Cutaneous features	• Dry, thin, pale, lax and wrinkled skin • Occasionally, fine scaling and hyperpigmentation (Fig. 51.2) • Follicular hyperkeratosis and folliculitis in adults • Ulcerations • Excess of lanugo-like hair • Thin hair that grows slowly and falls out readily • Impaired growth of nails and fissured nails • Purpura (Fig. 51.3)	• Dyschromia is a common finding • Pallor due to distention of the skin and loss of pigment • Hypopigmentation following abrasions, and ulcerations and hyperpigmentation in areas subject to trauma • Superficial desquamation in mild cases ("enamel paint spots"), but in severe cases large areas of erosion ("flaky paint") (Fig. 51.5) • Other cutaneous signs include erythema, thinning, petechiae, ecchymoses and purpura • Hair is sparse, dry, lusterless and brittle with a reddish tinge; bands of light and dark coloration ("flag sign") reflect intermittent periods of malnutrition; positive gentle hair pull test • Nails are soft and thin • Mucosal lesions: cheilitis, xerophthalmia and vulvovaginitis	• The skin is dry, scaly, and leathery with underlying erythema • Intertriginous erosions • Alopecia and more lightly pigmented hair • Increase in transepidermal water loss • Petechiae
Systemic features	• Starved appearance but alert • Reasonably preserved responsiveness to short-term stress • Loss of subcutaneous fat and muscle (Fig. 51.2) • "Monkey facies" or an aged appearance (due to loss of buccal fat pads) • Suppression of growth	• Relatively well-nourished appearance • Edema or even anasarca (Fig. 51.4) • Apathy, anorexia, irritability • Failure to thrive (retardation of growth and mental development) • Superimposed bacterial and fungal (e.g. candidal) infections • Bilateral parotitis, hepatomegaly, diarrhea, loss of muscle mass	• Growth failure • Poor wound healing • Impaired reproduction • Abnormal liver and kidney function tests • Capillary fragility • Increased susceptibility to infections • Neurologic damage
Lab findings and diagnostic criteria	• Triceps skin-fold <3 mm • Mid-arm muscle circumference <15 cm • Creatinine-height index <60% of standard • Low zinc levels • Epidermal acanthosis or atrophy (depending upon the stage), hyperkeratosis • Most hair bulbs are in the telogen phase • Abundant broken hairs	• At least one of the following: poor wound healing, decubitus ulcers or skin breakdown • Anergy • Hypoalbuminemia (<2.5 g/dl) • Total iron-binding capacity <200 microg/dl • Peripheral lymphocyte count <1500/microl • Steatohepatitis • In "enamel paint spots", thickened, pigmented stratum corneum with an underlying stratum lucidum • Decreased number of anagen hair follicles and increased number of telogen follicles • Structural abnormalities in anagen follicles – severe atrophy, shaft constriction, depletion of pigment • Exclude nephrotic syndrome	• Low plasma levels of linoleic, linolenic and arachidonic acids • Accumulation of 5,8,11-eicosatrienoic acid • Elevated levels of palmitoleic and oleic acids • Anemia, thrombocytopenia • Orthokeratotic hyperkeratosis, acanthosis with hypergranulosis, atrophic sebaceous glands, and papillary dermal vasodilation with a mixed cell infiltrate (in rat models) • Steatohepatitis
Treatment	• Treat cautiously, slowly replacing proteins and calories, allowing readaptation of metabolic and intestinal functions • Supplementation with linoleic acid and zinc • Monitor for hypophosphatemia and cardiorespiratory failure (associated with overly aggressive nutritional replacement) • Treatment of underlying diseases if possible	• Aggressive nutritional support is indicated to rapidly restore metabolic balance; correction of any electrolyte disturbances or hypoglycemia • Institute diet with adequate protein and caloric intake; supplementation with minerals and vitamins is required as patients often have multiple nutritional deficiencies • Identify and attempt to treat underlying cause(s), including bacterial and parasitic diseases • Topical moisturizers as needed	• Essential fatty acid replacement, depending upon severity: – topical – oral – intravenous • Correction of coexisting nutritional deficiencies
Prognosis	• 10% mortality, often secondary to diarrhea or pneumonia • Mortality rate related to underlying disease(s)	• Prognosis in adult patients is poor, even with aggressive nutritional support • In children, a lesser degree of stress is required to precipitate the disorder, so it is less foreboding • Severe, relapsing cases and those with coexistent HIV disease have a high mortality rate • Death usually occurs due to overwhelming infection despite antibiotic treatment	• Prognosis depends on the severity and coexistence of other nutritional deficiencies • Depends on awareness of this entity

*HIV infection is more often associated with marasmus than with kwashiorkor.

Table 51.1 Characteristics of protein–energy malnutrition and essential fatty acid deficiency.

conditions that can lead to a functional malnutrition (i.e. secondary causes). The latter include an increase in metabolic requirements (e.g. severe infections) and/or a decrease in the transport and utilization of nutrients (e.g. intestinal malabsorption, bariatric surgery). Malnutrition is also seen in individuals with late-stage internal malignancies and advanced AIDS (Table 51.1).

CLINICAL FEATURES

Clinically, the signs and symptoms of nutritional deficiencies are often due to a lack of multiple nutrients. Cutaneous manifestations in part reflect the fact that epidermal maturation (from basal cell layer to stratum corneum) occurs over a period of 10–14 days. Deficiencies, especially of macronutrients, can interfere with this process, resulting in skin that is dry and thin in appearance with associated epidermal atrophy sometimes leading to wrinkling. Prolonged deficiencies can reduce both protein production, including that of dermal collagen and muscle, and the amount of subcutaneous fat. As a result, patients may develop dermal atrophy, muscle wasting and/or lax skin.

Additional clinical findings of marasmus and kwashiorkor, such as dyschromia (hypo- and hyperpigmentation), desquamation and erosions (Fig. 51.2), are reviewed in Table 51.1. Patients may also have cutaneous manifestations from a deficiency in one or more micronutrients, and these are outlined in Table 51.2.

Protein–Energy Malnutrition

Worldwide, protein–energy malnutrition is the most prevalent nutritional deficiency and there are two major forms: marasmus and kwashiorkor. According to the WHO, on a global basis, *marasmus* affects more than 50 million children who are less than 5 years of age (Fig. 51.3). However, it can occur in individuals of all ages as marasmus results from a prolonged inadequate intake of calories and energy. Based on the Waterlow classification of protein–energy malnutrition in children (which accounts for the degree of stunted growth in children), marasmus represents a reduction in body weight that is >60% of expected weight for height[4]. These patients frequently develop recurrent infections due to their inability to mount a normal immune response.

Kwashiorkor is a more acute form of childhood and adult protein–energy malnutrition (see Table 51.1). A characteristic finding is peripheral edema or even anasarca in association with hypoalbuminemia (Fig. 51.4). One consequence of this edema is a body weight that is 60–80% of expected, in contrast to marasmus. However, some patients will have overlapping features of both disorders[4]. In at-risk populations, kwashiorkor can develop after a child is weaned from breast milk and begins a diet rich in carbohydrates but deficient in proteins.

Based upon this and other clinical observations, it was thought that kwashiorkor was due to a relative deficiency in protein *intake*. However, more recently, this proposed pathogenesis has been questioned based upon several observations. For example, protein intakes were found to be similar in a group of children, irrespective of whether they had marasmus or kwashiorkor[5]. In addition, kwashiorkor can develop within just a few weeks of an acute, life-threatening illness. A current theory is that kwashiorkor is related to physiologic stresses, caused by an acute or chronic illness (including infections), which increase protein and energy requirements at a time when intake is frequently limited[6]. This would help to explain why kwashiorkor has a higher mortality rate as well as the observation that kwashiorkor often occurs in the setting of an acute illness superimposed upon on a chronic state of milder malnutrition. It is hypothesized that the stress of the former blocks the protein-sparing response that is normally in effect during states of starvation.

In addition to peripheral edema, patients with kwashiorkor also develop desquamation and erosions that have been likened to "enamel paint" and "flaky paint" (Fig. 51.5). Both kwashiorkor and marasmus can have secondary causes such as "rice milk" diets or chronic diarrhea and these are outlined in Table 51.1. The cutaneous and systemic abnormalities associated with primary protein–energy malnutrition are

Fig. 51.2 Marasmus. This child is emaciated and has obvious hyperpigmentation. Both erosions and desquamation are present on the scalp. *Courtesy, Ramón Ruiz-Maldonado, MD.*

Fig. 51.3 Marasmus. Multiple purpuric lesions are seen. *Courtesy, Ramón Ruiz-Maldonado, MD.*

Fig. 51.4 Kwashiorkor. There is intense edema of the buttocks and lower extremities in addition to areas of erythema with erosions and desquamation. *Courtesy, Ramón Ruiz-Maldonado, MD.*

often reversible following nutritional therapy. However, if the malnutrition is prolonged, this may preclude normal physical and/or mental development[4].

Essential Fatty Acid Deficiency

Essential fatty acids (EFAs) are unsaturated fatty acids that must be obtained from an exogenous source because they cannot be synthesized by the human body. Linoleic, linolenic and arachidonic acids are the major EFAs, although arachidonic acid can be metabolized from linoleic acid. EFAs have multiple functions, both structural and synthetic, including being a precursor to prostaglandins, reducing fluidity within phospholipid membranes, energy storage and proper lamellar granule formation. They constitute between 13% and 30% of the skin's fatty acids.

While isolated deficiencies of EFAs are uncommon, this can occur in patients receiving parenteral nutrition without lipid supplementation and with overly aggressive low-fat diets. In most instances, however, EFA deficiency is associated with other nutritional deficiencies (see Table 51.1). The presence of decreased plasma levels of linoleic and arachidonic acids plus increased levels of eicosatrienoic acid (normally undetectable) establishes the diagnosis of EFA deficiency (see Fig. 51.12).

Fig. 51.5 Kwashiorkor. This child's arm has edema and superficial epidermal necrosis with an "enamel paint" appearance. *Courtesy, Ramón Ruiz-Maldonado, MD.*

Vitamins and Trace Elements

Micronutrients represent a diverse array of dietary components necessary to sustain health. The physiologic roles of micronutrients are as varied as their composition. Several micronutrients function as cofactors for enzymes, while others act as biochemical substrates or hormones; in addition, there are some whose function has not been well defined[7].

VITAMIN DEFICIENCIES IN ADULTS AND CHILDREN

Vitamin	Clinical manifestations			Reference values*	Replacement therapy
	Mucocutaneous	Systemic	Other		
FAT-SOLUBLE VITAMINS – CAN EASILY ACCUMULATE AND LEAD TO TOXICITY IF REPLACED IN HIGH DOSES FOR PROLONGED PERIODS					
A (retinol)	• Phrynoderma – follicular papules with central keratotic plug; favors extensor surfaces of extremities (Fig. 51.6) & buttocks • Generalized xerosis • Sparse, fragile hair	• Night blindness • Xerophthalmia (dryness of the cornea & conjunctivae) • Bitot spots (gray–white patches on the conjunctivae) • Keratomalacia (softness of the cornea, sometimes with ulceration)[12] • Stunted growth	• Increase in measles-related mortality • Increased susceptibility to and mortality from respiratory and diarrheal illnesses[12]	• Conventional: 30–100 microg/dl (<20 microg/dl only when hepatic stores depleted) • IU: 1.05–3.50 micromol/l	• Based on severity of ophthalmologic impairment • 10 000–50 000 IU/day PO or IM in infants on days 1, 2 & 14 • 200 000 IU/day PO or IM in children and adults on days 1, 2 & 14 • Higher doses given if keratomalacia
D: **D_2:** ergocalciferol **D_3:** cholecalciferol	• None	• Muscle weakness • Rickets in children • Osteomalacia in adults	• Possible decrease in innate immunity (see Table 51.3) • Possible increase in internal malignancies (e.g. colon, prostate)	• Total serum or plasma 25(OH) vitamin D is measured (D_2 plus D_3) • Deficiency: <20 ng/ml (IU: <50 nmol/l) • Insufficiency: 20–29 ng/ml (IU: 51–75 nmol/l)[13]	• For deficiency, 20 000 IU of vitamin D_3 or 50 000 IU of vitamin D_2 orally once weekly × 8 weeks; repeat for another 8 weeks if 25(OH) vitamin D still <30 ng/ml[14] • Plus 1 g/day of oral calcium if deficient
E (tocopherol)	• None	• Ophthalmoplegia, ptosis • Muscle weakness, ataxia • Pigmentary retinopathy			• 600 IU BID orally[15]
K **K_1:** phytanodione **K_2:** menaquinone	• Purpura, ecchymoses	• If severe hypoprothrombinemia, extensive hemorrhage at any body site • Hemorrhagic disease of the newborn – infants not given vitamin K at birth plus inadequate diet or mother on medications which inhibit vitamin K function[12,†]		• Elevated prothrombin time & INR • Serum or plasma vitamin K is measured • Conventional: 80–1160 pg/ml	• Newborns: 0.5–1 mg sc or IM • Children: 2 mg • Adults: 5–10 mg • Orally if asymptomatic • Intravenously in emergencies (risk of anaphylaxis) • Fresh frozen plasma • Doses for K_1 and K_2 similar

*In laboratory medicine, there has been a movement toward expressing values in international units (IU) rather than conventional units, e.g. mg/dl, but because this is not done universally, both values are provided in this table.

†Medications that inhibit hepatic vitamin K epoxide reductase: warfarin, anticonvulsants, certain cephalosporins (containing side chains of N-methylthiotetrazole or methylthiadiazole), high-dose salicylates and rifampin.

Table 51.2 Vitamin deficiencies in adults and children. Adapted in part from refs 7, 9,10 & 11. BID, twice daily; GI, gastrointestinal; GU, genitourinary; IM, intramuscularly; IV, intravenously; INR, international normalized ratio; PO, orally; RBCs, red blood cells; TID, three times daily; sc, subcutaneously.

VITAMIN DEFICIENCIES IN ADULTS AND CHILDREN					
Vitamin	**Clinical manifestations**			**Reference values***	**Replacement therapy**
	Mucocutaneous	**Systemic**	**Other**		
WATER SOLUBLE VITAMINS – LESS LIKELY TO ACCUMULATE & LEAD TO TOXICITY, BUT IN HIGH DOSES CAN LEAD TO SIDE EFFECTS, E.G. NEPHROLITHIASIS (VITAMIN C), HEPATITIS (NIACIN)					
C (ascorbic acid)	• Spongy gingivae with bleeding & erosions • Petechiae, ecchymoses • Follicular hyperkeratosis, especially forearms, abdomen & legs • Corkscrew hairs (flattened & curled) with perifollicular erythema or hemorrhage (Fig. 51.7)	• Subperiosteal hemorrhage with "pseudoparalysis", especially in children • Arthralgias, joint swelling, edema • Loose teeth • Impaired wound healing • Weakness, malaise, depression • Vasomotor instability[12] • In infants, hemorrhage into GI and GU tracts • Anemia • Impeded growth • Cerebral & femoral sheath hemorrhages	• Many of the signs of *scurvy* are related to impaired collagen synthesis • Fractures of cartilaginous matrix • Positive Rumpel–Leede capillary fragility test (>20 petechiae/inch^2)‡	• Conventional: 0.5–1.5 mg/dl (plasma) • IU: 28–85 mmol/l (plasma) • Absence of vitamin C in urine	• Adults: 800 mg/day orally • Children: 150 mg/day orally
B_1 (thiamine)	• Skin breakdown may be seen in "wet" beriberi due to edema • Glossitis and glossodynia	• Early – fatigue, apathy, irritability, depression, drowsiness, anorexia, nausea, abdominal pain • Late – peripheral neuropathy, weakness, cardiac failure, mental alterations, growth retardation • Prolonged deprivation – meningismus, coma	• *Beriberi* is divided into "wet" and "dry" forms§ • Korsakoff's syndrome – amnesia, confabulation & peripheral neuropathy • Wernicke's encephalopathy – ophthalmoplegia, horizontal nystagmus, ataxia, confusion	• Measurement of the RBC transketolase activity coefficient is recommended‖ • Circulating thiamine levels – Conventional: 0.2–2 microg/dl (plasma); 1.8–4.8 microg/dl (whole blood) • IU: 7.5–75 nmol/l (plasma); 70–180 nmol/l (whole blood)	• 100 mg TID IV × several days, followed by 100 mg/day orally until complete recovery[15] • Infantile beriberi – 5–20 mg IV[15]
B_2 (riboflavin, lactoflavin)	• Angular cheilitis • Glossitis – pebbly appearance, then atrophic with irregular denudation of papillae • In periorificial sites (head & neck, anogenital region) – painless scaly papules, ulcers, indolent fissures & seborrheic dermatitis-like lesions • Conjunctivitis	• Superficial keratitis • Photophobia • Changes in iris (pigment clumping) • Anemia due to bone marrow hypoplasia • Mental retardation in newborns	• In adults, *oro-oculo-genital syndrome* can occur, especially if there are additional B vitamin deficiencies	• Conventional: 4–24 microg/dl • IU: 106–638 nmol/l • Elevation of the activation coefficient for RBC glutathione reductase confirms diagnosis • Urinary or RBC riboflavin concentration also useful	• Riboflavin 3–10 mg/day orally • In refractory cases, 2 mg IM TID
B_3 (niacin, nicotinic acid)	• Photodistributed erythema that becomes scarlet or hyperpigmented, with scale-crust; surface has shellac-like appearance (Fig. 51.8) • "Casal's necklace" – well-demarcated band around the neck • Painful fissures of the palms & soles • Peri-anal & oral inflammation & erosions • Cheilitis & glossitis (atrophic, red) • Vaginitis with ulceration	• Peripheral neuropathy with dysesthesias, including burning • Esophagitis • Anorexia • Lassitude • Dizziness • Irritability, disorientation • Abdominal pain • Late – irritability, anxiety, apathy, diarrhea, nausea, dementia	• The classic triad of *pellagra* is dermatitis, diarrhea & dementia, with the fourth "d" possibly death • Because of large tissue stores, symptoms develop after months of niacin or tryptophan deficiency • Other causes of pellagra include carcinoid syndrome, Hartnup disease, and medications, e.g. isoniazid¶	• No sensitive or specific serum assays • Most reliable test is urinary excretion of niacin metabolites: N′-methylnicotinamide and its 2-pyridone derivative (N′-methyl-2-pyridone-5-carboxamide)[15]	• Mild cases – nicotinic acid 50 mg TID orally[15] • If symptomatic, nicotinic acid 25 mg TID IV[15] • Advanced stages – nicotinic acid 50–100 mg IM TID × 3–4 days, followed by similar quantities PO[15]

*In laboratory medicine, there has been a movement toward expressing values in international units (IU) rather than conventional units, e.g. mg/dl, but because this is not done universally, both values are provided in this table.
‡Following inflation of blood pressure cuff to a point between systolic and diastolic blood pressure for 5 minutes.
§"Wet" beriberi derives its name from the edema that occurs secondary to cardiac failure, which can be high-output. In "dry" beriberi, neurologic manifestations predominate, e.g. peripheral neuropathy (sensory and motor), confusion and nystagmus.
‖Transketolase activity coefficient measures enzyme activity before and after the addition of exogenous thiamine pyrophosphate; RBCs from a deficient individual express a substantial increase in enzyme activity with the addition of thiamine pyrophosphate[7]
¶Tryptophan (an essential fatty acid) is a precursor of niacin. In carcinoid syndrome, tryptophan is preferentially converted to serotonin instead of niacin, and in Hartnup disease, niacin deficiency is due to decreased intestinal absorption of tryptophan.

Table 51.2 Vitamin deficiencies in adults and children (cont'd). Adapted in part from refs 7, 9,10 & 11. BID, twice daily; GI, gastrointestinal; GU, genitourinary; IM, intramuscularly; IV, intravenously; INR, international normalized ratio; PO, orally; RBCs, red blood cells; TID, three times daily; sc, subcutaneously.

Continued

VITAMIN DEFICIENCIES IN ADULTS AND CHILDREN					
Vitamin	**Clinical manifestations**			**Reference values***	**Replacement therapy**
	Mucocutaneous	**Systemic**	**Other**		
B_5 (pantothenic acid)	• None	• Fatigue, headache & vomiting • Hypoglycemia • Paresthesias	• Rare		
B_6 (pyridoxine, pyridoxamine, pyridoxal)	• Periorificial seborrheic dermatitis-like lesions • Angular cheilitis, stomatitis • Glossitis – atrophic with ulceration • Conjunctivitis • Intertrigo	• Anorexia, nausea, vomiting • Neurologic symptoms including peripheral neuropathy, somnolence, confusion & seizures • Sideroblastic anemia, eosinophilia, lymphopenia		• Plasma pyridoxal phosphate levels are measured • Conventional: 5–30 ng/ml • IU: 10–121 nmol/L	• Pyridoxine 50–100 mg/day PO to prevent neuropathy[15] • 100 mg/day IV in those with seizures[15]
B_7 (biotin)	• Alopecia • Seborrheic dermatitis of the scalp, face, flexures & perianal region • Nummular eczema[12] • Blepharitis, conjunctivitis • Erythroderma in neonatal form • Juvenile form may resemble acrodermatitis enteropathica	• Depression, lassitude • Anorexia, nausea & vomiting • Paresthesias & hyperesthesias • Hypotonia, muscle pain • Developmental delay, hearing loss • Seizures, ataxia • Both forms fatal if not treated	• Neonatal form – holocarboxylase synthetase deficiency (see Fig. 51.12) • Juvenile form – biotinidase deficiency • Two forms have overlap; both autosomal recessive • Metabolic acidosis, lactic acidosis, hyperammonemia	• Measurement of plasma levels of biotin is unreliable • Increased urinary excretion of organic acids (e.g. 3-hydroxy-isovaleric acid) • Additional diagnostic tests include enzyme activity and genetic analysis (see Fig. 51.12)	• Infants & children – 5–20 mg/day PO or IM • Adults – 10–40 mg/day PO or IM
B_9 (folic acid)	• Cheilitis, glossitis, mucosal erosions • Diffuse hyperpigmentation, with accentuation in sun-exposed sites	• Megaloblastic anemia (macrocytosis plus hypersegmented neutrophils is pathognomonic)[12] • Weakness secondary to anemia • Neuropsychiatric symptoms due to impaired synthesis of myelin	• While folate can reverse the megaloblastic anemia of B_{12} deficiency, it cannot reverse the neurologic degeneration	• Conventional: 140–628 ng/ml in packed RBCs • IU: 317–1422 nmol/l in packed RBCs	• Replace folate and exclude B_{12} deficiency • Folate 1 mg TID PO, followed by 1 mg/day • Folate 1–5 mg/day IV if acutely ill[15]
B_{12} (cyanocobalamin [CNCbl])	• Cutaneous findings are uncommon • Diffuse or patchy hyperpigmentation, including flexural areas, palms, soles, nails, oral cavity • Glossitis with fissures of the oral mucosa (early sign prior to anemia)[16] • Painful, red, swollen tongue	• Megaloblastic anemia due to altered folic acid metabolism • Peripheral neuropathy, ataxia	• Pernicious anemia – decrease in gastric intrinsic factor • Juvenile form – normal gastric acid secretion (in contrast to adult form) • Use of Schilling test has been supplanted by serologic testing for anti-parietal cell and anti-intrinsic factor antibodies • As an autoimmune endocrinopathy, associated with vitiligo, alopecia areata	• Megaloblastic anemia with decreased serum B_{12} levels • Conventional: 200–835 pg/ml • IU: 148–616 pmol/l • More sensitive assay is serum levels of methylmalonic acid and homocysteine**	• CNCbl 1 mg IM twice weekly × 2 weeks then weekly × 2 months then monthly[15] • Oral route is now felt to be appropriate, even in pernicious anemia or in states of abnormal absorption – 500 microg/day of CNCbl

*In laboratory medicine, there has been a movement toward expressing values in international units (IU) rather than conventional units, e.g. mg/dl, but because this is not done universally, both values are provided in this table.

**These levels are increased early in vitamin B_{12} deficiency.

Table 51.2 Vitamin deficiencies in adults and children (cont'd). Adapted in part from refs 7, 9,10 & 11. BID, twice daily; GI, gastrointestinal; GU, genitourinary; IM, intramuscularly; IV, intravenously; INR, international normalized ratio; PO, orally; RBCs, red blood cells; TID, three times daily; sc, subcutaneously.

Fig. 51.6 Phrynoderma of vitamin A deficiency. Multiple clusters of follicular papules with central keratotic plugs. Histologically, keratinous plugs within follicles, hyperkeratosis and atrophy of sebaceous glands are seen. It must be differentiated from pityriasis rubra pilaris and keratosis pilaris.

Under normal circumstances, the recommended average daily dietary intake for each micronutrient is measured in milligrams or even smaller quantities. This distinguishes micronutrients from macronutrients (carbohydrates, fats, proteins) as well as the macrominerals (calcium, magnesium, phosphorus)[7].

Vitamins

Vitamins are required constituents of the human diet as they are essential for development and maintenance of bodily functions. However, they do not have a direct role as an energy source. Vitamins are categorized as either fat-soluble (A, D, E, K) or water-soluble (all the others), as outlined in Table 51.2. This categorization is physiologically meaningful since none of the fat-soluble vitamins appear to serve as cofactors for enzymes, whereas most of the water-soluble vitamins do[7]. In addition, symptomatic vitamin excess is more likely with fat-soluble vitamins (see below). Lastly, the use of vitamins as therapeutic interventions in dermatology includes topical vitamin D analogues for psoriasis[8] (see Ch. 129) and oral or topical retinoids to treat acne and disorders of cornification (see Ch. 126).

Tables 51.2 and 51.3 review the major fat- and water-soluble vitamins, including their functions and the causes as well as signs and symptoms of associated deficiencies. Current standards for diagnosing these deficiencies, recommendations for daily supplements, and replacement therapies are also included.

Vitamin excess

Excessive ingestion of vitamins most commonly occurs in individuals seeking potential (and often unproven) "anti-aging" or antineoplastic effects. Toxicity due to high doses of water-soluble vitamins is rarely seen, as these compounds are rapidly excreted via the urine. In contrast, high doses of fat-soluble vitamins may lead to harmful side effects, including hepatic toxicity, nephrolithiasis and peripheral neuropathy (Table 51.4). They may also have unanticipated effects at high doses in certain populations. For example, in the β-Carotene and Retinol Efficacy Trial (CARET), a large cancer prevention trial, patients at high risk for lung cancer were given supplements containing β-carotene and vitamin A. Not only did these supplements fail to prevent lung cancer, they were actually associated with increased rates of lung cancer[19]. The reported association of oral isotretinoin and topical tretinoin (more controversial) with increased mortality in smokers remains to be corroborated[20].

Vitamin D

The signs and symptoms of vitamin D deficiency, none of which are cutaneous, are outlined in Table 51.2. The preferred method for assessing vitamin D status (and excluding deficiency) is measurement of total serum levels of 25-hydroxyvitamin D. While secondary hyperparathyroidism can influence the 1,25-dihydroxyvitamin D assay, this is not the case with the 25-hydroxyvitamin D assay. In addition,

Fig. 51.8 Pellagra. A Hyperpigmentation with desquamation of the dorsal aspects of the hands and forearms. **B** Hyperpigmented desquamation of the distal lower extremity. Note the shiny shellac-like appearance on the lateral ankle. *B, Courtesy, Jeffrey Callen, MD.*

VITAMINS – SOURCES, FUNCTIONS AND RECOMMENDED PROPHYLACTIC DOSES

Vitamin	Natural sources	Functions	Underlying etiologies/risk factors	Recommended prophylactic doses
A	• Animal fats, liver, milk, green leafy vegetables	• Normal vision • Embryogenic development • Physical growth • Immune function • Keratinocyte proliferation and differentiation • Squamous metaplasia of sebaceous and eccrine glands	• Minimal, if any, animal fats in diet – Poverty – Alcoholism – Anorexia nervosa – Fad diets • Fat malabsorption	• Infants & children: 100 000–200 000 IU every 4–6 months from age 6 months to 5 years • In measles: 200 000 IU once daily × 2 days • Postpartum women: 200 000 IU within 6 weeks of delivery
D	• UVB irradiation of the skin • Cod liver oil, fish (salmon, mackerel), fortified milk or yogurt • Estimates of sources – 10% from food & 90% from UVB	• Induces antimicrobial peptide gene expression in keratinocytes, monocytes, NK cells, T cells, B cells & neutrophils[8] • Induces cathelicidins via the vitamin D receptor • Helps absorption of ~85% of calcium and 40% of phosphorus via the gut • Decreases proliferation of malignant cells & induces terminal differentiation[8]	• Risk factors include: breastfed infants, individuals with darkly pigmented skin or limited sun exposure, advanced age, BMI >30 (fat sequesters vitamin D), living at extreme degrees of latitude[8] • Generalized disorders of cornification	• Vitamin D_3 is three times more effective than D_2 • Currently, the recommendation for adults is 600–1000 IU of vitamin D_3 per day* • The American Academy of Pediatrics has recommended 400 IU of vitamin D per day until age 18 years[17]
E	• Ubiquitous in foods, so deficiency is rare	• Possible role in cellular homeostasis • Antioxidant • Interferes with vitamin K-dependent coagulation via unknown mechanism	• Chronic cholestasis & pancreatic insufficiency (absorption requires biliary and pancreatic secretions)[15] • Long-term fat malabsorption	• No clearly proven medical benefits of daily vitamin E supplementation beyond the recommended daily allowance ingested in food
K	• K_1: green leafy vegetables & meat • K_2: fermented foods & grass-fed animals • Diet: ~50% • Bacteria within large bowel: ~50%	• K_1: hepatic synthesis of coagulation factors II, VII, IX & X and proteins C & S • K_2: regulates mineral localization (e.g. calcium)[18]	• Broad-spectrum antibiotics (reduce intestinal bacteria) • Malabsorption syndromes • Low-birthweight infants (inadequate intake, non-colonized colon, low hepatic stores, maternal medications†) • Liver diseases, biliary atresia, cystic fibrosis • Medications: cholestyramine, colestipol, orlistat and inhibitors of vitamin K epoxide reductase†	• Newborns: 0.5–1 mg sc or IM routinely administered prophylactically at birth
C	• Fresh fruits & vegetables	• Collagen formation • Cofactor for several enzymes, e.g. lysyl hydroxylase • Antioxidant • Iron absorption • Folate metabolism (folic acid to active form folinic acid)	• Alcoholism, chronic drug abuse • Fad diets • Deficient intake for as few as 3 months can lead to scurvy[12] • Increased requirements in the setting of febrile illnesses, diarrhea, iron deficiency	• Children: 40–50 mg/day • Adults: 60–100 mg/day
B_1 (thiamine)	• Yeast, cereals, liver, meat, eggs, vegetables	• Role in pyruvate metabolism (a source of energy generation) • Cofactor in metabolism of carbohydrates, lipids, branched-chain amino acids[15]	• Starvation, alcoholism • Polished rice diet • Hyperemesis gravidarum • B_1-deficient diet (IV hyperalimentation or parenteral nutrition) followed by high-carbohydrate diet exacerbates symptoms[15,‡] • Hemodialysis, leukemia, rapidly growing carcinoma	• Infants: 0.05 mg/day • Children and adults: 0.05–1.5 mg/day
B_2 (riboflavin)	• Milk and nutrients listed for vitamin B_1 (see above)	• Intracellular oxidation–reduction reactions	• Achlorhydria & GI malabsorption • Alcoholism • Hypothyroidism • Neonatal phototherapy for hyperbilirubinemia • Medications: chlorpromazine, probenecid, tricyclic antidepressants • Exacerbated by respiratory infections	• Infants: 0.6 mg/day • Children and adults: 1–2 mg/day
B_3 (niacin)	• Liver, lean pork, salmon, poultry and red meat • Humans are able to synthesize niacin from tryptophan (an essential amino acid)	• Vital oxidation–reduction reactions • Biosynthesis of epidermal lipids, e.g. ceramides	• Malnutrition • Intestinal malabsorption • Alcoholism • Diet limited to tryptophan-deficient maize[§] • Carcinoid syndrome[§] • Hartnup disease[§] • Medications: isoniazid	• Infants: 8 mg/day • Children and adults: 9–20 mg/day

*Many countries and institutions have their own recommendations regarding the appropriate dose of oral vitamin D per day. Over the past several years, there has been a trend toward higher doses. Currently, the NIM-recommended daily allowances for vitamin D are: 400 IU/day (0–12 months of age), 600 IU/day (1–70 years of age), and 800 IU/day (>70 years of age), whereas the American Academy of Dermatology has recommended 1000 IU/day for adults at risk for deficiency.

†Medications which inhibit vitamin K epoxide reductase in the liver: warfarin, anticonvulsants, certain cephalosporins (containing side chains of N-methylthiotetrazole or methylthiadiazole), high-dose salicylates, isoniazid and rifampin.

‡Pyruvate and lactate, which interfere with carbohydrate metabolism, accumulate in a B_1-deficient state. A high-carbohydrate diet accentuates the pre-existing vitamin-deficient state, often precipitating a Wernicke's or Korsakoff's syndrome.

§Tryptophan (an essential fatty acid) is a precursor of niacin. Tryptophan is deficient in maize, and millet interferes with tryptophan metabolism as it is high in leucine. In carcinoid syndrome, tryptophan is preferentially converted to serotonin instead of niacin, and in Hartnup disease, niacin deficiency is due to decreased intestinal absorption of tryptophan.

Table 51.3 Vitamins – sources, functions and recommended prophylactic doses. Adapted in part from refs 7, 9 & 10. GI, gastrointestinal; IM, intramuscular; IV, intravenous; sc, subcutaneous; UVB, ultraviolet B radiation.

Continued

VITAMINS – SOURCES, FUNCTIONS AND RECOMMENDED PROPHYLACTIC DOSES				
Vitamin	**Natural sources**	**Functions**	**Underlying etiologies/risk factors**	**Recommended prophylactic doses**
B_5	• Synthesized in gut by bacterial flora	• Component of coenzyme A which plays major role in metabolism	• Protein–energy malnutrition	• Not well studied as deficiency is extremely rare
B_6	• Widely distributed in nature • Pyridoxine in plant food • Pyridoxal and pyridoxamine in animal products • All forms convert to the active form pyridoxal phosphate	• Cofactor for multiple enzymes involved in amino acid metabolism and conversion of linoleic acid to arachidonic acid • Ceramide synthesis • Gluconeogenesis & heme biosynthesis[15]	• Other vitamin or trace element deficiencies (metabolism of B_6 is dependent on riboflavin, niacin & zinc) • Medications: isoniazid, anticonvulsants, penicillamine, hydralazine, oral contraceptives, corticosteroids[15] • Inflammatory bowel disease, uremia & cirrhosis	• 0.5–2 mg per day • Supplementation required in those taking isoniazid
B_7 (biotin)	• Liver is best source • Other meats, egg yolks, yeast, tomatoes • Probably synthesized in gut by bacterial flora	• Essential cofactor for several carboxylases involved in cellular metabolism, e.g. of fatty acids • Plays role in gluconeogenesis[12]	• Inborn error of metabolism • Inadequate diet • Excessive raw egg white consumption‖ • Chronic anticonvulsant therapy	• Normal intake: – Infants: 5 microg/day – Children: 8–20 microg/day – Adults: 30 microg/day • Supplementation: – Children: 200 microg/day – Adults: 300 microg/day
B_9 (folate)	• Liver, green leaves, meat, milk, yeast • Easily destroyed with cooking[12] • Body stores are limited, so anemia can result after 4–5 months of deficient intake	• DNA synthesis	• Deficient diets • Medications (which interfere with folate metabolism): methotrexate, sulfasalazine, pyrimethamine	• Infants: 65–80 microg/day • Children: 150–300 microg/day • Adults: 400 microg/day • During breastfeeding: 500 microg/day • Prenatal and 1st trimester: 600 microg/day • If taking methotrexate: 1000 microg (1 mg)/day; maximum of 5000 microg (5 mg)/day
B_{12}	• Fish, shellfish, meat, dairy products • Body stores are large, so development of deficiency requires 3–6 years of a deficient state	• DNA synthesis	• Strict vegetarianism/veganism • Decrease in gastric intrinsic factor (pernicious anemia) • Gastrectomy, surgical resection of terminal ileum • Overgrowth of intestinal bacteria • Medications: metformin	• For the normal population on a regular diet, no need for supplementation

‖Excessive consumption of raw egg whites (>20 eggs/day) leads to high levels of the protein avidin, which binds to biotin, rendering it biologically unavailable. Avidin is deactivated by cooking, while biotin remains intact.

Table 51.3 Vitamins – sources, functions and recommended prophylactic doses (cont'd). Adapted in part from refs 7, 9 & 10. GI, gastrointestinal; IM, intramuscular; IV, intravenous; sc, subcutaneous; UVB, ultraviolet B radiation.

25-hydroxyvitamin D has a longer half-life (2 weeks) and therefore is thought to better reflect body stores[8,14]. Currently, although a consensus is lacking, vitamin D deficiency is defined by most experts as a serum level of 25-hydroxyvitamin D that is <20 ng/ml (50 nmol/l), and vitamin D insufficiency as circulating levels of 20–29 ng/ml (51–75 nmol/l) (see Table 51.2).

Based upon these levels, it is estimated that one billion people worldwide have either deficient or insufficient levels of vitamin D[13]. Depending upon the study, from 40% to 100% of elderly men and women in the US and Europe (excluding those in nursing homes) are deficient in vitamin D[13]. However, vitamin D deficiency is not limited to the elderly. Recently, it was reported that 52% of Hispanic and black adolescents and 48% of white preadolescent girls in the US had 25-hydroxyvitamin D levels <20 ng/ml[14].

As a result of these and other studies, concern has been raised that the recommended daily intake of 400 IU of vitamin D_3 is inadequate. Because the 25-hydroxyvitamin D assay is expensive and universal testing is not feasible, there has been a call to simply revise the current recommendations. While some have advocated 800–1000 IU of oral vitamin D_3 daily for children and adults (unless there are contraindications)[8,14,17], others such as the National Institute of Medicine has recommended: 400 U/day (0–12 months of age), 600 IU/day (1–70 years of age), and 800 IU/day (>70 years of age). All of these doses are below the age-dependent, tolerable, upper daily limits of 1000 IU for infants and children (up to 18 years old) and of 2000 IU for adults[17]. Vitamin D_3 (cholecalciferol; animal diet as source) is viewed as nutritionally superior to vitamin D_2 (ergocalciferol; source is plants) and therefore is regarded as the best form for supplementation and for fortifying foods. Of note, unless a person frequently eats foods rich in fish oils, it is very difficult to obtain enough vitamin D_3 from dietary sources alone[17].

Dermatologists in particular are well aware that there is also an endogenous source of vitamin D production, initiated with the conversion of 7-dehydrocholesterol to provitamin D_3 when skin is exposed to ultraviolet B radiation (Fig. 51.10). It is thought that typically over 90% of vitamin D is produced in this manner. Obviously, the balance between sun protection (to prevent photodamage and cutaneous malignancies) and increasing the risk of vitamin D deficiency has become a matter of debate. As effects of vitamin D, beyond calcium homeostasis and bone mineralization, have become increasingly recognized, the debate has intensified. For example, immunomodulatory effects via the innate immune system have been reported, as has an association between vitamin D deficiency and an increased risk of several internal malignancies[14]. While there are studies that refute the latter as well as no direct evidence linking sunscreen use with vitamin D deficiency[8,21], it is prudent to recommend supplementation to patients who are limiting sun exposure and/or have risk factors for the development of vitamin D deficiency (see Tables 51.2 & 51.3).

Trace elements

Trace elements and minerals constitute ~3% of body weight at birth and 4% in adults. Based upon animal studies, 15 trace elements have

VITAMIN EXCESS IN ADULTS AND CHILDREN				
Vitamin	**Mechanism of toxicity**	**Clinical manifestations**		**Comments**
		Cutaneous	**Systemic**	
A	• Chronic intake of >25 000 IU vitamin A per day • Ingestion of polar bear liver • Co-administration with other retinoids	• Cheilitis • Xerosis with pruritus • Dermatitis • Alopecia	• Painful swelling of the long bones in young children • Elevated hepatic enzymes • Skeletal hyperostosis • Calcification of extraspinal tendons and ligaments • Pseudotumor cerebri • Lethargy, anorexia	• Assessment by serum concentrations – unreliable • Similar side effects as oral retinoids (see Ch. 126) • Treatment – immediate discontinuation
Beta-carotene (natural provitamin of vitamin A)	• Carotenemia – high intake of carrots & yellow squash, including as baby food • Lycopenia – high intake of tomatoes, gac, papaya, pink guava & other fruits • Inability to convert β-carotene to vitamin A (e.g. hypothyroidism, diabetes, anorexia nervosa)	• Yellow–orange discoloration (Fig. 51.9) due to deposition of carotenes/lycopenes in areas with: – the thickest layer of stratum corneum (palms & soles) – abundant sebaceous glands (nasolabial folds, forehead) • Carotenoderma usually appears when carotene levels are 3–4× normal	• None	• Skin discoloration slowly disappears after altering diet • Measurement of serum carotenoids (normal range: 0.4–1.5 mg/l) differentiates this disorder from jaundice, in which mucous membranes have a yellow color (most apparent in sclerae)
D	• >50 000 IU/day of oral supplementation	• None	• Nausea, vomiting • Poor appetite • Diarrhea, constipation • Weakness • Nephrolithiasis, nephrocalcinosis • Hypercalcemia, hypercalciuria, hyperphosphatemia	• NOT caused by excessive UV exposure (previtamin D_3 and vitamin D_3 inactivated by sustained exposure of skin to heat) • Tolerable upper limit for adults is 2000 IU/day[17]
E	• High supplement doses	• Petechiae, ecchymoses	• May reduce platelet aggregation • Interferes with function of vitamin K	• Drug–drug interaction with warfarin (see Ch. 133)
K	• None	• None	• None	• Side effects at sc injection sites: – early – erythematous plaque, often annular (see Ch. 21) – late – morpheaform plaque (Texier's disease)
C	• Excessively high doses of oral supplements	• None	• GI upset • Osmotic diarrhea • Nephrolithiasis	• Abrupt discontinuation of excessive vitamin C intake can also lead to scurvy
B_3	• Excessively high doses of oral supplements	• Flushing, pruritus, xerosis • Acanthosis nigricans	• Dyspepsia • Hepatic failure • Hyper- or hypoglycemia • Hyperuricemia	
B_6	• Long-term oral doses of >200 mg/day	• Photosensitivity	• Loss of proprioception • Painful sensory neuropathy	

Table 51.4 Vitamin excess in adults and children. Adapted in part from refs 7, 9 & 10. GI, gastrointestinal; sc, subcutaneous; UV, ultraviolet.

Fig. 51.9 Carotenemia. The patient's legs are noticeably orange when compared to the photographer's hand.

been identified as essential for health: *iron*, *zinc*, *copper*, *chromium*, *selenium*, *iodine*, *fluoride*, *manganese*, *molybdenum*, *cobalt*, nickel, tin, silicon, vanadium and arsenic (in very small doses). As for being essential nutrients in humans, there is compelling evidence for just the first 10 (in italics). They serve multiple cellular functions including as cofactors for enzymes and as prosthetic groups in metalloproteins. An example of the latter is the complexing of iron and protoporphyrin IX via ferrochelatase to form heme[7]. Deficiency syndromes related to essential trace elements, other than iron, zinc, copper, iodine or cobalt, were not recognized until recently. Explanations include the exceedingly small requirements for these trace elements, their ubiquitous nature in foodstuffs[7], and the lack of routine laboratory assays. Only trace elements of dermatologic importance will be discussed in this chapter.

Zinc

Zinc is one of the most important trace elements in humans, playing a critical role in the function of more than 200 zinc-dependent metalloenzymes that regulate lipid, protein and nucleic acid synthesis and degradation. Zinc can be found in human breast milk, animal-based foods, shellfish, legumes and green leafy vegetables. There is evidence to suggest that zinc plays a role in enhancing wound healing and improving immune function[22] and this may explain the poor wound

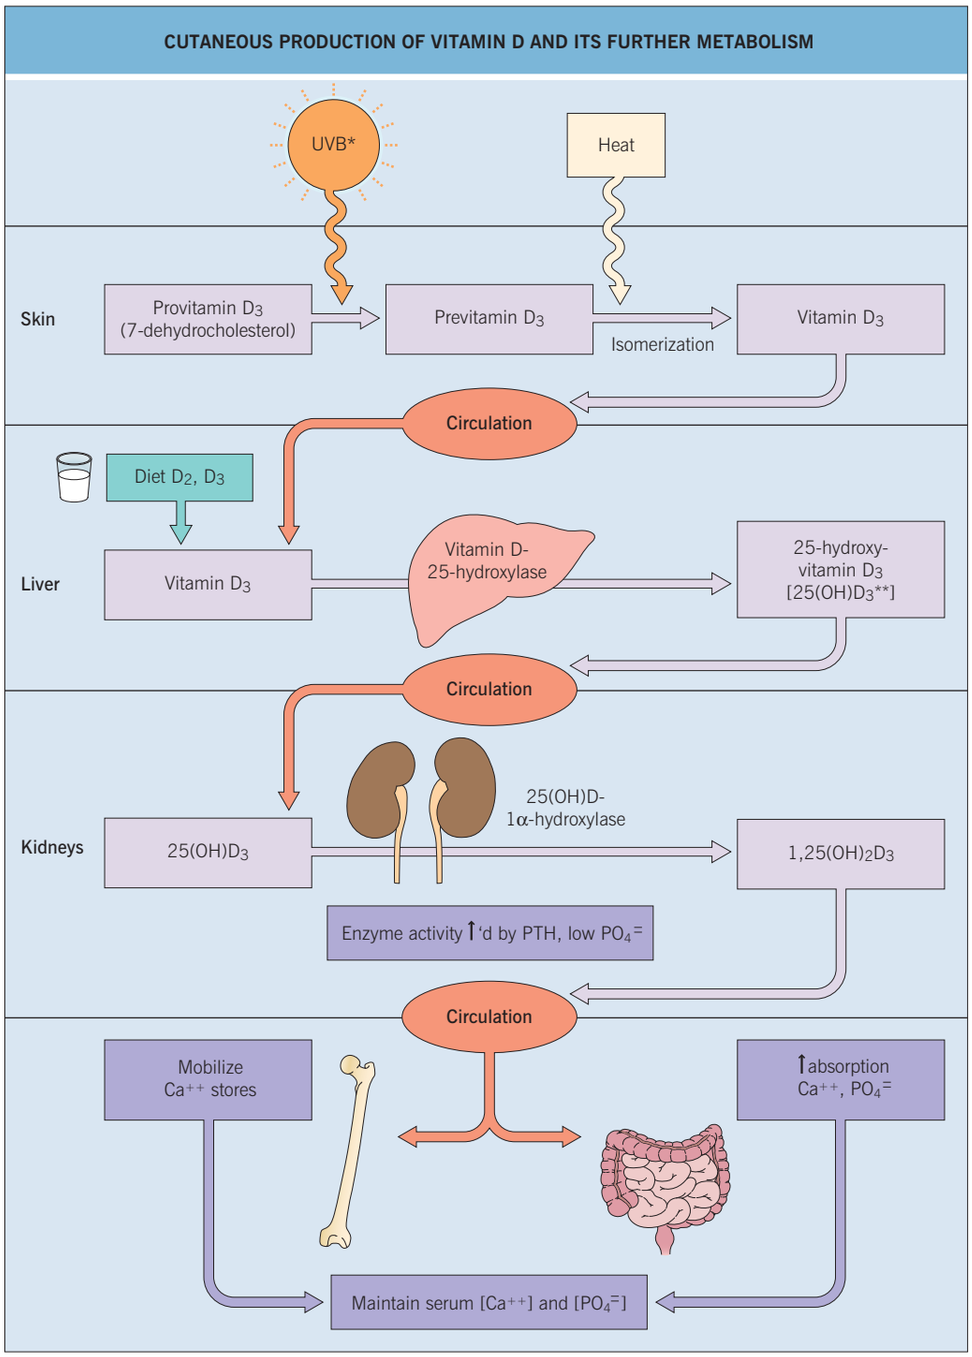

Fig. 51.10 Cutaneous production of vitamin D and its further metabolism. During exposure to ultraviolet B radiation, 7-dehydrocholesterol within the skin is converted to previtamin D_3, which is then immediately converted to vitamin D_3 in a heat-dependent process[14]. Of note, the heat from excessive sunlight exposure can degrade previtamin D_3 and vitamin D_3 into inactive photoproducts. Both forms of vitamin D (D_3 and D_2) are biologically inactive and they require activation in the liver and then the kidney. After binding to carrier proteins, vitamin D is transported to the liver, where it is enzymatically hydroxylated to 25-hydroxyvitamin D [25(OH)D], the major circulating form of vitamin D. 25-hydroxyvitamin D is then converted into its active form, 1,25-dihydroxyvitmain D [$1,25(OH)_2D$], within the kidney by the enzyme 1α-hydroxylase. Of interest, this final hydroxylation step can also occur in keratinocytes when the enzyme CYP27B1 is upregulated in response to wounding or by Toll-like receptor (TLR) activation from microbial-derived ligands[8].

Serum levels of phosphorus, calcium and fibroblast growth factor 23 can either increase or decrease renal production of $1,25(OH)_2D$. $1,25(OH)_2D$ decreases its own synthesis via feedback inhibition and decreases the synthesis and secretion of parathyroid hormone by the parathyroid glands. $1,25(OH)_2D$ also enhances intestinal calcium absorption in the small intestine by interacting with the vitamin D receptor–retinoic acid X receptor complex (VDR-RXR) to enhance the expression of the epithelial calcium channel and calbindin-D 9K, a calcium-binding protein. In addition, $1,25(OH)_2D$ is recognized by its receptor in osteoblasts, leading to a series of events that maintain calcium and phosphorus levels in the blood which in turn promotes mineralization of the skeleton. *Most effective wavelength = 300 ± 5 nm. **Measurement of this form most commonly done to assess vitamin D status.

healing and increased susceptibility to cutaneous infections that can be seen in patients with chronic zinc deficiency. Due to its antioxidant properties, zinc might protect the skin against UV-induced damage[23].

Patients with zinc deficiency can develop erythema, scale-crusts and erosions, especially in the following sites – perioral, acral and perineal (Fig. 51.11); occasionally, vesicles or bullae are seen as well as psoriasiform plaques. Zinc deficiency may also lead to alopecia, paronychia, onychodystrophy, blepharitis, conjunctivitis, stomatitis and angular cheilitis. Diarrhea, depression (apathy) and dermatitis (erosive) are sometimes considered the triad of zinc deficiency, but the triad is seen in only 20% of patients. Superimposed cutaneous infections with *Candida* spp. and staphylococci are very common. Patients are typically irritable and sleep poorly; children with chronic zinc deficiency may experience growth retardation and/or develop hypogonadism. If treatment is not initiated, death may ensue.

Zinc deficiency can be either acquired or inherited as an autosomal recessive disorder, acrodermatitis enteropathica (AE). The latter is due to mutations in the gene that encodes the zinc transporter SLC39A4 which is expressed in the intestine and kidney. Clinical manifestations usually appear within 1 to 2 weeks after weaning from breast milk, or at 4 to 10 weeks of age if bottle-fed. However, there are reports of zinc deficiency in breastfed babies where the breast milk contained low levels of zinc. Of note, infants and children with cystic fibrosis can also develop zinc deficiency (Fig. 51.12). This deficiency should be considered in patients who have treatment-resistant seborrheic dermatitis or anogenital dermatitis.

There are several risk factors for developing acquired zinc deficiency, including alcoholism, anorexia nervosa, diets high in mineral-binding phytate (Middle Eastern diets), and vegan diets. Of note, vegan diets can also lead to low levels of long-chain n-3 (omega-3) fatty acids, calcium, vitamin D and vitamin B_{12}[24]. In addition, intestinal malabsorption often results in multiple deficiencies, including zinc. Lastly, zinc deficiency can be seen in association with pregnancy, HIV infection, chronic renal failure and drugs (e.g. penicillamine).

The histologic finding of epidermal necrosis (see below) plus low serum alkaline phosphatase and zinc levels point to the diagnosis; the normal reference range for zinc is 70–150 microg/dl (10.7–22.9 micromol/l). An explanation for the abnormal alkaline phosphatase

Fig. 51.11 Zinc deficiency. Genetic (**A, B**) and acquired (**C, D**) forms. Both have erythema with erosions (**A, C**) as well as crusting and desquamation. Lesions favor acral and periorificial sites.

level is that for this enzyme, zinc is an essential trace element. Special trace element tubes should be used for blood collection in order to avoid metal contamination and EDTA-containing tubes should be avoided.

Cutaneous and other systemic manifestations respond dramatically to zinc sulfate or zinc gluconate (1–2 mg/kg/day in the acquired forms and 3 mg/kg/day for AE). The commercially available 220 mg zinc sulfate tablets contain 50 mg of elemental zinc. Patients with persistent malabsorption syndromes and AE require lifelong zinc supplementation, with repeated serum zinc determinations. Lastly, hypozincemia has been described in some patients with necrolytic acral erythema and treatment with zinc sulfate 220 mg orally twice daily resulted in resolution of the lesions.

Copper

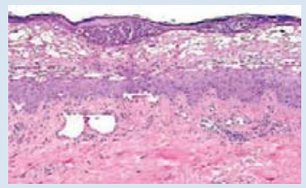
Copper is an essential trace element that is required for the function of a number of enzymes, e.g. tyrosinase, lysyl oxidase. The average adult body contains ~80 mg of copper. In the bloodstream, 90% of copper is associated with ceruloplasmin, and the remainder is bound to other plasma proteins, primarily albumin. Acquired copper deficiency is rare. It has been reported in infants receiving milk low in copper, in protein–energy malnutrition, and as a consequence of excessive zinc intake. Symptoms include anemia, neutropenia and failure to thrive, but cutaneous findings are limited to rare reports of pigmentary dilution of the skin and hair.

Menkes disease, also known as kinky hair disease, represents an inherited form of copper deficiency. It is an X-linked recessive condition characterized clinically by defective copper absorption with low copper levels in the blood, liver and hair. Affected infants may appear normal and develop normally until 2 to 3 months of age, when they gradually manifest failure to thrive, lethargy, hypothermia and hypotonia. In addition to seizures and developmental delay, patients may also have anemia and bony abnormalities (similar to those in scurvy). Arteriography demonstrates tortuosity and elongation of arteries, a reflection of immature elastin (as detected by ultrastructural studies)[25]. Decreased activity of several enzymes, including cytochrome C oxidase (in the brain), lysyl oxidase (in connective tissues and blood vessels) and ascorbic acid oxidase (in bones), may account for the associated clinical findings.

Pudgy cheeks, a cupid's bow of the upper lip, and horizontal eyebrows comprise the typical facies in Menkes disease[26]. However, a more obvious and characteristic finding is alopecia with abnormal hair shafts. There are 180° twists of the hair (pili torti), segmental shaft narrowing (monilethrix) and brush-like swellings of the hair shaft (trichorrhexis nodosa). The hairs appear to be light in color, sparse (Fig. 51.13), fragile and kinky. Patients may also have diffuse cutaneous pigmentary dilution due to decreased activity of tyrosinase, a copper-dependent enzyme. In addition, obligate female carriers may have patches of swirled hypopigmentation or pili torti along Blaschko's lines, as a result of lyonization.

DIFFERENTIAL DIAGNOSIS OF "NUTRITIONAL DERMATITIS"

Evaluation of the infant/child* with periorificial and acral erythema and erosions



Zinc deficiency	Essential fatty acid deficiency	Biotin deficiency	Organic acidurias**	Cystic fibrosis
Acrodermatitis enteropathica (genetic form): • Onset days to weeks after birth if bottle-fed, or after weaning if breast-fed **Acquired forms:** • Low zinc level in maternal milk • Parenteral nutrition without zinc supplementation • Gastrointestinal disorders/ surgeries or high-fiber diets (high phytate content) causing poor absorption • HIV infection	• Parenteral nutrition without lipid supplementation • Gastrointestinal disorders/ surgeries causing severe fat malabsorption • Nephrotic syndrome	**Biotinidase deficiency:** onset age 3 months to 2 years (juvenile form) **Holocarboxylase synthetase deficiency:** onset days to months after birth (neonatal form) **Acquired forms:** • Parenteral nutrition without biotin supplementation • Gastrointestinal disorders/ surgeries causing severe malabsorption • Excessive intake of raw egg whites • Chronic anticonvulsant therapy (e.g. phenytoin, carbamazepine, valproic acid)	**Propionic acidemia** (propionyl CoA carboxylase deficiency) **Methylmalonic acidemia** (methylmalonyl CoA mutase deficiency or lack of vitamin B_{12} activity) **Maple syrup urine disease** (branched-chain α-ketoacid dehydrogenase deficiency) **Citrullinemia** (argininosuccinic acid synthetase deficiency)	Onset typically at age 3–5 months (precedes respiratory symptoms)
Signs: • Stomatitis, glossitis • Alopecia • Secondary infections (e.g. candidiasis) • Photophobia • Diarrhea • Irritability • Failure to thrive	**Signs:** • Diffusely xerotic skin • Alopecia and lightly pigmented hair • Failure to thrive • Thrombocytopenia	**Signs:** • Alopecia • Blepharitis, conjunctivitis • Secondary infections (e.g. candidiasis) • Vomiting • Metabolic acidosis • Hypotonia, lethargy, seizures, developmental delay • Optic atrophy, hearing loss, ataxia (with biotinidase deficiency)	**Signs:** • Alopecia • Secondary infections (e.g. candidiasis) • Vomiting • Metabolic acidosis • Hypotonia, lethargy, developmental delay • Failure to thrive • Pancytopenia	**Signs:** • Eruption often involves the trunk • +/– Alopecia • No mucous membrane involvement • Diarrhea • Edema • Irritability • Failure to thrive
Laboratory: • Plasma zinc level • Serum alkaline phosphatase level (low) • +/– Zinc level of maternal milk • Genetic analysis	**Laboratory:** • Plasma linoleic, arachidonic and eicosatrienoic acid levels (eicosatrienoic:arachidonic ratio > 0.4)	**Laboratory:** • Plasma ammonia and lactate levels • Urine organic acid analysis • Biotinidase activity in serum • Holocarboxylase synthetase activity in skin fibroblasts or peripheral blood lymphocytes • Genetic analysis	**Laboratory:** • Plasma ammonia and glycine levels • Urine organic acid analysis • Plasma isoleucine level (if on low branched-chain amino acid diet)	**Laboratory:** • Serum albumin level • Plasma zinc level • Sweat test • Genetic analysis

* In older patients, the differential diagnosis includes necrolytic migratory erythema (as seen in glucagonoma syndrome) and necrolytic acral erythema (in association with hepatitis C infection); periorificial (oral and perineal) erythema and erosions can also be seen in niacin (pellagra) and riboflavin deficiencies, with a characteristic photodistributed eruption found in the former; severe infantile seborrheic dermatitis typically involves other intertriginous sites such as the neck as well as the diaper area, scalp and face

** Cutaneous eruptions may be associated with adherence to a therapeutic diet low in branched-chain amino acids (e.g. isoleucine deficiency)

Fig. 51.12 Differential diagnosis of "nutritional dermatitis" (in addition to exogenous protein–energy malnutrition). *Courtesy, Julie V Schaffer, MD. Photomicrograph, courtesy, Earl Glusac, MD.*

Fig. 51.13 Menkes disease. This child has the characteristic pale skin and sparse kinky hair. *Courtesy, Ramón Ruiz-Maldonado, MD.*

The clinical features, low serum levels of copper and ceruloplasmin, and microscopic hair shaft findings establish the diagnosis. Infants with Menkes disease have a poor prognosis, with a life expectancy of 3 to 5 years and progressive deterioration leading to death. Treatment with copper histidine is usually unsuccessful. Mutations in *ATP7A*, which encodes a copper-transporting ATPase, lead to Menkes disease (as well as occipital horn syndrome; see Ch. 95); therefore, prenatal diagnosis is possible.

Copper toxicity can be acquired or inherited. The acquired form usually results from the ingestion of excessive amounts of copper (e.g. milk boiled in eroded copper pots) and it leads to gastrointestinal symptoms and occasionally (in predisposed individuals) childhood cirrhosis. The inherited form is Wilson disease, an autosomal recessive disorder characterized by an accumulation of copper within internal organs (in particular the liver, cornea and brain). Affected individuals have mutations in the gene *ATP7B* which also encodes a copper-transporting P-type ATPase. Dysfunction of this protein leads to an impairment of both intrahepatic trafficking and biliary excretion of copper[26].

Because daily copper intake exceeds the body's requirements, an effective means of excreting excess copper is crucial. This is accomplished by ATP7B, which mediates both copper secretion into plasma (coupled with ceruloplasmin synthesis) and its excretion into bile. The presence of excess copper within tissues (due to dysfunction of ATP7B) induces free-radical reactions and lipid peroxidation. Resultant hepatic damage leads to steatosis, inflammation, cirrhosis and, finally, liver failure[27].

The diagnosis of Wilson disease is established by the detection of low serum ceruloplasmin, increased urinary copper excretion, increased hepatic copper content, and/or genetic testing. The clinical hallmarks of Wilson disease are hepatomegaly, cirrhosis, Kayser–Fleischer corneal rings, and neurologic symptoms (dysarthria, dyspraxia, ataxia, and parkinsonian-like extrapyramidal signs).

Chelating agents, in particular penicillamine, are used to treat Wilson disease. Oral zinc can be prescribed for pre-symptomatic patients or as maintenance therapy, as it induces a negative copper balance.

Selenium

Selenium, in the form of selenocysteine, is an essential component of several enzymes, including those involved in thyroid hormone metabolism and protection against oxidative damage (e.g. glutathione peroxidase). Deficiency of selenium typically results in a cardiomyopathy as well as muscle pain and weakness due to muscle degeneration. Cutaneous manifestations include hypopigmentation of the skin and hair (considered early signs), leukonychia and xerosis, all of which respond to selenium replacement[28]. There was also a report of erythematous scaly papules and plaques involving the cheeks, hips, thighs and popliteal fossae, along with erosions in the diaper area[29]. Elevated serum levels of creatine kinase and transaminases are often present in selenium deficiency as well.

Selenium deficiency has been reported in patients receiving total parenteral nutrition and in those who live in areas where the soil content of selenium is poor[30]. Low serum levels of selenium and glutathione peroxidase activity are indicative of selenium deficiency. The recommended replacement dosage in selenium-deficient patients is a maximum of 100–200 microg per day, with the Recommended Daily Allowance (RDA) being 70 microg per day for adults and 20 microg for infants.

Although controversial, over-supplementation can occur due to reported beneficial cardiovascular and anti-cancer effects[31]. If supplements are taken, they should not exceed 200 microg per day. Excessive selenium ingestion can produce selenosis in humans, leading to a peripheral neuropathy, dermatitis, alopecia, abnormal nails, nausea and vomiting as well as a garlic-like breath odor. The use of selenium sulfide shampoo in large areas of eroded or ulcerated skin may lead to excessive absorption, with loss of appetite and tremor.

Anorexia Nervosa and Bulimia (Nervosa)

Anorexia nervosa and bulimia nervosa are eating disorders characterized by starvation, excessive exercise, self-induced vomiting and/or abuse of medications (e.g. laxatives, diuretics). Both can result in primary and secondary nutritional deficiencies. Anorexia nervosa is a persistent unwillingness or inability to maintain adequate body weight, whereas patients with bulimia typically binge-eat then purge or fast. These disorders occur most commonly in adolescent girls and young adult women, but can affect both genders and all age groups. Skin disorders, either real or perceived, are common in these patients and women in particular report a greater dissatisfaction with the appearance of their skin when compared to a similar cohort[32].

The dietary changes and starvation associated with anorexia nervosa and bulimia can lead to a number of cutaneous findings, including telogen effluvium, lanugo-like hair, xerosis, generalized pruritus, carotenoderma and hyperpigmentation. In addition, these patients can develop acrocyanosis, perniosis and livedo reticularis. Signs of specific nutritional deficiencies (e.g. pellagra, scurvy, acrodermatitis enteropathica) may be present, as well as poor wound healing, seborrheic dermatitis and edema[33]. Additional clues to the diagnosis include petechiae, interdigital intertrigo, paronychia, and particularly calluses or scars on the knuckles or dorsal surface of the hand (Russell's sign) due to repeated self-induced vomiting over prolonged periods of time. Patients with bulimia may also have enlarged salivary glands and erosion of their tooth enamel. Psychiatric and nutritional support must be instituted as severe malnutrition is common.

Obesity

Obesity, whether acquired or inherited, is defined as a body mass index (BMI) over 30; the latter has been found to correlate with high levels of the adipokine leptin[34]. Genetic disorders such as Prader–Willi, Bardet–Biedl, Alström and Wilson–Turner syndromes have been associated with childhood-onset obesity. In addition, endocrine disorders such as Cushing's disease, Cushing's syndrome, and insulin resistance include obesity amongst their clinical manifestations.

Acquired obesity is at epidemic proportions in both adults and children in industrialized nations. Although paradoxical, it is a functional malnutrition due to the consumption of high-caloric foods that are low in nutrients. Obesity is a systemic disease, as evidenced by an increased incidence of hypertension, hyperglycemia and hyperlipidemia, components of the metabolic syndrome (see Table 53.5), as well as atherosclerotic cardiovascular disease and premature death. Cutaneous manifestations are nonspecific, but some of the more common findings, such as acanthosis nigricans, appear to be related to insulin resistance (Table 51.5)[35]. One speculation is that the insulin resistance may be related to the relative zinc deficiency observed in obese patients (zinc is thought to promote insulin-induced glucose uptake in peripheral tissues)[36].

Bariatric Surgery and Gastrointestinal Malabsorption

The increase in acquired obesity has led to an increase in the number and types of bariatric surgery performed. Due to subsequent alterations in gastrointestinal absorption, some post-bariatric surgery patients can develop nutritional deficiencies. Two of the more commonly performed surgeries are laparoscopic adjustable banding and the Roux-en-Y gastric bypass. Because the normal absorptive surface is left intact with the former, nutrient deficiencies in these patients are rare. On the other hand, the Roux-en-Y gastric bypass procedure reduces stomach size and, as a result, there are lower levels of intrinsic factor, gastrin, hydrochloric acid and pepsinogen, which lead to a reduction in protein digestion. The Roux-en-Y procedure also decreases the physical grinding of food

DERMATOSES OBSERVED IN OBESE INDIVIDUALS
• Plantar hyperkeratosis (presumably pressure-related)
• Acanthosis nigricans (insulin resistance*)
• Skin tags
• Striae distensae
• Intertrigo (*Candida* spp. and bacteria; related to increased temperature and humidity of permanent semi-occlusive skin folds)
• Hyperpigmentation (frictional; favors inner thighs and under bra straps)
• Hyperhidrosis
• Stasis dermatitis
• Leg ulcers, most commonly venous
• Lipodermatosclerosis, lower extremities and abdominal pannus
• Lymphedema, lower extremities and abdominal pannus
• Obesity-associated lymphoedematous mucinosis, lower extremities and pannus
*Perhaps due to excess insulin binding to insulin-like growth factor receptors on keratinocytes.

Table 51.5 Dermatoses observed in obese individuals. Individuals with psoriasis have an increased prevalence of obesity.

that typically helps to release vitamins and minerals. Abnormally low levels of micronutrients, such as iron, zinc, copper and vitamins A, E, B_9 (folate) and B_{12}, may be seen in these patients, and long-term monitoring is required, as it may take months or years for signs and symptoms to appear[37].

In disorders such as Crohn's disease that are associated with gastrointestinal malabsorption, at least 50% of patients may have low plasma concentrations of vitamin C, copper, niacin and zinc[38].

PATHOLOGY

Nutritional deficiencies generally occur in combination; therefore, the resultant pathologic changes are often very variable. Although nutritional diseases have been better studied biochemically than structurally, there are several helpful histologic clues, including necrosis of the upper one-third of the epidermis (see Fig. 51.12). This distinctive reaction pattern has been reported in pellagra, acrodermatitis enteropathica, acquired zinc deficiency, glucagonoma and pseudoglucagonoma syndromes. In the early stages, there is vacuolar degeneration of the upper half of the epidermis. This stage is followed by the development of acanthosis, with hyperkeratosis and an increase in pigment throughout the epidermis. The late stage is characterized by epidermal atrophy (with flattening of the rete ridges) and dermal fibrosis[39]. In protein–energy malnutrition, nonspecific histologic features are seen, such as epidermal atrophy and hyperkeratosis.

Hair is a superb model of growth and differentiation. The histologic study of the hair matrix and hair shaft may be useful in detecting moderate to severe degrees of protein–energy malnutrition[40].

DIFFERENTIAL DIAGNOSIS

Nutritional diseases rarely result from the deficiency of a single nutrient, element or vitamin. Therefore, clinical manifestations are often nonspecific and, in mild to moderate deficiencies, somewhat subtle. A few specific deficiencies have characteristic mucocutaneous and systemic features that are easily recognized by the experienced clinician. Most suspected deficiencies are easily confirmed via laboratory analysis (see Table 51.2), and readily respond to the administration of the deficient nutrient, element and/or vitamin.

TREATMENT

The treatment of nutritional diseases must be individualized, taking into account the likelihood of multiple deficiencies of both macro- and micronutrients. The recommended treatment for specific nutritional diseases is reviewed in this chapter, but management frequently requires a multidisciplinary approach.

Graft-versus-Host Disease 52

Edward W Cowen

Key features

- Currently, 25 000 allogeneic hematopoietic stem cell transplants (HSCTs) are performed worldwide each year
- Trends in the use of unrelated donors, non-myeloablative conditioning protocols, and donor lymphocyte infusions are impacting the incidence and presentation of graft-versus-host disease (GVHD)
- Acute GVHD is a major complication of allogeneic HSCT; severe skin involvement is associated with a high mortality rate
- Chronic cutaneous GVHD is a polymorphous condition with features resembling lichen planus, lichen sclerosus, morphea and eosinophilic fasciitis
- Chronic cutaneous GVHD is difficult to treat and the aggressiveness of treatment must be balanced against the complications of chronic immunosuppression

INTRODUCTION

Graft-versus-host disease (GVHD) is a multiorgan disease most commonly due to the transfer of foreign donor hematopoietic stem cells into a host recipient via an allogeneic hematopoietic stem cell transplant (HSCT). GVHD may also occur following transfusion of non-irradiated blood products (to immunocompromised hosts) by maternal–fetal transmission or in the setting of solid organ transplantation. Despite several decades of experience with HSCT for a broadening array of disorders (Table 52.1), GVHD remains a treatment dilemma and a significant cause of non-relapse-related morbidity and mortality. Acute GVHD (aGVHD) often presents in a more dramatic fashion and requires prompt diagnosis and treatment. Management of chronic GVHD (cGVHD), particularly in patients who are refractory to first-line therapy, remains challenging.

HISTORY

The first successful allogeneic bone marrow transplant was performed in 1968. Subsequent advances in histocompatibility antigen testing increased safety while establishment of bone marrow donor registries made HSCT accessible to thousands of patients each year who lacked a suitable related donor. However, use of matched unrelated donor (MUD) transplants carries a greater likelihood of a mismatch of minor human leukocyte antigen (HLA) loci compared to matched related donors, which may be partially responsible for the rising incidence of cGVHD. More recently, the use of umbilical cord blood and reduced-intensity conditioning regimens (which raise the age of eligibility) has led to a further increase in the number of transplants.

EPIDEMIOLOGY

Currently, 25 000 allogeneic HSCTs are performed worldwide each year. Although a variety of donor and recipient factors ultimately impact GVHD incidence (Table 52.2), the most important predictor of GVHD remains HLA compatibility between donor and recipient. Approximately 40% of HLA-identical HSCT recipients and 60–70% of HLA-mismatched HSCT recipients will develop GVHD.

Over the past decade, umbilical cord blood and especially peripheral blood have been increasingly utilized as the stem cell source in place of bone marrow. Cord blood transplantation is associated with a

PRIMARY DISORDERS TREATED WITH ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION
Leukemias (e.g. acute myelogenous, acute lymphoblastic > chronic myelogenous, chronic lymphocytic)
Lymphomas (e.g. non-Hodgkin)
Bone marrow failure (e.g. aplastic anemia, dyskeratosis congenita, Fanconi anemia)
High-risk myelodysplasia
Immunodeficiencies (e.g. severe combined immunodeficiency, Griscelli syndrome [type 2], Chédiak–Higashi syndrome, Wiskott-Aldrich syndrome, ataxia–telangiectasia syndrome, chronic granulomatous disease, DiGeorge syndrome, familial hemophagocytic lymphohistiocytosis)
Other myeloproliferative disorders (e.g. myelofibrosis, essential thrombocytosis, polycythemia vera)
Other hematologic disorders (e.g. plasma cell dyscrasias, hypereosinophilic syndrome, paroxysmal nocturnal hemoglobinuria, sickle cell disease, thalassemia)
Metabolic disorders (e.g. fucosidosis, Gaucher disease, mucopolysaccharidoses)
Autoimmune diseases (e.g. ALPS, IPEX syndrome)
Miscellaneous (e.g. congenital erythropoietic porphyria [Günther disease], histiocytoses)

Table 52.1 Primary disorders treated with allogeneic hematopoietic cell transplantation. ALPS, autoimmune lymphoproliferative syndrome; IPEX, immune dysregulation, polyendocrinopathy, X-linked.

RISK FACTORS ASSOCIATED WITH THE DEVELOPMENT OF GRAFT-VERSUS-HOST DISEASE
DONOR
HLA incompatibility with recipient Unrelated to recipient Female (especially multiparous) with male recipient
RECIPIENT
Age (older-aged > middle-aged > pediatric)
STEM CELL SOURCE
Peripheral blood > bone marrow > cord blood T-cell-replete graft
OTHER
Myeloablative conditioning regimen*
*Associated with higher rate of aGVHD compared with non-myeloablative HSCT, but does not affect incidence of cGVHD.

Table 52.2 Risk factors associated with the development of graft-versus-host disease (GVHD). a, acute; c, chronic; HSCT, hematopoietic stem cell transplant.

decreased incidence of GVHD, but higher rates of non-engraftment. In addition, because the number of stem cells present in cord blood is limited, two cord blood units are often required for successful engraftment into an adult recipient. Peripheral blood has clearly emerged as a preferred stem cell source at many major transplant centers. In peripheral blood HSCTs, the donor is treated with a colony-stimulating factor (e.g. filgrastim) which mobilizes the donor stem cells from the marrow into the circulation. Cells are then collected via apheresis and infused into the recipient. Peripheral blood HSCT avoids general anesthesia for the donor and is associated with more rapid engraftment when compared to bone marrow HSCT; however, there is an increased risk of cGVHD[1].

Several other trends in HSCT are also affecting the natural history of GVHD. Removal of donor T cells ("T-cell depletion") prior to transplantation through *ex vivo* graft manipulation (e.g. cell separation), or *in vivo* treatment of the recipient (e.g. antithymocyte globulin, alemtuzumab), significantly decreases the risk of GVHD, but at the expense of increased cancer relapse due to abrogation of donor T-cell graft-versus-tumor (GVT) effect. Recognition of the key role of GVT effect (rather than the conditioning chemotherapy) in cancer remission has also led to the proliferation of non-myeloablative, reduced-intensity conditioning regimens ("mini-transplants"). Although lower doses of chemotherapy and/or radiation are utilized, they are sufficiently immunosuppressive to allow engraftment. This minimizes conditioning-related toxicities (e.g. mucositis) and allows for HSCT in older patients and those with comorbidities. While these regimens appear to decrease the risk of aGVHD, they may also delay the appearance of "classic" aGVHD manifestations. Finally, donor lymphocyte infusions (DLI), administered to the recipient post-HSCT to augment the GVT effect, have altered the traditional timing of both "acute" and "chronic" disease. For

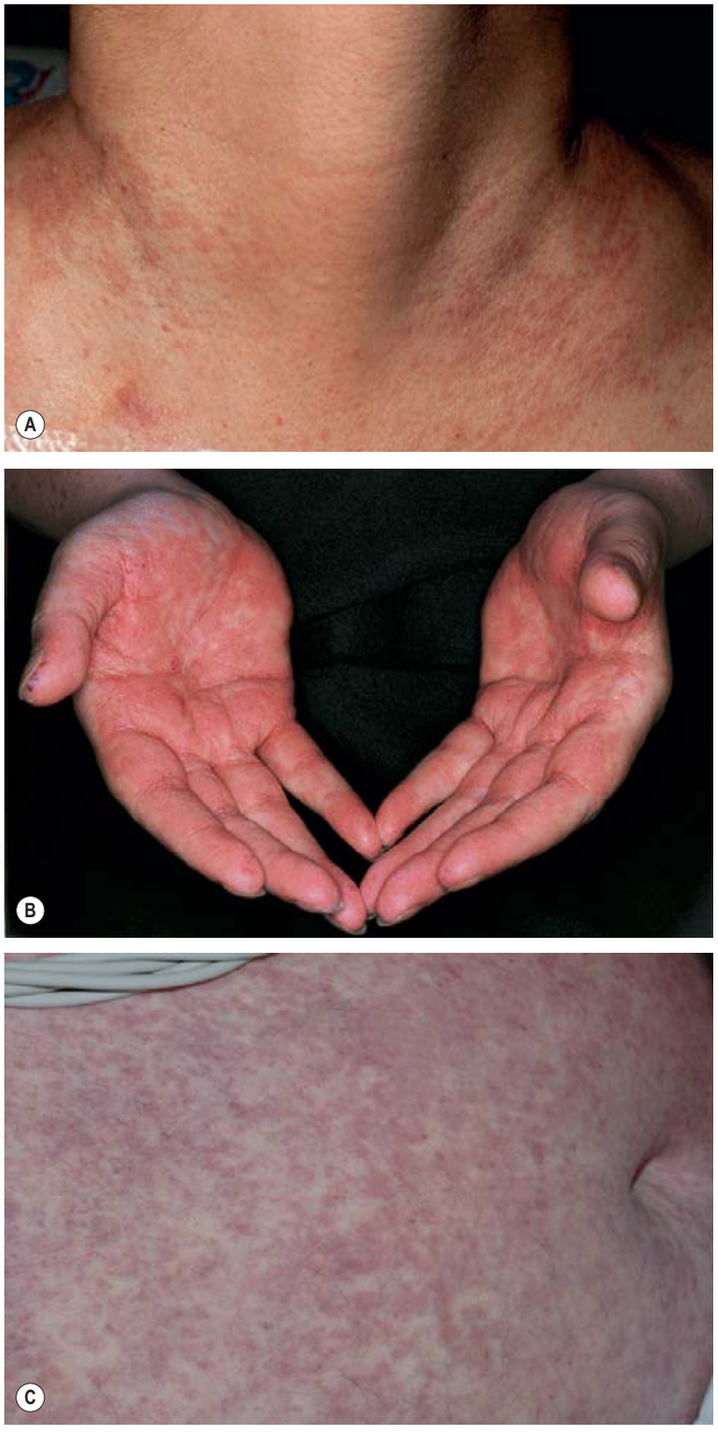

Fig. 52.1 Clinical spectrum of acute cutaneous graft-versus-host disease. A *Stage I* – discrete and coalescing small pink papules on the upper chest and neck of a woman 6 weeks following allogeneic bone marrow transplant. **B, C** *Stage II* – pink macules and papules of the palms that are becoming confluent 14 weeks post allogeneic bone marrow transplant and pink–violet macules and minimally elevated papules on the abdomen in a liver transplant recipient **D** *Stage III* – diffuse erythema with desquamation, but without bullae formation. **E** *Stage IV* – coalescence of bullae plus epidermal necrosis leading to large areas of denudation in a patient who had received an allogeneic bone marrow transplant; note the resemblance to toxic epidermal necrolysis. *B, Courtesy, Dennis Cooper, MD. CLINICAL STAGING AND HISTOLOGIC GRADING OF ACUTE GRAFT-VERSUS-HOST DISEASE					
Stage	**Skin**	**Liver**	**Gut**	**Grade**	**Histologic**
1	Erythematous macules and papules, <25% BSA	Bilirubin 2 to <3 mg/dl	Diarrhea, 500–1000 ml/day, or persistent nausea	I	Focal vacuolar change of basal keratinocytes
2	Erythematous macules and papules, 25–50% BSA	Bilirubin 3–6 mg/dl	Diarrhea, 1000–1500 ml/day	II	Grade 1 *plus* necrotic keratinocytes in the epidermis and/or hair follicle and a dermal lymphocytic infiltrate
3	Erythematous macules and papules (>50% BSA) to generalized erythroderma	Bilirubin 6–15 mg/dl	Diarrhea, >1500 ml/day	III	Grade 2 *plus* fusion of basilar vacuoles to form clefts and microvesicles
4	Generalized erythroderma with bulla formation	Bilirubin >15 mg/dl	Severe abdominal pain with or without ileus	IV	Grade 3 *plus* large areas of separation of epidermis from dermis

Table 52.3 Clinical staging and histologic grading of acute graft-versus-host disease (GVHD). Overall, grade 1 GVHD represents stage 1 or 2 cutaneous GVHD but no liver or gut involvement, while grades II–IV require internal involvement. BSA, body surface area.

MUCOCUTANEOUS MANIFESTATIONS OF CHRONIC GRAFT-VERSUS-HOST DISEASE
SKIN
Alopecia
Angiomatous papules
Bullae
Eczema craquelé
Edema
Erythema
Hypo- or hyperpigmentation
Ichthyosis-like
Keratosis pilaris-like
Lichen planus-like (see Fig. 52.2A)
Lichen sclerosus-like (see Fig. 52.2B,C)
Morbilliform (maculopapular)
Morphea-like (see Fig. 52.2D)
Poikiloderma
Scleroderma-like (see Fig. 52.2E)
Sweat impairment
Ulceration
NAILS
Brittleness
Longitudinal ridging or splitting
Onycholysis
Pterygium unguis (dorsal)
SUBCUTANEOUS TISSUE
Fasciitis (see Fig. 52.3)
Panniculitis
ORAL MUCOSA
Erythema
Gingivitis
Keratotic plaques
Lichen planus-like (see Fig. 52.4B)
Mucocele
Mucosal atrophy
Mucositis
Pseudomembranes
Restriction of oral opening from sclerosis
Ulceration
Xerostomia
GENITAL MUCOSA
Lichen planus-like (see Fig. 52.4A)
Vaginal scarring and/or stenosis
Vulvar erosions and/or fissures (see Fig. 52.4C)

Table 52.4 Mucocutaneous manifestations of chronic graft-versus-host disease. Diagnostic features (based on NIH Consensus Criteria[7]) are in bold; the other signs and symptoms listed are not considered sufficient to establish a diagnosis of chronic GVHD without further testing or evidence of other organ system involvement. For involvement of other organs, see text and ref. 7.

instance, DLI may induce classic aGVHD manifestations even when administered after the 100-day time period.

The skin is the most frequently affected organ in both aGVHD and cGVHD. Approximately 80% of patients who develop aGVHD have skin involvement at the time of diagnosis[2]; however, prevalence rates vary dramatically between HSCT protocols, and differentiation of sclerotic versus non-sclerotic features are often not reported, rendering estimates of specific manifestations difficult. In the cGVHD setting, non-sclerotic skin disease generally presents earlier than sclerotic disease. However, neither antecedent aGVHD nor antecedent "lichenoid" skin involvement is a prerequisite to the later development of sclerotic disease. In one institutional review of 270 consecutive patients following HLA-identical HSCT, only 7 (13%) of 53 patients with cGVHD manifested sclerotic features[3]. In contrast, in a review of 110 NIH patients with primarily refractory cGVHD evaluated in a referral setting, sclerotic features were detected in 58 (53%)[4].

PATHOGENESIS

The pathogenesis of aGVHD can be summarized in a three-step process. First, HSCT conditioning and consequent damage to host tissues leads to activation of *host* antigen-presenting cells (APC). Second, *donor* T cells proliferate in response to contact with activated APC. Finally, destruction of target tissues (skin, liver, gastrointestinal tract) occurs via cytotoxic T lymphocytes, natural killer cells, and soluble factors (TNF-α, INF-γ, IL-1, nitric oxide)[5].

By contrast, a clear understanding of cGVHD is still lacking and available murine models recapitulate only select features of human disease (e.g. sclerotic skin involvement, autoantibodies). Alloreactive T cells are again thought to play a central role, but a number of other immune mediators have been increasingly implicated. Many cGVHD manifestations resemble autoimmune disease, suggesting a role for B cells in the disease process. Indeed, rituximab (anti-CD20 antibody) is a beneficial salvage therapy in some patients. B cells appear to prime T cells to minor histocompatibility antigens, and levels of *B*-cell *a*ctivating *f*actor of the TNF *f*amily (BAFF), a marker of B-cell activation, correlate with cGVHD. Multiple autoantibodies are often present in patients with cGVHD, including antinuclear anti-dsDNA, and anti-smooth muscle antibodies, although, to date, they have not been shown to correlate with specific disease manifestations. Recently, activating antibodies against the platelet-derived growth factor receptor (PDGFR) were reported in patients with cGVHD and patients with systemic sclerosis, suggesting that blockage of this profibrotic pathway with agents such as imatinib mesylate may have potential efficacy.

Characterization of immunologic differences between "early" and "late" cGVHD may soon provide important insight into the phenotypic variety of cGVHD. Early-onset cGVHD (3–9 months) is associated with IFN-γ, increased regulatory T cells, and a T-cell cytokine response (IL-2Rα). By contrast, late cGVHD (>9 months) is characterized by lack of a Th2 shift, B-cell activation via soluble BAFF, induction of Toll-like

Fig. 52.2 Clinical spectrum of chronic cutaneous graft-versus-host disease. **A** Lichen planus-like – thin pink–violet papules and plaques with scale, admixed with postinflammatory hyperpigmentation. **B** Lichen sclerosus-like (early) – multiple gray–white thin plaques with obvious wrinkling are present on the mid back. **C** Lichen sclerosus-like (late) – thicker shiny white plaques on the upper back admixed with erosions. **D** Morphea-like (morpheaform) – shiny, hyperpigmented, sclerotic plaque extending circumferentially around the beltline and into the inguinal area. **E** Scleroderma-like (sclerodermoid) – the skin is shiny and bound-down with dyspigmentation, hair loss and multiple erosions; nail loss, small angiomatous nodules and marked reduction in range of motion of the ankles are also present. *B, Courtesy, Dennis Cooper, MD. C, Courtesy Joyce Rico, MD.*

Fig. 52.3 Eosinophilic fasciitis-like presentation of chronic cutaneous graft-versus-host disease. A rippled appearance and irregular nodular texture to the skin is indicative of involvement of subcutaneous tissues; extension of the elbow is limited. Especially in the earlier, more edematous phase, the presence of hypereosinophilia is a clue to the diagnosis.

receptor 9 (TLR9) highly-expressing B cells, and autoantibody formation[6]. Careful definitions of disease states, in particular distinction between sclerotic and non-sclerotic skin manifestations, will be invaluable for validation of this hypothesis.

CLINICAL FEATURES

Acute GVHD

Acute GVHD presents in the skin as a morbilliform exanthem (Fig. 52.1), with an initial predilection for acral areas (e.g. dorsal hands and feet, palms, soles, forearms, ears, as well as the upper trunk). Lesions most commonly appear 4–6 weeks following HSCT despite prophylactic immunosuppressive therapy. Pruritus is variable and a follicular pattern may be observed. Patients may be thrombocytopenic, which can give the eruption a hemorrhagic appearance. The gastrointestinal tract (nausea, voluminous diarrhea, abdominal pain) and the liver (transaminitis, cholestasis, bilirubin elevation) are the two other primary organ systems affected by aGVHD. Together with body surface area of skin involvement, these manifestations are used for staging and grading of disease severity (Table 52.3). Stage IV acute skin disease consists of generalized involvement with bullae formation which may lead to skin sloughing resembling toxic epidermal necrolysis, and it portends a very low likelihood of survival.

Chronic GVHD

In contrast to aGVHD, cGVHD may manifest in nearly any organ system. Skin and mucosal involvement are exceedingly common, and there is remarkable variability in both presentation and severity (Table 52.4). Other sites of involvement include the eyes (keratoconjunctivitis sicca, blepharitis, corneal erosions), salivary glands (sicca syndrome), esophagus (strictures, webs), liver, pancreas (exocrine insufficiency) and lungs (bronchiolitis obliterans).

In the past, differentiation of aGVHD and cGVHD was linked to time of onset following HSCT (≤ or > 100 days); however, this is a somewhat arbitrary distinction and changing HSCT regimens have altered the onset of classic aGVHD and cGVHD manifestations (see above). For instance, features of both aGVHD and cGVHD may occur simultaneously (overlap chronic GVHD), or acute features may first present after day 100 (delayed acute GVHD). The NIH Consensus Project proposed a new classification of cGVHD using organ-specific criteria[7]. "Diagnostic" skin criteria, i.e. those manifestations sufficient to make a clinical diagnosis of cGVHD, are provided in Table 52.4 (bold type). "Distinctive" cGVHD criteria are those which require biopsy confirmation as well as exclusion of other possible etiologies in order for a diagnosis of cGVHD to be established.

The most characteristic manifestation of epidermal cGVHD involvement is reticulate pink to violet papules and plaques with overlying scale, which in some patients resembles lichen planus (LP; Fig. 52.2A). Lesions often initially involve the dorsal aspects of the hands and feet, the forearms and trunk, but they can become widespread. In the past, the term

Fig. 52.4 Orogenital involvement in chronic cutaneous graft-versus-host disease. A, B Lichen planus-like – flat-topped violet papules on the penis and several ulcers on the tongue with a lacy white pattern on the upper vermilion lip and the distal dorsal tongue. **C** Severe erosive disease of the vulva, with nearly total resorption of the labia minora and agglutination of the lips of the clitoral hood. The vulvar introitus is also markedly narrowed.

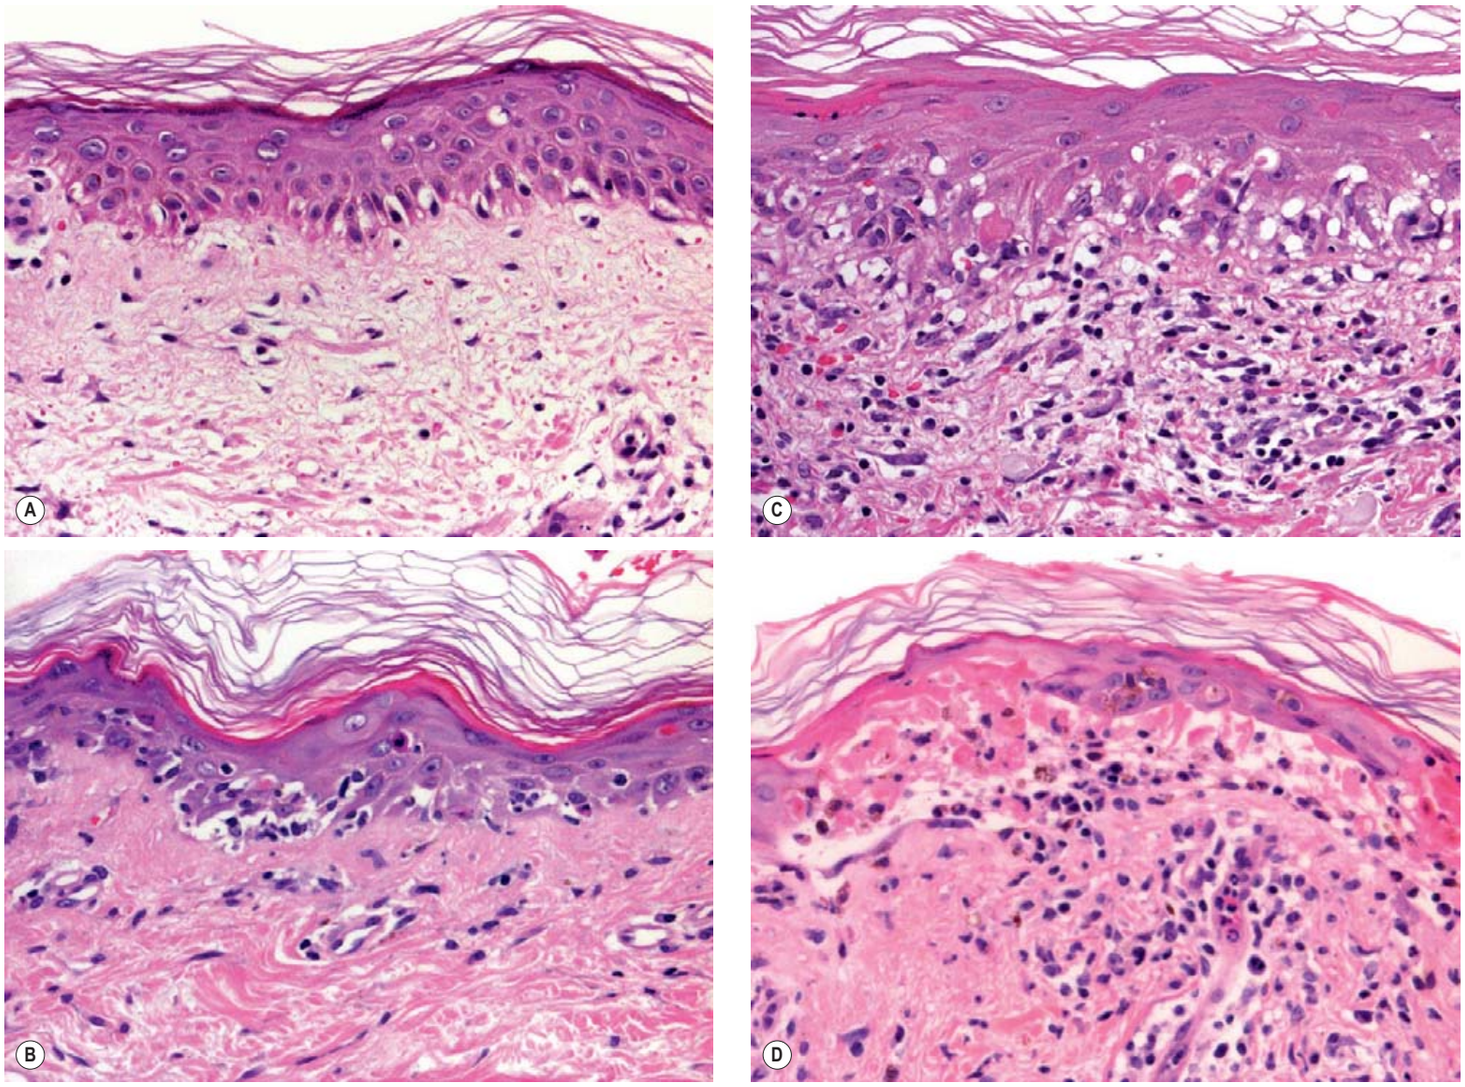

Fig. 52.5 Acute cutaneous graft-versus-host disease – histologic grades. A Grade I – focal vacuolar changes of the basal layer of the epidermis and sparse lymphocytic infiltrate. **B** Grade II – necrosis of keratinocytes and more obvious vacuolar degeneration of the basal layer. **C** Grade III – apoptosis of keratinocytes and blurring of the dermal–epidermal junction due to marked vacuolar degeneration and a lichenoid infiltrate of lymphocytes. **D** Grade IV – full-thickness necrosis of the epidermis with separation of the epidermis from the dermis. Of note, stage I changes are rather nonspecific and are also seen with autoimmune disorders showing the histopathologic pattern of an interface dermatitis (e.g. lupus erythematosus). *Courtesy, Lorenzo Cerroni, MD.*

"lichenoid" was used as a broad term which encompassed this presentation as well as all other non-sclerotic cGVHD skin eruptions. In light of the greater appreciation for the breadth of clinical presentations of cutaneous cGVHD and to utilize more precise diagnostic terminology, the term "lichenoid" should be reserved for histologic description rather than as designation of a GVHD phenotype. In addition to LP-like lesions, psoriasiform plaques, keratosis pilaris-like follicular erythema, a subacute cutaneous LE-like eruption, or poikiloderma may develop. Epidermal cGVHD involvement often leaves a remarkable patterned hyperpigmentation which resolves very slowly over several months.

Similar to the use of "lichenoid", the single designation "sclerodermoid" cGVHD is inadequate to describe the spectrum of sclerotic skin and subcutaneous tissue presentations. Sclerotic involvement includes superficial lichen sclerosus-like plaques, localized or widespread morphea-like involvement, and subcutaneous rippling of the skin with joint contractures resembling eosinophilic fasciitis[8]. Lichen sclerosus-like involvement commonly presents as shiny, wrinkled, gray–white plaques on the upper back (Fig. 52.2B,C); there may be associated follicular plugging. Morphea-like (morpheaform) areas of sclerosis may occur anywhere on the body, but frequently localize to sites of previous skin injury (e.g. port placement sites) as well as areas of friction (e.g. the waistband; Fig. 52.2D). Unlike systemic sclerosis, involvement is more patchy and diffuse symmetric induration with sclerodactyly and pinched facies is rare. Deep-seated fibrosis of the subcutaneous tissue and fascia may present with insidious loss of joint range-of-motion or as nonspecific myalgias and cramping. Subtle rippling of the overlying skin may be present with a firm, nodular texture noted with deep palpation (Fig. 52.3). Linear depressions within sites of fascial involvement (groove sign) demarcate the path of vascular structures or fascial bundles. Longstanding fibrosis may result in skin ulceration, particularly of the legs and frictional surfaces, and the proliferation of benign angiomatous nodules (Fig. 52.2E).

The mucosal surfaces are frequently affected by cGVHD (Fig. 52.4). Oral involvement is second only to skin involvement in disease prevalence. Oral involvement resembles LP with lacy white plaques on the non-attached mucosa, ulceration and gingivitis. Mucocele development is frequently seen. Genital involvement may affect as many as 50% of female patients, but may not be reported by the patient without specific questioning[9]. Symptoms of burning, pruritus and dyspareunia are common. Manifestations range from erythema and fissuring to labial resorption and fusion. Scarring of the vagina may lead to shortening and narrowing of the vaginal canal and risk of hematocolpos in menstruating women.

Nail changes are common and range from thin, brittle nails with distal splitting to anonychia (see Fig. 52.2E). Dorsal pterygium formation can be seen. Additional cutaneous findings include facial milia, nodular fibromas, scarring alopecia, alopecia areata, and vitiligo-like changes.

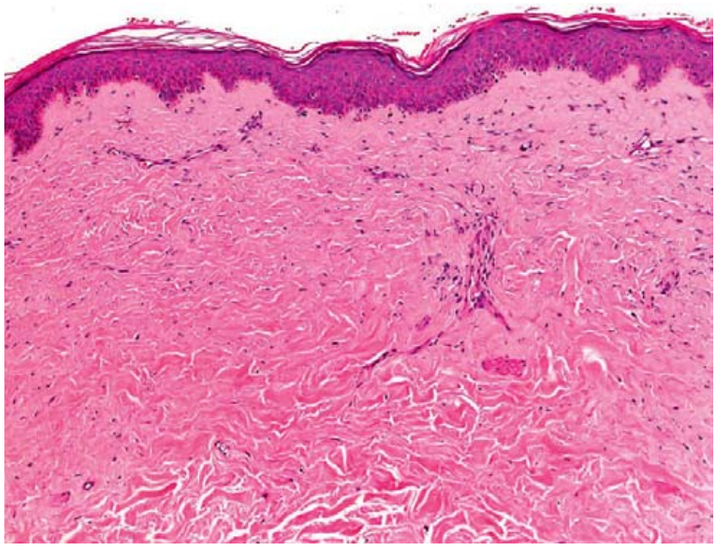

Fig. 52.6 Chronic cutaneous graft-versus-host disease (morpheaform type) – histologic features. There is sclerosis of the dermis with thickening of collagen bundles. These same histologic features can be seen in morphea and systemic sclerosis (scleroderma). Pigmentary incontinence, with a few melanophages within the papillary dermis can also be seen in this form of chronic GVHD. *Courtesy, Lorenzo Cerroni, MD.*

The round white circles represent blood vessels. *Courtesy, Dennis Cooper, MD.*

PATHOLOGY

Histologically, aGVHD is characterized by widespread keratinocyte necrosis, basal layer hydropic degeneration and a band-like lymphohistiocytic infiltrate in the upper dermis (Fig. 52.5); however, skin biopsies obtained shortly after disease onset may display more subtle findings, and early on the features of aGVHD may be limited to the hair follicle. In addition, these histologic features overlap with those of viral exanthems and drug eruptions, making a definitive diagnosis difficult to render in some patients. Because of the mortality associated with acute severe involvement, empiric treatment may be needed despite equivocal histologic results if there is a high level of clinical suspicion, particularly concurrent GI or hepatic manifestations.

The histology of cGVHD reflects the variable skin manifestations of the condition. cGVHD with epidermal involvement may resemble aGVHD with additional features of epidermal orthokeratosis and hypergranulosis. The sclerotic subtypes of cGVHD may have concurrent epidermal features or may just demonstrate fibrosis of the dermis (Fig. 52.6), subcutaneous tissue and/or fascia. While the location and extent of collagen thickening and fibrosis can vary, a panniculitis with thickening of subcutaneous fat septae is often seen. However, for the diagnosis of fasciitis, magnetic resonance imaging can often supplant the need for a deep fascial biopsy procedure (Fig. 52.7).

DIFFERENTIAL DIAGNOSIS

The primary differential diagnosis of aGVHD is a viral or drug exanthem and engraftment syndrome. Engraftment syndrome is a poorly understood phenomenon associated with a nonspecific erythematous skin eruption, fever, and pulmonary edema at the time of neutrophil engraftment; the pulmonary edema is associated with increased levels of B-type natriuretic peptide (BNP). When there is palmoplantar involvement during the first 2–6 weeks following HSCT, the possibility of toxic erythema of chemotherapy should be considered. Because of its clinical variability, the differential diagnosis of cGVHD is much broader, and includes lichenoid drug eruptions, autoimmune connective tissue diseases (lupus, dermatomyositis, morphea, systemic sclerosis), and papulosquamous disorders. Recent reports of transient acantholytic dermatosis[10] and voriconazole-associated photosensitivity[11] misdiagnosed as cGVHD emphasizes the value of biopsy confirmation when non-diagnostic features are encountered[12].

TREATMENT

Acute GVHD

Limited cutaneous aGVHD (without other organ involvement) may initially be managed with topical corticosteroids; however, most patients require systemic corticosteroids. First-line therapy consists of oral prednisone or IV methylprednisolone (1 mg/kg twice daily) and is typically added to ongoing prophylactic GVHD therapy with a systemic calcineurin inhibitor (tacrolimus, cyclosporine). This results in disease control in approximately 50% of patients. Patients who do not respond to corticosteroid therapy are at high risk of mortality, but a number of second-line therapies, including other immunosuppressive agents such as mycophenolate mofetil and TNF-α inhibitors (e.g. etanercept, infliximab), can be tried.

Chronic GVHD

Chronic GVHD continues to be a major therapeutic challenge because no single therapy with proven superiority has emerged. Skin-directed therapies play an important adjunctive role in select patients with cutaneous cGVHD disease. In addition to the severity of skin disease, the rate of symptom progression should be considered when choosing between a topical versus systemic regimen. For local control of the LP-like eruption or pruritus, medium- to high-potency topical corticosteroids and topical calcineurin inhibitors (pimecrolimus, tacrolimus) are appropriate. Unfortunately, topical medications are limited by the percentage of body surface area that is involved and may only provide partial relief. Phototherapy with PUVA, UVB and UVA1 have all shown some benefit in small series, however, controlled trial data are needed. The potential for increased skin malignancies in the setting of concurrent immunosuppressive therapy must also be weighed against the benefit of UV therapy.

As with aGVHD, first-line systemic therapy of cGVHD is systemic corticosteroids, but the dose and duration of treatment is

highly variable. Approximately 50% of cGVHD patients will not respond adequately to corticosteroid therapy, and for this group there is no standard salvage therapy of proven superiority. Options include hydroxychloroquine, mycophenolate mofetil, imatinib mesylate[12a], rituxumab[13], acitretin, basiliximab and extracorporeal photophoresis. In patients with ocular symptoms, site-specific therapies such as special contact lenses can prove very helpful. Referral to physical therapy is recommended when there is evidence of a decrease in the range of motion of joints.

Long term, the importance of sun protection should be emphasized, as patients are typically prescribed one or more photosensitizing agents, including trimethoprim/sulfamethoxazole, levofloxacin and voriconazole. In addition, the latter drug can increase the risk of developing cutaneous malignancies. Patients, especially those with significant photodamage and/or a previous history of cutaneous carcinomas, should be educated regarding skin cancer risk in the setting of immunosuppression, and they should receive regular surveillance for skin cancer.

	Sclerotic-type cGVHD	Systemic sclerosis
Autoantibodies	Variable, non-specific	Yes, associated with specific clinical subtypes
Cardiac involvement	Rare	Yes, conduction system abnormalities
GI dysmotility/strictures	Yes	Yes
Pulmonary hypertension	No	Yes
Pulmonary fibrosis	Yes*	Yes
Renal disease	Rare, nephrotic syndrome	Yes, scleroderma renal crises (in diffuse subtype)
Raynaud's disease	Rare	Yes
Sclerodactyly	Rare	Yes
Skin manifestations		
Fibrosis	Dermis, subcutaneous tissue, and/or fascia	Dermis
Natural history	Patchy involvement, variable course	Symmetric, acral to proximal progression
Facial involvement	Rare, usually patchy involvement	Common, diffuse skin tightening (scleroderma facies)

*In setting of bronchiolitis obliterans

Comparison of clinical and laboratory features of sclerotic-type cGVHD and systemic sclerosis

PATIENT HANDOUT General dermatologic recommendations for patients with cutaneous graft-versus-host disease (GVHD).

Dry skin and pruritus
Use moisturizing, non-scented soaps
Apply emollients frequently, in particular ointments and thicker creams
Avoid tight-fitting or abrasive clothing; wear cool, breathable fabrics
Avoid antihistamines if there is dryness of the eyes or mouth (sicca syndrome)

Nail dystrophy
Keep nails trimmed or filed to prevent breakage and pain
A clear nail lacquer can be used as a nail hardener

Signs of skin sclerosis (hardening)
Early signs of skin sclerosis (hardening) include darkening or tightening of the skin at the waistband or bra line, rippling or dimpling of the skin, and decreased joint range of motion of joints

Skin ulcers
Sites where there is breakdown of the skin serve as potential sites where bacteria can enter the body; these areas need to be kept clean and covered

Recommendations regarding sun exposure and skin cancer
The risk of skin cancer is increased in patients with GVHD, and the risk is potentiated by iatrogenic immunosuppression and/or phototherapy (e.g. UVB, PUVA)
Exposure to ultraviolet radiation (UVR) may also induce a flare of GVHD or exacerbate drug-induced photosensitivity
Several of the frequently prescribed medications can increase sun sensitivity; they include sulfamethoxasole/trimethoprim (Septra®, Bactrim®) and voriconazole (Vorinastat®)
If possible, avoid outdoor activities during peak hours of UVR (10am-4pm)
Apply broad-spectrum sunblock on sun-exposed sites on a regular basis
Use a broad-brimmed hat and protective clothing; consider using a laundry additive that increases the UV protective factor of clothing (e.g. Sun Guard™)
Perform self-skin examination on a regular basis

Residual dyspigmentation from chronic cutaneous graft-versus-host disease (GVHD). Extensive hyper- and hypopigmentation in an African-American child with a history of epidermal involvement of cGVHD.

Lichen sclerosus-like chronic cutaneous graft-versus-host disease. Gray-white ovoid plaques on the back.

Dermatologic Manifestations in Patients with Systemic Disease

Key features

- Cutaneous manifestations of systemic disease are frequently encountered in the practice of medicine
- Dermatologic disease may be the initial sign of an internal disease
- Skin disease may complicate therapy directed at internal disorders

Dermatologic disease is frequently associated with internal manifestations[1,2], and there are many cutaneous disorders that are traditionally associated with systemic disease, e.g. the autoimmune connective tissue diseases and sarcoidosis. In addition, most endocrinopathies have dermatologic manifestations, as do many infectious diseases. When one begins to closely examine many of the disorders that are discussed elsewhere in this text, it becomes clear that isolated dermatologic disease is relatively uncommon. Many of the conditions have associated systemic manifestations, the potential for such manifestations, or the potential to be treated with drugs that have systemic implications. Therefore, a detailed review of all dermatologic signs of internal disease is beyond the scope of this chapter. Rather, some of the disorders will be discussed specifically, while many others will be reviewed via the use of tables that present an overview of data relevant to these topics. The approach utilized is by organ system.

CUTANEOUS RHEUMATOLOGY

Topics traditionally included as cutaneous rheumatology[3] are as follows: lupus erythematosus (Ch. 41); dermatomyositis (Ch. 42); scleroderma, Raynaud's phenomenon, and related conditions (Ch. 43); vasculitides (Ch. 24); and miscellaneous disorders. Miscellaneous disorders usually include: rheumatoid arthritis (Ch. 45), pyoderma gangrenosum (Ch. 26), psoriatic arthritis (Ch. 8), Behçet's disease (Ch. 26), Sweet's syndrome (Ch. 26), bowel-associated dermatosis–arthritis syndrome (Ch. 26), reactive arthritis (formerly Reiter's disease) (Ch. 8), Kawasaki disease (Ch. 81), and relapsing polychondritis (Ch. 45).

Cutaneous conditions reported in patients with rheumatoid arthritis are summarized in Table 53.1 (Figs 53.1–53.6)[4,5]. Dermatologists should be particularly careful in this group of patients to couple laboratory evaluation with a complete cutaneous examination, including all mucosal surfaces, nails and nail folds, hair, and the entire cutaneous surface. Clinical criteria are published for the diagnosis of many of these disorders; dermatologists should be familiar with the criteria and should incorporate them into a focused, thorough history, including relevant negatives. It is very helpful to think of the clinicopathologic basis and pathogenesis of lesions. For example, in patients with systemic lupus erythematosus, photodistributed lesions with an interface histopathology, i.e. discoid lesions, subacute lesions and poikilodermatous lesions, have different implications and are treated differently than vessel-based lesions, such as those due to small or larger vessel vasculitis.

Sjögren's syndrome is characterized by the occurrence of keratoconjunctivitis sicca and xerostomia in association with an autoimmune disorder. Frequently, the skin can be involved in primary Sjögren's syndrome with vascular inflammation (e.g. small vessel vasculitis, hypergammaglobulinemic purpura) even before the clinical diagnosis has been made. Some patients from the Far East, including Japan and the Philippines, have been described with what has been called the

CUTANEOUS CONDITIONS ASSOCIATED WITH RHEUMATOID ARTHRITIS	
PALISADING GRANULOMAS	
• Rheumatoid nodules • Palisaded neutrophilic and granulomatous dermatitis – Rheumatoid papules (Fig. 53.1) – Interstitial granulomatous dermatitis (with plaques or cutaneous cords; Fig. 53.2) – Superficial ulcerating rheumatoid necrobiosis (Fig. 53.3)	
VASCULAR REACTIONS	
• Pigmented purpuric eruptions (capillaritis) • Bywater's lesions (purpuric papules of the distal digits due to small vessel vasculitis; Fig. 53.4) • Small, medium-sized and large vessel vasculitis • Erythema elevatum diutinum • Intravascular or intralymphatic histiocytosis (erythema, induration and papules in a reticular pattern overlying swollen joints, most often the elbows)	
NEUTROPHILIC DERMATOSES	
• Pyoderma gangrenosum • Rheumatoid neutrophilic dermatitis (rheumatoid neutrophilic dermatosis) • Sweet's syndrome • Pyoderma gangrenosum-like leg ulcers in Felty's syndrome • Neutrophilic lobular panniculitis	
COMPLICATIONS OF THERAPIES FOR RHEUMATOID ARTHRITIS	
• NSAIDs (naproxen, oxaprozin and others)	• Pseudoporphyria (Fig. 53.5) • Toxic epidermal necrolysis
• Penicillamine	• Pemphigus • Lichenoid drug reaction • Elastosis perforans serpiginosa • Pseudoxanthoma elasticum-like changes
• Gold	• Pityriasis rosea-like eruption • Lichenoid drug reaction
• Methotrexate	• Accelerated nodulosis* – most often on the hands; rarely involves heart & lung • Methotrexate-induced papular eruption – favors extremities
• Tumor necrosis factor-α inhibitors (see Ch. 128)	• Local injection site reaction (etanercept, adalimumab, golimumab) • Urticaria, angioedema, anaphylaxis (infliximab > adalimumab) • Urticarial eruption • Vasculitis (small or larger vessel vasculitis) • Interstitial granulomatous dermatitis • Lupus erythematosus – systemic or cutaneous (Fig. 53.6) • New-onset psoriasiform eruption and palmoplantar pustulosis (see Ch. 21) • Accelerated nodulosis* • Dermatomyositis
*Also referred to as accelerated rheumatoid nodulosis and accelerated cutaneous nodulosis.	

Table 53.1 Cutaneous conditions associated with rheumatoid arthritis. An evanescent erythematous eruption and persistent plaques also can develop in patients with Still's disease (see Ch. 45).

Fig. 53.1 Rheumatoid papules. Multiple red–brown papules, some with scale-crust, on the lower extremity. This entity is within the spectrum of palisaded neutrophilic and granulomatous dermatitis (see Table 53.1).

Fig. 53.2 Annular variant of interstitial granulomatous dermatitis (IGD). This clinical presentation with annular plaques on the medial thighs is often seen in the setting of rheumatoid arthritis. Of note, IGD has also been implicated as a side effect of medications, including calcium channel blockers , TNF-α inhibitors, and HMG-CoA reductase inhibitors ("statins").

Fig. 53.3 Superficial ulcerating rheumatoid necrobiosis. Shiny, yellow plaques with red–brown edges and areas of ulceration that clinically resemble necrobiosis lipoidica. This patient had active rheumatoid vasculitis.

Fig. 53.4 Bywater's lesions. Tender, purpuric papules on the distal fingers in a patient with rheumatoid vasculitis. Histologically, leukocytoclastic vasculitis is seen.

Fig. 53.5 Pseudoporphyria in a patient with rheumatoid arthritis. The cause was a nonsteroidal anti-inflammatory drug. *Courtesy, Kalman Watsky, MD.*

Fig. 53.6 Annular lupus-like lesions in a patient receiving etanercept. This is a potential side effect of the entire group of tumor necrosis factor-α inhibitors.

"annular erythema of Sjögren's syndrome". The original descriptions suggested that this was a distinct entity; however, we now believe that this represents a form of subacute cutaneous lupus erythematosus, and that it might be better classified as a form of secondary Sjögren's syndrome. Secondary Sjögren's syndrome may also occur in patients with other rheumatologic diseases, including rheumatoid arthritis, dermatomyositis and scleroderma. It is necessary to remember that the diagnosis of Sjögren's syndrome is a diagnosis of exclusion, and that it must be differentiated from conditions that might cause xerostomia/xerophthalmia, including GVHD, sarcoidosis, hepatitis C viral infection, and HIV disease.

CUTANEOUS HEMATOLOGY AND ONCOLOGY

Disorders of interest to the dermatologist and to hematologists or oncologists are also well covered in the following chapters of this textbook: metastatic disease (Ch. 122), leukemia/lymphoma (Chs 119–121), dysproteinemias (Ch. 119), histiocytoses (Ch. 91), vascular neoplasms (Ch. 114), cutaneous T-cell lymphoma (Ch. 120), pigmented lesions (Chs 112 & 113), and cutaneous reactions to chemotherapeutic agents (Ch. 21).

Skin signs of internal malignancy are summarized in Tables 53.2 and 53.3. Table 53.2 summarizes the criteria for the association of dermatoses and neoplasia that were first proposed by Helen O Curth, and Table 53.3 represents the application of these criteria to some of the specific associations (Figs 53.7–53.12)[6–10]. The use of "Curth's criteria" is important to establish whether a given criterion is a chance occurrence or truly a malignancy-associated event. In addition, an eczematous or psoriasiform plaque of the nipple and surrounding skin can be seen in Paget's disease due to epidermal extension of an underlying ductal adenocarcinoma of the breast (Fig. 53.13). While extramammary Paget's disease (EMPD) most commonly represents a primary intraepithelial adenocarcinoma (>75% of patients; Fig. 53.14), secondary EMPD can be due to an underlying visceral malignancy, e.g. colon, bladder.

Acanthosis nigricans is characterized by velvety hyperpigmentation of the intertriginous surfaces and, less often, extensor surfaces. Although this disorder is traditionally associated with internal malignancy (most frequently gastric adenocarcinoma), it is more often associated with an endocrinopathy, particularly insulin resistance[11] (Figs 53.15 & 53.16). The areas most often affected are the neck and axillae, but any fold, including that of the lower lip and chin, can be affected. Malignancy-associated acanthosis nigricans is usually rapid in onset and may be accompanied by skin tags, multiple seborrheic keratoses or tripe palms. The patients may even manifest changes on the lips, and weight loss is common. In contrast, acanthosis nigricans associated with endocrine dysfunction is more insidious in its onset, is less widespread, and the patients are often overweight or obese. In either instance, there are probably one or more circulating factors that stimulate the epidermal proliferation (i.e. papillomatosis) that is observed histopathologically. An approach to the patient with acanthosis nigricans in outlined in Figure 53.17. Treatment of the underlying malignancy, or effective treatment of the endocrinopathy, including weight loss and insulin sensitizers, will often result in improvement or disappearance of the acanthosis nigricans. Recurrence of malignancy-associated acanthosis nigricans requires a search for recurrent cancer.

CRITERIA USED TO ASSOCIATE A DERMATOSIS AND MALIGNANCY (CURTH'S POSTULATES)	
Concurrent onset	The neoplasm is discovered at the time of diagnosis of the dermatosis, or shortly following diagnosis
Parallel course	Therapy of the malignancy results in disappearance of the dermatosis, and, if the malignancy recurs, then the dermatosis relapses
Uniform site or type of neoplasm	The neoplasm is of a specific cell type within a specific organ or tissue
Statistical association	
Genetic linkage	

Table 53.2 Criteria used to associate a dermatosis and malignancy (Curth's postulates).

Fig. 53.7 Bazex syndrome (acrokeratosis paraneoplastica). The patient had a squamous cell carcinoma of the tonsillar pillar.

Fig. 53.8 Erythema gyratum repens. This patient had cancer of the breast.

Fig. 53.9 Paraneoplastic pemphigus. This patient had no history of malignancy, nor was one discovered with careful assessment, yet he had clinical features and immunopathologic confirmation for this immunobullous disorder.

PARANEOPLASTIC DERMATOSES		
Dermatoses	**Cutaneous findings**	**Comments**
DISORDERS THAT ARE ASSOCIATED WITH CANCER IN MOST OR ALL CASES		
Bazex syndrome (acrokeratosis paraneoplastica)	Acral psoriasiform plaques, typically with involvement of the nose and helices; often the lesions are violaceous (Fig. 53.7). Longitudinal and horizontal ridging of the nails occurs in 75% of patients	By definition, this condition is linked to malignancy, generally occurring in the upper aerodigestive tract (pharynx, larynx or esophagus)
Carcinoid syndrome	Flushing and erythema of the head and neck. Pellagra-like dermatitis and sclerodermoid changes may develop in advanced disease	Flushing associated with ~10% of mid-gut tumors (small intestine, appendix, proximal colon) and liver metastases are required; type III gastric and bronchial carcinoid tumors are also associated with flushing (liver metastases are not required)
Erythema gyratum repens	Concentric erythematous lesions, often giving the appearance of grains of wood (Fig. 53.8; see Ch. 19)	Variable sites and types of malignancy
Acquired hypertrichosis lanuginosa (malignant down)	Growth of fine lanugo hairs in a generalized distribution or localized to the face. With time, these hairs may become coarser (see Ch. 70)	Associated with a variety of internal malignancies, most often carcinoma of the lung, colon or breast
AESOP syndrome	Large red to violet–brown patch	Patch overlies a plasmacytoma
Ectopic adrenocorticotropic hormone (ACTH) syndrome	Generalized hyperpigmentation	Production of ACTH by a tumor (often a small cell carcinoma of the lung) may result in hyperpigmentation and features of Cushing's syndrome
Glucagonoma syndrome	Necrolytic migratory erythema, angular cheilitis, glossitis	Due to a glucagon-secreting tumor of the pancreas. Patients are often treated for intertrigo before the syndrome is diagnosed. Weight loss and diabetes mellitus accompany the dermatosis
Paraneoplastic pemphigus	Erosive disease of the mucous membranes (Fig. 53.9) and erythema multiforme-like, bullous pemphigoid-like or lichenoid skin lesions (see Ch. 29)	Most often associated with non-Hodgkin lymphoma, chronic lymphocytic leukemia or Castleman's disease (with the latter accounting for the majority of cases in children and Asian populations). Castleman's tumors have been shown to produce the autoantibodies responsible for paraneoplastic pemphigus, and their resection can lead to remission of mucocutaneous lesions. Bronchiolitis obliterans is a common complication
POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-protein and *s*kin changes)	Although the glomeruloid hemangioma (Fig. 53.10) is considered to be pathognomonic, it is present in a minority of patients. Other skin findings include cherry angiomas, hyperpigmentation, hypertrichosis, sclerodermatous thickening, hyperhidrosis, digital clubbing, plethora, acrocyanosis and leukonychia	Osteosclerotic myeloma, Castleman's disease and plasmacytomas have been reported in patients with POEMS. In addition to the findings designated in the acronym, patients may have peripheral edema, ascites, pulmonary effusions, papilledema, thrombocytosis, polycythemia and increased serum levels of VEGF
Sign of Leser-Trélat	Rapid appearance or growth of multiple seborrheic keratoses; keratoses may be inflamed	Often these patients have acanthosis nigricans and generalized pruritus. Controversy continues regarding the existence of this sign in the absence of generalized pruritus and acanthosis nigricans, in part because determining whether seborrheic keratoses are eruptive can be difficult. Eruptive seborrheic keratoses can also develop in erythrodermic patients who do not have an underlying malignancy
Tripe palms	Ridged velvety lesions on the palms	May or may not be accompanied by acanthosis nigricans
DISORDERS THAT ARE STRONGLY ASSOCIATED WITH CANCER IN A SUBSET OF CASES		
Acanthosis nigricans	Rapid onset of hyperpigmented velvety changes of the flexural surfaces (e.g. neck, axillae and groin). May also involve extensor surfaces (e.g. elbows, knees and knuckles) and, in malignancy-associated cases, the lips, oral mucosa and palms (see above, tripe palms). Glossitis is also frequently present in malignancy-associated acanthosis nigricans	Association with adenocarcinoma of the stomach or other sites within the GI or GU tracts; in this setting, acanthosis nigricans is often accompanied by weight loss. Acanthosis nigricans is more commonly associated with endocrinologic abnormalities, particularly insulin resistance (Figs 53.15 & 53.16); such patients are typically overweight, and the onset of the condition is usually insidious
Anti-epiligrin cicatricial pemphigoid (AECP)*	Oral ulcerations, conjunctival erosions and scarring. Tense blisters and erosions of the skin may also develop	Roughly one-third of patients with AECP have or develop cancer within the first year following diagnosis. The cancer is usually an adenocarcinoma and is often at an advanced stage at the time of diagnosis, possibly accounting for the high mortality rate of AECP
Dermatomyositis (adult)*	Heliotrope, Gottron's papules, photodistributed poikiloderma, nailfold overgrowth with dilated capillary loops, pruritic diffuse scaly alopecia of the scalp (see Ch. 42)	Population-based studies demonstrate an over-representation of ovarian, lung, colorectal and pancreatic carcinomas and non-Hodgkin lymphoma in Caucasians
Neutrophilic dermatoses	Sweet's syndrome (Fig. 53.11) or pyoderma gangrenosum (particularly the atypical bullous form) (see Ch. 26)	Approximately 10–20% of cases are associated with hematologic disorders such as acute myelogenous leukemia or plasma cell dyscrasia (IgA). Underlying solid tumors are rare

Table 53.3 Paraneoplastic dermatoses. AESOP syndrome – *a*denopathy, *e*xtensive *s*kin patch *o*verlying (a) *p*lasmacytoma. GI, gastrointestinal; GU, genitourinary; VEGF, vascular endothelial growth factor. *Statistical association.

Continued

PARANEOPLASTIC DERMATOSES		
Dermatoses	**Cutaneous findings**	**Comments**
DERMATOSES THAT MAY BE ASSOCIATED WITH CANCER IN A SUBSET OF PATIENTS		
Acquired angioedema due to C1 esterase inhibitor dysfunction	Acquired angioedema without associated wheals	Associated with B-cell lymphoproliferative disorders, including lymphomas, as well as monoclonal gammopathy of undetermined significance (MGUS)
Acquired ichthyosis	Resembles ichthyosis vulgaris; most often located on the legs	Lymphoma typically predates the diagnosis of the ichthyosis
Amyloidosis, primary systemic	Waxy, translucent or purpuric papules; periorbital and pinch purpura; macroglossia	Monoclonal gammopathy due to plasma cell dyscrasia >> multiple myeloma; deposits composed of immunoglobulin light chain (AL)
Cryoglobulinemia, type I	Retiform purpura and necrosis that favors cooler acral sites; acral cyanosis; livedo reticularis	Monoclonal gammopathy due to lymphoplasmocytic disorders
Cutaneous small vessel vasculitis	Palpable purpura	Less than 1% of patients with vasculitis have an associated malignancy, most commonly hairy cell leukemia and chronic lymphocytic leukemia
Dermatitis herpetiformis (DH)	Pruritic erosions and blisters on extensor surfaces, scalp and/or buttocks	Through the association of DH with gluten-sensitive enteropathy, enteropathy-associated T-cell lymphoma occasionally occurs
Exfoliative erythroderma	Diffuse, scaly, erythematous skin	May be associated with cutaneous T-cell lymphoma or, occasionally, with a systemic lymphoma or leukemia
Juvenile xanthogranulomas (JXGs) in the setting of neurofibromatosis 1 (NF1)	Pink–yellow to red–brown, dome-shaped papules and nodules, most often located on the head and neck	A triple association between JXGs, NF1 and JMML has been described
Multicentric reticulohistiocytosis	Nodular lesions, most often on the dorsal aspects of the hands (Fig. 53.12)	A variety of associated malignancies have been reported, developing in approximately one-quarter of adult patients
Mycosis fungoides	Patch, plaque or nodular disease	Some studies have demonstrated an increased risk of second malignancies
Necrobiotic xanthogranuloma	Indurated xanthomatous plaques with necrosis and ulceration, usually in a periorbital location	Paraproteinemia (>80% of cases, most often IgG with κ light chains); multiple myeloma or a lymphoproliferative disorder develop in a minority of patients
Normolipemic plane xanthoma	Yellowish patches and thin plaques that favor the skin folds, upper trunk and periorbital area	Paraproteinemia, due to a plasma cell dyscrasia or lymphoproliferative disorder
Porphyria cutanea tarda (PCT)	Erosions, blisters and scars on the dorsal aspect of the hands, hyperpigmentation, hypertrichosis, milia	Through its association with hepatitis C virus, PCT may also be associated with primary hepatocellular carcinoma (hepatoma)
Schnitzler's syndrome	Chronic urticaria	Associated with an IgM κ paraproteinemia; lymphoplasmacytic malignancies develop in approximately 15% of patients. Additional manifestations include fevers, arthralgias and bone pain
Scleromyxedema	Sclerodermoid induration and a widespread eruption of firm, waxy papules arranged in linear arrays	Almost always associated with paraproteinemia (usually IgG with λ light chains); multiple myeloma develops in <10% of cases
DERMATOSES THAT HAVE BEEN PROVEN NOT TO BE ASSOCIATED WITH CANCER		
Bowen's disease	Erythematous scaly plaque	The results of early studies that suggested an association with internal malignancy were likely explained by arsenic exposure in affected individuals and have not been replicated
FAMILIAL CANCER SYNDROMES AND THE SKIN		
• Cowden disease (breast, thyroid and GI carcinomas), Muir–Torre syndrome (GI carcinoma), Gardner syndrome (GI carcinoma), Peutz–Jeghers syndrome (various malignancies) – see Table 53.11 • Costello syndrome (rhabdomyosarcoma, bladder carcinoma), Werner syndrome (sarcomas and other malignancies) – see Table 53.13 • Birt–Hogg–Dubé syndrome, familial cutaneous leiomyomatosis (renal carcinoma) – see Table 53.14 • Howel–Evans syndrome (esophageal carcinoma) – see Ch. 58 • Ataxia–telangiectasia (leukemia, lymphoma, breast cancer) – see Ch. 60 • Neurofibromatosis (malignant peripheral nerve sheath tumors, JMML, rhabdomyosarcoma, pheochromocytoma, carcinoid), tuberous sclerosis (renal carcinoma) – see Ch. 61 • Multiple endocrine neoplasia syndromes – see Table 63.2 • Dyskeratosis congenita (leukemia, Hodgkin disease) – see Ch. 67 • Nevoid basal cell carcinoma syndrome (medulloblastoma, fibrosarcoma) – see Table 108.5 • Bloom syndrome (lymphoproliferative and GI malignancies), Rothmund–Thomson syndrome (osteosarcoma), xeroderma pigmentosum (sarcomas, leukemia, GI and lung carcinomas) – see Table 87.4 • Familial atypical mole and multiple melanoma syndrome (pancreatic carcinoma in a subset) – see Ch. 113		

Table 53.3 Paraneoplastic dermatoses (cont'd). GI, gastrointestinal; JMML, juvenile myelomonocytic leukemia.

Fig. 53.10 POEMS syndrome. This patient had multiple angiomas on his trunk as well as his face and scalp. All the angiomas that were examined histologically were glomeruloid hemangiomas. In addition, he reported a recent 10 lb weight loss, impotence and fatigue, and was found to have a neuropathy, adult-onset diabetes, hypothyroidism and peripheral edema. His underlying disorder was an osteosclerotic myeloma.

Fig. 53.11 Acute febrile neutrophilic dermatosis (Sweet's syndrome) associated with acute myelogenous leukemia. The hemorrhagic component is secondary to severe thrombocytopenia.

Fig. 53.12 Multicentric reticulohistiocytosis. Multiple nodules are present on the dorsal hands in this adolescent. This patient did not have a malignancy.

Fig. 53.13 Paget's disease of the breast. A chronic, erythematous plaque surrounds the nipple. *Courtesy, Robert Hartman, MD.*

Fig. 53.14 Extramammary Paget's disease. Note the well-demarcated border of the erythematous plaque. The patient had no underlying internal malignancy.

Fig. 53.15 Acanthosis nigricans and acrochordons of the neck in a patient with insulin resistance and obesity. Note the velvety texture of the skin.

Fig. 53.16 Acanthosis nigricans over the knuckles in a patient with insulin resistance and obesity. Acanthosis nigricans can involve extensor surfaces as well as flexural areas. *Courtesy, Jean L Bolognia, MD.*

The glucagonoma syndrome is characterized by the development of necrolytic migratory erythema, adult-onset diabetes mellitus, weight loss and glossitis. These patients also are frequently anemic, and may have alterations of their personality. Skin lesions of necrolytic migratory erythema are eroded, erythematous patches and plaques that characteristically involve intertriginous areas, the face (especially around the mouth), and distal extremities. Blisters may occur and lead to erythematous erosions. The eruption, which can be painful or pruritic, remits and recurs over the course of several weeks to months. It is frequently misdiagnosed as intertrigo or as seborrheic dermatitis.

Biopsy specimens reveal characteristic features of an abrupt necrolysis of the upper epidermis. Most, but not all, patients have a glucagon-secreting tumor of the pancreas. There have been patients with zinc deficiency, fatty acid deficiency, or biotin deficiency who have developed similar cutaneous findings (see Ch. 51). An occasional patient has had severe liver disease and necrolytic migratory erythema-like lesions. Effective treatment of the tumor will result in a disappearance of the disease, or, in the case of necrolytic migratory erythema associated with a deficiency state, replacement therapy will lead to resolution of the cutaneous findings. The differential diagnosis includes necrolytic acral erythema (see below).

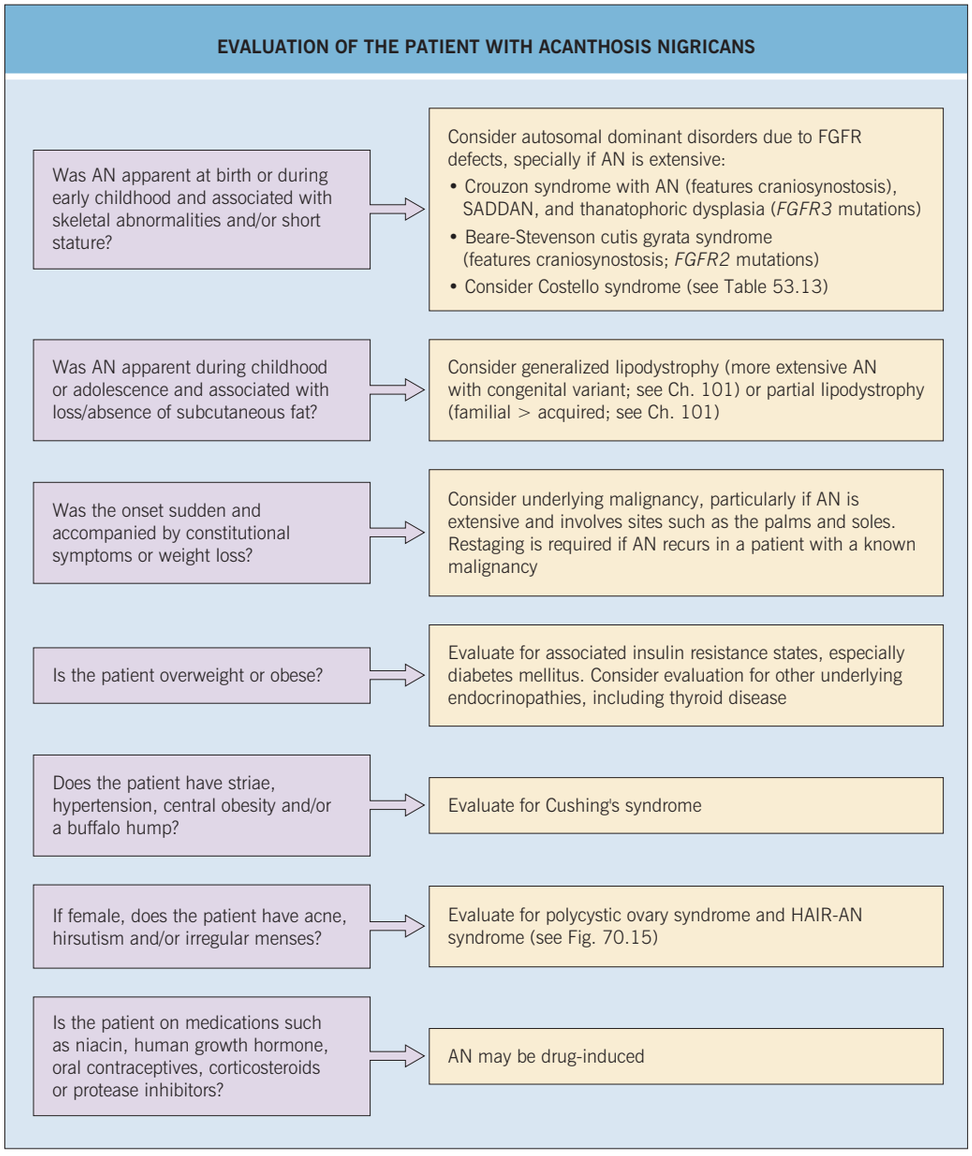

Fig. 53.17 Evaluation of the patient with acanthosis nigricans (AN). FGFR, fibroblast growth factor receptor; HAIR-AN, hyperandrogenemia, insulin resistance, acanthosis nigricans; SADDAN, severe achrondroplasia with developmental delay and AN.

CUTANEOUS ENDOCRINOLOGY AND METABOLIC DISEASE

Endocrine diseases, particularly diabetes mellitus, represent an area in which cutaneous manifestations may be important clues to diagnosis. Patients with endocrine diseases are especially susceptible to a number of associated mucocutaneous disorders.

Diabetes mellitus is a very common medical disease with sequelae that affect almost every organ system. The skin is no exception. Table 53.4 summarizes cutaneous manifestations of diabetes mellitus (Figs 53.18–53.22). Several recent reviews have been published on this topic[11].

The metabolic syndrome, previously known as syndrome X, is a common disorder in which there are multiple phenotypes with primary characteristics that include central obesity, hypertension, dyslipidemia, and type 2 diabetes. Almost all patients with this disorder have insulin resistance, and it is associated with a high risk of cardiovascular disease. Clinical criteria for the diagnosis of metabolic syndrome are outlined in Table 53.5. Women with polycystic ovary syndrome have a greater frequency of the metabolic syndrome and are often found to have cutaneous abnormalities including acanthosis nigricans, acne vulgaris and hirsutism[14]. An association between psoriasis vulgaris and the metabolic syndrome has also been identified. Patients with moderate to severe psoriasis are at increased risk of atherosclerotic cardiovascular disease, which is linked to their propensity for the metabolic syndrome. The components of the metabolic syndrome – hyperlipidemia, diabetes mellitus, hypertension and obesity – are established risk factors[15].

Fig. 53.18 Bullosis diabeticorum (diabetic bullae). Non-inflammatory bullae on the lower extremity in a patient with diabetes mellitus.

SELECTED DERMATOLOGIC ASSOCIATIONS OF DIABETES MELLITUS

Dermatosis	Clinical description	Comments
Acanthosis nigricans (AN)	Velvety hyperpigmentation of the intertriginous/flexural areas (Fig. 53.15) and, less often, extensor surfaces (Fig. 53.16)	Commonly associated with insulin resistance and most of the patients are obese. More common in Hispanics and individuals of African descent. Recent evidence strongly links AN in children with insulin resistance and diabetes
Acral dry gangrene	Necrosis of the fingertips or toes	Due to vascular disease in larger vessels
Acral erythema	Erysipelas-like erythema of the hands and/or feet	May be due to small vessel occlusive disease with compensatory hyperemia
Carotenemia	Diffuse orange–yellow skin color	Related to an increase in serum carotene level
Diabetic bullae (bullosis diabeticorum)	Tense non-inflammatory bullae on the lower extremities (Fig. 53.18)	Unknown pathogenesis
Diabetic cheiroarthropathy	Thickened skin and limited joint mobility of the hands and fingers, leading to flexion contractures (starting with the fifth digit and progressing radially) and an inability to approximate the palmar surfaces of the hands and fingers (prayer sign)	Postulated to result from increased glycosylation of collagen in the skin. Associated with retinopathy, nephropathy, and duration (but not control) of the DM
Diabetic dermopathy	Brown atrophic macules and patches on the legs (Fig. 53.19)	Possibly precipitated by trauma
Disseminated granuloma annulare	Erythematous annular lesions composed of papules	There is controversy about the exact relationship of disseminated granuloma annulare and DM (see Ch. 93)
Eruptive xanthomas	Red–yellow papules that appear over a period of weeks to months (Fig. 53.20)	Associated with elevated serum triglycerides in patients with poorly controlled diabetes. Control of the DM results in a disappearance of the xanthomas (see Ch. 92)
Hemochromatosis	Bronzing of the skin due to an increase in melanin rather than iron	Excess of iron stores associated with cirrhosis and cardiac dysfunction as well as DM. Due to mutations in *HFE*, most commonly C282Y. Also risk factor for porphyria cutanea tarda
Necrobiosis lipoidica	Yellow atrophic patches, most often on the shins. A red–brown rim may indicate activity at the border (Fig. 53.21). Ulceration can occur and is often slow to heal	Intralesional triamcinolone, aspirin, dipyridamole and/or pentoxyfylline are possibly helpful. Not all patients have DM (see Ch. 93)
Neuropathic leg ulcers	Non-painful ulcerations at sites of pressure, most commonly on the foot (Fig. 53.22); a keratotic rim is characteristic	Associated with sensory neuropathy (see Ch. 105)
Perforating disorders (e.g. acquired perforating dermatosis)	Keratotic papules, primarily on the extremities	Often occurs in African-American diabetic patients with chronic kidney disease on dialysis (see Ch. 96)
Rubeosis	Chronic, flushed appearance of the face, neck and upper extremities	Improved by dietary diabetic control. Flares with vasodilator therapies
Scleredema (adultorum of Buschke)	Erythematous induration of the upper back and nape due to glycosaminoglycan deposition	Unknown etiology. No relationship to control of the DM

Table 53.4 Selected dermatologic associations of diabetes mellitus (DM). Additional cutaneous conditions associated with DM include hirsutism (e.g. related to polycystic ovary syndrome or HAIR-AN – *h*yperandrogenemia, *i*nsulin *r*esistance, *a*canthosis *n*igricans; see Ch. 70), necrolytic migratory erythema (in the setting of DM due to a glucagon-secreting pancreatic tumor; see Table 53.3), and infections such as mucocutaneous candidiasis, erythrasma (especially the disciform variant), cellulitis and necrotizing fasciitis. Adapted from ref. 12.

Fig. 53.19 Diabetic dermopathy. Note the brown macules and patches on the shins. *Courtesy, Jean L Bolognia, MD.*

Fig. 53.21 Necrobiosis lipoidica. Controversy exists about the exact risk of diabetes mellitus in such patients, but it is much more strongly associated with diabetes than is granuloma annulare.

Fig. 53.20 Eruptive xanthomas are frequently associated with poorly controlled diabetes mellitus. This patient was first discovered to have diabetes following the appearance of these yellow–red papules.

Fig. 53.22 Neuropathic ulcers on the toes of a patient with diabetic sensory neuropathy.

CRITERIA FOR THE CLINICAL DIAGNOSIS OF THE METABOLIC SYNDROME
• Elevated waist circumference (population- and country-specific definitions)
• Elevated triglycerides (≥150 mg/dl)
• Reduced HDL (<40 mg/dl in males; <50 mg/dl in females)
• Elevated blood pressure (systolic ≥130 and/or diastolic ≥85 mm/Hg)
• Elevated fasting blood glucose (≥100 mg/dl)

Table 53.5 Criteria for the clinical diagnosis of the metabolic syndrome. Metabolic syndrome is identified by the presence of three of these five criteria. Drug treatment for dyslipidemia, hypertension or hyperglycemia also fulfills the corresponding criterion. Most patients with type 2 diabetes mellitus meet criteria for metabolic syndrome. Adapted from ref. 13.

Thyroid disease is also associated with a significant number of dermatologic disorders. Current reviews have highlighted these dermatologic manifestations and associations[16]. Table 53.6 summarizes the dermatologic manifestations of thyroid disease.

Adrenal disease classically manifests as excessive glucocorticoid activity (Cushing's syndrome) (Figs 53.23 & 53.24) or as insufficient glucocorticoid activity (Addison's disease) (Fig. 53.25), but there can also be excessive production of adrenal androgens (see Ch. 70). Features of these syndromes are outlined in Tables 53.7 and 53.8, respectively (see Ch. 125).

DERMATOLOGIC MANIFESTATIONS OF THYROID DISEASE		
	Hyperthyroidism	**Hypothyroidism**
Cutaneous changes	Fine, velvety, smooth skin Warm and moist due to increased sweating Hyperpigmentation – localized or generalized Pruritus	Dry, rough, coarse skin Cold and pale Boggy and edematous skin (myxedema) Yellow discoloration as a result of carotenemia Easy bruising (capillary fragility)
Cutaneous diseases	Pretibial myxedema*, thyroid acropachy Urticaria, dermatographism Increased incidence of vitiligo	Acquired ichthyosis and palmoplantar keratoderma Eruptive and/or tuberous xanthomas Increased incidence of vitiligo
Hair changes/diseases	Fine, thin Mild, diffuse alopecia Increased incidence of alopecia areata	Dull, coarse, brittle Slow growth (increase in telogen hair phase) Alopecia of the lateral third of the eyebrows Increased incidence of alopecia areata
Nail changes	Onycholysis Koilonychia Clubbing from thyroid acropachy	Thin, brittle, striated Slow growth Onycholysis (rare)

*Can persist when patient is treated and becomes euthyroid or can be associated with euthyroid Graves' disease.

Table 53.6 Dermatologic manifestations of thyroid disease. A serum thyroid-stimulating hormone (TSH) level is the most reliable test of thyroid function, and it is usually markedly suppressed in patients with hyperthyroidism. Additional laboratory findings in hyperthyroid patients include elevated free T_3 and/or free T_4 levels. Patients with primary hypothyroidism have elevated TSH levels and decreased free T_4 levels. The detection of anti-thyroid peroxidase and/or antithyroglobulin antibodies points to autoimmune thyroid disease (Hashimoto's thyroiditis, Graves' disease) while the presence of anti-TSH receptor antibodies points to Graves' disease. Ascher's syndrome consists of blepharochalasis, double lip and goiter.

DERMATOLOGIC MANIFESTATIONS OF CUSHING'S SYNDROME
ALTERED SUBCUTANEOUS FAT DISTRIBUTION
• Rounded facies • Fullness of the cheeks ("moon" facies) • Dorsal cervical vertebral fat deposition ("buffalo hump") (Fig. 53.23)* • Pelvic girdle fat deposition* • Reduced fat in the arms and legs*
SKIN ATROPHY
• Global atrophy with epidermal and dermal components affected • Multiple striae on abdomen, flanks, arms and thighs (Fig. 53.24) • Cutaneous fragility and prolonged wound healing • Purpura with minor trauma due to reduced connective tissue support
CUTANEOUS INFECTIONS
• Pityriasis (tinea) versicolor • Dermatophytosis and onychomycosis • Candidiasis
ADNEXAL EFFECTS
• Corticosteroid-related acne • Hirsutism
*This same change is indicative of insulin resistance and occurs in HIV-associated lipodystrophy.

Table 53.7 Dermatologic manifestations of Cushing's syndrome. An overnight dexamethasone suppression test (8 a.m. plasma cortisol >140 nmol/l after receiving 1 mg at midnight) or 24-hour urine free cortisol determination (>140 nmol/24 h) can be used as a screen for Cushing's syndrome due to endogenous cortisol production. Elevated plasma adrenocorticotropic hormone (ACTH) levels are found in Cushing's disease (pituitary overproduction of ACTH) and ectopic ACTH syndrome, whereas ACTH levels are suppressed in patients with adrenal tumors.

Fig. 53.23 "Buffalo hump" of Cushing's syndrome due to fat redistribution. The patient also has evidence of hirsutism. *Courtesy, Judit Stenn, MD.*

Fig. 53.24 Cushing's syndrome with multiple striae. *Courtesy, Judit Stenn, MD.*

Fig. 53.25 Diffuse hyperpigmentation of Addison's disease. The hyperpigmentation (shown in contrast to the physician's hand) is accentuated in sun-exposed skin and can also involve sites of trauma, skin creases and mucosae.

SELECTED DERMATOLOGIC MANIFESTATIONS OF ADDISON'S DISEASE
• Hyperpigmentation (MSH-like effect due to secretion of ACTH) – Diffuse with accentuation in sun-exposed areas (Fig. 53.25) – Sites of trauma – Axillae, perineum and nipples – Palmar creases – Melanocytic nevi – Mucous membranes – Hair – Nails • Loss of ambisexual hair in postpubertal women • Fibrosis and calcification of cartilage including the ear (rare) • Associated findings in candidiasis endocrinopathy syndrome – Vitiligo – Chronic mucocutaneous candidiasis

Table 53.8 Selected dermatologic manifestations of Addison's disease. The rapid adrenocorticotropic hormone (ACTH) stimulation test (which assesses adrenal reserve) should be performed when adrenal insufficiency is suspected, as basal serum cortisol levels may be normal in patients with partial deficiencies. Plasma ACTH levels are elevated in primary adrenocortical insufficiency (Addison's disease) and suppressed in secondary adrenocortical insufficiency (e.g. due to exogenous glucocorticoid therapy). MSH, melanocyte-stimulating hormone.

SKIN FINDINGS IN CROHN'S DISEASE AND ULCERATIVE COLITIS
• Erythema nodosum – often reflective of active bowel disease • Urticaria • Cutaneous small vessel vasculitis • Cutaneous polyarteritis nodosa • "Pustular" vasculitis or bowel-associated dermatosis–arthritis syndrome-like lesions • Pyoderma gangrenosum – primarily the classic (typical) ulcerative form (Fig. 53.26) or peristomal lesions (Fig. 53.27); a vegetative pustular variant (pyoderma vegetans) occasionally occurs. These lesions may or may not reflect activity of the bowel disease • Other neutrophilic dermatoses, ranging from acneiform lesions to Sweet's syndrome to panniculitis • Oral lesions – Granulomatous infiltrates (with Crohn's disease only) – Aphthosis – Angular cheilitis – Pyostomatitis vegetans (mucosal variant of pyoderma gangrenosum) • Contiguous (anogenital) and "metastatic" Crohn's disease (Fig. 53.28) • Fistulae (perianal and abdominal) • Acquired acrodermatitis enteropathica-like lesions (patients with zinc deficiency and/or essential fatty acid deficiency) • Epidermolysis bullosa acquisita • Psoriasis

Table 53.9 Skin findings in Crohn's disease and ulcerative colitis.

Fig. 53.26 Pyoderma gangrenosum associated with inflammatory bowel disease. The ulcer has typical features of pyoderma gangrenosum, including a ragged edge, undermined violet border and surrounding inflammation.

Fig. 53.27 Peristomal pyoderma gangrenosum in the setting of inflammatory bowel disease. Patients with ostomies, particularly ileostomies, are at risk for peristomal dermatoses, including pyoderma gangrenosum.

Fig. 53.28 "Metastatic" Crohn's disease. Non-contiguous granulomatous inflammation of the skin is often manifested by deep inflammatory fissures in the inguinal folds.

CUTANEOUS GASTROENTEROLOGY

With the exception of Table 26.12, cutaneous aspects of gastroenterologic or hepatic disease are not specifically discussed elsewhere in this text[17–19]. Table 53.9 is a list of selected cutaneous associations of Crohn's disease and ulcerative colitis (Figs 53.26–53.28). Patients with ostomies, particularly those with an ileostomy, are at risk for developing peristomal dermatoses, the most common of which are listed in Table 53.10. Table 53.11 lists dermatologic conditions associated with gastrointestinal bleeding or hemorrhage (Figs 53.29–53.32)[18].

Cutaneous hepatology has been the subject of recent reviews[19] and Table 53.12 is a list of selected dermatologic aspects of liver disease. An interesting disease that has been described in association with hepatitis C viral infection is necrolytic acral erythema. This entity is histologically similar to necrolytic migratory erythema (see above), but is clinically distinct as it primarily involves acral sites. The lesions present as painful or pruritic, pink to violet–brown plaques with hyperkeratosis (Fig. 53.33). Blisters and erosions are common, and disease activity tends to wax and wane. Almost all reported cases have been associated with hepatitis C viral infection, and variable success has resulted from treatment with interferon (alone or plus ribavirin) or oral zinc supplementation.

PERISTOMAL SKIN DISORDERS	
Skin disorder	**Comments**
Irritant contact dermatitis	Most common cause of peristomal dermatitis, especially in patients with an ileostomy. Primarily attributed to exposure to feces or urine
Pre-existing skin disease (e.g. psoriasis, seborrheic dermatitis, atopic dermatitis)	Exclude primary contact dermatitis or infection or superimposed contact dermatitis
Cutaneous infection (*Candida* spp. dermatophyte, herpes virus [primarily simplex], bacteria [especially *Staphylococcus aureus*])	Colonization with bacteria and/or yeast is common. Recent treatment with antibiotics predisposes to candidiasis. May initially improve then worsen if treated inappropriately with topical corticosteroids
Allergic contact dermatitis	Relatively uncommon. Potential allergens include: adhesive pastes, adhesive ring or wafer of stoma bag, ostomy bag, epoxy resin, rubber, lanolin and fragrances. Patch test with both standardized allergens and patient's own products
Pyoderma gangrenosum	Infrequent cause of peristomal dermatitis; most common in patients with inflammatory bowel disease (Fig. 53.27)
Pseudo-verrucous papules and nodules	Seen more commonly in association with urostomies; may be misdiagnosed as verrucae

Table 53.10 Peristomal skin disorders. Peristomal skin disorders are common and may limit use and efficacy of the stoma appliance. When the etiology is uncertain, evaluation can include KOH examination, microbial cultures, patch testing and histologic examination. Adapted from ref. 20.

Fig. 53.30 Blue rubber bleb nevus syndrome. Several venous malformations are evident on this patient's tongue.

Fig. 53.32 Gingival cobblestoning in Cowden disease. This patient also had trichilemmomas and a "Cowden's nodule" or sclerotic fibroma on the neck.

Fig. 53.29 Hereditary hemorrhagic telangiectasia. Multiple small bright red macules and papules on the tongue and lips.

Fig. 53.31 Peutz–Jeghers syndrome. Multiple brown macules on the lips and oral mucosa.

Fig. 53.33 Necrolytic acral erythema. This is a manifestation of hepatitis C viral infection.

CUTANEOUS DISEASES ASSOCIATED WITH GASTROINTESTINAL BLEEDING OR HEMORRHAGE				
Disorder	**Cutaneous findings**	**Gastrointestinal features**	**Other pertinent findings**	**Treatment and comments**
GENETIC (ESPECIALLY THOSE ASSOCIATED WITH VASCULAR MALFORMATIONS AND GI POLYPS)				
Hereditary hemorrhagic telangiectasia	Macular and papular telangiectasias on facial and acral skin (Fig. 53.29) as well as the oral mucosa	Recurrent hemorrhage in the upper GI tract	Epistaxis is often the initial manifestation. Arteriovenous malformations (AVMs) of the lungs, liver and CNS	Autosomal dominant; most commonly due to mutations in *ENG* and *ACVRL1*, which encode endoglin and ALK, TGF-β receptors. Treatment consists of surgical resection, embolization or laser therapy of AVM causing hemorrhage
Blue rubber bleb nevus syndrome	Subcutaneous blue to purple venous malformations (Fig. 53.30)	GI vascular malformations	Possible vascular malformations in other organs (e.g. CNS, lungs)	Autosomal dominant or sporadic
Pseudoxanthoma elasticum	Yellow papules and plaques in intertriginous zones, redundant lax skin	Upper or lower GI hemorrhage	Angioid streaks in the eye, hypertension, premature atherosclerosis, uterine hemorrhage, vascular calcification	Autosomal recessive disorder due to mutations in the *ABCC6* gene. Perhaps a diet high in magnesium is helpful
Ehlers–Danlos syndrome, vascular type (type IV)	Translucent fragile skin with extensive bruising	GI hemorrhage due to arterial rupture or intestinal perforation	Minimal joint hyperextensibility (limited to digits), rupture of other arteries or the uterus, acrogeric facies	Autosomal dominant, deficiency of type III collagen
Gardner syndrome	Epidermoid cysts, pilomatricomas, lipomas, fibromas and desmoid tumors	Hemorrhage from adenomatous colonic polyps. Adenocarcinoma of the colon is universal if the colon is not removed	Mandibular and maxillary osteomas and cysts, *c*ongenital *h*ypertrophy of the *r*etinal *p*igment *e*pithelium (CHRPE)	Autosomal dominant due to mutations in the *APC* gene. Colectomy must be appropriately timed
Peutz–Jeghers syndrome	Melanotic macules on mucosal surfaces (Fig. 53.31) and, less often, on acral or perioral skin	Hamartomatous polyps throughout the GI tract. Intussusception or hemorrhage may occur	Possibly increased incidence of breast, ovarian and GI cancer	Autosomal dominant due to mutations in *STK11*, which encodes a serine/threonine kinase. Remove symptomatic areas of the bowel
Cowden disease (multiple hamartoma syndrome; PTEN hamartoma syndrome)	Multiple facial or periorificial papules (trichilemmomas), perioral lentigines, cobblestoning of the oral mucosal surface (Fig. 53.32), acral keratotic papules, sclerotic fibromas, lipomas	Hamartomatous polyps throughout the GI tract. Bleeding is rare	Fibrocystic breast disease along with frequent cancers of the breast, often bilateral. Thyroid tumors including cancer	Autosomal dominant due to mutations in the *PTEN* tumor suppressor gene, which encodes a phosphatase
Muir–Torre syndrome	Sebaceous neoplasia and multiple keratoacanthomas	Multiple GI malignancies are possible	Cancer also may occur in the larynx and GU tract, as well as lymphomas	Autosomal dominant due to mutations in one of several mismatch repair genes, including *MSH2* (~90%), *MLH1* and *MSH6*
INFLAMMATORY/AUTOIMMUNE				
Cronkhite–Canada syndrome	Circumscribed areas of lentiginous hypermelanosis, alopecia, generalized nail thinning	Adenomatous GI polyps, diarrhea, abdominal pain	Weight loss due to malabsorption	Malignant degeneration is unusual
Vasculitis	Palpable purpura, necrotizing livedo reticularis, nodules, or ulcers	Ulcerations secondary to vasculitis of the vessels in the bowel. May be more common in IgA-associated vasculitis (Henoch–Schönlein purpura)	Arthritis and nephritis are two additional features of Henoch–Schönlein purpura	Corticosteroids and/or immunosuppressive agents may or may not be effective
Malignant atrophic papulosis (Degos disease)	Early lesions – pale red papules with central necrosis Late lesions – atrophic ivory scars	Similar lesions of the GI mucosa. Hemorrhage may result in death	CNS involvement, pleuritis, pericarditis	May be related to lupus erythematosus or to the antiphospholipid antibody syndrome
Ulcerative colitis	Erythema nodosum, vasculitis, pyoderma gangrenosum See Table 53.9	Uniform and continuous inflammation of the large bowel. Rectal involvement is present in majority (>95%) of patients. Toxic megacolon may develop	Aphthous stomatitis is common. Malignant degeneration in the large intestine is frequent in patients with uncontrolled, longstanding disease	Treatment options include sulfonamides, immunosuppressives, corticosteroids and total colectomy

Table 53.11 Cutaneous diseases associated with gastrointestinal bleeding or hemorrhage. CNS, central nervous system; GI, gastrointestinal; GU, genitourinary. Adapted from refs 12 & 21.

Continued

CUTANEOUS DISEASES ASSOCIATED WITH GASTROINTESTINAL BLEEDING OR HEMORRHAGE				
Disorder	**Cutaneous findings**	**Gastrointestinal features**	**Other pertinent findings**	**Treatment and comments**
Crohn's disease	Erythema nodosum, vasculitis, pyoderma gangrenosum, perianal fistulae and metastatic Crohn's disease See Table 53.9	Chronic inflammation, often granulomatous, of the bowel. Skip areas occur	Aphthous stomatitis, arthritis, chronic blood loss	Treatment options include sulfonamides, metronidazole, corticosteroids and other immunosuppressives, including TNF-α inhibitors
NUTRITIONAL				
Scurvy	Perifollicular purpura, corkscrew hairs	Collagen degeneration in the vasculature due to vitamin C deficiency. GI blood loss results in anemia	Gingivitis with friable gums and easy bleeding, conjunctival hemorrhage, difficulty walking	Vitamin C replacement
NEOPLASTIC				
Kaposi sarcoma	Violaceous macules, papules, and nodules of the skin and oral mucosa	Similar tumors may occur in the GI tract	Includes HIV-related, "African"and classic subtypes, with the latter favoring elderly men of Mediterranean heritage; related to HHV-8 infection	Chemotherapy or radiation therapy may be helpful

Table 53.11 Cutaneous diseases associated with gastrointestinal bleeding or hemorrhage (cont'd). GI, gastrointestinal; HHV, human herpesvirus. Adapted from refs 12 & 21.

DERMATOLOGIC ASPECTS OF LIVER DISEASE		
Liver disease	**Dermatologic manifestations/associations**	**Other features, treatment, and comments**
Cirrhosis	• Spider angiomas and other telangiectasias • Palmar erythema • Dilated abdominal wall veins • Terry's nails (white nail bed) • Muehrcke's nails (transverse white bands) • Sparse axillary, pubic and pectoral hair • Pruritus • Jaundice	• Gynecomastia • Parotid enlargement
Primary biliary cirrhosis (PBC)	• Jaundice • Diffuse hyperpigmentation • Xanthomas – eruptive, planar and, occasionally, tuberous • Pruritus • May coexist with scleroderma	Cholestyramine, rifampin, ursodiol and naloxone may help to relieve the pruritus. Osteoporosis is a common complication. Treatment options for PBC include ursodiol, colchicine, methotrexate and liver transplantation
Hemochromatosis ("bronze diabetes")	• Generalized hyperpigmentation	Due to mutations in *HFE*, most commonly C282Y. Phlebotomy to reduce iron stores is first-line therapy; also chelation (e.g. deferasirox)
Wilson disease (hepatolenticular degeneration)	• Kayser-Fleischer ring – golden brown or greenish circle of pigment in Descemet's membrane at the periphery of the cornea • Blue lunulae • Pretibial hyperpigmentation	Autosomal recessive; due to mutations in *ATP7B* which encodes a copper-transporting ATPase. Treatment with penicillamine, trientine or liver transplantation
Hepatitis B and C viruses	• Cutaneous small vessel vasculitis (B,C) • Cryoglobulinemic vasculitis (C>>B) • Urticarial vasculitis (B,C) • Polyarteritis nodosa (classic – B, cutaneous – C) • Necrotizing livedo reticularis (C) • Urticaria (B,C) • Porphyria cutanea tarda (C>B) • Pruritus (B,C) • Lichen planus – particularly erosive oral disease (C) • Sarcoidosis (following therapy with interferon and/or ribavirin) (C>B) • Necrolytic acral erythema (Fig. 53.33) (C) • Gianotti–Crosti syndrome (B>C) • Erythema multiforme (B,C) • Erythema nodosum (B>C)	Interferon and ribavirin are useful for hepatitis C viral infections and may prevent cirrhosis and hepatocellular cancer; telaprevir, an NS3/4A protease inhibitor, was recently FDA-approved for the treatment of genotype 1 chronic hepatitis C infection

Table 53.12 Dermatologic aspects of liver disease.

OTHER SYSTEMIC DISEASES WITH CUTANEOUS MANIFESTATIONS

Sarcoidosis is a multisystem disease with major cutaneous manifestations (see Ch. 93)[22]. Cardiovascular diseases and the skin are not specifically discussed elsewhere in this text. Table 53.13 is a review of cardiac and dermatologic abnormalities that are features of multisystem disorders (Figs 53.34 & 53.35)[23,24]. Pulmonary disorders are listed in Table 53.14 (Fig. 53.36).

Cutaneous aspects of renal disease are discussed in various chapters, but are not considered as a group elsewhere in this textbook. Table 53.15 is an overview of cutaneous changes that are particularly prevalent in patients with renal disease (Figs 53.37 & 53.38)[25–30].

Pruritus is a feature of uremia, but it can occur in non-uremic patients on hemodialysis. It is still unclear why patients with chronic kidney disease on dialysis experience itching. The pruritus may be localized or generalized. It is usually worse during dialysis, but may occur "round the clock" (see Ch. 6).

Patients who undergo renal transplantation usually receive immunosuppressive agents, including cyclosporine, tacrolimus, sirolimus, azathioprine, and/or corticosteroids, in order to prevent rejection. The combination of these drugs predisposes the patient to two major problems: infection (e.g. HPV, CMV) and malignancy (e.g. squamous cell carcinoma, Kaposi sarcoma, Merkel cell carcinoma).

Fig. 53.34 Antiphospholipid antibody syndrome. In addition to bland thromboses, these patients may have cardiac valvular vegetations.

Fig. 53.36 Periorificial and facial papules of sarcoidosis. The presence of lesions on the nasal rim is often associated with granulomatous inflammation of the upper respiratory tract.

Fig. 53.35 Relapsing polychondritis. The inflammation spares the earlobes, which lack cartilage.

Fig. 53.37 Calciphylaxis. This patient presented with these necrotic skin lesions and was found to have severe end-stage renal disease due to amyloidosis of the kidney.

CARDIOCUTANEOUS ABNORMALITIES IN MULTISYSTEM DISORDERS			
Disease	**Cutaneous features**	**Cardiovascular findings**	**Comments**
		GENETIC	
Cardio-facio-cutaneous syndrome	Generalized ichthyosis-like scaling, keratosis pilaris, café-au-lait macules, sparse curly hair	Pulmonic stenosis, atrial septal defects, hypertrophic cardiomyopathy	Autosomal dominant condition due to mutations in four genes in the mitogen-activated protein kinase (MAPK) pathway – *BRAF* > *KRAS, MEK1/2*. Patients also have characteristic facies, short stature and developmental delay
Costello syndrome	Lax skin on the hands and feet, deep palmoplantar creases, periorificial papillomas, acanthosis nigricans, curly hair	Pulmonic stenosis, hypertrophic cardiomyopathy, arrhythmias	Autosomal dominant condition due to *HRAS* > *KRAS* mutations. Patients also have mental and growth retardation and an increased risk of rhabdomyosarcoma and bladder carcinoma
Carvajal syndrome	Striate epidermolytic palmoplantar keratoderma, woolly scalp hair	Dilated left ventricular cardiomyopathy	Autosomal recessive disorder due to desmoplakin mutations
Cutis laxa	Looseness of the skin	Aortic dilation and rupture, pulmonary artery stenosis, right-sided heart failure	Autosomal dominant (AD) and recessive (AR) forms due to mutations in the elastin (AD > AR), fibulin-4 (AR) and fibulin-5 (AR > AD) genes; systemic involvement is more common in the AR form
Ehlers–Danlos syndrome (EDS)	Variable degree of skin hyperelasticity and fragility (e.g. "cigarette" paper scars, ecchymoses)	Classic and hypermobility types (I–III): aortic root dilation, mitral and tricuspid valve regurgitation or prolapse Vascular type (IV): arterial aneurysms, dissection and rupture Cardiac valvular type: valvular abnormalities	Due to mutations in the genes encoding collagen V (classic type), tenascin X (subset of classic and hypermobility types), collagen III (vascular type) and collagen I (cardiac valvular type)
Fabry disease	Angiokeratoma corporis diffusum, hypohidrosis	Hypertrophic cardiomyopathy, valvular abnormalities, conduction defects, progressive atherosclerotic disease of the coronary and cerebral arteries	α-Galactosidase A deficiency, X-linked recessive disorder. Cardiac and cerebrovascular disease and renal failure are the usual causes of death
Hemochromatosis	Generalized bronze hyperpigmentation	Congestive heart failure, supraventricular arrhythmias	Diabetes, cirrhosis. Genetic testing is available for *HFE* gene mutations
Homocystinuria	Livedo reticularis, malar rash, tissue-paper scars, diffuse pigmentary dilution	Atherosclerosis, arterial and venous thrombosis	Autosomal recessive disorder due to homozygous cystathionine β-synthase (CBS) deficiency. Patients also exhibit marfanoid characteristics and ectopia lentis. Hyperhomocysteinemia (due to homozygous methylenetetrahydrofolate reductase deficiency >> heterozygous CBS deficiency) also increases risk of arterial and venous thrombosis
LEOPARD syndrome	Multiple lentigines, café-au-lait and café-noir macules	ECG abnormalities, pulmonary artery stenosis	*L* – lentigines, *E* – ECG abnormality, *O* – ocular hypertelorism, *P* – pulmonary stenosis, *A* – abnormalities of the genitalia, *R* – retardation of growth, *D* – deafness. Autosomal dominant disorder due to mutations in the *PTPN11* gene
Loeys–Dietz syndrome	Translucent skin, easy bruising, atrophic scarring	Aortic aneurysms, arterial tortuosity; significant risk of aortic dissection and rupture, even at an early age	Autosomal dominant disorder due to mutations in the genes that encode TGF-β receptor 1 and 2. Overlapping clinical features with Marfan syndrome and vascular type (IV) EDS. Craniofacial anomalies are seen primarily in type I
Marfan syndrome	Striae, decreased subcutaneous fat	Dilation and dissection of the ascending aorta, mitral valve prolapse and regurgitation	Autosomal dominant disorder due to mutations in the gene that encodes fibrillin-1. Characterized by tall stature with long limbs, arachnodactyly, dolichocephaly, myopia and ectopia lentis. In addition to β-blockers, angiotensin II receptor blockers (e.g. losartan), which antagonize pathogenic TGF-β signaling, can prevent aortic root dilation
Multiple endocrine neoplasia (MEN) types 2A (Sipple syndrome) and 2B (multiple mucosal neuroma syndrome)	MEN 2A – notalgia paresthetica, macular or lichen amyloidosis, often with childhood onset MEN 2B – neuromas of the eyelids, lips, tongue and other mucosal sites; GI ganglioneuromatosis also occurs	Hypertensive crises due to pheochromocytomas (often bilateral)	Autosomal dominant conditions due to mutations in the *RET* proto-oncogene. Also manifest with medullary cell carcinoma of the thyroid (MEN 2A and 2B), parathyroid adenomas (MEN 2A) and a marfanoid habitus (MEN 2B)
Carney complex (NAME and LAMB syndromes)	Cutaneous myxomas, blue nevi, lentigines	Atrial myxoma	Endocrine neoplasia of the adrenal glands, pituitary gland, and/or testes. Autosomal dominant disorder due to mutations in the *PRKAR1A* gene
Naxos disease	Diffuse non-epidermolytic palmoplantar keratoderma, woolly scalp hair	Arrhythmogenic right ventricular cardiomyopathy	Autosomal recessive condition due primarily to mutations in the gene that encodes plakoglobin (rarely desmocollin 1)

Table 53.13 Cardiocutaneous abnormalities in multisystem disorders. ECG, electrocardiogram; GI, gastrointestinal; TGF, transforming growth factor. Adapted from ref. 12.

