the patient with suspected cutaneous small vessel vasculitis. *Best performed on an early lesion. **Vascular IgA deposits are found in less than one-third of cases. AI-CTD, autoimmune connective tissue disease; BUN, blood urea nitrogen; cryos, cryoglobulins; DIF, direct immunofluorescence; IFE, immunofixation electrophoresis; SPEP, serum protein electrophoresis; UPEP, urine protein electrophoresis.

Eosinophilic Dermatoses 25

Cloyce L Stetson and Kristin M Leiferman

Chapter Contents

Eosinophil biology 411
Eosinophilic dermatoses 412
Granuloma faciale 412
Papuloerythroderma of Ofuji 416
Wells' syndrome 416
Hypereosinophilic syndrome 418

Key features

- Many cutaneous diseases have prominent eosinophilic infiltrates, and clinicopathologic correlation is often needed to arrive at a specific diagnosis
- Eosinophilic infiltrates are frequently associated with arthropod bites or drug eruptions ("bugs and drugs") as well as autoimmune blistering diseases (especially bullous pemphigoid), in addition to other eosinophilic dermatoses (e.g. Wells' syndrome)
- Because eosinophils commonly disrupt and lose their morphologic integrity as they deposit toxic granule proteins and other mediators into tissue, the involvement of eosinophils in various inflammatory disorders may not be appreciated, given the absence of intact identifiable cells

EOSINOPHIL BIOLOGY

The eosinophilic leukocyte possesses distinctive cytoplasmic granules and circulates in the peripheral blood. With the exception of the gastrointestinal tract, lymphoid tissue (including the spleen, thymus and lymph nodes) and the bone marrow, eosinophils are found in tissues only during inflammation, and the latter is often associated with allergic reactivity or extra-gastrointestinal parasitic disease. In 1879, Paul Ehrlich named this cell the "eosinophil" because of the intense staining of its cytoplasmic granules with the acidic dye eosin. Ultrastructurally, the distinctive, membrane-bound, specific eosinophil granules show an electron-dense core and a less dense matrix (Fig. 25.1). The eosinophil produces multiple factors (e.g. toxic cationic proteins within specific granules and oxidative products) that reflect its role in inflammation[1,2,2a] and are released into tissues following activation. Surface molecule expression is important in activation and/or priming and further directs eosinophil involvement in inflammation. Many of the surface molecules expressed on eosinophils are included in Figure 25.1; they are also extensively reviewed in References 1 and 2.

Eosinophils are attracted into tissues and activated by at least three interrelated signals: (1) chemokines; (2) other cytokines; and (3) adhesion molecules. Several members of the C-C chemokine gene superfamily are chemotactic for eosinophils, and these chemoattractants include the eotaxin family and *r*egulated on *a*ctivation, *n*ormal *T* cell *e*xpressed and *s*ecreted (RANTES). Eosinophil-active chemokines signal primarily through C-C chemokine receptor (CCR)-3, which is expressed by eosinophils. Eotaxins 1–3 are specifically chemotactic for eosinophils, while RANTES is chemotactic not only for eosinophils but also for monocytes, T lymphocytes, natural killer cells and basophils (but not neutrophils). In addition to their chemotactic properties, the eotaxins and RANTES induce production of reactive oxygen species by eosinophils, indicating that they have both chemotactic and functional activation effects. As eosinophil chemoattractants, the eotaxins are stronger than RANTES, and eotaxins 1 and 2 are also stronger in inducing reactive oxygen species by eosinophils than are eotaxin 3 and RANTES. Eotaxins 1, 2 and 3 and RANTES are produced by dermal fibroblasts; RANTES is also produced by keratinocytes, positioning them well for participation in cutaneous inflammation[3].

For eosinophils to migrate from the peripheral blood into tissues, the cells must transmigrate blood vessels. Similar to other leukocytes, selectin, integrin and immunoglobulin gene superfamily members (see Ch. 102) contribute to the signaling needed for eosinophil transmigration[1,2]. In particular, eosinophils constitutively express the integrin very late antigen (VLA)-4, which interacts with its ligand, vascular cell adhesion molecule (VCAM)-1, which is induced on endothelial cells by chemokines and cytokines. After movement through vessels, eosinophils are present in the extracellular matrix. Here, integrins, expressed on the cell surface, recognize as receptors substances that exert effects on eosinophil activity, such as fibrous proteins (in particular, fibronectin, laminin and collagen) and glycosaminoglycans (especially hyaluronic acid and chondroitin sulfate). Integrin expression, specifically CD11b/CD18 (MAC-1), is critical for eosinophil effector functions, including degranulation.

Activating cytokines such as granulocyte–macrophage colony-stimulating factor (GM-CSF), interleukin (IL)-3 and IL-5 are also important for the effector functions of eosinophils[1,2]. Several lines of investigation indicate that eosinophils are recruited to and activated in tissues by cytokine activity from the Th2 subset of T cells, which produces IL-4, IL-5, IL-10 and IL-13, in addition to cytokines common to Th1 cells. Mast cell-derived cytokines also contribute indirectly to eosinophil activation via the induction of IL-5 and GM-CSF. Of note, human natural killer cells, which respond to some of the same C-C chemokines as eosinophils, also produce IL-5. Eosinophils themselves elaborate important inflammatory and regulatory cytokines; these include IL-1α, TGF-α and TGF-β_1, GM-CSF, IL-3, IL-5, IL-6, IL-8, TNF-α, and macrophage inflammatory protein 1α (see Fig. 25.1). As a result, eosinophil activation also occurs in an autocrine manner. In cytotoxicity assays, eosinophils are maximally activated by GM-CSF, followed by IL-3, IL-5, TNF-α and IL-4, in order of potency.

Granular contents

With activation, eosinophils release granule contents into their extracellular spaces via three mechanisms[1]: cytolytic degranulation, piecemeal degranulation, and regulated secretion. Cytolytic degranulation occurs in many inflammatory disorders, including skin diseases (e.g. atopic dermatitis), as well as all affected organs in patients with the hypereosinophilic syndromes. It is characterized by organelle rupture, chromatolysis of nuclei with loss of morphologic integrity and identity of eosinophils, and extensive deposition of eosinophil granules and granule products within tissue[1,4]. *Major basic protein-1* (MBP-1), the constituent of the crystalline cores of specific eosinophils (see Fig. 25.1), directly damages helminths and also damages mammalian cells and tissues, an example of which is its ability to cause exfoliation of bronchial epithelial cells. MBP-1, but none of the other eosinophil granule proteins, stimulates histamine release from human basophils. Furthermore, MBP-1 stimulates neutrophils, inducing release of superoxide and lysozyme. *Eosinophil cationic protein* (ECP or RNase3) and *eosinophil-derived neurotoxin* (EDN or RNase2) are members of the RNase family. ECP is a potent toxin for parasites through a different mechanism than MBP-1, and it is more effective at killing certain helminths than MBP-1. EDN, as its name implies, is a neurotoxin and also has antiviral activity against RNA viruses.

Eosinophil peroxidase (EPO) kills numerous microorganisms in the presence of hydrogen peroxide, generated by eosinophils and other phagocytes, and halide. This combination of products also initiates mast cell secretion. Binding of EPO to microbes, including *Staphylococcus aureus*, greatly potentiates their killing by phagocytes. EPO-coated

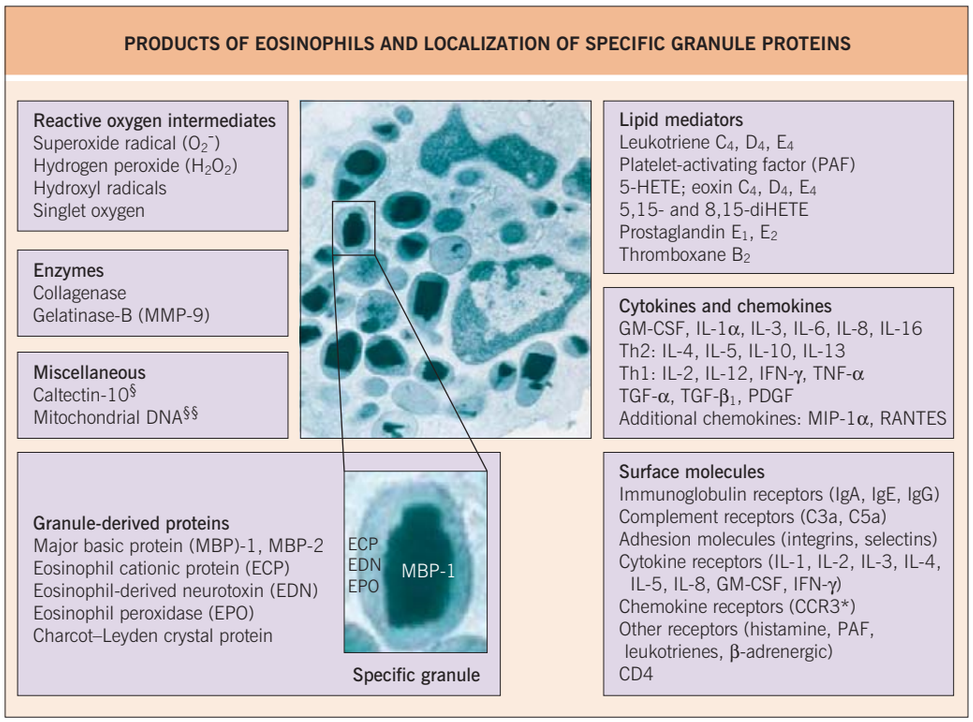

Fig. 25.1 Products of eosinophils and localization of specific granule proteins. The eosinophil produces myriad products that reflect its role in inflammation. Specific granules contain major basic protein (in the electron-dense core) and other toxic proteins (in the matrix). In addition eosinophils produce Calectin-10 (Charcot-Leyden crystal protein) Mitochondrial DNA (forms DNA traps with ECP and MBP-1). *Receptor for eotaxins and RANTES. §Charcot-Leyden crystal protein. §§Forms DNA traps with ECP and MBP-1. CCR, CC chemokine receptor; GM-CSF, granulocyte–macrophage colony-stimulating factor; HETE, *h*ydroxy*e*icosa*t*etra*e*noic acid; IFN, interferon; IL, interleukin; MIP, macrophage inflammatory protein; MMP, matrix metalloproteinase; PDGF, platelet-derived growth factor; RANTES, *r*egulated on *a*ctivation *n*ormal *T* cell *e*xpressed and *s*ecreted; TGF, transforming growth factor; TNF, tumor necrosis factor.

tumor cells are spontaneously lysed by activated macrophages, and MBP-1 is also toxic to tumor cells. EPO and MBP-1 are potent platelet agonists that lead to release of 5-hydroxytryptamine (serotonin) and promote clotting. Eosinophils also are associated with fibrotic processes, with resulting fibrosis in areas of infiltration. The presence of eosinophils in certain normal organs suggests a role in homeostasis. Eosinophils may act as antigen-presenting cells for microbial (including staphylococcal superantigens), viral and parasitic antigens to promote T cell proliferation. They can also regulate mast cell function. In addition, eosinophils are able to generate mitochondrial DNA traps that contain ECP and MBP-1 and display antimicrobial activity, demonstrating that eosinophils can participate in innate and acquired immunity[2a]. In summary, the functional diversity of eosinophils[1,2] has numerous ramifications in tissues and in disease.

EOSINOPHILIC DERMATOSES

Eosinophilic dermatoses encompass a wide variety of diseases that are characterized histologically by the presence of eosinophils in the inflammatory infiltrate and/or evidence of eosinophil degranulation[4] (Fig. 25.2). The most common causes of eosinophilic infiltrates include arthropod bites, drug eruptions, allergic contact dermatitis and atopic dermatitis (Fig. 25.3). In addition, several of the autoimmune blistering diseases frequently have prominent eosinophilic infiltrates. Bullous pemphigoid, in particular, should be considered whenever a biopsy specimen from an elderly patient has numerous eosinophils throughout the dermis. Parasitic infections, particularly with ectoparasites and helminths, often have a marked eosinophilic host response (see Chs 83 & 84). Urticaria, urticarial vasculitis, Churg–Strauss syndrome, and urticarial allergic eruption may have significant numbers of eosinophils. Table 25.1 lists the diseases associated with cutaneous eosinophilic infiltrates.

GRANULOMA FACIALE

Key features

- Granuloma faciale is an idiopathic cutaneous disorder characterized by red–brown plaques on the face and is unusual elsewhere
- Biopsy specimens demonstrate a diffuse, mixed, dermal infiltrate of lymphocytes, neutrophils and numerous eosinophils
- Leukocytoclastic vasculitis is classically present histopathologically, but it may be subtle or undetected in a single lesion
- A prominent Grenz zone is present with a narrow band of papillary dermal sparing that separates the epidermis from the dermal infiltrate

History

Wigley described the first patient, and labeled the disease "eosinophilic granuloma"[15] (a name now used instead for a variant of Langerhans cell histiocytosis). Subsequently, it was renamed "facial granuloma with eosinophilia". Pinkus recommended the current name, granuloma faciale[16].

Epidemiology

Granuloma faciale occurs predominantly in middle-aged white men, but it has been observed in black and Asian men as well as women.

Pathogenesis

Immunofluorescence microscopy has demonstrated IgG, IgA, IgM and C3 within blood vessel walls, a nonspecific finding that supports a role for immune complexes. While the precise pathogenesis remains unknown, a role for interferon-γ as an important proinflammatory mediator in this disorder has been suggested[17], as has elevated local IL-5 production.

Clinical Features

Granuloma faciale usually presents as a solitary, asymptomatic, smooth red–brown to violaceous plaque on the face[18] (Fig. 25.4). Upon closer inspection, prominent follicular openings are often observed. Less often, multiple papules or plaques may be present[19]; in one retrospective analysis of 66 patients, one-third were noted to have multiple sites of involvement[20]. As the name suggests, lesions of granuloma faciale appear predominantly on the face. Occasionally (7% of patients in above series[20]), there is involvement of extrafacial sites, e.g. the trunk, extremities and/or scalp, but facial lesions are present as well in the vast majority[21]. A sinonasal mucosal variant termed "eosinophilic angiocentric fibrosis" has been described and rarely there is involvement of other sites in the upper respiratory tract. Individual lesions of granuloma faciale are chronic and only occasionally spontaneously resolve. Granuloma faciale has not been associated with systemic disease.

Pathology

The epidermis is usually not affected. Within the dermis, a dense, nodular and diffuse polymorphous infiltrate of lymphocytes, neutrophils and plasma cells with numerous eosinophils is characteristic. This infiltrate spares the upper papillary dermis, creating a prominent Grenz zone (Fig. 25.5). Biopsy specimens taken from early lesions typically show many neutrophils, with neutrophilic dust and hemorrhage.

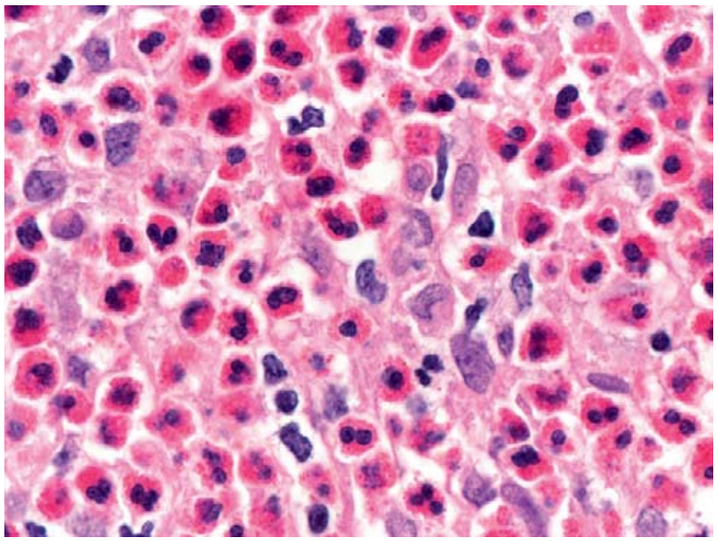

Fig. 25.2 Eosinophils within the dermis. Note the red-staining granules within their cytoplasm. *Courtesy, Lorenzo Cerroni, MD.*

Older lesions have fewer neutrophils and more eosinophils and macrophages. In addition, fibrosis may be pronounced in older lesions. Leukocytoclastic vasculitis is classically described as being present, but it may be subtle or multiple sections may be required to demonstrate diagnostic changes.

Differential Diagnosis

The clinical appearance of granuloma faciale is usually quite distinctive, but the clinical differential diagnosis includes lymphoma and pseudolymphoma, sarcoidosis, tumid lesions of lupus erythematosus, fixed drug eruption, rhinophyma, and other granulomatous diseases such as leprosy, foreign body granuloma and the granulomatous variant of rosacea. The histology of granuloma faciale may superficially resemble lymphoma, pseudolymphoma and granulomatous rosacea, but the prominent Grenz zone, normal epidermis, and polymorphous infiltrate with significant numbers of eosinophils aid in differentiating granuloma faciale.

Extrafacial granuloma faciale can be difficult to distinguish from erythema elevatum diutinum (EED), both clinically and histologically. EED usually presents as red–brown to violaceous papules, plaques or nodules on the extensor aspects of the extremities and the buttocks, with a predilection for the skin overlying joints. In addition to histologic evidence of leukocytoclastic vasculitis, epidermal changes are usually present and range from epidermal necrosis to epidermal hyperplasia; EED typically lacks a Grenz zone. The vasculitis is usually more pronounced and neutrophils predominate over eosinophils in EED. Prominent lipid-laden macrophages may be seen in EED, but not in granuloma faciale.

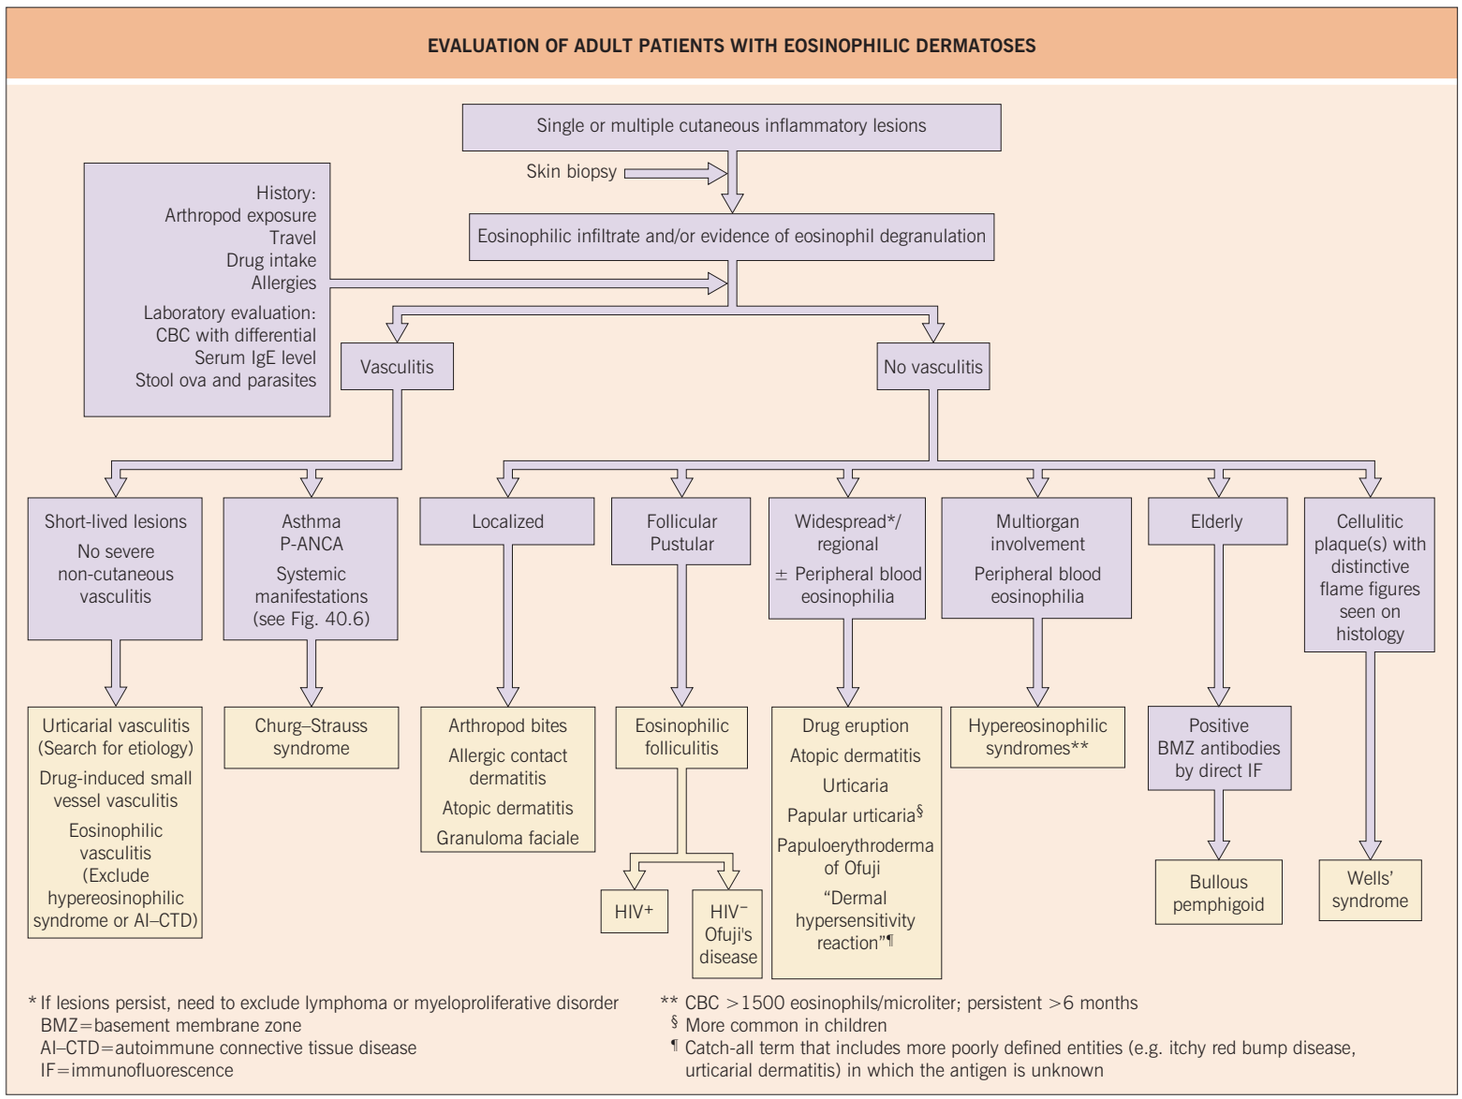

Fig. 25.3 Evaluation of adult patients with eosinophilic dermatoses. Histologically, these dermatoses are characterized by a prominent eosinophilic infiltrate and/or eosinophil granule protein deposition. Of note, systemic corticosteroids can significantly reduce the peripheral blood eosinophil count.

DIFFERENTIAL DIAGNOSIS OF EOSINOPHILIC DERMATOSES	
Diagnosis	**Clinical clues**
Allergic contact dermatitis	History of exposure; suggestive distribution; positive patch test
Angiolymphoid hyperplasia with eosinophilia (and Kimura's disease)	Single or multiple nodules on face, scalp and ears; histologically, prominent vascular channels and endothelial cells with vacuolization and "hobnail" appearance in addition to eosinophils
Annular erythema of infancy[5]	Annular or serpiginous non-pruritic plaques in infants
Arthropod assault	Primarily involves exposed skin; spiders, ticks, fleas, mites and mosquitoes; exaggerated reactions in patients with chronic lymphocytic leukemia
Atopic dermatitis	History of atopy; pruritus; flexural and extremity accentuation
Bullous pemphigoid	Initial phase may be urticarial; flexural sites and legs favored; elderly patients
Churg–Strauss syndrome (allergic granulomatosis)	Palpable purpura and tender papulonodules on the extremities or scalp; asthma and peripheral blood eosinophilia; peripheral neuropathy, cardiac involvement and glomerulonephritis may be present
Coccidioidomycosis	Verrucous plaques and nodules; history of travel to southwestern US; 30–80 μm spherules with endospores in biopsy specimens
Drug eruption	Drug history, especially new drugs within previous 2 weeks*
Eosinophilic fasciitis (Shulman syndrome)	Sudden onset of symmetric induration of the skin and subcutaneous tissues of the limbs
Eosinophilic (pustular) folliculitis	*HIV variant:* HIV+ patient with severe pruritus and papules on the face and upper trunk
	Ofuji's disease: typically a Japanese patient with chronic, recurrent follicular pustules in a seborrheic distribution with tendency to form circinate plaques
	Pediatric: follicular pustules on the scalp of an infant
Eosinophilic, polymorphic and pruritic eruption associated with radiotherapy (EPPER)[5a]	Local and generalized pruritus, erythematous papules and wheals, and vesicobullae
Eosinophilic vasculitis[6]	Pruritic urticarial and purpuric papules; angioedema
Eosinophilic ulcer of the oral mucosa	Rapidly enlarging nodule that develops a central ulceration; usually on the tongue
Erythema toxicum neonatorum	Newborn with erythematous macules, papules and pustules on the trunk; often have a prominent erythematous flare
Hypereosinophilic dermatitis of Nir-Westfried[7,†]	Pruritic, papular eruption with peripheral eosinophilia; often dapsone-responsive
Incontinentia pigmenti	Vesicles and bullae along Blaschko's lines in neonate (stage I); peripheral blood eosinophilia; biopsy specimen showing eosinophilic spongiosis with dyskeratosis
Itchy red bump disease (papular dermatitis)[†]	Markedly pruritic pink to red papules; may be associated with eczematous patches and/or dermographism
Juvenile xanthogranuloma	Yellow to red–brown papules or nodules on the head and neck, upper trunk or proximal extremities; early lesions may have numerous eosinophils
Langerhans cell histiocytosis (especially eosinophilic granuloma)	Disseminated pink and yellow–brown papules (often with crusts) to nodulo-ulcerative periorificial lesions; eosinophilic component may be intense
Lymphoma, especially Hodgkin disease and mycosis fungoides	Patches, plaques or nodules; lymphadenopathy
Mastocytosis	Pink–tan to red–brown macules, papules and plaques that urticate with stroking (Darier's sign)
Nummular dermatitis	Discrete round eczematous plaques on the extremities; pruritic
Oid-oid disease (exudative discoid and lichenoid chronic dermatosis of Sulzberger and Garbe)[8,†]	Middle-aged, predominantly Jewish, men; pruritic lesions commonly involving genitals; progressive stages: discoid → exudative → lichenified; peripheral blood eosinophilia
Pachydermatous eosinophilic dermatitis[9]	South African black teenage girls with generalized pruritic papules, hypertrophic genital lesions and peripheral blood eosinophilia; dapsone-responsive; possibly a variant of hypereosinophilic dermatitis of Nir-Westfried
Papular eruption of blacks[10]	Young, black men with intensely pruritic papules on the trunk and upper arms
Parasitic infestations	Cysticercosis, dirofilariasis, larva migrans, myiasis, onchocerciasis, tungiasis, schistosomiasis and others
Pemphigoid gestationis	Pregnant patient; periumbilical lesions; urticarial plaques and bullae
Pemphigus variants	Flaccid vesicles and crusted erosions; distribution depends on subtype
Polymorphic eruption of pregnancy (PEP; also referred to as pruritic urticarial papules and plaques of pregnancy [PUPPP])	Usually primigravida in third trimester; urticarial papules and plaques, especially in striae
Pruritic papular eruption of HIV disease[11]	Pruritic non-follicular papules in symmetric distribution; HIV infection; may be an exaggerated reaction to arthropod antigens
Pseudolymphoma	Association with arthropod bite or drug intake (especially phenytoin)
Scabies	Marked nocturnal pruritus; webspace, umbilical and groin involvement
Seabather's eruption (larvae of *Linuche unguiculata* and *Edwardsiella lineata*)	Pruritic papules in distribution of swimsuit; occurs after ocean swimming
Urticaria	Pruritic, migratory, transient (lasting <24 hours) wheals

*Eosinophils may also be present in drug-induced small vessel vasculitis[14].
†Not clearly defined entities.

Table 25.1 Differential diagnosis of eosinophilic dermatoses. Granuloma faciale, Wells' syndrome, papuloerythroderma of Ofuji, and the subtypes of hypereosinophilic syndrome are discussed in the text. Eosinophilic infiltrates are occasionally seen in epidermolysis bullosa.

Continued

DIFFERENTIAL DIAGNOSIS OF EOSINOPHILIC DERMATOSES	
Diagnosis	**Clinical clues**
Urticarial allergic eruption[12]	Annular or gyrate urticarial plaques that persist >24 hours; histologically more cellular than urticaria
Urticarial dermatitis[13,†]	Very pruritic lesions (sometimes eczematous, other times urticarial) on the trunk, sacrum and proximal extremities of elderly individuals (1.8 female : 1 male); persist for days to weeks; often accompanied by excoriated papules; minimally responsive to topical corticosteroids and oral antihistamines
Urticarial vasculitis	Lesions can burn rather than itch and persist >24 hours; associated with autoimmune disease and decrease in complement

[†]Not clearly defined entities.

Table 25.1 Differential diagnosis of eosinophilic dermatoses (cont'd). Granuloma faciale, Wells' syndrome, papuloerythroderma of Ofuji, and the subtypes of hypereosinophilic syndrome are discussed in the text. Eosinophilic infiltrates are occasionally seen in epidermolysis bullosa.

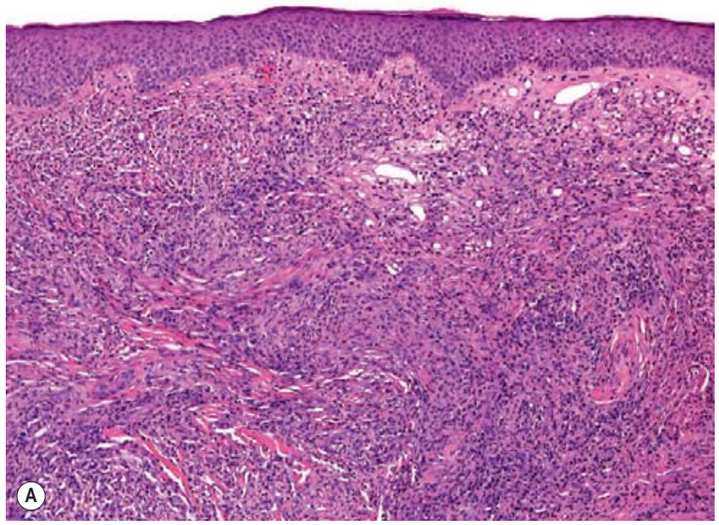

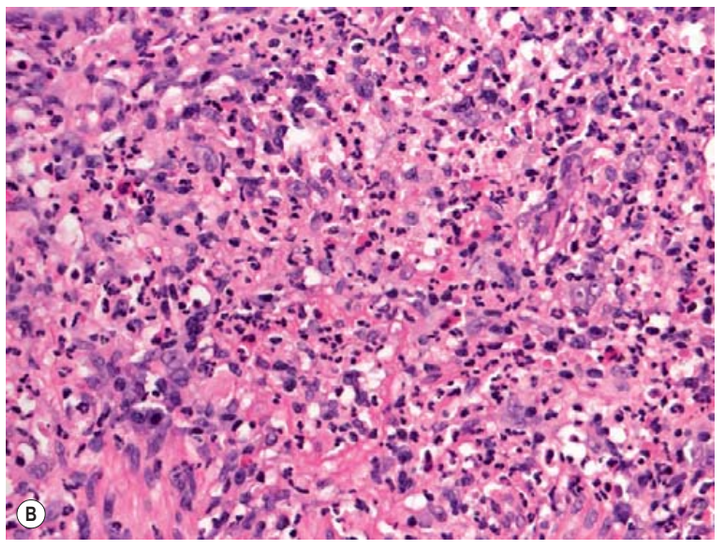

Fig. 25.5 Granuloma faciale. A Dense diffuse dermal infiltrate with a Grenz zone. **B** Higher-power view of polymorphous infiltrate of lymphocytes, eosinophils, neutrophils and plasma cells. *Courtesy, Lorenzo Cerroni, MD.*

Treatment

Because of the prominent location on the face, treatment is often desired. Unfortunately, granuloma faciale is frequently resistant to therapy. Intralesional triamcinolone (2.5–5 mg/ml) is often recommended as a first-line, non-scarring therapeutic intervention. As with other recalcitrant dermatoses, there are many anecdotal alternatives reported. Oral dapsone (50–150 mg daily) and oral clofazimine (300 mg daily) have been reported to be effective, as have topical PUVA and topical calcineurin inhibitors (pimecrolimus, tacrolimus).

With regard to physical modalities, surgical excision, cryosurgery, dermabrasion, electrosurgery, and CO_2 or pulsed dye laser therapy have all been advocated, but each carries a significant risk of scarring given

the depth of inflammation. Recurrences after excision have also been reported. Laser treatments that target the prominent vascular component, e.g. the 595 nm pulsed dye laser and 532 nm potassium-titanyl-phosphate laser, have also been reported to be effective.

PAPULOERYTHRODERMA OF OFUJI

Key features

- Occurs most commonly in elderly men
- Widespread red–brown papules can evolve into a confluent erythroderma with characteristic sparing of the skin folds ("deck-chair" sign)
- Chronic course, with periodic acute exacerbations
- Peripheral blood eosinophilia, lymphopenia and elevated serum IgE level in more than two-thirds of patients
- While most patients have no associated disorders, there can be an underlying disorder such as a T-cell lymphoma or gastric carcinoma
- Often responds to oral corticosteroids or PUVA, alone or in combination with a systemic retinoid

History

Papuloerythroderma of Ofuji was first described by Ofuji in 1984[22].

Epidemiology

Approximately 100 cases of papuloerythroderma of Ofuji have been reported to date. Over two-thirds of these individuals have been elderly Japanese men, with an average age of 72 years at presentation. The disorder is much less common in Caucasians. Overall, men outnumber women by a ratio of 7 : 1.

Pathogenesis

The pathogenesis remains unknown.

Clinical Features

Papuloerythroderma of Ofuji presents as a widespread, symmetrically distributed, pruritic eruption composed of flat-topped, red–brown papules. The trunk and extremities are typically involved. There are periodic acute exacerbations, often leading to an erythroderma that strikingly spares the skin folds; the latter finding is referred to as the "deck-chair" sign. A majority of the patients have peripheral blood eosinophilia and lymphopenia, and many will have peripheral lymphadenopathy. Reported neoplastic and infectious associations are listed in Table 25.2. The most commonly associated malignancies are T-cell lymphoma and gastric carcinoma.

Pathology

Histologic features are usually nonspecific. The epidermis is often normal in appearance, but there may be mild spongiosis, mild acanthosis and parakeratosis. Within the dermis, a superficial and mid-dermal mixed infiltrate composed of lymphocytes and eosinophils, along with a few plasma cells and histiocytes, is often seen. In patients with an associated T-cell lymphoma, epidermotropism of atypical lymphocytes may be present. Laboratory evaluation usually demonstrates peripheral blood eosinophilia, lymphopenia, and an elevated serum IgE level.

Differential Diagnosis

During an erythrodermic flare, the clinical presentation of papuloerythroderma is quite striking. In these patients, the differential diagnosis includes other causes of erythroderma such as psoriasis, cutaneous T-cell lymphoma, atopic dermatitis, pityriasis rubra pilaris, and drug eruptions (see Ch. 10). Sparing of skin folds (the "deck-chair" sign) aids in the clinical diagnosis. For those patients with predominantly flat-topped pruritic papules, the differential diagnosis includes pityriasis lichenoides chronica, lichen planus, papular eczema, arthropod bite reactions, a drug eruption and other entities listed in Table 25.1.

PAPULOERYTHRODERMA OF OFUJI – REPORTED ASSOCIATIONS	
NEOPLASMS	**INFECTIONS**
• Lymphomas: T-cell lymphoma (most common), Hodgkin disease, B-cell lymphoma	• Viruses: hepatitis C, human immunodeficiency virus
• Leukemias: chronic lymphocytic leukemia, acute myelogenous leukemia	• Fungi: dermatophytes
• Solid organ malignancies: gastric (most common), lung, colon, hepatocellular, prostate, renal, laryngeal	• Parasites: strongyloidiasis
DRUGS	**OTHER**
• Furosemide, ranitidine, dideoxyinosine (DDI), aspirin, isoniazid	• Atopic dermatitis

Table 25.2 Papuloerythroderma of Ofuji – reported associations.

Treatment

Systemic corticosteroids are usually effective. In a recent review, PUVA, alone or in combination with acitretin or etretinate, led to complete clearance in two-thirds of patients, with an additional one-quarter improved[23]. Additional reportedly effective treatments include UVB radiation, cyclosporine, etretinate and azathioprine. Topical corticosteroids, however, are usually ineffective as monotherapy.

Although often idiopathic, the possibility of an underlying neoplasm or infection or an inciting drug needs to be considered. Laboratory evaluation and diagnostic imaging should be directed by the history, physical examination and entities listed in Table 25.2.

WELLS' SYNDROME

Synonym: ■ Eosinophilic cellulitis

Key features

- Cutaneous lesions of Wells' syndrome present as recurrent painful or pruritic plaques that can resemble infectious cellulitis, infiltrative disorders, or other causes of pseudocellulitis (e.g. exaggerated arthropod bite reactions, Sweet's syndrome)
- Histologically, a diffuse eosinophilic infiltrate throughout the dermis is seen, as well as characteristic "flame figures"
- Flame figures can be seen in other disorders with numerous activated eosinophils, and, therefore, they are not diagnostic of Wells' syndrome
- Wells' syndrome usually improves dramatically after administration of systemic corticosteroids

Introduction

Wells' syndrome is a cutaneous disorder of unknown etiology characterized clinically by indurated plaques resembling cellulitis. The classic histologic appearance is that of a diffuse dermal infiltrate of eosinophils and characteristic "flame figures".

History

Wells described the first patient in 1971, and named the disease "recurrent granulomatous dermatitis with eosinophilia". He later renamed it "eosinophilic cellulitis"[24]. Spigel and Winkelmann[25] proposed the eponym Wells' syndrome in 1979.

Epidemiology

Over 100 cases of Wells' syndrome have been reported to date, ranging from newborns to patients over 70 years of age. Associated systemic diseases are extremely rare.

Pathogenesis

The pathogenesis of Wells' syndrome is unknown, but the possibility of local hypersensitivity has been proposed. So-called "triggers" have been described in some patients, including myeloproliferative disorders, infections/infestations (including dermatophytes, viruses and *Toxocara canis*), insect bites or stings, and drugs. Activated eosinophils are present and play a major role in Wells' syndrome. Simon and colleagues[26] have suggested that IL-2 primes eosinophil degranulation in patients with eosinophilia (including those with Wells' syndrome). This hypothesis was based on the following findings: (1) eosinophils from patients with eosinophilia expressed the α chain of the IL-2 receptor (CD25); and (2) IL-2 enhanced platelet-activating factor (PAF)-stimulated release of eosinophil cationic protein from CD25-expressing eosinophils. More recently, peripheral lymphocytes isolated from patients with Wells' syndrome were reported to have exaggerated responses to mosquito salivary gland extracts[27].

Clinical Features

Classically, Wells' syndrome presents as recurrent episodes of prodromal itching or burning, followed by markedly edematous nodules and plaques (Fig. 25.6), which may have an annular or arcuate configuration and sometimes have violaceous borders[28]. Blistering may occur. Initially, the lesions are bright red, and then they fade to a pink–brown, green, brown or slate-gray color. The plaques can become indurated and thereby resemble infiltrative skin disorders such as sarcoidosis, but lesions usually resolve over 4 to 8 weeks. Less common clinical presentations include papules, vesicles and hemorrhagic bullae. The most common systemic complaint in patients is malaise, with fever occurring in less than a quarter of patients. The extremities are most frequently affected, but truncal involvement also occurs. Peripheral blood eosinophilia is common. Patients have often been previously misdiagnosed as having erysipelas or acute cellulitis. Precipitating events, including arthropod bites and stings, have been described in a minority of Wells' syndrome patients.

Pathology

Wells' syndrome is characterized histologically by an interstitial infiltrate of eosinophils, with an admixture of lymphocytes and histiocytes (Fig. 25.7). The infiltrate is usually most impressive in the deep dermis, with occasional involvement of the subcutaneous fat, fascia and skeletal muscle. The superficial dermis may be affected with massive papillary dermal edema to the point of subepidermal bulla formation. Epidermal spongiosis and intraepidermal vesiculation may also be seen.

With the tremendous number of activated eosinophils, extracellular eosinophil granules are present in the dermis. Characteristic eosinophilic-staining flame figures consist of collagen fibers coated with eosinophil granule proteins[29] (Fig. 25.7, insert). Extracellular major basic protein from eosinophil granules has been localized to flame figures using indirect immunofluorescent assays[30]. These flame figures are a hallmark of Wells' syndrome, but they are not specific. Other diseases featuring flame figures include arthropod bites and stings (namely, ticks, bees, fleas and spiders), mastocytomas, scabies and other parasitic infestations, prurigo nodularis, eczema and dermatophyte infections. Vasculitis of dermal vessels is not seen.

Differential Diagnosis

Wells' syndrome often has a striking clinicopathologic presentation[31]. Bacterial cellulitis and erysipelas are said to be the most common clinical mimics of Wells' syndrome. The histopathologic findings of both erysipelas and bacterial cellulitis can include significant edema similar to that seen in Wells' syndrome, but usually neutrophils are the predominant inflammatory cell in those two entities, in contrast to the eosinophils of Wells' syndrome. Other causes of pseudocellulitis, including exaggerated reactions to arthropod bites, are listed in Table 74.10. Reports of Wells' syndrome occurring in patients with chronic lymphocytic leukemia and non-Hodgkin lymphoma may represent the latter.

Fig. 25.6 Wells' syndrome. Edematous nodules and plaques.

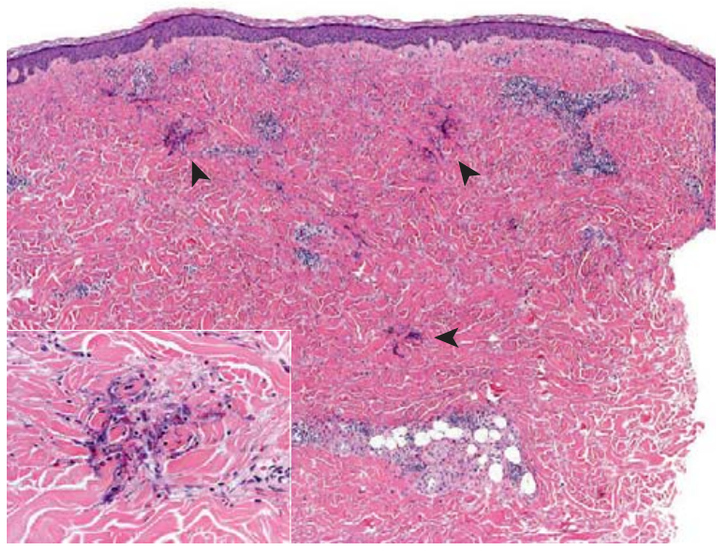

Fig. 25.7 Wells' syndrome. Perivascular and interstitial inflammatory infiltrate with a significant number of eosinophils within the dermis. There are also several flame figures at sites of degranulation of eosinophils (arrowheads; insert).

Toxocara canis and other parasitic disorders can present with clinical and pathologic findings similar to Wells' syndrome. When a parasitic infection is suspected, laboratory evaluation includes stool examinations, serum IgE levels and specific antibody assays. Allergic contact dermatitis (especially the dermal form) can also closely mimic Wells' syndrome. A careful history along with patch testing may be useful in establishing the former diagnosis. Several of the other disorders listed in Table 25.1 may present with urticarial plaques clinically and diffuse dermal infiltrates of eosinophils histologically. Nonetheless, there is rarely confusion between Wells' syndrome and the clinicopathologic presentations of these entities.

Treatment

Initial therapy usually consists of oral corticosteroids, typically prednisone at a dose of 10–80 mg daily, and this typically results in dramatic improvement within a few days. Tapering of the corticosteroid dose over 1 month is well tolerated in most patients. Flares may be treated with repeat courses. For patients who fail to respond completely, or who flare often enough to raise concerns about the long-term side effects of systemic corticosteroid therapy (see Ch. 125), other treatments may prove beneficial. Minocycline, colchicine, antimalarials, dapsone, griseofulvin, interferon-α and antihistamines have been reported to clear some patients. Cyclosporine (1.25–2.5 mg/kg/day) for 3–4 weeks resulted in clinical resolution in two patients, with no

relapse during the following 10 months. For mild cases, potent topical corticosteroids may be used.

HYPEREOSINOPHILIC SYNDROME

Key features

- With the discovery of the *FIP1L1-PDGFRA* fusion gene, whose protein product is a constitutively activated tyrosine kinase, the classification and treatment of hypereosinophilic syndrome (HES) have become more precise
- The *FIP1L1-PDGFRA* fusion gene is present in patients with the myeloproliferative form of HES, which includes eosinophilic leukemia
- In the lymphocytic variant of HES, there is a clonal proliferation of T cells with increased production of Th2 cytokines, particularly IL-5
- Mucocutaneous lesions are seen in over half of patients with HES and vary from pruritic erythematous papules or nodules to urticaria and angioedema; mucosal ulcers are associated with an aggressive course
- The 5-year survival rate is 80%, with a major cause of death being congestive heart failure from restrictive cardiomyopathy

Introduction

The term "hypereosinophilic syndrome (HES)" was originally coined in the late 1960s to refer to a spectrum of eosinophil-associated diseases with common clinical features, including skin disease in more than 50% of patients. In the 1990s, a subset of patients with HES was found to have clonal proliferations of T cells with increased production of Th2 cytokines (in particular, IL-5); that is, the *lymphocytic* form of HES was identified. Building upon the clinical observations that a subgroup of patients with HES responded to hydroxyurea, interferon and, more recently, imatinib mesylate (Gleevec®), i.e. treatments for chronic myelogenous leukemia (CML), a molecular explanation was subsequently discovered. The patients with this particular form of *myeloproliferative* HES possessed a *FIP1L1-PDGFRA* fusion gene[32], whose protein product is a constitutively activated tyrosine kinase that is over 100 times more sensitive to the inhibitory effects of imatinib than is the BCR-ABL kinase from CML patients (see Pathogenesis). There are some patients with HES who have neither the lymphocytic nor the myeloproliferative form of the disease, and additional subtypes of HES have been partially classified[33,34,34a] (Table 25.3), along with a corresponding treatment algorithm (Fig. 25.8). However, as pathogenetic mechanisms continue to evolve so will the classification and recommended evaluation of hypereosinophilia and HES.

History

Prior to 1968, patients with marked blood eosinophilia, in the absence of helminthiasis or allergic disease, were diagnosed using various terms. In 1968, Hardy and Anderson coined the term "hypereosinophilic syndromes (HES)" to refer to these patients. Chusid and colleagues[35] proposed diagnostic criteria in 1975, and the clinical spectrum of HES was defined. More recently, the two major forms of HES, lymphocytic and myeloproliferative, were described.

Epidemiology

HES occurs worldwide. Up to 25% of patients may have the lymphocytic form of HES, which has an equal gender distribution, while *FIP1L1-PDGFRA*-positive myeloproliferative HES has a striking male predominance (>90%, with few reported female cases). Other HES subtypes likely have an equal gender distribution. HES affects all age groups, including children, but principally affects adults. The average age of onset for the various HES subtypes is unknown, in part, because of delay in diagnosis. However, defining when HES begins is becoming more precise as disease markers are discovered.

Myeloproliferative HES includes patients with eosinophilic leukemia (who may have multiple cytogenetic abnormalities[37]). While individuals with the *FIP1L1-PDGFRA* fusion gene may be regarded as having chronic eosinophilic leukemia, there are clearly some patients who develop more aggressive disease with transformation to frank leukemia. Patients with lymphocytic HES are at risk of developing lymphoma.

DIAGNOSTIC CRITERIA AND CLASSIFICATION OF HYPEREOSINOPHILIC SYNDROMES

DIAGNOSTIC CRITERIA

- Peripheral blood eosinophil counts >1500/microliter for at least 6 months, or less than 6 months with evidence of organ damage
- Lack of evidence for parasitic, allergic, or other recognized causes of eosinophilia
- Symptoms and signs of organ system involvement

SUBTYPES

Myeloproliferative*	Lymphoproliferative	Other‡
• *FIP1L1-PDGFRA* fusion gene; other mutations are possible • Includes "classic HES" with endomyocardial disease and a male predominance • Mucosal ulcers are associated with severe disease • High serum tryptase and vitamin B_{12} levels, tissue fibrosis, splenomegaly, and bone marrow biopsies with increased numbers of $CD25^+$ atypical spindle-shaped mast cells†	• T-cell clone producing Th2 cytokines • T-cell clones have occurred in rare cases of EAE and NERDS	• Eosinophilic vasculitis • Episodic angioedema with eosinophilia (EAE; Gleich syndrome) • *N*odules, *e*osinophilia, *r*heumatism, *d*ermatitis and *s*welling (NERDS) syndrome • A variety of other diseases, including eosinophilic gastroenteritis

*Includes patients with eosinophilic leukemia, who may have other cytogenetic abnormalities; can also screen for other rare fusion genes or rearrangements involving *PDGFRB* or *FGR1*, which encode platelet-derived growth factor receptor (beta polypeptide) and fibroblast growth factor receptor-1, respectively

†In the WHO classification of mastocytosis, such patients (who have the *FIP1L1-PDGFRA* fusion gene) are designated as having systemic mastocytosis with associated clonal hematological non-mast cell-lineage disease (AHNMD).

‡Other HES subtypes have recently been reviewed and partially classified[33,34].

Table 25.3 Diagnostic criteria and classification of hypereosinophilic syndromes (HES)[35,36].

Pathogenesis

Eosinophils have been implicated as the cause of much of the end-organ damage in all forms of HES via the elaboration of eosinophil products (see Fig. 25.1), and clinical improvement usually parallels a decrease in the eosinophil count[35a]. While the pathogenesis of the lymphocytic and myeloproliferative forms is now better understood (see below), the etiologies of the other forms are likely varied[33,34,36]. Occasional patients with episodic angioedema and eosinophilia (Gleich syndrome) as well as those with *n*odules, *e*osinophilia, *r*heumatism, *d*ermatitis and *s*welling (NERDS) syndrome have developed T-cell clones (see Table 25.3). Therefore, as outlined in Figure 25.8, patients who do not have the lymphocytic or myeloproliferative forms of HES should continue to be monitored for the development of T-cell clonality or cytogenetic abnormalities.

Lymphocytic HES

Patients with the lymphocytic variant of HES have abnormal clonal lymphocyte populations, frequently with unique surface phenotypes such as $CD3^+CD4^-CD8^-$ or $CD3^-CD4^+$. Upon activation, these T cells secrete Th2 cytokines (IL-5, IL-4, IL-13). IL-5 induces eosinophilopoiesis and activates eosinophils, which then release their toxic granule contents. IL-2 may also play a role by enhancing platelet-activating factor (PAF)-stimulated eosinophil granule protein release from eosinophils (see above)[24]. In lymphocytic HES, high serum IgE levels are often found along with eosinophilia, likely attributable to IL-4 and IL-13 production. These patients develop severe pruritus, eczema, erythroderma and/or urticaria and angioedema.

Although, in general, the lymphocytic variant of HES appears to be a relatively benign disease and the T-cell clones can remain stable for

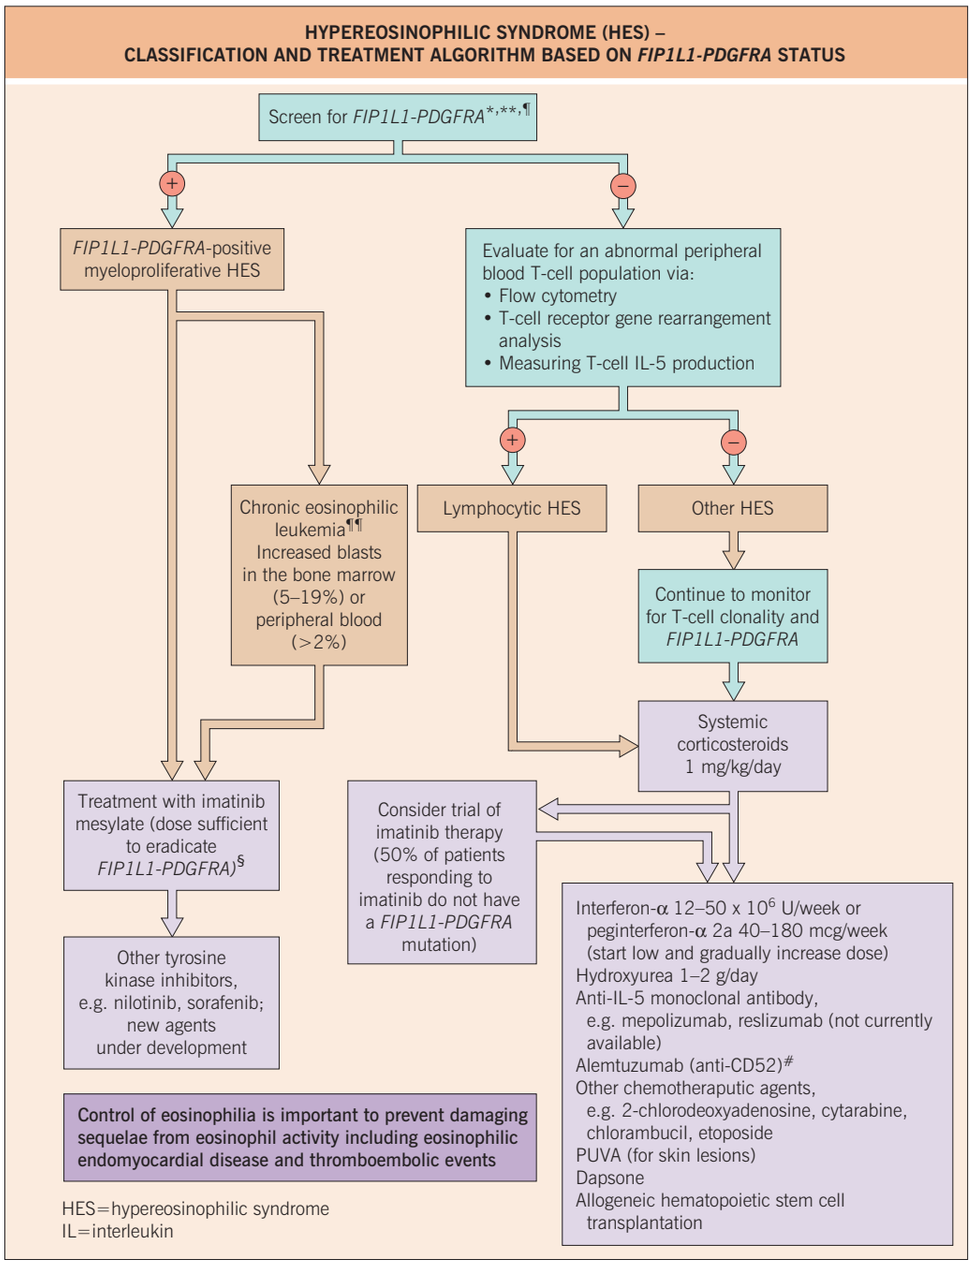

Fig. 25.8 Hypereosinophilic syndrome (HES) – classification and treatment algorithm based on *FIP1L1-PDGFRA* status. *An 800 kb deletion on chromosome 4 produces a fusion gene composed of a portion of the *PDGFRA* (platelet-derived growth factor receptor α) gene that encodes its kinase domain linked to a previously uncharacterized gene that resembles *Fip1*, which encodes an essential component of the *Saccharomyces cerevisiae* polyadenylation machinery. The resultant product is a constitutively activated tyrosine kinase. Screening can be performed on a peripheral blood sample via reverse transcriptase-PCR or fluorescence *in situ* hybridization (FISH). **Bone marrow biopsy with cytogenetic studies should be done to exclude hematologic disorders that can be accompanied by eosinophilia. Increased bone marrow mast cells and elevated serum tryptase may be observed. ¶Can also screen for other rare fusion genes or rearrangements involving *PDGFRB* or *FGR1*, which encode platelet-derived growth factor receptor (beta polypeptide) and fibroblast growth factor receptor-1, respectively. ¶¶May have other clonal cytogenetic and molecular genetic abnormalities; in the presence of eosinophilia, this is usually sufficient for diagnosis even in the absence of excess blasts. §Plus systemic corticosteroids if cardiac involvement. #CD52 is expressed on the surface of normal and malignant B and T lymphocytes, NK cells, monocytes, macrophages and eosinophils.

years, $CD3^{-}CD4^{+}$ T cells and other clonal T cells may undergo progressive transformation and evolve into lymphoma. Therefore, patients with such clones should be regarded as having premalignant or malignant T-cell lymphoma and be closely observed[38].

Myeloproliferative HES

Myeloproliferative HES includes patients with eosinophilic leukemia as well as individuals with the *FIP1L1-PDGFRA* fusion gene that results from an 800-kilobase deletion on chromosome 4q12, which, when present, may be regarded as evidence of chronic eosinophilic leukemia (see Fig. 25.8). Sensitive reverse transcriptase (RT)-PCR-based assays and fluorescence *in situ* hybridization (FISH) probes have been developed to detect the deletion which produces this fusion gene; the latter is composed of the portion of the platelet-derived growth factor receptor-α gene (*PDGFRA*) that encodes its tyrosine kinase domain linked to a previously uncharacterized gene resembling *Fip1*, which encodes an essential component of the *Saccharomyces cerevisiae* polyadenylation machinery. The resultant protein product is a constitutively activated tyrosine kinase that transforms hematopoietic cells *in vitro* and *in vivo*, analogous to the BCR-ABL kinase that results from the translocation [t(9;22)] that leads to the Philadelphia chromosome in CML. This molecular discovery provided an explanation for the clinical observation that a subgroup of patients with HES responded to imatinib (Gleevec®), a tyrosine kinase inhibitor first introduced for the treatment of CML (see Treatment)[36,39]. Unfortunately, as in CML where patients can develop new mutations in *BCR-ABL* (e.g. T315I) that lead to resistance, a few HES patients who initially responded to imatinib later became resistant, having developed T674I mutations (during blast crisis) or tandem S601P/L629P mutations (during the chronic phase)[40].

Some patients with HES have elevated serum tryptase levels and increased atypical, spindle-shaped mast cells in bone marrow biopsies (see Table 25.3)[36,41]. These patients develop splenomegaly, endomyocardial fibrosis, cardiomyopathy and elevated serum vitamin B_{12} levels; some also have mucosal ulcers. However, they lack the clinical manifestations of systemic mastocytosis as well as tissue mast cell aggregates and c-*KIT* mutations. These patients have the *FIP1L1-PDGFRA* fusion gene and are responsive to imatinib. In the World Health Organization (WHO) classification of mastocytosis, such patients are designated as systemic mastocytosis with *a*ssociated clonal *h*ematological *n*on-*m*ast cell-lineage *d*isease (AHNMD; see Ch. 118), although others would argue they are more appropriately considered a subset of HES. In some patients, the *FIP1L1-PDGFRA* fusion gene was detected in

mast cells, neutrophils and mononuclear cells; this is interesting because many HES patients also show marked neutrophilia. Presently, it is not clear whether the cell lineages mutated independently or if a common, yet unknown, precursor cell mutated.

Clinical Features

Diagnostic criteria for HES are as follows: (1) peripheral blood eosinophilia (≥1500 eosinophils/mcl) for at least 6 months *or* if less than 6 months, with evidence of organ damage; (2) signs and symptoms of multiorgan involvement; and (3) no evidence of parasitic or allergic disease, or other known causes of peripheral blood eosinophilia. Thus, HES is a diagnosis of exclusion. Patients with HES present with signs and symptoms related to the organ systems affected by eosinophilic infiltrates, and cutaneous lesions occur in more than half of all patients. The skin findings range from pruritic erythematous macules, papules, plaques or nodules on the trunk and extremities to urticaria and angioedema[42]. Occasionally, the nodules ulcerate. Mucosal ulcers may also occur, either in the oropharynx or in the anogenital region, and they are associated with myeloproliferative HES, with a majority of patients dying within 2 years of presentation unless treated[43]; recent reports indicate that these patients are very responsive to imatinib. Other cutaneous manifestations include erythema annulare centrifugum-like lesions, purpuric papules, retiform purpura, livedo reticularis and superficial thrombophlebitis.

Lymphocytic HES is commonly associated with severe pruritus, dermatitis, erythroderma and/or urticaria and angioedema, in addition to lymphadenopathy. These patients rarely develop endomyocardial fibrosis. In myeloproliferative HES, the usual presenting complex includes fever, weight loss, fatigue, malaise and skin lesions, in addition to increased serum vitamin B_{12} levels and increased serum tryptase levels[44]. The heart is often involved, with thrombus formation and progression to subendocardial fibrosis and restrictive cardiomyopathy. Mitral or tricuspid valvular insufficiency results from tethering of chorda tendineae. Hepatosplenomegaly is often present as well, indicating liver and spleen involvement. The central and peripheral nervous systems may also be affected, in addition to the lungs and, rarely, the kidneys[44a].

Eosinophilic endomyocardial disease can develop in any patient with prolonged peripheral blood eosinophilia, and HES patients must be monitored for its development by periodic performance of echocardiography. Embolic events may occur, particularly during the thrombotic stage, and constitute a medical emergency because of their likely serious sequelae; cutaneous involvement with splinter hemorrhages and/or nailfold infarcts may be present and can provide the initial clues to thromboembolic disease. More recently, intramural cardiac damage has been observed in patients with HES in the absence of appreciable blood eosinophilia.

Pathology

The histopathology of cutaneous lesions in HES is nonspecific and varies depending upon the type of skin lesion biopsied. Urticarial lesions have histologic findings that resemble urticaria, i.e. perivascular or interstitial infiltrates of lymphocytes, eosinophils, and occasional neutrophils. Biopsies from papules or plaques occasionally exhibit spongiosis in addition to the dermal infiltrate that nearly always contains at least a few eosinophils. Flame figures may also be present. When studied with stains for specific eosinophil granule proteins, episodic angioedema with eosinophilia and HES with mucosal ulcers show extensive deposition of granule proteins in the absence of morphologically identifiable intact eosinophils. Similar findings are observed in synovial tissues in the NERDS syndrome. Thrombosis of dermal blood vessels has been observed in biopsy specimens from retiform purpura and necrotic skin lesions in HES patients.

Differential Diagnosis

The differential diagnosis of HES includes those dermatoses that are characterized by prominent eosinophilic infiltrates (see Table 25.1), along with other dermatoses in which eosinophil degranulation occurs but infiltrates of intact eosinophils are not observed. The principal means of eosinophil degranulation is via cytolysis and the eosinophil disrupts within tissue soon after infiltrating or as it infiltrates. The footprints are its granule proteins which remain in the tissue while the cell itself is not morphologically identifiable, although parts of the eosinophil are often recognizable by electron microscopy.

In contrast to Wells' syndrome, patients with myeloproliferative HES may be more systemically ill, with fever and signs and symptoms of multiorgan involvement. Histologic features can be similar, but the classic flame figures of Wells' syndrome are less commonly seen in HES.

Churg–Strauss syndrome can resemble HES and is considered by some authors to be an HES-associated disease[33]. Characteristically, patients with Churg–Strauss syndrome have asthma along with other organ involvement. Cutaneous lesions classically consist of papulonodules located on the scalp or extremities and hemorrhagic lesions ranging from petechiae to hemorrhagic eschars. Cardiac involvement may occur and the histologic features are distinctive. Churg–Strauss syndrome exhibits vasculitis of the medium-sized arteries and veins, with extravascular granulomas in addition to the eosinophilic infiltrate. No vasculitis is seen in HES, although thromboembolic phenomena may produce lesions that mimic vasculitis (see Ch. 22).

Parasitic infections and infestations may closely resemble HES. A history of travel to endemic areas or a suggestive dietary history implicates helminthiasis. In such patients, serologic testing for anti-*Strongyloides* antibodies and three stool samples for ova and parasites should be obtained. A total serum IgE greater than 500 IU/ml is often seen in helminth infections. Inappropriate treatment of *Stronglyloides stercoralis* with systemic corticosteroids or other immunosuppressives may result in severe sequelae, including death.

In patients with HES whose cutaneous eruption consists of isolated urticarial plaques with or without angioedema, the differential diagnosis includes urticaria. Histopathology of such a cutaneous lesion may be indistinguishable from that of ordinary urticaria, and clinical correlation is required to distinguish between the two. Specifically, demonstration of multiorgan involvement favors HES. In addition, HES with episodic angioedema may resemble hereditary or acquired angioedema clinically, but complement studies help to make a distinction (see Fig. 18.18). Furthermore, the patients with hereditary angioedema often have a family history of the disease and rarely are their peripheral blood eosinophil counts as elevated as in HES.

Patients with lymphocytic HES commonly have pruritic skin lesions that become eczematous. The differential diagnosis in these patients includes atopic dermatitis, contact dermatitis, drug reaction, id reaction to a bacterial or fungal infection, and other types of T-cell lymphoma.

Treatment

In light of the *FIP1L1-PDGFRA* fusion gene discovery, an algorithmic approach for the evaluation and treatment of HES is provided in Figure 25.8. If *FIP1L1-PDGFRA* is present, imatinib therapy is warranted. Imatinib, a 2-phenylaminopyrimidine tyrosine kinase inhibitor, exerts its effect by binding to the amino acids of the fusion tyrosine kinase's ATP-binding site and stabilizes the inactive, non-ATP-binding form of the FIP1L1-PDFGRA fusion protein. This prevents autophosphorylation of the fusion protein and phosphorylation of other substrates. As a result, the signaling cascade that induces genes related to eosinophil proliferation and activation is terminated. Patients respond to varying doses of imatinib, depending upon the sensitivity of the particular patient and the ability of the given dosage to suppress the mutant clone. Imatinib doses ranging from 400 mg daily to 100 mg weekly or less have proven effective. A majority of patients with the fusion protein have achieved hematologic and molecular remission when treated with imatinib; however, maintenance therapy is required to avoid relapse. Of note, endomyocardial disease may worsen during the first several days of imatinib therapy so serum levels of troponin and NT-proBNP should be monitored. Preemptive and concurrent treatment with corticosteroids is also recommended to maintain cardiac function. For patients who lack the *FIP1L1-PDGFRA* fusion gene, further evaluation to detect clonal cytogenetic abnormalities or abnormal clonal T-cell populations is warranted.

First-line therapy for HES patients who lack the *FIP1L1-PDGFRA* fusion gene consists of prednisone at a dose of 1 mg/kg/day. Approximately 70% of patients will respond, with the peripheral eosinophilia returning to normal levels. As the peripheral eosinophilia normalizes, cardiac function improves. For those patients who fail corticosteroid monotherapy or develop significant long-term side effects, multiple

other agents have been reported to be beneficial (see Fig. 25.8). For example, imatinib treatment of patients with no detectable *FIP1L1-PDGFRA* fusion gene has resulted in partial hematologic responses, although the mechanism of response in these patients is unclear. Perhaps some patients had diagnostically occult *PDGFRA* or *PDGFRB* rearrangements, especially those individuals with the rare complete responses[40]. As a result, imatinib represents a reasonable therapeutic option, given its relative safety.

Interferon (IFN)-α (12–50 × 10^6 U/week) has been beneficial in the treatment of patients with both myeloproliferative and lymphocytic HES. Its mode of action is likely via myelosuppression but may include effects on Th2 helper cells by changing the cytokine milieu (including a decrease in IL-5 levels). Some patients tolerate pegylated interferon better (peginterferon -2α), responding to various doses, and it can be administered weekly. After prolonged therapy with IFN-α, a clinical and molecular remission may occur in patients with the *FIP1L1-PDGFRA* fusion gene, suggesting that prolonged IFN-α treatment may modify the disease in unanticipated ways. One concern regarding the use of IFN-α, based upon the findings of an *in vitro* study in which IFN-α acted as a growth factor for $CD3^-CD4^+$ cells, is probably minimized in patients receiving corticosteroids concomitantly. For some patients, pegylated IFN is better tolerated, and it can be administered weekly.

Two monoclonal antibodies against human IL-5 have been used for HES in clinical trials, mepolizumab and reslizumab. Analyses of cytokine production by lymphocytes before and after treatment with mepolizumab showed a striking reduction in Th2 cytokine production (e.g. IL-13, IL-10) in addition to the expected IL-5 reduction[45]. In a randomized, double-blind, placebo-controlled trial involving 85 *FIP1L1-PDGFRA*-negative patients who were already receiving prednisone (20–60 mg/day), administration of mepolizumab (750 mg IV every 4 weeks for 9 cycles) led to twice as many individuals (84% vs 43%) being successfully tapered to a stable prednisone dose of ≤10 mg/day[46]. Lastly, other kinase inhibitors (e.g. nilotinib, sorafenib) may be useful in treating patients who do not respond to imatinib or become resistant as a consequence of mutations such as T674I in *FIP1L1-PDGFRA*[40].

The overall goal in treating the HES is relief of the patient's symptoms while keeping the peripheral blood eosinophil count in the range of 1000–2000/mcl (by using single- or multiple-agent therapy) as well as minimizing side effects from the therapy. Patients also need to be monitored for organ involvement, particularly cardiac involvement, and treated appropriately. Those who fail corticosteroid monotherapy have a worse prognosis. Overall, HES is associated with a 5-year survival rate of 80%, with the leading cause of death usually being congestive heart failure followed by sepsis.

Neutrophilic Dermatoses 26

Samuel L Moschella and Mark DP Davis

The neutrophilic dermatoses constitute a heterogeneous but linked spectrum of diseases[1], with significant overlapping histopathologic findings and similar pathogenic mechanisms and therapeutic approaches. They are often associated with underlying internal diseases, which may have significant morbidity and mortality. Histologically, these disorders are characterized by perivascular and diffuse neutrophilic infiltrates without any identifiable infectious agents (Fig. 26.1). The cutaneous manifestations vary from vesiculopustules and plaques to nodules and ulcers. It is noteworthy that there may be several different types of lesions in the same patient. The dermatosis may be localized or more widespread, and, in an occasional patient, similar sterile neutrophilic infiltrates may occur in the eyes, joints, bones, lung, liver and lymph nodes. The neutrophilic infiltrate may be most prominent in the epidermis, dermis or even the panniculus. Distinct entities have been defined by the nature of their clinical and histologic presentations as well as their associated diseases.

NEUTROPHIL BIOLOGY

Granulocytes (neutrophils, eosinophils and basophils) are cells essential to our defense against microbes as well as other inflammatory responses. The neutrophil is a terminally differentiated, non-dividing cell which is packed with granules whose contents kill and degrade target microorganisms. Recent advances in our understanding of neutrophil biology include the molecular and cellular mechanisms responsible for their production and release from the bone marrow (e.g. chemokine CXC receptor 4; see Ch. 60); their recruitment, priming and activation within inflamed tissues (Table 26.1); and the events resulting in their removal.

Granulocytes, including neutrophils, originate in the bone marrow from pluripotent cells. In order to supply baseline requirements for sufficient numbers of circulating cells, neutrophils are produced within the bone marrow at a prodigious rate (>5–10 × 10^{10} neutrophils daily). The bone marrow also has the capacity to upregulate granulocyte production sharply in response to a number of stresses such as infection. Mature neutrophils circulate in the peripheral bloodstream for only 3–12 hours before migrating into tissues, where they survive for 2–3 days. Despite their short half-life within the bloodstream, neutrophils, unlike platelets and erythrocytes, appear to be removed from the circulation in a random rather than an age-related manner.

Transcriptional profiling studies suggest that granulocytes arise via the selective expression of a subset of transcription factors (e.g. Egr1, HoxB7, STAT3), granulocyte proteins (e.g. S100A8, S100A9, neutrophil elastase), and receptors (e.g. N-formyl-methionyl-leucyl-phenylalanine [FMLP], granulocyte–macrophage colony-stimulating factor). Differentiation from pluripotent stem cells requires 7–10 days, and during this period, under the influence of cytokines, neutrophils acquire their characteristic appearance and granules (primary, secondary and tertiary). The following stages of myeloid maturation are recognized: myeloblast, promyelocyte, myelocyte, metamyelocyte, band, and, finally, the segmented neutrophil. The progressive gain of differentiated characteristics is accompanied by a loss in the potential to proliferate, i.e. beyond the myelocyte stage, the cells are non-dividing. The intracellular granules acquired during maturation contain many of the enzymes that mediate the oxidative and non-oxidative killing functions of the neutrophil:

- primary (azurophilic) granules – acquired at the promyelocyte stage and their contents include myeloperoxidase, lysozyme, neutrophil elastase, defensins and myeloblastin
- secondary granules – acquired at the transition to the myelocyte stage and their contents include lactoferrin, neutrophil collagenase, neutrophil gelatinase, neutrophil gelatinase-associated lipocalin and transcobalamin 1
- tertiary granules – acquired during later stages of neutrophil maturation and contain neutrophil gelatinase.

Inflammation

A critical role of inflammation is to deliver neutrophils and other leukocytes to a site of injury and to activate these cells to perform their function of protecting the host against infection. Neutrophils are among the first cells to arrive at sites of inflammation; reasons for this include their abundance in the bloodstream and their rapid response to chemokines. When activated, neutrophils move at speeds up to 30 microns/min – the fastest cell in the body.

The motile responses of neutrophils to microbial infection include emigration out of the vasculature and movement toward the source of the inflammatory chemoattractant. This culminates in the phagocytic ingestion of opsonized microbes. In order to arrive at the site of infection, leukocytes must migrate out of the vasculature via margination, rolling, activation and tight adhesion (see Ch. 102). They then move toward the site of injury or infection (see Table 26.1) and eventually undergo degranulation then apoptosis.

The price to be paid for the defensive potency of neutrophils for destroying microbes and necrotic tissues is that they can injure normal tissue. During activation and phagocytosis, neutrophils release products (e.g. lysosomal enzymes, reactive oxygen intermediates, products of arachidonic acid metabolism [prostaglandins and leukotrienes]) not just within the phagolysosome, but also into the extracellular space. Endothelial injury and tissue damage ensue, thus contributing to a number of acute and chronic diseases that affect the skin as well as other organs.

SWEET'S SYNDROME

Synonym: ■ Acute febrile neutrophilic dermatosis

Key features

- Constitutional signs and symptoms such as fever and malaise
- Clinically, erythematous plaques that are occasionally bullous
- Histologically, dense perivascular neutrophilic infiltrate, edema and, infrequently, bullae; leukocytoclasia with minimal to no evidence of vasculitis
- Associated conditions include infections, malignancies (especially acute myelogenous leukemia), inflammatory bowel disease, autoimmune disorders, drugs and pregnancy

History

The prototype of the neutrophilic dermatoses is Sweet's syndrome. In 1964, Sweet[2] described eight middle-aged women who had an acute

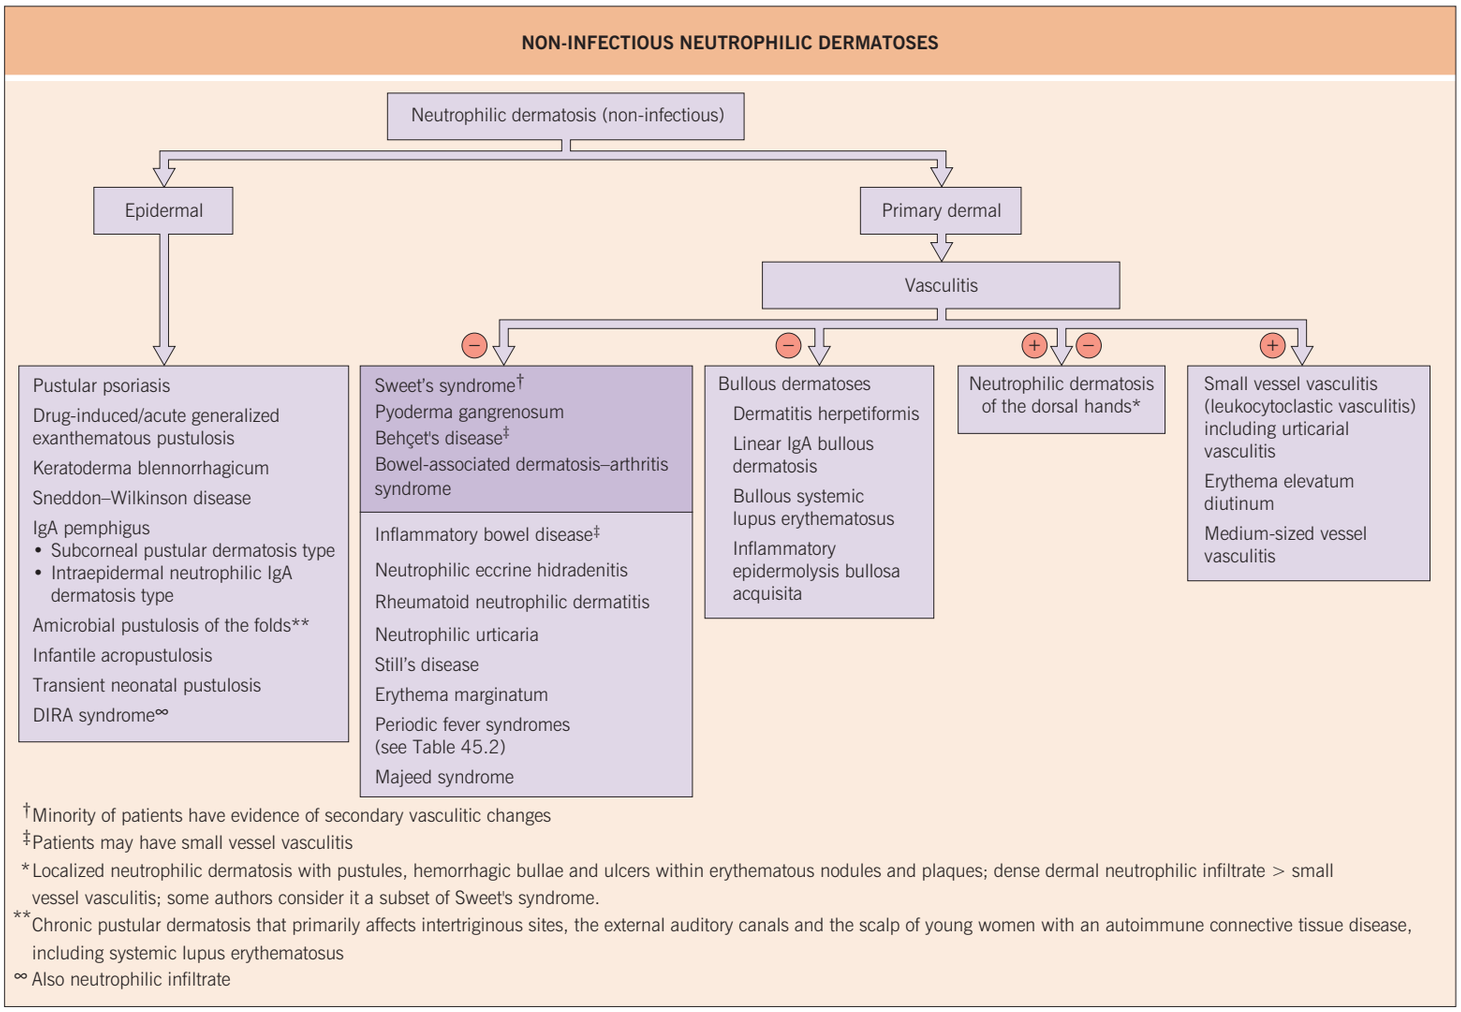

Fig. 26.1 Non-infectious neutrophilic dermatoses. Entities in the darker box are discussed in this chapter. DIRA, deficiency of the interleukin-1 receptor antagonist.

onset of fever and erythematous plaques associated with a nonspecific infection of the respiratory tract or gastrointestinal tract. Histologically, the skin lesions were characterized by a neutrophilic infiltrate. He named this constellation of findings "acute febrile neutrophilic dermatosis". In 1968, Whittle et al.[3] reported a similar case and named it "Sweet's syndrome".

Epidemiology

Sweet's syndrome is an uncommon disease, with a worldwide distribution and no obvious racial predilection, although the disorder appears to be more frequent in Japan. The average age of onset is 30–60 years, but infants, children and the elderly may be affected; there is a female predominance of 4 to 1. Up to 20% of patients have internal malignancies, and, in this subgroup, there is no female predominance. Drug-induced Sweet's syndrome occurs more frequently in women.

Pathogenesis

The pathogenesis of Sweet's syndrome is unknown. The association with underlying diseases suggests a hypersensitivity reaction. One hypothesis is a local or systemic dysregulation of cytokine secretion, involving interleukin (IL)-1, granulocyte colony-stimulating factor (G-CSF), granulocyte–macrophage colony-stimulating factor (GM-CSF) and interferon-γ[4,5].

Sweet's syndrome may be associated with inflammatory and autoimmune disorders (e.g. inflammatory bowel disease) or an underlying malignancy (paraneoplastic) as well as be drug-induced, postinfectious, or pregnancy-related. Up to 50% of patients may have idiopathic disease.

Clinical Features

The initial cutaneous lesions are tender, non-pruritic, erythematous plaques or papules (Fig. 26.2), which may enlarge or coalesce to form plaques with an uneven mammillated surface. Because of the pronounced associated edema (Fig. 26.3A), the lesions may have a pseudovesicular or pseudopustular appearance; however, some patients actually do develop vesiculation, bullae or pustules within their plaques. Occasionally, the plaques have a central yellowish discoloration creating a targetoid appearance (Fig. 26.3B). A facial erysipelas-like eruption has also been described. The vesiculobullous variant, which is most frequently associated with myelogenous leukemia, can progress to ulceration resembling superficial pyoderma gangrenosum (PG). In this form, there may be a single lesion or multiple, asymmetrically distributed lesions.

The cutaneous eruption of Sweet's syndrome favors the head (Fig. 26.4), neck and upper extremities (including the dorsal aspect of the hands), but can occur anywhere. In true malignancy-associated cases, the lesions tend to have a more widespread distribution. Papulonodules involving the lower legs may resemble erythema nodosum and, in fact, a small number of patients have concurrent erythema nodosum. As with PG, specific lesions may be initiated by wounding injuries such as needle sticks (pathergy). Oral lesions are uncommon, except in patients with hematologic disorders; initially they appear pseudopustular, and later ulcerate and appear as aphthae. The cutaneous eruption of Sweet's syndrome usually resolves spontaneously within 5–12 weeks but recurs in up to 30% of patients.

An upper respiratory tract infection or flu-like illness frequently precedes the development of the syndrome. Fever occurs in 40–80% of patients and can be intermittent. Extracutaneous involvement is also frequently seen (Fig. 26.5; Table 26.2).

NEUTROPHILS – THEIR RELATIONSHIP TO SITES OF INFLAMMATION
INTRAVASCULAR ADHESION, ACTIVATION AND MIGRATION
• Neutrophils are activated by chemoattractants, ligands of selectins, immune complexes and activated complement components to express β_2 integrins (e.g. LFA-1) that then adhere to ICAM-1 on endothelial cells (see Fig. 102.10) • Endothelial cells can be activated by thrombin, histamine, cytokines (e.g. IL-1, TNF-α), endotoxin and immune complex–C1q aggregates to express adhesive molecules (e.g. P-selectin, E-selectin, ICAM-1, VCAM-1) • Diapedesis represents migration of cells through inter-endothelial spaces towards a chemical concentration gradient (i.e. towards a site of infection or injury)
MIGRATION WITHIN TISSUE
• Leukocytes adhere to matrix proteins and move via chemotaxis (along a chemical gradient) • In response to the binding of chemoattractants (e.g. FMLP, C5a, PAF, LTB_4), neutrophils change their shape and crawl by alternating the extrusion and retraction of frontal lamellipodia
ACTIVATION WITHIN TISSUE
• Upon arrival at the site of injury or infection, neutrophils become activated via several signaling pathways (e.g. PKC, phospholipase A2, cytosolic [Ca^{2+}]) and surface receptors are expressed (e.g. Toll-like receptors, receptors for cytokines and opsonins) • Activation results in degranulation and secretion of lysosomal enzymes, activation of the oxidative burst, production of arachidonic acid metabolites and secretion of cytokines
PHAGOCYTOSIS
• Recognition and attachment of the particle to be ingested by the neutrophil is greatly enhanced by opsonization (coating by opsonins such as antibodies, complement or lectins), which targets it for phagocytosis • Binding of the particle to phagocytic neutrophil receptors initiates engulfment of the particle, which then fuses with a lysosomal granule, forming a phagolysosome
DESTRUCTION OF INGESTED MATERIAL
• Microbes are killed preferentially by oxygen-dependent, rather than oxygen-independent, mechanisms with formation of reactive oxygen intermediates • With discharge of the granule's contents into the phagolysosome, the neutrophil becomes degranulated • Neutrophils then rapidly undergo apoptosis and are ingested by macrophages

Table 26.1 Neutrophils – their relationship to sites of inflammation. SYSTEMIC MANIFESTATIONS OF SWEET'S SYNDROME
COMMON (≥50%)
Fever
Leukocytosis
LESS COMMON (20–50%)
Arthralgias
Arthritis: asymmetric, non-erosive, favors knees and wrists
Myalgias
Ocular involvement: conjunctivitis, episcleritis, limbal nodules, iridocyclitis
UNCOMMON
Neutrophilic alveolitis: cough, dyspnea and pleurisy; radiographic findings include interstitial infiltrates, nodules, pleural effusions
Multifocal sterile osteomyelitis (SAPHO syndrome)
Renal involvement (e.g. mesangial glomerulonephritis): hematuria, proteinuria, renal insufficiency, acute renal failure
UNUSUAL/RARE
Hepatitis
Acute myositis
Aseptic meningitis, encephalitis
Pancreatitis
Gastrointestinal involvement

Table 26.2 Systemic manifestations of Sweet's syndrome[6–8]. SAPHO, *s*ynovitis, *ac*ne, *p*ustulosis, *h*yperostosis and *o*steitis.

Associated Diseases

Among the more frequently reported diseases or conditions associated with Sweet's syndrome are: infections such as upper respiratory tract infections due to *Streptococcus* spp. and gastrointestinal yersiniosis; hematologic malignancies (10–20% of cases), in particular acute myelogenous leukemia; solid tumors, e.g. carcinoma of the genitourinary tract, breast and colon; inflammatory bowel disease; and drugs such as G-CSF[7,9]. Less common associations are other infections (e.g. atypical mycobacteria, cytomegalovirus, chronic active hepatitis, HIV, BCG vaccination), Behçet's disease, autoimmune connective tissue diseases (e.g. systemic lupus erythematosus [SLE], rheumatoid arthritis, dermatomyositis, relapsing polychondritis, Sjögren's syndrome), autoimmune thyroid disease and sarcoidosis. Recently, there has been greater recognition of the association with SLE. Additional drugs reported to induce this neutrophilic dermatosis include furosemide, hydralazine, minocycline, trimethoprim–sulfamethoxazole, and all-*trans*-retinoic acid given in the setting of acute promyelocytic leukemia (see Ch. 21).

Pathology

The histopathologic features are contingent upon the type of cutaneous lesion sampled. The characteristic histologic presentation is a diffuse nodular and perivascular neutrophilic infiltrate without evidence of vasculitis (Fig. 26.6), although occasionally leukocytoclastic vasculitis (LCV) can be observed. Leukocytoclasia with endothelial swelling, but without the fibrinoid necrosis that fulfills the criteria for LCV, is the usual finding. Occasionally, the dermal infiltrate may extend into the subcutis, creating a septal or, less frequently, a lobular panniculitis.

In general, epidermal changes are not significant. However, neutrophils occasionally invade the epidermis, producing subcorneal pustules, and they may also infiltrate the adnexa. In the setting of significant edema, there can be epidermal spongiosis and sometimes reticular degeneration as well as intraepidermal and subepidermal vesiculation.

The histiocytoid variant is characterized by a dermal, and sometimes subcutaneous, infiltrate composed of histiocyte-like immature myeloid cells[10,11]. These cells have myeloperoxidase activity (Fig. 26.7) and must be distinguished from those of leukemia cutis.

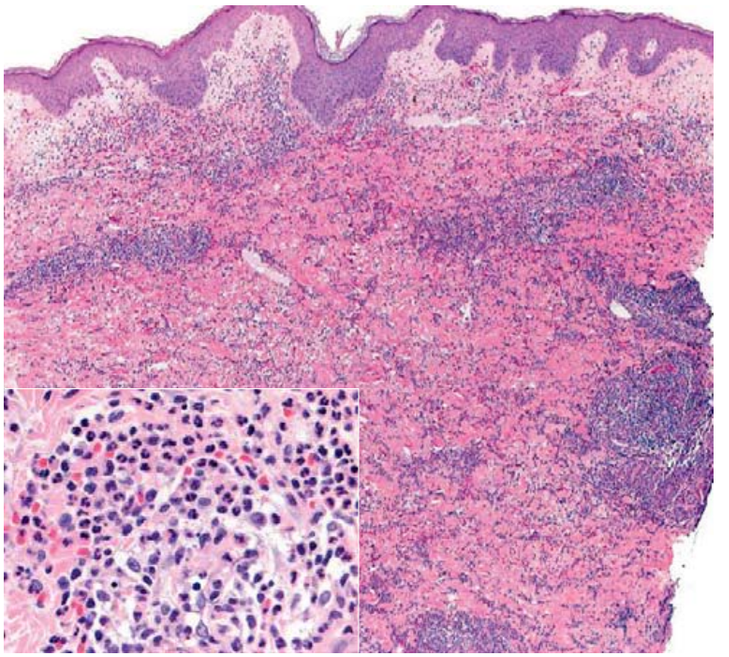

Fig. 26.6 Histologic features of Sweet's syndrome. Mild edema in the papillary dermis and a rather dense dermal infiltrate composed predominantly of neutrophils (insert). *Courtesy, Lorenzo Cerroni, MD.*

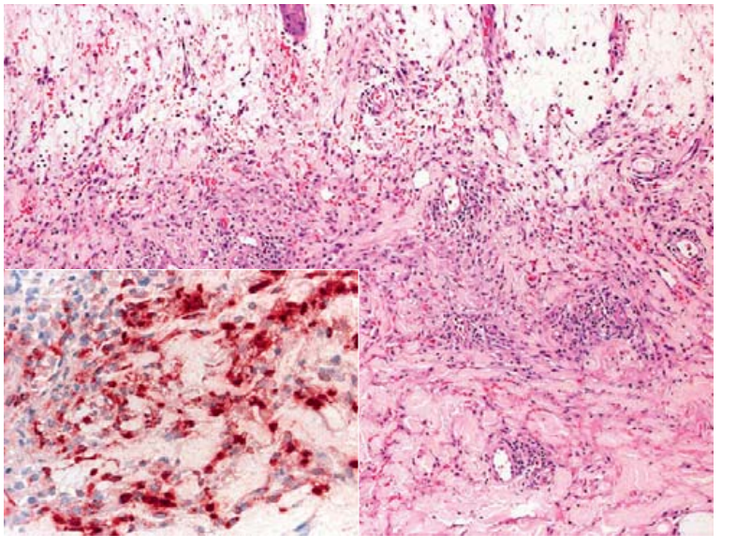

Fig. 26.7 Histologic features of histiocytoid Sweet's syndrome. There is edema in the papillary dermis as well as a dermal infiltrate composed of histiocytoid cells admixed with neutrophils, a few eosinophils, and hemorrhage. The histiocytoid cells represent immature myeloid cells and therefore have stained positively for myeloperoxidase (insert). *Courtesy, Lorenzo Cerroni, MD.*

CRITERIA FOR DIAGNOSIS OF SWEET'S SYNDROME
MAJOR CRITERIA
1. Abrupt onset of typical cutaneous lesions 2. Histopathology consistent with Sweet's syndrome
MINOR CRITERIA
1. Preceded by one of the associated infections or vaccinations; accompanied by one of the associated malignancies or inflammatory disorders; associated with drug exposure or pregnancy 2. Presence of fever and constitutional signs and symptoms 3. Leukocytosis 4. Excellent response to systemic corticosteroids

Table 26.3 Criteria for diagnosis of Sweet's syndrome[13]. Both of the major and two minor criteria are needed for the diagnosis.

Erythema nodosum-like lesions as well as PG can occur concomitantly in patients with Sweet's syndrome.

Differential Diagnosis

Although there are no specific diagnostic findings in this disease, a peripheral leukocytosis with neutrophilia, an elevated ESR and C-reactive protein, and an increased α_2-globulin fraction are frequently seen. In patients with an associated malignancy, there may be a high or low white cell count, lymphocytosis or lymphopenia, and thrombocytosis or thrombocytopenia. Although elevated serum levels of antineutrophil cytoplasmic antibody (ANCA) have been reported[12], there is no strong evidence that it is a serologic marker for this disease.

In 1986, Su and Liu[13] proposed two major and four minor criteria for the diagnosis of Sweet's syndrome, which have been widely accepted and are shown with minor revisions in Table 26.3. The differential diagnosis of the syndrome depends on the nature and age of the lesions and on the associated disease or condition (Table 26.4). Patients with neutrophilic dermatosis of the dorsal hands develop tender erythematous to violaceous plaques that may become bullous or ulcerative (Fig. 26.8)[14–16]. There is a spectrum of associated histologic features, from pustular vasculitis to those of PG or Sweet's syndrome. Hence, some authors consider this to be a variant of Sweet's syndrome.

In patients with hematologic malignancies, especially myelogenous leukemia, several neutrophilic dermatoses, e.g. Sweet's syndrome, atypical (bullous) pyoderma gangrenosum, and neutrophilic eccrine hidradenitis, can occur alone or in combination. The approach to such a patient is presented in Table 26.5.

Treatment

Sweet's syndrome is a benign condition which, if left untreated, may persist for weeks or months. Cutaneous lesions then involute spontaneously, leaving no scars. However, recurrences occur in approximately 30% of patients (with or without treatment) and occur even more often in those with hematologic disorders (approximately 50%). Although the early clinical presentation often suggests sepsis, antibiotics, in general, are ineffective. However, when the disease is associated with a recognized infection, such as that caused by *Streptococcus, Yersinia* or *Staphylococcus* spp., treatment of the underlying infection may result in improvement.

The most effective therapy for Sweet's syndrome is oral prednisone (0.5–1.0 mg/kg/day) for 4–6 weeks. There is prompt relief of not only the cutaneous but also the extracutaneous manifestations. In some patients, prolonged low-dose prednisone for an additional 2–3 months may be necessary to suppress recurrences. When the lesions are few and localized, topical superpotent or intralesional corticosteroids and/or topical calcineurin inhibitors may be helpful.

The major alternative drugs are potassium iodide (900 mg/day; see Table 100.6), dapsone (100–200 mg/day) and colchicine (1.5 mg/day). They can also be used as corticosteroid-sparing agents. Nonsteroidal anti-inflammatory drugs (e.g. indomethacin, naproxen, sulindac), clofazimine, cyclosporine, thalidomide and interferon-α have also been reported to lead to improvement of Sweet's syndrome. Evidence for any of these therapeutic regimens is based on small case series rather than double-blind placebo-controlled trials.

THE DIFFERENTIAL DIAGNOSIS OF SWEET'S SYNDROME
INFLAMMATORY DERMATOSES
• Pyoderma gangrenosum (bullous) • Neutrophilic eccrine hidradenitis • Rheumatoid neutrophilic dermatitis • Neutrophilic dermatosis of the dorsal hands* • Erythema multiforme • Urticaria with a prominent neutrophilic infiltrate (e.g. Schnitzler syndrome) • Urticarial vasculitis • Cutaneous small vessel vasculitis • Behçet's disease • Bowel-associated dermatosis–arthritis syndrome • Erythema elevatum diutinum • Panniculitis, including erythema nodosum • Halogenoderma (iododerma or bromoderma) • Wells' syndrome • Exaggerated arthropod bite reactions • Autoimmune connective tissue diseases – acute, subacute, tumid and neonatal lupus erythematosus • Granulomatous diseases – actinic granuloma, sarcoidosis, inflammatory granuloma annulare, interstitial granulomatous dermatitis • Periodic fever syndromes • Other neutrophilic dermatoses (see Fig. 26.1)
INFECTIONS
• Cellulitis, pyoderma, furunculosis • Septic vasculitis • Erythema migrans • "Deep" fungal infections (blastomycosis, cryptococcosis, coccidioidomycosis, histoplasmosis) • Mycobacterial infections (atypical and leprosy) • Leishmaniasis
NEOPLASMS
• Lymphoma cutis (T- and B-cell lymphomas including mycosis fungoides, cutaneous angiocentric lymphomas), leukemia cutis • Metastatic visceral carcinoma
*Some authors consider this a variant of Sweet's syndrome.

Table 26.4 The differential diagnosis of Sweet's syndrome[6,7].

Fig. 26.8 Neutrophilic dermatosis of the dorsal hands. This entity has overlapping clinical and histologic features with both Sweet's syndrome and pyoderma gangrenosum. Some patients have an associated pustular vasculitis. *Courtesy, Jean L Bolognia, MD.*

PYODERMA GANGRENOSUM

Key features

- Four major clinical forms: ulcerative, bullous, pustular and superficial granulomatous
- Initial lesion is often a pustule on an erythematous or violaceous base, an erythematous nodule, or a bulla
- Characteristic lesion is an ulcer with a necrotic undermined border; the base may be purulent or vegetative
- Histologically, a sterile dermal or adnexal abscess (without a vasculopathy) is seen in active, untreated, expanding lesions
- Associated illnesses include inflammatory bowel disease, arthritis, monoclonal gammopathies and other hematologic disorders

NEUTROPHILIC DERMATOSES ASSOCIATED WITH HEMATOLOGIC MALIGNANCIES			
	Sweet's syndrome	**Atypical (bullous) pyoderma gangrenosum**	**Neutrophilic eccrine hidradenitis**
1. Clinical manifestations			
a. Cutaneous	Painful plaques and nodules with occasional blisters and pustules within lesions Favors face, upper extremities and trunk Can recur (30–50% of patients)	Hemorrhagic bullae and superficial ulcerations Favors face and upper extremities (especially dorsal hands) Can recur	Erythematous edematous plaques and papules which may be painful, infrequent pustules Favors face, extremities, trunk Resolves spontaneously over ~2 weeks without scarring Can recur
b. Systemic	Fever, arthralgia or arthritis Multiorgan involvement (Table 26.2) Neutrophilia Elevated ESR	Systemic features usually absent	Fever, neutropenia*
2. Histopathology	Papillary edema with dermal neutrophilic infiltrate Histiocytoid variant – histiocyte-like immature myeloid cells	Subepidermal hemorrhagic bullae Pustules with neutrophilic dermal infiltrate	Neutrophilic† infiltrate about and within eccrine apparatus, necrosis of eccrine epithelium, and eccrine squamous syringometaplasia
3. Associations	Infections, hematologic malignancies, solid tumors, IBD, autoimmune diseases, pregnancy, G-CSF, all-*trans*-retinoic acid	Hematologic disorders, especially acute myelogenous leukemia and myelodysplasia, IBD, G-CSF	Leukemia with or without chemotherapy; post-chemotherapy for lymphoma and solid tumors; G-CSF; and rarely infections
4. Primary treatment (in addition to treatment of underlying disease)	Systemic corticosteroids (0.5–1 mg/kg/day for 4–6 weeks), potassium iodide (900 mg/day), dapsone (100–200 mg/day), colchicine (1.5 mg/day)	Systemic corticosteroids (Table 26.10)	None (spontaneous resolution)

*Usually In setting of chemotherapy.
†May be lymphocytic in setting of chemotherapy-induced neutropenia.

Table 26.5 Neutrophilic dermatoses associated with hematologic malignancies[7,17]. G-CSF, granulocyte colony-stimulating factor; IBD, inflammatory bowel disease.

Introduction

Pyoderma gangrenosum (PG) is an uncommon, chronic, recurrent, cutaneous ulcerative disease with a distinctive morphologic presentation. The laboratory and histopathologic findings can vary and therefore the diagnosis requires clinicopathologic correlation. This neutrophilic dermatosis is frequently associated with systemic disease[17–20].

History

In 1930, Brunsting, Goeckerman and O'Leary coined the term "pyoderma gangrenosum" and advanced the theory that it had an infectious etiology (streptococci and staphylococci)[18].

Epidemiology

PG is a global disease. It can occur at any age but most commonly afflicts women between 20 and 50 years of age. Fifty percent of patients have an underlying systemic disease, most commonly inflammatory bowel disease, arthritis or a hematologic disorder (e.g. IgA monoclonal gammopathy, acute myelogenous leukemia, myelodysplasia). Approximately 4% of cases of PG occur in infants and children.

Pathogenesis

Although the disease is idiopathic in 25–50% of patients, an underlying immunologic abnormality is currently favored, given its frequent association with systemic diseases that have a suspected autoimmune pathogenesis. Defects in cell-mediated immunity, neutrophil and monocyte function, and humoral immunity have been reported, but none of these findings have been demonstrated consistently and it is not clear whether they may represent an epiphenomenon[17]. Pathergy, which is a reflection of trivial trauma (Fig. 26.9), not only initiates the cutaneous lesions but also aggravates them, and is seen in 20–30% of patients with PG.

Clinical Features

Although the classic morphologic clinical presentation of PG is an ulcer, there are several variants (bullous, pustular and superficial granulomatous/vegetative) which differ by their clinical presentation, location and associated diseases (Table 26.6)[17]. Cutaneous lesions are painful and most frequently occur on the lower extremities, especially the pretibial area (Fig. 26.12A), but they can occur anywhere, including on mucous membranes and peristomal sites (Fig. 26.13A).

The lesions of PG usually begin as a tender papulopustule (Fig. 26.14) with surrounding erythematous or violaceous induration, an erythematous nodule, or a bulla on a violaceous base; the papulopustule may be

CLINICAL VARIANTS OF PYODERMA GANGRENOSUM
VESICULOBULLOUS (ALSO REFERRED TO AS ATYPICAL OR BULLOUS PG)
• Lesions favor the face and upper extremities, especially the dorsal hands • Clinical appearance overlaps with the superficial bullous variant of Sweet's syndrome (Fig. 26.10) • Occurs most commonly in the setting of acute myelogenous leukemia, myelodysplasia and myeloproliferative disorders such as chronic myelogenous leukemia
PUSTULAR
• Multiple, small, sterile pustules • Lesions usually regress without scarring, but can evolve into classic PG • Most commonly observed in patients with inflammatory bowel disease • Similar eruption may be seen in patients with Behçet's disease or bowel-associated dermatosis–arthritis syndrome
SUPERFICIAL GRANULOMATOUS PYODERMA
• Localized, superficial vegetative or ulcerative lesion[21], which favors the trunk and usually follows trauma (e.g. surgery) • Histologically, a superficial granulomatous response with a less intense neutrophilic infiltrate • Responds to less aggressive anti-inflammatory therapy • Controversy as to whether it is a variant of PG, a separate disorder, or related to Wegener's granulomatosis
PYOSTOMATITIS VEGETANS
• Chronic, vegetative, sterile pyoderma of the labial and buccal mucosa (Fig. 26.11A) • May be associated with vegetative or ulcerative cutaneous PG (Fig. 26.11B) • Seen in patients with inflammatory bowel disease

Table 26.6 Clinical variants of pyoderma gangrenosum (PG).

Fig. 26.9 Pathergy in a patient with pyoderma gangrenosum. The lesion appeared at the site of an intravenous catheter.

Fig. 26.10 Bullous pyoderma gangrenosum. This patient had ulcerative colitis.

Fig. 26.11 Variants of pyoderma gangrenosum. **A** Pyostomatitis vegetans in a patient with ulcerative colitis. **B** Vegetative form following trauma to the skin.

Fig. 26.12 Classic ulcerative pyoderma gangrenosum. A The edge of this ulceration on the shin is undermined with a violet–gray color as well as an inflammatory rim. Note the central scarring. **B** In addition to an overhanging border, this deep ulceration on the elbow has a purulent base.

follicular. All these lesions then undergo necrosis leading to a central shallow or deep ulcer; loss of tissue can expose underlying tendons or muscles. When fully developed, the ulcer has a purulent base with an irregular, undermined and overhanging, gunmetal-colored border which extends centrifugally (see Fig. 26.12). Re-epithelialization occurs from the margins and the ulcers heal with atrophic cribriform pigmented scars.

In PG, the number of ulcers can vary from one to over a dozen, and sometimes they coalesce (Fig. 26.13B). Although the ulcers are classically described as rapidly expanding, some are less inflammatory and expand rather slowly. The latter require less aggressive therapeutic interventions (see below).

In patients with hematologic disorders or in drug-induced cases, the clinical course is characterized by an acute onset of hemorrhagic or purulent bullous lesions, with a more widespread distribution that can include the dorsal hands. These lesions rapidly necrose and are often associated with fever and signs of toxicity. In those patients with associated inflammatory diseases, such as inflammatory bowel disease or arthritis, the more characteristic presentation is a chronic, slowly enlarging ulcer with excessive granulation tissue in its base and sometimes with evidence of spontaneous regression.

Clinical variants have been described based on the clinical presentation (see Table 26.6) or the location of the lesion (e.g. genital, peristomal[22]) or the age of the afflicted[19]. While the clinical appearance of PG in children is similar to that in adults, the lesions more frequently involve the head and anogenital region[23]. As with Sweet's syndrome,

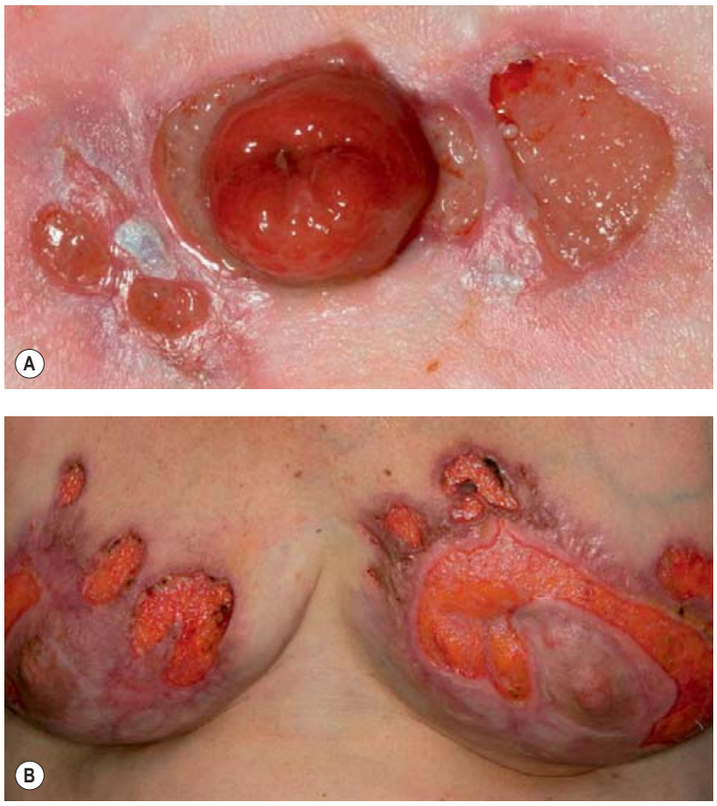

Fig. 26.13 Peristomal and postsurgical pyoderma gangrenosum (PG). **A** Multiple ulcers surround an ileostomy (following a total proctocolectomy) in a patient with refractory chronic ulcerative colitis. While periostomal PG occurs most commonly following intestinal resection of inflammatory bowel disease, it can also follow resection of gastrointestinal or bladder carcinoma. **B** Multiple ulcerations of the breasts following breast reduction. Because the original diagnosis postoperatively was soft tissue infection, multiple debridements had been performed and systemic antibiotics administered.

Fig. 26.14 The earliest clinical lesion in pyoderma gangrenosum is a pustule with an inflammatory base. This patient had Crohn's disease.

Fig. 26.15 Pyoderma gangrenosum in a patient with PAPA syndrome. Individuals with this autosomal dominant disorder have pyogenic sterile arthritis, pyoderma gangrenosum and acne. *Courtesy, Maria Chanco Turner, MD.*

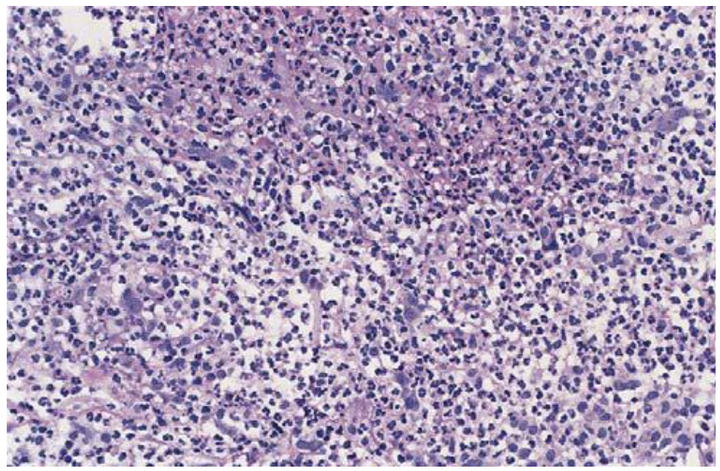

Fig. 26.16 Pyoderma gangrenosum. In expanding untreated lesions, a diffuse infiltrate of neutrophils is present at the base of an ulceration. *Courtesy, Ronald P Rapini, MD.*

extramucocutaneous sterile neutrophilic infiltrates have been reported in the bones, lung, liver, pancreas, spleen, kidneys and CNS of patients with PG[24].

Associated Diseases

Between 50% and 70% of patients with PG have an antecedent, coincident or subsequent associated disease or condition. The most common associations are inflammatory bowel disease (ulcerative colitis or Crohn's disease, 20–30%), arthritis (seronegative arthritis, spondylitis of inflammatory bowel disease or rheumatoid arthritis, 20%), and hematologic disease (in particular, acute and chronic myelogenous leukemia, hairy cell leukemia, myelodysplasia and monoclonal gammopathy, 15–25%). A monoclonal gammopathy is seen in up to 15% of patients and is often composed of IgA. Individuals with the *p*yogenic sterile *a*rthritis, *P*G and *a*cne (PAPA) syndrome (Fig. 26.15) have been shown to have mutations in the gene that encodes CD2-binding protein 1, presumably leading to abnormal inflammatory responses. Other so-called neutrophilic dermatoses that have been reported in association with PG are subcorneal pustular dermatosis, Behçet's disease and Sweet's syndrome.

Pathology

The histopathology of PG can be nonspecific, especially when the disease is partially treated or minimally inflamed, and therefore be non-diagnostic. In early lesions, there is a neutrophilic vascular reaction, which can be folliculocentric. Neutrophilic infiltrates, often with leukocytoclasia, are seen in active, untreated, expanding lesions (Fig. 26.16). In fully developed ulcers, there is marked tissue necrosis with surrounding mononuclear cell infiltrates. In most patients with typical PG, chronic ulcers have fibrosing inflammation at the edge of the ulcer bed. In one study, up to 10% of the patients who fulfilled the authors' diagnostic criteria for PG, rather than other entities in the differential diagnosis of PG, had histologic features inconsistent with PG[20]. This most likely results from a delay in suspecting the diagnosis of PG, with resultant sampling of chronic lesions that have been partially treated.

Differential Diagnosis

Since there are no specific or diagnostic laboratory tests or histopathologic features and some of the associated conditions may not have declared themselves, the physician must exclude other causes of ulceration of the skin and search for a treatable associated disease. PG can be misdiagnosed: of 157 consecutive patients seen at one tertiary care

PROPOSED DIAGNOSTIC CRITERIA FOR CLASSIC ULCERATIVE PYODERMA GANGRENOSUM
MAJOR CRITERIA
1. Rapid[a] progression of a painful[b], necrolytic cutaneous ulcer[c] with an irregular, violaceous and undermined border
2. Other causes of cutaneous ulceration have been excluded[d]
MINOR CRITERIA
1. History suggestive of pathergy[e] or clinical finding of cribriform scarring
2. Systemic diseases associated with pyodermal gangrenosum[f]
3. Histopathologic findings (sterile dermal neutrophilia, ± mixed inflammation, ± lymphocytic vasculitis)
4. Treatment response (rapid response to systemic corticosteroids)[g]
[a]Characteristic margin expansion of 1 to 2 cm per day, or a 50% increase in ulcer size within 1 month.
[b]Pain is usually out of proportion to the size of the ulceration.
[c]Typically preceded by a papule, pustule or bulla.
[d]Usually necessitates skin biopsy and additional evaluation (see Table 26.8) to exclude other causes (see Table 26.9).
[e]Ulcer development at sites of minor cutaneous trauma.
[f]Inflammatory bowel disease, arthritis, IgA gammopathy, or underlying malignancy.
[g]Generally responds to prednisone (1–2 mg/kg/day) or another corticosteroid at an equivalent dosage, with a 50% decrease in size within 1 month.

Table 26.7 Proposed diagnostic criteria for classic ulcerative pyoderma gangrenosum. Diagnosis requires both of the major criteria and at least two minor criteria[26].

EVALUATION OF A PATIENT WITH PRESUMED PYODERMA GANGRENOSUM
1. Thorough history and physical examination; review medications
2. Sterile skin biopsy of *active* skin lesion with sufficient depth (panniculus) and sufficient tissue for special stains and culture (bacterial, mycobacterial, fungal and viral). Possibility of future additional biopsies for immunofluorescence or PCR studies
3. Gastrointestinal tract studies – stool for occult blood and parasites, colonoscopy, biopsy, radiography, liver function tests and, if indicated, hepatitis evaluation
4. Hematologic studies – complete blood and platelet count, peripheral blood smear, and if indicated, bone marrow examination
5. Serologic studies – serum protein electrophoresis, immunofixation electrophoresis, antinuclear antibodies, antiphospholipid antibodies, ANCA antibodies, VDRL
6. Chest X-ray and urinalysis

Table 26.8 Evaluation of a patient with presumed pyoderma gangrenosum[17,20]. ANCA, antineutrophil cytoplasmic antibodies; PCR, polymerase chain reaction.

medical center with a referral diagnosis of resistant ulcers due to PG, 15 (approximately 10%) were found not to have PG[25]. Criteria for the diagnosis of classic PG have been proposed (Table 26.7)[27], but to date have not been validated. They basically serve as a guide and no one criterion can be used in isolation because each is seen in multiple disorders. The evaluation of a patient with presumed PG is summarized in Table 26.8.

The differential diagnosis clearly depends on the evolutionary stage of the process – the initial inflammatory process characterized by erythematous papules, pustules, plaques and nodules versus the later characteristic vegetative or ulcerative lesions (Table 26.9).

Treatment

There is neither specific nor uniformly effective therapy for PG. The nature and intensity of the therapeutic approach depend on the number, size and depth of the lesions, the rate of expansion and appearance of new lesions, the associated disorder, the medical status of the patient, and the risk and patient tolerance of prolonged therapy. The therapeutic goal is to reduce the inflammatory process of the wound in order to promote healing and reduce pain and to control the contributing underlying disease (especially leukemias and inflammatory bowel disease) with the least adverse side effects. The standard treatment of PG is local or combined local and systemic corticosteroid therapy with or without adjunctive systemic therapy[28].

THE DIFFERENTIAL DIAGNOSIS OF PYODERMA GANGRENOSUM
EARLY INFLAMMATORY NON-ULCERATIVE STAGE (PAPULES, PUSTULES, PLAQUES OR NODULES)
• Follicular infections (folliculitis, furuncle, carbuncle of bacterial, fungal or viral origin)
• Cellulitis or cellulitis-like lesion (bacterial, mycobacterial or fungal origin)
• Insect bite reaction
• Cutaneous T- and B-cell lymphomas
• Halogenoderma (iododerma or bromoderma)
• Panniculitides (inflammatory, infectious, metabolic, neoplastic)
• Cutaneous polyarteritis nodosa
• Sweet's syndrome (see Table 26.4 for additional entities)
• Behçet's disease
• Bowel-associated dermatosis–arthritis syndrome
LATER ULCERATIVE OR VEGETATIVE STAGE
• Infections – streptococcal synergistic gangrene, botryomycosis, ecthyma gangrenosum, gummatous treponemal ulcers, cutaneous lesions of the deep mycoses (e.g. blastomycosis, coccidioidomycosis, paracoccidioidomycosis, chromomycosis) and atypical and typical mycobacterial infections
• Parasitic infections – leishmaniasis, amebiasis, schistosomiasis
• Vascular diseases – ulcerations due to venous hypertension, arterial insufficiency, non-septic emboli, hemoglobinopathies, and thrombosis (secondary to hypercoagulability; see Ch. 105)
• Vasculitis – cutaneous polyarteritis nodosa, microscopic polyangiitis, granulomatous vasculitides (Wegener's granulomatosis, Churg–Strauss syndrome, temporal arteritis), autoimmune connective tissue disease (systemic lupus erythematosus, rheumatoid arthritis) and Behçet's disease
• Malignancy – squamous cell carcinoma, basal cell carcinoma, cutaneous T- and B-cell lymphoma
• Miscellaneous – brown recluse spider bite, ulcerative necrobiosis lipoidica, pemphigus vegetans of the Hallopeau or Neumann type, blastomycosis-like pyoderma, non-healing surgical wound, factitious ulcers, ulcers in patients with Chédiak–Higashi syndrome and leukocyte adhesion deficiency

Table 26.9 The differential diagnosis of pyoderma gangrenosum (PG)[17,20]. In a series of 95 patients *misdiagnosed* with PG, the most common etiologies were vascular (venous or arterial; 28), vasculitis (21), malignancy (16), infection (14) and drug-induced or exogenous tissue injury (13)[25].

Systemic corticosteroids have generally been the most predictable and effective medication when delivered in adequate dosage. Unfortunately, the more resistant lesions require more protracted therapy (>3 months) at a higher than desirable dosage, thus inviting adverse side effects. Such patients should be closely monitored and should receive supplemental calcium (1500 mg/day), vitamin D (800 IU/day) and, in most instances, bisphosphonates (see Ch. 125). Additional therapies, e.g. systemic calcineurin inhibitors, TNF-α inhibitors, are outlined in Table 26.10.

BEHÇET'S DISEASE

Key features

- A multisystem, polysymptomatic disease
- Diagnosis is based on International Study Group criteria of recurrent oral ulceration, recurrent genital ulceration, ocular abnormalities (e.g. uveitis, retinal vasculitis) and cutaneous lesions
- Cutaneous findings range from sterile papulopustules and palpable purpura to erythema nodosum-like lesions
- Histologically, a neutrophilic angiocentric infiltrate with leukocytoclastic (early) or lymphocytic (late) vasculitis is the characteristic finding

Introduction

Behçet's disease is a multisystem, polysymptomatic disease with unpredictable exacerbations and remissions[30–33]. All organs of the body can be affected concomitantly or consecutively. As a result, all subspecialties can be involved in the care of these patients.

THERAPEUTIC LADDER FOR THE TREATMENT OF PYODERMA GANGRENOSUM		
Treatment	**Dose**	**Level of evidence**
INFLAMMATORY DISEASE		
Mild disease and/or adjunctive therapy		
Superpotent topical corticosteroids		3
Intralesional corticosteroids		2
Topical tacrolimus		2
Oral antibiotics (e.g. sulfonamides, minocycline)		2
Colchicine	0.6 mg po thrice daily	3
Dapsone	50–150 mg po daily	3
Combination colchicine/dapsone		3
Clofazimine	100–400 mg po daily	2
Other (e.g. oral potassium iodide, intralesional cyclosporine, topical cromolyn sodium, nicotine patch or cream)		3
More severe disease		
Prednisone	60–120 mg po daily usual starting dose (including split-dose), with taper to alternate days	2
Methylprednisolone	1 g daily for 3–5 days (IV pulse)*	3
Thalidomide†	50–150 mg po nightly	2
Cyclosporine	2.5–5 mg/kg po daily	2
Tacrolimus	0.1–0.2 mg/kg po daily	3
TNF-α inhibitors‡	Infliximab 5 mg/kg IV at weeks 0, 2 and 6; adalimumab 80 mg sc as initial dose then 40 mg sc weekly or every other week; etanercept 50–100 mg sc weekly (in 1 or 2 doses)	1 (infliximab§); 3 (adalimumab); 3 (etanercept)
Methotrexate¶	2.5–25 mg po or IM weekly	3
Azathioprine¶	50–100 mg po twice daily	3
Mycophenolate mofetil¶	1–1.5 g po twice daily	3
Cyclophosphamide	Variable oral (50–200 g daily) or IV pulse (500–1000 mg monthly) dosing	3
Chlorambucil	4–6 mg po daily	3
IVIg	2–3 g/kg IV monthly (given over 2–5 consecutive days)	3
Granulocyte apheresis, plasmapheresis		3
Total colectomy (severe chronic ulcerative colitis)		3
NON-INFLAMMATORY DISEASE		
• Bio-occlusive dressings • Compression, limb elevation		

*Followed by daily oral prednisone.
†Especially in patients with Behçet's disease.
‡Especially in patients with inflammatory bowel disease.
§50–70% response rate.
¶Often used in combination with other agents or as maintenance therapy.

Table 26.10 Therapeutic ladder for the treatment of pyoderma gangrenosum[28,29]. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

History

In the fifth century BC, Hippocrates first described the symptomatology of this disease, and in 1936, Behçet reported a patient with eye disease and orogenital ulcers.

Epidemiology

Most patients are from Japan, the Middle East or the Mediterranean basin. Turkey has the highest prevalence, at 80 per 100 000. In Japan, it is 10 per 100 000; in the UK, 0.64 per 100 000; and in the US, 0.12 per 100 000[31]. In Japan and Korea, the incidence of Behçet's disease is greater in women, but in Middle Eastern countries it is seen more frequently in men. The peak incidence is between 20 and 35 years of age. The familial form usually comprises 2–5% of cases, except in the Middle East, where it represents 10–15%.

Pathogenesis

Epidemiologic evidence suggests that genetic and environmental factors contribute to the development of this disease. More than 80% of Asian patients have the HLA-B51 allele, but it is present in only about 15% of Caucasians from Western countries; thus, the allele appears to be an important risk factor for those who live along the Silk Road.

Earlier theories of pathogenesis entertained the possibility of an infectious etiology (viral or bacterial), but subsequent evidence failed to substantiate this hypothesis. Among the infectious agents investigated

were HSV, hepatitis C virus and parvovirus B19; more recently, in Japan, streptococcal strains were thought to be responsible[31]. These infections may potentially trigger an immunoregulatory defect in the genetically predisposed.

The pathomechanisms of Behçet's disease involve vascular injuries and autoimmune responses. Circulating immune complexes and neutrophils appear to be responsible for the mucocutaneous lesions that are characterized histologically by a neutrophilic vascular reaction or even leukocytoclastic vasculitis. The neutrophils of Behçet's disease produce an increased amount of superoxides and an excess of lysosomal enzymes, and they have enhanced chemotaxis, all of which bring about tissue injury. The elevated circulating levels of TNF-α, IL-1β and IL-8 may result in activation of neutrophils and augmentation of cellular interactions between neutrophils and endothelial cells. Clonal expansion of autoreactive T cells that recognize a peptide derived from heat shock protein 60 has also been described.

Clinical Features and Differential Diagnosis

Mucocutaneous involvement

Aphthous stomatitis, the major criterion, is frequently the first symptom of Behçet's disease (65–70% of patients), and it is almost always present during the course of the disease. The aphthosis may precede the other manifestations by many years, but a dramatic increase in severity often occurs in concert with the onset of other features. Oral ulcers begin as an erythematous papule, which develops a yellowish pseudomembrane and then forms a painful non-scarring ulcer (Fig. 26.17A), which heals over a period of weeks. The ulcers are indistinguishable from those that occur with complex aphthosis or inflammatory bowel disease[34] and must be differentiated from other causes of oral ulcers (e.g. pemphigus vulgaris). The genital aphthae involve primarily the scrotum and penis in men and the vulva in women. Compared to oral lesions, the anogenital aphthae tend to be larger with irregular margins (Fig. 26.17B), and they are more painful. Distinction of genital lesions from lesions of HSV requires viral culture, direct fluorescent antibody stain or PCR.

Among the primary cutaneous lesions are acral and facial sterile vesicopustules as well as pustular and/or purpuric papules[35]. Although the papulopustular lesions are usually not folliculocentric, they have nonetheless been described as acneiform, leading to some confusion (see Pathology below). The erythema nodosum-like lesions favor women and appear on their legs and buttocks, and less often on the face and neck; they have to be differentiated from both superficial thrombophlebitis (which occurs in 30% of patients with Behçet's disease) and erythema nodosum (which is seen in patients with Behçet's disease as well). Pathergy also occurs, as in pyoderma gangrenosum. Patients with features of both Behçet's disease and relapsing polychondritis have been described and reported as MAGIC (*m*outh *a*nd *g*enital *u*lcers with *i*nflamed *c*artilage) syndrome (see Ch. 45)[36].

Systemic involvement

Systemic manifestations are summarized in Table 26.11 and distinctions between Behçet's disease with bowel involvement and inflammatory bowel disease are outlined in Table 26.12.

Fig. 26.17 Behçet's disease: mucocutaneous lesions. A Oral aphthosis. **B** Perianal aphthosis.

SYSTEMIC MANIFESTATIONS OF BEHÇET'S DISEASE	
OCULAR (LEADING CAUSE OF MORBIDITY)[30,32,33]	**NEUROLOGIC**
• Occurs in 90% of patients; favors men, in whom it is more severe • Can be painful and may lead to blindness • Retinal vasculitis (more frequently associated with blindness) • Posterior uveitis (most characteristic ocular finding) • Anterior uveitis (Fig. 26.18), hypopyon • Secondary glaucoma, cataracts • Conjunctivitis, scleritis, keratitis, vitreous hemorrhage, optic neuritis	• Usually appears later during the evolution of the disease • Associated with a poor prognosis • Acute meningo-encephalitis which may resolve spontaneously • Cranial nerve palsies • Brainstem lesions that can induce swallowing difficulties, laughter and crying • Pyramidal or extrapyramidal signs
JOINTS	**VASCULAR**
• Approximately 50% of patients develop arthritis • In majority (~80% of patients), duration of attacks is <2 months • Mono- or poly-arthritic and non-erosive • Most commonly knees, wrists and ankles	• Aneurysmal or occlusive arterial disease • Superficial or deep venous thrombosis
	CARDIOPULMONARY
	• Coronary arteritis, valvular disease, myocarditis • Recurrent ventricular arrhythmias • Pulmonary artery aneurysms
GASTROINTESTINAL	**RENAL**
• Abdominal pain and/or hemorrhage may be difficult to distinguish from IBD (see Table 26.12) • Ulcerations* develop within the small bowel (in particular the ileocecal region) as well as the transverse and ascending colon and esophagus; perforation can occur	• Glomerulonephritis
*Resemble anogenital aphthae.	

Table 26.11 Systemic manifestations of Behçet's disease. IBD, inflammatory bowel disease.

Fig. 26.18 Behçet's disease: systemic involvement. Iritis and cutaneous pustular vasculitis.

NEUTROPHILIC DERMATOSES ASSOCIATED WITH BOWEL DISORDERS				
		Behçet's disease	**Bowel-associated dermatosis–arthritis syndrome**	**Inflammatory bowel disease**
Cutaneous lesions	Aphthosis	+ (oral and anogenital)	+ (oral)	+ (oral)
	Vesicopustular dermatosis	+	+	+
	Sweet's syndrome-like dermatosis	+	–	+
	Pyoderma gangrenosum	+	–	+
	Pyostomatitis vegetans	–	–	+
	Pyoderma vegetans	–	–	+
	Vasculitis	+	±	+ (including cutaneous polyarteritis)
	Superficial thrombophlebitis	+	–	+
	Erythema nodosum	+	+	+

	Neurologic involvement	+	–	–
Bowel pathology		Typical aphthae can occur in the esophagus and throughout the stomach and intestine and can produce severe, cramping pain; ulcerations similar in appearance to chronic ulcerative colitis	Blind loop of bowel	Ulcerations in Crohn's disease are superficial, linear, and segmental or diffuse and on biopsy reveal granulomatous disease

Table 26.12 Neutrophilic dermatoses associated with bowel disorders.

Pathology

The histopathology of the cutaneous lesions (especially the acneiform lesions) is an area of controversy, perhaps due in part to the age of the lesion sampled. The cutaneous vasculopathy can involve all sizes of blood vessels within the dermis and subcutis. It can present as a neutrophilic vascular reaction characterized by angiocentric, neutrophilic infiltrates with leukocytoclasia and erythrocyte extravasation, or as a leukocytoclastic vasculitis with or without mural thrombosis and necrosis; some authors suggest that the vasculitis may be secondary to the intense inflammation observed[37]. There may be a predominance of histiocytes associated with the vasculitis, which leads to the diagnosis of granulomatous vasculitis. An angiocentric lymphocytic infiltrate characterizes older lesions. With regard to the acneiform lesions, a sterile neutrophilic vasculopathy is now favored over a suppurative or mixed suppurative and granulomatous folliculitis.

Vascular thrombosis is not infrequent and should prompt investigation for an underlying coagulopathy. The histologic features of the erythema nodosum-like lesions can vary from a neutrophilic lobular panniculitis to a septal and lobular panniculitis with a mixed inflammatory infiltrate, fat necrosis and evidence of lymphocytic vasculitis; the above vascular changes may also be seen.

Diagnosis

Since Behçet's disease has no diagnostic test and is characterized by a complex constellation of signs and symptoms, various sets of clinical criteria have been created to assist in the diagnosis. Among the reported diagnostic criteria are those of the Japanese (1974), O'Duffy (1974), Zhang (1980), James (1986), and the International Study Group (ISG; 1990)[38]. The latter are presented in Table 26.13.

The development of the ISG criteria was based on the discriminating performance of various criteria-grouped combination sets, and the ISG criteria exhibited the highest sensitivity, specificity and relative value. Controversy exists, however, about the failure of these criteria to require exclusion of inflammatory bowel disease.

Treatment

The management of the disease is difficult because of its variable course and lack of sufficient double-blind studies. The therapeutic approach is a symptomatic one and is dictated by the nature of the mucocutaneous and visceral involvement. Because of the frequent vital organ involvement (e.g. the eye), and the tendency for the disease to recur, early and aggressive treatment is vital. CNS and large artery and vein involvement respond less favorably to therapy. There are multiple drugs available, both topical and systemic, that can be used as monotherapy or as combination therapy (Table 26.14). Evidence for many of the therapies is based on case-series data rather than double-blind, placebo-controlled trials.

INTERNATIONAL STUDY GROUP CRITERIA FOR THE DIAGNOSIS OF BEHÇET'S DISEASE	
Major criterion	**Required features**
Recurrent oral ulceration	Aphthous (idiopathic) oral ulceration observed by physician or patient, recurring at least three times in a 12-month period
PLUS ANY TWO OF THE FOLLOWING MINOR CRITERIA:	
Recurrent genital ulceration	Aphthous genital ulceration or scarring, observed by physician or patient
Eye lesions	Anterior or posterior uveitis; cells in the vitreous by slit lamp examination; or retinal vasculitis observed by ophthalmologist
Cutaneous lesions	Erythema nodosum-like lesions observed by physician or patient; papulopustular lesions or pseudofolliculitis; or characteristic acneiform nodules observed by physician in postadolescent patient not on corticosteroids
Pathergy test*	Interpreted at 24–48 h by physician

*Pathergy test is performed on the flexor forearm by obliquely inserting a 20–22-gauge sterile hypodermic needle to a depth of 5 mm ± an intradermal injection of 0.1 ml of normal saline. A positive reaction is defined as the development of a papule or pustule.

Table 26.13 International Study Group criteria for the diagnosis of Behçet's disease[38].

TREATMENT OF BEHÇET'S DISEASE		
Treatment	**Dose**	**Level of evidence**
MUCOCUTANEOUS DISEASE		
Viscous lidocaine, topical sucralfate and other symptomatic treatments		3
Topical and inhalant corticosteroids		2
Intralesional corticosteroids		3
Colchicine	0.6 mg po thrice daily	1
Dapsone	50–150 mg po daily (or sulfapyridine equivalent)	1
Combination oral colchicine and dapsone		3
SEVERE MUCOCUTANEOUS DISEASE		
Thalidomide	50–150 mg po nightly	1
Methotrexate	2.5–25 mg po or IM weekly	3
Prednisone, intermittent with taper	40–80 mg po daily usual starting dose	2
Interferon-α-2a	Variable dose (3–9 × 10^6 IU sc 3× weekly)	1
TNF-α inhibitors (e.g. etanercept, infliximab)	See Table 26.10	1 (etanercept)
SYSTEMIC DISEASE		
Prednisone	60–120 mg po daily usual starting dose (including split-dose), with taper to alternate days	2
Methylprednisolone acetate	40 mg IM 3× weekly	2
Azathioprine	50–100 mg po twice daily	1
Cyclophosphamide	Variable oral dose (50–200 mg daily) or iv pulse (500–1000 mg monthly then 500–1000 mg every 3 months)	3
Chlorambucil	4–6 mg po daily	1
Mycophenolate mofetil	1–1.5 g po twice daily	3
Cyclosporine	Variable doses (2–10 mg/kg po daily)	1
Tacrolimus	0.1–0.2 mg/kg po daily	2
IVIg	2–3 g/kg IV monthly (given over 2–5 consecutive days)	3
TNF-α inhibitors (e.g. etanercept, infliximab)	See Table 26.10	2

Table 26.14 Treatment of Behçet's disease[39–41]. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

BOWEL-ASSOCIATED DERMATOSIS–ARTHRITIS SYNDROME

Synonyms: ■ Bowel bypass syndrome ■ Bowel bypass syndrome without bowel bypass ■ Intestinal bypass arthritis–dermatitis syndrome

Key features

- Constitutional signs and symptoms are serum sickness-like
- Cutaneous lesions include erythematous and purpuric papules and vesicopustules as well as nodular panniculitis
- Associated polyarthritis and tenosynovitis
- Histopathology includes dermal nodular perivascular neutrophilic infiltrates with edema as well as a lobular neutrophilic or septal panniculitis

Introduction

Bowel-associated dermatosis–arthritis syndrome is characterized by diarrhea with resultant malabsorption, arthritis and skin lesions. It is seen in patients who have undergone intestinal bypass surgery, have blind loops of bowel following surgery, had biliopancreatic diversion or have gastrointestinal disorders (Table 26.15)[42,43].

CONDITIONS ASSOCIATED WITH BOWEL-ASSOCIATED DERMATOSIS–ARTHRITIS SYNDROME	
Surgical	**Medical**
• Gastric resection • Jejunoileal bypass • Blind loops of bowel following surgery • Biliopancreatic diversion	• Inflammatory bowel disease • Diverticulitis • Peptic ulcer disease

Table 26.15 Conditions associated with bowel-associated dermatosis–arthritis syndrome.

History

During the 1960s and 1970s, morbid obesity was being treated surgically by jejunoileal bypass surgery and 20% of these patients developed a syndrome initially referred to as bowel bypass syndrome. In the 1980s, a similar syndrome was described in patients with inflammatory bowel disease or with blind loops of bowel after intestinal surgery[43].

Pathogenesis

In bowel-associated dermatosis–arthritis syndrome, there is usually bacterial overgrowth in a blind loop of bowel. It is postulated that resultant immune complexes containing bacterial antigens are then deposited within the skin and synovium[44]. The pathogenic role of

Fig. 26.19 Bowel-associated dermatosis–arthritis syndrome. Multiple papulopustules on the upper extremity. *Courtesy, Joseph L Jorizzo, MD.*

THERAPEUTIC APPROACHES FOR BOWEL-ASSOCIATED DERMATOSIS–ARTHRITIS SYNDROME
MILD CLINICAL EXPRESSION
• Oral antibiotics to reduce bacterial overgrowth (4–8 weeks): tetracycline (500 mg 2–4 times daily), doxycycline (100 mg once to twice daily), minocycline (100 mg once to twice daily), clindamycin (600 mg daily), metronidazole (250–500 mg twice daily) • Aseptic neutrophilic inhibiting drugs (4–8 weeks): colchicine (0.6 mg thrice daily), dapsone (50–100 mg daily), thalidomide (50–200 mg daily)
SEVERE CLINICAL EXPRESSION
• Potent anti-inflammatory and immunomodulatory drugs (2–3 months): prednisone (40–60 mg daily then tapered), cyclosporine (200–300 mg daily), azathioprine (50–150 mg daily), mycophenolate mofetil (500 mg twice daily) • Surgical restoration of normal bowel anatomy • Possible role for TNF-α inhibitors (e.g. infliximab, adalimumab, etanercept)

Table 26.16 Therapeutic approaches for bowel-associated dermatosis–arthritis syndrome. Treatments based upon small case series and case reports.

bacteria in this syndrome is supported by the disappearance of the disease with antibiotic therapy or surgery.

Clinical Features

Bowel-associated dermatosis–arthritis syndrome is characterized clinically by constitutional symptoms, skin lesions[45], and a variety of serious complications. It can occur from 1 to 6 years after the responsible bowel surgery. Constitutional symptoms, which are usually present and may precede the cutaneous eruption, are similar to those of serum sickness, e.g. fever, chills, malaise, arthralgias and myalgias.

The characteristic skin lesions are erythematous macules, which progress to papules and purpuric vesicopustules within 48 hours and last for 2–4 weeks (Fig. 26.19); they may recur at 4–6-week intervals. The lesions may be few or many, and they favor the proximal extremities and trunk.

Recurrent tender erythematous subcutaneous nodules are also seen in these patients and may be associated with fever. They are due to either a nodular, non-suppurative, lobular neutrophilic panniculitis (involving both the trunk and extremities and healing with depressed scars) or erythema nodosum (generally involving only the lower extremities), two entities which differ clinically and histologically[46]. Among the more common non-cutaneous findings are tenosynovitis and non-destructive polyarthritis. Associated systemic complications include electrolyte imbalance from persistent diarrhea, hepatic dysfunction and failure, renal calculi composed of calcium oxalate, gallstones, zinc deficiency, vitamin A deficiency, beriberi, hyperuricemia and emotional disturbances.

Pathology

The characteristic lesions exhibit a perivascular, nodular neutrophilic infiltrate with nuclear dust and papillary and reticular dermal edema[45]. The infiltrate may be admixed with lymphocytes and histiocytes and may extend into the mid dermis and panniculus. A similar neutrophilic vascular pattern is seen in lesions of Sweet's syndrome, Behçet's disease and the early phase of PG.

Differential Diagnosis

The papular eruption must be differentiated from that seen in urticarial vasculitis and erythema multiforme, whereas the pustular vasculitic lesions must be distinguished from other causes of small vessel vasculitis, disseminated gonococcemia (septic vasculitis), systemic candidiasis, subacute bacterial endocarditis and Behçet's disease. Pustular lesions may be misdiagnosed as arthropod bites (e.g. fire ants) or folliculitis.

Treatment

Surgically, either revision of the bowel bypass or surgical resection of the blind loop of bowel is curative. Medically, systemic prednisone can produce significant symptomatic improvement of the cutaneous and rheumatologic manifestations, but it is not curative[43]. It is inadvisable to administer systemic corticosteroids as a long-term therapy. Antibiotics that have proven to be beneficial are listed in Table 26.16.

SYNOVITIS, ACNE, PUSTULOSIS, HYPEROSTOSIS AND OSTEITIS (SAPHO) SYNDROME

Key features

- Presence of aseptic pustular dermatosis and osteoarticular lesions
- Usually a gradual onset of painful, multifocal osteoarticular lesions, especially of the anterior chest and axial skeleton
- The course of the osteoarticular lesions oscillates and is protracted, with gradual improvement that can be hastened by anti-inflammatory drugs

Introduction

SAPHO syndrome consists of a wide spectrum of aseptic neutrophilic dermatoses in association with aseptic osteoarticular lesions that have distinctive histologic and radiographic features[47,48]. Recognition of SAPHO syndrome is important so as to avoid misdirected therapies and unnecessary invasive procedures.

History

In 1972, chronic recurrent multifocal osteomyelitis was described as a rare chronic inflammatory musculoskeletal process in children and adults. Although cutaneous pustulosis and acne were reported in association with osteomyelitis and arthritis in the 1960s, it was not until 1987 that the acronym SAPHO (*s*ynovitis, *a*cne, *p*ustulosis, *h*yperostosis and *o*steitis) syndrome was coined to describe this clinicoradiologic entity that involves skin, bone and joints.

Epidemiology

The syndrome affects primarily children and young and middle-aged adults, and rarely presents after 60 years of age. There is no sexual predilection, with the exception of a male predominance in those with acne. It has been observed most frequently in Japan, less often in Scandinavia, Germany and France, and infrequently in the US and Canada.

Pathogenesis

The pathogenesis of SAPHO is not understood. Some hypothesize that it is the result of an autoimmune response triggered by microorganisms and enhanced chemotaxis of neutrophils.

CUTANEOUS DISORDERS ASSOCIATED WITH SAPHO SYNDROME
• Palmar and plantar pustulosis
• Follicular occlusion tetrad, in particular acne conglobata
• Acne fulminans
• Pustular psoriasis
• Sneddon–Wilkinson disease
• Psoriasis
• Linear IgA bullous dermatosis
• Behçet's disease
• Sweet's syndrome
• Pyoderma gangrenosum
• Lyme disease

Table 26.17 Cutaneous disorders associated with SAPHO syndrome. SAPHO – synovitis, acne, pustulosis, hyperostosis and osteitis. A SAPHO phenotype can occur in the setting of PAPA syndrome (pyogenic sterile arthritis, pyoderma gangrenosum and acne), which is inherited in an autosomal dominant manner (*PSTPIP1* mutations). Majeed syndrome (congenital dyserythropoietic anemia; *LPIN2* mutations) and deficiency of the interleukin-1 receptor antagonist (DIRA) syndrome (*IR1RN* mutations; Fig. 26.20) are autosomal recessive conditions that feature the aseptic osteoarticular lesions of SAPHO together with Sweet's syndrome-like and pustular skin lesions, respectively.

Fig. 26.20 Deficiency of the interleukin-1 receptor antagonist (DIRA) syndrome. This infant has figurate lesions with multiple pustules and might be misdiagnosed as having pustular psoriasis. *Courtesy, Gillian Clarke, MD.*

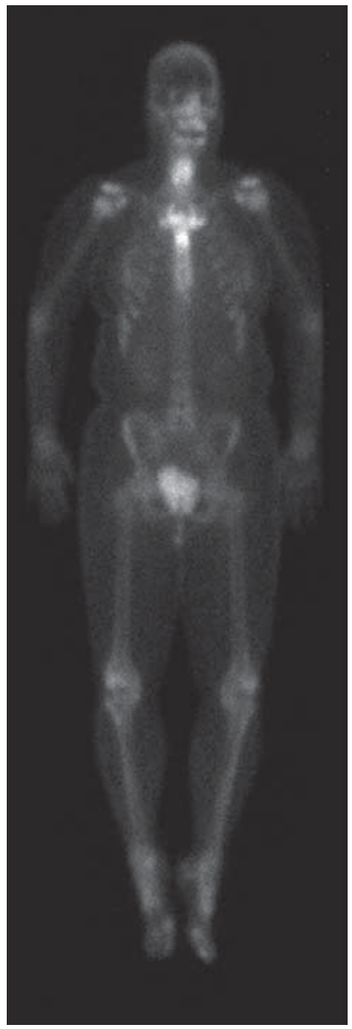

Fig. 26.21 Abnormal bone scan in a patient with SAPHO syndrome. There is abnormal tracer uptake within the mid and lower cervical spine and multiple thoracic vertebral bodies (T3 to T9) in addition to the manubrium and sternoclavicular joints bilaterally. The pattern and anatomic distribution are indicative of increased osteoblastic activity as is seen in the SAPHO syndrome.

Clinical Features

The cutaneous disorders that have been described to date as components of the SAPHO syndrome are listed in Table 26.17; the neutrophil is the "tie that binds" these disorders. The osteoarticular lesions of SAPHO are synovitis, arthrosteitis (inflammation of the osseous structures of a joint), and chronic recurrent multifocal aseptic osteomyelitis. The sites of involvement are usually the anterior chest wall (sternum, clavicles and ribs) and other axial skeleton sites (spine and pelvis). The affected bones are tender and the swollen joints are painful. Patients may be febrile with a leukocytosis and elevated ESR.

Bone scintigraphy demonstrates an increased uptake at involved sites (Fig. 26.21). MRI is very sensitive and can provide information about adjacent joint and tissue involvement and it helps in monitoring the disease. The osteoarticular involvement is intermittent with periodic exacerbations and remissions and there is no correlation with the activity of the associated sterile neutrophilic cutaneous disorders.

SAPHO is also regarded as one of the seronegative spondyloarthropathies because of its frequent association with inflammatory bowel disease, with the latter being an HLA-B27 phenotype with axial skeleton involvement (sacroiliitis).

Pathology

Early in the process, medullary bone contains an inflammatory cellular infiltrate, consisting primarily of neutrophils, osteoclasts and osteoblasts. Later on, cicatricial fibrosis surrounded by hypertrophic inactive bone is seen.

Differential Diagnosis

The differential diagnosis of the bone lesions includes classic bacterial osteomyelitis, primary bone tumors, metastases, and Langerhans cell histiocytosis. In children, the possibility of SAPHO developing in the setting of either Majeed syndrome (congenital dyserythropoietic anemia; *LPIN2* mutations) or deficiency of the interleukin-1 receptor antagonist (DIRA) syndrome (*IR1RN* mutations) should be considered[49].

THERAPIES FOR OSTEOARTICULAR LESIONS OF ADULT SAPHO SYNDROME	
Variable effectiveness	NSAIDs
	Colchicine
	Sulfasalazine
	Oral antibiotics (doxycycline, azithromycin, clindamycin)
More effective	Methotrexate (20 mg po/week)
	Corticosteroids (intralesional/oral*)
	Bisphosphonates†
	TNF-α inhibitors

*Usually prednisone 30 mg po daily.
†Pamidronate (30–60 mg IV), zoledronic acid (4 mg IV).

Table 26.18 Therapies for osteoarticular lesions of adult SAPHO syndrome. NSAIDs, nonsteroidal anti-inflammatory drugs; TNF, tumor necrosis factor.

Treatment

Since precise knowledge of the pathogenesis of SAPHO syndrome is lacking, a variety of anti-inflammatory therapies have been tried (Table 26.18). Although isotretinoin is used to treat associated severe acne, there are scattered case reports of isotretinoin-associated flares of SAPHO.

Chapter Contents

Pemphigoid gestationis 439
Polymorphic eruption of pregnancy 441
Intrahepatic cholestasis of pregnancy 443
Atopic eruption of pregnancy 445
Approach to the pregnant woman with pruritus 447
Physiologic changes during pregnancy 447
Autoimmune progesterone dermatitis 447

The specific dermatoses of pregnancy are a heterogeneous group of pruritic skin disorders that, for decades, represented a confusing group of overlapping entities, understood largely through anecdotes and case reports. However, more recent reviews have simplified and condensed the list of pregnancy-specific dermatoses (Table 27.1)[1–3]. For example, impetigo herpetiformis is now generally recognized as pustular psoriasis, perhaps induced by the relative hypocalcemia of pregnancy (see Ch. 8). Also, prurigo annularis, first reported in 1941 (without histology or laboratory information), and linear IgM disease of pregnancy (described in 1988) have not been subsequently reported, yet are frequently perpetuated in reviews.

Much of the confusion can be dispelled by reviewing the original articles: Besnier (1904) first used the term "prurigo gestationis" to include all patients with pregnancy-related dermatoses, other than those with pemphigoid gestationis. Costello (1941) subsequently referred to these patients as "prurigo gestationis of Besnier" and estimated an incidence of 2% of all pregnancies. Bourne (1962) characterized a subset of patients with intensely pruritic papules or urticarial plaques that tended to appear during the later part of the third trimester, coining the term "toxaemic rash of pregnancy". Initial lesions typically developed within the abdominal striae of short women who experienced excessive weight gain during pregnancy. Unfortunately, he offered neither histopathologic nor laboratory insight.

Spangler et al. (also 1962) reported on a series of women with intensely pruritic, widely scattered, excoriated papules. Initial onset was during the second or third trimester and all patients suffered recurrences during subsequent gestations. The hallmarks of Spangler's cases were biochemical: elevated urinary human chorionic gonadotropin (HCG), decreased plasma hydrocortisone, and decreased serum half-life of hydrocortisone. Liver function tests and histopathology were not reported and immunofluorescence (IF) was not yet available. Most notably, Spangler's papular dermatitis was associated with high fetal wastage, a finding now thoroughly discredited.

Nurse (1968) cited all of the above literature but ignored it, dividing patients with (non-pemphigoid gestationis) pregnancy eruptions into "early" and "late" forms. The late papular/urticarial form clearly overlapped with Bourne's "toxaemic rash of pregnancy", and has since been described as "pruritic urticarial papules and plaques of pregnancy" (PUPPP), "toxic erythema of pregnancy", and, most recently, "polymorphic eruption of pregnancy" (PEP). Nurse's "early onset" patients and Spangler's "papular dermatitis" patients were undoubtedly drawn from the same clinical spectrum, and subsequently these entities were reclassified as forms of "prurigo of pregnancy" (see Table 27.1).

Pruritic folliculitis of pregnancy was added to the list of pregnancy-specific diseases in 1981, yet all six of the original patients were thought to have papular dermatitis clinically. They were classified as different based solely upon shared histologic features (i.e. sterile folliculitis). In spite of their clinical similarity to the patients reported by Spangler, none had appropriate biochemical investigations. In 1998, an adaptation of the Holmes and Black classification scheme (1983)[2] was published[3] and listed pruritic folliculitis as a variant of prurigo of pregnancy (see Table 27.1).

Introduction of the term "atopic eruption of pregnancy (AEP)" represents the most recent revision to the classification of dermatoses of pregnancy[1]. Based upon an analysis of over 500 pregnant women with pruritus[1], significant overlap, both clinical and histologic, was noted amongst those patients (~50% in this series) with the diagnoses of prurigo of pregnancy, pruritic folliculitis of pregnancy, and eczema in pregnancy[4]. AEP was thought to be a useful diagnostic term that encompassed these three disorders and reminded the clinician that the eczema was more likely to be of new onset as opposed to a flare of previously diagnosed atopic dermatitis.

Because of the lack of primary lesions, intrahepatic cholestasis of pregnancy (ICP) had long been omitted from the list of pregnancy dermatoses. However, failure to appreciate ICP in a pregnant woman with widespread excoriations or even prurigo nodularis surely, in retrospect, accounts for some of the confusion in terminology. Furthermore, ICP is the most important diagnosis to exclude in a pregnant patient with pruritus, as it is associated with significant fetal risk (see below).

PEMPHIGOID GESTATIONIS

Synonyms: ■ Gestational pemphigoid ■ Herpes gestationis

Key features

- Rare pruritic vesiculobullous eruption that develops during late pregnancy or the immediate postpartum period
- Linear C3 deposition along the basement membrane zone (BMZ) by direct IF
- IgG1 autoantibodies directed against a transmembrane hemidesmosomal protein (BP180; collagen XVII)
- Increased risk of prematurity and small-for-gestational age neonates; the risk correlates with disease severity
- Commonly recurs in subsequent pregnancies

Introduction

Pemphigoid gestationis is a rare, self-limited, autoimmune bullous disease. It is the most clearly characterized dermatosis of pregnancy and the only one that may also affect the skin of the newborn.

History

Milton first coined the term "herpes gestationis" in 1872 and Bulkley (1874) canonized the term "as embodying the clinical characters of the eruption and signifying at the same time the sex and state of the body in which it appears". Little additional insight was gained until IF techniques revealed complement deposition along the BMZ in 1973, a feature now accepted as essential for the diagnosis of pemphigoid gestationis.

Epidemiology

The incidence of pemphigoid gestationis has been estimated at 1 : 1700–1 : 50 000 pregnancies[5,6], correlating with the prevalence of HLA-DR3

CLASSIFICATION OF THE DERMATOSES OF PREGNANCY	
Classification	**Synonym(s)**
Pemphigoid gestationis*	Herpes gestationis† **Gestational pemphigoid**
Polymorphic eruption of pregnancy (PEP)	Pruritic urticarial papules and plaques of pregnancy (PUPPP)† Toxic erythema of pregnancy Late-onset prurigo of pregnancy Toxemic rash of pregnancy
Intrahepatic cholestasis of pregnancy (ICP)	Cholestasis of pregnancy† Obstetric cholestasis Jaundice of pregnancy Pruritus/prurigo gravidarum
Atopic eruption of pregnancy (AEP)	Prurigo of pregnancy*,† Prurigo gestationis (Besnier) Early-onset prurigo of pregnancy (Nurse) Papular dermatitis of pregnancy (Spangler) Pruritic folliculitis of pregnancy* Linear IgM disease of pregnancy Eczema in pregnancy

*Former classification by Holmes & Black (1983)[2].
†Former classification by Shornick (1998)[3].

Table 27.1 Classification of the dermatoses of pregnancy[1]. The preferred terms are in bold.

Fig. 27.1 Pemphigoid gestationis. Intact tense bullae arising within areas of edematous erythema as well as erosions due to ruptured bullae. Lesions typically involve the umbilical region.

and -DR4 in different populations. While occurring primarily during pregnancy and the immediate postpartum period, pemphigoid gestationis has rarely developed in association with trophoblastic tumors (hydatidiform mole, choriocarcinoma). Interestingly, no case of a pemphigoid-like disease has been reported in men with choriocarcinoma, who have a biochemically similar yet entirely syngenic tumor; of note, the nuclear genome in placental tissue (and hence choriocarcinoma in women) is primarily paternal in origin. Patients with a history of pemphigoid gestationis appear to be at increased risk for the development of Graves' disease[7].

Pathogenesis

Historically, pemphigoid gestationis was thought to be caused by an anti-BMZ "serum factor" (the "herpes gestationis [HG] factor") that induces C3 deposition along the dermal–epidermal junction. This factor is now known to be complement-fixing autoantibodies of the IgG1 subclass directed against a 180 kDa transmembrane hemidesmosomal protein (BPAG2; collagen XVII). As in patients with bullous pemphigoid (BP), it is the non-collagenous (NC) segment closest to the plasma membrane of the basal keratinocyte (NC16A) that constitutes the immunodominant region of BP180. Circulating antibodies are almost exclusively directed against this domain, as demonstrated by ELISA and immunoblot studies of maternal or neonatal sera.

What initiates the production of autoantibody remains enigmatic. Because the antibodies also bind to amniotic basement membrane[8] (a structure derived from fetal ectoderm and antigenically similar to skin), attention has focused on immunogenetics and potential cross-reactivity between placental tissue and skin. Immunogenetic studies have revealed a marked increase in HLA antigens DR3 or DR4, and, curiously, nearly 50% of patients have the simultaneous presence of both. There is essentially a 100% incidence of anti-HLA antibodies in patients with a history of pemphigoid gestationis[9]. Since the only source of disparate HLA antigens is typically the placenta (which is primarily of paternal origin), the universal finding of anti-HLA antibodies implies a high frequency of immunologic insult during gestation. Women with pemphigoid gestationis also have increased expression of MHC class II antigens (DR, DP, DQ) within the villous stroma of their chorionic villi. It has therefore been proposed that pemphigoid gestationis is a disease, initiated by the aberrant expression of MHC class II antigens (of paternal haplotype), that serves to initiate an allogeneic response to placental BMZ, which then cross-reacts with skin[10].

Clinical Features

Pemphigoid gestationis may develop during any trimester as well as immediately postpartum, but classically it presents during late pregnancy. There is an abrupt onset of cutaneous lesions on the trunk, in particular the abdomen and often within or immediately adjacent to the umbilicus. Rapid progression to a generalized pemphigoid-like eruption then occurs (Fig. 27.1), with pruritic urticarial papules and plaques, followed by clustered (herpetiform) vesicles or tense bullae on an erythematous base. The eruption may involve the entire body, sparing only the mucous membranes. While the clinical presentation and course may vary considerably, spontaneous improvement during late gestation is common. This is followed, however, by a flare at the time of delivery in 75% of patients. Such flares may be dramatic, with an explosive onset of blistering within hours.

Most disease activity spontaneously remits during the weeks to months following delivery, but there are isolated reports of a protracted course postpartum. Flares and/or recurrences in association with menstruation are common, and in 25–50% of patients, they may also be induced by oral contraceptives (Table 27.2). Pemphigoid gestationis may not develop during the patient's first pregnancy, but, once established, it is quite likely to recur in subsequent pregnancies, usually with an earlier onset and more severe course. "Skipped" pregnancies have been observed in 5–8% of women.

Approximately 10% of newborns develop mild skin involvement due to passive transfer of maternal antibodies and this resolves spontaneously within days to weeks (see Ch. 34). There seems to be an increased risk of prematurity and small-for-gestational age neonates, presumably due to chronic placental insufficiency. Recently, it was shown that this risk correlates with disease severity (i.e. occurrence of blistering and early onset) and not with the use of systemic corticosteroids[11].

Pathology

The classic histologic finding of a subepidermal vesicle is seen in the minority of patients. Instead, a nonspecific mixed cellular infiltrate containing a variable number of eosinophils is more common. The presence of eosinophils is the most constant histologic feature of pemphigoid gestationis.

The essential component for the diagnosis of pemphigoid gestationis is a linear deposition of C3 along the BMZ of perilesional skin by direct IF microscopy (Fig. 27.2). This is observed in 100% of patients, and linear IgG deposition is seen in 30% of patients. When salt-split skin specimens are employed for *conventional* indirect IF, deposition of IgG along the bottom of the epidermal fragment is observed in 30% of

DERMATOSES OF PREGNANCY – FETAL RISK, INVOLVEMENT OF NEWBORN SKIN, AND RISK OF RECURRENCE			
Dermatosis	**Fetal risk**	**Newborn skin involvement**	**Risk of recurrence**
Pemphigoid gestationis	Increased risk of prematurity and small-for-gestational age neonates; risk correlates with disease severity	Mild and transient lesions of pemphigoid gestationis in up to 10% (see Ch. 34)	Commonly recurs ("skipped" pregnancies in only 5–8% of women); recurrences induced by oral contraceptives in 25–50%
Polymorphic eruption of pregnancy	None	None	Usually does not recur
Intrahepatic cholestasis of pregnancy	Increased risk of premature labor (20–60%), intrapartal fetal distress (20–30%) and stillbirths (1–2%)	None	Recurrence in 45–70% of subsequent pregnancies; may be triggered by oral contraceptives
Atopic eruption of pregnancy	None	None	Commonly recurs due to atopic diathesis

Table 27.2 Dermatoses of pregnancy – fetal risk, involvement of newborn skin, and risk of recurrence.

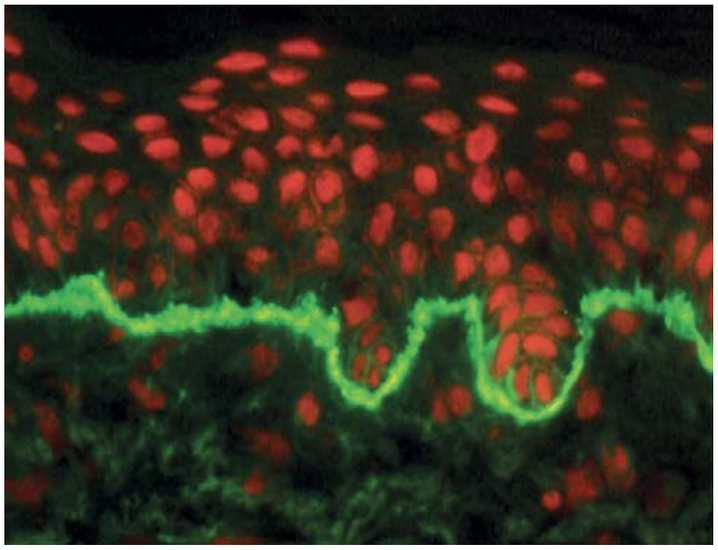

Fig. 27.2 Pemphigoid gestationis – direct immunofluorescence (IF) microscopy. Linear deposits of C3 are seen along the dermal–epidermal junction. *Courtesy, Immunofluorescence Department, St. John's Institute of Dermatology, St. Thomas' Hospital, London, UK.*

patients. However, *complement-added* indirect IF reveals the circulating anti-BMZ IgG1 autoantibodies in essentially all patients. Determination of antibody titers via BP180-NC16A ELISA may be helpful in following disease activity and monitoring therapy.

An increased incidence of antithyroid antibodies has been documented, but clinically apparent thyroid dysfunction is uncommon[7]. Routine laboratory investigations are normal.

Differential Diagnosis

The most frequent considerations in the differential diagnosis are PEP and drug eruptions. PEP is a particularly challenging exclusion, given the difficulty of distinguishing PEP and urticarial lesions of pemphigoid gestationis. IF and, more recently, the BP180-NC16A ELISA are key to the differentiation and are especially relevant in helping the patient plan for future pregnancies.

Treatment

The primary goal in treating this self-limited disease is to relieve pruritus and suppress blister formation. In mild cases, the use of potent topical corticosteroids combined with emollients and systemic antihistamines may be adequate. However, systemic corticosteroids remain the cornerstone of therapy (Table 27.3). Most patients respond to 0.5 mg/kg of prednisolone daily; the dose is tapered as soon as blister formation is suppressed. The common flare associated with delivery usually requires a temporary increase in dosage. Those rare patients with refractory disease may benefit from plasmapheresis during pregnancy. Persistent disease after delivery is uncommon and is treated like BP.

Anecdotal alternatives to corticosteroids (dapsone, doxycycline or minocycline ± nicotinamide, pyridoxine, cyclosporine) or adjuvants (methotrexate, cyclophosphamide, gold, IVIg) have been tried. None of these medications, with the possible exception of cyclosporine, are safe prior to term and thus should be avoided.

POLYMORPHIC ERUPTION OF PREGNANCY

Synonyms: ■ Pruritic urticarial papules and plaques of pregnancy (PUPPP) ■ Bourne's "toxaemic rash of pregnancy" ■ Nurse's "late onset prurigo" of pregnancy ■ Toxic erythema of pregnancy

Key features

- Urticarial papules and plaques that usually first appear within striae distensae during the latter portion of the third trimester or immediately postpartum
- Development of polymorphous features (vesicles; erythema; target and eczematous lesions) with disease progression
- Most frequent in primiparous women
- Nonspecific histologic features, negative IF, and normal routine laboratory evaluation
- No maternal or fetal risks; usually does not recur

Introduction

Polymorphic eruption of pregnancy (PEP), formerly known as PUPPP, is a common gestational dermatosis. It is characterized by a typical clinical presentation, normal laboratory tests, and negative IF or ELISA.

History

The term PUPPP, introduced by Lawley et al.[12] in 1979, focuses on the initial clinical findings in this disorder but overlooks its later polymorphous features. In order to encompass the entire clinical spectrum, the term "polymorphic eruption of pregnancy" has been introduced[3] and is now generally accepted.

Epidemiology

The incidence is ~1 in 160 deliveries[13]. It is seen predominantly in primiparous women and tends not to recur in subsequent pregnancies. There is neither an autoimmune diathesis nor an association with a specific HLA type.

Pathogenesis

The cause of PEP is unknown. Reference has been made to increased maternal weight gain and an increased frequency of multiple-gestation pregnancies[14,15]. It has therefore been suggested that rapid, late stretching of abdominal skin may lead to damage of connective tissue and elicitation of an allergic-type reaction, resulting in the initial appearance of the eruption within striae[16]. The lesions then become generalized as the inflammatory response develops cross-reactivity to collagen in otherwise normal-appearing skin. Immune tolerance during subsequent pregnancies might prevent recurrence. Additional theories

SPECIAL CONSIDERATIONS FOR CORTICOSTEROID AND ANTIHISTAMINE USE DURING PREGNANCY	
CORTICOSTEROIDS	
Topical	• Overuse of high-potency products can lead to systemic absorption and halogenated corticosteroids do cross the placenta; they may also add to the already considerable risk of striae • Class 6 and 7 corticosteroids are safest • Corticosteroids that have enhanced cutaneous metabolism, e.g. mometasone furoate, prednicarbate, methylprednisolone aceponate, can also be considered
Systemic	• Prednisolone is the systemic corticosteroid of choice for dermatologic indications as it is largely inactivated in the placenta (mother : fetus = 10 : 1) • During the first trimester, particularly between weeks 8 and 11, there is a possible (debated) slightly increased risk of cleft lip/cleft palate, especially if high doses prescribed and for >10 days; during this same period, a longer duration of therapy appears safe if dosages are <10–15 mg daily • If use is long-term and extends late into gestation, fetal growth should be monitored and the risk of adrenal insufficiency in the newborn should be addressed
ANTIHISTAMINES	
Systemic	• During the first trimester, the classic sedating agents (e.g. chlorpheniramine, clemastine, dimethindene) are preferred • During the second and third trimesters, if a non-sedating agent is requested, loratadine and cetirizine are considered safe

Table 27.3 Special considerations for corticosteroid and antihistamine use during pregnancy[25].

include increased levels of progesterone in association with multiple gestations and peripheral chimerism (deposition of fetal DNA) that favors skin with increased vascularity and damaged collagen.

Clinical Features

Pruritic erythematous and edematous papules and plaques usually first appear within the abdominal striae, typically with periumbilical sparing (Fig. 27.3). Onset is most often during the latter part of the third trimester (85%) or in the immediate postpartum period (15%)[15]. The eruption typically spreads over a matter of days, but in general spares the face, palms and soles. While pruritic urticarial papules are the initial lesions in almost all patients, approximately half will develop more polymorphic features as the disease evolves, including widespread erythema, target lesions, tiny vesicles, and eczematous plaques (Fig. 27.4). Irrespective of whether the eruption starts during pregnancy or postpartum, lesions resolve over an average of 4 weeks.

There are no maternal or fetal morbidities, and recurrences are unusual except for subsequent multiple-gestation pregnancies. To date, only a single possible case of newborn skin involvement has been described; however, the possibility of pemphigoid gestationis was not excluded by IF studies[17]. Thus, it is generally agreed that neonatal skin is not affected by PEP.

Pathology

Skin biopsy specimens reveal nonspecific findings. Epidermal changes vary from modest spongiosis to acanthosis with hyperkeratosis and parakeratosis, depending upon the stage of the disease. The dermis shows a nonspecific perivascular lymphocytic infiltrate with a variable degree of dermal edema and a variable number of neutrophils or eosinophils. Early lesions may resemble arthropod bite reactions, with a deeper dermal infiltrate and an absence of epidermal changes (Fig. 27.5). The histologic correlate of microvesiculation is severe epidermal spongiosis and/or dermal edema. Direct IF reveals no relevant abnormalities and indirect IF is negative. Routine laboratory evaluation is normal.

Differential Diagnosis

Since lesions of PEP may show microvesiculation, contact dermatitis must be considered. Drug eruptions, urticaria or viral exanthems may also be in the clinical differential diagnosis. The most important entity to exclude is urticarial pemphigoid gestationis, whose lesions tend to

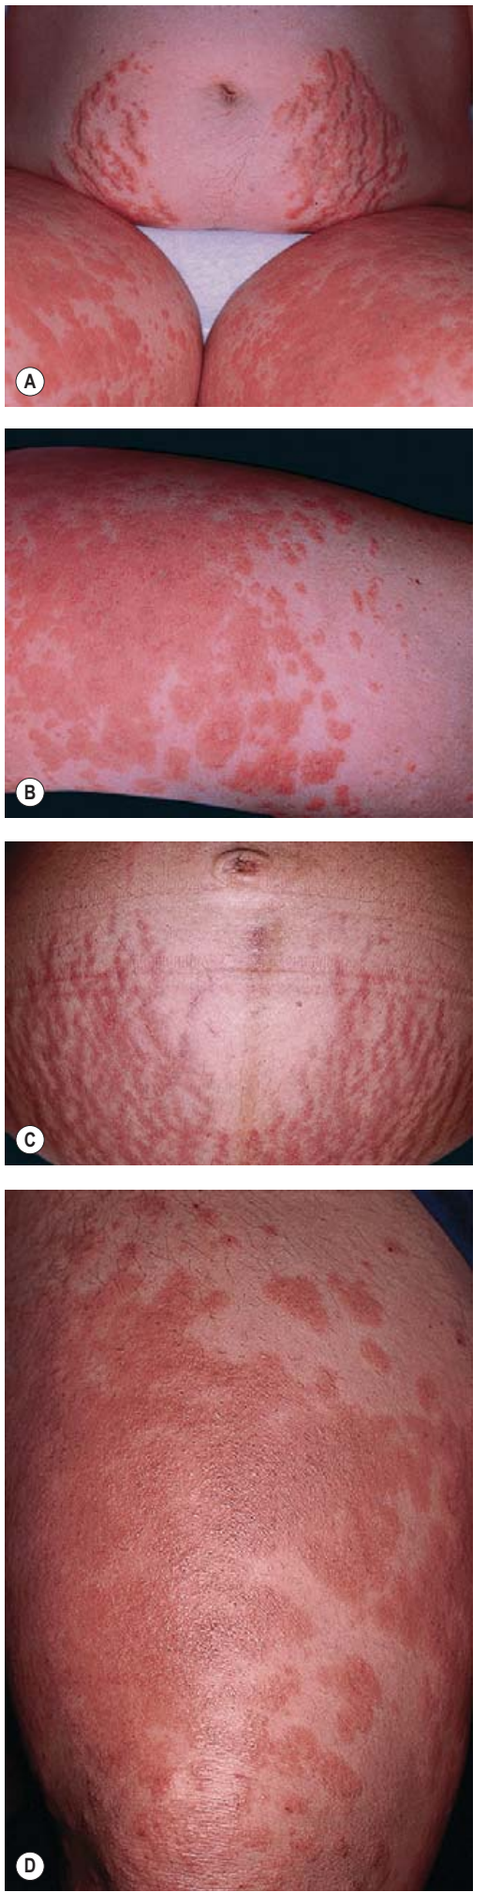

Fig. 27.3 Polymorphic eruption of pregnancy. The edematous urticarial lesions favor the striae (**A,C**) and the upper thighs (**B,D**) and spare the umbilicus. Note the pink color in a woman with skin phototype II versus the red–brown color in a more darkly pigmented patient.

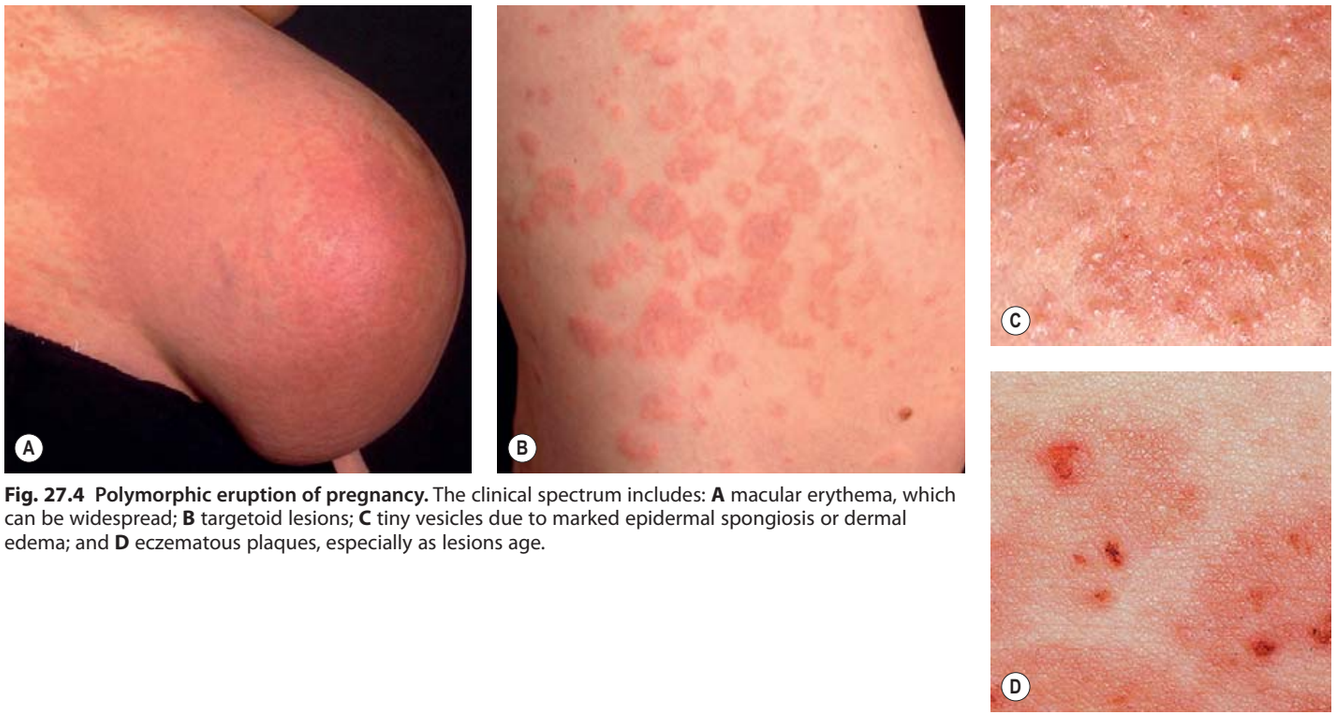

Fig. 27.4 Polymorphic eruption of pregnancy. The clinical spectrum includes: **A** macular erythema, which can be widespread; **B** targetoid lesions; **C** tiny vesicles due to marked epidermal spongiosis or dermal edema; and **D** eczematous plaques, especially as lesions age.

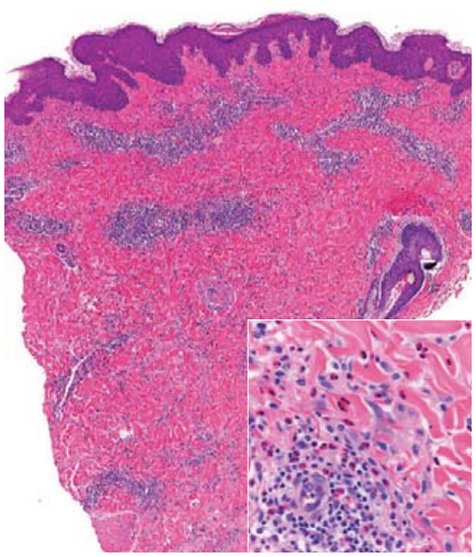

Fig. 27.5 Polymorphic eruption of pregnancy – histologic features. In this early lesion, a superficial and deep perivascular and interstitial lymphohistiocytic infiltrate is seen within the dermis. Numerous eosinophils are also present (insert).

appear earlier during gestation, have no association with abdominal striae and often involve the umbilicus, along with positive IF of perilesional skin.

Treatment

The majority of patients benefit from topical corticosteroids and oral antihistamines. More severe disease with a distressing degree of pruritus can be safely treated with a short course of systemic corticosteroids (see Table 27.3). Since the disease is self-limited and without serious sequelae, a conservative approach is justified.

INTRAHEPATIC CHOLESTASIS OF PREGNANCY

Synonyms: ■ Cholestasis of pregnancy ■ Obstetric cholestasis ■ Cholestatic jaundice of pregnancy ■ Pruritus/prurigo gravidarum

Key features

- Pruritus without primary skin lesions with an onset during the third trimester
- Secondary changes correlate with disease duration and vary from subtle excoriations to severe prurigo nodularis
- Elevated total serum bile acid levels are diagnostic; histology is nonspecific and IF is negative
- Increased risk of prematurity, intrapartum fetal distress, and stillbirths
- Recurs in 45–70% of subsequent pregnancies

Introduction

Intrahepatic cholestasis of pregnancy (ICP) is a rare form of genetically linked, hormone-dependent, reversible cholestasis. It typically presents late during pregnancy with dramatic pruritus. Although maternal prognosis is usually good (a small minority may develop steatorrhea and vitamin K deficiency), fetal risk is significant. As a result, ICP is the most important pruritic gestational condition to consider and promptly diagnose and treat in order to prevent fetal impairment.

History

ICP was first described in 1907 by Kehrer. In the past, much of the confusion arose from applying descriptive names such as "pruritus gravidarum" for ICP without skin changes or "prurigo gravidarum" if skin lesions associated with scratching were present. While the first term was often combined with the mild unexplained pruritus that occurs in many women during pregnancy (most likely related to an atopic diathesis), the latter was confused with "prurigo of pregnancy" (see below). Because laboratory evaluation, including measurement of serum bile acid levels, was performed in only a minority of women, ICP was often missed.

Epidemiology

There are striking geographic and ethnic differences in the incidence of ICP. For example, it is most commonly observed in South America, with the highest incidence rates in Bolivia and Chile (9–16%), particularly among Araucanian Indian women (28%). In contrast, rates of 0.1% to 1.5% have been described in Europe and North America, with relative "hot spots" in Scandinavia and the Baltic states (1–2%)[18]. Some of

the variance is probably explained by different reporting criteria; however, endemic clustering and a positive family history in up to 50% of those affected point towards a genetic predisposition. A higher incidence of ICP is also seen in multiple-gestation pregnancies, which may be related to higher hormonal levels (e.g. estrogen) in these patients.

Pathogenesis

The key element is reduced excretion of bile acids, which leads to increased serum levels. This not only provokes severe pruritus in the mother, but also may have deleterious effects on the fetus. Toxic bile acids crossing the placenta can lead to acute fetal anoxia due to abnormal uterine contractility and vasoconstriction of chorionic veins as well as impaired fetal cardiomyocyte function[18]. One predisposing factor is mutations in genes (e.g. *ABCB4*) that encode bile transporter proteins[19]. While mild dysfunction of these canalicular transporters may not lead to clinical symptoms in non-pregnant individuals, when the transporters' capacity to secrete substrates is exceeded (as occurs in the setting of high levels of sex hormones during pregnancy), signs and symptoms of cholestasis can develop. Other contributing factors are the cholestatic effect of estrogen and progesterone metabolites, which peak late during pregnancy, and hepatitis C viral infection (see below). Furthermore, dietary factors such as selenium deficiency and increased intestinal permeability ("leaky gut") have been suggested as possible triggers.

Clinical Features

Patients typically present during their last trimester with a sudden onset of intense, generalized pruritus that often starts on the palms and soles. No primary skin lesions are seen, and secondary changes due to scratching vary from subtle excoriations early on to pronounced prurigo nodularis in those with pruritus of longer duration (Fig. 27.6). The extensor surfaces of the extremities, buttocks and abdomen are usually most severely affected.

Although jaundice is often mentioned as a common finding in ICP, it actually occurs in only 10% of patients. Jaundice is usually a complication in those with the most severe and prolonged episodes of ICP. In such patients, concomitant extrahepatic cholestasis may be associated with steatorrhea and subsequent vitamin K deficiency, leading to an increased risk of intra- and postpartum hemorrhage.

Pruritus typically persists until delivery and then it resolves spontaneously within days. A protracted course is very unusual and should prompt one to exclude other liver diseases, especially primary biliary cirrhosis. Recurrence during subsequent pregnancies occurs in 45–70% of patients, and recurrence with oral contraceptives is routine. No detectable abnormalities are generally present between gestations.

ICP is associated with significant fetal risk, in particular an increase in premature births (20–60%), intrapartum fetal distress (20–30%; e.g. meconium staining of amniotic fluid, abnormal fetal heart rate), and fetal loss (1–2%)[18]. Fetal risk correlates with the elevation in serum bile acid levels, especially when levels exceed 40 µmol/l[20]. Thus, prompt diagnosis and treatment is essential, as is close obstetric surveillance.

Pathology

Histologic findings in the skin and the liver are nonspecific and direct IF of perilesional skin is negative. The diagnosis is confirmed by an increase in total serum bile acid levels (>11 µmol/l in a pregnant woman; normal range in non-pregnant women, 0–6 µmol/l). Levels may range from 3 to 100 times normal. During pregnancy, alkaline phosphatase levels typically increase (placental origin) even in the absence of ICP, and γ-glutamyl transferase levels are usually lower than in the non-pregnant state. Serum levels of transaminases are usually elevated in those with ICP, but may be normal in 30% of patients[21]. In women with jaundice, conjugated (direct) bilirubin levels are increased and the prothrombin time may be prolonged. Hepatic ultrasonography generally is normal but may reveal gallstones in jaundiced patients (who are at increased risk for their development).

Differential Diagnosis

In the absence of primary lesions, the clinical differential diagnosis includes other causes of primary pruritus (see Ch. 6), including those that lead to cholestatic pruritus. Viral hepatitis is a common disorder and should be excluded by appropriate serologies. Of note, a history of hepatitis C viral infection is considered a risk factor for the development of ICP, and in one study, 20% of the women who were HCV RNA-positive developed ICP[22].

Fig. 27.6 Intrahepatic cholestasis of pregnancy. Marked pruritus leads to secondary skin lesions that vary based on disease duration, from subtle linear excoriations and prurigo simplex early on (**A**) to pronounced prurigo nodularis when the pruritus is longstanding (**B**). *From Ambros-Rudolph CM, Glatz M, Trauner M, Kerl H, Müllegger RR. The importance of serum bile acid level analysis and treatment with ursodeoxycholic acid in intrahepatic cholestasis of pregnancy: a case series from central Europe. Arch Dermatol. 2007;143:757–62. © (2006) American Medical Association. All rights reserved.*

Treatment

Since fetal prognosis correlates with disease severity, the therapeutic goal is reduction of serum bile acid levels. This allows prolongation of the pregnancy and lessens both fetal risk and maternal symptoms. To date, the only successful agent has been oral ursodeoxycholic acid (UDCA)[18,21,23,24]. It is a naturally occurring, hydrophilic, non-toxic bile acid that has been used for a variety of cholestatic liver diseases. Although the exact mechanism of action in ICP is still not fully understood, there is evidence that UDCA corrects the maternal serum bile acid profile, decreases the passage of maternal bile acids to the fetoplacental unit, and improves the function of the bile acid transport system

across the trophoblast. UDCA is safe for mother and fetus, with its only side effect being mild diarrhea. Use of UDCA for ICP is off-label as it is only approved for primary biliary cirrhosis. The recommended oral dose is 15 mg/kg daily or, independent of body weight, 1 g daily. It should be started as early as possible and administered until delivery.

The use of S-adenosylmethionine, dexamethasone, epomediol, silymarin, phenobarbital or activated charcoal is not recommended as none have been shown to decrease fetal risk. Cholestyramine is contraindicated as it can further reduce vitamin K absorption and increase the risk of bleeding[24]. In jaundiced patients, the prothrombin time should be monitored, and intramuscular vitamin K administered as necessary. Close interdisciplinary collaboration with the obstetrician is essential and close monitoring of the fetus is recommended.

ATOPIC ERUPTION OF PREGNANCY

Synonyms: ■ Prurigo of pregnancy ■ Besnier's "prurigo gestationis" ■ Nurse's "early onset prurigo" of pregnancy ■ Spangler's "papular dermatitis of pregnancy" ■ Pruritic folliculitis of pregnancy ■ Eczema in pregnancy

Key features

- Eczematous and/or papular skin lesions in a patient with an atopic diathesis in whom other specific dermatoses have been excluded
- Most common pruritic disorder during pregnancy
- Generally appears earlier than other pregnancy-related dermatoses (75% before the third trimester)
- Nonspecific histology; negative direct IF; elevated serum IgE levels in up to 70% of patients
- No maternal or fetal risks; commonly recurs in subsequent pregnancies

Introduction

Atopic eruption of pregnancy (AEP) is defined as either an *exacerbation* or the *first occurrence* of eczematous and/or papular skin changes during pregnancy in atopic individuals. As the majority of patients belong to the second group, the atopic link is often overlooked, leading to a number of different diagnoses, as evidenced by the many synonyms.

History

In retrospect, an association with atopy dates back to the first reports. When Besnier described the disorder "prurigo gestationis" in 1904, "prurigo" was the term dermatologists used for atopic dermatitis (Besnier was the first to note the association between atopic dermatitis, allergic rhinitis and asthma). Nurse, in 1968, described accompanying eczematous features in most of the 31 patients in his "early onset" prurigo group. In 1983, Holmes and Black were the first to suggest that "prurigo of pregnancy" could simply result from pregnancy-related pruritus in women with an atopic diathesis rather than being a distinct entity[3].

Epidemiology

AEP is by far the most common pruritic disorder in pregnant women and it tends to appear earlier than the other pregnancy-related dermatoses[1]. Its incidence is not known but may be as high as 1 in 5 to 1 in 20.

Pathogenesis

To prevent fetal rejection, a normal pregnancy is characterized by a lack of strong maternal cell-mediated immune function and reduced Th1 cytokine production (e.g. IL-12, interferon-γ) as well as a dominant humoral immune response with increased Th2 cytokine production (e.g. IL-4, IL-10). This natural switch towards a dominant Th2 response, which worsens the imbalance already present in most atopic patients, is thought to favor the development of AEP[1].

Clinical Features

In contrast to the other specific dermatoses of pregnancy, AEP appears earlier, often during the first trimester, with 75% of patients presenting before the third trimester. Approximately 20% of women experience an exacerbation of pre-existing atopic dermatitis, while the remaining 80% develop atopic skin changes for the first time during pregnancy. Two-thirds of patients present with eczematous lesions (Fig. 27.7), often involving "atopic sites" such as the face, neck, and flexural aspects of the extremities. One-third develop a papular eruption on the trunk and extremities, composed of either classic prurigo lesions or small erythematous papules (Fig. 27.8). Findings typically include xerosis (often marked) and other signs of the underlying atopic diathesis (see Ch. 12). Fetal and maternal prognoses are excellent and recurrences in subsequent pregnancies are common.

Pathology

Depending on the stage of the lesion, histologic features can vary. Epidermal changes include spongiosis, acanthosis and erosions; the dermal infiltrate is composed of lymphocytes and usually admixed eosinophils. If the histologic section includes a hair follicle, there may be sterile follicular inflammation. Direct IF is negative. Serum IgE levels may be elevated in up to 70% of patients, usually to a mild degree.

Differential Diagnosis

Of the specific pregnancy dermatoses, PEP and ICP are the ones that in particular need to be excluded. In AEP, the eruption starts significantly earlier during gestation and has no association with striae; serum bile acid levels are also normal. Furthermore, other pruritic dermatoses not specifically associated with pregnancy (e.g. scabies, viral exanthems, drug eruptions) must be considered.

Fig. 27.7 Atopic eruption of pregnancy. Eczematous lesions often involving flexural areas and friction sites (**A,B**), as well as the breasts and abdomen (**B**). These changes are seen in approximately two-thirds of patients.

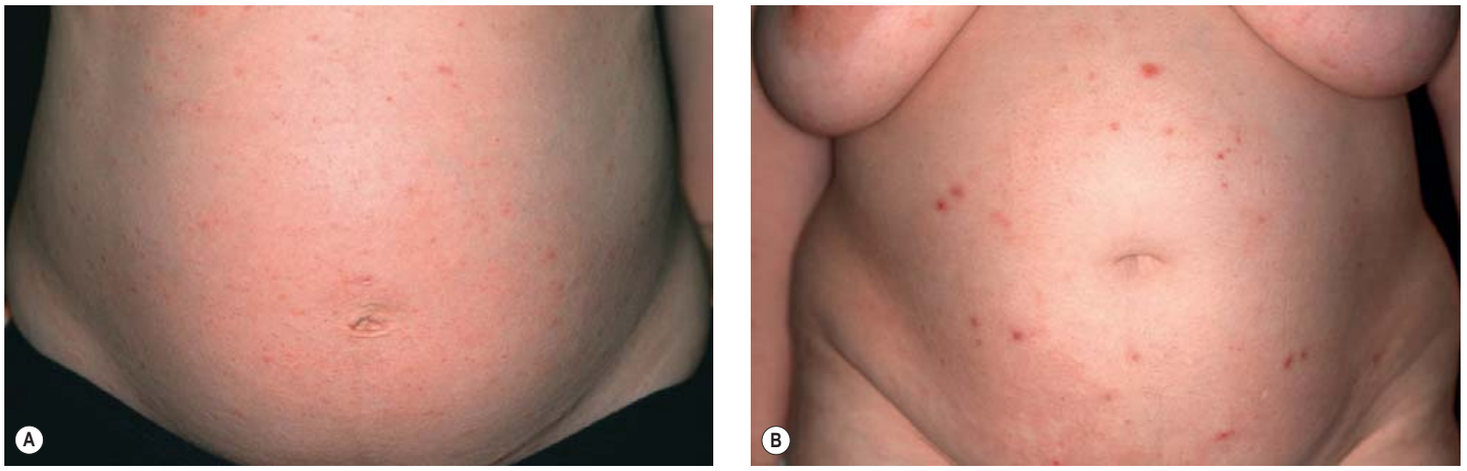

Fig. 27.8 Atopic eruption of pregnancy. Scattered small erythematous papules (**A**) or excoriated prurigo lesions (**B**) favor the abdomen and extremities. These changes are seen in approximately one-third of patients. Note the absence of striae distensae.

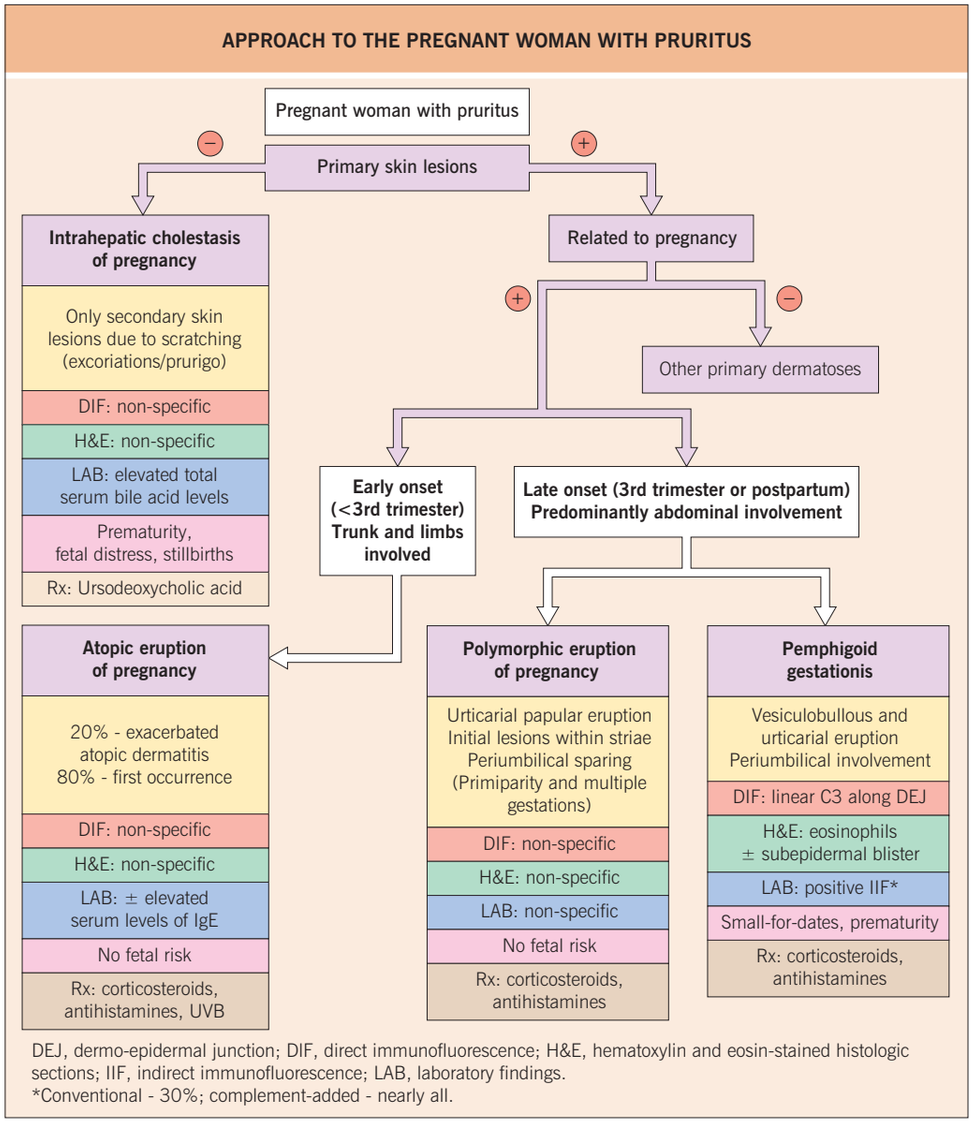

Fig. 27.9 Approach to the pregnant woman with pruritus[1]**.** Patients with refractory pemphigoid gestationis may benefit from plasmapheresis during pregnancy. See Table 27.3 for special considerations regarding the use of corticosteroids (topical and oral) and antihistamines during pregnancy.

Treatment

Cutaneous lesions respond rapidly to topical corticosteroids with or without systemic antihistamines. Emollients, humectants and topical antipruritic agents also play a role, as they do in non-pregnant patients with atopic dermatitis. Topical urea (10%), polidocanol and menthol are considered safe during pregnancy. UVB irradiation is very helpful for severe disease. Secondary bacterial infection may require systemic antibiotics (e.g. penicillins, cephalosporins).

APPROACH TO THE PREGNANT WOMAN WITH PRURITUS

Pruritus is the major symptom in all four of the pregnancy-related dermatoses, but it may also be associated with coincidental dermatoses (e.g. scabies, urticaria, pityriasis rosea). A pregnant woman with severe pruritus and skin lesions requires urgent clinicopathologic assessment, given the possibility of associated fetal risks. Figure 27.9 is an algorithm that has proven helpful in distinguishing amongst the various pruritic dermatoses of pregnancy[1]. Primiparity and multiple gestations are significantly linked to PEP, while a history of identical skin findings in past pregnancies (recurrence) suggests ICP. An early presentation (75% before the third trimester) is typical for AEP, while the other disorders present late during pregnancy or postpartum. Abdominal location of skin lesions is characteristic of pemphigoid gestationis and PEP, involvement of the trunk and extremities of AEP, and predominant involvement of the extremities of ICP. Pruritus as the sole presenting symptom followed by exclusively secondary cutaneous lesions due to scratching is only seen in ICP.