Continued

CARDIOCUTANEOUS ABNORMALITIES IN MULTISYSTEM DISORDERS			
Disease	**Cutaneous features**	**Cardiovascular findings**	**Comments**
Neurofibromatosis 1	Café-au-lait macules, neurofibromas, intertriginous freckling	Hypertension, essential or due to pheochromocytoma or renal artery stenosis	Due to mutations in the *NF1* gene, which encodes neurofibromin
Progeria	Sclerodermoid changes, mottled hyperpigmentation, loss of subcutaneous fat, alopecia	Premature atherosclerosis	Autosomal dominant premature aging syndrome due to mutations in the gene encoding lamins A and C
Pseudoxanthoma elasticum	Yellow papules and plaques in intertriginous areas, redundant lax skin	Premature atherosclerotic vascular disease, aortic aneurysm, hypertension	Upper or lower GI hemorrhage, angioid streaks in the eye, uterine hemorrhage. Autosomal recessive disorder due to mutations in the *ABCC6* gene
Tuberous sclerosis complex (TSC)	Facial angiofibromas, periungual and subungual fibromas, ash leaf macules, shagreen patch	Cardiac rhabdomyomas, arrhythmias	Renal angiomyolipomas, CNS tumors, mental retardation, seizures. Due to mutations in *TSC1* or *TSC2*, which encode hamartin and tuberin
Werner syndrome	Premature graying, alopecia, sclerodermoid changes, loss of subcutaneous fat, ankle ulcerations	Premature atherosclerosis	Myocardial infarction is usually responsible for death by the fifth decade. Autosomal recessive disorder due to mutations in the *RECQL2* gene, which encodes a helicase. Other features include cataracts and malignancy
		INFLAMMATORY/AUTOIMMUNE	
Behçet's disease	Oral and genital aphthae, pathergy, pustular vasculitis, pyoderma gangrenosum-like lesions, erythema nodosum-like lesions	Pericarditis, coronary arteritis, myocarditis, arrhythmias, valvular disease; vasculitis of the vasa vasorum, primarily of large blood vessels	Ocular and CNS involvement. Inflammatory bowel disease should be excluded
Dermatomyositis	Gottron's papules, heliotrope rash, photodistributed poikiloderma	Nonspecific ECG changes, pericarditis and congestive heart failure are rare	Cardiac involvement is a poor prognostic sign
DRESS/DIHS (drug hypersensitivity with eosinophilia and systemic symptoms/ drug-induced hypersensitivity syndrome)	Widespread morbilliform or urticarial eruption or erythroderma; facial edema often present	ECG changes may simulate acute myocardial infarction; acute myocardial dysfunction and hypotension	Hepatitis, polyarthritis and eosinophilia common. Symptoms suggestive of cholecystitis sometimes present. Treatment consists of discontinuation of offending drug and corticosteroids. Can follow levels of N-terminal pro-brain natriuretic peptide (NT-proBNP)
Kawasaki disease (mucocutaneous lymph node syndrome)	Glossitis, cheilitis, acral erythema, edema and desquamation, polymorphous eruption, conjunctival injection	Coronary arteritis, coronary artery aneurysms	High fever, lymphadenopathy. Treatment with intravenous immunoglobulin and aspirin is beneficial
Neonatal lupus erythematosus	Transient, non-scarring annular lesions of LE (SCLE-like) that favor the periorbital region	Congenital heart block	Presumed to be due to transplacental passage of autoantibodies, most commonly Ro (SS-A). May have transient cytopenias and hepatitis. Rash and cardiac disease rarely occur in the same patient; subsequent pregnancies may manifest either. Mothers often have or develop an autoimmune connective tissue disease
Systemic lupus erythematosus	Malar erythema, photosensitivity, lupus skin lesions. Patients with antiphospholipid antibodies may have necrotizing livedo reticularis, leg ulcers or widespread cutaneous necrosis (Fig. 53.34)	Pericarditis, verrucous endocarditis (Libman–Sacks), coronary artery disease	Anticardiolipin antibody may play a role. Treatment of LE with corticosteroids may predispose to coronary artery disease
Multicentric reticulohistiocytosis	Erythematous nodules of the hands and, less often, the extremities and the face (Fig. 53.12)	Pericarditis, congestive heart failure, coronary artery disease, cardiomegaly	Deforming arthritis is frequent
Psoriasis	Well-demarcated, pink-to-red plaques with silvery scale on the elbows, knees and scalp, around the umbilicus and in the gluteal cleft	Increased risk of cardiovascular disease, including cerebrovascular and peripheral artery disease. In patients with moderate to severe psoriasis, possible increased risk of death from atherosclerotic cardiovascular disease	High incidence of metabolic syndrome in patients with moderate to severe psoriasis (see Table 53.5)
Relapsing polychondritis	Beefy, red ears (sparing the lobes); inflammation in other tissues with cartilage (e.g. the nose). Late findings include floppy ears and weakness in other areas where the cartilage was affected (Fig. 53.35)	Aortic insufficiency, dissecting aortic aneurysm	Arthritis, tracheal collapse. Dapsone may be helpful. Corticosteroids and/or other immunosuppressive agents are also used
Rheumatic fever	Erythema marginatum, subcutaneous nodules	Pancarditis in the acute phase. Late manifestations include mitral and/or aortic valve dysfunction	Rare in US. Follows pharyngitis due to group A β-hemolytic streptococcal infection. Polyarthritis, chorea, fever

Table 53.13 Cardiocutaneous abnormalities in multisystem disorders (cont'd). CNS, central nervous system; ECG, electrocardiogram; GI, gastrointestinal; LAMB, lentigines, atrial myxoma, mucocutaneous myxoma, blue nevi; LE, lupus erythematosus; NAME, nevi, atrial myxoma, myxoma of the skin, ephelides. Adapted from ref. 12.

CARDIOCUTANEOUS ABNORMALITIES IN MULTISYSTEM DISORDERS			
Disease	**Cutaneous features**	**Cardiovascular findings**	**Comments**
Sarcoidosis	Papules, nodules, plaques and/or lesions in scars	Conduction defects, congestive heart failure	Pulmonary disease, lymphadenopathy, hepatic involvement, hypercalcemia. Cardiac involvement denotes a poor prognosis
Scleroderma	Cutaneous sclerosis, Raynaud's phenomenon	Pulmonary artery hypertension, conduction defects, pericarditis, visceral Raynaud's phenomenon	Cardiac involvement denotes a poor prognosis. May also have interstitial lung disease
Vasculitis	Palpable purpura, nodules, livedo reticularis, ulcerations	Coronary artery vasculitis	Arthritis, GI colic or bleeding. Cardiac involvement is uncommon
		NEOPLASTIC	
Primary systemic amyloidosis (AL)	Pinch purpura, waxy skin, translucent papules, macroglossia	Restrictive cardiomyopathy, conduction disturbances	Proteinuria, urinary light chains, association with plasma cell dyscrasia >> multiple myeloma
Carcinoid syndrome	Flushing; pellagra-like dermatitis and sclerodermoid features may occur as late manifestations	Endocardial plaques – tricuspid insufficiency, conduction defects	Flushing associated with approx. 10% of mid-gut tumors (small intestine, appendix, proximal colon) and liver metastases are required; type III gastric and bronchial carcinoid tumors are also associated with flushing (liver metastases are not required)
		INFECTIOUS	
Endocarditis – bacterial or fungal	Purpura, nailfold infarction, Janeway lesions, Osler's nodes	Vegetations and dysfunction of the valves	Fever. May simulate vasculitis or cryoglobulinemia
		METABOLIC/ENDOCRINE	
Diabetes mellitus	See Table 53.4	Coronary artery and peripheral artery disease	–
Hyperlipidemia	Xanthomas of multiple types	Coronary artery disease	see Ch. 92
		OTHER	
Exfoliative erythroderma	Exfoliative dermatitis	High-output cardiac failure	The eruption may be due to dermatitis, psoriasis, cutaneous T-cell lymphoma, a drug eruption or other causes
PHACES syndrome	Segmental infantile hemangioma, most often of the face and neck	Coarctation of the aorta, atrial and ventricular septal defects, anomalous cervical and cerebral arteries	*P* – posterior fossa malformations, *H* – hemangioma, *A* – arterial anomalies, *C* – cardiac defects and coarctation of the aorta, *E* – eye anomalies, *S* – sternal defects and supraumbilical raphe

Table 53.13 Cardiocutaneous abnormalities in multisystem disorders (cont'd). GI, gastrointestinal. Adapted from ref. 12.

PULMONARY DISEASE AND THE SKIN				
Disorder	**Cutaneous findings**	**Pulmonary disease**	**Other features**	**Treatment and comments**
		GENETIC		
Birt–Hogg–Dubé syndrome	Classic triad of fibrofolliculomas, trichodiscomas and acrochordons	Lung cysts, spontaneous pneumothoraces	Increased risk of renal carcinoma. Due to mutations in the gene encoding folliculin	Surveillance for renal tumors
Hereditary hemorrhagic telangiectasia	Mucosal, facial and acral telangiectatic macules and papules	Pulmonary AVMs	Epistaxis, recurrent GI bleeding, AVMs in other organs including the CNS	No therapy has been proven to be effective. Surgical correction of AVMs or excision of bleeding areas
Yellow nail syndrome	Thickened, slow-growing, excessively curved, yellow-to-green nails with onycholysis, transverse ridging, onychomadesis and absent cuticles and lunulae	Pleural effusions, bronchiectasis	Lymphedema, sinusitis	Complete triad of yellow nails, lymphedema and respiratory tract involvement seen in only one-third of patients; 2 of 3 findings needed for diagnosis
		INFLAMMATORY/AUTOIMMUNE		
Sarcoidosis – chronic	Papules, nodules (Fig. 53.36), plaques, lupus pernio, lesions in scars and tattoos	Fibrosis due to granulomatous inflammation	Hypercalcemia, ocular disease, CNS disease, bone cysts	Hydroxychloroquine may be useful for the skin lesions. Prednisone, methotrexate, or other immunosuppressive agents (e.g. oral tacrolimus, TNF-α inhibitors) may lead to improvement
Sarcoidosis – acute	Erythema nodosum	Bilateral hilar lymphadenopathy	Arthritis, anterior uveitis	Self-limiting. NSAIDs or potassium iodide may provide symptomatic relief
Wegener's granulomatosis	Vasculitic lesions (e.g. palpable purpura or nodules), cutaneous granulomas, pyoderma gangrenosum-like ulcers	Cavitating pulmonary nodules, vasculitis	Glomerulonephritis, upper respiratory tract inflammation, mucosal ulceration, friable hypertrophic gingiva	The presence of antineutrophil cytoplasmic antibody may aid in diagnosis. Cyclophosphamide, corticosteroids, sulfonamides, methotrexate

Table 53.14 Pulmonary disease and the skin. AVMs, arteriovenous malformations; CNS, central nervous system; GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs; TNF, tumor necrosis factor.

Continued

PULMONARY DISEASE AND THE SKIN				
Disorder	**Cutaneous findings**	**Pulmonary disease**	**Other features**	**Treatment and comments**
Churg–Strauss syndrome	Palpable purpura, urticarial plaques, nodules	Asthma	Allergic rhinitis, peripheral eosinophilia, neuropathy, systemic vasculitis	The presence of antineutrophil cytoplasmic antibody may aid in diagnosis. Systemic corticosteroids, methotrexate, cyclophosphamide, rituximab
Dermatomyositis	Gottron's papules, heliotrope, photodistributed poikiloderma	Interstitial lung disease, aspiration pneumonitis, hypoventilation	Proximal, symmetric muscle weakness	Corticosteroids, immunosuppressive agents, IVIg
Scleroderma	Sclerosis, Raynaud's phenomenon	Interstitial lung disease, pulmonary artery hypertension	Esophageal dysmotility, arthritis	Cyclophosphamide for neutrophilic alveolitis, endothelin receptor antagonists
Urticarial vasculitis	Urticarial papules and plaques, often with a subtle purpuric component	Chronic obstructive pulmonary disease	The hypocomplementemic variant may involve the joints, GI tract, kidneys and eyes as well as the lungs; patients may have systemic lupus erythematosus	Oral corticosteroids, hydroxychloroquine, dapsone, colchicine
NEOPLASTIC/PARANEOPLASTIC				
Kaposi sarcoma	Red–violet to dark purple plaques and/or nodules of the skin and oral mucosa; in the classic form, most commonly seen on the lower extremities	Multifocal involvement can be asymptomatic or lead to dyspnea, cough, hemoptysis and/or chest pain	Lymphedema of the lower extremities. Gastrointestinal involvement common	Related to HHV-8 infection. Four major forms (see Ch. 114). Treatment includes antiretroviral therapy (HIV-related form), radiotherapy, taxanes and liposomal doxorubicin
Lymphomatoid granulomatosis	Nodules or plaques or papules	Angiocentric, angiodestructive infiltrate of atypical lymphocytes	Systemic lymphoma	Immunosuppressive or cytotoxic therapy
Paraneoplastic pemphigus	Erosive disease of the mucous membranes (see Fig. 53.9) and erythema multiforme-like, bullous pemphigoid-like or lichenoid skin lesions	Bronchiolitis obliterans	Most often associated with non-Hodgkin lymphoma, chronic lymphocytic leukemia or Castleman's disease	Immunosuppressive/cytotoxic medications (including prednisone), plasmapheresis, IVIg, rituximab (alone or in combination). Resection of Castleman's disease can lead to remission of mucocutaneous lesions
INFECTIOUS				
Tuberculosis	Lupus vulgaris, scrofuloderma (see Table 75.5)	Apical infiltrates, cavitating infiltrates; non-productive or productive cough	Fever, weight loss	Triple-drug antituberculous therapy
Blastomycosis*	Verrucous, ulcerated plaques or nodules. May be studded with pustules, especially at the periphery	Patchy infiltrates or normal chest X-ray	Bone and GU involvement, including testes	Inhalation followed by dissemination, including to skin; treatment includes itraconazole, amphotericin B
Cryptococcosis	Variable cutaneous findings, from papulonodules and plaques to molluscum contagiosum-like lesions and cellulitis	Varies from asymptomatic infection to severe pneumonia and acute respiratory distress syndrome	Meningeal involvement (needs to be excluded via lumbar puncture)	Severe infections favor immunocompromised hosts. Depending upon severity, fluconazole, amphotericin B
Aspergillosis	Primary cutaneous lesions – plaques with black crusts Secondary cutaneous emboli – necrotic papules and plaques, often with ulceration and rapidly progressive	In those with disseminated cutaneous emboli, cavitating infiltrates and nodules	In immunocompromised hosts, can disseminate widely	Disseminated disease affects primarily patients who are neutropenic and immunosuppressed (e.g. chronic corticosteroids)
Varicella	Lesions in various stages of development, including papules, papulovesicles, pustules and hemorrhagic crusts; cephalocaudal progression	Pulmonary involvement correlates with severity of skin involvement. Interstitial infiltrates or patchy airway disease leads to cough and dyspnea	Liver and CNS additional sites of infection. Reye's syndrome associated with use of aspirin.	Adults, pregnant or postpartum women and immunocompromised individuals at highest risk for pulmonary disease. Systemic antiviral medications recommended
OTHER				
Toxic epidermal necrolysis	Widespread necrosis and detachment	Acute respiratory distress syndrome	Erosions of the oropharyngeal, nasal, conjunctival, esophageal and genitourinary mucosa	Prompt discontinuation of all potential culprit drugs, IVIg therapy, admission to an intensive care or burn unit

*Primary pulmonary infection also occurs in other systemic mycoses due to dimorphic pathogens, including coccidioidomycosis, histoplasmosis and paracoccidioidomycosis.

Table 53.14 Pulmonary disease and the skin (cont'd). CNS, central nervous system; GI, gastrointestinal; HHV, human herpesvirus; IVIg, intravenous immunoglobulin.

RENAL DISEASE AND THE SKIN				
Disorder	**Cutaneous findings**	**Renal abnormality**	**Other findings**	**Treatment and comments**
		GENETIC		
Tuberous sclerosis complex (TSC)	Facial angiofibromas, ash leaf macules, shagreen patch, periungual or subungual fibromas	Renal hamartomas (angiomyolipomas). Polycystic kidney disease may occur in a contiguous gene syndrome with *TSC2*	CNS tumors, mental retardation, cardiac rhabdomyomas, seizures	Autosomal dominant. Due to mutations in *TSC1* or *TSC2*, which encode hamartin and tuberin
Fabry disease	Angiokeratoma corporis diffusum	Proteinuria, renal failure due to accumulation of ceramide trihexoside	Acral pain and paresthesias, hypohidrosis, corneal and lenticular opacities. Hypertrophic cardiomyopathy, coronary artery disease, CVAs	Renal transplantation, replacement therapy with the deficient enzyme, α-galactosidase A. X-linked recessive disorder
Nail–patella syndrome	Hypoplasia of the nails, with greatest involvement of medial digits; triangular lunulae	Congenital nephrosis, glomerulonephritis	Absence or hypoplasia of the patella, iliac horns	Autosomal dominant disorder due to mutations in *LMX1B*
Birt–Hogg–Dubé syndrome	Classic triad of fibrofolliculomas, trichodiscomas and acrochordons	Renal tumors, particularly chromophobe and hybrid oncocytic carcinomas	Spontaneous pneumothoraces	Due to mutations in the gene encoding folliculin. Surveillance for renal tumors
Familial cutaneous leiomyomatosis	Multiple cutaneous leiomyomas	Predisposition to develop renal carcinoma	Uterine leiomyomas	Due to mutations in the gene encoding fumarate hydratase. Surveillance for renal tumors
		INFLAMMATORY/AUTOIMMUNE		
Systemic lupus erythematosus	Malar erythema, cutaneous LE lesions, photosensitivity, diffuse alopecia, vasculitis	Glomerulonephritis – focal, membranous or proliferative	Arthritis, serositis, cytopenias, multiple autoantibodies, hypocomplementemia	Varies, depending upon the organ system involved and the severity or type of involvement
Scleroderma	Raynaud's phenomenon, acral or diffuse sclerosis, CREST syndrome	Malignant hypertension, rapidly progressive renal failure	Esophageal dysmotility, arthritis, pulmonary fibrosis, pulmonary hypertension	Angiotensin-converting enzyme inhibitors, dialysis, cytotoxic agents
Henoch–Schönlein purpura	Palpable purpura	IgA-associated glomerulonephritis	Arthritis, GI vasculitis	Symptomatic therapy; systemic corticosteroids, and possibly other immunosuppressive agents, may be beneficial for nephritis and severe GI involvement
Polyarteritis nodosa	Nodules, livedo reticularis	Renal artery aneurysms, hypertension	Arthritis, mononeuritis multiplex, abdominal pain, serositis, fever	Corticosteroids with or without cytotoxic agents (e.g. cyclophosphamide)
Wegener's granulomatosis	Palpable purpura, nodules, cutaneous granulomas	Glomerulonephritis	Upper and lower respiratory tract inflammation	Cyclophosphamide, corticosteroids, sulfonamides, methotrexate
Cutaneous small vessel vasculitis	Palpable purpura	Glomerulonephritis may occur, but is less common than in the vasculitides mentioned above	Arthritis	Drug-induced and hepatitis C virus are possible etiologies. Symptomatic therapy or corticosteroids, with or without immunosuppressive agents
Sarcoidosis	Papules, nodules, plaques	Hypercalciuria, nephrolithiasis	Lymphadenopathy, uveitis, pulmonary fibrosis, hepatosplenomegaly, hypercalcemia	Corticosteroids, immunosuppressive agents
		NEOPLASTIC		
Primary systemic amyloidosis (AL)	Pinch purpura, translucent papules, macroglossia	Proteinuria, including nephrotic syndrome, and renal insufficiency	Restrictive cardiomyopathy, paraproteinemia due to plasma cell dyscrasia	Corticosteroids, melphalan, bortezomib, hematopoietic stem cell transplant
		OTHER		
Cutaneous changes of end-stage renal disease	1. Pale color, sallowness 2. Xerosis or acquired ichthyosis 3. Pruritus 4. Acquired perforating dermatosis 5. Pseudoporphyria 6. Calciphylaxis (Fig. 53.37) 7. Uremic frost	End-stage renal disease of various causes. 1–6 are more common in dialysis patients. 7 is rarely observed	1. Anemia of chronic disease 2. – 3. Possible increase in tissue mast cells 4. Related to pruritus 5. Porphyrins may be borderline elevated or within normal limits 6. Obese women are more often affected. Increased $Ca^{2+} \times PO_4^{2-}$ product, increased PTH level. Calcification of the vessel walls	1. Erythropoietin, transplantation 2. Emollients, lactic acid or urea preparations 3. UV light 4. See Table 96.4 5. Erythropoietin, N-acetylcysteine 6. Phosphate binders (non-calcium), surgical debridement, parathyroidectomy may be helpful 7. Dialysis

Table 53.15 Renal disease and the skin. CNS, central nervous system; CREST, *c*alcinosis, *R*aynaud's, *e*sophageal dysmotility, *s*clerodactyly and *t*elangiectasias; CVA, cerebrovascular accident; GI, gastrointestinal; LE, lupus erythematosus; PTH, parathyroid hormone.

Continued

RENAL DISEASE AND THE SKIN				
Disorder	**Cutaneous findings**	**Renal abnormality**	**Other findings**	**Treatment and comments**
Cutaneous diseases associated with long-term immunosuppression	1. Infections – mycobacterial, viral, bacterial, fungal 2. Neoplasia – porokeratosis, squamous cell carcinoma, Kaposi sarcoma	End-stage renal disease of various causes	–	Reduction in level of immune suppression. Treat infections with appropriate antimicrobials. Treat carcinomas with removal of lesions
Nephrogenic systemic fibrosis (NSF) – formerly nephrogenic fibrosing dermopathy (NFD)	Woody indurated plaques on the extremities > trunk, often becoming confluent and limiting motion of the joints. Peau d'orange appearance is common (Fig. 53.38)	Occurs primarily in patients with chronic renal failure on dialysis, but has also been described in renal transplant recipients and patients with acute renal failure	Systemic fibrosis (e.g. of the heart, lungs and skeletal muscle) has been observed. Linked to administration of gadolinium-containing contrast media. Hypercoagulable state also a risk factor	Prevention via assessment of renal function pre-MRI. Renal transplantation, and, based upon small case series, imatinib, rapamycin, UVA1 phototherapy

Table 53.15 Renal disease and the skin (cont'd).

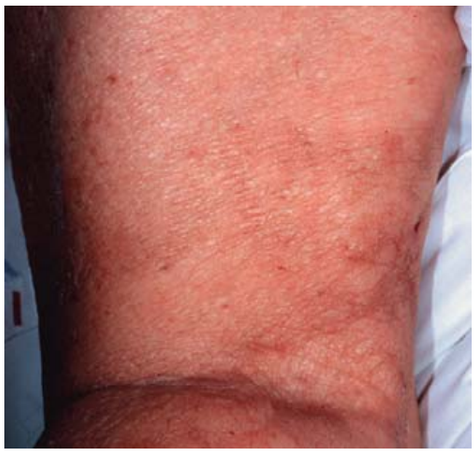

Fig. 53.38 Nephrogenic systemic fibrosis. This sclerosing disorder is seen almost exclusively in patients with renal failure who have received gadolinium-containing contrast media. In addition to the peau d'orange appearance of the skin, this patient had severe restriction of the movement of his hands, wrists and feet.

Pregnancy is an important physiologic state that is associated with its own specific dermatoses and with modification of other dermatoses (see Ch. 27)[31]. Mast cell disease is the subject of Chapter 118. Internal disease can produce profound effects on the nails, hair and mucous membranes, and the reader is referred to the chapters that review these structures in detail. Leg ulcers are also potential dermatologic clues to underlying disease and are discussed in Chapter 105.

54 Basic Principles of Genetics

Maija Kiuru, Amalia Martinez-Mir and Angela M Christiano

'Everything is genetic (except trauma)'
Francis Collins, MD, PhD, meeting of the American Academy of Dermatology, 1995

Key features

- Genetic disease may be caused by defects in one gene (Mendelian or monogenic diseases) or more than one gene (polygenic diseases), but it can also be a result of the interaction of environmental and genetic factors (complex or multifactorial traits)
- The major Mendelian patterns of inheritance are autosomal recessive (e.g. oculocutaneous albinism), autosomal dominant (e.g. Darier disease), X-linked recessive (e.g. hypohidrotic ectodermal dysplasia), and X-linked dominant (e.g. incontinentia pigmenti)
- Factors modifying the basic Mendelian pattern of inheritance include incomplete penetrance, age-dependent penetrance, variable expression, *de novo* mutations, pseudodominant inheritance, genomic imprinting and mitochondrial inheritance
- Chromosomal anomalies can consist of abnormalities in the number (e.g. polyploidy, aneuploidy) or structure (e.g. translocations, inversions) of the chromosomes
- Methods of disease gene identification include functional cloning, linkage analysis followed by positional cloning, and a combination of the two, known as the positional candidate approach
- Genetic variants associated with complex traits can be identified by genome-wide association studies (GWAS), which utilize detailed maps of human sequence variation (single nucleotide polymorphisms, SNPs)

INTRODUCTION

The completion of the human genome sequence, with an estimated size of 3.2 gigabases (gb) and containing approximately 20 000–25 000 genes[1], represents a powerful tool in medicine that facilitates the identification of disease-associated genes. Detailed information on human sequence variation and advanced technologies for its detection have broadened our knowledge of the genetic basis of human disease. It is also becoming clear that epigenetics (heritable changes in phenotype and/or gene expression that do not result from changes in the DNA sequence) are involved in the pathogenesis of medical disorders.

Rapid advances in the development of molecular biology techniques (see Ch. 3), together with the continuing flow of information and tools derived from the human genome, puts the physician in a privileged position, having direct access to clinically relevant genetic information. Consequently, it is important for physicians in general, and dermatologists in particular, to understand basic concepts of genetics (Table 54.1) and become familiar with new technology in order to apply them appropriately in caring for patients and interpret the results of studies that are performed. The wealth of new information also emphasizes the necessity of combined efforts between the clinical and research arms of dermatology.

Access to patients with genetic disorders and accurate clinical descriptions are essential for investigations aimed at the identification of disease-causing genes, which can in turn provide benefits to affected individuals. Such insights have importance in genetic counseling and prenatal diagnosis, and they can also contribute to the identification of at-risk individuals and families (e.g. in population-based screenings), presymptomatic diagnosis, prediction of possible complications and course of a disease, determination of response to pharmacologic interventions and even the development of treatments that target the underlying defect.

Since the early 1980s, the molecular bases of numerous cutaneous genetic disorders have been identified, including many forms of epidermolysis bullosa (EB; see Ch. 32), ectodermal dysplasia (ED; see Ch. 63), ichthyosis (see Ch. 57), and hypotrichosis (see Ch. 69). Although such conditions do not account for the majority of patients in a dermatologist's practice, understanding these diseases has helped to set the stage for the study of more common disorders, such as atopic dermatitis and psoriasis, that have more complex etiologies. The gene identification strategies developed for genetically simpler diseases, and the genes identified, have played a major role in determining the underlying causes of common complex disorders. In recent years, advances in mapping and detecting human sequence variation have led to insights into the genetic bases of complex diseases via genome-wide association studies. The clinician has played, and will continue to play, a key role in the feasibility of such investigations, which are completely dependent on a well-characterized collection of patient samples.

GENETIC DISEASES

Key features

- Accurate information about phenotype and family history is essential in identifying the pattern of inheritance of a particular genetic disease
- Single-gene disorders can follow several different inheritance patterns
- The phenotype can vary based on incomplete penetrance, variable expression and X inactivation
- Heterogeneity at the locus or allelic level can make identification of a gene defect challenging

Although genetic diseases can manifest in several members of a family, this is not the case for all genetic disorders. Likewise, it is not true that any disease present in more than one family member is genetic. Pedigrees in which a genetic disease is transmitted (i.e. segregates or is inherited) can range from a single affected member all the way to multiple generations with many affected members in each generation.

Genetic diseases may be caused by defects in one gene (Mendelian or monogenic diseases) or more than one gene (polygenic diseases), but they can also be the result of the interaction of environmental and genetic factors (multifactorial diseases). In other instances, an aberrant structure or number of one or more chromosomes or a differential parental chromosomal contribution can be the cause of the disease.

In the following sections, we provide an overview of the different types of genetic diseases.

MENDELIAN DISEASES: PATTERNS OF INHERITANCE

A key initial step in the assessment of the risk for each individual in a family with a particular inherited disease is the establishment of the mode of inheritance of the condition. For this purpose, it is essential to collect accurate information on the clinical phenotype and to examine as many family members as possible to define their status

BASIC CONCEPTS IN GENETICS	
Nuclear DNA	• Deoxyribonucleic acid (DNA) contained within nuclei of eukaryotic organisms • Packed into chromosomes • Selectively folded and unfolded to allow the expression of hundreds of genes at different times and in different cell types • Each somatic cell contains approximately 2 meters of DNA[2]
Chromosome	• Organized structures of DNA and proteins that are found within the nucleus • Each diploid organism (including humans) has two sets of chromosomes, one from its father and one from its mother • Each pair of chromosomes is composed of two homologous chromosomes, one from each parent • Humans normally have 23 pairs of chromosomes: 22 pairs of autosomes and one pair of sex chromosomes (XX in females and XY in males) • Chromosomes X and Y share only two small regions, known as the pseudoautosomal regions
Karyotype	• Describes the chromosomal constitution of an individual (e.g. 46, XY or 46, XX)
Haploid cell	• Contains only one chromosome complement or "n" (for humans, n = 23) • Gametes (paternal and maternal) are haploid cells
Diploid cell	• Contains two chromosome complements or "2n" (for humans, 2n = 46) • Human cells (other than gametes) are diploid
Centromere	• A site of constriction in a chromosome that is essential for correct cell division • Depending on the position of the centromere, chromosomes can be: – *Metacentric*: centromere near the middle, two "arms" of similar length – *Submetacentric*: centromere between the center and end, two "arms" of somewhat different lengths – *Acrocentric*: centromere near the end, two "arms" of very different lengths • Composed of a series of proteins (called histones) and repetitive DNA sequences (several thousand kilobases) • Divides the chromosome into two arms: the short (petite) arm or p, and the long arm or q
Telomere	• A region of repetitive DNA (TTAGGG sequence) and proteins at the ends of each chromosome • Plays a key role in the maintenance of chromosomal integrity and ensuring correct replication
Meiosis	• The process of cell division by which a diploid cell from the germline gives rise to haploid gametes via segregation and random assortment of homologous chromosomes • Results in combinations of chromosomes in the daughter cells that are different than that in the parental cell
Mitosis	• The process of somatic cell division of proliferating cells by which the genetic material of a cell is duplicated and equally distributed between the two resulting daughter cells • To achieve this duplication of genetic material, the chromosome replicates itself and forms two *sister chromatids*, which will each become the chromosome of a daughter cell
Locus	• The location of a particular sequence of DNA (a gene or any fragment of DNA) on a chromosome • Since we have two copies of each chromosome, we also have two copies of each locus, which can be identical or different
Gene	• A segment of DNA that encodes a protein (or occasionally an RNA chain) that serves a function
Allele	• Alternative forms of a particular gene or DNA sequence at a given locus • An individual has two alleles at each autosomal locus (one from each parent), and the locus/individual is referred to as: – *Homozygous* if the alleles are identical – *Heterozygous* if the alleles are different (Fig. 54.1) • Since males have only one copy of the X and Y chromosomes, they are *hemizygous* for loci on these two chromosomes
Polymorphic locus	• Exhibits at least two alleles with a frequency in the general population of >1% (see Fig. 54.1) • Can be located within or outside of a gene
Single nucleotide polymorphism (SNP)	• A single nucleotide in a particular location within the genome that has at least two different forms with a frequency of >1% in the general population • Occurs on average every 1000 nucleotides[3]
Mutation	• A change in the DNA sequence • Refers to variation resulting in a disease phenotype • Although any change in the DNA is technically a mutation, the term is often used to refer to a pathogenic variant that results in a disease phenotype
Genotype	• The alleles present at a specific locus (or in the whole genome) of an individual
Phenotype	• The manifestation of a particular genotype (in the context of the environment in which it is expressed) • Different genotypes are not always recognizable as distinct phenotypes • A change in a phenotype can be caused by variant alleles that are present in the general population (normal variation) or by pathogenetic variation that leads to a disease

Table 54.1 Basic concepts in genetics.

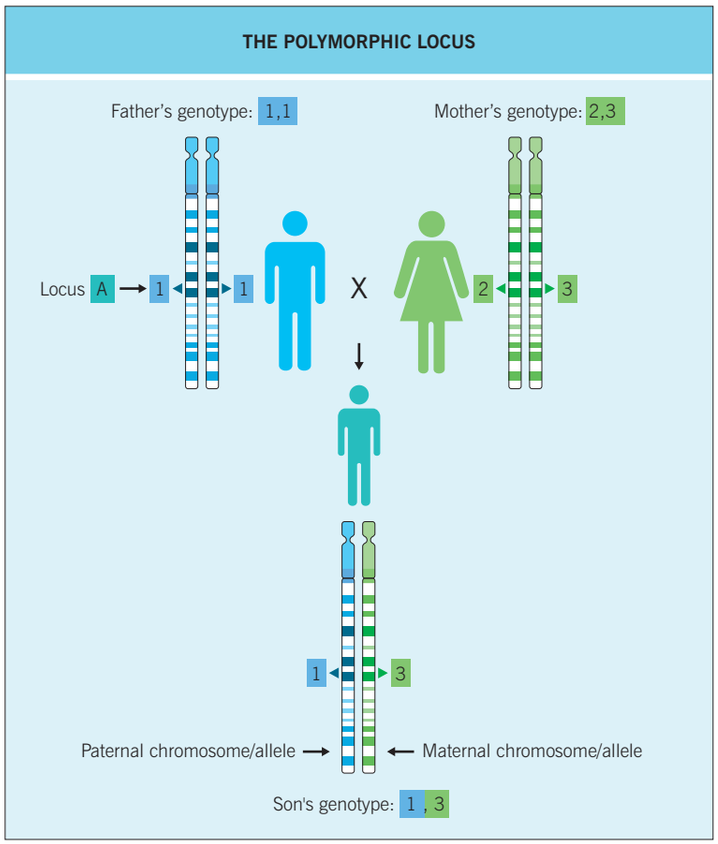

Fig. 54.1 The polymorphic locus. Locus *A* represents a polymorphic locus with three different alleles. The example shows a family in which the father is homozygous for allele 1 and the mother is heterozygous for alleles 2 and 3. The son of this family has inherited allele 1 from the father and allele 3 from the mother, and is thus heterozygous (1,3).

– affected or unaffected. The family is usually ascertained through one family member, the *proband*, around whom the pedigree is built with information on the phenotypes and relationships between different individuals.

Even when a single-gene defect is enough to cause a disease phenotype (monogenic disorders), its expression can be highly variable (see below for incomplete penetrance and variable expression). Genes are expressed on a particular genetic background, which is different in every individual, and genes and their products interact with other genes and proteins. Thus, one can expect that even monogenic disorders may show some degree of variability. If a gene can be subject to different genetic background effects in different individuals, and if this genetic background can modify its expression, then slightly or even considerably different clinical entities can be due to mutations in the same gene; this phenomenon is known as *allelic heterogeneity* (Table 54.2)[4–13]. This term also refers to separate diseases caused by different mutations in the same gene. On the other hand, defects in different genes can result in the same phenotype, known as *genetic or locus heterogeneity* (Table 54.3)[14–21]. Thus, a diagnosis based purely on clinical signs and symptoms can lead to misclassification of a patient on a genetic level, which underscores the relevance of the identification of disease genes.

There are several examples of both allelic and locus heterogeneity in dermatology. As an example of allelic heterogeneity, mutations in the *GJB3* gene that encodes connexin 31 can result in autosomal dominant erythrokeratodermia variabilis as well as autosomal dominant or recessive deafness. In contrast, EB simplex of the localized (Weber–Cockayne) type can result from heterozygous mutations in the keratin 14 or keratin 5 gene. Tables 54.2 and 54.3 list examples of cutaneous disorders with allelic and locus heterogeneity, respectively. Some diseases, such as EB simplex, display both allelic and locus heterogeneity.

Once a phenotype is defined, including its range of variability, the disease phenotype can be followed within the pedigree. The transmission of the trait in the pedigree will define the pattern of inheritance of the disease. The genes responsible for monogenic traits can be located either on autosomes, defining an autosomal phenotype, or on the X chromosome in the case of an X-linked phenotype. Irrespective of the location of the gene, when a mutation in one of two alleles is sufficient to produce the phenotype, the trait is *dominant*. On the contrary, when both alleles of a gene (or, in the case of hemizygotes, one allele) must be altered in order to produce the phenotype, the condition is called *recessive*. Therefore, a phenotype can be inherited as an autosomal dominant or recessive trait or as an X-linked dominant or recessive trait (Table 54.4). There are also Y-linked genes, normally affecting male fertility[22], although their relevance in more general diseases is possible.

EXAMPLES OF ALLELIC HETEROGENEITY IN GENODERMATOSES	
Gene	**Phenotype**
GJB3	Erythrokeratodermia variabilis
	AD non-syndromic sensorineural deafness
	AR non-syndromic hearing loss
	AD deafness with peripheral neuropathy
Desmoplakin	Striate palmoplantar keratoderma
	Dilated cardiomyopathy with woolly hair and keratoderma
	Arrhythmogenic right ventricular cardiomyopathy
Plectin	EBS and limb-girdle muscular dystrophy
	EBS of the Ogna type
	EBS with pyloric atresia
ATP7A	Menkes disease
	Occipital horn syndrome

Table 54.2 Examples of allelic heterogeneity in genodermatoses[4–13]. AD, autosomal dominant; AR, autosomal recessive; *ATP7A*, gene for ATPase, Cu^{2+}-transporting, α-polypeptide; EBS, epidermolysis bullosa simplex; *GJB3*, gene for connexin 31.

EXAMPLES OF GENODERMATOSES WITH GENETIC OR LOCUS HETEROGENEITY				
Phenotype	**Gene**			
EB simplex (Dowling–Meara, Koebner, and Weber–Cockayne variants)	*KRT5* *KRT14*			
Bullous congenital ichthyosiform erythroderma (epidermolytic hyperkeratosis)	*KRT1* *KRT10*			
Hermansky-Pudlak syndrome	*HPS1* *HPS5*	*AP3B1* *HPS6*	*HPS3* *DTNBP1*	*HPS4* *BLOC1S3*
Tuberous sclerosis	*TSC1* *TSC2*			
Hereditary hemorrhagic telangiectasia	*ENG* (endoglin) *ACVRL1*			
Hypohidrotic ectodermal dysplasia	*EDA* (ectodysplasin A) *EDAR* (ectodysplasin A receptor) *EDARADD* (EDAR-associated death domain)			

*Mutations in different genes result in X-linked recessive (EDA), autosomal recessive (EDAR, EDARADD) and autosomal dominant (EDAR, EDARADD) forms of the disorder.

Table 54.3 Examples of genodermatoses with genetic or locus heterogeneity[14–24]. *ACVRL1*, gene for activin A receptor type II-like 1; *AP3B1*, gene for beta-3A subunit of AP3; *BLOC1S3*, gene for biogenesis of lysosome-related organelles complex-1, subunit 3; *DTNBP1*, gene for dystrobrevin binding protein 1 (dysbindin); EB, epidermolysis bullosa; *HPS*, genes for Hermansky–Pudlak syndrome; *KRT*, genes for keratins; *TSC*, genes for tuberous sclerosis complex.

PATTERNS OF INHERITANCE					
Pattern	**Parents affected**	**Gender affected**	**Transmission**	**Recurrence risk**	**Risk factors**
Autosomal recessive	No (carriers)	Both equally	Disease seen in siblings of proband, not in parents or offspring Usually seen in one generation	1 in 4	Consanguinity, isolated population (e.g. geographically, linguistically)
Autosomal dominant	Yes	Both equally	Disease seen in every generation	1 in 2	*De novo* mutations
X-linked recessive	Mother a "carrier"	Males have the "full" disease Female "carriers" may have mild manifestations (e.g. in a mosaic pattern)	No male-to-male transmission (but all daughters of an affected male are "carriers")	1 in 2 male children born to a female "carrier" will be affected (and 1 in 2 of her female children will be carriers)	*De novo* mutations
X-linked dominant	Yes	Predominantly females if lethal in males during embryonic development; otherwise milder in females (often with a mosaic pattern of skin lesions) than in males	Affected males have: (1) no affected sons; and (2) all daughters affected No male-to-male transmission	1 in 2 children born to affected female (may spontaneously abort male fetuses if "male lethal" condition)	*De novo* mutations; tend to be lethal in males

*Unless the proband has a *de novo* mutation and is therefore the first generation affected.

Table 54.4 Patterns of inheritance.

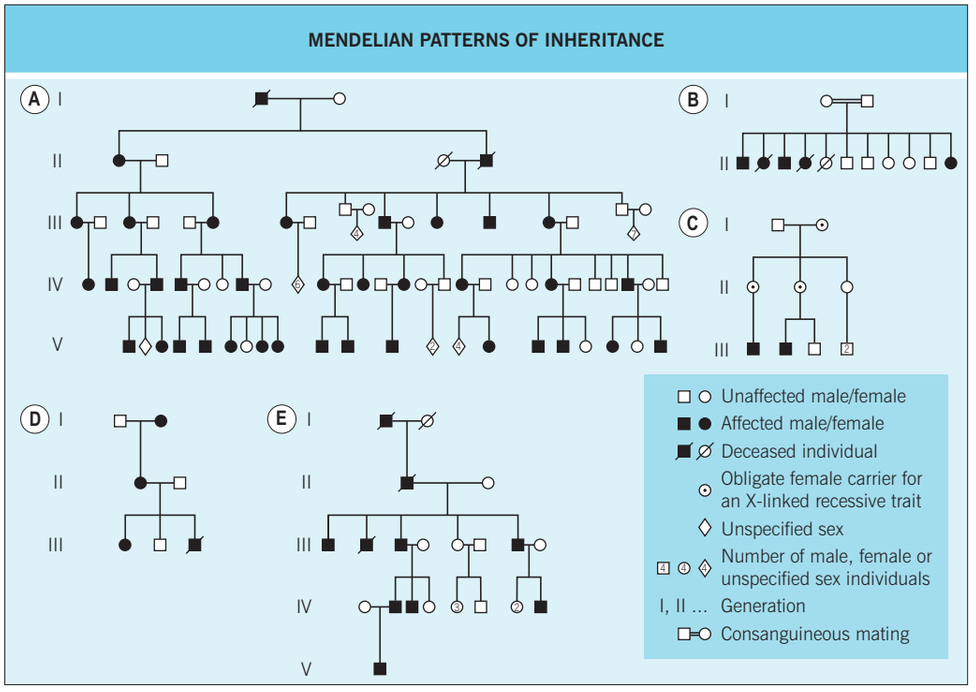

Fig. 54.2 Mendelian patterns of inheritance. **A** Autosomal dominant epidermolysis bullosa simplex superficialis (adapted from ref. 27). **B** Autosomal recessive woolly hair, palmoplantar keratoderma and cardiomyopathy (adapted from ref. 26). **C** X-linked recessive immune deficiency and hypohidrotic ectodermal dysplasia (adapted from ref. 24). **D** X-linked dominant incontinentia pigmenti (adapted from ref. 25). **E** Y-linked retinitis pigmentosa (adapted from ref. 23).

Of note, although this chapter focuses on genodermatoses, this information regarding Mendelian or complex traits applies to extracutaneous diseases.

Autosomal Dominant Inheritance

In a pedigree of an autosomal dominant disease, each affected person (other than the first affected family member, who has a *de novo* mutation) has an affected parent, both sexes are equally affected and can transmit the trait, and there is transmission from generation to generation (Fig. 54.2A)[23–27]. A single mutant allele is enough to give rise to the phenotype. Thus, each offspring of an individual with an autosomal dominant disorder has a 50% risk of inheriting the mutant allele.

An autosomal dominant trait can be transmitted from father to son, and it cannot be transmitted by an unaffected individual (see below for a discussion on incomplete penetrance). Examples of autosomal dominant genodermatoses are EB simplex, Darier and Hailey–Hailey diseases and nail–patella syndrome.

A patient with an autosomal dominant disease is usually heterozygous for the disease-causing mutation. Although infrequent, homozygotes for autosomal dominant diseases have been reported, and they usually exhibit a more severe phenotype compared with heterozygotes. An example of this would be a family with a mutation in the *KRT14* gene, which in heterozygous form gives rise to EB simplex of the localized type and in homozygous form results in more severe EB simplex of the generalized (Koebner) type[28].

There are, however, exceptions to the rules, mainly due to incomplete penetrance, variable expression or *de novo* mutations (see below).

Autosomal Recessive Inheritance

In a pedigree of an autosomal recessive disease, an affected individual has clinically unaffected parents, both sexes are equally affected, and there is no transmission from generation to generation (Fig. 54.2B). Both alleles of a given gene must be mutated for the disease to develop. For each offspring, the chance of inheriting the disorder is 25%.

Type I oculocutaneous albinism and atrichia with papular lesions (a rare form of total alopecia) are examples of autosomal recessive genodermatoses.

There is often an increased frequency of *consanguinity* (sharing a common ancestor) in families with recessive conditions. Consanguineous matings increase the probability that a mutated allele present in the common ancestor will become homozygous in the offspring of the related parents (homozygosity by descent). When more than one affected family member with an autosomal recessive disease is present in a single pedigree, they are usually part of the same generation. However, the presence of consanguinity (inbreeding) can also explain some pedigrees in which an autosomal recessive trait is observed in more than one generation. For example, matings between unaffected carriers and affected patients give rise to affected family members in two consecutive generations (pseudo-dominant inheritance; see below).

A patient with an autosomal recessive disease has inherited two copies of the disease-causing mutation, while both parents are heterozygotes for the mutant gene (i.e. they are carriers of one mutant copy as well as having one normal copy). Both parents can carry the same mutation, thus the patient will be homozygous for the disease-causing mutation, or the parents can carry two different mutations affecting the same gene, and the patient will be *compound heterozygous*.

X-linked Recessive Inheritance

Patients with an X-linked recessive disease are typically male; they usually have unaffected parents, but their mother may have some evidence of the condition due to functional mosaicism (see Ch. 62). There is no male-to-male transmission, since an affected male will transmit the Y chromosome and not the mutant X chromosome to his son, and (excluding mosaic manifestations in women, which remove the condition from the "true" X-linked recessive category) the trait does not appear in successive generations (Fig. 54.2C).

The inheritance risk for the offspring will depend on the parent transmitting the disease allele. An affected father will transmit the mutated allele (but not the complete disease) to all his daughters, but to none of his sons. All the daughters of an affected man will be obligate carriers, since they will all inherit the mutated allele from the father. An obligate female carrier will transmit the mutated allele to 50% of her children. Thus, sons and daughters of a carrier mother will have a 50% chance of being affected or carriers, respectively.

The two main characteristics of an X-linked recessive trait are the absence of male-to-male transmission and female carriers being asymptomatic. Regarding the former, one clearcut exception is the offspring of an affected male and a female carrier. In some instances, female "carriers" may have clinical manifestations in a mosaic pattern; with variable skewing of X-inactivation (see below), the spectrum of disease can range from absent to severe. As a result, the distinction between "recessive" and "dominant" may be blurred in this group of patients.

Examples of recessive X-linked diseases in dermatology are X-linked ichthyosis (steroid sulfatase deficiency; see Ch. 57), hypohidrotic ectodermal dysplasia, and Menkes disease.

X-linked Dominant Inheritance

In a pedigree of an X-linked dominant disease, affected individuals (other than the first affected family member, who has a *de novo* mutation) have at least one affected parent and (unless male-lethal) the disorder occurs in both males and females. However, females (who are heterozygous rather than hemizygous) generally have a milder and/or mosaic phenotype (see below). There is no male-to-male transmission, and the trait appears in successive generations (Fig. 54.2D). The risk of the offspring inheriting the disease depends on the transmitting parent. An affected father will transmit the trait to all his daughters, but to none of his sons. An affected mother, on the other hand, will transmit the trait to 50% of her children, regardless of the sex of the offspring. Some X-linked dominant diseases are lethal in males during early intrauterine development. In this situation, the disorder is seen almost exclusively in females (who may have an increased frequency of spontaneous abortions when they become pregnant). Occasional male patients can be explained by mosaicism, either functional in the setting of Klinefelter syndrome (47, XXY karyotype) or genomic due to mosaicism secondary to a *de novo* half-chromatid or postzygotic mutation (see Ch. 62).

Because of lyonization (the random epigenetic inactivation of one of the two X chromosomes in each cell in female embryos; see below), female patients with X-linked dominant skin diseases typically have a mosaic pattern of cutaneous lesions. Non-random patterns of X inactivation in these patients may reflect preferential survival of cells expressing the normal X chromosome. Examples of X-linked dominant diseases in which girls present with a mosaic pattern of skin findings are focal dermal hypoplasia (Goltz syndrome)[29] and incontinentia pigmenti[30]. Girls with both disorders present with cutaneous, dental and ocular abnormalities, whereas for boys, lethality *in utero* is presumed.

Y-linked Inheritance

In a pedigree with a Y-linked disease (holandric inheritance), affected boys always have affected fathers and only males are affected. All sons of affected fathers are affected (Fig. 54.2E).

There are relatively few Y-linked disorders, and most of them affect male fertility[22]. Possible examples affecting other organs have been described[23], but their Y-linked inheritance cannot be proven.

EXCEPTIONS TO BASIC MENDELIAN PATTERNS OF HERITANCE

By definition, Mendelian diseases are the result of mutations in a single gene. But, as mentioned previously, this gene can modify and be modified by other genes as well as by epigenetic factors and the environment. Thus, although the presence of the genotype at a single locus is still responsible for having the disease phenotype, the final manifestation of phenotype can be subject to variation in its expression. The following sections describe single-gene defects that, by means of variability in the expression of the mutant allele or by the location of the mutant gene, constitute apparent or real deviations from the basic Mendelian patterns of inheritance outlined above.

Incomplete or Reduced Penetrance and Late-Onset Diseases

As defined above, a carrier of a dominant mutation or a homozygote (or compound heterozygote) for recessive mutations will manifest the disease phenotype. This is true for many genetic traits, but there are some exceptions to this rule. In terms of genetic counseling, these exceptions can present a dilemma.

Incomplete or reduced penetrance refers to situations where not all the individuals who carry the disease genotype manifest the condition. The degree of penetrance indicates the probability of an individual with the disease genotype developing the disease phenotype. Penetrance is an "all-or-nothing" phenomenon, in which some individuals who have inherited the disease genotype do not express the disease phenotype at all. An example of the result of incomplete penetrance would be an autosomal dominant pedigree with an affected individual, unaffected parents, but an affected grandparent. As a consequence, the trait appears to skip a generation (Fig. 54.3A)[31,32].

A particular type of incomplete penetrance is the so-called late-onset diseases, characterized by age-dependent penetrance. Some diseases exhibit complete penetrance, but only starting from a certain age. The trait is manifest from birth in congenital diseases, but there are many other disorders where the symptoms appear later in life. Darier and Hailey–Hailey diseases are good examples of age-dependent penetrance, in which the main features of the disease usually develop in the second to fourth decades[33,34]. Age-dependent penetrance presents a challenge for genetic counseling and the establishment of the inheritance pattern of a trait, since some individuals may be too young to know whether or not they are affected.

Variable Expression

Not only can a disease genotype completely fail to appear (reduced penetrance), but there may be variation in the severity of the findings that develop. This variation can be interfamilial (between families) or even intrafamilial (within a family). Different degrees of phenotypic

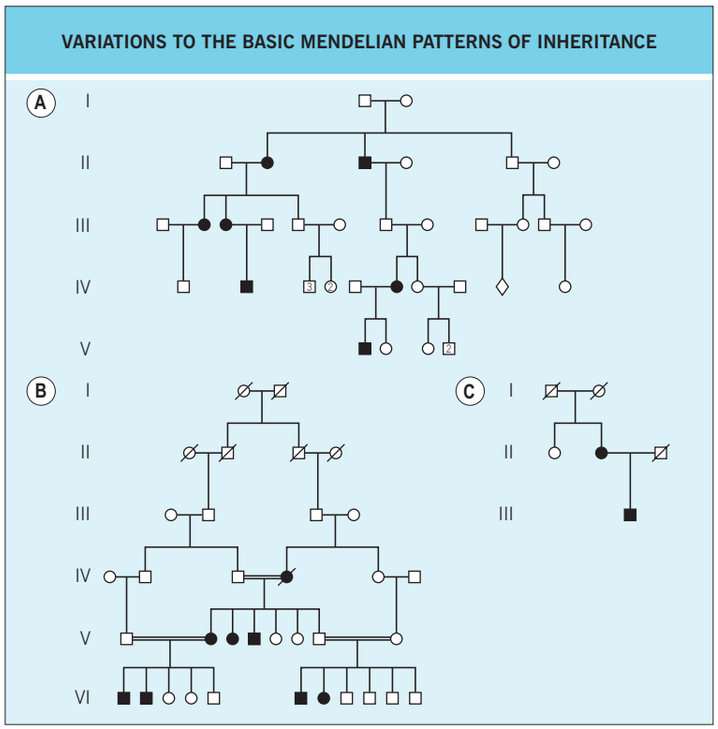

Fig. 54.3 Variations to the basic Mendelian patterns of inheritance. **A** Reduced penetrance in a pedigree with autosomal dominant retinitis pigmentosa (adapted from ref. 31). **B** High degree of consanguinity in a family with hypotrichosis, with affected family members in several generations. **C** Pseudodominant inheritance in autosomal recessive atrichia with papular lesions (APL). The inheritance of APL in this pedigree mimics an autosomal dominant pattern of inheritance resulting from the mating between a patient homozygous for the causative genetic mutation (II:2) and an unaffected carrier (adapted from ref. 32). The key for symbols commonly used for pedigree drawing is indicated at the bottom of Figure 54.2.

manifestation of a particular genotype is called *variable expression* (variable expressivity). Darier disease and neurofibromatosis type 1, for example, display complete penetrance in adults, but they have a broad range of severity[35].

The variable expression of some traits manifests as a tendency to increase in severity and decrease in the age of onset through successive generations. This phenomenon is referred to as *genetic anticipation*, and it presents an additional challenge in genetic counseling. Most of these disorders are neurologic or muscular diseases, such as Huntington disease and Friedreich ataxia. The molecular basis of genetic anticipation is now known. Certain genes contain a variable number of repeats of a three-nucleotide sequence, known as a trinucleotide. There is a range in the number of these repeats in the general population, as a part of normal variation. Through an unknown mechanism (DNA polymerase "slippage" has been hypothesized), the number of these repeats can increase dramatically and enter the disease-associated range. In general, the number of repeats within this range tends to increase through generations (although it can also decrease). The severity and age of onset of the resulting phenotype correlates with the length of the repeat. The paradigm of genetic anticipation is myotonic dystrophy, with a "cascade of mild, adult, childhood, and then congenital disease" in successive generations[36].

X Inactivation

Although women have a double dose of the X chromosome compared with men, for most of the X-linked genes (with one exception being those in the pseudoautosomal region), any particular cell in a woman's body has only a single active X chromosome. The mechanism of *X inactivation (lyonization)* is responsible for this dosage compensation in women. During embryonic development, one of the two X chromosomes in each cell is randomly inactivated via epigenetic mechanisms. From this stage on, all the derived ("daughter") cells have the same inactivated X chromosome as their progenitor cell. As a result, a woman has two alleles for every gene located within the X chromosome, but a given cell expresses only one of them. If one of these alleles contains a disease-causing mutation, the resulting phenotype will depend on the proportion of cells expressing that mutated allele in a particular tissue. As noted above, this explains why female "carriers" of X-linked recessive conditions can manifest some symptoms of the disease, and an X-linked dominant phenotype in girls is usually milder than in boys (where it may even be lethal).

On average, each allele of an X-linked gene is active in half of the cells in a woman. But this proportion varies, and in some instances a particular X chromosome is active in a large proportion of cells, which is known as skewed or non-random X inactivation. For example, girls with incontinentia pigmenti (due to mutations in the *NEMO* gene; see Ch. 62) have highly skewed X inactivation, suggesting a negative selection against cells with an active mutant allele[30]. Non-random X inactivation has also been observed in hematopoietic cells of female carriers of X-linked dyskeratosis congenita[37].

Balanced X;autosome translocations also result in non-random X inactivation, usually of the normal (not translocated) X chromosome. This is thought to explain fully affected females in some X-linked recessive diseases. Such is the case for hypohidrotic ectodermal dysplasia in carriers of a t(X;9) translocation[38].

De novo Mutations

In a population, the different alleles of a genetic locus responsible for both normal variation and disease phenotypes arise by mutational events in the DNA. An example is when a fully penetrant autosomal dominant genetic disease appears in a child with no previous family history of that condition. In such instances, the underlying *de novo* mutation usually occurred during meiosis in one of the parents. *De novo* mutations account for a higher proportion of affected individuals in dominant diseases that are severe or otherwise decrease reproductive fitness than in milder dominant conditions.

The identification of *de novo* mutations can have a profound impact on genetic counseling. A recessive condition commonly presents with a single affected child born to unaffected parents; future children born to these parents each have a risk of 25% of the disease, but (in the absence of further consanguinity) the likelihood of the child eventually having affected offspring will reflect the prevalence of the mutant allele in the general population. In contrast, if a single affected child born to unaffected parents has a *de novo* dominant mutation, there is no recurrence risk for the future offspring of the parents, since a second *de novo* mutation at the same gene would be highly unlikely. However, the affected child will transmit the mutation to 50% of his or her offspring, as typically seen for an autosomal dominant trait. An exception to the extremely low recurrence risk for the parents in the second scenario is the situation of gonadal mosaicism (see below).

De novo mutations occur with varying frequencies in different disorders. Up to 50% of patients with neurofibromatosis type 1 or tuberous sclerosis (both autosomal dominant conditions with very high penetrance) have a *de novo* mutation. As another example, in dominant dystrophic EB, the same *de novo* mutation, Gly2043Arg, in the type VII collagen gene *(COL7A1)* has occurred independently throughout the world[39].

Mosaicism and Chimerism

X inactivation represents a *functional* form of mosaicism, with each cell expressing the genes from only one of the two X chromosomes. *Genomic* mosaicism characterized by an alteration in the DNA sequence (affecting genes or chromosomes) can also occur, giving rise to a genetically heterogeneous organism and potentially causing disease. When a mutation or chromosomal abnormality occurs in a cell during embryonic development (referred to as a postzygotic or somatic mutation), its descendent cells carry the same mutation. The rest of the cells, not affected by the mutation, carry the wild-type (non-mutant) allele. The result is a mosaic individual with two different cell populations. The location of the cell and the timing of the mutational event during development determine both the distribution and extent of the cells carrying the mutation in the affected individual, and the potential for passing on the trait to future generations (see Ch. 62).

As noted above, when an individual has a *de novo* dominant mutation, the risk of the parents of that individual having a second

affected child is normally extremely low. But there are some instances in which a second child is unexpectedly affected, although a *de novo* mutation was initially suspected. This is usually due to *gonadal (germline) mosaicism* in one of the parents (see Ch. 62). If a dominant postzygotic mutation occurs after the separation of the gonadal and somatic cell lineages and it affects the latter, the risk for transmitting the trait to the offspring of that individual is zero. However, if the mutation took place in a gonadal cell or precursor, a proportion of that individual's gametes will carry the mutated allele. In the first affected generation, the inheritance pattern will mimic that of an autosomal recessive trait, since affected children will be born to unaffected parents. But inheritance will follow a classic autosomal dominant pattern in subsequent generations. The key information for genetic counseling is whether the mutation is present in the gondads of the mosaic individual. The extent of involvement of the gonads will determine the recurrence risk for the offspring.

Gonadal mosaicism has been documented in several disorders, including neurofibromatosis type 1 and dominant dystrophic EB. In one report involving dominant dystrophic EB, a mutation was identified in an affected child born to unaffected parents[40]. Although a *de novo* mutation was the most likely explanation, the possibility of gonadal mosaicism was considered and prenatal diagnosis was performed during the parents' next pregnancy. The results indicated that the fetus had an identical mutation to that of the affected child, indicating gonadal mosaicism in one of the parents.

When mosaicism affects the skin, it can become evident by the appearance of skin changes (e.g. hypo- or hyperpigmentation, scaling, inflammation) following the lines of Blaschko or in other segmental patterns (e.g. a block-like distribution) (see Ch. 62)[41]. Mosaic involvement of the skin in autosomal dominant disorders has been classified into two types (see Fig. 62.2). In *type 1*, the "segmental" affected skin carries a heterozygous mutant allele, while the genotype of the skin outside the affected areas (which is normal in appearance) bears two wild-type alleles. Examples include epidermal nevi and segmental forms of Darier disease. In *type 2*, the segmental disease occurs in the setting of milder, more diffuse involvement with the same phenotype. These individuals have one mutant allele in all the cells of the body (giving rise to the diffuse phenotype), and a "second hit" mutation that inactivates or deletes the wild-type allele (e.g. loss of heterozygosity; see below) in the more severely affected segment. Examples include linear porokeratosis superimposed on disseminated superficial actinic porokeratosis, segmental leiomyomas in individuals with hereditary leiomyomatosis (see below), and segmental Hailey–Hailey disease in the setting of milder classic symmetric disease[42–44]. In patients with type 1 segmental skin disease, the possibility of gonadal (in addition to somatic) mosaicism must be considered. An example would be a parent with an epidermolytic nevus having a child with epidermolytic ichthyosis (bullous congenital ichthyosiform erythroderma).

In *revertant mosaicism*, a postzygotic mutation leads to recovery of the wild-type phenotype (either partially or completely) within a subpopulation of cells in an individual who has a genetic disease[45]. Mechanisms for revertant mosaicism include a "back" mutation (i.e. reversing the original point mutation), mitotic recombination (with crossing-over of homologous chromosomes leading to homozygous mutant and homozygous normal daughter cells), gene conversion (where the donating chromosome is unchanged), and a second site mutation (e.g. that silences a dominant negative allele). Revertant mosaicism affecting the skin has been documented in ichthyosis en confetti and several types of EB[45].

Finally, the different populations of cells present in a mosaic derive from a single, homogenous zygote. In contrast, there are examples of individuals with cell populations that have completely different genetic composition. They are known as *chimeras,* and the different cell populations are thought to result from fusion of two zygotes (i.e. fused dizygotic twins) or fertilization of one egg by two sperm.

Inbreeding

Inbreeding is one of the factors that can modify the frequency of alleles in a population, increasing the number of homozygotes. Mating between two individuals who share a common ancestor is referred to as *consanguineous*.

A recessive mutation can pass undetected through generations in the heterozygous state. If a carrier of a recessive mutation has children with a carrier of another (or the same) recessive mutation in the same gene, each of their offspring has a 25% likelihood of inheriting both mutant alleles and therefore manifesting with the disease. The overall incidence of a recessive disorder depends upon the frequency of recessive mutant alleles of the affected gene in the general population. However, in inbred populations, the probability that two carriers of a mutation (typically the same mutation originating from a common ancestor) will mate is significantly higher. This explains the increased prevalence of consanguinity that is observed in families with autosomal recessive diseases. Consanguinity is especially frequent in diseases where the mutant alleles are extremely rare within the general population.

Affected offspring from a consanguineous mating are homozygous not only for the pathogenic mutation but also for the region surrounding that mutated gene, which reflects two copies of the same chromosomal region traveling from the common ancestor through different branches of the family and coming together again in the consanguineous mating. The affected offspring are called *homozygous by descent*, indicating that both mutant alleles originate from the same ancestral mutant allele. When there is only one affected family member, the presence of consanguinity in that individual's parents makes an autosomal recessive condition more likely. When analyzing a pedigree, it is important to consider the possibility of consanguinity (even if unknown to the parents), especially if unaffected parents of an affected child originate from the same geographic area or belong to the same small ethnic group.

Since there is a higher probability that any two persons are related in an inbred population, it is also possible that consanguineous matings can occur more than once in the same pedigree. In these situations, one can find affected individuals in different generations of a kindred, simulating an autosomal dominant trait (Fig. 54.3B).

Most of the considerations discussed previously for consanguineous matings can also be applied to populations derived from a small group of ancestors and subjected to geographic or linguistic isolation (e.g. Finnish, Icelandic and French-Canadian populations). If one of the ancestors carried a particular recessive mutation, it would be overrepresented in that "isolated" population. Known as the *founder effect*, this explains much higher incidences of certain diseases in isolated populations compared with other groups. For example, a large proportion of the current Caucasian population in South Africa descends from a small number of Dutch settlers, and the high incidence of porphyria variegata (see Ch. 49) in South Africans today has been traced back to a few of these settlers in the seventeenth century[46].

Quasidominant (Pseudodominant) Inheritance

The inheritance of an autosomal recessive trait can also mimic an autosomal dominant pattern (Fig. 54.3C) when an individual with an autosomal recessive disorder mates with a carrier of a recessive mutation in the same gene. In these situations, each child has a 50% probability of inheriting two mutant alleles. Although this is the same risk as for an autosomal dominant trait, this parent-to-child transmission does not occur in successive generations, unless the unlikely event of a mating between a homozygote and a heterozygote occurs a second time. Instead, the subsequent risk of having an affected child reflects the prevalence of the mutant allele in the general population. These situations can happen in both inbred and "outbred" populations, although the probability of such matings is increased in the former.

An example of pseudodominant inheritance was reported in a family in which a mother and her son had atrichia with papular lesions (suggesting dominant inheritance), even though this disorder is typically inherited in an autosomal recessive manner. Molecular analysis revealed that both the affected mother and son were homozygous for mutations in the same gene, in accordance with the recessive nature of the disease (see Fig. 54.3C)[32].

Loss of Heterozygosity

There are some disorders in which susceptibility to the development of certain tumors is inherited as a Mendelian trait. In these cases, affected individuals usually carry a heterozygous germline mutation in a tumor suppressor gene that is involved in the regulation of cell

growth. Inactivating (loss-of-function) mutations in both alleles of a tumor suppressor gene can contribute to tumor formation (see Ch. 107). Individuals in these families are at higher risk of developing a tumor, since a single somatic mutation inactivating the second (normal) allele of the same gene can trigger tumor formation. For this reason, inherited forms of cancer susceptibility often result in the development of multiple tumors in the same individual, as opposed to the single tumors typically found in sporadic cases. When the former tumors are analyzed, two mutations are identified in the tumor suppressor gene: (1) the germline mutation; and (2) a new somatic mutation, which is referred to as a "second hit"[47].

One type of somatic mutational event that commonly occurs in tumors is known as *loss of heterozygosity (LOH)*. When analyzing the DNA of tumor samples from an individual heterozygous for specific polymorphisms (usually microsatellites; see below), the results from the tumor may show homozygosity for a single allele instead of the heterozygosity seen in their constitutional DNA. Known as LOH, this phenomenon may result from a deletion that encompasses the normal allele or gene conversion that leads to two copies of the mutant allele (known as copy neutral LOH). Advanced tumor cells can show extensive LOH throughout the genome. Certain regions for which LOH is frequently observed have been shown to represent the locations of tumor suppressor genes.

Examples of inherited tumor susceptibility syndromes involving the skin include hereditary leiomyomatosis and renal cell cancer (HLRCC)[48] and the nevoid basal cell carcinoma syndrome (Gorlin syndrome)[49]. HLRCC is caused by a heterozygous germline mutation in the fumarate hydratase tumor suppressor gene (*FH*), and tumors (including cutaneous leiomyomas) display LOH or a second loss-of-function mutation in *FH*[48]. Gorlin syndrome (characterized by multiple basal cell carcinomas, medulloblastomas and jaw cysts) is caused by a germline mutation in the patched 1 gene (*PTCH1*)[49]. The tumors that develop in affected individuals typically display LOH in the *PTCH1* locus, also following the "two-hit" model of carcinogenesis.

Mitochondrial Inheritance

Mitochondrial inheritance is an example of a single-gene defect that does not follow a classic Mendelian pattern of inheritance (see Ch. 63). Every cell has many mitochondria, each containing one or more copies of the mitochondrial genome, a 16 kb circular DNA molecule. Only females pass mitochondria to their offspring, so there is no paternal complement. During cell division, mitochondria segregate randomly to each of the two daughter cells. Thus, if a mother carries a mutation in one gene located on the mitochondrial chromosome in only some of her mitochondria, the daughter cells can inherit a variable number of organelles carrying the mutation. A situation where all mitochondria carry the mutation is known as *homoplasmy*, and a mixture of mitochondria carrying the normal or the mutant version of the gene is known as *heteroplasmy*. The resulting phenotype will depend on the proportion of mutant versus normal mitochondria in a specific tissue.

Mitochondrial inheritance leads to a pedigree where both women and men can be affected, but only women transmit the disease trait. The proportion of affected children seems to be random, and there is a high degree of variability in the expression of the phenotype.

As an example, a transition from adenine (A) to guanine (G) at position 7445 of the mitochondrial DNA, affecting the gene encoding the tRNA for serine, has been identified as the cause of a form of palmoplantar keratoderma with or without associated sensorineural deafness. In these pedigrees, the disease presents with incomplete penetrance and with varying severity[50,51].

Phenocopy

A phenocopy refers to clinical findings caused by environmental factors that mimic the phenotype of a genetic disorder. Porphyria cutanea tarda (PCT), for example, is an autosomal dominant disorder caused by mutations in the *UROD* gene that encodes uroporphyrinogen decarboxylase. Affected patients are predisposed to fragility and bullae in sun-exposed areas. A similar phenotype can be caused by exposure to certain chemicals. Between 1955 and 1961, approximately 3000 patients developed PCT in Turkey because of exposure to hexachlorobenzene, which is used to preserve wheat seeds. PCT has also been reported in individuals with industrial exposure to certain hydrocarbons[52] and pesticides[53].

Epigenetics and Imprinting

Epigenetics refers to heritable changes affecting gene expression that do not result from alterations in the DNA sequence[54]. Epigenetic changes can involve DNA methylation or modification of histones (e.g. acetylation and deacetylation) and chromatin. RNA-dependent gene silencing can also occur under the influence of small and large RNA species, including small interfering RNAs (siRNAs)[55], microRNAs (miRNAs)[56] and large intervening non-coding RNAs (lincRNAs)[57].

Imprinting is an epigenetic phenomenon in which the sex of the transmitting parent determines whether particular genes are expressed in the offspring (Fig. 54.4). For example, mating of a male lion with a female tiger results in the giant "liger" (due to inheritance of a growth gene from the lion father that is "turned on"), whereas a male tiger and female lion produce a considerably smaller "tigon" (due to inheritance of a growth gene from the lion mother that is "turned off").

The effect of imprinting is especially apparent in the case of *uniparental disomy (UPD)*, where both homologous chromosomes are derived from the same parent, instead of one from each parent. In *heterodisomy* two different homologues are inherited from the same parent, and in *isodisomy* a single chromosome from one parent is duplicated. UPD can go undetected for some chromosomes, while it results in a disease phenotype for others. An example of the latter is UPD for chromosome 15 in Prader–Willi and Angelman syndromes (Fig. 54.5).

Uniparental isodisomy that affects a recessive mutant allele can result in homozygosity. The Herlitz type of junctional EB, (JEB-H; also an example of locus heterogeneity) is an autosomal recessive disorder

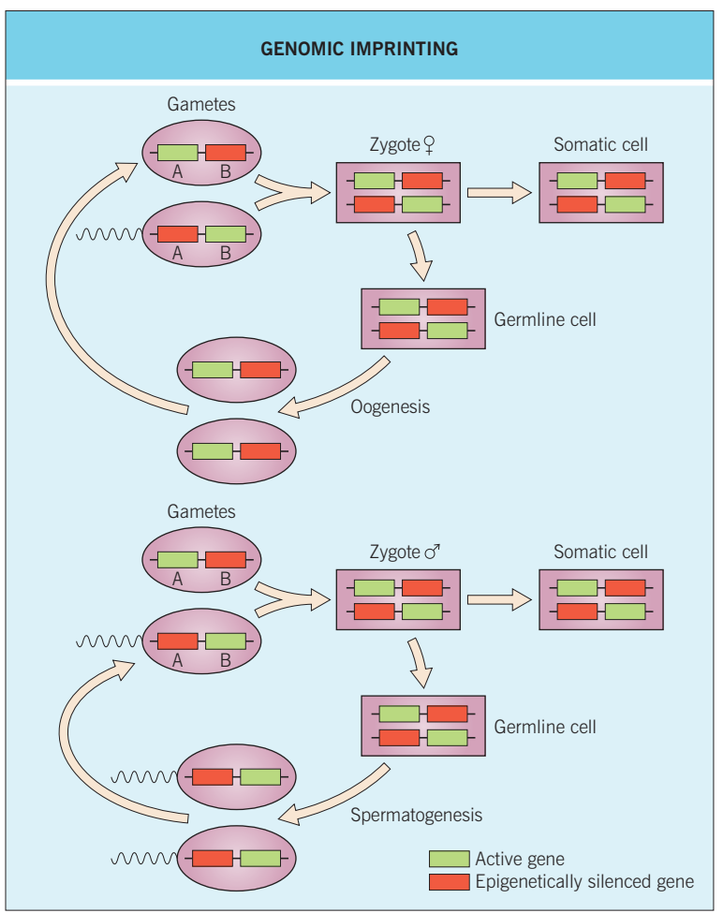

Fig. 54.4 Genomic imprinting. Genes A and B are epigenetically silenced in male and female gametes, respectively. Somatic cells in males and females will maintain the imprinting pattern present in the gametes. In the germline, on the contrary, the imprinting will be erased and the corresponding sex-specific imprint established.

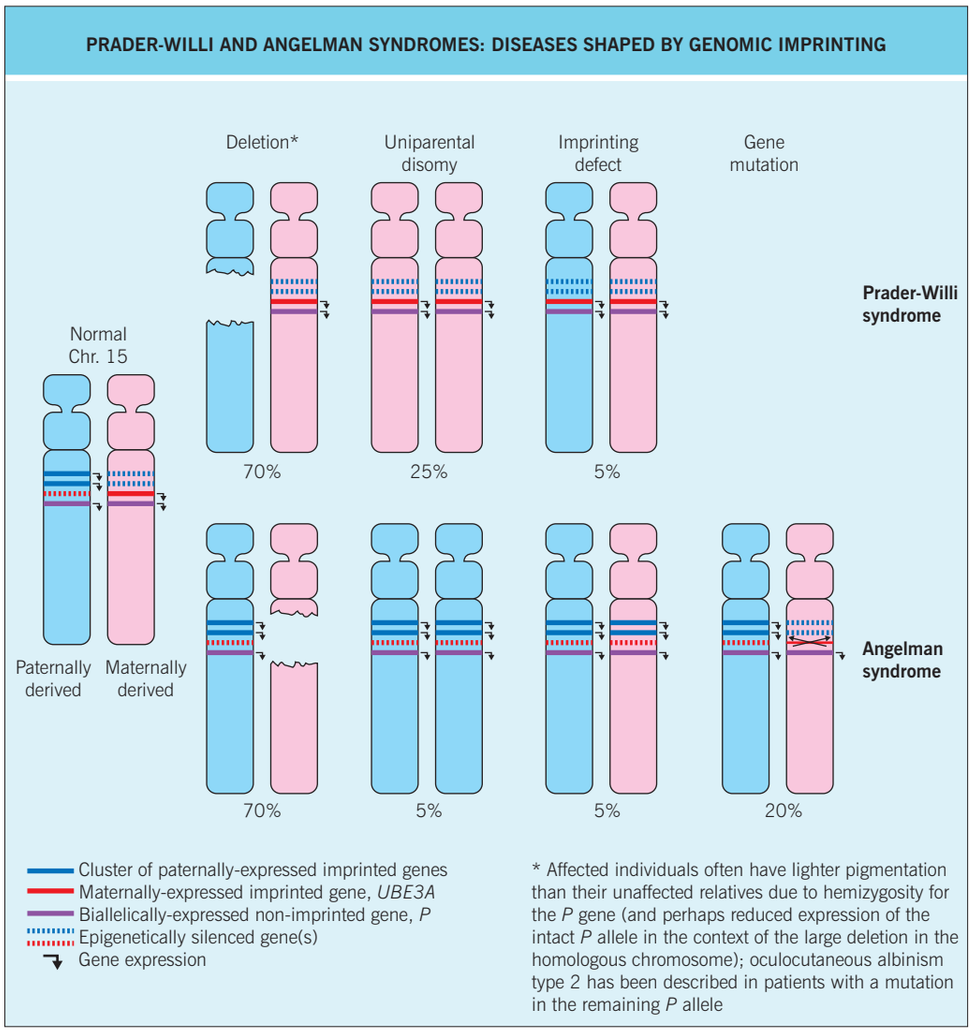

Fig. 54.5 Prader–Willi and Angelman syndromes: diseases shaped by genomic imprinting.

that can be caused by mutations in one of three genes encoding subunits of laminin – *LAMA3*, *LAMB3* and *LAMC2*. Both paternal and maternal UPD have been described in JEB-H patients[58]. For example, paternal uniparental isodisomy was found to underlie homozygosity for a paternal *LAMC2* mutation in one patient[59]. Similarly, maternal isodisomy has been reported to result in homozygosity for a maternal *COL7A* mutation in children with recessive dystrophic EB[60].

In addition to their roles in monogenic diseases, epigenetic changes are involved in cancer. Cancer is typically characterized by global hypomethylation and site-specific hypermethylation. The hypomethylation activates growth-promoting genes such as *HRAS*, cyclin D1 (*CCND1*) and those in the melanoma antigen family (*MAGE*)[54]. By contrast, hypermethylation silences tumor suppressor genes such as retinoblastoma 1 (*RB1*), von Hippel-Lindau (*VHL*), and adenomatosis polyposis coli (*APC*)[54]. Epigenetic alterations can also contribute to inflammatory disorders such as systemic lupus erythematosus.

CHROMOSOMAL DISORDERS

Key features

- Chromosomal abnormalities account for >50% of spontaneous abortions
- Defects in chromosomal number or structure can result in disease
- Chromosomal rearrangements can be useful in identifying disease genes located near breakpoints

The above sections discuss disease-causing mutations that affect a single gene, but this is not always the case. For example, the majority of spontaneous abortuses exhibit chromosomal anomalies[61], which typically involve multiple genes contained in the affected region.

Chromosomal anomalies can affect the number or structure of chromosomes. The differences in DNA composition along a chromosome have allowed the development of banding techniques that distinguish each chromosome in a karyotype; chromosomal anomalies, both numerical and structural, can also be recognized. In addition, the use of fluorescence *in situ* hybridization (FISH), which detects DNA sequences as short as 1 kb[2], allows the identification of very small changes in the chromosomal constitution that are not visible by the use of conventional banding techniques. Furthermore, advances in microarray technology have enabled the use of array-based comparative genomic hybridization for detection of genomic copy number variations at a considerably higher level of resolution than chromosome-based methods.

Chromosomal numerical abnormalities can involve the whole genome (polyploidy) or just one pair of homologues (aneuploidy). The only forms of polyploidy observed in humans are triploidy with three complete sets of chromosomes (3*n*), and tetraploidy with four chromosome complements (4*n*). However, unless mosaic, polyploidy results in a spontaneous abortion or death soon after birth. Aneuploidy refers to extra or missing chromosome(s). The only observed aneuploidies are trisomies, with three copies of a single chromosome, and, less often, monosomies. Trisomies for a whole chromosome that are compatible with extrauterine life (outside the setting of mosaicism) involve chromosomes 21 (Down syndrome), 18 (Edwards syndrome), 13 (Patau syndrome) and 23 (XXY, Klinefelter syndrome; XYY). Monosomy for

the X chromosome (Turner syndrome) can also occur. Other trisomies and monosomies may be observed in mosaic or partial (e.g. due to translocations) forms.

Structural abnormalities involve breakage of chromosomes. They are *balanced* if there is no net gain or loss of genetic material, or *unbalanced* when they are accompanied by additional or missing genetic information. The stability of the resulting rearranged chromosome through cell division will depend on the presence of a centromere and two telomeres, the necessary elements for the correct segregation of chromosomes.

Balanced chromosomal abnormalities include some types of translocations and inversions. In a reciprocal translocation, two breaks in two non-homologous chromosomes occur and the chromosomal segments distal to the breaks are exchanged. The total number of chromosomes remains the same. If the translocation breakpoint affects a gene or its regulatory sequence, or otherwise places a gene under the control of novel regulatory elements (e.g. the Philadelphia chromosome), it can result in an observable phenotype (e.g. chronic myelogenous leukemia). The major problem with reciprocal translocations arises in the offspring of the carriers. Depending on the combination of parental chromosomes inherited, they can result in partial trisomy or monosomy for the chromosomal regions involved in the translocation (i.e. an unbalanced chromosomal anomaly in the child).

Inversions are balanced rearrangements in which two breaks occur in the same chromosome and the intervening segment is inverted before the chromosome is reconstituted. In a *pericentric inversion*, the inverted segment includes the centromere, whereas in a *paracentric inversion*, the two breaks occur in the same chromosome arm, without involvement of the centromere.

Classic examples of skin conditions associated with chromosomal anomalies are "hypomelanosis of Ito" and "linear and whorled nevoid hypomelanosis", where streaks and swirls of hypo- or hyperpigmentation following Blaschko's lines are a reflection of mosaicism, and a chromosomal anomaly can often be identified in affected skin. Other genodermatoses are occasionally caused by chromosomal abnormalities. Hypohidrotic ectodermal dysplasia, for example, has been diagnosed in several patients with rearranged X chromosomes, such as X;autosome translocations or genomic deletions involving the *EDA* gene[62]. Another example is Ambras syndrome, a form of congenital universal hypertrichosis. Several cases have been reported with cytogenetic abnormalities involving one common chromosomal region, 8q22. One of the patients had a balanced pericentric inversion denoted (8) (p11.2, q22)[63] and a second patient had the paracentric inversion (8) (q12, q22)[64]. The fact that two independent chromosomal abnormalities involved the same chromosomal region in unrelated patients with the same rare disease suggests that the chromosomal region 8q22 contains a candidate gene or regulatory region responsible for the Ambras syndrome phenotype[65]. Recently, a position effect resulting in decreased expression of the trichorhinophalangeal syndrome I gene (*TRPS1*) at 8q23 was reported in Ambras syndrome patients[66].

IDENTIFICATION OF DISEASE GENES

Key features

- Functional cloning relies upon knowledge of the gene's function but not its location within the genome
- Positional cloning involves linking a particular disease gene to a region of a chromosome using genetic markers
- Positional candidate gene approaches to gene identification utilize both positional and functional information

In general, two major approaches, functional and/or positional cloning, are utilized for the identification of the gene responsible for a Mendelian (monogenic) disorder. The approach usually depends on the type of information available regarding the particular trait.

Functional cloning requires some previous knowledge about the defective function, but no positional information is needed. When the abnormal function leading to the disease phenotype is known, such as the biochemical defect or the defective protein itself, several approaches can be applied to clone the corresponding gene. However, even though functional cloning has facilitated the cloning of genes in the past, its application is very limited, since there are only a few disorders that feature an obvious biochemical defect, e.g. tyrosinase activity in oculocutaneous albinism.

The *candidate gene* approach uses information on the defective pathway, function, structure or tissue underlying the phenotype. The expression of a gene in the same tissues as those affected by the disease phenotype, its function (e.g. role in a given metabolic pathway or cellular structure), and its homology or relationship to mutated genes responsible for closely related phenotypes can be good starting points for choosing a candidate gene. Additional and very helpful sources of information are animal models. There are many examples, although also some exceptions, where closely related phenotypes in mice and humans were caused by mutations in orthologous genes (homologous genes in different species). By means of the candidate gene approach, two separate groups identified mutations in the transglutaminase 1 gene (*TGM1*) as the molecular basis for lamellar ichthyosis (LI; see Ch. 57), an autosomal recessive disorder of cornification[67,68]. Huber et al.[67] examined the *TGM1* gene following analyses that showed decreased or absent activity and expression of this protein in LI patients. On the other hand, Russell et al.[68] studied *TGM1* and other genes on the basis of the known role of their encoded proteins in the formation of the cornified envelope.

Positional cloning starts with the chromosomal assignment of the region containing the defective gene by means of linkage analysis. Positional cloning has been a powerful tool in disease-gene identification, since, for most diseases, the only information available is the observable phenotype segregating in pedigrees. The identification of the gene responsible for hypohidrotic ectodermal dysplasia is an example of positional cloning. The genetic locus was mapped to the chromosomal region Xq12–q13.1 by means of linkage analysis and translocations in female patients. After finding putative new genes in the disease interval, Kere et al.[69] identified the *EDA* gene, which encodes ectodysplasin (see Ch. 63).

The approach that has yielded most results, however, uses a combination of both functional and positional information. In the *positional candidate approach*, once the chromosomal location of the disease locus is known, functional information is utilized to directly analyze the candidate genes contained in that particular chromosomal region (see below). A positional cloning approach[70] as well as a candidate gene approach[71] were utilized by independent groups to identify *ABCA12* as the gene underlying harlequin ichthyosis.

Previous information on the location of the gene, such as the presence of chromosomal abnormalities or LOH in a patient, can considerably accelerate the identification of disease genes. These chromosomal abnormalities are usually translocations, inversions, deletions or duplications. The occurrence of X;autosome translocations involving the same breakpoint on the X chromosome in several women with hypohidrotic ectodermal dysplasia helped to indicate the location of the causative gene. Together with linkage analysis and observations of small deletions in affected patients, this led to the identification of the *EDA* gene[69].

In the same way, LOH can provide hints as to where the disease gene might be. This has proven to be particularly useful in the identification of tumor suppressor genes. Familial cylindromatosis is inherited as an autosomal dominant trait, and >70% of the tumors show LOH in the vicinity of the gene that causes the disease; in all cases, the allele lost in the tumors is the wild-type allele. Moreover, the tumors show no other regions of LOH within the genome. Linkage analysis combined with the presence of LOH led to the identification of the underlying mutated tumor suppressor gene, *CYLD*[72,73].

Linkage Analysis

For many disorders, there is no previous information on the defective function or possible location of the disease gene. In such situations, positional cloning by a linkage analysis approach is performed to map the location of the disease gene. The aim of linkage analysis is the

identification of a chromosomal region that is transmitted along with the disease phenotype (co-segregates). When this region is found, the disease is said to be linked to that genetic locus.

The requirements for performing a linkage analysis include a thorough definition of the phenotype, the availability of pedigrees with enough linkage information (power), a "dense" map of highly polymorphic markers, and the application of statistical analysis. When defining the phenotype to be studied, it must be kept in mind that the correspondence between a gene and a disease is not always linear. There are numerous examples of allelic heterogeneity, with mutations in the same gene resulting in different phenotypes (see Table 54.2), and locus heterogeneity, in which the same or very similar phenotypes are caused by mutations in different genes (see Table 54.3). Furthermore, since the disease gene is unknown and the phenotype itself will be used to track the disease gene along the pedigree, it is essential to know if special circumstances such as incomplete penetrance, age-dependent penetrance or phenocopies might be expected.

Once the phenotype has been clearly established, a large enough sample must be chosen to achieve statistically significant results. Linkage studies are usually performed either on a single large pedigree or on several smaller ones. The first approach ensures genetic homogeneity of the sample, but it may not be available for every disease, whereas the second approach introduces the unwanted possibility of locus heterogeneity.

With a well-characterized, large enough collection of samples, the linkage analysis itself can be performed. Linkage analysis, and genetic mapping methods in general, rely on genetic recombination or crossing-over. The rationale is that the closer together the two loci are, the less frequently they will be separated by recombination during meiosis. Loci very close together are rarely separated by recombination, while recombination occurs more often between loci on the same chromosome that are separated by a greater distance; the larger the distance, the higher the frequency of recombination. A particular combination of alleles for several loci close to one another on the same chromosome is known as a *haplotype* (Fig. 54.6). Due to the independent assortment of maternal and paternal homologous chromosomes during meiosis, loci located on different chromosomes segregate independently.

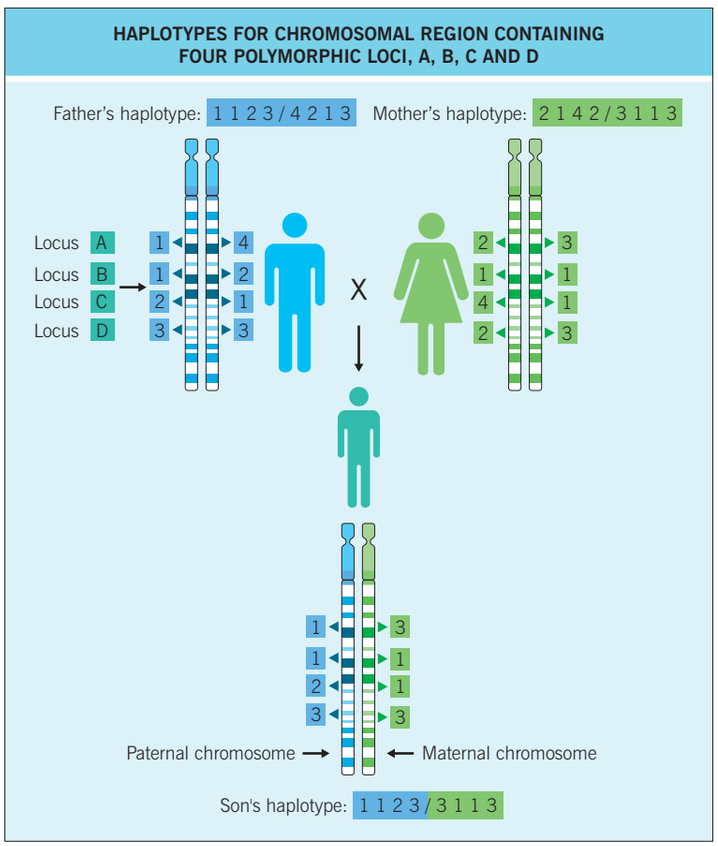

Fig. 54.6 Haplotypes for a chromosomal region containing four polymorphic loci, A, B, C and D. Loci very close together will rarely be separated by recombination.

The frequency of recombination (θ) between two loci reflects the genetic and physical distance between them. A recombination fraction of 1% or 0.01 is equivalent to approximately 1 centimorgan (cM), which is a unit of genetic distance.

When linkage analysis is performed, the disease gene is unknown. The inheritance of the disease phenotype is compared with the inheritance of polymorphic loci along the genome that serve as markers. The goal is to find one or more polymorphisms that are inherited in the same manner as would be expected for the disease gene. The disease locus is then said to be linked to this marker, which allows investigators to follow the disease gene through the pedigree until it is actually identified. It is important to note that the linked marker is not necessarily the disease gene itself, but simply a closely linked locus.

There are many types of DNA polymorphisms, but not all of them are useful markers for a linkage analysis. The two requirements are: (1) the informativeness, which reflects the number and frequency of different alleles at a locus (which increase the likelihood that an individual will be heterozygous); and (2) the distribution (density) of the polymorphisms, with shorter distances between loci allowing linkage to be detected with smaller samples.

Although microsatellites (tandem repeats of two to four nucleotides, e.g. $[CA]_n$) were used for linkage analysis in the past, genome-wide linkage analysis using single nucleotide polymorphism (SNP; Fig. 54.7) DNA microarrays has become the method of choice. SNPs refer to the presence of different nucleotides at a particular position (see Fig. 54.7 A,B)[3], whereas microsatellites vary in length due to different numbers of the repeated sequence[74] (see Fig. 54.7C). DNA microarrays used for linkage analysis enable genotyping of more than 1 million SNPs in a single experiment and also provide information on copy number variation and LOH.

Once the data from a genome-wide scan are gathered, statistical analyses are performed to determine the significance of the results. The possibility of false positives must be considered, since more than one region that mimics the inheritance of the disease gene in a particular pedigree can be found by chance. The statistical value used is the LOD score (Z), which is the logarithm of the odds in favor of linkage. The LOD score tests the linkage between two loci (one marker and the disease locus, or two polymorphic markers) in what is known as a two-point analysis. By convention, a LOD score of ≥3 (meaning ≥1000 : 1 odds that the observed linkage did not occur by chance) is interpreted as indicating linkage between two loci, whereas a LOD score of ≤–2 excludes linkage. The values between 3 and –2 are inconclusive (i.e. not sufficient to prove or disprove linkage). Calculations of LOD scores are performed using specialized statistical computer software. These calculations are done assuming a particular inheritance pattern, disease allele frequency, penetrance, possibility of phenocopies, etc. This type of analysis, where the model under study is specified, is known as parametric analysis.

The use of more than one marker can be helpful, since a particular pedigree can be informative for different markers. The analysis of data from different markers at one time is called multipoint analysis, as opposed to the two-point analysis described above.

Refinement of the Linkage Interval

The identification of the linkage interval gives an idea of the most likely location for the disease gene, but these intervals are often too large to work with (5–10 cM or even larger), containing hundreds of genes. Unless an obvious candidate gene maps to the interval that is initially identified, an additional step of narrowing down the disease locus is necessary. This refinement of the disease locus can be achieved by different means. Finding LOH or a chromosomal abnormality in a subset of patients is helpful, but such additional information is usually not available. For most genetic diseases, narrowing the linkage interval requires increasing the number of individuals studied and/or the number of markers analyzed within the defined region. When several close markers are analyzed, the disease gene is linked to a certain haplotype rather than a single marker.

In this step of the study, the analysis of haplotypes (see Fig. 54.6) is essential to find recombinations that narrow the linkage interval. The goal is to identify the boundaries of the smallest possible interval,

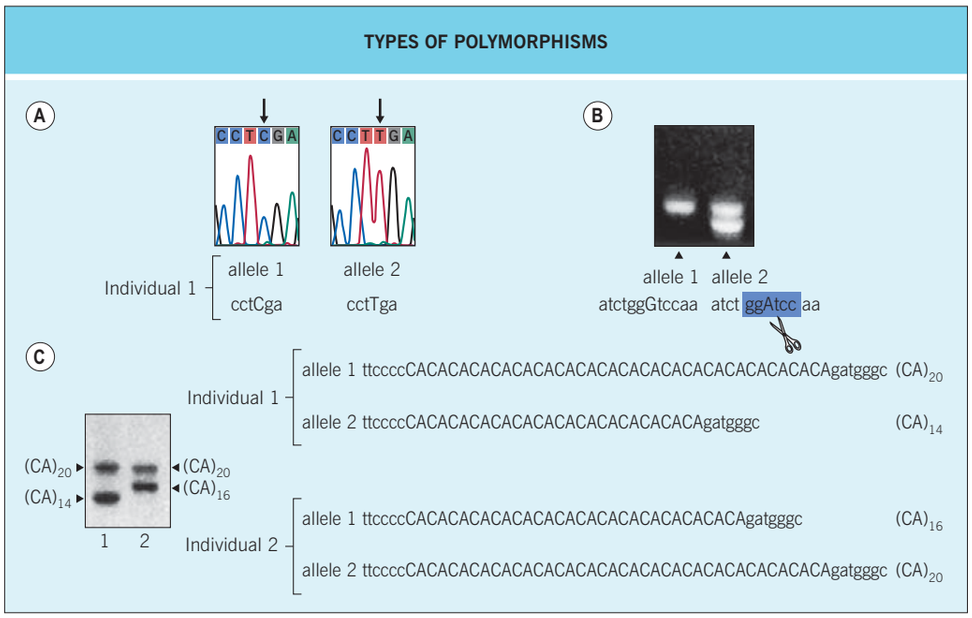

Fig. 54.7 Types of polymorphisms: single nucleotide polymorphisms (SNPs) and microsatellites. SNPs consist of single base substitutions and can be detected via DNA sequencing (**A**) and restriction enzyme cleavage (**B**). **A** Point substitution (arrows) replacing a cytosine (C) with a thymidine (T) identified by DNA sequencing. **B** The sequence *ggAtcc* is the target site for the restriction enzyme *BamH1*. In the presence of this particular sequence, the enzyme will cut the DNA into two fragments, detected as two bands in an agarose gel (allele 2). If this sequence is altered by a base substitution and, therefore, not recognized by the enzyme, no cleavage occurs (allele 1). A polymorphism that affects the recognition site for a restriction enzyme is referred to as an RFLP (restriction fragment length polymorphism). **C** Example of microsatellites. The repeat unit of the microsatellites shown here is the dinucleotide (CA). The number of tandem repeats of the (CA) unit can vary in each allele. The figure shows two individuals heterozygous for the number of repeats of this dinucleotide. The differences in length between these three alleles appear as bands of DNA of different sizes in a polyacrylamide gel.

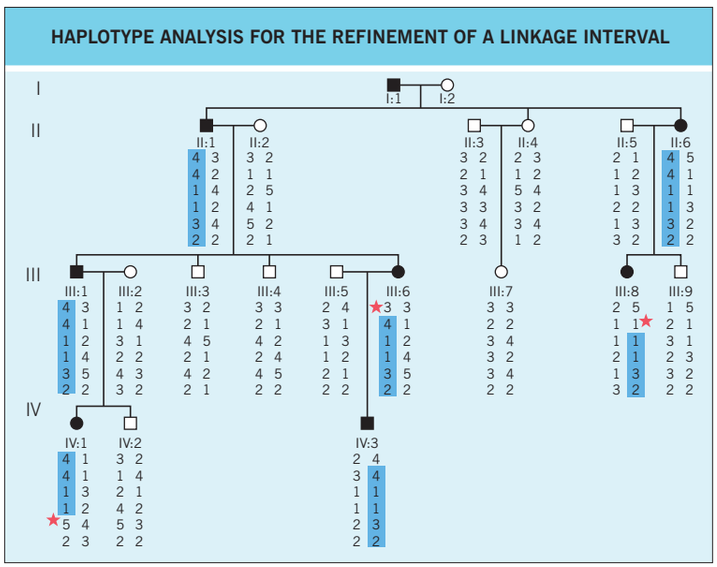

Fig. 54.8 Haplotype analysis for the refinement of a linkage interval. The disease-associated haplotype, 4 4 1 1 3 2 (shaded in blue), has been broken by genetic recombination in three family members (stars). The two key recombinant individuals, III:8 and IV:1, have allowed the narrowing of the disease interval. The key for symbols commonly used for pedigree drawing is indicated at the bottom of Figure 54.2.

defined by the closest markers that show recombination with the disease phenotype. Recombination events can 'break' the shared haplotype in different members/generations of the pedigree. Identification of an individual in whom recombination has occurred *inside* the disease-associated haplotype, known as a key recombination event, reduces the region where the disease gene is presumed to be located (Fig. 54.8). By identifying different key recombination events, the linkage interval can be progressively narrowed.

Positional Candidate Genes

When the linkage interval cannot be further reduced, attempts to identify the actual disease gene begin. The information now available on the human genome have made the positional candidate approach the most powerful disease-gene cloning strategy. Sequence data can be obtained through internet resources such as the National Center for Biotechnology Information (NCBI; www.ncbi.nlm.nih.gov) and Ensembl (www.ensembl.org/), where the user can browse integrated maps of polymorphic markers, known genes and predicted genes.

The process by which the genes responsible for Darier and Hailey–Hailey diseases were identified exemplify the positional candidate approach. The gene underlying Darier disease was localized to chromosome 12 by linkage analysis[75,76]. After refinement of the region, several genes were identified in the linkage interval. Among them, the *ATP2A2* gene encoding the calcium pump SERCA2 was considered a good candidate due to the role of calcium in epithelial junctions (defective in the epidermis of patients with Darier disease) and cell differentiation. Indeed, *ATP2A2* was found to be mutated in these patients.

In a separate study, linkage to chromosome 3 was established for the similar Hailey–Hailey disease phenotype[77]. Fortunately, one gene in the critical linkage interval, *ATP2C1*, showed homology to calcium ATPases and, consequently, was postulated to have a function related to SERCA2. As expected, this gene was mutated in Hailey–Hailey patients[78].

Mouse models represent another powerful tool in the identification of disease genes. This approach relies on the existence of chromosomal regions that share the same origin in evolution, known as syntenic regions. Once the genetic interval in humans is determined, the syntenic interval in mice can be analyzed to identify additional candidate genes. Also, if a similar phenotype in the mouse has been mapped to this region and the mutated gene is known, this becomes an excellent candidate for the human disease counterpart, and vice versa. This comparative genomic approach was used to identify mutations in the hairless gene in patients with atrichia with papular lesions[79] and mutations in the desmoglein 4 gene in patients with localized autosomal recessive hypotrichosis[80], as defects in these genes lead to similar phenotypes in mice (in which mutations were first discovered) and humans.

Identification of Mutations

Once a candidate gene is identified, its involvement in the disease must be proven. This involves the identification of pathogenic mutations, which are DNA variants present in affected patients and absent in a control population. There are several different types of mutations. Point mutations consist of the substitution of a single nucleotide position. This change can lead to an amino acid substitution (missense mutation), the generation of a termination codon (nonsense mutation), or no change in the protein sequence (silent mutation). There can also be small duplications, insertions or deletions. If they affect a piece of the protein-coding sequence in a manner that is not a multiple of three nucleotides (a codon), this will lead to a frameshift in the protein sequence and often the generation of a premature termination codon. These types of mutations can affect both coding and non-coding sequences, e.g. the promoter region, consensus splicing signals, and

other key intronic positions. Large rearrangements, such as partial or complete deletions of the entire gene, can also occur. It is important to recognize that some mutations, especially missense and silent substitutions, can be non-pathogenic variants present in the general population as polymorphisms.

COMPLEX TRAITS

Classic Mendelian diseases, where a defect in a single gene is sufficient to cause the disorder, represent only a small proportion of genetic diseases. There are many common conditions that, although heritable, are not due to a single-gene defect. Instead, they develop as a consequence of multiple genetic factors that confer disease susceptibility, interacting among themselves and with the environment. Such traits are referred to as complex or multifactorial traits. They tend to cluster or aggregate in families, but they do not follow Mendelian pattern of inheritance.

In contrast to the relatively clearcut recurrence risk for Mendelian traits, the risks for multifactorial traits are estimated based on epidemiologic data. Some examples of complex traits in dermatology include atopic dermatitis, vitiligo, psoriasis and alopecia areata. The absence of a Mendelian inheritance pattern can be observed when a collection of pedigrees with the same complex trait is analyzed (Fig. 54.9).

The goal in the study of complex traits is the identification of DNA variants in multiple different genes, each with a contribution to the final phenotype and conferring a degree of susceptibility to the carrier. Until recently, the identification of genetic variants contributing to complex traits was slow and challenging. However, the characterization of normal human genome variation and development of microarray-based technologies now enable genome-wide association studies (GWAS) in which several hundred thousand SNPs can be analyzed in thousands of individuals to determine the genetic architecture of complex diseases. The steps involved in GWAS are depicted in Fig. 54.10[81].

Although useful and extremely popular, GWAS pose significant challenges, primarily related to selecting a disease suitable for analysis and obtaining a large sample size of both cases and controls. A successful investigation requires that the phenotype of interest can be sensitively and specifically diagnosed or measured. Furthermore, extremely large collections of patients need to be studied in order to identify a statistically significant contribution for a given genetic factor.

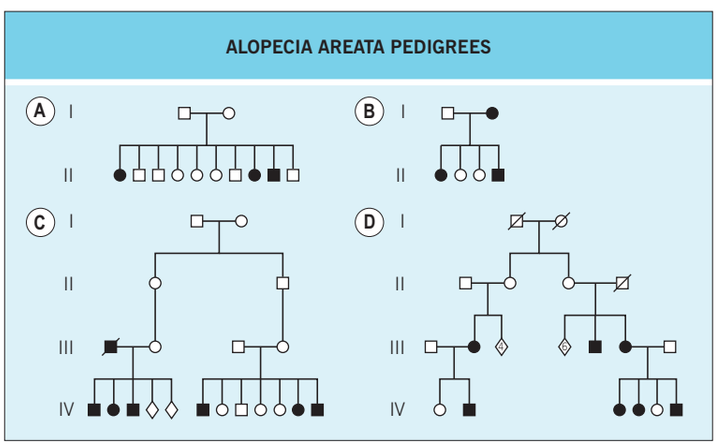

Fig. 54.9 Pedigrees with alopecia areata as an example of multifactorial dermatologic disease. Although some of the pedigrees individually can mimic Mendelian patterns of inheritance (**A, B**), others show a more complex pattern (**C,D**). In some cases, the disease can be inherited through two unrelated branches of the family (**C**). A single mode of inheritance cannot be established for the disease as a group. The key for symbols commonly used for pedigree drawing is indicated at the bottom of Figure 54.2.

The rationale for GWAS is that common diseases are attributable to common allelic variants present in more than 1–5% of the population[82]. With a few exceptions (e.g. age-related macular degeneration) in which heritability is explained by a small number of common variants with a large effect, the proportion of heritability explained by the identified variants is typically relatively small (e.g. 20%)[82]. The "missing heritability" is thought to be explained by large numbers of variants with small effects, rare variants, structural variants such as copy number alterations, gene–gene interactions, and the role of the shared environment among relatives.

Examples of GWAS in dermatology include those investigating susceptibility to psoriasis, atopic dermatitis, vitiligo, alopecia areata, melanocytic nevi, melanoma and basal cell carcinoma as well as variation in pigmentation of the skin and hair[83–91]. Studies of psoriasis have revealed several susceptibility loci, including major histocompatibility complex (MHC) and late cornified envelope gene clusters as well as genes involved in interleukin, tumor necrosis factor-α and nuclear factor-κB signaling[89,90]. GWAS in patients with alopecia areata have implicated genes involved in innate and adaptive immunity (e.g. controlling activation of natural killer cells and regulatory T cells) as well as those expressed specifically in the hair follicle[91]. Skin and hair pigmentation have been linked to variants in the melanocortin 1 receptor (*MC1R*), tyrosinase (*TYR*), two-pore segment channel 2 (*TPCN2*), solute carrier family 24 member 4 (*SLC24A4*), agouti signaling protein (*ASIP*) and Kit ligand (*KITLG*)[84]. Several of these loci (e.g. *MC1R*, *TYR*, *ASIP*) have also been associated with melanoma susceptibility[85,87].

In addition to GWAS, the knowledge gathered from Mendelian disorders has provided important clues to the etiology of more common related complex traits. As an example, loss-of-function mutations in the filaggrin gene (*FLG)* were first identified in patients with ichthyosis vulgaris, who also have a high incidence of atopic dermatitis[92,93]. The same loss-of-function alleles in the *FLG* gene were subsequently found to represent a strong predisposing factor for atopic dermatitis, with at least one allele present in 20–50% of affected children and adults in European and Asian populations[92]. Another gene associated with atopic dermatitis is *SPINK5*, loss-of-function mutations in which cause Netherton syndrome, an autosomal recessive ichthyosiform disorder with atopic manifestations[94]. A significant association has been observed between a particular *SPINK5* variant (Glu420Lys) and atopic dermatitis[94], providing potential insights into the pathogenesis of this multifactorial disorder.

Homozygosity for the mutation W185X in the *PVLR1* gene, has been shown to cause autosomal recessive cleft lip/palate (CLP) with ectodermal dysplasia, seen very frequently on Margarita Island, north of Venezuela[87]. This same mutation has been shown to be over-represented among individuals with the multifactorial isolated CLP in northern Venezuela (5.8%) when compared with control individuals from the same population (0.4%). Although these results are highly significant, they constitute only a moderate genetic risk factor, since just a small number of CLP patients carry the mutation[95].

The identification of genetic factors that increase susceptibility to complex traits can reveal pathways for the development of targeted therapies and ways to modify key environmental factors that contribute to common health issues. Disease-gene identification is thus of crucial importance not only for genetic counseling and prenatal diagnosis, but also as a step toward the elucidation of the mechanisms underlying a wide variety of diseases (from rare genodermatoses to common multifactorial conditions) and the eventual development of successful treatments.

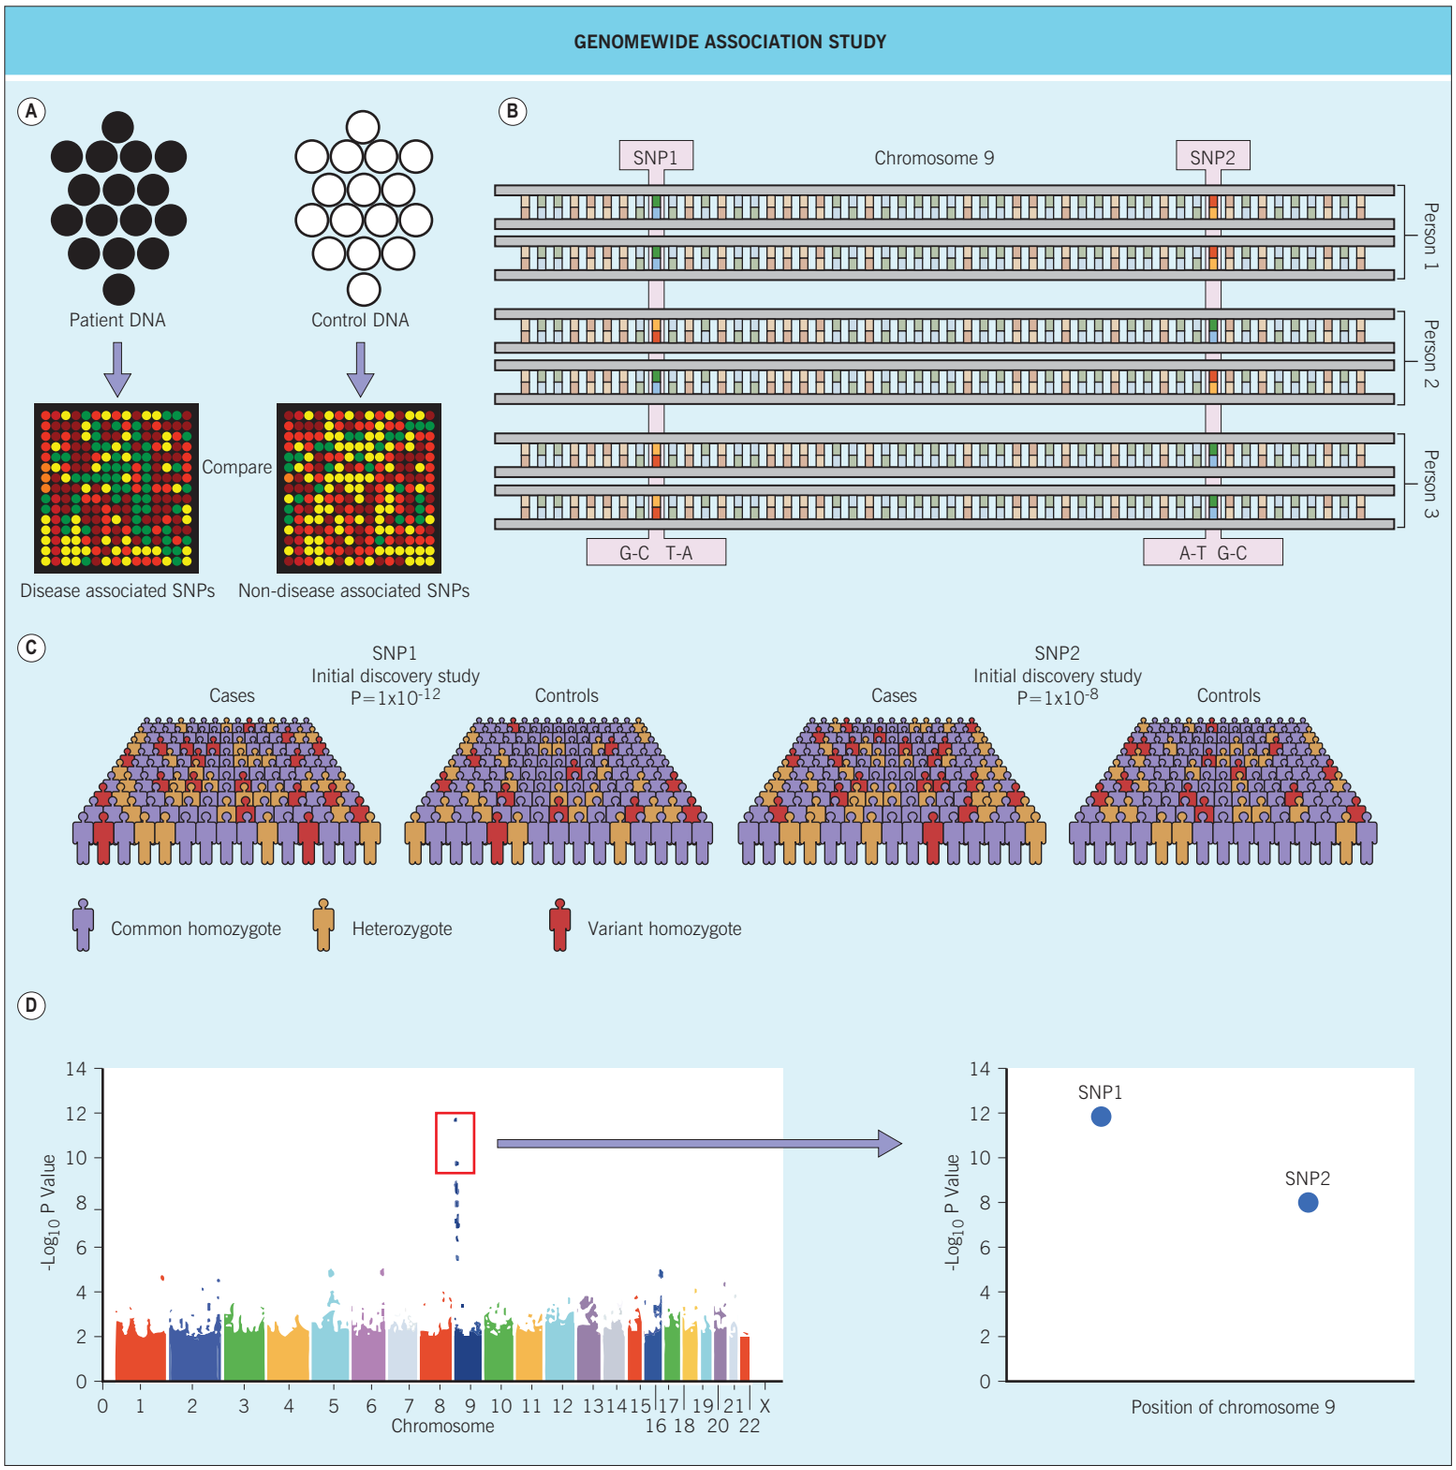

Fig. 54.10 Genome-wide association study (GWAS). A In a GWAS with a case–control design, single-nucleotide polymorphisms (SNPs; markers of genetic variation) across the human genome are genotyped using DNA microarrays in a large group of individuals with a certain disease and compared to controls from the general population. **B** A small locus on chromosome 9 (representing a tiny fragment of the genome) containing two SNPs is depicted as an example. **C** The strength of the association between each SNP and the disease is calculated based on that SNP's prevalence in cases versus controls. Because of the large number of statistical tests that are performed and the resulting high false-positive rate, statistical significance is typically set a P value of 10^{-8}. In this example, SNPs 1 and 2 on chromosome 9 are associated with the disease, with P values of 10^{-12} and 10^{-8}, respectively. **D** For all genotyped SNPs that have survived a quality-control screen, the chromosomal location is plotted on the x-axis and the negative logarithm of the P value on the y-axis (a Manhattan plot). Each chromosome is shown in a different color. The results implicate a locus on chromosome 9, marked by SNPs 1 and 2, which are adjacent to each other (graph at right), and other neighboring SNPs. *Adapted with permission from Manolio TA. Genetic Basis of Cutaneous Diseases

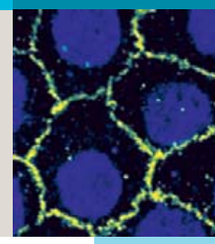
55



Vered Molho-Pessach and Julie V Schaffer

Key features

- Advances in molecular technology have led to elucidation of the genetic bases of the majority of single-gene inherited skin disorders, greatly improving our understanding of these conditions
- McKusick's Online Mendelian Inheritance in Man (OMIM) database provides easily accessible, up-to-date information on human genes and genetic diseases; each gene or phenotype entry is assigned a specific six-digit MIM number
- Genotype–phenotype correlations in genodermatoses are often complex, with multiple examples of allelic heterogeneity (mutations in a single gene causing more than one disorder) and locus heterogeneity (mutations in different genes causing the same disorder)
- Molecular classification of genodermatoses into categories such as keratin defects and nuclear envelope defects complements traditional morphologic classification, providing insights into pathomechanisms and relationships between conditions
- Certain syndromic associations actually represent contiguous gene syndromes caused by large deletions that affect two or more neighboring genes
- Types 1 and 2 mosaicism in autosomal dominant disorders have been confirmed on a molecular level, and functional X-chromosome mosaicism can lead to a mosaic distribution of skin lesions in female patients heterozygous for X-linked disorders
- Determining the molecular basis of a monogenic skin disorder (such as non-Herlitz junctional epidermolysis bullosa) may help us to understand the pathogenesis of an acquired skin disease (such as bullous pemphigoid)
- Molecular research has begun to pave the way to the ultimate goal of gene therapy for severe inherited skin disorders such as dystrophic or junctional epidermolysis bullosa

Abbreviations:
AD, autosomal dominant; AR, autosomal recessive; XD, X-linked dominant; XR, X-linked recessive.

INTRODUCTION

In 1987, deletions in the steroid sulfatase gene were found to underlie X-linked recessive ichthyosis[1]. This heralded an era of tremendous progress in the elucidation of the genetic bases of inherited skin disorders, made possible by rapid advances in molecular technology (including the recent development of next-generation sequencing), discovery of candidate genes, utilization of animal models, and sequencing of the human genome (including single nucleotide polymorphisms [SNPs] useful for linkage analysis and homozygosity mapping; see Ch. 54)[2–4]. Better understanding of signaling pathways, molecules involved in cell–cell communication and adhesion, and mechanisms of cutaneous differentiation have also contributed to the momentum.

As a result of this explosion in research, more than 1000 genes were recognized to be responsible for a particular human phenotype by the year 2000, with approximately 300 of these conditions including cutaneous abnormalities[5]; by 2012, these numbers had increased to over 3500 and 1000, respectively[6–8]. Currently, the molecular genetic bases of the majority of single-gene inherited skin disorders have been established[9,10]. The emergence of new genomic and proteomic databases has transformed laborious positional cloning approaches and traditional functional studies, circumventing previous obstacles to the study of rare conditions and facilitating identification of candidate genes. For example, microarray (see Ch. 3)-based SNP genotyping enabled the identification of *ABCA12* mutations as the cause of harlequin ichthyosis; although classic linkage analysis was not possible due to the limited size of the pedigrees, homozygosity mapping (utilizing the aforementioned technology) linked this autosomal recessive condition to a region of homozygosity shared by affected individuals from diverse ethnic backgrounds[11]. With whole-exome (the transcribed portion of the genome) and even whole-genome sequencing now feasible and relatively affordable, disease-causing genes (especially in recessive disorders) can potentially be identified without genetic mapping[8].

In the past, diagnosis of genodermatoses was complicated by the existence of multiple complex classification systems based on various combinations of clinical, histologic, radiographic and biochemical criteria. Inconsistent nomenclature laden with descriptive terms, eponyms and synonyms added to the confusion and potential for misdiagnosis[12]. As the genetic bases of genodermatoses have been determined, integration of molecular and clinical data has helped to simplify disease categorization and eliminate redundant terminology. This has been successfully accomplished for disorders such as epidermolysis bullosa (EB) and ichthyoses, but it represents a work in progress, to be continually refined as additional genotype–phenotype correlations are established[13,14]. In addition, grouping hereditary skin disorders according to their molecular bases (Table 55.1) can supplement traditional morphologic classification, clarifying pathomechanisms and the relationships between conditions.

As the "morbid anatomy of the dermatologic genome" continues to be established, new challenges will arise and additional questions will be answered[15]. Because of the rarity of many genodermatoses, their full clinical spectra have yet to be elucidated. However, with the increasing availability of genetic and biochemical testing (www.genetests.org), dermatologists can establish the diagnosis in patients with mild or atypical presentations, thereby expanding the range of phenotypes. Continuing to decipher heritable skin disorders will require close interactions between basic scientists and clinicians. Hopefully, such translational research will continue to lead to better understanding of cutaneous structure and function; insights into the pathogenesis of common multifactorial disorders; and effective therapies as well as diagnostic and prognostic information, improved genetic counseling and DNA-based prenatal/preimplantation testing for patients with genodermatoses.

In this chapter, Tables 55.3 to 55.12 divide monogenic skin disorders with a known genetic basis (as well as selected diseases where the locus but not gene has been defined) into categories according to their primary clinical features; groups of monogenic conditions similarly listed in tables elsewhere in the book (rather than in this chapter) are noted in Table 55.2. Groups of diseases with major findings that fit into more than one table (e.g. disorders of keratinization and ectodermal dysplasias that are characterized by prominent hair abnormalities) are indicated, but additional overlap is inevitable.

MOLECULAR CLASSIFICATION OF HEREDITARY SKIN DISORDERS	
Molecular defect	**Skin disorders that result**
Keratin defects	See Table 56.5
Defects in structural proteins of the cornified cell envelope	Ichthyosis vulgaris, loricrin keratoderma (variant Vohwinkel syndrome)
Lipid metabolism defects	Various ichthyoses, including CHILD syndrome, Conradi–Hünermann–Happle syndrome, neutral lipid storage disease, lamellar ichthyosis/congenital ichthyosiform erythroderma spectrum (e.g. defective lipoxygenase 3 or 12R, cytochrome p450 4F22), self-healing collodion baby (defective lipoxygenase 3 or 12R), late-onset autosomal recessive congenital ichthyosis, Refsum disease, rhizomelic chondrodysplasia punctata, Sjögren–Larsson syndrome, X-linked recessive ichthyosis and ichthyosis, intellectual disability and spastic quadriplegia; various hyperlipidemias; Farber lipogranulomatosis, Gaucher disease type 2, hyperimmunoglobulinemia D syndrome, localized autosomal recessive hypotrichosis II/autosomal recessive woolly hair, Niemann–Pick disease, psoriasiform dermatitis-microcephaly-developmental delay syndrome
Transglutaminase defects	Lamellar ichthyosis/congenital ichthyosiform erythroderma spectrum (defective transglutaminase 1), acral peeling skin syndrome
Protease/proteasome defects	Dermatosparaxis, familial hidradenitis suppurativa, hereditary angioedema (type III), ichthyosis–hypotrichosis syndrome, IFAP (*i*chthyosis *f*ollicularis–*a*trichia–*p*hotophobia) syndrome, KLICK (*k*eratosis *l*inearis–*i*chthyosis *c*ongenita–sclerosing *k*eratoderma) syndrome, Papillon–Lefèvre and Haim–Munk syndromes, prolidase deficiency, restrictive dermopathy (defective zinc metallopeptidase), hereditary thrombotic thrombocytopenic purpura, Torg–Winchester syndrome (including the nodulosis–arthropathy–osteolysis variant)
Protease inhibitor defects	Antithrombin III deficiency, hereditary angioedema (types I & II), Netherton syndrome
Desmosomal defects (see Table 56.3)	Acantholytic ectodermal dysplasia, arrhythmogenic right ventricular dysplasia/cardiomyopathy + palmoplantar keratoderma + woolly hair; Carvajal syndrome, hypotrichosis and skin lesions, hypotrichosis simplex of the scalp, lethal acantholytic epidermolysis bullosa, lethal congenital epidermolysis bullosa, localized autosomal recessive hypotrichosis I, monilethrix (autosomal recessive), Naxos disease, generalized inflammatory peeling skin syndrome, plakophilin deficiency, skin fragility/woolly hair syndrome, striate palmoplantar keratoderma
Connexin defects (see Table 58.3)	Bart–Pumphrey syndrome, erythrokeratodermia variabilis, hidrotic ectodermal dysplasia, hereditary lymphedema type IC, KID (*k*eratitis–*i*chthyosis–*d*eafness) syndrome, oculodentodigital dysplasia, palmoplantar keratoderma with deafness, Vohwinkel syndrome (classic)
Other defects in cell-to-cell adhesion	Ichthyosis–hypotrichosis–sclerosing cholangitis syndrome, cleft lip/palate–ectodermal dysplasia syndrome, ectodermal dysplasia–syndactyly syndrome, ectodermal dysplasia–ectrodactyly–macular dystrophy, hypotrichosis with juvenile macular dystrophy, leukocyte adhesion deficiency type I
Defects in keratinocyte–extracellular matrix (ECM) adhesion	Various forms of epidermolysis bullosa (EB) simplex, junctional EB and dystrophic EB (keratin–ECM linkage); Kindler syndrome (actin–ECM linkage)
ATP-binding cassette (ABC) transporter defects	Harlequin ichthyosis, lamellar ichthyosis/congenital ichthyosiform erythroderma spectrum (defective ABCA12), pseudoxanthoma elasticum, sitosterolemia, Tangier disease/familial hypoalphaproteinemia
Calcium pump defects	Darier disease, Hailey–Hailey disease
Copper transporter defects	Menkes disease, occipital horn syndrome, Wilson disease
Defects in other transporters	Acrodermatitis enteropathica (zinc transporter), arterial tortuosity syndrome (glucose transporter), autosomal dominant hemochromatosis (iron-regulated transporter), Ehlers-Danlos syndrome-like spondylocheirodysplasia (zinc transporter), H syndrome (nucleoside transporter), Hartnup disease (neutral amino acid transporter), ichthyosis–prematurity syndrome (fatty acid transporter), oculocutaneous albinism (transporters on lysosome-related organelles)
Collagen defects	Various types of dystrophic EB, various types of Ehlers–Danlos syndrome, Ullrich muscular dystrophy, lysyl hydroxylase 3 deficiency
Defects in other ECM proteins	Autosomal dominant cutis laxa, autosomal recessive cutis laxa type I, cutis laxa with severe pulmonary/gastrointestinal/urinary abnormalities, Ehlers–Danlos syndrome hypermobility type/due to tenascin-X deficiency, juvenile hyaline fibromatosis/infantile systemic hyalinosis, lipoid proteinosis, Marfan syndrome, stiff skin syndrome
Nuclear membrane defects (see Table 63.9)	Buschke–Ollendorff syndrome/melorheostosis, Néstor-Guillermo progeria syndrome, Hutchinson–Gilford progeria syndrome, mandibuloacral dysplasia, partial > generalized lipodystrophy (familial and "acquired" forms), restrictive dermopathy
Defects in pyrin/NOD-family members and related proteins (see Fig. 45.1)	Blau syndrome, CINCA syndrome, familial cold autoinflammatory syndrome, familial Mediterranean fever, Muckle–Wells syndrome, PAPA syndrome
RecQ DNA helicase defects	Bloom syndrome, Rothmund–Thomson syndrome, Werner syndrome
Classic DNA repair defects	Various subtypes of xeroderma pigmentosum, trichothiodystrophy and Cockayne syndrome; Muir–Torre syndrome, constitutional mismatch repair deficiency syndrome
Cell cycle checkpoint defects	Ataxia telangiectasia, familial atypical mole–malignant melanoma (FAMMM) syndrome, multiple endocrine neoplasia (MEN) 4
Defects in telomere maintenance	Dyskeratosis congenita (seven genes implicated to date)
Protein-tyrosine phosphatase (PTP) defects	Bannayan–Riley–Ruvalcaba syndrome*, Cowden disease*, LEOPARD syndrome†, Noonan syndrome†, lymphedema and choanal atresia

*The defective proteins also have a role in the phosphatidylinositol 3-kinase (PI3K)/AKT pathway (see Fig. 55.4).
†The protein-tyrosine phosphatase that is defective in LEOPARD and Noonan syndromes has a role in the RAS–MAPK pathway (see Fig. 55.6).

Table 55.1 Molecular classification of hereditary skin disorders. cAMP, cyclic adenosine monophosphate; CHILD, congenital *h*emidysplasia with *i*chthyosiform nevus and *l*imb *d*efects; CINCA, *c*hronic *i*nfantile *n*eurologic, cutaneous and *a*rticular syndrome; JAK, Janus kinase; MAPK, mitogen-activated protein kinase; NF-κB, nuclear factor-κB; NOD, nucleotide-binding oligomerization domain; PAPA, *p*yogenic *a*rthritis, *p*yoderma gangrenosum, and *a*cne; SCC, squamous cell carcinoma; STAT, signal transduction and activation of transcription; WNT, wingless-type integration site.

Continued

MOLECULAR CLASSIFICATION OF HEREDITARY SKIN DISORDERS	
Molecular defect	**Skin disorders that result**
RAS-MAPK pathway defects (see Fig. 55.5)	Capillary malformation–arteriovenous malformation, cerebral capillary malformations (familial), cardio-facio-cutaneous syndrome, Costello syndrome, Legius syndrome, LEOPARD syndrome, neurofibromatosis type 1, Noonan syndrome, Noonan-like disorder with loose anagen hair
cAMP and AMP-activated protein kinase pathway defects (see Fig. 55.4)	Albright hereditary osteodystrophy, Carney complex, McCune–Albright syndrome, Peutz–Jeghers syndrome*, tuberous sclerosis*
Defects in WNT/β-catenin signaling (see Fig. 55.7)	Anonychia congenita, ectodermal dysplasia–neoplastic syndrome, Gardner syndrome, Goltz syndrome (focal dermal hypoplasia), hereditary hypotrichosis simplex, palmoplantar keratoderma with cutaneous SCC and sex reversal, WNT10A-related ectodermal dysplasias (including odonto-onycho-dermal dysplasia and Schöpf–Schulz–Passarge syndrome)
Defects in transforming growth factor (TGF)-β signaling	Buschke–Ollendorff syndrome/melorheostosis, Ferguson–Smith multiple self-healing squamous epitheliomas, hereditary hemorrhagic telangiectasia, Loeys–Dietz syndrome, Marfan syndrome, stiff skin syndrome
Defective vesicle assembly/protein sorting to vesicles	ARC (*a*rthrogryposis–*r*enal *d*ysfunction–cholestasis) syndrome, Hermansky–Pudlak syndrome, MEDNIK (*m*ental retardation, *e*nteropathy, *d*eafness, *n*europathy, *i*chthyosis, *k*eratodermia) syndrome
Defective vesicle trafficking or transport	Autosomal recessive cutis laxa type IIA, CEDNIK (*ce*rebral *d*ysgenesis, *n*europathy, *i*chthyosis and *k*eratoderma) syndrome, Chédiak–Higashi syndrome, gerodermia osteodysplastica, Griscelli syndrome, ocular albinism type 1, wrinkly skin syndrome, MACS (*m*acroecphaly, *a*lopecia, *c*utis laxa and *s*coliosis) syndrome
*The defective proteins also have a role in the phosphatidylinositol 3-kinase (PI3K)/AKT pathway (see Fig. 55.4).

McKUSICK' S MENDELIAN INHERITANCE IN MAN

McKusick's Mendelian Inheritance in Man (MIM) database was first published in 1966 as "Catalogs of Autosomal Dominant, Autosomal Recessive and X-linked Phenotypes". In the 1994 edition, the subtitle was changed to "A Catalog of Human Genes and Genetic Disorders", reflecting the progress that had been made in the field. Online MIM (OMIM; www.ncbi.nlm.nih.gov/omim) has been widely available on the Internet for over 25 years, providing immediate access to current information on human genes and genetic diseases[6,7]. This database is updated continuously and can be searched by entering a constellation of clinical features as well as the name of a gene or syndrome.

A particular six-digit number (MIM number) is assigned to each OMIM entry. The first digit of the MIM number indicates the mode of inheritance of the corresponding genetic defect: 1 for autosomal dominant (entries before May 1994); 2 for autosomal recessive (entries before May 1994); 3 for X-linked; 4 for Y-linked; 5 for mitochondrial; and 6 for autosomal dominant or recessive (entries after May 1994). *Phenotype entries* describe the clinical and biochemical features, inheritance, mapping and molecular genetics of a given disease or trait; a "*#*" is used to designate those for which the molecular basis is known. *Gene entries* are marked by a "*", while *gene plus phenotype* entries are indicated with a "+"; both are appended with important disease-causing allelic variants (each of which is given a four-digit extension, beginning with .0001).

GENOTYPE–PHENOTYPE CORRELATIONS

Genotype–phenotype correlations in genodermatoses are often complex. Mutations in a single gene can cause more than one clinical disorder, a phenomenon referred to as *allelic* or *clinical heterogeneity* (see Table 53.1). This can result either from the same mutation occurring in patients with different genetic backgrounds or ages at presentation (e.g. identical *PTEN* mutations leading to Cowden disease and Bannayan–Riley–Ruvalcaba syndrome) or from different mutations (e.g. distinct mutations in the gene encoding lamin A/C leading to Hutchinson–Gilford progeria and familial partial lipodystrophy). Mutations that affect different domains of a protein can produce divergent phenotypes; for example, mutations in the sterile alpha motif (SAM) domain of the p63 protein typically cause AEC (*a*nkyloblepharon, *e*ctodermal dysplasia and *c*left lip/palate) syndrome, while those in the DNA-binding domain give rise to EEC (*e*ctrodactyly, *e*ctodermal dysplasia and *c*left lip/palate) syndrome. Various mutations in a particular gene can even lead to disorders with different modes of inheritance, such as X-linked dominant incontinentia pigmenti (a male-lethal condition due to a genomic rearrangement resulting in a partial deletion of the *n*uclear factor-κB *e*ssential *mo*dulator *[NEMO]* gene) and X-linked recessive hypohidrotic ectodermal dysplasia with immunodeficiency (due to milder, "hypomorphic" mutations in the *NEMO* gene). Conditions recently found to represent unexpected examples of allelic heterogeneity in the transforming growth factor-β (TGF-β) signaling pathway include mutations in the TGF-β receptor 1 gene (*TGFBR1*) in Ferguson–Smith multiple self-healing squamous epithelioma (loss-of-function) as well as Loeys–Dietz syndrome (gain-of-function), and fibrillin 1 gene (*FBN1*) mutations in stiff skin syndrome as well as Marfan syndrome.

The type of mutation can also affect the severity of a genodermatosis. The potentially lethal Herlitz type of junctional EB (JEB, an autosomal recessive disorder) is typically caused by mutations in the *LAMB3* gene that lead to a premature termination codon (resulting in a complete absence of the LAMB3 protein), whereas milder non-Herlitz forms of JEB are produced by missense or splice-site mutations in the same gene (resulting in a LAMB3 protein with decreased function). In contrast, in autosomal dominant conditions where there is dimerization of the mutated protein product (e.g. the KIT tyrosine kinase receptor that is defective in piebaldism), dominant negative missense mutations often result in more severe disease (via abnormal proteins binding to and disrupting normal proteins) than do mutations that lead to premature termination codons and thereby result in haploinsufficiency (complete loss of half of the proteins).

In other instances, mutations in different genes produce the same clinical disorder; this is referred to as *locus* or *genetic heterogeneity*. Locus heterogeneity can occur when mutated proteins serve a similar function (e.g. components of various *b*iogenesis of *l*ysosome-related *o*rganelle *c*omplexes [BLOCs] in Hermansky–Pudlak syndrome) or interact with one another in a complex (e.g. hamartin and tuberin in tuberous sclerosis), as a ligand and receptor (e.g. endothelin-3 and the endothelin-B receptor in type 4 Waardenburg syndrome) or in a signaling pathway (e.g. various RAS–mitogen-activated protein kinase [MAPK] pathway proteins in cardio-facio-cutaneous syndrome; see below). However, phenotypic differences can arise when these proteins also have distinct functions and/or tissue distributions; for example, the neurologic abnormalities in Griscelli syndrome 1 result from myosin Va expression in neurons, and the immunodeficiency and hemophagocytic syndrome that characterize Griscelli syndrome 2 reflect RAB27A expression in hematopoietic cells.

MOLECULAR CLASSIFICATION OF HEREDITARY SKIN DISORDERS

Molecular classification (see Table 55.1) represents a useful approach to the categorization of genodermatoses. Based on the pathogenetic

GROUPS OF MONOGENIC SKIN DISORDERS LISTED IN TABLES ELSEWHERE IN THE BOOK	
Category	**Table(s)**
Epidermolysis bullosa	32.1
Desmosomal disorders and keratinopathies	56.3 & 5
Connexin disorders	58.3
Nuclear membrane disorders	63.9
Disorders of hypopigmentation (diffuse or circumscribed)	66.3, 5 & 6
Hair disorders	69.7
Ehlers-Danlos syndrome, cutis laxa and other extracellular matrix disorders	95.5, 97.2 & 97.6
Vascular anomalies	104.2

Table 55.2 Groups of monogenic skin disorders listed in tables elsewhere in the book. In addition, other chapters (especially in the genodermatosis section) have tables that present more detailed information on monogenic skin disorders.

Fig. 55.1 Autosomal recessive monilethrix due to desmoglein 4 mutations. Sparse short hairs, stubble and follicular papules on the scalp. Insert: Trichogram showing alternating elliptical nodes and constrictions.

defect rather than the clinical presentation, it can highlight similarities between conditions with seemingly disparate phenotypes (e.g. classic ichthyoses and metabolic disorders such as Gaucher disease, both caused by defects in lipid metabolism) and facilitate better understanding of important cellular pathways (e.g. RAS signaling) and responses to external stimuli (e.g. pyrin/NOD family members that function in innate immunity). Several groups of genodermatoses for which molecular classification has been instructive are discussed below.

Keratin Defects

In 1991, EB simplex (EBS) became the first human disease shown to be caused by intermediate filament mutations. Since that time, molecular defects in keratins have been identified in a diverse group of hereditary disorders affecting the skin, leading to mechanical fragility and/or abnormal keratinization, depending on the layer of the epidermis in which the defective protein is expressed; the hair, nails and oral mucosa may also be involved (see Table 55.2)[16]. Dowling–Degos disease and Naegeli–Franceschetti–Jadassohn (NFJ) syndrome, which are characterized by reticulated pigmentation and (for NFJ) ectodermal dysplasia, represent entities more recently recognized as belonging to the keratin disorder category.

Keratin intermediate filaments, which are expressed in a tissue- and differentiation-specific fashion, are composed of heterodimeric subunits formed by the specific pairing of a type I (acidic; K9–20, 25–28 [inner root sheath], 31–40 [hair]) and type II (basic–neutral; K1–8, 71–75 [inner root sheath], 81–86 [hair]) keratin (see Ch. 56). Keratin genes are clustered at two loci in the human genome, 17q21 (type I keratins) and 12q13 (type II keratins). Many keratin disorders can be caused by mutations (often dominant negative) in either the type I or type II component of a particular keratin pair, thus exhibiting locus heterogeneity (e.g. K10 or K1 for epidermolytic ichthyosis; K14 or K5 for EBS). Allelic heterogeneity is also observed, with mutations in the highly conserved helix initiation and termination motifs leading to more severe phenotypes than those in other regions (e.g. the Dowling–Meara type of EBS versus localized EBS) (see Fig. 56.5).

Defects in Intercellular Junctions

Mutations in genes encoding components of desmosomes and gap junctions underlie a variety of genodermatoses, several of which have prominent extracutaneous manifestations.

Desmosomal defects

Desmosomes are intercellular junctions that provide mechanical integrity to tissues by anchoring intermediate filaments to the cell surface and mediating strong cell–cell adhesion (see Ch. 56). They are particularly important in stratified squamous epithelia and the myocardium, tissues that are subjected to substantial mechanical stress[17]. It is therefore not surprising that impaired keratinization, skin fragility and cardiomyopathy represent features of disorders caused by defects in desmosomal proteins such as desmoplakin, plakoglobin and plakophilin 1 (see Fig. 56.8 and Tables 55.3, 55.5 & 56.3). Abnormal hair (oftentimes woolly in nature) can also result from abnormalities in these proteins, and defects in other desmosomal components such as desmoglein 4 and corneodesmosin (which are highly expressed within the hair follicle) can lead to hypotrichosis and (for desmoglein 4) an autosomal recessive form of monilethrix (Fig. 55.1; see Table 55.6).

Connexin defects

Gap junctions are intercellular channels that connect the cytoplasm of neighboring cells, facilitating communication that coordinates cellular growth, differentiation and responses to stimuli as well as tissue morphogenesis and homeostasis (see Ch. 58). Transmembrane connexin proteins undergo oligomerization to form the connexons that compose gap junctions. Connexin proteins such as Cx26, Cx30, Cx31 and Cx43 are preferentially expressed in ectoderm-derived epithelia of the inner ear and cornea as well as in the epidermis and its appendages[18]. This accounts for the sensorineural deafness, keratitis and cutaneous abnormalities (ranging from keratoderma to erythrokeratoderma to ectodermal dysplasias affecting the hair and nails) that are observed in various connexin disorders (see Tables 55.1, 55.3 & 55.5). Several connexins are expressed in lymphatic cells, and mutations in the gene encoding Cx47 were recently found to cause a hereditary type of lymphedema[19].

Defects in Keratinocyte–Extracellular Matrix Adhesion

The hemidesmosome links keratin intermediate filaments (K5, K14) within basal keratinocytes to proteins within the lamina densa (basement membrane proper) and sublamina densa regions of the epidermal basement membrane zone (see Ch. 28). Defects in protein components of these structures lead to various forms of EB (simplex, junctional and dystrophic; see Ch. 32)[20]. The basement membranes of epithelia in other sites such as the eye, oral cavity, gastrointestinal tract and genitourinary tract may also be affected in patients with EB. Additional clinical manifestations can result when the abnormal protein has important functions in extraepithelial tissues, such as the skeletal muscle for plectin (leading to EBS with muscular dystrophy).

HEREDITARY DISORDERS OF KERATINIZATION					
Disorder	**Mode of inheritance**	**Gene or gene product**	**Gene symbol**	**Gene locus**	**MIM number(s)**
COMMON ICHTHYOSES					
Ichthyosis vulgaris	AsD	Filaggrin	*FLG*	1q21.3	146700, 135940

[§]Phenotypic overlap with IFAP syndrome, which is also caused by mutations in *MBTPS2*. In addition, a duplication involving the *SAT1* gene has been reported in a single patient to date with keratosis follicularis spinulosa decalvans.
[¶]To date, reported in a single Chinese family and not confirmed in subsequent studies.

Table 55.3 Hereditary disorders of keratinization (cont'd). These disorders are covered primarily in Chapters 57 and 58. CHILD, *c*ongenital *h*emidysplasia with *i*chthyosiform nevus and *l*imb *d*efects; ERCC, excision repair cross-complementing; XP, xeroderma pigmentosum.

Focal adhesions are structurally defined sites of linkage between the intracellular actin cytoskeleton and the extracellular matrix (ECM). Mutations in the gene encoding the focal adhesion protein kindlin-1 cause Kindler syndrome, an autosomal recessive disorder characterized by acral blistering and photosensitivity early in life, progressive poikiloderma and erosive periodontal disease (see Ch. 63). Kindlin-1 is found within basal keratinocytes along the cell surface that faces the basement membrane, and it has roles in keratinocyte adhesion, polarity, proliferation and motility. To date, Kindler syndrome represents the only skin fragility disorder known to be caused by disruption of linkage between actin microfilaments (rather than keratin intermediate filaments) and the ECM[20].

Transmembrane Transporter Defects

Abnormalities in transmembrane transporters underlie a variety of genodermatoses, ranging from occipital horn syndrome and Menkes disease (both due to mutations in the gene encoding the ATP7A copper transporter) to oculocutaneous albinism types 2 and 4 (due to defective transporters on lysosome-related organelles) to metabolic disorders such as acrodermatitis enteropathica, Hartnup disease and hemochromatosis. Recent additions to this list include implication of a fatty acid transporter in ichthyosis prematurity syndrome[21] and an intracellular nucleoside transporter in H syndrome (Fig. 55.2)[22]. Disorders of calcium pumps and ATP-binding cassette (ABC) transporters, which underscore the important roles of transmembrane transporters in cutaneous homeostasis, are discussed below.

Calcium pump defects

Darier disease and Hailey–Hailey disease are distinct autosomal dominant disorders that share the histologic feature of epidermal acantholysis leading to suprabasal cleft formation; on an ultrastructural level, this corresponds to disruption of the desmosome–keratin intermediate

Fig. 55.2 H syndrome. This autosomal recessive disorder due to mutations in the *SLC29A3* gene (which encodes a nucleoside transporter) presents with *h*yperpigmentation, *h*ypertrichosis, induration and varicose veins in a characteristic distribution pattern on the thighs with sparing of the knees (**A**). Additional features include *h*allus valgus and flexion contractures of the toes (**B**), *h*epatosplenomegaly, *h*eart anomalies, *h*earing loss, *h*ypogonadism, low *h*eight and *h*yperglycemia/diabetes mellitus.

filament complex. The two conditions also have some clinical similarities, including intertriginous involvement, vesiculobullous lesions (relatively uncommon in Darier disease), nail changes, exacerbation with heat, and frequent superinfections. As a result of these overlapping features, it was initially postulated that Darier disease and Hailey–Hailey disease were allelic disorders caused by defects in a gene encoding a structural component of the epidermis. However, linkage studies mapped Darier disease to chromosome 12 and Hailey–Hailey disease to chromosome 3, and no candidate structural genes were found in these regions.

In 1999, pathogenetic mutations in the *ATP2A2* gene, which encodes a sarcoplasmic/endoplasmic reticulum Ca^{2+} ATPase, were identified in patients with Darier disease. Subsequently, mutations in the *ATP2C1* gene on chromosome 3, which encodes a Ca^{2+} ATPase localized to the Golgi apparatus, were shown to cause Hailey–Hailey disease. Determining the molecular bases of these genodermatoses thus demonstrated the pivotal role of calcium homeostasis in epidermal differentiation and cell–cell adhesion[23].

ATP-binding cassette transporter defects

Members of the ABC transporter superfamily bind and hydrolyze adenosine triphosphate (ATP) in order to transport various molecules across a cell membrane or into a vesicle. Well-known examples include the cystic fibrosis transmembrane conductance regulator (CFTR, ABCC7; the chloride ion channel that is defective in patients with cystic fibrosis) and the P glycoprotein (ABCB1; an important cellular mechanism of multidrug resistance). Several phenotypically diverse genodermatoses are also caused by mutations in ABC transporters (see Table 55.1)[24].

Because fragmentation and calcification of elastic fibers in the skin, eyes and cardiovascular system are major features of pseudoxanthoma elasticum (PXE), the latter was initially thought to represent a heritable connective tissue disorder that (presumably) resulted from mutations in a gene encoding an extracellular matrix protein. Surprisingly, PXE was instead found to be caused by mutations in the *ABCC6* gene, which encodes an organic acid transporter (based on *in-vitro* studies) that is expressed almost exclusively in the liver and kidneys. Together with evidence that metabolites present in the sera of PXE patients interfere with the normal assembly of elastic fibers *in vitro*, this suggests that PXE is actually better characterized as a metabolic disorder with secondary connective tissue manifestations.

Biallelic mutations in *ABCA12*, which encodes a transporter that secretes lipids into lamellar granules, cause both harlequin ichthyosis and a form of lamellar ichthyosis[25] (see Fig. 56.2). Patients with harlequin ichthyosis tend to have nonsense mutations, whereas those with lamellar ichthyosis typically have missense mutations. This represents one of the most clearcut genotype–phenotype correlations observed to date for non-syndromic autosomal recessive ichthyoses. Defective formation of intercellular lipid layers, which are essential for epidermal barrier function, due to genetic defects in lipid metabolism also represents the pathomechanism of an expanding list of other ichthyosiform disorders (see Table 55.1 and Fig. 56.2)[25].

Nuclear Envelope Defects

"Nuclear envelopathies" represent a recently defined, clinically heterogeneous group of inherited disorders caused by defects in structural components of the nuclear envelope (see Table 63.9). In addition to a variety of extracutaneous findings (e.g. skeletal dysplasia, muscular dystrophy, cardiomyopathy and neuropathy), dermatologic manifestations include premature aging of the skin (e.g. in progeria and "atypical Werner syndrome" due to *LMNA* mutations), cutaneous fibrosis (e.g. in restrictive dermopathy and Buschke–Ollendorff syndrome/melorheostosis due to *LMNA* and *LEMD3* mutations, respectively) and partial lipodystrophy (e.g. familial Dunnigan and "acquired" Barraquer–Simons types due to *LMNA* and *LMNB2* mutations, respectively).

"Laminopathies" represent the largest subgroup of envelopathies and result from mutations in the genes that encode the lamin A/C and lamin B2 proteins of the nuclear membrane lamina, which lies just inside the inner nuclear membrane[26]. The *LEMD3* gene encodes MAN1, an inner nuclear membrane protein that associates with lamin A. In addition to "true" envelopathies, mutations in the *ZMPSTE24* gene, which encodes a zinc metallopeptidase involved in the processing of prelamin A into mature lamin A, can result in restrictive dermopathy and mandibuloacral dysplasia (characterized by lipodystrophy, premature aging and skeletal defects; can also be caused by *LMNA* mutations). The study of patients with envelopathies has provided insight into the importance of lamins and other nuclear envelope proteins to the structural integrity of the nucleus, chromatin organization, transcriptional regulation, control of differentiation, and mechanisms of aging[26].

Defects in Pyrin/NOD Family Members and Related Proteins

Over the past decade, the molecular bases of several hereditary periodic fever syndromes and other autoinflammatory disorders have been found to be due to defects in proteins containing *n*ucleotide-binding *o*ligomerization *d*omains (NODs) and/or pyrin domains (see Table 45.2)[27]. This has drawn attention to the NOD and pyrin families and related proteins (see Fig. 45.1), helping to uncover their importance in innate immune responses and acquired inflammatory disorders. Defects in such proteins lead to diverse cutaneous phenotypes, ranging from urticarial papules in cryopyrin-related disorders and erysipeloid erythema in familial Mediterranean fever to nodulocystic acne and pyoderma gangrenosum in PAPA syndrome to granulomatous dermatitis (together with arthritis and uveitis) in Blau syndrome (Fig. 55.3). Upon uncovering *NOD2* mutations as the defect in Blau syndrome, it was also established that this autosomal dominant disorder and

Plakophilin deficiency (ED/skin fragility syndrome)	AR	Plakophilin 1	*PKP1*	1q32	604536, 601975
"Pure" hair–nail type ED	AR	Keratin 85	*KRT85*	12q11–q13	602032, 602767
Tooth and nail (Witkop) syndrome	AD	Muscle segment homeobox 1	*MSX1*	4p16.1	189500, 142983
Tricho-dento-osseous syndrome	AD	Distal-related homeobox 3	*DLX3*	17q21.2–q22	190320, 600525

Table 55.5 Ectodermal dysplasias. Ectodermal dysplasias (EDs), genetic disorders characterized by abnormalities in two or more of the major structures derived from the ectoderm (e.g. hair, teeth, nails and sweat glands), are discussed in Chapter 63. See Table 55.7 for Naegeli–Franceschetti–Jadassohn syndrome and dermatopathia pigmentosa reticularis. AEC, *a*nkyloblepharon, *e*ctodermal defects, cleft lip/palate; EEC, *e*ctodermal dysplasia, *e*ctrodactyly, *c*left lip/palate; EEM, *e*ctodermal dysplasia, *e*ctrodactyly, *m*acular dystrophy.

"early-onset sarcoidosis" are identical on a genetic as well as phenotypic level (with the latter resulting from *de novo NOD2* mutations), thus representing a single disease entity. However, different *NOD2* variants have been implicated in Crohn's disease and susceptibility to leprosy.

Defects in DNA Repair Genes, Tumor Suppressor Genes and Oncogenes

Hereditary cancer syndromes that affect the skin can be divided into groups based upon whether the associated malignancies are primarily cutaneous (e.g. Gorlin syndrome; see Table 55.10) or extracutaneous (see Table 55.11); individuals in the latter group may have either benign cutaneous neoplasms (e.g. Cowden disease) or non-neoplastic skin lesions (e.g. ataxia–telangiectasia)[28]. To complement this clinical approach, molecular classification of such syndromes can help to explain relationships among disorders and understand the disrupted pathway or process, perhaps suggesting candidate genes for patients with similar phenotypes for which the underlying molecular defect has not yet been identified. In addition to characterization based on the specific pathomechanism (e.g. RAS-ERK pathway activation[29]; see below), hereditary cancer syndromes can be separated into three general categories: (1) defective DNA repair and protection of genomic integrity

HEREDITARY DISORDERS OF THE HAIR AND NAILS					
Disorder	**Mode of inheritance**	**Gene or gene product**	**Gene symbol**	**Gene locus**	**MIM number(s)**
DISORDERS WITH HYPOTRICHOSIS AND/OR HAIR SHAFT ABNORMALITIES (SEE CH. 69, WITH AN OVERVIEW IN TABLE 69.7)					
DISORDERS WITH HYPERTRICHOSIS (SEE TABLES 70.1 & 70.2)					
Congenital generalized hypertrichosis, X-linked	XR		Interchromosomal insertion mediated by a palindromic sequence	Xq27.1	307150
Congenital generalized hypertrichosis terminalis with or without gingival hyperplasia	AD		Microdeletion involving *ABCA5, ABCA6, ABCA10* and *MAP2K6*	17q24.2–q24.3	135400
Hypertrichosis universalis congenita (Ambras syndrome)	AD	(Tricho-rhino-phalangeal syndrome I)	(Chromosomal anomalies affect *TRPS1* expression)	8q22	145701
Leigh syndrome	mt	Various components of mitochondrial respiratory chain complexes			256000
	AR	Surfeit 1	*SURF1*	9q33–q34	256000, 185620
NAIL DISORDERS (SEE CH. 71)					
Anonychia congenita	AR	R-spondin family, member 4	*RSPO4*	20p13	206800, 610573
Isolated AR nail dysplasia	AR	Frizzled 6	*FZD6*	8q22.3	614157, 603409
Isolated congenital nail clubbing	AR	Hydroxyprostaglandin dehydrogenase 15-(NAD)	*HPGD*	4q34–q35	119900, 601688
Isolated toenail dystrophy	AD	Collagen VII, α1 chain	*COL7A1*	3p21.3	607523, 120120
Nail–patella syndrome	AD	LIM homeobox transcription factor 1β	*LMX1B*	9q34.1	161200, 602575
Pachyonychia congenita-6a	AD	Keratin 6a	*KRT6A*	12q13	167200, 148041
Pachyonychia congenita-16	AD	Keratin 16	*KRT 16*	17q12–q21	167200, 148067
Pachyonychia congenita-6b	AD	Keratin 6b	*KRT6B*	12q13	167210, 148042
Pachonychia congenita-17	AD	Keratin 17	*KRT17*	17q12–q21	167210, 148069
Tricho-rhino-phalangeal syndrome 1	AD	TRPS1 (zinc finger protein)	*TRPS1*	8q24.12	190350, 604386

Table 55.6 Hereditary disorders of the hair and nails. Hair and/or nail abnormalities can also be observed in patients with disorders of keratinization and ectodermal dysplasias (see Tables 55.3 & 55.5). Pachydermoperiostosis is included in Table 55.12. mt, mitochondrial inheritance.

("caretaker" genes); (2) defective tumor suppressor ("gatekeeper") genes; and (3) activated oncogenes.

Defective DNA repair and protection of genomic integrity

Inactivation of caretaker genes causes an increased mutation rate in all genes, including gatekeeper genes with critical roles in controlling tumor growth (see below). Classic examples of caretaker dysfunction include defects in various nucleotide excision repair proteins (required for correction of UV-induced DNA damage) in xeroderma pigmentosum and abnormal mismatch repair in Muir–Torre syndrome (a subtype of the hereditary non-polyposis colorectal cancer syndrome). Defects in RecQ helicases, which function in DNA replication, recombination and repair, underlie Bloom, Rothmund–Thomson and Werner syndromes. This leads to genomic instability, as evidenced by findings such as accumulation of chromosomal aberrations, increased sister chromatid exchange (Bloom syndrome) and shortened telomeres (Werner syndrome). The compromised telomere maintenance observed in dyskeratosis congenita can result from defects in telomerase subunits (RNA and reverse transcriptase) or associated proteins (e.g. dyskerin, a Cajal body protein, ribonucleoprotein analogs, a shelterin complex component).

Defective tumor suppressor genes

In hereditary cancer syndromes caused by a defective tumor suppressor gene, there is classically a heterozygous germline loss-of-function mutation followed by a somatic "second hit" that leads to loss of heterozygosity and abrogation of protein function in affected tissues. Examples include *PTCH* (encoding patched) in Gorlin syndrome (see Ch. 107), *CDKN2A* (encoding $p16^{INK4a}$ and $p14^{ARF}$, which maintain activity of the retinoblastoma [Rb] and p53 tumor suppressor proteins, respectively) in the familial atypical mole-malignant melanoma syndrome (see Ch. 113), and *PTEN* in the PTEN hamartoma tumor syndrome (see Ch. 63). The PTEN protein negatively regulates the phosphatidylinositol 3-kinase (PI3K)/AKT cascade, the same pathway that is positively regulated by the RET oncogene (Fig. 55.4; see below). Proteus syndrome is caused by mosaicism for an activating mutation in the *AKT1* oncogene, explaining its clinical similarity to type 2 mosaic PTEN hamartoma tumor syndrome (see below).

Activated oncogenes

Germline gain-of-function mutations in oncogenes have been identified in some autosomal dominant hereditary tumor syndromes, including *RET* in multiple endocrine neoplasia (MEN) 2A/2B (see Fig. 55.4), *KIT* in familial mastocytosis plus gastrointestinal stromal tumors, and those encoding RAS-MAPK pathway components in certain "RASopathies" (Fig. 55.5). The latter include Costello (Fig. 55.6), Noonan, cardio-facio-cutaneous (CFC) and LEOPARD syndromes[30]. In addition, neurofibromatosis type 1 (NF1) and Legius syndrome (previously referred to as NF1-like syndrome) represent RASopathies due to germline *loss*-of-function mutations in tumor suppressor genes that normally downregulate RAS-MAPK signaling[29].

RASopathies share extracutaneous features such as ocular hypertelorism, macrocephaly, cardiac defects (especially pulmonary stenosis) and developmental delay, as well as a spectrum of skin findings that includes hair abnormalities (e.g. curly, woolly, loose anagen), pigmented lesions (e.g. lentigines, melanocytic nevi, café-au-lait macules)[31], keratosis pilaris, acanthosis nigricans and distal phalangeal transverse creases (see Fig. 55.6B&C). Some RASopathies also have more specific cutaneous manifestations (e.g. neurofibromas in NF1, lax acral skin in Costello syndrome; see Fig. 55.6B).

HEREDITARY DISORDERS OF PIGMENTATION					
Disorder	**Mode of inheritance**	**Gene or gene product**	**Gene symbol**	**Gene locus**	**MIM number(s)**
DISORDERS WITH DIFFUSE PIGMENTARY DILUTION OR CIRCUMSCRIBED LEUKODERMA (SEE CH. 66, WITH OVERVIEWS IN TABLES 66.3, 66.5 & 66.6)					
DISORDERS WITH HYPERPIGMENTATION (SEE CH. 67)					
Dermatopathia pigmentosa reticularis	AD	Keratin 14	*KRT14*	17q12–q21	125595, 148066
Naegeli–Franceschetti–Jadassohn syndrome	AD	Keratin 14	*KRT14*	17q12–q21	161000, 148066
Dowling–Degos disease (including Galli–Galli disease)	AD	Keratin 5	*KRT5*	12q13	179850, 148040
Incontinentia pigmenti	XD	Inhibitor of κ light polypeptide gene enhancer in B cells, kinase γ (nuclear factor-κB essential modulator)	*IKBKG (NEMO)*	Xq28	308300, 300248

Wilson disease	AR	Cu^{2+}-transporting P-type ATPase 7B	*ATP7B*	13q14.3–q21.1	277900, 606882
HYPERLIPIDEMIAS (SEE CH. 92)					
Lipoprotein lipase deficiency (type I hyperlipoproteinemia)	AR	Lipoprotein lipase	*LPL*	8p22	238600, 609708
Apolipoprotein C-II deficiency (type I hyperlipoproteinemia)	AR	Apolipoprotein C-II	*APOC2*	19q13.2	207750, 608083
Familial chylomicronemia (type I hyperlipoproteinemia)	AR	Glycosyl-phosphatidylinositol-anchored high-density lipoprotein-binding protein 1	*GPIHBP1*	8q24.3	612757
Familial hypercholesterolemia (type II hyperlipoproteinemia)	AD AD AD AR	LDL receptor Apolipoprotein B-100, LDL receptor-binding domain Proprotein convertase subtilisin/kexin type 9 Low-density-lipoprotein receptor adaptor protein 1	*LDLR* *APOB* *PCSK9* *LDLRAP1*	19p13.2 2p24 1p34.1–p32 1p36–p35	143890, 606945 144010, 107730 603776, 607786 603813, 605747
Dysbetalipoproteinemia (type III hyperlipoproteinemia)	AR	Apolipoprotein E	*APOE*	19q13.2	107741
Familial hypertriglyceridemia (type IV/V hyperlipoproteinemia)	AD AD	Lipase, member I Apolipoprotein A-V	*LIPI* *APOA5*	21q11.2 11q23	145750, 609252 144650, 145750, 606368
Cerebrotendinous xanthomatosis	AR	Cytochrome P450, subfamily 27A, polypeptide 1 (sterol-27-hydroxylase)	*CYP27*	2q33-qter	213700, 606530
Hypoalphalipoproteinemia	AD AD	Apolipoprotein A-I ATP-binding cassette-1, sub-family A, member 1 (cholesterol efflux regulatory protein)	*APOA1* *ABCA1*	11q23.3 9q31	604091, 107680 604091, 600046
Tangier disease	AR	ATP-binding cassette-1, sub-family A, member 1 (cholesterol efflux regulatory protein)	*ABCA1*	9q31	205400, 600046
Sitosterolemia	AR AR	ATP-binding cassette, sub-family G, member 5 (sterolin 1) ATP-binding cassette, sub-family G, member 8 (sterolin 2)	*ABCG5* *ABCG8*	2p21 2p21	210250, 605459 210250, 605460
PORPHYRIAS (SEE CH. 49)					
Congenital erythropoietic porphyria (Günther disease)	AR	Uroporphyrinogen-III synthase	*UROS*	10q25.2–q26.3	263700, 606938
Hepatoerythropoietic porphyria	AR	Uroporphyrinogen-III decarboxylase	*UROD*	1p34	176100, 613521
Porphyria cutanea tarda§	AD	Uroporphyrinogen-III decarboxylase	*UROD*	1p34	176100, 613521
Hereditary coproporphyria	AD	Coproporphyrinogen oxidase	*CPOX*	3q12	121300, 612732
Variegate porphyria	AD	Protoporphyrinogen oxidase	*PPOX*	1q22	176200, 600923
Erythropoietic protoporphyria	AD	Ferrochelatase	*FECH*	18q21.3	177000, 612386

‡Including cases reported as pigmented hypertrichotic insulin-dependent diabetes mellitus syndrome and familial histiocytosis syndrome.
§Approximately 25% of affected individuals have an underlying *UROD* mutation, often together with additional genetic (e.g. mutations in the *HFE* gene that underlie hemochromatosis) or exogenous (e.g. alcohol, hepatitis C viral infection) factors.

Table 55.8 Hereditary metabolic skin disorders (cont'd).

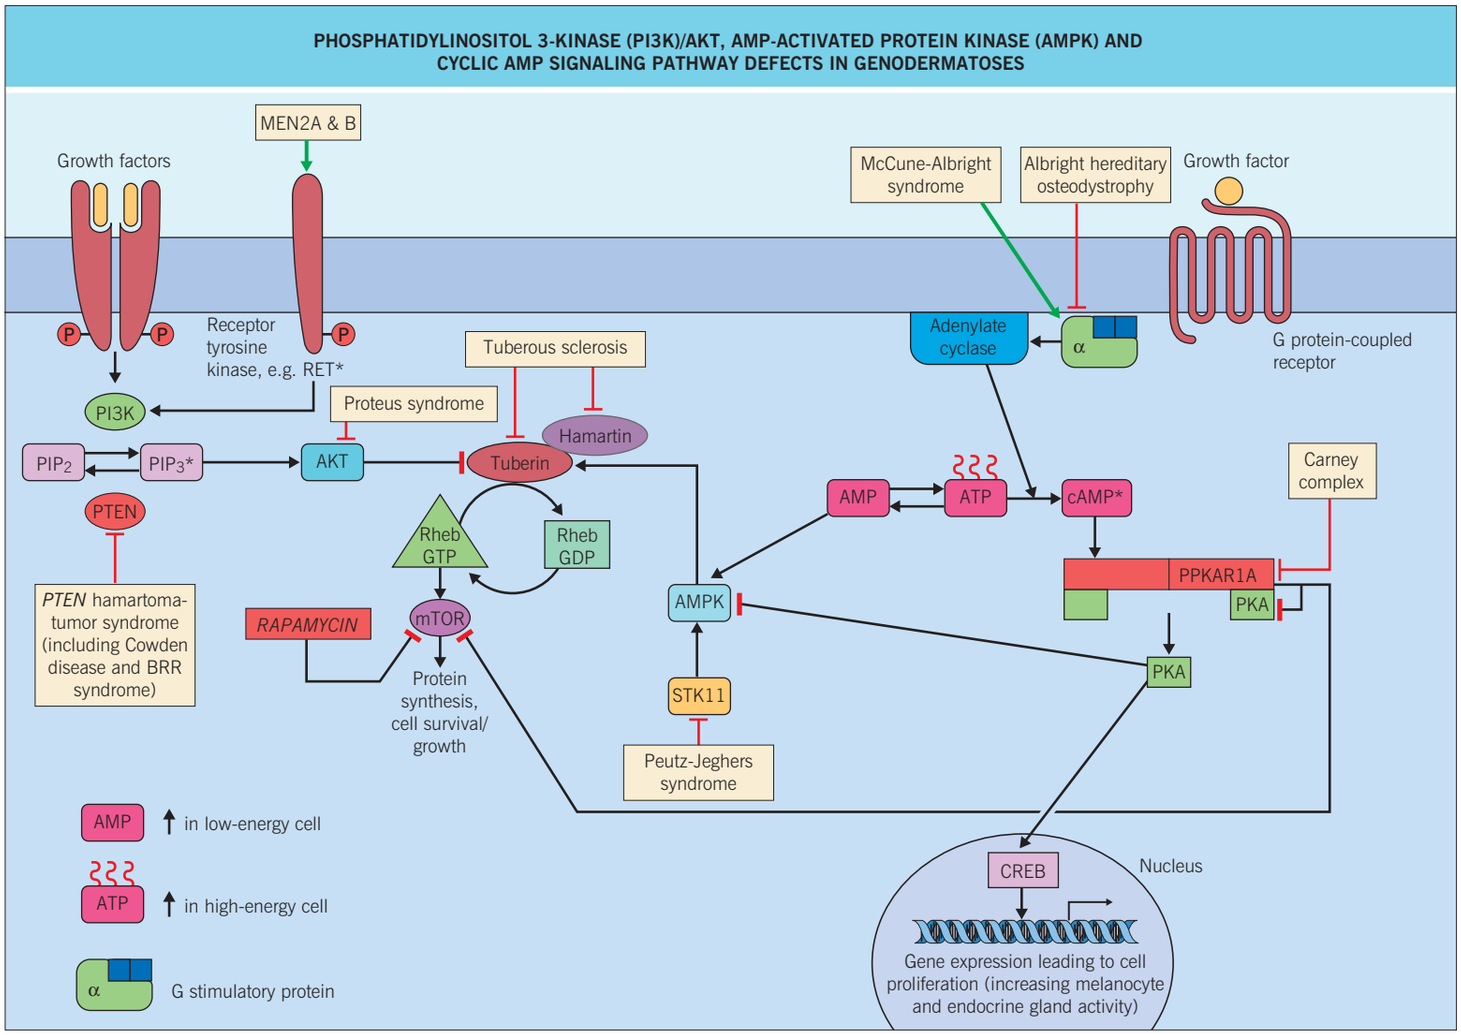

Fig. 55.4 Phosphatidylinositol 3-kinase (PI3K)/AKT, AMP-activated protein kinase (AMPK) and cyclic AMP signaling pathway defects in genodermatoses. The PI3K/AKT pathway is negatively regulated by the PTEN tumor suppressor protein and can be stimulated by a variety of receptor tyrosine kinases as well as by RAS (via cross-talk with the RAS-ERK pathway; see Fig. 55.3). AKT (protein kinase B) inhibits the GTPase activating-protein tuberin, which leads to increased *m*ammalian *t*arget *o*f *r*apamycin (mTOR) activity and resultant cell growth. During periods of nutrient depletion (high AMP/low ATP), serine-threonine kinase 11 (STK11) promotes AMPK-mediated activation of tuberin, which results in decreased mTOR activity and less protein synthesis. Ligand binding to G protein-coupled receptors activates adenylate cyclase, producing increased intracellular cAMP and activation of protein kinase A catalytic subunits (PKA; via release from *p*rotein *k*inase *A* *r*egulatory subunit 1α [PRKAR1A]); this leads to transcription of *c*AMP *r*esponse *e*lement *b*inding protein (CREB)-controlled genes as well as inhibition of AMPK (which is also negatively regulated by AKT). *Other effector pathways include activation of RAS-ERK (see Fig. 55.3). AMP, adenosine monophosphate; ATP, adenosine triphosphate; BRR, Bannayan–Riley–Ruvalcaba; ERK, *e*xtracellular signal-*r*egulated *k*inase; GDP, guanosine diphosphate; GTP, guanosine triphosphate; PIP2, phosphatidylinositol diphosphate; PIP3, phosphatidylinositol triphosphate; PTEN, phosphatase and tensin homolog deleted on chromosome 10.

These disorders are associated with variably increased risks for the development of benign (e.g. neurofibromas in NF1, infantile hemangiomas in CFC syndrome) and malignant (e.g. rhabdomyosarcoma in Costello syndrome) tumors. Targeted drugs aimed at proteins in the RAS-MAPK pathway hold promise for the treatment of sporadic cancers (e.g. BRAF inhibitors for melanoma) as well as RASopathies themselves.

Defects in WNT/β-Catenin Signaling

WNT (*w*ingless-type *int*egration site) family members are lipid-modified, secreted signaling proteins that play important roles in numerous physiologic and pathologic processes, ranging from stem cell differentiation, cell polarity/adhesion and tissue morphogenesis/maintenance (including hair follicle development) to wound repair, inflammation, oncogenesis and aging. WNT signaling can be divided into canonical (β-catenin-dependent) and non-canonical (β-catenin-independent) pathways. Several genodermatoses result from defects in proteins that function in the WNT/β-catenin pathway (Fig. 55.7). Goltz syndrome (focal dermal hypoplasia; see Ch. 62) (Fig. 55.8) is caused by mutations in the *PORCN* gene, which encodes an O-acyltransferase in the endoplasmic reticulum that palmitoylates and thereby facilitates secretion of WNT proteins. Mutations in the *WNT10A* gene produce several relatively common forms of ectodermal dysplasia as well as Schöpf–Schulz–Passarge syndrome (featuring hidrocystomas and palmoplantar keratoderma with eccrine syringofibroadenomatosis). Gardner syndrome (a variant of *a*denomatous *p*olyposis *c*oli) is due to mutations in the *APC* tumor suppressor gene that encodes an inhibitor of WNT/β-catenin signaling[32], and mutations in the APC downregulated 1 gene (*APCDD1*) were recently found to underlie hereditary hypotrichosis simplex. Lastly, anonychia congenita and "palmoplantar keratoderma with cutaneous SCC and sex reversal" are caused by mutations in genes encoding R-spondins that activate WNT/β-catenin signaling.

CONTIGUOUS GENE SYNDROMES

Certain syndromic associations actually represent contiguous gene syndromes caused by large deletions that affect two or more neighboring genes. For example, deletions in the Xp22.3 region can give rise to X-linked recessive ichthyosis, X-linked recessive chondrodysplasia

HEREDITARY SKIN DISORDERS CHARACTERIZED BY BENIGN TUMORS OR VASCULAR ANOMALIES					
Disorder	**Mode of inheritance**	**Gene or gene product**	**Gene symbol**	**Gene locus**	**MIM number(s)**
DISORDERS WITH BENIGN TUMORS (SEE CHS 61, 62, 104, 117 & 118)					
Familial cylindromatosis; Brooke–Spiegler syndrome; multiple familial trichoepitheliomas	AD	CYLD (deubiquitinating enzyme)	*CYLD*	16q12–q13	132700, 601606, 605041, 605018
Familial mastocytosis ± gastrointestinal stromal tumors*	AD	KIT proto-oncogene (stem cell factor receptor)	*KIT*	4q12	606764, 164920

Table 55.10 Hereditary disorders associated with cutaneous cancer. These conditions are discussed in Chapters 79, 87, 99, 108 and 112. ERCC, excision repair cross-complementing; SCC, squamous cell carcinoma; TFIIH, transcription factor IIH.

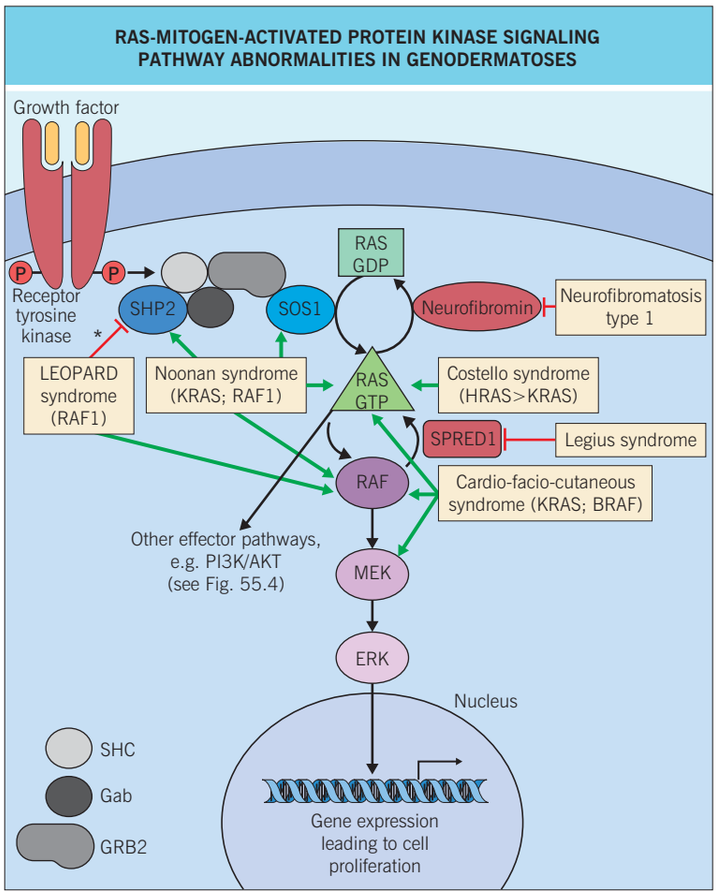

Fig. 55.5 RAS–mitogen-activated protein kinase (MAPK) signaling pathway abnormalities in genodermatoses. The phenotypic overlap among neurofibromatosis type 1 and Legius, Noonan, cardio-facio-cutaneous, Costello and LEOPARD syndromes is explained by underlying germline mutations in different components of the RAS-MAPK pathway that lead to activation of this signaling cascade. Of note, similar *somatic* activating mutations are found in a variety of benign and malignant tumors (e.g. *BRAF* or *NRAS* mutations in the majority of melanocytic nevi and melanomas; see Ch. 113). Growth factor binding to receptor tyrosine kinases results in activated receptor complexes containing adapters such as Src *h*omology 2 (SH2) domain-*c*ontaining (SHC), *g*rowth factor *r*eceptor-*b*ound 2 (GRB2) and *G*RB2-*a*ssociated *b*inding (Gab) proteins as well as SHP2, a SH2 domain-containing non-receptor protein tyrosine phosphatase that relays signals from activated receptors to RAS and deactivates negative regulators of RAS (e.g. Sprouty). The activated receptor complex recruits son of sevenless homolog 1 (SOS1), a guanine nucleotide exchange factor that increases levels of active RAS-guanosine triphosphate (GTP). In contrast, neurofibromin is a GTPase activating protein that promotes hydrolysis of RAS-GTP to RAS-guanosine diphosphate (GDP), which terminates signaling. **In vitro* studies suggest a dominant negative effect, but the consequences could vary depending on the substrate, cell type or developmental stage.

Fig. 55.6 Costello syndrome due to a heterozygous activating *HRAS* mutation in a 3-year-old girl. A Verrucous periorificial (periocular, perinasal) plaques. **B** Loose acral skin with deep palmoplantar creases. Note the distal phalangeal transverse crease on the thumb. **C** Acanthosis nigricans.

punctata, Kallmann syndrome (hypogonadotrophic hypogonadism with anosmia), ocular albinism type 1, short stature and mental retardation. Of note, more than 90% of patients with X-linked recessive ichthyosis have complete deletion of the *STS* gene and flanking sequences, which represents one of the highest incidences of chromosomal deletions among all genetic disorders. Additional genodermatoses that can present as contiguous gene syndromes include Ehlers–Danlos syndrome (due to tenascin-X deficiency) plus congenital adrenal hyperplasia (due to 21-hydroxylase deficiency), tricho-rhino-phalangeal syndrome plus multiple cartilaginous exostoses (together referred to as Langer–Giedion syndrome), and MIDAS (*mi*crophthalmia, *d*ermal *a*plasia and *s*clerocornea) syndrome plus Aicardi syndrome (agenesis of the corpus callosum with a chorioretinal abnormality).

CUTANEOUS MOSAICISM

A mosaic is defined as an organism composed of at least two genetically different populations of cells that originate from a genetically homogeneous zygote (see Ch. 62). As a uniquely accessible organ, the skin provides an excellent opportunity to visualize and study mosaicism, which can present with skin lesions that follow Blaschko's lines or have a checkerboard, phylloid (see below) or lateralized pattern of distribution.

Mosaic forms of autosomal dominant genodermatoses include: (1) a heterozygous postzygotic mutation occurring on a wild-type ("normal") background (type 1); and (2) a postzygotic "second hit" leading to loss-of-heterozygosity in the setting of a heterozygous constitutional mutation (type 2). The latter manifests clinically as a localized area or streaks of more severe disease on a background of milder disease (e.g. linear porokeratosis in a patient with disseminated superficial actinic porokeratosis). Examples of type 1 mosaicism that have been confirmed on a

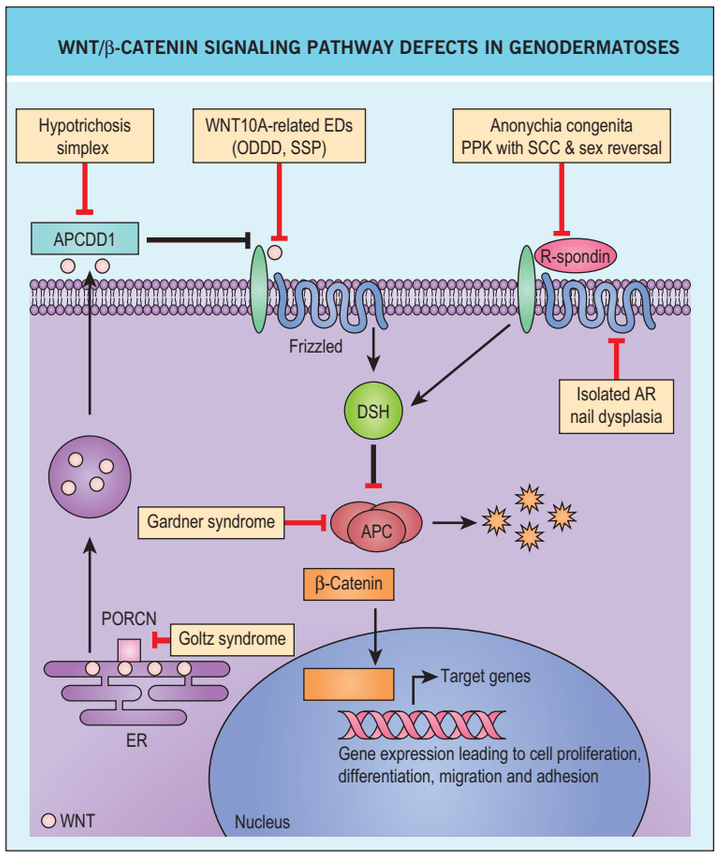

Fig. 55.7 WNT/β-catenin signaling pathway defects in genodermatoses. The porcupine homolog (PORCN) O-acyltransferase in the endoplasmic reticulum (ER) palmitoylates WNT proteins, facilitating their secretion. Extracellular WNT binds to the frizzled transmembrane receptor, which activates dishevelled (DSH), a cytosolic protein that inhibits the "destruction complex" (containing the adenomatous polyposis coli [APC] tumor suppressor protein) that mediates proteasomal degradation of β-catenin. As a result, β-catenin accumulates and is translocated to the nucleus, where it induces the transcription of genes that lead to cell proliferation, differentiation, migration and adhesion. APC downregulated 1 (APCDD1) can inhibit WNT signaling. R-spondins are other secreted proteins that bind to frizzled and activate the WNT/β-catenin pathway. AR, autosomal recessive; EDs, ectodermal dysplasias; ODDD, odonto-onycho-dermal dysplasia; PPK, palmoplantar keratoderma; SCC, squamous cell carcinoma; SSP, Schöpf–Schulz–Passarge syndrome.

Fig. 55.8 Goltz syndrome (focal dermal hypoplasia). **A** Hyperpigmented macules and dermal atrophy with fat "herniation" on the posterior thigh. **B** Raspberry-like papillomas on the lower lip. **C** Ectrodactyly.

molecular level include linear Darier disease *(ATP2A2* mutations), epidermolytic epidermal nevi *(K1* or *K10* mutations) and non-epidermolytic epidermal nevi (fibroblast growth factor receptor 3 *[FGFR3]* mutations); constitutional mutations in the latter gene produce craniosynostosis syndromes associated with severe acanthosis nigricans (Fig. 55.9). On a molecular level, type 2 mosaicism has been documented for Hailey–Hailey disease *(ATP2C1* mutations) (Fig. 55.10), Darier disease (*ATP2A2*), glomuvenous malformations (*GLMN* mutations), and *PTEN* hamartoma tumor syndrome (referred to as "SOLAMEN" [segmental *o*vergrowth, *l*ipomatosis, *a*rteriovenous *m*alformation and *e*pidermal *n*evus] or "Proteus-like" syndrome).

All women and girls are functional mosaics due to the random, irreversible, stably inherited inactivation of one of the two X chromosomes that occurs in each cell during early embryonic development (lyonization). However, 15% of genes on the human X chromosome escape lyonization and 10% are variably inactivated. In women heterozygous for X-linked disorders, functional mosaicism can result in skin lesions that follow Blaschko's lines or have other mosaic distribution patterns. This occurs in female patients with X-linked dominant, male-lethal disorders such as incontinentia pigmenti (*NEMO* mutations), CHILD (*c*ongenital *h*emidysplasia with *i*chthyosiform nevus and *l*imb *d*efects) syndrome (*NSDHL* mutations), Conradi–Hünermann–Happle syndrome (*EBP* mutations) and Goltz syndrome (*PORCN* mutations; see Fig. 55.8) as well as in female "carriers" of X-linked dermatoses such as hypohidrotic ectodermal dysplasia (*EDA* mutations; Fig 55.11) and *i*chthyosis *f*ollicularis-*a*trichia-*p*hotophobia (IFAP) syndrome (*MBTPS2*; Fig. 55.12). The gene encoding steroid sulfatase escapes lyonization, explaining why skin lesions in a mosaic pattern are not observed in female carriers of X-linked recessive ichthyosis.

HEREDITARY SKIN DISORDERS ASSOCIATED WITH EXTRACUTANEOUS CANCER

*Reported in only one patient to date.

Table 55.11 Hereditary skin disorders associated with extracutaneous cancer. These conditions are discussed in Chapters 60, 63, 67 and 87. CNS, central system.

TWIN SPOTTING

Twin spotting (didymosis) is a concept that may explain the coexistence of discrete areas of skin (usually near one another) that differ clinically and genetically from each other and from the background skin. This form of mosaicism can potentially occur in an embryo that has two different mutant alleles at the *same locus* (*allelic*; e.g. one encoding darker and the other lighter pigmentation) or at *nearby loci* (*non-allelic*; both heterozygous, one on each of a pair of homologous chromosomes). In these scenarios, mitotic recombination can give rise to two different homozygous populations of daughter cells that each manifest with a distinct phenotype (Fig. 55.13). Possible examples of *allelic twin spotting* include cutis tricolor (hyperpigmented and hypopigmented spots on background skin with intermediate pigmentation) and vascular twin nevi (port-wine stain and nevus anemicus; see Fig. 55.13), whereas phakomatosis pigmentokeratotica (papular SLN plus sebaceous/"organoid" epidermal nevus) and phakomatosis pigmentovascularis (see Table 104.4) may reflect *non-allelic twin spotting*.

REVERTANT MOSAICISM

Revertant mosaicism is a means of "natural gene therapy" in which a spontaneous secondary genetic phenomenon leads to rescue of a disease-causing mutation, allowing a mosaic clone of heterozygous cells to regain wild-type ("normal") function[33]. It has been described most often in patients with EB (see Ch. 32), potentially explaining the tendency of some forms of this condition to improve with age. A growth

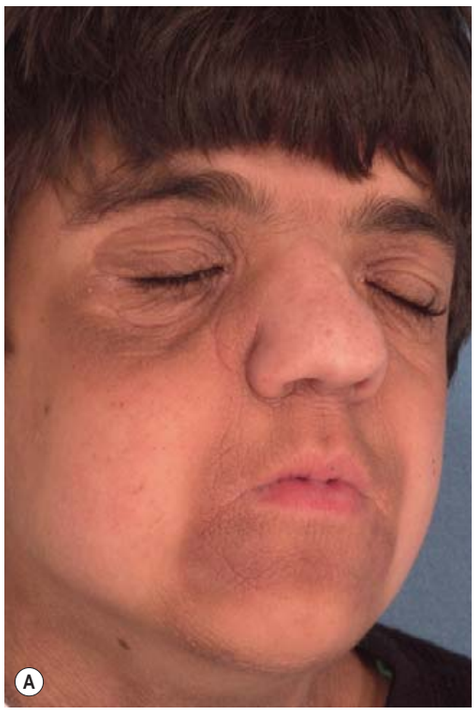

Fig. 55.9 Skin disease due to fibroblast growth factor receptor 3 (FGFR3) defects. **A** Severe acanthosis nigricans in a patient with the Crouzon craniosynostosis syndrome. **B** Systematized epidermal nevus in a young boy who had developmental delay. These conditions can be caused by germline and mosaic *FGFR3* mutations, respectively. *A, Courtesy, Seth J Orlow, MD, PhD.*

Fig. 55.10 Type 2 segmental Hailey–Hailey disease. This 7-year-old girl had a history of recurrent blistering on the right abdomen, groin and thigh since infancy.

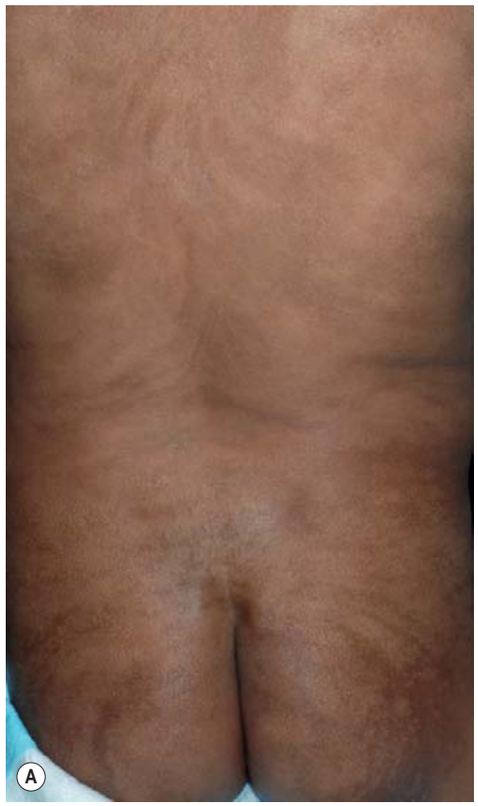

Fig. 55.11 Female "carriers" of X-linked hypohidrotic ectodermal dysplasia. **A** The skin within hyperpigmented streaks and swirls following Blaschko's lines is slightly depressed and very smooth, in contrast to follicular prominence in the surrounding areas. Starch-iodine testing on the back disclosed a patchy distribution of active sweat glands. This 2-year-old girl also had whorled areas of sparse hair on the posterior scalp and several cone-shaped teeth. **B** A color thermogram demonstrates an asymmetric distribution of skin temperature on the anterior trunk. *B, From Clark RP, Goff MR, MacDermot KD. Identification of functioning sweat pores and visualization of skin temperature patterns in X-linked hypohidrotic ectodermal dysplasia by whole body thermography. Hum Genet. 1990;86:7–13.*

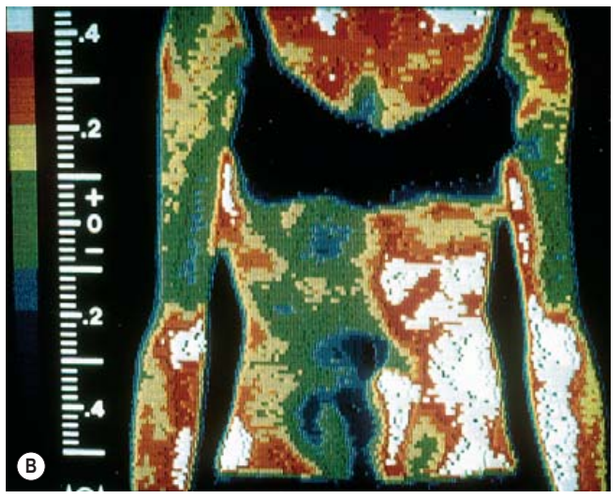

advantage and selective pressures (e.g. blistering) may help to increase the number of revertant cells over time. Recently, revertant mosaicism via mitotic recombination was found to account for the numerous small "islands" of normal skin in a background of ichthyosiform erythroderma that characterize ichthyosis en confetti[34]. Affected individuals have specific frameshift mutations in the *KRT10* gene, which produce mutant proteins with an arginine-rich C-terminus that redirects them to the nucleolus; this mislocalization may have a role in promoting the reversion.

CHROMOSOMAL DISORDERS

Chromosomal disorders represent abnormalities in the number or structure of chromosomes. Aneuploidy refers to having an additional or missing chromosome; examples that are compatible with postnatal survival include complete trisomies for chromosomes 21 (Down syndrome; Fig. 55.14), 18 (Edwards syndrome) and 13 (Patau syndrome) as well as monosomy for the X chromosome (Turner syndrome) and XXY (Klinefelter syndrome) or XYY karyotypes.

Table 55.12 Other inherited skin disorders (cont'd).

Fig. 55.12 Ichthyosis follicularis with atrichia and photophobia (IFAP) syndrome. Note the confluent psoriasiform plaques on the scalp.

Mosaic aneuploidies or partial trisomies and monosomies due to duplications, deletions or translocations of portions of chromosomes can also occur. The cutaneous and extracutaneous features of several relatively common chromosomal disorders are presented in Table 55.13.

Phylloid hypomelanosis, characterized by leaf-like hypopigmented patches (Fig. 55.15), usually results from mosaic trisomy 13. In contrast, hypomelanotic streaks and swirls that follow Blaschko's lines (so-called "hypomelanosis of Ito") can be caused by mosaicism for a wide variety of chromosomal aberrations (see Ch. 62).

INSIGHT INTO ACQUIRED SKIN DISORDERS PROVIDED BY THE STUDY OF GENODERMATOSES

Inherited monogenic skin disorders can serve as models to improve our understanding of the pathogenesis of common acquired skin diseases. For example, basement membrane proteins that are defective in JEB (e.g. type XVII collagen [bullous pemphigoid antigen 2], laminin 332 [5] subunits) and dystrophic EB (type VII collagen) are also targeted in autoimmune blistering diseases such as bullous pemphigoid, mucous membrane (cicatricial) pemphigoid, and EB acquisita (see Ch. 28). In addition, the excessive granulation tissue that develops due to a truncated laminin α3 subunit in patients with laryngo-onycho-cutaneous syndrome has provided clues to the role of this protein in regulating

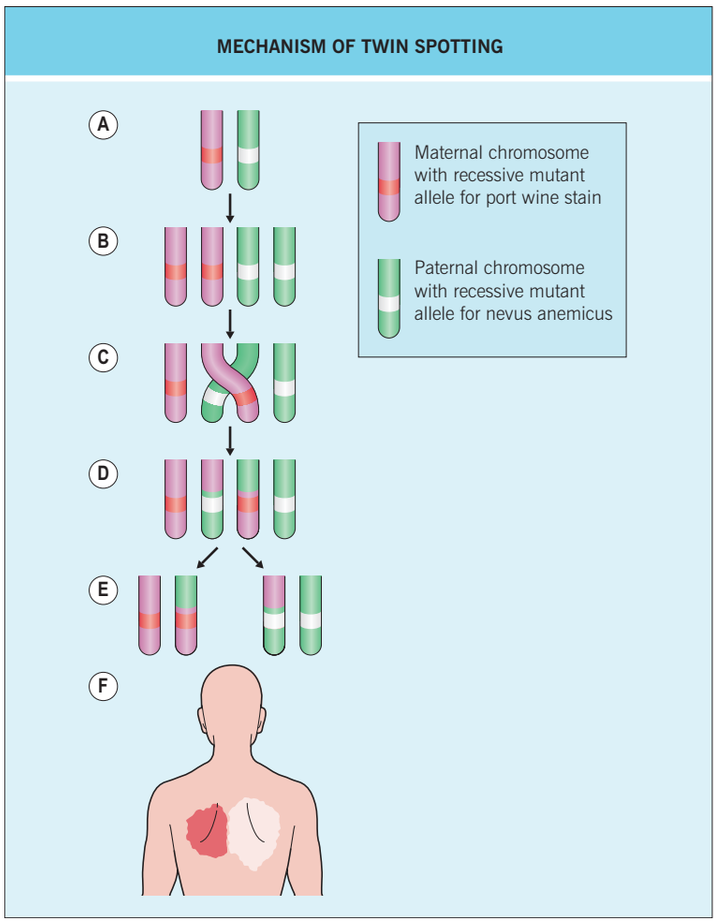

Fig. 55.13 Mechanism of twin spotting. This embryo has two different recessive mutant alleles at a *single locus* (the background of *allelic* twin spotting) that encodes a protein affecting the cutaneous vasculature. **A** The pair of homologous chromosomes containing this locus. **B** Semiconservative replication during mitosis. **C** Crossing over occurs, with exchange of the region carrying the two mutations. **D** As a result, each duplicated chromosome is composed of two different chromatid segments distal to the point of crossing over. **E** Random assortment of the chromatids during mitosis may result in two different daughter cells that are each homozygous for one of the mutations. **F** Population of the skin by these two lineages leads to a port wine stain adjacent to a nevus anemicus. The same phenomenon could occur with two different recessive mutant alleles at *neighboring loci* (both heterozygous), one on each of a pair of homologous chromosomes (the background of *non-allelic* twin spotting). Of note, gene conversion (where the "donating" chromosome is unchanged) occurs more frequently than mitotic crossing over.

Fig. 55.14 Cutaneous manifestations of Down syndrome (trisomy 21). **A** Full lips with cheilitis and a protruding, fissured tongue. **B** Multiple facial syringomas.

Fig. 55.15 Phylloid hypomelanosis due to mosaic trisomy 13. This condition is characterized by leaf-like and oblong patches of hypopigmentation in a pattern reminiscent of a floral ornament. *Courtesy, Arne König, MD, and Rudolf Happle, MD.*

angiogenesis and granulation tissue formation during normal wound healing. Likewise, observation of similar dermal hyalinization in the rare genodermatosis lipoid proteinosis and lichen sclerosus led to the discovery of autoantibodies against extracellular matrix protein 1, the protein that is defective in the former disorder, in the majority of patients with lichen sclerosus[35].

Loss-of-function variants in the gene that encodes filaggrin (the protein that aggregates keratin filaments during keratinocyte terminal differentiation; see Ch. 56) not only cause ichthyosis vulgaris but also represent a major predisposing factor for atopic dermatitis, with a significantly higher prevalence (20–50%) in individuals with atopic dermatitis compared to the general population (<5–10%). Defective filaggrin also represents a predisposing factor for asthma, but specifically that occurring in individuals with pre-existing atopic dermatitis. Barrier dysfunction due to abnormalities in the serine protease inhibitor (SPINK5) involved in Netherton syndrome may also play a role in the pathogenesis of atopic dermatitis, and polymorphisms in the *SPINK5* gene have been shown to be associated with this common acquired skin disease.

SKIN FINDINGS ASSOCIATED WITH CHROMOSOMAL ABERRATIONS				
Disorder	**Chromosomal aberration**	**Mucocutaneous anomalies**	**Extracutaneous anomalies**	**Comments**
Turner syndrome	45, XO	Congenital lymphedema (usually resolves by age 2 years), low posterior hairline, numerous melanocytic nevi, small hyperconvex nails, tendency to form keloids	Short stature, webbed neck, "shield-like" chest with widely spaced nipples, absence of sexual development, cardiovascular defects, renal malformations, sensorineural hearing loss, autoimmune hypothyroidism	Mosaicism (e.g. 45, XO/46, XX or 45, XO/46, XY) in ~40% of patients
Klinefelter syndrome	47, XXY	Varicose veins, leg ulcers	Tall stature, gynecomastia, small testes, infertility	Mosaicism 46, XY/47, XXY in ~20% of patients; uncommon variants include 48, XXXY and 48, XXYY
Trisomy 21 (Down syndrome)	47, XY, +21 47, XX, +21	Single palmar crease, protruding scrotal tongue, cheilitis (see Fig. 55.14A), multiple syringomas (often with calcification; see Fig. 55.14B), alopecia areata, ichthyosiform hyperkeratosis, keratosis pilaris, milia-like calcinosis cutis, elastosis perforans serpiginosa, multiple collagenomas, cutis marmorata/acrocyanosis; a predisposition to developing folliculitis, dermatophyte infections and Norwegian scabies; vesiculopustular eruptions associated with neonatal transient myeloproliferative disorder	Brachycephaly, characteristic facial appearance (e.g. epicanthal folds, flat nasal bridge), Brushfield spots (speckled irides), broad hands, brachydactyly, atlantoaxial instability, mental retardation, immunodeficiency, congenital heart defects, duodenal atresia, leukemia (especially acute myeloid leukemia), hearing loss, autoimmune hypothyroidism	
Phylloid hypomelanosis (see Fig. 55.15)	Mosaic trisomy 13	Round, oval or oblong hypopigmented macules resembling floral ornaments	Absence of corpus callosum, retinal coloboma, craniofacial defects, brachydactyly, clinodactyly, camptodactyly, conductive hearing loss	
Pallister–Killian syndrome	Mosaic tetrasomy 12p (isochromosome 12p)	Hypopigmented streaks and swirls following Blaschko's lines; fine, sparse hair during infancy	Postnatal growth deficiency, characteristic facies (anteverted nostrils, down-turned mouth with thin upper lip), mental retardation	

Table 55.13 Skin findings associated with chromosomal aberrations.

PRENATAL AND PREIMPLANTATION GENETIC DIAGNOSIS

In the past, prenatal diagnosis was based on techniques such as ultrastructural and immunohistochemical analysis of fetal skin biopsy specimens obtained between 18 and 22 weeks' gestational age (GA). Today, such methods have been largely replaced by DNA-based testing that is less invasive and more reliable. The diagnosis of genodermatoses for which the molecular basis is known can be established prenatally by performing chorionic villus sampling (at 10–12 weeks' GA) or amniocentesis (at 14–16 weeks' GA) and analyzing fetal DNA (after determining the underlying genetic defect in family members)[36]. Non-invasive prenatal diagnostic techniques that utilize fetal cells or cell-free genetic material from the maternal circulation are being developed and may become standard practices in the future[37]. Preimplantation genetic diagnosis can also be performed for a variety of severe genetic skin diseases. This involves analysis of DNA from single cells (blastomeres) extracted from late cleavage stage embryos following *in vitro* fertilization[38]. In this way, knowing the genetic bases of heritable skin conditions may be of tremendous value to affected families.

TREATMENT FOR HEREDITARY SKIN DISORDERS

Gene Therapy

The accessibility of the skin makes it an excellent target for gene therapy. Although the routine application of this treatment modality is not currently possible, steps have been taken to study its feasibility, particularly in patients with EB. For example, *ex vivo* gene therapy led to full functional correction of the skin fragility phenotype (stable after a several-year follow-up period) in a man with JEB due to *LAMB3* mutations, demonstrating for the first time successful gene therapy for a disease of solid tissue[38]. The technique that was utilized involved retroviral-mediated transduction of autologous epidermal stem cells with a wild-type copy of the *LAMB3* gene, followed by reconstitution of the patient's skin on the anterior thighs with epithelial sheets grown from the genetically corrected cells. A disadvantage of this *ex vivo* approach is the relatively small surface area that can be treated with each graft. Possible delivery methods to surmount the epidermal barrier in order to perform *in vivo* gene transfer into the skin include utilization of viral vectors as well as direct injection of naked plasmid DNA, microinjection of DNA, electroporation and lipofection of DNA-lipid complexes. However, limited long-term stability of the transferred genes represents a potential problem.

There are serious safety concerns regarding the use of retroviral vectors for gene therapy because of their uncontrolled insertion into the human genome[39]. Several patients with X-linked severe combined immunodeficiency who were treated with retroviral-mediated *ex vivo* gene transfer developed T-cell leukemias related to activation of a proto-oncogene via integration of the retroviral vector into its 5′ untranslated region. This has led to protocol modifications and investigation of alternative approaches such as use of other vectors based on lentiviruses (which tend to integrate into transcribed regions of genes).

For gene therapy of dominant-negative keratin disorders such as EBS and pachyonychia congenita, another strategy is to use small interfering RNA to specifically "knock down" expression of the mutant keratin.

Cell Therapy

Systemic administration of either genetically corrected autologous fibroblasts or the collagen VII protein has been shown to result in the appearance of this collagen in the basement membrane zone of wounded skin (with subsequent healing) in a mouse model of recessive dystrophic EB (RDEB). In patients with RDEB, intradermal injections of allogeneic fibroblasts have been found to result in the generation of new collagen VII and anchoring fibrils at the dermal–epidermal junction[40,41]. A systemic approach to cell therapy that has shown some promise for RDEB is transplantation of bone marrow-derived allogeneic stem cells following total or partial myeloablation. In an initial report, this resulted

in the sustained presence of donor cells in the skin, increased deposition of collagen VII at the dermal–epidermal junction, and variably decreased blistering in children with RDEB[42].

Therapy Targeting Affected Molecular Signaling Pathways

Loss-of-function mutations in different tumor suppressor genes that negatively regulate the mammalian target of rapamycin (mTOR) signaling pathway (which stimulates cell growth/proliferation when activated) underlie several hamartoma syndromes, including tuberous sclerosis, the PTEN hamartoma tumor syndrome, and Peutz–Jeghers syndrome (see Fig. 55.4). Recognition of the mTOR overactivation common to these disorders has led to successful treatment of affected individuals with the mTOR inhibitors rapamycin (sirolimus) and everolimus. For example, use of these agents in patients with tuberous sclerosis has resulted in regression of subependymal giant cell astrocytomas, renal angiomyolipomas, pulmonary lymphangioleiomyomatosis and (with topical as well as oral therapy) facial angiofibromas[43].

This illustrates how understanding the molecular pathway that is affected in a group of genodermatoses can translate into effective therapy. Another example of molecular advances resulting in novel approaches to treatment is targeted therapy of plexiform neurofibromas via inhibition of KIT signaling by imatinib mesylate upon recognition of the critical role of activated mast cells in the tumor microenvironment to neurofibroma formation in NF1.

Chapter Contents

The epidermis: structure and function 825
Keratin intermediate filaments 827
Epidermal differentiation 830
Keratinocyte adhesion 831
Keratinocyte–matrix interactions 834
Related diseases 834

Key features

- The epidermis functions as a barrier that provides protection against harmful substances and water loss
- Through a complex terminal differentiation program, the progeny of epidermal stem cells undergo molecular and biochemical changes that generate the morphologically different strata of the epidermis
- Keratinocyte terminal differentiation culminates in the replacement of the plasma membrane with the cornified cell envelope
- Keratin intermediate filaments, which are expressed by keratinocytes in a differentiation-specific manner, are required to maintain epidermal integrity and have additional roles in the regulation of basic cell functions
- Desmosomes, which integrate the keratin cytoskeleton into the cell membrane and establish adhesive points between opposing cells, are necessary for epidermal stability and stress resistance; these cell–cell junctions also function as signaling centers in epidermal morphogenesis and homeostasis
- Other cell–cell junctions that are found in keratinocytes include adherens junctions and tight junctions
- A variety of inherited skin diseases are caused by a failure of normal epidermal differentiation and function

INTRODUCTION

The main function of the epidermis is to provide a barrier between the organism and the environment. This barrier is the result of a complex terminal differentiation program in which the progeny of epidermal stem cells undergo a series of molecular and biochemical changes that lead to generation of the morphologically different strata of the epidermis (Fig. 56.1). This chapter reviews key signaling pathways that control this terminal differentiation program, with discussion of inherited skin diseases that are caused by a failure of normal epidermal differentiation.

THE EPIDERMIS: STRUCTURE AND FUNCTION

The epidermis, the outermost layer of the skin, functions as a barrier that provides the organism with protection against harmful substances and water loss. This barrier function is established during embryogenesis and maintained in mature epidermis through a continuous program of self-renewal. This self-renewal is mediated by epidermal stem cells, which are located in the basal layer of the interfollicular epidermis as well as in the bulge region of hair follicles (see Ch. 2). Although either of these stem cell types can regenerate both epidermal and hair follicle lineages in response to injury, under homeostatic conditions they only contribute to their own lineage. Through asymmetric cell division, interfollicular epidermal stem cells give rise to a daughter stem cell and a transit amplifying cell. Transit amplifying cells undergo a few cell divisions before beginning a terminal differentiation program, which is associated with an irreversible withdrawal from the cell cycle. Such committed cells detach from the basement membrane and move suprabasally, a process that is mediated by the inactivation of integrins, extracellular matrix receptors that anchor basal cells to the basement membrane (see Ch. 28). Newly formed spinous keratinocytes thus occupy the first suprabasal layer of the epidermis.

Keratinocyte terminal differentiation culminates in the replacement of the plasma membrane with the *cornified cell envelope* (CE), a composite of several covalently cross-linked proteins (Fig. 56.2)[1], most of which are encoded by genes located in the epidermal differentiation cluster on chromosome 1. Examples of CE components include

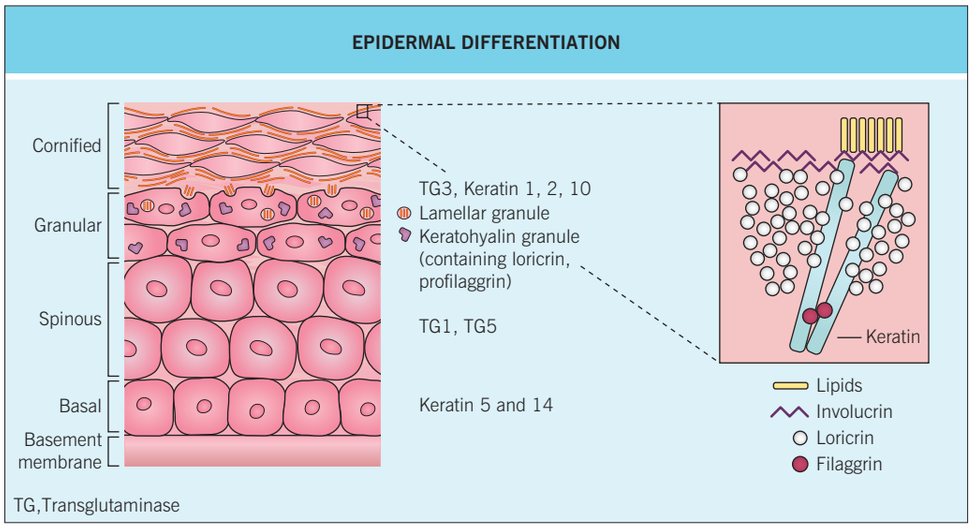

Fig. 56.1 Epidermal differentiation. As keratinocytes are transformed from mitotically active cells in the basal layer to fully differentiated, enucleated squames in the cornified layer, specific proteins are expressed at particular locations within the epidermis. Keratohyalin (profilaggrin- and loricrin-containing) and lamellar (lipid-containing) granules extrude their contents in the granular layer, leading to bundling of keratin filaments and replacement of the plasma membrane with the highly cross-linked, lipid-covered cornified cell envelope (see insert and Fig. 56.2). *Courtesy, Julie V Schaffer, MD.*

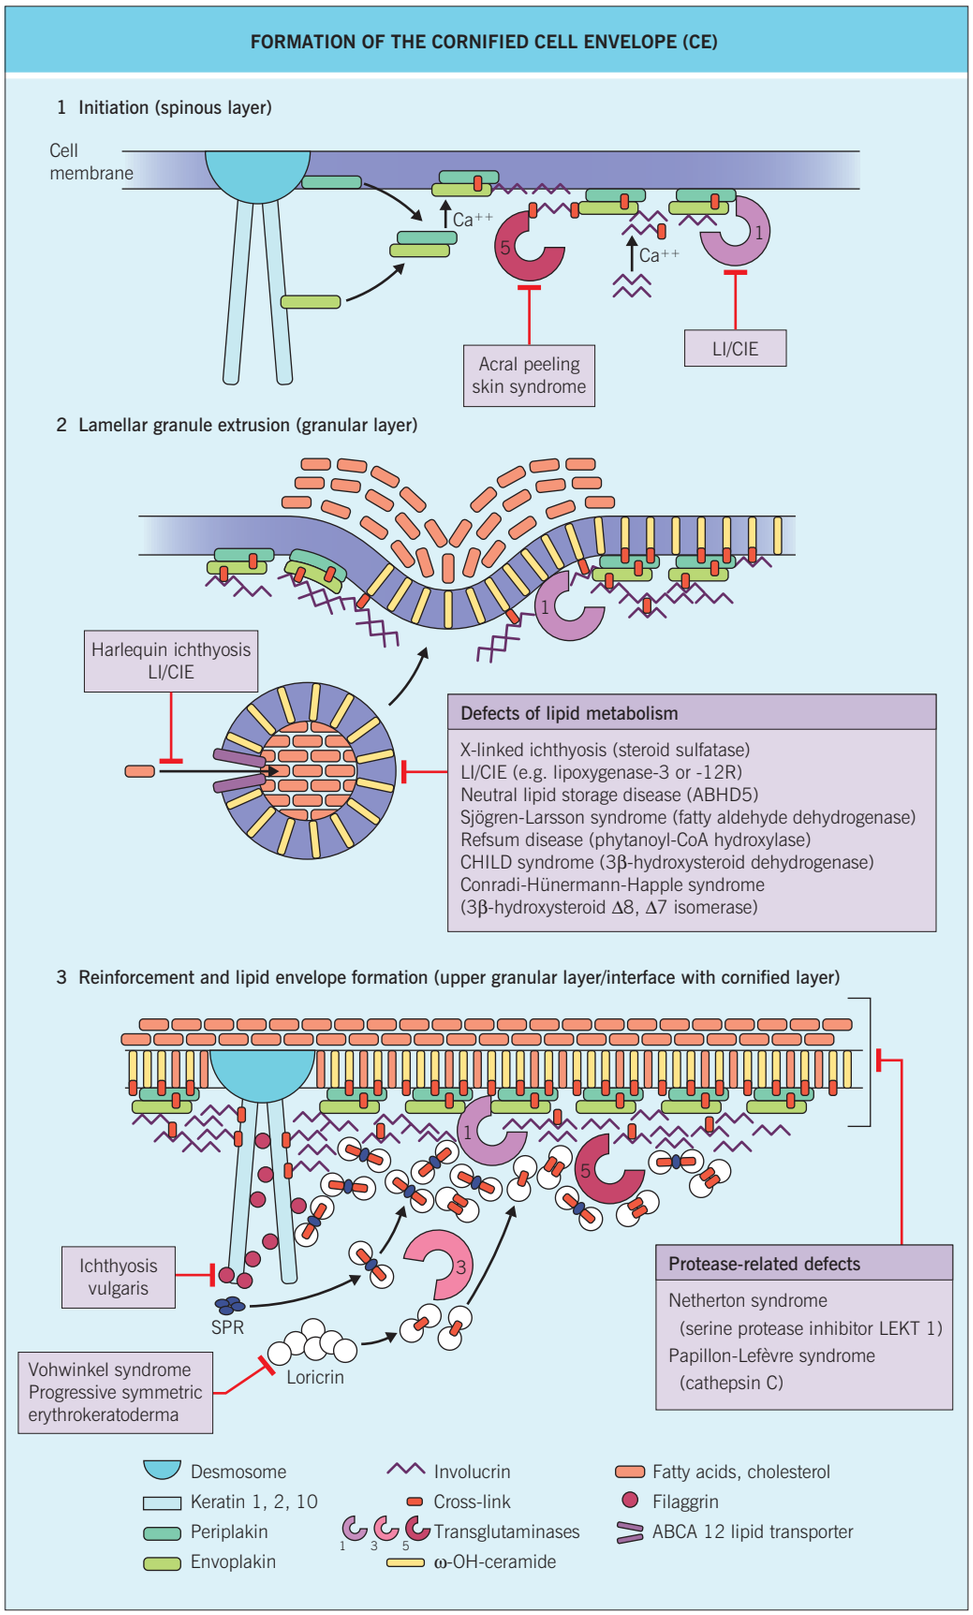

Fig. 56.2 Formation of the cornified cell envelope (CE). Terminal differentiation of keratinocytes is triggered by an increase in the intracellular Ca^{2+} concentration of the suprabasal epidermis. CE assembly is initiated in the upper spinous layer via formation of a cross-linked scaffold composed of envoplakin, periplakin and involucrin along the inner surface of the cell membrane (**1**). This is followed by (or perhaps coincident with) extrusion of lamellar granules into the extracellular space (**2**). Specialized ω-hydroxyceramides are delivered to and eventually replace the cell membrane, where they become linked to scaffold proteins. Reinforcement occurs via cross-linking and translocation to the cell periphery of loricrin (which accounts for >80% of the mass of the CE) and small proline-rich proteins (SPRs) (**3**). Complexes of keratin and filaggrin also become cross-linked to the CE. In addition, proteases play important roles in processing of CE proteins and the proteolysis of corneodesmosomes that is required for desquamation. A mature, terminally differentiated cornified cell thus consists of keratin filaments covalently attached to the CE, which is composed of protein and lipid envelope components and imbedded in extracellular lipid lamellae. Defects in transglutaminases, lipid metabolism, CE structural proteins and proteases lead to a variety of diseases characterized by ichthyosis and/or keratoderma (**1–3**). CHILD, congenital *h*emidysplasia with *i*chthyosiform erythroderma and *l*imb *d*efects; LI, lamellar ichthyosis; CIE, congenital ichthyosiform erythroderma. *Courtesy, Julie V Schaffer, MD.*

involucrin, small proline-rich proteins (SPR), XP-5/late envelope proteins (LEP), loricrin, cystatin, envoplakin, periplakin, elafin, repetin, filaggrin, S100 proteins, keratins and desmosomal proteins. Note that mutations in some of the genes that encode these proteins can lead to skin disorders. For example, mutations in the loricrin and filaggrin genes give rise to palmoplantar keratoderma (PPK) and ichthyosis vulgaris (see below), respectively.

The extracellular surface of the CE is covered by lipids, which form the *cornified lipid envelope* (CLE) (see Ch. 124). Keratinocytes that have assembled the CE/CLE and that have lost their nucleus and cell organelles are termed corneocytes. These cell remnants constitute the stratum corneum, which serves to cover the body surface of terrestrial mammals.

Both the CE and the CLE are required for establishing a cutaneous water barrier. Failure or impairment of the water barrier leads to increased transcutaneous water loss and an increased susceptibility to infections, a major problem in premature infants, and disorders such as Netherton syndrome.

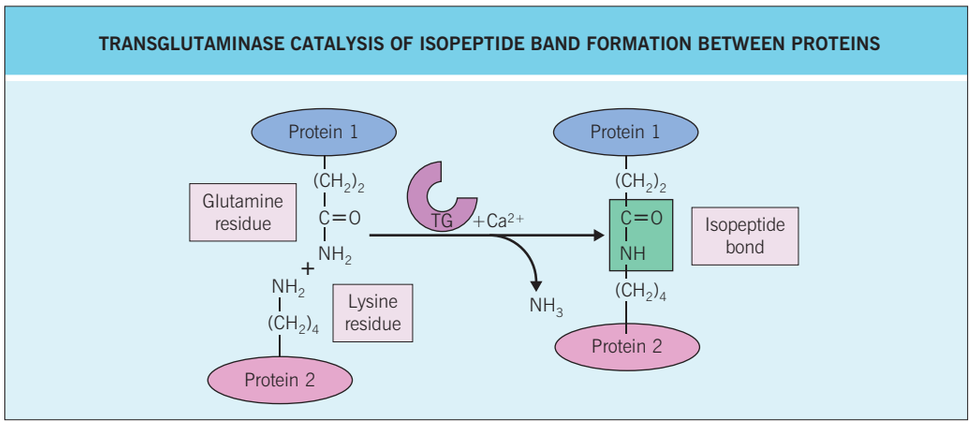

Fig. 56.3 Transglutaminase catalysis of isopeptide bond formation between proteins. Transglutaminases (TGs) are calcium-dependent enzymes that catalyze the formation of γ-glutamyl lysine isopeptide bonds between proteins. TGs also have a role in the creation of ester bonds between proteins and ω-hydroxyceramides. Such cross-linking is essential for assembly of the CE. Four TGs are expressed in the epidermis: TG1 (keratinocyte TG; membrane-bound), TG2 (tissue TG; basal layer), TG3 (epidermal TG; hair follicle and terminally differentiating keratinocytes) and TG5 (upper epidermis). *Courtesy, Julie V Schaffer, MD.*

CE assembly begins within the upper spinous and granular cell layers, where a growing list of proteins is chemically cross-linked, primarily by ε-(γ-glutamyl) lysine isopeptide bonds (Fig. 56.3). This reaction is catalyzed by a class of enzymes termed transglutaminases (TGases). Loss-of-function mutations in the gene that encodes TGase 1 lead to lamellar ichthyosis and congenital ichthyosiform erythroderma, generalized skin disorders resulting from a failure to form proper CEs.

Because the CE is highly resistant to chemical attack, very harsh conditions (e.g. boiling the epidermal cells in buffers containing high concentrations of detergents) are required to isolate and purify CE proteins. One surprising finding is that a loss of *individual* CE components in knockout mice does not necessarily have a major impact on barrier function. One possible explanation for this unexpected result is the presence of compensatory gene regulatory pathways that maintain barrier function even in the absence of major CE components[2]. Better characterization of these regulatory pathways will provide insights into how the barrier is established and maintained, hopefully leading to the development of new strategies for the treatment of diseases caused by impaired barrier function (see Ch. 124).

KERATIN INTERMEDIATE FILAMENTS

Keratin intermediate filaments provide resilience to keratinocytes, the most abundant cell type in the epidermis. Keratins represent the largest group of intermediate filament proteins (Table 56.1), with more than 50 individual members. Based upon their biochemical properties (e.g. isoelectric point, molecular weight), keratins are classified as either type I (K9–K28, K31–K40) or type II (K1–K8, K71–K86) (Table 56.2). Type I and type II keratins form obligatory heteropolymers (i.e. pairs composed of one keratin from each group) that become the basic building blocks of epithelial intermediate filaments (Fig. 56.4). The continuing identification of novel keratin genes plus the increasing number of keratins that have been recognized in mammalian species other than mice and humans made it necessary to revise the keratin nomenclature[3] (see Table 56.2). The new classification system divides the 54 human keratin genes into three categories: (1) epithelial keratin genes; (2) hair keratin genes; and (3) keratin pseudogenes.

Keratins have a common domain structure that they share with other intermediate filament proteins[4]. The central α-helical rod domain consists of 310 amino acid residues and is divided into four segments (1A, 1B, 2A, 2B), which are interrupted by three non-helical segments of variable lengths, termed linkers (Fig. 56.5). The rod domain is composed of seven-residue amino acid sequence repeats $(a\text{-}b\text{-}c\text{-}d\text{-}e\text{-}f\text{-}g)_n$ termed "heptad repeats", where positions "a" and "d" represent hydrophobic residues that are considered crucial for stabilization of the heterodimer. In the middle of the 2B domain, the heptad pattern is interrupted, giving rise to the "stutter". This helical segment is highly conserved among intermediate filaments and does not participate in the formation of the coiled-coil dimer that forms the basic building block of intermediate filaments (see Fig. 56.4).

The beginning and end of the α-helical rod domain, referred to as the helix initiation and helix termination motifs, are highly conserved among the different keratins and play a pivotal role in keratin intermediate filament assembly (e.g. filament elongation). These helix boundary peptides represent genetic "hot spots" for mutations in many of the hereditary keratin disorders (see Fig. 56.5). The severity and other phenotypic features of genodermatoses caused by a keratin defects often correlate with the position of the underlying mutation, with more severe disease resulting from mutations in the helix initiation and termination motifs (see Table 56.5).

The head and tail regions that flank the rod domain are subdivided into extreme end (E), variable (V) and (in type II keratins) homologous (H) domains. Whereas epithelial keratins possess glycine- and serine-rich head and tail domains, these regions have a high content of cysteine and proline in hair keratins. Variations in the head and tail domains account for much of the diversity among different keratin proteins, which suggests that these domains play an important role in cell type-specific functions.

Keratins and Signaling

Keratins are markers for keratinocyte differentiation and are required to maintain epidermal integrity. However, intermediate filaments may also influence other basic cell functions, such as cell cycle progression, metabolic activity and apoptosis. The mechanisms by which keratins regulate these processes are not well understood. However, accumulating evidence suggests that intermediate filaments can bind signaling proteins, thereby controlling the cytoplasmic and, indirectly, nuclear pools of these molecules[5–9]. Interestingly, deletion of the entire type II keratin gene cluster from the mouse genome (which completely prevented the assembly of keratin intermediate filaments) resulted in an early embryonic lethal phenotype associated with growth retardation and defects in yolk sac hematopoiesis and vasculogenesis, underscoring the importance of keratins to cellular signaling and differentiation of a non-epithelial cell lineage[10].

Hair Keratins

The mature hair is the differentiation product of trichocytes and is found within the central core of the hair follicle. The anagen (growing) follicle is a complex structure consisting of eight distinct, concentrically arranged cell layers (see Ch. 68). The innermost compartment is the hair shaft, which is composed of a medulla, cortex and one-layered cuticle; the latter serves as a protective coat for the hair shaft. The innermost living cell layer of the hair follicle (which surrounds the growing hair shaft) is the inner root sheath (IRS); it consists of the IRS cuticle as well as Huxley and Henle layers. The outermost compartment is the outer root sheath (ORS), which is continuous with the interfollicular epidermis. The companion layer is located between the IRS and the ORS.

The medulla contains a mixture of epithelial (K17, K75) and hair keratins (K33, K34, K36, K37, K81), whereas the cortex contains type I hair keratins (K31–K38) and type II hair keratins (K81, K83, K85 and K86) (Fig. 56.6). Hair keratins K32 and K35 and their partners K82 and K85 are found in the cuticle, and the three IRS layers can be detected with antibodies against K71, K74 and K73. The epithelial keratins K5 and K14 are found throughout the full thickness of the ORS, while expression of K6, K16 and K17 is limited to the isthmus and the lower ORS. Additional keratins expressed in the ORS are K15 and K19.

ALIGNMENT AND ASSEMBLY OF KERATIN MOLECULES AND KERATIN FILAMENT PACKING

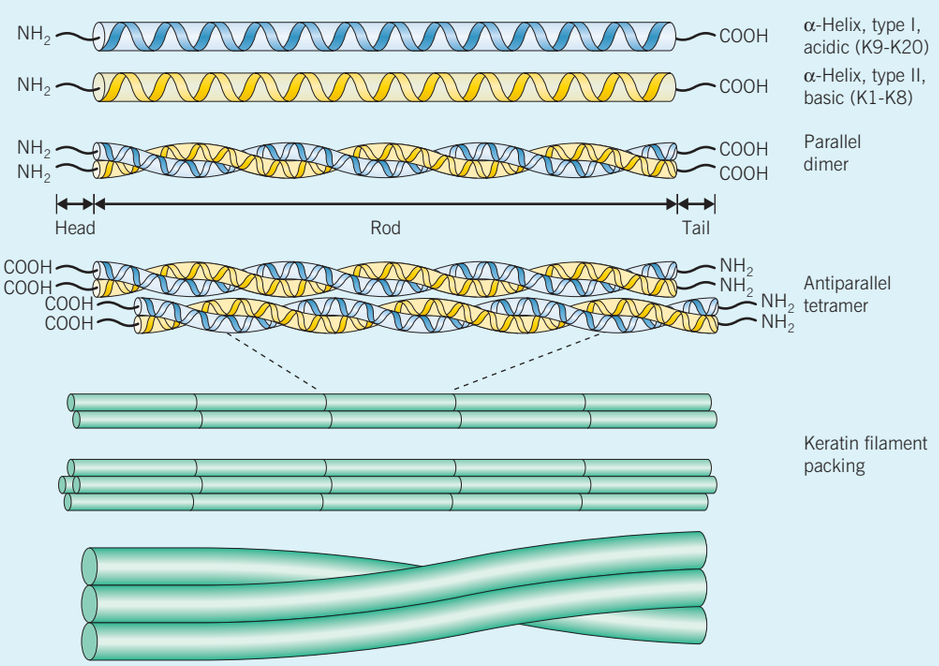

Fig. 56.4 Alignment and assembly of keratin molecules and keratin filament packing. Intermediate filament assembly takes place in several stages and begins with the heterodimerization of one type I and one type II keratin protein in a coiled-coil fashion. Two heterodimers then associate to form a tetramer. Lateral aggregation of tetramers yields higher-order polymers which eventually make up the filament network of the keratinocyte. *Courtesy, Julie V Schaffer, MD.*

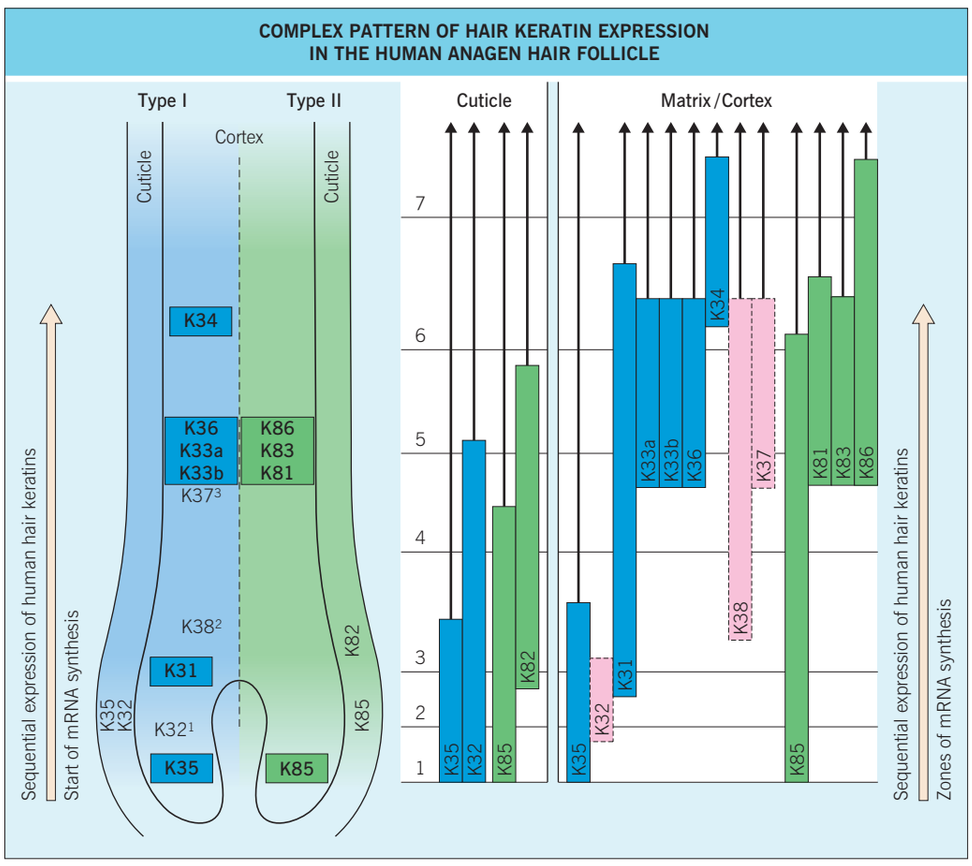

Fig. 56.6 Complex pattern of hair keratin expression in the human anagen hair follicle. Major type I hair keratins are in blue, and major type II hair keratins are in green. Minor hair keratins are in pink. [1]This protein is weakly expressed at this site. [2]To date, expression of this protein has only been detected in single cortex cells. [3]To date, this protein has only been detected in vellus hairs. Autosomal dominant monilethrix is caused by mutations in K81, K83, and K86. *Redrawn from Langbein L, et al. The catalog of human hair keratins. J Biol Chem. 2001;276:35123–32.*

EPIDERMAL DIFFERENTIATION

Epidermal differentiation is a tightly regulated process that involves the transformation of proliferating cells in the basal layer into the dead corneocytes of the stratum corneum. During this process, the keratins that are expressed are highly specific for the state of differentiation (Fig. 56.7). The mitotically active keratinocytes in the basal compartment of the epidermis express the keratin pair K5 and K14. In addition, but less abundantly, K15 is expressed. In the absence of K14, K15 can assemble with K5, thereby providing mechanical stability to the keratinocyte.

As keratinocytes move suprabasally to the spinous layer, they withdraw from the cell cycle. This process is associated with a down-regulation of K5 and K14 and an induction of the differentiation-specific keratins, K1 and K10. Further maturation of spinous keratinocytes into granular keratinocytes results in expression of K2, a reinforcement keratin. With further maturation, filaments containing the suprabasal keratins are bundled parallel to the surface and, eventually, keratinocytes lose their cytoplasmic organelles and differentiate into lifeless corneocytes that are shed into the environment.

Interestingly, a number of epidermal keratins have a more restricted anatomic distribution pattern. For example, K9 is specifically expressed in the suprabasal cells of palmoplantar skin. Another subset of keratins, K6, K16 and K17, are expressed not only in palmoplantar epidermis, but also in keratinocytes of the nail bed, hair follicle, and sebaceous and sweat glands. In addition, this group of keratins is rapidly induced by injury, ultraviolet radiation and wounding, as well as in hyperproliferative conditions[11].

Regulatory Pathways Involved in Epidermal Development and Differentiation

The regulatory pathways necessary for normal keratinocyte differentiation include those that: (1) establish and maintain basal keratinocytes; (2) initiate and execute terminal differentiation; (3) form the stratum corneum. Examples of these pathways are discussed in more detail below.

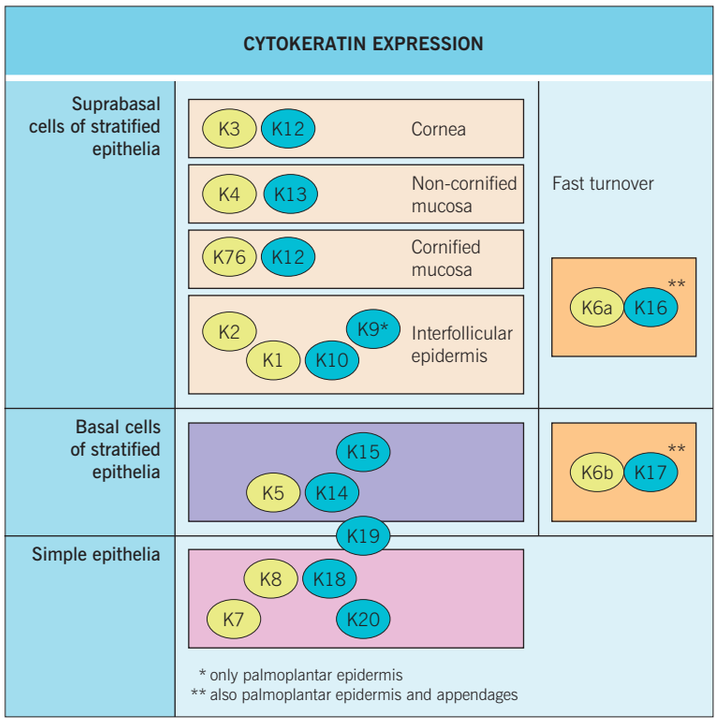

Fig. 56.7 Cytokeratin expression. Type II (basic) keratins are in yellow (K1–K8; K76) and type I (acidic) keratins are in blue (K9–K20). Keratin disorders are presented in Fig. 56.5 and Tables 56.3 & 56.5.

Genes required for establishing/maintaining basal keratinocytes

An example of a transcription factor whose importance in epidermal development and differentiation became apparent following the generation of a knockout mouse model is p63[12]. The *p63* gene encodes six different proteins, each of which can function as a transcriptional activator or repressor. Strikingly, completely p63-deficient mice fail to initiate epidermal morphogenesis, and they are born with a single-layered epithelium covering their bodies rather than a stratified epidermis. After birth, exposure of these mice to the environment leads to a rapid death due to dehydration. The failure of p63-deficient epithelial cells to adopt an epidermal fate suggests that p63 may play an important role in specifying the epidermal lineage.

Consistent with this hypothesis, ectopic p63 expression was shown to induce expression of the epidermal keratins K5 and K14. Subsequent studies demonstrated that p63 is required for both the initial induction of K5/K14 expression in embryonic basal keratinocytes and the maintenance of K5/K14 expression in the basal layer of mature epidermis. Besides regulating epidermal keratin expression, p63 is important for maintaining the proliferative state of basal keratinocytes. The latter is accomplished, in part, by the ability of p63 to repress the expression of cell cycle inhibitors. Thus, one role of p63 is to maintain basal keratinocytes in a proliferative state and to prevent the onset of terminal differentiation.

Genes required for terminal differentiation in mature epidermis

After basal keratinocytes have undergone a few rounds of cell division, they irreversibly withdraw from the cell cycle, move suprabasally, and become spinous keratinocytes. Surprisingly, this process is also controlled, in part, by an isoform of p63, ΔNp63α[12]. ΔNp63α synergizes with Notch signaling to induce K1 expression. In addition, ΔNp63α mediates cell cycle exit by inducing cell cycle inhibitors and by repressing genes required for cell cycle progression. The importance of p63 for normal epidermal development and differentiation is further underscored by the finding that *p63* mutations underlie a subset of ectodermal dysplasias, which are characterized by abnormalities in the skin and skin appendages (see Ch. 63).

The Notch signaling pathway is also required for the formation of the spinous layer[13]. *In vitro* studies initially suggested such a role for Notch signaling, and this was confirmed by the use of mouse models in which Notch signaling was altered. For example, ablation of Notch signaling resulted in the development of an extremely thin spinous layer, whereas constitutively active Notch signaling resulted in an expansion of the spinous layer. Notch activity promotes terminal differentiation by inducing K1 expression and mediating cell cycle withdrawal.

Ca^{2+} in epidermal differentiation

In addition to signaling via p63 and Notch, an important trigger of keratinocyte differentiation is an increase in extracellular Ca^{2+} concentration[14]. In mature epidermis, there is a gradient of increasing extracellular Ca^{2+} concentration from the basal layer to the cornified layers. Ca^{2+} plays an important role in keratinocyte differentiation. Increasing the Ca^{2+} concentration in the media of cultured keratinocytes can induce a differentiation program indistinguishable from that of keratinocytes *in vivo*, with successive expression of markers of keratinocyte terminal differentiation[15].

The importance of Ca^{2+} for keratinocyte differentiation has led to the identification of several Ca^{2+}-responsive proteins in the epidermis that are involved in the formation of the granular cell layer[16]. The protein kinase C (PKC) family of proteins is activated by Ca^{2+} signaling and functions specifically in the transition from spinous to granular cells. PKC proteins have a dual role, contributing to the down-regulation of K1 and K10 expression as well as to the induction of markers of granular keratinocytes, including loricrin, filaggrin and transglutaminases.

In addition to the PKC family, several proteins that undergo conformational changes upon binding to Ca^{2+} are expressed in mouse and human epidermis. Of these, the calcium-sensing receptor is specifically expressed in granular keratinocytes. Interestingly, mice lacking the full-length form of the calcium-sensing receptor fail to properly form a

granular layer, while overexpression of the calcium-sensing receptor in basal keratinocytes causes expanded spinous and granular cell layers[17].

Genes required for terminal differentiation in embryonic epidermis

Whereas the signaling pathways discussed above are critical for the formation of the spinous layer in postnatal skin, the molecular mechanisms that underlie the development of a spinous layer during epidermal morphogenesis appear to be different[18]. One reason for this distinction is that during epidermal morphogenesis, basal keratinocytes do not directly differentiate into spinous keratinocytes. Instead, basal keratinocytes initially differentiate into intermediate keratinocytes. Like spinous cells, intermediate cells express K1. However, unlike spinous keratinocytes, they still undergo proliferation. The intermediate cell layer exists only transiently during epidermal morphogenesis, and intermediate cells ultimately differentiate into spinous and granular cells, which then undergo further terminal differentiation.

The importance of the intermediate cell layer for normal epidermal development has been demonstrated by mouse models in which intermediate cells fail to mature into spinous and granular cells. Such a block in differentiation occurs in mice lacking expression of inhibitor of κB kinase-α (IKKα), interferon regulatory factor 6 (IRF6) or ovo-like 1 (Ovol1), as well as in mice expressing a mutant form of 14–3–3σ[18]. The latter mutant protein was identified in repeated epilation *(Er)* mutant mice. In all instances, an expanded intermediate cell layer develops, further terminal differentiation is disrupted, and the consequent failure to establish barrier function results in neonatal lethality.

KERATINOCYTE ADHESION

Desmosomes

Desmosomes are multi-protein complexes that function as cell–cell adhesion structures (junctions) in epidermal cells[19] (Fig. 56.8). They also provide attachment sites for the keratin intermediate filament cytoskeleton of keratinocytes. Consequently, these junctions are critical components of a supracellular filament network that traverses the interfollicular epidermis and the epithelia of skin appendages, such as hair follicles[20].

Although the biochemical composition of desmosomes varies from tissue to tissue, the core of the desmosome is formed mainly by transmembrane glycoproteins that belong to the desmoglein (Dsg) and desmocollin (Dsc) subfamilies of Ca^{2+}-dependent cell adhesion proteins (cadherins). The current hypothesis is that heterophilic and homophilic interactions between Dsg and Dsc proteins are required to establish cell–cell coupling (see Ch. 29)[21,22]. Another protein, termed "Perp", is also crucial for this process[23]. The transmembrane proteins are linked to the keratin intermediate filament network via a complex of several proteins, including desmoplakin, plakoglobin, one of several plakophilin (Pkp) isoforms, and often additional accessory proteins[24,25].

To complicate matters, several desmosomal components are encoded by multigene families. In humans, for example, there are four *Dsg* genes *(Dsg1–4)*, three *Dsc* genes, and three *Pkp* genes. In the epidermis, several Dsg and Dsc isoforms can be present in the same cell and even in the same desmosome. It is assumed that the specific composition of the desmosome affects its adhesive properties. Regulating adhesiveness of junctions (via changes in the protein composition or through protein modifications) is considered to be a crucial prerequisite for regulating cell migration, cell sorting and the formation of the proper tissue histo-architecture during embryonic development.

One example of differential regulation of desmosomes within the context of tissue/organ development is the formation of skin appendages, such as hair follicles and mammary glands. Regardless of the type of appendage that is being formed, the initial steps are very similar. First, keratinocytes from the basal cell layer change their polarity and down-regulate desmosomal proteins[26]. Next, these cells break through the basement membrane and invade the underlying dermal tissue. Eventually, the cells begin to differentiate in order to form the various cell layers and tissues that constitute the new appendage. During this process, desmosomal adhesion is re-established. The molecular pathways that control differential expression of desmosomal genes during such developmental processes are not yet known. However, based on work focusing on the regulation of classical cadherins (e.g. E-cadherin),

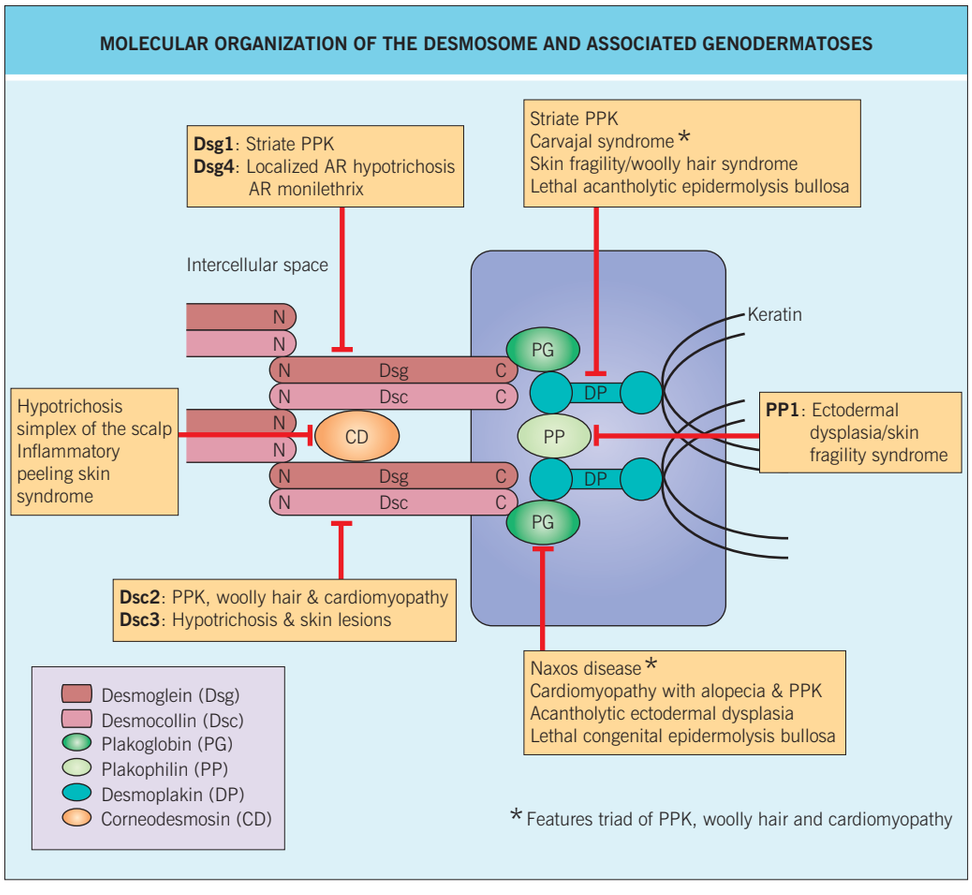

Fig. 56.8 Molecular organization of the desmosome and associated genodermatoses. Type 1 transmembrane glycoproteins from the cadherin family (desmogleins and desmocollins) are linked to intermediate filaments via a complex that contains catenins (plakoglobin, plakophilins) and plakin proteins (desmoplakin). Both homophilic and heterophilic interactions have been postulated to participate in establishing desmosomal adhesion. Examples of inherited skin diseases affecting the components of desmosomes are shown. AR, autosomal recessive; PPK, palmoplantar keratoderma.

it is likely that major epidermal signaling pathways, such as the Wnt and NF-κB cascades, are involved.

Of note, the phenomenon of local proliferation of keratinocytes followed by invasion into dermal tissue also occurs in cutaneous wound healing and the initial stages of cancer progression. It is therefore likely that the same gene regulatory pathways that govern adnexal development also control these biological processes.

What happens when desmosomes do not function properly?

Tissues that are exposed to a significant amount of mechanical stress, such as the skin and its appendages, mucous membranes (e.g. in the oral cavity) and the heart, are often affected by desmosomal defects. The clinical symptoms of desmosomal diseases can usually be ascribed to tissue fragility, with mucocutaneous blistering, abnormal hair and cardiomyopathy being the major manifestations of desmosomal defects[19,27]. In fact, dysfunction of more than 10 desmosomal proteins has been linked to either skin or heart diseases, including Dsc1, Dsc2, Dsg1, Dsg2, Dsg3, Dsg4, desmoplakin, plakoglobin, plakophilin1, plakophilin2 and corneodesmosin (Table 56.3). Most of the associated disorders represent genodermatoses, i.e. skin diseases caused by gene mutations. However, there are also acquired desmosomal diseases, such as pemphigus vulgaris (PV) and pemphigus foliaceus (PF) (with disruption due to autoantibodies) and staphylococcal scalded skin syndrome (with disruption due to bacterial toxins)[28].

The first mucocutaneous disorders linked to a desmosomal defect were PV and PF (see Ch. 29). In these diseases, autoantibodies bind to Dsg and induce epidermal and/or mucous membrane blistering via acantholysis, a process thought to be caused by loss of Dsg. In contrast to the blisters observed in patients with keratin mutations (e.g. individuals with epidermolysis bullosa simplex), PV and PF blisters are caused by cell–cell separation, not cytolysis. Nevertheless, both groups of diseases illustrate the point that desmosomes and the associated keratin intermediate filaments must function properly in order to maintain tissue integrity.

Besides their ability to stabilize tissues, desmosomes also function as signaling centers, for example, by controlling the cytoplasmic pool of signaling molecules. In fact, certain features of pemphigus are caused by abnormal signaling through the desmosomes that are targeted by autoantibodies[19]. This finding further supports the notion that desmosomes are more than merely cellular glue. The emerging picture is one of a highly dynamic structure that actively participates in signal transduction.

Plakoglobin is a core component of desmosomes that is involved in relaying signals to the nucleus. This protein belongs to the armadillo protein family, the prototype of which is β-catenin. Plakoglobin binds desmosomal cadherins (Dsg, Dsc) at the plasma membrane (see

MUTATIONS IN STRUCTURAL AND DESMOSOMAL PROTEINS FOUND WITHIN STRATIFIED SQUAMOUS EPITHELIA: ASSOCIATED HUMAN DISEASES AND MOUSE MODELS

Fig. 56.8). However, it can also form complexes with Tcf/Lef transcription factors and thus control gene expression within the nucleus. Furthermore, plakoglobin can influence other biological properties of a cell, such as proliferation, migration and apoptosis[19]. Plakophilins can also affect cytoplasmic signaling pathways, and at least two isoforms (Pkp1, Pkp2) have nuclear functions[24].

Other Types of Cell Junctions

In addition to desmosomes, several other morphologically and biochemically defined cell junctions are found in keratinocytes, including adherens junctions and tight junctions[20].

Adherens junctions

Adherens junctions consist of classical cadherins, in particular E- and P-cadherin, as well as a complex of cytoplasmic plaque proteins (α-catenin, β-catenin, γ-catenin [also known as plakoglobin]) that connect the transmembrane proteins to the actin microfilament cytoskeleton. Note that the armadillo protein plakoglobin can bind to both desmosomal and classical cadherins (see above).

P-cadherin is expressed primarily in the basal layer of mouse epidermis (the preferred experimental model of skin biologists), whereas E-cadherin is expressed throughout the interfollicular epidermis. A genetically engineered loss of P-cadherin in mice has little effect on the interfollicular epidermis, although it does affect the mammary gland. On the other hand, loss of E-cadherin in epidermis-specific (conditional) null mice can lead to severe defects in the homeostasis and function of the epidermis. Most interestingly, it appears that loss of E-cadherin can affect tight junctions (see below) and thus the skin barrier function of the epidermis. Based on an analysis of genetically engineered mice, it has become evident that normal expression of the plaque proteins α-catenin, β-catenin and plakoglobin is also required for normal epidermal function.

Similar to desmosomal cadherins, classical cadherins are differentially regulated during development of skin appendages[29]. For example, E-cadherin is down-regulated in keratinocytes that invade the underlying dermis. A failure to down-regulate cadherin-based adhesion appears to suppress invasive growth of keratinocytes and thus appendage formation.

As indicated above, armadillo proteins (e.g. β-catenin and plakoglobin) are involved in signaling from cell junctions to the nucleus. While β-catenin is a downstream effector of the classical (canonical) Wnt pathway, plakoglobin appears to be able to signal either via Wnt components or independently. Interestingly, in at least two cell types, plakoglobin counteracts classical Wnt signaling[30].

Signaling through adhesive junctions (i.e. adherens junctions and desmosomes) is still a new area in cutaneous research, and we can expect significant progress in our understanding of how these junctions affect skin and skin appendage development in the next few years.

Tight junctions

Together, tight junctions *(zonula occludens)*, adherens junctions and desmosomes form the apical junctional complex in polarized epithelial cells. Tight junctions are thought to "seal" the intercellular space, thus preventing the free diffusion of macromolecules. Consequently, these junctions are crucial for maintaining a barrier between two compartments. Surprisingly, until a few years ago, tight junctions were thought to be absent from the epidermis, but their presence has been demonstrated by several investigators. In the granular layer of the

KERATINOCYTE INTEGRIN RECEPTORS	
Integrin	**Ligand**

epidermis, they form a seal that is required for maintaining the water barrier function of the epidermis[31].

KERATINOCYTE–MATRIX INTERACTIONS

The epidermis is separated from the underlying dermis by a basement membrane (see Ch. 28), which consists of proteins secreted by epidermal keratinocytes and dermal fibroblasts[32]. Glycoproteins, including laminins, collagens, proteoglycans and fibronectin, constitute the main components of the skin basement membrane. Keratinocytes are anchored to the basement membrane through integrins, transmembrane receptors for extracellular matrix proteins (Table 56.4). In addition to their structural role, integrins function by transducing signals from the extracellular matrix to the epidermal keratinocytes.

Recently, another family of proteins that is required for basement membrane integrity during embryogenesis has been identified. This family consists of the protein products of *Fras1, Frem1* and *Frem2* genes, three proteins that form a complex within the basement membrane. Loss-of-function mutations in any of these three genes result in a destabilization of the protein complex, causing aberrant basement membrane formation and consequent skin blistering in mouse models; in humans, loss-of-function mutations in the *FRAS1* or *FREM2* genes underlie Fraser syndrome, a multisystem autosomal recessive disorder characterized by embryonic (but not postnatal) blistering of the skin, cutaneous syndactyly, cryptophthalmos and renal defects[33].

RELATED DISEASES

Keratin Disorders

Mutations in keratin genes cause a variety of disorders of the skin and other epithelia, usually with an autosomal dominant pattern of inheritance. The underlying mutations typically act in a dominant-negative fashion, interfering with normal intermediate filament assembly. This causes aggregation of disorganized keratin bundles, which often leads to clinically evident cell fragility. As noted above, mutations in the helix initiation and termination motifs are generally associated with relatively severe disease phenotypes, whereas mutations affecting other keratin domains usually cause milder disease (see Fig. 56.5). Specific genotype–phenotype correlations in skin disorders caused by mutations in keratin genes are presented in Table 56.5.

Epidermolysis bullosa simplex

Epidermolysis bullosa (EB) comprises a group of heritable skin fragility disorders characterized by skin blistering following minor mechanical trauma (see Ch. 32). In the simplex form of EB (EBS), tissue separation is within the epidermis. According to a revised classification, EBS is divided into two major subtypes: (1) *suprabasal*, which can be caused by mutations in genes encoding desmosomal components (see above and Table 56.3) and often features acantholysis histologically; and (2) *basal*, where the cleavage plane is within basal keratinocytes[34]. Genotype–phenotype correlations are well established for basal EBS due to *KRT5* and *KRT14* mutations (see Table 56.5). The clinical severity is related to the location of the mutations and the degree to which they perturb keratin structure[35]. Interestingly, hyperpigmentation is a major feature of Dowling–Degos disease, Naegeli–Franceschetti–Jadassohn syndrome and dermatopathia pigmentosa reticularis (which do not feature prominent blistering; see Ch. 67) as well as EBS with mottled pigmentation, demonstrating that mutations in keratin genes expressed in the basal epidermis can lead to pigmentary changes in addition to skin fragility.

Epidermolytic ichthyosis and palmoplantar keratoderma

Epidermolytic ichthyosis (bullous congenital ichthyosiform erythroderma) is a disorder of keratinization caused by mutations in *KRT1* or *KRT10*[36] (see Ch. 57). It is usually inherited in an autosomal dominant fashion due to heterozygous missense mutations (typically involving the helix initiation and termination motifs) that lead to clumping of keratin filaments in the suprabasal layers of the epidermis and subsequent cytolysis. A form of epidermolytic ichthyosis associated with PPK (mainly due to *KRT1* mutations) can be distinguished from a form where palmoplantar involvement is absent (mainly due to *KRT10* mutations). *KRT1* mutations (outside of the critical helix initiation and termination regions) have also been identified in epidermolytic and non-epidermolytic variants of isolated PPK, which is more commonly caused by mutations in *KRT9*[37] (Table 56.5). A recessive form of epidermolytic ichthyosis characterized by a complete absence of the K10 protein in the epidermis has also been described in several families. Mutations in *KRT1* or *KRT10* that occur during embryogenesis can cause a mosaic form of epidermolytic ichthyosis, which presents as an epidermolytic epidermal nevus (see Ch. 62). Vertical transmission of the mutation is possible if the gondads are involved, causing generalized disease in affected offspring. Genotype–phenotype correlations in other disorders of cornification caused by mutations in keratin genes are outlined in Table 56.5.

White sponge nevus of Cannon

White sponge nevus is characterized by white plaques involving the oral mucosa, with occasional involvement of other mucosal surfaces such as the esophagus, vagina, rectum and nasal cavity. The plaques may wax and wane over time, and suprabasal cytolysis and keratin clumping are observed histologically. Mutations in the genes encoding K4 and K13, which are specifically expressed in mucosal keratinocytes, cause this condition.

Gastrointestinal disorders

K8 and K18 are the major keratins that are expressed in gastrointestinal epithelia, including the liver, pancreas and gut. Mutations in these simple keratins are typically located within the head and tail domains and do not involve the highly conserved helix boundary regions. K8 and K18 mutations are considered as risk factors for developing liver and gastrointestinal disorders (e.g. cirrhosis, inflammatory bowel disease), with additional genetic and environmental alterations likely required for disease development[38]. The mutation-associated predisposition to tissue injury is likely related to mechanical and non-mechanical keratin functions, including maintenance of cell integrity and protection from oxidative injury and apoptosis.

Filaggrin Disorders

Filaggrin is a component of the cornified cell envelope and is responsible for aggregating keratins. It represents the processed product of profilaggrin, which is cleaved into individual filaggrin polypeptides by caspase 14. Loss-of-function mutations in filaggrin underlie ichthyosis vulgaris (Fig. 56.9), a semidominant condition with incomplete penetrance (~90% in homozygotes and ~60% in heterozygotes)[39] (see Ch. 57). Whereas patients with a heterozygous filaggrin mutation display

GENOTYPE–PHENOTYPE CORRELATIONS IN MUCOCUTANEOUS DISORDERS CAUSED BY MUTATIONS IN KERATIN GENES					
Disorder	**Inheritance**	**Gene**	**Type/location of mutation(s)**	**Clinical features**	**Chapter where covered**
EBS, localized (Weber–Cockayne)	AD	*KRT5, KRT14*	L12; H1 of *KRT5*	Blistering limited to palms/soles	32
EBS, generalized non-Dowling–Meara	AD		L12, L2; central portions of 1A & 2B	Generalized blistering, variable severity	
EBS, Dowling–Meara	AD		Helix initiation & termination motifs; "hotspot" Arg125Cys/His in *KRT14*	Severe, herpetiform generalized blistering; PPK	
EBS, autosomal recessive	AR		Truncating or splice-site mutations	Blistering, variable distribution and severity	
EBS with mottled pigmentation	AD	*KRT5 >> KRT14*	Pro25Leu in V1 of *KRT5*	Blistering, palmoplantar or generalized; "mottled" hypo- & hyperpigmentation or reticulated hyperpigmentation	
EBS with migratory circinate erythema	AD	*KRT5*	Frameshift mutation leading to extended V2 region	Migrating annular areas of erythema and vesiculation	
Dowling–Degos disease	AD		V1 – truncating (leading to haploinsufficiency)	Hyperpigmented macules in reticulated array in intertriginous sites	67
Naegeli–Franceschetti–Jadassohn syndrome & dermatopathia pigmentosa reticularis	AD	*KRT14*	V1 – truncating (leading to haploinsufficiency)	Reticulated hyperpigmentation; lack of dermatoglyphs, PPK; variable hypotrichosis, hypohidrosis, nail dystrophy, dental abnormalities	
Epidermolytic ichthyosis	AD	*KRT1, KRT10*	Helix initiation & termination motifs; "hotspot" Arg156 in KRT10	Erythroderma and blistering in neonates; later, corrugated hyperkeratosis; variable PPK (esp. with KRT1)	57
	AR	*KRT10*	2B – truncating		
Annular/cyclic epidermolytic ichthyosis	AD	*KRT1, KRT10*	2B		
Ichthyosis hystrix Curth–Macklin	AD	*KRT1*	V2 – truncated tail	Spiked/ridged hyperkeratosis; PPK	
Ichthyosis en confetti	AD	*KRT10*	Frameshift mutations leading to arginine-rich tail; revertant clones via mitotic recombination	Ichthyosiform erythroderma with progressive development of small islands of normal skin	
Superficial epidermolytic ichthyosis (ichthyosis bullosa of Siemens)	AD	*KRT2*	Helix termination > initiation motifs	Superficial blistering/molting; variable hyperkeratosis; no PPK	
Epidermolytic PPK	AD	*KRT1*	1B (diffuse with "tonotubular" keratin), 2B (mild diffuse/focal)	Focal/striate or diffuse epidermolytic PPK	58
		KRT9	Helix initiation > termination motifs, with "hotspot" Arg163		
Non-epidermolytic PPK	AD	*KRT1*	V1 (diffuse), V2 (striate)	Focal/striate or diffuse non-epidermolytic PPK	
		KRT6C	Helix initiation & termination motifs (focal > diffuse; with blistering)		
Pachyonychia congenita-6a/16 (type 1)	AD	*KRT6A, KRT16*	Helix initiation > termination motifs	Painful focal PPK; hypertrophic nail dystrophy; oral leukokeratosis; variable cysts	58, 71
Pachyonychia congenita-6b/16 (type 2)	AD	*KRT6B, KRT17*	Helix termination motif of *KRT6B*; helix initiation motif with "hotspots" Asn92 & Arg94 in *KRT17*	As above; frequently steatocystoma multiplex; also natal teeth	
Pseudofolliculitis barbae	Risk factor	*KRT75*	1A	Inflammatory papules due to short curled hairs penetrating back into skin	38
Monilethrix	AD	*KRT81, KRT83, KRT86*	Helix termination (*KRT86* > *KRT81* > *KRT83*) & initiation (*KRT86*) motifs	Fragile, "beaded" hairs; perifollicular hyperkeratosis	69
"Pure" hair–nail type ectodermal dysplasia	AR	*KRT85*	V1 (more severe phenotype), V2	Hypotrichosis; nail dystrophy	63
White sponge nevus	AD	*KRT4, KRT13*	Helix initiation > termination motifs	White plaques of the oral mucosa > other epithelia	

Table 56.5 Genotype–phenotype correlations in mucocutaneous disorders caused by mutations in keratin genes. Also see Fig. 56.5. AD, autosomal dominant; AR, autosomal recessive; EBS, epidermolysis bullosa simplex; H1, homologous subdomain 1; KRT, keratin; L12/L2, linker segments (non-helical); PPK, palmoplantar keratoderma; V1, variable head domain; V2, variable tail domain; 1A/1B/2A/2B, α-helical rod domain segments.

mild scaling or no phenotype, those with homozygous or compound heterozygous mutations have more severe ichthyosis vulgaris with dry, scaly skin and a substantially altered cutaneous barrier.

In addition to ichthyosis vulgaris, loss-of-function mutations in filaggrin are also a major predisposing factor for atopic dermatitis. Approximately 20–50% of patients with atopic dermatitis have at least one filaggrin null allele. Furthermore, individuals who carry filaggrin mutations and develop atopic dermatitis are also predisposed to the subsequent onset of asthma. This suggests that epicutaneous sensitization and inflammation of the skin in the context of an abnormal epidermal barrier may play a role in later development of airway hyperreactivity (see Ch. 12).

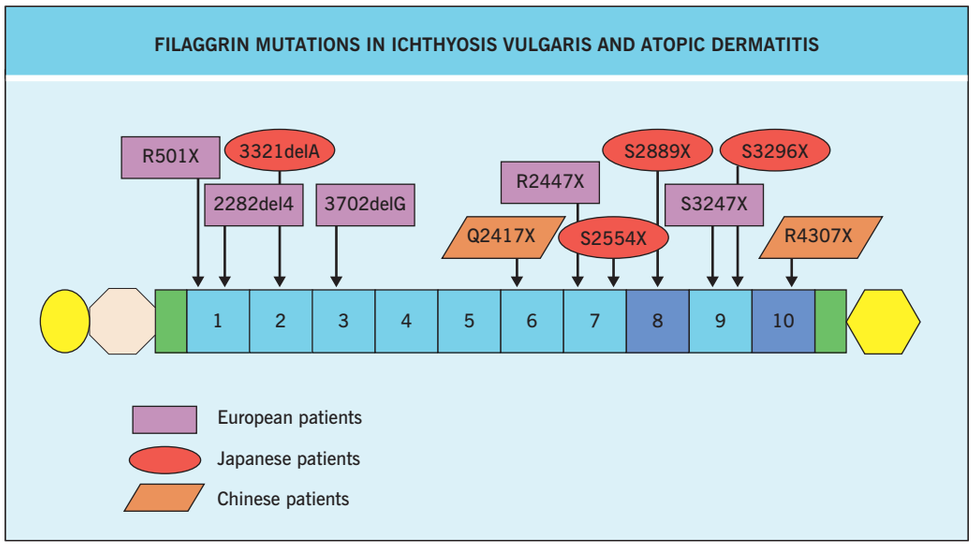

Fig. 56.9 Filaggrin loss-of-function variants in ichthyosis vulgaris and atopic dermatitis. The filaggrin protein consists of several domains: an S100 Ca^{2+}-binding domain (yellow oval), a B-domain (beige octagon), two imperfect filaggrin repeats (green rectangles), 10 filaggrin repeats (blue numbered rectangles; some individuals have two copies of repeat 8 and/or 10), and a C-terminal domain (yellow hexagon). Mutations in filaggrin that have been identified in patients with ichthyosis vulgaris and atopic dermatitis are indicated.

CONCLUSION

In recent years, we have made great progress towards understanding the structure and function of the epidermis. The challenge is now to better elucidate the gene regulatory mechanisms and cell signaling pathways that are required for the development and maintenance of this organ. The identification of epigenetic factors and modifier genes will help to explain phenotypic variations and establish more precise genotype–phenotype correlations. This knowledge will also form the foundation for the development of new therapeutic strategies for the treatment of acquired and inherited diseases of the skin.

Key features

- Ichthyoses and erythrokeratodermas are clinically and etiologically heterogeneous groups of disorders of cornification
- Ichthyoses are characterized by scaling of the skin in a widespread distribution
- Erythrokeratodermas feature discrete areas of erythema and hyperkeratosis, usually without substantial scale
- Most inherited ichthyoses and erythrokeratodermas are evident at birth or manifest in infancy
- Clinical features, pattern of inheritance and structural, biochemical and molecular abnormalities help to differentiate these disorders
- Therapy is symptomatic and primarily aimed at reducing hyperkeratosis. Topical management consists of emollients, keratolytics and retinoids
- Many, but not all, disorders respond well to oral retinoids. Treatment is initiated at low doses and titrated to response. Benefits and side effects must be carefully considered because of the chronic nature of these conditions

Ichthyoses and erythrokeratodermas are disorders of cornification in which abnormal differentiation and desquamation of the epidermis result in a defective epidermal barrier. Ichthyoses represent a large clinically and etiologically heterogeneous group of conditions that feature generalized scaling of the skin (Table 57.1). Erythrokeratodermas are characterized by circumscribed areas of erythema and hyperkeratosis without obvious scaling. Willan introduced the term "ichthyosis", derived from the Greek root "*ichthy*" meaning fish, in his textbook of dermatology in 1808[1]. Since then, nomenclature and nosology of congenital ichthyoses has continuously evolved, including a confusing medley of different terms (e.g. descriptive names, eponyms, synonyms) and classification systems.

Milestones in recognizing distinct entities include the description of harlequin ichthyosis in the nineteenth century, separation of the bullous and non-bullous types of ichthyosis by Brocq (who also coined the name "congenital ichthyosiform erythroderma") in the early 20th century[2], and differentiation between autosomal dominant "epidermolytic hyperkeratosis" and autosomal recessive "lamellar ichthyosis" by Frost and Van Scott in 1966[3]. Alibert mentioned the autosomal dominant inheritance of ichthyosis vulgaris as early as 1806[4]. X-linked ichthyosis, despite several earlier reports, was only fully recognized in Wells and Kerr's study in 1966[5], followed by the identification of steroid sulfatase deficiency in the 1970s[6]. Advances in the molecular etiology and biology of ichthyoses and erythrokeratodermas have provided tools to categorize these disorders of cornification, at least in part, on the basis of their underlying genetic defects. An international group of clinical and research experts recently developed a revised nomenclature and classification system for ichthyoses and other disorders of cornification, incorporating molecular causes as well as functional aspects of disease pathogenesis[7].

Establishing the correct diagnosis in a patient with ichthyosis is a prerequisite for making prognostic predictions, planning therapy and offering genetic counseling. This may pose a considerable challenge, as these disorders are uncommon and have overlapping clinical spectra. However, a variety of clinical and laboratory-based clues can aid in making the diagnosis (Table 57.2).

In general, it is helpful to determine whether an ichthyosis presented at birth (e.g. as a collodion baby) or later in life and whether manifestations are limited to the skin or are part of a multisystem disorder. The quality and distribution of the scale as well as the presence or absence of erythroderma, blistering and abnormalities of cutaneous adnexa are other useful clinical features. A thorough family history is essential for recognizing the inheritance pattern, and examination of both parents (even in a seemingly sporadic case) may reveal valuable diagnostic hints such as an epidermal nevus representing a mosaic presentation of epidermolytic ichthyosis. Patients whose parents are clinically unaffected may have a recessive ichthyosis (especially in the setting of consanguinity and/or affected siblings), a dominant ichthyosis due to a "new" mutation, or (for male patients) an X-linked recessive ichthyosis (where their mother may be an asymptomatic carrier and male relatives could potentially be affected). A few disorders can be recognized based on characteristic histopathologic and ultrastructural features, such as epidermolytic ichthyosis and ichthyosis hystrix Curth–Macklin. Laboratory studies suggest the diagnosis in other conditions, including steroid sulfatase deficiency (steroid sulfatase enzyme analysis) and neutral lipid storage disease (lipid vacuoles in circulating leukocytes) (see Table 57.2).

This diagnostic approach allows the clinician to identify many ichthyoses based on their key features. For conditions with a known molecular etiology, genetic testing can confirm the diagnosis, allow more precise genetic counseling and provide the basis for prenatal testing.

FEATURES OF SELECTED ICHTHYOSES AND ERYTHROKERATODERMAS								
Diagnosis	**Gene**	**Chromosomal location**	**Mode of inheritance**	**Incidence**	**Onset**	**Primary cutaneous features**	**Associated features**	**Diagnosis**
COMMON ICHTHYOSES								
Ichthyosis vulgaris	*FLG*	1q21.3	Autosomal semi-dominant	1:250	Infancy/ childhood	Fine, adherent scales on extremities and trunk with sparing of flexures; larger scale on lower legs; hyperlinear palms/soles, furrowed heels	Keratosis pilaris; atopic diathesis	Clinical; diminished/ absent stratum granulosum; absent/ reduced FLG immunostaining; molecular testing
Steroid sulfatase deficiency (X-linked recessive ichthyosis)	*STS*	Xp22.31	X-linked recessive	1:2000–1:6000 boys/men	Infancy	Fine to large, dark, adherent scales on extremities, trunk, neck and lateral face	Corneal opacities; cryptorchidism *Female carriers*: corneal opacities; prolonged labor with affected child	Lipoprotein electrophoresis (increased mobility of β-fraction); plasma cholesterol sulfate increased; decreased steroid sulfatase activity in leukocytes; FISH, array CGH, other molecular testing
NONSYNDROMIC AUTOSOMAL RECESSIVE CONGENITAL ICHTHYOSES								
Lamellar ichthyosis (LI)	*TGM1* *ABCA12** *CYP4F22**	14q12 2q35 19p13.12	Autosomal recessive†	1:200 000–1:300 000	Birth	Frequently collodion membrane at birth; large, thick, plate-like brown scales in generalized distribution; absent or mild erythroderma; variable palm/sole involvement	Heat intolerance; frequent scarring alopecia, ectropion, eclabium	Clinical; electron microscopy; *in situ* transglutaminase-1 expression and activity assay; molecular testing
Congenital ichthyosiform erythroderma (CIE)	*TGM1* *ALOXE3*‡ *ALOX12B*‡ *NIPAL4 (ICHTHYIN)*‡ *PNPLA1*‡	14q12 17p13.1 17p13.1 5q33.3 6p21.31	Autosomal recessive†	1:100 000–1:200 000	Birth	Frequently collodion membrane at birth; fine, white scale in generalized distribution; erythroderma; variable palm/sole involvement	Heat intolerance; variable scarring alopecia, ectropion	See lamellar ichthyosis; molecular testing
Harlequin ichthyosis	*ABCA12*	2q35	Autosomal recessive	Rare	Birth	Very thick, yellow–brown plates of scale that tightly encase the neonate; large, deep, bright red fissures; extreme ectropion, eclabium and ear deformities; survivors develop severe CIE-like phenotype	Premature delivery; often neonatal death due to sepsis or respiratory insufficiency	Clinical; molecular testing
KERATINOPATHIC ICHTHYOSES (also include ichthyosis en confetti – see text)								
Epidermolytic ichthyosis (bullous CIE)	*KRT1* *KRT10*	12q13.13 17q21.2	Autosomal dominant (very rarely autosomal recessive)	1:300 000	Birth	*At birth:* erythroderma, blistering and erosions *Later:* hyperkeratosis with cobblestone pattern (most prominent over joints), ridging of the flexures; generalized or localized; variable degree of erythroderma, palmoplantar involvement and blistering	Frequent skin infections; malodor; gait and posture abnormalities	Clinical; histopathology; molecular testing
Superficial epidermolytic ichthyosis (ichthyosis bullosa of Siemens)	*KRT2*	12q13.13	Autosomal dominant	Rare	Birth	Erythroderma and blistering at birth; later, hyperkeratosis with flexural accentuation, 'molting' of the skin; palms and soles spared		Clinical; histopathology; molecular testing
Ichthyosis hystrix Curth–Macklin	*KRT1*	12q13.13	Autosomal dominant	Rare	Birth	Mild to severe, mutilating palmoplantar keratoderma; hyperkeratosis with verrucous, cobblestone or hystrix-like pattern on extremities and trunk	Pseudoainhum; digital contractures	Clinical; electron microscopy; molecular testing

*Also occasionally associated with CIE or intermediate LI/CIE phenotypes; a CIE-like phenotype is also seen in harlequin ichthyosis survivors.
†There are also rare reports of autosomal dominant inheritance of LI or CIE phenotypes (occasionally with a collodion membrane at birth) with unknown genetic bases.
‡Also occasionally associated with mild LI or intermediate LI/CIE phenotypes.

FEATURES OF SELECTED ICHTHYOSES AND ERYTHROKERATODERMAS								
Diagnosis	**Gene**	**Chromosomal location**	**Mode of inheritance**	**Incidence**	**Onset**	**Primary cutaneous features**	**Associated features**	**Diagnosis**
SYNDROMIC ICHTHYOSES								
Comèl–Netherton syndrome	*SPINK5*	5q33.1	Autosomal recessive	1:50 000–1:300 000	Birth/infancy	Congenital erythroderma and peeling; two principal phenotypes: ichthyosis linearis circumflexa and CIE-like; pruritus and eczematous plaques are common	Trichorrhexis invaginata and other hair shaft abnormalities; highly elevated serum IgE; neonatal temperature instability, electrolyte imbalance, failure to thrive; recurrent infections; food and other allergies; nonspecific aminoaciduria	Clinical; psoriasiform histopathology; light microscopic hair shaft analysis; serum IgE measurement; electron microscopy (ruthenium tetroxide); molecular testing
Sjögren–Larsson syndrome	*ALDH3A2*	17p11.2	Autosomal recessive	1:250 000	Birth	Fine to plate-like scaling or non-scaling hyperkeratosis; favors abdomen, neck, flexures; lichenification; pruritus	Spastic di- and tetraplegia; mental retardation; perifoveal glistening white dots; white matter disease of the brain	Fatty aldehyde hydrogenase activity assay in cultured fibroblasts; molecular testing (preferred method)
Neutral lipid storage disease with ichthyosis	*ABHD5 (CGI-58)*	3p21.33	Autosomal recessive	Rare	Birth	Generalized fine, white scales with variable erythema	Developmental delay; hepatomegaly; myopathy; hearing impairment; cataracts; lipid-containing vacuoles in leukocytes	Peripheral blood smear to detect lipid vacuoles; oil stains of frozen skin biopsy specimens; molecular testing
Trichothiodystrophy (Tay syndrome, (P) IBIDS)	*ERCC2* *ERCC3* *GTF2H5* *C70RF11***	19q13.32 2q14.3 6q25.3 7p14.1	Autosomal recessive	Rare	Birth	Generalized scaling with absent or minimal erythroderma, except during infancy	Ichthyosis; brittle hair and nails; intellectual impairment; decreased fertility; short stature; photosensitivity	Clinical; microscopic hair shaft examination under polarizing light; analysis of hair sulfur/cysteine content
Refsum disease	*PHYH* *PEX7*	10p13 6q23.3	Autosomal recessive	Rare	Childhood to adulthood	Fine, white scales on extremities and trunk, resembling ichthyosis vulgaris	Peripheral neuropathy; cranial nerve dysfunction (deafness, anosmia); cerebellar ataxia; atypical retinitis pigmentosa; cardiomyopathy	Increased plasma phytanic acid; phytanoyl-CoA hydroxylase activity assay in cultured fibroblasts; molecular testing
ERYTHROKERATODERMAS								
Erythrokeratodermia variabilis	*GJB3* *GJB4*	1p34.3 1p34.3	Autosomal dominant (very rarely autosomal recessive)	Rare	Birth/infancy	Transient, variable erythematous patches; more stable, geographic, hyperkeratotic plaques over knees, elbows, Achilles tendons, extremities, buttocks, lateral trunk; face and scalp often spared; less common generalized hyperkeratosis; palmoplantar keratoderma in ~50% of patients	Burning or stinging sensation preceding or accompanying erythema	Clinical, particularly history or presence of transient erythema; molecular testing
Progressive symmetric erythrokeratoderma	(*LOR*) (*GJB4*)	(1q21.3) (1p34.3)	Autosomal dominant or recessive	Rare	Infancy/childhood	Fixed, slowly progressive, erythematous, hyperkeratotic plaques with sharp, figurate borders; on cheeks, over knees, elbows, extremities, rarely trunk; palmoplantar keratoderma common		Clinical

**Mutations in this gene are not associated with ichthyosis or photosensitivity.

FEATURES OF SELECTED ICHTHYOSES AND ERYTHROKERATODERMAS								
Diagnosis	**Gene**	**Chromosomal location**	**Mode of inheritance**	**Incidence**	**Onset**	**Primary cutaneous features**	**Associated features**	**Diagnosis**
Keratitis–ichthyosis–deafness syndrome	*GJB2 (GJB6)*	13q12.11 (13q12.11)	Autosomal dominant	Rare	Birth/ infancy	Transient neonatal erythroderma; erythematous, hyperkeratotic plaques with well-demarcated, borders on face and extremities; follicular keratoses; thickening of the skin with an appearance of "coarse-grained leather"; stippled palmoplantar keratoderma	Congenital sensorineural hearing impairment; progressive keratitis with corneal neovascularization, conjunctivitis; recurrent mucocutaneous infections, especially with *Candida albicans*; increased susceptibility to oral and cutaneous squamous cell carcinoma; nail, hair and dental anomalies	Clinical; molecular testing
SYNDROMIC X-LINKED DOMINANT ICHTHYOSIFORM CONDITIONS								
CHILD syndrome	*NSDHL*	Xq28	X-linked dominant	Rare	Birth	At birth, unilateral erythema and waxy, yellowish adherent scale; later, verrucous; hyperkeratosis of variable extent, with affinity for skin folds	Ipsilateral skeletal hemidysplasia, organ hypoplasia	Clinical; molecular testing
Conradi–Hünermann–Happle syndrome	*EBP*	Xp11.23	X-linked dominant	Rare	Birth	At birth, ichthyosiform erythroderma with feathery, adherent scale along Blaschko's lines; later, follicular atrophoderma along Blaschko's lines	Unilateral cataracts; chondrodysplasia punctata (during infancy); asymmetric skeletal abnormalities; patchy scarring alopecia	Clinical; epiphyseal stippling on X-rays during infancy; accumulation of plasma 8(9) cholesterol; molecular testing

Table 57.1 Features of selected ichthyoses and erythrokeratodermas (cont'd).

Despite advances in our understanding of the pathomechanisms underlying ichthyoses, effective therapies are available for only a small subset of these conditions. Hopefully, ongoing research will lead to the development of targeted treatments that will be of greater benefit to ichthyosis patients. Patient organizations such as the Foundation for Ichthyosis and Related Skin Types (FIRST; www.scalyskin.org) can provide valuable support to affected individuals and their families.

ICHTHYOSES

ICHTHYOSIS VULGARIS

Synonyms: ■ Ichthyosis simplex ■ Autosomal dominant ichthyosis

History

In 1806, Alibert[4] described "ichthyose nacrée", which represented the first well-documented report of ichthyosis vulgaris. In 1966, Wells and Kerr[5] separated autosomal dominant and X-linked recessive forms of ichthyosis and delineated their clinical and epidemiological features.

Epidemiology

Ichthyosis vulgaris is the most common disorder of cornification, with an estimated prevalence of 1 in 250 individuals[5]. It is inherited in an autosomal semidominant manner, with mild ichthyosis in individuals with heterozygous filaggrin mutations and more severe ichthyosis in those with mutations in both filaggrin alleles. There is incomplete penetrance in heterozygotes and variable phenotypic expression between and within families.

Pathogenesis

Loss-of-function mutations in the filaggrin gene (*FLG*) underlie ichthyosis vulgaris (see Fig. 56.9)[8]. *FLG* encodes profilaggrin, a major component of the keratohyalin granules located in the granular layer of the epidermis. During keratinocyte terminal differentiation, profilaggrin is cleaved into filaggrin peptides, which aggregate keratin intermediate filaments. These complexes are cross-linked to the cornified cell envelope (see Figs 56.1 & 56.2) and are responsible for proper formation of compact squamous cells. Filaggrin is eventually degraded into water-retaining amino acids that serve as a natural moisturizer. Filaggrin deficiency results in impaired squamous cell formation, transepidermal water loss, and a propensity to develop inflammatory responses upon exposure to allergens and haptens; this explains the association of *FLG* mutations with atopic dermatitis as well as ichthyosis vulgaris (see Ch. 12). The flaky-tail mouse (caused by loss-of-function mutations in the murine *Flg* gene) is an animal model that serves as a tool for the study of ichthyosis vulgaris.

Clinical Features

Ichthyosis vulgaris is usually not evident at birth. Dry skin and mild to moderate scaling appear during infancy or early childhood. Fine, white, flaky scales develop on the extremities (Fig. 57.1), especially the extensor surfaces. The groin and flexural areas are spared because of increased humidity in those regions. On the lower legs, the scales are usually larger with an adherent center and detached, outward-turning edges. Mild hyperkeratosis of the palms and soles leading to accentuated skin markings (hyperlinearity) is common (Fig. 57.2).

In more severe disease, scaling occurs on the trunk, scalp, forehead and cheeks. Palmoplantar involvement is also more pronounced and often results in furrows or painful fissures of the heels.

CLUES IN THE DIAGNOSIS OF ICHTHYOSES AND ERYTHROKERATODERMAS

Initial evaluation of a neonate/young infant with a collodion membrane/ichthyosis may include the following*:

- Complete blood count, electrolytes, hepatic panel, immunoglobulin levels (including IgE)
- Peripheral blood smear (to evaluate for vacuoles in leukocytes)
- Light microscopic examination of clipped hairs (including eyebrow hairs)
- Hearing screen (e.g. via the auditory brainstem response or otoacoustic emission test)
- Ophthalmologic examination
- Consider skin biopsy, especially if bullae (to assess for epidermolysis) or following resolution of a collodion membrane (e.g. for transglutaminase-1 immunostaining)
- Consider X-rays to evaluate epiphyses, especially if ichthyosiform lesions are in a mosaic distribution pattern

Feature	Disorder
Anosmia	• Refsum disease • Steroid sulfatase deficiency in a contiguous gene deletion syndrome on Xp (X-linked ichthyosis + Kallmann syndrome)
Arthrogryposis†	• Gaucher syndrome type 2 • Arthrogryposis–renal dysfunction–cholestasis (ARC) syndrome
Ataxia	• Refsum disease • Neutral lipid storage disease • Erythrokeratodermia with ataxia
Bullae/blisters†	• Epidermolytic ichthyosis • Superficial epidermolytic ichthyosis (ichthyosis bullosa of Siemens)
Di- or tetraplegia	• Sjögren–Larsson syndrome • Rhizomelic chondrodysplasia punctata
Diarrhea, chronic†	• MEDNIK syndrome
Elevated serum IgE†	• Netherton syndrome • Generalized inflammatory peeling skin syndrome
Erythroderma†	• Congenital ichthyosiform erythroderma • Lamellar ichthyosis (mild) • Harlequin ichthyosis (survivors) • Netherton syndrome • Generalized inflammatory peeling skin syndrome • Trichothiodystrophy • CHILD syndrome (unilateral) • Conradi–Hünermann–Happle syndrome • Neutral lipid storage disease • Sjögren–Larsson syndrome • Epidermolytic ichthyosis (during infancy) • Steroid sulfatase deficiency (mild during infancy)
Fast-moving β-lipoprotein fraction on electrophoresis†	• Steroid sulfatase deficiency
Hair shaft abnormalities†	
"Tiger-tail" hair‡	• Trichothiodystrophy
Trichorrhexis invaginata	• Netherton syndrome
Trichorrhexis nodosa	• Trichothiodystrophy • Netherton syndrome
Pili torti	• Arthrogryposis–renal dysfunction–cholestasis (ARC) syndrome
Hyperlinear palms and soles	• Ichthyosis vulgaris • Refsum disease • CYP4F22-related congenital ichthyosis
Hypernatremic dehydration in neonates†	• Netherton syndrome • Harlequin ichthyosis • Collodion babies (with various underlying disorders)
Hypogonadism/cryptorchidism†	• Steroid sulfatase deficiency • Multiple sulfatase deficiency • Trichothiodystrophy without photosensitivity
Hypotrichosis†	• KID syndrome (occasionally atrichia) • Ichthyosis–hypotrichosis syndrome • Ichthyosis–hypotrichosis–sclerosing cholangitis syndrome • IFAP syndrome (often atrichia) • Trichothiodystrophy • Netherton syndrome • Arthrogryposis–renal dysfunction–cholestasis (ARC) syndrome

*With additional studies as indicated based on the clinical presentation; see Figure 10.10 for other considerations in an erythrodermic infant.
†Finding often evident in the neonatal period or early infancy.
‡Also seen in normal infants, but usually not in all hairs.

Table 57.2 Clues in the diagnosis of ichthyoses and erythrokeratodermas. CHILD, congenital hemidysplasia with ichthyosiform erythroderma and limb defects; IFAP, ichthyosis follicularis with atrichia and photophobia; KID, keratitis–ichthyosis–deafness; MEDNIK, mental retardation, enteropathy, deafness, peripheral neuropathy, ichthyosis, and keratodermia.

Fig. 57.1 Ichthyosis vulgaris. Fine white scales on the leg. *Courtesy, Julie V Schaffer, MD.*

Fig. 57.2 Hyperlinear palms in ichthyosis vulgaris. *Courtesy, SJ Bale, PhD, and JJ DiGiovanna, MD.*

Clinical symptoms (e.g. pruritus) and severity depend on season and climate, improving during the summer and with higher humidity, and worsening in a dry, cold environment. Although the ichthyosis may be progressive during childhood, it usually improves with age.

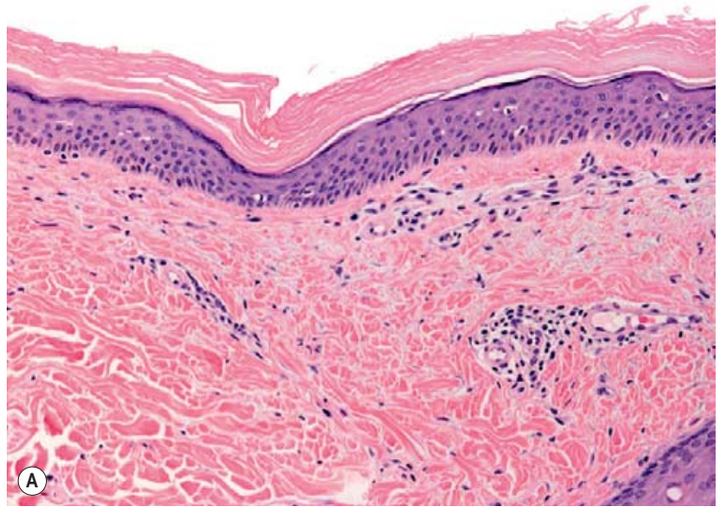
Ichthyosis vulgaris is frequently associated with keratosis pilaris and the atopic triad of asthma, hay fever and atopic dermatitis. The latter is encountered in at least 25–50% of patients with ichthyosis vulgaris and can obscure the characteristic sparing of the flexures. Conversely, approximately 10–15% of individuals with atopic dermatitis also have moderate to severe ichthyosis vulgaris.

Pathology

Mild orthokeratotic hyperkeratosis is seen and many (but not all) patients have an attenuated or diminished granular layer (Fig. 57.3A). Approximately 30–50% of affected individuals have no detectable granular layer and no keratohyalin granules by electron microscopy[9], while others have structural abnormalities in keratohyalin granules. Immunohistochemistry demonstrates diminished or absent filaggrin staining in most patients (Fig. 57.3B & C).

Differential Diagnosis

The border between dry skin (xerosis) and mild ichthyosis vulgaris is not clear-cut, and both can be associated with atopic dermatitis. In male patients, X-linked ichthyosis may be differentiated by larger, darker scales and involvement of the neck and other flexures; a maternal history of delayed or prolonged labor, cryptorchidism and the inheritance pattern can represent additional clues. Biochemical, array comparative genomic hybridization (CGH) or fluorescent *in situ* hybridization (FISH) testing can exclude steroid sulfatase deficiency. Acquired ichthyosis is distinguished by its development later in life and association with conditions such as malnutrition, infections (e.g. leprosy), neoplasms (e.g. lymphoma) and inflammatory disorders (e.g. sarcoidosis).



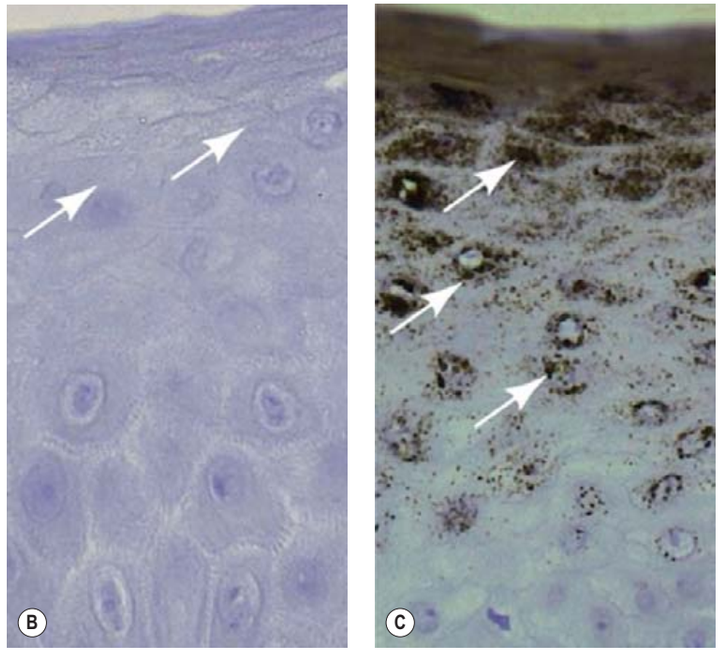


Fig. 57.3 Histologic features of ichthyosis vulgaris (IV). A Orthokeratotic hyperkeratosis and a diminished granular layer are evident. Immunostaining with an anti-filaggrin antibody demonstrates a complete absence of filaggrin in an IV patient homozygous for a deleterious *FLG* mutation (**B**), while filaggrin is strongly expressed throughout the granular layer in normal skin (**C**). *A, Courtesy, Lorenzo Cerroni, MD. B & C, Courtesy, WH Irwin McLean, PhD.*

Treatment

The mainstay of treatment is reduction of scaling through the use of emollients and humectants, and those containing ceramides together with other lipids may be especially effective. Preparations that contain urea or keratolytics such as α-hydroxy, lactic and salicylic acids are beneficial; with the latter, care must be taken to prevent salicylate toxicity. Topical retinoids may decrease scaling, but irritation of the skin limits their use. Vitamin D analogues seem ineffective. Systemic treatment with acitretin or isotretinoin is possible but rarely necessary. The use of moisturizing cleansers and humidifiers may also be helpful.

STEROID SULFATASE DEFICIENCY

Synonym: ▪ X-linked recessive ichthyosis

History

The first report of a type of ichthyosis occurring only in boys and men dates back to the beginning of the nineteenth century, but it was not until the 1920s that its X-linked recessive inheritance was clearly recognized. In 1966, the clinical features of this entity were distinguished from those of ichthyosis vulgaris[5]. The underlying steroid sulfatase deficiency was identified in the late 1970s.

Epidemiology

The worldwide incidence is between 1 in 2000 and 1 in 9500 male births. It is an X-linked recessive disorder that is transmitted by asymptomatic female carriers and almost exclusively affects boys and men.

Pathogenesis

Diminution or complete absence of steroid sulfatase activity is caused by a deletion of the entire *STS* gene on chromosome Xp22.31 in 90% of patients and inactivating mutations in others[10]. Steroid sulfatase deficiency results in impaired hydrolysis of cholesterol sulfate and dehydroepiandrosterone sulfate (DHEAS), with subsequent accumulation of cholesterol 3-sulfate in the epidermis. High levels of this metabolite can inhibit transglutaminase-1, explaining the partial overlap with lamellar ichthyosis and underscoring the pivotal role of transglutaminase-1 in formation of the cornified envelope and epidermal barrier.

In women pregnant with an affected fetus, steroid sulfatase deficiency in the fetal placenta causes low or absent levels of estrogen in the urine and amniotic fluid because of inadequate deconjugation of DHEAS (which is necessary for estrogen synthesis). As a result, labor often fails to initiate spontaneously or progress, due to insufficient dilation of the cervix. This can only be partially overcome by oxytocin administration, often necessitating cesarean section.

Clinical Features

In ~90% of affected boys, X-linked ichthyosis presents during the neonatal period with mild erythroderma and generalized peeling, often with exfoliation of large, translucent scales. The typical polygonal, dark-brown, adherent scales develop later during infancy and are distributed symmetrically on the extremities, trunk and neck (Fig. 57.4). The scales are occasionally grayish or white, and they tend to be larger on the lower extremities. The neck is almost invariably involved, which has resulted in the descriptive term "dirty neck disease" (Fig. 57.4D); other flexural areas may or may not be affected. Fine scaling of the scalp is frequently seen during early childhood but diminishes over time. The palms, soles and face are characteristically spared, with the exception of the preauricular area; some clinicians consider the latter to be a

Fig. 57.4 Steroid sulfatase deficiency. Large light-brown (**A**) and more prominent dark-brown (**B**) scales on the lower legs. **C** Smaller dark-brown scales on the trunk, with sparing of the skin folds. **D** Dark scales on the neck, sometimes referred to as a "dirty neck". *A–C, Courtesy, Julie V Schaffer, MD.*

pathognomonic feature[11]. The ichthyosis tends to improve in the summer, but (in contrast to ichthyosis vulgaris) does not significantly subside with age.

Asymptomatic corneal opacities occur in 10–50% of male patients and in some female carriers, but other ocular abnormalities such as deuteranopia (green color-blindness) are rare. Male patients have a 20-fold increased incidence of cryptorchidism and, independent of testicular maldescent, are thought to be at higher risk for developing testicular cancer and hypogonadism[12]. There have been rare reports of seizures, reactive psychological disorders, attention deficit disorder, developmental delay, pyloric hypertrophy, a congenital defect in the abdominal wall and acute lymphoblastic leukemia in patients with steroid sulfatase deficiency. Although steroid sulfatase activity is measurably reduced in 85% of female carriers, the remaining activity seems sufficient to prevent any skin manifestations.

Pathology

Histopathologic findings include hyperkeratosis or parakeratosis overlying a normal or slightly thickened granular layer. Follicular hyperkeratosis may be present. Electron microscopy shows an increased size and number of keratohyalin granules. In the stratum corneum, desmosomes are retained and cells contain a large number of melanosomes. Biochemical and cell kinetic studies show normal epidermal cell turnover and water homeostasis.

Other diagnostic tests

Array CGH, FISH, Southern blot and PCR-based analysis are available through many diagnostic laboratories and are useful for detecting the underlying genetic defect, which, when known in a female carrier, may also be utilized for prenatal diagnosis (via chorionic villi or amniotic fluid samples). However, non-invasive prenatal diagnosis through decreased serum estriol levels and the presence of non-hydrolyzed sulfated steroids in maternal urine is preferred. Accumulation of cholesterol sulfate can be detected indirectly by increased migration of the β-fraction in serum lipoprotein electrophoresis. It can also be measured directly by chromatography or spectrophotometry using epidermal scale, placental tissue or amniotic fluid. In addition, a biochemical assay is available to measure steroid sulfatase enzymatic activity in leukocytes, fibroblasts, keratinocytes or placental tissue.

Differential Diagnosis

Clinically, ichthyosis vulgaris is distinguished by sparing of flexural areas (including the neck) and an association with hyperlinear palms and keratosis pilaris. An identical cutaneous phenotype can be associated with X-linked recessive chondrodysplasia punctata and hypogonadotropic hypogonadism with anosmia (Kallmann syndrome) in male patients with a contiguous Xp microdeletion syndrome. Ichthyosis with hypogonadism (Rud syndrome) is probably not a distinct disorder but may result from submicroscopic deletions in the telomeric portion of the short arm of the X chromosome. Refined karyotyping, FISH or array CGH analysis is essential for detecting X;Y translocations and X chromosome deletions in patients who present with these additional findings.

Treatment

Topical humectants (in particular propylene glycol), keratolytics and retinoids are effective alone or in combination, whereas vitamin D analogues are disappointing and cause significant irritation. Systemic retinoids are rarely necessary.

EPIDERMOLYTIC ICHTHYOSIS

Synonyms: ■ Bullous congenital ichthyosiform erythroderma (Brocq) ■ Epidermolytic hyperkeratosis ■ Bullous ichthyosis

History

Nikolsky first recognized the characteristic histopathology of the bullous form of congenital ichthyosis in 1897[13], and Brocq differentiated between dry (non-bullous) and wet (bullous) forms of congenital ichthyosiform erythroderma in 1902[2]. Based on the distinctive histopathologic features of the epidermis, Frost and Van Scott[3] introduced the name "epidermolytic hyperkeratosis" for this autosomal dominant blistering form of congenital ichthyosis in 1966.

Epidemiology

Epidermolytic ichthyosis (EI) has an estimated worldwide prevalence of 1 in 200 000 to 1 in 300 000. It is generally an autosomal dominant disorder with complete penetrance, with rare reports of autosomal recessive inheritance. Both genders are affected equally. About 50% of all cases occur sporadically (reflecting new mutations).

Pathogenesis

EI is caused by heterozygous mutations in the genes encoding keratin 1 *(KRT1)* and keratin 10 *(KRT10)*[14]. These keratins are expressed in the differentiated spinous and granular layers of the epidermis, which are the sites of disease pathology in this disorder. *KRT1* mutations are usually associated with severe palmoplantar keratoderma, whereas *KRT10* mutations spare the palms and soles because this gene is not expressed in these locations[15]. Pathogenic mutations leading to non-conservative amino acid substitutions cluster at the boundaries of the α-helical rod region (mutational "hot spots" in the helix initiation and termination motifs; see Fig. 56.5)[14]. Mutations in other sites are uncommon and generally associated with a milder or unusual phenotype[14].

Mutations perturb keratin alignment, oligomerization and filament assembly, thus weakening the cytoskeleton, compromising the mechanical strength and cellular integrity of the epidermis, and leading to cytolysis and blistering. Epidermal acanthosis and hyperkeratosis result from hyperproliferation, decreased desquamation and other factors. The barrier function of the skin is markedly disturbed, leading to increased transepidermal water loss and bacterial colonization of the stratum corneum.

Clinical Features

EI presents at birth with erythroderma, peeling, erosions and widespread areas of denuded skin (Fig. 57.5A; see Ch. 34). Hyperkeratosis may be present, but it often develops later during infancy. Skin fragility, blistering and erythema decrease over time, and severe hyperkeratosis prevails (Fig. 57.5B–D). However, patients may still periodically shed large plates of superficial epidermis, revealing a tender, erythematous base. Ridges along skin lines are common in flexures (see Fig. 57.5D), while hyperkeratosis over the extensor surfaces of the joints often forms a cobblestone pattern (see Fig. 57.5C).

The clinical presentation varies considerably among patients and families, and six characteristic clinical patterns with or without palmoplantar involvement have been described[15]. Unusual clinical variants of EI include "cyclic ichthyosis with epidermolytic hyperkeratosis" and "annular epidermolytic ichthyosis", which are caused by distinct mutations outside the helix boundary regions of *KRT1* and *KRT10*, respectively[14].

EI is disfiguring and has tremendous impact on patients' quality of life and social interactions. Sepsis as well as fluid and electrolyte imbalances can be life-threatening in the neonatal period. Episodes of blistering and secondary skin infections are also problematic later in life. The disorder is accompanied by a pungent body odor, and it is occasionally associated with posture and gait abnormalities. Angular cheilitis and severe scalp involvement leading to encasement of hair shafts and hair loss are additional associated findings.

Epidermolytic nevi (mosaic epidermolytic ichthyosis)

The mosaic form of EI is characterized by unilateral or bilateral streaks of hyperkeratosis that follow the lines of Blaschko[16]. Extensive involvement with marked hyperkeratosis leading to protruding, porcupine-like spines has been referred to as "ichthyosis hystrix", but this is a descriptive term rather than the name of a distinct disorder. Epidermolytic nevi are caused by a postzygotic mutation in *KRT1* or *KRT10* that arises during embryogenesis. If this mutation involves gonadal cells, it can potentially be transmitted to the patient's offspring, resulting in full-blown, generalized disease[16]. Examination of both parents of a child with sporadic EI is therefore recommended.

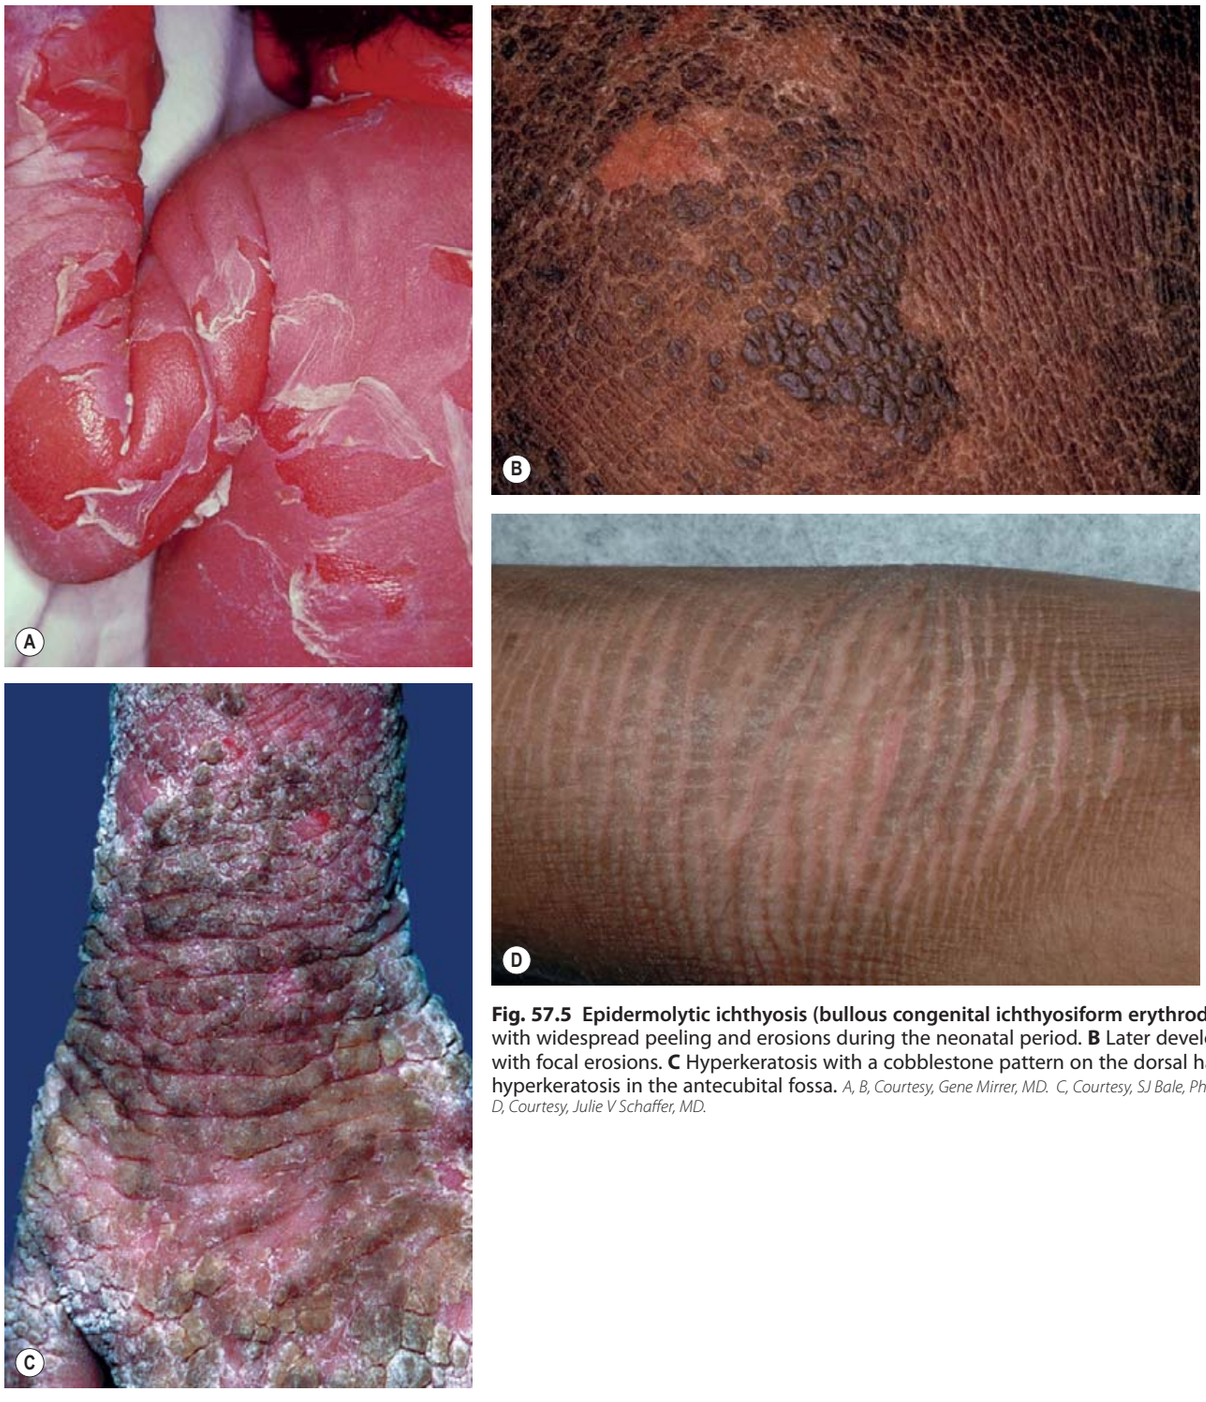

Fig. 57.5 Epidermolytic ichthyosis (bullous congenital ichthyosiform erythroderma). A Erythroderma with widespread peeling and erosions during the neonatal period. **B** Later development of hyperkeratosis with focal erosions. **C** Hyperkeratosis with a cobblestone pattern on the dorsal hand. **D** Corrugated hyperkeratosis in the antecubital fossa. *A, B, Courtesy, Gene Mirrer, MD. C, Courtesy, SJ Bale, PhD, and JJ DiGiovanna, MD. D, Courtesy, Julie V Schaffer, MD.*

Pathology

Highly characteristic structural and ultrastructural abnormalities allow EI to be distinguished from other congenital ichthyoses. Key features on routine histologic examination are dense orthokeratotic hyperkeratosis, prominent acanthosis, hypergranulosis, and cytolysis of the suprabasal and granular layers leading to small intraepidermal blisters (Fig. 57.6). Keratinocytes exhibit marked intracellular vacuolization and dense clumps of keratin intermediate filaments (KIFs). Collectively, these histopathologic changes are described as "epidermolytic hyperkeratosis". A mild perivascular lymphohistiocytic infiltrate is usually present in the upper dermis. Ultrastructural analysis reveals fragmented, clumped KIFs in the lower epidermis and perinuclear KIF shells in the upper epidermis.

Other diagnostic tests

Mutation screening and complete sequencing of *KRT1* and *KRT10* is commercially available. Prenatal diagnosis can be performed when

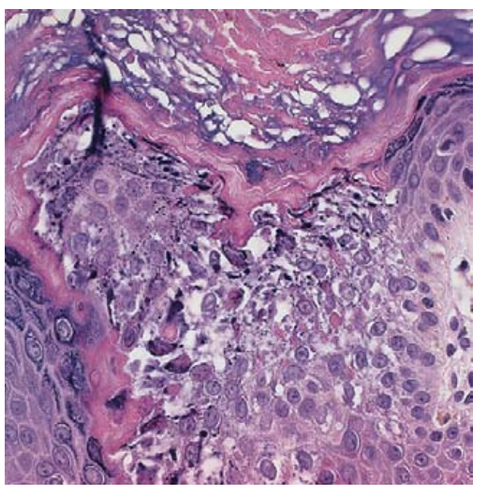

Fig. 57.6 Histology of epidermolytic ichthyosis. Striking ortho-hyperkeratosis, intracellular vacuolization of keratinocytes, and a prominent granular layer with clumped keratin filaments are seen.

Table 57.3 Neonatal presentation of selected ichthyoses and related disorders. Parentheses indicate inconsistent or occasional findings.

the underlying mutation has been identified in affected family members[17].

Differential Diagnosis

In the neonatal period, the presence of blisters and erosions differentiates EI from non-bullous congenital ichthyoses (Table 57.3). Clinical distinction from the various forms of epidermolysis bullosa, staphylococcal scalded skin syndrome, and other vesiculobullous and erosive disorders that can present in neonates may require skin biopsy specimens and cultures (see Chs 32 & 34).

Later during infancy and childhood, EI can be distinguished from other congenital ichthyoses by the history of blistering (at birth and focal recurrences) and cutaneous superinfections as well as the distinctive histologic features. Although the latter may also be seen in epidermolytic palmoplantar keratoderma (see Ch. 58), hyperkeratosis in this autosomal dominant disorder is limited to the palms and soles. Superficial EI (ichthyosis bullosa of Siemens) lacks erythroderma and shows "molting" of the superficial epidermis due to epidermolysis within the granular layer. Ichthyosis hystrix Curth–Macklin sometimes resembles EI, with ridged, verrucous hyperkeratosis over joints and in flexures, but many patients have only palmoplantar keratoderma (see below). In contrast to EI, there is no clinical or histologic evidence of either blister formation or epidermolysis, and specific ultrastructural abnormalities of the KIFs are present.

Treatment

The disfigurement and malodor often affect psychosocial functioning. Treatment is symptomatic and should be adapted to the age of the patient and clinical issues. In the neonatal period, patients require management in an intensive care nursery to provide protective isolation and prevent or treat dehydration, electrolyte imbalance and cutaneous superinfection. Sepsis should be treated with broad-spectrum antibiotics. When the neonate is handled carefully and protective padding and lubricants are used, erosions and denuded skin usually heal rapidly.

In children and adults, therapy is aimed at reducing hyperkeratosis, removing scale and softening the skin. Keratolytic creams and lotions containing urea, salicylic acid and α-hydroxy acids are effective but often not well tolerated, especially in children, because of burning and stinging. Widespread topical application of higher-concentration salicylic acid preparations should be avoided because of the risk of systemic salicylism. Topical tretinoin and vitamin D preparations may be beneficial but often cause skin irritation. Frequent use of emollients and humectants can be combined with hydration (e.g. soaking of the skin during bathing) and mechanical abrasion of keratotic skin (e.g. gentle scrubbing with a soft brush or sponges).

Bacterial skin infections are common and often trigger blistering; they require topical or systemic antibiotic treatment. Use of antiseptics such as antibacterial soaps, chlorhexidine or dilute sodium hypochlorite baths may help to control bacterial colonization. Continuous preventive therapy (oral or topical antibiotics) should be avoided because of the risk of developing antibiotic resistance. Because of the increased skin fragility, it is also important to prevent mechanical trauma (e.g. by wearing comfortable clothing and shoes). Oral retinoids may drastically reduce hyperkeratosis and the frequency of infections in patients with generalized EI, but they also increase epidermal fragility and blistering. Low initial doses with gradual increase and careful monitoring are advisable, with use of the lowest effective maintenance dose[18].

SUPERFICIAL EPIDERMOLYTIC ICHTHYOSIS

Synonyms: ▪ Ichthyosis bullosa of Siemens ▪ Ichthyosis exfoliativa

History

In 1937, Siemens[19] first recognized this congenital ichthyosis as a distinct entity and differentiated it from classic EI.

Epidemiology

This is a rare autosomal dominant ichthyosis.

Pathogenesis

Superficial EI is caused by heterozygous mutations in the gene for keratin 2 (*KRT2*), which is expressed only in the uppermost spinous and granular cell layers of the epidermis. Mutations cluster in the boundaries of the rod region of *KRT2;* Glu487Lys in the helix termination motif is most frequently identified[20].

Clinical Features

The phenotype is milder than in classic EI. At birth, the skin may appear normal or show mild blistering. Trauma-induced small blisters on the extremities occur during infancy but usually subside by early childhood, while hyperkeratosis develops. Predilection sites are the skin overlying the joints, the flexures and the dorsa of the hands and feet (Fig. 57.7), always sparing the palms and soles. The skin may appear

Fig. 57.7 Superficial epidermolytic ichthyosis (ichthyosis bullosa of Siemens). Increased skin markings and "collarettes" where the skin has been superficially shed ("Mauserung"). *Courtesy, Anthony J Mancini, MD.*

ridged, shiny or lichenified. A characteristic feature is superficially denuded areas with collarette-like borders, described as "molting" or "Mauserung", which develop due to superficial blistering and shedding of the stratum corneum.

Pathology

Histopathologic abnormalities include orthokeratotic hyperkeratosis, acanthosis and vacuolization of the granular cell layer, occasionally leading to superficial intraepidermal separation. By electron microscopy, clumping of tonofilaments is present but limited to the upper spinous and granular cell layers.

Differential Diagnosis

Infants usually do not present with the marked erythroderma and widespread blistering seen in classic EI, and later in life there is a milder course with skin shedding that is more superficial and a lack of erythema. Peeling skin syndromes can have a similar clinical appearance but do not feature vacuolization of the granular layer. Recurrent blistering is also a feature of epidermolysis bullosa simplex, but this disorder does not have associated hyperkeratosis (with the exception of occasional palmoplantar keratoderma) and can be differentiated based on deeper blisters due to basal epidermolysis.

Treatment

The management is similar to that of EI.

ICHTHYOSIS EN CONFETTI

Synonyms: ■ Confetti ichthyosis ■ Congenital reticular ichthyosiform erythroderma ■ Ichthyosis with confetti ■ Ichthyosis variegata

Ichthyosis en confetti is a rare autosomal dominant disorder in which affected individuals are born with an ichthyosiform erythroderma and palmoplantar keratoderma[21]. During infancy and childhood, hundreds to thousands of small, confetti-like "islands" of normal skin appear in a widespread distribution, increasing in number and size over time. Histologic findings in ichthyotic skin include acanthosis, perinuclear vacuolization of keratinocytes in the upper epidermis, and parakeratotic hyperkeratosis.

This condition was recently found to be caused by heterozygous frameshift mutations in the *KRT10* gene[21]. The mutant keratin 10 protein has an arginine-rich C-terminus that redirects it from its normal location in the keratin intermediate filament network to the nucleolus. Each island of normal skin represents a revertant clone that arises via mitotic recombination (i.e. crossing-over that leads to homozygous mutant and homozygous normal daughter cells). The exact role of the frameshift mutations in the markedly elevated rate of mitotic recombination remains to be determined.

ICHTHYOSIS HYSTRIX CURTH–MACKLIN

History

In 1954, Ollendorff-Curth and Macklin[22] described a family with hystrix-like hyperkeratosis and palmoplantar keratoderma. Electron microscopic examinations by Anton-Lamprecht et al.[23] revealed peculiar ultrastructural abnormalities of the keratinocyte cytoskeleton. Since the initial description, only a few large families and sporadic cases have been reported.

Epidemiology

This is a rare disorder with autosomal dominant inheritance.

Pathogenesis

In two unrelated families with ichthyosis hystrix Curth–Macklin, heterozygous mutations in the keratin 1 gene (*KRT1*) have been demonstrated. In contrast to EI, the mutations were small nucleotide deletions/insertions leading to a frameshift and production of a keratin 1 protein with an aberrant tail domain lacking the usual glycine loop motifs[24]. In another family without palmoplantar keratoderma, the disorder was not linked to the keratin gene loci on chromosomes 12q13.3 and 17q21.2, suggesting clinical or genetic heterogeneity[25].

Clinical Features

The hyperkeratotic areas in ichthyosis hystrix Curth–Macklin can clinically mimic EI, but there is no skin fragility. Clinical expression varies even within families, ranging from palmoplantar keratoderma (which may be severe and mutilating) to localized hyperkeratotic plaques to generalized hystrix-like hyperkeratosis (i.e. horny, rigid spikes). Hyperkeratosis is present at birth or develops during early childhood. It has a cobblestone-like or ridged surface over large joints and in skin folds. Circular constriction bands (pseudoainhum), starfish-like keratoses, knuckle pads, digital flexion contractures and secondary bacterial infections have been described.

Pathology

Most histopathologic features, including orthokeratotic hyperkeratosis, hypergranulosis, acanthosis and church spire-like papillomatosis, are nonspecific. Cells in the differentiated cell layers may be vacuolated or binucleated. Ultrastructural abnormalities in the upper epidermis are diagnostic, with a shell-like, interspersed network of tangled KIFs, often associated with perinuclear vacuolization and formation of binucleated cells. In contrast to EI, there is no epidermolysis or keratin clumping.

Differential Diagnosis

Ichthyosis hystrix Curth–Macklin can be differentiated from EI and epidermolytic palmoplantar keratoderma by the absence of blistering and skin fragility as well as electron microscopic findings.

Treatment

The most effective treatments are systemic retinoids and topical keratolytic agents (see EI above).

ICHTHYOSIS HYSTRIX

Synonyms: ■ "Porcupine man" ■ Ichthyosis hystrix gravior type Lambert ■ Ichthyosis hystrix gravior type Rheydt (the initial term for hystrix-like ichthyosis with deafness [HID] syndrome) ■ Systematized verrucous nevus

Ichthyosis hystrix is a descriptive term for massive hyperkeratosis that has a verrucous surface or forms protruding, porcupine-like spines; it does not represent a distinct clinical entity. This phenotype is most commonly observed in patients with EI, but it can also be seen in clinically and genetically heterogeneous disorders ranging from verrucous epidermolytic nevi to ichthyosis hystrix Curth-Macklin to hystrix-like ichthyosis with deafness (HID) syndrome (a variant of keratitis–ichthyosis–deafness [KID] syndrome due to mutations in the *GJB2* gene)[26,27]. A well-known example of the ichthyosis hystrix phenotype is the "porcupine men" of the Lambert family from Suffolk, England[28]. Since no blister formation was mentioned in the records of this kindred, it remains unclear if they had a form of EI.

COLLODION BABY

Synonyms: ■ Collodion fetus ■ Ichthyosis congenita ■ Self-healing collodion baby – lamellar exfoliation of the newborn, desquamation of the newborn, self-improving collodion baby

Epidemiology

The collodion baby is a shared presentation of several congenital ichthyoses, most with autosomal recessive inheritance. It is not a distinct disorder.

Pathogenesis

The pathomechanisms leading to formation of a collodion membrane are not completely understood, but this presentation points to disturbed adaptation of the fetal epidermis to postnatal life. Collodion babies who eventually develop lamellar ichthyosis have been shown to harbor mutations in the transglutaminase-1 gene, leading to deficiency of this crucial cross-linking enzyme of the epidermis[29,30]. Transglutaminase-1 deficiency perturbs formation of the cornified cell envelope, resulting in hyperkeratosis, profoundly impaired barrier function and transepidermal water loss. Defects in multiple lipid-processing enzymes or lipid transporters have been demonstrated in other congenital ichthyoses with a collodion membrane presentation, such as lipoxygenase deficiency in congenital ichthyosiform erythroderma, ABCA12 deficiency in lamellar ichthyosis, fatty aldehyde dehydrogenase deficiency in Sjögren–Larsson syndrome, abhydrolase 5 deficiency in neutral lipid storage disease, and β-glucocerebrosidase deficiency in Gaucher disease. These findings underscore the importance of lipids to epidermal barrier function.

A milder phenotype of a self-healing (or self-improving) collodion baby has been reported in association with *TGM1, ALOX12B* or *ALOXE3* mutations, which were shown to fully inactivate the encoded protein only *in utero* but not after birth[31–33]. It has been postulated that the self-healing collodion baby has a "dynamic" phenotype that is dependent on environmental conditions, which influence the stability of the mutant protein. A self-healing collodion baby with membranes localized to acral areas due to compound heterozygous *TGM1* mutations has also been reported[34].

Clinical Features

Collodion babies are often born prematurely and have increased perinatal morbidity and mortality. At birth, the neonate is covered with a taut, shiny, transparent membrane formed by the thickened stratum corneum, which resembles a plastic wrap (Fig. 57.8). Its tautness often leads to ectropion, eclabium and hypoplasia of nasal and auricular cartilage. Sucking and pulmonary ventilation may also be impaired, resulting in dehydration, malnutrition, hypoxia and pneumonia. After birth, the parchment-like membrane gradually dries, cracks and breaks up. In the process, fissures develop that impair epidermal barrier function, which can lead to percutaneous loss of water and permit the entry of microorganisms; fluid and electrolyte imbalances, skin infections and sepsis may follow. In addition, circular bands of hardened skin can lead to vascular constriction and distal edema.

Within two weeks, the membrane peels off in sheets and a transition to the underlying disease phenotype takes place. Most commonly, congenital ichthyosiform erythroderma or lamellar ichthyosis ensue. Sjögren–Larsson syndrome, trichothiodystrophy, neutral lipid storage disease, infantile Gaucher disease, Conradi–Hünermann–Happle syndrome and ectodermal dysplasias may rarely present as collodion baby (Table 57.4). In self-healing or self-improving phenotypes, desquamation of the collodion membrane leaves normal skin or an extremely mild generalized ichthyosis.

Pathology

Light microscopic and electron microscopic abnormalities of the collodion membrane are nonspecific and reveal mostly an excessively thickened, orthokeratotic stratum corneum. Therefore, it is usually preferable to defer a skin biopsy until after transition to the underlying disease phenotype occurs. At that time, immunostaining can demonstrate the presence or absence of transglutaminase-1 protein in the upper epidermis[35]. *In situ* assays of transglutaminase activity can be performed on skin biopsy sections and allow rapid identification of patients with transglutaminase-1 deficiency, even as a collodion

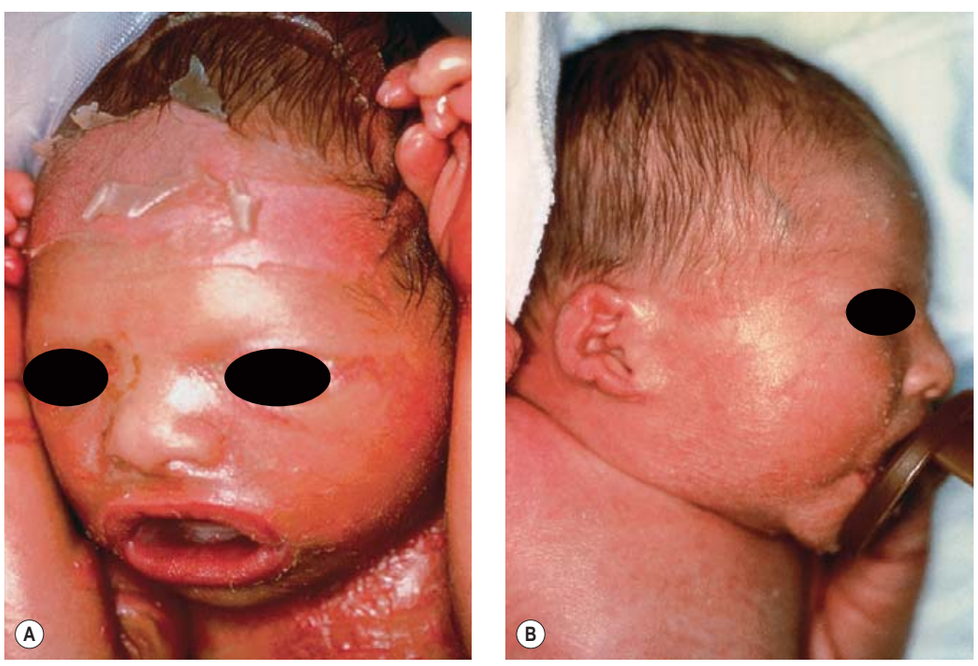

Fig. 57.8 Collodion baby. A Day 1 with eclabium. **B** Day 8 with erythema and diffuse mild scaling and misshapen ears.

DIFFERENTIAL DIAGNOSIS OF A COLLODION BABY	
Disorder	**Frequency**
Self-healing/self-improving collodion baby	Always
Lamellar ichthyosis	Common
Congenital ichthyosiform erythroderma	Common
Autosomal dominant lamellar ichthyosis	Rare
Autosomal dominant congenital ichthyosiform erythroderma	Rare
Sjögren–Larssen syndrome	Rare
Trichothiodystrophy	Rare
Infantile Gaucher disease	Rare
Ectodermal dysplasias (EDs)*	Very rare
Neutral lipid storage disease	Very rare
Conradi–Hünermann–Happle syndrome	Very rare
*E.g. hypohidrotic ED or ankyloblepharon-ED-clefting (AEC) syndrome.	

Table 57.4 Differential diagnosis of a collodion baby.

baby[32,35]. However, interpretation of the transglutaminase activity assay requires experience, and this test is not widely available.

Differential Diagnosis

The phenotype of harlequin ichthyosis is much more severe and so striking that a clinical distinction between the two disorders is, in most circumstances, not difficult.

Treatment

Collodion babies are at risk for thermoinstability, hypernatremic dehydration, skin infections and sepsis. It is therefore essential to keep them in a controlled environment and to carefully monitor for fluid and electrolyte imbalances. Collodion babies are also at risk for pneumonia secondary to restricted ventilation and aspiration of amniotic fluid containing scales. To facilitate gradual desquamation of the collodion membrane, it is generally recommended that infants be placed in a humidified incubator and the skin treated with wet compresses and light emollients to increase its elasticity and pliability. Manual removal of the collodion membrane and use of topical keratolytic agents are not advisable, because of the increased risk of infections and percutaneous absorption.

LAMELLAR ICHTHYOSIS

Synonyms: ■ Ichthyosis congenita type 2 ■ Non-erythrodermic autosomal recessive lamellar ichthyosis

History

In 1966, Frost and Van Scott[3] coined the term "lamellar ichthyosis" for all autosomal recessive forms of non-bullous congenital ichthyosis. Williams and Elias[36] further separated this group into two distinct phenotypes, lamellar ichthyosis (LI) and (non-bullous) congenital ichthyosiform erythroderma (CIE), which now have been recognized as part of a continuum with intermediate phenotypes. In the current classification system, the LI–CIE spectrum (as well as harlequin ichthyosis) falls within the non-syndromic autosomal recessive congenital ichthyosis (ARCI) category[7]. However, a rare autosomal dominant form of LI with almost indistinguishable clinical features has also been identified[37].

Epidemiology

LI occurs worldwide with an estimated prevalence of 1 in 200 000 to 1 in 300 000 live births, but it may be more common in certain regions such as Norway (1 in 90 000) or in inbred populations. LI is genetically heterogeneous and in most families is inherited as an autosomal recessive trait, although there are rare reports of autosomal dominant transmission.

Pathogenesis

Transglutaminase-1 deficiency due to deleterious mutations in both copies of the *TGM1* gene accounts for 38–55% of all patients with an ARCI on the LI–CIE spectrum and 65–90% of those with classic LI[29,30,38,39]. LI–CIE spectrum patients with a collodion membrane at birth, plate-like scale, ectropion and/or alopecia are approximately four times more likely to have *TGM1* mutations than those without at least one of these features[38]. Many patients of northern European descent share a mutation (thought to originate from a German predecessor) that leads to alternative splicing of *TGM1* mRNA[40].

Transglutaminase-1 catalyzes the calcium-dependent cross-linking of proteins through the formation of ε-(γ-glutamyl) lysine isopeptide bonds; it also creates ester bonds between proteins and ω-hydroxyceramides (see Fig. 56.3). This enzyme is expressed in the upper differentiated layers of the epidermis, where it facilitates the formation of the cornified cell envelope by cross-linking numerous structural proteins (e.g. involucrin, small proline-rich proteins, loricrin, keratins and desmosomal proteins) to one another as well as to the lipid envelope. Hence, pathogenic *TGM1* mutations seriously perturb the complex process of cornification and desquamation.

Transgenic mice deficient in transglutaminase-1 exhibit a phenotype similar to LI, with impaired barrier function leading to tremendous transepidermal water loss and abnormal percutaneous absorption. In mice, the lack of transglutaminase-1 results in complete loss of the cornified cell envelope, disturbed degradation of nuclei and keratohyalin granules, and cytoplasmic accumulation of loricrin. These observations emphasize the essential role of transglutaminase-1 in the development and maturation of the stratum corneum and for postnatal adaptation of the skin to a dry environment.

Biallelic missense mutations in the ATP-binding cassette subfamily A member 12 gene (*ABCA12*) have been reported primarily in LI patients of Northern African decent (Morocco, Mali, Algeria)[41]. These mutations cluster within the five exons (28–32) that encode the first nucleotide binding fold of this ABC transporter, which is responsible for the energy-dependent transport of lipid substrates across membranes and is found in lamellar bodies. Of note, more deleterious mutations in the *ABCA12* gene cause harlequin ichthyosis (see below).

Mutations in the *CYP4F22* gene, which encodes a cytochrome P450 enzyme thought to function in lipoxygenase pathways (see below), underlie a form of LI associated with hyperlinear palms (but usually no collodion membrane) that has been described in consanguineous families from Algeria, France, Italy and Lebanon[42]. Mutations in the *ALOX12B* and *ALOXE3* genes, which encode lipoxygenases, and the *NIPAL4* (*ICHTHYIN*) gene (see CIE section below) are occasionally associated with mild LI or intermediate LI/CIE phenotypes.

Clinical Features

Classic LI is a severe disorder that is apparent at birth and persists throughout life, although milder variants also occur. Most affected neonates are encased in a collodion membrane (see previous section). Over the first weeks of life, the collodion membrane is gradually replaced by generalized large scales. LI is characterized by large, brown, plate-like scales that form a mosaic or bark-like pattern with minimal to no associated erythroderma (Fig. 57.9A). The scales are centrally attached and have raised borders, often leading to superficial fissures. South African "bathing suit ichthyosis" represents a form of LI (caused by a particular *TGM1* mutation) that affects only the trunk and scalp.

Tautness of facial skin commonly results in ectropion (Fig. 57.9B), eclabium, and significant hypoplasia of nasal and auricular cartilage. Severe ectropion may lead to madarosis, conjunctivitis and incomplete lid closure with ensuing keratitis. Traction and compression exerted by the taut skin can cause scarring alopecia, especially at the periphery of the scalp. Hair shafts are normal but often encased by the thickened stratum corneum. The degree of palmoplantar keratoderma is variable and can range from accentuated skin markings to severe thickening with cracking and fissuring. Secondary nail dystrophy with thickened nail plates and ridging is not uncommon. Intraepidermal constriction of sweat ducts often results in severe heat

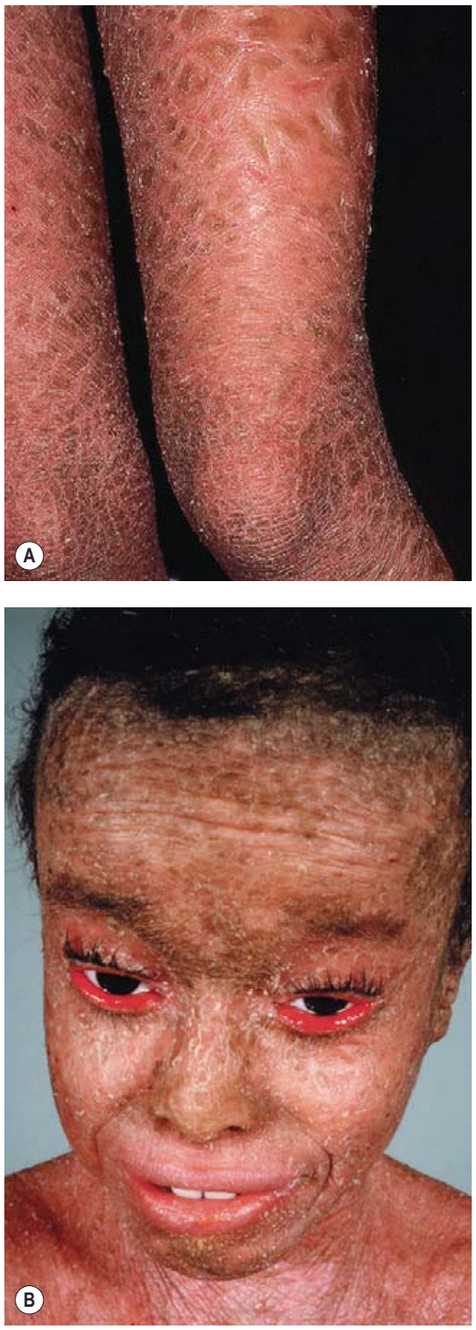

Fig. 57.9 Lamellar ichthyosis. A Large, plate-like scales on the lower extremities forming a mosaic pattern. **B** Obvious ectropion as well as plate-like scales.

intolerance, while accumulation of scale in the external ear canals can lead to occlusion, bacterial colonization and recurrent infections.

Pathology

The histologic abnormalities are not diagnostic. Massive orthokeratotic hyperkeratosis covers an acanthotic epidermis, sometimes with psoriasiform or papillomatous hyperplasia. In contrast to CIE, the epidermal proliferation rate is normal or only slightly elevated. Elongated cholesterol clefts, variable numbers of translucent lipid droplets in the stratum corneum, and a thin or absent cornified cell envelope have been observed by electron microscopy, although these findings overlap with those of CIE[43].

Other diagnostic tests

In addition to measuring transglutaminase-1 activity in cultured keratinocytes, screening procedures to detect transglutaminase-1 deficiency in skin biopsy specimens include immunostaining with anti-transglutaminase-1 antibodies, *in situ* measurement of transglutaminase-1 activity (e.g. covalent incorporation of biotinylated substrate peptides into skin cryostat sections)[32,35] and testing for the presence of cross-linked cell envelopes[44]. Although these assays are not widely available for diagnostic purposes, genetic testing is commercially available for detecting pathogenic mutations in *TGM1* and *ABCA12* (as well as *ALOX12B, ALOXE3* and *NIPAL4*); *CYP4F22* testing is offered mainly in research laboratories. Prenatal diagnosis can be performed in families with known mutations from chorionic villus sampling (CVS) or amniocentesis material obtained at an early gestational age[45]. Molecular testing has now largely replaced light and electron microscopic examination of fetal skin biopsy specimens or skin cells sloughed into the amniotic fluid, which must be obtained after 20 weeks of gestation to reliably show characteristic findings (e.g. hyperkeratinization of hair follicles, which can be difficult to interpret)[46].

Differential Diagnosis

In the neonatal period, there is considerable clinical overlap with other congenital ichthyoses that present with a collodion membrane, especially CIE and the self-healing collodion baby (see Tables 57.4 & 57.5). Later in life, the large, dark, plate-like scales, ectropion and no discernible erythroderma of LI can be readily distinguished from most other ichthyoses. Although classic CIE is differentiated by marked erythroderma and small white scales, some patients exhibit intermediate LI/CIE phenotypes with variable degrees of erythroderma as well as quality and size of scales. Autosomal dominant LI is extremely rare, and it remains to be determined whether the presence of a transformation zone between the stratum granulosum and stratum corneum and an abnormal lipid profile in the scales represent distinct characteristics of this entity.

Treatment

Neonatal care is detailed in the section describing collodion babies. Severe disease often necessitates systemic therapy with oral retinoids from early childhood. Acitretin can be very effective in alleviating hyperkeratosis and scaling. Treatment is usually initiated at a low dose and then titrated to the minimal effective dose, which is dictated by the course and severity of the disease[18]. The therapeutic benefits may also include an improvement of the ectropion, thus avoiding eye complications and reconstructive eyelid surgery. However, the benefits of long-term systemic retinoid therapy must be weighed against the potential toxicities. A randomized controlled study in patients with LI and other moderate to severe forms of ichthyosis found that liarozole (a retinoic acid metabolism blocking agent; currently not available in the US) was equally effective as acitretin but showed a trend towards a more favorable tolerability profile.

Topical management should always take into consideration the severely impaired desquamation and barrier function of the skin. The use of keratolytics is often limited due to skin irritation and an increased risk of systemic absorption, especially in children. Topical vitamin D_3 derivatives, tazarotene[47], and formulations containing lactic acid and propylene glycol in a lipophilic cream base[48] have been effective. Heat intolerance can be ameliorated by frequent moistening of the skin with water or the use of air conditioning and humidifiers. Severe ectropion requires longitudinal ophthalmologic evaluation; surgical repair is sometimes necessary to prevent irreversible corneal damage.

LI and other severe forms of ARCI are often disfiguring, which may hinder the psychosocial development of affected children and adolescents. Families and patients need support in dealing with these issues, and patient advocacy groups such as FIRST (www.scalyskin.org) are excellent resources.

CONGENITAL ICHTHYOSIFORM ERYTHRODERMA

Synonyms: ■ Non-bullous congenital ichthyosiform erythroderma ■ Ichthyosis congenita type 1 ■ Erythrodermic autosomal recessive lamellar ichthyosis

Epidemiology

CIE appears to be slightly more common than LI, affecting 1 in 100 000 to 1 in 200 000 people. In the vast majority of families, CIE is inherited

as an autosomal recessive trait, although there are rare reports of autosomal dominant transmission. This type of ARCI is clinically and genetically very heterogeneous.

Pathogenesis

To date, mutations in at least five genes have been shown to cause CIE: *TGM1*, *ALOXE3*, *ALOX12B*, *NIPAL4* (*ICHTHYIN*) and *ABCA12*. Two additional CIE loci on chromosome 12p11.2–q13 have been identified, and ARCI without erythema has been mapped to 19p13.1–p13.2. In contrast to LI, only a minority of CIE patients carry recessive mutations in the *TGM1* gene, which lead to transglutaminase-1 deficiency with resulting abnormal formation of the cornified cell envelope and perturbed barrier function of the skin[29,40].

Approximately 10–15% of CIE patients from diverse ethnic backgrounds without *TGM1* mutations harbor inactivating mutations in two lipoxygenase (LOX) genes, *ALOX12B* and *ALOXE3*, each accounting for about half of the cases[31,49]. The majority of these individuals are born with a collodion membrane, with subsequent development of mild to moderate CIE. The enzymes 12R-LOX and eLOX are preferentially synthesized in the epidermis and function in sequence to generate epoxy alcohol metabolites, which are crucial for formation of the epidermal lipid barrier. 12R-LOX is responsible for generating fatty acid hydroperoxide, while eLOX functions as hydroperoxide isomerase to produce epoxy alcohols.

The *NIPAL4* (*ICHTHYIN*) gene has been found to underlie CIE in families from the Mediterranean basin, Iran, South America and Northern Europe[50,51]. In a Scandinavian study, this gene was mutated in 16 of 18 kindreds with an ARCI characterized ultrastructurally by abnormal lamellar bodies and elongated perinuclear membranes in the stratum granulosum[51]. Affected individuals have widespread congenital ichthyosis with variable associated erythema and usually no collodion

ADDITIONAL RARE ICHTHYOSES FOR WHICH THE GENETIC BASIS OR CHROMOSOMAL LOCUS IS KNOWN

Disorder	Gene (protein)	Chromosomal location	Mode of inheritance	Dermatologic features	Associated features	Diagnosis*
			GENERALIZED ICHTHYOSIS			
Arthrogryposis–renal dysfunction–cholestasis (ARC) syndrome	*VPS33B* (vacuolar protein sorting 33 homolog B)	15q26.1	AR	Generalized fine to large scales on trunk and extremities with sparing of skin folds	Arthrogryposis, metabolic acidosis and aminoaciduria due to renal tubular dysfunction, cholestasis, sensorineural deafness, CNS abnormalities, lethal within first year of life	Clinical; molecular testing
*C*erebral *d*ysgenesis, *n*europathy, *i*chthyosis and *k*eratoderma (CEDNIK) syndrome	*SNAP29* (SNARE protein involved in vesicle fusion)	22q11.2	AR	Normal skin in infancy, later widespread large scale with variable erythema; palmoplantar keratoderma	Dysmorphic facies, microcephaly, neuropathy, delayed psychomotor development, hearing impairment, optic nerve atrophy, cachexia, fatal within first decade of life	MRI showing cortical dysplasia and abnormal corpus callosum; electron microscopy showing clear vesicles within the epidermis
Ichthyosis, intellectual disability and spastic quadriplegia	*ELOVL4* (elongase of very long chain fatty acids 4)	6q14	AR	Generalized fine scale and variable erythema with involvement of skin folds; variable collodion membrane	Seizures, mental and growth retardation, spastic tetraplegia	Clinical
Ichthyosis–hypotrichosis syndrome	*ST14* (matriptase, a transmembrane serine protease)	11q24.3–q25	AR	Large scales on trunk, extensor extremities and scalp; curly, sparse, brittle scalp hair with pili torti and pili bifurcate, absent eyebrows and eyelashes; improvement in adulthood	Photophobia, corneal opacities, pitted or conical teeth	Clinical
Ichthyosis–hypotrichosis–sclerosing cholangitis syndrome	*CLDN1* (claudin 1, a tight junction protein)	3q28	AR	Fine to large scales on trunk and extremities with sparing of flexures; hypotrichosis, coarse hair, scarring alopecia of scalp (frontal, temporal) and eyebrows	Neonatal jaundice and hepatomegaly due to sclerosing cholangitis or congenital paucity of biliary ducts; hypodontia and enamel dysplasia	Clinical; peripheral blood smear to detect eosinophil vacuoles
Ichthyosis prematurity syndrome	*SLC27A4* (solute carrier family 27 member 4, a fatty acid transporter)	9q34.11	AR (Scandinavian families)	Thick, caseous, desquamating scale at premature birth; widespread perifollicular hyperkeratosis, larger scale on distal extremities	Polyhydramnios, premature birth, neonatal respiratory distress, peripheral eosinophilia, atopy	Clinical; electron microscopy showing membrane aggregations within upper epidermis
Late-onset autosomal recessive ichthyosis	*LIPN* (lipase N, involved in epidermal triglyceride metabolism)	10q23	AR	Onset in childhood of generalized ichthyosis with fine white scales or (especially on legs) larger brown scales; little associated erythema	None	Clinical

*Although the disease-causing genes have been identified for most of these disorders, unless noted otherwise, molecular testing is currently available only through research laboratories.

Table 57.5 Additional rare ichthyoses and related disorders for which the genetic basis or chromosomal locus is known. Ichthyosis may also occur in autosomal recessive congenital disorders of glycosylation due to deficiency in dolichol kinase (also features alopecia, microcephaly and cardiomyopathy) or steroid 5-α-reductase 3 (also features lax skin, colobomas and cerebellar hypoplasia). AD, autosomal dominant; AR, autosomal recessive; ER, endoplasmic reticulum.

ADDITIONAL RARE ICHTHYOSES FOR WHICH THE GENETIC BASIS OR CHROMOSOMAL LOCUS IS KNOWN						
Disorder	**Gene (protein)**	**Chromosomal location**	**Mode of inheritance**	**Dermatologic features**	**Associated features**	**Diagnosis***
Multiple sulfatase deficiency (mucosulfatidosis, Austin disease)	*SUMF1* (sulfatase-modifying factor 1, responsible for post-translational modification of a cysteine residue at the active site of all sulfatases, including steroid sulfatase)[108]	3p26.2	AR	Similar to steroid sulfatase deficiency, but often less severe	Findings depend upon residual sulfatase activity; may resemble metachromatic leukodystrophy or various mucopolysaccharidoses (see Ch. 48); coarse facies; broad great toes, chondrodysplasia calcificans, dysostosis multiplex; deafness; hypotonia, hydrocephalus, developmental delay, neurologic deterioration	Reduced arylsulfatase A/B/C, heparan sulfatase and iduronate-2 sulfatase activity/ levels in fibroblasts (cultured), leukocytes, plasma or chorionic villi; tandem mass spectrometry profile in amniotic fluid for prenatal diagnosis[109,110]
Rhizomelic chondrodysplasia punctata (autosomal recessive chondrodysplasia punctata type 1; chondrodystrophia calcificans punctata)	*PEX7* (peroxisomal type 2 targeting signal receptor; functions in peroxisomal biogenesis[111])	6q23.3	AR	Ichthyosis and alopecia occur in ~25% of patients; at birth, erythroderma and thick, sticky vernix with underlying adherent scale; diffuse or patchy scales with feather-like edges in infancy; later, follicular atrophoderma, scarring alopecia of the scalp, sparse or absent eyebrows and eyelashes *Histologic findings*: (during infancy) hyperkeratosis, focal parakeratosis, follicular plugging	Symmetric skeletal anomalies with rhizomelia (shortening of the proximal limbs), scoliosis, chondrodysplasia punctata (in infancy)[112]; facial dysmorphism (frontal bossing, flat nasal bridge); bilateral congenital cataracts; progressive psychomotor retardation usually results in death by 2 years of age; occasional survival with spastic tetraplegia	Stippled epiphyses (punctate calcifications) on X-rays prenatally and during infancy; in plasma/RBCs: low plasmalogen in first month of life, later increased phytanic acid; electron microscopy shows small vacuoles with needle-like calcium inclusions in keratinocytes; peroxisomal dysfunction in cultured chorionic villous or amniotic fluid cells[113]; molecular testing (not available in the US)
ERYTHROKERATODERMA OR FOCAL ICHTHYOSIFORM LESIONS						
Ichthyosis follicularis, atrichia and photophobia (IFAP) syndrome	*MBTPS2* (membrane-bound transcription factor peptidase site 2, a zinc metalloprotease with roles in cholesterol homeostasis and the ER stress response[114])	Xp22.12-p22.11	X-linked "recessive"	*Affected males*: congenital atrichia with absence of eyebrows and lashes; follicular keratoses ("nutmeg grater" skin); psoriasiform plaques; occasionally lamellar scaling or hyperkeratosis of the palms and soles; nail dystrophy; increased susceptibility to mucocutaneous bacterial and fungal infections *"Carrier" females*: linear streaks with follicular keratoses or scaling; patchy hypotrichosis *Histologic findings*: hyperkeratosis, absent/ poorly developed hair follicles and sebaceous glands	Vascularizing keratitis; short stature; variable intellectual disability, cerebral atrophy, temporal lobe malformation, hypoplasia of the corpus callosum, seizures; inguinal hernias; occasional urogenital, renal and vertebral malformations or Hirschsprung disease	Clinical
*M*ental retardation, *e*nteropathy, *d*eafness, *n*europathy, *i*chthyosis, *k*eratodermia (MEDNIK) syndrome	*AP1S1* (adaptor-related protein complex 1 sigma 1 subunit, involved in vesicular protein trafficking)[115]	7q22.1	AR	Erythematous patches and hyperkeratotic plaques of variable sizes and shapes; mucosal involvement	Chronic diarrhea; sensorineural deafness; peripheral neuropathy; mental and growth retardation	Clinical; elevated plasma very-long-chain fatty acids

*Although the disease-causing genes have been identified for most of these disorders, unless noted otherwise, molecular testing is currently available only through research laboratories.