PHYSIOLOGIC CHANGES DURING PREGNANCY

Table 27.4 outlines many of the physiologic changes that have been associated with pregnancy. While some are very common, such as hyperpigmentation, others are more loosely associated, for example, nail changes. The majority of changes spontaneously regress following delivery[26].

AUTOIMMUNE PROGESTERONE DERMATITIS

Although autoimmune progesterone dermatitis is not a specific dermatosis of pregnancy, it can first appear during pregnancy or postpartum[27]. Classically, there are recurrent cyclic flares of dermatitis that correspond to the luteal phase of the menstrual cycle (when progesterone levels increase). In addition to eczematous changes, lesions can vary from urticaria to papulovesicles to erythema multiforme-like. Some patients have primarily pruritus or oral erosions. At sites of intradermal

PHYSIOLOGIC CHANGES DURING PREGNANCY	
PIGMENTARY	
Hyperpigmentation (e.g. areolae, linea nigra; Figure 27.10) Melasma	Hyperpigmentation (up to 90% of patients) and melasma (up to 70% of patients) are presumably of hormonal etiology. Melasma tends to persist postpartum in those with darkly pigmented skin types
HAIR	
Hirsutism Postpartum telogen effluvium Postpartum androgenetic alopecia	Some hirsutism is normal and typically regresses postpartum. Telogen effluvium may last up to 15 months. Postpartum patterned alopecia may or may not revert to normal
NAIL	
Subungual hyperkeratosis Distal onycholysis Transverse grooving Brittleness	There are no pathognomonic nail changes
GLANDULAR	
Increased eccrine function (except palms) Increased sebaceous function Decreased apocrine function	The effect of pregnancy on glandular function is contradictory. Eccrine function seems to increase (except on the palms). However, the effect on apocrine function and sebaceous gland activity is incompletely understood
CONNECTIVE TISSUE	
Striae	Striae gravidarum develop in up to 90% of patients and often resolve. Both hormonal factors and physical stretching of the skin appear to be relevant in their development
VASCULAR	
Spider angiomas Palmar erythema (Figure 27.10) Non-pitting edema Varicosities Vasomotor instability Purpura Gingival hyperemia or hyperplasia Pyogenic granuloma Hemorrhoids	Vascular changes result from distention, instability and new vessel formation. Clinically obvious changes are most pronounced during the third trimester and most changes regress spontaneously following delivery

Table 27.4 Physiologic changes during pregnancy. *Adapted from Kroumpouzos G, Cohen LM. Dermatoses of pregnancy. J Am Acad Dermatol. 2001;45:1–19.*

Fig. 27.10 Physiologic changes during pregnancy. Palmar erythema of pregnancy (**A**) and linea nigra (**B**).

injection of progesterone (e.g. 50 mg/ml), the vast majority of affected patients develop a cutaneous reaction characterized by urticaria (immediate [30 min]) and/or erythema and induration (delayed [24–48 h])[27]. Injections of saline and estrogen (e.g. estrone [1 mg/ml]) are often done concurrently, to serve as a control and to examine for evidence of estrogen dermatitis[28], respectively. Both oral and intramuscular progesterone have been used as a challenge test in patients with delayed reactions. Treatment consists primarily of inhibiting ovulation via estrogen-containing preparations. Anecdotally, additional reported therapies include tamoxifen and danazol, each possibly suppressing ovulation via interaction with the hypothalamic–pituitary axis. Of note, some patients have had remissions during pregnancy.

Chapter Contents

Origin of the epidermal basement membrane *450*
Hemidesmosome-anchoring filament complexes and integrins in the plasma membranes of basal keratinocytes..... *450*
The lamina densa *452*
Anchoring fibrils and the sublamina densa region *455*
The epidermal basement membrane in bullous diseases..... *456*

Synonyms: ■ Bullous pemphigoid antigen 1: BP230 ■ Bullous pemphigoid antigen 2: BP180; type XVII collagen ■ Laminin 332: laminin 5; epiligrin; kalinin; nicein; GB3 antigen; BM600 ■ Type VII collagen: the epidermolysis bullosa acquisita antigen ■ Nidogen: entactin

Key features

- Basement membranes serve as: (1) a substrate for attachment of cells; (2) a template for tissue repair; (3) a matrix for cell migration; (4) a substratum to influence differentiation, morphogenesis and apoptosis of epithelial cell layers; and (5) a permeability barrier for cells and macromolecules
- By transmission electron microscopy, the major ultrastructural subregions (from superior to inferior) of the epidermal basement membrane are: (1) the cytoskeleton, hemidesmosomal plaques and plasma membranes of basal keratinocytes; (2) an electron-lucent region termed the lamina lucida; (3) the lamina densa (or basement membrane proper); and (4) the sublamina densa region of the papillary dermis
- In the "laminated" model of the epidermal basement membrane, keratin intermediate filaments in basal keratinocytes attach to small (i.e. <0.5 microns), electron-dense units (hemidesmosomes) on the basal plasma membranes of these cells. In turn, anchoring filaments (small thread-like strands) connect hemidesmosomes to the lamina densa. The lamina densa is tethered to the dermis by anchoring fibrils, units that by originating and ending in the underside of the lamina densa create ultrastructural loops that serve as attachment sites for fibrillar proteins in the papillary dermis
- Acquired or inherited abnormalities in structural proteins within the epidermal basement membrane often result in a disease phenotype characterized by blister formation

INTRODUCTION

Basement membranes are specialized structures located between cells and their underlying stroma or between different cell types[1]. Basement membranes of various tissues differ ultrastructurally, biochemically and functionally. All basement membranes contain an electron-dense, somewhat granular matrix of variable thickness that is referred to as the lamina densa. Major components of the lamina densa include type IV collagen, laminin and heparan sulfate proteoglycan. Other components of the lamina densa vary depending upon the tissue type. Basement membranes serve a variety of functions that are manifest in a tissue-specific manner. Roles common to virtually all basement membranes include acting as: (1) substrates for attachment of cells; (2) templates for tissue repair; (3) matrices for cell migration; (4) substrata to influence differentiation, morphogenesis and apoptosis of epithelial cell layers; and (5) permeability barriers for cells and macromolecules. The two major basement membrane complexes in skin are found at the epidermal–dermal interface and around the dermal microvasculature. This chapter will deal largely with the epidermal basement membrane.

The epidermal basement membrane is a highly specialized structure that contains numerous tissue-specific elements (Table 28.1). The first characterization of this ultrastructural region in the skin was made by electron microscopists, who identified four distinct subregions of the epidermal basement membrane (Fig. 28.1). These subregions, from superior to inferior distribution, are:

- the cytoskeleton, hemidesmosomal plaques and plasma membranes of basal keratinocytes

REPRESENTATIVE ADHESION PROTEINS IN THE EPIDERMAL BASEMENT MEMBRANE
CYTOSKELETON OF BASAL KERATINOCYTES
• Keratin 5 • Keratin 14
HEMIDESMOSOME-ANCHORING FILAMENT COMPLEXES
• Plectin • Bullous pemphigoid antigen 1 • Bullous pemphigoid antigen 2 (type XVII collagen) • Integrin subunit α_6 • Integrin subunit β_4 • Tetraspan CD151 • Laminin 332 (formerly laminin 5)
LAMINA DENSA
• Heparan sulfate proteoglycans (e.g. perlecan) • Laminin 332 • Laminin 311 (formerly laminin 6) • Laminin 511 (formerly laminin 10) • Nidogen • Type IV collagen
SUBLAMINA DENSA REGION
• Type VII collagen • Type IV collagen • Elastin • Fibulins (glycoproteins found in microfibrillar bundles in the papillary dermis) • Fibrillins (large proteins that form an integral part of the microfibril structure) • Latent TGF-β-binding proteins • Linkin (main component of microthread-like fibers that comprise a delicate mesh-like network in the upper papillary dermis) • Type III collagen • Type I collagen

Table 28.1 Representative adhesion proteins in the epidermal basement membrane. TGF-β, transforming growth factor β.

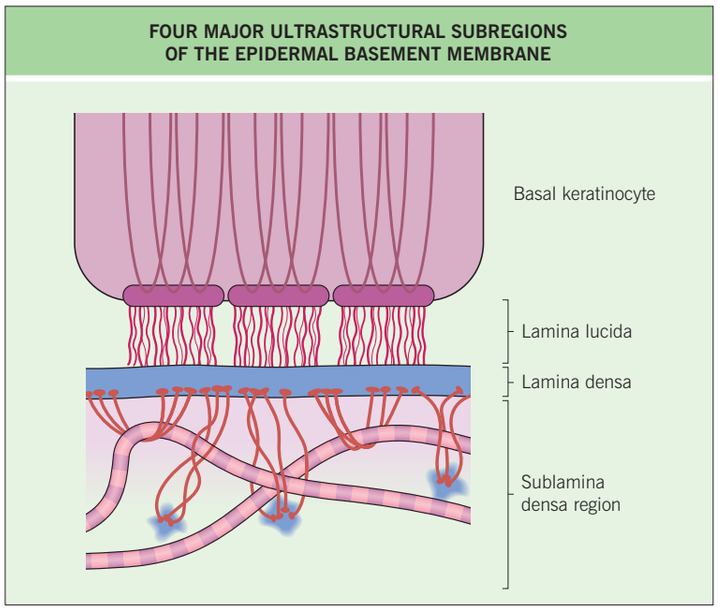

Fig. 28.1 Four major ultrastructural subregions of the epidermal basement membrane. The four major ultrastructural subregions of the epidermal basement membrane consist of the following: (1) cytoskeleton, hemidesmosomal plaques and plasma membranes of basal keratinocytes; (2) electron-lucent lamina lucida; (3) lamina densa; and (4) sublamina densa region of the papillary dermis.

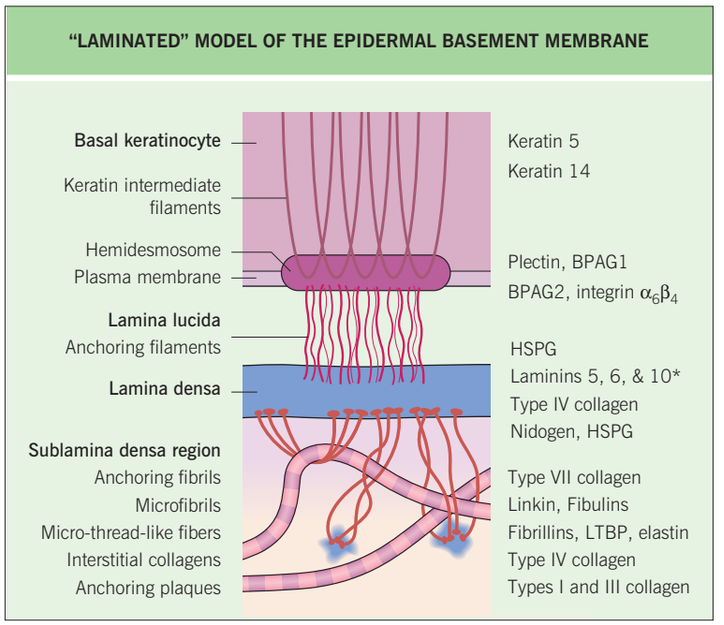

Fig. 28.2 "Laminated" model of the epidermal basement membrane. In the laminated model, keratin intermediate filaments attach to electron-dense hemidesmosomes on the basal plasma membranes of keratinocytes. Hemidesmosomes connect to the underlying lamina densa (basement membrane proper) by small thread-like strands termed anchoring filaments. The lamina densa and the overlying epidermis are tethered to the papillary dermis by anchoring fibrils, a series of looping elements along the underside of the lamina densa that serve as attachment sites for fibrillar proteins in the papillary dermis. *Laminins 5, 6 and 10 are now termed laminins 332, 311 and 511 (see Table 28.3). HSPG, heparan sulfate proteoglycans; LTBP, latent TGF-β-binding proteins.

- an electron-lucent region called the lamina lucida that contains delicate filaments connecting hemidesmosomes (HDs) in basal keratinocytes to the underlying lamina densa
- the lamina densa or basement membrane proper
- the sublamina densa region containing anchoring fibrils, anchoring plaques and filamentous proteins of the papillary dermis.

These subregions of the epidermal basement membrane, readily identified in fixed skin samples by transmission electron microscopy, have served as a useful conceptual model of a highly complex adhesion unit that preserves the integrity of the skin (Fig. 28.2). Interestingly, specialized transmission electron microscopy studies of cryopreserved skin have suggested that the lamina lucida may actually represent an artifact of tissue dehydration[2]. Nonetheless, the classic laminated model of the epidermal basement membrane serves as a useful framework to guide understanding of its structure, function and impairment in disease.

ORIGIN OF THE EPIDERMAL BASEMENT MEMBRANE

The epidermal basement membrane is comprised of proteins derived from keratinocytes of ectodermal origin as well as dermal fibroblasts of mesodermal origin. Proteins in HDs (i.e. plectin, bullous pemphigoid antigen 1 [BPAG1], bullous pemphigoid antigen 2 [BPAG2] and integrin subunits α_6 and β_4), CD151 tetraspan, types IV and VII collagen, laminins 332 ($\alpha3\beta3\gamma2$; formerly known as laminin 5) and 311 ($\alpha3\beta1\gamma1$; formerly known as laminin 6), and heparan sulfate proteoglycans are produced by basal keratinocytes and incorporated within the epidermal basement membrane. Dermal fibroblasts produce nidogen (entactin), types IV and VII collagen, and other proteins that are translocated to plasma membranes of basal keratinocytes where they condense and are incorporated within the epidermal basement membrane. Integrins and other proteins within the plasma membrane of basal keratinocytes are thought to provide key localization and organizational cues that facilitate the incorporation of fibroblast-derived proteins within the epidermal basement membrane. The major proteins that comprise the various subregions of the epidermal basement membrane are described below (Fig. 28.3).

HEMIDESMOSOME-ANCHORING FILAMENT COMPLEXES AND INTEGRINS IN THE PLASMA MEMBRANES OF BASAL KERATINOCYTES

Plectin

Plectin is a 500 kDa protein associated with the cytoplasmic plaque of HDs[3]. It is a member of the plakin family and consists of large, multidomain cytolinker proteins that connect cytoskeletal networks to each other and to adhesive junctions such as desmosomes and HDs; additional members of the plakin family include BPAG1 (see below), desmoplakin, periplakin and envoplakin (see Ch. 29).

The carboxy terminus of plectin binds intermediate filaments (specifically, keratins or vimentin) and the amino terminus contains domains that bind the cytoplasmic tail of integrin subunit β_4, BPAG2 and actin[4]. Hence, plectin attaches intermediate filaments to HDs and plasma membranes of basal keratinocytes and also cross-links other proteins associated with the cytoplasmic plaques of HDs[5]. Mutations in the gene encoding plectin are responsible for epidermolysis bullosa (EB) simplex associated with muscular dystrophy as well as for the Ogna type of EB simplex and a rare subset of EB simplex with pyloric atresia (see Ch. 32). Targeted inactivation of the gene encoding plectin impairs the cytoarchitecture of skin, muscle and heart in mice[6].

Bullous Pemphigoid Antigen 1

Circulating autoantibodies from patients with bullous pemphigoid (BP) were used to define two autoantigens that reside in HDs of basal keratinocytes. The first of these autoantigens characterized (BPAG1) is a plakin and, like other proteins of this family, plays an important role in promoting adhesion of the intermediate filament cytoskeleton with adhesion units (in this case, HDs) in plasma membranes[7].

BPAG1 is a 230 kDa non-collagenous protein localized to the cytoplasmic plaque of HDs[8]. It has a central coiled-coil α-helical rod domain that contains a regular periodicity of acidic and basic amino acid

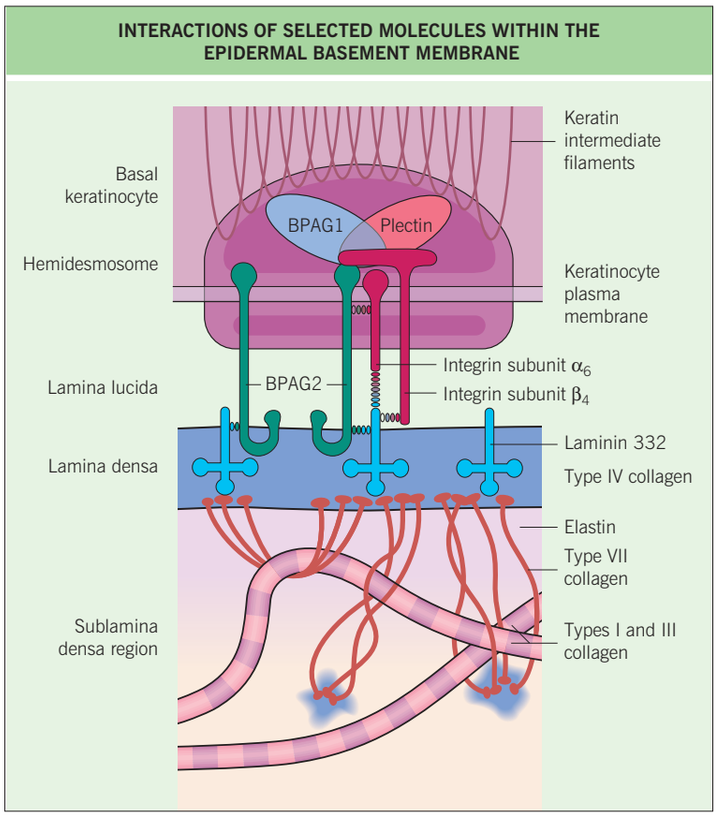

Fig. 28.3 Interactions of selected molecules within the epidermal basement membrane. These interactions promote epidermal adhesion and also play a key role in a number of dermatologic diseases. Important molecular interactions include those between: (1) plakin family members, BPAG1 and plectin, with keratin intermediate filaments; (2) the former with BPAG2 and integrin $\alpha_6\beta_4$ (specifically, the large cytoplasmic domain of integrin subunit β_4); (3) the cytoplasmic domains of BPAG2 and integrin subunit β_4; (4) the extracellular domains of BPAG2 and integrin subunit α_6 as well as laminin 332 (formerly laminin 5); (5) integrin $\alpha_6\beta_4$ in hemidesmosomes and laminin 332 in the lamina densa; (6) laminin 332 and type VII collagen; (7) type VII collagen with type IV collagen, fibronectin, and type I collagen in the sublamina densa region.

TARGETS COMMON TO AUTOIMMUNE AND INHERITED BLISTERING DISEASES

Protein target	Structural target	Autoimmune disease	Genetic disease
BPAG1	HD	BP	Recessive EB simplex
Type XVII collagen (BPAG2)	HD-anchoring filament complexes	BP, PG, MMP, linear IgA bullous dermatosis	Junctional EB-non-Herlitz
Integrin subunit β_4	HD-anchoring filament complexes	Ocular MMP	Junctional EB with pyloric atresia
Laminin 332 (formerly 5)	Lamina lucida–lamina densa interface	Anti-epiligrin MMP	Junctional EB-Herlitz
Type VII collagen	Anchoring fibrils	EB acquisita Bullous eruption of SLE	Dystrophic EB (dominant and recessive)

Table 28.2 Targets common to autoimmune and inherited blistering diseases. BP, bullous pemphigoid; EB, epidermolysis bullosa; HD, hemidesmosome; MMP, mucous membrane (cicatricial) pemphigoid; PG, pemphigoid gestationis; SLE, systemic lupus erythematosus.

residues. Studies showing that the periodicities of these residues are 180 degrees out of phase suggested that these proteins may self-aggregate by ionic interactions. The globular carboxy terminus of BPAG1 contains acidic and basic amino acids with a periodicity that promotes association with keratin intermediate filaments. The amino terminus of BPAG1 associates with the cytoplasmic domain of BPAG2, the integrin subunit β_4 and ERBIN (a protein that interacts with the transmembrane tyrosine kinase receptor Erb-B2, thus serving as a potential link between HD biology and Erb-B2 signaling)[5,9].

Consistent with the role that BPAG1 plays in cytoskeletal organization, BPAG1 knockout mice show signs of epithelial fragility in basal keratinocytes[10]. Unexpectedly, these mice also demonstrate neurologic impairment characterized by dystonia and ataxia. Neurologic manifestations in BPAG1 knockout mice develop as a consequence of concomitant inactivation of neuronal isoforms of BPAG1 referred to as nBPAG1 (or dystonin). The amino termini of neuronal isoforms of BPAG1 differ from their epithelial counterparts in that nBPAG1 contains either actin- or microtubule-binding domains essential for maintaining the cytoarchitecture of neurons. Recently, a homozygous mutation in each copy of the gene that encodes BPAG1 (affecting the epithelial isoform and a putative minor neuronal isoform with an unknown expression pattern) was found to underlie a novel form of EB simplex in a man who also had neurologic abnormalities[11].

Bullous Pemphigoid Antigen 2

BPAG2 is a type II transmembrane collagen (specifically, type XVII collagen) associated with HD-anchoring filament complexes in basal keratinocytes[12]. The cytoplasmic amino terminus of BPAG2 consists of approximately 500 amino acid residues, containing several potential phosphorylation sites within its central portion. The extracellular domain of BPAG2 contains 15 interrupted repeats that have multiple glycine-X-Y amino acid sequences; the latter are characteristic of proteins in the collagen family (see Ch. 95) and therefore are referred to as collagenous domains (coll 1–15; see Fig. 31.9). The deduced length of the largest collagenous domain of BPAG2 (coll 15) suggests that this portion of the protein spans the lamina lucida. By rotary shadowing of purified BPAG2, the intracytoplasmic region appears as a globular head and the extracellular region as a central rod (corresponding to coll 15) with a flexible tail (corresponding to coll 1–14)[13]. Immunoelectron microscopy studies suggest that the rod domain of BPAG2 inserts into the lamina densa and that its carboxy-terminal tail then loops back through the lamina densa into the lamina lucida (see Fig. 28.3)[14,15].

BPAG2 occurs in two forms[16]: (1) the 180 kDa full-length protein; and (2) the 120 kDa extracellular domain that is shed from plasma membranes of basal keratinocytes by proteolysis. Proteolytic processing of BPAG2 is mediated by "sheddases" of the disintegrin and metalloproteinase (ADAM) family (in particular the tumor necrosis factor-α-converting enzyme, TACE). Phosphorylation of BPAG2 by ecto-casein kinase 2 inhibits its proteolysis by TACE, a mechanism whereby the adhesion and motility of adjacent basal keratinocytes may be modulated[17].

After processing, the extracellular domain of BPAG2 is retained within the epidermal basement membrane as a homotrimer in which the collagenous domains form a cross-linked triple helix. The helix forms independently of amino acid sequences in the amino terminal portion of BPAG2 and is apparently organized in a 5′ to 3′ orientation using the 16th *n*on-collagenous portion of the protein (NC16) as a nucleation site[18]. The cytoplasmic domain of BPAG2 associates with BPAG1, integrin subunit β_4 and plectin[5]. The first extracellular segment of BPAG2 (NC16) contains 73 amino acid residues that are thought to bind integrin subunit α_6[19]. Immunogold electron microscopy studies have suggested that the carboxy-terminal portion of BPAG2 interacts with laminin 332 at the interface of these two proteins near the junction of the lamina lucida and the lamina densa (see Fig. 28.3)[14].

BPAG2 is targeted by autoantibodies from patients with BP, pemphigoid gestationis (PG), mucous membrane (cicatricial) pemphigoid (MMP) and linear IgA bullous dermatosis (LABD)[20]. Autoantibodies from patients with BP, PG and LABD typically target the NC16A domain of BPAG2 (see Fig. 31.9), whereas those from patients with MMP tend to target the distal carboxy terminus of BPAG2 (which extends deeper into the basement membrane) as well as NC16A. Patients with non-Herlitz subtypes of junctional EB often possess null mutations in the gene encoding BPAG2 (*COL17A1*) (Table 28.2). These individuals characteristically demonstrate a complete lack of BPAG2 in their epidermal basement membrane, along with a tendency for skin

fragility, subepidermal blister formation, alopecia, dystrophic nails and dental enamel hypoplasia[21]. Interestingly, *COL17A1* mutations resulting in deletion of the intracellular domain of BPAG2 that associates with BPAG1, plectin and integrin subunit β_4 result in a phenotype characterized by intraepidermal as well as junctional blister formation[22].

Integrins

Integrins are heterodimeric transmembrane receptors that promote cell–cell and cell–matrix interactions. Ligand binding to integrin receptors modulates cell adhesion, signal transduction, gene expression, growth and other fundamental biologic processes. All integrins are αβ-heterodimers. Numerous α- and β-subunits have been identified; several of these have alternatively spliced cytoplasmic domains (e.g. α_{IIb}, α_3, α_6, α_1 and α_4). Although some of the α-subunits can associate with more than one β-subunit, there is restriction in the number of heterodimers that actually form. Both α- and β-integrin subunits are transmembrane glycoproteins with a single hydrophobic transmembrane domain and a short cytoplasmic domain (i.e. ≤50 amino acid residues). An exception to this design is integrin subunit β_4, which contains a large cytoplasmic domain of >1000 amino acid residues.

The extracellular domains of integrin subunits associate to form dimers; subunits do not rely upon associations in their cytoplasmic or transmembrane regions for dimerization. Both subunits of the heterodimer are required for ligand binding. In fact, α- and β-subunits are thought to form a pocket that serves as a specific ligand-binding site. Switching either the α- or β-subunit can change ligand specificity.

Individual integrins can often bind to more than one ligand, and, similarly, individual ligands are often recognized by more than one integrin. Integrins often bind specific sequences of peptides in a given group of adhesion molecules (e.g. the Arg-Gly-Asp [RGD] sequence present in fibronectin, vitronectin and other adhesion proteins). Integrin ligand binding is divalent cation-dependent, and the cation itself (e.g. Ca^{2+}, Mg^{2+}, Mn^{2+}) can affect the affinity and the ligand specificity of the integrin. Cytoplasmic domains of integrins typically interact with cytoskeletal elements (e.g. talin, vinculin, actin filaments) as well as other intracellular proteins. The cytoplasmic domains and associations of integrin $\alpha_6\beta_4$ represent an exception to this model in that they are concentrated within HDs of epithelial cells[23].

Hemidesmosome-associated integrin $\alpha_6\beta_4$

The large cytoplasmic tail of integrin subunit β_4 contains sequences that appear to be required for HD assembly. The membrane-proximal region of integrin subunit β_4 directly associates with plectin, while its distal carboxyl-terminal region binds BPAG2 (see Fig. 28.3)[24]. Integrin subunit α_6 exists in two forms, A and B; the former predominates in keratinocytes. The proximal extracellular domain of integrin subunit α_6 binds the NC16A region of BPAG2[19]. Using K562 cells stably expressing $\alpha_{6A}\beta_4$ and $\alpha_{6B}\beta_4$, investigators demonstrated that laminins 111 and 332 serve as the preferred ligands for this HD-integrin[25].

Patients harboring biallelic mutations in genes encoding either α_6 or β_4 integrin subunits develop junctional EB associated with pyloric atresia. Such individuals typically have subepithelial blistering of the oral and respiratory epithelia as well as the skin. Targeted deletions of genes encoding murine integrin subunits α_6 or β_4 also result in extensive subepithelial blisters of the same tissues. Evidence of nuclear and cytoplasmic degeneration in basal keratinocytes of β_4-null mice suggests that this integrin subunit plays a role in cell survival[26]. Transgenic mice carrying a targeted deletion of the cytoplasmic domain of integrin subunit β_4 have a proliferative defect of stratified and simple epithelia[27]. However, targeted deletion of integrin subunit α_6 does not result in obvious developmental problems in murine epithelia.

Plasma membrane-associated integrins

Non-hemidesmosomal integrins expressed in basal keratinocytes include integrins $\alpha_2\beta_1$ and $\alpha_3\beta_1$[28]. The former is located predominantly along lateral and apical aspects of basal keratinocytes, and the latter is found in the same distribution as well as along the basal aspect of these cells' plasma membranes. Integrins bind the actin cytoskeleton and are thought to play a key role in cell–cell adhesion. Keratinocytes in culture utilize integrin $\alpha_3\beta_1$ to mediate initial adhesion to extracellular matrix via interaction with laminin 332.

Though integrin $\alpha_3\beta_1$ does not play a role in HD assembly, it is thought to provide key signals regulating cytoskeletal assembly, function of integrin $\alpha_6\beta_1$, and the establishment and/or maintenance of basement membrane integrity[29]. Mice with targeted deletion of integrin subunit α_3 have disorganized basement membranes in the kidney and skin[30]. More specifically, while the lamina densa in these mice is missing (or sparse) at sites between HDs, that beneath their HDs appears to be normal. Mild blistering in mice lacking integrin subunit α_3 further substantiates the idea that this polypeptide plays an important role in maintaining the integrity of the epidermal basement membrane and assembly of extracellular matrix.

Tetraspan CD151

CD151 is a cell surface protein that belongs to the tetraspan superfamily. Tetraspan proteins, named for their four membrane-spanning domains, form "web-like" networks with other membrane proteins and have roles in regulating a variety of cellular processes. To date, CD151 is the only tetraspan known to be associated with HDs. In human skin, CD151 associates with integrins $\alpha_6\beta_4$ (via its α-subunit) and $\alpha_3\beta_1$ in the basolateral plasma membrane of basal keratinocytes. Immunoelectron microscopy studies show that CD151 is concentrated in HDs.

In integrin subunit β_4-deficient keratinocytes, CD151 clusters with $\alpha_3\beta_1$ at the basal cell surface. Introduction of integrin subunit β_4 into the latter cells yields $\alpha_6\beta_4$ integrins that become incorporated into $\alpha_3\beta_1$–CD151 clusters, where they are thought to induce the formation of HDs. Soon thereafter, the amount of $\alpha_3\beta_1$ integrins in such clusters diminishes, and CD151 becomes predominantly associated with $\alpha_6\beta_4$ integrins within HDs. CD151 is therefore considered to be a component of pre-HDs whose recruitment is regulated by integrin $\alpha_6\beta_4$. CD151 is thought to provide a framework for the spatial organization of different HD components[31].

THE LAMINA DENSA

Laminins

Laminins are a family of heterotrimeric glycoproteins composed of at least 15 members[32]. Laminins consist of three subunits (α, β and γ) that are joined and stabilized by interchain disulfide bonds and other associations (Fig. 28.4). Each laminin subunit is encoded by a different

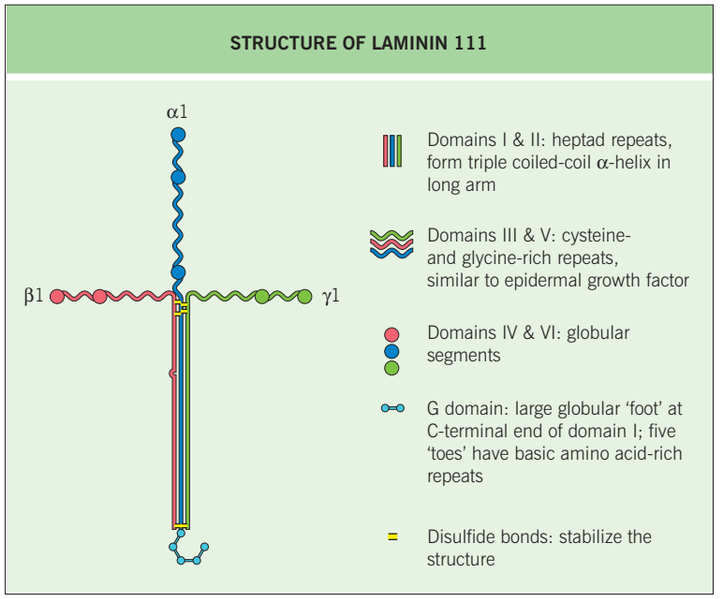

Fig. 28.4 Structure of laminin 111. Laminin 111 (laminin 1) serves as a prototype for the other laminin isoforms, which have similar structure and organization. Laminins consist of three subunits (α, β,γ), each encoded by a different gene and composed of six primary domains (domains I to VI).

gene. To date, five α-subunits, three β-subunits and three γ-subunits have been characterized[32]. Of note, the laminin subunit α3 gene (*LAMA3*) encodes two transcripts, α3A and α3B, corresponding to short and long variants, respectively.

Different laminin isoforms are created by the pairing of various α-, β- and γ-subunits. In the current laminin nomenclature (introduced in 2005 to replace the previous convention of naming isoforms based on the order of their discovery), each isoform's name reflects the numbers of its α-, β- and γ-subunits (e.g. α3, β3 and γ2 in laminin 332, formerly termed laminin 5). Laminin isoforms are distributed in a tissue-specific manner, with each displaying a wide variety of biologic functions. Laminins within basement membranes serve as ligands for overlying cell surface receptors (e.g. integrins), thereby providing key signals regarding the epithelial microenvironment.

The predominant laminins in epidermal basement membranes are 332 (α3β3γ2; formerly laminin 5), 311 (α3β1γ1; formerly laminin 6) and 511 (α5β1γ1; formerly laminin 10). The overall structure of laminins is presented in Figure 28.4 using laminin 111 (α1β1γ1; formerly laminin 1), a primary component of dermal microvascular (but not epidermal) basement membranes, as a prototype. The salient features of the aforementioned laminin isoforms are summarized in Table 28.3.

The essential role that laminin 332 plays in the epidermal basement membrane is exemplified by inherited disruptions in the genes that encode its subunits (*LAMA3, LAMB3, LAMC2*), which yield a phenotype characterized by extensive subepidermal blister formation and often early death in junctional EB-Herlitz. Moreover, patients with one form of MMP have IgG anti-basement membrane autoantibodies against laminin 332[39,40]. Passive transfer of rabbit anti-laminin 332 IgG to mice or of patient IgG to grafts of human skin on immunodeficient mice elicit non-inflammatory subepithelial blisters with clinical, histologic and immunopathologic features like those seen in patients with this form of MMP[41,42].

Type IV Collagen

Type IV collagen is a unique macromolecule that is specifically localized within basement membranes[1,43]. The structure of type IV collagen most closely resembles a procollagen (i.e. an intracellular form that retains globular domains at its amino and carboxy termini). Like all collagens,

FEATURES OF SELECTED LAMININS

Laminin isoform (αβγ)*	Previous numerical name†	Other names	Molecular weight, KDa	Processing, structure and assembly	Distribution	Interactions and functions
111	1	EHS laminin, "classic" laminin	~800 (α: ~400; β: ~220; γ: ~210)	• Asymmetric cross: 3 short arms, 1 long arm (see Fig. 28.4) • Self-assembles into a network *in vitro*	• Dermal microvascular BMs • Little or none in epidermal BM	• Diverse biologic functions, largely mediated by interactions with integrin receptors • Nidogen binds with high affinity to domain III of the γ1-subunit, connecting this laminin to the type IV collagen network, heparan sulfate proteoglycans (e.g. perlecan) and fibulins (see Fig. 28.6)
332	5	Epiligrin, kalinin, nicein, GB3 antigen, BM600	~410 (α: 200 for precursor/165 post processing; β: 140; γ: 155 for precursor/105 post processing)	• Cell-associated precursors of the α3- & γ2-subunits are processed following secretion • α3-subunit is truncated, lacks key N-terminal domains, and has a small G domain • β3-subunit is homolog of β1-subunit but does not undergo processing after secretion and has a truncated short arm • γ2-subunit's aa sequence has ~50% identity to that of the γ1-subunit, but the former's domains are truncated (I, II, III, IV, V) or absent (VI) • *Not* able to self-assemble into networks	• Found at interface of lamina lucida and lamina densa in epidermal BM • Produced and secreted by growing/migrating keratinocytes • Also in BMs of the trachea, gastrointestinal tract and amnion	• Attaches keratinocytes to the epidermal BM • γ2-subunit *lacks* domain that binds nidogen; instead, N-terminus of laminin 332 covalently associates with the branch points of the short arms of laminins 311 and 321, forming a complex that contains binding sites for nidogen (on γ1-subunit) and polymerization (on β1-, β2- & γ1-subunits) (see Fig. 28.6) • α3-subunit's G domain (positioned superiorly) binds integrins $\alpha_6\beta_4$ (in HDs; see Fig. 28.3) and $\alpha_3\beta_1$ (in plasma membrane) • β3- or γ2-subunits of monomeric laminin 332 can bind the N-terminal NC1 domain of type VII collagen of anchoring fibrils (see Fig. 29.3) • Thereby links HD-anchoring filament complexes with underlying anchoring fibrils
311	6		~600 (α: 200 for precursor/165 post processing; β: ~220; γ: ~210)	• See above for processing and structure of α3-subunit	• As for laminin 332	• Joined with laminin 332 in a disulfide-bonded complex (see above) • Connected to type IV collagen and other molecules in the lamina densa via nidogen bound to the γ1-subunit (see laminin 111 above and Fig. 28.6)
511	10		~640–880 (α: 450 for precursor/210–380 post processing; β: ~220; γ: ~210)	• α5-subunit is thought to be processed	• BMs of many tissues	

*Each isoform's name reflects the numbers of its α-, β- and γ-subunits.
†Numbers reflect the order of the isoforms' discovery.

Table 28.3 Features of selected laminins[32–38]. aa, amino acid; BM, basement membrane; C-terminal, carboxy-terminal; EHS, Engelbreth–Holm–Swarm (a mouse tumor from which laminin 111 was initially isolated); G domain, globular segment at C-terminal end of domain I; HD, hemidesmosome; NC1, non-collagenous 1; N-terminal, amino-terminal.

type IV collagen consists of three α-chain subunits; these subunits can be identical or genetically distinct but structurally related. To date, six type IV collagen α-chain subunits have been identified (polypeptides: α_1(IV)–α_6(IV); corresponding genes: *COL4A1–COL4A6*).

Type IV collagen is a heteropolymer that contains either two genetically identical α-chain subunits and one dissimilar α-chain subunit or three different α-chain subunits. Subunits α_1(IV) and α_2(IV) are ubiquitous components of basement membranes, where their highly cross-linked organization provides considerable structural support. Subunits α_5(IV) and α_6(IV) are present in the epidermal basement membrane, whereas α_3(IV), α_4(IV) and α_5(IV) subunits are found within renal glomerular basement membranes.

Like all collagens, the α-chain subunits of type IV collagen associate to form a triple-helical structure[1]. The stability of this triple helix is dependent upon characteristic repeating glycine-X-Y amino acid sequences, accompanying residues rich in proline, and post-translational hydroxylation of the latter to hydroxyproline (see Ch. 95). The resulting triple helix has an extended, somewhat rigid conformation that is resistant to "ordinary" proteases (e.g. trypsin) and sensitive to specialized proteases (i.e. collagenases). Unlike classic fibrillar collagens, type IV collagen is not helical through its entire length. Short discontinuities in glycine-X-Y repeats within its α-subunits create non-helical domains that confer increased flexibility to this macromolecule as well as sites susceptible to damage by "ordinary" proteases.

The retained globular domains at the ends of type IV collagen make it resemble a procollagen[1]. The globular amino terminus of this protein is referred to as its 7S domain; a smaller globular domain at its carboxy terminus is referred to as its non-collagenous 1 (NC1) domain. The macromolecular structure of type IV collagen has been described as resembling a "hockey stick", where the blade of the stick corresponds to the amino-terminal 7S domain, the handle corresponds to the largely continuous triple-helical portion of the molecule, and the handle grip corresponds to the short globular NC1 domain at its carboxy terminus[1]. This model is particularly useful when one relates the lattice structure of type IV collagen matrices to an arrangement of hockey sticks created by: (1) the overlapping of four 7S blades to create a type IV collagen "spider" in which the handles are oriented at roughly right angles to each other; and (2) the subsequent polymerization of "spiders" at sites of their abutting carboxy termini (the handle grips/ends of the spiders' "legs") (Fig. 28.5). Such end-to-end, antiparallel interactions result in a two-dimensional type IV collagen lattice that serves as a key matrix within the lamina densa.

Defective type IV collagen underlies several diseases of basement membranes. For example, the majority of patients with Alport syndrome (characterized by hematuria, progressive renal failure, sensorineural hearing loss, and, occasionally, ocular abnormalities) have mutations in the *COL4A5* gene encoding α_5(IV). In addition to this X-linked form of Alport syndrome, an autosomal recessive form of the disorder is caused by mutations in *COL4A3* or *COL4A4,* and a rare autosomal dominant variant results from mutations in *COL4A3*.

Goodpasture disease, a potentially lethal autoimmune disorder characterized by pulmonary hemorrhage and glomerulonephritis, is caused by anti-basement membrane antibodies directed against the NC1 domain of α_3(IV) and α_5(IV)[44]. Exposure of potentially pathogenic epitope(s) within α_3(IV) and/or α_5(IV) by infections or other events may represent an essential element in the development of this disease. Interestingly, antibodies against α_5(IV) ± α_6(IV) can cause a rare disorder characterized by subepidermal blisters and glomerulonephritis[45].

Fragments of type IV collagen α-chain subunits have important biologic activities. One such fragment is canstatin, a human basement membrane-derived inhibitor of angiogenesis and tumor growth that corresponds to a fragment of α_2(IV)[46]. Another example is tumstatin, a fragment of the NC1 domain of α_3(IV) that possesses antiangiogenic activity[47].

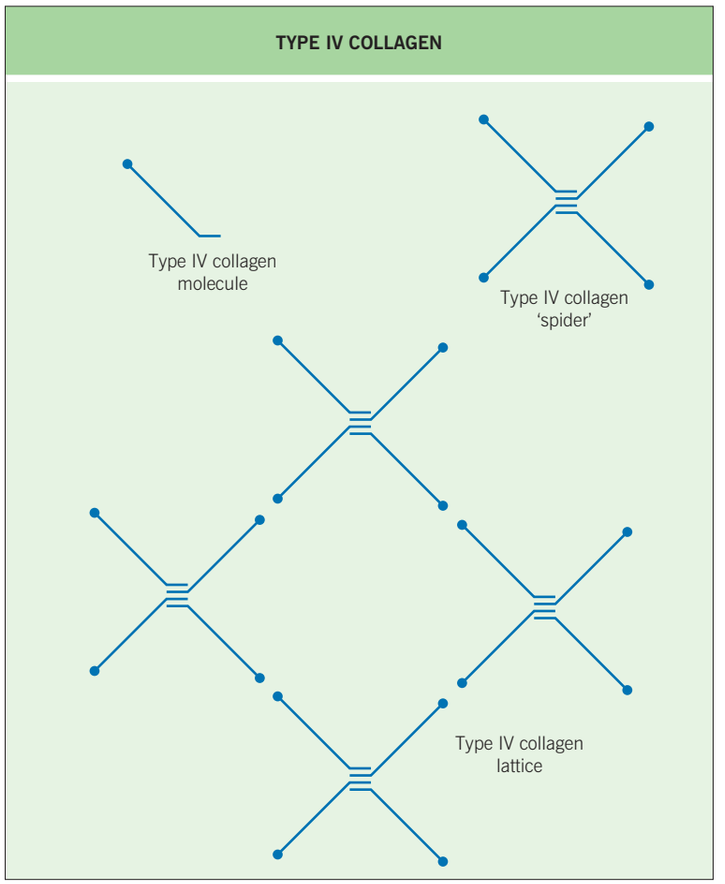

Fig. 28.5 Type IV collagen. A monomer, a tetramer "spider" and a lattice are depicted. The latter results from the aggregation of type IV collagen molecules.

Nidogen

Nidogen (entactin) is a 150 kDa glycoprotein localized to the lamina densa of basement membranes, where it links networks of type IV collagen and various laminin isoforms (Fig. 28.6)[1]. By rotary shadowing, nidogen has the shape of a dumbbell[1]. Nidogen binds laminin isoforms containing the γ1-subunit (e.g. laminins 111, 311 and 511; see Table 28.3) with high affinity. More specifically, the G3 domain at the carboxy terminus of nidogen binds the cysteine-rich, epidermal growth factor-like repeat in domain III of the γ1-subunit[34]. In turn, the G2 domain at the amino terminus of nidogen binds with high affinity to type IV collagen. In addition to binding type IV collagen, complexes of nidogen and laminin can also bind the core protein of heparan sulfate proteoglycan and fibulins 1 and 2. Nidogen is thought to stabilize various macromolecules in the lamina densa. A second form of nidogen (nidogen 2) that has ~45% identity with classic nidogen has been identified[48]. Nidogen 2 is thought to link fibulins to heparan sulfate proteoglycans as well as to types I and IV collagen. No autoimmune or inherited blistering diseases have been linked to nidogen. Interestingly, mice engineered to lack nidogen 1 show no overt abnormalities; they have basement membranes that appear to be normal and they are fertile.

Heparan Sulfate Proteoglycans

Heparan sulfate proteoglycans (HSPGs) are a diverse group of macromolecules that are ubiquitous components of basement membranes. They consist of a central core protein that is lined with laterally emanating glycosaminoglycans in a so-called "bottle-brush" configuration[1] (see Ch. 95). Different basement membranes contain HSPGs of various types and configurations, with perlecan representing the best-characterized basement membrane HSPG. HPSGs can interact with various components of the lamina densa (e.g. type IV collagen, nidogen; see Fig. 28.6) and also self-polymerize to contribute to the overall matrix of the basement membrane proper. The high sulfate content of HSPGs confers an overall negative charge to basement membranes and thereby restricts the permeability of these matrices. By immunoelectron microscopy, HSPGs are found within, just above, and just below the lamina densa of the epidermal basement membrane[49].

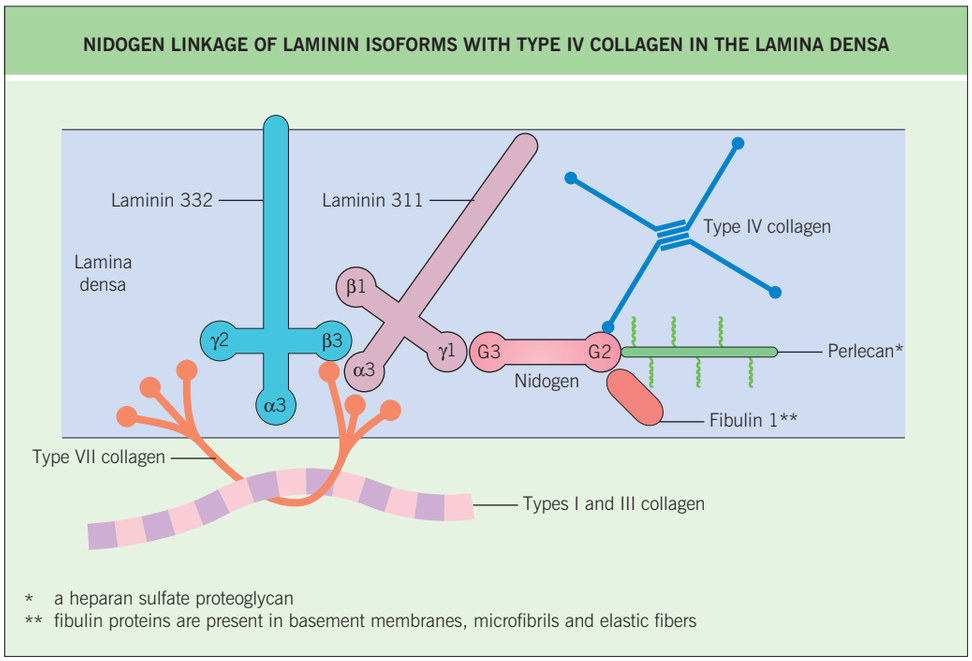

Fig. 28.6 Nidogen linkage of laminin isoforms with type IV collagen in the lamina densa. Nidogen binds the γ-subunit of laminin 311 (formerly laminin 6), linking it to networks of type IV collagen, heparan sulfate proteoglycans, and fibulins. Laminin 332 (formerly laminin 5), which lacks the γ-domain required for nidogen binding, is stably bound to the basement membrane via a covalent association with the branch points of the short arms of laminin 311. Note that this figure is not drawn to scale.

ANCHORING FIBRILS AND THE SUBLAMINA DENSA REGION

Type VII Collagen

Type VII collagen is restricted to the basement membrane of stratified squamous epithelia, where it localizes to the sublamina densa in the upper papillary dermis[1]. It is the major component of anchoring fibrils and consists of three identical α-chains, each with a molecular weight of approximately 290 kDa[50]. At its amino terminus, it contains a large globular non-collagenous domain termed NC1. A smaller non-collagenous domain termed NC2 lies at its carboxy terminus (see Ch. 95).

The assembly of anchoring fibrils initiates when NC2 "tails" of individual type VII collagen molecules align in an antiparallel fashion and unite via disulfide bonds[1]. Once these tail-to-tail dimers form, the NC2 domain is proteolytically cleaved, leaving a long thread-like macromolecule characterized by a central rod with large globular NC1 domains at each end. Newly formed type VII collagen dimers then aggregate laterally with other dimers to form bundles resembling "wheat-stacks", which are termed anchoring fibrils (see Fig. 28.2). The aggregated globular NC1 domains in anchoring fibrils are free to bind matrix elements in basement membranes of stratified squamous epithelia.

Ultrastructural studies have suggested that the globular NC1 domains of type VII collagen molecules bind the lamina densa at one end and either loop back into the lamina densa or connect to electron-dense elements in the sublamina densa region termed anchoring plaques (see Fig. 28.2). More recently, it has been suggested that anchoring plaques are actually portions of lamina densa that have "dropped out" and fallen into the sublamina densa region as a consequence of basement membrane remodeling[51]. On a molecular level, specific subdomains within the NC1 domains of type VII collagen demonstrate affinity for type I fibrillar collagen in the dermis as well as type IV collagen in the lamina densa (and anchoring plaques)[52,53]. Type VII collagen also interacts with laminin 332 as outlined in Table 28.3[38], and the network of looping bands and tethers formed by anchoring fibrils connects the lamina densa with a series of fibrillar elements in the sublamina densa region.

The gene encoding type VII collagen, *COL7A1*, contains 118 exons but is compact due to its extremely small introns. Mutations in *COL7A1* cause both dominant and recessive forms of dystrophic EB[54] (see Ch. 32). Patients with recessive dystrophic EB typically have mutations that result in premature termination codons, nonsense-mediated mRNA decay, and no detectable type VII collagen mRNA or protein. Accordingly, these patients have no anchoring fibrils in their epidermal basement membrane and manifest extreme skin fragility, mutilating scars and an increased risk for cutaneous squamous cell carcinomas. Because carriers of recessive dystrophic EB harbor only one mutant allele (that is, for the reasons outlined above, "silent"), sufficient amounts of type VII collagen are derived from the normal allele to maintain basement membrane integrity and a normal skin phenotype. In contrast, patients with dominant dystrophic EB usually have a missense mutation in one *COL7A1* allele that creates a dominant-negative effect on protein derived from the patient's other, normal *COL7A1* allele. Most dominant-negative *COL7A1* mutations result in glycine substitutions at critical points in the collagenous portion of type VII collagen. These abnormal proteins are incorporated (together with normal α-chains) into type VII collagen trimers and disrupt their function. Consequently, patients with dominant dystrophic EB produce abnormal-appearing and/or reduced numbers of anchoring fibrils and demonstrate a blistering phenotype that is usually less severe than that seen in patients with recessive dystrophic EB.

EB acquisita (EBA) is an acquired autoimmune subepidermal bullous disease in which blister formation occurs in the sublamina densa region, usually as the result of mechanical trauma[55]. A 290 kDa protein in extracts of lamina densa/dermis was identified as the autoantigen in EBA. Subsequent studies showed that this "EBA antigen" was type VII collagen and that IgG from most EBA patients binds four immunodominant epitopes within the NC1 domain of this protein[56,57].

It has been postulated that such autoantibodies disrupt the assembly of type VII collagen into anchoring fibrils and/or interfere with the interaction of type VII collagen with other extracellular matrix molecules, resulting in skin fragility and the development of non-inflammatory, trauma-induced subepidermal blisters. Passive transfer of anti-type VII collagen IgG into mice can elicit lesions with clinical, histologic and immunopathologic features like those seen in patients with EBA[58,59]. Of note, the bullous eruption of systemic lupus erythematosus (SLE), which tends to be more inflammatory, is also caused by antibodies directed against type VII collagen. IgG targeting the same four immunodominant epitopes that are recognized in EBA has been identified in patients with the bullous eruption of SLE[57].

Microfibrils

By transmission electron microscopy, elastic fibers have two distinct components: (1) an amorphous, non-banded component that consists of the protein elastin; and (2) a microfibrillar component that has a regular diameter of 10–12 nm and consists primarily of fibrillins, which are associated with other proteins such as microfibril-associated glycoproteins, fibulins, and latent transforming growth factor (TGF)-β-binding proteins (see Ch. 95). In the papillary dermis, microfibrillar elements insert vertically into the lamina densa and

comprise what has classically been referred to as oxytalan fibers. At their inferior aspect, oxytalan fibers merge with microfibrillar elements oriented parallel to the skin's surface. These parallel microfibrillar elements contain some amorphous component, and they have been designated elaunin fibers. The network of oxytalan and elaunin fibers is contiguous with elastic fibers within the reticular dermis. The latter consist of microfibrillar elements associated with substantial amounts of amorphous material. The gradient of increasing amorphous component deeper in the dermis has been suggested to reflect maturation of elastic fibers in a top-down manner within the skin.

Microthread-like Fibers

Linkin is an 80 kDa protein localized to the upper papillary dermis just beneath the epidermal basement membrane[33]. Linkin is the major component of a microthread-like filamentous network within the sublamina densa that appears to interconnect microfibrillar bundles, anchoring fibrils and interstitial collagen fibers.

Basement Membrane Remodeling

Though the epidermal basement membrane is thought of as a physical barrier between cells of the epidermis and the underlying dermis, this matrix (like other basement membranes) is a dynamic structure that is constantly remodeled. For example, the epidermal basement membrane is routinely penetrated by Langerhans cells trafficking into and out of the epidermis under normal physiologic conditions. Lymphocytes also cross the epidermal basement membrane in both inflammatory and neoplastic diseases. However, other non-immune and non-malignant cells rarely cross this ultrastructural barrier. Indeed, an absence of basement membranes in tumors correlates with malignancy, and propensity for metastasis. Metalloproteinases expressed by immune or malignant cells enable penetration of basement membranes. Such proteases also have important functions in remodeling epidermal (and other) basement membranes during morphogenesis, development and various physiologic processes (e.g. modification of mammary epithelia during pregnancy and lactation). In addition, metalloproteinases play a key role in alterations (e.g. thinning) of the epidermal basement membrane in aged and photoaged skin.

THE EPIDERMAL BASEMENT MEMBRANE IN BULLOUS DISEASES

Patients with acquired immunobullous diseases have autoantibodies directed against autoantigens in the epidermis (e.g. pemphigus) or epidermal basement membrane (e.g. various forms of pemphigoid). Autoantibodies from such patients were used to establish the identity of many autoantigens and demonstrate that individuals with a given disease have (in most instances) autoantibodies directed against the same protein. Patient autoantibodies were also used to isolate cDNAs corresponding to genes encoding autoantigens. These autoantigens were often recognized as important structural proteins in the skin, and some of the genes encoding them were found to harbor mutations in patients with various forms of EB. Hence, acquired or inherited alterations in key adhesion proteins in the skin result in disease phenotypes characterized by blister formation (see Table 28.2). The biology of the epidermal basement membrane in patients with various autoimmune or inherited blistering diseases is briefly summarized below. Further details are provided in Chapters 30, 31 and 32.

Autoimmune Subepidermal Blistering Diseases

The autoantigens recognized in patients with well-characterized subepidermal immunobullous diseases are outlined in Table 28.4. These disorders were once only partially classified based on their clinical and histologic features, but they are now defined by the autoantigen that is targeted (Fig. 28.7). In addition to improving diagnostic capabilities,

WELL-CHARACTERIZED SUBEPIDERMAL IMMUNOBULLOUS DISEASES

Disease	Antigen	Size (kDa)	Localization
Bullous pemphigoid	BPAG1 BPAG2	230 180	Intracytoplasmic plaque of hemidesmosomes Hemidesmosome-anchoring filament complexes
Pemphigoid gestationis	BPAG2	180	Hemidesmosome-anchoring filament complexes

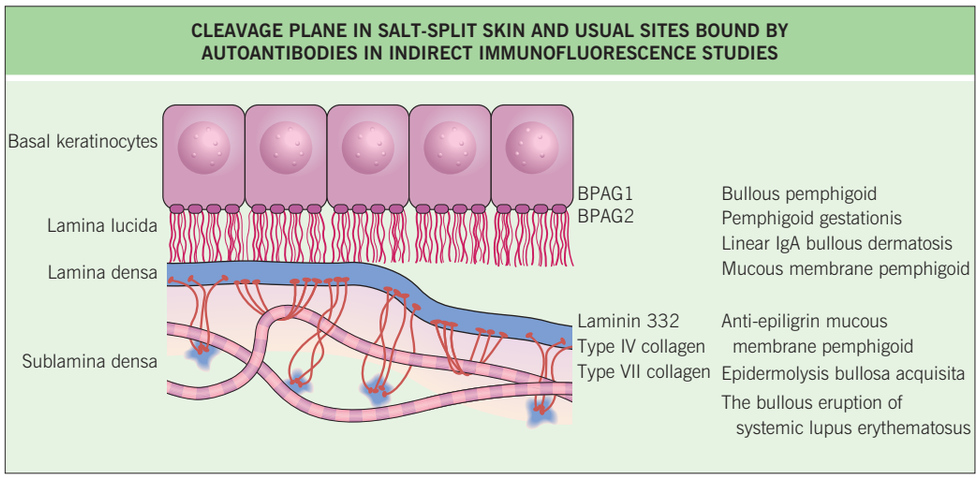

Fig. 28.8 Cleavage plane in salt-split skin and usual sites bound by autoantibodies in indirect immunofluorescence studies. The cleavage plane in 1 M NaCl salt-split skin is in the lower portion of the lamina lucida. Circulating autoantibodies from patients with various subepidermal immunobullous diseases bind to different sites, e.g. the epidermal versus dermal side of the split.

profiling patients' autoantibodies for classification of their bullous diseases has led to an ever-growing appreciation of the polymorphic nature of these conditions. For example, while EBA was once largely considered to be a diagnosis of exclusion for a rare, acquired skin fragility disorder, it is now recognized as a disease that may clinically resemble "classic" BP or MMP as well as dystrophic EB.

Advances in our understanding of the epidermal basement membrane, the proteins that comprise this matrix, and how this ultrastructural unit is targeted in various immunobullous diseases have also led to the development of a number of immunopathologic techniques that have great utility in clinical dermatology. One example of these techniques is the utilization of 1 M NaCl salt-split skin (cleaved within the lamina lucida) in immunofluorescence (IF) microscopy studies of patient sera and skin[60–62] (Fig. 28.8; Table 28.5). Indirect IF studies of salt-split skin first gained widespread attention when it was shown that patients with "inflammatory" EBA could be distinguished from those with "classic" BP in that IgG anti-basement membrane autoantibodies from these patients bound dermal and epidermal sides, respectively, of salt-split skin[60]. When it was found that IgG anti-basement membrane autoantibodies from patients with one form of MMP bound the dermal side of salt-split skin yet showed no reactivity to type VII collagen, the search began for a previously unrecognized autoantigen in the epidermal basement membrane[39]. This autoantigen, specific to patients with this form of MMP (anti-epiligrin cicatricial pemphigoid), is now known to be laminin 332[39,40].

For individuals who lack detectable circulating anti-basement membrane autoantibodies, the direct salt-split skin technique has been applied to studies of patient skin[61,62] (see Table 28.5). This approach has, in many instances, replaced the need for direct immunoelectron microscopy. In this technique, skin from a patient is split in the laboratory with 1 M NaCl then studied by direct IF microscopy to determine where immunoreactants localize *in situ*. Patients with EBA and anti-epiligrin MMP have deposits of immunoreactants (i.e. IgG and C3) that localize to the dermal side of salt-split skin. In contrast, patients with BP have deposits of IgG that localize to the epidermal (or both) side(s) of the split within the lamina lucida created by this treatment. Interestingly, patients with BP may have *in situ* deposits of C3 that exclusively localize to the dermal side of their salt-split skin. Accordingly, direct IF mapping studies of patient salt-split skin are most accurate when based on the localization of IgG rather than C3.

LOCALIZATION OF IMMUNOREACTANTS IN IMMUNOFLUORESCENCE MICROSCOPY STUDIES OF 1 M NaCl SALT-SPLIT SKIN

INDIRECT IMMUNOFLUORESCENCE MICROSCOPY STUDIES

Disease	Localization
Bullous pemphigoid	IgG characteristically epidermal; occasionally both sides with higher titer against the epidermal side
Pemphigoid gestationis	IgG characteristically epidermal; occasionally both sides with higher titer against the epidermal side
Linear IgA bullous dermatosis	IgA characteristically epidermal; rare patients with "IgA EBA" bind the dermal side
MMP	IgG characteristically epidermal; occasionally both sides with higher titer against the epidermal side
Anti-epiligrin MMP	IgG against dermal side of substrate
EB acquisita	IgG against dermal side of substrate

Anti-epiligrin MMP	Dermal	Dermal
EB acquisita	Dermal	Dermal

*See Schmidt & Zillikens[20] for specific information about these incompletely characterized immunobullous diseases.
†These studies utilize patient skin after it is split with 1 M NaCl.

Table 28.5 Localization of immunoreactants in immunofluorescence microscopy studies of 1 M NaCl salt-split skin. EB, epidermolysis bullosa; MMP, mucous membrane (cicatricial) pemphigoid.

Inherited Subepidermal Blistering Diseases

Advances in the understanding of the epidermal basement membrane structure and composition paralleled (and in many instances were derived from) studies of patients with various forms of EB[63] (Table 28.6; see Fig. 28.7). Moreover, advances in cutaneous immunopathology facilitated the study of patients with EB. For example, rather than relying upon transmission electron microscopy to map the plane of blister formation in the skin of patients with EB, investigators garnered this information from IF microscopy studies using antibodies directed against known structural components of the epidermal basement membrane. For example, because patients with EB simplex display cleavage within the cytoplasm of their basal keratinocytes, BPAG1 and type IV collagen localize to the dermal side of their blistered skin. In patients with various forms of junctional EB, BPAG1 localizes to the epidermal side of blistered skin while type IV collagen remains attached to the dermis. Lastly, in patients with dystrophic EB, both BPAG1 and type IV collagen localize to the epidermal side of the cleavage plane, which sits within the sublamina densa region.

REPRESENTATIVE FORMS OF EPIDERMOLYSIS BULLOSA (EB)			
Disease	**Gene**	**Protein**	**Localization**
EB simplex	*KRT5*	Keratin 5	Intermediate filament cytoskeleton of basal keratinocytes
	KRT14	Keratin 14	Intermediate filament cytoskeleton of basal keratinocytes
EB simplex with muscular dystrophy EB simplex, Ogna EB simplex with pyloric atresia	*PLEC1*	Plectin	Intracytoplasmic plaque of hemidesmosomes
Recessive EB simplex	*DST*	BP230	Intracytoplasmic plaque of hemidesmosomes
Junctional EB, non-Herlitz	*COL17A1*	BPAG2 (type XVII collagen)	Hemidesmosome-anchoring filament complexes
	ITGB4	β_4 integrin	Hemidesmosome-anchoring filament complexes
	LAMA3	Laminin 332, α3 subunit	Lamina lucida–lamina densa interface
	LAMB3	Laminin 332, β3 subunit	Lamina lucida–lamina densa interface
	LAMC2	Laminin 332, γ2 subunit	Lamina lucida–lamina densa interface
Junctional EB with pyloric atresia	*ITGA6*	α_6 integrin subunit	Hemidesmosome-anchoring filament complexes
	ITGB4	β_4 integrin subunit	Hemidesmosome-anchoring filament complexes
Junctional EB, Herlitz	*LAMA3*	Laminin 332, α3 subunit	Lamina lucida–lamina densa interface
	LAMB3	Laminin 332, β3 subunit	Lamina lucida–lamina densa interface
	LAMC2	Laminin 332, γ2 subunit	Lamina lucida–lamina densa interface
Dominant dystrophic EB	*COL7A1*	Type VII collagen	Anchoring fibrils
Recessive dystrophic EB	*COL7A1*	Type VII collagen	Anchoring fibrils

Table 28.6 Representative forms of epidermolysis bullosa (EB). BPAG, bullous pemphigoid antigen.

In addition to mapping the plane of blister formation in patients with various forms of EB for purposes of classification, studies of the immunoreactivity and ultrastructure of skin from EB patients have provided key insights regarding disease pathophysiology. For example, monoclonal antibodies against various subunits of laminin 332 generally fail to bind the skin of patients with junctional EB-Herlitz. Similarly, monoclonal antibodies against BPAG2 (type XVII collagen) almost always fail to bind the skin of patients with junctional EB-non-Herlitz. Beyond the diagnostic utility of these observations was the implication that these (and other) inherited bullous diseases developed as a consequence of mutations in genes encoding structural proteins in the epidermal basement membrane (rather than unrestrained activity of proteases resulting in degradation of the epidermal basement membrane). Consequently, skin samples from patients with EB have been studied extensively with panels of antibodies against constituents of the epidermal basement membrane in the hope of finding "candidate genes" that might harbor pathogenic mutations. Such IF microscopy "screens" can guide molecular genetic studies. Hence, a patient with junctional EB who lacks integrin subunit β_4 in the epidermal basement membrane would be screened for mutations in *ITGB4* before genes responsible for other forms of junctional EB (e.g. *COL17A1*, *LAMA3*, *LAMB3*, *LAMC2*, *ITGA6*) were analyzed[64].

SUMMARY

The basement membranes of various tissues differ in their ultrastructure, biochemical composition and biological function. The epidermal basement membrane contains many highly specialized structures that are largely tissue-specific. Cell–matrix interactions between keratinocytes and the epidermal basement membrane provide key positional and environmental clues that directly modulate tissue morphogenesis, homeostasis, differentiation, wound healing, and acquisition of specialized functions.

Pemphigus 29

Masayuki Amagai

Synonyms: ■ Fogo selvagem: endemic pemphigus foliaceus; Brazilian pemphigus ■ Pemphigus erythematosus: Senear–Usher syndrome ■ IgA pemphigus: intercellular IgA dermatosis; intraepidermal neutrophilic IgA dermatosis; intercellular IgA vesiculopustular dermatosis ■ Paraneoplastic pemphigus: paraneoplastic autoimmune multiorgan syndrome

Key features

- Pemphigus is a group of autoimmune blistering diseases of the skin and mucous membranes that is characterized by:
  - histologically, intraepidermal blisters due to the loss of cell–cell adhesion of keratinocytes
  - immunopathologically, the finding of *in vivo* bound and circulating IgG autoantibodies directed against the cell surface of keratinocytes
- Pemphigus is divided into three major forms: pemphigus vulgaris, pemphigus foliaceus and paraneoplastic pemphigus
- The functional inhibition of desmogleins, which play an important role in cell–cell adhesion of keratinocytes, by IgG autoantibodies results in blister formation
- Patients with pemphigus vulgaris and pemphigus foliaceus have IgG autoantibodies against desmoglein 3 and desmoglein 1, respectively, while patients with paraneoplastic pemphigus have IgG autoantibodies against plakin molecules in addition to autoantibodies against desmogleins
- IgA autoantibodies directed against the keratinocyte cell surface define IgA pemphigus, the pathophysiology of which is yet to be clarified

INTRODUCTION

The term pemphigus stems from the Greek *pemphix*, meaning blister or bubble, and it describes a group of chronic blistering skin diseases in which autoantibodies are directed against the cell surface of keratinocytes, resulting in the loss of cell–cell adhesion of keratinocytes through a process called acantholysis[1]. Pemphigus can be divided into three major forms: pemphigus vulgaris, pemphigus foliaceus and paraneoplastic pemphigus (Table 29.1).

Pemphigus vulgaris and pemphigus foliaceus are the originally characterized, classic forms of pemphigus. All patients with pemphigus vulgaris have mucosal membrane erosions, and more than half will also have cutaneous blisters and erosions. The blisters of pemphigus vulgaris develop in the deeper portion of the epidermis, just above the basal cell layer. Patients with pemphigus foliaceus have only cutaneous involvement without mucosal lesions, and the splits occur in the superficial part of the epidermis, mostly at the granular layer. Pemphigus vegetans is a variant of pemphigus vulgaris, and pemphigus erythematosus and fogo selvagem represent localized and endemic variants of pemphigus foliaceus, respectively.

More recently, paraneoplastic pemphigus was recognized as a disease distinct from the classic forms of pemphigus[2]. Patients with paraneoplastic pemphigus have a known or occult associated neoplasm, usually of lymphoid tissue. Painful, severe oral and conjunctival erosions are a prominent feature of paraneoplastic pemphigus.

IgA pemphigus is characterized by IgA, but not IgG, autoantibodies directed against keratinocyte cell surfaces and is divided into two major subtypes:

- intraepidermal neutrophilic (IEN) type, with pustule formation throughout the entire epidermis
- subcorneal pustular dermatosis (SPD) type, with pustules primarily in the upper epidermis.

History

The modern history of pemphigus began with the discovery by Beutner and Jordon in 1964 of circulating antibodies directed against the cell surface of keratinocytes in the sera of pemphigus vulgaris patients[3] (Fig. 29.1). This was followed by the finding of *in vivo* IgG deposition on the cell surface of keratinocytes in patients' skin. These findings formed the basis of our understanding of pemphigus as a tissue-specific autoimmune disease of the skin and mucous membranes. In the late 1970s and early 1980s, pemphigus autoantibodies were shown to be pathogenic, i.e. they could induce blister formation in skin organ-culture systems as well as by passive transfer of patients' IgG to neonatal mice[4]. In the mid and late 1980s, the target antigens of pemphigus were characterized by immunochemical methods, such as immunoprecipitation and immunoblotting[5]. In the early 1990s, the isolation of cDNA for pemphigus antigens demonstrated that pemphigus is an anti-cadherin autoimmune disease[6].

EPIDEMIOLOGY

The prevalence of pemphigus vulgaris and pemphigus foliaceus in men and women is approximately equal. The mean age of onset of disease is 50 to 60 years, although the range is broad and disease arising in the elderly and in children has been described. Pemphigus can be found all over the world. Although limited data are available regarding the incidence of pemphigus, in general it ranges from 0.76 to 5 new cases per million per year. However, the incidence is much higher (16 to 32 cases per million per year) in those of Jewish ancestry. Occasionally, this ancestry may not be readily apparent, as in the Hispanic descendants of the *conversos*, who currently reside in the southwestern USA. In most countries, pemphigus vulgaris is more common than pemphigus foliaceus; exceptions include Finland, Tunisia and Brazil. For example, in Japan (incidence of pemphigus: 3.5 cases per million per year), the ratio of pemphigus vulgaris to pemphigus foliaceus is 2:1. In France (incidence: 1.7 cases per million per year), pemphigus vulgaris accounts for the majority of all cases (73%), as it does in Bulgaria. In contrast, in Finland (incidence: much lower at 0.76 cases per million per year) and in Tunisia (incidence: 6.7 cases per million per year), pemphigus foliaceus is twice as common as pemphigus vulgaris. More interestingly, the female-to-male ratio in Tunisia is 4:1, and the incidence is higher in young women ages 25 to 34 years (15.5 cases per million per year). In addition to Brazil, Tunisia may have endemic foci of pemphigus foliaceus (see below).

CLASSIFICATION OF PEMPHIGUS
• Pemphigus vulgaris
• Pemphigus vegetans
• Pemphigus foliaceus
• Pemphigus erythematosus: localized
• Fogo selvagem: endemic
• Herpetiform pemphigus
• Drug-induced pemphigus
• Paraneoplastic pemphigus
• IgA pemphigus

Table 29.1 Classification of pemphigus.

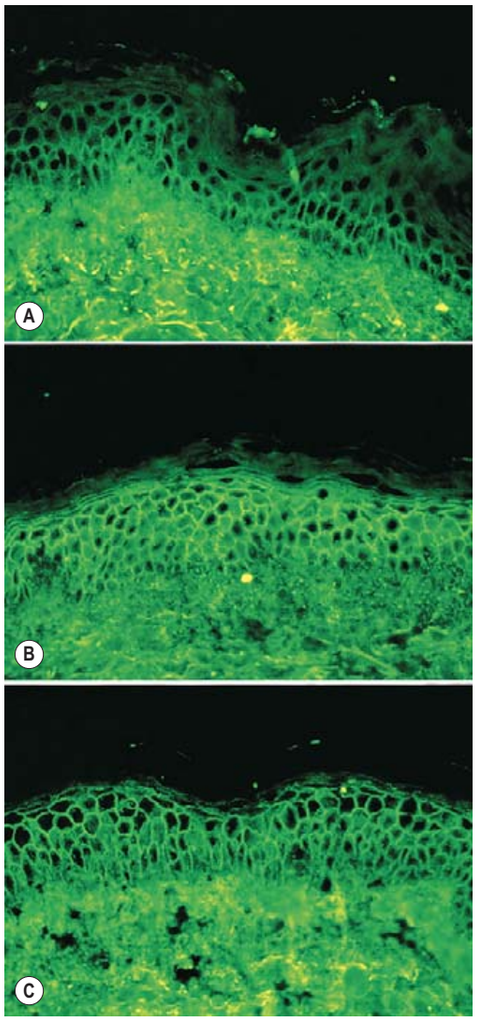

Fig. 29.1 Indirect immunofluorescence of pemphigus sera with normal human epidermis as a substrate. The hallmark of pemphigus is the finding of IgG autoantibodies directed against the cell surface of keratinocytes. **A** Pemphigus vulgaris sera containing anti-desmoglein 3 (anti-Dsg3) IgG alone stain the cell surfaces in the lower epidermis. **B** Pemphigus vulgaris sera containing both anti-Dsg3 IgG and anti-Dsg1 IgG stain the cell surfaces throughout the epidermis. **C** Pemphigus foliaceus sera, which contain only anti-Dsg1 IgG, stain the cell surfaces throughout the epidermis, but more intensely in the superficial layers.

Fogo Selvagem

Patients with fogo selvagem are clinically, histologically and immunopathologically similar to patients with sporadic pemphigus foliaceus. However, fogo selvagem occurs in an endemic fashion in certain regions of Brazil and is thought to be caused by an environmental factor(s)[7]. Unlike sporadic pemphigus foliaceus, which is a disease of mostly middle-aged and older patients, fogo selvagem affects young adults and children of either sex or any race who are exposed to the local ecology in rural areas, and the incidence gradually decreases as the area is developed. The majority of patients live close to rivers and within the 10–15 km flying range of black flies (*Simulium* spp.), which may be the vector that precipitates the disease. There is also a high frequency of hematophagous insects (bedbugs and kissing bugs) in the homes of patients with fogo selvagem.

Fogo selvagem frequently occurs in genetically related family members, although it is not contagious, and, to date, spread by blood products or body fluids has not been documented. In rural Brazil, the ratio of pemphigus foliaceus to pemphigus vulgaris is a remarkable 17:1. The prevalence in some rural areas of Brazil is as high as 3.4% of the population[8]. Furthermore, in these areas, more than 50% of normal individuals have anti-desmoglein 1 (anti-Dsg1) IgG autoantibodies, and it has been shown that the onset of the disease is preceded by a sustained antibody response consisting of non-pathogenic IgG1 and IgG4 antibodies. In certain genetically predisposed individuals, predominant IgG4 antibodies directed against the N-terminal extracellular EC1 and EC2 domains are responsible for inducing disease[9]. Certainly, fogo selvagem provides a fascinating model for understanding the pathophysiologic and immunologic mechanisms involved in triggering an autoimmune response against skin components.

PATHOGENESIS

Pathogenic Autoantibodies in Pemphigus

The hallmark of pemphigus is the finding of IgG autoantibodies against the cell surface of keratinocytes (see Fig. 29.1)[3]. The pemphigus autoantibodies found in patients' sera play a primary pathogenic role in inducing the loss of cell adhesions between keratinocytes, and subsequent blister formation. Neonates of mothers with pemphigus vulgaris may have a transient disease caused by maternal IgG that crosses the placenta. As maternal antibody is catabolized, the disease subsides. IgG fractions from patients can induce blister formation in the absence of complement or inflammatory cells in a skin organ-culture system[4]. Furthermore, passive transfer of patients' IgG to neonatal mice results in blisters in the mice with typical histologic findings[4]. Even monovalent Fab' fragments of IgG from patients with endemic pemphigus foliaceus are sufficient to cause blisters in neonatal mice, indicating complement activation and surface cross-linking may not be relevant in keratinocyte detachment[10]. Although it was shown that pemphigus IgG causes release of plasminogen activator resulting in acantholysis in a skin organ-culture system[11], pemphigus IgG caused blisters to the same degree in plasminogen activator knockout mice and control mice, demonstrating that plasminogen activator is not absolutely required for antibody-induced blisters[12].

The direct and indirect immunofluorescent (IF) staining pattern of paraneoplastic pemphigus differs from that of classic forms of pemphigus. In perilesional skin, direct IF shows deposition of IgG and the third component of complement (C3) on epidermal cell surfaces as well as variably along the basement membrane zone. Unlike classic forms of pemphigus, in which autoantibodies only bind to stratified squamous epithelia, as detected by indirect IF, autoantibodies in paraneoplastic pemphigus also react with simple or transitional epithelia such as urinary bladder epithelium. The latter can be used to differentiate paraneoplastic pemphigus from classic pemphigus.

Desmogleins as Pemphigus Antigens

Immunoelectron microscopy localized both pemphigus vulgaris and pemphigus foliaceus antigens to the desmosomes, the most prominent cell–cell adhesion junctions in stratified squamous epithelia[13]. Immunochemical characterization of pemphigus antigens by immunoprecipitation or immunoblotting with extracts from cultured keratinocytes or epidermis demonstrated that the pemphigus vulgaris and foliaceus antigens were 130 kDa and 160 kDa transmembrane glycoproteins, respectively (Table 29.2)[6,14]. By comparative immunochemical studies using anti-Dsg1 monoclonal and polyclonal antibodies, the 160 kDa protein recognized by pemphigus foliaceus sera was subsequently shown to be identical to Dsg1. An 85 kDa plaque protein, plakoglobin, was co-immunoprecipitated with the 130 kDa and 160 kDa pemphigus antigens, demonstrating that plakoglobin forms a molecular complex with pemphigus vulgaris and foliaceus antigens[15].

Molecular cloning of cDNA encoding Dsg1 and pemphigus vulgaris antigens indicated that both molecules were members of the cadherin supergene family[6,16]. Thus, pemphigus was discovered to be an anti-cadherin autoimmune disease. The pemphigus vulgaris antigens were

termed desmoglein 3 (Dsg3). The basic pathophysiology of pemphigus is as follows: autoantibodies inhibit the adhesive function of desmogleins and lead to the loss of the cell–cell adhesion of keratinocytes, resulting in blister formation.

Cadherins are a family of calcium-dependent cell–cell adhesion molecules that play an important role in the formation and maintenance of complex tissue integrity[17]. Based on sequence similarity, cadherins have two major subgroups, classic cadherins (e.g. E-, P-, N-cadherins) and desmosomal cadherins (desmogleins and desmocollins). All members of the cadherin family contain conserved repeated amino acid sequences (cadherin repeats) with calcium-binding motifs in their extracellular domains (Fig. 29.2). When classic cadherins were introduced by gene transfection into non-adhesive mouse fibroblast L cells, the cells acquired strong cell adhesion activity mediated by a homophilic type of interaction. Cadherins require their well-conserved cytoplasmic domains in order to associate with the plaque proteins, α-catenin, β-catenin and plakoglobin, which mediate and regulate binding to the cytoskeleton network. As a consequence of these interactions, cadherins produce strong cellular adhesion and morphologic changes in the cells. Cadherin molecules form dimers as their functional unit, with the distal extracellular domain (EC1) of the cadherin from one cell binding to the same region of a second cadherin from an opposing cell[18] (Fig. 29.3).

Based on morphologic and biochemical criteria, two major types of adhering junctions of epithelial cells are commonly distinguished: adherens junctions and desmosomes (see Fig. 29.3)[19]. The adherens junction anchors bundles of actin microfilaments and contains classic cadherins as its transmembrane components and α-catenin, β-catenin and plakoglobin as its cytoplasmic components. In contrast, the desmosome anchors intermediate filaments like keratins and contains desmosomal cadherins as its transmembrane components and plakoglobin, plakophilin and desmoplakin as its cytoplasmic components. In general, adherens junctions mediate quick but weak cellular adhesion, whereas desmosomes mediate slow but strong cellular adhesion.

Desmogleins have four cadherin repeats in their extracellular domain, as do classic cadherins, and they have unique repeats of 29 ± 1 amino acid residues in their intracytoplasmic domain (see Fig. 29.2). Desmogleins have four isoforms (Dsg1–4). Expression of Dsg1 and Dsg3 is basically restricted to stratified squamous epithelia, where blisters are formed in pemphigus, while Dsg2 is expressed in all desmosome-possessing tissues, including simple epithelia and myocardium. Dsg4 plays an important adhesive role primarily in hair follicles, and mutations in the *DSG4* gene can lead to abnormal hair development (e.g. localized autosomal recessive hypotrichosis)[20].

Desmocollins are another group of transmembrane glycoproteins within desmosomes and they have three isoforms (Dsc1–3). Each isoform has two products derived from alternatively spliced mRNA of a single gene. Desmosomes always have desmoglein and desmocollin as a pair, but the exact molecular fashion of their interaction as well as the reason why desmocollin does not compensate for the loss of desmoglein in pemphigus remain to be elucidated.

Plakoglobin and plakophilin, together with β-catenin, are members of the armadillo family of nuclear and junctional proteins, which are not only simple anchoring molecules but also dynamic regulators of cellular adhesion and proliferation. Desmoplakin is a dumbbell-shaped molecule composed of three domains: a central α-helical coiled-coil rod, flanked by globular carboxyl- and amino-terminal domains that interact with intermediate filaments and armadillo family members, respectively (see Fig. 29.3). Desmoplakin has two products derived from alternatively spliced mRNA of a single gene: desmoplakin I (250 kDa) and II (210 kDa) (see Table 29.2). Desmoplakin, a member of the

Table 29.2 Target antigens in pemphigus. A2ML1, alpha-2-macroglobulin-like-1 protease inhibitor; BPAG1, bullous pemphigoid antigen 1.

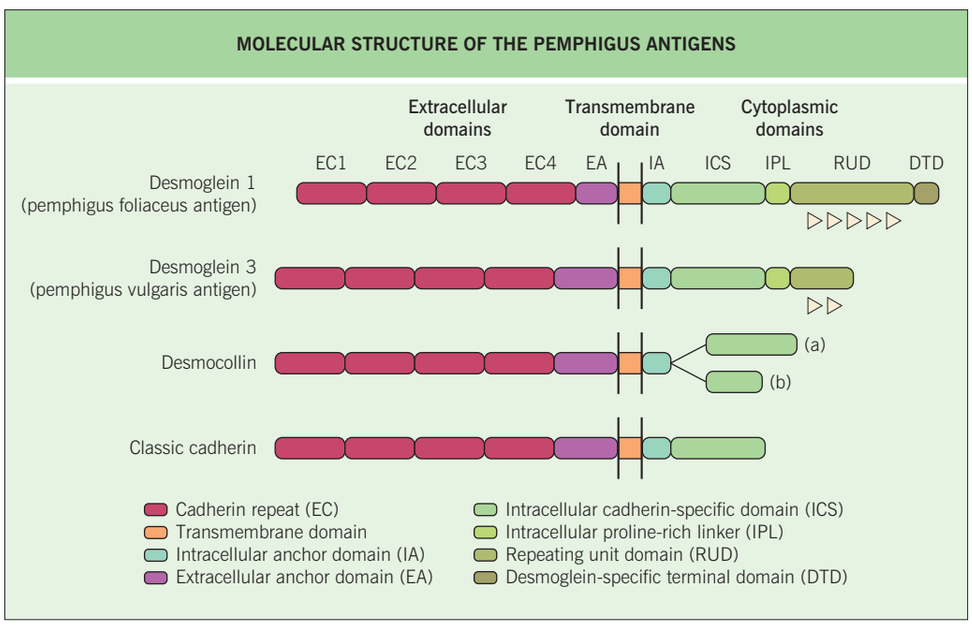

Fig. 29.2 Molecular structure of the pemphigus antigens. The extracellular (EC) region has four cadherin repeats, which have calcium-binding motifs. The intracellular cadherin-specific (ICS) domain is well conserved among cadherins and it is responsible for interactions with β-catenin or plakoglobin (see Fig. 29.3). Desmogleins have their own unique sequences (repeating unit domain or RUD) of repeats of 29 ± 1 residues (arrowheads). Each desmocollin isotype has two products (a and b) derived from alternatively spliced transcripts of a single gene.

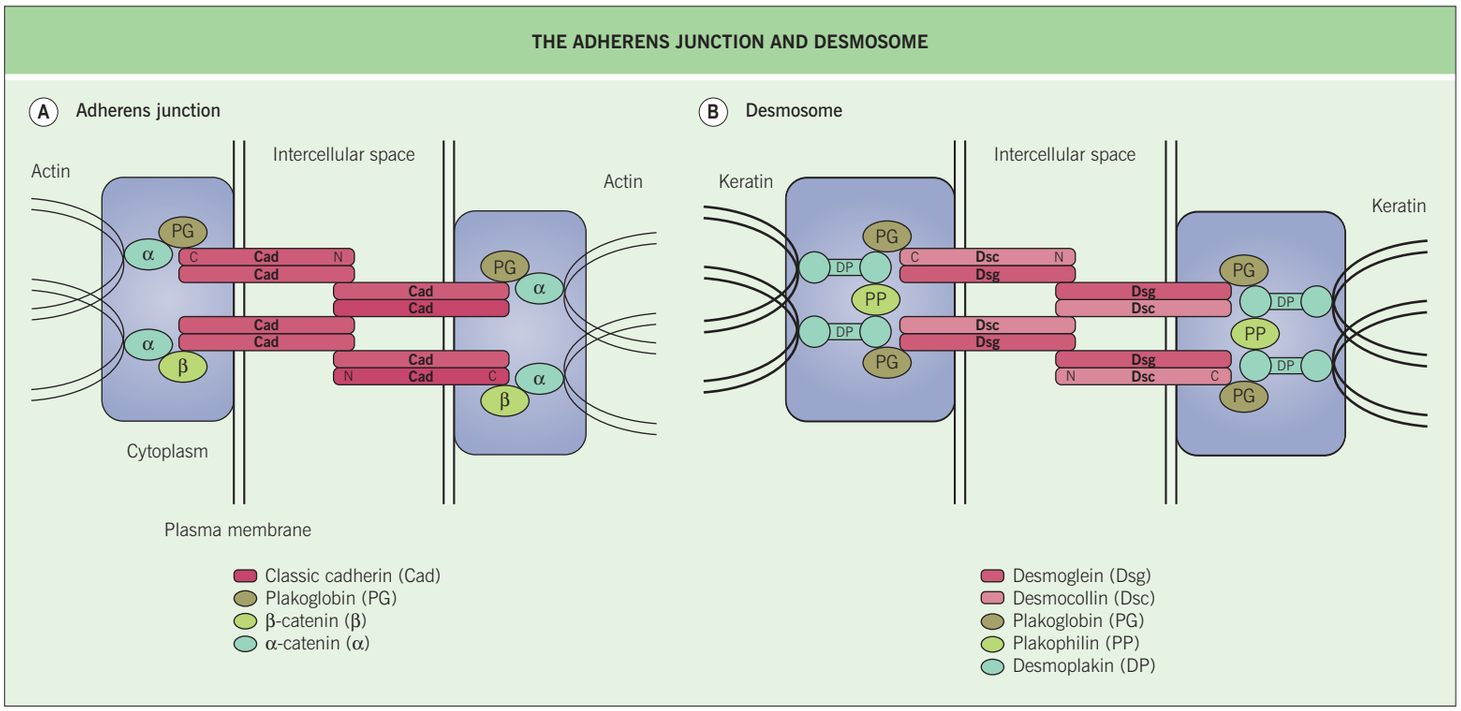

Fig. 29.3 The adherens junction and desmosome. A The adherens junction complex contains classic cadherins as transmembrane constituents and α-catenins, β-catenins and plakoglobin as cytoplasmic constituents. A classic cadherin is directly coupled through its cytoplasmic tail to β-catenin or plakoglobin, which in turn is linked to α-catenin, which binds to actin. **B** The desmosome complex includes desmogleins and desmocollins as transmembrane constituents, and plakoglobin, plakophilin and desmoplakin as cytoplasmic constituents. Desmogleins and desmocollins associate with plakoglobin, which in turn binds to desmoplakin, which links keratin to the membrane. N = amino-terminus; C = carboxy-terminus.

plakin family, plays an important role in the anchorage of the cytoskeleton to filament attachment sites on desmosomes. This intermediate filament-associated plakin family includes bullous pemphigoid antigen 1 (230 kDa), plectin (500 kDa), envoplakin (210 kDa) and periplakin (190 kDa), which are recognized by IgG autoantibodies in paraneoplastic pemphigus.

Compelling evidence has accumulated that IgG autoantibodies against Dsg1 and Dsg3 are pathogenic and play a primary role in inducing the blister formation in pemphigus. Essentially, all patients with pemphigus have IgG autoantibodies against Dsg1 and/or Dsg3, depending on the subtype of pemphigus[21,22]. When anti-desmoglein IgG autoantibodies are removed from the sera of patients with pemphigus vulgaris, pemphigus foliaceus or paraneoplastic pemphigus (by immunoadsorption with recombinant desmoglein proteins), the sera are no longer pathogenic in inducing blister formation[23,24]. Furthermore, anti-desmoglein IgG autoantibodies that have been affinity-purified from pemphigus sera via desmoglein recombinant proteins can cause blisters when injected into neonatal mice[24,25]. Some pemphigus sera react with Dsg4 due to cross-reactivity of a subset of anti-Dsg1 IgG, although Dsg4/Dsg1-cross-reacting IgG has no demonstrable pathogenic effect[26]. IgG autoantibodies against acetylcholine receptors or annexin-like molecules have also been detected, but their pathogenic relevance in pemphigus remains to be determined.

Desmoglein Compensation Theory as Explanation for Localization of Blisters

The sites of blisters in pemphigus vulgaris and foliaceus are explained logically by the desmoglein compensation theory: Dsg1 and Dsg3 compensate for each other when they are coexpressed in the same cell (Fig. 29.4)[27,28]. While patients with pemphigus foliaceus have only anti-Dsg1 IgG autoantibodies, individuals with the mucosal-dominant type of pemphigus vulgaris have only anti-Dsg3 IgG autoantibodies. Those with the mucocutaneous type of pemphigus vulgaris have both anti-Dsg3 and anti-Dsg1 IgG autoantibodies[29]. Of note, the intraepithelial expression pattern of Dsg1 and Dsg3 differs between the skin and mucous membranes. In the skin, Dsg1 is expressed throughout the epidermis, but more intensely in the superficial layers (see Fig. 29.1C), whereas Dsg3 is expressed in the lower portion of the epidermis, primarily in the basal and parabasal layers (see Fig. 29.1A). In contrast to the skin, Dsg1 and Dsg3 are expressed throughout the squamous layer of mucosa, but Dsg1 is expressed at a much lower level than Dsg3 (see Fig. 29.4B)[30].

When sera contain only anti-Dsg1 IgG (which interferes with the function of Dsg1), blisters appear only in the superficial epidermis of the skin because that is the only area in which Dsg1 is present without coexpression of Dsg3. In the unaffected deep epidermis, the presence of Dsg3 compensates for the loss of function of Dsg1. Although the anti-Dsg1 IgG binds to mucosa, no blisters are formed, because of the coexpression of Dsg3. Thus, sera containing only anti-Dsg1 IgG cause superficial blisters in the skin without mucosal involvement, as is seen in patients with pemphigus foliaceus.

When sera contain only anti-Dsg3 IgG, they are inefficient in producing cutaneous blisters because coexpressed Dsg1 compensates for the impaired function of Dsg3, resulting in no, or only limited, skin lesions. However, in the mucous membranes, Dsg1 cannot compensate for the impaired Dsg3 function because of its low expression. Therefore, sera containing only anti-Dsg3 IgG cause oral erosions without apparent skin involvement, as is seen in patients with the mucosal-dominant type of pemphigus vulgaris.

When sera contain both anti-Dsg1 and anti-Dsg3 IgG, they interfere with the function of both Dsg1 and Dsg3, resulting in extensive blisters and erosions of the skin as well as the mucous membranes, as is seen in patients with the mucocutaneous type of pemphigus vulgaris. It is not clear why splits appear just above the basal layer instead of the whole epithelium falling apart. However, it is speculated that cell–cell adhesion in the basal and parabasal layers might be weaker than in other parts of the epithelium because there are fewer desmosomes. In addition, autoantibodies, which penetrate from the dermis, might have better access to the lower part of the epithelia.

In pregnant women with pemphigus, autoantibodies cross the placenta and bind to the fetal epidermis. However, neonates develop blisters if the mother has pemphigus vulgaris, but very rarely if she has pemphigus foliaceus. This confusing observation is also explained by the desmoglein compensation theory[31]. The distribution of Dsg3 within neonatal epidermis is unlike that in adult epidermis; it is

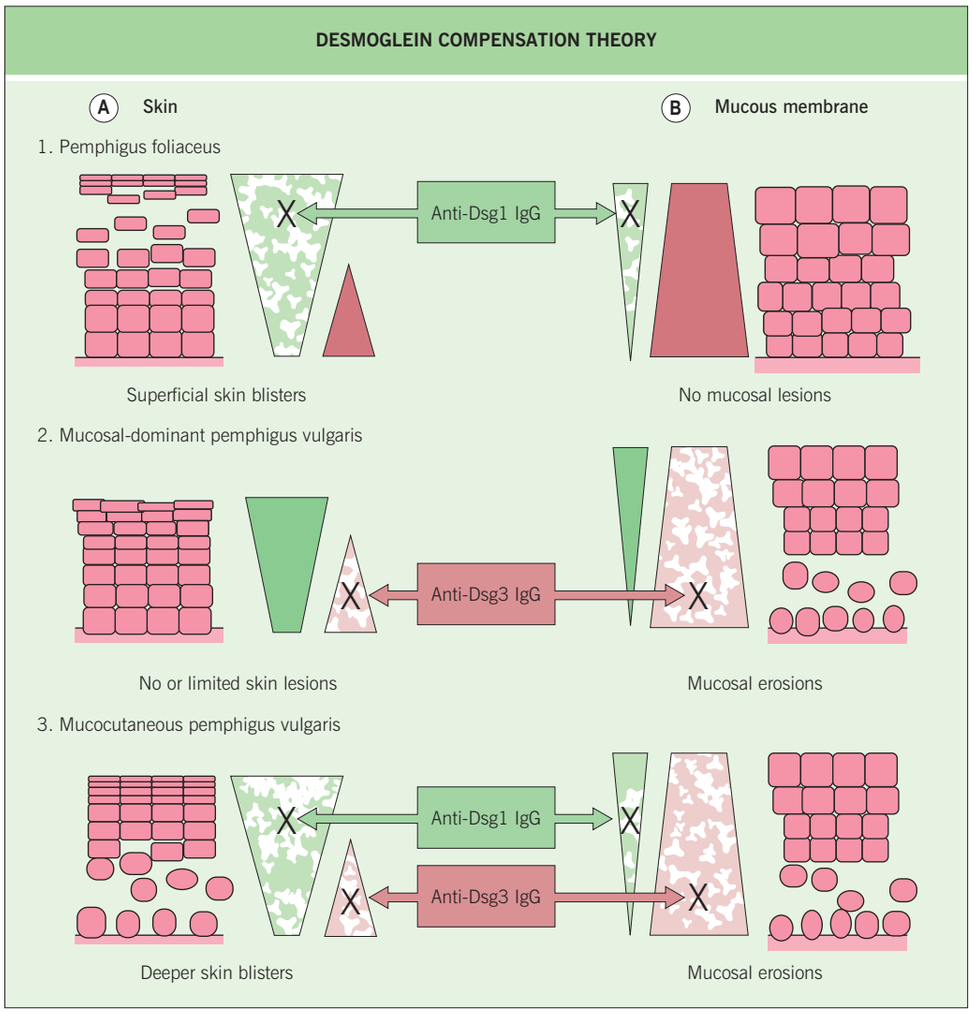

Fig. 29.4 Logical explanation for the localization of blister formation in classic pemphigus by desmoglein compensation theory. The colored triangles represent the distribution of desmoglein 1 (Dsg1) and desmoglein 3 (Dsg3) in the skin (**A**) and mucous membranes (**B**). Pemphigus foliaceus sera contain only anti-Dsg1 IgG, which causes superficial blisters in the skin because Dsg3 functionally compensates for the impaired Dsg1 in the lower part of the epidermis (**A1**), whereas those antibodies do not cause blisters in the mucous membranes because cell–cell adhesion is mainly mediated by Dsg3 (**B1**). Sera containing only anti-Dsg3 IgG cause no or only limited blisters in the skin because Dsg1 compensates for the loss of Dsg3-mediated adhesion (**A2**); however, these sera induce separation in the mucous membranes, where the low expression of Dsg1 will not compensate for the loss of Dsg3-mediated adhesion (**B2**). When sera contain both anti-Dsg1 and anti-Dsg3 IgG, the function of both Dsgs is compromised and blisters occur in both the skin and mucous membranes (**A3, B3**). In neonatal skin, the situation is similar to that shown here for mucous membranes.

found on the surface of keratinocytes throughout the epidermis, which is similar to its distribution in mucous membranes (remember, neonatal skin is bathed in amniotic fluid). Therefore, pemphigus foliaceus sera containing only anti-Dsg1 IgG cannot induce blisters in neonatal skin.

As an extension of this compensation theory, exfoliative toxins, which are produced by *Staphylococcus aureus* and lead to bullous impetigo as well as staphylococcal scalded skin syndrome, specifically cleave Dsg1[32]. Inactivation of Dsg1 by this toxin induces superficial blisters in the epidermis that are clinically and histologically similar to those seen in pemphigus foliaceus.

The exact mechanisms responsible for acantholysis remain to be elucidated; however, it is currently thought that the disruption of cell–cell adhesion is mediated via the combined effects of direct inhibition by antibodies and subsequent signal transduction induced by antibody binding. The direct inhibition is mediated by steric hindrance, i.e. the binding of autoantibodies to desmogleins spatially interferes with the adhesive interaction of desmogleins between cells. This possibility, supported by the observation that dominant epitopes are localized to the functionally important N-terminal region of desmogleins in pemphigus vulgaris and foliaceus[25,33,34], and pathogenic anti-Dsg3 mouse or human monoclonal antibody, but not non-pathogenic monoclonal antibodies, recognizes the N-terminal adhesive surface of Dsg3[34,35]. The phenotype of the *Dsg3* null mouse (whose *Dsg3* gene is genetically deleted) closely resembles that of human pemphigus vulgaris patients and it also supports this direct interference explanation[36]. The role of signal transduction induced by antibody binding is supported by the *in vitro* observation that IgG from pemphigus vulgaris sera (when added to the media of cultured keratinocytes) causes a transient increase in intracellular calcium and/or inositol 1,4,5-triphosphate, activation of protein kinase C, or phosphorylation of Dsg3[37,38]. Furthermore, with desmosomal disassembly, Dsg3 is internalized or endocytosed from the cell surface in association with keratin retraction[39,40]. Further studies are needed to clarify this issue.

Autoimmunity Against Desmogleins and Plakins in Paraneoplastic Pemphigus

Patients with paraneoplastic pemphigus develop characteristic IgG autoantibodies against multiple antigens, including those originally described with molecular weights of 250, 230, 210, 190 and 170 kDa (see Table 29.2)[2]. By immunochemical studies and cDNA cloning, these antigens have been identified. The 250 kDa and 210 kDa antigens are desmoplakins I and II, respectively. The 230 kDa antigen is bullous pemphigoid antigen 1, the major plaque protein of the epidermal hemidesmosome and also a target antigen in bullous pemphigoid. The 210 kDa band also contains envoplakin, and the 190 kDa antigen is periplakin. Later, plectin (500 kDa) was also found to be recognized, as were Dsg3 and Dsg1[24]. Most recently, the 170 kDa antigen was identified as alpha-2-macroglobulin-like-1, a broad-range protease inhibitor expressed in stratified epithelia and other tissues[40a]. In summary, all the members of the plakin family, as well as desmogleins, are targeted by IgG autoantibodies in paraneoplastic pemphigus.

Anti-desmoglein antibodies play a role in inducing the loss of cellular adhesion of keratinocytes and initiate blister formation, while the pathophysiologic relevance of the anti-plakin autoantibodies is unclear. The intracellular location of plakin proteins makes it unlikely that anti-plakin autoantibodies initiate pathology in paraneoplastic pemphigus, because IgG cannot penetrate cell membranes. It is also important to bear in mind that not only humoral immunity but also cell-mediated cytotoxicity is involved in the pathogenesis of paraneoplastic pemphigus, in which more severe and refractory oral erosions and stomatitis as well as more polymorphic skin eruptions are seen, in comparison with classic forms of pemphigus.

Immunologic Mechanism of Pathogenic Autoantibody Production in Pemphigus

In contrast to the significant progress since the late 1980s in understanding the pathophysiologic mechanisms of blister formation in pemphigus, it is still unclear why patients with pemphigus begin to produce the pathogenic autoantibodies.

Pemphigus autoantibodies are composed of IgG isotypes, which may be produced after isotype switching, and they have a high affinity towards the antigen, which may be a result of affinity maturation of the antibodies. In addition, pemphigus sera recognize several distinct epitopes on desmogleins[33], and the presence of autoantibodies is associated with specific HLA class II alleles, including DRB1*0402, DRB1*1401 and DQB1*0302 in Caucasians[41] and DRB1*14 and DQB1*0503 in Japanese[42]. All of these features suggest that autoantibody production in pemphigus is T cell-dependent. More recently, T cells reactive against Dsg3 were shown to be present in peripheral blood from patients with pemphigus vulgaris as well as healthy individuals[43–45]. Certain peptides from Dsg3, predicted to fit into the DRB1*0402 pocket, were able to stimulate T cells from the pemphigus patients. An essential step in the clarification of the immunologic mechanism of autoantibody production will be the characterization of those T cells involved in autoantibody production.

Another advance that will allow the study of T cells and B cells is the development of an active disease mouse model for pemphigus vulgaris using autoantigen knockout mice, in which self-tolerance to the absent gene product is not acquired[46]. When lymphocytes from Dsg3 knockout mice are adoptively transferred into mice expressing Dsg3, anti-Dsg3 IgG is stably produced in the recipient mice and they develop the phenotype of pemphigus vulgaris. This model is valuable not only for dissecting the cellular and molecular mechanisms involved in antibody production but also for developing novel therapeutic strategies[47,48].

CLINICAL FEATURES

Pemphigus Vulgaris

Essentially all patients with pemphigus vulgaris develop painful erosions of the oral mucosa. More than half of the patients also develop flaccid blisters and widespread cutaneous erosions. Pemphigus vulgaris is therefore divided into two subgroups: (1) the *mucosal-dominant* type with mucosal erosions but minimal skin involvement; and (2) the *mucocutaneous* type with extensive skin blisters and erosions in addition to mucosal involvement (see Fig. 29.4).

Mucous membrane lesions usually present as painful erosions (Fig. 29.5A,B). Intact blisters are rare, probably because they are fragile and break easily. Although scattered or extensive erosions may be seen anywhere in the oral cavity, the most common sites are the buccal and palatine mucosa. The erosions are of different sizes with an irregular ill-defined border, which, when extensive or painful, may result in decreased oral intake of food or liquids. The diagnosis of pemphigus vulgaris tends to be delayed in patients presenting with only oral involvement, as compared to patients with skin lesions.

The lesions may extend out onto the vermilion lip and lead to thick, fissured hemorrhagic crusts. Involvement of the throat produces hoarseness and difficulty in swallowing. The esophagus also may be involved and sloughing of its entire lining in the form of a cast has been reported. The conjunctivae, nasal mucosa, vagina, penis, anus and labia can develop lesions as well. Cytology of vaginal cells may be misread as a malignancy when vaginal lesions are present.

The primary skin lesions of pemphigus vulgaris are flaccid, thin-walled, easily ruptured blisters (Fig. 29.5C). They can appear anywhere on the skin surface and arise on either normal-appearing skin or erythematous bases. The fluid within the bullae is initially clear but may become hemorrhagic, turbid, or even seropurulent. The blisters are fragile and soon rupture to form painful erosions that ooze and bleed easily. These erosions often attain a large size and can become generalized. The erosions soon become partially covered with crusts that have little or no tendency to heal. Those lesions that do heal often leave hyperpigmented patches with no scarring. Associated pruritus is uncommon. Table 29.3 outlines more unusual clinical presentations of pemphigus vulgaris (Fig. 29.5D).

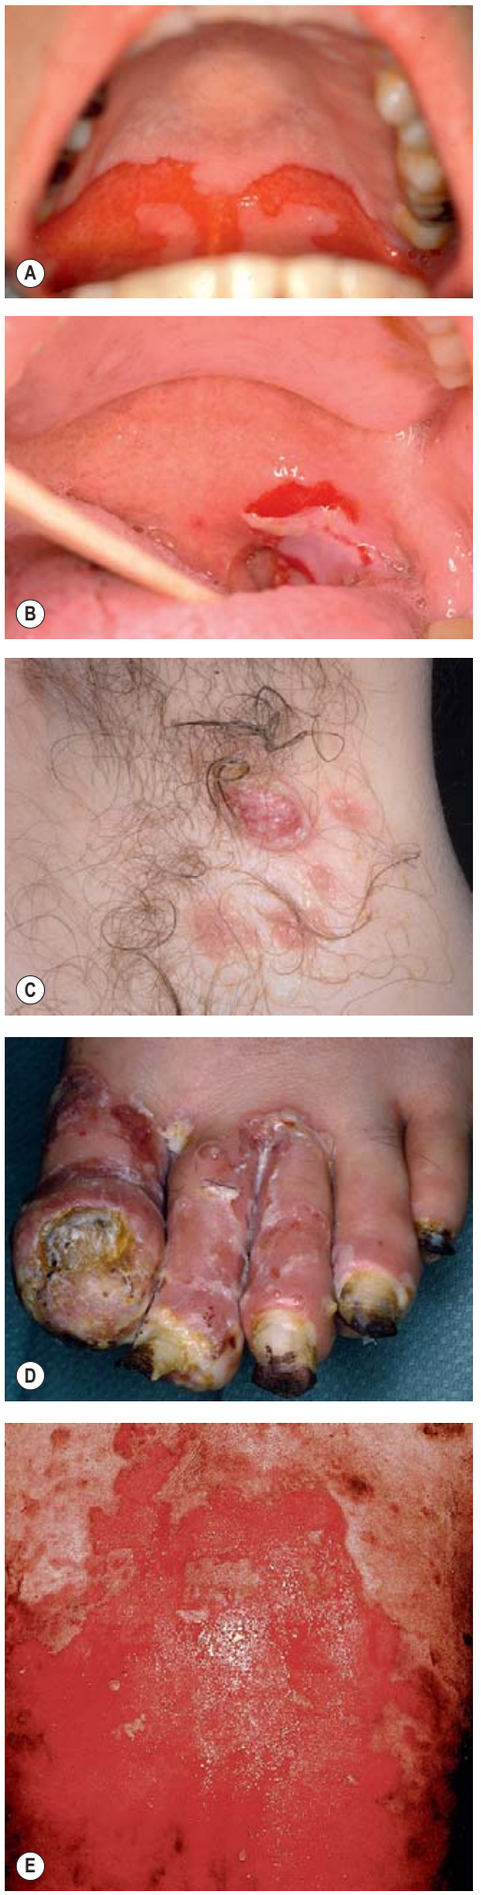

Fig. 29.5 Pemphigus vulgaris. A,B Essentially all patients develop painful oral mucosal erosions, with the most common sites being the buccal and palatine mucosae. **C** Flaccid blisters and an erosion due to rupture of a bulla. **D** The dyshidrosiform variant is uncommon. **E** In a severe case, a large area of the back is affected, leading to a loss of body fluids and secondary bacterial infections. *B–D, Courtesy, Louis A Fragola, Jr, MD. UNUSUAL CLINICAL PRESENTATIONS OF PEMPHIGUS VULGARIS
Isolated crusted plaque on face or scalp
Paronychia
Foot ulcers
Dyshidrotic eczema or pompholyx
Macroglossia

Table 29.3 Unusual clinical presentations of pemphigus vulgaris.

Fig. 29.6 Pemphigus vegetans. Extensive vegetating papillomatous lesions are noted.

Because of an absence of cohesion within the epidermis, its upper layers easily move laterally with slight pressure or rubbing in patients with active disease (Nikolsky sign). The lack of cohesion of the skin may also be demonstrated with the "bulla-spread phenomenon" – gentle pressure on an intact bulla forces the fluid to spread under the skin away from the site of pressure (Asboe–Hansen sign, also referred to as the "indirect Nikolsky" or "Nikolsky II" sign). Without appropriate treatment, pemphigus vulgaris can be fatal because a large area of the skin loses its epidermal barrier function, leading to the loss of body fluids or to secondary bacterial infections (Fig. 29.5E).

Pemphigus Vegetans

Pemphigus vegetans is a rare vegetative variant of pemphigus vulgaris, and it is thought to represent a reactive pattern of the skin to the autoimmune insult of pemphigus vulgaris.

Pemphigus vegetans is characterized by flaccid blisters that become erosions and then form fungoid vegetations or papillomatous proliferations, especially in intertriginous areas and on the scalp or face (Fig. 29.6). Pustules rather than vesicles characterize early lesions, but these soon progress to vegetative plaques. The tongue may show cerebriform-like changes. Two subtypes are recognized: the severe Neumann type and the mild Hallopeau type. A vegetative response may occasionally also be seen in lesions of pemphigus vulgaris that tend to be resistant to therapy and remain for long periods of time in one location.

Pemphigus Foliaceus

Patients with pemphigus foliaceus develop scaly, crusted cutaneous erosions, often on an erythematous base, but they do not have clinically apparent mucosal involvement even with widespread disease.

The onset of disease is often subtle, with a few scattered crusted lesions that are transient and are frequently mistaken for impetigo. They are usually well demarcated and have a seborrheic distribution, i.e. they favor the face, scalp and upper trunk (Fig. 29.7A,B). Because the vesicle is so superficial and fragile, often only the resultant crust and scale are seen (Fig. 29.7C,D). The disease may stay localized for years or it may rapidly progress, in some cases to generalized involvement and an exfoliative erythroderma (see Ch. 10). The Nikolsky sign is present. In contrast to the extensive oral lesions in pemphigus vulgaris, it is extremely rare, if ever, for patients with pemphigus foliaceus to develop mucosal involvement. Generally, patients with pemphigus foliaceus are not severely ill. They do complain of burning and pain in association with the skin lesions.

Pemphigus Erythematosus (Senear–Usher Syndrome)

Pemphigus erythematosus is simply a localized variant of pemphigus foliaceus. Typical scaly and crusted lesions of pemphigus foliaceus appear in the malar region of the face (Fig. 29.8) and in other "seborrheic" areas. Originally, the term "pemphigus erythematosus" was introduced to describe patients with immunologic features of both lupus erythematosus and pemphigus, i.e. *in vivo* IgG and C3 deposition on cell surfaces of keratinocytes as well as the basement membrane zone, in addition to circulating antinuclear antibodies[49]. However, only a few patients have been reported to actually have the two diseases concurrently.

Herpetiform Pemphigus

Most patients with herpetiform pemphigus have a clinical variant of pemphigus foliaceus and the remainder may have a variant of pemphigus vulgaris. This disorder is characterized by: (1) erythematous urticarial plaques and tense vesicles that present in a herpetiform arrangement; (2) eosinophilic spongiosis and subcorneal pustules with minimal or no apparent acantholysis histologically; and (3) IgG autoantibodies directed against the cell surfaces of keratinocytes[50]. The target antigen is Dsg1 in most cases and Dsg3 in the remainder[51]. Some patients with herpetiform pemphigus will have features of pemphigus foliaceus or vulgaris during the course of their disease, and some patients will evolve into having pemphigus foliaceus or vulgaris. It is assumed that the pathogenic blister-inducing activity of the IgG autoantibodies in herpetiform pemphigus might be weaker than that seen in classic forms of pemphigus. Although often clinically less severe than pemphigus vulgaris, the course may be more chronic[52].

Drug-Induced Pemphigus

There are sporadic cases of pemphigus associated with the use of drugs, in particular penicillamine and captopril[53]. In patients receiving penicillamine, pemphigus foliaceus is seen more commonly than pemphigus vulgaris, with a ratio of approximately 4 : 1. Although most patients with drug-induced pemphigus are shown to have autoantibodies against the same molecules involved in sporadic pemphigus, evidence suggests that some drugs may induce acantholysis without the production of antibodies. Both penicillamine and captopril contain sulfhydryl groups that are speculated to interact with the sulfhydryl groups in Dsg1 and Dsg3. This interaction may modify the antigenicity of the desmogleins, which may lead to autoantibody production, or their interaction may directly interfere with the adhesive function of the desmogleins. Most, but not all, patients with drug-induced pemphigus go into remission after the offending drug is discontinued.

Paraneoplastic Pemphigus

Paraneoplastic pemphigus is associated with underlying neoplasms, both malignant and benign. The most commonly associated neoplasms are non-Hodgkin lymphoma (40%), chronic lymphocytic leukemia (30%), Castleman's disease (10%), malignant and benign thymomas (6%), sarcomas (6%) and Waldenström's macroglobulinemia (6%)[2]. Non-Hodgkin lymphoma and chronic lymphocytic leukemia together account for two-thirds of patients. Castleman's disease, a very rare lymphoproliferative disorder, is the third most commonly associated neoplasm in adults and the most commonly associated tumor in children and adolescents; its association with paraneoplastic pemphigus is strikingly disproportionate to its general occurrence. The absence of

Fig. 29.7 Pemphigus foliaceus. A Scaly, crusted erosions widely distributed on the back. **B** As the disease progresses, the lesions become confluent. **C** Because the vesicles are fragile and rupture easily, the typical lesions of pemphigus foliaceus are erosions with scale-crust. **D** The scales have been likened to cornflakes.

Fig. 29.8 Pemphigus erythematosus. Erythematous plaques with scale-crust and erosions on the nose and malar area of the face. *Courtesy, Ronald P Rapini, MD.*

Fig. 29.9 Paraneoplastic pemphigus. The characteristic clinical feature is severe intractable stomatitis that extends onto the vermilion lip. Erosions and hemorrhagic crusts are also present.

common tumors, such as adenocarcinomas of the breast or colon and squamous cell carcinomas, is notable.

The most constant clinical feature of paraneoplastic pemphigus is the presence of intractable stomatitis. Severe stomatitis is usually the earliest presenting sign and, after treatment, it is the one that persists and is extremely resistant to therapy. This stomatitis consists of erosions and ulcerations that affect all surfaces of the oropharynx and characteristically extend onto the vermilion lip (Fig. 29.9). Most patients also have a severe pseudomembranous conjunctivitis, which may progress to scarring and obliteration of the conjunctival fornices. Esophageal, nasopharyngeal, vaginal, labial and penile mucosal lesions may also be seen.

Cutaneous findings are quite polymorphic and may present as erythematous macules, flaccid blisters and erosions resembling pemphigus vulgaris, tense blisters resembling bullous pemphigoid, erythema multiforme-like lesions, and lichenoid eruptions. The occurrence of

Fig. 29.10 IgA pemphigus. **A** Subcorneal pustular dermatosis (SPD) type. Pustules tend to coalesce to form an annular or circinate pattern with crusts present centrally. Note the accumulation of the pustular component in the dependent portion of the vesiculopustule. **B** Intraepidermal neutrophilic (IEN) type. The characteristic sunflower-like configuration of pustules is seen.

blisters and erythema multiforme-like lesions on the palms and soles is often used to differentiate paraneoplastic pemphigus from pemphigus vulgaris, in which lesions on the palms and soles are unusual. In the chronic form of the disease, a lichenoid eruption may predominate over blistering lesions. Some patients with paraneoplastic pemphigus develop bronchiolitis obliterans, which can be fatal as a result of respiratory failure, although its pathophysiologic mechanism is still unclear[54]. Of note, a chest X-ray or CT scan obtained at the onset of bronchiolitis obliterans may be normal but pulmonary function tests will show small airway obstruction that does not reverse with bronchodilators.

IgA Pemphigus

IgA pemphigus represents a more recently characterized group of autoimmune intraepidermal blistering diseases presenting with a vesiculopustular eruption, neutrophilic infiltration of the skin, and *in vivo* bound and circulating IgA autoantibodies against the cell surface of keratinocytes, but with no IgG autoantibodies. IgA pemphigus usually occurs in middle-aged or elderly persons. Two distinct types of IgA pemphigus have been described: the subcorneal pustular dermatosis type and the intraepidermal neutrophilic type. Patients with both types of IgA pemphigus present with flaccid vesicles or pustules on either erythematous or normal skin. In both types, the pustules tend to coalesce to form an annular or circinate pattern with crusts in the center of the lesion (Fig. 29.10A), although a sunflower-like configuration of pustules is a characteristic sign of the intraepidermal neutrophilic type (Fig. 29.10B)[55]. The most common sites of involvement are the axilla and groin, but the trunk and proximal extremities can also be involved. Mucous membrane involvement is rare, and pruritus is often a significant symptom. Because the subcorneal pustular dermatosis type of IgA pemphigus is clinically and histologically indistinguishable from classic subcorneal pustular dermatosis (Sneddon–Wilkinson disease; see Ch. 8), immunologic evaluation is essential to differentiate the two diseases.

IgA deposition on cell surfaces of epidermal keratinocytes is present in all cases, as shown by direct IF, and many patients have detectable circulating IgA autoantibodies, as shown by indirect IF. In the subcorneal pustular dermatosis type, IgA autoantibodies react against upper epidermal surfaces, while in the intraepidermal neutrophilic type, IgA autoantibodies are found throughout the entire epidermis. The subclass of IgA autoantibodies is exclusively IgA1. IgA autoantibodies in the subcorneal pustular dermatosis type were shown to recognize desmocollin 1 when it was expressed on COS7 cells[56], while the autoimmune targets of the intraepidermal neutrophilic type remain to be identified. A subset of IgA pemphigus patients have IgA autoantibodies directed against Dsg1 or Dsg3, making the autoimmune targets of IgA pemphigus more heterogeneous. The exact pathogenic role of IgA autoantibodies in inducing pustular formation in IgA pemphigus remains to be elucidated.

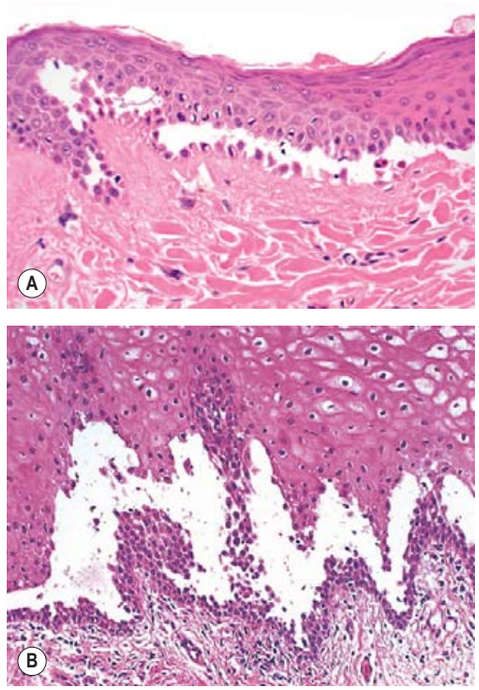

Fig. 29.11 Histology of pemphigus vulgaris. **A** Blisters in the skin show suprabasilar acantholysis with a few acantholytic cells in the blister cavity. Attachment of the basal cells to the basement membrane via hemidesmosomes leads to the "tombstones" appearance. **B** The border of a blister on the buccal mucosa shows intraepithelial separation in the lower part of the mucosal epithelia. *A, Courtesy, Lorenzo Cerroni, MD.*

PATHOLOGY

Pemphigus Vulgaris

The characteristic histologic finding in this form of pemphigus is intraepidermal blister formation due to a loss of cell–cell adhesion of keratinocytes (acantholysis) without keratinocyte necrosis (Fig. 29.11A). Whereas acantholysis usually occurs just above the basal cell layer (suprabasilar acantholysis), intraepithelial separation may occasionally be higher in the stratum spinosum (Fig. 29.11B). A few rounded-up (acantholytic) keratinocytes as well as clusters of epidermal cells are often seen in the blister cavity. Although the basal cells lose lateral desmosomal contact with their neighbors, they maintain their attachment to the basement membrane via hemidesmosomes, thus giving the appearance of a "row of tombstones". The acantholytic process may involve hair follicles.

The dermal papillary outline is usually maintained and, frequently, the papillae protrude into the blister cavity. The blister cavity may contain a few inflammatory cells, notably eosinophils, and in the dermis there is a moderate perivascular mononuclear cell infiltrate with

CAUSES OF EOSINOPHILIC SPONGIOSIS
Pemphigus vulgaris
Pemphigus foliaceus
Bullous pemphigoid
Pemphigoid gestationis (herpes gestationis)
Polymorphic eruption of pregnancy (pruritic urticarial papules and plaques of pregnancy)
Linear IgA bullous dermatosis
Insect-bite reaction
Drug eruptions
Erythema toxicum neonatorum
Incontinentia pigmenti
Atopic dermatitis
Contact dermatitis
Transient acantholytic dermatosis (Grover's disease)

Table 29.4 Causes of eosinophilic spongiosis.

conspicuous eosinophils. In rare instances, the earliest histologic finding consists of eosinophilic spongiosis (Table 29.4), in which eosinophils invade a spongiotic epidermis with little or no evidence of acantholysis.

It is essential to take a biopsy from an early lesion in order to establish the correct diagnosis because pemphigus blisters rupture easily. In patients with only oral lesions, a biopsy specimen should be obtained from the active border of a denuded area because intact blisters are rarely encountered (see Fig. 29.11B). Cytologic examination (Tzanck smear) is useful for the rapid demonstration of acantholytic epidermal cells in the blister cavity. However, this bedside test merely represents a preliminary diagnostic tool, and it should not supplant histologic examination because acantholytic keratinocytes are occasionally seen in various non-acantholytic vesiculobullous or pustular diseases as a result of secondary acantholysis.

In pemphigus vegetans, suprabasilar acantholysis is seen, in addition to considerable papillomatosis and acanthosis. Characteristically, there is an intense inflammatory cell infiltrate containing numerous eosinophils, and intraepidermal microabscesses are often seen.

Pemphigus Foliaceus

The histologic changes of pemphigus foliaceus, pemphigus erythematosus and fogo selvagem are identical. Early blisters in pemphigus foliaceus have acantholysis in the upper epidermis, within or adjacent to the granular layer (Fig. 29.12). As the blisters are superficial and fragile, it is often difficult to obtain an intact lesion for histologic examination. As a result, acantholysis is sometimes difficult to detect, but usually a few acantholytic keratinocytes can be found attached to the roof or floor of the blister. Although the deeper epidermis usually remains intact, secondary clefts may develop, leading to detachment of the epidermis in its midlevel, but rarely giving rise to limited areas of separation above the basal layer. These superficial blisters are histologically indistinguishable from those seen in staphylococcal scalded skin syndrome or bullous impetigo, because Dsg1 is targeted in both diseases[32]. Sometimes the blister cavity contains numerous acute inflammatory cells, particularly neutrophils. Eosinophilic spongiosis can be also seen in very early lesions of pemphigus foliaceus (see Table 29.4). The dermis shows a moderate number of inflammatory cells, among which eosinophils are often present.

Paraneoplastic Pemphigus

The histologic findings of cutaneous lesions in paraneoplastic pemphigus show considerable variability, reflecting the polymorphism seen clinically. The lesions show a unique combination of pemphigus vulgaris-like, erythema multiforme-like, and lichen planus-like histologic features, sometimes in the same specimen (Fig. 29.13). Intact cutaneous blisters demonstrate suprabasilar acantholysis and individual keratinocyte necrosis with lymphocytes within the epidermis. In addition, basal cell liquefactive degeneration or a band-like dense lymphocytic infiltrate in the upper dermis can be seen. Eosinophils are rare. Biopsy specimens of the severe ulcerative stomatitis usually yield only nonspecific changes of inflammation, but the perilesional oral epithelium should show suprabasilar acantholysis.

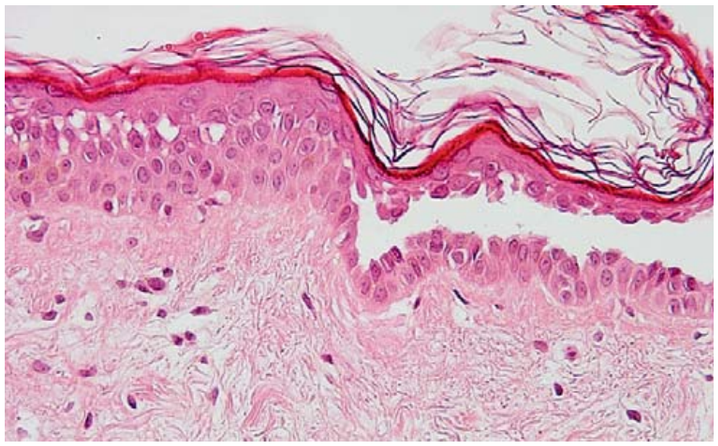

Fig. 29.12 Histology of pemphigus foliaceus. Clefting is seen in the upper spinous layer of the epidermis with several acantholytic cells detaching from the roof of the blister.

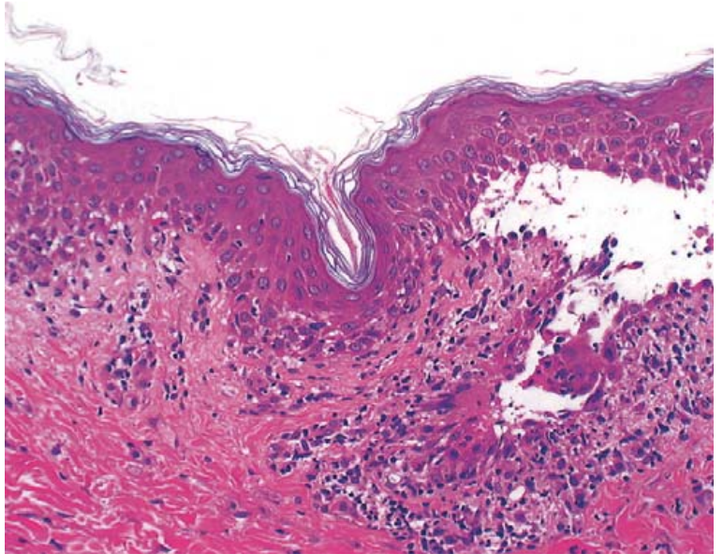

Fig. 29.13 Histology of paraneoplastic pemphigus. Suprabasilar acantholysis is seen along with a combination of basal cell vacuolar change, necrotic keratinocytes, and lymphocytes within the epidermis.

IgA Pemphigus

The characteristic histologic feature in IgA pemphigus is formation of an intraepidermal pustule or vesicle (Fig. 29.14). The contents of the pustules consist predominantly of neutrophils. Acantholysis is usually not seen. IgA pemphigus is divided into two subtypes depending on the level of intraepidermal pustule; in the subcorneal pustular dermatosis type, pustules are located subcorneally in the upper epidermis, while in the intraepidermal neutrophilic type, suprabasilar pustules involving the lower or entire epidermis are present.

DIFFERENTIAL DIAGNOSIS

Demonstration of IgG (or IgA for IgA pemphigus) autoantibodies directed against the cell surface of keratinocytes is the gold standard for the diagnosis of pemphigus. By detection of these autoantibodies, pemphigus can be differentiated from other vesiculobullous or pustular diseases. Methods for demonstrating pemphigus autoantibodies include direct IF, indirect IF, immunoprecipitation, immunoblotting and enzyme-linked immunosorbent assay (ELISA).

Direct IF examines patients' skin or mucous membranes in order to demonstrate *in vivo* bound IgG deposition on the keratinocyte cell surfaces. The biopsy specimen should be taken from perilesional normal skin or mucous membrane. Direct IF is the most reliable and

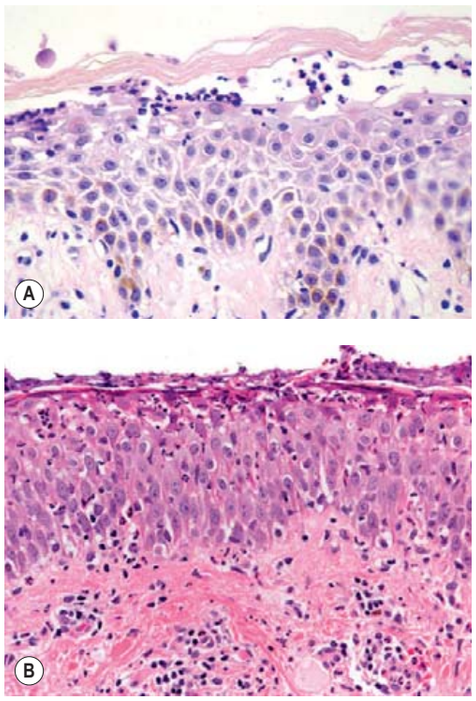

Fig. 29.14 Histology of IgA pemphigus. Intraepidermal pustule with neutrophils present subcorneally in the subcorneal pustular dermatosis type (**A**), and within the entire epidermis in the intraepidermal neutrophilic type (**B**). *B, Courtesy, Lorenzo Cerroni, MD.*

sensitive diagnostic test for all forms of pemphigus. However, on occasion, nonspecific cell surface staining may occur in other skin diseases, such as spongiotic dermatitis, burns, toxic epidermal necrolysis, systemic lupus erythematosus and lichen planus, or in patients with antibodies directed against blood groups A and B. If the direct IF is negative, the diagnosis of pemphigus should be seriously questioned. IgG deposition is seen in up to 100% of patients with active pemphigus vulgaris, pemphigus foliaceus and paraneoplastic pemphigus. IgM deposition is not found, but occasionally IgA deposition may also be seen. Complement (C3) deposition is not necessarily observed, probably because the dominant subclass of IgG is IgG4, which does not fix complement. In IgA pemphigus, IgA deposition (but not IgG deposition) is detected on keratinocyte cell surfaces.

Indirect IF examines patients' sera in order to demonstrate circulating IgG autoantibodies directed against epithelial cell surfaces (see Fig. 29.1). As a substrate for indirect IF staining, monkey esophagus is more sensitive for pemphigus vulgaris (anti-Dsg3 autoantibodies) and normal human skin or guinea pig esophagus is better for pemphigus foliaceus (anti-Dsg1 autoantibodies)[57]. Rat bladder is used to detect paraneoplastic pemphigus (antiplakin autoantibodies). Except for a few patients with early localized disease or those in remission, most patients with pemphigus have circulating anti-epithelial cell surface IgG as determined by indirect IF. Despite the different antigens involved in pemphigus vulgaris and foliaceus, the staining pattern using direct or indirect IF is similar, which makes it difficult to serologically distinguish the two diseases (compare Fig. 29.1B & C). Immunoprecipitation, immunoblotting and ELISA can be used to demonstrate the target molecules of these autoantibodies.

Immunoprecipitation and immunoblotting detect the target antigens as protein bands of a particular molecular weight that have been separated by electrophoresis (see Ch. 3). Immunoblotting requires denaturation of the protein substrates, but immunoprecipitation does not. Therefore, immunoprecipitation is superior to immunoblotting in detecting antibodies that react with epitopes dependent on three-dimensional structure (conformational epitopes), while immunoblots detect antibodies that react with epitopes that are preserved even after denaturation (linear epitopes). However, an immunoblot is easier to perform because immunoprecipitation requires radioisotopes to label protein substrates.

A recent innovation has been the introduction of an antigen-specific ELISA for the diagnosis of pemphigus[21,22]. The patient's serum is tested on ELISA plates pre-coated with recombinant Dsg1 or Dsg3 protein. Thus, specific antibodies directed against Dsg1 or Dsg3 can be detected. This assay has enabled investigators to serologically distinguish subtypes of pemphigus vulgaris and foliaceus. If a serum is positive against Dsg1 but negative against Dsg3, this suggests a diagnosis of pemphigus foliaceus. If negative against Dsg1 but positive against Dsg3, this suggests a diagnosis of the mucosal-dominant type of pemphigus vulgaris. If positive against both Dsg1 and Dsg3, this suggests a diagnosis of mucocutaneous type of pemphigus vulgaris (see Fig. 29.4). Furthermore, ELISA scores demonstrate parallel fluctuations with disease activity and are useful in monitoring disease activity, planning schedules for tapering corticosteroids, and predicting flares or relapses before there is clinical evidence.

Differential Diagnosis of Pemphigus Vulgaris

Establishing the diagnosis in patients with only oral lesions is more difficult than in those with cutaneous blisters and erosions. The differential diagnosis of mucosal lesions of pemphigus vulgaris includes acute herpetic stomatitis, aphthous stomatitis, erythema multiforme or Stevens–Johnson syndrome, lichen planus, systemic lupus erythematosus and mucous membrane (cicatricial) pemphigoid. For cutaneous lesions of pemphigus vulgaris, the differential diagnosis includes other forms of pemphigus, bullous pemphigoid, linear IgA bullous dermatosis, erythema multiforme, Hailey–Hailey disease and transient acantholytic dermatosis (Grover's disease). The differential diagnosis of pemphigus vegetans includes Hailey–Hailey disease, blastomycosis-like pyoderma, pemphigoid vegetans and pyodermatitis–pyostomatitis vegetans.

The demonstration of IgG autoantibodies against keratinocyte cell surfaces and anti-Dsg3 IgG, as mentioned above, will exclude these diseases (with the exception of drug-induced pemphigus vulgaris and paraneoplastic pemphigus). Fresh blisters of bullous pemphigoid are tense due to a subepidermal split. Hailey–Hailey disease has full-thickness acantholysis ("dilapidated brick wall") with epidermal hyperplasia and an impetiginized scale, and the acantholysis does not extend down follicles as it does in pemphigus. Transient acantholytic dermatosis exhibits only small foci of intraepidermal acantholysis.

Differential Diagnosis of Pemphigus Foliaceus

This differential includes other forms of pemphigus, bullous impetigo, subcorneal pustular dermatosis, subacute cutaneous lupus erythematosus, and seborrheic dermatitis. As discussed earlier for pemphigus vulgaris, the demonstration of IgG autoantibodies against epidermal cell surfaces is essential for separating these disorders from the pemphigus family. A complete review of medications should be done to exclude the possibility of drug-induced pemphigus foliaceus. Because the lesions of pemphigus foliaceus may become secondarily infected, the finding of bacteria does not confirm a diagnosis of bullous impetigo. Likewise, a clinical flare or recalcitrant disease may represent a superimposed disorder, e.g. tinea corporis, especially in patients on systemic corticosteroids.

Differential Diagnosis of Paraneoplastic Pemphigus

This differential includes pemphigus vulgaris, mucous membrane (cicatricial) pemphigoid, erythema multiforme or Stevens–Johnson syndrome, lichen planus, GVHD, persistent HSV infection, and other viral infections; stomatitis due to chemotherapy will be limited in duration (7–14 days). In two-thirds of patients with paraneoplastic pemphigus, it arises in the context of a known underlying neoplasm, usually a lymphoproliferative disorder, which may have been treated for years before the mucocutaneous lesions appear. In approximately one-third of patients, the underlying neoplasm is undiagnosed at the time the mucocutaneous disease develops. In these latter patients, examination for an occult neoplasm is required, and, given the most commonly associated ones (see earlier), a CT scan of the chest, abdomen and pelvis should accompany a complete blood count, flow cytometry, LDH, and serum protein and immunofixation electrophoreses. Severe intractable stomatitis that extends onto the vermilion lip is a key clinical feature in differentiating paraneoplastic pemphigus from most cases of pemphigus vulgaris or cicatricial pemphigoid. The gold standard for the diagnosis of paraneoplastic pemphigus is the demonstration of the characteristic combination of IgG autoantibodies (anti-plakin autoantibodies by immunoprecipitation or immunoblotting and anti-desmoglein autoantibodies by ELISA).

Differential Diagnosis of IgA Pemphigus

The differential diagnosis includes subcorneal pustular dermatosis, pemphigus foliaceus, bullous impetigo, dermatitis herpetiformis, linear IgA bullous dermatosis, and pustular psoriasis. The clinical and histologic features of the SPD type of IgA pemphigus and classic subcorneal pustular dermatosis are indistinguishable. The demonstration of IgA autoantibodies is essential for separating these other disorders from IgA pemphigus.

TREATMENT

Pemphigus Vulgaris

Before the advent of systemic corticosteroids, pemphigus vulgaris was usually a fatal disease; most patients died within 2–5 years of the onset of the disease because large areas of the skin lost their epidermal barrier function, leading to the loss of body fluids or to secondary bacterial infections. Pemphigus foliaceus had a better prognosis, except for the occasional acute cases with generalized involvement. Because pemphigus is caused by pathogenic autoantibodies, therapy must be designed to reduce autoantibody production, not just to suppress local inflammation. The introduction of systemic corticosteroids and immunosuppressive agents has greatly improved the prognosis of pemphigus; however, the morbidity, and occasional mortality, is still significant due to complications of therapy. Systemic corticosteroids are the mainstay of therapy for pemphigus. Immunosuppressive agents are often used for their corticosteroid-sparing effect in order to reduce the side effects of the corticosteroids (Table 29.5), with the goal of therapy being to control the disease with the lowest possible dose of corticosteroids. High-dose IVIg and rituximab represent promising new treatment options. More recently, PDAI (pemphigus disease area index) and ABSIS (autoimmune bullous skin disorder intensity score) have been introduced as a means of standardizing the assessment of disease extent in patients with pemphigus[58].

Systemic corticosteroid therapy, usually in the form of oral prednisone, is standard treatment (see Ch. 125). Prednisone at 1.0 mg/kg/day (usually 60 mg/day) is a typical initial dosage. The therapeutic effects are clinically estimated by the number of new blisters per day and the rate of healing of new lesions, and the prednisone is then gradually tapered. Once clinical remission is obtained, changes in the titer of circulating autoantibodies, as determined by indirect IF or ELISA, are helpful in gauging the dose of prednisone[22]. If there is no response in 3–7 days, other options may be employed, as discussed below. Intravenous pulse therapy with 1 g/day methylprednisolone (over a period of 2–3 hours, with continuous cardiac monitoring) for 3–5 consecutive days is an alternative choice for severe cases.

In general, immunosuppressive agents, such as *azathioprine*, *mycophenolate mofetil* and *cyclophosphamide*, when combined with corticosteroids, may result in gaining early control of the disease and an increased percentage of clinical remissions[59–63a]. For example, in patients with mild to moderate disease who received corticosteroids plus either placebo or mycophenolate mofetil in a prospective, randomized trial, the latter group showed faster and more durable responses[63b]. Azathioprine is used at a dose of 2–4 mg/kg/day (usually 100–300 mg/day) and its major side effects are nausea and dose-dependent myelosuppression (see Ch. 130). Mycophenolate mofetil is used at a dose of 2–3 g/day and it has a similar action to azathioprine, with less myelosuppression but more gastrointestinal toxicity[62]. Cyclophosphamide is given at a dose of 1–3 mg/kg/day (usually 50–200 mg/day) and its major side effects are hemorrhagic cystitis, sterility and leukopenia. If complete remission is achieved with the combined therapy, the dosage of the immunosuppressive drug is maintained while the prednisone is slowly tapered; when a dose of 5–10 mg/day is reached, careful tapering of the immunosuppressive drug is attempted. In young patients, the potential increase in malignancies that might be associated with the use of these drugs must be taken into account. In some patients, especially those who are elderly with limited disease or those in whom corticosteroids are contraindicated, immunosuppressive agents alone may be used.

While in some patients with pemphigus vulgaris, *cyclosporine* (5 mg/kg/day) has been used as an immunosuppressive agent, gold therapy is rarely utilized nowadays. One factor has been its replacement by newer agents, especially bioengineered immunomodulators, for the treatment of rheumatoid arthritis (historically, gold's major indication). *Plasmapheresis* is useful for quickly reducing the titers of circulating autoantibodies and should be considered for severe pemphigus if the disease is unresponsive to a combination of prednisone and immunosuppressives[63]. Concomitant immunosuppression with corticosteroids and cyclophosphamide prevents a post-plasmapheresis rebound increase in the production of autoantibody.

High-dose IVIg is another option for resistant disease. IVIg is a blood product prepared from pooled plasma that has immunomodulatory effects when used in a high dose. It is thought to exert its effect via multiple modes of action, including modulation of expression and function of Fc receptors and the cytokine network; provision of anti-idiotypic antibodies; and modulation of dendritic cell, T-cell and B-cell activation, differentiation and effector functions[64]. A multicenter, randomized, placebo-controlled, double-blind trial demonstrated that high-dose IVIg is an effective and safe treatment for steroid-resistant pemphigus[65].

Rituximab is a potent B-cell-depleting chimeric anti-CD20 monoclonal antibody that was first used to treat B-cell malignancies, but increasingly is used for a variety of autoimmune diseases, including pemphigus. CD20 is a transmembrane glycoprotein specifically expressed on B cells (from the pre-B stage in the bone marrow to the activated and memory B stage in blood or secondary lymphoid organs), but its expression is lost upon plasma cell differentiation[66]. Rituximab seems not only to induce a depletion of $CD20^+$ B cells and a decline in IgG (including anti-desmoglein autoantibodies), but also decreases desmoglein-specific T cells[67]. When used as adjuvant therapy in nonrandomized prospective studies, rituximab led to a complete remission in most of the patients with refractory pemphigus vulgaris and foliaceus[68,69]. The side effects of rituximab, including progressive multifocal leukoencephalopathy, are discussed in Chapter 130.

In the future, desmoglein-specific immune suppression, via targeting T cells or B cells, needs to be developed. It would represent an ideal therapeutic strategy given that the target antigens and pathophysiological mechanisms of pemphigus have been well characterized.

THERAPEUTIC LADDER FOR PEMPHIGUS VULGARIS	
STANDARD TREATMENT	
Oral prednisone	1.0 mg/kg/day as an initial dose (usually 60 mg/day) (1)
AGGRESSIVE TREATMENT	
Immunosuppressive agents in combination with oral prednisone:	
Azathioprine	2–4 mg/kg/day (usually 100 to 300 mg/day) (1)
Mycophenolate mofetil	2–3 g/day (2)
Cyclophosphamide	1–3 mg/kg/day (usually 50 to 200 mg/day) (2)
Cyclosporine	5 mg/kg/day (2)
Pulse methylprednisolone	1 g/day over a period of 2–3 hours for 3–5 consecutive days (2)
Methotrexate	7.5–20 mg/week (3)
Pulse cyclophosphamide	50 mg/kg/day × 4 days (3)
Plasmapheresis	1–2 times per week, at the onset (2)
High-dose IVIg	400 mg/kg/day for 5 consecutive days (1); may need to be repeated
Rituximab	375 mg/m^2 once weekly for 4 weeks (2)
Extracorporeal photopheresis	2 days per month (3)
TOPICAL TREATMENT	
Topical corticosteroids (1), especially Class I to localized persistent sites Topical antibiotics (2) Topical immunomodulators (e.g. cyclosporine, tacrolimus) (3)	

Table 29.5 Therapeutic ladder for pemphigus vulgaris. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

Pemphigus Foliaceus

When pemphigus foliaceus is active and widespread, the treatment is, in general, similar to that for pemphigus vulgaris. In some patients, pemphigus foliaceus may be localized for many years; they do not necessarily have to be treated with systemic therapy, and superpotent

topical corticosteroids may be sufficient to control the disease. Dapsone can also be used when neutrophils are dominant histologically.

Paraneoplastic Pemphigus

Patients with benign tumors, such as thymomas or localized Castleman's disease, should have the tumor surgically excised. The majority of these patients will either improve substantially or clear completely. However, it may take 6–18 months to see complete resolution of lesions after excision of a benign neoplasm. In patients with malignant neoplasms, there is no consensus on a standard effective therapeutic regimen. Administration of tumor-specific chemotherapy may result in complete resolution of the malignancy and a slow resolution of the skin lesions. Cutaneous lesions respond more rapidly to therapy, in contrast to the stomatitis, which is generally refractory to most forms of treatment. Overall, the prognosis of paraneoplastic pemphigus is poor due to its resistant nature to treatment.

IgA Pemphigus

Dapsone is the drug of choice for most patients with IgA pemphigus. A clinical response usually occurs within 24–48 hours. If dapsone is not well tolerated, sulfapyridine and acitretin are useful alternatives. Occasionally, those drugs are not effective, and low- to medium-dose prednisone may be considered, as well as photochemotherapy (PUVA) or colchicine.

BULLOUS PEMPHIGOID

Synonym: ■ Pemphigoid

Key features

- Bullous pemphigoid (BP) is the most common autoimmune subepidermal blistering disease; it predominantly affects the elderly
- It is usually a chronic disease, with spontaneous exacerbations and remissions, which may be accompanied by significant morbidity
- BP is associated with tissue-bound and circulating autoantibodies directed against BP antigen 180 (BP180, BPAG2 or type XVII collagen) and BP antigen 230 (BP230 or BPAG1e), components of junctional adhesion complexes called hemidesmosomes that promote dermal–epidermal cohesion
- The spectrum of clinical presentations is extremely broad. Characteristically, BP is an intensely pruritic eruption with widespread blister formation. In early stages, or in atypical variants of the disease, only excoriated, eczematous or urticarial lesions (either localized or generalized) are present
- Diagnosis relies on immunopathologic examinations, particularly direct and indirect immunofluorescence microscopy as well as anti-BP180/BP230 ELISAs

Introduction

Bullous pemphigoid (BP) is the most common autoimmune subepidermal blistering disease of the skin. The disease typically presents in the elderly with a generalized pruritic bullous eruption, and it is potentially associated with significant morbidity. The clinical presentation can be quite polymorphic, particularly during the early stages of the disease or in atypical variants, in which full-blown bullous lesions may be absent. In these cases, establishing the diagnosis of BP requires a high degree of suspicion. BP has emerged as a paradigm of organ-specific autoimmune disease. The antigens targeted by patients' autoantibodies represent two components of hemidesmosomes – the junctional adhesion complexes found in skin and mucosae.

History

During the eighteenth century, the term "pemphigus" was often used to describe any type of bullous eruption. It was not until 1953 that Lever, on the basis of specific clinical and histologic features, recognized BP as a disorder distinct from the various types of "true" pemphigus[1].

A decade later, Jordon, Beutner and colleagues[2] demonstrated that BP patients had tissue-bound and circulating autoantibodies directed against the cutaneous basement membrane zone (BMZ), an observation that suggested that subepidermal dysadhesion was due to autoantibodies directed against structural components of the skin that promoted dermal–epidermal adhesion[2]. Further milestones in our understanding of BP included the immunochemical characterization of targeted proteins, the cloning of their genes, and the development of animal models of the disease[3–5].

Epidemiology

BP is typically a disease of the elderly, with an onset after 60 years of age. The annual incidence has been estimated to be at least 6–13 new cases per million population (with a rapid increase after the age of 60 years); however, these figures require further refinement (e.g. utilizing age-matched individuals as the denominator).[6] The relative risk for patients over 90 years of age appears to be about 300-fold higher than for those 60 years of age or younger, with an apparent higher predominance in men than in women[6]. The disease also occurs in children, but rarely. Certain HLA class II alleles are more prevalent in patients with BP than in the general population[7]. In Caucasians, a significant association with the allele DQB1*0301 has been found, while an increased frequency of the alleles DRB1*04, DRB1*1101 and DQB1*0302 has been observed in Japanese patients.

Pathogenesis

BP is an example of an immune-mediated disease that is associated with a humoral and cellular response directed against two well-characterized self-antigens: BP antigen 180 (BP180, BPAG2 or type XVII collagen) and BP antigen 230 (BP230 or BPAG1e) (Table 30.1)[3,4]. While the former is a transmembrane protein with a large collagenous extracellular domain, the latter is a cytoplasmic protein belonging to the plakin family (see Ch. 28). These two antigens are components of the hemidesmosomes, which are adhesion complexes promoting epithelial–stromal adhesion in stratified and other complex epithelia.

In vitro studies and *in vivo* animal models have provided strong evidence for the pathogenic role of autoantibodies in BP[5]. Furthermore, in gestational pemphigoid, a disease closely related to BP, the transplacental transfer of autoantibodies to BP180 from the mother into the neonate can result in a transient bullous eruption (see Ch. 34). Finally, the autoimmune etiology of BP is indirectly supported by its association with distinct class II major histocompatibility complex (MHC) haplotypes and its response to immunosuppressive therapy.

Humoral and cellular responses

Almost all patients with BP have circulating IgG autoantibodies that bind to BP180. More specifically, it is the non-collagenous NC16A domain, a region of BP180 located extracellularly but close to the transmembrane domain, that constitutes the immunodominant region (see Fig. 31.9). However, additional antigenic sites exist within both the extracellular and intracellular domains of BP180, and they are recognized by up to 70% of BP sera[3,8–12]. Patients with BP also exhibit significant autoreactivity to intracellular BP230[4,11,12]. BP230-reactive autoantibodies bind predominantly, but not exclusively, to the C-terminal region of this autoantigen. The presence of several antigenic sites throughout BP180 and BP230 most likely results from the phenomenon known as "epitope spreading" (see below). This phenomenon may also account for the finding that patients' sera rarely contain autoantibodies targeting additional components of the BMZ.

Patients with BP develop an autoreactive T-cell response to BP180 and BP230, and this is probably crucial for stimulating B cells to produce autoantibodies[13]. The responsiveness of anti-BP180

MAJOR AUTOANTIGENS OF SUBEPIDERMAL AUTOIMMUNE-MEDIATED BLISTERING DISEASES			
Disease	**Target antigen(s)**	**Mol. wt. (kDa)**	**Morphologic structures**
Bullous pemphigoid (BP)	BP180/BPAG2/collagen XVII	180	Hemidesmosomal plaque/anchoring filaments
	BP230/BPAG1e	230	Hemidesmosomal plaque
Gestational pemphigoid	BP180/BPAG2/collagen XVII	180	Hemidesmosomal plaque/anchoring filaments
	BP230/BPAG1e	230	Hemidesmosomal plaque
Mucous membrane (cicatricial) pemphigoid	BP180/BPAG2/collagen XVII	180	Hemidesmosomal plaque/anchoring filaments
	BP230/BPAG1e†	230	Hemidesmosomal plaque
	Laminin 5 (332; $\alpha_3\beta_3\gamma_2$; epiligrin)	165, 140, 105	Anchoring filaments
	Laminin 6 (311; $\alpha_3\beta_1\gamma_1$)‡	165, 220, 200	Anchoring filaments/extracellular matrix
	Integrin β_4 subunit§	200	Hemidesmosomal plaque/anchoring filaments
Linear IgA bullous dermatosis (LABD)	LAD antigen¶	97/120	Anchoring filaments
	BP180/BPAG2/collagen XVII	180	Hemidesmosomal plaque/anchoring filaments
	BP230/BPAG1e†	230	Hemidesmosomal plaque
	Type VII collagen†	290/145	Anchoring fibrils
Epidermolysis bullosa acquisita	Type VII collagen†	290/145	Anchoring fibrils
Anti-p200 pemphigoid	Laminin gamma-1 chain	200 kDa	Extracellular matrix
Bullous systemic lupus erythematosus	Type VII collagen†	290/145	Anchoring fibrils

†Detectable in a subset of patients
‡Binding to laminin 6 (331) depends on the presence of cross-reactive autoantibodies directed against the α-chain of laminin 5 (332).
§Reactivity with the cytoplasmic domain of the β4 subunit of the $\alpha6\beta4$ integrin described in a subset of patients with ocular cicatricial pemphigoid.
¶It constitutes the most characteristic serologic marker for LABD. The 120 kDa LAD antigen corresponds to the cleaved, shed extracellular domain of BP180/BPAG2. The 97 kDa protein results from its further proteolytic degradation.

Table 30.1 Major autoantigens of subepidermal autoimmune-mediated blistering diseases. Not an exhaustive list. In the course of these diseases, it is possible to detect autoantibodies directed against additional antigens, the significance of which remains to be established. In certain cases, a so-called "intermolecular epitope spreading" phenomenon is thought to occur.

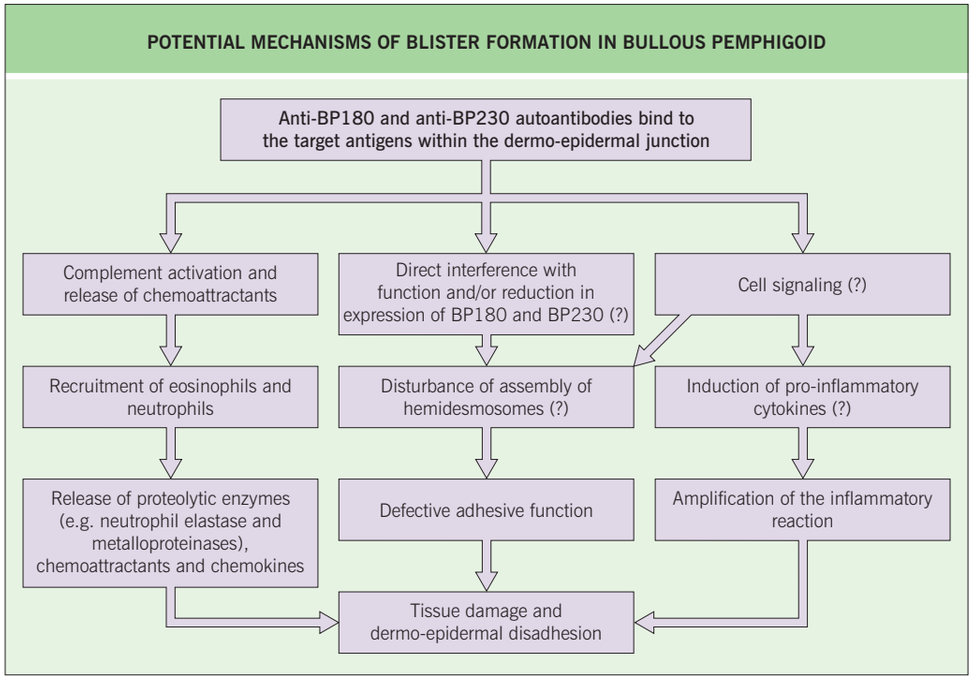

Fig. 30.1 Potential mechanisms of blister formation in bullous pemphigoid. IgG autoantibodies are classically involved in the pathogenesis, but more recently IgE autoantibodies have also been described. (?), possible explanation.

autoreactive T cells is restricted by certain HLA class II alleles (e.g. HLA-DQB1*0301), which are prevalent in BP patients. These T lymphocytes, whose major relevant epitopes seem to be harbored within the NC16 domain, have a $CD4^+$ phenotype and produce both Th1 (e.g. interferon-γ) and Th2 cytokines (e.g. interleukin [IL]-4, IL-5 and IL-13; see Ch. 4)[13]. Th2 cytokines may be particularly relevant to the pathophysiology of BP; they predominate within lesional tissue and in patients' sera. Also, the IgG4 subclass, the secretion of which is regulated by Th2 cytokines, is one of the major isotypes of the anti-BP180 autoantibodies.

Upon binding of autoantibodies to their target antigens, subepidermal blister formation results from a cascade of events that involves complement activation, recruitment of inflammatory cells (mainly neutrophils and eosinophils), and liberation of various chemokines and proteases, such as matrix metalloproteinase-9 and neutrophil elastase[14,15]. These proteinases proteolytically degrade various extracellular matrix proteins as well as BP180. Infiltrating mast cells and eosinophils (that can be activated by specific IgE anti-BP180 autoantibodies) are also significantly implicated in producing tissue damage via the release of proteases and proinflammatory mediators, such as IL-5

Fig. 30.2 Bullous pemphigoid – bullous presentation. Classic presentation with multiple tense bullae arising on normal and erythematous skin. Several of the bullae have ruptured, leaving circular erosions.

Fig. 30.3 Bullous pemphigoid – urticarial (and bullous) presentation. A Pink urticarial papules and plaques as well as tense bullae containing serous fluid. **B** Firm annular urticarial plaques.

and eotaxin.[15] Autoantibodies to BP180 can probably also amplify the inflammatory response by directly stimulating keratinocytes to express various cytokines (e.g. IL-6 and IL-8) (Fig. 30.1)[16]. Finally, IgG autoantibodies reduce hemidesmosomal BP180 content and by this means may contribute to weakening of dermal–epidermal cohesion[17].

Various animal models have provided strong evidence that autoantibodies against BP180 are pathogenic. When passively transferred to neonatal mice (in which BP180 had been fully or partially humanized by genetic engineering), human autoantibodies against the NC16A domain (the immunodominant determinant of human BP180) were able to induce a blistering disorder that reproduced all the key features of BP[5,18]. In contrast, autoantibodies against BP230 caused an inflammatory reaction in rabbits only after additional injury to their epidermis; however, recent findings suggest that anti-BP230 antibodies are able to induce an inflammatory reaction and subepidermal blistering in a murine model[19]. Together, these studies have led to the speculation that antibodies against the ectodomain of BP180 are pathophysiologically critical, whereas the development of antibodies against BP230 represents a secondary event that contributes to tissue damage.

Clinical Features

Non-bullous phase

The cutaneous manifestations of BP can be extremely polymorphic (Figs 30.2–30.6)[1,20]. In the prodromal, non-bullous phase of the disease, signs and symptoms are frequently nonspecific, with mild to severe intractable pruritus alone or in association with excoriated, eczematous, papular and/or urticarial lesions that may persist for several weeks or months. These nonspecific skin findings may remain as the only signs of the disease.

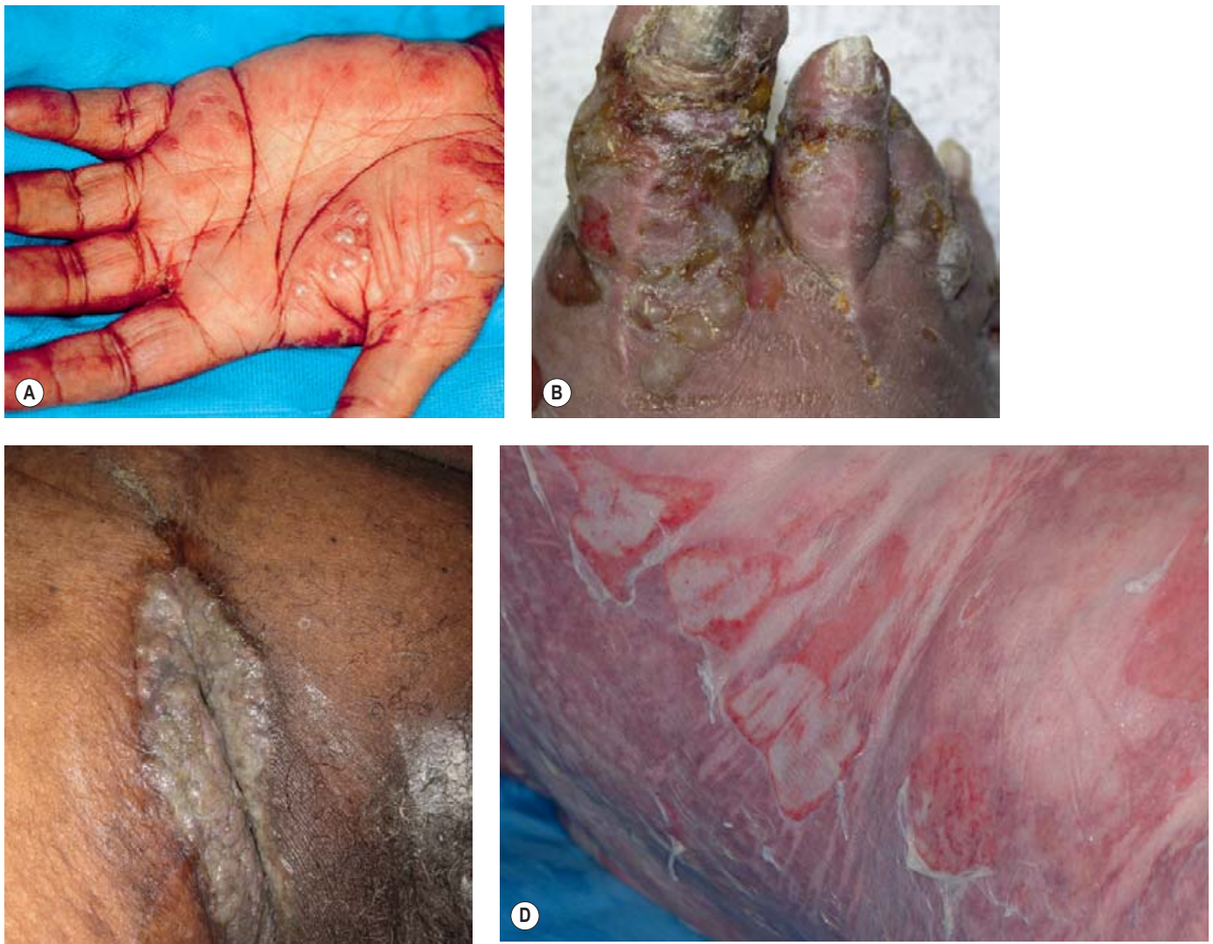

Fig. 30.5 Bullous pemphigoid – unusual clinical variants. Grouped vesicles and bullae on the palms **(A)** and toes **(B)** that can resemble pompholyx (dyshidrosiform pemphigoid). **C** Vegetating plaque in the inguinal crease (pemphigoid vegetans). **D** Toxic epidermal necrolysis-like lesions with large erosions.

Bullous phase

The bullous stage of BP is characterized by the development of vesicles and bullae on apparently normal or erythematous skin together with urticarial and infiltrated papules and plaques that occasionally assume an annular or figurate pattern (see Figs 30.2 & 30.3). The blisters are tense, up to 1–4 cm in diameter, contain a clear fluid, and may persist for several days, leaving eroded and crusted areas. Occasionally, the blister fluid becomes blood-tinged. The lesions frequently have a symmetrical distribution pattern, and they predominate on the flexural aspects of the limbs and the lower trunk, including the abdomen. Within intertriginous zones, vegetating plaques can be observed (see Fig. 30.5C). Residual postinflammatory changes include hyper- and hypopigmentation and, only occasionally, milia. Involvement of the oral cavity is observed in 10–30% of patients. The mucosae of the eyes, nose, pharynx, esophagus and anogenital region are more rarely affected. In approximately 50% of patients, a peripheral blood eosinophilia is noted.

Clinical variants

Several clinical variants of BP have been described and are outlined in Table 30.2[20]. *Pemphigoid gestationis* (or *gestational pemphigoid*) is also a variant of BP, which typically occurs during pregnancy (see Ch. 27).

While the individual lesions of BP in infants and in older children (*infantile* and *childhood BP*) are similar to those observed in the elderly, the sites of involvement can differ. In infants, bullae often first appear acrally and then can generalize to other sites, including the face. Involvement of the genital region (e.g. *vulvar childhood pemphigoid*) as well as other mucosal sites/mucosae has been observed in children[20].

Associated Diseases

The association of internal malignancies with BP is probably related primarily to the older age of the patient. Although some reports have suggested an increased frequency of certain cancers (e.g. digestive tract, urinary bladder, lung) as well as lymphoproliferative disorders, in three case–control studies, the trend towards an increased risk of malignancy in patients with BP appeared to be marginal[6,20]. Nonetheless, patients with BP should be up-to-date with age-related cancer screening tests recommended for the general population.

Rarely, BP has been described in patients with inflammatory bowel disease or other autoimmune disorders such as rheumatoid arthritis, Hashimoto's thyroiditis, dermatomyositis, lupus erythematosus and autoimmune thrombocytopenia. It is thought that these associations are not fortuitous but reflect a genetically determined susceptibility to develop autoimmune diseases. Nevertheless, a case–control study did not find any increased risk for autoimmune disorders in those with BP[21].

In some patients, BP appears to be triggered by trauma, burns, radiotherapy or UV irradiation (including PUVA). BP has also been found in association with certain dermatoses, such as psoriasis and lichen planus, and the bullae may be localized to the psoriatic plaques (Fig. 30.7). It has been speculated that a chronic inflammatory process at the dermal–epidermal junction results in the exposure of antigens to

Fig. 30.6 Childhood bullous pemphigoid. **A** Generalized tense bullae and crusted erosions. **B** Localized vulvar involvement (vulvar childhood pemphigoid).

UNUSUAL CLINICAL VARIANTS OF BULLOUS PEMPHIGOID

Dyshidrosiform pemphigoid – palmoplantar vesicles and bullae (Fig. 30.5A,B)
Pemphigoid vegetans – intertriginous vegetating plaques (Fig. 30.5C)
Pemphigoid nodularis – prurigo nodularis-like lesions
Vesicular pemphigoid – dermatitis herpetiformis-like presentation with small grouped vesicles
Large erosive TEN-like lesions (Fig. 30.5D)
Papular pemphigoid
Eczematous pemphigoid (Fig. 30.4)
Erythrodermic pemphigoid
Lichen planus pemphigoides (see Ch. 11)
Localized lesions:
- pretibial
- vulvar
- peristomal
- umbilical
- distal end of amputated limb*
- paralyzed limb
- sites of radiotherapy†
- Brunsting–Perry form‡

*Also referred to as "stump" pemphigoid.
†Radiotherapy can also provoke generalized form of pemphigoid.
‡Also variant of mucous membrane (cicatricial) pemphigoid.

Table 30.2 Unusual clinical variants of bullous pemphigoid.

autoreactive T lymphocytes, leading to a secondary immune response (epitope spreading phenomenon)[22].

Finally, BP is significantly associated with neurological disorders, such as Parkinson's disease, dementia, psychiatric disorders (unipolar and bipolar disorders), and stroke. A strong association with multiple sclerosis was also observed in a population-based study[23]. It should be noted that neuronal variants of BP230 are expressed in the central and peripheral nervous systems.

Drug-induced bullous pemphigoid

In certain patients, systemic medications can lead to the development of BP[24]. The implicated drugs are numerous, including diuretics (e.g. furosemide, bumetanide), analgesics (e.g. phenacetin), D-penicillamine, antibiotics (e.g. amoxicillin, ciprofloxacin), potassium iodide, gold and captopril. Reproduction of BP lesions following drug rechallenge has been observed with some medications (e.g. furosemide), but for others, the association is based on less evidence. In a case–control study assessing the drugs used on a long-term basis prior to onset of the disease, it was found that two classes of drugs, diuretics and neuroleptics, were used more frequently by BP patients than by control subjects. Among diuretics, the risk was linked to aldosterone antagonists[24]. Hence, in all patients, a careful drug history is mandatory to exclude the triggering effect of a drug, since its prompt discontinuation may result in rapid improvement.

The mechanisms by which drugs favor the development of BP remain to be elucidated. It is likely that the drugs act as triggers in patients with an underlying genetic susceptibility by either modifying the immune response or altering the antigenic properties of the epidermal basement membrane.

Diagnosis and Differential Diagnosis

The diagnosis of BP is based upon the typical clinical presentation, the histologic features, and, most importantly, the positive findings of direct and indirect immunofluorescence (IF) microscopy studies[20], or BP180 ELISA. In the majority of cases, IF microscopy provides clues that are essential and sufficient for a correct classification of patients. Nevertheless, particularly in patients in whom indirect IF microscopy is negative, additional immunochemical studies (e.g. ELISA; see below) are helpful and are required to demonstrate an autoantibody response to the targets of the disease, BP180 and/or BP230. In the absence of full-blown bullous lesions, such as in early stages or in atypical variants of the disease, the diagnosis of BP uniquely relies on the positive results of direct IF microscopy and the characterization of the targeted autoantigens (see Table 30.1).

Light microscopy and electron microscopy

In the non-bullous phase or in atypical variants of BP, light microscopy studies may provide less specific information, since only subepidermal clefts, eosinophilic spongiosis and/or dermal infiltrates of eosinophils may be found (Fig. 30.8). In biopsy specimens of an early bulla, a subepidermal blister accompanied by a dermal inflammatory infiltrate composed of eosinophils and mononuclear cells is typically observed.

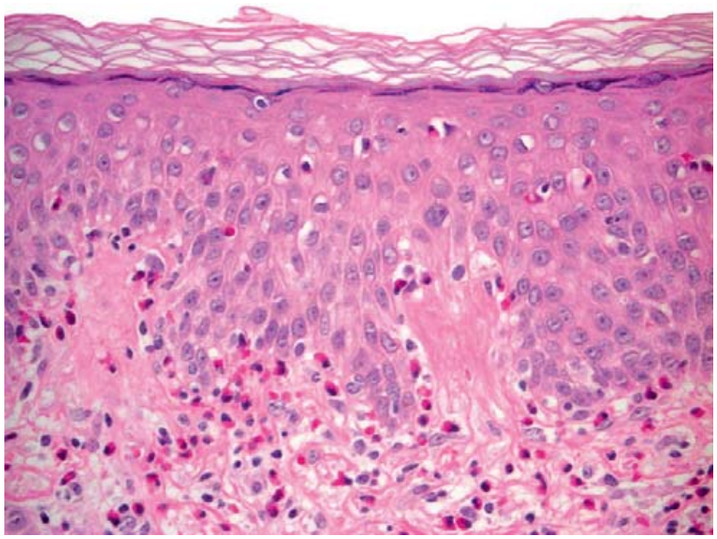

Fig. 30.8 Urticarial phase of bullous pemphigoid – histologic features. Eosinophils are present within the dermis as well as the epidermis (eosinophilic spongiosis). Some of the eosinophils have lined up at the dermal–epidermal junction, a typical finding in the urticarial stage of BP. *Courtesy, Lorenzo Cerroni, MD.*

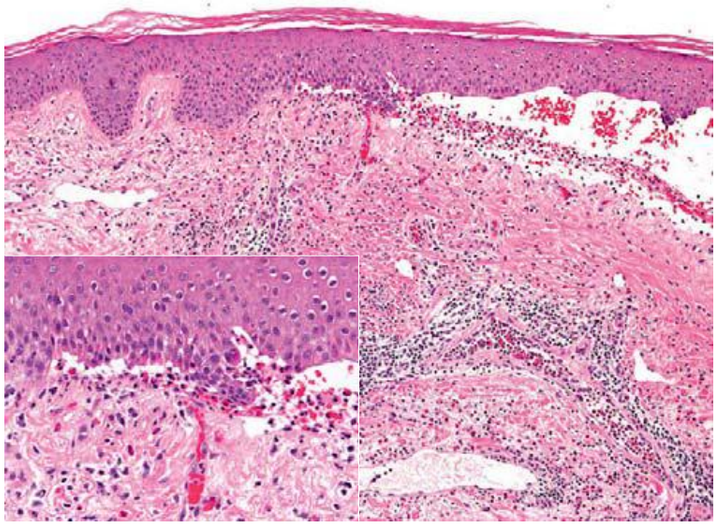

Fig. 30.9 Bullous pemphigoid – histologic features. Subepidermal blister which contains fibrin, eosinophils and mononuclear cells (see insert). *Courtesy, Lorenzo Cerroni, MD.*

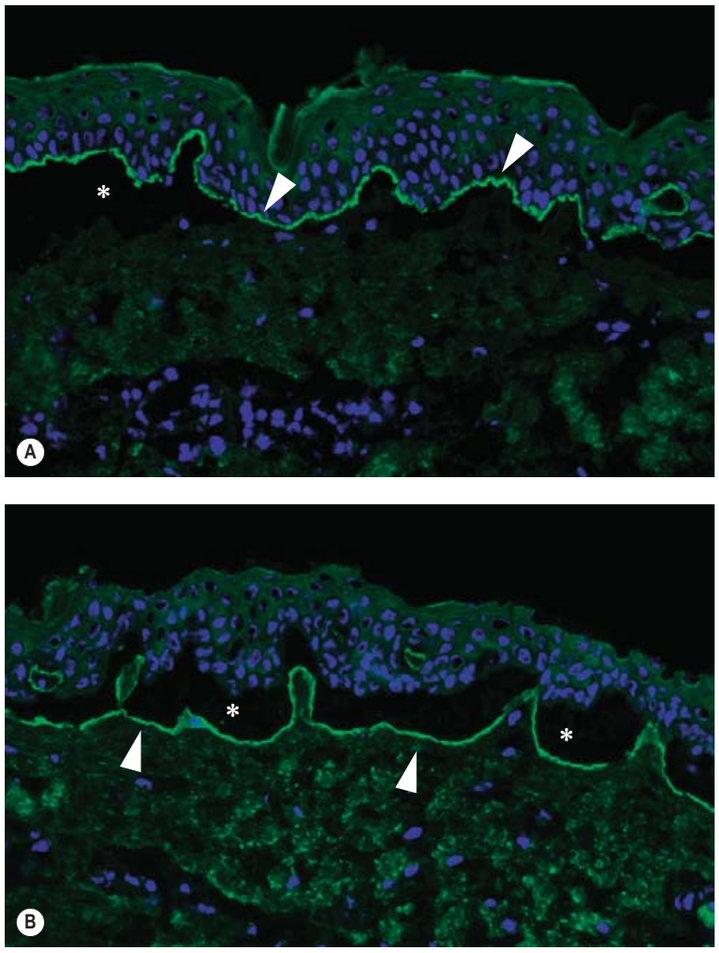

Fig. 30.10 Immunofluorescence microscopy (indirect) utilizing salt-split human skin. A Circulating IgG autoantibodies from BP patients bind to the epidermal side (roof) of the salt-induced split (arrows); the artificial separation is indicated by an asterisk. **B** IgG autoantibodies from patients with EBA, anti-p200 pemphigoid and certain forms of mucous membrane pemphigoid (e.g. with antibodies against laminin 5/332) react with the dermal side (floor) of the blister (arrows). *Courtesy, H Pas, MD.*

The infiltrate favors the uppermost dermis, and the cavity of the bulla contains a net of fibrin with a variable inflammatory infiltrate (Fig. 30.9). Electron microscopy studies have shown that subepidermal blister formation occurs at the level of the lamina lucida.

Immunofluorescence microscopy

In almost all patients, direct IF microscopy studies of *perilesional, uninvolved* skin will characteristically demonstrate the presence of fine, linear, continuous deposits of IgG and/or C3 (and, more rarely, other Ig classes) along the epidermal basement membrane (see Ch. 27). IgG4 and IgG1 are the predominant IgG subclasses. Close analysis of the linear fluorescence pattern at the BMZ (n-serrated in BP and linear IgA bullous dermatosis *versus* u-serrated in epidermolysis bullosa acquisita)[25] as well as examination of perilesional skin after treatment with 1 M NaCl (referred to as salt-split skin; see Fig. 28.8) can be helpful in distinguishing BP from other autoimmune blistering disorders. In BP, immune deposits are found in the epidermal side (roof) or in both the epidermal and dermal sides of the split. Although not routinely available, the computer-aided fluorescence overlay antigen mapping (FOAM) technique allows one to determine more precisely the localization of deposited immunoreactants[26].

In 60–80% of patients, circulating anti-basement membrane autoantibodies of the IgG class, and, less frequently, of the IgA and IgE classes, are detectable. These autoantibodies typically bind to the epidermal side or, less frequently, to both the epidermal and dermal sides of saline-separated normal human skin (Fig. 30.10)[26]. For indirect IF studies, salt-split normal human skin is the substrate of choice, rather than intact normal human skin or monkey esophagus. Finally, when available, testing of circulating autoantibodies against skin substrates or keratinocyte cell lines that are deficient in specific basement membrane proteins, such as BP180 or type VII collagen, represents an easy method for determining their exact reactivity pattern.

Immunoelectron microscopy

Although less often utilized nowadays, immunoelectron microscopy studies using gold labeling demonstrate that *in vivo*-deposited IgG antibodies are predominantly localized to the outside of the basal cell membrane beneath hemidesmosomes, in a distribution corresponding to the location of the extracellular domain of BP180. By indirect immunoelectron microscopy, circulating autoantibodies to BP230 and BP180 can be seen to bind to the hemidesmosomal plaque (Fig. 30.11) and at the level of the lamina lucida beneath the hemidesmosomes, respectively[27].

Immunochemical studies

In immunoblot and immunoprecipitation studies of keratinocyte extracts, 60–100% of patients' sera contain IgG autoantibodies that bind to BP180 and BP230, respectively (see Table 30.1; Fig. 30.12A,B)[3,4]. Patients' sera also frequently contain specific IgA and IgE autoantibodies. Recombinant forms of BP180 and BP230 expressed in prokaryotic or eukaryotic systems have been used increasingly for the detection of autoantibodies (Fig. 30.12C)[8,20].

ELISAs utilizing recombinant proteins that encompass specific regions of the BP antigens (e.g. the NC16A domain of BP180 and the C-terminus of BP180 or BP230) have been found to be fairly *specific* (>90%)[8,20]. Occasionally, low-titer, false-positive results are observed in healthy subjects and elderly patients with pruritic cutaneous eruptions. Overall *sensitivity* of the BP180-NC16A ELISA is probably comparable to that of indirect IF (with salt-split skin as a substrate) when the test is performed in unselected BP patients[12,20]. To increase overall sensitivity, various ELISAs for BP180 and BP230 proteins should be combined[11,12,20]. In contrast to immunoblotting, ELISA antigens are tested under native conditions, and, as a result, binding activity against conformational antigens is not lost. These tests are now commercially available and enable rapid characterization of the reactivity of patients' sera[20].

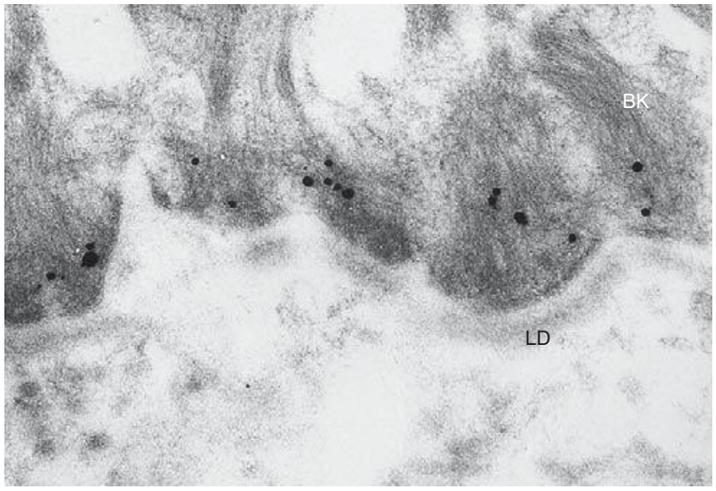

Fig. 30.11 Bullous pemphigoid – indirect immunoelectron microscopy utilizing immunogold labeling. Autoantibodies directed against BP230 specifically label the hemidesmosomal plaque of the hemidesmosomal adhesion complex (gold labeling = black dots). Differential diagnosis

Because the clinical findings in the non-bullous phase of BP may be nonspecific, they can resemble a variety of dermatoses, including drug reactions, contact dermatitis, prurigo (simplex and nodularis), urticarial dermatoses, arthropod reactions, and scabies[20]. These disorders are usually distinguished on the basis of the clinical history and setting, pathologic features, and the negative findings with IF microscopy. The presence of bullae raises the possibility of bullous arthropod bites, allergic contact dermatitis, Stevens–Johnson syndrome, bullous drug eruptions (see Ch. 33), dyshidrotic eczema, pseudoporphyria or porphyria cutanea tarda. In children, bullous impetigo, inherited epidermolysis bullosa, and bullous mastocytosis must also be considered.

The pemphigus group, paraneoplastic pemphigus, and dermatitis herpetiformis can be differentiated on the basis of distinctive immunopathologic findings and clinical context. A recent study found that, in patients with a subepidermal blistering disorder associated with linear deposits of IgG or C3 along the epidermal basement membrane, the presence of the following four clinical criteria strongly indicated a diagnosis of BP: (1) absence of skin atrophy, (2) absence of mucosal involvement, (3) absence of head and neck involvement, (4) age greater than 70 years[28]. Nevertheless, the distinction of BP from the following autoimmune subepidermal blistering disorders can sometimes prove challenging (see Table 30.1).

- **Epidermolysis bullosa acquisita (EBA)** has a wide spectrum of clinical presentations (see below). While the classic "non-inflammatory" form of EBA is sufficiently distinctive, the "inflammatory" form closely mimics BP. As with BP, mucosal involvement may be present.
- **Linear IgA bullous dermatosis (LABD)** represents a group of subepidermal blistering diseases rather than a single entity (see Ch. 31). While features of LABD are polymorphic in adults, during childhood the condition is frequently associated with annular and polycyclic lesions as well as involvement of the genital and perioral region. However, identical features are also observed in childhood BP.
- **Mucous membrane (cicatricial) pemphigoid** is a heterogeneous group of diseases which have in common the predominant involvement of the mucosae, a chronic course, and a scarring tendency (see below). Skin lesions are only found in up to 25–30% of patients, and they generally involve the head and upper trunk.

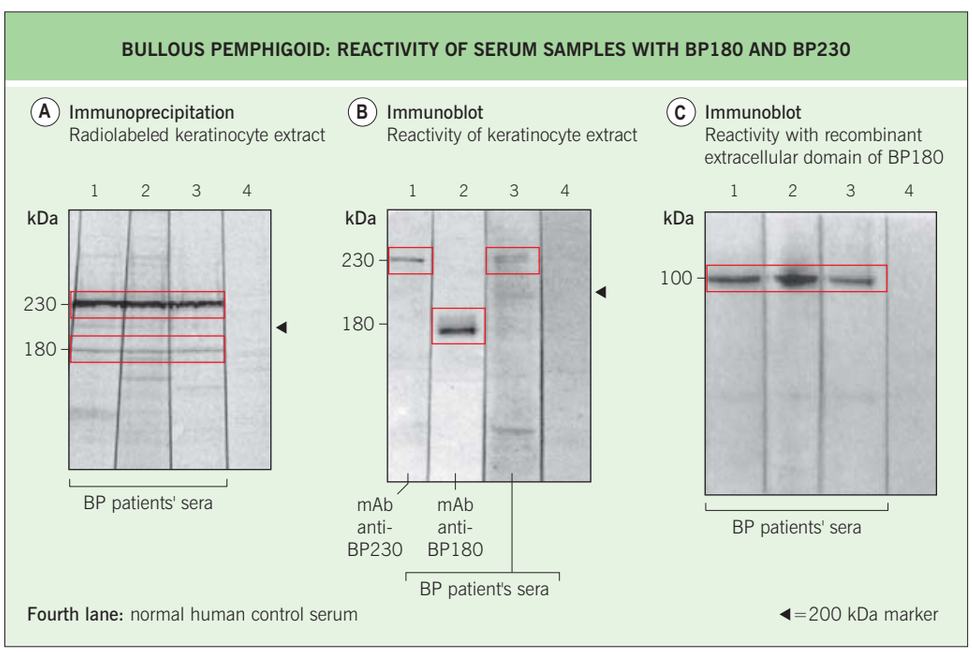

Fig. 30.12 Bullous pemphigoid (BP): reactivity of serum samples with BP180 and BP230. A Immunoprecipitation studies utilizing radiolabeled human keratinocyte extracts: lanes 1–3, serum samples from BP patients immunoprecipitate proteins of 230 kDa (BP230) and 180 kDa (BP180); lane 4, reactivity of normal human serum. **B** Immunoblot studies of keratinocyte extracts: lane 1, reactivity of monoclonal antibodies directed against BP230; lane 2, reactivity of monoclonal antibodies directed against BP180; lane 3, reactivity of a BP serum sample with a protein of approximately 230 kDa; lane 4, reactivity of normal human serum. **C** Reactivity with the extracellular domain of BP180, which was expressed by transfection of COS-7 cells: lanes 1–3, serum samples from BP patients; lane 4, normal human serum.

In patients with both oral and cutaneous lesions, the differentiation of mucous membrane pemphigoid from BP is difficult, and classification relies on the presence of an obvious scarring tendency of involved mucosal sites and limited skin involvement, and, occasionally, on the results of immunologic assays (see Table 30.1).

- **Pemphigoid incipiens**. A difficult issue is how to categorize the group of elderly patients with generalized pruritus (with or without skin lesions), in whom circulating autoantibodies to the epidermal BMZ and reactivity with BP180 and/or BP230 are found, but routine IF microscopy remains negative. Some of these patients, with initially negative direct IF microscopy findings, eventually do develop BP and could be thought of as having pemphigoid incipiens[20].
- **Anti-p200 pemphigoid**. A small group of patients have been described with features identical to those observed in BP, i.e. vesicles and tense blisters as well as eczematous and urticarial papules and plaques. Occasionally, grouped papulovesicles with a dermatitis herpetiformis-like presentation are also present. There may also be mucosal involvement. These patients have circulating autoantibodies that specifically bind the dermal side of salt-split human skin. The targeted 200 kDa BMZ protein is the gamma 1 chain of laminin (see Table 30.1)[29,30].

Prognosis

BP is a chronic disease characterized by spontaneous exacerbations and remissions. Because of the intractable pruritus, and the presence of bullous, eroded or impetiginized lesions, the disease is often accompanied by significant morbidity with a profound impact on quality of life. Although the majority of patients finally go into clinical remission with treatment, the mortality is considerable among elderly patients. The estimated death rate during the first year varies between 10% and 40%, depending on the series[31,32]. Age and a Karnofsky score that is <40 (range, 0–100) have been shown to significantly affect prognosis. It is likely that comorbidities and practice patterns (use of systemic corticosteroids and/or immunosuppressive drugs) also influence overall morbidity and mortality.

ELISA-based studies have recently shown that the serum level of IgG and IgE autoantibodies to BP180 correlated with disease severity[20,33]. Furthermore, IgG reactivity with both the NC16A domain *and* the C-terminus of BP180 has been associated with a distinct clinical phenotype of BP, presenting with a preferential mucosal involvement[9,11]. While the practical use of ELISA results as a means of guiding treatment remains to be established, a recent study found that a high BP180-NC16A ELISA score and (to a lesser degree) positive direct IF findings at cessation of therapy are both good indicators of future relapse of BP[33].

Treatment

The treatment of BP is grounded more on clinical experience than on controlled studies (Tables 30.3 & 30.4)[19,32,34–42].

Systemic corticosteroids represent the most endorsed treatment. For patients with generalized disease, a regimen of oral prednisone at a dose of 0.5–1 mg/kg/day usually controls the disease within 1 or 2 weeks. This dose is then progressively tapered over a period of 6–9 months, or occasionally longer. The use of corticosteroids in the elderly, however, is associated with significant side effects (see Ch. 125). Recent large controlled studies have emphasized the role of potent topical corticosteroids, which appeared to control even generalized BP with the same efficacy as oral corticosteroids, and, most importantly, with fewer systemic side effects[40,42]. However, these studies did not address the patients' ability to achieve complete disease-free remissions as compared with systemic corticosteroids. Occasionally, pulse therapy with methylprednisolone may be required for rapid control of the disease.

The use of immunosuppressive drugs is a matter of debate. Some clinicians prefer to use them solely as second-line therapy when corticosteroids alone fail to control the disease, or if the latter are contraindicated. The most frequently employed agents are azathioprine, mycophenolate mofetil (1.5–3 g/day), methotrexate, chlorambucil (0.1 mg/kg/day, frequently 4–6 mg/day), and cyclophosphamide (1–3 mg/kg/day) (see Table 30.4). The dosage of azathioprine (0.5–2.5 mg/kg/day) should be adjusted according to the level of thiopurine methyltransferase, in order to increase efficacy and reduce toxicity. The choice of a particular immunosuppressive drug depends on its side-effect profile (see Ch. 130), the patient's overall condition, and the experience of the physician.

The combination of nicotinamide (500–2000 mg/day) and minocycline or tetracycline has been tried with some success in small series and can serve as a therapeutic alternative in mild disease when obvious contraindications to corticosteroids exist. Unless there is glucose-6-phosphate dehydrogenase deficiency, the use of dapsone may also be warranted, particularly in the presence of mucosal involvement. The benefit of topical immunomodulators, such as tacrolimus, remains to be confirmed. In treatment-resistant cases, IVIg, plasma exchange or anti-CD20 immunotherapy (rituximab) may be tried.

While the optimal duration of therapy has not been established, BP patients usually need to be treated for approximately 12–18 months. This includes a maintenance phase in which low-dose oral prednisone (<10 mg/day) or topical clobetasol propionate (10 g/week) is continued for 3 to 6 months after any evidence/cessation of clinically active disease[33]. Finally, in all patients with BP, it is important to minimize the complications of both the cutaneous lesions and the systemic treatment, including using osteoporosis prophylaxis, gastric protection, and assessment of cardiovascular function and infection risk (see Ch 125).

MUCOUS MEMBRANE (CICATRICIAL) PEMPHIGOID

Synonyms: ■ Desquamative gingivitis, benign mucous membrane pemphigoid, ocular pemphigus, scarring pemphigoid ■ Anti-epiligrin cicatricial pemphigoid ■ Anti-laminin 5 cicatricial pemphigoid

Key features

- Mucous membrane pemphigoid is a chronic, autoimmune, subepithelial blistering disorder characterized by predominant involvement of the external mucosal surfaces and a tendency for scarring
- It is associated with tissue-bound and, less often, circulating autoantibodies directed against distinct structural components of basement membranes in stratified and some complex epithelia, e.g. bullous pemphigoid antigen 180 (BP180, BPAG2 or type XVII collagen), laminin 332 (laminin 5)
- The condition should not be regarded as a clinical entity, but as a "disease phenotype" shared by a heterogeneous group of diseases with lesions that favor the mucosal surfaces and, less frequently, the skin
- When scarring and fibrosis affect the conjunctivae, the disorder can be devastating and ultimately lead to blindness
- Diagnosis relies on immunopathologic examinations, especially immunofluorescence microscopy, and immunochemical studies

Introduction

Mucous membrane pemphigoid is a rare autoimmune subepithelial blistering disorder characterized by predominant involvement of the mucosae, a chronic course, and a tendency towards scarring of the affected areas. The disorder should not be regarded as a clinical entity, but rather as a "disease phenotype" shared by a heterogeneous group of blistering diseases, with predilection for the mucosal surfaces[43]. The majority of patients have linear deposits of immunoglobulins and/or complement components along the epithelial BMZ of the skin and mucosae. Circulating anti-basement membrane autoantibodies are detected in the serum of some patients (20–30% by standard indirect IF), usually at a low titer. It is a chronic and progressive disease, which may result in serious local complications. When atrophic scarring and fibrosis affect the conjunctivae, the disorder can be devastating and ultimately lead to blindness.

SURVEY OF CONTROLLED TRIALS FOR THE TREATMENT OF PATIENTS WITH BULLOUS PEMPHIGOID						
Authors (year)	**Design**	**Intervention**		**Number of patients**	**Response**	**Remarks**
Roujeau et al.[34] (1984)	Randomized multicenter	Group 1: Group 2:	Prednisolone (0.3 mg/kg/day) Prednisolone + 8 plasma exchanges	41	Total and daily corticosteroid doses needed for disease control lower in group 2	Low prednisolone dose
Morel & Guillaume[35] (1984)	Randomized multicenter	Group 1: Group 2:	Prednisone (0.75 mg/kg/day) Prednisone (1.25 mg/kg/day)	42	At day 51, remission in group 1 (33%) and group 2 (55%) not significantly different	Trend for a better response in group 2
Guillot et al.[36] (1986)	Non-randomized retrospective	Group 1: Group 2:	Prednisolone alone Prednisolone plus long-term plasma exchange	21	At month 6, relapse rate and total corticosteroid doses lower in group 2	Risk of severe side effects in group 2
Dreno et al.[37] (1993)	Randomized multicenter	Group 1: Group 2:	Methylprednisolone (1–1.5 mg/kg/day) Prednisolone (1–1.5 mg/kg/day)	57	At day 10, no difference in response except for better decline of pruritus in group 1	Analysis of early response only
Guillaume et al.[38] (1993)	Randomized multicenter	Group 1: Group 2: Group 3:	Prednisolone (1 mg/kg/day) alone Prednisolone and azathioprine (100–150 mg/day) Prednisolone and 4 plasma exchanges	98	At month 6, no significant difference in remission rate between group 1 (42%), group 2 (39%) and group 3 (29%)	More complications in group 2. No adjustment of doses of azathioprine based on TPMT levels
Fivenson et al.[39] (1994)	Randomized single center	Group 1: Group 2:	Nicotinamide (1.5 g/day) plus tetracycline (2 g/day) Prednisone (40–80 mg/day)	18	At month 1, no difference in response, but fewer side effects in group 1	Low number of studied patients. High drop-out rate
Joly et al.[40] (2002)	Randomized multicenter	Group 1: Group 2:	Topical clobetasol propionate Prednisone 0.5–1 mg/kg/day	341	At week 3, control rates better in group 1	At year 1, topical therapy is associated with a significantly reduced mortality and complication rate
Beissert et al.[41] (2007)	Randomized multicenter prospective	Group 1 Group 2	Methylprednisolone (0.5 mg/kg) with azathioprine (2 mg/kg) Methylprednisolone (0.5 mg/kg) with mycophenolate mofetil (2 g daily)	38 35	Disease control similar in the two groups	In group 1, higher incidence and severity of liver toxicity. Trend for faster disease control and less total cumulative doses of steroids in group 1. No adjustment of doses of azathioprine based on TPMT
Joly et al.[42] (2009)	Randomized multicenter prospective	Group 1 Group 2	Topical clobetasol propionate *standard* regimen for 12 months (40 g daily as starting dose) Topical clobetasol propionate, *mild* regimen for 6 months (10–30 g daily as starting dose)	153 159	Time to achieve disease control of BP similar in both groups. At 1 year, trend for higher relapse rate in patients with moderate BP treated with mild regimen	In moderate BP treated with mild regimen, decrease in the risk of death/side effects. Lower cumulative dose of clobetasol in mild regimen

Table 30.3 Survey of controlled trials for the treatment of patients with bullous pemphigoid. TPMT, thiopurine methyltransferase.