ADDITIONAL RARE ICHTHYOSES FOR WHICH THE GENETIC BASIS OR CHROMOSOMAL LOCUS IS KNOWN						
Disorder	**Gene (protein)**	**Chromosomal location**	**Mode of inheritance**	**Dermatologic features**	**Associated features**	**Diagnosis***
Erythrokeratodermia with ataxia (Giroux–Barbeau syndrome)	Unknown	1p34–35.1	AD (French-Canadian family)	Erythematous, hyperkeratotic plaques with fine, white, adherent scales on extremities (knees, ankles, elbows, wrists); diminish or disappear during adulthood[116] *Histologic findings*: acanthosis, hyperkeratosis, focal parakeratosis, perinuclear vacuolization, clumped keratohyalin granules	Progressive neurologic symptoms develop during 4th–5th decades of life, including nystagmus, ataxia, dysarthria and hyporeflexia	Clinical
*K*eratosis *l*inearis with *i*chthyosis congenita and sclerosing *k*eratoderma (KLICK) syndrome	*POMP* (proteasome maturation protein)	13q12.13	AR	Mild generalized ichthyosiform scaling, linear distribution of keratotic papules in flexural sites; hyperkeratotic plaques on knees, palmoplantar keratoderma with constriction bands	Digital flexion contractures	Clinical
PEELING SKIN						
Generalized inflammatory peeling skin syndrome†	*CDSN* (corneodesmosin, a desmosomal protein)[79]	6p21.3	AR	Erythroderma with fine white scales; widespread, patchy superficial (subcorneal) peeling of the skin; pruritus; fine hair during infancy	Mild failure to thrive and staphylococcal skin infections during infancy; atopic manifestations (e.g. asthma, food allergies); elevated serum IgE	Clinical
Autosomal recessive exfoliative ichthyosis	*CSTA* (cystatin A, a protease inhibitor)	3q21	AR	Peeling skin on palms, soles, elbows and knees; fine white scale on trunk and extremities; no histologic evidence of epidermolysis	None	Clinical; electron microscopy showing widened intercellular spaces and aggregates of keratin filaments in basal keratinocytes
Generalized peeling skin syndrome	*CHST8* (carbohydrate sulfotransferase 8)	19q13.1	AR	Generalized peeling skin, especially on the extremities	None	Clinical
Acral peeling skin syndrome	*TGM5* (transglutaminase 5)[117]	15q15.2	AR	Superficial (subcorneal) skin peeling on acral extremities with associated erythema (Fig. 57.18); exacerbated by elevated ambient temperature and humidity	None	Clinical
Erythrokeratolysis hiemalis (keratolytic winter erythema, Oudtshoorn disease)	Unknown	8p23–p22	AD (South African families)	Episodic/seasonal development of circinate erythematous plaques with scaling and centrifugal peeling; predominantly on palms/soles with occasional extension to legs > arms (rarely on trunk and face); occasional blisters in center of new plaques; triggered by viral infection or fever; improves with age[118] or with tar + UV therapy or topical 5-fluorouracil	None	Clinical; histologic findings of parakeratosis, necrosis in the stratum spinosum and basaloid proliferation

*Although the disease-causing genes have been identified for most of these disorders, unless noted otherwise, molecular testing is currently available only through research laboratories.
†Netherton syndrome can also present with a phenotype of generalized peeling skin and erythroderma.

Table 57.5 Additional rare ichthyoses and related disorders for which the genetic basis or chromosomal locus is known (cont'd). AD, autosomal dominant; AR, autosomal recessive; ER, endoplasmic reticulum.

membrane at birth[51]. Ichthyin is a transmembrane protein with homologies to both transporters and G-protein-coupled receptors, and it is hypothesized to represent a membrane receptor for ligands (trioxilins A3 and B3) from the hepoxilin pathway[50].

Homozygous mutations in the patatin-like phospholipase domain-containing 1 gene (*PNPLA1*) were recently found to cause CIE with a collodion membrane presentation in families from northern Africa[51a]. The PNPLA1 protein has a role in epidermal lipid barrier formation. Patients with CIE resulting from biallelic *ABCA12* mutations (at least one of which is missense) have been reported, but they tend to have somewhat larger scales than in classic CIE[52]. In addition, individuals with harlequin ichthyosis (which generally results from truncating

mutations and/or deletions in *ABCA12*) who survive the neonatal period typically develop a very severe CIE-like phenotype.

Clinical Features

CIE usually presents at birth with a collodion membrane, with subsequent evolution into generalized erythroderma and scaling that remain throughout life. The clinical features of CIE tend to be milder than those of classic LI, but there is variability in the intensity of erythema as well as the size and type of scale. In severely affected patients, CIE is characterized by an intense, bright red erythroderma; generalized white, small scales with a "powdery" consistency (Fig. 57.10); and additional findings such as ectropion and scarring alopecia. Scales may become larger, darker or plate-like, especially on the extensor surface of the lower extremities. The palms and soles are usually severely affected with a diffuse, fissuring keratoderma that contrasts with the fine, translucent scales elsewhere on the body. Patients with milder disease exhibit less intense erythroderma and scaling (although the latter still tends to be generalized) and have variable palmoplantar involvement.

The obstruction of sweat ducts and pores often results in hypohidrosis and heat intolerance. Secondary nail dystrophy, onychomycosis and digital flexion contractures are not uncommon. Severe exfoliative erythroderma can cause metabolic stress in growing children, including substantial energy expenditure through evaporation in the setting of increased transepidermal water loss and failure to meet their high caloric needs can lead to growth retardation[53]. However, most children with CIE have normal growth and development. Adults with CIE may have an increased risk of developing cutaneous squamous cell carcinoma (SCC), so longitudinal skin surveillance should be considered[54].

Pathology

The histopathologic and ultrastructural features of CIE are nondiagnostic. Compared to LI, there is more parakeratosis (focal or extensive) and the acanthosis is typically more pronounced and accompanied by hypergranulosis. Unlike LI, the epidermal cell turnover rate in CIE is markedly increased. Ultrastructural abnormalities in CIE include an increased number of lamellar bodies, an accumulation of lipid droplets in the stratum corneum (often more prominent than in LI)[55,56] and disorganized intercellular lipid lamellae[55]; although characteristic of CIE, these findings overlap with those seen in LI and other hyperproliferative disorders.

Other diagnostic tests

As in LI, transglutaminase-1 deficiency can be detected by immunostaining for and/or assessing the activity of this enzyme in skin biopsy specimens. Prenatal molecular diagnosis is possible when disease-causing mutations have been identified in family members. Interpretation of ultrastructural findings in fetal skin biopsy specimens is difficult, and diagnostic features may not be present before the 21st week of gestation.

Differential Diagnosis

A collodion membrane at birth requires consideration of LI, a self-healing collodion baby and other forms of ichthyosis (see Tables 57.4 & 57.5). After transition to the ichthyosis phenotype, pronounced erythroderma and fine white scales in classic CIE differentiate it from classic LI, which is characterized by less erythema, large dark scales and more frequent ectropion, eclabium and scarring alopecia. However, many intermediate phenotypes with variable degrees of erythema and size and quality of scale exist. As noted above, harlequin ichthyosis survivors typically develop an extremely severe CIE-like phenotype. A variety of clinical, histologic and laboratory findings differentiate CIE from other erythrodermic forms of ichthyosis, including syndromic as well as non-syndromic conditions (see Tables 57.1 & 57.2).

Treatment

A summary of therapeutic strategies is provided above in the section on LI. Erythrodermic patients have a special need for increased intake of fluids, calories, iron and protein to balance substantial loss through the skin, which can be 3–10 times higher than normal[53]. Therapy with oral retinoids can reduce scaling, but it is less beneficial in suppressing the erythroderma.

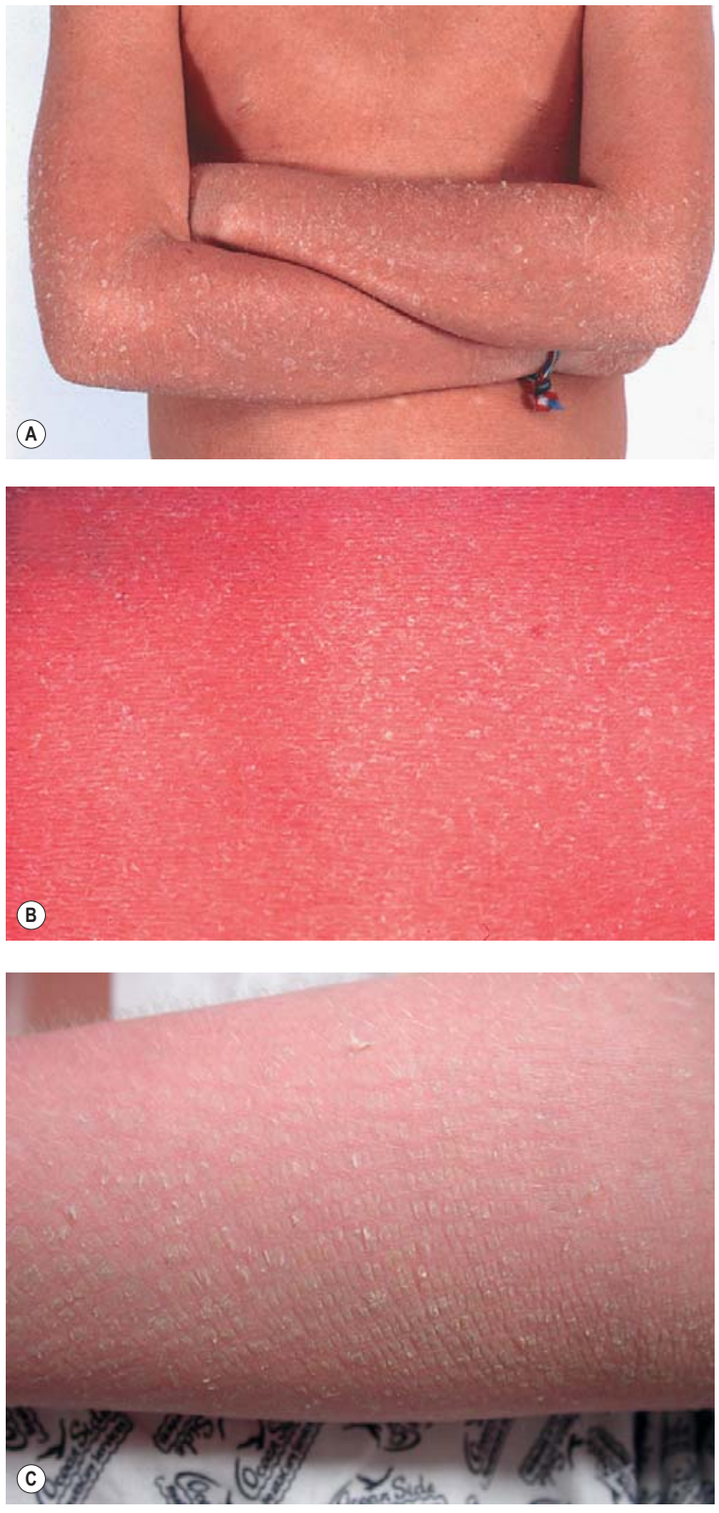

Fig. 57.10 Congenital ichthyosiform erythroderma. A Intense redness and fine, flaky, white scale on the trunk and arms. Close-up of fine white (**B**) and coarser yellowish (**C**) scale in a background of prominent erythema. *A, Courtesy, SJ Bale, PhD, and JJ DiGiovanna, MD.*

HARLEQUIN ICHTHYOSIS

Synonyms: ■ Harlequin baby ■ Harlequin fetus ■ Ichthyosis congenita gravior

History

This most extreme and distinct form of ARCI was described as early as 1750 by the Reverend Oliver Hart. In 1900, Riecke recognized the histopathologic features of dramatic thickening of the stratum corneum and follicular hyperkeratosis, and he distinguished this disorder from other types of congenital ichthyosis. "Harlequin" refers to the resemblance of the facial features and diamond-shaped scales in affected neonates to the costume of the comic servant character with this name. Initially called a "harlequin fetus" because of the premature delivery and fatal outcome, increasing survival rates due to improved neonatal care and systemic retinoid treatment have resulted in evolution to the terms "harlequin baby" and (currently) "harlequin ichthyosis" (HI).

Epidemiology

This rare disorder is inherited in an autosomal recessive manner and has been reported in patients with a wide variety of ethnic backgrounds.

Pathogenesis

In 2005, biallelic loss-of-function mutations in the ABC transporter gene *ABCA12* were identified as the cause of HI[57,58]. Truncating mutations and deletions in this gene are usually associated with severe HI, whereas missense mutations may cause a somewhat milder phenotype that overlaps with CIE/LI[59,60]. *ABCA12* encodes a membrane protein of epidermal lamellar bodies that is involved in energy-dependent lipid transport.

Lamellar bodies are absent or improperly formed in patients with HI[61], and essential epidermal lipids (e.g. glucosylceramide) are abnormally processed and incompletely secreted (or not secreted at all) into intercellular spaces. These changes prevent the formation of lipid bilayers in the stratum corneum and result in massive hyperkeratosis and a severe breakdown of the permeability barrier. Akiyama et al.[57] demonstrated that *in vitro* correction of the ABCA12 deficiency in HI keratinocytes restores normal production and distribution of glucosylceramide and the formation of lamellar bodies.

Clinical Features

Individuals with HI are usually born prematurely (mean gestational age, 35 weeks) and often die within a few days or weeks because of respiratory insufficiency or sepsis[62]. Affected neonates are encased in a hard, armor-like, tremendously thickened stratum corneum that results in severe immobilization and restricts ventilation. Shortly after birth, the hyperkeratotic cast cracks and forms large, yellow, adherent plates separated by broad, deep, intensely red fissures (Fig. 57.11). Increased transcutaneous loss of water and heat results in dehydration, electrolyte imbalances (e.g. hypernatremia) and temperature instability. The latter may impede recognition of skin infections or sepsis, which are promoted by the large fissures.

The tautness of the skin results in marked eversion of the eyelids (ectropion) and lips (eclabium), rudimentary development of ear and nasal cartilage, and sometimes microcephaly, giving the face an extremely distorted appearance. The hands and feet are edematous and swollen, often covered by a mitten-like casing. Although the digits are well developed, autoamputation due to constricting skin bands occasionally occurs. Eyelashes and eyebrows are usually missing, while scalp hair may be present. Eclabium and taut facial skin prohibit effective suckling by the infant.

Over the past two decades, improved prenatal care and oral retinoid therapy have led to prolonged survival in an increasing number of HI patients. More than half of affected individuals now live beyond the neonatal period, with the oldest HI patient to date being 25 years of age[58,59,62]. All survivors develop a severe, exfoliative ichthyosiform erythroderma, and half have a painful palmoplantar keratoderma; dystrophic nails (e.g. small, thickened) and poor hair growth are also common. Complications in these patients include recurrent skin infections, reduced sweating with heat intolerance, ocular problems related to persistent ectropion, chronic constipation and joint contractures[62]. Although affected children often have delayed growth and development (especially of motor skills), intelligence is typically normal.

Fig. 57.11 Harlequin ichthyosis. Severe hyperkeratosis with fissuring as well as eclabion and ectropion. *Reproduced from Morillo M, Novo R, Torrelo A, et al. Feto arlequin. Actas Dermosifiliogr. 1999;90:185–7.*

Pathology

The histologic hallmark is an extraordinarily thickened and compact orthokeratotic stratum corneum, although parakeratosis is occasionally observed. Hair follicles and sweat ducts have prominent hyperkeratotic plugging. Ultrastructural features include abnormal or missing lamellar bodies in the granular layer, absent extracellular lipid lamellae, and the presence of lipid inclusions or remnant organelles in the stratum corneum[61]. However, similar findings have been described in patients with CIE without transglutaminase-1 deficiency. Hair follicles show concentric accumulation of keratotic material around hair shafts, a highly characteristic feature that was historically used to establish the diagnosis based on prenatal skin biopsy specimens obtained in the second trimester[63,64].

Other diagnostic tests

Prenatal molecular testing (as early as the 10th week of gestation with CVS) is available for HI families.

Differential Diagnosis

The clinical presentation of harlequin ichthyosis at birth is striking and highly characteristic. Hyperkeratosis and associated abnormalities, such as ectropion and eclabium, are usually much milder in collodion babies. However, the clinical findings in children and adults with HI overlap with severe forms of CIE. The facial features and taut, scaling skin in Neu–Laxova syndrome may be reminiscent of HI, but this rare autosomal recessive disorder also features microcephaly, lissencephaly (few and shallow convolutions of the brain), syndactyly and a variety of other congenital malformations.

Treatment

HI remains a life-threatening and often fatal disorder, and survivors require long-term multidisciplinary management. During the neonatal period, intensive care is needed to provide sufficient nutrition, monitor and manage body temperature, correct fluid and electrolyte imbalances, and prevent and treat respiratory dysfunction, pneumonia or sepsis. Severe ectropion necessitates ophthalmologic care. Infants should be kept in humidified incubators and treated topically with light emollients. Early administration of systemic retinoids, in particular acitretin (usually with an initial dose of 1 mg/kg/day)[65], has been shown to result in shedding of the large, keratotic plates within weeks as well as improvement of the ectropion and eclabium. It is important to discuss

the overall prognosis, therapeutic options and potential side effects with each family before beginning treatment.

COMÈL–NETHERTON SYNDROME

Synonyms: ■ Netherton syndrome ■ Ichthyosis linearis circumflexa ■ Trichorrhexis invaginata

History

This disorder is named after Comèl, an Italian who first described the clinical features of ichthyosis linearis circumflexa, and Netherton, an American who discovered an unusual hair shaft abnormality that he termed "bamboo hair" in a child with a CIE phenotype. Wilkinson et al.[66] delineated the triad of congenital ichthyosis, trichorrhexis invaginata and atopy as "Netherton's syndrome" in 1964. It was later recognized that this disorder encompasses different cutaneous presentations, such as ichthyosiform erythroderma, localized ichthyosis linearis circumflexa and continuous skin peeling[12,67].

Epidemiology

Comèl–Netherton syndrome (NTS) is an autosomal recessive disorder that occurs worldwide, with a higher prevalence in inbred populations. Considering the phenotypic variability and clinical overlap with atopic dermatitis as well as other forms of ichthyosis, it has been estimated that the incidence of NTS might be as high as 1 in 50 000[12]. In one series, 18% of patients who presented with erythroderma during the neonatal period had NTS[68].

Pathogenesis

NTS is caused by biallelic mutations in the serine protease inhibitor Kazal type 5 gene (*SPINK5*)[69,70]. More than 50 *SPINK5* mutations have been identified, with small deletions, insertions or nonsense mutations that result in premature termination of translation in ~65% of cases and missense mutations that compromise enzyme function in the remainder.

SPINK5 encodes the multi-domain serine protease inhibitor LEKTI, which is predominantly expressed in the lamellar granules of epithelia and lymphoid tissues. A lack of functional LEKTI leads to uncontrolled activity of serine proteases, and a significant increase (up to five-fold) of trypsin-like proteolytic activity in the stratum corneum has been documented in NTS patients[71]. This disturbs the regulation of lipid-processing enzymes that is critical to proper formation of the lamellar lipid bilayer system in the stratum corneum. Hastened degradation of desmoglein 1 results in disintegration and shedding of horny cells, ultimately producing superficial clefts within the stratum corneum and severely disrupted skin barrier function[72]. In addition, LEKTI deficiency leads to a loss of crucial anti-inflammatory and antimicrobial mechanisms in the skin.

Histochemical analysis of hair shafts in NTS demonstrates a reduced number of disulfide bonds, which is suggestive of diminished cross-linkage of hair keratin structures and a weaker coherence of cortical cells. Such focal softening of the hair shaft may allow intussusception of the distal shaft into the dilated proximal cup.

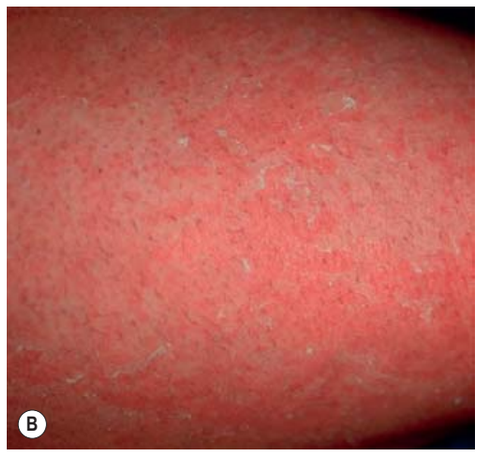

Fig. 57.12 Netherton syndrome. A Generalized involvement with features of congenital ichthyosiform erythroderma. **B** Close-up showing "peeling" quality of the scale. **C** Short, thin hair on the scalp, sparse eyebrows and a lack of eyelashes.

Clinical Features

NTS presents in most (but not all) patients at or soon after birth with generalized erythroderma and scaling (resembling CIE) or continuous peeling of the skin. A collodion membrane is not a feature of NTS. Approximately 20% of neonates develop potentially fatal complications such as hypernatremic dehydration, electrolyte imbalances, perturbed thermoregulation, failure to thrive, pneumonia and sepsis. In patients with severe disease, generalized ichthyosis and erythroderma persist throughout life (Fig. 57.12).

In the majority of patients, the ichthyosis gradually evolves into serpiginous or circinate scaling and erythematous plaques, which are bordered by a peculiar double-edged scale and descriptively named "ichthyosis linearis circumflexa" (Fig. 57.13). The plaques are usually distributed on the trunk and extremities and change over time in size, shape and location, reflecting the undulating course of NTS. The lesions are pruritic, and many patients develop eczematous plaques and/or lichenification in flexural sites, especially the wrists and antecubital and popliteal fossae. Scalp involvement with thick scale is common.

Hair shaft abnormalities usually develop during infancy and early childhood and improve with age, but they vary tremendously in age of onset, extent, severity and type. While in some patients the scalp hair grows slowly and is sparse, thin and fragile, it has a normal appearance in others. Light microscopic examination of clipped hair from the scalp and (of particularly high yield) the eyebrows[73] often reveals trichorrhexis invaginata (bamboo hair) with a ball-and-socket appearance (Fig. 57.14) or nodular thickening of the distal end of broken hair shafts ("golf tee"). Multiple additional abnormalities may be observed, including pili torti,

Fig. 57.13 Ichthyosis linearis circumflexa. Note the double-edged scale.

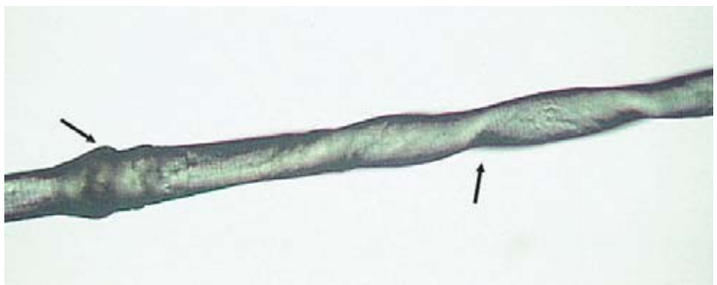

Fig. 57.14 Abnormal hair shaft in Netherton syndrome. Trichorrhexis invaginata with its ball-and-socket appearance (left arrow) and twist in the hair shaft (right arrow).

trichorrhexis nodosa and "helical" hair. Eyelashes and secondary sexual hair can also be affected.

The third characteristic feature of NTS is immune imbalance. Serum levels of IgE are usually markedly elevated, ranging from 100 to >10 000 IU/ml. Eosinophilia and allergic reactions to various foods (e.g. nuts, eggs, fish) and other antigens are common, with clinical manifestations ranging from an exacerbation of eczematous skin lesions to urticaria and angioedema to anaphylactic shock. Children have an increased susceptibility to cutaneous, respiratory and systemic infections, which might reflect defective production of antibodies against protein and polysaccharide antigens. Human papilloma virus (HPV) infections are relatively common and can result from epidermodysplasia verruciformis-associated HPV types. HPV infections may increase the incidence of SCC (e.g. of the vulva or skin) in patients with NTS.

During infancy and early childhood, patients with generalized skin involvement often continue to experience failure to thrive, which may be related to enteropathy with villus atrophy and malnutrition (especially considering the increased caloric needs associated with erythroderma); this often results in short stature[74]. Intermittent aminoaciduria is not uncommon. A few patients with substantial developmental delay have been reported. Although this could be due to consanguinity in these families, in one patient, persistent, mild diffuse volume loss indicative of a permanent injury of brain tissue was documented by MRI[75].

Pathology

On light microscopic examination, the epidermis shows pronounced parakeratotic hyperkeratosis with a diminished or absent granular layer, acanthosis and papillomatosis. There are often dense, almost band-like, lymphohistiocytic perivascular infiltrates in the papillary dermis. Subcorneal clefting, spongiosis, exocytosis and Munro's microabscesses can occur. The stratum corneum may be strongly eosinophilic on PAS stain. Trichorrhexis invaginata, in which the distal hair shaft is telescoped into the proximal segment, is a highly characteristic light microscopic finding in clipped hairs; other hair shaft abnormalities may also be evident (see above).

Ultrastructural abnormalities in the epidermal lipid system that are not present in other erythrodermic disorders may assist in differentiating NTS from CIE and erythrodermic psoriasis. In particular, premature secretion of lamellar body contents in the upper epidermis as well as the presence of intercellular electron-dense accumulations and abnormal splitting in the superficial stratum corneum seem specific for NTS[72,76]. Other ultrastructural abnormalities that are not consistently found include round cytoplasmic inclusion bodies in the upper cell layers (potentially representing lysosomes), a decreased tonofilament–desmosome system and a lack of lamellar bodies. Transmission electron microscopy of hair shafts reveals faulty keratinization, cleavage and electron-dense depositions in the cortex.

Other diagnostic tests

Molecular testing of the *SPINK5* gene is available and can facilitate diagnosis of NTS. Prenatal diagnosis can be performed in families with known *SPINK5* mutations from CVS (as early as the 10th gestational week) or amniocentesis material[70]. In addition, immunostaining of skin biopsy specimens with LEKTI antibodies can be used to determine absence or aberrant distribution of LEKTI protein in the epidermis of affected patients[77,78].

Differential Diagnosis

During infancy, NTS often presents a diagnostic challenge due to its clinical overlap with CIE, erythrodermic psoriasis, and disorders of the immune system (e.g. Omenn syndrome). Although the presence of trichorrhexis invaginata and other hair shaft abnormalities can distinguish NTS from these conditions, characteristic hair shaft abnormalities may not be present at birth or in early infancy, and their detection requires repeated microscopic analysis of many hairs from different locations (e.g. scalp, eyebrows). Elevated serum IgE levels can also help to differentiate NTS from CIE and psoriasis.

In addition to Omenn syndrome, hyper-IgE syndrome may represent a diagnostic consideration; the latter is characterized by elevated IgE levels in association with recurrent bacterial and candidal infections and a neonatal papulopustular eruption that is followed by the development of atopic-like dermatitis. However, the facial, dental and skeletal anomalies observed in classic hyper-IgE syndrome are not seen in NTS. To differentiate among these and other primary immunodeficiencies, including Wiskott–Aldrich syndrome (see Ch. 60), infants with failure to thrive and generalized eczematous or scaling skin require a comprehensive immunologic evaluation.

In acrodermatitis enteropathica (see Ch. 51), erythematous, sometimes figurate plaques with scale-crust are usually restricted to periorificial areas and the distal extremities. If zinc deficiency cannot be excluded with certainty, an empirical trial of zinc treatment is indicated. The migratory, serpiginous plaques of ichthyosis linearis circumflexa can also resemble those seen in erythrokeratodermia variabilis. Prominent borders with a double-edged scale and associated hair shaft abnormalities are specific for NTS, while transient, variable erythematous patches are characteristic of erythrokeratodermia variabilis.

Peeling skin syndromes (PSSs) are clinically and genetically heterogeneous disorders characterized by perpetual peeling and desquamation of the skin with variable associated erythema. They share many features with NTS, including congenital erythroderma (in the generalized inflammatory subtype of PSS), pruritus, and histologic and ultrastructural abnormalities. Although mutations in the corneodesmosin gene (*CDSN*) were recently found to cause generalized inflammatory PSS[79], *SPINK5* mutations have been identified in some patients with erythroderma and generalized skin peeling[75].

Treatment

Treatment is symptomatic and should be adjusted to the patient's specific needs. Neonates with exfoliative erythroderma and severe impairment of skin barrier function often require management in an intensive care nursery. Patients who develop failure to thrive and enteropathy may need nutritional support to ensure sufficient intake of calories and protein.

Topical emollients, keratolytics, tretinoin, calcipotriene (calcipotriol) and corticosteroids (alone or in combination) are variably effective.

Although the skin lesions of NTS may respond well to topical tacrolimus, dramatically increased percutaneous absorption of this medication has been described in NTS patients, presumably due to their severe skin barrier dysfunction[80]. Use of topical tacrolimus in NTS patients therefore requires monitoring of plasma drug levels. Topical pimecrolimus has also been successfully used in NTS patients, with considerably less systemic absorption[81]. Topical or systemic antimicrobial agents are often required to treat bacterial and fungal skin infections, but continuous preventive antibiotic therapy (oral or topical) should be avoided because of the risk of developing antibiotic resistance. Oral antihistamines may be helpful in controlling pruritus. Systemic retinoids have variable efficacy, leading to dramatic improvement in some patients and exacerbation of the disease in others. Benefit from treatment with psoralen plus UVA (PUVA), UVA1 and balneophototherapy (broadband UVB plus salt water baths) has been reported.

SJÖGREN–LARSSON SYNDROME

History

In 1957, Sjögren and Larsson[82] defined the clinical triad of congenital ichthyosis, gradually developing di- or tetraplegia, and mental retardation as a distinct disorder in 28 Swedish patients. In 1988, Rizzo et al.[83] discovered an underlying deficiency in the oxidation of long-chain fatty acids due to malfunction of the fatty alcohol dehydrogenase : fatty aldehyde dehydrogenase enzyme complex. Subsequently, De Laurenzi et al.[84] identified the underlying defect in the fatty aldehyde dehydrogenase gene (*ALDH3A2/FALDH*).

Epidemiology

Sjögren–Larsson syndrome (SLS) is an autosomal recessive neurocutaneous disorder. It occurs worldwide with an estimated prevalence of less than 1 in 100 000. It is most common in northern Sweden, where it is estimated that 1.3% of the population are heterozygous carriers[82].

Pathogenesis

SLS is caused by a deficiency of the microsomal fatty aldehyde dehydrogenase enzyme due to recessive inactivating mutations in the *ALDH3A2* (*FALDH*) gene[84]. More than 80 distinct mutations have been identified to date, and sequence analysis of the *ALDH3A2* gene has almost 100% sensitivity in patients with a clinical diagnosis of SJS. In a group of 121 SLS families, 38% had missense, 16% splice site and 5% nonsense mutations, with deletions, insertions and complex mutations in the remainder[85]. A few mutations have a high allelic frequency in northern European and Middle Eastern populations due to a founder effect[85].

The microsomal fatty aldehyde dehydrogenase enzyme (FALDH) catalyzes NAD-dependent oxidation of long-chain aliphatic aldehydes (derived from metabolism of 16- to 18-carbon straight-chain fatty alcohols and ether glycerolipids) into fatty acids. This pathway is important for the synthesis of epidermal lipids as well as the catabolism of ether phospholipids and sphingolipids in the brain[86]. The symptoms of SLS are thought to stem from membrane alterations due to accumulation of fatty alcohol- or fatty aldehyde-modified lipids and proteins. Retarded myelination and a variable degree of dysmyelination probably result from the accumulation of free lipids in the periventricular white matter. In addition, FALDH catalyzes steps downstream of lipoxygenases (12R-LOX and eLOX) in the hepoxilin pathway of arachidonic acid metabolism (which is also modulated by ichthyin). FALDH also degrades leukotriene B_4, and the accumulation of leukotrienes may contribute to pruritus in SLS patients.

Clinical Features

SLS presents at birth with varying degrees of erythema, hyperkeratosis and scaling. A collodion membrane and ectropion are rare. After infancy, the erythema tends to fade, while hyperkeratosis and scaling become more prominent and darker in color. The ichthyosis varies from fine, white scales to larger, plate-like scales to non-scaling, yellowish hyperkeratosis (Fig. 57.15). Predilection sites include the lower abdomen (especially around the umbilicus), the neck (especially the sides and nape) and flexural areas. Approximately 70% of patients develop palmoplantar keratoderma. Accentuated skin markings and lichenification of flexural areas are common. In contrast to most other ichthyoses, SLS is associated with persistent pruritus, which often leads to visible excoriations.

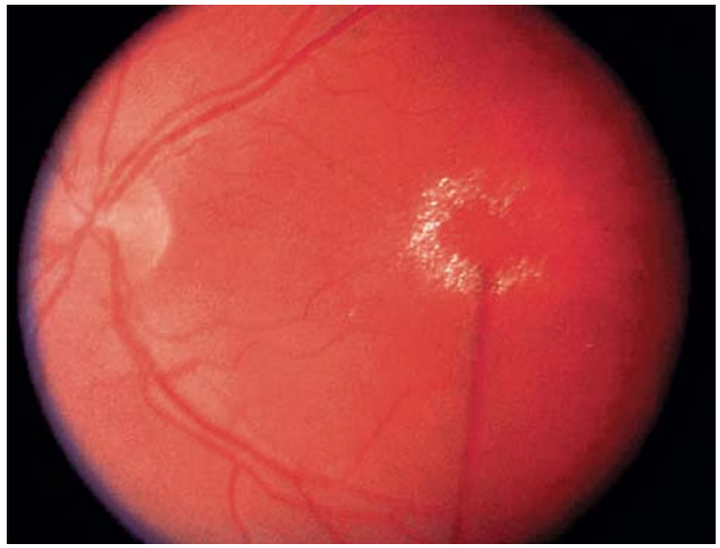

Fig. 57.16 Sjögren–Larsson syndrome. Perifoveal glistening white dots of the ocular fundus. *Courtesy, WB Rizzo, MD.*

An important diagnostic and almost pathognomonic finding in SLS is the presence of perifoveal glistening white dots in the ocular fundus, which represents a form of juvenile macular dystrophy (Fig. 57.16)[87]. These dots can be detected in many, but not all, patients during the first year of life, and they increase in number over time. Involvement of the CNS usually manifests at the end of the first year of life with delayed motor development, an abnormal gait, pyramidal signs, spasticity and contractures. The lower extremities are usually more severely affected than the arms. The di-or tetraplegia is gradually progressive and accompanied by speech defects and mental retardation. Seizures are present in almost 40% of affected individuals, and MRI of the brain shows white matter disease in most patients. Other variable clinical features of SLS include superficial corneal defects and photophobia, dental and/or osseous dysplasia, and hypertelorism.

Pathology

The histopathologic features are nonspecific and include primarily orthokeratotic hyperkeratosis, papillomatosis and moderate acanthosis

with a well-developed granular layer. Similarly, the ultrastructural abnormalities are not diagnostic. Keratinocytes may show mitochondrial proliferation and a prominent Golgi apparatus, with lamellar membranous inclusions and clefts in corneocytes.

Other diagnostic tests

Cultured skin fibroblasts, keratinocytes or leukocytes have drastically reduced or absent FALDH activity. Biochemical analysis has proven to be a reliable diagnostic tool that also allows detection of unaffected carriers, who exhibit half of the normal levels[88]. Another sensitive marker for the enzyme deficiency in SLS is the detection of elevated free fatty alcohols in cultured fibroblasts and plasma. However, the preferred method for confirming the diagnosis of SLS is DNA-based molecular testing. Prenatal molecular diagnosis from CVS or amniocentesis material can also be performed[85,88].

Differential Diagnosis

Clinically, the combination of congenital ichthyosis with spasticity and/or retinal glistening dots is diagnostic for SLS. The skin findings can overlap with those of steroid sulfatase deficiency, severe ichthyosis vulgaris and mild forms of CIE or lamellar ichthyosis. In contrast to the latter two disorders, ectropion, eclabium and alopecia are usually not seen in SLS.

Treatment

Management of SLS patients requires a multidisciplinary approach, including dermatologic, neurologic, ophthalmologic and orthopedic care as well as social support. Topical keratolytics and vitamin D preparations in combination with hydration of the skin are helpful in reducing hyperkeratosis and scaling. Systemic retinoids, especially acitretin, are effective and relatively safe even in children when a minimal effective dose is maintained and patients are monitored for side effects. The 5-lipoxygenase inhibitors (e.g. zileuton) block the synthesis of leukotriene B_4 and have been shown to decrease pruritus in a subset of SLS patients, but a beneficial effect on the ichthyosis and CNS symptoms has not been demonstrated. Treatment of neurologic abnormalities is symptomatic, including anticonvulsive agents for seizures as well as aggressive physical therapy and (if indicated) surgical intervention to improve mobility. Various forms of a fat-reduced diet have yet to provide consistent and reproducible results.

NEUTRAL LIPID STORAGE DISEASE WITH ICHTHYOSIS

Synonym: ▪ Chanarin–Dorfman syndrome

History

This disorder of lipid metabolism was first recognized as a distinct entity by Dorfman et al.[89] in 1974, and Chanarin et al.[90] coined the name in 1975.

Epidemiology

This is a rare autosomal recessive disorder. Most cases have been observed in consanguineous families from the Middle East and Mediterranean basin (e.g. Sicily, Greece, Turkey, Algeria and Morocco).

Pathogenesis

Neutral lipid storage disease with ichthyosis is an inborn error of lipid metabolism with accumulation of triglycerides in the skin and other organs. The disorder is caused by deleterious germline mutations in the abhydrolase domain containing 5 gene (*ABHD5*; previously known as *CGI-58*), which encodes a protein in the esterase/lipase/thioesterase subfamily[91]. This lipid droplet-associated protein facilitates lipolysis in cooperation with triglyceride lipases, perilipin and other factors[92]. Cytoplasmic accumulation of triglyceride droplets presumably results from a block in the degradation of endogenously produced diacylglycerols[93]. Hydrolyzed fatty acids and the acylated glycerol backbone of triglycerides cannot be properly incorporated into phospholipids, and they are instead re-esterified to form triglycerides. Hydrolysis of triglycerides of exogenous origin (serum lipoproteins) via liposomal acid lipase as well as endogenous triglycerides via cytosolic lipase is normal. In the skin, deficiency of the ABHD5 protein is thought to result in defective lipid production within lamellar granules[94].

Clinical Features

The disorder presents at birth with generalized, fine, white scaling of the skin and a variable degree of erythema, thus resembling CIE[90,91,93]. At least one patient with a collodion membrane has been reported and several patients have had ectropion, eclabium and alopecia[93]. On the lower extremities and scalp, the scales may be grayish, larger and plate-like with detached borders.

The widespread tissue deposition of neutral lipids results in a broad array of systemic manifestations during childhood. Serum liver enzymes and muscle phosphocreatine kinase are usually elevated, although the myopathy may be mild and detectable only by neurologic examination. Hepatomegaly is common, and liver biopsy often reveals severe fatty degeneration and fibrosis, which may not be reflected in liver function studies.

Cataracts, neurosensory deafness and developmental delay are frequent features, while growth retardation, ataxia, microcephaly, splenomegaly and intestinal malabsorption have been observed only in a subset of patients. The prognosis of neutral lipid storage disease with ichthyosis depends primarily on the course of the liver disease and extent of hepatic fibrosis.

Pathology

A diagnostic feature is the presence of numerous lipid-containing vacuoles in circulating granulocytes (Jordan's anomaly), eosinophils and monocytes, a finding detectable on a fresh peripheral blood smear but not by automated blood counting methods (Fig. 57.17). Similar findings (but to a lesser extent) may be seen in heterozygous carriers of the disease. Using lipid stains (oil red O, Sudan III), cytoplasmic lipid droplets can be also detected in fresh frozen skin sections, particularly in the epithelium of eccrine sweat glands and ducts but also in fibroblasts and basal and sometimes suprabasal keratinocytes. Ultrastructural abnormalities of the epidermis include globular electron-lucent inclusions, which disrupt the normal structure of lamellar bodies in the cells of the granular layer and change the conformation of intercellular lipid lamellae throughout the stratum corneum[95].

Fig. 57.18 Acral peeling skin syndrome. Superficial peeling of the skin on the ankle and dorsal aspect of the foot. *Courtesy, E Sprecher, MD, PhD.*

Differential Diagnosis

The associated ichthyosis is clinically similar to CIE, but the microscopic detection of lipid vacuoles in circulating white blood cells is diagnostic for neutral lipid storage disease with ichthyosis. In Refsum disease, a peroxisomal disorder characterized by accumulation of phytanic acid, the ichthyosis is not congenital and is more reminiscent of ichthyosis vulgaris. Although cytoplasmic lipid accumulations in basal keratinocytes may be found in both disorders, lipid droplets on a peripheral blood smear are not seen in Refsum disease.

Treatment

Therapy is symptomatic. Topical emollients and keratolytics as well as systemic retinoids have been shown to improve the ichthyosis. A fat-restricted diet (e.g. low in long-chain but enriched in medium-chain fatty acids) has been reported to be beneficial in a few patients, but data are too limited to determine if systemic complications can be prevented.

TRICHOTHIODYSTROPHY WITH ICHTHYOSIS

Synonyms: ■ IBIDS: ichthyosis, brittle hair, infertility, developmental delay, short stature ■ Tay syndrome ■ PIBIDS: photosensitivity + IBIDS ■ Sulfur-deficient brittle hair syndrome

History

The first description of this disorder was in 1968, when Pollitt et al.[96] reported siblings with brittle hair, trichorrhexis nodosa, short stature and mental retardation. In 1971, Tay[97] described three siblings with similar features and additional skin involvement resembling CIE. Several years later, the term "trichothiodystrophy" was proposed to encompass a heterogeneous group of neuroectodermal disorders that share the finding of sulfur-deficient, short, brittle hair.

Epidemiology

With the exception of one reported case with possible X-linked transmission, the disorder is inherited in an autosomal recessive fashion, affecting both genders equally.

Pathogenesis

Trichothiodystrophies are a heterogeneous group of neuroectodermal disorders. In types that are associated with photosensitivity, there is reduced stability or altered function of the large transcription factor IIH (TFIIH) (see Ch. 86). This can be due to recessive mutations in two genes that encode its helicase subunits, *ERCC2*/XPD and, less frequently, *ERCC3*/XPB. These genes are also mutated in patients with xeroderma pigmentosum (XP; complementation groups D and B, respectively) and combined Cockayne syndrome–XP. Mutations in the *GTF2H5* gene, which encodes the TFIIH subunit TTD-A, have also been implicated in a small subset of patients with photosensitive trichothiodystrophy[98]. In addition, mutations in *C7ORF11*, which encodes a protein with a potential role in regulating mitosis and cytokinesis, have been identified in patients with a non-photosensitive form of trichothiodystrophy that typically lacks ichthyosis.

The TFIIH deficiency in patients with trichothiodystrophy due to abnormal XPD or XPB results in impaired DNA repair, thus leading to photosensitivity, as well as repression of the basal transcription of genes that are highly expressed in differentiated cells of various tissues. The latter mechanism might explain defective synthesis of high-sulfur matrix proteins in hair and nails, growth retardation, short stature and neurologic abnormalities, and it is supported by findings in transgenic animals[99]. In contrast, the TFIIH defect in XP profoundly impairs global genome nucleotide excision repair (which is particularly important for UV-induced DNA damage) and thereby leads to cancer formation as well as photosensitivity, while abnormal transcription-coupled repair in Cockayne syndrome results in apoptosis of metabolically active cells (e.g. neurons) rather than carcinogenesis. This lack of carcinogenesis in trichothiodystrophy might be attributed to the fact that the TFIIH defects in these patients do not completely abolish its nucleotide excision repair function[100]. Analysis of the steady-state level of TFIIH in fibroblast strains of trichothiodystrophy patients with *ERCC2*/XPD mutations revealed a substantial and specific reduction (up to 70%) in the cellular concentration of TFIIH complex[101].

Clinical Features

The obligatory finding in all types of trichothiodystrophy is short, unruly, fragile hair of the scalp, eyebrows and eyelashes due to abnormally low sulfur content (i.e. deficient cysteine and/or methionine). Body, axillary and pubic hair may also be affected. Nail changes are common and can include thinning, longitudinal ridging, yellow discoloration, splitting and onychogryphosis. Patients with trichothiodystrophy may present at birth or in the neonatal period with erythroderma and generalized fine scaling similar to that seen in CIE. A collodion membrane presentation is rare and not associated with ectropion or eclabium. The erythema usually resolves during infancy. The size and color of the associated scale is variable, ranging from fine and translucent to large and dark.

Photosensitivity occurs in half of patients, but (similar to Cockayne syndrome) there is no propensity to develop cutaneous malignancies[99]. Additional cutaneous findings that have been described in trichothiodystrophy patients include follicular keratoses, folliculitis, erythema, atopic-like dermatitis, cheilitis, hypohidrosis, pruritus, hyperpigmentation of the eyelids, lentigines, hypopigmented macules, telangiectasias, poikiloderma, "hemangiomas", lipoatrophy, pyoderma and palmar pustules. Other associated abnormalities depend upon the type of trichothiodystrophy and include short stature, mental retardation, hypogonadism, progeria-like features (e.g. decreased subcutaneous fat), cataracts, joint contractures and (very rarely) osteosclerosis.

Pathology

By light microscopy, hair shafts show transverse fractures (trichoschisis) in conjunction with an irregular surface and diameter. Occasionally, a nodal appearance similar to trichorrhexis nodosa or 180° twists as in pili torti may be observed. Polarizing light microscopy is the gold standard for detecting the characteristic light and dark bands, the so-called "tiger-tail" or "zigzag" pattern (see Ch. 69), which has been incorrectly referred to as alternating birefringence[99]. On transmission electron microscopy, an abnormal arrangement of microfibers as well as an absence of the exocuticle and cuticular A-layer may be seen. If ichthyosis is present, histopathologic changes are typically similar to those found in ichthyosis vulgaris (see above). Occasionally, perinuclear vacuoles are seen.

Other diagnostic tests

Hair sulfur content can be semi-quantitatively analyzed by scanning electron microscopy. Determination of cysteine content through amino acid analysis of hydrolyzed hair is also possible.

Differential Diagnosis

Although Cockayne syndrome shares several features with the photosensitive form of trichothiodystrophy, the former lacks ichthyosis and

tiger-tail hairs. Likewise, the characteristic findings on microscopic hair analysis distinguish trichothiodystrophy from other conditions that feature congenital alopecia or hypotrichosis, including Menkes disease. Polarized hairs can also have a tiger-tail pattern in healthy infants, but this is usually not prominent in all hairs as it is in trichothiodystrophy. Hair shaft abnormalities (including trichorrhexis nodosa), ichthyosiform erythroderma and failure to thrive are also seen in NTS; although differentiation from trichothiodystrophy can be difficult in the neonatal period, elevated serum IgE levels are suggestive of NTS. Patients with Sjögren–Larsson syndrome, lamellar ichthyosis and CIE have no hair shaft abnormalities.

Treatment

If photosensitivity is present, sun protection is essential. Treatment of the ichthyosis should be tailored to its severity. Symptomatic relief is best achieved with humectants or (in more severe cases) systemic retinoids.

REFSUM DISEASE

Synonyms: ■ Heredopathia atactica polyneuritiformis ■ Phytanic acid storage disease

Refsum disease is a rare autosomal recessive neurocutaneous disorder that results from abnormal lipid metabolism. It is caused by mutations in the phytanoyl-CoA hydroxylase (*PHYH*) or peroxisome biogenesis factor 7 (*PEX7*) genes, which lead to impaired degradation of phytanic acid[102–104]. As a result, this 20-carbon, saturated, branched-chain fatty acid (exclusively derived from exogenous sources) accumulates in multiple tissues and body fluids.

During childhood or adolescence, half of patients with Refsum disease develop ichthyosis of mild to moderate severity that is characterized by small white scales on the extremities and trunk, often resembling ichthyosis vulgaris. Larger, adherent scales and hyperlinear or hyperkeratotic palms and soles may also be seen. Histologic examination of affected skin shows orthokeratotic hyperkeratosis and lipid-containing vacuoles in basal keratinocytes.

Adolescents with Refsum disease present with the insidious onset of neurologic symptoms such as weakness, difficulty walking and poor night vision. Cardinal features are atypical retinitis pigmentosa, hypo- or anosmia, peripheral polyneuropathy of a mixed motor and sensory type, cerebellar dysfunction and elevated protein levels in the cerebrospinal fluid. Other findings can include sensorineural deafness, cataracts, renal tubular dysfunction, cardiomyopathy and skeletal hyperostosis.

Refsum disease typically follows a progressive but undulating course and results in gradual neurologic deterioration. However, drastic reduction of dietary phytanic acid intake (<5 mg daily; found mainly in dairy products and animal fats) can both prevent acute attacks and arrest neurologic progression, although retinal changes are usually irreversible[105–107]. LDL apheresis can be performed to eliminate (V)LDL-bound phytanic acid in settings of acute toxicity[105–107].

OTHER ICHTHYOSES

Additional rare ichthyoses for which the genetic basis or chromosomal locus is known are presented in Table 57.5.

ERYTHROKERATODERMAS

ERYTHROKERATODERMIA VARIABILIS

Synonyms: ■ Erythrokeratoderma variabilis ■ Erythrokeratodermia figurata variabilis ■ Mendes da Costa disease

History

De Buy Wenninger published the first description of this entity in 1907[119]. Eighteen years later, Mendes da Costa presented a detailed clinical description of the disease in a mother and daughter, reviewed eight previously reported cases, and coined the name "erythroet keratodermia variabilis"[120]. Over the next several decades, large Dutch and Swiss kindreds with this condition were described. The first case in the American literature was reported by Barsky and Bernstein in 1964[121].

Epidemiology

Erythrokeratodermia variabilis (EKV) is a rare disorder, predominantly inherited in an autosomal dominant fashion with nearly complete penetrance but considerable intra- and interfamilial variability. More than 200 cases have been reported, the majority of which were in Caucasians, although EKV has also been observed in African-Americans and Asians. In a few families, autosomal recessive inheritance has been documented.

Pathogenesis

Most, but not all, cases of EKV are caused by dominant mutations in the connexin genes *GJB3* and *GJB4*[122,123] (see Table 58.3). These genes encode the gap junction proteins β3 (connexin 31) and β4 (connexin 30.3), which belong to a large family of transmembrane proteins that form intercellular channels (see Ch. 58). To date, 14 dominant and 2 recessive mutations have been reported in *GJB3* or *GJB4* in >20 unrelated families and sporadic cases with EKV. All mutations result in amino acid substitutions of conserved residues in connexin 31 or connexin 30.3, which have been shown to alter the structure or function of gap junction channels, impair cytoplasmic trafficking of the mutant gap junction proteins to the cell membrane and/or induce cell death, thereby impairing normal epidermal differentiation[124].

Clinical Features

The hallmark of EKV is the coexistence of transient erythematous patches and more stable hyperkeratotic plaques. One of these features frequently predominates, and occasionally one is missing. The erythematous component is most prevalent during childhood and later slowly subsides. More than 50% of patients present at birth or in the neonatal period, and 90% within the first year of life, with transient erythematous patches that can involve any part of the integument. These lesions are well demarcated with a geographic, circinate or target-like appearance, and they can coalesce into large figurate patches (Fig. 57.19). Circinate or gyrate erythematous patches have been associated predominantly with mutations in *GJB4*, and this variant might be identical to the previously described "erythrokeratodermia en cocarde". The erythema is of variable intensity and is sometimes surrounded by a blanched halo. Individual lesions usually persist for only minutes to hours, although they may last for days. In about 35% of patients, the erythema is preceded or accompanied by a burning sensation, which

Fig. 57.19 Erythrokeratodermia variabilis. Transient erythematous patches and generalized brownish hyperkeratosis.

Fig. 57.20 Erythrokeratodermia variabilis. A Symmetrically distributed hyperkeratotic plaques with hypertrichosis. **B** Brown hyperkeratotic plaques with geographic borders in a 7-year-old child. *B, Courtesy, Julie V Schaffer, MD.*

may cause discomfort. The remarkable variability in number, size, shape, location and duration of erythematous patches is reflected in the name of the disease.

Hyperkeratosis evolves simultaneously with or following the appearance of transient erythematous lesions. Sharply demarcated, yellow–brown to pink–brown thickened plaques with geographic borders progressively develop on the limbs, buttocks and trunk in an almost symmetric distribution (Fig. 57.20). In approximately half of all patients, the thickening of the skin extends onto the palms and soles, while the flexures, face and scalp tend to be spared. The surface can be ridged, verrucous or velvety, and it may have collarette-like peeling or fine, adherent scales. Lesions on the elbows, knees, Achilles tendons, dorsal aspect of the feet, and waistline are particularly common and tend to persist for months to years. In a subset of patients with severe disease, hyperkeratosis is generalized and persistent, with a yellow–brown–gray thickening of the skin and accentuated skin markings. Fine scaling, peeling and hypertrichosis may be observed. Some patients develop thick, dark plates of hyperkeratosis with a spiny, hystrix-like appearance, especially on the lower extremities.

After gradual progression throughout infancy and childhood, EKV tends to stabilize after puberty. Improvement over time and periodic clearing of the skin are not unusual. Skin lesions may be triggered by factors such as emotional stress, sudden temperature changes, mechanical friction and sun exposure.

Pathology

Histopathologic features are orthokeratotic, basket-weave hyperkeratosis, moderate to severe acanthosis with a prominent granular layer, and papillomatosis. There are dilated, elongated capillaries with minimal perivascular inflammation in the papillary dermis. Severe papillomatosis with suprapapillary thinning may result in a "church spire" configuration of the epidermis. Ultrastructural studies have had variable results, including a reduced number of lamellar bodies in the granular layer.

Differential Diagnosis

EKV shares many clinical features with progressive symmetric erythrokeratoderma (PSEK), making it difficult to distinguish these disorders. In contrast to EKV, hyperkeratotic plaques in PSEK usually develop on an erythematous base and there are no additional "migrating" red patches. However, transient erythematous patches are subtle or absent in some EKV patients, especially during adulthood. Although a *GJB4* mutation has been identified in some patients with a PSEK phenotype, the absence of pathogenic mutations in *GJB3* or *GJB4* in at least six patients/families with PSEK suggests that it also exists as a genetically distinct entity[122,125]. More thorough genotype-phenotype correlations are needed to better understand the phenotypic spectra of EKV and PSEK and the relationship between these conditions.

The migratory, serpiginous erythematous plaques of ichthyosis linearis circumflexa (a presentation of NTS) are typically bordered by a double-edged scale, and patients usually have additional manifestations such as hair shaft abnormalities, eczematous lesions and pruritus. The micaceous scale and histopathologic findings of psoriasis distinguish it from EKV. Patients with erythrokeratolysis hiemalis (see Table 57.5) develop erythematous circinate plaques with centrifugal peeling that primarily affect the palms and soles but occasionally extend to the arms and legs. Sharply demarcated hyperkeratotic plaques that wax and wane may also be seen in rare cyclic and annular subtypes of epidermolytic ichthyosis (due to *KRT1* and *KRT10* mutations, respectively; see above). Greither syndrome (see Ch. 58) is another condition due to *KRT1* mutations that features a transgredient palmoplantar keratoderma as well as hyperkeratotic plaques that can resemble lesions in EKV and PSEK, but no transient erythema. Lastly, MEDNIK syndrome (*m*ental retardation, *e*nteropathy, *d*eafness, peripheral *n*europathy, *i*chthyosis, *k*eratoderma) has skin findings (erythematous patches and hyperkeratotic plaques) similar to EKV (see Table 57.5).

Treatment

Therapy is symptomatic and depends on the severity and extent of hyperkeratosis, which varies over time and from patient to patient. Topical management with keratolytic agents (e.g. lactic acid, urea, α-hydroxy acids) and/or retinoids (e.g. tretinoin, tazarotene) may be sufficient for mild disease. Systemic retinoids such as acitretin and isotretinoin are the treatment of choice for more extensive or severe EKV. These agents often produce dramatic improvement or complete clearing of hyperkeratosis and significant reduction in the development of erythematous lesions, although the latter cannot be completely suppressed. The minimal maintenance dose for patients with EKV is usually considerably lower than that required for other disorders of cornification. Nevertheless, the use of retinoids should always be considered carefully, since chronic therapy is necessary to avoid relapse and long-term side effects, especially in children, may ensue. The red patches in EKV often result in cosmetic concerns, which can be limited by masking uncovered skin with camouflaging makeup. Avoidance of sudden temperature changes and trauma to the skin (e.g. friction or irritation) may be beneficial.

PROGRESSIVE SYMMETRIC ERYTHROKERATODERMA

Synonyms: ■ Erythrokeratoderma progressiva symmetrica ■ Gottron syndrome

History

The original description of PSEK dates back to Darier in 1911[126], and Gottron coined the name in 1922[127].

Epidemiology

PSEK is a rare disorder that appears to be genetically heterogeneous. Autosomal dominant and, less frequently, autosomal recessive transmission have been reported.

Pathogenesis

This disorder of cornification is characterized by increased epidermal cell proliferation in lesional skin. Two patients reported to have PSEK were found to have a dominant mutation in the *GJB4* gene (as seen in EKV)[125]. In a single Japanese family with PSEK-like features associated with mutilating palmoplantar keratoderma including pseudoainhum (which is usually not seen in PSEK), Ishida-Yamamoto et al.[128] detected a frameshift mutation in the loricrin gene. However, in one study, none of six PSEK patients/families from different ethnic backgrounds harbored disease-causing mutations in either the loricrin gene or the connexin genes implicated in EKV, indicating that additional genes must be causally involved[122]. A locus for PSEK on chromosome 21q11.2–q21.2 has been identified in a five-generation Chinese family[129].

Clinical Features

PSEK usually begins during infancy or early childhood with the development of fixed, sharply demarcated, polycyclic hyperkeratotic plaques on an erythematous base covered by fine scale or with a rough, verrucous surface, especially over joints. They are symmetrically distributed on the extremities (Fig. 57.21), buttocks, face (especially the cheeks) and, occasionally, the trunk. A subset of patients initially presents with bright red, progressively thickening plaques on the cheeks. Diffuse, erythematous palmoplantar keratoderma has been observed in at least half of the patients. The hyperkeratotic plaques slowly increase in number and size during childhood, but they tend to stabilize after puberty.

Pathology

Acanthosis of the epidermis with basket-weave and often patchy parakeratotic hyperkeratosis is seen. The granular layer is prominent and sometimes shows intracellular vacuolization. Follicular plugging is not uncommon. Dilated capillaries and sparse lymphocytic perivascular infiltrates are found in the papillary dermis. Electron microscopic examination reveals perinuclear vacuolization and lipid-like vacuoles or laminated inclusions in the stratum corneum, but these features are not diagnostic. Occasionally, swollen mitochondria and irregular keratohyalin granules may be observed.

Fig. 57.21 Progressive symmetric erythrokeratoderma. Well-demarcated, symmetrically distributed hyperkeratotic plaques on the lower extremities with underlying erythema and fine, white scale; the patient also had a plantar keratoderma.

Differential Diagnosis

The skin findings in PSEK, EKV and erythrokeratodermia associated with ataxia (see Table 57.5) overlap considerably, although the occurrence of transient erythema and relative sparing of the face can differentiate EKV. Diffuse palmoplantar keratodermas, especially the transgredient type described by Greither, may be associated with hyperkeratotic plaques on the knees, elbows and other extensor surfaces. The presence of perifollicular papules, islands of sparing and a salmon color distinguish pityriasis rubra pilaris, while psoriasis has characteristic micaceous scale and distinctive histopathologic findings.

Treatment

Topical keratolytics (urea, α-hydroxy acids, salicylic acid), propylene glycol and emollients are usually not very helpful. The use of topical retinoids or vitamin D preparations has not yet been reported. Several PSEK patients have been noted to respond well to systemic treatment with retinoids (isotretinoin, acitretin), while others did not. There are also anecdotal reports of successful PUVA therapy.

KERATITIS–ICHTHYOSIS–DEAFNESS SYNDROME

Synonyms: ▪ KID syndrome ▪ Erythrokeratodermia progressiva Burns

History

In 1915, Frederick Burns provided a detailed clinical description delineating all the key features of this syndrome[130]. Subsequently, several case reports emerged in the literature using different names to describe the skin involvement, such as "atypical erythrokeratodermia with deafness", "atypical ichthyosiform erythroderma", "ichthyosiform dermatosis" and others. In 1981, Skinner summarized the previous reports and coined the acronym "KID" (keratitis–ichthyosis–deafness) syndrome[131]. Although several authors[12,132] argued that the skin findings represent erythrokeratoderma rather then ichthyosis, the widely used acronym prevailed. KID syndrome presents an overlap between disorders of cornification and ectodermal dysplasias.

Epidemiology

KID syndrome is a rare disorder, with about 200 published cases. Although it is inherited in an autosomal dominant manner, the majority (>90%) of reported cases have been sporadic.

Pathogenesis

The vast majority of KID syndrome patients harbor mutations in *GJB2*, which encodes connexin 26, a β-type gap junction protein[133,134]. In a single patient with features of KID syndrome and congenital atrichia, a causative mutation was identified in the *GJB6* gene encoding connexin 30[135]. All pathogenic mutations identified to date have been heterozygous missense mutations. A *GJB2* mutation substituting aspartic acid with asparagine in codon 50 (D50N) is particularly common and accounts for almost 80% of KID patients[133,134]; it is likely due to a mutational "hot spot" (CpG island). D50N usually results in "classic" KID syndrome, but the follicular occlusion triad and the allelic hystrix-like–ichthyosis–deafness (HID) syndrome have also been described in patients with this mutation[27]. Other *GJB2* mutations affecting the amino terminus or transmembrane domains of connexin 26 have been associated with atypical clinical features such as lack of palmoplantar keratoderma or corneal involvement, generalized spiny or verrucous keratoses, mucosal involvement and the follicular occlusion triad.

ADDITIONAL MUCOCUTANEOUS MANIFESTATIONS OF KID SYNDROME
INFLAMMATORY
• Follicular occlusion triad (onset usually at puberty): acne conglobata, dissecting cellulitis of the scalp, hidradenitis suppurativa • Folliculitis • Cheilitis with red, "chapped", fissured lips (especially at the angles of the mouth*) • Stomatitis with erythematous patches, adherent white plaques and erosions*
INFECTIOUS
• Recurrent or chronic mucocutaneous bacterial (e.g. *Staphylococcus aureus*), fungal (e.g. *Candida* spp.) and viral infections • Sepsis in the neonatal period (may be fatal)
NEOPLASTIC
• Cutaneous and oral squamous cell carcinoma (10–20% of patients) • Epidermoid and pilar cysts • Proliferating pilar tumors, benign or malignant (the latter aggressive/metastasizing)
*May have candidal superinfection.

Table 57.6 Additional mucocutaneous manifestations of KID syndrome. The spectrum of hyperkeratotic manifestations is described in the text.

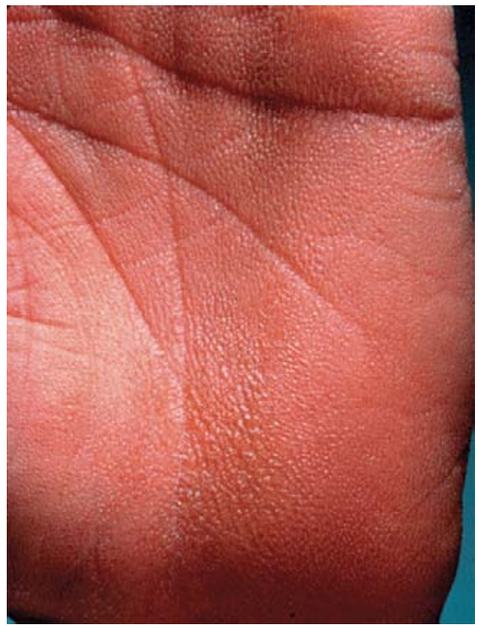

Fig. 57.23 KID syndrome. Palmar keratoderma with a grainy surface.

Fig. 57.22 KID syndrome. In addition to the erythematous plaques, characteristic radial furrows are seen. *Courtesy, L Russell, MD, and SJ Bale, PhD.*

Clinical Features

There is considerable variability in the type, extent and severity of cutaneous features in patients with KID syndrome (Table 57.6). The first manifestation is often transient erythroderma at birth or during infancy. Later, most patients develop symmetrically distributed, well-demarcated, hyperkeratotic plaques with an erythematous base and a rough, ridged or verrucous surface (i.e. erythrokeratoderma) (Fig. 57.22); psoriasiform plaques have also been described. The plaques are predominantly localized to the knees, elbows and face (often with radial furrows around the mouth), although the helices, scalp, groin and other skin folds, skin overlying small joints and other parts of the extremities, and, rarely, trunk may be affected. A plaque-like or diffuse palmoplantar keratoderma with a grainy, reticulated or stippled-appearing surface pattern (reminiscent of Vohwinkel syndrome) is almost always present (Fig. 57.23). Prominent follicular keratoses and cheilitis (especially perlèche) are common. Some patients develop diffuse thickening of the skin with a coarse-grained appearance, which may also lead to deep facial furrows. Nails may be dystrophic and show leukonychia. Although most patients have normal hair, some affected individuals have lusterless hair or alopecia of the scalp, eyelashes and eyebrows. Heat intolerance rarely occurs.

The spectrum of cutaneous lesions in KID syndrome also includes folliculitis, the follicular occlusion triad, cysts and proliferating pilar tumors (with rare reports of malignant lesions) (see Table 57.6). Another serious complication is the development of SCC of the skin and oral mucosa, which occurs in 10–20% of patients at a median age of 25 years (but as early as the first decade of life)[132]. KID syndrome is also associated with increased susceptibility to mucocutaneous bacterial, viral and fungal infections, in particular with *Candida albicans*.

All KID patients have congenital sensorineural hearing impairment that (in contrast to the keratitis) is not progressive. Hearing loss is generally severe and bilateral, although unilateral or moderate hearing impairment has been observed. Approximately 95% of patients have ocular involvement, which typically presents at birth, during infancy or in early childhood with photophobia and blepharitis. Vascularizing keratitis, chronic blepharitis and conjunctivitis develop and worsen with age. Scarring and neovascularization often cause a progressive decline in visual acuity and may eventuate in blindness. Dental abnormalities such as small or absent teeth, delayed eruption or excessive caries have been described in patients with KID syndrome. The Dandy–Walker malformation (a congenital anomaly of the cerebellar vermis and fourth ventricle), short heel cords, facial dysmorphism and other developmental abnormalities have also been reported.

Pathology

Histologically, there are no uniform findings, even if multiple biopsy specimens are obtained from the same patient. Acanthosis and papillomatosis of the epidermis with basket-weave hyperkeratosis and follicular plugging are the most consistent features. Vacuolization of the cells in the granular layer has also been described. Two ultrastructural studies did not reveal any significant skin abnormalities. The corneal epithelium may be dyskeratotic, atrophic or absent centrally and Bowman's membrane may be absent. In the inner ear, the organ of Corti is immature or atrophic.

Differential Diagnosis

There have been a few reports of *Desmons (Senter) syndrome*, an autosomal recessive metabolic disorder characterized by skin changes similar to KID syndrome and hearing impairment (but no keratitis) together with glycogen deposition leading to hepatomegaly, cirrhosis, growth failure and mental retardation. Other erythrokeratodermas, such as EKV and PSEK, are not associated with impaired hearing and keratitis. *Ichthyosis follicularis with atrichia and photophobia (IFAP)* syndrome (X-linked due to *MBTPS2* mutations; see Table 57.5) and *hereditary mucoepithelial dysplasia* (autosomal dominant) are both characterized by follicular keratoses, psoriasiform plaques, alopecia, keratitis and susceptibility to mucocutaneous infections (but not hearing impairment); in the latter disorder, the plaques favor the perineal area and fiery red oral mucosal patches are present. *Keratosis follicularis spinulosa decalvans* (allelic to IFAP; see Ch. 38) also features follicular keratoses and keratitis, but it progresses to scarring alopecia and does not manifest with hyperkeratotic plaques, palmoplantar keratoderma or hearing impairment.

Hystrix-like–ichthyosis–deafness (HID) syndrome (also referred to as ichthyosis hystrix type Rheydt) shares all the features of KID syndrome and is also caused by *GJB2* mutations[27]. Compared to KID syndrome, skin involvement is more severe and keratitis is milder in HID syndrome.

Treatment

Skin treatment consists of emollients and keratolytics; topical retinoids may be beneficial. Oral retinoid therapy yields mixed results: the hyperkeratosis may or may not respond, the palmoplantar keratoderma is recalcitrant, and ocular side effects may aggravate the keratitis and neovascularization. Corneal transplants, although often the only possibility for improving vision, are usually not very successful because of revascularization[132]. Hearing aids and cochlear implants have been used successfully to improve communication. Mucocutaneous infections often require systemic therapy. Surveillance for the development of SCC and other tumors via periodic examination of the mucous membranes as well as the skin (including the scalp) is required.

X-LINKED DOMINANT ICHTHYOSIFORM DISORDERS

CHILD SYNDROME

Synonyms: ▪ Congenital hemidysplasia with ichthyosiform erythroderma (or nevus) and limb defects ▪ CHILD nevus

History

The first description of this condition in 1948[136] was followed by 17 case reports before Happle delineated the key features and proposed the acronym CHILD syndrome in 1980[137].

Epidemiology

This is a rare X-linked dominant disorder that is generally lethal in affected male embryos. However, two affected boys, one of who was known to have a normal karyotype (and presumably a postzygotic rather than germline *NSDHL* mutation), have been reported[136,138].

Pathogenesis

CHILD syndrome is a disorder of lipid metabolism that results in disturbed cholesterol biosynthesis. Inactivating mutations in *NSDHL*, which encodes the enzyme 3β-hydroxysteroid-dehydrogenase, were initially identified in five families with right-sided skin and skeletal involvement[139]; such mutations were subsequently described in additional patients with left-sided involvement. The striking hemilateral phenotype has been postulated to result from deficient sonic hedgehog signaling (which helps to confer left–right asymmetry during embryogenesis) in cells expressing the X-chromosome with a *NSDHL* mutation, resulting in selection against these cells on one side of the body. Cholesterol has critical roles in mammalian development (including its importance in hedgehog signaling), and inborn errors in cholesterol biosynthesis have been found to cause several other malformation syndromes.

Clinical Features

CHILD syndrome classically presents at birth or in the neonatal period with a striking unilateral distribution of erythema and thickened skin with a waxy surface or yellowish adherent scale (Fig. 57.24). The erythema most often involves the right side of the body and is sharply demarcated at the anterior and posterior midline of the trunk. The face is typically spared. Occasionally, there is partial spontaneous resolution or periodic exacerbation of the cutaneous inflammation[137]. During infancy, the erythema lessens, while hyperkeratotic plaques or bands with a verrucous surface prevail and often become more pronounced. They may follow Blaschko's lines or uniformly affect large areas on half of the body, with affinity for the skin folds (ptychotropism). Because of the clinical resemblance to inflammatory linear verrucous epidermal nevus (ILVEN), the terms "CHILD nevus" and "psoriasiform epidermal nevus" have been used. The contralateral side of the body may have mild skin involvement in a mosaic pattern, but symmetric distribution is extremely rare. Linear alopecia (on the affected side of the scalp and/or body) and claw-like nail dystrophy or onychorrhexis are common.

Fig. 57.24 CHILD syndrome. Note the sharp midline demarcation on the trunk. *From Happle R, Mittag H, Kuster W. Dermatology. 1995;191:210–6, with permission. Courtesy, R Happle, MD.*

Ipsilateral skeletal abnormalities range from hypoplasia of digits or ribs to complete amelia; congenital or secondary scoliosis may also occur. Stippled epiphyses can be identified on radiologic examination in early infancy but tend to resolve during childhood. The teeth are typically normal. Asymmetric organ hypoplasia commonly affects the brain, kidneys, heart and lungs on the (severely) affected side of the body. Mild hearing loss and cleft palate may be present. Analogous with the cutaneous manifestations, minor organ anomalies may be observed on the contralateral side.

Pathology

Histopathologic changes include an acanthotic and papillomatous epidermis with marked ortho- and parakeratosis, overlying a mild superficial perivascular infiltrate. Numerous vacuoles are present within the cells of the lower stratum corneum. Multiple layers of granular cells surround the sweat ducts, while the granular zone in the surrounding epidermis may be absent, normal or thickened[138]. Occasionally, foamy histiocytes have been noted in dermal papillae. Ultrastructural abnormalities include abundant pale-staining mitochondria, cytoplasmic glycogen, lipid retention in the stratum corneum, and altered lamellar granular content, both intracellularly and intercellularly.

Other diagnostic tests

Molecular analysis of the *NSDHL* gene is available. Plasma cholesterol is normal despite defective cholesterol biosynthesis.

Differential Diagnosis

Sebaceous nevus syndrome may resemble CHILD syndrome but can be clinically differentiated by its distribution pattern and the lack of erythema and scaling. ILVEN is a less extensive condition that is not associated with visceral abnormalities. Punctate epiphyseal calcifications and asymmetric limb shortening together with congenital ichthyosiform erythroderma in a distribution following Blaschko's lines may be seen in X-linked dominant chondrodysplasia punctata (see below). However, the skin manifestations are not unilateral and are replaced by atrophoderma by 2 years of age; in addition, skeletal defects are usually less severe than in CHILD syndrome[139].

Treatment

Cosmetically and functionally satisfactory results from dermabrasion of affected skin followed by placement of split-thickness skin grafts

obtained from the clinically normal contralateral side of the body have been described[140]. Single case reports have noted successful treatment of skin lesions with topical tretinoin or systemic retinoids. Emollients and corticosteroids are ineffective. Requirements for multidisciplinary care depend on the extent of associated organ involvement.

CONRADI–HÜNERMANN–HAPPLE SYNDROME

Synonyms: ■ X-linked dominant chondrodysplasia punctata ■ Chondrodysplasia punctata type 2 (CDPX2) ■ Conradi–Hünermann syndrome ■ Happle syndrome

History

In 1971, the dominant Conradi–Hünermann type of chondrodysplasia was differentiated from the more severe, autosomal recessive, rhizomelic form. Happle subsequently reviewed the literature and established that the Conradi–Hünermann type has an X-linked dominant mode of inheritance[141].

Epidemiology

Conradi–Hünermann–Happle syndrome (CHHS) is a rare X-linked dominant disorder. It is lethal in male embryos outside the setting of an XXY karyotype or mosaicism due to a postzygotic mutation in the *EBP* gene. However, an X-linked recessive multiple congenital anomaly syndrome (with male patients who die by early childhood and unaffected female carriers) caused by a less severe germline mutation in the *EBP* gene was recently described[142].

Pathogenesis

Conradi–Hünermann–Happle syndrome is due to a defect in cholesterol biosynthesis that is caused by mutations in the *EBP* gene, which encodes emopamil-binding protein (EBP)[143,144]. The resulting deficiency of EBP, a widely expressed integral membrane protein with Δ8-Δ7-sterol isomerase activity, leads to accumulation of 8-dehydrocholesterol and 8(9)cholesterol[144], which can be detected in plasma and cultured fibroblasts. However, levels of the end product cholesterol sulfate are normal in plasma and fibroblasts because of X-inactivation[143,144]. Impaired cholesterol synthesis during a critical period of mammalian development is thought to be responsible for the phenotype. A particular hemizygous missense mutation affecting the first transmembrane domain of EBP (presumably with less deleterious effects on enzyme function) and accumulation of the aforementioned cholesterol precursors have been found in boys with an allelic multiple congenital anomaly syndrome[142].

Clinical Features

At birth, the majority of CHH syndrome patients have generalized erythema with thick, adherent, feathery scale; streaks and whorls of hyperkeratosis following Blaschko's lines are often observed (Fig. 57.25A). The erythroderma resolves substantially, if not completely, within the first weeks or months of life. In older children, hyperkeratosis is largely replaced (with residual mild scaling) by linear or patchy follicular atrophoderma with dilated follicular openings and ice-pick-like scars. The atrophoderma is most pronounced on the forearms and dorsal hands, whereas the palms and soles are usually spared. Hyper- or hypopigmentation along Blaschko's lines may coexist separately from atrophodermic areas[141]. Scalp involvement results in patchy scarring alopecia. In addition, hair may be sparse, coarse or lusterless. Nail changes include onychoschizia and flattening of the nail plate, while the teeth are normal.

Skeletal anomalies are usually asymmetric. They include frontal bossing, malar hypoplasia, a flat nasal bridge, a short neck, rhizomelic shortening of the limbs, and scoliosis. Widespread premature calcifications manifesting as stippled epiphyses (chondrodysplasia punctata) typically involve the trachea and vertebrae and can be detected on radiographs during infancy (Fig. 57.25B). These are not apparent once bone maturation progresses. Unilateral cataracts, which are present at birth or develop within the first months of life, are the most common ocular abnormality and may be accompanied by microphthalmia or microcornea. Occasionally, other features may be associated and include congenital heart defects, sensorineural deafness, CNS malformations and congenital renal anomalies. Intellect is usually not impaired and life expectancy is normal.

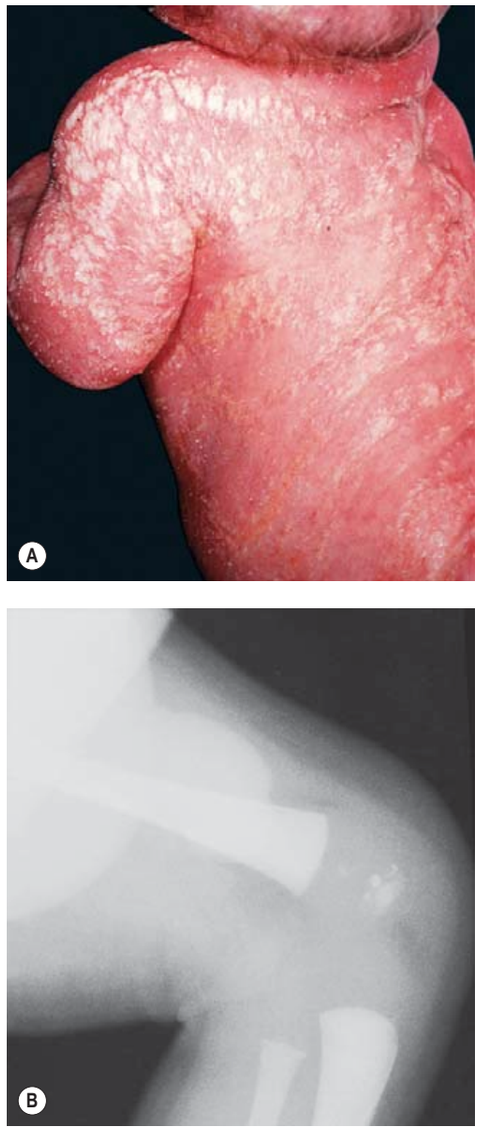

Fig. 57.25 Conradi–Hünermann–Happle syndrome.
A Erythroderma and linear streaks and whorls of hyperkeratosis.
B Epiphyseal stippling at the knee. *A, Courtesy, R Happle, MD. B, Courtesy, Jean L Bolognia, MD.*

Boys with the allelic X-linked recessive syndrome have a collodion-like presentation at birth and evolution to variable ichthyosis phenotype[142]. Additional features include a Dandy-Walker malformation, hydrocephalus, cataracts, cryptorchidism, and cardiovascular, craniofacial and skeletal anomalies.

Pathology

Hyperkeratosis with focal parakeratosis is common and most prominent in follicular ostia, where dystrophic calcification may be observed within keratotic plugs. The granular layer is diminished and keratinocytes contain small vacuoles with needle-like calcium inclusions on electron microscopy.

Other diagnostic tests

Radiographs reveal premature calcifications in the cartilage of the trachea, spine and long bones during the first year of life (see Fig. 57.25B). Accumulation of 8(9)cholesterol in plasma can be detected by mass spectrophotometry and often confirms the diagnosis. Molecular analysis of the *EBP* gene is also available.

Differential Diagnosis

Stippled epiphyses during infancy and asymmetric limb shortening are also seen in girls with CHILD syndrome, but the skin involvement

usually shows striking lateralization and does not fade completely. However, some overlap in the clinical findings of CHILD and CHH syndromes is not surprising, since both represent disorders of cholesterol biosynthesis. Ichthyosis linearis circumflexa in Netherton syndrome is readily distinguished by its double-edged scale, and the lesions do not follow Blaschko's lines. Cutaneous manifestations in congenital ichthyosiform erythroderma are more generalized. Hyper- and hypopigmentation in "pigmentary mosaicism", incontinentia pigmenti and epidermal nevi (including epidermolytic variants) follow Blaschko's lines but lack follicular atrophoderma.

Treatment

Although the erythema gradually resolves, residual mild scaling may benefit from application of emollients, and products containing urea or lactic acid. Orthopedic and ophthalmologic care are essential.

58 Keratodermas

Alfons L Krol and Dawn Siegel

Key features

- Palmoplantar keratodermas can be inherited or acquired
- The three major patterns of involvement are diffuse, focal and punctate
- Additional distinguishing features include an erythematous border, associated hyperhidrosis and transmigration to areas beyond the palmoplantar skin
- It is important to determine whether other features are present, e.g. impaired hearing, cardiomyopathy (in patients with woolly hair), starfish keratoses, pseudoainhum, knuckle pads, atrophy, oral lesions, nail changes, blisters
- Histologic examination can determine whether or not epidermolytic hyperkeratosis is present

INTRODUCTION

Palmoplantar keratodermas (PPKs) represent a diverse group of hereditary and acquired disorders characterized by hyperkeratosis of the skin on the palms and soles (Table 58.1). Progress in our knowledge of keratins and the keratinocyte cytoskeleton as well as desmosomes and gap junctions has increased our understanding of the pathogenesis of these conditions (Table 58.2). Conversely, essential biologic functions of widely expressed proteins have been discovered from the study of PPKs[1].

Keratins are heteropolymeric proteins that form the intermediate filament cytoskeleton of keratinocytes. Keratin proteins directly associate with a number of subcellular structures, including desmosomes, hemidesmosomes and protein complexes within the cornified cell envelope (see Ch. 56). Keratins interact with these structures in a highly regulated and complex manner in order to maintain the integrity of the skin.

There are two types of keratins: (1) acidic or type I (encoded on chromosome 17q), which encompass K9 to K28 and K31 to K40 (including those formerly referred to as Ha trichocyte keratins); and (2) basic or type II (encoded on chromosome 12q), which encompass K1 to K8 and K71 to K86 (including those formerly referred to as Hb trichocyte keratins) (see Table 56.2). Type I keratins partner with type II keratins in a tissue- and differentiation-specific manner (see Fig. 56.7). Keratin pairs expressed in the epidermis include K1/K10 in suprabasal keratinocytes, K5/K14 in basal keratinocytes (also in mucosa), and K6a/K16 as well as K6b/K17 in keratinocytes of the palms/soles, epidermal appendages and hyperproliferative skin (also in mucosa). K9 is highly expressed only in suprabasal keratinocytes of the palmoplantar epidermis[2], and its partner is thought to be K1. Keratin intermediate filaments represent heteropolymers assembled from coiled-coil keratin heterodimers (see Fig. 56.4).

The molecular structure of keratins and other intermediate filaments consists of a central α-helical rod domain composed of four segments (1A, 1B, 2A, 2B) that are interrupted by non-helical linker segments (see Fig. 56.5). The amino (1A) and carboxy (2B) terminal regions of the central α-helical rod domain are most critical for keratin function. Keratin gene mutations are responsible for several types of inherited PPK[3].

Desmosomes are cell–cell junctions that integrate the intermediate filament cytoskeleton into the cell membrane and establish adhesive points between opposing cells (see Fig. 56.8). Desmosomes are vital to the maintenance of mechanical integrity and stress resistance of individual cells and multicellular sheets, functions that are particularly critical in the epidermis and heart. Desmosomes also have important roles in the regulation of tissue morphogenesis and homeostasis.

Desmoglein and desmocollin proteins belong to the cadherin superfamily of cell–cell adhesion mediators and form the core of the desmosome (see Ch. 56). Each of these type I membrane glycoproteins exists as multiple isoforms (desmoglein 1–4 and desmocollin 1–3), which are products of different genes and are expressed in a cell type- and differentiation-specific manner[4]. The intracellular portions of desmogleins and desmocollins bind to plakoglobin (an armadillo protein/catenin family member). Plakoglobin in turn binds directly to the N-terminus of desmoplakin, a plakin protein. Desmoplakin forms a bridge between the desmosomal cadherin/catenin complex and the intermediate filament cytoskeleton, which interacts with the desmoplakin C terminus[5]. Striate PPK has been shown to be due to mutations in the genes that encode desmoplakin and desmoglein 1[6], whereas PPK plus woolly hair and cardiomyopathy can result from mutations in the genes for desmoplakin and plakoglobin[7] (see Table 58.2 and Fig. 56.8).

Gap junctions are specialized transmembrane channels that connect the cytoplasm of neighboring cells, facilitating cell-to-cell communication[8]. The status of the channels (i.e. open or closed) is controlled by several mechanisms, including voltage, calcium concentration, pH and phosphorylation. Each gap junction channel is composed of integral membrane proteins called connexins. Six connexin monomers oligomerize to form an annular hemichannel called a connexon; connexons then cluster at the plasma membrane to dock with the connexons of an apposing cell to form functional channels (Fig. 58.1). The half-life of each connexin is short (i.e. a matter of hours), which results in a constant state of assembly and degradation of channels. Different connexins are expressed in a tissue- and differentiation-specific manner as well as in response to stimuli.

The first human disorder shown to be due to a connexin defect was X-linked dominant Charcot–Marie–Tooth disease, where loss of connexin 32 (Cx32) was found to result in impaired diffusion of nutrients and signaling molecules into peripheral nerves. In 1997, the association of defects in several connexins with hearing impairment was demonstrated, and it is now known that recessive mutations in the gene that encodes Cx26 are the single most important cause of non-syndromic congenital hearing impairment (with carrier frequencies ranging from 3% to 10% in the general population)[9]. In addition to peripheral neuropathy and hearing impairment, the clinical manifestations of connexin disorders can involve the skin, cutaneous appendages and eyes (Table 58.3)[10]. The phenotypic spectrum of autosomal dominant disorders caused by defects in Cx26 range from Vohwinkel syndrome (mutilating PPK with deafness)[11] to keratitis–ichthyosis–deafness (KID) syndrome (which also features a "stippled" PPK; see Ch. 57). Hidrotic ectodermal dysplasia (due to mutations in the gene that encodes Cx30)[12] and erythrokeratodermia variabilis (EKV; due to mutations in the genes that encode Cx31 and Cx30)[13] are other connexin disorders that can manifest with a PPK. For example, a patchy or diffuse PPK, often associated with peeling, affects approximately half of families with EKV (see Ch. 57).

The inherited PPKs are uncommon disorders, and reports of individual families have resulted in non-uniform nomenclature that includes many eponyms. Several attempts have been made to classify keratodermas, none of which is entirely satisfactory. However, a straightforward working classification[14] divides PPKs into three broad types based on the pattern of palmoplantar involvement:

- ***diffuse PPK*** – involvement of the entire palmoplantar surface (Fig. 58.2)

PALMOPLANTAR KERATODERMAS	
HEREDITARY	**ERYTHROKERATODERMAS (SEE CH. 57)**
Diffuse type Unna–Thost type: non-epidermolytic PPK Vörner type: epidermolytic PPK Meleda type: Mal de Meleda Greither type: transgrediens and progrediens PPK Gamborg–Nielsen (Norrbotten) type Sybert type	Keratitis–ichthyosis–deafness (KID) syndrome* Hystrix-like ichthyosis–deafness (HID) syndrome* Erythrokeratodermia variabilis* Progressive symmetric erythrokeratoderma*
Diffuse type with associated features Vohwinkel syndrome: mutilating PPK PPK with sensorineural deafness due to mitochondrial or *GJB2* gene defect Bart–Pumphrey syndrome: knuckle pads, leukonychia, and sensorineural deafness Huriez syndrome: PPK with scleroatrophy PPK with sex reversal and squamous cell carcinoma Hidrotic ectodermal dysplasia: Clouston syndrome Olmsted syndrome: mutilating PPK with periorificial plaques Papillon–Lefèvre syndrome: PPK with periodontitis Haim–Munk syndrome: PPK with periodontitis, arachnodactyly and acro-osteolysis Naxos disease: diffuse PPK with woolly hair and arrhythmogenic cardiomyopathy	**ICHTHYOSES WITH ASSOCIATED KERATODERMA (SEE CH. 57)** Epidermolytic ichthyosis (bullous congenital ichthyosiform erythroderma)* Ichthyosis hystrix Curth–Macklin* Congenital ichthyosiform erythroderma* Lamellar ichthyosis Harlequin ichthyosis Sjögren–Larsson syndrome* Refsum syndrome CEDNIK (*c*erebral *d*ysgenesis, *n*europathy, *i*chthyosis and *k*eratoderma) syndrome* MEDNIK (*m*ental retardation, *e*nteropathy, *d*eafness, *n*europathy, *i*chthyosis and *k*eratoderma) syndrome* KLICK syndrome (*k*eratosis *l*inearis with *i*chthyosis *c*ongenita and *s*clerosing *k*eratoderma) Netherton syndrome (rarely)
Focal type PPK striata/areata type: striate PPK, focal non-epidermolytic PPK, Wachters type, Brünauer–Fuhs–Siemens type Hereditary painful callosities: nummular epidermolytic PPK, focal epidermolytic PPK	**OTHER ECTODERMAL DYSPLASIAS WITH ASSOCIATED KERATODERMA** Ectodermal dysplasia with skin fragility* Acantholytic ectodermal dysplasia* Schöpf–Schulz–Passarge syndrome*: PPK with hidrocystomas, hypodontia and hypotrichosis Odonto-onycho-dermal dysplasia* Ectodermal dysplasia–ectrodactyly–clefting (EEC) syndrome Cleft lip/palate ectodermal dysplasia Oculo-dento-digital dysplasia Naegeli–Franceschetti–Jadassohn syndrome, dermatopathia pigmentosa reticularis
Focal type with associated features Howel–Evans syndrome: non-epidermolytic PPK with carcinoma of the esophagus Richner–Hanhart syndrome: oculocutaneous tyrosinemia Pachyonychia congenita-6a/16: type 1, Jadassohn–Lewandowsky type Pachyonychia congenita-6b/17: type 2, Jackson–Lawler type Carvajal syndrome: striate PPK with woolly hair and dilated cardiomyopathy Focal palmoplantar and gingival keratosis	**OTHER** Epidermolysis bullosa: simplex (Dowling–Meara, with mottled pigmentation >> Weber–Cockayne), non-Herlitz junctional (occasionally) Kindler syndrome Erythropoietic protoporphyria Familial pityriasis rubra pilaris* Linear PPK associated with epidermal nevus* Dyskeratosis congenita Darier disease (typically punctate) Cowden disease (punctate) Porokeratotic eccrine ostial and dermal duct nevus (PEODDN; porokeratotic adnexal ostial nevus)* Cardio-facio-cutaneous syndrome HOPP (*h*ypotrichosis, acro-*o*steolysis/*o*nychogryphosis, *p*almoplantar keratoderma and *p*eriodontitis) syndrome* Cantu syndrome*: hyperkeratosis–hyperpigmentation syndrome Cole disease*: guttate hypopigmentation with punctate PPK
Punctate type Punctate palmoplantar keratoderma: keratosis punctata palmaris et plantaris, Buschke–Fischer–Brauer type Acrokeratoelastoidosis Focal acral hyperkeratosis Porokeratosis punctata palmaris et plantaris	
ACQUIRED	
Keratoderma climactericum Spiny keratoderma Keratoderma associated with hypothyroidism/myxedema Keratoderma associated with cancer Aquagenic PPK Drug-induced keratoderma (e.g. lithium, verapamil, venlafaxine, tegafur, imatinib, glucan, capecitabine)	

*PPK is a major feature of the disorder.

Table 58.1 Palmoplantar keratodermas (PPKs). Progrediens means progressive, referring to the tendency to involve additional sites (e.g. the elbows and knees) over time.

- ***focal PPK*** – localized areas of hyperkeratosis, located mainly over pressure points. There are two patterns of focal PPK: (a) the areata/nummular type, which is characterized by oval lesions, usually on the plantar surface; and (b) the striate type, which presents as linear hyperkeratotic lesions, most commonly extending from the palms to the volar surface of the fingers (Fig. 58.3)
- ***punctate PPK*** – small (1 mm to 1 cm) keratotic papules on the palms and soles (Fig. 58.4).

Of note, focal involvement sometimes evolves to a diffuse PPK over time (e.g. from infancy to adulthood). Further classification depends upon the presence or absence of: (1) associated cutaneous and/or extracutaneous findings; and (2) epidermolytic hyperkeratosis on histologic evaluation (see Table 58.1)[14]. Another feature that has been used to characterize PPKs is whether or not *transgrediens* is evident; this term refers to extension of hyperkeratosis across the "line of transgredience" onto the dorsal aspects of the fingers, toes, hands and feet as well as the flexor aspects of the wrists and heels. In the future, as our knowledge of the genetic bases of specific clinical syndromes improves, keratodermas may be classified by their molecular pathology (see Table 58.2).

HEREDITARY KERATODERMAS

DIFFUSE PALMOPLANTAR KERATODERMA (ISOLATED)

Diffuse Non-epidermolytic and Epidermolytic Palmoplantar Keratoderma

Synonyms: ■ Unna–Thost type: non-epidermolytic PPK ■ Vörner type: epidermolytic PPK

History

In 1880, Thost described a family with diffuse non-transgrediens PPK. This was followed by Unna's description of a clinically identical, autosomal dominant PPK in two families. Although "Unna–Thost type" is used to designate non-epidermolytic PPK (NEPPK), in 1992,

HEREDITARY PALMOPLANTAR KERATODERMAS WITH KNOWN GENETIC BASES								
Type	**Protein product of mutated gene**	**Synonyms**	**Inheritance**	**Onset**	**Hyperhidrosis**	**Extensor surfaces of extremities involved?**	**Erythematous border**	**Comments**
				DIFFUSE				
Unna–Thost	K1* K6c*	Non-epidermolytic PPK (NEPPK)	AD	2–5 years, sometimes later	++	No	Yes	Second most common type of diffuse PPK (after EPPK)
Vörner	K9 K1	Epidermolytic PPK (EPPK)	AD	0–3 years	+	No	Yes	Clinically identical to diffuse NEPPK, but histology shows epidermolytic hyperkeratosis
Meleda	SLURP-1	Mal de Meleda	AR	0–3 years	+	Yes	Yes	Atopic dermatitis, often infected
Greither	K1 (in some families)	Transgrediens and progrediens PPK	AD	Infancy	Yes	Yes	Yes	
Mutilating	Loricrin (+ ichthyosis) Connexin 26 (+ deafness)	Vohwinkel syndrome, keratoderma hereditaria mutilans	AD	Infancy	No	Yes	Yes	Honeycomb palms, pseudoainhum, starfish keratoses on the knuckles, sensorineural deafness (Cx26)
With deafness	Mitochondrial tRNA for serine		Mitochondrial	Variable	No	No	No	Deafness
With sex reversal & SCC	R-spondin 1		AR	Infancy	No	No	No	Acral SCC, XX sex reversal (i.e. female-to-male)
Papillon–Lefèvre syndrome	Cathepsin C	PPK with periodontitis	AR	Birth to early infancy	Yes	Yes	Yes	Periodontitis, premature loss of teeth, psoriasiform lesions on extremities, pyogenic infections
Naxos disease	Plakoglobin Desmocollin 2*	Diffuse NEPPK with woolly hair and cardiomyopathy	AR	Infancy	No	No	Yes	Woolly hair; arrhythmias and right ventricular cardiomyopathy develops during adolescence

Küster et al.[15] reviewed the family described by Thost and found the histologic features of epidermolytic hyperkeratosis, which characterize the "Vörner type" of PPK. Subsequently, after K9 mutations were reported in epidermolytic PPK (EPPK)[16], identical mutations were found in the descendants of the family studied by Thost. These findings brought into question the previously held belief that the non-epidermolytic type was the most common form of PPK, as multiple biopsies may be required to identify epidermolytic hyperkeratosis.

Epidemiology

EPPK is one of the more common keratin disorders, with an estimated incidence of at least 4.4 per 100 000 in Northern Ireland[15]. The incidence of NEPPK is unknown.

Pathogenesis

The expression of *keratin 9* is limited to the suprabasal cell layers of palmar and plantar skin. In patients with the diffuse form of EPPK (Vörner type), the majority of K9 mutations are localized to a very small area of this type I keratin gene that encodes the helix initiation motif in the 1A domain (see Ch. 56). Such mutations are highly disruptive to keratin filament assembly, causing tonofilament aggregation and cytolysis.

Within palmoplantar skin, keratin 9 is thought to partner with *keratin 1*. Of note, mutations in K1 and K10 are associated with epidermolytic ichthyosis (EI; bullous congenital ichthyosiform erythroderma) in which epidermolytic hyperkeratosis is seen histologically (see Ch. 57). As might be expected, patients with EI caused by K1 mutations often have severe PPK, whereas those with K10 mutations typically lack palmoplantar involvement because the latter gene is usually not expressed in these sites. The majority of mutations reported in EI patients have been in the critical 1A and 2B domains of the keratin molecule. However, families with diffuse EPPK alone caused by K1 mutations (often in the beginning of the 1B domain) have also been described[17].

Kimonis et al.[18] reported a pedigree with a K1 mutation that resulted in diffuse NEPPK rather than the expected EI or EPPK. The mutation was in a non-critical portion of the *K1* gene and thus had less of an effect on the K1 protein. This may be analogous to the situation in epidermolysis bullosa simplex (EBS), where the Weber–Cockayne type, due to mutations in non-critical portions of the *K5* and *K14* genes, is characterized by a milder, acrolocalized form of the disorder[19]. Of note, *K1* mutations have also been identified in patients with focal forms of PPK (see below). However, the gene(s) responsible for most cases of diffuse NEPPK remain to be determined. Linkage analysis, based upon three pedigrees from England, identified a diffuse NEPPK locus proximal to the type II keratin gene cluster on chromosome 12q[20].

Some patients with EBS (especially the Dowling–Meara type) develop diffuse (or focal) keratoderma. Interestingly, mutations in the *K5* gene

Fig. 58.4 Punctate palmoplantar keratoderma. Keratotic papules, some coalescing to form plaques, on the palm (**A**) and sole (**B**).

Fig. 58.5 Diffuse epidermolytic palmoplantar keratoderma. **A,B** Diffuse hyperkeratosis with involvement of the lateral aspect of the foot; note the erythema at the border with uninvolved skin. **C** Erythema is present at the border on the flexor wrist as well as in areas where there is reduced hyperkeratosis.

that result in the production of a truncated *keratin 5* protein have been associated with severe diffuse PPK as well as the skin fragility and blistering of EBS, suggesting that the K5 tail domain may have a function that is particularly important in palmoplantar skin[19].

Until patients who have been assigned separate eponyms, such as Gamborg–Nielsen (Norrbotten) or Sybert types of keratoderma, have had molecular screening of appropriate keratin genes and other genes implicated in PPKs, these entities are best thought of as variants of the diffuse type of EPPK or NEPPK.

Clinical features

The clinical features of EPPK and NEPPK are identical. The palmoplantar skin is initially red, followed by the appearance of thick, yellow hyperkeratosis that expands to involve the lateral aspects of the hands and feet. The surface can be smooth and waxy (see Fig. 58.2) or irregular and verrucous. The condition may present during the first few months of life and is usually well developed by 3–4 years of age. Both epidermolytic and non-epidermolytic forms are typically non-transgredient, with a sharp demarcation of the lesions at the wrists and no tendency to involve the extensor surfaces. The border of the hyperkeratosis tends to be erythematous (Fig. 58.5).

Hyperhidrosis, secondary dermatophyte infections and pitted keratolysis are observed more frequently in NEPPK than EPPK. Blisters are occasionally reported in EPPK, in particular during childhood; however, the etiology may be a secondary dermatophyte infection rather than the underlying genetic defect. Constriction of the pulps of the distal fingertips, knuckle pads and thickened nails without dystrophy are occasionally seen[14].

Pathology

EPPK is characterized by the histologic findings of epidermolytic hyperkeratosis. Clumping of tonofilaments leading to perinuclear vacuolization is seen, as are large keratohyalin granules and cellular degeneration in the spinous and granular cell layers (see Ch. 57). A careful search of several biopsy specimens may be required to identify these changes, which are often subtle and patchy. NEPPK shows nonspecific changes, with orthohyperkeratosis, acanthosis, and either thickening or a reduction of the granular cell layer (Fig. 58.6).

Differential diagnosis

Diffuse NEPPK and EPPK are distinguished from one another histologically. Analysis of the *K9* (if epidermolytic) or *K1* gene can further characterize diffuse PPK without associated features in some affected individuals. The possibility of associated sensorineural deafness (suggesting an underlying Cx26 or mitochondrial defect) should be investigated, and a cardiac evaluation is indicated for individuals with woolly

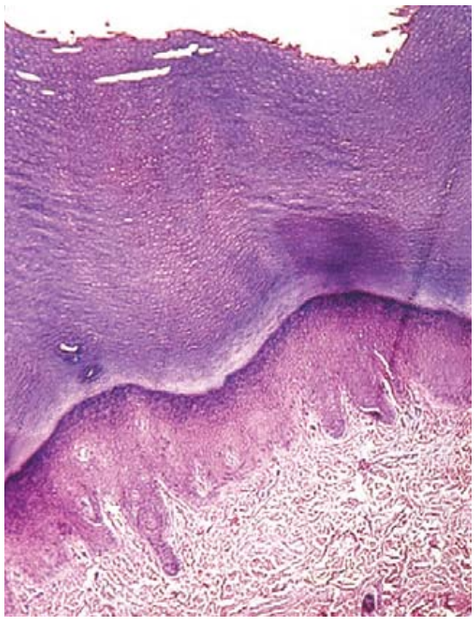

Fig. 58.6 Histologic features of non-epidermolytic palmoplantar keratoderma. Note the massive hyperkeratosis, acanthosis and hypergranulosis.

hair in addition to a diffuse PPK to exclude Naxos disease and related conditions. Patients with hidrotic ectodermal dysplasia also have hypotrichosis and nail dystrophy, individuals with Huriez syndrome display scleroatrophic changes on the dorsal aspect of the hands and hypoplastic nails, and those with Papillon–Lefèvre syndrome develop psoriasiform lesions and destructive periodontitis. Both Mal de Meleda and Olmsted syndrome present with a diffuse transgredient PPK together with periorificial lesions, which are more severe in the latter disorder. Vohwinkel syndrome is characterized by transgredient mutilating PPK associated with starfish keratoses on the knuckles and pseudoainhum (as well as deafness in patients with Cx26 defects).

Treatment

Factors to consider in selecting a local treatment for diffuse PPK include the severity of symptoms, the degree of hyperkeratosis and the age of the patient. Salicylic acid 4–6% in petrolatum may be helpful in reducing the degree of hyperkeratosis but must be used with caution in children. Application of 50% propylene glycol in water under plastic occlusion several nights per week can also be beneficial, and lactic acid- and urea-containing creams and lotions represent additional keratolytic options. Mechanical debridement with a blade or dental drill may be useful for troublesome areas. Secondary fungal and bacterial infections often require systemic therapy for eradication.

Oral retinoid therapy can have variable effects. It may improve the hyperkeratosis but also tends to increase the fragility of the skin. In a study of patients with EI, those with *K1* mutations and associated PPK did not benefit from treatment with oral acitretin or topical retinoids (tazarotene or tretinoin), whereas most individuals with *K10* mutations improved[21]. The epidermis of non-responders had reduced expression of *K2* mRNA, which may function as a substitute for the mutated protein in those with K1 defects. Further studies on genotype/phenotype correlations in PPKs and their response to treatment are needed.

Mal de Meleda

Mal de Meleda is a rare autosomal recessive disorder that was first described in inhabitants of the island of Mljet (Meleda) off the Dalmatian coast. Shortly after birth, patients have the onset of diffuse palmar and plantar thickening with an erythematous border. The disease is progressive and transgredient, with lesions present on the dorsal surfaces of the hands and feet as well as the elbows and knees. Severe hyperhidrosis accompanied by malodor is characteristic of this PPK. It is often complicated by fissuring and secondary fungal or bacterial infections, and there are reports of melanoma arising in affected acral sites[22]. Periorificial lesions reminiscent of those seen in Olmsted syndrome also develop. Thickened nails with koilonychia or subungual hyperkeratosis are common, and constricting bands of the digits may occur. Histologically, palmoplantar skin displays orthohyperkeratosis with a normal granular layer.

Mal de Meleda is caused by mutations in the *s*ecreted *l*eukocyte antigen-*6*/*u*rokinase-type plasminogen activator *r*elated *p*rotein-1 gene (*SLURP1*)[23]. The SLURP-1 protein is an allosteric agonist of the nicotinic acetylcholine receptor with pro-apoptotic activity and roles in keratinocyte differentiation and T-cell activation[22].

Greither Syndrome

Greither syndrome (transgrediens and progrediens PPK), originally described in 1952, is characterized by a diffuse transgredient PPK with onset in early infancy. The severity of the PPK is variable and it is accompanied by hyperhidrosis. There are usually hyperkeratotic plaques on the knees and elbows, and, in some patients, in flexural regions. Histologically, epidermolytic changes of the granular layer are seen.

The disease is inherited in an autosomal dominant fashion. Two large families with features of Greither syndrome (and a history of neonatal blistering) were shown to have a missense mutation in their *K1* gene[24], emphasizing the variability of the clinical phenotype seen in patients with *K1* mutations.

DIFFUSE PALMOPLANTAR KERATODERMA WITH ASSOCIATED FEATURES

Mutilating Palmoplantar Keratoderma

Synonyms: ■ Vohwinkel syndrome ■ Keratoderma hereditaria mutilans ■ Subtype due to loricrin mutations: loricrin keratoderma, variant Vohwinkel syndrome, Vohwinkel syndrome with ichthyosis ■ Subtype due to connexin 26 mutations: classic Vohwinkel syndrome, Vohwinkel syndrome with deafness

Fig. 58.7 Mutilating palmoplantar keratoderma (Vohwinkel syndrome). A Diffuse honeycombed keratoderma of the sole. **B** Pseudoainhum formation.

Vohwinkel first described this autosomal dominant disorder in 1929. Honeycombed, diffuse hyperkeratosis of the palms and soles appears in infancy (Fig. 58.7A) and then becomes transgredient. This is followed by the development of constricting bands of the digits during early childhood, which may lead to digital autoamputation, i.e. pseudoainhum (Fig. 58.7B). Peculiar starfish-shaped keratoses appear over the knuckles of the fingers and toes and are said to be characteristic of the disorder. Hearing loss of at least a moderate degree is seen in many patients (see below). Additional reported findings are alopecia and ichthyosis. Histologic features include hyperkeratosis, acanthosis and a thickened granular cell layer with retained nuclei in the stratum corneum.

The disorder was originally mapped to the epidermal differentiation complex on chromosome 1q21 and associated with a mutation in the gene that encodes *loricrin,* a major cornified envelope protein (see Ch. 56). The family that was analyzed also displayed mild generalized ichthyosis but had normal hearing. It has since been shown that the subtype of Vohwinkel syndrome associated with deafness is caused by mutations in the gap junction β2 gene (*GJB2*) encoding ***Cx26***[11], in particular a heterozygous substitution (D66H) affecting the first extracellular domain of this protein. Notably, different mutations in the *GJB2* gene have been found to underlie other forms of PPK associated with hearing impairment[10] (see Table 58.3). Mutilating PPK without hearing impairment associated with ichthyosis hystrix (Curth–Macklin type; see Ch. 57) is caused by mutations in the variable tail region of K1[25]. One patient with the latter condition had previously been reported in the literature as having Vohwinkel syndrome in association with ichthyosis, stressing the necessity of combining clinical, histologic, ultrastructural and molecular data to properly categorize patients with mutilating PPK.

Bart–Pumphrey Syndrome

Synonym: ▪ PPK with knuckle pads, leukonychia and deafness

Bart, a dermatologist, and Pumphrey, an otolaryngologist, described this autosomal dominant syndrome in 1967[26]. All patients reported to date have been profoundly hearing impaired from birth, and during early childhood they developed a diffuse PPK together with hyperkeratoses (knuckle pads) over the metacarpophalangeal and proximal and distal interphalangeal joints (Fig. 58.8). Leukonychia is variable and tends to improve with age. The keratoderma may have a pitted or stippled surface reminiscent of the "honeycomb" appearance seen in Vohwinkel syndrome. Bart–Pumphrey syndrome has been shown to be caused by mutations in the *GJB2* gene encoding Cx26[27], providing an explanation for its clinical overlap with Vohwinkel syndrome.

Huriez Syndrome

Synonyms: ▪ Palmoplantar keratoderma with scleroatrophy ▪ Sclerotylosis

Fig. 58.8 Bart–Pumphrey syndrome. Leukonychia and knuckle pads in a patient with sensorineural deafness.

This rare syndrome has an autosomal dominant inheritance pattern. At birth, red, atrophic skin is present on the dorsal aspect of the hands and feet. The associated diffuse keratoderma is mild and more evident on palmar skin than plantar skin. With time, sclerodactyly and nail changes appear, including ridging, koilonychia, fissuring and hypoplasia. Affected patients have an increased risk of developing squamous cell carcinoma (SCC) in areas of atrophic skin[28]. The differential diagnosis of Huriez syndrome includes PPK with sex reversal and SCC (see below).

Histologic features of the keratoderma include orthohyperkeratosis, acanthosis and an increased granular layer. By electron microscopy, dense bundles of tonofilaments are seen throughout the epidermis and coarse clumped keratohyalin granules are evident in the granular layer. A characteristic finding is an almost complete absence of Langerhans cells in the affected skin. The gene responsible for Huriez syndrome has been mapped to 4q23[29].

Palmoplantar Keratoderma with Sex Reversal and Squamous Cell Carcinoma

This rare autosomal recessive syndrome, thus far described in several consanguineous Italian kindreds[30,31], features a diffuse NEPPK with onset in infancy and marked predisposition to the development of acral SCC. In addition, affected individuals with an XX genotype have either (1) a male phenotype (i.e. female-to-male sex reversal), often associated with hypospadias and hypogonadism; or (2) ambiguous genitalia, sometimes with hermaphroditism (existence of both male and female gonadal structures). Other manifestations include sclerodactyly with variable cutaneous atrophy (causing some patients to initially be reported as having Huriez syndrome), nail dystrophy (e.g. hypoplasia, longitudinal ridging, skin growth over the nail plate) and periodontitis leading to early loss of teeth.

In 2006, this condition was found to be due to mutations in the R-spondin1 gene (*RSPO1*), which encodes a protein that activates β-catenin signaling and has important roles in gonadal development[32]. *RSPO1* mutations represent the only known cause of XX sex reversal or XX hermaphroditism other than translocation of the testis-determining gene (*SRY*; normally on the Y chromosome) to the X chromosome or an autosome.

Hidrotic Ectodermal Dysplasia

Synonym: ▪ Clouston syndrome

Hidrotic ectodermal dysplasia is an autosomal dominant disorder in which a diffuse PPK occurs in conjunction with hypotrichosis and nail dystrophy. The condition is most common in individuals of French-Canadian ancestry, where large kindreds have been described[33], but it has been reported in individuals with a variety of ethnic backgrounds. Patients have hypotrichosis involving the scalp, eyebrows, eyelashes, and axillary and genital regions. Alopecia may be severe, even in infancy, although usually its onset is gradual, becoming more pronounced after puberty. The nails, which may be normal at birth, gradually become thickened and dystrophic, displaying short nail plates that are easily shed (Fig. 58.9; see Fig. 63.16). The nail abnormalities may mimic those of pachyonychia congenita or other syndromes of "hair–nail hypoplasia", resulting in misdiagnosis of these patients[34]. The PPK initially develops over pressure points and then increases with age. Thickened skin with a "pebbled" appearance may also be evident on the dorsal aspects of the digits (see Fig. 58.9), knees and elbows.

Histologic evaluation of thickened palms and soles shows orthohyperkeratosis with a normal granular layer. Papular lesions may demonstrate proliferation of ductal structures within a fibrovascular stroma, which is referred to as eccrine syringofibroadenomatosis. Ultrastructural examination of the hair shows disorganization of the hair fibers, with a loss of the hair shaft cuticle.

Hidrotic ectodermal dysplasia is caused by missense mutations in the *GJB6* gene, which encodes Cx30[12]. To date, four mutations in this gene have been found to underlie hidrotic ectodermal dysplasia; two of these are recurrent and account for the majority of affected families, and one was also identified in a boy with clinical features of keratitis–ichthyosis–deafness (KID) syndrome plus atrichia. The dysfunctional

Fig. 58.9 Hidrotic ectodermal dysplasia (Clouston syndrome). Note the "pebbled" skin on the dorsal aspect of the toes as well as the dystrophic nail plates. *Courtesy, D Sasseville, MD, and R Wilkinson, MD.*

Cx30 interferes with normal function of epithelial cells by disturbing their cell-to-cell communication[10].

Olmsted Syndrome

Synonym: ▪ Mutilating PPK with periorificial plaques

More than 45 patients with Olmsted syndrome have been described to date in the literature, and approximately two-thirds of them were male. The mode of inheritance has not been clearly established, although both autosomal dominant and X-linked recessive modalities have been proposed. During the first year of life, well-defined erythematous, hyperkeratotic plaques appear in the perioral and often the inguinal, genital and intergluteal areas. Keratoderma also begins during infancy, often initially focal and then becoming diffuse and severe. This leads to flexion deformities and constriction of the digits, and autoamputation may eventually occur. SCC and melanoma have been observed in the areas of keratoderma[35]. Thus far, investigation of a single patient failed to detect mutations in the genes for K1, Cx26, loricrin and SLURP-1[36].

Diffuse NEPPK with Sensorineural Deafness

Diffuse (or occasionally focal) NEPPK, sometimes with a "stippled" texture, together with impaired hearing can be caused by dominant-negative mutations in the *GJB2* gene that encodes Cx26. In addition, diffuse NEPPK and sensorineural hearing loss have been associated with a particular mutation (A7445G) in the mitochondrially encoded tRNA for serine (*MT-TS1)* in several kindreds[37].

Papillon–Lefèvre Syndrome

This syndrome, which is inherited in an autosomal recessive fashion, is characterized by diffuse, transgredient PPK (Fig. 58.10) in association with destructive periodontitis (beginning in childhood) and premature loss of teeth. Scaly psoriasiform lesions may be seen on the extremities. Frequent cutaneous and systemic pyogenic infections may occur, including hepatic abscesses[38]. Acral melanomas have also been reported in several affected individuals.

Loss-of-function mutations in the cathepsin C gene (*CTSC*) are responsible for Papillon–Lefèvre syndrome[39]. *Haim–Munk syndrome*, which features arachnodactyly, acro-osteolysis and atrophic nail changes in addition to PPK and periodontitis, is also due to mutations in cathepsin C[40]. Cathepsin C (dipeptidyl peptidase I) is a physiologic activator of groups of serine proteases found in inflammatory cells that are vital to the body's immune defenses[41]. An adult with a late-onset Papillon–Lefèvre syndrome phenotype was noted to have no alterations in the cathepsin C gene[42], suggesting that such patients have a different underlying genetic defect.

Fig. 58.10 Papillion–Lefèvre syndrome. Plantar keratoderma.

Naxos Disease

Synonym: ▪ Diffuse non-epidermolytic PPK with woolly hair and cardiomyopathy

This autosomal recessive disorder is prevalent on the Greek island of Naxos. It is characterized by arrhythmogenic right ventricular cardiomyopathy, mild NEPPK, and woolly hair[7]. The keratoderma appears during the first year of life, is diffuse in nature (with an erythematous border), and is non-transgredient. Woolly scalp hair is present at birth. Cardiac disease, manifested by arrhythmias, heart failure and/or sudden death, is usually not evident until after puberty.

In 2000, a homozygous two-base pair deletion in the plakoglobin gene (which leads to a truncated protein) was found to cause Naxos disease[43]. Plakoglobin is an important component of both desmosomes and adherens junctions in the skin and cardiac myocytes. A member or the armadillo protein family, plakoglobin links the inner and outer portions of the desmosomal plaque by binding tightly to the cytoplasmic domain of cadherins (e.g. desmoglein, desmocollin) (see Ch. 56). Dysfunction of the plakoglobin protein may lead to detachment of cardiac myocytes and ultimately to their death. Plakoglobin defects may also lead to desmosomal junction fragility in the hair follicle and shaft, explaining the woolly hair. Alopecia (rather than woolly hair) associated with focal PPK and cardiomyopathy due to a homozygous missense mutation in the plakoglobin gene has also been described[43a]. Homozygous truncating or splice-site plakoglobin mutations have also been identified in patients with *"acantholytic ectodermal dysplasia"* (featuring skin fragility and dystrophic nails as well as PPK and woolly hair) and *"lethal congenital epidermolysis bullosa"*, neither of which is associated with cardiac abnormalities[44,45].

A similar condition characterized by striate EPPK, dilated cardiomyopathy and woolly hair is caused by mutations in the gene that encodes desmoplakin[46,47] (Carvajal syndrome; see below). A homozygous mutation in the gene encoding desmocollin 2 has also been shown to cause the triad of a mild diffuse PPK, arrhythmogenic right ventricular cardiomyopathy and woolly hair[48]. Clinicians must be aware of these associations, and any patient with a PPK and woolly hair (or alopecia) should be sent for a cardiac evaluation.

FOCAL PALMOPLANTAR KERATODERMA (ISOLATED)

Synonyms: ▪ PPK striata/areata: striate PPK, focal non-epidermolytic PPK, Wachters PPK, Brünauer–Fuhs–Siemens PPK ▪ Hereditary painful callosities: nummular epidermolytic PPK, focal epidermolytic PPK

Focal areas of keratoderma can occur as localized circular lesions (areata/nummular) corresponding to sites of friction or pressure points (typically on the plantar surface) or as linear (striate) lesions extending from the palms onto the fingers (see Fig. 58.3). Repetitive trauma (e.g. from manual labor) increases the severity, and affected individuals with sedentary occupations tend to have milder changes. The major histologic features are acanthosis and an increased granular layer.

Focal isolated PPK can be inherited in an autosomal dominant fashion due to mutations in several genes encoding desmosomal components or keratins (which bind to the desmosomal plaque) (see Fig. 56.8). Desmosomal function is particularly important on the palms and soles, which are subject to friction and mechanical trauma on a regular basis. Heterozygous mutations in the *desmoglein 1* gene (*DSG1*) can cause isolated focal PPK. The majority of these are truncating mutations that are thought to lead to haploinsufficiency. Isolated focal PPK can also result from mutations in the gene that encodes the desmosomal plaque protein *desmoplakin*[49], with haploinsufficiency due to a heterozygous null mutation underlying the disorder.

Heterozygous mutations in the *K6c* or *K16* genes have been identified in patients with a focal NEPPK but no other features of pachyonychia congenita[50,51]; a combination of diffuse (on the feet) and focal (on the hands) PPK due to a K6c mutation has also been described in a single patient to date[51a].

However, individuals in some of these families also displayed dystrophic nails, oral leukokeratosis and/or follicular keratoses, suggesting a forme fruste of pachyonychia congenita. A kindred with striate PPK caused by a frameshift mutation within the variable tail domain of *K1* has also been reported. Lastly, focal PPK (striate in one patient) and sensorineural hearing loss have been described in individuals with mutations in the gene encoding *Cx26*[52].

Hereditary painful callosities (nummular EPPK) differ in that changes are localized to pressure points on the plantar surface, and histology shows epidermolytic hyperkeratosis. The underlying genetic abnormalities have not yet been identified.

FOCAL PALMOPLANTAR KERATODERMA WITH ASSOCIATED FEATURES

Howel–Evans Syndrome

Synonyms: ■ Focal non-epidermolytic PPK with carcinoma of the esophagus ■ Tylosis–esophageal carcinoma

This autosomal dominant disorder has been reported in several families over many generations. Two types have been described: type A, with a late onset of the PPK and higher risk of esophageal carcinoma, and type B, with an early onset of PPK and benign course. The designation may be artificial in that type B families who never develop esophageal carcinoma may actually have other variants of focal PPK. Type A families develop focal PPK by 5 to 10 years of age, often limited to the pressure areas of the balls of the feet, with milder involvement of the palms (Fig. 58.11). Manual labor aggravates the lesions. Keratosis pilaris, dry rough skin, and oral leukokeratosis are often present. In affected individuals, carcinoma of the esophagus typically develops during the fifth decade. The gene responsible for this condition has been mapped to a small region on chromosome 17q25 distal to the keratin gene cluster. Loss of heterozygosity in this region has been shown to occur in a variety of human cancers, including esophageal cancer, suggesting that it contains one or more tumor suppressor genes[53].

Richner–Hanhart Syndrome

Synonyms: ■ Tyrosinemia type II ■ Oculocutaneous tyrosinemia

This is a rare autosomal recessive disorder of tyrosine metabolism, and many of the reported families are of Italian origin. Photophobia and dendritic keratitis with corneal ulcerations often appear in the first year of life (Fig. 58.12). Tyrosine crystal deposition is seen on slit-lamp examination, and serum and urinary tyrosine levels are elevated. Painful, focal hyperkeratotic plaques on the palms and soles represent the characteristic cutaneous finding (Fig. 58.13). The skin changes can appear during early childhood or be delayed until adolescence; blistering and hyperhidrosis may be seen. Progressive mental retardation occurs if the patient is not treated with a restrictive diet.

Histologic features of hyperkeratotic lesions are usually nonspecific: acanthosis with hypergranulosis and hyperkeratosis. However, electron microscopy reveals aggregations of tonofilaments, and needle-shaped tyrosine crystalline inclusions are found within the keratinocytes.

Richner–Hanhart syndrome is caused by mutations in the gene that encodes hepatic tyrosine aminotransferase (TAT)[54]. A diet restricted in tyrosine and phenylalanine will clear the keratitis and the skin lesions, and it may delay or prevent cognitive impairment[55].

Fig. 58.11 Howel–Evans syndrome. Focal palmoplantar keratoderma in association with carcinoma of the esophagus.

CLINICAL FEATURES OF PACHYONYCHIA CONGENITA		
Feature	**PC-6a/16 (formerly PC-1)**	**PC-6b/17 (formerly PC-2)**
Painful focal palmoplantar keratoderma	++	++
Hypertrophic nail dystrophy	++	++
Oral leukokeratosis	++	+
Follicular keratoses	++	++
Steatocystoma multiplex & vellus hair cysts	+ (uncommon)	++
Other cysts (e.g. epidermoid)	+	++
Natal/prenatal teeth	-	+ (primarily in PC-17)
Pili torti/other hair abnormalities*	+ (uncommon)	+

*E.g. coarse, brittle, and/or curly hair.

Table 58.4 Clinical features of pachyonychia congenita (PC). PC-6a tends to be more severe than PC-16. ++, present in majority of patients; + present in minority of patients.

Pachyonychia Congenita

Synonyms: ■ Pachyonychia congenita type 1: Jadassohn–Lewandowsky type ■ Pachyonychia congenita type 2: Jackson–Lawler type

The cardinal features of pachyonychia congenita (PC) include a focal NEPPK (predominantly plantar) as well as hypertrophic nail dystrophy, oral leukokeratosis, and (in a subset of patients) pilosebaceous cysts. The disorder is inherited in an autosomal dominant manner, and two major variants have classically been described: (1) PC1 (Jadassohn–Lewandowsky type), associated with a more severe PPK; and (2) PC2 (Jackson–Lawler type), associated with steatocystoma multiplex and natal teeth. However, there is considerable overlap between these groups, and classification based on the affected gene has recently been established (Table 58.4)[56,57].

The focal NEPPK is often extremely painful and typically develops on the soles in areas of friction and pressure; spread to the dorsal feet is occasionally observed, usually in association with trauma, excessive friction or infection[58]. Hyperhidrosis is common, and acral blistering (clinical or subclinical underlying hyperkeratotic skin) may occur. Multiple pilosebaceous cysts (characteristically steatocystoma multiplex or eruptive vellus hair cysts but also epidermoid and trichilemmal cysts) develop in some patients (see Table 58.4), usually after puberty. Other features include follicular keratoses, angular cheilitis, oral leukokeratosis, and hoarseness secondary to laryngeal involvement[1].

The hypertrophic nail dystrophy of PC presents as wedge-shaped thickening of the nail bed due to subungual hyperkeratosis; this leads to elevation of the nail plate, which can be marked (Fig. 58.14). The nail plates are frequently thickened, darkened and friable, and they may assume an omega shape. Overall, involvement of the nail apparatus is greater distally than proximally. All 20 nails may or may not be involved, and changes tend to be more severe in the toenails and nails of the thumb and index fingers. During infancy, erythema of the nail bed may be the only visible sign, preceding the characteristic nail changes[59].

Histologically, the areas of focal NEPPK show hyperkeratosis with patchy hypergranulosis. Large misformed keratohyalin granules are present, which, on electron microscopy, appear as perinuclear keratin aggregates.

PC results from heterozygous mutations in the genes encoding the following proteins: (1) K6a (~50% of cases; associated with more severe disease) and its partner K16 (~30% of cases), classically the causes of PC1; and (2) K6b (~5% of cases) and its partner K17 (~15% of cases), classically the causes of PC2[57,60,61]. Most PC patients have a dominant-negative missense mutation in the helix initiation or termination motif of one of these keratins[56,57] (see Fig. 56.5). Individuals with identical missense mutations in K17 can have the classic nail findings of PC or steatocystoma multiplex but little or no nail dystrophy[61,62].

Fig. 58.14 Pachyonychia congenita. **A** Thickening of palmar skin and hypertrophic nail dystrophy with wedge-shaped subungual hyperkeratosis. **B** Painful focal plantar keratoderma with associated erythema and blistering.

Treatment with emollients and keratolytics may be helpful in milder cases of PC[63]. Attempts should be made to minimize repeated trauma and friction. Systemic retinoids have led to some improvement of the nails and skin, and botulinum toxin-A injections can reduce hyperhidrosis and pain[64]. Surgical excision of severely deformed nails (with matrix ablation) is usually followed by recurrence, as the keratins

involved in PC are expressed in the nail bed. K17 is also expressed in the nail matrix, and this may explain the occasional patient who improves with simple matrix ablation. Treatment with small interfering RNAs (siRNAs) that specifically target and silence expression of dominant-negative mutant *K6a* is currently being investigated[65], including the development of novel delivery methods to avoid the pain of intradermal injection. Another possible therapeutic approach is oral or topical administration of statins (e.g. simvastatin), which down-regulate *K6a* promoter activity, to patients with K6a defects (considering that loss of expression of this keratin is likely tolerated due to the functional redundancy of K6a, K6b and K6c)[66].

Carvajal syndrome

Synonym: ▪ Striate EPPK with woolly hair and dilated cardiomyopathy

Classic Carvajal syndrome has autosomal recessive inheritance and was first described in families from Ecuador[67]; variants (some with dominant inheritance) were subsequently recognized in other ethnic groups. This disorder features the triad of focal/striate EPPK, dilated cardiomyopathy and woolly hair. As with Naxos disease (see above), the PPK appears during early infancy and hair abnormalities are present at birth. The cardiac disease may begin during adolescence or have onset in early childhood; although it involved the left ventricle in the original kindreds, the right or both ventricles can be affected[46,47]. In addition to the core triad, scaly plaques and keratoses can develop on the elbows and knees or in flexural sites. Skin fragility with intraepidermal blistering (and acantholysis histologically), nail dystrophy and dental enamel defects have been observed in a Carvajal syndrome variant[68].

Histologic features of the PPK include spongiform edema with widened intercellular spaces in the epidermis and a variable degree of epidermolytic hyperkeratosis. The keratinocytes are abnormal, with dense eosinophilic cytoplasm surrounding a pyknotic nucleus. Immunohistochemistry demonstrates perinuclear localization of keratin in suprabasal keratinocytes, suggesting a collapsed intermediate filament network.

Carvajal syndrome is due to mutations in the gene that encodes desmoplakin, classically in both alleles and affecting the protein's carboxy-terminal tail (which binds to intermediate filaments and is important in cardiac myocytes)[67]. However, the same triad of findings (with the additional feature of hypodontia) has been reported in individuals with dominant-negative mutations in the desmoplakin gene[47]. As noted above, desmoplakin mutations also cause *isolated focal/striate PPK* with autosomal dominant inheritance. Other autosomal recessive conditions due to desmoplakin defects include *skin fragility/woolly hair syndrome* (also features PPK and nail dystrophy but not cardiac abnormalities) and *lethal acantholytic epidermolysis bullosa* (also features total alopecia, anonychia and [variably] cardiomyopathy).

PUNCTATE PALMOPLANTAR KERATODERMA AND RELATED CONDITIONS

Punctate Palmoplantar Keratoderma

Synonyms: ▪ Keratosis punctata palmaris et plantaris ▪ Buschke–Fischer–Brauer type

Over the last century, multiple variants of punctate PPK (PPPK) have been described in the medical literature. However, imprecise terms and redundant nomenclature have hampered classification. Lack of linkage of PPPK to the keratin gene cluster has led to the suggestion that molecular aberrations in non-keratin structural proteins involved in keratin filament assembly and function may be responsible[69]. Although to date no specific genes have been identified, linkage analyses in three large kindreds with PPPK mapped the disease locus to the region between 15q22.2 and 15q22.31[70].

This disorder is inherited as an autosomal dominant trait with an equal sex ratio; sporadic cases are also seen. The incidence is approximately 1 per 100 000. Unlike other forms of PPK, lesions are uncommon in childhood, usually beginning to appear during adolescence or early adulthood.

Punctate keratodermas are characterized by multiple keratoses, 2–9 mm in diameter, which vary in appearance (see Fig. 58.4). The lesions begin as pinhead-sized, firm, translucent papules, which may remain translucent or become opaque and verrucous over time. Sometimes there is a central keratotic core, which leaves a depression when removed. The papules can enlarge to form callus-like lesions, and they are aggravated by manual work; large lesions may be painful. In patients of African ancestry, punctate keratoses frequently occur in the palmar creases[71] (Fig. 58.15).

Histologically, PPPK lesions show compact columns of massive hyperkeratosis over a sharply limited area of the epidermis. There is increased thickness of the granular cell layer, and the dermis is devoid of inflammation.

PPPK is commonly misdiagnosed as verrucae vulgaris, but the papules do not demonstrate multiple bleeding points upon paring. Punctate porokeratosis of the palms and soles can have a similar clinical appearance to PPPK and is distinguished by the presence of a cornoid lamella histologically (rather than a column of orthohyperkeratosis). A parakeratotic column is also seen in spiny keratoderma, but the lesions in

Fig. 58.15 Punctate keratoses of the palmar creases in an African-American.

DIFFERENTIAL DIAGNOSIS OF PALMOPLANTAR PITS
HEREDITARY DISORDERS
Nevoid basal cell carcinoma syndrome
Basaloid follicular hamartoma syndrome
Darier disease
Reticulate acropigmentation of Kitamura
Punctate PPK (including punctate keratoses of the palmar creases)*
Cowden disease*
Porokeratotic eccrine ostial & dermal duct nevus (PEODDN)*
ACQUIRED DISORDERS
Pitted keratolysis
Associated with Dupuytren's contracture
Punctate porokeratoses*
*Characterized primarily by keratoses, which may leave a pit upon removal of the keratotic plug.

Table 58.5 Differential diagnosis of palmoplantar pits. They are rarely seen in alkaptonuria, epidermodysplasia verruciformis, Blau syndrome, and lesions of lichen nitidus, lichen planus or psoriasis. Occasionally, lesions of circumscribed palmar or plantar hypokeratosis can be multiple and <5 mm. PPK, palmoplantar keratoderma.

this disorder resemble music box spines. Multiple punctate palmoplantar keratoses can also be seen in patients with Darier disease and Cowden disease, and a search for other mucocutaneous signs of these disorders should be performed. Arsenical keratoses tend to appear later in life and can be distinguished by their histologic appearance. Because the palmoplantar pits of nevoid basal cell carcinoma syndrome and plantar pitted keratolysis are characterized by foci of absent or reduced stratum corneum, they are usually not confused with PPPK. Additional conditions that can present with palmoplantar pits are listed in Table 58.5.

Treatment is symptomatic, and keratolytics can help to soften individual lesions. Both topical and systemic retinoids have been used, with variable success.

Acrokeratoelastoidosis and Focal Acral Hyperkeratosis

Synonyms: ▪ Acrokeratoelastoidosis of Costa ▪ Keratoelastoidosis marginalis

These two entities are characterized by 2–4 mm skin-colored papules that occur on the marginal borders of the hands, digits and/or feet (Fig. 58.16). Some of the papules may be umbilicated[72]. Both disorders can have an autosomal dominant inheritance pattern. Histologic features represent the major difference between these two conditions: only hyperkeratosis is seen in focal acral hyperkeratosis, while the additional finding of fragmentation and degeneration of dermal elastic fibers characterizes acrokeratoelastoidosis.

In addition to whether or not they represent separate entities, areas of debate with regard to these disorders include: (1) whether the term focal acral hyperkeratosis should be reserved for the clinical scenario described by Dowd et al.[72], i.e. an onset prior to the age of 20 years and predilection for female patients with African ancestry; and (2) if the term acrokeratoelastoidosis should be used to describe the band of solar elastosis found on the inner thumb and index finger of patients with severe solar damage.

ACQUIRED KERATODERMAS AND RELATED CONDITIONS

Keratoderma Climactericum

This disorder was first described by Haxthausen in 1934. Hyperkeratosis begins over pressure points on the heels in women over the age of 45 years. There is no preceding history of skin disorders, including eczema or psoriasis. As the hyperkeratosis extends, fissures form and make walking painful. Obesity and cold dry climates aggravate the condition, as can wearing backless shoes, e.g. sandals. If present, involvement of the hands is much milder and more discrete. Deschamps et al.[73] investigated 10 patients with keratoderma climactericum, measuring serum levels of sex hormones and vitamin A levels as well as performing fungal scrapings and patch tests, all of which were normal or negative. Others have reported similar changes following oophorectomy in young women that responded to estrogen replacement. Low-dose oral retinoid treatment has produced improvement over a period of several weeks. Topical estradiol 0.05% ointment[74] or preparations containing 25–40% urea may prove useful.

Aquagenic Palmoplantar Keratoderma

Synonyms: ▪ Acquired aquagenic palmoplantar keratoderma ▪ Aquagenic wrinkling of the palms and soles ▪ Transient reactive papulotranslucent acrokeratoderma ▪ Aquagenic syringeal acrokeratoderma

Patients with aquagenic PPK develop thickening and white to translucent, "pebbly" changes on their palms shortly after immersion in water (e.g. within 3 minutes) (Fig. 58.17), often in association with edema and burning pain[75,76]. Plantar involvement is less frequently observed. Onset is typically during the second decade of life, with a predilection for girls and women; familial occurrence has been described (in a parent plus child or in siblings). Aquagenic PPK is common in patients with cystic fibrosis (CF), with studies documenting characteristic findings on the hands in approximately 40–80% of CF patients, 25% of CF carriers and no controls following 3 minutes of immersion in room-temperature water[77,78].

Histologically, normal skin or dilated eccrine ostia and a mildly hyperkeratotic stratum corneum may be seen. Treatment with 20% aluminum chloride hexahydrate has been reported to decrease the frequency of skin changes and symptoms.

Palmoplantar Keratoderma Associated with Hypothyroidism/Myxedema

There are at least 10 reports in the literature of diffuse or focal PPK developing in association with hypothyroidism, often in the setting of myxedema. The PPK improved or resolved with thyroid replacement in these patients.

Keratoderma and Cancer

Esophageal carcinoma in association with focal PPK (Howel–Evans syndrome) as well as the increased risk of acral SCC in patients with

Fig. 58.16 Focal acrokeratoelastoidosis. Multiple skin-colored papules at the margin of the palmar skin.

Fig. 58.17 Aquagenic keratoderma. White "pebbly" changes on the palm following immersion in water. *Courtesy, Julie V Schaffer, MD.*

Huriez syndrome and "PPK with sex reversal" are discussed above. Epithelioma cuniculatum and acral melanoma have also been reported in individuals with mutilating forms of PPK. Acquired diffuse PPK has been described in patients with carcinomas of the lung, breast, kidney and colon. "Tripe palms" refers to velvety, thickened palmar skin with exaggerated ridges. It is often associated with acanthosis nigricans and may herald malignancies of the lung, stomach or genitourinary tract[79].

Arsenical keratoses present as small, corn-like areas of hyperkeratosis on the palms and soles. Over time, the lesions enlarge, thicken and increase in number, spreading to the dorsal surfaces of the hands and feet. Ulceration often occurs when SCC develops. On histologic examination, epidermal changes vary from benign hyperplasia to moderate atypia or frank SCC. The latent period between ingestion of inorganic arsenic and onset of keratoses is 10 to 30 years or longer[80]. Visceral malignancies, particularly of the lung and genitourinary tract, usually develop after the onset of skin tumors.

Circumscribed Palmar or Plantar Hypokeratosis

This entity, which was first described in 2002[81], presents as a well-circumscribed, mildly erythematous, circular depression on the palm (favoring the thenar and hypothenar regions) or medial side of the sole. Lesions are solitary or few in number, and they typically develop in middle-aged or older women. Histologically, a sharp drop-off is evident between involved and adjacent skin, and the lesional epidermis has an extremely thin stratum corneum and diminished granular layer (Fig. 58.18). The clinical differential diagnosis may include a porokeratosis or Bowen's disease, but neither a cornoid lamella nor atypical keratinocytes are observed. Although the etiology remains unknown, aberrant keratin expression (e.g. diminished K9) has been documented, and a localized loss in the ability of keratinocytes to undergo palmoplantar differentiation has been postulated[82].

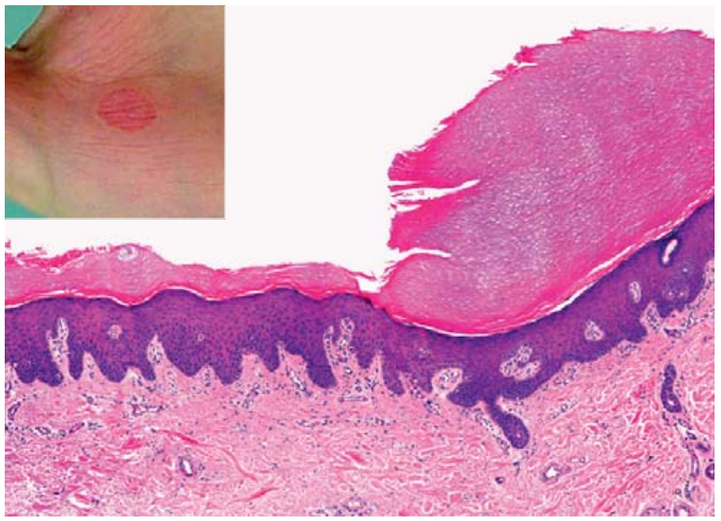

Fig. 58.18 Circumscribed palmar hypokeratosis. A sharp drop-off is seen between the lesional epidermis, which has a very thin stratum corneum, and the surrounding skin. Clinically, a pink depression is seen (see insert).

Hailey–Hailey disease 893

DARIER DISEASE

Synonyms: ■ Darier–White disease ■ Keratosis follicularis ■ Dyskeratosis follicularis

Key features

- An uncommon autosomal dominant disorder in which mutations in the *ATP2A2* gene result in dysfunction of an endoplasmic reticulum Ca^{2+} ATPase (SERCA2), thus interfering with intracellular Ca^{2+} signaling
- Keratotic and crusted papules and plaques favor seborrheic areas; additional features include palmoplantar papules, variable nail changes, and whitish oral mucosal papules
- Clinical subtypes include an acral hemorrhagic variant and segmental forms (types 1 and 2)
- Histologically, acantholytic dyskeratosis is seen with suprabasilar clefting, "corps ronds" and "grains"

Introduction

Darier disease is an autosomal dominant genodermatosis with characteristic mucocutaneous findings such as keratotic papules on the upper trunk and longitudinal erythronychia. Insufficient function of the 2b isoform of the sarco/endoplasmic reticulum Ca^{2+} ATPase (SERCA2b) leads to abnormal intracellular Ca^{2+} signaling, notably involving the endoplasmic reticulum. The result is a loss of suprabasilar cell adhesion (acantholysis) and an induction of apoptosis (dyskeratosis).

History

In 1889, the French dermatologist Jean Darier[1], at the Hôpital Saint-Louis in Paris, and James C White[2], Professor of Dermatology at Harvard University, independently reported a skin disease characterized by brown, crusted, malodorous lesions with a follicular distribution. Darier called the disease "psorospermose folliculaire végétante" because of his histopathologic studies, where throughout the malpighian layer he saw a large number of round bodies surrounded by a double-layered membrane. He and others thought that these bodies represented psorosperms, a type of parasitic protozoa now referred to as coccidia, which they postulated were the causative agents for the disease. However, attempts to culture or inoculate the supposed parasites failed, and the histologic changes were subsequently recognized as sequelae of abnormal keratinization[3]. The supposed follicular origin of the disease could not be confirmed either, as lesions were noted to occur outside the pilosebaceous unit[4]. It was White who first suggested the hereditary character of the disorder, when the daughter of his initially described patient developed similar skin lesions[5].

Epidemiology

In different studies, the prevalence of Darier disease has ranged from 1 in 100 000 in Denmark[6] to 1 in 55 000 or 1 in 36 000 in England[7], and the estimated incidence is 4 per million per 10 years. Men and women are equally affected. Darier disease has an autosomal dominant mode of inheritance with complete penetrance and variable expressivity. For example, in a series of 42 patients with Darier disease, 7 of 18 affected individuals who recalled no family history were found to be members of known Darier kindreds with mildly affected parents[7]. The clinical severity varies greatly among different families carrying identical mutations and even among members of the same family. Indeed, subtle changes of the skin or nails may remain unnoticed by affected persons.

Pathogenesis

Mutations in the endoplasmic reticulum Ca^{2+} ATPase *ATP2A2* (protein product SERCA2) cause both acantholysis and apoptosis (accounting for the histologic finding of acantholytic dyskeratosis in Darier disease), most likely through haploinsufficiency[8]. More than 120 distinct *ATP2A2* mutations have been identified, and in general there is no clear genotype–phenotype correlation. Possible exceptions include particular *ATP2A2* mutations associated with acrokeratosis verruciformis of Hopf[9] and the acral hemorrhagic subtype of Darier disease[10,11].

ATP2A2 mutations result in high cytosolic Ca^{2+} concentrations due to inadequate filling of the endoplasmic reticulum (ER) Ca^{2+} stores (Fig. 59.1)[12]. Although both SERCA2a and SERCA2b isoforms are found in the epidermis, SERCA2b is the major product and its dysfunction alone can produce Darier disease[13]. SERCA2 is ubiquitously expressed, but a lack of compensatory SERCA3 expression in keratinocytes may explain the particular vulnerability of these cells to SERCA2 deficiency.

Several pathogenic mechanisms have been proposed for the acantholytic dyskeratosis of Darier disease. Defects in Ca^{2+} sequestration into the ER may produce acantholysis by impairing the normal synthesis, processing, folding and trafficking of junctional proteins (e.g. desmoplakin)[14]. In contrast to Golgi Ca^{2+} stores, keratinocyte ER Ca^{2+} depletion is also associated with apoptosis. The latter may be mediated by accumulation of unfolded proteins within the ER, which can lead to two highly conserved stress responses: the "unfolded protein response" and the "ER overload response" (reviewed in ref. 15). Alternatively, Ca^{2+} dysregulation may result in impaired control of cell cycle checkpoints and a lower threshold for skin trauma to trigger keratinocyte apoptosis. ATP receptors, which are thought to have roles in apoptosis as well as calcium signaling, have been found to localize abnormally in lesional Darier disease epidermis, with decreased P2Y2 (a G protein-coupled receptor) but increased P2X7 (a death receptor) in the plasma membrane of acantholytic cells[16].

Clinical Features

Onset and clinical pattern

In approximately 70% of patients, the disease begins between the ages of 6 and 20 years, with a peak onset during puberty (ages 11–15 years)[17]. The primary lesions are keratotic, sometimes crusted, red to brown papules, which develop preferentially in a "seborrheic" distribution involving the trunk (Fig. 59.2), scalp (especially its margins; Fig. 59.3), face and lateral aspects of the neck (Fig. 59.4). Despite its initial description as follicular dyskeratosis, the papules are not limited to a perifollicular location. The lesions tend to become confluent and may form papillomatous masses (Fig. 59.2B,D). Small (2–3 mm) hypomelanotic macules may be admixed with the keratotic papules and occasionally are the predominant feature (Fig. 59.5). Rarely, sterile vesicles or

Fig. 59.2 Darier disease. Truncal involvement with a predilection for seborrheic areas. Keratotic papules can vary from red (**A, B**) to brown (**C, D**) in color and may become confluent. *A & C, Courtesy, Julie V Schaffer, MD.*

bullae are prominent, and, in these cases, herpetic infection (Kaposi's varicelliform eruption) must be excluded[18].

In approximately 50% of patients, flat-topped, skin-colored or brownish, 2–4 mm papules reminiscent of flat warts are found on the dorsal aspects of the hands (Fig. 59.6) and feet, and, less often, on the forearms and legs (also see below for the acral hemorrhagic type). Most patients have lesions in the axillae, groin (Fig. 59.7) and/or inframammary area. Although these intertriginous lesions are usually mild, they are occasionally the predominant finding and may result in the misdiagnosis of Hailey–Hailey disease (HHD)[19]. Occasionally, macerated, fungating masses are seen in the axillae or groin. In Darier disease, malodor is a frequent and distressing associated finding.

Palmoplantar papules, many of which are keratotic, and keratin-filled depressions are almost invariably found (Fig. 59.8). Subtle changes can be detected by obtaining finger or palm prints, which show interruption of the dermatoglyphic pattern. Nail changes (Fig. 59.9) include longitudinal red and/or white lines, longitudinal ridging and fissuring, and wedge-shaped subungual hyperkeratosis. The nails are brittle and tend to break distally, forming V-shaped notches[19].

The prevalence of oral manifestations has varied in different cohorts. In one study, painless whitish papules of varying severity were present in 50% (12/24) of patients with Darier disease; the palate was the most common site of involvement (Fig. 59.10), followed by the gingiva, buccal mucosa and tongue[20]. In another series, mucosal lesions were found in only 15% (24/163) of Darier disease patients[17].

Symptoms

Most patients complain of moderate itching. Equally distressing are the appearance and the odor, which can lead to social isolation.

Modifying factors

The disease frequently worsens in the summer. Darier disease has been experimentally induced in uninvolved skin by UV irradiation[21]. However, sweating, heat and occlusion appear to be equally important exacerbating factors, since lesions occur primarily in covered areas and flares often develop without UV exposure (e.g. after long airplane flights). Lithium carbonate (commonly used to treat bipolar disorder) can provoke skin lesions in patients with Darier disease and should be avoided[22].

Course of the disease

Darier disease follows a chronic course without spontaneous remission. Disease severity can fluctuate, with some patients reporting improvement and others deterioration over time[17].

Infectious complications

The keratotic and papillomatous lesions of Darier disease are prone to secondary infections with bacteria, yeast and dermatophytes[17], often leading to vegetating, malodorous plaques. In addition, patients occasionally develop widespread skin infections with human papillomaviruses (HPV) and herpesviruses. Kaposi's varicelliform eruption due to rapid cutaneous spread of a herpes simplex viral (HSV) infection (Fig. 59.11) is a potentially serious complication that must be suspected when there is a sudden onset of vesicular and crusted lesions accompanied by fever and malaise[23]. Systemic antiviral therapy (e.g. acyclovir, valacyclovir) is necessary, and oral antibiotic treatment of secondary bacterial infections may also be indicated. Immunologic studies in patients with Darier disease have shown no consistent abnormalities[24–26]. Thus, the increased frequency of skin infections is likely caused by disruption of the epidermal barrier.

Fig. 59.9 Darier disease. Alternating longitudinal red and white streaks as well as notching of the free edge of the nail plate. *Courtesy, Antonella Tosti, MD.*

Salivary glands

Oral salivary gland obstruction with painful swelling may occur in some patients. Darier-like histologic changes are responsible for the obstruction of the salivary ducts[26].

Fig. 59.10 Oral mucosal Darier disease. Whitish papules on the palate.

Fig. 59.11 Darier disease with superimposed HSV infection (Kaposi's varicelliform eruption). Multiple hemorrhagic crusts of a similar size are seen.

Neuropsychiatric disorders

Various neuropsychiatric conditions such as epilepsy, intellectual impairment and mood disorders have been reported in association with Darier disease[17,27]. In a recent study, neuropsychiatric assessment of 100 Darier disease patients revealed higher lifetime rates of major depression (30%), suicide attempts (13%), bipolar disorder (4%) and epilepsy (3%) than in the general population[28]. Such findings, however, have not been consistently observed; for example, in a study of 75 Darier disease patients, significant neuropsychiatric abnormalities were not identified[7]. Although a predominance of missense mutations and clustering of mutations in the 3′ portion of the *ATP2A2* gene were reported to be associated with neuropsychiatric features in some families[29], this correlation could not be substantiated by others[10]. More recent analysis of the same families speaks against a neuropsychiatric role of the *ATP2A2* mutation itself, but for the existence of a closely linked susceptibility gene for bipolar disorder[30]. Disfigurement and social isolation associated with severe skin diseases are known to cause psychiatric and social morbidity[31]. Therefore, developmental disorders, depression and increased suicidal ideation in patients with Darier disease might be explained, at least in part, by non-genetic factors[19].

Others

Ocular complications, e.g. corneal ulcerations or staphylococcal endophthalmitis, occur very rarely. There have been a few reports of squamous cell carcinomas arising in cutaneous or mucosal sites chronically affected by Darier disease[32]. Malignant transformation is a rare event and may be related to infection with oncogenic types of HPV or changes in keratinocyte adhesion and proliferation secondary to SERCA2 haploinsufficiency, which has been associated with squamous cell carcinomas of the skin and upper gastrointestinal tract in mice. Observations of bone cysts, renal agenesis and autoimmune thyroiditis in patients with Darier disease are thought to represent chance associations.

Fig. 59.12 Type 1 segmental Darier disease. Note the distribution of the papules along Blaschko's lines.

Clinical subtypes of Darier disease (Table 59.1)

Acral hemorrhagic type

In addition to the classic clinical features, patients with Darier disease can develop red to blue–black, irregularly shaped, sharply demarcated macules on the palms and soles as well as the dorsal aspects of the hands[17]. The lesions represent hemorrhage into acantholytic vesicles. Specific missense mutations were found in several non-related families with the acral hemorrhagic type of Darier disease[10,11]. Further studies are needed to confirm this genotype–phenotype correlation; if true, it might provide insight into the pathogenesis of intraepidermal hemorrhage.

Segmental types 1 and 2

Two types of segmental Darier disease have been described, both with a distribution of lesions along Blaschko's lines (see Ch. 62). In the more common type 1 (Fig. 59.12), the age of onset, severity, and histologic findings within the streaks are similar to those of generalized Darier disease. Type 1 segmental Darier disease results from a postzygotic mutation in the *ATP2A2* gene during embryogenesis, which leads to a mosaic pattern of skin involvement. Heterozygous *ATP2A2* mutations in affected but not background skin have been documented in patients with this form of segmental Darier disease[33]. If there are mutant cells in the gonads, a patient with type 1 segmental manifestations may have offspring with generalized Darier disease.

In the type 2 segmental variant, patients with generalized Darier disease have linear streak(s) with increased severity[34]. Type 2 segmental manifestations of autosomal dominant disorders occur when patients with a heterozygous germline mutation also have a postzygotic inactivating mutation in the *other* allele of the same gene (i.e. a "second hit" causing loss of heterozygosity), which leads to more severe manifestations in a mosaic distribution. A second hit in the *ATP2A2* gene was recently identified in skin from erosive patches following Blaschko's lines in a 1-year-old boy with a family history of Darier disease[34a]. This molecular mechanism is well known from tumor suppressor

LESS COMMON PRESENTATIONS OF DARIER DISEASE
MORPHOLOGIC VARIANTS
• Guttate hypopigmentation (see Fig. 59.5) > hyperpigmented flat-topped papules and macules ("freckle-like")*
• Vesiculobullous lesions
• Acral hemorrhagic lesions
• Keratoderma (spiked; see Fig. 59.8B)
• "Cornifying" (e.g. with cutaneous horns)
• Comedones†, facial cysts, acne conglobata
• Periocular nodulocystic lesions
• Alopecia, cutis verticis gyrata
DISTRIBUTION PATTERNS
• Predominantly involving intertriginous areas, sun-exposed skin, the extremities, acral sites, or the scalp (pityriasis amiantacea-like)
• Segmental (type 1 > 2) (Fig. 59.12)
EXTRACUTANEOUS
• Oral mucosal erosions
• Corneal opacities or ulcers
• Salivary gland obstruction
• Laryngeal involvement
*A persistent acantholytic dermatosis and extensive lentiginous "freckling" without an underlying *ATP2A2* mutation has also been described.
†The differential diagnosis may include familial dyskeratotic comedones.

Table 59.1 Less common presentations of Darier disease.

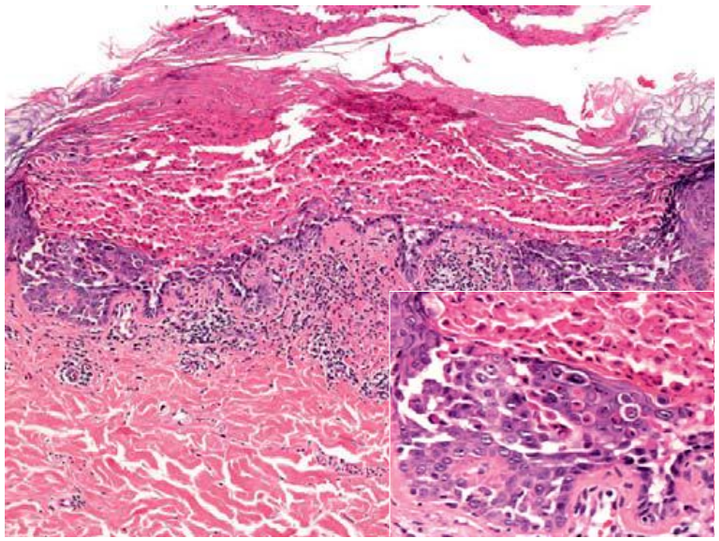

Fig. 59.13 Histopathology of Darier disease. Hyperkeratosis, grains and corp ronds (insert) are seen in addition to acantholysis leading to suprabasilar clefting. *Courtesy, Lorenzo Cerroni, MD.*

Fig. 59.14 Acrokeratosis verruciformis of Hopf. Involvement of the dorsal aspect of the foot with flat-topped papules.

gene syndromes, e.g. nevoid basal cell carcinoma syndrome, where loss of heterozygosity results in tumor formation.

Pathology

There are two prominent histologic features in Darier disease, acantholysis and dyskeratosis (Fig. 59.13). Acantholysis is due to a disturbance in cell adhesion that leads to suprabasilar cleft formation. At the ultrastructural level, this corresponds to a loss of desmosomes and detachment of keratin filaments from the desmosomes[35]. Dyskeratosis is due to apoptosis of keratinocytes and is characterized by nuclear condensation and perinuclear keratin clumping. Two types of dyskeratotic cells are observed in Darier disease[36]:

- "Corps ronds" – acantholytic enlarged keratinocytes in the malpighian layer with darkly staining and partially fragmented nuclei surrounded by a clear cytoplasm and encircled by a bright ring of collapsed keratin bundles.
- "Grains" – small, oval cells in the stratum corneum characterized by an intensely eosinophilic cytoplasm composed of collapsed keratin bundles containing shrunken parakeratotic nuclear remnants. "Grains" are likely derived from "corps ronds", but formal proof that they indeed represent different stages of the same pathologic process has not been provided.

The epidermis overlying acantholytic and dyskeratotic foci is thickened and shows papillomatosis and hyperkeratosis. In the superficial dermis, there is a mild to moderate perivascular inflammatory infiltrate. Diagnostic histologic changes are often focal, necessitating a careful search. Similar histologic features may be observed in Grover's disease, but in the latter there tends to be more acantholysis, less dyskeratosis, and fewer "corps ronds" or "grains". The two conditions can be histologically indistinguishable, but the findings are typically more pronounced, widespread and follicularly based in Darier disease.

Differential Diagnosis

Acrokeratosis verruciformis of Hopf

Flat-topped, wart-like papules on the dorsal aspects of the extremities are a common manifestation of Darier disease. They are clinically indistinguishable from the lesions in the autosomal dominant disorder described by Hopf as "acrokeratosis verruciformis" (Fig. 59.14)[37]. There has been debate as to whether acrokeratosis verruciformis is a separate entity or an allelic forme fruste of Darier disease, and reports of an underlying *ATP2A2* mutation in some but not all patients with acrokeratosis verruciformis suggest genetic heterogeneity[9,38]. Acrokeratosis verruciformis and Darier disease have traditionally been separated on the basis of their histologic features, with the former lacking acantholysis and dyskeratosis. However, serial sectioning is often required to find foci of acantholysis and dyskeratosis in acral skin biopsy specimens from patients with Darier disease[39].

Hopf actually described nail changes and palmoplantar keratotic papules in his initial report, and there have been subsequent observations of patients who had the classic skin findings of Darier disease as well as acrokeratosis verruciformis[40]. Because patients with Darier disease often develop warty lesions on the extremities before keratotic papules appear in a seborrheic distribution[7], it is possible that some patients who present with acrokeratosis verruciformis could later be diagnosed with classic Darier disease. Of note, a particular *ATP2A2* mutation (P602L) was identified in a British family with acrokeratosis verruciformis alone[9] and a Swiss kindred with acrokeratosis verruciformis together with a forme fruste of Darier disease appearing only after intense UV exposure (author's unpublished observation).

Others

Although the clinical differential diagnosis may include severe seborrheic dermatitis and Grover's disease (transient acantholytic dermatosis; see Fig. 59.4 and Ch. 87), Darier disease is readily distinguished by involvement of acral skin, the nails and the oral mucosa. A family history may also be a clue to the diagnosis of Darier disease, and histologic findings differentiate it from seborrheic dermatitis. In Grover's disease, the pruritic crusted papules are not confluent, and they typically develop after occlusion and/or sweating. However, in a persistent form of acantholytic dermatosis that affects patients with significant actinic damage, the papules are scalier and the histologic features closely resemble those of Darier disease[41].

In patients with predominantly flexural involvement, pemphigus vegetans (Hallopeau type), blastomycosis-like pyoderma (pyoderma vegetans) and HHD may represent diagnostic considerations. Pemphigus vegetans usually develops at an older age and is characterized histologically by exocytosis of eosinophils as well as acantholysis; direct immunofluorescence (DIF) shows the intercellular pattern of the pemphigus group, and anti-desmoglein antibodies can be detected by ELISA. Pyoderma vegetans features a neutrophilic infiltrate, and acantholysis is not observed. HHD is sometimes difficult to separate clinically from primarily intertriginous Darier disease. The presence of palmoplantar papules, longitudinal erythronychia, distal notching of the nails, mucosal lesions and prominent dyskeratosis as well as acantholysis histologically can serve as clues to the diagnosis of Darier disease. Occasionally, a sporadic disorder referred to as "papular acantholytic dyskeratosis" may be localized to the vulvocrural area.

Treatment

General measures

Lightweight clothes and sunscreen help prevent aggravation due to heat, sweating and sun exposure. Daily skin care includes the use of antimicrobial cleansers to prevent malodorous bacterial colonization and keratolytic emollients to reduce scaling and irritation.

Topical therapy

Topical corticosteroids (see Ch. 125) are usually less effective as monotherapy than are topical retinoids (see Ch. 126). However, retinoid-associated irritation is common and can be reduced by alternate-day application, liberal use of emollients[42,43], and combination therapy with mid-potency topical corticosteroids. Intermittent use of topical antibiotics and antifungal agents is helpful in treating malodor due to microbial colonization and mild secondary infections. Several reports have suggested that topical 5-fluorouracil (1% or 5%) may be efficacious[44], but calcipotriene (calcipotriol) had no clear benefit in a small randomized controlled study[45].

Systemic therapy

Isotretinoin and acitretin are very effective treatments for Darier disease, with significant improvement and control of the disease in approximately 90% of patients[19,46]. Unfortunately, the use of these agents is limited by their side effects and patients relapse after cessation of therapy. Thus, systemic retinoids should be reserved for patients with severe disease unresponsive to topical treatment. Because of the teratogenic potential of systemic retinoids, contraception is mandatory for women of childbearing potential (see Ch. 126). Individual dose titration is important to ensure maximal therapeutic effect with minimal dose-related side effects, such as mucosal dryness (cheilitis, epistaxis, conjunctivitis) and elevation of serum lipids and liver enzymes. Intermittent therapy to prevent exacerbations during the summer months is a useful approach. In patients with predominantly bullous or intertriginous lesions, oral retinoids may aggravate the disease and are not recommended[47].

A small subset of female patients with Darier disease report premenstrual exacerbations of their skin condition. In these cases, oral contraceptives can mitigate symptoms[48]. There are case reports of cyclosporine being used to control severe Darier disease[49], and it may be helpful for patients who cannot tolerate or do not respond to oral retinoids.

Surgical therapy

Surgical therapy may be an effective alternative for focal recalcitrant lesions, particularly in the flexural and gluteal areas. Excision followed by split-thickness grafting, dermabrasion or laser removal (CO_2 or erbium:YAG) may yield a long-term remission[50,51]. Destructive treatment must include the follicular infundibulum in order to prevent recurrences. Experience is necessary to avoid scarring, particularly in body areas at risk for hypertrophic scar or keloid formation. From this standpoint, the erbium:YAG laser might have an advantage over the CO_2 laser[52]. Small series also describe successful pulsed dye laser and photodynamic therapy[53,54].

HAILEY–HAILEY DISEASE

Synonym: ■ Familial benign chronic pemphigus

Key features

- An uncommon autosomal dominant disorder in which mutations in the *ATP2C1* gene result in dysfunction of a Golgi-associated Ca^{2+} ATPase, thus interfering with intracellular Ca^{2+} signaling
- Clinically, flaccid blisters and erosions are seen on the neck and in intertriginous areas, especially the axillae and groin; moist malodorous vegetations and fissures can develop
- Segmental variants (types 1 and 2) can occur
- The major histologic finding is acantholysis throughout the spinous layer, sometimes referred to as a "dilapidated brick wall"

Introduction

HHD is an autosomal dominant genodermatosis characterized by vesicular and erosive lesions that favor the intertriginous areas, especially the axillae and groin. Mutations in the *ATP2C1* gene that encodes the Golgi-associated Ca^{2+} ATPase hSPCA1 lead to abnormal intracellular Ca^{2+} signaling, resulting primarily in a loss of cellular adhesion (acantholysis) in the stratum spinosum.

History

In 1939, Howard and Hugh Hailey, brothers working in the Department of Dermatology at Emory University School of Medicine in Atlanta, Georgia, described a chronic dermatosis in two sets of brothers. The disorder was characterized by recurrent blisters and erosive, crusted lesions on the neck (in one pair of brothers) and in the axillae and groin (in the second pair)[55]. Histologic sections from all four patients showed similar features – intraepidermal vesicles, mild dyskeratosis, hyperkeratosis and a moderate dermal lymphocytic infiltrate. Different dermatopathologists interpreted these findings variably as pemphigus, pemphigus-like or Darier disease. The authors themselves believed that they were dealing with a novel entity unrelated to Darier disease and coined the name "familial benign chronic pemphigus".

A disease called "pemphigus congénital familiale héréditaire" had been described 6 years prior to the report by the Hailey brothers. Therefore, some believe that HHD should also bear the name of the French dermatologists Gougerot and Allée. However, they did not perform a biopsy, and the early onset and initial localization on pressure points suggest that their patients may have actually suffered from epidermolysis bullosa simplex[56]. The subsequent controversy as to whether "familial benign chronic pemphigus" was a unique disease or a phenotypic variant of Darier disease was finally solved by our understanding of the molecular genetics of both disorders.

Epidemiology

There are no data regarding the exact prevalence of HHD. Based upon clinical experience, HHD is seen approximately as frequently as Darier disease. The mode of inheritance is autosomal dominant with complete penetrance, but the age of onset and expressivity varies greatly among the affected members of a family[57]. In one series, 9 of 58 patients had no family history[57]. However, very mild forms of the disease may go unnoticed in patients carrying the same mutated *ATP2C1* gene as their more severely affected relatives. Thus, the proportion of cases caused

by sporadic mutations may be lower than previously assumed. There is no evidence to date of a correlation between the phenotype and the underlying *ATP2C1* mutation[58].

Pathogenesis

HHD is caused by mutations in the *ATP2C1* gene[59,60], which encodes a Ca^{2+} ATPase, hSPCA1, that is localized to the Golgi apparatus[61,62] (see Fig. 59.1). hSPCA1 transports Ca^{2+} and Mn^{2+}, and it sequesters Ca^{2+} within the Golgi lumen. Like Darier disease, HHD is likely caused by haploinsufficiency[63]. Acantholysis due to *ATP2C1* mutations appears to be mediated through impaired Ca^{2+} sequestration, resulting in the observed depletion of Ca^{2+} within the Golgi lumen[61], via one or more of the following mechanisms. First, normal Golgi Ca^{2+} levels are required for complete processing of proteins through the Golgi apparatus[64], and Golgi Ca^{2+} depletion may impair processing of junctional proteins. Indeed, junctional proteins required for normal cell-to-cell adhesion are reduced in epidermal biopsies from HHD patients[65]. In addition, HHD keratinocytes and epidermis demonstrate altered ATP signaling, possibly leading to lower calcium content of basal keratinocytes and abnormal transition from keratin 14 to keratin 10 expression[16]. Reduced cellular ATP levels may result in impaired actin reorganization and abnormal formation of the adherens junctions required for normal keratinocyte cell-to-cell adhesion[66].

Clinical Features

Onset and clinical pattern

The initial lesions and associated symptoms usually develop during the second or third decade of life but may be delayed until the fourth or fifth decade[57]. HHD has a predilection for intertriginous sites, such as the axillae (Fig. 59.15), groin, lateral aspects of the neck, and perianal region (see Fig. 59.4). The scalp, antecubital and popliteal fossae, and trunk are less frequently involved. Inframammary (Fig. 59.16) and vulvar lesions are common in women, and female patients occasionally present with isolated vulvar disease[67].

The primary lesion is a flaccid vesicle on erythematous or normal-appearing skin, which ruptures easily and therefore is often overlooked (see Fig. 59.15). The blisters give rise to macerated or crusted erosions (see Fig. 59.16), which tend to spread peripherally, producing a circinate border with crusts and small vesicles when examined carefully (Fig. 59.17). Development of chronic, moist, malodorous vegetations and painful fissures is common. Healing occurs without scarring, leaving postinflammatory hyperpigmentation.

Asymptomatic, longitudinal white bands in the fingernails (longitudinal leukonychia) may serve as a subtle diagnostic clue in patients with limited or atypical disease[68]. Involvement of the buccal[69], vaginal[70] or conjunctival[71] mucosa is rare.

Symptoms

Painful intertriginous erosions and crusting may interfere with physical and professional activities. Fetid odor and pruritus add to the psychosocial distress of the patients.

Modifying factors

Given the abnormal cell–cell adhesion within the epidermis, friction can induce new lesions. Heat and sweating can also exacerbate this disease, and patients often note worsening during the summer months. UV irradiation does not appear to influence the course of the disease[57]; however, recent data reveal that *ATP2C1* mRNA expression is suppressed by UVB[72]. Microbial colonization and secondary infections are important modifying factors, as discussed below. In particular, staphylococcal infection potentiates acantholysis and may lead to severe and widespread blistering[73].

Course of the disease

Complete remissions as well as flares are common, and the clinical course in an individual patient is difficult to predict. Some patients report attenuation of the disease at an older age, whereas others state that there is no change or worsening with aging. Life expectancy is not altered.

Complications

Infections

As in Darier disease, colonization and secondary bacterial, fungal and viral infections play an important role in disease exacerbation and persistence[74]. Vegetating lesions and malodor suggest bacterial and/or fungal overgrowth. Topical and, sometimes, systemic antimicrobial agents may be required to induce a clinical remission.

Recalcitrant intertriginous lesions have been described in association with HSV infections[74]. Direct fluorescent antibody assays, viral cultures or PCR-based testing of infected keratinocytes can confirm this diagnosis; occasionally, a skin biopsy is required. Kaposi's varicelliform eruption due to HSV is a rare complication of HHD[75]. It is characterized by fever and a rapidly spreading vesicular eruption, and should be promptly treated with an oral antiviral medication (e.g. acyclovir, valacyclovir). Generalized cowpox infection in a patient with Darier disease has also been reported.

Malignant transformation

There are a few case reports of cutaneous squamous cell carcinoma developing within chronic lesions of HHD in the anogenital region[76]. It is possible that impairment of the structural integrity of the epidermis may predispose patients to infection with oncogenic strains of HPV (see Ch. 79).

Clinical subtypes of Hailey–Hailey disease

Segmental type 1

Segmental type 1 HHD is caused by a heterozygous postzygotic mutation in an otherwise normal embryo, resulting in a mosaic distribution of disease with age of onset and severity similar to the non-mosaic phenotype. Only a few cases of segmental type 1 involvement in HHD have been reported.

Segmental type 2

There are rare patients with generalized HHD who also have a segmental area of more pronounced involvement with earlier onset (analogous to type 2 segmental lesions described above for Darier disease). This results from postzygotic inactivation of the normal *ATP2C1* allele (loss of heterozygosity), which leads to more severe disease in a mosaic pattern[77]. Unlike HHD due to a heterozygous mutation, the affected segments display acantholysis within adnexal structures, which might make it impossible to eradicate foci of blistering using superficial surgical methods (see below).

Pathology

Whereas acantholysis in Darier disease occurs primarily in discrete foci, the loss of intercellular bridges in HHD is generally more widespread within the epidermis. Thus, larger areas of dyscohesion with single or groups of acantholytic cells are seen, which have been likened to a "dilapidated brick wall". Dermal papillae, lined by a single layer of basal cells, protrude into the blister cavities and are referred to as "villi" (Fig. 59.18). In contrast to Darier disease, necrotic keratinocytes are uncommon, and only rare acantholytic dyskeratotic cells, i.e. "corps ronds" as in Darier disease, may be observed. In more chronic lesions, epidermal hyperplasia, parakeratosis and focal crusts are found. A moderate perivascular lymphocytic infiltrate is observed in the superficial dermis. DIF is negative, thus excluding pemphigus vulgaris. Ultrastructurally, the disturbance of cellular adhesion is reflected in the dissolution of the desmosome–tonofilament complex and formation of perinuclear tonofilament aggregates[78].

Histologically, Grover's disease may be indistinguishable from HHD, but these two entities are readily distinguished on the basis of clinical features.

Differential Diagnosis

The blisters in HHD are typically fragile and rupture easily. Therefore, clinical experience and a high index of suspicion may be necessary to diagnose this disorder, especially in patients with limited disease. Lesions confined to the axillae or groin may be mistaken for intertrigo or candidiasis. Isolated perianal maceration is easily misdiagnosed as irritant dermatitis, and vulvar involvement may resemble lichen simplex chronicus[67]. Histologic examination of affected skin is often the key to the diagnosis.

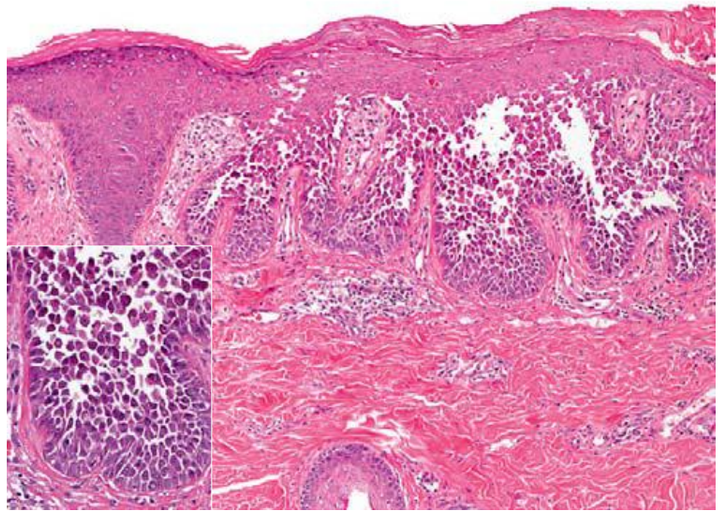

Fig. 59.18 Histopathology of Hailey–Hailey disease. Focal crusting and acantholysis beginning in the suprabasilar area and extending throughout the epidermis. The latter has been likened to a "dilapidated brick wall". *Courtesy, Lorenzo Cerroni, MD.*

The lesions of inverse psoriasis have sharper borders, fewer erosions and less crusting. A total skin examination, looking for additional sites of involvement and associated signs, e.g. nail pitting, will aid in the diagnosis. Vegetating intertriginous lesions in HHD may be identical to those of pemphigus vegetans (Hallopeau type), but the latter can be differentiated by positive DIF of perilesional skin.