THERAPEUTIC LADDER FOR BULLOUS PEMPHIGOID
MILD AND/OR LOCALIZED DISEASE
Superpotent topical corticosteroids (1*)
Nicotinamide in association with minocycline, doxycycline or tetracycline (3)
Erythromycin, penicillins (3)
Dapsone, sulfonamides (3)
Topical immunomodulators (e.g. tacrolimus) (3)
EXTENSIVE/PERSISTENT CUTANEOUS DISEASE
Superpotent topical corticosteroids (1*)
Oral corticosteroids† (1‡)
Azathioprine (2)
Mycophenolate mofetil (2)
Methotrexate§ (2)
Chlorambucil (3)
Cyclophosphamide (3)
IVIg (3)
Plasma exchange (2)
Rituximab (3)
Note: Superpotent topical corticosteroids should be considered in any patient and may be combined with a systemic therapy.
*Validated.
†Prednisone doses of at least 0.5–0.75 mg/kg/day seem to be necessary to control extensive disease, but increase serious side effects, including mortality.
‡Validated for prednisone.
§In elderly patients, low-dose regimen (2.5–10 mg/wk) can be effective.

Table 30.4 Therapeutic ladder for bullous pemphigoid. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

Fig. 30.13 Mucous membrane (cicatricial) pemphigoid. Erythema and erosions of the gingival margins (desquamative or erosive gingivitis).

History

In 1794, Wichmann first described a chronic blistering disease associated with involvement of the eyes. In 1949, Civatte separated this disorder from pemphigus on the basis of peculiar histopathologic findings, and Lever later suggested the name "benign mucous membrane pemphigoid", a misnomer in view of the potentially devastating complications of the disorder. Over the past few decades, the term "cicatricial pemphigoid" has been used with increasing frequency. Demonstration of immunoreactants deposited along the epithelial BMZ by IF microscopy pointed to an autoimmune origin.

Epidemiology

Mucous membrane pemphigoid is rare, with an annual incidence in Western Europe of approximately 1–5 cases per million[44]. The disorder typically occurs in the elderly, with a mean age at the time of diagnosis of between 60 and 80 years. Nonetheless, isolated cases have been reported in children. Women are affected more often than men (estimated ratio 1.5–2 : 1). Although no geographic or racial predilection has been described, several studies have shown an association with specific immunogenetic haplotypes, primarily HLA-DQw7 (subtyped HLA-DQB1*0301), in both oral and ocular forms of the disease[45]. There is no overall association with malignancy, but in a distinct subtype associated with autoantibodies directed against laminin 332 (laminin 5), also known as anti-epiligrin cicatricial pemphigoid, an increased relative risk for cancer has been reported[46].

Pathogenesis

Mucocutaneous lesions are thought to result from the binding of autoantibodies to the BMZ of stratified epithelia of mucosae and skin. These autoantibodies recognize distinct structural components of the hemidesmosomal adhesion complex. Specifically, they appear to bind predominantly to antigenic sites located extracellularly within the anchoring filament zone rather than within the hemidesmosomal plaque[47]. However, the pathogenicity of various autoantibodies associated with this disease phenotype (see Table 30.1) has not yet been established unequivocally and other mechanisms may also be involved. In a minority of patients with mucous membrane pemphigoid, NC16A domain-specific T cells were detectable[48]. For patients with ocular disease, increased expression of collagen-binding *h*eat *s*hock *p*rotein 47 (HSP47) and TGF-β1 by conjunctival fibroblasts may contribute to conjunctival scarring[49]. Nonetheless, mucous membrane pemphigoid can be separated into four distinct subgroups on the basis of the reactivity profile of patients' autoantibodies.

The *first* subgroup includes patients with autoantibodies directed against laminin 332 (previously termed laminin 5), and is known as anti-laminin 5 cicatricial pemphigoid or anti-epiligrin cicatricial pemphigoid[50]. These patients with anti-laminin 5 (332) autoantibodies cannot be distinguished clinically from those with other variants of mucous membrane pemphigoid. They have circulating IgG autoantibodies that bind to the dermal side of salt-split skin and react with the α_3 chain (G domain) and, less frequently, the β_3 and/or γ_2 chain of laminin 5 (332) ($\alpha_3\beta_3\gamma_2$). Occasionally, binding to the α_3 chain of laminin 311 (previously termed laminin 6; a heterotrimer of $\alpha_3\beta_1\gamma_1$ chains) is also observed, because of the presence of cross-reacting antibodies. *In vitro* and *in vivo* studies have provided convincing evidence that autoantibodies to laminin 5 (332) are pathogenic[51].

The *second* group of patients has pure or predominant ocular disease. In this subset with so-called ocular mucous membrane pemphigoid, the presence of autoantibodies that bind to the β_4 subunit of $\alpha_6\beta_4$ integrin, a transmembrane hemidesmosomal component that interacts with laminin 5 (332), has been described[52]. A *third* group of patients, who present with lesions affecting both mucosae and the skin, have tissue-bound and circulating IgG antibodies that react with the same target antigens as for BP, especially BP180 (see above)[53]. Hence, these patients should be classified as having anti-BP antigen mucous membrane pemphigoid. The antigenic regions targeted on BP180 are probably preferentially located on its distal C-terminal portion, which ultrastructurally appears to extend into the lamina densa region[20,47]. The *fourth* group is rather heterogeneous. It includes patients who have variable involvement of mucosae without involvement of the skin. In these patients, it is as yet unclear whether injury occurs as a result of an autoantibody-mediated response to proteins of the epithelial basement membrane.

Clinical Features

Mucous membranes

The two most frequently involved sites in patients with the "mucous membrane pemphigoid phenotype" are the oral and conjunctival mucosae. However, the disease may also start in, and affect, any mucosal site, including the external genitalia, the anus, the upper aerodigestive tract, and/or the esophagus[54,55]. Approximately 85% of patients have oral involvement (often in the absence of skin lesions), and the oral cavity may be the only site of disease activity. Lesions often involve the gingiva, buccal mucosa, and palate; the alveolar ridges, tongue and lips are less frequently affected.

A common oral presentation is desquamative gingivitis (Fig. 30.13), accompanied by bleeding erosions and paresthesias; small intact

blisters are rarely observed. Chronic inflammation may lead to periodontal ligament damage and loss of teeth. In other areas of the mouth, transient vesicles give rise to chronic erosions, especially on the palate (Fig. 30.14), with variable associated pain. Lesions on the tongue are usually localized to its lateral and ventral surfaces. Adhesions may develop in the area of the uvula and tonsillar fossae as well as between the tongue and the floor of the mouth. After healing, lesions may lead to white, reticulated striations, resembling lichen planus.

Conjunctival involvement is common and may result in blindness[56]. The conjunctiva is frequently the only site affected. Although the disease can begin unilaterally, in the majority of cases, lesions appear in both eyes. Ocular involvement starts as a nonspecific, chronic conjunctivitis, with burning, soreness, foreign-body sensation, or mucus production. Both exacerbations and remissions are typical, with eventual progression to subepithelial conjunctival fibrosis (Fig. 30.15).

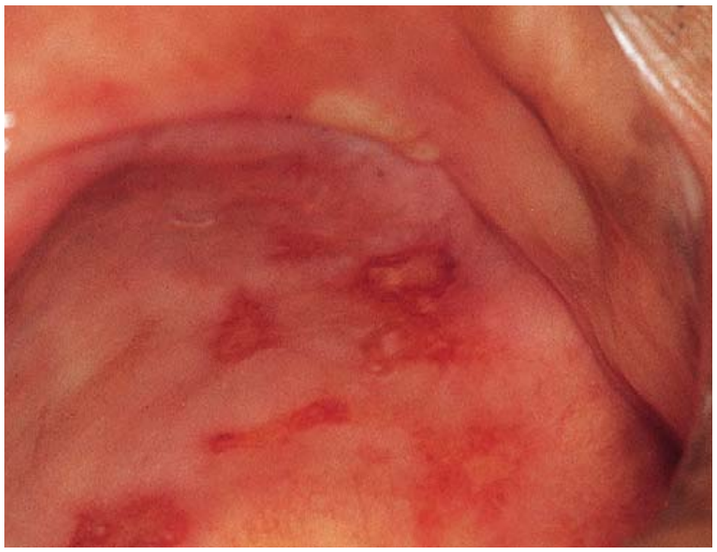

Fig. 30.14 Mucous membrane (cicatricial) pemphigoid. Chronic erosions on the hard palate. *Courtesy, C Prost, MD.*

Conjunctival vesicles or blisters are rare on the tarsal conjunctiva. Chronic inflammation may result in progressive scar tissue formation, including shortened inferior fornices and symblepharon formation (adhesion between bulbar and palpebral conjunctival surfaces; Fig. 30.16). Conjunctival fibrosis can also lead to trichiasis (inwardly angled eyelashes) and entropion[56]. In uncontrolled disease, trichiasis, entropion and xerosis (due to scarring of the lacrimal ducts) result in superficial corneal trauma, corneal neovascularization with subsequent corneal ulceration, and blindness.

Nasopharyngeal involvement is typically chronic and can be associated with extensive lesions of the upper aerodigestive tract. It results in crusted ulcerations, epistaxis, fibrous adhesions between adjacent mucosal surfaces, and airway obstruction. Pharyngeal involvement presents as ulcerations of the posterior or lateral pharynx and dysphagia. Laryngeal involvement is a potentially serious manifestation, presenting as hoarseness, loss of speech, and even life-threatening stenosis, which requires tracheostomy.

Although esophageal disease may be accompanied by dysphagia resulting from erosions of the esophageal mucosa, involvement can be entirely asymptomatic. Chronic inflammation can lead to strictures and stenosis, with associated dysphagia.

Involvement of genital and anal mucosae is relatively rare. Early lesions consist of blisters and chronic erosions. In female patients, progressive disease leads to atrophic scarring and narrowing of the introitus. In male patients, adhesions can form between the prepuce and the glans penis. Anal involvement can also lead to scarring and, in severe cases, to stricture formation.

Cutaneous lesions

The skin is involved in 25–30% of patients. The most frequently involved sites are the scalp, face, neck and upper trunk. Lesions typically present as erythematous plaques, which become sites for recurrent blister formation and erosions, with subsequent atrophic scarring (Fig. 30.17). Their extent and number are generally limited, but an occasional patient can have a BP-like clinical presentation.

In the Brunsting–Perry variant, skin lesions are limited to the head and neck region and mucosal involvement is usually absent or minimal. On the scalp, scarring alopecia can result.

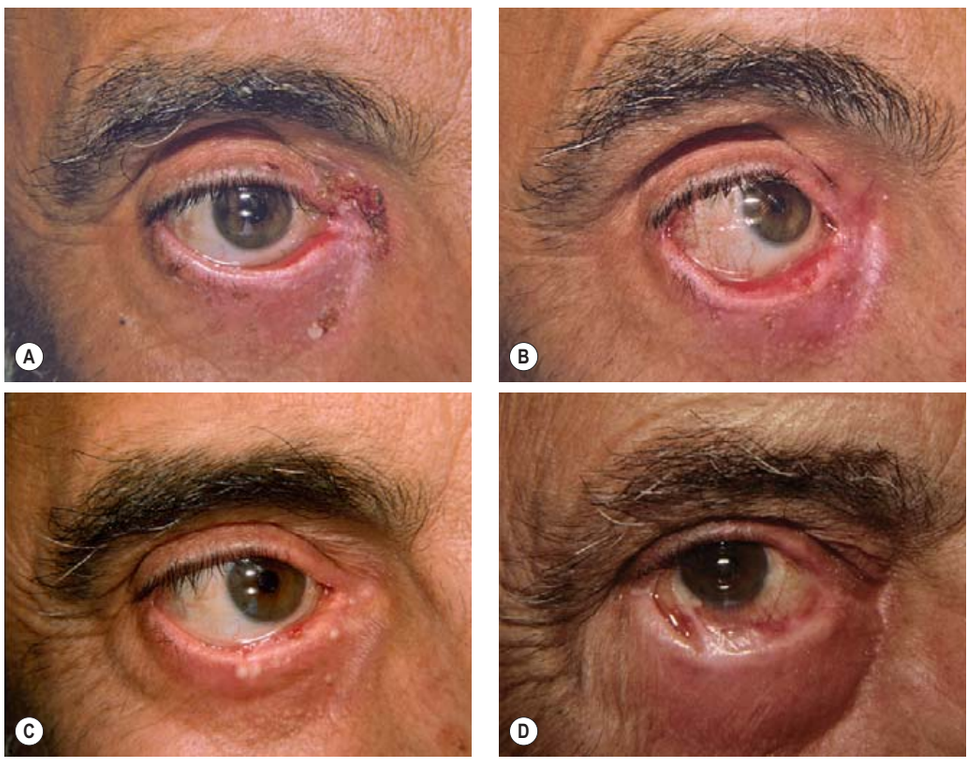

Fig. 30.15 Mucous membrane (cicatricial) pemphigoid progression. A Erosion of the lower eyelid margin and erythema plus scale-crust of the inner canthus and lower eyelid. **B** Three months later, ectropion and thickening of the lower eyelid in addition to erosions. **C** Six months later, smaller erosions but scarring and milia formation. **D** Seven years later, further scarring with significant shortening of the inferior fornix due to symblepharon. *Courtesy, Louis A Fragola, Jr, MD.*

Diagnosis and Differential Diagnosis

Light microscopy and electron microscopy

The histopathologic features of mucous membrane pemphigoid and BP are often similar. Examination of an intact vesicle demonstrates subepidermal or subepithelial blister formation (without acantholysis) and a mixed infiltrate of variable intensity, composed primarily of mononuclear cells. Older lesions tend to demonstrate fibrosis in the upper dermis. In oral lesions, the inflammatory infiltrate typically contains some plasma cells. The epithelium of affected conjunctivae is often invaded by inflammatory cells, including mononuclear cells and mast cells, while granulation tissue is found in the submucosa.

As in BP, electron microscopy studies of a recent blister demonstrate that the dermal–epidermal cleavage occurs within the lamina lucida. In advanced conjunctival lesions with scarring, the lamina densa appears to be discontinuous, focally thickened or duplicated.

Immunofluorescence microscopy

By *direct* IF microscopy, 80–95% of patients with mucous membrane pemphigoid have *in vivo* bound autoantibodies directed against the BMZ of mucosae and/or skin. The majority of patients exhibit continuous, fine, linear deposits of IgG and/or C3 along the epithelial BMZ in perilesional biopsy specimens. It should be noted that direct IF microscopy studies of mucosae are more frequently positive (50–90%) than those of skin (20–50%). IgG deposits belong primarily to the IgG4 and IgG1 subclasses; linear deposits of IgA and IgM are less common. Direct IF microscopy of salt-split skin is of less diagnostic value. Although a combined pattern with staining of both the epidermal and dermal sides is frequently observed, reactivity with either the epidermal roof or the dermal floor of the separated skin is occasionally noted.

By standard *indirect* IF, anti-BMZ antibodies can be detected in serum samples from 20–30% of patients with mucous membrane pemphigoid. Antibodies are mainly of the IgG class, but circulating IgA and, less frequently, IgM autoantibodies are also observed. Antibody titers are usually very low. Some authors have suggested that patients with higher titers and both IgG and IgA circulating anti-BMZ autoantibodies have more severe disease[57]. The sensitivity of indirect IF can be increased either by the use of normal oral or genital mucosa and conjunctiva as substrates, or by utilizing salt-split skin. Using this latter technique, most patients with mucous membrane pemphigoid have antibodies that bind to the epidermal roof, whereas patients with anti-laminin 5 (332) cicatricial pemphigoid have IgG antibodies that bind to the dermal side (see Fig. 30.10B). The use of salt-split oral mucosa does not improve the overall sensitivity. Distinguishing anti-epiligrin cicatricial pemphigoid (anti-laminin 5[332]) from EBA may be possible by indirect IF microscopy using either "knockout" skin substrates (i.e. substrates deficient in specific basement membrane proteins) or the FOAM technique (see above)[58].

Immunoelectron microscopy

Direct immunoelectron microscopy studies in mucous membrane pemphigoid have demonstrated immune deposits distributed either in the lower lamina lucida and over the lamina densa or, alternatively, on and around hemidesmosomes, with most of the labeling on the outside of basal keratinocytes below the plasma membrane[47]. By indirect electron microscopy, autoantibodies typically bind to the lower lamina lucida at the interface with the lamina densa, beneath and beside hemidesmosomes[47]. Although electron microscopy studies are not routinely available and are time consuming, they may be extremely useful for establishing the diagnosis of mucous membrane pemphigoid in patients in whom the presence of tissue-deposited immunoreactants cannot be demonstrated by conventional IF studies.

Immunochemical studies

Immunochemical techniques, especially immunoblotting and immunoprecipitation studies, have demonstrated that the autoantigens targeted in patients with a mucous membrane pemphigoid phenotype are heterogeneous[46,50–53,57,59–61]. Circulating autoantibodies react with various proteins located within the epithelial BMZ, e.g. laminin 5 (332), BP180 (see Table 30.1). These targeted antigens appear to constitute serologic markers for different clinical subsets (see above).

Patients frequently have IgA autoantibodies directed against the ectodomain of BP180[59]. In certain cases, these autoantibodies appear to preferentially bind to antigenic reactive sites present on the proteolytically cleaved and shed portion of the extracellular domain of BP180, the linear IgA bullous dermatosis antigen (see Ch. 31). Other target antigens have been reported, including a 168 kDa antigen (which appears to be strongly expressed in buccal mucosa) and a 45 kDa antigen in certain patients with pure ocular disease.

ELISAs utilizing recombinant proteins or affinity-purified native proteins (e.g. BP180, laminin 5 [332]) appear to be very useful in the search for circulating autoantibodies, with excellent sensitivity and specificity, and hold significant promise as diagnostic and prognostic tests[61].

Differential diagnosis

The diagnosis of mucous membrane pemphigoid has to be considered in all patients who have blistering or erosive lesions that predominantly involve mucous membranes and whose affected tissues exhibit linear, continuous deposits of immunoreactants along the epithelial basement membrane. Distinction from other subepidermal autoimmune bullous diseases (including BP, EBA and linear IgA bullous dermatosis) may be very difficult and often requires sophisticated immunopathologic studies (see above). On the contrary, pemphigus vulgaris and non-autoimmune bullous diseases are more easily eliminated by histology and IF microscopy.

When they are the only manifestation of the disease, oral lesions are clinically difficult to differentiate from those of pemphigus vulgaris or erosive lichen planus. End-stage, scarring conjunctival lesions may mimic severe chronic infectious conjunctivitis, ocular pseudopemphigoid due to ophthalmologic preparations (including pilocarpine, idoxuridine, guanethidine, β-blockers), or late stages of Stevens–Johnson syndrome and toxic epidermal necrolysis. The rare, generalized skin eruption of mucous membrane pemphigoid is impossible to distinguish from that of BP. Nevertheless, a prominence of mucosal lesions along with scarring favors the former.

Prognosis

Mucous membrane pemphigoid is a particularly chronic, potentially devastating, but rarely fatal disease. The most important complication is impairment of vision due to ocular involvement. It can also lead to

weight loss as well as respiratory, sexual or urinary complications. Even with localized involvement, this disease can have a major negative impact on quality of life. Life-threatening complications, due to severe laryngeal, tracheal or esophageal disease, are rare. Patients with anti-laminin 5 (332) autoantibodies have an increased relative risk for solid organ carcinomas, especially adenocarcinomas[50].

Treatment

Treatment can be difficult and is often disappointing. Therapeutic regimens are based primarily on clinical experience[62].

Local therapy is crucial and, in some cases, may be sufficient to control the disease. Mild to moderate disease activity may be successfully treated with potent topical corticosteroids. Oral lesions can respond to topical corticosteroids (as mouthwashes or topical preparations in a gel or occlusive base) in conjunction with tetracycline mouthwashes and good hygiene. Corticosteroid sprays and inhalers may prove useful in nasal, pharyngeal or esophageal disease. Recalcitrant lesions of both skin and mucous membranes may improve with intralesional injections of corticosteroids. Esophageal strictures may require dilatations to prevent dysphagia, while severe tracheal involvement may require a tracheostomy to prevent asphyxiation.

Systemic medications include dapsone (50–150 mg/day) as a first-line therapy for controlling oral and cutaneous lesions, and it may also be used for mild ocular disease without rapid worsening. Cyclophosphamide (1–2 mg/kg/day) is the treatment of choice for rapidly progressive or severe ocular disease[56] – alone, in combination with oral corticosteroids, or as pulse therapy. Such regimens are effective in resolving severe conjunctival inflammation and preventing recurrences and scarring. Azathioprine (2 mg/kg/day) and mycophenolate mofetil (2 g/day) have also been reported to be helpful in partially controlling ocular disease and cutaneous lesions.

Systemic corticosteroids alone are generally insufficient therapy for patients with significant disease, and they are less effective for mucosal than for cutaneous disease. Patients with significant esophageal or laryngotracheal involvement should be treated aggressively with the combination of prednisone and cyclophosphamide or mycophenolate mofetil to prevent potentially life-threatening complications. Other therapies reported to be of potential value in the treatment of mucous membrane pemphigoid include sulfapyridine, minocycline, a combination of tetracycline and niacinamide, topical tacrolimus, topical or systemic cyclosporine, thalidomide and subconjunctival mitomycin. Recent studies and case series have suggested that IVIg[63], methotrexate, TNF-α inhibitors such as etanercept, and rituximab could be helpful in controlling progressive ocular involvement[62,64,65].

Surgical therapy may occasionally be necessary for severe scarring involving the eye, larynx, esophagus or genitalia. It should be performed when the disease is fully controlled by medical therapy. For ocular disease, surgical intervention includes corneal grafts, allograft limbal transplantation, amniotic membrane transplantation, and tarsorrhaphy.

EPIDERMOLYSIS BULLOSA ACQUISITA

Synonym: ■ Acquired epidermolysis bullosa; dermolytic pemphigoid

Key features

- Epidermolysis bullosa acquisita is a rare, acquired, subepidermal bullous disease associated with autoimmunity to type VII collagen, the major component of the anchoring fibrils of the dermal–epidermal junction
- Patients may present either with a mechanobullous disorder, mimicking dystrophic epidermolysis bullosa, or with clinical features indistinguishable from those found in bullous pemphigoid or, more rarely, mucous membrane pemphigoid
- The disease is usually chronic and more refractory to treatment than is BP
- Diagnosis relies on immunopathologic examinations, especially immunofluorescence microscopy, immunochemical studies and immunoelectron microscopy

Introduction

Epidermolysis bullosa acquisita (EBA) is a rare, acquired, subepidermal bullous disease associated with autoimmunity to type VII collagen, the major component of the anchoring fibrils of the dermal–epidermal junction. Patients may present either with a mechanobullous disorder, the features of which strikingly resemble those observed in patients with dystrophic epidermolysis bullosa, or with clinical features indistinguishable from those typically found in BP or mucous membrane pemphigoid.

History

The first cases of an acquired bullous disease with clinical features mimicking hereditary dystrophic epidermolysis bullosa were described by Elliot in 1895. In the early 1970s, before the era of cutaneous immunopathology, Roenigk and colleagues proposed the initial clinical criteria for EBA. A few years later, IF microscopy studies demonstrated that EBA patients have anti-BMZ antibodies, similar to BP patients. In the early 1980s, immunoelectron microscopy studies separated EBA from BP by demonstrating that IgG deposits in EBA were located in the sublamina densa region. In the 1990s, using sophisticated immunopathologic techniques, it was shown that EBA autoantibodies bind to type VII collagen, the major component of anchoring fibrils.

Epidemiology

EBA has been reported in both children and adults and may occur at any age. It is one of the rarest subepidermal bullous diseases in Western Europe, with an estimated annual incidence of approximately 0.25 per million[44]. It may be more common among Korean/Asian populations as well as in African-Americans.

Pathogenesis

The idea that EBA is an immune-mediated disease is supported by several observations:

- Patients have tissue-bound and circulating autoantibodies to a well-characterized structural component of the dermal–epidermal junction.
- Tissue injury occurs where antibody–antigen complexes are found.
- *In vitro* models and *in vivo* animal models of the disease have provided evidence for the pathogenic role of autoantibodies.
- The disease appears to occur in association with distinct class II MHC haplotypes.
- The disease responds, although inconstantly, to immunosuppressive therapy.

Patients with EBA possess IgG autoantibodies directed against the basement membrane of stratified squamous and other complex epithelia. Specifically, these autoantibodies characteristically react with type VII collagen, the major component of anchoring fibrils located in the lamina densa and sublamina densa region (see Table 30.1). Type VII collagen is composed of three identical α-chains, each of which consists of a central 145 kDa collagenous triple helical segment, flanked by a large 145 kDa non-collagenous N-terminal domain (NC1) and a short 30 kDa C-terminal region (NC2). Patients' autoantibodies target immunodominant epitopes within the NC1 domain of the protein. However, reactivity with either the central collagenous domain or the NC2 domain is also observed, albeit rarely. It is, as yet, unclear if binding activity to certain antigenic regions of the molecule correlates with a distinct clinical phenotype (see below).

In vitro, EBA autoantibodies, together with the complement system and neutrophil elastase and gelatinase B, are able to mediate leukocyte infiltration and dermal–epidermal separation[14]. Furthermore, passive and active transfer studies in mice have shown that antibodies to type VII collagen can induce a subepidermal bullous disease resembling EBA[66–68].

EBA autoantibodies may be pathogenic by interfering with the association and assembly of type VII collagen molecules into anchoring fibrils and/or by critically affecting the interactions between type VII collagen and other matrix proteins, such as laminin 5 (332)[68].

As in the case of other autoimmune diseases, certain HLA class II alleles appear to be more prevalent in EBA, e.g. an association with

Fig. 30.18 Epidermolysis bullosa acquisita – mechanobullous presentation. Milia and scarring that favors sites of trauma overlying joints, in association with skin fragility.

Fig. 30.19 Epidermolysis bullosa acquisita – inflammatory bullous pemphigoid-like presentation. Bullous and erosive lesions in a patient with multiple myeloma.

DRB1*1501 and DR5 in Caucasians and African-Americans or DRB1*13 in Koreans. It is likely that the expression of distinct HLA alleles has a critical impact on the susceptibility for developing EBA. The observation that deficient expression of type VII collagen in patients with various forms of dystrophic epidermolysis bullosa causes skin fragility and dermal–epidermal separation demonstrates unequivocally the importance of this protein in maintaining the integrity of the epidermal BMZ.

Clinical Features

EBA usually occurs in adult patients, although pediatric cases have been reported. The classic presentation is that of a non-inflammatory mechanobullous disease characterized by the development of acral blisters that heal with atrophic scarring, milia and hyper- or hypopigmentation[68]. Cutaneous blisters and subsequent erosions, which appear within non-inflamed skin or on areas of scarring, may be serous, or, less frequently, hemorrhagic. They are localized to trauma-prone surfaces (Fig. 30.18), especially the elbows, knees, and dorsal aspects of the hands, feet and toes. Acral involvement may be mutilating, leading to a "mitten" deformity of the digits, syndactyly, nail dystrophy and complete nail loss. Scalp involvement occurs in up to 20% of patients, and, in isolated cases, extensive non-healing erosions with scarring alopecia have been described.

Other clinical variants include an "inflammatory" BP-like presentation[69,70] with widespread vesicles and bullae involving intertriginous and flexural areas that heal without milia or atrophic scars (Fig. 30.19), and a mucous membrane pemphigoid-like presentation, including the Brunsting–Perry pemphigoid phenotype with scarring alopecia[71]. Most of these patients are clinically indistinguishable from those with BP or mucous membrane pemphigoid. Of note, during the course of the disease, the clinical features can convert from one variant to another or, alternatively, a mixture of inflammatory and non-inflammatory features may coexist.

Mucous membrane involvement is variable. Erosions and intact vesicles may be seen in the mouth (Fig. 30.20), larynx and esophagus, and they may lead to dysphagia and laryngeal stenosis. Ocular involvement and blindness have been reported in the mucous membrane pemphigoid-like phenotype. Finally, features of childhood EBA have substantial overlap with those observed in childhood BP and linear IgA bullous dermatosis.

In anecdotal reports, a number of systemic diseases have been described in association with EBA, including inflammatory bowel disease, myeloma, systemic lupus erythematosus, rheumatoid arthritis, thyroiditis and diabetes mellitus. Among these, inflammatory bowel disease, particularly Crohn's disease, is the most frequently associated condition.

Diagnosis and Differential Diagnosis

Light microscopy and electron microscopy

By light microscopy, biopsy specimens of bullae show a subepidermal cleavage without acantholysis. In the BP-like or mucous membrane pemphigoid-like variants of EBA, there is a variable inflammatory infiltrate within the dermis, composed of neutrophils, eosinophils or lymphocytes. In the mechanobullous, non-inflammatory lesions, there is a minimal-to-absent cellular infiltrate.

Electron microscopy studies of fresh vesicles demonstrate that dermal–epidermal cleavage occurs within the sublamina densa zone. In addition, a reduction in the number of anchoring fibrils may be observed. However, in some cases, separation within the lamina lucida has been noted, most likely reflecting the formation of a subepidermal blister at the *locus minoris resistentiae*. The cleavage plane is, therefore, not always a reliable criterion for discriminating EBA from other subepidermal bullous disorders.

Immunofluorescence microscopy

Direct IF microscopy studies of perilesional skin demonstrate IgG deposits distributed in a continuous, rather broad, linear pattern along the epidermal BMZ. Less commonly, linear deposits of C3, IgA or IgM

are found. In salt-split skin preparations of perilesional skin, the immune deposits are typically located on the dermal side of the cleavage. Finally, in EBA, the FOAM technique (see above), employing a confocal laser scanning microscope, localizes the immunoreactants to below the lamina densa in a relatively simple and inexpensive way, compared with electron microscopy.

By standard indirect IF, circulating anti-BMZ antibodies can be detected in approximately half of the patients with EBA. They are primarily of the IgG class, but circulating IgA autoantibodies have also been reported. By indirect IF on salt-split skin, circulating antibodies bind to the dermal side of the artificial blister[70]. Although rarely available, testing of patients' sera against a panel of skin substrate specimens lacking distinct basement membrane molecules (e.g. BP180, type VII collagen or laminin 5[332]) can prove helpful in characterizing the antigens targeted by circulating autoantibodies.

Immunoelectron microscopy

By immunogold techniques, which allow a more precise localization than direct immunoelectron microscopy utilizing peroxidase labeling, EBA autoantibodies specifically bind to the anchoring fibrils and the lamina densa where anchoring fibrils originate and terminate[72]. When circulating autoantibodies are absent and therefore cannot be characterized by indirect IF microscopy, immunoblotting studies or ELISA (see below), then immunoelectron microscopy constitutes the "gold standard" for the diagnosis of EBA.

Immunochemical studies

In Western immunoblotting studies of dermal extracts, circulating autoantibodies from patients with EBA bind to proteins of approximately 290 kDa and, less frequently, 145 kDa. These proteins have been clearly shown to correspond to type VII collagen and its NC1 N-terminal half, respectively[73,74]. Epitope mapping studies using recombinant forms of type VII collagen have demonstrated that immunodominant epitopes are located within the NC1 domain[75]. An ELISA utilizing a eukaryotic-expressed recombinant protein consisting of the entire NC1 domain has been found to be more sensitive than immunoblotting studies[76]. The advantage of this ELISA is that, in addition to its rapid performance and high specificity, antigens are tested under non-denaturing conditions; thus, reactivity against conformational epitopes is also assessed.

Differential diagnosis

EBA may be confused with inherited dystrophic epidermolysis bullosa, BP, mucous membrane pemphigoid, porphyria cutanea tarda, pseudoporphyria or rare variants of porphyria (e.g. porphyria variegata). Clinically, the mechanobullous type of EBA most closely resembles mild dominant dystrophic epidermolysis bullosa, but the lack of a family history, late onset, and the positive direct IF findings allow the distinction. The involvement of the hands may mimic porphyria cutanea tarda, but the latter can easily be excluded by porphyrin studies. Occasionally, patients with EBA on incriminating medications are misdiagnosed as having pseudoporphyria. The inflammatory type of EBA is clinically indistinguishable from BP or mucous membrane pemphigoid, including Brunsting–Perry pemphigoid. These conditions may be distinguished by using indirect IF (with salt-split skin as a substrate), BP180-NC16A ELISA, Western immunoblotting of both epidermal and dermal extracts, and direct immunoelectron microscopy studies.

Bullous systemic lupus erythematosus (SLE) usually presents as a transient, widespread, inflammatory subepidermal blistering condition (see Ch. 41), and, less frequently, as a mechanobullous eruption with milia and scarring[59]. In a number of these cases, circulating autoantibodies show binding activity with type VII collagen and the possibility of SLE–associated EBA might be considered. In addition to differences in histology, EBA in adults has a poor response to treatment, whereas a dramatic improvement following initiation of dapsone or azathioprine therapy is generally seen in patients with bullous SLE[77].

Treatment

The treatment of EBA is difficult and often unsatisfactory. Because of the rarity of the condition, most data on treatment are based on anecdotal reports[62,69]. Systemic corticosteroids and standard immunosuppressive agents, such as azathioprine, methotrexate, mycophenolate mofetil and cyclophosphamide, are sometimes helpful in controlling the BP-like variant of EBA, which may go into remission. Colchicine, dapsone, gold, IVIg and cyclosporine have also been reported to have some benefit. A combination of dapsone and prednisolone has been recommended by some authors for the treatment of childhood EBA.

Christopher M Hull and John J Zone

Chapter Contents

Dermatitis herpetiformis 491
Linear IgA bullous dermatosis 496

Key features

- Dermatitis herpetiformis (DH) is differentiated from linear IgA bullous dermatosis (LABD) on the basis of granular IgA versus linear IgA deposition at the basement membrane zone, as observed by direct immunofluorescence
- DH is a cutaneous manifestation of celiac disease (CD) and is associated with gluten sensitivity in virtually all cases
- DH and CD are genetic disorders strongly associated with the HLA-DQ2 genotype, in which IgA anti-endomysial antibodies are directed against *tissue* transglutaminase; the presumed autoantigen within the skin is *epidermal* transglutaminase
- The intestinal and cutaneous disease in DH can be controlled by gluten restriction; both DH and LABD respond to sulfone therapy
- In adults, LABD is frequently drug-induced

DERMATITIS HERPETIFORMIS

Synonym: ■ Duhring's disease

Introduction

Dermatitis herpetiformis (DH) is a cutaneous manifestation of gluten sensitivity. Although over 90% of DH patients have evidence of a gluten-sensitive enteropathy, only about 20% have intestinal symptoms of celiac disease (CD). Both the skin disease and the intestinal disease respond to gluten restriction and recur with institution of a gluten-containing diet.

Four findings support the diagnosis of DH:

- pruritic papulovesicles or excoriated papules on extensor surfaces
- neutrophilic infiltration of the dermal papillae with vesicle formation at the dermal–epidermal junction
- granular deposition of IgA within the dermal papillae of clinically normal-appearing skin adjacent to a lesion
- a response of the skin disease, but not the intestinal disease, to dapsone therapy.

Although DH is usually a lifelong condition, the course may wax and wane. A spontaneous remission may occur in up to 10% of patients, but most clinical remissions are related to dietary gluten restriction[1].

History

Dr Louis Duhring described DH at the University of Pennsylvania in 1884. It was the first skin disease described by an American dermatologist. The subsequent critical discoveries in our understanding of DH are listed in Table 31.1.

Epidemiology

DH occurs most commonly in people of northern European origin. It is uncommon in African-Americans and Asians. According to a study in Finland in 1978, the prevalence of DH is 10.4 per 100 000 individuals and the annual incidence is 1.3 per 100 000. The mean age of onset is during the fourth decade, but it may first appear from age 2 to 90 years. Adolescent and prepubescent children are infrequently affected. Men outnumber women two to one, but in children with DH, there is a female preponderance. From 1979 to 1996, the familial incidence of DH in Finland was studied prospectively. DH was diagnosed in 1018 patients and 10.5% of these patients had one or more affected first-degree relatives[2].

With regard to the US, a study in Utah (1987) found a prevalence of 11.2 per 100 000. The incidence during the years 1978 to 1987 was 0.98 per 100 000 per year. Mean age of onset for men was 40.1 years and for women was 36.2 years. The male-to-female ratio was 1.44 : 1[3].

Pathogenesis

Our knowledge of the pathogenesis of DH is based on a number of clinical and laboratory observations. The key observations that have been integrated into theories of pathogenesis are:

- a strong genetic association with the HLA genotype DQ A1 *0501, B1 *02 (which encodes HLA-DQ2 heterodimers), in addition to other unidentified non-HLA genes
- some degree of gluten-sensitive enteropathy on small bowel biopsy in virtually all patients, accompanied by stimulation of the mucosal immune system
- granular IgA deposition within the papillary dermis of the skin (this is essential for the diagnosis and occurs at the site of eventual inflammation)
- neutrophilic infiltration into the dermal papillae
- improvement of symptoms with dapsone therapy and worsening of symptoms with inorganic iodide ingestion.

Genetic predisposition

Specific HLA genes, which encode molecules that interact with T-cell receptors, are believed to provide the antigenic specificity that processes the gliadin antigen in genetically susceptible individuals. This HLA association is the same for patients with CD and DH. Genes encoding the DQ2 (A1 *0501, B1 *02) heterodimer are carried by 90% of CD and DH patients. Genes encoding the DQ8 (A1 *03, B1 *03) heterodimer are carried by the remaining DH patients[4]. Previous descriptions of associations with HLA-B8, as well as HLA-DR3 and HLA-DR5/DR7, represent class I and class II molecules that are in linkage dysequilibrium with DQ2. However, it has been established that less than 50% of the genetic predisposition in CD and DH is due to specific HLA genes. Genomic searches for non-HLA genes are currently underway and a susceptibility locus for CD (chromosome 4q27) has been proposed which includes the genes for IL-2 and IL-21[5]. Monozygotic twins, one with DH and the other with CD, have been reported, indicating that environmental as well as genetic factors play a role in the development of CD and/or its extraintestinal manifestation, DH[6].

Gluten-sensitive enteropathy

On small bowel biopsy, more than 90% of DH patients have some degree of gluten-sensitive enteropathy. The bowel abnormality is caused by gluten, a family of grain proteins present in wheat, rye, barley and hybrids of these grains (e.g. kamut, spelt and triticale), but not oats. Gliadin is the alcohol-soluble fraction of gluten and is believed to be the antigenic component. The spectrum of intestinal involvement ranges from minimal infiltration of the lamina propria by lymphocytes (with normal villi), to minimal atrophy of the jejunum accompanied by intraepithelial lymphocytic infiltrates, to total villous atrophy of the

DERMATITIS HERPETIFORMIS – HISTORIC LANDMARKS	
1884	Louis Adolphus Duhring of Philadelphia described in detail "dermatitis herpetiformis" (DH)
1888	Jean Louis Brocq of Paris renamed the condition "dermatite polymorphe prurigineuse"
1890	T Caspar Gilchrist outlined the histologic changes of DH, which were included in the 1897 edition of Duhring's textbook *Cutaneous Medicine: A Systemic Treatise on Diseases of the Skin*
1940	Sulfapyridine was reported to be an effective treatment for DH. The clinical response to sulfapyridine became a diagnostic test
1950	Dicke, a Dutch pediatrician, observed that patients with celiac disease (CD) improved during World War II when bread was in short supply, and their disease worsened when grain supplies were restored
1953	Diamino-diphenyl sulfone (dapsone), the parent compound of sulfapyridine, also proved to be effective in DH
1969	JB van der Meer demonstrated IgA deposits in the papillae of uninvolved skin in DH
1967	Independent accounts connect DH with CD
1972	Stephen Katz links DH to the HLA-B8 antigen. This strengthens the association between CD and DH
1986	IgA class anti-endomysial antibodies were found to be highly specific for DH and CD
1997	DH and CD were found to have a common immunogenetic background with strict association with HLA alleles DQ A1 *0501 and B1 *02, which encode HLA-DQ2 heterodimers
2003	Epidermal transglutaminase was identified as an autoantigen in DH

Table 31.1 Dermatitis herpetiformis – historic landmarks.

small intestine. The enteropathy is often patchy and may require multiple small bowel samples for diagnosis. Symptomatic malabsorption occurs in 20% of patients with DH.

The proposed pathogenesis of DH and CD is presented in Figure 31.1. Following ingestion of gluten-containing grains (see above), one of the products of digestion is gliadin (Fig. 31.1A). Once gliadin is absorbed via the lamina propria, glutamine residues within gliadin are deamidated by tissue transglutaminase (TG2) and covalent cross-links (isopeptidyl bonds) are formed between lysine residues in TG2 and glutamines in gliadin. Deamidation by TG2 is thought to be a critical step as it serves to optimize antigen presentation.

Deamidated gliadin peptides bind to the groove of the HLA-DQ2 molecule on dendritic antigen-presenting cells (Fig. 31.1B), and the gliadin antigen is then presented to sensitized helper T cells in the context of HLA-DQ2 specificity. These helper T cells can stimulate B cells, with differentiated plasma cells producing IgA antibodies to multiple antigens, including gliadin, gliadin cross-linked to TG2, TG2, and epidermal transglutaminase (TG3). In addition, stimulated natural killer lymphocytes cause crypt hyperplasia and villous atrophy. Of note, IgA anti-TG2 antibodies have become the serologic hallmark for CD.

In the setting of continued exposure to gliadin, epitope spreading is thought to lead to development of IgA anti-TG3 antibodies in patients who already have IgA anti-TG2 antibodies; a subgroup of those who develop IgA anti-TG3 antibodies then develop DH (see Fig. 31.1). Epitope spreading is a possible explanation for why DH tends to present at a later age than symptomatic CD (the latter often manifests in childhood) and why patients with CD (but not DH) tend to have more severe intestinal disease than patients with DH. Formation of IgA anti-TG3 antibodies is thought to require time and continued exposure to gluten and this would be more likely to occur in patients with less severe, relatively asymptomatic intestinal involvement. Findings in support of

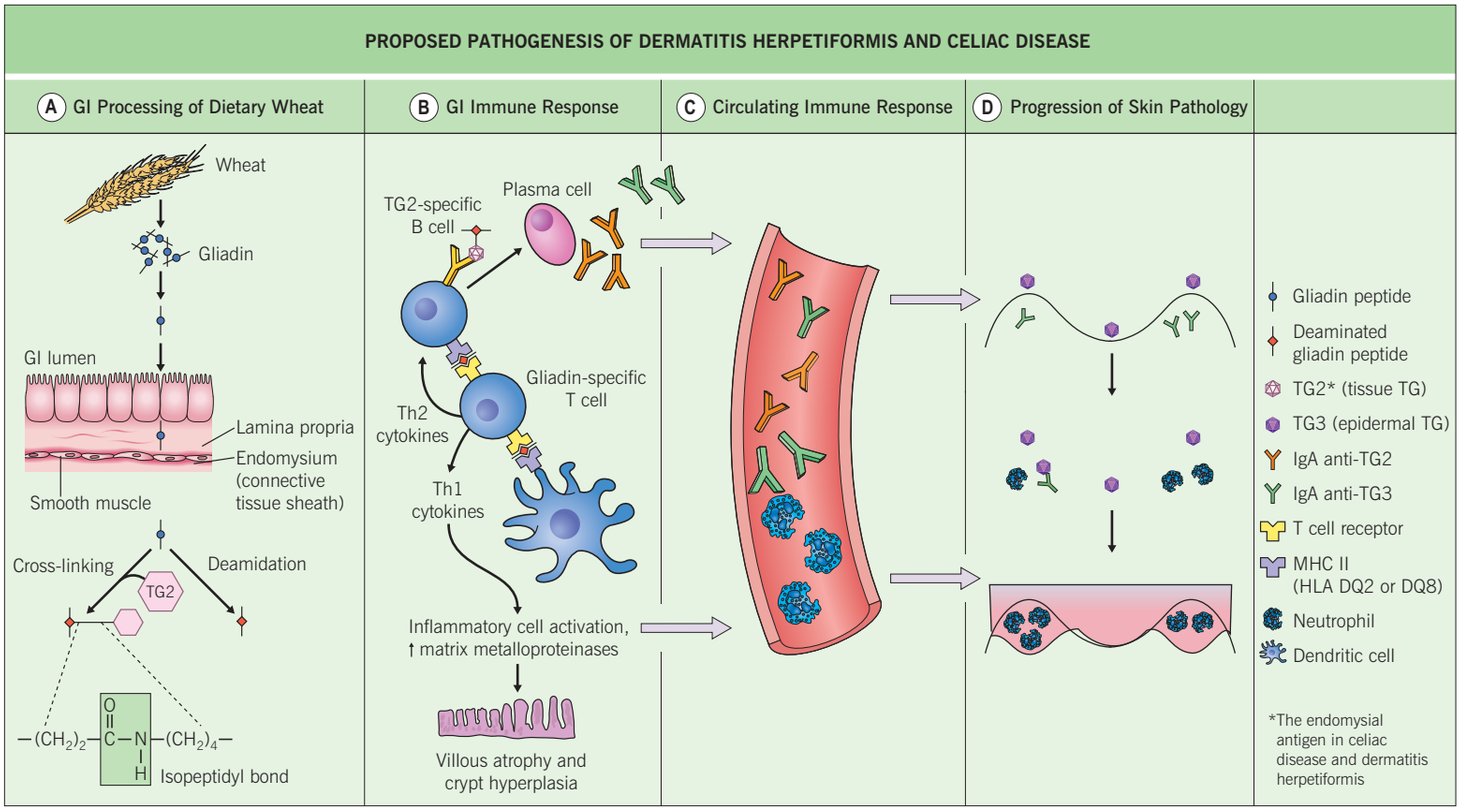

Fig. 31.1 Proposed pathogenesis of dermatitis herpetiformis and celiac disease. A Dietary wheat, barley or rye is processed by digestive enzymes into antigenic gliadin peptides, which are transported intact across the mucosal epithelium. Within the lamina propria, tissue transglutaminase (TG2): (1) deamidates glutamine residues within gliadin peptides to glutamic acid; and (2) becomes covalently cross-linked to gliadin peptides via isopeptidyl bonds (formed between gliadin glutamine and TG2 lysine residues). **B** $CD4^+$ T cells in the lamina propria recognize deamidated gliadin peptides presented by HLA-DQ2 or -DQ8 molecules on antigen-presenting cells, resulting in the production of Th1 cytokines and matrix metalloproteinases that cause mucosal epithelial cell damage and tissue remodeling. In addition, TG2-specific B cells take up TG2–gliadin complexes and present gliadin peptides to gliadin-specific helper T cells, which stimulate the B cells to produce IgA anti-TG2. **C** Over time, IgA directed against TG3 (IgA anti-TG3) forms as a result of epitope spreading and both IgA anti-TG2 and IgA anti-TG3 circulate in the bloodstream. **D** When IgA anti-TG3 antibodies reach the dermis, they complex with TG3 antigens which have been produced by keratinocytes (epidermal TG) and then have diffused into the dermis. That is, IgA/TG3 immune complexes are formed *locally* within the papillary dermis. This leads to neutrophil chemotaxis (with formation of neutrophilic abscesses), proteolytic cleavage of the lamina lucida, and subepidermal blister formation.

AUTOIMMUNE DISORDERS ASSOCIATED WITH DERMATITIS HERPETIFORMIS
COMMON
• Autoimmune thyroid disease (Hashimoto's thyroiditis) • Insulin-dependent diabetes mellitus
UNCOMMON
• Pernicious anemia
RARE
• Addison's disease • Autoimmune chronic active hepatitis • Alopecia areata • Myasthenia gravis • Sarcoidosis • Systemic sclerosis (scleroderma) • Sjögren's syndrome • Systemic lupus erythematosus • Vitiligo

Table 31.2 Autoimmune disorders associated with dermatitis herpetiformis.

this theory include the presence of IgA anti-TG2 antibodies in most DH patients and a higher prevalence of IgA anti-TG3 antibodies in adults than in children with CD (i.e. developing later in the evolution of the disease).

The formation of IgA anti-TG3 antibodies also activates circulating neutrophils (Fig. 31.1C). Deposition of these antibodies within the dermal papillae results in the infiltration of activated neutrophils from the circulation into the dermal papillae (Fig. 31.1D). Degranulation of neutrophils releases proteases which disrupt the lamina lucida and produce a subepidermal blister.

Since both the skin disease and the intestinal disease resolve with dietary gluten restriction and recur with return to a regular diet, it is clear that the dietary protein gluten is central to the pathogenesis of the cutaneous eruption. In addition, it is the HLA class II antigen that acts as a gate through which gluten can reach the inflammatory cells and initiate the autoimmune process[7,8].

Circulating antibodies

The first serologic difference between DH and CD was initially described in 2002, with TG3 identified as the autoantigen in DH[9]. Additional studies have demonstrated that IgA anti-TG3 antibodies not only are elevated in patients with DH, but also represent a sensitive serologic assay[10,11]. TG3 was also found to co-localize with IgA in dermal papillae of DH patients (see Fig. 31.5)[9,12]. TG3 is expressed in many tissues of the body, including the epidermis. When IgA anti-TG3 antibodies reach the dermis, they complex with TG3 antigens which have been produced by keratinocytes (epidermal TG) and then have diffused into the dermis. In other words, IgA/TG3 immune complexes are formed *locally* within the papillary dermis (see Fig. 31.1D). Circulating immune complexes are not known to be involved in the deposition of these immune complexes in the papillary dermis.

Granular IgA deposition

Granular IgA deposition within dermal papillae is the hallmark of DH (see Fig. 31.5). The deposits are composed of IgA1 antibodies directed against TG3 antigen that has diffused from the epidermis. Circulating IgA antibodies to TG2 (an endomysial antigen) have been identified by indirect immunofluorescence microscopy using a monkey esophagus substrate, and the presence of these antibodies correlates with the degree of gluten-sensitive enteropathy. IgA anti-TG2 antibodies are not responsible for the IgA deposition in skin.

Iodide and dapsone

Ingestion of iodide can lead to worsening of DH and topical application of iodide onto the normal skin of DH patients produces lesions that are histologically identical to spontaneous lesions[13]. Even in normal subjects, topical iodides may produce follicular neutrophilic pustules. The mechanism by which iodide stimulates neutrophil infiltration into the skin is unclear. Dapsone is known to have an effect on neutrophil

Fig. 31.2 Dermatitis herpetiformis. A A few pink papulovesicles, erosions and hemorrhagic crusts on the elbow. **B** Multiple urticarial pink papules on the knee, in addition to a few erosions and small subtle intact vesicles (arrows); a collarette of scale is seen at the site of a previous vesicle. **C** Pink plaques on the knee composed of grouped papules and papulovesicles, admixed with tiny hemorrhagic crusts. *C, Courtesy, Thomas Horn, MD.*

Fig. 31.3 Dermatitis herpetiformis. **A** Grouped pink papulovesicles on the upper back, neck and scalp in a child. **B** Pruritic pink papules on the buttocks, some of which have central hemorrhagic crusts. *B, Courtesy, Louis A Fragola, Jr, MD.*

chemotaxis and neutrophil attachment to IgA *in vitro*[14]. Although the exact mechanism of its beneficial effect in DH is unknown, it seems likely that dapsone blocks the neutrophil-mediated inflammatory process.

Associated Disorders and Malignancies

A strong association exists between DH and thyroid disease, particularly Hashimoto's thyroiditis. In one study, the presence of some type of thyroid abnormality was found in 26 of 50 patients with DH[15]. Although the pathogenetic relationship between DH and thyroid disease is unknown, it may represent a coexistence of autoimmune disease[15]. The incidence of enteropathy-associated T-cell lymphoma is also increased in patients with DH and warrants increased surveillance. Of note, adhering to a gluten-free diet protects against lymphoma in this population. This further supports advising patients with DH to adhere to a strict gluten-free diet for life. Other autoimmune disorders reported to be associated with DH and CD are listed in Table 31.2.

Clinical Features

DH has a symmetric distribution and favors the elbows, extensor forearms, back, buttocks and knees (Figs 31.2 & 31.3). Isolated scalp involvement is an occasional clinical presentation. The primary lesions are pleomorphic, with urticarial plaques, papules and vesicles. Grouped or "herpetiform" papulovesicles with an erythematous base are characteristic of this autoimmune disorder. Intense pruritus leads to secondary excoriation and crusting. Even if only hemorrhagic crusts or secondary changes from scratching are present, the diagnosis should be suspected on the basis of the distribution of lesions. Less common presentations are isolated facial involvement, exclusively macular lesions, and hemorrhagic acral macules (usually palmoplantar).

Pathology

For routine histology, it is optimal to capture a small, intact vesicle. If this is not available, an area of erythema should be biopsied. Areas of erythema will show dermal papillary edema and neutrophil infiltration associated with a superficial perivascular lymphocytic infiltrate. When an intact vesicle is biopsied, a subepidermal blister containing predominantly neutrophils will be seen (Fig. 31.4).

In patients with DH, IgA is not uniformly distributed throughout the skin. IgA deposits are present in greater amounts near active lesions. The optimal biopsy site for direct immunofluorescence (DIF) testing is normal-appearing skin immediately adjacent to a lesion. A false-negative DIF can occur if lesional skin is biopsied, since the inflammatory infiltrate can destroy the IgA[16]. A definitive diagnosis of DH cannot be made without this diagnostic DIF finding. Granular IgA deposits localized to the dermal papillae are found in 85% of cases of DH (Fig. 31.5), while continuous granular deposition of IgA along the basement membrane occurs in 5% to 10% of cases. A fibrillar pattern of IgA deposition occurs rarely.

The lack of histologic and immunopathologic confirmation is a source of misdiagnosis and confusion in DH. Since DH is a lifelong diagnosis with significant systemic and therapeutic implications, definitive immunopathologic confirmation of the diagnosis is essential in all cases.

Laboratory evaluation

Anti-endomysial antibodies are very specific for CD and DH. Their levels indicate the severity of the gluten-sensitive enteropathy and reflect the degree of compliance to dietary gluten restriction. Anti-endomysial antibodies are found in approximately 80% of patients with DH and >95% of patients with active CD. The endomysium is the connective tissue covering the smooth muscle layers of the esophagus, stomach and small intestine (see Fig. 31.1A). Studies have confirmed a high sensitivity and specificity for IgA class antireticulin and anti-endomysial antibodies in DH patients with villous atrophy.

The endomysial antigen has been identified as TG2, and antibodies directed against transglutaminase are important in the pathogenesis of DH and CD (see Pathogenesis section). The normal physiologic function of transglutaminase is to repair injured tissue by cross-linking extracellular matrix proteins in the tissue, protecting the surrounding tissue from further damage. Transglutaminase facilitates the linkage of the carboxamide group of the amino acid glutamine, found in gluten,

to an ε-amino group of a lysine residue in transglutaminase located in the intestinal tract (see Fig. 31.1A). The glutamine in gliadin is especially vulnerable to a cross-linkage with transglutaminase, and this linkage is perceived as a foreign antigen by the host immune system. As antibodies to transglutaminase are produced, the normal function of transglutaminase in repairing the damaged intestinal mucosa is impaired.

An approach to the patient with suspected DH is outlined in Figure 31.6.

Differential Diagnosis

The differential diagnosis includes erythema multiforme, bullous lupus erythematosus, linear IgA bullous dermatosis (LABD) and bullous pemphigoid. Table 31.3 outlines the clinical and histologic features that help differentiate DH from LABD and bullous pemphigoid. Erythema multiforme is characterized by target lesions that are often acral in distribution and show vacuolar degeneration and epidermal necrosis histologically; also there are no IgA deposits at the basement membrane zone (BMZ; see Ch. 20). Bullous lupus erythematosus presents with urticarial papules and vesicles on an erythematous base and a histologic picture similar to LABD and DH. However, the patients have clinical and serologic findings of systemic lupus erythematosus. DIF reveals multiple immunoglobulins (including IgA) in a granular and band-like pattern along the BMZ, whereas in LABD there is a fine linear IgA deposition.

Crusted papules are also seen on the elbows and knees in patients with Wegener's granulomatosis and Churg–Strauss syndrome, but histologic features of vasculitis are observed. Additional entities in the differential diagnosis include urticarial vasculitis, scabies and arthropod bites.

Treatment

The treatment of DH includes dapsone and a gluten-free diet, as well as a combination of the two therapies. The pruritus of DH is relieved within 48–72 hours of instituting dapsone (4′,4′ diamino-diphenyl sulfone). The lesions abruptly recur within 24–48 hours of discontinuation of therapy. Unfortunately, dapsone has no effect on the intestinal pathology.

Dapsone is begun after screening for glucose-6-phosphate dehydrogenase (G6PD) deficiency, with initial dosages of 25–50 mg in adults and 0.5 mg/kg in children. Initiation of therapy with higher doses may precipitate severe hemolysis and cardiac decompensation in susceptible individuals. The average maintenance dose in adults on a normal diet is 100 mg daily. The half-life ranges from 12 to 24 hours, so divided doses are seldom of benefit. The daily dose can be regulated on a weekly

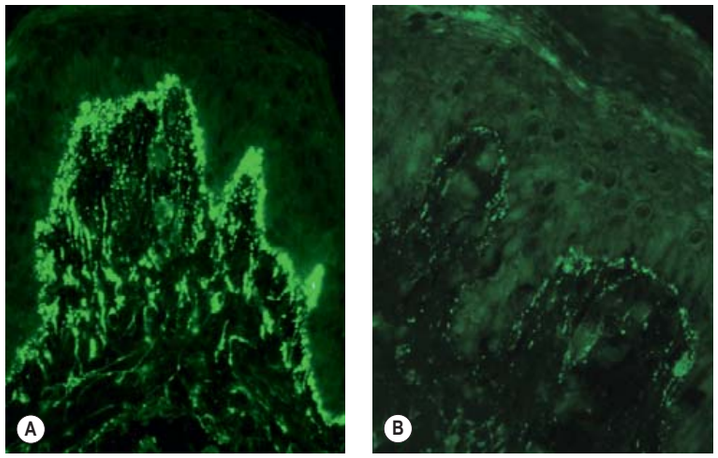

Fig. 31.5 Dermatitis herpetiformis – direct immunofluorescence. **A** Granular IgA deposition along the dermal–epidermal junction of normal-appearing skin adjacent to a lesion. **B** Granular deposition of epidermal transglutaminase (TG3) within the dermal papillae, which co-localizes with the IgA. *A, Courtesy, Kristin Leiferman, MD.*

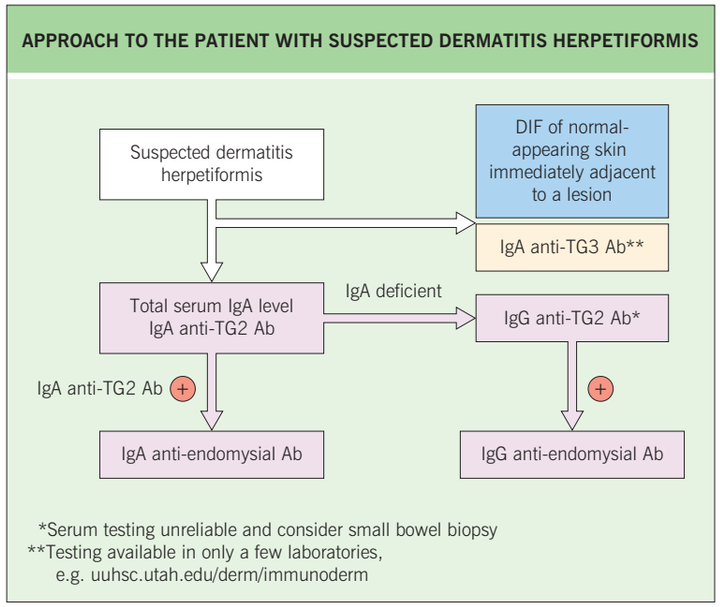

Fig. 31.6 Approach to the patient with suspected dermatitis herpetiformis. IgA anti-TG2 and anti-endomysial antibodies can be monitored over time to assess compliance with a gluten-free diet. The authors do not recommend anti-gliadin antibody testing because of high false-positive rates. Ab, antibody; DIF, direct immunofluorescence; TG, transglutaminase.

CHARACTERISTICS THAT DIFFERENTIATE DH, LABD AND BP

	DH	LABD	BP
Cutaneous lesion	Grouped papules and small vesicles, often excoriated	Small vesicles and/or large bullae	Large tense bullae
Distribution	Extensor surfaces, symmetrical	Similar to DH or BP	Trunk, extremities, occasionally mucosal surfaces
Histology	Subepidermal bullae with neutrophilic infiltrate	Subepidermal bullae with neutrophilic infiltrate	Subepidermal bullae with eosinophilic infiltrate
Direct IF	Granular IgA in dermal papillae	Linear IgA at BMZ, possibly also IgG	Linear IgG and C3 at BMZ
Site to biopsy for direct IF	Adjacent normal-appearing skin	Perilesional	Perilesional
Indirect IF	Negative	Linear IgA at BMZ (70%)	Linear IgG at BMZ (70%)
Enteropathy	>90%	Rare	None
HLA-DQ2	>90%	30%	Normal (20%)
Dapsone responsiveness	Excellent	Good, may also require systemic corticosteroids	Minimal to moderate

Table 31.3 Characteristics that differentiate dermatitis herpetiformis (DH), linear IgA bullous dermatosis (LABD) and bullous pemphigoid (BP). BMZ, basement membrane zone; IF, immunofluorescence.

SIDE EFFECTS OF DAPSONE	
Red blood cell toxicity	• Hemolytic anemia • Methemoglobinemia
White blood cell toxicity	• Leukopenia • Agranulocytosis
Dapsone hypersensitivity syndrome	• Hepatitis, lymphadenopathy, fatigue, anorexia
Cutaneous reactions	• Morbilliform eruption • Urticaria • Fixed drug eruption • Erythema nodosum • Exfoliative dermatitis • Stevens–Johnson syndrome • Toxic epidermal necrolysis • Phototoxicity • Drug-induced cutaneous lupus erythematosus
Gastrointestinal manifestations*	• Anorexia, nausea • Hepatitis • Cholestatic jaundice • Severe hypoalbuminemia
Neurologic associations*	• Headache, dizziness • Peripheral neuropathy • Blurred vision, tinnitus • Insomnia • Psychosis
Miscellaneous	• Fever • Nephrotic syndrome

*In decreasing order of frequency.

Table 31.4 Side effects of dapsone.

basis to optimize control. One to two new lesions per week should be expected on the optimal dose. Higher doses simply increase toxicity with little benefit.

Outbreaks of facial and scalp lesions while on otherwise adequate treatment can occur, but are not common. Facial disease may prove refractory to dapsone therapy. Breaking the vesicles followed by application of a potent corticosteroid gel may be helpful.

Although there are many side effects of dapsone (Table 31.4), the drug is well tolerated for years in more than 90% of patients (see Ch. 130). Hemolysis occurs in virtually every patient on dapsone therapy, since sulfones produce an oxidant stress on aging red blood cells. In patients with G6PD deficiency, dapsone may produce severe hemolysis. Although most patients have evidence of drug-induced hemolysis, a compensated hemolytic anemia does develop. Drug-induced hemolysis can be confirmed and followed by a reticulocyte count, which should show increased erythropoiesis. Of note, dapsone is secreted in breast milk and may cause hemolytic anemia in breastfed infants. In the setting of a persistent severe anemia, a search for contributing causes, such as iron, vitamin B_{12} or folate deficiencies or hereditary spherocytosis, should be performed.

Methemoglobin is present in the blood of most patients taking 100 mg of dapsone daily. Although the amount of methemoglobin usually does not exceed 5%, there are patients who have maintained levels between 10% and 15%. Methemoglobinemia in the absence of cardiopulmonary symptoms does not require alteration of dapsone dose.

Fatal agranulocytosis has developed in patients with DH treated with dapsone. This drug-induced agranulocytosis usually occurs after 2–12 weeks of continuous dapsone treatment. A hypersensitivity reaction involving the formation of leukocyte agglutinins seems to be the underlying mechanism. Re-administration of dapsone then causes leukopenia within hours. A simple measure is to warn the patient to discontinue the drug and report immediately if fever, a sore throat, or other signs of infection develop.

Dapsone hypersensitivity syndrome (see Ch. 21) is a rare, but potentially severe, reaction, characterized by fever, a cutaneous eruption and internal organ involvement, which is usually seen 2–7 weeks after initiation of therapy. The cutaneous manifestations vary from a morbilliform eruption to exfoliative dermatitis, while the systemic manifestations include fever, pruritus, lymphadenopathy, hepatitis, an elevated ESR, leukocytosis, and, rarely, eosinophilia[17]. Patients should be educated about this syndrome and instructed to discontinue therapy and notify their medical provider if any signs or symptoms of the dapsone hypersensitivity syndrome develop.

Peripheral neuropathy induced by dapsone may occur as early as during the first 4 months of therapy. Indeed, neuropathic signs can develop within the first few weeks of therapy. The neuropathy was initially reported as a pure motor neuropathy (involving primarily distal extremity muscles); however, pure motor, pure sensory, and combined motor and sensory neuropathies have subsequently been reported. Relatively high daily doses of dapsone (200–500 mg) and high cumulative doses in the range of 25 to 500 g have been implicated[17a].

If patients are intolerant to dapsone, therapy with sulfapyridine should be considered. The initial dose of sulfapyridine is usually 500 mg three times a day and it can be safely increased to 2 g three times a day; however, some patients may not respond to sulfapyridine at any dose. Adequate fluid intake and alkalinization of the urine minimizes the risk of nephrolithiasis.

Dapsone therapy monitoring includes a baseline complete blood count (CBC) and liver function tests, then weekly CBCs for the first month, monthly CBCs for the next 5 months, and semiannual CBCs thereafter while the patient remains on therapy. Liver function tests should be repeated at 6 months and annually thereafter. Some clinicians measure baseline G6PD activity in all patients, while others focus on those of African, Asian or southern Mediterranean ancestry. Sulfapyridine produces less hemolytic anemia, but the potential for agranulocytosis does exist. Consequently, similar monitoring is recommended for chronic sulfapyridine therapy.

Patients can also be treated with a gluten-free diet (which includes corn, rice and oats). Because several months of gluten-free diet therapy are needed for a response, concurrent suppression of symptoms with dapsone is usually necessary. Most patients with granular IgA deposits respond to a strict gluten-free diet such that they can either decrease or eliminate their need for dapsone. With a prolonged gluten-free diet, IgA in the skin decreases and eventually disappears, but with the reintroduction of gluten, IgA deposits and skin disease return. In addition, minor fluctuations in disease severity are most likely related to oral gluten intake. The gluten-free diet is inconvenient and unacceptable to some patients.

Patient Support

The Gluten Intolerance Group and the Celiac Disease Foundation (www.celiac.org) offer information on acceptable foods as well as foods and additives that should be avoided. The former patient support group has a *Quick Start Diet Guide for Celiac Disease* that may be useful for patients. Their website is www.gluten.net.

LINEAR IgA BULLOUS DERMATOSIS

Synonyms:
Adults: ■ Linear IgA dermatosis (LAD) ■ Linear IgA disease of adults ■ Linear IgA disease ■ Linear IgA dermatitis herpetiformis ■ Linear dermatitis herpetiformis ■ Adult linear IgA disease ■ IgA bullous pemphigoid ■ Pemphigoid linear IgA

Children: ■ Chronic bullous disease of childhood ■ Benign chronic bullous dermatosis of childhood ■ Childhood linear IgA dermatitis herpetiformis ■ Linear IgA disease of childhood

Introduction

LABD is an immune-mediated, subepidermal vesiculobullous eruption that occurs in both adults and children. It has been defined on the basis of a unique immunopathology consisting of linear deposition of IgA along the cutaneous BMZ. In adults, the clinical findings associated with this immunopathologic pattern may resemble those of DH or bullous pemphigoid (BP) (see Table 31.3), but in children, the cutaneous features may be clinically unique.

Fig. 31.7 Linear IgA bullous dermatosis. The circumferential and linear vesicles and bullae are typical of this disorder.

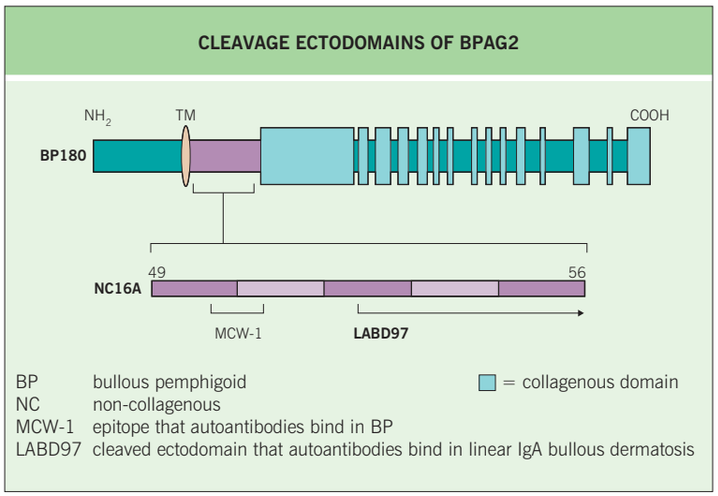

Fig. 31.9 Cleavage ectodomains of BPAG2. COOH, carboxy terminus; NH_2, amino terminus; TM, transmembrane region.

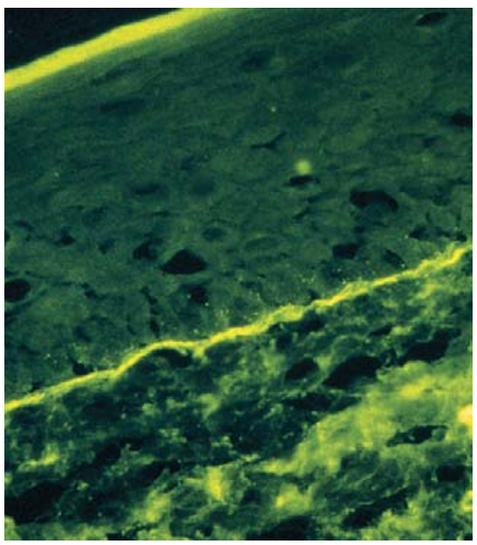

Fig. 31.8 Linear IgA bullous dermatosis – direct immunofluorescence. A linear pattern of IgA deposition is present within perilesional skin.

The childhood form is most frequently termed "chronic bullous disease of childhood" (CBDC). It is a subepidermal vesiculobullous disease that was initially described on the basis of its clinical findings of annular erythema and blisters (often referred to as a "crown of jewels"; Fig. 31.7), which developed predominantly in flexural areas, particularly the lower trunk, thigh and groin in preschool children. However, it is invariably characterized by the linear deposition of IgA along the BMZ (Fig. 31.8) as well as circulating antibodies against the same BMZ antigens described in the adult form[18].

Based upon the site of IgA deposition as determined by immunoelectron microscopy, there are at least two distinct types of LABD: a lamina lucida type (majority) and a sublamina densa type. In adults, LABD is frequently drug-induced.

History

In 1969, it was noted that patients with vesiculobullous lesions and the histologic findings of DH could have linear rather than granular deposits of IgA along the epidermal BMZ[19]. In 1975, Chorzelski and Jablonska[20] first suggested that LABD was a separate entity based on its immunopathologic findings. Subsequently, there has been general agreement that LABD is a distinct disease entity[21,22].

In 1970, Jordon et al.[23] first proposed the name "benign chronic bullous dermatosis of childhood". Subsequent investigators, using antisera specific for IgA, identified the characteristic linear IgA deposition along the epidermal BMZ in children with CBDC[24]. On a molecular basis, CBDC is the same disease as LABD in that the circulating IgA antibody found in the serum of patients with CBDC binds to the same 97 kDa antigen described in LABD of adults[18].

Epidemiology

The true incidence of LABD is unknown. The incidence in southern England has been estimated to be 1 in 250 000 per year. The incidence in the US has not been reported, but we have estimated the prevalence of LABD in Utah to be 0.6 per 100 000 adults. In adults, the average age of onset of LABD is after 60 years of age[21]. There appears to be a slight female preponderance, although this has not been observed in all series[21,25]. Childhood LABD occurs at a mean age of 4.5 years[25–27].

Pathogenesis

Both BP and the lamina lucida type of LABD have lamina lucida deposition of immunoglobulin and are associated with BMZ vesiculation. However, the antigenic specificity differs. In BP, the pathogenic IgG antibodies bind the MCW-1 region of the NC16 domain of BP antigen 2 (BPAG2; BP180), whereas the epitopes that have stimulated an IgA response in LABD are more toward the carboxy terminus of the same molecule (Fig. 31.9). In adult and childhood LABD patients, this IgA antibody was found, on immunoblot, to react against a 97 kDa antigen in an epidermal extract[28]. Subsequently, the 97 kDa antigen was found to represent a cleaved ectodomain of BPAG2, referred to as LABD97 (see Fig. 31.9). Why BP antibodies should react predominantly with antigens near the transmembrane portion of BPAG2 and LABD antibodies react with cleaved epitopes near or within the collagenous domain is unclear[29].

IgA class antibodies from patients with the sublamina densa type of LABD have been reported to bind to type VII collagen in anchoring fibrils[30,31]. However, in a series of 10 sera from such patients, this was not substantiated (authors' observations). Currently, the antigenic specificity of these sublamina densa-binding antibodies is not known.

There have been reports in the literature of the association of LABD with various disorders such as gastrointestinal diseases, autoimmune diseases, malignancies and infections (see below). The significance of these associations has yet to be determined, but they may play a role in the initial stimulation of the IgA mucosal immune system.

The incidence of gluten-sensitive enteropathy in LABD has been reported in the literature to range from 0 to 24%[20,22,32]. Leonard et al.[32] noted that two of six patients with LABD had gluten-sensitive enteropathy, and two of six patients' skin lesions improved on a gluten-free diet; however, none of the patients completely cleared. In contrast, Lawley et al.[22] found no histologic evidence of gluten-sensitive enteropathy in the six patients they studied. LABD clearly has a much lower prevalence of small bowel histologic abnormalities than does DH. Ulcerative colitis, Crohn's disease and gastric hypochlorhydria have also been described in association with LABD[21,33]. LABD associated with ulcerative colitis was reported to remit after colectomy[34].

DRUG-INDUCED LINEAR IgA BULLOUS DERMATOSIS
COMMON
• Vancomycin*
LESS COMMON
• Penicillins • Cephalosporins • Captopril > other ACE inhibitors • NSAIDs: diclofenac, naproxen, oxaprozin, piroxicam
UNCOMMON
• Phenytoin • Sulfonamide antibiotics: sulfamethoxazole, sulfisoxazole
RARE
• Amiodarone • Angiotensin receptor blockers: candesartan, eprosartan • Atorvastatin • Carbamazepine • Cyclosporine • Furosemide • Gemcitabine • Glyburide • Granulocyte colony-stimulating factor • Influenza vaccination • Interferon-α and interferon-γ • Interleukin-2 • Lithium carbonate • PUVA • Rifampin • Somatostatin • Verapamil • Vigabatrin
*Unusual variants include toxic epidermal necrolysis-like and morbilliform.

Table 31.5 Drug-induced linear IgA bullous dermatosis. ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

Data on the association of autoimmune diseases with LABD are not sufficient to allow statistical analysis of prevalence. However, there are reports in the literature of the association of systemic lupus erythematosus and dermatomyositis with LABD, as well as thyrotoxicosis, autoimmune hemolytic anemia, rheumatoid arthritis, and one case of glomerulonephritis[20,35,36].

An association between LABD and malignancy has also been described. Tumors that have been reported in patients with LABD include: B-cell lymphoma, chronic lymphocytic leukemia, and carcinoma of the bladder, thyroid, colon and esophagus; single case reports of plasmacytoma, hydatiform mole, renal cell carcinoma and ocular melanoma have also been described[21,37–41]. In addition, LABD has been reported to be associated with several infections, including varicella zoster virus, antibiotic-treated tetanus, and upper respiratory infections. It has been postulated that the infectious agent may have triggered an immune response[41–43].

There are multiple reports of drug-induced LABD; the drugs associated with LABD are listed in Table 31.5, with vancomycin being one of the more common inducers (Fig. 31.10)[44,45]. In the case of these medications, they may stimulate the immune system to produce an IgA class antibody in a predisposed individual. Drug-induced LABD usually remits within 2–6 weeks of cessation of the drug. However, some cases have persisted for months[45].

Clinical Features

Clinical manifestations in LABD are variable and patients can present with findings suggestive of DH as well as subepidermal tense bullae that are often indistinguishable from BP. However, the vesiculobullous lesions often appear in a herpetiform arrangement on erythematous and/or normal-appearing skin (Figs 31.11 & 31.12). Some patients present with expanding annular plaques (Fig. 31.13), while others have lesions that are scattered and asymmetric[21]. An isomorphic response, including lesions appearing at previous sites of adhesive tape, has been reported.

Fig. 31.13 Linear IgA bullous dermatosis. Annular and polycyclic plaques of the trunk in two women with the disorder.

LABD may present as a variant of mucous membrane (cicatricial) pemphigoid, with oral, nasal, pharyngeal and esophageal lesions. Involvement of the tracheobronchial mucosa was reported in a severe case[46]. The ocular form of LABD is clinically indistinguishable from ocular mucous membrane pemphigoid[47].

Pathology

LABD is a subepidermal vesicular dermatosis in which neutrophils predominate. In early urticarial papules or plaques, neutrophils are aligned along the BMZ, accompanied by vacuolar change and sometimes by neutrophilic microabscesses in dermal papillae. These papillary dermal collections, if numerous enough, can resemble the picture seen in DH[21]. In fully developed lesions, there are subepidermal bullae in which neutrophils are present in the underlying dermis, either alone or with eosinophils. Eosinophils can become more numerous over time. While distinguishing between DH and LABD can, on occasion, be impossible by light microscopy, a linear distribution of neutrophils along the BMZ and neutrophils at the very tips of dermal papillae favor LABD[48].

LABD can be subdivided on the basis of immunoelectron microscopy findings: most patients have IgA deposits within the lamina lucida[22,49]. Less commonly, there is deposition of IgA in the sublamina densa, associated with anchoring fibrils[22]. In a few cases, deposits of IgA have been observed in both sites[50]. In one report, the deposition of IgA was initially in the lamina lucida, but later had a combined pattern[50].

Differential Diagnosis

LABD can be difficult to diagnose clinically, especially in adults, and is often confused with DH and BP. By definition, LABD is separated from DH and BP on the basis of findings by DIF (see Table 31.3). Linear IgA deposition along the BMZ in perilesional skin biopsy specimens is characteristic of LABD, in contrast to DH, which shows granular deposition of IgA in dermal papillary tips or in a continuous pattern along the basement membrane[20–22], or BP, which shows linear deposition of IgG along the epidermal BMZ. The classification of cases demonstrating both IgG and IgA along the BMZ is problematic. Some authorities include only those patients with IgA as the sole BMZ immunoglobulin under the term LABD and categorize all others as BP. Others categorize patients with both IgG and IgA along the BMZ on the basis of the predominant immunoglobulin on DIF. Distinguishing the sublamina densa form of LABD from epidermolysis bullosa acquisita is also made on the basis of the class of immunoreactant and classification can be problematic.

Circulating anti-BMZ antibodies of the IgA class can be demonstrated in 60–70% of LABD sera. In contrast, patients with DH have not been shown to have circulating antibodies that bind to skin, and 60–70% of patients with BP demonstrate circulating IgG class antibodies (see Table 31.3)[20]. Circulating IgA class anti-BMZ antibodies from the lamina lucida type of LABD have been shown to adhere to the epidermal side (roof) of salt-split skin, while patients with sublamina densa binding of IgA on direct immunoelectron microscopy have serum antibodies which bind to the dermal side of salt-split skin. Patients with both IgA and IgG at the BMZ demonstrate binding to the epidermal side of salt-split skin[51]. Whether or not such antibody titers correlate with disease activity has not yet been established.

LABD secondary to drugs, in particular vancomycin, may have a toxic epidermal necrolysis-like or morbilliform presentation. Routine microscopy plus DIF can allow a distinction.

Treatment

The majority of patients with LABD respond to either oral dapsone or sulfapyridine therapy. These medications have been reviewed in detail in the section on the treatment of DH. Most patients with LABD have a clinical response within 48–72 hours. In occasional patients, it may be necessary to add oral prednisone in doses up to 40 mg daily to achieve complete control of the disease[21,22,49,50]. The majority of our patients have been controlled by dapsone alone. It is our observation that cases in which both IgG and IgA deposits are present in the BMZ are those that are likely to require additional therapy with systemic corticosteroids. The average dose of dapsone required to control LABD in adults is 100 mg daily, but doses as high as 300 mg daily may be needed. If doses greater than 200 mg per day are necessary, close monitoring should be undertaken. Children usually respond to a dose of 1–2 mg/kg daily.

Successful treatment of both adult and childhood LABD with antibiotics, including dicloxacillin, erythromycin, tetracycline (in those >9 years of age), and trimethoprim–sulfamethoxazole, has been reported. No specific microorganism was incriminated in these cases and therapeutic trials were empirical. A clinical trial of these relatively benign therapies may be undertaken, but no method of predicting a response has been identified. Mycophenolate mofetil, azathioprine and IVIg can be used as steroid-sparing agents in patients who do not respond to a combination of prednisone and dapsone or in patients with severe disease.

The natural course of the disease is characterized by persistence for several years with eventual spontaneous remission in many patients. Although a remission rate of 10–15% was originally described[21,39], additional studies have reported remission rates of 30–60%. There should be repeated attempts to taper medications given, on the chance that a spontaneous remission has occurred. Childhood LABD remits within 2–4 years.

Epidermolysis Bullosa 32

Jo-David Fine and Jemima E Mellerio

Synonyms: ■ All forms of EB: EB hereditaria ■ EB simplex: epidermolytic EB ■ Junctional EB: EB atrophicans, EB letalis ■ Dystrophic EB: EB dystrophica

Key features

- Epidermolysis bullosa (EB) encompasses multiple clinically distinctive disorders that share three major features: genetic transmission, mechanical fragility of the skin, and blister formation
- There are four major forms of inherited EB – EB simplex, junctional EB, dystrophic EB, and Kindler syndrome – which differ in the ultrastructural site within which cutaneous blisters form
- EB may be diagnosed by immunofluorescence antigenic mapping, transmission electron microscopy or genetic analysis
- Any epithelial-lined or epithelial-covered organ is at potential risk for involvement in the more severe forms of inherited EB
- In the absence of specific therapy, management is primarily focused on prevention of blisters and the correction of extracutaneous complications

INTRODUCTION

Inherited epidermolysis bullosa (EB), the prototypic mechanobullous disease, is characterized by the development of blisters following seemingly minor or insignificant trauma or traction to the skin[1]. It traditionally encompasses three major forms (simplex, junctional and dystrophic) and at least 30 distinctive clinical phenotypes[2] (Table 32.1). Kindler syndrome, an inherited disease characterized by poikiloderma, photosensitivity and mechanically fragile skin (see Ch. 63), is now classified as a fourth major form of EB. Inherited EB can result from mutations within the genes for any of at least 15 structural proteins: keratins 5 and 14; the subunits of laminin 332 (formerly laminin 5); type VII and XVII collagens; plectin; $\alpha_6\beta_4$ integrin; dystonin (bullous pemphigoid antigen 1); kindlin; and the desmosomal components plakophilin-1, plakoglobin and desmoplakin. Although most of these diseases are rare, research into their underlying pathophysiologic bases has led to major advances in our understanding of the cell and molecular biology of keratins, other keratinocyte-associated structural proteins, collagens and the cutaneous extracellular matrix (ECM). Study of EB has also helped to elucidate mechanisms of epithelial cell adhesion, migration and differentiation and to highlight the role of the basement membrane zone in health and disease. The creation of *in vitro* and animal models of EB has enabled principles of gene therapy to be tested and refined, with development of novel approaches for the treatment of EB patients.

HISTORY

Epidermolysis bullosa was first described in 1870 by von Hebra under the name "erblichen pemphigus"[3]. Its current name, "epidermolysis bullosa hereditaria", was coined by Koebner in 1886. Hallopeau recognized the distinct clinical features of simplex and dystrophic forms of EB in 1898. Junctional EB was first identified in 1935 by Herlitz and termed "EB letalis". Precise characterization of these three major EB types via the use of transmission electron microscopy was first achieved by Pearson in 1962[4]. In the ensuing years, additional EB phenotypes were described. Monoclonal antibody studies provided the first suggestion that specific protein defects underlie individual types and subtypes of this disease[5–8]. In 1986, the National EB Registry was established in the US by the National Institutes of Health, facilitating epidemiologic, clinical and laboratory characterization of each major EB type and subtype[9,10]. In 1991, Bonifas et al.[11] (through utilization of linkage analysis) were the first to demonstrate the molecular basis for a specific form of EB (simplex). Subsequent work by others has established the precise molecular basis for each of the EB subtypes.

EPIDEMIOLOGY

Based on National EB Registry data[12], the estimated prevalence and incidence of EB in the US are 8.2 per 1 million population and 19.6 per 1 million live births, respectively. Carrier frequencies have also been reported[13]. The approximate prevalences and incidences (respectively) of the major types of EB are as follows: EB simplex, 4.6 and 10.8; junctional EB, 0.4 and 2.0; dominant dystrophic EB, 1.0 and 2.9 and recessive dystrophic EB, 0.9 and 2.0.

PATHOGENESIS

EB is caused by mutations within genes that encode structural proteins that reside within the epidermis (EB simplex), dermo-epidermal junction (junctional EB), or uppermost papillary dermis (dystrophic EB). The site within which each of these proteins resides determines the ultrastructural location where the blisters arise (Table 32.1 & Fig. 32.1).

EB Simplex

Most forms of EB simplex (EBS) are transmitted in an autosomal dominant manner. There are two main subgroups of EBS, suprabasal and basal, which differ in the ultrastructural level of the intraepidermal blistering (see Table 32.1). The vast majority of EBS cases are in the basal group, most often resulting from a dominant-negative mutation (see Ch. 54) within the keratin 5 (*K5*) or 14 (*K14*) genes, expression of which is primarily within the basal layer of the epidermis[14,15]. The clinical severity and other phenotypic features of EBS are closely associated with the genotype. For example, mutations in the helix initiation and termination motifs of K5 and K14 (see Fig. 56.5) lead to the Dowling–Meara subtype of EBS (EBS-DM), which is more severe than EBS due to mutations in other regions of these keratins. An autosomal recessive form of EBS due to mutations in the gene encoding plectin is associated with muscular dystrophy (EBS-MD), which is not surprising considering that this protein is expressed in skeletal muscle as well as in the hemidesmosomes of basilar keratinocytes; other patients with plectin deficiency present with pyloric atresia (EBS-PA). Suprabasal forms of EBS caused by mutations in the genes encoding the desmosomal proteins plakophilin-1, plakoglobin and desmoplakin and a basal variant due to a homozygous mutation in the dystonin gene have also been reported (see Table 32.1).

Junctional EB

Junctional EB (JEB) was transmitted in an autosomal recessive manner in all but one family reported to date (see Table 32.1). The most severe subtype, JEB-Herlitz (JEB-H), typically results from homozygous or compound heterozygous truncating mutations within a gene encoding one of the three subunits of laminin 332, a key component of the lamina lucida of the dermo-epidermal junction (see Ch. 28)[16]. The milder generalized form of junctional EB, JEB-non-Herlitz

EPIDERMOLYSIS BULLOSA: SIMPLEX, JUNCTIONAL AND DYSTROPHIC SUBTYPES		
Subtype	**Inheritance**	**Defective protein(s)**

*Desmoplakin defects also cause the skin fragility/woolly hair syndrome (see Table 32.4).
†May also be caused by defects in $\alpha_6\beta_4$ integrin, which more often lead to JEB-PA.
‡Formerly referred to as generalized atrophic benign EB.
§One kindred with a dominant-negative mutation in the gene encoding type XVII collagen has been reported to date.

Table 32.1 Epidermolysis bullosa (EB): simplex, junctional and dystrophic subtypes. Entities with a lighter background represent rare variants. AD, autosomal dominant; AR, autosomal recessive; BPAG, bullous pemphigoid antigen; DDEB, dominant dystrophic EB; EBS, EB simplex; JEB, junctional EB; RDEB, recessive dystrophic EB.

(JEB-nH; previously named generalized atrophic benign EB, GABEB), results from mutations within the genes for either a subunit of laminin 332 or type XVII collagen. JEB with pyloric atresia (JEB-PA) is caused by mutations within either of the two genes that encode the subunits of $\alpha_6\beta_4$ integrin. In the laryngo-onycho-cutaneous (LOC) syndrome, the underlying mutations are in the α_3 chain of laminin 332.

Dystrophic EB

Dystrophic EB (DEB) is transmitted in either an autosomal dominant or autosomal recessive manner. Dominant DEB (DDEB) results from a dominant-negative mutation within the type VII collagen gene[17,18]. Typically, a missense mutation results in substitution of another amino acid for a glycine within the triple-helical domain of this collagen.

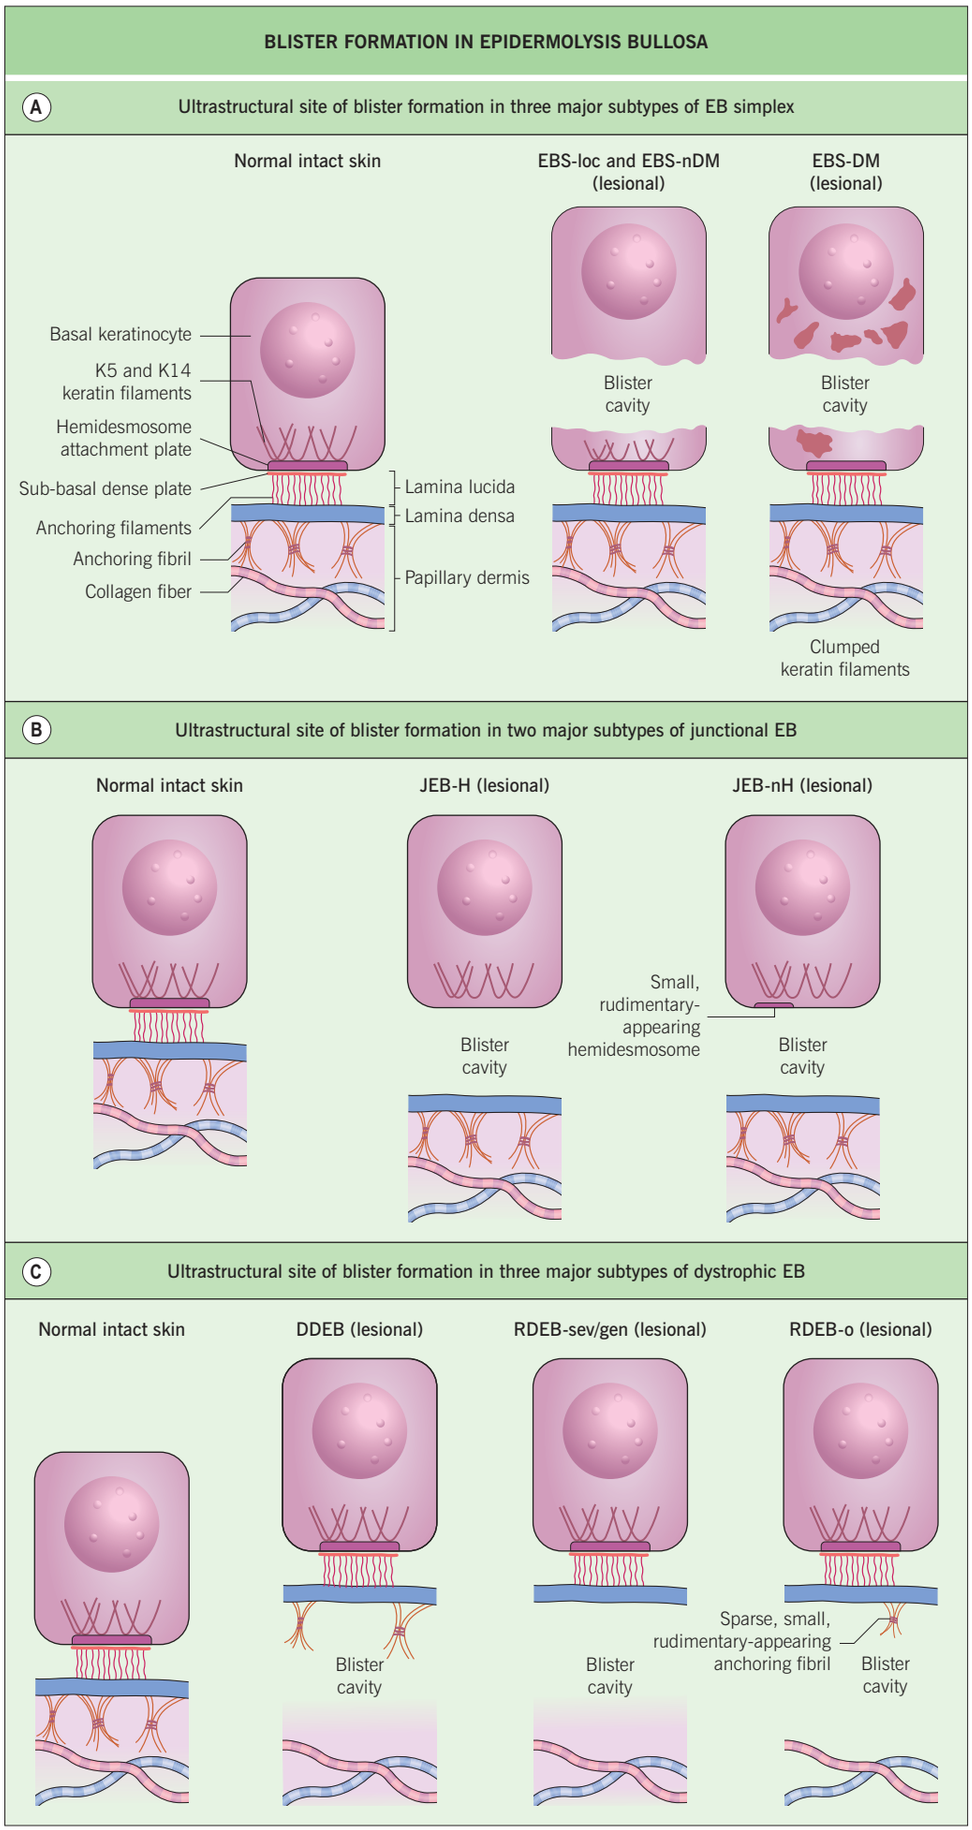

Fig. 32.1 Ultrastructural sites of blister formation in major forms of epidermolysis bullosa (EB). **A** Ultrastructural sites of blister formation in three subtypes of EB simplex. The ultrastructure of normal intact skin is presented for comparison. In all three major subtypes of EB simplex – localized (EBS-loc), generalized non-Dowling–Meara (EBS-nDM) and Dowling–Meara (EBS-DM) – blisters arise within the lowermost intracytoplasmic portion of the basilar keratinocyte. In one subtype, EBS-DM, keratin filaments tend to coalesce into larger electron-dense clumps. **B** Ultrastructural sites of blister formation in two major subtypes of junctional EB (JEB). All forms of JEB are characterized by blister formation within the lamina lucida of the dermal–epidermal junction. As such, the lamina densa remains firmly attached to the dermis which forms the base of the blister cavity. Sub-basal dense plates and anchoring filaments are absent in both subtypes of JEB. Hemidesmosomes are absent in JEB-Herlitz (JEB-H), whereas they are reduced in number and appear rudimentary in structure within skin from patients with the JEB-non-Herlitz (JEB-nH) subtype. **C** Ultrastructural sites of blister formation in three major subtypes of dystrophic EB. Blister formation occurs beneath the lamina densa in all forms of dystrophic EB. Whereas anchoring fibrils appear normal in size and structure in dominant dystrophic EB (DDEB) skin, they may be somewhat reduced in number. Consistent with the presence of sub-lamina densa cleavage, these anchoring fibrils remain attached to the blister roof, which is composed of intact epidermis and an attached basement membrane (which includes the lamina densa). In contrast, anchoring fibrils are completely absent in lesional skin from patients with severe generalized recessive dystrophic EB (RDEB-sev/gen). If detectable in skin from patients with other generalized forms of recessive dystrophic EB (RDEB-o), they are both markedly reduced in number and rudimentary in appearance.

Continued

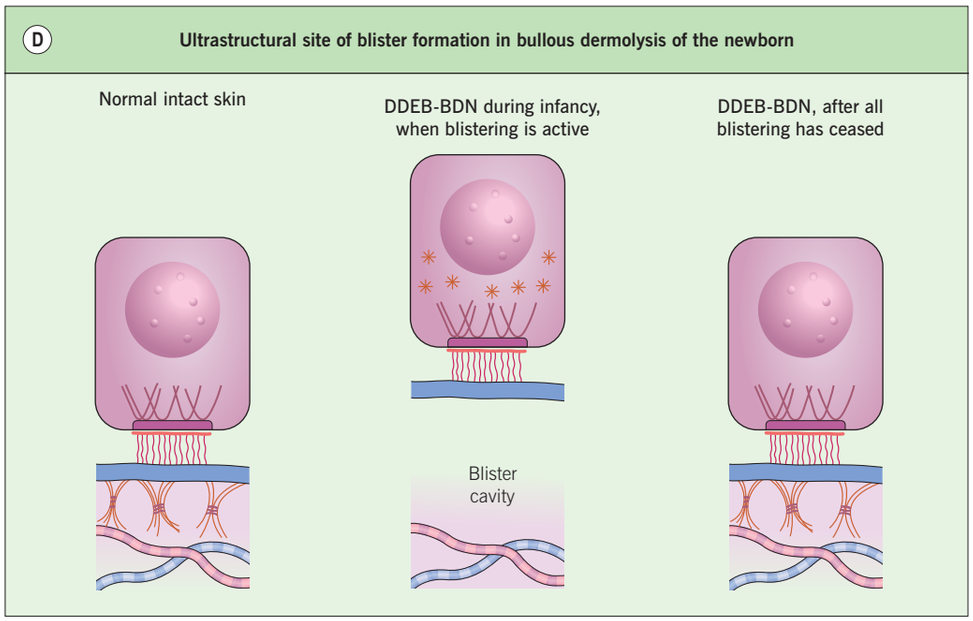

Fig. 32.1 Ultrastructural sites of blister formation in major forms of epidermolysis bullosa (EB) (cont'd). D Ultrastructural findings in the form of dominant dystrophic EB (DDEB) referred to as bullous dermolysis of the newborn (DDEB-BDN). With age, there is improvement in the transport and deposition of type VII collagen from the keratinocyte cytoplasm to the anchoring fibrils of the basement membrane.

Although the resultant protein is structurally abnormal, immunohistochemical staining of the dermal–epidermal junction is usually indistinguishable from that of normal skin.

Recessive DEB (RDEB) usually results from compound heterozygous mutations within the type VII collagen gene[17–19]. Premature stop codons (which result in truncated proteins) are characteristic of the severe generalized RDEB subtype (RDEB-sev/gen; traditionally known as RDEB-Hallopeau–Siemens). Consistent with the severity of these mutations, anchoring fibrils are undetectable or extremely sparse and poorly formed in skin biopsy specimens, and immunohistochemical staining with antibodies against the major epitopes of the type VII collagen molecule is absent or barely detectable. Milder forms of generalized RDEB are associated with less severe biallelic mutations in the type VII collagen gene.

Some patients with RDEB retain a specific fragment of type VII collagen (the amino terminal non-collagenous domain [NC1]), and this may contribute to an increased susceptibility to develop squamous cell carcinomas (SCCs)[20]. In a Ras-driven model of tumorigenesis, keratinocytes from RDEB patients that contained no collagen VII did not form tumors in mice, whereas RDEB keratinocytes that produced the NC1 domain of collagen VII (and null keratinocytes forced to express NC1) were tumorigenic. Additional studies pointed to the fibronectin-like sequences within NC1 as key to promoting tumor cell invasion. However, SCCs can develop in RDEB patients who do not express the NC1 domain[21].

In a rare form of DEB referred to as bullous dermolysis of the newborn, inheritance is usually dominant and blistering is typically confined to the first 1–2 years of life[22–24]. Clinical expression coincides with a time during which type VII collagen is present primarily within basilar keratinocytes in these patients' skin, rather than along the dermal–epidermal junction (see Fig. 32.1D). This suggests that there is a temporary disruption in the transport of this protein from the keratinocyte cytoplasm to the underlying ECM.

Fig. 32.2 Localized epidermolysis bullosa simplex. A, B Bullae arising on the toes and plantar surfaces at sites of lateral or rotary traction. The majority of blisters occur in acral sites. *B, Courtesy, Julie V Schaffer, MD.*

CLINICAL FEATURES

Cutaneous Findings

Patients with EB are classified on the basis of the ultrastructural level of blister formation, antigenic alterations in the skin, the mode of inheritance, and the clinical phenotype[2,25]. Although cutaneous findings play an important role in the overall determination of the EB phenotype, there is overlap in the frequency of cutaneous manifestations in different subtypes of EB. In addition, the severity, distribution and type of skin findings in an individual patient may change over time

Fig. 32.3 Epidermolysis bullosa simplex, other generalized. Extensive blistering on the buttocks (**A**) and blistering in association with focal keratoderma on the soles (**B**) of a 2-year-old girl. *Courtesy, Julie V Schaffer, MD.*

Fig. 32.4 Dominant dystrophic epidermolysis bullosa. A, B Erosions, scarring and milia on the digits, as well as partial shedding of a toenail (**A**). **C** A discrete area of scarring on the elbow with blisters, crusting and milia.

(e.g. evolution from generalized to localized blistering or delayed development of sequelae such as scarring and nail dystrophy)[2]. Mutational analysis is not currently considered to be a first-line diagnostic test for EB, with the exceptions of prenatal and preimplantation diagnosis[2].

All forms of inherited EB are characterized by mechanically fragile skin, erosions and (with rare exceptions) macroscopic blisters (Figs 32.2 & 32.3). In most forms of EB, minimal lateral or rotary traction on the skin leads to shearing within ultrastructurally uniform cleavage planes, resulting in blister formation. Blisters can usually be readily induced in EB patients (e.g. by rotating a pencil eraser on intact skin), facilitating diagnosis by immunohistochemical or ultrastructural techniques (see below). However, in localized EBS and DDEB, it may be difficult to induce blisters in clinically uninvolved areas.

Scarring (almost always atrophic) can occur in any type or subtype of EB (Fig. 32.4), including localized EBS. However, its frequency is greatest in the subtypes that are characterized ultrastructurally by disruption of the basement membrane zone (particularly the lamina densa) and clinically by generalized cutaneous and extracutaneous disease activity (Fig. 32.5). Whereas scarring is estimated to occur in only 15% of patients with localized EBS, it is present in essentially every patient with RDEB[26]. Other cutaneous findings that have similar variations in frequency across the major types and subtypes of EB include dystrophic or absent nails (see Fig. 32.4), milia, and scarring alopecia of the scalp.

Some cutaneous findings have diagnostic implications (Fig. 32.6)[2]. Reticulated hyperpigmented macules distinguish a rare subset of EB simplex termed *EBS with mottled pigmentation (EBS-MP)*. Superficial peeling of the skin, often in the absence of overt blistering, is seen in *EBS superficialis (EBSS)*. Grouped ("herpetiform") blisters, often in an arcuate (Fig. 32.7) or polycyclic array, are highly characteristic of *EBS-DM*, which is also associated with the gradual development of a diffuse palmoplantar keratoderma (Fig. 32.8). Migratory circinate erythema with vesiculation of the advancing edge has been described in patients with EBS caused by a frameshift mutation that leads to an elongated K5 protein. Excessive or exuberant granulation tissue, usually in a symmetric distribution involving the periorificial skin, axillary vaults, upper back, nape of the neck and periungual areas, is typical of *JEB-H* (Fig. 32.9).

Distribution of skin disease activity is also useful in the subclassification of EB[25], although the pattern of involvement tends to be less distinctive in infants than in adults. Patients with the *"inversa" subtypes of JEB and RDEB* experience disease activity primarily in intertriginous areas (e.g. axillae, inguinal creases). Lesions primarily affect acral sites in patients with *localized JEB-nH* and are almost exclusively on the shins in those with *pretibial DEB*. Another extremely rare subtype is *RDEB centripetalis*, which initially features acral blistering,

followed by slow progression of disease activity toward the trunk over the years.

Extracutaneous Findings

The same molecular defects that affect the skin in patients with EB are also present in other tissues with an epithelial lining or surface[27,28], including the eye, oral cavity, and gastrointestinal and genitourinary tracts. The extracutaneous manifestations that result are summarized in Table 32.2[29]. Although exceptions exist, extracutaneous involvement occurs most frequently in RDEB and (to a lesser extent) JEB, and it can result in blisters, erosions, ulcers and/or scarring. Pyloric atresia is evident at birth in patients with the rare JEB-PA and EBS-PA subtypes. In other forms of EB, complications related to extracutaneous disease may arise as early as the first year of life. Repeated blistering of the external eye can result in neovascularization and blindness[30]. Chronic involvement of the esophagus leads to scarring, stricture formation and, rarely, even complete obstruction[31]. Involvement of the small intestine presents with chronic malabsorption, whereas disease activity within the large intestine is associated with severe constipation and anal fissures or strictures. Recurrent genitourinary tract blistering may result in urethral or ureterovesical strictures; if persistent, the latter may lead to ureteric reflux and hydronephrosis. Lastly, tracheolaryngeal blistering and associated soft tissue edema, seen most often in infants and young children with *JEB-H*, may lead to potentially fatal acute airway obstruction[32].

Dental enamel hypoplasia, which occurs in all forms of *JEB*[33,34], is associated with pitting of the surfaces of primary and permanent teeth. If untreated, these patients lose teeth during childhood due to excessive caries[35]. Severe caries and resultant tooth loss also occur in *RDEB-sev/gen*, likely resulting from impaired clearance of food from the mouth and poor dental hygiene in the setting of intraoral injury and scarring, ankyloglossia and microstomia.

Pseudosyndactyly ("mitten" deformities of the hands and feet) primarily affects patients with RDEB, especially *RDEB-sev/gen*, although it occasionally occurs to a lesser degree in *DDEB* and *JEB*[36] (Fig. 32.10). Initially presenting as proximal "web" formation between adjacent digits, the digits may eventually become totally fused and encased by scar tissue. Lack of mobility leads to bony resorption and muscular atrophy, eventuating in marked impairment of hand function.

Osteoporosis, detectable by dual-emission X-ray absorptiometry (DEXA) scanning, is common in severe generalized forms of EB, most notably *RDEB-sev/gen* and *JEB-H*. Radiographs may demonstrate vertebral crush fractures in severe cases. EBS due to plectin deficiency is associated with mild to severe muscular dystrophy. The muscle disease presents during infancy in some patients, but weakness often develops insidiously during later childhood or early adulthood in those who are less severely affected.

Chronic renal failure develops in a minority of patients with severe generalized forms of EB, most notably RDEB-sev/gen, which is associated with a 12% risk of death from renal failure by age 35 years[37]. Renal disease may result from untreated outflow obstruction, glomerulonephritis or secondary systemic amyloidosis. Nephrotic syndrome associated with altered expression of laminin isoforms in renal basement membranes has been reported in an infant with JEB-H. A small subset of patients with severe generalized forms of EB, especially RDEB-sev/gen, develop potentially fatal dilated cardiomyopathy[38]. Although as yet unproven, selenium or carnitine deficiency may be a contributing factor.

Although it was a common occurrence several decades ago, potentially lethal bacterial sepsis is now relatively rare in inherited EB[39], presumably due to improved wound care and the availability and judicious use of broad-spectrum antibiotics. When sepsis does occur in EB, it tends to affect infants with generalized disease, especially EBS-DM, JEB-H and RDEB-sev/gen[40]. However, failure to thrive is still common among infants with JEB-H and may lead to death.

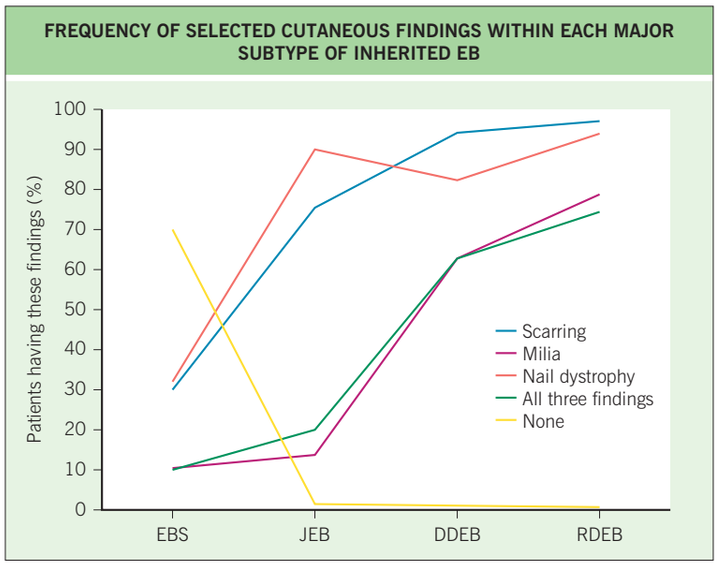

Fig. 32.5 Frequency of selected cutaneous findings within each major subtype of inherited epidermolysis bullosa (EB). Note the increasing frequency from localized EB simplex (EBS) to recessive dystrophic EB (RDEB). JEB, junctional EB; DDEB, dominant dystrophic EB.

Cutaneous Malignancies

A major complication, usually of RDEB, is the development of multiple cutaneous SCCs[41]. These tumors most often arise in chronic non-healing wounds or hyperkeratotic lesions (Fig. 32.11). Histologically, they are usually well differentiated. However, the borders of the lesions are often indistinct and they are difficult to completely excise, with a tendency to recur locally. In addition, SCCs in EB patients frequently metastasize and are strikingly unresponsive to chemotherapy or radiotherapy. Indeed, they represent the leading cause of death in EB at or after mid-adolescence, with death from an SCC of cutaneous origin occurring in most patients within 5 years of the diagnosis of their first SCC[39]. These tumors occur almost exclusively in RDEB (especially RDEB-sev/gen), although rare patients with JEB have also developed SCCs. The cumulative risk of at least one SCC in patients with RDEB-sev/gen is only 7.5% by age 20 years but rises to 68%, 80% and 90% by ages 35, 45 and 55 years, respectively[29]. In contrast, the risk of SCC in other forms of RDEB is <25% by age 45 years[41].

MAJOR EXTRACUTANEOUS COMPLICATIONS OF EPIDERMOLYSIS BULLOSA		
Complication	**EB subtype(s) most commonly affected**	
	≥50% of patients	**<50% of patients**
EYES		
Corneal blisters, ulcers and scarring	RDEB-sev/gen	JEB-H > RDEB-o, RDEB-I, JEB-nH
Ectropion formation		JEB-H; Kindler
ORAL CAVITY AND UPPER AIRWAY (EXCLUDING BLISTERS)		
Microstomia	RDEB-sev/gen	JEB-H, RDEB-I
Enamel hypoplasia	JEB (all subtypes)	
Excessive caries and premature loss of teeth	RDEB sev/gen; JEB-H	
Tracheolaryngeal stenosis	JEB-H	JEB-nH
GASTROINTESTINAL TRACT		
Esophageal strictures	RDEB-sev/gen, RDEB-I	RDEB-o, Kindler > JEB-H
Pyloric atresia	JEB-PA, EBS-PA	
Malnutrition/failure to thrive	RDEB-sev/gen, JEB-H	JEB-nH
Severe constipation	RDEB-sev/gen	JEB-H
GERD	RDEB	JEB, EBS-DM
GENITOURINARY TRACT		
Urethral meatal stenosis		RDEB-sev/gen, JEB-H, Kindler
Chronic renal failure*		RDEB-sev/gen
Hydroureter and hydronephrosis		JEB-PA, JEB-H
HEART		
Dilated cardiomyopathy		RDEB-sev/gen > JEB, RDEB-o
MUSCULOSKELETAL SYSTEM		
Pseudosyndactyly	RDEB-sev/gen	RDEB-o
Osteoporosis or osteopenia	RDEB-sev/gen	RDEB-o, JEB-H
Muscular dystrophy	EBS-MD	
BONE MARROW		
Severe multifactorial anemia	RDEB/sev-gen, JEB-H	

*Causes include renal amyloidosis and glomerulonephritis.

Table 32.2 Major extracutaneous complications of epidermolysis bullosa (EB). EBS, EB simplex; EBS-DM, EBS, Dowling–Meara; EBS-MD, EBS with muscular dystrophy; EBS-PA, EBS with pyloric atresia; GERD, gastroesophageal reflux disease; JEB, junctional EB; JEB-H, JEB, Herlitz; JEB-PA, JEB with pyloric atresia; RDEB, recessive dystrophic EB; RDEB-I, RDEB inversa; RDEB-o, RDEB, other generalized; RDEB-sev/gen, RDEB, severe generalized.

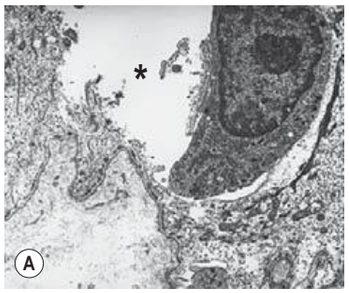
Fig. 32.11 Squamous cell carcinoma. Large squamous cell carcinoma on the ankle of a 21-year-old man with severe generalized recessive dystrophic epidermolysis bullosa. *Courtesy, Julie V Schaffer, MD.*

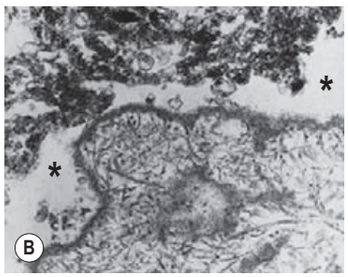
Melanoma occurs in a small number of children with RDEB-sev/gen, with a cumulative risk of 2.5% by the age of 12 years[41]. Although this is a relatively infrequent complication, careful surveillance during childhood is indicated. Children with EB, in particular those with JEB-nH, can develop large, irregularly shaped, darkly pigmented melanocytic nevi ("EB nevi") (Fig. 32.12) that clinically resemble melanoma, although they are histologically and biologically benign. A large size from the onset rather than a relatively slow horizontal expansion is a clue to the diagnosis of these EB-associated nevi.

Fig. 32.12 Large acquired melanocytic nevus at a site of blistering in a patient with junctional epidermolysis bullosa. *Courtesy, Julie V Schaffer, MD.*

PATHOLOGY

Light microscopy has no role in the diagnosis of classic forms of inherited EB, since it may be difficult to distinguish between even lower intraepidermal and subepidermal blister formation, let alone between intra-lamina lucida (i.e. JEB) and sub-lamina densa (i.e. DEB) types, without more sophisticated staining techniques[42]. However, suprabasal





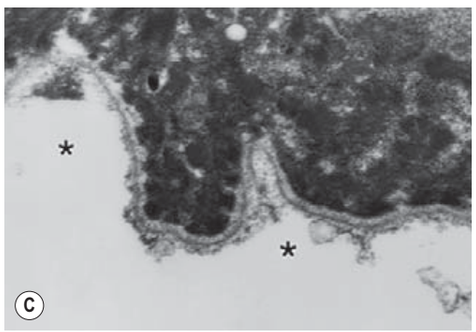


Fig. 32.13 Ultrastructure of epidermolysis bullosa simplex (EBS), junctional epidermolysis bullosa (JEB) and recessive dystrophic epidermolysis bullosa (RDEB). A Electron microscopy (EM) of an induced blister in localized EBS demonstrates skin cleavage (asterisk) within the inferior-most portion of the basilar keratinocyte. **B** EM of a spontaneous blister from a patient with the Herlitz subtype of JEB reveals skin cleavage (asterisks) within the lamina lucida. Hemidesmosomes, sub-basal dense plates and anchoring filaments are all absent, diagnostic of Herlitz disease. In contrast, anchoring fibrils are still present in normal amounts within the underlying dermis. **C** EM of the roof of a spontaneous blister from a patient with severe generalized RDEB reveals cleavage (asterisks) beneath the level of the lamina densa. Anchoring fibrils are absent along the epidermal roof of the blister, diagnostic of severe generalized RDEB.

forms of EBS due to desmoplakin, plakophilin or plakoglobin deficiency share the histologic finding of acantholysis (see Table 32.4). The two diagnostic tests that are routinely employed are transmission electron microscopy (TEM) and immunofluorescence antigenic mapping. Discrepancies between these two techniques arise in only about 3% of all specimens, suggesting that either approach may serve as the gold standard for the non-molecular diagnosis of inherited EB.

TEM distinguishes among the four major EB types by defining the ultrastructural level of blister formation (Figs 32.1 & 32.13). TEM can also be used to quantitatively and qualitatively assess specific structures, such as basilar tonofilaments, hemidesmosomes, sub-basal dense plates, anchoring filaments and anchoring fibrils[2]. Ultrastructural features of the major EB types and subtypes are summarized in Table 32.3. Immunofluorescence antigenic mapping, when coupled with the use of selected anti-basement membrane monoclonal antibodies, can distinguish among EB subtypes by the qualitative or semiquantitative assessment of the expression of specific skin-associated proteins (in particular, laminin 332 and types VII and XVII collagen)[2]. Abnormal skin staining may be seen with antibodies to plectin, $\alpha_6\beta_4$ integrin, kindlin-1 and several other structural proteins in selected EB subtypes.

DIFFERENTIAL DIAGNOSIS

Although it is difficult to determine the subtype of inherited EB on the basis of clinical findings alone, the diagnosis of EB itself is usually straightforward in anyone beyond early childhood. There is a limited differential diagnosis for a chronic mechanobullous disease with early onset and/or a positive family history[2]. The clinicopathologic features of the rare suprabasal EBS subtypes (which have adnexal and histologic manifestations that differ from classic forms of EB) and other genodermatoses that can be associated, at least transiently, with blisters and therefore potentially misdiagnosed as EB are outlined in Table 32.4. Less often, EB may be confused with acrodermatitis enteropathica, incontinentia pigmenti or pachyonychia congenita. The differential diagnosis of blisters and erosions in neonates or young infants may also include infectious diseases (e.g. herpes simplex, staphylococcal scalded

ULTRASTRUCTURAL (ELECTRON MICROSCOPIC) FINDINGS IN EPIDERMOLYSIS BULLOSA		
EB type or subtype	**Level of skin cleavage**	**Associated findings**
EB SIMPLEX (EBS)		
EBS, localized	Intracytoplasmic within basilar keratinocytes	–
EBS, Dowling–Meara	Subnuclear cytoplasm within basilar keratinocytes	Electron-dense clumps of keratin filaments (more often in lesional than perilesional skin sites)
EBS with muscular dystrophy	Intracytoplasmic within basilar keratinocytes (above the level of the HD attachment plaque)	Lack of integration of keratin filaments into the underlying HDs
EBS, autosomal recessive	Intracytoplasmic within basilar keratinocytes	Absent or reduced keratin filaments within basilar keratinocytes
EBS superficialis	Between granular and cornified cell layers	–
EBS, lethal acantholytic	Suprabasal, with acantholysis	Perinuclear retraction of keratin filaments
EBS, plakophilin-1 deficiency	Mid-epidermal	Diminutive suprabasal desmosomes; perinuclear retraction of keratin filaments
JUNCTIONAL EB (JEB)		
JEB, Herlitz	Intra-lamina lucida	Absent HDs or markedly reduced number of rudimentary HDs; absent SBDPs
JEB, non-Herlitz	Intra-lamina lucida	Normal or reduced number of HDs, which may be rudimentary
JEB with pyloric atresia	Intra-lamina lucida	Small HD plaques; attenuated SBDPs
DOMINANT DYSTROPHIC EB (DDEB)		
DDEB, generalized	Sub-lamina densa	Normal or diminished AFs
DDEB, bullous dermolysis of newborn	Sub-lamina densa	Electron-dense perinuclear stellate bodies within basilar keratinocytes; diminished AFs
RECESSIVE DYSTROPHIC EB (RDEB)		
RDEB, severe generalized	Sub-lamina densa	Absent AFs or markedly reduced number of rudimentary AFs
RDEB, generalized other	Sub-lamina densa	Reduced number of rudimentary AFs
RDEB, bullous dermolysis of newborn	Sub-lamina densa	Electron-dense perinuclear stellate bodies within basilar keratinocytes (only during time of clinically active disease); diminished AFs

Table 32.3 Ultrastructural (electron microscopic) findings in epidermolysis bullosa (EB). AFs, anchoring fibrils; HD, hemidesmosome; SBDPs, sub-basal dense plates.

SUPRABASAL FORMS OF EPIDERMOLYSIS BULLOSA SIMPLEX AND ADDITIONAL GENODERMATOSES ASSOCIATED (AT LEAST TRANSIENTLY) WITH BLISTERS		
Disorder	**Defective protein (inheritance)**	**Clinicopathologic features**
SUPRABASAL FORMS OF EPIDERMOLYSIS BULLOSA SIMPLEX (EBS)		
EBS, plakophilin deficiency (ectodermal dysplasia/skin fragility syndrome)	Plakophilin 1 (AR)	Trauma-induced blisters and erosions, especially of perioral area and extremities; PPK; hypotrichosis; nail dystrophy; occasionally defective sweating; acantholysis in skin biopsy specimens
Lethal acantholytic EBS	Desmoplakin (AR)	Generalized erosions at birth; universal alopecia; natal teeth, anonychia; variable cardiomyopathy; acantholysis in skin biopsy specimens
Skin fragility/woolly hair syndrome*	Desmoplakin (AR)	Acral blisters and erosions; focal or diffuse PPK; sparse, woolly hair; nail dystrophy; acantholysis in skin biopsy specimens
Lethal congenital EBS	Plakoglobin (AR)	Generalized erosions at birth; universal alopecia; onycholysis; acantholysis in skin biopsy specimens
Acantholytic ectodermal dysplasia	Plakoglobin (AR)	Trauma-induced blisters and erosions; hyperkeratotic, fissured perioral plaques; woolly hair; nail dystrophy; acantholysis in skin biopsy specimens
ADDITIONAL GENODERMATOSES ASSOCIATED WITH BLISTERING		
Ichthyosis bullosa of Siemens	Keratin 2 (AD)	Mauserung phenomenon (desquamation); superficial intraepidermal blistering in skin biopsy specimens
Epidermolytic ichthyosis (bullous congenital ichthyosiform erythroderma)	Keratin 1 and 10 (AD)	Blistering primarily in first few years of life; later corrugated hyperkeratosis; epidermolytic hyperkeratosis in skin biopsy specimens
Günther disease (congenital erythropoietic porphyria)	Uroporphyrinogen III synthase (AR)	Severe photosensitivity leading to blistering and deep ulcerations; elevated uroporphyrin I and coproporphyrin I; red urine; hemolytic anemia
AEC (ankyloblepharon–ectodermal dysplasia–clefting) syndrome	p63 (AD)	Ankyloblepharon; ectodermal dysplasia; cleft lip/palate; erythroderma and widespread erosions in neonates; chronic erosive scalp dermatitis; patchy alopecia
Mendes da Costa syndrome	? (X-linked)	Spontaneous formation of bullae (not provoked by trauma); absence of hair; acrocyanosis; dyspigmentation; microcephaly; mental retardation

*Patients with the additional findings of cardiomyopathy (as in Carvajal syndrome) ± dental enamel defects have also been described.

Table 32.4 Suprabasal forms of epidermolysis bullosa simplex and additional genodermatoses associated (at least transiently) with blisters.
AD, autosomal dominant; AR, autosomal recessive; PPK, palmoplantar keratoderma.

skin syndrome, bullous impetigo), sucking blisters, bullous mastocytosis, autoimmune blistering diseases, and congenital erosive and vesicular dermatosis (see Ch. 34).

The differential diagnosis of EBSS includes peeling skin syndrome[43]. Bart syndrome, which is defined as the coexistence of any type of EB and congenital localized absence of skin (CLAS; aplasia cutis congenita; see Ch. 64), is distinguished from other causes of CLAS by the presence of blisters and mechanical fragility of the skin, as well as the anatomic location of EB-associated CLAS (i.e. typically acral rather than favoring the scalp).

TREATMENT

There are currently no specific therapies for any form of inherited EB. In the future, effective gene therapy may become a reality for at least some forms of EB[44]. For example, there are reports of the successful transfer of genes, such as those that encode one of the chains of laminin 332[45], into keratinocytes from affected individuals; when these genetically corrected keratinocytes are transplanted onto immunodeficient mice, the resultant epithelium has no evidence of blistering. In a proof-of-principle experiment, a small portion of *ex vivo*-produced skin equivalent containing a corrected laminin 332 gene was transplanted onto a recipient with JEB-nH, and after several years has yet to develop blistering within its borders[46].

It has been shown that injection of either human type VII collagen or normal allogeneic fibroblasts into a mouse engrafted with type VII collagen-deficient RDEB skin can result in increased deposition of this protein along the dermo-epidermal junction and the cessation of blistering[47,48]. There are now several clinical trials in progress that are exploring the therapeutic benefit of intradermally injecting allogeneic fibroblasts into non-healing wounds in RDEB patients. Clinical trials are also ongoing to investigate the value of bone marrow-derived stem cell transplantation as a systemic treatment for RDEB[49]. In an initial report[50], bone marrow transplantation after total or partial myeloablation resulted in substantial proportions of donor cells in the skin, increased collagen VII deposition at the dermal–epidermal junction and variably decreased blistering in children with RDEB. Other investigators are studying alternative sources of stem cells for the cellular correction of this disease.

Revertant mosaicism in the skin of EB patients represents "natural gene therapy" that can restore wild-type function to a clone of cells, providing a model for potential gene manipulation strategies and possibly explaining the tendency for improvement with age in some subtypes of EB. Mitotic gene conversion, true back mutations and second-site mutations that prevent a premature termination codon or restore the reading frame have been shown to reverse disease-causing type XVII collagen mutations in individuals with JEB-nH, leading to decreased blistering in discrete areas of skin[51]. Second-site nonsense mutations have also been shown to abrogate blistering by silencing a dominant-negative keratin 14 allele in those with EBS-DM.

For now, day-to-day management of EB revolves around the prevention of mechanical trauma (including padding over bony prominences and soft/loose-fitting clothing) and infection. Bathing or soaking with 0.005% sodium hypochlorite (0.5 cup household bleach [6% sodium hypochlorite] in a full standard bathtub) or 0.25% acetic acid (1 part white vinegar [5% acetic acid] to 20 parts water) may help to reduce bacterial colonization. Antibiotics should be used judiciously, with avoidance of chronic treatment with topical mupirocin or oral antibiotics. Problematic plantar hyperhidrosis in EBS patients may improve following the topical application of aluminum chloride hexahydrate, although its effect on blistering is less certain, and injection of botulinum toxin A can reduce plantar blistering and associated pain in individuals with EBS[52].

A number of dressings are available for cutaneous wounds in EB patients (Table 32.5; see Ch. 145). As a general rule, only those that are non-adhesive or "low-tack" should be applied to EB skin. Soft silicone dressings, some of which incorporate an absorbent foam backing, are

DRESSINGS FREQUENTLY USED IN PATIENTS WITH EPIDERMOLYSIS BULLOSA		
Dressing type	**Use**	**Examples®™**
Soft silicone dressings ("low-tack")	• Suitable as primary or secondary dressings in many types of EB • May have a foam backing for mechanical protection or to wick exudate away from the wound	Mepitel, Mepilex, Mepilex Transfer, Mepilex Border
Non-adherent lipido-colloid dressings	• Suitable for primary contact	Urgotul
Hydrogel dressings	• Provide moisture to drier wounds to facilitate healing • May provide relief from pain or itch	Flexigel, Curagel, ActiForm Cool
Foam dressings	• Useful to absorb moderate amounts of wound exudate	Mepilex, Allevyn
Absorptive dressings	• Useful to absorb heavy amounts of wound exudate	Eclypse, Sorbion Sana
Silver-containing dressings	• Clinically infected or highly colonized wounds • Avoid prolonged use due to risk of silver absorption	Urgotul SSD, Mepilex AG
Other antimicrobial dressings	• Clinically infected or highly colonized wounds	Polymem, Cutimed Sorbact, Activon Tulle, Suprasorb X + PHMB

Table 32.5 Dressings frequently used in patients with epidermolysis bullosa (EB).

widely used. Silver-impregnated dressings may be helpful for heavily colonized or infected wounds, although long-term application should be avoided to minimize systemic silver absorption. Less expensive Vaseline®-impregnated gauze is another suitable dressing for non-infected wounds. Tissue culture-derived artificial skin bioequivalents are also available for use in the management of chronic, recalcitrant ulcers[53].

Systemic phenytoin inhibits collagenase and has been used in the past in JEB and RDEB patients[54], but it was not found to be effective in a randomized controlled trial[55]. Other systemic drugs that may be of benefit include tetracycline for EBS[56] and thalidomide and cyclosporine for symptomatic relief in DEB pruriginosa[57,58].

There are few reports on the use of systemic retinoids in any form of EB, although these drugs appear to be tolerated, at least in low dosage, in patients with RDEB[59]. Whether long-term treatment with low-dose systemic retinoids would help to prevent the development of SCCs in RDEB-sev/gen patients remains to be determined.

Strategies for the medical and surgical management of long-term complications of EB are outlined in Table 32.6. Multidisciplinary clinics can provide care and support for the wide range of needs that patients with EB and their families have. Families can also obtain helpful information from several educational websites, in particular www.debra.org and www.debra-international.org.

MANAGEMENT OF LONG-TERM COMPLICATIONS OF EPIDERMOLYSIS BULLOSA		
Complication	**Prevention and monitoring/detection**	**Management**
	ORAL AND GASTROINTESTINAL	
Excessive caries	• Diligent oral hygiene • Antiseptic and fluoride mouthwashes • Periodic evaluation and cleaning by a dentist	• Restorative dentistry
Microstomia		• Physical therapy • "Mouth expanding" devices
Oral ulceration		• Topical antiseptics, topical NSAIDs, barrier preparations (e.g. sucralfate suspension)
Esophageal strictures	• Evaluate dysphagia with contrast studies	• Dietary modification (soft foods/purées, caloric supplementation) • Fluoroscopically guided balloon dilatation; repeated procedures are often required • In severe and recalcitrant cases, surgical options include colonic interposition
Gastroesophageal reflux disease		• Proton pump inhibitors, H_2 blockers, prokinetic agents (e.g. domperidone [not available in the US])
Constipation	• Ensure adequate fluid intake and dietary fiber	• Osmotic laxatives (e.g. containing polyethylene glycol), mineral oil • Avoid suppositories and enemas
	NUTRITIONAL	
Growth retardation/inadequate intake to meet nutritional needs	• Monitor height, weight and body mass index • Periodically assess serum zinc, selenium, iron, vitamin D and carnitine levels (e.g. yearly) • Oral supplements to optimize intake of calories, protein, vitamins and minerals	• Consider gastrostomy feedings
	HEMATOLOGIC	
Anemia due to iron deficiency and chronic inflammation	• Monitor CBC and measures of iron stores	• Iron supplementation (oral or IV) • Consider erythropoietin or darbepoetin alpha • Consider blood transfusion if hemoglobin ≤7–8 g/dl and/or symptomatic

Table 32.6 Management of long-term complications of epidermolysis bullosa (EB)[29,60,61]. CBC, complete blood count; NSAID, nonsteroidal anti-inflammatory drug.

Continued

MANAGEMENT OF LONG-TERM COMPLICATIONS OF EPIDERMOLYSIS BULLOSA		
Complication	**Prevention and monitoring/detection**	**Management**
	GENITOURINARY AND RENAL	
Urinary outflow obstruction (e.g. urethral or ureteral strictures)	• Consider annual ultrasound of the urinary tract and urodynamic studies (especially for JEB)	• Dilatation procedures as needed to treat obstruction • Avoid unnecessary instrumentation
Renal disease (e.g. hydronephrosis, post-infectious glomerulonephritis, renal amyloidosis, IgA nephropathy)	• Blood urea nitrogen & serum electrolyte levels, urinalysis and blood pressure evaluation every 6 months in RDEB patients • Adequately treat streptococcal infections	• Hemodialysis or peritoneal dialysis if renal failure develops
	MUSCULOSKELETAL	
Osteopenia and osteoporosis	• Annual DEXA scan and spinal radiographs beginning at age 5 years in RDEB and JEB patients • Calcium and vitamin D supplementation	• Consider IV bisphosphonate therapy
Pseudosyndactyly of hands/feet	• Cushioned splints on hands/forearms and individual wrapping of fingers in RDEB patients	• Surgery to release contractures and webbing
	ONCOLOGIC	
Cutaneous squamous cell carcinoma	• Periodic total-body skin examinations; for RDEB patients, approximately every 3–6 months beginning at age 10 years and every 3 months after age 16 years • Biopsy or monitor non-healing ulcers (see Fig. 32.11) • Consider taking serial photographs	• Excision ± skin grafting (sometimes amputation); consider MRI to assess extent of local disease • Consider staging with CT, PET-CT, sentinel lymph node biopsy
	OCULAR	
Chronic complications include corneal scarring, symblepharon, ectropion	• Periodic ophthalmologic evaluation for patients with eye involvement • Lubricating eye drops	• Surgical procedures, e.g. division of symblepharon, amniotic membrane transplantation
	CARDIAC	
Dilated cardiomyopathy	• Consider annual echocardiography beginning in late childhood for RDEB patients	• Medical management • Supplement selenium and carnitine if deficient
	PSYCHOLOGICAL AND PSYCHIATRIC	
Disrupted family unit (e.g. via divorce)	• Consider family counseling, support groups	• Psychological/family counseling
Depression and suicidal ideation/attempts	• Consider psychological counseling, support groups	• Psychiatric evaluation, antidepressant therapy

Table 32.6 Management of long-term complications of epidermolysis bullosa (EB) (cont'd)[29,60,61]. CT, computed tomography; JEB, junctional EB; MRI, magentic resonance imaging; PET, positron emission tomography; RDEB, recessive dystrophic EB.

Bullous small vessel vasculitis 518
Bullous drug eruptions 518
Bullous insect bite reactions 518
Delayed postburn/postgraft blisters 520
Edema blisters 520
PUVA-induced acrobullous dermatosis 521

Vesiculobullous diseases of the skin encompass a wide range of entities, including autoimmune bullous diseases and hereditary blistering dermatoses. However, there are other diseases or situations in which blisters may develop. This chapter will focus on the latter group of vesiculobullous diseases.

BULLOSIS DIABETICORUM

Synonyms: ■ Diabetic bullae ■ Bullous eruption of diabetes mellitus

Key features

- A rare condition associated with diabetes mellitus
- Tense blisters develop on normal-appearing skin in acral sites (feet, lower legs, hands); there is frequently an association with peripheral neuropathy
- Histologically, intraepidermal and/or subepidermal blisters are observed
- Spontaneous healing usually occurs within 2 to 6 weeks

History

Bullosis diabeticorum was first described by Kramer in 1930. In 1967, Cantwell and Martz[1] introduced the term "bullosis diabeticorum".

Epidemiology

The exact prevalence of bullosis diabeticorum is unknown. Although it has often been described as one of the rarest cutaneous complications of diabetes[2], the authors of a more recent case series argued that it is probably more common than previously thought[3]. The age of onset ranges from 15 to 85 years, with a mean age of 55 years. A 2:1 male-to-female ratio has been reported.

Pathogenesis

Although bullosis diabeticorum has been related to trauma and the microangiopathy of diabetes, little is known about its cause. Diabetics can develop blisters after minimal trauma, and some authors have found a reduced threshold for inducing suction blisters in these patients[2,4]. There is no evidence of an infectious etiology.

Clinical Features

Bullosis diabeticorum is characterized by a sudden and spontaneous appearance of bland vesicles and bullae on the distal extremities of diabetics. The most frequent locations (in decreasing order) are the feet, lower legs, hands, and forearms. Lesions are rarely seen on the trunk. There are usually no symptoms, except for a mild burning sensation. The lesions often develop "overnight", and in the absence of known trauma. Blisters arise within normal-appearing skin, are tense, and vary in diameter from 0.5 to several centimeters (Fig. 33.1). They contain a clear, sterile fluid that can be more viscous than that found in friction blisters.

Most patients are longstanding diabetics, but in some cases bullosis diabeticorum has been the presenting sign of diabetes mellitus. It can be associated with insulin-dependent diabetes mellitus, as well as non-insulin-dependent (type 2) diabetes mellitus. Many of these patients have associated polyneuropathy, retinopathy or nephropathy.

Pathology

The histologic findings are heterogeneous. Initial reports described intraepidermal blisters, whereas recent publications have usually described subepidermal bullae. It has been suggested that the level of cleavage is subepidermal, and that intraepidermal blisters represent older lesions undergoing re-epithelialization. Direct immunofluorescence (DIF) examination is usually negative, although one report described nonspecific IgM and C3 deposits within dermal blood vessel walls. By electron microscopy, subepidermal blisters with a separation at the level of the lamina lucida or below the lamina densa have been observed[3].

Differential Diagnosis

In porphyria cutanea tarda and pseudoporphyria associated with dialysis and medications, the blisters are usually <1 cm in diameter and favor the hands rather than the feet and ankles. Because chronic renal failure, atherosclerotic cardiovascular disease and bacterial infections are well-established complications of diabetes, patients may be receiving dialysis, diuretics and/or antibiotics. Localized bullous pemphigoid, epidermolysis bullosa acquisita (EBA) and linear IgA bullous dermatosis (including drug-induced) are differentiated by histologic examination, DIF, and, if needed, indirect immunofluorescence (IIF) or ELISA. In addition, there is an accentuation of lesions at sites of friction in the majority of patients with EBA. If there is surrounding erythema, warmth and tenderness, the possibility of bullous cellulitis must be considered, and if serous crusts, bullous impetigo.

Treatment

Most patients have spontaneous healing of their lesions in 2 to 6 weeks. Treatment focuses on aspiration of blisters or placement of a small window in the blister roof and application of topical antiseptics to reduce discomfort and prevent secondary infection.

COMA BLISTERS

Synonyms: ■ Coma bullae ■ Drug-induced coma blisters ■ Barbiturate blisters ■ Neurologic blisters

Fig. 33.1 Bullosis diabeticorum. A tense blister on the palm as well as desquamation at sites of previous bullae.

Fig. 33.2 Coma bullae. Blisters developed in an area of pressure in a previously comatose patient.

Fig. 33.3 Neurologic blisters. Tense blisters on the dorsal aspect of the fingers on the hemiplegic side of a patient with a previous cerebrovascular accident.

Key features

- Associated with loss of consciousness, neurologic diseases or prolonged immobilization
- Tense blisters develop on normal-appearing skin
- Biopsy specimens show intraepidermal or subepidermal blisters, with a characteristic necrosis of sweat glands
- Spontaneous healing occurs in 1 to 2 weeks

Introduction

In some comatose patients, blisters will develop within 48–72 hours of loss of consciousness, primarily at pressure sites. Although classically associated with barbiturate overdose, they can be seen in the setting of coma due to other medications (e.g. opioids), infections (e.g. viral encephalitis), metabolic disturbances (e.g. hypoglycemia) and neurologic dysfunction (e.g. cerebrovascular accidents).

History

Coma blisters were first described in 1806 by Larrey, Napoleon's surgeon, who noticed these lesions in soldiers who had been comatose from carbon monoxide intoxication.

Epidemiology

In 1952, Holten reported the appearance of coma blisters in 4% of a series of 501 patients with barbiturate poisoning[5]. In another study, blisters were found in 6.5% of barbiturate overdoses[6]. Although most reported cases have been associated with barbiturate overdose, blisters have also been observed in those whose comas were induced by overdosage of other medications, such as benzodiazepines, tricyclic antidepressants, opioids, hypnotics or antipsychotics, as well as alcohol intoxication[7]. Similar lesions have also been described in patients with non-drug-induced coma, e.g. coma resulting from carbon monoxide poisoning, head trauma, cerebrovascular accidents, viral encephalitis, hypoglycemia, diabetic ketoacidosis or hepatic encephalopathy[8,9]. In addition, bullous lesions have been observed in non-comatose patients, in particular those with severe neurologic disease or prolonged immobilization (e.g. secondary to accidents or postoperative)[9].

Pathogenesis

The pathogenesis is unclear. Originally, a direct toxic drug effect was implicated, particularly because of the association with drug intoxication and the frequent finding of eccrine gland necrosis (many drugs are thought to be excreted by sweat glands). However, this did not explain the non-drug-induced cases. Therefore, pressure, friction and local hypoxia have been implicated as etiologic factors. The pressure/ischemic hypothesis is supported by the fact that most, if not all, lesions appear at sites of pressure.

Clinical Features

Lesions appear at body sites exposed to maximum pressure during unconsciousness or prolonged immobilization. They first appear 24 hours after the onset of coma as blanchable erythematous patches or plaques that progress to violaceous plaques. Blisters or erosions then develop within 48–72 hours after the onset of coma within these locations (Fig. 33.2). If the patient survives, the erosions usually heal spontaneously over 1 or 2 weeks. In some patients, residual scarring can result. Compression neuropathies and non-traumatic rhabdomyolysis are additional complications seen in patients with coma bullae[7–10]. As previously mentioned, the same type of blisters can occur in patients with neurologic diseases (Fig. 33.3).

Pathology

The blisters are predominantly subepidermal. However, intraepidermal blisters are also observed as the result of re-epithelialization of older lesions or epidermal spongiosis. There is a variable degree of epidermal necrosis. Sweat gland necrosis is a characteristic finding (Fig. 33.4), and focal necrosis of the epithelium of the pilosebaceous follicles can also be seen. There is only a sparse inflammatory cell infiltrate. DIF is usually negative, but nonspecific granular deposits of IgM and C3 have been found within the walls of dermal blood vessels[7].

Differential Diagnosis

In most patients, the clinical setting alone is sufficient to make the diagnosis (Table 33.1). A cutaneous biopsy will allow differentiation from friction blisters. An intraepidermal blister cavity just below the granular layer is seen in friction blisters, whereas a subepidermal split with sweat gland/follicular necrosis is characteristic of coma bullae. Based upon distribution, clinical appearance and histologic findings, multiple fixed drug eruptions can be excluded (see Fig. 33.8).

Treatment

Coma blisters heal spontaneously over 1 or 2 weeks. In non-comatose patients, frequent postural changes help to resolve and prevent the disorder.

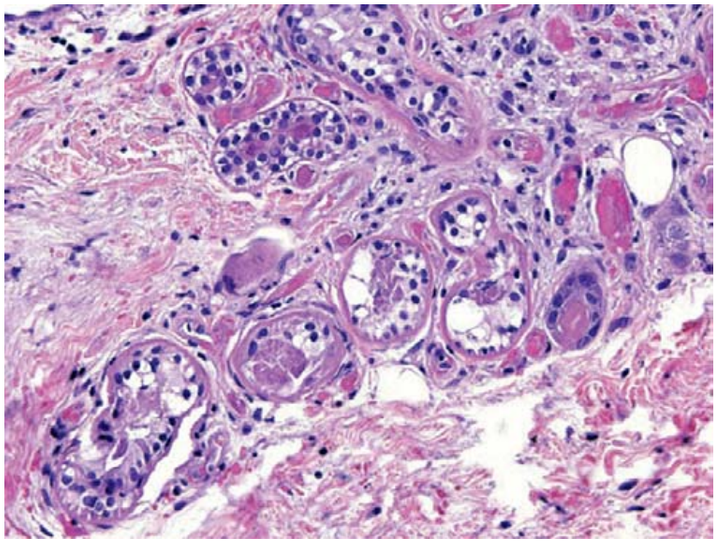

Fig. 33.4 Bulla due to prolonged immobilization – histologic features. The patient had sustained a hip fracture and was immobilized for 2 days on the floor. Detection of the characteristic sweat gland necrosis aided in the diagnosis.

FRICTION BLISTERS

Key features

- Friction blisters occur most commonly on the soles and heels
- They are the result of repeated friction, e.g. walking or running in ill-fitting shoes; they may also develop on the palms and fingers if a repetitive action is performed
- Histologically, blistering occurs just below the stratum granulosum

Epidemiology

Friction blisters are very common in the general population. Almost every person remembers developing such lesions when wearing a new pair of shoes. They are particularly common in young and active persons, especially those engaged in the military and sports.

Pathogenesis

Frictional shearing forces occur within the epidermis when the surface of an object rubs against the skin surface. Repetition of this rubbing action over a period of time can induce the appearance of blisters. Rubbing of moist skin produces higher frictional forces than with very dry or very wet skin[11]. Poorly fitting shoes, heat and sweating are predisposing factors.

DIFFERENTIAL DIAGNOSIS OF VESICULOBULLOUS DISEASES*

Disease	Clinical setting	Clinical features	Histopathology
Bullosis diabeticorum	Longstanding diabetes mellitus	Tense blisters in acral sites	Subepidermal or intraepidermal blisters with minimal inflammation
Coma blisters	Coma (drug- and non-drug-induced), neurologic disease, prolonged immobilization	Tense blisters at sites of maximal pressure	Subepidermal blister Necrosis of eccrine glands
Friction blisters	Primarily on soles (secondary to shoes) or hands	Burning, erythematous macules and blisters at friction sites	Initially intraepidermal blisters (below stratum granulosum)
Bullous small vessel vasculitis	Patients with small vessel vasculitis (cutaneous or systemic)	Palpable purpura, hemorrhagic vesicles and bullae, ulceration Usually on the distal extremities	Leukocytoclastic vasculitis Subepidermal blister with epidermal necrosis
Bullous drug eruptions	Patients receiving medications	Depends on eruption type (see Table 33.2)	Depends on eruption type (see Table 33.2)
Bullous insect bites	Any (more common in children) Underlying hematologic malignancy (e.g. CLL, mantle cell lymphoma, NK/T-cell lymphoma)†	Grouped pruritic papules with central blistering and/or bland vesicobullae May also have persistent papulonodules	Intraepidermal blisters with spongiosis; coalescence leads to subepidermal blisters Abundant eosinophils Flame figures, especially in exaggerated reactions
Delayed postburn/ postgraft blisters	Patients with burns (burn site, graft recipient site, graft donor site) or injured skin	Blisters and vesicles appear within injured skin several weeks after healing	Subepidermal or intradermal blisters with minimal inflammation
Edema blisters	Acute exacerbation of chronic edema Anasarca	Tense blisters in areas of edema, often in dependent sites, e.g. feet or ankles	Marked spongiosis and dermal edema

*Excluding autoimmune bullous diseases, hereditary blistering dermatoses, infections, lichenoid dermatoses (e.g. lichen planus, lichen sclerosus) and entities covered in Tables 34.1 and 34.2.
†Also develop insect bite-like reactions with similar clinical appearance and histologic findings.

Table 33.1 Differential diagnosis of vesiculobullous diseases. CLL, chronic lymphocytic leukemia; NK, natural killer.

Clinical Features

Friction blisters most frequently develop in areas with thick stratum corneum (soles, heels, palms, fingers). They are particularly common in regions where friction is intense and repeated (e.g. feet). The lesions initially present as erythematous macules at sites of friction and later develop into blisters. The patients complain of an associated burning sensation or pain, and the blister fluid may be clear or blood-tinged.

Pathology

Friction blisters are intraepidermal blisters resulting from necrosis of keratinocytes. The level of the split is variable but usually in the stratum spinosum just below the stratum granulosum. The roof of the blister is formed by the stratum corneum, the stratum granulosum, and some cellular debris. The upper portion of the floor of the blister cavity contains pale and degenerated keratinocytes that stain faintly. The deeper layers of the epidermis are normal[12]. There is only a sparse perivascular inflammatory infiltrate in the superficial dermis.

Differential Diagnosis

Most cases of friction blisters can be easily diagnosed clinically (see Table 33.1). The localized variant of epidermolysis bullosa simplex (Weber–Cockayne) is suspected when there is an exaggerated response to friction; histologic examination of a fresh or induced blister should show separation subepidermally or within the basal layer of the epidermis. Immunofluorescence antigenic mapping provides confirmation of the diagnosis. EBA can mimic friction blisters, but it is differentiated by histologic examination and DIF (see Fig. 33.8).

Treatment

Friction blisters can heal spontaneously without treatment. Drainage of blister contents via a small "window" in the blister roof relieves pressure and discomfort and prevents the accumulation of fluid; it also allows the blister roof to remain largely intact. Hydrocolloid or simple dressings can also be utilized.

BULLOUS SMALL VESSEL VASCULITIS

Occasionally, patients with small vessel vasculitis will develop superimposed vesicles and bullae, especially on the distal extremities (Fig. 33.5). These are often hemorrhagic and can progress to ulceration. Histopathologically, a leukocytoclastic vasculitis is seen, which differentiates this entity from other blistering diseases. This may be a sign of more severe disease (see Ch. 24).

Fig. 33.5 Bullous variant of small vessel vasculitis. Histologic examination demonstrated leukocytoclastic vasculitis. *Courtesy, Jean L. Bolognia, MD.*

BULLOUS DRUG ERUPTIONS

Key features

- Some drug eruptions can present as blistering eruptions
- Eruptions can be both localized and widespread
- Clinical, histologic and immunofluorescence findings vary, depending on the type of drug eruption

Vesicles and bullae can develop in a variety of drug eruptions. The latter include fixed drug eruption, Stevens–Johnson syndrome, toxic epidermal necrolysis, drug-induced variants of linear IgA bullous dermatosis, bullous pemphigoid and pemphigus, pseudoporphyria, toxic erythema of chemotherapy, halogenodermas, acute generalized exanthematous pustulosis, drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS), and phototoxic drug eruptions (e.g. doxycycline; see Ch. 87). These eruptions are discussed elsewhere in detail and are briefly summarized in Table 33.2.

BULLOUS INSECT BITE REACTIONS

Key features

- Bullous insect bite reactions are frequent, particularly in children, although patients rarely recall being bitten
- Severe insect bite reactions as well as insect bite-like reactions can be seen in patients with hematologic malignancies

Introduction

Although most insect bite reactions present as pruritic erythematous papules (see Ch. 85), vesiculobullous reactions are not uncommon.

Epidemiology

There seems to be no difference in the incidence of insect bites based on sex, race or age. Certain individuals may be bitten more frequently because of their body temperature, odor, use of perfumes, or carbon dioxide excretion. Children tend to have more severe reactions than adults because the latter tend to become desensitized by repeated exposures over time. Over the past 15 years, it has been increasingly recognized that patients with chronic lymphocytic leukemia (CLL), as well as other hematologic malignancies (e.g. mantle cell lymphoma, natural killer [NK]/T-cell lymphoma), can develop both exaggerated reactions to insect bites and insect bite-like reactions[13]. The latter term is used to describe lesions that resemble insect bites clinically and histologically, but for which a clear link to insect bites cannot be established[14]. Of note, these exaggerated reactions can precede the diagnosis of the lymphoma or be associated with a relapse.

Pathogenesis

Most lesions are the result of an individual's immune response to insect antigens introduced by the bite. Both humoral (IgE-mediated) and cell-mediated immunity (delayed hypersensitivity) are involved. Initial bites typically do not produce significant lesions, but sensitization occurs over a few weeks. Subsequent bites then induce a stronger reaction and even bullae formation. With time, repeated bites can result in desensitization.

In patients with NK/T-cell lymphomas, severe hypersensitivity to mosquito bites has been well documented and a possible role for an EBV-induced clonal proliferation of NK cells has been raised[15]. For patients with ALK-positive anaplastic large cell lymphoma, the possibility has been raised that insect bite-associated antigens lead to an influx of T lymphocytes, some of which bear t(2;5). The release of cytokines then results in activation of these cells, expression of NPM-ALK protein and subsequent uncontrolled proliferation[15a]. Malignant B cells, on the other hand, may stimulate Th2 cells to produce interleukin-5, explaining the associated tissue eosinophilia.

BULLOUS DRUG ERUPTIONS		
Disease	**Characteristic features**	**Commonly implicated drugs**
Fixed drug eruption (see Ch. 21)	• Sharply circumscribed erythematous to dusky violaceous patches • Central blisters or erosions may appear • Often resolves with postinflammatory hyperpigmentation • Recurrence at same location(s) following drug re-exposure	Sulfonamides, NSAIDs, tetracyclines, barbiturates, aspirin, acetaminophen (paracetamol), metronidazole, phenolphthalein
Stevens–Johnson syndrome (SJS), toxic epidermal necrolysis (TEN) (see Ch. 20)	• Prodrome of fever and painful skin • Areas of dusky erythema associated with epidermal detachment (varying from <10% [SJS] to >30% [TEN]) • Mucosal involvement	NSAIDs, antibiotics (sulfonamides and β-lactams), anticonvulsants, allopurinol
Drug-induced autoimmune blistering diseases (see Chs 29–31)	• Primarily, linear IgA bullous dermatosis, pemphigus, bullous pemphigoid • Diagnosis based on histologic findings, immunofluorescence studies and drug history	• Linear IgA bullous dermatosis: vancomycin > β-lactams, captopril, NSAIDs • Pemphigus: penicillamine, captopril, β-lactams, gold • Bullous pemphigoid: diuretics (especially furosemide), antibiotics
Drug-induced pseudoporphyria (see Ch. 49)	• Eruption resembles porphyria cutanea tarda • Porphyrin determinations are within normal limits	NSAIDs (especially naproxen), nalidixic acid, thiazides, furosemide, tetracyclines
Acute generalized exanthematous pustulosis (see Ch. 21)	• Acute onset, usually occurring within 2 days of drug exposure • Areas of erythema studded with pustules; occasionally vesicles • Fever, malaise, leukocytosis	β-lactams, macrolides, pristinamycin, terbinafine, calcium channel blockers (diltiazem), hydroxychloroquine, carbamazepine, acetaminophen, metronidazole
Phototoxic drug eruptions (see Ch. 87)	• Limited to sun-exposed areas • Resembles exaggerated sunburn	Tetracyclines (especially doxycycline), quinolones, psoralens, NSAIDs, diuretics
Bromoderma and iododerma (see Ch. 21)	• Acneiform lesions, papulopustules, nodules, or even vegetating lesions simulating pemphigus vegetans • Clear or hemorrhagic blisters can develop (more common in iododerma)	Bromides, iodine-containing drugs (e.g. amiodarone), radiographic contrast media
Palmoplantar erythrodysesthesia (acral variant of toxic erythema of chemotherapy; see Ch. 21)	• Painful erythema develops primarily on the palms, soles and digits following chemotherapy administration • The skin becomes edematous, its color changes to dark red or violet, and blisters and erosions may develop	Cytarabine, doxorubicin, capecitabine, 5-fluorouracil (especially prolonged infusions), multikinase inhibitors (e.g. sorafenib, sunitinib), busulfan, taxanes, clofarabine, pralatrexate

Table 33.2 Bullous drug eruptions. Occasionally, eczematous drug reactions (e.g. secondary to warfarin, calcium channel blockers) and systemic contact dermatitis can be papulovesicular; patients with drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS) can also develop vesicles. See Table 33.1 for coma blisters and bullous small vessel vasculitis. NSAIDs, nonsteroidal anti-inflammatory drugs.

Clinical Features

Insect bites usually appear as intensely pruritic erythematous papules or nodules. They are usually grouped, and a linear arrangement is commonly seen. Vesicular and bullous bite reactions are not uncommon. Flea bites are the most likely to cause blisters, especially on the legs, and bedbug bites can also be bullous. Some insects (e.g. fire ants) can produce pustular lesions. In patients with hematologic malignancies, the exaggerated reactions consist of persistent papulonodules, vesicles, bullae and even necrotic lesions (Fig. 33.6).

Fig. 33.6 Exaggerated insect bite-like reactions in a patient with chronic lymphocytic leukemia. There are multiple bullae as well as hemorrhagic crusts.

Pathology

The typical pattern is that of a superficial and deep perivascular and periadnexal lymphocytic infiltrate with abundant eosinophils. A wedge-shaped pattern is characteristic. During the initial phase, intraepidermal spongiotic vesicles are present and they can be associated with eosinophilic spongiosis. With time, confluence of these vesicles leads to subepidermal blisters. Sometimes, epidermal necrosis develops. Flame figures (extruded eosinophilic granules aggregated onto collagen fibers that are classically associated with eosinophilic cellulitis) can be observed, particularly in the exaggerated reactions seen in patients with hematologic malignancies.

Differential Diagnosis

The presence of intense pruritus and lesion distribution usually suggests a bullous bite reaction. However, these reactions can mimic bullous pemphigoid, linear IgA bullous dermatosis, bullous erythema multiforme, bullous impetigo or allergic contact dermatitis (see Fig. 33.8). "Eosinophilic dermatosis associated with hematological disorders" is another name for the phenomenon described above and is a more appropriate and less restrictive term than "eosinophilic dermatosis of myeloproliferative disease"[16] (strictly speaking, CLL is not categorized as one of the myeloproliferative disorders).

Treatment

Most patients with bullous insect bites can be managed with drainage of blisters, topical corticosteroids, and systemic antihistamines to relieve pruritus. In the most severe reactions, a short course of systemic corticosteroids may be necessary. Treatment of the exaggerated reactions seen in patients with hematologic malignancies may prove more

difficult. While systemic corticosteroids can lead to improvement, lesions tend to recur when the dose is reduced. Dapsone has been suggested as a therapeutic option for these patients[17]. Protective clothing and insect repellants are an important intervention (see Ch. 85).

DELAYED POSTBURN/POSTGRAFT BLISTERS

Key features

- Delayed postburn and postgraft blisters represent an underreported condition
- Tense blisters develop weeks to months after the initial injury has healed
- Blistering can persist for several weeks or months

Introduction

Delayed blisters have been observed weeks to months after the initial healing of second-degree thermal burns, donor sites of split-thickness skin grafts, and recipient sites of split-thickness skin grafts[18,19].

History

The first report of this phenomenon is attributed to Barker and Cotterill in 1980.

Epidemiology

Delayed blisters have received little attention in the literature. However, it appears to occur to some degree in almost every patient with a thermal burn involving more than 30% of the body surface area[19]. Most descriptions refer to patients with thermal burns, where delayed blisters have been observed on the spontaneously healed skin, graft donor sites, and graft recipient sites[18]. They have also been seen after skin grafting for toxic epidermal necrolysis and within laser-resurfaced skin[20].

Pathogenesis

The exact pathogenesis is not known. The antigenic components of the normal dermal–epidermal junction appear sequentially during fetal life or wound healing. Therefore, it has been hypothesized that this phenomenon is due to the enhanced fragility of a newly synthesized, "immature" dermal–epidermal junction[18,19].

Clinical Features

Tense vesicles or blisters develop weeks after the injured skin (burned, donor site, recipient site) has completely healed. In one study, blisters appeared between 19 and 55 days after the patients had sustained their burns, with an average of 37 days[19]. Blisters do not develop within uninvolved skin. Although they heal spontaneously, there is a tendency for recurrences over a period of weeks to months.

Pathology

Histologically, subepidermal blisters with a minimal inflammatory infiltrate are seen. Electron microscopy has shown that the blisters occur either in the dermis (below the dermal–epidermal junction) or intraepidermally through the basal keratinocytes. DIF studies have been negative. Immunofluorescence mapping has shown a diminished or variable expression of dermal–epidermal junction antigens, including type IV and type VII collagens, laminin, and bullous pemphigoid antigen[18].

Differential Diagnosis

Blistering associated with a healed injured site can also be due to herpetic infection, ischemia (in the case of graft recipient sites) or autoimmune bullous diseases. Herpetic infection can be excluded by a negative Tzanck smear, direct fluorescent antibody test, viral culture, and/or biopsy findings; ischemia is diagnosed on the basis of clinical findings; and autoimmune blistering diseases can be excluded by histologic features and DIF/IIF examinations (see Fig. 33.8).

Treatment

These blisters heal spontaneously with simple care, topical antibiotics, wound dressings, and local compression.

EDEMA BLISTERS

Synonyms: ■ Stasis blisters ■ Hydrostatic bullae ■ Edema bullae

Key features

- Edema blisters develop in patients with an acute exacerbation of chronic edema, particularly of the lower extremities, and in the setting of anasarca
- The tense lesions are usually non-inflammatory and surrounded by edematous skin
- Blisters resolve when the edema resolves

Epidemiology

This phenomenon has received little attention in the literature. These blisters are not infrequent and usually develop in elderly and immobile hospitalized patients as well as in the setting of anasarca. In a recent study of 13 patients, the mean age was 74 years[21].

Pathogenesis

The bullae usually develop on the legs in association with an acute exacerbation of chronic edema. Edema develops when the capillary filtration rate exceeds lymphatic drainage. This can be due to heart failure, renal disease, hepatic cirrhosis, hypoalbuminemia, venous occlusion (thrombosis) or drugs, particularly calcium channel blockers. Cutaneous vesicles and bullae also occur with acute exacerbations of lymphedema.

Clinical Features

Most patients develop blisters on the distal lower extremities (particularly the dorsum of the foot and ankle). With acute exacerbations of chronic edema, blisters appear and enlarge slowly to reach a diameter of up to several centimeters. The bullae are tense and asymptomatic,

Fig. 33.7 Edema bullae on the thigh of an infant. The bullae are tense and are surrounded by edema. Desquamation from a ruptured bulla is also seen.

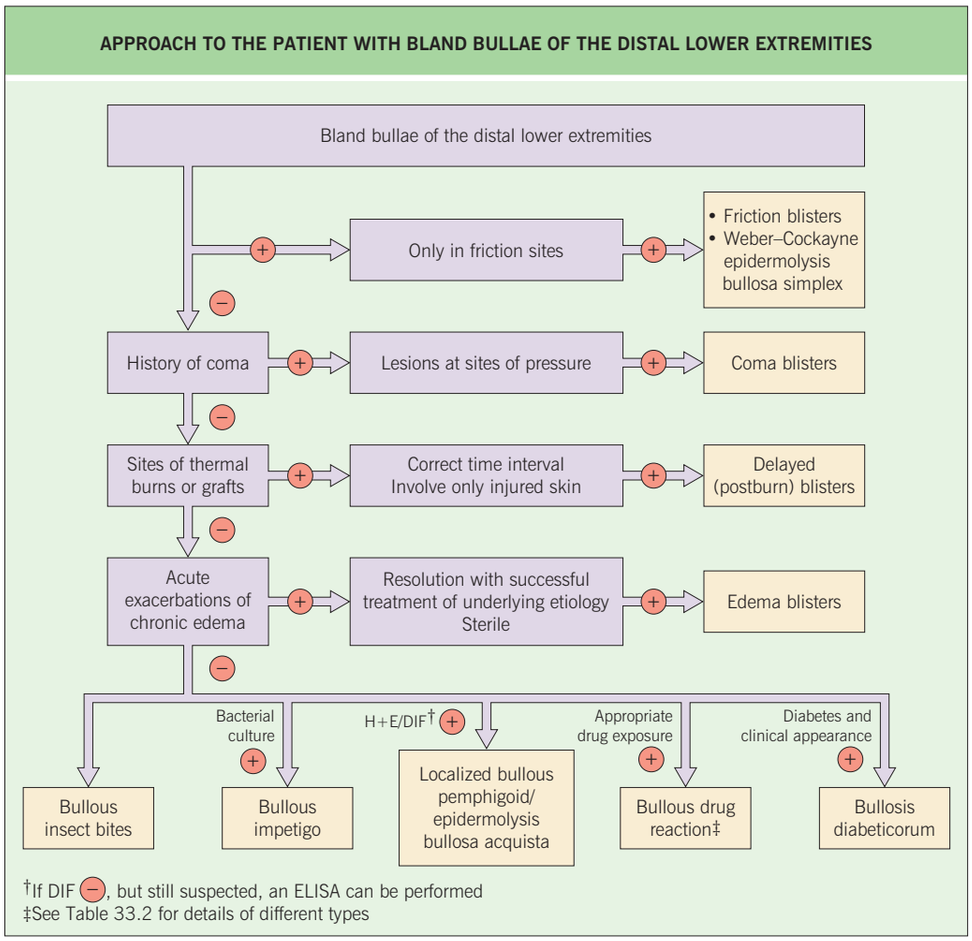

Fig. 33.8 Approach to the patient with bland bullae of the distal lower extremities.

and the surrounding skin is edematous. The sterile blister fluid is usually clear, but it can be serous or bloody. In patients with anasarca, there is a more widespread distribution (Fig. 33.7).

Pathology

Marked epidermal spongiosis is observed, with dilated dermal blood vessels and a mild inflammatory infiltrate. The dermis is markedly edematous with wide separation of collagen bundles. In some cases, subepidermal blisters can be found. DIF is negative.

Differential Diagnosis

Blistering in the setting of acute edema is usually not difficult to diagnose. However, the possibility of bullous pemphigoid, bullosis diabeticorum or a drug eruption must also be considered. The correct diagnosis can usually be established via the clinical history and physical examination (Fig. 33.8). If needed, bullous pemphigoid can be excluded by negative DIF and IIF examinations.

Treatment

These blisters resolve rapidly when the etiology of the edema is successfully treated. Diuretics, discontinuation of calcium channel blockers, leg elevation, and compressive bandages (followed by maintenance compression hose) may prove helpful.

PUVA-INDUCED ACROBULLOUS DERMATOSIS

This disease is characterized by the sudden occurrence of tense blisters, usually on the distal extremities, during long-term PUVA therapy. The tense bullae apparently arise as a result of chronic PUVA-induced weakening of epidermal–dermal cohesion coupled with friction or trauma. This disorder needs to be distinguished from phototoxic reactions due to PUVA overdosage, which usually affect the entire skin surface, not just acral sites, and from PUVA-induced bullous pemphigoid. There is no need to interrupt PUVA therapy, but mechanical stress should be avoided.

34 Vesiculobullous and Erosive Diseases in the Newborn

Deborah S Goddard, Amy E Gilliam and Ilona J Frieden

A number of conditions can cause vesicles, pustules, bullae, erosions and ulcerations during the newborn period. Accurate and prompt diagnosis is important because several of the disorders presenting with these skin findings can be life-threatening; conversely, others are benign and self-limited. Therefore, it is essential to develop a systematic approach to the evaluation and treatment of newborns with these types of cutaneous lesions. This chapter highlights many of the causes, and more exhaustive lists are provided in Tables 34.1 and 34.2. The majority of infectious causes are covered in these tables as well as in Chapters 74–82.

COMMON CAUSES

Erythema Toxicum Neonatorum

Synonyms: ■ Erythema toxicum ■ Toxic erythema of the newborn

Key features

- Common benign vesiculopustular neonatal eruption
- Affects ~50% of full-term neonates
- Most often involves the face, trunk, proximal limbs and buttocks
- Almost always spares the palms and soles
- Small, highly inflammatory papules, pustules and/or vesicles surrounded by blotchy erythema
- Resolves spontaneously over a few days without therapy

Erythema toxicum neonatorum (ETN) is a common benign condition. Originally described by Netlinger in 1472, it was called "toxic erythema of the newborn" and was renamed erythema toxicum neonatorum by Leiner in 1912[1]. The condition has no gender or racial predilection, although discrepancies in incidence rates may be related to the difficulty in discerning erythema in darker-skinned infants. ETN occurs in approximately half of full-term neonates and only rarely in premature infants or those weighing less than 2500 g[2].

Occasionally presenting at birth, most cases of ETN begin 24 to 48 hours after delivery and wax and wane for a few days. There are rare reports of an onset as late as 2 weeks of age. Four distinct skin lesions may present in varying combinations: erythematous macules, wheals, pustules (or vesicles) and papules. The papules, pustules and vesicles are small, generally measuring 1 to 3 mm. The central papule with a surrounding erythematous flare is reminiscent of a flea bite (Fig. 34.1). Mechanical irritation may precipitate new lesions.

ETN usually begins on the face, and then progresses to involve the proximal extremities, trunk and buttocks; it almost always spares the palms and soles[3]. Individual lesions rarely persist for more than a day, are asymptomatic, heal without sequelae, and require no therapy.

The diagnosis of ETN is usually made on clinical grounds. When necessary, the demonstration of numerous eosinophils via Wright's stain of the pustular contents can help to confirm the diagnosis. Peripheral eosinophilia is occasionally present. Histologically, the outer root sheaths of hair follicles are infiltrated by eosinophils, and coalescing subcorneal pustules composed of eosinophils are found in a perifollicular distribution. An eosinophilic infiltrate is also evident in the upper dermis and around blood vessels. The pathogenesis of ETN is unknown. Mechanisms related to hypersensitivity and fragility of newborn skin have been suggested[1,4].

Because the differential diagnosis includes other pustular disorders of the newborn, some of which may have important medical sequelae, rapid diagnosis is important (see Table 34.1). Transient neonatal pustular melanosis (TNPM) is primarily neutrophilic, usually affects infants with darkly pigmented skin, and resolves as pigmented macules that last weeks to months. However, an overlap between ETN and TNPM has been suggested[5]. Infantile acropustulosis is an acral, rather than truncal, eruption that usually appears after the neonatal period (3–6 months of age). Eosinophilic pustular folliculitis in infancy favors the scalp and features lesions that often become crusted and recur in crops over a period of months to years. Herpes simplex viral (HSV) infection is typically more vesicular, with hemorrhagic crusting. *Staphylococcus aureus* infections manifest as more well-developed pustules or bullae that rapidly rupture, resulting in an erythematous base with a surrounding collarette (remnant) of the blister roof (Fig. 34.2A). Congenital candidiasis presents with multiple tiny pustules, scrapings of which are positive on potassium hydroxide (KOH) examination, and often there is associated desquamation (Fig. 34.2B). Both staphylococcal and candidal infections result in more persistent lesions that do not undergo the rapid spontaneous resolution characteristic of ETN. Miliaria rubra (prickly heat) is usually concentrated on the head, neck and upper torso, with somewhat longer-lived lesions that lack a prominent erythematous flare or eosinophilic infiltrate[3].

Transient Neonatal Pustular Melanosis

Synonyms: ■ Transient neonatal pustulosis ■ Lentigines neonatorum

Key features

- Develops in up to 5% of newborns with darkly pigmented skin
- Prominent pustules without erythema that rupture, leaving a collarette of scale and hyperpigmentation that may last several months
- Sterile subcorneal neutrophilic pustules
- Favors the forehead, chin, neck, back and shins but may be widespread
- The infants are otherwise well and no treatment is necessary

Originally described in 1961 as "lentigines neonatorum"[6], the full spectrum of TNPM was not recognized until 15 years later[7]. It occurs in 4–5% of African-American and 0.5% of Caucasian newborns who are full-term, and lesions are virtually always present at birth.

Clinically, TNPM manifests as a continuum of three phases. At delivery, superficial, 2–10 mm vesiculopustules (Fig. 34.3A) are present at sites such as the chin, forehead, nape of the neck, lower back, buttocks and shins, and, less often, the remainder of the face, trunk, palms and soles. This phase may go undetected, as the fragile intra- and subcorneal pustules can be absent, overlooked or wiped away during the first bath. The second phase features slightly hyperpigmented macules with fine collarettes of scale at sites of ruptured and resolving pustules (Fig. 34.3B). The final phase features residual hyperpigmented

DIFFERENTIAL DIAGNOSIS OF VESICULOPUSTULAR DISEASES					
Disease	**Usual age of onset**	**Skin: morphology**	**Skin: distribution**	**Diagnostic studies (skin)**	**Comments**
INFECTIOUS DISEASES					
Staphylococcal diseases: pyoderma and bullous impetigo (see Ch. 74) (Fig. 34.2A)	Few days to weeks	Pustules, bullae, occasional vesicles	Favors diaper and periumbilical areas	Gram stain: Gram-positive cocci in clusters; bacterial culture	Boys more than girls; may occur in epidemics
Group A streptococcal infection (see Ch. 74)	Few days to weeks	Isolated pustules, honey-colored crusts	Any body region; may affect moist umbilical stump	Gram stain: Gram-positive cocci in chains; bacterial culture	Occasional cellulitis, meningitis, pneumonia
Group B streptococcal infection	Birth to first few days	Vesicles, bullae, erosions, pustules, honey-colored crusts	Any body region	Gram stain: Gram-positive cocci in chains; bacterial culture	Pneumonia, bacteremia, meningitis
Listeria monocytogenes infection (see Ch. 74)	Birth to first few hours	Hemorrhagic pustules and petechiae	Generalized, especially trunk and extremities	Gram stain: Gram-positive rods; bacterial culture	Sepsis; respiratory distress; history of maternal fever and premature labor
Haemophilus influenzae infection (see Ch. 74)	Birth to first few days	Vesicles, crusted papules	Any body region	Gram stain: Gram-negative bacilli; bacterial culture	Bacteremia, meningitis
Pseudomonas aeruginosa infection (see Ch. 74)	Days to weeks	Erythema, pustules, hemorrhagic bullae, necrotic ulcerations	Any region, especially anogenital area	Gram stain: Gram-negative rods; bacterial culture	Prematurity, low birthweight, immunodeficiency
Congenital candidiasis (Fig. 34.2B)	Birth to first few days	Erythema, small papules and pustules, fine scaling	Any region; palms/soles often involved; nails may be affected	KOH: budding yeast; fungal culture; placental/umbilical cord lesions may be present	Prematurity, foreign body in cervix/uterus are risk factors; ascending *in utero* infection
Neonatal candidiasis	1–2 weeks of age	Scaly red patches with satellite pustules and papules	Diaper area, other intertriginous zones, face	KOH: budding yeast, pseudohyphae; fungal culture	Usually otherwise healthy; acquisition during delivery or postnatally; oral thrush
Aspergillus infection (see Ch. 77)	Few days to weeks	Pustules (often clustered) rapidly evolve to necrotic ulcers	Any region, especially macerated skin in the diaper area and under adhesive tape/occlusive dressings	Skin biopsy: septate hyphae; tissue fungal culture	Extreme prematurity
Neonatal HSV infection (see Ch. 80) (Fig. 34.11)	Birth to 2 weeks, usually after 5 days	Vesicles, pustules, crusts, erosions	Any region, especially scalp, torso; may involve mucosa	Tzanck preparation, DFA or immunoperoxidase slide test, PCR, viral culture	Signs of sepsis; irritability, lethargy; must exclude herpes meningitis and encephalitis
Intrauterine HSV infection	Birth	Vesicles, pustules, widespread erosions, scars, areas of absent skin	Any body region	Tzanck preparation, DFA or immunoperoxidase slide test, PCR, viral culture	Low birthweight, microcephaly, chorioretinitis
Neonatal varicella (see Ch. 80)	Birth to 2 weeks	Vesicles on an erythematous base	Generalized distribution	Tzanck preparation, DFA, viral culture, serology	Maternal primary varicella infection 7 days before to 2 days after delivery
Herpes zoster (see Ch. 80)	Typically 2 weeks or older	Vesicles on an erythematous base	Dermatomal pattern	Tzanck preparation, DFA, viral culture	Maternal primary varicella infection during pregnancy or up to a few days after delivery
Scabies (see Ch. 84)	Typically 3–4 weeks or older	Papules, nodules, crusted areas, vesicles, pustules, burrows	Any region; accentuated in axillae and groin and on palms/soles, wrists	Mineral oil preparation; dermoscopy	Family members may have pruritus, similar lesions

Table 34.1 Differential diagnosis of vesiculopustular diseases. Additional etiologies include irritant contact dermatitis (see Table 34.2), dermatophyte infection and intrauterine coxsackievirus infection. CNS, central nervous system; DFA, direct fluorescent antibody; HSV, herpes simplex virus; KOH, potassium hydroxide examination; PCR, polymerase chain reaction. *Adapted from Frieden IJ, Howard R. In: Eichenfield LF, Frieden IJ, Esterly NB (eds). Textbook of Neonatal Dermatology. Philadelphia: WB Saunders, 2008:134–5.*

Continued

brown macules, which may persist for several months. The name "lentigines" is a misnomer since the lesions actually represent postinflammatory hyperpigmentation. Sometimes only the brown macules are noted at birth, suggesting that the first two phases occurred *in utero*. Less commonly, infants with TNPM may present at a few weeks of life with extensive pigmented macules without a history of preceding pustules.

Histologic examination is rarely necessary to make the diagnosis, but, when performed on early lesions, it demonstrates intra- or subcorneal pustules containing neutrophils, fibrin and (rarely) eosinophils. Neutrophils also predominate within a spongiotic epidermis. In the pigmented macules, an increase in melanin within basilar keratinocytes is noted[7,8].

The pathogenesis is unknown. Some authors have postulated that TNPM is a clinical variant of ETN, based on reports of the two conditions coexisting in the same patient, and have proposed the term *sterile transient neonatal pustulosis* because of this potential clinical overlap[5]. The differential diagnosis is similar to that discussed above for ETN, and no treatment is necessary. Parents should be reassured of the benign and self-limited nature of the condition.

DIFFERENTIAL DIAGNOSIS OF VESICULOPUSTULAR DISEASES					
Disease	**Usual age of onset**	**Skin: morphology**	**Skin: distribution**	**Diagnostic studies (skin)**	**Comments**
COMMON TRANSIENT CONDITIONS					
Erythema toxicum neonatorum (Fig. 34.1)	Typically 24–48 hours but can be birth to 2 weeks	Erythematous macules, papules, pustules > vesicles, wheals	Any region, except almost always spares palms/soles	Clinical; Wright's stain: eosinophils	Term infants >2500 g
Transient neonatal pustular melanosis (Fig. 34.3)	Birth	Pustules without erythema; collarettes of scale; hyperpigmented macules	Any region; most often forehead, neck, lower back, shins; may affect palms/soles	Clinical; Wright's stain: neutrophils, occasional eosinophils, cellular debris	Term infants; more common in infants of African descent
Miliaria crystallina (see Ch. 39) (Fig. 34.4)	Birth or early infancy	Fragile vesicles without erythema	Forehead, upper trunk, arms most common	Clinical; Wright's, Gram stains and Tzanck preparation negative	Sometimes history of overheating, fever
Miliaria rubra (see Ch. 39)	Typically ≥1 week	Erythematous papules with superimposed pustules	Forehead, neck, upper trunk and occluded areas most common	Clinical; Wright's stain: variable inflammatory cells but not prominent eosinophils; Gram stain and Tzanck preparation negative	Sometimes history of overheating, fever
Neonatal cephalic pustulosis (neonatal "acne") (Fig. 34.5)	Days to weeks	Papules and pustules on erythematous base	Cheeks, forehead, chin, eyelids; less commonly neck, upper chest, scalp	Clinical; Giemsa stain: yeast forms, neutrophils	Otherwise well
UNCOMMON AND RARE NON-INFECTIOUS DISEASES					
Acropustulosis of infancy (Fig. 34.7)	Typically 3–6 months, occasionally birth to weeks	Vesicles and pustules	Hands and feet; occasionally scalp, trunk	Clinical; assess for scabies infestation; skin biopsy: intraepidermal vesicle/pustule; neutrophils, occasionally eosinophils	Severe pruritus; lesions recur in crops
Eosinophilic pustular folliculitis in infancy (Fig. 34.8)	Birth to months	Follicular papules and pustules	Mainly scalp and face; occasionally trunk, extremities	Skin biopsy: dense perifollicular mixed infiltrate with eosinophils	Pruritus; waxing and waning course with recurrent crops of lesions
Congenital Langerhans cell histiocytosis (see Ch. 91) (Fig. 34.9)	Birth to days	Vesicles, crusts, papules, nodules, petechiae	Any body region, especially flexural sites, palms/soles, scalp	Skin biopsy: histiocytes with reniform nuclei, focal invasion of epidermis; S100- and CD1a-positive cells	Occasional mucosal or extracutaneous involvement; pure cutaneous form often resolves spontaneously; cutaneous and systemic relapses possible
Incontinentia pigmenti (see Ch. 62) (Fig. 34.10)	Birth to weeks	Vesicles, hyperkeratotic papules in linear or whorled array along the lines of Blaschko	Vesicular lesions most common on the extremities	Skin biopsy: eosinophilic spongiosis with dyskeratosis	Extracutaneous involvement possible (dental, ocular, CNS) but often not evident at birth
Hyper-IgE syndrome (autosomal dominant form; see Ch. 60)	Birth to weeks	Single and grouped vesicles or papulopustules	Face, scalp, upper trunk, axillae, diaper area	Skin biopsy: intraepidermal vesicle with eosinophils, eosinophilic folliculitis; genetic analysis (*STAT3*)	Eosinophilia; elevated IgE levels, *S. aureus* infections, abscesses, eczematous dermatitis, pneumonias and pneumatoceles often develop after neonatal period
Vesiculopustular eruption of transient myeloproliferative disorder in Down syndrome	Few days	Vesicles and pustules	Face > trunk, extremities; sites of adhesive dressings, minor trauma	Intraepidermal spongiotic vesiculopustules, infiltrate containing immature myeloid cells	Trisomy 21 or mosaicism for trisomy 21; severe leukocytosis with immature myeloid cells; increased risk of leukemia
Neonatal Behçet's disease (see Ch. 26)	First week of life	Vesiculopustular, purpuric and necrotic skin lesions as well as oral and genital ulcers	Lesions favor hands and feet as as well as oral and genital mucosae	Clinical	Maternal history of Behçet's disease; diarrhea, vasculitis
Pustular psoriasis (see Ch. 8)	First weeks of life	Pustules and pustular lakes within areas of erythema	Generalized (erythroderma); pustules in any body region, especially the palms/soles	Skin biopsy: spongiform pustules and microabscesses within the epidermis, parakeratosis, dilated dermal capillaries	Often resistant to therapy

Table 34.1 Differential diagnosis of vesiculopustular diseases (cont'd). Additional etiologies include irritant contact dermatitis (see Table 34.2), dermatophyte infection and intrauterine coxsackievirus infection. CNS, central nervous system; DFA, direct fluorescent antibody; HSV, herpes simplex virus; KOH, potassium hydroxide examination; PCR, polymerase chain reaction. *Adapted from Frieden IJ, Howard R. In: Eichenfield LF, Frieden IJ, Esterly NB (eds). Textbook of Neonatal Dermatology. Philadelphia: WB Saunders, 2008:134–5.*

DIFFERENTIAL DIAGNOSIS OF BULLAE, EROSIONS AND ULCERATIONS					
Disease	**Usual age**	**Skin: morphology**	**Skin: distribution**	**Diagnostic studies (skin)**	**Comments**
INFECTIOUS DISEASES					
Staphylococcal scalded skin syndrome (see Ch. 74) (Fig. 34.14)	Few days to weeks; rarely congenital	Erythematous patches, fragile bullae, superficial erosions, peeling in sheets	Generalized with periorificial and intertriginous accentuation	Biopsy: epidermal separation at granular cell layer; culture positive only at primary site(s) of infection (toxin-mediated)	Irritability; temperature instability; high risk of secondary sepsis, fluid/electrolyte abnormalities
Group B streptococcal infection	(see Table 34.1)				
Pseudomonas aeruginosa infection	(see Table 34.1)				
Congenital syphilis (see Ch. 82)	Birth to first few days	Bullae or erosions; erythema and desquamation	Any region, especially perioral, palms/soles	Darkfield examination of serous exudates, DFA, serologic studies (treponemal and non-treponemal)	Snuffles, hepatosplenomegaly, periostitis with pseudoparalysis
Aspergillus infection	(see Table 34.1)				
Zygomycosis/trichosporonosis (see Ch. 77)	Days to weeks	Generalized peeling and skin breakdown or cellulitis evolving into necrotic ulcer	Any body region	Skin biopsy and tissue fungal culture	Extreme prematurity
Intrauterine HSV infection	(see Table 34.1)				
Congenital varicella (see Ch. 80)	Birth	Erosions, scarring	Any region, especially extremities	Tzanck preparation, DFA, viral culture, serology	Maternal varicella in the first or early second trimester; limb atrophy, CNS/eye abnormalities
CONDITIONS WITH EXOGENOUS CAUSES					
Sucking blisters	Birth	Flaccid bulla or linear erosion; most often solitary	Radial forearm, wrist, hand, fingers, occasionally foot	Clinical	Due to sucking on affected areas *in utero*
Irritant contact dermatitis	First few days to weeks	"Glazed" erythema, vesiculation, "punched-out" erosions	Diaper area, especially on convex surfaces	Usually clinical	Severe form referred to as "Jacquet's erosive diaper dermatitis"
Perinatal trauma/iatrogenic injury	Birth or neonatal period	Erosions, ulcerations, scars, atrophic lesions	Depends on cause of trauma	Usually clinical	Perinatal history of fetal scalp electrode monitor, prolonged labor and/or vacuum or forceps delivery, history of amniocentesis, etc.
UNCOMMON AND RARE NON-INFECTIOUS DISEASES					
Mastocytosis (see Ch. 118) (Fig. 34.15)	Birth to weeks or months	**Localized/discrete lesions**: papules, plaques or nodules with intermittent superimposed wheals or bullae; often hyperpigmented **Diffuse form**: blistering superimposed on infiltrated skin with *"peau d'orange"* appearance	Any body region	Skin biopsy: increased mast cells in dermis	Variably present: flushing, irritability, diarrhea, abdominal pain
Epidermolysis bullosa (see Ch. 32)	Birth to first few days	Mechanically induced blisters and erosions; depending on type: mucosal erosions, aplasia cutis of anterior legs, scarring, milia, nail dystrophy	Widespread or limited, depending on type; most often extremities, especially hands/feet	Biopsy of induced blister for immunofluorescent mapping ± electron microscopy; genetic analysis	Difficulty feeding, failure to thrive; occasionally corneal, respiratory tract or gastrointestinal (e.g. pyloric atresia) involvement; anemia
Bullous congenital ichthyosiform erythroderma (see Ch. 57) (Fig. 34.13)	Birth	Erythroderma with blisters and erosions	Generalized	Skin biopsy: epidermolytic hyperkeratosis	Risk of sepsis, fluid and electrolyte imbalances
Kindler syndrome (see Ch. 63)	Birth to weeks	Trauma-induced blisters and erosions; progressive poikiloderma	Bullae most common in acral sites; poikiloderma is widespread with skip areas	Skin biopsy: immunostaining with anti-kindlin-1 antibody; genetic analysis (*KIND1/FERMT1*)	Photosensitivity; gingivitis, colitis, mucosal stenoses (e.g. esophageal, urethral); acquired syndactyly (toes, proximal fingers)
Maternal autoimmune bullous disease (Fig. 34.16)	Birth	Depends on type of maternal disease: tense or flaccid bullae, erosions	Variable; often widespread	Maternal history; skin biopsy with DIF usually diagnostic	Maternal history of blistering disease (but occasionally inactive during pregnancy)
Bullous pemphigoid (see Ch. 30)	Usually 2 months of age or older	Tense bullae	Favor hands and feet but may be generalized	Skin biopsy: subepidermal bullae with eosinophils; DIF: linear pattern IgG at DEJ	

Table 34.2 Differential diagnosis of bullae, erosions and ulcerations. CNS, central nervous system; CSF, cerebrospinal fluid; DEJ, dermal–epidermal junction; DFA, direct fluorescent antibody; DIF, direct immunofluorescence; FDP, fibrin degradation product; GVHD, graft-versus-host-disease; PT, prothrombin time; PTT, partial thromboplastin time. *Adapted from Frieden IJ, Howard R. In: Eichenfield LF, Frieden IJ, Esterly NB (eds). Textbook of Neonatal Dermatology. Philadelphia: WB Saunders, 2008:136–8.*

DIFFERENTIAL DIAGNOSIS OF BULLAE, EROSIONS AND ULCERATIONS					
Disease	**Usual age**	**Skin: morphology**	**Skin: distribution**	**Diagnostic studies (skin)**	**Comments**
Linear IgA bullous dermatosis (see Ch. 31)	Rarely at birth, usually develops in late infancy or childhood	Tense blisters often form rosette or sausage shapes	Widespread but often concentrated in the girdle area; usually spares mucosa	Skin biopsy: subepidermal bullae with neutrophils; DIF: linear pattern IgA at DEJ	
Toxic epidermal necrolysis (TEN; see Ch. 20) or TEN-like GVHD (see Chs 52, 60)	Usually 6 weeks of age or older, except for intrauterine GVHD	Tender erythema, bullae, epidermal sloughing/erosions	Often widespread, evolving rapidly over hours to days; mucosal involvement	Skin biopsy: subepidermal blister with epidermal necrosis (usually full thickness)	Usually associated with Gram-negative sepsis or due to GVHD (maternofetal or transfusion-associated) in infants with severe combined immunodeficiency
Intrauterine epidermal necrosis	Birth	Widespread erosions and ulcerations without vesicles or pustules	Generalized, spares mucous membranes	Skin biopsy: epidermal necrosis and calcification of pilosebaceous units	Prematurity, rapid mortality
Congenital erosive and vesicular dermatosis (Fig. 34.12)	Birth	Erosions, vesicles, crusts, "scalded skin"	Generalized with relative sparing of face, palms/soles	Clinical diagnosis, often retrospective; skin biopsy (nonspecific): epidermal necrosis, neutrophils or mixed infiltrate; must exclude other etiologies (e.g. HSV)	Prematurity; heals with supple reticulated scarring; CNS/developmental abnormalities
Pyoderma gangrenosum (see Ch. 26)	Rare reports of congenital or neonatal disease	Sharply demarcated ulcerations with undermined borders	Any site, especially groin, buttocks	Clinical; exclusion of other etiologies; skin biopsy: infiltration of neutrophils without primary vasculitis or infection	Associations include inflammatory bowel disease, hematologic malignancies
Acrodermatitis enteropathica (see Ch. 51)*	Weeks to months	Sharply demarcated, eroded erythematous plaques with scale-crust; occasionally intact vesicles/bullae	Periorificial (i.e. around mouth, nose, eyes, genitalia), neck folds, hands/feet	Low serum zinc (less than 50 microg/dl) and alkaline phosphatase levels	Irritability, diarrhea, failure to thrive; onset classically after weaning if breastfed; acquired zinc deficiency: low maternal breast milk zinc or prematurity
Methylmalonic acidemia, other organic acidemias/ aminoacidopathies (see Fig. 51.12)*	Days to weeks	Erythema with or without erosions	Periorificial or more widespread	Urine organic acid analysis; plasma isoleucine level (if restricted diet)	Lethargy, hypotonia, neutropenia, metabolic acidosis; in some cases, skin findings are associated with therapeutic restrictions of dietary amino acids
Restrictive dermopathy	Birth	Rigid tense skin with linear erosions, tears	Generalized; skin tears most common in flexural creases	Clinical; distinguish from Neu–Laxova syndrome (intrauterine growth retardation, microcephaly, abnormal brain development, edema, parchment-like or ichthyosiform skin); genetic analysis (*LMNA, ZMPSTE24*)	Joint contractures, micrognathia, fixed facial expression, restrictive pulmonary disease, early mortality
Infantile hemangioma (see Ch. 103)	Birth to first few weeks	Ulceration without initial vesicle or bullae	Any site, but often diaper area or lip	Clinical	Cause often not clinically apparent until hemangioma begins to proliferate
Aplasia cutis congenita (see Ch. 64) (Fig. 34.6)	Birth	"Bullous" form: round/oval, sharply demarcated with overlying membrane; other types with raw, full-thickness ulcer; may occasionally present in newborns as scar	Scalp (especially vertex) or face most common; other sites depending on etiology	Usually clinical; imaging studies to evaluate underlying bone, CNS	Possible associations: sagittal sinus thrombosis, meningitis, CNS defects, trisomy 13, limb-reduction abnormalities
Linear porokeratosis, porokeratotic eccrine ostial and dermal duct nevus (PEODDN) (see Ch. 62)	Rarely evident at birth, usually appears later	Erosions occasionally develop; usually erythema and keratotic border or (in PEODDN) spines	Often extremities, but any site possible	Skin biopsy: cornoid lamella (may not be evident in newborn period)	Risk of squamous cell carcinoma
Erosions overlying large congenital melanocytic nevi (see Ch. 112)	Birth to first few days	Erosions, ulcerations	Superimposed on the congenital melanocytic nevus	Clinical; skin biopsy to exclude melanoma if persistent or other unusual features	In some cases, neurocutaneous melanosis may be present

*An acrodermatitis enteropathica-like eruption (periorificial or more widespread), often associated with edema and hypoalbuminemia, can occur in infants (typically 3–5 months of age) with cystic fibrosis as well as in those with organic acidemias/aminoacidopathies (see Ch. 51).