The cutaneous features of HHD and Darier disease may overlap. Older reports described patients with characteristic skin findings of both genodermatoses who therefore carried two diagnoses[79], but genetic analysis can now establish a single diagnosis in such individuals. In general, the two disorders have different patterns of distribution that are fairly easily distinguished (see Fig. 59.4). Moreover, a predominantly vesicular eruption in patients with Darier disease is rare[18]. Palmar pits were previously reported in a woman with HHD, but she may have been misdiagnosed[80]. Additional features such as V-shaped notches in the distal free edge of the nail plate, longitudinal erythronychia, and oral papules point to the diagnosis of Darier disease.

Treatment

General measures

Wearing lightweight clothes is recommended to avoid friction and sweating. Colonization and secondary bacterial, fungal and viral infections should be prevented with antimicrobial cleansers and treated with appropriate topical and/or systemic antimicrobial agents.

Topical therapy

Topical corticosteroids are an effective treatment in many patients and are often combined with topical antimicrobials and cleansers. Early application of corticosteroids can ameliorate developing lesions[57]. When the disease is refractory to topical preparations, it may respond to intralesional corticosteroids. In order to minimize the potential side effects of topical corticosteroids in intertriginous zones (e.g. atrophy, striae, telangiectasias; see Ch. 125), the lowest potency that is effective should be used; these medications can be applied intermittently and/or steroid-sparing agents can be substituted.

Anecdotal reports have described a therapeutic benefit from topical application of tacrolimus[81], cyclosporine, 5-fluorouracil[82], calcitriol and tacalcitol[83]. Improvement of axillary disease after chemodenervation of sweat glands with botulinum toxin has also been observed[84].

Surgical therapy

Surgical therapy should be considered for disease unresponsive to general measures and topical treatments. Wide excision and grafting

have been reported to be successful[85], but this aggressive approach has been replaced by more superficial ablative techniques. The most well-documented method is dermabrasion[86], but vaporization of the epidermis with a scanned CO_2 or erbium:YAG laser[52] and photodynamic therapy with 5-aminolevulinic acid[87] seem to be equally effective. These approaches remove diseased epidermis and their dermal niche of fibroblasts to the level of the mid-dermis. Re-epithelialization (from the spared adnexal structures) occurs within 7–14 days.

Systemic therapy

With the exception of antimicrobial agents for superinfections, there is no strong evidence to support the use of any particular systemic therapy in HHD. Oral retinoids are not clearly effective[57], and there are only anecdotal reports of severely affected individuals improving with the use of immunomodulatory drugs, e.g. prednisone, cyclosporine, methotrexate, dapsone and alefacept[88–90].

INTRODUCTION

Primary immunodeficiencies represent a heterogeneous group of inherited disorders characterized by immune system defects that result in susceptibility to infections as well as additional manifestations such as autoimmunity, allergy and malignancy. The molecular bases have been defined for more than 150 monogenic primary immunodeficiency diseases, providing valuable insight into the function of the human immune system[1,2].

Patients with genetic immunodeficiency disorders often manifest with cutaneous abnormalities[1,3]. Some of these skin findings are highly characteristic of a particular disorder, while others, such as eczematous or granulomatous dermatitis, are shared by other immunodeficiencies[4] (Table 60.1). Screening laboratory tests for a patient with recurrent cutaneous infections that raise suspicion of a primary immunodeficiency[5] are listed in Table 60.2.

ATAXIA–TELANGIECTASIA

Synonym: ■ Louis–Bar syndrome

Key features

- Progressive cerebellar ataxia
- Oculocutaneous telangiectasias, initially of the bulbar conjunctivae
- Selective deficiency of humoral and cell-mediated immunity, leading to sinopulmonary infections
- Increased sensitivity to ionizing radiation
- Leukemias and lymphomas

Introduction

Ataxia–telangiectasia (AT) is characterized by oculocutaneous telangiectasias, progressive cerebellar ataxia beginning in infancy, a variable immunodeficiency with a tendency to develop sinopulmonary infections, and chromosomal instability with persistent DNA damage after exposure to ionizing radiation.

Epidemiology

AT is an autosomal recessive disorder that occurs in 1:40 000 to 1:100 000 live births, with a carrier rate of up to 1% of the population.

Pathogenesis

AT results from mutations in the ataxia–telangiectasia mutated gene (*ATM*), which encodes a phosphatidylinositol 3-kinase-like serine/threonine protein kinase that plays a central role in activating apoptotic and cell cycle responses to DNA damage, particularly double-stranded breaks[6]. These DNA breaks are sensed directly by the MRE11–RAD50–NBS1 (MRN) complex, which recruits ATM and triggers its dissociation from inactive multimers to active monomers[7]. Autophosphorylated ATM monomers subsequently activate (via phosphorylation) a variety of targets, including p53, BRCA1, FANCD2, and Artemis in addition to NBS1 and MRE11. The result is cell cycle arrest and facilitation of DNA repair, both in the setting of external insults (e.g. ionizing radiation) and in the processing of physiologic DNA breaks that occur during V(D)J recombination in lymphocytes, telomere maintenance and meiosis[6]. This provides an explanation for the sensitivity to ionizing radiation, immunodeficiency, premature aging, and defective spermatogenesis that are observed in patients with AT. Progressive neurologic deterioration in affected individuals likely reflects defective DNA repair in a cell population that cannot replicate. Oxidative stress related to ATM dysfunction has also been implicated in the pathogenesis of the disease.

Of note, mutations in the *MRE11* and *NBS1* genes cause two related conditions, AT-like disorder (featuring radiosensitivity and neurologic manifestations similar to AT, but no telangiectasias) and Nijmegen breakage syndrome (characterized by microcephaly, immunodeficiency, chromosomal instability and cancer predisposition), respectively.

Clinical Features

The first manifestation of AT is usually ataxia, which typically appears when the affected child begins to walk. However, the diagnosis is often not recognized until the oculocutaneous telangiectasias are well developed, at a median age of 6 years[8]. The telangiectasias first appear at 3–6 years of age on the lateral and medial bulbar conjunctivae as red, symmetric horizontal streaks (Fig. 60.1A). Telangiectasias subsequently develop on the ears, eyelids, malar prominences, antecubital and popliteal fossae and presternal area, and less commonly on the dorsal aspects of the hands and feet and the hard and soft palate. The nonfacial cutaneous telangiectasias are often subtle, resembling fine petechiae (Fig. 60.1B).

Progeric changes of the skin and hair are noted in almost 90% of patients. Subcutaneous fat is lost early and the facial skin tends to become atrophic and sclerotic. Gray hairs frequently appear in young children, and diffuse graying of the hair may occur by adolescence. Non-infectious cutaneous granulomas are another common cutaneous manifestation of AT[9] (Fig. 60.2). These granulomatous plaques tend to be persistent and ulcerate, leading to significant discomfort. Nevoid hyper- and/or hypopigmentation (particularly large segmental café-au-lait lesions) are often observed in children with AT, with chromosomal instability likely explaining this pigmentary mosaicism. Other dermatologic findings that have been described in individuals with AT include poikiloderma, eczematous dermatitis, seborrheic dermatitis

CUTANEOUS FINDINGS IN PRIMARY IMMUNODEFICIENCY DISORDERS										
Disorder	***S. aureus* infections**		**CMC**	**Warts**	**Eczematous dermatitis**	**Granulomatous dermatitis* (non-infectious)**	**LE**	**SVV**	**Ulcers (PG-like)**	**Other findings**

X-linked agammaglobulinemia	+	++			+	+				Dermatomyositis-like eruption (due to echovirus); ecthyma gangrenosum

*Extensive cutaneous and extracutaneous granulomatous disease (including destructive midfacial granulomas) has been described in children with hypomorphic *RAG1* or *RAG2* mutations.
†Defective thymic function, hypocalcemia secondary to hypoparathyroidism, congenital heart defects, and craniofacial anomalies; due to 21q11 deletions.
‡Patients with the autosomal recessive form of hyper-IgE syndrome are also at increased risk of developing mucocutaneous squamous cell carcinoma and severe warts, molluscum contagiosum and herpes simplex or varicella–zoster viral infections.

Table 60.1 Cutaneous findings in primary immunodeficiency disorders. +, occasional finding; ++, common finding; BCC, basal cell carcinoma; CALM, café-au-lait macules; CMC, chronic mucocutaneous candidiasis; DLE, discoid lupus erythematosus; GVHD, graft-versus-host disease; IL, interleukin; JIA, juvenile idiopathic arthritis; LE, lupus erythematosus; PG, pyoderma gangrenosum; SCID, severe combined immunodeficiency; SVV, small vessel vasculitis; TAP, transporter associated with antigen processing; WHIM, warts, hypogammaglobulinemia, infections and myelokathexis.

with blepharitis, keratosis pilaris, vitiligo, warts, hirsutism and acanthosis nigricans.

Cerebellar ataxia usually begins during infancy and is characterized by swaying of the head and trunk. Choreoathetosis, dysarthric speech, oculomotor abnormalities and myoclonic jerks often become prominent during childhood. Despite good muscle strength, patients are typically confined to a wheelchair by 11 years of age. The facies become dull and hypotonic, with mask-like changes developing concurrently with progressive progeric features. Of note, milder AT with onset of neurologic manifestations in adulthood has been described in individuals with *ATM* mutations that result in residual kinase activity.

Chronic or recurrent sinopulmonary infections occur in more than 80% of AT patients[10]. The most common cause of death is bronchiectasis with respiratory failure. Mildly elevated hepatic transaminase levels are noted in approximately half of patients, and the majority of affected individuals have evidence of glucose intolerance, hyperinsulinemia and insulin resistance. Other manifestations of AT include growth retardation (70%), developmental delay (33%) and hypogonadism.

Although lymphoid malignancy has been reported as the presenting sign of AT during infancy, most neoplasias occur in young adults. Patients who survive into their late teenage years have an up to 40% risk of developing a malignancy, especially leukemia (70-fold increase compared to unaffected individuals) and lymphoma (200-fold increase). Occasionally, patients develop basal cell carcinomas during the third decade of life.

SCREENING LABORATORY TESTS FOR A PATIENT WITH RECURRENT CUTANEOUS INFECTIONS		
Test	**Finding**	**Immunodeficiency identified**
Complete blood count with differential, platelet count, and examination of smear	• Giant granules within neutrophils, ± neutropenia • Neutrophilia • Small platelets, thrombocytopenia	Chédiak–Higashi syndrome Leukocyte adhesion deficiency Wiskott–Aldrich syndrome
Hair shaft examination	• Small, regular clumps of melanin • Large, irregular clumps of melanin	Chédiak–Higashi syndrome Griscelli syndrome (type 2; *RAB27A*)
Quantitative immunoglobulins	• All Ig ↓ • IgA ↓, IgG ↓, ± IgM ↓ • IgA ↓ or IgM ↓ • IgM ↑, all other Ig ↓ • IgM ↑, ± IgA ↑, ± IgG ↓ • IgA ↓, IgE ↓, $IgG_{2,4}$ ↓ • IgE ↑↑ • IgM ↓, ± IgG ↓, IgA ↑, IgE ↑	X-linked agammaglobulinemia Common variable immunodeficiency Selective IgA or IgM deficiency Hyper-IgM syndrome Hypohidrotic ectodermal dysplasia with immunodeficiency Ataxia–telangiectasia Hyper-IgE syndrome Wiskott–Aldrich syndrome
Total hemolytic complement (CH50)	• Marked ↓	Various complement deficiencies
Nitroblue tetrazolium (NBT) reduction assay	• <10% of normal NBT reduction	Chronic granulomatous disease
T- and B-cell analysis by flow cytometry	• Lack of T cells ± B cells	Severe combined immunodeficiency

Fig. 60.2 Persistent granulomatous plaques on the leg of a child with ataxia–telangiectasia. These lesions often ulcerate and are difficult to manage.

Carriers of heterozygous ATM mutations have a two- to threefold increase in both the risk of developing breast cancer and the likelihood of death from cancer (e.g. malignancies of the stomach, colon and lung as well as breast), with greater excess mortality in individuals less than 50 years of age[11].

Pathology

Immunologic defects in patients with AT include: (1) decreased serum levels of IgA (in 70% of patients), IgE (in up to 80% of patients) and IgG (especially IgG_2 and IgG_4; in 60% of patients); (2) low-molecular-weight (8S) IgM (in 80% of patients) and increased serum levels of IgM (in a minority of patients); (3) defects in cell-mediated immunity such as lymphopenia (in 70% of patients) and deficient *in vitro* responses to antigens and mitogens[10]. Affected individuals tend to have a relative deficiency of $CD4^+$ T cells, an excess of γ/δ T cells and elevated serum levels of interleukin-8 (IL-8; a chemokine that may contribute to pathogenic inflammation in AT). The majority of patients have an absent or abnormal thymus. Individuals with no ATM activity have more severe immunologic deficits that those with low levels of ATM activity[12].

Spontaneous chromosomal abnormalities (fragments, breaks, gaps and translocations) occur 2–18 times more frequently in patients with AT than in unaffected individuals, and an increased rate of telomeric shortening is also observed. Rearrangements of chromosomes 7 and 14 are particularly common and may predict the development of lymphoma. Fibroblast DNA from both patients and carriers is extremely sensitive to ionizing radiation and to radiomimetic agents such as bleomycin.

Almost all patients with AT have elevated levels of α-fetoprotein and carcinoembryonic antigen, and measuring the former can aid in establishing the diagnosis in individuals older than 2 years of age. MRI demonstrating cerebellar atrophy represents another clue to the diagnosis in patients older than 2 years. Radiosensitivity testing with the colony survival assay, analysis of radioresistant DNA synthesis (which demonstrates an abnormal S phase checkpoint), immunoblotting for the ATM protein, assessment of ATM kinase activity, karyotyping to identify 7;14 translocations, and sequencing the *ATM* gene may be utilized to confirm the diagnosis. Prenatal diagnosis of AT can be performed when parental mutations have been identified.

Differential Diagnosis

Children with AT may be thought to have Friedreich's ataxia until the ocular telangiectasias become apparent. The conjunctival telangiectasias are occasionally misdiagnosed as conjunctivitis, but the chronicity and size of the telangiectatic vessels distinguish AT. Bloom syndrome (see Ch. 87) can present with facial and occasionally conjunctival telangiectasias, café-au-lait macules, decreased immunoglobulin levels, recurrent respiratory infections and hematologic malignancies, but patients do not have neurologic abnormalities. RIDDLE syndrome is a recently described autosomal recessive condition that features *r*adiosensitivity, *i*mmunodeficiency, facial *d*ysmorphism, *d*ifficulty *le*arning, abnormal motor control and short stature due to mutations in the *RNF168* gene, which encodes a protein that mediates ubiquitin-dependent signaling at sites of DNA double-stranded breaks.

Treatment

The median lifespan in patients with AT is 20 to 25 years. More than half of patients die from chronic sinopulmonary disease and up to a third succumb to malignancy or complications of cancer treatment. Some of the patients who survive into adulthood show improvement in neurologic and immunologic status.

Therapy is supportive:

- antibiotics for infections; prophylactic antibiotics and IVIg replacement therapy for patients with severe immunodeficiency
- avoidance of sun exposure and use of sunscreens
- early physiotherapy for patients with bronchiectasis and consideration of systemic corticosteroid therapy for interstitial lung disease
- physical therapy to prevent contractures related to neurologic dysfunction
- screening for the development of malignancy.

If malignancy occurs, chemotherapy is typically necessary; radiation and radiomimetic chemotherapeutic agents, especially bleomycin, should be avoided. AT patients have a decreased threshold for postradiation erythema, tissue necrosis and radiation-induced cutaneous malignancy. If radiation is necessary, restriction of the fractions to 1 Gy and total radiation to less than 20 Gy is recommended. Bone marrow and fetothymic transplants, transfer factor administration and levamisole therapy have not resulted in clinical improvement. In patients with truncating *ATM* mutations, treatment with aminoglycosides can induce read-through of premature termination codons and restore production of functional ATM protein, providing the basis for a potential therapeutic approach[13].

CHRONIC MUCOCUTANEOUS CANDIDIASIS

Key features

- Recurrent and progressive candidal infections of skin, nails and mucosae
- Variable immunodeficiency, with a particular inability to mount a response against *Candida albicans*
- May be associated with autoimmune endocrinopathies

Introduction

Chronic mucocutaneous candidiasis (CMC) represents a heterogeneous group of disorders characterized by progressive and recurrent infections of the skin, nails and mucous membranes with *Candida albicans*[14]. Affected individuals demonstrate an ineffective immune response against this organism, and patients with an earlier onset and greater severity of candidal infections typically have more severe underlying immunologic abnormalities.

Epidemiology

Many patients with CMC do not have a family history of candidal infections or immunodeficiency. However, patients with the candidiasis endocrinopathy syndrome (*a*utoimmune *p*olyendocrinopathy–*c*andidiasis–*e*ctodermal *d*ystrophy syndrome, APECED[15]) often have similarly affected relatives. Inheritance of APECED and other familial forms of CMC is usually autosomal recessive (Table 60.3).

Pathogenesis

Patients with CMC have a T-cell deficiency that prevents effective handling of candidal organisms, although T-cell deficits are not always detectable *in vitro*. In some patients, the defect is specific to *Candida* spp. in others, the immunologic response to other organisms is also abnormal.

APECED results from mutations in the *AIRE* (*a*uto*i*mmune *re*gulator) gene, which encodes a transcription factor[16]. The AIRE protein regulates the ectopic expression of self antigens in the thymus, which allows the development of peripheral tolerance via negative selection of autoreactive T cells and the generation of antigen-specific regulatory T cells[17]. In APECED patients, failure to delete autoreactive T cells leads to autoimmune disease.

Recent investigations have implicated defective maturation of dendritic cells and impaired Th17 responses in the predisposition to *Candida* infections that characterizes APECED and other forms of CMC[18,19]. "Pure" forms of CMC with autosomal dominant inheritance can be caused by either *IL17F* mutations that lead to IL-17F deficiency or gain-of-function signal transducer and activator of transcription 1 (*STAT1*) mutations that impair IL-17 immunity, and an autosomal recessive CMC variant results from *IL17RA* mutations that abolish function of the IL-17 receptor A[19a,19b]. Neutralizing autoantibodies targeting Th17-associated cytokines (e.g. IL-17A/F, IL-22) have been identified in APECED patients and individuals with thymoma-associated CMC[20]. CMC can result from defects in the genes encoding dectin-1 (a pattern-recognition receptor that binds to β-glucan in the *Candida* cell wall) and caspase recruitment domain family member-9 (CARD9) (see Table 60.3), proteins that act together to activate a Th17 response[21,22]. In other types of CMC, inadequate production of IL-23 and overproduction of IL-6, which result in an inefficient IL-17 response, have been observed.

Clinical Features

The clinical severity of CMC ranges from recurrent, treatment-resistant thrush (Fig. 60.3) or a few erythematous scaly plaques and dystrophic nails to severe, generalized, crusted granulomatous plaques. The cutaneous plaques occur most frequently on the scalp and in perioricial and intertriginous sites. Scalp infections may lead to scarring alopecia. Affected nails are thickened, brittle and discolored, with associated paronychia (Fig. 60.4). Although mucosal involvement is usually limited to oral thrush with hyperkeratotic plaques, chronic lesions on esophageal, genital and laryngeal mucosae with resultant stricture formation may occur. Systemic candidiasis is rare, but cutaneous dermatophyte infections are common. Up to 80% of patients with childhood-onset CMC develop recurrent or severe infections with organisms other than *Candida*, including bacterial septicemia.

Subgroups of CMC in children and adolescents include those described in Table 60.3. An association of CMC with abnormalities of iron metabolism or (as noted above) thymoma has also been described in adult patients.

Fig. 60.3 Chronic mucocutaneous candidiasis. Extensive, recalcitrant thrush on the tongue of a 5-year-old child with chronic mucocutaneous candidiasis.

SUBGROUPS OF CHRONIC MUCOCUTANEOUS CANDIDIASIS IN CHILDREN AND ADOLESCENTS	
Subgroup	**Features**
Familial "pure" CMC	• Autosomal dominant form due to mutations in the *STAT1* gene (which lead to impaired IL-17 immunity) or IL-17F gene (*IL17F*), and autosomal recessive form due to mutations in the IL-17 receptor A gene (*IL17RA*) • Oral candidiasis usually begins by age 2 years • Cutaneous and ungual candidiasis also common • No associated endocrinopathy
Chronic localized candidiasis ("candidal granuloma")	• Majority have cutaneous lesions by age 5 years • Thick, adherent crusts, most commonly on the face and scalp • Usually concomitant oral candidiasis • Histologically, epidermal hyperkeratosis and acanthosis; dermal infiltrates of lymphocytes, plasma cells and, sometimes, giant cells
Autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy syndrome (APECED)*	• Caused by mutations in the *AIRE* gene, usually with autosomal recessive inheritance • Increased prevalence among Finns, Iranian Jews, and Sardinians • Candidal infections usually begin by age 5 years • Candidal granulomas, especially of the face and scalp • Endocrinologic dysfunction may not be apparent until teenage or even adult years • Associated autoimmune endocrinopathies – hypoparathyroidism (90%) – hypoadrenocorticism (60%) – both of the above (30%) – hypogonadism (45%) – thyroid disease (15%) – type 1 diabetes mellitus – hypopituitarism • Cutaneous autoimmune disorders – alopecia areata (20%) – vitiligo – lupus-like panniculitis • Other autoimmune disorders – pernicious anemia (15%) – chronic active hepatitis/juvenile cirrhosis (10%) • Chronic diarrhea and malabsorption (usually associated with hypoparathyroidism; 25%), pulmonary fibrosis, keratoconjunctivitis, splenic atrophy, dental enamel hypoplasia • Antithyroglobulin, antimicrosomal, antiparietal cell and antiadrenal antibodies; rheumatoid factor • An autosomal dominant form of CMC associated with autoimmune thyroid disease may occur due to dominant-negative *AIRE* mutations and has also been linked to chromosome 2p in one family
CARD9-associated CMC	• Autosomal recessive form of CMC due to mutations in the *CARD9* gene • Chronic oral and vulvovaginal candidiasis; also dermatophytosis • Fatal candidal infections of the brain during the second decade of life in some affected individuals
Dectin-1 deficiency	• Due to biallelic polymorphisms that result in a truncated dectin-1 protein • Chronic/recurrent vulvovaginal candidiasis and onychomycosis
Late-onset CMC	• Initial infections in late childhood or early teenage years • Milder involvement than in other subgroups • Responses against *Candida albicans* may normalize after effective therapy
Familial chronic nail candidiasis	• Autosomal dominant form of CMC mapped to the pericentromeric region of chromosome 11 in a five-generation Italian family • Onset in infancy of candidiasis limited to the nails of the hands and feet • Association with low serum levels of intercellular adhesion molecule-1 (ICAM-1)
CMC associated with keratitis	• A family with CMC (oral and vaginal), alopecia and keratitis has been described – photophobia developed by age 2 years, and the remainder of the findings by age 5 years – inheritance pattern appeared to be autosomal dominant • Keratitis can be a feature of APECED • CMC can occur in patients with keratitis–ichthyosis–deafness (KID) syndrome
CMC associated with other immunodeficiency disorders	• Severe combined immunodeficiency • DiGeorge syndrome • Hyper-IgE syndrome
CMC associated with predominantly non-immunologic conditions	• KID syndrome • Multiple carboxylase deficiency • Acrodermatitis enteropathica • Ectodermal dysplasia–ectrodactyly–clefting syndrome
*The latter refers primarily to dental enamel hypoplasia; also known as autoimmune polyendocrine syndrome type 1.	

Table 60.3 Subgroups of chronic mucocutaneous candidiasis (CMC) in children and adolescents. CARD9, caspase recruitment domain family member-9; IL, interleukin; STAT1, signal transducer and activator of transcription 1.

Pathology

Candidal organisms are confined to the stratum corneum and are demonstrable in scrapings and cultures. Approximately 70% of patients have direct evidence of an immunologic defect, including decreased lymphocyte proliferation *in vitro*, impaired cytokine production and absent delayed-type hypersensitivity (DTH) in response to *Candida*, as well as nonspecific findings such as abnormal leukocyte chemotaxis or phagocytosis, depressed IgA levels, and complement dysfunction. These heterogeneous immune abnormalities reflect the variety of underlying clinical disorders. Candidal polysaccharides may act as serum factors

Fig. 60.4 Chronic mucocutaneous candidiasis. **A,B** Marked onychodystrophy with significant paronychial swelling and erythema (**A**) and crusted plaques on the palm (**B**) in patients with chronic mucocutaneous candidiasis. **C** Recurrent cutaneous candidiasis presenting as erythema, pustules and scale-crust near the site of an intravenous line on the arm in an infant with DiGeorge syndrome.

that inhibit the immune response, and, in some patients, DTH to candidal antigens has been restored after antifungal therapy[16].

Differential Diagnosis

Candidal infections, particularly thrush, are fairly common in infants. Recurrent thrush in young children with frequent otitis media may reflect alterations in bacterial flora caused by the administration of systemic antibiotics; this is seen much more often than CMC or other immunodeficiencies. Recurrent or recalcitrant candidal infections should prompt consideration of HIV infection. Clearance after traditional therapy helps to distinguish secondary candidal infections from mild CMC.

The IPEX (*i*mmune dysregulation, *p*oly-endocrinopathy, *e*nteropathy, *X*-linked) syndrome (see below) can present with autoimmune skin conditions and endocrinopathies together with recurrent infections, but the latter are typically bacterial rather than candidal. Autoimmune endocrinopathies, enteropathy, eczematous dermatitis, and a predisposition to bacterial, viral and fungal infections have also been described in patients with IL-2 receptor α-chain deficiency (see Table 60.5).

Treatment

Patients with CMC do not respond well to standard topical medications, and the cutaneous granulomas are especially difficult to treat. Most patients benefit from long-term therapy with systemic antifungal agents such as itraconazole, fluconazole and terbinafine. Attempts at immune enhancement are usually ineffective, although transfer factor administration may be beneficial to some patients with defective cell-mediated immunity. Hematopoietic stem cell transplantation, fetal thymus grafts, and leukocyte infusions have been utilized in patients with severe immunologic deficiencies. Patients should be evaluated at least annually for the development of endocrinopathies, particularly if there is a family history of CMC or APECED.

CARTILAGE–HAIR HYPOPLASIA SYNDROME

Synonym: ■ MuKusick-type metaphyseal chondrodysplasia

Key features

- Fine, sparse, hypopigmented hair
- Short-limbed dwarfism with metaphyseal dysostosis
- Doughy skin with abnormal elastic tissue
- Defective cell-mediated and (in a minority of patients) humoral immunity

Cartilage–hair hypoplasia (CHH) syndrome is a pleiotropic autosomal recessive disorder that occurs most commonly in Amish individuals and Finns. The condition results from mutations in the *RMRP* gene that encodes the RNA component of a ribonucleoprotein endoribonuclease, RNase MRP, which cleaves RNA primers responsible for DNA replication in mitochondria and processes pre-rRNA in the nucleolus[23].

Affected individuals are most likely to visit the dermatologist for their fine, sparse, hypopigmented hair, although they may also have soft, doughy skin with degenerated elastic tissue[24]. The short-limbed dwarfism results from metaphyseal dysostosis, and ligamentous laxity is often observed. Most patients have some degree of defective cell-mediated immunity, which predisposes them to severe varicella and herpes simplex viral infections. Approximately a third of patients also have abnormal humoral immunity, most frequently an IgA or IgG deficiency, which increases their susceptibility to recurrent respiratory tract infections that can lead to bronchiectasis. Severe combined immunodeficiency and an Omenn syndrome-like phenotype (e.g. erythroderma, eosinophilia, chronic diarrhea, lymphadenopathy, hepatosplenomegaly; see below) occasionally occur in affected individuals. Neutropenia and anemia can develop due to autoimmunity or bone marrow hypoplasia. Hirschsprung disease, other autoimmune disorders and impaired spermatogenesis represent additional manifestations of CHH. Patients also have an increased risk of developing non-Hodgkin lymphoma and basal cell carcinomas. Hematopoietic stem cell transplantation, which can restore function of the immune system and bone marrow, should be considered in patients with severe immunodeficiency or cytopenias.

CHÉDIAK–HIGASHI SYNDROME

Synonyms: ■ Béguez César–Steinbrinck syndrome ■ Chédiak–Higashi disease ■ Chédiak–Steinbrinck–Higashi syndrome ■ Chédiak–Steinbrinck anomaly

Key features

- Autosomal recessive disorder of vesicle trafficking that results in giant organelles, including melanosomes, leukocyte granules and platelet-dense granules
- Silvery hair, mild diffuse pigmentary dilution (often with an admixture of hyper- and hypopigmentation in sun-exposed sites), and a variable degree of photophobia and nystagmus
- Recurrent pyogenic infections and a mild bleeding diathesis
- An "accelerated phase" with pancytopenia and organomegaly due to lymphohistiocytic infiltration, which is fatal without hematopoietic stem cell transplantation
- Progressive neurologic deterioration in survivors

Epidemiology

Chédiak–Higashi syndrome (CHS) is a rare autosomal recessive disease reported most often in individuals of Northern European, Spanish, Middle Eastern and Japanese ancestry[25]. Patients of African descent have also been described[26].

Pathogenesis

CHS represents a disorder of vesicle trafficking and is caused by mutations in the *lys*osomal *t*rafficking regulator gene (*LYST*)[27]. Most patients have frameshift or nonsense mutations that result in a truncated protein and lead to a severe phenotype with progression to a fatal lymphoproliferative "accelerated phase" during childhood, but 10–15% of affected individuals have missense mutations that are associated with a milder phenotype and survival to adulthood[28].

The giant intracytoplasmic granules that characterize CHS result from dysregulated fission/fusion of lysosome-related organelles, which include melanosomes, platelet-dense granules and leukocyte cytolytic granules[25]. The latter granules cannot effectively migrate or discharge their peroxidative and proteolytic enzymes, leading to defective target cell killing. The localization of cytotoxic T lymphocyte-associated antigen (CTLA-4) to enlarged vesicles rather than the cell surface may play a role in the development of lymphoproliferative disease. In addition, abnormal antigen presentation by B cells and generalized impairment in plasma membrane repair may contribute to the pathogenesis of CHS.

Clinical Features

Patients with CHS usually present in infancy with mild diffuse pigmentary dilution of the skin, hair and eyes. In individuals with relatively dark constitutive pigmentation, areas of bronze to slate-gray hyperpigmentation may be evident in sun-exposed sites, often admixed with guttate hypopigmented macules. Hair color is variable, but a silvery, metallic sheen is characteristic. Decreased ocular pigment can result in photophobia, nystagmus and strabismus, but visual acuity is usually normal.

Infections primarily involve the skin and respiratory tract, and they are typically caused by *Staphylococcus aureus*, *Streptococcus pyogenes* and *Streptococcus pneumoniae*. The skin infections are most often superficial pyodermas. Cutaneous ulcerations resembling pyoderma gangrenosum, gingivitis and ulceration of the oral mucosa have also been described. Although the bleeding diathesis of CHS is generally mild, patients may report easy bruising, petechiae and epistaxis.

Approximately 85% of patients with CHS enter a lymphoproliferative "accelerated phase" characterized by pancytopenia and lymphohistiocytic infiltration of the liver, spleen, lymph nodes, oral mucosa and other internal organs. This "hemophagocytic syndrome" results from uncontrolled T-cell and macrophage activation, possibly associated with EBV infection, and typically leads to death by age 10 years (usually from overwhelming infection or hemorrhage) unless hematopoietic stem cell transplantation is performed.

Patients with CHS who survive the first decade of life experience progressive neurologic deterioration, with clumsiness, abnormal gait and paresthesias. Peripheral and cranial neuropathies, spinocerebellar degeneration, parkinsonism and dementia can manifest in adult patients who were treated with hematopoietic stem cell transplantation as children as well as in those with otherwise mild disease.

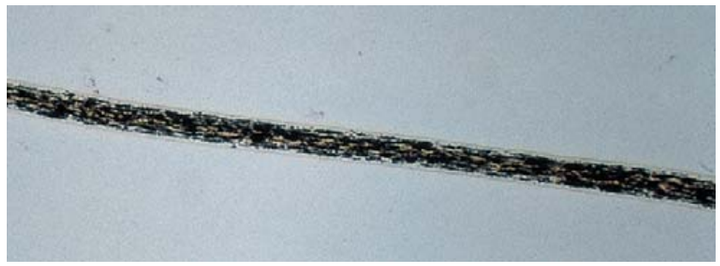

Fig. 60.5 Chédiak–Higashi syndrome. Light microscopic examination of hair shows small, regularly spaced clumps of melanin in patients with Chédiak–Higashi syndrome.

Pathology

The silvery hair of patients with CHS is characterized by clumps of melanin microscopically (Fig. 60.5), and giant melanosomes may be evident within melanocytes in skin biopsy specimens. A peripheral blood smear demonstrating abnormally large granules in the perinuclear area of granulocytes can assist in establishing the diagnosis. Immunologic defects in CHS include neutropenia, diminished leukocyte chemotaxis, impaired antibody-dependent cell-mediated cytotoxicity, reduced cytotoxic and regulatory T-cell activity, and markedly decreased natural killer (NK) cell function.

Differential Diagnosis

The features of CHS and the three types of Griscelli syndrome (GS), another autosomal recessive disorder that can present with immune dysfunction and silvery hair (but with a different pattern of pigment clumping), are compared in Table 60.4 (see also Ch. 66). Although leukocytes have a normal appearance in GS, hypogammaglobulinemia can be observed. Hermansky–Pudlak syndrome type 2 (*AP3B1* mutations) can manifest with recurrent infections due to neutropenia and abnormal cytotoxic T-cell function as well as a bleeding diathesis and diffuse pigmentary dilution, but not silvery hair. Tricho-hepato-enteric syndrome (phenotypic diarrhea of infancy), an autosomal recessive disorder caused by mutations in the tetratricopeptide repeat domain 37 gene (*TTC37*), can present with diffuse pigmentary dilution of the skin and hair, immunodeficiency and platelet abnormalities; unlike CHS, it is also characterized by brittle hair with trichorrhexis nodosa, intractable diarrhea during infancy, primary liver disease, facial dysmorphism and cardiac defects. Other inherited disorders characterized by lymphoproliferation due to immune dysregulation are presented in Table 60.5.

Treatment

Hematopoietic stem cell transplantation may reverse the immunodeficiency of CHS and prevent or (following immunochemotherapy with etoposide, corticosteroids and cyclosporine) abrogate the lymphoproliferative accelerated phase. However, it has no effect on pigmentary alteration and does not halt neurologic degeneration. Management of the CHS is otherwise largely supportive, with administration of prophylactic antibiotics to prevent recurrent infections.

COMPLEMENT DISORDERS

Key features

- Deficiency or dysfunction of early complement components increases susceptibility to pyogenic infections caused by encapsulated bacteria and autoimmune disorders, especially systemic lupus erythematosus
- Deficiency of late complement components leads to a markedly increased risk of neisserial infections

Introduction

The complement system represents an important effector of the innate immune response (see Ch. 4). An enzymatic cascade of complement

FEATURES OF CHÉDIAK–HIGASHI SYNDROME AND GRISCELLI SYNDROME					
	CHS	**GS1***		**GS2**	**GS3**
Gene defect	*LYST*	*MYO5A*		*RAB27A*	*MLPH*
Major sites of gene expression	Melanocytes, platelets, granulocytes, CNS	Melanocytes, CNS		Melanocytes, cytotoxic T cells	Melanocytes
Cellular defect	Vesicle trafficking (e.g. fission/fusion)	Vesicle movement/transfer		As in GS1	As in GS1
Pigmentary dilution of the skin†	+	+	+		+
Silvery/metallic hair	+	+	+		+

Ocular findings	+	–	–		–
Bleeding diathesis	+	–	–		–
Recurrent infections	+	–	+		–
Accelerated phase	+	–	+		–
Primary neurologic abnormalities	+	+	–‡		–

*Elejalde syndrome (neuroectodermal melanolysosomal disease), which presents with pigmentary features of GS plus severe neurologic dysfunction, likely represents a variant of GS1. Elejalde syndrome is not associated with immunodeficiency. A form of GS with manifestations limited to the skin and hair can result from deletion of the MYO5A F-exon, which is only expressed in melanocytes.
†Often accompanied by hyperpigmentation ± guttate hypopigmented macules in acral and sun-exposed sites.
‡May develop neurologic symptoms secondary to the hemophagocytic syndrome of the accelerated phase.

Table 60.4 Features of Chédiak–Higashi syndrome (CHS) and Griscelli syndrome (GS). The latter is caused by defective attachment of organelles to the actin cytoskeleton (see Ch. 64). CNS, central nervous system.

INHERITED DISORDERS CHARACTERIZED BY LYMPHOPROLIFERATION DUE TO IMMUNE DYSREGULATION				
Disorder	**Inh**	**Gene**	**Protein (function)**	**Clinical features**
Chédiak–Higashi syndrome	AR	*LYST*	See Table 60.4	See Table 60.4
Griscelli syndrome type 2	AR	*RAB27A*		
Familial hemophagocytic lymphohistiocytosis	AR	*PRF1*	Perforin (major cytolytic granule protein of CTL and NK cells)	• Hemophagocytic syndrome • Absent NK cell cytotoxicity • Fatal during early childhood unless hematopoietic stem cell transplantation is performed
	AR	*UNC13D*	Munc13–4 (primes cytolytic granules for secretion)	
	AR	*STX11*	Syntaxin 11 (involved in cytolytic granule trafficking and fusion)	
	AR	*STXBP2*	Syntaxin-binding protein 2 (regulates cytolytic granule trafficking)	
X-linked lymphoproliferative syndrome (Duncan disease)	XR	*SH2D1A*	Signaling lymphocyte activation molecule-associated protein (adaptor protein that regulates B-, T- and NK-cell function; particularly important for immune responses to EBV)	• Severe EBV-related infectious mononucleosis in childhood or adolescence (e.g. fever, pharyngitis, LAN, HSM), often associated with morbilliform eruptions, purpura and/or jaundice • ± Hypogammaglobulinemia • Fatal EBV-related B-cell lymphoma (70%) • Lymphocytic vasculitis
	XR	*XIAP*	X-linked inhibitor of apoptosis	
EBV-associated lymphoproliferative syndrome	AR	*ITK*	IL-2-inducible T-cell kinase	
Autoimmune lymphoproliferative syndrome (Canale–Smith syndrome) (see Fig. 20.6)	AD >AR	*TNFRSF6*	CD95 (Fas; cell-surface apoptosis receptor)	• Massive LAN and/or splenomegaly • Increased $CD4^-/CD8^-$ α/β T cells • Autoimmune cytopenias, LE, small vessel vasculitis • Recurrent bacterial and viral infections (*CASP8*) • Increased risk of lymphoma
	AD >AR	*TNFSF6*	CD95L (Fas ligand)	
	AD > AR	*CASP10*	Caspase 8 and 10 (proteases in intracellular apoptosis cascade)	
	AR	*CASP8*		
	AD	*NRAS*	NRAS (gain of function leads to decreased lymphocyte apoptosis)	
Immunodeficiency with lymphoid proliferation	AR	*IL2RA*	IL-2 receptor α-chain (apoptosis of developing T cells in the thymus)	• Bacterial, viral and fungal infections • Extensive lymphocytic infiltration of the liver, lung, gut and bones • Eczematous dermatitis; autoimmune polyendocrinopathy, cytopenias and enteropathy

Table 60.5 Inherited disorders characterized by lymphoproliferation due to immune dysregulation. Hemophagocytic syndromes result from uncontrolled T-cell and macrophage activation, manifesting with fever, pancytopenia, hepatosplenomegaly (HSM) and lymphadenopathy (LAN) (due to lymphohistiocytic infiltration), hypertriglyceridemia and hypofibrinogenemia. AD, autosomal dominant; AR, autosomal recessive; CTL, cytotoxic T lymphocytes; Inh, inheritance; LE, lupus erythematosus; NK, natural killer; XR, X-linked recessive.

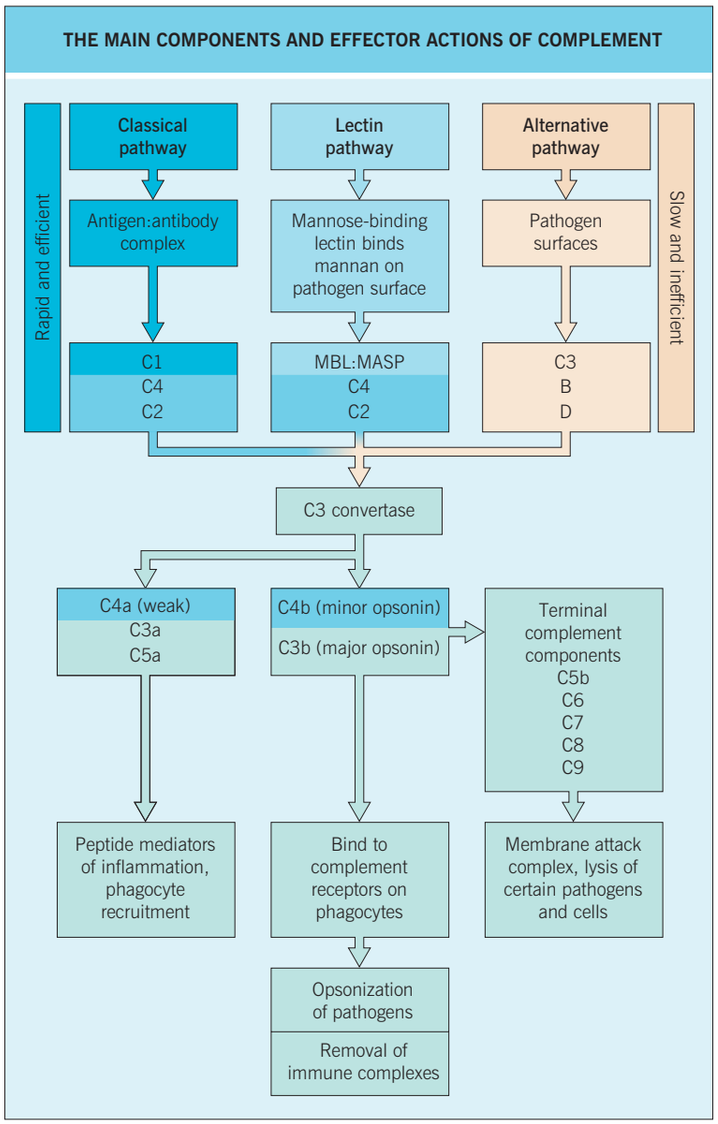

Fig. 60.6 The main components and effector actions of complement. The C3b bound to the C3 convertase binds C5, allowing the C3 convertase to generate C5b, which associates with the bacterial membrane and triggers the late events. activation can be triggered by three different pathways: classical, alternative and lectin (Fig. 60.6). In addition to their roles in killing microbial pathogens, complement proteins (Table 60.6) serve as regulators of a variety of humoral and cellular immune functions. As a result, clinical manifestations of complement deficiency include autoimmune diseases as well as increased susceptibility to infection[29].

Epidemiology

Deficiency of C2 represents the most common hereditary complement disorder[29]. Homozygous C2 deficiency occurs in approximately 1 : 20 000 individuals, and 1–2% of the population has the heterozygous form. Homozygous deficiencies of C1q, C1r, C1s and C4 are rare, but affected individuals manifest with autoimmune disease more frequently than those with homozygous C2 deficiency. Heterozygotes usually make enough protein to ensure function and are in general asymptomatic, so most of the complement disorders are inherited as autosomal recessive traits. One exception is hereditary angioedema (HAE), an autosomal dominant condition due to deficiency or dysfunction of the C1 inhibitor (see Ch. 18).

In contrast to the low prevalence of deficiencies in components of the classical complement pathway, 5–10% of the population is homozygous or compound heterozygous for alleles that lead to a lack of functional mannose-binding lectin (MBL), the major recognition factor of the lectin pathway of complement activation[30]. Although the clinical penetrance of MBL deficiency is low, it may have a substantial impact on immunity and autoimmunity at the population level. In addition, approximately 1 : 10 000 individuals has a homozygous deficiency in the MBL-associated serum protease (MASP) that functions in this pathway.

Pathogenesis

Deficiency of C2 can result from a defect in either protein synthesis (type 1) or secretion (type 2). Defects involving the early components of the classical complement pathway (C1, C4, C2) manifest with an increased risk of autoimmune disorders, especially systemic lupus erythematosus (SLE) (Table 60.7). The genes that encode these complement components, including four highly polymorphic genes for C4 (two each for C4A and C4B), are located within the HLA region on chromosome 6. C4-null alleles have been linked with SLE, and the C4A gene is deleted in the Caucasoid extended haplotype (HLA A1, B8, DR3) that is strongly associated with SLE.

The pathogenesis of SLE in the setting of complement deficiency may also be related to impaired physiologic clearance of autoantigen-containing apoptotic cells[31]. Epidermal keratinocytes undergoing UVB-induced apoptosis preferentially display autoantigens such as Ro in plasma membrane blebs. Binding of C1q to the blebs results in activation of the classical complement pathway and removal of the apoptotic cells by phagocytes; in the absence of C1q, autoantibodies have the opportunity to bind to Ro, leading to activation of B and T cells and loss of immune tolerance. Decreased MBL-mediated clearance of apoptotic debris and DNA might likewise explain the predisposition to SLE associated with MBL deficiency. Furthermore, the complement system may enhance the elimination of self-reactive B cells during lymphocyte development, with complement deficiency leading to a lack of B-cell self-tolerance. Complement components are also important for handling immune complexes and regulating production of cytokines (e.g. type I interferons) that have a key role in SLE pathogenesis.

The variety of recurrent infections associated with complement deficiencies underscores the central role of complement in bacterial clearance. Patients deficient in the early classical components, especially C2, have increased susceptibility to infections with encapsulated bacteria, especially *Str. pneumoniae*. Opsonization of bacteria and fungi may be ineffective in disorders of the classical pathway because of the slow, inadequate formation of C3b. However, because the lectin and alternative pathways can bypass early classical components to intersect with the cascade at the level of C3 (see Table 60.6 & Fig. 60.6), these deficiencies do not usually lead to overwhelming infections. C5 deficiencies result in impaired generation of chemotactic factors, which may lead to inadequate neutrophil function. Individuals with C5 to C9 (membrane attack complex), properdin and factor D deficiencies develop recurrent neisserial infections in their teenage years. This underscores the importance of the bactericidal MAC complex and the alternative complement pathway (which requires properdin and factor D) in the destruction of these organisms. However, because a lack of lytic activity limits release of bacterial products (e.g. lipopolysaccharide) that stimulate a damaging cytokine response, the mortality of meningococcal infections in patients with MAC deficiency is actually lower than that in immunocompetent individuals. In contrast, patients with a properdin or factor D deficiency are unable to eradicate *Neisseria* spp. via opsonophagocytosis and have severe disease that is often fatal.

Clinical Features

Individuals with homozygous deficiencies in the early components of the classical complement pathway (C1, C4, C2) have a risk of SLE that ranges from >90% for C1q to 10–20% for C2. Among those with C2 deficiency, features of lupus erythematosus (especially photosensitivity and subacute cutaneous lupus erythematosus) are most common in women, with the age at onset ranging from early childhood to adulthood (median 30 years). Other manifestations of C2 deficiency-associated SLE are presented in Table 60.8. SLE in the setting of C1q/r/s or C4 deficiency usually develops during childhood, affects boys and girls equally, and is often associated with renal disease and palmoplantar keratoses as well as photosensitivity. Other autoimmune and/or inflammatory disorders and susceptibilities to infection associated

COMPLEMENT SPLIT PRODUCTS AND COMPLEXES			
Split product	**Function**	**Complex**	**Function**
C1q	Recognition factor of CP (binds Ag-Ab complexes) Activates C1r	C1inh-C1r-C1s	Formed during C1 activation
C1r	Cleaves C1s to an active protease		
C1s	Cleaves C4 and C2		
C4a	Anaphylatoxin (weak)	C4b2a	CP C3 convertase
C4b	Part of the CP C3 and C5 convertases Opsonization		
C2a	Part of the CP C3 and C5 convertases		
C2b	Unknown		
C3(H_2O)	Recognition factor of AP (binds bacterial surfaces, including lipopolysaccharide)	C3bBb	AP C3 convertase
C3a	Anaphylatoxin Chemotaxis (eosinophils) Direct antimicrobial effect	C4b2a3b	CP C5 convertase
C3b	Part of CP C5 and AP C3/C5 convertases Opsonization	$C3b_{(n)}Bb$	AP C5 convertase
C5a	Anaphylatoxin (strong) Chemotaxis (neutrophils and monocytes) Regulation of apoptosis		
C5b	Part of membrane attack complex	$C5b\text{-}9_n$ SC5b-9	Membrane attack complex Soluble terminal complement complex

Table 60.6 Complement split products and complexes. Dark blue, classical pathway (CP); medium blue, CP and lectin pathway; yellow, alternative pathway (AP); green, all three pathways. Anaphylatoxins are inflammatory mediators that increase vascular permeability and cause mast cell degranulation. Opsonization represents binding of a protein to the pathogen surface in order to target it for destruction. C1 inh, C1 esterase inhibitor; SC, soluble complex.

with complement deficiencies are listed in Table 60.7. C2 deficiency may coexist with common variable immunodeficiency, and the development of Hodgkin disease has occasionally been reported.

MBL deficiency may confer an increased risk of acute respiratory infections in children aged 6–18 months, who no longer have maternal antibodies but are not yet able to mount an efficient antibody response to the carbohydrate antigens of encapsulated bacteria[30]. Several studies have shown that MBL deficiency is associated with an increased risk of developing SLE or dermatomyositis and a higher incidence of infections in the setting of immunosuppressive therapy.

Pathology

The total hemolytic complement (CH50) is markedly decreased or undetectable in complement deficiencies other than hereditary angioedema. The alternative pathway lytic test (AP50) can be used to screen for deficiencies in components of this pathway, although it is less sensitive than the CH50. Immunoprecipitation assays (e.g. radial immunodiffusion or ELISA) can determine the levels of specific complement components and MBL[32], and functional studies of individual components may be informative when antigen levels are normal.

Differential Diagnosis

Complement components may be specific targets of autoimmune responses; for example, anti-C1q antibodies are found in 30–50% of patients with SLE (often with renal involvement) and virtually all of those with hypocomplementemic urticarial vasculitis. The "*Leiner phenotype*" of exfoliative dermatitis, failure to thrive, chronic diarrhea and recurrent infections has been observed in infants with C3 or C5 deficiency or C5 dysfunction. However, this constellation of findings can also develop in patients with other disorders such as X-linked agammaglobulinemia, hyper-IgE syndrome and severe combined immunodeficiency. Low complement levels related to bacterial and viral infections should also be differentiated from primary complement deficiencies.

Treatment

Conservative therapy is often effective for patients with autoimmune manifestations of complement deficiency. The use of topical corticosteroids and sun protection may be sufficient to treat cutaneous lupus erythematosus in these individuals. Antimalarial drugs, systemic corticosteroids, and other immunosuppressive medications are typically required in more severe cases, with consideration of the increased risk of infections in patients with complement deficiencies. The use of plasma transfusions to replace the deficient components may actually activate the cascade and accelerate immune complex deposition. Infections should be treated with early, aggressive antibiotic therapy.

CHRONIC GRANULOMATOUS DISEASE

Synonyms: ■ Chronic granulomatous disorder ■ Bridges–Good syndrome ■ Quie syndrome

Key features

- Inability to kill intracellular organisms through generation of oxidative metabolites
- X-linked recessive or autosomal recessive inheritance
- Recurrent pneumonias and cutaneous infections, lymphadenopathy and hepatosplenomegaly
- Patients develop granulomas as a compensatory effort to confine organisms

Introduction

Chronic granulomatous disease (CGD) is a group of disorders characterized by severe, recurrent infections due to an inability of leukocytes to kill phagocytosed bacteria and fungi by generating oxidative metabolites. The activity of the nicotinamide dinucleotide phosphate (NADPH) oxidase complex is reduced in all forms of CGD.

Epidemiology

The incidence of CGD is approximately 1:200 000 live births[33,34]. Ninety percent of patients are boys. Approximately three-quarters of

COMPLEMENT DISORDERS		
Complement component	**Common infectious agents**	**Autoimmune/inflammatory disorders**
CLASSICAL PATHWAY		
C1q	Encapsulated bacteria, *Candida* spp.	SLE*, GN
C1r	Encapsulated bacteria	SLE*, GN
C1s	Encapsulated bacteria	SLE*
C1 inhibitor		Hereditary angioedema, SLE, GN, partial lipodystrophy, vasculitis
C4	Encapsulated bacteria	SLE* with PPK and scars, HSP, GN, urticaria, JIA‡
C2†	Encapsulated bacteria, especially *Streptococcus pneumoniae*	SLE*, SCLE, DLE, dermatomyositis, HSP, other vasculitides, atrophoderma, cold urticaria, JIA‡, IBD, atherosclerosis
LECTIN PATHWAY		
MBL§	Encapsulated bacteria, especially *N. meningitides*	SLE, dermatomyositis, atherosclerosis, chronic pulmonary disease
MASP-2	Encapsulated bacteria, especially *S. pneumoniae*	SLE, IBD
C3 AND ALTERNATIVE PATHWAY		
C3	Encapsulated bacteria (severe infections)	SLE, vasculitis, lipodystrophy (partial [cephalo]thoracic), GN, "Leiner phenotype"
Factor H	Encapsulated bacteria	SLE, HUS, GN, age-related macular degeneration
Factor I (C3b inactivator)	Encapsulated bacteria	SLE, HUS, aquagenic urticaria, angioedema
Properdin¶	*Neisseria* spp. (fulminant infections)	
Factor D	*Neisseria* spp.	
MEMBRANE ATTACK COMPLEX		
C5 dysfunction	Gram-negative bacteria	"Leiner phenotype"
C5 deficiency	*Neisseria* spp. *S. pneumoniae*	SLE
C6	*Neisseria, Brucella, Toxoplasma* spp.	SLE, JIA, GN
C7	*Neisseria* spp.	SLE, CREST syndrome, ankylosing spondylitis
C8α	*Neisseria* spp.	SLE, fever with HSM, eosinophilia, hypergammaglobulinemia
C8β	*Neisseria* spp.	SLE, JIA
C9	*Neisseria* spp.	

*Hierarchy of SLE risk with homozygous mutations: C1q (~90%) > C1r/s > C4 > C2 (~10–20%).
†Most common of the homozygous complement deficiencies.
‡Especially in heterozygous girls.
§Very low penetrance.
¶X-linked recessive.

Table 60.7 Complement disorders. Unless otherwise specified, affected individuals usually have biallelic defects. Pyogenic infections caused by encapsulated organisms (e.g. *Streptococcus pneumoniae, Haemophilus influenzae* and *Streptococcus pyogenes*) in individuals with classical pathway component deficiencies are not as frequent as neisserial infections in those with membrane attack complex component deficiencies. CREST: *c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, *t*elangiectasias; DLE, discoid lupus erythematosus; GN, glomerulonephritis; HSM, hepatosplenomegaly; HSP, Henoch–Schönlein purpura; HUS, hemolytic uremic syndrome; IBD, inflammatory bowel disease; INH, inhibitor; JIA, juvenile idiopathic arthritis; MBL, mannose-binding lectin; MASP, MBL-associated serum protease; PPK, palmoplantar keratoderma; SCLE, subacute cutaneous lupus erythematosus; SLE, systemic lupus erythematosus. *Adapted with permission from Schachner L, Hansen R, eds. Pediatric Dermatology, 4th edn. London: Mosby, 2011.*

FEATURES OF SYSTEMIC LUPUS ERYTHEMATOSUS IN C2 DEFICIENCY	
Common features	**Features more suggestive of C2 deficiency-associated SLE than classic SLE**
Photosensitivity*	Childhood onset
SCLE*, ACLE, or DLE	Extensive, treatment-resistant skin lesions
Cicatricial alopecia	Mild or absent renal disease
Oral ulcerations (50%)	Absent or low-titer ANA and anti-dsDNA
Fever (>50%)	Antibodies
Arthralgias and/or arthritis (80%)	Negative lupus band test
Leukopenia (50%)	Less severe disease overall
Anti-Ro antibody (75%)	Pyogenic infections with encapsulated
Rheumatoid factor (40%)	bacteria, e.g. *Streptococcus pneumoniae*
	Increased risk of atherosclerosis

*Most common cutaneous manifestations.

Table 60.8 Features of systemic lupus erythematosus (SLE) in C2 deficiency. Less frequent manifestations include central nervous system vasculitis, pleuritis, pericarditis, Raynaud's phenomenon, thrombocytopenia, anti-Sm or anti-RNP antibodies, circulating immune complexes and a positive RPR. ACLE, acute cutaneous lupus erythematosus; DLE, discoid lupus erythematosus; SCLE, subacute cutaneous lupus erythematosus. *Adapted with permission from Schachner L, Hansen R, eds. Pediatric Dermatology, 4th edn. London: Mosby, 2011.*

cases have X-linked recessive transmission, while the remainder are autosomal recessive.

Pathogenesis

The defects in CGD involve five subunits of the phagocyte NADPH oxidase: the membrane-bound gp91^{phox} (phagocyte oxidase) and p22^{phox}; and the cytoplasmic p47^{phox}, p67^{phox} and p40^{phox} (Table 60.9). The failure of microbial killing that characterizes CGD results from an inability of the NADPH oxidase system to rapidly generate toxic reactive oxygen species (ROS) by transferring electrons from NADPH to molecular O_2 (the "respiratory burst") after phagocytosis of a pathogen. Regardless of the gene affected in patients with CGD, having residual NADPH oxidase activity and the resultant ability to generate ROS is associated with less severe disease and longer survival[35].

NADPH oxidase activity results in the activation of antimicrobial proteases within the phagosome and the formation of microbicidal "neutrophil extracellular traps" (NETs)[36,37]. In addition to killing and degrading microorganisms, ROS produced by the NADPH oxidase system have roles in the induction of neutrophil apoptosis (which prevents tissue damage at sites of inflammation) and regulation of cytokine synthesis. Animal models of CGD have shown that a lack of ROS leads to excess inflammation via decreased regulatory T-cell activity,

GENETIC DEFECTS AFFECTING COMPONENTS OF THE PHAGOCYTE NADPH OXIDASE					
Disorder	**Gene**	**Protein**	**Location within NADPH oxidase**		**% of CGD patients**
			Resting state	**Active state**	
X-linked recessive chronic granulomatous disease	*CYBB*	gp91^{phox}	Membrane-bound subunits of flavocytochrome b_{558}	Same	70
Autosomal recessive chronic granulomatous disease	*CYBA*	p22^{phox}			≤5
	NCF1	p47^{phox}	Cytosolic complex	Associated with flavocytochrome b_{558}	20
	NCF2	p67^{phox}			≤5
	NCF4	p40^{phox}			Rare
Neutrophil immunodeficiency syndrome	*RAC2*	Rac2 GTPase*	Cytosolic complex with RhoGDI	Membrane- and GTP-bound	–

*Also has a role in actin cytoskeletal dynamics, integrin-dependent adhesion and neutrophil migration; see Table 60.12.

ORGANISMS THAT CAUSE INFECTIONS IN PATIENTS WITH CHRONIC GRANULOMATOUS DISEASE		
Type of organism	**Common causes**	**Less frequent causes**
Gram-positive bacteria	*Staphylococcus aureus**	*Propionibacterium* spp.
	Nocardia spp.	
Gram-negative bacteria	*Burkholderia cepacia*	*Acinetobacter* spp.
	Klebsiella spp.	Other *Burkholderia* spp.
	Serratia marcescens†	*Chromobacterium violaceum*
		Enterobacter spp.
		Escherichia coli
		Granulobacter bethesdensis
		Proteus spp.
		Pseudomonas spp.
		Salmonella spp.
Mycobacteria		*Mycobacterium tuberculosis*
		Atypical mycobacteria
Fungi	*Candida* spp.	*Paecilomyces* spp.
	Aspergillus spp.‡	*Penicillium* spp.
		Phaeohyphomycetes
		Trichosporon spp.

*Most common cause of cutaneous infections, abscesses and suppurative adenitis.
†Most common cause of osteomyelitis; also a frequent cause of cutaneous abscesses and ulcers.
‡Most common cause of pneumonia.

Table 60.10 Organisms that cause infections in patients with chronic granulomatous disease.

Fig. 60.7 Lupus erythematosus-like skin lesions in chronic granulomatous disease due to p47^{phox} deficiency. A biopsy specimen from an annular plaque showed findings typical of cutaneous lupus erythematosus. *Courtesy, Edward Cowen, MD.*

unrestrained γ/δ T-cell activity and augmented production of cytokines such as IL-8 and IL-17. Increased inflammasome activity leading to IL-1β production has also been identified in cells from CGD patients.

Clinical Features

The skin, perianal area, lymph nodes and lungs are the sites most often affected by CGD. In general, the X-linked form tends to be more severe than the autosomal recessive forms, with a younger mean age at diagnosis (3 years versus 8 years)[33]. Organisms that commonly cause infections in patients with CGD are listed in Table 60.10. Most carriers of CGD do not have an increased susceptibility to infections.

The earliest manifestations of CGD are usually staphylococcal infections of the skin around the ears and nose, which may begin in the neonatal period and progress to extensive purulent dermatitis with regional lymphadenopathy during infancy. Cutaneous abscesses occur in 40% of patients, usually due to *S. aureus* but also caused by *Serratia marcescens* infection, which can also present with large, poorly healing cutaneous ulcers[38]. Purulent inflammatory reactions may develop at sites of minor cutaneous trauma or regional lymph node drainage and heal slowly with scarring. Cutaneous granulomas, which are often nodular and necrotic, occur less frequently than infections. Seborrheic dermatitis, scalp folliculitis, acute or chronic cutaneous lupus erythematosus-like skin lesions (Fig. 60.7; especially discoid lesions), Sweet's syndrome, and ulcers involving the oral mucosa (resembling aphthous stomatitis), the perioral area and other cutaneous sites have also been described in patients with CGD. Female carriers of X-linked CGD occasionally present with discoid lesions, Jessner's lymphocytic infiltrate, photosensitivity, Raynaud's phenomenon, severe aphthous stomatitis and granulomatous cheilitis.

The extracutaneous organs most frequently involved in CGD are the lymph nodes, lungs, liver, spleen and gastrointestinal tract (Table 60.11). Suppurative lymphadenitis develops in half of patients, most often affecting cervical nodes and leading to abscess and fistula formation. Granulomas of the lungs, liver, spleen, and gastrointestinal and genitourinary tracts occur more frequently than those of the skin. These granulomas can lead to obstruction of the gastric outlet or urinary tract. Excessive inflammatory responses may also lead to wound dehiscence, pneumonitis, and clinical presentations that mimic inflammatory bowel disease, sarcoidosis, rheumatoid arthritis and IgA nephropathy[34,39].

Pathology

Common nonspecific abnormalities in CGD include leukocytosis, anemia, elevated ESR, hypergammaglobulinemia, a decreased number of T cells, and an abnormal chest radiograph. Skin testing for delayed-type hypersensitivity is normal, as are studies of phagocytosis and chemotaxis.

FREQUENCY OF SIGNS AND SYMPTOMS IN PATIENTS WITH CHRONIC GRANULOMATOUS DISEASE	
Symptom	**Percentage of patients**
Lymphadenopathy	90
Hepatosplenomegaly	85
Pneumonia	80
Underweight	75
Short stature	50
Persistent diarrhea and/or abdominal pain	40
Hepatic/perihepatic abscess	35
Pleuritis/empyema	35
Septicemia or meningitis	35
Osteomyelitis	25
Conjunctivitis and/or chorioretinitis	25
Facial periorificial dermatitis	20
Perianal abscess	15
Lung abscess	15
Ulcerative stomatitis	15
Peritonitis	10
Onset by age 1 year	65
Onset with lymphadenitis	25

Table 60.11 Frequency of signs and symptoms in patients with chronic granulomatous disease.

Biopsy specimens from cutaneous granulomas that develop in CGD patients demonstrate histiocytic infiltrates associated with foreign body giant cells and accumulation of neutrophils with necrosis. Lupus erythematosus-like skin lesions in CGD patients and carriers may have histologic features similar to classic discoid lesions, but they sometimes lack vacuolar degeneration of basal keratinocytes; immunofluorescence examination of lesional skin is negative in the majority of cases.

The screening test for CGD is the nitroblue tetrazolium (NBT) reduction assay. NBT is yellow in its soluble, oxidized form; when reduced, the dye precipitates and becomes blue (formazan precipitate). Only 5–10% of leukocytes from patients with CGD are able to reduce NBT during phagocytosis, compared to 80–90% of leukocytes from unaffected individuals and approximately 50% of leukocytes from carriers of X-linked CGD. The ferricytochrome c reduction and dihydrorhodamine 123 assays are more accurate and quantitative in measuring the respiratory burst, and they can be performed to verify the diagnosis of CGD[40]. Immunoblot analysis may demonstrate lack of the $gp91^{phox}$ and $p22^{phox}$ proteins; however, gene sequencing must still be done to ascertain which gene is affected, since mutations resulting in the absence of one protein lead to the absence of the other. A lack of the $p47^{phox}$, $p67^{phox}$, or $p40^{phox}$ protein by immunoblot analysis indicates the affected gene.

Differential Diagnosis

Laboratory tests allow differentiation of CGD from other immunodeficiency disorders characterized by increased susceptibility to bacterial infections. Additional inherited phagocyte disorders are listed in Table 60.12.

Treatment

The use of antibiotics has markedly reduced the morbidity and mortality rates of CGD. Although cutaneous and nodal infections are often readily apparent, localized foci of internal infection, (which may or may not be associated with fever) can be difficult to detect. Thorough periodic evaluation of the lungs, liver and bones by routine radiographs, ultrasounds or CT, MRI, positron emission tomography (PET) and bone scans often uncovers occult foci of inflammation or infection. Cultures should be performed to identify the infectious agent, and invasive procedures may be necessary to obtain adequate tissue samples. While awaiting culture results or in situations where material from the affected site cannot be obtained, patients with evidence of infection should be treated empirically with broad-spectrum parenteral antibiotics that cover *S. aureus* as well as Gram-negative bacteria. Intravenous therapy should be continued for at least 10–14 days, followed by a several-week course of oral antibiotics. Surgical interventions such as debridement, irrigation and prolonged drainage are important for deeper infections.

Chronic prophylaxis with trimethoprim–sulfamethoxazole has been shown to decrease the incidence of bacterial infection in CGD patients without increasing the incidence of fungal infections. The rate of *Aspergillus* spp. infections has been reduced by prophylaxis with itraconazole[41]. Patients with CGD have shown clinical improvement after administration of interferon-γ, which likely augments oxidant-independent antimicrobial pathways. Leukocyte transfusions have been used for rapidly progressive, life-threatening infections. Short courses of systemic corticosteroids have also been helpful for patients with obstructive granulomas of the bronchopulmonary, gastrointestinal or genitourinary tract[31].

Hematopoietic stem cell transplantation represents a potentially curative treatment for CGD, and its use for this condition has increased in recent years. Although younger patients without infection at the time of transplantation have the best outcomes (survival >90–95%), use of reduced-intensity conditioning regimens has enabled high-risk adults with recalcitrant fungal infections to be successfully transplanted. In children with a history of recurrent severe infections or corticosteroid-dependent inflammatory disease, especially those who have an HLA-identical family member, transplantation should be considered before irreversible organ damage occurs.

Gene therapy was initially performed in five adults with the $p47^{phox}$-deficient form of CGD, and a single infusion of transduced $CD34^+$ peripheral blood stem cells led to peak levels of corrected granulocytes in 3–6 weeks with persistence for as long as 6 months[42]. More recently, two young men with X-linked recessive CGD were treated with non-myeloablative conditioning prior to the infusion of $CD34^+$ peripheral blood stem cells transduced *ex vivo* with a retroviral vector expressing $gp91^{phox}$; this led to sustained engraftment of functionally corrected phagocytes. However, following initial resolution of infections, the transgene was silenced due to methylation of the viral promoter in both patients, and within 3 years they developed myelodysplasia with monosomy 7 as a result of insertional activation of ecotropic viral integration site 1 (*EVI1*)[43].

Dihydrorhodamine 123 flow cytometric studies may be utilized in determining the carrier status of the sisters and other female relatives of patients with X-linked CGD, which is important for genetic counseling prior to pregnancy. Prenatal diagnosis of CGD is also possible.

HYPERIMMUNOGLOBULIN E SYNDROMES

Synonyms: ■ Hyper-IgE syndromes ■ Job syndrome ■ Buckley syndrome

Key features

- Classic form is an autosomal dominant disorder characterized by extremely high immunoglobulin E levels
- Recurrent infections of the skin (particularly "cold abscesses") and sinopulmonary tract with S. *aureus* and, especially during infancy, *C. albicans*
- A neonatal papulopustular eruption is followed by severe atopic-like dermatitis
- Coarse facial features, osteopenia with fractures, scoliosis and dental abnormalities
- An autosomal recessive form with a broader spectrum of infectious complications also exists

Introduction

Hyperimmunoglobulin E syndrome (HIES) is characterized by recurrent cutaneous and sinopulmonary infections, dermatitis beginning in

OTHER INHERITED PHAGOCYTE DEFECTS				
Disorder	**Inh**	**Gene**	**Protein (defect or function)**	**Clinical features**
DISORDERS FEATURING NEUTROPENIA OR NEUTROPHIL DEFECTS				
Severe congenital neutropenia	AD	*ELA2*	Neutrophil elastase (abnormal elastase trafficking and accumulation)	• Neutropenia • MDS, AML
	AD	*GFI1*	Transcriptional repressor of elastase (abnormal elastase accumulation)	• Neutropenia, lymphopenia • Circulating myeloid progenitors
	AR	*HAX1*	Mitochondrial HS1-associated protein X1 (protects against apoptosis in myeloid cells)	• Neutropenia • Increased apoptosis of myeloid cells
	AD	*CSF3R*	Granulocyte colony-stimulating factor receptor	• Neutropenia • Severe myeloid hypoplasia
	AR	*G6PC3*	Glucose 6 phosphatase catalytic subunit 3 (glucose metabolism)	• Neutropenia, thrombocytopenia • Urogenital and cardiac malformations • Ectatic veins on trunk/extremities
Cyclic neutropenia	AD	*ELA2*	Neutrophil elastase	• Alternating 21-day cycles of neutropenia & monocytopenia • Fever and oral ulcers at nadir
X-linked neutropenia	XR	*WASP*	WASP (gain of function; see text, Wiskott–Aldrich syndrome)	• Neutropenia
p14 deficiency	AR	*MAPBPIP*	MAP binding partner 1-interacting protein (p14; endosomal biogenesis)	• Neutropenia • Pneumococcal infections • Diffuse pigmentary dilution of the skin and hair • Short stature, coarse facies
Shwachmann–Bodian–Diamond syndrome	AR	*SBDS*	SBDS protein (ribosomal RNA metabolism)	• Neutropenia > pancytopenia • MDS, AML • Exocrine pancreatic insufficiency • Chondrodysplasia
Specific granule deficiency	AR	*CEBPE*	C/EBPε transcription factor (granulocyte differentiation)	• Bilobed neutrophils • Recurrent bacterial infections
Myeloperoxidase deficiency	AR	*MPO*	Myeloperoxidase (microbial killing by granulocytes)	• *Candida* spp. and *S. aureus* infections • Often asymptomatic
LEUKOCYTE ADHESION DEFICIENCIES (LADS) AND RELATED CONDITIONS				
LAD-I	AR	*ITGB2*	β_2-integrin subunit of LFA-1, CR3, and p150 (see text)	• Neutrophilia; ↓ tissue neutrophils • Necrotic abscesses, ulcers • Poor wound healing, delayed umbilical stump separation • Gingivitis • Bleeding diathesis (LAD-III)
LAD-II	AR	*SLC35C1 (FUCT1)*	GDP-fucose transporter 1 (sialyl-Lewis X expression; see text)	
LAD-III	AR	*FERMT3*	Kindlin-3 (defective integrin activation; see text)	
Rac2 deficiency	AD	*RAC2*	Rac2 GTPase (NADPH oxidase, integrin-dependent adhesion, and neutrophil migration; see Table 60.9)	
DEFECTS RESULTING IN PREDISPOSITION TO SPECIFIC INFECTIONS				
Defects of the interleukin-12/interferon-γ axis	AR	*IL12B*	Subunit of IL-12 and IL-23 (stimulation of IFN-γ production)	• Severe mycobacterial and *Salmonella* infections • Disseminated BCG infection** • Viral infections (*STAT1, TYK2*) • Hyper-IgE syndrome (*TYK2*; see text)
	AR	*IL12RB1*	IL-12 and IL-23 receptor β1 chain	
	AR, AD	*IFNGR1*	IFN-γ receptor (ligand binding)	
	AR	*IFNGR2*	IFN-γ receptor (signaling)	
	AR, AD	*STAT1**	Signal transducer and activator of transcription 1 (STAT1)* (IFN receptor signaling is impaired by loss-of-function mutations)	
	AR	*TYK2*	Tyrosine kinase 2 (IFN/IL-12/other cytokine receptor signaling)	
Defects in Toll-like receptor (TLR) signaling	AD	*TLR3*	TLR3 (signals IFN-α/β production)	• Herpes simplex encephalitis
	AR	*UNC93B1*	UNC-93B (endoplasmic reticulum protein required for TLR3 signaling)	
	AR	*IRAK4*	IL-1 receptor associated kinase-4 (IL-1 receptor & TLR signaling)	• Recurrent pyogenic sinopulmonary and skin infections with *Streptococcus pneumoniae* and *S. aureus*, respectively
	AR	*MYD88*	Myeloid differentiation primary response gene 88 (recruits IRAK4 to the IL-1 receptor and TLRs)	

*Gain-of-function STAT1 mutations impair IL-17 immunity and lead to chronic mucocutaneous candidiasis; defects in STAT3 underlie AD hyper-IgE syndrome (see text), and defects in STAT5B (involved in IL-2 and growth hormone receptor signaling) lead to an AR syndrome of growth hormone insensitivity, decreased $CD4^+/CD25^+$ regulatory T cells, viral infections and eczematous dermatitis.

**Disseminated BCG infections have also been associated with mutations in the interferon regulatory factor 8 gene (*IRF8*; AD or AR inheritance), which impair the development of monocytes and dendritic cells. In addition, a deficiency in B and natural killer cells as well as monocytes and dendritic cells caused by heterozygous mutations in the *GATA2* gene (which encodes a transcription factor expressed in hematopoietic cells) is associated with susceptibility to mycobacterial infections and predisposition to leukemia/myelodysplasia.

Table 60.12 Other inherited phagocyte defects. See text and Tables 60.4 and 60.9 for Chédiak–Higashi syndrome and chronic granulomatous disease. AD, autosomal dominant; AML, acute myeloid leukemia; AR, autosomal recessive; BCG, bacillus Calmette-Guérin; IFN, interferon; IL, interleukin; Inh, inheritance; MAP, mitogen-activated protein kinase kinase 1; MDS, myelodysplastic syndrome; LFA-1, lymphocyte function-associated antigen-1; WASP, Wiskott–Aldrich syndrome protein; XR, X-linked recessive.

infancy or early childhood, and extremely elevated IgE levels[44]. Job syndrome is a subgroup of HIES that was originally described in female patients with fair skin, red hair and hyperextensible joints as well as the typical features of HIES.

Epidemiology

The classic form of HIES is inherited in an autosomal dominant fashion with variable expressivity. Many patients show a partial phenotype. Clinically distinct autosomal recessive forms of HIES (AR-HIES) have also been described[45–47].

Pathogenesis

Heterozygous mutations in the gene encoding *s*ignal *t*ransducer and *a*ctivator of *t*ranscription 3 (STAT3) cause autosomal dominant HIES[48,49]. Cytokine signals are transduced by different combinations of receptor-associated Janus kinases (JAKs) and STAT proteins; upon phosphorylation by JAKs, the latter dimerize, translocate to the nucleus and activate target genes. Susceptibility to bacterial and candidal infections in HIES reflects the roles of STAT3-dependent cytokines (e.g. IL-6, IL-21, IL-23) in the differentiation of IL-17-producing $CD4^+$ T cells (which help to defend against these organisms)[50]. A lack of stimulation of β-defensin production by IL-22 (which is produced by Th17 cells and signals via STAT3) may contribute to the development of infections at epithelial surfaces (e.g. skin, lungs) in HIES.

Because STAT3 is critical to the signaling pathways for IL-6 (which promotes acute phase responses and acts as a pyrogen) and IL-10 (an anti-inflammatory cytokine), STAT3 dysfunction can explain the "cold" abscesses and destructive inflammation (e.g. in the lung) that characterize HIES. Defective generation of IL-10-induced tolerogenic dendritic cells and $FOXP3^+$-induced regulatory T cells may contribute to other inflammatory features of HIES, such as the atopic-like dermatitis and high IgE levels[51]. STAT3 also down-regulates differentiation of osteoclasts, and osteoporosis represents a feature of STAT3 deficiency in mice as well as HIES. Lastly, leukocytes from both STAT3-deficient animals and patients with HIES produce higher levels of interferon-γ and tumor necrosis factor (TNF)-α upon stimulation with IL-12 and lipopolysaccharide/interferon-γ, respectively, than do leukocytes from unaffected controls[48,49].

Homozygous mutations in the gene encoding tyrosine kinase 2 (TYK2), a member of the JAK family, were identified in a patient with a form of AR-HIES characterized by defects in signaling pathways for IL-12 and interferon-α/β (see Table 60.12) as well as IL-6 and IL-10[52]. This patient presented with elevated serum IgE levels, eczematous dermatitis and recurrent bacterial (including *Salmonella*), mycobacterial, fungal and viral infections. Biallelic mutations in the dedicator of cytokinesis 8 protein (*DOCK8*) gene cause another type of AR-HIES (see below)[46,47]. The DOCK8 protein, a member of the DOCK180-related family of atypical guanine nucleotide exchange factors, is thought to regulate cytoskeletal rearrangements that have important roles in immune functions such T-cell expansion and antibody responses.

The dermatitis of HIES shares several immunopathologic features with atopic dermatitis, including reactivity against *S. aureus*, abnormal cytokine responses and increased levels of IgE. The expression of IgE in patients with HIES is maximally activated and does not increase further upon IL-4 administration; in contrast, IL-4 has a stimulatory effect on IgE production in both atopic dermatitis patients and normal individuals.

Clinical Features

Patients with classic HIES typically present during the first month of life with a non-infectious, folliculocentric papulopustular eruption involving the face, scalp, neck, axillae and diaper area[53,54]. Chronic candidiasis of the oral mucosa, periungual areas and nails occurs in approximately 80% of HIES patients and may represent the initial infectious manifestation during infancy.

Cutaneous staphylococcal infections include impetiginized plaques and retroauricular fissures, folliculitis, furunculosis, abscesses, cellulitis, lymphangitis, and paronychia leading to nail dystrophy[54]. The cutaneous abscesses are often large, and they most commonly involve the neck, scalp (Fig. 60.8), periorbital area, axillae and groin. Such lesions are referred to as "cold abscesses" because they are not as red or tender as those that develop in healthy individuals. Patients are often afebrile or have only a low-grade fever. Although the abscesses tend to be staphylococcal, many patients have recurrent skin infections with other organisms, including *Str. pyogenes* as well as *C. albicans.*

Fig. 60.8 Hyperimmunoglobulin E syndrome. Several erythematous, slightly purulent "cold" abscesses are apparent on the forehead and scalp of this infant.

The eczematous rash of HIES shares many clinical features with atopic dermatitis, including severe pruritus, lichenification and staphylococcal superinfection[54]. It is virtually always present in young children with classic HIES but frequently clears by adolescence. Unlike individuals with atopic dermatitis, patients with HIES do not commonly exhibit allergic rhinitis, asthma or other cutaneous signs of atopy.

Although some HIES patients have only cutaneous manifestations, most also develop recurrent bronchitis and pneumonias. Pulmonary infections are usually caused by *S. aureus* and *Haemophilus influenzae*, and they may result in empyema, bronchiectasis and pneumatocele formation. The pneumatoceles tend to persist and become the site of further infections with bacterial or fungal organisms, particularly *Aspergillus* spp. Massive hemoptysis occasionally ensues. *Pneumocystis jiroveci* pneumonia can also occur in infants and children with HIES. Other common sites of infection include the ears, oral mucosa, sinuses and eyes. Visceral infections other than pneumonia are unusual.

Due to both bony defects and the deforming effects of chronic facial abscesses, HIES patients develop progressive facial coarsening with thickened doughy skin, large follicular ostia, pitted scarring, a broad nasal bridge, a wide fleshy nasal tip, deep-set eyes, a prominent forehead, and irregularly proportioned cheeks and jaw. Osteopenia is frequently present and is associated with an increased risk of fractures of the long bones, ribs and pelvis. More than half of adolescents and adults with HIES have had at least three fractures, often due to unrecognized or minor trauma. Scoliosis occurs in 75% of patients 16 years of age or older, and hyperextensibility of joints has been reported in 70% of patients. Approximately half of individuals with HIES have a high-arched palate, and dental abnormalities associated with HIES include retention of primary teeth (due to failure of root resorption) and lack of eruption of secondary teeth. Additional manifestations include brain abnormalities (e.g. Chiari malformations, lacunar infarctions, focal hyperintensities in white matter on T2-weighted MRI sequences) and the development of coronary artery aneurysms in adulthood. HIES is associated with an increased risk of non-Hodgkin lymphoma of B-cell origin

AR-HIES due to *DOCK8* mutations shares some features with classic HIES, including highly elevated serum IgE levels, peripheral eosinophilia, chronic eczematous dermatitis (Fig. 60.9A), and recurrent staphylococcal and candidal infections of the skin (including cold abscesses) and respiratory tract[45–47]. However, these AR-HIES patients do not present with skeletal and dental abnormalities or pneumatoceles, but instead develop severe viral (e.g. warts, herpes simplex, varicella–zoster and molluscum contagiosum; Fig. 60.9B) and opportunistic infections, asthma, allergies resulting in anaphylaxis,

Fig. 60.9 Autosomal recessive hyperimmunoglobulin E syndrome due to DOCK8 deficiency. A Widespread eczematous dermatitis. **B** Extensive molluscum contagiosum. *Courtesy, Edward Cowen, MD.*

autoimmunity, central nervous system vasculitis, mucocutaneous squamous cell carcinomas and lymphomas.

Pathology

All HIES patients, by definition, have markedly elevated serum levels of polyclonal IgE, usually peaking at >2000 IU/ml and sometimes declining during adulthood. Patients develop particularly high levels of anti-staphylococcal and anti-candidal IgE antibodies and often have immediate wheal-and-flare reactions to a variety of foods and environmental allergens. Many affected individuals also have eosinophilia of the peripheral blood and sputum. Cell-mediated immunity is often abnormal, as manifested by anergy to skin testing and impaired *in vitro* lymphoproliferative responses to specific antigens. Serum levels of IgG, IgA and IgM are usually normal in classic HIES, as are lymphocyte subsets. In contrast, AR-HIES due to DOCK8 deficiency features a combined immunodeficiency that is characterized by lymphopenia (deficiency of $CD4^+$ T cells > $CD8^+$ T cells > B cells), low IgM levels and variable IgG levels as well as elevated IgE levels and peripheral eosinophilia[46,47].

The infantile papulopustular eruption of HIES is characterized histologically by eosinophilic folliculitis, eosinophilic spongiosis, and a superficial and deep perivascular infiltrate with abundant eosinophils[53,54].

Differential Diagnosis

Diagnostic guidelines for classic HIES have recently been proposed[55], with criteria including IgE >1000 IU/ml and a weighted score of five clinical features (Table 60.13); these characteristics plus a lack of Th17 cells or the detection of a heterozygous *STAT3* mutation allow for a probable or definitive diagnosis, respectively.

HIES must be differentiated from a number of other disorders that feature elevated IgE levels and a cutaneous eruption, including atopic dermatitis, Wiskott–Aldrich syndrome, Netherton syndrome, Omenn syndrome, DiGeorge syndrome, IPEX syndrome and GVHD. Atopic dermatitis and Wiskott–Aldrich syndrome are most easily confused with HIES because they present with eczematous dermatitis and staphylococcal infections. However, the development of cold abscesses, recurrent pneumonia, coarse facial features and osteopenia help to differentiate HIES from these disorders, and Wiskott–Aldrich syndrome can be distinguished by the associated platelet abnormalities. In a recent series of pediatric patients who had a serum IgE level of >2000 IU/ml, 69% (48/70) had atopic dermatitis and only 8% (6/70) had HIES; no correlation was observed between the IgE level and diagnosis of HIES[56]. Elevated IgE levels, susceptibility to pyogenic infections and eczematous dermatitis have also been described in patients with prolidase deficiency, an autosomal recessive condition due to *PEPD* mutations that also features chronic leg ulcers, facial dysmorphism and mental retardation. Lastly, patients with chronic granulomatous disease

DIAGNOSTIC GUIDELINES FOR HYPERIMMUNOGLOBULIN E SYNDROME DUE TO *STAT3* MUTATIONS							
Clinical finding	**Points**						**Multiplication factor**
	0	**2**	**4**	**5**	**6**	**8**	
Pneumonias (X-ray proven, total #)	none	1	2	–	3	>3	2.5
Newborn papulopustular eruption*	absent	–	present	–	–	–	2.1
Pathologic bone fractures	none	–	1–2	–	–	>2	3.3
Characteristic facies	absent	mild	–	present	–	–	3.3
High-arched palate	absent	present	–	–	–	–	2.5
Possible HIES: IgE >1000 IU/ml *plus* weighted score of >30 **Probable HIES**: As above plus lack of Th17 cells† or a family history of definitive HIES **Definitive HIES:** As above plus a dominant-negative heterozygous mutation in *STAT3*							
*In the first 3 weeks of life. †IL-17-producing $CD4^+$ T cells; in the peripheral blood by flow cytometry.							

Table 60.13 Diagnostic guidelines for hyperimmunoglobulin E syndrome (HIES) due to *STAT3* mutations[55].

and myeloperoxidase deficiency develop bacterial and candidal abscesses, but they do not typically have markedly elevated levels of IgE.

Treatment

Treatment of the infectious complications of HIES includes incision and drainage of abscesses as well as therapeutic and prophylactic administration of antibiotics. Interferon-γ has been shown to help control infections, and IVIg may improve the dermatitis, prevent infections and lower IgE levels. In anecdotal reports, treatment with omalizumab (a monoclonal antibody that targets IgE) improved the eczematous dermatitis of HIES.

IMMUNOGLOBULIN DEFICIENCIES

Synonyms: ■ X-linked agammaglobulinemia ■ Bruton agammaglobulinemia ■ Bruton–Gitlin syndrome ■ Congenital hypogammaglobulinemia ■ X-linked hypogammaglobulinemia

Key features

Agammaglobulinemia

- The inheritance pattern is X-linked recessive in 90% of patients and autosomal recessive in 10%
- Recurrent bacterial infections begin in the first few years of life

Common variable immunodeficiency (CVID)

- Heterogeneous group of disorders with defects in both humoral and cell-mediated immunity
- May manifest during childhood or adulthood, with clinical onset at an average age of 30 years
- Variable severity of infectious and autoimmune complications

Selective IgA deficiency

- Most common immunoglobulin deficiency, but usually asymptomatic, with clinical manifestations in only 10–15% of affected individuals
- Bacterial sinopulmonary infections and autoimmune disorders may occur

Hyper-IgM syndromes

- Usually has an X-linked recessive inheritance pattern, but autosomal recessive forms also exist
- Recurrent sinopulmonary and gastrointestinal infections with pyogenic bacteria and opportunistic organisms
- Oral ulcerations and verrucae may develop

The most common immunoglobulin deficiency is selective IgA deficiency, found in 1:500 persons with an equal sex distribution. Panhypogammaglobulinemia has a prevalence of 1:25 000, with X-linked agammaglobulinemia[54] (affecting primarily boys) and common variable immunodeficiency[57] (CVID; no sexual predilection) representing the most frequent forms. The clinical onset of CVID (average age 30 years) is typically later than that of X-linked agammaglobulinemia (often during the first few years of life, after levels of maternal antibodies wane at ~6 months of age). Approximately 15% of patients with CVID have family members with selective IgA deficiency. The pathogenesis and clinical features of immunoglobulin deficiencies[57–62] are presented in Figure 60.10 and Table 60.14.

The treatment of hypogammaglobulinemia is antibody replacement by IVIg or subcutaneous immunoglobulins and antibiotic therapy for infections. However, IVIg and other blood products containing IgA should be avoided in individuals with profound IgA deficiency, who may develop anti-IgA antibodies; fatal anaphylactic reactions have been reported. Recalcitrant non-infectious granulomas (cutaneous and extracutaneous) in patients with CVID may respond to treatment with TNF-α inhibitors.

Female carriers of X-linked agammaglobulinemia may be detected via examination of B-cell X-inactivation patterns, which show skewing towards cells with inactivation of the mutated X chromosome. DNA-based prenatal diagnosis is possible when the genetic defect in affected family members has been identified.

IPEX SYNDROME

Key features

- X-linked recessive disorder due to mutations in the *FOXP3* gene
- Cutaneous findings include a widespread eczematous dermatitis during infancy and a variety of autoimmune skin conditions
- Also features enteropathy and endocrinopathies with autoimmune etiologies

IPEX (*i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *X*-linked) syndrome is an X-linked recessive disorder caused by *FOXP3* gene mutations that result in abnormal development of regulatory T cells. Affected individuals typically present during infancy with severe diarrhea secondary to autoimmune enteropathy and develop a variety of autoimmune endocrinopathies (e.g. early-onset type 1 diabetes mellitus, thyroiditis, cytopenias). Most IPEX patients have a widespread eczematous dermatitis and elevated IgE levels during early infancy, and this is often complicated by staphylococcal superinfections and sepsis. Cutaneous manifestations of IPEX can also include psoriasiform dermatitis, cheilitis, nail dystrophy, and autoimmune skin conditions such as alopecia areata, chronic urticaria and bullous pemphigoid[63]. Autoimmune endocrinopathies, enteropathy and eczematous dermatitis have also been described in patients with IL-2 receptor α-chain (CD25) deficiency[64] (see Table 60.3) In addition, an autosomal recessive disorder due to mutations in the *ADAM17* gene encoding the TNF-α converting enzyme features a widespread psoriasiform dermatitis with pustular flares, brittle hair, staphylococcal skin infections and chronic diarrhea[64a].

LEUKOCYTE ADHESION DEFICIENCY

Key features

- Gingivitis and periodontitis
- Necrotic ulcerations clinically resembling pyoderma gangrenosum
- Poor wound healing; delayed separation of the umbilical stump
- Life-threatening bacterial and fungal infections

Introduction

Leukocyte adhesion deficiency (LAD) comprises three autosomal recessive disorders that affect the ability of neutrophils, monocytes and lymphocytes to adhere to the vascular endothelium and migrate to sites of infection and tissue injury[65,66].

Pathogenesis

Leukocyte adhesion requires a group of integrins (cell surface glycoproteins) that share a common 95 kDa β_2-subunit known as CD18. The β_2-subunit can be linked to different a chains to form three distinct cell surface glycoproteins: (1) lymphocyte function antigen 1 (LFA-1; CD11a); (2) complement receptor type 3 (CR3; $iC3_b$ receptor; Mac-1, CD11b); and (3) p150,95 (complement receptor type 4; CD11c). The primary ligand for these glycoproteins is intercellular adhesion molecule-1 (ICAM-1), which participates in the initiation and evolution of localized inflammation in the skin and other tissues. LAD-I is caused by mutations in the *ITGB2* gene that encodes CD18, and it manifests with dysfunction of all three glycoproteins. This leads to profound impairment of leukocyte firm adhesion to the vascular endothelium and mobilization into extravascular sites of inflammation, as well as defective neutrophil and monocyte chemotaxis and phagocytosis.

LAD-II is due to mutations in the *FUCT1* gene, which encodes a GDP-fucose transporter that is required for formation of sialyl-Lewis X

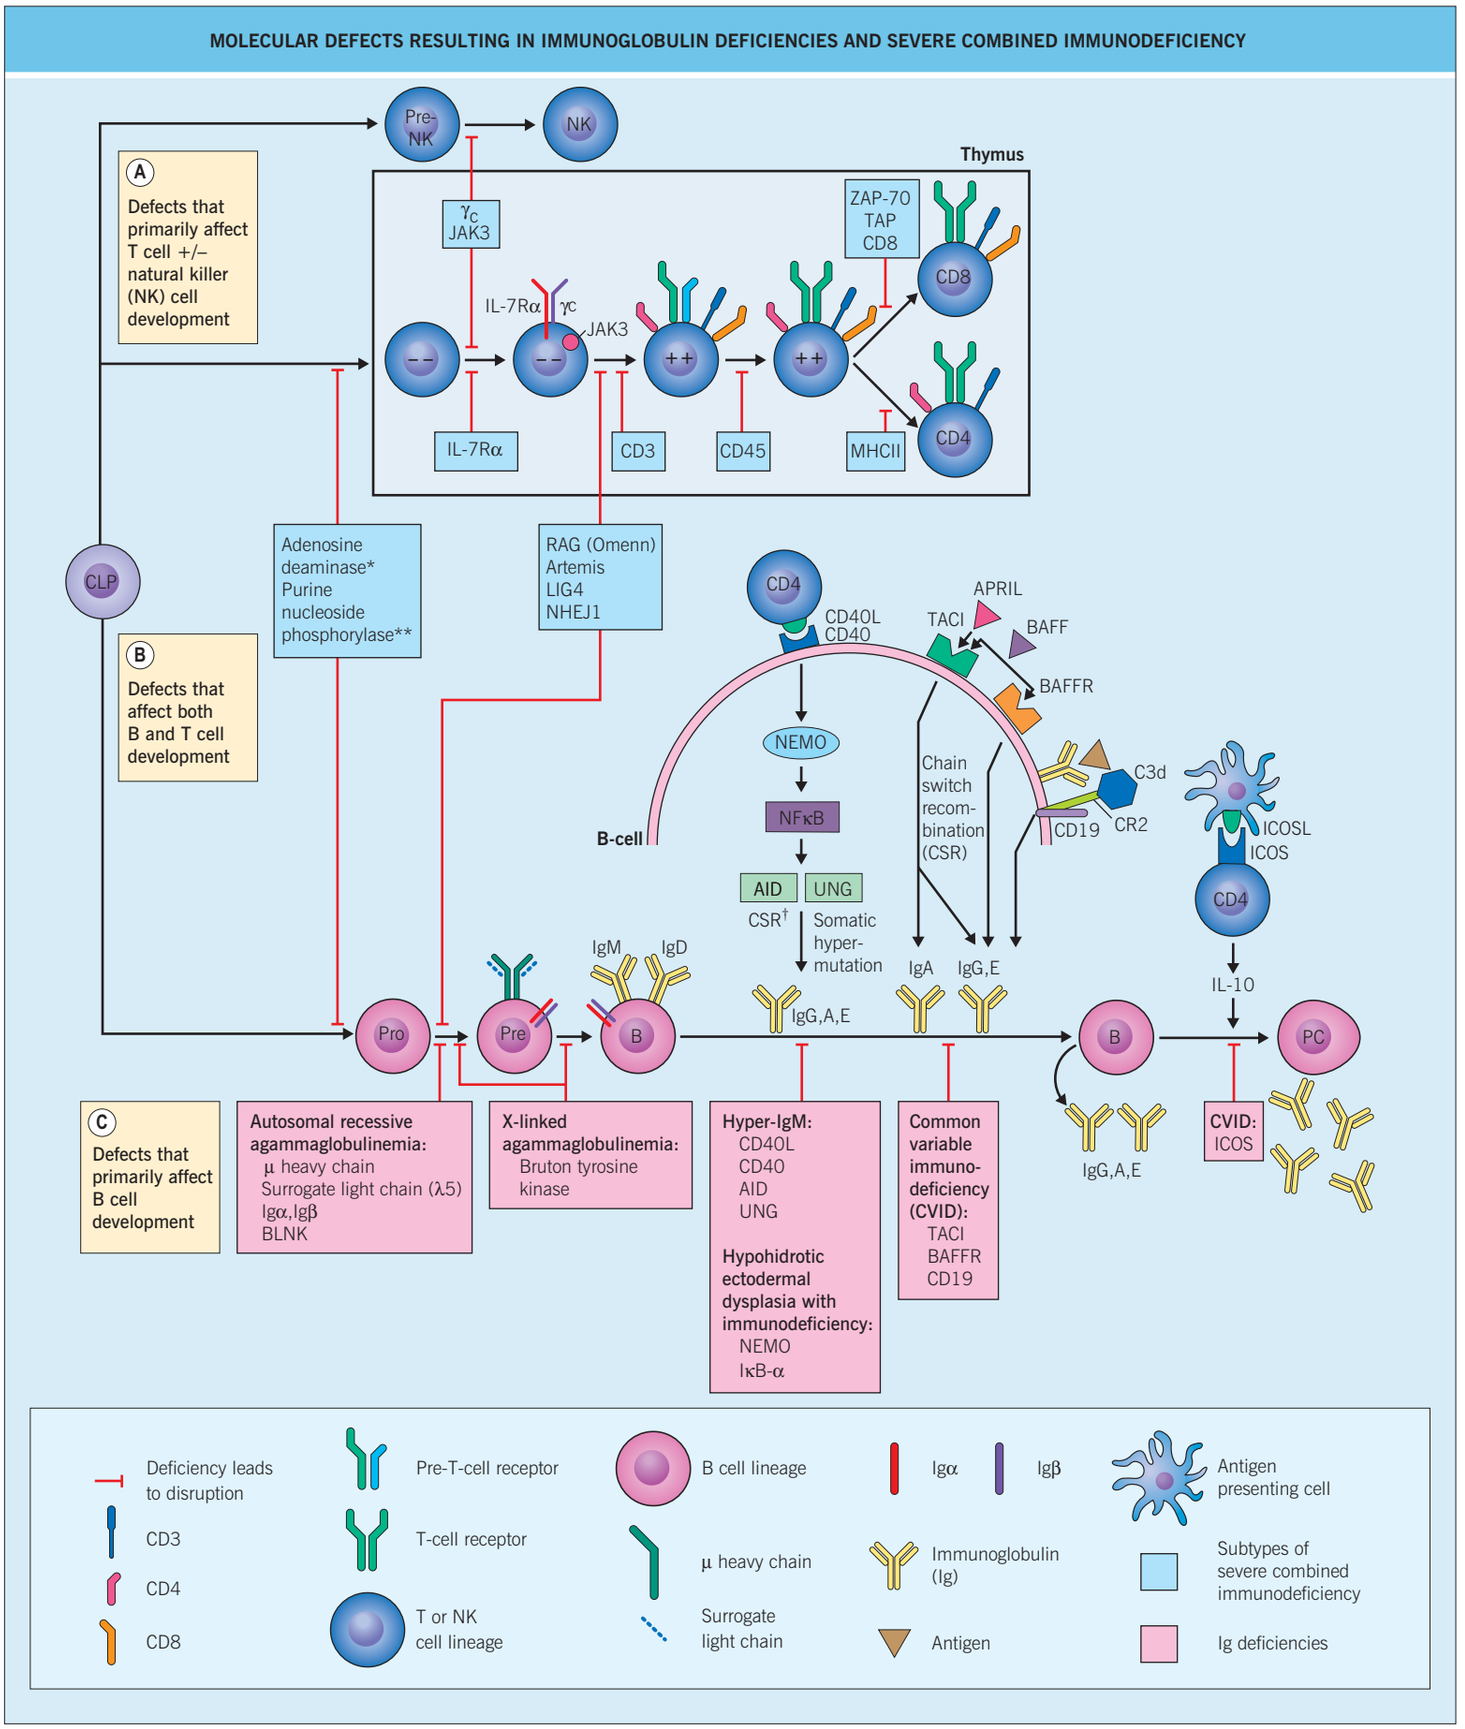

Fig. 60.10 Molecular defects resulting in immunoglobulin deficiencies and severe combined immunodeficiency (SCID). *Also important for B-cell maturation in germinal centers. **Affects T cells more than B cells. †Switch from IgM to IgG, IgA or IgE. AID, activation-induced cytidine deaminase; APRIL, *a pro*liferation-*i*nducing *l*igand; BAFF(R), B-cell activating factor (receptor); BLNK, B-cell linker protein (binds Bruton tyrosine kinase); CD40L, CD40 ligand; CLP, common lymphoid precursor; CR2, complement receptor 2; γ_c, common γ chain; ICOS(L), inducible costimulator on activated T cells (ligand); IκB-α, inhibitor of κB-α; IL, interleukin; IL-7Rα, IL-7 receptor α-chain; MHC, major histocompatibility complex; NEMO, NF-κB essential modulator; NHEJ1, non-homologous end-joining 1; NK, natural killer cell; PC, plasma cell; TACI, transmembrane activator and CAML interactor; TAP, transporter associated with antigen processing; UNG, uracil-DNA glycosylase; –, double-negative thymocyte; ++, double-positive thymocyte.

PRIMARY IMMUNOGLOBULIN DEFICIENCY DISORDERS						
Disorder	**Gene**	**Protein (function)**	**Ig levels**	**B cells**	**Infectious and systemic manifestations**	**Cutaneous manifestations**
BLOCK IN B-CELL DIFFERENTIATION AT THE PRO-B- TO PRE-B-CELL TRANSITION						
X-linked agammaglobulinemia	*BTK*	Bruton tyrosine kinase (pre-B-cell receptor [BCR] signaling)	All ↓	↓↓	• Recurrent infections with *Staphylococcus, Streptococcus, Pneumococcus, Haemophilus* and *Pseudomonas* spp. • Hepatitis B and enteroviral infections • Lymphomas (~5%)	• The skin is the most common site of infection – Furuncles and cellulitis – Ecthyma gangrenosum • Eczematous dermatitis • Papular dermatitis due to lymphohistiocytic infiltration • Non-infectious granulomas • Dermatomyositis-like disorder associated with chronic echoviral meningoencephalitis
AR agammaglobulinemia	*IGHM*	μ heavy chain of IgM (component of pre-BCR)				
	CD79A, CD79B	Igα chain, Igβ chain (bind μ heavy chain)				
	IGLL1	λ5 (surrogate light chain of pre-BCR)				
	BLNK	B-cell linker protein (binds Bruton tyrosine kinase)				
AD agammaglobulinemia	*LRRC8A*	Leucine-rich repeat-containing 8 family member A				
DEFECTIVE CLASS SWITCH RECOMBINATION (E.G. FROM IGM TO IGG, IGA OR IGE) AND SOMATIC HYPERMUTATION*						
Common variable immunodeficiency (CVID)†	*ICOS*	Inducible co-stimulator on activated T cells (T-cell help for B-cell differentiation)	IgG,A ↓; ± IgM ↓	NI or ↓	• Bacterial sinopulmonary infections (organisms similar to X-linked agammaglobulinemia) • *Giardia* spp. gastroenteritis • Autoimmune diseases, especially hemolytic anemia and idiopathic thrombocytopenic purpura • Increased risk of cancer (10-fold overall) and lymphoma (400-fold)	• Pyodermas and mucocutaneous candidiasis • Extensive warts and dermatophyte infections • Eczematous dermatitis • Non-infectious granulomas (may also involve the lungs, liver and spleen) • Autoimmune conditions such as vitiligo, alopecia areata and vasculitis • Clonal $CD8^+$ lymphocytic infiltration of the skin
	TNFRSF13B (AD or AR)	Transmembrane activator and CAML interactor (TACI; B-cell isotype switching)				
	TNFRSF13C	B-cell activating factor receptor (BAFFR; B-cell isotype switching)				
	CD19‡	CD19 antigen (B-cell survival and differentiation)				
	MSH5 (AD)	Mismatch repair protein (regulates class switch recombination)				
Selective IgA deficiency	*TNFRSF13B* (AD)	See above section	IgA ↓§; anti-IgA antibodies in ~half	NI	• Clinical manifestations in 10–15% • Similar to CVID	• Mucocutaneous candidiasis • Eczematous dermatitis • Autoimmune conditions such as SLE, vitiligo and lipodystrophia centrifugalis abdominalis
	MSH5 (AD)					
Selective IgM deficiency	?	?	IgM ↓	NI	• Recurrent bacterial infections • Autoimmune diseases	• Extensive warts • Eczematous dermatitis • SLE
X-linked hyper-IgM syndrome	*CD40LG*	CD40 ligand (on T cells)	IgM ↑; isohemagglutinins ↑; IgA,E,G ↓↓	NI	• Recurrent sinopulmonary and GI infections with pyogenic bacteria and opportunistic organisms (e.g. PCP)	• Pyodermas • Extensive warts • Oral (Fig. 60.11) and anogenital ulcers
AR hyper-IgM syndromes	*CD40*	CD40 (on B cells)				
	AICDA	Activation-induced cytidine deaminase			• As above, but massive LAN (with germinal centers), HSM and no	• Pyodermas
	UNG	Uracil-DNA glycosylase				

†Heterogeneous group of disorders with defects primarily in humoral but also involving cell-mediated immunity; TNFRSF13b is the most common of the underlying genetic defects identified to date, accounting for approximately 10% of CVID.
‡*CD81* is required for CD19 expression, and a homozygous mutation in the CD81 gene was reported in a patient with hypogammaglobulinemia and autoimmune vasculitis. Of note, a homozygous loss-of-function mutation in the *MS4A1* gene that encodes CD20 can result in recurrent sinopulmonary infections associated with low IgG levels, a normal total number of B cells, decreased memory B cells and poor T cell-independent antibody responses.
§Symptomatic patients often develop the immunodeficiency pattern of CVID.

Table 60.14 Primary immunoglobulin deficiency disorders. Autosomal recessive (AR) unless otherwise specified. AD, autosomal dominant; CAML, calcium-modulating cyclophilin ligand; GI, gastrointestinal; HSM, hepatosplenomegaly; Ig, immunoglobulin; *IKBKG*, inhibitor of κ light polypeptide gene enhancer in B cells, kinase γ; LAN, lymphadenopathy; MR, mental retardation; NI, normal; PCP, *Pneumocystis jiroveci* pneumonia; SLE, systemic lupus erythematosus.

Continued

Disorder	Gene	Protein (function)	Ig levels	B cells	Infectious and systemic manifestations	Cutaneous manifestations
PRIMARY IMMUNOGLOBULIN DEFICIENCY DISORDERS						
Hypohidrotic ectodermal dysplasia with immunodeficiency	*IKBKG (NEMO)* (X-linked recessive)	NF-κB essential modulator (activates NF-κB, which is involved in CD40 signaling)	IgM ↑; ± IgA ↑; ± IgG ↓	NI	• Pyogenic bacterial and opportunistic infections • Subset of *NEMO* patients with osteopetrosis and lymphedema	• Pyodermas • Ectodermal dysplasia (see Ch. 62)
	IKBA (*NFKBIA*; AD, gain of function)	Inhibitor of κB-α (inhibits NF-κB)				
ABNORMAL DNA METHYLATION LEADING TO DEFECTIVE B-CELL NEGATIVE SELECTION AND TERMINAL DIFFERENTIATION						
*I*mmunodeficiency, centromeric instability, and *f*acial anomalies (ICF) syndrome	*DNMT3B*	DNA methyltransferase 3β	All ↓	NI or ↓	• Bacterial sinopulmonary and GI infections • Abnormal facies, MR	• Telangiectasias (uncommon) • Nevoid hyperpigmentation
ABERRANT CHEMOKINE SIGNALING						
WHIM syndrome[¶]	*CXCR4* (AD, gain-of-function)	CXC chemokine receptor 4 (binds CXCL12; key role in bone marrow homeostasis and lymphocyte trafficking)	IgG ↓; ± IgA,M ↓	↓	• Recurrent bacterial sinopulmonary infections • Myelokathexis (mature neutrophils fail to exit the bone marrow)	• Cellulitis and pyodermas • Extensive verruca vulgaris and condyloma acuminata (Fig. 60.12)
DELAYED MATURATION OF HELPER T-CELL FUNCTION						
Transient hypogammaglobulinemia of infancy	?	?	IgG,A ↓ (resolves by age 3 y)	NI	• Failure to thrive in infancy • Recurrent sinopulmonary and GI infections	• Recurrent pyodermas and abscesses

[*]T-cell priming may also be defective, particularly in CD40–CD40L disorders (leading some authors to classify the latter as subtypes of severe combined immunodeficiency).
[¶]Warts, hypogammaglobulinemia, infections and myelokathexis; treatment with plerixafor (AMD 3100) , a CXCR4 antagonist, is under investigation.

Table 60.14 Primary immunoglobulin deficiency disorders (cont'd). Autosomal recessive (AR) unless otherwise specified. AD, autosomal dominant; GI, gastrointestinal; Ig, immunoglobulin; *IKBKG*, inhibitor of κ light polypeptide gene enhancer in B cells, kinase γ; MR, mental retardation; NI, normal.

(the fucosylated ligand for selectins) on the surface of leukocytes[67]. This causes a defect in the initial steps of tethering and rolling of leukocytes on the endothelial cell surface (via interaction of sialyl-Lewis X on leukocytes with E- or P-selectin on endothelial cells) that are required for their targeting to sites of infection and inflammation.

In order to undergo firm adhesion and subsequently extravasate from the bloodstream, circulating leukocytes must activate integrins *in situ* to rapidly increase their affinity and avidity for endothelial ligands. Patients with LAD-III have impaired integrin activation in hematopoietic cells, which leads to impaired leukocyte β_1- and platelet β_3-integrins in addition to leukocyte β_2-integrins as in LAD-I. It is caused by loss-of-function mutations in the *FERMT3* gene that encodes kindlin-3, an effector of integrin activation in hematopoietic cells[68].

Clinical Features

The most common manifestation of LAD is gingivitis with periodontitis, which often leads to the loss of teeth. Minor injuries to the skin

Fig. 60.13 A 7-year-old boy with leukocyte adhesion deficiency type I was scratched by his sister, resulting in a large gaping wound that healed poorly. *Reprinted with permission from Schachner L, Hansen R, eds. Pediatric Dermatology, 4th edn. London: Mosby, 2011.*

may rapidly expand to form large, chronic ulcerations (Fig. 60.13) that can resemble "burnt out" pyoderma gangrenosum. Poor wound healing also results in paper-thin, atrophic scars. A history of delayed separation of the umbilical stump represents a clue to the diagnosis.

Patients with LAD develop recurrent otitis media, pneumonia and cutaneous infections caused by pyogenic bacteria. The latter often present as cellulitis and necrotic abscesses with relatively little production of purulent material, typically located in the perianal area or on the face. Life-threatening bacterial, fungal or (less frequently) viral infections may also occur. More than three-quarters of patients with severe LAD-I (<1% of normal CD18 levels) die within the first 5 years of life, whereas approximately half of patients with moderate disease (1–10% of normal CD18 levels) live to age 30 years[66].

Additional clinical manifestations of LAD-II include mental retardation, microcephaly, hypotonia, short stature and distinctive facies[67]. Patients with LAD-III often present with a bleeding tendency, developmental delay, osteopetrosis and hepatosplenomegaly. Dermal hematopoiesis with a "blueberry muffin" appearance secondary to myelodysplastic syndrome has been described in infants and children with LAD-III[69].

Pathology

Individuals with LAD have marked *peripheral blood neutrophilia* (5–20 times normal levels). Although cutaneous ulcerations may resemble pyoderma gangrenosum clinically, histologic examination reveals a relative *paucity of tissue neutrophils*. Flow cytometric analysis reveals markedly decreased leukocyte CD18 expression in individuals with LAD-I. Patients with LAD-II have the Bombay red blood cell type due to a lack of the H blood group antigen, and those with LAD-III have abnormal platelet aggregation (reflecting defective activation of β_3-integrin) and (less often) anemia.

Differential Diagnosis

A mutation in the gene encoding the Rac2 GTPase, which has a role in phagocyte NADPH oxidase activation as well as integrin-dependent adhesion and neutrophil migration, can lead to clinical features similar to those of LAD, including delayed separation of the umbilical stump, poor wound healing, neutrophilia, and recurrent perirectal abscesses with an absence of pus (see Tables 60.9 & 60.12).

Treatment

Soft tissue infections in LAD patients require prolonged courses of antimicrobial therapy and, in some cases, surgical debridement. Meticulous dental hygiene is important in reducing the severity of the periodontitis. Oral administration of fucose may improve immune function in patients with LAD-II[67], and healing of chronic ulcers following IVIg administration to a patient with LAD-I has been reported. Hematopoietic stem cell transplantation represents the only definitive therapy for LAD, but it is limited by infectious complications and GVHD. Two patients with severe LAD-I were treated without prior conditioning with an infusion of autologous hematopoietic stem cells that had been corrected *ex vivo* with a retroviral vector encoding CD18, but circulating $CD18^+$ cells persisted for less than 2 months[66]. However, canine LAD-I has been successfully treated with non-myeloablative conditioning followed by infusion of autologous hematopoietic stem cells transduced *ex vivo* by a CD18-expressing foamy virus vector (which has less potential for genotoxicity than a retroviral vector); this led to complete reversal of the LAD phenotype that was sustained for more than 2 years[70].

SEVERE COMBINED IMMUNODEFICIENCY

Synonyms: ■ Severe combined immunodeficiency (SCID) syndrome ■ Severe mixed immunodeficiency syndrome ■ Glanzmann–Riniker syndrome ■ Alymphocytosis ■ Thymic alymphoplasia

Key features

- Recurrent infections, diarrhea and failure to thrive within the first 3–6 months of life
- Risk of GVHD, especially from unirradiated blood products
- Lack of lymphoid tissue
- Deficiencies of T, B and/or NK cells

Introduction

Severe combined immunodeficiency (SCID) is a heterogeneous group of disorders that share clinical manifestations related to defective function of both cell-mediated and humoral immunity[71,72] (Table 60.15).

Epidemiology

SCID occurs in 1:30 000 to 1:100 000 live births. Three-quarters of affected patients are boys. More than 40% of cases have X-linked recessive inheritance, most due to defects in the gene encoding the common γ (γ_c) chain of the IL-2 receptor, and the remainder are autosomal recessive. Approximately 20% of cases occur because of adenosine deaminase (ADA) deficiency, and 6% result from *JAK3* mutations.

Pathogenesis

Molecular defects that can lead to the SCID phenotype are presented in Figure 60.10 and Table 60.15.

Clinical Features

Infants with SCID may present with widespread seborrheic-like dermatitis or morbilliform eruptions, often reflecting maternofetal GVHD. Cutaneous eruptions may also resemble lichen planus, acrodermatitis enteropathica, Langerhans cell histiocytosis, ichthyosiform erythroderma and scleroderma. Extensive eczematous dermatitis or erythroderma, often with alopecia, may occur outside the setting of GVHD in infants with Omenn syndrome, which also features hepatosplenomegaly and peripheral eosinophilia.

Recurrent infections, chronic diarrhea and failure to thrive are apparent within the first few months of life. Common early infections include mucocutaneous candidiasis, persistent viral gastroenteritis, and pneumonias due to bacteria, viruses or *Pneumocystis jiroveci*. Cutaneous infections are most often caused by *C. albicans, S. aureus* and *Str. pyogenes*. Despite recurrent infections, patients with SCID typically lack tonsillar buds and palpable lymphoid tissue. SCID due to ADA deficiency is associated with an increased risk of developing dermatofibrosarcoma protuberans (often multiple and morpheaform) during the first two decades of life[72a].

CLASSIFICATION OF SEVERE COMBINED IMMUNODEFICIENCY			
Disorder	**Gene**	**Protein function**	**Cells**
DEFECTS IN CYTOKINE RECEPTORS AND THEIR SIGNALING			
X-linked SCID*	*IL2RG*	Common γ chain (γ_c) of the receptors for IL-2, 4, 7, 9, 15 and 21	$T^-/B^+/NK^-$
JAK3 deficiency	*JAK3*	Tyrosine kinase with a role in signal transduction via the receptors for IL-2, 4, 7, 9, 15, and 21	$T^-/B^+/NK^-$
Interleukin-7 receptor deficiency†	*IL7R*	α-chain of the IL-7 receptor; critical for development and differentiation of T cells	$T^-/B^+/NK^+$
INCREASED APOPTOSIS OF LYMPHOCYTES ± OTHER HEMATOPOIETIC CELLS			
Defects in purine pathway enzymes that result in the build-up of toxic metabolites			
Adenosine deaminase (ADA) deficiency*	*ADA*	Enzyme in the purine salvage pathway‡	$T^-/B^-/NK^-$
Purine nucleoside phosphorylase (PNP) deficiency	*PNP*	Enzyme in the purine salvage pathway (downstream of ADA)‡	$T^-/B^-/NK^-$
Defects disrupting mitochondrial energy production			
Reticular dysgenesis (aleukocytosis)	*AK2*	Adenylate kinase 2, a mitochondrial enzyme that regulates ADP levels in leukocytes; profound neutropenia and sensorineural deafness	$T^-/B^-/NK^-$
Defects disrupting actin polymerization			
Coronin 1A deficiency	*CORO1A*	Actin regulator expressed in T-cell precursors	$T^-/B^+/NK^+$
DEFECTS IN (PRE-)T-CELL RECEPTORS (TCRS) ± B-CELL RECEPTORS (BCRS) AND THEIR SIGNALING			
Omenn syndrome†	*RAG1* and *RAG2*	Mediate V(D)J recombination of the genes that encode BCRs (immunoglobulins) and TCRs§	$T^-/B^-/NK^+$
Artemis deficiency†	*DCLRE1C (Artemis)*	Repairs the DNA double-stranded breaks that occur during V(D)J recombination and upon exposure to ionizing radiation§	$T^-/B^-/NK^+$
PRKDC deficiency	*PRKDC*	DNA-activated protein kinase catalytic subunit critical for V(D)J recombination§	$T^-/B^-/NK^+$
LIG4 syndrome	*LIG4*	Ligase component of the DNA non-homologous end-joining (NHEJ) machinery required for the repair of DNA double-stranded breaks§	$T^-/B^-/NK^+$
NHEJ1 deficiency	*NHEJ1*	NHEJ factor required for the repair of DNA double-stranded breaks§	$T^-/B^-/NK^+$
T-cell receptor deficiencies	*CD3γ*, *CD3δ*, *CD3ε* and *CD3ζ*	TCR-associated proteins required for cell surface expression of and signal transduction by the TCR; most severe with defective CD3δ	$T^-/B^+/NK^+$
	TRAC	TCR-α constant region; relatively mild immunodeficiency	
CD45 deficiency	*PTPRC*	Transmembrane tyrosine phosphatase with a role in TCR signaling	$T^-/B^+/NK^+$
ZAP-70 deficiency	*ZAP-70*	Tyrosine kinase with a role in TCR signaling	$CD4^+CD8^-/B^+/NK^+$
CD8 deficiency	*CD8A*	Co-receptor for TCRs recognizing MHC class I-associated peptides; role in TCR signaling¶	$CD4^+CD8^-/B^+/NK^+$
Calcium channel deficiency	*ORAI1*	Pore-forming subunit of calcium channel with a role in TCR signaling; hypohidrotic ectodermal dysplasia and myopathy	$T^+/B^+/NK^+$
	STIM1	Calcium channel component with a role in TCR signaling; hepatosplenomegaly, lymphadenopathy, autoimmune cytopenias, dental dysplasia, myopathy	$T^+/B^+/NK^+$
ANTIGEN PRESENTATION DEFECTS (BARE LYMPHOCYTE SYNDROMES)			
MHC class II deficiency	*CIITA, RFXANK, RFX5 and RFXAP*	Transactivate the MHC class II promoter; MHC class II molecules are required for the positive selection of $CD4^+$ T cells in the thymus as well as for antigen presentation to $CD4^+$T cells	$T^+/B^+/NK^+$, but fewer and dysfunctional $CD4^+$T cells
MHC class I deficiency	*TAP1* and *TAP2*	*T*ransporter associated with *a*ntigen *p*rocessing; translocates peptides from the cytosol to MHC class I molecules in the endoplasmic reticulum¶	$CD4^+CD8^-/B^+/NK^+$
DEFECTIVE THYMIC DEVELOPMENT			
Winged helix nude (forkhead box N1) deficiency	*WHN (FOXN1)*	Transcription factor important to thymic development; defect leads to complete congenital alopecia and nail dystrophy (human equivalent of "nude" mice)	$T^-/B^+/NK^+$

*Two most common forms, accounting for approximately two-thirds of cases.
†Artemis and interleukin-7 receptor deficiencies can also lead to an Omenn syndrome phenotype (see text).
‡Defective ADA or PNP activity results in accumulation of (deoxy)adenosine or deoxyguanosine triphosphate metabolites, respectively, which are particularly toxic to developing lymphocytes; measuring red blood cell levels of the enzymes and/or metabolites can help establish the diagnosis.
§Patients are unable to produce the diversity of B- and T-cell receptors that are required for adaptive immunity; Artemis, PRKDC, LIG4 and NHEJ1 defects lead to sensitivity to ionizing radiation; both of the latter two conditions are associated with microcephaly and bird-like facies, and photosensitivity and telangiectasias have been described in patients with LIG4 syndrome.
¶Not true SCID; present with bacterial sinopulmonary infections and, in TAP deficiency, cutaneous granulomas; a milder form of bare lymphocyte syndrome can result from TAP binding protein (tapasin) deficiency.

Table 60.15 Classification of severe combined immunodeficiency (SCID). Cartilage–hair hypoplasia (see text) occasionally presents as SCID with an Omenn-like phenotype. *DCLRE1C*, DNA cross-link repair protein 1C; MHC, major histocompatibility complex; V(D)J, variable/diversity/joining.

Pathology

Nearly all patients with SCID have a profound T-cell deficiency and a low absolute lymphocyte count. Patients are further classified by the results of fluorescent activated cell sorter (FACS) analysis into those with and without B lymphocytes and NK cells. The laboratory abnormalities observed in different types of SCID are noted in Table 60.15. Certain forms of SCID show distinctive radiographic manifestations; for example, patients with ADA deficiency demonstrate cupping and flaring of the costochondral junction on chest radiographs. Flow cytometric analysis of peripheral blood mononuclear cells with antibodies directed against a particular protein that is missing from the cell surface (e.g. γ_c or JAK3) as well as direct gene analysis can help to establish a specific diagnosis.

Maternal T-cell engraftment is detectable (e.g. maternal T cells representing ≥1% of peripheral blood leukocytes) in approximately half of infants with SCID. The presence of maternal T cells is asymptomatic in the majority of cases, and a third of patients have mild changes such as cutaneous erythema and scale, a morbilliform eruption, elevated hepatic transaminases, and eosinophilia. Skin biopsy specimens show the histopathologic features of GVHD. Maternofetal GVHD is typically less severe than that resulting from postnatal inoculation of allogeneic lymphocytes (e.g. from unirradiated blood product transfusions), which can be fatal.

Differential Diagnosis

SCID must be differentiated from other immunodeficiency disorders, especially HIV infection. The latter is distinguished by normal to increased immunoglobulin levels, a relative decrease in $CD4^+$ T cells, and the presence of anti-HIV antibodies.

Treatment

Without intervention, the outcome for SCID patients is death by 1 year of age. Early diagnosis of SCID is critical, preferably before the administration of live vaccines or unirradiated blood products. A blood screening test for T-cell lymphopenia has been developed and was recently implemented in population-wide pilot programs for the detection of SCID in newborns in the US. Infants with SCID should be kept in protective isolation and monitored for the development of infections, which should be treated aggressively.

Hematopoietic stem cell transplantation during infancy is the treatment of choice for SCID. Because the patient's immune system is unable to reject the transplanted cells, myeloablative therapy is not required. The result is engraftment of donor T and NK cells, but usually not B cells. With an HLA-identical sibling donor, T-cell reconstitution typically occurs within 3–4 months, GVHD is uncommon and the long-term survival rate is >90%. Transplantation of haploidentical parental stem cells, which can be depleted of post-thymic T cells to reduce the risk of GVHD, often requires some chemotherapeutic conditioning to facilitate engraftment and results in ≤80% survival. *In utero* injection of haploidentical $CD34^+$ cells has also been used to treat X-linked SCID. SCID patients often require IVIg replacement therapy for persistent B-cell deficiency following hematopoietic stem cell transplantation, and T-cell function may decline over time.

Enzyme replacement via injection of polyethylene glycol-conjugated ADA can lead to improved immune function in children with ADA deficiency. Gene therapy has been successfully performed in more than 50 children with X-linked SCID or ADA deficiency via retroviral-mediated *ex vivo* gene transfer into $CD34^+$ cells[73,74]. Follow-up studies on 19 of these patients (4 months–4 years after treatment) showed that transcriptional start sites and coding regions of active genes were the preferred retroviral integration sites in circulating T cells as well as in pre-infusion transduced $CD34^+$ cells; in the former cells, ~25% of all integrations were clustered at common sites, suggesting *in vivo* selection of transduced cells with a higher capacity for engraftment, survival and proliferation[75]. Although T- and NK-cell function was restored, at least five patients with X-linked SCID have developed T-cell leukemias (2–6 years after treatment) related to activation of proto-oncogenes such as *LMO2* by the retroviral vector[76]. These complications raised serious concerns regarding the safety of gene therapy, and this has led to protocol modifications and investigation of alternative approaches such as lentiviral vectors and *in situ* gene transfer.

Prenatal diagnosis of SCID can be performed by fetal DNA analysis in families with a known genetic defect; ADA assays and examination of maternal X-chromosome inactivation may also be utilized for specific types of SCID.

WISKOTT–ALDRICH SYNDROME

Synonyms: ■ Wiskott–Aldrich–Huntley syndrome ■ Eczema–thrombocytopenia–immunodeficiency syndrome

Key features

- X-linked recessive immunodeficiency disorder characterized by the classic triad of atopic-like dermatitis, a bleeding tendency due to microthrombocytopenia, and recurrent sinopulmonary infections
- Onset of bacterial infections is early in life, with later development of viral and *Pneumocystis* spp. infections
- Hepatosplenomegaly, lymphadenopathy and autoimmune diseases often develop
- Lymphomas occur in approximately one-quarter of survivors

Introduction

Wiskott–Aldrich syndrome (WAS) is characterized by recurrent pyogenic infections, bleeding due to thrombocytopenia and platelet dysfunction, and recalcitrant eczematous dermatitis[77]. The full triad develops in a minority of patients, with platelet abnormalities representing the most constant feature.

Epidemiology

Most patients with this X-linked recessive immunodeficiency are boys, but girls are occasionally affected in the setting of non-random X-chromosome inactivation or homozygosity for a mild mutation. WAS has an incidence of approximately 1 : 250 000 live male births in European populations; it is less common in blacks and Asians.

Pathogenesis

WAS is caused by loss-of-function mutations in the *WASP* gene, which is constitutively expressed in all hematopoietic cell lineages. The WAS protein (WASP) controls the assembly of actin filaments, which are required for microvesicle and pro-platelet formation as well as T-cell activation and polarization toward antigen-presenting cells[78]. Loss-of-function *WASP* mutations also cause X-linked recessive thrombocytopenia, an allelic disorder with a phenotype limited to platelet abnormalities, while gain-of-function *WASP* mutations can lead to X-linked congenital neutropenia.

Abnormal T-cell function is central to the immunologic defect in WAS, with resultant diminution of both cell-mediated and humoral responses[78]. Although the number of T cells in WAS patients has been observed to decrease with age, affected infants also have reduced numbers of T cells (especially naive T cells) and B cells[79]. This suggests that impaired lymphocyte maturation and output from the thymus are central to the immunodeficiency of WAS. WASP function is required for the activation of regulatory T cells, helping to explain the autoimmune manifestations of WAS. Defects in B-cell migration, differentiation and organization into germinal centers have roles in the impaired humoral immunity of WAS, with reduced expression of CD21 and CD35 (complement receptors involved in antigen capture and presentation) also potentially contributing to autoimmunity[79]. Although NK cells are not decreased in number, their cytolytic activity is abnormal in WAS. Lastly, small, structurally abnormal platelets with a reduced half-life (due in part to splenic destruction) account for the thrombocytopenia of WAS[78].

Clinical Features

Because thrombocytopenia and platelet dysfunction are present from birth, the first clinical signs of WAS are usually petechiae and ecchymoses of the skin and oral mucosa. Spontaneous bleeding from the oral

Fig. 60.14 Severe atopic dermatitis in an infant with Wiskott–Aldrich syndrome. The boy was successfully treated with bone marrow transplantation, and his dermatitis virtually cleared owing to the T-cell engraftment. *Reprinted with permission from Schachner L, Hansen R, eds. Pediatric Dermatology, 4th edn. London: Mosby, 2011.*

cavity, epistaxis, hematemesis, melena and hematuria are commonly observed.

The dermatitis of WAS typically develops during the first few months of life, and it fulfills the diagnostic criteria for atopic dermatitis (see Tables 12.1 & 12.2). The face, scalp and flexural areas are most severely affected, although patients often have widespread involvement with progressive lichenification. Exfoliative dermatitis occasionally develops. Excoriated areas frequently have serosanguineous crusts and petechiae (Fig. 60.14). Secondary bacterial infections are common, as are eczema herpeticum and molluscum contagiosum.

Recurrent bacterial infections begin during the first 3 months of life, coincident with diminishing levels of placentally transmitted maternal antibodies. These infections include otitis externa and media, pneumonia, sinusitis, conjunctivitis, furunculosis, meningitis and septicemia. Encapsulated bacteria such as *Str. pneumoniae, H. influenzae* and *Neisseria meningitides* are the predominant organisms. With advancing age, there is increased susceptibility to infections with viruses (e.g. herpes simplex) and *P. jiroveci*.

The majority of children with WAS develop at least one autoimmune disease, most commonly cutaneous small vessel vasculitis (often associated with painful edema), autoimmune hemolytic anemia or neutropenia, arthritis, inflammatory bowel disease and cerebral vasculitis[80]. IgE-mediated conditions such as urticaria, food allergies and asthma also occur with increased frequency. Hepatosplenomegaly and lymphadenopathy are additional features of WAS. Lymphomas develop in up to a quarter of WAS patients 20 years of age and older, especially those with a history of autoimmune disease. Non-Hodgkin lymphomas predominate, and are most often diffuse large B-cell in type with extranodal and brain involvement (similar to AIDS-related lymphomas).

The median survival for WAS patients is now approximately 15 years. The most common causes of death (outside the setting of transplantation) are infection (50%), bleeding (25%) and malignancy (25%).

Pathology

The most frequent laboratory abnormalities in WAS are persistent thrombocytopenia (platelet counts <80 000/mm^3) and low mean platelet volume (<5.0 fl). WAS patients may also have lymphopenia and eosinophilia. Serum IgM and IgG_2 levels are typically low, while IgA, IgE and IgD levels tend to be elevated. Antibody responses to polysaccharide antigens are markedly diminished. Delayed-type hypersensitivity skin test reactions are usually absent, and responses to mitogens are often depressed, especially in older patients. Monocyte and neutrophil chemotaxis may also be defective.

Assessment of WASP expression in peripheral blood mononuclear cells by flow cytometry-based assays or immunoblot analysis can be performed in suspected cases prior to mutational analysis. Patients with a complete lack of WASP expression in circulating cells tend to have a more severe phenotype.

Differential Diagnosis

The cutaneous and laboratory features of other immunodeficiency syndromes characterized by eczematous dermatitis are summarized in Tables 60.1 and 60.2, and an approach to the differential diagnosis of infantile erythroderma is presented in Figure 10.10.

Treatment

Hematopoietic stem cell transplantation is the treatment of choice for patients with WAS. Full engraftment results in normal platelet numbers and function, restoration of immunologic status, and clearance of the dermatitis. Affected children who receive a hematopoietic stem cell transplant now have an overall survival rate of >85%, with lower rates (~70%) in those transplanted at >5 years of age with an unrelated donor[80a]. Gene therapy using retrovirally transduced, WASP-reconstituted, autologous $CD34^+$ cells has also been successfully performed[81].

Appropriate prophylactic use of antibiotics and antivirals can decrease the risk of fatal infections in WAS patients[82]. IVIg therapy has a role in preventing infections (considering patients' lack of antibodies to polysaccharide antigens) and may potentially improve the dermatitis. Topical corticosteroid preparations remain a mainstay of treatment for the latter. Splenectomy can help to reduce bleeding complications in patients with recurrent severe hemorrhage; unfortunately, splenectomy further increases the risk of infections with encapsulated organisms. Platelet transfusions may be given prior to surgery and in the setting of life-threatening hemorrhage.

Genetic counseling is important for the sisters and other female relatives of WAS patients. Female carriers may be detected by genetic analysis or detection of selective inactivation of the abnormal X chromosome in lymphocytes and platelets. Prenatal diagnosis can be performed by direct mutational analysis.

Chapter Contents

Neurofibromatosis type 1 925
Tuberous sclerosis 933

INTRODUCTION

Neurofibromatosis (NF) and tuberous sclerosis (TS) are neurocutaneous disorders, or phakomatoses. They are characterized by cutaneous lesions as well as peripheral and/or central nervous system neoplasms. Like most hereditary cancer syndromes, NF and TS are autosomal dominant in inheritance. Despite a high penetrance for both diseases, new cases of NF type 1 (NF1) and TS frequently represent *de novo* mutations. The pleiotropic nature of these two neurocutaneous syndromes has led to complex schemes for their classification and diagnosis. Dermatologists are frequently asked to participate in the clinical diagnosis of patients with NF1 and TS due to the early appearance of cutaneous, especially pigmentary, findings. Advances in the molecular characterization of these disorders have revealed related, but distinct, pathogenic mechanisms.

In 1982, Riccardi proposed a classification scheme for patients with NF (Table 61.1). Elucidation of the molecular bases of NF1, NF2, segmental/mosaic NF1 (formerly known as NF5), and "NF1-like" syndromes has further refined the categorization of patients. Among these conditions, NF1 has the most well-characterized and diagnostic skin findings and is the main focus in this chapter.

NEUROFIBROMATOSIS TYPE 1

Synonym: ■ von Recklinghausen disease

Key features

- NF1 is an autosomal dominant disorder with an incidence of approximately 1 in 3000 births
- Clinical characteristics include café-au-lait macules, neurofibromas, freckling in the axillae and groin, Lisch nodules, and bony defects
- Patients with NF1 have an increased risk of developing juvenile myelomonocytic leukemia and a variety of extracutaneous tumors, including optic gliomas, malignant peripheral nerve sheath tumors, pheochromocytomas and CNS tumors
- Up to 50% of patients with NF1 have a new spontaneous mutation rather than an inherited mutation
- The protein product of the *NF1* gene (neurofibromin) is involved in the negative regulation of Ras signaling
- Other well-characterized forms of NF include segmental/mosaic NF1 and NF2 (vestibular schwannomas)

History

Individuals with NF1 have been described throughout history[1,2]. In 1882, von Recklinghausen[3] provided the first in-depth report of the clinical and pathologic nature of the neurofibromas. Fifty years later, the Viennese ophthalmologist Lisch described the iris nodules that were more recently recognized as an important criterion in the clinical diagnosis of NF. In the mid twentieth century, Crowe, Schull and Neel compiled a landmark monograph with a comprehensive description of the manifestations of this disease[4].

Epidemiology

NF1 has been reported worldwide. Its incidence is approximately 1 in 3000 births[4–6].

Pathogenesis

NF1 is inherited in an autosomal dominant manner. Most large series have found that 30–50% of patients have no affected relatives and thus likely harbor new spontaneous mutations[4–6]. There is also the possibility of germline mosaicism in a parent, especially when two siblings develop NF1 in the absence of a family history. The penetrance of NF1 approaches 100% in carefully examined adults[7], but expressivity is variable. A wide range of clinical findings and complications can develop among individuals with the same underlying mutation. The specific *NF1* mutation is therefore not the only factor that determines phenotype.

In 1987, an international consortium found evidence of linkage to the pericentromeric region of chromosome 17 in families with NF1[8]. Subsequent descriptions of two NF1 patients with balanced translocations involving the long arm of chromosome 17 (17q11.2) further refined the position of the *NF1* locus[9,10]. The localization data derived from these studies led to the cloning of the *NF1* gene[11–13].

The *NF1* gene spans over 350 kilobases (kb) of genomic DNA, with at least 59 exons encoding a 327 kDa protein (neurofibromin) that consists of 2818 amino acids (Fig. 61.1)[14]. Over 80% of NF1 patients have a mutation that predicts truncation of the neurofibromin protein, and approximately 5% of patients have a large deletion ("microdeletion") that encompasses the entire *NF1* gene plus a variable number of flanking genes[15]. Although there is usually no clear genotype–phenotype correlation, exceptions include: (1) a 3-base pair in-frame deletion (AAT in exon 17) that is associated with an absence of cutaneous neurofibromas[16]; and (2) a recurrent 1.4-mega-base pair deletion ("type 1 microdeletion") that results in a more severe phenotype[17,18]. The latter can include an earlier onset and larger number of neurofibromas, an increased risk of malignant peripheral nerve sheath tumors, marked

RICCARDI'S CLASSIFICATION OF NEUROFIBROMATOSIS

Category	Description
NF1	von Recklinghausen disease
NF2	Acoustic schwannoma
NF3*	Mixed (central and peripheral neurofibromas)
NF4*	Variant
NF5*,†	Segmental café-au-lait macules, neurofibromas, or both, affecting one or more dermatomes
NF6*,‡	Café-au-lait macules only
NF7*	Late onset
NF-NOS	Not otherwise specified

*Primarily of historical/conceptual interest.
†Now referred to as segmental NF1.
‡Includes Legius (NF1-like) syndrome.

Table 61.1 Riccardi's classification of neurofibromatosis.

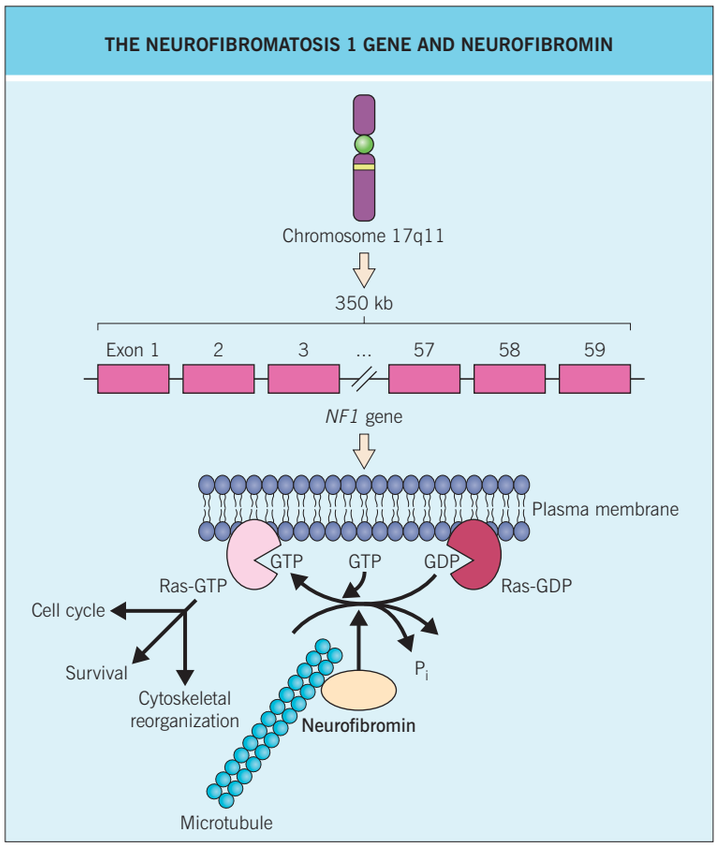

Fig. 61.1 The neurofibromatosis 1 gene and neurofibromin. *NF1* is located on chromosome 17q11.2 and encodes the *G*TPase-*a*ctivating *p*rotein (GAP)-related protein neurofibromin. One of the functions of neurofibromin is to negatively regulate the activity of Ras proteins. Ras, like other related G proteins, is dependent upon GTP binding for its full activity, and GAP proteins shut off the signal by accelerating the hydrolysis of GTP to GDP.

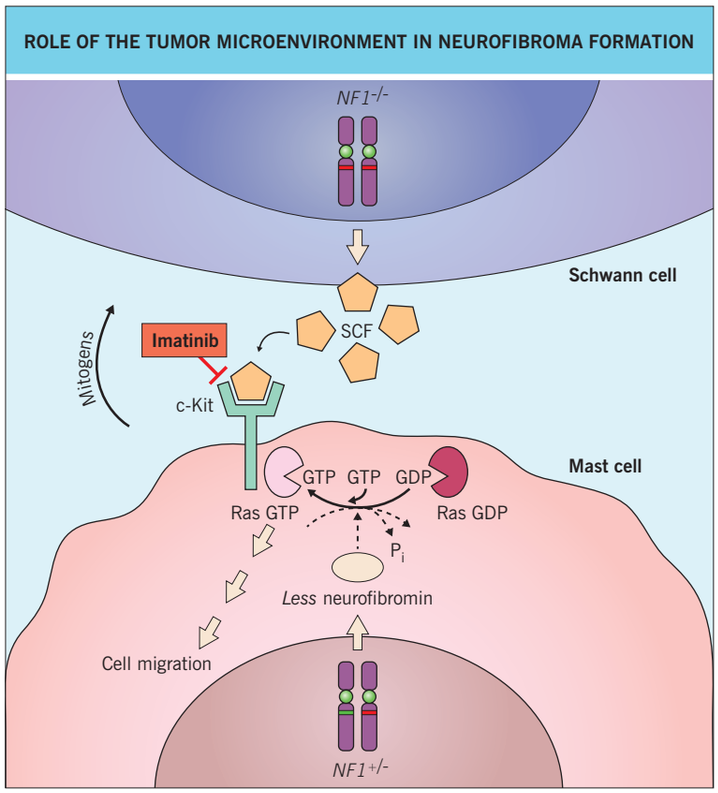

Fig. 61.2 Role of the tumor microenvironment in neurofibroma formation. *NF1* nullizygous (*Nf1*$^{-/-}$) Schwann cells oversecrete stem cell factor (SCF), which binds the Kit receptor on *NF1* heterozygous (*Nf1*$^{+/-}$) mast cells. This leads to mast cell recruitment and their activation to produce growth factors that stimulate neurofibroma development. Inhibition of KIT signaling by imatinib mesylate can block neurofibroma formation and progression.

cognitive deficiencies, facial dysmorphism, overgrowth and connective tissue dysplasia (e.g. hyperextensible skin, joint laxity, mitral valve prolapse)[17,18].

Sequence similarities between a central 300–400 amino acid domain within neurofibromin and *G*TPase-*a*ctivating *p*roteins (GAPs) led to recognition of neurofibromin's role in the negative regulation of the Ras–*m*itogen-*a*ctivated *p*rotein *k*inase (MAPK) pathway that promotes cell survival and proliferation (see Fig. 61.1 and Fig. 55.6)[19]. Like all G proteins, Ras activity requires GTP. Neurofibromin and other GAPs accelerate the hydrolysis of GTP to GDP, thereby terminating the Ras signal and functioning as tumor suppressor proteins. Neurofibromin has also been shown to associate with microtubules[20], although the consequences of this interaction remain unclear.

As observed in other autosomal dominant genodermatoses (e.g. nevoid basal cell carcinoma syndrome) caused by a defective tumor suppressor gene, a *somatic* mutation inactivating the remaining allele of the gene (i.e. a "second hit" causing loss of heterozygosity [LOH]) can be found within skin lesions of NF1. Biallelic *NF1* inactivation has been identified in Schwann cells from neurofibromas as well as melanocytes from café-au-lait macules in patients with NF1[21,22]. In a mouse model, *Nf1* nullizygosity (*Nf1*$^{-/-}$) in Schwann cells was shown to be necessary, but not sufficient, for neurofibroma formation[23]; however, plexiform neurofibromas did arise from *Nf1*$^{-/-}$ Schwann cells when the microenvironment included *Nf1*$^{+/-}$ (rather than wild-type) mast cells[24]. The latter cells appear early in neurofibroma development and are hypermotile in response to the c-Kit ligand (stem cell factor), which is oversecreted by *Nf1*$^{-/-}$ Schwann cells. Once recruited, mast cells produce growth factors that likely promote neurofibroma tumorigenesis (Fig. 61.2). Of note, genetic or pharmacologic attenuation of kit signaling in *Nf1*$^{+/-}$ mast cells has been found to diminish neurofibroma initiation and progression (see Treatment section below).

Clinical Features

The clinical features of NF1 (Table 61.2) are myriad, although some occur with greater frequency than others[4–6,25–35].Through decades of careful study, almost every organ system has been found to be involved in NF1. However, the cutaneous manifestations of NF1 represent particularly important clinical features and have a central role in the diagnosis of the condition.

Oculocutaneous manifestations

Café-au-lait macules (CALMs) are tan to dark brown (depending on the degree of pigmentation of uninvolved skin), uniformly pigmented macules and patches that are randomly distributed on the body (except for the scalp, palms and soles). They are sharply demarcated with regular borders and often have an oval shape (Fig. 61.3); the diameter can vary from a few millimeters to over 4 cm. CALMs may not be apparent at birth and frequently become more noticeable during the first year of life; fading of these lesions during later adulthood has also been described[35a]. When located within areas of dermal melanocytosis, CALMs are usually surrounded by a rim of normally pigmented skin (see Ch. 112). Larger CALMs, especially those with associated hypertrichosis, should be palpated to exclude the possibility of an underlying plexiform neurofibroma (see below).

Crowe et al.[4] reported that 10% of the normal population has one to five CALMs, and Burwell et al.[36] found that 26% of 732 white schoolchildren had at least one CALM greater than 1 cm in diameter. In the latter study, only three children (0.4%) had six or more CALMs and all three were siblings with a family history of NF1. For the clinical diagnosis of NF1, a minimum of six CALMs is required to meet the specificity of this criterion (Table 61.3). Although the distinction between CALMs and freckles is generally straightforward, larger lentigines, especially in younger children and infants, can mimic CALMs. Thus, CALMs must be >5 mm in prepubertal individuals and >15 mm in

MAJOR CLINICAL FEATURES OF NEUROFIBROMATOSIS TYPE 1
CUTANEOUS
• Neurofibromas (60–90%) • Café-au-lait macules (>90%) • Axillary and/or inguinal freckling (~80%) • Plexiform neurofibroma (25%)
OCULAR
• Lisch nodules (>90%) • Hypertelorism (25%) • Glaucoma
SKELETAL

• *Cranial*
  • Macrocephaly (20–50%)
  • Sphenoid wing dysplasia (<5%)
• *Spinal*
  • Scoliosis (5–10%)
  • Spina bifida
• *Limbs*
  • Pseudarthrosis (2%)
  • Thinning of long bone cortex
  • Local bony overgrowth
  • Absent patellae

TUMORS
• Optic glioma (10–15%) (with or without precocious puberty) • Malignant peripheral nerve sheath tumors (3–15%) • Pheochromocytoma (~1%) • Juvenile myelomonocytic leukemia (especially in patients with concomitant JXGs) • CNS tumors other than optic gliomas (~5%) • Rhabdomyosarcoma, especially of the genitourinary tract • Duodenal carcinoid • Somatostatinoma • Parathyroid adenoma • Gastrointestinal stromal tumors (GIST) • Breast cancer (~5-fold increased risk in women <50 years of age)
NEUROLOGIC
• Unidentified bright objects (UBO) on MRI (50–75%) • Learning difficulties (30–50%) • Seizures (~5%) • Mental retardation (severe in <5%) • Aqueductal stenosis and hydrocephalus (~2%)
CARDIOVASCULAR
• Hypertension (~30%), mostly essential, some from renal artery stenosis or pheochromocytoma • Pulmonic stenosis (~1%) • Renal artery stenosis (~2%) • Cerebrovascular anomalies (2–5%), including vascular stenoses and aneurysms

Table 61.2 Major clinical features of neurofibromatosis type 1. JXGs, juvenile xanthogranulomas.

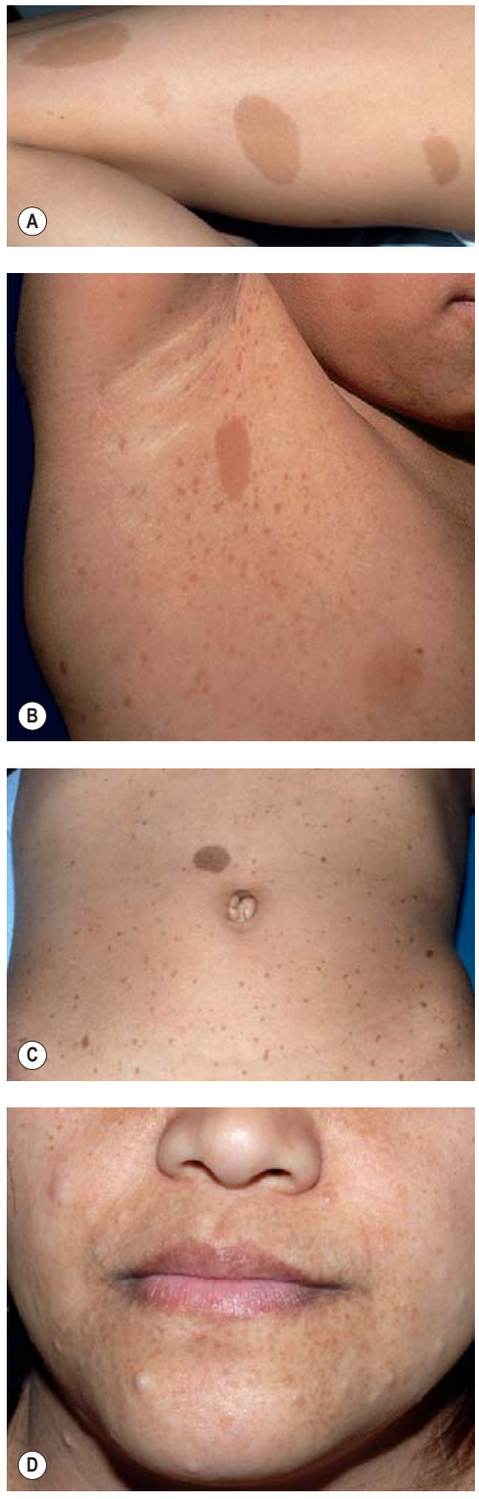

Fig. 61.3 Café-au-lait macules and "freckling". Oval-shaped, light- to medium-brown patches with regular borders and uniform pigmentation (**A**–**C**). Numerous 1–3 mm lentigines are most commonly found in the axillae (Crowe's sign) (**B**) but can also develop in other locations such as the abdomen (**C**) and perioral region (**D**). *A–D, Courtesy, Julie V Schaffer, MD.*

DIAGNOSTIC CRITERIA FOR NEUROFIBROMATOSIS TYPE 1
Two or more of the following must be present: • Six or more café-au-lait macules >5 mm in prepubertal individuals and >15 mm in postpubertal individuals • Two or more neurofibromas of any type or one plexiform neurofibroma • "Freckling" in the axillary or inguinal regions • Optic gliomas • Two or more Lisch nodules (iris hamartomas) • Osseous lesion, such as sphenoid wing dysplasia or thinning of long bone cortex, with or without pseudarthrosis • First-degree relative (parent, sibling or offspring) with NF1 by the above criteria

Table 61.3 Diagnostic criteria for neurofibromatosis type 1.

postpubertal individuals in order to satisfy the diagnostic criterion for NF1.

In its fullest expression, NF1 can manifest as thousands of neurofibromas in an affected individual, hence the appellation *neurofibromatosis* (Fig. 61.4). Several variants of neurofibromas are observed in NF1. Most commonly, proliferations of spindle cells occur within the dermis, leading to *cutaneous* neurofibromas (CNFs). CNFs are skin-colored to pink, tan or brown, dome-shaped or pedunculated papulonodules that are soft or slightly rubbery in texture and can range from a few millimeters to several centimeters in diameter; early lesions, however, may be barely elevated. They invaginate easily with gentle pressure, thereby exhibiting the pathognomonic "buttonhole" sign. Although usually asymptomatic, these soft nodules may become pruritic or, occasionally, irritated. CNFs appear as early as 4–5 years of age but more typically develop around puberty, with occasional acceleration during pregnancy.

Subcutaneous neurofibromas (SNFs) occur deeper in the dermis and subcutis, tending to be firmer and less well-circumscribed than CNFs. Nearly one-fifth of NF1 patients have at least one SNF[37] and

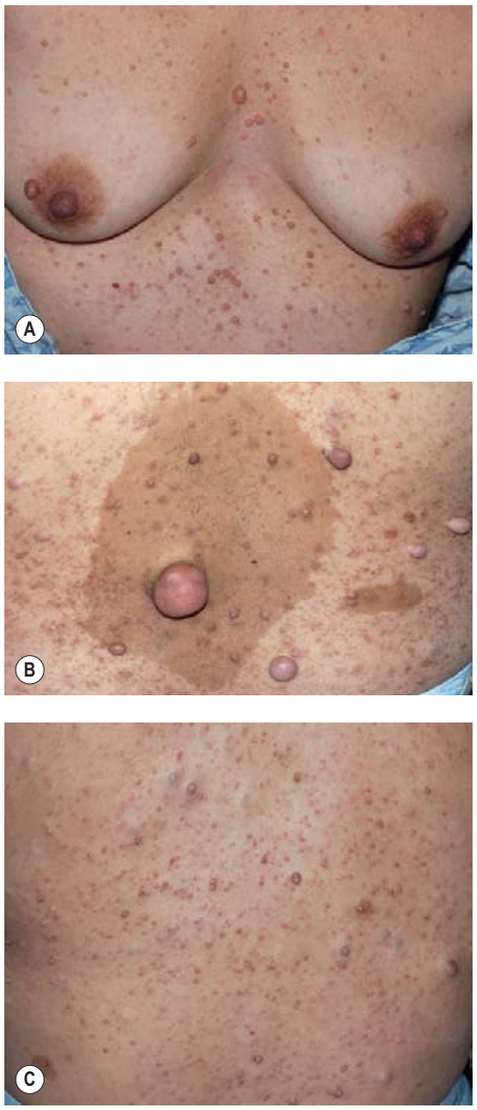

Fig. 61.4 Multiple cutaneous neurofibromas. Soft, skin-colored to pinkish-tan, dome-shaped or polypoid, well-demarcated papules and nodules of various sizes (**A**–**C**) as well as ill-defined violaceous lesions (**C**) can occur in patients with NF1. Neurofibromas may be superimposed on café-au-lait macules and lentigines (**B**, **C**). *A–C, Courtesy, Julie V Schaffer, MD.*

Fig. 61.5 Spectrum of cutaneous neurofibromas. Lesions range from subtle blue–red macules (**A**) to exophytic nodules with associated hypertrichosis (**B**). *Courtesy, Julie V Schaffer, MD.*

one-quarter of these individuals develop tumor-related local complications. Less common cutaneous presentations of neurofibromas in patients with NF1 include: (1) *blue–red macules* due to thick-walled blood vessels as well as neurofibromatous tissue in the papillary dermis (Fig. 61.5); and (2) *pseudo-atrophic macules* due to replacement of collagen in the reticular dermis with neurofibromatous tissue[38].

Plexiform neurofibromas (PNFs) (Fig. 61.6) may track along nerves to create tender, firm nodules or masses (classically resembling a "bag of worms" upon palpation) in the subcutaneous tissue, or they can infiltrate diffusely to involve all layers of the skin, fascia, muscle, or even internal structures. Approximately 25% of NF1 patients have clinically apparent PNFs. These lesions often cause soft tissue and bony hypertrophy, and massive distortion of the head, neck or extremities may result. Impingement upon nerves may lead to neurologic deficits.

Unlike other neurofibromas, PNFs are probably all congenital in origin. Superficial and/or diffuse lesions usually become clinically apparent by the age of 4 or 5 years[25], while deep/internal nodular lesions may remain undetected even in adulthood unless a full-body MRI is performed[39]. Older children without evidence of soft tissue overgrowth related to a PNF are unlikely to develop this finding later in life. Both hyperpigmentation and hypertrichosis can overlie PNFs[40], sometimes leading to misdiagnosis as a congenital melanocytic nevus (see Fig. 61.6).

The transformation of PNFs into malignant peripheral nerve sheath tumors (MPNSTs, also known as "neurofibrosarcomas") occurs in 3–15% of patients with NF1[6,37], with a peak incidence in young adults. The onset of rapid growth, increased firmness or persistent pain within an established PNF or the development of a new neurologic deficit may herald malignant degeneration (see Management section). MPNSTs can be very aggressive and are often fatal[41].

"Freckling" in the axillae (see Fig. 61.3) and groin in NF1 patients was first noted by Crowe[4] and is therefore referred to as "Crowe's sign". Numerous 1–3 mm brown macules (more akin to lentigines than ephelides) typically populate these intertriginous zones, the neck, and, occasionally, the majority of the skin surface (see Figs 61.3 & 61.4). Involvement of the axillae is most common, occurring in about 80% of NF1 patients[37,42]. The lesions usually arise by 4–6 years of age, following the emergence of CALMs but preceding the development of neurofibromas. As a result, intertriginous "freckling" is a useful clinical sign in the evaluation of a young child with multiple CALMs[43].

There are numerous reports of patients with NF1, juvenile myelomonocytic leukemia (JML) and juvenile xanthogranulomas (JXGs). As many as 18% of children with NF1 are diagnosed with one or more JXGs during the first 3 years of life[44], and young children with NF1 also have a 200- to 500-fold greater risk of developing JML (incidence 1/2000–1/5000) compared to the general pediatric population. In 1995, Zvulunov et al.[45] reviewed the world literature and calculated a 30–40-fold higher-than-expected rate of a triple association between NF1, JML and JXG. Based on this, they estimated that the risk of JML in children with NF1 is 20 to 30 times higher if JXGs are present; however, these authors' assumptions and statistical methods have been criticized[44]. Although neurofibromin is known to regulate the proliferation of myeloid cells, the exact etiopathogenesis of the "triple association" remains unclear.

Glomus tumors of the fingers and toes have recently been recognized as a manifestation of NF1, and bialleic inactivation of the *NF1* gene

Fig. 61.6 Plexiform neurofibromas. Clinical presentations include: a hyperpigmented plaque that may be misdiagnosed as a congenital melanocytic nevus or (if not palpated) a café-au-lait macule (**A**); a sharply demarcated reddish-brown plaque (**B**); and a poorly circumscribed, sagging pink mass (**C**). *A–C, Courtesy, Julie V Schaffer, MD.*

Fig. 61.7 Lisch nodules. Multiple yellow–brown papules of the iris.

Fig. 61.8 Segmental neurofibromatosis. A cluster of soft, pink to pink–brown papules limited to the thigh. There were no associated café-au-lait macules. *Courtesy, Jean L Bolognia, MD.*

has been documented within these lesions in NF1 patients[46]. The tumors are often multiple and, like their sporadic counterpart, present with localized tenderness, paroxysmal pain, and sensitivity to cold (see Ch. 114). Focal swelling, ill-defined reddish discoloration (often of the nail bed) and nail dystrophy may be observed.

Pigmented iris hamartomas, or Lisch nodules, begin to develop at about the age of 3 years and occur, in about 90% of NF1 patients who are 20 years of age and older[31,37,47,48]. The lesions are 1–2 mm, dome-shaped, yellow–brown papules that are best seen on slit-lamp examination (Fig. 61.7). Although Lisch nodules are useful in diagnosing NF1, they rarely lead to symptoms or complications.

In segmental NF1 (formerly known as NF5), cutaneous neurofibromas, CALMs and/or "freckling" are present in one or more dermatomes (especially for neurofibromas; Fig. 61.8) or in other mosaic distribution patterns such as along the lines of Blaschko (especially for CALMs and freckling; see Ch. 62). This form of NF1 is a reflection of mosaicism due to a postzygotic mutation in the *NF1* gene. If the mutation involves the gonads (germline mosaicism) as well as the skin, there is a chance of full-blown NF1 in the patient's offspring.

Neurologic manifestations

Optic gliomas occur in up to 15% of children with NF1[49]. The behavior of these CNS neoplasms is variable, ranging from asymptomatic enlargement to progressive visual compromise and proptosis associated with tumor expansion[50]. Precocious puberty occurs in about 3% of children with NF1, most of whom have optic gliomas[51,52]. Non-optic CNS tumors occur in about 5%[42] and pheochromocytomas in about 1% of NF1 patients[25,53].

In MRI studies of the brain, T_2-weighted unidentified bright objects (UBOs) can be observed in 50–75% of children with NF1[54]. These are most commonly seen in the basal ganglia, brainstem and cerebellum. UBOs have been shown to evolve over time[55], and they may contribute to cognitive impairment via thalamocortical dysfunction[56].

Although severe mental retardation is uncommon, learning difficulties occur in 30–50% of affected children[37,57]; there is also an increased likelihood of attention deficit disorder and sleep disturbances. Seizures develop in about 5% of NF1 patients, although no specific cortical lesions have been linked to the abnormal electroencephalographic (EEG) activity[30].

Skeletal manifestations

Macrocephaly[26] and scoliosis[34,57] are the most common skeletal abnormalities seen in individuals with NF1. A highly distinctive but less common finding is pseudarthrosis of the long bones. This is a congenital defect that begins as bowing, especially of the tibia. Eventually, the process erodes the cortex of the bone, leading to pathologic fractures and false joint formation, or pseudarthrosis[25,37]. Sphenoid wing dysplasia is a congenital, typically unilateral, bony defect in the posterior wall of the orbit[37]. This abnormality usually presents with pulsating exophthalmos.

Cardiovascular manifestations

Hypertension is a common finding in NF1 patients. Although essential hypertension is most frequent, renovascular stenosis[58] (especially in children) and unsuspected pheochromocytomas[59] may be the etiology in some patients.

Timing of onset of clinical manifestations

The prevalence of various clinical features in patients with NF1 evolves over the first two decades of life (Fig. 61.9). PNFs and skeletal defects are probably congenital, whereas the CALMs are congenital or become apparent in the first few years of life. Intertriginous "freckling", Lisch nodules, and optic gliomas begin to occur by the school-age years, and multiple CNFs typically start to develop closer to puberty. The National Institutes of Health (NIH) criteria for NF1 are met in 97% of affected individuals by age 8 years and in 100% by age 20 years (see Table 61.3)[31].

Pathology

The CALMs, CNFs and MPNSTs associated with NF1 are histologically similar to their sporadic counterparts. CALMs from affected individuals are characterized primarily by increased epidermal melanin; other nonspecific findings may include a higher number of melanocytes compared to the surrounding skin and giant melanosomes[60].

CNFs feature a well-circumscribed but unencapsulated dermal collection of small nerve fibers and loosely arranged spindle cells; the latter have scanty pale cytoplasm and elongated wavy nuclei (see Ch. 115). These spindle cells represent a mixture of fibroblasts, Schwann cells and perineural cells, and they are set in a collagenous stroma with varying amounts of mucin and scattered mast cells. The nuclei are relatively banal, and mitotic activity should raise a suspicion of malignancy.

PNFs are specific to NF1. Histologically, they are composed of large hypertrophied nerves surrounded by spindle-shaped fibroblasts and Schwann cells embedded in a myxoid matrix (see Ch. 115). In some PNFs, neurofibromatous changes extend diffusely into the papillary and reticular dermis. The stroma may be more collagenous than myxoid, and organoid differentiation may occur, forming structures resembling Meissner's corpuscles.

MPNSTs are comprised of alternating cellular and myxoid areas. The cells (as in neurofibromas) stain positively with S100, but they are much more pleomorphic, with wavy and hyperchromatic nuclei (see Ch. 115). Increased mitotic activity and perivascular whorling of tumor cells are often observed. Areas of bony or cartilaginous differentiation may also be present, along with hyalinized nodules.

Differential Diagnosis

In an affected individual with complete expression of NF1, the criteria set by the NIH Consensus Conference are met[61] (see Table 61.3) and the diagnosis is usually straightforward. In infants, establishing the diagnosis can sometimes be difficult because of the lack of age-dependent features. This is particularly true for children with six or more CALMs but no other findings (NF1 suspect)[62]. An approach to this clinical situation is outlined in Figure 61.10. In a recent series of 110 children (median age 3 years; range, 1 month to 17 years) who presented to a NF1 clinic with CALMs but no other features of NF1, 34/44 (77%) of those with six or more "typical" CALMs (distinct regular borders, uniform pigmentation) eventually met criteria for NF1 (almost all before age 6 years), compared to 2/15 (15%) of those with six or more "atypical" CALMs (smudgy irregular borders, non-homogeneous pigmentation) and 0/51 of those with fewer than six CALMs[63].

Comprehensive testing of the *NF1* gene via a multistep approach (including reverse transcriptase–polymerase chain reaction [RT-PCR], direct sequencing, microsatellite marker analysis, multiplex ligation-dependent probe amplification [MLPA] and interphase fluorescence *in situ* hybridization [FISH]) is clinically available and can identify the underlying mutation in ≥95% of non-founder patients who fulfill the NIH diagnostic criteria, detecting pathogenic splice-site mutations and deletions that are missed by genomic DNA-based sequencing. This allows an accurate diagnosis to be established in young children who do not (yet) meet diagnostic criteria and individuals with atypical clinical presentations. It also makes prenatal or preimplantation diagnosis an option for affected families.

In addition to segmental NF1 (see above), unilateral lentigines in the axilla or groin may be seen in patients with partial unilateral lentiginosis (PUL) or a large speckled lentiginous nevus (nevus spilus)[64]. These segmental conditions are characteristically sharply demarcated at the midline, but bilateral involvement occasionally occurs. PUL and

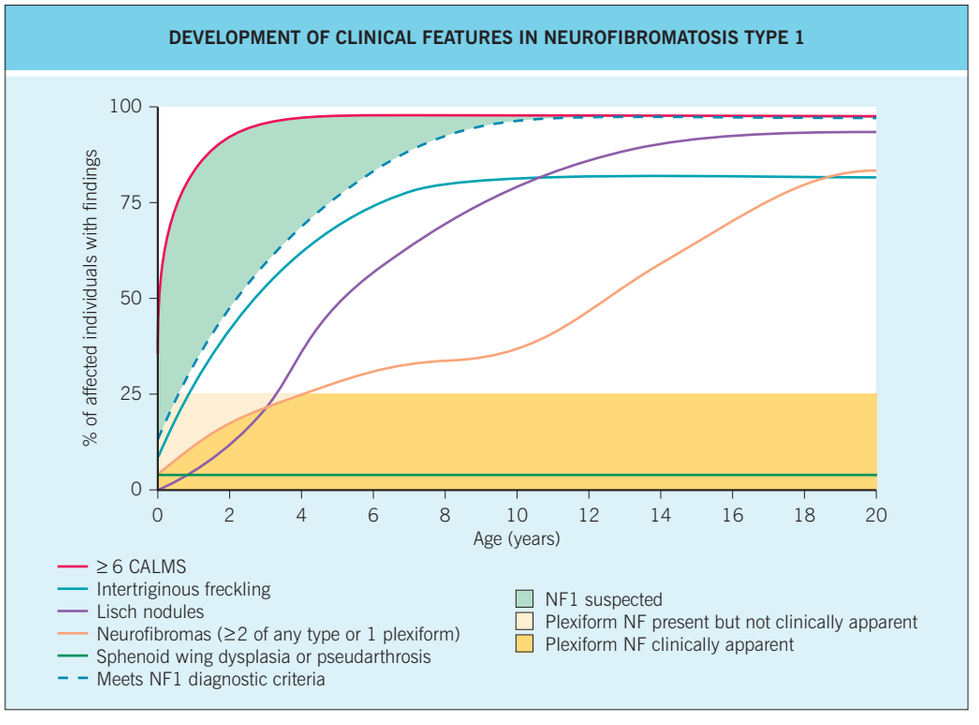

Fig. 61.9 Development of clinical features in neurofibromatosis type 1. The time course of major diagnostic lesions that develop in NF1. During the first few years of life, a child may have only café-au-lait macules. *Adapted from DeBella K, Szudek J, Friedman JM. Use of the National Institutes of Health criteria for diagnosis of neurofibromatosis 1 in children. Pediatrics 2000;105:608–14.*

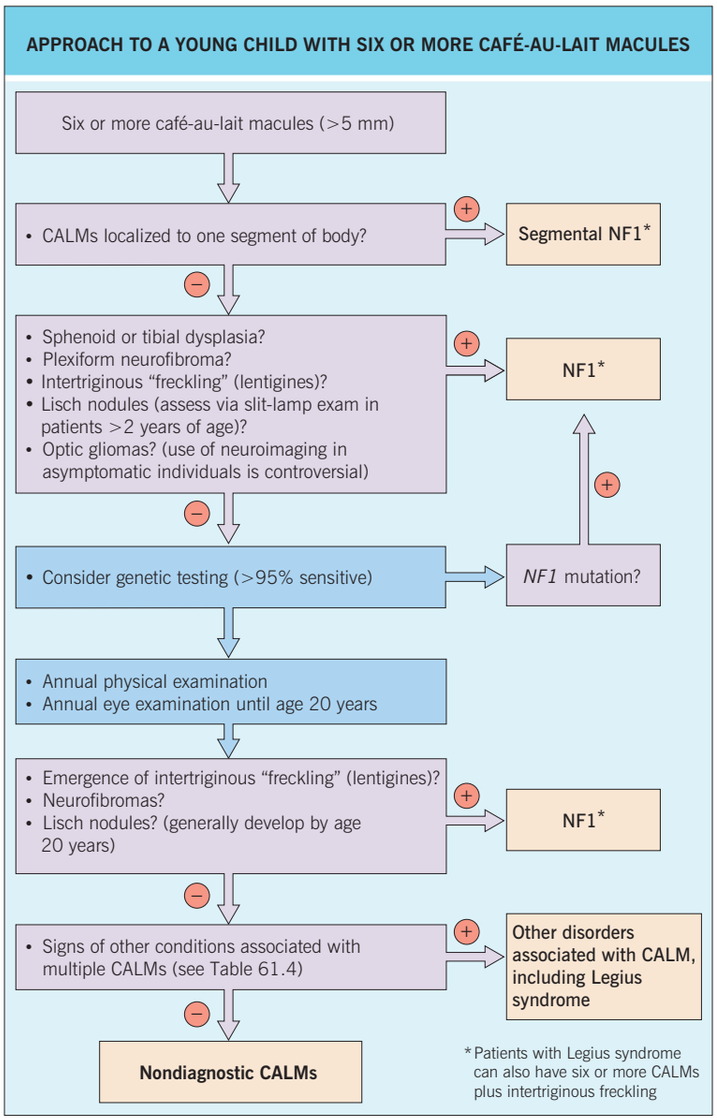

Fig. 61.10 Approach to a young child with six or more café-au-lait macules. More than half of these patients will eventually prove to have NF1 or, less often, one of the other CALM-associated syndromes (see Table 61.4). Although uncommon, the latter should be considered if other NF1 signs do not develop. Genetic analysis for NF1 is commercially available (www.genetics.uab.edu/medgenomics/#testservice).

segmental NF1 can coexist in the same patient[65]. The presence of CALMs in addition to lentigines increases the likelihood of segmental NF1. When individuals suspected of having segmental NF1 do not have a detectable mutation in the peripheral blood, the diagnosis can be confirmed by analyzing the *NF1* gene in melanocytes or Schwann cells cultured from a lesional skin biopsy specimen (e.g. of a CALM or neurofibroma, respectively).

Some patients with a familial tendency to develop multiple "typical" NF1-like CALMs, often in association with intertriginous "freckling", do not develop neurofibromas or Lisch nodules and lack an underlying *NF1* mutation. Recent studies have demonstrated that >70% of such individuals have a heterozygous germline mutation that inactivates the *SPRED1* gene, which encodes a protein that inhibits Ras–Raf interaction and thereby (like neurofibromin) negatively regulates MAPK signaling[66,67]. This autosomal dominant condition, known as *NF1-like syndrome* or *Legius syndrome*, accounts for ~2% of all patients who meet NF1 criteria[67]. Additional disorders associated with multiple CALMs, some caused by other genetic defects that lead to increased MAPK signaling, are presented in Table 61.4.

Historically, neurofibromatosis type 2 (NF2) has been discussed in the context of NF1. However, the clinical manifestations and molecular genetics of NF2 are distinct from those of NF1 (Table 61.5). NF2 is less common and has a lower frequency of cutaneous findings than NF1; Lisch nodules are not a feature of NF2. The tumor upon which a diagnosis of NF2 typically rests is the vestibular schwannoma. In the 1990 diagnostic criteria for NF2, neurofibromas were included as one of the index tumors[68]. However, in a 1997 update, neurofibromas were excluded from the diagnostic criteria for NF2[69]. Mautner et al.[70] found that 60% of NF2 patients had skin tumors, usually schwannomas appearing as flat or spherical nodular subcutaneous tumors of the peripheral nerves on the limbs and trunk. Although one-third of the affected individuals in this series had CALMs, only 2 of 88 patients had six or more CALMs.

McCune–Albright syndrome also features CALMs that are present at birth or become apparent during infancy. Additional manifestations of this sporadic disorder (thought to be lethal unless in a mosaic state) include polyostotic fibrous dysplasia and endocrine hyperfunction (most commonly precocious puberty). Affected tissues harbor an *activating* mutation in the gene encoding $G_s\alpha$ (i.e. the α-subunit of the G protein that stimulates adenylate cyclase), which leads to increased intracellular levels of cyclic AMP. Compared to the CALMs that occur in NF1, those of McCune–Albright syndrome and other forms of "pigmentary mosaicism" are generally larger, have a linear (e.g. broad bands along Blaschko's lines) or segmental distribution pattern, usually do not cross the midline, and have an irregular border that may resemble the "coast of Maine". The most common sites are the head, neck, trunk and buttocks.

PNFs need to be distinguished from congenital melanocytic nevi, especially when they are hyperpigmented with hypertrichosis. It is equally important not to misdiagnose patients with large congenital melanocytic nevi with smaller "satellite" lesions and prominent neurotization as having NF1.

Management

Management of NF1 patients requires a multidisciplinary approach[61,69]; if available, a multispecialty NF clinic can help to optimize care. Dermatologists are often consulted to assist in establishing the diagnosis in affected children. Evaluation of individuals newly diagnosed with NF1 should include a thorough history (personal and family) and physical examination, with particular attention to signs and symptoms of disease manifestations (see Table 61.2). As part of the initial care of NF1 patients, an in-depth educational discussion should include the natural history of the condition, possible medical complications and neurodevelopmental sequelae, and psychosocial considerations; genetic counseling should also be provided. Table 61.6 summarizes recommendations for the evaluation and management of NF1 patients[71,72]. Goals of longitudinal care include early recognition and treatment of complications, maximization of academic and vocational achievement, and minimization of the disease's psychosocial impact.

The cutaneous lesions of NF1 can lead to a variety of age-dependent management issues. PNFs may grow into large, bulky tumors during early childhood. Multidisciplinary teams are often required to excise deep and extensive neurofibromatous tissue, and the lesions tend to recur following surgery. CALMs do not need or respond well to treatment, although it may be desired for cosmetic purposes. When laser therapy is performed, CALMs tend to persist or recur (see Ch. 137). During adolescence and adulthood, removal of CNFs may be indicated for functional or cosmetic reasons. Simple surgical excision is the treatment of choice for selected bothersome lesions; laser ablation or electrocautery can be used to remove numerous small CNFs[73,74], but recurrences are common and hypertrophic scarring may develop.

Lifelong surveillance for the development of MPNSTs is essential, particularly for patients at increased risk of this malignancy due to the known presence of PNFs, polyneuropathy secondary to multiple nerve root tumors, a history of radiation therapy (with reports of MPNSTs arising in the radiation field), or a germline *NF1* microdeletion[39]. An increase in the growth rate, firmness, pain or neurologic symptoms associated with a PNF merits further evaluation. ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography/computed tomography (PET/CT) can aid in the early detection of malignant change within PNFs[75]. Based on the largest study to date, histologic evaluation has been recommended for symptomatic lesions with a maximum standardized uptake value (SUVmax) of ≥3.5 on delayed imaging (4 hours after ^{18}F-FDG injection)[76].

Targeted medical treatments that are currently under investigation in NF1 patients include imatinib mesylate (a potent inhibitor of the

DISORDERS ASSOCIATED WITH MULTIPLE CAFÉ-AU-LAIT MACULES	
Disorder	**Notes**
NEUROFIBROMATOSIS AND RELATED DISORDERS	
Neurofibromatosis 1 (NF1)	AD; six or more CALMs in >90% of patients; mutations in *NF1* gene; see text
Neurofibromatosis 2	AD; six or more CALMs in minority of patients; mutations in *NF2* gene; see Table 61.5
Segmental NF1 (neurofibromatosis 5)	CALMs ± "freckling" in a block-like distribution or following Blaschko's lines; occasionally also neurofibromas; reflects mosaicism due to a postzygotic *NF1* mutation, which may involve the gonads in some patients
Legius (NF1-like) syndrome	AD; six or more CALMs in >80% and intertriginous "freckling" in ~50% of patients; lack neurofibromas, Lisch nodules, optic gliomas and typical osseous lesions of NF1; macrocephaly and learning disabilities are common; lipomas, hypopigmented macules and vascular anomalies in small minority; loss-of-function mutations in *SPRED1* gene, the protein product of which inhibits MAPK signaling
Watson syndrome	AD; short stature; pulmonic valve stenosis; MR; may also have Lisch nodules, axillary/inguinal freckling, and neurofibromas; allelic with NF1; 60/100*
Noonan syndrome	AD; short stature; pterygium colli; characteristic facies; cardiac defects, esp. pulmonic valve stenosis; skeletal and testicular abnormalities; keratosis pilaris atrophicans; lymphedema; nevi; activating mutations in *PTPN11* (allelic with LEOPARD syndrome) > *SOS1, RAF1* > *KRAS, NRAS*; patients with an NF1–Noonan overlap phenotype have mutations in *NF1* gene
Cardio-facio-cutaneous syndrome	AD; short stature; characteristic facies; low-set ears; cardiac defects; MR; sparse curly hair; dry skin to generalized ichthyosiform eruption; activating mutations in MAPK pathway genes – *BRAF* > *MEK1, MEK2* > *KRAS*
Jaffe–Campanacci syndrome	Disseminated non-ossifying fibromas of long and jaw bones; hypogonadism or cryptorchidism; MR; giant cell granulomas (jaws)
Juvenile xanthogranulomas + multiple CALMs	Juvenile myelomonocytic leukemia in some patients; association usually (but not always) occurs in the setting of NF1
Constitutional mismatch repair deficiency syndrome (childhood tumor syndrome with NF1 phenotype; Turcot syndrome type 1)	AR; multiple CALMs, axillary freckling, neurofibromas and/or CNS gliomas (i.e. features similar to NF1) as well as hypopigmented macules, hematologic malignancies and colorectal carcinoma; patients have mutations in both copies of a DNA mismatch repair gene, e.g. *MLH1, MSH2, MSH6, PMS2*; hereditary non-polyposis colorectal cancer (HNPCC) syndrome can occur in heterozygotes
McCune–Albright syndrome	Not inherited; presumably lethal unless in mosaic state; polyostotic fibrous dysplasia; hyperfunction of endocrine glands, esp. gonads (e.g. precocious puberty); CALMs usually appear during infancy and can overlie bony changes; CALMs classically end at midline, but so can larger CALMs of NF; CALMs may follow Blaschko's lines; activating mutations in the *GNAS1* gene that encodes $G_s\alpha$; 35/100*
DISORDERS WITH ADDITIONAL CUTANEOUS FINDINGS	
Tuberous sclerosis (TS)	AD; MR; seizures; hypopigmented macules; angiofibromas; fibrous plaques; mutations in *TSC1* and *TSC2* genes; see text
Westerhof syndrome†	AD; congenital hypopigmented macules; MR; growth retardation; ?forme fruste of TS
Piebaldism	AD; CALMs in involved as well as uninvolved skin; mutations in *KIT* proto-oncogene
Familial progressive hyper- and hypopigmentation	AD; CALMs of variable sizes admixed and overlapping with lentigines and hypopigmented macules and patches; activating mutations in *KITLG* gene
Mukamel syndrome	AR; premature graying (infancy); lentigines; depigmented macules; MR; spastic paraparesis, microcephaly, scoliosis
LEOPARD syndrome	Called café noir macules because of dark color; mutations in *PTPN11*; 38/100*
Partial unilateral lentiginosis	Agminated lentigines; debatable if associated neurologic or psychiatric problems; unilateral axillary freckling and Lisch nodules have been described (such patients may actually have segmental NF1)
Bannayan–Riley–Ruvalcaba syndrome‡	AD; penile lentigines; vascular malformations; lipomas; intestinal hamartomas; macrocephaly; mutations in *PTEN* gene; ≤10% of patients have CALMs
Cowden disease‡	AD; multiple trichilemmomas; cobblestoning of oral mucosa; palmoplantar keratoses; sclerotic fibromas, hamartomas and carcinoma of breast, thyroid, colon; mutations in *PTEN* gene; ≤10% of patients have CALMs
Gastrocutaneous syndrome†	AD; peptic ulcer/hiatal hernia; multiple lentigines; hypertelorism; myopia
Ataxia–telangiectasia	AR; telangiectasias of conjunctivae, head/neck, and acral sites; premature canities; cerebellar ataxia; abnormal DNA repair; lymphomas and leukemias; immunodeficiency; sinopulmonary infections; mutations in *ATM* gene; 20/100*
Bloom syndrome	AR; telangiectatic erythema of face; photosensitivity; growth retardation; increased sister chromatid exchanges; malignancies; hypogonadism; mutations in *BLM* gene that encodes the RecQ protein-like-3 DNA helicase
Fanconi anemia	AR; generalized hyperpigmentation, esp. flexural ± guttate "hypopigmented" macules; pancytopenia; skeletal malformations, e.g. aplasia radii; chromosomal fragility and malignancies, e.g. acute myelogenous leukemia
Chromosomal anomalies/ mosaicism	In particular, ring chromosomes (7, 11, 12, 15, 17); rearrangements of 7 and 14; ring 7 also associated with vascular lesions (hemangiomas and capillary malformations) and congenital melanocytic nevi
Extensive epidermal and sebaceous nevi	Sporadic; "syndrome" includes seizures, MR, musculoskeletal and ocular abnormalities; hypophosphatemic vitamin D-resistant rickets
Multiple endocrine neoplasia 1	AD; tumors of the pituitary, parathyroid, and pancreatic islet cells; multiple facial angiofibromas, collagenomas, lipomas; *MEN1* gene
Multiple endocrine neoplasia 2B	AD; mucosal neuromas; marfanoid habitus; medullary thyroid carcinoma; intestinal ganglioneuromatosis; pheochromocytoma; mutations in *RET* proto-oncogene
Johnson–McMillin syndrome	Probable AD; alopecia; anosmia; deafness; hypogonadism; microtia

*Estimates of prevalence of CALMs[62].
†To date, observed in a single family.

KEY FEATURES OF NEUROFIBROMATOSIS 2
• Autosomal dominant transmission; affects approximately 1 in 40 000 individuals • Approximately half of the cases are due to *de novo* mutations rather than inherited germline mutations (similar to NF1) • Bilateral vestibular schwannomas, meningiomas and spinal tumors • Two-thirds of patients develop cutaneous schwannomas, and approximately 50% develop café-au-lait macules (CALMs), but fewer in number compared to NF1* • No Lisch nodules or mental retardation/learning disabilities • *NF2* gene is located on chromosome 22q12 and encodes a cytoskeleton-associated protein of ~600 amino acids named merlin/neurofibromin 2, which is structurally related to the ERM (ezrin-radixin-moesin) protein family of membrane-cytoskeleton linkers
*In two large series of patients with NF2 (n = 161), only two individuals had more than five CALMs of the required size to meet NF1 criteria and over half of those with any CALMs had only one (41 of 72).

TUBEROUS SCLEROSIS

Synonyms: ■ Tuberous sclerosis complex (TSC) ■ Bourneville disease ■ Epiloia (*e*pilepsy, *l*ow *i*ntelligence, *a*ngiofibroma)

Key features

- Tuberous sclerosis is an autosomal dominant disorder with an incidence of approximately 1 in 10 000 births
- Key cutaneous features include hypopigmented macules, facial angiofibromas, collagenomas, and periungual fibromas
- The characteristic oral findings are gingival fibromas and dental enamel pits
- Hamartomas can be found in the eye as well as several internal organs, including the brain, kidneys, heart and lungs
- Seizures, mental deficits and neuropsychiatric disturbances are common
- Up to 75% of cases are due to new spontaneous mutations
- Mutations have been identified in two genes: *TSC1* and *TSC2*; their protein products are hamartin and tuberin, respectively

EVALUATION AND MANAGEMENT OF NEUROFIBROMATOSIS 1 (NF1) PATIENTS
AT TIME OF DIAGNOSIS AND ANNUALLY DURING CHILDHOOD AND ADOLESCENCE (UNLESS OTHERWISE INDICATED)
Dermatologic examination (especially if a plexiform neurofibroma [PNF] is present) • Surgical consultation if painful or disfiguring neurofibromas • PET/CT if rapid growth, increased firmness or persistent pain within an established PNF or the development of a new neurologic deficit* Ophthalmologic examination with visual assessment (prior to age 8 years) • Orbital/brain MRI if signs/symptoms of optic glioma Evaluation for scoliosis (also initial evaluation for tibial bowing) • Referral to orthopedics if scoliosis develops Neurologic examination, developmental/behavioral evaluation, and (in young children) measurement of head circumference • Orbital/brain and/or spinal MRI if neurologic signs/symptoms develop[†] • Comprehensive developmental assessment prior to starting school and if problems arise Cardiac assessment and measurement of blood pressure • Referral to cardiology if murmur is detected • Renal arteriography and 24-hour urine collection for catecholamines and metanephrines if hypertension develops Assessment for pubertal development • Orbital/brain MRI and referral to endocrinology if precocious puberty develops
MINIMUM ANNUAL EVALUATION FOR ADULTS WITH UNCOMPLICATED DISEASE
Dermatologic evaluation if PNF is present • PET/CT for indications described above Neurologic examination (especially if a PNF is present) • MRI and/or other studies as indicated if neurologic signs/symptoms develop Measurement of blood pressure • Evaluation as described above if hypertension develops In women, screening for breast cancer with clinical examination + mammography ± MRI (beginning by age 40 years)
POTENTIALLY AFFECTED FAMILY MEMBERS
Dermatologic examination for cutaneous manifestations of NF1 Ophthalmologic examination for Lisch nodules Consider genetic testing if a mutation has been identified in the proband
*Immediate assessment is required for any of these findings. [†]The role of neuroimaging in asymptomatic patients is controversial.

Table 61.6 Evaluation and management of neurofibromatosis 1 (NF1) patients. CT, computed tomography; MRI, magnetic resonance imaging; PET/CT, positron emission tomography/computed tomography.

Introduction

Tuberous sclerosis (TS) is an autosomal dominant disorder characterized by seizures, mental retardation and skin findings, including congenital hypomelanotic macules and facial angiofibromas. As with NF1, cutaneous lesions are often the initial clinical features, and, dermatologists are routinely called upon to assist in the diagnosis of TS.

History

During the mid-1800s, Virchow recognized scleromas in the brain and von Recklinghausen described a similar patient with both scleromas and myomata in the heart[37]. Between 1880 and 1900, Bourneville provided the first systematic descriptions of the disease, including neural and cutaneous findings. Vogt posited the classic triad of epilepsy, low intelligence and angiofibromas (termed the Vogt triad) in 1908, and Sherlock coined the term "epiloia" a few years later. In 1920, van der Hoeve described the significance of retinal hamartomas, which he termed "phakomas" (hence the designation "phakomatosis")[78]. At that time, examination of the ocular fundi was the only external access to the CNS before death.

Epidemiology

TS has an incidence of approximately 1 in 10 000 births, and the overall prevalence is estimated to be between 1 in 10 000 and 1 in 30 000[79,80].

Pathogenesis

TS is a hamartomatous condition characterized by disordered cellular proliferation, migration and differentiation. It has an autosomal dominant pattern of inheritance. However, the majority of affected individuals have new spontaneous mutations.

In the 1980s, TS kindreds from around the world were analyzed and the disease locus was mapped to chromosome 9q34 in a subset of affected families. Further study led to the discovery of a second disease locus on chromosome 16p13[81]. In 1994, Povey et al.[82] studied 32 TS families and found that about half demonstrated linkage to chromosome 9q34 (*TSC1*), whereas the other half showed linkage to chromosome 16p13 (*TSC2*).

In 1993, the *TSC2* gene on chromosome 16 was identified and found to be deleted or mutated in the subset of TS families linked to this region[83]. *TSC2* is composed of 41 small exons that encode an 1807 amino acid, 200 kDa protein referred to as tuberin. Like neurofibromin, tuberin contains a GAP domain (Fig. 61.11). Tuberin stimulates the GTPase activities of Rab5, a protein involved in endocytosis[84], and Rheb, a Ras-related protein that activates the mTOR pathway. By "turning off" Rheb, tuberin inhibits the cell growth and proliferation that result from mTOR signaling. The latter is a central regulator of cellular responses to nutrition, energy levels, and a variety of growth factors.

Despite its earlier localization, the *TSC1* gene was identified after *TSC2*[85]. The *TSC1* gene consists of 23 exons that encode a 130 kDa protein termed hamartin. Hamartin shares no sequence homology with tuberin or any other known tumor suppressor gene. However, hamartin interacts with tuberin[86] and other cytoskeletal components, and it functions together with tuberin to negatively regulate mTOR signaling (see Fig. 61.11)[87,88].

In large series of TS patients, *TSC2* mutations have been identified more frequently than *TSC1* mutations, with an overall ratio of approximately 3 : 1[89,90]. Individuals with *TSC2* mutations tend to have a more severe phenotype than those with *TSC1* mutations. There is a more equal proportion of *TSC2* and *TSC1* mutations in familial cases of TS, and among patients with *TSC2* mutations, familial cases tend to have a milder phenotype than *de novo* cases[89,90]; these findings may reflect a decreased likelihood of reproduction in more severely affected individuals. Some patients with mild sporadic TS are mosaics for a mutation in *TSC1* or *TSC2*. If such patients have gonadal involvement, they may pass on more severe disease to their offspring.

In mouse models, heterozygous Tsc1 mutant ($Tsc1^{+/-}$) mice develop renal and extrarenal tumors such as hepatic hemangiomas with loss of the wild-type *Tsc1* allele. Homozygous Tsc1 mutants ($Tsc1^{-/-}$) die during the embryonic period, frequently with evidence of lack of closure of the neural tube[91]. Heterozygous Tsc2 mice ($Tsc2^{+/-}$) display a high incidence of multiple bilateral renal cystadenomas, liver hemangiomas and lung adenomas. Progression to renal carcinoma, fatal bleeding from the liver hemangiomas, and angiosarcomas are occasionally observed. Like *Tsc1*-null mice, *Tsc2*-null ($Tsc2^{-/-}$) mice die during the embryonic period, but the cause is hepatic hypoplasia[92]. More recently, $Tsc2^{+/-}$ mice were shown to have abnormalities in learning and memory that were associated with hyperactive hippocampal mTOR signaling. Treatment of adult mice with the mTOR inhibitor rapamycin resulted in improved cognitive function. Whether similar results would be observed in humans awaits further study[93].

Clinical Features

As with NF1, the diagnosis of TS often involves a dermatologist, as some of the earliest findings of TS appear on the skin (Table 61.7).

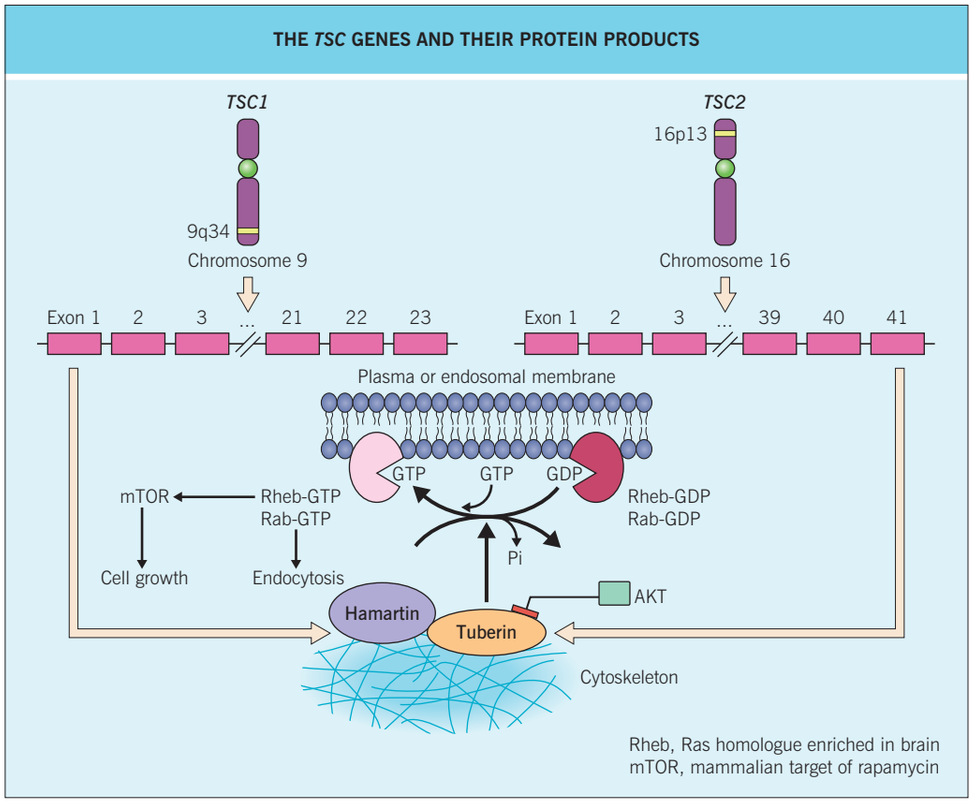

Fig. 61.11 The *TSC* genes and their protein products. *TSC1* and *TSC2* are located on chromosomes 9q34 and 16p13, respectively. The *TSC1* product, hamartin, interacts with the *TSC2* product, tuberin, and negatively regulates signaling by the small GTPases Rab and Rheb. Like Ras, the activity of Rab and Rheb is dependent upon bound GTP, and tuberin (like neurofibromin) accelerates hydrolysis of GTP to GDP in order to turn off Rab and Rheb. AKT, human homologue of the murine AKT8 retrovirus transforming sequence.

MAJOR CLINICAL FEATURES OF TUBEROUS SCLEROSIS
CUTANEOUS
• Facial angiofibromas (~80%) and fibrous plaque of the forehead (~20%)
• Hypomelanotic macules (90–100%) – polygonal; lance-ovate (ash leaf); confetti
• Shagreen patch (40–50%)
• Periungual fibromas (30–60%)
• Molluscum pendulum
• Café-au-lait macules
OCULAR
• Retinal hamartomas (~40%)
• Achromatic retinal patches (~40%)
• Retinal astrocytoma
SKELETAL
• Cystic areas of bone rarefaction, especially phalanges
DENTAL
• Pitted enamel (>90%)
• Gingival fibromas (up to 70%)
PULMONARY
• Lymphangioleiomyomatosis (~30% of women)
RENAL
• Multiple bilateral angiomyolipomas (75–90%)
• Cysts
• Carcinoma
ENDOCRINE
• Precocious puberty
• Hypothyroidism
NEUROLOGIC
• Seizures (70–95%)*
• Subependymal nodules (>80%)†
• Cortical tubers (>90%)
• Infantile spasms (~70%)
• Mental retardation
• Intracranial calcification on plain radiography or CT
• Giant cell astrocytoma
CARDIOVASCULAR
• Myocardial rhabdomyoma‡ (80%)
• Wolff–Parkinson–White syndrome
*Includes infantile spasms.
†Nearly all patients by puberty.
‡Increasingly difficult to distinguish from normal myocardium as patient ages.

Table 61.7 Major clinical features of tuberous sclerosis.

Oculocutaneous manifestations

The time course for developing the cutaneous findings of TS is shown in Figure 61.12. The hypomelanotic macules are not depigmented (as in vitiligo) but instead are hypopigmented (Fig. 61.13). A Wood's light can help to diagnose these lesions, which may be very subtle in children with lightly pigmented skin. The macules are usually present at birth or within the first few months of life, although their appearance is sometimes delayed until early childhood in individuals with fair skin). They may adopt several configurations, and small (<2 cm) polygonal or "thumbprint"-shaped macules are most common[94]. The lance-ovate hypopigmented macule or "ash leaf spot" (named after the Eastern Mountain ash tree) is rounded at one end and tapered at the other, and it can range from 1 to 12 cm in size. Although less frequent than polygonal macules, ash leaf spots are quite characteristic of TS.

More than 90% of TS patients have more than one hypomelanotic macule[95], and some have over 100 lesions. Scores of small (1–2 mm), "guttate" hypopigmented macules (also known as "white freckles" or "confetti" macules) may also be seen, especially on the extremities (Fig. 61.14). Although these guttate lesions occur in less than 5% of affected infants, they are probably the most specific pigmentary manifestation of TS[94,95]. Areas of poliosis are also occasionally observed in infants with TS.

Approximately 1–4% of healthy infants and children have a circumscribed hypopigmented macule or patch, i.e. a nevus depigmentosus[94,96,97]. Debard and Richardet[96] examined the skin of 9737 infants aged 1–18 months and found that 0.7% had one or two white spots that were larger than 1 cm; however, no unaffected infant had more than three spots. Thus, three or more hypomelanotic macules was chosen as a major criterion for the clinical diagnosis of TS (Table 61.8).

Café-au-lait macules (CALMs) have been reported in up to 30% of patients with TS and are usually present within the first few months of life[94,95]. Most TS patients, however, have fewer than the six CALMs required to diagnose NF1.

Angiofibromas (previously referred to as "adenoma sebaceum"), which are not typically present at birth, start to appear in the centrofacial area as early as the first 2 years of life and develop by adolescence in approximately 80% of TS patients. The lesions may begin with mild erythema of the cheeks and forehead and then mature into pink to red or red–brown papules or papulonodules, which may coalesce into plaques. The papules are often dome-shaped and have a smooth, shiny surface (Fig. 61.15). With the exception of individuals with mosaic TS, facial angiofibromas have a bilateral and symmetric distribution.

A larger variant of the angiofibroma, the fibrous plaque of the forehead, can be seen in about 20% of TS patients[95]. The forehead plaques are usually firm and yellow–brown to pink–tan in color (see Fig. 61.15). They grow very slowly over time.

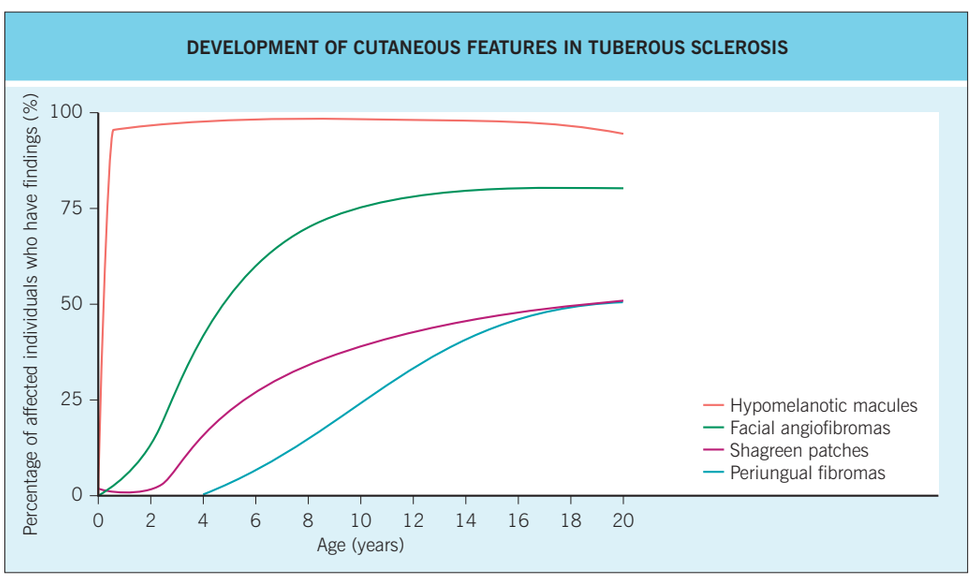

Fig. 61.12 Development of cutaneous features in tuberous sclerosis. Hypomelanotic macules are usually the only cutaneous finding at birth.

DIAGNOSTIC CRITERIA FOR TUBEROUS SCLEROSIS COMPLEX
MAJOR FEATURES
Facial angiofibromas or forehead plaque
Non-traumatic ungual or periungual fibromas
Hypomelanotic macules (three or more)
Shagreen patch (connective tissue nevus)
Multiple retinal nodular hamartomas
Cortical tubers
Subependymal nodules
Subependymal giant cell astrocytoma
Renal angiomyolipoma
Cardiac rhabdomyoma, single or multiple
Lymphangioleiomyomatosis
MINOR FEATURES
"Confetti" hypopigmented skin lesions
Multiple, randomly distributed pits in dental enamel
Gingival fibromas
Retinal achromic patch
Cerebral white matter radial migration lines
Multiple renal cysts
Hamartomatous rectal polyps
Bone cysts
Non-renal hamartoma
Definite tuberous sclerosis
• Either two major features *or* one major feature plus two minor features
Probable tuberous sclerosis
• One major plus one minor feature
Possible tuberous sclerosis
• Either one major feature *or* two or more minor features
Key:
Cutaneous *Extracutaneous*

Table 61.8 Diagnostic criteria for tuberous sclerosis complex[98].

Fig. 61.13 Ash leaf macule in a child with tuberous sclerosis.

Fig. 61.14 Guttate leukoderma of tuberous sclerosis. Multiple 1–2 mm hypopigmented "confetti" macules.
Courtesy, Jean L Bolognia, MD.

Fig. 61.15 Facial angiofibromas and fibrous plaques. Multiple shiny, dome-shaped papules on the cheeks and nose of two adolescents. Fibrous plaques can occur on the cheek (**A**) as well as on the forehead (**B**).
B, Courtesy, Julie V Schaffer, MD.

A characteristic truncal lesion is the shagreen ("leather") patch, which represents a connective tissue nevus. These occur most commonly in the lumbosacral area and typically begin to develop at around 2 years of age (although they occasionally become apparent earlier), eventually affecting approximately half of TS patients[95]. Clinically, they appear as skin-colored, hyperpigmented or (occasionally) hypopigmented plaques that can reach up to 10 cm in diameter and often have an uneven surface (Fig. 61.16). Multiple lesions may be present. A distinctive feature is prominent, but slightly depressed, follicular openings, giving rise to a pigskin-like appearance.

Periungual papules or nodules (Koenen tumors; Fig. 61.17) begin to develop later in childhood and can continue to form throughout adulthood. These fibromas are seen more commonly around the toenails than the fingernails, and some lesions lead to distortion of the nail plate (e.g. a longitudinal groove) without a visible tumor. Soft, pedunculated, skin-colored papules and nodules (molluscum pendulum) can also be seen in some TS patients. These lesions favor flexural areas, such as the neck, axillae and groin, and resemble large acrochordons.

Fig. 61.16 Connective tissue nevi (shagreen patches) in tuberous sclerosis. These plaques can be hyperpigmented (**A**) or hypopigmented (**B**) relative to the patient's background skin. The surface is said to resemble leather or pigskin. *A, Courtesy, Julie V Schaffer, MD.*

Fig. 61.17 Periungual fibromas of tuberous sclerosis. Multiple fibromas of the toes arising in a periungual location.

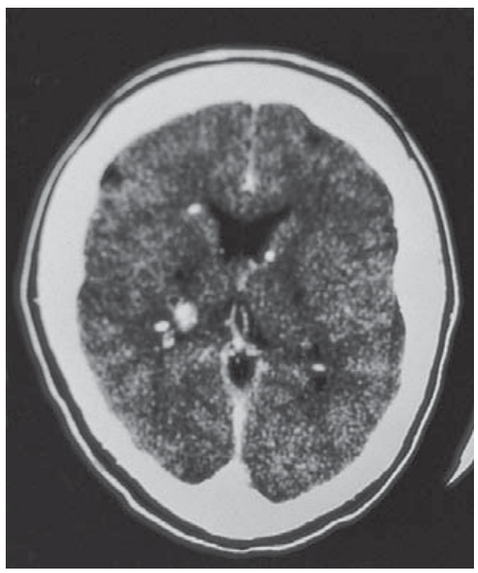

Fig. 61.19 Cranial CT demonstrating multiple calcified subependymal nodules in a paraventricular location. *Courtesy, Jean L Bolognia, MD.*

Gingival fibromas have been described in 10–70% of affected individuals[94,99]. Enamel pits are seen in nearly all TS patients and (upon close examination) in 70% of unaffected individuals; however, in one study, 70% of TS patients had more than 14 pits, compared with less than 5% of controls[100]. Thus, the presence of many enamel pits is suggestive of TS.

Retinal lesions are present in about half of TS patients, with retinal hamartomas seen in approximately 40% (Fig. 61.18). The most common morphologic type of hamartoma is the flat, translucent lesion (70%), followed by the multinodular "mulberry" lesion (55%) and the transitional-type lesion (9%). Punched-out areas of retinal depigmentation can also be found in about 40% of affected individuals[101]. Most ocular lesions in TS patients do not lead to visual loss.

Neurologic manifestations

Infantile spasms occur in approximately 70% of infants with TS. They are characterized by massive flexion or extension of the limbs, trunk and head lasting from a fraction of a second to 3 seconds, occurring in series separated by intervals of a few seconds, for periods of several minutes. These spasms typically begin at about 3 months of age, as opposed to other types of TS-associated seizures, which usually develop after 1 year of age[102]. The EEG changes seen in this setting have been termed hypsarrhythmia[102,103].

Mental deficits occur with a high frequency in children and adults with TS[102,103]. Other neuropsychiatric disturbances, including autism, attention deficit disorders and psychoses, are also common[104–106].

Multiple calcified subependymal nodules along the ventricular surface can be seen on CT scan (Fig. 61.19) in over 80% of TS patients under the age of 2 years. These nodules can be found in essentially all patients by puberty[107]. Occasionally, subependymal giant cell astrocytomas develop that can resemble these more benign nodules. However, additional radiographic characteristics and clinical behavior over time (astrocytomas tend to enlarge, whereas nodules remain stable) are helpful in distinguishing between the two types of lesions[98]. Multiple cortical tubers (an abnormal growth of neuronal and glial cells), which were once thought to be pathognomonic for TS, can also be detected by neuroimaging (e.g. MRI) in the vast majority of patients[107].

Cardiovascular manifestations

Cardiac rhabdomyomas, which can be detected prenatally as well as after birth by echocardiography or MRI, are found in over 80% of infants with TS[107]. However, cardiac rhabdomyomas tend to involute during the first 3 years of life[108], and they often disappear altogether by adulthood. Arrhythmias, especially Wolff–Parkinson–White syndrome, appear to be more common in affected individuals[109].

Renal manifestations

Multiple bilateral angiomyolipomas are frequently noted on routine renal ultrasounds of TS patients. Most of these lesions are asymptomatic, especially during childhood and when they measure less than 4 cm in diameter[108]. Children with TS who develop severe renal cysts often have a contiguous gene syndrome in which both *TSC2* and the polycystic kidney disease (*PKD*) genes are lost in a single large chromosomal deletion[110]. Occasionally, renal cell carcinomas develop in TS patients.

Other manifestations

Although once thought to be rare, pulmonary lymphangioleiomyomatosis is often asymptomatic and occurs in up to one-third of women with TS. On high-resolution CT scan, these lesions appear as cysts. Men rarely develop this manifestation of TS[111], and estrogen is suspected to be involved in stimulating growth of smooth muscle cells in the lung. Hamartomatous polyps in the gastrointestinal tract have also been reported in affected individuals[112,113].

Pathology

Hypopigmented macules have a reduction in the amount of epidermal melanin but a normal number of melanocytes. The melanocytes have poorly developed dendrites[114]. On electron microscopy, small, immature melanosomes are seen whose number, degree of melanization and transfer to keratinocytes are reduced[114–116].

Angiofibromas consist of an irregular proliferation of fibrous tissue and blood vessels. Expansion of the hamartomatous process can lead to compression of adnexae. Characteristically, there is perifollicular concentric fibrosis. Sebaceous glands are normal in size and number but are often prominent in the background facial skin, especially after puberty.

The *shagreen patch* (Fig. 61.20) and *periungual fibromas* represent collagenomas. The dermis is replaced by thick bundles of collagen, and elastin fibers are typically absent. The fibroblasts may be large and morphologically atypical.

Differential Diagnosis

Prior to 1998, a diagnosis of TS could be rendered with a single primary feature (facial angiofibromas, periungual fibromas, cortical tubers, subependymal nodule or astrocytoma, multiple calcified subependymal nodules, or multiple retinal hamartomas). However, debate regarding the specificity of TS-related findings led to a revision of the diagnostic criteria for TS complex in 1998 (see Table 61.8)[98]. Four of the major features are cutaneous, and a thorough dermatologic examination frequently helps to establish the diagnosis. Although seizures occur in the majority of affected infants, the possibility of TS is often considered in asymptomatic infants with multiple hypomelanotic macules. An approach to this clinical situation is outlined in Figure 61.21. Echocardiography can be helpful in establishing the diagnosis in infants and is easier to perform in this age group than cranial CT or MRI studies to detect CNS lesions.

Comprehensive genetic testing (including sequencing and duplication/deletion analysis) is clinically available and can identify a mutation in the *TSC1* or *TSC2* gene in approximately 85% of individuals who meet criteria for TS. TS patients without a detectable mutation may be mosaics or have an unusual mutation in a non-coding region, and they tend to have relatively mild disease.

Multiple facial angiofibromas, collagenomas, gingival papules, confetti-like hypomelanotic macules and CALMs can occur in patients with multiple endocrine neoplasia type 1 (MEN 1; see Ch. 63)[117]. The overlap in cutaneous phenotype suggests that the protein product of the *MEN1* gene may affect the same pathways (e.g. mTOR signaling) as tuberin and hamartin. Multiple facial angiofibromas have also been observed in adults with Birt–Hogg–Dubé syndrome (see Ch. 111).

As discussed above, a nevus depigmentosus represents a common cause of a congenital hypopigmented macule or patch, and some infants have more than one of these lesions. A larger nevus depigmentosus that has a segmental distribution (also referred to as segmental pigmentation disorder) or follows Blaschko's lines may be composed of multiple hypopigmented macules and patches but in one region of the body. Piebaldism presents with congenital leukoderma, and vitiligo occasionally develops soon after birth. Piebaldism can usually be easily distinguished by its distribution (midportions of the extremities and mid-abdomen), the presence of normal and hyperpigmented "islands" within the areas of leukoderma, and chalk-white depigmentation (rather than hypopigmentation as in TS) due to an absence of melanocytes within affected areas. In vitiligo there is also depigmentation due to an absence of melanocytes. Postinflammatory hypopigmentation (e.g. from atopic or seborrheic dermatitis) is a frequent cause of acquired hypopigmented macules in infants; a history of preceding erythema or roughness can usually be elicited. Idiopathic guttate hypomelanosis

EVALUATION AND MANAGEMENT OF TUBEROUS SCLEROSIS (TS) PATIENTS
NEWLY DIAGNOSED
Neurodevelopmental and behavioral evaluation (especially for children)
Ophthalmologic examination
Cranial CT or MRI*
Electroencephalogram (EEG; only if history of seizures)
Electrocardiogram (ECG)
Echocardiography (if cardiac symptoms or ECG abnormalities; also generally done in children <5 years of age)
Renal ultrasonography to detect polycystic kidney disease (and angiomyolipomas)
Chest CT to detect lymphangioleiomyomatosis (adult women only)
ESTABLISHED (TO MONITOR FOR COMPLICATIONS)
Comprehensive developmental assessment at school entry and as needed for educational/behavioral concerns
Ophthalmologic examination (as needed)
Cranial CT or MRI every 1–3 years during childhood and adolescence*,†
EEG (only to monitor seizure treatment or if new-onset seizures or cognitive performance declines)
Echocardiography (only if cardiac symptoms occur)
Renal ultrasonography every 1–3 years if no history of renal lesions, twice yearly if known angiomyolipomas‡
Chest CT (to screen adult women for lymphangioleiomyomatosis; thereafter, if pulmonary symptoms develop)
POTENTIALLY AFFECTED FAMILY MEMBERS
Dermatologic and (if skin findings not diagnostic) ophthalmologic examinations for manifestations of TS
Consider cranial CT, renal ultrasonography or (for infants only) echocardiography
Consider genetic testing if a mutation has been identified in the proband
*Findings have correlated with seizure activity and cognitive deficits in some but not all studies.
†Assess for enlarging lesions suggestive of subependymal giant cell astrocytomas, which are most common during childhood.
‡Angiomyolipomas >3.5–4 cm in diameter have a greater risk of hemorrhage and should be assessed with CT or MRI; prophylactic renal arterial embolization or kidney-sparing surgery is recommended for symptomatic lesions of this size.

Table 61.9 Evaluation and management of tuberous sclerosis (TS) patients. CT, computed tomography; MRI, magnetic resonance imaging.

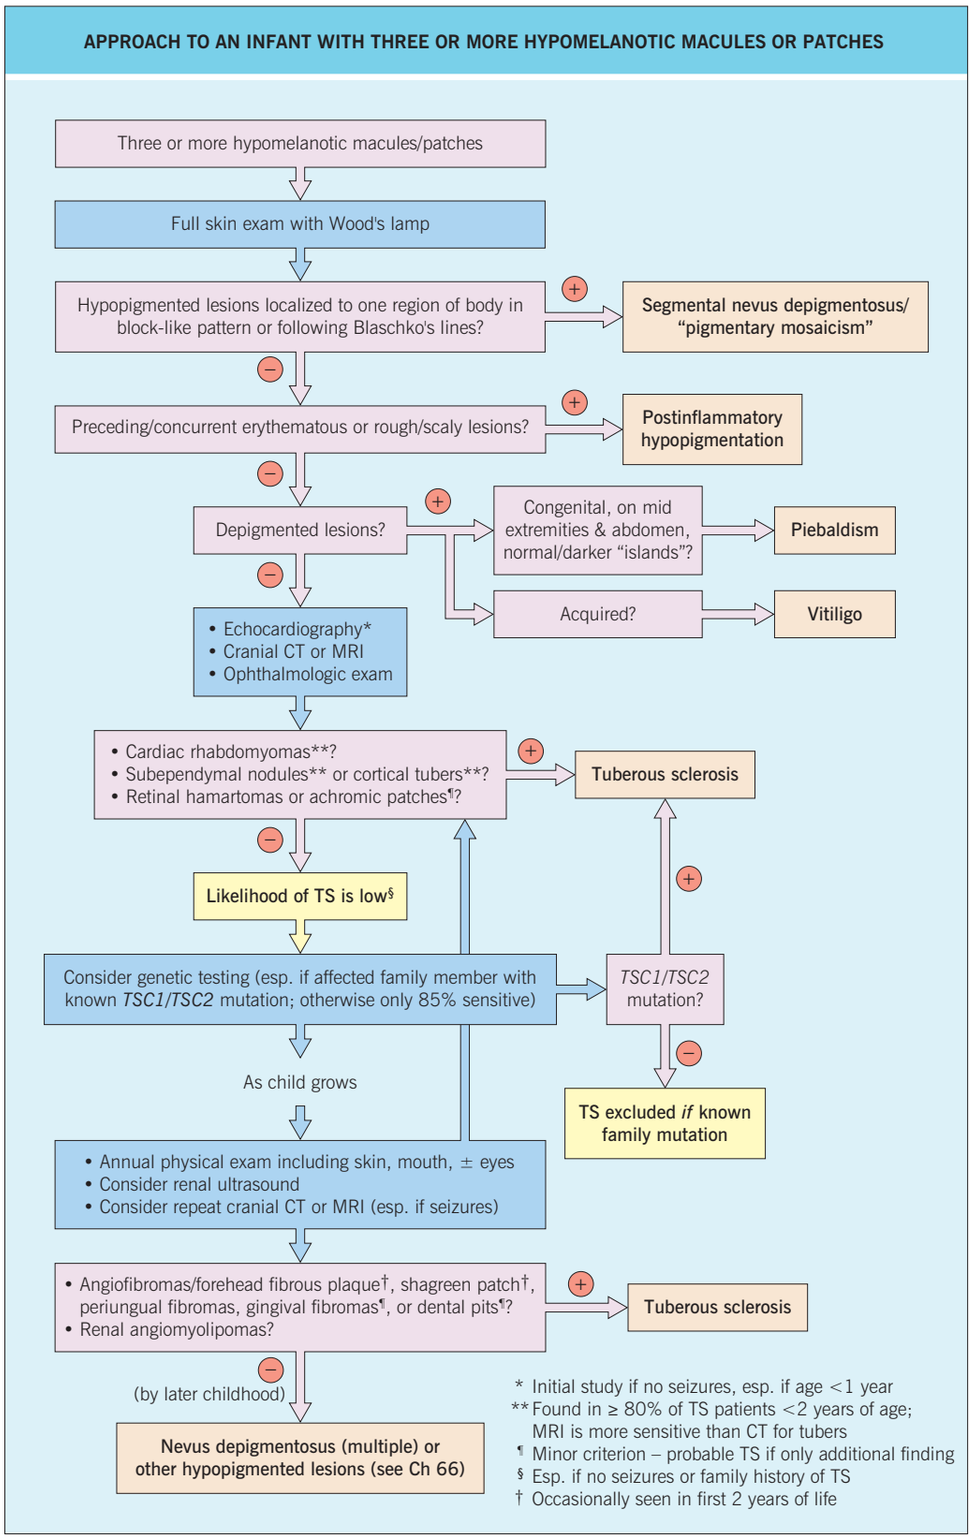

Fig. 61.21 Approach to an infant with three or more hypomelanotic macules or patches. A child with fewer than three macules and no family history of tuberous sclerosis (TS) has an extremely low likelihood of having this disease.

(IGH) may resemble the confetti-like leukoderma of TS; however, IGH is an acquired disorder with a preference for the shins and extensor forearms of older adults.

A congenital smooth muscle hamartoma can present during infancy as a firm, skin-colored to hyperpigmented plaque that may resemble a shagreen patch, but often it contains follicular papules (due to hyperplastic arrector pili muscles), accentuates with rubbing (pseudo-Darier's sign), and has associated hypertrichosis rather than prominent but depressed follicular orifices. Histologically, smooth muscle hamartomas are characterized by numerous intradermal bundles of smooth muscle rather than collagen.

The differential diagnosis for facial angiofibromas may include acne vulgaris and trichoepitheliomas. Individual acneiform lesions should resolve over a period of weeks. Trichoepitheliomas are clinically less red in color, although a biopsy is often indicated to ascertain a definitive diagnosis. Additional causes of multiple facial papules are listed in Table 36.1 and Figure 111.4.

Management

Nearly every organ can be affected by TS, and clinical findings vary tremendously even within families. Certain signs and complications typically appear at birth, whereas others develop much later in life. The NIH-sponsored Tuberous Sclerosis Consensus Conference subcommittee's recommendations for the evaluation and management of individuals newly diagnosed with TS, established patients, and potentially affected family members are presented in Table 61.9[108,108a].

Investigations in TS patients should focus on detecting disease manifestations and complications that are potentially significant and treatable, and it is important to provide genetic counseling to affected individuals and families.

Increasing numbers and sizes of facial angiofibromas may become a cosmetic concern as the patient grows older. Techniques such as dermabrasion, electrosurgery and treatment with ablative (including fractional resurfacing) and pulsed dye (for thinner erythematous lesions) lasers have been used with variable efficacy. Patients should understand that the lesions often recur after treatment.

In clinical trials, targeted therapy with the mTOR inhibitor rapamycin in TS patients has led to reduction in the size of renal angiomyolipomas and (in two of three trials to date) improvement of lung function in women with lymphangioleiomyomatosis[118,118a]. Rapamycin-induced regression of TS-associated subependymal giant cell astrocytomas has also been reported. In addition, improvement of facial angiofibromas with oral or topical administration of rapamycin (e.g. in a 1% solution or ointment) has been described[119,120,121]. Further studies (including large randomized control trials) of mTOR inhibitors for the treatment of renal, pulmonary, neurologic and cutaneous manifestations of TS are underway.

Mosaicism and Linear Lesions

62

Celia Moss

Chapter Contents

Mosaicism in X-linked conditions *947*
Mosaicism for autosomal dominant conditions *952*
Linear inflammatory disorders *955*
Lethal disorders rescued by mosaicism *956*
Chromosomal mosaicism *959*
Chimerism *960*

Key features

- In the skin, mosaicism (genomic or functional) classically appears as cutaneous findings that follow Blaschko's lines
- The pattern may vary according to cell type and timing of mosaicism
- Diagnostically, it helps to consider what the differential diagnosis would be if the lesions were generalized
- If there is also gonadal mosaicism, offspring may have the generalized condition

INTRODUCTION

The term "mosaic" is used to describe individuals composed of cells of different genotypes that are derived from a genetically homogeneous zygote. For example patients with mosaic Turner syndrome have both 45,XO and 46,XX cells. The skin provides an ideal canvas to visualize patterns of mosaicism.

In 1901, Alfred Blaschko[1] documented the characteristic lines and whorls that are followed by epidermal nevi and other skin conditions now known to result from mosaicism (Fig. 62.1A). In 1961, Mary Lyon postulated that similar striped patterns in female mice heterozygous for coat color genes on the X chromosome reflected two populations of cells, one expressing the maternal X chromosome and one the paternal X chromosome. She hypothesized that all women are functional mosaics with regard to the X chromosome. In 1965, Curth and Warburton[2] used the Lyon hypothesis to explain the linear pattern of skin findings in the X-linked disorder incontinentia pigmenti. A decade later, Happle[3] recognized lyonization as the reason that skin lesions follow Blaschko's lines in heterozygous female patients with other X-linked genodermatoses.

We now know that cutaneous findings along Blaschko's lines and with other mosaic distribution patterns can result from: (1) *genomic*

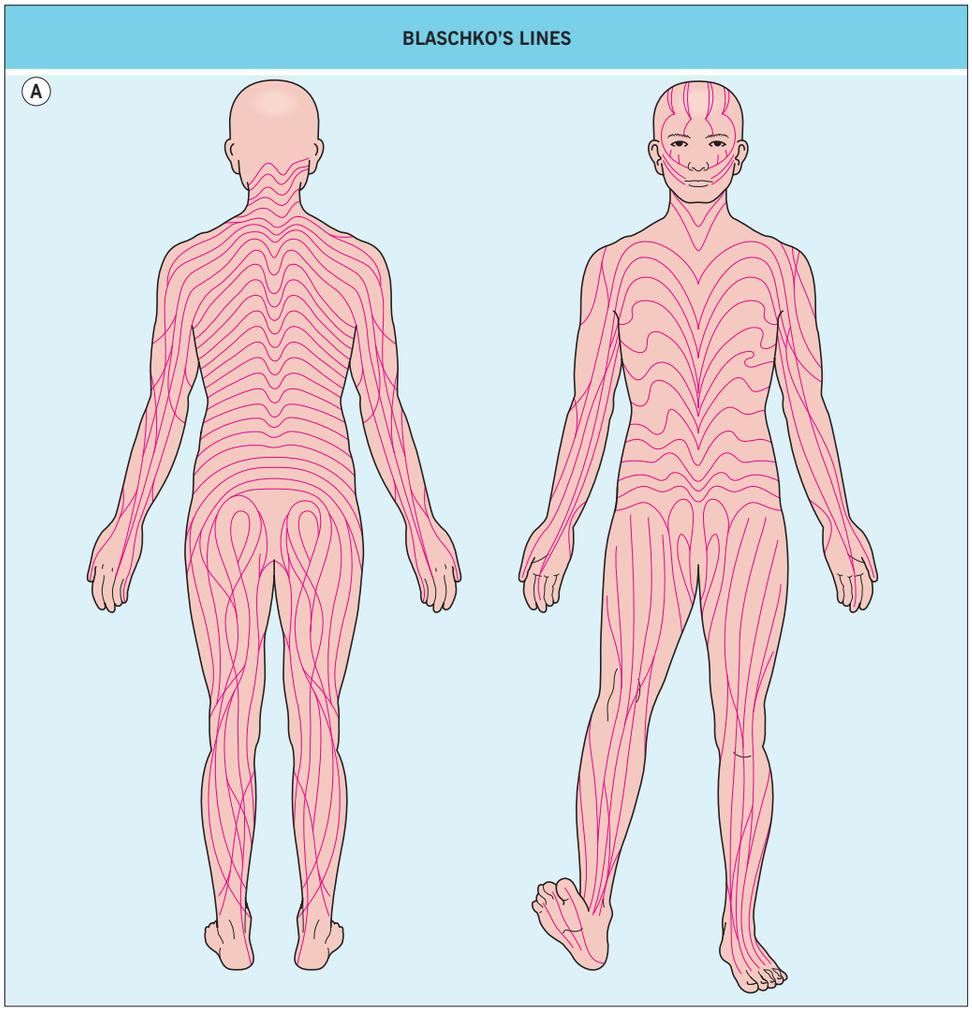

Fig. 62.1 Blaschko's lines. A These diagrams are taken from Blaschko's original drawings[1]. Note the S-shape of the abdominal lines and the V-shape on the central back.

Continued

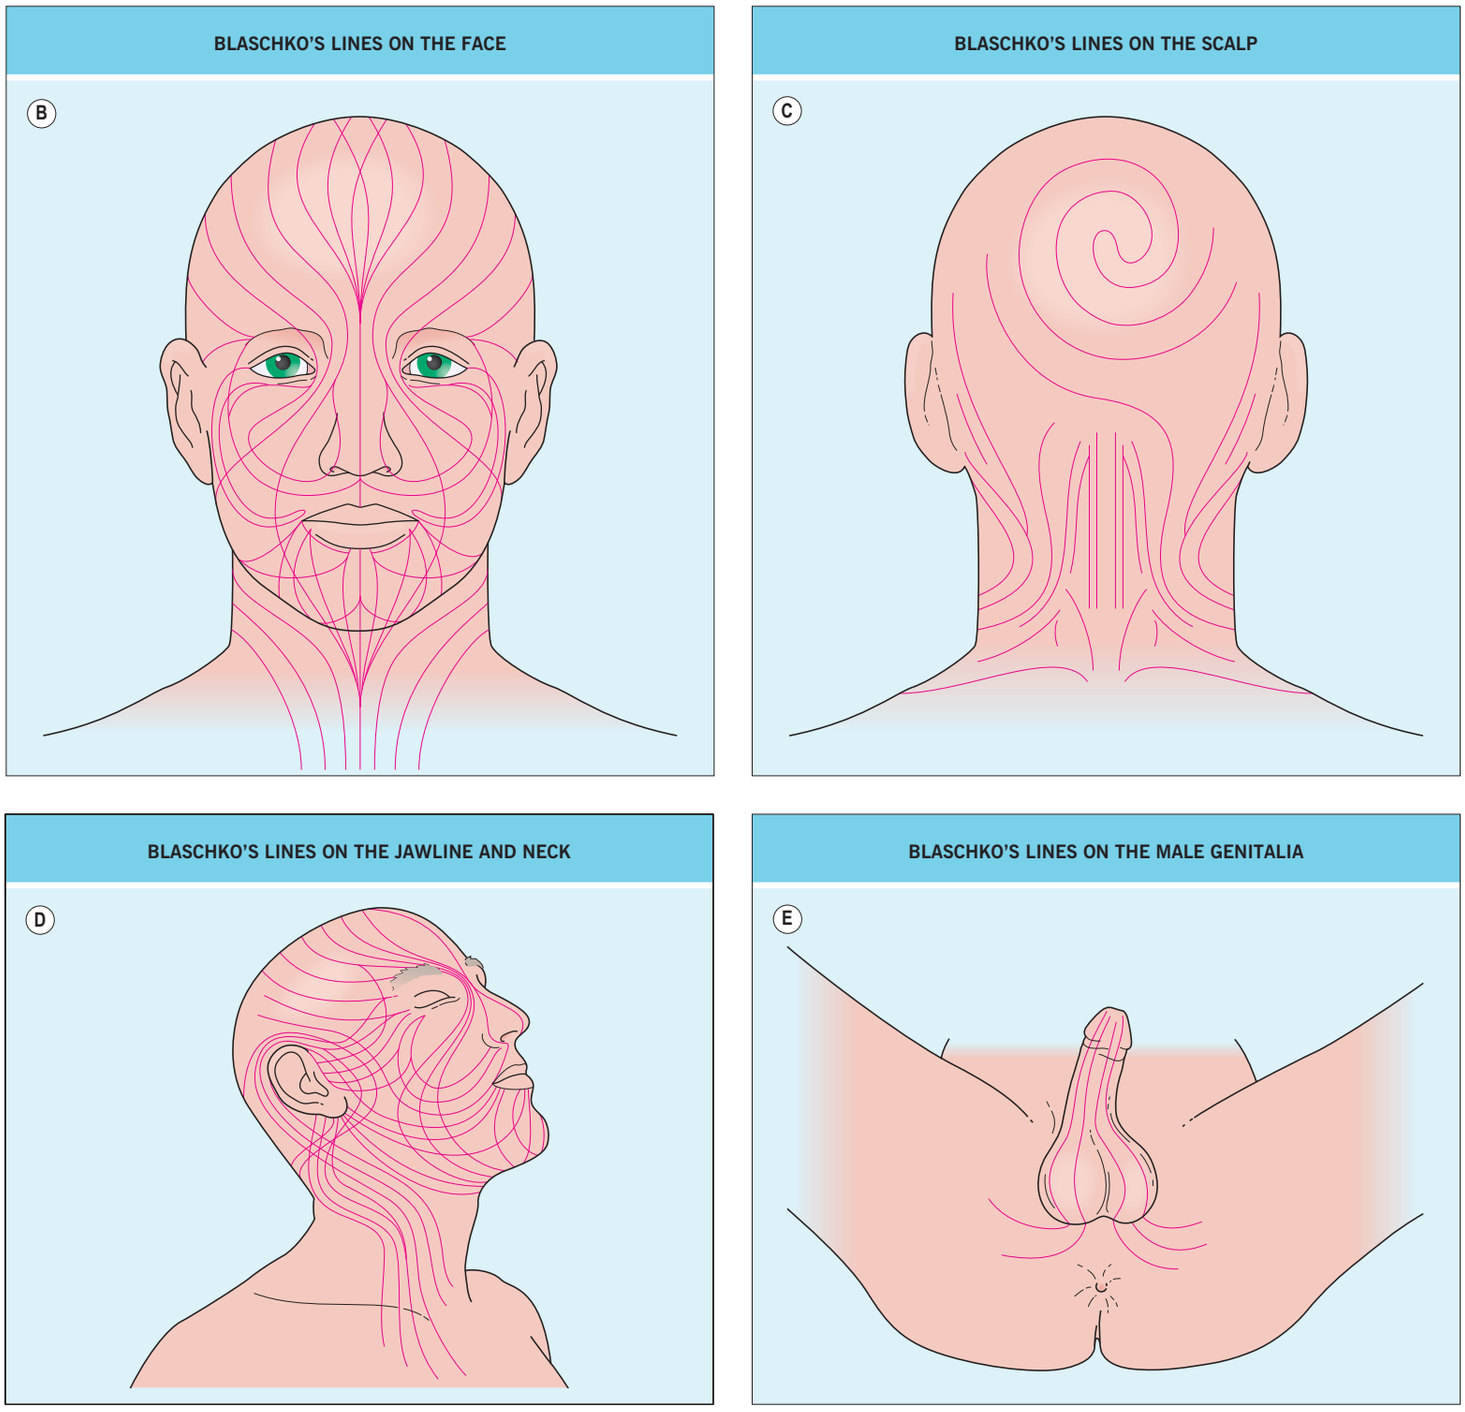

Fig. 62.1 Blaschko's lines (cont'd). **B** Blaschko's lines on the face, based on personal observations and ref. 8. **C** Blaschko's lines on the scalp, based on ref. 8. **D** Blaschko's lines on the jawline and neck, based on personal observations and ref. 8. **E** Blaschko's lines on the male genitalia, based on ref. 1.

(genetic) mosaicism due to changes in the DNA sequence (e.g. mutations or chromosomal alterations); and (2) *functional (epigenetic) mosaicism* due to changes in gene expression that are passed on to subsequent cell generations (e.g. lyonization[4]) (Table 62.1). Epigenetic mosaicism due to autosomally inherited retrotransposons (elements of retroviral origin that can affect the activity of neighboring genes) may explain occasional familial aggregation of non-X-linked disorders with a mosaic distribution pattern[5]. Mosaic skin conditions can be categorized based upon the nature of the corresponding generalized condition (Table 62.2).

The idea that Blaschko's lines represent the embryonic migration pathways of skin cells was first expressed by Douglass Montgomery, who concluded that the linear patterns of epidermal nevi "may be due to the streams or trend of growth of the tissues"[6]. Intriguingly, Montgomery presented his work to the American Dermatological Association in the same month (May 1901) that Blaschko presented his to the Deutschen Dermatologischen Gesellschaft in Breslau. Although both of these dermatologists published their findings, Montgomery's remarkable contribution was eclipsed by that of his German contemporary. In fact, the now widely held theory that Blaschko's lines reflect routes of embryonic cell migration did not surface again until the late 1970s[3,7].

Blaschko's original diagram (see Fig. 62.1A) omitted the midface, scalp, lateral neck, and genital area. The trajectories of Blaschko's lines in these areas have now been established[8] (Fig. 62.1B–E), as have analogous patterns in the eyes, teeth and oral mucosa. Considerable variability occurs in the degree of whorling on the flanks and the directions of lines on the face; the posterior midline may be shifted to the left or right, but the anterior midline tends to be sharply centered from the upper sternum to the pubis.

CAUSES OF MOSAICISM AND THE CORRESPONDING PATHOGENESIS	
Cause of mosaicism	**Pathogenesis**
GENOMIC (GENETIC)	
Half-chromatid mutation	A mistake during the first meiotic division of gametogenesis whereby an incorrect base is added. When the resulting mismatched double strand separates in mitosis, it will provide two templates that are not exactly complementary, giving rise to two different lines of daughter cells
Postzygotic (somatic) mutation	A mutation occurring after fertilization
Chromosomal non-disjunction	The failure of chromosomes to separate correctly during either meiosis or mitosis, resulting in daughter cells with aberrations of chromosome number or structure
Chimerism*	Fertilization of one egg by two sperm, or fusion of two zygotes, resulting in an individual composed of two genetically different cell lines
FUNCTIONAL (EPIGENETIC)	
Lyonization	Random inactivation of one of the two X chromosomes (which forms the Barr body) in each female cell during early embryonic development. Whether the paternal or maternal X chromosome is inactivated is random, but once the choice has been made, it is the same in all daughter cells
Epigenetic modification of autosomal gene(s)	A change in gene expression, passed from one cell generation to the next, but not resulting from an alteration in the DNA sequence, that affects some cells in an otherwise genetically homogeneous individual

*Because the clones originate from distinct organisms, chimerism differs from true mosaicism.

Table 62.1 Causes of mosaicism and the corresponding pathogenesis.

MOSAIC SKIN CONDITIONS CLASSIFIED ACCORDING TO THE NATURE OF THE CORRESPONDING GENERALIZED CONDITION	
Nature of the generalized condition	**Linear condition**
X-linked dominant single-gene disorder, lethal in males and mosaic manifestations in females	• Incontinentia pigmenti (*NEMO*) • Goltz syndrome (*PORCN*) • Conradi–Hünermann–Happle syndrome (*EBP*) • CHILD syndrome (*NSDHL*) • MIDAS syndrome (*HCCS*) • Oral–facial–digital syndrome type 1 (*OFD1*) • Terminal osseous dysplasia with pigmentary defects (*FLNA*)*
X-linked single-gene disorder, diffuse disease in males and variable mosaic manifestations in females	Female "carriers" of the following disorders: • Hypohidrotic ectodermal dysplasia (*EDA*) • Hypohidrotic ectodermal dysplasia with immune deficiency (*NEMO*) • X-linked reticulate pigmentary disorder • X-linked dyskeratosis congenita (*DKC1*) • Menkes disease (*ATP7A*) • Ichthyosis follicularis with atrichia and photophobia/keratosis follicularis spinulosa decalvans (*MBTPS2*) • X-linked congenital generalized hypertrichosis
Autosomal dominant single-gene disorder	• Epidermolytic verrucous epidermal nevus (*KRT1*, *KRT10*) [epidermolytic ichthyosis] • Non-epidermolytic verrucous epidermal nevus† (*FGFR3*) [acanthosis nigricans of thanatophoric dysplasia] • PTEN ("Cowden") epidermal nevus/segmental hamartomas (*PTEN*) [PTEN hamartoma tumor syndrome] • Palmoplantar verrucous epidermal nevus (*KRT16*) [pachyonychia congenita] • Acneiform nevus (*FGFR2*) [acne of Apert syndrome] • Linear Darier disease (*ATP2A2*) • Linear Hailey–Hailey disease (*ATP2C1*) • Linear porokeratosis • Linear basal cell carcinomas and basaloid follicular hamartomas • Segmental neurofibromatosis type 1 (*NF1*) • Linear/segmental angiofibromas (likely *TSC1* or *TSC2*) [tuberous sclerosis complex] • Segmental venous malformations (*TEK*) [cutaneous and mucosal venous malformation syndrome] • Segmental plaque-type glomuvenous malformations (*GLMN*) [hereditary glomuvenous malformations] • Parkes Weber syndrome (*RASA1*) [familial CM-AVM] • Segmental leiomyomas (*FH*) [multiple cutaneous and uterine leiomyomatosis]

*Features hyperpigmented, atrophic (with dermal hypoplasia) facial macules and digital fibromas.

Table 62.2 Mosaic skin conditions classified according to the nature of the corresponding generalized condition. The (gene) and [generalized condition] are noted when not evident from the name of the linear variant. *ATP7A*, ATPase, copper-transporting, α polypeptide; CHILD, congenital *h*emidysplasia with *i*chthyosiform erythroderma/nevus and *l*imb *d*efects; *EBP*, emopamil binding protein; *EDA*, ectodysplasin A; *FLNA*, filamin A; *HCCS*, holocytochrome c synthase; *MBTPS2*, membrane-bound transcription factor peptidase, site 2; MIDAS, *mi*crophthalmia, *d*ermal *a*plasia and *s*clerocornea; *NEMO*, NF-κB essential modulator; *NSDHL*, NAD(P)-dependent steroid dehydrogenase like.

Continued

MOSAIC SKIN CONDITIONS CLASSIFIED ACCORDING TO THE NATURE OF THE CORRESPONDING GENERALIZED CONDITION	
Nature of the generalized condition	**Linear condition**
Possible autosomal dominant single-gene disorder	• Linear seborrheic keratoses (possibly *FGFR3*) [thanatophoric dysplasia/related disorders] • Nevoid telangiectasia, angioma serpiginosum and angiokeratoma circumscriptum (possibly *RASA1* or *KRIT1*) [familial CM-AVM or CCM] • Maffucci syndrome • Linear syringomas • Linear trichoepitheliomas, spiradenomas and/or cylindromas (likely *CYLD*) [multiple familial trichoepitheliomas, Brooke-Spiegler syndrome and cylindromatosis] • Segmental agminated acquired melanocytic nevi • "Zosteriform" speckled lentiginous nevus‡
Multifactorial inflammatory disorder (genetic susceptibility + environmental contributions)	• Linear psoriasis • Linear lichen planus • Linear lichenoid GVHD • Linear lupus erythematosus and dermatomyositis • Linear fixed and lichenoid drug eruptions • Linear lichen nitidus • Lichen striatus • "Blaschkitis" • Linear morphea • Linear atrophoderma of Moulin • Segmental vitiligo
Presumed autosomal dominant lethal disorder rescued by mosaicism (never seen in a generalized form)	• Non-epidermolytic verrucous epidermal nevus or linear seborrheic keratoses (*PIK3CA*) • Sebaceous nevus • PEODDN (porokeratotic eccrine ostial and dermal duct nevus) • Proteus syndrome (*AKT1*) • ILVEN (inflammatory linear verrucous epidermal nevus) • Nevus lipomatosis superficialis • Encephalocraniocutaneous lipomatosis • Oculocerebrocutaneous syndrome • McCune–Albright syndrome (*GNAS*) • Segmental vascular malformations§ • Linear fibromatosis
Chromosomal anomalies (may be lethal in a generalized form)	• Hypomelanosis of Ito • Nevus depigmentosus • Linear and whorled nevoid hypermelanosis • Pallister–Killian syndrome (tetrasomy 12p)
Chimerism	• Segmental hyper- and hypopigmentation

†Also (*KRAS*) [cardiofaciocutaneous syndrome, which is occasionally associated with acanthosis nigricans]; mosaicism for an activating mutation reported in one patient to date.
‡Candidates include genes for autosomal dominant lentiginosis syndromes, e.g. LEOPARD (*PTPN11*), Carney complex (*PRKAR1A*) and neurofibromatosis type 1 (*NF1*).
§Possible examples include those associated with Klippel–Trenaunay and Sturge–Weber syndromes as well as cutis marmorata telangiectatica congenita and "lymphangioma circumscriptum" (microcystic lymphatic malformations).

Table 62.2 Mosaic skin conditions classified according to the nature of the corresponding generalized condition (cont'd). The (gene) and [generalized condition] are noted when not evident from the name of the linear variant. *ATP2A2* and *APT2C1*, ATPase, calcium-transporting; CCM, cerebral capillary malformation (sometimes associated with hyperkeratotic cutaneous capillary–venous malformations); CM-AVM, capillary malformation–arteriovenous malformation; *FGFR*, fibroblast growth factor receptor; *FH*, fumarate hydratase; *GLMN*, glomulin; *GNAS*, guanine nucleotide binding protein (G protein), alpha stimulating polypeptide 1; GVHD, graft-versus-host disease; *KRT*, keratin gene (e.g. *KRT16*); *NF1*, neurofibromin 1; *PIK3CA*, phosphatidylinositol 3-kinase catalytic subunit alpha.

EXPECTED PATTERN OF CUTANEOUS MOSAICISM ACCORDING TO ITS TIMING OF ONSET				
Timing	**Configuration/shape of skin lesions**	**Number of skin lesions**	**Laterality**	**Organs affected**
Meiosis	Linear	Multiple	Bilateral	Multiorgan
Very early blastocyst (includes lyonization)	Linear	Multiple	Bilateral	Multiorgan
Later blastocyst	Linear	Fewer	Uni- or bilateral	Multiorgan
Later in first trimester, pre-organogenesis	Linear or oval	Fewer	Uni- or bilateral	Multiorgan
First trimester, post-organogenesis	Linear or oval	Few or single	Uni- or bilateral	Skin only
Second/third trimester	Oval or round	Single	Unilateral	Skin only
Postnatal	Round (smaller)	Single	Unilateral	Skin only

Table 62.3 Expected pattern of cutaneous mosaicism according to its timing of onset.

Mosaic skin conditions do not always follow Blaschko's lines[9]. Assuming that the pattern is determined by cell migration, it depends on the stage of development at which mosaicism arises (Table 62.3) and the cell type affected (Table 62.4). The classic pattern defined by Blaschko is seen in disorders of epidermal cells, which is not surprising since Blaschko based his diagrams on epidermal nevi[10]. Embryonic keratinocytes move outwards from the neural crest by directional proliferation, in more-or-less continuous lines that are deflected by the complex interplay between cell migration and surface remodeling. In contrast, melanoblasts are thought to migrate individually to the skin, where they then proliferate antenatally. This explains the block-like, patchy and phylloid patterns seen in some pigmentary conditions that

	Type 1 in AD	Type 2 in AD	Revertant in AD	Mosaic abnormal in AR	Revertant in AR
Background genotype	Normal	Heterozygous	Heterozygous	Heterozygous	Homozygous abnormal
Background phenotype	Normal	Abnormal	Abnormal	Normal	Abnormal
"Line" genotype	Heterozygous	Homozygous abnormal	Homozygous normal	Homozygous abnormal	Heterozygous
"Line" phenotype	Abnormal	Very abnormal	Normal	Abnormal	Normal
Mosaic event	Somatic mutation ("gain of heterozygosity")	Loss of heterozygosity	Reversion to normal*	Loss of heterozygosity	Reversion to heterozygous state**
Example	Type 1 linear Darier disease	Type 2 linear Darier disease	Ichthyosis en confetti	Not described	Revertant recessive dystrophic EB

Fig. 62.2 Mosaicism for autosomal traits. With revertant mosaicism (**C** and **E**), the phenotype depends on the degree of gene reversion (complete or partial), the timing of the revertant mutation (large segment or multiple bands if during embryogenesis versus smaller spot if postnatally), and a selective advantage of revertant cells (e.g. blistering of non-revertant skin in epidermolysis bullosa, EB). AD, autosomal dominant; AR, autosomal recessive. *Additional mechanisms include mitotic recombination (with crossing over of homologous chromosomes leading to homozygous mutant and homozygous normal daughter cells) and a second-site mutation (e.g. that silences a dominant negative allele). **Additional mechanisms include gene conversion (where the donating chromosome is unchanged) and a second-site mutation (e.g. that restores the reading frame, prevents a termination codon or affects RNA splicing). *Courtesy, Julie V Schaffer, MD.*

EXPECTED PATTERN OF CUTANEOUS MOSAICISM ACCORDING TO CELL OR TISSUE TYPE		
Cell affected	**Embryonic movement**	**Expected pattern**
Melanoblast	Single cell migration	Blaschko's lines, block-like or phylloid
Keratinocyte	Directional proliferation following surface forces	Blaschko's lines
Fibroblast, fat cell, other mesodermal cells	Multidirectional proliferation following growth of segment	Segmental
Nerve cell	Along future dermatomes	Dermatomal
Endothelial and other blood vessel cells	Within segments/future dermatomes	Segmental/dermatomal

Table 62.4 Expected pattern of cutaneous mosaicism according to cell or tissue type.

result from mosaicism. Cutaneous blood vessels, fibroblasts and other mesodermal derivatives take different routes; mosaic disorders involving these tissues are rarely distributed along Blaschko's lines, more often displaying patterns that correspond to embryonic segments or dermatomes. The distribution of skin lesions along Blaschko's lines in Goltz syndrome (focal *dermal* hypoplasia) and linear morphea are postulated to reflect mutated genes that are expressed in the epidermis but lead to changes in the underlying dermis.

Sometimes, a more severe linear lesion is superimposed upon the background of a generalized autosomal dominant disease, with or without a family history of the same generalized condition. This phenomenon, referred to as *type 2 mosaicism*, occurs when an individual with a germline mutation in one allele of a gene (which leads to the autosomal dominant disorder) also has a postzygotic mutation affecting the other allele (a "second hit" causing loss of heterozygosity), resulting in a linear area where the genetic burden is doubled (Fig. 62.2B). Type 2 mosaicism has been proven on a molecular level for conditions including Hailey–Hailey disease,[11] Darier disease[11a] and PTEN hamartoma tumor syndrome (which encompasses Cowden disease and Bannayan–Riley–Ruvalcaba syndrome)[12,13]. Other patients have a linear distribution of the skin lesions that characterize an autosomal dominant genodermatosis (e.g. Darier disease) in the absence of background lesions. Such lesions vary in severity and can also be dense or confluent. In these patients, there is a localized region with a postzygotic mutation in one allele of a gene that is normal in the remainder of the affected individual; this is referred to as *type 1 mosaicism* (Fig. 62.2A).

Theoretically, linear autosomal recessive skin disease could also develop through clonal loss of heterozygosity in a carrier (Fig. 62.2D). While this has not been reported, the opposite phenomenon – regional absence of skin disease attributed to a back/correcting mutation (revertant mosaicism) – has been shown in patients with autosomal recessive as well as autosomal dominant forms of epidermolysis bullosa (where revertant cells have a particular advantage due to the selective pressure of blistering) and in ichthyosis en confetti[14,15] (Fig. 62.2C,E).

Figure 62.3 provides an approach to the differential diagnosis of skin lesions that follow Blaschko's lines. Selected mosaic disorders will be discussed in more detail below.

MOSAICISM IN X-LINKED CONDITIONS

In women heterozygous for X-linked disorders, functional mosaicism due to random X-chromosome inactivation (lyonization) may produce skin lesions following Blaschko's lines. Sons who inherit the abnormal

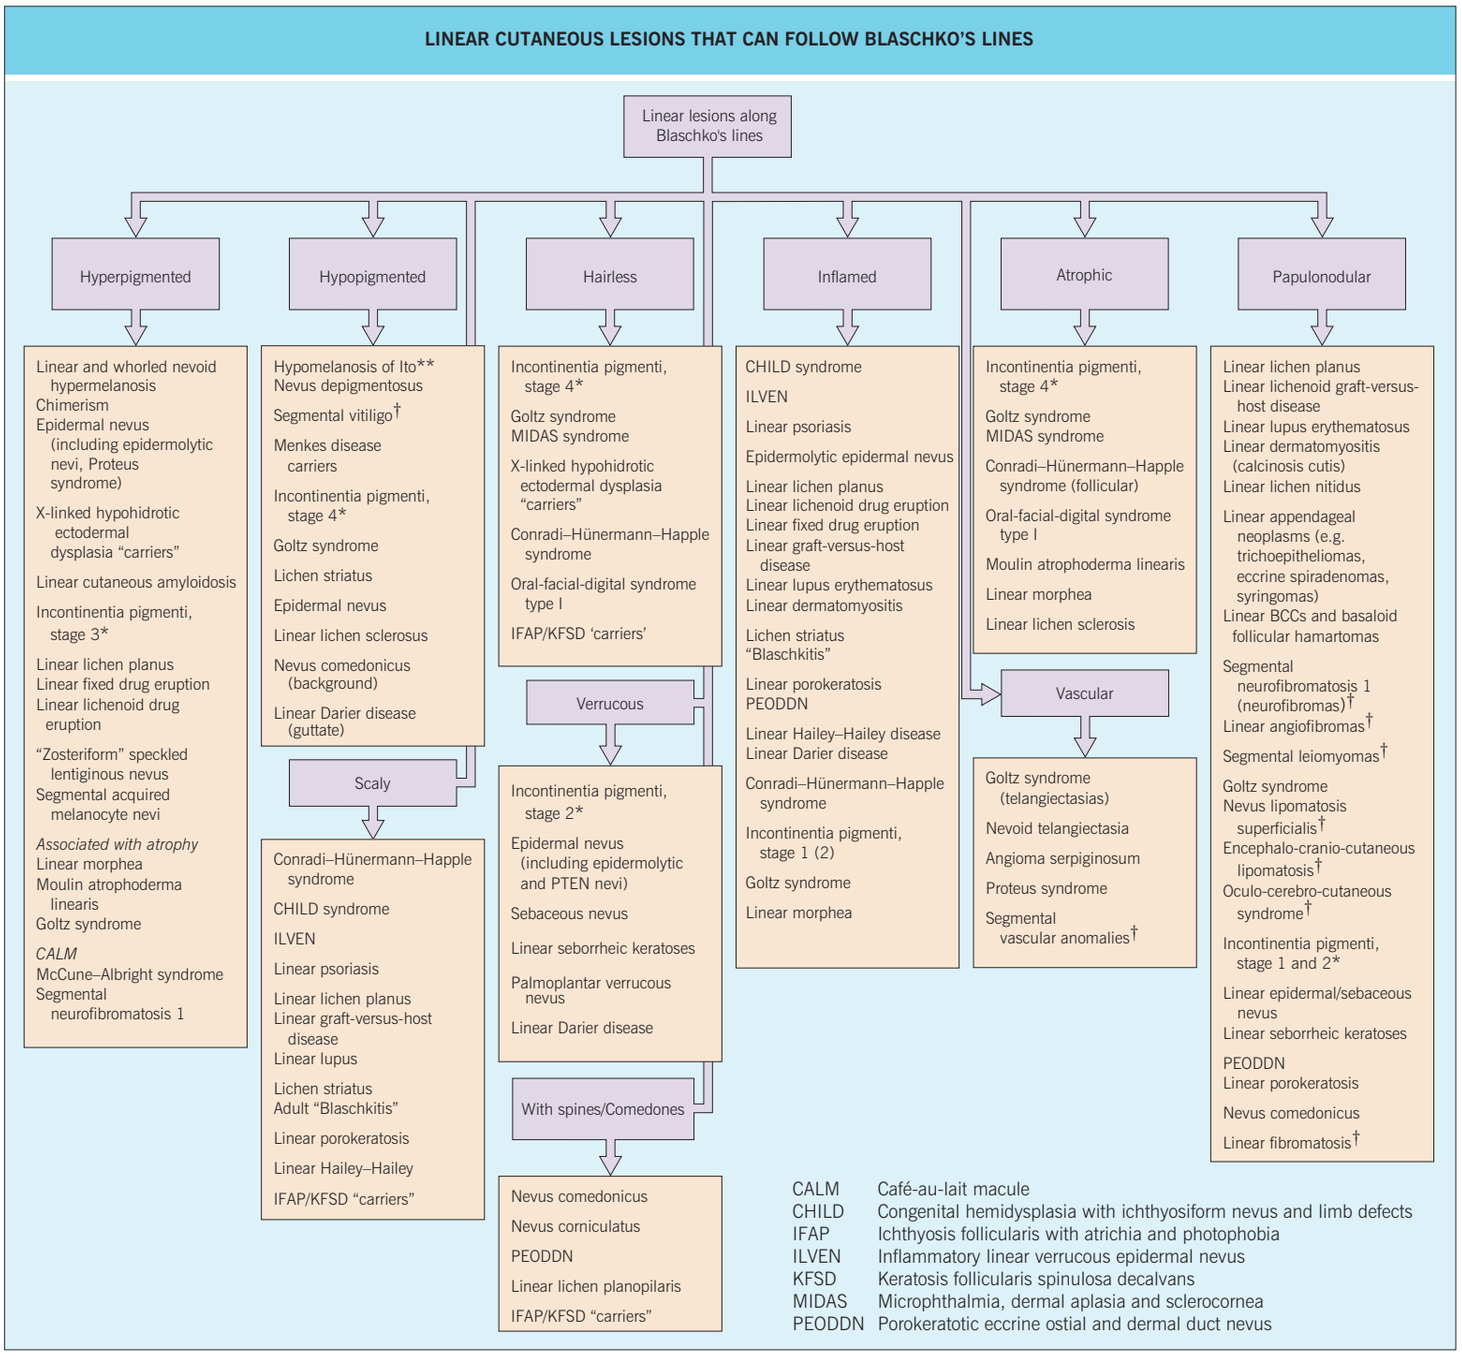

Fig. 62.3 Linear cutaneous lesions that can follow Blaschko's lines. *Also female "carriers" of hypohidrotic ectodermal dysplasia with immune deficiency. **Including Pallister–Killian syndrome. †More often have a segmental or (for neural and vascular lesions) dermatomal pattern.

X chromosome carry and express the mutation in all cells; if recessive, the disorder is usually compatible with survival (e.g. hypohidrotic ectodermal dysplasia), but if dominant, the disorder is generally so severe that males die before birth (e.g. incontinentia pigmenti and Goltz syndrome) because this lethal phenotype can only be rescued by mosaicism (see below). Occasionally, male patients present with the female skin phenotype because they themselves are mosaic, and, therefore, protected by the presence of some normal X chromosomes. X-chromosome mosaicism in boys and men can result from Klinefelter syndrome (where the extra X chromosome permits lyonization), a half-chromatid mutation (see Table 62.1) or a postzygotic mutation (see Table 62.5). These mosaic men can pass on the mutation to their daughters if it is present in their sperm (gonadal mosaicism).

Lyonization occurs synchronously in all cells at about the 1000-cell stage, so the two clones are intimately mixed from the beginning. Female patients with X-linked genodermatoses typically have numerous skin lesions that follow Blaschko's lines in narrow bands. A curious exception is CHILD (*c*ongenital *h*emidysplasia with *i*chthyosiform nevus and *l*imb *d*efects) syndrome, which characteristically shows large unilateral blocks of abnormal skin. This lateralization pattern may reflect the effects of expression of the mutant versus normal X-chromosome in organizer cells that control large developmental fields. Alternatively, a deficiency in sonic hedgehog signaling (which normally helps to confer left–right asymmetry) in cells expressing the *NSDHL* mutation, may result in selection against these cells on one side of the body.

Not all X-linked skin disorders follow Blaschko's lines. For example, women who are heterozygous for the gene defects that underlie Fabry disease, Wiskott–Aldrich syndrome and chronic granulomatous disease have either no lesions or scattered lesions in a non-linear pattern. This is likely because the cells that express the mutated gene are circulating leukocytes or non-epidermal cells (e.g. endothelial cells) for which lyonization does not produce a clinically apparent pattern. In the case of steroid sulfatase-deficient ichthyosis, where the defect is epidermal

but not evident in female carriers, the steroid sulfatase gene is on a part of the X chromosome that does not undergo lyonization.

Incontinentia Pigmenti

Synonym: ■ Bloch–Sulzberger syndrome

Key features

- A disorder with X-linked dominant inheritance and skin lesions that follow Blaschko's lines
- Four stages: (1) inflammatory/vesicular; (2) verrucous; (3) hyperpigmented; and (4) hypopigmented/atrophic
- Other ectodermal abnormalities may be present (e.g. alopecia, nail dystrophy, pegged or missing teeth)
- Occasional involvement of the eyes and central nervous system
- Caused by mutations in the *NEMO* gene

Introduction

Incontinentia pigmenti (IP) is a rare multisystem disorder that may present to neonatologists, neurologists, ophthalmologists or dentists as well as dermatologists. However, the diagnosis rests on the cutaneous findings. The name refers to the pathologic finding of pigmentary incontinence (i.e. dermal melanophages) in the third stage of the disease. The linear skin lesions reflect mosaicism secondary to X inactivation (lyonization).

History

Although Garrod probably first described IP in 1906, Bloch's 1926 report of a "previously unreported pigment disorder" and that 2 years later by Sulzberger are remembered eponymously. In the 1990s, "IP1" (a sporadic condition) was differentiated from "IP2" (classic inherited IP). In 2000, the International Incontinentia Pigmenti Consortium established that "IP2" (now referred to simply as IP) is caused by mutations in the *NEMO* (*N*F-κB *e*ssential *mo*dulator) gene. The condition previously known as "IP1", which is characterized by X/autosome translocations (often involving Xp11) and pigmentary abnormalities along Blaschko's lines without a preceding inflammatory phase, is now recognized as a form of pigmentary mosaicism (see below).

Genetics

IP is an X-linked dominant disorder, usually antenatally lethal in boys, that is caused by mutations in the *NEMO* (also known as *IKBKG*) gene at Xq28[16]. Approximately two-thirds of patients have a particular large deletion that tends to arise during paternal meiosis (male gametogenesis). Occasional occurrences of clinically typical IP in boys are attributed to Klinefelter syndrome (8 of 72 male patients reported to date) or to genomic mosaicism due to a half-chromatid or postzygotic *NEMO* mutation (Table 62.5)[17]. In the latter patients, the distribution of the skin lesions may be relatively limited.

Pathogenesis

The NEMO protein is a subunit of a kinase that activates NF-κB, a transcription factor that protects against TNF-α-induced apoptosis (Fig. 62.4). The idea of IP as a pro-apoptotic state explains male lethality, destruction of epidermal cells, and progressive replacement of cells expressing the mutant X chromosome by those expressing the normal allele[16]. In one report, a liveborn boy whose mother had classic IP died hours after birth due to lethal hematopoietic and immunologic disturbances[18]. Milder *NEMO* mutations are responsible for hypohidrotic ectodermal dysplasia with immune deficiency (HED-ID) in boys, whose mothers often have relatively subtle features of IP (see Table 62.5 and Ch. 63)[19].

Clinical features[20]

IP typically presents with linear erythema and blisters (stage 1) during the first few months of life in an otherwise well baby girl (see Fig. 34.10). Vesiculobullous lesions are most common on the limbs and scalp, frequent on the trunk, and rare on the face. They resolve within days to weeks and are often replaced by verrucous linear plaques (stage 2) that favor the extremities (Fig. 62.5A) and disappear later in infancy. Streaks and swirls of reticulate grayish-brown hyperpigmentation (stage 3) develop next and have a predilection for the trunk and intertriginous sites, with scalloped edges that are thought to reflect the growth of normal keratinocytes into affected skin (Fig. 62.5B). The inflammatory sequence sometimes recurs within pigmented areas during infancy or later in childhood together with intercurrent febrile illnesses. In addition, acral keratotic nodules (including subungual lesions) occasionally arise after puberty. The hyperpigmented streaks tend to fade by adolescence, although a few areas of slate-gray pigmentation may persist lifelong. From the teen years onward, linear hypopigmented bands lacking hair and sweat glands (stage 4) appear on the posterior aspects of the limbs (especially the calves; Fig. 62.5C) and may be the only stigmata of the disease during adulthood[21]. Individual stages of IP may

FINDINGS IN GIRLS AND BOYS WITH NEMO MUTATIONS

	Girl with IP	Boy with IP + Klinefelter syndrome	Son of mother with classic IP	Somatic mosaic boy with IP	Boy with HED-ID†
Karyotype	XX	XXY	XY	XY	XY
***NEMO* genotype**	Heterozygous for typical mutation*	Heterozygous for typical mutation*	Hemizygous for typical mutation*	Mosaic hemizygous for typical mutation* (half-chromatid or postzygotic)	Hemizygous for milder ("hypomorphic") mutation that does not abolish activity
Skin findings	Classic IP	Classic IP	NA	Classic IP, although may have a more limited distribution (e.g. unilateral or localized)	Hypotrichosis, hypohidrosis, recurrent pyogenic infections, extensive seborrheic- or atopic-like dermatitis, reticulated hyperpigmentation (less common)
Immunodeficiency	No	No	Yes, extremely severe	No	Yes, with dysgammaglobulinemia (↑IgM, ↓IgG)
Life expectancy	Normal	Normal	Usually lethal before birth	Normal	Typically shortened due to pyogenic and opportunistic infections; may improve with hematopoietic stem cell transplantation

*A particular large deletion that removes exons 4–10 is found in ~65% of female patients with IP; a *NEMO* mutation may be difficult to detect in peripheral blood samples from mosaic male patients (since mutant leukocytes are prone to apoptosis), so analysis of DNA from lesional skin may be required.
†Mother may have a mild variant of IP; affected boys typically have missing/conical teeth. An allelic variant features osteopetrosis and lymphedema, and an autosomal dominant condition with a similar phenotype can result from mutations in the inhibitor of κBα gene (*IKBA*).

Table 62.5 Findings in girls and boys with *NEMO* mutations. HED-ED, hypohidrotic ectodermal dysplasia with immune deficiency; IP, incontinentia pigmenti; NA, not applicable; *NEMO*, NF-κB essential modulator.

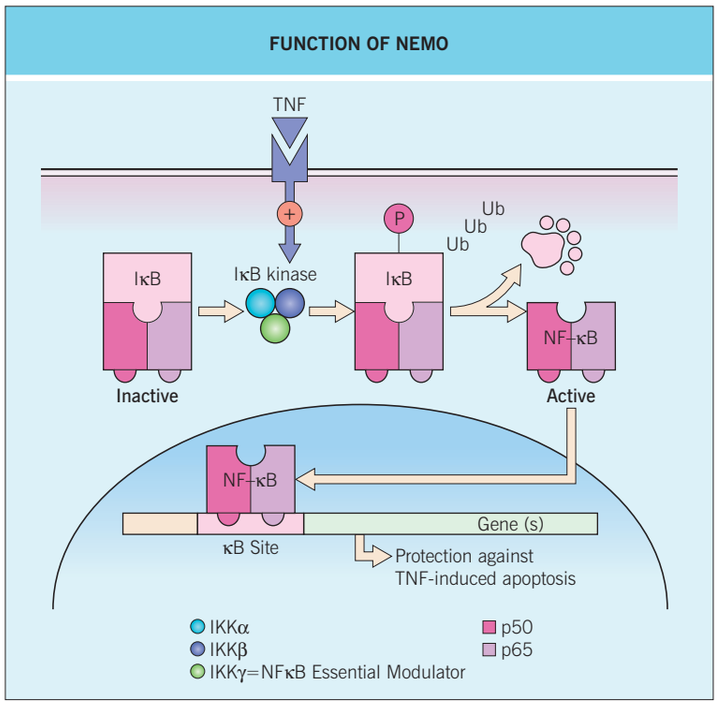

Fig. 62.4 Function of NEMO. In incontinentia pigmenti, lack of NF-κB essential modulator (NEMO; also known as *i*nhibitor of κ light polypeptide gene enhancer in *B* cells, *k*inase γ [IKBKG]) results in failure to activate NF-κB, which normally protects against tumor necrosis factor (TNF)-α-induced apoptosis.

ADDITIONAL MANIFESTATIONS OF INCONTINENTIA PIGMENTI
SURFACE ECTODERMAL DEFECTS
• Missing and conical *teeth* (60–80% of patients) • Linear absence of *hair* (swirled at the vertex in 30–40% of patients) and *sweat glands* • Dystrophic *nails* (ridging, pitting > subungual keratoses; 10–30% of patients) • Asymmetric *breast* development or supernumerary *nipples*
EYE ANOMALIES (20–40% OF PATIENTS)
• Retinal vascular abnormalities • Strabismus • Cataracts • Microphthalmia • Optic atrophy
CENTRAL NERVOUS SYSTEM ABNORMALITIES (20–30% OF PATIENTS)
• Seizures • Developmental delay • Spastic hemi/di/tetraplegia
SKELETAL DEFECTS (UNCOMMON)
• Skull anomalies • Scoliosis
OTHER ORGANS (UNCOMMON)
• Pulmonary hypertension

Table 62.6 Additional manifestations of incontinentia pigmenti.

be absent or overlap. Additional manifestations of this condition are listed in Table 62.6.

Pathology

The early inflammatory phase of IP demonstrates eosinophilic spongiosis and scattered dyskeratotic keratinocytes. The epidermis of verrucous lesions is acanthotic with hyperkeratosis and foci of dyskeratosis. In stage 3, there is pigmentary incontinence as well as variable vacuolization of basal keratinocytes, whereas stage 4 is characterized by a thinned epidermis and dermis devoid of adnexa[21].

Fig. 62.5 Incontinentia pigmenti. A, B Stages 2 (verrucous) and 3 (hyperpigmented). Note the erythematous background of the keratotic papules and plaques on the leg (**A**) and the remaining keratotic lesions on the toes (**B**). The scalloped edges of the hyperpigmented streaks are thought to reflect growth of normal keratinocytes into areas of apoptosis. **C** Stage 4 (atrophic and hypopigmented). Note absence of hairs within the streaks on the calf. *A & B, Courtesy, Julie V Schaffer, MD.*

Differential diagnosis

Neonatal IP can usually be distinguished from infectious conditions (e.g. herpes zoster, varicella or herpes simplex viral infections) by the wellbeing of the child and characteristic patterning of the skin lesions. Peripheral eosinophilia and leukocytosis are common in neonates with

IP, and histologic examination provides confirmation of the diagnosis. There is no preceding inflammatory phase in linear and whorled nevoid hypermelanosis or hypomelanosis of Ito, and adnexa are typically normal. Biopsy specimens of the former condition show predominantly epidermal hyperpigmentation rather than dermal melanophages (see Ch. 67).

Treatment

Baseline and longitudinal ophthalmologic (especially important during infancy) and neurologic evaluations are recommended, as are dental assessments and early intervention when anomalies are present. The mother should be examined and genetic counseling provided; genetic analysis is available. The Incontinentia Pigmenti International Foundation (www.ipif.org) is a good resource for families.

Hypohidrotic Ectodermal Dysplasia with Immune Deficiency

This condition is discussed in detail in Chapter 63.

Goltz Syndrome

Synonyms: ■ Focal dermal hypoplasia ■ Goltz–Gorlin syndrome

Key features

- X-linked dominant condition in which skin lesions follow Blaschko's lines and consist of dermal atrophy in association with telangiectasias, hypopigmentation and/or hyperpigmentation
- Approximately half of patients have areas of fat "herniation" within the streaks
- Raspberry-like papillomas favor the perioral and anogenital regions
- The characteristic digital anomaly is ectrodactyly (lobster-claw deformity)
- Additional findings include hypodontia and ocular defects
- Caused by mutations in the *PORCN* gene

Introduction

Goltz syndrome, an uncommon genetic disorder first described by Goltz in 1962, affects ectodermal and mesodermal structures – primarily the skin, bones, teeth and eyes – in a mosaic pattern.

Genetics

Goltz syndrome is an X-linked dominant condition caused by mutations in the *PORCN* gene. The mosaic distribution of skin lesions in female patients reflects lyonization. Although Goltz syndrome is antenatally lethal in boys with non-mosaic hemizygous mutations (as in IP; see Table 62.5), male patients with genomic (e.g. due to a postzygotic mutation) or functional (in the setting of Klinefelter syndrome) mosaicism account for 10% of affected individuals.

Approximately 95% of all Goltz syndrome cases are sporadic, which likely reflects both a decreased likelihood of reproduction by severely affected women and the lethality of *PORCN* mutations with widespread expression. Some authors have postulated that either preferential inactivation of the mutant X chromosome or a postzygotic mutation is required for survival of affected female fetuses[22]. Patients with the most deleterious mutations (deletions) have more extreme skewing in favor of wild-type[22]. Rare familial cases show anticipation, with the offspring being much more severely affected than the parent and having a higher proportion of mutant cells. Therefore the possibility that an apparently normal mother is a carrier must be considered when counseling families.

Pathogenesis

PORCN belongs to the evolutionarily conserved porcupine gene family and is expressed in the skin, craniofacial and long bones, tooth buds and eyes – structures affected in Goltz syndrome. The PORCN protein has multiple transmembrane domains and is located in the endoplasmic reticulum. It functions as an O-acyltransferase involved in palmitoylation and secretion of Wnt, a morphogen important in ectomesodermal tissue development[22,23]. Wnt signaling stimulates fibroblast proliferation, inhibits adipogenesis and induces osteogenesis, explaining the dermal hypoplasia, fat "herniations" and osteopathia striata (streaks of decreased bone density) observed in Goltz syndrome. Wnt also has key roles in early limb patterning and tooth formation.

Although the primary cutaneous abnormality in Goltz syndrome is in the dermis, the distribution of skin lesions along Blaschko's lines reflects embryonic migration pathways of epidermal cells. Ectoderm-specific deletion of *PORCN* in mice has shown that expression of this gene in the epidermis and resultant Wnt signaling regulate development of the underlying dermis and fat[23a]. Of note, patients with Goltz syndrome have a thin epidermis (as well as dermis) and abnormal adnexal structures. This is not surprising considering that Wnt signaling, including β-catenin-dependent pathways, is known to have critical roles in epidermal regeneration and adnexal morphogenesis/maintenance.

In 3 of 24 patients in one series, a microdeletion affected both the *PORCN* gene and the adjacent *EBP* gene responsible for Conradi–Hünermann–Happle syndrome (see below). Curiously, however, these patients showed no features of the latter disorder. This implies that the *PORCN* hypoplastic skin phenotype predominates over the ichthyosis and follicular changes of Conradi-Hünermann-Happle syndrome[22].

Clinical features[23]

The phenotype of Goltz syndrome varies depending on the proportion and distribution of cells expressing a mutant X chromosome. Streaks of vermiculate dermal atrophy and/or telangiectasias are often present from birth (Fig. 62.6A,B). Later, hypo- and hyperpigmentation as well as outpouchings of fat develop. Although raspberry-like papillomas may appear in any location, they favor the anogenital region as well as the lips (Fig. 62.6C), larynx and acral sites. Bony reduction deformities of the hands are common, particularly ectrodactyly (split-hand/foot or "lobster-claw" malformation). Radiographs of the mid portion of the lower extremities characteristically show osteopathia striata. Eye abnormalities, often unilateral, include coloboma, aniridia, microphthalmia and anophthalmia. Dystrophic nails (e.g. longitudinal fissures, hypoplasia), sparse hair, abnormal teeth (e.g. vertical grooving, hypodontia) and dysmorphic facies (e.g. notched nasal alae, pointed chin, large malformed ears) may be observed. Other occasional features include aplasia cutis congenita, myelomeningocele, cleft lip/palate, deafness, urinary tract anomalies and gastrointestinal maldevelopment.

Pathology

Affected skin shows a reduction in dermal collagen, which can be marked[23], with telangiectasias and a decreased number of adnexal structures. Fat cells of varying sizes are often present in the upper dermis. By electron microscopy, the basement membrane zone can be seen to contain multiple layers of lamina densa-like material, a change consistent with keratinocyte damage. Dermal microfibrils are also increased in the upper dermis.

Differential diagnosis

The distinctive cutaneous and extracutaneous findings of Goltz syndrome, especially dermal atrophy/fat "herniations" and osteopathia striata, distinguish it from other X-linked dominant genodermatoses. Examples of such conditions include MIDAS (which does not involve the distal extremities), Conradi–Hünermann–Happle and oral–facial–digital type 1 syndromes. Although an inflammatory component is occasionally observed, the skin lesions of Goltz syndrome are relatively static in comparison to the evolving lesions of IP.

Treatment

Treatment is supportive, with appropriate subspecialist referral based on the associated abnormalities. The telangiectasias may be improved by pulsed dye laser treatment. Troublesome exophytic papillomas can be treated with curettage or photodynamic therapy.

Fig. 62.6 Goltz syndrome. A Streaks of vermiculate atrophy (hypopigmented) and fat herniation/hamartoma in a girl with Goltz syndrome. **B** Streaks of telangiectasias plus erosions on the leg. **C** Several erythematous, raspberry-like papules on the lips. The most prominent lesion is at the angle of the mouth. Similar lesions can occur in the anogenital region and may be confused with warts.

Conradi–Hünermann–Happle syndrome (X-linked dominant chondrodysplasia punctata)

This rare X-linked dominant disorder presents in female neonates with ichthyosiform erythroderma characterized by feathery, adherent scale and a distribution along Blaschko's lines (see Ch. 57). Extracutaneous findings include rhizomelic limb shortening with epiphyseal stippling (chondrodysplasia punctata) and ocular anomalies such as sectorial cataracts and microphthalmia. Patients often have swirled alopecia following Blaschko's lines and coarse, lusterless hair. After infancy, the skin changes evolve into follicular atrophoderma. Conradi–Hünermann–Happle syndrome is caused by mutations in the *emopamil binding protein* (*EBP*) gene[24], which lies on the X chromosome adjacent to the *PORCN* gene and encodes an isomerase essential for cholesterol biosynthesis. Of note, chondrodysplasia punctata occurs in a variety of other genetic and non-genetic disorders.

CHILD Syndrome (Congenital *H*emidysplasia with *I*chthyosiform Erythroderma [or Nevus] and *L*imb *D*efects)

CHILD syndrome is a rare X-linked dominant congenital disorder that, in its full-blown form, affects half the body with severe limb reductions, scoliosis, diffuse erythema with scale, chondrodysplasia punctata and, occasionally, defects in internal organs (see Ch. 57). Less complete forms show affected areas following Blaschko's lines, sometimes bilaterally, or have a predilection for skin folds. Some authors have postulated that ILVEN (*i*nflammatory *l*inear *v*errucous *e*pidermal *n*evus) may represent a limited form of CHILD syndrome, but this has not been proven on a molecular level. Most cases of CHILD syndrome, including those with bilateral involvement, are caused by mutations in the *NSDHL* gene located on Xq28, which encodes a 3β-hydroxysteroid dehydrogenase enzyme involved in cholesterol biosynthesis[25].

MIDAS Syndrome

MIDAS syndrome is an X-linked dominant condition, antenatally lethal in males, characterized by *mi*crophthalmia, *d*ermal *a*plasia (see Table 64.4), *s*clerocornea and, sometimes, cardiac arrhthymias[26]; it is also known as MLS syndrome (*m*icrophthalmia with *l*inear *s*kin defects). MIDAS is caused by mutation or deletion of the *HCCS* gene on Xp22, which encodes mitochondrial holocytochrome c synthase[27].

Oral–Facial–Digital Syndrome Type I

Oral–facial–digital syndrome type I is an X-linked dominant condition characterized by cleft (or pseudocleft) lip/palate, lobulations and hamartomas of the tongue, hypertrophic oral frenula (associated with alveolar clefts), malformations of the digits, structural brain abnormalities, intellectual disability, polycystic kidneys, facial milia (primarily during infancy) and patchy alopecia that is typically whorled at the vertex. This disorder is caused by mutations in the *OFD1* (*CXORF5*) gene at Xp22.3–p22.2[28], which encodes a centrosomal protein located at the base of primary (non-motile) cilia. The latter structures are present on most cells and mediate signaling pathways such as hedgehog and Wnt during embryonic development.

X-linked Hypohidrotic Ectodermal Dysplasia (Female Patients)

Female patients ("carriers") with the X-linked form of hypohidrotic ectodermal dysplasia may have mild dental anomalies, patchy alopecia and variable degrees of reduced sweating, with a lack of adnexa and sometimes hyperpigmentation in a distribution corresponding to Blaschko's lines (see Ch. 63 and Fig. 55.12).

Menkes Disease (Female Carriers)

Menkes disease, an X-linked recessive disorder caused by dysfunction of a Cu^{2+}-transporting ATPase (α-polypeptide), is described elsewhere (see Ch. 69). Female carriers may have patchy pili torti and hypopigmentation along Blaschko's lines, attributable to functional mosaicism for cells with abnormal copper metabolism.

X-linked Reticulate Pigmentary Disorder

X-linked reticulate pigmentary disorder (initially described by Partington as "familial cutaneous amyloidosis") has been mapped to Xp22–p21. Female patients have hyperpigmented streaks following Blaschko's lines, whereas male patients have generalized reticulated hyperpigmentation and systemic manifestations (see Ch. 67). Histologic findings, which are similar in both sexes, include increased epidermal melanin, dermal melanophages, necrotic keratinocytes and (in some adult patients) cutaneous amyloid in the papillary dermis.

MOSAICISM FOR AUTOSOMAL DOMINANT CONDITIONS

When examining a linear skin disorder, it is helpful to consider what the diagnosis might be if the condition affected the whole skin surface, as some classic autosomal dominant skin disorders occasionally occur in a mosaic pattern. While the lesional morphology and histology are similar in the mosaic and generalized forms, the diagnosis may not be immediately obvious without clues provided by distribution and overall appearance of the generalized disorder. If no generalized disorder exists to match the linear lesions, then it could represent a dominant lethal mutation only survivable in the mosaic form; the latter can be either X-linked (see above) or autosomal.

Mosaicism for autosomal dominant disorders arises either during gametogenesis (half-chromatid mutation) or after fertilization (postzygotic/somatic mutation) (see Table 62.1). Forms of mosaicism in autosomal dominant skin conditions, including type 1 and type 2 as well as revertant mosaicism, are discussed above and summarized in Figure 62.2. For a *de novo* heterozygous mutation, there is generally no antecedent family history. However, there is a risk of passing on the full-blown disorder to the next generation, because mutant cells may be present in the gonads (gonadal mosaicism) as well as in the skin. An unstable premutation or epigenetic mosaicism[5] may explain rare instances of linear skin conditions with autosomal dominant inheritance.

Verrucous epidermal nevi represent a heterogeneous group. Although mosaicism for mutations in genes that cause autosomal dominant disorders have been shown to underlie a subset of verrucous epidermal nevi (Table 62.7), others have no known counterpart in a generalized form and may possibly result from a lethal genetic defect rescued by mosaicism (see below).

Epidermolytic Verrucous Epidermal Nevus

Verrucous epidermal nevi are tan to brown, warty lesions that are distributed along Blaschko's lines and often present from birth (see Ch. 109 and below). They are occasionally referred to as ichthyosis hystrix, a less specific, descriptive term that has been used for generalized as well as mosaic conditions characterized by thick, spiny hyperkeratosis (see Ch. 57). Some verrucous epidermal nevi have the histologic finding of epidermolytic hyperkeratosis and represent a type 1 mosaic form of the autosomal dominant disorder epidermolytic ichthyosis (previously referred to as bullous congenital ichthyosiform erythroderma; see Ch. 57) caused by mutations in keratin 1 or 10 (Fig. 62.7). In patients with epidermolytic epidermal nevi, a heterozygous mutation is present in keratinocytes within the nevus but not in adjacent uninvolved skin. Patients with generalized epidermolytic ichthyosis sometimes inherit their disorder from a parent with the mosaic form[29], presumably because the parent had gonadal as well as cutaneous mosaicism. It is noteworthy that neurologic and other systemic manifestations (epidermal nevus syndrome; see below), occasionally associated with non-epidermolytic verrucous epidermal nevi, are *not* seen with epidermolytic nevi caused by mutant keratin genes, which are not expressed in the brain.

Unilateral Palmoplantar Verrucous Epidermal Nevus due to Keratin 16 Mosaicism

Mosaicism for a heterozygous *keratin 16* (*KRT16*) mutation was reported in a patient with *unilateral* palmoplantar keratotic streaks that followed Blaschko's lines[30]. This condition can be considered to represent a type 1 mosaic form of pachyonychia congenita. It is distinct from striate palmoplantar keratoderma, which features keratotic bands that radiate up the flexor aspects of the digits bilaterally and is often inherited in an autosomal dominant manner due to germline mutations in the genes encoding desmoglein 1, desmoplakin or keratin 1 (see Ch. 58).

Non-epidermolytic Verrucous Epidermal Nevus due to Fibroblast Growth Factor Receptor 3 Pathway Mosaicism

Non-epidermolytic verrucous epidermal nevi often share clinicopathologic features with acanthosis nigricans, including hyperpigmentation,

Fig. 62.7 Epidermolytic verrucous epidermal nevus. Note the shedding of scale and associated relative hypopigmentation within several of the lesions.

EPIDERMAL NEVI: CANDIDATE GENES AND POTENTIAL SYNDROMIC ASSOCIATIONS

Type of nevus	Genes	Potential syndromic associations
Epidermolytic verrucous epidermal nevus	*KRT1, KRT10*	None
Unilateral palmoplantar verrucous epidermal nevus	*KRT16*	Features of pachyonychia congenita
Verrucous epidermal nevus (non-epidermolytic)	*FGFR3* (R248C mutation)	Features of thanatophoric dysplasia (skeletal, CNS abnormalities)
	PIK3CA	?
	KRAS	Features of cardiofaciocutaneous and Noonan syndromes (include skeletal, CNS abnormalities)
	Epidermal differentiation genes at 1q23?	?
Acneiform/comedonal nevus	*FGFR2*	Features of Apert syndrome (skeletal > CNS abnormalities)
PTEN ("Cowden") epidermal nevus	*PTEN* (germline + 2nd hit in affected tissues)	"Proteus-like" features: *s*egmental *o*vergrowth, *l*ipomatosis, *a*rteriovenous *m*alformations, *e*pidermal *n*evi (SOLAMEN); macrocephaly and other features of Cowden disease/Bannayan–Riley–Ruvalcaba syndrome (see Ch. 63)
Proteus nevus	*AKT1*	Feature of Proteus syndrome (see text)
Woolly hair nevus	?	Skeletal and CNS abnormalities
Nevus sebaceous	*PTCH?*	Schimmelpenning syndrome (skeletal, CNS, ocular); phakomatosis pigmentokeratotica (association with papular speckled lentiginous nevus; occasionally neurologic abnormalities, hypophosphatemic vitamin D-resistant rickets)
Inflammatory linear verrucous epidermal nevus (ILVEN)	*NSDHL?*	Ipsilateral limb reductions
CHILD nevus	*NSDHL*	CHILD syndrome

Table 62.7 Epidermal nevi: candidate genes and potential syndromic associations. CHILD, *c*ongenital *h*emidysplasia with *i*chthyosiform erythroderma/nevus and *l*imb *d*efects; CNS, central nervous system; *FGFR*, fibroblast growth factor receptor; *KRT*, keratin; *PIK3CA*, phosphatidylinositol 3-kinase catalytic subunit alpha; PTEN, phosphatase and tensin homolog.

Fig 62.8 Epidermal nevus due to *FGFR3* mutation and seborrheic keratoses following Blaschko's lines. **A** This lesion represents a mosaic counterpart of the acanthosis nigricans in patients with thanatophoric dysplasia, perhaps reflected in its flexural prominence. **B** Unilateral seborrheic keratoses in bands following Blaschko's lines. Seborrheic keratoses often have a somatic activating mutation in *FGFR3* or *PIK3CA*. *B, Courtesy, Luis Requena, MD.*

a "velvety" texture, flexural accentuation (Fig. 62.8A) and histologic findings of acanthosis and papillomatosis[31]. Approximately one-third of non-epidermolytic keratinocytic (i.e. non-organoid, meaning no sebaceous/other adnexal involvement) epidermal nevi are caused by mosaicism for a particular heterozygous activating mutation (R248C) in the *fibroblast growth factor receptor 3* gene (*FGFR3*), which has been found in lesional but not adjacent skin of affected individuals[32]. When present in all of the cells in the body, the same heterozygous mutation causes *thanatophoric dysplasia*, a disorder characterized by widespread acanthosis nigricans as well as short-limbed dwarfism, severe craniofacial malformations, CNS defects and perinatal lethality. This explains reports of craniofacial anomalies[33] and mental retardation[34] in patients with extensive epidermal nevi associated with mosaicism (presumably affecting extracutaneous tissues) for the R248C *FGFR3* mutation.

Mosaic activating mutations in the *PIK3CA* gene, which encodes a phosphatidylinositol-3-kinase subunit that functions downstream of FGFR3, have been identified in other non-epidermolytic verrucous epidermal nevi (see Table 62.7 and below)[35]. A substantial proportion of seborrheic keratoses and related acquired lesions have a somatic activating mutation in *FGFR3* or *PIK3CA*[35,36], and adult onset of seborrheic keratoses distributed along Blaschko's lines (Fig. 62.8B) has been described[37]. In addition, an activating mutation in the *KRAS* gene was identified in an epidermal nevus and rhabdomyosarcoma but not in peripheral blood or unaffected skin from an infant who also had polycystic kidneys and growth retardation (see Table 62.2 and Fig. 55.6)[38]. Of note, some patients with an extensive non-epidermolytic verrucous epidermal nevus develop vitamin D-resistant rickets due to overproduction of fibroblast growth factor 23 (see below, Epidermal nevus syndromes).

Acneiform/Comedonal Nevus due to Fibroblast Growth Factor Receptor 2 Mosaicism

Comedonal nevi, which are often evident at birth but become more prominent at puberty, consist of numerous keratin-filled pits in a linear distribution. Additional findings may include associated inflammatory acne lesions; hypopigmentation of lesional interfollicular epidermis and/or hairs; digital anomalies such as syndactyly and a broad thumb; and CNS defects[39]. A particular activating mutation (S252W) in the *fibroblast growth factor receptor 2* gene (*FGFR2*) has been found in the affected epidermis but not normal skin of patients with acneiform nevi characterized by numerous comedones, inflammatory lesions and (in one individual) hypopigmentation[40,41]. The same *FGFR2* mutation causes most cases of the autosomal dominant disorder Apert syndrome, which features craniosynostosis, digital anomalies (syndactyly, broad thumbs), severe acne, diffuse pigmentary dilution, and (occasionally) brain malformations. The proportion of acneiform/comedonal nevi (with or without "syndromal" associated findings) that represent a type 1 mosaic form of Apert syndrome remains to be determined.

Non-epidermolytic Verrucous Epidermal Nevus and Additional "Proteus-like" Manifestations due to PTEN Mosaicism

In some patients, non-epidermolytic verrucous epidermal nevi, most often thick papillomatous lesions, are associated with macrocephaly and additional segmental manifestations. The latter can include lipomatosis, fibromas, vascular malformations (frequently with an arteriovenous component) and asymmetric overgrowth of the soft tissues and bones. Heterozygous germline mutations in the *PTEN* gene cause the autosomal dominant PTEN hamartoma tumor syndrome, and a "second hit"/loss of *PTEN* heterozygosity has been found within tissue from segmental lesions including epidermal nevi, lipomas, fibromas and vascular malformations in these individuals. Such patients have *type 2 segmental PTEN hamartoma tumor syndrome*[12,13]. This mosaic "Proteus-like" (see below) entity has also been referred to as "SOLAMEN syndrome" (*s*egmental *o*vergrowth, *l*ipomatosis, *a*rteriovenous *m*alformation and *e*pidermal *n*evus) and "type 2 segmental Cowden disease" featuring the "linear Cowden nevus", but more appropriately termed the "PTEN epidermal nevus" to evoke the full spectrum of the PTEN hamartoma tumor syndrome[13,42].

PTEN negatively regulates PIK3CA/AKT signaling and, further downstream, the mammalian target of rapamycin (mTOR) pathway. The mTOR inhibitor rapamycin was reported to slow overgrowth in a boy with type 2 segmental PTEN hamartoma tumor syndrome[43].

Linear Darier Disease (Acantholytic Dyskeratotic Epidermal Nevus)

Morphologically, linear Darier disease (Fig. 62.9) is usually identical to the generalized form (see Ch. 59). Heterozygous mutations in the *ATP2A2* gene have been found in lesional but not normal-appearing skin, documenting type 1 mosaic Darier disease on a molecular level[44]. Less commonly, linear streaks with earlier onset and increased severity due to a "second hit" in the *ATP2A2* gene are found in patients with generalized Darier disease, reflecting type 2 mosaicism[11a].

Linear Hailey–Hailey Disease (Relapsing Linear Acantholytic Dermatosis)

Linear Hailey–Hailey disease is characterized by relapsing erosions and crusting within a particular segmental area; histologically, acantholysis resembling a "dilapidated brick wall" is observed (see Ch. 59). Inactivation of the second *ATP2C1* allele (loss of heterozygosity) was found in linear regions with earlier and more severe involvement in a patient with generalized Hailey–Hailey disease, confirming type 2 mosaicism[11].

Fig. 62.9 Linear Darier disease with hyperpigmented, keratotic papules.

Linear Porokeratosis

Linear porokeratosis is composed of multiple plaques with keratotic borders (cornoid lamellae). It is often congenital, usually persists throughout life, and likely represents a mosaic form of porokeratosis variant(s) with autosomal dominant inheritance, such as porokeratosis of Mibelli, disseminated superficial actinic porokeratosis, and porokeratosis palmaris, plantaris et disseminata. Linear porokeratosis may occur in a background of disseminated lesions, reflecting type 2 mosaicism. Linear lesions are associated with a higher risk of squamous cell carcinomas than are other porokeratosis variants[45], with a postzygotic "second hit" in the underlying gene presumably contributing to cancer development. Although possible chromosomal loci and candidate genes have been identified, the genetic bases of the porokeratosis variants remain unknown. Interestingly, a patchy unilateral distribution of porokeratoses, hyperpigmentation, hypertrichosis, telangiectasias and skeletal anomalies was observed in a man with mosaic trisomy 16[46].

Linear Basal Cell Carcinomas or Basaloid Follicular Hamartomas

Basal cell carcinomas (BCCs) occasionally develop in a linear distribution in an otherwise normal individual. It has been hypothesized that this might represent a mosaic form of nevoid BCC syndrome or nonsyndromic hereditary multiple BCCs, both of which have autosomal dominant inheritance. To date, mutations in the *PTCH* gene have not been identified in linear BCCs.

A linear distribution of basaloid follicular hamartomas (sometimes referred to as basal cell nevi) may occur as a mosaic form of generalized basaloid follicular hamartoma syndrome, an autosomal dominant condition of unknown etiology that presents with skin-colored to hyperpigmented papules, milia-like lesions, comedo-like plugs, palmoplantar pits and hypotrichosis[47,48]. In Happle–Tinschert syndrome, linear or segmental basaloid follicular hamartomas (variably accompanied by hyperpigmentation, hypopigmentation, atrophoderma, hypertrichosis and/or hypotrichosis) are associated with skeletal, dental and cerebral anomalies[48].

Segmental Neurofibromatosis Type 1

Patients with café-au-lait macules and/or neurofibromas limited to a segmental distribution may have a type 1 mosaic form of neurofibromatosis type 1 (NF1; see Ch. 61) due to a postzygotic mutation in the gene encoding neurofibromin[49]. The distribution of café-au-lait macules, which are often accompanied by lentigines, may be block-like or follow Blaschko's lines, whereas neurofibromas usually occur in a dermatomal pattern (see Table 62.4). Like other type 1 mosaic conditions, segmental NF1 usually has no antecedent family history, but offspring may have full-blown NF1[50]. In addition, large segmental plexiform neurofibromas or café-au-lait macules may also occur as a manifestation of type 2 mosaicism (i.e. due to a postzygotic "second hit" in the *NF1* gene) in patients with generalized NF1.

Linear or Segmental Angiofibromas and Mosaicism in Tuberous Sclerosis

Linear or segmental angiofibromas might represent a mosaic form of tuberous sclerosis (TS; see Ch. 61). Although additional manifestations of TS have been described in a subset of such patients, mosaicism for an underlying mutation has not been proven. However, there have been reports of families where somatic or gonadal mosaicism was found in mildly affected (without an obvious segmental distribution of skin lesions) or clinically unaffected parents of children with TS[51].

Venous and Glomuvenous Malformations (see Ch. 104)

A heterozygous postzygotic mutation in the *TEK* gene can be found in approximately half of sporadic venous malformations. These mutations cause constitutive activation of the TIE-2 endothelial cell tyrosine kinase receptor. This therefore represents a type 1 mosaic form of the autosomal dominant cutaneous and mucosal venous malformation syndrome caused by germline *TEK* mutations[52]. Large segmental plaque-type glomuvenous malformations, which are typically congenital, can occur as a type 2 mosaic manifestation of hereditary glomuvenous malformations due to *GLMN* mutations.

Nevoid Telangiectasia

Unilateral nevoid telangiectasia often appears at puberty and usually affects women (see Ch. 106). It has been postulated to represent a mosaic form of hereditary benign telangiectasia or the autosomal dominant capillary malformation–arteriovenous malformation syndrome caused by *RASA1* mutations (see Ch. 104). The *KRIT1* gene that is mutated in patients with the autosomal dominant cerebral capillary malformation and hyperkeratotic cutaneous capillary–venous malformation syndrome represents another candidate gene for segmental telangiectatic or angiokeratoma-like lesions.

"Zosteriform" Speckled Lentiginous Nevus or Segmental Agminated Melanocytic Nevi

It is possible that some speckled lentiginous nevi (SLN; especially macular lesions) represent a type 1 mosaic form of an autosomal dominant lentiginosis syndrome (e.g. LEOPARD)[53,54]. A patchy distribution of affected and spared areas of skin was described in a boy with LEOPARD syndrome due to a germline *PTPN11* mutation inherited from his father (who had classic LEOPARD syndrome) plus sex chromosome mosaicism; the authors postulated that revertant mosaicism represented one of several possible explanations[54]. Of note, segmental NF1 can also present with lentigines (typically together with café-au-lait macules) and background hyperpigmentation reminiscent of a macular SLN. Development of numerous acquired melanocytic nevi in a segmental distribution without the background hyperpigmentation of a SLN has also been described, suggesting mosaicism for a mutation in a nevus-susceptibility gene[55].

Other Linear Benign Tumors

Trichoepitheliomas, spiradenomas and/or cylindromas occasionally occur in a linear distribution. These may represent mosaic forms of autosomal dominant conditions such as multiple familial trichoepitheliomas, Brooke–Spiegler syndrome, and cylindromatosis caused by heterozygous germline mutations in the *CYLD* gene. Likewise, both sporadic linear syringomas and autosomal dominant inheritance of multiple syringomas with a non-linear distribution have been reported[56]. Leiomyomas often occur in a segmental pattern as a type 2 mosaic manifestation of autosomal dominant multiple cutaneous and uterine leiomyomatosis due to fumarate hydratase mutations (i.e. with a "second hit" in the affected segment).

LINEAR INFLAMMATORY DISORDERS

Several inflammatory skin conditions are occasionally distributed along Blaschko's lines. When generalized, these disorders are multifactorial,

Fig. 62.10 Linear psoriasis. Erythema and scale are seen within the streak as well as in small scattered lesions.

Fig. 62.11 Linear lichen planus. More active lesions are seen on the calf, while postinflammatory hyperpigmentation predominates on the thigh. *Courtesy, Anthony J Mancini, MD.*

typically with both a familial susceptibility and environmental contributions. Some display the Koebner phenomenon as well, implying triggering factors localized to the skin. Linear presentations likely result from mosaicism for a "susceptibility" mutation. In some cases, a streak of more severe disease is superimposed on a generalized background of the same condition, perhaps reflecting clonal loss of heterozygosity[57].

Linear Psoriasis

Linear psoriasis[58] is rare (Fig. 62.10), and some reported cases have subsequently been reclassified as ILVEN (see below). Psoriasis following Blaschko's lines may be confused with the Koebner phenomenon where linearity is imposed by exogenous injury (see Ch. 8). However, both can occur in the presence of generalized psoriasis, as can psoriasis superimposed on an epidermal nevus. It may be that the linear clone is characterized by a susceptibility mutation (see above).

Linear Lichen Planus

Linear lichen planus (LP) is more common than linear psoriasis and is seen at all ages. It presents as typical LP lesions in a linear distribution (Fig. 62.11), and postinflammatory hyperpigmentation is often the most prominent feature. Histology may be required to distinguish this disorder from other causes of linear pigmentation (see Fig. 62.3). If the LP lesions extend to the end of a digit, the nail is often affected.

Lichen Striatus

This self-limited linear inflammatory condition usually occurs during childhood (see Ch. 11), most commonly on an extremity in an atopic individual[59]. The condition is not particularly itchy, but it has histologic features of both eczema and lichen planus. Postinflammatory hypopigmentation points to the diagnosis of lichen striatus rather than linear lichen planus; both can be associated with nail dystrophy. Lichen striatus may reflect a susceptibility mutation or loss of heterozygosity in an atopy gene.

Segmental Vitiligo

Vitiligo (see Ch. 66) is another multifactorial disorder that occasionally occurs in a segmental distribution. Compared with symmetric vitiligo, the segmental type is earlier in onset, less likely to spread to other areas of the body, and less frequently associated with other autoimmune diseases. The lesions tend to be broad bands, patches or blocks, less often following Blaschko's lines. The occasional association of segmental with non-segmental vitiligo is in keeping with a polygenic disorder, with loss of heterozygosity for a vitiligo gene expressed in the skin[60].

Segmental vitiligo may occasionally be confused with nevus depigmentosus, but the latter is characterized by hypopigmentation rather than depigmentation, a stable size and shape relative to the growth of the child, and presence at birth or soon thereafter. A congenital linear band with complete absence of pigment raises the possibility of mosaicism for piebaldism.

Blaschkitis

Blaschkitis is a rare inflammatory dermatosis that typically presents as pruritic papules and vesicles along multiple lines of Blaschko, particularly on the trunk. More common in adults than children[61], it follows a relapsing course, with episodes often resolving spontaneously within days. It bears some resemblance to lichen striatus, but the histology is more eczematous and less lichenoid.

Other Linear Inflammatory Disorders

Several other inflammatory disorders occasionally occur in a distribution along Blaschko's lines, suggesting mosaicism for a susceptibility mutation. These conditions include lupus erythematosus (with scleroderma features in one variant)[62,63], dermatomyositis, lichenoid and fixed drug eruptions[64,65], lichenoid GVHD[66], morphea[67], and atrophoderma of Pasini and Pierini (linear atrophoderma of Moulin[68]).

LETHAL DISORDERS RESCUED BY MOSAICISM

For some linear or segmental disorders, no generalized counterpart can be recognized. These cases probably represent mosaicism for an autosomal mutation that would be incompatible with life if it involved all cells in the body. Such conditions occur sporadically.

Non-epidermolytic Epidermal Nevus (Including Sebaceous Nevus)

A linear epidermal nevus may be warty, smooth or barely palpable; brown (Fig. 62.12), pink, yellow or tan (Fig. 62.13); localized or extensive; unilateral or systematized; and isolated or associated with systemic abnormalities. The appearance is affected by both the age of the patient and the site of the lesion. Epidermal nevi are often white and velvety at birth, due to maceration by amniotic fluid. They may first become evident later in infancy or extend over time, a phenomenon parents find worrisome and hard to reconcile with the term "birthmark". Epidermal nevi are more likely to show sebaceous differentiation if they occur on the face or scalp, and this element becomes more prominent after puberty. Epidermal nevi on the scalp tend to have overlying alopecia or hair with an abnormal (e.g. woolly) texture.

This is a heterogeneous group (see Table 62.7); some associated genes are already known and undoubtedly more will be identified. Genes responsible for both generalized autosomal dominant disorders and epidermal nevi are discussed above. Activating mutations in the *PIK3CA* oncogene, which encodes a protein that functions in FGFR signaling, are associated with seborrheic keratoses as well as epidermal nevi[35,36]. There are no known generalized disorders caused by *PIK3CA* mutations, which may be survivable only in a mosaic state. Two patients have been reported with isolated epidermal nevi and mosaicism for a chromosomal break at 1q23, a major locus for genes involved in epidermal differentiation[69]. Mosaic trisomy 6 has also been associated with epidermal nevi[70].

Despite considerable evidence that they are variants of the same condition, smooth round sebaceous nevi of the scalp behave differently from linear sebaceous nevi. Linear lesions are more likely to be associated with neurologic abnormalities; this may relate to the fact that linear lesions arise earlier than round lesions and are more likely to involve multiple organs (see Table 62.3). However, round lesions are more tumor-prone, occasionally developing basal cell carcinoma in adult life, perhaps due to loss of heterozygosity. Deletion of *PTCH* (the Gorlin syndrome gene) has been reported in a nevus sebaceus.

Epidermal Nevus Syndromes

Synonyms/variants: ■ Nevus sebaceus syndrome ■ Schimmelpenning–Feuerstein–Mims syndrome ■ Solomon syndrome ■ Jadassohn syndrome

Key features

- The term encompasses a heterogeneous group of disorders
- The linear lesions are most commonly non-epidermolytic verrucous epidermal nevi, sebaceous nevi, or organoid nevi (with variable combinations of epidermal and adnexal elements)
- Systemic abnormalities involve primarily the skeleton, eyes and CNS

Introduction

Epidermal nevus syndromes (ENSs) are heterogeneous disorders in which epidermal nevi of various types are associated with musculoskeletal, ocular and/or neurologic abnormalities[71,72]. The phenotype is determined not only by the nature of the underlying mutation but also by the timing of origin and distribution of the mosaic clone. A vast array of systemic abnormalities, some of which may have occurred by chance, have been described in patients with epidermal nevi.

History

Reports of epidermal nevi together with abnormalities in other organ systems date back over a century. Various authors are credited with descriptions of these associations, including Jadassohn, Schimmelpenning, Feuerstein and Mims. Solomon and Esterly reviewed the syndrome in 1975[73], and Solomon is often credited with naming the disorder. In 1995, Happle[74] suggested that no one "ENS" exists, but rather that this term encompasses multiple, more specific entities such as Schimmelpenning, Proteus and CHILD syndromes. The term "ENS" is restricted here to sebaceous or verrucous epidermal nevi with associated features that do not fit into other specific disorders.

Genetics

Like epidermal nevi in general, ENSs typically occur in a sporadic fashion and may represent lethal disorders rescued by mosaicism.

Pathogenesis

ENSs are genetically heterogeneous. The diverse abnormalities of the skin and other organs in ENSs suggest basic underlying defects in regulation of cellular growth and differentiation. Among the genes known to be associated with epidermal nevi, *FGFR3* and *PTEN* mutations can also result in musculoskeletal and CNS anomalies (see Table 62.7 and above).

Fig. 62.12 Extensive epidermal nevus. The lesions on the neck are more verrucous.

Fig. 62.13 Epidermal nevus with the classic V-shaped pattern seen on the mid-back.

Clinical features

Other skin findings described in association with verrucous epidermal or sebaceous nevi include hypo- or hyperpigmentation (e.g. café-au-lait macules) in a mosaic distribution, woolly hair nevi, "hemangiomas" or vascular malformations, lipomatous overgrowth, aplasia cutis congenita and melanocytic nevi.

Systemic abnormalities most often involve the CNS (e.g. hemimegalencephaly, seizures, hemiparesis, developmental delay)[75], eye (e.g. lipodermoids, coloboma, choristoma) and skeleton (e.g. asymmetry, abnormal skull shape, kyphoscoliosis, limb hypertrophy). Other reported associations include cardiac and genitourinary anomalies. Hypophosphatemic vitamin D-resistant rickets has been observed in patients with extensive epidermal nevi, especially sebaceous nevi in the setting of phakomatosis pigmentokeratotica (a form of "twin spotting" [see Ch. 55] that also features papular SLN). This phenomenon has been associated with overproduction of fibroblast growth factor 23, a phosphaturic protein that causes oncogenic hypophosphatemic osteomalacia when secreted by various tumors. There is a suggestion that epidermal nevi involving the head are more likely to be associated with cerebral defects, although this observation has not been systematically evaluated.

Pathology

The histopathologic findings depend on the type of epidermal nevus.

Differential diagnosis

Although the clinical and histologic features of various types of epidermal nevi are often distinctive (see above), the clinician also needs to determine whether or not the patient has associated systemic abnormalities. In general, the older the child, the easier the task. The possibility that the epidermal nevus is a component of another multisystem disorder, such as Proteus syndrome or type 2 segmental PTEN hamartoma tumor syndrome, also needs to be considered.

Treatment

There is no specific treatment, so therapy is supportive. Neurologic, ophthalmologic and orthopedic referrals are often required.

Porokeratotic Eccrine Ostial and Dermal Duct Nevus

Porokeratotic eccrine ostial and dermal duct nevus (PEODDN) features keratotic spines and/or punctate pits with keratotic plugs. It can resemble a comedonal nevus but favors the palms and soles (see Fig. 111.39), where pilosebaceous follicles are absent; widespread involvement along Blaschko's lines can also occur[76]. Neonatal erosions, coexisting linear psoriasis, and associated squamous cell carcinomas have been described[76,77].

Proteus Syndrome

Key features

- Asymmetric overgrowth that is progressive and disproportionate
- Non-epidermolytic keratinocytic epidermal nevi and vascular malformations
- Areas of dermal atrophy with prominent venous patterns
- Palmoplantar cerebriform hyperplasia
- Lipomas and regional lipohypoplasia

Introduction

This syndrome, named after the Greek god of many forms, is a mosaic disorder characterized by asymmetric overgrowth of a variety of tissues.

History

Before Proteus syndrome was defined in 1983, patients with this condition were often classified as having ENS, Klippel–Trenaunay syndrome or NF1. Diagnostic criteria for Proteus syndrome were established in 1999, emphasizing the mosaic distribution of lesions, progressive course (particularly during childhood), and disproportionate nature of the overgrowth[78].

Genetics

Proteus syndrome occurs sporadically and is caused by mosaic activating mutations in the *AKT1* gene[78a].

Pathogenesis

The involvement of multiple organ systems in Proteus syndrome is consistent with the expression of AKT1, a serine-threonine protein kinase that promotes cell growth and survival, in many tissues. Although *PTEN* mutations have not been identified in patients with classic Proteus syndrome, some patients with Proteus-like phenotypes have a type 2 segmental form of PTEN hamartoma tumor syndrome (see above)[12,13,42]. This is not surprising considering that PTEN negatively regulates the growth-promoting PIK3CA/AKT pathway that is activated in affected tissues of Proteus syndrome patients.

Clinical features

Epidermal nevi in Proteus patients tend to be relatively thin and "soft"[72]. Other cutaneous manifestations include slow-flow vascular malformations (particularly port-wine stains), cerebriform palmar or plantar connective tissue nevi, patchy dermal hypoplasia resulting in prominent subcutaneous veins, and abnormal fat deposition producing lipomas and lipoatrophy (Fig. 62.14). Disproportionate overgrowth typically results in asymmetric macrodactyly or limb gigantism, usually with abnormal bones and deficient soft tissue, and scoliosis related to megaspondylodysplasia. Visceral overgrowth, especially of the spleen, can also occur.

Pathology

Histopathologic examination of epidermal nevi reveals hyperkeratosis, papillomatosis and acanthosis without adnexal differentiation or epidermolytic hyperkeratosis.

Differential diagnosis

Several other disorders feature epidermal nevi and vascular malformations together with asymmetric overgrowth. However the latter to be relatively proportionate, leading to a "ballooning" effect but normal structure, and less progressive than that of Proteus syndrome. Type 2 segmental PTEN hamartoma tumor syndrome (also known as SOLAMEN syndrome; see above) is characterized by macrocephaly, thicker and more verrucous epidermal nevi, vascular malformations

Fig. 62.14 Proteus syndrome. Epidermal nevus, vascular malformations and localized fatty infiltration of the thigh.

with a fast-flow component, and a lack of truly "cerebriform" palmoplantar connective tissue nevi. Another entity in the differential diagnosis is CLOVE(S) syndrome – *c*ongenital *l*ipomatous *o*vergrowth, *v*ascular anomalies, *e*pidermal nevi and *s*coliosis/other *s*keletal abnormalities (especially broad hands and feet)[79]. Epidermal nevi are an occasional feature of macrocephaly–capillary malformation syndrome (see Ch. 104). Although the association of an epidermal nevus with a port-wine stain was originally included as a form of phakomatosis pigmentovascularis (PPV type I), this variant was removed from more recent versions of the PPV classification scheme (see Table 104.4) because epidermal nevi are not melanocytic lesions. The disfiguring plexiform neurofibromas of NF1 can be distinguished from Proteus syndrome by the clinicopathologic features and presence of café-au-lait macules and other stigmata of NF1. Unlike Proteus syndrome, the overgrowth in Klippel–Trenaunay syndrome (KTS) is spatially associated with a vascular malformation.

Treatment

Management is symptomatic and organ-specific. Individual hamartomas and localized overgrowth can sometimes be treated surgically. Limb gigantism usually requires vascular imaging, with selective embolization sometimes providing an alternative or adjunct to surgery. Patients with Proteus syndrome (like those with KTS) are susceptible to deep venous thrombosis and pulmonary embolism.

ILVEN (Inflammatory Linear Verrucous Epidermal Nevus)

ILVEN is a linear, erythematous, scaly plaque that follows Blaschko's lines and is characteristically pruritic (Fig. 62.15; see Ch. 109). While occasionally present at birth, it usually appears during childhood (or, less often, adult life) and extends over months to years. It responds temporarily, if at all, to topical anti-inflammatory agents and rarely remits spontaneously. There are anecdotal reports of improvement with etanercept. Surgical excision is an option, but possible complications related to scarring need to be considered. This entity has been confused in the past with linear psoriasis.

Unlike the non-inflammatory epidermal nevi, ILVEN is not associated with neurologic defects. Rarely, there are ipsilateral skeletal abnormalities, usually reduction deformities, suggesting that ILVEN is possibly a forme fruste of CHILD syndrome. An alternative acronym is PEN/PENCIL (*p*soriasiform *e*pidermal *n*evus + *c*ongenital *i*psilateral *l*imb defects)[80].

Fig. 62.15 Inflammatory linear verrucous epidermal nevus. Scaly psoriasiform plaques distributed in a linear array.

Encephalocraniocutaneous Lipomatosis (Haberland Syndrome)

Encephalocraniocutaneous lipomatosis (ECCL) is a rare condition characterized by cerebral malformations with ipsilateral eye abnormalities (usually choristomas) and papulonodular skin lesions including lipomas, fibromas, fibrolipomas and angiolipomas. These lesions favor the eyelids and scalp, and alopecia overlying scalp lipomas, referred to as nevus psiloliparus, is occasionally associated with aplasia cutis congenita[81]. The cranial and eye lesions are usually unilateral, but lipomas occasionally occur on both sides of the scalp. Of note, Blaschko's lines cross the cranial midline in a spiral pattern (see Fig. 62.1C). Oculoectodermal syndrome, which also features aplasia cutis congenita (see Table 64.4), may represent a milder variant of ECCL[82].

Oculocerebrocutaneous Syndrome (Delleman–Oorthuys Syndrome)

The primary features of this syndrome are CNS malformations (e.g. cysts, cerebellar hypoplasia, absent corpus callosum), orbital cysts, microphthalmia, finger-like cutaneous appendages representing striated muscle hamartomas (especially around the eye), and aplasia cutis congenita above the ear[83].

McCune–Albright Syndrome

McCune–Albright syndrome is characterized by large blocks of café-au-lait pigmentation, demarcated at the midline and sometimes following Blaschko's lines in broad bands, together with polyostotic fibrous dysplasia of the bone and/or endocrine hyperfunction (classically precocious puberty). It is due to a postzygotic activating mutation in *GNAS*, the gene encoding the α-subunit of the G protein that stimulates adenylate cyclase activity. This results in increased signaling in pathways where cyclic AMP acts as a "second messenger", explaining endocrine overactivities and increased pigmentation due to stimulation of tyrosinase. Large café-au-lait patches in otherwise healthy individuals may represent more limited involvement due to a *GNAS* mutation later in embryonic development. It has proved more difficult to identify the mutation in skin than in other affected tissues[84].

Vascular Malformations

Vascular malformations, including those associated with Klippel–Trenaunay and Sturge–Weber syndromes as well as cutis marmorata telangiectatica congenita and microcystic lymphatic malformations ("lymphangioma circumscriptum"), may also be due to mosaicism for otherwise lethal mutations.

CHROMOSOMAL MOSAICISM

Hypomelanosis of Ito

Synonyms: ■ Linear nevoid hypopigmentation ■ Pigmentary mosaicism ■ Incontinentia pigmenti achromians (historical)

Key features

- A descriptive term rather than a diagnosis
- Hypopigmentation following Blaschko's lines, which can be evident at birth or appear later and may extend over time
- Variable extracutaneous involvement, which can include CNS, musculoskeletal and ocular abnormalities
- The underlying mosaic defect (often a chromosomal aberration) varies

Introduction

Hypomelanosis of Ito represents a description rather than a diagnosis. It refers to hypopigmentation in a distribution following Blaschko's lines due to a clone of skin cells with decreased ability to produce

pigment. Extracutaneous findings are highly variable and are found in a minority of individuals with hypopigmentation along Blaschko's lines. The author reserves the term "hypomelanosis of Ito" for patients with extracutaneous manifestations.

History

Ito, when describing this condition in 1952, interpreted the appearance as a negative image of incontinentia pigmenti, with markings following the same pattern of Blaschko's lines but lighter than the normal skin rather than darker.

Epidemiology

HI affects both sexes and all races, but it is easier to see in darkly pigmented skin.

Genetics

HI is almost always sporadic. There are a few published reports of possible familial occurrence.

Pathogenesis

Chromosomal mosaicism can be identified in the blood by standard cytogenetic analysis in about a third of HI patients. In other cases, the clonal abnormality may be too subtle to be detected cytogenetically or only expressed in tissues other than blood. Fibroblasts cultured from lesional skin show chromosomal mosaicism in some patients with normal blood karyotypes. The yield is increased further by studying cultured keratinocytes (since the mosaic abnormality may be confined to the epidermis; however, keratinocyte cultures are not routinely performed at most cytogenetic laboratories)[85] and by the use of array-comparative genomic hybridization (CGH), which can detect structural variations with much higher resolution[86].

HI can be caused by mosaicism for a wide variety of abnormalities in the structure (e.g. unbalanced translocations) or number (aneuploidies) of autosomes and X chromosomes. Approximately 90% of the chromosomal aberrations that have been reported in patients with HI or linear and whorled nevoid hypermelanosis (LWNH; see below) overlapped with the locations of genes known to be involved in pigmentation[87]. Extracutaneous findings depend upon the particular chromosomal defect and the tissues affected. Diploid/triploid mosaicism, mosaic tetrasomy 12p (Pallister–Killian syndrome; mental retardation, seizures and facial dysmorphism as well as hypo- or hyperpigmentation along Blaschko's lines)[88], and mosaic trisomy (or tetrasomy) 13q (phylloid hypomelanosis rather than hypopigmentation along Blaschko's lines)[89] are specific subtypes.

Clinical features

Streaks and swirls of hypopigmentation along Blaschko's lines can occur anywhere on the cutaneous surface and may be apparent at birth or (especially in those with fair skin) become evident during childhood. Occasional associated skin findings include lentigines, hypertrichosis and alopecia. Approximately one-third of children with hypopigmentation along Blaschko's lines who present to a pediatric dermatologist at a tertiary referral center have extracutaneous abnormalities, which generally became apparent during infancy. The extracutaneous abnormalities are highly variable, most often affecting the CNS, eyes and musculoskeletal system.

Pathology

Lesional skin may appear normal or show reduced numbers of melanocytes.

Differential diagnosis

Figure 62.3 shows the differential diagnosis of hypopigmented lesions following Blaschko's lines. Some patients with chromosomal mosaicism may have linear streaks of both hypo- and hyperpigmentation or a combination of linear and block-like hypopigmentation (see below).

Treatment

Therapy is symptomatic and organ-specific.

Nevus Depigmentosus

A nevus depigmentosus is a hypopigmented skin condition that (like HI) is thought to reflect cutaneous mosaicism. However, it is generally more limited in extent and usually lacks extracutaneous associations. The most common presentation is a localized patch that breaks apart into smaller macules at its periphery (resembling a splash of paint). A segmental variant (block-like; hypopigmented form of "segmental pigmentation disorder"[90]) typically features midline demarcation and less distinct lateral borders, and a linear or "systematized" variant has been described that overlaps with the cutaneous findings in HI[90a]. Although classically evident at birth, a nevus depigmentosus sometimes becomes apparent later in childhood, especially in lightly pigmented individuals.

Linear and Whorled Nevoid Hypermelanosis

LWNH is characterized by hyperpigmentation along Blaschko's lines due to a clone of skin cells with increased (rather than decreased as in HI) pigment production. Similar to HI, a variety of underlying mosaic chromosomal anomalies have been reported. The term "pigmentary mosaicism" therefore describes both HI and LWNH. Although LWNH (like HI) is usually sporadic, epigenetic mosaicism due to autosomally inherited retrotransposons may explain occasional familial aggregation[5]. The skin findings in LWNH typically appear at or soon after birth. Approximately a quarter of patients with LWNH who present to a pediatric dermatologist have extracutaneous findings, which can involve the CNS, musculoskeletal system and (occasionally) heart. Skin histology shows primarily increased epidermal pigmentation in affected skin.

CHIMERISM

Block-like Hyper- and Hypopigmentation due to Chimerism

Chimerism differs from mosaicism in that the different clones originate from different organisms. Human chimeras can result from fusion of two zygotes (i.e. fused dizygotic twins) or fertilization of one egg by two sperm. Usually detected by hematologists as anomalous blood groups, chimerism is exceedingly rare. Findlay and Moores[91] studied more than a million routine blood samples and found evidence of chimerism in only two. Pigmentary variation in chimerism typically presents in a checkerboard pattern; however, streaks along Blaschko's lines and mixtures of light and dark skin that do not correspond to recognized patterns of mosaicism have also been described[92]. In cases of XX/XY chimerism, the karyotype of dermal fibroblasts does not necessarily correspond to the overlying skin color, probably reflecting the different embryonic migration routes in the dermis and epidermis[10].

Introduction

In this chapter, a number of genodermatoses are discussed that are not covered in other chapters of this textbook (Table 63.1).

Disorders characterized by cutaneous or mucosal tumors in conjunction with a variety of extracutaneous neoplasias (both benign and malignant) as well as endocrine abnormalities are the focus of the first section. It includes multiple endocrine neoplasia types 1, 2A and 2B in addition to Cowden disease, Gardner syndrome and Muir–Torre syndrome. This is followed by enzyme deficiencies, premature aging syndromes, poikilodermas and, lastly, ectodermal dysplasias.

DISORDERS FEATURING TUMORIGENESIS

Susan J Bayliss and David R Berk

MULTIPLE ENDOCRINE NEOPLASIA

Multiple endocrine neoplasia (MEN) refers to a group of disorders marked by the presence of neoplasia or hyperplasia in two or more endocrine organs, often in association with mucocutaneous findings. Three major MEN syndromes, termed types 1, 2A and 2B, have been clinically and genetically defined and are described in Table 63.2.

Mucocutaneous features are most notable in MEN types 1 and 2B. In type 1, facial angiofibromas (previously considered pathognomonic for tuberous sclerosis) are seen, in addition to collagenomas (Fig. 63.1), lipomas and hypopigmented macules[1]. Compared to those in tuberous sclerosis, angiofibromas in MEN 1 tend to be smaller and fewer in number, and they are more likely to arise on the upper lip and its vermilion border (in addition to the nose and medial cheeks). Although melanoma has been reported in patients with MEN 1 and the *MEN1* gene is affected in a small subset of sporadic melanomas[2], it remains unclear whether individuals with this syndrome have an increased risk of melanoma.

MEN 2B is notable for multiple mucosal neuromas (especially of the conjunctivae, lips and tongue; Fig. 63.2), which may be present at birth or develop during childhood. They are considered relatively specific for this diagnosis, although mucosal neuromas are occasionally observed in patients with the PTEN hamartoma tumor syndrome (see below)[3]. Cutaneous neuromas are rare and when present are usually in a perinasal location.

COWDEN DISEASE

Synonyms: ■ Multiple hamartoma syndrome ■ Cowden syndrome

Key features

- Autosomal dominant disorder characterized by multiple hamartomatous tumors of ectodermal, mesodermal and endodermal origin
- Mucocutaneous findings include trichilemmomas, acral keratoses, oral papillomas and sclerotic fibromas
- Two major sites of involvement are the thyroid (e.g. adenomas, follicular carcinoma) and the breast (e.g. fibrocystic disease, carcinoma)
- Caused by mutations in the *PTEN* gene

Introduction

Cowden disease (CD) is an uncommon genetic disorder that is characterized by multiple hamartomas of ectodermal, mesodermal and endodermal origin. Mucocutaneous lesions (trichilemmomas, acral keratoses and oral papillomas) are the most constant and characteristic features[4,5]. Neoplasms (benign and malignant) of the breast and thyroid occur in up to two-thirds of patients[6].

History

In 1963, Lloyd and Dennis reported a multisystem disorder with characteristic mucocutaneous lesions and tumors of the breast, thyroid and gastrointestinal tract[4]. They named the disorder "Cowden disease" after their first patient.

Epidemiology

CD is probably more common than is reflected by the number of cases reported, because the clinical findings can be subtle. It is inherited as an autosomal dominant trait with variable expressivity; a female predominance has been noted in some series[7]. Most of the reported patients have been Caucasian, and it is estimated to affect 1 in 200 000 individuals[8].

GENODERMATOSES
Hereditary connective tissue disorders
Disorders of keratinization
Hereditary epidermolysis bullosa
Hereditary disorders of hair and nails
Hereditary disorders of pigmentation
Metabolic skin disorders (including enzyme deficiencies; see below)
Disorders featuring cutaneous cancer
Disorders featuring benign tumors
Skin disorders associated with extracutaneous cancer
• MEN 1, 2A, 2B*
• Cowden disease*
• Gardner syndrome*
• Muir–Torre syndrome*
• Birt–Hogg–Dubé syndrome
• Reed syndrome
Ectodermal dysplasias*
Premature aging syndromes*
Poikilodermas*
Enzyme deficiencies*

Pathogenesis

Germline mutations in the tumor suppressor gene *PTEN*, located on chromosome 10q22–23, are found in most patients with CD[9]. Mutations in this gene have also been observed in patients with Bannayan–Riley–Ruvalcaba syndrome (BRRS), Lhermitte–Duclos disease (LDD; hamartomatous overgrowth of cerebellar ganglion cells), and autism/macrocephaly syndrome. Of note, there is significant overlap in the clinical findings in patients with CD and BRRS (Table 63.3). Identical mutations have been found in patients with CD and BRRS, and in some families both CD and BRRS phenotypes are observed. As a result these disorders are grouped as PTEN hamartoma tumor syndrome

The primary defect in CD is thought to be an abnormality in the regulation of cellular proliferation[6]. The protein product of the *PTEN* gene is a lipid and protein phosphatase that plays a role in cell-cycle regulation and apoptosis. In particular, PTEN downregulates the phosphatidylinositol 3-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) pathway (see Fig. 55.5). PTEN also helps to promote chromosomal stability. Importation of the PTEN protein into the nucleus (via monoubiquitination) is essential for its tumor suppressor activity, and some mutations have been shown to disrupt major monoubiquitination sites[10]. Affected tissues include those with physiologic proliferation, such as the epidermis, oral and gastrointestinal mucosa, and thyroid and breast epithelium.

Clinical Features

In 1995, the International Cowden Syndrome Consortium developed operational diagnostic criteria that have since been updated multiple times. The most recent criteria are outlined in Table 63.4. Cutaneous involvement occurs in >80% of patients, and the characteristic mucocutaneous lesions usually begin to appear during the second to third decades of life (average, 22 years; range, birth to 75 years). The facial trichilemmomas present as multiple skin-colored or yellowish-tan verrucous papules that resemble common warts (Fig. 63.3)[5,11]. Other nonspecific cutaneous papules show a predilection for the face and distal extremities, and they may coalesce around facial orifices and the ears.

Multiple sclerotic fibromas of the skin are another relatively specific cutaneous marker of CD[12]. These lesions present as sharply circumscribed dermal papules with a strikingly uniform storiform pattern of collagen bundles on histologic examination (see Ch. 116). Punctate palmoplantar keratoses, often with a central depression, are present in more than half of patients[13] (Fig. 63.4). Keratotic papules can also be seen on the heels, the dorsal aspects of the hands and feet, and the extensor surfaces of the forearms and lower legs.

Other cutaneous lesions observed in patients with CD include lipomas, angiolipomas, vascular anomalies[14,15], acrochordons, and inverted follicular keratoses[5]. Oral lesions of CD appear as 1–3 mm skin-colored papules that often lead to a cobblestone appearance; there can be extensive involvement of the entire oral cavity, including the tongue[13]. The vascular anomalies of CD and BRRS tend to be multifocal, fast-flow lesions with intramuscular involvement and prominent associated ectopic fat. Intracranial developmental venous anomalies are also common (see Ch. 104)[15].

Thyroid disease occurs in approximately two-thirds of patients with CD and can include goiter, adenomas, and carcinoma (follicular > papillary; lifetime risk 5% to 10%)[4,8]. Fibrocystic disease and fibroadenomas of the breast affect three-quarters of female patients. Ductal papillomas and virginal hypertrophy may also be seen. Breast carcinoma develops in 25% to 50% of female patients with CD (at a mean age of approximately 40 years)[8,16], and it has also been reported in affected men[17].

Multiple hamartomatous polyps, usually less than 5 mm in diameter, may be found anywhere in the gastrointestinal tract, including the esophagus, stomach, small intestine, colon and anus. The polyps may involve the entire gastrointestinal tract, but they are most common in the colon. These lesions are usually asymptomatic and their malignant degenerative potential is small, with a recent review identifying only five published cases of colorectal carcinoma in patients with CD[8].

Benign ovarian cysts and uterine leiomyomas commonly develop and endometrial carcinoma occurs in 5–10% of women with CD[8]. Less frequent tumors include teratomas, other genitourinary carcinomas (urethral, cervical, renal cell, and transitional cell of the renal pelvis, ureter or bladder), cysts (Gartner's duct [vaginal], epidermoid, apocrine

TYPES OF MULTIPLE ENDOCRINE NEOPLASIA (MEN)							
MEN type (synonyms)	**Mode of inheritance**	**Gene locus**	**Gene**	**Protein product**	**Location and type of mutations**	**Clinical manifestations**	
						Systemic	**Mucocutaneous**
1 (Wermer syndrome, multiple endocrine adenomatosis)	AD	11q13	*MEN1** [*MENIN*]	Menin (a nuclear protein)	Variable; truncating mutations in >70%	**Pituitary**: prolactinoma > acromegaly, Cushing syndrome **Parathyroid**: hyperplasia or adenoma, hyperparathyroidism **Pancreas**: islet cell hyperplasia, adenoma or carcinoma, e.g. gastrinoma, insulinoma, glucagonoma Less common: foregut carcinoid tumors, adrenal (cortical) tumors, follicular adenomas (thyroid) Uncommon: pheochromocytoma	Multiple facial angiofibromas Collagenomas Lipomas (cutaneous and visceral) Less common: multiple gingival papules, confetti-like hypopigmented macules, possibly CALM
2A (MEN type 2, Sipple syndrome, pheochromocytoma and amyloid-producing medullary thyroid carcinoma, PTC syndrome)	AD	10q11.2	*RET*†	Tyrosine kinase receptor	Point mutations in the cysteine-rich extracellular domain, especially codon 634‡	**Parathyroid**: hyperplasia or adenoma; hyperparathyroidism (less frequent than in MEN 1) **Thyroid**: C-cell hyperplasia, medullary carcinoma§ **Adrenal**: pheochromocytoma (50% bilateral) Unusual: Cushing syndrome	Pruritus¶ Lichen amyloidosis¶ Notalgia paresthetica¶ Macular amyloidosis¶
2B (MEN type 3, multiple mucosal neuroma syndrome, mucosal neuromata with endocrine tumors, Wagenmann–Froboese syndrome)	AD	10q11.2	*RET*†	Tyrosine kinase receptor	>95% of patients have missense mutation (Met^{918}Thr) in substrate-recognition pocket	**Thyroid**: medullary carcinoma§ **Adrenal**: pheochromocytoma (50% bilateral) **GI**: Diffuse ganglioneuromatosis (megacolon, diverticulosis) Medullated corneal nerve fibers Proximal myopathy Marfanoid habitus Reduced subcutaneous fat High-arched palate Flat nasal bridge Pectus excavatum Other: Bilateral pes cavus, high patella, scoliosis, kyphosis, lordosis, joint laxity Rare: Cushing syndrome	Multiple mucosal neuromas, especially eyelid margins, conjunctivae, lips, anterior tongue > gingiva, palate, nasal and laryngeal mucosa Increased nerve fibers in normal skin Prominent, everted lips Everted eyelids Hyperpigmentation around mouth and overlying small joints of hands and feet CALM Circumoral lentigines Hypertrichosis, synophrys Rare: multiple neuromas of perinasal skin

*A tumor suppressor gene.
†Rearranged during transfection of proto-oncogene; mutations in the same gene can be responsible for Hirschsprung disease and familial medullary thyroid carcinoma.
‡Induce dimerization and activation of receptor in the absence of its ligand.
§Screen via measurement of serum calcitonin level after calcium or pentagastrin injection.
¶Onset usually prior to medullary thyroid carcinoma.

Table 63.2 Types of multiple endocrine neoplasia (MEN). A rare fourth type of MEN (MEN 4), caused by mutations in cyclin-dependent kinase inhibitor 1B (CDKN1B) and characterized by pituitary and parathyroid tumors, has been described; familial medullary thyroid carcinoma can result from *NTRK1* mutations as well as *RET* mutations. A woman with medullary thyroid carcinoma, macular amyloidosis, and multiple cutaneous neuromas in a widespread distribution (overlapping features of MEN 2A and MEN 2B) with a RET mutation in codon 768 has also been reported. AD, autosomal dominant; CALM, café-au-lait macules; NTRK1, neurotrophic tyrosine kinase receptor type 1.

hidrocystomas), and benign urethral polyps. Menstrual irregularities may also be present.

Craniomegaly is the most common skeletal manifestation, occurring in 80–100% of patients[7]. One-third of patients with CD have additional skeletal abnormalities, including adenoid facies, a high-arched palate, thoracic kyphosis or kyphoscoliosis, pectus excavatum, bone cysts, large hands and feet, syndactyly and other digital anomalies[11]. Ocular abnormalities have been reported in 13% of patients and include myopia, angioid streaks and retinal vascular anomalies[18].

Lhermitte–Duclos disease (LDD) is characterized by hamartomatous overgrowth of cerebellar ganglion cells, which can lead to elevated intracranial pressure, ataxia and seizures. LDD may be an isolated finding or occur in association with CD[19]. Patients with adult-onset LDD usually have a mutation in the *PTEN* gene.

Pathology

Histologically, trichilemmomas are characterized by a lobular proliferation of pale keratinocytes, often in association with a hair follicle. Basal keratinocytes are oriented to form a palisade, and hyperkeratosis can lead to a cutaneous horn. Histologically, some facial papules in patients with CD may simply be squamous papillomas, while others show follicular infundibular hyperplasia. Oral lesions often represent fibromatous nodules with collagen fibers arranged in whorls. On biopsy, extrafacial and palmoplantar papules tend to be hyperkeratotic papillomas, and they may have changes reminiscent of verrucae or acrokeratosis verruciformis[20].

Differential Diagnosis

The clinical differential diagnosis of the oral papillomas of CD includes verrucae, focal epithelial hyperplasia (Heck's disease), traumatic fibromas, mucosal neuromas of MEN 2B, papillomas of Goltz syndrome, and papular lesions of lipoid proteinosis. A combination of acral keratoses (including palmoplantar) plus oral and facial papules can also be seen in Darier disease, whereas multiple facial angiofibromas and gingival fibromas are characteristic of tuberous sclerosis. These disorders can usually be differentiated from CD by other characteristic features as well as histologic evaluation.

The clinical differential diagnosis of multiple facial trichilemmomas may include angiofibromas (as seen in tuberous sclerosis or MEN 1), trichoepitheliomas, and fibrofolliculomas (Birt–Hogg–Dubé syndrome); in addition to their histologic features, the tendency of trichilemmomas to have a verrucous appearance clinically can help to distinguish them from these lesions. Common warts, seborrheic keratoses, basaloid follicular hamartoma syndrome, and epidermodysplasia verruciformis

CLINICAL MANIFESTATIONS OF PTEN HAMARTOMA TUMOR SYNDROME			
	Onset typically at birth or in childhood	**Onset typically in adolescence or adulthood**	**Variable onset**
Mucocutaneous	Pigmented macules of genitalia (glans and shaft of penis, vulva) Lipomas Vascular anomalies* Neuromas (facial, acral, mucosal) Epidermal nevi Café-au-lait macules	Multiple facial papules† Multiple oral papillomas (lips, tongue)‡ Sclerotic fibromas Inverted follicular keratoses Multiple acrochordons Acanthosis nigricans	Acral/palmoplantar keratoses Scrotal tongue Perioral pigmented macules (rare)
Craniofacial and skeletal	Macrocephaly Down-slanting palpebral fissures Frontal bossing High-arched palate, long philtrum Pectus excavatum Joint hyperextensibility Hand and foot abnormalities§		Scoliosis, kyphoscoliosis
Thyroid		Goiter and/or adenomas Carcinoma (follicular > papillary)	
Breast		Fibrocystic disease Fibroadenomas Adenocarcinoma	
Gastrointestinal tract	Hepatic vascular anomalies	Adenocarcinoma (rare)	Hamartomatous polyps Ganglioneuromas Glycogenic acanthosis of esophagus
Genitourinary system		Ovarian cysts Uterine leiomyomas Menstrual irregularities Testicular lipomatosis Endometrial carcinoma Renal cell carcinoma Testicular tumors (e.g. seminoma)	
Central nervous system	Developmental delay, autism Seizures Hypotonia Developmental venous anomalies	Lhermitte–Duclos disease	Meningioma Spinal neurinoma
Ocular	Prominent corneal nerves Prominent Schwalbe lines Strabismus, amblyopia Retinal vascular anomalies Pseudopapilledema		Cataracts Myopia Angioid streaks
Muscular	Lipoid storage myopathy		
Other	Neonatal macrosomia Persistent drooling		

*Typically multifocal lesions with fast-flow channels, intramuscular involvement and associated ectopic fat; may have capillary, venous and/or lymphatic components.
†Includes trichilemmomas, lesions with histologic features of verrucae and very rarely tumors of the follicular infundibulum.
‡May represent epithelial hyperplasia, sclerotic fibromas or (less often) glycogenic acanthosis.
§Includes accelerated growth of the first metacarpal and first and second middle phalanges, syndactyly and brachydactyly.

Table 63.3 Clinical manifestations of PTEN hamartoma tumor syndrome. In general, the clinical manifestations that are usually evident at birth or during childhood have classically been associated with Bannayan–Riley–Ruvalcaba syndrome and those that usually develop during adolescence or adulthood have classically been associated with Cowden disease.

may represent additional diagnostic possibilities. Less commonly, multiple syringomas or the nevoid basal cell carcinoma syndrome might be considered (see Fig. 111.4).

Mutations in the *SDHB* or *SDHD* genes, which encode subunits of mitochondrial succinate *deh*ydrogenase, can cause an autosomal dominant "Cowden-like" syndrome that is characterized by a predisposition to the development of breast, thyroid and renal carcinomas; to date, cutaneous manifestations have not been described[21].

Treatment

Because approximately one-third of women with CD develop breast cancer, periodic mammograms and magnetic resonance imaging (annually, starting at 30–35 years of age or 5–10 years before the youngest breast cancer diagnosis in the patient's family) are recommended, along with biannual clinical examinations (beginning by age 25 years) and monthly self-examinations. Prophylactic mastectomies can be considered on an individual basis[22]. Thyroid function studies and thyroid ultrasound should be performed at baseline, and current guidelines recommend an annual thyroid ultrasound beginning at age 18 years.

Surveillance for endometrial cancer (annual blind endometrial biopsies beginning at 35–40 years of age or 5 years prior to the earliest endometrial cancer diagnosis in that family) and renal cancer (annual renal ultrasounds and urinalysis with urine cytology) are recommended for individuals with a family history of these malignancies. Evaluation of the gastrointestinal tract should be based on symptomatology; because hamartomatous polyps have little potential for malignant degeneration, screening examinations beyond those recommended for the general population are generally not indicated. Due to the substantial genotypic and phenotypic overlap of CD and BRRS, many authors recommend that patients with BRRS follow the same cancer surveillance protocol.

Although the recognition of CD is based upon clinical and histologic evaluation, genetic testing may be helpful to confirm the diagnosis and to facilitate identification of affected family members[23]. Agents that downregulate the mTOR pathway, such as rapamycin, represent promising therapeutic approaches for CD that are currently under investigation[24]. The facial papules of CD respond variably to topical 5-fluorouracil, oral isotretinoin, curettage, laser ablation or surgical excision[11,25].

COWDEN DISEASE CRITERIA, NATIONAL COMPREHENSIVE CANCER NETWORK 2011
MAJOR CRITERIA
Mucocutaneous lesions – One biopsy-proven trichilemmoma, *or* – Multiple palmoplantar keratoses, *or* – Multifocal or extensive oral mucosal papillomatosis, *or* – Multiple cutaneous facial papules (often verrucous), *or* – Pigmented macules on the glans penis
Macrocephaly (>97th percentile; 58 cm in adult woman, 60 cm in adult man)
Breast carcinoma
Thyroid carcinoma (non-medullary; especially follicular)
Endometrial carcinoma
Multiple gastrointestinal hamartomas or ganglioneuromas
MINOR CRITERIA
Fibromas
Lipomas
Fibrocystic breast disease
Other thyroid lesions (e.g. adenoma, nodules, goiter)
Uterine leiomyomas (fibroids)
Single gastrointestinal hamartoma or ganglioneuroma
Renal cell carcinoma
Mental retardation (IQ ≤75)
Autism spectrum disorder
INDICATIONS FOR *PTEN* GENE TESTING/PROVISIONAL DIAGNOSIS (A, B, *OR* C)
(A) Individual from a family with a known *PTEN* mutation
(B) Individual with a personal history of: • Bannayan–Riley–Ruvalcaba syndrome (BRRS), *or* • Adult Lhermitte–Duclos disease, *or* • Autism spectrum disorder + macrocephaly, *or* • Two or more biopsy-proven trichilemmomas, *or* • Two major criteria, including macrocephaly, *or* • Three major criteria, without macrocephaly, *or* • Two major criteria + two minor criteria, *or* • One major criterion + three minor criteria, *or* • Four minor criteria
(C) Individual with a first-degree relative with a clinical diagnosis of Cowden disease or BRRS plus a personal history of: • One major criterion, *or* • Two minor criteria

Table 63.4 Cowden Disease Criteria, National Comprehensive Cancer Network 2011. Now considered as criteria for *PTEN* gene testing rather than clinical diagnostic criteria; however, patients who meet criteria but do not undergo genetic testing should be managed as though they have Cowden disease. www.nccn.org/professionals/physician_gls/PDF/genetics_screening.pdf.

Fig. 63.4 Cowden disease. Multiple palmar keratoses, many of which have a glassy appearance. A few have a central depression. *Courtesy, Joyce Rico, MD.*

GARDNER SYNDROME

Synonym: ■ Familial polyposis of the colon

Key features

- Autosomal dominant disorder characterized by premalignant intestinal polyposis and adenocarcinoma of the gastrointestinal tract
- Extraintestinal manifestations include epidermoid cysts, osteomas, desmoid tumors and fibrous tumors (skin, mesentery, retroperitoneum)
- Congenital hyperpigmentation of the retinal pigment epithelium (CHRPE) is an early sign
- Caused by mutations in the *APC* (adenomatous polyposis coli) gene

Introduction

The main features of Gardner syndrome (GS) are premalignant intestinal polyposis, epidermoid cysts, osteomas, and desmoid or fibrous tumors of the skin and other sites[26]. It is considered to represent a phenotypic variant of the familial adenomatous polyposis syndrome with prominent extraintestinal involvement[27].

History

In 1953, Gardner and Stephens described a large family in which many individuals had multiple cutaneous lesions, osteomatosis and fatal bowel cancer. The syndrome now bears Gardner's name.

Epidemiology

The incidence of GS is approximately 1 in 8000 to 1 in 16000 births. It is inherited as an autosomal dominant trait with high penetrance and variable expressivity, affecting men and women equally[28].

Pathogenesis

GS is caused by heterozygous germline mutations in the adenomatous polyposis coli (*APC*) tumor suppressor gene, which resides on chromosome 5q21–22. The *APC* gene encodes a protein that downregulates the Wnt/β-catenin signaling pathway, which has important functions in cellular proliferation, differentiation and adhesion.

Clinical Features

Skin lesions and bony abnormalities appear during childhood and adolescence, frequently occurring before the polyposis develops. Cutaneous

epidermoid cysts affect approximately one-third of patients with GS. These lesions are commonly found on the head and neck, may be present at birth, and tend to increase in size and number and then stabilize.

Osteomas occur in approximately 80% of patients and favor the mandible and maxilla, although they can develop in other bones of the skull and in long bones. Seen in children as young as 8 years of age, osteomas are painless and may grow large enough to be clinically obvious or be detectable only by radiographic studies. Other skeletal lesions include exostoses, endostoses and cortical thickening of the long bones. Dental anomalies are seen in approximately 20% of patients with GS and include supernumerary teeth, odontomas, unerupted teeth and multiple caries.

Desmoid tumors are non-encapsulated, non-metastasizing, locally aggressive benign tumors that occur in 3% to 17% of patients with GS. There is a marked female predominance (70% to 85%). Desmoid tumors may occur spontaneously or at incision sites, arising from musculo-aponeurotic soft tissues. They commonly develop after colectomy and can occur within the abdominal wall or intra-abdominally, with the latter causing greater morbidity via obstruction of the small bowel and/or ureters. Although cytologically benign, desmoid tumors can be invasive, recur, and even cause death. Hereditary desmoid disease characterized by multiple desmoid tumors, often at unusual sites, in patients with few or no colonic polyps has been described in association with *APC* mutations[29].

Fibromas may occur in the skin, subcutaneous tissues, mesentery or retroperitoneum. The "Gardner fibroma" often arises in the first decade of life, favors the back and paraspinal region, and can serve as a desmoid precursor. Lipomas, leiomyomas, trichoepitheliomas, neurofibromas and ovarian cysts are observed less commonly.