Table 34.2 Differential diagnosis of bullae, erosions and ulcerations (cont'd). CNS, central nervous system; CSF, cerebrospinal fluid; DEJ, dermal–epidermal junction; DFA, direct fluorescent antibody; DIF, direct immunofluorescence; FDP, fibrin degradation product; GVHD, graft-versus-host-disease; PT, prothrombin time; PTT, partial thromboplastin time. *Adapted from Frieden IJ, Howard R. DIFFERENTIAL DIAGNOSIS OF BULLAE, EROSIONS AND ULCERATIONS					
Disease	**Usual age**	**Skin: morphology**	**Skin: distribution**	**Diagnostic studies (skin)**	**Comments**
Focal dermal hypoplasia (see Ch. 62)	Birth	Occasional blisters, but more often hypoplasia or aplasia of skin; linear and whorled pattern; also fat "herniation", telangiectasias	Any body region	Clinical; skin biopsy: dermal hypoplasia with fat abutting epidermis; genetic analysis (*PORCN*)	Skeletal, eye and CNS abnormalities to varying degrees
Absent dermal ridges and congenital milia (Basan syndrome; see Ch. 64)	Birth	Bullae; absent dermal ridge patterns, multiple milia	Fingers, plantar surface of feet	Clinical	Family history (autosomal dominant); findings overlap with those of Naegeli–Franceschetti–Jadassohn syndrome (see Ch. 67)
Porphyrias (see Ch. 49)	Days to months	Photosensitive blistering	Sun-exposed areas or more generalized if exposed to phototherapy for hyperbilirubinemia	Transient form: elevated plasma porphyrins; heritable forms: elevated urine, fecal and/or plasma porphyrins ± pink/fluorescent urine	Transient form usually related to hemolytic disease; heritable forms presenting with blistering in infancy (e.g. congenital erythropoietic porphyria) are rare
Perinatal gangrene of the buttock	Days	Sudden-onset erythema and cyanosis, then gangrenous ulcers	Buttocks	Clinical	Umbilical artery catheterization in some cases
Neonatal purpura fulminans	Days	Initially purpura or cellulitis-like areas evolving to necrotic bullae or ulcers	Buttocks, extremities, trunk and scalp	Prolonged PT/PTT, low fibrinogen, elevated FDPs, low protein C or S levels	Related to sepsis or inherited protein C or S deficiency
Ankyloblepharon–ectodermal dysplasia–clefting (AEC) syndrome	Birth	Erythroderma, peeling skin and superficial erosions	Generalized, with prominent scalp involvement	Clinical; genetic analysis (*p63*)	Associated findings include ankyloblepharon, ectodermal dysplasia and cleft lip/palate

Table 34.2 Differential diagnosis of bullae, erosions and ulcerations (cont'd). CNS, central nervous system; PT, prothrombin time; PTT, partial thromboplastin time. *Adapted from Frieden IJ, Howard R. In: Eichenfield LF, Frieden IJ, Esterly NB (eds). Textbook of Neonatal Dermatology. Philadelphia: WB Saunders, 2008:136–8.*

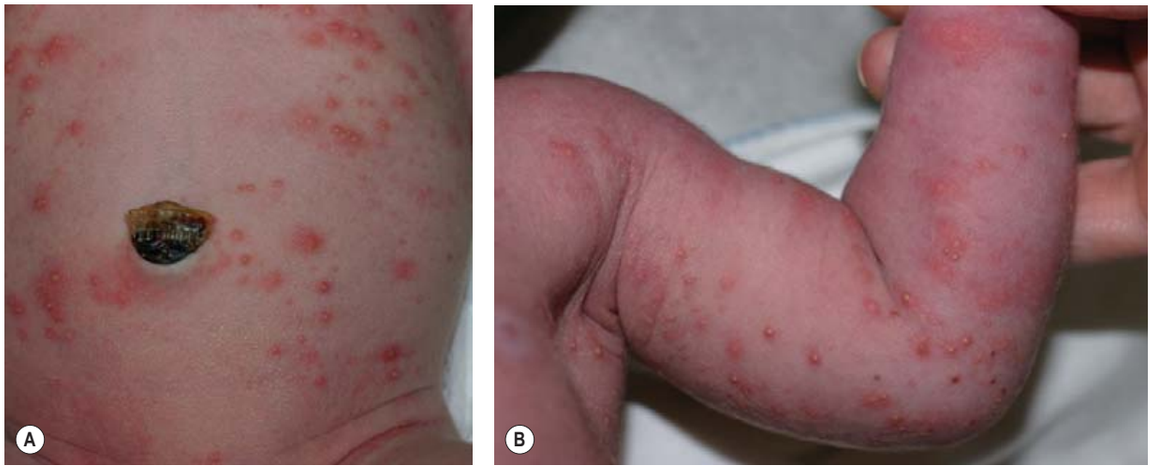

Fig. 34.1 Erythema toxicum neonatorum. Scattered papulovesicles and pustules with an erythematous flare on the abdomen (**A**) and upper extremity (**B**).

Miliaria

Synonyms: ■ Heat rash ■ Miliaria crystallina – "dew drops" ■ Miliaria rubra – prickly heat

Key features

- Three variants: miliaria crystallina, miliaria rubra and miliaria profunda (rare)
- Due to obstruction of eccrine sweat ducts, often in association with increased temperature (exogenous or endogenous)
- Sites of predilection include the forehead, neck, upper trunk and occluded areas
- Spontaneous resolution with cooling
- Prevention consists of avoidance of overheating and limiting excessive swaddling

Miliaria is a common condition, present in up to 15% of newborns, and is seen more frequently in warm climates. Two types of miliaria (see Ch. 39) are typically observed in the newborn period. *Miliaria crystallina*, sometimes present at birth, is due to obstruction of the eccrine sweat duct as it courses through the stratum corneum. Sweat collects beneath the stratum corneum, causing clear, small, flaccid vesicles that are often likened to "dew drops" (Fig. 34.4). *Miliaria rubra*, usually seen after the first week of life, is also caused by a blockage of the sweat ducts, but at a deeper level (the malpighian layer) of the epidermis. The obstructed flow leads to leakage of fluid into the lower epidermis and upper dermis, resulting in an inflammatory response that accounts for the development of erythematous papules and pustules. *Miliaria profunda*, a more inflammatory variant, is related to deeper obstruction of the eccrine duct and is very rare in infants.

Both miliaria crystallina and miliaria rubra may be seen in relation to excessive warming inside an incubator, overswaddling, fever or occlusive dressings. Lesions occur most commonly on the forehead, neck and upper trunk as well as in areas of skin that have been occluded.

In miliaria crystallina, the characteristic histologic features are subcorneal or intracorneal vesicles that are centered on the acrosyringium

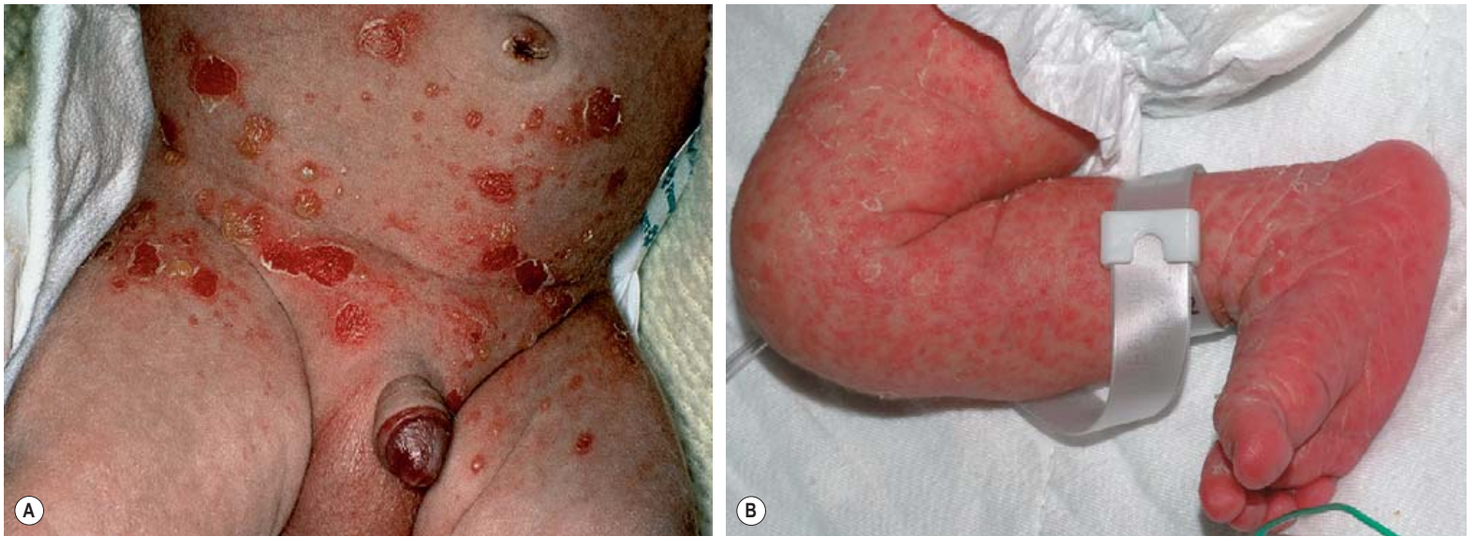

Fig. 34.2 Bullous impetigo versus congenital candidiasis. A Multiple superficial erosions with collarettes of scale in the diaper area in an infant with bullous impetigo. Note the scattered vesiculopustules. **B** Numerous pink papules admixed with small superficial pustules and desquamation due to congenital candidiasis. Note the plantar involvement. *B, Courtesy, Julie V Schaffer, MD.*

Fig. 34.3 Transient neonatal pustular melanosis in an African-American neonate. A One hour after birth, flaccid vesiculopustules and superficial erosions with minimal surrounding erythema are present in the groin. **B** On the 8th day of life, hyperpigmented macules and a few collarettes of scale are evident on the lower leg.

Fig. 34.4 Miliaria crystallina. Tiny, superficial vesicles, seen on the back and neck of this newborn, are characteristic of miliaria crystallina. *From Eichenfield LF, Frieden IJ, Esterly NB, et al. (eds). Textbook of Neonatal Dermatology. © 2001 Saunders.*

with relatively little surrounding inflammation. In miliaria rubra, intraepidermal spongiosis and vesicles are seen along with a chronic inflammatory infiltrate in the dermis[3,8]. The exact cause of miliaria is unknown. A pathophysiologic link to an extracellular polysaccharide produced by *Staphylococcus epidermidis* that blocks sweat ducts has been proposed[9], but this may not explain all cases, particularly congenital forms.

Miliaria resolves without treatment. Prevention is accomplished by avoidance of overheating and overswaddling when feasible.

Neonatal Cephalic Pustulosis

Synonym: ■ Neonatal acne

Key features

- Onset usually within the first 2–3 weeks of life
- Inflammatory non-comedonal pustular eruption, most commonly observed on the cheeks, and less often on the forehead, chin, scalp and chest
- *Malassezia* spp. have been implicated in its etiopathogenesis
- Spontaneous involution over weeks to months

Fig. 34.5 Neonatal cephalic pustulosis. Papulopustules on the forehead and cheeks of a 3-week-old infant. *Courtesy, Julie V Schaffer, MD.*

Historically referred to as "neonatal acne", neonatal cephalic pustulosis lacks several of the features associated with classic acne vulgaris, in particular open and closed comedones and a prolonged course. Young infants with this condition tend to exhibit relatively rapid resolution of lesions within days to weeks and therapy is usually not necessary. Discrete papulopustules are most commonly seen on the cheeks but may also develop on the forehead (Fig. 34.5), chin, eyelids, neck, upper chest and scalp. Onset is usually within the first 2–3 weeks of life, and there is no association with other medical problems.

The results of some studies have suggested that an inflammatory response to *Malassezia (Pityrosporum)* spp. (including *M. furfur, M. sympodialis* and *M. globosa*) may be involved in the etiopathogenesis of neonatal cephalic pustulosis[10–12], but other studies have found no correlation between colonization of neonatal skin with *Malassezia* spp. and the presence or severity of neonatal cephalic pustulosis[13]. While these yeasts have been cultured from lesional skin in affected patients, they are part of the normal skin flora in humans, and thus their exact etiologic role in the condition remains uncertain.

A Giemsa-stained smear of pustular contents may demonstrate yeast forms, neutrophils and other inflammatory cells; culture of *Malassezia* spp. requires specialized media. Treatment with a topical imidazole may improve the condition, but it usually remits spontaneously within several weeks.

While many authors now consider neonatal cephalic pustulosis to be synonymous with neonatal acne, there are some infants (typically 3–6 months of age or older) whose clinical presentation is more reminiscent of classic acne vulgaris, including the presence of comedones as well as inflammatory lesions and a more prolonged course. This is usually referred to as infantile acne (see Ch. 36).

Cutaneous Candidiasis

Key features

- Most commonly due to infection with *Candida albicans* in both term and preterm infants
- Two distinct clinical presentations: *neonatal* candidiasis (due to infection acquired during delivery or postnatally) and *congenital* candidiasis (due to infection acquired *in utero*)
- *Neonatal* candidiasis is characterized by oral thrush as well as pink–red patches with satellite papules and pustules that favor the diaper area, other intertriginous sites and the face
- First-line therapy consists of topical anti-yeast medications (e.g. imidazole creams), unless there is concern for systemic infection

There are two clinical patterns of infection with *Candida albicans* in the newborn period: *neonatal* candidiasis, which is quite common and acquired during delivery or postnatally, and *congenital* candidiasis, which is uncommon and acquired *in utero*.

Neonatal candidiasis typically presents after the first week of life, involving primarily the diaper area and oral mucosa. In some patients, other intertriginous areas as well as the face may be affected. Pink–red patches with satellite papules and pustules are the characteristic findings; pustules and scaling may also be present at the peripheral border. Therapy with topical anti-yeast medications (e.g. an imidazole cream) is usually sufficient. Premature infants and those with very low birthweights should be closely observed and cultures of blood, urine and cerebrospinal fluid obtained as indicated; treatment with parenteral antifungals should be considered if there are signs of systemic infection[3].

In contrast, the relatively uncommon *congenital* candidiasis presents with a more widespread eruption, usually evident at birth but sometimes appearing as late as the 6th day of life. Risk factors include a foreign body in the uterus or cervix (such as a retained intrauterine device or cervical cerclage), premature delivery and a maternal history of vaginal candidiasis[3]. Skin lesions occur on the face, trunk and extremities, while the diaper area and oral mucosa are usually spared. Cutaneous findings vary from erythematous papules and vesiculopustules to diffuse erythema and a "burn-like" dermatitis[14] to fine scaling. Typically, an erythematous papular eruption appears first and is followed by pustules and desquamation (see Fig 34.2B). In contrast to ETN and TNPM, the palms and soles are often involved, and nail dystrophy can be present. In some infants, nail changes (yellow discoloration and transverse ridging) are the only manifestations of congenital candidiasis[14a].

The differential diagnosis includes other infections (e.g. with *Listeria* spp. or HSV) as well as miliaria, ETN and TNPM (see Table 34.1). The presence of budding yeast and pseudohyphae in a KOH preparation points to the correct diagnosis. If the placenta is examined, characteristic yellow–white papules may be found on the umbilical cord[3].

Treatment of *congenital* candidiasis is dependent on the gestational age and weight of the infant. Premature infants (<27 weeks gestational age and <1500 g) are at greater risk for the development of disseminated systemic candidiasis and therefore should be treated with parenteral antifungal agents after cultures have been obtained from the blood, urine and cerebrospinal fluid[14]. Infants of a more advanced gestational age with no evidence of systemic infection can be treated with topical therapy as discussed for *neonatal* candidiasis. However, regardless of gestational age, systemic antifungal therapy should be considered for infants with *congenital* candidiasis who have respiratory distress, an elevated white blood cell count with a left shift, or other signs of systemic infection[14].

Sucking Blisters

Key features

- Caused by vigorous sucking of the affected region *in utero*
- Common locations include the radial forearm, wrist, hands and fingers
- May present with an intact bulla, erosion, callus or superficial ulceration on a non-inflamed base
- Usually an isolated finding without associated abnormalities
- Resolves over days to weeks and therapy is supportive

Sucking blisters are found in 1 of every 250 newborns, although they may be small and go unnoticed. They are an isolated finding caused by sucking *in utero* and are usually seen on the radial forearm, wrist, hand or fingers. The flaccid bullae occur on a non-inflamed base and rupture easily, leading to linear or round erosions. Lesions are usually 5–15 mm in diameter and may be unilateral or bilateral.

The diagnosis of sucking blisters is usually straightforward and suggested by a non-inflammatory and (in most cases) solitary lesion in a typical location and the overall healthy status of the infant. The lesions clear in days to weeks without specific treatment[3].

Fig. 34.6 Aplasia cutis congenita. Ulcerations on the vertex of the scalp may be misdiagnosed as an HSV infection. The angulated appearance of the larger ulceration would not be characteristic of HSV infection.

Exogenous Causes of Erosions

Key features

- There are multiple exogenous causes for erosions, including friction from diapers, fetal scalp electrodes, pulse oximetry probes, "heel stick" phlebotomy and removal of adhesive materials
- A typical location and known exposure to exogenous materials/procedures assist in diagnosis

Neonatal skin is more susceptible to erosions and ulcerations than is the skin of older infants or adults. This fragility is even more pronounced in preterm infants. As a result, there are a number of etiologies, including iatrogenic injury, for erosive skin changes.

Superficial erosions in the diaper area frequently occur within the first 2 weeks of life in full-term infants but become less common in older infants. These erosions are primarily due to friction and irritation from the diaper, urine and feces in the setting of transient neonatal skin fragility. A common cause of skin injury on the scalp is the fetal scalp electrode monitor placed during delivery. These erosions are usually superficial, but occasionally lacerations or frank ulcers may ensue. Differentiation from aplasia cutis congenita (Fig. 34.6) is usually straightforward, but may be more difficult in severe cases.

Pulse oximetry probes may lead to small blisters or erosions related to thermal burns and therefore should not be left in one place for more than 24 hours. Removal of adhesive materials (e.g. tape over dressings and electrode leads) can also cause erosions due to neonatal skin fragility. Puncture wounds from "heel sticks", a common method of phlebotomy utilized in the newborn nursery, are a potential cause of acral erosions; the medial or lateral (versus midline) location and procedural history are clues to the diagnosis[3]. Occasionally, heel-stick sites may develop calcinosis cutis.

UNCOMMON AND RARE CAUSES

Acropustulosis of Infancy

Synonym: ■ Infantile acropustulosis

Key features

- Onset usually between 3 and 6 months of age, occasionally at birth
- Pruritic acral vesiculopustular eruption without burrows
- Recurrences occur in crops, typically every 3–4 weeks, and then decrease in frequency and severity with time, resolving completely by approximately 3 years of age
- Therapy is symptomatic and consists of potent topical corticosteroids and oral antihistamines

Fig. 34.7 Acropustulosis of infancy. Multiple vesiculopustules with an erythematous base on the medial ankle of an infant.

Acropustulosis of infancy (AI) is an uncommon skin condition that more frequently affects darkly pigmented male infants, but occurs in both genders and all races. Onset is usually around 3–6 months of age, although lesions may be present in the neonatal period. Extremely pruritic vesicles and pustules appear on acral sites, including the palms and soles, dorsal aspects of the hands and feet, lateral fingers and toes, and, less often, wrists and ankles (Fig. 34.7). Occasionally, lesions are found on the scalp, torso or proximal extremities. The lesions appear in crops, last 7–14 days, and then recur in 3–4 weeks. The natural history of AI is marked by decreasing frequency and severity of the intermittent flares over time, with spontaneous involution usually occurring by 3 years of age.

A smear of pustular contents reveals numerous neutrophils, occasional eosinophils, and no bacteria or fungal elements. Histologic examination of lesional skin, while generally unnecessary, can help to confirm the diagnosis of AI. Histologic features include intraepidermal (subcorneal) vesicles filled with neutrophils and occasionally eosinophils, focal degeneration of keratinocytes, and, in some cases, dermal edema. Occasionally, peripheral eosinophilia is present.

The major entity in the differential diagnosis of AI is scabies, which can be difficult to differentiate clinically. In some patients, AI may represent a post-scabetic hypersensitivity phenomenon following successful treatment of the infestation. Linear burrows are pathognomonic of active scabies, and genital or more widespread lesions and pruritic eruptions in family members also suggest a diagnosis of scabies. Mineral oil examination of skin scrapings for signs of scabies should be performed when evaluating an infant or a toddler with acral vesicles and pustules; in addition, dermoscopy can be used for *in vivo* visualization of mites. In uncertain cases, empiric treatment for scabies may be warranted.

Other conditions with clinical overlap include dyshidrotic eczema and pustulosis palmaris et plantaris – both of which are extremely rare in infancy. Congenital candidiasis is usually not limited to acral skin, and transient neonatal pustular melanosis is not pruritic, does not favor acral locations, and does not recur.

The etiology of AI is unknown. Some cases have been associated with a personal or family history of atopy. Symptoms can usually be effectively controlled with intermittent application of potent or superpotent topical corticosteroids[15] and administration of oral antihistamines. Dapsone (1–2 mg/kg/day) can be considered when the eruption is especially severe, but the risks of methemoglobinemia and other hematologic side effects usually outweigh the benefits of this form of treatment[3,16].

Eosinophilic Pustular Folliculitis in Infancy

Synonyms: ■ Neonatal eosinophilic pustular folliculitis ■ Infantile eosinophilic pustular folliculitis ■ Eosinophilic pustular folliculitis of infancy

Fig. 34.8 Eosinophilic pustular folliculitis in infancy. Crusted papules and pustules on the scalp of a 1-year-old boy.

Key features

- Recurrent pruritic crops of follicular vesiculopustular lesions
- Favors the scalp and face; rarely involves the trunk and extremities
- Similar natural history as acropustulosis of infancy, exhibiting spontaneous resolution within 3–5 years
- An eosinophilic infiltrate surrounds the hair follicles and invades the outer root sheath
- Therapy is symptomatic
- Rare relationship with HIV infection in infants

Eosinophilic pustular folliculitis (EPF) in infancy is an uncommon entity that presents at birth or during the first few days to weeks of life with sterile pustules on the scalp, face (especially the brow region), and, less commonly, the trunk and extremities. The pruritic pustules often develop hemorrhagic crusts (Fig. 34.8) and recur in crops, occasionally leaving scars. It has been postulated that this condition may be related to acropustulosis of infancy, due to occasional acral involvement and similar cyclical recurrences. The cause of EPF is unknown. It is more frequently seen in male infants, and HIV infection is not commonly associated with this form of EPF as it is in adults. Some authors have suggested that EPF in infancy represents a clinicopathologic reaction pattern with heterogeneous underlying causes rather than a distinctive inflammatory dermatosis.

A smear of pustular contents demonstrates primarily eosinophils, without bacteria or yeast forms. Histologically, a dense eosinophilic and mixed infiltrate is seen around follicles and in the dermal interstitium. The perifollicular cuffing is often associated with invasion of the outer root sheath. Peripheral blood eosinophilia may be present.

The differential diagnosis includes ETN, TNPM, acropustulosis of infancy, bacterial folliculitis, tinea capitis, scabies and reactions to arthropod bites. Since the histologic findings of EPF are quite similar to those of the vesicular and papulopustular lesions seen in association with hyper-IgE syndrome[17] (see below), this diagnosis should also be considered especially in more severe cases.

Symptomatic therapy is the same as that for acropustulosis of infancy and includes potent topical corticosteroids and oral antihistamines[3]. EPF usually resolves spontaneously over 3 to 5 years.

Congenital Langerhans Cell Histiocytosis

Synonyms: ■ Hashimoto–Pritzker disease* ■ Congenital self-healing reticulohistiocytosis*

*Now recognized to be part of Langerhans cell histiocytosis spectrum

Fig. 34.9 Congenital Langerhans cell histiocytosis. Numerous erosions with crusting on the face and trunk of a newborn.

Key features

- Presents at birth and lasts weeks to months
- Crusted papules, vesiculopustules, erosions or nodules; occasionally petechiae or purpura
- May be limited to the skin or, uncommonly, associated with extracutaneous involvement
- Cutaneous infiltrates of $S100^+/CD1a^+$ Langerhans cells; electron microscopy demonstrates characteristic Birbeck granules
- Pure cutaneous form often resolves without treatment
- Both cutaneous and extracutaneous relapses may occur; patients require longitudinal evaluation

Congenital Langerhans cell histiocytosis (LCH) is a rare condition that is virtually always evident at the time of birth. The most typical lesions are crusted papules, pustules and papulovesicles (Fig. 34.9), but nodules may also be present (see Ch. 91). Additional skin findings include petechiae, atrophy, milia and mucosal erosions. Lesions are often widespread but can be solitary, and they may continue to develop and evolve over the first days to weeks of life. Lesions of congenital LCH can develop anywhere on the skin surface, including the palms and soles[3]. The differential diagnosis includes neonatal varicella or HSV infection, congenital candidiasis, congenital syphilis, intrauterine GVHD, and the early-onset form of infantile acropustulosis.

Histologically, a proliferation of Langerhans cells – large, polygonal, histiocytic cells with "coffee bean" nuclei – is present in the superficial dermis and occasionally in the epidermis (epidermotropism). These cells stain positively with S100, CD1a and Langerin immunostains. Ultrastructurally, they contain the characteristic Birbeck granules[18,19].

In an infant diagnosed with congenital cutaneous LCH, a prompt evaluation for systemic involvement is indicated, including a complete physical examination, liver function tests, a complete blood cell count with differential, and a skeletal survey. Distinction between purely cutaneous and multisystem disease is not possible based solely on the skin findings. In fact, the histologic and immunohistochemical features of "congenital self-healing reticulohistiocytosis" and disseminated Langerhans cell histiocytosis are indistinguishable, suggesting that these entities represent different ends of a clinical spectrum[20,21].

In patients whose disease is limited to the skin, lesions usually resolve spontaneously over a period of weeks to months and the prognosis is very good. However, relapses of cutaneous or extracutaneous disease (e.g. diabetes insipidus due to pituitary involvement) may occur months or years later, highlighting the importance of longitudinal evaluation of these patients. The prognosis of multisystem

congenital LCH is less favorable, and systemic therapy is generally required.

Incontinentia Pigmenti

Synonym: ■ Bloch–Sulzberger syndrome

Key features

- X-linked dominant disease, lethal in male fetuses unless mosaic
- Cutaneous lesions are characterized by four distinct phases: vesicular, verrucous, hyperpigmented and hypopigmented/atrophic
- The most common forms of extracutaneous involvement are dental, ophthalmologic and neurologic
- Defect in gene on chromosome Xq28 that encodes NEMO, the NF-κB essential modulator

Incontinentia pigmenti (IP) is an uncommon X-linked dominant multisystem disease that presents within the first 2 weeks of life in 90% of patients. It is usually lethal in male fetuses and is caused by mutations in the *NEMO* gene (NF-κB essential modulator) on Xq28, the protein product of which confers protection against apoptosis induced by the tumor necrosis factor family of cytokines (see Ch. 62).

Cutaneous lesions tend to follow the lines of Blaschko and occur in four classic phases. The vesicular stage is characterized by yellow or clear vesicles in linear and whorled streaks, usually most prominently distributed on the lower extremities (Fig. 34.10A). The verrucous phase of IP consists of hyperkeratotic linear plaques. The third phase, characterized by linear and whorled grayish-brown hyperpigmentation, occurs most often on the trunk and in some patients may be the only cutaneous feature. The first three phases typically resolve during infancy or childhood. The fourth phase, consisting of atrophic, hypopigmented thin streaks favoring the calves, may persist indefinitely. The various clinical stages of IP can overlap, occur *in utero*, or occasionally be skipped entirely. Associated cutaneous findings include patchy scarring alopecia (typically at the vertex), areas of woolly hair, nail dystrophy and anhidrosis within atrophic linear streaks. Extracutaneous features can include dental abnormalities such as hypodontia and conical or peg-shaped teeth; CNS abnormalities manifesting as seizures, delayed psychomotor development and spastic paralysis; and ocular disease characterized by retinal vascular abnormalities that have the potential to lead to blindness. During the vesicular phase, patients often have peripheral blood leukocytosis and eosinophilia.

Histologically, lesions from the vesicular stage of IP demonstrate spongiosis with necrotic keratinocytes, dyskeratosis and infiltrating eosinophils (Fig. 34.10B). A dermal infiltrate composed predominantly of eosinophils is also present[8].

The cutaneous lesions generally do not require therapy. All affected infants should be referred for baseline and longitudinal ophthalmologic examinations and should have periodic neurodevelopmental and dental evaluations. Genetic testing is available.

B, Courtesy, Laura B Pincus, MD.*

Hyperimmunoglobulin E (Hyper-IgE) Syndrome

Synonym: ■ Job syndrome

Key features

- A multisystem immunologic disorder
- Papulopustular and vesicular eruption with crusting favoring the face, scalp and neck as well as in the axillae and diaper area
- Peripheral blood eosinophilia
- During the first few months of life, other features such as "cold" abscesses, eczematous dermatitis, recurrent infections and elevated levels of serum IgE are often not present

Hyper-IgE syndrome is a disease of abnormal inflammatory responses that frequently presents at birth or during the first month of life with a vesicular or papulopustular eruption (see Ch. 60). These skin lesions are usually concentrated on the head and shoulders, but they can also affect the axillae and diaper area[22]. Hyper-IgE syndrome is classically associated with high circulating levels of IgE (over 2000 IU/ml) and eosinophilia, but elevated IgE levels may not be evident during early infancy and can fluctuate independently of the severity of the skin disease. Histologic features of the vesicular and papulopustular lesions include intraepidermal vesicles containing eosinophils, perivascular infiltrates of eosinophils, and an eosinophilic folliculitis similar to that seen in eosinophilic pustular folliculitis[17].

Outside of the neonatal period, hyper-IgE syndrome is associated with "cold" abscesses, eczematous dermatitis, recurrent pneumonias with pneumatocele formation, osteopenia, and retention of deciduous teeth. Mutations in the gene encoding signal transducer and activator of transcription 3 (STAT3) are responsible for the classic form of hyper-IgE syndrome, which is inherited in an autosomal dominant manner[23].

VERY RARE DISORDERS

Neonatal Behçet's Disease

Key features

- Most commonly seen in offspring of mothers with known Behçet's disease
- Favorable outcome for most affected infants
- Transient orogenital ulcerations as well as vesiculopustular, purpuric or necrotic skin lesions presenting during the first week of life
- Differential diagnosis includes neonatal HSV infection

Neonatal Behçet's disease has been described in infants born to mothers with active Behçet's disease during pregnancy (see Ch. 26). Cutaneous findings in neonatal Behçet's disease develop during the first week of life and are transient, suggesting pathogenesis involving placental transfer of maternal immunoglobulin. These infants have been described as having ulcerations of the oral and genital mucosae as well as vesiculopustular, purpuric and necrotic skin lesions on the hands and feet and at sites of trauma. Most infants have no other symptoms, although there are isolated reports of life-threatening disease[24]. Intestinal involvement with colitis has also been observed.

The primary differential diagnosis is neonatal HSV infection (Fig. 34.11), which is differentiated by positive direct fluorescent antibody assays, Tzanck smear, viral culture and polymerase chain reaction (PCR).

Fig. 34.11 Neonatal HSV infection. Note the clustering of the vesicles on an erythematous base.

Vesiculopustular Eruption and Transient Myeloproliferative Disorder in Down Syndrome

Key features

- Neonatal vesiculopustular eruption seen in patients with Down syndrome
- Associated with a congenital leukemoid reaction referred to as transient myeloproliferative disorder
- Skin lesions favor the face but may be more extensive; they usually resolve spontaneously

There are a number of reports of a vesiculopustular eruption in neonates with trisomy 21 or mosaicism for trisomy 21. The eruption typically begins during the first few days of life and is associated with transient myeloproliferative disorder, a congenital leukemoid reaction that affects approximately 10% of neonates with Down syndrome. Vesicles and pustules are located most prominently on the face but may also involve the trunk and extremities. Lesions have a predilection for sites of minor trauma or adhesive dressings. Histologically, intraepidermal spongiotic vesiculopustules are present in association with a perivascular infiltrate. The infiltrating cells include immature myeloid cells, which are usually also present in the peripheral blood.

Although the skin lesions tend to resolve spontaneously as the leukemoid reaction subsides, affected patients are at increased risk for the development of acute megakaryocytic leukemia during the first few years of life and thus should be followed by a pediatric oncologist[25,26].

Intrauterine Epidermal Necrosis

Key features

- Reported in premature infants, all of whom died shortly after birth
- Skin erosions and ulcerations only; there are no vesicles or pustules
- No mucous membrane involvement
- Associated with brain infarcts, cardiomegaly and renal tubular necrosis
- Etiology unknown

Four premature infants were reported to have widespread epidermal necrosis at birth, followed by death shortly thereafter. Erosions and ulcerations were noted, but no vesicles or pustules; the mucous membranes were spared. Histologically, the epidermis demonstrated confluent necrosis and the adnexal pilosebaceous structures were calcified. There were brain infarcts with associated leukomalacia as well as cardiomegaly and renal tubular necrosis. The etiology of the findings remains unknown[27,28]. The differential diagnosis includes intrauterine infection, epidermolysis bullosa, acute GVHD, toxic epidermal necrolysis, and congenital erosive and vesicular dermatosis.

Congenital Erosive and Vesicular Dermatosis

Key features

- Widespread vesicles and erosions with "scalded skin"-like areas
- Heals with characteristic reticulated scarring that is also widespread

At least 18 cases of a condition referred to as "congenital erosive and vesicular dermatosis" have been reported[29,30]. At birth, the neonates – almost all premature – have widespread erosions, vesicles, crusting and

Fig. 34.12 Congenital erosive and vesicular dermatosis. **A,B** Widespread bright red, irregularly shaped erosions on the buttocks, thighs and back of a 2-week-old infant. Note the jagged outline of the healing lesion on the back. **C** Residual supple and reticulate scarring in a 9-month-old child. *A,B, Courtesy, Anthony J Mancini, MD. C, Courtesy, Julie V Schaffer, MD.*

Fig. 34.13 Bullous congenital ichthyosiform erythroderma. Diffuse scaling and a large erosion with scale-crust in a neonate. Histologically, epidermolytic hyperkeratosis was seen.

Fig. 34.14 Staphylococcal scalded skin syndrome. Radiating perioral scale-crusts due to exfoliative toxins.

"scalded skin"-like erythematous areas affecting up to 75% of the body surface area (Fig. 34.12A,B). Reported associated findings include a collodion-like membrane, transparent areas of skin, livedo reticularis-like vascular patterns, and ulcerations. The face, palms and soles are usually relatively spared. The lesions heal in 1 to 2 months with characteristic reticulated scars that often cover large areas of the skin (Fig. 34.12C). Later on, scarring alopecia of the scalp and eyelashes, scarring of the tongue, absent or hypoplastic nails, and heat intolerance with hypohidrosis may be seen; mild ongoing blistering is occasionally observed. Mental retardation, brain atrophy, hemiparesis and retinal scars have also been reported.

The cause of congenital erosive and vesicular dermatosis remains unknown, but an unidentified intrauterine infection has been suspected. The diagnosis is often made in retrospect, after other etiologies (most notably HSV infection) have been excluded. Biopsy specimens from the acute phase have demonstrated epidermal necrosis, subepidermal vesiculation, or an eroded epidermis with a neutrophilic or mixed dermal infiltrate and no evidence of vasculitis or thrombosis. Later in the course, biopsy specimens have shown scar formation with loss of eccrine structures.

For affected neonates, the differential diagnosis may include intrauterine infection (especially HSV and varicella), acute intrauterine GVHD, epidermolysis bullosa, bullous congenital ichthyosiform erythroderma (Fig. 34.13) and intrauterine epidermal necrosis. Infants with congenital erosive and vesicular dermatosis should be followed for evidence of diminished sweating and neurologic defects. Treatment is supportive, with no specific therapy available.

Pyoderma Gangrenosum

Key features

- Rare in newborns and infants
- Deep ulcers with undermined borders
- The perineum is the most common location in infants

Rarely reported in infants and newborns, most cases of pyoderma gangrenosum in this age group involve the perineum. Otherwise, the clinical features of the ulcer, including an undermined violaceous border, are similar to those seen in older children and adults[31]. Biopsy specimens show a neutrophilic infiltrate without evidence of infection, but the diagnosis is often one of exclusion after other causes of ulceration such as infection, immunodeficiency, thrombosis and vasculitis are eliminated. The treatment options vary, but intralesional or systemic corticosteroids are usually first-line choices.

Fig. 34.15 Bullous mastocytosis. A Tense bulla on the wrist and flaccid bullae on the dorsal hand as well as pink plaques on the trunk in a 1-month-old infant. **B** Second infant with erosions and diffuse infiltration of the skin with mast cells, leading to a thickened leathery appearance.

Fig. 34.16 Neonatal pemphigoid gestationis. Vesiculobullous lesions in a neonate whose mother had active pemphigoid gestationis. *Courtesy, Jean L. Bolognia, MD.*

Restrictive Dermopathy

Key features

- Rare, fatal laminopathy due to mutations in *LMNA* or *ZMPSTE24* genes that encode lamin A and a zinc metallopeptidase essential for lamin A processing, respectively
- Taut, shiny skin with spontaneous linear splits in flexural creases and prominent vessels
- Intrauterine growth retardation, abnormal facies, flexion contractures of the extremities, restrictive lung disease, bone mineralization defects, and early neonatal death

Restrictive dermopathy is a rare disease characterized by rigid, tense skin with erosions and linear tears that occur most commonly in flexural creases. The disorder results in a fetal akinesia or hypokinesia deformation sequence characterized by multiple joint contractures, dysmorphic facies with a fixed facial expression, and polyhydramnios with reduced fetal movements; the latter results in premature delivery, often at about 31 weeks' gestation. Other features include translucent skin with prominent vessels, micrognathia, sparse/absent eyelashes, natal teeth, large fontanelles, dysplasia of the clavicles, and poorly expanded lungs as a result of the restrictive skin changes. Most affected newborns die from pulmonary disease within the first week of life. Restrictive dermopathy is now known to be a lethal neonatal laminopathy, caused by either dominant *de novo* mutations in *LMNA*, which encodes lamin A, or recessive null mutations in *ZMPSTE24*, which encodes a zinc metallopeptidase essential for lamin A processing[32].

Noma Neonatorum

Key features

- Usually related to *Pseudomonas aeruginosa* septicemia
- Necrotic ulcerations of orofacial and anogenital regions
- Predisposing factors include premature birth, low birthweight and malnutrition

Two forms of noma have been described in the newborn period. The first is a manifestation of infection, usually *Pseudomonas aeruginosa* septicemia, and has been reported almost exclusively in developing countries[33]. Infants present with an abrupt onset of gangrenous ulcerations of the nose, lips, mouth, eyelids, anus and scrotum. In severe cases, the ulcerations can destroy underlying bony structures and cause extensive deformity. Predisposing factors include premature birth, low birthweight, malnutrition and previous illness. Some authors suggest that this form of noma neonatorum may represent a form of neonatal ecthyma gangrenosum[34].

The second form of noma has been seen in Native American infants who present with perineal and oral ulcerations in the setting of severe combined immunodeficiency[35]. The presence of oral and perineal ulcerations in newborns and infants should prompt an evaluation for infection and immunologic deficiencies.

Perinatal Gangrene of the Buttock

Key features

- Erythema of the buttocks that progresses to ulceration and gangrene
- May be related to occlusion or spasm of the internal iliac artery

This rare condition is characterized by the sudden onset of erythema and cyanosis of the buttocks, followed by progressive development of gangrene and ulcerations. Although some cases have been associated with umbilical artery catheter infusions, others have been spontaneous. Occlusion or spasm of the internal iliac artery has been postulated as a potential cause[36]. Other disorders to consider when evaluating a neonate with hemorrhagic bullae and gangrenous soft tissue infarction include purpura fulminans, congenital coagulopathies (including protein C and S deficiency), and disseminated intravascular coagulation due to infection[3].

Eccrine, apocrine and apoeccrine sweat glands 539
Sebaceous glands 542

ECCRINE, APOCRINE AND APOECCRINE SWEAT GLANDS

Key features

- Eccrine sweat glands are activated by emotional and thermal stimuli and are necessary for thermoregulation; they have a generalized distribution, with the highest density on the palms and soles
- The eccrine secretory unit consists of a coiled secretory portion that drains into a long thin duct whose apical portion (acrosyringium) opens to the skin surface
- Innervation of eccrine glands consists of postganglionic sympathetic fibers that have acetylcholine as the principal neurotransmitter
- Apocrine sweat glands are androgen-dependent for their development and have an unclear function in humans; primary locations are the axillae, anogenital region, periumbilical region and nipples
- Apocrine glands, whose apical portion (acrosyringium) drains into terminal hair follicles, continuously secrete a sterile odorless viscous fluid that is rich in precursors of odoriferous substances

INTRODUCTION

The major sweat glands in humans are eccrine and apocrine glands (Table 35.1)[1,2]. They vary in type and density, depending on anatomic location.

Disorders of sweating are common and can be due to dysfunction of central sweat centers; sympathetic ganglia and their pre- and postganglionic fibers; or secretory glands and ducts[3]. Clinical disorders include hyperhidrosis, hypohidrosis and sweat retention. Hyperhidrosis, which can be emotional or secondary to systemic disease, often leads to social stigmatization. Hypohidrosis and anhidrosis may be markers for genodermatoses (see Ch. 63) and can lead to life-threatening hyperthermia. Sweat retention disorders (i.e. miliaria) are typically transient and often occur after extensive sweating[3]. Knowledge of the structure and function of sweat glands is important for proper diagnosis and treatment of sweating disorders (see Chs 39 & 159).

STRUCTURE, FUNCTION AND PATHOPHYSIOLOGY

In humans, there are two main types of sweat glands: eccrine and apocrine. They are distinct from one another structurally, developmentally and functionally (Fig. 35.1). A third type of sweat gland, the apoeccrine gland, was described in 1987 by Sato et al.[4], who found such glands consistently in the axillae of adults but not children. These apoeccrine sweat glands possessed certain morphologic and functional features of eccrine and apocrine glands[4,5]. However, a recent study that examined serial histologic sections of normal axillary skin using routine and immunofluorescent staining found no evidence of apoeccrine glands[6].

Eccrine Sweat Glands

Structure

Approximately 1.5 to 4 million eccrine sweat glands are distributed over the entire cutaneous surface (with the exception of the external auditory canals, vermilion lips, clitoris and labia minora) and are active from birth. The highest density is found on the palms and soles. The eccrine secretory unit consists of a proximal coiled secretory portion in the lower dermis and subcutaneous tissue. This drains into a long thin duct with an apical portion (acrosyringium) that opens directly onto the skin surface (see Fig. 35.1)[7]. The secretory coils contain two cell types interspersed within a single cell layer: (1) large clear cells responsible for the gland's secretion of electrolytes and water; and (2) dark cells, of unknown function, with basophilic granules that are thought to produce sialomucin (Fig. 35.2). Both cell types are surrounded by myoepithelial cells, which probably function to enhance the delivery of sweat to the skin surface[1,2]. The ductal epithelium is composed of two or more layers of cuboidal cells without surrounding myoepithelium. The intraepidermal portion of the duct, the acrosyringium, is twisted like a corkscrew with similar coils in the stratum corneum[8]. Recent investigations revealed expression of stem cell markers (e.g. prominin-1/CD133) in the secretory and ductal portions of eccrine glands[9].

Innervation of the eccrine glands is provided by postganglionic sympathetic fibers that have acetylcholine (not norepinephrine) as their principal terminal neurotransmitter (Table 35.2). These sympathetic fibers are controlled by the hypothalamic sweat center[8]. The sweat center responds to its own temperature (as a reflection of core body temperature) as well as neural stimuli from the periphery.

Development

During embryogenesis, at 3 months' gestation, sweat glands begin to develop as a cord of epithelial cells that buds from the epidermal ridge on the palms and soles. By 5 months' gestation, similar structures have appeared over the remainder of the body. Functional eccrine glands are present at birth and react to thermal and emotional stimuli. Unlike apocrine glands, they have no developmental relationship with the pilosebaceous follicle[2,8].

Function

Eccrine sweat is a sterile, dilute electrolyte solution that contains primarily sodium chloride (NaCl), potassium and bicarbonate. Other components include antimicrobial peptides (e.g. dermcidin)[11], proteolytic enzymes, glucose, pyruvate, lactate, urea, ammonia, calcium, amino acids, epidermal growth factor, cytokines and immunoglobulins. Additional organic compounds and heavy metals are also excreted in sweat.

The quantity and quality of eccrine sweat secretion varies greatly, depending on emotional and environmental stimuli[1–3]. There are several methods for measuring sweat production (Table 35.3). Under maximal

CHARACTERISTICS OF SWEAT GLANDS			
	Eccrine	**Apocrine**	**Apoeccrine***
Localization	Entire body skin, highest density on palms and soles	Axillae, anogenital, periumbilical, nipples and areolae	Axillae
Morphology	Long, thin duct opens to skin surface	Short, thick duct opens into upper part of follicular canal	Duct comparable to eccrine gland duct
	Secretory coil with narrow lumen	Secretory coil with wide lumen	Secretory coil with dilated and non-dilated tubular segments
Cell types in secretory coil	Large secretory clear cells, dark cells, and myoepithelial cells	Epithelial (typically cuboidal) and myoepithelial cells	Eccrine and apocrine morphologic features
Main innervation/neurotransmitter	Sympathetic fibers/acetylcholine	Unclear/possible humoral effects of β-adrenergic receptor agonists	Sympathetic fibers/acetylcholine
Development	Present at birth	Present at birth	Probably not present before adolescence
	No relationship to pilosebaceous follicle	Associated with terminal hair follicle	No relationship to pilosebaceous follicle
Function/pathogenic role	Thermoregulation/role in hyperhidrosis and hypohidrosis	Unclear/some role in olfactory communication; role in follicular apocrine Fox–Fordyce disease	Unclear/possible roles in thermoregulation, axillary hyperhidrosis and non-follicular apoeccrine Fox–Fordyce disease

*Observed in some but not all studies of normal axillary skin.

stimulation, the body can produce 3 liters in 1 hour. Sweat is formed in two steps[12]: (1) release of nearly isotonic primary sweat by the secretory coil; and (2) partial reabsorption of NaCl by duct cells, resulting in the delivery of a hypotonic fluid to the skin surface. The final concentration of NaCl may be higher when sweat is produced at a more rapid rate.

Continuous secretion of sweat provides a mechanism for thermoregulation via evaporative heat loss, maintenance of electrolyte balance, and keeping the stratum corneum moist to insure fine tactile skills and pliability of the palms and soles[1–3]. The excretory function of the sweat gland can be instrumental in the delivery of systemically administered drugs to the stratum corneum (e.g. ketoconazole and griseofulvin)[13], and it provides an explanation for cutaneous side effects of certain chemotherapeutic drugs. Botulinum toxin can be used to treat eccrine hyperhidrosis. After dermal injection, botulinum toxin taken up by the nerve terminal interferes with proteins required to release acetylcholine at the neuroglandular junction (see Fig. 159.1).

Pathophysiology

Disorders affecting eccrine function involve modifications of sweat quantity or quality; these can be localized (e.g. Frey's syndrome) or

INNERVATION AND RECEPTOR PROFILES OF SWEAT GLANDS		
	Eccrine	**Apocrine**
Nerve fibers near gland	+	±
Cholinergic muscarinic (M_3) receptors	++	±
α_1-adrenergic receptors	+	–
β_2- > β_3-adrenergic receptors	+	+
Purinergic receptors	+	+

Table 35.2 Innervation and receptor profiles of sweat glands. Apoeccrine glands are thought to have the same innervation and receptor profile as eccrine glands. Based on data from ref. 10.

METHODS FOR EVALUATING SWEAT PRODUCTION
• Visualization of sweat by the starch–iodine reaction or quinizarin method • Measurement of electric potential and resistance of the skin • Measurement of skin temperature (e.g. infrared thermography) • Gravimetry (e.g. weighing filter paper before and after application to the skin) • Measurement of evaporative water loss from the skin

Table 35.3 Methods for evaluating sweat production.

Fig. 35.3 Toxic erythema of chemotherapy (palmar erythrodysesthesia). Erythema and blister formation, most notably on the distal portion of the first and second digits and the digital creases (arrows).

generalized (e.g. hypohidrotic ectodermal dysplasia). The sweat glands are also affected in cystic fibrosis (CF). Individuals with CF lose excessive amounts of salt (NaCl) when they sweat, and the most common screening test for CF measures the amount of Cl^- in the sweat.

Hyper- and hypohidrosis

Excess function of eccrine glands is typically due to enhanced cutaneous sympathetic outflow in response to mental and thermal stimuli. The former results primarily in increased sweating of the palms, soles and axillae[14]. This emotional form of hyperhidrosis can be a major inconvenience, but it is not associated with morphologic or functional abnormalities of the glands, nor with internal diseases[2].

Stimulation of eccrine sweat glands may occur in association with a variety of underlying disorders (see Ch. 39), including neurologic, infectious, neoplastic (e.g. lymphomas) and endocrine diseases, in particular the hypoestrogenemia associated with menopause[1,2,4].

Increased sweating can lead to overhydration and even maceration of the skin. This may be accompanied by secondary bacterial and fungal infections (see Chs 74 & 77). Proteolytic activity by resident and transient skin flora (microbiota) can lead to odor-producing substances (e.g. ammonia and short-chain fatty acids); this is referred to as eccrine bromhidrosis.

Hypohidrosis or anhidrosis may be congenital, e.g. due to a reduced number of eccrine glands in patients with hypohidrotic ectodermal dysplasia (see Ch. 63), or acquired, e.g. due to poral occlusion in patients with scleroderma or administration of medications with anticholinergic effects. Acquired or inherited neuropathies also represent another important cause of hypohidrosis[1,2,4].

Drug-related eccrine disorders

Concentration of drugs in the eccrine glands is well known. Drugs known to be secreted into eccrine sweat include chemotherapeutic agents (e.g. cyclophosphamide, cytarabine), antibiotics (e.g. ciprofloxacin, β-lactam antibiotics) and antifungals. In patients receiving chemotherapy, excretion of toxic components into eccrine sweat is thought to play a role in the production of neutrophilic eccrine hidradenitis and other forms of toxic erythema of chemotherapy (Fig. 35.3). Toxic insult to the eccrine ductal cells from chemotherapy leads to the histologic finding of eccrine squamous syringometaplasia (see Ch. 21)[1,2,4,13].

Disorders of sweat retention

Occlusion of the eccrine ducts can result from a parakeratotic plug of PAS-positive material, which then leads to sweat retention. Miliaria may be triggered by a high environmental or body temperature, excessive sweating (especially under occlusive clothing or dressings) and an increased density of resident bacteria, e.g. *Staphylococcus epidermidis*. Ductal plugs within the stratum corneum lead to superficial miliaria (miliaria crystallina), while intraepidermal and dermal duct occlusion induce miliaria rubra and profunda, respectively (see Ch. 39)[15].

Apocrine Sweat Glands

Structure

Apocrine sweat glands are confined to certain anatomic locations (axillae, anogenital region, periumbilical region, areolae, nipples, vermilion border of the lip) and are larger than eccrine glands[1,2]. Modified forms of apocrine glands are found in the external auditory canals (ceruminous glands) and on the eyelid margins (glands of Moll). Apocrine glands consist of a secretory portion, which is located in the deep dermis and subcutaneous fat, and a stretched duct that opens into the upper portion of the follicular canal, i.e., the apocrine acrosyringium (see Fig. 35.1)[1,2]. The secretory unit is a convoluted tube with a single layer of epithelial cells (typically columnar) surrounded by myoepithelial cells. The duct consists of a double layer of cuboidal cells, as well as myoepithelial cells that support the movement of secretions to the skin surface. Although immunohistochemical staining may help to differentiate between apocrine and eccrine sweat glands (e.g. CD15 staining of apocrine but not eccrine secretory cells), the specificity of several markers (e.g. human milk fat globule-1 [HMFG-1], gross cystic disease fluid protein-15 [GCDFP-15]) has been questioned[6,16] and distinction may require serial routine sectioning or electron microscopy[17].

Apocrine gland secretion increases in response to local or systemic administration of catecholamines and cholinergic agonists, but the mechanisms controlling physiologic secretion are poorly understood. In a recent study of normal axillary skin, secretory coils of apocrine glands were found to have β-adrenergic and purinergic but not cholinergic receptors (see Table 35.2)[10]. Nerve fibers were found near eccrine glands but not apocrine glands, suggesting that catecholamines stimulate the latter through humoral mechanisms[10].

Development

Embryologically, the apocrine sweat gland is derived from the primary epithelial germ layer, which also gives rise to the sebaceous gland and hair follicle. In the embryo, apocrine sweat glands are present over the entire skin surface, but most of them subsequently disappear, resulting in the characteristic distribution found in adults. Enlargement of the glands occurs with the approach of puberty and is due to hormonal stimulation (primarily by androgens).

Function

Apocrine glands continuously secrete very small quantities of an oily fluid. This sweat is sterile, odorless and viscous, with a pH between 5.0 and 6.5. It is rich in precursors of odoriferous substances (cholesterol, triglycerides, fatty acids, cholesterol esters, squalene). It also contains androgens, carbohydrates, ammonia and ferric iron. Apocrine or "decapitation" secretion refers to the "pinching off" and release of the luminal portion of secretory cells; apocrine glands also employ merocrine (exocytosis of vesicles) and holocrine (rupture of the plasma membrane) secretion.

In animals, apocrine glands are the source of pheromones, which act as chemical signals that instigate behavioral responses (e.g. sexual attraction) or mark territorial boundaries. In humans, apocrine glands do not have a clear function but may play some role in olfactory communication[1,2].

Pathophysiology

Although apocrine sweat is initially sterile and odorless, bacteria on the skin surface modify and degrade the secreted substances, resulting in typical, rancid (*Corynebacterium* spp.) or sweaty (*Micrococcus* spp.) body odor termed bromhidrosis. When biopsies from bromhidrosis patients have been compared with controls, the apocrine glands were more abundant and larger with active decapitation. These histologic differences may reflect increased production of apocrine sweat and thus may help explain bromhidrosis[18]. Insufficient body and textile hygiene will worsen the condition. Of note, some androgenic steroids have an odor similar to natural axillary odor.

Apocrine chromhidrosis refers to the secretion of pigmented (yellow, green or black) sweat. It is a reflection of the rich lipofuscin content of apocrine sweat. Pseudo- or extrinsic apocrine chromhidrosis results from staining of the sweat by chromogenic bacteria (especially *Corynebacterium* spp.) or colored garments. Occlusion of apocrine ducts by a keratinous plug influenced by functional hormonal changes underlies follicular apocrine miliaria (Fox–Fordyce disease; see Ch. 39).

Apoeccrine Sweat Glands

Structure

Apoeccrine sweat glands have been found only in the adult axilla[19]. As noted above, there are conflicting data about the existence of this third type of sweat gland, with no evidence of axillary apoeccrine glands in a recent study[6]. The secretory coil of apoeccrine sweat glands has been described as consisting of dilated and non-dilated tubular segments[2,4]. The dilated segments and their secretory cells are ultrastructurally very similar to those of apocrine glands, while the non-dilated segments, which are smaller in diameter, resemble eccrine secretory coils. The apoeccrine duct opens directly onto the skin surface and not via follicular structures; it has the same morphologic features as the eccrine gland duct. The innervation of the apoeccrine gland consists of postganglionic sympathetic fibers with acetylcholine as the principal terminal neurotransmitter[2,4] (see Table 35.1). Adrenergic stimulation also occurs.

Development

Apoeccrine sweat glands are thought to develop during puberty from eccrine-like precursor cells and have been identified only in adult axillae[2,4]. The relative percentage of axillary apoeccrine sweat glands has been noted to be higher in patients with hyperhidrosis as compared to normohidrotic individuals.

Function

Apoeccrine sweat is a clear fluid that is secreted persistently after cholinergic stimulation. The constituents of apoeccrine sweat are not known. The secretory rate can be as much as 10 times that of the eccrine gland[2,4].

Pathophysiology

Epidermal or other growth factors in sweat may be involved in stimulating the differentiation of apoeccrine glands[17]. It has been postulated that these glands play an important role in axillary hyperhidrosis[4,5] and non-follicular apoeccrine Fox–Fordyce disease[20].

SEBACEOUS GLANDS

Key features

- Sebaceous glands produce sebum via holocrine secretion and have multiple biological functions, including hormonal and immune modulation
- Except for ectopic or free sebaceous glands of the vermilion lips, orogenital mucosae, areolae and eyelids, these glands are associated with hair follicles
- Sebum consists of free fatty acids, wax and sterol esters, triglycerides and squalene
- Sebum production is a sensitive indicator of androgenic activity; it increases at the time of puberty and decreases in later adulthood (particularly in postmenopausal women)
- Sebaceous follicles are rich in microorganisms including *Malassezia* spp., *Staphylococcus epidermidis* and *Propionibacterium* spp.

INTRODUCTION

Except for the free sebaceous glands found on the vermilion lips and oral mucosa (Fordyce granules), eyelids (meibomian glands), areolae (Montgomery tubercles), labia minora and prepuce (Tyson glands), sebaceous glands are associated with hair follicles. Sebaceous glands produce sebum, which is released into the infundibular portion of the hair follicle. Sebum production increases at the time of puberty and is a critical factor in the pathogenesis of acne vulgaris[21]. Sebaceous glands also play important roles in cutaneous endocrine function (including the hypothalamus–pituitary–adrenal-like axis of the skin as well as androgen metabolism) and innate immunity, producing neuropeptides, androgens, cytokines and antimicrobial peptides that also contribute to acne pathogenesis (Table 35.4).

STRUCTURE, FUNCTION AND PATHOPHYSIOLOGY

Structure

The distribution of sebaceous glands within the skin is variable. However, they are particularly well developed on the scalp, face, upper back and chest. There are three different types of pilosebaceous units: vellus, sebaceous and terminal (Fig. 35.4).

A sebaceous follicle consists of four parts: the keratinized follicular infundibulum, the hair, the cauliflower-like convoluted sebaceous gland, and the sebaceous duct which connects the gland with the infundibulum (Figs 35.1 & 35.5). The infundibulum is divided into two parts. The distal portion, or acroinfundibulum, is very similar to the adjacent epidermis. It displays keratinization with a granular layer, and corneocytes (squames) are shed into the lumen. The lower part, or infrainfundibulum, is quite different. It shows a distinct pattern of trichilemmal keratinization and no granular layer.

Sebaceous follicles have a rich normal flora (resident microbiota) of bacteria (e.g. *S. epidermidis* and *Propionibacterium* spp. such as *P. acnes*) and fungi (e.g. *Malassezia* spp.) (see Fig. 35.5)[22]. They also harbor *Demodex* mites, which increase in number in older adults and are rarely seen in prepubertal children.

Development

Sebaceous glands are derived from the epidermis as buds from developing hair follicle root sheaths and grow downward into the dermis. Sebaceous glands are present at birth, and sebum production is relatively high at this time. It soon declines and remains low until puberty, at which time it again increases. Androgens, in particular 5α-dihydrotestosterone (DHT), appear to be the major factor that controls the development of the glands and the production of sebum. The level of sebum production at the end of puberty remains constant through mid-adulthood. Sebum production declines in women after menopause, and in men during the sixth to seventh decade of life.

Although stem cells in the hair follicle bulge can regenerate sebaceous glands following injury, under homeostatic conditions bulge cells do

ROLES OF THE SEBACEOUS GLAND IN PATHOGENESIS OF ACNE VULGARIS AND ROSACEA		
SG component	**Actions in SGs**	**Observations in SGs of patients with AV and R**
HYPOTHALAMIC–PITUITARY–ADRENAL-LIKE AXIS		
Corticotropin-releasing hormone (CRH)* and CRH receptors (CRH-Rs)	↑ lipid and androgen synthesis ↑ production of IL-6, IL-8 (CRH-R2)	↑ levels of CRH and (in sebaceous ducts) CRH-R1 in **AV**
α-Melanocyte stimulating hormone (MSH)* and melanocortin-1 & -5 receptors (MC1-R, MC5-R†)	↑ sebocyte differentiation and lipid synthesis (MC5-R)	↑ levels of MC1-R in **AV**
OTHER NEUROPEPTIDES		
Substance P	↑ sebocyte proliferation/ differentiation ↑ production of inflammatory cytokines	↑ substance P-containing nerves in **AV**
ANDROGENS		
Testosterone* and dihydrotestosterone (DHT)*	↑sebocyte proliferation/ differentiation and lipid synthesis (especially DHT) May ↑ infundibular keratinization	↑ conversion of testosterone to DHT in **AV** Association of hyperandrogenic disorders with **AV**‡
SEBUM COMPONENTS AND DERIVATIVES		
Monounsaturated fatty acids (MUFAs), lipoperoxides (LPs), other proinflammatory lipids (e.g. generated via 5-lipoxygenase), linoleic acid (LA)	↑ infundibular keratinization (MUFAs, LPs, *deficient* LA) ↑cytokine production, chemotaxis, and PPAR activation (MUFAs, LPs)	↑ overall sebum production, MUFAs and LPs in **AV** ↑ 5-lipoxygenase in **AV** ↓ linoleic acid in **AV**
INNATE IMMUNE SYSTEM		
Toll-like receptors (TLRs, especially TLR2)	Upon stimulation (e.g. by *P. acnes*), ↑production of IL-1, IL-8, IL-12, TNF-α (TLR2)	↑ expression of TLR2 and TLR4 in **AV** Possible ↑ expression of TLR2 in **R**
Defensins, cathelicidins, MUFAs (e.g. sapienic acid)	Antimicrobial properties ↑ cytokine production and chemotaxis	↑ levels of cathelicidin (especially a proteolytically processed form with ↑ proinflammatory and vasoactive effects) in **R**
ORGANISMS		
Propionibacterium acnes§	↑ production of antimicrobial peptides & inflammatory cytokines/ chemokines (e.g. via TLR2 stimulation) ↑ free fatty acids (e.g. via lipase activity) May ↑ infundibular keratinization	↑ *P. acnes* in **AV**
Demodex folliculorum	May stimulate or carry bacteria (e.g. *Bacillus oleronius*) that stimulate innate and adaptive immune reactions	↑ density of *D. folliculorum* and reactivity to *B. oleronius* in **R**

*Can be produced locally by the SG as well as remotely.
†Marker of sebocyte differentiation.
‡Most AV patients have normal levels of circulating androgens.
§Different phylogenetic clusters of *P. acnes* vary in their ability to induce immune responses.

Table 35.4 Roles of the sebaceous gland (SG) in pathogenesis of acne vulgaris (AV) and rosacea (R). IL, interleukin; PPAR, peroxisome proliferator-activated receptor; TNF, tumor necrosis factor.

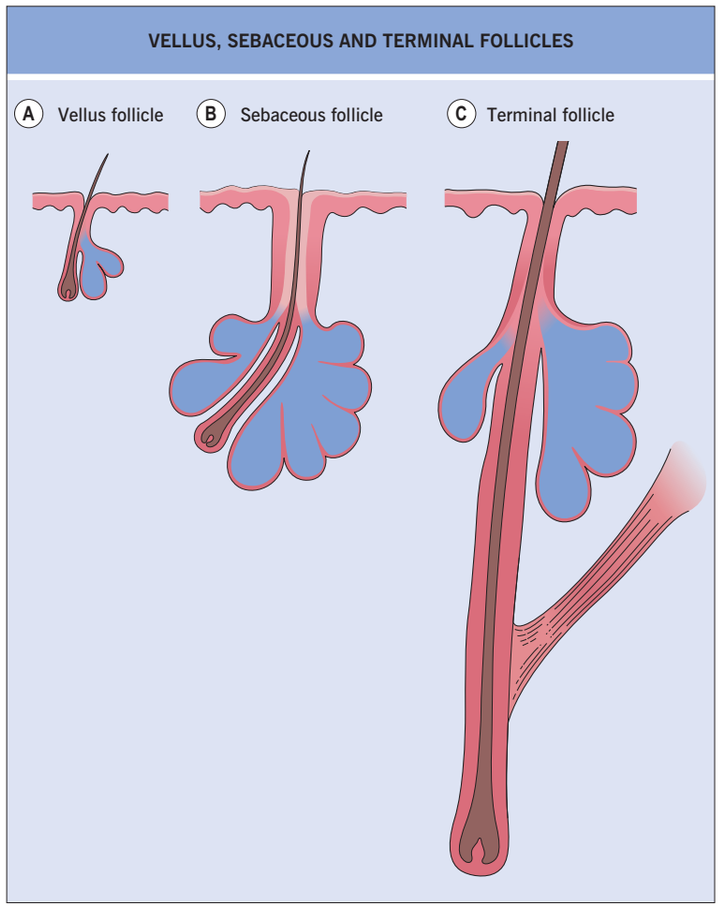

Fig. 35.4 Vellus, sebaceous and terminal follicles. Three different types of pilosebaceous units. **A** Vellus follicle with a small sebaceous gland and short thin hair. **B** Sebaceous follicle with a large multilobular sebaceous gland and mid-sized hair. **C** Terminal follicle with a fairly large sebaceous gland and thicker hair. *Adapted from Plewig G, Kligman AM. Acne and Rosacea, 3rd edn. Berlin: Springer, 2000.*

not appear to contribute to the formation of sebaceous glands[23]. Human sebocytes can differentiate into both sebocytes and interfollicular epidermal cells, suggesting a bipotential stem cell function[21,24]. In cultured human sebocytes and an *in vivo* mouse model, overexpression of c-Myc stimulates *sebaceous* differentiation, whereas overexpression of β-catenin induces *epidermal* differentiation[24]. Expression of the stem cell marker keratin 15 has been observed in human basal sebocytes[23]. Blimp-1 (*B-l*ymphocyte-*i*nduced *m*aturation *p*rotein-1) was found to be a marker for sebocyte progenitor cells in mice, but in humans it is expressed by terminally differentiating cells of the sebaceous gland, hair follicle and interfollicular epidermis[24].

Function

Sebum is a light yellow viscous fluid. It is composed of triglycerides, free fatty acids, squalene, wax and sterol esters, and free sterols. The admixture of ceramides, mostly derived from epidermal lipids, occurs in the acroinfundibulum before the entire sebum mixture reaches the skin surface. Secretion of sebum is holocrine, that is, the sebocytes disintegrate and thereby release their sebum as they migrate towards the central gland and sebaceous duct. Sebocyte turnover time is approximately 14 days, and the flow of sebum is relatively continuous. The amount of sebum produced varies among individuals and races, but the average rate in adults is approximately 1 mg/10 cm^2 every 3 hours[25].

Sebaceous glands contain androgen receptors that bind DHT, which is then translocated to the nucleus[26]. They also express functional receptors for neuropeptides such as corticotropin-releasing hormone (CRH), melanocortins and substance P[21,27]. The latter receptors contribute to proliferation and differentiation of cells in the sebaceous gland (sebocytes) and modulate their production of lipids, androgens and cytokines in response to stimuli such as emotional stress (see Table 35.4).

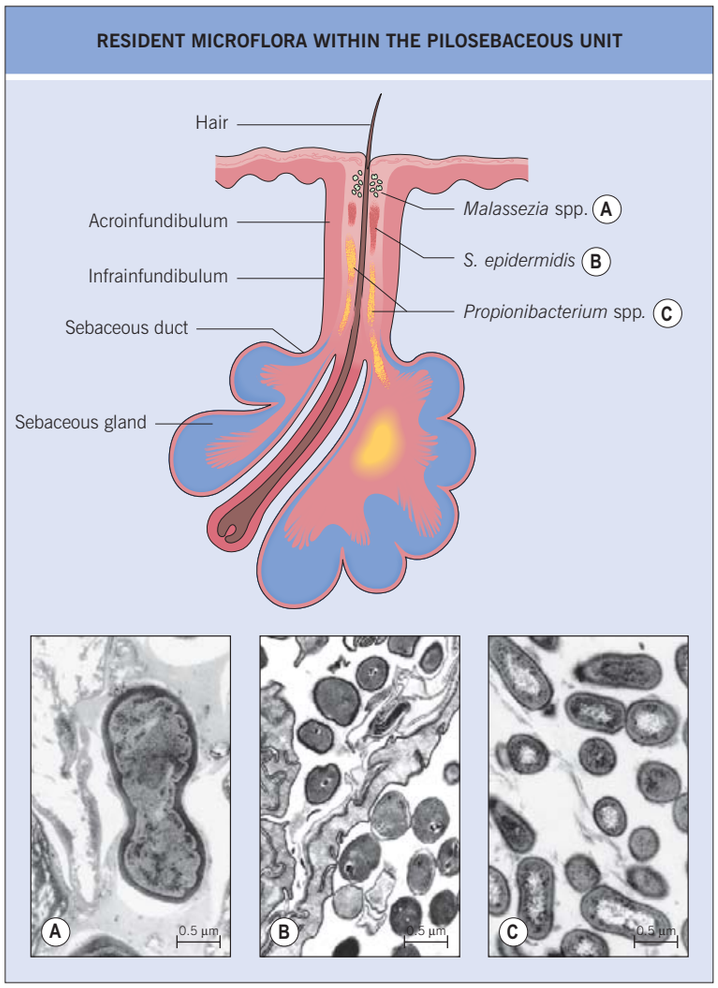

Fig. 35.5 Resident microflora within the pilosebaceous unit. Localization of resident microflora within the pilosebaceous unit and electron microscopic view of organisms: **A** *Malassezia* spp.; **B** *Staphylococcus epidermidis*; **C** *Propionibacterium* spp., including *P. acnes*, *P. granulosum* and (least often) *P. parvum*.

Pathophysiology

Sebum production that is less than 0.5 mg/10 cm^2 every 3 hours is associated with sebostasis or dry skin, and 1.5–4.0 mg/10 cm^2 every 3 hours is considered excessive and results in the clinical condition known as seborrhea. Sebaceous follicles are most commonly found on the face, behind the ears, and on the upper portions of the chest and back – the same distribution as acne vulgaris. Clinically, these areas tend to be oilier than the rest of the body. In general, acne patients have larger sebaceous glands and produce more sebum than do patients with normal skin. The function of sebaceous follicles is influenced by genetic factors and levels of circulating hormones.

Growth of sebaceous glands and increased sebum production are both induced by androgens, particularly DHT. In men, DHT is mainly derived from testosterone, while in women, androstenedione is the main precursor. The conversion of testosterone to DHT is 30 times higher in skin affected by acne than in normal skin. Eunuchs, who lack testicular function, do not get acne. However, increased sebum alone is insufficient to cause acne vulgaris, as witnessed by the fact that patients with Parkinson's disease have marked seborrhea but do not get acne.

Sebaceous glands play several major roles in the pathogenesis of acne vulgaris and may also contribute to the pathogenesis of rosacea (see Table 35.4)[26]. Sebum in sebaceous glands and within the ducts is sterile and contains no free fatty acids, but the microenvironment of the infundibulum favors the growth of *P. acnes* and *S. epidermidis*[28]. In patients with acne vulgaris, the resident microorganisms (especially *P. acnes*) are quantitatively increased in sebaceous follicles. Their lipases split di- and triglycerides, producing free fatty acids that alter the pattern of keratinization within the infundibulum. Abnormal keratinization is one of the first pathogenic steps in acne vulgaris, with increased proliferation and retention of corneocytes in the infundibulum resulting in a microcomedo. Free fatty acids are also chemotactic and attract neutrophils.

The infrainfundibulum of acne patients responds to a variety of physiologic and exogenous stimuli more readily than that in patients without acne. Therefore, comedogenic agents such as halogenated cyclic hydrocarbons, tar products and some cosmetics cause more problems in acne patients than in other individuals[25]. Follicular acneiform eruptions also develop in patients receiving inhibitors of the *e*pidermal growth *f*actor *r*eceptor (EGFR); they occur with antibodies that block the interaction of EGF with its receptor (e.g. cetuximab) as well as with inhibitors of EGFR tyrosine kinase activity (e.g. gefitinib; see Ch. 36). EGFR is strongly expressed in keratinocytes and in cells of eccrine and apocrine glands. Inhibition of the EGFR disturbs the normal differentiation and morphogenesis of hair follicles, inducing excessive follicular hyperkeratosis, follicular plugging, and growth of microorganisms in the dilated infundibula[29].

Acne Vulgaris 36

Andrea L Zaenglein and Diane M Thiboutot

Synonym: ■ Acne

Key features

- A multifactorial disorder of the pilosebaceous unit
- Significant psychologic and economic impact
- Clinically characterized by comedones, papules, pustules, cysts and scarring

INTRODUCTION

Acne vulgaris is a multifactorial disorder of the pilosebaceous unit. The clinical picture can vary significantly, from mild comedonal acne to fulminant systemic disease. Although all age groups may be affected by its many variants, acne is primarily a disorder of adolescence. Acne has an undeniable psychosocial impact, and affected individuals have an increased likelihood of self-consciousness, social isolation, depression and even suicidal ideation[1]. Recent insights into the pathogenesis of acne have aided significantly in further defining the subtypes of acne and establishing effective treatment regimens.

HISTORY

In the sixth century AD, the term "acne" was first used by the Emperor Justinian's physician, Aetius Amidenus. It was later translated from Greek into Latin, and through these translations confusion arose regarding its original meaning[2]. The debate continues as to whether its origin is from the Greek *acme*, meaning peak, or whether acne was actually the original term. Its use became obsolete until the 1800s, when "acne" regained a place in medical dictionaries. In 1842, Erasmus Wilson separated acne simplex (acne vulgaris) from acne rosacea[3].

EPIDEMIOLOGY

Acne vulgaris affects approximately 40–50 million individuals each year in the US alone, leading to an estimated annual cost in the US of at least $2.5 billion. With a peak incidence during adolescence, acne affects approximately 85% of young people between 12 and 24 years of age and is therefore a physiologic occurrence in this group. Although it is typically thought of as a disease of youth, acne often continues to be problematic well into adulthood. In a recent survey-based study, 35% of women and 20% of men reported having acne in their 30s, while 26% of women and 12% of men were still affected in their 40s[4]. Caucasian boys and men have a tendency to have more severe nodulocystic disease than other groups.

Individuals at increased risk for the development of acne include those with an XYY karyotype or endocrine disorders such as polycystic ovarian syndrome, hyperandrogenism, hypercortisolism and precocious puberty. Patients with these conditions tend to have more severe acne that is less responsive to standard therapy.

PATHOGENESIS

The development of acne involves a complex interaction of multiple factors, both internal and external to the pilosebaceous apparatus. Appreciating the anatomy and physiology of this unique structure is vital to understanding the pathogenesis of acne (Fig. 36.1) and essential for formulating effective treatment regimens. The structure and function of sebaceous glands are reviewed in detail in Chapter 35, and Table 35.4 summarizes their roles in acne.

Genetic Factors

The pathogenesis of acne is multifactorial, and the precise role of genetic predisposition is uncertain. The number, size and activity of sebaceous glands is inherited. In addition, the concordance rate for the prevalence and severity of acne among identical twins is extremely high. It is a widely held belief that acne (including nodulocystic acne) runs in families, and an association between moderate to severe acne and a family history of acne has been observed in several studies[5]. However, because of the extremely high prevalence of acne, it is difficult to attribute its presence exclusively to genetic factors.

Sebum Production

The sebaceous gland is controlled primarily by hormonal stimulation (see below). After the first 6 months of life (when sebum production is relatively high), the rate decreases and remains stable throughout childhood. At adrenarche, sebum production dramatically increases. Although the overall composition of sebum is the same in persons with or without acne, those with acne have variable seborrhea[6].

Comedo Formation

One of the first steps in the production of acne is the formation of the microcomedo. This begins in the keratinized lining of the upper portion of the follicle, the infundibulum (Fig. 36.1A). Comedo formation occurs when the corneocytes, which are normally shed into the lumen of the follicle and extruded through the follicular ostium, are retained and accumulate, leading to hyperkeratosis. Increased cohesiveness of these cells is responsible for this phenomenon. The ultrastructural components of the cell that are responsible for adhesiveness all play a role, including lamellar granules, cell membranes, epidermal lipids, and intercellular cementing substances.

In addition to increased intercellular cohesiveness of the corneocytes, their production is accelerated as well. This combination of increased cellular cohesion and proliferation occurs in the proximal portion of the infundibulum, the infrainfundibulum, and it creates a bottleneck phenomenon and subsequent microcomedo formation. In the underlying follicular epithelium, keratohyaline granules are increased in size and number, whereas lamellar granules and tonofilaments are decreased.

As the comedo expands, the sebaceous lobule undergoes regression (Fig. 36.1B,C). Because of the very narrow opening to the skin surface, there is initially an accumulation of loosely packed shed keratinocytes and sebum. With expansion of the comedo, the contents become closely packed, creating whorled lamellar concretions. As the forces increase, rupture of the comedo wall with extrusion of the immunogenic keratin and sebum occurs, with resultant inflammation (Fig. 36.1C,D).

Inflammatory Responses

Inflammation is not only the result of comedo rupture, as it is also seen early in acne lesion formation. For example, in acne-prone sites, the number of $CD4^+$ T cells and levels of interleukin-1 (IL-1) have been shown to be increased perifollicularly prior to hyperkeratinization[7]. The type of inflammatory response determines the clinical lesion seen. If neutrophils predominate (typical of early lesions), a suppurative pustule is formed. Neutrophils also promote the inflammatory response by releasing lysosomal enzymes and generating reactive oxygen species, and levels of the latter in the skin and plasma may correspond with

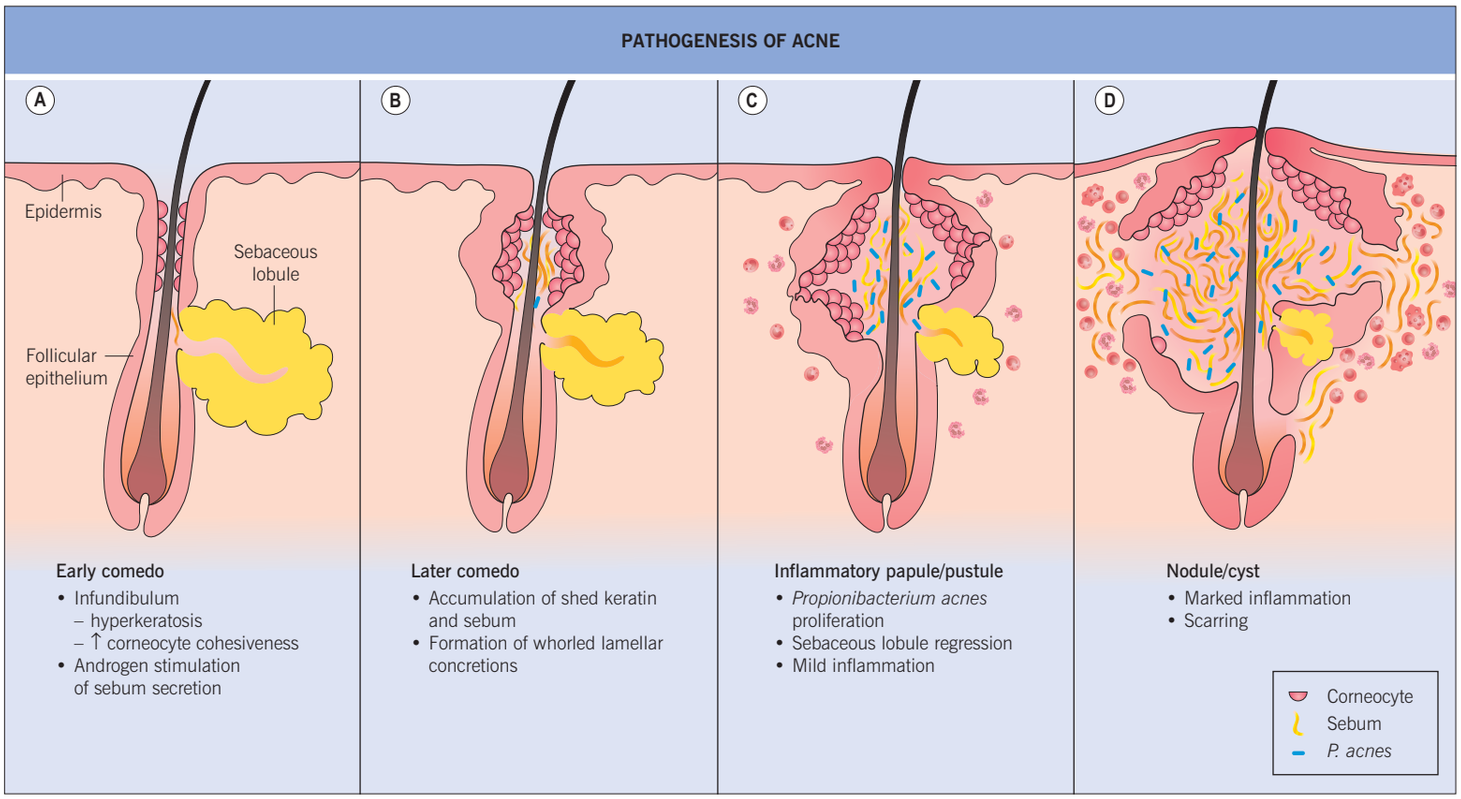

Fig. 36.1 Pathogenesis of acne.

acne severity[8]. Influx of lymphocytes (predominately T-helper [Th] cells) and foreign body-type giant cells, in addition to neutrophils, results in inflamed papules, nodules and cysts. The type of inflammatory response also plays a role in the development of scarring. Early, nonspecific inflammation results in less scarring than does a delayed, specific inflammatory response[9].

Propionibacterium acnes and the Innate Immune System

Propionibacterium acnes contributes significantly to the pathogenesis of acne. These Gram-positive, non-motile rods are found deep within the sebaceous follicle, along with *P. granulosum* and, rarely, *P. parvum*. They are anaerobic/microaerophilic and naturally produce porphyrins (primarily coproporphyrin III) that fluoresce with Wood's lamp illumination. The pathogenicity of these microorganisms stems from several of their properties, including the release of enzymes that contribute to comedo rupture, lipases and chemotactic factors, as well as stimulation of a host response (by inflammatory cells and keratinocytes) that involves production of proinflammatory mediators and reactive oxygen species. Increased numbers of *P. acnes* have been reported in acne patients, but their numbers do not correlate with clinical severity[10]. Different strains of *P. acnes* have been shown to induce varying degrees of sebocyte differentiation and proinflammatory cytokine/chemokine reponses[11].

Interactions between the skin's innate immune system and *P. acnes* play an important role in acne pathogenesis. One mechanism is via Toll-like receptors (TLRs), a class of transmembrane receptors that mediates the recognition of microbial pathogens by immune cells such as monocytes, macrophages and neutrophils as well as by keratinocytes (see Ch. 4). TLR2 (which recognizes lipoproteins and peptidoglycans) is found on the surface of macrophages surrounding acne follicles, and *P. acnes* has been found to increase expression of TLR2 and TLR4 on keratinocytes. *P. acnes* has been shown to stimulate the release of proinflammatory mediators (e.g. IL-1α, IL-8, IL-12, tumor necrosis factor-α [TNF-α], matrix metalloproteinases) through the TLR2 pathway[12–14]. IL-8 results in neutrophil recruitment, the release of lysosomal enzymes and subsequent disruption of the follicular epithelium, whereas IL-12 promotes Th1 responses (see Ch. 4). The degree to which IL-8, IL-12 and interferon-γ production is augmented does not appear to depend upon the strain of *P. acnes* that is present[14,15].

In contrast, certain strains of *P. acnes* may have an increased propensity to upregulate expression of human β-defensin-2 by the pilosebaceous unit via a TLR-dependent mechanism[14,16]. Beta-defensin-2 (production of which is also augmented by sebum free fatty acids), cathelicidins (expressed by sebocytes with upregulation by *P. acnes*), and other antimicrobial peptides such as psoriasin (see Ch. 4) work synergistically to protect the pilosebaceous unit from *P. acnes*[17,18]. Histone H4, which is secreted in a holocrine manner by sebocytes, also directly kills *P. acnes* and may function together with free fatty acids to augment innate immune defenses[19]. Lastly, *P. acnes* can induce monocytes to differentiate into two distinct innate immune cell subsets: (1) $CD209^+$ macrophages (development of which is promoted by tretinoin) that more effectively phagocytose and kill *P. acnes*; and (2) $CD1b^+$ dendritic cells that activate T cells and release proinflammatory cytokines[20].

Hormonal Influences

Hormonal effects on sebum secretion are key to the pathogenesis of acne. Androgens are produced both outside the sebaceous unit, primarily from the gonads and adrenal glands, and locally within the gland via the action of androgen-metabolizing enzymes such as 3β-hydroxysteroid dehydrogenase (HSD), 17β-HSD and 5α-reductase (Fig. 36.2). Androgen receptors, found in the cells of the basal layer of the sebaceous gland and the outer root sheath of the hair follicle, are responsive to testosterone and 5α-dihydrotestosterone (DHT), the most potent androgens. DHT has a 5–10-fold greater affinity than testosterone for the androgen receptor and is thought to be the principal androgen mediating sebum production.

The role of androgens in sebaceous gland activity begins during the neonatal period. From birth until approximately 6–12 months of age, infant boys have elevated levels of luteinizing hormone (LH), which stimulates testicular production of testosterone. In addition, both male and female infants exhibit increased levels of dehydroepiandrosterone (DHEA) and DHEA sulfate (DHEAS) secondary to a large, androgen-producing "fetal zone" in the adrenal gland that involutes over the first

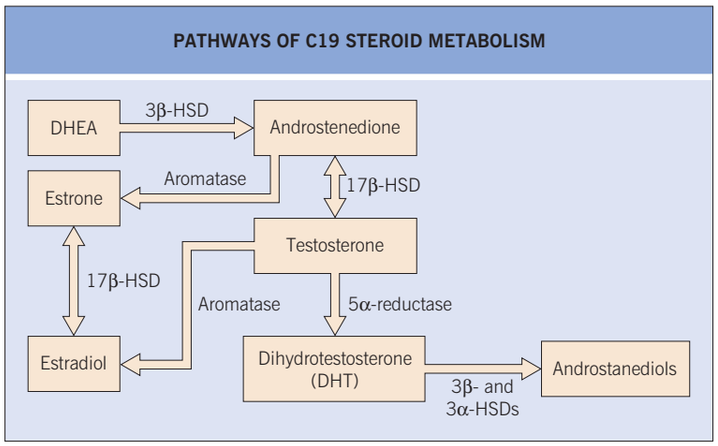

Fig. 36.2 Pathways of C19 steroid metabolism. Dehydroepiandrosterone (DHEA) is a weak androgen that is converted to the more potent testosterone by 3β-hydroxysteroid dehydrogenase (HSD) and 17β-HSD. 5α-reductase then converts testosterone to dihydrotestosterone (DHT), the predominant hormonal effector on the sebaceous gland. Both DHEA and testosterone can be metabolized to estrogens by the enzyme aromatase. The sebaceous gland expresses each of these enzymes.

Fig. 36.3 Comedonal acne vulgaris. On the cheek, there are open and closed comedones as well as postinflammatory hyperpigmentation.

year of life. Of note, sebaceous gland activity in infants is not due to persistent maternal hormonal stimulation, as was previously hypothesized. Both testicular and adrenal androgen production decrease substantially by 1 year of age and remain at a stable nadir until adrenarche.

With the onset of adrenarche (typically at 7–8 years of age, usually heralding menarche by several years), circulating levels of DHEAS begin to rise due to adrenal production. This hormone can serve as a precursor for the synthesis of more potent androgens within the sebaceous gland (see Fig. 36.2). The rise in serum levels of DHEAS in prepubescent children is associated with an increase in sebum production and the initial development of comedonal acne[21].

Little is known about the physiologic role of estrogens in modulating sebum production. Any estrogen given systemically in sufficient amounts will decrease sebum production. However, the dose of estrogen required to suppress sebum production is greater than the dose required to suppress ovulation. Although acne may respond to treatment with lower-dose oral contraceptives containing 0.035–0.050 mg of ethinyl estradiol or its esters, higher doses of estrogen are often required to demonstrate a reduction in sebum secretion[22]. As with androgens, it is not known whether circulating estrogens or locally produced estrogens are important in modulating sebum secretion. Estrogens may act by several mechanisms, including:

- directly opposing the effects of androgens locally within the sebaceous gland
- inhibiting the production of androgens by gonadal tissue via a negative feedback loop whereby pituitary gonadotropin release is inhibited
- regulating genes that negatively influence sebaceous gland growth or lipid production.

Dietary Factors

The relationship between diet and acne remains a subject of controversy. Over the past decade, observational studies have found that milk intake (especially skim milk) is positively associated with acne prevalence and severity, and prospective studies have documented a link between a high glycemic-load diet and acne risk[23].

CLINICAL FEATURES

Acne is typically found in sites with well-developed sebaceous glands, most often the face and upper trunk. Non-inflammatory acne is characterized by open and closed comedones (Fig. 36.3). The histologic features of these follicular-based lesions are reflected in their clinical appearance. Closed comedones (whiteheads) are generally small (~1 mm), skin-colored papules with no apparent follicular opening or associated erythema. These lesions may be subtle and better appreciated upon palpation, stretching or side-lighting of the skin (Fig. 36.4). In contrast, open comedones (blackheads) are dome-shaped papules with a conspicuous dilated follicular opening that is filled with an inspissated core of shed keratin (Fig. 36.5). Melanin deposition and lipid oxidation within the debris may be responsible for the black coloration. "Ice-pick"-type scarring sometimes results from comedones alone.

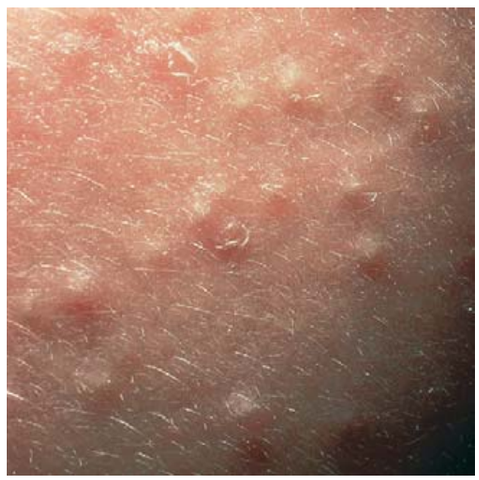

Fig. 36.4 Closed comedones highlighted by side lighting. *Courtesy, Ronald P Rapini, MD.*

Inflammatory acne also originates with (micro)comedo formation, followed by the development of papules, pustules, nodules and cysts of varying severity (Figs 36.6 & 36.7). Erythematous papules typically range from 1 to 5 mm in diameter. Pustules tend to be approximately equal in size and are filled with white pus and normal flora. As the severity of lesions progresses, nodules form and become markedly inflamed, indurated and tender. The cysts of acne are deeper and filled with a combination of pus and serosanguineous fluid. In patients with severe nodulocystic acne, these lesions frequently coalesce to form large, complex inflamed plaques that can include sinus tracts.

Early treatment of acne is essential for the prevention of lasting cosmetic disfigurement due to scarring. Erythema and postinflammatory hyperpigmentation (Fig. 36.8) often persist after resolution of inflammatory acne lesions. Although the pigmentary changes usually fade over many months if the acne is brought under control, occasionally

Fig. 36.5 Open comedones in a patient with scarring cystic acne.

Fig. 36.7 Severe cystic acne. This form is best treated with low doses of isotretinoin initially, to avoid precipitating a flare.

Fig. 36.6 Inflammatory acne vulgaris. Papules, obvious pustules, and atrophic scars are present.

Fig. 36.8 Postinflammatory hyperpigmentation secondary to acne. Such pigmentary changes are most common in patients with darker skin colors.

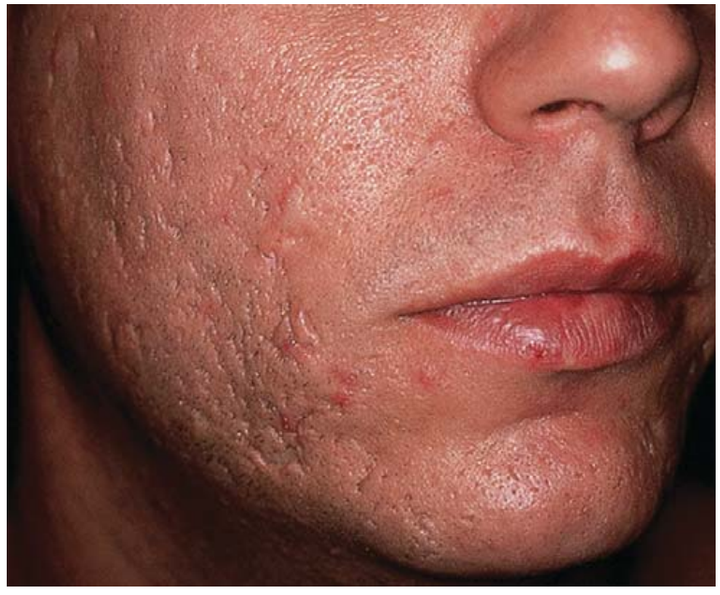

Fig. 36.9 "Ice-pick" scarring secondary to acne.

they can be permanent. Unfortunately, pitted scars (Fig. 36.9) or hypertrophic scars (most commonly on the trunk; see Fig. 98.5) are often sequelae of nodulocystic acne.

Acne Variants

Post-adolescent acne

Inflammatory acne persisting beyond 25 years of age is most common in women, tends to flare during the week prior to menstruation, and typically features tender, deep-seated papulonodules on the lower third of the face, jawline and neck[24]. Approximately one-third of affected women have other signs of hyperandrogenism (see below), but regardless of androgen levels, hormonal therapy is often effective. A predominantly comedonal, adult-onset form of acne that is associated with smoking has also been described[24].

Acne fulminans

Acne fulminans is the most severe form of acne and is characterized by the abrupt development of nodular and suppurative acne lesions in association with systemic manifestations. This uncommon variant primarily affects boys 13–16 years of age. Patients typically have mild to moderate acne prior to the onset of acne fulminans, when numerous microcomedones suddenly erupt and become markedly inflamed. There is rapid coalescence into painful, oozing, friable plaques with hemorrhagic crusts (Fig. 36.10). The face, neck, chest, back and arms are all affected. Lesions tend to ulcerate and can lead to significant scarring.

Osteolytic bone lesions may accompany the cutaneous findings; the clavicle and sternum are most commonly affected, followed by the ankles, humerus and iliosacral joints. Systemic manifestations include fever, arthralgias, myalgias, hepatosplenomegaly and severe malaise. The related *s*ynovitis, *a*cne, *p*ustulosis, *h*yperostosis and *o*steitis (SAPHO) syndrome, which can present with acne fulminans, is discussed in detail in Chapter 26. Erythema nodosum may also arise in association with acne fulminans. Laboratory abnormalities vary and include an elevated ESR, proteinuria, leukocytosis and anemia. Labora-

Fig. 36.11 Solid facial edema due to acne vulgaris. There is soft tissue swelling in the central portion of the face.

tory studies are not required to establish the diagnosis, but their evolution may parallel the clinical course and response to therapy.

Treatment of acne fulminans usually includes oral corticosteroids and oral isotretinoin, often with initiation of the latter at a low dose and/or after the acute inflammation subsides. Paradoxically, an acne fulminans-like flare occasionally develops during the first few weeks of isotretinoin therapy for acne[25], and this may be avoided by starting with a low dose of isotretinoin (see Ch. 126). Additional treatment options for acne fulminans include topical or intralesional corticosteroids, oral antibiotics (generally of limited efficacy), TNF-α inhibitors and immunosuppressive agents (e.g. azathioprine). Dapsone may be particularly beneficial in the treatment of acne fulminans associated with erythema nodosum[26].

Acne conglobata and associated conditions

Acne conglobata is a severe form of nodulocystic acne that may have an eruptive onset but without systemic manifestations. This recalcitrant acne variant is part of the follicular occlusion tetrad, along with dissecting cellulitis of the scalp, hidradenitis suppurativa and pilonidal cysts (see Ch. 38).

The association of sterile *p*yogenic *a*rthritis, *p*yoderma gangrenosum, and *a*cne conglobata can occur in the context of an autosomal dominant autoinflammatory disorder referred to as PAPA syndrome, which is caused by mutations in the gene that encodes *p*roline–*s*erine–*t*hreonine *p*hosphatase *i*nteracting *p*rotein 1 (PSTPIP1; also known as CD2 antigen-binding protein 1 [CD2BP1])[27]. Dysfunction of CD2BP1, which has a role in actin reorganization and interacts with the pyrin protein (defective in familial Mediterranean fever), compromises the physiologic signaling required for maintenance of a proper inflammatory response. The triad of acne conglobata, hidradenitis suppurativa and pyoderma gangrenosum has also been described outside the setting of PAPA syndrome[27a]. Of note, a possible association between nodulocystic acne and inflammatory bowel disease may potentially confound links that have been observed between the latter disorder and acne therapies such as tetracyclines and isotretinoin[27,27b].

Solid facial edema

An unusual and disfiguring complication of acne vulgaris is solid facial edema (Morbihan's disease). Clinically, there is a distortion of the midline face and cheeks due to soft tissue swelling (Fig. 36.11). The woody induration may be accompanied by erythema. Impaired lymphatic drainage and fibrosis (potentially induced by mast cells) in the setting of chronic inflammation are thought to be involved in the pathogenesis of solid facial edema, and a report of its occurrence in identical twins with acne suggests that genetic factors may also have a role. Similar changes have been described in patients with rosacea and Melkersson–Rosenthal syndrome (see Table 36.2). Although fluctuations in severity are common, solid facial edema does not usually resolve spontaneously. Treatment with isotretinoin (0.2–1 mg/kg/day), alone or in combination with ketotifen (1–2 mg/day; not available in the US) or prednisone (10–30 mg/day), for 4–5 months has been reported to be useful[28,29].

Acne mechanica

Acne mechanica occurs secondary to repeated mechanical and frictional obstruction of the pilosebaceous outlet. Comedo formation is the result. Well-described mechanical factors include rubbing by helmets, chin straps, suspenders and collars. A classic example of acne mechanica is fiddler's neck, where repetitive trauma from violin placement on the lateral neck results in a well-defined lichenified, hyperpigmented plaque interspersed with comedones. Linear and geometrically distributed areas of involvement should suggest acne mechanica. Treatment is aimed at eliminating the inciting forces.

Acne excoriée des jeunes filles

Acne excoriée des jeunes filles, as the name implies, occurs primarily in young women. Typical comedones and inflammatory papules are systematically excoriated in a ritualistic manner, leaving crusted erosions that may scar (see Ch. 7). Linear erosions suggest self-manipulation, and an underlying psychiatric component should be considered. Individuals with an anxiety disorder, obsessive–compulsive disorder or personality disorder are particularly at risk. Antidepressants or psychotherapy may be indicated in such patients.

Drug-induced acne

Acne or eruptive acneiform lesions can be seen as a side effect of a number of medications (Table 36.1). An abrupt, monomorphous eruption of inflammatory papules and pustules is often observed in drug-induced acne (Figs 36.12 & 36.13), in contrast to the heterogeneous morphology of lesions seen in acne vulgaris. This explains why some clinicians use the term "folliculitis".

High-dose intravenous or oral corticosteroids commonly induce characteristic acneiform eruptions with a concentration of lesions on the chest and back (see Fig. 36.12). Steroid-induced acne (and rosacea) can also result from the inappropriate use of topical corticosteroids on the face. Inflamed papules and pustules develop on a background of erythema that favors the distribution of corticosteroid application. Lesions eventually resolve following discontinuation of the corticosteroid, although "steroid dependency" can lead to prolonged and severe flares post-withdrawal (see Ch. 37). When a history of prescription medication use is not elicited, a comprehensive review of all over-the-counter medications and supplements, as well as recent medical procedures, may reveal the responsible agent (see Table 36.1).

CAUSES OF DRUG-INDUCED ACNE	
Common	**Uncommon**
• Anabolic steroids (danazol, testosterone) • Bromides* • Corticosteroids (see Fig. 36.12) • Corticotropin • EGFR inhibitors (see Fig. 36.16) • Iodides† • Isoniazid (see Fig. 36.13) • Lithium • Phenytoin • Progestins (see text)	• Azathioprine • Cyclosporine • Disulfiram • Phenobarbital • Propylthiouracil • Psoralen + ultraviolet A • IQuinidine • Vitamins B_6 and B_{12}
*Found in sedatives, analgesics and cold remedies. †Found in contrast dyes, cold/asthma remedies, kelp and combined vitamin–mineral supplements.	

Table 36.1 Causes of drug-induced acne. EGFR, epidermal growth factor receptor.

Fig. 36.12 Acneiform eruption secondary to high-dose dexamethasone. Abrupt eruption of monomorphous follicular papules and pustules on the trunk.

Occupational acne, acne cosmetica and pomade acne

Exposure to insoluble, follicle-occluding substances in the workplace is responsible for occupational acne (see Ch. 16). Offending agents include cutting oils, petroleum-based products, chlorinated aromatic hydrocarbons, and coal tar derivatives. Comedones dominate the clinical picture, with varying numbers of papules, pustules and cystic lesions distributed in exposed as well as typically covered areas. Primarily comedonal facial acne (with a predominance of closed comedones) can also develop in areas of skin chronically exposed to follicle-occluding cosmetics (*acne cosmetica*) or hair products (*pomade acne*; favors forehead and temples).

Chloracne

Chloracne, the term used to define occupational acne caused by exposure to chlorinated aromatic hydrocarbons, develops after several weeks of exposure. The malar, retroauricular and mandibular regions of the head and neck (see Fig 16.13), as well as the axillae and scrotum, are most commonly afflicted with small cystic papules and nodules. The extremities, buttocks and trunk are variably involved. Cystic lesions can heal with significant scarring, and recurrent outbreaks may occur for many years following exposure. The following agents, found in electrical conductors and insulators, insecticides, fungicides, herbicides and wood preservatives, have all been implicated: polychlorinated naphthalenes, biphenyls, dibenzofurans and dibenzodioxins; polybrominated naphthalenes and biphenyls; tetrachloroazobenzene; and tetrachloroazoxybenzene.

Prevention of exposure is integral to the safety of at-risk employees. Initial management is aimed at vigorous removal of chemical agents at the time of exposure. Topical or oral retinoids and oral antibiotics may be beneficial therapeutic interventions.

Neonatal acne (neonatal cephalic pustulosis)

Neonatal acne occurs in more than 20% of healthy newborns (see Ch. 34). Lesions usually appear at about 2 weeks of age and generally resolve within the first 3 months of life. Small, inflamed papulopustules (but typically not comedones) arise primarily on the cheeks and nasal bridge, but the forehead, chin, neck and upper trunk can also be involved (see Fig. 34.5).

The pathogenesis of neonatal acne has been the subject of debate. An inflammatory response to *Malassezia* spp. (e.g. *sympodialis, furfur*) has been proposed as the etiology by some investigators, leading to renaming of the disorder as "neonatal cephalic pustulosis". Additional support for this view comes from the clinical response to treatment with topical imidazoles (e.g. ketoconazole 2% cream). The active sebaceous glands and high sebum excretion rate in neonates (see Pathogenesis) are also thought to play a role. The substantial decline in sebum production after the first few months of life helps to explain the limited period of susceptibility to neonatal acne. Given the transient and benign nature of this eruption, parental reassurance alone is usually adequate. However, as noted previously, therapy with topical imidazoles can be effective.

Infantile acne

If acne presents at 3–12 months of age (occasionally as late as 18–24 months), it is classified as infantile (Fig. 36.14). In contrast to neonatal acne, comedo formation is prominent and pitted scarring can develop. Deep cystic lesions and suppurative nodules are occasionally seen. The pathogenesis of infantile acne reflects the androgen production intrinsic to this stage of development (see Pathogenesis), including elevated levels of LH stimulating testicular production of testosterone in boys during the first 6–12 months of life (with levels transiently equivalent to those during puberty) and elevated levels of DHEA produced by the infantile adrenal gland in both boys and girls. These androgen levels normally decrease substantially by 12 months of age and remain at nadir levels until adrenarche.

Infantile acne typically resolves within 1–2 years and remains quiescent until around puberty. In unusual cases, however, infantile-onset acne may persist into adolescence. Topical retinoids (e.g. tretinoin, adapalene) and benzoyl peroxide are first-line treatments for infantile acne. Oral antibiotics (e.g. erythromycin, azithromycin) can be helpful for patients with a more severe inflammatory component, and

Fig. 36.14 Infantile acne. Presentations can range from scattered papulopustules (**A**) to multiple coalescing papulonodules and inflammatory cysts (**B**). If the latter child failed to improve with a topical retinoid plus an oral antibiotic, consideration would be given to oral isotretinoin. *Courtesy, Kalman Watsky, MD.*

isotretinoin is occasionally required for recalcitrant or nodulocystic presentations[30].

Endocrinologic abnormalities

Although most patients with acne do not have overt endocrinologic abnormalities, hyperandrogenism should be suspected in female patients with hirsutism (see Ch. 70) or irregular menstrual periods, as well as in children who develop acne between 2 and 7 years of age. Acne in such patients is often severe or more difficult to treat, and the onset can be fairly abrupt. Other signs and symptoms of hyperandrogenism in women and children include coarsening of the voice, a muscular habitus, androgenetic alopecia, clitoromegaly with variable posterior labial fusion, and increased libido. *I*nsulin *r*esistance and *a*canthosis *n*igricans can occur in association with *h*yper*a*ndrogenism in the HAIR-AN syndrome. These patients are at increased risk for accelerated cardiovascular disease and diabetes mellitus, and they should be followed by appropriate medical specialists.

The evaluation of patients suspected of having hyperandrogenism includes a thorough history and physical examination; the age of the patient and pubertal status are also important parameters. Prepubertal boys and girls and postpubertal women with signs of hyperandrogenism should undergo appropriate evaluation. Laboratory studies should not be performed while the patient is taking oral contraceptives. Initial tests should include serum levels of total and free testosterone, DHEAS, and 17-hydroxyprogesterone. Patients with clinical signs and symptoms suggestive of hypercortisolism should also have an AM serum cortisol level, and X-rays of the hand and wrist to evaluate bone age should be obtained in prepubertal children.

Understanding pathways of hormone production is essential in the evaluation of hyperandrogenic states (see Fig. 70.15). For example, an elevated serum DHEAS or 17-hydroxyprogesterone level indicates an adrenal source of excess androgen production. The degree to which levels of these hormones are increased is then useful in discerning an etiology. DHEAS values in the range of 4000–8000 ng/ml or 17-hydroxyprogesterone levels >3 ng/ml may be indicative of congenital adrenal hyperplasia. Defects in adrenal enzymes, most commonly 21-hydroxylase or (less often) 11-hydroxylase, lead to this condition. Patients with severe deficiencies of these enzymes become symptomatic during infancy, whereas those with partial deficiencies present in adolescence. If the serum DHEAS is >8000 ng/ml, with or without an elevated testosterone level, an adrenal tumor should be suspected.

If the testosterone levels (total and free) are elevated and the DHEAS level is relatively normal, an ovarian source is likely. Polycystic ovary syndrome (PCOS) is the most common condition associated with an elevated serum testosterone, with levels typically ranging from 100 to 200 ng/dl. An increased LH/FSH ratio (>2–3) is also commonly observed. Symptoms of PCOS include irregular menstrual periods, hirsutism, obesity, insulin resistance and reduced fertility (see Fig. 70.11). When levels of serum testosterone exceed 200 ng/dl, an ovarian tumor should be considered.

Apert syndrome

Also known as acrocephalosyndactyly type I, Apert syndrome is an autosomal dominant disorder that features disfiguring synostoses of the bones of the hands and feet, vertebral bodies and cranium. Affected individuals have an increased incidence of severe (frequently nodulocystic), early-onset acne with a more widespread distribution than in classic acne, often involving the entire extensor aspects of the arms, buttocks and thighs[31]. Acne in patients with Apert syndrome also tends to be highly resistant to therapy, although isotretinoin has been reported to be beneficial. Other cutaneous findings in this disorder can include marked seborrhea, nail anomalies (e.g. a single nail for the second through fourth digits), and diffuse pigmentary dilution of the hair and skin. Of note, Apert syndrome results from *activating* mutations in the *FGFR2* gene, which encodes fibroblast growth factor receptor 2; mosaicism for the same *FGFR2* mutations has been found to underlie acneiform/comedonal nevi (see Ch. 62). FGFR2 signaling has been shown to have effects on follicular keratinocyte proliferation, sebaceous lipogenesis and inflammatory cytokine production, and it may be associated with a nuclear deficiency of the forkhead box O1 (FoxO1) transcription factor.

Acneiform Eruptions

Epidermal growth factor receptor inhibitor-induced papulopustular eruption

Inhibitors of *e*pidermal *g*rowth *f*actor *r*eceptor (EGFR/HER1) signaling represent an expanding class of therapeutic agents currently being used for the treatment of solid tumors, including head and neck squamous cell carcinoma and lung, colon and breast carcinoma. Inhibitors include gefitinib, cetuximab, erlotinib, lapatinib and panitumumab, with a number of tyrosine kinase inhibitors and monoclonal antibodies in clinical trials or under development (Fig. 36.15). The incidence of acneiform eruptions due to EGFR inhibitors is very high, e.g. up to 95% of patients treated with panitumumab; additional cutaneous side effects of these agents are presented in Table 21.14. In some studies, the presence or severity of the acneiform eruption had a positive correlation with treatment outcomes (e.g. response rate and survival time).

Patients present with an eruption of monomorphous follicular pustules and papules involving the face, scalp and upper trunk, usually 1–3 weeks after beginning treatment with an EGFR inhibitor (Fig 36.16). Secondary infection with *Staphylococcus aureus* often occurs, with oozing and the formation of honey-colored crusts. While frequently described as acneiform, histopathology reveals a pattern of folliculitis, with intrafollicular collections of neutrophils and perifollicular lymphocytes. No comedonal lesions are seen either microscopically or clinically, further differentiating this eruption from acne vulgaris.

In the oncology patient, the differential diagnosis includes corticosteroid-induced acne, various forms of folliculitis (e.g. *Pityrosporum, Demodex* spp.), neutrophilic eccrine hidradenitis and viral-associated trichodysplasia spinulosa. Because discontinuation of the medication is not an option in a patient who is responding to therapy,

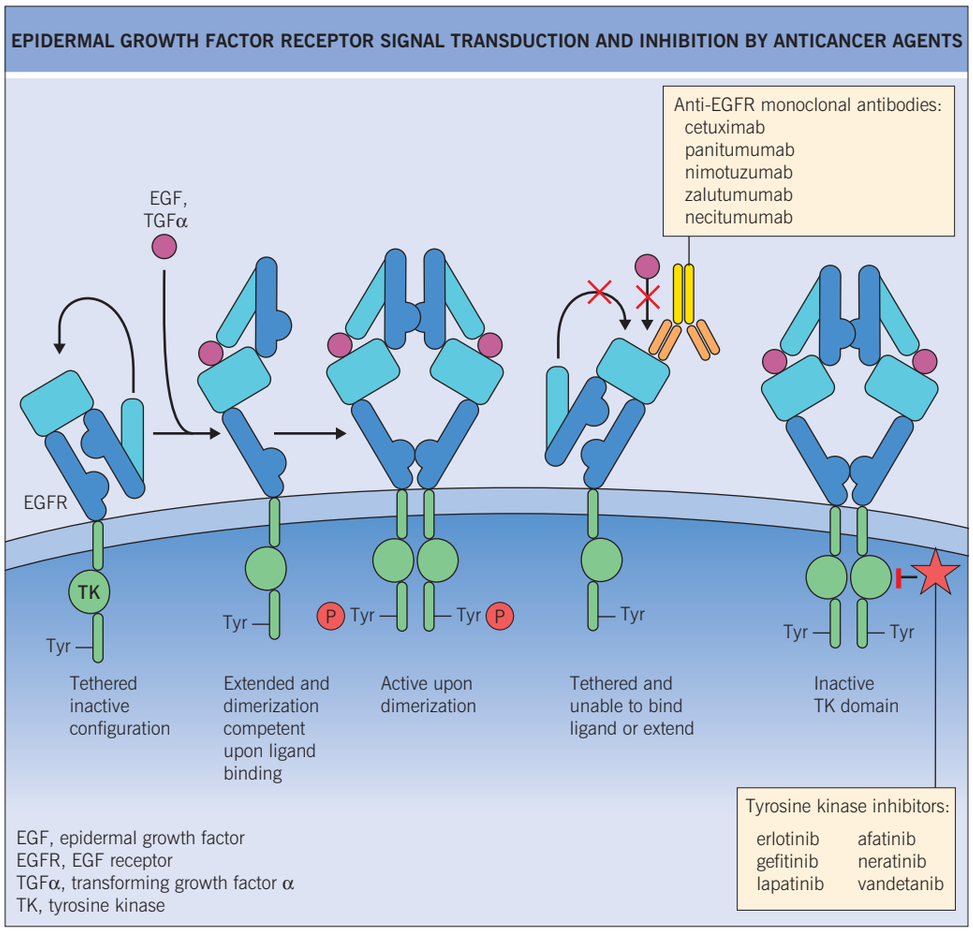

Fig. 36.15 Epidermal growth factor receptor (EGFR) signal transduction and inhibition by anticancer agents.

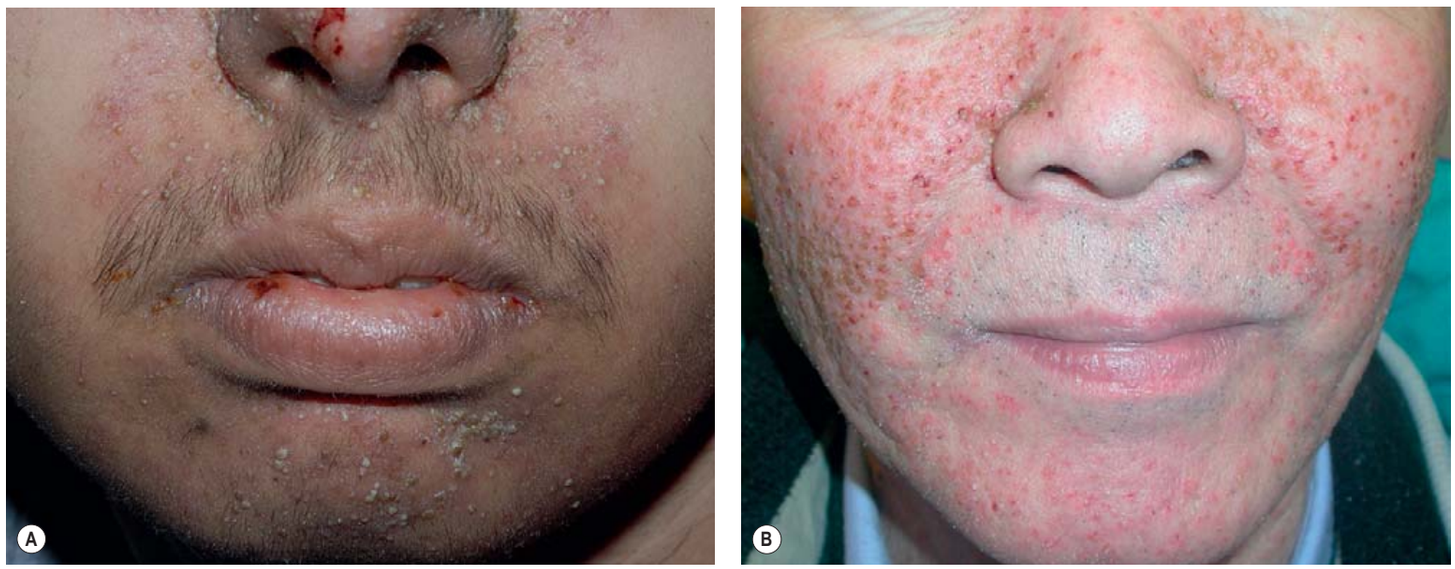

Fig. 36.16 Acneiform eruptions due to epidermal growth factor receptor inhibitors. A,B Numerous monomorphous follicular pustules and crusted papules on the face of two patients treated with erlotinib. *A, Courtesy, Julie V Schaffer, MD.*

multiple treatments have been tried with variable success, including topical and oral antibiotics, topical and (for severe eruptions) oral corticosteroids, and topical and oral retinoids; prophylaxis with oral doxycycline or minocycline may also be of benefit.

Tropical acne

Tropical acne is a follicular acneiform eruption that results from exposure to extreme heat. This can occur in tropical climates or secondary to scorching occupational environments, as in furnace workers. Historically, tropical acne caused significant morbidity among military troops. Markedly inflamed nodulocystic acne involving the trunk and buttocks is typically seen, and secondary staphylococcal infection is a frequent complication. Treatment is often of limited efficacy until the patient returns to a more moderate climate.

Radiation acne

Radiation acne is characterized by comedo-like papules occurring at sites of previous exposure to therapeutic ionizing radiation. The lesions

begin to appear as the acute phase of radiation dermatitis starts to resolve. The ionizing rays induce epithelial metaplasia within the follicle, creating adherent hyperkeratotic plugs that are resistant to expression.

"Pseudoacne" of the transverse nasal crease

The transverse nasal crease is a horizontal anatomical demarcation line found in the lower third of the nose which corresponds to the separation point between the alar cartilage and the triangular cartilage. Milia, cysts and comedones can line up along this fold (Fig. 36.17A)[32]. These acne-like lesions are not hormonally responsive and arise during early childhood prior to the onset of puberty. Treatment consists of surgical expression as needed.

Idiopathic facial aseptic granuloma

This chronic, painless, solitary nodule with an acneiform appearance can develop on the cheeks of young children (mean age, 3.8 years)[33]. Multiple lesions are uncommon. Histopathologic evaluation reveals a dermal lymphohistiocytic infiltrate with foreign body-type giant cells. Cultures are typically negative (70% of patients) and the lesions do not respond to antibiotic therapy. They eventually resolve spontaneously, after an average of 11 months, without treatment[33].

Childhood flexural comedones

This recently described entity is characterized by discrete, double-orifice comedones localized to the axillae and, less commonly, the groin[34]. The majority of patients have a single lesion and the average age at diagnosis is 6 years, with boys and girls equally affected. A small subset of cases are familial. There is no association with other signs of hidradenitis suppurativa, acne vulgaris or precocious puberty. In most cases, the flexural comedones are discovered incidentally in patients presenting with other dermatologic concerns such as molluscum contagiosum.

PATHOLOGY

Histopathologic examination of acne lesions demonstrates the stages of acnegenesis that parallel the clinical findings (see Fig. 36.1). In early lesions, microcomedones are seen. A mildly distended follicle with a narrowed follicular opening is impacted by shed keratinocytes. The granular layer at this stage is prominent. In closed comedones, the degree of follicular distension is increased and a compact cystic structure forms. Within the cystic space, eosinophilic keratinaceous debris, hair, and numerous bacteria are present. Open comedones have broad, expanded follicular ostia and greater overall follicular distension. The sebaceous glands are typically atrophic or absent. A mild perivascular mononuclear cell infiltrate circles the expanding follicle.

As the follicular epithelium distends, the cystic contents inevitably begin to rupture into the dermis (Fig. 36.18). The highly immunogenic cystic contents (keratin, hair and bacteria) induce a marked inflammatory response. Neutrophils first appear, creating a pustule. As the lesion matures, foreign body granulomatous inflammation engulfs the follicle and end-stage scarring can result.

In acne fulminans, there is massive inflammation with varying degrees of overlying necrosis. Comedones are rarely observed. Severe scarring may be seen in resolving lesions.

DIFFERENTIAL DIAGNOSIS

Although classic acne vulgaris is usually easily recognized clinically, the differential diagnosis of acneiform eruptions is broad and depends upon the age of onset, lesional morphology and location (Table 36.2). During the neonatal period, acne must be differentiated from other common dermatoses. Sebaceous hyperplasia occurs in the majority of healthy neonates, presenting as transient yellowish papules on the cheeks, nose and forehead. Miliaria rubra is also very common during the neonatal period, when overheating and bundling can cause temporary obstruction of the eccrine ducts that leads to formation of small inflammatory papulopustules. Small, white milia often appear on the cheeks and nose of neonates, but they generally resolve within a few months.

Predominantly comedonal acne vulgaris needs to be differentiated from comedonal eruptions caused by follicular occlusion or friction, including pomade and occupational acne, acne cosmetica and acne mechanica (see above); history as well as location can help to make the diagnosis of these forms of "contact acne". Sebaceous hyperplasia, a very common finding in adults, is relatively uncommon in adolescents. These yellowish, lobulated papules arise primarily on the forehead and cheeks.

A solitary enlarged comedo is better classified as a dilated pore of Winer; rarely it represents a large-pore basal cell carcinoma. Multiple open comedones are clustered in the lateral malar region in Favre–Racouchot disease (see Ch. 87) or appear in a linear array in nevus comedonicus (see Chs 62 and 109). If multiple vellus hairs are seen arising from a dilated follicular orifice (in association with keratinous debris), trichostasis spinulosa is the likely diagnosis (Fig. 36.17B). The most common location is the nose.

Angiofibromas and appendageal tumors of follicular origin, e.g. trichoepitheliomas, trichodiscomas and fibrofolliculomas, often present as multiple facial papules (see Ch. 111). They are typically non-inflammatory, and, in the case of trichoepitheliomas, lesions are concentrated in the nasolabial folds. Non-inflammatory, closed cystic papules and nodules on the central chest and back characterize steatocystoma multiplex (see Ch. 110). This autosomal dominant disorder must be differentiated from a similar clinical condition, eruptive vellus hair cysts. These smaller cysts may become inflamed and, as the name implies, contain multiple vellus hairs that can be easily visualized histologically.

The follicle-based inflammatory papules and pustules of acne vulgaris must be distinguished from the many forms of folliculitis, including staphylococcal, Gram-negative, and eosinophilic variants (see Ch. 38). In folliculitis, the lesions are typically monomorphous and comedones are not present. Gram-negative folliculitis can complicate acne vulgaris treated with oral antibiotics for a prolonged period. The inflammatory

DIFFERENTIAL DIAGNOSIS OF ACNE	
ACNE VULGARIS – COMEDONAL	
Closed	**Open**
• Milia • Osteoma cutis • Sebaceous hyperplasia • Syringomas • Trichoepitheliomas* • Trichodiscomas, fibrofolliculomas • Eruptive vellus hair cysts†, steatocystoma multiplex† • Colloid milia • Acne exacerbated by systemic corticosteroids‡ or anabolic steroids • Contact acne (occupational, pomade, cosmetica, mechanica; chloracne) • Follicular mucinosis	• Contact acne (see above) • Acne exacerbated by systemic corticosteroids‡ or anabolic steroids • Trichostasis spinulosa (see Fig. 36.17B) • Favre–Racouchot disease • Nevus comedonicus • Basaloid follicular hamartoma syndrome • Familial dyskeratotic comedones • Radiation-induced comedones • Dilated pore of Winer (single lesion) • Follicular spines (in settings such as viral-associated trichodysplasia spinulosa§, type VI pityriasis rubra pilaris§, multiple myeloma, demodicosis§, follicular mucinosis and lithium therapy)
ACNE VULGARIS – INFLAMMATORY	
• Rosacea • Perioral dermatitis • Folliculitis – culture-negative (normal flora), staphylococcal, Gram-negative, eosinophilic§, *Pityrosporum, Demodex* spp. (adults > children§) • Acne/acneiform eruptions due to topical or systemic corticosteroids‡, anabolic steroids or other medications (e.g. lithium, EGFR inhibitors; see Table 36.1) • Pseudofolliculitis barbae, acne keloidalis nuchae • Furuncle/carbuncle • Neutrophilic dermatoses and neutrophilic eccrine hidradenitis	• Keratosis pilaris • Viral-associated trichodysplasia spinulosa (also referred to as viral-associated trichodysplasia of immunosuppression)§ • Lupus miliaris disseminatus faciei • Psychogenic (neurotic) excoriations, factitial lesions • Follicular mucinosis, follicular mycosis fungoides • Tinea faciei • Molluscum contagiosum (especially inflamed lesions) • Angiofibromas
NEONATAL ACNE (NEONATAL CEPHALIC PUSTULOSIS)	
• Sebaceous hyperplasia • Milia • Miliaria rubra (especially pustular variant)	• Candidal infections • Papulopustular eruption of hyper-IgE syndrome • Vesiculopustular eruption of transient myeloproliferative disorder
SOLID FACIAL EDEMA SECONDARY TO ACNE VULGARIS	
• Solid facial edema secondary to rosacea • Melkersson–Rosenthal syndrome, sarcoidosis (e.g. Heerfordt's syndrome), lepromatous leprosy • Lymphoma (B- or T-cell), leukemia cutis, angiosarcoma • Scleromyxedema, myxedema, self-healing (juvenile) cutaneous mucinosis • Autoimmune connective tissue disease (e.g. dermatomyositis, lupus erythematosus, Still's disease)	• Angioedema (lasts <24–48 hours), C1 esterase inhibitor deficiency (lasts 42–72 hours), blepharochalasis/Ascher syndrome • Sweet's syndrome or cellulitis – more abrupt onset • Superior vena cava syndrome • Lymphatic malformation • Other – trichinosis, primary systemic amyloidosis, pachydermoperiostosis

*Early or small-sized.
†In the differential diagnosis of cystic lesions of the trunk.
‡Can also lead to rosacea-like picture (see Ch. 38).
§Often in the setting of HIV infection and/or other immunocompromised states.

Table 36.2 Differential diagnosis of acne. EGFR, epidermal growth factor receptor.

lesions typically appear on the central face (including the upper lip) and cheeks as well as on the upper trunk and, in the case of *Pseudomonas* ("hot tub") folliculitis, on the lower trunk. Eosinophilic folliculitis usually occurs in the setting of HIV infection and is markedly pruritic.

Pseudofolliculitis barbae and acne keloidalis nuchae most often affect men of African descent (see Ch. 38). The papular component of rosacea favors the malar region, chin and forehead; the presence of telangiectasias, an absence of comedones and a history of easy flushing can aid in diagnosis (see Ch. 37). Rosacea typically occurs at a later age than acne, but both can develop in a single individual. Prolonged use of topical corticosteroids on the face may lead to rosacea-like lesions or perioral/periorificial dermatitis, and patients treated with oral corticosteroids can develop an eruption of monomorphous papulopustules that favors the trunk ("steroid folliculitis"; see Fig. 36.12). This can occur at any age and resolves upon discontinuation of the corticosteroid. Lastly, psychogenic (neurotic) excoriations and factitial dermatitis concentrated on the face, chest and back can mimic acne, particularly acne excoriée des jeunes filles. Linearity and the lack of a clinically detectable primary lesion are clues.

TREATMENT

A thorough history and physical examination are key to developing an appropriate and maximally effective treatment plan (Table 36.3). The physician should review with the patient all prescription and over-the-counter medications used for acne or other conditions, and note the clinical responsiveness to them. A review of cosmetics, sunscreens, cleansers and moisturizers is also helpful. In female patients, a menstrual and oral contraceptive history is important in determining hormonal influences on acne. On physical examination, careful note should be taken of lesion morphology, including the presence of comedones, inflammatory lesions, nodules and cysts. Secondary changes such as scarring and postinflammatory pigmentary changes are also important clinical findings. The patient's skin color and type can influence the chosen formulation of a topical medication. Patients with oily skin tend to prefer the more drying gels and lotions, whereas those with drier skin types may prefer creams.

Common therapies for the treatment of acne are listed in Tables 36.4 and 36.5.

Topical Treatments

Topical retinoids

The anti-acne activity of topical retinoids involves normalization of follicular keratinization and corneocyte cohesion, which aids in the expulsion of existing comedones and prevents the formation of new ones. Topical retinoids also have significant anti-inflammatory properties and thus may be used as monotherapy for acne with both comedonal and mild inflammatory components. In addition, concurrent use of a topical retinoid can enhance the efficacy of benzoyl peroxide and topical antibiotics by increasing the penetration of the latter medications into the sebaceous follicle. Topical retinoids used for acne include tretinoin, adapalene, tazarotene and (in some countries) isotretinoin (see Ch. 126); topical products that combine tretinoin or adapalene with clindamycin, or adapalene with benzoyl peroxide, are also available.

HISTORY AND PHYSICAL EXAMINATION OF THE ACNE PATIENT

History	Physical examination
Sex Age Motivation Lifestyle/hobbies Occupation Current and previous treatments Use of cosmetics, sunscreens, cleansers, moisturizers Menstrual history Medications • Corticosteroids • Oral contraceptives • Anabolic steroids • Other (e.g. lithium, EGFR inhibitors; see Table 36.1) Concomitant illnesses	Skin type (e.g. oily versus dry) Skin color/phototype Distribution of acne • Face (e.g. "T-zone", cheeks, jawline) • Neck, chest, back, upper arms Overall degree of involvement (mild, moderate or severe) Lesion morphology • Comedones • Inflammatory papules • Pustules • Cysts • Sinus tracts Scarring • Pitted • Hypertrophic • Atrophic Postinflammatory pigmentary changes

Table 36.3 History and physical examination of the acne patient. EGFR, epidermal growth factor receptor.

TREATMENT OF ACNE VULGARIS

	Mild		Moderate		Severe
	Comedonal	Papular/pustular	Papular/pustular	Nodular	Conglobata/fulminans
First line	Topical retinoid	Topical retinoid + topical antimicrobial*	Oral antibiotic† + topical retinoid ± BPO	Oral antibiotic† + topical retinoid ± BPO	Oral isotretinoin (may require concurrent oral corticosteroid, esp. for acne fulminans)
Second line	Alternative topical retinoid Azelaic acid Salicylic acid	Alternative topical retinoid + alt. topical antimicrobial Azelaic acid Salicylic acid Topical dapsone	Alternative oral antibiotic‡ + alt. topical retinoid ± BPO/azelaic acid	Oral isotretinoin Alternative oral antibiotic† + alt. topical retinoid ± BPO/azelaic acid	Dapsone High-dose oral antibiotic + topical retinoid + BPO

COMMON THERAPIES FOR ACNE VULGARIS	
Topical therapy	**Systemic therapy**
Benzoyl peroxide (1) Antibiotics – Clindamycin (1) – Erythromycin (1) – Sodium sulfacetamide/sulfur (1) Retinoids (1) Salicylic acid (2) Azelaic acid (1) Dapsone (1)	Oral minocycline (1) Oral doxycycline (1) Oral tetracycline (1) Oral erythromycin (1) Oral azithromycin (1) Oral contraceptives (1) Oral spironolactone (1) Oral isotretinoin (1)

Table 36.5 Common therapies for acne vulgaris. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

The most common side effect of topical retinoids is local irritation resulting in erythema, dryness, peeling and scaling. Delivery systems have been developed to permit a greater concentration of retinoid while decreasing irritancy, primarily through controlled slow release (e.g. tretinoin impregnated into inert microspheres or incorporated within a polyolprepolymer). A pustular flare of acne occasionally occurs during the initial 3–4 weeks of treatment with a topical retinoid. This resolves spontaneously with continued usage. Thinning of the stratum corneum and irritation may also increase the user's susceptibility to sunburn. Therefore, the use of sunscreens should be advised.

Tretinoin (all-*trans*-retinoic acid), a naturally occurring metabolite of retinol, was the first topical comedolytic agent used for the treatment of acne. Because tretinoin is photolabile, night-time application is recommended to prevent early degradation. To decrease the potential for irritation, treatment is often started with a lower-concentration cream formulation of tretinoin and the strength later increased (or the vehicle changed to a gel). Alternate-night to every-third-night application may be necessary initially, with increased frequency as tolerated. Stepwise increments are typically done at 3–4-week intervals.

Although epidemiologic studies have not shown an increased risk of birth defects in infants of mothers using topical tretinoin during the first trimester, sporadic case reports of birth defects have been published[35,36]. Because of this and the fact that systemic retinoids are known teratogens, the use of topical tretinoin in pregnancy is discouraged. However, dietary intake of vitamin A has been shown to have a greater influence on serum retinoid levels than facial application of tretinoin[37].

The synthetic retinoid *adapalene* is an aromatic naphthoic acid derivative (see Fig. 126.1). In the skin, it primarily binds the retinoic acid receptor γ (RARγ), whereas tretinoin binds to both RARα and RARγ. Although animal studies have shown adapalene to have milder comedolytic properties than tretinoin, it is also less irritating[38]. Unlike tretinoin, adapalene is light-stable and resistant to oxidation by benzoyl peroxide.

Tazarotene is a synthetic acetylenic retinoid that, once applied, is converted into its active metabolite, tazarotenic acid. Like adapalene, this metabolite selectively binds RARγ but not RARα or RXR (see Ch. 126). Both daily overnight application of tazarotene and short contact therapy regimens have been used and shown to be effective in the treatment of comedonal and inflammatory acne. Topical tazarotene has been designated pregnancy category X, so contraceptive counseling should be provided to all women of childbearing age who are prescribed this medication.

Benzoyl peroxide and other topical antibacterial agents

Benzoyl peroxide is a potent bacteriocidal agent that reduces *P. acnes* within the follicle. It also has mild comedolytic properties and is particularly effective when used in combination with other therapies. In contrast to topical antibiotics, microbial resistance to benzoyl peroxide has not been reported. Many preparations for all skin types are available in both over-the-counter and prescription formulations. These include bar soaps, washes, gels, lotions, creams, foams and pads in concentrations ranging from 2.5% to 10% as well as products that combine benzoyl peroxide with clindamycin, erythromycin or adapalene. As benzoyl peroxide is a bleaching agent, whitening of clothing and bedding can occur. Development of contact dermatitis (irritant > allergic) to benzoyl peroxide is also possible, and should be suspected in patients who develop marked erythema with its use.

Topical antibiotics are widely used for the treatment of acne and are available alone as well as in combination with benzoyl peroxide or a retinoid. *Clindamycin* and *erythromycin* represent the two most commonly utilized antibiotics and the formulations vary from creams and gels to solutions and pledgets (see Ch. 127).

Azelaic acid is a naturally occurring dicarboxylic acid found in cereal grains. It is available as a topical cream and gel, which have been shown to be effective in inflammatory and comedonal acne. By inhibiting the growth of *P. acnes*, azelaic acid reduces inflammatory acne. It also reverses the altered keratinization of follicles affected by acne and thus demonstrates comedolytic properties. The activity of azelaic acid against inflammatory lesions may be greater than its activity against comedones. Azelaic acid is applied twice daily and its use is reported to have fewer local side effects than topical retinoids. In addition, it may help to lighten postinflammatory hyperpigmentation.

Sodium sulfacetamide is a well-tolerated topical antibiotic that is thought to restrict the growth of *P. acnes* through competitive inhibition of the condensation of para-aminobenzoic acid with pteridine precursors (see Ch. 127). It is formulated in a 10% lotion, suspension, foam and cleanser, either alone or in combination with 5% sulfur. Tinted formulations are also available.

Topical *dapsone* 5% gel is approved for the treatment of acne vulgaris. Of note, a temporary yellow–orange staining of the skin and hair occasionally occurs with concomitant use of topical dapsone and benzoyl peroxide.

Other topical medications

Salicylic acid is a widely used comedolytic and mild anti-inflammatory agent (see Ch. 153). It is also a mild chemical irritant that works in part by drying up active lesions. Salicylic acid is available over the counter in concentrations of up to 2% in numerous delivery formulations, including gels, creams, lotions, foams, solutions and washes. Side effects of topical salicylic acid include erythema and scaling.

Oral Treatments

Antibiotics

Oral tetracycline derivatives, especially doxycycline and minocycline, and less often macrolides (e.g. erythromycin, azithromycin) are prescribed for moderate to severe inflammatory acne unresponsive to topical combinations. In this setting, the primary mechanism of action of these agents is suppression of the growth of *P. acnes*, thereby reducing bacterial production of inflammatory factors. However, several of these antibiotics also possess intrinsic anti-inflammatory properties.

Details regarding the mechanisms of action, recommended dosages, and side effects of tetracyclines and macrolides are reviewed in Chapter 127. Resistance of *P. acnes* to erythromycin and the three major tetracyclines (tetracycline and doxycycline more so than minocycline) has been reported. The enhanced efficacy of minocycline, a lipophilic derivative of tetracycline, may be due to its greater penetration into the sebaceous follicle; however, it is also associated with a higher incidence of serious adverse events, including a minocycline-induced hypersensitivity syndrome and autoimmune reactions (see Ch. 21). The latter typically develop after many months to years of therapy and can include hepatitis, a lupus erythematosus-like syndrome and cutaneous polyarteritis nodosa (often associated with antineutrophil cytoplasmic antibodies).

Hormonal therapy

Hormonal therapy is an established second-line treatment for female patients with acne and can be very effective, irrespective of whether or not the serum androgen levels are abnormal. Although women and girls with acne may have higher serum levels of androgens than those without acne, the levels in acne patients are often within the normal range. Hormonal therapies seem to work best in adult women with inflammatory papules and nodules that tend to flare in the week prior to menstruation and involve the lower face and neck. These patients often note little improvement in their acne despite multiple courses of various oral antibiotics.

In such patients, hormonal therapy with oral contraceptives, which block both ovarian and adrenal production of androgens, can be initiated

and oral antibiotics discontinued. The use of oral contraceptives is also indicated for women of childbearing potential if treatment with spironolactone is anticipated (see below). Because of the potential risks associated with oral contraceptive use and the need for breast and pelvic examinations, consultation with a gynecologist is recommended.

Most oral contraceptive formulations combine an estrogen with a progestin in order to minimize the risk of endometrial cancer, which is known to occur with unopposed estrogen administration. Although progestins have intrinsic androgenic activity, second-generation, low-androgenic progestins (e.g. ethynodiol diacetate, norethindrone, levonorgestrel) have been developed. Newer, third-generation progestins (e.g. desogestrel, norgestimate, gestodene [Europe]) have even less androgenic activity than their predecessors, and other progestins (e.g. drospirenone, cyproterone acetate, dienogest) have *anti*androgenic properties.

Three oral contraceptives are currently FDA-approved for the treatment of acne, although others also have evidence of efficacy[39] (Table 36.6). The first is a triphasic oral contraceptive composed of a norgestimate–ethinyl estradiol (35 mcg) combination. The second contains a graduated dose of ethinyl estradiol (20–35 mcg) in combination with norethindrone acetate, while the third contains a stable dose of ethinyl estradiol (20 mcg) plus drospirenone (3 mg) with a 24-day dosing regimen. Side effects from oral contraceptives include nausea, vomiting, abnormal menses, weight gain and breast tenderness; agents containing drospirenone can lead to elevations in serum potassium levels, but this is generally not clinically significant in otherwise healthy individuals. Rare but more serious complications include hypertension and thromboembolism (e.g. deep venous thrombosis, pulmonary embolism). The increase in risk of the latter ranges from 2–4-fold with levonorgestrel or norethindrone to 3.5–7-fold with desogestrel, drospirenone and cyproterone acetate[40,41]; it is higher for women over the age of 35 years, smokers and those with other prothrombotic risk factors (e.g. hereditary thrombophilia)[42].

The progestational antiandrogen cyproterone acetate is currently marketed in Europe and Canada but is not available in the US. Its anti-acne effects are mediated primarily through androgen receptor blockade. The standard formulation combines cyproterone acetate (2 mg) with ethinyl estradiol (35 or 50 mcg) in an oral contraceptive formulation. This preparation is widely used in Europe as the treatment of choice for sexually active women with hormonally responsive acne. Singular formulations of cyproterone acetate are also available. Studies have indicated that approximately 75–90% of patients treated with doses of 50–100 mg daily (with or without ethinyl estradiol 50 mcg) show substantial improvement[43]. Although similar efficacy has been reported for the 2 mg cyproterone acetate dose in the oral contraceptive formulation, higher doses (e.g. on days 5–14 of the menstrual cycle) may be helpful in women with severe hyperandrogenism. The most frequent side effects are breast tenderness, headache, nausea and irregular menses; hepatotoxicity or thromboembolism represent uncommon complications.

COMMONLY USED ORAL CONTRACEPTIVES	
Oral contraceptive®	**Estrogen mcg/Progestin mcg**
FDA-APPROVED FOR ACNE VULGARIS	
Ortho Tri-Cyclen	Ethinyl estradiol 35/norgestimate 180, 215, 250
Estrostep	Ethinyl estradiol 20, 30, 35/norethindrone 1000
Yaz, Loryna and Beyaz*	Ethinyl estradiol 20/drospirenone 3000
CLINICAL DATA TO SUPPORT USE	
Alesse	Ethinyl estradiol 20/levonorgestrel 100
Diane-35†	Ethinyl estradiol 35/cyproterone acetate 2000
Yasmin, Syeda, Zarah and Safyral*	Ethinyl estradiol 30/drospirenone 3000
Natazia	Estradiol valerate 1000, 2000, 3000/dienogest 2000, 3000
NO/INSUFFICIENT CLINICAL DATA	
Demulen	Ethinyl estradiol 35, 50/ethynodiol diacetate 1000
Desogen	Ethinyl estradiol 35/desogestrel 150
Mircette	Ethinyl estradiol 20, 10/desogestrel 150
Ortho-Cept	Ethinyl estradiol 35/desogestrel 150
Ortho-Cyclen	Ethinyl estradiol 35/norgestimate 250
Ortho-Novum 7/7/7	Ethinyl estradiol 35/norethindrone 500, 750, 1000
Ortho-Novum 10/11	Ethinyl estradiol 35/norethindrone 500, 1000
Ortho Tri-Cyclen Lo	Ethinyl estradiol 25/norgestimate 180, 215, 250
Ovcon-35	Ethinyl estradiol 35/norethindrone 400
TriPhasil	Ethinyl estradiol 35, 50/levonorgestrel 50, 75, 125

*Also contains levomefolate calcium for protection against neural tube defects.
†Not available in the US.

Table 36.6 Commonly used oral contraceptives.

Spironolactone functions as both an androgen receptor blocker and an inhibitor of 5α-reductase. In doses of 50–100 mg twice daily, it has been shown to reduce sebum production and improve acne[44]. Side effects are dose-related and include potential hyperkalemia, irregular menstrual periods, breast tenderness, headache and fatigue. However, hyperkalemia is rare in young healthy patients. Although breast tumors have been reported in rodent models given spironolactone, this drug has not been directly linked to the development of cancer in humans[45]. Because it is an antiandrogen, there is a risk of feminization of a male fetus if a pregnant woman takes this medication. The potential risk to a fetus and the symptoms of irregular menstrual bleeding can be alleviated by combining spironolactone with an oral contraceptive. Side effects can also be minimized if therapy is initiated with a low dose (25–50 mg/day). Effective maintenance doses range from 25 to 200 mg/day. As with other hormonal therapies, a clinical response may take up to 3 months.

Records were reviewed of 85 women treated with 50–100 mg daily of spironolactone, administered either as a single agent or as an adjunct to standard therapies[46]. The maximum length of treatment was 24 months. Clearing of acne occurred in 33% of women treated with low-dose spironolactone, 33% had marked improvement, 27% showed partial improvement and 7% showed no improvement. The treatment was well tolerated, with 58% reporting no adverse effects. Menstrual irregularities occurred in 17.5%, and symptoms of lethargy, fatigue, dizziness or headache (CNS symptoms) were reported in 16%. Less common side effects included breast tenderness, a diuretic effect, postural hypotension and nausea. Slight elevations in serum potassium (range 4.8–5.3 mEq/l) were identified in 13.7% of the 73 patients examined, but this was not considered to be clinically significant. The following benefits were noted in some patients: an improvement in premenstrual syndrome, decreased facial oiliness, decreased metrorrhagia, reduced endometriosis pain and increased libido. The results of this study suggested that:

- most side effects of spironolactone are dose-dependent, including menstrual irregularities (the most common side effect)
- CNS symptoms are also relatively common, but appear to be unrelated to dose
- hyperkalemia may be measurable but is clinically insignificant in the absence of cardiac or renal disease
- reductions in blood pressure are slight, but rarely can be associated with orthostatic symptoms.

Flutamide, a nonsteroidal androgen receptor blocker that is approved by the FDA for the treatment of prostate cancer, can also be an effective treatment for acne in women at doses of 62.5–500 mg/day. In addition to side effects similar to those of other antiandrogens (e.g. menstrual irregularities, breast tenderness, risk of feminization of a male fetus), severe dose-related hepatotoxicity occasionally occurs.

Isotretinoin

Since 1971, oral isotretinoin (13-*cis*-retinoic acid) has been available in Europe for the treatment of acne. Twelve years later, the FDA approved it for patients with severe, nodulocystic acne refractory to treatment, including oral antibiotics. Over time, other clinical forms of acne have also been shown to benefit greatly from the use of isotretinoin[47]. These include significant acne that is unresponsive to therapy (including oral antibiotics) and/or results in scarring, as well as Gram-negative folliculitis, pyoderma faciale and acne fulminans. The mechanism of action of isotretinoin, as well as dosing regimens, side effects and monitoring protocols, are discussed in detail in Chapter 126.

Patients with acne are typically treated with an isotretinoin dose of 0.5–1 mg/kg/day (taken with a fatty meal to increase gastrointestinal absorption), often with a lower dose during the first month of treatment to prevent an initial acne flare and to allow the patient to adjust to dose-dependent side effects. Reaching a cumulative dose of 120–150 mg/kg (e.g. 4–5 months of treatment with 1 mg/kg/day) has been shown to reduce the risk of relapse. However, a 6-month course of low-dose isotretinoin (e.g. 0.25–0.4 mg/kg/day, 40–70 mg/kg cumulative) can be effective in the treatment of moderate acne, with fewer side effects and improved patient satisfaction[48]. Subsets of patients who are less likely to respond to isotretinoin and/or more likely to require multiple courses of treatment include adolescents under 16 years of age who have nodulocystic acne, individuals with endocrine abnormalities, and women with less severe acne. Considering that improvement may continue for several months after discontinuing isotretinoin, a hiatus of at least 2–3 months is recommended before starting another course of therapy. Scarred nodules and sinus tracts that represent sequelae from previously active cystic acne are not isotretinoin-responsive but may improve with surgical modalities, which are generally delayed at least 6–12 months after completing isotretinoin therapy to avoid the possible risk of atypical healing or scarring responses.

The most common adverse effects of isotretinoin involve the skin and mucous membranes and are dose-dependent. These include cheilitis, dryness of the oral and nasal mucosa, generalized xerosis and skin fragility. With the institution of isotretinoin therapy, induction of an acne fulminans-like flare, formation of excessive granulation tissue, and cutaneous infections (in particular with *Staphylococcus aureus*) can also occur (Fig. 36.19).

Teratogenicity is a serious potential complication (see Table 126.7), and female patients of childbearing potential must have at least one (in the US, two) negative pregnancy test(s) before starting treatment and practice effective contraception for 1 month prior to, during, and for 1 month after completing therapy. In the US, prescription of isotretinoin requires all physicians and patients to register with a pregnancy risk management program (iPLEDGE™), which mandates monthly office visits for all patients (with counseling not to share the medication) and monthly pregnancy testing for female patients with childbearing potential. Isotretinoin therapy leads to elevated serum triglyceride levels in 25–50% of patients and may have side effects involving the musculoskeletal system (most often myalgias), eyes, liver (occasionally elevated transaminases); intestines (controversial link to inflammatory bowel disease) and central nervous system (see Table 126.8 and Ch. 126). To date, no firmly established causal association with depression or suicide attempts has been demonstrated.

Fig. 36.19 Impetigo in a patient treated with isotretinoin. Multiple serous crusts are evident.

Surgical Treatment

Comedo extraction can improve the cosmetic appearance of acne and aid in therapeutic responsiveness to topical comedolytic agents. The keratinous contents of open comedones may be expressed using a comedo extractor. The Schamberg, Unna and Saalfield types of comedo expressers are most commonly used. Nicking the surface of a closed comedo with an 18-gauge needle or a #11 blade allows easier expression. Extraction is especially beneficial for deep, inspissated and persistent comedones. This procedure should be used in conjunction with a topical retinoid or other comedolytic treatment for maximum benefit. Comedo extraction should not be performed on inflamed comedones or pustules because of the risk of scarring. Light electrocautery and electrofulguration (see Ch. 140) have also been reported as effective treatments for comedones. Electrofulguration has the added benefit of not requiring the prior use of a topical anesthetic. In selected patients, cryotherapy represents another surgical option for the treatment of comedonal acne (see Ch. 138).

Photodynamic therapy utilizing topical 5-aminolevulinic acid together with various light sources (e.g. blue, red, intense pulsed) or lasers (e.g. pulsed dye, 635 nm red diode) as well as methyl aminolevulinate plus red light have been successfully used to treat acne (see Ch. 135). In addition, blue or intense pulsed light alone and lasers such as the pulsed dye, the 1320 nm neodymium:YAG and especially the 1450 nm diode may be of therapeutic benefit for inflammatory acne (see Ch. 137).

Intralesional injection of corticosteroid (triamcinolone acetonide 2–5 mg/ml) can quickly improve the appearance and tenderness of deep, inflamed nodules and cysts. Larger cysts may require incision and drainage prior to injection. The maximal amount of corticosteroid used per lesion should not exceed 0.1 ml. The risks of corticosteroid injections include hypopigmentation (particularly in darkly pigmented skin), atrophy, telangiectasias, and needle tract scarring.

Low-concentration chemical peels are also beneficial for the reduction of comedones. The α-hydroxy acids (including glycolic acid), salicylic acid and trichloroacetic acid are the most common peeling agents. These lipid-soluble comedolytic agents act by decreasing corneocyte cohesion at the follicular opening and assist in comedo plug extrusion. Such agents are generally well tolerated by most skin colors and types, and they can be used by the patient at home or in the dermatologist's office. Higher-concentration glycolic acid peels (20–70%, depending on the patient's skin type) and the less predictable phenol peel may also be performed in the office setting. Risks of chemical peels include irritation, pigmentary alteration and scarring.

One of the most distressing consequences of acne vulgaris is scarring. Surgical treatments should be aimed at the type of scarring present. Laser resurfacing (fractional as well as traditional), dermabrasion and deeper chemical peels seek to reduce the variability of the skin surface and smooth out depressed scars that improve when the skin is stretched. For discrete depressed scars, soft tissue augmentation can be temporarily beneficial. Filler substances used include poly-L-lactic acid, calcium hydroxylapatite and autologous fat (see Ch. 158). Punch grafting is an option for patients with "ice-pick" scarring. Surgical subscision is also a commonly used technique in the management of acne scars. For larger hypertrophic scars, aggregated pitted scars and sinus tracts, full-thickness surgical excision may result in improved scar placement and a better cosmetic appearance.

Rosacea and Related Disorders 37

Frank C Powell and *Síona Ní Raghallaigh*

INTRODUCTION

The clinical and histologic parameters of rosacea remain poorly defined despite the fact that it is a relatively common dermatosis. There is no laboratory test that can simply confirm the diagnosis of rosacea. In addition, the concept that certain disorders are "related" to rosacea is not based on scientific evidence but on clinical similarities.

The term *rosacea* is used to encompass a constellation of signs and symptoms. The latter include: persistent facial erythema, telangiectasias, inflammatory papules and pustules, a tendency for frequent facial flushing, non-pitting facial edema, ocular inflammation of various types, and phymatous changes, primarily of the nose, but also of the ears, forehead, chin or eyelids. Some authors also include (as variants of rosacea) *rosacea fulminans*, which is characterized by the explosive onset of inflammatory papules and pustules superimposed on a background of facial erythema and sometimes even accompanied by fever, and *rosacea conglobata* where inflammatory facial cysts with associated scarring are seen[1]. However, inclusion of these variants under the title rosacea is controversial, and some authors regard them related more to acne vulgaris. Persistent red–brown to skin-colored facial papules with a characteristic non-caseating granulomatous histology is referred to as *granulomatous rosacea*, while individuals with frequent facial flushing and easily irritated facial skin have been classified as having "pre-rosacea". In addition to the labeling of certain clinical presentations as "stages" of progression, the inclusion of this diverse spectrum of clinical features under the heading of rosacea has impeded an understanding of the pathogenesis of this disease.

In 2002, a classification of the subtypes of rosacea was published[2] and it has helped to clarify the situation (see Table 37.2). The hope is that this classification scheme will provide a framework for future investigations.

HISTORY

Robert Willan is credited with the earliest medical descriptions of "acne rosacea"[3]. The form of the disease he described would nowadays be classified as papulopustular rosacea. Early on, rosacea was thought by many dermatologists of that time to have a "seborrheic pathogenesis", similar to acne vulgaris. Radcliff-Crocker later postulated that repeated flushing lead to dilated, leaky, facial blood vessels with subsequent inflammatory skin changes. This hypothesis retains its supporters to this day.

EPIDEMIOLOGY

Previously published reports regarding the frequency of rosacea in the population have sometimes suffered from inadequate definitions of disease. In 1989, a study of over 800 Swedish office workers reported a prevalence of rosacea of 10%[4]. However, the majority of these individuals had facial erythema and telangiectasias without inflammatory skin lesions, but these findings can be impossible to distinguish clinically from the facial skin changes induced by chronic exposure to ultraviolet (UV) light (dermatoheliosis). A population study of 1000 individuals in Ireland that used an agreed clinical definition of papulopustular rosacea found a prevalence of 2.7%. This study also showed that papulopustular rosacea was not associated with photodamage[5]. An additional 14% of this study population had skin changes similar to the Swedish group that could be attributed to either erythematotelangiectatic rosacea or dermatoheliosis. These latter changes were associated with photodamage.

PATHOGENESIS

The exact pathogenesis of rosacea is unknown. The disorder which is known today as rosacea will probably be shown in time to comprise several similar, possibly related, but different clinical conditions, each with separate predominant pathogenic mechanisms. Some of the factors currently thought to be relevant are listed in Table 37.1.

Rosacea occurs most frequently in Caucasians and in those with fair sun-sensitive skin, i.e. skin phototypes I and II. There may be a genetic predisposition to the disorder, as 10–20% of patients report a family history of rosacea. Epidemiologic studies suggest that erythematotelangiectatic rosacea may be related to UV exposure and photodamage (see above). UVB exposure has been shown to induce angiogenesis and to increase the secretion of angiogenic factors such as vascular endothelial growth factor (VEGF) from keratinocytes[6]. Evidence suggests that exposure to UV radiation leads to the production of reactive oxygen species, which then induce an upregulation of matrix metalloproteinases[7], leading to damage to blood vessels and the dermal matrix. It may be that these factors are most relevant to those patients with erythematotelangiectatic rosacea.

Histologic examination of papulopustular rosacea demonstrates inflammatory changes that are most pronounced at the pilosebaceous follicle[8,9]. These changes may result from dysfunction of the innate immune response which protects the skin against infection as well as other environmental stimuli such as UV radiation and chemical trauma. Triggering the innate immune system leads to a controlled release of cytokines and antimicrobial molecules such as the peptide cathelicidin. In rosacea, there is an upregulation of cathelicidin and its processing serine protease (kallikrein 5), suggesting dysfunction of the innate immune system[10]. When injected into murine skin, cathelicidin peptides and their associated enzymes induced pro-inflammatory and angiogenic activity, features which may be of greater relevance to papulopustular rosacea[11].

Persistent centrofacial erythema and telangiectasias are common features of rosacea, as is flushing (transient erythema). An elevation in cutaneous blood flow has been observed in skin affected by papulopustular rosacea, when compared with non-affected skin[12]. In addition, there is elevated expression of VEGF, CD31 (a pan-endothelial cell marker) and lymphatic endothelial marker D2-40 (podoplanin) in lesional skin, suggesting stimulation of vascular and lymphatic endothelial cells[13]. Aberrant control of cutaneous thermal mechanisms has also been proposed as a cause of vasodilation. Compared to controls, rosacea patients flush more readily in response to heat, and their heat pain thresholds have been demonstrated to be lower[12].

Patients with rosacea often report symptoms of facial dryness, stinging or burning. Studies have confirmed a lowered threshold for irritancy in the skin of rosacea patients[14]. This may be due to epidermal barrier dysfunction, characterized by increased transepidermal water loss, which has been demonstrated in patients with rosacea[15]. In addition, it has been suggested that disruption or abnormality of the stratum corneum allows penetration of sensory irritants which then leads to a stinging sensation[16]. These findings have practical implications when advising rosacea patients regarding appropriate facial skin care.

Neurogenic inflammation (an inflammatory response induced by sensory nerves which release neuromediators at the site of inflammation) can result in vasodilation, extravasation of plasma proteins and recruitment of inflammatory cells. Environmental triggers are known to activate G protein-coupled receptors and ion channels on sensory nerves (see Ch. 5); upon stimulation, neuropeptides such as calcitonin gene-related peptide (CGRP) and pituitary adenylate cyclase activating polypeptide (PACAP) induce vasodilation of arterioles and capillaries[17].

PATHOGENIC HYPOTHESES FOR ROSACEA	
Theory	**Explanation**
Aberrant innate immune system	• The innate immune response protects against microbial infection without requiring specific recognition of the pathogenic stimulus • Activation of innate immunity leads to release of cytokines and antimicrobial molecules such as the peptide cathelicidin • In rosacea, there is upregulation of cathelicidin and its processing serine protease, suggesting dysfunction of the innate immune system
Ultraviolet radiation (UVR)	• UVR exposure has been shown to: – induce angiogenesis – increase production of reactive oxygen species, which then leads to upregulation of matrix metalloproteinases (MMPs) • MMPs result in damage to blood vessels and the dermal matrix
Vascular changes	• An increase in blood flow is seen within affected skin in rosacea • Rosacea patients flush more readily in response to heat as compared with controls • An elevated expression of VEGF and lymphatic endothelial markers is observed, suggesting stimulation of blood vascular and lymphatic endothelial cells
Epidermal barrier dysfunction	• Increased transepidermal water loss • Lowered threshold for skin irritancy • Seen in both erythematotelangiectatic and papulopustular rosacea
Neurogenic inflammation	• Sensory nerves release neuromediators at the site of inflammation, resulting in vasodilation, extravasation of plasma proteins and recruitment of inflammatory cells • Exact mechanisms not well understood
Microbes	• *Demodex* mites (*folliculorum* and *brevis*), which are commensals of normal skin, are found in greater numbers in rosacea patients • *Demodex* infestation is associated with an intense perifollicular infiltrate of predominantly $CD4^+$ helper T cells • Staphylococcal organisms are also thought to play a role in rosacea pathogenesis

Table 37.1 Pathogenic hypotheses for rosacea. VEGF, vascular endothelial growth factor.

Fig. 37.1 Erythematotelangiectatic rosacea. Persistent erythema of the medial and lateral cheeks is seen. In this patient, there are no telangiectasias, indicating mild (grade 1) disease.

Fig. 37.2 Dermatoheliosis in a skin phototype I patient. Telangiectasias and erythema due to chronic actinic damage are particularly marked on the facial prominences. Features of dermatoheliosis overlap with those of erythematotelangiectatic rosacea.

However, these pathways are not well understood and their relevance to rosacea is unclear.

Although *Demodex* mites (*folliculorum* and *brevis*) are facial skin commensals, they are often prominent within the pilosebaceous follicle when rosacea skin is examined histologically. Using the skin surface biopsy technique, several investigators have shown that these mites are present in far greater numbers in rosacea patients than in control subjects[18,19]. Follicular infestation with multiple mites has been shown to be associated with an intense perifollicular infiltrate of predominantly $CD4^+$ helper T cells[20]. Antigenic proteins produced by a bacterium (*Bacillus oleronius*) isolated from *Demodex* mites have been shown to stimulate an inflammatory response in patients with papulopustular rosacea[21]. It has been suggested that *Demodex* mites and their associated bacteria upregulate cutaneous proteases, thereby potentiating the dysregulation of the local innate immune response (see above)[22]. These pathomechanisms are probably most relevant for the papulopustular subtype of rosacea.

Lastly, it seems unlikely, based on current evidence, that *Helicobacter pylori* infection plays an etiologic role in the pathogenesis of rosacea.

CLINICAL FEATURES

Rosacea usually has its onset during middle age, with women being affected somewhat earlier than men. Rosacea has been observed in children, with associated ocular changes and therapeutic responses that are similar to those in adult patients, but the lack of adequate criteria to verify the diagnosis hinders the establishment of childhood rosacea as a specific entity. Although women are said to be more frequently affected by rosacea than men, the evidence for this is unclear. Rhinophyma, however, clearly occurs primarily in men. The prevalence of rosacea in individuals with darker skin phototypes has not been well studied, but it may be greater than was previously assumed. In more darkly pigmented skin, erythema and telangiectasias may be difficult to appreciate clinically, so a history of skin sensitivity and flushing, along with centrofacial or ocular inflammatory lesions, may assist in establishing the diagnosis.

In 2002, a consensus publication provided a classification scheme for rosacea[2] (Table 37.2), and the clinical characteristics of the four major forms will be discussed separately.

- *Erythematotelangiectatic rosacea* includes individuals who have a tendency for flushing, combined with a background of persistent facial erythema (Fig. 37.1) and sometimes telangiectasias. Such patients typically have skin phototypes I or II. The clinical definition of erythematotelangiectatic rosacea can prove challenging because of overlap with the cutaneous findings of chronic actinic damage in fair-skinned individuals (dermatoheliosis) (Fig. 37.2). Patients with dermatoheliosis can also have thermolabile facial skin and may experience flushing, particularly with environmental temperature change. In addition, individuals who complain of flushing as a solitary symptom should not be labeled as having "pre-rosacea" but rather should be investigated for other causes of flushing as listed in Table 106.2.

CLASSIFICATION, CLINICAL FEATURES AND MANAGEMENT OF SUBTYPES OF ROSACEA				
Subtype	**Predominant clinical features**	**Severity**		**Management**
		Grade	**Features**	
Erythematotelangiectatic	• Persistent centrofacial erythema • Flushing • Telangiectasias • Skin sensitivity	1	Occasional mild flushing; faint persistent centrofacial erythema; few telangiectasias	• General recommendations for facial skin care (see Table 37.5) • Reduce flushing • Minimize irritation • Topical treatments used in papulopustular rosacea may cause irritation • Laser therapy of prominent blood vessels in grades 2 and 3 disease
		2	Frequent troublesome flushing; moderate persistent centrofacial erythema; several distinct telangiectasias	
		3	Frequent severe flushing; pronounced persistent centrofacial erythema; many prominent telangiectasias; possible edema	
Papulopustular	• Persistent centrofacial erythema • Papules • Pustules/papulopustules • Overlap with other subtypes may occur	1	Few papules and/or papulopustules; mild persistent centrofacial erythema	• Topical or systemic medications for grades 1 and 2 disease • Systemic medications for grade 3 • May require repeated courses or gradual taper
		2	Several papules and/or papulopustules; moderate persistent centrofacial erythema	
		3	Extensive papules and/or papulopustules; pronounced persistent centrofacial erythema; inflammatory plaques or edema may be present	
Phymatous	• Thickened, nodular skin • Prominent pores • Can affect nose (rhinophyma), chin (gnathophyma), forehead (metophyma), ears (otophyma), eyelids (blepharophyma) • May be associated with other features of rosacea or occur in isolation	1	Puffiness; mildly patulous follicles; no clinically apparent hypertrophy of connective tissue or sebaceous glands; no change in contour	• Surgical or laser therapy for grades 2 and 3 rhinophyma • Other phymas are more difficult to treat but may improve with systemic treatments, if an inflammatory component is present
		2	Moderate swelling; moderately dilated patulous follicles; clinically, mild hypertrophy of the sebaceous glands or connective tissue; change in nasal contour without nodular component	
		3	Marked swelling; large dilated follicles; distortion of contour due to hypertrophy of the sebaceous glands and/or connective tissue, with a nodular component	
Ocular	• Dry, gritty sensation • Blepharitis • Conjunctivitis • Chalazia and hordeola • Keratitis, episcleritis, scleritis, iritis (rare)	1	Mild itch, dryness or grittiness; fine scaling of eyelid margins; telangiectasia of eyelid margins; mild conjunctival injection	• Topical medications for grade 1 • Systemic medications for grade 2 • Refer to ophthalmologist for persistent grade 1 or 2 disease or suspected grade 3 disease
		2	Burning or stinging; crusting, irregularity, erythema and/or edema of eyelid margins; definite conjunctival injection; chalazion or hordeolum	
		3	Pain, photosensitivity, blurred vision; severe eyelid changes with loss of lashes, severe conjunctival inflammation; corneal changes, with potential loss of vision; episcleritis, scleritis; iritis	

Table 37.2 Classification, clinical features and management of subtypes of rosacea. Adapted from ref. 23.

- *Papulopustular rosacea* is characterized by a centrofacial eruption of multiple, small (<3 mm), dome-shaped, erythematous papules, some of which are surmounted by a seropustule (Fig. 37.3). These lesions can appear singly or in crops. The patient may complain of slight tenderness or itch associated with the lesions, but in general the social distress caused by the appearance of the eruption far exceeds the physical symptoms. Individual lesions last about 2 weeks then subside into a blotchy erythema, which gradually fades; resultant scarring is not seen. As some lesions fade, others appear.

  A halo of erythema may surround the larger inflammatory lesions and tiny telangiectatic blood vessels may be visible within this rim. In severely affected skin, slight scaling or a crusted appearance may sometimes be seen (Fig. 37.4). These findings should not be confused with seborrheic dermatitis, which may accompany papulopustular rosacea but is characterized by a greasy, yellowish scale and involvement of the facial creases and the eyebrows.
- The most common expression of *phymatous rosacea* is rhinophyma, which reflects hypertrophy of the sebaceous glands in nasal skin. Rhinophyma is usually seen in patients with other features of rosacea but may occur in patients with acne vulgaris; occasionally it is due to chronic actinic damage or may arise *de novo*. Specifically, rhinophyma does not represent "end-stage" rosacea as many patients have had only mild or no preceding rosacea. Male patients are predominantly affected by rhinophyma[24], and telangiectatic vessels of the distal nose may predispose to subsequent development of hypertrophic changes of rhinophyma (Fig. 37.5A). The earliest clinical sign of rhinophyma is the appearance of dilated pores (patulous follicles) on the distal portions of the nose (Fig. 37.5B). In severe cases of rhinophyma,

Fig. 37.3 Moderate papulopustular rosacea of the forehead. Note the superficial nature of the inflammatory lesions.

Fig. 37.4 Moderate to severe papulopustular rosacea. There is a typical centrofacial distribution of erythema, telangiectasias, papules and pustules. In addition, the skin has a scaly, crusty surface and this is often a sign of more severe disease.

TYPES OF PHYMATOUS ROSACEA	
Phyma	**Clinical features**
Rhinophyma	Apparent initially as dilated patulous follicles at the distal end of the nose When marked, can lead to debilitating nasal deformity
Gnathophyma	Rare occurrence, with central chin typically involved May give rise to asymmetrical swelling
Otophyma	Usually affects the lower half of the helices and lobes of the ears
Mentophyma	Cushion-like, firm swelling of central forehead
Blepharophyma	Swelling of the eyelids Usually seen as a component of edematous rosacea but may accompany severe papulopustular or ocular rosacea

Table 37.3 Types of phymatous rosacea.

there is hypertrophy of tissue with nasal distortion as soft, fleshy, nodular growths increase in size (Fig. 37.5C).

Although basal cell carcinomas have been reported to arise in skin affected by rhinophyma, there is insufficient evidence to suggest that this condition predisposes to malignant change. Other phymatous skin changes are rare (Table 37.3). Of note, the edematous changes sometimes seen in patients with severe inflammatory rosacea (Fig. 37.6) should not be confused with phymatous rosacea, as such changes (unlike those of phymatous rosacea) often subside with successful management of the inflammation.

- *Ocular rosacea* can occur without accompanying cutaneous changes (in which case the diagnosis is difficult to make with certainty) or it may be seen in patients with any of the other subtypes of rosacea. Those with erythematotelangiectatic and papulopustular rosacea appear to be particularly vulnerable to the development of ocular inflammation, with up to 50% of patients affected. Symptoms consist of nonspecific complaints of itching, tearing, dryness, gritty sensations, crusting of eyelids and an inability to wear contact lenses, as well as frequent styes. However, patients may not volunteer these symptoms unless specifically asked.

  The clinical signs of ocular rosacea are diverse and lacking in specificity. There may be tiny concretions at the bases of the cilia (conical dandruff), or mild scaling of the eyelid margins (scurf). More active disease manifests as blepharitis, often with eyelid swelling and conjunctival injection; the latter gives the affected eye a reddish appearance (Fig. 37.7). Cysts arising from the meibomian glands (chalazia) present as firm non-tender swellings of the cutaneous tarsal surface, while hordeola are similar, but are tender swellings often referred to by patients as "styes". Severe ocular disease (keratitis, corneal neovascularization, uveitis, scleritis or iritis) is fortunately rarely seen in patients with rosacea. Patients who complain of pain or photophobia require specialist attention.

Fig. 37.5 Rhinophyma – early versus advanced disease. A Tortuous, telangiectatic vessels on the distal aspect of the nose contribute to its hyperemic appearance; this hyperemia may predispose to the subsequent hypertrophic changes of rhinophyma. Note the early sign of dilated follicles. **B** Prominent follicular openings or patulous follicles with evidence of the early swelling of glandular rhinophyma. **C** Distortion of nasal tissue due to nodular hypertrophy of sebaceous glands. Electrosurgery or laser therapy can be used to debulk and resculpt this nose.

In addition to the four major types of rosacea, there are variants that include granulomatous rosacea and rosacea fulminans, also referred to

Fig. 37.6 Inflammatory rosacea with edematous changes. An intensely erythematous plaque is present on the medial aspect of the cheek. This may improve once the underlying inflammation is treated appropriately.

Fig. 37.7 Ocular rosacea. A Tiny concretions of keratin (conical dandruff) are visible at the bases of some of the eyelashes of the lower eyelid. There is also evidence of blepharitis of the lower eyelid and conjunctival injection. **B** Marked injection of the conjunctivae, leading to the appearance of red eyes. Ectropion is also present.

Fig. 37.8 Variants of rosacea. **A** Discrete skin-colored to brown papules scattered on the face. Histologically, granulomas with central caseation necrosis were observed, which led to the diagnosis of lupus miliaris disseminatus faciei; nowadays this entity is thought to fall within the spectrum of granulomatous rosacea. **B** Rosacea fulminans (pyoderma faciale). Striking plaque on the cheek studded with pustules.

as pyoderma faciale (see Introduction) (Fig. 37.8). Also, rarely extrafacial lesions of rosacea are seen, primarily on the scalp of male patients with androgenic alopecia.

PATHOLOGY

Histologic changes in the erythematotelangiectatic form of rosacea may be subtle and are often limited to vascular ectasia and mild edema (Fig. 37.9A). In the inflammatory papulopustular form, a more prominent perivascular and perifollicular lymphohistiocytic infiltrate appears (Fig. 37.9B). Sebaceous hyperplasia may be prominent in some patients. Comedo formation is notably lacking. In the granulomatous form of rosacea, non-caseating epithelioid granulomas are seen within the dermis (Fig. 37.9C).

DIFFERENTIAL DIAGNOSIS

Acne vulgaris (see Ch. 36) is in the differential diagnosis of the papulopustular subtype of rosacea. However, unlike in acne vulgaris, open and closed comedones are not seen in patients with rosacea. Since both disorders are so common, a patient with rosacea may have features of coexistent or previous acne vulgaris (e.g. scarring). Rosacea-like disorders also need to be considered (see below) – in particular, periorificial dermatitis and steroid-induced rosacea. The differential diagnosis also includes *Demodex* folliculitis.

The erythematotelangiectatic form of rosacea needs to be distinguished from chronic actinic damage (in fair-skinned individuals), seborrheic dermatitis (see Ch. 13), cutaneous lupus (lacks pustules; see Ch. 41), keratosis pilaris rubra and erythromelanosis faciei. The latter two disorders have characteristic tiny follicular white papules (see Ch. 38). The differential diagnosis of the blepharitis of ocular rosacea includes seborrheic dermatitis and allergic contact dermatitis.

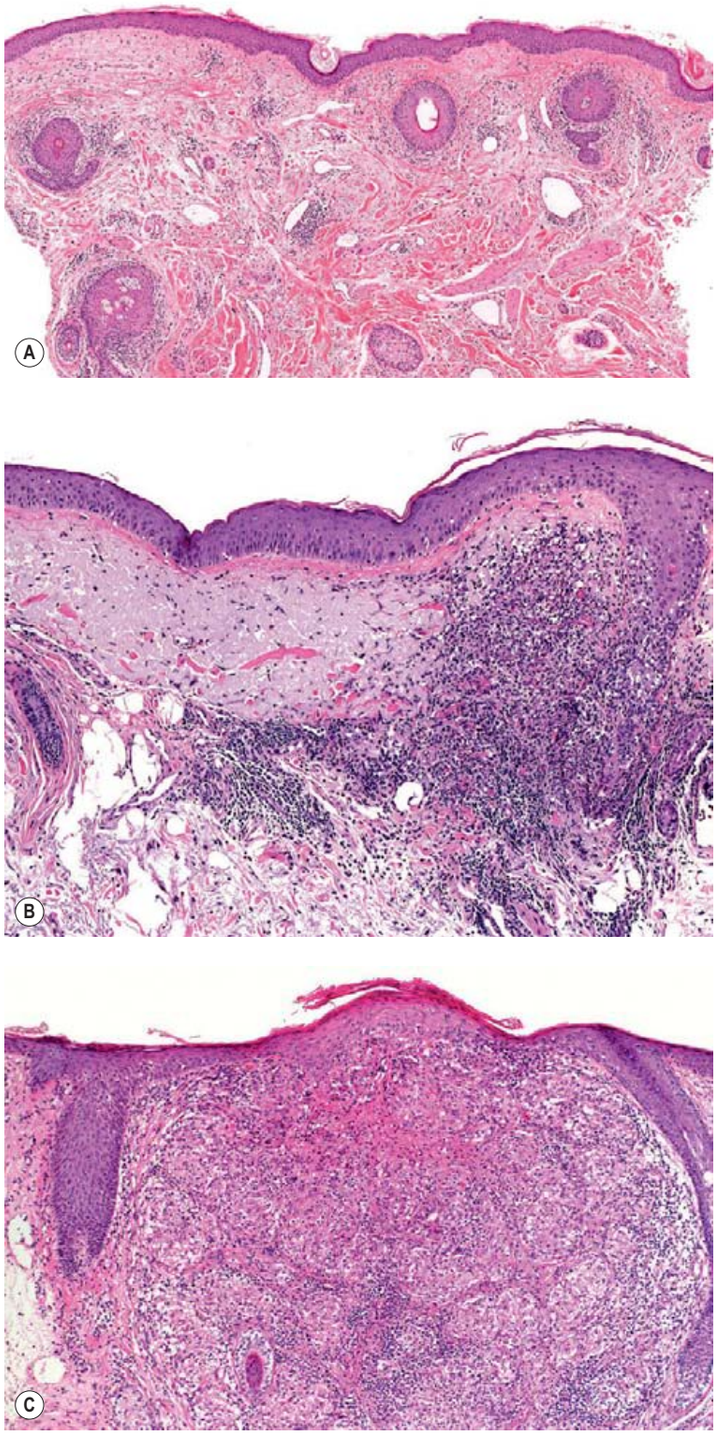

Fig. 37.9 Rosacea – range of histologic findings. A *Erythematotelangiectatic form* with multiple dilated blood vessels within the dermis as well as minimal perifollicular and perivascular lymphocytic infiltrates. **B** *Papulopustular form* with a dense dermal infiltrate of lymphocytes, predominantly surrounding an involved hair follicle. There is also marked solar elastosis. **C** *Granulomatous form* with a nodular granulomatous infiltrate composed of histiocytes, histiocytic giant cells and admixed lymphocytes filling the upper interfollicular dermis. *Courtesy, Lorenzo Cerroni, MD.*

TREATMENT

Categorizing rosacea into subtypes is especially useful when therapeutic options are being considered (Table 37.4). The particular subtype determines the management that will be required, with treatment of acute inflammation different from the therapy necessary to maintain clearance. Grading each subtype into mild, moderate and severe (grades 1–3; see Table 37.2) will also help the physician decide on the most appropriate treatment(s). Grading is also useful for monitoring progress[27].

It is important to educate the patient at the initial consultation as to the chronic relapsing nature of this disorder and the need for a maintenance regimen. Otherwise, the expectation might be that one course of therapy is curative.

Patients with grade 1 erythematotelangiectatic rosacea present with mild fixed facial erythema and intermittent flushing. Frequent flushing with the presence of multiple telangiectatic blood vessels is characteristic of grades 2 and 3 disease (see Table 37.2). Therapy focuses on recommendations for facial skin care (Table 37.5), reduction of the tendency for flushing by avoiding precipitating factors and specific medications, diminishing the facial erythema, and removing the telangiectasias (see Table 37.4). Topical and systemic therapies used to treat papulopustular rosacea are often ineffective in the treatment of erythematotelangiectatic rosacea and may irritate the skin. Avoidance of sun exposure and the constant use of a sunblock cream (SPF ≥15) are important, as a significant component of the patient's skin changes may be due to dermatoheliosis.

Patients with papulopustular rosacea are treated primarily with topical and systemic antibiotics (used separately or in combination), although other agents have also been used to treat this subtype of rosacea (see Table 37.4). Many of the recommended systemic antibiotics are the same as those used for the treatment of acne vulgaris, but the courses for rosacea are usually shorter (4 to 6 weeks as opposed to 4 to 6 months). Sometimes, successful treatment of the inflammatory lesions of papulopustular rosacea reveals background telangiectasias (the PERT phenomenon – "post-erythema-revealed telangiectasias"). It is useful to warn patients of this possibility, as otherwise they might attribute the appearance of these telangiectasias to the prescribed treatment. Following successful treatment of inflammatory lesions, individuals with papulopustular rosacea should continue with maintenance therapy (usually topical); otherwise, relapse is likely 3 to 6 months after discontinuation of treatment. Many patients with moderate to severe (grades 2 and 3) papulopustular rosacea require repeated courses of systemic antibiotic therapy.

Rhinophyma is the most common manifestation of phymatous rosacea and is the phyma most amenable to surgical treatment (see Table 37.4). Mild disease may be responsive to medical treatment with isotretinoin, although conclusive evidence of efficacy is lacking. More severe (grades 2 and 3) disease with marked swelling and deformity responds best to physical modalities such as CO_2 laser therapy, electrosurgery or surgical excision. Other phymatous variants are very rare and therapeutic interventions are based solely on case reports.

Patients with mild ocular rosacea (grade 1 disease) often complain of itch or a dry gritty feeling in the eye(s). Lavage of eyelid margins with a mild shampoo on cotton-tipped applicators and tear replacement therapy are usually sufficient for this grade of ocular rosacea. Burning or stinging of the eyes with crusting of the eyelid margins or the formation of chalazia or hordeola are manifestations of moderate (grade 2) disease and patients require either topical antibiotics (such as metronidazole gel or fucidic acid) or systemic antibiotic therapy as outlined for papulopustular rosacea (see Table 37.4). Symptoms such as pain and photophobia as well as visual disturbances are features of severe (grade 3) disease. Such symptoms or lack of response to treatment requires prompt referral to an ophthalmologist for evaluation.

ROSACEA-LIKE DISORDERS

- *Morbihan's disease* is a rare disorder characterized by progressive then persistent, asymptomatic, non-pitting swelling of the central upper face that is associated with fixed facial erythema (Fig. 37.10). It is a poorly defined clinical entity and the exact etiology is not known. Histologic examination shows dermal edema with prominent mast cells within a mild inflammatory infiltrate. It may represent the endpoint of diverse initiating factors such as injury or allergic contact dermatitis[30] and it is debatable as to whether there is any relationship to rosacea. In general, there is no effective therapy, but prolonged courses of low-dose oral isotretinoin have been reported to be helpful in individual patients, as have systemic antihistamines.
- *Periorifical dermatitis*, also referred to as perioral dermatitis, has a superficial resemblance to rosacea but the morphology of the lesions – grouped tiny superficial papulovesicles or papulopustules

MEDICAL AND SURGICAL THERAPIES FOR ROSACEA	
ERYTHEMATOTELANGIECTATIC ROSACEA	
Treatment	**Comments**
Facial skin care recommendations (see Table 37.5)	Particularly useful as this subtype is prone to skin irritation and "sensitivity"
Photoprotection	UVR may potentiate dermal matrix damage
Topical agents, e.g. azelaic acid, metronidazole	May reduce erythema, but their use is often limited by their irritant effects
Topical oxymetazoline[25]	Selective α_1-agonist that may improve erythema
Laser therapy	Use of lasers (e.g. pulsed dye, potassium-titanyl-phosphate) as well as intense pulsed light may improve grades 2 and 3
PAPULOPUSTULAR ROSACEA	
Topical treatments	**Comments**
Metronidazole (0.75% gel or cream; 1% cream)*,† once or twice daily	Can be used as initial treatment to clear inflammatory lesions or as indefinite maintenance therapy
Azeleic acid (15% gel)*,† twice daily	Appears to be more effective than topical metronidazole but with more side effects, e.g. irritation Azeleic acid (20% cream bid) is a non-FDA-approved alternative dose
Sodium sulfacetamide (10%) and sulphur (5%) in a cream or lotion* once or twice daily	May include 10% urea
Erythromycin (2% solution) twice daily	Alcohol in solution may reduce tolerance
Clindamycin (1% lotion) daily	
Benzoyl peroxide 5% and clindamycin 1% daily	May cause skin irritation
Tretinoin (0.025% cream; 0.05% cream; 0.01% gel) daily	Alters epidermal keratinization and may improve photodamage Poorly tolerated by some patients
Permethrin (5% cream) daily–weekly	Shown to be as effective as topical metronidazole for the treatment of papules and erythema May have future role in combination with antibiotics, but further studies needed
Pimecrolimus (1% cream) twice daily	Some studies have shown improvement in erythema, but there have been case reports of exacerbations, so further studies needed
Systemic treatments	**Dosage and duration**
Doxycycline*,†	40 mg daily (30 mg immediate release and 10 mg delayed release) for 6–12 weeks As effective as the 100 mg dose but with less adverse effects
Doxycycline	50–100 mg once or twice daily for 6–12 weeks
Minocycline	50–100 mg twice daily or sustained action formula (1 mg/kg) daily for 6–12 weeks
Tetracycline	250–500 mg twice daily for 6–12 weeks
Erythromycin	250–500 mg once or twice daily for 6–12 weeks
Azithromycin	250–500 mg (5–10 mg/kg) thrice weekly
Metronidazole	200 mg once or twice daily for 4–6 weeks
Isotretinoin	10–40 mg daily
PHYMATOUS ROSACEA	
Treatment	**Comments**
Isotretinoin	May reduce nasal volume and halt the progression of rhinophyma
Surgical excision	Can effectively debulk and resculpt the nose
Electrosurgery	
CO_2 laser	
OCULAR ROSACEA	
Treatment	**Comments**
Eyelid hygiene and artificial tears	Frequently used to treat mild disease Useful for maintaining remission following treatment of grades 2 and 3 disease with systemic antibiotics
Fuscidic acid	
Metronidazole gel	
Cyclosporine 0.5% ophthalmic emulsion†	More effective than artificial tears in treatment of ocular rosacea
Systemic antibiotics (see above section)	For grade 2–3 disease
*The only FDA-approved treatments for rosacea (evidence-based support = 1) †In a Cochrane review of randomized controlled trials conducted for moderate to severe rosacea, these were the only treatments shown to be effective[26].	

Table 37.4 Medical and surgical therapies for rosacea. UVR, ultraviolet radiation.

GENERAL RECOMMENDATIONS FOR FACIAL SKIN CARE AND EDUCATION IN PATIENTS WITH ROSACEA
FACIAL SKIN CARE
• Wash with lukewarm water and use soap-free cleansers that are pH balanced
• Cleansers are applied gently with fingertips
• Use sunscreens with both UVA and UVB protection and an SPF ≥15
• Sun-blocking creams containing the physical barriers titanium dioxide and/or zinc oxide are usually well tolerated
• Use cosmetics and sunscreens that contain protective silicones
• Water-soluble facial powder containing inert green pigment helps to neutralize the perception of erythema
• Moisturizers containing humectants (e.g. glycerin) and occlusives (e.g. petrolatum) help to repair the epidermal barrier
• Avoid astringents, toners and abrasive exfoliators
• Avoid cosmetics that contain alcohol, menthols, camphor, witch hazel, fragrance, peppermint and eucalyptus oil
• Avoid waterproof cosmetics and heavy foundations that are difficult to remove without irritating solvents or physical scrubbing
• Avoid procedures such as glycolic peels or dermabrasion
PATIENT EDUCATION
• Reassure the patient about the benign nature of the disorder and the rarity of rhinophyma, particularly in women
• Emphasize the chronicity of the disease and the likelihood of exacerbations
• Direct patients to information websites such as those of the National Rosacea Society (www.rosacea.org) or the American Academy of Dermatology (www.aad.org)
• Advise to avoid recognized triggers
• Explain the importance of compliance with topical regimens
• Educate on the importance of sun avoidance

Table 37.5 General recommendations for facial skin care and education in patients with rosacea. Adapted from refs 23, 28 & 29.

Fig. 37.10 Morbihan's disease. Erythematous, firm, non-pitting, non-painful swelling of the upper face. Areas of greatest involvement have acquired a "peau d'orange" appearance.

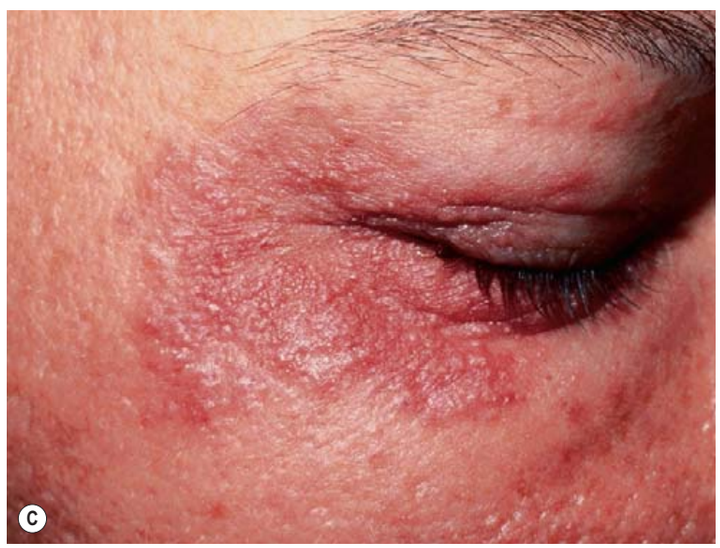

Fig. 37.11 Periorificial dermatitis (also referred to as perioral dermatitis). **A** Accentuation of erythema with superimposed fine superficial papulo-pustules and papulovesicles around orifices, i.e. in a perioral, perinasal and periorbital distribution pattern. The papular lesions are often agminated and, in contrast to papulo-pustular rosacea, are usually all at the same stage of evolution. **B** Granulomatous periorificial dermatitis in a child with mono-morphous pink papules that have become confluent around the mouth. The eruption, which had previously worsened upon treatment with topical and oral corticosteroids, resolved with a 6-week course of azithromycin. **C** Periocular dermatitis with multiple fine papules and pustules superimposed on a pink plaque. *B, Courtesy, Julie V Schaffer, MD. C, Courtesy, Ronald P Rapini, MD.*

in the same stage of development rather than larger crops of papules and pustules in varying stages of development – and the distribution – perioral rather than centrofacial – usually indicate the correct diagnosis (Fig. 37.11). In addition, papules may be superimposed on or admixed with thin plaques that can resemble a nonspecific dermatitis. Sometimes the papules have a granulomatous component. These patients may or may not have a history of topical or inhaled corticosteroid usage. Affected individuals often describe an intolerance of sunlight, cosmetic applications and/or hot water. Systemic antibiotics (tetracycline, doxycycline, minocycline, erythromycin, azithromycin) are prescribed for 4 to 6 weeks. Topical corticosteroid therapy should be discontinued. Unlike rosacea, clearance is not usually followed by a subsequent relapse.

- *Rosaceiform dermatitis* refers to a drug eruption caused by the application of topical calcineurin inhibitors to the face. It is characterized by facial erythema, small papules and numerous pustules. In contrast to the centrofacial eruption of papulopustular rosacea, the distribution is generally more widespread. *Demodex* mites have been found to be abundant on the facial skin of some of these patients and it may be that the immunomodulating effect of these agents facilitates their proliferation on the skin.

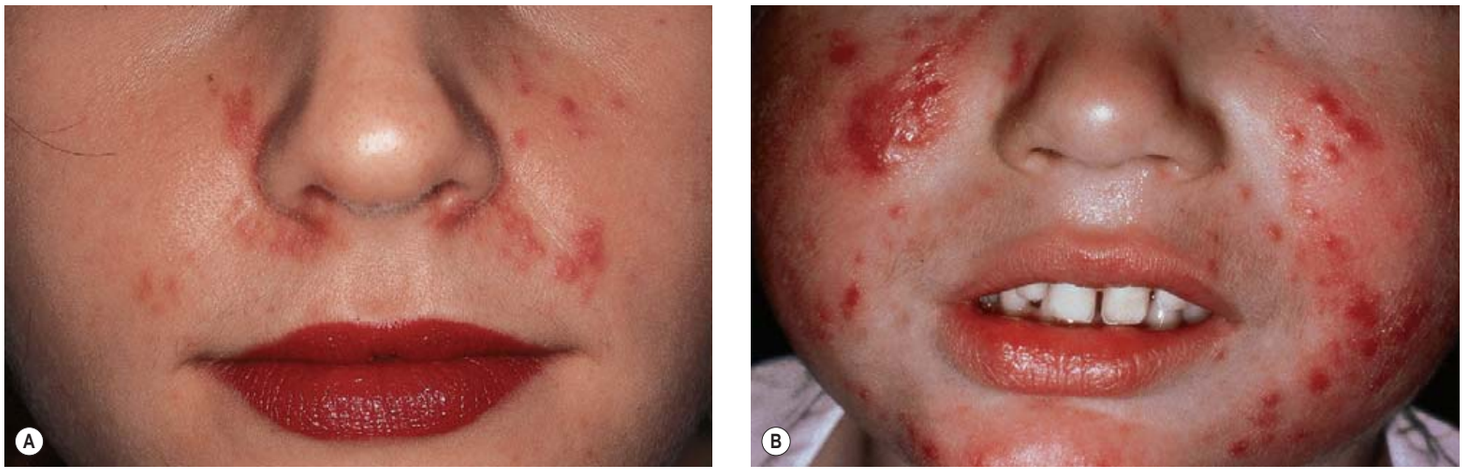

Fig. 37.12 Steroid rosacea. A Milder disease in an adult with scattered erythematous papules and papulopustules. **B** Severe disease in a child with confluence of papulopustules. *A, Courtesy, Kalman Watsky, MD.*

- *Papulopustular eruptions due to epidermal growth factor receptor (EGFR) inhibitors* are increasingly being seen (see Ch. 36). Depending upon the particular inhibitor, up to 90% of patients can develop this side effect. Although perhaps more similar in morphology to rosacea (e.g. lacks the comedones seen in acne vulgaris), inflammatory lesions are often more widespread and can involve the entire face, scalp and trunk. Pre-emptive therapy with doxycycline (100 mg twice daily) as well as topical sunscreens and moisturizers can lead to a reduction in severity. The eruption has been attributed to the importance of EGFR signalling in the skin[31]. Patients with this rosaceiform eruption have also been shown to have an increased density of *Demodex folliculorum*[32].
- *Steroid-induced rosacea* presents with erythema, papules, pustules and sometimes telangiectasias and atrophy due to repeated applications of potent topical corticosteroid preparations to the face (Fig. 37.12). Again, *Demodex* mites are present in high numbers. Reducing the strength of the topical corticosteroid application rather than its abrupt discontinuation is advisable in order to avoid a rebound flare. Systemic antibiotics (tetracycline, doxycycline or minocycline) are usually required for up to 6 weeks to allow the skin to settle.
- *Pityriasis folliculorum* is a poorly recognized disorder that primarily affects young to middle-aged women. These patients rarely, if ever, allow water to contact the skin of their face and continually apply moisturizing creams and cosmetic preparations. The predominant feature is a roughened, whitish, scaling skin surface (referred to as "frosty") superimposed on a background of faint erythema plus scattered fine papules and pustules; the lesions are not limited to the central portion of the face. Often the patient complains of burning or stinging sensations. Gentle scraping of the skin surface with a glass slide reveals the presence of multiple dead and some live *Demodex* mites. Application of a topical sulfur preparation or permethrin 5% cream at night for up to 2 weeks is effective when combined with resumption of facial washing. Complaints of skin irritation (especially during the initial phases) may limit the patient's compliance with these measures and gentle persuasion to persist with treatment is required.
- *Haber's syndrome* is a rare familial genodermatosis characterized by early-onset facial erythema, verrucous papules, truncal keratotic lesions and pitted atrophic scars. Some authors group this disorder with Dowling-Degos disease and reticulate acropigmentation of Kitamura.

Chapter Contents

Superficial folliculitis 571
Disorders of follicular keratinization 577
Deep folliculitis 579
Trichostasis spinulosa 585
Folliculodystrophy of immunosuppression 585

Key features

- Follicular pustules, often arising on an erythematous base
- Favors areas with terminal hairs, such as the scalp and beard, as well as the upper trunk, buttocks and lower extremities
- Bacterial culture of pustular contents most commonly reveals normal flora, followed by *Staphylococcus aureus*
- Treatment depends on the particular type of folliculitis

INTRODUCTION

This chapter will review both superficial and deep forms of folliculitis as well as disorders of follicular keratinization and the follicular occlusion tetrad (acne conglobata, hidradenitis suppurativa, dissecting cellulitis, and pilonidal sinus). Examples of superficial forms of folliculitis include those due to *Staphylococcus aureus* or *Pseudomonas aeruginosa* infections, whereas acne keloidalis and pseudofolliculitis barbae are examples of deep forms. The disorders of follicular keratinization represent a varied group of dermatoses that have in common prominent keratotic follicular plugs. Some of these disorders are reviewed in other chapters, e.g. lichen planopilaris, pityriasis rubra pilaris and keratosis pilaris, while others are discussed here, e.g. lichen spinulosus and erythromelanosis follicularis faciei. Lastly, there are inflammatory disorders that can have a follicular predilection such as GVHD or, in darkly pigmented skin, papular eczema and pityriasis rosea.

SUPERFICIAL FOLLICULITIS

Synonym: ■ Impetigo of Bockhart

Introduction

Folliculitis is a very common disorder and is characterized by follicular pustules. Microbial cultures may fail to identify a pathogen, but, of the infectious etiologies, *Staphylococcus aureus* is the most common. Folliculitis, however, can be due to a wide range of microorganisms (Fig. 38.1).

Clinical features

Follicular pustules are usually accompanied by an erythematous rim (Fig. 38.2). Lesions may be pruritic, especially those on the occipital scalp, or even tender or painful. Occasionally, when there is more widespread involvement, patients can complain of generalized pruritus, a condition sometimes referred to as "itching folliculitis"[1].

Folliculitis occurs most commonly in the head and neck region (especially the scalp and beard area; Fig. 38.3), upper trunk, buttocks and legs, as well as in the axillae and groin. It favors areas that are occluded and/or have terminal hairs. In addition, shaving (e.g. pubic hair) and occlusion can exacerbate folliculitis. If no pustules are present, follicular-based erythematous papules or a superimposed collarette of scale serve as clues to the diagnosis[1].

Pathology

A moderately intense follicular infiltrate of lymphocytes, neutrophils and macrophages is seen, with extension of the neutrophils into the

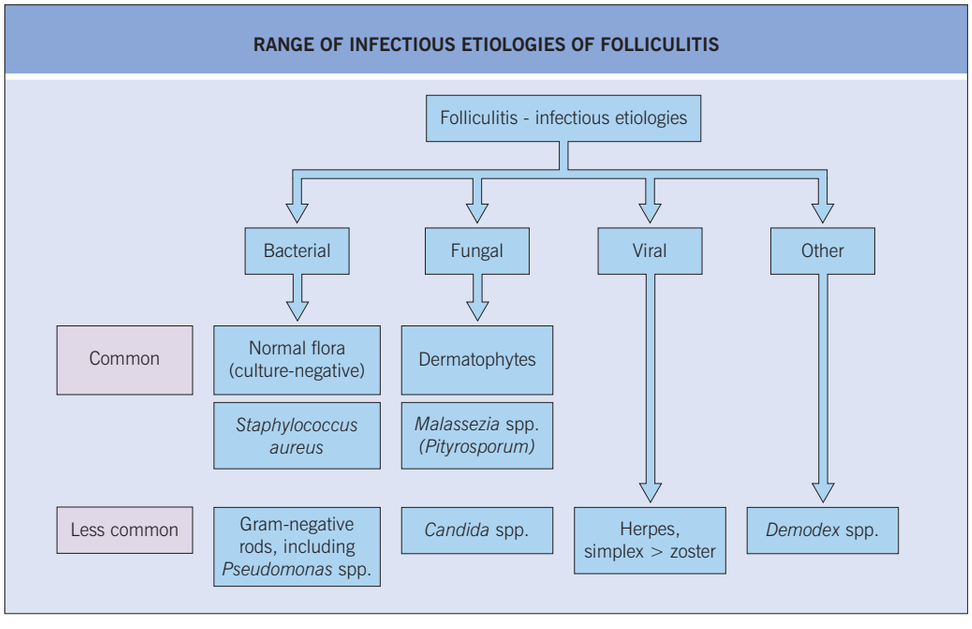

Fig. 38.1 Range of infectious etiologies of folliculitis. Non-infectious causes that need to be considered include eosinophilic folliculitis, drug-induced folliculitis and irritant folliculitis. Edematous lesions of folliculitis are most suggestive of eosinophilic folliculitis, *Demodex* folliculitis and *Pseudomonas* "hot tub" folliculitis. *Courtesy, Jean L Bolognia, MD.*

Fig. 38.2 Folliculitis (culture-negative). Follicular pustules with an erythematous rim are present on the upper back. The differential diagnosis is primarily folliculitis due to *Staphylococcus aureus* and acne.

Fig. 38.3 Folliculitis of the beard area due to *Staphylococcus aureus.* Discrete papulopustules are seen posteriorly. Centrally, there is deeper involvement with plaque formation (sycosis barbae).

follicular epithelium and follicular canal aggregating variably to form an abscess. Late-stage changes include follicular rupture and a granulomatous response. Tissue Gram stain and stains for fungi may reveal pathogenic organisms. Occasionally, cytopathic changes due to herpes simplex viral infection may be seen within the follicular epithelium (see Ch. 80) or multiple *Demodex* organisms within the follicular canal in demodicidosis (see Fig. 38.5D).

Differential diagnosis

The differential diagnosis includes the entities outlined in Table 38.1 as well as acne vulgaris, pseudofolliculitis barbae and, occasionally, rosacea. Microscopic examination of follicular contents may provide a clue to the type of folliculitis as well as microbial cultures and histologic examination. In hospitalized patients who are confined to bed, folliculitis may develop predominantly on the posterior trunk and thus needs to be distinguished from other disorders exacerbated by occlusion including Grover's disease, miliaria rubra and cutaneous candidiasis.

Treatment

The treatment chosen depends upon the culture results and severity (see Chs 74 & 127). For patients whose cultures fail to demonstrate a pathogenic microbe, the treatments, as in acne, include topical benzoyl peroxide, topical antibiotics (e.g. clindamycin) and oral antibiotics (e.g. tetracycline or doxycycline), with the anti-inflammatory properties of these antibiotics probably playing a role. This should be combined with an attempt to reduce overhydration of the skin, occlusion and irritation[1].

Eosinophilic Folliculitis

Three major forms of eosinophilic folliculitis have been described – eosinophilic pustular folliculitis (Ofuji's disease), AIDS (or immunosuppression)-associated eosinophilic folliculitis, and eosinophilic pustular folliculitis in infancy.

Eosinophilic pustular folliculitis

Synonym: ■ Ofuji's disease

Key features

- Follicular papulopustules as well as erythematous patches and plaques with superimposed coalescent pustules; central clearing leads to figurate lesions
- Most commonly involves the face, followed by the upper extremities and trunk
- Moderate to severe pruritus is a frequent symptom
- Recurrent crops of lesions that involute over 7–10 days
- Peripheral blood eosinophilia is also seen
- Histologically, eosinophils predominate around and within the follicular epithelium

Introduction

Eosinophilic pustular folliculitis is characterized by recurrent episodes of eruptive, intensely pruritic, follicular papulopustules. It typically affects "acne-prone" areas of the body such as the face, back and extensor surface of the arms[2]. To date, this disorder has not been associated with systemic disease.

History

In 1965, Ise and Ofuji[3] were the first to report a patient who had repeated episodes of follicular pustules on the face and back with peripheral blood eosinophilia. Five years later, Ofuji et al.[4] described three additional patients and proposed the name "eosinophilic pustular folliculitis" for this new clinical entity.

Epidemiology

Eosinophilic pustular folliculitis is a relatively rare entity, with most of the reported cases emanating from Japan. The majority of patients are adults and the average age of onset is 30 years[2]. The ratio of men to women is approximately 5:1. There have been occasional reports of eosinophilic pustular folliculitis in children, often with clinical features similar to the infantile form (see below).

Pathogenesis

The etiology and pathogenesis of eosinophilic pustular folliculitis is unknown. Perhaps tryptase-positive, chymase-negative mast cells play a role.

Clinical features

Recurrent crops of intensely pruritic, grouped, follicular pustules and papulopustules develop in a somewhat explosive fashion. In addition, there may be erythematous patches and plaques with superimposed coalescent pustules; central clearing and centrifugal extension produce annular and serpiginous lesions. Typically, areas with "sebaceous" follicles, such as the face, back and extensor surface of the arms, are affected. However, the digits, palms and soles may be involved, proving that not all lesions are follicular. Lesions last approximately 7–10 days. Spontaneous involution followed by relapses (on average every 3–4 weeks) is common. The patients have no accompanying systemic symptoms.

Pathology

Involved follicles may show spongiosis, with exocytosis of lymphocytes and eosinophils into the follicular epithelium. These findings can

LESS COMMON FORMS OF FOLLICULITIS		
Etiology/risk factors	**Clinical features**	**Therapy**
IRRITANT FOLLICULITIS		
Usually occurs following the application of topical medications (e.g. tar preparations), ointments Exacerbated by application in a direction opposite that of hair growth	Follicular pustules in the sites of application or exposure to irritant Favors areas with terminal hairs	• Discontinue inciting topical agent • Apply medications in the same direction as hair growth • Topical mid-potency corticosteroid lotion
GRAM-NEGATIVE FOLLICULITIS		
Due to *Klebsiella*, *Enterobacter* and *Proteus* spp. Usually seen in patients with acne vulgaris receiving long-term antibiotic therapy	Pustules in the facial T-zone and in a perinasal distribution Adult men with oily skin	• Topical: gentamicin, benzoyl peroxide • Systemic: quinolones (e.g. ciprofloxacin) • If severe or recurrent: isotretinoin, 0.5–1 mg/kg/day for up to 16 weeks
Hot tub folliculitis due to *Pseudomonas aeruginosa* in the setting of use of a hot tub/whirlpool 12–48 hours prior to onset	Edematous, pink to red follicular papules and pustules, primarily on the trunk (Fig. 38.4) Often pruritic and resolves spontaneously in immunocompetent host May be serious illness in immunocompromised host	• Generally self-limited; can use antibacterial soap • If severe or immunocompromised host: ciprofloxacin, 500 mg po twice daily for 7–14 days • Water in hot tub, whirlpool or swimming pool must be maintained with chlorine (0.4–1.0 ppm, pH 7.2–7.4) and changed every 6–8 weeks to lower organic carbon level
DERMATOPHYTE FOLLICULITIS		
Tinea barbae due to *Trichophyton mentagrophytes* var. *mentagrophytes* or *T. verrucosum* classically occurs in male farm workers	Inflammatory papules and pustules in the beard more often than the mustache areas, with crusting and loosened hairs that can be removed without pain	• Topical antifungals (may be ineffective) • Micronized or ultramicronized griseofulvin, 500–1000 mg/day or 500–700 mg/day po, respectively, for 4–6 weeks • Terbinafine, 250 mg/day po for 2–3 weeks • Itraconazole, 200 mg po twice daily for 1 week per month, for 2 pulses
Majocchi's granuloma, usually due to *T. rubrum*, characteristically develops in women who shave their legs	Follicular pustules and follicular papules or nodules (Fig. 38.5A), most often located on the lower legs Pustules at edges of tinea cruris or corporis	
***PITYROSPORUM* FOLLICULITIS**		
Typically occurs in young adults, with aggravating factors including warm weather, occlusion and excessive sebum production May also develop in association with antibiotic therapy (especially tetracyclines) or iatrogenic immunosuppression (e.g. organ transplant recipients)	Pruritic follicular papules and occasionally pustules, primarily on the back, chest and shoulders Central white–yellow color often represents compact keratin rather than pus A KOH preparation of follicular contents reveals abundant yeast forms	• Topical: antifungals, selenium sulfide shampoo, 50% propylene glycol in water • Systemic: fluconazole 100–200 mg/day for 3 weeks; itraconazole 200 mg/day for 1–3 weeks
***CANDIDA* FOLLICULITIS**		
Primarily in diabetics	Pruritic satellite pustules surrounding areas of intertriginous candidiasis Facial lesions may mimic tinea barbae or acne rosacea	• Prevent skin-to-skin contact in intertriginous areas • If possible, discontinue antibiotics and/or corticosteroid therapy • Mild to moderate disease: topical antifungals • Recalcitrant or severe disease: fluconazole 100 mg daily for 1 week then every other day for 1 month
HERPES SIMPLEX FOLLICULITIS		
Herpetic sycosis is usually seen in men with a history of recurrent localized facial herpes simplex infection who shave with a blade razor Widespread or unusual presentations of herpes simplex folliculitis may be seen in HIV-infected or otherwise immunosuppressed individuals (Fig. 38.5B)	Rapid development of individual and grouped follicular pustules and vesicles on an erythematous base in the beard area A Tzanck smear or biopsy reveals multinucleated giant cells Direct immunofluorescent antibody (DFA) assay+	• Acyclovir 200 mg po 5 times per day for 5–10 days • Famciclovir 500 mg po three times per day for 5–10 days • Valacyclovir 500 mg po three times per day for 5–10 days
***DEMODEX* FOLLICULITIS (DEMODICIDOSIS)**		
May be associated with immune suppression	Erythematous follicular papules and pustules on the face, often with a background of diffuse erythema (Fig. 38.5C) Skin scrapings reveal numerous *Demodex* mites (Fig. 38.5E)	• Topical: 5% permethrin cream • Systemic: single dose of ivermectin 200 microg/kg po
DRUG-INDUCED FOLLICULITIS (ACNEIFORM ERUPTION)		
Most common in acne-prone patients and age groups Corticosteroids, androgenic hormones, EGFRI, iodides, bromides, lithium, isoniazid and anticonvulsants Can develop within 2 weeks of starting the offending agent, but the risk is proportional to the dose and duration of therapy	Acute eruption of monomorphic erythematous follicular papules and pustules on the trunk, shoulders and upper arms Unlike acne vulgaris, comedones are rarely present	• Discontinue the offending drug, if possible • Topical: benzoyl peroxide, clindamycin, erythromycin, retinoids • Systemic: tetracycline, doxycycline, minocycline
ACTINIC FOLLICULITIS		
Seasonal Follows initial summer sun exposure	Development of follicular pustules on the upper trunk and arms 24–30 hours after first sun exposure of the summer Lesions spare the face and are not pruritic	• Sun avoidance; sunscreens will not prevent lesion formation • Topical mid-potency corticosteroids • Isotretinoin 0.35–0.5 mg/kg/day for 3–6 months

Table 38.1 Less common forms of folliculitis. EGFRI, epidermal growth factor receptor inhibitor.

Fig. 38.4 ***Pseudomonas*** **"hot tub" folliculitis. A, B** Edematous follicular papules on the flank that begin to develop 2–3 days following the use of a hot tub. The number and size can vary. *B, Courtesy, Kalman Watsky, MD.*

extend from the sebaceous gland and its duct up to and including the infundibular zone. A dermal infiltrate of lymphocytes and eosinophils may also be present. Micropustular aggregation develops, followed by the hallmark finding, infundibular eosinophilic pustules[5]. Secondary follicular mucinosis is sometimes seen.

Differential diagnosis

Clinically, some of the lesions may resemble other forms of superficial folliculitis (see previous section). However, the explosive crops, annular plaques with central clearing, intense pruritus, peripheral blood eosinophilia, and histologic findings enable differentiation from clinically similar entities.

Treatment

To date, potential treatments are based upon small case series or case reports. Topical antipruritics, oral antihistamines, and topical corticosteroids or tacrolimus ointment can be prescribed for the associated pruritus. Open wet dressings may provide some relief. First-line treatment for eosinophilic pustular folliculitis is oral indomethacin (50 mg/day). Second-line therapies include UVB phototherapy, oral minocycline (100 mg twice daily), oral dapsone (100 to 200 mg/day for ≥2 weeks), systemic corticosteroids and colchicine (0.6 mg twice daily).

AIDS-associated eosinophilic folliculitis

Synonym: ■ Immunosuppression-associated eosinophilic folliculitis

Key features

- Pruritic follicular papules that favor the face, scalp and upper trunk in the setting of HIV infection or other immunosuppressed states
- Usually occurs in HIV-infected patients whose CD4 count is <300 cells/mm^3
- Histologically, lesions are characterized by spongiosis and exocytosis of eosinophils and lymphocytes into the follicular epithelium
- Clinical improvement occurs with elevation of the CD4 count via antiretroviral therapy

Introduction

A pruritic papular eruption with histologic features that are similar to eosinophilic pustular folliculitis (Ofuji's disease) can develop in HIV-infected patients, many of whom fulfill the criteria for AIDS. Eosinophilic folliculitis has also been observed in patients with lymphoma, chronic lymphocytic leukemia, acute myelogenous leukemia and myeloproliferative disorders, as well as those who have undergone allogeneic hematopoietic stem cell transplantation; hence, the use of the term immunosuppression-associated eosinophilic folliculitis. However, in comparison to Ofuji's disease, there are neither large coalescent pustules nor figurate lesions and the individual lesions are more persistent.

History

AIDS-associated eosinophilic folliculitis was first described in 1986 as a pruritic papular dermatosis occurring in HIV-infected individuals[6].

Epidemiology

The disorder is more prevalent in adult men, but this probably reflects the relative proportion of this group amongst the population with AIDS. The possibility of *Demodex* mites triggering an immune reaction in advanced HIV infection has been raised[7], as has a possible association with the use of foscarnet. The development of eosinophilic folliculitis correlates with a low CD4 count (in particular <300/mm^3), and clinical improvement has been observed following antiretroviral-induced increases in CD4 counts. However, in one study of 57 patients, eosinophilic folliculitis developed within 3 to 6 months of initiating different regimens of antiretroviral therapy (that led to a modest increase in CD4 counts), lending support to the conclusion that eosinophilic folliculitis can be part of the immune reconstitution syndrome (see Ch. 78)[8].

Pathogenesis

Little is known about the exact pathogenesis of AIDS-associated eosinophilic folliculitis. However, Amerio et al.[9] found that, as in other eosinophilic diseases, a Th2 pattern can be seen. They found elevated levels of interleukin (IL)-4, IL-5, RANTES and eotaxin mRNA within lesional skin; the latter two are chemokines.

Clinical features

AIDS (or immunosuppression)-associated eosinophilic folliculitis is characterized by a chronic, pruritic, follicular papular eruption of the face, scalp and upper trunk (Fig. 38.6). HIV-infected individuals characteristically have a CD4 count <300 cells/mm^3. The papules may be slightly edematous and there may be no pustules. The associated pruritus can be intense.

Pathology

The histologic features are similar to those of Ofuji's disease (see above)[10].

Differential diagnosis

The differential diagnosis includes more common causes of folliculitis (see above) as well as the entities outlined in Table 38.1, especially *Demodex* folliculitis. Microscopic examination of follicular contents as well as performance of a biopsy may be necessary to establish the diagnosis (see Fig. 38.1). Necrotizing eosinophilic folliculitis is said to be distinguished by its association with atopy and the presence of

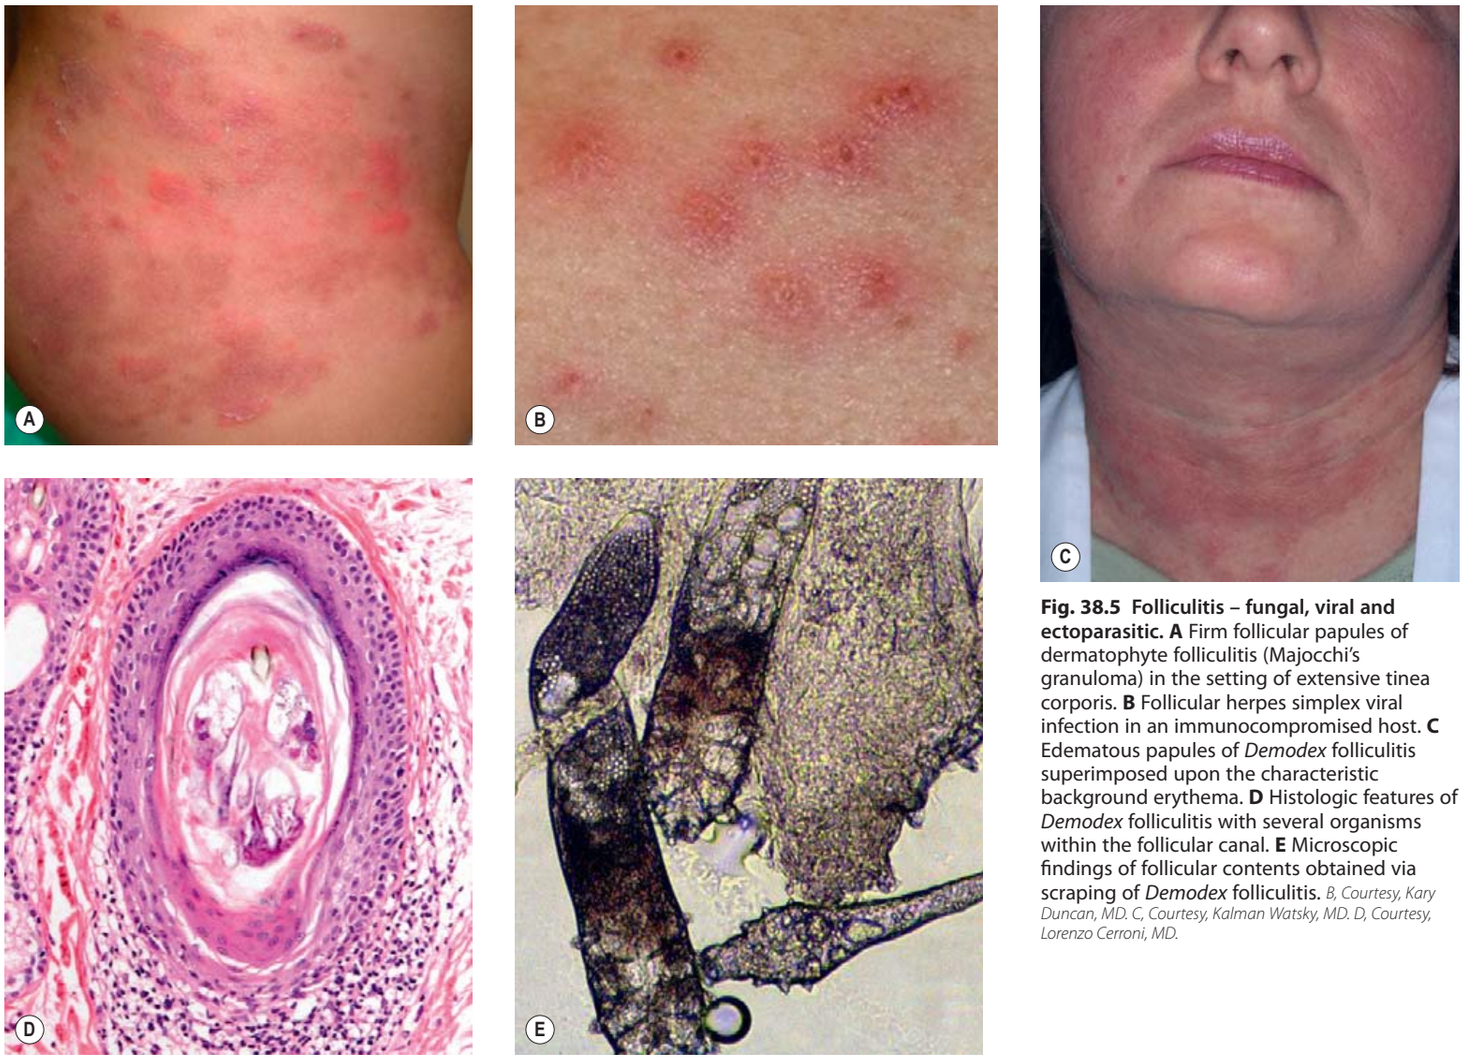

Fig. 38.5 Folliculitis – fungal, viral and ectoparasitic. nodules and ulceration, with evidence of follicular necrosis and eosinophilic vasculitis histologically.

Treatment

Treatment of the underlying HIV infection, with a resultant rise in the CD4 cell count, may lead to a resolution of lesions. In patients who have failed antiretroviral therapy or in other immunosuppressed hosts, oral and topical antipruritics in combination with topical corticosteroids may prove inadequate, and UVB phototherapy may be required. Additional therapies include topical permethrin, topical tacrolimus[11], oral itraconazole (100–400 mg daily), oral antibiotics, isotretinoin (0.5–1 mg/kg/day × 1–4 weeks, then taper), and interferon (β and γ).

Eosinophilic pustular folliculitis in infancy

Synonyms: ■ Infantile eosinophilic pustular folliculitis ■ Neonatal eosinophilic pustular folliculitis ■ Eosinophilic pustular folliculitis in childhood ■ Eosinophilic pustulosis (of the scalp) in childhood

Key features

- Unusual, self-limiting disorder that typically appears during early infancy
- Multiple, pruritic, follicular pustules and vesicopustules on an erythematous base
- Seen primarily on the scalp and brow region
- Secondary crusting is common
- Histologically, there is a dense dermal perifollicular infiltrate of eosinophils and lymphocytes, which may spare the sebaceous glands and outer root sheath

Introduction
Eosinophilic pustular folliculitis in infancy is a rare, self-limiting disorder of unknown etiology that occurs during infancy (see Ch. 34). It differs from adult eosinophilic pustular folliculitis by primarily involving the scalp and by frequently developing secondary crusting.

History
In 1984, Lucky et al.[12] first described five infants with this disorder. To date, approximately 40 cases have been reported. In several patients, the eosinophilic folliculitis developed within the first 24 hours of life[13]. However, the lesions typically appear within the first few days to weeks of life. To date, one HIV-related case has been reported in an infant, with an onset at 3 months of age[14].

Epidemiology
Eosinophilic pustular folliculitis in infancy occurs primarily in children less than 1 year of age and is more common in boys. The limited number of reported cases precludes any more detailed epidemiologic analysis.

Pathogenesis
The etiology of this self-limiting disorder is unknown, and the pustules are sterile. The eosinophil clearly plays a role in this disease, and the regulation of its function is reviewed in Chapter 25. Of note, some authors have proposed that eosinophilic pustular folliculitis in infancy is better characterized as a clinicopathologic reaction pattern (with heterogeneous underlying causes such as arthropod bites and dermatophytosis) than as a specific inflammatory dermatosis.

Clinical features
Pruritic follicular-based pustules and vesicopustules with an erythematous rim appear, primarily on the scalp. Involvement of the neck, face and trunk may be seen and, occasionally, lesions develop on the extremities[12,13]. They often have an erythematous base and secondary crusting. The lesions follow a cyclical course for a period of 3 months to up to 5 years.

Pathology
Similar to Ofuji's disease, there is exocytosis of eosinophils into the epidermis in association with spongiosis and subcorneal pustules; a dense dermal perifollicular infiltrate of eosinophils, histiocytes and lymphocytes is seen[12,13]. The infiltrate may not invade the sebaceous glands or outer root sheath of the hair follicles. Peripheral blood eosinophilia is present in some patients.

Differential diagnosis
The differential diagnosis includes erythema toxicum neonatorum, transient neonatal pustular melanosis, acropustulosis of infancy, scabies (which can involve the scalp in infants), Langerhans cell histiocytosis, and the following two rare disorders: papulopustular eruption of hyper-IgE syndrome and vesiculopustular eruption of transient myeloproliferative disorder. Erythema toxicum neonatorum has almost identical histologic features, but its onset is within the first 48 hours of life and the eruption, which has a more widespread distribution pattern, usually resolves within 1 week (see Ch. 34). This natural history easily separates the two entities.

Transient neonatal pustular melanosis occurs in 4–5% of infants with darkly pigmented skin. Lesions are present at the time of birth and favor the face, neck and shins. Neutrophils are the predominant cells. The lesions of acropustulosis of infancy occur more frequently in male infants with darkly pigmented skin, and are seen most often on the hands and feet and less often on the scalp, proximal extremities and trunk. The disorder may occur during the neonatal period, but usually appears at 3–6 months of age. Lesions last 7–10 days and crops occur for months to years, usually resolving completely by the age of 3 years. Given that eosinophilic pustular folliculitis in infancy occasionally involves the extremities and has a similar natural history of cropping, some authors have suggested a relationship between the two entities.

Langerhans cell histiocytosis is a rare disorder that often has cutaneous involvement when it develops during infancy. Papules, pustules, vesicles and crusts are seen, especially on the scalp and in flexural areas. Histologic examination demonstrates the presence of $S100^+$, $CD1a^+$ Langerhans cells.

Treatment
Parents should be reassured regarding the benign, self-limited nature of the disorder. Topical corticosteroids and oral antihistamines can help to relieve pruritus during flares of the disease.

Disseminate and Recurrent Infundibulofolliculitis

Synonyms: ■ Hitch and Lund disease ■ Recurrent disseminated infundibulofolliculitis

Key features
- Seen primarily in adults with darkly pigmented skin
- Hundreds of uniform, skin-colored papules that have been likened to "goose bumps"
- Favored sites of involvement are the trunk, neck and upper extremities
- May last for months to years and can be pruritic
- Histologically, there is mild inflammation of the follicular infundibulum

The first individuals with disseminate and recurrent infundibulofolliculitis were described by Hitch and Lund in 1968[15]. Four years later, they reported an additional two cases, bringing the total to five patients; all were young adults with darkly pigmented skin. Although the lesions may resemble papular eczema, the patients do not have a history of atopy. There seems to be neither seasonal variation nor an association with systemic disease, medications, atopy or contact dermatitis.

The disease is characterized by numerous 1–2 mm, pruritic, skin-colored papules, often pierced by a hair, forming large areas of what looks like "goose bumps" (Fig. 38.7). The trunk is involved most often, followed by the neck, buttocks and arms. The lesions may last for weeks, months or years. Disseminate and recurrent infundibulofolliculitis occurs almost exclusively in individuals with darkly pigmented skin.

Although the lesions most closely resemble papular eczema (and some authors do not separate the two entities), other diseases that may be considered in the differential diagnosis are lichen nitidus and folliculitis (see above), but the follicular pattern and the lack of erythema or pustules exclude these two entities, respectively. The lack of keratotic plugs or spines within the hair follicles distinguishes this disorder from

Fig. 38.7 Disseminate and recurrent infundibulofolliculitis (of Hitch and Lund). Numerous monotonous follicular papules on the chest. *Courtesy, Jean L Bolognia, MD.*

keratosis pilaris, pityriasis rubra pilaris, lichen planopilaris, and the disorders discussed in the next section (e.g. phrynoderma). Careful examination of the primary lesions excludes the diagnosis of Darier disease.

Histologically, the principal findings are in the infundibular portion of the hair follicle. There is perifollicular edema, slight infiltration of lymphocytes with occasional neutrophils, and a slight proliferation of fibroblasts[16].

Topical corticosteroids are sometimes effective, and lactic acid preparations (12%) or 20–40% urea may be helpful. If topical medications prove unsuccessful, PUVA may be tried (three times a week for 3 weeks, followed by maintenance therapy twice a month). Vitamin A (50 000 IU twice daily) and isotretinoin (0.5 mg/kg/day for 16 weeks) have also been tried, but evidence for their efficacy is anecdotal as well.

DISORDERS OF FOLLICULAR KERATINIZATION

Although this group of dermatoses has a wide spectrum of clinical presentations, all are characterized by a prominent plug of keratin within the follicular orifice. For most of these entities, the cause of the abnormal keratinization is unknown. The dermatoses are usually distinguished on the basis of the size, extent and distribution of the keratotic lesions, as well as the presence or absence of perifollicular erythema and associated scarring. Disorders in this group that are discussed in other chapters include keratosis pilaris (Ch. 12), pityriasis rubra pilaris (Ch. 9) and lichen planopilaris (Ch. 11).

Erythromelanosis Follicularis Faciei

Synonym: ■ Erythromelanosis follicularis faciei et colli

Key features

- An uncommon disorder that involves the lateral cheeks and sometimes the lateral aspects of the neck
- Multiple pinpoint follicular papules are superimposed on a red–brown patch; the papules appear relatively hypopigmented
- May be accompanied by keratosis pilaris

Introduction

Erythromelanosis follicularis faciei was first described in 1960 by Kitamura and associates in Japanese men. Six years later, the first patient was described in the English literature by Mishima and Rudner[17]. It can begin during the second decade of life and is characterized by background erythema and hyperpigmentation as well as tiny follicular papules.

Epidemiology

Although the disorder was initially reported in Japanese men, it is now known to affect all races and both sexes[18]. However, it does favor people of Asian ancestry.

Pathogenesis

The pathogenesis is unknown.

Clinical features

On the lateral aspect of the cheeks, and sometimes the lateral aspects of the neck, there is a background of red–brown-colored skin. The latter is due to a combination of vasodilation and hyperpigmentation. However, in skin type I patients, there may be only erythema, leading to significant overlap with keratosis pilaris rubra. Numerous pinhead-sized follicular papules are present within the involved areas, and they appear relatively hypopigmented. Patients may also have keratosis pilaris of the upper outer arms, with a small rim of erythema surrounding the follicular keratotic plug (see Ch. 12).

Pathology

There is slight follicular hyperkeratosis with increased epidermal pigmentation. Diameters of the hair shafts and outer root sheaths are decreased, as is the thickness of the inner root sheath. The adnexa are often surrounded by a lymphocytic infiltrate. Both the thickness and the compactness of the horny layer are usually increased[19]. By quantitative histopathology, an increase in the percent area of superficial blood vessels was observed that correlated with visual grading of the associated erythema[20].

Differential diagnosis

The differential diagnosis of erythromelanosis follicularis faciei includes primarily keratosis pilaris rubra and a combination of melasma plus telangiectatic erythema from photodamage. However, the latter combination lacks tiny follicular papules, while keratosis pilaris rubra of the cheeks lacks hyperpigmentation and favors children (see Ch. 12).

Poikiloderma of Civatte is another entity that is sometimes confused with erythromelanosis follicularis faciei et colli. The former involves the anterolateral aspects of the neck with obvious sparing of the midsubmental region. The areas of erythema are a reflection of multiple interfollicular telangiectasias. Because the telangiectasias spare the immediate thin rim of skin around each follicle, these areas appear relatively hypopigmented. Occasionally, poikiloderma of Civatte extends onto the mandibular region.

Less often, two disorders within the spectrum of keratosis pilaris atrophicans, ulerythema ophryogenes and atrophoderma vermiculatum, may be considered (Table 38.2). Although ulerythema ophryogenes is characterized by small follicular papules, they are erythematous, usually appear during early childhood, and favor the eyebrows (Fig. 38.8). In addition, there is associated follicular atrophy and scarring alopecia of the lateral eyebrows. Atrophoderma vermiculatum affects the cheeks but presents with honeycomb scarring or a worm-eaten appearance (see Ch. 99).

Treatment

Various topical keratolytic agents have been used, including urea cream (10–20%), ammonium lactate lotion (6–12%), tretinoin cream (0.025–0.1%), adapalene (0.1–0.3%) and an ammonium lactate plus hydroquinone (4%) cream combination, but evidence for their use is anecdotal. Both salicylic acid peels (20–30%) and glycolic acid peels have been employed. When severe, limited courses of isotretinoin (0.1–1 mg/kg/day) have been tried. Laser treatment of the background erythema or hyperpigmentation may be attempted, but it requires multiple sessions.

Keratosis Pilaris Atrophicans

Keratosis pilaris atrophicans encompasses a group of disorders in which the abnormality in follicular keratinization is accompanied by atrophy and scarring alopecia. The key features of ulerythema ophryogenes, atrophoderma vermiculatum, keratosis follicularis spinulosa decalvans, and folliculitis spinulosa decalvans are outlined in Table 38.2. Treatment with keratolytics, topical retinoids, topical or intralesional corticosteroids, oral antibiotics and phototherapy has limited efficacy, but

Fig. 38.8 Ulerythema ophryogenes. Alopecia of the eyebrow admixed with tiny follicular papules. *Courtesy, Jean L Bolognia, MD.*

THE SPECTRUM OF KERATOSIS PILARIS ATROPHICANS							
Disorder	**Mode of inheritance**	**Genetic locus**	**Age at onset**	**Distribution**	**Cutaneous features**	**KP***	**Other occasional features and associations**
Keratosis pilaris atrophicans faciei (ulerythema ophryogenes)	AD	18p11.2	Infancy	Eyebrows (particularly the lateral third; see Fig. 38.8) > temples, cheeks, forehead	• Erythematous follicular papules with central keratotic plugs, eventuating in follicular atrophy • Scarring alopecia of the lateral eyebrows	+	• Associated with Noonan syndrome, cardio-facio-cutaneous syndrome, Cornelia de Lange syndrome and woolly hair
Atrophoderma vermiculatum	?AD	?	Childhood (usually 5–12 years)	Cheeks > preauricular area, upper lip	• Pitted, atrophic depressions in a reticulate pattern ("worm-eaten" or "honeycomb" appearance)†	–	• Associated with Rombo, Nicolau–Balus, Tuzun, and Braun–Falco–Marghescu syndromes (see Ch. 99)
Keratosis follicularis spinulosa decalvans (KFSD)	XR	Xp22.11–p22.12; mutations in *MBTPS2*‡	Childhood (inflammation often remits at puberty)	Face, scalp, limbs, trunk	• Erythematous follicular papules with central keratotic plugs, eventuating in follicular atrophy • Scarring alopecia of the scalp, eyebrows, and eyelashes	++	• Palmoplantar keratoderma, facial erythema • Keratitis, photophobia • Aminoaciduria
Folliculitis spinulosa decalvans	?AD	?	Puberty (onset or worsening)	Scalp	• Follicular pustules • Features of KFSD	++	• Palmoplantar keratoderma • Blepharitis, conjunctivitis, keratitis, photophobia

*Associatd keratosis pilaris (KP) on the extremities and trunk, which does not typically eventuate in atrophy.
†May be preceded by erythematous follicular papules.
‡Protein product (membrane-bound transcription factor peptidase, site 2) is required for cleavage of sterol regulatory element-binding proteins (SREBPs) and its dysfunction leads to decreased sterol responsiveness.

Table 38.2 The spectrum of keratosis pilaris atrophicans. AD, autosomal dominant; XR, X-linked recessive; +, mild to moderate; ++, severe.

combination therapy may benefit individual patients and, anecdotally, oral retinoids and intense pulsed light have been reported to lead to improvement. In later stages, dermabrasion, laser resurfacing and dermal fillers may help to improve the appearance of atrophic scarring.

Lichen Spinulosus

Synonym: ■ Keratosis spinulosa

Key features

- Clusters of multiple follicular papules, each with a keratotic spine
- Texture likened to that of a nutmeg grater
- Usually asymptomatic, arises suddenly, and enlarges over a week
- Appears most often in children and adolescents; favors the neck, extensor arms, abdomen and buttocks
- Can persist indefinitely

Introduction, history and epidemiology

Lichen spinulosus is characterized by grouped, skin-colored, keratotic follicular papules. The disorder was first described by Adamson in 1908 as a chronic superficial dermatitis within circumscribed patches in children and adolescents[21]. In one series, the average age at onset was 16 years[22].

Pathogenesis

Although several factors, such as atopy, infections and heredity, have been proposed as playing a role in lichen spinulosus, the exact etiology is unknown and most patients do not have associated systemic abnormalities. There are reports of lichen spinulosus-like lesions arising in the setting of HIV infection[23]. Additional associations reported in the literature (but possibly coincidental) include seborrheic dermatitis, a drug reaction (omeprazole), Hodgkin disease, Crohn's disease, syphilis, and an id reaction to fungal infections.

Fig. 38.9 Lichen spinulosus. Grouped, skin-colored follicular papules on the extensor surface of the arm. Central keratotic plugs can be seen.

Clinical features

Typical lesions measure 2–6 cm in diameter (Fig. 38.9) and are composed of multiple, skin-colored, keratotic follicular papules, each of which has a keratotic spine. Lichen spinulosus favors the neck, shoulders and extensor surfaces of the arms, as well as the abdomen, buttocks and popliteal fossae, and the distribution pattern is often symmetric. The face is usually spared, as are the hands and feet. Lesions often arise suddenly in crops, enlarge over a week, and then remain stationary. Idiopathic lichen spinulosus usually appears during childhood and adolescence and is asymptomatic, although in some patients the lesions are pruritic and the patches may be surrounded by faint erythema. Spinulosis of the face (tiny follicular keratotic spicules of the cheeks) may be a manifestation of lichen spinulosus.

Pathology
Histologically, lichen spinulosus most resembles keratosis pilaris.

Differential diagnosis
The differential diagnosis of lichen spinulosus includes keratosis circumscripta, follicular ichthyosis, and juvenile pityriasis rubra pilaris (especially type IV; see Ch. 9). Keratosis circumscripta, also referred to as psoriasis circumscripta with palmoplantar keratosis, is characterized by well-circumscribed lesions consisting of grouped folliculocentric papules, with or without palmoplantar hyperkeratosis. Lesions favor the nape of the neck, elbows and knees, as well as the hips, sacrum and posterior axillary folds. Onset is usually at age 3–5 years and it has been described primarily in Africans[24,25]. The pathogenesis is unknown, but it may be a variant of psoriasis[24] as the histologic findings are similar to those of plaque-type psoriasis. This entity may be of historical interest, as the most recent published report was in 1979.

Follicular ichthyosis is an unusual disorder characterized by keratotic papules with follicular plugging and prominent follicular ostia and an onset in early childhood[26]. The predominant site of involvement is the head and neck region. Lesions can also occur on the extensor surfaces of the extremities, especially the fingers, elbows and knees. *I*chthyosis *f*ollicularis with *a*trichia and *p*hotophobia (IFAP) syndrome is a rare disorder whose X-linked recessive form is allelic with keratosis follicularis spinulosa decalvans (see Table 38.2). It is characterized by widespread non-inflammatory follicular keratoses, generalized non-scarring alopecia, and photophobia. Hereditary mucoepithelial dysplasia is an autosomal dominant condition that manifests with severe keratitis, erythema of the oral mucosa (characterized by a paucity of desmosomes and dyskeratotic cells with internalized gap junctions) and psoriasiform perineal plaques, as well as widespread follicular keratoses and non-scarring alopecia similar to IFAP.

Less often, lichen spinulosus may be confused with keratosis pilaris (has perifollicular erythema and lacks discrete clusters), lichen planopilaris or phrynoderma (see below). Facial spines can also be seen in pityriasis rubra pilaris (especially that which occurs in HIV-infected individuals with preceding severe acne and/or hidradenitis suppurativa), folliculodystrophy of immunosuppression (trichodysplasia spinulosa), demodicosis, follicular mucinosis, and in patients with multiple myeloma. Some authors group lichen spinulosus in the setting of HIV infection under the term "HIV-associated follicular syndrome". Lastly, widespread follicular plugging has been reported as a side effect of systemic lithium therapy[27].

Treatment
Topical therapies such as 12% lactic acid, 20%–40% urea and 6% salicylic acid may improve the texture. Glycolic acid and salicylic acid peels have also been reported to be beneficial.

Phrynoderma
Phrynoderma, which means "toad skin", is seen primarily in Asia and Africa and is rare in high-income countries, except in settings such as intestinal malabsorption[28], anorexia nervosa or fad diets (see Ch. 51). Phrynoderma is seen most often in association with vitamin A deficiency, but some patients may have measurable deficiencies in other vitamins and/or proven malnutrition[29,30]. Follicular papules of various sizes with conical keratotic plugs favor the extensor surfaces of the extremities (see Fig. 51.7), but may then spread to involve other locations. The face is the last site to become involved, and the hands and feet are spared. Associated systemic findings (e.g. ocular, CNS), histologic features, diagnosis via measurement of serum vitamin A levels, and treatment are discussed in Chapter 51.

DEEP FOLLICULITIS
The major forms of deep folliculitis are furuncles (see Ch. 74), sycosis (barbae, lupoid, mycotic; Table 38.3), pseudofolliculitis barbae, acne keloidalis and hidradenitis suppurativa. The lesions are firm, tender erythematous papules or nodules that measure up to 2 cm in diameter. Deep lesions should never be manipulated (i.e. squeezed) by the patient, because this may cause bacteremia or seeding of the heart valves (endocarditis), brain (abscess) or bones (osteomyelitis).

FORMS OF SYCOSIS

Type	Characteristics
Barbae	• Bacterial folliculitis of the beard and/or mustache areas, usually caused by *Staphylococcus aureus* • Deep-seated, edematous, perifollicular papules and pustules that may coalesce to form plaques studded with pustules and crusts • Subacute to chronic course with frequent relapses
Lupoid	• Scarring form of deep folliculitis, typically affecting the beard area; may be caused by *S. aureus* (although cultures often fail to reveal pathogenic organisms) • Peripheral extension of perifollicular papules and pustules with central atrophic scarring/cicatricial alopecia; granulomatous inflammation can lead to an appearance reminiscent of lupus vulgaris • Chronic course, refractory to treatment
Mycotic	• Dermatophyte folliculitis of the beard area (most often the chin), usually caused by zoophilic organisms • Inflammatory perifollicular papules and pustules coalesce to form nodules and plaques with purulent discharge from patulous follicles, crusting and loose hairs that can be painlessly removed (Fig. 38.10)
Herpetic	• See Table 38.1

Table 38.3 Forms of sycosis.

Pseudofolliculitis Barbae

Synonyms: ■ Shave bumps ■ Razor bumps ■ Barber's itch ■ Folliculitis barbae traumatica ■ Scarring pseudofolliculitis of the beard ■ Chronic sycosis barbae ■ Ingrown hairs

Key features
- A common chronic disorder occurring most often in the beard area of men who shave
- It favors those of African descent with darkly pigmented skin and tightly curled hair
- The etiology is tightly curved hairs curving back into the skin when shaved
- Lesions range from inflammatory papules and pustules to firm papules and keloidal scars
- Although the only way to cure the disease is to stop shaving, shaving techniques can be optimized

Introduction

Pseudofolliculitis barbae is a common chronic inflammatory disorder occurring most often in the beard area of men who shave, especially in men with darkly pigmented skin and tightly curled hair. It may also develop in other shaved areas, in women, and in any racial group.

Epidemiology

Pseudofolliculitis barbae primarily affects men of African descent with darkly pigmented skin. The prevalence ranges from 45% to 80%, depending upon the particular study. Men of all races may develop pseudofolliculitis barbae within the beard area, but it is less common and is usually mild in those with lightly pigmented skin and straight hair. Women who shave may also develop pseudofolliculitis barbae, especially in the groin.

Pathogenesis

The disorder is thought to be caused by intrafollicular and transfollicular penetration of tightly curled, coarse hairs within the beard area. When shaved, tightly curled hair is usually cut at an oblique angle, creating a sharp tip at the distal end of the hair that enables it to penetrate into the skin 1–2 mm from where the hair exits the follicle (Fig. 38.11). Thus, transfollicular penetration occurs when the cut hair grows out of the follicle normally but penetrates the skin as it grows in a spiral fashion back toward the skin surface. Once the hair penetrates the dermis, an inflammatory reaction ensues.

More recently, the presence of a single nucleotide polymorphism in the 1A α-helical subdomain of the hair follicle companion layer-specific keratin K6hf (K75) was reported to be an additional genetic risk factor for pseudofolliculitis barbae[31].

Clinical features

In men who shave, inflammatory papules appear in the beard area and on the anterolateral neck. However, the mustache area, which may also be shaved daily, does not develop pseudofolliculitis barbae. Pustules and even abscesses may be seen. Hyperpigmentation of the resultant firm papules can occur (Fig. 38.12), as can hypertrophic scars and keloids, especially in longstanding disease. Chronic lesions may cause the hair to create grooves in the skin; the anterior neck and submandibular areas are particularly prone to this complication. Once the grooves have formed, shaving becomes extremely difficult.

Pathology

The sharp cut end of the hair initially causes an invagination in the epidermis, which is accompanied by inflammation and frequently by an intralesional microabscess. As the hair penetrates the epidermis, a heavy mixed inflammatory cell infiltrate develops as a reaction to the downgrowth of the epidermis in an attempt to ensheathe the hair[32]. This is accompanied by abscess formation within the pseudofollicle and a foreign body giant cell reaction at the tip of the invading hair[32]. Naked hair shafts surrounded by acute and chronic inflammation or primarily fibrotic dermis are commonly observed.

Differential diagnosis

Facial acne vulgaris is similar in appearance, but differs by having comedones as well as papules and pustules. Histologically, the foreign body reaction needs to be differentiated from cutaneous sarcoidosis.

Treatment

Before therapy is initiated, the patient should be given a candid explanation regarding the cause of pseudofolliculitis barbae. It should be stressed that the only way to cure the disease is to stop shaving, but there are several treatments that may control the process. In those with severe disease, a hiatus of several months without shaving is recommended. Once inflammatory lesions have completely cleared, patients resume shaving; therefore they need to be given advice on shaving methods (Table 38.4).

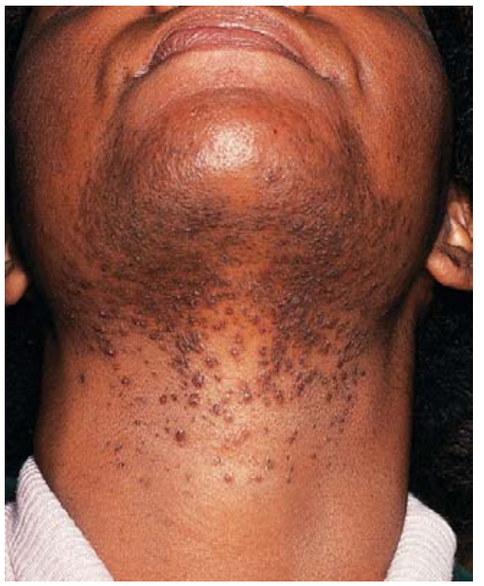

Fig. 38.12 Pseudofolliculitis barbae. Multiple firm hyperpigmented papules on the lower face and neck (beard distribution).

ADVICE ON SHAVING METHODS FOR PATIENTS WITH PSEUDOFOLLICULITIS BARBAE

IMPORTANT POINTS

- Do not pull the skin taut
- Do not shave against the grain/direction of hair growth
- Use a sharp razor each time, preferably multi-blade
- Take short strokes (with the grain of the hair) and do not shave over the same areas more than twice

METHOD

1. Remove pre-existing hairs with electric clippers, leaving approximately 1–2 mm of stubble
2. Wash area with non-abrasive acne soap and rough wash-cloth; in areas with "ingrown hairs", gentle massaging with a soft toothbrush may help
3. Rinse area with water, then compress face with warm tap water for several minutes
4. Using shaving cream of your choice, massage moderate amount of lather on area to be shaved (do not allow lather to dry; if it does, reapply it)
5. Use a sharp blade (whichever type seems to cut best but not too close) and shave with the grain of the hair using short even strokes with minimal tension (and no more than twice over one area); in hard-to-shave areas, you may need to shave against the grain
6. After shaving, rinse with tap water and then apply the most soothing aftershave preparation of your choice. If significant burning or itching ensues, a topical corticosteroid cream or lotion (1–2.5% hydrocortisone) can be used as an alternative aftershave preparation

Table 38.4 Advice on shaving methods for patients with pseudofolliculitis barbae.

THERAPEUTIC APPROACH TO PSEUDOFOLLICULITIS BARBAE	
Shaving	• Mild to moderate cases: continue shaving daily, but follow guidelines in Table 38.4 • Severe cases: consider discontinuing shaving, with no resumption of shaving until all inflammatory lesions have cleared and all "ingrown hairs" are released; during this period, the patient can trim his beard to a minimum length of 0.5 cm using scissors or electric clippers
Compresses and release of ingrowing hairs	• Warm tap water, saline or Burow's solution (aluminum acetate) compresses for 10 minutes three times daily to soothe lesions, remove any crusts, reduce drainage secondary to inflammation and/or excoriations, and soften the epidermis to allow easier release of "ingrown hairs"
Topical therapy	• Low-potency topical corticosteroid lotion and/or topical clindamycin should be applied after compresses and freeing of embedded hairs
Secondary bacterial infection	• Appropriate systemic antibiotic should be prescribed, based upon bacterial cultures
Recalcitrant disease	• Prednisone (45–60 mg) or its equivalent every morning for 7–10 days may be necessary • Topical eflornithine cream twice daily may be helpful* • Laser hair removal (utilizing appropriate laser for skin color) with goal of permanent hair reduction (see Ch. 137)
*Based upon case series.	

Table 38.5 Therapeutic approach to pseudofolliculitis barbae.

Except for very mild cases, pseudofolliculitis barbae requires medical intervention during its acute phase, when it is often painful and/or pruritic. Although antibiotics, topical or systemic, are not particularly beneficial (unless secondary infection is present), they may provide some anti-inflammatory effect. The recommended therapeutic approach is outlined in Table 38.5.

Adjunct treatments such as topical tretinoin solution, gel or cream, α-hydroxy acids or benzoyl peroxide (e.g. Benzashave®) may be used in patients with mild to moderate pseudofolliculitis barbae. However, those with severe and chronic disease usually have only slight improvement. These products are thought to work by alleviating hyperkeratosis as well as "toughening" the skin. Initially, tretinoin is applied every other night, and the patient should be told to expect some stinging, burning and peeling. Depending on the individual's response, the concentration and frequency of application may be increased or decreased. Of note, the shaving methods outlined in Table 38.4 still need to be followed.

A more recently developed therapy for pseudofolliculitis barbae is the use of hair removal lasers. For example, the Nd:YAG laser can be used with a long pulse duration and continuous contact cooling, even in patients with skin types V or VI, as can a modified 810 nm superlong-pulse diode laser. Treatment is given at 3- to 4-week intervals for two to three sessions. Of course, care must be taken when selecting the energy settings, especially in patients with deeply pigmented skin[33]. Additional therapeutic options are eflornithine cream[34] and chemical depilatories. With the latter, the beard should be trimmed prior to application of the depilatory and, to avoid irritation, treatments should be limited to, at most, every second or third day.

Acne Keloidalis

Synonyms: ■ Acne keloidalis nuchae ■ Folliculitis keloidis nuchae ■ Nuchal keloid acne ■ Folliculitis keloidalis ■ Dermatitis papillaris capillitii (historical)

Key features

- Begins as a chronic folliculitis of the posterior neck and occipital scalp
- With time, keloidal papules and plaques develop
- Vast majority of affected individuals are men of African descent

Fig. 38.13 Acne keloidalis. An admixture of follicular pustules, crusted papules and firm fibrotic hyperpigmented papules on the posterior neck and occipital scalp. There is associated alopecia.

Introduction

Acne keloidalis refers to the presence of keloid-like papules and plaques on the occipital scalp and posterior neck. This disorder occurs almost exclusively in men of African descent. The patients usually develop a chronic folliculitis and perifolliculitis of the posterior scalp and neck initially, which then heals with keloid-like papules. Over time, these papules may coalesce to form one or several large plaques, which gradually enlarge over a period of years. The lesions are usually pruritic and may also be painful and cosmetically disfiguring. The sooner the condition is treated, the less likely it will become disfiguring.

History

Acne keloidalis was first described by Kaposi in 1869 as "dermatitis papularis capillitii". However, the disorder had been previously recognized in Hebra's clinic and referred to as "sycosis frambroisiformis". Three years after Kaposi's publication (1872), Bazin named the condition "acne keloidalis". Since then, this disorder has been described in the literature under a variety of names (see Synonyms above).

Epidemiology

In the US, acne keloidalis occurs most often in young African-American men, followed in frequency by Hispanics, Asians and, least often, Caucasians. It accounts for less than 1% of dermatologic disorders seen in African-Americans. Acne keloidalis may occur in women, but the male:female ratio is at least 20:1. Development prior to puberty and after the age of 50 years is extremely rare.

Pathogenesis

The cause of acne keloidalis is unknown. In one study, two-thirds of affected patients had concomitant seborrheic dermatitis and one-third had concomitant pseudofolliculitis barbae. No specific genetic factor has been identified. Shaving or cutting short, tightly curled hair (as is found in many individuals with darkly pigmented skin) and then having the new hair curve back and penetrate the skin may be the precipitating event (see Fig. 38.11). Other frequently incriminated etiologies are constant irritation from shirt collars, chronic low-grade folliculitis, and an autoimmune process.

Clinical features

Acne keloidalis often begins as a posterior scalp and/or neck folliculitis, followed by the development of firm, dome-shaped follicular papules that are 2–4 mm in diameter and may or may not be pruritic (Fig. 38.13). Pustules may also be present within the same area but are usually short-lived because they are traumatized when the hair is combed or brushed and they are easily ruptured by scratching. In contrast to acne vulgaris, comedones are not present.

As the disease progresses, more hard papules develop and slowly enlarge. Some coalesce and form keloid-like plaques, which are often

Fig. 38.14 Acne keloidalis. Keloidal papulonodules and a large plaque of the occipital scalp, associated with scarring alopecia. Note the tufts of hair at the superior border of the scar.

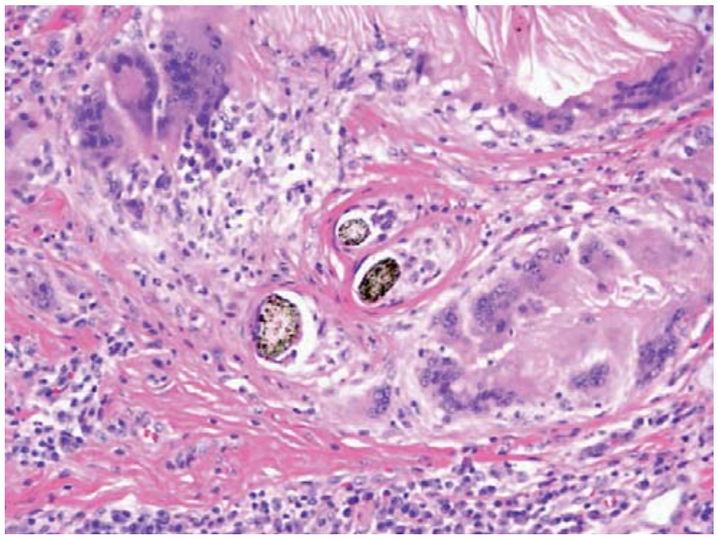

Fig. 38.15 Acne keloidalis – histologic features. Naked hair shafts in the dermis with perifollicular fibrosis and surrounding granulomatous inflammation with multinucleated giant cells.

arranged in a band-like distribution near the posterior hairline (Fig. 38.14). The plaques are usually only a few centimeters in diameter but may grow to more than 10 cm. Even when only papules are present, a large portion of the posterior scalp may be involved.

When the area of involvement is significant, there is usually patchy alopecia or complete hair loss. In occasional patients, the scarring process may extend onto the vertex and/or parietal scalp. Often, the upper borders of large lesions are fringed with tufted hairs that resemble the hair on a doll's head, as in other scarring alopecias such as folliculitis decalvans (see Ch. 69). Occasionally, subcutaneous abscesses with draining sinuses may be present, and they may emit a malodorous discharge.

Pathology

Inflammation begins in the upper one-third of the hair follicle. Descriptions of the initial infiltrate vary from it being composed of neutrophils and lymphocytes to predominantly plasma cells[35]. Sebaceous glands are markedly diminished or absent in all stages of the disease[35]. In the more advanced lesions, hair follicles are disrupted, and fragments of naked hair shafts surrounded by granulomatous inflammation may be seen (Fig. 38.15). Dermal fibrosis is also present at this stage, and the collagen fibers resemble those seen in scar tissue rather than those in keloids. Sometimes, a single follicle may show several different stages of inflammation when viewed throughout its length. The lower portion of the follicle, including the matrix, is usually spared until later in the disease process. Actual keloid formation can be seen in late stages.

Differential diagnosis

Clinically, the initial lesions may resemble more common forms of folliculitis (see above). Although keloids and hypertrophic scars secondary to trauma enter the differential diagnosis, the number, shape and distribution of the lesions usually point to the correct diagnosis. On the neck there may be overlap with pseudofolliculitis barbae, and when there is more extensive or severe scalp involvement, folliculitis decalvans and dissecting cellulitis may enter the differential diagnosis.

Treatment

The first line of defense is prevention. Those who have acne keloidalis should not wear any kind of head-dress or head gear that causes mechanical irritation of the posterior hairline. In addition, they should neither edge their posterior hairline with a razor nor wear shirts or sweaters that irritate the posterior scalp and neck.

The sooner therapy is initiated, the less likely the patient is to develop large lesions. Twice-daily application of a tretinoin gel and a mid- to high-potency corticosteroid gel may be sufficient to relieve all symptoms and flatten existing lesions. Topical or systemic antibiotics, as for acne vulgaris, may clear the folliculitis but do not soften or clear the secondary keloidal lesions. Triamcinolone acetonide (5–20 mg/ml) can be injected into the keloidal papules, but if they persist, one author (PK) prefers to do a punch excision with a hair transplant trephine followed by either a primary closure or healing by second intention (Table 38.6). The punch must extend below the level of the hair follicle to be successful. In addition, a 50:50 mixture of 2% lidocaine (with epinephrine) and triamcinolone acetonide (40 mg/ml) can be used for local anesthesia in order to help prevent recurrence. If the patient sleeps on his or her back or has a short neck, then the lesions can be closed with silk sutures to prevent stiff suture ends from piercing the skin. One week after suture removal, the excision sites are injected with triamcinolone acetonide (40 mg/ml), and this can be performed three more times at 3-week intervals. A bacterial culture should be obtained from any site with oozing or drainage, followed by treatment with the appropriate systemic antibiotic.

For plaques 1.0–1.5 cm in vertical diameter (i.e. superior to inferior border), excision with primary closure is the treatment of choice. Some

THERAPEUTIC OPTIONS FOR ACNE KELOIDALIS	
Non-inflamed papules and plaques	Mixture of tretinoin gel and potent corticosteroid gel twice daily
Inflamed lesions with pustules	Bacterial culture and appropriate systemic antibiotic or a course of oral isotretinoin
Small papules	Punch excision to below level of hair follicles
	Close primarily or allow to heal secondarily
	Laser hair removal for permanent hair reduction
Plaques ≤1.5 cm in vertical diameter	Excise and close primarily
Larger plaques and nodules (>1.5 cm in vertical diameter)	Excise with horizontal ellipse
	Extend excision below posterior hairline and include fascia or deep subcutaneous tissue
	Allow to heal by second intention
	Do not inject corticosteroids into postoperative site
	Laser excision and cryosurgery are sometimes successful
Postoperative care	Topical imiquimod daily for 6 weeks (8 weeks every other day if irritation)
Maintenance	Tretinoin–corticosteroid gel mixture, intermittent intralesional corticosteroids and/or oral or topical antibiotics (when needed)

Table 38.6 Therapeutic options for acne keloidalis.

claim that daily topical imiquimod, starting immediately postoperatively and continuing for 6–8 weeks, may prevent recurrence (see Ch. 128). If the imiquimod causes irritation, then it should be discontinued for a few days and subsequently applied every other day for a total of 8 weeks. While controversial, radiation therapy following excision of keloids is discussed in Chapter 98.

Lesions >1.5 cm in vertical diameter should not be closed primarily, because the postoperative scar usually spreads to the width of the excisional defect, producing a non-hair-bearing flat scar. For these lesions, the area of acne keloidalis is excised to the level of the fascia or deep subcutaneous tissue and left to heal secondarily. The excision must include the posterior hairline within the surgical ellipse[36]. It will take 8–12 weeks for the defect to close. Corticosteroids are not injected into these sites because they may prevent wound contracture.

Some patients have been successfully treated with CO_2 laser excision, but it requires postoperative triamcinolone injections (10–40 mg/ml) every 3 weeks for four sessions, starting 2 weeks after the laser procedure. As with pseudofolliculitis barbae, the diode laser has been reported (case series) as being helpful in clearing papular lesions[37]. Cryotherapy is also sometimes useful, but it requires freezing for 30–40 seconds. In individuals with darkly pigmented skin, freezing for more than 25 seconds may cause hypopigmentation (which can last 12–18 weeks) or even depigmentation.

Following surgical procedures, intralesional or potent topical corticosteroids (e.g. gel, foam), alone[38] or in combination with oral or topical antibiotics, can be used, as well as a tretinoin–corticosteroid gel mixture (see Table 38.6). Based upon case reports, a course of oral isotretinoin may prove helpful in recalcitrant inflammatory cases of acne keloidalis.

Follicular Occlusion Tetrad

In 1956, Pillsbury, Shelley and Kligman coined the term "follicular occlusion triad" for the common association of acne conglobata (see Ch. 36), hidradenitis suppurativa, and dissecting cellulitis of the scalp (see Ch. 69). They proposed that the pathologic event unique to each disease was follicular hyperkeratinization[39]. In 1975, a fourth component, pilonidal sinus (further discussion of which is beyond the scope of this text; Fig. 38.16), was added, creating the follicular tetrad. The term "acne inversa" is sometimes used as an all-inclusive term for this group of associated disorders. Systemic retinoids and corticosteroids have been successful in treating all four of these disorders, but specific therapies for each entity are usually more successful.

Hidradenitis Suppurativa

Synonyms: ■ Acne inversa ■ Verneuil's disease ■ Pyoderma fistulans significa

Key features

- Poral occlusion of the pilosebaceous units within intertriginous zones, especially the axillary, anogenital and inframammary regions
- Secondary inflammation of the apocrine glands
- Inflamed nodules and sterile abscesses are followed by sinus tracts, fistulae and hypertrophic scars

Introduction

Hidradenitis suppurativa is a cutaneous disorder that targets apocrine gland-bearing skin sites, in particular the axillae and anogenital region. It is a chronic condition characterized by recurrent "boils" and draining sinus tracts with subsequent scarring.

History

Hidradenitis suppurativa was first conceptualized as a specific disease and then named by Verneuil in 1854. He described its association with sweat glands. Although apocrine gland dysfunction was initially considered to be the underlying cause, it is now known that occlusion of the follicular infundibula followed by rupture of the follicle is the inciting event.

Epidemiology

Hidradenitis suppurativa starts at or soon after puberty. Children are not affected unless they have precocious puberty, and women are affected three times as often as men. In Denmark, 4% of the young adult population and 1% of the general population were said to be affected. In England, the incidence is 1 : 600[40]. People of African descent have a higher incidence than those of European descent.

Pathogenesis

Currently, hidradenitis suppurativa is thought to represent an inflammatory disorder originating from the hair follicle. Primary "apocrinitis" has been observed in only 5% of the patients with the disease[41]. Rupture of the follicle allows introduction of its contents, including keratin and bacteria, into the surrounding dermis[42]. This excites a vigorous chemotactic response and abscess formation. Epithelial strands are generated, possibly from ruptured follicular epithelia, and form sinus tracts[42].

Despite the apparent strong clinical influence of sex hormones, most patients have normal androgen profiles[43]. In addition, apocrine glands (unlike sebaceous glands) are not androgen-sensitive[43]. Although a familial form of hidradenitis suppurativa with autosomal dominant inheritance has been described[44], further studies found no significant associations with specific human leukocyte antigen (HLA)-A, -B or -DR subtypes[45]. Lithium therapy has been reported to exacerbate hidradenitis suppurativa and a role for tumor necrosis factor-α has been suggested by the therapeutic response to TNF-α inhibitors in some studies[45a] as well as increased serum levels of TNF-α in patients with hidradenitis suppurativa[46]. Increased serum levels of interleukin (IL)-2, which correlate with disease activity, have also been observed[47].

Clinical features

Initially, inflammatory nodules and sterile abscesses develop in the axillae, groin, perianal and/or inframammary areas (Fig. 38.17A). These lesions may be very tender and extremely painful. Over time, sinus tracts (Fig. 38.17B) and hypertrophic scars (Fig. 38.17C) may develop. This is accompanied by chronic drainage, leading to a marked degree of frustration, embarrassment, self-consciousness and depression, especially when the discharge is malodorous. The discharged fluid is often a mixture of serous exudate, blood and pus, in varying proportions. There are grading systems for assessment of severity and response to treatment (Table 38.7).

Complications of hidradenitis suppurativa include anemia, secondary amyloidosis, lymphedema, and fistulae to the urethra, bladder, peritoneum and rectum. Other complications include hypoproteinemia, nephrotic syndrome and SAPHO syndrome (see Ch. 26). Squamous cell carcinoma, sometimes with metastasis or humoral hypercalcemia, is an occasional complication of this chronic scarring disease[48,49].

Fig. 38.17 Hidradenitis suppurativa. A Papulopustules, nodules, sinus tracts and scarring in the axilla (Hurley stage II). **B** Superficial sinus tracts that serve as a clue to the diagnosis, even in the absence of active disease. **C** Severe disease (Hurley stage III) with inflammatory nodules, hypertrophic scarring, draining fistulae and sinus tract formation of the perianal region, buttocks and upper thighs. This is the type of patient who is at risk for the development of squamous cell carcinoma and secondary amyloidosis. *A, Courtesy, Kalman Watsky, MD.*

HIDRADENITIS SUPPURATIVA – GRADING SYSTEMS AND TREATMENT APPROACH
HURLEY STAGING SYSTEM
Stage I – one or more abscesses with no sinus tract or scar formation Stage II – one or more widely separated recurrent abscesses, with sinus tract and scar formation Stage III – multiple interconnected tracts and abscesses throughout an affected region
SARTORIUS GRADING SYSTEM[51]
• Anatomical region involved: axilla, groin, gluteal or other region or inframammary region (left and/or right) – 3 points per region involved • Number and scores of lesions: abscesses, nodules, fistulae, scars (points per lesion of all regions involved) – nodules = 2; fistulae = 4; scars = 1; others = 1 • The longest distance between two relevant lesions*, i.e. nodules and fistulae, in each region – <5 cm = 2; <10 cm = 4; >10 cm = 8 • Are all lesions clearly separated by normal skin? In each region – yes 0/no 6
THERAPEUTIC APPROACH
• Weight reduction (if overweight) and smoking cessation • Reduce friction and moisture (loose-fitting clothing and undergarments, absorbent powders, topical aluminum chloride) • Antiseptic soaps and topical antibiotics (e.g. clindamycin may reduce *Staphylococcus aureus* colonization and secondary infection) • Intranasal mupirocin (5-day course for nasal carriers of *S. aureus*) • Intralesional triamcinolone (5 mg/ml) into early inflammatory lesions • Oral antibiotics, alone or in combination (doxycycline, minocycline, clindamycin, rifampin, dapsone, trimethoprim–sulfamethoxazole)[52] • Hormonal therapy (ethinyl estradiol plus cyproterone acetate, finasteride) • Systemic retinoids (disappointing results with isotretinoin, but acitretin has anecdotally been reported as beneficial) • Immunosuppressive and anti-inflammatory agents (prednisone†, mycophenolate mofetil, cyclosporine[53], azathioprine, TNF-α inhibitors[54]) • Surgical excision, followed by primary closure or grafting • CO_2 laser stripping and second intention healing[55]; Nd:YAG laser • Other (botulinum toxin A[56], photodynamic therapy[57])
*Or size if only one lesion. †Disease often flares with taper.

Table 38.7 Hidradenitis suppurativa – grading systems and treatment approach. *From Sartorius K, Lapins J, Emtestam L, Jemec GBE. Suggestions for uniform outcome variables when reporting treatment effects in hidradenitis suppurativa. Br J Dermatol. 2003;149:211–13.*

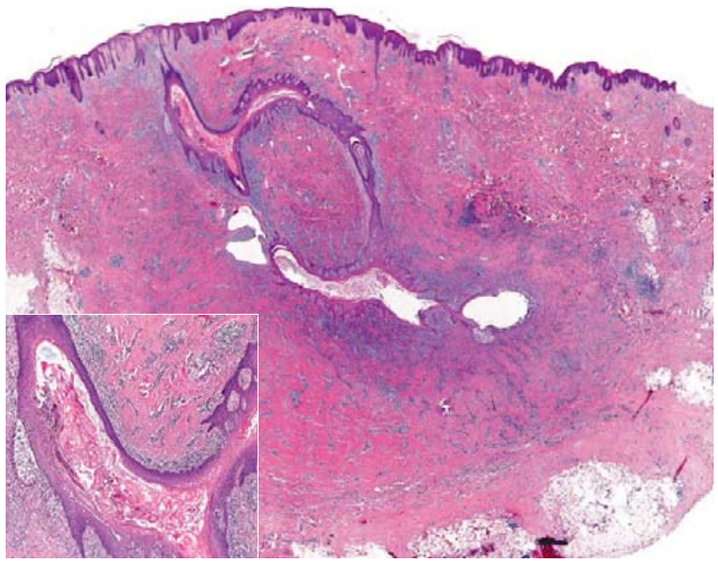

Fig. 38.18 Hidradenitis suppurativa – histologic features. A keratin-filled sinus tract (insert) is seen within the dermis, extending into the subcutaneous fat. It is surrounded by marked fibrosis and mixed inflammatory infiltrates. *Courtesy, Lorenzo Cerroni, MD.*

Pathology

There is a heavy mixed inflammatory cell infiltrate in the lower half of the dermis, usually with extension into the subcutis. Abscesses are present in active cases, and they may connect to the skin surface via a sinus tract[50]. The sinus tracts contain inflammatory cells and keratinous debris (Fig. 38.18). Granulation tissue with inflammatory cells and occasional foreign body giant cells is present in up to 25% of biopsy specimens[50]. In chronic disease, there may be extensive fibrosis with destruction of pilosebaceous follicles and sweat glands.

Differential diagnosis

Initially, hidradenitis suppurativa may resemble staphylococcal furunculosis, but the latter usually has central pointing or ulceration and usually does not form sinus tracts. Crohn's disease, granuloma inguinale, mycetoma and tuberculosis may resemble hidradenitis suppurativa. Elephantiasis nostras verrucosa secondary to recurrent

streptococcal infections accompanied by lymphangitis may cause distortion of the external genitalia and resemble hidradenitis suppurativa.

Treatment

A variety of therapeutic interventions have been described[45a]. Many are successful some of the time, but none are successful all of the time. A therapeutic approach to the patient with hidradenitis suppurativa is outlined in Table 38.7. The clinician must consider the degree of severity and response to previous treatments.

TRICHOSTASIS SPINULOSA

Trichostasis spinulosa is a common but often underdiagnosed follicular disorder of unknown etiology. Asymptomatic comedo-like lesions that contain keratin and multiple vellus hairs are seen, primarily on the face (especially its mid to lower central portion; see Fig. 36.17B) and the trunk, in particular the interscapular region. Histologically, there is follicular hyperkeratosis and multiple vellus hairs in the follicular canal enveloped within a keratotic sheath. Patients seek treatment because of the cosmetic appearance, but options are limited; the latter include keratolytics, depilatories, topical tretinoin and lasers (e.g. long-pulsed alexandrite, pulsed diode, fractional resurfacing)[58].

FOLLICULODYSTROPHY OF IMMUNOSUPPRESSION

Synonym: ■ Trichodysplasia spinulosa ■ Viral-associated trichodysplasia of immunosuppression ■ Viral-associated trichodysplasia spinulosa ■ Cyclosporine-induced follicular dystrophy

Follicular dystrophy of immunosuppression was first described in 1995 in the context of drug-induced immunosuppression in organ transplant recipients, hence its original association with cyclosporine[59]. The etiology of this entity is not known, but a viral etiology has been proposed due to the detection of intranuclear viral particles by electron microscopy[60]. Skin-colored to pink follicular papules and follicular spines favor the central face and they may be accompanied by loss of the eyebrows and eyelashes; extrafacial lesions with associated alopecia may also develop. Histologically, enlarged anagen-type follicles have dilated lumina due to marked hyperkeratosis, with some authors suggesting that the entire machinery of the follicular bulb is devoted to the manufacture of inner root sheath-like keratin[60]. The spicules can be identified by surface microscopy or light microscopy (spicule pull-test)[61]. If immunosuppressive therapy cannot be reduced, topical cidofovir or tazarotene gel or oral valganciclovir (900 mg once or twice daily) may be tried.

Chapter Contents

Hyperhidrosis *587*
Hypohidrosis and anhidrosis *594*
Specific diseases of the sweat gland *595*
Sweat as a predisposing influence on skin disease *598*
Apocrine sweat gland disorders *601*

Key features

- 2–5 million eccrine glands are unevenly distributed over the skin surface
- In healthy individuals, eccrine sweat is 99% water
- Sweating is a reflex sympathetic autonomic function mediated by cholinergic neurons

Sweating is an essential thermoregulatory function. There are two main mechanisms to cool the body: radiative cooling via cutaneous vasodilation and evaporative cooling via sweat. Sweat, primarily produced by the eccrine sweat glands, leads to dissipation of heat through evaporation. For the purposes of this discussion, the term "sweat" applies to eccrine glands and their secretory products unless otherwise specified.

While each individual has 2–5 million eccrine glands, none are found on the clitoris, glans penis, labia minora, external auditory canal and lips. Eccrine glands are separate from the apocrine-pilosebaceous apparatus (see Ch. 35). By dermoscopy, eccrine ductal orifices can be seen along the dermatoglyphic ridges. In healthy individuals, eccrine sweat is 99% water. The average adult can produce over 0.5 liters of sweat per hour; athletes or those acclimatized to hot environments can produce up to 3–4 liters per hour[1]. Physically fit or acclimatized persons initiate sweating earlier and conserve sodium, chloride and other electrolytes more efficiently. Thermoregulatory control is similar in men and women and diminishes only slightly with age[2].

Sweating is a reflex function controlled primarily by the sympathetic nervous system. These nerves are anatomically sympathetic but functionally cholinergic, i.e. acetylcholine, rather than norepinephrine, is the principal terminal neurotransmitter. Neural impulses for sweating (sudomotor impulses) travel from the anterior hypothalamus via the reticulospinal tracts to the appropriate level in the spinal cord, out through the rami communicantes to autonomic ganglia, and then within sympathetic cholinergic neurons to the secretory cells of the eccrine glands. Adrenergic innervation has also been demonstrated for the eccrine glands, but it is not believed to be physiologically important[3]. In addition, the sweat glands, via a direct effect on the secretory cells, respond to certain drugs (e.g. cholinergic agonists) as well as to the local application of heat.

HYPERHIDROSIS

Key features

- Excessive sweating
- Primary hyperhidrosis is the most common type, typically affecting the palms, soles and/or axillae
- Secondary hyperhidrosis is due to an underlying condition (e.g. genetic syndrome, infection, tumor) or medication and may be localized or generalized

Hyperhidrosis is estimated to affect 3% of the US population[4]. The most widely used classification system divides it into primary and secondary types. Other classification systems separate hyperhidrosis into categories based on the source of the neural impulses that drive it: cortical (emotional), hypothalamic (thermoregulatory), medullary (gustatory), spinal cord and local axon reflexes.

Primary Hyperhidrosis

Synonym: ■ Primary focal hyperhidrosis

Key features

- Main sites are volar (palms, soles) and axillary skin; the face may also be involved
- Hyperhidrosis arises from increased cortical stimulation and occurs *only* during waking hours (diurnal)
- While other hyperhidroses develop during childhood, axillary hyperhidrosis begins at or following puberty; patients are otherwise healthy
- As many as 80% of affected individuals have a family history of hyperhidrosis

Primary hyperhidrosis, the most common type of hyperhidrosis, is defined as excessive sweating in localized areas (usually the palms, soles and/or axillae) that is not associated with a systemic disorder. Men and women of all races are equally affected and Table 39.1 lists the diagnostic criteria[5]. Between 60% and 80% of patients with primary hyperhidrosis have a family history[6], with a pattern of inheritance suggesting autosomal dominant transmission with incomplete penetrance. A locus for primary palmar hyperhidrosis was mapped to chromosome 14q in three Japanese families[7].

Intense emotion or stress can elicit sweating in anyone. It occurs most often on the palms, soles or axillae and can also affect the face (Fig. 39.1), especially the forehead and the cutaneous upper lip. The post-orgasmic sweating observed with sexual activity[8] may also derive from emotional stimulation.

Clinically significant primary hyperhidrosis occurs in two major forms: volar (palmoplantar) and axillary, which can coexist[1]. However, one of the two forms usually predominates. The onset of volar hyperhidrosis is often during childhood, whereas axillary hyperhidrosis typically develops at or soon after puberty. Primary hyperhidrosis is

CRITERIA FOR THE DIAGNOSIS OF PRIMARY HYPERHIDROSIS
1. Focal, visible excess sweating
2. Present for at least 6 months
3. No apparent secondary causes
4. At least two of the following:
• Bilateral and symmetric
• Impairs activities of daily life
• At least one episode per week
• Age of onset <25 years
• Positive family history
• Stops during sleep

CAUSES OF CORTICAL HYPERHIDROSIS
PRIMARY HYPERHIDROSIS*
SECONDARY HYPERHIDROSIS
Disorders of cornification
• Palmoplantar keratodermas • Pachyonychia congenita • Congenital ichthyosiform erythroderma (bullous and non-bullous forms)
Other genodermatoses
• Epidermolysis bullosa: simplex > junctional • Dermatopathia pigmentosa reticularis • Dyskeratosis congenita • Pachydermoperiostosis (digital clubbing and thick, furrowed skin on the face and scalp) • Apert syndrome (craniosynostosis, digital anomalies, severe acne; *FGFR2* mutations) • Nail–patella syndrome
Hereditary sensory and autonomic neuropathies (HSANs)†
• Familial dysautonomia (Riley–Day syndrome; HSAN type III; blotchy erythema, decreased lacrimation, postural hypotension, and dysautonomic crises [vomiting, hypertension]) • Congenital autonomic dysfunction with universal pain loss • Congenital sensory neuropathy (HSAN type II)
*Synchronous discharge of vasoconstrictor and sudomotor impulses can result in symmetrical lividity of the palms and soles. †Caused by episodes of increased central sympathetic outflow to peripheral sudomotor neurons that are hypersensitive via a compensatory mechanism (in the setting of an overall decrease in sympathetic fibers); hypothalamic (thermal) hyperhidrosis can also occur.

Table 39.2 Causes of cortical hyperhidrosis. *Adapted from Moschella S, Hurley HV. Dermatology. Philadelphia: WB Saunders, 1992.*

seen in both cold and warm environments, but it is usually more problematic in hot weather. A chronic and unremitting course is characteristic, with little or no variation in association with age, disease or hormonal status.

Volar hyperhidrosis is the most common form of primary hyperhidrosis (Fig. 39.2), affecting approximately 50–60% of patients[3,4]. The entire palm and sole, as well as the lateral aspects, tips and distal dorsal skin of the fingers, display sweating. It can clearly have an impact on quality of life.

Axillary hyperhidrosis is the second most common form of primary hyperhidrosis, affecting 30–50% of patients[4]. The right axilla usually produces more sweat than the left (60:40). Exceptionally, one axilla may be hyperhidrotic while the opposite axilla is hypohidrotic or virtually anhidrotic. Odor (axillary bromhidrosis) is usually absent; the excessive quantities of eccrine sweat presumably wash away or dilute odorogenic apocrine sweat droplets and bacteria.

Secondary Hyperhidrosis

Secondary hyperhidrosis is caused by or associated with another systemic disorder. It may be localized or generalized. There are many causes, which can be divided into categories based on the source of the neural impulse driving the response: cortical, hypothalamic, medullary, spinal cord or local.

Disorders associated with cortical hyperhidrosis

Key features

- Several disorders of cornification and other genodermatoses affecting palmoplantar skin are associated with volar hyperhidrosis
- Patients with hereditary autonomic neuropathies can also exhibit cortical hyperhidrosis

Isolated sweating of the palms and soles is due to cortical excitation by emotional or sensory stimuli. Excessive volar sweating associated with certain inherited palmoplantar keratodermas is therefore assumed to be cortical in nature, although the pathogenic relationship between the abnormal keratinization and hyperhidrosis has not been precisely

delineated. Many palmoplantar keratodermas are malodorous, likely related to sweat-induced maceration of the thickened stratum corneum and bacterial degradation of keratin. Other genodermatoses affecting the volar skin, such as epidermolysis bullosa simplex, can also have associated palmoplantar hyperhidrosis.

In familial dysautonomia (Riley–Day syndrome), episodic (often emotionally induced) hyperhidrosis of the face and trunk is accompanied by blotchy erythema. Other hereditary sensory and autonomic neuropathies such as congenital autonomic dysfunction with universal pain loss can present with emotional and thermal hyperhidrosis. Additional causes of cortical hyperhidrosis are listed in Table 39.2.

Hypothalamic (thermal) hyperhidrosis

Key features

- Due to elevated body temperature (e.g. acute febrile illness, lymphoma, chronic infection) or direct hypothalamic stimuli (e.g. pheochromocytoma, medications, toxins)
- May be nocturnal (night sweats) or diurnal

The hypothalamus is responsible for many autonomic activities, including thermoregulation. Elevation of the temperature of the blood by 0.5°F or more excites the hypothalamic nuclei and results in vascular dilation and generalized sweating responses aimed at dissipating body heat[3].

Febrile illnesses are among the more common pathologic states that cause hypothalamic sweating. At the height of the fever, notably with temperatures of 39–40°C (102–104°F) or above, sweating is absent, the apparent result of inhibition of the hypothalamic center for sweating. With defervescence, sweating characteristically ensues. Lymphomas and chronic infections (e.g. tuberculosis) can present with episodic thermoregulatory sweating, which may be described as "night sweats" (that actually follow unperceived mild febrile pulses). Such conditions should be considered in any patient with a fever of undetermined origin.

Generalized sweating of hypothalamic origin can also be seen in a number of metabolic and endocrine disorders (Table 39.3). Patients with diabetes mellitus may exhibit hypohidrosis (e.g. the legs) as well as various forms of hyperhidrosis. For example, hyperhidrosis is a characteristic sign of insulin-induced hypoglycemia (but not diabetic ketoacidosis), and compensatory hyperhidrosis of the trunk can develop in the setting of diabetic neuropathy affecting the extremities (see below). In addition, diabetics may exhibit gustatory hyperhidrosis, primarily of the face and neck. Troublesome sweating of the scalp can also be seen in poorly controlled diabetics, and, with regulation of the hyperglycemia, the hyperhidrosis often improves.

Disorders with vasomotor instability, such as Raynaud's phenomenon, autoimmune connective tissue diseases, frostbite and other cold injuries, and reflex sympathetic dystrophy, may be associated with excessive sweating because of disturbed autonomic function[9]. A synchronous discharge of vasoconstrictor and sudomotor impulses evokes a "cold sweat", usually of the hands and feet, producing macerated, soggy wet, violaceous skin known as symmetrical lividity.

Cerebral cortex lesions, such as a tumor, abscess or cerebrovascular accident, may be associated with a contralateral hyperhidrosis. This apparently results from release of a cortical inhibitory influence that normally exerts a regulatory effect on hypothalamic sudomotor activity[10]. Hypothalamic sweating is also observed in Parkinson's disease and occurs as the "sweating sickness" following encephalitis. Harlequin syndrome, characterized by unilateral flushing and hyperhidrosis in association with contralateral anhidrosis, may be due to peripheral or central nervous system (CNS) abnormalities[11].

Episodic release of catecholamines from pheochromocytomas directly stimulates the hypothalamus and may elicit sweating[12]. Exposures to toxins and medications can also lead to hypothalamic hyperhidrosis, and a number of drugs that act on the CNS have increased sweating as a potential side effect (Table 39.4). Additional causes of hypothalamic hyperhidrosis are presented in Table 39.3.

Pressure and postural hyperhidrosis may be due to hypothalamic or possibly cortical stimulation. With changes in posture or the application of pressure to one side of the supine individual, a variety of sweating patterns have been described, such as lateral hyperhidrosis, horizontal hemihidrosis and crossed hemihidrosis. Idiopathic localized unilateral hyperhidrosis of the face and neck or forearm has been reported as an episodic disorder triggered by heat, emotional or gustatory stimuli[13].

CAUSES OF HYPOTHALAMIC HYPERHIDROSIS

Infection	Tumors	Endocrine/ metabolic	Vasomotor	Neurologic	Drugs/toxins	Miscellaneous
• Acute febrile illnesses (defervescence) • Tuberculosis • Brucellosis • Malaria • Subacute bacterial endocarditis • Other	• Lymphoma • Pheochromocytoma* • Carcinoid*	• Hyperthyroidism • Acromegaly • Hypoglycemia • Obesity • Menopause • Pregnancy • Porphyria (acute intermittent) • Phenylketonuria • Gout	• Congestive heart failure† • Myocardial ischemia • Raynaud's phenomenon • Acrocyanosis • Cold injury • Symmetrical lividity of the palms and soles‡ • Reflex sympathetic dystrophy • Autoimmune connective tissue disease (e.g. rheumatoid arthritis, SLE)	• Tumors • Cerebrovascular accidents • Parkinson's disease • Postencephalitic • Episodic spontaneous hypothermia with hyperhidrosis§ • Cold-induced sweating syndrome‖ • Familial dysautonomia‡	• Alcoholism • Alcohol or opioid withdrawal • Mercury toxicity (acrodynia) • Chronic arsenic toxicity • See Table 39.4	• Compensatory hyperhidrosis (e.g. in association with miliaria, diabetic neuropathy, sympathectomy)¶ • Localized unilateral hyperhidrosis (face and neck, forearm)‡ • POEMS syndrome • Speckled lentiginous nevus syndrome • Mitochondrial disorders • Pressure and postural hyperhidrosis‡

*Via release of catecholamines (pheochromocytoma) and serotonin (carcinoid tumors, usually metastatic).
†Patients have sympathetic activation, with impaired vasodilatory responses to heating but preserved sweating.
‡Also associated with cortical hyperhidrosis.
§Referred to as Hines–Bannick syndrome or, when associated with agenesis of the corpus callosum, Shapiro syndrome.
‖Autosomal recessive condition caused by mutations in the genes encoding cytokine receptor-like factor-1 and cardiotrophin-like cytokine factor-1; additional features include facial dysmorphism, flexion deformities (elbows, fingers) and scoliosis.
¶Compensatory hyperhidrosis is also a feature of Ross' syndrome (segmental anhidrosis, generalized areflexia and tonic pupils).

Table 39.3 Causes of hypothalamic hyperhidrosis. POEMS, polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes; SLE, systemic lupus erythematosus. *Adapted from Moschella S, Hurley HV. Dermatology. Philadelphia: WB Saunders, 1992.*

DRUGS THAT CAN STIMULATE ECCRINE SWEATING	
DIRECT-ACTING CHOLINOMIMETIC AGENTS	
• Acetylcholine • Anti-xerostomia drugs – Cevimeline – Pilocarpine • Methacholine	
CHOLINESTERASE INHIBITORS	
• Anti-Alzheimer's drugs* – Donepezil – Galantamine – Rivastigmine – Tacrine • Anticholinergic antidote – Physostigmine	• Antimyasthenics – Ambenonium – Edrophonium (for diagnosis) – Neostigmine – Pyridostigmine
ADRENOMIMETIC AGENTS	
• Dopamine • Epinephrine • Isoproterenol	• Norepinephrine • Phenylpropanolamine
ANTIDIABETIC (HYPOGLYCEMIC) AGENTS	
• Insulins • Sulfonylureas	
CNS STIMULANTS	
• Amphetamines • Caffeine • Theophylline	
ANTIDEPRESSANTS	
• MAOIs† – Isocarboxazid – Phenelzine – Selegiline – Tranylcypromine • SSRIs† – Citalopram – Duloxetine – Escitalopram – Fluoxetine – Fluvoxamine – Paroxetine – Sertraline	• Tricyclics† – Amitriptyline – Amoxapine – Desipramine – Doxepin – Imipramine – Maprotiline – Nortriptyline – Protriptyline – Trimipramine • Other – Buspirone† – Trazodone†
ANTIPSYCHOTICS	
• Phenothiazines – Chlorpromazine – Fluphenazine – Perphenazine – Thioridazine – Triflupromazine	• Other typical antipsychotics – Chlorprothixene – Haloperidol – Loxapine – Molindone – Thiothixene
ANTIPYRETICS	
• Acetylsalicylic acid • NSAIDs	
OPIOIDS	
• Fentanyl† • Meperidine† • Methadone†	
OTHER DRUGS	
• ACE inhibitors • Amlodipine • Atomoxetine • Dextromethorphan*,† • Ipecac • Pentoxifylline	• Phosphodiesterase inhibitors (e.g. sildenafil) • Sibutramine† • Sumatriptan† • Tramadol† • Yohimbine

*Increased sweating is infrequently observed at pharmacologic doses but represents a sign of overdose.

†Combination of MAOIs (which include linezolid as well as antidepressants) with drugs such as tricyclics, SSRIs, certain opioids and tryptophan can result in the serotonin syndrome, which is characterized by mental status changes, autonomic hyperactivity (including sweating) and neuromuscular abnormalities.

Table 39.4 Drugs that can stimulate eccrine sweating. ACE, angiotensin converting enzyme; CNS, central nervous system; MAOI, monoamine oxidase inhibitor; NSAID, nonsteroidal anti-inflammatory drug; SSRI, selective serotonin reuptake inhibitor.

Medullary (gustatory) hyperhidrosis

Key features

- Taste receptors in the mouth are the source of the afferent impulses that stimulate sweating
- Physiologic medullary hyperhidrosis is most commonly triggered by spicy foods, alcohol and citrus fruits
- Pathologic medullary hyperhidrosis occurs when disrupted nerves for sweat aberrantly connect with nerves for salivation; this can be caused by local injury to, or disease of, the parotid gland (Frey's syndrome), trauma to the sympathetic trunk, and CNS disorders (e.g. encephalitis, syringomyelia)

Physiologic medullary hyperhidrosis

Any food or drink that stimulates the taste buds may induce sweating in normal individuals, particularly of the face. This is thought to occur via a variant reflex arc in which afferent impulses from taste bud receptors travel via the glossopharyngeal nerve to nuclei within the medulla oblongata (hence the term "medullary" hyperhidrosis), but lead to provocation of sweating rather than (or in addition to) the usual response of salivation. A few minutes after ingestion of a stimulating food or beverage, sweating and erythema are seen most commonly on the upper cutaneous lip or cheeks. It may be unilateral or bilateral and may be brief or persist as long as the stimulating food or beverage is ingested. Associated vasodilation localized to the areas of sweating causes the erythema, which may be faint. Spicy or sharp-tasting foods and beverages, such as citrus fruits, alcohol and condiments, may elicit the reaction. It is most common in children and young adults and in warmer environments. A familial tendency has been described[14]. There are no other concurrent local or systemic signs or symptoms. A variant of gustatory hyperhidrosis can occur on the face in diabetics. Unusual types of gustatory hyperhidrosis involving the scalp and the knee have also been described and support the concept of a central medullary mechanism for these sweating responses[15].

Pathologic medullary hyperhidrosis

This disorder arises after disruption of nerves. During healing, nerve fibers mediating sweating aberrantly connect to nerves that mediate salivation. Impulses in parasympathetic fibers normally supplying the salivary glands are now misdirected to the sweat glands. As a result, salivary stimulation elicits sweating. Of note, thermal sweating in the areas of affected skin is reduced.

The parotid form appears weeks to months following surgery, trauma, an abscess or other diseases (including herpes zoster) affecting the parotid gland. These patients experience vasodilation and sweating on the cheek and adjacent neck with salivary stimulation produced by eating, drinking or even chewing (Fig. 39.3). Sweating most often occurs in the distribution of the auriculotemporal nerve (see Ch. 142); at times there is also unilateral localized pain.

Auriculotemporal syndrome (Frey's syndrome) is common after parotid surgery, developing in 40% or more of patients, although many are not aware of it. It can also occur during infancy (frequently as a consequence of trauma to the parotid region in a forceps-assisted delivery), presenting with gustatory flushing, but usually no obvious sweating, that is often erroneously attributed to food allergy.

Another variant of gustatory hyperhidrosis, the chorda tympani syndrome, results from transposition of sympathetic sudomotor and parasympathetic secretomotor fibers to the submandibular gland that are carried in the chorda tympani nerve. In this syndrome, salivary stimuli induce sweating on the chin and lower jaw line.

Patients with cluster headaches can have sympathetic deficits that result in impaired thermoregulatory sweating on the affected side of the forehead. However, ipsilateral hyperhidrosis and flushing may occur together with excessive lacrimation during headache attacks. This is due to misdirection of parasympathetic fibers, that normally supply the lacrimal glands, to sweat glands and blood vessels. Patients with Raeder's syndrome (Horner's syndrome [ptosis, meiosis ± anhidrosis] plus unilateral temporofrontal headaches and pain) may also have excessive supraorbital sweating (lacrimal sweating). Gustatory lacrimation, rather than gustatory or lacrimal sweating, is the clinical problem in the

Fig. 39.3 Gustatory sweating in the auriculotemporal (Frey's) syndrome, as a consequence of parotid surgery. The blue–black area represents sweating (starch–iodine technique). Salivary stimulation induced this sweating response.

OTHER CAUSES OF SECONDARY HYPERHIDROSIS

Medullary (gustatory)	Spinal cord	Axon reflex	Abnormal blood vessels or eccrine glands (non-neural)
• Physiologic gustatory sweating • Frey's syndrome • Chorda tympani syndrome • Cluster headaches • Sympathectomy • Sympathetic trunk injury (e.g. by lung carcinoma, mesothelioma, thyroidectomy) • Encephalitis • Syringomyelia	• Spinal injury • Syringomyelia • Tabes dorsalis	• Inflammatory skin diseases • Drugs (see Table 39.4)	• Eccrine nevi • Aquagenic palmoplantar keratoderma • Eccrine angiomatous hamartoma • Maffucci syndrome • Arteriovenous fistula • Klippel–Trenaunay syndrome • Glomuvenous malformation • Blue rubber bleb nevus syndrome • Cold erythema • Granulosis rubra nasi • Pretibial myxedema

Table 39.5 Other causes of secondary hyperhidrosis. *Adapted from Moschella S, Hurley HV. Dermatology. Philadelphia: WB Saunders, 1992.*

"crocodile tears" syndrome that can occur due to transposition of autonomic fibers for lacrimation and salivation after facial nerve injury.

Any condition that injures the vagus nerve and sympathetic trunk, as they lie close together in the thorax, may cause a pathologic medullary hyperhidrosis (Table 39.5). Sympathectomy, thyroidectomy, carcinoma of the lung, mesothelioma, osteoma of the spine, and subclavian aneurysm are possible causes[16]. Cholinergic fibers from the vagus nerve sprout into the adjacent sympathetic trunk during the healing process and can result in a gustatory hyperhidrosis with sweating on the face, neck and portions of the trunk and upper extremities.

In patients with syringomyelia or encephalitis, gustatory hyperhidrosis is occasionally seen on the face and upper trunk. It involves the glossopharyngeal and vagus nerves. Disturbances in the brainstem apparently lead to transposition of the central medullary nuclei for salivation and sweating. There is no peripheral crossing of sympathetic and parasympathetic nerve fibers as is seen in other forms of pathologic gustatory hyperhidrosis.

Spinal (cord transection) sweating

Key features
- Spinal disorders may result in a lack of thermal sweating below the injury as well as unusual patterns of hyperhidrosis
- Mass reflex sweating may occur around the injured level

Any injury or disease process that severs or interferes with the reticulospinal tracts of the cord can disrupt the sweating reflex (see Table 39.5). A lack of sweating in response to *thermal* stimulation usually occurs below the level of the injury. Abnormal patterns of segmental sweating may occur in conjunction with other autonomic, sensory and motor alterations. Onset and duration are unpredictable. Sweating can be excessive, drenching the patient in the regions involved. Bouts of "mass reflex sweating" are initiated in the skin below the level of the cord interruption. It is most intense in skin segments close to the level of the transection. Mass reflex sweating does not occur in transections below T8–T10.

Autonomic dysreflexia

Key features
- Direct stimulation (e.g. electrical, physical or drug-induced) of a sympathetic axon can cause sweating
- May be seen with inflammatory skin diseases

Autonomic dysreflexia is a syndrome that may occur with spinal injury at or above T6[17]. Massive episodic sympathetic discharge results in sweating above the level of the transection accompanied by headache, hypertension, facial flushing, bradycardia or tachycardia, piloerection and paresthesias.

Direct stimulation of a cutaneous sympathetic axon can induce sweating in an area approximately 4 cm in diameter[3]. Electrical and physical impulses as well as subcutaneous injection of drugs with nicotine-like effects on autonomic ganglia can incite this local form of hyperhidrosis. Mediators from inflammatory skin conditions (e.g. psoriasis, dermatitis) can also elicit localized hyperhidrosis. Substance P is believed to participate in the mediation of axon reflex sweating, and a number of other mediators, including kinins, dopamine, prostaglandins, angiotensin and adenine, may be involved[18].

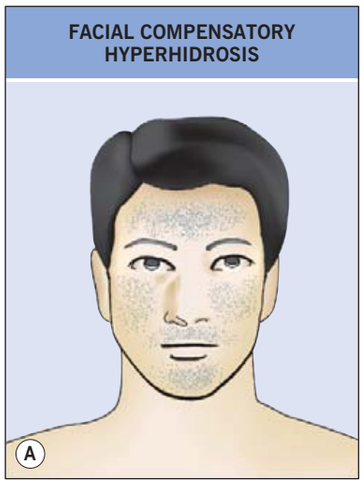
Compensatory hyperhidrosis

Key features
- Anhidrosis in one area may cause hyperhidrosis in another
- Miliaria, diabetic neuropathy and sympathectomy are well-known causes

The coordinated functioning of the body's eccrine sweat glands is illustrated by the phenomenon of compensatory hyperhidrosis, in which the sweat glands of one area become hyperactive in an effort to compensate for hypo- or anhidrosis, caused by denervation or disease, in another. Apparently, a threshold number of sweat glands must be nonfunctional in order for the compensatory response to occur. The nature or type of the underlying process that produces the anhidrosis also appears to be important. For example, compensatory hyperhidrosis does not seem to develop secondary to the anhidrosis produced by lymphomas.

The best-known clinical forms of compensatory hyperhidrosis occur in the following three situations:

- *Miliaria*: longstanding or recurrent miliaria rubra or profunda typically results in numerous non-functional sweat glands within large areas of the trunk. This induces compensatory hyperhidrosis of the face (Fig. 39.4A), especially in response to ambient heat or exercise.
- In *diabetes mellitus*, disturbance of the autonomic nervous system due to peripheral neuropathy and microangiopathy often causes



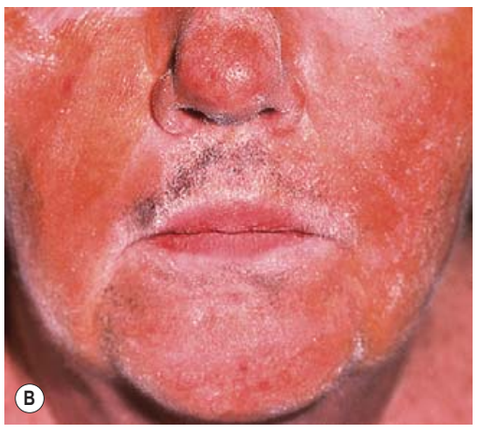


Fig. 39.4 Compensatory hyperhidrosis of the face. A Outline of the sites of facial compensatory hyperhidrosis in patients with extensive miliaria. **B** Facial compensatory hyperhidrosis (upper lip and chin) in a patient with diabetes mellitus (starch–iodine technique). *Courtesy, Harry Hurley, MD.*

Fig. 39.5 Eccrine angiomatous hamartoma. Cluster of painful pink–violet papules and plaques on the thigh and knee that had been present since one year of age. There was associated hyperhidrosis, but not hypertrichosis. Histologically, an increased number of both eccrine glands and small blood vessels is seen. *Courtesy, Julie V Schaffer, MD.*

anhidrosis or hypohidrosis of the affected skin, particularly the legs. With the loss of sweating on the lower extremities, these patients may develop compensatory increases in thermal sweating on the trunk, especially the back. A second type of compensatory hyperhidrosis, gustatory in character and usually on the face and neck (Fig. 39.4B), may also be seen in diabetic patients with peripheral neuropathy of the lower extremities.

- *Post-sympathectomy*: with the loss of sweating that results from cervicothoracic sympathectomy, a thermal hyperhidrosis, usually on the trunk, is common. Sympathectomized patients may also experience gustatory hyperhidrosis.

Non-neural hyperhidrosis

Key features

- Direct stimulation of eccrine glands can cause sweating
- Triggers include local heat, drugs and vascular tumors

Direct stimulation of eccrine sweat glands by heat or sudomimetic drugs can lead to localized sweating. Even denervated skin sweats when heat is applied[3]. Table 39.5 outlines additional non-neural causes of localized hyperhidrosis, including increased activity of eccrine glands overlying vascular lesions such as eccrine angiomatous hamartoma (Fig. 39.5).The rare disorder "cold erythema" affects the skin and gastrointestinal tract – exposure to cold produces local cutaneous erythema and intense pain along with a central area of hyperhidrosis. As with other entities in which local pain is a clinical feature (e.g. glomuvenous malformations), increased blood flow or an axon reflex (secondary to the pain) may be the casual mechanism for this sweating.

Diagnosis of Hyperhidrosis

Key features

- Differentiation between primary and secondary hyperhidrosis is important
- Colorimetric and gravimetric methods document hyperhidrosis

The first step is to differentiate between primary and secondary hyperhidrosis. History will elicit location, duration and specific triggers. Other medical disorders and medications (including over-the-counter products) must be documented. An extensive review of systems should point to any secondary causes.

Patients who do not fit the classic pattern of primary hyperhidrosis (see Table 39.1) should undergo further evaluation, focusing on possible etiologies (see Tables 39.2–39.5) during a complete history and physical examination. Laboratory testing and radiographic studies may be needed (Table 39.6).

Measurement of sweat can be performed. A grading scale for volar disease lists "low" as a moist palm or sole without visible sweat droplets. "Moderate" disease is characterized by sweating toward the fingertips. "Severe" cases drip sweat. Axillary involvement can be measured by the sweat stains on clothing: <5 cm is considered normal; 5–10 cm, mild; 10–20 cm, moderate; and >20 cm, severe.

Colorimetric techniques such as the starch–iodine or quinizarin methods[19] demonstrate the sweating pattern and reveal the location of the most active sweat glands in a given area. In the starch–iodine technique, iodine solution (e.g. 3.5% in alcohol) is applied to clean, shaved skin and allowed to dry, then starch powder (e.g. cornstarch) is brushed onto the area; the mixture turns blue–black in sites with sweating (Fig. 39.6). A combination of paper impregnated with starch and iodine can also be utilized (Fig. 39.7). Although not routinely performed in patients with hyperhidrosis, these tests can be used to plan treatment with botulinum toxin or local surgical ablation.

Additional quantitative assessment methods are available. In order to document amounts of sweat produced, gravimetric (via weighing filter paper before and after application to the skin) and evaporative (via a device that assesses water vapor loss from the skin) measurements can be made in volar or axillary sites[19]. Most patients with axillary hyperhidrosis will produce at least 100–300 mg of sweat in a 5-minute test period with mental arithmetic as a sweating stimulus. Infrared thermography represents another method of evaluating sweat gland

INITIAL PATIENT EVALUATION FOR SECONDARY HYPERHIDROSIS	
Laboratory test	**Disease**
Serum electrolytes, BUN, creatinine	Renal disease (rare)
Fasting blood glucose level and/or HbA1c	Diabetes mellitus
Thyroid function tests	Hyperthyroidism
Skin and/or blood tests for tuberculosis (e.g. PPD, QFTB-G)	Tuberculosis
Chest X-ray	Tuberculosis, neoplasm
Complete blood count	Infection
Sedimentation rate	Infection, neoplasm, inflammatory disease
Antinuclear antibodies	Autoimmune connective tissue disease
Urinary catecholamines*	Pheochromocytoma
*If suggestive signs or symptoms.	

Table 39.6 Initial patient evaluation for secondary hyperhidrosis. Further evaluation depends upon results and consideration of entities in Table 39.3. PPD, (tuberculin) purified protein derivative; QFTB-G, QuantiFERON-TB Gold.

Fig. 39.6 Delineation of area for injections of botulinum toxin A for axillary hyperhidrosis (starch–iodine technique). Blue–black areas represent foci of sweating. In the case of onabotulinumtoxinA, a total of 50–100 U is injected, utilizing 10 to 15 injection sites. *Courtesy, Alastair Carruthers, MD, and Jean Carruthers, MD.*

Fig. 39.7 Palmar hyperhidrosis as assessed by the semiquantitative starch paper–iodine technique. Sweating can also be demonstrated directly on palmar skin by the starch–iodine technique, as shown in Figure 39.6 for axillary hyperhidrosis. *Courtesy, Harry Hurley, MD.*

function, allowing comparison between anatomic areas and even individual glands.

Treatment of Hyperhidrosis

Key feature

- Treatment options for hyperhidrosis include topical aluminum chloride preparations, oral agents (anticholinergics, α- or β-adrenergic blockers, α_2-adrenergic agonists), botulinum toxin A, iontophoresis, biofeedback therapy, and surgical procedures

Treatment options available for hyperhidrosis are outlined in Table 39.7. With the exception of 12% aluminum chloride, over-the-counter antiperspirants are usually not strong enough to significantly improve the problem. More effective topical preparations are available: 6.25% or 20% aluminum chloride hexahydrate (depending upon site and severity) is usually the first-line treatment for localized hyperhidrosis. These solutions should be applied to dry surfaces at night, when sweating is diminished. Occlusion with gloves or plastic film enhances penetration of the drug. Application is recommended for three to five consecutive nights, then one to two times a week as needed to control sweating. Treated skin can be washed the following morning. The salt precipitates in the sweat duct and blocks it. With chronic use, atrophy of secretory cells may develop. Burning and irritant contact dermatitis are common side effects, particularly in women who shave their axillae.

Some patients who sweat significantly at night require a preliminary dose of an anticholinergic (glycopyrrolate 1 mg or propantheline bromide 15 mg) 1 hour before application for the first few applications. This reduces sweating enough to prevent washing away of the topical solution. Topical aldehyde agents such as formaldehyde and glutaraldehyde are effective, especially for volar disease, but allergic sensitization may develop that can result in cross-reactions with aldehydes in the environment (lotions, soaps, shoes). Other side effects include discoloration of the skin.

Tap water iontophoresis over 20 minutes two to three times a week may be helpful. The mechanism of action is unknown but is thought to lead to blockage of the sweat duct in the stratum corneum. Side effects are minimal and include tingling of the skin during treatment. Introduction of anticholinergic medications via iontophoresis is not advised due to potential systemic absorption.

Oral anticholinergics will decrease sweating in most patients. The most commonly used agents are oxybutynin[20] and glycopyrrolate[21] (see Table 39.7 for recommended regimens). When higher doses are required to control the hyperhidrosis, unacceptable side effects can often develop, including dry eyes, dry mouth, insomnia, mental status changes (e.g. confusion, hallucinations), palpitations, seizures, blurred vision, bowel disturbances, urinary retention and hypertension.

Clonidine (an α_2-adrenergic agonist that decreases central sympathetic outflow) and phenoxybenzamine (an α-adrenergic blocker) have been used with some success in anecdotal reports[22,23]. Potential side effects include hypotension, rebound hypertension, sedation, constipation, weakness and headache.

Propranolol, a β-adrenergic blocker, is commonly used for the treatment of performance anxiety and it may improve hyperhidrosis temporarily. However, long-term use may induce hyperhidrosis.

Botulinum toxin type A (BTA) has been approved by the Food and Drug Administration in the US for the treatment of axillary hyperhidrosis (see Fig. 39.6); it is also effective for volar disease. BTA prevents release of acetylcholine from cholinergic neurons (see Ch. 159). Injection into hyperhidrotic skin will produce near anhidrosis for 4 to 6 months. Side effects, if any, are short-lived. Muscle weakness, especially of the intrinsic muscles of the hands or feet, has been reported and resolves spontaneously over 2 to 5 weeks. Compensatory hyperhidrosis has not been observed[24].

Surgical treatment represents the final option after other therapeutic modalities have failed. Excision of the sweat glands is often effective for axillary disease, but resection of the entire axillary skin causes significant scarring. Compensatory hyperhidrosis is not seen with this form of local surgery. Newer methods include removal or destruction of the axillary sweat gland layer by surgical dissection, curettage or liposuction[24,25].

TREATMENT OF HYPERHIDROSIS					
	Therapy	**Frequency & recommended dose**	**Side effects**	**Duration**	**Comments**
First-line	*Topicals* Aluminum chloride hexahydrate – 6.25% (e.g. Xerac AC®), 15% (with 2% SA), 20% (e.g. Drysol®) Aluminum chloride – 12% (e.g. Certain Dri®) Zirconium salts Aldehydes	Use nightly for 3–5 nights, then every few days as needed	Burning Irritant contact dermatitis	Days	Blocks sweat ducts Aldehydes not recommended due to sensitization Zirconium salts may be effective in axillae, but not volar surfaces
Second-line	*Iontophoresis*	2–3 times a week	Discomfort during procedure	Days	Blocks sweat ducts
	Botulinum toxin A	Every 4–6 months	Discomfort during injection Weakness of underlying muscles	Months	Prevents release of acetylcholine
	Oral therapy	As needed		Hours	
	Oxybutynin	1.25–5 mg bid	Dry mouth and urinary retention most common; also confusion and decreased mental status		Anticholinergic
	Glycopyrrolate	1–2 mg bid			Anticholinergic
	Clonidine	0.1–0.3 mg bid	Hypotension, rebound hypertension		α_2-Adrenergic agonist
	Propranolol	10–40 mg bid	Hypotension, bradycardia, hyperhidrosis with long-term use		β-Adrenergic blocker
	Clonazepam	0.25–0.5 mg bid	Sedation		Anxiolytic
Third-line	*Local excision*	Once	Scarring	Permanent	Last resort
	Sympathectomy		Compensatory hyperhidrosis Horner's syndrome	Usually permanent	

Table 39.7 Treatment of hyperhidrosis. bid, twice daily; SA, salicylic acid.

Although sympathectomy is the last resort for patients with volar hyperhidrosis, advances in endoscopic surgery have decreased the morbidity associated with this procedure. Sympathectomy at the T2–T3 level for palmar disease and the lumbar area for plantar disease is effective. Risks of the procedure include Horner's syndrome, hypotension and pneumothorax. Compensatory hyperhidrosis of the trunk or gustatory facial sweating may occur[24] and the hyperhidrosis may gradually recur.

HYPOHIDROSIS AND ANHIDROSIS

Key features

- An inability to sweat can be life-threatening due to the development of heat-related illnesses (see Ch. 88)
- Causes of hypo- and anhidrosis include central or neuropathic disruption of neural impulses, sweat gland abnormalities, and medications

Three major categories of disorders are recognized causes of anhidrosis: (1) central and neuropathic diseases or medications that disrupt stimuli as they track from the anterior hypothalamus to the eccrine gland; (2) peripheral (non-neural) alterations in the gland itself; and (3) conditions of idiopathic origin.

Central and Neuropathic Hypohidrosis

Disturbance or interruption of innervation at any level, from the sweating centers in the brain down through the descending neural tracts to the sweat glands, can result in decreased or absent sweating. Causes are listed in Table 39.8. Pontine or medullary lesions lead to unilateral facial anhidrosis on the ipsilateral side of the face and neck. Fiber tracts carrying sudomotor neurons to lower levels in the spinal cord, however, are both crossed and uncrossed and the resultant anhidrosis of the skin may be ipsilateral or contralateral.

Both peripheral neuropathies and degenerative neurologic disorders can cause anhidrosis. Chronic orthostatic (postural) hypotension may be associated with decreased sympathetic innervation of the sweat glands and syncopal episodes in these patients are not accompanied by sweating (in contrast to the sweating, pallor and nausea seen in common vasodepressor fainting).

CAUSES OF CENTRAL AND NEUROPATHIC HYPOHIDROSIS AND ANHIDROSIS
• Tumors, infarctions and other lesions of the hypothalamus, pons or medulla • Spinal cord tumors and injuries • Degenerative syndromes – Pure autonomic failure – Multiple system atrophy (Shy–Drager syndrome)* – Ross' syndrome • Autoimmune autonomic neuropathy • Congenital insensitivity to pain with anhidrosis • Peripheral neuropathy due to: – Diabetes – Alcoholism – Amyloidosis (immunoglobulin light chain and transthyretin types) – Leprosy
*Progressive autonomic dysfunction, parkinsonism and ataxia.

Table 39.8 Causes of central and neuropathic hypohidrosis and anhidrosis.

Ross' syndrome, which consists of Adie's syndrome (myotonic pupils and absent deep tendon reflexes) plus segmental anhidrosis that is typically associated with compensatory hyperhidrosis, also falls into this group. Congenital insensitivity to pain with anhidrosis (hereditary sensory and autonomic neuropathy type IV) is a rare autosomal recessive disorder which presents with recurrent fevers due to anhidrosis, self-mutilation due to insensitivity to pain and mental retardation. Immunohistochemical staining (e.g. for an axonal marker such as protein gene product 9.5 [PGP 9.5]) of skin biopsy specimens reveals a lack of innervation of eccrine sweat glands.

Disruption of the superior cervical ganglion, an occasional complication of cervicothoracic sympathectomy, results in Horner's syndrome, and chemical blockade of selected sympathetic ganglia will result in regional anhidrosis. Any drug that interrupts synaptic transmission in autonomic ganglia will suppress sweating (Table 39.9).

DRUGS THAT CAUSE HYPOHIDROSIS AND ANHIDROSIS
BLOCKADE OF NEUROTRANSMISSION
• **Nicotinic acetylcholine receptor antagonists (ganglion-blocking agents)**
– Hexamethonium
– Mecamylamine
– Tetraethylammonium
– Trimethaphan
• **Muscarinic acetylcholine receptor antagonists***
– Atropine
– Glycopyrrolate
– Oxybutynin
– Scopolamine
• **Calcium channel blockers**
• **α-Adrenergic blockers**
– Phenoxybenzamine (hypohidrosis occasionally observed)
– Phentolamine†
• **α_2-Adrenergic agonists‡**
– Clonidine
DYSFUNCTION OR DESTRUCTION OF THE ECCRINE GLAND§
– Aldehydes (topical)
– Aluminum salts (topical)
– 5-Fluorouracil
– Quinacrine
– Topiramate¶
– Zirconium salts (topical)
– Zonisamide¶
*Antipsychotic drugs (e.g. phenothiazines), tricyclic antidepressants and some antihistamines can also have anticholinergic effects, especially when administered in combination and at high doses.
†Thought to suppress eccrine sweating by inhibiting ganglionic transmission.
‡Decrease sympathetic outflow from the CNS.
§Eccrine gland necrosis is also a feature of coma bullae, which are classically associated with barbiturate overdose but can also be observed in comas induced by other drugs (see Ch. 33); syringosquamous metaplasia may result from the toxic effects of chemotherapeutic agents (e.g. cytarabine, doxorubicin) on the eccrine glands.
¶Decreased sweating has been attributed to inhibition of carbonic anhydrase isoenzymes in the eccrine glands.

Table 39.9 Drugs that cause hypohidrosis and anhidrosis. Refers to systemic administration unless otherwise indicated.

PERIPHERAL CAUSES OF HYPOHIDROSIS AND ANHIDROSIS DUE TO SWEAT GLAND ABNORMALITIES
GENETIC DISORDERS
• Ectodermal dysplasias
– Hypohidrotic ectodermal dysplasia
– Hypohidrotic ectodermal dysplasia with immune deficiency
– Rapp–Hodgkin syndrome
– Naegeli–Franceschetti–Jadassohn syndrome
• Incontinentia pigmenti
• Bazex syndrome
• Fabry disease*
DESTRUCTION
• Tumors (e.g. lymphoma)
• Burns
• Radiation therapy
• Systemic sclerosis (scleroderma) and morphea
• Sjögren's syndrome†
• Graft-versus-host disease
• Acrodermatitis chronica atrophicans
OBSTRUCTION
• Miliaria
• Ichthyoses
• Psoriasis
• Eczematous dermatoses
• Bullous diseases
• Porokeratosis
*Hyperhidrosis (related to autonomic dysfunction) can also occur.
†Hypohidrosis can also result from peripheral neuropathy.

Table 39.10 Peripheral causes of hypohidrosis and anhidrosis due to sweat gland abnormalities.

Peripheral Anhidrosis

Congenital and acquired alterations or disturbances of the sweat glands result in an absence or significant reduction in sweating (Table 39.10). A near absence of sweat glands is found in male patients with X-linked hypohidrotic ectodermal dysplasia, while female carriers show reduced sweating[26]. Bazex syndrome, also known as Bazex–Dupré–Christol syndrome, is an X-linked dominant disease characterized by hypohidrosis, hypotrichosis, multiple basal cell carcinomas and follicular atrophoderma (see Ch. 99).

The skin of elderly individuals may show some atrophy of the sweat glands, but overall they are preserved and continue to function with advancing age. Toxic and thermal insults to the skin and a variety of inflammatory and neoplastic disorders can destroy or produce atrophy of the sweat glands with resultant anhidrosis (see Table 39.10)[27]. Perhaps the most common causes of anhidrosis are inflammatory and hyperkeratotic disorders that produce sweat duct obstruction.

Diagnosis of Anhidrosis

Heat intolerance may be due to many underlying disorders as well as to personal preference. New symptoms such as drowsiness, fatigue or inability to concentrate in hot environments in association with a decrease in the patient's "normal sweating" point to acquired hypo- or anhidrosis. As with hyperhidrosis, a careful history will yield clues to the diagnosis. Special attention must be given to new medications, recent medical events (e.g. a cerebrovascular accident), the presence of diabetes or other chronic conditions (see Tables 39.8–39.10) and family history.

Examination of the patient's skin may not reveal the presence or extent of anhidrosis. A hot environment or exercise may be required, but excessive overheating must be avoided. Colorimetric or gravimetric testing (as for hyperhidrosis) will demonstrate diminished or absent sweating. Local intradermal injection of cholinergic drugs to stimulate sweating in small areas can also be utilized, but the risk of side effects generally precludes their injection into large areas. Testing for axon reflex sweating with intradermal nicotine sulfate or picrate in appropriate doses (e.g. 0.001 mg) may be performed in patients in whom peripheral neuropathies are suspected.

Finally, a biopsy specimen from an affected area of skin should be obtained in virtually all patients with anhidrosis. Immunohistochemical stains and electron microscopy may be necessary to identify sweat gland abnormalities.

Treatment of Anhidrosis

Unfortunately, treatment options for anhidrosis are limited. Offending medications should be discontinued. Keeping the patient in a cool environment is essential. For disorders due to clogged sweat ducts, gentle exfoliation may be helpful. Disorders of keratinization (e.g. lamellar ichthyosis) associated with overheating should be treated aggressively, with restoration of sweating as a minimal therapeutic endpoint. Use of water-containing spray bottles can prove useful.

SPECIFIC DISEASES OF THE SWEAT GLAND

Miliaria

Key features

- Sweat retention can be caused by obstruction of the eccrine duct at various levels
- Miliaria crystallina or sudamina (superficial ductal occlusion) – clear vesicles
- Miliaria rubra or prickly heat (intermediate ductal occlusion) – erythematous papules or pustules
- Miliaria profunda or mammillaria (deeper ductal occlusion) – white papules
- Common in neonates (whose eccrine sweat ducts are not fully developed) and adults living in hot, humid conditions
- Resolves with relocation to a cool environment

Miliaria is a group of eccrine disorders having in common obstruction of the eccrine sweat duct. Three types, each reflecting obstruction of sweat ducts at different levels, from the stratum corneum to the dermal–epidermal junction, are recognized (Table 39.11). Blockage results in retention of sweat within the duct, causing a sweat retention vesicle to form.

Epidemiology

Miliaria is most common in children, particularly neonates whose eccrine ducts are not fully developed. Congenital miliaria crystallina has been described[27]. It is also common in adults who live or work in very hot, humid environments. There is no racial or sex predisposition and it can be seen in the elderly. Miliaria has not been associated with an underlying systemic disease.

Pathogenesis

Excessive sweating, particularly under occlusive clothing, can lead to maceration of the stratum corneum which is sufficient to cause blockage of the eccrine duct[28]. Keratinous plugs form, causing obstruction.

Clinical features

Each type of miliaria is clinically distinctive (see Table 39.11). Miliaria crystallina presents as small, clear vesicles (Fig. 39.8) that rupture easily. It is most commonly observed on the face and upper trunk of infants and on the trunk in adults, and it poses no systemic risk for the patient.

The most common and clinically important form is miliaria rubra, which is characterized by small, non-follicular, erythematous macules and papules topped by a punctate vesicle (Fig. 39.9). Lesions are usually pruritic and occasionally burn. Onset is within days to weeks of exposure to hot environments. Miliaria rubra may become pustular, especially in chronic, extensive cases. Miliaria pustulosa, as this variant is known, is sterile, although secondary bacterial infection may occur. Miliaria rubra typically occurs on the upper trunk and neck in both children and adults. Extensive cases of miliaria rubra can lead to hyperpyrexia as a result of the obstruction of large numbers of sweat glands and compromise of their thermoregulatory role (see Ch. 88). When miliaria rubra is chronic or recurrent, occlusion may extend to a deeper level and produce miliaria profunda. Because of their deeper location, the sweat retention vesicles of miliaria profunda appear clinically as white papules, 1 to 3 mm in diameter. They start within minutes of initiation of sweating and subside within 1 to 2 hours after the sweating ceases. Since the sweat retention vesicle lies in the upper dermis below the level of the itch receptors, lesions of miliaria profunda are asymptomatic. Only in those patients with concomitant miliaria rubra can pruritus or burning develop. Miliaria profunda is relatively rare and typically occurs on the trunk and proximal extremities. When large numbers of sweat glands are occluded and essentially non-functional, these individuals are at risk for significant thermoregulatory problems and a compensatory hyperhidrosis of the face is routinely observed (see Fig. 39.4). Axillary and inguinal lymphadenopathy can also be seen, with resolution upon clearing of the miliaria. The term "tropical anhidrotic asthenia" has been applied to these patients.

Pathology

Biopsy specimens demonstrate ductal blockage. Keratinous obstruction of sweat ducts at the level appropriate for each type of miliaria may be seen: in the stratum corneum for miliaria crystallina; the mid-epidermis or spinous layer for miliaria rubra; and at the dermal–epidermal junction for miliaria profunda. Sweat retention vesicles may be seen

Fig. 39.8 Miliaria crystallina. Multiple small superficial vesicles with clear fluid.

Fig. 39.9 Miliaria rubra. Multiple erythematous non-follicular papules and papulovesicles on the back.

THREE TYPES OF MILIARIA				
Type	**Location of obstruction**	**Cutaneous lesions**	**Patient population(s)**	**Most common locations**
Crystallina	Stratum corneum	Non-pruritic, clear, fragile, 1 mm vesicles	Neonates <2 weeks of age Children and adults in hot climates	Face and trunk
Rubra	Mid-epidermis	Pruritic, erythematous, 1–3 mm papules; may have pustules	Neonates 1–3 weeks of age Children and adults in hot climates	Neck and upper trunk
Profunda	Dermal–epidermal junction	Non-pruritic, white, 1–3 mm papules	Adults in hot climates; often with multiple bouts of miliaria rubra	Trunk and proximal extremities

Table 39.11 Three types of miliaria.

underlying the respective sites of occlusion. Dermal inflammation is absent in miliaria crystallina, whereas perivascular lymphocytic infiltrates and vasodilation are evident in miliaria rubra. An eosinophilic cast can be seen occluding sweat ducts at the dermal–epidermal junction or intraepidermally in miliaria profunda. Periductal infiltration of lymphocytes is also seen along with mild focal spongiosis of the adjacent epidermis. Special stains may reveal Gram-positive bacteria in both rubra and profunda lesions, but cultures are typically negative unless the lesions are secondarily infected.

Differential diagnosis

Each type of miliaria has such a classic clinical presentation that the diagnosis is usually apparent. A simple diagnostic test involves the puncture of a miliaria vesicle with a fine needle, resulting in release of the trapped clear sweat. In neonates, miliaria rubra must be distinguished from erythema toxicum neonatorum, neonatal cephalic pustulosis (which can involve the upper trunk as well as the face), candidiasis, and (in atypical cases) other vesiculopustular diseases of the newborn (see Table 34.1). In adults, the differential diagnosis for miliaria rubra includes other conditions with a predilection for sites of occlusion and excessive sweating, such as folliculitis (with normal flora or *Staphylococcus aureus*), candidiasis and Grover's disease (see Ch. 87). The regression of miliaria profunda within hours of ceasing physical exertion and/or exposure to high temperatures distinguishes it from other papular eruptions.

Treatment

Management of all types of miliaria requires placement of the patient in a cool environment, in which sweating stops, for several days to weeks. Gradually, the obstructed sweat ducts shed their occluding keratinous plugs and normal sweating is restored. Topical anhydrous lanolin may dissolve the plugs in miliaria profunda[28]. Anecdotally, other topicals (including corticosteroids and antibiotics) as well as oral antibiotics, retinoids, and vitamins A and C have been advocated as therapeutic options.

Altered Composition of Eccrine Sweat

Key features

- Some disorders (e.g. cystic fibrosis) lead to abnormal chemical composition of sweat
- Eccrine bromhidrosis is most commonly caused by maceration of the stratum corneum and bacterial degradation of keratin
- Eccrine chromhidrosis is caused by exogenous chemicals that color the sweat, whereas apocrine chromhidrosis is due to intrinsic causes

Abnormalities of eccrine sweat composition, as evidenced by altered electrolyte content or the presence of other anomalous substances, should be recognized as disorders of eccrine function. Some of these glandular disturbances are not accompanied by clinically distinctive signs or symptoms, whereas others result in well-defined clinical conditions that are associated with profound effects on the general health of the affected individual.

Most notable among this group of disorders are those in which there is altered electrolyte concentration in sweat (Table 39.12). Cystic fibrosis, an autosomal recessive disorder caused by mutations in the *c*ystic *f*ibrosis *t*ransmembrane conductance *r*egulator (*CFTR*) gene, is an important example in which all of the exocrine glands in the body are affected, leading to dysfunction of multiple organs, including the lungs, exocrine pancreas, intestines and liver. Cystic fibrosis patients demonstrate decreased electrolyte reabsorption by the eccrine duct, which results in increased loss of sodium, chloride and (to a lesser extent) potassium in sweat. Increased Cl^- concentration in sweat (>60 mEq/l on two separate occasions) remains the most widely used diagnostic test for this disease (the sweat chloride test). Cystic fibrosis patients still produce sweat in response to heat and most pharmacologic stimuli, but the increased loss of electrolytes poses a systemic risk for them in hot environments. An absent or markedly diminished response of the eccrine glands and other exocrine glands to β-adrenergic agonists is another marker for this disorder. This reflects the underlying pathogenic defect in the CFTR protein, a Cl^- channel that regulates other ion channels and is activated via cyclic adenosine monophosphate (cAMP) via β-adrenergic stimulation.

SYSTEMIC DISORDERS THAT AFFECT THE LEVELS OF ELECTROLYTES IN SWEAT

INCREASED LEVELS OF ELECTROLYTES IN SWEAT*

- Cystic fibrosis
- Endocrine disorders
  - Adrenal insufficiency (e.g. due to Addison's disease or congenital adrenal hyperplasia)
  - Myxedema
  - Nephrogenic diabetes insipidus
- Familial intrahepatic cholestasis
- Malnutrition
- Metabolic disorders
  - Fucosidosis
  - Glycogen storage disease type I
- Unacclimatized individuals exposed to heat

DECREASED LEVELS OF ELECTROLYTES IN SWEAT

- Endocrine disorders
  - Aldosteronism
  - Cushing's syndrome
  - Thyrotoxicosis
- Hypoproteinemic edema (e.g. due to cirrhosis or nephrotic syndrome)

*Elevated sweat electrolytes (which may result in a false-positive chloride sweat test) can also be observed in patients with skin conditions such as widespread atopic dermatitis, ichthyosiform erythroderma or ectodermal dysplasia.

Table 39.12 Systemic disorders that affect the levels of electrolytes in sweat.

Excretion of calcium in eccrine sweat has been demonstrated in patients with widespread idiopathic calcinosis cutis. In uremia, high levels of urea can produce a "uremic frost" on the skin of these seriously ill patients. However, this is rarely seen now that dialysis is a common procedure. Decreased size of the sweat glands, the significance of which is unknown, has also been described in patients with uremia[29]. Many drugs, including opiates (e.g. methadone, morphine), amphetamines, anticonvulsants, antimicrobials (e.g. azole antifungals, griseofulvin, quinolones, cephalosporins) and chemotherapeutic agents (e.g. cytarabine, cyclophosphamide, thiotepa), as well as metals such as copper and mercury have also been shown to be secreted in sweat[30,31].

In healthy individuals, eccrine sweat is odorless when it is secreted. Odor (bromhidrosis) can develop secondary to maceration of the stratum corneum with bacterial degradation of keratin. This may be seen on the feet and in intertriginous areas, especially the inguinal region. The types of bromhidrosis are listed in Table 39.13.

Malodorous sweat can be caused by abnormal secretion of amino acids and their analogues or breakdown products. This occurs in several heritable metabolic disorders (see Table 39.13), with the sweat often having a distinctive smell such as musty or "mousy" in phenylketonuria (see Ch. 63) or a sweet odor in maple syrup urine disease. Odorogenic compounds may also be detected in the saliva and urine of these patients. Some foods, such as garlic and asparagus, can cause eccrine bromhidrosis.

Individuals with an inherited deficiency in the enzyme *f*lavin-containing *m*onoo*x*ygenase-3 (FMO3) excrete large quantities of trimethylamine in their urine, sweat and saliva after ingestion of marine fish (which contains trimethylamine-*N*-oxide) or choline- and lecithin-containing foods (e.g. eggs, kidney and liver)[32]. The resultant "fishy" odor characterizes this disorder, trimethylaminuria. The clinical spectrum of trimethylaminuria ranges from a severe, constant, socially debilitating condition with onset in early childhood (e.g. with a homozygous mutation that abrogates FMO3 function) to mild or intermittent manifestations (often related to dietary factors or overgrowth of intestinal bacteria) that begin during adulthood (e.g. with a heterozygous polymorphism that decreases FMO3 function).

Colored eccrine sweating (*eccrine* chromhidrosis) results from contamination of colorless eccrine sweat by a chromogen such as a dye

TYPES OF BROMHIDROSIS
APOCRINE
• Axillary (no odor from other apocrine areas)
ECCRINE
• Keratinogenic – Plantar – Intertriginous • Metabolic – Phenylketonuria (musty or "mousy" odor) – Maple syrup urine disease (sweet odor) – Methionine adenosyltransferase deficiency ("boiled cabbage" odor) – Methionine malabsorption syndrome (oasthouse syndrome) – Trimethylaminuria ("fishy" odor) – Dimethylglycine dehydrogenase deficiency ("fishy" odor) – Isovaleric acidemia ("sweaty feet" odor) • Exogenous – Foods, e.g. garlic, asparagus, curry – Drugs, e.g. penicillins, bromides – Chemicals, e.g. dimethyl sulfoxide (DMSO)

Table 39.13 Types of bromhidrosis.

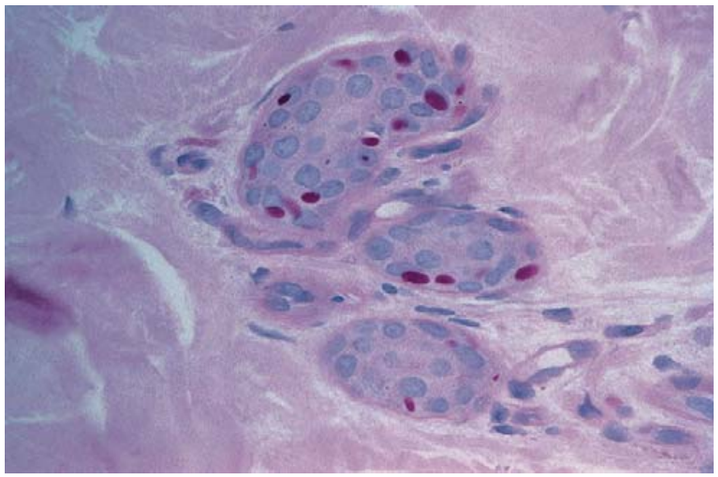

Fig. 39.10 Lafora disease. Large, purplish-red granules in the outer layer of eccrine duct cells (PAS stain). *Courtesy, Harry Hurley, MD.*

(e.g. from clothing), paint, pigment from a microorganism (e.g. *Piedraia* or *Corynebacterium* spp.), or another colored chemical on the surface of the skin. Copper miners or workers in industry often exhibit blue or blue–green skin from external deposits of copper salts that color the sweat. The use of self-tanning products can result in brown sweat. Hematidrosis (bloody sweat) has not been confirmed scientifically. Red sweat has been described in patients receiving clofazimine and rifampin. In contrast, *apocrine* chromhidrosis is usually intrinsic in origin, resulting from the excretion in apocrine sweat of lipofuscin in large amounts or in a highly oxidized state. Chromhidrosis, primarily axillary in location and presumably of apocrine origin, can be seen in alkaptonuria (see Ch. 63) and may be a presenting sign of the disease as the excreted pigment stains the undershirts of these patients.

Cytologic Inclusions and Other Morphologic Changes of Diagnostic Importance in the Sweat Glands

A variety of disorders display diagnostic microscopic findings within the eccrine sweat glands, ranging from intracellular inclusions and degenerative alterations to changes in the size of the glands or their components (Fig. 39.10). Table 39.14 summarizes these distinctive histopathologic features, which may be overlooked in the diagnostic evaluation of patients. Most of the findings listed can be visualized by light microscopy. Of note, viral particles from Ebola virus and severe acute respiratory syndrome (SARS) have been found in eccrine sweat ducts by electron microscopy[33]. Whether the sweat is contagious remains to be proven.

DIAGNOSTIC MICROSCOPIC CHANGES IN ECCRINE GLANDS	
Disorder	**Microscopic changes**
Hypothyroidism	PAS-positive, diastase-resistant granules in secretory cells
Lymphoma Multiple myeloma Heat stroke	Vacuolar degeneration of secretory cells or ducts
Neuronal ceroid lipofuscinoses	Cytoplasmic inclusions in secretory cells
Mucopolysaccharidoses (e.g. Hurler, Hunter, Sanfilippo) Mucolipidoses Acid maltase deficiency Adrenoleukodystrophy	Membrane-bound vacuoles in secretory cells
Sphingolipidoses (e.g. Fabry, Niemann–Pick, Sandhoff)	Lipid inclusions in secretory cells
Lafora disease	PAS-positive granules in outer layer of duct cells
Argyria	Granules in eccrine basement membrane (darkfield)
Trisomy 13, 18 or 21	Differences in duct:secretory coil length
Ebola hemorrhagic fever Severe acute respiratory syndrome (SARS)	Viral particles in lumen of sweat gland tubule
Uremia	Reduced size of sweat glands

Table 39.14 Diagnostic microscopic changes in eccrine glands.

SWEAT AS A PREDISPOSING INFLUENCE ON SKIN DISEASE

Key features

- Wet skin is more permeable than dry skin
- Wet skin is more likely to develop contact allergies than dry skin
- Several diseases are aggravated by sweat, including Hailey–Hailey disease, Grover's disease, folliculitis and pitted keratolysis

That wet skin is more permeable than dry skin has been clearly established, and skin wetted by perspiration is more likely to be sensitized to contact allergens. Sweaty skin is also more susceptible to absorption of toxic chemicals. The macerative effect of sweat is an essential early step in the pathogenesis of sweat retention syndromes, such as miliaria. Sweat-saturated keratin, upon bacterial degradation, gives rise to plantar bromhidrosis and pitted keratolysis. Softening of the skin by sweat facilitates the entry and growth of microorganisms, encouraging the development of flexural candidiasis, bacterial folliculitis, bullous impetigo, superficial dermatophyte infections, tinea versicolor, verrucae and molluscum contagiosum. Grover's disease and Hailey–Hailey disease are clearly aggravated by sweating. Some systemic drugs, such as antifungal agents, are excreted in eccrine sweat and diffuse from the sweat ducts to the surrounding stratum corneum, exerting inhibitory effects on microorganisms. Finally, the decreased electrical skin resistance that occurs with sweating causes increased conductance of electrical currents.

Granulosis Rubra Nasi

Key features

- Hyperhidrosis of the nose is followed by macular erythema; papules and vesicles can also develop
- The process may extend to the cheeks, lips and upper chin
- Onset is during the first decade of life and it usually resolves by puberty
- Autosomal dominant transmission

Granulosis rubra nasi is a rare inherited condition. It generally appears during childhood (peak incidence between ages 7 and 12 years), but adolescent or adult onset is possible. The etiology and pathogenesis of this disorder have not been elucidated. An autosomal dominant inheritance pattern has been described.

The condition starts with hyperhidrosis of the tip of the nose that may be present for years before the characteristic erythema develops on the nose; the latter can extend to the cheeks, chin and upper lip. The entire area of erythema displays excessive sweating. Papules, sweat droplets and vesicles may form at the orifices of the eccrine ducts. Cystic lesions can also develop and the nose may be cold. It may itch but is not painful. Primary hyperhidrosis of the palms and soles is a common concomitant finding, as is poor peripheral circulation with pernio or acrocyanosis. Granulosis rubra nasi usually resolves at puberty but may continue into adulthood.

Histopathologically, dilation of dermal blood and lymphatic vessels with perivascular lymphocytic infiltration and dilation of sweat ducts (at times simulating a hidrocystoma) are seen. The epidermis, connective tissue and pilosebaceous apparatus are otherwise normal and no heterotopic apocrine glands are found. No associated systemic disease or abnormal laboratory findings have been described.

The differential diagnosis includes rosacea, acne vulgaris, periorificial dermatitis, lupus pernio and lupus erythematosus. Treatment is disappointing and limited to drying lotions and reassurance that the disorder typically resolves spontaneously at puberty.

Keratolysis Exfoliativa

Synonyms: ■ Lamellar dyshidrosis ■ Recurrent focal palmar peeling ■ Dyshidrosis lamellosa sicca

Key features

- Superficial desquamation of the palms and occasionally the soles
- Non-inflammatory
- May be associated with primary hyperhidrosis
- Treatment is with keratolytics

Keratolysis exfoliativa is a common, asymptomatic, superficial desquamative process of palmar and (less often) plantar skin; it usually worsens in warm weather and is occasionally associated with hyperhidrosis. Keratolysis exfoliativa is seen in healthy adults and probably reflects low-grade physical or chemical damage to the thick stratum corneum of volar skin. Concurrent irritant dermatitis may also be present. Maceration from imbibition of water by the thick stratum corneum may also be a pathogenic influence, although hyperhidrosis is not a regular feature.

Clinically, it appears as an irregular annular or circinate pattern of scaling, 2 to 15 mm in diameter (Fig. 39.11). There are no antecedent or concurrent vesicles or papules, and no fungi are recoverable from the lesions. Treatment is disappointing. Humectant and keratolytic topical products containing urea, ammonium lactate or salicylic acid (5–6%) may be helpful. Topical corticosteroids are not useful unless there is associated dermatitis.

Fig. 39.11 Keratolyis exfoliativa. Small annular collarettes of scale on the palm. *Courtesy, Jean L Bolognia, MD.*

Multiple Sweat Gland Abscesses

Synonym: ■ Periporitis staphylogenes

Key features

- Rare neonatal disorder that often occurs in the setting of malnourishment or debilitation
- Miliaria lesions become infected and form abscesses
- Most common on the neck, back and buttocks
- May be associated with systemic symptoms

Multiple sweat gland abscesses represent a rare disorder of newborn infants that is likely due to a secondary staphylococcal infection of miliaria lesions. Malnourished or debilitated neonates are preferentially affected.

Clinically, erythematous papules and nodules are distributed on the neck, back, buttocks and occipital skin. They are typically round or oval erythematous swellings that measure 1 to 2 cm in diameter and do not exhibit warmth, tenderness or fluctuance. Lymphangitis and constitutional signs and symptoms such as fever and lassitude may occur with larger or more numerous lesions. Bacterial smears and cultures reveal *S. aureus*. Microscopically, abscess formation involving the sweat glands is seen.

The differential diagnosis includes furuncles or carbuncles and subcutaneous fat necrosis of the newborn. Neutrophil dysfunction, hypogammaglobulinemia and other signs of immunodeficiency have not been reported in neonates with multiple sweat gland abscesses. However, primary immunodeficiencies (e.g. chronic granulomatous disease, hyper-IgE syndrome; see Ch. 60) should be considered in affected infants with recurrent infections (cutaneous or extracutaneous). Systemic antibiotics, correction of the child's nutritional state and elimination of factors encouraging the development of miliaria should be undertaken in the management of this condition.

Neutrophilic Eccrine Hidradenitis

Synonyms: ■ Chemotherapy-associated eccrine hidradenitis ■ Drug-associated eccrine hidradenitis

Key features

- Typically occurs following administration of chemotherapy (most often cytarabine in patients with acute myelogenous leukemia)
- Both children and adults can be affected
- Painful erythematous papules and plaques are classically found on the trunk
- Usually resolves within a few days to weeks

Fig. 39.12 Neutrophilic eccrine hidradenitis. Pink annular plaque on the dorsal hand.

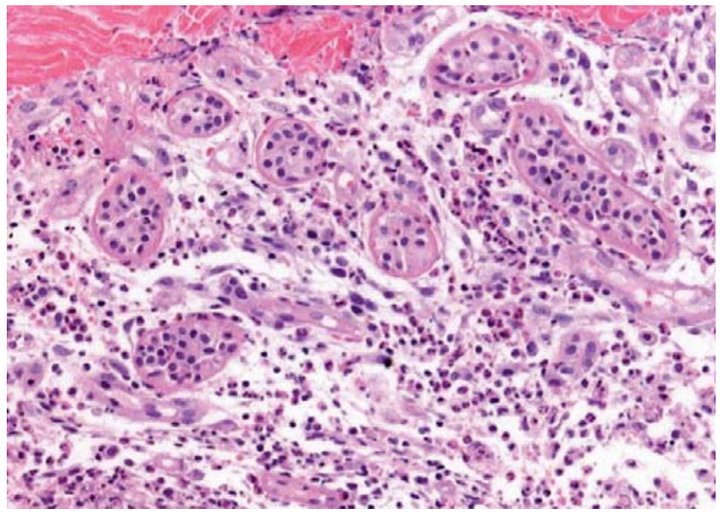

Fig. 39.13 Neutrophilic eccrine hidradenitis – histologic features. The inflammatory infiltrate is composed primarily of neutrophils which surround and are within the eccrine glands and coils. There are slight degenerative changes of primarily secretory cells. *Courtesy, Lorenzo Cerroni, MD.*

Epidemiology and pathogenesis

Neutrophilic eccrine hidradenitis (NEH) is a disorder of the eccrine sweat glands that usually develops 7–14 days after initiating chemotherapy[27]. It is most commonly associated with administration of cytarabine (often in patients with acute myelogenous leukemia); other agents that have been implicated include anthracyclines, mitoxantrone, methotrexate, cyclophosphamide, 5-fluorouracil, bleomycin, vinca alkaloids, and imatinib mesylate. Adults and children are equally affected. It has also been reported after zidovudine treatment in HIV patients and following administration of granulocyte colony-stimulating factor. In a small number of patients, NEH preceded and was believed to herald a new malignancy (usually acute myelogenous leukemia) or its relapse. It is generally regarded as a cytotoxic process directed at the sweat glands, e.g. via a direct toxic effect of chemotherapeutic drugs that are excreted in the sweat.

Clinical features

Clinically, erythematous papules and plaques occur on the trunk and may also affect the extremities (Fig. 39.12) and face. Polymorphic lesions, e.g. linear, annular, erythema multiforme-like, of varying sizes have been described, some of which were purpuric (typically in association with chemotherapy-related thrombocytopenia) or pustular. Patients are often febrile and, as a consequence of chemotherapy, neutropenic.

Pathology

Histopathologic evaluation reveals eccrine sweat glands with degenerative vacuolar changes within secretory and (to a lesser degree) ductal cells; the process usually spares the acrosyringium. A neutrophilic inflammatory infiltrate classically accompanies these changes (Fig. 39.13). However, the infiltrate may be sparse or lymphocytic in the setting of chemotherapy-induced neutropenia. Squamous metaplasia of the cuboidal epithelial cells of the eccrine ducts (eccrine squamous syringometaplasia) is occasionally observed.

Differential diagnosis

The clinical differential diagnosis includes primarily Sweet's syndrome and infection, e.g. cellulitis, bacterial or fungal emboli. An infectious form of NEH has been described; most of the patients were immunocompromised, and the pathogenic organism (e.g. *Serratia, Enterobacter, S. aureus, Nocardia*) was often identified in tissue culture but not via light microscopy plus special stains of lesional specimens.

The clinical presentations of eccrine squamous syringometaplasia vary from vesicles to large erythematous patches, which may occur in a widespread or localized (e.g. major body folds, elbows and knees) distribution. Because such eruptions can be induced by the same group of chemotherapeutic agents implicated in NEH, and eccrine squamous syringometaplasia can be observed histologically in some classic cases of NEH, it has been postulated that the two entities exist on a spectrum of chemotherapy-associated eccrine changes (see Ch. 21). Finally, idiopathic palmoplantar hidradenitis (described below) has distinct clinical features and can easily be differentiated from NEH.

Treatment

The eruption of NEH resolves several days to weeks after cessation of chemotherapy, but may recur in subsequent cycles. Because NEH usually arises in the setting of fever and neutropenia, empiric antimicrobial therapy is frequently administered until the possibility of infection is excluded. Corticosteroids seem to shorten the duration of the lesions and relieve the pain in some patients. Dapsone can be beneficial in treating NEH and preventing recurrences[34].

Idiopathic Palmoplantar Hidradenitis

Synonyms: ■ Palmoplantar eccrine hidradenitis ■ Recurrent palmoplantar hidradenitis

Key features

- Occurs primarily in otherwise healthy children
- Sudden onset of painful nodules on the palms and/or soles
- Likely due to mechanical rupture of eccrine sweat glands
- Resolves spontaneously within a few days to weeks, but may be recurrent

Idiopathic palmoplantar hidradenitis is primarily a disease of children, and it is not associated with underlying medical conditions or drug intake[35]. Onset is often preceded by vigorous physical activity. The proposed pathomechanism involves eccrine gland rupture due to mechanical and thermal trauma.

This disorder is characterized by the sudden onset of multiple, tender, erythematous nodules on the soles and (less often) the palms (Fig. 39.14). Neutrophilic infiltration of the secretory and ductal components of the coiled portion of the sweat glands is seen in biopsy specimens. This infiltrate is distinctly nodular, and neutrophilic abscesses may be observed. The differential diagnosis includes the "pseudomonas hot-foot syndrome", panniculitis (e.g. erythema nodosum), pernio and vasculitis (e.g. polyarteritis nodosa). Several authors have suggested that the entity "traumatic plantar urticaria" belongs within the spectrum of idiopathic palmoplantar hidradenitis. Spontaneous resolution

Fig. 39.14 Idiopathic palmoplantar hidradenitis. Erythematous papulonodules on the plantar surface. *Courtesy, Michael L Smith, MD.*

in a matter of days to weeks is the rule, although recurrent attacks occur in as many as half of affected children.

Grover's Disease

Sweating is one of several factors, along with chronic photodamage, that play a role in Grover's disease. See Chapter 87 for a discussion of this disorder.

APOCRINE SWEAT GLAND DISORDERS

Not all sweat gland disorders involve the eccrine glands. Apocrine sweat glands are confined to the axillae, eyelids (Moll's glands), external auditory meatus, areola and nipple of the breast, periumbilical region, and anogenital region, in particular the mons pubis, labia minora, prepuce, scrotum and circumanal area. Apocrine secretion is a slow, usually continuous process analogous to milk formation in the mammary gland. Bacterial degradation of apocrine sweat yields ammonia and short-chain fatty acids that account for apocrine bromhidrosis (see above).

Fox–Fordyce Disease

Synonym: ■ Apocrine miliaria

Key features

- Caused by plugging of the apocrine sweat glands
- Occurs primarily in women 15–35 years of age
- Skin-colored follicular papules develop in the axillary, anogenital and periareolar areas
- May be intensely pruritic

Fox–Fordyce disease is a chronic, pruritic disorder of the apocrine glands.

Epidemiology

Most commonly affecting women between the ages of 15 and 35 years, it usually remits after menopause.

Pathogenesis

The etiology of Fox–Fordyce disease is unknown, but hormonal factors are thought to play a role. Emotional and physical stimuli may also have a role in the disease course.

Fig. 39.15 Fox–Fordyce disease. Monomorphic skin-colored papules in the axillary vault. Lesions may be intensely pruritic or patients may be unaware of the condition.

Clinical features

Fox–Fordyce disease presents as dome-shaped, skin-colored, discrete perifollicular papules in the axillary (Fig. 39.15), anogenital and periareolar skin. Less common locations include the medial thighs, periumbilical area and sternal region. Loss of hair in affected areas is frequently observed. The condition is often intensely pruritic. Pregnancy and oral contraception may ameliorate the itching, while heat and emotional stress can aggravate symptoms.

Pathology

Early histologic findings of Fox–Fordyce disease include a keratin plug in the follicular infundibulum, which obstructs the entrance of the apocrine duct. This blockage leads to apocrine sweat retention and subsequent rupture of the duct at the level of the epidermis. Epidermal spongiosis and vesiculation are seen. Associated findings include a perifollicular and periadnexal inflammatory infiltrate, consisting of lymphocytes with occasional histiocytes and eosinophils.

Treatment

Treatment of Fox–Fordyce disease is difficult. Topical and intralesional corticosteroids are often a first-line therapy, although their use may be limited by the risk of cutaneous atrophy in naturally occluded sites. Topical calcineurin inhibitors may reduce pruritus and improve the appearance of skin lesions. Topical tretinoin has been shown to reduce pruritus, but has little effect on the clinical appearance of the disease and may produce irritation[36]. Twice-daily clindamycin lotion may also be useful in minimizing symptoms[37]. Some women respond to oral contraceptives[38], while other patients receive temporary relief from oral isotretinoin. Physical interventions that may be beneficial include phototherapy, electrocautery and excision of periareolar skin.

Sweating pattern in axillary hyperhidrosis. Blue–black areas represent foci of sweating, as demonstrated by the starch–iodine technique: iodine solution (e.g. 3.5% in alcohol) is applied to clean, shaved skin and allowed to dry, then starch powder (e.g. cornstarch) is brushed onto the area.

Autoantibodies Encountered in Patients with Autoimmune Connective Tissue Diseases

40

Heidi T Jacobe, Richard D Sontheimer and Stephanie Saxton-Daniels

Chapter Contents

Autoantibodies encountered in lupus erythematosus *607*
Autoantibodies encountered in idiopathic inflammatory dermatomyopathies *609*
Autoantibodies encountered in systemic sclerosis (scleroderma) and morphea (localized scleroderma) *613*
Autoantibodies encountered in other rheumatic disorders that can affect the skin *613*

Key features

- Autoantibodies can be of significant value in the diagnosis, management and prognosis of the autoimmune connective tissue diseases (AI-CTDs), but their interpretation depends on the type of autoantibody and the specific AI-CTD
- The classic ANA assay remains the entrée into the world of AI-CTD serology, and understanding its limitations is critical to clinical decision-making
- The evolution of clinical immunology laboratory technology has altered the significance of some of the original clinical–serologic correlations reported at the time of discovery of the autoantibodies. Basic understanding of key technical issues related to current laboratory methodologies is therefore important
- There has been a trend toward adopting solid-phase immunoassay techniques (e.g. ELISA) to detect many autoantibodies. For several autoantibodies, including anti-Ro/SS-A and anti-double-stranded (ds) DNA antibodies, this has resulted in some decrease in disease specificity
- Certain autoantibodies have significant disease specificity and thus can be of great diagnostic value: anti-dsDNA and anti-Smith (Sm) for systemic lupus erythematosus (SLE); anti-Mi-2 for classic dermatomyositis; anti-Jo-1 for antisynthetase syndrome; anti-topoisomerase-1 (Scl-70), anti-RNA polymerases (RNAP), and anticentromere for different clinical forms of systemic sclerosis; and cytoplasmic antineutrophil cytoplasmic antibodies (C-ANCA) for Wegener's granulomatosis. However, most autoantibodies fall into the disease-nonspecific category
- The absolute blood levels of a few autoantibodies can correlate positively with underlying autoimmune disease activity (e.g. anti-dsDNA in SLE, C-ANCA in Wegener's granulomatosis), but in most cases the titer does not correlate with disease activity

INTRODUCTION

The autoimmune connective tissue diseases (AI-CTDs) are a group of polygenic clinical disorders often having heterogeneous and overlapping clinical features; the term "rheumatic diseases" can be used synonymously for AI-CTD. It should be noted that the older designation, "collagen vascular diseases", is an obsolete term that should be avoided. Furthermore, the unqualified term "connective tissue diseases" can cause confusion with genetic disorders that involve structural abnormalities of connective tissue, e.g. Ehlers–Danlos syndrome.

A hallmark of these disorders is the production of circulating autoantibodies (aAb) that have been identified by various immunochemical techniques. When the diagnosis of an AI-CTD is being considered, the most commonly requested laboratory test is measurement of antinuclear antibodies (ANA). For the purposes of this chapter, ANA are defined as all aAb that can be detected by indirect immunofluorescence microscopy and are reactive against nuclei (or sometimes the cytoplasm) of human cells. ANA preferentially target cellular structures vital to cellular function (e.g. DNA- and RNA-binding proteins) and they are primarily of the IgG class. These aAb reflect basic inflammatory events in tissue, but rarely carry pathogenic potential (the exception being ANCA).

If used appropriately, clinical laboratory testing for ANA can be useful in the diagnosis and management of AI-CTD patients. In order to maximize the clinical utility of aAb testing in AI-CTD, familiarity with the serologic tests currently used to identify these aAb, as well as the disease associations of the various aAb, is helpful.

When approached comprehensively, serologic testing in the AI-CTDs is a broad and intimidating subject. However, our discussion will focus on the clinical significance of the various aAb associated with AI-CTDs that have expression in the skin (i.e. lupus erythematosus [LE], dermatomyositis [DM], systemic sclerosis [SSc] and ANCA-associated vasculitides). Chapters 41–45 present an in-depth discussion of these disorders. Therefore, the molecular identity of the various autoantigens and their clinical associations are summarized in table form (see Tables 40.2–40.4). For the reader who desires a more comprehensive analysis, several review articles are listed.

An effort will be made to illustrate the often complex relationships that can exist between the presence and relative amounts of these aAb, disease diagnosis, and prognosis. The basic principles of clinical utility as related to the various aAb laboratory tests (e.g. sensitivity, specificity) will be briefly addressed. The related subjects of circulating immune complexes and cryoglobulins are discussed in Chapters 4, 23 and 24.

Chapter Organization

Although the various AI-CTDs are distinct clinical entities, they can have features in common. Consequently, each AI-CTD has aAb specific to that particular disorder as well as other aAb that are shared with the other diseases. In addition, some patients can display overlapping clinical features of several different AI-CTDs and, as a result, an overlap in the pattern of aAb production (Fig. 40.1).

This chapter is organized based upon two major considerations in the use of aAb testing:

- historical and technical aspects of ANA assays
- aAb associated with AI-CTDs that have cutaneous manifestations.

HISTORICAL PERSPECTIVE

One can better appreciate the evolution of thought that has occurred in this area by considering the change in methodology used to identify and measure these aAb over the past 50 years[1]. In 1948, Hargraves, aided by the observations of John Haserik, described the LE cell phenomenon that is still thought to be specific for systemic LE (SLE), but is rarely performed. Approximately 10 years later, Friou and co-workers used the newly described indirect immunofluorescence microscopy technique to establish the classic, cell-based ANA assay.

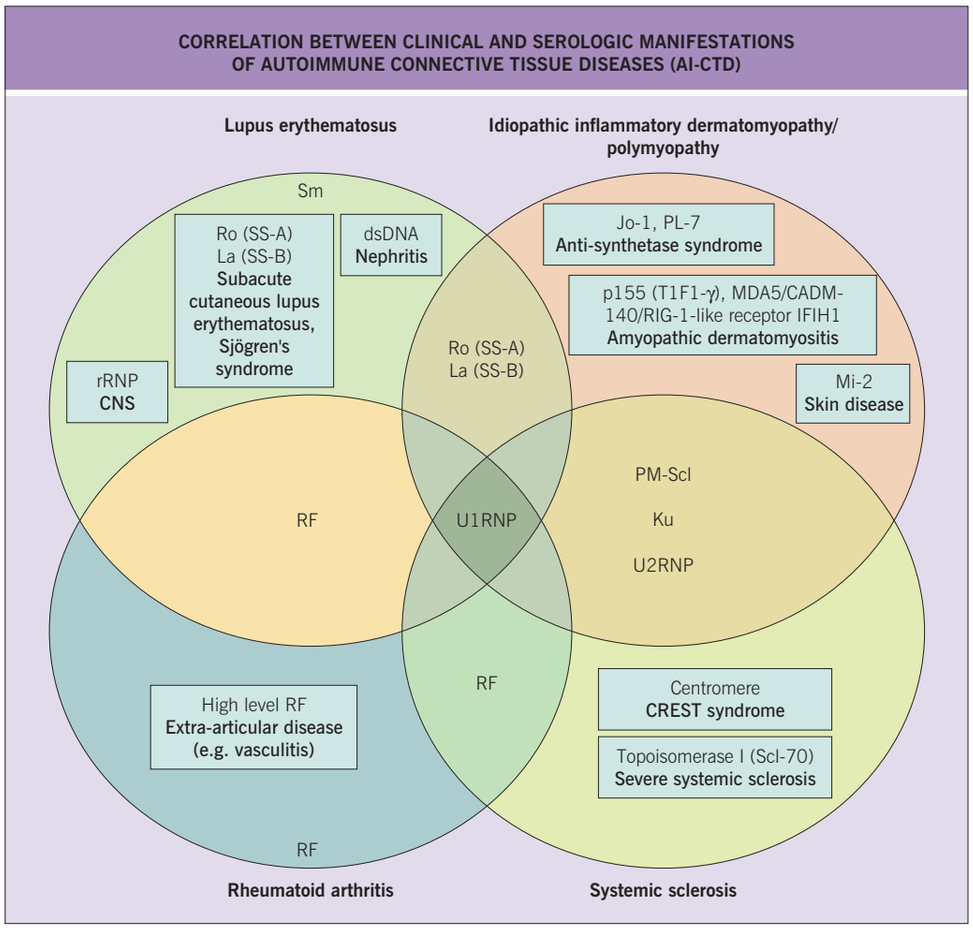

Fig. 40.1 Correlation between clinical and serologic manifestations of autoimmune connective tissue diseases (AI-CTD). Venn diagram representation of major clinico-serologic correlations in the primary AI-CTD that impact the skin. Some targets of autoantibodies are specific (boxed with clinical associations) while others are seen in the context of overlapping clinical features. High levels of U1RNP autoantibody with overlapping features of all four of these AI-CTD defines the concept of mixed connective tissue disease. With thanks to Jan Dutz, MD, for contributory comments. CADM, clinically amyopathic dermatomyositis; IFIH1, interferon induced with helicase C domain-containing protein 1; MDA5, melanoma differentiation-associated gene 5; p155, a 155 kDa polypeptide; RF, rheumatoid factor; RNP, ribonucleoprotein, TIF1-γ, transcriptional intermediary factor 1 gamma.

A decade later, Tan and co-workers (followed shortly by Clark, Reichlin and co-workers) employed the Ouchterlony double immunodiffusion technique to identify and define precipitating serum aAb that reacted with saline extractable nuclear antigens (ENA) such as nuclear ribonucleoprotein (nRNP), Sm, Ro/SS-A and La/SS-B. Unfortunately, the Ouchterlony double immunodiffusion technique is time-consuming and expensive. However, a more efficient adaptation of the double immunodiffusion technique, counterimmunoelectrophoresis, can be used as an alternative to the less expensive solid-phase immunoassays (e.g. *e*nzyme-*l*inked *i*mmuno*s*orbent *a*ssay [ELISA]; see below)[2].

In 1979, the molecularly and genetically defined ANA era began as the result of work by Lerner and Steitz, who employed immunodiffusion and Western blotting (see Chs 3 & 81) to define the molecular identities of the nRNP and Ro : La families of ribonucleoprotein autoantigens. These observations generated the notion that the various AI-CTD aAb might be more efficiently and cost-effectively assayed by using purified and/or recombinant forms of the various autoantigens in solid-phase immunoassays such as the ELISA. While less expensive and more convenient, there are a number of drawbacks to employing the ELISA and related immunoassay techniques to detect ANA such as anti-Ro/SS-A and anti-dsDNA aAb, in particular increased sensitivity and decreased specificity (see below). Newer techniques (e.g. proteasome microarrays, Luminex xMAP® technology) are currently under development and in the future they may allow the simultaneous profiling of all relevant aAb in a given patient.

Understanding the actual immunochemical techniques used to detect and quantify the various types of ANA can be helpful to the clinician, but is beyond the scope of this chapter. The reader is referred to a review by Griesmacher and Peichl[3].

THE CLASSIC ANA ASSAY

Although there is debate about its role in the diagnosis and management of AI-CTD[4,5], the classic ANA indirect immunofluorescence assay is still the most clinically efficient screening test for systemic autoimmune disorders such as SLE. A number of potential pitfalls must be considered when interpreting the results of the ANA assay (Table 40.1). The following discussion will focus on the key aspects of interpreting ANA test results. More detailed discussions are available elsewhere[1,3,6–9].

Importance of Technical Aspects of the ANA Assay

As the name implies, the ANA assay identifies antibodies present in serum that bind to autoantigens present in the nuclei (or cytoplasm) of mammalian cells. The current version of the ANA assay used in almost all clinical laboratories employs a *human* tumor cell line such as Hep-2 for the nucleated cell substrate. aAb are detected with a fluorochrome-conjugated antiserum that is specific for human immunoglobulin (the aAb) that is bound to nuclei in the cell substrate (Fig. 40.2). Earlier versions of the ANA assay utilized rodent cell lines and the latter lacked some of the autoantigens present in human cell nuclei (e.g. Ro/SS-A). Thus, sera from some SLE patients could be negative when assayed on rodent cells, especially if the predominant aAb were anti-Ro/SS-A (i.e. "ANA-negative SLE"). This occurred in up to 15% of certain SLE patient populations, particularly those enriched in anti-Ro/SS-A aAb-associated disorders such as subacute cutaneous LE (SCLE) and Sjögren's syndrome (SjS). Nowadays, because of the use of human

MAJOR ISSUES RELATED TO THE INTERPRETATION OF RESULTS OF ANTINUCLEAR ANTIBODY ASSAYS
• Methods of detecting and reporting ANA
• Subjective nature of ANA assay endpoint
• "Normal" versus "abnormal" ANA levels
• Patient age
• Drug-induced ANA
• ANA can be seen in disorders other than AI-CTDs
• Sontheimer's corollary to Greenwald's Law of Lupus

Table 40.1 Major issues related to the interpretation of results of antinuclear antibody (ANA) assays.

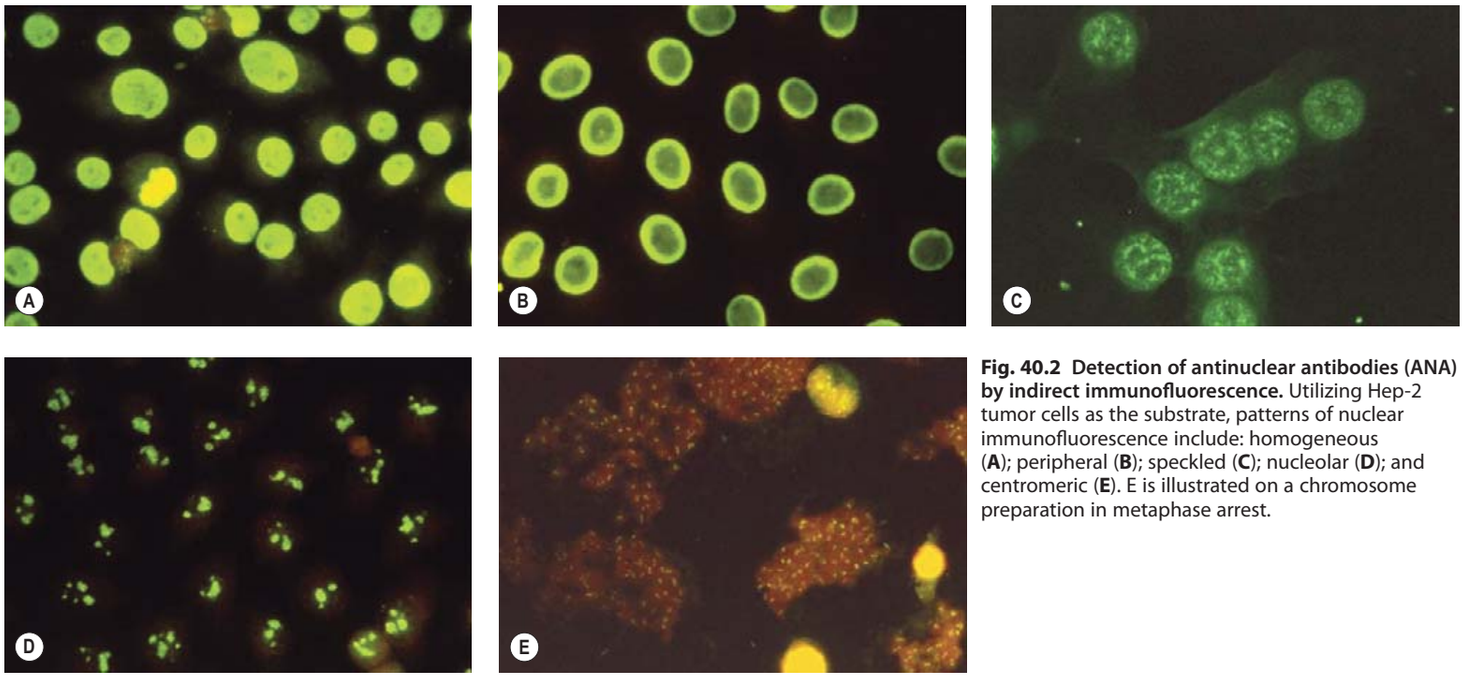

Fig. 40.2 Detection of antinuclear antibodies (ANA) by indirect immunofluorescence. Utilizing Hep-2 tumor cells as the substrate, patterns of nuclear immunofluorescence include: homogeneous (**A**); peripheral (**B**); speckled (**C**); nucleolar (**D**); and centromeric (**E**). E is illustrated on a chromosome preparation in metaphase arrest.

Hep-2 cells, only ~1–2% of SLE patients are ANA-negative. Thus, "ANA-negative SLE" is predominantly an historical phenomenon.

It is also important to remember that determination of the ANA assay *titer* (which reflects the serial serum dilutions necessary for fluorescence to disappear) depends upon subjective interpretation by a laboratory technician. Consequently, even in the same laboratory, a single serum specimen can have an ANA titer result that varies within a two-tube dilution range. In other words, a serum sample reported as having an ANA titer of 1:320 might be read as 1:160 or 1:640 upon repeat testing in the same laboratory within the same timeframe. Such variability is more often encountered when different laboratory technicians read and report ANA results. Although an attempt has been made by the World Health Organization to standardize reporting of ANA results with an international unit system (e.g. 1 IU rather than a titer of 1:160), virtually all clinical laboratories in the US continue to report ANA results using a titer system.

"Normal" Versus "Abnormal" ANA Values

The ANA titer that is considered to be abnormal can vary significantly, depending upon how the assay is performed and interpreted. The commercial ANA kits that are used most commonly in laboratories today usually indicate that an ANA titer of 1:40 or 1:80 is considered abnormal (presumably because accepting such relatively low levels of ANA as being abnormal retains a high degree of *sensitivity* of the ANA assay in detecting systemic AI-CTD). However, using such low ANA titer cut-offs creates a lot of positive, but clinically insignificant, ANA test results, i.e. it reduces specificity. A number of studies that have compared ANA results in SLE populations with those in normal control populations have indicated that a titer of <1:160, using a human tumor cell line substrate, has little clinical utility. For example, in one report based upon 15 international laboratories, the ANA positivity rate in a population of healthy individuals (ages 20–60 years) was 13.3% at 1:80, 5.0% at 1:160, and 3.3% at 1:320[10]. Of note, the elderly, relatives of those with SLE, and patients with other autoimmune disorders (e.g. autoimmune thyroid disease), as well as healthy individuals, may have abnormally elevated ANA titers.

CLINICAL SIGNIFICANCE OF ANA

Immunofluorescence Patterns

Various patterns of nuclear immunofluorescence can be observed in the ANA assay (i.e. homogeneous [syn. diffuse; Fig. 40.2A], peripheral [syn. rim; Fig. 40.2B], speckled [syn. particulate; Fig. 40.2C], nucleolar [Fig. 40.2D], and centromeric [syn. discrete speckled; Fig. 40.2E]). With one exception (see below), these patterns have little disease specificity and are of little value in the management of patients. Furthermore, most commercial laboratories report primarily homogeneous and speckled nucleoplasmic staining patterns. Because these two patterns commonly occur in healthy and older individuals, a higher threshold may need to be set for determining whether a titer is clinically relevant (e.g. ≥1:160).

The exception is the centromeric (discrete speckled) pattern (see Fig. 40.2E), which is a reflection of antibodies binding to the polypeptide components of chromosomal centromeres (e.g. CENP-B); this pattern is associated primarily with the limited form of SSc (see Table 40.4). A peripheral (rim) ANA pattern can be suggestive of the presence of aAb to DNA, including dsDNA (SLE). The nucleolar ANA pattern is due to aAb binding to ribosomal RNA processing molecules such as fibrillarin, and it can be indicative of SSc. A high-titer speckled (particulate) ANA pattern is due to a number of antibodies, including those that recognize Sm, RNP, Ro/SS-A, La/SS-B, Sc1-70 and RNA polymerases (RNAP). In general, however, specific tests for nuclear and cytoplasmic antigens, rather than ANA patterns, are used nowadays to identify specific aAb.

Concept of Clinical Utility as Applied to aAb Testing

A comprehensive discussion of the concept of clinical utility in laboratory testing (i.e. sensitivity, specificity, positive predictive value, negative predictive value) can be found elsewhere[6–9]. However, by way of summary, the key concepts of clinical utility analysis are presented in Figure 40.3. These principles should be kept in mind

CONCEPT OF CLINICAL UTILITY IN LABORATORY TESTING

	Disease present	Disease absent
Positive result	True positive (TP)	False positive (FP)
Negative result	False negative (FN)	True negative (TN)

Sensitivity=TP/(TP+FN)
Specificity=TN/(TN+FP)
Positive predictive value=TP/(TP+FP)
Negative predictive value=TN/(TN+FN)

at all times when considering the cost–benefit ratio of the various types of laboratory testing currently available for autoimmune diseases.

The ANA test is used most often for the diagnosis of SLE, and in populations of SLE patients, sensitivity is 98% and specificity 90%[7,8]. However, in *unselected populations of individuals*, the positive predictive value of ANA testing for the detection of SLE is 30–40%, while the negative predictive value is 99%. Thus, about two-thirds of positive ANAs seen in a general medical population will be associated with disorders other than SLE and only very rarely will a person with a negative ANA have SLE. It is also important to remember that a positive ANA can be found in a large percentage of patients with other AI-CTDs: SSc (90%), SjS (70%), idiopathic inflammatory dermatomyopathies (DM/PM) (40–65%). There are numerous clinical associations for a positive ANA test[11], and it is very important to realize that often clinically silent systemic autoimmune diseases, such as autoimmune thyroiditis, pernicious anemia or Addison's disease, can contribute to a positive ANA in patients who present with organ-specific autoimmune dermatologic disorders such as vitiligo and alopecia areata.

Clinical Value of aAb in Diagnosis Versus Disease Activity Monitoring

In everyday practice, these laboratory tests can be used to: establish the diagnosis of an AI-CTD; provide prognostic information; and, in specific instances, monitor the level of systemic activity of an AI-CTD[7,8]. For example, the Sm aAb is highly specific for SLE and thus has considerable diagnostic value. However, the absolute amounts of anti-Sm aAb present in the circulation of a patient at different points in time do not correlate strongly enough with SLE disease activity to have practical clinical value in patient management. Likewise, there is not much value in serial determinations of titers of the ANA assay to monitor disease activity in SLE. However, a few aAb can be used for establishing the diagnosis and monitoring systemic activity, e.g. anti-dsDNA in LE nephritis and cytoplasmic antineutrophil cytoplasmic antibodies (C-ANCA) in Wegener's granulomatosis. In the case of providing prognostic information, an example would be the presence of anti-RNAP aAb as a risk factor for the development of renal crisis in scleroderma.

"Sontheimer's Corollary" to Greenwald's Law of Lupus

Robert A Greenwald formulated a law stating that if a patient is diagnosed as having SLE, everything that happens to that patient afterwards, rightly or wrongly, is attributed to SLE. One of us (RDS) formulated a corollary to Greenwald's Law, stating that anything happening to a patient with a positive ANA that is not immediately otherwise explicable will automatically be blamed on SLE[12]. This is especially true in patients presenting with non-lupus photosensitive facial eruptions (e.g. rosacea, polymorphic light eruption, photoallergic contact dermatitis) who might also have a positive ANA test for reasons other than SLE[13].

Phototherapy and the ANA Assay

The question of ANA and anti-Ro/SS-A antibody testing often arises in patients being considered for phototherapy, especially if there is any concern about an underlying photosensitive state. However, when screening patients for a multisystem autoimmune disease such as SLE, it is a good rule to remember that patients having any degree of clinically significant SLE are virtually never asymptomatic. Symptoms such as easy fatigability, malaise and arthralgias are almost always present. In addition, studies have shown that phototherapy protocols such as PUVA do not significantly induce the appearance of ANA and other AI-CTD aAb. Therefore, while a thorough history, review of systems and physical examination are indicated in all patients prior to phototherapy, ANA testing is not, unless there is a consistent history or suggestive physical findings.

How Does One Evaluate a Positive ANA Result in a Patient Suspected of Having SLE?

This question would likely be answered differently by different specialists. Dermatologists usually see a highly selected population of LE patients by virtue of their having some form of cutaneous involvement that at times can be the only significant clinical manifestation of the autoimmune disease process (e.g. chronic or subacute cutaneous LE). Therefore, in comparison to a rheumatologist evaluating a patient with suspected SLE, a more focused approach can be undertaken by a dermatologist evaluating a positive ANA in a patient who has or is suspected of having cutaneous LE (Fig. 40.4).

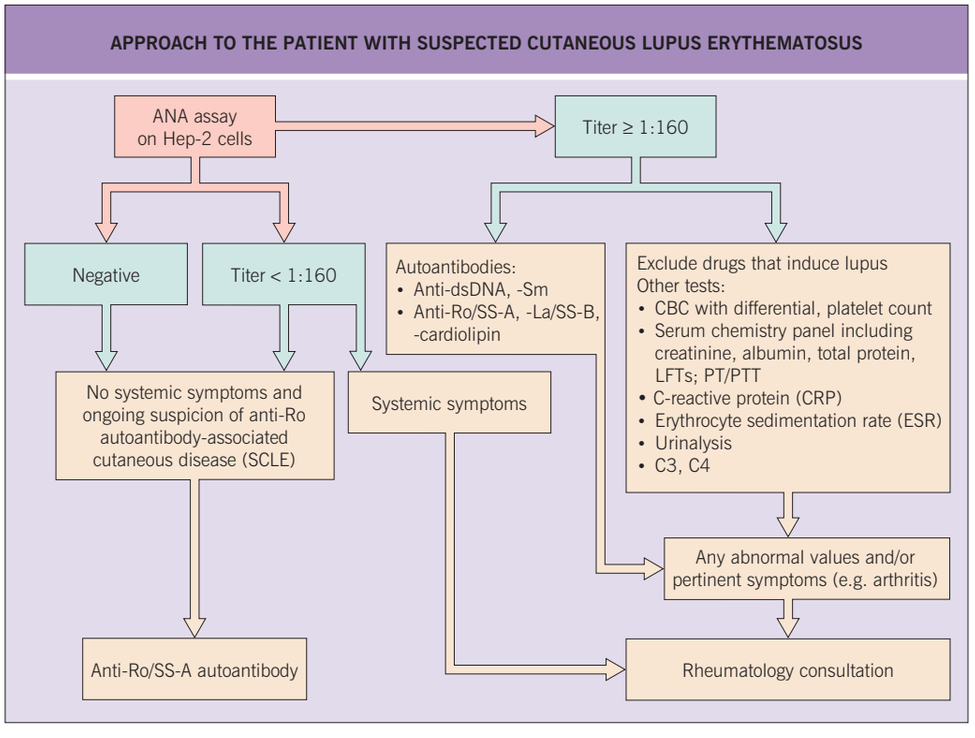

Fig. 40.4 Approach to the patient with suspected cutaneous lupus erythematosus. It should be noted that these recommendations are most relevant within the context of a dermatology practice setting. CBC, complete blood count; LFTS, liver function tests; PT, prothrombin time; PTT, partial thromboplastin time; SCLE, subacute cutaneous lupus erythematosus. With thanks to Jan Dutz, MD, for contributory comments.

AUTOANTIBODIES ENCOUNTERED IN LUPUS ERYTHEMATOSUS

A listing of aAb that can be seen in patients with LE (see Ch. 41) is presented in Table 40.2. In addition, data related to the prevalence with which they are observed, their specific clinical associations, and their molecular specificities are also provided; the latter are addressed in depth in several reviews[1,3,7,8,14,15]. The prevalences of the aAb presented in the tables in this chapter represent the estimated median values reported from different cross-sectional studies where the conventional assay techniques used in most clinical laboratories today were employed (unfortunately, the results of such studies can vary widely). In addition, the various aAb encountered in SLE are subdivided into those that are and are not specific for SLE.

aAb to Sm and dsDNA are specific and prevalent enough to represent one of the 11 ACR classification criteria for SLE (see Ch. 41). aAb to single-stranded (ss) DNA are also seen in LE but are not at all specific for this disorder. Rising levels of anti-dsDNA aAb correlate positively with SLE disease activity, especially when associated with falling complement values. High levels can reflect an increased risk for LE nephritis. Unfortunately, the clinical value of anti-dsDNA aAb measurements is somewhat diluted by the characteristics of modern assay techniques. The popular ELISA assays preferentially detect *low-avidity* anti-dsDNA aAb that are also seen in patients who do not have SLE. It is recommended that all positive anti-dsDNA aAb ELISA results be confirmed by a second assay technique that detects *high-avidity* anti-dsDNA aAb, such as the Farr radioimmunoassay or the *Crithidia luciliae* indirect immunofluorescence assay. Unfortunately, there are similar issues associated with the current assay techniques for a number of the AI-CTD aAb[3,14,16] (see below).

Anti-Ro/SS-A and anti-La/SS-B aAb were originally thought to react exclusively with cytoplasmic RNP and were thus designated as

AUTOANTIBODIES ASSOCIATED WITH LUPUS ERYTHEMATOSUS

Target	Median prevalence*	Molecular specificity	Clinical associations
		HIGH SPECIFICITY FOR SLE	
dsDNA†	60%	Double-stranded (native) DNA	LE nephritis and monitoring activity of nephritis
Sm	10–30% of Caucasians; 30–40% of Asians and African-Americans	Splicesome RNP (ribonucleoprotein particles involved in splicing pre-mRNA)	
rRNP	7–15%; 40% of Asians	Ribosomal P proteins (proteins involved in ribosome function)	Neuropsychiatric LE
		LOW SPECIFICITY FOR SLE	
ANA (most common IF patterns: homogeneous, peripheral)	99%		
ssDNA	70%	Denatured DNA	Possible risk for SLE in DLE patients; also seen in RA, DM/PM, MCTD, SSc, SjS, morphea
C1q	60%	C1q component of complement	Severe SLE, hypocomplementemic urticarial vasculitis syndrome
PCNA	50%	A component of multiprotein complexes involved in cell proliferation	–
U1RNP	50%	Splicesome RNP	Overlapping features with other AI-CTDs; MCTD (100%)
Ro/SS-A	50%	hYRNP (quality control function for misfolded RNA molecules)	SCLE (75–90%), neonatal LE/congenital heart block (99%), SCLE–SjS overlap, primary SjS (70%); associated with vasculitis
La/SS-B	20%	hYRNP	SCLE (30–40%), SCLE–SjS overlap, primary SjS (40%); occurs in conjunction with Ro/SS-A
Cardiolipin	50%	Cardiolipin, a negatively charged phospholipid	Recurrent spontaneous abortions, thrombocytopenia, and hypercoagulable state in SLE (cutaneous manifestations include livedo reticularis, leg ulcers, acral infarction/ulceration, hemorrhagic cutaneous necrosis); similar associations in primary antiphospholipid antibody syndrome; clinical manifestations have strongest association with IgG class of anticardiolipin
β2 glycoprotein I	25%	An important cofactor for cardiolipin in cardiolipin aAb assays	Relatively high risk of thrombosis in SLE and primary antiphospholipid antibody syndrome
Histones	40%	Histones	Drug-induced SLE; also RA, SLE and SSc with pulmonary fibrosis (in conjunction with other aAb)
Rheumatoid factor	25%	Fc portion of IgG	Nonspecific
Ku	10%	DNA end-binding repair protein complex	Overlap with other AI-CTDs such as DM/PM, SSc
Alpha-fodrin	10%	An actin-binding protein found at the periphery of chromaffin cells that may be involved in secretion	SjS

*Based on most common assay techniques currently employed in clinical immunology laboratories. Note that these figures represent the authors' best estimates based on most recently published data.
†Listed in decreasing order of prevalence within categories.

Table 40.2 Autoantibodies associated with lupus erythematosus. aAb, autoantibody; AI-CTDs, autoimmune connective tissue diseases; ANA, antinuclear antibodies; DLE, discoid lupus erythematosus; DM/PM, dermatomyositis/polymyositis; IF, immunofluorescence; LE, lupus erythematosus; MCTD, mixed connective tissue disease; PCNA, proliferating cell nuclear antigen; RA, rheumatoid arthritis; RNP, ribonucleoprotein; SCLE, subacute cutaneous lupus erythematosus; SjS, Sjögren's syndrome; SLE, systemic lupus erythematosus; SSc, systemic sclerosis. Adapted from ref. 1.

cytoplasmic aAb. However, subsequent work has documented that these aAb react with proteins present in human cytoplasmic RNP (hYRNP) that are found in both the cytoplasm and nucleus. The Ro and La proteins are a "linked set" of autoantigens by virtue of their being present in the same RNP particles. As a result, an autoimmune response that develops against one of these autoantigens often spreads to the other. This explains the observation that when one aAb is present in an individual, the other is frequently present as well. (Anti-Ro/SS-A aAb can occur alone; however, it is extremely rare for anti-La/SS-B aAb to occur without anti-Ro/SS-A aAb.)

As with anti-dsDNA aAb assays, it is important to understand certain technical considerations relating to anti-RNP aAb assays, such as those used to measure anti-Ro/SS-A, anti-La/SS-B, anti-U1RNP and anti-Sm aAb (i.e. ENA). A number of these aAb were originally identified by Ouchterlony double immunodiffusion, which is a less sensitive but highly specific technique for identifying such aAb. However, this assay has been replaced by solid-phase immunoassays such as ELISA (see earlier), and the ELISA is more sensitive but less specific for detecting anti-RNP aAb. As a result, some of the original clinical correlations for anti-Ro/SS-A, anti-La/SS-B, anti-Sm and anti-U1RNP aAb that related to the results of immunodiffusion analysis do not hold with regard to the results of modern ELISA.

This issue can be illustrated by the results of studies that examined the measurement of anti-Ro/SS-A and anti-La/SS-B aAb, aAb of importance to dermatologists given their association with idiopathic and drug-induced SCLE, neonatal LE, annular erythema of SjS, and SLE. Lee and colleagues[17] compared the sensitivity of Ouchterlony double immunodiffusion and ELISA assays for the detection of aAb to native forms of the human Ro/SS-A antigen in different clinical settings. In unselected populations of SLE patients, abnormal levels of anti-Ro/SS-A aAb detected by ELISA were twice as prevalent (50%) as those detected by immunodiffusion (25%). Greater than 90% of SCLE patients had anti-Ro/SS-A antibody by ELISA, whereas only 65–75% were positive by immunodiffusion. Sixty percent of DLE patients were positive for anti-Ro/SS-A aAb by ELISA, while fewer than 5% were positive by immunodiffusion. Ten percent of normal individuals had anti-Ro/SS-A antibody by ELISA, with fewer than 0.3% having such antibodies by immunodiffusion. Therefore, the ELISA technique was much more sensitive in detecting anti-Ro/SS-A aAb; however, it was considerably less specific than the Ouchterlony double immunodiffusion assay. The authors of this chapter would support the more recent suggestion that any equivocal anti-RNP aAb results obtained by ELISA should be confirmed with more specific assays such as counterimmunoelectrophoresis[2], given that up to 10% of the population has anti-Ro/SS-A antibodies by ELISA.

As another strategy for ascertaining the clinical value of aAb, some investigators have sought to determine whether specific clinical correlations exist with regard to aAb to individual molecular constituents of autoantigen-containing particles. For example, three polypeptides, 60 kDa Ro, 52 kDa Ro and calreticulin, have been associated with hYRNP. Careful attempts have been made to determine whether aAb to 60 kDa Ro and 52 kDa Ro have differential clinical correlations with respect to anti-Ro/SS-A aAb-associated skin diseases, i.e. SCLE, annular erythema of SjS, and neonatal LE/congenital heart block[18]. However, the results of such studies have been equivocal and today no consensus exists in this area.

As can be seen in Table 40.2, there are a number of nonspecific aAb that can be seen in SLE patients that have additional clinical associations. An in-depth discussion of this group of aAb is available in several recent reviews[3,14].

Drug-Induced ANA/SLE

A number of drugs are capable of triggering a positive ANA and/or a drug-induced SLE syndrome (e.g. procainamide, hydralazine, isoniazid, chlorpromazine, phenytoin, quinidine, methyldopa). An important dermatologic drug, minocycline, has also been added to this list. The predominant clinical manifestations of drug-induced SLE are musculoskeletal symptoms (arthritis, arthralgia, myalgia) and serositis (pleuritis, pericarditis). Skin involvement is seen much less commonly in the drug-induced form of SLE. In a comprehensive review of this subject, only 25% of hydralazine-induced SLE patients had "skin involvement", and fewer than 5% of procainamide-induced SLE patients experienced "skin changes". In the same analysis, 71% of idiopathic SLE patients had some type of skin change[19]. It has been the experience of one of the authors (RDS) that when LE-specific skin disease is present, it manifests as acute cutaneous LE (ACLE; see Ch. 41). Antihistone aAb represent a serologic marker of drug-induced ANA and the classic form of drug-induced SLE (present in 95%). A different set of drugs (e.g. hydrochlorothiazide, terbinafine, diltiazem, naproxen, griseofulvin) has been reported to trigger anti-Ro/SS-A aAb production and the cutaneous lesions of SCLE. Antihistone aAb do not appear to be produced in this setting.

Induction of ANA and Anti-dsDNA Antibodies by Tumor Necrosis Factor-α Inhibitors

TNF-α blockade by recombinant proteins has become an increasingly common therapeutic intervention. This form of immunomodulation is associated with the induction of aAb, especially ANA and anti-dsDNA antibodies. However, the clinical significance of these aAb is less clearly defined, as there is a relatively low incidence of clinically detectable autoimmune disease.

Etanercept, a recombinant human TNF receptor fusion protein composed of a dimer consisting of the extracellular portion of two p75 receptors fused to the Fc portion of human IgG1 (see Ch. 128), is approved for use in several disorders, including psoriasis and psoriatic arthritis. There are multiple reports of etanercept inducing ANA and anti-dsDNA antibodies. In a prospective study of 20 spondyloarthropathy patients treated with etanercept for 1 year, three patients (15%) developed newly positive ANAs and one patient (5%) developed a significantly increased titer; anti-dsDNA aAb were present in 3 of 20 patients (15%). None of these patients developed clinically apparent SLE or cutaneous LE[20]. These observations are similar to those previously reported in rheumatoid arthritis (RA) patients treated with etanercept[21,22]. Of those patients in a French national survey who were treated with etanercept for different indications (3800 patients), 4 developed anti-DNA aAb plus cutaneous lesions while 3 had systemic manifestations and fulfilled the diagnostic criteria for SLE[23].

Cutaneous findings noted in patients treated with etanercept include: a butterfly rash (ACLE), SCLE and DLE as well as small vessel vasculitis and chilblains. Additional findings were phlebitis (with anticardiolipin antibodies), leukopenia, thrombocytopenia, serositis, and general manifestations, e.g. fever, weight loss, asthenia. The signs and symptoms of SLE occurred within a mean of 4 months. Once treatment with etanercept was discontinued, serologic and clinical abnormalities abated in all the patients over several weeks (median, 8 weeks)[22,23]. A few patients did receive oral corticosteroids for the associated systemic illness[23], but none developed nephritis (the latter is rare[24]). Women were preferentially affected[22].

Compared with etanercept, *infliximab* (chimeric monoclonal anti-TNF-α antibody) induces a higher rate of aAb formation, but as with etanercept this can have unclear clinical significance. In a prospective study of 34 patients with spondyloarthropathy and 59 patients with RA treated with infliximab for 2 years, 62% and 41% of the patients, respectively, developed newly positive ANAs after 1 year. High rates of anti-dsDNA aAb were also observed (71% of spondyloarthropathy and 49% of RA patients)[20]. These figures have been corroborated in similar patient groups[25] as well as extended to patients with psoriasis treated with infliximab[26]. Of note, none of the spondyloarthropathy patients were on concomitant immunosuppressive therapy, while all of the RA patients were, perhaps accounting for the difference between the two groups. Similarly, Crohn's disease patients who were on immunosuppressive therapy at baseline developed fewer antibodies[27]. Of note, isolated IgM anti-dsDNA aAb are typically not associated with clinical findings, as opposed to the development of multiple aAb (e.g. IgG anti-dsDNA, antihistone aAb), which are commonly seen in patients with TNF-α inhibitor-induced lupus or lupus-like syndrome.[28,29]

Despite the high rate of aAb development in patients treated with infliximab, reports of SLE are relatively unusual. In the French national survey discussed previously[23], 9 patients were diagnosed as having infliximab-induced SLE. The clinical manifestations observed in the etanercept and infliximab groups were similar (see above). Signs of SLE developed after a mean of 9 months of treatment and resolved after a mean of 6 months. In clinical trials involving 2468 patients with RA who had received *adalimumab*, 12.6% developed newly positive ANA

(titer > 1:40) and 10 patients developed findings consistent with lupus[29a]. Of 29 patients with RA who received adalimumab for 24 weeks, 12 (41%) developed newly positive ANA and 1 anti-dsDNA aAb[29b].

In sum, TNF-α inhibitor-induced lupus differs from typical drug-induced lupus in several ways. Firstly, skin manifestations, including a malar rash, SCLE, DLE, photosensitivity and purpura, are prominent[30]. Secondly, ANA and anti-dsDNA aAb are more common than antihistone antibodies[22]. Although the development of aAb occurs relatively commonly, only occasionally are they of clinical significance. Therefore, in the absence of suggestive clinical signs or symptoms, we do not recommend screening for ANA prior to initiation of TNF-α inhibitors.

AUTOANTIBODIES ENCOUNTERED IN IDIOPATHIC INFLAMMATORY DERMATOMYOPATHIES

aAb that can be encountered in patients with the idiopathic inflammatory dermatomyopathies (syn. DM/polymyositis [PM], idiopathic inflammatory myopathies; see Ch. 42) are presented in Table 40.3. At this time, the clinical utility of routine laboratory testing for these antibodies is not well established. Although some are indicative of internal organ involvement and prognosis, they occur so infrequently that they are not helpful in most clinical settings. The designation for this group of diseases, "idiopathic inflammatory *dermato*-myopathies", has been coined to allow inclusion of cutaneous-only or cutaneous-predominant subsets of DM, such as clinically amyopathic DM (i.e. amyopathic DM and hypomyopathic DM)[31–34].

p155 (TIF1-γ) and MDA5/CADM-140/RIG-I-like receptor IFIH1

Patients with adult-onset, clinically amyopathic DM appear to have a somewhat higher prevalence of ANA (65%) than do patients with classic DM and PM. However, not until recently has the molecular specificity of these ANA been examined.