Congenital hypertrophy of the retinal pigment epithelium (CHRPE) is seen in an estimated two-thirds of patients with GS and can be an early sign of the disorder (Fig. 63.5)[30]. Because CHRPE is present at birth and easily detected by ophthalmologic examination, it is a useful finding in patients who do not yet have other manifestations. While unilateral solitary CHRPE may occur in unaffected individuals, multiple and bilateral lesions represent a sensitive and specific marker for GS. There are rare reports of adenocarcinoma arising from CHRPE.

Patients with GS are at increased risk for the development of other tumors, including papillary carcinoma of the thyroid (particularly in women), hepatoblastoma (usually affecting children less than 3 years of age), pancreatic and biliary tract carcinomas, adrenal adenomas (and occasionally carcinomas) and various sarcomas (e.g. fibrosarcoma, osteosarcoma). The association of brain tumors (most often medulloblastomas) with adenomatous polyposis in patients with heterozygous *APC* mutations has been referred to as Turcot syndrome type 2, while brain tumors (primarily glioblastomas) plus colonic polyposis in patients with *biallelic* mutations in mismatch repair genes (see below) is known as Turcot syndrome type 1; the latter may also present with multiple café-au-lait spots and hematologic malignancies[31].

Gastrointestinal lesions

In adults, the diagnosis of GS is commonly made when the patient presents with gastrointestinal bleeding secondary to adenomatous polyps. Other findings may include anemia, abdominal pain, diarrhea or constipation, and weight loss. Premalignant adenomatous polyps most commonly occur in the colon but are also found in the small intestine and stomach in over half of patients. Polyps are typically <1 cm in diameter and are rarely seen before the age of 10 years. By the age of 20 years, 50% of patients with GS have demonstrable polyps. Without surgical intervention, colorectal carcinoma is inevitable; it usually develops before age 40 years and arises by early adolescence in approximately 5% of affected individuals[32,33]. Carcinomas of the small intestine (especially the duodenum) can also occur[32].

Fig. 63.5 Congenital hypertrophy of the retinal pigment epithelium. *Courtesy, L Tychsen, MD.*

Pathology

Histologically, intestinal polyps show adenomatous hyperplasia of the mucosa[33]. Cutaneous cysts in patients with GS usually demonstrate the same microscopic changes as ordinary epidermoid cysts, with a lining of keratinizing epithelium that includes a granular layer. Pilomatricoma-like changes, with characteristic basophilic and shadow cell populations, have also been noted in the cysts of GS.

Differential Diagnosis

Epidermoid cysts usually occur in the absence of a particular syndrome, but multiple lesions should prompt a thorough family history and evaluation for other findings of GS (e.g. osteomas, CHRPE). In Peutz–Jeghers syndrome, mucocutaneous lentigines (intraoral, perioral and acral) are seen and the gastrointestinal polyps are hamartomatous rather than adenomatous. Hamartomatous gastrointestinal polyps are also found in juvenile polyposis syndromes (which may be associated with a hereditary hemorrhagic telangiectasia phenotype; see Table 104.2) and PTEN hamartoma tumor syndrome. Additional manifestations such as osteomas, CHRPE and desmoid tumors distinguish GS from these conditions. Of note, mutations in the *MUTYH* base excision repair gene can cause an autosomal recessive form of colorectal adenomatous polyposis, with osteomas, CHRPE, desmoid tumors, pilomatricomas and sebaceous neoplasms (see below) having been described in affected individuals[34].

Treatment

Because of the inevitable development of colorectal carcinoma, prophylactic colectomy is recommended when polyp formation becomes evident, and it is usually performed between 15 and 25 years of age. Initially, children with GS should be monitored with annual sigmoidoscopy beginning at 10–12 years of age. Once polyps are detected, patients should undergo annual colonoscopy until a colectomy is done. Upper gastrointestinal endoscopy is recommended every 1–3 years (depending on polyp burden), with careful inspection of the ampulla of Vater because of the increased risk of cancer in this area. Barium studies or (preferably) capsule endoscopy can be utilized periodically to evaluate the remainder of the small bowel. Because of the increased risk of hepatoblastoma, some experts recommend annual abdominal ultrasounds and measurement of serum α-fetoprotein levels during the first 5 years of life.

Symptomatic epidermoid cysts can be surgically excised. Desmoid tumors are also treated by surgical excision, although there tends to be a high recurrence rate. Preoperative MRI of the abdomen can demonstrate the origin of the tumor and the extent of involvement. If wide surgical excision fails, radiotherapy, hormonal therapy (e.g. tamoxifen, raloxifene), chemotherapy or a combination thereof can be tried. The osteomas of GS may or may not be amenable to surgical intervention. Medications that affect prostaglandin metabolism, such as nonsteroidal anti-inflammatory drugs (NSAIDs), may reduce the risk of colorectal cancer and desmoids[35].

Genetic counseling is imperative, and family members should be evaluated for extraintestinal and intestinal signs of the disorder. Molecular testing for *APC* mutations is commercially available.

MUIR–TORRE SYNDROME

Synonym: ▪ Cutaneous sebaceous neoplasms and keratoacanthomas, with gastrointestinal and other carcinomas

Key features

- An autosomal dominant disorder associated most commonly with adenocarcinoma of the colon, followed by genitourinary carcinomas
- The cutaneous manifestations are sebaceous neoplasms and keratoacanthomas
- Caused by mutations in three DNA mismatch repair genes (*MSH2*, *MLH1*, *MSH6*)

Introduction

Muir–Torre syndrome (MTS) is a rare autosomal dominant genodermatosis that is characterized by sebaceous neoplasms (adenoma, epithelioma or carcinoma), keratoacanthomas and internal malignancies. It is considered to represent a subtype of the hereditary non-polyposis colorectal cancer (HNPCC) syndrome (Lynch syndrome).

History

Muir in 1967 and Torre in 1968 independently reported the syndrome that bears their names. Their two patients had malignancies in several organs plus either keratoacanthoma-like lesions or multiple tumors of sebaceous origin.

Epidemiology

The male:female ratio of MTS is 3:2; affected individuals present with cutaneous manifestations at a mean age of 55 years. In a recent study, MTS was observed in 28% (14/50) of families and 9% (14/152) of individuals with HNPCC (all confirmed to have a germline mismatch repair gene mutation)[36].

Pathogenesis

MTS is caused by heterozygous germline mutations in one of several DNA mismatch repair genes, including *MSH2* (approximately 90% of MTS cases), *MLH1* and *MSH6*[37]. In patients with MTS, somatic loss of heterozygosity (due to inactivation of the other allele of the affected gene) results in microsatellite instability (increased variability in the lengths of repetitive "microsatellite" sequences in the genome that are prone to replication errors) and tumor formation[38].

Clinical Features

Sebaceous tumors can present prior to (~30%), concurrently with (~10%), or after (~60%) the diagnosis of a visceral malignancy. The skin tumors sometimes appear decades before or after a visceral malignancy develops. In general, sebaceous tumors favor the head and neck region (Fig. 63.6) and sebaceous carcinomas tend to affect the periocular area; however, in patients with MTS, these neoplasms often occur in other locations (trunk > extremities)[39]. Sebaceous adenomas are the most common tumor type, and they present as yellow papules or nodules numbering from one to hundreds[40,41]. Keratoacanthomas, which are keratotic skin-colored to erythematous papules or nodules that arise quickly, are seen in approximately 25% of patients with MTS and may exhibit sebaceous differentiation.

Fig. 63.6 Muir–Torre syndrome with multiple sebaceous neoplasms. *Courtesy, Dan Ring, MD.*

The most frequently observed malignancies are colorectal (61%) and genitourinary (22%) carcinomas[42]. Colorectal carcinoma in MTS most often involves the proximal colon and develops at a median age of 50 years, about one decade before colorectal carcinoma typically occurs in the general population. In addition, MTS patients can develop breast carcinomas (6%), hematologic malignancies (11%), head and neck cancers (5%), and neoplasms of the small intestine (3%) or stomach[43].

The diagnosis of MTS is based on the presence of at least one sebaceous tumor (or keratoacanthoma with sebaceous differentiation) and a visceral malignancy in the absence of any known predisposing factor. In the absence of a sebaceous tumor, the diagnosis can be made in a patient with multiple keratoacanthomas, multiple visceral malignancies and a family history of MTS. Findings that suggest a higher or lower likelihood of MTS in patients with sebaceous neoplasms are summarized in Table 63.5.

Pathology

Skin tumors arising as part of MTS fall into two general categories: sebaceous neoplasms and keratoacanthomas. Sebaceous adenomas (with a predominance of mature sebocytes), sebaceomas (vertically oriented with a predominance of basaloid seboblastic cells), so-called sebaceous epitheliomas (inconsistently defined term used for various lesions with seboblastic differentiation) and sebaceous carcinomas may occur (see Ch. 111). A type of sebaceous adenoma that may be specific to this syndrome has been called a seboacanthoma; it has the architecture of a keratoacanthoma but contains well-differentiated sebaceous lobules[44]. In addition, cystic sebaceous tumors, which are well-circumscribed, deep sebaceous lesions with a cystic growth pattern, have been identified in some MTS patients[45].

Immunohistochemical staining for MSH2, MSH6, MLH1 and PMS2 can be a valuable screening tool for MTS-associated tumors, which

RISK ASSESSMENT FOR MUIR–TORRE SYNDROME (MTS)	
Higher likelihood of MTS	**Lower likelihood of MTS**
CLINICOPATHOLOGIC CHARACTERISTICS OF SKIN LESIONS	
• Multiple sebaceous neoplasms • Located outside of the head and neck region • Sebaceous neoplasm with high specificity for MTS, e.g. seboacanthoma	• Single sebaceous neoplasm • Located in photodamaged facial skin • Sebaceous hyperplasia
CHARACTERISTICS OF PATIENT	
• History of colorectal cancer, especially if before 50 years of age or with high MSI histology* • History of other HNPCC-related malignancies† (e.g. small bowel, gastric, endometrial, bladder, ureteral, renal, biliary, pancreatic, glioblastoma), especially if more than one	• Elderly patient with no history of an HNPCC-related malignancy
FAMILY HISTORY	
• Multiple diagnoses of colorectal cancer and/or other HNPCC-related malignancies in family member(s), especially if before 50 years of age and in first-degree relative(s)	• No first-degree relatives with colorectal cancer/other HNPCC-related malignancies, or diagnosis in a single elderly relative
ADDITIONAL ANALYSIS OF SEBACEOUS NEOPLASMS	
• Loss of MSH2, MLH1, MLH6, and/or PMS2 expression shown by immunohistochemical staining‡ • Evidence of MSI in lesional tissue§	• Expression of MLH1, MSH2, MSH6, and PMS2 shown by immunohistochemical staining • No evidence of MSI in lesional tissue§

*Characterized by tumor-infiltrating lymphocytes, Crohn's disease-like lymphocytic reaction, medullary growth pattern, or signet ring/mucinous differentiation.
†Patients with MTS may also have an increased risk of breast, head and neck, and hematologic malignancies.
‡MSH2 and MSH6 proteins form a heterodimer, so lack of one can lead to the absence of the other; likewise, PMS2 is unstable without a functional MLH1 protein.
§Testing can be performed on paraffin-embedded tissue.

Table 63.5 Risk assessment for Muir–Torre syndrome (MTS). HNPCC, hereditary non-polyposis colorectal cancer; MSI, microsatellite instability.

typically show a lack of expression of one or more of these proteins (see Table 63.5)[40,42]. In addition, polymerase chain reaction (PCR)-based assays can be used to demonstrate microsatellite instability in tissue from MTS-associated neoplasms.

Differential Diagnosis

Sebaceous hyperplasia is a common finding in normal individuals and sebaceous adenomas and carcinomas can occur in patients without MTS. Sebaceous adenomas and carcinomas as well as colorectal carcinomas and other malignancies have been described in patients with autosomal recessive colorectal adenomatous polyposis caused by mutations in the *MUTYH* base excision repair gene[34]. Multiple keratoacanthomas may occur as an isolated finding (i.e. without visceral malignancy), especially in patients with the Ferguson–Smith (multiple self-healing) or Grzybowski (generalized eruptive) types of keratoacanthomas. However, these patients should be evaluated to exclude the possibility of MTS.

Treatment

Patients with an internal malignancy require appropriate oncologic referral and management. High-risk individuals (see Table 63.5) should undergo biennial screening colonoscopy beginning at age 20–25 years, as well as serial renal ultrasounds, urinalyses and complete blood counts. For women, routine gynecologic evaluations including yearly breast and pelvic examinations and Pap smears should begin by age 30 years. If indicated, endometrial biopsy and transvaginal ovarian ultrasound can be performed.

Treatment options for the benign sebaceous tumors include curettage, excision, cryosurgery and radiotherapy. Mohs micrographic surgery is recommended for sebaceous carcinomas on the face. Oral retinoids with or without interferon-α may be useful in the prevention of new sebaceous neoplasms.

Molecular testing of mismatch repair genes is commercially available, and identification of the underlying mutation can facilitate early diagnosis and surveillance of affected family members.

ENZYME DEFICIENCY DISEASES

Barbara K Burton

ALKAPTONURIA

Synonym: ■ Ochronosis

Key features

- An autosomal recessive disorder due to deficiency of homogentisic acid oxidase
- Clinical signs include pigmentation of cartilage (e.g. the helices), sclerae and skin (e.g. the axillae)
- Extracutaneous findings include urine that darkens on standing and arthritis

Alkaptonuria is a rare inborn error of metabolism in which homogentisic acid, an intermediate in phenylalanine and tyrosine metabolism, cannot be further metabolized and therefore accumulates in body fluids and tissues. The disorder results from a deficiency of the enzyme homogentisic acid oxidase and is inherited in an autosomal recessive fashion. The cardinal clinical features of the disorder (Fig. 63.7) include urine that turns dark on standing, pigmentation of cartilage and other connective tissues, and arthritis. The arthritis often presents in the fourth decade of life with chronic back pain and stiffness[46], with radiographs showing flattened and calcified intervertebral discs. Later involvement of large peripheral joints can resemble rheumatoid arthritis clinically but osteoarthritis radiographically. Renal complications, including an increased incidence of calculi and occasionally kidney failure, and valvular heart disease may also occur. Life expectancy is normal.

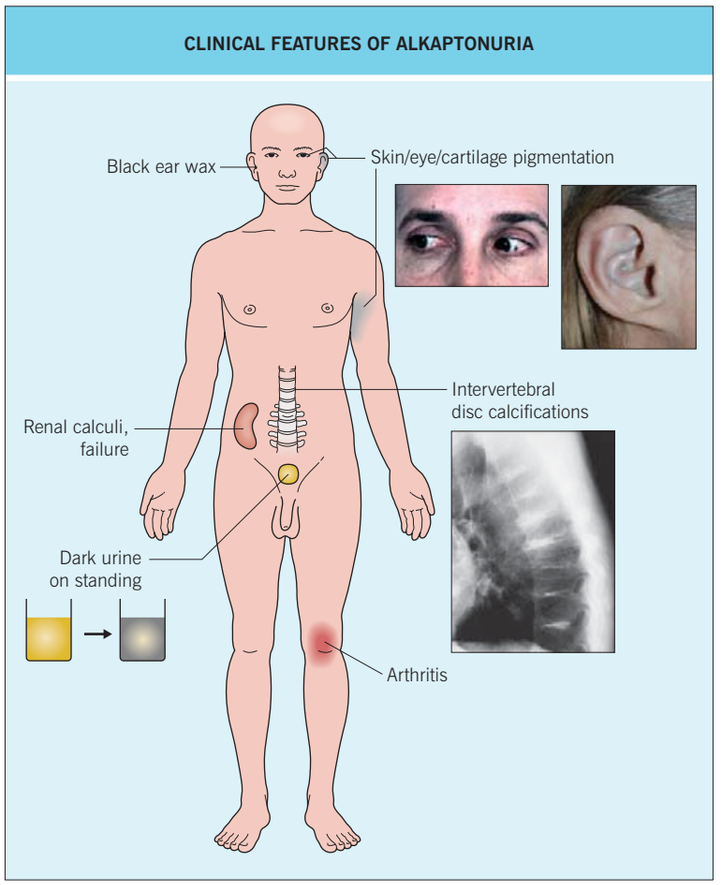

Fig. 63.7 Clinical features of alkaptonuria. *Eyes, courtesy, William Gahl, MD PhD; ear, courtesy, Julie V Schaffer, MD; radiograph, courtesy, Jean L Bolognia, MD.*

The dermatologic features of alkaptonuria are rarely noted prior to 10–15 years of age and typically become apparent during adulthood (often in the fourth decade of life). Axillary skin may be one of the initial sites to develop discoloration, which can range in color from blue to yellow to brown. The classic blue–grey pigmentation associated with this disorder is often first noted in the helices of the ear and sclerae (see Fig. 63.7). Later, it may affect the entire face as well as the palmar and plantar surfaces. Features that may present early in life include brownish discoloration of diapers (due to the dark urine) and cerumen that is more brown to black in color than normal. Diagnosis of alkaptonuria can be confirmed by urine organic acid analysis. There is no definitive treatment, although administration of nitisinone (an inhibitor of homogentisic acid production) or 1 g/day of ascorbic acid in divided doses may be beneficial[47].

BIOTINIDASE AND HOLOCARBOXYLASE SYNTHETASE DEFICIENCIES

Synonyms: ■ Late- and early-onset forms of multiple carboxylase deficiency

Key features

- As biotin is an essential cofactor for carboxylases, there is overlap in the two autosomal recessive disorders
- Cutaneous findings include alopecia and periorificial erythema and erosions (features of "nutritional dermatitis")
- Metabolic acidosis is seen in both disorders
- Biotinidase deficiency is associated with developmental delay, hearing loss and seizures (classically during childhood), while patients with holocarboxylase synthetase deficiency develop encephalopathy and hypotonia (classically during early infancy)

Biotinidase deficiency and holocarboxylase synthetase deficiency are genetically distinct disorders that result in late- and early-onset multiple carboxylase deficiency, respectively. Both disorders are inherited in an autosomal recessive fashion. Biotinidase deficiency, a pan-ethnic disorder with an incidence of approximately 1 in 60 000 births, represents a defect in biotin recycling. Patients with this disorder become functionally biotin-deficient under conditions of normal dietary biotin intake. Since biotin is an essential cofactor for the activity of carboxylases, multiple carboxylase deficiency ensues. The clinical manifestations of the disorder, although entirely preventable with the administration of 5–20 mg of biotin daily, are highly variable and may go unrecognized. This has led to the inclusion of biotinidase deficiency in the newborn screening panel of a number of countries, including the US. Common extracutaneous features of the disorder include developmental delay, hearing loss, seizures, conjunctivitis and metabolic acidosis. Abnormalities on urine organic acid analysis are commonly, but not invariably, noted. The definitive diagnosis is established by an assay of biotinidase activity in blood; prenatal diagnosis is possible via enzymatic and molecular analyses.

Holocarboxylase synthetase deficiency is significantly less common than biotinidase deficiency, although the precise incidence has not been determined. It represents a defect in biotinylation of the apocarboxylases, leading to a failure in synthesis of intact functional holocarboxylases. Patients typically present within the first 3 months of life with symptoms of a metabolic encephalopathy, including poor feeding, lethargy, respiratory distress and hypotonia. Metabolic acidosis, hyperammonemia and organic aciduria are often observed. Definitive diagnosis is established by assays of carboxylases in leukocytes or cultured skin fibroblasts. Most patients exhibit significant improvement when treated with 10 mg of biotin daily. Prenatal diagnosis via enzymatic assay is possible by chorionic villus sampling (CVS) or amniocentesis.

The dermatologic features of biotinidase deficiency and holocarboxylase synthetase deficiency are similar. They occur in over 50% of patients with the former and a smaller proportion of patients with the latter[48,49]. Characteristic findings include alopecia (sometimes evolving to alopecia totalis) and a scaly dermatitis which often begins in the perioral and perianal regions but can become generalized. This periorificial-predominant eruption is notable for its markedly erythematous and, at times, erosive quality. It is similar to the eruptions seen with other nutritional deficiencies, e.g. zinc (see Figs 51.11 & 51.12). Fissures may be prominent on the feet, face and in the perianal area, and cutaneous candidiasis may also be present.

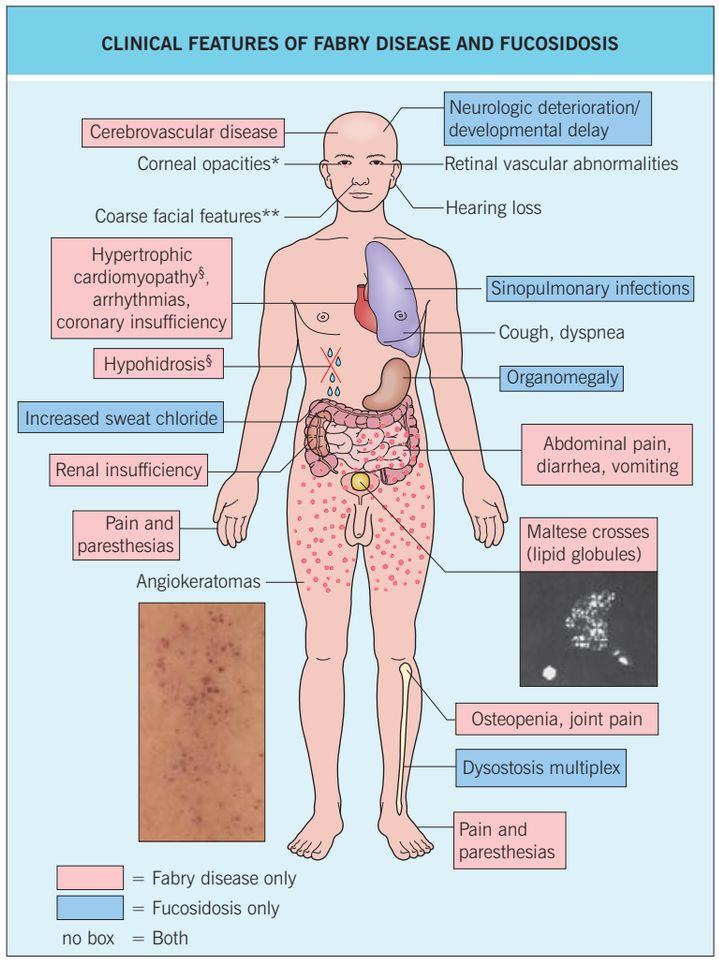

Fig. 63.8 Clinical features of Fabry disease and fucosidosis. *Also lenticular in Fabry disease. **Milder in Fabry disease. §Occasionally observed in fucosidosis. *Angiokeratomas of Fabry disease, courtesy, Anthony J Mancini, MD; photomicrograph of urinary sediment demonstrating Maltese crosses (via polarization), courtesy, Robert J Desnick, MD PhD.*

FABRY DISEASE

Synonym: ■ Anderson–Fabry disease

Key features

- X-linked disorder due to a deficiency of α-galactosidase A
- Characteristic mucocutaneous finding is multiple angiokeratomas
- Additional features include pain and paresthesias of the extremities, hypohidrosis, and renal and coronary insufficiency

Fabry disease is an X-linked lysosomal storage disorder resulting from a defect in glycosphingolipid metabolism[50]. It is a pan-ethnic disorder affecting an estimated 1 in 40 000 men. Female heterozygotes are also often affected, although their clinical manifestations are more variable than those in male hemizygotes and often have later onset. The defect in Fabry disease is deficiency of α-galactosidase A due to mutations in the *GLA* gene that encodes this enzyme. This leads to systemic deposition of glycosphingolipids, predominantly globotriaosylceramide, galabiosylceramide and blood group B substances. The clinical manifestations of the condition result primarily from the accumulation of glycosphingolipids in the vascular endothelium.

The cardinal clinical features of Fabry disease in the first two to three decades of life are pain and paresthesias of the extremities often with onset during childhood or adolescence), angiokeratomas of the skin and mucous membranes, and hypohidrosis (see below; Fig. 63.8). Characteristic corneal opacities (classically whorled "cornea verticillata") are evident in approximately 75% of male hemizygotes and female heterozygotes (including children and adolescents); posterior lenticular opacities and tortuous retinal or conjunctival vessels may also be observed. With increasing age, progressive renal insufficiency develops, leading to the need for dialysis or transplantation. Cardiac sequelae include hypertrophic cardiomyopathy, arrhythmias and coronary insufficiency. Patients may also have cerebrovascular (transient ischemic attacks, strokes), gastrointestinal (abdominal pain, diarrhea, vomiting), pulmonary (chronic cough, dyspnea, wheezing) and musculoskeletal (joint pain, osteopenia) manifestations[50,51]. Characteristic facial features such as periorbital fullness, bushy eyebrows, a broad forehead and nasal bridge, thick lips, prognathism and prominent ear lobes have been noted in men with Fabry disease.

Angiokeratomas are one of the earliest signs of Fabry disease, typically beginning to appear during childhood or adolescence, and may lead to diagnosis of the disorder[52]. In addition to appearing in most male patients, they are observed in approximately 30% of heterozygous girls and women. Angiokeratomas classically develop slowly as individual punctate, dark-red to blue–black macules or slightly elevated papules. The lesions do not blanch with pressure and may become slightly keratotic as they enlarge. The angiokeratomas of Fabry disease tend to be clustered between the umbilicus and the knees but can be present anywhere. Involvement of the oral mucosa and conjunctiva is common. Less frequent vascular findings include linear telangiectasias (favoring the face, lips and oral mucosa), episodic acral vasospasm resembling Raynaud's phenomenon (typically accompanied by pain and paresthesias), peripheral edema and lymphedema[53]. In addition to vascular lesions, hypohidrosis is an early and almost

constant feature of Fabry disease. Decreased body hair has also been described.

Histologically, angiokeratomas are composed of dilated capillaries in the uppermost dermis, partially enclosed by elongated rete ridges (see Ch. 114); hyperkeratosis is seen in older lesions. In the skin, there is evidence of lipid storage in the endothelium, pericytes and smooth muscle of capillaries, venules and arterioles, as well as in arrector pili muscles. This can be detected by a lipid stain such as Sudan black B, or highlighted by periodic acid-Schiff (PAS) staining. Lipid accumulation may also be observed in sweat gland epithelium (see Ch. 39) and perineural cells. Ultrastructural examination of eccrine sweat glands reveals characteristic cytoplasmic inclusions in the clear cells of the secretory coil, coiled duct and basal cells of the straight duct[54]. Inclusions are also seen in the unmyelinated axons innervating the sweat glands.

A definitive diagnosis of Fabry disease is established by demonstration of deficient α-galactosidase A activity in plasma or leukocytes (or, for prenatal testing, cultured amniocytes or chorionic villi), but enzyme activity is within the normal range in up to a third of female heterozygotes. Analysis of the *GLA* gene is clinically available and can be helpful in determining the disease status of girls and women as well as in prenatal/preimplantation diagnosis. Polarizing microscopy of urine reveals birefringent lipid globules ("Maltese crosses") (see Fig. 63.8). Although most commonly seen in association with Fabry disease, it is important to recognize that angiokeratomas are not unique to this condition. They are also observed in a number of other lysosomal storage disorders, as outlined in Table 63.6.

Until recently, treatment for Fabry disease was largely symptomatic. Oral administration of phenytoin, gabapentin or carbamazepine can alleviate the debilitating limb pain experienced by patients with this disorder. Angiotensin-converting enzyme inhibitors are helpful in reducing proteinuria, and end-stage renal disease has historically been treated with dialysis and renal transplantation. Enzyme replacement therapy is now available for Fabry disease and is administered biweekly by intravenous infusion. Accumulated data indicate that it is effective in arresting progression of the disorder[62,63].

FUCOSIDOSIS

Key features

- Autosomal recessive disorder due to deficiency of α-fucosidase
- Multiple angiokeratomas of the skin and oral mucosa
- Extracutaneous findings include coarse facial features, growth retardation, dysostosis multiplex and mental retardation

Fucosidosis is a rare autosomal recessive oligosaccharide storage disorder resulting from deficiency of the lysosomal enzyme α-fucosidase. The precise incidence of the disorder is unknown. The severity of clinical manifestations in affected patients varies across a wide spectrum. In the past, patients were classified into two groups: type I, the more severe form of the disorder with onset in the first year of life; and type II, the milder form with onset in the second year or later[58]. The characteristic extracutaneous manifestations of fucosidosis type I include coarse facial features, growth

INHERITED METABOLIC DISORDERS ASSOCIATED WITH ANGIOKERATOMA CORPORIS DIFFUSUM

Disorder	Enzyme deficiency	Other clinical features	Inheritance pattern	Diagnostic tests	Reference
Aspartylglycosaminuria	Aspartylglycosaminidase	MR, coarse facial features, frequent respiratory infections	AR	Urine oligosaccharides; enzyme assay in leukocytes or fibroblasts*	55
Galactosialidosis	β-Galactosidase and sialidase (neuraminidase) secondary to a defect in the protective protein/ cathepsin A (PPCA)	Coarse facial features, dysostosis multiplex, myoclonus, ataxia, neurologic deterioration, cherry red macular spots	AR	Urine oligosaccharides; enzyme assay in leukocytes or fibroblasts	56
GM1 gangliosidosis	β-Galactosidase	Coarse facial features, dysostosis multiplex, neurologic deterioration, organomegaly, dermal melanocytosis	AR	Urine oligosaccharides; enzyme assay in leukocytes or fibroblasts*	57
Fabry disease	α-Galactosidase A	Pain and paresthesias of extremities, hypohidrosis, corneal and lenticular opacities, renal insufficiency, cardiac and cerebrovascular disease	X-L	Enzyme assay in plasma or leukocytes*	52
Fucosidosis	α-Fucosidase	Coarse facial features, developmental regression, organomegaly, dysostosis multiplex	AR	Urine oligosaccharides; enzyme assay in leukocytes or fibroblasts*	58
Kanzaki disease	α-*N*-Acetylgalactosaminidase	Highly variable, ranging from no other findings to lymphedema, hearing loss and cardiomegaly; normal intelligence	AR	Urine oligosaccharides; enzyme assay in plasma or leukocytes	59
β-Mannosidosis	β-Mannosidase	MR, mild facial dysmorphism, hearing loss	AR	Urine oligosaccharides; enzyme assay in leukocytes or fibroblasts*	60
Sialidosis	Sialidase (neuraminidase)	Coarse facial features, dysostosis multiplex, MR, myoclonus, cherry red macular spots	AR	Urine oligosaccharides and sialic acid; enzyme assay in fibroblasts*	61

*Genetic testing is also available.

Table 63.6 Inherited metabolic disorders associated with angiokeratoma corporis diffusum. AR, autosomal recessive; MR, mental retardation; X-L, X-linked (variable manifestations in female heterozygotes).

retardation, organomegaly, dysostosis multiplex and neurologic deterioration (see Fig. 63.8). An elevated sweat chloride concentration is usually observed. In type II, developmental delay is typically the first finding noted, with the other features of type I often present but less prominent. Sweat chloride is normal in patients with type II. Patients with fucosidosis may also have corneal opacities, retinal vascular abnormalities and a propensity towards frequent sinopulmonary infections.

With increasing age, angiokeratomas virtually indistinguishable from those associated with Fabry disease are observed in patients with fucosidosis. Such lesions are found in about one-third of patients <10 years of age and 85% of those <20 years of age; they are distributed primarily on the trunk and lower extremities. Angiokeratomas can also develop within the oral mucosa. Other reported cutaneous findings include xerosis, thin skin, acrocyanosis and nevus anemicus. The light microscopy findings of the angiokeratomas are similar to those seen in Fabry disease. Electron microscopic examination of clinically normal skin may reveal empty-appearing storage vesicles in endothelial cells, melanocytes, eccrine glands and fibroblasts.

The diagnosis of fucosidosis is supported by demonstration of characteristic abnormalities on urine oligosaccharide analysis and established definitively by assay of α-fucosidase in leukocytes or cultured skin fibroblasts. Prenatal diagnosis is possible by CVS or amniocentesis via enzyme analysis and (when the underlying mutation has been identified in affected family members) genetic testing.

There is no definitive treatment for fucosidosis, and the mortality rate is high, especially after the second decade of life. Bone marrow transplantation has been attempted in the past, with some evidence of clinical improvement[64].

GAUCHER DISEASE

Key features

- Autosomal recessive disorder due to a deficiency of β-glucosidase (glucocerebrosidase)
- Hepatosplenomegaly and bone pain can be seen in all three types of the disease
- Cutaneous manifestations of type 1 disease include yellow–brown pigmentation, easy tanning and petechiae
- A subset of patients with type 2 (acute neuronopathic) Gaucher disease have severe congenital ichthyosis

Gaucher disease is a relatively common autosomal recessive lysosomal storage disorder in which the glycolipid glucocerebroside accumulates as a result of a deficiency of the enzyme β-glucosidase (glucocerebrosidase). There are three distinct clinical subtypes of the disorder, although phenotypic variability is observed in each form. Hepatosplenomegaly and lytic bone lesions occur in all of the subtypes. Type 1 Gaucher disease is most common in individuals of Ashkenazi Jewish descent. Indeed, it is the most common of the so-called "Jewish genetic disorders", occurring with an incidence of 1 in 850 births in this population. The incidence is much lower in other populations and has not been precisely defined. Gaucher disease types 2 and 3 are pan-ethnic disorders; there are no reliable incidence figures.

Type 1, by far the most common variant, is distinguished from types 2 and 3 by a lack of CNS involvement. Presenting findings in type 1 may include hepatosplenomegaly; bruising or bleeding secondary to thrombocytopenia; anemia; and bone pain, which can be very severe and reminiscent of the bone crises associated with sickle cell disease. The cutaneous manifestations of type 1 Gaucher disease are infrequent and relatively nonspecific[65]. They include diffuse brown or yellow–brown pigmentation of the skin and easy tanning. In addition, petechiae and ecchymoses may be observed as a result of the thrombocytopenia that results from infiltration of the bone marrow with glycolipid-filled macrophages (Gaucher cells) or from hypersplenism.

Type 2 Gaucher disease, also referred to as the acute neuronopathic form of the disorder, is a severe and rapidly progressive condition that usually results in death before 2 years of age. Clinical manifestations are present at the time of birth or develop within the first few months of life. They include hepatosplenomegaly, muscle tone abnormalities (e.g. severe spasticity, opisthotonus), oculomotor apraxia and progressive neurologic deterioration. A subgroup of patients with this disorder has severe congenital ichthyosis with a collodion baby phenotype[66,67]. Occasionally, these findings may precede the development of neurologic or visceral abnormalities, suggesting that Gaucher disease should be considered in the differential diagnosis of congenital ichthyosis.

Studies in a mouse model of type 2 Gaucher disease indicate that glucocerebrosidase is required to generate functionally competent membranes for normal epidermal barrier function. The low levels of residual enzymatic activity present in patients with types 1 and 3 Gaucher disease are apparently adequate to protect them, since similar epidermal abnormalities are not observed in patients with these forms. In fact, no specific cutaneous abnormalities have been described in patients with type 3 Gaucher disease, also referred to as the chronic neuronopathic form of the disorder.

The diagnosis of Gaucher disease is established by demonstration of a deficiency of β-glucosidase in leukocytes or cultured skin fibroblasts. Carrier detection is possible by DNA analysis, and prenatal diagnosis can be accomplished by CVS or amniocentesis.

The treatment of symptomatic patients with type 1 Gaucher disease involves intravenous enzyme replacement therapy using a recombinant product. Infusions are typically administered biweekly, and treatment results in an arrest of the progression of the disorder, gradual resolution of organomegaly and some improvement in the bone disease[68]. Experience with enzyme replacement therapy in the neuronopathic forms of Gaucher disease is limited, but it does not ameliorate the CNS manifestations of the disorder. Encouraging results have been reported from bone marrow or peripheral blood stem cell transplantation in patients with type 3 Gaucher disease, so this may be an option for some affected individuals.

HARTNUP DISEASE

Key features

- An autosomal recessive disorder associated with defective renal and intestinal neutral amino acid transport
- Marked aminoaciduria and tryptophan deficiency
- A pellagra-like dermatosis associated with photosensitivity
- Systemic manifestations include ataxia and tremors

Hartnup disease is an autosomal recessive disorder caused by mutations in the *SLC6A19* gene, which encodes a transporter that mediates epithelial uptake of neutral amino acids in the kidneys and intestines[69]. The hallmark of the disorder is a specific hyperaminoaciduria due to diminished renal reabsorption of neutral amino acids. In most affected individuals, there is also reduced intestinal absorption of at least some neutral amino acids, most notably tryptophan. Hartnup disease is one of the most common amino acid disorders, occurring in about 1 in 30 000 births. Most affected individuals, particularly those in high-income countries, remain asymptomatic throughout life, although symptoms can occur when certain exacerbating factors are present, e.g. poor nutrition or persistent diarrhea. Modifying genes may also play a role in producing clinical symptoms.

When clinical features develop, the most common finding is a "pellagra-like" dermatosis[70]. This photosensitive eruption may be related to a relative niacin deficiency, as tryptophan is a precursor in niacin synthesis. It typically appears in patients <13 years of age, resembles a severe sunburn, and is distributed primarily on exposed areas of the body. After the development of erythema following sun exposure, the affected skin becomes dry and scaly with well-defined margins, at times resembling chronic eczema; later findings include desquamation and hypopigmentation. The lesions on the face may resemble acute cutaneous lupus erythematosus. The dermatosis is occasionally pruritic, and blistering may occur, at times resulting in a hydroa vacciniforme-like presentation. The second major manifestation of symptomatic Hartnup disease is intermittent ataxia, which may be accompanied by nystagmus and tremors. Psychiatric disturbances

and other nonspecific neurologic abnormalities have been reported in some patients, but mental retardation is not a feature.

Despite the resemblance of the clinical features of Hartnup disease to pellagra, the disorder is not associated with a demonstrable niacin deficiency. Nonetheless, some patients have responded clinically to administration of oral nicotinamide in doses of 50–300 mg/day. Reversibility of both the dermatologic and neurologic findings has been reported, although there is no change in the aminoaciduria or intestinal transport defect. In addition to nicotinamide, a high protein diet or protein supplementation may be beneficial in some patients. The efficacy of various treatment modalities is difficult to assess in individual cases because of the intermittent nature of the clinical findings in untreated patients.

The definitive diagnosis of Hartnup disease is readily established by urine amino acid analysis, which reveals marked aminoaciduria.

MITOCHONDRIAL DISORDERS

Synonyms: ■ Respiratory chain defects ■ Oxidative phosphorylation defects

Key features

- Marked phenotypic heterogeneity
- 5–10% of patients have pigmentary changes, alopecia, hypertrichosis and hair shaft anomalies
- Neuromuscular dysfunction (e.g. seizures, hypotonia, mental retardation) is common
- Multisystem involvement (e.g. cardiac, renal, hepatic) is characteristic

Mitochondrial respiratory chain defects result in clinically and biochemically heterogeneous metabolic disorders affecting intracellular energy production[71]. The spectrum of clinical phenotypes associated with respiratory chain defects is rapidly expanding and the true incidence of these disorders is unclear. They can present at any age and may potentially affect any organ system. Indeed, one of the hallmarks of these disorders is multisystem involvement. Neuromuscular manifestations are common and can include mental retardation, seizures, stroke, weakness, hypotonia, and absent or excessive sweating. Cardiomyopathy, hearing loss, proximal renal tubular defects, hepatic dysfunction, poor growth, and fatigue are other frequent findings. The clinical course and progression are highly variable, even in patients with similar biochemical abnormalities[72].

The respiratory chain, which is responsible for producing much of the adenosine triphosphate (ATP) required for cellular functioning, is composed of over 100 individual subunits whose genes are located in either the nuclear DNA or the mitochondrial DNA. Mutations in a number of these genes have been identified in patients with various mitochondrial disorders. Depending on the subunit involved, inheritance of a respiratory chain defect can be either Mendelian (usually autosomal recessive) or mitochondrial (maternal). The subunits are organized into five respiratory chain enzyme complexes (complexes I–V), the activity of which can be measured in muscle or in other tissues to aid in the diagnosis of mitochondrial disorders. Although some mitochondrial syndromes are characterized by a particular constellation of clinical findings, there is often poor correlation between the enzyme complex involved and the clinical phenotype.

A wide range of hair and skin abnormalities has been described in association with mitochondrial disorders (Table 63.7)[73]. Such findings have been reported in about 5–10% of patients with documented mitochondrial disorders and can be present in the early stages of these diseases. When such findings are noted in conjunction with seemingly unrelated abnormalities in other organ systems, the possibility of a mitochondrial disorder should be considered.

Biochemical and/or molecular genetic confirmation of the diagnosis of a mitochondrial disorder is rarely straightforward. Measurement of plasma lactate, plasma amino acids and urine organic acids can be helpful in assessing mitochondrial function. Other components of the evaluation may include muscle biopsy for histologic and histochemical evaluation, assays of respiratory chain enzyme complexes in muscle tissue or cultured skin fibroblasts, and (as indicated by clinical and/or biochemical findings) genetic analysis.

Treatment of patients with mitochondrial disorders is problematic and largely symptomatic. A variety of dietary modifications have been tried and may be helpful for some patients. Coenzyme Q10, L-carnitine and riboflavin supplementation are commonly used and may be beneficial. A wide range of other vitamins and cofactors have also been administered, although the benefits are largely unproven.

CUTANEOUS MANIFESTATIONS OF MITOCHONDRIAL RESPIRATORY CHAIN DISORDERS

- Alopecia
- Hair shaft abnormalities – trichoschisis, pili torti, longitudinal grooving, trichorrhexis nodosa, trichothiodystrophy
- Hypertrichosis
- Pigmentary abnormalities – mottled or reticulated pigmentation
- Palmoplantar keratoderma (linked with deafness)
- Hypoplastic nails
- Lipomas
- Acrocyanosis

Table 63.7 Cutaneous manifestations of mitochondrial respiratory chain disorders.

NIEMANN–PICK DISEASE

Key features

- An autosomal recessive disorder due to deficiency of sphingomyelinase
- Rare skin involvement in type A consists of yellow–brown discoloration and facial papules
- Failure to thrive, hepatosplenomegaly and neurologic deterioration (type A)
- Minimal neurologic involvement and milder disease (type B)

Niemann–Pick disease is an autosomal recessive lysosomal storage disorder with several subtypes. Type A is most common in the Ashkenazi Jewish population, where it occurs with an incidence of 1 in 40 000 births. Type B is much less common in this ethnic group and is the predominant phenotype in non-Jewish patients, although precise estimates of its incidence are not available. Types A and B are allelic disorders, both associated with accumulation of sphingomyelin as a result of a deficiency of the enzyme sphingomyelinase. Type A is a severe disorder associated with failure to thrive, hepatosplenomegaly and rapid neurologic degeneration leading to death by 2 to 3 years of age. Type B is characterized by little or no neurologic involvement and survival into adult life. Progressive pulmonary infiltration may occur in either subtype and is associated with significant morbidity in type B. More recently, a third type (type C) has been described that is associated with an accumulation of unesterified cholesterol.

Cutaneous manifestations are typically observed only in patients with Niemann–Pick disease type A[74]. The skin may exhibit a generalized ochre or brownish-yellow discoloration. Papular lesions, most commonly located on the face and upper extremities, may also be present. Histologically, the papules of Niemann–Pick disease consist of foamy histiocytes, multinucleated cells and a variable infiltrate of lymphocytes.

Diagnosis of Niemann–Pick disease type A or B is established by demonstration of deficient sphingomyelinase activity in leukocytes or cultured skin fibroblasts. Prenatal diagnosis is available by CVS or amniocentesis. Carrier detection for type A is possible in the Ashkenazi Jewish population, using DNA analysis.

There is no effective therapy for Niemann–Pick disease type A. Bone marrow transplantation has reversed the clinical manifestations of type B disease.

PHENYLKETONURIA

Key features

- Autosomal recessive disorder due to a deficiency of phenylalanine hydroxylase
- Pigmentary dilution of the skin, eyes and hair
- Atopic-like dermatitis and sclerodermatous skin changes
- Progressive developmental delay/mental retardation if not treated

Phenylketonuria (PKU) is one of the most common inborn errors of metabolism, occurring worldwide with an incidence of approximately 1 in 10 000 births. It is an autosomal recessive disorder resulting from a deficiency of the enzyme phenylalanine hydroxylase that is responsible for conversion of phenylalanine to tyrosine. As a result of this enzyme deficiency, phenylalanine levels rise in blood and tissues of the untreated patient on a phenylalanine-containing diet, and high levels of this amino acid are extremely toxic to the CNS. Progressive developmental delay leading ultimately to moderate to profound mental retardation occurs and may be accompanied by seizures, behavioral problems and psychiatric symptoms.

A relative deficiency of tyrosine in patients with PKU (versus competitive inhibition of tyrosinase by excess L-phenylalanine) leads to diminished melanin production and resultant diffuse pigmentary dilution. The classic patient is described as blonde and blue-eyed, although pigmentation varies depending on the family and ethnic background. Sweat with a musty or "mousy" odor can represent a clue to the diagnosis. Nonspecific dermatitis occurs with increased frequency, and early-onset atopic dermatitis seems particularly common in patients with PKU. Scleroderma-like skin changes that favor the proximal extremities may also be observed[75] (Fig. 63.9) and often have their onset in the first year of life[76], in contrast to the acral predilection and older age of onset in systemic sclerosis.

The classic PKU phenotype is now primarily of historical interest in high-income countries where newborn screening is almost uniformly practiced. The diagnosis is established by plasma amino acid analysis. Identification of affected infants at birth with early institution of a phenylalanine-restricted diet and careful control of blood phenylalanine levels prevents the development of mental retardation and skin changes, although subtle neurocognitive consequences may be observed. Unfortunately, untreated patients are still encountered among children from low-income countries, and despite recommendations that dietary therapy be continued for life, some adolescents and adults in developed countries are not compliant with the dietary restrictions. In such cases, dermatologic manifestations may develop. In patients who resume treatment in later childhood or adult life, the hair color often darkens and sclerodermatous changes may regress. Dietary therapy involves not only restriction of phenylalanine, but also supplementation of tyrosine and other amino acids in the form of special medical foods. Close monitoring by an experienced nutritionist is vital.

PREMATURE AGING SYNDROMES AND POIKILODERMAS

Bernard A Cohen

The study of rare progeroid syndromes has led to better understanding of the normal aging process. These disorders can be distinguished by their time courses, associated clinical findings, and biochemical and genetic markers (Table 63.8). The inherited congenital and childhood poikilodermas (Fig. 63.10) can also demonstrate some of the features associated with premature aging and may be confused with progeria.

HUTCHINSON–GILFORD PROGERIA SYNDROME

Synonyms: ■ Progeria ■ Hutchinson–Gilford syndrome

Key features

- Rare, occurring in 1 in 8 million to 1 in 4 million births
- Due to mutations in the *LMNA* gene, which encodes nuclear lamins A and C
- Normal motor and mental development
- Characteristic facies with prominent scalp veins and beaked nose
- Wrinkled as well as scleroderma-like skin, alopecia and poor growth
- Generalized atherosclerosis with premature death from cardiovascular and cerebrovascular disease at a median age of 12 years
- Clinical trials using farnesyltransferase inhibitors to prevent accumulation of farnesylated mutant prelamin A ("progerin") are ongoing

Introduction

Hutchinson–Gilford progeria syndrome (HGPS) is a genetic disease characterized by accelerated aging that begins during infancy[77,78]. The term "progeria" originates from the Greek word for old age, "*geras*",

Fig. 63.10 Facial poikiloderma in a 3-year-old boy with Rothmund–Thomson syndrome. This child also had short stature and photosensitivity. *Courtesy, Sarah Chamlin, MD.*

Table 63.8 Progeroid syndromes and inherited poikilodermas (cont'd).

and was proposed by Gilford when he described several patients with the disorder in 1904.

History

The syndrome was first reported in 1886 by Hutchinson, who described a young boy with an absence of hair and an aged appearance. Nine years later, Gilford reported a second patient and documented the postmortem features. In 1972, DeBusk[77] summarized 60 cases from the world literature plus four new cases.

Epidemiology

DeBusk[77] estimated that HGPS occurred in 1 in 8 million births, and an incidence of 1 in 4 million was observed in the Netherlands from 1900 to 2005[79]. The male:female ratio is 1.2:1[79], and approximately 90% of the patients reported to date have been Caucasian.

In the cases reviewed by DeBusk[77], median and mean paternal ages were advanced, consanguinity was uncommon, and the abortion rate in affected families was normal. These observations favored a sporadic dominant mutation, which was later confirmed by genetic studies (see below). Since HGPS patients usually do not become sexually mature and typically succumb to the disease early in the second decade of life, familial occurrence is rare; however, it can occur in the setting of gonadal mosaicism[77,78]. Consanguineous families with an autosomal recessive variant of HGPS have been described, but additional clinical features such as clavicular aplasia/hypoplasia in affected individuals suggest an overlap with mandibuloacral dysplasia (which is caused by biallelic mutations in *LMNA*; Table 63.9)[80].

Pathogenesis

The vast majority of patients with HGPS have *de novo* point mutations in the lamin A gene (*LMNA*)[81,82]. This gene encodes two protein products (lamin A and lamin C) that represent major components of the nuclear membrane lamina and contribute to the structural scaffolding of the nucleus. In patients with classic HGPS, there is a common mutation within exon 11 that activates a cryptic splice site and leads to an internal deletion of 50 amino acids; this deletion includes a cleavage site that is necessary for the conversion of prelamin A to mature lamin A[83] (Fig. 63.11). As a result, the cells contain a dominant mutant prelamin A ("progerin") that disrupts the nuclear scaffolding. In the patients' cells, including lymphocytes and fibroblasts, there is evidence of altered nuclear sizes and shapes, as well as lobulation of the nuclei, extrusion of chromatin, and nucleolar alterations. Such structural changes presumably lead to functional defects[84] and the premature aging phenotype.

In families with the autosomal recessive progeria–mandibuloacral dysplasia overlap syndrome described above, homozygous missense mutations have been found in the *LMNA* gene[80]. Interestingly, mice with a homozygous mutation in *Lmna* display a progeroid phenotype with many similarities to HGPS, including abnormalities of bone, muscle and skin, as well as early death[85].

Several cellular and biochemical abnormalities have also been described[77,78,86], including short telomeres in progeria cells; of note, progressively decreasing telomere length is seen with normal aging and is associated with low levels of telomerase activity. In a telomerase knockout mouse model (see Ch. 4), some of the clinical features of accelerated aging have been observed.

End-organ growth hormone resistance and/or structurally defective growth hormone have also been observed in some patients with HGPS. A dramatic increase in linear growth may occur in some of these patients after exogenous growth hormone replacement. Additional abnormalities associated with the normal aging process, such as insulin resistance and decreased survival of fibroblast cultures, are also seen in patients with HGPS.

Clinical Features

Although affected children usually appear normal at birth, growth failure and other clinical features appear rather abruptly some time during the first year of life[77,78,87]. Weight gain is very slow, with marked loss during episodes of illness. Linear growth proceeds at half the normal pace and does not undergo the normal acceleration around puberty. Sexual maturation is absent in most patients. Consequently, affected individuals remain sexually immature with short stature and a low weight for height.

Following the development of growth failure, the skin becomes thin and dry, with fewer hairs than normal. Some areas may appear taut and shiny, whereas others (especially the fingers and toes) appear lax and wrinkled. At birth or during early infancy, some patients have thick, inelastic, scleroderma-like skin, usually on the lower abdomen, flanks, thighs and buttocks. Infantile fat is rapidly lost with the onset of growth failure, resulting in prominent superficial veins and the appearance of perioral cyanosis. As the aged appearance progresses, irregular brown pigmentation becomes evident in sun-exposed areas.

At the onset of growth failure, patients begin to develop characteristic facial features, including a disproportionately large cranium, frontal

NUCLEAR ENVELOPATHIES	
Primary feature and associated diseases	**Inheritance**
LAMINOPATHIES – due to mutations in the *LMNA* gene which encodes the lamin A and C proteins of the nuclear membrane lamina*	
Premature aging and/or cutaneous sclerosis	
Hutchinson–Gilford progeria syndrome	AD
Restrictive dermopathy†	AD
"Atypical Werner syndrome"	AD

Lipodystrophy	
Dunnigan familial partial lipodystrophy	AD
Generalized lipodystrophy with pubertal onset‡	AD
Muscular dystrophy	
Emery–Dreifuss muscular dystrophy	AD > AR
Limb-girdle muscular dystrophy type 1B	AD
Early-onset myopathy with progeroid features	AD
Cardiomyopathy	
Dilated cardiomyopathy type 1A	AD
"Heart–hand syndrome"	AD
Neuropathy	
Charcot–Marie–Tooth type 2B1	AR
CUTANEOUS DISORDERS WITH INNER NUCLEAR MEMBRANE DYSFUNCTION – due to mutations in the *LEMD3* gene, whose protein product associates with lamin A	
Cutaneous sclerosis and/or skeletal dysplasia	
Buschke–Ollendorff syndrome	AD
Osteopoikilosis	AD
Melorheostosis	Type 2 segmental§

*Heterozygous mutations in the *LMNB2* gene, which encodes the lamin B2 protein of the nuclear membrane lamina, can cause "acquired" partial lipodystrophy (Barraquer–Simons syndrome).

†Can also result from recessive mutations in the *ZMPSTE24* gene, which encodes a zinc metalloproteinase involved in the processing of prelamin A into mature lamin A; mandibuloacral dysplasia often presents with progeroid features and lipodystrophy.

‡Overlaps with atypical Werner syndrome; numerous whitish, fibrotic papules on a background of diffuse hyperpigmentation have been described in some patients.

§Germline heterozygous mutation (resulting in Buschke–Ollendorff syndrome or osteopoikilosis) with a presumed second hit in area of melorheostosis.

Table 63.9 Nuclear envelopathies. A heterogeneous group of genetic disorders that share the common findings of cutaneous fibrosis and bone dysplasia. Néstor-Guillermo progeria syndrome (see Table 63.8) is also characterized by abnormalities in the nuclear membrane lamina; this autosomal recessive disorder results from mutations in the barrier-to-autointegration factor 1 gene (*BANF1*), which encodes a protein that interacts with prelamin A (and progerin). AD, autosomal dominant; AR, autosomal recessive.

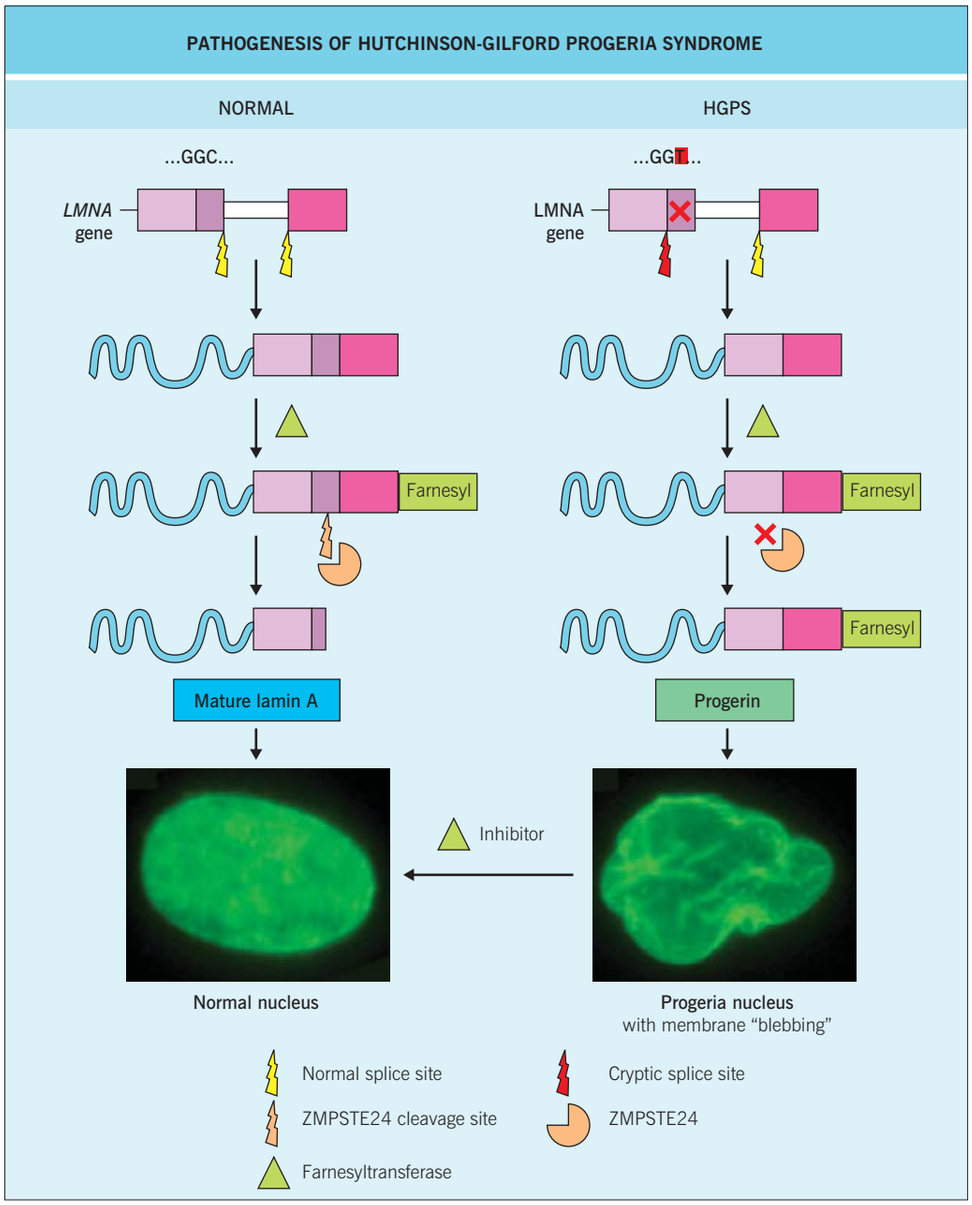

Fig. 63.11 Pathogenesis of Hutchinson-Gilford progeria syndrome (HGPS). Most patients with classic HGPS have a C-to-T point mutation that activates a cryptic splice site and leads to an internal in-frame deletion of 50 amino acids. The deleted region includes a cleavage site for the ZMPSTE24 zinc metalloproteinase, so removal of a farnesylated portion of prelamin A by this enzyme to produce mature lamin A does not occur in HGPS patients. Mutant "progerin" therefore remains farnesylated and, as a result, anchored to the nuclear membrane, where it disrupts nuclear scaffolding and causes blebbing. Administration of farnesyltransferase inhibitors can prevent this disruption of nuclear structure and function by progerin.

bossing, a large open anterior fontanelle, pronounced scalp veins, prominent eyes (due to relatively slow growth of the facial bones), a thin beaked nose with a sculpted appearance, and micrognathia. The facial stigmata tend to become marked by age 2 to 3 years, giving a "plucked-bird" appearance.

Alopecia develops during the first year of life and becomes diffuse and generalized, with later hair growth tending to be fine and lightly pigmented. Eyebrows and eyelashes are often sparse or absent. Although the nails may be normal, dystrophy in the form of small, short and thin nails is common. Marked delay in the eruption of primary and secondary dentition has also been noted in most patients. Teeth may be crowded, rotated, overlapped and maloccluded, and the voice tends to be high-pitched and piping.

Truncal features include a narrow pyriform thorax, shoulders with thin and short clavicles, and prominent thoracic kyphosis giving a stooped appearance. Prominence of the abdomen (relative to the chest) and hypoplastic nipples also contribute to the peculiar habitus. The limbs are usually proportionate and become progressively thinner with increasing prominence of the joints, especially the knees, elbows and small joints of the hand. Coxa valga is usually present by age 2 to 3 years and, in combination with increasing joint stiffness, contributes to a wide-based gait.

Patients are of normal intelligence, and many appear shy and aware of their unusual appearance. Early onset of progressive coronary and cerebral atherosclerosis results in a median lifespan of 12 years.

Pathology and Laboratory Findings

Cutaneous histopathology varies with the site and the age of the patient, and it is usually not helpful in diagnosing the condition[88,89]. The epidermis is fairly normal with minimal hyperkeratosis and a slight increase in melanin in the basal cell layer. Although dermal elastic tissue is normal, dermal collagen tends to be thickened and hyalinized. Adnexal structures are normal or decreased in density and arrector pili muscles are usually prominent.

Radiographic findings include hypoplasia of the facial bones, thinned cranial bones, open fontanelles, and hypoplasia of the mandible with crowding of the teeth. Progressive resorption of bone from the distal phalanges of the fingers and toes is also characteristic, but not diagnostic, of HGPS.

Differential Diagnosis

The differential diagnosis is outlined in Table 63.8 and includes Werner syndrome, "atypical Werner syndrome", Néstor-Guillermo progeria

syndrome, metageria and acrogeria[90]. In distinction to HGPS, patients with Werner syndrome have premature canities, cataracts and an increased incidence of malignancy.

HGPS should also be distinguished from the following disorders: Cockayne syndrome (Ch. 87), Rothmund–Thomson syndrome (Ch. 87), ataxia–telangiectasia (Ch. 60), Kindler syndrome (see below), and Wiedemann–Rautenstrauch syndrome (neonatal progeroid syndrome with premature aging already noted at birth). Lastly, clinical overlap may be seen with other disorders that are due to mutations in the *LMNA* gene (see Table 63.9), such as early-onset myopathy with progeroid features, restrictive dermopathy (see Ch. 34) and mandibuloacral dysplasia.

Treatment

Treatment is directed toward known complications, particularly cardiovascular and cerebrovascular. Although recommended by some investigators, to date, no dietary regimen has been shown to decrease the risk of these complications. Some patients may benefit from administration of exogenous growth hormone. Patients distressed by their unusual physical appearance may benefit from psychiatric counseling. Genetic counseling is also indicated for affected families.

Based upon the finding that the dominant mutant form of prelamin A ("progerin"; see above) contains a persistent abnormal C-terminus that has undergone farnesylation (leading it to be permanently anchored to the nuclear membrane), human HGPS fibroblasts were treated with inhibitors of farnesylation. The result was reversal of the abnormal nuclear morphology[83], and in a mouse model of progeria, treatment with a protein farnesyltransferase inhibitor led to improved body weight, strength and survival, as well as a decrease in osteoporosis[91]. As a result, clinical trials are underway to evaluate a farnesyltransferase inhibitor (lonafarnib) in HGPS patients[92].

Treatment with a combination of a bisphosphonate and statin (which inhibit farnesylation and a related modification, geranylgeranylation) increased survival and prevented premature aging in mice deficient in the Zmpste24 metalloproteinase that processes prelamin A, and these agents are being administered together with lonafarnib (a farnesyltransferase inhibitor; see Fig. 63.11) in some human HGPS studies. Of note, *ZMPSTE24* mutations underlie some human cases of restrictive dermopathy and mandibuloacral dysplasia (see Table 63.9). Lastly, the possibility of targeting mutant mRNAs via RNA interference or the activated cryptic splice site (see above) via modified oligonucleotides is also being explored.

WERNER SYNDROME

Synonym: ■ Progeria of the adult

Key features

- Occurs in 1 in 1 million births, with a higher incidence in Japan
- Autosomal recessive disorder due to mutations in the gene *RECQL2 (WRN)* that encodes a DNA helicase
- Premature aging with the appearance of canities, cataracts, osteoporosis, diabetes mellitus and atherosclerosis during the second decade
- Additional features include sclerodermoid changes, keratoses and ulcerations over bony prominences, short stature, and vascular and soft tissue calcification
- Similar facies to progeria patients, with a pinched appearance and micrognathia
- Increased risk of malignancy

Introduction

Werner syndrome is a genetic disorder of accelerated aging with an onset in the second decade of life. This rare progeroid syndrome has a higher incidence in select populations in Japan[93–97]. Although it is often referred to as progeria of the adult, Werner syndrome has some distinctive clinical findings not typically associated with the normal maturational process (e.g. hypogonadism, laryngeal atrophy, osteosclerosis of the distal extremities)[93–96]. The discovery of underlying mutations in the *RECQL2 (WRN)* gene has allowed investigation into the molecular aspects of Werner syndrome[94,96].

History

In 1904, Werner described a family with two brothers and two sisters between the ages 36 and 40 years who displayed clinical features of premature aging. In 1934, Oppenheimer and Kugel reported two similar cases and established the eponym Werner syndrome.

Epidemiology

Werner syndrome is a rare autosomal recessive disorder with an overall incidence of 1 in 1 million births. However, its incidence in Japan is higher and may approach 1 in 3500 in some communities owing to high rates of consanguinity. It was the study of several large Japanese families that led to identification of the gene responsible for this disorder.

Werner syndrome has been reported in all races and affects both sexes equally. Mild clinical findings have been noted in heterozygote relatives of affected patients.

Pathogenesis

Werner syndrome is caused by mutations in the *RECQL2 (WRN)* gene, which encodes a homolog of the *Escherichia coli* RecQ DNA helicase. Almost all of the mutations identified to date predict a truncated protein, and over half of Japanese patients are homozygous for a specific splice-site mutation[94,96].

The Werner protein (WRN) has both exonuclease and helicase activities, and it plays a role in optimizing DNA repair (particularly base excision repair) and in suppressing illegitimate recombination. Therefore, loss of RecQ helicase results in genomic instability. The accumulation of senescent cells with decreasing replicative capacity and an increasing number of mutations is thought to lead to the clinical findings of premature aging and an increased risk of malignancy. Loss of function of the *RECQL2* gene may occur in the normal population as a function of age[94].

A subset of patients have "atypical Werner syndrome" and lack pathogenic changes in the *RECQL2* gene. Rather, they have heterozygous missense mutations in the *LMNA* gene (see HGPS section) that affect the heptad repeat region and are predicted to interfere with protein–protein interactions[98]. Compared to patients with *RECQL2* mutations, those with atypical Werner syndrome tend to have an earlier onset of disease and more severe age-related manifestations. The latter patients may be better classified as having late-onset HGPS.

Clinical Features

In most affected individuals, growth progresses normally until the beginning of the second decade, when short stature and thin limbs become noticeable. Graying of the hair may begin during childhood but characteristically appears in late adolescence or the early twenties. Other findings of Werner syndrome become evident during the second and third decades of life[93–96].

The typical patient is short, with an average height of 5 ft (1.5 m), and has spindly limbs but central obesity. The hands and feet are small, and the face is thin with a pinched appearance, prominent eyes, beaked nose, circumoral radial furrows, taut lips, protuberant teeth and micrognathia (Fig. 63.12). The voice is high-pitched and raspy.

Cutaneous changes, including atrophy (epidermal, dermal and subcutaneous), scale, mottled hyperpigmentation and tightness reminiscent of scleroderma, are most prominent on the face, forearms, hands, legs and feet. Nails may be dystrophic, hypoplastic or absent, and plantar hyperkeratosis is common. Thick keratoses develop over pressure points such as the fingers, toes, ankles, elbows and, occasionally, the ears. Removal of these keratoses by accidental or deliberate trauma leaves painful progressive ulcers. Ulcers may be resistant to therapy and prone to infection because of ischemia related to peripheral vascular disease. Dystrophic soft tissue calcification and osteomyelitis can also complicate chronic ulcers.

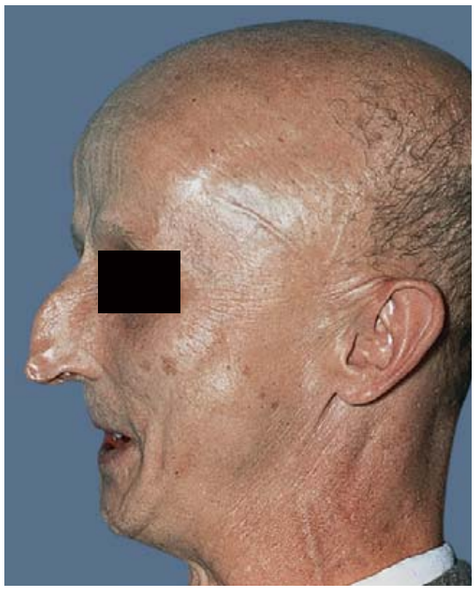

Fig. 63.12 Werner syndrome. Characteristic features include a beaked nose, tautness of the skin, prominent veins, and micrognathia. *Courtesy, Ronald P Rapini, MD.*

Other characteristic findings in Werner syndrome that reflect accelerated aging include cataracts, diabetes mellitus, hyperlipidemia, generalized atherosclerosis, osteoporosis, cerebral cortical atrophy, thymic atrophy and lymphoid depletion. Additional features not usually associated with normal aging include hypogonadism, laryngeal atrophy, osteosclerosis of the extremities, an increased risk of certain malignancies (e.g. soft tissue sarcomas, osteosarcoma), and meningiomas. In the Japanese population, there may be an increased risk of thyroid carcinoma and melanoma.

The average lifespan is approximately 50 years, and death is usually related to cardiovascular and cerebrovascular disease. Of interest, otherwise healthy heterozygotes in families of affected individuals tend to have higher rates of malignancy and myocardial infarction than the general population[94–97].

Pathology and Laboratory Findings

The epidermis is hyperkeratotic and atrophic, with focal hypermelanosis of the basal layer. Appendages are decreased in number and atrophic, and there is fibrosis and variable hyalinization of the dermis. The fat is also atrophic and often replaced by hyalinized connective tissue. Vessels may show changes typical of diabetic angiopathy.

Differential Diagnosis

As with HGPS, the clinical diagnosis is easily made when the characteristic premature canities, dysmorphic facies, and body habitus are recognized. In addition to the other premature aging syndromes outlined in Table 63.8, Werner syndrome must be distinguished from ataxia–telangiectasia as well as disorders associated with plantar keratoderma and scleroderma-like skin changes (e.g. Huriez syndrome).

Treatment

Genetic counseling should be provided, and prenatal diagnosis can be offered to affected families. Identification of heterozygotes in affected families may allow preventive measures and screening protocols to be implemented.

Skin ulcers may prove resistant to therapy and should be treated aggressively and early, with skin grafting occasionally necessary. Case reports have suggested that etidronate may ameliorate painful soft tissue calcifications. Management of diabetes mellitus and hyperlipidemia with proper diet and appropriate medications (e.g. pioglitazone and lipid-lowering agents) can help to reduce complications, including atherosclerosis. Of note, a recent study found that vitamin C supplementation increased the lifespan and reversed age-related metabolic abnormalities in a mouse model of Werner syndrome, suggesting that vitamin C might be beneficial for Werner syndrome patients[99].

KINDLER SYNDROME

Synonyms: ■ Kindler–Weary syndrome ■ Bullous acrokeratotic poikiloderma of Kindler and Weary ■ Congenital poikiloderma with bullae and progressive cutaneous atrophy ■ Hereditary acrokeratotic poikiloderma ■ Congenital poikiloderma with blisters and keratoses

Key features

- Due to loss-of-function mutations in *FERMT1 (KIND1)*, which encodes a protein that mediates anchorage between the actin cytoskeleton and the extracellular matrix via focal adhesions
- Congenital/infantile onset of trauma-induced acral bullae and skin fragility that improves during childhood
- Progressive poikiloderma and diffuse cutaneous atrophy
- Photosensitivity that decreases with age
- Variable features include palmoplantar hyperkeratosis, webbing of the fingers and toes, and mucosal involvement leading to gingivitis, colitis, stenoses and ectropion

Introduction

Now classified as a subtype of epidermolysis bullosa (see Ch. 32), Kindler syndrome is a rare genodermatosis that features progressive poikiloderma, cutaneous atrophy and mucosal inflammation in addition to trauma-induced blistering[100–103].

History

In 1954, Theresa Kindler described a patient with acral blistering and photosensitivity during infancy, followed later in life by progressive poikiloderma and atrophy. Twenty years later, Weary reported 10 members of a single family with similar findings in addition to widespread atopic dermatitis during early childhood and keratotic papules over the joints of the arms and legs that appeared in childhood and persisted indefinitely. Oral involvement was emphasized in subsequent cases[100–102,104,105].

Epidemiology

Cases of Kindler syndrome have been described worldwide, and it has an autosomal recessive inheritance pattern.

Pathogenesis

Kindler syndrome is caused by loss-of-function mutations in the *FERMT1* (*KIND1*) gene, which encodes the fermitin family homolog 1 (kindlin-1) protein that plays a role in linking the actin cytoskeleton to the extracellular matrix[106]. This protein represents the human homolog of the *Caenorhabditis elegans* unc-112 protein. FERMT1 is found throughout the epidermis, especially in basal keratinocytes, and it co-localizes with actin and vinculin in focal adhesions[107–109]. Through integrin-mediated signaling, FERMT1 affects the shape, polarity, adhesion, proliferation, and motility of keratinocytes.

Clinical Features

Characteristic features include congenital or neonatal blistering and photosensitivity, both of which improve during early childhood, and progressive poikiloderma with marked cutaneous atrophy[100–103]. Blistering and skin fragility are most prominent in trauma-prone areas of the arms and legs, particularly the hands and feet (Fig. 63.13A). Bullae usually heal without scarring, but milia and scarring sometimes develop. Occasionally, multiple erosions are present on the extremities (especially the shins and forearms) at birth, producing a clinical picture of aplasia cutis congenita similar to that observed in other forms of epidermolysis bullosa ("Bart syndrome"; see Ch. 64). Photosensitivity, manifested as an increased susceptibility to sunburn, tends to be a problem primarily during early childhood.

In prepubertal children, progressive reticulated hyperpigmentation and telangiectasias develop in sun-exposed areas, and after puberty

Fig. 63.13 Kindler syndrome. A Atrophy, erosions and fusion of the toes in an infant. **B** Poikiloderma of the face and neck with "skip" areas. **C** Wrinkling due to atrophy and fusion between the fourth and fifth toes. *C, Courtesy, Jean L Bolognia, MD.*

these findings spread to sun-protected sites as well. The predominant feature in adult patients with Kindler syndrome is poikiloderma (Fig. 63.13B), which persists throughout life. Diffuse cigarette paper-like atrophy is often present (Fig. 63.13C), particularly on the dorsal surfaces of the hands and feet. Webbing of the fingers and toes (see Fig. 63.13C) and palmoplantar hyperkeratosis may also be evident. Eczematous dermatitis, typically beginning during infancy and resolving by 5 years of age, is occasionally observed.

Patients with Kindler syndrome frequently have erosive gingivitis and poor dentition[104,105]. Mucosal involvement can also lead to ectropion, colitis, and stenoses of the urethral meatus, anus, vagina and esophagus. Malignancies have occasionally been reported, including squamous cell carcinoma of the lip, hard palate and acral skin, as well as transitional cell carcinoma of the bladder[110].

Pathology

In older patients, skin biopsy specimens show the typical changes of poikiloderma, including epidermal atrophy, vacuolization of the basal cell layer, variable epidermal melanin content, dermal melanophages and capillary dilation. Ultrastructural features of blistered skin vary and can include cleavage within basal keratinocytes, through the lamina lucida, and/or below the lamina densa. Clumping of tonofilaments may be observed in keratinocytes adjacent to blistered areas[102], but hemidesmosomes and anchoring fibrils are usually intact[111]. Ultrastructural analysis of non-blistered skin typically demonstrates duplication of the lamina densa and clefting at sites of focal interruption of the lamina densa; these basement membrane changes may also be evident via light microscopy with immunohistochemical staining for type IV or type VII collagen (e.g. broad, patchy staining at the dermal–epidermal junction). Immunostaining of skin biopsy specimens with anti-kindlin-1 antibodies often shows a marked reduction or absence of this protein.

Differential Diagnosis

In infants, the differential diagnosis of Kindler syndrome consists primarily of other forms of epidermolysis bullosa. The predominantly acral distribution of the blisters and associated atrophy are findings that point to Kindler syndrome. Additional causes of blisters in newborns and infants are reviewed in Chapter 34. As poikiloderma becomes a prominent feature (usually by the age of 5 years), the differential diagnosis may include Rothmund–Thomson syndrome, Cockayne syndrome, and other entities outlined in Table 63.8.

Treatment

Treatment is supportive. In infants with bullae and erosions, meticulous wound care is indicated in an effort to prevent infection and minimize scarring. Emollients are useful for dry pruritic skin, and diligent sun avoidance and protection may impede the progression of the cutaneous poikiloderma, particularly the atrophic component. Periodic examination of the skin and oral mucosa can aid in early detection of squamous cell carcinomas. Stenoses occasionally require procedures such as esophageal dilation or surgical intervention, and elective cesarean section should be considered for pregnant women with vaginal stenoses. Regular dental care is important to manage erosive gingivitis and periodontitis. Hemorrhagic colitis can lead to iron deficiency anemia, and bowel resection may be necessary in severe cases[108].

ECTODERMAL DYSPLASIAS

Alanna F Bree and Virginia P Sybert

Key features

- Genetic disorders resulting in structural or functional abnormalities in two or more of the major structures derived from the ectoderm
- Ectodermal structures affected include hair, teeth, nails, sweat glands, mucous glands and sebaceous glands
- Ectodermal dysplasia syndromes are often associated with abnormalities in non-ectodermally derived structures
- Differentiation among the different disorders is based on the types of ectodermal defects, associated non-ectodermal anomalies and mode of inheritance, as well as the underlying genetic defect
- Inherited abnormalities limited to one ectodermal structure (e.g. hair, nails) are not categorized as ectodermal dysplasias

CLASSIC ECTODERMAL DYSPLASIAS				
	Hypohidrotic ED	**Hypohidrotic ED–immune deficiency**	**Hidrotic ED**	**Witkop tooth and nail syndrome**
Inheritance (associated gene)	XLR (*EDA*); AD, AR (*EDAR*); AD, AR (*EDARADD*)	XLR (*NEMO*); AD (*NFKBIA*)	AD (*GJB6*)	AD (*MSX1*)
Protein product	Ectodysplasin A; EDAR; EDARADD	NF-κB essential modulator; NF-κB inhibitor-α	Connexin 30	Muscle segment homeobox 1
Scalp hair	Sparse to absent; often lightly pigmented in children	Sparse	Wiry, brittle; patchy alopecia; often lightly pigmented	Normal to thin
Teeth	Hypodontia, conical	Hypodontia, conical	Normal	Hypo- or anodontia of secondary teeth; primary teeth normal or small
Sweating	Markedly decreased	Mildly decreased	Normal	Normal
Nails	Normal	Normal	White during infancy; thickened, distal separation	Koilonychia improves with age; toenails worse than fingernails
Other	Characteristic facies; neonates may have collodion-like membrane; eczema common; frequent respiratory tract infections; variable phenotype, including mosaic pattern, in female patients with XLR form	Intertrigo, seborrheic-like dermatitis, erythroderma; colitis; recurrent infections (pyogenic or opportunistic); ↑ IgM and IgA, ↓ IgG; rare osteopetrosis, lymphedema	Palmoplantar keratoderma; blepharitis, conjunctivitis	Prolonged retention of primary teeth

Table 63.10 Classic ectodermal dysplasias. AD, autosomal dominant; AR, autosomal recessive; ED, ectodermal dysplasia; EDAR, EDA receptor; EDARADD, EDAR-associated death domain; *GJB6*, gap junction β6; XLR, X-linked recessive.

p63-RELATED ECTODERMAL DYSPLASIA SYNDROMES				
	AEC*	**EEC**	**Limb–mammary**	**ADULT**
Inheritance	AD	AD	AD	AD
Typical *p63* mutations	Missense in SAM domain	Missense in DNA-binding domain	Truncating in C-terminal region†	Missense in hotspot at end of DNA-binding domain†,‡
Scalp hair	Lightly pigmented, wiry, coarse; patchy alopecia	Lightly pigmented, coarse; may be sparse	Normal	Lightly pigmented, sparse; frontal alopecia
Teeth	Hypodontia, misshapen (e.g. conical) teeth	Hypodontia, premature loss of teeth	Hypodontia	Hypodontia, small teeth, premature loss of teeth
Sweating	Hypohidrosis in some patients	Usually normal	Hypohidrosis in some patients	Usually normal
Nails	Hyperconvex, thickened or absent	Transverse ridges, pitting	Variable dystrophy	Ridges, pitting
Cleft lip/palate	~80%; palate ± lip	~50%; usually lip + palate	~30%; palate only	None
Digital anomalies	Syndactyly in some patients; rarely ectrodactyly	Ectrodactyly > syndactyly	Ectrodactyly > syndactyly	Ectrodactyly, syndactyly
Skin findings	Neonatal erythroderma; erosive dermatitis (esp. of scalp)	Xerosis, palmoplantar keratoderma	None	Xerosis, photosensitivity, freckling
Other	Ankyloblepharon; lacrimal duct defects; ectopic breast tissue; hypospadias; GER	Lacrimal duct defects; GU anomalies	Lacrimal duct defects, hypoplastic nipples/breasts; GU anomalies	Lacrimal duct defects; hypoplastic nipples/breasts

*Rapp-Hodgkin syndrome is now included within the AEC spectrum.
†May also be caused by missense mutations in the proline-rich domain.
‡This mutation is thought to constitutively activate a transactivation domain.

Table 63.11 p63-related ectodermal dysplasia syndromes. *p63* mutations also occur in a subset of patients with autosomal dominant non-syndromic split-hand/foot malformation (SHFM). AD, autosomal dominant; ADULT, *a*cro-*d*ermato-*u*ngual-*l*acrimal-*t*ooth; AEC, ankyloblepharon–ectodermal dysplasia–clefting; EEC, ectrodactyly–ectodermal dysplasia–clefting; GER, gastroesophageal reflux; GU, genitourinary; SAM, sterile alpha motif.

Ectodermal dysplasias have long been recognized as distinct inherited entities. For example, affected individuals were described by Wedderburn in 1838 and Darwin in 1875. While these disorders are uncommon, their features are so distinctive that they have received a great deal of medical attention. For over 200 years, they have been defined by their clinical characteristics and mode of inheritance. More than one hundred single-gene disorders qualify as ectodermal dysplasias by having abnormalities in two or more major ectodermal structures (hair, teeth, nails, and sweat glands); other ectodermal structures (e.g. sebaceous glands, mucous glands) can also be affected[112]. Some of these conditions have not been traditionally thought of as ectodermal dysplasias, such as Ellis–van Creveld syndrome, because they are recognized and diagnosed by their prominent involvement of non-ectodermal structures.

There have been many classification schemes proposed over the years, including a descriptive categorization by Pinheiro and Freire-Maia[113], a clinical–genetic model by Priolo and Lagana[114], and a functional classification by Lamartine[115]. In the past decade, the molecular basis of many ectodermal dysplasias has been elucidated, and we are beginning to understand the processes of cell signaling involved in the induction and development of ectodermal structures as well as their interactions with mesodermal structures[116,117]. An international

conference was held in 2008 with the aim of developing a classification system for ectodermal dysplasias that integrates clinical and molecular data[118].

Tables 63.10, 63.11 and 63.12 summarize the key clinical and genetic features of ectodermal dysplasias with a known molecular basis and/or prominent cutaneous manifestations. Several classic ectodermal dysplasias are discussed in detail in this chapter.

HYPOHIDROTIC ECTODERMAL DYSPLASIA

Synonyms: ■ Anhidrotic ectodermal dysplasia ■ Christ–Siemens–Touraine syndrome

Hypohidrotic ectodermal dysplasia (HED) refers to a group of disorders that share the following features: sparse or absent hair; missing or peg-shaped teeth; and decreased ability to sweat. The most common form is X-linked, and traditionally the term HED has referred to this condition. However, both autosomal dominant and autosomal recessive inheritance of clinically similar conditions have been documented and the underlying molecular defects defined.

Epidemiology

The X-linked form of HED occurs in approximately 1 in 10 000 live-born boys and can affect all racial and ethnic groups. The autosomal dominant and recessive forms are much less common.

Pathogenesis

HED is caused by genetic defects that affect the ectodysplasin signal transduction pathway (Fig. 63.14)[119]. Epithelial cells in the developing tooth, hair follicle and eccrine gland utilize this pathway during morphogenesis, and errors in signaling result in aplasia, hypoplasia or dysplasia of these structures. The pathway is activated at a critical time during development. With activation, a transcription factor, NF-κB, is translocated into the nucleus of these cells and alters the expression of a variety of target genes. The change in gene expression likely has an effect on both cellular proliferation and survival[120].

The gene that is defective in the X-linked form of HED (*EDA*) codes for a soluble ligand, ectodysplasin A. It is secreted by a subset of epithelial cells and binds to its receptor (*ecto*dysplasin-*A* receptor; EDAR) on another group of epithelial cells. Mutations in *EDAR* cause either autosomal recessive or autosomal dominant HED[121]. Autosomal recessive and autosomal dominant HED can also be caused by mutations

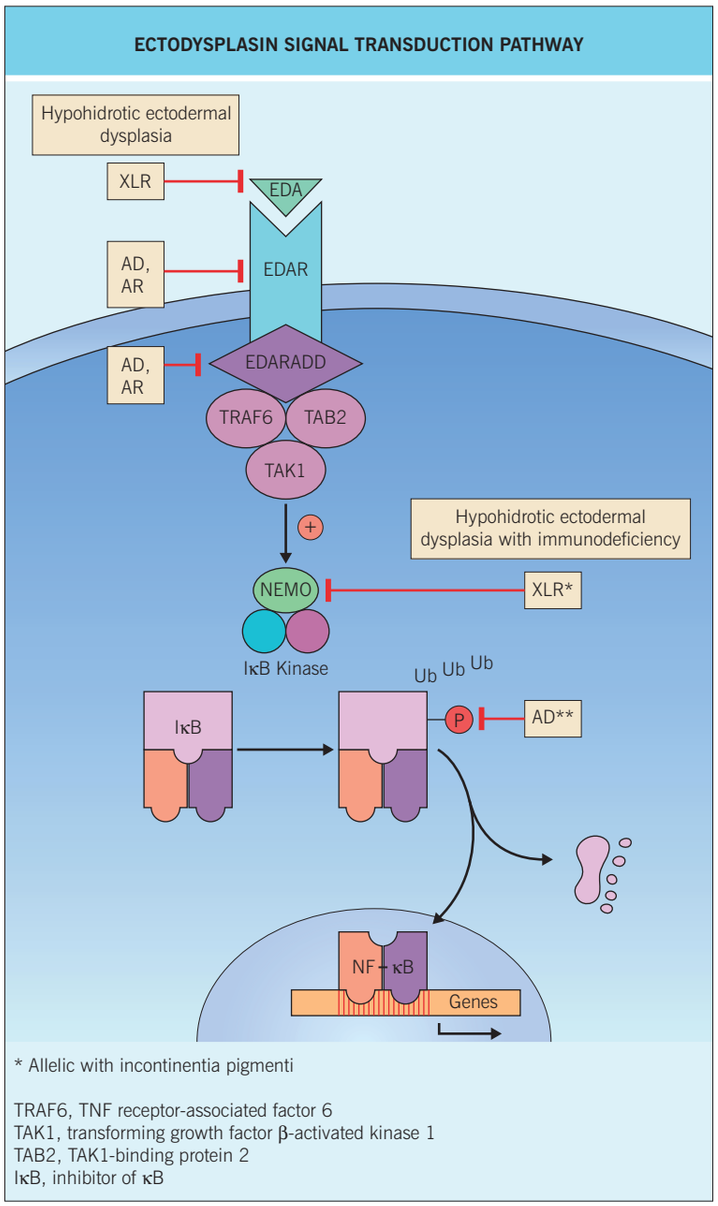

Fig. 63.14 The ectodysplasin signal transduction pathway. **A hypermorphic mutation in the gene encoding IκBα that prevents this protein's phosphorylation (and subsequent ubiquitination/degradation) can result in continued inhibition of NF-κB and a phenotype of hypohidrotic ectodermal dysplasia with immunodeficiency. AD, autosomal dominant; AR, autosomal recessive; EDA, ectodysplasin A; EDAR, EDA receptor; EDARADD, EDAR-associated death domain adapter protein; NEMO, NF-κB essential modulator; XLR, X-linked recessive. Additional details of NEMO function are in Figure 62.4.

in the *EDARADD* (EDAR-associated death domain) gene, which encodes an intracellular adapter protein that assists in transducing the signal from the activated receptor to the nucleus[122]. Molecular analysis of the *EDA* and *EDAR* genes is available in commercial laboratories, but *EDARADD* gene testing is currently available on a research basis only[123].

Clinical Features

Affected newborns may present with a collodion-like membrane or with marked skin scaling. Scalp hair is sparse to absent (Fig. 63.15), and, when present, is usually blonde. Hair may darken at puberty and secondary sexual hairs are typically normal, although body hair is usually sparse or absent. Affected male patients are unable to sweat to a detectable degree[124]. This leads to an inability to maintain core temperature in warm environments, and hyperpyrexia is a major problem. Affected infants often present with fever of unknown origin. The skin is smooth and dermatoglyphics may be effaced because of absent eccrine pores. Atopy is a major problem in these individuals, with eczema affecting nearly two-thirds of patients. Periorbital wrinkling and hyperpigmentation are common. Sebaceous hyperplasia of the face, clinically resembling milia, can develop over time (see Fig. 63.15D). The nails are usually normal.

Both the primary and secondary dentition are affected. Teeth may be absent or reduced in number and abnormally shaped (e.g. peg-shaped). Affected individuals typically have an alteration in their facial appearance characterized by a saddle nose, full everted lips and frontal bossing (see Fig. 63.15). Nasal secretions and cerumen are thick and viscous, and recurrent respiratory tract infections are common. The voice is frequently hoarse or raspy. Affected infants often develop gastroesophageal reflux and feeding problems.

Female patients (Fig. 63.16) with the X-linked form of HED fall into one of three categories: (1) carriers with no detectable clinical features; (2) limited involvement with findings such as decreased hair density, one or more peg-shaped or missing teeth, and patchy distribution of sweat glands along Blaschko's lines (sometimes with relative hyperpigmentation of the skin that lacks adnexa); or (3) full-blown features of the disorder. This variability results from the random nature of X-inactivation (see Ch. 62).

Pathology

A skin biopsy is usually not necessary, but a scalp or palmar biopsy specimen lacking eccrine structures is considered diagnostic of HED[125].

Differential Diagnosis

The majority of affected individuals, either male or female, have the X-linked form. In sporadic cases, molecular diagnosis may be helpful. At birth, HED can be confused with an ichthyosis if a collodion-like membrane is present (see Ch. 57; Table 57.5). Recurrent fevers in an infant may lead to consideration of infectious diseases before the features of HED are recognized. HED with immune deficiency (HED-ID) due to mutations in the *NEMO* gene can be differentiated by the clinical and laboratory features of the associated immune system abnormalities (see below).

Treatment

Controlling ambient temperatures to prevent high fever and external methods of cooling, e.g. wet T-shirts, wet headbands and cooling vests, are important in the care of children with HED. Dentures can be fitted in children as young as 3 years of age, and dental restoration through implants should be employed for older patients. Multidisciplinary care is often required for treatment of other manifestations, which range from nasal concretions, asthma and recurrent respiratory infections to weight deficits and reduced salivary secretion. Referral to the National Foundation for Ectodermal Dysplasias is also an important aspect of care. This organization publishes booklets for patients and physicians and provides yearly conferences and a bimonthly newsletter for member education (http://www.nfed.org/).

The potential for gene or protein therapy for HED is on the horizon[126]. In Tabby mice (the murine form of X-linked recessive HED), the administration of recombinant EDA protein *in utero* or in the immediate postnatal period can completely or partially correct the phenotype[127]. Neonatal administration of recombinant EDA in a canine model of X-linked HED has also led to significant correction of ectodermal defects[128,129].

HYPOHIDROTIC ECTODERMAL DYSPLASIA WITH IMMUNE DEFICIENCY

HED-ID is a rare condition that shares many features with classic HED but is differentiated by the associated immune abnormalities (see Ch. 60).

Pathogenesis

HED-ID is most commonly inherited in an X-linked recessive pattern due to mutations in the *NEMO* (*n*uclear factor-κB *e*ssential *mo*dulator)

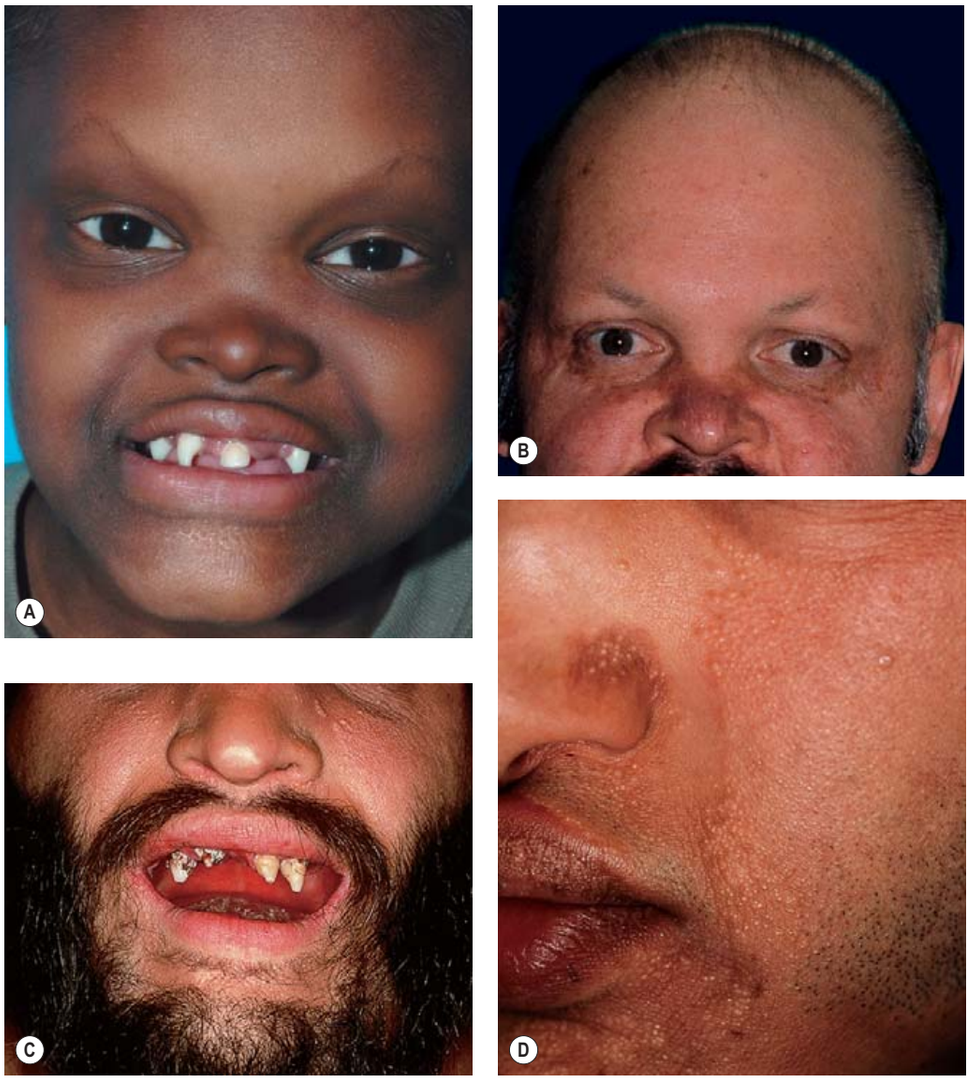

Fig. 63.15 Male patients with hypohidrotic ectodermal dysplasia. Note the flat nasal bridge, depressed nasal tip, sparse hair (scalp, eyebrows, eyelashes), peg-shaped teeth, full lips and sebaceous hyperplasia. Also note the normal secondary hair in adults. *A, Courtesy, Julie V Schaffer, MD; B & D, Courtesy, Mary Williams, MD.*

gene; the latter encodes a subunit of a regulatory kinase that activates NF-κB downstream in the ectodysplasin (see Fig. 63.14) and tumor necrosis factor-α (TNF-α) pathways[130]. The condition is allelic to incontinentia pigmenti, which is caused by more severe *NEMO* mutations that are lethal in male embryos unless rescued by mosaicism (see Ch. 62). An autosomal dominant form of HED-ID due to mutations in the *NFKBIA* gene has also been described. These patients have decreased NF-κB signaling because the mutated α-component of the NF-κB inhibitor is resistant to degradation (see Fig. 63.14).

Clinical Features

Individuals with HED-ID often have milder abnormalities of ectodermal structures than do patients with classic HED. The findings can include hypodontia, conical teeth, hypotrichosis and a reduced ability to sweat; frontal bossing, periorbital wrinkling and everted lips may also be seen. Extensive intertrigo, seborrheic or atopic-like dermatitis that develops into erythroderma, and inflammatory colitis may represent clues to the diagnosis[131], and reticulated hyperpigmentation is occasionally observed. The immunodeficiency results in recurrent pyogenic bacterial (especially of the skin and respiratory tract) and opportunistic infections, and it is characterized by a poor antibody response to polysaccharide antigens, dysgammaglobulinemia (typically with elevated IgM and IgA but decreased IgG levels), and defective natural killer cell activity. Patients with the autosomal dominant form of HED-ID also have a severe T-cell deficiency. Occasionally, infants with X-linked HED-ID present with osteopetrosis (abnormally dense bones) and lymphedema[130,132]. Female carriers may have mild features of incontinentia pigmenti (see Ch. 62).

Treatment

Intravenous immunoglobulin (IVIg) administration does not typically decrease affected individuals' propensity to develop infections. Allogeneic hematopoietic stem cell transplantation has resulted in correction of the immune abnormalities and (in one patient to date) resolution of erythroderma, but reported recipients have had difficulty achieving engraftment and experienced post-transplant complications such as worsening colitis[131,133].

HIDROTIC ECTODERMAL DYSPLASIA

Synonym: ▪ Clouston syndrome

Hidrotic ectodermal dysplasia was first described in a French-Canadian kindred[134] and the ancestry of many affected individuals was traced to a single founder. Subsequently, the disorder has been reported in individuals of varying racial and ethnic backgrounds[135].

Pathogenesis

Hidrotic ectodermal dysplasia is an autosomal dominant condition that is caused by missense mutations in the *GJB6* gene, which encodes the connexin 30 protein[136]. Connexins oligomerize to form gap junctions that are important for communication between cells (see Ch. 58), and *GJB6* is expressed in keratinocytes. Mutations in genes that encode other connexins cause skin disorders ranging from Vohwinkel

Fig. 63.16 Female patients with X-linked hypohidrotic ectodermal dysplasia. Note the peg-shaped teeth, hypodontia, full lips, and sparse eyelashes (**A**) as well as periorbital hyperpigmentation (**B**) and sebaceous hyperplasia (**C**). *A, Courtesy, Julie V Schaffer, MD.*

and keratitis–ichthyosis–deafness (KID) syndromes (*GJB2*) to erythrokeratodermia variabilis (*GJB3* and *GJB4*) (see Table 58.3). Mutations in *GJB6* can also cause non-syndromic autosomal dominant, digenic (together with a *GJB2* mutation) and (less often) recessive deafness, with normal teeth and hair in affected individuals. To date, a *GJB6* mutation has been described in a single patient with KID syndrome (associated with congenital atrichia). Molecular testing of the *GJB6* gene is available in clinical laboratories.

Clinical Features

This condition primarily affects the hair and nails. The teeth and sweating are normal. The hair is wiry, brittle and pale; patchy alopecia is common. Both hair loss and nail changes may progress over time. In affected infants, the nails are typically milky white, gradually thickening throughout childhood. In adults, the nail plates grow slowly, are thick, and separate from the nail bed distally (Fig. 63.17). Hyperkeratosis with stippling of the palms and soles can also be progressive (see Ch. 58). Tiny papules in a grid-like array (corresponding to eccrine acrosyringia) or larger papules coalescing in a cobblestone-like pattern may extend from the palms and soles onto the dorsal surface of the digits, especially distally (see Fig. 63.17 and Fig. 58.9), or even affect other extensor surfaces of the extremities. Oral leukoplakia has been described. Sparse eyelashes may predispose patients to conjunctivitis and blepharitis.

Fig. 63.17 Hidrotic ectodermal dysplasia (Clouston syndrome). Note the thickened, shortened nails with distal separation and tiny papules in a regular distribution on the fingertips.

Fig. 63.18 Witkop tooth and nail syndrome. Small primary teeth, some conical, in a 7-year-old boy. Radiographs showed an absence of nearly all of the secondary teeth. *Courtesy, Julie V Schaffer, MD.*

Pathology

Histologic evaluation of thickened palms and soles shows orthohyperkeratosis with a normal granular layer. Eccrine syringofibroadenomatosis, which is characterized by proliferation of ductal structures within a fibrovascular stroma, may be observed when papular lesions are biopsied. By electron microscopy, there is an increased number of desmosomes in the stratum corneum. The hair does not have specific microscopic changes.

Differential Diagnosis

The hair abnormalities in hidrotic ectodermal dysplasia distinguish it from pachyonychia congenita, which has similar hair findings. A hidrotic ectodermal dysplasia-like phenotype plus deafness has been reported in a patient with a *GJB2* mutation.

Treatment

The National Foundation for Ectodermal Dysplasias can provide support to affected individuals and families. Ablation of the nail matrix is occasionally necessary for pain relief, and patients with substantial alopecia may choose to use hairpieces. Management of hyperkeratotic palms and soles is difficult; similar strategies to those used for the palmoplantar keratodermas, e.g. α-hydroxy acids, urea, soaking and paring, can be employed.

WITKOP TOOTH AND NAIL SYNDROME

Synonyms: ■ Tooth and nail syndrome ■ Witkop syndrome ■ Hypodontia with nail dysgenesis

First described in 1965, this autosomal dominant disorder is probably more common than suggested by the relatively small number of reports in the literature[137]. Affected individuals have small, thin, brittle nail plates, and koilonychia may be evident at birth. The toenails are usually more prominently involved than the fingernails, and nail abnormalities tend to improve with age. Thin, fine scalp hair is an occasional feature. The primary teeth may be normal or small and (in some patients) peg-shaped (Fig. 63.18). There is usually partially or totally absent secondary dentition with prolonged retention of primary teeth.

A mutation in the *MSX1* (muscle segment homeobox 1) gene, which is expressed in developing teeth and nail beds in mice, has been identified in a family with Witkop tooth and nail syndrome[138]. Mutations in *MSX1* have also been described in families with isolated tooth agenesis or non-syndromic cleft lip and/or palate. MSX1 is a transcription factor that has roles in the development of teeth and presumably nails. Fried tooth and nail syndrome represents a similar condition with autosomal recessive inheritance.

ANKYLOBLEPHARON–ECTODERMAL DYSPLASIA–CLEFTING SYNDROME

Synonyms: ■ Hay–Wells syndrome ■ Rapp–Hodgkin syndrome

This autosomal dominant ectodermal dysplasia, first described in 1976[139], has been reported in ethnically and geographically distinct individuals and families[140].

Pathogenesis

The ankyloblepharon–ectodermal dysplasia–clefting (AEC) syndrome is caused by mutations in the sterile alpha motif (SAM) region of the *p63* gene[141]. p63, a transcription factor, is expressed within basal keratinocytes of the skin, which have a high proliferative capacity that is lost in differentiated keratinocytes. The p63 protein has multiple isotypes, with the protein domain present in only some forms. This helps to explain the phenotypic differences between AEC syndrome and ectodermal dysplasia–ectrodactyly–clefting (EEC) syndrome (see Table 63.11 and below), which is due to mutations within the DNA-binding domain of *p63*[141,142].

Clinical Features

This disorder is evident at birth. Up to 90% of affected infants present with erythroderma, peeling skin or erosions, which can result in life-threatening infectious complications (Fig. 63.19A). The scalp is almost always involved (Fig. 63. 19B), and a chronic, erosive scalp dermatitis is common. Patients often develop abnormal granulation tissue and recurrent bacterial infections of the skin. Progressive reticulated hyperpigmentation frequently appears in intertriginous areas, and hypopigmentation of the scalp and face may be seen in children with darkly pigmented skin.

Cribriform and stellate scarring tends to occur in a shawl-like distribution on the shoulders and upper trunk[143]. Patchy alopecia on the scalp is typical and the hairs are wiry, coarse and light-colored; body hair is decreased or absent. Some degree of nail dystrophy is usually evident, with findings ranging from hyperconvex, thickened nail plates to anonychia. Patients may have decreased sweating and heat intolerance[143,144].

Congenital strands of tissue between the eyelids (ankyloblepharon adnatum filiforme) are observed in approximately three-quarters of affected individuals (Fig. 63.19C). These may lyse spontaneously, even prior to birth, or require surgical correction. The lacrimal ducts may be atretic. Approximately 80% of patients with AEC syndrome are born with a cleft palate with or without a cleft lip. Malformed external ears

Fig. 63.19 Ankyloblepharon–ectodermal dysplasia–clefting syndrome. and recurrent otitis media with secondary conductive hearing loss are common[145]. Dental abnormalities include hypodontia and misshapen (e.g. conical) teeth, and many patients have maxillary hypoplasia.

Gastroesophageal reflux affects the majority of AEC patients, while one-quarter of affected children fail to thrive and require gastrostomy placement[146]. Supernumerary nipples, ectopic breast tissue and hypospadias have been described[147]. Limb abnormalities are more common in AEC syndrome than once thought[143,144,148]; these malformations, which are typically less severe than the defects seen in EEC syndrome (see below), can include syndactyly (partial or complete), camptodactyly, brachydactyly and even ectrodactyly (Fig. 63.19D)[147].

Pathology

Hair shaft abnormalities such as pili torti and pili trianguli et canaliculi may be observed. Histopathologic changes are nonspecific and often include mild epidermal atrophy and dermal melanophages[149].

Differential Diagnosis

Rapp–Hodgkin syndrome, once considered to be a distinct entity, is now thought to fall within the AEC spectrum. Affected individuals have heterozygous mutations in the SAM domain of *p63* and clinical findings (including maxillary hypoplasia, cleft palate ± lip, nail dystrophy, and abnormalities of the teeth and hair) that overlap with those of AEC syndrome but do *not* include ankyloblepharon[150]. The clinical features of *c*urly *h*air–*a*nkyloblepharon–*n*ail *d*ysplasia *s*yndrome (CHANDS) also overlap with those of AEC syndrome, but the molecular basis of CHANDS has not yet been determined. The peeling erythroderma of neonates with AEC syndrome can lead to a misdiagnosis of epidermolysis bullosa or congenital ichthyosis.

Treatment

Treatment should be individualized. Surgical repair of oral clefting is usually necessary. Treatment for the erosive scalp dermatitis should be gentle and non-occlusive, with surveillance for and treatment of secondary infections. Debridement and grafting should be avoided as they typically fail or lead to worsening of erosions. Ulceration and granulation tissue may be very difficult to treat, and healing of erosions tends to be slow.

ECTODERMAL DYSPLASIA–ECTRODACTYLY–CLEFTING SYNDROME

Synonym: ▪ Split hand–split foot–ectodermal dysplasia–clefting syndrome

Described by Cockayne in 1936, this disorder occurs in all ethnic groups and has been reported worldwide[151].

Pathogenesis

Ectodermal dysplasia–ectrodactyly–clefting (EEC) syndrome is an autosomal dominant disorder caused by mutations in the *p63* gene[152]. These mutations disrupt the DNA-binding ability of the p63 transcription factor, which is expressed in proliferating epidermal basal cells. *p63* mutations also occur in several related autosomal dominant disorders, including non-syndromic split hand/foot malformation (minority of affected families), limb–mammary syndrome and ADULT (*a*cro-*d*ermato-*u*ngual-*l*acrimal-*t*ooth) syndrome, as well as in AEC syndrome (see Table 63.11 and above). Patients with EEC syndrome typically have missense mutations within the DNA-binding domain that differ from those seen in the other disorders[153]. Molecular testing for *p63* mutations is commercially available.

Clinical Features

The ectodermal changes in this highly variable condition may be quite mild[154]. The scalp hair is usually light in color and coarse. It may be sparse and grow slowly. The secondary sexual hair may also be affected. Scalp folliculitis and dermatitis are rare[155,156]. Approximately 80% of affected individuals have transverse ridging, pitting and slow growth of the nail plates. Xerotic skin and palmoplantar hyperkeratosis can occur, and sweating is usually normal.

Clefting of the palate/lip occurs in approximately 50% of affected individuals, and additional oral abnormalities include enamel hypoplasia, hypodontia and premature loss of secondary teeth. Lacrimal duct defects leading to blepharitis and dacryocystitis are frequently present. Secondary conductive hearing loss is also common.

Ectrodactyly (more specifically referred to as a split-hand/foot malformation) due to failure of normal development of the central digits represents a defining feature of EEC syndrome (Fig. 63.20). The ectrodactyly is frequently asymmetric, usually with more severe involvement of the feet than the hands. Intrafamilial variability is marked. Genitourinary abnormalities are an under-appreciated manifestation of EEC syndrome; renal and urogenital malformations (often resulting in hydronephrosis) affect more than one-third of patients.

Pathology

Histologic features are neither diagnostic nor specific.

Differential Diagnosis

The presence of split-hand/foot malformations and the absence of ankyloblepharon or cutaneous erosions help to distinguish EEC syndrome from AEC syndrome. The findings that differentiate limb–mammary syndrome and ADULT syndrome from EEC are presented in Table 63.11. Other ectodermal dysplasias that feature digital abnormalities include ectodermal dysplasia–ectrodactyly–macular dystrophy (EEM) syndrome, cleft lip/palate ectodermal dysplasia, oculodentodigital dysplasia and ulnar–mammary syndrome (see Tables 63.12 and 64.6). Although Goltz syndrome (focal dermal hypoplasia) can present with split-hand/foot and other digital malformations, nail dystrophy, sparse hair, dental anomalies and (occasionally) cleft lip/palate, it is easily recognized based on the highly characteristic skin findings as well as ocular and additional skeletal (e.g. osteopathia striata) defects (see Ch. 62).

Treatment

As for the other ectodermal dysplasias with oral clefting and lacrimal abnormalities, management involves a multidisciplinary approach. Limb defects may or may not be ameliorated by surgical interventions. All affected individuals should be screened with a renal ultrasound.

Fig. 63.20 Ectodermal dysplasia–ectrodactyly–clefting syndrome. Note the characteristic split-hand/foot deformities in three children.

Developmental Anomalies 64

Richard Antaya and Julie V Schaffer

Chapter Contents

The midline lesion 993
Aplasia cutis congenita 1000
Other developmental anomalies 1004

Key features

- The human neural tube is thought to close in an intermittent, multisite pattern, and neural tube defects that present as midline cutaneous lesions (e.g. cephaloceles, heterotopic brain tissue, rudimentary meningoceles) typically occur at the junction between two closure sites
- Midline lesions of the nose and scalp have a high likelihood of representing developmental defects with a potential intracranial connection, and an evaluation with CT or MRI prior to surgical intervention is critical
- The presence of a "hair collar" surrounding a lesion on the scalp is a sign of ectopic neural tissue or membranous aplasia cutis; the latter is thought to represent a forme fruste of a neural tube defect
- Cutaneous lesions overlying the spinal axis can serve as a marker for spinal dysraphism, and their presence is often an indication for radiologic evaluation
- Aplasia cutis congenita, a physical finding reflecting a disruption of intrauterine skin development, can be approached clinically based on the morphology and distribution of lesions as well as the presence or absence of associated abnormalities
- A number of other developmental anomalies affect the skin; although they usually represent isolated defects, it is important to be aware of potential associated conditions

INTRODUCTION

Developmental anomalies are a diverse group of congenital disorders that result from faulty morphogenesis. They include both *malformations*, defined as structural defects arising due to errors in embryologic development, and *disruptions*, which occur when a structure programmed to develop normally is damaged before it is fully formed. A classic example of the former is incomplete closure of the neural tube resulting in an encephalocele, while the latter process is illustrated by the anomalies associated with varicella embryopathy. Although developmental anomalies that affect the skin are often recognized at birth or during infancy, occasionally diagnosis is delayed until later in life. The cutaneous abnormalities range in severity from isolated, minor physical findings (e.g. rudimentary supernumerary digits) to deforming, potentially life-threatening defects (e.g. deep, irregular scalp aplasia cutis congenita in Adams–Oliver syndrome). Furthermore, some skin lesions that themselves appear to be innocuous may serve as important clues to the presence of a multiple congenital anomaly syndrome or, particularly when involving the midline, the existence of a serious defect of the underlying tissues. Such associations reflect the complex interactions between various ectodermal and mesodermal elements that occur during the intricate processes of morphogenesis and differentiation.

This chapter begins with an overview of the midline lesion and its relationship to closure of the neural tube. A discussion of specific issues pertaining to midline lesions of the nose, scalp and spine follows, including a review of the different types of anomalies that can present in these sites. An overview of aplasia cutis congenita is followed by presentation of a clinical approach based on the morphology and distribution of lesions and the presence or absence of associated abnormalities. Finally, a variety of non-midline developmental anomalies are discussed, including lip pits, accessory tragi, supernumerary nipples, skin dimples, malformations of the dermatoglyphs, rudimentary supernumerary digits, and the amniotic band syndrome. Some cysts that represent developmental anomalies (e.g. branchial cleft cyst, thyroglossal cyst) are covered in Chapter 110.

THE MIDLINE LESION

A number of critical events occur during the third to fifth weeks of embryologic development (see Ch. 2). These include formation of the neural tube, separation of neuroectoderm from surface ectoderm, and interposition of mesodermal elements. Inherent in such a complicated process is the potential for error, which spans a spectrum from obvious, fulminant neural tube defects to subtle cutaneous anomalies. However, the latter may represent a sign of a significant underlying malformation.

Classically, closure of the human neural tube was thought to be a continuous process, beginning at a single focus in the cervical region and progressing bidirectionally in a "zipper-like" fashion to culminate in the closure of the anterior and subsequently posterior neuropores. However, evidence suggests that in humans as well as other mammals, the cranial segment of the neural tube closes in an intermittent or multisite pattern. Four distinct initiation sites of neural tube closure have been identified in the mouse, and a similar pattern of closure has been proposed for humans, with an additional caudal site (Fig. 64.1)[1].

In support of the multisite closure model, major neural tube defects (e.g. partial anencephaly, encephaloceles, myelomeningoceles) have been observed to cluster in discrete regions, either entirely within one closure site or at the junction of two sites[1]. Individuals with two independent cranial neural tube defects have also been described. The multisite model is of particular importance in understanding the etiology of midline cutaneous lesions. For example, the root of the nose (fronto-ethmoidal region) and the vertex of the skull – frequent locations of cephaloceles as well as more subtle neural tube defects such as heterotopic brain tissue (e.g. nasal gliomas) and rudimentary meningoceles – both correspond to the junction of two closure sites (see Fig. 64.1). Interestingly, neural tube closure in the posterior cranial area is thought to occur via a membrane rather than a midline fusion of folds, and the appearance of this site during embryologic development in animals resembles that of membranous aplasia cutis in human neonates[2]. Lastly, it has been suggested that specific genes may control individual closure sites, explaining repetitive events within families.

Midline Lesions of the Head and Neck

The pathogenesis, differential diagnosis and management of midline lesions of the nose (Fig. 64.2) and scalp are discussed below, followed by a review of the individual developmental anomalies that may present with a midline lesion on the head or neck. Midline cysts of this region (e.g. thyroglossal duct cysts, bronchogenic cysts) are discussed in detail in Chapter 110.

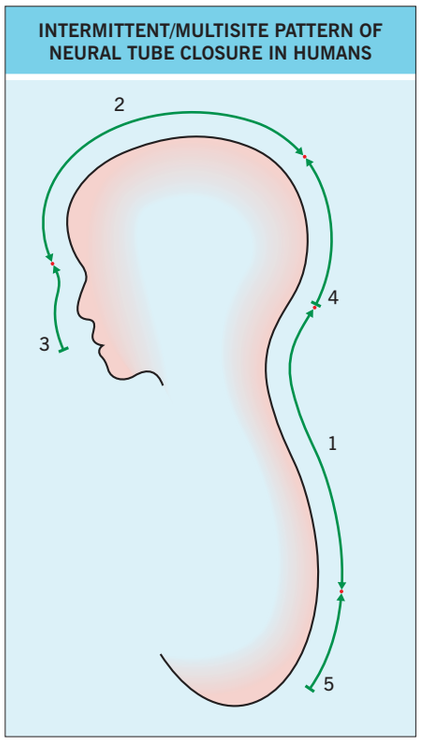

Fig. 64.1 Intermittent/multisite pattern of neural tube closure in humans. The five separate initiation sites are labeled (in chronological order, 1–5), the direction of neural tube closure is indicated by the arrows, and the junctions (where defects tend to occur) designated with dots. The 2–3 junction corresponds to the location of frontoethmoidal neural tube defects, the 2–4 junction to parietal defects, and the 1–4 junction to occipital defects. Closure in region 4 is thought to occur via membranous growth, proceeding in a superior direction; incomplete closure at this site could therefore result in a membranous defect at the 2–4 junction (i.e. the vertex).

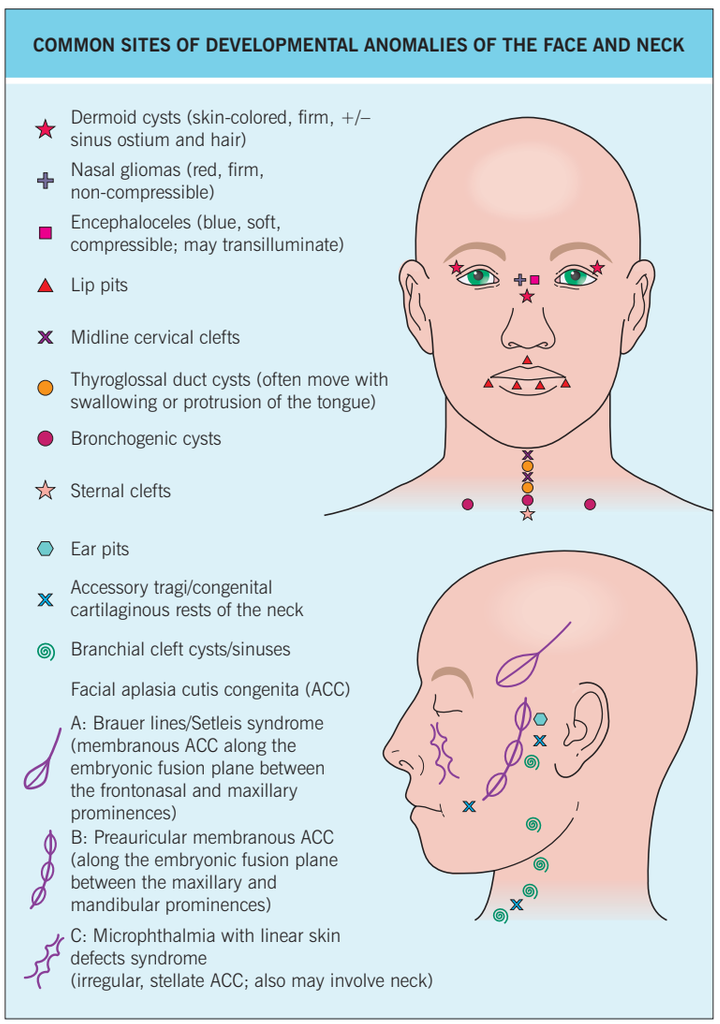

Fig. 64.2 Common sites of developmental anomalies of the face and neck.

Midline nasal lesions

Although most physicians recognize that a midline cutaneous lesion over the spine may be a marker of an underlying defect, the potential intracranial connection of a midline nasal mass or pit is less widely appreciated[3]. Dermoid cysts, dermal sinuses, cephaloceles and heterotopic brain tissue (nasal gliomas) resulting from faulty embryologic development of the frontobasal skull and/or adjacent ectodermal/neuroectodermal tissues all may present as congenital nasal lesions (Table 64.1). As a group, these midline nasal masses occur in only 2–5 per 100 000 live births. They are often misdiagnosed as more familiar entities such as epidermoid cysts and infantile hemangiomas, and patients may present with a history of recurrent cutaneous infections or meningitis.

The various congenital midline nasal masses have similar developmental origins. As the bones of the skull form during the second month of gestation, diverticula of dura mater project: (1) inferiorly into the prenasal space that extends from the base of the skull to the nasal tip, deep to the nasal bone and skin but superficial to the nasal cartilage; and (2) anteriorly through the nasofrontal fontanelle into the glabellar area. These diverticula may make connections with the overlying dermis, but usually they regress completely, with subsequent bony fusion to form the base of the skull and the cribriform plate. However, if the dura mater does not separate, an ectodermal residue with or without a patent intracranial connection can persist; furthermore, if faulty neural tube closure results in a bony defect, there may be herniation of brain tissue. Such ectopic elements can occur either within the prenasal space (nasoethmoidal, "intranasal") or superiorly at the glabella (nasofrontal, "extranasal")[4]. Depending on the contents of the lesion (e.g. cutaneous versus neural tissue, cyst versus tract only) and the patency of the intracranial connection, a dermoid cyst, dermal sinus, cephalocele or nasal glioma results (see below).

It is important to recognize that many of these midline nasal lesions have the potential for intracranial communication, and, consequently, present a risk for the development of serious CNS infections (e.g. meningoencephalitis, a frontal lobe abscess). In addition, recurrent inflammation and progressive expansion of the mass may result in bony atrophy and nasal distortion. Early and complete surgical excision

THE DIFFERENTIAL DIAGNOSIS OF NASAL MASSES PRESENTING AT BIRTH OR DURING INFANCY

DEVELOPMENTAL DEFECTS
• Dermoid cyst*,†
• Cephalocele (encephalocele > meningocele)*
• Nasal glioma*
• Lymphatic malformation
• Nasolacrimal duct cyst
OTHER CYSTS
• Epidermoid cyst
• Pilomatricoma
• Ethmoid mucocele
BENIGN NEOPLASMS AND HAMARTOMAS
• Infantile hemangioma
• Hemangiopericytoma
• Neurofibroma
• Melanotic neuroectodermal tumor of infancy
• Hamartomas: chondromesenchymal, chondroid, lipomatous or angiomatous
• Teratoma‡
MALIGNANT NEOPLASMS
• Rhabdomyosarcoma
• Fibrosarcoma
• Osteosarcoma
• Neuroblastoma

‡May also be malignant.

Table 64.1 The differential diagnosis of nasal masses presenting at birth or during infancy.

with repair of associated bony and dural defects is imperative, and this often requires a multidisciplinary approach. In order to prevent ascending infections, biopsy, needle aspiration or other preoperative manipulations should be avoided. A thorough radiologic evaluation prior to surgery is mandatory. While CT is the most accurate method in defining bony defects of the skull, false-positive studies are common, particularly in young children undergoing the process of bone maturation. MRI is superior in demonstrating intracranial masses and other soft tissue changes, and images in multiple planes may aid in planning surgical approaches[5]. In some instances, a combination of CT and MRI findings may be required to adequately complete the preoperative evaluation. In addition, surgical exploration is necessary to definitively exclude the presence of an intracranial connection, as small fibrous tracts may not be detectable with imaging studies.

Midline lesions of the scalp

Subcutaneous nodules of the scalp are common, and in adults they are usually acquired lesions, such as epidermoid and trichilemmal cysts. However, midline scalp lesions that are noted at birth or in early childhood have a high likelihood of representing developmental defects, such as dermoid cysts, cephaloceles, heterotopic brain or meningeal tissue, and aplasia cutis congenita. In one series of 70 children presenting with a solitary, non-traumatic scalp nodule[6], 61% of the lesions were dermoid cysts and 4% cephaloceles. More importantly, 37% of the lesions were found to extend intracranially to the dura or brain.

In the evaluation of a patient with a subcutaneous nodule on the scalp, there are a number of clinical clues that heighten suspicion of a developmental anomaly with potential intracranial extension[7]. These include:

- a patient who is an infant or child
- a lesion first noted at birth or during early childhood
- a family history of neural tube defects
- a history of meningitis
- the presence of neurologic signs or symptoms
- location of the lesion along the midline or over the suture lines of the scalp
- lesions that pulsate, fluctuate in size with crying or straining, transilluminate, or have a central pore (the latter particularly in children, in whom epidermoid cysts are uncommon)
- an overlying capillary malformation (port-wine stain)
- a positive hair collar sign (see below).

A congenital midline lesion, or a scalp nodule with other concerning features, requires a thorough evaluation prior to surgical excision or biopsy. The work-up includes CT or MRI to help determine whether an intracranial connection is present. If a bony defect is detected by CT, a follow-up MRI may be indicated to better evaluate whether there is extension of soft tissue transcranially. A neurosurgical referral is indicated if imaging studies are positive, and, as small communications may be missed, complete surgical removal may be prudent even if they are negative[8].

The *hair collar sign* consists of a ring of long, dark, coarse hair surrounding a congenital scalp nodule. The presence of a hair collar is a relatively specific marker for ectopic neural tissue[8,9]. Hair collars are also seen in membranous aplasia cutis (Figs 64.3 & 64.4), a disorder thought to represent a forme fruste of a neural tube defect (i.e. without the presence of ectopic neural tissue)[2]. Drolet et al.[8] hypothesized that cerebral herniation produces aberrant shearing forces during the formation of hair follicles early in development, causing them to point outward from the defect. The proximity of neuroectoderm expressing neural adhesion molecules may also alter normal epidermal–dermal interactions, thereby inducing the development of large, abnormal follicles[2]. These speculations correlate with the histologic finding of numerous horizontally oriented, hypertrophic follicles emerging from the edge of scalp lesions to form the hair collar[9,10]. The differential diagnosis and evaluation of a positive hair collar sign is presented in Figure 64.5.

Other developmental anomalies of the scalp

Sinus pericranii is a rare disorder characterized by a congenital (or, occasionally, acquired) epicranial venous malformation of the scalp that communicates with an intracranial dural sinus through dilated diploic cranial veins[11]. The lesion is usually located near the midline, especially in the frontal region. Most are asymptomatic and appear as a compressible, fluctuant mass that varies in size with changes in intracranial pressure (Fig. 64.6). The differential diagnosis includes a simple venous or arteriovenous malformation, meningocele or encephalocele.

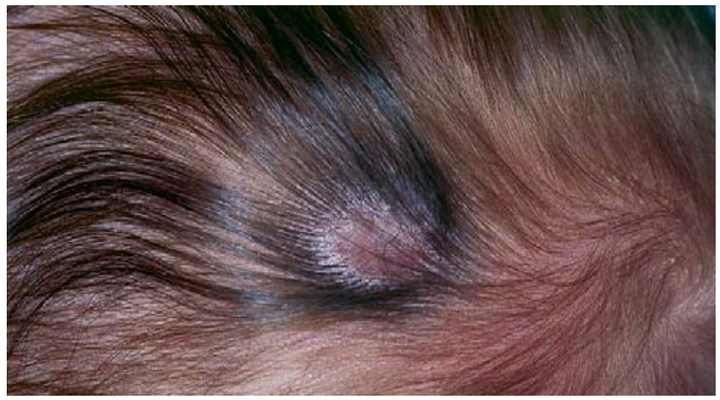

Fig. 64.3 Hair collar sign. Membranous aplasia cutis congenita with a hair collar and an associated capillary malformation. *Courtesy, Kalman Watsky, MD.*

Fig. 64.4 Hair collar sign. Membranous aplasia cutis congenita with a bullous appearance and a surrounding hair collar.

Nevus psiloliparus, a rare scalp anomaly characterized by a variable degree of alopecia and an excessive amount of adipose tissue, is the hallmark of encephalocraniocutaneous lipomatosis (see Ch. 62)[12]. The latter disorder also features papules and nodules, which represent fibromas and fibrolipomas, in a unilateral distribution on the face (especially the eyelids) and scalp; extracutaneous findings include ipsilateral ocular (usually choristomas) and intracranial abnormalities. Nevus psiloliparus presents as a skin-colored, round to oval, smooth, hairless patch or soft plaque located unilaterally on the parietal or frontoparietal scalp.

Dermoid cysts

Dermoid cysts result from sequestration of ectodermal tissue along embryonic fusion planes during development. They are a separate entity from benign cystic teratomas, neoplasms that are also referred to as dermoids. Although dermoid cysts are congenital defects and may be recognized at birth, these lesions often escape notice until they become enlarged, inflamed or infected. This typically occurs by early childhood, but diagnosis may be delayed until as late as the sixth decade of life. Dermoid cysts present as firm, non-compressible, non-pulsatile subcutaneous nodules that often reach a size of 1–4 cm in diameter. The lesions usually do not transilluminate. They are most commonly located around the eyes, particularly the lateral eyebrow (Fig. 64.7), but may also be found on the nose, scalp (often over the anterior fontanelle or the midline occiput), neck, sternum, sacrum and scrotum.

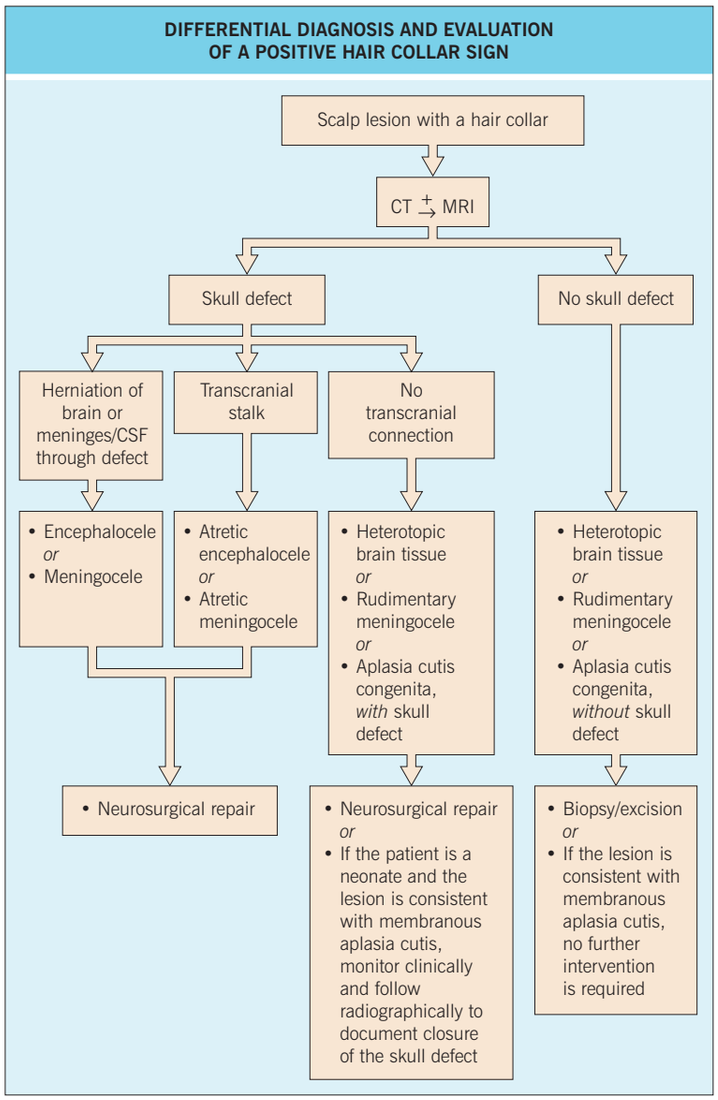

Fig. 64.5 Differential diagnosis and evaluation of a positive hair collar sign. In general, CT is the most accurate method of detecting skull defects. However, if a bony defect is detected by CT, a follow-up evaluation by MRI may be indicated to better determine whether there is extension of soft tissue transcranially.

Fig. 64.6 Sinus pericranii. This venous malformation involving the midline forehead and communicating with an intracranial dermal sinus was evident at birth. Fluctuations in fullness occurred with crying. *Courtesy, Susan Psaila, MD.*

Fig. 64.7 Dermoid cyst. This dermoid cyst presented in an infant as a firm subcutaneous nodule superior to the lateral left eyebrow. *Courtesy, Kalman Watsky, MD.*

Dermoid cysts on the nose or midline scalp have a much higher likelihood of intracranial extension than those in a periocular location[13]. Nasal lesions account for <10% of cervicofacial dermoids. They can occur anywhere from the glabella to the tip of the nose (see above, Midline nasal lesions), and they may result in a widened nasal bridge. The presence of a sinus ostium, which may be heralded by protruding hairs or a sebaceous discharge, increases the risk of intracranial involvement of a nasal dermoid to almost 50%, versus approximately 25% overall[3]. A dermal sinus tract without an associated subcutaneous mass sometimes connects with an intracranial dermoid cyst; this is seen most often on the midline occipital scalp, where especially long hairs may mark the sinus ostium[7]. In addition to infectious complications, a chemical meningitis or even hydrocephalus due to release of keratinous and sebaceous material into the cerebrospinal fluid (CSF) can occur with intracranial dermoid cysts. Lastly, dermoid cysts and dermal sinuses overlying the spine may be associated with occult dysraphism (see below), and, if a tract connects with the subarachnoid space, an increased risk of meningitis.

Histologically, dermoid cysts are lined by keratinizing stratified squamous epithelium and contain mature adnexal structures (see Ch. 110). Malignant degeneration in adulthood is extremely rare. Treatment is by excision, and preoperative imaging studies are required for lesions on the nose, midline scalp or posterior axis in order to exclude a connection to the CNS.

Cephaloceles

Cephalocele is a general term for congenital herniation of intracranial structures through a defect in the skull. *Cranial meningoceles* are herniations in which the sac contains meninges and CSF, while *encephaloceles* contain both meninges and brain (Fig. 64.8). Therefore, by definition, all cephaloceles have an intracranial connection. These lesions result from faulty closure of the cephalic portion of the neural tube during development, and they are much less common than their caudal counterparts (e.g. myelomeningoceles). Cephaloceles occur in approximately 1–3 per 10 000 live births, with a higher incidence in those with a family history of neural tube defects and an approximately 5% risk of neural tube defects in subsequent siblings. They are usually midline or paramedian, occurring most frequently at the occiput or vertex (75%) (see Fig. 64.1), followed by extranasal (e.g. glabella or medial orbit; 15%) and intranasal or pharyngeal (10%) locations[4].

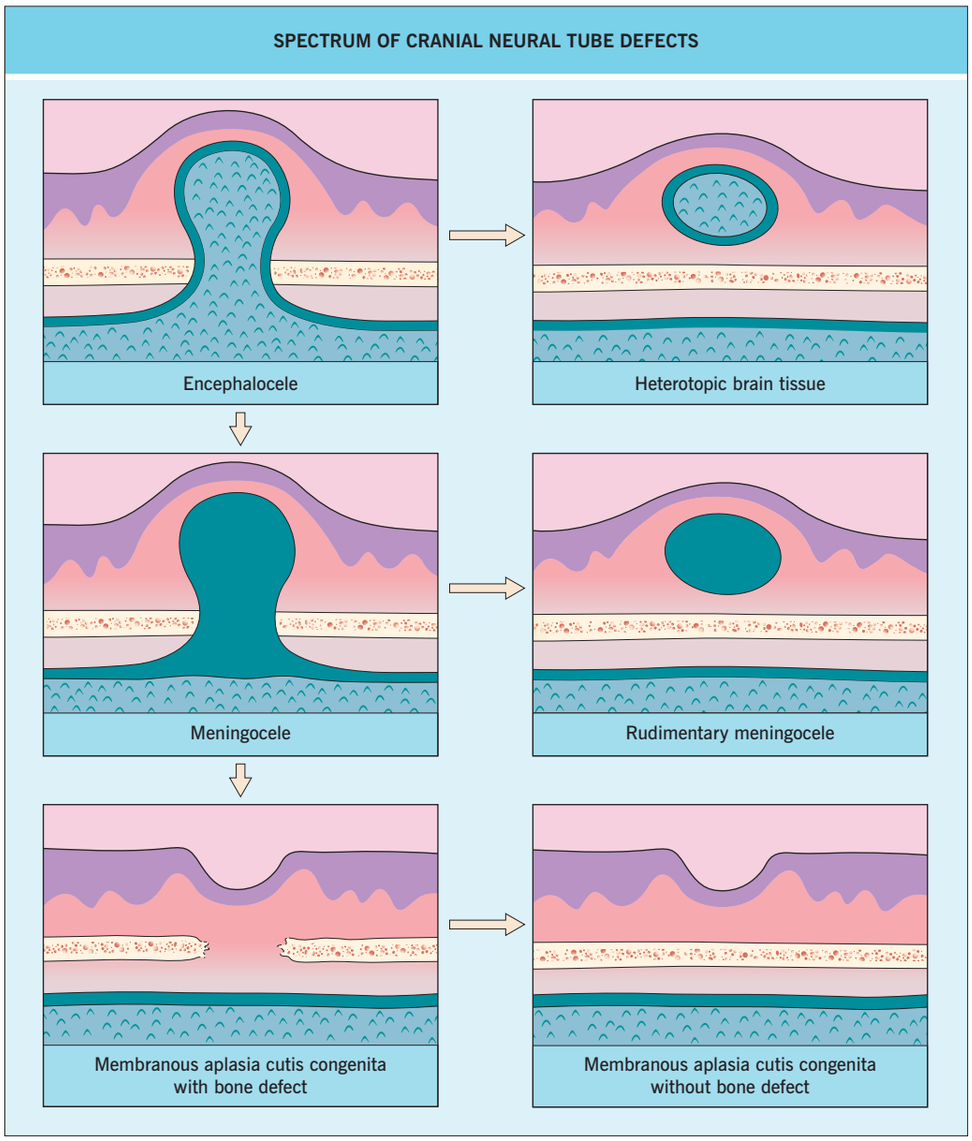

Fig. 64.8 Spectrum of cranial neural tube defects.

Encephaloceles are generally noted early in life due to the resultant deformity. Occasionally, small frontal lesions are misdiagnosed as deep infantile hemangiomas, vascular malformations, hypertelorism or nasal polyps[3,4]; of note, the latter are almost never seen in children younger than 3 years of age.

Cephaloceles typically appear as a soft, compressible, pulsatile mass with a bluish color. They may be covered with either normal skin or a thin, glistening epithelial membrane. The size of cephaloceles varies tremendously, from 1 cm nodules to lesions containing nearly half of the brain, and the size does not necessarily correlate with the extent of the underlying bony defect. Clinical manifestations vary by location. For example, patients with intranasal cephaloceles often present with a broadened nasal bridge but no palpable mass, whereas lesions on the scalp may have an overlying capillary malformation and/or a surrounding hair collar (see above, Midline lesions of the scalp)[8]. Transillumination frequently indicates the presence of CSF; in addition, increased flow of CSF into lesions with crying, the Valsalva maneuver or compression of the jugular veins (Furstenberg test) may result in transient expansion. Leaks of CSF can occur (e.g. CSF rhinorrhea), and patients may have a history of meningitis. Nasal cephaloceles may develop in conjunction with facial clefts and other midline defects, while encephaloceles in particular are often associated with neurologic abnormalities.

On histologic examination, encephaloceles show mature neuroglial tissue embedded in varying amounts of fibrous stroma. Heterotopic brain tissue (see Fig. 64.8) demonstrates similar features, and these lesions cannot be reliably distinguished histologically. When a patient is suspected of having a cephalocele, imaging studies and subsequent neurosurgical repair should be performed as soon as possible.

Nasal gliomas

Synonyms: ■ Nasal cerebral heterotopia ■ Nasal heterotopic brain tissue

Nasal gliomas are masses of heterotopic brain tissue that are located extranasally (e.g. at the nasal root or glabella; 60%), intranasally (30%) or both (10%)[14]. Of note, the nasal glioma, a developmental anomaly with no malignant potential, is an entirely separate entity from the similarly named glioma, a malignant brain tumor. Nasal gliomas result when herniated brain tissue (i.e. an encephalocele) is sequestered extracranially by the bony fusion that forms the base of the skull during development (see Fig. 64.8; see above, Midline nasal lesions). Although a vestigial fibrous stalk connecting with the intracranial space persists in 15–25% of cases[14], unlike encephaloceles, there is no communication with the intracranial leptomeninges or the CSF of the subarachnoid space. Nasal gliomas are present at birth, accounting for <5% of congenital nasal midline masses[3,15], and they typically enlarge in proportion to the growth of the child. Diagnosis is occasionally delayed until adulthood.

An extranasal glioma typically presents as a firm, non-compressible, non-pulsatile, non-transilluminating mass at or just lateral to the nasal

Fig. 64.9 Nasal glioma. A mass was noted on prenatal ultrasound, and this reddish, slightly pedunculated, rubbery nodule was evident at birth. *Courtesy, Mary Chang, MD.*

root (see Fig. 64.9 and Fig. 115.21). The overlying skin is often red with prominent telangiectasias, which may result in misdiagnosis as an infantile hemangioma; however, nasal gliomas do not undergo the proliferative and involutional phases that characterize the latter lesions. Intranasal gliomas may manifest as a widened nasal bridge or a polypoid nodule within the nasal cavity, sometimes protruding from a nostril. They occasionally cause nasal obstruction resulting in respiratory distress, and lesions involving the nasopharynx may be associated with a cleft palate[16]. Excessive lacrimation may occur ipsilateral to nasal gliomas.

Histologically, nasal gliomas demonstrate strands of astrocytes, other glial cells and loosely textured intercellular glial substance interwoven with fibrous tissue. Neurons may or may not be present focally, and there are often prominent dilated blood vessels in the lesion and overlying skin. Immunoperoxidase staining for S100 protein and glial fibrillary acidic protein (GFAP) is positive. After imaging studies to determine whether an intracranial extension is present, nasal gliomas should be surgically excised.

Heterotopic brain tissue and rudimentary meningoceles

Synonyms: ▪ Rudimentary meningoceles – heterotopic meningeal tissue, sequestrated meningoceles, meningeal hamartomas

Heterotopic brain or meningeal tissue is thought to represent an encephalocele or meningocele that has lost its intracranial attachment (see Fig. 64.8). The term *rudimentary meningocele* is preferred for the latter to emphasize its developmental origin and the lack of associated brain tissue[8,17]. The bone underlying heterotopic brain tissue and rudimentary meningoceles is usually intact. However, the spectrum of cranial neural tube defects also includes intermediate forms in which a stalk that connects intracranially remains, but becomes fibrotic with some degree of luminal ablation; these entities are referred to as *atretic encephaloceles* and *atretic meningoceles*[8]. Heterotopic brain tissue may be located in the scalp, orbit, lip and oropharynx, as well as in the nasal area (see above, Nasal glioma); rudimentary meningoceles are usually found on the scalp or overlying the spine[10,17]. These are uncommon congenital anomalies that are diagnosed much less frequently than more fulminant neural tube defects such as encephaloceles.

Heterotopic brain tissue and rudimentary meningoceles typically present as a 1–4 cm solid or cystic subcutaneous nodule, often with a blue–red hue. Occasionally, rudimentary meningoceles have a bullous appearance and are clinically indistinguishable from membranous aplasia cutis[17]. Lesions are often located in the midline occipital or parietal scalp, where they can manifest with alopecia of the overlying skin and/or a surrounding hair collar. An overlying capillary malformation also may be present.

Histologic features of heterotopic brain tissue are as described for nasal glioma. Although classic findings such as cystic cavities lined by meningothelial cells are present in some cases of rudimentary meningocele, the histologic features are often subtle, with meningeal elements simulating the appearance of vascular or loose connective tissue. While signs such as the tendency of meningocytes to encircle collagen bundles and the presence of psammoma bodies may be helpful, immunohistochemical staining for epithelial membrane antigen (EMA) and vimentin are critical in establishing the diagnosis[17]. Because the presence or absence of an intracranial connection cannot be reliably determined by clinical examination, lesions suspected of representing heterotopic neural tissue should be evaluated with imaging studies prior to surgical excision.

Midline cervical clefts

A midline cervical cleft is a rare congenital anomaly resulting from incomplete fusion of the branchial arches in the ventral midline of the neck. Approximately 80 cases have been reported to date in the English-language literature, with a female-to-male ratio of 2 : 1[18]. Midline cervical clefts may be isolated or found in association with a spectrum of other defects, including midline clefts of the lower lip, tongue or mandible, and thyroglossal, branchial cleft or bronchogenic cysts.

Patients present at birth with a vertically oriented, linear cleft on the midline neck at any point between the inferior edge of the mandible and sternum. The lesion is covered with atrophic skin, which is often weeping in the neonatal period. Additional features may include a blind mucosal sinus tract originating from the inferior portion and a skin protuberance at the superior tip. A subcutaneous fibrous cord arising deep to the latter and extending upward to the chin may result in progressive cervical contracture and/or webbing of the neck with extension (pterygium colli medianum).

Histologically, midline cervical clefts consist of parakeratotic stratified squamous epithelium without normal adnexal structures. The subcutis often contains dense connective tissue, and fibrous cords may include bundles of skeletal muscle. In order to prevent progressive deformity, it is recommended that complete surgical excision and closure via multiple Z-plasties be performed within the first year of life. Vertical primary closure is avoided to reduce the risk of cicatricial contracture.

Sternal clefts and supraumbilical raphae

Sternal clefts are rare congenital malformations that result from defective embryologic fusion of paired mesodermal bands in the ventral midline. These lesions most frequently involve the superior sternum, but inferior clefts and a complete bifid sternum can also occur. The skin overlying sternal clefts may be atrophic (Fig. 64.10), scarred or ulcerated, and a dermal sinus tract is occasionally present. Approximately 40% of sternal clefts are associated with large cervicofacial hemangiomas, representing a presentation of the PHACE(S) syndrome (*p*osterior fossa malformations; *h*emangiomas; *a*rterial, *c*ardiac and *e*ye anomalies; *s*ternal cleft/supraumbilical raphe)[19]. Predominantly affecting female infants (female-to-male ratio: 9 : 1), this spectrum of malformations is thought to result from a developmental field defect that occurs between the eighth and tenth weeks of gestation. Of note, the sternal abnormality in PHACE(S) syndrome may be limited to cutaneous atrophy or a pit in the presternal area, with intact underlying bone[20]. For sternal clefts associated with a substantial bony defect, surgical repair can be performed to protect the mediastinal organs and improve respiration as well as cosmesis. A supraumbilical raphe is a midline abdominal defect that presents as a firm, scar-like, linear protuberance extending from the umbilicus cephalad for a few centimeters. Supraumbilical raphae often occur in association with sternal clefts, with or without other features of PHACE(S) syndrome.

Midline Lesions of the Spine

Spinal dysraphism refers to abnormal fusion of dorsal midline structures during embryologic development[21]. This term encompasses a wide variety of congenital spinal defects, ranging from myelomeningoceles

Fig. 64.10 Sternal cleft. Note the atrophic skin overlying the defect and prominent veins in the midline chest. Generalized desquamation is also evident in this 1-day-old post-term neonate. She did not develop an infantile hemangioma and had no cardiac defects or other features of PHACE(S) syndrome.

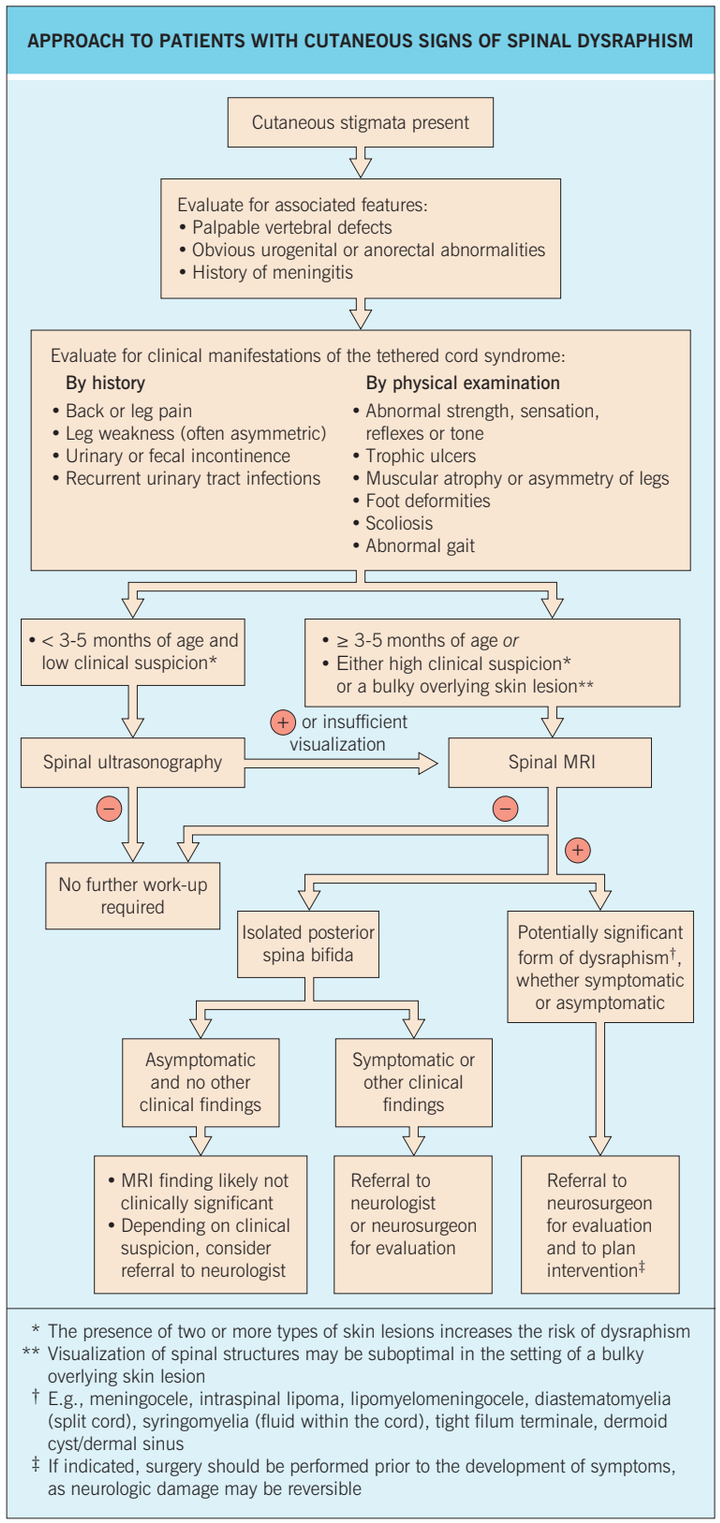

Fig. 64.11 Approach to patients with cutaneous signs of spinal dysraphism.

(protrusion of the spinal cord and meninges with no overlying skin) and other overt anomalies in which neural tissue is exposed (*open spinal dysraphism*) to less obvious, skin-covered malformations (*closed* or *"occult" spinal dysraphism*). The latter include diastematomyelia (a split in the spinal cord), meningoceles, intraspinal lipomas, lipomyelomeningoceles (protrusion of the cord extraspinally into an attached lipoma), tight or fatty filum terminale, dermoid cysts, dermal sinuses and isolated posterior spina bifida[22].

The degree of neurologic impairment associated with closed spinal dysraphism is variable. Any lesion that produces traction and/or pressure can cause progressive damage to the spinal cord, resulting in neurologic symptoms. Whereas isolated posterior spina bifida, an incidental radiographic finding in 15–25% of the general population, is not clinically significant, other forms of dysraphism may become symptomatic by childhood or adolescence. Some patients, however, do not present until adulthood. When diagnosis is delayed, many of the aforementioned malformations can result in the tethered cord syndrome, which occurs when the conus medullaris (normally at the adult position of L1–L2 by 3 months of age) is low-lying and/or immobile. This syndrome is characterized clinically by back pain, urinary incontinence, motor and sensory deficits of the lower extremities, and orthopedic deformities (Fig. 64.11). Occasionally, an acute onset of symptoms is precipitated by childbirth, heavy lifting or spinal trauma. Although neurosurgical intervention can halt progression, neurologic damage is often irreversible. Diagnosis and treatment prior to the development of symptoms is, therefore, critical.

Because the skin and the nervous system share an ectodermal origin, concurrent anomalies of these tissues are common. Midline cutaneous lesions thus serve as a valuable marker for spinal dysraphism, and, in the majority of patients, they are the finding that leads to the diagnosis. Approximately 80% of individuals with closed spinal dysraphism have paraspinal skin abnormalities (with more than one type of skin lesion in the majority of cases)[23,24], compared with <3% of all neonates[25]. Shallow coccygeal dimples and deep gluteal clefts occur in an additional 4% of infants; however, in contrast to dimples located superior to the gluteal cleft (Fig. 64.12), these are considered as normal variants rather than a sign of an underlying malformation[25–27]. Most of the cutaneous lesions associated with spinal dysraphism are located in the lumbosacral area, reflecting the relative rarity of neural tube defects in the cervicothoracic region[28].

Hypertrichosis is the cutaneous marker of spinal dysraphism most often evident at birth. Affected individuals may be born with a V-shaped lumbosacral patch of long, coarse or silky hair on the dorsal midline (Fig. 64.13) known as a "faun tail"[29]. Overall, however, lumbosacral lipomas are the skin lesions most commonly associated with spinal dysraphism[23]. An intraspinal lipoma or lipomyelomeningocele often represents a portion of a larger subcutaneous lipoma, typically presenting as a soft mass located above the gluteal cleft and extending asymmetrically into one buttock. A curved gluteal cleft is suggestive of such a lesion, but clinical findings may be subtle initially, becoming more noticeable with time.

Infantile hemangiomas and vascular malformations located on or near the dorsal midline may also be signs of dysraphism. Infantile hemangiomas associated with spinal anomalies typically span the midline (usually in the lumbosacral area), are superficial (sometimes

Fig. 64.12 Midline deep sacral dimple. The dimple was located above the gluteal cleft in association with a small tail. In contrast, a shallow dimple within the gluteal cleft is a common finding and not a sign of spinal dysraphism. *Courtesy, Seth J Orlow, MD, PhD.*

Fig. 64.13 Hypertrichosis associated with spinal dysraphism. A Circumscribed midline hypertrichosis overlying the lower thoracic spine in an adult with occult dysraphism. The patient periodically trims the hairs. **B** V-shaped patch of long, coarse hair on the mid back in a boy born with a large thoracic myelomeningocele. Severe scoliosis remains after multiple surgeries. *A, Courtesy, Jean L Bolognia, MD.*

with minimal growth beyond reticular erythema and telangiectasias), and tend to have a segmental pattern (Fig. 64.14; see Ch. 103)[30–32]. A patient with an isolated midline lumbosacral hemangioma >2.5 cm in diameter has an approximately 35% risk of having spinal dysraphism, which is higher if the hemangioma is larger, ulcerated or associated with additional cutaneous markers[32]. Several acronyms have been proposed for the constellation of regional extracutaneous anomalies that can occur in individuals with segmental hemangiomas of the lower body, and the most inclusive is ***LUMBAR*** *syndrome*: ***L***, *l*ower body/*l*umbosacral hemangioma and *l*ipomas or other cutaneous anomalies (e.g. "skin tags"); ***U***, *u*rogenital anomalies and *u*lceration; ***M***, *m*yelopathy (spinal dysraphism); ***B***, *b*ony deformities; ***A***, *a*norectal and *a*rterial anomalies; ***R***, *r*enal anomalies. Of note, a telangiectatic patch overlying a spinal defect may actually represent an early or "minimal growth" hemangioma (when found in a neonate or infant/young child, respectively) or the residua after involution of a hemangioma (when found in an older patient).

Vascular malformations are most often an indicator of dysraphism when they occur together with other midline cutaneous lesions (most notably lipomas). In Cobb syndrome (cutaneomeningospinal angiomatosis), capillary malformation- or angiokeratoma-like lesions found in a dermatomal distribution are contiguous with an arteriovenous malformation in the corresponding segment of the spinal cord, and neurologic manifestations of cord compression can develop (see Ch. 104). Lastly, the common occipital capillary stain ("stork bite"), a form of nevus simplex (salmon patch), is *not* a marker for a spinal defect. Lumbosacral capillary stains often have rhomboidal or triangular shapes ("butterfly-like") and are frequently associated with additional nevus simplex lesions of the head, neck and (occasionally) upper back. Many authors feel that regardless of spinal level, capillary stains alone are rarely a sign of dysraphism[26,28]. A prospective study of 3623 neonates found that 1 of the 25 individuals noted to have a sacral capillary stain in the absence of other lumbosacral skin lesions had a spinal abnormality revealed by imaging studies[33].

Cutaneous lesions of the spinal axis that should alert the clinician to the possibility of dysraphism are summarized in Table 64.2. In one study[27], 39% (22/56) of neonates with "high-risk" stigmata (e.g. hypertrichosis, subcutaneous masses, hemangiomas, tails, or dimples above the gluteal cleft) were found to have spinal dysraphism (see Figs 64.13 & 64.14). The presence of two or more skin lesions is a particularly strong sign; in another series, 61% (11/18) of such patients had spinal dysraphism, compared to 8% (3/36) of those with only one skin lesion[34].

High-risk cutaneous stigmata overlying the spine represent an indication for radiologic evaluation, and superficial removal for cosmetic reasons is contraindicated until an underlying abnormality is excluded. The most sensitive modality is MRI, which is the study of choice in patients ≥3–5 months of age. As the vertebrae are not yet completely ossified in infants <3–5 months of age, ultrasonography may serve as a rapid, relatively inexpensive screening tool, allowing sufficient visualization of the spinal cord and canal to exclude dysraphism in many unaffected patients. However, MRI is required preoperatively to better define any positive ultrasonographic findings and to confirm a negative study when visualization of spinal structures is suboptimal, which often occurs in the setting of bulky overlying skin lesions (e.g. lipomas, tags and hemangiomas)[35]. In infants found to have anomalies with the potential to cause traction and/or pressure on the spinal cord, neurosurgical intervention during infancy may be recommended. Figure 64.11 provides an algorithm for the approach to patients with cutaneous signs of spinal dysraphism.

APLASIA CUTIS CONGENITA

Synonyms: ■ Cutis aplasia ■ Congenital absence of skin ■ Congenital scars

Fig. 64.14 Multiple midline cutaneous stigmata overlying the sacral spine. This infant with a segmental distribution of infantile hemangiomas in the lumbosacral area, a dimple, a pseudotail and a deviated gluteal cleft had an underlying lipomeningomyelocele.

SKIN LESIONS OF THE SPINAL AXIS ASSOCIATED WITH DYSRAPHISM	
Lesion	**Features**
Hypertrichosis	A V-shaped patch of long, coarse or silky hair ("faun tail") (Fig. 64.13)
Lipomas	Soft subcutaneous mass, asymmetric buttocks, curved gluteal cleft (Fig. 64.14)
Dimples	Above the gluteal cleft or >2.5 cm from the anal verge in neonates (Figs 64.12 & 64.14); >0.5 cm in size or deep*
Dermal sinuses	Hair may be present at the ostium*
Acrochordons	May be associated with a dimple or dermal sinus
Pseudotails	Caudal protrusion due to prolonged vertebrae or hamartomatous elements, e.g. adipose tissue or cartilage (Fig. 64.14)
True tails	Persistent vestigial appendage with a central core of mature adipose tissue, muscle, blood vessels and nerves
	May be capable of spontaneous or reflex motion
Infantile hemangiomas	Superficial, usually segmental pattern (Fig. 64.14), often ulcerated
Telangiectasias	May represent an early, minimal/arrested growth or regressed infantile hemangioma
Capillary malformations (CM)	Typically found together with other skin lesions
	Cobb syndrome: CM- or angiokeratoma-like lesions in a dermatomal distribution associated with a spinal arteriovenous malformation
Aplasia cutis congenita (ACC)	Ulcer, scar, or atrophic skin
Connective tissue nevus	Typically found together with other skin lesions
Hypo/depigmentation	May represent a nevus depigmentosus (typically found together with other skin lesions) or the residua of ACC
Hyperpigmentation	Typically found together with other skin lesions
Congenital melanocytic nevi	Spinal dysraphism has been reported in patients with neurocutaneous melanosis
Subcutaneous masses	May represent meningoceles, lipomyelomeningoceles, teratomas, ependymomas or plexiform neurofibromas

*Due to a potential risk of meningitis, these lesions should not be probed.

Table 64.2 Skin lesions of the spinal axis associated with dysraphism. The presence of two or more types of lesions increases the risk of a spinal anomaly.

Fig. 64.15 Facial aplasia cutis congenita. Atrophic cutaneous defect extending from the lateral eyebrow to the anterior hairline in a patient with Setleis syndrome. Note the upward-slanting eyebrows and "leonine" facial appearance. *Courtesy, Seth Orlow, MD, PhD.*

Fig. 64.16 Preauricular skin defects. Multiple discrete, round, atrophic skin defects in an infant, extending from the scalp line toward the angle of the mouth in a strikingly linear arrangement (arrows). *Courtesy, Jean L Bolognia, MD.*

Aplasia cutis congenita (ACC) is a condition in which localized or widespread areas of skin are absent or scarred at birth. It may occur as an isolated defect, in association with other developmental anomalies, or as a feature of a variety of disorders (Tables 64.3 & 64.4). There is no single underlying cause of ACC, which simply represents a physical finding that reflects an abnormality in intrauterine skin development. The many possible etiologies include genetic factors, vascular compromise, trauma, teratogens and intrauterine infections[36].

As a result of its causal heterogeneity, the clinical appearance of ACC at birth is extremely variable, ranging from an erosion or deep ulceration to a scar (as a consequence of healing *in utero*) to a discrete ovoid defect covered by a membrane. The latter, referred to as *membranous aplasia cutis*, is the most common form. Occurring primarily on the scalp and often surrounded by a "hair collar" (see Figs 64.3 & 64.4; see above, Midline lesions of the scalp), such lesions may represent a forme fruste of a neural tube defect[2]. However, membranous aplasia cutis can also be seen along the embryonic fusion lines of the face (Table 64.4; Figs 64.2, 64.15 & 64.16)[37,38]. Membranous aplasia cutis typically presents at birth as a sharply marginated ("punched-out"), oval or round defect covered by a thin, translucent, glistening epithelial membrane. Lesions may contain serous fluid in the neonatal period, resulting in a bullous appearance (see Fig. 64.4). Eventually, they flatten and transform into an atrophic scar (Fig. 64.17A).

A second major type of ACC consists of stellate or angulated lesions, which are thought to result from vascular abnormalities and/or intrauterine ischemic events. Examples include irregular midline scalp defects in Adams–Oliver syndrome[39,39a] and extensive, symmetric lesions on

CLASSIFICATION SCHEME FOR APLASIA CUTIS CONGENITA (ACC)			
	Inheritance	**Features**	**Associated abnormalities**
Group 1: Scalp ACC without multiple anomalies	Sporadic > AD	Usually at the vertex Membranous Hair collar	**No associated abnormalities** **Isolated abnormalities** (most often associated with membranous ACC): cleft lip and/or palate, tracheoesophageal fistula, high myopia and cone-rod dysfunction, patent ductus arteriosus, intestinal lymphangiectasia, omphalocele, polycystic kidneys, double cervix and uterus, mental retardation, temporal triangular alopecia
	Often AD	Usually at the vertex Irregular and scar-like	
Group 2: Scalp ACC associated with Adams–Oliver syndrome	AD > AR	Midline scalp Often large, irregular lesions Skull defect Dilated scalp veins	**Adams–Oliver syndrome**: terminal transverse limb defects (e.g. reductions, syndactyly, nail dystrophy), cutis marmorata telangiectatica congenita, cardiac malformations, CNS abnormalities; caused by dominant mutations in the Rho GTPase activating protein 31 gene (*ARHGAP31*) or recessive mutations in the dedicator of cytokinesis 6 gene (*DOCK6*); both of these genes encode proteins with roles in organizing the actin cytoskeleton via regulation of Rho GTPases
Group 3: Scalp ACC associated with epidermal and organoid nevi (and, occasionally, large congenital melanocytic nevi)	Sporadic (may represent a form of twin spotting; see Ch. 55)	Scalp, often unilateral Membranous	**Epidermal nevus or nevus sebaceus**, usually in proximity to the ACC **Large congenital melanocytic nevus**: in a few reports* **Ipsilateral ophthalmologic abnormalities**: corneal opacities, scleral dermoids, eyelid colobomas, retinal dystrophy **CNS abnormalities**: psychomotor retardation, seizures
Group 4: ACC overlying embryologic malformations	Variable	Scalp, often with a hair collar if overlying a neural tube defect Lumbosacral Chest, abdomen	**Cranial malformations**: cephalocele, heterotopic brain or meningeal tissue, congenital midline porencephaly, holoprosencephaly, cranial stenosis, leptomeningeal vascular malformation, posterior fossa arteriovenous fistula **Spinal malformations**: occult dysraphism, myelomeningocele **Thoracic malformations**: sternal cleft **Abdominal malformations**: omphalocele, gastroschisis **Multiple malformations associated with generalized, lethal ACC ('systemic' ACC)**: corneal opacities, choanal atresia, hypoplastic lungs, absent greater omentum, intestinal malrotation & atresias, hepatosplenomegaly, skull defects, syndactyly, anonychia
Group 5: ACC associated with fetus papyraceus, placental infarcts or other ischemic events	Sporadic	Scalp, chest, flanks, axillae and/or extremities (see Fig. 64.18) Multiple, symmetric Stellate/angulated configuration	**Associated fetus papyraceus** due to second-trimester death of twin/triplet or fetal reduction of higher-order pregnancies **Placental infarction**, single umbilical artery **Duodenal, ileal and/or biliary atresias with intestinal infarction** Volkmann ischemic contracture of the forearm Intracranial hemorrhage/CNS abnormalities Amniotic bands, clubbed hands/feet, nail dystrophy
Group 6: ACC associated with EB	AD or AR, depending on EB type	Lower extremities ("Bart syndrome") or large areas of the trunk and extremities	**Simplex, junctional and dystrophic types of EB**: blistering of skin and/or mucous membranes, skin fragility, nail dystrophy **In more severe cases (most associated with junctional EB)**: pyloric atresia, ureteral stenosis, renal abnormalities, arthrogryposis, abnormal ears and nose, amniotic bands
Group 7: ACC localized to extremities without blistering	AD or AR	Pretibial areas, extensor forearms, dorsal hands and feet	**Radial dysplasia** (associated with ACC on the extensor forearm)
Group 8: ACC caused by specific teratogens, maternal conditions or intrauterine infections	Not inherited	Scalp with drugs Any site with congenital infections	**Methimazole (thiamazole), carbimazole**: imperforate anus, urachal malformations **Misoprostol** **Low-molecular-weight heparin** **Valproic acid** **Maternal antiphospholipid syndrome** **Intrauterine varicella, herpes simplex or rubella infection**: signs of these infections
Group 9: ACC associated with malformation syndromes	Variable	Variable	See Table 64.4 **Amniotic band sequence and disorganization syndrome** (see text)

*Referred to as "SCALP" syndrome (*s*ebaceous nevus, *C*NS malformations, *A*CC, *l*imbal dermoid, *p*igmented nevus).

Table 64.3 Classification scheme for aplasia cutis congenita (ACC). Bold text in column 4 signifies main topics, followed by details. AD, autosomal dominant; AR, autosomal recessive; CNS, central nervous system; EB, epidermolysis bullosa. *Adapted from Frieden IJ. J Am Acad Dermatol. 1986;14:646–60, with permission.*

the trunk and/or extremities associated with fetus papyraceus, placental infarction and other forms of vascular insufficiency (Fig. 64.18)[40]. These defects usually appear as ulcers of variable depth with a raw, hemorrhagic or granulating base (Fig. 64.17B,C).

Other patterns of ACC include a lack of skin overlying embryologic malformations, either obvious or occult, and large erosions with jagged borders on the extremities of neonates with epidermolysis bullosa. The latter likely result from the mechanical trauma of fetal movements in a setting of increased skin fragility. The morphology and distribution of the skin defects (see Fig. 64.18) as well as the presence or absence of associated abnormalities represent important clues to the etiology of ACC. Table 64.3 presents a classification scheme for ACC based on these features, and Table 64.4 describes several syndromes associated with ACC. However, because ACC is a physical finding that may result from *any* intrauterine event that disrupts skin development, not all cases can be neatly categorized. Unusual presentations of ACC range from an isolated defect on the ventral penis to an extreme form with absence of skin and subcutaneous tissue over >90% of the body surface area associated with extracutaneous anomalies ("systemic" ACC; see Table 64.3).

The scalp is the most common site for ACC, accounting for >85% of solitary lesions. The majority of cases of scalp ACC, whether membranous or irregular and scar-like, are located at or near the vertex, in proximity to the parietal hair whorl[41]. Approximately 25% of patients

SYNDROMES ASSOCIATED WITH APLASIA CUTIS CONGENITA (ACC, GROUP 9)			
	Inheritance	**Features of ACC**	**Other features**
		FACIAL ACC (SEE FIG. 64.2)	
Brauer lines & Setleis syndrome (bitemporal ACC, focal facial dermal dysplasia)	**Brauer lines:** AD, variable penetrance and expressivity **Setleis syndrome:** AR	Bilateral temples, from lateral eyebrow to anterior hairline* Round or oval, membranous Linear arrangement	**Brauer lines:** no additional abnormalities **Setleis syndrome**: *TWIST2* gene (encoding a transcription factor); abnormal eyelashes, upward-slanting eyebrows, "leonine" facies (Fig. 64.15)
Preauricular skin defects (focal facial dermal dysplasia)	?	Bilateral, from preauricular cheek to angle of mouth† Round or oval, membranous, often with a hair collar Linear arrangement (Fig. 64.16)	No additional abnormalities
Microphthalmia with linear skin defects syndrome (MIDAS syndrome	X-linked dominant	Mid-cheek to bridge of nose Also may occur on neck Stellate erosions that heal with reticulolinear scarring	*HCCS* gene (holocytochrome c synthase); microphthalmia, sclerocornea, agenesis of the corpus callosum, genital anomalies, short stature
		SCALP ACC	
Adams–Oliver syndrome (see Table 64.3, ACC group 2)			
Oculocerebrocutaneous syndrome (Delleman syndrome)	Sporadic or AD	Membranous on supra-auricular scalp (often crescentic shape) Also may occur on neck and lumbosacral area	Orbital cysts, microphthalmia, giant tectum-absent vermis, agenesis of the corpus callosum, facial appendages composed of skeletal muscle
Oculoectodermal syndrome	?AD	Membranous	Epibulbar dermoids, macrocephaly, truncal hyperpigmentation
Johanson–Blizzard syndrome	AR	Stellate or membranous	*UBRI* gene (ubiquitin-protein ligase); dwarfism, hypoplastic nasal alae, hypodontia/peg-like teeth, deafness, microcephaly, hypothyroidism, pancreatic insufficiency
Scalp–ear–nipple syndrome (Finlay–Marks syndrome)	AD	May heal with hypertrophic scarring	Nipple/breast hypo- or aplasia, abnormal ears and teeth, nail dystrophy, syndactyly, reduced apocrine secretion
Trisomy 13 (Patau syndrome)	Sporadic	Membranous Large defects	Holoprosencephaly, ocular abnormalities, deafness, cleft lip/palate, cardiac malformations, polydactyly, narrow and convex nails; early death
4p- (Wolf–Hirschhorn) syndrome	Sporadic	Midline	Microcephaly, ocular abnormalities, cleft lip/palate, preauricular pits and accessory tragi; often early death

*Along the embryonic fusion line between the frontonasal prominence and the maxillary prominence of the first branchial arch.
†Along the embryonic fusion line between the maxillary and mandibular prominences of the first branchial arch.

Table 64.4 Syndromes associated with aplasia cutis congenita (ACC, group 9). ACC also may be found in patients with Goltz syndrome (focal dermal hypoplasia), branchio-oculo-facial syndrome, and several types of ectodermal dysplasias, including the EEC syndrome (*e*ctrodactyly, *e*ctodermal dysplasia, *c*lefting), AEC syndrome (*a*nkyloblepharon, *e*ctodermal dysplasia, *c*left lip/palate) and tricho-odonto-onychial dysplasia. In addition, there have been reports of scalp ACC in patients with Pallister–Killian syndrome (tetrasomy 12p), Opitz syndrome, popliteal pterygium syndrome, Marshall syndrome, and hereditary sensory and motor neuropathy type I (www.ncbi.nlm.nih.gov/omim). AD, autosomal dominant; AR, autosomal recessive; MIDAS, microphthalmia, dermal aplasia and sclerocornea.

have more than one lesion, and multiple membranous lesions may occur in a linear arrangement. Most defects are 1–2 cm in diameter, although the size can range from 0.5 to >10 cm. Scalp ACC involves the underlying skull in 20–30% of cases[42]. Large, irregular lesions are more likely to extend to deeper structures and may affect the dura and/or leptomeninges. Dilated scalp veins may also be seen in association with ACC, especially in patients with Adams–Oliver syndrome (see Table 64.3)[39].