In a pilot study of 19 patients with adult-onset, clinically amyopathic DM, aAb to a 155 kDa polypeptide were identified in the majority of individuals (via radiolabeled immunoprecipitation and immunoblots)[35]. This same aAb was subsequently detected in 20–30% of patients with the classic form of juvenile-onset or adult-onset DM[36], and the 155 kDa polypeptide was reported to be identical to transcriptional intermediary factor 1 gamma (TIF1-γ)[37]. In adult-onset, classic DM patients, the presence of anti-TIF1-γ aAb has been associated with an increased risk of internal malignancy[38–40].

Utilizing the same immunoprecipitation/immunoblot approach, adult Japanese patients with clinically amyopathic DM and (often severe) interstitial lung disease were noted to have aAb that recognized a 140 kDa molecule[41]. This autoantigen, CADM-140, was subsequently found to be identical to two previously identified gene products, interferon induced with helicase C domain protein 1 (IFIH1) and melanoma differentiation-associated gene 5 (MDA5)[42,43]. Reportedly, it represents one of the RIG-1-like receptors that plays a role in innate immunity. In a recent retrospective series, plasma samples from 77 patients with DM were screened for anti-MDA5 aAb[43a]. The ten patients (13%) with these aAb had a rather distinct clinical phenotype with cutaneous ulcerations and/or tender palmar papules, oral pain

AUTOANTIBODIES ENCOUNTERED IN THE IDIOPATHIC INFLAMMATORY DERMATOMYOPATHIES

Target	Median prevalence*	Molecular specificity	Clinical association
HIGH SPECIFICITY FOR DM/PM			
p155	80% (clinically amyopathic); 20–30% (classic)	Transcriptional intermediary factor 1 gamma (TIF1-γ)	Clinically amyopathic DM; in adult-onset classic DM, increased risk of malignancy
Mi-2	15%	Helicase nuclear proteins	Gottron's papules/sign, shawl sign, periungual telangiectasias, cuticular overgrowth/dystrophy
Jo-1	20%	Histidyl tRNA synthetase	Antisynthetase syndrome
PL-7	5%	Threonyl tRNA synthetase	Antisynthetase syndrome
PL-12	3%	Alanyl tRNA synthetase	Antisynthetase syndrome
OJ	Rare	Isoleucyl tRNA synthetase	Antisynthetase syndrome
EJ	Rare	Glycyl tRNA synthetase	Antisynthetase syndrome, possibly increased frequency of skin changes
SRP	5%	Signal recognition particle (intracytoplasmic protein translocation)	Fulminant DM/PM, cardiac involvement
Fer	Rare	Elongation factor 1-α	–
Mas	Rare	Small RNA	–
MDA5/CADM-140	10–15%	IFN induced with helicase C domain protein 1 (IFIH1)/melanoma differentiation-associated gene 5 (MDA5)	Clinically amyopathic DM, rapidly progressive interstitial lung disease, palmar papules, painful ulcers with associated vasculopathy, gum pain
LOW SPECIFICITY FOR DM/PM			
ANA (most common IF patterns: speckled, nucleolar)	40%		Clinically amyopathic DM (65%)
ssDNA	40%	Single-stranded DNA	SLE, SSc, morphea
PM-Scl (PM-1)	10%	Ribosomal RNA processing enzyme	Overlap with SSc
Ro/SS-A (especially 52 kDa Ro)	15%	hYRNP	Overlap with SjS, SCLE, neonatal LE/CHB, SLE
U1RNP	10%	Splicesome RNP	Overlap with other AI-CTDs
Ku	3%	DNA end-binding repair protein complex	Overlap with SSc
U2RNP	1%	Splicesome RNP	Overlap with SSc

*Using current assay techniques.

Table 40.3 Autoantibodies encountered in the idiopathic inflammatory dermatomyopathies (DM/PM). ANA, antinuclear antibodies; CHB, congenital heart block; DM/PM, dermatomyositis/polymyositis; IF, immunofluorescence; IFN, interferon; LE, lupus erythematosus; RNP, ribonucleoprotein; SCLE, subacute cutaneous lupus erythematosus; SjS, Sjögren's syndrome; SLE, systemic lupus erythematosus; SSc, systemic sclerosis. Adapted from ref. 1.

AUTOANTIBODIES ASSOCIATED WITH SSc AND MORPHEA (LOCALIZED SCLERODERMA)				
Target	**SSc, all**	**SSc with diffuse cutaneous scleroderma**	**SSc with limited cutaneous scleroderma (also referred to as CREST syndrome)**	**Morphea (localized scleroderma)**
ANA (most common IF patterns: speckled, nucleolar, centromere)	95%*			40%
Centromere (CENP-B)		30%	80% (pulmonary hypertension)	
Scl-70 (DNA topoisomerase I, which unwinds DNA)		60% (pulmonary fibrosis)	15%	
Fibrillin-1 (major component of microfibrils in the extracellular matrix)		5%	10%	30%
Histones	40%			35%†
Rheumatoid factor	25%			25%
ssDNA	10–30%			50% (may correlate with disease severity or activity; most prevalent in linear morphea)
Fibrillarin (U3RNP)	5%	Internal organ involvement		
PM-Scl	5%	Polymyositis, SSc overlap		
RNA polymerases	5–20%	45% (aAb levels correlate positively with extent of skin involvement & renal disease)	6%	
Th/To RNP (mitochondrial enzyme) (associated with limited pulmonary fibrosis)		11%	19%	5%
Calpastatin‡	25%			
HMG (a non-histone nucleosomal protein)		30%	40%	
MMP 1 and 3 (degrade ECM proteins; aAb prevents degradation)	52%	71%	33%	
PDGFR (expressed on fibroblasts)§	16–100%§			

*Median prevalence using current assay techniques.
†Higher in patients with linear scleroderma and generalized morphea.
‡Endogenous inhibitor of the calcium-dependent protease, calpain.
§Results vary, depending upon study; evidence that aAb does not activate the receptor; up to 18% of controls may have this aAb.

Table 40.4 Autoantibodies associated with systemic sclerosis (SSc) and morphea (localized scleroderma). A more in-depth discussion of these aAb and autoantigens can be found elsewhere[16,44–48]. The shaded areas represent the hallmark aAb of SSc. Patients with SSc can also develop additional aAb including: anti-endothelial cell aAb which may induce apoptosis of endothelial cells, but are non-specific; anti-NAG-2 aAb which are expressed on vascular endothelial cells and fibroblasts and may also induce endothelial cell apoptosis; and anti-topoisomerase II aAb which are more commonly seen in patients with morphea. ANA, antinuclear antibodies; ECM, extracellular matrix; HMG, high mobility group; IF, immunofluorescence; NAG-2, tetraspan novel antigen-2; PDGFR, platelet-derived growth factor receptor; RNP, ribonucleoprotein. Adapted from ref. 1.

and ulceration, hand swelling, arthritis/arthralgia and diffuse hair loss. Recognition of this subset of patients is clinically important because of the association of anti-MDA5 aAb with rapidly progressive interstitial lung disease.

An enzyme-linked solid-phase immunoassay for detection of CADM-140/IFIH1/MDA aAb5 has recently been developed which will be easier for commercial laboratories to perform[42]. Hopefully, a similar solid-phase immunoassay will be developed for the p155 (TIF1-γ) autoantigen. Then it will be possible to perform larger prospective studies in more ethnically diverse patient populations in order to document disease specificities and the true clinical utility of these two aAb for both classic DM and clinically amyopathic DM.

Jo-1 and Mi-2

Anti-Jo-1 and anti-Mi-2 are better-established, myositis-specific aAb; however, their prevalence is so relatively low that they often have limited utility in a routine clinical setting. Anti-Jo-1 is one of several myositis-specific aAb that are directed against the various individual aminoacyl transfer RNA synthetases that deliver amino acids to the ribosome during protein translation (see Table 40.3). The presence of one or more of these "antisynthetase" aAb correlates positively with a subset of mostly PM and some DM patients who have an increased risk of arthritis, Raynaud's phenomenon, and interstitial lung disease (this clinico-serologic constellation has been referred to as the "antisynthetase syndrome"). The mechanic's hand skin lesion was originally described to occur in this setting. However, it has subsequently been observed in other DM subsets, including clinically amyopathic DM.

Anti-Mi-2 aAb are seen in highest frequency in patients having the hallmark skin lesions of DM (Gottron's papules, Gottron's sign, shawl sign). aAb to the signal recognition particle (SRP) are seen even less commonly than anti-Jo-1 and anti-Mi-2. However, when present, they do signal a risk for fulminant DM/PM with cardiac involvement and a high rate of mortality.

Table 40.3 also lists a number of other aAb that can be seen in DM/PM; however, they are not at all specific for this disease group. Thus, it is not surprising that some of the aAb also appear in Tables 40.2 and 40.4. There are case reports of TNF-α inhibitor-induced dermatomyositis, but some of the patients had anti-Jo-1 aAb prior to therapy, raising the possibility that they were already at risk for the disease.

AUTOANTIBODIES ASSOCIATED WITH OTHER RHEUMATIC DISEASES HAVING CUTANEOUS MANIFESTATIONS			
Autoantibody	**Median prevalence***	**Molecular specificity**	**Clinical associations**
RHEUMATOID ARTHRITIS			
Rheumatoid factor	80%	Fc portion of IgG	Low levels: very nonspecific (healthy elderly individuals, SLE, SSc, MCTD, neoplasia, chronic infections, chronic inflammatory lung diseases, chronic liver disease, sarcoidosis, systemic vasculitides). High levels: associated with erosive, crippling RA (25–90%) and extra-articular manifestations of RA, e.g. systemic vasculitis (i.e. peripheral neuropathy, cutaneous vasculitis); mixed cryoglobulinemia secondary to hepatitis C infection (types II, III; 40–100%); SjS
Anti-cyclic citrullinated protein (CCP) antibodies	70%	Citrullinated proteins in the skin (e.g. filaggrin) and joints	Increased severity of RA, including radiologic progression of erosive arthritic changes; predictor for the development of RA
SJÖGREN'S SYNDROME			
Alpha-fodrin	70%	An actin-binding protein found at the periphery of chromaffin cells that may be involved in secretion	More specific for SjS than anti-Ro aAb; also seen in SLE
Ro/SS-A	60%	hYRNP	SLE, SCLE, neonatal LE/CHB
La/SS-B	20%	hYRNP	SLE, SCLE, neonatal LE/CHB
MIXED CONNECTIVE TISSUE DISEASE (SHARP'S SYDROME)			
U1RNP†	100%‡	Splicesome RNP	Raynaud's phenomenon, swollen hands with sausage-like swelling of digits, polyarthritis, myositis, inverse association with nephritis

*Using current assay techniques.
†In MCTD, associated with high-titer ANA and lack of other aAb.
‡By definition at time of diagnosis.

Table 40.5 Autoantibodies associated with other rheumatic diseases having cutaneous manifestations. More in-depth information concerning clinico-serologic associations can be found elsewhere[3,7,8,16]. aAb, autoantibodies; CHB, congenital heart block; LE, lupus erythematosus; MCTD, mixed connective tissue disease; RA, rheumatoid arthritis; RNP, ribonucleoprotein; SCLE, subacute cutaneous lupus erythematosus; SjS, Sjögren's syndrome; SLE, systemic lupus erythematosus; SSc, systemic sclerosis.

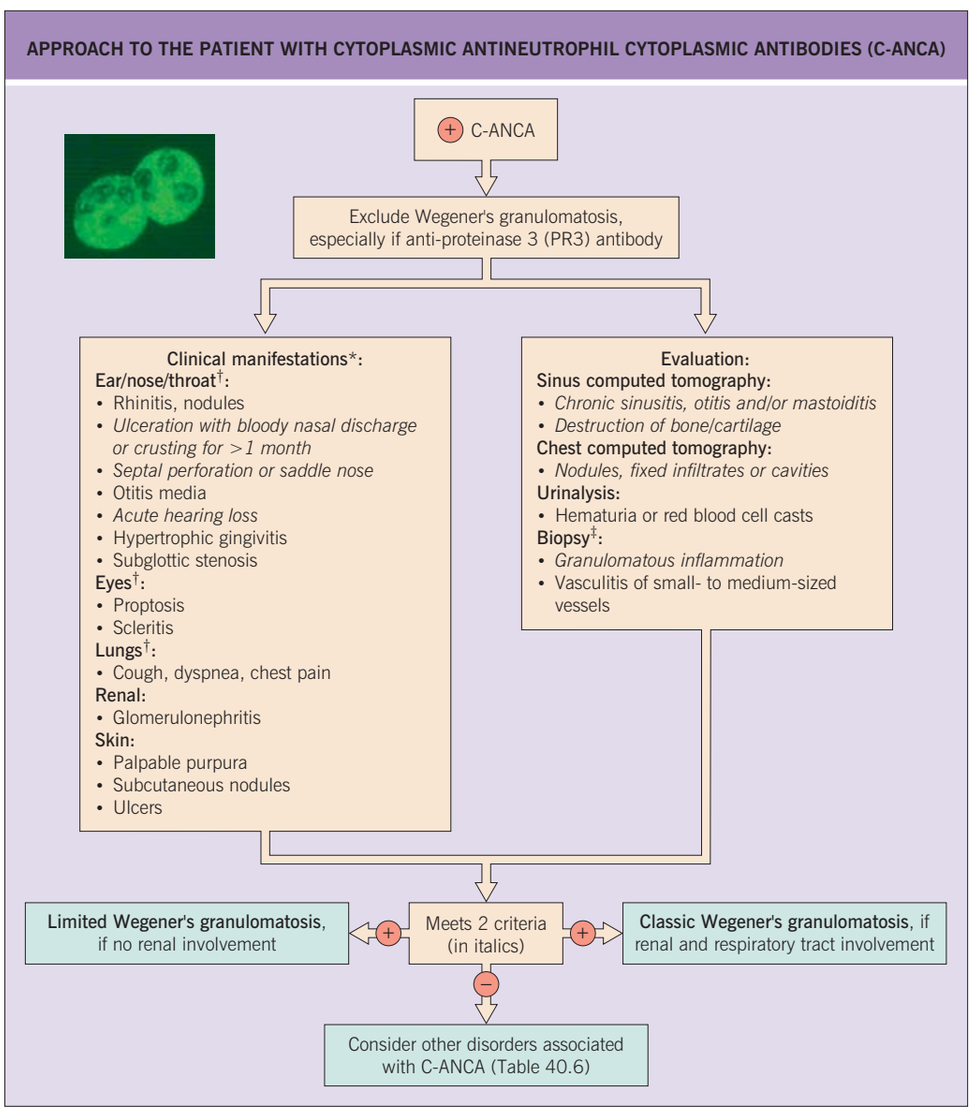

Fig. 40.5 Approach to the patient with cytoplasmic antineutrophil cytoplasmic antibodies (C-ANCA). *Some patients also have gastrointestinal, cardiac and/or neurologic involvement. †Granulomatous inflammation. ‡Of skin, mucosa, respiratory tract (upper/lower) or kidney. *Courtesy, Julie V Schaffer, MD. Fig. 40.6 Approach to the patient with perinuclear antineutrophil cytoplasmic antibodies (P-ANCA). Use of leukotriene inhibitors (see Ch. 130) has been associated with the onset of Churg–Strauss syndrome. Whether this represents unmasking of previously undiagnosed CSS is a subject of ongoing debate. *Courtesy, Julie V Schaffer, MD. Photomicrograph from Wiik AS, Fritzler MJ. Laboratory tests in rheumatic disorders. In: Hochberg MC, Silman AJ, Smolen JS, et al. (eds). Rheumatology, 4th edn. London: Mosby Elsevier; 2008.*

AUTOANTIBODIES ENCOUNTERED IN SYSTEMIC SCLEROSIS (SCLERODERMA) AND MORPHEA (LOCALIZED SCLERODERMA)

aAb associated with SSc and morphea (see Chs 43 & 44) are presented in Table 40.4[44–47]. The major scleroderma aAb are those that react with: (1) a centromere protein (CENP-B); (2) a DNA-unwinding enzyme, topoisomerase I (originally named Scl-70); and (3) RNA polymerases (RNAP). Anticentromere aAb correlate most strongly with the limited cutaneous form of SSc (CREST syndrome) while aAb against DNA topoisomerase I and RNAP are seen more commonly in diffuse cutaneous scleroderma; anti-RNAP aAb are also associated with an increased risk of developing scleroderma-associated renal crisis[48]. However, as the data in the table indicate, there can be overlap, e.g. ~30% of diffuse cutaneous scleroderma patients have anti-CENP-B aAb. The latter can also be seen in other clinical disorders such as primary biliary cirrhosis. As with other AI-CTDs, some of the other aAb that can be encountered in scleroderma patients have very little specificity for this group of disorders (i.e. antihistone, anti-ssDNA, anti-PM/Scl).

While there is little clinical overlap between SSc and morphea, some degree of serologic overlap has been described (e.g. anti-fibrillin-1 aAb). aAb to fibrillin-1 (as distinguished from fibrillarin [U3RNP]), histones and ssDNA occur in 30–50% of patients with morphea. As with classic ANA, these antibodies have been observed more often in patients who have the more widespread forms of morphea, such as linear scleroderma and generalized morphea. To date, a morphea-specific aAb has not been identified nor has an aAb that clearly reflects disease activity or prognosis.

AUTOANTIBODIES ENCOUNTERED IN OTHER RHEUMATIC DISORDERS THAT CAN AFFECT THE SKIN

aAb that can be seen in patients with some of the other rheumatic disorders that can have cutaneous manifestations[49,50] are presented in Table 40.5 (see Ch. 45).

Antineutrophil cytoplasmic antibodies (ANCA) are a subgroup of neutrophil-specific aAb. A clinical approach to a patient with either cytoplasmic ANCA (C-ANCA) or perinuclear ANCA (P-ANCA), which are characteristic of systemic vasculitides, is outlined in Figures 40.5 and 40.6. Other disorders associated with ANCA are summarized in Table 40.6. See Chapter 24 for additional clinical details.

OTHER DISORDERS ASSOCIATED WITH ANTINEUTROPHIL CYTOPLASMIC ANTIBODIES (ANCA)

	Type of ANCA*	Major antigen(s)†	Evaluation
INFLAMMATORY BOWEL DISEASE			
Ulcerative colitis (50–70%) > Crohn's disease (20–40%)	P > C	Catalase, BPI, α-enolase, LF, CG, HMG1/2 > MPO, PR3	Colonoscopy
AUTOIMMUNE LIVER DISEASE			
Autoimmune hepatitis (type 1; 80%), primary sclerosing cholangitis (70%) > primary biliary cirrhosis (30%)	P > C	Actin, HMG1/2	LFTs; ANA; anti-smooth muscle Ab; antimitochondrial Ab
AUTOIMMUNE CONNECTIVE TISSUE DISEASE			
Systemic lupus erythematosus, rheumatoid arthritis, systemic sclerosis (20–30%) > Sjögren's syndrome, dermatomyositis, reactive arthritis, relapsing polychondritis, antiphospholipid syndrome	P > C	MPO, PR3, BPI, CG, LF, lysozyme, HMGI/2	ANA panel; RF; anticardiolipin Ab
DRUG-INDUCED VASCULITIS/LUPUS/HEPATITIS			
Propylthiouracil (20%), minocycline > levamisole, sulfasalazine Hydralazine, penicillamine > allopurinol‡ TNF-α inhibitors High-dose intravenous immunoglobulin	P > C P P, C C	MPO > PR3, elastase MPO, elastase MPO, PR3 –	Skin biopsy; ANA panel; LFTs; discontinue drug
OTHER CUTANEOUS AND/OR SYSTEMIC VASCULITIDES§			
Mixed cryoglobulinemia, Behçet's disease, paraneoplastic Henoch–Schönlein purpura, Buerger's disease	P > C P	Variable Variable	Skin biopsy; cryoglobulins; hepatitis B, C panels; exclude malignancy
OTHER GLOMERULONEPHRITIDES			
Anti-GBM Ab-associated (30%) > immune complex (15%) > poststreptococcal	P	MPO	UA; BUN/creatinine; ASO; renal biopsy
INFECTIONS			
Respiratory tract infections (bacterial/mycobacterial/ fungal), enteritis, periodontitis, HIV, parvovirus B19, malaria, leprosy	P, C	MPO, others	Cultures; serologies; echocardiogram
Onchocerciasis	P	Defensin	
Hepatitis C virus infection	P, C	CG, BPI, MPO	Serologies
Subacute bacterial endocarditis, chromomycosis, invasive amebiasis	C	PR3	
CYSTIC FIBROSIS (80%)	C > P	BPI	Sweat test
HYPERGAMMAGLOBULINEMIA	P, C	–	Serum protein electrophoresis

*C-ANCA are often atypical; in addition, immunofluorescence testing in some laboratories may not distinguish C-ANCA (atypical) from atypical ANCA.
†P-ANCA often have antigen specificity other than MPO, e.g. LF, elastase, CG, lysozyme, BPI, HMG1/2, α-enolase, catalase, actin, defensin; C-ANCA (atypical) have antigen specificity other than proteinase 3, e.g. BPI, lysozyme or multiple antigens.
‡Other drugs associated with P-ANCA in scattered case reports include cimetidine, cefotaxime, phenytoin, isotretinoin, clozapine and thioridazine.
§Although primarily associated with C-ANCA, 5–15% of patients with Wegener's granulomatosis have P-ANCA; likewise, although primarily associated with P-ANCA, 5–10% of patients with Churg–Strauss syndrome and ~40% of those with microscopic polyangiitis have C-ANCA; ANCA have also been reported in leukocytoclastic vasculitis of unknown etiology and unclassified vasculitis.

Table 40.6 Other disorders associated with antineutrophil cytoplasmic antibodies (ANCA). Ab, antibodies; ANA, antinuclear antibodies; ASO, antistreptolysin O; BPI, bactericidal/permeability-increasing protein; C, cytoplasmic [C-ANCA or C-ANCA (atypical)]; CG, cathepsin G; GBM, glomerular basement membrane; HMG1/2, high mobility group non-histone chromosomal proteins; LF, lactoferrin; LFTs, liver function tests; MPO, myeloperoxidase; P, perinuclear (P-ANCA); RF, rheumatoid factor; UA, urinalysis. *Courtesy, Julie V Schaffer, MD.*

Lupus Erythematosus 41

Lela A Lee and Victoria P Werth

Synonyms/variants: ■ Discoid lupus erythematosus: a subset of chronic cutaneous lupus erythematosus ■ Lupus profundus: a variant of lupus panniculitis ■ Lupus erythematosus tumidus: tumid lupus

Key features

- There are several variants of cutaneous lupus, defined in part by the location and depth of the inflammatory infiltrate
- Acute cutaneous lupus involves primarily the epidermis and upper dermis and is usually associated with systemic disease
- Subacute cutaneous lupus involves primarily the epidermis and upper dermis and is associated with anti-Ro/SSA autoantibodies and photosensitivity; the majority of patients do not have significant systemic disease
- Discoid lesions of lupus involve the epidermis, upper and lower dermis, and adnexal structures, and they can scar; the majority of patients do not have significant systemic disease
- Lupus erythematosus tumidus involves the dermis but there is no prominent epidermal or adnexal involvement
- Lupus panniculitis involves the subcutaneous tissue and may result in disfiguring depressed scars

INTRODUCTION

Lupus erythematosus is a multisystem disorder that prominently affects the skin. Cutaneous lesions are a source of disability and, on many occasions, an indicator of internal disease.

HISTORY

The term "lupus erythemateaux" was first used by Cazenave in the mid-1800s[1]. Cazenave and others helped to articulate the difference between lupus erythematosus (LE) and lupus vulgaris, a clinical variant of cutaneous tuberculosis. Due in part to observations of Hutchinson, Osler and Jadassohn, it was recognized that cutaneous lesions of LE may be associated with significant internal abnormalities, including arthritis, nephritis, serositis, cytopenias and neurologic disease. In 1964 and during the following years, Dubois developed the concept of lupus as a spectrum of disease, ranging from isolated cutaneous lesions to life-threatening, multiorgan disease. Gilliam also developed the concept of a spectrum of disease, and, in 1979, he, Sontheimer and Thomas described a subset of cutaneous disease, which they termed "subacute" cutaneous lupus[2]. The description was virtually identical to that of "ANA-negative" lupus (see Ch. 40), reported by Maddison, Provost and Reichlin in 1981[3].

Important diagnostic advances included discovery of the LE cell phenomenon by Hargraves, Richmond and Morton in 1948[4]; the ANA by Friou in 1957[5]; the lupus band by Burnham, Neblett and Fine in 1963[6]; and the association of specific clinical manifestations of lupus with specific autoantibodies by a variety of investigators[7–9]. With regard to skin disease, the associations of anti-Ro (also known as anti-SSA) autoantibodies with neonatal lupus by Weston et al. in 1981[10] and with subacute cutaneous lupus (SCLE) by Sontheimer et al. in 1982[11] are noteworthy milestones.

Antimalarial therapy in the form of quinine was used for cutaneous lupus by Payne in 1894[12]. By the late 1950s, synthetic antimalarials had become a mainstay of therapy. Systemic corticosteroids and other immunosuppressive agents also came into use during the mid twentieth century.

EPIDEMIOLOGY

Systemic lupus erythematosus (SLE) is a common disease with significant morbidity and mortality. The strongest factor affecting risk for lupus is gender: women with systemic lupus outnumber men by at least 6 to 1[13]. Since lupus occurs most commonly in women during their childbearing years, it is likely that hormonal factors influence susceptibility to lupus. Consistent with the importance of sex steroids in the expression of disease, lupus is rare in prepubertal children. With regard to patients who have only cutaneous lesions, there appears to be a somewhat lower female-to-male ratio (perhaps 3:1) but there is still a female predominance.

Ethnicity is also a major risk factor, and its effect in some populations is almost as strong as that of gender. For example, the prevalence of SLE is fourfold higher in African-American women as compared to Caucasian American women (4 in 1000 vs 1 in 1000)[13]. In addition, African-Americans tend to develop disease at an earlier age and have a higher mortality rate. A long-term study of a multi-ethnic cohort of 587 SLE patients from Texas, Alabama and Puerto Rico found that African-Americans and Hispanics from Texas had more severe disease than Caucasian Americans or Hispanics from Puerto Rico, suggesting that both genetic and non-genetic factors play a role[14].

It is difficult to compare data from different countries, and this is sometimes even a problem with data from within the same country, due in part to differences in case identification and validation (reviewed in ref. 15). It is likely that Caucasian populations in Europe have a similar prevalence of lupus as do Caucasians living in the US. It also appears that the prevalence of lupus among both Asians and Latin Americans is similar to that of Caucasian Americans. A retrospective study from a single county in Minnesota indicated that the incidence of cutaneous LE, excluding patients who also had SLE, was similar to the incidence of SLE[15].

PATHOGENESIS

The pathogenesis of cutaneous LE is complex, and it involves an interaction between genetic and environmental factors. The latter include ultraviolet radiation (UVR), medications, and possibly viruses. This interplay triggers a complex inflammatory cascade of cytokine, chemokine and inflammatory cell responses that include cells residing within as well as recruited to the skin. Overall, the lichenoid tissue reaction, defined as epidermal basal cell damage and a band-like lymphocytic infiltrate in the upper dermis, characterizes most subsets of cutaneous LE. It involves activation of keratinocytes, endothelial cells and skin dendritic cells plus the production of type I interferons (IFNs), followed by the recruitment and activation of $CD4^+$ and $CD8^+$ cytotoxic T cells. The end result is cytotoxic keratinocyte damage.

Genes that can affect overall immunoreactivity include those whose protein products are involved in B- and T-cell function, innate immunity, immune complex clearance, apoptosis, ubiquitination, DNA methylation or cellular adhesion[16]. Examples from all these gene classes, in addition to genes with unknown function, have been implicated in some way in human or animal models of SLE (Table 41.1; see Ch. 4).

Both genetic background based upon ancestry and mutations in specific genes contribute to the clinical heterogeneity in cutaneous LE. For

example, the incidences of photosensitivity and discoid LE (DLE) differ in those of northern versus southern European ancestry[17], and SCLE is associated with the HLA-B8-DR3 extended haplotype (including *TNF2*), as well as C2 and C4 deficiencies[18]. Genes previously associated with SLE, e.g. *TYK2*, *IRF5* and *CTLA4*, also confer an increased risk for developing DLE and SCLE[19], while mutations in *TREX1*, which encodes a DNA exonuclease, are associated with familial chilblain lupus[20]. In the latter patients, dysfunction of the exonuclease leads to an accumulation of IFN-stimulatory nucleic acids.

Autoantibodies clearly play a role in SCLE and neonatal lupus, where anti-Ro (more specifically, anti-Ro60 and anti-Ro52) and anti-La autoantibodies are frequently observed (see Ch. 40); in the case of neonatal lupus, these antibodies are transmitted transplacentally. Blocking the function of either Ro60 or Ro52 presumably predisposes one to these diseases. Of note, Ro60 plays an important role in cell survival following UVR, possibly via binding to misfolded non-coding RNAs and targeting them for degradation, and mice which lack Ro60 develop a lupus-like syndrome[21]. Ro52 has a known regulatory role in inflammation, targeting both interferon regulatory factor 3 (IRF3) and IRF8 for degradation[22]; thus, antibodies to Ro52 may be proinflammatory. Alternatively, or in addition, these autoantibodies could lead to disease via activation of proteins and cells of the immune system, following immune complex formation.

Both ultraviolet B (UVB) and ultraviolet A radiation have been implicated in exacerbation of cutaneous LE, although UVB is a more efficient cause of photo-induced changes in the skin[23]. UVR induces apoptosis, which leads to translocation of cellular and nuclear antigens[24], and there may also be a reduction in the clearance of apoptotic cells[25]. In addition, UVR increases keratinocyte production of Ro52[26].

A number of proinflammatory cytokines, including tumor necrosis factor (TNF)-α, interleukin (IL)-1, HMGB1 (high-mobility group box 1), and IL-18[27–29], are induced by UVR. Following UV irradiation of keratinocytes, a complex array of chemokines, including chemokine (C-C motif) ligand 5 (CCL5), CCL20, CCL22, and chemokine (C-X-C motif) ligand 8 (CXCL8), is produced. Of note, there is an increase in these chemokines within lesions of cutaneous LE, likely leading to leukocyte recruitment to the skin[30]. These effects require adhesion molecules, with activation of endothelial cells (increased expression of ICAM-1, VCAM-1 and E-selectin) and induction of ICAM-1 on basal keratinocytes (Fig. 41.1A)[31,32].

GENES ASSOCIATED WITH SYSTEMIC LUPUS ERYTHEMATOSUS	
B- and T-cell function	***HLA-DR*** – major histocompatibility complex, class II
	BLK – B lymphoid tyrosine kinase
	BANK1 – B-cell scaffold protein (with ankyrin repeats) 1
	CTLA4 – cytotoxic T lymphocyte antigen 4
	FCGR2B – Fc fragment of IgG, low affinity IIb, receptor (CD32)
	LYN v-yes-1 – Yamaguchi sarcoma viral related oncogene homolog
	PTPN22 – protein tyrosine phosphatase, non-receptor type 22 (lymphoid)
	STAT4 – signal transducer and activator of transcription 4
	PDCD1 – programmed cell death 1
	IRAK1 – interleukin-1 receptor-associated kinase 1
	TNFSF4 – tumor necrosis factor (ligand) superfamily, member 4
	IL21 – interleukin 21
Innate immunity	***IRF5*** – interferon regulatory factor 5
	TNFAIP3 – tumor necrosis factor, alpha-induced protein 3
	SPP1 – secreted phosphoprotein 1 (osteopontin)
	TREX1 – three prime repair exonuclease 1 (see text)
	TYK2 – tyrosine kinase 2
	IRAK1 – see above
	STAT4 – see above
Immune complex clearance	*FCGR3A* – Fc fragment of IgG, low affinity IIIa, receptor (CD16a)
	FCGR3B – Fc fragment of IgG, low affinity IIIb, receptor (CD16b)
	CRP – C-reactive protein, pentraxin-related
	ITGAM – integrin, alpha M (complement component 3 receptor 3 subunit; CD11b)
	C4A – complement component 4A
	C4B – complement component 4B
	C2 – complement component 2
	C1Q – complement component 1, q subcomponent
Apoptosis	*ATG5* – autophagy related 5 homolog
	STAT4 – see above
Ubiquitination	*UBE2L3* – ubiquitin-conjugating enzyme E2L 3
	TNFAIP3 – tumor necrosis factor, alpha-induced protein 3
DNA methylation	*MECP2* – methyl CpG binding protein 2 (Rett syndrome)
Cellular adhesion	*ITGAM* – see above
Other/unknown	*PXK* – PX domain containing serine/threonine kinase
	ICA1 – islet cell autoantigen 1

Table 41.1 Genes associated with systemic lupus erythematosus. For detailed information on the function of these protein products, see www.genecards.org. The most strongly associated genes are in bold. *Adapted from ref. 16.*

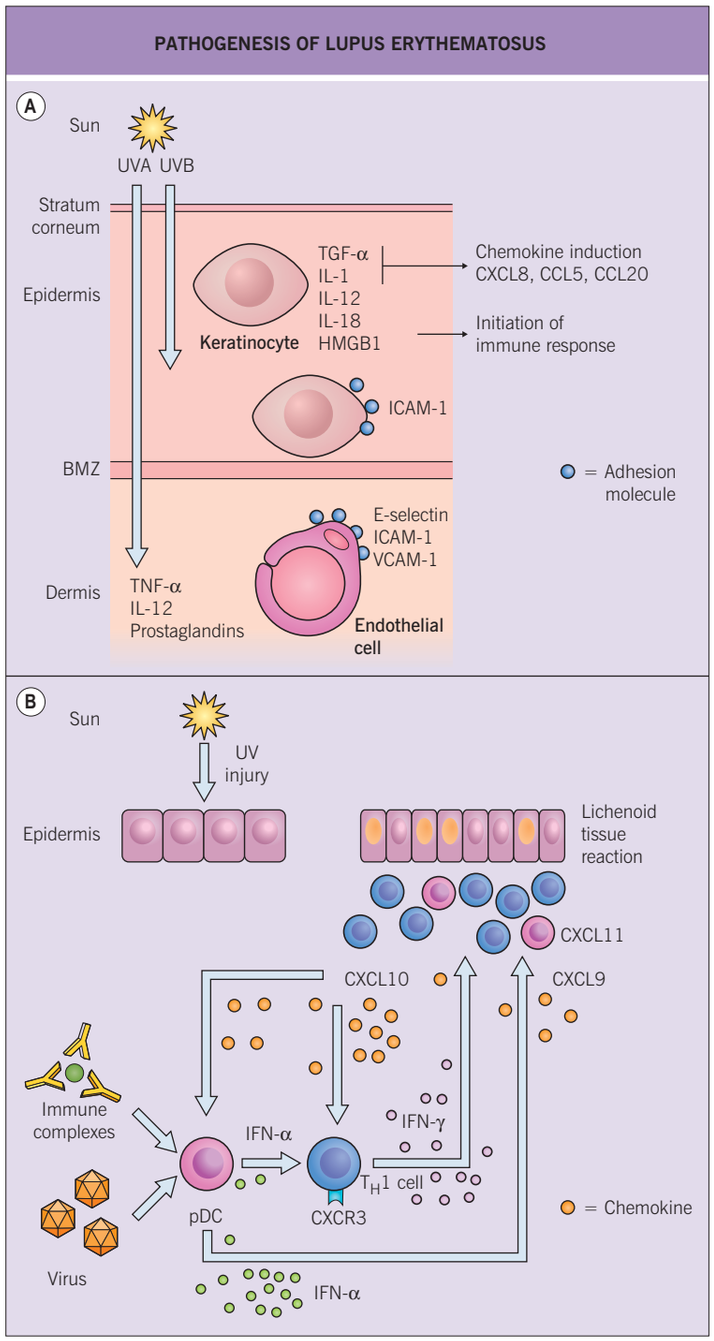

Fig. 41.1 Pathogenesis of lupus erythematosus. A In photosensitive cutaneous LE, ultraviolet radiation (UVA and UVB) triggers cytokine and chemokine production, initiating an immune response. **B** A lichenoid tissue reaction is the endpoint of a complex cascade that includes activation of dendritic cells, release of interferon (IFN), production of chemokines, and activation of T cells. BMZ, basement membrane zone; CCL, chemokine (C-C motif) ligand; CXCL, chemokine (C-X-C motif) ligand; CXCR, chemokine (C-X-C motif) receptor; HMGB1, high-mobility group box 1; IL, interleukin; ICAM, intercellular adhesion molecule; pDC, plasmacytoid dendritic cell; TNF, tumor necrosis factor; VCAM, vascular cell adhesion molecule. *Adapted from Dutz JP et al., In: Wallace DJ, Hahn BH (eds). Dubois' Lupus Erythematosus, 7th edn. Philadelphia: Lippincott, Williams & Wilkins, 2006, and Meller S, Gilliet M, Homey B. Chemokines in the pathogenesis of lichenoid tissue reactions. J Invest Dermatol. 2009;129:315–19.*

IFN is another cytokine that plays a role in the pathogenesis of cutaneous LE. Increased secretion of IFN can result from binding of apoptotic cells to Fcγ receptors on macrophages; binding of viral pathogens, DNA, RNA or immune complexes to Toll-like receptors on plasmacytoid dendritic cells; and single nucleotide polymorphisms (SNPs) in genes that encode proteins in the IFN pathway[33]. Notably, an increase in proteins upregulated by IFN, including the chemokines CXCL9 and CXCL10, has been observed in the skin of patients with cutaneous LE[30,34] (Fig. 41.1B). IFN-α further drives the differentiation of monocytes to plasmacytoid dendritic cells, which are potent producers of IFN-α/β, thus forming an amplification loop[35]. Increased numbers of plasmacytoid dendritic cells have been found within cutaneous LE lesions[34]. Epidermal and dermal dendritic cells can acquire keratinocyte-derived antigens and prime $CD8^+$ T cells to these antigens within the skin-draining lymph nodes[36]. Corroborating evidence for the role of IFN-α is provided by the induction of cutaneous LE in patients receiving IFN-α for other medical conditions. The increased IFN signature seen in SLE has also been detected in peripheral blood mononuclear cells from patients with DLE and SCLE, but not those with LE tumidus[37].

The IFN-upregulated chemokines can recruit CXCR3-positive $CD4^+$ and $CD8^+$ T cells to the skin, as well as immature plasmacytoid dendritic cells, contributing to the characteristic interface infiltrate of cutaneous LE[30,38]. In addition, via the production of IFN-α, plasmacytoid dendritic cells drive the activation and expansion of T cells. There is also evidence for the presence of granzyme B and TIA1 (poly(A)-binding protein), two cytotoxic granule-associated proteins involved in apoptosis, in the skin of all subsets of cutaneous LE, although somewhat less so in SCLE, suggesting that there are fewer $CD8^+$ T cells in SCLE[38]. In patients with disseminated, scarring DLE, high numbers of circulating $CCR4^+$ cytotoxic T cells were detected[39]. One study found *decreased* numbers of $Foxp3^+CD4^+CD25^+$ T regulatory cells in the skin, but not the blood, of cutaneous LE patients, and Treg cells are known to down-regulate the immune response[40].

A scenario that integrates current theories regarding the pathogenesis of several subsets of cutaneous LE is shown in Figure 41.1. In the proposed model, a response to UVR triggers cytokine and chemokine production by keratinocytes as well as endothelial cell activation, thereby initiating the immune response (see Fig. 41.1A). In the context of genetic risk and environmental factors, a complex cascade ensues that includes activation of dendritic cells, release of IFN, activation of T cells, and production of chemokines; a positive feedback loop ultimately results in a lichenoid tissue reaction (see Fig. 41.1B).

DIFFERENT FORMS OF CUTANEOUS LUPUS AND THEIR ASSOCIATION WITH SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

Type of cutaneous lupus	Association with SLE
• Acute cutaneous lupus erythematosus (ACLE)	++++
• Subacute cutaneous lupus erythematosus (SCLE)	++
• Chronic cutaneous lupus erythematosus (CCLE)	
– Discoid lupus erythematosus (DLE)

– Rowell's syndrome	++ to ++++

Table 41.2 Different forms of cutaneous lupus and their association with systemic lupus erythematosus (SLE).

CLINICAL FEATURES

Cutaneous Lupus – Three Major Forms

Classification

The most commonly used classification of cutaneous lesions in LE is that of the late Professor James Gilliam[41]. He segregated skin lesions into those that are specific and those that are not specific. Within the category of specific cutaneous lesions, he subdivided these into acute, subacute and chronic (Table 41.2). This choice of terms was based upon the observation that three distinct types of cutaneous LE are commonly seen: the often transient acute cutaneous LE (ACLE) typified by malar

erythema; the frequently long-lived, intensely inflammatory discoid lesions which can lead to permanent disfiguring scars (DLE); and a photosensitive eruption characteristically more long-lasting than ACLE but without the potential for scarring, for which the term subacute cutaneous LE (SCLE) was coined. Typically grouped within the chronic cutaneous LE category are not only DLE, but also the less common LE tumidus, lupus panniculitis and chilblain lupus.

Formal studies have not been done comparing duration of disease activity for the various types of cutaneous LE, and there is a considerable range in the duration of activity within each subtype. On occasion, ACLE and SCLE lesions may be chronic, and DLE and LE tumidus lesions may be relatively short-lived. In fact, some authorities have proposed that LE tumidus should be removed from the chronic category and be given its own category, intermittent cutaneous LE[42]. These caveats aside, Gilliam's classification schema has proven utility in the organization of the various types of cutaneous LE and it is the basis for the classification herein, accompanied by a focus on the morphology and histopathology of lesions (Fig. 41.2). The three major forms of cutaneous LE will be discussed first, followed by the remaining entities outlined in Table 41.2.

Discoid lupus erythematosus

Discoid lesions represent one of the most common skin manifestations of lupus, and they are certainly the most common type of cutaneous LE that a dermatologist is requested to evaluate. Discoid lesions are found most often on the face, scalp and ears (Fig. 41.3), but may be present in a widespread distribution (Fig. 41.4). It is unusual for discoid lesions to be present below the neck without lesions also being present above the neck[43]. On occasion, discoid lesions occur on mucosal surfaces, including the lips, nasal mucosa, conjunctivae and genital mucosa.

Some patients with discoid lesions exhibit a photodistribution, and sun exposure appears to have a role in lesional development. However, many patients have discoid lesions in sun-protected skin, and there is no clear association between sun exposure and their development.

Discoid lesions have the potential for scarring, and, with time, a substantial proportion of patients develop disfiguring scarring. Active lesions are intensely inflammatory, with a pronounced inflammatory infiltrate in both the superficial and deep dermis. As a result, active lesions tend to feel indurated on palpation. The adnexa are prominently

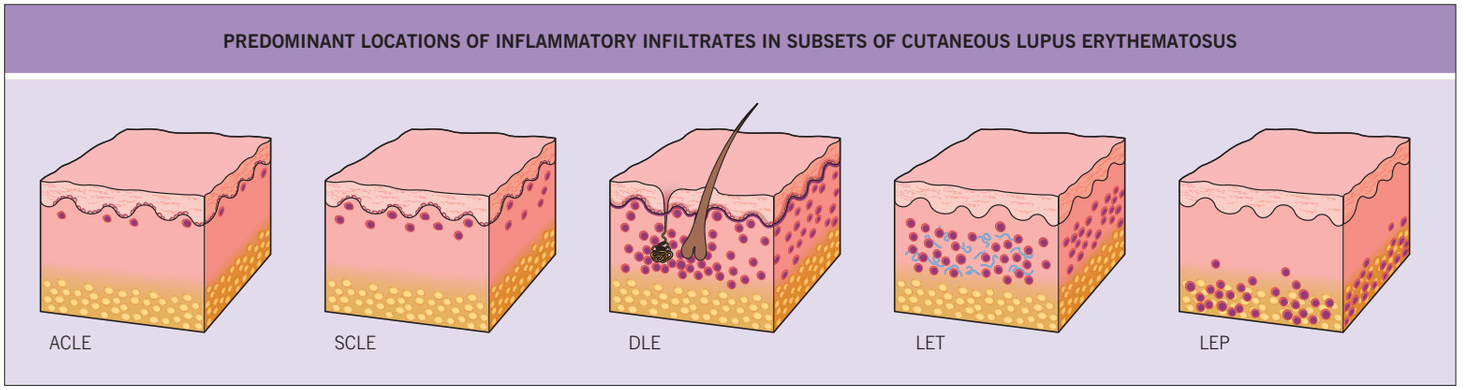

Fig. 41.2 Predominant locations of inflammatory infiltrates in subsets of cutaneous lupus erythematosus. The types of cutaneous lupus erythematosus are: acute cutaneous lupus erythematosus (ACLE), subacute cutaneous lupus erythematosus (SCLE), discoid lupus erythematosus (DLE), lupus erythematosus tumidus (LET) and lupus panniculitis (LEP); the latter three are forms of chronic cutaneous lupus erythematosus (see Table 41.2). The primary locations of the infiltrates are as follows: superficial dermis, ACLE and SCLE; superficial plus deep dermis and periadnexal, DLE; superficial and deep dermis, LET; and subcutaneous fat, LEP. The final diagnosis requires clinicopathologic correlation.

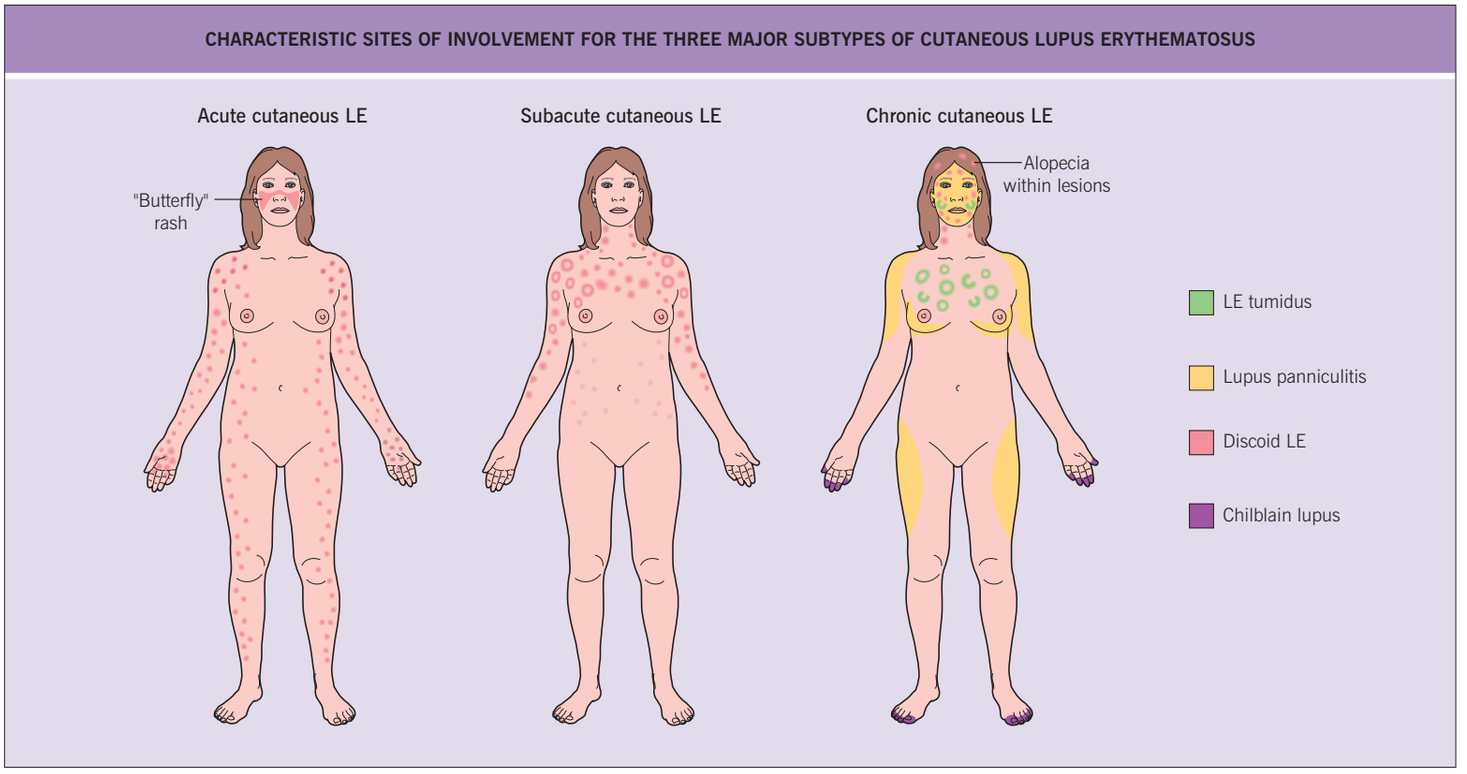

Fig. 41.3 Characteristic sites of involvement for the three major forms of cutaneous lupus erythematosus (LE).

Fig. 41.4 Various presentations of discoid lesions of lupus erythematosus. Lesions, which favor the head and neck region, may show erythema, scaling, atrophy and dyspigmentation in addition to scarring (and alopecia) (**A–D**). The scarring process may be destructive (**E**). Less common sites include the palms (**F**) and soles (**G**), where lesions can be keratotic or ulcerative as in lichen planus. The patients with plantar involvement had systemic lupus erythematosus and responded well to isotretinoin. **H** Occasionally, hypertrophic lesions develop with significant hyperkeratosis. *C, Courtesy, Kalman Watsky, MD; H, Courtesy, Julie V Schaffer, MD.*

involved, with follicular plugging and scarring alopecia commonly observed. Dyspigmentation is to be expected in longstanding lesions, typically with hypopigmentation in the central area and hyperpigmentation at the periphery (Fig. 41.5), but sometimes with vitiligo-like depigmentation. Rarely, squamous cell carcinoma develops in a longstanding discoid lesion.

Of the various forms of chronic cutaneous LE, discoid lesions (often referred to as DLE) are the most common (see Table 41.2). Patients with only discoid lesions may have associated arthralgias, but, over time, only 5–15% of these patients eventually develop clear-cut SLE[44–46a]. The risk may be higher in patients with widespread (disseminated) discoid lesions[43,45,46]. However, it is important to remember that

discoid lesions represent one of the 11 ARA criteria for SLE (see below) and can be a common presenting manifestation of SLE.

An unusual variant of DLE is hypertrophic DLE, characterized by thick scaling overlying the discoid lesion or occurring at the periphery of the discoid lesion. The intensely hyperkeratotic lesions are often prominent on the extensor arms (see Fig. 41.4H), but the face and upper trunk may also be involved. Frequently, there are typical discoid lesions present in other locations.

Subacute cutaneous lupus erythematosus

SCLE is typically photosensitive, with lesions confined to sun-exposed skin. It is notable that the midfacial skin is usually spared, while the sides of the face, upper trunk and extensor aspects of the upper extremities are commonly involved (Fig. 41.6; see Fig. 41.3)[47]. In some patients, the disease may be mild, with only a few small scaly patches appearing after sun exposure.

Lesions of SCLE may have an annular configuration, with raised red borders and central clearing (Fig. 41.7), or a papulosquamous presentation with an eczematous or psoriasiform appearance. SCLE lesions characteristically have a relatively sparse, superficial inflammatory infiltrate, and, consequently, there is usually no induration. Lesions often result in dyspigmentation, particularly hypopigmentation or even depigmentation, but do not scar.

In some instances, lesions of SCLE have appeared in patients receiving certain medications, in particular hydrochlorothiazide and terbinafine, but also calcium channel blockers, nonsteroidal anti-inflammatory drugs (e.g. naproxen), griseofulvin and antihistamines. The lesions may or may not clear once the medication is discontinued.

The long-term prognosis of patients who have SCLE is not completely known, largely because this subset of cutaneous LE only recently has been widely recognized. It is clear that a certain percentage of patients, perhaps 10–15%, will over time develop significant internal disease, including nephritis[44]. Since anti-Ro autoantibodies are associated with Sjögren's syndrome as well as SCLE, it is not surprising that some patients have features of both conditions, and some may have serious internal manifestations of Sjögren's syndrome such as pulmonary or neurologic disease.

An important feature of SCLE, from the standpoint of understanding the pathogenesis of lupus, is its regular association with the anti-Ro autoantibody (see Ch. 40). Although investigators differ in their opinions as to the prevalence of anti-Ro in SCLE, it is likely that a substantial majority of patients with this condition (approximately 70% in a large series, reported range of 60–100%) have anti-Ro antibody[47,48].

Acute cutaneous lupus

The lesions of ACLE are exemplified by the development of bilateral malar erythema ("butterfly rash"; Fig. 41.8). These lesions tend to be transient, follow sun exposure, and resolve without scarring (but sometimes with dyspigmentation). An association with anti-dsDNA

Fig. 41.7 Subacute cutaneous lupus erythematosus (SCLE). Lesions are most commonly seen on the sun-exposed aspects of the upper extremities. The margins of the annular lesions may have scale-crust (**A**) or be composed of multiple papules (**B**). *A, Courtesy, Jean L Bolognia, MD.*

antibodies and lupus nephritis has been proposed and is plausible[44], although some patients with a malar rash have neither anti-dsDNA antibodies nor lupus nephritis. Patients presenting with this type of eruption must be evaluated carefully for evidence of internal disease.

The morphology of the lesions ranges from mild erythema to intense edema. The presence of telangiectasias, erosions, dyspigmentation and epidermal atrophy (i.e. poikiloderma) may help to distinguish the malar erythema of ACLE from that of common facial eruptions such as seborrheic dermatitis and the vascular type of rosacea. Occasionally, there is a papular component, and occasionally lesions develop scaling (see Fig. 41.8C). The duration may range from a few hours to several weeks. The face, particularly the malar area, is most commonly affected, but sometimes lesions may be more widespread in distribution (Fig. 41.9; see Fig. 41.3). When lesions occur on the hands, the knuckles are typically spared. It is not unusual for the acute cutaneous eruption to be accompanied by oral ulcerations.

Rarely, patients with lupus develop an acute eruption clinically similar to toxic epidermal necrolysis or erythema multiforme major (Fig. 41.10). The presence of erythema multiforme-like lesions in lupus patients has been termed Rowell's syndrome[49]. These lesions may represent a severe variant of ACLE or, in some cases, SCLE.

The three major types of cutaneous LE are not mutually exclusive. In a given patient, more than one type of cutaneous lesion may occur.

Cutaneous Lupus – Additional Variants

(see Table 41.2)

Lupus erythematosus tumidus

Some patients with cutaneous LE have lesions characterized by induration and erythema but no scale or follicular plugging. The epidermis appears to be uninvolved in the disease process, although there is an intense dermal inflammatory infiltrate. LE tumidus lesions may be the same as the "urticarial plaques" described in lupus patients. However, these fixed plaques should not be confused with urticarial vasculitis (see Ch. 24). Some authors state that the lesions are most common on the face, although they can be quite common on the trunk (Fig. 41.11). Morphologically, the lesions are similar to those of Jessner's lymphocytic infiltrate and may have central clearing (see Ch. 121); some believe that Jessner's lymphocytic infiltrate and LE tumidus are either very closely related or one and the same[50].

Both the very low prevalence of SLE and the relatively low prevalence of immunoglobulin deposition within the cutaneous lesions in patients reported to have LE tumidus have made it difficult to determine whether LE tumidus is actually a variant of LE or an independent entity. However, the presence of LE tumidus lesions in patients with other specific types of cutaneous LE is evidence in favor of its being classified as a form of cutaneous LE. LE tumidus has been reported to be reproducible by phototesting in the majority of patients[51]. The lesions tend to resolve without scarring or atrophy.

Lupus panniculitis

Intense inflammation in the fat leads to indurated plaques that can evolve into disfiguring, depressed areas. Lesions of lupus panniculitis have a distinctive distribution, occurring predominantly on the face, upper arms (Fig. 41.12), upper trunk, breasts, buttocks and thighs (see Fig. 41.3). Some patients have discoid lesions overlying the panniculitis, and, in those cases, the condition is sometimes referred to as lupus profundus. For further discussion of lupus panniculitis, see Chapter 100.

Chilblain lupus

Chilblain lupus (SLE pernio; Fig. 41.13) consists of red or dusky purple papules and plaques on the toes, fingers, and sometimes the nose, elbows, knees and lower legs. The lesions are brought on or exacerbated

Fig. 41.8 Acute cutaneous lupus erythematosus (ACLE). The facial erythema, often referred to as a "butterfly rash" may be variable (**A**), edematous (**B**) or have associated scale (**C**). The presence of small erosions can aid in the clinical differential diagnosis. *A, Courtesy, Kalman Watsky, MD.*

by cold, particularly moist cold climates. These lesions may represent the concurrence of ordinary chilblains with LE (see Ch. 88), although, with time, the lesions may develop a gross and microscopic appearance consistent with a discoid lesion.

Neonatal lupus erythematosus

A neonatal form of SCLE may occur in infants whose mothers have anti-Ro autoantibodies. In babies who have neonatal lupus erythematosus (NLE), the SCLE-like lesions are histologically identical to those of SCLE in adults, and there is a strong association with anti-Ro antibodies. Indeed, almost 100% of babies with NLE have anti-Ro antibodies[52]. Unlike SCLE in adults, lesions have a predilection for the face, especially the periorbital region and scalp (Fig. 41.14). Photosensitivity is very common in NLE, but sun exposure is not required for lesions to form, as it is possible for lesions to be present at birth. Neonatal lupus skin lesions typically resolve without scarring, although dyspigmentation may persist for many months, and some children have residual telangiectasias.

Children who have the cutaneous lesions of NLE may also exhibit internal manifestations. The major extracutaneous findings are congenital heart block (with or without cardiomyopathy), hepatobiliary disease and thrombocytopenia. The heart block is almost always present by birth, but on rare occasions has developed after birth. Clinically significant cardiomyopathy occurs concurrently in a small percentage of babies who have heart block. Usually, the cardiomyopathy is apparent in the neonatal period, but it is possible for it to become apparent only after several months have elapsed. Cardiac NLE has a mortality rate of approximately 20%, and about two-thirds of children require pacemakers[53].

Hepatobiliary disease and cytopenias, especially thrombocytopenia, may be present at birth, or they may develop within the first few months of life[54]. Hepatobiliary disease has been reported to present as liver failure during gestation or in the neonatal period, as conjugated hyperbilirubinemia during the first few weeks of life, or with mild elevations of aminotransferases at 2–3 months of life.

It is common for babies with NLE to exhibit only one of the above clinical manifestations, and thus many children with cutaneous NLE have no other significant clinical findings. However, children who have skin signs of NLE should be evaluated for internal manifestations with a physical examination in addition to an electrocardiogram, complete blood count, and liver function tests, when indicated.

Other Variants

In the clinical setting of lupus, bullous lesions may appear for several reasons. On occasion, bullous or crusted lesions occur simply as a result of the intensity of the basal cell damage in lesions of ACLE or SCLE (see Fig. 41.7A) or, possibly, DLE. Rarely, a dramatic, acute eruption similar to erythema multiforme major or toxic epidermal necrolysis (TEN) may occur in patients with preexisting ACLE or SCLE, or it may appear *de novo*. Blisters occurring within ACLE and SCLE lesions and erythema multiforme-like and TEN-like cutaneous lupus fit within the category of lupus-specific skin lesions.

The term bullous eruption of SLE, or bullous SLE, has been used to describe a blistering eruption that consists of vesicles and bullae whose

histopathology often resembles dermatitis herpetiformis, with a primarily neutrophilic infiltrate and microabscesses within the dermal papillae (Fig. 41.15)[55]. In some patients, the clinical and histologic features may resemble bullous pemphigoid or epidermolysis bullosa acquisita. Immunoreactants are often found at the basement membrane zone and antibodies to type VII collagen have been detected in several patients[56]. This eruption may represent the concurrence of lupus with an autoimmune blistering disease due to autoantibodies to a component of the basement membrane zone. There are also a number of case reports of other autoimmune bullous diseases appearing in patients with lupus (reviewed in ref. 57).

A *lupus/lichen planus overlap syndrome* has been described, in which lesions have features of both conditions (see Ch. 11).

Systemic Lupus Erythematosus

Lupus erythematosus is potentially a multiorgan disease, although in individual patients it is often only one or a few organs that are significantly affected. The organ systems most commonly affected are joints, skin, hematologic, pulmonary, renal and the CNS. Many of the internal organ manifestations classically associated with lupus are part of the criteria for the classification of SLE (see Table 41.7), and reference to these criteria may serve as a useful reminder of the possible character of internal organ involvement (e.g. non-erosive arthritis, pleuritis, pericarditis, proteinuria, cellular casts in the urine, seizures, psychosis, hemolytic anemia, leukopenia, lymphopenia, thrombocytopenia). However, it should be remembered that these systemic features have been selected as criteria due to their usefulness in distinguishing SLE from other rheumatic diseases. They are not necessarily the most common systemic features of SLE, and certainly do not represent a comprehensive listing of possible organ involvement. Signs and symptoms such as fever, weight loss, fatigue, myalgias and lymphadenopathy are exceedingly common, if nonspecific, and may be useful indicators of increased risk for SLE in patients who present with cutaneous lesions. Although ACLE is the cutaneous phenotype with the strongest association with systemic disease, patients with any type of cutaneous LE may develop internal involvement.

Fig. 41.14 Neonatal lupus erythematosus. Annular erythematous plaques on the forehead and scalp. Note the resemblance to the annular form of subacute cutaneous lupus erythematosus. *Courtesy, Julie V Schaffer, MD.*

Fig. 41.15 Bullous eruption of systemic lupus erythematosus. Vesicles and bullae due to autoantibodies against type VII collagen can develop in patients with systemic disease.

Nonspecific Cutaneous Lesions

Vascular lesions are common in patients with LE, particularly in those who have systemic disease (Table 41.3). These lesions include Raynaud's phenomenon (see Ch. 43), livedo reticularis, palmar erythema and periungual telangiectasia. Purpura, urticarial papules or ulcerations due to vasculitis may occur, as well as cutaneous infarction resembling Degos' disease or atrophie blanche. Patients with cutaneous LE who have any of these findings should be evaluated for systemic disease. Livedo reticularis, thromboses, ulcerations, and lesions resembling Degos' disease have each been associated with antiphospholipid antibodies[58] (see Ch. 23). The association of livedo reticularis with ischemic CNS disease has been called Sneddon syndrome, and the phenotype of the antiphospholipid syndrome has been called Hughes syndrome[59].

Alopecia often occurs as a result of scarring discoid lesions. However, non-scarring diffuse alopecia can appear in patients with systemic disease. It has been reported that patients with lupus have an increased likelihood of alopecia areata compared with the general population[60].

Sclerodactyly, calcinosis and rheumatoid nodules, findings more consistent with scleroderma or rheumatoid arthritis, have been observed in some patients with lupus, although many of the patients with these findings may have overlap syndromes rather than classic lupus. Other skin findings reported to occur in patients who have lupus include erythromelalgia, papulonodular mucinosis (of Gold; see Ch. 46) and anetoderma (see Ch. 99).

Patients with SLE have more subtle nailfold capillary abnormalities than do patients with scleroderma or dermatomyositis. Prominent large, tortuous capillaries and areas of marked avascularity are not characteristic of SLE.

CUTANEOUS FINDINGS (NONSPECIFIC) THAT SUGGEST THE DIAGNOSIS OF SYSTEMIC LUPUS ERYTHEMATOSUS
Diffuse non-scarring alopecia
Raynaud's phenomenon
Nailfold telangiectasias and erythema
Vasculitis
• Urticarial vasculitis
• Small vessel vasculitis (e.g. palpable purpura)
• Polyarteritis nodosa-like lesions
• Ulcerations
Cutaneous signs of antiphospholipid syndrome
• Livedo reticularis
• Ulcerations
• Acrocyanosis
• Atrophie blanche-like lesions
• Degos'-like lesions
Livedoid vasculopathy
Palmar erythema
Papular and nodular mucinosis

Table 41.3 Cutaneous findings (nonspecific) that suggest the diagnosis of systemic lupus erythematosus. These are in addition to skin signs of other autoimmune connective tissue diseases, which raise the possibility of an overlap syndrome.

PATHOLOGY

Routine Histopathology

Histologic findings in cutaneous LE depend in large part on the subtype (Fig. 41.16; see Fig. 41.2). Characteristic findings in ACLE, SCLE, discoid lesions, LE tumidus, and lupus panniculitis are outlined in Table 41.4. However, in practice, an overlap in histologic findings occurs among the various clinical phenotypes, particularly ACLE, SCLE and discoid lesions. Some of the more distinctive histologic features of cutaneous LE are basal cell damage (also referred to as vacuolar degeneration or hydropic change), lymphohistiocytic inflammatory infiltrates and, primarily in discoid lesions, periadnexal inflammation, follicular plugging, and scarring. In lesions of ACLE, dermal changes can be relatively subtle although basal cell damage may be pronounced. In SCLE, epidermal changes and a superficial lymphocytic infiltrate are common. In contrast to discoid lesions, SCLE lesions tend to have little or no hyperkeratosis, basement membrane thickening, periadnexal infiltrate,

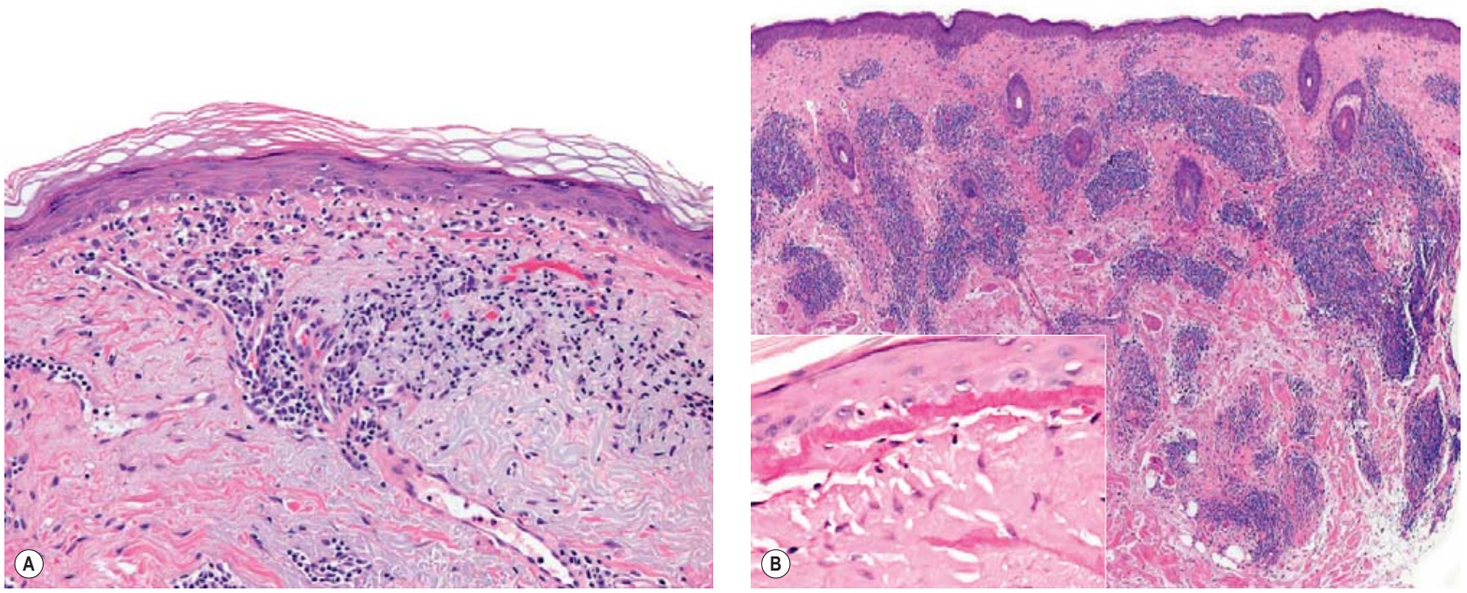

Fig. 41.16 Histologic features of cutaneous lupus erythematosus (LE). A Acute cutaneous LE showing interface dermatitis with vacuolization of basal keratinocytes and sparse superficial lymphoid infiltrates. **B** Chronic discoid LE showing focal interface dermatitis and dense perivascular and periadnexal lymphoid infiltrates throughout the entire dermis. A thickened basement membrane is a characteristic finding and can be highlighted by PAS staining (insert). *Courtesy, Lorenzo Cerroni, MD.*

CHARACTERISTIC HISTOLOGIC FINDINGS IN CUTANEOUS LUPUS ERYTHEMATOSUS (LE)

Table 41.4 Characteristic histologic findings in cutaneous lupus erythematosus (LE). The table is intended as a broad overview only. Not every feature will be present in every lesion, some features may be present that are not indicated as characteristic, and overlap exists amongst subtypes. [–], not a defining feature; [+/–], a feature that may be present in some lesions; [+], a feature that is typically present; [++], a defining feature that may be prominent.

follicular plugging, deep dermal infiltrate, or scarring[61]. LE tumidus has prominent dermal mucin deposition and lymphocytic infiltrates with a lack of epidermal change. While changes of lupus panniculitis are most prominent in the subcutis, an overlying discoid lesion can be found in many cases[62].

Immunopathology of Lesional Skin

Examination of the skin for deposits of immunoreactants is called direct immunofluorescence (DIF). DIF of lesional skin does not replace routine histologic staining as the method of choice for establishing a diagnosis of cutaneous LE. DIF is not even necessary as an adjunctive diagnostic test if the histopathology and clinical presentation are definitive. In those cases where the routine histopathology is equivocal, DIF can be a valuable asset in establishing a diagnosis.

The most characteristic DIF finding in cutaneous LE is antibody deposition at the dermal–epidermal junction and around hair follicles[6]. These deposits are typically granular, and they are composed primarily of IgG and/or IgM (Fig. 41.17), although IgA can also occasionally be seen. In addition, deposits of complement proteins are to be expected. Some investigators have reported that in SCLE, granular deposits of IgG and IgM are observed primarily within the epidermis rather than at the dermal–epidermal junction[63]. There is evidence that the epidermal deposits are due to anti-Ro autoantibodies depositing directly within the skin[64].

In ACLE, SCLE and DLE, DIF of lesional skin is positive in the majority of cases. In general, a positive DIF supports the diagnosis of cutaneous LE, but a negative DIF does not exclude the diagnosis. It has been noted that DIF is most likely to be positive in well-established, active lesions. There is relatively little information about the expected frequency of positive DIF in LE tumidus. Many reports have noted nonspecific findings. In lupus panniculitis, DIF may show immunoreactants around dermal vessels, but granular deposits at the dermal–epidermal junction are not uniformly present.

Immunopathology of Normal-Appearing Skin

In normal-appearing skin, the presence of antibody deposits at the dermal–epidermal junction correlates reasonably well with systemic disease. The antibody deposits are sometimes referred to as a "lupus band", and examination for them as the "lupus band test". The terminology is confusing, because some authors use the term "lupus band" to apply to the antibody deposits at the dermal–epidermal junction, whether the skin tested is normal-appearing or lesional, and other authors reserve the term "lupus band" to describe antibody deposits in normal-appearing skin. It has been proposed that, if this terminology is used, the investigator should modify the term "lupus band" by a preceding adjective of "lesional" or "non-lesional", so that the subject of discussion is clearly identified[37]. The antibody and complement deposits at the dermal–epidermal junction are usually described as granular, although some experienced observers have identified subtypes of deposits, variously classified as fibrillar, thready, stippled, shaggy, linear, lumpy-bumpy or homogeneous[65].

Weak, discontinuous deposits may be seen in persons who do not have LE, including healthy adults, particularly when chronically sun-exposed skin is examined. For this reason, many investigators do not consider a non-lesional lupus band test to be positive unless the deposition of immunoreactants is strong and continuous. A true positive non-lesional lupus band test occurs in three-quarters or more of patients with SLE if sun-exposed skin is examined, and in about one-half of patients with SLE if sun-protected skin is examined[66]. A positive non-lesional lupus band test is unlikely to occur in patients who do not have SLE, but there are instances where the non-lesional lupus band test has been positive in patients with other autoimmune diseases.

In most cases, clinical evaluation and serologic testing for specific autoantibodies provides the required information, and the non-lesional lupus band test is superfluous. In cases where the clinical presentation or laboratory findings are atypical, the non-lesional lupus band test may have diagnostic value.

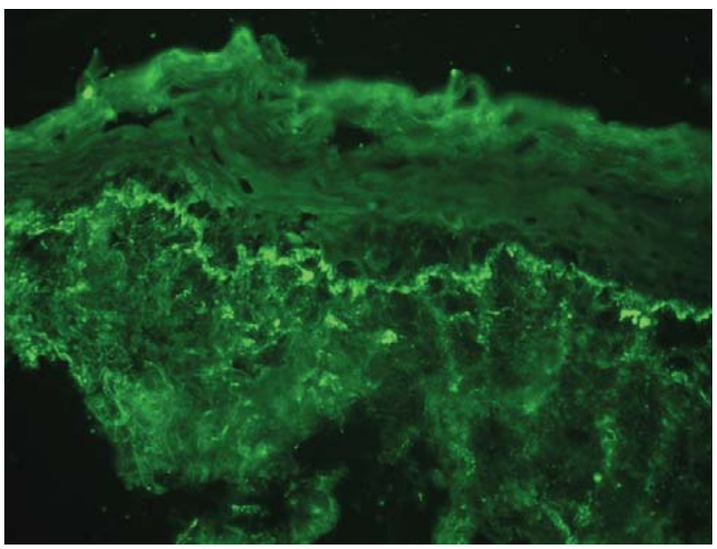

Fig. 41.17 Direct immunofluorescence of cutaneous lupus. Granular deposits of IgM are present at the dermal–epidermal junction within lesional skin. Antibody deposits at the dermal–epidermal junction are the most characteristic immunohistologic finding in lesions of cutaneous lupus and normal skin of patients with systemic lupus erythematosus. *Courtesy, Janet Fairley, MD.*

DIFFERENTIAL DIAGNOSIS

The differential diagnosis varies considerably with the subtype of cutaneous LE under consideration. Some of the major entities in each of the differential diagnoses are outlined in Table 41.5.

In evaluating a patient with cutaneous lesions, lesional biopsy for H&E is, in general, the most valuable diagnostic test. An approach to the diagnosis of cutaneous LE is shown in Figure 41.18. In an occasional situation, such as that of a patient with known SLE who has transient facial lesions that appear to be ACLE, the clinician may forego a biopsy because of the high likelihood of obtaining nonspecific findings and the cosmetic sequela of a scar on the face. Thus, the diagnostic tree presented is not intended to be followed strictly for each situation, but rather is meant as a general overview of the diagnostic approach, to be individualized for each patient.

In evaluating a patient with cutaneous lesions for the presence of systemic disease, the dermatologist can take a directed history, perform a cutaneous examination looking for signs of possible systemic disease (such as vasculitic lesions), and perform blood and urine testing for evidence of hematologic or renal disease, ANA, and SLE-specific autoantibodies (Table 41.6). Many clinicians also obtain an ESR and complement levels. Autoantibodies to dsDNA, Sm and possibly also ribosomal P are relatively specific for SLE, and are, therefore, helpful indicators of a high likelihood of systemic disease (see Ch. 40). Autoantibodies to Ro, La, U1RNP, histones and ssDNA are common in patients with SLE, but they are not disease-specific. An ANA is helpful if negative, as it is quite unusual for patients with SLE to have a negative ANA. It is common for the ANA to be positive in patients with cutaneous lesions, and a positive ANA is neither an indicator of systemic disease nor of LE. Positive ANAs may be found in patients with many other diseases (see Ch. 40) and even in apparently normal individuals. Approximately a third of apparently normal individuals have a positive ANA at a dilution of 1:40, 13% at a dilution of 1:80, and 5% at a dilution of 1:160[67].

In many cases, the decision to make a diagnosis of SLE is done on the basis of whether or not the patient's findings fulfill four or more criteria for the classification of SLE (Table 41.7)[68]. It should be noted that the classification was developed by rheumatologists to help distinguish patients with SLE from patients with other rheumatic diseases. In particular, most of the control subjects evaluated in the study that defined the SLE criteria were patients with rheumatoid arthritis. Therefore, the criteria are especially useful in distinguishing SLE from other conditions that affect joints, and they are quite useful as a means of standardizing patient groups for experimental protocols. However, the criteria should not be used in lieu of clinical judgment, i.e. patients

DIFFERENTIAL DIAGNOSES OF CUTANEOUS LUPUS SUBTYPES
ACUTE CUTANEOUS LUPUS/MALAR RASH
• Rosacea (including corticosteroid-induced) • Seborrheic dermatitis (especially photosensitive form) • Sunburn • Drug-induced photosensitivity (phototoxic and photoallergic) • Dermatomyositis • Erysipelas • Pemphigus erythematosus • Dermatitis, atopic, contact and photocontact • Acne vulgaris (rarely)
SUBACUTE CUTANEOUS LUPUS
• Psoriasis • Dermatophytosis, including tinea incognito • Photolichenoid drug eruption • Granuloma annulare • Figurate erythemas (e.g. erythema annulare centrifugum) • Dermatitis, atopic, contact and photocontact • Pemphigus foliaceus
DISCOID LESIONS
• Facial discoid dermatosis • Tinea faciei, tinea capitis, tinea corporis • Lichen planus and lichen planopilaris • Jessner's lymphocytic infiltrate • Polymorphous light eruption • Sarcoidosis • Lymphocytoma cutis • Lymphoma cutis • Granuloma faciale • Dimorphic fungal infections, lupus vulgaris • When single lesion, non-melanoma skin cancer
TUMID LUPUS LESIONS
• Jessner's lymphocytic infiltrate* • Polymorphous light eruption • Reticular erythematous mucinosis
LUPUS PANNICULITIS
• Other panniculitides (see Ch. 100)
*Some authorities believe that Jessner's lymphocytic infiltrate and LE tumidus are the same condition.

Table 41.5 Differential diagnoses of cutaneous lupus subtypes. Mothers of boys with chronic granulomatous disease and patients with Sjögren's syndrome have an annular erythema similar to annular SCLE; patients with GVHD can develop SCLE-like lesions.

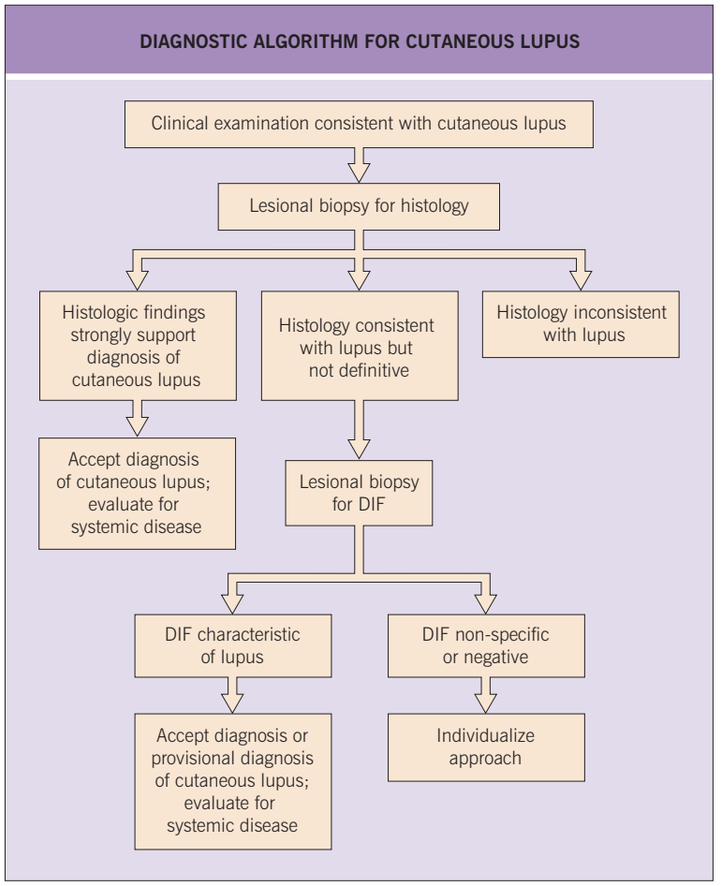

Fig. 41.18 Diagnostic algorithm for cutaneous lupus. This algorithm is intended as a guide to diagnosis and should be individualized for each situation. For example, lesional biopsy for direct immunofluorescence (DIF) may be performed at the same time as a lesional biopsy for routine histology. Less definitive histologic findings might sometimes be acceptable if the patient is already known to have SLE. Whether a diagnosis is clear-cut or provisional may be, on occasion, a subjective determination.

EVALUATION FOR SYSTEMIC LUPUS ERYTHEMATOSUS
HISTORY
PHYSICAL EXAMINATION
• Specific cutaneous lesions (see Table 41.2) • Nonspecific cutaneous lesions (see Table 41.3) • Lymphadenopathy, arthritis
LABORATORY TESTS
• ANA with profile (anti-dsDNA, -Sm) • Urinalysis • CBC with differential, platelet count • Chemistries (BUN, creatinine) • Erythrocyte sedimentation rate • Complement levels (C3, C4)

Table 41.6 Evaluation for systemic lupus erythematosus. ANA, antinuclear antibodies; BUN, blood urea nitrogen; CBC, complete blood count; ds, double-stranded; Sm, Smith.

who do not have four or more criteria may still have SLE, and, conversely, it is possible to meet four criteria and yet not have SLE.

The SLE classification criteria do emphasize the need to exclude drug-induced systemic lupus. The latter presents as a lupus-like systemic illness with arthralgias, myalgias, pleuritis and fever, but lacking nephritis and CNS disease. It is observed in patients who are receiving specific medications, in particular procainamide and hydralazine, and who develop antihistone autoantibodies (although these autoantibodies are nonspecific and are also common in patients with SLE). In contrast to drug-induced SCLE with anti-Ro autoantibodies (see above), patients with drug-induced SLE rarely have specific lesions of cutaneous LE, but they may have nonspecific lesions. Of note, patients receiving TNF inhibitors may develop autoantibodies, particularly ANA and anti-dsDNA, and on occasion develop cutaneous lesions that can resemble ACLE, SCLE or DLE.

TREATMENT

Topical Therapy

Topical or intralesional corticosteroids are a mainstay of therapy (Table 41.8). They offer a high degree of safety as well as the potential for a relatively rapid response. The systemic side effects of corticosteroids are largely avoided, although the cutaneous side effects are not. It is frequently the case that topical corticosteroids need to be of high potency in order for a response to occur, and discoid lesions are one of the few instances where it may be appropriate to use high-potency corticosteroids on the face. Patients should be instructed about the risks and benefits of therapy, the need to limit the application to affected areas, and the need for monitoring for cutaneous side effects.

THE AMERICAN COLLEGE OF RHEUMATOLOGY 1982 REVISED CRITERIA FOR CLASSIFICATION OF SYSTEMIC LUPUS ERYTHEMATOSUS*	
Criterion	**Definition**
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by physician
5. Arthritis	Non-erosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling or effusion
6. Serositis	a) **Pleuritis** – convincing history of pleuritic pain, rubbing heard by a physician, or evidence of pleural effusion *OR* b) **Pericarditis** – documented by ECG, rub or evidence of pericardial effusion
7. Renal disorder	a) Persistent **proteinuria** greater than 0.5 g/day or greater than 3+ if quantitation not performed *OR* b) **Cellular casts** – may be red cell, hemoglobin, granular, tubular or mixed
8. Neurologic disorder	a) **Seizures** – in the absence of offending drugs or known metabolic derangements, e.g. uremia, ketoacidosis or electrolyte imbalance *OR* b) **Psychosis** – in the absence of offending drugs or known metabolic derangements, e.g. uremia, ketoacidosis or electrolyte imbalance
9. Hematologic disorder	a) **Hemolytic anemia** with reticulocytosis *OR* b) **Leukopenia** – less than 4000/mm^3 total WBC on two or more occasions *OR* c) **Lymphopenia** – less than 1500/mm^3 on two or more occasions *OR* d) **Thrombocytopenia** – less than 100 000/mm^3 in the absence of offending drugs
10. Immunologic disorder	a) **Anti-DNA antibody to native DNA** in abnormal titer *OR* b) **Anti-Sm:** presence of antibody to Sm nuclear antigen *OR* c) Positive finding of **antiphospholipid antibodies** based on: (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies; (2) a positive test result for lupus anticoagulant using standard methods; or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test (FTA-ABS)
11. Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence (or an equivalent assay) at any point in time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome

*The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have systemic lupus erythematosus if any four or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

Table 41.7 The American College of Rheumatology 1982 revised criteria for classification of systemic lupus erythematosus[69]. ECG, electrocardiogram; Sm, Smith; WBC, white blood cell.

Particularly in active discoid lesions and LE tumidus lesions, intralesional triamcinolone, often given in a concentration of 4–5 mg/ml, can be very effective. The injections may be repeated monthly while the lesions are active. There are anecdotal reports of the use of new topical immunomodulators (e.g. tacrolimus) for cutaneous lesions.

Systemic Therapy

Antimalarial therapy has been used for more than a half-century for cutaneous LE, and it remains the gold standard for systemic therapy. Hydroxychloroquine sulfate is the most commonly chosen antimalarial, as it is usually well tolerated. Chloroquine and quinacrine (mepacrine) are alternatives. In patients who are not responsive to hydroxychloroquine sulfate, quinacrine may be added to the regimen[69a]. Quinacrine can turn the skin yellow, although it does not invariably do so. The dose of hydroxychloroquine sulfate chosen is usually 200 mg once or twice per day. It has been reported that if the dose does not exceed 6.5 mg/kg ideal body weight/day, eye toxicity is quite unlikely[70]. For chloroquine, the usual dose is 125–250 mg/day, with the eye toxicity-minimizing dose being no more than 3.5–4 mg/kg ideal body weight/

THERAPY OF CUTANEOUS LUPUS
LOCAL THERAPY
Sun protection (2)
Topical and intralesional corticosteroids (2)
Topical calcineurin inhibitors (2)
Topical retinoids (3)
SYSTEMIC ANTIMALARIAL THERAPY
Hydroxychloroquine (200 mg po qd–bid in adults; up to 6.5 mg/kg ideal body weight/day) (2)
Chloroquine (125–250 po qd in adults; up to 3.5–4 mg/kg ideal body weight/day) (2)
Quinacrine (100 mg po qd) (2)
Combination of hydroxychloroquine or chloroquine and quinacrine (2)
SYSTEMIC THERAPY FOR ANTIMALARIAL-RESISTANT CUTANEOUS DISEASE
Retinoids (e.g. acitretin, isotretinoin) (2)
Thalidomide (50–100 mg po qd for clearing and, if necessary, 25–50 mg po qd–twice weekly for maintenance) (2)
Dapsone (primarily for bullous eruption of SLE) (2)
Immunosuppressive agents (e.g. mycophenolate mofetil, azathioprine) (2)
Sulfasalazine (2)
Clofazimine (3)
Systemic corticosteroids (3)
Immune response modifiers (e.g., rituximab, abatacept,* belimumab, anti-IL-6 Ab, anti-IL-10 Ab) (3)
*Not more effective than placebo in non life-threatening SLE.

Table 41.8 Therapy of cutaneous lupus. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. bid, twice daily; qd, daily.

day[70]. Quinacrine is thought by most not to cause eye toxicity. For patients on hydroxychloroquine sulfate or chloroquine, eye examinations should be done by a physician knowledgeable in antimalarial eye toxicity.

The response to antimalarials is relatively slow. It may take 2 or 3 months for efficacy to be appreciated, and sometimes several more months to achieve maximal efficacy. Consequently, for patients who are beginning therapy for cutaneous LE, topical or intralesional therapy should usually be given along with antimalarial therapy. It has been observed that there is a larger than expected percentage of cigarette smokers among patients who present with cutaneous lupus, and that smokers may have more extensive cutaneous disease. It has also been observed that smokers do not respond as well to antimalarial therapy as do non-smokers. Thus, smoking cessation may be a useful adjunctive therapy in some individuals.

Some patients do not respond either to single antimalarial therapy or to the combination of quinacrine with either hydroxychloroquine sulfate or chloroquine. Disease that is refractory to antimalarials is often refractory to other therapies as well. Nonetheless, it is reasonable to seek a therapy that will work well, if the risks of therapy are deemed to be worth the potential benefits. In antimalarial-resistant patients, therapeutic options include oral retinoids, thalidomide, immunosuppressive agents such as mycophenolate mofetil or azathioprine, clofazimine, sulfasalazine and systemic corticosteroids[71]. Dapsone has been used, but usually with little success except in the rare subset of bullous eruption of SLE. Both retinoids and thalidomide are potent teratogens, making them difficult choices in women of childbearing potential. Thalidomide also frequently causes a peripheral neuropathy. For that reason, some clinicians have advocated giving thalidomide in low or intermittent dosing in an attempt to minimize toxicity. In the future, immune response modifiers (such as rituximab, and anti-B-lymphocyte stimulator [BlyS], -IL-6 and -IL-10 antibodies) may play an important role in the treatment of cutaneous LE.

In patients with systemic LE but no major organ involvement (i.e. potentially life-threatening involvement of visceral organs), treatment for mild disease includes NSAIDs, while corticosteroids and immunosuppressives (e.g. azathioprine, leflunomide, mycophenolate mofetil) are usually prescribed for moderate to severe disease. When there is a mild degree of major organ involvement, corticosteroids are the primary treatment, but for moderate to severe involvement, pulse cyclophosphamide +/– pulse corticosteroids are often recommended. Immune response modifiers (biologic therapies) are reserved for refractory disease (see Table 41.8)[72]. For a recent more comprehensive review, the reader is referred to reference 73.

Adjunctive Therapy

Sun protection is a vital part of therapy for many patients because the sun exacerbates or initiates their skin lesions. For others, sun protection is important for cancer prevention, particularly in hypopigmented skin or in chronic discoid lesions, where the risk of skin cancer development may be higher. Cancer prevention is also essential for patients who are on immunosuppressive therapy. Lastly, it has been reported that sun exposure can exacerbate systemic disease in patients who have SLE. Therefore, there are a variety of reasons why sun protection should be emphasized, even in persons whose skin lesions are not induced or exacerbated by sun exposure.

Sunscreens should be applied to exposed skin daily, and more often if sun sensitivity is great or sun exposure is intense or prolonged. Broad-spectrum, high-SPF sunscreens are preferred (see Ch. 132). In some cases, the addition of a physical sunblock such as titanium dioxide or zinc oxide is useful. Protective clothing is important to emphasize, as the proper protective clothing is often significantly more effective than sunscreens. Sun avoidance is even more effective than protective chemicals and clothing. Midday sun is particularly high in UVB, a spectrum of UV radiation to which many patients are susceptible. It is more difficult to minimize UVA exposure, as UVA is present in substantial quantities throughout the day and can penetrate some types of window glass. Education on the optimal use of sunscreens and protective clothing and effective approaches to sun avoidance is important for most patients with lupus. Careful attention should be given to vitamin D and calcium intake.

For some patients, cosmetic cover-up is the most helpful therapeutic intervention (see Ch. 153). Particularly in situations where the disease activity has subsided but dyspigmentation remains, cosmetic camouflage of the hyperpigmentation or hypopigmentation may be the best approach.

Dermatomyositis 42

Joseph L Jorizzo and Ruth Ann Vleugels

Synonyms: ■ Dermatomyositis/polymyositis ■ Idiopathic inflammatory myopathies ■ Idiopathic inflammatory dermatomyopathies

Key features

- Autoimmune connective tissue disease of uncertain etiology demonstrating a bimodal age distribution with both juvenile and adult forms
- Clinical and laboratory signs of proximal extensor inflammatory myopathy
- Distinctive, photodistributed, pink–violet poikiloderma favoring the scalp, periocular region, and extensor surfaces, in addition to nail fold telangiectasias
- Histopathologic evidence of interface dermatitis with mucin in skin biopsy specimens and lymphocytic myositis in biopsy specimens from affected muscle
- Therapy includes systemic corticosteroids and possibly immunosuppressive drugs with the prognosis being very good, except for adults with associated advanced malignancy, refractory myositis or systemic involvement

INTRODUCTION

Along with polymyositis and inclusion body myositis, dermatomyositis is classified as one of the idiopathic inflammatory myopathies. Dermatomyositis is a disease of presumed autoimmune pathogenesis that presents with a symmetric, proximal extensor inflammatory myopathy and a characteristic cutaneous eruption. Previously, polymyositis was thought to represent the same disease process, but just limited to the muscle. However, there is now increasing evidence that the pathogenetic mechanisms of polymyositis and dermatomyositis differ significantly. In polymyositis, clonally expanded, autoreactive $CD8^+$ T cells invade myocytes expressing MHC class I antigens and cause necrosis via the perforin pathway. In contrast, there are data to support the theory that autoantigens activate a humoral immune process in dermatomyositis, in which complement is deposited in capillaries causing capillary necrosis and ischemia[1]. Because an appreciation of these pathogenetic differences occurred rather recently, previous studies often pooled cases of dermatomyositis and polymyositis, making interpretation of their data challenging.

Both dermatomyositis and polymyositis can occur in association with other autoimmune connective tissue diseases, including overlap syndromes with additional features of lupus erythematosus (LE), scleroderma, Sjögren's syndrome, rheumatoid arthritis, and mixed connective tissue disease. Dermatomyositis is characterized by a bimodal age distribution, with up to one-quarter of patients in the adult group having an associated occult malignancy. Patients with juvenile dermatomyositis do not have an increased risk of malignancy but do have an increased incidence of calcinosis cutis and associated small vessel vasculitis. There is a subset of patients in whom the cutaneous manifestations of dermatomyositis exist without objective evidence of muscle inflammation, referred to as amyopathic dermatomyositis, and formally known as dermatomyositis sine myositis. For dermatologists, establishing the diagnosis of dermatomyositis is important because it is a serious, treatable, multisystem disease that has a different prognosis and treatment approach from LE. The malignancy association in adults provides the dermatologist with an opportunity to assist medical colleagues in detecting the tumor at an early stage because the skin disease often precedes the onset of symptoms related to the malignancy. The diagnosis is commonly missed, which gives the dermatologist an opportunity to make a very meaningful contribution.

The treatment of dermatomyositis with muscle and/or systemic involvement requires systemic corticosteroids (e.g. prednisone 1 mg/kg/day) with a taper that is slower than in the treatment of systemic LE. If this approach is used, as many as three-quarters of patients may enter a clinically disease-free period without medication, usually within 2–3 years[2].

HISTORY

Polymyositis and dermatomyositis have been recognized as clinical entities for more than 100 years. Although the first adult patients with dermatomyositis and malignancy were described early in the twentieth century, a causal association was not suggested until the 1940s. A major step forward in the understanding of these disorders occurred in 1975, when Bohan and Peter proposed generally accepted clinical criteria for their diagnosis[3,4]. Over the past 15 years, it has become more widely accepted that a subset of patients has skin-limited disease (i.e. amyopathic dermatomyositis). For this reason, Sontheimer[5] has proposed a revised classification of the idiopathic inflammatory myopathies that includes amyopathic forms of dermatomyositis, with muscle involvement no longer required for a definitive diagnosis (Table 42.1).

EPIDEMIOLOGY

Dermatomyositis and polymyositis are relatively rare diseases that occur throughout the world. In adults, both dermatomyositis and polymyositis affect women two to three times more often than men. The incidence of dermatomyositis ranges from 2 to 9 per million amongst various populations[7–9] and seems to be increasing, although this may simply be a result of increased detection, as well as better diagnosis and reporting. Table 42.2 summarizes the findings in four recent studies[9–12].

PATHOGENESIS

Dermatomyositis is believed to result from an immune-mediated process triggered by outside factors (e.g. malignancy, drugs, infectious agents) in genetically predisposed individuals. Table 42.3 illustrates some of the evidence that supports this theory[13–33]. Serum antinuclear autoantibodies are often present, as are other myositis-specific autoantibodies, as summarized in Table 42.4[34,35]. The antisynthetase antibodies are directed against cytoplasmic antigens; therefore the antinuclear antibody test may even be negative. Patients with antisynthetase antibodies often have overlap syndromes. The term antisynthetase syndrome has been coined to refer to patients with these autoantibodies,

fever, erosive polyarthritis, "mechanic's hands", Raynaud's phenomenon, and interstitial lung disease[36].

CLINICAL FEATURES

Cutaneous Disease

The most important diagnostic feature of the cutaneous eruption of dermatomyositis is poikiloderma. This feature occurs both in patients with dermatomyositis, where it is characterized by a pink–violet color, and in patients with lupus erythematosus, where the poikiloderma is red. Poikiloderma includes features of hyperpigmentation, hypopigmentation, telangiectasias and epidermal atrophy, and these features are common to both diseases. If the clinician misses the poikiloderma, the eruption of dermatomyositis may occasionally be misdiagnosed as psoriasis because some lesions can present as well-marginated plaques on the elbows and knees and be covered with fine silvery scale.

Additional clinical clues to the diagnosis of dermatomyositis are a photodistribution and nail fold changes. Photodistributed poikiloderma involving the "V" of the chest and the upper back is often referred to as the "shawl sign". Cuticular dystrophy (i.e. "ragged" cuticles) is quite characteristic, as are nail fold telangiectasias (Fig. 42.1). If the photodistribution and nail fold changes are missed, the eruption may be misdiagnosed as other conditions characterized by poikiloderma, such as cutaneous T-cell lymphoma. Often, the dermatologist correctly notices the photodistribution but thinks first of a photodrug eruption

REVISED CLASSIFICATION SYSTEM FOR THE IDIOPATHIC INFLAMMATORY DERMATOMYOPATHIES
Dermatomyositis
Adult-onset
Classic DM
Classic DM with malignancy
Classic DM as part of an overlapping connective tissue disorder
Clinically amyopathic DM*
Amyopathic DM
Hypomyopathic DM
Juvenile-onset
Classic DM
Clinically amyopathic DM
Amyopathic DM
Hypomyopathic DM
Polymyositis
Isolated polymyositis
Polymyositis as part of an overlapping connective tissue disorder
Polymyositis associated with internal malignancy (?)†
Inclusion body myositis

*Both adult-onset and juvenile-onset amyopathic DM and hypomyopathic DM can be further subcategorized as "provisional" and "confirmed" when patients have biopsy-confirmed hallmark cutaneous manifestations of DM without muscle weakness and with normal muscle enzymes for ≥6 months (provisional) or 24 months (confirmed).
†Although more recent population-based studies have clearly confirmed that adult-onset classic DM is associated with a significant risk for internal malignancy, these same studies have questioned whether such a relationship exists for polymyositis.

Table 42.1 Revised classification system for the idiopathic inflammatory dermatomyopathies. This classification scheme recognizes, with equal weighting, the cutaneous and muscle manifestations of this group of disorders. Adapted from ref. 6

PATHOGENESIS OF DERMATOMYOSITIS
GENETICS[13–15]
• Monozygotic twins affected • Associated human leukocyte antigens (HLA) – HLA-DR3 and -B8 (juvenile dermatomyositis) – HLA-DR52 (patients with anti-Jo-1 antibodies) – HLA-DR7 and -DRw53 (patients with anti-Mi-2 antibodies) – HLA-B14 and -B40 (adults with dermatomyositis overlap) – HLA-DRB1*15021 (Japanese with juvenile dermatomyositis) • TNF-α 308A allele polymorphism
CELLULAR IMMUNITY/APOPTOSIS[16–22]
• Histopathologic findings in skin and muscle ($CD8^+$ lymphocytes) • Lymphocyte-mediated experimental myositis in mice • Increased Ki-67 and p53 expression in keratinocytes after UVB irradiation • Increased CD40 expression on muscle cells • Decreased circulating CD54 (ICAM-1)-positive lymphocytes • Fas ligand on T cells and Fas receptor on muscle cells • MHC class I overexpressed in affected muscle tissues • Elevated expression of COX-1, COX-2 and 5-LOX mRNA in affected muscle tissues
HUMORAL IMMUNITY[23]
• Association with autoimmune diseases (Hashimoto's thyroiditis, Graves' disease, myasthenia gravis, type I diabetes mellitus, primary biliary cirrhosis, dermatitis herpetiformis, vitiligo, and other autoimmune connective tissue diseases) • Myositis-specific antibodies versus antibodies against aminoacyl-tRNA synthetases, non-synthetases, cytoplasmic antigens, and nuclear antigens. Examples include: antisynthetase, anti-Jo-1 (lung disease) and anti-Mi-2 (most specific for dermatomyositis)
INFECTIOUS PRECIPITANTS[24,25]
• Seasonal variation • Picornavirus substrate for aminoacyl-tRNA synthetases • *Escherichia coli*, muscle protein and a capsid protein of a picornavirus that induces mouse myositis all have some homology in amino acid sequences with Jo-1 • Echovirus infection in patients with hypogammaglobulinemia • Coxsackievirus-9 myositis • AIDS myositis
DRUG AND VACCINE PRECIPITANTS[26–31]
• Hydroxyurea, D-penicillamine, TNF-α inhibitors, nonsteroidal anti-inflammatory drugs, lipid-lowering drugs (statins > gemfibrozil), cyclophosphamide, BCG vaccine; single case reports of phenytoin, alfuzosin (α-agonist for BPH), omeprazole, ipecac (repeated exposures), interferon-α-2b, tegafur, etoposide, articaine, sulfacetamide sodium ophthalmic drops
MALIGNANCY ASSOCIATION (ADULTS)[32,33]

Table 42.3 Pathogenesis of dermatomyositis. BCG, Bacillus Calmette-Guérin; BPH, benign prostatic hyperplasia; ICAM, intercellular adhesion molecule; TNF, tumor necrosis factor.

CLINICAL SUBTYPES OF DERMATOMYOSITIS – DEMOGRAPHICS AND ASSOCIATED FINDINGS				
	Clinical subtype			
	Adult-onset classic dermatomyositis[9]	Adult-onset clinically amyopathic dermatomyositis[10]	Juvenile-onset classic dermatomyositis[11]	Juvenile-onset clinically amyopathic dermatomyositis[12]
No. of patients	20	291	120	38
Mean age (years)	51.9	50	7.7	10.5
Malignancy detected	6/20 (30%)	41/291 (14%)	0/120 (0%)	0/38 (0%)
Sex ratio (F:M)	3:1	3:1	2.2:1	3:2

Table 42.2 Clinical subtypes of dermatomyositis – demographics and associated findings.

SERUM AUTOANTIBODIES IN ADULT AND JUVENILE DERMATOMYOSITIS				
Autoantibodies	**Target antigen function**	**Clinical phenotype**	**Autoantibody frequency, %**	
			Adult DM	**Juvenile DM**
Anti-aminoacyl-tRNA synthetases (e.g. anti-Jo-1 [histidyl], anti-PL-7 [threonyl]; see Ch. 40)	Intracytoplasmic protein synthesis	Antisynthetase syndrome (myositis, mechanic's hands, Gottron's papules, arthritis, fever, Raynaud's phenomenon, high frequency of interstitial lung disease)	up to 20%	1–3
Anti-SRP	Protein translocation	Acute-onset necrotizing myopathy (severe weakness, high CK); may be refractory to treatment	5	<1
Anti-Mi-2	Helicase – transcription	Adult DM and juvenile DM (hallmark is cutaneous disease, milder muscle disease with good response to treatment)	15	<10
Anti-p155/140	See Ch. 40	Cancer-associated myositis in adult DM; severe cutaneous disease in adult DM and juvenile DM	80 (amyo); 20–30 (classic)	~25
Anti-p140	Likely NXP-2 – nuclear transcription, RNA metabolism	Juvenile DM with calcinosis	NA	~25
Anti-SAE	Post-translational modification	Adult DM; may present with clinically amyopathic DM	NA	NA
Anti-CADM-140 (MDA5)	Innate immunity	Clinically amyopathic DM; rapidly progressive interstitial lung disease	10–15	NA

Table 42.4 Serum autoantibodies in adult and juvenile dermatomyositis (DM). The autoantigen CADM-140 was subsequently found to be identical to two previously identified gene products, interferon induced with helicase C domain protein 1 (IFIH1) and melanoma differentiation-associated gene 5 (MDA5). CADM, cancer-associated dermatomyositis; CK, creatine kinase; NA, not applicable; NXP-2, nuclear matrix protein NXP2; SAE, small ubiquitin-like modifier activating enzyme; SRP, signal recognition particle. *Adapted from ref. 35.*

Fig. 42.1 Dermatomyositis – cuticular dystrophy and nail fold telangiectasias. The cuticles are "ragged" and within the proximal nail fold, dilated capillary loops alternate with vessel dropout (insert). Atrophy, telangiectasias and hypopigmentation are present on the fingers. *Courtesy, Julie V Schaffer, MD.*

or lupus erythematosus and does not include dermatomyositis in the differential diagnosis.

The features that are most characteristic, and that distinguish dermatomyositis from lupus erythematosus, are the violaceous hue of the poikiloderma and the tendency of lesions to be distributed around the eyes (the heliotrope sign) and on extensor surfaces. However, the heliotrope sign can be quite subtle, with only mild erythema of the eyelids, and it may wax and wane over time. Associated periorbital edema can range from mild to marked (Fig. 42.2). In addition, a more diffuse facial erythema, or even malar erythema, is often present (see Fig. 42.12).

The cutaneous lesions of dermatomyositis are accentuated on extensor surfaces, including the knuckles. When lesions on the knuckles develop a secondary lichenoid quality, they are termed Gottron's papules (Fig. 42.3); violaceous discoloration of the knuckles, elbows and/or knees is known as Gottron's sign (Fig. 42.4). Calcinosis cutis is more prevalent in juvenile dermatomyositis, affecting between 25% and 70% of patients[7,37]. The cutaneous lesions of dermatomyositis are often pruritic (Fig. 42.5), and this can significantly affect the patients' quality of life[38–40]. Of note, pruritus is a feature that can occasionally help distinguish dermatomyositis from LE.

Additional manifestations range from poikiloderma of the scalp to centripetal flagellate erythema (Fig. 42.6A) to erosions and ulcerations (Fig. 42.6B; Table 42.5)[41–43]. It is also important to look for dermatologic signs of other connective tissue diseases in patients with dermatomyositis, because of the frequency of overlap syndromes. The most common cutaneous findings would be signs of overlap with systemic sclerosis, especially limited disease with CREST features (*c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, *t*elangiectasias), annular lesions suggestive of subacute cutaneous lupus erythematosus, or nodules suggestive of rheumatoid arthritis. Cutaneous small vessel vasculitis can occur as an associated finding, especially in patients with juvenile dermatomyositis.

It is important to understand that patients may present with classic cutaneous manifestations of dermatomyositis but no muscle disease. Careful patient evaluation and longitudinal assessment will demonstrate that some of these patients have skin disease alone (amyopathic dermatomyositis) while others eventually evolve into full-blown dermatomyositis (with muscle disease) or they develop hypomyopathic dermatomyositis, i.e. no muscle weakness clinically, but myositis by

Fig. 42.2 Dermatomyositis – eyelid edema and heliotrope sign. **A** Inflammation of the upper eyelid can be more subtle in darkly pigmented skin; note involvement of the lateral nasal root and the cheeks. **B** The characteristic pink–violet color is seen with involvement of the hairline, lower forehead, upper eyelids and cheeks; the edema is striking and involves the nasal root as well as the eyelids. *B, Courtesy, Jean L Bolognia, MD.*

Fig. 42.3 Dermatomyositis – Gottron's papules. **A** The flat-topped (lichenoid) papules overlying the proximal interphalangeal (IP) and metacarpophalangeal (MCP) joints are subtle and were misdiagnosed as verrucae vulgaris in this child. **B** Obvious accentuation of skin lesions over the MCP joints, with coalescence of pink–violet lichenoid papules. **C** Papulosquamous plaques with a somewhat linear configuration proximally; clues against psoriasis are the Gottron's papules of the distal IP joints, cuticular dystrophy and nail fold telangiectasias. *A, B, Courtesy, Julie V Schaffer, MD.*

radiographic or laboratory testing[44]. The clinical characteristics of patients with classic dermatomyositis and with amyopathic dermatomyositis have recently been reviewed[10], in particular with respect to differences in malignancy risk. Although it has generally been thought that the malignancy risk is greater in the setting of classic dermatomyositis, there have been several case series that have observed associated malignancies in patients with amyopathic dermatomyositis, even in those who remain muscle disease-free for years and therefore can be considered confirmed cases of amyopathic disease. Fulminant lung disease has also been reported in patients with amyopathic dermatomyositis. Therefore, both malignancy screening and evaluation for systemic involvement are recommended, irrespective of muscle involvement.

Systemic Disease

Patients with dermatomyositis usually present with complaints of malaise and loss of energy. The dermatologic manifestations precede the onset of objective muscle disease in most patients; however, when the muscle disease begins, it is indistinguishable clinically from that seen in patients with polymyositis. The myopathy affects proximal muscle groups, especially the extensor groups (triceps and quadriceps), in a symmetric fashion. In advanced disease, all muscle groups can be affected. Patients may be unable to complete simple tasks such as combing their hair or rising to their feet from a sitting position. The affected muscle groups are often tender to palpation in more advanced disease. Muscle strength should be graded on sequential visits by

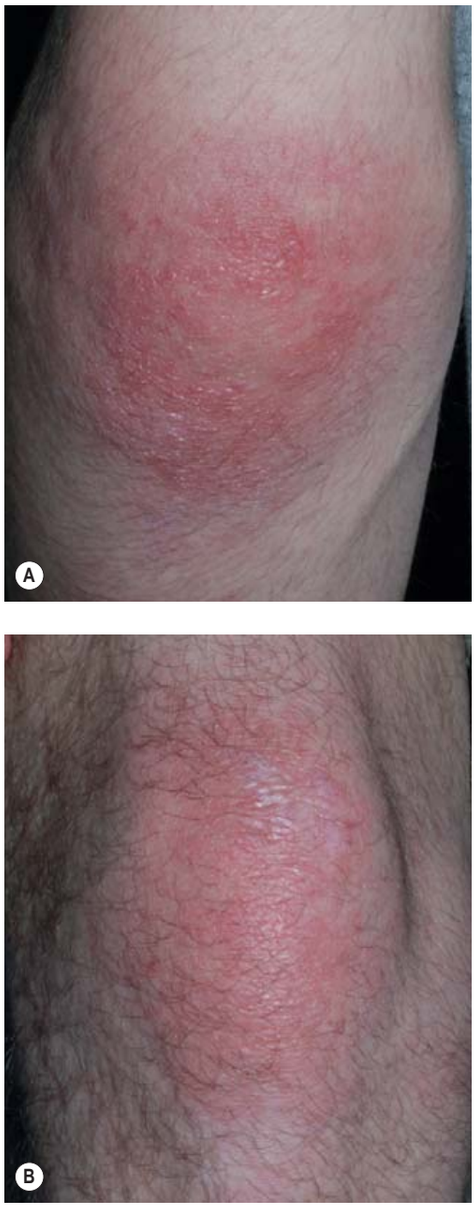

Fig. 42.4 Dermatomyositis – Gottron's sign. Thin pink papules and plaques of the elbow (**A**) and knee (**B**). Some of the papules on the elbow are flat-topped (lichenoid). *Courtesy, Julie V Schaffer, MD.*

Fig. 42.5 Dermatomyositis – involvement of the upper back. The pink–violet plaques, some with associated scale, were very pruritic, as evidenced by multiple excoriations. Linear streaks of erythema are also seen. *Courtesy, Jean L Bolognia, MD.*

muscle groups (e.g. right and left triceps 3/5, right and left quadriceps 4/5, etc.), although other more formal methods of quantification, such as the use of a hand-held pull gauge, have been described[45]. Symptoms of true dysphagia should prompt investigation for overlap with scleroderma, although patients with advanced muscle disease can have cricopharyngeal muscle dysfunction and consequently difficulty initiating swallowing. Distal esophageal involvement can present as gastroesophageal reflux disease.

Calcinosis is more common in patients with juvenile dermatomyositis than in adults and is most often associated with a delay in the institution of systemic corticosteroids or with advanced, therapy-resistant disease. In addition to calcinosis cutis, deposits may occur in the deep fascia and in intramuscular connective tissue. Lesions occur as hard, irregular nodules, which on occasion drain a chalky material via fistulae to the surface. Calcinosis cutis favors sites of trauma, such as the elbows, knees and fingers, but can occur anywhere. The lesions may be painful and can complicate return to normal function.

Pulmonary disease occurs in approximately 15–30% of patients with dermatomyositis, and generally presents as a diffuse interstitial fibrosis that is similar to that seen in patients with rheumatoid arthritis or scleroderma[46]. A recent study suggested that lung disease may be present in as many as 65% of patients[47]; however, this conclusion was based on a small series of patients (n = 17) and methodologic issues were raised[48]. Pulmonary involvement is a particular feature of the antisynthetase syndrome[36]. Patients may also develop acute respiratory distress syndrome (ARDS). Because this disease is resistant to corticosteroid therapy, it follows a course independent from that of the muscle disease and can adversely affect prognosis in much the same way as in patients with mixed connective tissue disease.

Cardiac disease is not commonly symptomatic. When it is, it usually presents as arrhythmias or as conduction defects[49]. Patients with dermatomyositis are often not thoroughly evaluated for possible cardiac disease, and prompt treatment of the muscle disease may mask the true frequency of cardiac disease. In one retrospective review, cardiac involvement was shown to be the major prognostic factor for death in patients with dermatomyositis (not associated with an underlying malignancy)[50]. Additional reported indicators of poor prognosis (other than malignancy) include older age, progressive disease, initiation of therapy after 24 months of muscle weakness, longer duration of symptoms before diagnosis, pulmonary disease, dysphagia, and extensive cutaneous involvement of the trunk[51].

For the patient with dermatomyositis, a thorough review of systems should include a discussion of arthritis, renal disease, gastrointestinal disease, pulmonary disease, cardiac disease, and other manifestations such as neuropathy and Raynaud's phenomenon. Their presence may suggest systemic involvement and/or overlap with other connective tissue diseases – in particular, systemic LE, rheumatoid arthritis and scleroderma. One dermatology-based case series observed a 19% overlap rate in adult patients with dermatomyositis[2].

Malignancy

The reported frequency of an internal malignancy in adults with dermatomyositis varies from less than 10% to over 50%. The malignancy association occurs with adult dermatomyositis, but not with the juvenile form or with polymyositis. Patients with amyopathic dermatomyositis also appear to be at increased risk for an associated malignancy. A disproportionate number of the associated malignancies are carcinomas. Genitourinary malignancies, especially ovarian cancer, and colon cancer may be overrepresented[52,53]; in some Southeast Asian

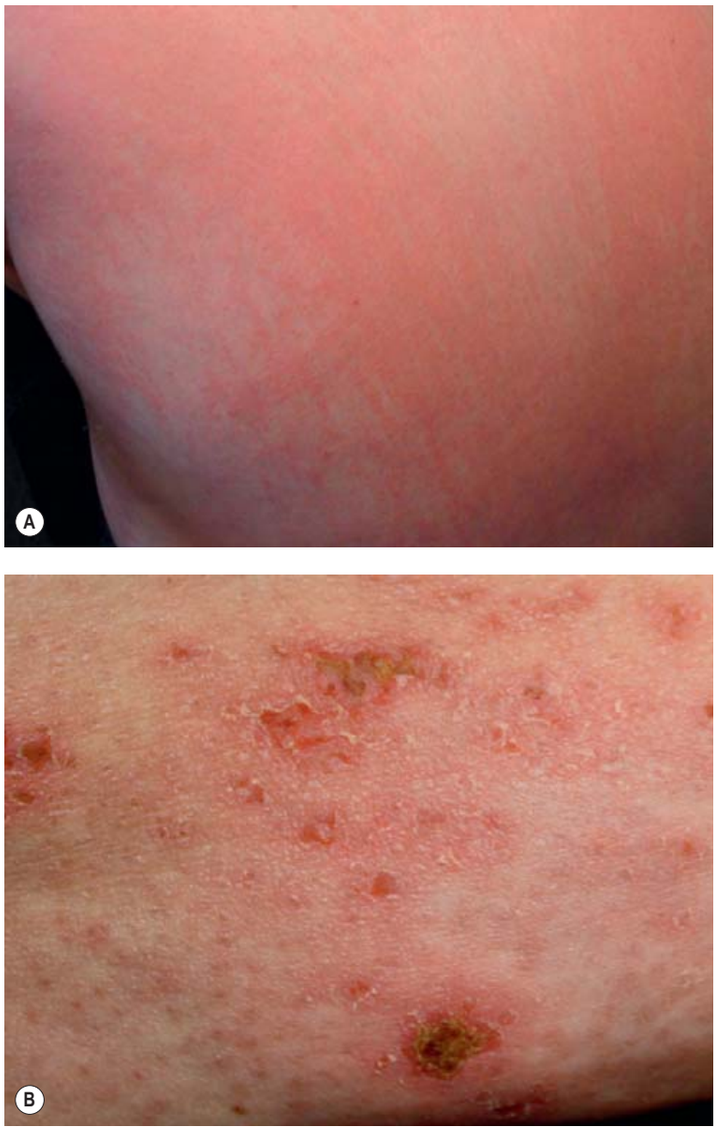

Fig. 42.6 Dermatomyositis – less common presentations. A Flagellate erythema of the posterior trunk. **B** Secondary changes with the lesions include scale, erosions and serous as well as hemorrhagic crusts.

populations, nasopharyngeal carcinoma is overrepresented[54]. Other commonly seen malignancies include breast, lung, gastric, pancreatic, lymphomas (including non-Hodgkin), and other female genital cancers[53,55]. The risk of malignancy may return to normal after 2–5 years[33,53,56]. Callen has suggested that the best approach to patient management in this setting is ongoing vigilance with frequent and thorough medical histories, repeated review of systems, complete physical examinations, and screening laboratory tests.[57] More recently, he has advocated additional investigations, including CT of the chest, abdomen and pelvis, in the malignancy assessment (Table 42.6)[56]. With regard to long-term survival, as expected, patients with cancer-associated inflammatory myopathy (including dermatomyositis) have an inferior survival curve when compared to patients with juvenile or non-cancer-associated adult myopathies[50].

CUTANEOUS MANIFESTATIONS OF DERMATOMYOSITIS

Common	Uncommon
Heliotrope sign (Fig. 42.2)	Cutaneous erosions or ulcerations (Fig. 42.6B)
Eyelid edema (Fig. 42.2)	Holster sign (poikiloderma of the lateral thighs)
Gottron's papules (Fig. 42.3)	Flagellate erythema (Fig. 42.6A)
Gottron's sign (Fig. 42.4)	Vesicobullous lesions
Photodistributed poikiloderma (includes facial erythema, shawl sign) (Fig. 42.12)	Exfoliative erythroderma
Scalp poikiloderma (see Fig. 13.3)	Panniculitis
Non-scarring alopecia	Gingival telangiectasias
Nail fold changes (includes ragged cuticles, nail fold telangiectasias*) (Fig. 42.1)	Pustular eruption of the elbows and knees
Calcinosis cutis (especially in juvenile dermatomyositis)	Lipoatrophy (especially in juvenile dermatomyositis)
	Small vessel vasculitis (especially in juvenile dermatomyositis)

*Dilated capillary loops alternating with vessel dropout.

Table 42.5 Cutaneous manifestations of dermatomyositis.

EVALUATION OF THE PATIENT WITH DERMATOMYOSITIS

- History, including potential triggers (see Table 42.3) and previous malignancies, and a review of systems
- Physical examination – skin, muscle and complete general examination (including, in adults, breast and pelvic* [women], testicular and prostate [men], and rectal [both sexes]); in Southeast-Asian patients, consider full ENT examination
- Laboratory evaluation

• ***Cutaneous –***	Skin biopsy(ies)
• ***Muscle –***	• Serum creatine kinase, serum aldolase, occasionally urine creatine†
	• Electromyography (EMG); muscle biopsy; MRI or U/S (if EMG or muscle biopsy are negative or declined; increasingly, MRI is being done in lieu of EMG and muscle biopsy, if classic cutaneous findings and consistent histology)
• ***Pulmonary –***	• Pulmonary function tests (PFTs) with CO diffusion
	• Chest X-ray and/or high-resolution chest CT
• ***Cardiac –***	• Electrocardiogram (EKG)
	• If symptomatic, echocardiogram and/or Holter monitor
• ***Esophageal –***	• If symptoms, barium swallow
• ***General –***	Complete blood count, comprehensive metabolic panel with fasting levels of glucose and lipids‡, autoantibody panel
• ***Malignancy screen (adults)***§,¶	• Urinalysis, stool occult blood testing
	• Serum prostate-specific antigen (PSA) [men]
	• Serum CA125 [women]
	• Mammogram and transvaginal pelvic U/S [women]
	• CT of chest, abdomen and pelvis
	• Colonoscopy, if age-appropriate, iron deficiency anemia, occult blood in stool, or symptoms
	• Upper endoscopy – if colonoscopy negative in the setting of iron deficiency anemia, occult blood in stool, or symptoms
• If planning chronic systemic corticosteroids	DEXA bone density scan (see Ch. 125)

*Includes Papanicolaou smear.
†Aspartate transaminase (AST), alanine transaminase (ALT), and lactic dehydrogenase (LDH) may also be elevated due to myositis.
‡Fasting levels of glucose and lipids are important in children.
§Malignancy screening should be performed at the time of diagnosis and annually for a minimum of 3 years thereafter; history and physical examination can be performed more frequently.
¶Can also consider serum protein and immunofixation electrophoreses.

Table 42.6 Evaluation of the patient with dermatomyositis. CO, carbon monoxide; CT, computerized tomography; DEXA, dual energy x-ray absorptiometry; ENT, ear, nose and throat; MRI, magnetic resonance imaging; U/S, ultrasound.

PATHOLOGY

The characteristic changes seen in skin biopsy specimens from patients with dermatomyositis can be very subtle (Fig. 42.7) and include epidermal atrophy, basement membrane degeneration, vacuolar alteration of basal keratinocytes, and dermal changes consisting of interstitial mucin deposition and a sparse lymphocytic infiltrate. In some cases, a colloidal iron stain may help to highlight the presence of mucin. The histopathologic changes may be indistinguishable from those seen in specimens from patients with poikilodermatous lesions of LE. Gottron's papules show a lichenoid infiltrate but have acanthosis rather than epidermal atrophy[58].

Muscle biopsy specimens also show characteristic changes. The combination of type II muscle fiber atrophy, necrosis, regeneration, and hypertrophy with centralized sarcolemmal nuclei, plus lymphocytes in both a perifascicular and a perivascular distribution, is classic[59]. It is best for the clinician to request that the surgeon sample triceps muscle rather than the usually biopsied deltoid muscle because the latter is often spared until late in the disease. Another option, especially for patients with mild involvement, is to choose the biopsy site based upon MRI findings (see below).

DIFFERENTIAL DIAGNOSIS AND EVALUATION

Although a detailed differential diagnosis of the patient who presents with proximal muscle weakness in the absence of skin lesions (i.e. the differential diagnosis of polymyositis) is beyond the scope of this dermatologic review, it is the subject of a recent textbook[60]. Two validated instruments, the Dermatomyositis Skin Severity Index (DSSI) and the updated Cutaneous Dermatomyositis Disease Area and Severity Index (CDASI), can be used to classify the severity of the cutaneous disease of dermatomyositis. These indices should be helpful in assessing therapeutic responses in future clinical trials[61,62].

The patient with a characteristic cutaneous eruption should have a skin biopsy performed to confirm the clinical impression of dermatomyositis (Fig. 42.8). Once the presumed diagnosis is confirmed histopathologically, then a search for muscle and/or associated systemic disease must begin, because it is their presence or absence that dictates therapeutic decisions (see Table 42.6). The evaluation for myositis can include: strength testing of proximal extensor muscles and other muscles, serum levels of muscle enzymes, an electromyogram, and/or triceps muscle biopsy. However, increasingly, an MRI (Figs 42.9 & 42.10) or ultrasound (Fig. 42.11) of proximal muscles is obtained prior to, or in lieu of, a muscle biopsy; the latter applies especially to patients with classic cutaneous lesions (both clinically and histologically).

Patients with normal muscle enzyme levels should be followed at regular intervals because these patients can have occult muscle disease, evolve into classic dermatomyositis, or remain as amyopathic dermatomyositis[44]. Additional baseline investigations for pulmonary disease (often predicted by anti-Jo-1 antibodies; see Table 42.6), for cardiac disease, for symptomatic esophageal disease (barium swallow or manometry) and for features of overlap connective tissue disease should be performed at this stage, prior to the institution of systemic therapy unless immediate therapy is warranted to halt rapidly progressive disease. Adult patients should have screening for occult malignancy annually for at least 2–3 years, or more frequently based upon symptoms. A detailed history, review of symptoms, and complete physical examination should be performed at regular intervals of 4–6 months. Adult patients with amyopathic dermatomyositis should have similar evaluations for malignancy and associated systemic disease.

The classic muscle enzymes that should be assessed at baseline and at regular intervals throughout the treatment period are creatine kinase (CK) and aldolase. Aspartate and alanine transaminases and lactate dehydrogenase are often elevated as well, since they also are released from damaged muscle tissue. It has been estimated that 95% of patients with dermatomyositis have an elevated CK at some point during their

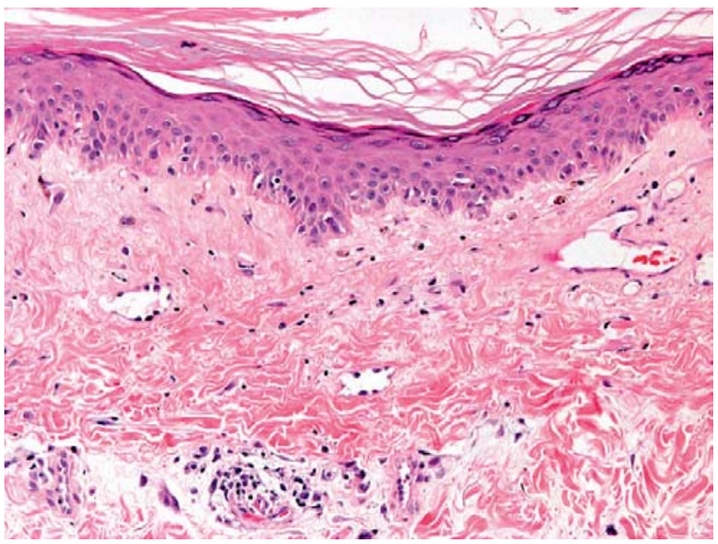

Fig. 42.7 Dermatomyositis – histopathologic features. The vacuolar changes within the basal layer can be subtle. In the dermis, dilated blood vessels and a sparse lymphocytic infiltrate are seen (poikilodermatous changes). *Courtesy, Lorenzo Cerroni, MD.*

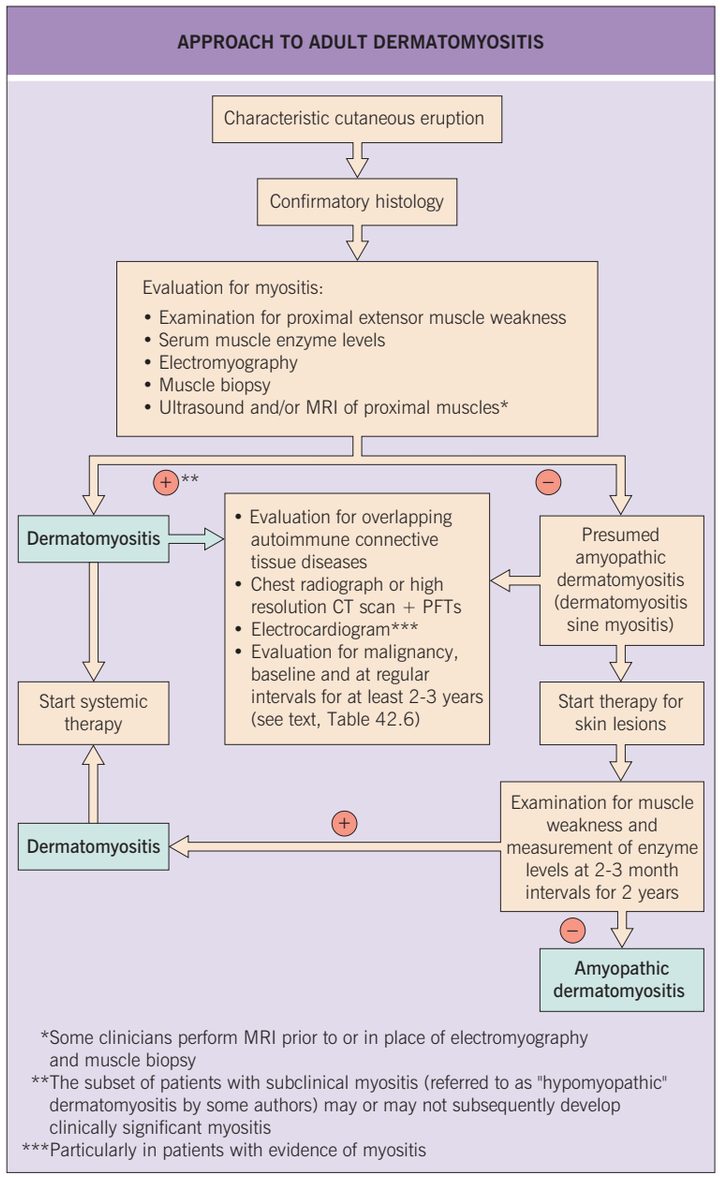

Fig. 42.8 Approach to adult dermatomyositis. The approach for children is similar but without the malignancy evaluation. Some authors classify patients with no evidence of myositis ≥6 months after the onset of skin disease as having amyopathic dermatomyositis, but such individuals may go on to develop muscle disease. PFTs, pulmonary function tests.

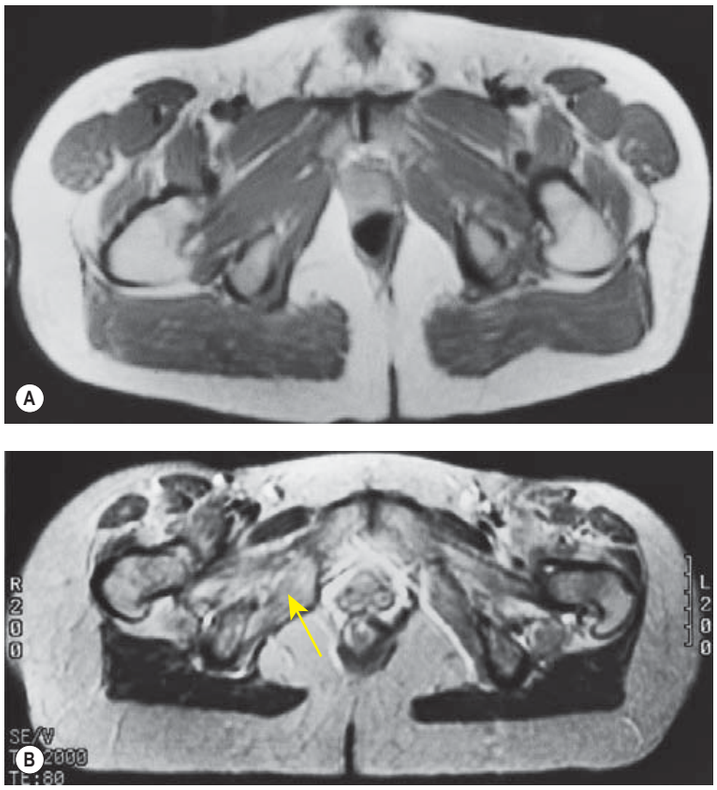

Fig. 42.9 T2-weighted MR images of the pelvic region. A In a normal control patient. **B** In a patient with dermatomyositis. This shows increased signal intensity (white color; arrow) diffusely in multiple muscle groups. The increased signal correlates with inflammation.

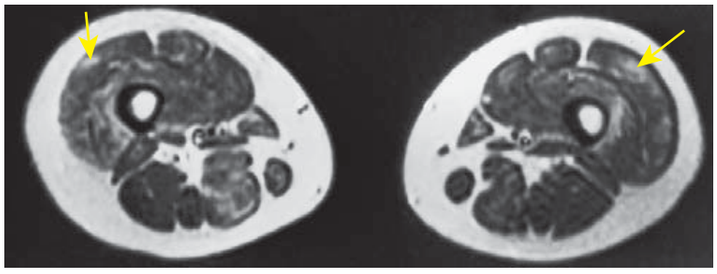

Fig. 42.10 T2-weighted MR images of the proximal thigh in a patient with dermatomyositis. Note the increased signal density, primarily in the extensor muscles (white color, arrows). The increased signal correlates with inflammation.

illness[8]. Urine creatine is elevated in some patients who have a normal serum CK, but this test is not routinely performed. Myoglobin, another protein released by damaged muscle, can be detected in the serum even in patients with mild muscle disease. Its detection in urine is a cause for concern, and, rarely, severe myoglobinuria can result in acute renal failure.

Electromyography (EMG) is a sensitive but nonspecific test in patients with dermatomyositis. Over 90% of patients have abnormal EMG results. The combination of an abnormal electromyogram with classic cutaneous lesions (clinically and histologically) makes the diagnosis of dermatomyositis very likely. EMG findings are less helpful in patients with polymyositis because there is overlap with other myopathies in the differential diagnosis[63].

In the absence of classic cutaneous lesions, the muscle biopsy is a very important test for confirming the diagnosis and excluding other inflammatory myopathies. Surgeons will usually biopsy the deltoid muscle for convenience, but this muscle is relatively spared until late in the disease; therefore, the surgeon should be directed to perform a triceps muscle biopsy.

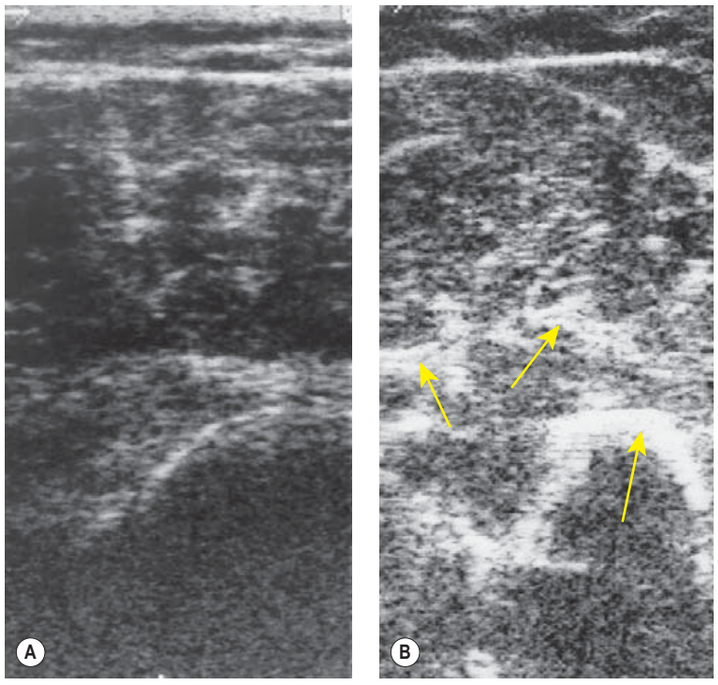

Fig. 42.11 Ultrasound images of the triceps muscle. A Cross-sectional ultrasound image from normal (control) triceps muscle. **B** Ultrasound image from affected triceps muscle in a patient with dermatomyositis. An increase in interstitial echoes is seen (arrows).

MRI (see Figs 42.9 & 42.10) and ultrasound (see Fig. 42.11) of muscles are sensitive tests that can add greatly to patient evaluation. Both can be used to determine the appropriate site for a muscle biopsy[44]. Ultrasound is less expensive and easier to perform sequentially. MRI may be the most sensitive test for muscle disease, but it is more expensive[44,64]. Recent studies suggest that MRI might be useful in evaluating children for soft tissue changes that might precede calcinosis cutis[64].

The differential diagnosis of the dermatologic findings in dermatomyositis is summarized in Table 42.7.

TREATMENT

A therapeutic ladder for the treatment of patients with dermatomyositis is summarized in Table 42.8. As with many rare dermatologic diseases, double-blind, placebo-controlled trials are lacking. However, a dermatology-based case series supported the belief that a number of patients (75–85%) can become muscle disease-free, off treatment, after a period of 24–48 months, utilizing a slow corticosteroid taper[2]. Long-term follow-up of pediatric patients also confirmed this conclusion[65,66]. There is a clear discordance between response of the muscle disease to therapy and response of the skin disease[2]. Available therapy for the skin disease is clearly inadequate, with many patients exprienc-ing persistent cutaneous disease and pruritus, especially of the scalp, which can become a major complaint once the muscle disease is under control. Aggressive topical therapy and systemic therapy (e.g. antimalarials or weekly methotrexate) added specifically for the skin disease often do not provide adequate relief. It is clear however, that, except in adult patients with an advanced malignancy, the prognosis for corticosteroid-treated dermatomyositis in children and in adults is excellent, especially when compared with a mortality of up to 50% in the pre-corticosteroid era[66].

The treatment of dermatomyositis must take into account the discordance between the response of the muscle disease and that of the dermatologic disease to systemic therapy. The search for muscle involvement must be thorough, even in the patient with normal serum muscle enzymes. Two positive objective tests documenting muscle disease (e.g. EMG and muscle biopsy, or one of these plus MRI or muscle ultrasound) should trigger the initiation of systemic corticosteroid therapy in doses aimed at control of the muscle disease (i.e. generally prednisone 1 mg/kg/day). Patients with dermatologic

DIFFERENTIAL DIAGNOSIS OF DERMATOMYOSITIS
SYSTEMIC LUPUS ERYTHEMATOSUS
Physician might notice the nail fold telangiectasias and photodistributed poikiloderma but miss the muscle weakness, heliotrope, extensor distribution, pruritus, and the violaceous hue (true lupus erythematosus might be present in the setting of an overlap syndrome) (Fig. 42.12)
PSORIASIS
Involvement of elbows and knees with papulosquamous lesions can lead to misdiagnosis
AIRBORNE OR ALLERGIC CONTACT DERMATITIS
Eyelid edema can be marked in dermatomyositis; look for additional sites of dermatitis
PHOTODRUG ERUPTION
Photodistribution
CUTANEOUS T-CELL LYMPHOMA
The poikiloderma often begins in intertriginous zones rather than on the scalp, face and extensor surfaces
ATOPIC DERMATITIS
Usually in children, where the physician focuses on the pruritus and secondary lichenification
SCLERODERMA
The nail fold telangiectasias are similar in appearance, but the dyspigmentation is quite different; edema of the hands is an early sign (true scleroderma may be present in the setting of an overlap syndrome)
TRICHINOSIS
Patients have painful muscles and periorbital edema, but not other features
PHOTODISTRIBUTED FORM OF MULTICENTRIC RETICULOHISTIOCYTOSIS
Firm papules have distinct histologic features

Table 42.7 Differential diagnosis of dermatomyositis.

Fig. 42.12 Dermatomyositis. Misdiagnoses include psoriasis, contact dermatitis, and if there is significant facial involvement as in this patient, acute cutaneous lupus erythematosus.

THERAPEUTIC LADDER FOR DERMATOMYOSITIS	
SYSTEMIC THERAPY	
Oral prednisone:	1 mg/kg/day tapered to 50% over 6 months and to zero over 2–3 years (1) Option to use pulse, split-dose, or alternate-day (2)
Methotrexate:	5–20 mg weekly (2)
Azathioprine:	2–3 mg/kg/day (1)
Others:	High-dose IVIg (2 g/kg/month) (1)
	Pulse cyclophosphamide (0.5–1.0 g/m^2 monthly) (2)
	Chlorambucil (4 mg/day) (2)
	Cyclosporine (3–5 mg/kg/day) (2)
	Tacrolimus (0.12 mg/kg/day) (3)
	Mycophenolate mofetil (1 g twice daily) (2)
	Sirolimus (5 mg/day × 2 weeks, 2 mg/day × 2 weeks, then 1 mg/day) (3)
	Infliximab (5–10 mg/kg every 2 weeks initially) (3)
	Etanercept (3)†
	Rituximab (375 mg/m^2/infusion for 4 weekly infusions) (2)
	Fludarabine (3)
	Hematopoietic stem cell transplantation (3)
	Plasmapheresis (3)†
CUTANEOUS LESIONS	
Sunscreens (high sun protection factor including protection against UVA) (3) Topical corticosteroids (3) Topical tacrolimus (3) Hydroxychloroquine (200 mg twice daily; increased frequency of drug eruptions in patients with dermatomyositis) (2) Hydroxychloroquine (200 mg twice daily) plus quinacrine (100 mg/day) (3) Low-dose weekly methotrexate (5–15 mg weekly) (2) Mycophenolate mofetil (3) High-dose IVIg (2 g/kg/month) (1) Retinoids (3) Dapsone (3) Thalidomide (3) Leflunomide (3) Antiestrogens (e.g. tamoxifen, anastrazole) (3) TNF-α inhibitors (e.g. infliximab, etanercept) (3)* Rituximab (3) Tacrolimus (3)	
*Reported cause of drug-induced dermatomyositis. †Double-blind trial showed no benefit.	

Table 42.8 Therapeutic ladder for dermatomyositis. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

manifestations alone can be treated as described below, with repeated clinical muscle examination and enzyme screening (i.e. generally CK and aldolase) at 2–3-month intervals. If muscle disease is confirmed, then systemic corticosteroid therapy is initiated.

If CK and aldolase serum levels are minimally elevated and corticosteroid therapy is initiated early, the disease generally comes under control rapidly over 2–4 weeks and corticosteroids can be used as monotherapy with doses tapered to half the starting dose by 6 months. If the disease is advanced and enzyme levels are high (e.g. CK > 1000 U/1), the disease can be much more difficult to control, requiring pulse prednisone, split-dose prednisone in doses above 1 mg/kg/day, and/or initiation of a steroid-sparing agent such as low-dose weekly methotrexate at the onset. Again, an attempt is made to taper the prednisone to 0.5 mg/kg/day in a single morning dose by 6–8 months.

Attention to general health maintenance principles and osteoporosis prevention is a key element of patient management (see Ch. 125). This can be accomplished by joint longitudinal care with an internist or pediatrician. Adults also need frequent (e.g. every 4–6 months for at least 2–3 years) complete physical examinations for malignancy.

Children with juvenile dermatomyositis should be followed by a pediatrician comfortable with monitoring their developmental milestones while on immunosuppressive therapy (e.g. at least every 6 months). In addition, lipodystrophy and metabolic abnormalities, including hypertriglyceridemia and insulin resistance, have become increasingly recognized as potential complications of juvenile dermatomyositis[67,68].

There is support for steroid-sparing therapies (especially in the setting of severe or recalcitrant disease), including IVIg[69], methotrexate[70], chlorambucil[71], pulse cyclophosphamide[72,73], cyclosporine (also for lung disease)[74,75], fludarabine[76], mycophenolate mofetil[77,78], azathioprine[79], tacrolimus[80], siroliumus[81], infliximab[82], etanercept[83], rituximab[84] and hematopoietic stem cell transplantation[85]. A placebo-controlled study showed no benefit from plasmapheresis or leukapheresis in dermatomyositis[86]. In children with severe or refractory disease, IVIg is often administered[86a]. Adjunctive physical therapy is also very important in improving muscle strength and endurance[87]. Benefits of exercise and rehabilitation have been demonstrated, even in the course of active disease and without inducing flares of the myositis[88].

Dermatologic disease can be particularly challenging therapeutically, and not all patients clear their cutaneous manifestations when their muscle disease remits on systemic corticosteroids. Patients with dermatologic disease without active muscle disease are generally not treated with systemic corticosteroids as a mainstay of their therapy, and they often present a unique therapeutic challenge. As a result, the treatment of amyopathic dermatomyositis often differs significantly from the treatment of classic dermatomyositis in that systemic corticosteroids are not traditionally utilized.

For cutaneous disease, anecdotal reports and small case series support the use of topical corticosteroids (which are especially useful when there is lichenification due to chronic pruritus as a component of the illness), topical tacrolimus[89], antimalarial therapy[90,91] (either as monotherapy or in combination, which is less dramatic in its effect than when used for LE lesions), low-dose weekly methotrexate, mycophenolate mofetil[92], IVIg[93], dapsone[94] and thalidomide[95], as well as additional agents listed in Table 42.8. Calcinosis cutis may respond to diltiazem and/or surgical excision; other therapies include low-dose warfarin, bisphosphonates, probenecid, aluminum hydroxide, and electric shock wave lithotripsy (ESWL). Early and aggressive therapy of juvenile dermatomyositis does seem to reduce the risk of calcinosis cutis, which can be extremely challenging to treat. The rare panniculitis associated with dermatomyositis may respond to antimalarial therapy[96].

SYSTEMIC SCLEROSIS

Synonyms: Systemic sclerosis: ■ Scleroderma ■ Progressive systemic sclerosis

Subtypes of clinical involvement: ■ Diffuse ■ Limited (includes CREST syndrome)

Key features

- An autoimmune connective tissue disease of unknown etiology
- Characterized by symmetric hardening of the skin of the fingers, hands and face that may generalize
- Raynaud's phenomenon is common and digital ulcers develop
- Internal organ involvement is frequent and affects the lungs, gastrointestinal tract, heart and kidneys; lung involvement is the leading cause of death
- Treatment focuses on internal organ involvement; effective therapy for cutaneous fibrosis remains inadequate

Introduction

Systemic sclerosis (SSc, scleroderma) is an autoimmune connective tissue disease (AI-CTD) of unknown etiology that affects the skin, blood vessels and internal organs. The name *systemic sclerosis* is meant to convey the systemic nature of the disease, which has two major clinical subtypes: *limited* and *diffuse*. Limited SSc is characterized by fibrotic skin changes that are limited to the fingers, hands and face and includes the CREST syndrome. In diffuse SSc, generalized fibrotic skin changes are seen and they usually start in the fingers and hands but spread to involve the forearms, arms, trunk, face and lower extremities. Because SSc is not invariably progressive, the word "progressive" has been dropped from the terminology for this condition.

The diagnosis of SSc is based on clinical findings and laboratory abnormalities[1]. The differential diagnosis of symmetric and widespread cutaneous induration includes SSc as well as generalized morphea, eosinophilic fasciitis, scleromyxedema, nephrogenic systemic fibrosis, and scleredema (favors neck and upper trunk) (Table 43.1).

History

The first reported case of SSc (in 1754) was a young Italian woman who developed progressive induration of her skin. From the clinical description, it is impossible to determine whether she had true SSc or another sclerodermoid disorder.

Epidemiology

SSc has a worldwide distribution and affects all races. The annual incidence and prevalence rates in the US are approximately 20 and 250 cases per million population, respectively[1]. Women are affected three to four times as often as men are. Although SSc can occur in children and the elderly, the onset is typically between the ages of 30 and 50 years. Black patients have an earlier mean age of onset and a higher likelihood of diffuse disease[2]. Approximately 1.5% of SSc patients have one or more affected first-degree relatives, representing a 10- to 15-fold higher risk of SSc in family members than in the general population[3]. SSc is associated with a significant mortality rate, with an overall 10-year survival of less than 70%[1]. Parameters that predict a worse prognosis include male sex, black race, older age at diagnosis, internal organ involvement at diagnosis, skin fibrosis affecting the trunk, and elevated erythrocyte sedimentation rate (ESR)[1].

Pathogenesis

The pathogenesis of SSc is unknown. Key pathogenic abnormalities in the skin and internal organs are vascular dysfunction, immune activation with autoantibody production, and tissue fibrosis characterized by deposition of collagen and other extracellular matrix proteins (Fig. 43.1)[4–6].

Vascular dysregulation

Vascular dysfunction in the form of impaired angiogenesis is an early event in the pathogenesis of SSc[6]. The blood vessels affected range from the smallest capillaries within the proximal nail fold to the large pulmonary arteries. Endothelial cell injury occurs early (before fibrosis is evident), based on changes seen by electron microscopy, such as perivascular leak and edema[7]. Surrounding smooth muscle cells are also affected and have altered production of and responsiveness to vasoconstrictive (e.g. cold, endothelin) and vasodilatory (e.g. nitric oxide) factors. Structural abnormalities such as intimal proliferation leading to luminal occlusion develop and lead to hypoxia which induces synthesis of profibrotic cytokines, fibroblast activation and collagen production[8]. Raynaud's phenomenon and digital ulcers are caused by reversible vasospasm as well as irreversible arterial damage with intimal proliferation and luminal obstruction. Scleroderma renal crisis and pulmonary artery hypertension are manifestations of large vessel dysregulation.

Immune dysregulation

Patients with SSc produce specific, and therefore diagnostic, autoantibodies (e.g. anticentromere, anti-topoisomerase I [Scl-70]; see Ch. 40), and these autoantibodies also have prognostic implications[9,10]. Complexes containing topoisomerase I autoantibody, when bound to the surface of fibroblasts, have been found to stimulate monocyte adhesion and activation. In addition, anti-endothelial cell antibodies from SSc patient sera can trigger endothelial cell apoptosis. One group described *stimulatory* autoantibodies against the platelet-derived growth factor (PDGF) receptor in SSc sera which induced reactive oxygen species and expression of type I collagen by normal human fibroblasts[11]. However, two subsequent studies were unable to confirm these findings[12].

Lymphocytic infiltrates have been observed in both the skin and lungs of SSc patients before the development of fibrosis. Oligoclonal T-cell expansion has been identified in lesional skin, indicating an antigen-driven response, and T cells demonstrate a Th2-predominant profile with increased production of profibrotic cytokines such as interleukin (IL)-4 and IL-13. More recently, Th17 cells and IL-17 have been implicated as playing a role in SSc, as have the innate immune system and

MAJOR CLINICAL AND LABORATORY MANIFESTATIONS OF SYSTEMIC SCLEROSIS AND OTHER SELECTED CONDITIONS CHARACTERIZED BY CUTANEOUS INDURATION

INTERACTIONS BETWEEN ENDOTHELIAL CELLS, LEUKOCYTES AND FIBROBLASTS IN SCLERODERMA PATHOGENESIS

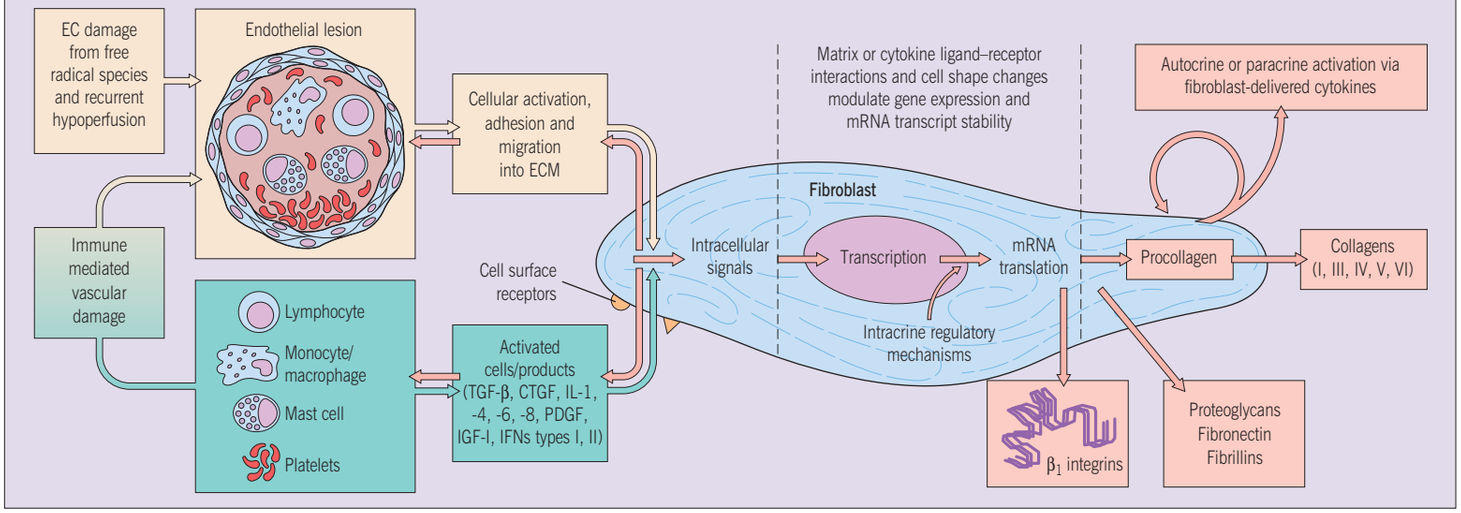

Fig. 43.1 Interactions between endothelial cells, leukocytes and fibroblasts in scleroderma pathogenesis. CTGF, connective tissue growth factor; EC, endothelial cell; ECM, extracellular matrix; IFN, interferon; IGF, insulin-like growth factor; PDGF, platelet-derived growth factor; TGF, transforming growth factor. Genetic susceptibility loci that may increase the risk of developing scleroderma include a region on chromosome 15q (which contains the fibrillin-1 gene) as well as polymorphisms in *STAT4* and the promotor for CTGF. *Adapted from Hochberg MC, Silman AJ, Smolen JS, et al (eds). Rheumatology, 3rd edn. Edinburgh: Mosby, 2003.*

types I (α,β) and II (γ) interferons. SSc patients also have expansion of naive B cells and chronic activation, but a decreased number, of memory B cells.

Fibrosis

Fibrosis represents the final common pathway in SSc. There is excessive deposition of collagens, proteoglycans, fibronectin, fibrillins and adhesion molecules (e.g. β_1-integrins), which sequester cytokines and growth factors (see Fig. 43.1). Attention has focused on transforming growth factor-β (TGF-β) and connective tissue growth factor (CTGF). The latter is induced by TGF-β and may be responsible for maintenance of collagen synthesis.

Given the complex extracellular matrix changes seen in SSc[13], both the fibroblast and the myofibroblast have been a focus of attention. Some evidence suggests that there is an inherent defect, an autocrine loop, or a hypersensitivity to growth factors in SSc fibroblasts. However, the possibility exists that SSc fibroblasts actually have a normal phenotype, but are exposed to an abnormal microenvironment with enhanced activity of growth factors or ischemic mediators. The accumulation of collagen in SSc seems to be primarily the result of increased synthesis, rather than decreased degradation.

Fig. 43.2 Late stage of systemic sclerosis with diffuse cutaneous scleroderma. Note the fixed flexion contractures, sclerodactyly, and the digital ulceration overlying the third proximal interphalangeal joint.

Clinical Features

Diagnostic criteria and classification

For the purposes of clinical trials, the classification scheme of the American College of Rheumatology has been helpful, with either the one major criterion – symmetric cutaneous sclerosis proximal to the metacarpophalangeal (MCP) or metatarsophalangeal (MTP) joints – or two or more minor criteria – sclerodactyly (Fig. 43.2); digital pitted scars or loss of substance from finger pads (Fig. 43.3); bibasilar pulmonary fibrosis – considered diagnostic of SSc[1,2].

Based upon the degree of skin involvement, there are two major clinical subtypes: limited and diffuse[1]. When the skin disease involves the distal and proximal portions of the extremities plus the trunk and face, it is considered diffuse disease, but when the induration is limited to the distal extremities and face, it is considered limited disease[1]. While both subtypes represent systemic diseases, there are variable degrees of internal organ involvement (Table 43.2). Typically, diffuse SSc is associated with early internal organ involvement (within 5 years of disease onset) and a worse prognosis[1], whereas patients with limited SSc tend to develop internal involvement later in the disease course, occasionally after decades.

The acronym *CREST syndrome* describes the clinical features in a subset of patients with limited SSc: *c*alcinosis, *R*aynaud's phenomenon, *e*sophageal involvement, *s*clerodactyly and *t*elangiectasia. Rarely, patients present with characteristic internal organ involvement, Raynaud's phenomenon and positive serologies but no cutaneous involvement, which is referred to as *systemic sclerosis sine scleroderma*.

Cutaneous features

Many patients with SSc experience an early edematous phase, which often features pitting edema of the digits (Fig. 43.4). The skin

COMPARISON OF CLINICAL AND LABORATORY FEATURES OF DIFFUSE AND LIMITED SYSTEMIC SCLEROSIS

	Diffuse SSc (%)	Limited SSc (%)
Raynaud's phenomenon	90	99

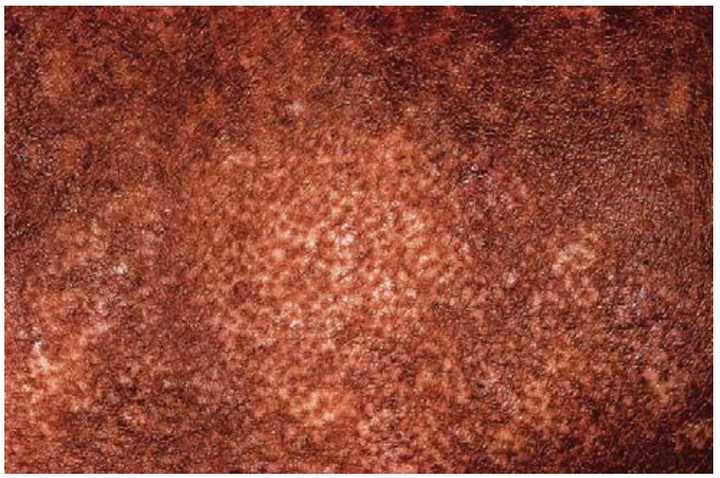

Fig. 43.5 The "salt and pepper" sign. Leukoderma with retention of perifollicular pigmentation in a patient with systemic sclerosis.

Fig. 43.6 Mat/matted (squared-off) telangiectasias in two patients with systemic sclerosis. The first patient (**A**) had CREST syndrome (limited-disease subtype) while the second patient (**B**) presented with diffuse hyperpigmentation and had interstitial lung disease. *B, Courtesy, Jean L Bolognia, MD.*

Fig. 43.7 Calcinosis cutis of the finger in a patient with systemic sclerosis.

subsequently hardens and develops a taut, shiny appearance (indurated phase). Eventually, there may be gradual thinning of the skin (late atrophic phase). The fingers can develop flexion contractures and ulcers (see Fig. 43.2) while involvement of the face can lead to a beaked nose, microstomia and a somewhat youthful appearance.

There are a number of cutaneous changes other than fibrosis in patients with SSc. Dyspigmentation in areas of sclerosis is commonly observed. Some patients develop diffuse hyperpigmentation, with accentuation in sun-exposed areas and sites of pressure. The "leukoderma of scleroderma" is characterized by localized areas of depigmentation with sparing of the perifollicular skin; this helpful diagnostic finding is sometimes referred to as the "salt and pepper" sign (Fig. 43.5). Pigment may also be retained in the skin overlying superficial veins. This leukoderma favors the upper trunk and central face and may overlie uninvolved or sclerotic skin.

Telangiectasias are more common in patients with limited SSc but also occur in patients with diffuse disease (see Table 43.2). The telangiectasias most often involve the face, lips and palms. These telangiectatic macules are matted or squared-off (Fig. 43.6). Capillary abnormalities in the proximal nail fold are present in more than 90% of SSc patients and can be useful in supporting the diagnosis[14]. Use of an ophthalmoscope or dermatoscope may enhance appreciation of the changes. A distinct pattern of capillary loss ("drop out") alternating with dilated loops is characteristic of SSc.

Dystrophic calcinosis cutis most commonly develops on the extremities, usually near joints and in distal locations (Fig. 43.7). In addition, the skin is often dry due to decreased sweating, and pruritus can be quite marked. Fibrotic skin in SSc may show diminished hair growth, but this is variable; hypertrichosis can also occur, particularly during the recovery phase. Overall, the cutaneous changes are extremely troublesome to patients with SSc. For example, in a questionnaire-based study involving 300 patients with SSc, facial involvement and microstomia were the patients' greatest concerns[15].

CLINICAL AND LABORATORY FEATURES OF PRIMARY AND SECONDARY RAYNAUD'S PHENOMENON		
Feature	**Primary Raynaud's**	**Secondary Raynaud's**
Sex	F:M 20:1	F:M 4:1
Age at onset	Puberty	>25 years
Frequency of attacks	Usually <5 per day	5–10+ per day
Precipitants	Cold, emotional stress	Cold
Ischemic injury	Absent	Present
Abnormal capillaroscopy	Absent	>95%
Other vasomotor phenomena	Yes	Yes
Antinuclear antibodies	Absent/low titer	90–95%
Anticentromere antibody	Absent	50–60%
Anti-topoisomerase I (Scl-70) antibody	Absent	20–30%
In vivo platelet activation	Absent	>75%

Table 43.3 Clinical and laboratory features of primary and secondary Raynaud's phenomenon. *Adapted from Hochberg MC, Silman AJ, Smolen JS, et al. (eds). Rheumatology, 3rd edn. Edinburgh: Mosby, 2003. © Elsevier 2003.*

Fig. 43.8 Raynaud's phenomenon in a patient with severe sclerodermoid chronic graft-versus-host disease. The fingers have a violaceous hue as well as areas of blanching (white) and digital ulceration. Oral sildenafil led to a significant improvement.

Raynaud's phenomenon is characterized by episodic vasospasm of the digital arteries resulting in white, blue and red discoloration of the fingers secondary to cold stimuli. Raynaud's phenomenon occurs in two settings (Table 43.3). *Primary Raynaud's phenomenon (Raynaud's disease)* typically develops in adolescent girls and young women and is not associated with any underlying medical problems[16]. Primary Raynaud's phenomenon is common and estimated to affect 3% to 5% of the population. In contrast, *secondary Raynaud's phenomenon* is uncommon and is associated with an underlying medical problem (Fig. 43.8; Table 43.4). Notably, SSc represents one of the leading causes of secondary Raynaud's phenomenon. An approach to differentiating primary from secondary Raynaud's phenomenon is presented in Figure 43.9.

Cutaneous ulcers are common in patients with SSc (Fig. 43.10). Whereas ulcers on the tips of the digits are probably due to ischemia, those on the interphalangeal joints are more likely to persist because of continued trauma (see Fig. 43.2). Ulcers can lead to osteomyelitis and even amputation (autoamputation or surgical intervention).

Extracutaneous features

The majority of patients with SSc have internal organ involvement (Table 43.5), which is the cause of significant morbidity and mortality in this disease[1,2]. Occasionally, a patient with SSc will present with internal organ involvement before skin involvement is evident. The most commonly affected organs are the gastrointestinal tract, lungs, heart and kidneys. However, renal crisis is no longer the leading cause of death in SSc, having been replaced by pulmonary disease. There are two major forms of pulmonary involvement in SSc[1,2]. The first is interstitial lung disease (alveolitis) that eventuates into pulmonary fibrosis. The second form of involvement is pulmonary arterial hypertension. Screening tests for both disorders are outlined in Table 43.5.

Autoantibodies

Autoantibody testing is useful in confirming the diagnosis of SSc (see Ch. 40). Most patients have elevated titers of antinuclear antibodies (ANA)[1,9], with the nucleolar and discrete speckled patterns being relatively specific for SSc. Patients with antibodies to topoisomerase I (Scl-70) are more likely to have diffuse disease with an increased risk of interstitial lung disease. In contrast, patients with anticentromere antibodies are more likely to have limited disease. Autoantibodies to RNA polymerase are usually associated with diffuse disease.

DIFFERENTIAL DIAGNOSIS OF RAYNAUD'S PHENOMENON
STRUCTURAL VASCULOPATHIES
Large and medium-sized arteries
Thoracic outlet syndrome
Brachiocephalic trunk disease (atherosclerosis, Takayasu's arteritis)
Buerger's disease (thromboangiitis obliterans)*
Crutch pressure
Small arteries and arterioles
Systemic sclerosis
Systemic lupus erythematosus
Dermatomyositis
Overlap syndromes
Cold injury
Vibration disease (hand-arm vibration syndrome, hypothenar hammer syndrome)
Chemotherapy (bleomycin, vinca alkaloids, cisplatin, carboplatin)
Vinyl chloride disease
Arsenic poisoning
NORMAL BLOOD VESSELS – ABNORMAL BLOOD ELEMENTS
Cryoglobulinemia (monoclonal or mixed)
Cryofibrinogenemia
Cold agglutinin disease
Myeloproliferative disorders (e.g. essential thrombocythemia)
NORMAL BLOOD VESSELS – ABNORMAL VASOMOTION
Primary (idiopathic) Raynaud's phenomenon
Drug-induced (ergot alkaloids, bromocriptine, interferon, estrogen, cyclosporine, sympathomimetic agents, clonidine, cocaine, nicotine)
Carpal tunnel syndrome
Pheochromocytoma
Carcinoid syndrome
Reflex sympathetic dystrophy
Other vasospastic disorders (migraine, Prinzmetal)
*Can also affect small arteries.

Table 43.4 Differential diagnosis of Raynaud's phenomenon. Paraneoplastic acral vascular syndrome, which can present with Raynaud's phenomenon as well as acrocyanosis and gangrene, has been observed in patients with various solid tumors (e.g. lung or ovarian carcinoma). *Adapted from Hochberg MC, Silman AJ, Smolen JS, et al. (eds). Rheumatology, 3rd edn. Edinburgh: Mosby, 2003. © Elsevier 2003.*

EVALUATION AND TREATMENT OF INTERNAL ORGAN INVOLVEMENT IN PATIENTS WITH SYSTEMIC SCLEROSIS			
	Symptoms/signs*	**Studies**	**Treatment**
Pulmonary: • Interstitial lung disease • Pulmonary artery hypertension	Shortness of breath, dyspnea on exertion, dry cough Tachypnea, bibasilar rales, signs of right-sided CHF (e.g. peripheral edema, hepatomegaly, dilated neck veins)	• Interstitial lung disease: Pulmonary function tests, including DLCO† High-resolution CT† • Pulmonary artery hypertension: Echocardiogram Right heart catheterization	• Interstitial lung disease: immunosuppression, primarily cyclophosphamide or mycophenolate mofetil • Pulmonary artery hypertension: vasodilators including endothelin receptor antagonists (bosentan, sitaxsentan, ambrisentan), prostacyclin analogues (iloprost [inhaled], epoprostenol [IV], trepostinil [sc]), and PDE5 inhibitors (sildenafil, tadalafil)
Cardiac	Shortness of breath, dyspnea on exertion, palpitations Signs of right- or left-sided CHF (e.g. tachypnea, rales, peripheral edema [see above])	Electrocardiogram Right heart catheterization	Diuretics, ACE inhibitors, β-blockers (unless contraindicated), angiotensin II receptor blockers, aldosterone antagonists May need to consider withdrawal of calcium channel blockers
Renal, including scleroderma renal crisis‡	Headache, blurry vision Hypertension	Blood pressure BUN, creatinine, urinalysis	Blood pressure control, in particular the use of ACE inhibitors
Gastrointestinal	Dyspepsia, dysphagia, postprandial bloating, constipation, diarrhea Signs of malnutrition	Upper gastrointestinal series (barium swallow) with small bowel follow-through Manometry Endoscopy Malabsorption evaluation	Proton-pump inhibitors for gastroesophageal reflux Domperidone or metoclopramide to improve motility and bloating

*Patients may be asymptomatic.
†At baseline and every 6–12 months for first five years after initial diagnosis, then yearly.
‡Suspected if, compared to baseline, the systolic pressure is elevated >20 mmHg or the diastolic pressure is elevated >10 mmHg.

Table 43.5 Evaluation and treatment of internal organ involvement in patients with systemic sclerosis. ACE, angiotensin-converting enzyme; BUN, blood urea nitrogen; CHF, congestive heart failure; CT, computerized tomography; DLCO, diffusion capacity of carbon monoxide; IV, intravenous; PDE5, phosphodiesterase type 5; sc, subcutaneous.

Antifibrillarin antibodies (present in <10% of SSc patients) are associated with diffuse SSc but can also occur in other AI-CTDs such as systemic lupus erythematosus (SLE)[10].

Pathology

Histologically, areas of cutaneous induration are characterized by compact or hyalinized collagen, excessive deposition of collagen, atrophic eccrine and pilosebaceous glands, loss of subcutaneous fat, and a sparse lymphocytic infiltrate in the dermis and subcutis (Fig. 43.11). Adnexal structures, especially eccrine glands, may be "trapped" by the excessive deposition of collagen. However, the different subsets of SSc cannot be distinguished histologically[17].

Direct immunofluorescence studies are usually negative in patients with SSc. While endothelial damage can occur in cutaneous blood vessels, this finding is only seen at the ultrastructural level[7]; reduplication of the basement membrane is also observed. It should be noted that, in its end stage, areas of sclerosis may be indistinguishable histologically from other diseases characterized by collagen deposition, such as morphea (which tends to have a more robust inflammatory infiltrate than SSc in its earlier stages).

Differential Diagnosis

The differential diagnosis of dermal sclerosis is extensive[18]. Table 43.1 compares the features of SSc to those of morphea, eosinophilic fasciitis, scleredema, scleromyxedema and nephrogenic systemic fibrosis. SSc can be distinguished by the characteristic symmetric induration of the skin of the distal extremities (especially the upper extremity), nail fold capillary findings, association with Raynaud's phenomenon, autoantibody profile, and internal organ involvement. Some patients with SSc also have features of another AI-CTD (e.g. overlap syndromes). Additional entities in the sclerodermoid differential diagnosis are presented in Table 43.6. Localized forms of scleroderma (e.g. morphea) are discussed in Chapter 44. Chronic GVHD can mimic certain features of SSc. The cutaneous sclerosis of chronic GVHD typically begins as circumscribed morpheaform plaques that favor the trunk (which may eventually coalesce and become more reminiscent of scleroderma) as well as lesions that resemble lichen sclerosus or eosinophilic fasciitis (see Ch. 52). Patients with chronic GVHD can also have pulmonary (e.g. bronchiolitis obliterans) and gastrointestinal involvement.

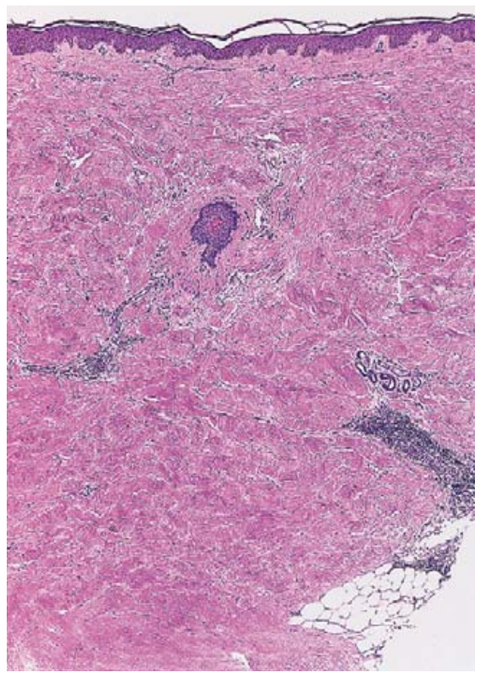

Fig. 43.11 Systemic sclerosis – histologic features. There is a dense sclerosis of the dermis with decreased adnexal structures and "trapping" of remaining adnexal structures that are encased by collagen. Sparse perivascular infiltrates of lymphocytes are present. *Courtesy, Ronald P Rapini, MD.*

DIFFERENTIAL DIAGNOSIS OF SCLERODERMOID CONDITIONS	
	Clinical features
MUCINOSES	
• Scleredema	Induration of the upper back, neck and face; occasional internal involvement (see Ch. 46)
• Scleromyxedema	Waxy papules (often in a linear array); diffuse induration favoring the face, upper trunk, arms and thighs; monoclonal gammopathy; neurologic, gastrointestinal and pulmonary involvement (see Ch. 46)
IMMUNOLOGIC	
• Chronic GVHD*	Morpheaform plaques favoring the trunk, which may become generalized; eosinophilic fasciitis (see Ch. 52)
• Eosinophilic fasciitis	Symmetric induration with a "pseudo-cellulite" appearance on the extremities (sparing hands and feet) (see text)
• Generalized morphea*	Expansion and coalescence of morphea plaques to involve a large portion of the trunk and extremities (see Ch. 44)
• Fibroblastic rheumatism	Sclerodactyly; fibrotic nodules on the hands
PARANEOPLASTIC	
• POEMS syndrome	Sclerotic skin on the extremities (see Ch. 114)
• Amyloidosis (primary systemic)†	Diffuse induration favoring the face, distal extremities and trunk (see Ch. 47)
• Carcinoid syndrome	Sclerotic skin on the legs (see Table 53.3)
NEOPLASTIC	
• Carcinoma *en cuirasse**	Sclerodermoid encasement of the chest by metastatic carcinoma (usually breast cancer)
METABOLIC	
• Diabetic cheiroarthropathy	Thickened skin and limited mobility of the hands (see Table 53.4)
• Porphyria cutanea tarda*,‡	Morpheaform plaques in sun-exposed areas (see Chs 44 & 49)
NEUROLOGIC	
• Reflex sympathetic dystrophy*	Painful, cold, swollen extremity eventually develops cutaneous sclerosis (see Ch. 6)
• Spinal cord injury	Sclerotic skin in affected areas
TOXIN-MEDIATED	
• Nephrogenic systemic fibrosis*	Associated with exposure to gadolinium-based contrast agents (US, 1997–present; now worldwide) (see text)
• Eosinophilia–myalgia syndrome	Associated with L-tryptophan ingestion (US, 1989) (see text)
• Toxic oil syndrome*	Associated with toxic oil ingestion (Spain, 1981) (see text)
DRUG- OR CHEMICAL-INDUCED (SEE TEXT)	
• Bleomycin*	Acrosclerosis, Raynaud's phenomenon; pulmonary fibrosis (more common, usually no concurrent skin lesions)
• Taxanes*	Edema followed by sclerosis of the lower extremities; acrosclerosis
• Vinyl chloride, chlorinated hydrocarbons*	Acrosclerosis, acral fibrotic papulonodules, Raynaud's phenomenon, acro-osteolysis; pulmonary fibrosis
VENOUS INSUFFICIENCY	
• Lipodermatosclerosis*	Woody induration and hemosiderin pigmentation on the lower legs; may also involve the pannus (see Ch. 100)
GENETIC DISORDERS	
• Restrictive dermopathy§	Tight, thin skin over the entire body; joint contractures; *LMNA* or *ZMPSTE24* mutations
• Hutchinson–Gilford progeria	Sclerotic skin on the lower trunk, buttocks and thighs; *LMNA* mutations (see Ch. 63)
• Werner syndrome	Tight, sclerotic skin on the distal extremities; *RECQL2* mutations (see Ch. 63)
• Stiff skin syndrome*	Fibrosis of the skin/fascia of the buttocks and thighs with hip contractures (see text)
• Phenylketonuria	Sclerotic skin on the thighs and buttocks with hip contractures (see Ch. 63)
• Winchester syndrome*	Diffuse, symmetric, leathery skin thickening; fibrotic plaques or bands; *MMP2* mutations (see Table 70.2)
• Ataxia–telangiectasia	Tight, sclerotic facial skin (see Ch. 60)
• Huriez syndrome	Sclerodactyly; atrophic skin on dorsal surfaces of hands and feet; palmoplantar keratoderma (see Ch. 58)
• H syndrome	*H*ypertrichosis in association with areas of hyperpigmentation and induration (primarily lower trunk and lower extremities), sensorineural *h*earing loss, short *h*eight, *h*eart anomalies, *h*epatosplenomegaly, scrotal masses, hypergonadotropic *h*ypogonadism, antibody-negative insulin-dependent diabetes mellitus, facial telangiectasias; mutations in *SLC29A3* which encodes nucleoside transporter hENT3

*Can overlap with morpheaform disorders, which are listed in Table 44.1.
†Primary cutaneous amyloidosis can also occur in patients with systemic sclerosis and generalized morphea.
‡May also be observed in patients with congenital erythropoietic porphyria and hepatoerythropoietic porphyria.
§Sclerodermoid changes are typically present at birth.

Table 43.6 Differential diagnosis of sclerodermoid conditions. Disorders with a clinical presentation similar to systemic sclerosis are referred to as *sclerodermoid*, while those reminiscent of morphea are referred to as *morpheaform* (see Ch. 44).

Treatment

SSc is a challenging disease to treat. Therapeutic interventions focus primarily on internal organ involvement, but unfortunately most of these treatments have had no significant impact on cutaneous manifestations[19].

Raynaud's phenomenon

First-line therapy for Raynaud's phenomenon is behavioral and involves educating patients to keep warm and avoid smoking to minimize the frequency and severity of attacks.

Second-line therapy is pharmacologic, starting with vasodilators[16]. Calcium channel blockers (e.g. nifedipine) have been the most widely used medications. Angiotensin II receptor blockers (e.g. losartan) may also be effective, and combinations of these medications can be used. More recently, phosphodiesterase type 5 inhibitors (e.g. sildenafil, tadalafil) that target the nitric oxide-mediated vasodilation pathway have been employed, and results have been mixed[20–22]. Care must be taken so that the vasodilators do not excessively lower systemic blood pressure. In addition, calcium channel blockers may exacerbate gastroesophageal reflux disease.

Oral antiplatelet agents (e.g. low-dose aspirin) and/or pentoxifylline may theoretically provide additional blood flow to compromised distal sites and may be used empirically. While biofeedback can also be helpful, topical preparations in general have been ineffective.

Cutaneous ulcers

Digital ulcers on the fingers are difficult to treat and a source of great morbidity. The approach to digital ulcers includes the treatments for Raynaud's phenomenon outlined above. Detailed occupational and recreational histories are important to identify risk factors and sources of injury. Based upon two randomized controlled trials, bosentan, an oral endothelin receptor antagonist, has been approved in Europe, but not the US, for the prevention of new digital ulcers in SSc patients[23]. While disappointing results were observed in a double-blind randomized trial of oral iloprost (a prostacyclin analogue)[24], when administered intravenously, it resulted in a reduction in digital ulcers and improved healing[25]. More limited studies of the subcutaneous prostacyclin analogue treprostinil suggest that it may also be effective. In refractory cases, nerve blocks and sympathectomies may be considered.

In patients with SSc, autolytic debridement of ulcers via occlusive dressings is thought to be safer than mechanical debridement. In general, moist hydrocolloid dressings provide a better wound healing environment than dry or wet-to-dry dressings. Enzymatic debriding agents (e.g. collagenase) and topically applied growth factors (e.g. PDGF) have been utilized in a few SSc patients. Skin equivalents or grafts can also be used to stimulate the wound bed and decrease wound pain.

Cutaneous sclerosis

In the early stage of SSc, cutaneous and subcutaneous edema develops rapidly, but during the indurated and atrophic stages, the cutaneous involvement progresses more slowly and tends to gradually improve, independent of treatment. Unfortunately, objective, quantitative measurements of cutaneous fibrosis that are sensitive to change over short periods of time are currently lacking for SSc. The traditional instrument for measuring skin involvement in SSc is the modified Rodnan skin score[1]. Although this is a validated outcome measure, it is not ideal and is relatively insensitive to small changes over short periods of time. An adapted engineering tool, the durometer, may be more suitable for assessing cutaneous induration and hardness in patients with SSc[26].

In a trial of D-penicillamine in 134 patients with diffuse disease, there was no difference between the low-dose and the high-dose treatment groups[27]. Although minocycline looked promising in a pilot study, a larger follow-up study failed to show a benefit[28]. Methotrexate can be helpful in SSc patients with overlap polymyositis. However, in a randomized, placebo-controlled trial (involving 71 patients with early SSc) where methotrexate was administered for 1 year, there was a trend in favor of methotrexate but it did not reach statistical significance[29].

A long list exists of additional agents that have been tried in SSc, but ultimately most have been shown to be ineffective. For example, interferons were abandoned due to lack of benefit. Relaxin, a hormone that relaxes ligatures, did decrease skin scores, but it had no benefit systemically and is no longer used. Photopheresis has been shown to have a marginal effect on skin scores. PUVA and UVA1 may also have a role in SSc therapy[29a,29b].

Other cutaneous complications

Calcinosis cutis represents a serious problem for which no effective medical therapy exists. Low-dose warfarin (i.e. a dose that does not alter the prothrombin time) can decrease the inflammatory reaction associated with calcium deposits. Although there were case reports of the effectiveness of calcium channel blockers for calcinosis, this was not observed in larger patient series. In certain situations, surgical removal of the calcium deposits may be necessary. Treatment with extracorporeal shock wave lithotripsy has also been reported. Telangiectasias can be treated cosmetically with pulsed dye laser therapy.

Internal organ involvement

Treatment of specific internal organ involvement is outlined in Table 43.5. Detailed discussions of these therapeutic approaches are available in other texts[1,2]. Of note, the use of ACE inhibitors to treat scleroderma renal crisis has been a major therapeutic advance[1].

In several retrospective studies, immunosuppression with cyclophosphamide was reported to be beneficial in the treatment of interstitial lung disease. A prospective, randomized, controlled trial showed a modest benefit with oral cyclophosphamide (1 to 2 mg/kg/day for 1 year) compared to placebo[30]. There are significant potential side effects, such as cytopenias, hemorrhagic cystitis and an increased risk of bladder carcinoma. Other immunosuppressive agents such as mycophenolate mofetil, azathioprine, chlorambucil, 5-fluorouracil, cyclosporine and systemic corticosteroids may also be beneficial for certain patients, but their use has not been well studied.

Advances in the treatment of pulmonary artery hypertension have also occurred, in particular the use of oral vasoactive compounds, some of which are also used for Raynaud's phenomenon and digital ulcers. These include endothelin receptor antagonists (bosentan[31], sitaxsentan, ambrisentan) and phosphodiesterase type 5 inhibitors (sildenafil, tadalafil). Prostacyclin analogues (iloprost [inhaled], epoprostenol [intravenous], treprostinil [subcutaneous]) are approved for pulmonary arterial hypertension in SSc patients[32], but are no longer sole or first-line therapy.

Autologous hematopoietic stem cell transplantation is currently being studied in both Europe and the US. The "SCOT" trial, "scleroderma cyclophosphamide or transplant", is underway in the US and should help clarify how effective high-dose immunosuppression is in treating SSc patients. Lastly, treatment with the tyrosine kinase inhibitor imatinib has shown some promise in small studies[33] and warrants further investigation for SSc as well as for other fibrosing disorders such as chronic GVHD and nephrogenic systemic fibrosis.

EOSINOPHILIC FASCIITIS

Synonyms: ■ Shulman's syndrome ■ Diffuse fasciitis with eosinophilia

History

Eosinophilic fasciitis was first reported in 1975 by Shulman, who described a fibrosing disorder characterized by the rapid onset of woody induration of the extremities in association with peripheral eosinophilia[34].

Clinical Features

A history of strenuous physical activity precedes the clinical findings in about 30% of patients with eosinophilic fasciitis. Initial manifestations include edema and pain of the involved extremities, which quickly progresses to fibrosis and a dimpled or "pseudo-cellulite" appearance (Fig. 43.12). The distribution is symmetric, but usually spares the

Fig. 43.12 Eosinophilic fasciitis – clinical features. Induration of the skin with a dimpled or "pseudo-cellulite" appearance, also referred to as rippling or puckering. *Courtesy, Joyce Rico, MD.*

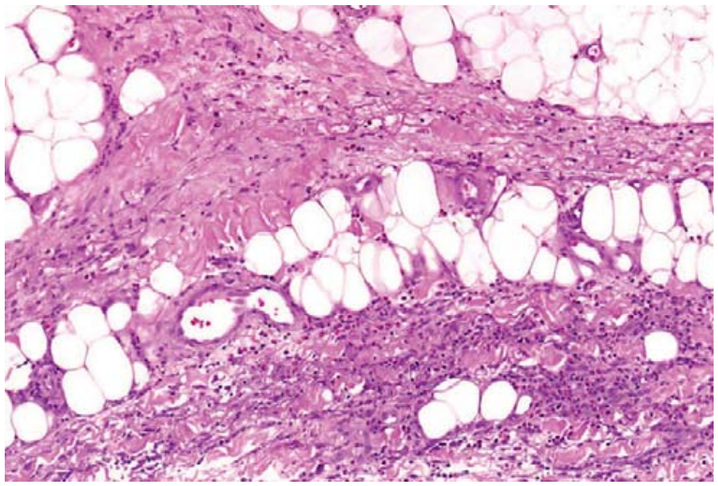

Fig. 43.13 Eosinophilic fasciitis – histologic features. Thickening of the deep fascia and septae of the subcutis with an inflammatory infiltrate comprised of lymphocytes, histiocytes and eosinophils. *Courtesy, Philip E LeBoit, MD.*

hands, feet and face. The "groove sign" refers to linear depressions where veins appear to be sunken within the indurated skin.

Laboratory findings include an elevated ESR, hypergammaglobulinemia and a striking peripheral eosinophilia[35]. Antinuclear antibodies are not elevated (compared to controls) and complement levels are normal. Pancytopenia, anemia, thrombocytopenia and myeloproliferative disorders have been reported in association with this disease. Some authors have advocated that patients with eosinophilic fasciitis and unexplained anemia undergo bone marrow biopsy to evaluate for a hematologic malignancy. Patients with chronic GVHD can develop eosinophilic fasciitis (see Ch. 52).

Pathology

Histologically, there is a thickening of the deep fascia, which may be 10 to 50 times the normal width (Fig. 43.13). Within the fascia and subfascial muscle, a patchy infiltrate composed of lymphocytes and plasma cells is seen. Eosinophils and mast cells may be present, and dermal fibrosis is a feature[36].

Treatment

Once the diagnosis of eosinophilic fasciitis is established via fascial biopsy and/or MRI (see Fig. 52.7), prompt treatment is essential to preserve mobility and function. Therapy is usually initiated with oral corticosteroids. Response is typically noted within the first few weeks, and clinical improvement may be seen over several months. The dose of prednisone is tapered over 6–24 months as tolerated. If an inadequate response is observed, hydroxychloroquine, cyclosporine, dapsone, methotrexate, PUVA or infliximab may be used alone or in combination with prednisone. UVA1, alone or in combination with a retinoid, can also be considered.

PROPOSED DIAGNOSTIC CRITERIA FOR NEPHROGENIC SYSTEMIC FIBROSIS – CLINICAL AND HISTOPATHOLOGIC	
Clinical	**Histologic**
MAJOR CRITERIA • Patterned plaques • Joint contractures • "Cobblestoning" • Marked induration/*peau d'orange* appearance	• Increased dermal cellularity (score +1) • $CD34^+$ cells (score +1) • Thick and thin collagen bundles (score +1) • Preserved elastic fibers (score –1 if *absent*) • Septal involvement (score +1) • Osseous metaplasia (score +3)
MINOR CRITERIA • Puckering/linear banding • Superficial plaque/patch • Dermal papules • Scleral plaques (age < 45 years)	

Interpretation	Clinical	Histologic score
Highly consistent with NSF	2 or more major criteria	4
Consistent with NSF	1 major criterion	3
Suggestive of NSF	2 or more minor criteria	2
Inconsistent with NSF	1 or no minor criteria	1
NSF excluded	Diagnostic of another entity	0

Table 43.7 Proposed diagnostic criteria for nephrogenic systemic fibrosis – clinical and histopathologic. *Adapted from Girardi M, Kay, J, Elston DM, et al. Nephrogenic systemic fibrosis: clinicopathological definition and work-up recommendations J Am Acad Dermatol. www.ncbi.nlm.nih.gov/pubmed/21724294*

NEPHROGENIC SYSTEMIC FIBROSIS

Synonym: ■ Nephrogenic fibrosing dermopathy

History

Nephrogenic systemic fibrosis (NSF) is a relatively new entity in the differential diagnosis of scleroderma-like disorders that affects both the skin and internal organs (see Table 43.1)[37]. Acute kidney injury or chronic severe renal insufficiency, together with exposure to gadolinium-based contrast agents used in medical imaging, are now known to be the underlying causative factors in this disorder[38]. In addition to a strengthening of black box warnings, the FDA in 2010 stated that three contrast agents – gadopentetate dimeglumine (Magnevist™), gadodiamide (Omniscan™) and gadoversetamide (OptiMARK™) – were contradicted in patients with acute kidney injury or chronic severe kidney disease.

Epidemiology and Pathogenesis

NSF is most often observed in middle-aged adults but has been described in children and elderly patients. It has no sex or race predilection. Since the recognition of the causal link between renal dysfunction and exposure to gadolinium-based contrast medium, the number of new cases per year has markedly decreased. Exposure to a greater amount of contrast material as is used in magnetic resonance angiography is thought to increase the risk of developing NSF.

Although the evidence that gadolinium is present in affected tissue in NSF patients is irrefutable, the mechanisms by which the fibrosis develops is unknown. One hypothesis involves aberrant tissue targeting

Fig. 43.14 Nephrogenic systemic fibrosis (NSF) – clinical features. Thickening and induration of the skin can be obvious (**A**), or lesions may present as purple–brown plaques (**B**). Scleral plaques (**C**) in a patient less than 45 years of age is a minor criterion for NSF. *A, Courtesy, Jean L Bolognia, MD. B, Courtesy, Kalman Watsky, MD.*

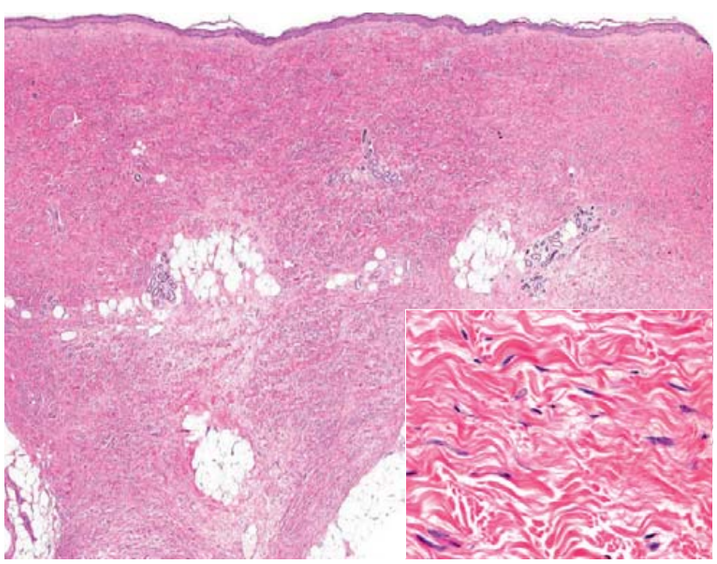

Fig. 43.15 Nephrogenic systemic fibrosis – histologic features. There is an increase in the cellularity and amount of collagen in the dermis and within the septae of the panniculus. The spindle cells (insert) stain positively for CD34 and procollagen I. *Courtesy, Lorenzo Cerroni, MD.*

of the "circulating fibrocyte", a bone marrow-derived leukocyte that is normally recruited to injured tissues, where it participates in matrix deposition and remodeling.

Clinical Features

NSF presents with patterned, thick, indurated plaques distributed symmetrically on the extremities (Fig. 43.14A,B) and trunk. The plaques are erythematous to hyperpigmented and can have an irregular advancing edge with an "amoeboid" appearance. Confluent involvement on the extremities often results in joint contractures. The condition is frequently associated with considerable pain and loss of mobility. Extracutaneous manifestations include yellow scleral plaques (Fig. 43.14C) and systemic fibrosis affecting the heart, lungs and skeletal muscle. Proposed diagnostic clinical criteria are outlined in Table 43.7.

Pathology

Because the disease process typically extends along fibrous septa into the subcutis, a deep biopsy specimen is required for diagnosis (Fig. 43.15). Histologic features include a haphazard arrangement of thickened collagen bundles and increased dermal fibroblast-like cells that stain positively for CD34 and procollagen I (an immunohistochemical profile identical to that of the circulating fibrocyte). Vascular proliferation, mucin deposition and an increased number of dendritic cells can also be observed in NSF, but there is no significant lymphoplasmacytic infiltrate. By energy dispersive spectroscopy, particles of gadolinium can be detected within involved tissues[39].

Treatment

The lesions of NSF are refractory to treatment with corticosteroids and other immunosuppressive drugs. There have been anecdotal reports of improvement with imatinib, rapamycin, UVA1 phototherapy, extracorporeal photochemotherapy, photodynamic therapy, plasmapheresis, high-dose IVIg, and discontinuation of erythropoietin.

STIFF SKIN SYNDROME

Synonym: ■ Congenital fascial dystrophy

History

Stiff skin syndrome was first described by Esterly and McKusick in 1971[40].

Epidemiology

This condition may be congenital or develop during early childhood. Familial occurrences have been described, but the mode of inheritance has not been established.

Pathogenesis

The underlying genetic defect is not definite but mutations in the fibrillin-1 gene have been implicated. The presence of giant "amianthoid-like" collagen fibrils in affected fascia has been postulated to reflect a disturbance in the organization of collagen and glycosaminoglycans in the extracellular matrix.

Clinical Features

Stiff skin syndrome is characterized by "rock hard" induration and thickening of the skin and subcutaneous tissues, which is most pronounced on the buttocks and thighs, with characteristic sparing of the inguinal folds[41]. The hands and feet are not involved. Mild hypertrichosis is often observed in affected areas. Restricted joint mobility leads to a characteristic posture of hip and knee flexion and prominent lumbar lordosis while standing, and patients may have short stature. The condition is stable or slowly progressive, and abnormalities of internal organs are not typically observed. Patients with unilateral involvement have been reported, some with features that overlapped with scleredema, deep morphea and linear melorheostotic scleroderma.

Pathology

Histologic examination demonstrates markedly thickened, hyalinized fascia without an associated inflammatory infiltrate. Thickened collagen bundles and mucin deposition may or may not be present in the overlying dermis.

Treatment

Stiff skin syndrome has a chronic course, and no effective treatments have been reported. Physical therapy can help to prevent progressive joint contractures.

SCLERODERMOID SYNDROMES INDUCED BY EXOGENOUS SUBSTANCES

Exposure to drugs, chemicals and other exogenous substances can lead to cutaneous and extracutaneous sclerosis (see Table 43.6)[42]. The clinical presentation may be similar to that of SSc, including acrosclerosis, Raynaud's phenomenon and pulmonary fibrosis. Other exposures to exogenous agents can result in the development of circumscribed sclerotic plaques resembling morphea. Exogenous substances that induce sclerodermoid conditions are discussed below, and those responsible for morpheaform lesions are discussed in Chapter 44.

Toxic Oil Syndrome

In 1981, the toxic oil syndrome affected more than 25 000 people in Spain; 600 died and approximately 300 remained permanently disabled. It resulted from the ingestion of aniline-degraded and reprocessed rapeseed oil, which led to a specific immune response in genetically susceptible individuals. New cases are no longer seen, as exposure to these contaminated cooking oils was halted. Many of the manifestations of toxic oil syndrome have been reproduced in experimental animal models, and clinical symptoms and severity in mice were shown to be dependent on the genetic background. In humans, toxic oil syndrome started with a morbilliform eruption and flu-like symptoms such as fever and headache; peripheral eosinophilia was observed in half of affected individuals. The inflammatory process subsequently affected the CNS, lungs and salivary glands. Skin involvement either resolved, evolved into a lichen planus-like eruption, or progressed to a morpheaform or sclerodermoid picture.

Eosinophilia–Myalgia Syndrome

In 1989, a contaminated preparation of L-tryptophan led to an outbreak of "eosinophilia–myalgia syndrome", which affected more than 1500 people in the US and led to at least 30 fatalities. The acute phase of the condition was characterized by severe myalgias, fever, dyspnea, edema, a macular exanthem and peripheral eosinophilia. Despite the discontinuation of L-tryptophan intake, approximately half of patients went on to a chronic phase that featured diffuse, deep sclerodermoid induration of the extremities (with acral sparing), progressive peripheral neuropathy and myopathy.

Sclerodermoid Syndromes Induced by Drugs

Several drugs, particularly bleomycin and the taxanes (see Table 43.6), can induce cutaneous sclerosis and pulmonary fibrosis mimicking SSc. Additional medications that have been associated with sclerodermoid changes include other chemotherapeutic agents such as peplomycin (a bleomycin analogue), cisplatin, carboplatin, gemcitabine, uracil-tegafur and topotecan, as well as ergot alkaloids, L-5-hydroxytryptophan ± carbidopa, penicillamine, appetite suppressants and cocaine. Specific autoantibodies are usually absent, and the sclerosis often (but not always) regresses upon withdrawal of the drug.

Sclerodermoid Syndromes Induced by Chemicals

Exposure to certain organic chemicals can lead to a clinical picture that resembles SSc (see Table 43.6). In contrast to the acute onset of the toxic oil and eosinophilia–myalgia syndromes, exposure to vinyl chloride (typically by individuals who clean the autoclaves used to polymerize the monomer), organic solvents (e.g. trichloroethylene, trichloroethane, perchloroethylene), pesticides or epoxy resins induces a slowly progressive process of sclerosis. It typically begins with insidious acrosclerosis and Raynaud's phenomenon (especially with vinyl chloride exposure), but morpheaform plaques and fibrotic nodules can also develop. Acral osteolysis, hepatic toxicity and pulmonary involvement are often observed. In addition, patients experience fatigue, weight loss, arthralgias and myalgias. Autoantibodies are absent, and cessation or reversal of the disease process follows removal of the exposure.

Silicosis

The incidence of SSc is approximately 20-fold higher in individuals with occupational exposure to silica, such as miners and foundry workers, than in the general population. In an epidemiologic study from Germany, three-quarters of men with typical SSc had been exposed to silica dust in the workplace. The mean duration of exposure was 14 years, with a mean delay in onset of the disease of 24 years from the first exposure. Quartz is absorbed via inhalation and percutaneously, and silicosis is caused by particles with a diameter less than 5 microns. Once absorbed, silica cannot be removed from the body. Although silica has nonspecific proinflammatory and profibrotic effects, HLA and TNF-α subtype associations suggest the need for a specific pre-existing immunophenotype for disease progression to occur. SSc associated with pulmonary silicosis is clinically, serologically and immunologically indistinguishable from the idiopathic form of the disease. Silica exposure has also been associated with the development of other AI-CTD, including Sjögren's syndrome, SLE and rheumatoid arthritis.

Morphea and Lichen Sclerosus

44

Martin Röcken and Kamran Ghoreschi

Morphea and lichen sclerosus are inflammatory skin diseases that ultimately evolve into two distinct modes of scar formation. Morphea affects primarily the dermis and may extend to subcutaneous structures. Lichen sclerosus is most often a disease of the genital mucosa (but may also involve extragenital sites) and it affects both the epidermis and the superficial dermis. Neither one leads to involvement of internal organs other than occasionally the underlying muscle or bone. While an individual patient may have both disorders simultaneously, they are addressed separately because of their multiple dissimilarities. Therapy of these two diseases will be discussed together.

MORPHEA

Subtypes/synonyms: ■ Plaque-type morphea – localized scleroderma, circumscribed scleroderma ■ Linear morphea – linear scleroderma ■ Morphea *en coup de sabre* – scleroderma *en coup de sabre* ■ Deep morphea – morphea profundus

Key features

- Asymmetric sclerotic plaques, usually 2–15 cm in diameter
- Active lesions can have a lilac border with central hypo- or dyspigmentation, while inactive lesions often become hyperpigmented
- The sclerosis may extend deeply into the fat or underlying structures (e.g. fascia, muscle, bone), causing disability
- There is no associated systemic disease
- Often progresses for several years, then regresses; the linear subtype is usually persistent

INTRODUCTION

Morphea is a clinically distinct inflammatory disease, primarily of the dermis and subcutaneous fat, which ultimately leads to a scar-like sclerosis. The small vessel changes, the inflammatory infiltrate and the ultimate structural modifications are identical in morphea and systemic sclerosis, but the two diseases are distinct entities that can easily be distinguished clinically. Morphea has an asymmetric patchy or linear distribution, whereas systemic sclerosis usually begins as symmetric tightening of the hands and fingers that extends progressively toward the proximal upper extremities. Although generalized morphea may resemble early diffuse scleroderma, the presence in the latter condition of Raynaud's phenomenon, digital sclerosis, and involvement of the gastrointestinal tract and the lung generally allows separation of systemic sclerosis from morphea. Distinguishing between deep morphea and eosinophilic fasciitis can prove more difficult.

Morphea has associated morbidity and impacts quality of life as a result of symptoms such as pain, skin tightness or decreased range of motion of joints[1]. In ~10% of patients, scar formation may lead not just to the usual disfigurement but also to significant contractures or growth retardation, handicapping the affected individual for life[2]. Thus, prompt treatment (e.g. UVA1, PUVA) is indicated when morphea affects more than the superficial dermis.

HISTORY

A condition of thickened skin was first mentioned by Hippocrates around 400 BC. The term "scleroderma" is derived from the Greek words *skleros* (hard or indurated) and *derma* (skin). The first description of a generalized "hardness" of the skin in a young woman was by an Italian physician, Carlo Curzio, in 1753, and the French physician Gintrac coined the term "sclérodermie" in 1847. Thomas Addison has been credited with the first detailed description (in 1854) of morphea, which he referred to as Alibert's keloid syndrome[3]. In 1924, Matsui described the typical histopathologic changes of scleroderma, including the increase in collagen and thickening of vessel walls in involved skin. O'Leary and Nomland[4] elaborated the distinctive features of systemic sclerosis versus morphea in 1930.

EPIDEMIOLOGY

Even though morphea has been long recognized as a well-defined entity, few population-based studies have been published. One of the best analyses is a survey from Olmsted County, Minnesota, that attempted to register all patients with the disorder from 1960 to 1993[5]. During this period, the annual incidence rate was 27 per million inhabitants. According to this study, 56% of patients had plaque-type, 20% linear, 13% generalized, and 11% deep morphea. Overall, the incidence appears to be increasing slightly[2].

The prevalence of morphea increases with age. It is approximately 500 and 2200 per million at ages 18 and 80 years, respectively[2]. The disease is more prevalent in women than in men (2.6 to 1), with the exception of linear morphea, which has no gender preference. Data published on the incidence and prevalence of morphea probably reflect an underestimation, as they critically depend on clinical recognition and diagnosis.

Morphea is very rarely life-threatening. In the Olmsted County study, the survival rate of patients with morphea was not significantly different from that of the general population[5]. However, in 11% of the patients, substantial disability occurred. This is of particular concern since disability occurs primarily with linear morphea, and the latter often has its onset before age 18 years (approximately two-thirds of patients)[5].

PATHOGENESIS

Autoantibodies are usually as prevalent in morphea as in the general population, with two exceptions: (1) an increased prevalence of anti-single strand DNA (ssDNA), -topoisomerase IIα, -phospholipid, -fibrillin-1 and -histone antibodies in patients with morphea (see Ch. 40); and (2) high titers of antinuclear antibodies (ANA) in juvenile patients with linear morphea and individuals with generalized morphea. Autoantibodies that activate receptors on fibroblasts, in particular the platelet-derived growth factor receptor (PDGFR), and presumably trigger a cascade that leads to increased collagen synthesis have not been described in patients with morphea (see Ch. 43).

Neither histology nor immunohistology of a single lesion will distinguish between morphea and systemic sclerosis. In most clinicopathologic reviews, it is assumed that the two diseases are triggered by distinct events. However, the development of sclerosis following the initiating event seems to follow a common pathway. It is therefore

assumed that pathogenic steps leading to systemic sclerosis also contribute to the development of morphea, so they will be included in this discussion.

Currently, sclerosis of the skin is thought to involve three major, closely connected components: vascular damage, activated T cells, and altered connective tissue production by fibroblasts (Fig. 44.1)[6].

Vascular Changes

A prominent feature of advanced sclerosis is a reduction in the number of capillaries. Studies performed in systemic sclerosis suggest that microvascular injury is a very early – and perhaps even the primary – event. Endothelial cell markers such as soluble adhesion molecules and vascular endothelial growth factor (VEGF) are elevated in the sera of patients with systemic sclerosis, indicating endothelial activation. The morphologic changes principally affect capillaries and small arterioles 50–500 microns in diameter. The initial changes include expression of adhesion molecules and endothelial swelling, followed by thickening of the basement membrane and intimal hyperplasia. An extrapolation is that similar changes may be occurring in patients with morphea.

Control of Fibroblast Function by T-Cell-Derived Cytokines

Pioneering work by Leroy[7] showed that fibroblasts isolated from sclerotic tissue produce increased amounts of collagen (types I, II and III) and other extracellular matrix proteins when they are cultured *in vitro*. These fibroblasts can maintain this phenotype for weeks over several passages. This raised the question as to whether scleroderma results from an inborn or an acquired error in collagen metabolism within fibroblasts. Today, most data favor the concept that abnormal collagen production is due to instructions from surrounding cells. T cells in particular have the capacity to modify collagen synthesis by fibroblasts and they are regularly present, at least in a perivascular location and especially at the leading edge of developing sclerosis (see Fig. 44.1).

Pathologically enhanced production of collagen and other extracellular matrix proteins is induced by T-cell-derived cytokines, especially interleukin (IL)-4, IL-13 and transforming growth factor-β (TGF-β). IL-4 is produced by $CD4^+$ T helper type 2 (Th2) lymphocytes (see Ch. 4) and can directly enhance TGF-β production[8]. In contrast, pathologic production of collagen (types I, II, III) and other extracellular matrix proteins can be significantly suppressed by interferon-α (IFN-α) or IFN-γ. IFN-γ is produced by $CD4^+$ Th1 lymphocytes and IFN-α is capable of promoting Th1 responses[8]. Th1 differentiation also implicates IL-12 signaling via the transcription factor STAT4. An association between *STAT4* polymorphisms (e.g. rs7574865) and an increased susceptibility to systemic sclerosis, especially the limited subtype, was recently reported[9,10].

While IL-4 is the most potent force in driving Th2-cell differentiation (see Fig. 4.10)[11], it is also produced by Th2 lymphocytes. Because IL-4 enhances pathologic collagen production by fibroblasts and induces recruitment of eosinophils, it is believed that immune responses dominated by IL-4- as well as IL-13- and TGF-β-producing cells are critically involved in the development of skin sclerosis. This concept is supported by clinical and experimental data:

- *In situ* analysis of progressing inflammatory margins of skin sclerosis has revealed predominantly IL-4 expression[12].
- Th2-associated cytokines IL-13 and IL-33 have been shown to promote skin fibrosis experimentally in mice and early treatment of scleroderma-developing mice with anti-IL-4 antibodies prevented scleroderma[13,14].
- Systemic retinoids (which interact with TGF-β signaling) appear to reduce pathologic collagen synthesis by fibroblasts and case series suggest that retinoids can improve sclerosis in patients with sclerodermoid GVHD[15,16].

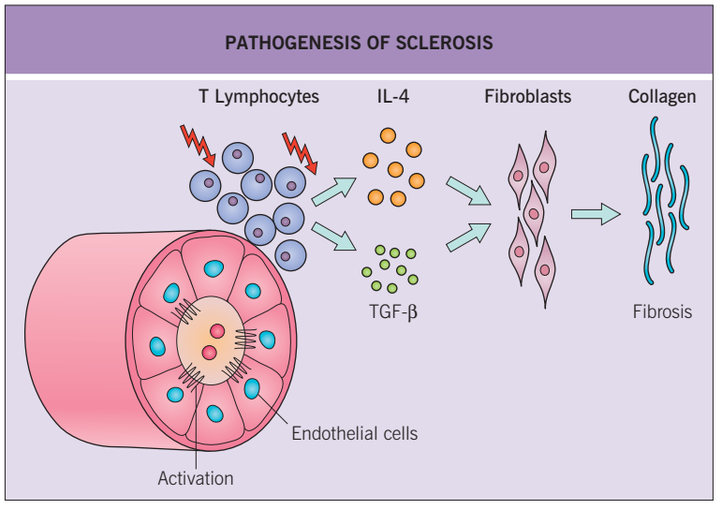

Fig. 44.1 Pathogenesis of sclerosis. Three components are involved during the formation of sclerosis: vascular damage, lymphocyte activation, and altered connective tissue production. IL, interleukin; TGF, transforming growth factor.

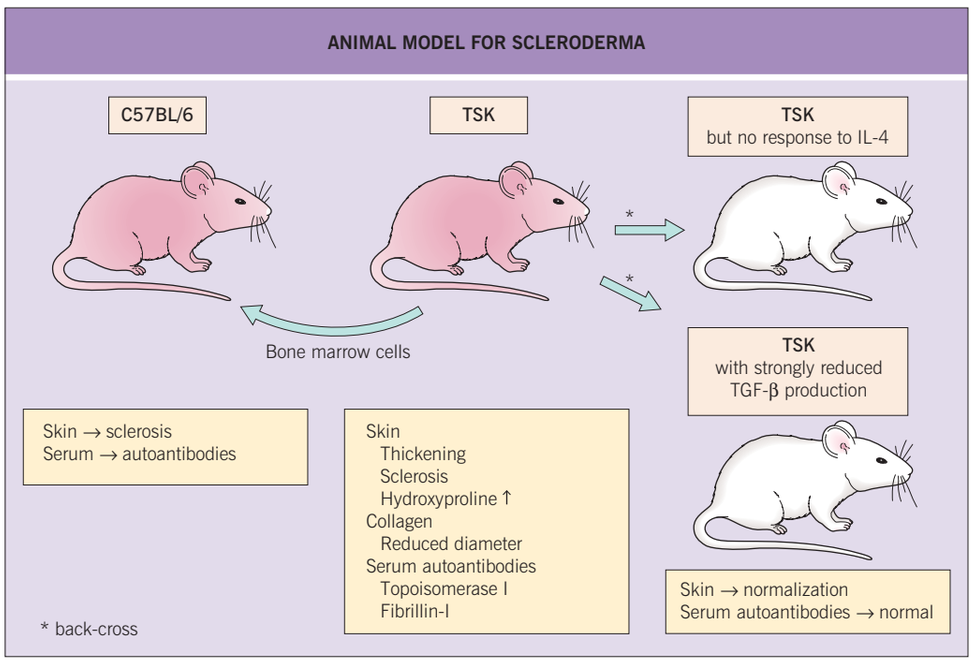

Fig. 44.2 Animal model for scleroderma. Transfer of scleroderma phenotype from diseased animals (TSK mice) to healthy syngeneic mice (C57BL/6) by bone marrow cells. Lack of tight skin and autoantibody production by back-crossing TSK mice with mice that cannot respond to IL-4 or mice that produce minimal amounts of TGF-β. IL, interleukin; TGF, transforming growth factor; TSK, tight skin strain of mice.

Fig. 44.3 Early inflammatory plaque-type morphea of the trunk. Early-stage lesion presenting as an erythematous edematous plaque.

One therapeutic approach for morphea would be to shift from Th2 responses to Th1 responses. However, a series of placebo-controlled clinical trials that tested the efficacy of IFN-γ or IFN-α in morphea had negative results[17]. Perhaps establishment of more effective cytokine-based therapies for skin sclerosis requires a more detailed understanding of cytokine actions *in vivo*.

Lastly, when scleroderma fibroblasts are compared to control fibroblasts, there are differences in intracellular signaling proteins. Examples include activation of p38 mitogen-activated protein kinase and higher levels of both Ha-Ras protein and reactive oxygen species (ROS)[18,19]. These findings and data from animal studies demonstrating the development of skin fibrosis after injections of pro-oxidative agents point to a role for oxidative stress in the pathogenesis of skin sclerosis[20].

Animal Model and Genetics

Currently, the best animal model for studying pathogenic events in scleroderma is the tight skin (TSK) mouse (Fig. 44.2). A partial duplication of the fibrillin-1 gene may be responsible for the increased synthesis and accumulation of collagen in the skin and internal organs of TSK mice. TSK mice not only have increased collagen deposits, but also the collagen fibers are reduced in length and the amounts of hydroxyproline are increased in the dermis, as is the case in morphea and systemic sclerosis. Moreover, the mice have high antibody titers against topoisomerase I and fibrillin-1, similar to patients with systemic sclerosis and morphea, respectively. One major difference is that blood vessels remain uninvolved in TSK mice, demonstrating that sclerosis of the skin can develop in the presence of apparently normal vessels[21]. The phenotype can be transferred from diseased animals to healthy syngeneic mice via bone marrow cells (see Fig. 44.2).

Fibroblasts from TSK mice have elevated IL-4 receptor α expression and back-crossing the TSK mice onto a genetic background that either can not respond to IL-4 or is deficient in producing TGF-β prevents skin sclerosis. Moreover, this back-cross normalizes collagen length, skin thickness and hydroxyproline content and prevents antibody formation to topoisomerase I (see Fig. 44.2)[21]. Promising therapeutic interventions include CpG motif-containing oligodeoxynucleotides that promote Th1 responses (and suppress IL-4 production) and PDGFR-targeting kinase inhibitors (e.g. imatinib), both of which reduce dermal thickening and fibrosis in TSK mice[22]. Of note, in case series, imatinib has led to improvement of cutaneous sclerosis in both fibrotic chronic GVHD and nephrogenic systemic fibrosis.

Besides the phenotypic similarities, the genetic locus associated with the TSK phenotype appears to be related to risk of developing scleroderma. In humans, this susceptibility locus is on chromosome 15q in a region of 2-cM that contains the fibrillin-1 gene (mutations in the fibrillin-1 gene have been implicated in stiff skin syndrome)[23]. Other genetic variations reported to be associated with scleroderma include polymorphisms in both *STAT4* (see above) and the promotor region of the gene encoding connective-tissue growth factor (CTGF)[9,10,24].

Fig. 44.4 Plaque-type morphea of the back. Multiple, large hyperpigmented plaques, several of which have an inflammatory border.

Triggering Events

Most immunologic and metabolic studies were designed to understand systemic sclerosis, and the question remains as to whether they can also explain focal, asymmetric inflammation and sclerosis of the skin. The major discriminating factor between morphea and systemic sclerosis might be the triggering event, with morphea being caused by a local trigger within the skin and systemic sclerosis being initiated by triggers with systemic effects.

These questions initiated the search for potential triggers and studies of diseases that share clinical features with morphea and scleroderma. One intensively investigated area was the potential role of infection with *Borrelia burgdorferi*. The isolation of *B. burgdorferi* from the skin of some selected patients with morphea originally supported this speculation. However, larger studies by several groups from different countries found that morphea lesions normally do not contain mRNA for *B. burgdorferi* or related strains and the prevalence of antibodies against *B. burgdorferi* is similar in patients with and without morphea[25]. Thus, this theory has been abandoned.

CLINICAL FEATURES

Morphea can be subdivided into several subgroups: plaque-type morphea, linear morphea, generalized morphea, and other less common variants (e.g. deep, guttate, nodular). There are also inflammatory syndromes leading to superficial or deep sclerosis of the skin that resemble morphea (i.e. morpheaform; see below). Patients with morphea do not have Raynaud's phenomenon or involvement of internal organs, except for underlying fascia, muscle and bone in some patients with linear morphea. In rare patients with presumptive morphea, clinically insignificant fibrosis of the lung or slightly reduced esophageal motility has been detected radiographically or by scintigraphy. Clinically relevant involvement of internal organs is only observed in certain types of pseudoscleroderma (see Ch. 43).

Clinical Manifestations

Plaque-type morphea, the most frequent variant, is characterized by the insidious onset of a slightly elevated, erythematous or violaceous, somewhat edematous plaque that undergoes centrifugal expansion (Fig. 44.3). It is generally asymptomatic and therefore frequently goes unnoticed by the patient. The central portion of the progressing lesion starts to transform into sclerotic, scar-like tissue. Depending on the depth of the sclerosis, the skin becomes progressively indurated.

Fig. 44.5 Comparison of deep morphea and eosinophilic fasciitis. **A** Note the "pseudocellulite" appearance of the involved skin of the thigh in deep morphea. **B** In eosinophilic fasciitis, the level of fibrosis is also deep, resulting in a similar clinical appearance.

Centrally, it can acquire a shiny white color, and peripherally, a violaceous or "lilac" ring. Postinflammatory hyperpigmentation often dominates over the white sclerosis as the lesions mature (Fig. 44.4).

Skin structures such as hairs and sweat glands are frequently lost. Some patients complain of itch, perhaps due to associated xerosis. Once the "lilac" ring vanishes, the lesion's progression also halts. Although this inflammatory margin may be difficult to appreciate, especially in linear sclerosis, it is an important component of the physical examination as it is an indicator of clinical activity.

The plaques of morphea most commonly develop on the trunk and are between 2 and 15 cm in diameter. They are usually multiple and asymmetric, but marked variation exists. Individual lesions may enlarge significantly or remain stable in size.

The course of morphea is also variable. In most patients, morphea progresses over 3–5 years, then arrests and eventually resolves spontaneously. However, residual atrophy and/or dyspigmentation are commonly observed. Rarely, patients have relapsing disease for more than 5 years. Because many patients are lost to follow-up, no definitive long-term statistical data have been published.

Variants

Various manifestations of morphea have become associated with specific names. They do not really reflect unique entities, but rather different morphologic features, distribution patterns or depth of involvement. In most patients, morphea seems to be randomly distributed. However, in some patients, the lesions are unilateral, and they may follow dermatomes or Blaschko's lines.

- **Guttate morphea** presents primarily as multiple, rather superficial, nummular plaques. Even though relatively small, they may become deeply indurated.
- **Atrophoderma of Pasini and Pierini** is considered by some to be a very superficial variant of plaque-type morphea, while others consider it to be a separate entity in the differential diagnosis of "burnt-out" morphea (see Ch. 99). Hyperpigmented patches are seen most commonly on the posterior trunk; occasionally, lesions follow Blaschko's lines (linear atrophoderma of Moulin).
- **Deep morphea** reflects an inflammation and sclerosing process that affects primarily the deep dermis and subcutaneous fat and may even involve underlying structures (e.g. the fascia) (Fig. 44.5A). Patients normally develop a single or few hard deep plaques that may impair motility of the skin; ultimately, lesions may calcify, leading to deep osteoma cutis. Because of the location of the sclerosis, individual lesions can share some clinical features with eosinophilic fasciitis (Fig. 44.5B and see Ch. 43).
- In **nodular or keloidal morphea**, inflammation within the dermis leads to thick, keloid-like nodules (Fig. 44.6) or streaks. It is clinically indistinguishable from indurated keloids.
- In rare patients, especially those where sclerosis of the skin is associated with diffuse, rapidly progressive edema, lymphoceles

Fig. 44.8 Linear morphea of the leg. The differential diagnosis includes linear melorheostosis which is often associated with underlying candlewax-like linear hyperostosis.

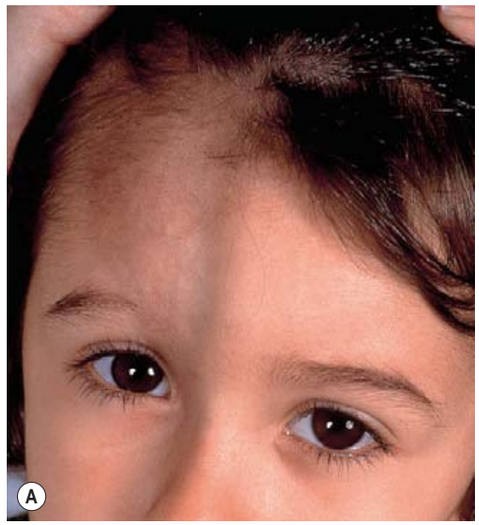

Fig. 44.9 Morphea *en coup de sabre*. Linear depressions and sclerosis are more frequently paramedian (rather than midline) and can be wide **(A)** or narrow **(B).** Note the prominent veins and loss of the medial eyebrow in A. *B, Courtesy, Julie V Schaffer, MD.*

may result from stasis of lymphatic fluid. When the latter develop into bullae, this is referred to as **bullous morphea**. It is more frequently observed in generalized morphea or sclerodermoid GVHD and is rarely a feature of plaque-type morphea. Bullous morphea has to be distinguished from mechanical blisters that may occur in the central scar and are secondary to impaired mechanical stability of the dermal–epidermal junction.

Linear Morphea and Parry–Romberg Syndrome

Linear morphea is different from plaque morphea, with respect to age of onset, distribution, clinical outcome and serologies. Morphea *en coup de sabre* (meaning stroke or blow with a single-edged sword) is a term used for linear morphea of the forehead and scalp. Hemifacial atrophy, or Parry–Romberg syndrome, is probably a very severe variant of linear morphea, but it may be a phenotype for more than one entity. There is a progressive loss of subcutaneous fat, but little or no sclerosis (Fig. 44.7). The entire distribution of the trigeminal nerve, including the eye and the tongue, may be affected.

Linear morphea may present initially as a linear, erythematous (inflammatory) streak, but more frequently it begins as a harmless-appearing lesion of plaque-type morphea that extends longitudinally as a series of plaques that then join to form a scar-like band (Fig. 44.8). This band may severely impair the mobility of the affected limb. Linear morphea tends to involve the underlying fascia, muscle and tendons. This leads not only to muscle weakness but also to a shortening of the muscles and fascia that impairs joint motility. Linear morphea is especially dangerous when extending over joints, as this almost invariably results in disabling joint immobilization. In some patients, involvement is circular rather than linear and results in progressive atrophy of the limb similar to the Parry–Romberg variant of facial morphea.

The *en coup de sabre* type of morphea represents linear morphea of the head (Fig. 44.9). It is normally unilateral and extends from the forehead into the frontal scalp. It may start either as a linear streak or as a row of small plaques that coalesce. A paramedian location is more common than a median location. Like plaque morphea, it may initially be surrounded by a discrete lilac ring that extends longitudinally and may reach the eyebrows, nose and even the cheeks. The waning inflammation leaves a linear, hairless crevice that in some patients is more sclerotic, while in others is more atrophic.

En coup de sabre morphea can also involve the underlying muscles and osseous structures. Rarely, the inflammation and sclerosis progress to involve the meninges and even the brain, creating a potential focus for seizures. Alternatively, very slowly progressing inflammation, indistinguishable from the inflammatory process of linear morphea, leads to gradual involution of the skin, fatty tissues and underlying bones.

Generalized Morphea

Rarely, plaque-type morphea is rapidly progressive, where multiple enlarging plaques appear simultaneously and coalesce until they involve nearly the entire integument. Rather, this variant normally begins insidiously on the trunk as plaque morphea. An individual lesion is indistinguishable from classic plaque morphea, except that it does not stop expanding. Just as in the diffuse form of systemic sclerosis, the plaques rapidly coalesce and affect the entire trunk, often only sparing the nipples. The sclerosis may involve the extremities down to the hands (presenting initially as puffy edema). As the cutaneous sclerosis progresses, it may result in disabling constrictions that even cause difficulty in breathing due to impaired thorax mobility and inflammation of the intercostal muscles. Although an aggressive therapeutic approach is recommended, the disease is usually persistent given its often limited response.

Morphea in Childhood

About 20% of those with morphea are children and teenagers. The female-to-male ratio for plaque-type morphea is about 2:1, with a mean age of disease onset of 7 years[26]. Linear morphea is more of a problem, as two-thirds of all patients with this variant are younger than 18 years of age when it develops. Also, in young children and adolescents, linear morphea often leads to growth retardation of the affected limb. Thus, if left untreated, linear morphea may result not only in decreased range of motion of joints but also in permanent limb asymmetry from

Fig. 44.10 Linear morphea of the leg in two adolescents. A Extensive induration of the left leg with hypoplasia and an obvious flexion contracture of the knee; there is also involvement of the right foot. **B** Linear distribution of coalescing sclerotic plaques on the thigh; note the lilac-colored border. *B, Courtesy, Julie V Schaffer, MD.*

unilateral hypoplasia (Fig. 44.10). Linear morphea that is indistinguishable from the idiopathic variant can also follow allogeneic hematopoietic stem cell transplantation.

Disabling pansclerotic morphea of children is similar to generalized morphea of the adult. It usually starts before 14 years of age and tends to cause lifelong severe disability due to persistent atrophy of the underlying muscles and contractures of the involved joints. The disease tends to extend from the trunk to the hands and feet. Periodontal atrophy may occur, but there is only slight involvement of the esophagus and lung. Distinction from systemic sclerosis may prove challenging.

Importantly, in a large multicenter study of children with morphea (85% of whom had linear morphea or Parry–Romberg syndrome [PRS]), 22% had extracutaneous findings that were primarily articular (11%), neurologic (4%) and ocular (2%)[26]. The latter were seen primarily in those with linear morphea of the head or PRS.

LABORATORY FINDINGS

Laboratory abnormalities are not a prominent feature of morphea, except for generalized and linear morphea. The ESR and serum protein levels are usually normal, but eosinophilia may occur, especially during early active phases of the disease. The presence of ANA or antibodies to ssDNA and histones are unusual in patients with plaque-type morphea (see Ch. 40). They are more frequent in linear and generalized morphea, where ANA can be found in high titers in 40–80% of patients. About 40% of children and adolescents with morphea have elevated ANA titers[26,27].

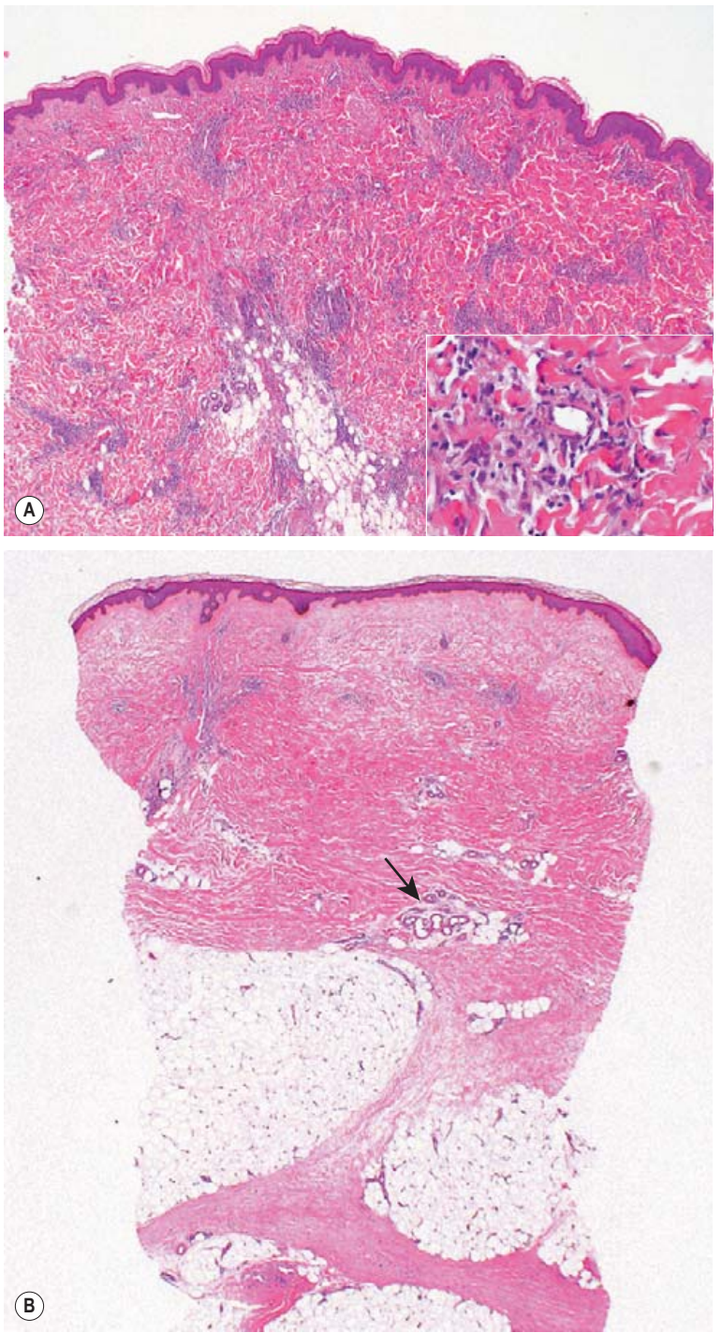

Fig. 44.11 Morphea – histologic features. A Overview with thickening of the dermis and perivascular infiltrates of lymphocytes and plasma cells (insert). **B** Advanced sclerosis of the entire dermis extending into the fat with thickened collagen bundles and "trapped" eccrine glands (arrow).

PATHOLOGY

The histology of scleroderma depends on two factors: the stage and area of the lesion sampled (early inflammatory margin or central sclerosis) and the depth to which the disease extends. In most situations, morphologic changes are best seen at the border between the dermis and subcutaneous fat. Specimens for histology must include subcutaneous fat and it is important to note whether the biopsy specimen is taken from the inflammatory border or from the fibrotic center.

At the inflammatory border, vascular changes are relatively discrete by light microscopy. Vessel walls show endothelial swelling and edema. Capillaries and small arterioles are surrounded by an infiltrate that contains primarily $CD4^+$ T cells and sometimes eosinophils, plasma cells and mast cells (Fig. 44.11A).

In later stages, the inflammatory infiltrate wanes and ultimately disappears completely, except in some areas of the subcutaneous fat.

The epidermis is basically normal in appearance, but the rete ridges may be diminished, leaving a flattened dermal–epidermal junction. Edema is no longer visible in the dermis and upper subcutis. Capillaries and small vessels are significantly reduced in number, and homogeneous collagen bundles with decreased space between the bundles replace most structures. At this stage, collagen bundles in the reticular dermis appear densely packed, as evidenced by a more intense eosinophilic staining, and are aligned parallel to the dermal–epidermal junction (Fig. 44.11B). Eccrine glands appear atrophic and "trapped" within the thickened dermis. The underlying subcutis is homogenized and hyalinized.

Deep morphea affects primarily the deep subcutaneous tissue. Following the inflammatory phase, extensive sclerosis and hyalinization extend into the underlying fascia. Involvement of the underlying fascia is obligatory in deep morphea and is also frequently observed in linear and generalized types of morphea. In these patients, the fascia and even the underlying muscle (frequently vacuolated) are involved in the process of progressive sclerosis, characterized by replacement of the differentiated tissue by collagen bundles.

MORPHEAFORM (AND SCLERODERMOID) INFLAMMATORY SYNDROMES

Some entities (e.g. sclerosis secondary to exposure to bleomycin, vinyl chloride or epoxy resin) that are characterized by acrosclerosis and Raynaud's phenomenon have a clinical presentation similar to scleroderma (i.e. sclerodermoid or pseudoscleroderma), while others present with circumscribed plaques similar to morphea (i.e. morpheaform). The former are discussed in Chapter 43 and the latter are discussed below and presented in Table 44.1. There are also clinical disorders that may have either type of clinical presentation, such as toxic oil syndrome.

DIFFERENTIAL DIAGNOSIS OF MORPHEAFORM SKIN LESIONS
Morphea (plaque-type, linear, generalized* or deep*)
Chronic graft-versus-host disease*
Lichen sclerosus (may coexist with morphea)
Lipodermatosclerosis*
Sclerosis at injection sites†
• Vitamin K_1 (Texier's disease) or vitamin B_{12}
• Silicone or paraffin implants
• Interferon-β
• Glatiramer
• Enfuvirtide
• Bleomycin (intralesional therapy)
• Opioids (e.g. pentazocine, ketobemidone, methadone)
Chemical/toxin exposures
• Aromatic/chlorinated hydrocarbons (e.g. benzene or toluene at sites of contact with skin)*
• Nephrogenic systemic fibrosis (induced by gadolinium-containing contrast media)*
• Toxic oil syndrome (historical)*
Radiation-induced morphea
Porphyria (porphyria cutanea tarda, hepatoerythropoietic porphyria, congenital erythropoietic porphyria)
Muckle–Wells syndrome
Winchester syndrome*
Asymmetric childhood scleredema/stiff skin syndrome*
Linear melorheostosis
Reflex sympathetic dystrophy*
Morpheaform sarcoidosis
Sclerosing congenital melanocytic nevus
Dermatofibrosarcoma protuberans
Cutaneous metastases (e.g. carcinoma *en cuirasse*)
*Can overlap with sclerodermoid disorders, which are outlined in Table 43.6; in particular, deep morphea and eosinophilic fasciitis may have a similar appearance.
†Systemic medications for which there have been reports of an association with morpheaform lesions include bleomycin, taxanes (e.g. paclitaxel, docetaxel), bromocriptine, ethosuximide, valproic acid, appetite suppressants and penicillamine.

Table 44.1 Differential diagnosis of morpheaform skin lesions.

While a variety of inflammatory diseases ultimately lead to superficial or deep sclerosis of the skin, their exact relationship to morphea is enigmatic. Some of these diseases are preceded by or associated with eosinophilia in blood or tissue. Infiltration by eosinophils may be of unknown etiology, as in eosinophilic fasciitis, or it may reflect an immune reaction to a defined toxic insult or antigenic stimulus, as in the L-tryptophan syndrome (eosinophilia–myalgia syndrome), toxic oil syndrome, or GVHD following hematopoietic stem cell transplantation. Lastly, since certain exogenous drugs or chemicals, endogenous metabolites or X-ray irradiation induce sclerosis at the site of tissue injury in only a subset of individuals, this suggests that unique metabolic events and innate or adaptive immune responses to these compounds determine the individual's susceptibility to develop sclerosis.

- **Lipodermatosclerosis**. Chronic venous insufficiency that persists for many years leads to sclerosis in association with chronic hypoxia. Lipodermatosclerosis favors the lower extremities, but can also involve the pannus; it is discussed in Chapter 100.
- **Injections of vitamin K_1 (Texier's disease)**. Injection of oil-soluble vitamin K_1 rarely causes a strictly localized, deep eosinophilic fasciitis that is indistinguishable from deep morphea. It may ultimately resolve with atrophy of the dermis and/or subcutis.
- **Paraffin and silicone injections or implants**. It is suspected that injection of silicone or liquid paraffin during reconstructive surgery or leakage of silicone implants may cause chronic inflammation that results in localized morphea-like sclerosis. The belief that these substances can cause more generalized inflammation and trigger systemic diseases such as systemic sclerosis, eosinophilic fasciitis or mixed connective tissue disease was not substantiated when meta-analyses were performed[28].
- **Porphyrias**. In adults, porphyria cutanea tarda can lead to morphea-like sclerosis in UV-exposed sites, such as the face, hairless scalp, dorsal aspects of the hands, and the upper chest. Histology and electron microscopy findings may resemble morphea except for the presence of PAS-positive deposits around dermal blood vessels. Other rare forms of porphyria can also lead to scarring in UV-exposed sites (see Ch. 49).
- **Radiation-induced morphea**. This disorder is characterized by marked sclerosis, erythema and pigmentary changes occurring within the radiation field or even beyond it. The incidence of radiation-induced morphea is about 1 in 500 patients and it is seen primarily in patients treated for breast carcinoma. Predictive risk factors for the development of radiation-induced morphea are unknown and disease onset can even occur several years after radiation therapy. In addition to the changes of radiation dermatitis, histopathology demonstrates perivascular and subcutaneous inflammation together with dermal fibrosis and collagen deposition.
- **Chronic GVHD**. Patients with chronic GVHD develop lesions that resemble morphea and lichen sclerosus as well as eosinophilic fasciitis (see Ch. 52).
- **Nephrogenic systemic fibrosis**. This entity is discussed in detail in Chapter 43.

DIFFERENTIAL DIAGNOSIS

In addition to the other morpheaform and sclerodermoid conditions discussed above, the most important entity in the differential diagnosis is systemic sclerosis (see Ch. 43). Absence of Raynaud's phenomenon and lung or esophageal involvement is characteristic of morphea. The other common considerations are lichen sclerosus and keloids; however, the former can coexist with morphea. Dupuytren's contracture and camptodactyly, a benign ulnar deviation of the fourth and fifth finger, can be clinically distinguished from linear morphea.

Scleredema leads to diffuse woody induration of the upper back and neck. Symmetric tightness and induration of acral sites can be seen in insulin-dependent diabetes with cheiroarthropathy, also referred to as waxy skin and stiff joints. In children, progeria and premature aging syndromes need to be distinguished from Parry–Romberg syndrome, but the latter is unilateral. Additional entities in the sclerodermoid differential diagnosis (e.g. scleromyxedema) are listed in Table 43.6.

LICHEN SCLEROSUS

Synonyms: ■ Lichen sclerosus et atrophicus ■ Kraurosis vulvae ■ Balanitis xerotica obliterans (lichen sclerosus of the penis)

Key features

- Sclerotic, ivory-white, flat papules and plaques with epidermal atrophy and, in extramucosal sites, follicular plugging
- Most commonly affects female or male genitalia, less often extragenital skin
- May cause scarring of the vaginal introitus or phimosis
- Severe pruritus may occur
- No systemic manifestations

INTRODUCTION

Lichen sclerosus is a clinically distinct inflammatory disease primarily of the superficial dermis or submucosa that leads to ivory-white scar-like atrophy. Extragenital lichen sclerosus may itch and be cosmetically disturbing. Genital lichen sclerosus causes both dryness and severe, persistent pruritus, and it often leads to progressive atrophy and functional impairment. Phimosis or scarring of the vaginal introitus are the most frequent complications.

HISTORY

Francois Henri Hallopeau's report on a "lichen plan atrophique" in 1887 is considered to be the first description of lichen sclerosus. The typical histopathologic changes of lichen sclerosus et atrophicus were published by Ferdinand Jean Darier in 1892. Unna, Westberg, von Zumbusch and others elucidated the clinical features of lichen sclerosus in various case reports[29–31]. This contributed to the panoply of terms, such as white spot disease or lichen albus, an aspect that complicates any literature survey. Lichen sclerosus in the genital area was first described in women by Breisky as kraurosis vulvae[32] and 40 years later in men by Stühmer as balanitis xerotica obliterans[33]. Today, lichen sclerosus, the term proposed by the International Society for the Study of Vulvar Disease, is most frequently used[34,35].

EPIDEMIOLOGY

Lichen sclerosus is relatively uncommon, although the exact prevalence is unknown. It occurs at all ages and seems to have a similar incidence in all races; the reported female-to male-ratio varies widely, depending upon the study, from 10:1 to 1:1[34,35].

In both sexes, the anogenital area is affected in at least 85% of patients. However, the best epidemiologic studies concentrate on vulvar disease. Since lichen sclerosus of non-genital skin frequently causes no symptoms, it is likely that the prevalence of extragenital lichen sclerosus is underestimated.

Prospective and retrospective studies in adult patients suggest that lichen sclerosus is one of the most common causes of symptomatic vulvar disease. In two large series, lichen sclerosus was diagnosed in 13% to 19% of patients[36] presenting with symptomatic vulvar disease. In women, the peak incidence is during the fifth and sixth decades, and a second peak occurs in girls between 8 and 13 years of age. Among prepubertal girls with vulvar disease, the relative frequency of lichen sclerosus is similar to that in adults. Extragenital lichen sclerosus is rare in children. In boys and men, lichen sclerosus frequently leads to phimosis (seen in 14 of 100 prepubertal boys undergoing circumcision for phimosis). Of 357 male patients attending a dermatology clinic with genital skin disease, 14% had lichen sclerosus[37].

PATHOGENESIS

As in most inflammatory diseases, genetic predisposition contributes to the development of lichen sclerosus, as it may be found in monozygotic and fraternal twins. In addition, association with the MHC class II antigen HLA-DQ7 was observed in a relatively large study[38]. The existence of a susceptibility gene for sclerosis within this region of the MHC is underlined by the finding that the same region is associated with an increased risk of autoimmune diseases. Even though inflammation seems essential for initiation and progression of lichen sclerosus, the mechanisms leading to subsequent sclerosis remain speculative.

Perhaps with the exception of autoantibodies against extracellular matrix protein 1 (ECM-1), no specific immunologic parameters have been identified in patients' sera that clearly correlate with either risk of disease or disease activity. IgG autoantibodies against ECM-1 are found in 80% of patients with lichen sclerosus and the latter may act as an autoantigen[39]. Oxidative stress may also play a role in the pathogenesis of lichen sclerosus, based upon analysis of lesional skin that showed lipid peroxidation of epidermal basal cell layers, oxidative DNA damage and oxidative protein damage.

CLINICAL FEATURES

Lichen sclerosus is a disease that can affect both extragenital skin and the anogenital region. Lichen sclerosus of the oral cavity, the palms or soles is rare. In the oral mucosa, bluish white papules up to 5 mm in diameter may occur on the buccal mucosa or under the tongue. They can lead to superficial scar-like atrophy or erosions.

Extragenital lichen sclerosus normally does not cause symptoms except for dryness and associated pruritus. Lesions favor the trunk (Fig. 44.12A) and the proximal extremities. More specific predilection sites include the neck (Fig. 44.12B), shoulders, flexor surfaces of the wrists, and sites of physical trauma or continuous pressure (e.g. the shoulder or hip). The periorbital area and scalp are rarely affected.

It is unusual to see extragenital disease during its early phases when single lesions begin as polygonal, bluish-white, shiny, slightly elevated, interfollicular papules. Over time, these papules often enlarge or coalesce into larger plaques. Most patients present with slightly sclerotic, scar-like papules and plaques that are usually ivory in color and have a shiny and/or wrinkled surface. Occasionally, lesions have a pink or light violet hue. At sites of continuous pressure, the surface may acquire a parchment-like appearance.

In more advanced stages, telangiectasias or follicular plugging can be seen (Fig. 44.13A). The flattened interface between the epidermis and dermis results in fragility of the dermal–epidermal junction; as a result, lichen sclerosus is occasionally complicated by the development of bullae that tend to become hemorrhagic (Fig. 44.13B).

In women, the vulva and the perianal region are commonly involved, often in a figure-of-eight configuration (see Ch. 73). Although the disease may be symptom-free, it frequently causes severe pruritus and soreness. These symptoms may be considerable and lead to dysuria, dyspareunia, or pain upon defecation (often manifesting as constipation in children). Lichen sclerosus often begins as a slightly elevated, sharply demarcated area of erythema, which can be slightly eroded (Fig. 44.14). Over time, the involved skin becomes shiny, hypopigmented and sclerotic, and fissures may develop. Associated scarring can lead to burying of the clitoris and fusion of the labia minora to the labia majora. With severe disease, loss of the labia minora and significant narrowing of the introitus can occur. Sexual intercourse may become impossible.

Areas of purpura often develop within lesions of anogenital lichen sclerosus and can even aid in clinical diagnosis. However, the hemorrhage combined with erosions may be misdiagnosed as sexual abuse. Careful examination, perhaps with confirmation of the diagnosis by histology, is mandatory. The two disorders can coexist and sexual abuse may (although rarely) trigger the onset of lichen sclerosus as a Koebner phenomenon. False accusations can be as problematic or traumatic to the child and family as overlooking sexual abuse.

In boys and men, acquired phimosis or recurrent balanitis are the primary presenting features, and perianal involvement is very rare. Itching and soreness are common. On the glans and the inner aspect of the foreskin, lichen sclerosus starts as sharply demarcated, sometimes slightly blue–red lesions, occasionally with erosions. This inflammation tends to evolve into an atrophic white sclerotic scar (Fig. 44.15). The constriction may cause pain on erection and, at advanced stages, dysuria and urinary obstruction. If the foreskin is affected,

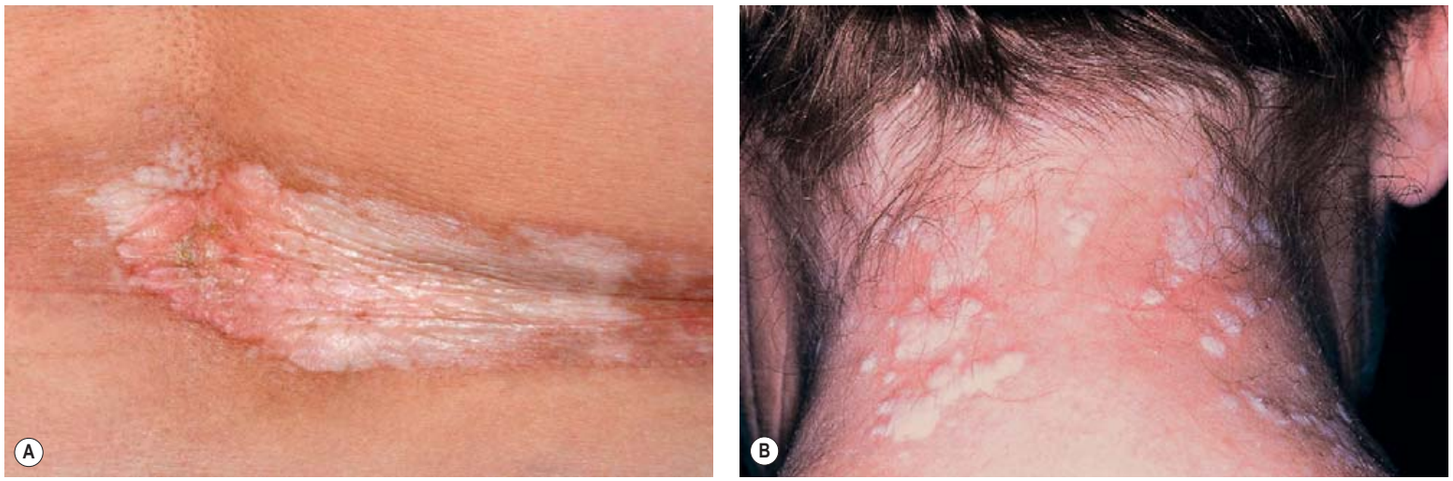

Fig. 44.12 Lichen sclerosus. A large shiny, ivory-colored plaque of the lower back (**A**) and white papules and small plaques on the neck (**B**).

Fig. 44.13 Lichen sclerosus. **A** Follicular plugging in a plaque of lichen sclerosus on the back of a patient with chronic GVHD. **B** Hemorrhagic bullae on the leg. *A, Courtesy, Jean L Bolognia, MD.*

Fig. 44.14 Vulvar lichen sclerosus. Centrally, there is erythema with superficial erosion and purpura. More peripherally, white plaques with a wrinkled surface are seen. Note fissuring of the perineum.

Fig. 44.15 Lichen sclerosus of the penis (balanitis xerotic obliterans). Note the ivory color, erosion and scarring.

lichen sclerosus invariably leads to phimosis (difficulty in retracting the foreskin to uncover the glans), with the additional risk of paraphimosis (when a foreskin retracted behind the glans can not be returned to its original position); the latter represents a urologic emergency. Many boys and men first present when the phimosis impairs repositioning of the foreskin; in these situations, diagnosis depends on histology. Progressive disease can be associated with poorly healing ulcers of the glans. While circumcision is clearly a first-line therapy, lichen sclerosus may recur at the site of a circumcision.

An open question is whether genital lichen sclerosus is a precancerous condition. Interpretation and comparison of the data are complicated by two factors: some of the patients reported as developing cancer had previously received X-ray therapy for the disease or had previous dysplasia due to human papillomavirus (HPV) infection. It is therefore very difficult to establish a useful meta-analysis. Most data suggest that lichen sclerosus is not intrinsically precancerous, but that it has to be considered as a chronic scar continuously exposed to a humid milieu, where carcinogenesis may be promoted[34,35].

PATHOLOGY

Lichen sclerosus has a specific histologic pattern. Initially, superficial dermal edema is associated with a band-like lymphocytic infiltrate (Fig. 44.16A). The epidermis is thinned, with orthohyperkeratosis and vacuolar degeneration of the basal layer. Hyperkeratosis is especially pronounced at follicular openings and may lead to plugging. The vacuolar degeneration at the dermal–epidermal interface and the flattening of the rete ridges predisposes to the development of blisters, which may become hemorrhagic. The most important changes are found in the superficial dermis, where the pale staining reflects homogenized dermal collagen (Fig. 44.16B) or edema (early stage). Loss of elastic fibers is typical for lichen sclerosus but is not observed in morphea. Clefting and hemorrhage within the homogenized papillary dermis is often seen.

During the early phases, the inflammatory infiltrate is especially pronounced along the zone of hyalinization and consists of lymphocytes ($CD3^+$, $CD4^+$, $CD8^+$), macrophages and mast cells. In older lesions, the mononuclear infiltrate is reduced and sparse, and patchy islands of mononuclear cells are dispersed within the hyalinized dermis. Ultrastructural studies reveal shortened collagen fibers.

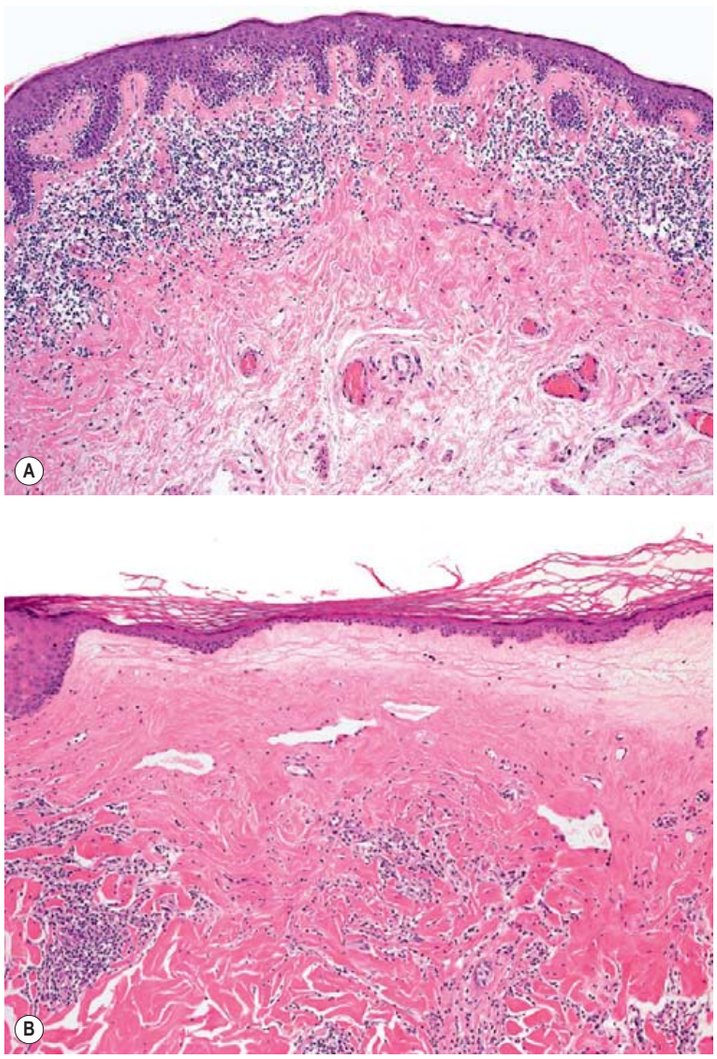

Fig. 44.16 Lichen sclerosus – histologic features. A Early lesion with band-like infiltrate of lymphocytes in the upper dermis and vacuolar change at the dermal–epidermal junction. Mild homogenization of the papillary dermis is present. **B** Late lesion with orthohyperkeratosis, thinning of the epidermis and homogenization of the upper dermis. There is also hyalinization and sclerosis of the papillary dermis, telangiectasias and an interstitial lymphocytic infiltrate. *Courtesy, Lorenzo Cerroni, MD.*

DIFFERENTIAL DIAGNOSIS

The most important entity in the differential diagnosis of extragenital lichen sclerosus is morphea, and for genital lichen sclerosus in girls and boys, it is sexual abuse[40]. In adults, genital lichen sclerosus may mimic erythroplasia of Queyrat or erosive lichen planus (see Ch. 73). Distinction often requires histologic examination. Biopsies may also be needed to exclude malignant transformation, especially when there is a superimposed infection with potentially carcinogenic HPV-16 or HPV-18. Histologically, lichen sclerosus-associated pseudoepitheliomatous hyperplasia has to be distinguished from squamous cell carcinoma (SCC). A past history of allogeneic hematopoietic stem cell transplant points to chronic GVHD.

TREATMENT OF MORPHEA AND LICHEN SCLEROSUS

Various therapeutic modalities have been reported for lichen sclerosus and morphea (Table 44.2). Most reports are based on single or limited observations or, occasionally, larger numbers of patients but without controls. Well-designed, randomized controlled trials are rare. Meta-analysis of the literature suggests that some treatments are well established and effective in a majority of patients while others seem to be effective in only a small number of patients. Well-established treatment options should not be confused with therapeutic suggestions based on a single observation or those that require more substantial investigation.

A major problem has been the lack of standardized outcome measures for assessing the efficacy of various therapies for morphea and lichen sclerosus. However, there has been a recent attempt to devise a reproducible severity index score for morphea[41]. In addition, 20 MHz ultrasound measurements of individual plaques (pre- and post-therapy) can prove helpful.

Phototherapies

Phototherapy for morphea was first described in 1994[42], and since then, the efficacy has been confirmed by more than 30 publications[43,44]. Due to the nature of phototherapy, placebo-controlled studies can not be performed. Nonetheless, little doubt exists as to the efficacy of this therapy, as untreated morphea normally progresses over 3–5 years and then regresses very slowly over years. More rapid spontaneous improvement only occurs in a small minority of patients[2]. The clinical course is definitely different in patients receiving either bath PUVA therapy or UVA1. If 30–36 treatments of bath PUVA therapy (at slightly suberythematous doses) or 30–36 treatments of UVA1 (30–60 J/cm^2) are given, morphea either completely resolves or markedly improves in at least 60% of patients[45] (Fig. 44.17). Further advantages of phototherapy, and especially UVA1, include clinical improvement in all skin types[46] and long periods of remission[47].

Both photochemotherapy and UVA1 induce expression of matrix metalloproteinase 1, a collagenase that reduces procollagen and collagen within the skin. The regression of morphea can be objectively documented by measuring skin thickness and skin density by 20 MHz ultrasound (Fig. 44.18) or by histology[44,48,49]. Both phototherapies seem

to be effective in all types of morphea except for morphea profunda. There is less experience with extensive linear or pansclerotic morphea, but these subtypes may also improve with either mode of phototherapy[50]. In the case of photochemotherapy, it has been administered primarily as bath PUVA therapy[16,51] (few reports exist on the use of cream PUVA or systemic PUVA[50]).

Another open question is the ideal dose for UVA1 therapy. Most initial studies were performed with either low (20 J/cm^2) or medium doses (30–70 J/cm^2) of UVA1 and reported similar efficacy. A recent study that utilized 20 MHz ultrasound rather than clinical assessment of morphea lesions reported a better response (after 30 treatments) with medium-dose (70 J/cm^2) than with low-dose (20 J/cm^2) UVA1[48]. In agreement with these reports, we have observed that 36 treatments with 30 J/cm^2 of UVA1 markedly improved morphea in the majority of patients[45]. Importantly, in responding patients, lesions of morphea continue to improve beyond the end of the therapy. Thus, therapy can be terminated after 36 treatments, even if the sclerosis has not yet completely resolved. The only exception appears to be linear morphea, which may require significantly more treatments. In our experience, selected patients who fail to respond to one mode of phototherapy may benefit from a switch to the other, i.e. if a patient does not improve within 4 months with one type of phototherapy (e.g. bath PUVA), a new therapy cycle should be initiated utilizing another mode of phototherapy (e.g. UVA1). Patients may also benefit from phototherapy plus low-dose systemic retinoids as this combination has led to improvement of sclerodermoid GVHD and plaque-type morphea[16,52].

Much less experience exists with regard to phototherapy for lichen sclerosus. Based upon observations in a small number of patients with extragenital lichen sclerosus, bath or cream PUVA therapy or UVA1 therapy may improve lesions in some selected patients; similar results have been reported for genital lichen sclerosus. For example, a preliminary study reported clinical improvement in 10 patients with extragenital lichen sclerosus following 40 treatments with low-dose UVA1 (20 J/cm^2)[53]. Based upon our experience with extragenital lichen sclerosus, phototherapy seems less effective than in morphea. More detailed studies are required and phototherapy may be an alternative for selected patients with extensive lichen sclerosus who respond poorly to topical corticosteroids and/or calcineurin inhibitors.

There are no consistent results from the use of extracorporeal photophoresis. The associated costs and the invasiveness are very high, and the efficacy of UVA1 or photochemotherapy clearly appears to be superior. Although preliminary data from a prospective study of

photodynamic therapy for vulvar lichen sclerosus pointed to significant relief of symptoms, similar results were not observed in more recent studies.

Topical Therapies

Corticosteroids

Retrospective and prospective studies have clearly documented that ultrapotent topical corticosteroids are highly effective in the treatment of genital lichen sclerosus. In the majority of these studies, clobetasol propionate 0.05% cream was applied for 12–24 weeks[54]. Clinical improvement was confirmed by histopathology. Both safety and efficacy of clobetasol in the treatment of genital lichen sclerosus were documented for all age groups and in both sexes. Nearly all the patients with vulvar lichen sclerosus responded to ultrapotent topical corticosteroids, and amongst those who improved, about 20% experienced complete clearance[55]. However, topical corticosteroids do not cure the disease and relapses may occur.

Major side effects were not reported, even with long-term and maintenance use of clobetasol. Therefore, potent topical corticosteroids represent first-line therapy for genital lichen sclerosus, including in children (Fig. 44.19). Alternatively, corticosteroids such as triamcinolone can be injected intralesionally. Of note, vulvar SCC appeared to develop primarily in untreated or irregularly treated lesions of vulvar lichen sclerosus.

The benefit of topical corticosteroids in the treatment of morphea is questionable. Ultrapotent topical corticosteroids may be useful for reducing inflammation in superficial active lesions. Similarly, intralesional injection of triamcinolone into the margins may reduce or prevent progression. Topical corticosteroids are ineffective in resolving sclerosis.

Calcineurin inhibitors

The macrolide immunosuppressants pimecrolimus (1% cream) and tacrolimus (0.1% ointment) have been used as topical treatments for vulvar lichen sclerosus. Several case reports and initial trials involving limited numbers of patients suggest that these therapies are effective[56]. Concerns have been raised as to the possibility of increasing the risk of developing SCC or reactivating HPV following the use of topical calcineurin inhibitors for vulvar lichen sclerosus. Long-term safety and efficacy studies as well as randomized trials comparing these agents with clobetasol are needed. With regard to morphea, improvement following topical tacrolimus (0.1% ointment) has been reported in case series, especially in patients with early inflammatory lesions[57,58]. Again, prospective, double-blind, randomized trials are needed.

Vitamin derivatives

Derivatives of vitamin D and vitamin A are still under study in morphea. *In vitro*, calcipotriol inhibits the proliferation of cultured fibroblasts and topical calcipotriene (0.005% ointment) has been used for the treatment of morphea[59]. Single reports have described improvement of both vulvar lichen sclerosus and morphea when treated with topical vitamin A derivatives. All of these observations require confirmation by controlled studies.

Hormones

For years, topical testosterone or progesterone preparations were frequently used for the treatment of genital lichen sclerosus. In sharp contrast to ultrapotent topical corticosteroids, there is no evidence to support the efficacy of these agents. Controlled clinical studies have clearly shown that hormone preparations have no clinical benefit in lichen sclerosus[60]. In one study, 2% testosterone propionate was even less effective than petrolatum ointment[61].

Systemic Treatments

Immunosuppression

Oral corticosteroids (methylprednisolone or prednisone 1–2 mg/kg/day) may be helpful during the inflammatory stages of morphea, especially in those patients with rapidly progressive linear or disabling morphea. However, systemic corticosteroids do not improve established sclerosis and disease activity may rebound following discontinuation.

Alternatively, 15–20 mg/week of methotrexate seems to be helpful in the acute phase of morphea[62]. Based on experience with other autoimmune diseases, some authors favor the combination of methotrexate plus corticosteroids, especially in rapidly progressive disabling types of morphea[63]. Clinical data from a prospective pilot study confirmed the therapeutic effectiveness of methotrexate (15 mg/week) combined with pulsed high-dose intravenous methylprednisolone (1 g 3 days per month)[64]. Placebo-controlled studies are still lacking, but the potential benefit documented in systemic sclerosis suggests that this mode of immunosuppression, administered for several months to up to 1 year, may be indicated in selected patients with disabling morphea.

In contrast, cyclosporine has not been shown to be effective. Furthermore, cyclosporine should not be combined with any form of phototherapy.

Although systemic immunosuppression is normally not indicated for lichen sclerosus, there is a subset of patients with recalcitrant generalized disease. In a small series of such patients, a combination of pulsed high-dose intravenous corticosteroids plus low-dose oral methotrexate led to improvement[65].

Penicillin and its derivatives

Regression of morphea or systemic sclerosis during prolonged treatment with penicillin or penicillamine has been observed in adults and in children[66]. Penicillin in the range of 30×10^6 IU/day for 3–4 weeks is helpful in about 5% of patients, as documented by several authors. In addition, the response is reproducible in those individuals who relapse following previously successful penicillin regimens. Penicillamine seems to be similarly effective but is used less often because of its potential side effects.

In lichen sclerosus, neither penicillin nor other antibiotics nor penicillamine are helpful.

Vitamin derivatives

Treatment with the oral vitamin A derivatives etretinate or acitretin at doses of 10–50 mg/day is effective in morphea and lichen sclerosus[67,68]. Importantly, the response can only be assessed after several months of therapy. The exact mechanism by which retinoids improve sclerosis is unclear. However, in cultured scleroderma fibroblasts, retinoids can induce COX-2 and PGE_2 while inhibiting the profibrotic factor CTGF and collagen production (types I and III)[69]. Moreover, retinoids interact with TGF-β signaling, one of the key cytokine pathways for promoting collagen synthesis by fibroblasts (see Fig. 44.1). Retinoids (e.g. etretinate, isotretinoin) are also effective in certain pseudoscleroderma disorders such as "sclerodermoid" GVHD[15,16].

The other vitamin derivative investigated for the treatment of morphea is calcitriol. 1,25-Dihydroxyvitamin D_3 has pronounced anti-inflammatory effects, and it modulates fibroblast growth as well as TGF-β[70]. Despite promising case reports, a double-blind, placebo-controlled study did not confirm the clinical efficacy of oral calcitriol in morphea[71].

Cytokines, TNF-α inhibitors, multi-kinase inhibitors

As IFN-γ and IFN-α normalize pathogenic collagen production by fibroblasts *in vitro*, both cytokines have been tested for the treatment of morphea. However, in controlled studies, neither cytokine reversed cutaneous sclerosis[17]. Whether TNF-α has a pathogenic role in morphea and systemic sclerosis is unclear. In a pilot study of patients with systemic sclerosis, infliximab did not improve skin sclerosis[72].

The signaling pathways of growth factors such as TGF-β and PDGF, which play a role in generating cutaneous sclerosis, represent potential therapeutic targets. Imatinib is an example of a multi-kinase inhibitor that can inhibit the PDGF receptor (hence its effect on dermatofibrosarcoma protuberans). In case series, systemic administration of imatinib reduced skin sclerosis in patients with systemic sclerosis[22,73].

Surgery

In the case of persistent contractures, reconstructive surgery may be needed. Similarly, surgical revision may be required in linear or *en coup de sabre* morphea. Autologous fat transplantation has been used successfully for the latter as well as for Parry–Romberg syndrome.

Circumcision is the treatment of choice for genital lichen sclerosus complicated by phimosis or paraphimosis.

Physical Therapy

Expert and longstanding physiotherapy is obligatory for patients in whom morphea threatens to impair mobility.

SYSTEMIC-ONSET JUVENILE IDIOPATHIC ARTHRITIS (STILL'S DISEASE)

Synonyms: ■ Juvenile idiopathic arthritis: juvenile rheumatoid arthritis (JRA); juvenile chronic arthritis

Key features

- There are several types of juvenile idiopathic arthritis, including systemic-onset, polyarticular (either rheumatoid factor [RF]-positive or RF-negative) and oligoarticular
- Systemic-onset juvenile idiopathic arthritis, also known as Still's disease, is characterized by high spiking fevers, lymphadenopathy, hepatosplenomegaly, transient cutaneous eruptions of erythematous macules and papules (often accompanying the fevers and associated with Koebner phenomena), and arthritis

Introduction

Juvenile idiopathic arthritis (JIA) is classified into seven major types (Table 45.1)[1], including systemic-onset, rheumatoid factor (RF)-positive polyarticular, RF-negative polyarticular, and oligoarticular. Systemic-onset JIA (SoJIA), also known as Still's disease, is characterized by an evanescent, erythematous eruption that typically accompanies spiking fevers. Cutaneous manifestations are less common in the other types, although the RF-positive subgroup of polyarticular JIA can present with rheumatoid nodules and other skin findings similar to those of adult rheumatoid arthritis (see below), and nearly all patients with psoriatic arthritis have cutaneous and/or nail psoriasis (see Ch. 8).

History

In 1897, George Still, an English pediatrician, first described a chronic arthritis in children that was associated with fever, lymphadenopathy and organomegaly.

Epidemiology

JIA is the most common rheumatic disease in childhood, and its overall prevalence is estimated to be 0.2–1 per 1000 children (by definition ≤16 years of age)[2]. SoJIA comprises 15–20% of all cases of JIA and can occur at any time from infancy through adolescence, with a mean age at onset of 6 years. Whereas most other types of JIA have a female predominance, SoJIA affects both sexes equally.

Pathogenesis

Recent insight into the pathogenesis of SoJIA suggests that it is better classified as an autoinflammatory rather than an autoimmune disease. The inflammation characteristic of this disease appears to result from activation of *innate* immune responses rather than adaptive phenomena characterized by antigen-specific, lymphocyte-driven immune responses. Dysregulated production of interleukin (IL)-1 appears to play a critical role in the pathogenesis of SoJIA. When peripheral blood mononuclear cells (PBMCs) from healthy individuals are exposed to sera from patients with SoJIA, there is upregulation of gene expression for the innate inflammatory cytokines IL-1α and IL-1β (as well as upregulation of other innate immunity genes)[3]. The PBMCs of SoJIA patients produce an excess of IL-1β upon activation, and administration of IL-1 receptor antagonists (e.g. anakinra, rilonacept) can reduce disease activity (see below). The dysregulated IL-1 production may be due to inflammasome activation[4] (Fig. 45.1) and/or dysregulation of the alternative secretory pathway downstream of caspase-1 that is responsible for the production of the calcium-binding proteins S100A8, S100A9 and S100A12; the latter are secreted during activation of neutrophils and monocytes[5]. Patients with SoJIA have exceptionally high serum levels of S100A8, S100A9 and S100A12, and these proteins do exhibit proinflammatory effects on endothelial cells and leukocytes.

At the onset and during flares of SoJIA, vascular endothelial cells express leukocyte adhesion molecules, leading to a perivascular infiltrate of neutrophils and activated monocytes that secrete proinflammatory cytokines including tumor necrosis factor-α (TNF-α), IL-1 and IL-6[5]. Many of the clinical features of SoJIA can be explained by the effects of these cytokines. For example, IL-1 stimulates granulopoiesis in the bone marrow and activates thermoregulatory functions of the hypothalamus to cause fever. The chronic overexpression of IL-6 observed in SoJIA increases osteoclastogenesis and reduces osteoblast activity. IL-6 also stimulates hepatocytes and induces the production of acute phase reactants such as C-reactive protein.

Clinical Features

Daily high fevers (usually above 38.9°C) that typically occur in the late afternoon or early evening are characteristic of SoJIA. The arthritis is frequently polyarticular, and the joints most commonly affected are the knees, ankles and hips, followed by the small joints of the hands. A subgroup of patients may develop destructive joint disease similar to that seen in RF-positive polyarticular arthritis (see Table 45.1).

An exanthem is present in up to 90% of patients with the acute febrile presentation of SoJIA[6], and it is often preceded or accompanied by arthralgias. Although arthritis usually develops during the first few months of the disease course, in approximately one-quarter of patients the exanthem begins prior to the onset of arthritis, occasionally predating joint involvement by several years. The eruption is typically transient, non-pruritic and erythematous, and it coincides with fevers (Fig. 45.2). There is a predilection for the axillae and waist, and linear lesions secondary to the Koebner phenomenon are often observed. Other less common cutaneous features include persistent plaques (which also may be linear) and periorbital edema and erythema[7]. Rheumatoid nodule-like lesions that favor extensor surfaces have been described in the setting of methotrexate therapy for SoJIA[8]. Additional systemic features of SoJIA are outlined in Table 45.1. Although there are no laboratory findings specific for SoJIA, leukocytosis, granulocytosis, thrombocytosis, elevated hepatic enzymes, an elevated ESR, extremely high serum

CLASSIFICATION OF JUVENILE IDIOPATHIC ARTHRITIS	
Systemic onset (20%) (Still's disease)	**Features required for diagnosis** • High episodic fevers – daily for ≥2 weeks and documented to be quotidian for ≥3 days • At least one of the following: *evanescent eruption*, generalized lymphadenopathy, hepatomegaly or splenomegaly, serositis • Symmetric polyarthritis > oligoarthritis (erosive in 20%)* ***Other features*** • Leukocytosis with neutrophilia, anemia (often severe), thrombocytosis, elevated ESR, elevated ferritin and C-reactive protein levels • Occasionally myocarditis, pneumonitis, anterior uveitis (<1%), CNS involvement, macrophage activation syndrome (6–13%); rarely amyloidosis • RF- and ANA- negative in >95% of patients
RF-negative polyarthritis (5%)	• 3–9 years of age • ≥5 joints in the first 6 months • Small joints of the hands & feet > knees, wrists, ankles; erosive arthritis (15%) • RF-negative; ANA-negative
RF-positive polyarthritis (15%)	• 10–16 years of age • ≥5 joints in the first 6 months • Small joints of the hands & feet > knees, wrists, ankles; erosive arthritis (>50%) • *Rheumatoid nodules*, low-grade fever, mild anemia, weight loss • RF-positive (100%); ANA-positive (70%)
Oligo/pauciarticular arthritis (60%): • type I – 50% • type II – 10%	• ≤4 joints in the first 6 months† • Knees > ankles, wrists; often asymmetric • Type I: 1–8 years of age; uveitis 30–50%; ANA-positive 60%; RF-negative • Type II: 9–16 years of age; HLA-B27; RF-negative; ANA-negative
Enthesitis-related arthritis	• Arthritis *and* enthesitis - or - • Arthritis *or* enthesitis plus ≥2 of the following: sacroiliac joint tenderness/spinal pain, HLA-B27, family history of HLA-B27-associated disease in first- or second-degree relative, anterior uveitis, onset of arthritis in a boy after age 8 years
Psoriatic arthritis	• Arthritis and *psoriasis* - or - • Arthritis and ≥2 of the following: dactylitis, *nail abnormalities* (see Ch. 71), family history of psoriasis in ≥1 first-degree relative • Other features: anterior uveitis, ANA-negative
Other arthritis	• Children with arthritis of unknown cause persisting ≥6 weeks that does not fulfill criteria for any other categories or fulfills criteria for more than one category

*Onset may be delayed for months to years.
†The persistent oligoarthritis subtype never affects more than 4 joints, whereas the extended oligoarthritis subtype affects a cumulative total of ≥5 joints after the first 6 months of disease.

Table 45.1 Classification of juvenile idiopathic arthritis. The previous term was juvenile rheumatoid arthritis. Enthesitis is inflammation at the site of insertion of muscles. For all the types, diagnosis requires onset before 16 years of age and duration of arthritis for ≥6 weeks in at least one joint. ANA, antinuclear antibody; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor.

ferritin levels, and a polyclonal gammopathy are commonly observed; ANA and RF are rarely present.

Pathology

Histologic features of the transient exanthem include edema of the superficial dermis and a mild mixed perivascular infiltrate (including neutrophils), but leukocytoclastic vasculitis is not seen. Persistent plaques are characterized by parakeratosis, necrotic keratinocytes within the epidermis, and a dermal infiltrate similar to that of the evanescent eruption.

Differential Diagnosis

The differential diagnosis of a transient exanthem associated with fever and arthritis includes rheumatic fever, urticarial vasculitis, and periodic fever syndromes (Table 45.2). The characteristic cutaneous findings in rheumatic fever are erythema marginatum (see Ch. 19) and urticarial lesions; rheumatic fever nodules are unusual. Patients with urticarial vasculitis may have arthralgias and fever; however, the urticarial lesions persist for greater than 24 hours, and they often resolve with purpura or postinflammatory hyperpigmentation. Histologic examination of recent-onset lesions demonstrates leukocytoclastic vasculitis.

Additional disorders to consider include other autoimmune connective tissue diseases, leukemia (which may present with fevers and musculoskeletal complaints prior to the development of diagnostic abnormalities in the peripheral blood), and infections such as parvovirus B19 and malaria.

Treatment

The course and prognosis of SoJIA is variable. In approximately 40–50% of patients, the arthritis resolves completely. However, approximately one-half of the children may have a chronic course that includes persistent arthritis and systemic complications such as macrophage activation syndrome (non-remitting fevers, leukopenia, thrombocytopenia), hepatitis, pericarditis and rarely amyloidosis (see Table 45.1)[9]. Patients with symptoms that persist for longer than 6 months carry a worse prognosis[9].

Mild articular or extra-articular disease can be treated with nonsteroidal anti-inflammatory drugs (NSAIDs) with or without hydroxychloroquine. Moderate or severe disease often requires the use of systemic corticosteroids with or without adjuvant drugs such as methotrexate. Inhibitors of TNF-α have been increasingly used as adjuvant or monotherapy; however, these agents are less effective in patients with SoJIA than in those with other types of JIA[10]. Potent corticosteroid-sparing or immunomodulating agents, such as abetacept, azathioprine and leflunomide, are required infrequently[10]. Thalidomide is also a therapeutic option for children with SoJIA. It suppresses the activity of cytokines (e.g. TNF-α and IL-6) that have been shown to play a role in the fever and malaise associated with SoJIA. Trials of biologic agents that are antagonists of the IL-1 receptor (e.g. anakinra, rilonacept, canakinumab) or the IL-6 receptor (e.g. tocilizumab) have demonstrated promising results in patients with SoJIA, and they will likely figure prominently in the treatment of refractory disease[10]. Hematopoietic stem cell transplantation has been successfully performed in children who have failed to respond to combinations of medications[10].

ADULT-ONSET STILL'S DISEASE

Synonyms:
- Still's disease in the adult
- Adult Still's disease

Key features

- A characteristic feature is recurrent episodes of high spiking fevers that often occur in the late afternoon
- An asymptomatic macular exanthem accompanies the fevers, is salmon-pink in color, and frequently demonstrates the Koebner phenomenon
- Arthritis with subsequent carpal ankylosis is a distinctive feature

Introduction

Adult-onset Still's disease can be a severe debilitating systemic illness that is often difficult to diagnose. The vast majority of these patients have an exanthem, and this can be the most distinctive sign of the disorder.

Epidemiology

Adult-onset Still's disease primarily affects young adults, with an onset before the age of 30 years in the majority of patients. Rarely it occurs

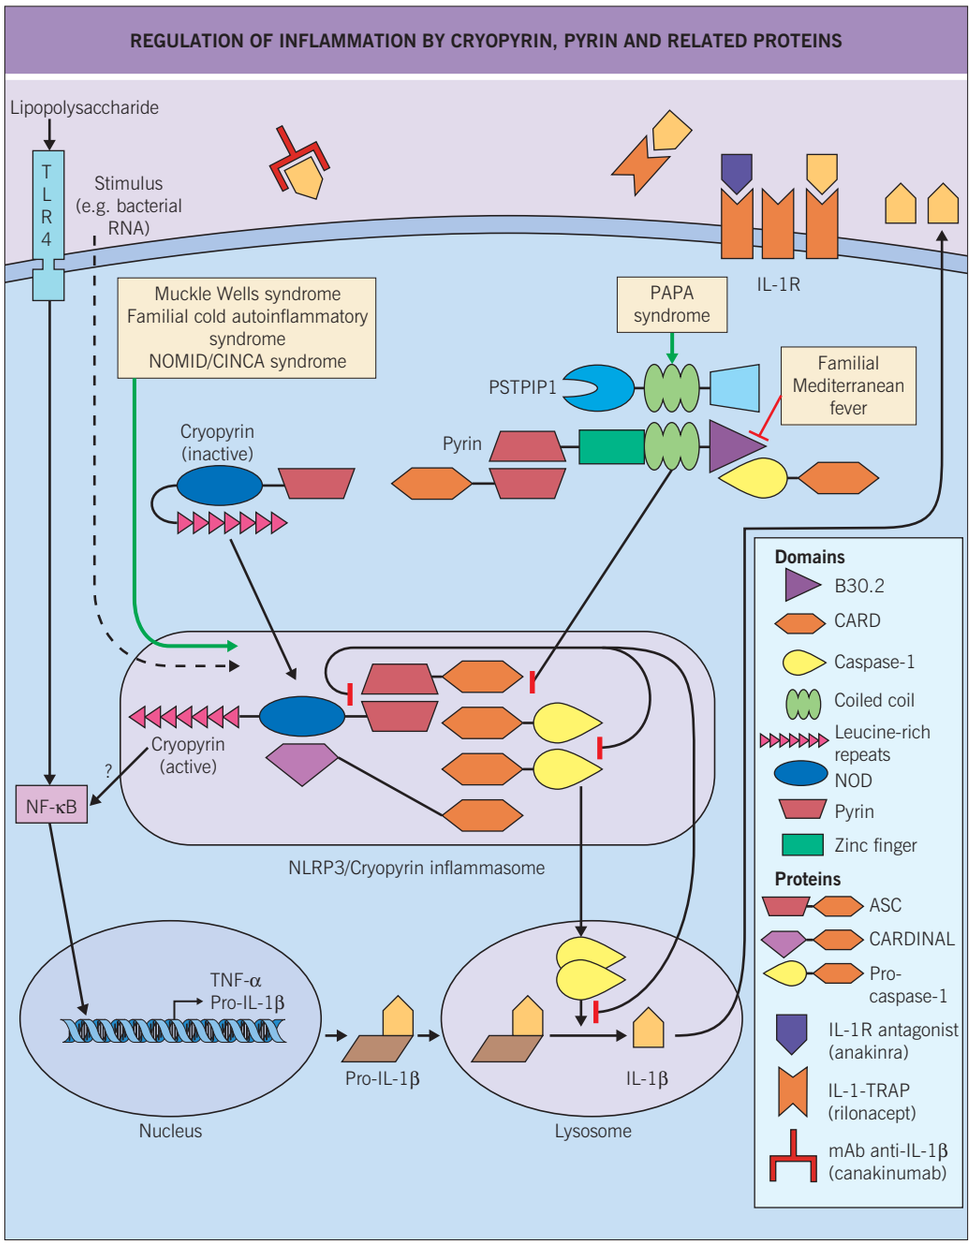

Fig. 45.1 Regulation of inflammation by cryopyrin, pyrin and related proteins. Upon release of autoinhibition, cryopyrin interacts with apoptosis-associated speck-like protein with a CARD domain (ASC) and *CARD-i*nhibitor of *N*F-κB-*a*ctivating *l*igand (CARDINAL) in an "inflammasome", leading to activation of caspase-1 (and perhaps NF-κB) and generation of mature interleukin (IL)-1β. Pyrin can competitively bind ASC and (pro)-caspase-1, thereby preventing them from being incorporated into the cryopyrin inflammasome; the formation of a separate pyrin inflammasome leading to IL-1β activation has also been postulated. *P*roline-*s*erine-*t*hreonine *p*hosphatase-*i*nteracting *p*rotein 1 (PSTPIP1) binds (and perhaps inhibits) pyrin, and this interaction is strengthened by the *PSTPIP1* mutations that underlie PAPA syndrome. CARD, *ca*spase-*r*ecruitment *d*omain; CINCA, *c*hronic *i*nfantile *n*eurologic, *c*utaneous and *a*rticular syndrome; IL-1R, interleukin-1 receptor; NF-κB, nuclear factor-κB; NLRP3, *N*OD-*l*ike *r*eceptor *p*yrin domain-containing protein 3; NOD, *n*ucleotide-binding *o*ligomerization *d*omain; NOMID, *n*eonatal-*o*nset *m*ultisystem *i*nflammatory *d*isease; PAPA, *p*yogenic *a*rthritis, *p*yoderma gangrenosum and *a*cne; RIP2, *r*eceptor-*i*nteracting *p*rotein-2; TLR, Toll-like receptor; TNF, tumor necrosis factor. *Courtesy, Julie V Schaffer, MD.*

in individuals over the age of 60 years. Women are affected slightly more often than men.

Pathogenesis

The etiology of adult-onset Still's disease is unknown. The disease has been linked with a number of HLA antigens, including HLA-B14, -B17, -B18, -B35, -Bw35, -Cw4, -DR2, -DR7, -DR4, and -Dw6, suggesting a genetic component[11]. It has been hypothesized to occur in a susceptible individual as a reactive condition triggered by a variety of infectious agents, including viruses (rubella, mumps, echovirus 7, cytomegalovirus, EBV, parainfluenza, influenza A, coxsackievirus B4, adenovirus, human herpesvirus 6, parvovirus B19, hepatitis B, hepatitis C) and bacteria (*Mycoplasma pneumoniae*, *Chlamydophila* [*Chlamydia*] *pneumoniae*, *Yersinia enterocolitica* 3 and 9, *Brucella abortus*, *Borrelia burgdorferi*)[11]. To date, however, no infectious agent has been implicated consistently.

The role of Th1 cytokines in the pathogenesis of adult-onset Still's disease has been the subject of more recent investigation. Of note, serum levels of IL-2, IL-6, IL-18, TNF-α and IFN-γ are elevated in patients with the disease[11,12].

Clinical Features

The onset of the disease is frequently heralded by a sore throat and constitutional symptoms including arthralgias and myalgias. Fever is a prominent feature; it is usually above 39°C and has a spiking pattern, often occurring in the late afternoon or early evening and resolving within several hours. The skin eruption is asymptomatic and transient, occurring in association with the fever spikes. It is most often macular with a characteristic salmon-pink color (Fig. 45.3A), favors sites of

pressure, and can exhibit the Koebner phenomenon. Although the trunk is most commonly involved, lesions can appear on the extremities, including the palms and soles. Violaceous to reddish brown, scaly, persistent papules and plaques can also occur, and were observed in more than half of patients with adult-onset Still's disease in a recent Taiwanese series[13].

Depending upon the series, arthritis occurs in 65–100% of patients, and most often it affects the knees, wrists and ankles, although other joints may also be involved. The pattern is usually symmetric, and most patients ultimately develop joint pain associated with the fever spikes. A distinctive feature of the arthritis of adult-onset Still's disease is carpal ankylosis, which results in minimal pain but a limited range of motion in the carpal joints. Similar ankylosis may occur in the proximal and distal interphalangeal joints as well as the cervical spine. The metacarpophalangeal (MCP) joints are usually spared.

There may be hepatomegaly, but splenomegaly is less common. Involvement of the lungs (pleuritis, pleural effusions, pulmonary fibrosis), heart (pericarditis, myocarditis, cardiac tamponade), and kidneys (nephritis) is rare.

Laboratory findings in adult-onset Still's disease are similar to those of SoJIA and include elevations in the C-reactive protein level, ESR, and platelet count. Leukocytosis and anemia are common, as are abnormalities in hepatic function tests. There are often significant elevations in serum ferritin levels, sometimes >4000 mg/ml, and ferritin levels may correlate with disease activity[11]. Titers of ANA and RF are usually low or negative.

Pathology

Histologic examination of the exanthem reveals an interstitial and perivascular neutrophil-dominant mixed infiltrate without vasculitis (Fig. 45.3B). Immunofluorescence microscopy findings are nonspecific. As in SoJIA, persistent plaques demonstrate necrotic keratinocytes within the epidermis and a dermal infiltrate of neutrophils.

Adult-onset Still's disease should always be considered in an adult with fever of unknown origin (defined as fever >38.3°C on several occasions over a period of at least 3 weeks or uncertain diagnosis after 1 week of hospitalization). The differential diagnosis is similar to that of SoJIA (see above). Additionally, Schnitzler's syndrome should be considered in an adult patient with recurrent fevers, arthralgia and an urticarial eruption. In addition to non-pruritic urticaria, patients have recurrent fevers, bone pain (lower extremity, iliac and vertebral due to hyperostosis), and a monoclonal IgM gammopathy. Angioedema is observed in about 15% of patients with Schnitzler's syndrome, and lymphoplasmacytic malignancies in 10–15%[11]. Histologically, a neutrophil-predominant dermal infiltrate is seen, and, occasionally, urticarial vasculitis.

Treatment

Although some patients respond to high-dose aspirin or NSAIDs, the majority require oral corticosteroids (e.g. 40–60 mg prednisone daily) to control acute systemic features. When corticosteroids cannot be tapered, methotrexate is the most commonly employed second-line therapy. As in SoJIA, biologic agents that inhibit the IL-1 receptor or IL-6 receptor (e.g. tocilizumab) appear to be promising[14,14a]. A therapeutic response to TNF-α inhibitors has also been reported.

RELAPSING POLYCHONDRITIS

Synonyms: ■ Atrophic polychondritis ■ Systemic chondromalacia

Key features

- A prominent clinical feature is erythema, swelling and pain of the cartilaginous portion of the ear, followed by destruction of the cartilage
- Additional findings include nasal chondritis (which may result in a saddle nose deformity) and arthritis of the joints of the central chest
- The most serious complications result from ocular, renal and respiratory tract involvement

Introduction

Relapsing polychondritis is an uncommon inflammatory disorder with a suspected autoimmune origin that primarily affects cartilaginous structures. The diagnosis is usually established based upon the presence of: (1) histologically confirmed chondritis in *two* of the following three sites: auricular, nasal and laryngotracheal cartilage; or (2) chondritis in *one* of the aforementioned sites plus at least *two* other features, including: ocular inflammation, audiovestibular damage and inflammatory arthritis. Relapsing polychondritis has been associated with other autoimmune disorders (25–30%) and with myelodysplastic syndromes. Dermatologic manifestations may be the initial presenting sign and early diagnosis and treatment can prevent later complications (e.g. ascending aortitis, glomerulonephritis).

History

The disease was first described in 1923 by Jaksch-Wartenhorst and was called "polychondropathia". It was later renamed "relapsing polychondritis" due to its episodic nature[15].

Epidemiology

Relapsing polychondritis is most common in Caucasians, but has been reported in other races. In 80% of cases, the onset is between the ages of 20 and 60 years. Men and women are equally affected.

Pathogenesis

Although the etiology of relapsing polychondritis is unknown, the pathogenesis seems to involve an immunologic reaction against type II collagen[16]. However, circulating antibodies against type II collagen are present in fewer than half of affected individuals, and antibodies against types IX and XI collagen have also been described[17]. The clinical usefulness of these antibodies in the diagnosis, prognosis or monitoring of disease activity or the response to therapy is unclear. That said, transmission of relapsing polychondritis to a neonate from an affected mother has been reported (with subsequent recovery of the infant), lending support to an antibody-mediated pathogenesis. Antibodies to matrilin-1, an extracellular matrix protein located in auricular, septal, tracheal and sternal cartilage, may also play a role in the immune response seen in relapsing polychondritis[18]. Additionally, there is a positive association with HLA-DR4, while the extent of organ involvement has been negatively associated with HLA-DR6[17].

Clinical Features

The most prominent clinical feature is erythema, swelling and pain of the cartilaginous portion of the auricle, sparing the earlobe (Fig. 45.4). Symptoms can persist for several days to weeks and may encroach on the external auditory meatus, compromising hearing. Chronic inflammation leads to destruction of the cartilage, leaving the ear unsupported and scarred. During the course of their disease, 90% of patients will develop auricular involvement, and in at least 25% it is a presenting sign.

Nasal chondritis eventually develops in up to 70% of patients and may result in a saddle nose deformity. Symptoms include pain, stuffiness, crusting, rhinorrhea, epistaxis and compromise of olfaction. Nasal chondritis is typically less recurrent than the auricular chondritis, and the saddle nose deformity is more common in men[16].

Involvement of the cartilage of the respiratory tract (larynx, trachea, bronchi) and/or costochondral joints occurs in approximately 50% of patients and can be the most serious complication. Signs and symptoms include cough, hoarseness, choking, dyspnea, wheezing or tenderness to palpation of the anterior neck overlying the larynx or trachea. Complications include airway obstruction or collapse, flail chest and secondary pulmonary infections.

Fig. 45.4 Relapsing polychondritis. Erythema and swelling of the ear with sparing of the earlobe. *Courtesy, Kalman Watsky, MD.*

Arthritis is common (50–80% of patients) and it is the presenting symptom in one-third of patients. An episodic, migratory, asymmetric, non-erosive oligo- or polyarthritis can affect any joint, although the knees and MCP and proximal interphalangeal joints are those most commonly affected. There may also be involvement of the sternoclavicular and sternomanubrial joints.

Ocular inflammation develops in approximately 65% of patients. It can involve virtually any component of the eye, leading to conjunctivitis, scleritis, corneal ulcerations, uveitis or optic neuritis[16]. A variety of reactive cutaneous lesions are seen in patients with relapsing polychondritis[19], including aphthae, small vessel vasculitis, annular urticarial plaques[19a] livedo reticularis, erythema elevatum diutinum and erythema nodosum. None is pathognomonic and some may be coincidental or due to a coexisting disease. The presence of cutaneous small vessel vasculitis and/or aphthae is reported to increase the likelihood of an associated myelodysplastic syndrome (see Ch. 24). In addition, an overlap between relapsing polychondritis and Behçet's disease, termed *m*outh *a*nd *g*enital ulcers and *i*nflamed *c*artilage (MAGIC) syndrome, has been reported[20].

Less common systemic features include audiovestibular damage, cardiovascular disease (aortitis, valvular dysfunction, pericarditis, conduction system abnormalities, myocarditis), renal dysfunction (glomerulonephritis, glomerulosclerosis, tubulointerstitial disease), and neurologic sequelae (cranial nerve palsies, vasculitis of the central or peripheral nervous system).

Pathology

Histopathologically, there is breakdown of the normal lacunar structure of the cartilage, with neutrophilic infiltrates initially, followed by lym-

Table 45.3 Differential diagnosis of nasal deformity or destruction.

phoplasmacytic infiltrates. In late stages there is replacement of cartilage by granulation tissue and fibrosis.

Differential Diagnosis

In the early inflammatory phase, the erythema and pain may be misdiagnosed as erysipelas or cellulitis. Infectious chondritis, traumatic chondritis, Wegener's granulomatosis, and congenital syphilis may mimic the cartilage destruction seen in relapsing polychondritis (Table 45.3). Wegener's granulomatosis can be distinguished from relapsing polychondritis by the presence of anti-proteinase 3 antibodies (C-ANCA; see Ch. 40) and the absence of auricular involvement.

Treatment

Although relapsing polychondritis has traditionally been associated with significant morbidity and mortality, it is a treatable disease (with survival rates of 94% at 8 years). A comprehensive evaluation for systemic involvement should be performed prior to initiation of therapy, as systemic disease requires more aggressive treatment. The most common causes of death are pneumonia, systemic vasculitis, airway collapse and renal failure[16].

The initial treatment is with prednisone (0.5–1 mg/kg/day; higher doses are given if there is visceral involvement), which improves acute flares and decreases the number and severity of recurrences. NSAIDs and colchicine may be employed to decrease fever, auricular chondritis and arthralgias. Dapsone (50–150 mg/day) can also be used. Hydroxychloroquine and immunosuppressive agents (e.g. methotrexate, cyclosporine, azathioprine, 6-mercaptopurine, cyclophosphamide, mycophenolate mofetil) have been tried alone or in conjunction with corticosteroids, with variable responses. More recently, successful results with infliximab and the IL-1 receptor antagonist anakinra have been reported, while a retrospective series of nine patients treated with the anti-CD20 antibody rituximab failed to demonstrate significant clinical improvement[21]. Surgery is sometimes performed to repair damage to cartilaginous structures after the inflammation has been controlled.

SJÖGREN'S SYNDROME

Synonyms: ■ Mikulicz disease ■ Sicca syndrome

Key features

- This autoimmune disorder primarily affects secretory glands
- The most common features are xerostomia, xerophthalmia and arthritis
- Cutaneous manifestations include xerosis, petechiae, purpura (palpable and non-palpable), urticarial vasculitis and annular erythema
- Serious complications include B-cell lymphomas – in particular, extranodal marginal zone lymphomas of the MALT (mucosa-associated lymphoid tissue) type, peripheral neuropathy and systemic vasculitis
- Factors associated with a poorer prognosis include hypocomplementemia, vasculitis and/or cryoglobulinemia

Introduction

Sjögren's syndrome (SjS) is an autoimmune disorder that affects secretory glands, in particular the lacrimal and salivary glands. In addition to exocrine gland dysfunction, patients may develop a range of systemic manifestations due to autoimmune-mediated insults to multiple organ systems. This disease can be difficult to diagnose due to its insidious onset and initially nonspecific symptomatology. Mucocutaneous manifestations are prominent and may be the initial presenting signs. SjS may exist as a primary disorder or in association with other autoimmune diseases (secondary SjS), including rheumatoid arthritis, systemic lupus erythematosus (LE) and scleroderma.

EUROPEAN–AMERICAN CONSENSUS GROUP MODIFICATION OF THE EUROPEAN COMMUNITY CRITERIA FOR THE DIAGNOSIS OF SJÖGREN'S SYNDROME

- Symptoms of xerophthalmia
- Signs of xerophthalmia (Schirmer test, Rose Bengal test)
- Symptoms of xerostomia
- Signs of impaired salivary gland function (sialogram, scintigraphy)
- Positive salivary gland biopsy (see text)
- Presence of autoantibodies (anti-Ro/SS-A or anti-La/SS-B)

Table 45.4 European-American Consensus Group modification of the European community criteria for the diagnosis of Sjögren's syndrome. Patients must have either a positive salivary gland biopsy or positive autoantibodies (anti-Ro/SS-A or anti-La/SS-B) plus fulfill ≥3 of the additional criteria. A positive salivary gland biopsy or the presence of autoantibodies (in addition to the first four criteria) is associated with a diagnostic sensitivity of 97% and a specificity of 90%[22].

History

The first description of SjS was by Hadden in 1888. Four years later, Mikulicz described a patient with bilateral enlargement of the parotid glands and associated lymphocytic infiltrates. However, it was not until 1933 that Henrik Sjögren described the triad of keratoconjunctivitis sicca, xerostomia and arthritis. Castleman and Morgan determined that the histopathology of Sjögren's syndrome and Mikulicz disease were identical. Over the past several decades, the diagnostic criteria for SjS have been debated and revised, and the currently accepted criteria are the European–American Consensus Group modification of the European community criteria for SjS (Table 45.4)[22].

Epidemiology

Although SjS most commonly presents during the fourth and fifth decades, pediatric cases have been reported. The female : male ratio is 9 : 1 and men with this syndrome tend to have a less aggressive disease course with fewer extraglandular manifestations. SjS is one of the most common autoimmune disorders, affecting approximately 0.3–0.6% of the total population[23]. The overall mortality rate in primary SjS is comparable to that in the normal population[23].

Pathogenesis

The pathogenesis of SjS is unknown. As in other autoimmune diseases, environmental factors likely trigger inflammatory events in a genetically susceptible host, resulting in the autoimmune phenomena characteristic of the disease. In SjS, it has been proposed that abnormalities intrinsic to glandular epithelial, dendritic and/or stromal cells may initiate the lymphocytic infiltration and aberrant signaling. Viral infection of the glands may stimulate the innate immune system via Toll-like receptors, leading to autoimmune destruction of glandular cells due to molecular mimicry[24]. While no single virus has been consistently or reproducibly demonstrated as a predominant trigger, EBV, coxsackievirus, human T-cell lymphotropic virus-1 (human T-cell leukemia virus), and hepatitis C virus have all been implicated in various populations[23]. There is upregulation of type I and II interferon gene expression, possibly related to viral infection and perpetuated by immune complexes such as anti-SS-A or anti-SS-B antibodies complexed with hYRNA. Activation of the Th17/IL-23 system has also recently been described in SjS patients[25].

Serum levels of B-cell activating factor are elevated in patients with SjS. It is possible that this protein allows autoreactive B cells to escape apoptosis and have autoimmune potential. Patients with SjS frequently have hypergammaglobulinemia and autoantibodies that recognize Ro/

SS-A and La/SS-B; presence of these autoantibodies increases the risk of developing cutaneous small vessel vasculitis, both in patients with SjS and in those with systemic LE. In lymphocytes infiltrating the salivary glands, increased levels of costimulatory molecules CD40 and CD40 ligand (CD154) have been noted, as has increased expression of the genes that encode the antiapoptotic proteins bcl-2 and bcl-x[26]. This could play a role in the development of marginal zone B-cell lymphoma in the salivary gland.

Clinical Features

The most prominent feature of SjS is xerosis of the mucous membranes, particularly of the eyes, mouth and vagina. Keratoconjunctivitis sicca occurs as a result of destruction of the lacrimal gland, and patients may experience ocular dryness, a foreign body sensation, pain or photophobia. Objective tests to verify decreased tear production and assess the integrity of the corneal surface, such as the Schirmer test and Rose Bengal dye test, respectively, should be performed by an ophthalmologist[24]. In the Schirmer test, a piece of Whatman paper wick is folded over the lower eyelid for 5 minutes, and if the aqueous component of the tear film migrates <5 mm, there is lacrimal gland dysfunction. Complications of xerophthalmia include keratitis, corneal thinning and ulceration, and recurrent infections[24].

Xerostomia due to destruction of the major and minor salivary glands may present as a dry, sore, burning mouth and lips. Patients may have difficulty swallowing or require frequent ingestion of fluids during conversations. On examination, the infralingual salivary pool may be absent and the saliva cloudy and stringy. Although the major salivary glands (parotid and submandibular) may become transiently enlarged (~20% of patients), persistent swelling of these salivary glands or lymphadenopathy should prompt an evaluation for lymphoma. Of note, patients with SjS have a 16-fold greater risk of developing lymphoma (as compared to the general population)[23]; these B-cell lymphomas are often extranodal and can originate in salivary as well as lacrimal glands.

Xerostomia may be assessed functionally by salivary gland scintigraphy, sialometry or parotid sialography, but these tests are not commonly employed. On the other hand, salivary gland biopsy is a readily available procedure and represents an important component of the diagnosis of SjS (see Table 45.4). Perlèche or thrush can result from candidal overgrowth, and should be suspected when patients report a sudden increase in pain. Dental caries are a common problem, particularly along the gingival margin, and scrupulous dental hygiene with frequent dental examinations is crucial. Because saliva has an elevated pH that neutralizes gastric acid, patients with SjS may experience more severe gastroesophageal reflux disease or gastro-tracheal reflux (which can mimic upper respiratory tract infections), and aggressive reflux treatment is warranted[24]. Assessment for *Helicobacter pylori* infection is also performed, because the presence of this organism has been associated with MALT lymphomas in patients with SjS[24].

Vaginal xerosis is common, and since many patients are perimenopausal or postmenopausal, it may be multifactorial. It may present as dryness, burning and/or dyspareunia. Candidal and bacterial overgrowth are common complications.

The most common skin finding is xerosis, usually presenting as pruritus. Other cutaneous manifestations include palpable and nonpalpable purpura, urticarial vasculitis, erythema nodosum, nodular amyloidosis and Sweet's syndrome. Lesions of annular erythema, clinically reminiscent of subacute cutaneous LE or LE tumidus, have been reported primarily in Japanese patients with SjS. Whether or not these patients have an LE/SjS overlap is a matter of debate. Raynaud's phenomenon has been reported in 30% of patients with primary SjS.

Vasculitis is the most important cutaneous finding in SjS, as it is associated with an increased risk of morbidity and mortality[27]. Patients with cutaneous small vessel vasculitis may present with palpable purpura (Fig. 45.5) or with urticarial lesions (the latter either in the setting of hypo- or normo-complementemia; see Ch. 24). Some patients develop lesions of pigmented purpura (capillaritis) or macular hemorrhage which can be identical to the lesions seen in patients with hypergammaglobulinemic purpura of Waldenström (see Ch. 22). Of note, many of the patients with the latter disorder have evidence of an autoimmune connective tissue disease (including SjS). The presence of purpura should prompt an evaluation for cryoglobulinemia. Patients found to have vasculitis, cryoglobulinemia and/or hypocomplementemia have an increased mortality rate and an increased risk of developing B-cell lymphomas[28].

Fig. 45.5 Cutaneous small vessel vasculitis in a patient with Sjögren's syndrome. Patients can also develop lesions of pigmented purpura (capillaritis). *Courtesy, Penn State Department of Dermatology.*

Extraglandular and extracutaneous involvement may present with a diverse array of symptoms due to involvement of a variety of tissues including the lungs (interstitial pneumonitis, often subclinical), kidneys (interstitial nephritis, tubular dysfunction), bone marrow, and peripheral and central nervous systems (peripheral neuropathy, short-term memory loss, depression, immune-mediated hearing loss, multiple sclerosis-like presentation)[24]. Arthritis is a common finding; it is usually polyarticular, non-erosive , chronic and progressive, and it can be asymmetric. The most frequently involved joints are the knees and ankles.

As discussed above, the risk of developing B-cell lymphomas is increased in patients with SjS. The lymphomas are often extranodal in origin (e.g. salivary glands, lacrimal glands) and usually marginal zone lymphomas of the MALT type[29]. In a series of 380 patients with primary SjS, approximately 3% developed lymphoma during 9 years of observation[30].

Laboratory Findings

Primary SjS is associated with anti-Ro/SS-A (~60–80%), and anti-La/SS-B (~40–60%) autoantibodies. Patients with secondary SjS may have additional autoantibodies, depending upon the specific autoimmune connective tissue disease (see Ch. 40). Because both specificity and sensitivity of anti-Ro antibodies depend upon the diagnostic assay utilized (e.g. an ELISA is more sensitive but less specific), a rather wide range of "Ro-positivity" exists. This topic is discussed in detail in Chapter 40.

Other laboratory abnormalities often observed in patients with SjS include an elevated ESR and a positive RF.

Pathology

To confirm the diagnosis of SjS, a biopsy of the minor salivary glands is often performed. The presence of two or more aggregates of inflammatory cells (50 or more lymphocytes) in 4 mm^2 of salivary gland tissue is required for the diagnosis. A mixture of T and B cells (with a normal CD4:CD8 ratio) is usually seen.

The typical histopathologic features of pigmented purpuric eruptions, cutaneous small vessel vasculitis, cryoglobulinemic vasculitis, and

urticarial vasculitis are seen in the vasculopathies associated with SjS; however, none of the histologic findings is specific for SjS.

Differential Diagnosis

Sicca symptoms are common in the elderly in part due to age-related atrophy of secretory glands. Xerostomia is a common side effect of drugs with anticholinergic properties and it may also result from previous irradiation, salivary gland stones, and chronic viral infections. Xerophthalmia can be a symptom of ocular rosacea (see Ch. 37), infiltration of the lacrimal glands (e.g. sarcoidosis, amyloidosis), irradiation, estrogen deficiency, and hypovitaminosis A. It may reflect impaired blinking (e.g. Parkinson's disease) or herald the onset of mucous membrane (cicatricial) pemphigoid. In addition, patients with chronic graft versus host disease can have both xerophthalmia and xerostomia.

Early in the disease course, it may be difficult to distinguish SjS from other autoimmune connective tissue diseases. Complaints such as arthralgias and myalgias are often nonspecific. Because 50% of the salivary glands must be destroyed before symptoms arise, sicca symptoms may not be a prominent complaint initially. Patients with SjS/LE overlap can pose a diagnostic challenge. They are often anti-Ro-positive and may have prominent cutaneous disease or they may be asymptomatic but give birth to a child with neonatal LE (anti-Ro antibodies are associated with subacute cutaneous LE as well as with neonatal LE). Overlap patients may initially present with only symptoms of LE but subsequently develop SjS, or vice versa, and some may have late-onset disease (age >50 years).

Treatment

Therapy for most manifestations of SjS is symptomatic. Xerophthalmia may be treated with preservative-free artificial tears and lubricating ointments. The placement of punctual plugs that occlude the nasolacrimal ducts may increase accumulation of tear film. Home humidifiers may help relieve symptoms of xerophthalmia. Cyclosporine (0.05%) eyedrops may prove helpful, but it can take several months to achieve a therapeutic effect.

Xerostomia can be treated with methylcellulose drops (artificial saliva), but this is often unpalatable. Frequent ingestion of water or sugarless fluids and chewing sugar-free gum are generally the most acceptable forms of therapy. Use of a cool mist vaporizer at bedtime may also help. Prevention of dental caries is essential; scrupulous dental hygiene and topical fluoride treatments are recommended. Antifungal medications to treat and prevent candidiasis as well as chlorhexidine rinses (0.12%) can improve oral symptoms. Salivary gland massage to prevent inspissation of mucous plugs and promote salivary flow can be helpful. Muscarinic receptor agonists (e.g. pilocarpine, cevimeline) are systemic secretagogues that may alleviate xerostomia and xerophthalmia, but their use may be limited by unwanted side effects such as excessive sweating.

Dryness of the skin can be treated with emollients. Vaginal dryness may be improved with artificial lubricants. Frequent monitoring for and treatment of candidal and bacterial overgrowth is recommended; prophylactic use of vaginal antifungal agents is an option. In postmenopausal women, estrogen replacement therapy may be a helpful supplemental therapy.

In general, immunosuppressive agents should be reserved for patients with cutaneous vasculitis or involvement of the nervous system and internal organs. Systemic corticosteroids, hydroxychloroquine and steroid-sparing immunosuppressants (e.g. methotrexate, azathioprine, mycophenolate mofetil) are used in patients with serious internal manifestations. Therapy with TNF-α inhibitors has not proven to be very useful overall[24]. In initial small series, B-cell depletion with the anti-CD20 antibody rituximab led to conflicting results[31,32], but in a more recent randomized, double-blind, placebo-controlled trial, rituximab led to a significant improvement in saliva flow rate[32a].

MIXED CONNECTIVE TISSUE DISEASE

Synonyms: ■ Undifferentiated connective tissue disease ■ Sharp's syndrome

Key features

- The existence of mixed connective tissue disease (MCTD) as a distinct entity is controversial, as patients often have overlapping clinical and serologic features of various combinations of rheumatoid arthritis, systemic sclerosis, systemic LE and polymyositis
- Major disease features include: high-titer IgG anti-U1 ribonuclear protein (U1RNP) antibodies, Raynaud's phenomenon, swollen hands or sclerodactyly, myositis, esophageal dysmotility and arthritis
- Compared with systemic LE, there is a lower incidence of renal disease and a higher incidence of pulmonary disease
- Pulmonary hypertension is the most serious complication

Introduction

The designation of mixed connective tissue disease (MCTD) as a distinct disease entity continues to be debated. However, there is little argument that there exists a group of patients with a constellation of serologic and clinical manifestations for whom MCTD is a useful label. These patients have high titers of antibodies to U1RNP and certain clinical features observed in other autoimmune connective tissue diseases, including arthritis, pulmonary hypertension, esophageal dysmotility, myopathy, digital swelling and constitutional symptoms. Over time, some patients with MCTD develop manifestations more consistent with the diagnosis of systemic LE or systemic sclerosis.

History

MCTD was first described by Sharp et al.[33] in 1972, including its clinical features and the presence of an antibody to an extractable nuclear antigen.

Epidemiology

MCTD is much more common in women than in men (9:1), with most patients presenting during the second or third decade of life. The exact incidence of MCTD is unclear, especially since some authors do not consider it to be a separate entity. A number of patients would be more appropriately classified as having an overlap syndrome, and others may actually have systemic LE, systemic sclerosis, or dermatomyositis/polymyositis. It is believed that "classic" MCTD is the least common of the autoimmune connective tissue diseases. In the past, the prognosis of MCTD was thought to be better than that of systemic LE; however, long-term evaluation of patients with MCTD has found their prognosis to be poorer than that expected in patients with systemic LE. The majority of deaths in MCTD have been attributable to pulmonary hypertension[34,35].

Pathogenesis

Although the pathogenesis is not clear, there appears to be an immune response to U1RNP. U1RNP plays an essential role in the splicing of pre-mRNA into mRNA. The U1RNP molecule consists of three polypeptides (U1-A, U1-C, U1-70kD) that associate with U1RNA as well as a series of proteins that are common to multiple U-RNA and RNA-splicing molecules, including Smith (Sm) and splicing factors (SR proteins). Although anti-U1RNP IgG antibodies may be seen in LE, systemic sclerosis and polymyositis, titers of anti-U1RNP tend to be higher in MCTD. Another distinct autoantigen often recognized by MCTD sera is hnRNP-A2, which is another spliceosome component. Of note, antibodies to EBV and cytomegalovirus cross-react with components of U1RNP, suggesting that molecular mimicry related to prior exposure to these viruses may be involved in the development of anti-U1RNP autoimmunity[36]. Genetic studies have demonstrated an association of HLA-DR4, -DR1 and -DR2 in patients with MCTD[37].

Clinical Features

MCTD often presents with prominent cutaneous symptoms, including Raynaud's phenomenon and edematous erythematous digits. Raynaud's phenomenon is often an early manifestation, and it eventually

develops in almost all patients; "ice-pick" digital infarcts or even gangrenous digits can be observed. The patients often have periungual telangiectasias with dropout areas, and the hands and fingers may feel sclerodermatous and tight due to increased dermal collagen deposition as well as edema. Calcinosis cutis can also occur.

Poikilodermatous areas on the upper trunk and proximal extremities are common, in addition to the sclerodermoid changes of the distal extremities. However, the diffuse involvement of the face, upper trunk or extremities observed in patients with progressive systemic sclerosis is usually not seen. Photosensitivity and lesions indistinguishable clinically and histopathologically from acute systemic LE (e.g. malar rash) or subacute cutaneous LE may also occur. Cutaneous small vessel vasculitis and livedoid vasculopathy may develop as well[38]. Rheumatoid nodules and orogenital mucosal lesions such as buccal ulcers and nasal septal perforation have been described[38,39].

An inflammatory myopathy is common in patients with MCTD. However, dermatomyositis-specific findings such as Gottron's papules, a periorbital heliotrope eruption, and erythema and scaling of the scalp are not usually seen. Arthralgias or polyarthritis occur in 50–70% of patients with MCTD, often early in the disease course[38]. The arthritis ranges from mild to erosive.

Pulmonary hypertension is the most serious complication of MCTD (occurring in up to 25% of patients), and it may be associated with the presence of antiphospholipid antibodies[34]. Pulmonary fibrosis, often mild, may also occur, and, like pulmonary hypertension, is frequently asymptomatic early during its course. Pleurisy and pericarditis occur in ~60% of patients[35]. Periodic pulmonary examinations, chest radiographs, high-resolution CT scans, echocardiography, and pulmonary function tests are warranted. Esophageal dysmotility is common, occurring in up to 85% of patients; it can be asymptomatic, but most commonly manifests as reflux esophagitis and dysphagia[38].

Pathology

There are no histopathologic features pathognomonic for MCTD. The histologic findings vary depending upon the type of skin lesion examined. In general, cutaneous manifestations clinically resembling acute or subacute cutaneous LE, leukocytoclastic vasculitis or livedoid vasculopathy will have the histologic features characteristic of these entities.

Differential Diagnosis

The differential diagnosis of MCTD consists primarily of systemic LE, systemic sclerosis, dermatomyositis/polymyositis, and overlap syndromes. Some patients initially diagnosed with MCTD may over time develop a preponderance of clinical and serologic features of one of these diseases, requiring a change in diagnosis. The absence of hypocomplementemia or anti-dsDNA and anti-Sm antibodies helps to distinguish MCTD from systemic LE, while the more severe arthritis and the myositis help distinguish MCTD from systemic sclerosis. The inflammatory myopathies usually manifest with more severe myositis than is encountered in MCTD, and the former do not usually feature the lower esophageal dysmotility common in MCTD. The presence of Raynaud's phenomenon plus coarse periungual telangiectasias excludes other sclerodermoid disorders such as POEMS syndrome and porphyria cutanea tarda (see Ch. 43).

Treatment

The goal of therapy in MCTD is to control symptoms and maintain function. Therapy should be tailored to the specific organ involvement and disease severity. Patients with pulmonary hypertension require longitudinal care with a pulmonologist or rheumatologist experienced in managing pulmonary complications.

In general, manifestations of MCTD that often overlap with LE or polymyositis, such as serositis, cutaneous lesions, arthritis and myositis, usually respond to corticosteroids, while scleroderma-like features such as Raynaud's phenomenon and pulmonary hypertension generally do not[40]. Topical corticosteroids and systemic antimalarials are often helpful for LE-like dermatoses. Raynaud's phenomenon can be treated with vasodilators in addition to non-pharmacologic measures (avoidance of cold, gloves, etc.). For severe systemic disease, a variety of therapies have been evaluated, including immunosuppressive agents (e.g. methotrexate, cyclosporine, azathioprine, mycophenolate mofetil and cyclophosphamide), plasmapheresis and autologous hematopoietic stem cell transplantation. It is difficult to evaluate the efficacy of these treatments since there are no prospective large-scale studies, and most are based on single cases or small case series.

EXTRA-ARTICULAR MANIFESTATIONS OF RHEUMATOID ARTHRITIS

Key features

- In addition to deforming arthritis, patients can develop rheumatoid nodules, pyoderma gangrenosum, and small and medium-sized vessel vasculitis
- Other cutaneous manifestations include rheumatoid neutrophilic dermatitis and palisaded neutrophilic and granulomatous dermatitis

Introduction

Rheumatoid arthritis (RA) is a systemic disease where the primary manifestation is arthritis but in which there can be cutaneous manifestations (see Table 53.1). Several of these can serve as helpful diagnostic clues or, in the case of rheumatoid vasculitis, point to serious illness.

Epidemiology

RA is common, affecting 1–3% of the adult population in the US. Women are affected two to three times more often than men, and although it may develop in any age group, the peak onset is between 30 and 55 years of age.

Pathogenesis

The cause of RA is unknown, but, as with other autoimmune diseases, it is thought to result from a complex interaction between genetic susceptibility and environmental factors, particularly infectious agents. The concordance rate for RA in monozygotic twins is 34%, whereas in dizygotic twins it is only 3%. As in other autoimmune diseases, a complex interplay between innate and acquired immune responses appears to be involved. Initiating events in RA may involve the binding of extracellular matrix constituents in the synovium to Toll-like receptors, leading to the subsequent induction of inflammatory responses (increased TNF-α, IL-6, chemokines and angiogenic factors) and maturation of antigen-presenting cells[41]. A gain-of-function polymorphism in the *PTPN22* gene, which encodes a lymphoid-specific protein tyrosine phosphatase that serves as a negative regulator of T-cell activation, confers susceptibility to RA and JIA, as well as other autoimmune disorders such as systemic LE, Graves disease and type 1 diabetes mellitus (perhaps by impairing thymic negative selection or regulatory T cells). Of note, there is a reduction in the number of regulatory T cells in RA[42].

RA is also associated with HLA-DR1 and -DR4. The HLA-DRB1 shared epitope allele, a highly significant genetic risk factor for RA, contributes to its pathogenesis primarily by increasing the propensity to develop antibodies that target citrullinated proteins (which are found in the skin and joints). Such antibodies represent specific and predictive serologic markers for RA, and they have been shown to bind the synovium and enhance tissue injury in animal models of autoimmune arthritis. A variety of infectious agents, including particular proteins produced by EBV and *Escherichia coli*, have been thought to play a role due to molecular mimicry of the hypervariable domain of HLA-DRB1*0401 or induction of anti-citrullinated protein antibody production.

Clinical Features

Rheumatoid nodules

Rheumatoid nodules are present in 20% of patients with RA, and they occur in patients with moderate to high titers of RF (IgG, IgM or IgA). Most, if not all, of the cases of seronegative RA with "rheumatoid nodule"-like lesions were proven to be subcutaneous granuloma

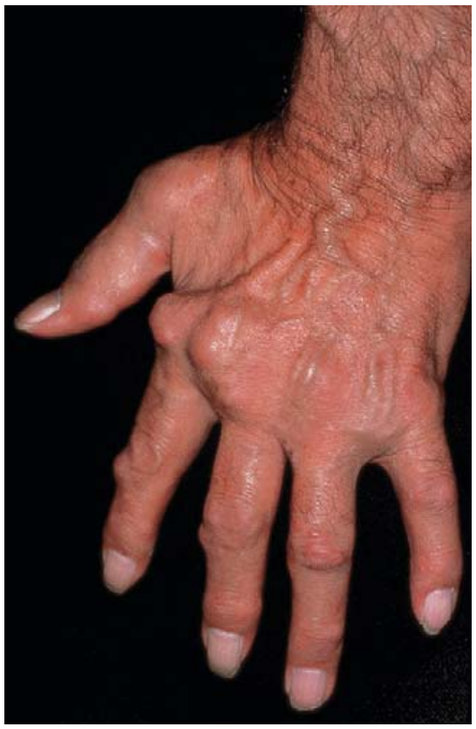

Fig. 45.6 Rheumatoid arthritis and rheumatoid nodules. Note the periarticular location of the skin-colored nodules. *Courtesy, Kalman Watsky, MD.*

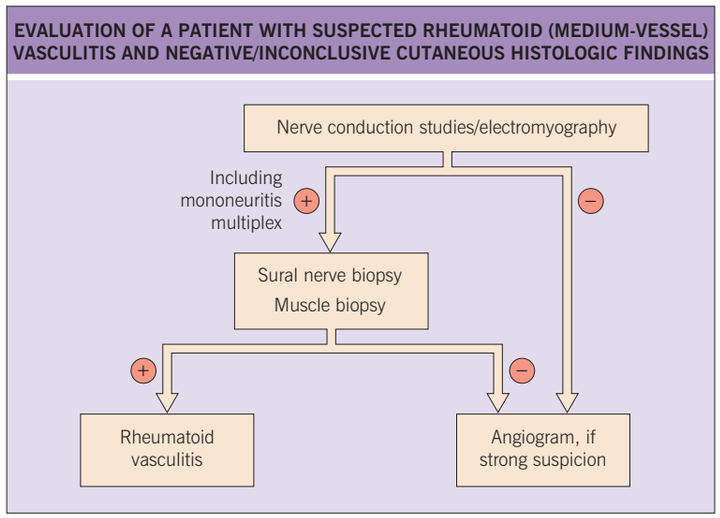

Fig. 45.8 Evaluation of a patient with suspected rheumatoid vasculitis (involving medium-sized vessels) in whom cutaneous histologic findings are negative or inconclusive.

Fig. 45.7 Methotrexate-induced nodulosis in a patient with rheumatoid arthritis. *Courtesy, Jean L Bolognia, MD.*

annulare or other entities with palisading granulomas histologically (see below). Rheumatoid nodules are firm, semi-mobile papulonodules that occur most commonly in periarticular locations over extensor surfaces (Fig. 45.6), and in areas subject to pressure or trauma. They range from several millimeters to as much as 5 cm in diameter and are typically asymptomatic. Occasionally the nodules are tender or painful, especially if there is associated trauma or ulceration. Rheumatoid nodules may also occur in visceral organs.

Accelerated rheumatoid nodulosis is characterized by the sudden appearance of multiple rheumatoid nodules (Fig. 45.7). Lesions usually appear following the initiation of methotrexate therapy, but can also be seen after the initial administration of TNF-α inhibitors. In some of these patients, there had also been a tapering of systemic corticosteroids.

Rheumatoid vasculitis

Rheumatoid vasculitis is a rare and typically late complication of RA. It is thought to occur in only 2–5% of those with RA, but, at autopsy, vasculitis has been found in up to a third of patients. Rheumatoid vasculitis typically occurs in the context of high-titer RF, rheumatoid nodules, and a history of severe erosive arthritis. The vasculitis may affect vessels of any size, and the clinical presentations reflect this, with palpable and non-palpable purpura in small vessel disease versus nodules, ulcerations, necrotizing livedo reticularis and/or digital infarcts in medium-sized vessel disease. Systemic manifestations of rheumatoid vasculitis can include neuropathies, cerebral infarction, scleritis, alveolitis, carditis, intestinal ulcers and proteinuria. Clinicopathologic correlation and serologic assessment should be performed when rheumatoid vasculitis is suspected. For example, if an ulcer is biopsied, a wedge perpendicular to the edge of the ulcer which includes both surrounding non-ulcerated skin as well as the ulcer base should be obtained. In up to 40% of patients with RA and medium-sized vessel vasculitis, there is evidence of a peripheral neuropathy (subclinical or clinical) that often presents as mononeuritis multiplex. This incidence seems to be even higher in patients with extensive cutaneous disease. Therefore, if vasculitis cannot be identified after multiple deep skin biopsies but the diagnosis is still suspected, nerve conduction studies followed by sural nerve biopsy (or a muscle biopsy) can be performed (Fig. 45.8). Mortality may be as high as 43%[43], and, therefore, aggressive intervention and rheumatologic consultation is warranted.

Bywater's lesions

Bywater's lesions include nailfold thromboses and purpuric papules on the distal digits (especially the digital pulp; see Fig. 53.4). Histologically, there is a small vessel leukocytoclastic vasculitis. Typically these lesions are not associated with systemic vasculitis[44].

Felty syndrome

Felty syndrome represents an uncommon but severe subset of seropositive RA that is characterized by granulocytopenia, splenomegaly and therapy-resistant leg ulcers (often pretibial). These patients are predisposed to cutaneous and systemic infections that can be refractory to standard treatment, and they are at increased risk of lymphomas and leukemias[45]. The ulcers are likely multifactorial and may be secondary to pyoderma gangrenosum, medium-sized vessel vasculitis (although vasculitis is often not confirmed histologically), venous hypertension, neuropathy, or perhaps an ulcerating form of palisaded neutrophilic and granulomatous dermatitis (PNGD)[46].

Neutrophilic dermatoses

Sterile infiltration of the skin by neutrophils can occur in patients with RA. The primary disorders are pyoderma gangrenosum, Sweet's syndrome, and rheumatoid neutrophilic dermatitis (see Chs 26 & 53), but there may be overlap and the term "neutrophilic dermatosis" is often used.

Pyoderma gangrenosum (PG) (Fig. 45.9) occurs at a higher frequency in patients with RA than in the general population. Although PG

Fig. 45.9 Pyoderma gangrenosum in a patient with rheumatoid arthritis. The chronic relapsing ulcerations involved the lower extremities. *Courtesy, Carlos H Nousari, MD.*

frequently occurs as a single, painful lesion on the lower extremities, the presence of chronic relapsing lesions in unusual sites such as the face, upper extremities and abdomen should raise the suspicion of an underlying disease, especially rheumatologic and hematologic disorders or inflammatory bowel disease. Sweet's syndrome classically presents with erythematous, edematous, tender plaques that favor the head and neck region and the upper extremities. As with PG, the presence of bullous lesions or involvement of atypical locations should prompt the exclusion of an underlying rheumatologic or hematologic disorder.

Rheumatoid neutrophilic dermatitis (also referred to as rheumatoid neutrophilic dermatosis) resembles Sweet's syndrome, both clinically and histologically. It occurs in patients with severe and usually seropositive RA, and it is characterized by erythematous urticarial papules and plaques that are persistent and asymptomatic, but occasionally ulcerate. Lesions are symmetrically distributed, most commonly on the extensor forearms and hands, but they can occur elsewhere.

Other

Patients with RA may also develop erythema elevatum diutinum (see Ch. 24) and PNGD (see below) as well as a number of cutaneous side effects from medications used to treat the arthritis (see Table 53.1).

Pathology

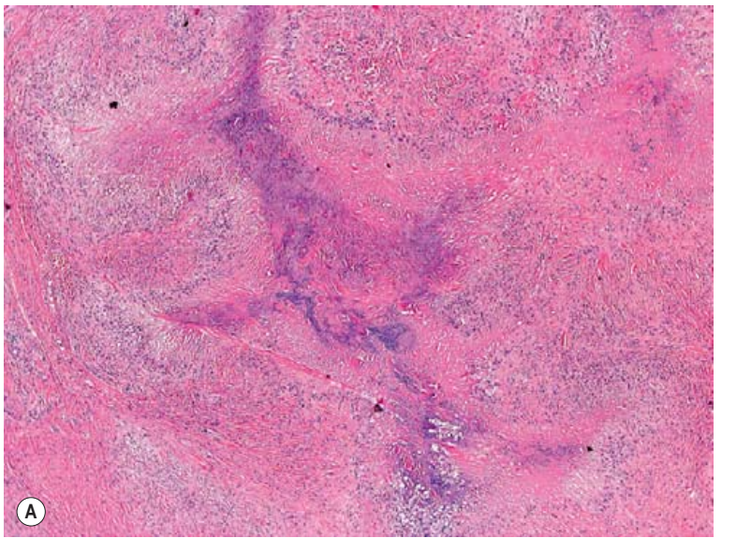
Rheumatoid nodules are typically located in the deep dermis or subcutis and are composed of a central zone of brightly eosinophilic fibrin surrounded by a palisaded layer of histiocytes and granulation tissue (Fig. 45.10). Acute or early lesions may show leukocytoclastic vasculitis and/or an interstitial neutrophilic infiltrate.

The histologic findings of PG, Sweet's syndrome, and small, medium-sized and large vessel vasculitis are discussed in Chapters 24 and 26. When rheumatoid vasculitis affects medium-sized vessels, it can be histologically indistinguishable from polyarteritis nodosa. Direct immunofluorescence in rheumatoid vasculitis shows prominent deposition of IgM as well as C3 in small and medium-sized vessels, whereas in polyarteritis nodosa the IgM and C3 vascular deposits are weaker and sparse and limited to medium-sized vessels.

Differential Diagnosis

Although rheumatoid nodules share several histologic features with PNGD, in the latter the clinical lesions are more polymorphous, with papules and plaques rather than periarticular skin-colored nodules. Because both the clinical and histologic findings can be similar, subcutaneous granuloma annulare may be misdiagnosed as rheumatoid nodules. However, individuals with subcutaneous granuloma annulare are otherwise healthy and are usually children. Occasionally, gouty tophi may be mistaken for rheumatoid nodules.

The differential diagnosis of cutaneous vasculitis is discussed in detail in Chapter 24. Specifically, rheumatoid vasculitis may be confused with mixed cryoglobulinemia given the presence of arthritis, RF, and complement activation in both entities. However, in the former



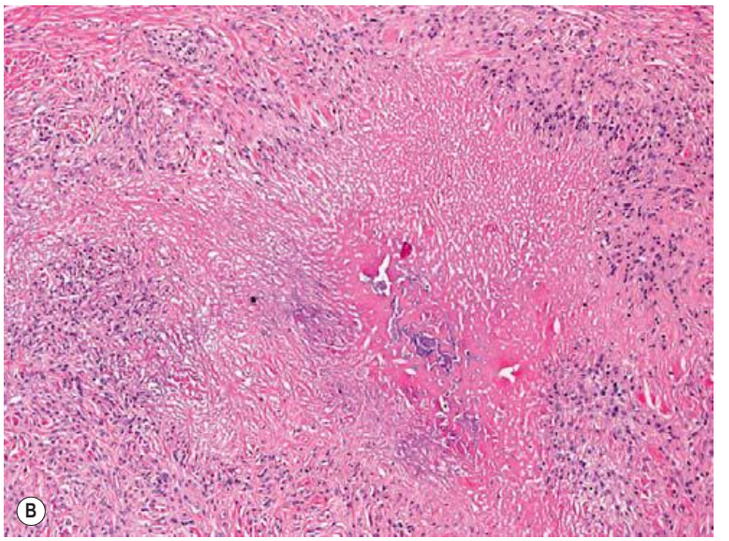


Fig. 45.10 Rheumatoid nodule – histiologic features. A Large, irregular area of necrobiosis surrounded by a palisade of histiocytes. **B** Details of necrobiosis and palisade of histiocytes with elongated nuclei. *Courtesy, Lorenzo Cerroni, MD.*

the titer of RF is significantly higher and levels of both C3 and C4 are decreased, whereas in cryoglobulinemia C4 levels are low with relatively normal levels of C3. Bywater's lesions may resemble septic emboli, traumatic lesions and, less often, pernio.

As previously mentioned, rheumatoid neutrophilic dermatitis strongly resembles Sweet's syndrome, but could also be mistaken for urticaria or urticarial vasculitis. Ulcerations in RA and Felty syndrome may have a variety of causes, including PG, rheumatoid vasculitis, superficial ulcerating rheumatoid necrobiosis (see Ch. 53) and secondary antiphospholipid syndrome, as well as infections (especially in patients receiving immunosuppressives), lymphoma (particularly angiocentric variants) and thromboembolic disorders.

Treatment

RA therapy is aimed at improving symptoms and preventing end-organ damage. Some of the cutaneous manifestations may improve with treatment of the joint disease, while others (e.g. rheumatoid nodules) often persist. Rheumatoid nodules can be excised, but recurrence is common. Intralesional corticosteroid injections may decrease the size of the nodules, but do not lead to complete resolution. Rheumatoid neutrophilic dermatitis is treated with oral corticosteroids or antineutrophilic agents such as dapsone or colchicine, while Felty syndrome may be treated with recombinant granulocyte colony-stimulating factor (G-CSF) and/or splenectomy.

Rheumatoid vasculitis involving medium-sized and large vessels requires aggressive treatment as it can be rapidly progressive and life-threatening. Intravenous methylprednisolone (500–1500 mg/day for 3 days) followed by prednisone (1 mg/kg/day) plus cyclophosphamide (daily or monthly) and plasmapheresis should be considered.

In less severe cases, including the small vessel variant of rheumatoid vasculitis, azathioprine and mycophenolate mofetil may be considered; methotrexate does not have a consistent effect in this complication of RA. Although there are reports of vasculitis developing in patients with RA after the initiation of TNF-α inhibitors, there are also multiple reports documenting the beneficial effects of this class of drugs in the treatment of rheumatoid vasculitis as well[46]. Several reports have also documented improvement in rheumatoid vasculitis after rituximab therapy[46]. Recurrences of rheumatoid vasculitis are less likely to occur when a stable, long-term regimen re-establishes control of the underlying RA.

For the treatment of RA-associated PG, systemic corticosteroids and cyclosporine are highly effective. Excellent results have also been reported with TNF-α inhibitors. Additional treatments are reviewed in Chapter 26.

INTERSTITIAL GRANULOMATOUS DERMATITIS AND PALISADED NEUTROPHILIC AND GRANULOMATOUS DERMATITIS

Synonyms:
Interstitial granulomatous dermatitis (IGD) with arthritis:
■ IGD with plaques and arthritis ■ IGD with plaques ■ IGD with cutaneous cords and arthritis

Palisaded neutrophilic and granulomatous dermatitis (PNGD):
■ Rheumatoid papules ■ Churg–Strauss granuloma ■ Cutaneous extravascular necrotizing granuloma ■ Superficial ulcerating rheumatoid necrobiosis

Key features

- Granulomatous dermatitis presenting in the context of autoimmune disease occurs in two major clinicopathologic patterns
- In *interstitial granulomatous dermatitis (IGD) with arthritis*, annular plaques or linear cords favor the trunk, axillae and medial thighs in patients with RA or seronegative arthritis; histologically, rosettes of palisading histiocytes surround tiny foci of degenerated collagen, often accompanied by neutrophils but without evidence of vasculitis
- In *palisaded neutrophilic and granulomatous dermatitis (PNGD)*, symmetrically distributed, umbilicated papules favor the elbows and extensor surfaces of the digits in patients with disorders such as RA, systemic LE and Wegener's granulomatosis; the histologic findings range from small vessel vasculitis with prominent neutrophils and leukocytoclasis (early lesions) to palisading granulomas (fully developed lesions), and both stages demonstrate basophilic degenerated collagen
- Interstitial granulomatous drug eruptions may mimic IGD or PNGD

Introduction

Palisaded neutrophilic and granulomatous dermatitis (PNGD) and interstitial granulomatous dermatitis (IGD) with arthritis represent two clinicopathologic patterns of granulomatous dermatitis that occur in patients with RA and other autoimmune disorders. These entities may exist on a spectrum.

History

In 1994, Chu and colleagues[47] proposed the term "palisaded neutrophilic and granulomatous dermatitis" for the histologic reaction pattern that characterizes papular eruptions on the extensor extremities that present in the context of autoimmune connective tissue disease and other conditions characterized by immune complex generation. Such skin lesions were originally described in the setting of Churg–Strauss syndrome, and their association with a broad spectrum of autoimmune and inflammatory disorders was first recognized by Winkelmann in 1978 (cutaneous extravascular necrotizing granuloma). Some authors include "interstitial granulomatous dermatitis with arthritis", a term coined by Ackerman in 1993, within the PNGD spectrum. Others argue that the former represents a separate entity with distinct clinical (annular plaques and cords favoring the lateral trunk and skin folds) and histologic (histiocytic rosettes without evidence of vasculitis) features.

Pathogenesis

It is thought that the initiating insult in PNGD and IGD is immune complex deposition on or around the walls of small dermal blood vessels as a result of the underlying disease, which leads to a subacute or chronic neutrophil-rich small vessel vasculitis (more prominent in PNGD). This then impairs blood flow to the area in a smoldering fashion, as opposed to the abrupt vascular occlusion of classic vasculitis; consequently, there is degeneration of the local collagen rather than acute necrosis. The degenerated collagen incites an immune response resulting in a palisading lymphohistiocytic infiltrate. Moderate but persistent levels of immune complexes may contribute to this phenomenon. The cascade of events is likely aggravated or precipitated by exogenous trauma, which explains the predilection of PNGD lesions for the extensor surfaces. Variable sizes, amounts and sites of immune complex deposition (e.g. dermal venules versus the interstitial dermis) as well as different triggers and underlying systemic inflammatory disorders may account for the distinct clinical and histologic features of PNGD and IGD.

Clinical Features

PNGD typically presents as skin-colored to erythematous papules that appear symmetrically on extensor surfaces, particularly the elbows and fingers. Central umbilication with crusts or perforation (with extrusion of necrobiotic collagen) may be present (see Fig. 53.1), and ulceration occasionally occurs. These lesions are observed most often in patients with RA, systemic LE or systemic vasculitis, particularly Wegener's granulomatosis.

IGD with arthritis is characterized by erythematous plaques (often with an annular configuration) or linear cords (the "rope sign"; Fig. 45.11A) that favor the lateral trunk, axillae, buttocks, medial thighs (see Fig. 53.3), and groin. Large areas of involvement can be seen (Fig. 45.11B). It usually occurs in women with RA, seronegative arthritis or polyarthralgias and is often associated with autoimmune thyroiditis.

Pathology

The histopathologic features of PNGD and IGD exist on a spectrum and vary depending on the stage of evolution of the lesion that is biopsied. Early lesions of PNGD often show a pandermal infiltrate of neutrophils and focal leukocytoclastic vasculitis. Classic, fully developed lesions are characterized by zones of basophilic degenerated collagen surrounded by palisades of histiocytes, neutrophils and nuclear debris (Fig. 45.12). "Incomplete" early lesions may display focal basophilic collagen necrosis and histiocytes without orderly palisading in association with prominent neutrophils, whereas late lesions can exhibit well-developed palisading granulomas with only a sparse complement of neutrophils.

The histologic pattern of IGD features smaller "rosettes" of palisading histiocytes surrounding tiny, discrete foci of degenerated collagen (piecemeal fragmentation) within a dense, "bottom-heavy" dermal interstitial infiltrate that contains variable numbers of neutrophils and eosinophils. There is no evidence of vasculitis, and dermal mucin is usually absent.

A Fully developed lesions usually demonstrate neutrophils and histiocytes in association with basophilic degenerating collagen bundles; some eosinophils may be present as well. **B** Details of histiocytes admixed with lymphocytes, neutrophils and eosinophils. *Courtesy, Lorenzo Cerroni, MD.*

Differential Diagnosis

The clinical differential for PNGD includes perforating disorders, early rheumatoid nodules, accelerated rheumatoid nodulosis, and papular granuloma annulare (GA). The interstitial granulomatous drug reaction, which is most often caused by calcium channel blockers and angiotensin-converting enzyme inhibitors (Table 45.5), can mimic PNGD and IGD, both clinically and histologically. Onset typically occurs after months to years of therapy with the culprit medication. In addition, the development of IGD- and PNGD-like lesions has been associated with TNF inhibitor therapy in patients with RA. The clinical presentation of IGD with plaques may resemble patch-type GA, the inflammatory stage of morphea, erythema migrans or mycosis fungoides.

The histologic differential diagnosis includes other palisaded granulomatous dermatitides such as GA, necrobiosis lipoidica (see Ch. 93) and rheumatoid nodules. GA is more likely to have a patchy infiltrate concentrated in the upper dermis ("top heavy") and abundant mucin deposition. A relative paucity of neutrophils and leukocytoclasis distinguishes GA from PNGD, whereas the presence of either larger palisades or a lack of palisades (e.g. in the interstitial pattern seen in patch-type GA) differentiates GA from IGD. Rheumatoid nodules can be recognized by their central eosinophilia (rather than basophilia) and predominantly subcutaneous location. All of these entities may show transepidermal elimination of degenerated collagen. Additional diagnostic considerations for an interstitial granulomatous infiltrate with variable neutrophils may include dimorphic fungal or atypical mycobacterial infections, Lyme disease and leprosy. Histologic features that favor an interstitial granulomatous drug reaction over IGD include a vacuolar interface dermatitis, atypical lymphocytes, prominent eosinophils, a lack of neutrophils and minimal collagen degeneration.

The evaluation of a patient with palisaded necrotizing granulomas and a suspected rheumatologic disorder is outlined in Figure 45.13, and the relationship of PNGD and IGD with other dermatoses that have granulomatous, neutrophilic or vasculitic components and affect this patient population is depicted in Figure 45.14.

Treatment

No specific therapy is required for these skin conditions, although improvement has been reported with the use of high-potency topical or intralesional corticosteroids, dapsone and hydroxychloroquine. Treatment of the underlying disease can also lead to resolution of existing lesions and prevent recurrences.

CAUSES OF INTERSTITIAL GRANULOMATOUS DRUG REACTION

COMMON

- Calcium channel blockers: diltiazem, verapamil, nifedipine
- HMG-CoA reductase inhibitors: simvastatin, pravastatin, lovastatin
- Furosemide
- Beta-blockers: labetalol, metoprolol, atenolol, propranolol
- Antihistamines (H_1 or H_2 blockers): famotidine, cimetidine, ranitidine, brompheniramine
- Angiotensin-converting enzyme inhibitors: enalapril, lisinopril
- TNF-α inhibitors: infliximab, etanercept, adalimumab; lenalidomide, thalidomide
- Anakinra

UNCOMMON

- Hydrochlorothiazide (HCTZ)
- Carbamazepine
- Diazepam
- Bupropion
- Darifenacin
- Sennoside
- Ganciclovir

Mucinoses 46

Franco Rongioletti and Alfredo Rebora

Key features

- The cutaneous mucinoses are a heterogeneous group of disorders in which an abnormal amount of mucin accumulates in the skin
- The etiopathogenesis of cutaneous mucinoses is unknown
- The cutaneous mucinoses are divided into two groups: (1) primary cutaneous mucinoses, in which the mucin deposition leads to clinically distinctive lesions and is the major histologic feature; and (2) secondary mucinoses, in which the mucin deposition is simply an associated finding
- Primary cutaneous mucinoses are further divided into degenerative–inflammatory forms (which may be dermal or follicular) and hamartomatous–neoplastic forms
- Associated disorders include paraproteinemia (scleromyxedema, scleredema), diabetes mellitus (scleredema), thyroid disease (pretibial myxedema, myxedema) and autoimmune connective tissue disease (lupus erythematosus, dermatomyositis)

INTRODUCTION

The cutaneous mucinoses are a heterogeneous group of disorders in which an abnormal amount of mucin accumulates in the skin, either diffusely or focally[1].

Mucin is a component of the dermal extracellular matrix and is normally produced in small amounts by fibroblasts. It is a jelly-like, amorphous mixture of acid glycosaminoglycans (formerly referred to as acid mucopolysaccharides), which are complex carbohydrates composed of multiple repeating polysaccharide units (see Ch. 95). The acid glycosaminoglycans may be attached to both sides of a protein core (proteoglycan monomer), as in the case of dermatan sulfate and chondroitin sulfate, or they may be free, as in the case of hyaluronic acid, which is the most important component of dermal mucin.

Mucin is capable of absorbing 1000 times its own weight in water, playing a major role in maintaining the salt and water balance of the dermis. In routinely stained sections, the presence of either a blue-staining material between separated collagen bundles or empty spaces within the dermis is a good clue that there is mucin deposition. For confirmation, special stains can be used, such as Alcian blue, colloidal iron or toluidine blue (Table 46.1). Furthermore, dermal mucin is PAS-negative and, if composed of hyaluronic acid, hyaluronidase-sensitive. Fixation of biopsy specimens in absolute alcohol (rather than formalin) may improve its detection, and monoclonal antibodies have been used to detect sulfated acid glycosaminoglycans[2]. An alternative approach is to utilize biotinylated hyaluronan (HA)-binding proteins coupled to an avidin-peroxidase reaction[3].

Why mucin abnormally accumulates within the skin of some individuals is unclear. Certain "serum factors", e.g. immunoglobulins and/or cytokines, could promote the upregulation of glycosaminoglycan synthesis[4]. For example, increased serum immunoglobulin levels (monoclonal or polyclonal) and circulating autoantibodies can be found in association with cutaneous mucinoses such as scleromyxedema, Graves disease-associated pretibial myxedema, and papulonodular mucinosis of lupus erythematosus. However, the serum from these patients stimulates mucin production even *after* the elution of either the IgG paraprotein in those with scleromyxedema or the autoantibodies in those with Graves disease-associated pretibial myxedema. Circulating cytokines such as interleukin (IL)-1, TNF-α and TGF-β, which are known to stimulate glycosaminoglycan synthesis in the skin, could play a role in excess mucin deposition. A reduction in the normal catabolic degradation of mucin could also be a factor.

This chapter focuses on the disorders characterized by abnormal dermal deposits of mucin, composed primarily of hyaluronic acid (Fig. 46.1). The mucopolysaccharidoses (MPS), in which the predominant dermal mucin is dermatan sulfate or heparan sulfate (e.g. Hunter syndrome), are discussed in Chapter 48.

Table 46.1 Staining characteristics of acid glycosaminoglycans (mucopolysaccharides). GAG, glycosaminoglycan.

CLASSIFICATION

The cutaneous mucinoses may be classified as primary, in which mucin deposition is the major histologic feature resulting in clinically distinctive lesions (Table 46.2), and secondary, in which mucin simply represents an associated histologic finding (Table 46.3). Primary mucinoses can then be divided into degenerative–inflammatory forms and hamartomatous–neoplastic types. The former are further subdivided into dermal and follicular forms, based upon the location of the mucin (see Table 46.2).

PRIMARY DEGENERATIVE–INFLAMMATORY MUCINOSES

Dermal Mucinoses

Scleromyxedema

Synonyms: ■ Papular mucinosis ■ Generalized and sclerodermoid lichen myxedematosus

CLASSIFICATION OF THE PRIMARY CUTANEOUS MUCINOSES
DEGENERATIVE–INFLAMMATORY MUCINOSES
Dermal
Scleromyxedema or papular mucinosis*
Lichen myxedematosus (localized variants)
• Discrete papular form†
• Acral persistent papular mucinosis†
• Cutaneous mucinosis of infancy
• Nodular form
Self-healing cutaneous mucinosis
• Juvenile type
• Adult type
Scleredema
Mucinoses associated with altered thyroid function
• Localized (pretibial) myxedema
• Generalized myxedema
Reticular erythematous mucinosis
Papulonodular mucinosis associated with autoimmune connective tissue diseases (most commonly LE)
Cutaneous focal mucinosis
Digital mucous cyst (myxoid cyst)
Miscellaneous mucinoses
Follicular
Follicular mucinosis (Pinkus)
Urticaria-like follicular mucinosis
HAMARTOMATOUS–NEOPLASTIC MUCINOSES
Mucinous nevus
(Angio)myxoma
*Also referred to as generalized and sclerodermoid lichen myxedematosus.
†Also seen in HIV-infected individuals.

Table 46.2 Classification of the primary cutaneous mucinoses. LE, lupus erythematosus.

DISORDERS ASSOCIATED WITH HISTOLOGIC DEPOSITION OF MUCIN (SECONDARY MUCINOSES)
EPITHELIAL MUCINOSIS
• Basal cell carcinoma
• Rare – squamous cell carcinoma, keratoacanthoma, verruca, seborrheic keratosis, mycosis fungoides
DERMAL MUCINOSIS
• Granuloma annulare
• Lupus erythematosus, dermatomyositis >> scleroderma
• Mesenchymal tumors (e.g. myxosarcoma, myxoid lipoblastoma, DFSP)
• Neural tumors (e.g. neurofibroma, lobular neuromyxoma)
• Epithelial tumors (e.g. basal cell carcinoma, eccrine carcinoma)
• Other tumors (e.g. cutaneous metastases, mucinous carcinoma of the eyelid)
• Obesity-associated lymphedema
• Hypertrophic scar
• Rare – chronic GVHD, cutaneous reactions to interferon, herpes zoster, venous insufficiency, hereditary progressive mucinous histiocytosis
FOLLICULAR MUCINOSIS
• Lymphoma, T-cell
• Eczematous dermatoses
• Rare – lupus erythematosus, insect bites (including in the setting of CLL), side effect of imatinib, familial reticuloendotheliosis

Table 46.3 Disorders associated with histologic deposition of mucin (secondary mucinoses). A limited amount of dermal mucin can occasionally be observed in virtually all cutaneous disorders. CLL, chronic lymphocytic leukemia; DFSP, dermatofibrosarcoma protuberans.

DIAGNOSTIC CRITERIA OF SCLEROMYXEDEMA VERSUS LOCALIZED VARIANTS OF LICHEN MYXEDEMATOSUS	
Scleromyxedema	**Localized variants of lichen myxedematosus**
Generalized papular eruption and sclerodermoid features	Papular eruption (or nodules and/or plaques due to confluence of papules)
Microscopic triad (mucin deposition, fibroblast proliferation, fibrosis)	Mucin deposition with variable fibroblast proliferation
Monoclonal gammopathy	Absence of monoclonal gammopathy
Absence of thyroid disorder	Absence of thyroid disorder

Table 46.4 Diagnostic criteria of scleromyxedema versus localized variants of lichen myxedematosus.

Introduction and definition

Scleromyxedema is a chronic idiopathic disorder characterized by numerous firm papules and areas of induration that are due to dermal mucin deposition in association with an increase in dermal collagen[4]. Patients also have a monoclonal gammopathy and systemic, even lethal, manifestations. This entity must be distinguished from localized variants of lichen myxedematosus where the skin is the sole site of involvement (Table 46.4). There are, however, occasional patients who have an atypical constellation of findings and fall between scleromyxedema and localized lichen myxedematosus (atypical forms; see below).

History

Although the first descriptions of scleromyxedema were attributed to Dubreuilh in 1906 and Reitman in 1908, it was not until the review of Montgomery and Underwood in 1953 that the disease was distinguished from scleroderma and generalized myxedema. A year later, Gottron and his colleagues gave the name "scleromyxedema" to the generalized and sclerotic form. The association of a monoclonal gammopathy with scleromyxedema was first described in 1963.

Epidemiology and pathogenesis

Scleromyxedema is a fairly uncommon disease, affecting middle-aged adults of both sexes equally. The pathogenesis of scleromyxedema is unknown. The role of the associated monoclonal gammopathy remains a matter of debate. While patients have evidence of a plasma cell dyscrasia, paraprotein levels do not correlate with either the extent or the progression of the disease. In addition, sera from patients with scleromyxedema enhanced fibroblast proliferation *in vitro*, but an immunoglobulin purified from paraprotein-containing sera failed to do so, suggesting a pathogenetic role for circulating factors other than the paraprotein. Clinical remission of scleromyxedema (and reduction of the M-protein) following autologous hematopoietic stem cell transplantation points to the bone marrow as a source of these circulating factors. Lastly, the development of scleromyxedema following a cutaneous granulomatous reaction to intradermal injections of hyaluronic gel suggests the possibility of a human adjuvant disease[5].

Clinical features

In scleromyxedema, numerous, 2–3 mm, firm, waxy, closely spaced papules develop in a widespread symmetrical distribution pattern. The most common sites of involvement are the head and neck region (Fig. 46.2), upper trunk, hands, forearms and thighs. Papules are often arranged in a strikingly linear array. The surrounding skin is shiny and indurated, i.e. sclerodermoid in appearance, and the glabella is typically involved with deep longitudinal furrowing. Severe involvement of the face can result in a leonine facies (Fig. 46.3). Erythema, edema and a brownish discoloration may also be seen in the involved areas; pruritus is not rare. The mucous membranes and scalp are spared. As the condition progresses, erythematous and infiltrated plaques may appear with skin stiffening, sclerodactyly and decreased motility of the mouth and joints. Overlying the proximal interphalangeal joints, a central depression surrounded by an elevated rim (due to skin thickening) can be seen and is referred to as the "doughnut sign". Mat and cuticular telangiectasias and calcinosis, as seen in systemic sclerosis, are absent.

Scleromyxedema is almost always associated with paraproteinemia. The monoclonal gammopathy is usually IgG and the light chains are

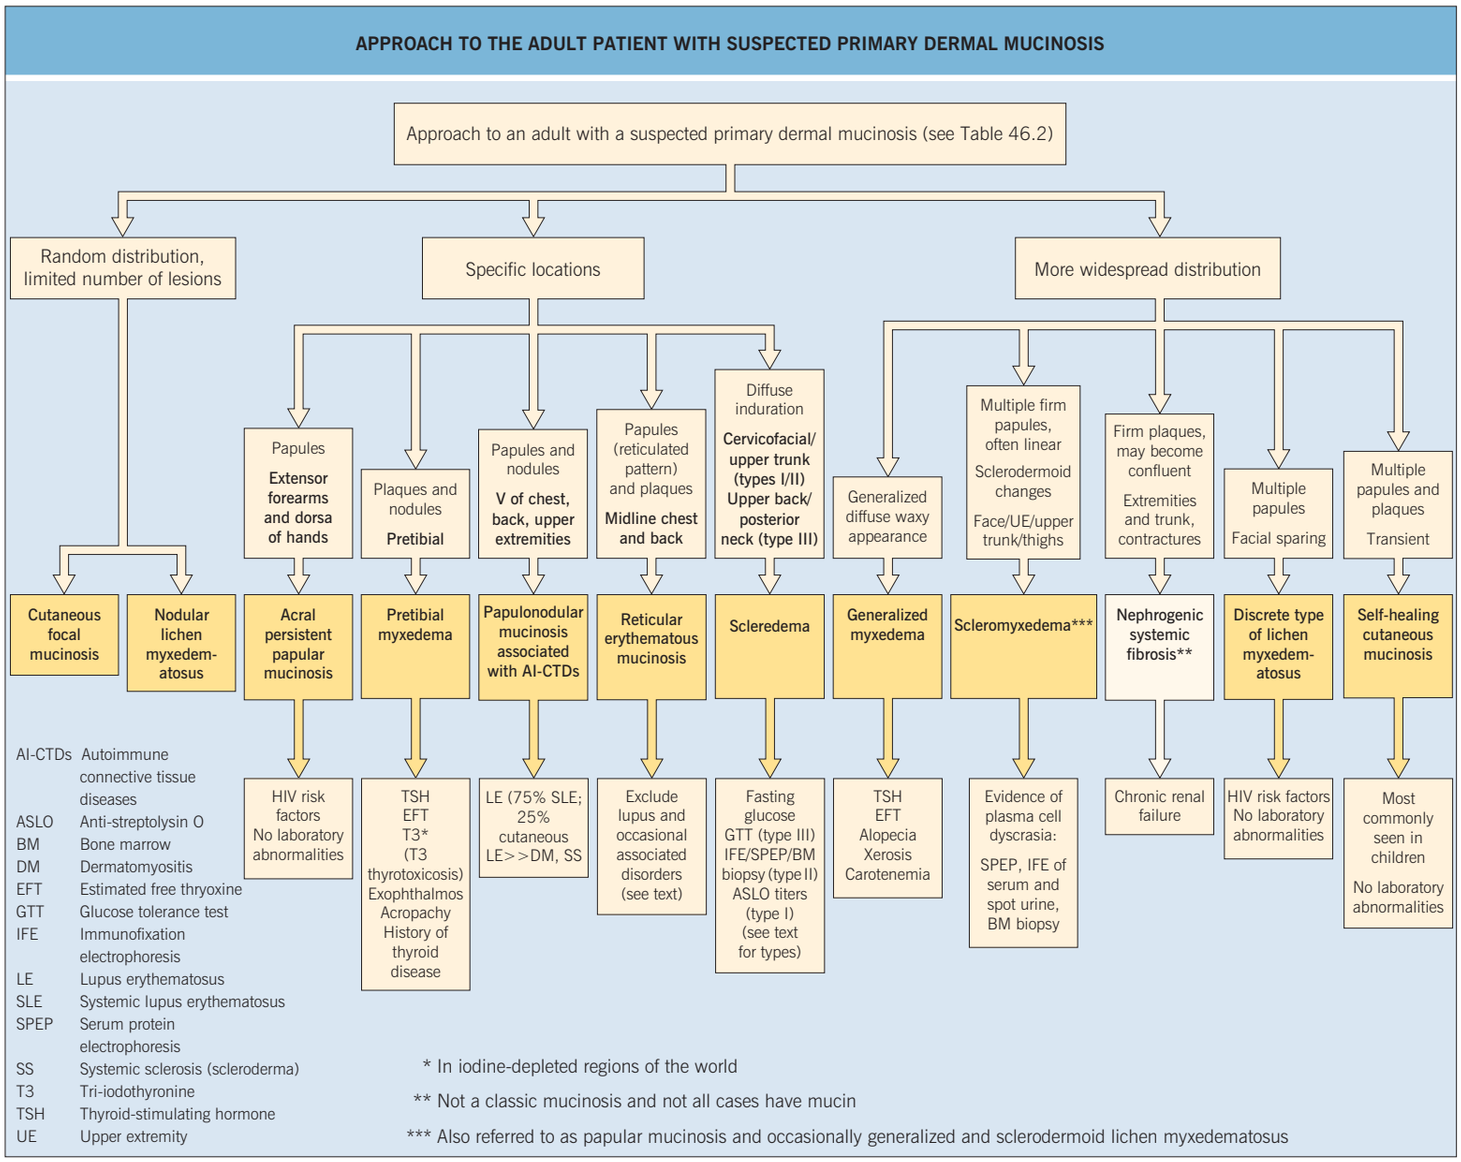

Fig. 46.1 Approach to the patient with suspected primary dermal mucinosis. Pretibial myxedema must be distinguished from obesity-associated lymphedematous mucinosis.

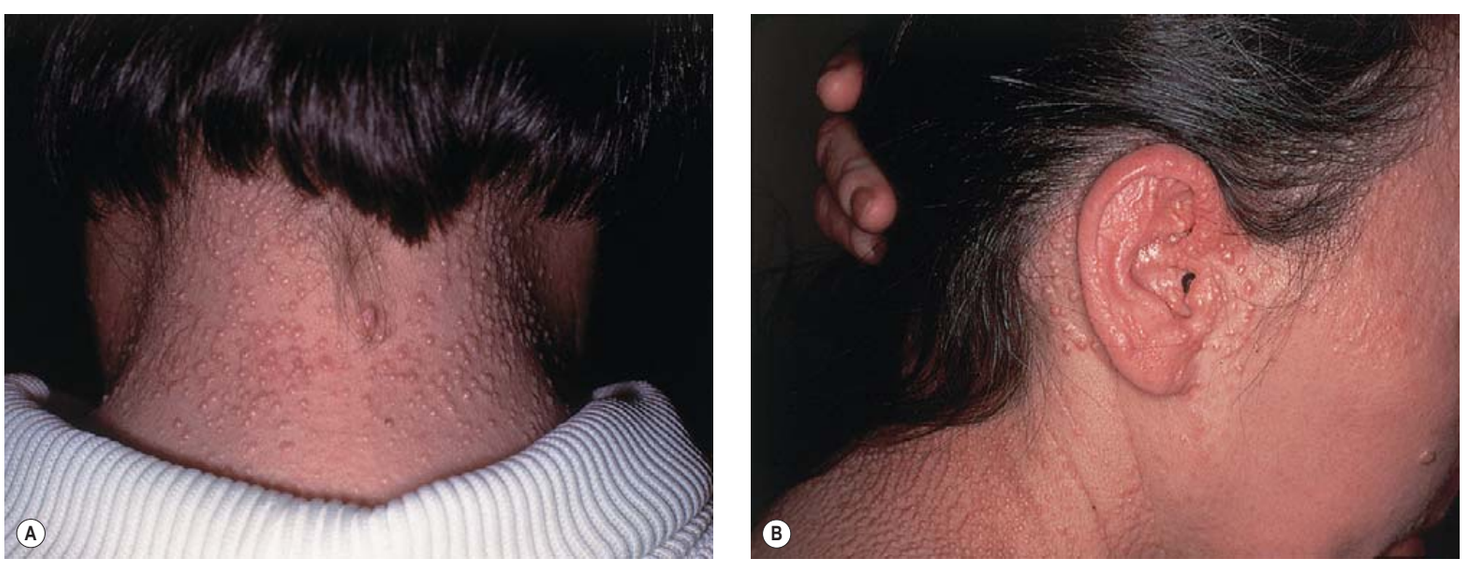

Fig. 46.2 Scleromyxedema. A,B Numerous monomorphic, firm, skin-colored to pink papules which can have a linear arrangement (most obvious on the left neck [**A**] and the upper back [**B**]).

more commonly lambda. Although a mild plasmacytosis may be observed in bone marrow biopsies, less than 10% of patients with scleromyxedema progress to multiple myeloma. Patients with scleromyxedema can have a number of internal manifestations, in particular muscular, neurologic, rheumatologic, pulmonary, renal and cardiovascular. Dysphagia, proximal muscle weakness due to myositis, disturbances of the CNS leading to unexplained coma[6], peripheral neuropathy, arthropathies, carpal tunnel syndrome, restrictive or obstructive lung disease, and a scleroderma-like renal disease may accompany or follow the cutaneous manifestations. While the predominantly sensory peripheral neuropathy typically affects older men and has an insidious onset, the dermato-neuro syndrome is a potentially life-threatening encephalopathy. This syndrome begins abruptly with a worsening of skin lesions, a flu-like prodrome, fever and seizures, and it can eventuate in an unexplained coma[6].

Pathology

Scleromyxedema is characterized by a triad of microscopic features[7]:

- a diffuse deposit of mucin in the upper and mid reticular dermis
- an increase in collagen deposition
- a marked proliferation of irregularly arranged fibroblasts (Fig. 46.4).

The epidermis may be normal or thinned by the pressure of the underlying mucin and fibrosis; the hair follicles may be atrophic. A slight superficial, perivascular, lymphoplasmacytic infiltrate is often present. The elastic fibers are fragmented and decreased in number. Mucin may fill the walls of myocardial blood vessels as well as the interstitium of the kidney, pancreas, adrenal glands and nerves. In the dermato-neuro syndrome, autopsy findings have not proved helpful in elucidating its underlying pathogenesis.

Differential diagnosis

The primary differential diagnosis for scleromyxedema is scleroderma (systemic sclerosis) and scleredema. The presence of papules, especially in linear arrays, is a very helpful clinical sign in distinguishing scleromyxedema. Additional entities in the sclerodermoid differential diagnosis should be excluded (see Ch. 43). In particular, nephrogenic systemic fibrosis, which develops in individuals with renal dysfunction, may have mucin in biopsy specimens, but patients lack both facial involvement (commonly seen in scleromyxedema) and paraproteinemia. Criteria for diagnosing scleromyxedema versus localized variants of lichen myxedematosus are summarized in Table 46.4 and the dermatologic disorders in which leonine facies can develop are outlined in Table 46.5.

Treatment

The treatment of scleromyxedema can be disappointing. In the past, monthly courses of melphalan were often the therapy of choice, targeting the plasma cell dyscrasia. However, while this alkylating agent can result in some clinical improvement, it has also been implicated in 30% of the deaths secondary to its induction of hematologic malignancies and septic complications[8]. Other chemotherapeutic agents (e.g. cyclophosphamide, methotrexate, chlorambucil, 2-chlorodesoxyadenosine) have been tried, but with no better results and the risk of similar side effects.

Nowadays, therapeutic regimens are based primarily upon those used to treat myeloma and include various combinations of melphalan, dexamethasone or prednisone, thalidomide (100–200 mg daily long term, with higher doses initially), lenalidomide, and bortezomib (a proteasome inhibitor)[9]. As in myeloma, corticosteroids are usually not administered as monotherapy due to more limited sustained responses. In appropriate candidates who have disabling or potentially life-threatening disease, autologous hematopoietic stem cell transplantation is an option[9a,9b]. Of note, there is increasing evidence that IVIg may represent an effective and relatively safe treatment for both cutaneous and extracutaneous manifestations of scleromyxedema, including the dermato-neuro syndrome[10].

Additional therapies include intralesional and topical corticosteroids, but they are of limited value. Primarily in case series, topical and intralesional hyaluronidase, PUVA, UVA1, systemic retinoids, electron beam radiation, plasmapheresis[10a], extracorporeal photochemotherapy, dermabrasion, and topical dimethyl sulfoxide have all produced some improvement without treating the underlying disease. Granulocyte

LEONINE FACIES – ASSOCIATED DERMATOLOGIC DISEASES
Scleromyxedema
Systemic amyloidosis
Lipoid proteinosis
Lepromatous leprosy
Leishmaniasis
Cutaneous lymphoma (T-cell, B-cell)
Actinic reticuloid form of chronic actinic dermatitis
Leukemia cutis
Mastocytosis (nodular)
Sarcoidosis
Multicentric reticulohistiocytosis
Progressive nodular histiocytosis
Pachydermoperiostosis

colony-stimulating factor proved beneficial in one patient with idiopathic neutropenia, as did cyclosporine in a second patient. Interferon-α has led to paradoxical effects, with both improvement and worsening of the disease[11].

Dysarthria and a flu-like illness may herald the life-threatening coma, and the patient should be promptly admitted to the hospital for close observation. Occasionally, spontaneous improvement and clinical resolution, even after 15 years, have been described[4].

Lichen myxedematosus (localized variants)

Introduction

In the localized variants of lichen myxedematosus, patients develop small, firm, waxy papules (or nodules and plaques produced by the confluence of papules) that are limited to only a few sites – usually the upper and lower limbs and/or trunk. The skin is the only site of involvement and these variants, in contrast to scleromyxedema, are not associated with sclerosis, paraproteinemia or systemic involvement nor are they associated with thyroid disease (see Fig. 46.1)[4]. While most dermatologists equate lichen myxedematosus with localized, skin-limited disease, a source of potential confusion is the uncommon and more historical use of the term "generalized and sclerodermoid lichen myxedematosus" to describe scleromyxedema.

The localized variants of lichen myxedematosus are subdivided into four subtypes:

- a discrete papular form
- acral persistent papular mucinosis
- cutaneous mucinosis of infancy
- a pure nodular form.

Localized variants of lichen myxedematosus may be observed in association with HIV infection, exposure to toxic oil or L-tryptophan (historical), and hepatitis C viral (HCV) infection.

Epidemiology

Exact incidence and prevalence rates for the localized variants of lichen myxedematosus are not known.

Clinical features

Discrete papular lichen myxedematosus is characterized by 2–5 mm papules, numbering from just a few to hundreds and involving the limbs and trunk in a symmetrical pattern[12] (Fig. 46.5). The affected skin is not indurated and the face is spared. The lesions progress slowly without systemic involvement. However, they rarely resolve spontaneously. Progression to scleromyxedema has never been proven.

In **acral persistent papular mucinosis**, first described in 1986 by Rongioletti et al.[13], multiple ivory to skin-colored papules develop exclusively on the dorsal aspect of the hands and extensor surface of the distal forearms (Fig. 46.6). A female predominance (female : male ratio of 3 : 1) has been noted. The lesions persist without systemic manifestations[14].

In **cutaneous mucinosis of infancy** (syn. papular mucinosis of infancy), first described by Lum in 1980, firm opalescent papules appear on the neck (Fig. 46. 7), upper arms (especially the elbows), and trunk[4].

Fig. 46.5 Localized lichen myxedematosus – discrete papular type. Persistent whitish papules on the arms.

Fig. 46.6 Acral persistent papular mucinosis. Skin-colored papules on the dorsal aspect of the hands.

Neither systemic symptoms nor spontaneous resolution are observed. Of the handful of patients described to date, at least two have had a congenital linear variant, which might be better categorized as an example of a mucinous nevus[15].

Nodular lichen myxedematosus is characterized by multiple nodules on the limbs and trunk, with a mild or absent papular component.

Localized lichen myxedematosus in HIV-infected patients has been described in HIV-positive men who have either had sex with other men or abused illicit drugs. The majority developed the discrete papular form of lichen myxedematosus on the limbs and trunk, while the remainder had acral persistent papular mucinosis. All became infected with HIV before the onset of the lichen myxedematosus. Most of them had hypergammaglobulinemia, which is a well-recognized manifestation of HIV infection, and to date only two had a paraproteinemia. Of note, up to 10% of HIV-infected individuals can have a monoclonal gammopathy of undetermined significance (MGUS) and how this relates to the mucinosis remains to be determined. None of the patients had visceral involvement due to mucin deposition[16].

Fig. 46.7 Cutaneous mucinosis of infancy. Skin-colored papules on the back of the neck in a young girl.

Localized lichen myxedematosus in "toxic" syndromes. Multiple papules due to mucin deposition with a clinical appearance similar to the discrete form of lichen myxedematosus have also been described in the setting of toxic oil syndrome and L-tryptophan-associated eosinophilia–myalgia syndrome. Although unrelated epidemiologically and both of historical interest, toxic oil syndrome (due to the ingestion of adulterated rapeseed oil in Spain in the early 1980s) and L-tryptophan-associated eosinophilia–myalgia (related to a contaminant in L-tryptophan-containing products used as sedatives during the late 1980s) share several clinical features, including constitutional symptoms, peripheral eosinophilia, hyperpigmentation and a sclerodermoid appearance[17], in addition to this mucinous papular eruption. Usually 1–5 months after the onset of the illness, white or skin-colored papules (1–5 mm in diameter) appeared, primarily on the limbs. The lesions resolved slowly after exposure to the toxic substance ceased.

Localized lichen myxedematosus and HCV infection. An association of lichen myxedematosus with chronic hepatitis due to HCV infection has been reported[18], especially from Japan[19], but this relationship needs to be confirmed by more extensive studies.

Atypical forms of lichen myxedematosus. Occasional patients with lichen myxedematosus have atypical features or features intermediate between scleromyxedema and localized lichen myxedematosus[4]. This group includes patients with scleromyxedema who lack a monoclonal gammopathy as well as individuals with localized forms of lichen myxedematosus who also have a monoclonal gammopathy and/or systemic symptoms. One possible explanation for the former group is performance of just a serum protein electrophoresis (SPEP), rather than a SPEP plus an immunofixation electrophoresis of serum and urine; the latter is a more sensitive assay.

Pathology

In the localized forms of lichen myxedematosus, the histologic changes are less characteristic than in scleromyxedema. Mucin accumulates in the upper and mid reticular dermis and fibroblast proliferation is variable; fibrosis is not marked and may even be absent. In acral persistent papular mucinosis, mucin accumulates focally in the upper reticular dermis (sparing a subepidermal zone) and fibroblasts are not increased in number. In cutaneous mucinosis of infancy, the mucin may be so superficial as to look as if it were "enclosed" by epidermis[7].

Differential diagnosis

Histologic examination of the skin helps to distinguish localized variants of lichen myxedematosus from several papular eruptions that can have a similar appearance, such as granuloma annulare, lichen amyloidosus, lichen planus and other lichenoid eruptions, papular elastorrhexis and eruptive collagenomas. It is also important to differentiate these entities from scleromyxedema and the cutaneous mucinosis that can occur in the setting of autoimmune connective tissue diseases (see below).

Treatment

Localized lichen myxedematosus does not require therapy, and a wait-and-see approach is recommended. Topical application of corticosteroids, pimecrolimus or tacrolimus may be of some benefit[12]. One patient with associated HIV infection had a complete remission after treatment with oral isotretinoin. However, spontaneous resolution may occur[20], even in the setting of HIV infection[16].

Self-healing cutaneous mucinosis

Although previously considered a subtype of localized lichen myxedematosus, self-healing cutaneous mucinosis is best regarded as a distinct rare form of primary dermal mucinosis. It was initially described in children, with ages of reported patients ranging from 1 to 15 years[21]. However, the same disorder was subsequently observed in a few adults, but in the authors' opinion, some of the adult patients were actually examples of localized lichen myxedematosus with spontaneous resolution[22].

Self-healing cutaneous mucinosis is characterized by the following clinical presentations: (1) an acute eruption of multiple papules, sometimes coalescing into linear infiltrated plaques, on the face, neck, scalp, abdomen and thighs; and (2) mucinous subcutaneous nodules in periarticular areas and on the face, with periorbital swelling. In addition, systemic symptoms (e.g. fever, arthralgias and muscle tenderness) may accompany the cutaneous lesions, but paraproteinemia, bone marrow plasmacytosis and thyroid dysfunction are not observed. Spontaneous resolution over a period of a few weeks to several (i.e. 2 to 8) months is characteristic, hence the name. Histologically, papular lesions show dermal mucin deposition with mild inflammation and a small increase in the number of fibroblasts, whereas nodules have deep mucinous deposits associated with bands of fibrosis and a prominent proliferation of fibroblasts[21].

Scleredema

Synonyms: ■ Scleredema adultorum of Buschke ■ Scleredema diabeticorum

Introduction

Scleredema is a symmetrical diffuse induration of the upper part of the body due to a thickened dermis and deposition of mucin.

History

Although Buschke has been credited with first describing scleredema, the original description dates back to Pitford in 1876. A relationship with diabetes mellitus was only established in 1970.

Epidemiology and pathogenesis

Scleredema is an unusual disease that affects all races. Diabetes mellitus is considered to be a pathogenetic factor. The form that is associated with diabetes is more prevalent in men, while other forms are seen more commonly in women. Irreversible glycosylation of collagen and resistance to degradation by collagenase may lead to an accumulation of collagen. Alternatively, excess stimulation by insulin, microvascular damage and hypoxia may increase the synthesis of collagen and mucin. Streptococcal hypersensitivity (type I), injury to lymphatics, and paraproteinemia (type II) may also play a role.

Clinical features

Classically, there are three types of scleredema, although a simpler division into those with and those without diabetes has been suggested[23]. The *first type* affects primarily middle-aged women, but also children. It is preceded by fever, malaise and an infection (usually streptococcal) of the upper or lower respiratory tract. The skin of the cervicofacial region suddenly hardens with extension to the trunk and proximal upper limbs. The face is expressionless and opening of the mouth and swallowing are difficult because of the involvement of the tongue and pharynx. This type usually resolves in a few months.

The *second type* shares the same clinical features as the first but has a more subtle onset, without a preceding illness; it persists for years. This type is more frequently associated with a monoclonal gammopathy[23].

Fig. 46.8 Scleredema in association with diabetes mellitus. Diffuse induration of the upper part of the body with overlying erythema.

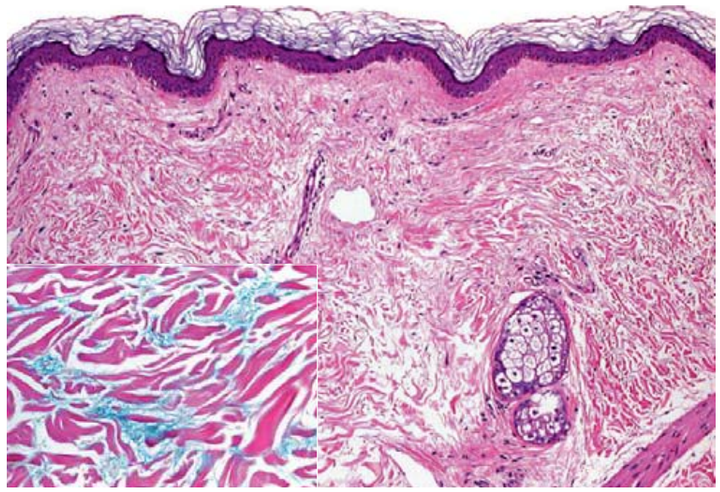

Fig. 46.9 Histopathology of scleredema. Slightly separated collagen bundles and normal dermal cellularity. Insert: Mucin deposits between collagen bundles. *Courtesy, Lorenzo Cerroni, MD.*

The *third type* occurs primarily in obese middle-aged men with insulin-dependent diabetes *(scleredema diabeticorum)*. The onset is subtle and the involvement persistent. Erythema and induration of the posterior neck and the back are commonly observed (Fig. 46.8), as is a *peau d'orange* appearance of the skin. In those patients who also have cheiroarthropathy, the skin of the distal extremities may appear waxy (presumably due to increased amounts of glycosylated collagen).

Unusual cases with limited site involvement, e.g. periorbital skin, have also been reported[24]. Systemic manifestations (in all three forms) include serositis, dysarthria, dysphagia, myositis, parotitis, and ocular and cardiac abnormalities (e.g. ophthalmoplegia, congestive heart failure). Reported associations include hyperparathyroidism, rheumatoid arthritis, Sjögren's syndrome, malignant insulinoma, multiple myeloma, gall bladder carcinoma, carcinoid[25] and HIV infection[16]. Except for limitation of movement, scleredema usually causes little morbidity. Type 1 may clear in 6 months to 2 years, whereas the other types last longer. Type 3 scleredema has even proved fatal when there was internal involvement.

Pathology

The principal alteration in scleredema is the thickening of the reticular dermis, with large collagen bundles separated from one another by clear spaces filled with mucin, resulting in fenestration of the dermis (Fig. 46.9). There is no increase in the number of fibroblasts, but the elastic fibers are reduced in number. At times, the mucin deposition can be so slight that multiple biopsies or staining of unfixed frozen sections are required to detect it. There is often a sparse perivascular lymphocytic infiltrate. Direct immunofluorescence is usually negative, but deposits of IgG and C3 have been found at the dermal–epidermal junction. Mucin also accumulates within skeletal muscle and the heart.

Differential diagnosis

Scleredema may be confused with scleroderma, but the absence of Raynaud's phenomenon and cuticular and mat telangiectasias points to scleredema. Patients with scleromyxedema also have firm papules (often in a linear array) in addition to dermal induration as well as a proliferation of fibroblasts histologically. The other types of cutaneous mucinoses are usually distinguished on the basis of clinical findings. Additional entities in the sclerodermoid differential diagnosis should be excluded (see Ch. 43). Occasionally, because of associated erythema, patients with diabetes-associated scleredema are sometimes misdiagnosed as having cellulitis (usually by non-dermatologists).

Treatment

Therapy is unnecessary for scleredema associated with streptococcal infections because it is self-limited. Regression of scleredema associated with diabetes or monoclonal gammopathy is uncommon and no specific treatment is available. Unfortunately, control of the hyperglycemia does not have any influence on the skin. Based upon case series and case reports, PUVA, UVA1, narrowband UVB, pulse therapy with cyclophosphamide plus oral corticosteroids, cyclosporine, factor XIII infusion, IVIg and electron beam therapy have all been reported to be of benefit[26,27]. Systemic and intralesional corticosteroids, intralesional hyaluronidase, methotrexate, antibiotics and penicillamine have not proved helpful. Because several of these therapies have been used for scleromyxedema, they were tried in patients with gammopathy-associated scleredema, with mixed results. Aggressive therapies, however, should be limited to individuals with disabling disease or systemic manifestations.

Mucinoses associated with altered thyroid function

Localized (pretibial) myxedema

Definition

Localized or pretibial myxedema is characterized by cutaneous induration of the shins due to mucin deposition. It is often associated with hyperthyroidism (most commonly due to Graves disease), but may appear following treatment of the thyroid disease.

Epidemiology and pathogenesis

Graves disease is seven times more common in women than in men and its onset is usually during the third or fourth decade. Pretibial myxedema is one of the signs of Graves disease, along with goiter, exophthalmus, thyroid acropachy, and thyroid-stimulating immunoglobulins that recognize the thyroid-stimulating hormone (TSH) receptor. Overall, it is found in 1–5% of patients with Graves disease, but in up to 25% of those patients with exophthalmus[28]. It can also appear in the setting of hypothyroidism following the treatment of Graves disease. Rarely, localized myxedema occurs in Hashimoto's thyroiditis without thyrotoxicosis, and even in euthyroid patients.

A serum factor (unrelated to thyroid-stimulating immunoglobulins) may incite fibroblasts to produce mucin. Fibroblasts from the dermis of the lower extremities have been found to be more sensitive to such a factor than are fibroblasts from other areas of the body. An insulin-like growth factor, trauma, and lymphatic obstruction due to mucin may also play a role[29].

Clinical features

Localized myxedema presents as erythematous to skin-colored, sometimes purple–brown or yellowish, waxy indurated nodules or plaques; they characteristically have a *peau d'orange* appearance[28] (Fig. 46.10). Usually, the lesions are located on the anterolateral aspect of the lower legs or feet. Localized myxedema can also present as a diffuse non-pitting edema of the shins or feet that evolves into elephantiasis. Even more rarely, localized myxedema affects the face, shoulders, upper extremities, lower abdomen, scars or donor graft sites. Large plaques are often painful and pruritic. When present, hypertrichosis and hyperhidrosis are confined to pretibial myxedematous skin.

Apart from appearance, associated morbidity is usually minimal. Entrapment of peroneal nerves by mucinous connective tissue may cause foot drop or faulty dorsiflexion.

Fig. 46.10 Pretibial myxedema. Purple–brown plaques on the shins of a patient with Graves disease. A *peau d'orange* appearance is present.

Pathology
Large quantities of mucin are deposited within the reticular dermis, causing collagen bundles to separate and the dermis to thicken[7]. A grenz zone of normal collagen is also observed. A perivascular and periadnexal lymphocytic infiltrate with mast cells is seen, as well as large stellate fibroblasts. Elastic fibers are reduced in number. There is often hyperkeratosis in addition to papillomatosis and hyperplasia of the epidermis.

Differential diagnosis
In addition to lichen simplex chronicus and hypertrophic lichen planus, pretibial myxedema should be distinguished from lymphedema, lipedema and obesity-associated lymphedematous mucinosis. In the latter disorder, semi-translucent papules, plaques with woody induration and occasionally vesicles develop on the shins of euthyroid, morbidly obese individuals with significant lower extremity edema. Histologically, in addition to epidermal atrophy (with effacement of the rete ridge pattern), vertically oriented capillaries and deposits of hemosiderin, mucin deposition is present within the superficial papillary dermis and around vessels[29].

Treatment
Corticosteroids, either applied under occlusive dressings or delivered by intralesional injection, may lead to improvement and provide symptomatic relief, especially if there is associated pruritus and superimposed dermatitis. Usually, skin grafting is followed by relapses. Plasmapheresis, gradient pneumatic compression, IVIg and octreotide (synthetic eight-amino acid peptide with somatostatin-like properties including inhibition of growth hormone and insulin secretion), with or without surgical shave removal, have been of some benefit[30]. Therapy for the associated hyperthyroidism does not improve the cutaneous lesions and, often, localized myxedema develops after treatment has been instituted. Localized myxedema may clear spontaneously (after an average of 3.5 years).

Generalized myxedema

Definition
Generalized myxedema is a manifestation of severe hypothyroidism in which mucin is deposited in the dermis, leading to waxiness of the skin.

Pathogenesis
Generalized myxedema is due to a quantitative or functional deficiency of thyroxine. Impaired degradation, rather than increased synthesis, of mucin has been suggested.

Fig. 46.11 Generalized myxedema in an adult with hypothyroidism. The face is puffy with a dull expression and the hair is dry.

Clinical features
Hypothyroidism may be congenital (with sequelae formerly referred to as cretinism) or of juvenile or adult onset.

Congenital hypothyroidism affects 1 in 5000 neonates and may cause a distinctive syndrome of dwarfism, mental retardation, and systemic and cutaneous findings. Somnolence, constipation, poor feeding, low muscle tone, persistence of jaundice, and respiratory distress all suggest the diagnosis. However, more than a third of infants have no symptoms. Periorbital tissues and the tongue, lips, hands and genitals are puffy. The skin is dry, cold and pale. Nails and hair are dry and brittle, and there can be patchy alopecia. The presence of a clavicular pad is diagnostic.

Juvenile hypothyroidism develops in a previously euthyroid child. Clinical features include short stature, abnormal physical and mental development, retardation of sexual maturity, and poor performance at school. Hypertrichosis may develop on the shoulders and upper back.

Adult hypothyroidism is the most common form of the disease. It is seen primarily in women 40–60 years of age, often as a result of autoimmune disease (usually Hashimoto's thyroiditis), therapy of hyperthyroidism (usually Graves disease) or, rarely, pituitary or hypothalamic failure. Rarely, the ingestion of large quantities of foodstuffs that contain inhibitors of iodine uptake by the thyroid gland, e.g. raw bok choy, can lead to myxedema.

The initial symptoms are subtle and include mental and physical sluggishness, weight gain, constipation, leg cramps, loss of appetite, and cold intolerance. The face has a dull expression. The eyelids, lips, tongue and hands are puffy, the nose is broad (Fig. 46.11), and the speech becomes hoarse and slurred. The skin is pale, cool, waxy and dry; an absence of sweating can lead to acquired ichthyosis or eczema craquelé. A yellowish discoloration of the palms and soles due to carotenemia may appear. Hair and nails are dry and brittle, and a diffuse non-scarring alopecia is common; alopecia of the lateral third of the eyebrows can also be seen. Purpura involving the extremities, blue telangiectatic fingertips, delayed wound healing, and xanthomas may be seen. Systemic manifestations include cardiomegaly, megacolon or bowel obstruction, psychiatric symptoms mimicking Alzheimer's disease, serositis, carpal tunnel syndrome, and seventh nerve paralysis[29].

Pathology
Mucin deposits, mainly perivascular and perifollicular, splay collagen bundles and may extend into the subcutaneous fat and nerves. Fibroblasts are not increased in number, but elastic fibers are reduced. Mucin deposits in the brain probably cause the psychiatric symptoms.

Diagnosis and differential diagnosis
The diagnosis is suspected clinically. Low levels of circulating free T_4 confirm the diagnosis. The serum TSH level is high in primary hypothyroidism and low in secondary hypothyroidism. Myxedema does not seem to occur in secondary hypothyroidism.

Treatment
Early treatment is crucial for proper mental development of neonates with hypothyroidism, but it is also critical for the juvenile and adult forms. Measurement of serum levels of T_4 and/or TSH is performed between 2 and 4 days of age in newborn screening panels, and

treatment should be initiated within the first 2 weeks of life. Usually, symptoms subside with thyroxine administration and recur if it is discontinued. Even areas of hair loss regrow with proper treatment. If untreated, patients can die as a result of "myxedema coma".

Reticular erythematous mucinosis

Synonyms: ■ Plaque-like cutaneous mucinosis ■ Reticular erythematous mucinosis syndrome ■ Midline mucinosis

Introduction and definition

Reticular erythematous mucinosis (REM) is a photoaggravated disorder in which persistent, erythematous papules or plaques develop in the midline of the back or chest. The papules often have a reticular or net-like configuration. This disorder has some overlap with lupus erythematosus (LE) tumidus.

History

Steigleder and colleagues coined the term "reticular erythematous mucinosis" in 1974. However, the initial description of similar cases appeared in 1960, when Perry and colleagues described three patients with plaque-like cutaneous mucinosis. Some authors regard these two entities as identical, while others view them as being on a continuum[31].

Epidemiology and pathogenesis

REM is a rare disorder that occurs most often in middle-aged women, although men and children are not spared. It is seen worldwide, and sunlight may be a causal or promoting factor. Familial cases, suggesting a genetic predisposition, have been reported[32] . Within endothelial cells and pericytes of lesional skin, tubuloreticular inclusions have been detected. Although these inclusions occur in viral infections, they can also be produced by high levels of interferon and are also found within endothelial cells in LE. Lastly, the fibroblasts of REM patients exhibit an abnormal overstimulation induced by exogenous IL-1.

Clinical features

Plaque-like cutaneous mucinosis and REM are probably different clinical presentations of the same rare syndrome. On the mid back or chest, pink to red macules and papules merge into reticulated and annular patterns (Fig. 46.12) or plaque-like lesions. They may be slightly pruritic and sometimes lesions spread to the abdomen. Sun exposure usually worsens the eruption, but it has occasionally been reported to be beneficial. Provocative phototests (UVA and/or UVB) can sometimes reproduce REM lesions. In general, REM is not associated with systemic diseases or abnormal laboratory tests. However, LE, breast and colon carcinoma, diabetes, myxedema, hypothyroidism, Hashimoto's thyroiditis, thrombocytopenia, monoclonal gammopathies and HIV infection have been reported in patients with REM[16,31]. Oral contraceptives, menses, pregnancy, heat, X-ray therapy and perspiration may promote or exacerbate REM.

Fig. 46.12 Reticular erythematous mucinosis. Grouped pink papules on the central chest with no surface changes; there is a subtle annular and reticulated configuration. Note the significant tan.

Pathology

The epidermis is normal. Interstitial deposits of small amounts of mucin are seen in the upper dermis, along with a perivascular and, at times, perifollicular T-cell infiltrate[7]. Vascular dilation is present. Usually, direct immunofluorescence is negative, but, rarely, granular deposits of IgM, IgA and C3 have been seen at the dermal–epidermal junction[31].

Differential diagnosis

In biopsy specimens of discoid lesions of LE, there is involvement of the epidermis and deposits of IgG and C3 are found at the dermal–epidermal junction, and in lymphocytic infiltrate of Jessner, there is minimal, if any, dermal mucin. LE tumidus can be impossible to distinguish microscopically from REM, and some authors group REM with LE tumidus. Seborrheic dermatitis and tinea versicolor may involve the central chest, but they have associated scale and can be diagnosed clinically, as can confluent and reticulated papillomatosis.

Treatment

Antimalarials (e.g. hydroxychloroquine) are usually effective in clearing the lesions within 4–8 weeks. Broad-spectrum sunscreens should also be used. Results from other treatments such as topical and systemic corticosteroids, topical calcineurin inhibitors, oral antihistamines, tetracycline, cyclosporine, UVB irradiation and pulsed dye laser are quite variable. Despite the potential for an exacerbation, successful results with UVA1 irradiation have been reported[33]. The lesions may clear spontaneously, even after 15 years.

Papulonodular mucinosis associated with autoimmune connective tissue diseases

Synonyms (when associated with LE): ■ Cutaneous lupus mucinosis ■ Papulonodular mucinosis in (systemic) lupus erythematosus ■ Papular and nodular mucinosis of Gold

Papules, nodules and plaques secondary to mucin deposition may accompany or even antedate an autoimmune connective tissue disease, most commonly LE and, rarely, dermatomyositis or scleroderma. Cutaneous lupus mucinosis occurs in 1.5% of patients with LE[34]. Only in Japan has a male predominance been observed. The lesions present as asymptomatic skin-colored, at times erythematous, 0.5–2 cm papules and nodules (Fig. 46.13); rarely will they merge into large plaques. Tangential illumination can be used to enhance detection of the lesions. A central depression and pigmentation may be additional features. The back, V of the chest, and the upper extremities are the most common sites of involvement. In only a few reported patients was there a flare of the papulonodules after sun exposure.

Fig. 46.13 Lupus cutaneous mucinosis. Skin-colored papules and nodules leading to a "lumpy" appearance of the chest.

Cutaneous lupus mucinosis can antedate LE or begin concurrently. The clinical course may correlate, in some patients, with underlying disease activity. Approximately 75% of patients with LE who develop papular and nodular mucinosis have systemic involvement, primarily renal and articular. The minority have only skin involvement, usually discoid or subacute cutaneous LE lesions.

Histologically, mucin abounds in the upper and mid dermis but may involve the subcutaneous fat as well. Sometimes, it is accompanied by a slight perivascular lymphocytic infiltrate. The epidermal changes of LE are absent, but linear or granular deposits of immunoglobulin and/or C3 are detected at the dermal–epidermal junction.

Cutaneous lesions of dermatomyositis often have dermal mucin histologically; rarely, patients develop erythematous nodules and plaques due to mucin deposition. The latter appear primarily on the trunk[35] and usually follow the myositis. Papular and nodular mucinosis can also occur in association with scleroderma, both systemic and cutaneous forms[36].

Treatment

Therapies for papular and nodular mucinosis are similar to those used for LE and dermatomyositis, i.e. sunscreens, topical corticosteroids and oral antimalarials. For unresponsive cases, systemic corticosteroids can be prescribed. Intralesional corticosteroids may prove useful for reducing the size of large nodules and plaques.

Cutaneous focal mucinosis

Cutaneous focal mucinosis presents as an asymptomatic skin-colored papule or nodule, less than 1 cm in diameter. The lesion can occur anywhere on the body or in the oral cavity. Cutaneous focal mucinosis favors adults and only rarely has it been linked to thyroid disorders (without myxedema), REM or scleromyxedema[37]. The diagnosis is based upon histologic findings.

Histologically, mucin is dispersed throughout the upper and mid dermis, sparing the subcutaneous fat. Cleft-like spaces, but no cysts, are seen. Spindle-shaped or stellate, vimentin-positive fibroblasts are present[38]. There is also a minor population of dermal dendrocytes that are partially factor XIIIa-positive and partially CD34-positive. The elastic and reticulum fibers are absent, but capillaries are normal in number.

Cutaneous focal mucinosis results from a "muciparous" reaction of the connective tissue to nonspecific stimuli and should be distinguished from a digital mucous cyst as well as an angiomyxoma, which represents a true neoplasm. Cutaneous focal mucinosis can be surgically excised, and relapses are uncommon.

Digital mucous cyst (myxoid cyst) is discussed in Chapter 110.

Miscellaneous mucinoses

There are other degenerative–inflammatory mucinoses that are not easily assigned to any of the entities previously described.

Neuropathia mucinosa cutanea was described only once, in a young man who had livedo reticularis on his legs and hyperesthesia. Hypertrophic (onion-like) intradermal nerves were encased by mucin[1].

Atypical tuberous myxedema (Jadassohn–Dosseker) probably represents a pure nodular variant of lichen myxedematosus[1].

Perifollicular mucinosis and **eccrine mucinosis**, which have been described in HIV-infected patients, appear to basically represent a histologic epiphenomenon (secondary mucinosis) that reflects a "muciparous" reactive tendency in HIV-infected individuals. This tendency manifests itself not only in the skin (see above), but also in the bone marrow[16].

Familial forms of "papular mucinosis" have also been described, but whether they represent a distinct entity or a familial form of localized lichen myxedematosus[39] is uncertain.

Secondary dermal mucinoses are outlined in Table 46.3[40].

Primary Follicular Mucinoses

Mucin accumulates within the follicular epithelium in two distinctive primary disorders: Pinkus' follicular mucinosis and urticaria-like follicular mucinosis. Otherwise, follicular mucinosis is considered a histologic epiphenomenon (i.e. secondary mucinosis), most often associated with cutaneous T-cell lymphoma (in particular mycosis fungoides and Sézary syndrome) or other skin diseases (e.g. atopic dermatitis; see Table 46.3).

Follicular mucinosis

Synonyms: ■ Alopecia mucinosa ■ Mucinosis follicularis ■ Pinkus' follicular mucinosis – benign primary form

History, epidemiology and pathogenesis

This uncommon inflammatory disorder, described in 1957 by Pinkus, has a predilection for children and for adults in the third and fourth decades of life. It is far from clear why dermal-type mucin is deposited selectively within an epithelial structure. Although follicular keratinocytes have been considered to be the source of the mucin, an etiologic role for cell-mediated immune mechanisms has been proposed[41], including a reaction to persistent antigens such as *Staphylococcus aureus*.

Clinical features

Primary follicular mucinosis is an idiopathic benign form of the disease, apparently not linked to lymphoma[42]. Clinically, it presents as an acute or subacute eruption in children and young adults and is characterized by one or several pink plaques (that sometimes have associated scale) or plaques composed of grouped follicular papules. Lesions are limited to the face (Fig. 46.14A) and scalp and are associated with alopecia. Papulonodules (Fig. 46.14B), annular plaques, folliculitis, follicular spines and acneiform eruptions have also been described[43]. A second type of follicular mucinosis, characterized by: (1) a more generalized distribution (extremities, trunk and face; Fig. 46.14C); (2) larger and more numerous plaques; (3) a chronic clinical course; and (4) occurrence in a slightly older age group[41], is probably best regarded as a secondary follicular mucinosis associated with atopic dermatitis or cutaneous T-cell lymphoma, rather than a primary condition.

Pathology

Mucin accumulates within the follicular epithelium and sebaceous glands, causing keratinocytes to disconnect (Fig. 46.14D). In more advanced lesions, the follicles are converted into cystic spaces containing mucin, inflammatory cells and altered keratinocytes. A perifollicular infiltrate of lymphocytes, histiocytes and eosinophils is seen[7].

Differential diagnosis

The differentiation between primary follicular mucinosis and mycosis fungoides-associated follicular mucinosis is very difficult[7], and there is no single reliable criterion. Although the existence of a primary form of follicular mucinosis has been questioned by some authors (who consider it an "indolent" localized form of cutaneous T-cell lymphoma[41]), features in favor of a primary form are the young age of the patient, a solitary plaque or limited number of lesions in the head and neck region, spontaneous resolution, and the absence histologically of epidermotropism and atypical lymphocytes. Detection of clonal T-cell gene rearrangements does not seem to help differentiate the two types[41].

Treatment

There is no specific treatment. A wait-and-see approach is recommended for primary follicular mucinosis as many cases resolve spontaneously within 2–24 months. Based upon case series and case reports, topical, intralesional and systemic corticosteroids, PUVA, dapsone, antimalarials, indomethacin, minocycline, oral isotretinoin, interferon-α-2b, orthovoltage irradiation, and UVA1 phototherapy[44] have been reported to be beneficial. For secondary forms, treatment of the underlying disease is indicated. Longitudinal evaluation and assessment for cutaneous T-cell lymphoma is recommended for patients with presumed primary follicular mucinosis that is persistent or becomes more extensive.

Urticaria-like follicular mucinosis

Urticaria-like follicular mucinosis is a very rare disorder that occurs primarily in middle-aged men. Pruritic urticarial papules or plaques appear on the head and neck within an erythematous "seborrheic" background. As lesions resolve, red macules persist for a few weeks. Hair-bearing regions may be involved, but neither follicular plugging nor alopecia is seen. Urticaria-like follicular mucinosis waxes and wanes irregularly over a period that can vary from a few months to 15 years. There are no associated systemic diseases. Response to natural

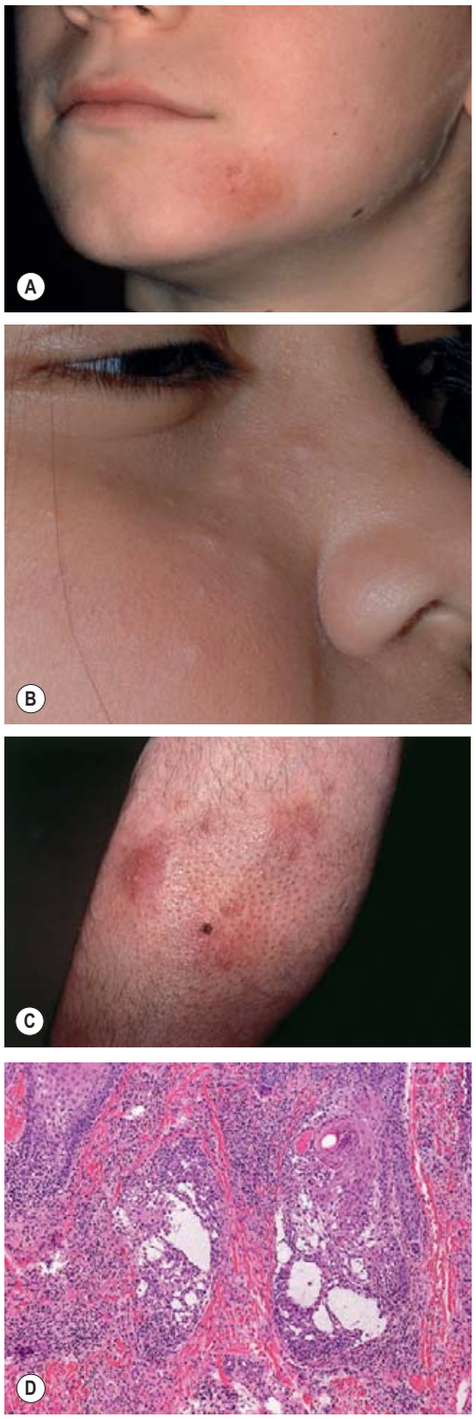

Fig. 46.14 Follicular mucinosis. A Pink plaque containing multiple follicular papules in a young boy. **B** Skin-colored papules on the cheek of a child. **C** Grouped follicular papules on the leg of an older adult in association with erythematous plaques. Note the associated alopecia. The hemorrhagic crust is the site of a previous biopsy. **D** Histology of follicular mucinosis (patient in A). sunlight has been inconsistent, but it has been beneficial in a small number of cases.

As in primary follicular mucinosis, mucin-filled cystic spaces occupy hair follicles. In the upper dermis, lymphocytes and eosinophils are seen around blood vessels and hair follicles. In only a single patient to date were vascular C3 deposits seen by direct immunofluorescence. The prognosis is good, and, based upon a limited number of case reports, antimalarials and dapsone were reportedly beneficial[45].

PRIMARY HAMARTOMATOUS–NEOPLASTIC MUCINOSES

Although stromal mucin deposition may be found in a variety of cutaneous tumors as an additional finding (e.g. basal cell carcinomas and neurofibromas), only in mucinous nevus and (angio)myxoma is the mucin deposition a distinctive feature.

Mucinous Nevus

A mucinous nevus (nevus mucinosus) is a benign hamartoma that can be congenital or acquired. It consists of a plaque that usually has a unilateral linear nevoid pattern[46]. Histologically, a diffuse deposit of mucin is seen in the upper dermis, and collagen and elastic fibers are absent within the mucinous area. The epidermis can be normal or it may be acanthotic with elongation of the rete ridges and hyperkeratosis, as in an epidermal nevus. The latter set of findings points to a combined hamartoma, in which features of an epidermal nevus are associated with those of a connective nevus of the proteoglycan type. The cellular component of a mucinous nevus consists of CD34-positive fibroblasts and scarce factor XIIIa-positive dendritic cells[47].

The term "familial multiple acral mucinous fibrokeratomas" has been used to describe a patient with multiple, hereditary keratotic and mucinous lesions of the hands[48].

(Angio)myxoma

A cutaneous myxoma is an acquired benign neoplasm that is usually nodular and measures 1–5 cm in diameter. It favors the trunk, head and neck, and genital region; rarely, cutaneous myxomas have an acral location[49]. These tumors can be solitary, without any systemic abnormalities, or multiple. When multiple, they may be a manifestation of Carney complex (cutaneous myxomas, cardiac myxomas, numerous lentigines, multiple blue nevi, endocrine overactivity).

Histologically, a cutaneous myxoma is a lobulated, well-defined lesion characterized by a mucinous matrix within the dermis and the subcutis, with variably shaped fibroblasts, mast cells, and a few collagen and reticulin fibers. Bizarre multinucleated cells and regular mitotic figures can be seen. The stromal cells are smooth muscle actin (SMA)-positive and factor XIII-negative. Myxomas must be distinguished from cutaneous focal mucinosis, a reactive lesion which is usually <1 cm and ill-defined histologically; the latter does not have an epithelial component and the mucin deposits are in the dermis but not the subcutis. This differentiation is important as myxomas are true neoplasms, although benign, which can recur after incomplete excision.

47 Amyloidosis

Richard W Groves and Martin M Black

Chapter Contents

Primary (localized) cutaneous amyloidosis *702*
Secondary cutaneous amyloidosis *705*
Systemic amyloidosis *705*

Synonyms: ■ Primary systemic amyloidosis – AL amyloidosis ■ Secondary systemic amyloidosis – AA amyloidosis

Subtypes: ■ Primary cutaneous amyloidosis – macular amyloidosis, friction amyloidosis, lichen amyloidosis (lichen amyloidosus), biphasic amyloidosis, dyschromic amyloidosis, nodular amyloidosis

Key features

- Characteristic properties of amyloid include congophilia and green birefringence under polarized light, distinctive fibrillar ultrastructure, and cross-β-pleated sheet configuration by X-ray crystallography
- The three major forms of primary cutaneous amyloidosis are:
  - macular amyloidosis: confluent or rippled hyperpigmentation, often on the upper arm and back
  - lichen amyloidosis: hyperpigmented papules, often in a rippled pattern; favors the extensor surfaces of the extremities and back
  - nodular amyloidosis: waxy skin-colored to pink nodules
- Biphasic amyloidosis has features of both macular amyloidosis and lichen amyloidosis
- The amyloid deposits in macular amyloidosis and lichen amyloidosis are keratinocyte-derived, whereas those in nodular amyloidosis are composed of immunoglobulin light chains and are often accompanied by an infiltrate of plasma cells
- Mucocutaneous lesions are seen in 30–40% of patients with primary systemic (AL) amyloidosis and include waxy papulonodules and plaques, ecchymoses, pinch purpura, and macroglossia; carpal tunnel syndrome in association with the latter is a classic presentation
- In the absence of specific mucocutaneous lesions, aspiration of abdominal fat can be performed as amyloid deposits may be detected in some patients with primary systemic amyloidosis
- Once the diagnosis of AL amyloidosis is established, evaluation for systemic involvement is indicated

INTRODUCTION

Amyloidosis is not a single disease; rather, the term is used to refer to several diseases that share the common feature of abnormal extracellular deposition of amyloid, a fibrillar proteinaceous material, within tissues[1]. Amyloidosis can therefore occur in a wide variety of clinical settings, which may be as diverse as multiple myeloma, Alzheimer's disease, familial polyneuropathies and primary cutaneous lichen amyloidosis.

Amyloid itself is not a single chemically distinct substance, and several types of amyloid have been described. However, regardless of the source, pathogenetic mechanisms or the disease process involved, amyloid material does share some common tinctorial and other physicochemical properties, e.g. the cross-β-pleated sheet configuration[2].

The two clinical settings in which dermatologists are likely to encounter amyloidoses are: (1) the more common, primary cutaneous forms of amyloidosis; and (2) the less common systemic amyloidosis with cutaneous manifestations.

History

Virchow, in 1854, introduced the term "amyloid"[3]. He believed that the substance resembled starch or cellulose because, like starch, it turned blue when stained with iodine followed by dilute sulfuric acid. In 1928, Gutmann first described a patient with clinical features of lichen amyloidosis, while Freudenthal, in 1930, introduced the term "lichen amyloidosus"[3].

Epidemiology

The precise epidemiology of systemic amyloidosis is not known, as the disease is often undiagnosed or misdiagnosed[4]. In the US, the incidence of primary systemic amyloidosis is estimated to be approximately 1275 to 3200 new cases per year[4]. Amyloidosis has been estimated to occur in ~6–15% of patients with multiple myeloma (primary systemic

CLINICAL CLASSIFICATION OF AMYLOIDOSIS
SYSTEMIC AMYLOIDOSIS
Primary systemic amyloidosis (AL >> AH amyloid protein) • Plasma cell dyscrasias (more common) • Multiple myeloma-associated
Secondary systemic amyloidosis (reactive; AA amyloid protein) • Chronic inflammation (e.g. rheumatoid arthritis) • Chronic infection (e.g. tuberculosis)
Hemodialysis-associated amyloidosis
Genetic (inherited) forms of amyloidosis (various amyloid proteins) • Familial amyloid polyneuropathy (AD) • Muckle–Wells syndrome and other cryopyrin-associated periodic syndromes (AD) • Familial Mediterranean fever (AR) • TNF receptor-associated periodic syndrome (TRAPS; AD) • Familial amyloidosis, Finnish type (AD)
ORGAN-LIMITED (LOCALIZED) AMYLOIDOSIS
Cutaneous • Primary: macular*, lichen*, biphasic*, dyschromic, nodular • Secondary: incidental finding within various skin tumors (e.g. dermatofibromas, intradermal melanocytic nevi, seborrheic keratoses, adnexal tumors, basal cell carcinomas, Bowen's disease, porokeratosis); following PUVA therapy
Endocrine • Medullary carcinoma of the thyroid, insulinoma, type 2 diabetes
Cerebral • Alzheimer's disease
*Seen in patients with Sipple syndrome.

Table 47.1 Clinical classification of amyloidosis. Familial amyloid polyneuropathy is also known as familial amyloidotic polyneuropathy. See Table 45.2 for details on several of the genetic forms of amyloidosis. AD, autosomal dominant; AR, autosomal recessive.

CHEMICAL CLASSIFICATION OF AMYLOIDOSES		
Precursor protein	**Amyloid protein**	**Clinical syndrome**
(Apo) serum AA*	AA	Secondary systemic amyloidosis, hereditary periodic fever syndromes (e.g. familial Mediterranean fever, Muckle–Wells syndrome, TRAPS; see Ch. 45)
Apolipoprotein AI	AApoAI	Familial amyloid polyneuropathy
Calcitonin	ACal	Medullary carcinoma of the thyroid
Cystatin C	ACys	Hereditary cystatin C amyloid angiopathy†
Gelsolin	Agel	Familial amyloidosis, Finnish type
Immunoglobulin heavy chain (very rare)‡	AH	Primary systemic amyloidosis
Keratin	Aker	Primary (localized) cutaneous amyloidosis
Immunoglobulin light chain	AL	Primary systemic amyloidosis (associated with plasma cell dyscrasia§ >> multiple myeloma), primary cutaneous nodular amyloidosis
Transthyretin	ATTR	Familial amyloid polyneuropathy, senile systemic amyloidosis
Aβ precursor protein (AβPP)	Aβ	Alzheimer's disease, aging
β_2-microglobulin	$A\beta_2M$	Chronic hemodialysis
Corneodesmosin	–	Hypotrichosis simplex of the scalp

*Amyloid-associated protein synthesized by the liver.
†Detection of deposits within clinically normal skin allows diagnosis prior to clinical symptoms (cerebral hemorrhage).
‡More commonly, heavy chains produce a non-amyloid type deposit termed heavy chain deposition disease.
§Monoclonal gammopathy; progression depends upon risk factors (see Ch. 119).

Table 47.2 Chemical classification of amyloidoses. Adapted from ref. 10.

amyloidosis) and in ~5–11% of patients with rheumatoid arthritis (secondary systemic amyloidosis)[5]. However, better control of the inflammatory response in rheumatoid arthritis appears to have led to a marked decline in the incidence of renal replacement therapy (i.e. dialysis or transplantation) for associated secondary systemic amyloidosis[6].

Primary cutaneous amyloidosis also has a worldwide prevalence. It is commonly observed in Southeast Asian countries, including Singapore, Taiwan and Thailand[7]. Lichen amyloidosis appears to be more common in those of Chinese descent. Macular amyloidosis is also commonly seen in Central and South American countries, especially those close to the equator[8]. In general, macular amyloidosis and lichen amyloidosis occur more frequently in individuals with skin phototypes III and IV.

Classification

Amyloidosis can be classified clinically into systemic (generalized) forms, with involvement of several organ systems, and organ-limited (localized) forms, in which deposits are limited to a single organ such as the skin (Table 47.1). In the localized forms, amyloid deposition occurs at or near the site of synthesis, while, in the systemic forms, the precursors are secreted into the circulation and amyloid is usually deposited at distant sites[9]. Amyloidosis can also be classified on the basis of the specific precursor protein (Table 47.2; see next section).

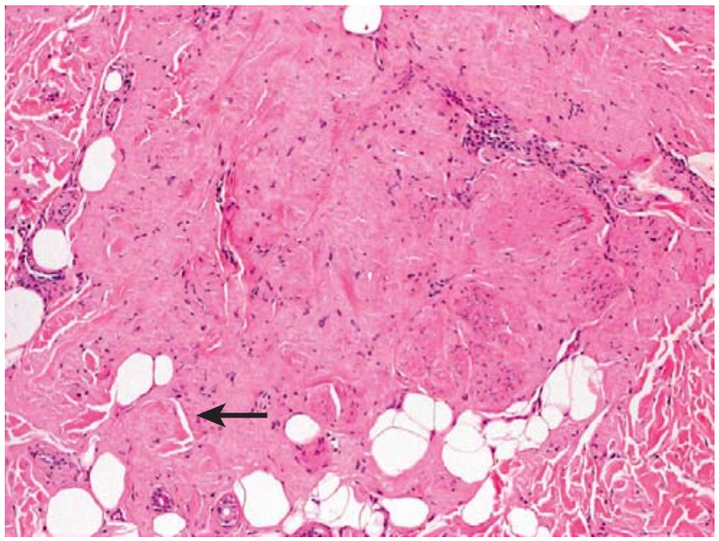

Fig. 47.1 Histologic features of amyloid deposits within the skin. In this example of nodular amyloidosis, the dermal deposits are eosinophilic, amorphous and contain fissures (arrow). *Courtesy, Lorenzo Cerroni, MD.*

HISTOLOGIC CRITERIA USED TO DEFINE AMYLOID
• Homogeneous, hyaline, eosinophilic deposits in H&E-stained sections (Fig. 47.1)
• Crystal violet metachromasia
• Positive staining with alkaline Congo red
• Apple-green birefringence under polarized light after Congo red staining; also dichroic (Fig. 47.2)
• Fibrillar structure on electron microscopy (Fig. 47.3)
• Stains brightly by ultraviolet fluorescence microscopy after Thioflavin T staining (Fig. 47.2)
• Staining with antibodies to amyloid P component
• Staining with antibodies directed against specific precursors (e.g. keratin)

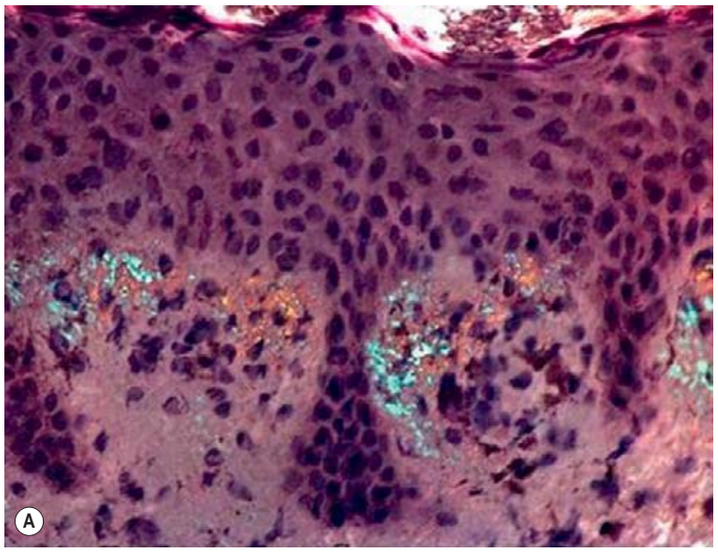
Table 47.3 Histologic criteria used to define amyloid[2].

Pathogenesis

The major component of amyloid is the fibril protein; the minor components are amyloid P component, glycosaminoglycans and apoE lipoprotein. Amyloid P is a glycoprotein derived from serum amyloid P protein (SAP) and it has a specific calcium-dependent binding affinity for amyloid. Approximately 18 distinct forms of amyloid fibril proteins and their precursors have been identified, including: AL (amyloid light chains), containing immunoglobulin light chains; AA (amyloid-associated), a protein synthesized by the liver; Aβ amyloid, found in cerebral lesions of Alzheimer's disease; and ATTR (transthyretin-associated), found in some forms of familial amyloidosis[9]. Each condition is associated with a specific precursor protein, many of which are listed in Table 47.2. The precursor proteins[10] are initially soluble proteins. They then undergo changes leading to aggregation, polymerization, fibril formation, and, finally, extracellular deposition in tissues as insoluble amyloid.

The process by which this transformation takes place is multifactorial and differs amongst the various types of amyloidoses. In primary systemic amyloidosis, substitution of amino acids in specific positions in the variable region of the immunoglobulin light chain potentially destabilizes the light chains and increases their likelihood of being converted to amyloid fibrils. Similarly, mutations in the transthyretin gene have been shown to alter significantly the stability of the transthyretin protein and increase its amyloidogenicity[2,4]. The accumulation of these relatively inert amyloid fibrils within vital organs leads to pressure atrophy and eventually interferes with the normal functioning of the organ.

The precise pathogenesis of primary cutaneous amyloidosis is not yet fully understood. Prolonged friction, genetic predisposition, Epstein-Barr virus and environmental factors have all been proposed as possible etiologic factors. The precursor protein involved has not been fully characterized; however, the amyloid of macular and lichenoid variants



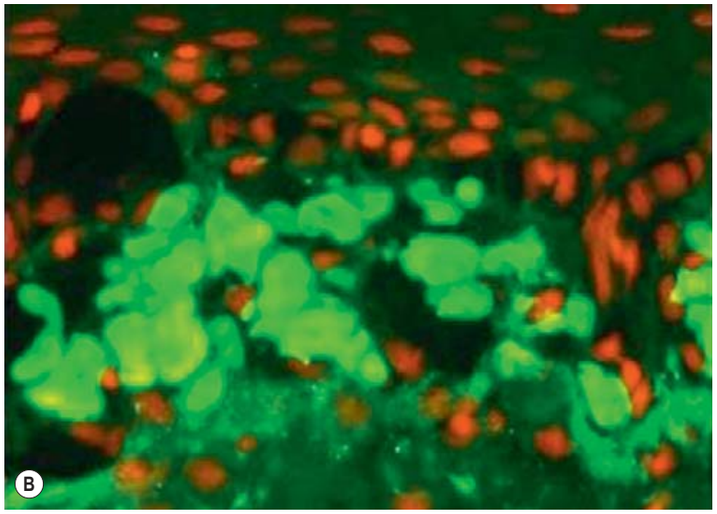


Fig. 47.2 Use of special stains to identify amyloid deposits within the papillary dermis in lichenoid amyloidosis. Fig. 47.4 Characteristic cross-β-pleated sheet arrangement of amyloid fibrils. Schematic representation of findings seen by X-ray crystallography. There is an antiparallel configuration of paired filaments, and sites of binding of the planar Congo red dye are indicated by the solid blue blocks. *Adapted from Cooper JH. Selective amyloid staining as a function of amyloid composition and structure: histochemical analysis of the alkaline Congo red, standardized toluidine blue, and iodine methods. Lab Invest. 1974;31:232–8.*

of primary cutaneous amyloidosis is thought to be keratinocyte-derived[11]. This has been supported by ultrastructural studies demonstrating transitional forms between viable keratinocytes and amyloid, as well as by positive reactions with monoclonal antibodies directed against keratins of basal keratinocytes. The fibrillar theory proposes that the tonofilaments of keratinocytes undergo filamentous degeneration and pass into the dermis, where, presumably, they are modified by histiocytes and fibroblasts into amyloid material. An alternative theory suggests that the material is produced at the epidermo-dermal interface, with precursor proteins being secreted by basal keratinocytes. This hypothesis has also been supported by both ultrastructural findings and demonstration of basement membrane antigens such as type IV collagen and laminin within amyloid deposits[12]. These cutaneous amyloid deposits stain positively with anti-human antibodies directed against IgG, IgM and IgA immunoglobulins, but this staining is thought to be the result of nonspecific absorption of the immunoglobulins rather than being an indicator of immunoglobulin as the precursor protein. Apolipoprotein E4 has also been shown to be associated with this type of cutaneous amyloid deposit and may be synthesized locally by epidermal keratinocytes[13].

In nodular amyloidosis, there is no specific staining with antikeratin antibodies. The amyloid deposits are composed of immunoglobulin light chains, suggesting plasma cell derivation akin to the nodular cutaneous lesions of primary systemic amyloidosis. Thus, its origin is very different from that of either macular or lichen amyloidosis[11,12]. However, in nodular amyloidosis, presumably there is local production of light chains, whereas in primary systemic amyloidosis, the light chains are present in the systemic circulation.

Amyloid characteristics

In H&E-stained sections, amyloid appears as amorphous, eosinophilic fissured masses (Fig. 47.1 & Table 47.3). With Congo red staining, amyloid has an orange–red color by light microscopy, and it has a characteristic green birefringence under polarized light (Fig. 47.2A). Other special stains that can be used to detect amyloid deposits include crystal violet, methyl violet, periodic acid–Schiff (PAS), Sirius red, pagoda red, Dylon stain and Thioflavin T (Fig. 47.2B)[1,11]. AA (but not AL) amyloid loses its affinity for Congo red after exposure to potassium permanganate.

By electron microscopy, amyloid appears as 7 to 10 nm wide, non-branching, non-anastomosing fibrils (Fig. 47.3). X-ray crystallography and infrared spectroscopy reveal a characteristic cross-β-pleated sheet conformation (Fig. 47.4). These findings are identical in all types of amyloid, regardless of clinical setting or chemical composition[1]. The cross-β-pleated sheet configuration of amyloid is believed to be responsible for the staining and birefringence with Congo red.

Immunohistochemical stains utilizing antibodies directed against the amyloid fibril proteins (e.g. immunoglobulin γ light chain, transthyretin, keratin, AA protein) can help to differentiate between the types of amyloid. However, these immunohistochemical stains do have limitations. For precise identification of the nature of an amyloid protein, especially AL amyloid, tandem mass spectrometry (MS/MS) can be done, and the latter can be performed on formalin-fixed, paraffin-embedded sections or subcutaneous fat aspirates[14].

PRIMARY (LOCALIZED) CUTANEOUS AMYLOIDOSIS

Primary cutaneous amyloidosis is associated with the deposition of amyloid in apparently normal skin without associated deposits in internal organs (see Table 47.1). The most common variants are macular amyloidosis, lichen amyloidosis and biphasic amyloidosis.

Clinical features

Although primary cutaneous amyloidosis is classically divided into macular (macular amyloidosis), papular (lichen amyloidosis) and nodular (nodular amyloidosis) forms, the first two entities actually represent the ends of a clinical spectrum. In some patients and even some lesions, both forms can be present, and the term "biphasic amyloidosis" is used to describe this situation[15,16].

Macular amyloidosis is often pruritic but it may be asymptomatic. The lesions of macular amyloidosis are hyperpigmented, either in a confluent manner or a characteristic rippled pattern. The latter can be best appreciated by stretching the skin. The most common site of involvement is the upper back, especially over the scapular area, followed by the extensor surfaces of the extremities. Extensive involvement can be seen in an occasional patient. Macular amyloidosis usually presents in early adulthood, and women may be affected more often than men[1,17]. In biphasic amyloidosis, fine papular lesions are superimposed upon a background of hyperpigmentation (Fig. 47.5A).

The term "friction amyloidosis" has been used to describe a subgroup of patients in whom local friction from nylon brushes, towels and other rough materials contributes to the production of macular and lichenoid lesions. There is also significant clinical overlap between macular amyloidosis and the pigmented type of notalgia paresthetica, where pruritus of the scapular areas leads to rubbing and scratching[11] (see Ch. 7).

Lichen amyloidosis is the most common form of primary cutaneous amyloidosis and usually presents as persistent, pruritic plaques on the shins or other extensor surfaces of the extremities, e.g. the anterior thighs or forearms (Fig. 47.6)[10,15]. Initial lesions are discrete, firm, scaly, skin-colored or hyperpigmented papules, which later coalesce into plaques that often have a rippled or ridged pattern. At the onset, lesions are usually unilateral, but a bilateral, symmetrical distribution can develop[11,15].

Primary cutaneous amyloidosis manifesting as pigmentation and lichenification of the anal and sacral regions has been described as an ano-sacral variant, but these patients often have lichen amyloidosis or biphasic amyloidosis elsewhere[15,16]. Bullous lesions have also been described in the setting of lichen amyloidosis, but they are more commonly associated with systemic amyloidosis. Dyschromic amyloidosis is a rare variant in which a guttate leukoderma is superimposed upon a background of hyperpigmentation and admixed with characteristic lesions of macular and lichenoid amyloidosis (see Ch. 67).

Macular and/or lichenoid amyloidosis has also been described in association with autoimmune connective tissue disorders (e.g. scleroderma [Fig. 47.7], systemic lupus erythematosus, dermatomyositis) and primary biliary cirrhosis[1]. In one series of patients with scleroderma, 9% had hyperpigmentation of the upper back in association with dermal deposits that stained positively with antikeratin antibodies[18]. Lastly, one patient was observed to have sparing of lichen amyloidosis lesions in areas with higher cutaneous temperatures (such as along the course of large superficial veins), suggesting that amyloid fibril formation may be a temperature-dependent process *in vivo*[19].

Familial forms of macular and lichenoid amyloidosis are unusual. Included in this group are families with Sipple syndrome, which is due to mutations in the *RET* oncogene (see below). In addition, several families with primary localized cutaneous amyloidosis have been

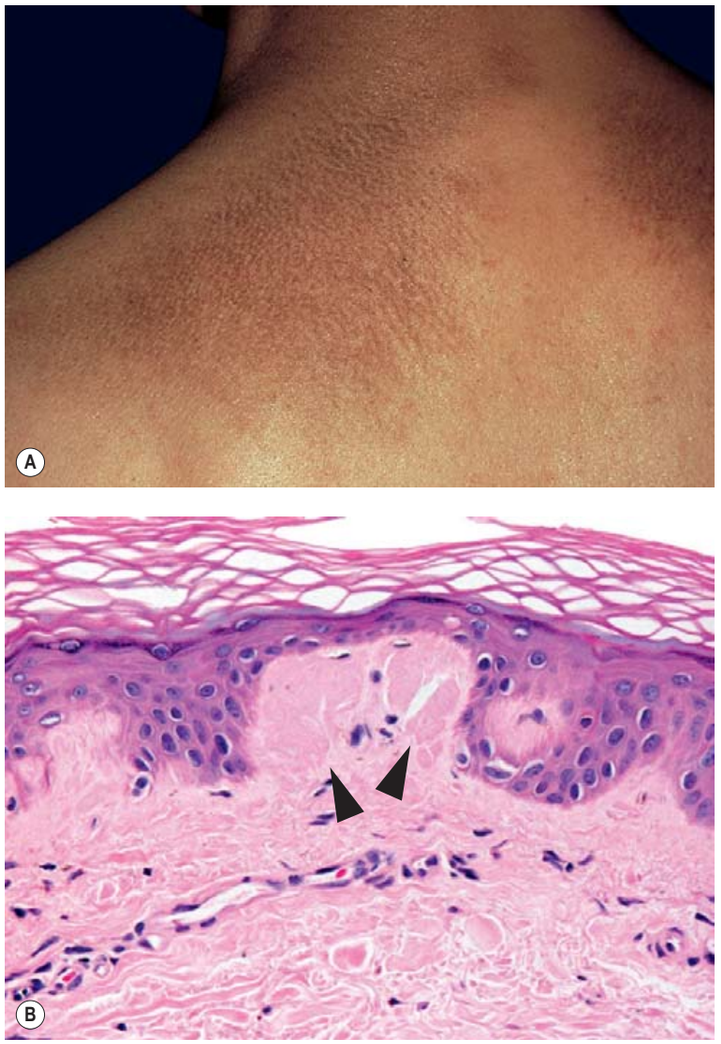

Fig. 47.5 Biphasic amyloidosis. A Characteristic rippled hyperpigmentation of macular amyloidosis (superiorly) as well as papules of lichenoid amyloidosis (inferiorly). **B** Histologically, deposits of amyloid within the dermal papillae (arrowheads) as well as melanophages within the papillary dermis; note the characteristic fissure in the amyloid deposit. These deposits may be subtle. *B, Courtesy, Lorenzo Cerroni, MD.*

Fig. 47.7 Primary cutaneous amyloidosis in a patient with systemic scleroderma. Note the numerous papules, some of which are in a linear array.

shown to have mutations in the genes that encode either oncostatin M receptor β (OSMRβ)[20] or the alpha subunit of the interleukin (IL)-31 receptor (IL-31RA)[21]. OSMRβ is a component of both the OSM type II receptor and the IL-31 receptor whose ligands are OSM and IL-31, respectively; IL-31RA combines with OSMRβ to form the IL-31 receptor[22]. Of note, IL-31 has been shown to be of importance in pruritic skin conditions (e.g. dermatitis, prurigo nodularis), and in some animal models, anti-IL-31 antibodies can alleviate itch. Primary cutaneous amyloidosis has also been reported in association with pachyonychia congenita, dyskeratosis congenita and familial palmoplantar keratoderma[1].

Nodular amyloidosis is rare, and it presents as single or multiple waxy nodules or infiltrated plaques, most commonly on the trunk or extremities (Fig. 47.8A,B). Immunoglobulin γ light chains as well as β_2-microglobulin have been demonstrated within the deposits in this type of cutaneous amyloidosis, and both are thought to be produced by plasma cells in the vicinity of the deposits (see Fig. 47.8D)[23]. In two patients, gene rearrangement studies identified a clone of amyloid-producing plasma cells in the skin of a nodular lesion while there was no evidence of a clonal plasma cell proliferation in the bone marrow of one patient[24,25]. There may be an association between Sjögren's syndrome and nodular amyloidosis of the skin or lung.

The nodular variant has been reported to progress to systemic involvement, hence long-term follow-up is necessary. However, recent observations suggest that this risk is approximately 7%, much less than the previously quoted 50%. Although 40% of patients in this long-term study had a paraproteinemia at presentation, the gammopathy remained static during the follow-up period and progression to systemic involvement was observed in only 1 of 15 patients, 23 years after the initial presentation[26]. A similar study of 16 patients with nodular amyloidosis found a near equal sex distribution, with a tendency for an acral distribution. There was one patient who subsequently died from systemic amyloidosis[27].

Pathology

In macular and lichenoid forms of amyloidosis, amyloid deposits are restricted to the upper dermis, particularly the papillary dermis (see Fig. 47.5B). In lichen amyloidosis, the deposits may expand the papillae and displace the elongated rete ridges laterally, and the overlying epidermis is often acanthotic and hyperkeratotic. Melanophages and a sparse perivascular lymphohistiocytic infiltrate can be seen in both forms. Antikeratin antibodies (such as LP34, MNF 116 and RCK 102) may be useful in identifying these two forms of primary cutaneous amyloidosis.

In contrast, in the nodular variant, the dermis, subcutis and blood vessel walls are diffusely infiltrated with amyloid (Fig. 47.8C). A perivascular infiltrate of plasma cells may also be seen (Fig. 47.8D)[26]. Immunostaining for light chain deposition can aid in the diagnosis of nodular amyloidosis.

TREATMENT OF MACULAR AND LICHENOID AMYLOIDOSIS
Potent topical corticosteroids, including under occlusion (2)
Topical calcineurin inhibitors (3)
Intralesional corticosteroids (3)
Occlusive dressings (e.g. hydrocolloid) or wraps (e.g. zinc oxide-impregnated) (3)
UVB phototherapy (2)
PUVA phototherapy (2)
Systemic retinoids (2)
Dermabrasion (2)
CO_2 laser therapy (2)
Low-dose cyclophosphamide (3)
Cyclosporine (3)

Table 47.4 Treatment of macular and lichensoid amyloidosis. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. PUVA, psoralen plus UVA; UVB, ultraviolet B.

Differential diagnosis

The diagnosis of primary cutaneous amyloidosis is based upon the morphology of the lesions and on the histologic demonstration of the cutaneous amyloid deposits (see Table 47.3).

There is significant overlap in the appearance of macular amyloidosis and notalgia paresthetica. The latter is also seen on the upper back and can have rippled hyperpigmentation. Biopsy specimens of notalgia paresthetica contain melanophages but no amyloid deposits. When macular amyloidosis is more diffuse or confluent, it has to be differentiated from postinflammatory hyperpigmentation. Other entities in the differential diagnosis may include pityriasis versicolor, atrophic lichen planus, erythema dyschromicum perstans (ashy dermatosis), and drug-induced pigmentation.

The primary differential diagnosis for lichen amyloidosis includes lichen simplex chronicus (LSC) and hypertrophic lichen planus (LP). Both of these are characterized by chronic pruritic plaques, often on the shins. Histologically, both have hyperkeratosis, acanthosis and a mild to moderate lymphohistiocytic inflammatory infiltrate but no amyloid deposits. In LSC, lichenification is often prominent, while hypertrophic LP lesions may have a violaceous hue and, on histologic examination, a lichenoid infiltrate with vacuolar degeneration. Other entities that may be considered in the differential diagnosis include papular mucinosis, pretibial myxedema, prurigo simplex/nodularis, pemphigoid nodularis, lichen ruber moniliformis, colloid milium and epidermolysis bullosa pruriginosa.

Nodular amyloidosis may resemble the cutaneous lesions of primary systemic amyloidosis and the latter should be excluded (see above). The clinical differential diagnosis also includes lymphoma cutis, cutaneous lymphoid hyperplasia (pseudolymphoma), pretibial myxedema, sarcoidosis, granuloma annulare, reticulohistiocytosis and granuloma faciale, all of which have rather distinctive histopathologic features and therefore can be easily differentiated.

Treatment

To date, none of the treatment modalities described (Table 47.4) has proven to be curative or uniformly effective in patients with macular and lichenoid amyloidosis. Treatment must be directed at breaking the itch–scratch–itch cycle usually present in these patients. Chronic friction, scratching and rubbing, for example with towels and nylon brushes, can serve as possible precipitating or aggravating factors, and patients should be advised of this. Potent topical corticosteroids are useful to some extent, especially in mild cases, and their use under occlusion or in combination with a mild keratolytic agent such as salicylic acid (particularly in lichen amyloidosis) may have added benefit. Access to the involved sites can be limited by occlusive dressings such as hydrocolloid dressings or gauze wraps impregnated with zinc oxide for weeks to months, but recurrence rates may be high. A trial of topical dimethyl sulfoxide (DMSO; 50% or 100% solution) in 25 patients has been reported to have little beneficial effect[28]. Based upon case reports, topical calcineurin inhibitors may play an adjunctive role.

A study that compared the efficacy of topical corticosteroids with either UVB phototherapy or topical PUVA phototherapy in patients

with lichen amyloidosis found the pruritus and roughness scores to be better on the sides treated with either form of phototherapy, with PUVA being marginally better in reducing pruritus[29]. Dermabrasion was shown to be beneficial in lichen amyloidosis involving the limbs: the epidermis and part of the papillary dermis along with some of the amyloid was removed, permitting re-epithelialization to occur from the adnexal structures[30]. After more than 5 years of follow-up, there was significant improvement in symptoms and appearance without recurrence. Postinflammatory hypo- and hyperpigmentation did occur but usually improved over time.

Oral retinoids such as etretinate (1 mg/kg/day) have been reported to improve pruritus and result in flattening of lesions. Acitretin (0.5 mg/kg/day) produced similar results with some clearance of the associated hyperpigmentation[31]. In a preliminary study, low-dose cyclophosphamide (50 mg daily) was reported to be effective in reducing pruritus and papules in lichen amyloidosis[11]. However, the side effects of these systemic medications (see Chs 126 & 130) must be weighed against the possible benefits.

Surgical excision, cryotherapy, electrodesiccation and CO_2 laser can be used to treat nodular amyloidosis, but local recurrences are

common[30]. Strategies for the future treatment of amyloidosis include the depletion of the ubiquitous amyloid P component via complexes with the experimental agent R-1-[6-[R-2-carboxypyrrolidin-1-yl]-6-oxohexanoyl]pyrrolidine-2-carboxylic acid (CPHPC) and immunotherapy to promote clearance of amyloid using specific antibodies[32,33].

SECONDARY CUTANEOUS AMYLOIDOSIS

Secondary cutaneous amyloidosis refers to clinically inapparent amyloid deposits that are seen histopathologically within skin tumors, including dermatofibromas, intradermal melanocytic nevi, seborrheic keratoses, pilomatricomas, trichoepitheliomas, sweat gland tumors, basal cell carcinomas, Bowen's disease and porokeratosis[1,11]. The argument has been made that deposits in this setting represent a histologic epiphenomenon without obvious clinical implications. It has also been reported following PUVA therapy.

SYSTEMIC AMYLOIDOSIS

Primary Systemic Amyloidosis

Primary systemic amyloidosis is a manifestation of an underlying plasma cell dyscrasia, although patients usually do not fulfill the criteria for multiple myeloma (e.g. hypercalcemia, osteolytic lesions; see Ch. 119). The fibrils are composed of AL protein, which consists of immunoglobulin light chains, usually λ chains (75–80%).

Clinical features

Primary systemic amyloidosis is associated with a wide spectrum of organ involvement. The presenting symptoms are often varied and nonspecific, such as fatigue, weight loss, paresthesias, dyspnea, and syncopal attacks due to orthostatic hypotension[4,34].

In the oral cavity, amyloid deposits appear as soft rubbery swellings and an infiltration of the mucosa. An associated hemorrhagic component is frequently seen. The tongue can be uniformly enlarged and firm (Fig. 47.9A), or it may have hemorrhagic papules, plaques and blisters on its surface (Fig. 47.9B); the latter may vary from translucent to yellow–brown in color. Xerostomia can result from infiltration of the salivary glands.

Following minor trauma, petechiae, purpura and ecchymoses are often observed, especially on the eyelids and neck and in the axillae and anogenital region (due to infiltration of vessel walls with amyloid; Fig. 47.10). Characteristically, periorbital purpura (the "raccoon eyes" sign) may be precipitated by coughing, the Valsalva maneuver, or proctoscopy for a rectal biopsy, as well as after pinching or rubbing the skin (pinch purpura).

Clinically evident skin involvement occurs in approximately 25% of individuals with primary systemic amyloidosis. Skin infiltration by amyloid presents as waxy, translucent or purpuric papules (Fig. 47.11A,B), nodules and plaques that resemble nodular amyloidosis. A smooth erythematous waxy infiltration can appear on the palms and volar aspect of the fingertips. Smooth, skin-colored papules, a few millimeters in diameter, may be seen on the face, neck and scalp and in the anogenital region.

Less often, diffuse cutaneous infiltration may result in an infiltrated sclerodermoid appearance and cause the scalp skin to be thrown into folds resembling cutis verticis gyrata with associated alopecia. Bullous lesions, especially hemorrhagic blisters resembling those of porphyria cutanea tarda and epidermolysis bullosa acquisita, may be the initial sign of the disease. In addition, nail dystrophy due to amyloid deposits around blood vessels and in the dermis of the nail bed can be observed. Rarely, patients also have evidence of acquired acral cutis laxa. The presence of macroglossia together with carpal tunnel syndrome is a classic presentation and should trigger an investigation for amyloidosis.

Other signs and symptoms of primary systemic amyloidosis depend upon the organs involved. Renal involvement manifests as proteinuria (albuminuria), and consequently hypoalbuminemia and edema (i.e. nephrotic syndrome). Cardiac involvement may eventually lead to a restrictive cardiomyopathy and congestive heart failure, resulting in dyspnea, hepatomegaly and bilateral lower extremity as well as presacral edema. Autonomic and sensory neuropathies are common.

Fig. 47.9 Primary systemic amyloidosis. A Macroglossia with dental impressions on the tongue. **B** Papulonodues of the tongue and external nares; some are purpuric while others are translucent with a yellowish hue. *B, Courtesy, Dennis Cooper, MD.*

Fig. 47.11 Primary systemic amyloidosis. A Numerous waxy translucent facial papules. Some have a yellow to yellow–brown color. **B** Some of the waxy papules have become purpuric, but this can be more difficult to appreciate because of the pigmentation of the skin (compare to Fig. 47. 10). The periorbital region is a characteristic site of involvement. *A, Courtesy, Jean L Bolognia, MD. B, Courtesy, Judith Stenn, MD.*

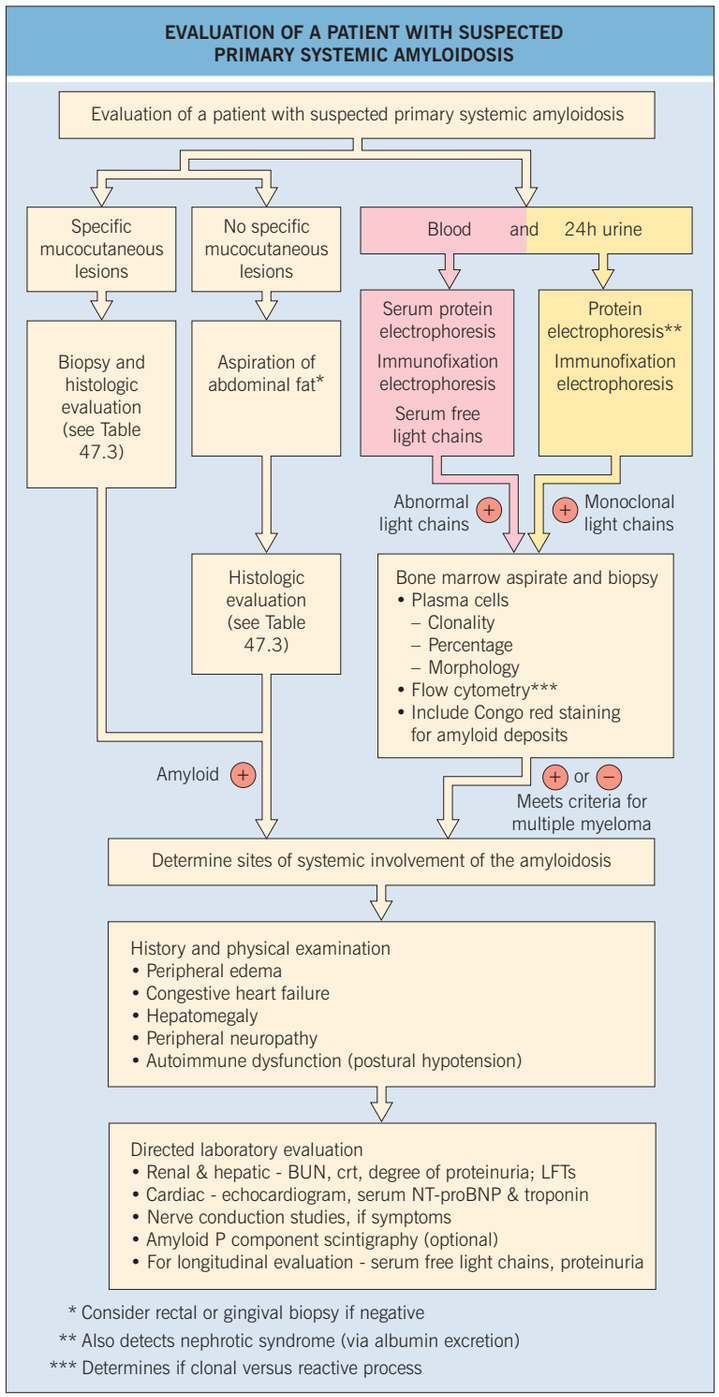

Fig. 47.12 Evaluation of a patient with suspected primary systemic amyloidosis. Because the amyloid is formed from immunoglobulin light chains, an abnormality of light chains in the blood or urine (e.g. increased concentration or abnormal ratio in the blood, positive immunofixation electrophoresis [IFE] of the urine) is required for diagnosis. BUN, blood urea nitrogen; crt, creatinine; LFTs, liver function tests; NT-proBNP, N-terminal pro-brain natriuretic peptide.

Sensory involvement is usually bilateral and symmetrical, while autonomic involvement can result in postural hypotension, impotence and disturbances in gastrointestinal motility (e.g. gastroparesis). Hepatomegaly due to amyloid infiltration or congestive heart failure may be present.

In up to 80–90% of patients with primary systemic amyloidosis, amyloid deposits can be demonstrated in random rectal mucosal biopsies or in abdominal subcutaneous fat aspirates; the latter is favored because of the potential risk for bleeding with the former. Gingival or tongue biopsies may also be obtained to demonstrate the presence of amyloid, but in the absence of involvement clinically, they are less sensitive. In addition, bone marrow biopsies are examined for the presence of amyloid deposits. Based upon the finding that all of these amyloid deposits contain amyloid P (which is derived from serum amyloid protein [SAP]), SAP scintigraphy is also employed, primarily outside the US. It utilizes radioiodine-labeled SAP and is a sensitive, non-invasive method for locating amyloid deposits and monitoring disease. A more practical method for assessing response to therapy is measurement of serum free light chains.

The approach to a patient with suspected primary systemic amyloidosis as well as the evaluation of a patient with confirmed primary systemic amyloidosis is outlined in Figure 47.12.

Pathology

In primary systemic amyloidosis, cutaneous lesions are characterized by amyloid deposits in the dermis and subcutis. Amyloid is also often found around sweat glands and within blood vessel walls (Fig. 47.13). In the kidneys, deposits are seen primarily in the glomeruli; arteries and arterioles may also be affected. In the liver, amyloid is first deposited in the space of Disse between endothelial and parenchymal cells. It then progressively encroaches upon adjacent hepatocytes and sinusoids, leading to atrophy and replacement of large areas of liver parenchyma with amyloid material.

Differential diagnosis

The differential diagnosis of the waxy papules includes papular mucinosis, nodular amyloidosis and lipoid proteinosis, and when the lesions are primarily on the face, they could be confused with adnexal tumors (see Ch. 111). Entities in the sclerodermoid differential diagnosis (see Ch. 43) need to be considered when there is diffuse infiltration of the skin.

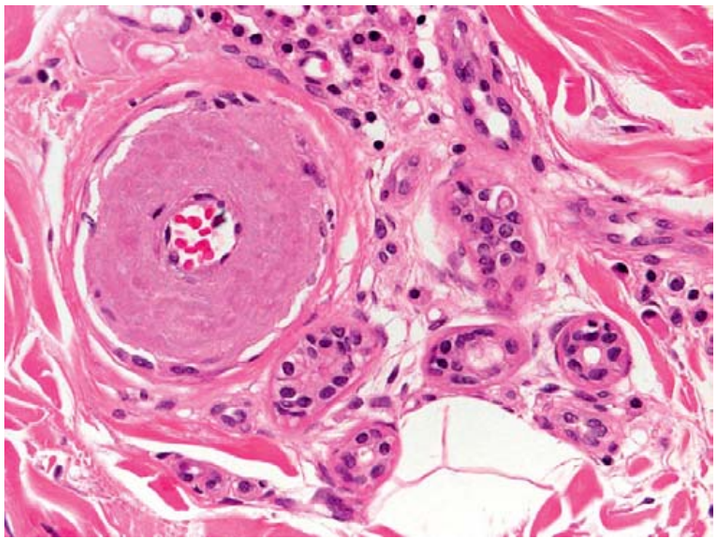

Fig. 47.13 Primary systemic amyloidosis – histologic features. Amyloid deposits are seen in a perivascular location. *Courtesy, Lorenzo Cerroni, MD.*

Treatment

Without therapy, the prognosis for primary systemic amyloidosis is poor: median survival is ~13 months[34], especially if there is cardiac involvement. Treatment strategies have paralleled those for multiple myeloma, including melphalan and systemic corticosteroids[4,35,36]. Nowadays, the treatment of choice for younger patients with minimal cardiac involvement is high-dose melphalan followed by autologous peripheral blood stem cell transplantation. In one study with an 8-year follow-up period, a complete hematologic response was observed in 40% of transplanted patients and was associated with a prolonged survival. A survival benefit and clinical improvement in organ function was also seen in those who did not achieve a complete hematologic response[37]. For older patients or those with cardiac involvement, newer targeted agents (e.g. lenalidomide, bortezomib) are used alone or in combination with systemic corticosteroids and melphalan.

Supportive measures are administered according to the organs affected and the consequent manifestations. Nephrotic syndrome and congestive heart failure require diuretic therapy and treatment of associated arrhythmias. Neuropathy and gastrointestinal involvement are treated symptomatically.

Secondary Systemic Amyloidosis

Secondary systemic amyloidosis occurs as a complication of severe chronic inflammatory diseases of an infectious or non-infectious nature, such as tuberculosis, lepromatous leprosy, rheumatoid arthritis and ankylosing spondylitis. It has also been observed in patients with hidradenitis suppurativa, dystrophic epidermolysis bullosa, generalized psoriasis, chronic pustular psoriasis, scleroderma, dermatomyositis and systemic lupus erythematosus. Secondary systemic amyloidosis is characterized by the deposition of a distinctive non-immunoglobulin protein designated AA (amyloid A protein). The precursor is an acute phase protein which is synthesized by the liver and appears to have a regulatory function in lipoprotein metabolism during inflammation. AA amyloidosis usually affects the kidneys, liver, spleen, adrenals and heart. Cutaneous lesions due to amyloid deposits are rarely seen in this type of amyloidosis (however, amyloid can sometimes be detected within aspirates of subcutaneous fat)[1,11].

Successful treatment of the underlying infectious or inflammatory disease may halt the progression of the reactive amyloidosis. For example, the use of systemic immunomodulators ("biologic agents") such as TNF-α inhibitors in rheumatoid arthritis and ankylosing spondylitis patients with secondary amyloidosis has been shown to be clinically beneficial, resulting in a significant reduction in acute phase reactants and proteinuria[38]. Recently, a controlled clinical study found that eprodisate may slow the loss of renal function in AA amyloidosis. Interestingly, this oral drug acts by changing the conformational configuration of the amyloid protein, rather than by affecting its production[39].

Hemodialysis-Associated Amyloidosis

Hemodialysis-associated amyloidosis results from decreased excretion of β_2-microglobulin and is seen in patients receiving long-term hemodialysis for renal failure. Beta$_2$-microglobulin is retained in the circulation as it fails to be filtered through the dialysis membranes, and it has a tendency to deposit in the synovial membranes. Thus, the predominant manifestations are musculoskeletal, including carpal tunnel syndrome, bone cysts and a destructive spondylo-arthropathy[4]. Occasionally, skin lesions, in particular subcutaneous nodules, have been reported[40,41].

Inherited Amyloidoses

The genetic bases of primary (localized) cutaneous amyloidosis have been previously discussed (see above). Additional inherited forms of amyloidosis have either an autosomal dominant or autosomal recessive inheritance pattern (see Table 47.1). Several of the diseases in this group, such as familial amyloid polyneuropathy and senile systemic amyloidosis, are associated with mutations in the transthyretin gene on chromosome 18; its protein product is a single polypeptide chain of 127 amino acid residues. Transthyretin is synthesized in the liver, choroid plexus and eye, and it is a serum transport protein for thyroxine and retinol-binding protein[9]. The predominant clinical features are due to the peripheral sensorimotor and autonomic neuropathy, with paresthesias, trophic ulcers, carpal tunnel syndrome, postural hypotension, impotence, and disturbances of gastrointestinal motility. Orthotopic liver transplantation removes the major supply of transthyretin and is an effective treatment for this form of amyloidosis[32].

Patients with the extremely rare disorder familial amyloidosis, Finnish type, which is due to mutations in the gene that encodes gelsolin, present with a characteristic triad of corneal lattice dystrophy, cranial neuropathies and skin findings. The latter include cutis laxa-like changes and skin fragility[42].

Muckle–Wells syndrome

Muckle–Wells syndrome can present as familial urticaria during early childhood (see Chs 18 and 45). The symptoms include periodic attacks of fever, lancinating limb pains and an urticarial eruption, with the development of progressive perceptive deafness over time. There may be an associated AA amyloid nephropathy (see Table 45.2)[43].

Familial Mediterranean fever

Familial Mediterranean fever (FMF) is inherited in an autosomal recessive fashion and is characterized by recurrent febrile episodes lasting for 1 or 2 days, with recurrent painful self-limiting episodes of pleuritis, peritonitis or synovitis (see Ch. 45). It tends to affect certain ethnic groups, including Arabs, Sephardic Jews and Armenians. Cutaneous manifestations include an erysipelas-like erythema that develops over the joints, lower legs and dorsal aspect of the feet, in addition to small vessel vasculitis and nonspecific purpuric lesions[44]. FMF is due to mutations in the gene that encodes pyrin, which plays a role in the regulation of the NLRP3/cryopyrin inflammasome (see Fig. 45.1). Colchicine is used prophylactically to prevent polyserositis and AA amyloid deposition.

Sipple syndrome or multiple endocrine neoplasia (MEN) type 2A

Sipple syndrome is an autosomal dominant disorder with the triad of medullary carcinoma of the thyroid, pheochromocytomas and hyperparathyroidism (see Ch. 63). Increased serum levels of calcitonin are a reflection of hyperplasia or carcinoma of the parafollicular calcitonin-producing C cells of the thyroid. Multiple endocrine neoplasia (MEN) type 2A is associated with pruritic areas of hyperpigmentation on the upper back. The lesions have been described as notalgia paresthetica, macular amyloidosis and lichen amyloidosis, depending upon the observer. The unusual finding is the early age of onset, often before the age of 10 years. Recognition of this skin sign of systemic disease can lead to a preventive thyroidectomy once the diagnosis is established[45]. A recent study of 10 families with MEN 2A found an incidence of lichen amyloidosis of 36%; moreover, all those with cutaneous amyloidosis had a specific mutation in codon 634 of the *RET* proto-oncogene[46].

Hypotrichosis simplex of the scalp

Hypotrichosis simplex of the scalp is an uncommon autosomal dominant disorder in which patients have normal hair at birth, but then progressively lose almost all scalp hair by the third decade. Eyebrows, beard and axillary hair, nails and teeth develop normally. Mutations in the gene that encodes corneodesmosin, a glycoprotein expressed in the epidermis and inner root sheath, lead to truncated proteins. Deposits of the truncated protein accumulate as amorphous amyloid deposits around hair follicles and in the papillary dermis[47].

X-Linked Reticulate Pigmentary Disorder (Partington Amyloidosis)

Partington and colleagues described a family with an X-linked disease in which adult women had linear streaks of hyperpigmentation and male patients manifested a reticulated mottled brown pigmentation of the skin, which, on biopsy, demonstrated dermal deposits of amyloid (in adults but not children). In women, the involvement was limited to the skin, but in male patients, recurrent respiratory infections, corneal dystrophy and photophobia were seen (see Ch. 67). As in macular amyloidosis, the amyloid deposits are keratin-positive and amyloid deposits have not been found in other tissues[48]. The gene for this disorder has been localized by linkage analysis to Xp21–p22[48].

INTRODUCTION

The cutaneous deposition disorders are a heterogeneous group of conditions characterized by the presence of primarily endogenous substances within the dermis or the subcutis. Deposition disorders can be associated with localized or generalized cutaneous findings, and skin involvement is sometimes the earliest sign of a deposition disease. Histologic examination of cutaneous lesions, with the use of special stains, is the most specific diagnostic tool (Table 48.1). In addition, specific enzymatic assays or genetic mutational analysis can then be performed to establish the precise diagnosis.

This chapter will focus on gout, pseudogout, lipoid proteinosis, colloid milium and the mucopolysaccharidoses. Additional deposition disorders such as papular mucinosis, amyloidosis, porphyria and calcinosis cutis are reviewed in Chapters 46, 47, 49 and 50.

GOUT

Synonyms: ■ Urate crystal arthropathy ■ Podagra ■ Urate deposition disease

Key features

- Gout is a metabolic disease in which the underlying abnormality is hyperuricemia
- Deposits of needle-like crystals of monosodium urate are found in several sites, most commonly the skin (as tophi) and the joints
- In fresh preparations of synovial fluid and expressed material from tophi, the crystals exhibit negative birefringence when examined by polarized light
- In routinely fixed histologic sections, amorphous deposits that contain needle-like clefts are seen in the dermis and subcutis

DISORDERS WITH DERMAL DEPOSITS – HISTOLOGIC FEATURES

Disease	Microscopic findings	Histochemical stains	Special processing
Gout	Dermal deposits of amorphous material with needle-like clefts surrounded by giant cells Polarizing light/fresh preparation – fine, needle-like crystals; negative birefringence	20% silver nitrate solution: urate crystals appear black and the surrounding tissue yellow De Galantha stain: crystals brown–black	Best fixative to preserve crystals: ethanol-based (Carnoy's fluid)
Lipoid proteinosis	Masses of amorphous or laminated hyalin-like material Also surrounds capillaries in the papillary dermis and appendages	Contains type IV collagen and laminin PAS-positive and diastase-resistant ⊕ Alcian blue, hyaluronidase-sensitive Sudan III (+/–) Congo red (usually –)	
Colloid milium (adult form)	Nodules of amorphous eosinophilic material Artifactual clefts Solar elastosis	Stains similarly to amyloid ⊕ Congo red ⊕ Thioflavin T ⊕ Crystal violet	
Mucopolysaccharidoses	Granules within fibroblasts Large vacuolated cells in sweat glands and the external root sheath of hair follicles (gargoyle cells)	Granules within fibroblasts: ⊕ Metachromasia with toluidine blue and Giemsa ⊕ Alcian blue ⊕ Colloidal iron (see Table 46.1)	Fixation in absolute alcohol better than in formalin (consider when clinical diagnosis not supported by histologic findings)
Mucinoses, e.g. papular mucinosis, scleredema, pretibial myxedema (Ch. 46)	Mucin between collagen and variable fibroblast proliferation	⊕ Metachromasia with toluidine blue ⊕ Alcian blue ⊕ Colloidal iron (see Table 46.1)	Fixation in absolute alcohol better than in formalin
Amyloidosis (Ch. 47)	Fractured, amorphous, faintly eosinophilic material in dermis	⊕ Congo red ⊕ Thioflavin T ⊕ Crystal violet	In glutaraldehyde for electron microscopy
Ochronosis (Ch. 67)	Sausage- or banana-shaped brown/yellow structures	Black staining with methylene blue or cresyl violet	
Calcinosis cutis (Ch. 50)	Irregular masses of deeply basophilic material Variable granulomatous inflammation	⊕ von Kossa ⊕ Alizarin red is more specific	May fracture microtome blade May need decalcification solution first
Porphyrias, in particular EPP (Ch. 49)	Perivascular rim of delicate eosinophilic fibrillar material In chronic lesions, also dense homogeneous deposits	PAS-positive and diastase-resistant Immunohistochemistry for BMZ components (type IV collagen)	

Table 48.1 Disorders with dermal deposits – histologic features. BMZ, basement membrane zone; EPP, erythropoietic protoporphyria.

Introduction

Gout is a metabolic disease in which needle-like crystals of monosodium urate (the ionized form of uric acid) from supersaturated fluids are deposited in tissue. Clinical manifestations include gouty arthritis, accumulation of crystals in connective tissue (tophi), uric acid nephrolithiasis and renal impairment[1,2].

Epidemiology

Gout is the most common form of crystal-induced arthritis, and its prevalence seems to have increased over the past few decades. Men 40–50 years of age are most commonly affected. The male-to-female ratio is 9:1, and most women with gout are postmenopausal. In England, gout is found in up to 1.6% of adults and approximately 20% of patients have a family history of gout[2,3].

Pathogenesis

Gout is a consequence of deposits of urate crystals that have precipitated from supersaturated body fluids. Uric acid is the end product of the catabolism of purines. When the body increases its production of uric acid or if the kidneys do not excrete sufficient amounts, the result is hyperuricemia (Table 48.2).

Urate crystals can activate the NLRP3 inflammasome (see Fig. 45.1) and stimulate the production of the proinflammatory cytokine interleukin-1 by monocytes and macrophages[4]. The subsequent migration and activation of neutrophils as well as complement activation initiate a vicious cycle. The ingestion of crystals by neutrophils triggers cell damage and leakage of lysosomes, which then result in further inflammation and tissue damage.

Clinical Features

The typical patient with gout is a middle-aged or older man, who may have a family history of the disease. Risk factors include obesity, excessive alcohol intake, renal insufficiency and certain medications, most commonly diuretics. The natural history of gout involves four clinical stages[1]: (1) asymptomatic hyperuricemia; (2) acute gouty arthritis; (3) intercritical gout (the intervals between attacks, which progressively become shorter in duration); and (4) chronic tophaceous gout.

Acute gouty arthritis

The most common symptom of gout is the development of severe joint pain over a period of 6–12 hours, accompanied by tenderness, erythema, warmth and swelling. Usually, initial attacks are monoarticular, but in up to 40% of patients they may be polyarticular[5]. In 75% of patients, the first metatarsophalangeal joint is involved (referred to as podagra); additional sites include the knee, ankle and foot, and, less commonly, the hand, wrist and elbow. Fever and systemic symptoms may accompany an acute attack of gout. As the swelling subsides, the skin acquires a violaceous hue and this is often followed by desquamation.

Chronic tophaceous gout

Cutaneous deposits of monosodium urate, known as "tophi", usually appear an average of 10 years after the onset of gout. These tophi present as firm dermal or subcutaneous papules and nodules or as a fusiform swelling. Their contours may be smooth or multilobulated (Fig. 48.1) and the lesions can vary from skin-colored to white–yellow to red (Fig. 48.2). The surface may be ulcerated and there may be associated drainage of material (varies from clear fluid with white flecks to a thick chalky material).

The most common locations for tophi are the skin overlying joints and the helix of the ear. Unusual sites include the eyes, nose, larynx, breast and heart valves. However, tophi develop in fewer than 10% of patients with gout. Depending upon the size and location of the tophi,

CLASSIFICATION OF HYPERURICEMIA	
Overproduction of uric acid	• Primary idiopathic • Excessive dietary purine intake and obesity • Increased nucleotide turnover – High-grade lymphomas (e.g. Burkitt's) and myeloma – Myeloproliferative disorders, esp. acute myelogenous leukemia – Tumor lysis syndrome – Hemolysis – Psoriasis (severe) • Accelerated ATP degradation – Alcohol abuse – Severe muscle exertion • Hypoxanthine–guanine phosphoribosyl transferase deficiency (Lesch–Nyhan syndrome) • Phosphoribosyl pyrophosphatase synthetase overactivity
Decreased excretion of uric acid	• Primary idiopathic • Renal insufficiency • Enhanced tubular urate reabsorption (e.g. diuretics, dehydration) • Drug ingestion (e.g. cyclosporine > tacrolimus, pyrazinamide, low-dose salicylates) • Toxins (e.g. lead-induced nephropathy) • Miscellaneous – lactic acidosis, hypertension, hyperparathyroidism, hypothyroidism

Table 48.2 Classification of hyperuricemia.

Fig. 48.1 Tophaceous gout of a digit. The deposits create a multilobulated appearance. A small incision over the yellow–white areas followed by microscopic examination of the expressed material would allow a bedside diagnosis.

Fig. 48.2 Tophaceous gout of the tragus. The erythema reflects surrounding inflammation.

complete, partial or minimal resolution can occur when the serum uric acid level is normalized[2,6].

Elevated levels of uric acid in the urine can lead to uric acid nephrolithiasis and even acute renal failure when uric acid precipitates in the renal tubules and collecting ducts. The most common setting for the latter is the tumor lysis syndrome in which chemotherapy is given for a rapidly dividing chemosensitive malignancy, e.g. leukemias, lymphomas.

The initial diagnosis of gout is usually made in the setting of acute arthritis, based upon the presence of urate crystals in an aspirate of joint fluid. Hyperuricemia is usually present, but alone it is insufficient for establishing the definitive diagnosis of gout. Additional laboratory abnormalities during an acute attack include an elevated white blood cell count (in the joint fluid and blood) and an elevated ESR.

When examined by polarized light microscopy, the needle-shaped urate crystals change color from yellow to blue based upon their alignment relative to the axis of the "red plate" compensator, i.e. they exhibit negative birefringence. In patients with recurrent attacks, radiographs of involved joints often show "punched-out" erosions with sclerotic "overhanging" margins, but no osteophytes. A 24-hour urine collection for uric acid allows the identification of patients at risk for nephrolithiasis (see Table 48.2).

Pathology

In gouty tophi, the key histologic feature is the presence of deposits of amorphous material within the dermis and subcutis. These deposits contain needle-like clefts (which represent dissolved urate crystals) and are surrounded by an infiltrate composed of histiocytes and multinucleated giant cells as well as lymphocytes (Fig. 48.3). Secondary calcification or even ossification can occasionally be seen.

In order to preserve the crystals, the biopsy specimen needs to be placed in an ethanol-based fixative, such as Carnoy's fluid. Then, under regular or polarized light, brightly refractile brown sheaths of fine needle-like crystals can be seen. Upon staining with 20% silver nitrate solution, the crystals appear black and the surrounding tissue yellow, whereas with the De Galantha stain, the crystals appear brown to black[7].

Differential Diagnosis

The differential diagnosis of acute gouty arthritis includes pseudogout (see below), osteoarthritis, psoriatic arthritis, reactive arthritis (previously referred to as Reiter's disease) and septic arthritis. Given its destructive nature, septic arthritis needs to be considered even in patients in whom the diagnosis of gout has been previously established. The presence of needle-shaped crystals with negative birefringence in an aspirate of joint fluid is diagnostic of gout, while Gram stain and culture exclude septic arthritis.

The differential diagnosis of cutaneous gouty tophi includes xanthomas, rheumatoid nodules and calcinosis cutis. Examination of expressed fluid or chalky material by polarized light can provide a "bedside" diagnosis. By ultrasonography, central clear spaces are seen within tophi whereas rheumatoid nodules contain central echodense areas[6].

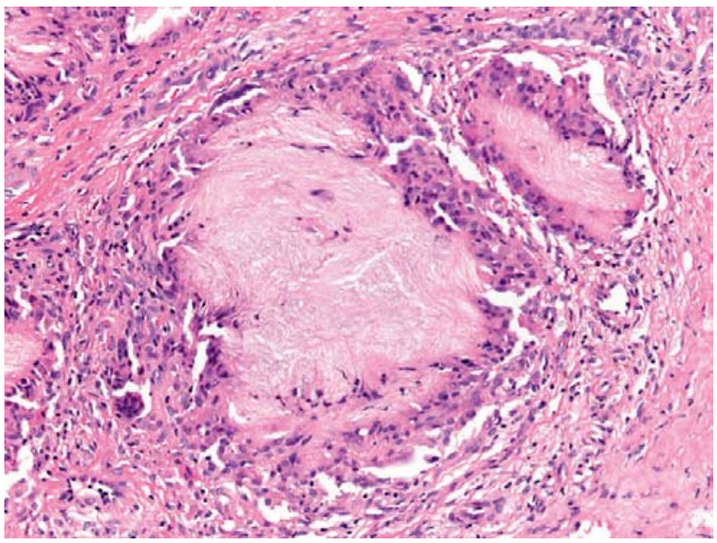

Fig. 48.3 Tophaceous gout – histologic features. Deposits of amorphous, acellular material within the dermis. Needle-like spaces are present within the amorphous deposits and histiocytes and multinucleated giant cells surround the deposits. *Courtesy, Lorenzo Cerroni, MD.*

Treatment

In acute gout, short-acting nonsteroidal anti-inflammatory drugs (*NSAIDs*) are taken orally at the highest safe dosage as long as symptoms persist, e.g. indomethacin 50 mg three times daily for several days. Contraindications include peptic ulceration, renal insufficiency and anticoagulation[6,8].

Colchicine, a derivative of the autumn crocus, has been used to treat gout for centuries. This drug relieves pain and swelling and can help to prevent future attacks. The primary effect of colchicine is an inhibition of the transport of phagocytized urate crystals to lysosomes within neutrophils via its binding to microtubules. Colchicine also interferes with leukocyte migration, chemotaxis and adhesion. For patients with normal renal function who are not receiving strong CYP3A4 inhibitors, the Food and Drug Administration (FDA)-recommended dosage for acute gout flares is 1.2 mg orally followed by 0.6 mg 1 hour later. Prophylaxis in such patients consists of colchicine 0.6 mg once or twice daily. Even at these lower doses, gastrointestinal toxicity is still a concern. Systemic *corticosteroids* may be used for a period of 1–3 weeks if NSAIDs and colchicine are ineffective or contraindicated[6,8].

The xanthine oxidase inhibitor *allopurinol* blocks uric acid production and is often used for chronic therapy of gout, including those with high levels of excreted uric acid (overproducers and hyperexcretors) as well as those who are poor excretors. Side effects include diarrhea, thrombocytopenia, hepatitis, and skin eruptions that can range from morbilliform to erythroderma or toxic epidermal necrolysis (see Ch. 21). More recently, *febuxostat*, an oral non-purine xanthine oxidase inhibitor, was approved for the chronic treatment of gout; its major side effects are liver enzyme elevations and cardiovascular thromboembolic events[9]. Drug–drug interactions, e.g. with azathioprine, can occur with both of these medications (see Fig. 130.3). Uricosuric agents such as oral *probenecid* and *sulfinpyrazone* can be used as second-line therapy for patients with normal renal function and no renal stones.

Some patients may benefit from a reduction in purine-rich foods (e.g. organ meats [liver, heart], fish), alcohol consumption and body weight[6]. In the setting of potential tumor lysis syndrome, intravenous *rasburicase* can be administered, which rapidly converts uric acid to the more soluble allantoin. Bimonthly intravenous *pegloticase*, which has the same mechanism of action, is now approved for patients with chronic gout refractory to conventional therapy, and improvement in tophi has been observed. Lastly, given the evidence for inflammasome activation, *anakinra* has been used for refractory gout and *rilonacept* for prevention of gout flares in patients on allopurinol.

PSEUDOGOUT

Synonyms: ■ Chondrocalcinosis ■ Calcium pyrophosphate disease ■ Calcium gout

Key features

- Pseudogout is a form of arthritis that is due to deposits of calcium pyrophosphate dihydrate (CPPD) crystals within the joint
- It most commonly affects the knee and other large joints of older persons with osteoarthritis
- In aspirates of joint fluid, rhomboid CPPD crystals are seen and they exhibit weakly positive birefringence under polarized light

Pseudogout, which may be clinically indistinguishable from gout, was recognized as a distinct disease entity in 1962[10]. It results when calcium pyrophosphate dihydrate (CPPD) crystals (produced by nucleo-

side triphosphate pyrophosphohydrolase, a catalytic enzyme found in osteoarthritic cartilage) form within joint fluid and then lead to lysis of neutrophils that have ingested the crystals. Although pseudogout is often related to osteoarthritis, it has also been associated with metabolic abnormalities such as hyperparathyroidism and hemochromatosis.

Symptoms of pseudogout include intermittent attacks of pain and swelling of affected joints, most commonly the knee, wrist and shoulder. The onset of symptoms in pseudogout is usually more insidious than in gout. Occasionally, extra-articular CPPD deposition (tophaceous pseudogout) may present as a hard subcutaneous nodule overlying joints primarily of the head (especially the temporomandibular joint), neck or distal extremities[11].

Microscopically, CPPD crystals appear shorter than urate crystals and are often rhomboidal in shape. Polarizing microscopy of sections stained with a non-aqueous alcoholic eosin stain (NAES)[12] allows the demonstration of CPPD crystals with positive birefringence (in contrast to urate crystals with negative birefringence [see above] and calcium hydroxyapatite crystals without birefringence [in tumoral calcinosis]). Treatment of the acute phase of pseudogout is identical to that of gout[11]. In patients with chronic renal failure, the interleukin-1 receptor antagonist anakinra may be considered (see Fig. 45.1)[13].

LIPOID PROTEINOSIS

Synonyms: ■ Hyalinosis cutis et mucosae ■ Urbach–Wiethe disease

Key features

- A rare autosomal recessive deposition disorder due to mutations in the extracellular matrix protein 1 *(ECM1)* gene
- Hyalin-like material is deposited in multiple organs, including the skin, oral mucosa, larynx and brain
- Papules and nodules favor the face, as do pitted scars; diffuse waxy thickening of the skin can be associated with verrucous changes, especially on the elbows, knees and hands

History

Lipoid proteinosis was first described by Siebenmann in 1908. Twenty years later, it was established as a distinct entity by two Viennese physicians, Erich Urbach, a dermatologist, and Camillo Wiethe, an otorhinolaryngologist.

Epidemiology

Most patients are of European ancestry, including descendants of Dutch immigrants who settled in South Africa in the middle of the seventeenth century[14]. Not only do Afrikaners have the highest incidence of this genetic disease, they also exhibit a founder effect, i.e. the population shares a common mutation.

Pathogenesis

In 2002, lipoid proteinosis was shown to be due to loss-of-function mutations in the extracellular matrix protein 1 *(ECM1)* gene[15]. The latter encodes a secretory glycoprotein that can act as a negative regulator of endochondral bone formation and a promoter of angiogenesis. In addition, ECM1a (see below) is found within the basement membrane zone and can enhance the binding of collagen IV to laminin 332. It also interacts with components of the extracellular matrix such as fibronectin and glycosaminoglycans (e.g. hyaluronic acid, chondroitin sulfate)[16].

The *ECM1* gene has three splice variants that result in three isoforms: (1) ECM1a, a protein of 540 amino acids encoded by a 10-exon gene; (2) ECM1b, a protein of 415 amino acids reflecting a lack of exon 7; and (3) ECM1c, a protein of 559 amino acids due to an additional exon 5a within intron 5. Patients with mutations in exon 7 still express the ECM1b isoform and tend to have milder disease as compared to those with mutations in exon 6, who tend to have more severe disease and reduced expression of all three isoforms. Approximately one-third of pathogenic mutations reported to date occur in each of these two exons[15]. The degree of cutaneous immunofluorescent staining (utilizing an anti-ECM1 antibody) points to the location; reduced staining suggests mutations in exon 7, while an absence of staining suggests mutations in exon 6[16].

Clinical Features

The first clinical sign of lipoid proteinosis is often a weak cry or hoarseness due to infiltration of the laryngeal mucosa. Hoarseness remains throughout life. Cutaneous lesions usually appear during the first 2 years of life, in two overlapping stages. The first stage consists of vesicles and hemorrhagic crusts on the skin of the face and extremities and in the mouth, often in association with trauma. The skin lesions may resolve with scarring including "ice-pick"-like scars.

In the second stage, there is an increase in the hyalin deposits within the dermis (Fig. 48.4). The skin becomes diffusely thickened and waxy and develops a yellow discoloration. Papules, plaques and nodules appear on the face (including the eyelid margin) as well as in the axillae and on the scrotum. Verrucous lesions may develop on the extensor surfaces, especially the elbows (see Fig. 48.4C), knees and hands. Generalized scaling has also been observed[17] as has alopecia of the eyebrows and eyelashes. Corneal ulcers may occur due to infiltration of the eyelids.

In addition to involvement of the tongue (diffuse infiltration), the frenulum (restricted motion of the tongue) and the oropharynx, recurrent parotitis can occur due to occlusion of the salivary duct. Dental anomalies include hyperplasia or aplasia of the upper incisors, premolars or molars. Patients usually lose their teeth at an early age. Neurologic manifestations are common and consist primarily of seizures, and, less often, abnormal behavior[18]. A pathognomonic radiographic finding is bilateral, intracranial, sickle-shaped calcification within the temporal lobes.

In general, the disease has a stable or slowly progressive course that is compatible with a normal lifespan, except for the risk of respiratory obstruction in infancy. An elevated ESR may be seen due to increased α- or γ-globulins.

Pathology

The major clinical manifestations are related to the deposition of an amorphous or laminated material around blood vessels and in the connective tissues. The amorphous deposits consist primarily of non-collagen proteins, while the concentric layers of basement membrane-like material contain collagen (types II and IV) and laminin. In addition, the deposits are PAS-positive and diastase-resistant, indicating the presence of neutral mucopolysaccharides.

H&E-stained sections of early lesions reveal pink, hyalin-like thickening of the capillaries within the papillary dermis, and in one patient, vesicles were due to non-dyskeratotic acantholysis. Older lesions are characterized by hyperkeratosis, occasionally papillomatosis, and a thickened dermis in which bundles of pink hyalin deposits are found in a diffuse pattern (Fig. 48.5); the bundles are often oriented perpendicularly to the dermal–epidermal junction. There are smaller scattered deposits of hyalin in the lower dermis. Hyalin mantles can surround the eccrine glands as well as the hair follicles, sebaceous glands and, rarely, arrector pili muscles.

In addition to type IV collagen, laminin and neutral mucopolysaccharides, hyaluronic acid is also present in the dermis, as demonstrated by Alcian blue and hyaluronidase staining (see Ch. 46). Fat stains (e.g. Sudan III) give inconsistent results, and, rarely, the deposits stain with Congo red. Ultrastructurally, reduplication of the basement membrane of vessels and, occasionally, the dermal–epidermal junction is seen; the deposits appear to be composed of small granules and short filaments of low electron density that measure 3–5 nm in diameter.

Differential Diagnosis

The clinical differential diagnosis includes erythropoietic protoporphyria (EPP), amyloidosis, papular mucinosis (scleromyxedema), colloid milium and non-X histiocytoses. In infants, the possibility of juvenile hyaline fibromatosis and infantile systemic hyalinosis need to be considered, both of which are due to mutations in the gene that encodes

Fig. 48.4 Lipoid proteinosis – clinical features. A Beaded eyelid papules, hemorrhagic crusts, and confluent waxy papules of the glabella leading to an early leonine facies. **B** Skin-colored papulonodules of the elbow as well as irregular hypopigmented scars of the extensor forearm. **C** Characteristic verrucous changes of the elbow. **D** A firm tongue with numerous tiny papules on the dorsal surface. **E** Multiple, round hypopigmented and depressed scars on the shoulder. **F** Waxy, yellowish plaque on the back. *B,D,E, Courtesy, Julie V Schaffer, MD. capillary morphogenesis protein 2 (see Ch. 98). Histologically, the differential diagnosis includes EPP and colloid milium. In cutaneous lesions of EPP, colloid milium and amyloidosis (see Table 48.1), the hyalinization is milder, more focal and superficial, and it rarely involves the eccrine glands. The deposits in colloid milium do not have the striking perivascular pattern seen in lipoid proteinosis.

Treatment

Currently, there is no known cure or effective treatment for lipoid proteinosis. Topical glucocorticoids have been used with some beneficial effect, as have humectants. Plastic surgery and dermabrasion have also been successfully performed in selected patients[19], and there are scattered reports of the use of systemic retinoids[20], D-penicillamine and oral dimethyl sulfoxide (DMSO)[21].

COLLOID MILIUM

Synonyms: ■ Colloid degeneration of the skin ■ Elastosis colloidalis conglomerata ■ Miliary colloidoma

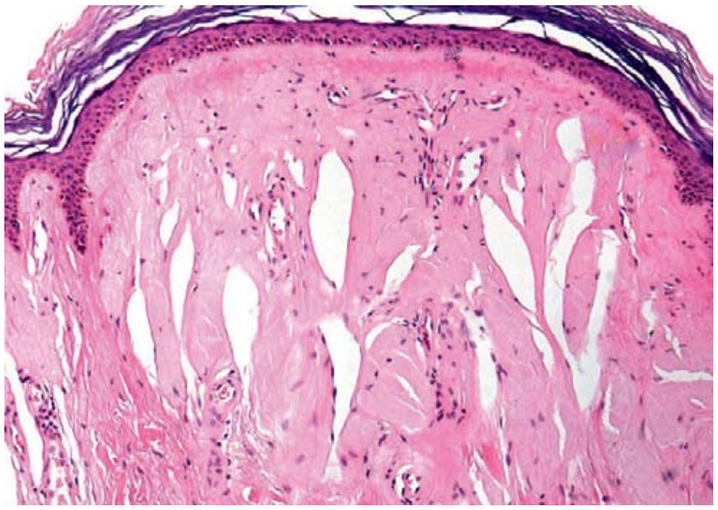

Fig. 48.5 Lipoid proteinosis – histologic features. Hyperkeratosis, a flattened epidermis and vertically oriented eosinophilic deposits in the dermis. Note the cleft formation. *Courtesy, Lorenzo Cerroni, MD.*

Key features

- A rare disorder in which dome-shaped, translucent papules develop in sun-exposed skin
- Four variants are recognized: adult, juvenile, pigmented and nodular colloid degeneration
- Histologically, amorphous, eosinophilic, granular deposits within the superficial dermis

Introduction/Epidemiology

Adult colloid milium is the most common form of the disease. It usually occurs in middle-aged, fair-skinned individuals who have had significant cumulative sun exposure, with a male-to-female ratio of 4:1. The adult form has also been observed in outdoor oil refinery workers, suggesting an additional effect of petrochemicals. In general, *juvenile* colloid milium develops before puberty and both an autosomal recessive and an autosomal dominant inheritance pattern have been reported[22].

Pathogenesis

Although excessive sun exposure clearly plays a role in *adult* colloid milium, the precise pathogenesis is not known. Photoinduced damage to dermal elastic fibers, as in solar elastosis, has been suggested. In *juvenile* colloid milium, ultraviolet light-induced damage to epidermal keratinocytes has been observed and this may reflect an inherited susceptibility. *Pigmented* colloid milium is a variant of the adult form in which there is a combination of excessive sun exposure plus topical application of hydroquinone or phenols[23].

Clinical Features

In both the adult and juvenile forms, multiple, dome-shaped, translucent to yellow or yellow–brown papules are seen in areas of chronic sun exposure, e.g. the face (especially periorbitally), ears, posterolateral neck, and the dorsal aspect of the hands and forearms. With minor trauma, lesions can become hemorrhagic. In *pigmented* colloid milium, grouped to confluent gray–brown papules are present on the face, whereas in *nodular colloid degeneration*, skin-colored to yellowish nodules or plaques develop, often on the face[22,23].

Pathology

In *adult* colloid milium, nodules composed of homogeneous eosinophilic colloid material are seen in the papillary dermis. Within the nodules, there may be clefts and fissures. A grenz zone is often present, as is evidence of solar elastosis beneath the nodules. Although the colloid masses contain degenerated elastic fibers, they often exhibit a staining profile similar to amyloidosis, i.e. positive staining with crystal violet, Congo red and thioflavin T stains. In addition, PAS staining is positive.

In *juvenile* colloid milium, amorphous eosinophilic deposits are also found within the papillary dermis, but when compared to the adult form, there is less clefting and no grenz zone. As with colloid bodies (which are also keratinocyte-derived), nonspecific staining for immunoglobulins, complement and fibrin is seen. In addition, staining for keratin is positive.

In *pigmented* colloid milium, lightly pigmented islands of colloid material are found in the upper dermis. In *nodular colloid degeneration*, homogenized amorphous dermal collagen with small fissures and clefts are found. Whether this entity is a variant of nodular amyloidosis is still under debate. Ultrastructurally, colloid milium is characterized by amorphous and granular material which lacks the straight, nonbranching filaments seen in amyloidosis.

Differential Diagnosis

Clinically, the differential diagnosis of juvenile and adult forms of colloid milium includes erythropoietic protoporphyria (EPP), mucinoses (e.g. papular, self-healing), lipoid proteinosis, adnexal tumors and primary systemic amyloidosis (adults). Pigmented colloid milium needs to be distinguished from exogenous ochronosis. Histologically, colloid milium must be distinguished from EPP, lipoid proteinosis and amyloidosis. In cutaneous lesions of EPP, there are hyaline deposits around and within the superficial blood vessel walls, whereas the dermal deposits of lipoid proteinosis are accentuated around the blood vessels. Cutaneous amyloidosis may be indistinguishable from the juvenile type of colloid milium, as both stain positively for keratin; some authors consider juvenile colloid milium to be a variant of lichen amyloidosis. Unlike lipoid proteinosis and lichen amyloidosis, the dermal deposits of adult colloid milium do not stain positively for laminin and type IV collagen or cytokeratin, respectively.

Treatment

Treatment modalities are limited and include laser therapy (e.g. long-pulsed Er:YAG, fractional photothermolysis), dermabrasion, intense pulsed light, cryotherapy and chemical peels[24].

MUCOPOLYSACCHARIDOSES

Key features

- A group of inherited disorders, primarily autosomal recessive, characterized by deficiencies of specific lysosomal enzymes involved in the catabolism of glycosaminoglycans (GAGs), also referred to as mucopolysaccharides
- Excessive amounts of the GAGs are found in various tissues and lead to coarse facies, mental retardation, hepatosplenomegaly, skeletal abnormalities and corneal clouding
- One of the mucopolysaccharidoses, Hunter syndrome (X-linked recessive), has distinctive skin-colored to white papules over the scapulae (pebbling)
- Screening tests include examination of the urine, peripheral leukocytes and dermal fibroblasts for the presence of excessive GAGs

Clinical Features and Pathology

The mucopolysaccharidoses are due to mutations in several genes that encode the enzymes involved in the catabolism of glycosaminoglycans (GAGs)[25]. Examples of GAGs include dermatan sulfate, heparan sulfate and chondroitin sulfate. The storage of excessive amounts of the GAGs in various tissues leads to a constellation of findings; the most common manifestations are coarse facies, mental retardation, hepatosplenomegaly, skeletal abnormalities (dysostosis multiplex), joint stiffness, cardiovascular disease and corneal clouding (Table 48.3). Depending upon the

THE MUCOPOLYSACCHARIDOSES										
Disorder	**Enzyme deficiency**	**Stored material**	**Clinical types (onset)**	**Inheritance**	**Clinical features**					
					Neurologic	**Liver and/or spleen enlargement**	**Skeletal disease**	**Ophthalmologic**	**Hematologic**	**Other features**
MPS 1 H, Hurler	α-L-Iduronidase	Dermatan sulfate Heparan sulfate	Infancy	AR	Mental retardation	+++	++++	Corneal clouding	Vacuolated lymphocytes	Coarse facies, cardiovascular involvement, respiratory compromise, joint stiffness, dermal melanocytosis*
MPS I H/S, Hurler/ Scheie	α-L-Iduronidase	Dermatan sulfate Heparan sulfate	Childhood	AR	Mild mental retardation	++	++	Corneal clouding	Vacuolated lymphocytes	Severity intermediate between Hurler and Scheie
MPS I S, Scheie	α-L-Iduronidase	Dermatan sulfate Heparan sulfate	Late childhood/ early adulthood	AR	None	+	+	Corneal clouding	Vacuolated lymphocytes	Normal stature, valvular heart disease, joint stiffness, carpal tunnel syndrome
MPS II, Hunter	Iduronate 2-sulfatase	Dermatan sulfate Heparan sulfate	Severe – infancy Mild – late childhood	X-linked recessive	Mental retardation, less in mild form	++ to +++	++ to ++++	Retinal degeneration, no corneal clouding	Granulated lymphocytes	Coarse facies, cardiovascular involvement, joint stiffness, distinctive pebbly skin lesions
MPS III A–D, Sanfilippo A–D	A: Heparan-*N*-sulfatase B: *N*-acetyl-α-glucosaminidase C: Acetyl-CoA: α-glucosaminide *N*-acetyltransferase D: *N*-acetyl-glucosamine-6-sulfatase	Heparan sulfate	Early childhood	AR	Severe mental retardation, with deterioration during early childhood	+	+	None	Granulated lymphocytes	Mild coarse facies, usually normal stature, severe behavioral problems
MPS IV A, Morquio A	*N*-acetylgalactosamine-6-sulfatase	Keratan sulfate Chondroitin-6 sulfate	Childhood	AR	None	+	++++	Corneal clouding	Granulated neutrophils	Distinctive skeletal deformity, odontoid hypoplasia, aortic valve disease
MPS IV B, Morquio B	β-Galactosidase†	Keratan sulfate Chondroitin-6 sulfate	Childhood	AR	None	±	++++	Corneal clouding	Granulated neutrophils	See above, Morquio A
MPS VI, Maroteaux–Lamy	Arylsulfatase B (*N*-acetylgalactosamine-4-sulfatase)	Dermatan sulfate	Late infancy/ childhood	AR	None	++	++++	Corneal clouding	Granulated neutrophils and lymphocytes (most prominent of all MPS)	Coarse facies, valvular heart disease, upper airway obstruction
MPS VII, Sly	β-Glucuronidase	Dermatan sulfate Heparan sulfate Chondroitin-4 and -6 sulfate	Wide range Severe – neonatal Mild – adolescence	AR	Mental retardation, absent in some adults	+ to +++	+ to +++	Corneal clouding	Granulated neutrophils	Coarse facies, cardiovascular involvement, hydrops fetalis in neonatal form

*Persistent and extensive, often involving the anterior as well as posterior trunk; has also been described in patients with GM1-gangliosidosis (see Ch. 63).
†Allelic with GM1-gangliosidosis.

Table 48.3 The mucopolysaccharidoses (MPS). AR, autosomal recessive. *Adapted with permission from Hopkin R, Grabowski GA. Lysosomal storage diseases. In: Longo DL, Fauci AS, Kasper DL, Hauser SL, Jameson JL, Loscalzo J (eds). Harrison's Principles of Internal Medicine, 18th edn. New York:McGraw-Hill, 2011.*

specific type of mucopolysaccharidosis (MPS), the presence and severity of the clinical findings varies.

Cutaneous manifestations are nonspecific (e.g. hypertrichosis, thickening of the skin), except for the presence of skin-colored to white papules or nodules over the scapulae ("pebbling") in patients with Hunter syndrome[26], which is inherited in an X-linked recessive fashion. The lesions measure 1–10 mm in diameter and may become confluent; they can extend from the posterior axillary line to the midline. Less common sites of involvement are the arms, the lateral upper chest and the buttocks. Extensive dermal melanocytosis has also been reported in patients with Hurler syndrome as well as those with GM1 gangliosidosis type 1.

Screening tests include examination of the urine for excessive amounts of GAGs and examination of circulating leukocytes (usually lymphocytes; see Table 48.3) or dermal fibroblasts for vacuoles or granules. The latter contain sulfated acid GAGs that can be demonstrated via special stains (see Table 46.1). The peripheral blood smear should be fixed in absolute methanol and fixation of the skin biopsy specimen in absolute alcohol is preferred. Specific enzyme assays or genetic mutational analysis can then be performed; prenatal diagnosis is also possible.

In addition to the presence of vacuoles or granules within fibroblasts, the cutaneous papules of Hunter syndrome have extracellular deposits of metachromatic material[26]. Biopsy specimens from all types of MPS can have vacuolated cells within sweat glands and the external root sheath of hair follicles. Keratinocytes may develop a pale distended cytoplasm which displaces the nucleus to one side. Biopsy specimens of diffusely thickened skin demonstrate fragmentation and hyalinization of collagen and increased amounts of mucin. By electron microscopy, fibrillogranular material is seen within lysosomes in all types of MPS.

Treatment

Although symptomatic and supportive interventions (e.g. home oxygen, physical therapy for joint stiffness, and cardiac valve replacement) still play an important role in the treatment of mucopolysaccharidoses, nowadays there are additional therapeutic options – in particular, enzyme replacement and hematopoietic stem cell transplantation[27]. The mucopolysaccharidoses are ideal candidates for enzyme replacement therapy because there is a high-affinity uptake mechanism for lysosomal enzymes. Currently available enzymes include α-L-iduronidase (laronidase; Aldurazyme™) for MPS I, *N*-acetylgalactosamine 4-sulfatase (galsulfase; Naglazyme™) for MPS VI, and iduronate-2-sulfatase (idursulfase; Elaprase™) for MPS II. For example, a reduction in hepatic lysosomal storage was observed with laronidase, while an improvement in walking and stair-climbing abilities were observed with galsulfase[28].

Since 1981, bone marrow transplants have been attempted with varying degrees of success. More recently, results of allogeneic hematopoietic stem cell transplants and cord-blood transplants from unrelated donors have been more encouraging, particularly in patients with MPS I H, II, III and VI.

49 Porphyria

Jorge Frank and Pamela A Poblete-Gutiérrez

Key features

- The porphyrias result from dysfunction of enzymes involved in heme biosynthesis
- The different types can be classified into either acute versus non-acute or cutaneous versus non-cutaneous forms
- Cutaneous symptoms exclusively involve sun-exposed areas of the body
- Life-threatening neurologic attacks can occur in the acute porphyrias
- Diagnosis of specific types of porphyria may at times be difficult because clinical symptoms are often nonspecific and biochemical findings can overlap
- The genetic bases of the porphyrias have been well characterized, facilitating accurate molecular diagnosis and genetic counseling

INTRODUCTION

The porphyrias are metabolic disorders, each arising from a predominantly hereditary deficiency of one of the eight enzymes of the porphyrin-heme biosynthetic pathway (Fig. 49.1)[1]. Traditionally, these disorders are subdivided into erythropoietic and hepatic forms, according to the major site of expression of the enzyme deficiency. From a dermatologist's perspective, the porphyrias can be classified into cutaneous versus non-cutaneous forms (Table 49.1). However, from a general clinician's point of view, it is more appropriate to classify the porphyrias into acute and non-acute forms, thereby emphasizing the presence or absence of potentially life-threatening acute neurologic attacks (Table 49.2)[2]. Therefore, we will adhere to the latter classification throughout this chapter.

The porphyrias are of particular dermatologic interest because most forms have distinct cutaneous manifestations that allow a presumptive diagnosis. Laboratory tests are then used to confirm the suspected diagnosis. The genetic defects underlying the porphyrias have been well characterized (Table 49.3), facilitating molecular diagnosis and genetic counseling for affected families.

HISTORY

In 1874, Schultz described a man with a history of cutaneous photosensitivity, accompanied by the excretion of wine-red urine[3]. Subsequently, Baumstark detected urinary pigments, which he named "urorubrohaematin" and "urofuscohaematin"[4]. Günther established the first classification of the porphyrias in 1911, recognizing them as hereditary metabolic disorders characterized by increased porphyrin excretion. He distinguished between two different forms: (1) haematoporphyria acuta, characterized by acute neurovisceral attacks without skin lesions; and (2) haematoporphyria congenita and chronica, both disorders having cutaneous findings in sun-exposed areas of the body[5]. In 1937, the terms "acute intermittent porphyria" and "porphyria cutanea tarda" were introduced. Over the next four decades, variegate porphyria (in 1953), hereditary coproporphyria (in 1955), erythropoietic protoporphyria (in 1961), hepatoerythropoietic porphyria (in 1969) and δ-aminolevulinic acid (ALA) dehydratase deficiency porphyria (in 1979) were described[6]. Most recently, X-linked dominant protoporphyria was recognized[7].

EPIDEMIOLOGY

The porphyrias are rare disorders, occurring in all races and both sexes. Whereas some forms appear during infancy, other variants usually do not present until puberty or adulthood. Prevalence rates vary from 0.1 to 10 per 100 000 individuals (see Table 49.2)[1]. However, the precise prevalence of the various porphyrias is not known, due primarily to geographic differences, the likelihood of underdiagnosis, and the incomplete penetrance of the dominantly inherited porphyrias.

PATHOGENESIS

Mutations in any of the genes encoding the enzymes in the heme biosynthetic pathway can lead to a pathologic accumulation and measurable excretion of porphyrins and/or porphyrin precursors, as a result of enzyme dysfunction[1]. Except for patients with acquired porphyria cutanea tarda, all forms of porphyria are inherited as monogenetic traits (see Table 49.3).

Cutaneous Findings

To date, no single factor can explain the photosensitization evoked by porphyrins plus UV radiation. Nonetheless, there are a number of cellular and soluble factors that are thought to be involved, among them reactive oxygen species, particular cell types (e.g. erythrocytes, mast cells, polymorphonuclear cells, fibroblasts), and soluble mediators (e.g. components of the complement system or factor XII-dependent pathways, eicosanoids), as well as matrix metalloproteinases[6]. Most likely, interactions between these factors contribute to the development of cutaneous lesions. Porphyrins absorb light energy intensely in the Soret band (major absorption peak between 400 and 410 nm). As a result, they enter into an excited state and can then transfer this absorbed energy to oxygen molecules, thus creating reactive oxygen species. Cellular and tissue damage induced by photoactivated porphyrins is believed to result primarily from the formation of reactive singlet oxygen and free radicals, with subsequent lipid peroxidation and protein cross-linking[8,9]. The type of cellular damage depends on the solubility and tissue distribution of the porphyrins. Accumulation of water-soluble uro- and coproporphyrins leads to blistering, as is seen in most of the cutaneous porphyrias (e.g. porphyria cutanea tarda, variegate porphyria). In contrast, accumulation of lipophilic protoporphyrins leads to an immediate cutaneous burning sensation after exposure to the appropriate wavelengths of light, accompanied by erythema and edema, as is seen in erythropoietic protoporphyria[9].

Acute Porphyric Attack

Two porphyria variants, acute intermittent porphyria and ALA dehydratase deficiency porphyria, are not associated with cutaneous findings. The dysfunctional enzymes in these two porphyrias act early in heme biosynthesis, and their substrates, ALA and porphobilinogen (PBG), are non-phototoxic porphyrin precursors (see Fig. 49.1). However, both acute intermittent porphyria and ALA dehydratase deficiency

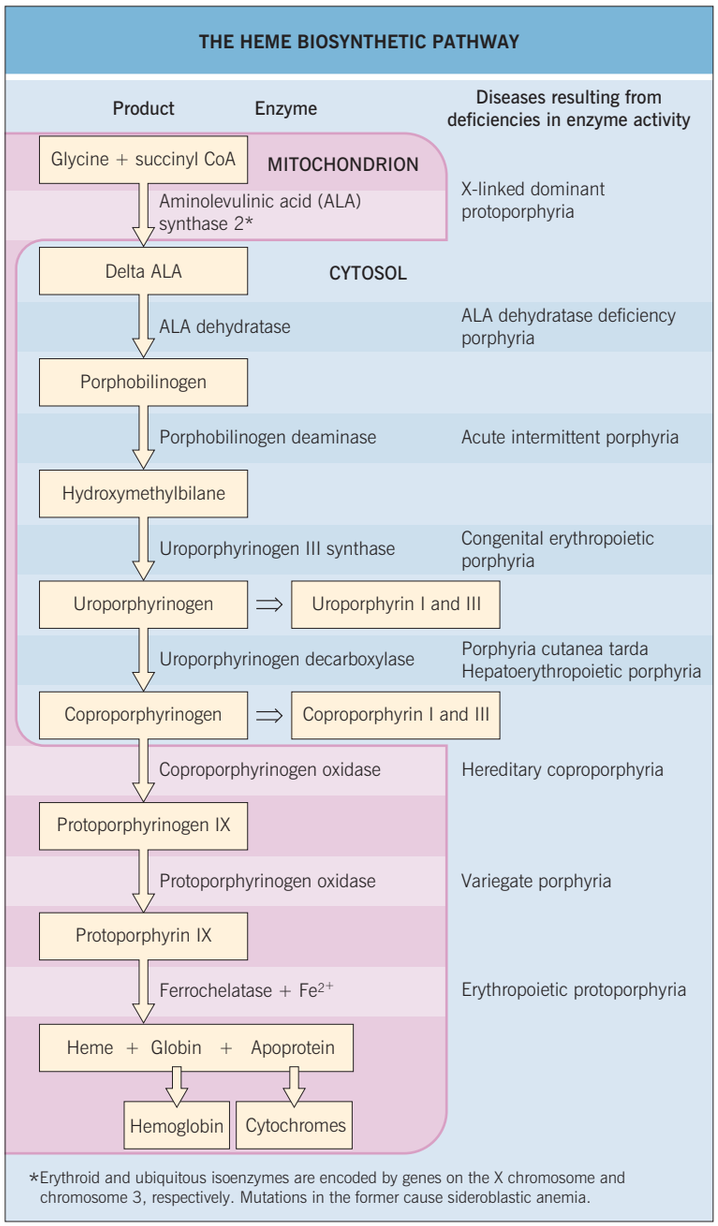

Fig. 49.1 The heme biosynthetic pathway. ALA, aminolevulinic acid. δ-aminolevulinic acid is also referred to as 5-aminolevulinic acid.

CLASSIFICATION OF THE PORPHYRIAS INTO CUTANEOUS AND NON-CUTANEOUS FORMS

Cutaneous	Non-cutaneous
Porphyria cutanea tarda	Acute intermittent porphyria
Erythropoietic protoporphyria	ALA dehydratase deficiency porphyria
Variegate porphyria	
Hereditary coproporphyria	
Congenital erythropoietic porphyria	
Hepatoerythropoietic porphyria	
X-linked dominant protoporphyria	

Table 49.1 Classification of the porphyrias into cutaneous and non-cutaneous forms. ALA, aminolevulinic acid.

porphyria can manifest with life-threatening acute neurologic attacks (see Table 49.2). It appears that ALA and PBG, which are excreted in massive amounts from the liver during an acute attack, are extremely neurotoxic. Lacking appropriate barrier protection, the autonomic and peripheral nervous systems are particularly susceptible to the toxic effects[10].

Of note, porphyrin abnormalities are also observed in the setting of lead poisoning, sideroblastic and hemolytic anemia, iron deficiency, renal failure, cholestasis, liver disease and gastrointestinal hemorrhage. However, associated photosensitivity has only been documented in rare cases of sideroblastic anemia[6].

CLINICAL AND LABORATORY INVESTIGATION

In establishing the diagnosis of a specific type of porphyria, the medical evaluation involves up to four steps:

- a thorough clinical assessment that includes a family history and physical examination, with particular reference to sun-exposed sites
- biochemical measurement of porphyrins and porphyrin precursors in urine, feces, blood and/or plasma (Table 49.4)
- determination of the activity of specific enzymes (specialized laboratories)
- DNA mutational analysis (specialized laboratories).

Difficulties in obtaining a definitive diagnosis are primarily a result of the different types of porphyria having overlapping clinical and/or biochemical features (Fig. 49.2). This is especially true of variegate porphyria and hereditary coproporphyria, which may present with cutaneous lesions similar to those observed in porphyria cutanea tarda and/or neurologic and visceral findings resembling those encountered in acute intermittent porphyria.

With regard to biochemical analyses, markedly elevated urinary levels of the porphyrin precursors ALA and PBG can be found during an acute attack. However, asymptomatic "carriers" (who harbor mutations) are rarely detected via measurement of urinary porphyrin precursors because the latter can exhibit significant variability and levels may be only slightly elevated or even normal during the intervals between acute attacks. In addition, diagnoses based upon measurements of enzymatic activity in fibroblasts or lymphocytes are not always conclusive. This is because an overlap exists between the values obtained in patients, asymptomatic carriers, and normal control individuals[11].

Therefore, the ability to detect specific genetic mutations has made a significant impact on the precise diagnosis of porphyrias and the ability to provide accurate genetic counseling[6,10].

THE NON-ACUTE PORPHYRIAS

The non-acute porphyrias consist of porphyria cutanea tarda (PCT), erythropoietic protoporphyria (EPP), X-linked dominant protoporphyria (XLDPP), congenital erythropoietic porphyria (CEP), and hepatoerythropoietic porphyria (HEP). All these porphyrias present primarily with cutaneous findings (see Tables 49.1 & 49.2)[1,6]. While histologic examination of involved skin is not required to confirm a presumptive diagnosis of any of the cutaneous porphyrias, a biopsy specimen may have been obtained to exclude other entities in the differential diagnosis. Occasionally, the pathologist may suggest the diagnosis of a cutaneous porphyria (based upon histologic findings) even though the clinician suspected another disorder, e.g. epidermolysis bullosa acquisita.

Porphyria Cutanea Tarda (PCT)

Worldwide, PCT is the most common type of porphyria. It results from decreased catalytic activity of uroporphyrinogen decarboxylase, the fifth enzyme in heme biosynthesis (see Fig. 49.1)[1,6].

At least two types of PCT can be distinguished: (1) a sporadic (acquired) variant, designated type I PCT, in which the dysfunctional enzyme is exclusively expressed in the liver; and (2) an autosomal dominant familial (hereditary) variant, designated type II PCT, in which the catalytic enzymatic defect is detected in all tissues (see Table 49.3). In most countries, the ratio of type I to type II PCT is currently estimated to be approximately 3:1 to 4:1[12]. Interestingly, Elder[13] reported several families with typical clinical and biochemical features of overt PCT but with normal uroporphyrinogen decarboxylase activity in their red blood cells. This variant of the disease has been designated type III PCT.

CLASSIFICATION OF THE PORPHYRIAS INTO ACUTE AND NON-ACUTE FORMS			
	Incidence	**Age of onset**	**Important aspects**
ACUTE PORPHYRIAS			
Acute intermittent porphyria	0.5–1 per 100 000	Second to fourth decade of life; rarely before puberty	Most common acute porphyria in the world; acute neurologic attacks but no photosensitivity/cutaneous manifestations
Variegate porphyria	~1 per 300 in South Africa; relatively rare elsewhere	Second to third decade of life; usually not before puberty	Cutaneous manifestations similar to porphyria cutanea tarda, and acute attacks similar to acute intermittent porphyria can occur (neurocutaneous porphyria); founder mutations identified in South Africa and Chile
Hereditary coproporphyria	Very rare (<75 cases reported)	Usually not before puberty	Acute attacks similar to acute intermittent porphyria, and cutaneous manifestations including erythema and blistering in sun-exposed areas can occur (neurocutaneous porphyria)
ALA-D deficiency porphyria	Extremely rare (<10 cases reported)	Early and late onset have been described	Neurologic symptoms similar to acute intermittent porphyria can occur; no photosensitivity/cutaneous manifestations
NON-ACUTE PORPHYRIAS			
Porphyria cutanea tarda	Most common porphyria worldwide	Third to fourth decade of life; usually not before puberty	Acquired and hereditary variants exist; moderate to severe photosensitivity; cutaneous findings in sun-exposed areas include skin fragility, erosions, crusts, vesicles and bullae, milia, scarring, hyperpigmentation and hypertrichosis; indistinguishable from variegate porphyria
Erythropoietic protoporphyria	Second-highest incidence of the cutaneous porphyrias	Early childhood (1 to 4 years); late onset extremely rare	Cutaneous manifestations include erythema, edema, crusts, purpura, skin thickening, and waxy scars, primarily on the dorsal hands and face; usually no blistering; in ~5% of patients, severe liver disease can occur; cholelithiasis; palmar keratoderma in rare AR form
Congenital erythropoietic porphyria	Very rare (~170 cases reported)	Infancy/first decade of life	Very severe clinical course; in sun-exposed sites, vesicles and bullae, erosions, ulcerations, crusts, milia, scarring, hyperpigmentation and hypertrichosis; mutilation; hemolytic anemia; hepatosplenomegaly; porphyrin deposition in bones and teeth (erythrodontia); pink, red or violet staining of diapers
Hepatoerythropoietic porphyria	Extremely rare (~35 cases reported)	Early infancy	Recessive variant of porphyria cutanea tarda; markedly increased photosensitivity and severe clinical course possible; in sun-exposed sites, vesicles and bullae, skin fragility, erosions, crusts, milia, scarring and hypertrichosis; mutilation can occur; diapers stained by darkly colored urine
X-linked dominant protoporphyria	Very rare	Early childhood	Skin symptoms indistinguishable from erythropoietic protoporphyria; most recent type of porphyria to be recognized; liver disease appears to occur more frequently than in erythropoietic protoporphyria

Table 49.2 Classification of the porphyrias into acute and non-acute forms. Important clinical and epidemiological aspects are highlighted. ALA-D, aminolevulinic acid dehydratase; AR, autosomal recessive.

GENETIC ASPECTS OF THE PORPHYRIAS			
	Gene locus	**Protein product and gene symbol**	**Mode of inheritance**
ACUTE PORPHYRIAS			
Acute intermittent porphyria	11q23.3	Porphobilinogen deaminase; *PBGD*	AD
Variegate porphyria	1q22–23	Protoporphyrinogen oxidase; *PPOX*	AD
Hereditary coproporphyria	3q12	Coproporphyrinogen oxidase; *CPO*	AD
ALA-D deficiency porphyria	9q34	δ-Aminolevulinic acid dehydratase; *ALAD*	AR
NON-ACUTE PORPHYRIAS			
Porphyria cutanea tarda	1p34	Uroporphyrinogen decarboxylase; *UROD*	AD (up to 25% of cases); otherwise acquired
Erythropoietic protoporphyria	18q21.3	Ferrochelatase; *FECH*	AD*; rarely, AR
Congenital erythropoietic porphyria	10q25.2–q26.3	Uroporphyrinogen III synthase; *UROS*	AR
Hepatoerythropoietic porphyria	1p34	Uroporphyrinogen decarboxylase; *UROD*	AR
X-linked dominant protoporphyria	Xp11.21	δ-Aminolevulinic acid synthase 2; *ALAS2*	XLD

*Actually semi-dominant inheritance with a mutation in one allele and a specific intronic polymorphism in the second allele ("hypomorphic" allele; see text).

Table 49.3 Genetic aspects of the porphyrias. ALA-D, aminolevulinic acid dehydratase; AD, autosomal dominant; AR, autosomal recessive; XLD, X-linked dominant.

CHARACTERISTIC BIOCHEMICAL FINDINGS IN THE PORPHYRIAS											
Type of porphyria	**Urine**				**Feces**			**Erythrocytes**			**Plasma**

†Approximately 40% zinc protoporphyrin.

Table 49.4 Characteristic biochemical findings in the porphyrias. In patients with variegate porphyria or hereditary coproporphyria who have no symptoms (cutaneous or systemic), urine porphyrins may not be elevated (shaded areas). ALA, aminolevulinic acid; ALA-D, aminolevulinic acid dehydratase; COPRO, coproporphyrin; ISOCOPRO, isocoproporphyrin; PBG, porphobilinogen; PROTO, protoporphyrin; URO, uroporphyrin. N = normal; NA, not available; + = above normal range; ++ = slightly elevated; +++ = highly elevated; ++++ = very highly elevated; ↑ = increase.

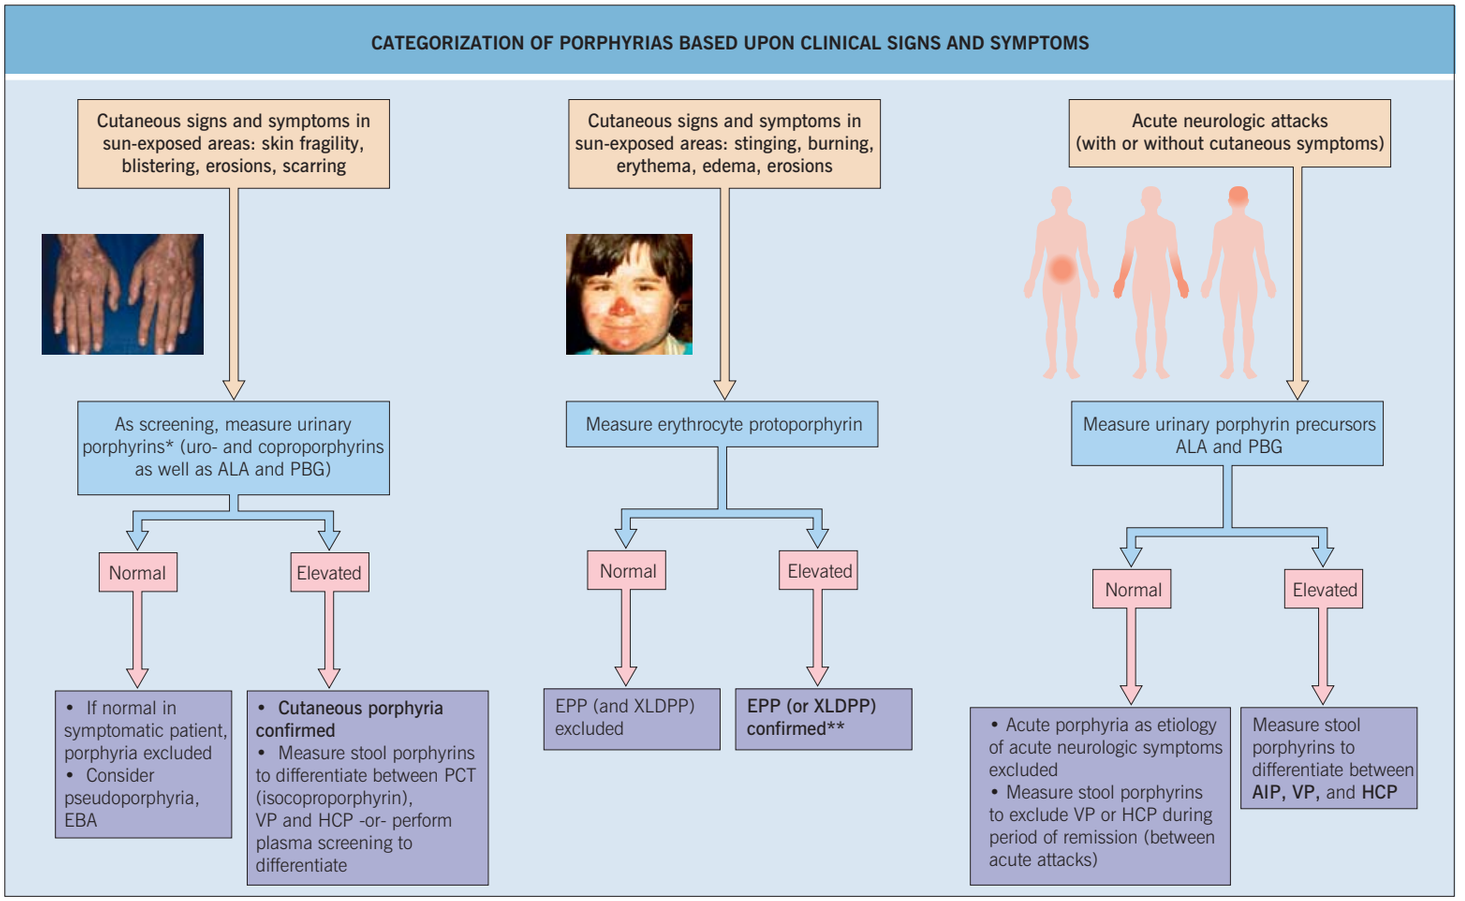

Fig. 49.2 Categorization of porphyrias based upon clinical signs and symptoms. AIP, acute intermittent porphyria; ALA, aminolevulinic acid; EBA, epidermolysis bullosa acquisita; EPP, erythropoietic protoporphyria; HCP, hereditary coproporphyria; PBG, porphobilinogen; VP, variegate porphyria; XLDPP, X-linked dominant protoporphyria. *24-hour collection. **To confirm diagnosis of XLDPP, measure zinc-chelated protoporphyrin.

Fig. 49.3 Porphyria cutanea tarda. A Marked fragility with multiple hemorrhagic crusts, erosions and milia as well as scars. **B** Flaccid hemorrhagic bulla and tense vesicle with clear fluid on the forefinger, accompanied by crusts and scars.

Fig. 49.4 Porphyria cutanea tarda. Hypertrichosis of the malar region of the cheek. *Courtesy, Judit Stenn, MD.*

Fig. 49.5 Porphyria cutanea tarda presenting as yellow–brown morpheaform plaques. The plaques were in sun-exposed areas in this patient with a history of alcohol abuse.

Indeed, there is increasing evidence that some facets of the etiology of PCT have yet to be completely elucidated.

The cutaneous manifestations of PCT include increased photosensitivity and skin fragility as well as blistering, erosions, crusts, milia and scars in sun-exposed sites (Fig. 49.3; see Table 49.2). Additionally, postinflammatory hyperpigmentation, hypertrichosis (Fig. 49.4), scarring alopecia, and morpheaform and sclerodermoid changes (Fig. 49.5) can be observed.

Histologic examination of vesiculobullae commonly reveals subepidermal cell-poor blisters with a characteristic festooning of dermal papillae; the latter is most likely due to the deposition of PAS-positive glycoproteins in and around the wall of vessels localized in the upper dermis (Fig. 49.6). Direct immunofluorescence microscopy often demonstrates immunoglobulins (mainly IgG; less commonly IgM), complement and fibrinogen at the dermal–epidermal junction and around blood vessels of the papillary dermis. In sclerotic lesions, there is dermal fibrosis as well as PAS-positive deposits around blood vessels.

Biochemically, increased urinary excretion of uroporphyrin (type I isomers > type III isomers), hepta-carboxylated porphyrins (type III isomers > type I isomers), and coproporphyrin can be detected, as well as increased excretion of isocoproporphyrin in the feces; the latter finding being exclusive to PCT and hepatoerythropoietic porphyria. Historically, a presumptive clinical diagnosis of PCT was followed by an examination of the patient's urine, both under Wood's lamp illumination (in the dark) and after exposure to natural light. Due to the excessive excretion of porphyrins, the urine of PCT patients turns red to brown after several hours of exposure to natural light and it has a pink to red fluorescence when exposed to a UVA light source. However, it has to be borne in mind that these bedside observations are neither sensitive nor specific diagnostic tests.

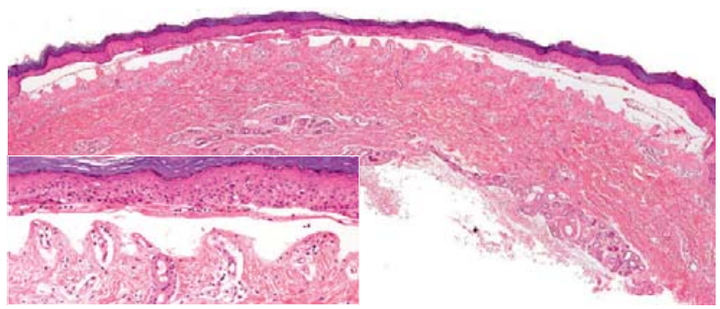

Fig. 49.6 Porphyria cutanea tarda – histologic features. Subepidermal blister of acral skin with a minimal ("cell-poor") dermal inflammatory infiltrate. Festooning of the dermal papillae is seen (insert). *Courtesy, Lorenzo Cerroni, MD.*

A wide variety of triggering factors (including hepatotoxins) have been reported to precipitate the clinical manifestations of PCT, among them alcohol, estrogens, polychlorinated hydrocarbons, dialysis in patients with renal failure, iron, inheritance of specific mutations in the *HFE* gene which underlie classic hemochromatosis, and viral infections such as hepatitis C and HIV. Interestingly, homozygosity for the *HFE* gene mutation C282Y has been found to be associated with an earlier onset of disease in both sporadic and familial PCT, with the effect being more marked in familial PCT[14]. PCT patients appear to have a higher risk of developing hepatocellular carcinoma[1,6].

Erythropoietic Protoporphyria (EPP)

EPP is due to a semi-dominantly inherited deficiency of ferrochelatase, the last enzyme in the heme biosynthetic pathway (see Fig. 49.1)[1,6].

Clinically, EPP is characterized by cutaneous photosensitivity that manifests early in life, i.e. during early childhood. Acute photosensitivity episodes are characterized by intense burning, stinging and pruritus of sun-exposed skin, particularly on the nose, cheeks and dorsal aspects of the hands, followed by erythema, edema, crusts, petechiae and then wax-like scarring (Figs 49.7 & 49.8; see Table 49.2). Skin symptoms can occur within minutes of sun exposure, often starting early in the springtime, continuing throughout the summer, and diminishing during fall and winter. Window glass does not protect the patient. Patients suffering from EPP often report that the only way to relieve the burning and stinging sensations is to cool the affected skin under cold water. In patients with EPP who have not had recent sun exposure, the only detectable cutaneous findings may be scars on the nose and lips (see Fig. 49.8). In rare patients with recessively inherited EPP, palmar keratoderma can be seen[15].

Histologically, vacuolization of epidermal cells is seen in acute lesions. Intercellular edema may also be present, as well as vacuolization and lysis of endothelial cells within superficial dermal blood vessels. In older lesions (e.g. areas of waxy scarring), eosinophilic PAS-positive deposits are observed around blood vessels (Fig. 49.9). There can be a resemblance to the amorphous protein depositions seen in lipoid proteinosis. Ultrastructurally, thickening and degeneration of capillary basement membranes is seen.

Biochemically, EPP is characterized by an increase in free protoporphyrin levels in erythrocytes, plasma, feces, and other tissues such as the liver (see Table 49.4)[1,6]. Historically, microscopic examination of a blood smear via UV illumination was performed to detect erythrocyte fluorescence. However, this test is not particularly sensitive or specific. The greatest concern in patients with EPP is a rapid accumulation of protoporphyrin within the liver and biliary system, with the development of cholestasis. This can lead to hepatic damage and progressive (even fatal) liver failure. Of note, liver function tests may remain normal until late in the course of the disease[16].

The genetic basis for the development of cutaneous symptoms in EPP has been elucidated. Only those individuals who inherit a heterozygous ferrochelatase gene mutation involving one parental allele (allele A) *and* a specific intronic polymorphism (IVS3–48T/C) of the other parental allele (allele B) develop skin symptoms. This latter specific polymorphism *in trans* constitutes a "hypomorphic" allele and leads to abnormal modulation of splicing. As a result, the aberrantly spliced mRNA is degraded by a nonsense-mediated decay mechanism, producing a decreased steady-state level of mRNA. Combined, a mutation in allele A plus the polymorphism in allele B lead to a marked reduction in ferrochelatase activity that is ~15–25% of normal[17].

Certainly, the identification of the molecular mechanisms underlying the photosensitivity observed in EPP has to be considered a milestone in porphyria research. Still, the development of protoporphyrin-induced hepatic disease and the molecular mechanisms underlying the phenotype associated with severe liver injury are not yet well understood.

Fig. 49.7 Erythropoietic protoporphyria. Erythema, edema and hemorrhagic crusts on the nose as well as the fingers in a young girl.

X-linked Dominant Protoporphyria (XLDPP)

XLDPP is characterized by a deficiency of the erythroid tissue-specific isoform of the first enzyme in the heme biosynthetic pathway, δ-aminolevulinic acid synthase 2. It is encoded by the *ALAS2* gene on the X chromosome.

Fig. 49.8 Erythropoietic protoporphyria. Subtle scarring on the nose and linear scars on the upper cutaneous lip in a 6-year-old child. *Courtesy, Gillian Murphy, MD.*

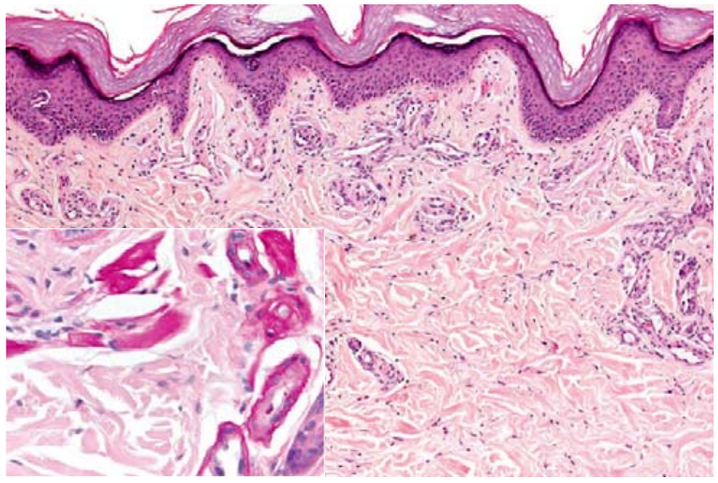

Fig. 49.9 Erythropoietic protoporphyria – histologic features. Eosinophilic deposits around blood vessels are more pronounced than in porphyria cutanea tarda. These deposits are highlighted by a PAS stain (insert). *Courtesy, Lorenzo Cerroni, MD.*

Clinically, this variant of protoporphyria is indistinguishable from EPP. However, the percentage of patients at risk for potentially fatal liver disease appears to be higher than in classic EPP. Biochemical profiling demonstrates higher total protoporphyrin levels in erythrocytes (as compared to EPP due to ferrochelatase deficiency), with approximately 40% being zinc-protoporphyrin[7].

Congenital Erythropoietic Porphyria (CEP)

Synonym: ■ Günther disease

With approximately 170 cases reported to date, CEP is a very rare, autosomal recessively inherited disorder that results from markedly decreased catalytic activity of uroporphyrinogen III synthase, the fourth enzyme in heme biosynthesis (see Fig. 49.1). CEP manifests shortly after birth with severe cutaneous photosensitivity, blistering, erosions, crusts and ulcerations, followed by extensive scarring and deformation, primarily of the hands (Fig. 49.10A; see Table 49.2). On the face, a loss of eyebrows and eyelashes, as well as severe mutilation of cartilaginous structures (e.g. the nose), are frequently observed. Furthermore, erythrodontia (Fig. 49.10B), acro-osteolysis and skeletal abnormalities (e.g. demineralization) are common clinical features. In addition, a variable degree of hematologic involvement, ranging from mild forms of hemolytic anemia to intrauterine hydrops fetalis and hepatosplenomegaly, can be observed. Pink, red or violet staining of diapers can serve as an early clue to the diagnosis. Biochemically, there is increased urinary excretion of uroporphyrin I and coproporphyrin I plus elevated levels of coproporphyrin I in the stool (see Table 49.4)[18].

Hepatoerythropoietic Porphyria (HEP)

HEP, the homozygous (or compound heterozygous) variant of hereditary PCT, is an extremely rare disease that is due to a pronounced decrease in uroporphyrinogen decarboxylase activity (see Table 49.3). Clinically, HEP usually presents during early childhood, with dark urine in the diapers often the initial clinical finding. Subsequently, severe cutaneous photosensitivity develops, associated with blistering, pruritus, hypertrichosis, hyperpigmentation and scleroderma-like scarring (Fig. 49.11; see Table 49.2). If the clinical course is severe, the symptoms closely resemble those observed in CEP. However, unlike the latter, HEP is not usually associated with hematologic abnormalities (e.g. severe anemia).

Urinary levels of uroporphyrin and hepta-carboxylated porphyrins are elevated, as are fecal levels of coproporphyrin and isocoproporphyrin. Increased levels of zinc-chelated protoporphyrin within erythrocytes can also be seen (see Table 49.4)[1,19].

Pseudoporphyria

Pseudoporphyria (also referred to as pseudoporphyria cutanea tarda or bullous dermatosis of dialysis) encompasses those conditions that closely resemble PCT. However, in contrast to PCT, no biochemical abnormalities in porphyrin metabolism are detected (see Fig. 49.2). Skin fragility, erosions, blisters, and scarring have a predilection for the dorsal aspect of the hands (Fig. 49.12), the face, and the extensor surfaces of the legs. Pseudoporphyria is commonly encountered in patients suffering from chronic renal insufficiency or in those undergoing renal dialysis (hemodialysis more often than peritoneal dialysis). It is also seen in association with the ingestion of specific drugs, including

*When caused by NSAIDs, consider prescribing diclofenac, indomethacin or sulindac.

Table 49.5 Drug-induced pseudoporphyria. The most common causes are in bold. NSAID, nonsteroidal anti-inflammatory drug. *Courtesy, Misty Sharp, MD.*

nonsteroidal anti-inflammatory drugs (e.g. naproxen, nabumetone, ketoprofen), furosemide, antibiotics (e.g. nalidixic acid, tetracycline) and retinoids (Table 49.5), and it can occur in association with the use of tanning beds. In the latter situation, vesicles may be seen on the palms.

Histologic findings are indistinguishable from those found in lesions of PCT. Patients who require renal dialysis may develop PCT or pseudoporphyria. Even if they are anuric, it is important to remember that the diagnosis of PCT can be established via plasma or stool studies (see Table 49.4). Treatment is easier for drug-induced pseudoporphyria, as the major recommendation is discontinuation of exposure to the suspected precipitant[20]. Sun protection is advised for all patients.

Differential Diagnosis

PCT must be distinguished from other types of cutaneous porphyria that manifest with blistering. These include mild variants of CEP and HEP and importantly (since they can be associated with life-threatening acute attacks), VP and HCP. Furthermore, pseudoporphyria (see above), epidermolysis bullosa acquisita, polymorphous light eruption, and phototoxic and bullous drug eruptions have to be excluded. All aforementioned diseases can easily be differentiated from PCT by porphyrin analysis[1,6,14,21]. If no porphyrin abnormalities are detected, histologic examination of lesional skin (routine and immunofluoresence) can aid in establishing the diagnosis.

In ***EPP***, the differential diagnosis consists of solar urticaria, phototoxic or photoallergic contact dermatitis and drug reactions, polymorphous light eruption, hydroa vacciniforme and lipoid proteinosis[1,6,15,21].

CEP has to be differentiated from HEP and the rare homozygous (or compound heterozygous) variants of VP and HCP. Mild variants can sometimes mimic PCT. Likewise, the most important entities in the differential diagnosis of ***HEP*** are CEP and the rare aforementioned homozygous variants of VP and HCP.

Treatment

A causal therapeutic strategy would consist of either enzyme replacement therapy or gene therapy. However, such therapeutic modalities are not currently available.

The avoidance of UV light exposure, sun-protective clothing, and regular application of broad-spectrum sunscreens are crucial, both prophylactically and therapeutically. Because the wavelengths that induce the porphyrias are in the 400–410 nm range, sunscreens are limited in their therapeutic effectiveness, with the exception of titanium dioxide and zinc oxide (see Ch. 132).

Patients with PCT should be encouraged to eliminate triggering factors such as alcohol ingestion and estrogen therapy. In patients with iron overload, successful treatment can be achieved by repeated phlebotomy (venesection) of approximately 500 ml blood every 2 weeks, as tolerated by the patient; some authors recommend weekly venesections of 300 ml blood. When required, maintenance phlebotomy is performed at less frequent intervals.

Therapeutic phlebotomy reduces iron stores, thereby improving heme synthesis by reducing iron-induced inhibition of uroporphyrinogen decarboxylase activity. While the therapeutic goal is to reduce serum ferritin levels to the lower limit of the reference range, care should be taken to not induce anemia. Phlebotomy usually leads to resolution of skin fragility and blistering within 2–4 months. However, normalization of urinary porphyrin concentrations will usually take longer (about 12 months).

Another therapeutic option is low-dose hydroxychloroquine or chloroquine. These antimalarials are thought to work by accelerating the secretion of porphyrins, and they may also inhibit porphyrin synthesis. Standard therapy consists of 200 mg of hydroxychloroquine or 125 mg of chloroquine *twice weekly*, and complete remission can be expected within 6–9 months (Table 49.6). Administration of higher doses of these antimalarials (as are used in cutaneous lupus erythematosus) can lead to hepatotoxicity. The antimalarials can be used in combination with phlebotomy to induce a remission more rapidly[1,6,15].

The genetic background of PCT patients, with respect to the presence of *HFE* gene mutations, appears to play a critical role in the outcome of chloroquine or hydroxychloroquine treatment. Whereas heterozygosity for mutation C282Y and compound heterozygosity for *HFE* mutations did not compromise the therapeutic response, PCT patients homozygous for C282Y failed to respond to antimalarial therapy and retained high serum iron and ferritin levels as well as transferrin saturation[22].

In some patients with EPP, β-carotene minimizes burning, stinging and photosensitivity reactions. Although β-carotene has no effect on the protoporphyrin levels in erythrocytes, it reduces photosensitivity by quenching the formation of free radicals that occurs during the cutaneous photoreaction. The administered doses range from 30 to 90 mg/day in children and from 60 to 180 mg/day in adults, with desired maximum plasma levels of 600–800 mcg/dl. In five patients treated with afamelanotide ([Nle^4, $D\text{-}Phe^7$]-α-MSH; 20 mg every 60 days as a resorbable implant) in an open-label study, increased tolerance to artificial light (11×) was observed at day 120[23]. Afamelanotide has been designated an orphan drug for the treatment of EPP. Single reports of cysteine therapy or narrowband UVB phototherapy exist, but the usefulness of these treatments has not been demonstrated convincingly. Cholestyramine or charcoal can be considered in order to reduce enterohepatic recirculation of porphyrins and bile acids. Overall, current therapeutic options for EPP are more limited than for PCT[1,6,10,15].

Patients with CEP require surveillance for anemia and skin infections. Frequent blood transfusions can suppress erythropoiesis, thereby decreasing porphyrin production and photosensitivity. Concomitant administration of deferoxamine or deferasirox can reduce the resulting iron overload. Bone marrow or hematopoietic stem cell transplantation leads to marked reduction of porphyrin levels and photosensitivity and has been reported to be curative[1,10,18].

No specific treatment options are currently available for patients with HEP and XLDPP. Careful patient education regarding sun protection is very important.

THERAPEUTIC APPROACHES TO THE ACUTE AND NON-ACUTE PORPHYRIAS	
Acute porphyrias	**Therapy strategies**
Acute intermittent porphyria; variegate porphyria; hereditary coproporphyria; ALA-dehydratase deficiency porphyria	**Acute attacks** 1. Identification and elimination of precipitating factors (porphyrinogenic drugs; alcohol; hormones) 2. Monitoring in intensive care unit and input from porphyria specialists 3. Adequate pain therapy, e.g. with opioid analgesics 4. Adequate therapy of nausea and vomiting, e.g. with promethazine, ondansetron 5. Intravenous administration of either: (1) heme arginate (Normosang®; Europe only), 3 mg/kg once daily for 4 consecutive days; or (2) hemin (Panhematin®; FDA-approved), usually 1–4 mg/kg/day (over 10–15 min) for 3–14 days *versus* 3-4 mg/kg once daily for 4 days with more extended treatment for severe cases 6. If necessary, until heme preparations become available, intravenous glucose infusions 7. Measurement of urinary porphyrin excretion during the acute attack (daily, if possible) **Cutaneous symptoms (variegate porphyria; hereditary coproporphyria)** 1. Photoprotection, e.g. broad-spectrum sunscreens and/or protective clothing 2. Avoidance of sunlight exposure and trauma
Non-acute porphyrias	**Therapy strategies**
Porphyria cutanea tarda	1. Photoprotection, e.g. broad-spectrum sunscreens and/or protective clothing 2. Avoidance of sunlight exposure and trauma 3. Cease alcohol ingestion; stop estrogen therapy 4. Phlebotomy: 400–500 ml every 2 weeks over ~3–6 months 5. Low-dose hydroxychloroquine or chloroquine: 200 mg or 125 mg twice weekly (e.g. on Monday and Thursday), respectively, over 6–12 months, until porphyrin excretion is within normal range 6. Measurement of urinary porphyrin excretion to monitor therapeutic outcome
Erythropoietic protoporphyria/ X-linked dominant protoporphyria	1. Photoprotection, e.g. broad-spectrum sunscreens and/or protective clothing 2. Avoidance of sunlight exposure (common window glass does not provide protection) 3. Oral β-carotene: 30–90 mg/day in children; 60–180 mg/day in adults. Desirable maximum plasma level: 600–800 mcg/dl. Administration during the spring, summer and fall, with a hiatus during the winter in higher latitudes 4. Afamelanotide ([Nle^4, D-Phe^7]-α-MSH; 20 mg every 60 days as a resorbable implant) may increase tolerance to light exposure 5. Consider cholestyramine or charcoal to reduce enterohepatic recirculation of porphyrins and bile acids in order to enhance hepatic porphyrin excretion; results vary
Congenital erythropoietic porphyria	1. Photoprotection, e.g. broad-spectrum sunscreens and/or protective clothing 2. Strict avoidance of sunlight exposure 3. Change day–night rhythm 4. Splenectomy (reduces hemolysis and platelet consumption) 5. Bone marrow or hematopoietic stem cell transplantation
Hepatoerythropoietic porphyria	1. Photoprotection, e.g. broad-spectrum sunscreens and/or protective clothing 2. Strict avoidance of sunlight exposure and trauma 3. Change day–night rhythm 4. Of note, therapeutic approaches used in porphyria cutanea tarda (e.g. phlebotomy, antimalarials) are not effective

Table 49.6 Therapeutic approaches to the acute and non-acute porphyrias. While the therapeutic measures for an acute porphyric attack are the same for each of the acute porphyrias, different treatment strategies are recommended for each of the non-acute porphyrias, depending upon the prevailing manifestations and the respective form of porphyria. ALA, aminolevulinic acid.

THE ACUTE PORPHYRIAS

The acute porphyrias consist of acute intermittent porphyria (AIP), variegate porphyria (VP), hereditary coproporphyria (HCP), and δ-aminolevulinic acid dehydratase (ALA-D) deficiency porphyria (see Tables 49.1 & 49.2)[2,6].

Patients with acute porphyrias can present with a broad range of clinical findings, including persistent colicky abdominal pain, nausea and vomiting, obstipation, tachycardia, hypertension, seizures, paresthesias, para- and tetraplegia, and acute psychosis (Table 49.7). Unfortunately, this spectrum of fairly nonspecific symptoms can mimic a number of other diseases and the porphyrias are often not included in the differential diagnosis, especially if neurologic symptoms prevail[2,24]. Acute attacks can be precipitated by a variety of factors, including porphyrinogenic drugs (e.g. antimalarials, tetracyclines, sulfonamides), alcohol, hormonal changes, recurrent or chronic infections, and reduced caloric intake due to fasting or diets. The latter may be a result of enhanced expression of the transcriptional coactivator PGC-1α[25].

In addition to the manifestations outlined in Table 49.7, patients with VP and HCP may have cutaneous findings that are clinically indistinguishable from those of PCT. As a result, VP and HCP are also referred to as neurocutaneous porphyrias[1,2].

A consortium of porphyria specialists from several European porphyria centers has recently established the European Porphyria Initiative (EPI). The goals of the EPI are to set standards and provide guidelines for the diagnosis and treatment of porphyrias. On the EPI (www.porphyria-europe.org) and the American Porphyria Foundation (www.porphyriafoundation.com) websites, important information is available for both patients and physicians.

Acute Intermittent Porphyria (AIP)

Worldwide, AIP is the most common type of acute porphyria. This autosomal dominantly inherited disorder is characterized by a deficiency of porphobilinogen deaminase, the third enzyme in heme biosynthesis (see Fig. 49.1).

AIP will not be discussed in detail here because patients do not have skin manifestations. It usually presents after puberty with acute porphyric attacks (see Table 49.7) that may be precipitated by the various trigger factors outlined above. Elevated urinary levels of the porphyrin precursors ALA and PBG can be detected during an acute attack: ALA levels range from 5 to 20 times normal and PBG levels are increased to as high as 20- to 50-fold normal[1,26].

Variegate Porphyria (VP)

Synonyms: ■ South African porphyria ■ Mixed porphyria

POSSIBLE MANIFESTATIONS OF AN ACUTE PORPHYRIC ATTACK		
Gastrointestinal and metabolic	**Neurologic**	**Cardiac and pulmonary**
Colicky abdominal pain	**Paresthesias**	**Tachycardia**
Nausea and vomiting	**Motor and sensory peripheral neuropathy (para- and tetraplegia)**	Hypertension
Constipation	Seizures	Respiratory paralysis
Obstipation	Muscle pain, back pain	
Hyponatremia	Encephalopathy	
	Paralysis	
	Anxiety	
	Acute psychosis	
	Coma	

Table 49.7 Possible manifestations of an acute porphyric attack. The more prevalent symptoms are in bold.

VP is characterized by an autosomal dominantly inherited deficiency of protoporphyrinogen oxidase, the seventh enzyme in the pathway of heme biosynthesis (see Fig. 49.1).

Cutaneous and neuropsychiatric symptoms can occur separately or simultaneously in affected individuals. Clinically, the skin findings in VP cannot be differentiated from those observed in PCT. Likewise, the acute attacks observed in VP are identical to those encountered in AIP.

During acute attacks, elevated urinary levels of ALA and PBG are encountered. However, during periods of remission, urinary ALA and PBG levels may be within normal range. Therefore, additional biochemical analyses of fecal porphyrins are mandatory in order to establish the diagnosis of VP. Elevated levels of stool protoporphyrin and coproporphyrin can be detected, with the concentration of protoporphyrin usually being higher than that of coproporphyrin. It is noteworthy that this abnormal biochemical stool profile can also be detected during periods of remission between attacks[1,27]. On the other hand, a plasma fluorescence emission peak of 624–626 nm is seen only in symptomatic patients, including those with cutaneous involvement.

Hereditary Coproporphyria (HCP)

HCP is a very rare autosomal dominantly inherited disease, characterized by a deficiency of coproporphyrinogen oxidase, the sixth enzyme in the porphyrin-heme biosynthetic pathway (see Fig. 49.1). The clinical symptoms are similar to those encountered in VP. However, in contrast to the latter, the concentrations of coproporphyrin in the stool are usually higher than those of protoporphyrin (see above)[1,28].

δ-Aminolevulinic Acid Dehydratase (ALA-D) Deficiency Porphyria

Synonyms: ■ Plumboporphyria ■ Doss porphyria

This autosomal recessively inherited porphyria variant is extremely rare. As fewer than 10 cases have been reported worldwide, ALA-D deficiency porphyria does not have an important clinical presence. The disease can present during early childhood (as well as in adulthood) with acute neurologic symptoms that resemble those encountered in AIP[1,7].

Differential Diagnosis

When patients with VP or HCP present with cutaneous manifestations, the differential diagnosis is identical to that of PCT (see above). If acute neurologic attacks prevail, a broad range of gastrointestinal, neurologic and psychiatric diseases have to be excluded, including an "acute abdomen", peripheral neuropathies and viral infections[1,2,6]. A more detailed discussion can be found in textbooks of internal medicine.

Treatment

Cutaneous symptoms

Patients with VP or HCP must minimize UV light exposure by wearing sun-protective clothing and applying broad-spectrum sunscreens. In contrast to in PCT, phlebotomy seems to be of no benefit. Although it is conceivable that chloroquine and hydroxychloroquine might be helpful in decreasing the associated photodermatoses (see PCT), these antimalarials belong to the group of drugs considered to be potential inducers of acute porphyric attacks. Thus, their use is not recommended.

Acute porphyric attack

An acute porphyric attack is a potentially life-threatening event associated with a significant mortality rate (up to 5%). It requires rapid therapeutic intervention to prevent complications such as paralysis, respiratory failure and coma. Treatment should consist of the following consecutive measures (see Table 49.6)[2].

1. Precipitating factors, e.g. porphyrinogenic drugs, must be identified and eliminated. If necessary, patients should be initially monitored in an intensive care unit.
2. Systemic symptoms such as abdominal pain, nausea and vomiting should be treated symptomatically, e.g. by administration of opioid analgesics and promethazine or ondansetron, respectively.
3. The most important therapeutic step is prompt intravenous administration of heme preparations such as heme arginate (Normosang® [Orphan Europe]) or hemin (FDA-approved; Panhematin® [Lundbeck])[29]. Heme arginate reduces the overproduction of porphyrin precursors via a negative feedback mechanism in that it represses the increased activity of the rate-limiting enzyme in heme biosynthesis, ALA synthase. Of note, heme preparations have the disadvantage of being unstable, and thrombophlebitis is a fairly common side effect[30–32].

Historically, acute attacks were treated primarily with glucose infusions. However, given the availability of effective heme preparations (see above), glucose should only be administered adjunctively or as a temporary measure if heme arginate or hematin are not immediately available.

Calcifying and Ossifying Disorders of the Skin 50

Janet A Fairley

Chapter Contents

Cutaneous calcification *729*
Cutaneous ossification (osteoma cutis) *733*

Synonyms: ■ Calcinosis cutis: cutaneous calcification ■ Osteoma cutis: cutaneous ossification ■ Calciphylaxis: calcific uremic arteriolopathy; calcifying panniculitis; uremic gangrene syndrome ■ Subepidermal calcified nodule: solitary congenital nodular calcification; Winer's nodular calcinosis

Key features

- Calcium regulates several key physiologic events in the skin, including epidermal proliferation, differentiation and cell–cell adhesion
- Disruption of normal calcium regulatory pathways can lead to calcification and/or ossification of the skin
- Four major types of cutaneous calcification are seen: dystrophic, in which pre-existing damage to the skin results in calcium deposits; metastatic, where systemic metabolic disorders lead to calcium deposits in the skin and often other tissues; iatrogenic, as a result of medical therapy or testing; and idiopathic, in which no cause can be identified
- Ossification can occur in conjunction with calcification or it may occur primarily in a number of genetic syndromes
- A careful evaluation of parameters of calcium-phosphate metabolism, combined with an assessment for associated systemic abnormalities, is necessary for the correct classification of calcifying disorders
- Therapy of calcifying disorders is difficult. Treatment of any associated disorder, such as hyperparathyroidism, is essential to prevent further calcification. Agents that modify calcium metabolism may be tried, but evidence of efficacy is often based upon case series. Surgical excision may be useful in circumscribed disease that interferes with function

INTRODUCTION

Calcium plays a vital role in regulating key physiologic events in many tissues, including the skin. In the epidermis, calcium shares in the control of major functions, including proliferation, differentiation and cell–cell adhesion. While the full range of pumps, channels and regulatory factors in the skin is still being elucidated, control of intra- and extracellular calcium concentrations and maintenance of gradients is known to be essential for its regulatory role. When factors that regulate calcium in the skin are disrupted, by either local or systemic events, the result can be cutaneous calcification or ossification as well as acantholysis and dyskeratosis.

Calcification represents the deposition of amorphous, insoluble calcium salts, while ossification is the deposition of calcium and phosphorus in a proteinaceous matrix as hydroxyapatite crystals. Ossification may follow pre-existing calcification in the skin, but in most disorders one mode of calcium deposition predominates. Each of the calcifying and ossifying disorders of the skin is rare. In aggregate, however, the finding of calcium deposition within the skin is not rare.

CUTANEOUS CALCIFICATION

Calcifying disorders of the skin are generally divided into four broad categories: dystrophic, metastatic, idiopathic and iatrogenic calcification[1]. Dystrophic calcification is calcification that occurs in the setting of localized tissue damage without systemic metabolic abnormalities in calcium regulation. Theoretically, dystrophic calcification occurs because the underlying disease process damages cell membranes, allowing calcium influx and subsequent intracellular crystallization. Alternatively, the acidity that accompanies cell damage may disrupt normal processes that inhibit calcification. In contrast, metastatic calcification occurs in normal tissue when there is dysfunction of the calcium regulatory systems. When no known local or systemic factors can be identified, the calcification is categorized as idiopathic, and that related to medical therapy or testing is iatrogenic.

DYSTROPHIC CALCIFICATION

Autoimmune Connective Tissue Disease

Autoimmune connective tissue diseases (AI-CTDs) represent some of the more common disorders in which one sees dystrophic calcification. While cutaneous calcification may be seen in any of the AI-CTDs, it is most commonly observed in the CREST form of scleroderma and in childhood dermatomyositis. Approximately 50–70% of children with dermatomyositis develop some degree of cutaneous calcification, while the latter occurs in ~20% of patients with the adult form of the disease[2]. Small deposits may occur in the skin or larger firm masses may begin in the muscle groups most severely affected; it is most frequently seen on the elbows, knees, buttocks and shoulders. Extrusion of calcium through the skin causes significant morbidity with pain and secondary infection.

In calcinosis universalis, the most severe form of dystrophic calcification, there is diffuse involvement with sheet-like masses of calcium. The calcification occurs along fascial planes, often leading to severe functional impairment. Aggressive treatment of dermatomyositis with immunosuppressive agents and/or IVIg may be warranted to try to avoid this serious complication (see Ch. 42). However, once calcification has developed, the effectiveness of these therapies can be quite variable.

The CREST (*c*alcification, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly and *t*elangiectasia) variant of scleroderma is the other AI-CTD in which cutaneous calcification is frequently seen. Calcification is usually less severe than in dermatomyositis and is usually restricted to the hands and upper extremities (Fig. 50.1); it is also seen over bony prominences and tendons. Extrusion of white chalky material is sometimes followed by localized ulceration, often at sites of trauma such as the digits. Calcinosis universalis can occur in scleroderma, but much less frequently than in dermatomyositis.

Dystrophic calcification has occasionally been reported in chronic cutaneous, acute systemic and subacute cutaneous lupus erythematosus as well as generalized morphea (Fig. 50.2)[3–5]. The calcification may occur within lesions of lupus panniculitis or elsewhere. In systemic lupus erythematosus, calcification is most often an asymptomatic radiologic finding.

Fig. 50.1 Dystrophic calcification in a patient with CREST syndrome.

Fig. 50.2 Radiograph of calcinosis cutis in a patient with generalized morphea. Areas that were previously firm became rock-hard and lesions of perforating calcinosis cutis (transepidermal elimination) developed on both legs. *Courtesy, Jean L Bolognia, MD.*

Treatment of dystrophic calcification

Therapies that have been tried for dystrophic calcification include a low calcium and phosphate diet, aluminum hydroxide and bisphosphonates, though no controlled trials have convincingly shown clinical improvement. Colchicine, probenecid and sodium thiosulfate have been described as helpful in a small number of patients. Long-term treatment with diltiazem was reported to decrease the size of calcium deposits, presumably through its effect on calcium transport into cells[6,7]. Months to years of treatment may be required if the calcification is extensive. Surgical excision is appropriate in selected patients with localized masses that are painful or interfere with function.

Panniculitis

Lobular panniculitis may also result in dystrophic calcification. Patients with pancreatitis or pancreatic cancer release pancreatic enzymes that cause lipolysis of subcutaneous fat (see Ch.100). Fatty acids formed in this process combine with calcium to form calcium soaps. Clinically, crops of nodules appear on the lower extremities and, less often, on the trunk, which may ulcerate and drain. Histologically, calcium deposits are seen both intra- and extracellularly within the areas of fat necrosis. Other forms of panniculitis that may calcify include subcutaneous fat necrosis of the newborn and lupus profundus. In subcutaneous fat necrosis of the newborn, there are erythematous nodules and plaques on the cheeks, back, buttocks and extremities. The nodules usually clear spontaneously, but, in some patients, symptomatic and even dramatic hypercalcemia may occur. Generally, the calcium deposits are small and are most easily noted radiologically; occasionally, more widespread deposits may be seen.

Genetic Disorders

A number of genetic disorders may be accompanied by cutaneous calcification. Pseudoxanthoma elasticum (PXE) is characterized by calcification of the elastic fibers of the skin (see Ch. 97). The coexistence of typical elastic fiber calcification along with small discrete foci of cutaneous calcification or ossification has also been reported[8,9]. In addition, progressive calcification of elastic tissue in Bruch's membrane of the retina and in the cardiovascular system may occur in these patients. Mutations in the *ABCC6* gene (ATP-binding cassette) that encodes a membrane transporter system have been identified in PXE patients[10,11]. Serum levels of fetuin-A, a major anti-mineralization protein, are significantly reduced in PXE patients and this may allow unchecked calcification of elastic fibers in affected tissues[12].

Ehlers–Danlos syndrome encompasses multiple disorders in which genetic mutations lead to abnormal collagen synthesis, metabolism or function (see Ch. 95). In Ehlers–Danlos syndrome, patients develop hard subcutaneous nodules known as spheroids or spherules, which are thought to represent herniated fat lobules that have become calcified (see Ch. 97).

Dystrophic calcification may also occur in patients with porphyria cutanea tarda[13] (PCT; see Ch. 49). It is most often seen in patients with longstanding disease who develop sclerodermoid changes and secondary calcification within these areas. As is the case with other lesions of PCT, the calcification appears most commonly in the head and neck region or on the dorsal surface of the hands. Ulceration has also been reported, although rarely, in association with these lesions.

Other rare genetic syndromes in which cutaneous calcification may be seen include Werner syndrome and Rothmund–Thompson syndrome (see Ch. 63). Cerebral amyloid angiopathy, an autosomal dominant condition due to mutations in the gene encoding the amyloid precursor protein, can present with dementia, patchy leukoencephalopathy, hemorrhagic strokes, external carotid artery dysplasia and occipital calcifications[14]. Biopsy specimens of the skin may show microcalcification of the dermal blood vessels. While the latter is asymptomatic, dermatologists might be called upon to biopsy the skin as a diagnostic measure.

Infections

Infections, particularly parasitic, can lead to dystrophic calcification. Calcified cysts form around larvae or worms, including *Onchocerca volvulus* and the tapeworm, *Taenia solium*. Intrauterine herpes simplex has also been reported to cause unusual annular plaques of calcinosis cutis in newborns.

Fig. 50.3 Dystrophic calcification in an infant at the site of a previous "heel stick" for obtaining blood. *Courtesy, Julie V Schaffer, MD.*

Neoplasms

Incidental calcification has been noted in a large number of benign and malignant tumors of the skin. Up to 75% of pilomatricomas develop calcification and in 15–20% there is evidence of ossification. A chalky, calcium-containing material may drain from the surface of these tumors. Activating mutations in the β-catenin gene have been demonstrated in sporadic pilomatricomas[15]. Other calcifying adnexal tumors or cysts include basal cell carcinomas, pilar cysts, epidermoid inclusion cysts and chondroid syringomas[16,17]. Rarely, melanocytic nevi, atypical fibroxanthomas, pyogenic granulomas, trichoepitheliomas and seborrheic keratoses have been reported to calcify.

Other

Trauma, "heel sticks" (for obtaining blood in neonates; Fig. 50.3), subcutaneous or intramuscular injections sites, surgical and burn scars, and keloids have also been reported as triggers of dystrophic calcification.

METASTATIC CALCIFICATION

Renal Disease

The most common cause of metastatic calcification is chronic renal failure (Fig. 50.4). In patients with renal failure, there are two major factors that lead to calcifications in the skin and soft tissues. First, patients with renal disease have an impaired ability to clear phosphate. Secondly, there is impaired synthesis of 1,25-dihydroxyvitamin D_3, since 1-α hydroxylation, which is necessary for activation of vitamin D_3, takes place in the kidney. This impaired production of 1,25-dihydroxyvitamin D_3 leads to decreased absorption of calcium from the intestine and hypocalcemia. Hypocalcemia, in turn, induces increased levels of parathyroid hormone (PTH) and increased mobilization of calcium and phosphate. The serum calcium concentration is normalized, but significant hyperphosphatemia may develop, and, if the solubility product of calcium and phosphate is exceeded, metastatic calcification can result. This metastatic calcification may take one of two forms: benign nodular calcification or calciphylaxis.

Benign nodular calcification usually develops in the setting of chronic renal failure with prolonged secondary hyperparathyroidism. Clinically, there are large deposits of calcium in the skin and subcutaneous tissue, often in periarticular sites. The number and size correlate with the severity of the hyperphosphatemia. The lesions are usually asymptomatic except for the pressure they can place on surrounding structures. Normalization of serum calcium and phosphate levels may result in resorption of the lesions; however, if larger deposits interfere with function, surgical removal is recommended.

More recently, deposition of calcium in the skin was reported following subcutaneous administration of low-molecular-weight heparin in two renal transplant patients. Both patients developed nodules with ulceration at the sites of the heparin injections. Histologic evaluation confirmed the diagnosis of calcinosis cutis. The process was self-limited and resolved following discontinuation of nadroparin. The calcium content of the nadroparin in combination with hyperphosphatemia due to renal dysfunction was hypothesized as the underlying pathogenic mechanism[18].

Calciphylaxis (synonyms: uremic gangrene syndrome, calcific uremic arteriolopathy, calcifying panniculitis) is characterized by progressive vascular calcification as well as ischemic necrosis of the skin and soft tissues. Early lesions are violaceous reticulated patches (Fig. 50.5A,B). Bullae or a gray color may develop within the lesions, signifying imminent tissue necrosis and ulcer formation (Fig. 50.5C). The lesions are extremely painful even at the earliest stages of development. Death is often due to gangrene and sepsis.

Patients who develop calciphylaxis are predominantly female and often have diabetes mellitus[19–21]. Obesity and poor nutritional status are also risk factors for calciphylaxis. A case–control study showed no statistical differences in the serum levels of calcium, phosphate, PTH

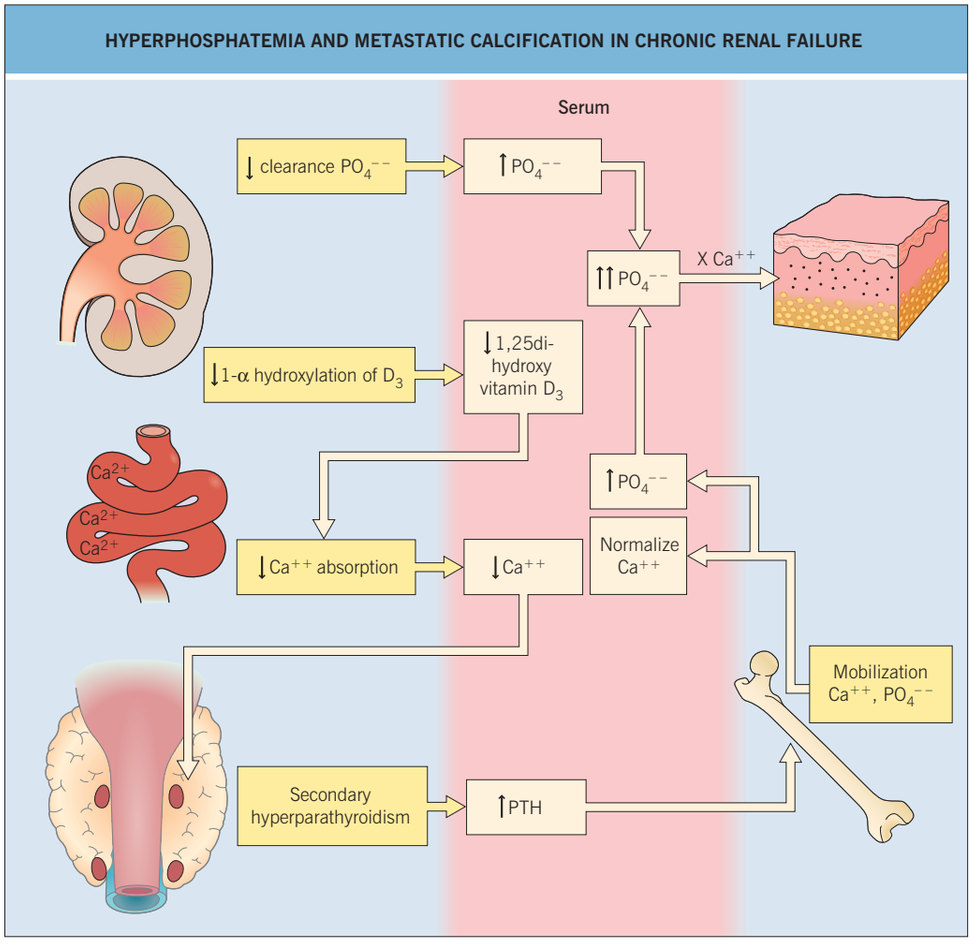

Fig. 50.4 Mechanisms of hyperphosphatemia and metastatic calcification in patients with chronic renal failure.

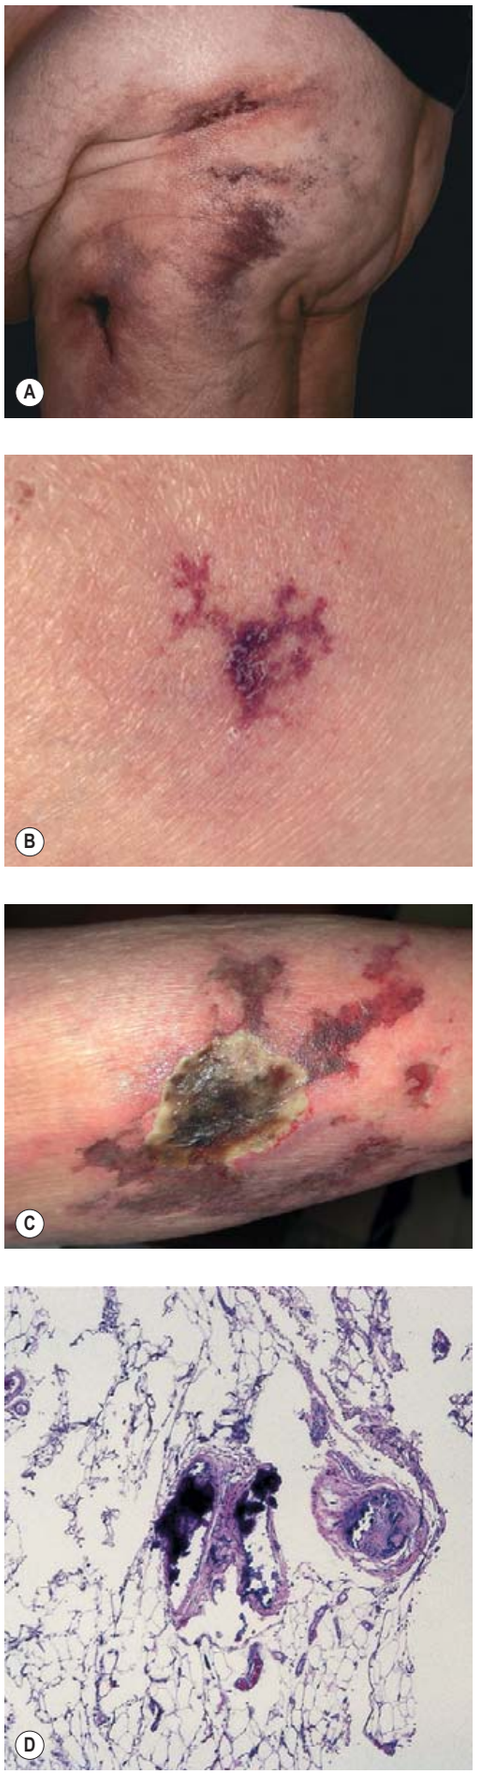

Fig. 50.5 Calciphylaxis in three patients with chronic renal failure. **A,B** Typical reticulated, violaceous plaques that usually precede ulceration. **C** Ulceration of the leg with surrounding retiform purpura and ischemia. **D** Perivascular deposition of calcium is seen within the walls of blood vessels in the subcutaneous fat. Of note, even when the clinical lesions are impressive, the degree of calcification seen histologically may be subtle. *B, Courtesy, Kalman Watsky, MD.*

or the calcium-phosphate product in patients with calciphylaxis as compared to control dialysis patients. The use of calcium salts as phosphate binders was the only risk factor that could be identified; however, the number of patients in the study was small[19].

The cause of calciphylaxis remains unclear. Animal studies have suggested that exposure to a "sensitizing" agent such as PTH followed by exposure to a "challenging" agent such as metal salts could cause precipitation of calcium in tissues[22]. The relevance of this work to the clinical disorder, however, remains unproven. Protein C dysfunction has been identified in a number of calciphylaxis patients, but is not consistently found in all patients. Since functional or quantitative abnormalities in protein C lead to a hypercoagulable state (see Ch. 23), it is possible that alterations in protein C function may contribute to the tissue necrosis in that subset of patients. While the majority of patients who develop calciphylaxis have end-stage renal disease, occasionally it is seen in the setting of severe primary hyperparathyroidism and, less often, in the absence of a clearly identifiable trigger.

For vascular calcification to occur, one important step is the conversion of vascular smooth muscle cells into osteoblast-like cells. Phosphates, inflammatory mediators in the vessel wall and bone morphogenic protein (BMP)-2 have all been proposed as potential stimuli for this conversion. In addition, BMP-7, matrix gla protein, fetuin-A (see above), osteoprotegerin and phosphatonins are currently being investigated as positive or negative regulators of the process[23].

Treatment of calciphylaxis

In patients with calciphylaxis, the overall mortality is as high as 85%, though it is hoped that early recognition and better treatments may improve the outcome. Proximal involvement in particular is associated with a worse prognosis. The current standard management of calciphylaxis includes normalization of the calcium-phosphate product by low calcium dialysis, use of phosphate binders, and parathyroidectomy (if medical management of hypercalcemia fails), along with aggressive wound care. Phosphate binders containing a combination of calcium acetate and magnesium carbonate have been shown to be more beneficial than calcium carbonate-containing binders[24], and parathyroid resection can normalize serum calcium, phosphate and PTH levels in calciphylaxis patients. A recent multivariate analysis suggested that overall survival is improved by surgical debridement and aggressive management of wound infections[25]. There was no clear benefit from parathyroidectomy, but a trend towards improved survival was observed when debridement and parathyroidectomy were combined.

Other proposed treatment modalities include sodium thiosulfate[26], pamidronate, cinacalcet (a calcimimetic), hyperbaric oxygen and low-dose tissue plasminogen activator[27,28]. Most of these treatment suggestions are based on small case series of patients.

Milk–Alkali Syndrome

Ingestion of excessive amounts of calcium-containing foods or antacids can lead to hypercalcemia and the milk–alkali syndrome. Patients with milk–alkali syndrome have acute manifestations including nephrocalcinosis, irreversible renal failure and diffuse subcutaneous calcification.

Hypervitaminosis D

Chronic ingestion of supraphysiologic doses of vitamin D can lead to hypercalcemia and hypercalciuria. Clinical signs include weakness and lethargy, nausea, headache and polyuria. Nephrolithiasis and calcinosis cutis may occur. Hypercalcemia is also seen in patients with sarcoidosis secondary to increased calcium absorption due to 1,25-dihydroxyvitamin D production by the granulomas. For other causes of metastatic cutaneous calcification, see Table 50.1.

IDIOPATHIC CALCIFICATION

Idiopathic Calcified Nodules of the Scrotum

The term "idiopathic calcified nodules of the scrotum" is used to describe firm, whitish nodules that develop on the scrotum. There are

DISORDERS OF CUTANEOUS CALCIFICATION
DYSTROPHIC
• Autoimmune connective tissue diseases, especially dermatomyositis, CREST • Cutaneous tumors or cysts, e.g. pilomatricomas, pilar cysts • Infections, especially parasitic • Trauma, including "heel sticks" in neonates, injection sites, surgical scars • Panniculitis • Genetic disorders, e.g. pseudoxanthoma elasticum, Ehlers–Danlos syndrome
METASTATIC
• Chronic renal failure Calciphylaxis* Benign nodular calcification of renal disease • Hypervitaminosis D • Milk–alkali syndrome • Sarcoidosis • Tumoral calcinosis (familial) • Hyperparathyroidism • Neoplasms (e.g. multiple myeloma, adult T-cell leukemia/lymphoma, SCC of the lung or head and neck)
IDIOPATHIC
• Idiopathic calcified nodules of the scrotum • Subepidermal calcified nodule • Tumoral calcinosis (sporadic) • Milia-like calcinosis
IATROGENIC
• Extravasation of intravenous solutions containing calcium or phosphate • Application of calcium-containing electrode paste for EMGs and EEGs • Application of calcium alginate dressings to denuded skin • Organ transplantation, especially liver
*Can occasionally occur in the setting of severe primary hyperparathyroidism and, less often, in the absence of a clearly identifiable trigger.

Table 50.1 Disorders of cutaneous calcification. CREST, *c*alcification, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly and *t*elangiectasia; EEG, electroencephalogram; EMG, electromyography; SCC, squamous cell carcinoma.

often multiple lesions. Histologically, some of them seem to represent calcified epidermoid inclusion cysts; however, in some lesions, no precursor cyst can be identified[29]. Based upon a recent study of 100 scrotal nodules, a spectrum of disease emerged – from epidermoid cysts with foci of calcification, to calcification with degeneration of some to most of the cyst wall, to unencapsulated calcium. The authors concluded that pre-existing epidermoid cysts may account for most of these calcified nodules[30]. A female equivalent, idiopathic calcinosis of the vulva, has also been described[31].

Subepidermal Calcified Nodule

Subepidermal calcified nodule (synonyms: solitary congenital nodular calcification, Winer's nodular calcinosis) is a solitary firm nodule that favors the head and neck region, most commonly the ears. They are also seen on the lateral aspects of the digits. Subepidermal calcified nodules usually develop in children but have been observed in all age groups. Trauma, perhaps *in utero*, or calcification of a pre-existing milium, eccrine duct hamartoma or hair follicle nevus has been hypothesized as the cause. Histologically, focal amorphous masses of calcium with a surrounding inflammatory infiltrate are seen. Epidermal ulceration and transepidermal elimination of the calcium deposits occur frequently. Surgical removal is recommended if the lesions are symptomatic.

Tumoral Calcinosis

Tumoral calcinosis may be either sporadic or familial. In both forms, patients develop large, often painful, deposits of calcium-phosphate in the dermis and subcutaneous tissues around large joints. Ulceration of the overlying skin may occur in larger lesions. The familial form is associated with either hyperphosphatemia or a normophosphatemic state. The former is inherited as an autosomal recessive trait and these patients have primary hyperphosphatemia due to increased reabsorption of phosphate in the renal tubule[32]. Mutations in the *GALNT3* gene, which encodes N-acetylgalactosaminyltransferase 3 (ppGalNAc-T3) which initiates mucin-type O-glycosylation, have been identified in a number of these families[33]. It is hypothesized that this glycosylation is important in regulating a class of proteins called "phosphatonins" that modulate circulating phosphate levels. Hyperphosphatemic familial tumoral calcinosis can also be caused by loss-of-function mutations in the genes that encode fibroblast growth factor 23 (FGF23, a phosphaturic protein that is glycosylated by ppGalNAc-T3) and klotho (a co-receptor for FGF23).

A homozygous mutation in the *SAMD9* (*s*terile *a*lpha *m*otif *d*omain containing 9) gene, which encodes a protein involved in the regulation of extraosseous calcification, has been found to underlie normophosphatemic familial tumoral calcinosis in families of Jewish Yemenite origin[34]. Dietary phosphate restriction and antacids that inhibit phosphate absorption may be of some benefit, but surgical excision of symptomatic lesions remains the treatment of choice.

Milia-like Calcinosis

Idiopathic calcinosis may sometimes take the form of small, milia-like lesions that develop on the dorsal surface of the hands and the face. Most commonly, these lesions appear in the setting of Down syndrome, although rarely they have been reported in patients with no other abnormalities[35]. In some patients, the calcinosis appears to result from calcification of pre-existing syringomas, but usually no precursor lesions can be found.

IATROGENIC CALCIFICATION

Iatrogenic calcification is due to the rapid precipitation of calcium salts within the skin. When the tissue concentration of calcium rises and exceeds the solubility product, calcium precipitates within the tissue, resulting in firm nodules in the dermis and/or subcutaneous tissue. A secondary inflammatory response is elicited and, over a period of weeks to months, the calcium is either absorbed or is transepidermally eliminated, depending on the depth of the deposit.

Iatrogenic calcification most commonly occurs with extravasation of calcium gluconate, calcium chloride or phosphate-containing intravenous solutions[36–38]. In a rabbit model of iatrogenic calcification, intralesional injections of triamcinolone into sites of extravasation decreased inflammation and ulceration. This treatment appeared to be most helpful when given immediately after the initial extravasation. Iatrogenic calcification has also been reported following prolonged electroencephalograms, electromyography and brainstem auditory evoked potential testing when a high-calcium electrode paste is employed[39]. Several patients were noted to develop calcification in split-thickness skin graft donor sites following the use of calcium alginate dressings[40].

Transient cutaneous calcifications have been observed in patients following liver transplantation[41,42]. They are generally small deposits in the skin that appear shortly after the transplant. They are hypothesized to arise as a consequence of the large amounts of calcium and blood products containing citrate required during surgery, combined with metabolic abnormalities during the perioperative period. In addition to the skin, calcinosis has been reported in the lungs, grafted liver, kidneys, vascular walls and colon. Calcinosis cutis has also been observed in a patient following lung transplantation[43].

CUTANEOUS OSSIFICATION (OSTEOMA CUTIS)

There are four genetic disorders that regularly have cutaneous or subcutaneous ossification as a clinical feature: fibrodysplasia ossificans progressiva, progressive osseous heteroplasia, plate-like osteoma cutis, and Albright hereditary osteodystrophy. Of these disorders, *fibrodysplasia ossificans progressiva* differs from the others in that the mechanism of bone formation is endochondral and involvement of the skin and subcutaneous tissue is only via extension from deeper tissues. These

patients have extreme morbidity and often die at an early age due to restriction in movement of the chest. Fibrodysplasia ossificans progressiva is an autosomal dominant disorder with dysregulation of the bone morphogenic protein (BMP) signaling pathway. Heterozygosity for mutations in the *ACVR1* gene, which encodes the activin A receptor (a BMP type I receptor), has been observed in both inherited and sporadic forms of the disease. Of note, an arginine (R) to histidine (H) substitution at position 206 (R206H) was found not only in affected family members (i.e. the inherited form of the disease), but also in 30 of 32 *de novo* cases of fibrodysplasia ossificans progressiva, leading the authors to suggest that the R206H-associated mutation may represent one of the most specific codons in the human genome to be associated with a disease phenotype[44,45]. These patients are unlikely to present to a dermatologist due to their limited and late skin involvement.

The three entities progressive osseous heteroplasia (Fig. 50.6), plate-like osteoma cutis, and Albright hereditary osteodystrophy are all characterized by intramembranous ossification that begins in the dermis.

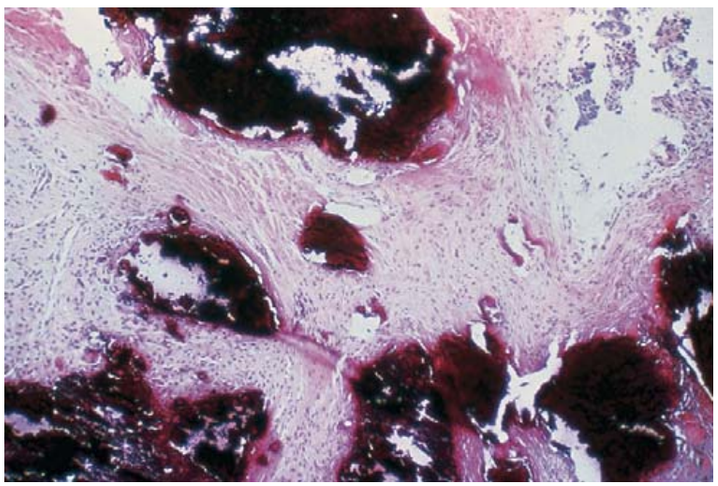

Fig. 50.6 Progressive osseous heteroplasia – histologic features. Deposits of calcium are seen more superficially, often with foci of cartilage and bone formation in the subcutaneous tissue.

While distinctive features are seen in each of these entities, there is also considerable clinical overlap. The cutaneous lesions in *progressive osseous heteroplasia* are asymptomatic papules and nodules. Some are more plaque-like and studded with papules that give rise to a "rice-grain" texture. The lesions generally appear shortly after birth and may be rapidly progressive[46,47]. The location and extent of the ossification determines the associated morbidity; in general, there are no associated developmental or endocrine abnormalities. Initially, progressive osseous heteroplasia was thought to be limited to female patients, but this later proved not to be the case. Unilateral involvement has also been described.

The lesions of *plate-like osteoma cutis* often have an appearance that is similar to those of progressive osseous heteroplasia, but there will only be a single or limited number of sites of involvement, leading to the suggestion that the former represents a more limited form of the latter. *Albright hereditary osteodystrophy* is distinguished from these two entities by its associated findings such as pseudohypoparathyroidism or pseudo-pseudohypoparathyroidism plus brachydactyly, obesity, short stature and round facies. The algorithm in Figure 50.7 demonstrates how clinical features may be used to classify these genetic disorders of cutaneous ossification.

The argument that progressive osseous heteroplasia and plate-like osteoma cutis may represent related disorders is strengthened by the report of a family in which two members had plate-like osteoma cutis and one had progressive osseous heteroplasia[48]. Genetic analysis has provided further evidence of the pathogenic relationship of these disorders – patients with progressive osseous heteroplasia, plate-like osteoma cutis, and Albright hereditary osteodystrophy all have mutations in the gene (*GNAS1*) that encodes the α-subunit of the stimulatory G protein which regulates adenyl cyclase activity[49–51]. The latter is believed to be a negative regulator of bone formation. In a study of 18 patients with progressive osseous heteroplasia, heterozygous inactivating mutations were found in 13 of the probands. While the defective allele was inherited from the *father* in almost all cases of progressive osseous heteroplasia[52,53], in some of these families, inheritance of a defective *GNAS1* from the *mother* resulted in Albright hereditary osteodystrophy. This indicates that the *GNAS1* locus is subject to imprinting (see Ch. 54); more recent data demonstrate that different splice variants are expressed solely by maternal or paternal alleles[54].

Therapy for most forms of cutaneous ossification is difficult. Underlying abnormalities in calcium and/or phosphorus should be addressed; however, when complete ossification develops, the only therapeutic

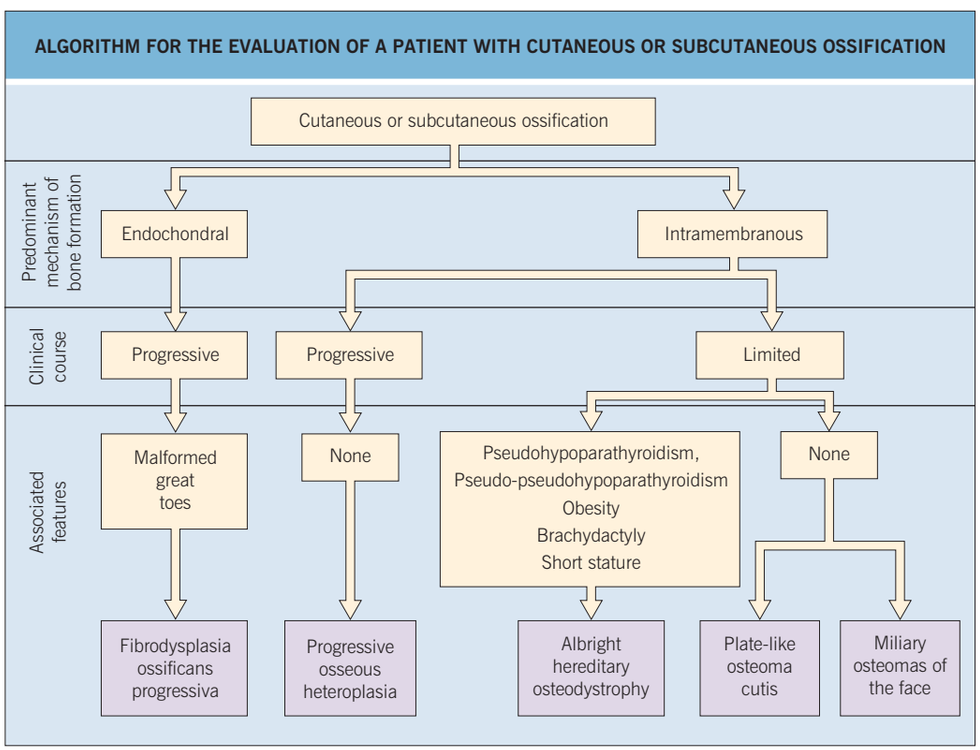

Fig. 50.7 Algorithm for the evaluation of a patient with cutaneous or subcutaneous ossification.

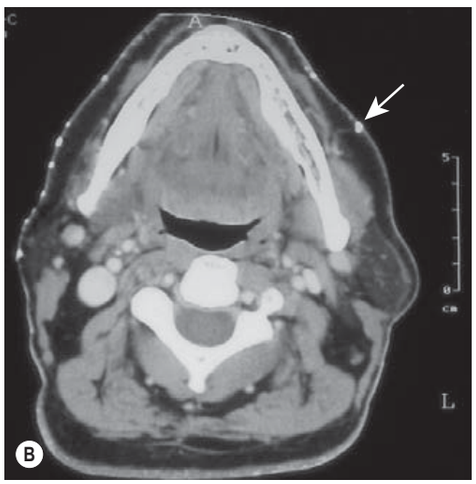

Fig. 50.8 Miliary osteoma cutis. **A** Multiple discrete whitish papules developed on the face of a patient with no previous history of acne. **B** The foci of ossification are readily apparent on CT scan (arrow). **C,D** In contrast, many of the papules in these patients with a history of acne are skin-colored or blue.

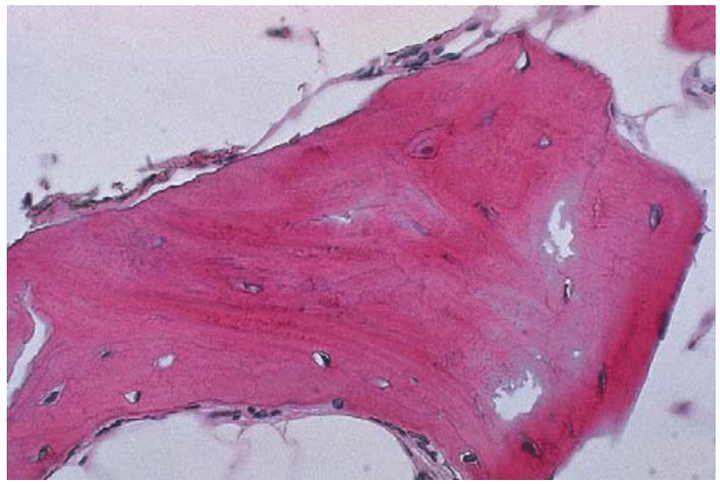

Fig. 50.9 Osteoma cutis – histologic features. Islands of bone formation are present within the dermis. Occasionally, osteoblasts and bone marrow elements can also be seen.

intervention is excision of neoformed bone. Even with surgical removal, recurrence of the bony deposits is common in the genetic disorders that lead to cutaneous ossification.

Miliary osteomas of the face is a fairly common entity characterized by multiple, scattered foci of cutaneous ossification. Small, firm papules appear on the face of adults and they can be skin-colored, white or bluish (Fig. 50.8)[55]. Although these osteomas are often observed in the setting of chronic acne vulgaris, a number of patients with identical clinical findings (but without predisposing acne) have also been reported. The unusual appearance of these osteomas on CT scan is shown in Figure 50.8B. Histologically, islands of bone formation are seen in the dermis (Fig. 50.9).

Treatment of miliary osteoma cutis is primarily surgical. An incision over each lesion followed by gentle curettage of the bony material with the edge of a surgical blade and then suture closure has been recommended. When lesions are numerous, however, this may not be practical. Laser resurfacing with curettage of exposed osseous fragments has been employed in this situation. Topical tretinoin gel has also been reported to have a beneficial effect on miliary osteomas[56].

"SECONDARY" CUTANEOUS OSSIFICATION

Ossification may also develop as a secondary event. Most disorders in which calcification can be seen have also been reported to ossify. Ossification occurs as a result of inflammatory or neoplastic processes and is often preceded by calcification. Secondary ossification has been described in melanocytic nevi and other benign tumors such as pilomatricomas as well as in pilar and epidermoid cysts and basal cell carcinomas.

LABORATORY EVALUATION OF PATIENTS WITH CUTANEOUS CALCIFICATION AND OSSIFICATION

In addition to a thorough history and physical examination focusing on the associated features that have been described, some selected laboratory investigations may be helpful in the evaluation of calcifying and ossifying disorders. A summary of this evaluation is outlined in Table 50.2. Abnormalities are expected most often in association with metastatic causes of calcification rather than in the other categories (see Table 50.1). Serum calcium and phosphate levels should be obtained and the calcium-phosphate product determined. While this may give a general clue about the patient's metabolic status with regard to calcium and phosphate, a normal value does not necessarily exclude these disorders. Rare reports of patients with calcinosis cutis and a normal serum calcium level but abnormally low urinary excretion of calcium have appeared; thus, an assessment of the 24-hour urinary calcium excretion may be warranted in some patients.

LABORATORY EVALUATION OF PATIENTS WITH CUTANEOUS CALCIFICATION/OSSIFICATION
Special histologic stains for calcium: • von Kossa • Alizarin red S Serum levels of: • Calcium • Phosphate • Parathyroid hormone (PTH) • Vitamin D_3 24-hour urinary calcium excretion Protein C activity and function (if calciphylaxis suspected) Genetic analysis (if hereditary disorder suspected; see text and Table 55.12)

Nutritional Diseases 51

Stephanie McLeish Schaefer and Chad M Hivnor

Key features

- Nutritional deficiencies may affect any organ system, including the skin, which may provide clues to the diagnosis
- The two classic protein–energy malnutrition syndromes are kwashiorkor and marasmus
- In addition to inadequate oral intake, there are secondary causes of nutritional deficiencies, e.g. intestinal malabsorption due to medical conditions or surgical procedures
- Vitamin and trace element deficiencies can lead to a wide range of mucocutaneous findings, from follicular keratoses to periorificial erosions and glossitis
- Insufficient and deficient levels of vitamin D have been noted worldwide, in both low-income and high-income countries
- Obesity can be associated with high-calorie malnutrition and a number of skin changes, from acanthosis nigricans to lipodermatosclerosis

INTRODUCTION

Both isolated nutritional deficiencies and general malnutrition due to inadequate intake and/or abnormalities in the metabolism of nutrients necessary to sustain life can result in multisystem disorders. Deficiency of one isolated nutrient is rare, as individuals are usually deficient in multiple nutrients at the same time. In general, nutrients are categorized as macronutrients (carbohydrates, proteins and fats) or micronutrients (vitamins and minerals). Most people who suffer from nutritional deficiencies live in low-income countries. However, there are certain conditions that predispose individuals from high-income countries to develop nutritional deficiencies, such as alcoholism, intestinal malabsorption, bulimia and fad diets.

Nutrients must follow an orderly process of ingestion, digestion, absorption and circulation plus subsequent metabolism in order to be beneficial. When any one of these processes is disrupted, clinical manifestations may appear.

EPIDEMIOLOGY AND PATHOGENESIS

In low-income countries, malnutrition stems primarily from inadequate ingestion of all macronutrients as well as many micronutrients (Fig. 51.1). The World Health Organization (WHO) has estimated that worldwide in 2001, 54% of childhood deaths were due directly or indirectly to the multisystem ramifications of malnutrition. In industrialized regions of the world, malnutrition is directly linked to the per capita gross national product; if a country has a per capita income that is less than US$300 per year, endemic malnutrition is likely, especially in infants and young children.

The incidence of primary malnutrition in high-income countries is unknown, but the pathogenesis is thought to be at least twofold. Firstly, excessive consumption of foods high in calories but low in nutrients can lead to obese patients who lack essential vitamins and minerals. This is supported by a study in which 57% of morbidly obese patients undergoing preoperative assessment for bariatric surgery were found to have a deficiency in at least one micronutrient[1]. A second etiology involves various restrictive diets, including those based upon real or perceived need (e.g. food allergies), psychiatric illness (e.g. anorexia nervosa) or mental impairment (e.g. illicit drug abuse), all of which disrupt the intake of appropriate nutrients and can result in malnutrition.

In addition to a diet inadequate in the quantity and/or quality of macro- and micronutrients (i.e. primary causes), there are medical

CHARACTERISTICS OF PROTEIN–ENERGY MALNUTRITION AND ESSENTIAL FATTY ACID DEFICIENCY			
	Protein–energy malnutrition		Essential fatty acid deficiency[2,3]
	Marasmus	Kwashiorkor	
Causes	• Decreased energy intake over months to years • Other primary causes: alcoholism, psychiatric disorders (anorexia nervosa, bulimia), diets for treatment of diseases or "allergic disorders", child neglect/abuse • Secondary causes: intestinal malabsorption, chronic diarrhea, malignancies, chronic systemic diseases (e.g. hepatic failure), AIDS*, metabolic disorders	• Decreased protein intake during periods of stress lasting a few weeks or more • Can result from diets consisting primarily of rice or rice-based beverages (e.g. "rice milk") for perceived milk intolerance • Other causes: protein-losing enteropathies, extensive gastrointestinal surgeries, HIV disease*	• Protein–energy malnutrition • Gastrointestinal disorders/surgeries causing severe fat malabsorption • Long-term parenteral nutrition without lipid supplementation • Diets extremely low in fat • Nephrotic syndrome