Histologic features of membranous aplasia cutis include an atrophic, flattened epidermis, replacement of the dermis by loose connective tissue, and an absence of adnexal structures. Findings in other types of ACC vary but lesions that have healed generally show scarring and a lack of adnexa. Although histologic examination may be helpful in some instances, the diagnosis of ACC is primarily clinical.

Cutaneous defects noted at birth may be erroneously attributed to obstetric trauma, such as injuries from forceps or fetal scalp electrodes. In many cases, particularly in the setting of affected family members, the diagnosis is made retrospectively when characteristic scarring is observed later in life. Evaluation of a patient with ACC is directed by the history (including obstetric and family history) and physical examination, and, in a neonate, it may include specific investigations such as examination of the placenta and viral studies for herpes simplex and varicella zoster (Fig. 64.17D)[43]. In patients with large, deep, irregular or membranous lesions of the scalp (Fig. 64.17B,E), imaging studies are indicated to assess for underlying bone defects, vascular anomalies or brain malformations. Lastly, elevated α-fetoprotein in midtrimester maternal serum and amniotic fluid as well as elevated acetylcholinesterase in the amniotic fluid may represent early signs of ACC, although they are neither sensitive nor specific for this condition.

Most small lesions of ACC heal within the first few months of life, leaving an atrophic (see Fig. 64.17A) or, less often, hypertrophic ("lumpy") scar. In such instances, daily cleansing and application of a topical antibiotic ointment until healing is complete are often the only interventions required. Underlying skull defects also tend to resolve spontaneously during infancy. However, potential complications of deep ACC of the scalp include life-threatening sagittal sinus hemorrhage/thrombosis and meningitis. Because the risk of complications increases if the period of healing is prolonged, early surgical repair of large stellate scalp lesions or those associated with a dural defect or exposure of the sagittal sinus is recommended. Preoperative imaging studies are required to identify underlying vascular structures. Even without surgical intervention, residual scarred, hairless areas generally become less conspicuous as the child grows. If desired for cosmetic reasons, excision or hair transplants can be performed later in life.

Fig. 64.17 Aplasia cutis congenita (ACC). A This hairless, round, scarred plaque on the scalp of a 6-month-old was present at birth. **B** Stellate ACC on the midline scalp of a neonate. This hemorrhagic lesion was associated with an underlying skull defect and cerebrovascular anomalies. **C** Stellate ACC on the lateral trunk of a neonate born of an initial sextuplet gestation for which fetal reduction was performed. The lesions had a bilateral, symmetric distribution. **D** ACC resulting from congenital varicella. Note the sharply demarcated, deep ulcer on the lower abdominal wall. **E** Membranous ACC associated with a large defect of the underlying skull in a patient with Goltz syndrome. *A, Courtesy, Anthony J Mancini, MD.*

OTHER DEVELOPMENTAL ANOMALIES

Congenital Lip Pits

Synonyms: ■ Lip sinuses ■ Congenital sinuses of the lower lip ■ Midline sinuses of the upper lip

Congenital lip pits are divided into three types based on their location: (1) commissural; (2) upper lip; and (3) lower lip. Commissural lip pits are by far the most common, occurring in 1–2% of newborns. Lip pits likely result from defective embryologic fusion of facial processes with epithelial entrapment. They usually represent the opening of a blind sinus tract, which can extend inward through the orbicularis oris muscle to a depth of >10 mm. This tract occasionally communicates with the ducts of underlying minor salivary glands, and saliva or mucus may drain from the ostium. Lesions are sometimes associated with swelling of the lip or, particularly if located on the philtrum, recurrent infection.

Commissural lip pits are typically found bilaterally in the mucosal surface at the angles of the mouth (Fig. 64.19A). Although most often an isolated anomaly, they may be inherited in an autosomal dominant fashion along with preauricular pits and hearing impairment in patients with a form of branchio-otic syndrome linked to chromosome 1q31[44].

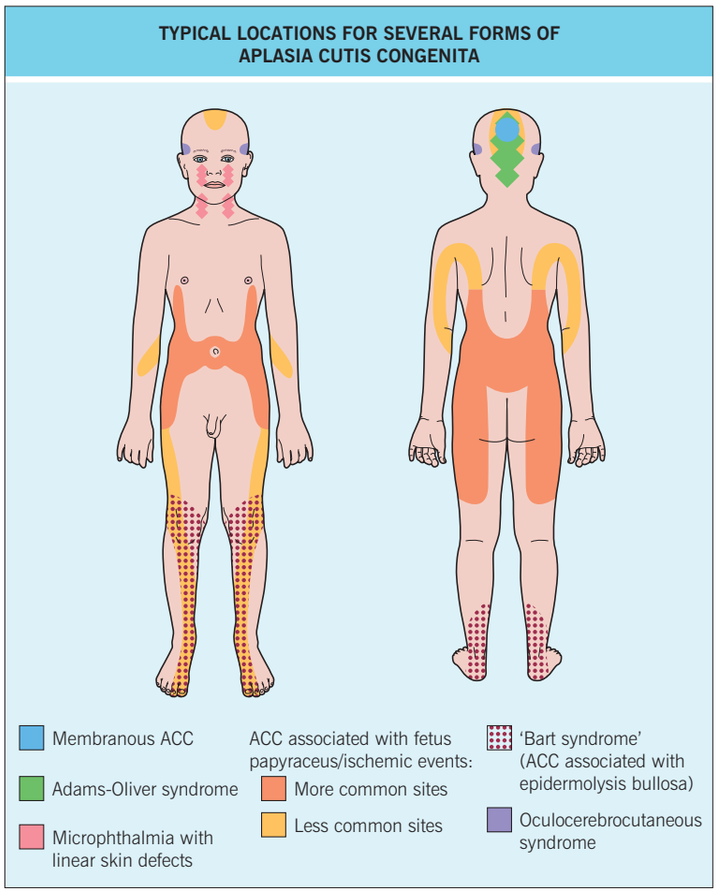

Fig. 64.18 Typical locations for several forms of aplasia cutis congenita (ACC). See Figure 64.2 for Brauer lines/Setleis syndrome, preauricular membranous ACC and another depiction of microphthalmia with linear skin defects.

DISEASES AFFECTING THE SKIN THAT ARE ASSOCIATED WITH CLEFT LIP AND/OR PALATE	
Syndrome	**Other features**
Ectodermal dysplasias (see Ch. 63)	
• EEC syndrome	AD, *p63* gene; *e*ctodermal dysplasia, *e*ctrodactyly, *c*left lip/palate
• AEC syndrome	AD, *p63* gene; *a*nkyloblepharon, *e*ctodermal dysplasia, *c*left lip/palate
• Cleft lip/palate– ectodermal dysplasia*	AR, nectin-1 (*PVRL1*) gene; ectodermal dysplasia, pili torti, syndactyly
Branchio-oculo-facial syndrome	See text – branchial cleft sinuses
Oral–facial–digital syndrome, type 1	X-D, *OFD1* gene; lobulated tongue, hypertrophic oral frenula, digital malformations, whorled alopecia of the vertex, transient facial milia, polycystic kidneys, CNS anomalies
Oculocerebrocutaneous syndrome	See Table 64.4
4p- syndrome (Wolf–Hirschhorn syndrome)	See Table 64.4
Pai syndrome	Facial skin tags, nasal polyps, CNS lipomas
Nevoid basal cell carcinoma syndrome	See Ch. 107
Goltz syndrome (focal dermal hypoplasia)	See Ch. 62
Waardenburg syndrome, type 1 or 3	See Ch. 66
Van der Woude syndrome†	See text – congenital lip pits
Popliteal pterygium syndrome†	See text – congenital lip pits
Nail–patella syndrome	See Ch. 71
Beare–Stevenson cutis gyrata syndrome	AD, *FGFR2* gene; craniosynostosis, cutis gyrata, acanthosis nigricans
LOCAL LESIONS	
Dermal melanocytosis	
Encephaloceles or nasal gliomas	

*Includes Zlotogora–Ogur syndrome, Rosselli–Gulienetti syndrome, and Margarita Island ectodermal dysplasia.
†Allelic disorders.

Table 64.5 Diseases affecting the skin that are associated with cleft lip and/or palate. Other disorders associated with cleft lip/palate that also can affect the skin include Cornelia de Lange, Roberts, Simpson–Golabi–Behmel, Pallister–Hall and CHIME (colobomas [ocular], *h*eart defects, *i*chthyosis, *m*ental retardation and *e*ar anomalies) syndromes, hemifacial microsomia, Meige disease (familial lymphedema praecox) and trisomy 13. AD, autosomal dominant; AR, autosomal recessive; CNS, central nervous system; *PVRL1*, poliovirus receptor-related 1; X-D, X-linked dominant.

Fig. 64.19 Lip pits.
A Bilateral commissural lip pits, representing an incidental finding.
B Bilateral paramedian lower lip pits, each located on the apex of a conical elevation. This was an isolated, asymptomatic anomaly.

Commissural lip pits also have been described in association with alveolar synechiae, ankyloblepharon filiforme adnatum (congenital adhesions between the upper and lower eyelids and ectodermal defects.

Upper lip pits, also known as midline sinuses of the upper lip, are rare. These lesions are typically located along the philtrum. They usually occur as an isolated defect, but they may be associated with hypertelorism and other dysmorphic facial features. In addition, bilateral paramedian upper lip pits may be found in patients with the branchio-oculo-facial syndrome (see below, Branchial cleft sinuses and fistulae).

Lower lip pits may be an isolated finding or seen as a part of Van der Woude syndrome, which is characterized by paramedian pits in the vermilion portion of the lower lip, cleft lip and/or palate, and hypodontia. The lip pits are usually bilateral, and they may be located on the apex of a conical elevation (Fig. 64.19B). Van der Woude syndrome occurs in approximately 1–3 per 100 000 live births, is inherited in an autosomal dominant fashion, and is caused by mutations in the interferon regulatory factor 6 gene (*IRF6*)[45]. Another condition in which lower lip pits are a feature, the popliteal pterygium syndrome, is allelic with Van der Woude syndrome. Additional findings in the popliteal

Fig. 64.20 Accessory tragi. Multiple skin-colored papulonodules in a typical preauricular location as well as on the mandibular cheek.

pterygium syndrome include cleft lip and/or palate, syngnathia, popliteal webbing, nail dysplasia, syndactyly and genital anomalies. Lastly, lower lip pits are occasionally seen in oral–facial–digital syndrome type I (see Table 64.5) and Kabuki syndrome (www.ncbi.nlm.nih.gov/omim).

Histologically, the sinus tracts associated with lip pits are lined by stratified squamous epithelium; associated salivary or mucous glands are occasionally observed. The evaluation of patients with lip pits should include a family history and a physical examination to exclude associated anomalies. If lip pits of any type are symptomatic or cosmetically undesirable, surgical excision is the treatment of choice. The extent of the sinus can be estimated preoperatively by injection of a radiopaque contrast medium.

Accessory Tragi

Synonyms: ▪ Preauricular tags ▪ Preauricular appendages

Accessory tragi are relatively common congenital anomalies of the first branchial arch, and they are found in approximately 3–6 per 1000 live births. Familial occurrence has been reported, sometimes with a consistent anatomic site within kindreds. During development, the external ear is formed by the fusion of six tubercles, three each from the first and second branchial arches; the tragus and anterior crus of the helix are the only portions of the ear derived from the former[46]. Whereas preauricular pits and cysts reflect defective fusion of the tubercles (see Ch. 110), accessory tragi represent remnants of and/or extra tubercles originating from the first branchial arch.

Accessory tragi typically manifest as skin-colored papules or nodules in the preauricular area, but they also may be found on the mandibular cheek (Fig. 64.20) or on the neck along the anterior border of the sternocleidomastoid muscle (also referred to as congenital cartilaginous rests of the neck, see below)[47]. The latter locations reflect the embryologic migration of the external ear from the neck to the side of the head as the mandible develops. Although most often solitary, accessory tragi may be multiple (see Fig. 64.20), and they are bilateral in approximately 10% of cases. They can be either soft or firm due to a cartilaginous core, and they are commonly covered by vellus hairs[46].

Although they usually represent an isolated malformation, accessory tragi are sometimes associated with other developmental anomalies of the first branchial arch, such as cleft lip and palate[48]. Together with ipsilateral facial hypoplasia, ear deformities, epibulbar dermoids and vertebral abnormalities, accessory tragi are a cardinal feature of hemifacial microsomia (Goldenhar syndrome). Accessory tragi may be seen in a number of other multiple congenital anomaly syndromes, including Nager acrofacial dysostosis, Townes–Brocks syndrome, Treacher Collins–Franceschetti syndrome, VACTERL association, Wildervanck syndrome and Wolf–Hirschhorn syndrome (www.ncbi.nlm.nih.gov/omim). Isolated accessory tragi may be associated with an increased risk of hearing impairment, but recent large controlled studies have failed to confirm a purported association between isolated accessory tragi and urinary tract abnormalities.

Histologically, accessory tragi show numerous tiny, mature hair follicles, a prominent connective tissue framework within abundant subcutaneous fat, and often a central plate of elastic cartilage. When accessory tragi are surgically excised for cosmetic reasons, care must be taken to remove any protruding portion of underlying cartilage[47]. Evaluation of an infant with an accessory tragus should include assessment of hearing and examination for other dysmorphic features.

Congenital Cartilaginous Rests of the Neck

Synonyms: ▪ Wattles ▪ Cervical accessory tragi

Congenital cartilaginous rests of the neck are branchial arch remnants that are considered to be the cervical variant of accessory tragi (see above). The alternative term "wattle" refers to the fleshy appendage that hangs from the throat of certain animals, such as turkeys and goats. Typically located over the lower anterior border of the sternocleidomastoid muscle, these asymptomatic lesions may be unilateral or bilateral, and they are not cystic or fistulous. They may be attached to the underlying fascia by a fibrous band, which can be safely transected if excision is desired[49].

Branchial Cleft Sinuses and Fistulae

Synonym: ▪ Lateral cervical sinuses and fistulae

Branchial cleft sinuses most often represent remnants of the second branchial cleft. Unlike the more common branchial cleft cysts that lack a primary cutaneous opening and typically present in older children and adults (see Ch. 110), these lesions are usually detected at birth or during the first few years of life. In the majority of cases, a sinus ostium (frequently with discharge of mucus) is noted on the lateral lower third of the neck along the anterior border of the sternocleidomastoid muscle; the associated tract extends superiorly in the subcutis, and it may be palpable. The less common first branchial cleft sinus can manifest with a cutaneous opening located higher on the neck or in the periauricular region. Approximately 70% of branchial cleft sinuses are located on the right neck and 5–10% are bilateral. There may be a history of recurrent infection, and a skin tag, sometimes with a cartilaginous component, can mark the ostium. Most branchial sinus tracts end blindly, but occasionally there is a fistulous connection with the tonsillar fossa of the pharynx or the external auditory canal[50].

Although usually an isolated malformation, branchial cleft sinuses and fistulae are also features of several multiple congenital anomaly syndromes. These include the branchio-otic and branchio-oto-renal syndromes, autosomal dominant disorders that are further characterized by ear pits, hearing loss, and, in the latter, renal anomalies. These syndromes can be caused by mutations in the *EYA1* (both conditions), *SIX1* (branchio-otic) and *SIX5* (branchio-oto-renal) genes, which encode transcription factors that interact within a complex. Atrophic, eroded or "hemangiomatous" skin overlying branchial cleft sinuses on the neck or in the periauricular area is a distinctive feature of the branchio-oculo-facial syndrome, which is caused by mutations in the gene encoding transcription factor AP2-α. Additional manifestations of this disorder include cleft lip/palate, imperforate nasolacrimal ducts, eye and ear anomalies, and early graying of the hair.

Histologically, a branchial sinus may be lined by stratified squamous or pseudostratified ciliated columnar epithelium. In order to prevent infectious complications, complete surgical excision of branchial sinuses and fistulae is indicated. Imaging may be helpful in delineating the course and extent of the lesion, although recommendations vary among otolaryngologists. Preoperative options include CT fistulography and MRI; in addition, intraoperative contrast fistulography and/or injection of methylene blue dye can be considered[50,51].

Supernumerary Nipples and Other Forms of Accessory Mammary Tissue

Synonyms: ■ Accessory nipples ■ Polythelia ■ Pseudomamma ■ Supernumerary breasts ■ Polymastia

Supernumerary nipples and other forms of accessory mammary tissue are remnants of the embryologic mammary ridges or "milk lines", symmetric ectodermal thickenings that extend from the anterior axillary fold to the upper medial thigh (Fig. 64.21). Normally, there is further development in the pectoral region to form the nipples, while the remainder of the milk line regresses; focal areas of persistence result in accessory mammary tissue. Supernumerary nipples, the most common type of accessory mammary tissue, are found in 1–6% of the population[52]. They usually represent a sporadic developmental anomaly, although approximately 10% of cases are familial. The incidence of supernumerary nipples is similar in men and women. However, accessory mammary tissue in women often becomes prominent at puberty or during pregnancy, and it is then more easily recognized. Conversely, changes in supernumerary nipples may actually represent an early cutaneous sign of pregnancy.

Supernumerary nipples are most commonly seen on the inframammary chest, but they may be located anywhere along the milk lines (including on the vulva) and occasionally in other sites such as the upper back, shoulder, posterior thigh, face, neck or even foot. In addition, supernumerary nipples sometimes overlie the primary nipple or areola. Lesions are most often single, but they may be multiple and/or bilateral. Supernumerary nipples typically present as a small, soft, pink or brown papule, either with a surrounding areola (Fig. 64.22) or without (referred to as pseudomamma and polythelia, respectively). An areola also can develop in the absence of a nipple (polythelia areolaris), and ectopic glandular breast tissue can be found either associated with a nipple and/or areola (supernumerary breasts, polymastia) or alone. In the latter situation, tissue is most often located in the axilla or vulva, and it may demonstrate all of the functional changes of normal breasts, from tenderness and swelling related to the menstrual cycle to lactation through pores in the overlying skin. Of note, a patch of hair located along the milk lines may be a marker of underlying mammary tissue (polythelia pilosa)[53].

A number of other abnormalities have been described in patients with supernumerary nipples. The association between supernumerary nipples and malformations of the kidneys and urinary tract is controversial. Although early reports supported the existence of a "supernumerary nipple/renal field defect", several controlled studies failed to confirm this association[54]. However, a few studies have found supernumerary nipples to be significantly more common in patients with urogenital or renal malignancies than in control groups[55]. An increased incidence of predominantly ipsilateral Becker's nevi has also been noted in patients with supernumerary nipples. Supernumerary nipples are found in several multiple congenital anomaly syndromes, including Simpson–Golabi–Behmel syndrome, cleft lip/palate–ectodermal dysplasia syndrome and tricho-odonto-onychial dysplasia (www.ncbi.nlm.nih.gov/omim).

Histologic features of accessory mammary tissue are similar to those of normal breasts. For example, supernumerary nipples show acanthosis, pilosebaceous structures, smooth muscle, and, in many cases, mammary glands. Fine-needle aspiration cytology can be helpful for evaluation of an axillary or vulvar mass suspected to represent breast tissue, although an incisional or excisional biopsy may be required for definitive diagnosis. Ectopic glandular breast tissue can develop any of the disorders that occur in normally positioned breasts, including fibrocystic changes, mastitis, fibroadenomas and carcinoma. Although such tissue does not have an increased malignant potential compared with the normal breast and prophylactic excision for cancer prevention is not required, routine screening should be performed with periodic physical examination and radiologic studies such as mammography or ultrasonography. Complete surgical excision is the treatment of choice for accessory mammary tissue that is symptomatic or cosmetically undesirable. Most authors do not recommend imaging studies to exclude an associated urinary tract malformation in asymptomatic individuals with accessory mammary tissue as an isolated anomaly.

Absent, Hypoplastic or Anomalous Nipples

Synonyms: ■ Athelia ■ Amastia ■ Hypomastia

Absence or hypoplasia of the nipples may occur either as an isolated developmental abnormality or together with other malformations in a variety of congenital syndromes. The Poland anomaly is a

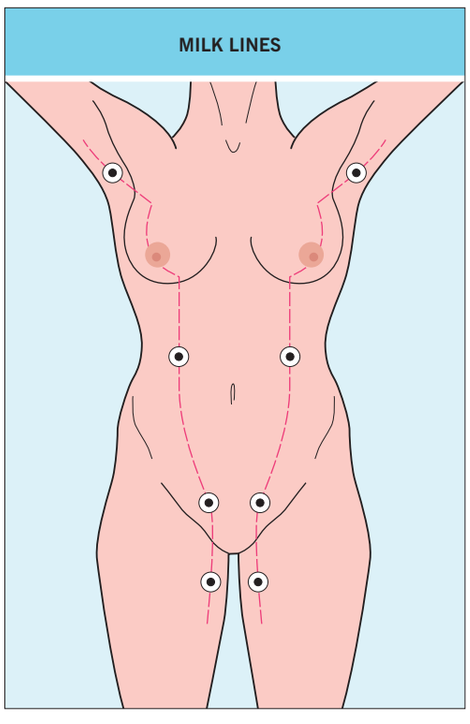

Fig. 64.21 "Milk lines". Supernumerary nipples and other forms of accessory mammary tissue represent focal remnants of the embryologic mammary ridges that extend from the anterior axillary fold to the upper medial thigh bilaterally.

Fig. 64.22 Supernumerary nipple. Note the supernumerary nipple with a surrounding areola in a typical location on the inframammary chest. *Courtesy, Jean L Bolognia, MD.*

predominantly sporadic developmental field defect in which hypoplasia or absence of the nipple and/or breast is associated with ipsilateral aplasia of the sternal head of the pectoralis major muscle, patchy absence of axillary hair, and symbrachydactyly. The Becker's nevus syndrome may also include hypoplasia of the ipsilateral nipple and breast, pectoralis major muscle and/or arm. In addition, nipple and breast hypoplasia or aplasia may occur in X-linked hypohidrotic, tricho-odonto-onychial type and various other ectodermal dysplasias as well as the scalp–ear–nipple syndrome (see Table 64.4), limb–mammary syndrome (ectrodactyly, other hand/foot anomalies and nail dysplasia), ulnar–mammary syndrome (ulnar ray defects, apocrine gland hypoplasia, genital anomalies and abnormal canine teeth; caused by mutations in the *TBX3* gene; see Table 64.6) and ablepharon–macrostomia syndrome. In a rare, lethal form of dwarfism known as Blomstrand chondrodysplasia, loss-of-function mutations in the gene encoding parathyroid hormone receptor 1 result in lack of nipples. Interestingly, during embryonic development, mammary bud epithelium produces a parathyroid hormone-related protein that is required for formation of the nipple and mammary ducts[56].

Inverted nipples are most often inherited as an isolated autosomal dominant trait, but they may also be found in congenital syndromes. For example, inverted nipples occur together with psychomotor retardation, hypotonia, cerebellar hypoplasia, strabismus and abnormal fat distribution as a part of the congenital disorder of glycosylation type Ia. Widely spaced nipples are a feature of a number of congenital disorders, including Turner syndrome, Noonan syndrome, cerebro-oculo-facio-skeletal syndrome, renal hypoplasia syndromes and various chromosomal abnormalities (www.ncbi.nlm.nih.gov/omim).

Skin Dimples

Synonym: ▪ Skin fossae

DISEASES AFFECTING THE SKIN THAT ARE ASSOCIATED WITH CONGENITAL DIGITAL ANOMALIES

Syndrome	Digital anomaly (-dactyly)					Other features
	Syn-	Ectro-	Poly-	Clino-	Brachy-	
Ectodermal dysplasias (see Ch. 63)						
• EEC syndrome*	x	x				AD; *e*ctodermal dysplasia, *e*ctrodactyly, cleft lip/palate
• EEM syndrome	x	x				AR, P-cadherin gene; *e*ctodermal dysplasia, *e*ctrodactyly, *m*acular dystrophy
• Cleft lip/palate–ectodermal dysplasia	x					See Table 64.5
• ED–syndactyly	x					AR, nectin 4 (*PVRL4*) gene; hypotrichosis with pili torti, hypodontia, PPK
• Oculodentodigital dysplasia	x				x	AD, *GJA1* gene; small eyes, enamel hypoplasia, midphalangeal hypoplasia, PPK, hypotrichosis
• Scalp–ear–nipple syndrome	x					See Table 64.4
• Ulnar–mammary syndrome		x	x			See text – absent/hypoplastic nipples
Oral–facial–digital syndrome, type 1	x		x			See Table 64.5
Goltz syndrome (focal dermal hypoplasia)	x	x	x			See Ch. 62
Terminal osseous dysplasia with pigmentary defects				x	x	X-D, filamin A gene; hyperpigmented, atrophic facial macules representing focal dermal hypoplasia, digital fibromas, multiple frenula, hypertelorism
Happle–Tinschert syndrome	x		x			Basaloid follicular hamartomas in a mosaic distribution; dental, skeletal and cerebral anomalies
Epidermal/sebaceous nevus "syndromes"	x		x	x		See Ch. 62
Mosaicism/hypomelanosis of Ito	x		x	x		See Ch. 62
Klippel–Trenaunay syndrome†	x		x			See Ch. 104
Proteus syndrome†	x					See Ch. 62
Adams–Oliver syndrome	x				x	See Table 64.3
Macrocephaly–capillary malformation	x		x			See Ch. 104
Waardenburg syndrome, type 3	x					See Ch. 66
Apert syndrome	x					AD, *FGFR2* gene; craniosynostosis, severe acne, diffuse pigmentary dilution
Nevoid basal cell carcinoma syndrome			x		x	See Ch. 107
Popliteal pterygium syndrome	x					See text – congenital lip pits
Trichorhinophalangeal syndrome					x	AD, *TRPS1* gene; cone-shaped epiphyses, pear-shaped nose, sparse hair
Congenital anonychia–onychodysplasia	x			x	x	See Ch. 71

*Caused by mutations in the *p63* gene; allelic disorders with overlapping manifestations (e.g. ectrodactyly, nipple hypo-/aplasia) include ADULT (acro-dermato-ungual-lacrimal-tooth) syndrome and limb-mammary syndrome.
†Patients often have macrodactyly.

Table 64.6 Diseases affecting the skin that are associated with congenital digital anomalies. Other disorders associated with digital anomalies that also may affect the skin include Cornelia de Lange, Roberts, Simpson–Golabi–Behmel, Pallister–Hall, Russell–Silver, Rubinstein–Taybi and Hurler syndromes, trisomy 13, Fanconi anemia and the Poland anomaly. **Syndactyly**, fused digits; **ectrodactyly**, absent digits resulting in a split hand–foot deformity ("lobster claw"); **polydactyly**, extra digits; **clinodactyly**, laterally or medially "bent" digits; **brachydactyly**, short digits. AD, autosomal dominant; AR, autosomal recessive; PPK, palmoplantar keratoderma; *PVRL4*, poliovirus receptor-related 4; X-D, X-linked dominant.

Skin dimples are deep cutaneous depressions that are seen most commonly on the cheeks or chin, occurring in a familial pattern suggestive of autosomal dominant inheritance. Unilateral or bilateral dimples also may be found in a variety of other locations, most often overlying bony prominences, such as the acromion process of the scapula, elbow, patella, tibia and sacrum. These represent regions in which there is close proximity of the skin to the underlying bone during fetal development, and the dimples are thought to result from early fixation of the skin and deficient formation of the subcutaneous tissue.

Bilateral skin dimples on the shoulders overlying the acromion processes can be inherited in an autosomal dominant fashion as an isolated anomaly. This finding is thought to be more common than the scarcity of reports in the literature would suggest. In addition, bilateral acromial dimples are a feature of several congenital malformation syndromes, including the 18q deletion syndrome, trisomy 9p syndrome, Say syndrome and Russell–Silver dwarfism[57]. Skin dimples also may be seen in association with skeletal abnormalities. For example, dimpling may be found overlying the tibial bend in patients with camptomelic dysplasia and over bowing convexities or exostoses of long bones in those with hypophosphatasia. A characteristic H-shaped dimple on the chin is seen in the whistling face syndrome. Dimples located on the lumbosacral midline may represent a cutaneous sign of spinal dysraphism, and they are also associated with a number of malformation syndromes[57]. In contrast, shallow coccygeal dimples are a relatively common finding in normal newborns[25–27]. Lastly, skin dimples overlying the knees and/or elbows have been reported in association with congenital rubella, Joubert syndrome, limb–mammary syndrome, ulnar–mammary syndrome and multiple pterygium syndrome (www.ncbi.nlm.nih.gov/omim). In other sites, an enlarging dimple in a young child may indicate a nascent lipoblastoma (see Ch. 117).

Congenital Malformations of the Dermatoglyphs

Congenital malformations of the dermatoglyphs (fingerprints) are divided into four main categories based on the appearance of the dermal ridges of which they are composed: (1) ridge aplasia (absent); (2) ridge hypoplasia (poorly formed); (3) ridge dissociation (discontinuous pattern with short segments); and (4) ridges-off-the-end (run off the end of the fingertip rather than looping around). Embryologic development of the dermal ridges occurs in conjunction with that of the eccrine glands of the palms and soles, and the sweat pores are found on the ridges. The lack of eccrine ducts and glands in the palmar skin of patients with ridge aplasia reflects this close relationship[58].

Congenital dermatoglyph malformations types 2–4 can be inherited in an autosomal dominant fashion as an isolated defect. They may also occur in association with conditions such as chromosomal abnormalities, malformations of the distal limbs, and ectodermal dysplasias. The latter, which may feature ridge aplasia as well, include hypohidrotic ectodermal dysplasia, AEC syndrome (*a*nkyloblepharon, *e*ctodermal dysplasia, *c*left lip/palate), dermatopathia pigmentosa reticularis and Naegeli–Franceschetti–Jadassohn (NFJ) syndrome (see Chs 63 & 67). Autosomal dominant inheritance of ridge aplasia together with acral hypohidrosis, neonatal acral blistering (with occasional later recurrences), palmoplantar keratoderma, and variable hypotrichosis and dental anomalies has been described in a few families; although referred to as Basan syndrome, the features overlap with those of NFJ syndrome. Ridge dissociation also may be seen in patients with Rosenthal–Kloepfer syndrome (acromegaloid changes, cutis verticis gyrata, and corneal leukoma) and cystic fibrosis. The differential diagnosis of abnormal dermatoglyphs may also include acquired loss as seen in Kindler syndrome (see Ch. 63).

Rudimentary Supernumerary Digits

Synonym: ▪ Rudimentary polydactyly

Rudimentary supernumerary digits are soft-tissue duplications without a skeletal component that typically arise from the lateral surface of a normal digit, most often the ulnar side of the fifth finger (postaxial; those arising from the thumb are termed preaxial). Such lesions are found in approximately 0.5–1 per 1000 live births in white populations and 3–10 per 1000 live births in black populations. They usually occur as an isolated malformation with a familial pattern suggestive of autosomal dominant inheritance. In some cases, rudimentary supernumerary digits represent the stump remaining after intrauterine amputation of a larger structure. Present at birth and frequently bilateral, lesions range from small, fleshy or wart-like papules (Fig. 64.23) to larger, often pedunculated nodules that may contain cartilage or a vestigial nail. Congenital ectopic nails located on the tips of the fifth fingers also have been described, and these are regarded as a separate entity.

Histologically, rudimentary supernumerary digits often show fascicles of nerve fibers in a pattern similar to that of an acquired neuroma. When removal is desired, surgical excision is the method of choice[59]. Removal via ligation with suture material increases the risk of infection and often leaves a residual papule, which may result in a painful neuroma later in life.

Amniotic Band Sequence and Disorganization Syndrome

Synonyms: ▪ Amniotic band syndrome ▪ Congenital constriction bands ▪ ADAM (*a*mniotic *d*eformity, *a*dhesions and *m*utilations) complex

The amniotic band sequence (ABS) encompasses a variety of congenital anomalies of the limbs, head, body wall and viscera with asymmetric, seemingly random distribution patterns that do not correspond to embryonic fusion planes. Characteristic findings include constriction rings and amputations of the limbs and digits that are associated with fibrous bands. Occurring in approximately 1–10 per 10 000 live births, ABS is primarily a sporadic disorder, although familial cases have been reported.

There are two classic hypotheses for the pathogenesis of ABS. The *extrinsic theory* postulates that early rupture of the amniotic membrane is followed by loss of amniotic fluid and entanglement of fetal parts in fibrous strands of torn amnion, which form rings that encircle and constrict the limbs, portions of the face or even the entire trunk. The *intrinsic theory* proposes that an abnormal endogenous developmental process leads to production of fibrous bands as well as other anomalies (e.g. internal malformations, duplicated structures) not explained by bands alone. Although the former theory has traditionally been more widely accepted, the substantial overlap between ABS and the "disorganization syndrome" (the human equivalent of the mouse disorganization mutant, which has autosomal dominant inheritance) provides support for an intrinsic mechanism[60,61]. The disorganization syndrome features a haphazard pattern of defects, most often limb anomalies (including duplications as well as reductions/circumferential constrictions with attached fibrous bands), craniofacial > truncal clefts, and hamartomatous digit-like appendages.

Fig. 64.23 Bilateral rudimentary supernumerary digits. The ulnar side of the fifth digit is the most common location (referred to as postaxial).

The clinical spectrum of ABS is broad, ranging from isolated minor limb anomalies to major craniofacial and visceral defects. It includes the limb–body wall complex, which is characterized by body wall defects with evisceration of thoracic and/or abdominal organs, irregular anencephaly/encephaloceles and bizarre facial clefting[62]. Variations in severity may depend upon differences in the timing of amniotic rupture or variable expressivity of genetic trait(s). Constriction rings present as circumferential grooves of variable depth on the digits, extremities, neck or trunk. Deep lesions located on an extremity may be associated with distal lymphedema, nerve compression, deformity or intrauterine amputation. Acrosyndactyly can result from a constriction band that encircles adjacent digits. In addition to the distinctive fibrofatty appendages of the disorganization syndrome, other cutaneous manifestations of ABS may include aplasia cutis congenita, often with a stellate morphology, and abnormal dermatoglyphs.

Plastic surgery with wound closure via Z-plasty is indicated for release of constriction bands that restrict growth, compress underlying nerves, or interfere with vascular and/or lymphatic circulation.

Other Developmental Anomalies Associated with Cutaneous Diseases

Skin disorders that are associated with cleft lip/palate or congenital digital anomalies are presented in Tables 64.5 and 64.6, respectively.

Melanocyte Biology 65

Jean L Bolognia and Seth J Orlow

Key features

- The major determinant of normal skin color is the activity of melanocytes, i.e. the quantity and quality of pigment production, not the density of melanocytes
- Melanocytes contain a unique intracytoplasmic organelle, the melanosome, which is the site of melanin synthesis and deposition
- Compared with lightly pigmented skin, darkly pigmented skin has melanosomes that contain more melanin and are larger; once transferred to keratinocytes, the melanosomes are singly dispersed and degraded more slowly
- Tyrosinase is the key enzyme in the melanin biosynthetic pathway
- Two major forms of melanin are produced in melanocytes: brown–black eumelanin and yellow–red pheomelanin
- The production of eumelanin versus pheomelanin is influenced by the binding of melanocyte stimulating hormone to the melanocortin-1 receptor

INTRODUCTION

In order to understand the underlying pathophysiology of cutaneous disorders of hypopigmentation and hyperpigmentation, as well as the process of normal physiologic pigment production, an appreciation of the structure and function of the melanocyte is required. A classic example of basic pathogenesis is type 1 oculocutaneous albinism (OCA), in which pigmentary dilution of the skin, hair and eyes is due to a reduction or absence of tyrosinase activity secondary to mutations in both copies of the tyrosinase gene. Within the realm of physiologic pigmentation, melanocytes in individuals with red hair often express variants of the melanocortin-1 receptor (MC1-R)[1] and population genetics also implicate the *OCA2* (*P*), *ASIP* and *SLC24A5* genes in normal pigment variation (see Table 65.5)[2–4]. As a consequence of the altered amino acid sequences of the variant MC1-Rs, their cell surface expression and interactions with melanocyte stimulating hormone (MSH) can be affected, leading to an increase in the production of pheomelanin as opposed to eumelanin.

The major sections in this chapter are:

- the origin and function of the melanocyte
- the formation and function of the melanosome
- the regulation of melanin biosynthesis.

ORIGIN AND FUNCTION OF THE MELANOCYTE

The melanocyte is a neural crest-derived cell, and during embryogenesis precursor cells (melanoblasts) migrate along a dorsolateral pathway via the mesenchyme to reach the epidermis and hair follicles. Additional sites of melanocyte migration include the uveal tract of the eye (choroid, ciliary body and iris), the leptomeninges and the inner ear (cochlea) (Fig. 65.1). Presumably, the death of melanocytes within the leptomeninges, inner ear and skin is responsible for the aseptic meningitis, auditory symptoms and areas of vitiligo, respectively, seen in patients with the Vogt–Koyanagi–Harada syndrome (see Ch. 66). Recently, it was shown that cutaneous melanocytes can also arise from neural crest-derived Schwann cell precursors that are found along nerves within the skin, having migrated there by a ventral pathway[5].

In the inner ear, particularly in the stria vascularis, melanocytes are thought to play a role in the development of the ability to hear. Aberrant migration or survival of melanocytes within the inner ear, the iris, and mid portions of the forehead and extremities explains the presence of congenital deafness, heterochromia irides, and patches of leukoderma, respectively, in patients with Waardenburg syndrome, the classic neurocristopathy. Also, aberrant migration or survival of enteric ganglion cells, another neural crest-derived cell population, provides an explanation for the association of congenital megacolon (Hirschsprung disease) with either piebaldism or Waardenburg syndrome.

The survival and migration of neural crest-derived cells during embryogenesis depends upon interactions between specific receptors on their cell surface and extracellular ligands. For example, KIT ligand (also known as steel factor or stem cell growth factor) binds to the transmembrane KIT receptor on melanocytes and melanocyte precursors (melanoblasts) (Figs 65.2 & 65.3). Heterozygous germline

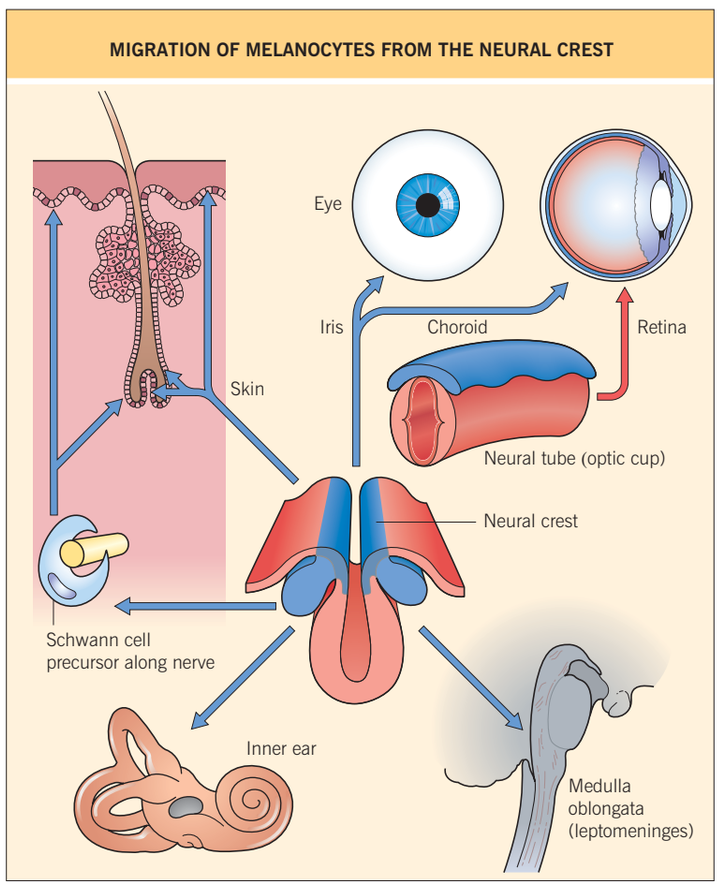

Fig. 65.1 Migration of melanocytes from the neural crest. Melanocytes migrate to the uveal tract of the eye (iris and choroid), the leptomeninges and the cochlea of the inner ear, as well as to the epidermis and hair follicle. Cutaneous melanocytes can also arise from Schwann cell precursors located along nerves in the skin, which also originate from the neural crest. The retina actually represents an outpouching of the neural tube.

mutations in the *KIT* gene that decrease the ability of the KIT receptor to be activated by KIT ligand are responsible for human piebaldism, whereas in mice, mutations in either the *kit* gene or the *steel* gene can lead to white spotting. In the developing CNS, interactions occur between endothelin-3 (ET3 [EDN3]) and the endothelin B receptors (EDNRB) found on melanoblast-ganglion cell precursors (see Fig. 65.3). Mutations in one or both copies of the *EDN3* gene or the *EDNRB* gene can result in Waardenburg syndrome plus congenital megacolon (see Ch. 66).

Transcription factors represent another group of proteins that play an essential role during embryogenesis. Because transcription factors can bind DNA and influence the activity of other genes, they are able to regulate the complex interplay of various sets of genes that is required for embryonic development. Several of the genes that, when mutated, give rise to Waardenburg syndrome encode transcription factors (e.g. *PAX3, MITF, SOX10*; see Table 66.5). Figure 65.4 demonstrates some of these interactions (e.g. PAX3 and SOX10 can control expression of MITF)[7,8].

During embryogenesis, melanin-producing melanocytes are found diffusely throughout the dermis. They first appear in the head and neck region at approximately 10 weeks of gestation. However, by the end of gestation, active dermal melanocytes have "disappeared", except in

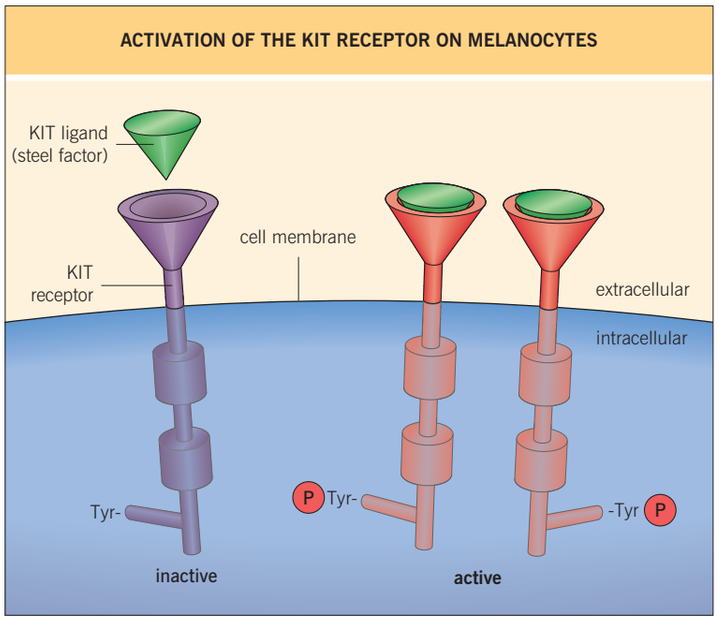

Fig. 65.2 Activation of the KIT receptor on melanocytes. Because the KIT receptor is a tyrosine kinase receptor, it has the ability to place phosphate groups on the tyrosine residues of other proteins (as well as autophosphorylation). Heterozygous germline mutations in the *KIT* gene that prevent the activation of the KIT receptor by KIT ligand, also referred to as steel factor, lead to piebaldism, whereas somatic activating mutations in the *KIT* gene are seen in patients with mastocytosis as well as melanomas arising in acral sites, mucosa and chronically photodamaged skin. A form of familial progressive hyperpigmentation can result from heterozygous gain-of-function germline mutations in the gene that encodes KIT ligand[6].

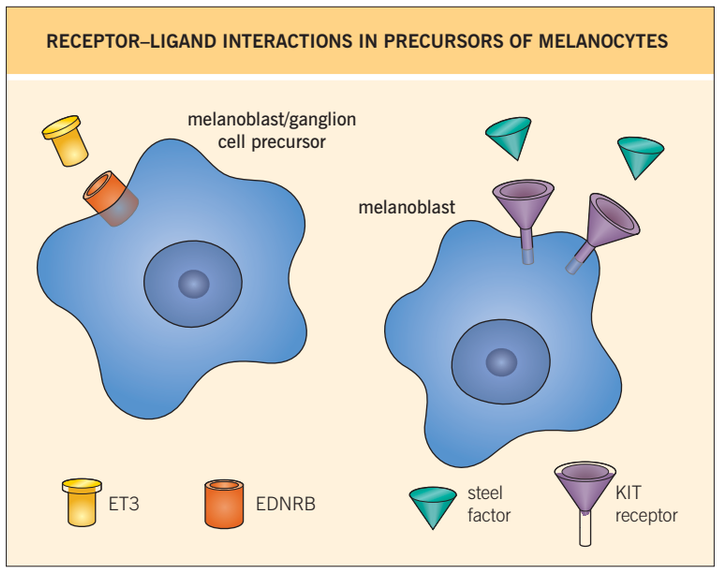

Fig. 65.3 Receptor–ligand interactions in precursors of melanocytes. In the developing CNS, endothelin B receptors (EDNRB) on melanoblast-ganglion cell precursors interact with endothelin-3 (ET3), and in the mesenchyme and final destination sites, KIT receptors on melanoblasts and melanocytes interact with KIT ligand (steel factor).

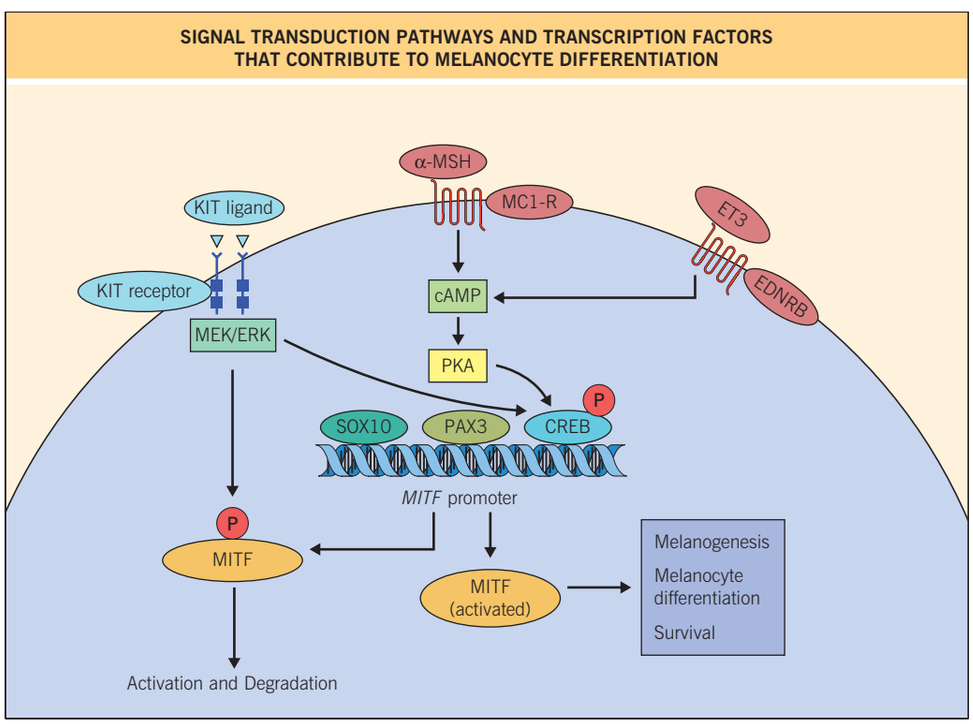

Fig. 65.4 Signal transduction pathways and transcription factors that contribute to melanocyte differentiation. MITF expression is activated early on during the transition from pluripotent neural crest cells to melanoblasts and is required for melanoblast survival[7]. MITF also regulates the expression of multiple pigment genes including those that encode tyrosinase, TYRP1, TYRP2, gp100/Pmel17 and MART-1/Melan-A. Additional transcriptional targets are *CDK2*, *CDKN2A* and *BCL-2* (whose protein product is an inhibitor of apoptosis)[8]. Beyond the role of SOX10, PAX3 and CREB, the T-cell factor/lymphoid enhancer factor (TCF/LEF) family of transcription factors can enable MITF expression to be regulated by Wnt; in mice, Wnt signaling in melanocyte stem cells is critical for hair pigmentation[8a]. Details of how activation of G-protein-coupled receptors leads to an increase in intracellular cAMP is shown in Fig. 65.15. MEK and ERK are key kinases in the mitogen-activated protein kinase (MAPK) pathway (see Fig. 113.2). cAMP, cyclic adenosine monophosphate; CREB, cAMP response-element binding protein; ET3, endothelin-3; EDNRB, endothelin B receptor; MC1-R, melanocortin 1 receptor; MITF, microphthalmia-associated transcription factor; MSH, melanoctye stimulating hormone; PKA, protein kinase A; SOX10, SRY-box containing gene 10.

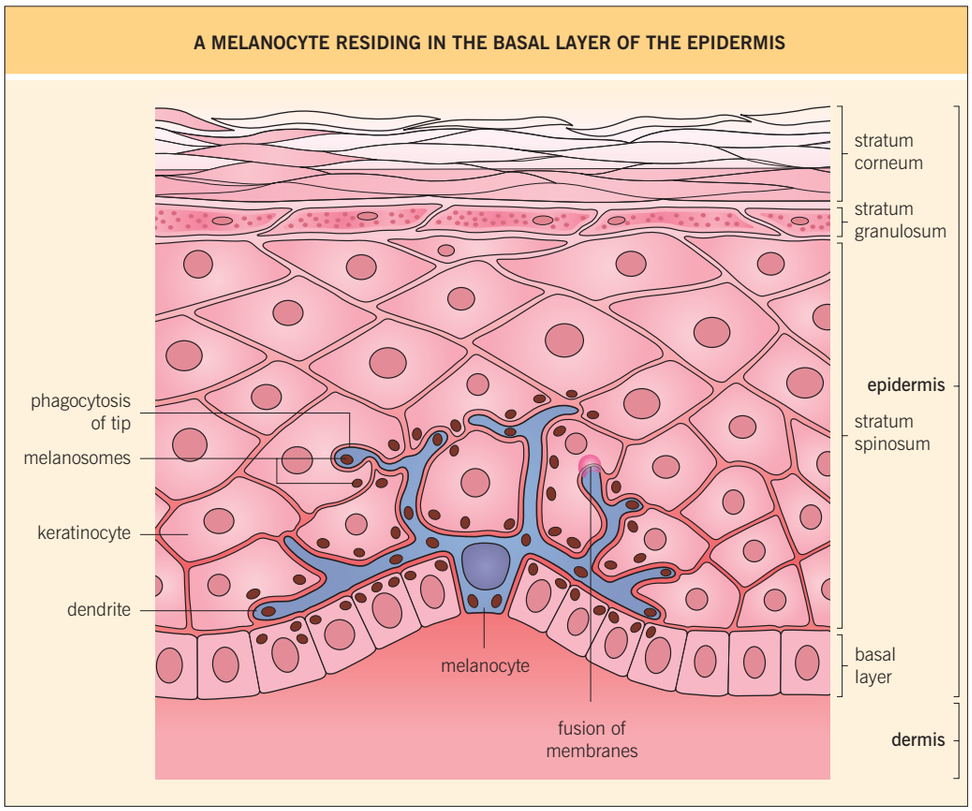

Fig. 65.5 A melanocyte residing in the basal layer of the epidermis. In normal skin, approximately every tenth cell in the basal layer is a melanocyte. Melanosomes are transferred from the dendrites of the melanocyte into neighboring keratinocytes of the epidermis, hair matrices and mucous membranes; no transfer occurs in the pigment epithelium of the retina.

three anatomic locations – the head and neck, the dorsal aspects of the distal extremities, and the presacral area[9]. Some of the dermal melanocytes have clearly migrated into the epidermis, but, given the absolute numbers of cells in the two compartments, death (presumably programmed) of pigment cells has also occurred. The three sites where active dermal melanocytes are still present at the time of birth coincide with the most common sites for dermal melanocytoses and dermal melanocytomas (blue nevi). Hepatocyte growth factor may play a role in the survival and proliferation of these dermal melanocytes as well as somatic activating mutations in *GNA11* and *GNAQ*, which encode G proteins (see Ch. 112).

As depicted in Figure 65.1, melanocytes also migrate to the basal layer of the hair matrix and the outer root sheath of hair follicles. Cells that are actively producing melanin are easily recognized in the matrices of pigmented anagen hairs, whereas melanocytes in the outer root sheath are usually amelanotic and more difficult to identify[10]. It has been hypothesized that there are two populations of melanocytes in the skin, one in the interfollicular epidermis and the second in the hair follicle[11]. Based upon antigen expression and clinical observations, it is the former that is more sensitive to the destructive forces of vitiligo. As a result, repigmentation of patches of vitiligo in which the hairs are still pigmented relies upon activation and subsequent upward migration of the melanocytes present in the outer root sheath[10]. Of note, melanocyte stem cells have been identified within the hair follicle and are discussed in Chapter 2.

By immunohistochemical staining, melanocytes are identified within the fetal epidermis as early as 50 days of gestation[12]. Melanin-containing melanosomes are recognizable by electron microscopy during the fourth month of gestation. Except in benign and malignant neoplasms, melanocytes reside within the basal layer of the epidermis, a location they maintain throughout life (Fig. 65.5). Although the cell body of the melanocyte sits on a specialized region of basal lamina, its dendrites come into contact with keratinocytes as far away as the mid stratum spinosum. This association of a melanocyte with approximately 30–40 surrounding keratinocytes to which it transfers melanosomes has been called the epidermal melanin unit[13]. However, as intruders into the epidermis, melanocytes fail to form desmosomal connections with neighboring keratinocytes; their interactions with keratinocytes are via cadherins.

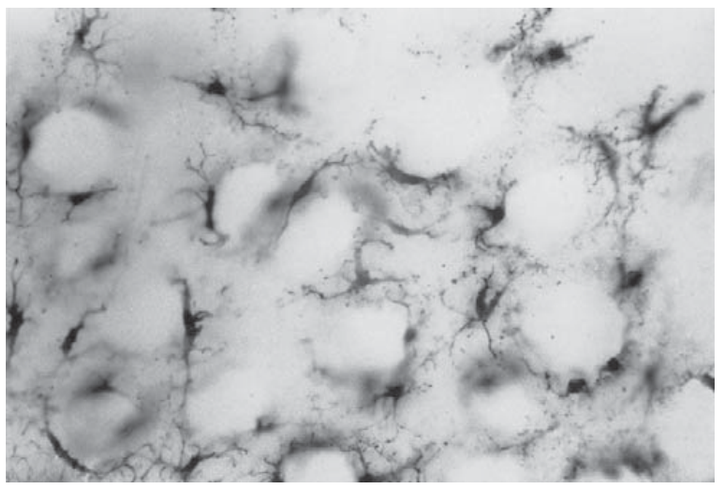

Fig. 65.6 Dihydroxyphenylalanine (DOPA)-stained epidermal sheet. Following incubation with 5 mM L-DOPA for 4–5 hours, the epidermal melanocytes turn black because they contain the enzyme tyrosinase, which converts DOPA to black DOPA-melanin. Note the multiple dendrites and regular spacing of the melanocytes.

Although there is variation in the density of epidermal melanocytes per square millimeter when different regions of the body are analyzed via DOPA-stained epidermal sheets (Fig. 65.6), e.g. the density of melanocytes is greater in the genital region (~1500/mm^2) compared with the back (~900/mm^2), there are smaller differences between individuals when the same anatomic site is examined. This is despite the wide variation in pigmentation seen within the human race. In other words, a person who has minimal baseline pigmentation and an inability to tan has a similar density of melanocytes when compared with a person whose skin is dark brown to black in color. Indeed, even patients with the most severe form of OCA, OCA type 1A, have a normal complement of epidermal melanocytes.

The major determinant of normal skin color is the activity of the melanocytes, i.e. the quantity and quality of pigment production, not

the density of melanocytes[14]. Several factors play a role in determining the level of melanocyte activity; they include specific characteristics of the individual melanosomes (e.g. the dimensions) as well as both baseline (constitutive) and stimulated (facultative) levels of activity of the enzymes involved in the melanin biosynthetic pathway. The latter are influenced by receptor-mediated interactions with extracellular ligands, e.g. MSH (see below).

FORMATION AND FUNCTION OF THE MELANOSOME

Within the cytoplasm of melanocytes is a unique organelle known as the melanosome, in which melanin pigments are synthesized, deposited and transported. The melanosome is most closely related to the lysosome[15]. Through compartmentalization, both organelles provide protection for the remainder of the cell; lysosomes protect against proenzymes such as proteases, and melanosomes protect against melanin precursors (e.g. phenols, quinones) that can oxidize lipid membranes.

The melanosome contains both matrix proteins (e.g. gp100/Pmel17), which form a scaffolding upon which the melanin is deposited, and proteins (primarily enzymes) that regulate the biosynthesis of melanin. Following their formation via ribosomes, all these proteins are found within the lumen of the rough endoplasmic reticulum (RER, Fig. 65.7). In patients with OCA1 and OCA3 (Table 65.1), misfolded tyrosinase or aberrant tyrosinase-related protein 1 (TYRP1) plus tyrosinase polypeptides, respectively, are retained too long within the lumen of the endoplasmic reticulum (ER; see Fig. 65.7 insert)[16]. As a result of ER quality control, these proteins become targets for destruction by proteasomes and therefore are not incorporated into melanosomes.

Several of the enzymes in the melanin biosynthetic pathway are glycoproteins that require the attachment of sugars in order to gain full function. For this reason, they undergo post-translational modification in the ER and the Golgi apparatus and then join up with the matrix proteins (e.g. gp100/Pmel17) to initiate melanogenesis. The targeting of proteins to the plasma membrane versus intracytoplasmic organelles and the targeting of specific proteins to the correct type of organelle are complicated processes. This triaging requires the equivalent of traffic police within the cell, an example of which is adaptor protein 3 (AP-3). Mutations in the gene that encodes the β3A subunit of AP-3 are responsible for a subset of patients with Hermansky–Pudlak syndrome (HPS2)[17]. Other forms of HPS are due to dysfunction of the proteins that serve as components of *b*iogenesis of *l*ysosome-related *o*rganelles *c*omplexes (BLOCs; Fig. 65.8)[18]. It then follows that these patients have dysfunction of more than one intracytoplasmic organelle (see Table 65.1). The associated hypopigmentation can be explained by the failure to efficiently deliver melanogenic proteins, e.g. tyrosinase, TYRP1, to the melanosomes.

The progression of a melanosome from an organelle that lacks melanin to one that is fully melanized is arbitrarily divided, for convenience, into four stages (Fig. 65.9). Proteins that play a key role in the biogenesis of early-stage melanosomes are gp100/Pmel17, MART-1/Melan-A and the ocular albinism type 1 (OA1) G-protein-coupled receptor[19]. Cleavage and processing of gp100/Pmel17, an amyloidogenic protein, leads to a fibrillar matrix that acts as a scaffold upon which melanin is deposited[20]. As melanin is deposited within the melanosome, the organelle migrates via microtubules into the

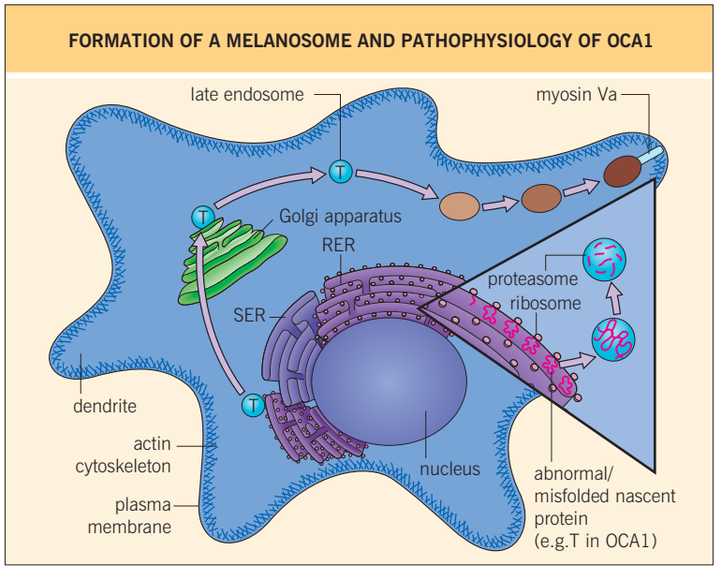

Fig. 65.7 Formation of a melanosome and pathophysiology of oculocutaneous albinism type 1 (OCA1). After glycosylation and processing within the endoplasmic reticulum and Golgi apparatus, several of the enzymes involved in the formation of melanin (including tyrosinase) are packaged in vesicles and then combine with the matrix proteins (e.g. gp100/Pmel17). As more melanin is deposited within the melanosomes, they migrate into the dendrites in preparation for their transfer into neighboring keratinocytes. In patients with OCA1 and OCA3 (triangular insert), tyrosinase polypeptides are retained too long within the lumen of the RER and then become targets for destruction within proteasomes. Thus, they are not incorporated into melanosomes. The primary matrix protein is gp100/Pmel17/silver protein (recognized by HMB45 antibody); formation of the matrix fibers requires cleavage of this protein by a proprotein convertase[15a]. Sorting of proteins to the correct organelles is a complex process and it requires regulators such as adaptor protein 3 (AP-3; see Fig. 65.8); in the case of tyrosinase, specific dileucine residues in its cytoplasmic tail aid in the sorting. RER, rough endoplasmic reticulum; SER, smooth endoplasmic reticulum; T, tyrosinase.

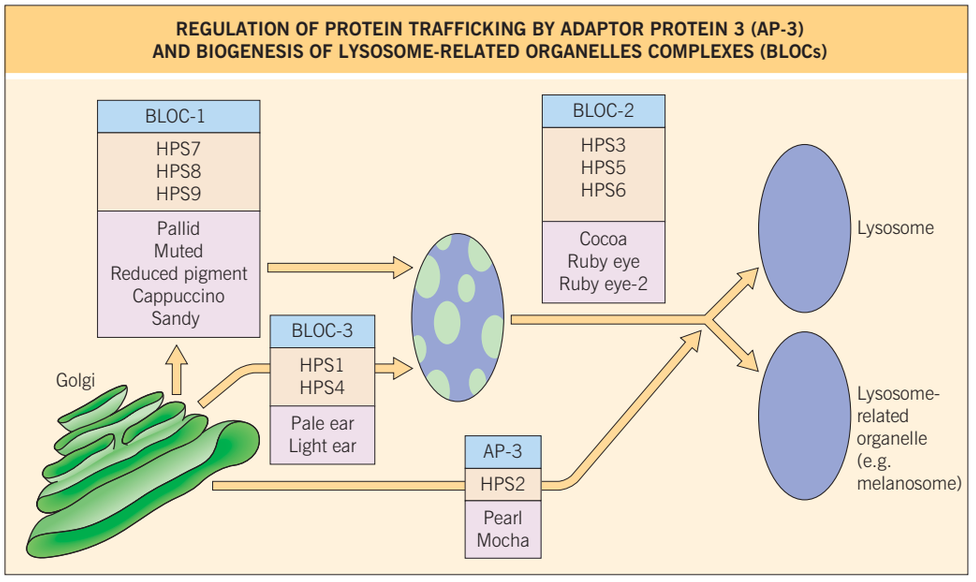

Fig. 65.8 Regulation of protein trafficking by adaptor protein 3 (AP-3) and biogenesis of lysosome-related organelles complexes (BLOCs). The various mouse phenotypes are in light purple-colored boxes. Lysosome-related organelles include melanosomes, platelet dense granules, and lytic granules of cytotoxic lymphocytes and natural killer cells. HPS, Hermansky–Pudlak syndrome. Subtypes of HPS that are associated with a particular BLOC can have similar clinical findings, e.g. patients with HPS1 and HPS4, both members of BLOC-3, develop pulmonary fibrosis and granulomatous colitis.

DISORDERS CHARACTERIZED BY DIFFUSE PIGMENTARY DILUTION IN WHICH THE GENETIC DEFECT IS KNOWN			
Disorder	**Gene**	**Protein product**	**Comments**
		OCULOCUTANEOUS ALBINISM (OCA)	
Type 1A	*TYR*	Tyrosinase	• Complete absence of tyrosinase activity and melanin production • Retention of tyrosinase protein within the ER
Type 1B	*TYR*	Tyrosinase	• Decreased tyrosinase activity; can produce pheomelanin • Retention of tyrosinase protein within the ER • Variant with temperature-sensitive tyrosinase (normal activity at 35°C, but diminished at 37°C)
Type 2	*OCA2* (*P*)	P protein	• Transmembrane protein found in the ER and melanosomes • Possible functions include regulating organelle pH, facilitating vacuolar accumulation of glutathione, and processing/trafficking of tyrosinase
Type 3 (rufous)	*TYRP1*	Tyrosinase-related protein 1*	• TYRP1 stabilizes tyrosinase in mice and humans, and it also functions as a DHICA oxidase in mice • Both "mutant" TYRP1 and tyrosinase are retained in the ER and then degraded
Type 4	*SLC45A2* (*MATP*)	Membrane-associated transporter protein	• Variable phenotype, with hair ranging from white to yellow–brown; most common in Asians • Transmembrane transporter with a role in tyrosinase processing and intracellular trafficking of proteins to the melanosome
		HERMANSKY–PUDLAK SYNDROME†	
1	*HPS1*	HPS1	• Defective trafficking of organelle-specific proteins to melanosomes, lysosomes and cytoplasmic granules (including platelet dense granules and lytic granules in cytotoxic T lymphocytes) • Component of BLOC-3 (see Fig. 65.8)
2	*AP3B1*	β3A subunit of AP-3	• AP-3 is involved in the trafficking of proteins from the trans-Golgi network to appropriate organelles (see Fig. 65.7) • Abnormal binding of AP-3 to CD1 may play a role in associated immunodeficiency
3	*HPS3*	HPS3	• Component of BLOC-2
4	*HPS4*	HPS4	• Component of BLOC-3
5	*HPS5*	Ruby-eye 2 (ru2)	• Component of BLOC-2
6	*HPS6*	Ruby-eye (ru)	• Component of BLOC-2
7	*DTNBP1*	Dysbindin	• Component of BLOC-1
8	*BLOC1S3*	BLOC1S3	• Component (subunit 3) of BLOC-1
9	*PLDN*	Pallidin	• Component of BLOC-1
		CHÉDIAK–HIGASHI SYNDROME	
	CHS1 (*LYST*)	Lysosomal trafficking regulator	• Abnormal vesicle trafficking and fission/fusion of lysosome-related organelles result in giant organelles (e.g. melanosomes, neutrophil granules [lysosomes], platelet dense granules)
		GRISCELLI SYNDROME	
1	*MYO5A*	Myosin Va (attaches melanosomes to actin filaments)	• In all three forms, melanosomes are retained in the body of the melanocyte rather than trafficking to the tips of dendrites for transfer to keratinocytes • Myosin Va expressed in neurons (as well as melanocytes) and dysfunction leads to neurologic abnormalities
2	*RAB27A*	RAB27A (melanosomal membrane GTPase that binds melanophilin)	• GTPase also expressed in hematopoietic cells; defective release of cytotoxic granule contents leads to recurrent infections and hemophagocytic syndrome
3	*MLPH*	Melanophilin (links myosin Va and RAB27A)	• Melanophilin only expressed in melanocytes, so only pigmentary dilution in type 3
	MYO5A	Myosin Va F-exon deletion	• F-exon only expressed in melanocytes

*Recognized by Mel-5 antibody.
†In mice, there are 15 inherited models of Hermansky–Pudlak syndrome; additional genes may be discovered in humans with the condition. Individuals of Puerto Rican origin have HPS1 and 3 (3:1 ratio, respectively); non-Puerto Ricans most commonly have HPS1, followed by 3 and 4.

Table 65.1 Disorders characterized by diffuse pigmentary dilution in which the genetic defect is known. See Chapter 66 for details of clinical findings. AP-3, adaptor protein 3; BLOC, biogenesis of lysosome-related organelles complex (see Fig. 65.8); DHICA, 5,6-dihydroxyindole-2-carboxylic acid; ER, endoplasmic reticulum; TYRP, tyrosinase-related protein.

FOUR MAJOR STAGES OF EUMELANIN MELANOSOMES

Stage	Description	Electron micrographs
I	Spherical; no melanin deposition	II	Oval; obvious matrix in the form of parallel longitudinal filaments; minimal deposition of melanin; high tyrosinase activity	III	Oval; moderate deposition of melanin; high tyrosinase activity	IV	Oval; heavy deposition of melanin; electron-opaque; minimum tyrosinase activity	
Fig. 65.9 Four major stages of eumelanin melanosomes. *Courtesy, Raymond Boissy, PhD.*

MOVEMENT OF MELANOSOMES WITHIN MELANOCYTE DENDRITES

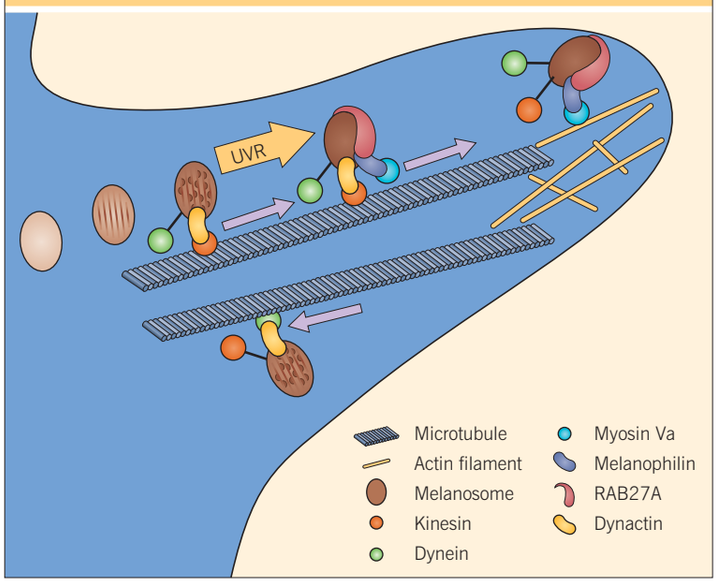

Fig. 65.10 Movement of melanosomes within melanocyte dendrites. As melanin is deposited within melanosomes, they migrate along microtubules from the cell body into dendrites in preparation for transfer to keratinocytes. Kinesin and dynein serve as molecular motors for microtubule-associated anterograde and retrograde melanosomal transport, respectively, and UVR results in augmented anterograde transport via increased kinesin and decreased dynein activity. Myosin Va, which is linked to the melanosomal RAB27A GTPase by melanophilin, captures mature melanosomes when they reach the cell periphery and attaches them to the actin cytoskeleton.

dendrites in preparation for transfer into the neighboring keratinocytes, either within the epidermis or within the anagen hair matrix. In addition to microtubules, proteins such as kinesin and dynein are involved in the movement of melanosomes (Fig. 65.10)[21].

Within the dendrites, there is a specialized myosin (Va) protein that aids in the process of melanosome transfer by assisting attachment between the actin cytoskeleton beneath the plasma membrane and the organelle itself (via RAB27A and melanophilin). The importance of the interactions between these three proteins – myosin Va, RAB27A and melanophilin – is illustrated by the three different forms of Griscelli syndrome in which there are mutations in the respective genes (see Table 65.1)[22,23]. The associated diffuse pigmentary dilution is a reflection of a lack of transfer of melanosomes from the melanocytes to nearby keratinocytes. Histologically, numerous melanosomes are seen to congregate within the center of the melanocytes.

VARIATION OF PREDOMINANT MELANOSOMAL STAGES WITH LEVEL OF CUTANEOUS PIGMENTATION

	Predominant melanosomal stages	
Pigmentation of skin	Melanocytes	Keratinocytes
Fair	II, III	Occasional III
Medium	II, III, IV	III, IV
Dark	IV > III	IV

Table 65.2 Variation of predominant melanosomal stages with level of cutaneous pigmentation.

MELANOSOMES IN LIGHTLY PIGMENTED VERSUS DARKLY PIGMENTED SKIN

	Lightly pigmented skin	Darkly pigmented skin
Melanization	Stages II, III	Stage IV
Size (diameter)	0.3–0.5 microns	0.5–0.8 microns
Number per cell	<20	>200
Distribution of melanosomes within the lysosomes of keratinocytes	Groups of 2–10	Single
Degradation	Fast	Slow

Table 65.3 Melanosomes in lightly pigmented versus darkly pigmented skin.

To reiterate, normal pigmentation of the skin is dependent on an orderly transfer of melanosomes from melanocytes to keratinocytes. When this transfer is disrupted, either in inherited diseases such as Chédiak–Higashi and Griscelli syndromes or in acquired diseases such as atopic dermatitis, the result is hypopigmentation. In the former there is diffuse pigmentary dilution, whereas in the latter the hypopigmentation is circumscribed. Phagocytosis of melanosomes by keratinocytes can be triggered by activation of the keratinocyte growth factor (KGF) receptor (KGFR/FGFR2b) by KGF, also referred to as fibroblast growth factor 7[24], as well as by activation of protease-activated receptor 2 (PAR-2). Inhibitors of PAR-2 receptor–ligand interactions (e.g. inhibitors of serine proteases) have led to cutaneous hypopigmentation in animal models[25] and in the future may be used to treat disorders of hyperpigmentation.

In summary, it is the activity of the melanocytes and their interactions with neighboring keratinocytes, not their density, that is the major determinant of normal skin color. The activity of a melanocyte is reflected in the number of melanized melanosomes it produces as well as in its efficiency at transferring those melanosomes to keratinocytes. For example, primarily stage II and stage III melanosomes are seen in lightly pigmented skin, whereas primarily stage IV melanosomes are seen in darkly pigmented skin (Table 65.2). An additional factor is the rate of degradation of the melanosomes once they are transferred to the surrounding keratinocytes and this is related in part to the size of the individual melanosomes. The smaller melanosomes of lightly pigmented skin are clustered in groups of two to ten within secondary lysosomes in the keratinocytes and are degraded by the mid stratum spinosum (Table 65.3)[14]. In darkly pigmented skin, the melanosomes are larger and singly dispersed within lysosomes of the keratinocytes; they are degraded more slowly, such that melanin granules can still be found in the stratum corneum.

REGULATION OF MELANIN BIOSYNTHESIS

This section will begin with a review of the melanin biosynthetic pathway and then examine the factors, both external and internal, that

can influence the level of melanin production. The "starting material" for the production of melanin, both the brown–black eumelanin and the yellow–red pheomelanin, is the amino acid tyrosine. The key regulatory enzyme in the pathway is tyrosinase, which controls the initial biochemical reaction in this pathway, tyrosine hydroxylation. Tyrosinase also catalyzes additional steps in the biosynthesis of melanin, e.g. the oxidation of dihydroxyindole (Fig. 65.11). It should then come as no surprise that the initial investigations into the molecular basis of OCA focused on the gene that encodes tyrosinase.

In OCA1A, the form of OCA where mutations in both copies of the tyrosinase gene lead to complete loss of enzyme activity, no melanin is found in the hair, skin or eyes (see Table 65.1). However, in OCA1B, where there is decreased enzyme activity, pheomelanin is produced, especially in the hair as the patient ages. As a result, patients with this form of OCA were previously referred to as yellow mutants, a name that has fallen out of favor for obvious reasons. The formation of pheomelanin requires less tyrosinase activity than does the formation of eumelanin (see Fig. 65.11) and therefore the formation of pheomelanin can be thought of as a default pathway.

The activity of tyrosinase is enhanced by DOPA and is stabilized by tyrosinase-related protein 1 (TYRP1) (see below). Competitive inhibitors of tyrosinase activity include hydroquinone, which is used to treat disorders of hyperpigmentation such as melasma, and L-phenylalanine. In patients with phenylketonuria (PKU), there is a diffuse pigmentary dilution due to elevated levels of L-phenylalanine resulting from a deficiency in the enzyme L-phenylalanine hydroxylase that converts L-phenylalanine to L-tyrosine[14]. The characteristic blonde hair of PKU can undergo darkening when the patient is on a low-phenylalanine diet. Of note, tyrosinase is a copper-requiring enzyme and it has two putative copper-binding sites. Rare cases of copper deficiency can lead to diffuse cutaneous pigmentary dilution, and in patients with Menkes kinky hair disease, where a transmembrane Cu^{2+}-transporting ATPase that delivers copper to melanosomes is dysfunctional[26], the kinky hair is hypopigmented.

In a test tube, L-DOPA can spontaneously oxidize to form melanin, an insoluble biopolymer. For this reason, original descriptions of the melanin biosynthetic pathway had tyrosinase as its sole enzyme. However, by the late 1970s, it was becoming clear that there were additional control points in the pathway (see Fig. 65.11). For example, tyrosinase-related protein 2 (TYRP2), so named because its amino acid sequence is similar to that of tyrosinase, converts DOPAchrome to 5,6-dihydroxyindole-2-carboxylic acid (DHICA), hence its initial name DOPAchrome tautomerase. In mice and humans, TYRP1 stabilizes tyrosinase[27] and mutations in both copies of the *TYRP1* gene lead to OCA3 (rufous OCA; see Table 65.1).

Decreased function of yet another transmembrane protein, the P protein (Fig. 65.12), leads to OCA2[28] (see Table 65.1). Based upon its amino acid sequence, a prediction was made that the P protein was involved in the transport of small molecules across the membrane of the melanosome. Tyrosine, the initial precursor in the melanin biosynthetic pathway, was considered the most likely candidate for transmembrane transport. However, this appears not to be the case. More recent data suggest that the P protein regulates processing and trafficking of tyrosinase, possibly via control of pH or glutathione content within intracellular compartments[29].

Melanins represent a group of complex polymers whose functions vary from camouflage to the quenching of oxidative free radicals generated via exposure to UV radiation (UVR). The level and type of melanin production is a complex interplay of the activity of the various enzymes involved in the biosynthetic pathway as well as the activity of proteins such as the P protein and those that stabilize the activity of tyrosinase (e.g. TYRP1). Several factors are known to influence the activity of

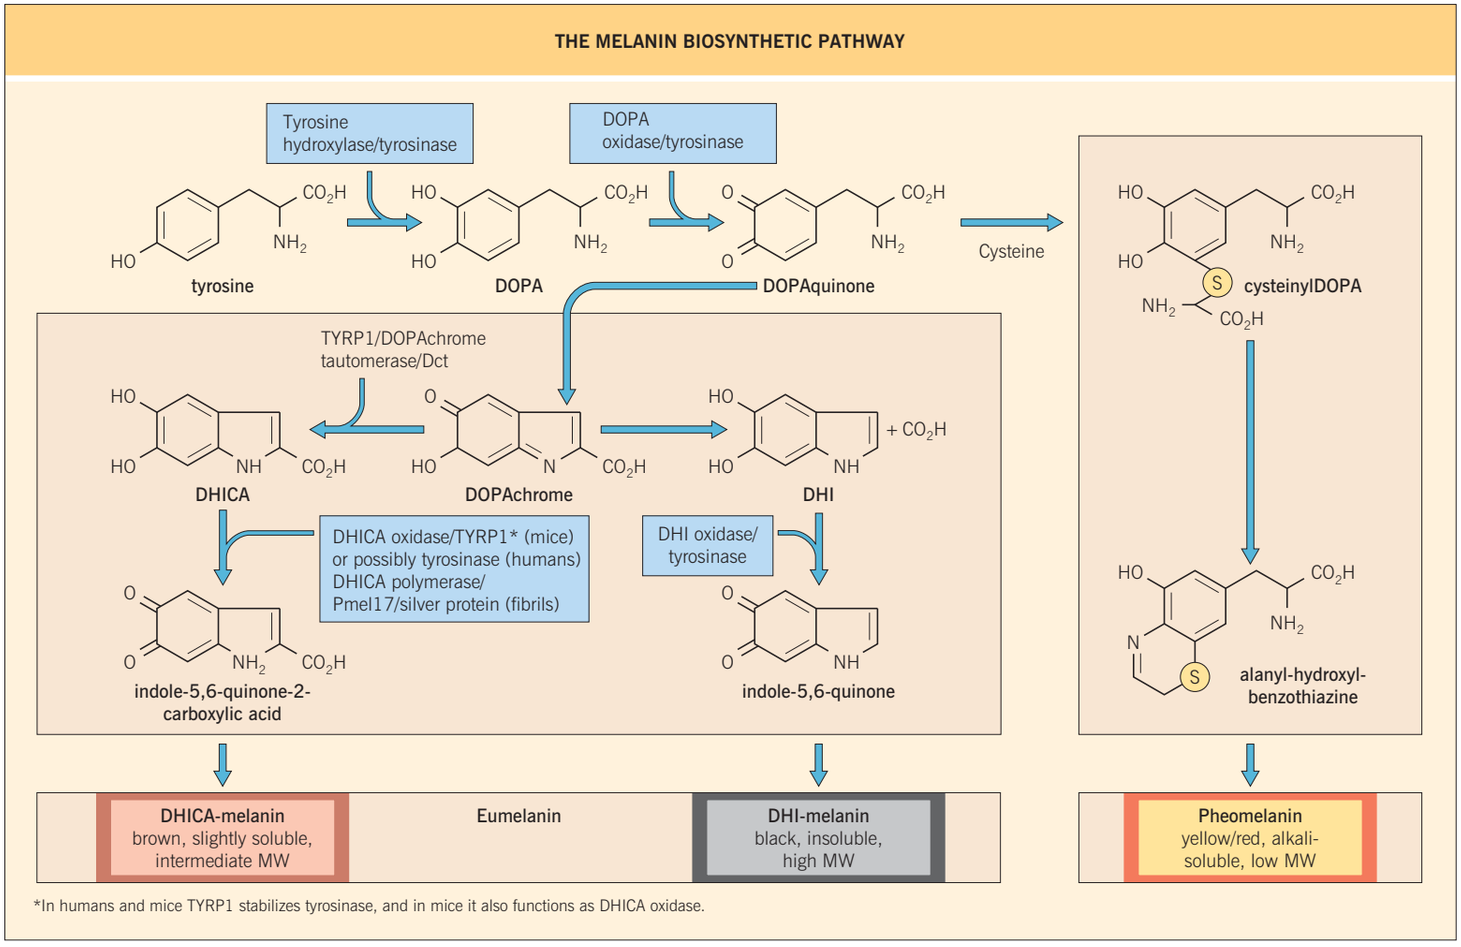

Fig. 65.11 The melanin biosynthetic pathway. The pathway includes the sites of dysfunction in OCA1 (tyrosinase) and OCA3 (TYRP1). The two major forms of melanin in the skin and hair are brown–black eumelanin and yellow–red pheomelanin. The enzymes are transmembrane proteins located within the melanosome. these key proteins of melanogenesis, and they include MSH, basic fibroblast growth factor (bFGF), endothelin-1 and UV light (see below).

Among the multiple protein products of the proopiomelanocortin (*POMC*) gene are adrenocorticotropic hormone (ACTH), β-endorphin, and the three forms of MSH (α, β and γ) (Fig. 65.13); in humans, α-MSH represents the major biologically active form of MSH. The primary site of expression of the *POMC* gene is the pituitary gland; however, other sites of expression include the testis, the endothelium, and, of particular importance, the epidermis (keratinocytes). Although MSH is classically associated with the pigmentary system, this peptide has a wide range of biologic properties, including suppression of inflammation and regulation of body weight. For example, mutations in the *POMC* gene can result in severe early-onset obesity, adrenal insufficiency and red hair[30]. It should then come as no surprise that mutations in the genes that encode the receptors to which the protein products of the *POMC* gene bind can lead to similar clinical findings; for example, mutations in the *MC4-R* gene are associated with morbid obesity and "mutations" (variants) in the *MC1-R* gene are associated with red hair (see below). Of note, afamelanotide (4-norleucyl-7-phenylalanine-α-MSH), which has enhanced binding to MC1-R, can lead to cutaneous hyperpigmentation when administered subcutaneously; patients with erythropoietic protoporphyria treated with a subcutaneous implant of afamelanotide experienced less phototoxic reactions and could tolerate more direct sunlight without pain.

As outlined in Table 65.4, there are five major melanocortin receptors, all of which have seven transmembrane domains (Fig. 65.14). Although the MC1-R is present on a variety of cells found within the

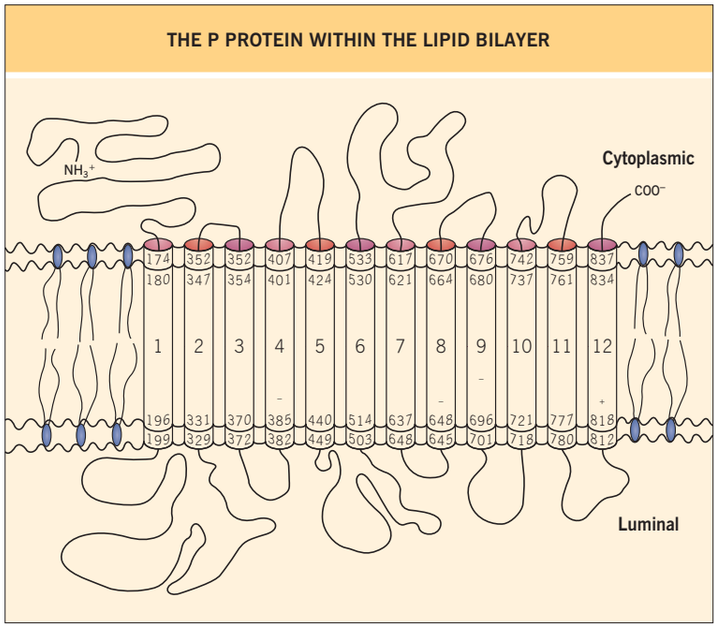

Fig. 65.12 The P protein within the lipid bilayer. The polypeptide has 12 putative transmembrane domains. The membrane-associated transporter protein (MATP) which is dysfunctional in OCA4 has a similar configuration within the plasma membrane. *Adapted from Rinchik EM, Bultman SJ, Horsthemke B, et al. Pituitary hypersecretion of ACTH and/or α-MSH can lead to generalized hyperpigmentation in patients with Addison's disease. ac, acetylated; ACTH, adrenocorticotropic hormone; des, desacetyl; END, endorphin; JP, joining peptide; LPH, lipotropic hormone; MSH, melanocyte stimulating hormone; PC, prohormone-converting enzyme; POMC, proopiomelanocortin.

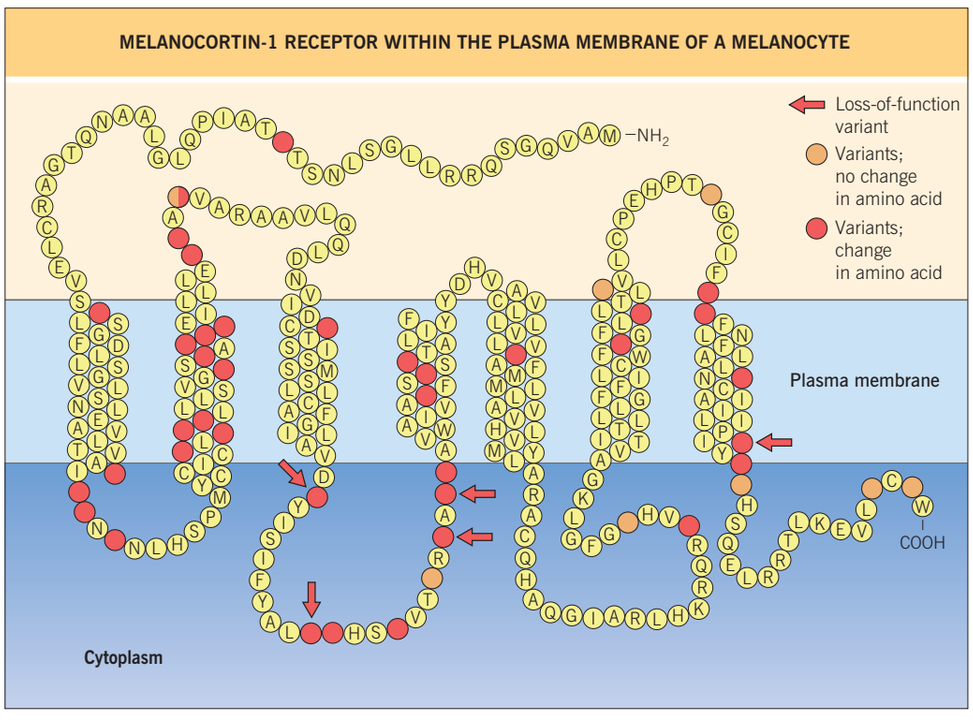

Fig. 65.14 Melanocortin-1 receptor within the plasma membrane of a melanocyte. The red dots represent alterations in the amino acid sequence (variants) compared with the wild type. Some of the variants are due to loss-of-function mutations, i.e. the expected increase in intracellular cAMP is not observed following the binding of MSH, whereas others have no effect on function or lead to decreased function. Loss-of-function variants, e.g. Arg151Cys, Arg160Trp and Asp294His, have been associated with red hair as well as cutaneous melanoma (see Table 65.5). The tan dots represent synonymous variants where there is no change in amino acid sequence.

MAJOR FORMS OF THE MELANOCORTIN RECEPTOR		
Receptor	**Distribution, major (minor)**	**Ligands**
MC1-R*	Melanocytes (keratinocytes, fibroblasts, endothelial cells, antigen-presenting cells)	α-MSH, ACTH > β-MSH
MC2-R	Adrenal cortex (adipocytes)	ACTH
MC3-R†	Brain (gut, placenta)	α-, β-, γ–MSH, ACTH
MC4-R†	Brain	α-, β-MSH, ACTH
MC5-R	Peripheral tissues (sebaceous glands, fibroblasts, adipocytes)	α-, β-MSH, ACTH

*Antagonistic ligands – agouti protein (mouse) and agouti signaling protein (ASIP; human).
†Antagonistic ligand – agouti-related protein (AGRP).

skin, from endothelial cells to fibroblasts, the highest density of this receptor is seen on melanocytes[31]. As in the case of the β-adrenergic receptor, the MC1-R is a G-protein-coupled receptor, i.e. it uses proteins that bind guanosine triphosphate (GTP) and guanosine diphosphate (GDP) as intermediary messengers (Fig. 65.15). Following the binding of MSH to the MC1-R, the protein pair interacts with a complex of G proteins. The GTP-$G_s\alpha$ subunit then activates adenylate cyclase, leading to increased production of cyclic adenosine monophosphate (cAMP) within the melanocyte. An increase in the intracellular concentration of cAMP leads to an increase in tyrosinase activity and eumelanin production via MITF (see Fig. 65.4). If the MC1-R is dysfunctional and fails to initiate a significant rise in the intracellular level of cAMP, then pheomelanogenesis is favored (Fig. 65.16). Of note, the majority of individuals with red hair are compound heterozygotes or homozygotes for a loss-of-function mutation in the gene that encodes the MC1-R[1,32] (see Fig. 65.14).

MC1-R also interacts with a protein known as the agouti protein (mouse) or agouti signaling protein (ASIP; human). Agouti is a term

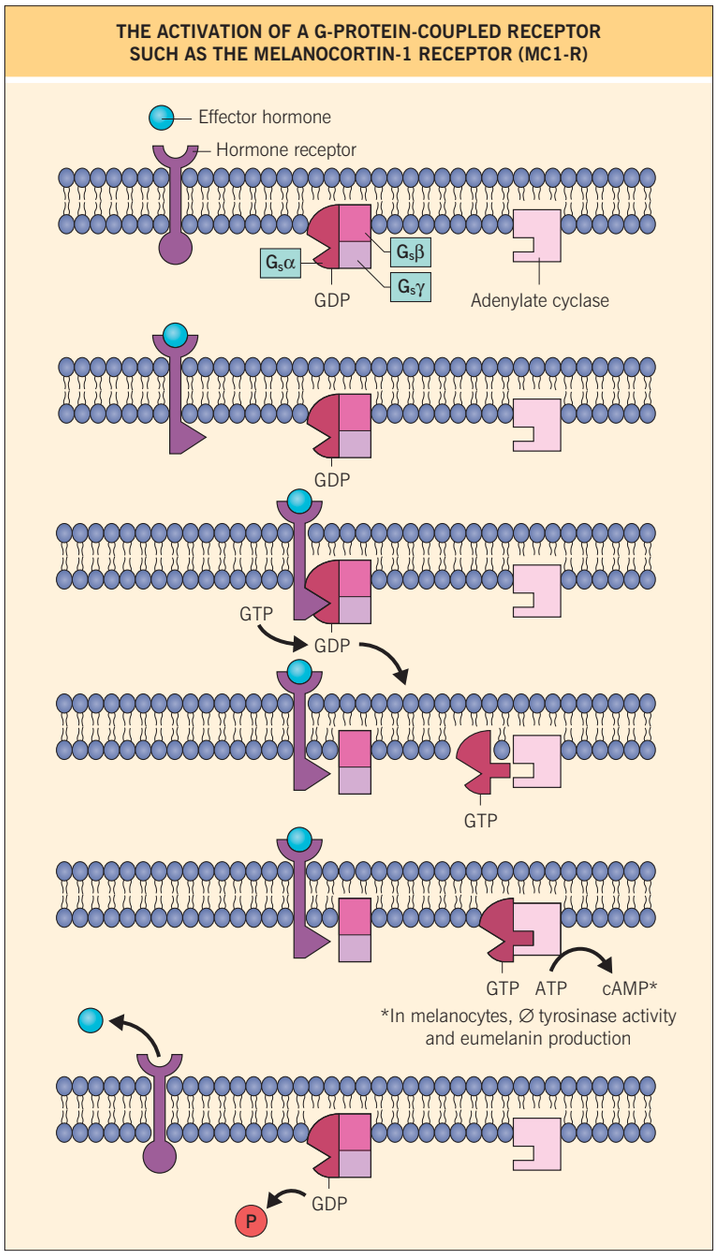

Fig. 65.15 Activation of a G-protein-coupled receptor such as the melanocortin-1 receptor (MC1-R). In the case of the MC1-R, the increase in the intracellular concentration of cAMP leads to an increase in tyrosinase activity and eumelanin production. Fig. 65.16 Interaction of melanocyte stimulating hormone (MSH) and agouti protein with the melanocortin-1 receptor (MC1-R). A There is baseline activity of the MC1-R, enhanced by binding with MSH. Agouti protein represents an antagonist ligand for the MC1-R whose binding can lead to pheomelanogenesis. Dysfunction of the MC1-R can also lead to pheomelanogenesis, as in the case of humans with red hair. **B** Interactions are actually more complex, in that to be fully effective, agouti requires attractin and mahogunin; the former aids in the binding of agouti to MC1-R while the latter acts on the cytosolic side. There is also a neutral agonist, β-defensin, which interferes with both agonist and antagonist binding. *Adapted from Schiaffino MV. Signaling pathways in melanosome biogenesis and pathology. Int J Biochem Cell Biol. 2010;42:1094–104.*

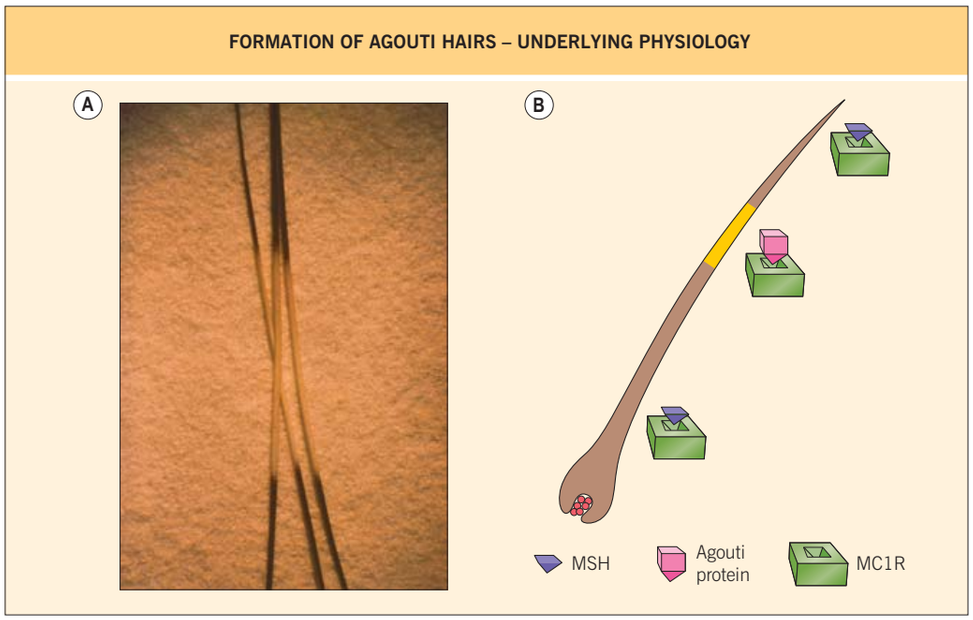

Fig. 65.17 Formation of agouti hairs – underlying physiology. A Fox hairs with alternating eumelanin and pheomelanin production within individual hairs, a pattern referred to as agouti. **B** Explanation for the agouti pattern based on different ligands interacting with the melanocortin 1 receptor (MC1-R). Both gain-of-function mutations at the agouti locus and loss-of-function of MC1-R can lead to yellow-haired mice. In the CNS, an abundance of agouti protein leads to obesity, and yellow mice with gain-of-function mutations at the agouti locus are also obese[33].

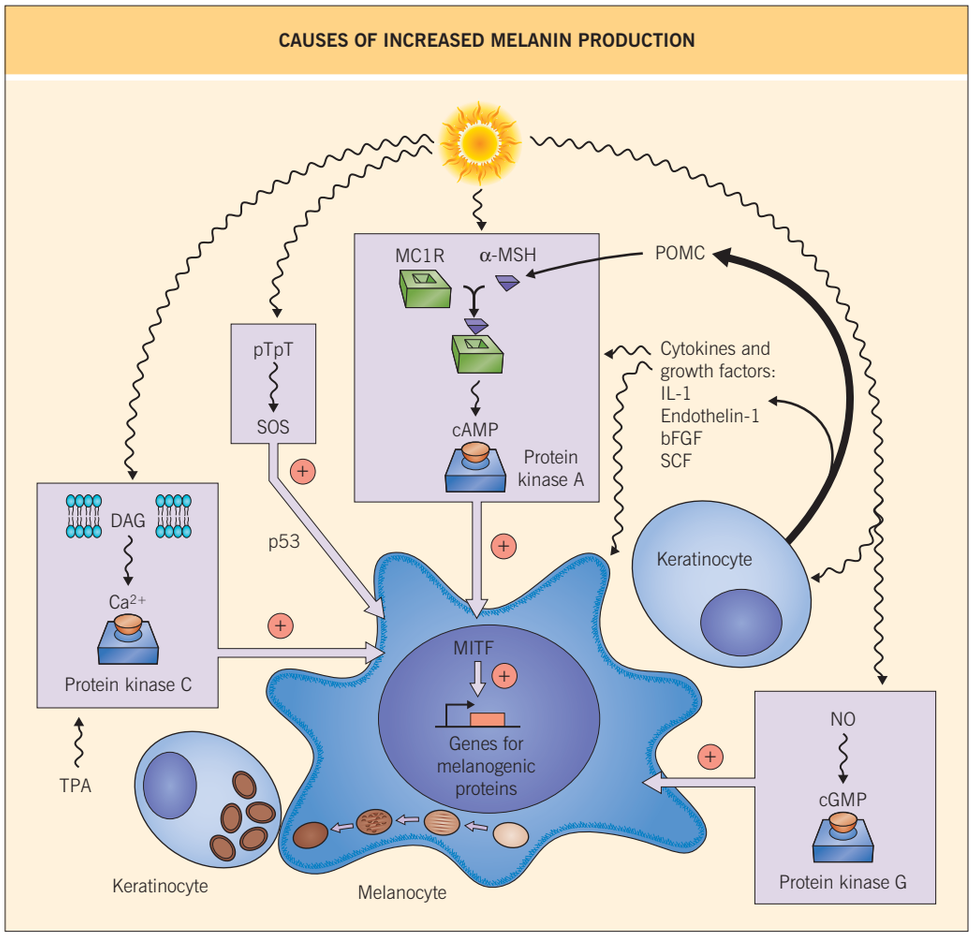

Fig. 65.18 Causes of increased melanin production. These include an increase in one or more of the following: (1) expression of proopiomelanocortin (POMC) and its derivative peptides by cells within the skin, in particular keratinocytes; (2) the number of melanocortin-1 receptors (MC1-R) on melanocytes; (3) the release of diacylglycerol (DAG) from the plasma membrane, which activates protein kinase C; (4) the induction of an SOS response to UVR-induced DNA damage; (5) nitric oxide (NO) production, which activates the cGMP pathway; and (6) production of cytokines and growth factors by keratinocytes. As a result, there is enhanced transcription of the genes that encode microphthalmia-associated transcription factor (MITF) and melanogenic proteins including tyrosinase, tyrosinase-related protein 1 (TYRP1), TYRP2, gp100/Pmel17, and P. In addition, melanocyte dendricity and transfer of melanosomes to keratinocytes is stimulated via increased activity of Rac1 (involved in dendrite formation), the ratio of kinesin to dynein, and expression of protease-activated receptor-2 (PAR2; involved in melanosome transfer). TPA, tetradecanoyl phorbol acetate.

used to describe the banding of hairs seen in some mammals, e.g. dogs, foxes and mice, which is due to alternating production of eumelanin and pheomelanin (Fig. 65.17). The production of agouti protein by the cells in the hair papillae is cyclic, and, when the agouti protein is present, it effectively competes with MSH and the formation of pheomelanin within pheomelanosomes is favored[34,35] (see Fig. 65.16); the latter are characterized by a more spherical shape (compared with eumelanosomes) and the presence of an unstructured matrix with vesicular bodies.

An enhancement of pigment production can be seen following exposure of melanocytes to agents that increase intracytoplasmic levels of cAMP (see Fig. 65.15) such as cholera toxin, forskolin[36], dibutyryl cAMP and MSH. The activation of protein kinase A (PKA) by cAMP leads to the placement of phosphate groups on other proteins, which leads to their activation. One of the proteins that is phosphorylated by PKA is the *c*AMP *r*esponse-*e*lement *b*inding protein (CREB), which functions as a transcription factor, regulating the expression of other genes, including *MITF* (see Fig. 65.4). Patients with the

McCune–Albright syndrome (polyostotic fibrous dysplasia) are mosaics for an activating mutation in the gene that encodes the G protein $G_s\alpha$ (see Fig. 65.15). As a result, the cAMP cascade is permanently "turned on" and, with continued transcription of the CREB-controlled genes, there is hyperplasia of the bones and endocrine organs, albeit in a mosaic pattern. Presumably within the segmental café-au-lait macules typical of this disorder, the increase in intracellular cAMP leads to increased tyrosinase activity and eumelanin production.

Exposure of melanocytes to phorbol esters, e.g. tetradecanoyl phorbol acetate (TPA), can lead to increased melanin formation via the activation of protein kinase C (PKC) (Fig. 65.18). Growth factors, in particular bFGF, can also lead to an increase in the pigment content within melanocytes. Endothelin-1, a small peptide originally isolated from endothelial cells, is produced by keratinocytes and can lead to an increase in tyrosinase activity followed by an increase in melanin production.

Multiple genes have been implicated as playing a role in normal pigment variation in humans, including *MC1-R*, *SLC24A5*, *ASIP* and *OCA2 (P)* (Table 65.5)[2,3]. For example, the presence of a variant (rather than the African ancestral) allele of *SLC24A5*, whose protein product is a putative cation exchanger in the melanosomal membrane, correlates with lighter skin color[4]. In addition, variants in the *OCA2 (P)* gene are thought, at least in part, to determine the normal phenotypic variation in human eye color[2]. A haplotype with several polymorphisms in *ASIP* (and presumably a gain of ASIP function) has been associated with red or blonde hair, freckling and a tendency to burn, while variants that lead to destabilized *ASIP* mRNA have been associated with darker skin phototypes[3,37,38]. Of note, some loss-of-function mutations in *MC1-R* confer a risk for developing cutaneous melanoma, independent of pigmentary phenotype (see Table 65.5)[32].

Ultraviolet Irradiation

Following a single exposure to UVR, an increase in the size of melanocytes can be observed, along with an increase in tyrosinase activity[14]. Repeated exposures to UVR lead to an increase in the number of stage IV melanosomes transferred to keratinocytes, as well as an increase in the number of active melanocytes. When chronically sun-exposed sites (e.g. the upper outer arm) are compared with non-sun-exposed sites

GENES ASSOCIATED WITH PHYSIOLOGIC VARIATION IN HUMAN PIGMENTATION

Table 65.5 Genes associated with physiologic variation in human pigmentation[44–49]. Gray highlight = polymorphism associated with darker pigmentation. The genes in the first four rows are those responsible for OCA types 1 to 4. ASIP, agouti signaling protein; BCC, basal cell carcinoma; MATP, membrane-associated transporter protein; MC1R, melanocortin-1 receptor; NCKX5, Na-Ca-K exchanger 5; NMSC, non-melanoma skin cancer; SCC, squamous cell carcinoma; SLC24A4/5, solute carrier family 24, member 4/5; SLC45A2, solute carrier family 45, member 2; TPCN2, two-pore segment channel 2; TYRP1, tyrosinase-related protein 1. *From Schaffer JV, Bolognia JL. The biology of the melanocyte. In: Cancer of the Skin. Rigel DS, et al. (eds). 2nd ed. St Louis, MI: Elsevier, 2011:23–39.*

(e.g. the upper inner arm), the density of melanocytes is up to two times greater in sun-exposed sites[39]. Melanocytes, like other neural-derived tissues, have a low mitotic rate, and whether this increase in number represents an increase in mitotic rate or an activation of "inactive" melanocytes or melanocyte precursors is not known.

Following exposure to UVA irradiation, an *immediate pigmentary darkening* can be observed, which occurs within minutes and fades over 6–8 hours. It is clinically most obvious in darkly pigmented skin and is thought to represent oxidation of pre-existing melanin or melanin precursors. *Delayed tanning* is visible within 48–72 hours of exposure to UVB and UVA radiation and represents new pigment production via an increase in tyrosinase activity. In addition to an increase in melanocyte size and number, tyrosinase activity, and transfer of melanosomes to keratinocytes, the response to PUVA includes an alteration in size and aggregation pattern of melanosomes, i.e. from smaller and grouped to larger and singly dispersed (see Table 65.3).

UVR may work by increasing one or more of the following:

- transcription of the tyrosinase gene (via MITF)
- the number or activity of MC1-R on melanocytes
- the expression of POMC and its derivative peptides by keratinocytes and other cells within the dermis
- the release of diacylglycerol from the plasma membrane, which activates protein kinase C
- an activation of the nitrous oxide/cGMP pathway
- the production of cytokines and growth factors (e.g. endothelin-1) by keratinocytes
- the induction of an SOS response to UVR-induced DNA damage[31,40,41]
- transactivation of the *POMC* promoter by p53[42,43]
- the ratio of kinesin to dynein (see Fig. 65.10).

The inability of the majority of red-haired individuals to develop a tan following exposure to UVR can be explained, at least in part, by dysfunction of the MC1-R on their melanocytes. This phenomenon, along with the production of oxygen radicals following the UV irradiation of pheomelanins, probably contributes to the increased incidence of both cutaneous melanoma and non-melanoma skin cancers in persons with red hair.

INTRODUCTION

Leukoderma and hypopigmentation are general terms used to designate disorders characterized by lightening of the skin. They are classically the result of decreased epidermal melanin content (melanin-related), but they may be secondary to a decreased blood supply to the skin (hemoglobin-related). Hypomelanosis is a more specific term that denotes an absence or reduction of melanin within the skin; amelanosis signifies the total absence of melanin. Depigmentation usually implies a total loss of skin color, most commonly due to disappearance of pre-existing melanin pigmentation, as in vitiligo. The term pigmentary dilution is used to describe a generalized lightening of the skin and hair, as in oculocutaneous albinism; this may be apparent only if affected individuals are compared with unaffected relatives.

Cutaneous hypomelanosis is often classified into two groups:

- *melanocytopenic hypomelanosis*, caused by a partial or total absence of epidermal and/or follicular melanocytes
- *melanopenic hypomelanosis*, in which the number of epidermal and/or follicular melanocytes is normal but the pigment cells fail to synthesize normal amounts of melanin and/or transfer it to surrounding keratinocytes.

Melanocytopenic hypomelanosis may be hereditary and/or congenital due to a defect in melanoblast differentiation, proliferation, migration and/or survival, or it may be acquired. In the latter case, functional melanocytes often disappear as a result of their destruction (e.g. via external trauma, such as cryosurgery, or an autoimmune attack). The factors controlling melanocyte survival may also play a role in the postnatal disappearance of dermal melanocytes. Melanopenic hypomelanosis may result from a number of complex pathologic mechanisms, including abnormalities in melanosomes (e.g. their biogenesis, melanization, transfer or degradation) or melanin removal.

DIAGNOSIS OF LEUKODERMAS[1]

Any patient with a leukoderma should be fully examined under both visible and UVA light (i.e. ~365 nm wavelength in a Wood's lamp). The latter is particularly useful in circumscribed leukodermas, individuals who have very lightly pigmented skin (types I or II), and neonates. Under visible light, it is sometimes difficult to distinguish between hypomelanosis and amelanosis, but the greater the loss of epidermal pigmentation, the more marked the contrast on Wood's lamp examination. This technique is also helpful in differentiating hypomelanotic macules from hemoglobin-related leukodermas; for example, nevus anemicus becomes inapparent.

Most leukodermas are diagnosed clinically following a complete history and physical examination. Histologic examination of involved skin is most helpful for hypomelanoses associated with inflammatory processes (e.g. sarcoidosis, lichen sclerosis). Occasionally, quantification of the epidermal melanocyte density is performed via incubation of biopsy specimens with dihydroxyphenylalanine (DOPA; detects melanocytes with tyrosine activity) or melanocyte-specific immunohistochemical stains such as Mel-5 and Melan-A/MART-1. Ultrastructural studies are performed primarily for research purposes to characterize the subcellular events of melanogenesis (see Ch. 65) because very few hypomelanotic disorders have specific ultrastructural findings.

VITILIGO

Vitiligo is an acquired disorder characterized by circumscribed depigmented macules and patches that result from a progressive loss of functional melanocytes.

Epidemiology

Vitiligo affects approximately 0.5–2% of the general population worldwide[2], and it may appear any time from shortly after birth to late adulthood. The average age of onset is approximately 20 years. Although patients with vitiligo often attribute the onset of their disease to specific life events (e.g. physical injury, sunburn, emotional distress, illness or pregnancy), with the exception of the Koebner phenomenon, there is no proof that these factors cause or precipitate vitiligo.

Pathogenesis

Vitiligo is a multifactorial disorder related to both genetic and non-genetic factors. It is generally agreed that there is an absence of functional melanocytes in vitiligo skin and that the loss of immunohistochemically recognizable melanocytes is the result of their destruction.

In addition to the typical "absolute" type of vitiligo in which there are no DOPA-positive melanocytes (see Fig. 65.6), "relative" types of vitiligo in which melanocytes remain within the lesions but have decreased DOPA-positivity have been observed. It is possible that relative types of vitiligo are forerunners of the absolute type. In general, immunohistochemical evaluation of the epidermis from vitiligo lesions with antibodies to melanocyte markers (related and unrelated to melanogenic activity) cannot detect melanocytes[3]. In addition, the KIT receptor, a protein expressed early in melanocyte differentiation, is undetectable in vitiligo skin, suggesting that putative melanocyte precursors are no longer present. It is therefore thought that melanocytes are absent or present in very small numbers in lesions of vitiligo.

With regard to the epidermal milieu, cytoplasmic vacuolization of keratinocytes and the presence of extracellular granular material (which may be derived from the cytoplasm of altered keratinocytes) have been noted; these findings are most prominent in adjacent normal-appearing skin but may also be evident at the border between lesional and adjacent skin and, occasionally, in lesional skin. Keratinocyte-derived cytokines such as stem cell factor (SCF; KIT ligand), tumor necrosis factor-α (TNF-α) and interleukin (IL)-1 could play a role in the disappearance of the melanocytes[4]. Indeed, levels of SCF are decreased and levels of TNF-α and IL-1 are increased in lesional vitiligo skin compared to non-lesional skin[5–8]. Of note, topical tacrolimus, which has been found to be an effective treatment for vitiligo (see below), decreases TNF-α expression when applied to affected skin[9].

The Langerhans cell density of vitiligo skin, evaluated either by histochemical techniques (ATPase) or by monoclonal antibodies

SELECTED SUSCEPTIBILITY LOCI AND CANDIDATE GENES FOR VITILIGO		
Chromosomal location	**Candidate gene**	**Defective protein**
1p13	*PTPN22*	Protein tyrosine phosphatase, non-receptor type 22
1p31.3	*FOXD3**	Forkhead box D3*
1p36.23	*RERE*	Arginine–glutamic acid dipeptide (RE) repeats
3p14.1	*FOXP1*	Forkhead box P1
3q27–q28	*LPP*	LIM domain containing preferred translocation partner in lipoma
5q22.1	*TSLP*	Thymic stromal lymphopoietin
6p21.3	*HLA* (various genes)	Major histocompatibility complex classes I, II and III
6q27	*CCR6*	Chemokine (C-C motif) receptor 6
	SMOC2	SPARC related modular calcium binding 2
10p15–p14	*IL2RA*	Interleukin 2 receptor α
11q14–q21	*TYR*	Tyrosinase
14q11.2	*GZMB*	Granzyme B
17p13	*NLRP1* (formerly *NALP1*)	Nod-like receptor family, pyrin domain containing 1 (Fig. 66.1)
21q22.3	*UBASH3A*	Ubiquitin associated and SH3 domain containing A
22q12.1	*XBP1*	X-box binding protein 1
22q13.1	*C1QTNF6*	C1q and tumor necrosis factor related protein 6
Xp11.23	*FOXP3*	Forkhead box P3

*In one family to date, a functional variant in the promoter of the *FOXD3* melanoblast developmental regulator gene was associated with autosomal dominant inheritance of an atypical vitiligo phenotype (early onset, widespread, progressive depigmentation).

Table 66.1 Selected susceptibility loci and candidate genes for vitiligo. Virtually all of these genes encode immunoregulatory proteins, with the notable exception of tyrosinase. Genome-wide association studies have identified other susceptibility loci, including 7p13, 7q11, 9q22 and (in Chinese patients) 4q13–q21. HLA, human leukocyte antigen.

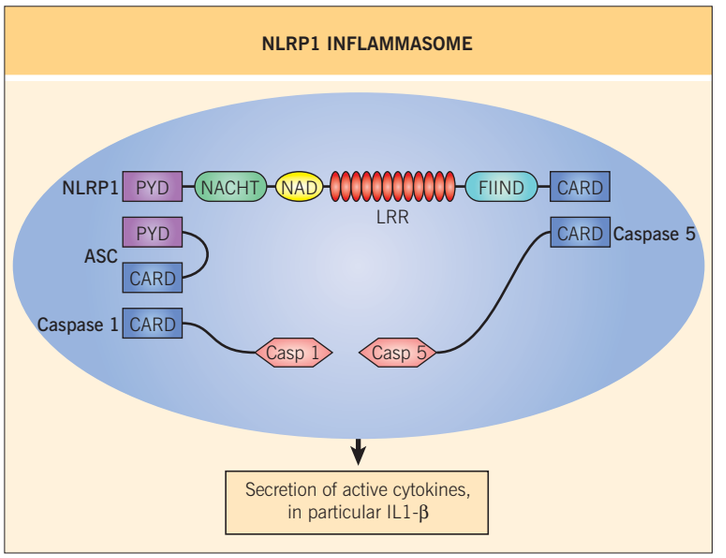

Fig. 66.1 NLRP1 inflammasome. NLRP1 (NOD-like receptor family, pyrin domain containing 1; previously known as NALP1 [NACHT, leucine rich repeat and pyrin domain containing 1]) is an intracellular pattern recognition receptor that stimulates the innate immune system in response to pathogen-associated molecular patterns (e.g. bacterial peptides) and host-derived danger signals. It functions in a cytoplasmic complex, referred to as the NLRP1 inflammasome, that activates caspase-1 and converts proinflammatory interleukins (e.g. pro–IL-1β, pro–IL-18) into their active forms. Variants in the *NLRP1* gene have been associated with vitiligo and other autoimmune diseases. CARD, caspase-recruitment domain; LRR, leucine-rich repeats; NAD, NACHT-associated domain; PYD, pyrin domain.

(anti-CD1a and HLA-DR), has been variably reported as decreased, normal or increased. Functional impairment and degenerative changes (particularly in marginal areas where they are more plump and have shorter dendrites) in Langerhans cells have also been observed. These findings suggest that vitiligo affects the entire keratinocyte–Langerhans cell–melanocyte unit[10].

Genetics of vitiligo

Both twin and family studies indicate the importance of genetic factors in the development of vitiligo, which represents a heterogeneous and complex genetic disease with environmental influences[11,12]. Genome-wide linkage analyses have been performed in multiple patient populations with non-segmental vitiligo, resulting in the identification of a number of susceptibility loci and candidate genes (Table 66.1)[13–18]. Most of these genes are associated with other autoimmune disorders and play a key role in the immune system.

Pathogenic hypotheses for vitiligo

Many pathogenic hypotheses have been proposed for vitiligo, reflecting the complex nature of this condition. A primary challenge is the fact that vitiligo most likely represents a heterogeneous group of disorders with different genetic backgrounds as well as exogenous and intrinsic triggers. Indeed, there is increasing evidence that non-segmental and segmental forms of vitiligo (see below) do not have the same genetic influences and may be distinct entities. For non-segmental vitiligo, accumulated data strongly support an autoimmune etiology in genetically predisposed individuals. Intrinsic defects in melanocytes and exogenous triggers may also play a role in the development of vitiligo. The relative contributions of these factors, and potentially others, in precipitating vitiligo remain to be elucidated. The various hypotheses are not mutually exclusive, and a "convergence theory" has also been proposed[19]. Arguments for and against proposed theories for the pathogenesis of vitiligo are summarized in Table 66.2.

Is there a reliable animal model for vitiligo?

A wide variety of animals (e.g. chickens, mice, cats, dogs, pigs and horses) develop vitiligo, as manifested by progressive depigmentation with a loss of active melanocytes. Circulating anti-melanocyte autoantibodies have been detected in some affected animals. Grafting of human vitiligo skin onto nude mice has also been used as a model for vitiligo, with repigmentation of the grafts in these studies suggesting an important role for systemic factors in the pathogenesis of vitiligo.

Recently, a T-cell receptor (TCR) transgenic mouse that recognizes an epitope of tyrosinase was found to progressively develop vitiligo in a pattern similar to that of human disease, initially involving the face in a symmetric periorificial distribution and later arising on the body. The vitiligo in this model is entirely dependent upon $CD8^+$ T cells, requiring both interferon-γ (IFN-γ) and the chemokine C-X-C motif receptor 3 (CXCR3). However, $CD8^+$ T cells were also present in clinically unaffected skin, suggesting spatial and temporal differences in melanocyte susceptibility and immunologic effector mechanisms[20].

Clinical Features

The most common presentation of vitiligo is totally amelanotic (i.e. milk- or chalk-white) macules or patches surrounded by normal skin. The lesions characteristically have discrete margins, and they can be round, oval, irregular or linear in shape. The borders are usually convex, as if the depigmenting process were "invading" the surrounding normally pigmented skin. Lesions enlarge centrifugally over time, and the rate may be slow or rapid. Vitiligo macules and patches range from millimeters to centimeters in diameter and often vary in size within areas of involvement. In lightly pigmented individuals, the lesions may be subtle or inapparent without the use of a Wood's lamp. In darkly pigmented individuals or after tanning of uninvolved skin, the contrast between vitiliginous areas and the surrounding skin is

PATHOGENIC HYPOTHESES FOR VITILIGO		
Hypothesis	**Evidence for hypothesis**	**Evidence against hypothesis**
Autoimmune destruction of melanocytes	• Epidemiologic association with several autoimmune disorders (see text) • Variants in immunoregulatory genes linked with vitiligo and associated autoimmune disorders (see Table 66.1) • Detection of antibodies against melanocyte proteins (e.g. TYR, TYRP1, DCT, MCHR1, SOX10) in the sera of patients with vitiligo • Destruction of melanocytes in normal human skin engrafted onto nude mice after injection with vitiligo patient sera • Infiltration of $CD8^+$ T cells into perilesional vitiligo skin • Skin-homing, melanocyte-specific cytotoxic T cells (e.g. against surface proteins such as Melan-A/MART-1) frequently detectable in the peripheral blood of vitiligo patients • Reports of generalized vitiligo following bone marrow transplantation from donors with vitiligo • T-cell receptor transgenic mice that recognize an epitope of tyrosinase develop depigmented lesions with characteristics similar to human vitiligo	• Limited evidence for autoimmune pathogenesis of segmental vitiligo • Although there is strong evidence for an autoimmune etiology of generalized vitiligo, it is unclear whether a primary immune attack targets normal melanocytes or if immune activation is triggered by damage to melanocytes by an exogenous or endogenous factor
An intrinsic defect in melanocytes, their adhesive properties and/or factors critical to their survival	• Abnormalities of cultured vitiligo melanocytes: – Dilation of the rough endoplasmic reticulum – Abnormal synthesis/processing of TYRP1 – Increased sensitivity to oxidative stress (e.g. UVB) • Evidence for *transepidermal melanocytorrhagy* due to defective melanocyte adhesion: – Detachment and transepidermal loss of melanocytes observed in *in vivo* studies of vitiligo skin – Induction of detachment by mechanical stress, which could explain the Koebner phenomenon – Decreased adhesion to collagen type IV and "stubby" dendrites in melanocytes cultured from perilesional skin of unstable vitiligo • Evidence for reduced melanocyte survival and dysregulation of melanocyte apoptosis in vitiligo: – The progressive loss of hair follicle melanocytes observed in *bcl-2*$^{-/-}$ mice provides a model of apoptotic loss of melanocytes – Deficiency of factors important for melanocyte maintenance (e.g. SCF, KIT, MITF) in vitiligo skin – Vitiligo-like depigmentation and hair graying observed in patients treated with tyrosine kinase inhibitors that target KIT	• Melanocytorrhagy is observed only in lesional and perilesional areas of vitiligo and appears to be a secondary process • No alteration in the expression of apoptosis regulatory molecules in vitiligo melanocytes compared with normal melanocytes
Defective defense against oxidative stress leading to destruction of melanocytes	• Detection of high *in vivo* levels of epidermal H_2O_2 in vitiligo skin, with potential sources including: – Accumulation of oxidized pteridines, e.g. 6-biopterin (bluish fluorescence) and 7-biopterin (yellow/green fluorescence) – Increased catecholamine biosynthesis in association with increased monoamine oxidase A activity – Inhibition of thioredoxin/thioredoxin reductase by calcium in the setting of defective calcium transfer/homeostasis in vitiligo epidermis • Oxidative degradation of catalase resulting in low levels of this protective enzyme in vitiligo skin	• Whether these abnormalities are the cause of vitiligo lesions, versus secondary consequences of immune attack or an intrinsic defect in melanocytes has not been determined • No conclusive evidence of benefit from therapeutic approaches using pseudocatalase or systemic antioxidant agents in clinical studies

Table 66.2 Pathogenic hypotheses for vitiligo. A "convergence theory" that vitiligo results from a combination of several of these pathogenic mechanisms has also been proposed. Hypotheses with less support include destruction of melanocytes by neurochemical substances or a viral infection (e.g. cytomegalovirus). DCT, dopachrome tautomerase; MCHR1, melanin-concentrating hormone receptor 1; MITF, microphthalmia-associated transcription factor; SCF, stem cell factor; TYR, tyrosinase; TYRP1, tyrosinase-related protein 1; UVB, ultraviolet B.

striking (Fig. 66.2). Vitiligo is usually asymptomatic, but pruritus is sometimes noted.

Vitiligo can develop anywhere on the body. Interestingly, it has a predilection for sites that are normally relatively hyperpigmented, such as the face, dorsal aspect of the hands, nipples, axillae, umbilicus, and sacral, inguinal and anogenital regions (see Fig. 66.2). Facial vitiligo typically occurs around the eyes and mouth (i.e. periorificial), and on the extremities it favors the elbows, knees, digits, flexor wrists (Fig. 66.3), dorsal ankles and shins (Fig. 66.4). Many of the common sites of involvement are subjected to repeated trauma, pressure or friction. Vitiligo on the palms, soles, lips and oral mucosa in lightly pigmented individuals may not be evident without Wood's lamp examination. In acrofacial vitiligo, periungual involvement of one or more digits may be associated with lip depigmentation; however, either can be an isolated finding.

The incidence of body leukotrichia varies from 10% to >60%, as follicular melanocytes are often spared in vitiligo. The occurrence of leukotrichia does not correlate with disease activity, but it is rarely, if ever, seen in the absence of depigmentation of the surrounding epidermis (Fig. 66.5). Vitiligo of the scalp most often presents as one or several localized patches of white or gray hair (poliosis), but scattered

Fig. 66.2 Vitiligo. Complete loss of pigment of the glans penis. Note the lack of any secondary changes. *Courtesy, Jean L Bolognia, MD.*

white hairs due to involvement of individual follicles or even total depigmentation of all the scalp hair can also occur. Isolated early graying or whitening before 30 years of age has been suggested to represent a form of vitiligo. In general, spontaneous repigmentation of depigmented hair in vitiligo does not occur.

Clinical variants

Vitiligo ponctué, an unusual clinical presentation of vitiligo, is characterized by multiple small (confetti-like), discrete amelanotic macules, sometimes superimposed upon a hyperpigmented macule. Although a *hyperpigmented margin* around a macule of leukoderma has been said to be specific for vitiligo, this is not a common feature. Erythema is occasionally observed at the margins of vitiligo lesions, which is referred to as *inflammatory vitiligo* or *"vitiligo with raised inflammatory borders"* (Fig. 66.6); a figurate papulosquamous variant has also been described. *Blue vitiligo* can result when vitiligo develops in areas already affected by postinflammatory hyperpigmentation.

Fig. 66.3 Vitiligo. Depigmentation of the volar wrists as well as the palmar surfaces. *Courtesy, Jean L Bolognia, MD.*

Trichrome vitiligo features a hypopigmented zone between normal and totally depigmented skin. The intermediate zone does not have a gradation of color from white to normal, but rather a fairly uniform hue. The number of melanocytes is also intermediate in this zone, suggesting slower centrifugal progression than in typical vitiligo[21]. In *quadrichrome vitiligo*, a fourth darker color is present at sites of perifollicular repigmentation. *Pentachrome vitiligo* with five shades of color (black, dark brown, medium brown [unaffected skin], tan and white) has also been described.

One of the manifestations of vitiligo is the isomorphic Koebner phenomenon (IKP), characterized by the development of vitiligo in sites of trauma (e.g. a laceration, burn or abrasion). The IKP is more common in patients with progressive non-segmental vitiligo, but it can also affect those with segmental vitiligo. There appears to be a minimal threshold of injury required for the IKP to occur, bringing into question the hypothesis that minor trauma, such as friction from clothes (in the absence of true injury), can induce vitiligo lesions.

Clinical classification of vitiligo

Multiple classification systems for vitiligo have been proposed, leading to confusing terminology. Two major forms are generally recognized: (1) the *segmental* form, which usually does not cross the midline; and (2) the *non-segmental form*, also called vitiligo vulgaris[22]. Segmental and non-segmental vitiligo are occasionally seen in the same patient, with involvement of >1% of the body surface area and the presence of leukotrichia or halo nevi representing possible predictors of the evolution from the former to the latter[22a]. However, genetic and clinical data strongly suggest that they represent two distinct forms of vitiligo.

The following classification scheme divides vitiligo into three general types (see Fig. 66.4): localized, generalized and universal.

Localized:

- *Focal*: one or more macules in one area, but not clearly in a segmental distribution
- *Unilateral/segmental*: one or more macules involving a unilateral segment of the body (Fig. 66.7); lesions usually stop abruptly at the midline
- *Mucosal*: mucous membranes alone

Generalized:

- *Vulgaris*: scattered patches that are widely distributed
- *Acrofacial*: distal extremities and face
- *Mixed*: various combinations of segmental, acrofacial and/or vulgaris

Fig. 66.5 Segmental vitiligo. Under normal light, vitiligo can be subtle in lightly pigmented individuals. The clue to the diagnosis is the poliosis of the eyelashes. *Courtesy, Jean L Bolognia, MD.*

Fig. 66.6 Inflammatory vitiligo. There is a figurate outline to the inflammatory border, which is sometimes misdiagnosed as tinea corporis.

Fig. 66.7 Segmental vitiligo. Unilateral band of depigmentation on the face, the most common location for segmental vitiligo. Note the pigmented and depigmented hairs within the affected area. *Courtesy, Kalman Watsky, MD.*

Universal:

- Complete or nearly complete depigmentation.

In our experience, over 90% of vitiligo patients have the generalized type. In the remainder, localized vitiligo is more common than universal vitiligo. Segmental vitiligo is more common in children than adults, accounting for ~15–30% of vitiligo in pediatric patients (see below).

Course of the disease

The onset of vitiligo is usually insidious. Many patients become aware of the depigmented patches, especially in sun-exposed areas, during the summer, when tanning increases the contrast between involved and uninvolved skin. The exact evolutionary appearance of early lesions is unknown, but it is postulated that there is progressive, uniform loss of pigment until a discrete white macule is apparent, which is followed by centrifugal enlargement. Clinical erythema rarely precedes vitiligo.

The course of vitiligo on a case-by-case basis is unpredictable. It becomes more extensive by the appearance of new depigmented macules, enlargement of pre-existing lesions, or both processes. The natural course of the disease is usually one of slow progression, but it may stabilize for a long period of time or spread rapidly. Total body involvement that develops within a few weeks or even a few days is known to occur. Some degree of sun-induced or spontaneous repigmentation is not uncommon in vitiligo, but complete and stable spontaneous repigmentation is rare.

The definitions for active and stable vitiligo are not universally accepted. Furthermore, there is no validated scoring system available to assess vitiligo activity. The *vi*tiligo *d*isease *a*ctivity (VIDA) score and a scoring system that was recently proposed by the Vitiligo European Task Force[22] have yet to be validated.

Vitiligo and ocular disease

The uveal tract (iris, ciliary body and choroid) and retinal pigment epithelium contain pigment cells. Uveitis is the most significant ocular abnormality associated with vitiligo. The most severe form of uveitis is seen in the *Vogt–Koyanagi–Harada (VKH) syndrome*. This is a multisystem disorder characterized by uveitis, aseptic meningitis and otic involvement (e.g. dysacousia), together with vitiligo, especially of the head and neck region, and associated poliosis. Histologic examination of amelanotic skin (which often appears after the systemic symptoms) demonstrates a mononuclear infiltrate consisting primarily of $CD4^+$ lymphocytes, suggesting a prominent role for cell-mediated immunity.

Non-inflammatory depigmented lesions of the ocular fundus are present in some patients with vitiligo, presumably representing focal areas of melanocyte loss. Although sensory hearing loss has been described in a few vitiligo patients (possibly reflecting impairment of cochlear melanocytes), clearcut evidence of otic abnormalities remains to be demonstrated.

Alezzandrini syndrome is a rare disorder characterized by whitening of scalp hair, eyebrows and eyelashes as well as depigmentation of the skin on the forehead, nose, cheek, upper lip and chin in association with ipsilateral visual changes. In the affected eye, there is decreased visual acuity and an atrophic iris. The pathogenesis of Alezzandrini syndrome is unknown, but it is believed to be closely related to VKH syndrome.

Associated disorders

Although most vitiligo patients are otherwise healthy, generalized vitiligo is epidemiologically associated with a number of other autoimmune diseases, especially in patients with a family history of vitiligo or other forms of autoimmunity. The associated conditions include autoimmune thyroid disease, pernicious anemia, Addison's disease, lupus erythematosus, rheumatoid arthritis, and adult-onset autoimmune diabetes mellitus[23,24]. An increased risk of developing these conditions is not surprising considering that they have been linked to the same autoimmunity predisposition genes (e.g. *PTPN22*, *NLRP1*) that have been implicated in the pathogenesis of vitiligo (see Table 66.1).

Patients with the autosomal recessive *a*utoimmune *p*oly*e*ndocrinopathy–*c*andidiasis–*e*ctodermal *d*ystrophy (APECED) syndrome are predisposed to the development of vitiligo as well as the autoimmune destruction of endocrine cells. The gene responsible for

APECED, *AIRE* (*a*uto*i*mmune *re*gulator), encodes a transcription factor that regulates the ectopic expression of self antigens in the thymus, which allows the development of peripheral tolerance. In APECED patients, failure to delete autoreactive T cells leads to autoimmune disease.

Halo melanocytic nevi (see below), alopecia areata and lichen sclerosus are additional autoimmune disorders that may be associated with vitiligo. An increased prevalence of vitiligo in patients with the *m*itochondrial *e*ncephalomyopathy, *l*actic *a*cidosis, and *s*troke-like episodes (MELAS) syndrome was noted in one small study, but whether this represents a true association has not been confirmed.

Childhood vitiligo

Although vitiligo vulgaris is the most common clinical type observed in children, the frequency of segmental vitiligo is significantly increased in children compared to adults (~15–30% versus ≤5–10%, respectively)[25]. The incidence of associated endocrinopathies is significantly less than in the adult vitiligo population. A family history of vitiligo is associated with an earlier age of onset[24]; among pediatric patients, those with a positive family history are more likely to develop vitiligo before 7 years of age.

Pathology

The pathology of vitiligo is described above (see Pathogenesis).

Differential Diagnosis

When there is complete depigmentation, the differential diagnosis includes chemical or drug-induced (e.g. imatinib) leukoderma, postinflammatory depigmentation, the leukodermas associated with melanoma and scleroderma, and the late stages of treponematosis and onchocerciasis. If there is a single circular lesion on the trunk of a young person, a stage III halo nevus should be considered (see below). Early lesions or those with a partial loss of pigment need to be distinguished from postinflammatory hypopigmentation, pityriasis versicolor and other cutaneous infections (e.g. leprosy). A nevus depigmentosus can be distinguished by its early onset (although lesions may not be clinically apparent until mid-childhood in lightly pigmented individuals) as well as hypopigmentation rather than depigmentation. Treatment with potent topical corticosteroids may also lead to hypomelanosis.

Treatment

The aims of vitiligo treatment are repigmentation and stabilization of the depigmentation process. Although there is still no therapeutic panacea for vitiligo, the available options lead to satisfactory results in a substantial number of patients. The choice of therapy depends on the extent, location, and activity of disease as well as the patient's age, skin type, and motivation to undergo treatment. In general, a period of at least 2–3 months is required to determine whether a particular treatment is effective. The areas of the body that typically have the best response to medical therapy are the face, neck, mid extremities and trunk, while the distal extremities and lips are the most resistant to treatment. Repigmentation usually appears in a perifollicular pattern (Fig. 66.8) and/or from the periphery of the lesions. When the hairs within an area of vitiligo are depigmented, the former pattern is not observed.

Corticosteroids

Topical corticosteroids are useful for localized areas of vitiligo. A meta-analysis showed that approximately half of patients with vitiligo affecting ≤20% of the body surface area achieved >75% repigmentation with either class 1 (superpotent) or class 2–3 (high-potency) topical corticosteroids; cutaneous atrophy was observed in 14% and 2% of these groups, respectively[26]. To minimize side effects, class 1 corticosteroids can be used in 6–8-week cycles or on a twice-weekly basis, alternating with topical tacrolimus or a less potent topical corticosteroid; treatment should be discontinued if there is no visible improvement after 2 months.

In general, intralesional corticosteroids should be avoided because of the pain associated with injection and the risk of cutaneous atrophy, which occurs in approximately one-third of vitiligo patients who receive this treatment. Systemic corticosteroids (high-dose pulsed therapy, mini-pulsed regimens or a low daily oral dose) have been reported to arrest rapidly spreading vitiligo and induce repigmentation[27]. However, given the potential for serious side effects, the role of systemic corticosteroids in the treatment of vitiligo remains controversial.

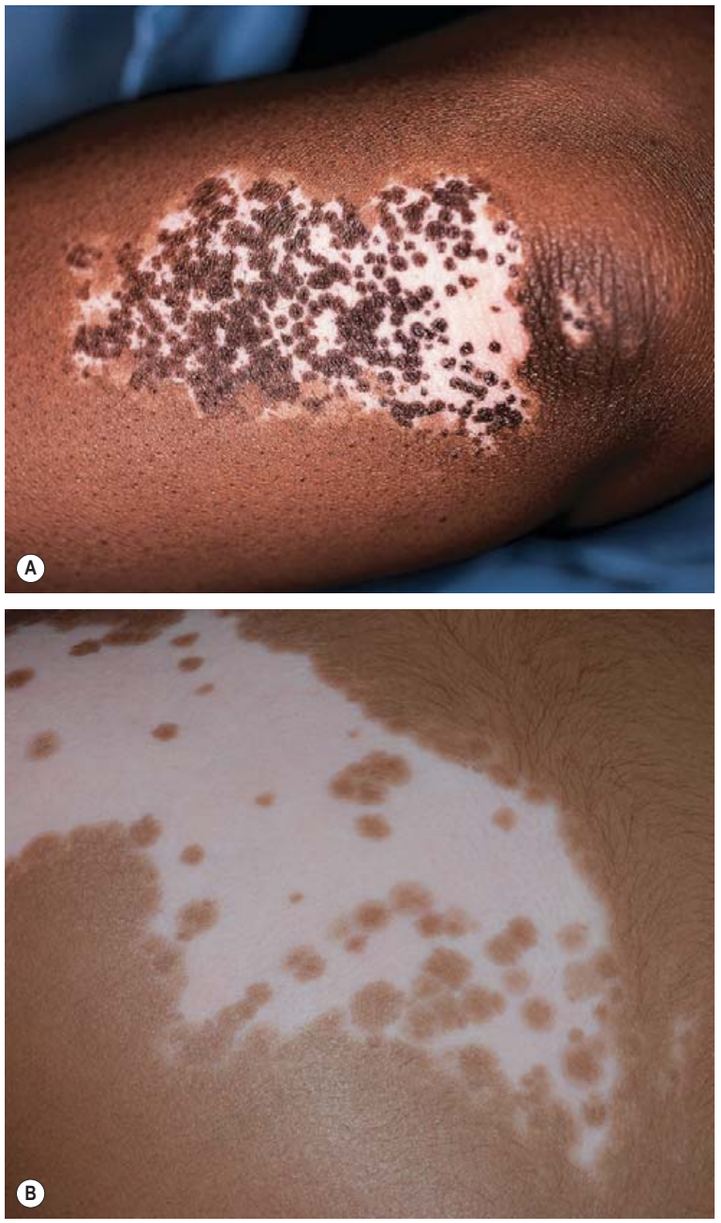

Fig. 66.8 Perifollicular repigmentation. Vitiligo on the elbow (**A**) and segmental vitiligo on the back (**B**) responding to PUVA and narrowband UVB therapy, respectively, with repigmentation in a prominent perifollicular pattern as well as from the periphery. The areas of repigmentation are darker in color than the uninvolved skin in (**A**) and have two shades (darker where well established and lighter at the expanding edge) in (**B**). *A, Courtesy, Jean L Bolognia, MD. B, Courtesy, Julie V Schaffer, MD.*

Topical calcineurin inhibitors

Multiple studies have shown that topical application of tacrolimus 0.1% ointment or pimecrolimus 1% cream twice daily can lead to repigmentation of vitiligo, with response rates in pediatric patients similar to those achieved with topical corticosteroids. The best results are obtained when these agents are used for facial lesions and/or combined with sun exposure, with the latter suggesting a synergistic effect. In addition, topical calcineurin inhibitors (TCIs) have been shown to enhance repigmentation when used together with narrowband UVB phototherapy or the 308 nm excimer laser[28,29]. Of note, avoidance of UV light is suggested by the package insert for TCIs, and the risk : benefit ratio needs to be discussed with patients and further studied (especially

in children). Topical tacrolimus can also be used in conjunction with topical corticosteroids, as discussed above.

Photo(chemo)therapy

Narrowband UVB

In general, narrowband UVB (NB-UVB) is considered to be more effective than broadband UVB in the treatment of vitiligo (see Ch. 134). Several studies have demonstrated the efficacy of NB-UVB monotherapy[30,31]. The starting dose ranges from 100 to 250 mJ/cm^2, which is increased in increments of 10–20% at each subsequent exposure until mild asymptomatic erythema is achieved within the lesions. Treatments are administered two to three times per week, but not on two consecutive days[30]. Short-term side effects include pruritus and xerosis; long-term side effects (e.g. cutaneous carcinogenesis) have not been described. The advantages of NB-UVB over psoralen plus UVA (PUVA) therapy include shorter treatment times, a lack of gastrointestinal side effects, reduced phototoxic reactions and no need for post-treatment photoprotection; in addition, NB-UVB can be used in children, pregnant or lactating women, and individuals with hepatic or kidney dysfunction. Furthermore, NB-UVB produces less accentuation of the contrast between depigmented and normally pigmented skin[32]. NB-UVB has become the first choice of therapy for adults and children with generalized vitiligo, especially if it involves ≥20% of the body surface area or cosmetically sensitive areas that normally respond to treatment.

Psoralen plus UVA

Psoralen photochemotherapy involves the use of psoralens combined with UVA light (see Ch. 134). The psoralen most commonly utilized is 8-methoxypsoralen (8-MOP, methoxsalen). 5-methoxypsoralen (5-MOP, bergapten) is not approved for use in the US and 4,5′,8-trimethylpsoralen (TMP, trioxsalen) is no longer commercially available. Psoralens can be administered orally (oral PUVA) or applied topically (topical PUVA), followed by exposure to either artificial UVA light or natural sunlight (PUVASOL).

Oral PUVA treatments using 8-MOP (0.4–0.6 mg/kg) are typically administered two times weekly. For patients with vitiligo, the initial dose of UVA is usually 0.5–1.0 J/cm^2, which is gradually increased until minimal asymptomatic erythema of the involved skin occurs. To reduce the risk of the Koebner phenomenon, significant erythema (phototoxicity) is avoided. 5-MOP has about the same response rate as 8-MOP in repigmenting vitiligo, but a lower incidence of adverse effects, including reduced phototoxicity as well as less nausea and vomiting.

The response rate of PUVA is variable; although the majority of patients obtain cosmetically acceptable improvement, complete repigmentation is achieved in only a few patients. The total number of PUVA treatments required is generally between 50 and 300. The absolute and relative contraindications, as well as the short- and long-term side effects, of oral PUVA therapy are reviewed in Chapter 134. To date, only a few vitiligo patients with PUVA-induced cutaneous carcinomas have been reported. Although this probably reflects a smaller cumulative UVA dose than in patients treated for other disorders such as psoriasis, large follow-up studies have not yet been done in PUVA-treated vitiligo patients. Until more data are available, it seems wise to recommend that vitiligo patients receive a maximum cumulative UVA dose of 1000 J/cm^2 and a maximum number of 300 treatments.

Topical (paint) PUVA is more difficult to perform because of the high risk of phototoxicity (e.g. blistering, koebnerization) from topical psoralen formulations. Low concentrations (≤0.1%) should be used, which necessitates dilution of the commercially available preparation. Approximately 20–30 minutes after applying the topical preparation (cream or ointment) onto the lesions, the patient should be exposed to initial UVA doses of no more than 0.25 J/cm^2, with the same fractional increments until mild erythema is achieved in the treated sites.

PUVASOL (psoralens + natural sunlight) can be used in sunnier climates, according to the same principles as for PUVA. Less phototoxic oral psoralens such as 5-MOP are preferred, to avoid phototoxic reactions.

Other forms of phototherapy

There have been conflicting reports regarding the efficacy of *oral khellin plus UVA* and *oral phenylalanine plus UVA* for the treatment of vitiligo, and concern has been raised about the hepatic toxicity of khellin. As a result, these modalities are not recommended. *Topical khellin plus UVA* has a relatively low risk of phototoxicity, but it requires a longer duration of treatment and higher UVA doses than oral PUVA to provide the same degree of repigmentation[33].

Focused microphototherapy has the advantage of irradiating only the affected skin. A directed beam of broadband or narrowband UVB light is applied to areas of vitiligo. Treatments are administered from several times weekly to twice monthly, sometimes with an initial boost of daily treatments for 5 days. In one large study, 70% of patients who received a mean of 24 treatments over a 12-month period achieved >75% repigmentation.

Lasers and related light devices

Excimer laser and lamp

The operational wavelength of the 308 nm excimer laser and lamp is close to that of NB-UVB[34]. The therapeutic benefit of the excimer laser for vitiligo has been investigated in multiple studies, and, overall, 20–50% of lesions achieve ≥75% repigmentation[35,36]; the excimer lamp appears to have similar efficacy[37]. Localized patches of vitiligo are treated one to three times weekly for an average of 24 to 48 sessions, with the repigmentation rate depending on the total number of sessions, not their frequency[36]. Erythema and (rarely) blistering represent potential side effects[35].

Helium–neon laser

The helium–neon laser emits a wavelength (632.8 nm) in the red visible light range that can enhance melanocyte proliferation and melanogenesis *in vitro*[38]. In a study performed in 30 patients with segmental vitiligo, 20% of lesions achieved ≥75% repigmentation after a mean of 79 treatment sessions, which were administered once or twice weekly[39].

Surgical therapies

For vitiligo patients who fail to respond to medical therapy, surgical treatment with autologous transplantation techniques may be an option[40]. The general selection criteria for autologous transplantation are stable disease for at least 6 months, an unsatisfactory response to medical therapy, absence of the Koebner phenomenon, a positive minigrafting test (retention/spread of pigment at the recipient site and no koebnerization at the donor site after 2–3 months), no tendency for scar or keloid formation, and age above 12 years[41].

Several methods of surgical repigmentation have been successfully utilized. *Minigrafting* is the simplest technique. Small punch grafts (1–2 mm) from uninvolved skin are implanted within achromic areas, separated from each other by 5–8 mm. A cobblestone effect, a variegated appearance of the grafts, and sinking pits represent potential unfavorable outcomes. Because scarring and dyspigmentation may occur at the donor sites, cosmetically insensitive areas are chosen. The advantages of *suction blister epidermal grafting* are the absence of scarring at the donor site and the possibility of reusing this area. However, failure of the graft to take and koebnerization may occur. *Grafting of cultured autologous melanocytes* is an expensive technique that requires specialized laboratory expertise; grafts consist of pure melanocytes or melanocytes admixed with keratinocytes[42]. To avoid the need for *in vitro* culture (which involves mitogens to enhance cell growth), *grafting of non-cultured epidermal cell suspensions* that include melanocytes has been advocated[43]. *Grafting of individual hairs* to repigment vitiligo leukotrichia has also been successfully performed. Most of these techniques require clinical expertise, and candidates should be carefully selected.

Combination therapy

Combination therapy may produce higher rates of repigmentation compared to traditional monotherapies. Examples include phototherapy following surgical procedures and TCIs or topical corticosteroids together with each other, NB-UVB or excimer laser therapy[44–48]. Although topical vitamin D derivatives are relatively ineffective as monotherapy, these agents may result in additional repigmentation when used in conjunction with phototherapy.

Micropigmentation

The technique of permanent dermal micropigmentation utilizes a nonallergenic iron oxide pigment to camouflage recalcitrant areas of vitiligo. This tattooing method is especially useful for sites known to have

a poor rate of repigmentation with currently available treatments (e.g. the lips, nipples and distal fingers). Although the color may not match perfectly with the normal surrounding skin, the result is immediate and can represent a dramatic aesthetic improvement. However, the color may fade slightly over a period of years.

Depigmentation

Depigmentation represents a treatment option for patients who have widespread vitiligo with only a few areas of normally pigmented skin in exposed sites. The patients must be carefully chosen, i.e. adults who recognize that their appearance will be altered significantly and who understand that depigmentation requires lifelong strict photoprotection (e.g. sunscreens, clothing, umbrellas). The most commonly used agent is 20% monobenzyl ether of hydroquinone (MBEH), applied once to twice daily to the affected areas for 9–12 months or longer[49]. MBEH is a potent irritant and allergen, and an open use test should be performed before more widespread application. It typically takes 1–3 months to initiate a response, and a loss of pigment can occur at distant sites. Although depigmentation from MBEH is considered permanent, repigmentation (especially perifollicular in areas with pigmented hairs) can be seen following a sunburn or even intense sun exposure. Monomethyl ether of hydroquinone in a 20% cream can be used as an alternative to MBEH[50]. Side effects include contact dermatitis, exogenous ochronosis and leukomelanoderma en confetti. Depigmentation via Q-switched ruby laser therapy was reported to achieve faster depigmentation than that achieved with a bleaching agent[50], and this laser has also been used in combination with topical 4-methoxyphenol to induce depigmentation[51]. Depigmentation with the Q-switched alexandrite laser has also been described[52].

Psychological support

The impact of vitiligo on quality of life is severe in many affected individuals, and it is critical for physicians to recognize this aspect of the condition and address their patients' psychological needs. Although a "magic" treatment is not yet available, there is always something beneficial that can be done for vitiligo patients. They first need to know what their skin disorder is. Explaining the nature of the disease process and the potential and limits of available therapies is important and more productive than a fatalistic attitude that there is no cure and vitiligo is "only" a cosmetic disorder. Even helping patients to conceal the condition so that it is not visible can be part of the management plan. The use of support groups and, if indicated, psychological counseling are important supplementary therapies.

Additional controversial therapies

Pseudocatalase with narrowband UVB

The rationale for this treatment is based on the hypothesis that accumulation of hydrogen peroxide leads to pathogenic inactivation of catalase in the skin of patients with vitiligo (see Table 66.2). In an open uncontrolled study, complete repigmentation of lesions on the face and hands was observed in 90% of patients (30 of 33) treated with topical pseudocatalase and calcium twice daily plus UVB twice weekly, with initial repigmentation at 2–4 months[53]. A recent controlled trial, however, showed no additional benefit of pseudocatalase compared to UVB alone[54].

Systemic antioxidant therapy

The rationale for this approach rests on the hypothesis that vitiligo results from a deficiency of natural antioxidant mechanisms. Although to date not validated by a controlled clinical trial, selenium, methionine, tocopherols, ascorbic acid and ubiquinone are prescribed by some physicians.

Potential emerging treatments

Dermabrasion followed by topical 5-fluorouracil and narrowband UVB

Erbium:YAG laser ablation of vitiligo lesions followed by topical application of 5-fluorouracil and NB-UVB therapy twice weekly for 4 months was found to lead to ≥75% repigmentation in ~45% of patients, compared with a rate of 8% for lesions on the opposite side of the body that were treated with NB-UVB alone[55].

Topical prostaglandins

A preliminary study suggested the utility of topical prostaglandin E_2 in the treatment of vitiligo[56]. Although interesting, these results require confirmation.

HEREDITARY HYPOMELANOSIS[57]

Oculocutaneous Albinism

Oculocutaneous albinism (OCA) consists of a group of genetic disorders characterized by diffuse pigmentary dilution due to a partial or total absence of melanin pigment within melanocytes of the skin, hair follicles and eyes[57]. The number of epidermal and follicular melanocytes is normal. Hypopigmentation involving primarily the retinal pigment epithelium is termed ocular albinism (OA).

Epidemiology

OCA is the most common inherited disorder that leads to diffuse hypomelanosis. In most populations, the estimated frequency is 1:20 000; however, it is as high as 1:1500 in some African tribes.

Pathogenesis

All well-characterized types of OCA have an autosomal recessive inheritance pattern, although a few rare families with autosomal dominant OCA have been described[58]. Based upon molecular studies, four types of OCA have been defined (Table 66.3). OCA type 1 (OCA1) results

CLASSIFICATION OF OCULOCUTANEOUS AND OCULAR ALBINISM

Type	Gene	Phenotype	Function of protein
OCA1A] ~40%	*TYR*	Tyrosinase-negative OCA	Melanogenic enzyme (inactive/missing in OCA1A)
OCA1B]	*TYR*	Minimal pigment OCA Platinum OCA Yellow OCA Temperature-sensitive OCA	Melanogenic enzyme (partially active in OCA1B)
OCA2 (~50%)	*OCA2* (previously known as *P*, pink-eyed dilution)	Tyrosinase-positive OCA African brown OCA	Transmembrane transporter with roles in vacuolar glutathione accumulation, regulation of organelle pH and tyrosinase processing/trafficking
OCA3	*TYRP1*	Rufous OCA	Stabilizes tyrosinase
OCA4	*SLC45A2* (formerly *MATP*)	OCA	Transmembrane transporter with roles in tyrosinase processing and trafficking of proteins to the melanosome
OA1	*GPR143*	Nettleship–Falls type OA X-linked OA + macromelanosomes (skin, eyes)	Pigment cell-specific intracellular G protein-coupled receptor that regulates melanosome formation and transport

Table 66.3 Classification of oculocutaneous and ocular albinism. *GPR143*, G protein-coupled receptor 143; *MATP*, membrane-associated transporter protein; OA, ocular albinism; OCA, oculocutaneous albinism; *SLC45A2,* solute carrier family 45 member 2; *TYR*, tyrosinase; *TYRP1*, tyrosinase-related protein-1.

from reduced (OCA1B) or absent (OCA1A) tyrosinase activity (see Ch. 65); at least 230 distinct mutations in the tyrosinase gene (*TYR*) have been identified in patients with OCA1[59]. OCA type 2 (OCA2) is due to mutations in the *P* gene (pink-eyed dilution; now referred to as *OCA2*)[60]. Although the function of the P protein is still debated, more recent studies have pointed to its role in regulating organelle pH and facilitating vacuolar accumulation of glutathione.

OCA type 3 (OCA3) results from mutations in the tyrosinase-related protein 1 (*TYRP1*) gene[61]. TYRP1 protein is a melanocyte-specific gene product involved in eumelanin synthesis (see Fig. 65.11), probably via stabilization of tyrosinase. Both OCA1 and OCA3 appear to be endoplasmic reticulum (ER) retention diseases wherein the abnormal proteins (tyrosinase or TYRP1) never leave the ER to become incorporated into melanosomes[62] (see Fig. 65.7). Of note, dysfunction of the P protein can also lead to abnormal processing and trafficking of tyrosinase. A fourth type of OCA (OCA4) was identified more recently[63]. The gene involved, solute carrier family 45 member 2 (*SLC45A2*; formerly *MATP*, membrane-associated transporter protein), encodes a transmembrane transporter protein with roles in tyrosinase processing and intracellular trafficking of proteins to the melanosome.

Autosomal recessive OA (AROA) is genetically heterogeneous. Some cases of AROA actually represent OCA1B or OCA2, but with subtle cutaneous findings. The most common form of OA is an X-linked recessive disorder caused by mutations in the G protein-coupled receptor 143 gene (*GPR143*; formerly *OA1*), which encodes a pigment cell-specific intracellular G protein-coupled receptor that regulates melanosome formation and transport within melanocytes and cells of the retinal pigment epithelium[64]. Mutations in *GPR143* that lead to ocular albinism can result in retention of the aberrant protein within the ER.

Clinical features

Ocular manifestations

The many ocular manifestations of OA and OCA reflect a reduction in melanin within eye structures or misrouting of optic nerve fibers during development. The former leads to a translucent iris that transmits light upon globe transillumination, as well as a relatively hypopigmented retina and fovea that are associated with photophobia and reduced visual acuity; the severity of these findings correlates with the amount of reduction in melanin pigment. Misrouting of the optic fibers is thought to be responsible for the characteristic strabismus, nystagmus and lack of binocular vision.

OCA1

There are two clinical subtypes of OCA1, based upon whether tyrosinase activity is reduced (OCA1B) or absent (OCA1A).

OCA1A

OCA1A corresponds to the classic "tyrosinase-negative" OCA. The melanocytes of the skin, hair and eyes synthesize no melanin. The characteristic phenotype includes white hair, milky white skin, and blue–gray eyes at birth. With age, the skin color remains white and melanocytic nevi amelanotic, but the hair may develop a slight yellow tint due to denaturing of hair keratins. These patients have an extreme sensitivity to UV light and a strong predisposition to skin cancer. Reduced visual acuity is most severe in OCA1A, and some patients are legally blind.

OCA1B

Because the decrease in tyrosinase activity can vary, the phenotype ranges from obvious to subtle pigmentary dilution when compared with first-degree relatives. One of the original OCA1B phenotypes was called "yellow albinism" because of the eventual color of the patient's hair (the formation of yellow pheomelanin requires less tyrosinase activity). Other clinical types of OCA1B have been referred to as "minimal pigment OCA", "platinum OCA" and "temperature-sensitive OCA". All of these patients have little or no pigment at birth, but they develop some pigmentation of the hair and skin during the first and second decades of life. The majority burn without tanning after sun exposure, and some degree of iris translucency is often present. Amelanotic or pigmented melanocytic nevi can develop.

In the temperature-sensitive OCA1B phenotype, patients are born with white hair and skin and blue eyes. During puberty, scalp and axillary hairs remain white, but arm hairs turn light reddish brown and leg hairs turns dark brown. The abnormal tyrosinase enzyme is temperature-sensitive, losing its activity above 35°C. As a result, melanin synthesis does not occur in warmer areas of the body, akin to the phenotype of a Siamese cat, which also has temperature-sensitive tyrosinase activity.

Fig. 66.10 Oculocutaneous albinism type 2 (OCA2). African patient with hypopigmented hair and large pigmented lentigines. *Courtesy, James Nordlund, MD.*

OCA2

The OCA2 phenotype (in addition to OCA1B) corresponds to the classic "tyrosinase-positive" OCA. The clinical spectrum of OCA2 is broad, ranging from minimal to moderate pigmentary dilution of the hair, skin and iris, with little to no ability to tan. The vast majority of individuals of African descent who have "tyrosinase-positive" OCA have OCA2. With time, pigmented melanocytic nevi and lentigines may develop in sun-exposed areas (Fig. 66.9); the latter can become rather large and darkly colored (Fig. 66.10). Another phenotype called "brown OCA" in African and African-American populations results primarily from mutations in the *P* gene. In these individuals, the hair and skin are light brown, the irides are gray to tan at birth, and sunburns are unusual.

The hypopigmentation seen in a subset of patients with Prader–Willi syndrome (PWS) and Angelman syndrome (AS) represents a form of OCA2. PWS features hyperphagia, obesity, hypogonadism and mental retardation, whereas AS is characterized by severe mental retardation, microcephaly, ataxic movements and inappropriate laughter. Due to genomic imprinting (see Ch. 54), deletions of the 15q region (which includes the *P* gene) in the paternal chromosome lead to PWS, while deletions in the maternal chromosome give rise to AS. Approximately 1% of patients with AS or PWS also have OCA2, which occurs when deletion of one copy of the *P* gene is accompanied by a mutation in the second copy.

OCA3

The phenotypes of individuals with OCA3 are classified as "rufous" (vast majority of OCA3 patients) and "brown" (more often seen

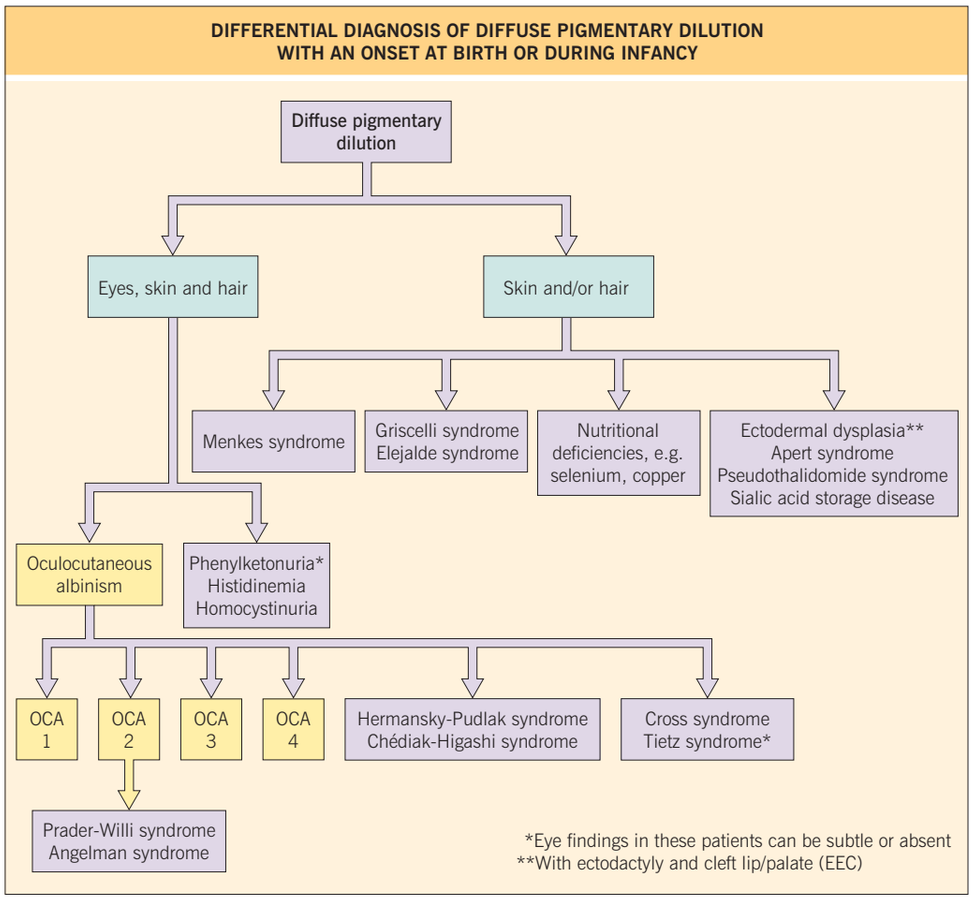

Fig. 66.11 Differential diagnosis of diffuse pigmentary dilution with onset at birth or during infancy. *Adapted from Bolognia JL. A clinical approach to leukoderma. Int J Dermatol. 1999;38:568–72.*

in OCA2). Rufous OCA has been identified in individuals with type III–V skin color, and the phenotype includes a red–bronze skin color, ginger-red hair, and blue or brown irides. Rufous OCA is associated with mutations in the *TYRP1* gene. A patient with the brown OCA phenotype due to mutations in both copies of the *TYRP1* gene has also been described: an African-American child with light brown skin, light brown hair and blue–grey irides.

OCA4

OCA4 is most common among individuals with albinism who are from Japan (~25% of patients), China (10–20% of patients) and India (~10% of patients), and it accounts for ~5% of albinism in Caucasians[65]. The phenotype of OCA4 is variable; hair color ranges from white to yellow–brown, and patients may or may not develop increased pigmentation of the skin and hair over time.

Ocular albinism type 1 (OA1)

Ocular albinism type 1 is characterized by a substantial reduction in visual acuity, hypopigmentation of the retina, and the presence of macromelanosomes in the eyes. Affected boys have nystagmus, photophobia and foveal hypoplasia[64]. Their skin is usually clinically normal without notable pigmentary dilution, although hypopigmented macules have been described in affected individuals who have darkly pigmented skin. Macromelanosomes are evident on histologic examination of the skin.

Pathology

Although there is a reduction in melanin content, a normal number of melanocytes are present within the epidermis.

Differential diagnosis

This is outlined in Figure 66.11. Occasionally, patients with total body vitiligo may be thought to have OCA, but their epidermis lacks melanocytes.

Treatment

No specific treatment is available. Photoprotection (sunscreens, hats, clothing, sun avoidance) is mandatory in patients who have minimal or no pigmentation, in order to avoid cutaneous photocarcinogenesis, in particular the development of squamous cell carcinomas. The latter are a significant cause of morbidity and mortality, especially in tropical regions (see Fig. 66.9). All patients should undergo ophthalmologic evaluation early in life, with longitudinal care as required.

Piebaldism

Piebaldism is an uncommon autosomal dominant disorder characterized by poliosis and congenital, stable, circumscribed areas of leukoderma due to an absence of melanocytes within involved sites.

Epidemiology

The exact prevalence of this condition is not known, but it is estimated to occur in approximately 1 in 40 000 Caucasians.

Pathogenesis

Piebaldism usually results from mutations in the *KIT* proto-oncogene[66], which encodes a member of the tyrosine kinase family of transmembrane receptors that is found on the surface of melanocytes (see Fig. 65.2). A functioning KIT receptor is required for the normal development of melanocytes, both immediately before melanoblast migration from the neural crest and postnatally. Heterozygous deletion of the *SNAI2* gene, which encodes a transcription factor important to melanocyte development, has been found to cause piebaldism in a few patients.

Clinical features

The leukoderma has a characteristic distribution pattern that favors the central anterior trunk, mid extremities, central forehead, and mid-frontal portion of the scalp; the latter results in a white forelock (Fig. 66.12). The lesions are present at birth and classically spare the posterior midline. The white forelock, which is present in 80–90% of patients, is the most familiar feature of piebaldism. However, its absence does not exclude the diagnosis. All the hairs of the forelock are white, and the underlying skin is also amelanotic. This depigmented patch is midline in location, triangular or diamond-shaped, and often symmetrical. The apex can reach the vertex posteriorly, and the affected

DIFFERENTIAL DIAGNOSIS OF CIRCUMSCRIBED SCALP POLIOSIS
INFLAMMATORY OR AUTOIMMUNE
• Vitiligo • Halo nevus • Alopecia areata (primarily initial cycle of growth) • Postinflammatory (e.g. discoid lupus) • Post-traumatic • Vogt–Koyanagi–Harada syndrome • Alezzandrini syndrome
INHERITED
• Tuberous sclerosis* • Piebaldism (midline frontal) • Waardenburg syndrome (primarily midline frontal) • Isolated white forelock† • Isolated occipital white lock (X-linked recessive) • White forelock with osteopathia striata (autosomal or X-linked dominant) • White forelock with multiple malformations (autosomal or X-linked recessive)
NEVOID
• Associated with nevus comedonicus • Angora hair nevus • Scalp heterochromia secondary to mosaicism*
IDIOPATHIC
*May be lighter than surrounding hair rather than white (e.g. blond streaks in a patient with brown hair). †Separate entity vs possible forme fruste of piebaldism.

Table 66.4 Differential diagnosis of circumscribed scalp poliosis. *Adapted from Bolognia JL, Shapiro PE. Albinism and other disorders of hypopigmentation. In: Arndt KA, et al (eds). Cutaneous Medicine and Surgery. Philadelphia: WB Saunders, 1995.*

area may extend to the root of the nose and include the medial third of the eyebrows; involvement of the nose is rare.

The areas of leukoderma are distinctive and can establish the diagnosis of piebaldism, even in the absence of a white forelock. They are irregular in shape, well-circumscribed and milk-white in color. Normally pigmented and hyperpigmented macules and patches (ranging from a few millimeters to several centimeters in diameter) are typically apparent within the leukodermic patches (Fig. 66.13). Hyperpigmented patches also occur within uninvolved skin and should not be misinterpreted as evidence of neurofibromatosis 1. Poliosis of the eyebrows and eyelashes is a common finding, as are white hairs within areas of leukoderma. Limited contraction of the areas of involvement over time is occasionally observed, and premature graying of the hair is not uncommon.

Pathology

By light and electron microscopy, no melanocytes can be identified in either the interfollicular epidermis or the hair follicles of amelanotic skin[67]. The hyperpigmented macules are characterized by an abundance of melanosomes in the melanocytes and keratinocytes.

Differential diagnosis

The presence of stable amelanotic patches since birth, the characteristic distribution pattern, and the distinctive normally pigmented or hyperpigmented macules within the areas of leukoderma allow the differentiation of piebaldism from vitiligo. The differential diagnosis of circumscribed poliosis of scalp hairs is broad (Table 66.4) and includes both inherited (autosomal dominant and X-linked recessive) and acquired causes. Of note, an isolated white forelock can also be inherited as an autosomal dominant trait. The diagnosis of piebaldism should prompt the clinician to exclude the possibility of Waardenburg syndrome via an ocular examination and evaluation of hearing.

Treatment

Autografts of normal skin into amelanotic areas, including grafting of autologous melanocytes, are a therapeutic option, but this typically requires multiple procedures. Cosmetic products can be used to camouflage affected areas; protection against sunburn is also necessary.

Waardenburg Syndrome

Waardenburg syndrome (WS) is a rare autosomal dominant or autosomal recessive disorder that is characterized by various combinations of the following features[68]:

- achromia of the hair, skin or both in the same pattern as piebaldism (see above)
- congenital deafness
- partial or total heterochromia irides (including isohypochromia)
- medial eyebrow hyperplasia (synophrys)
- a broad nasal root
- dystopia canthorum (an increase in the distance between the inner canthi, with a normal inter-pupillary distance).

Four clinical subtypes of WS have been described (Table 66.5): WS type I, the classic form (WS1); WS type II, which lacks dystopia canthorum (WS2); WS type III, with associated limb abnormalities (WS3, Klein–Waardenburg syndrome); and WS type IV, with Hirschsprung disease (WS4, Shah–Waardenburg syndrome).

Epidemiology

The incidence of WS in the Netherlands has been estimated as approximately 1 in 200 000. In the US, deafness in the setting of WS afflicts 1 in 50 000. WS has been observed in various races and from all regions of the world. Men and women are equally affected.

DISORDERS OF MELANOCYTE DEVELOPMENT					
Human disease		**Mouse model**	**Inheritance**	**Gene**	**Protein**
Piebaldism		Dominant spotting	AD AD	*KIT* *SNAI2*	KIT tyrosine kinase Snail homolog 2 transcription factor
WAARDENBURG SYNDROME					
WS1		Sploch	AD	*PAX3*	Paired box 3 transcription factor
WS2*	A D E	Microphthalmia	AD AR AD	*MITF* *SNAI2* *SOX10*	Microphthalmia-associated transcription factor Snail homolog 2 transcription factor SRY-box 10 transcription factor
WS3†		Sploch	AD	*PAX3*	Paired box 3 transcription factor
WS4	A B C	Piebald spotting Lethal spotting Dominant megacolon	AD, AR AD, AR AD	*EDNRB* *EDN3* *SOX10*	Endothelin B receptor Endothelin-3 SRY-box containing 10
Tietz syndrome			AD	*MITF*	Microphthalmia-associated transcription factor
Albinism, black lock, cell migration disorder of the neurocytes of the gut, and deafness (ABCD) syndrome			AR	*EDNRB*	Endothelin receptor type B

*Other forms of WS2 have been linked to 1p21–p13.3 (WS2B) and 8p23 (WS2C).
†Homozygous *PAX3* mutations have been described in individuals with WS3 whose parents were affected with WS1.

Table 66.5 Disorders of melanocyte development. AD, autosomal dominant; AR, autosomal recessive.

Pathogenesis

The facial dysmorphism seen in WS points to abnormalities during fetal development. It should therefore come as no surprise that several of the genes responsible for WS (*PAX3, MITF, SNAI2, SOX10*; see Table 66.5) encode transcription factors that (by binding DNA and regulating the expression of other genes) have important functions during embryogenesis (see Fig. 65.4). The neural crest is the source of the connective tissues of the head and neck and intestinal ganglion cells as well as melanoblasts, explaining the manifestations of this neurocristopathy. Presumably, the deafness in WS reflects the role of melanocytes in the development of the inner ear.

The PAX3 transcription factor that is mutated in WS1 and WS3 activates melanoblasts and other cells to proliferate and then migrate from the neural crest. The abnormalities of the upper extremities that characterize WS3 imply that PAX3 also regulates limb development[69]. Mutations in the *mi*crophthalmia-associated *t*ranscription *f*actor gene (*MITF*; expression of which is regulated by PAX3 and SOX10), which encodes a helix-loop-helix/leucine zipper transcription factor, can result in WS2. Of note, a mutation in the *MITF* gene that affects the nuclear localization of this protein underlies Tietz syndrome (see below)[70]. In addition to its critical role in melanocyte development, MITF regulates the expression of a number of melanocyte-specific genes (e.g. tyrosinase; see Ch. 65). Homozygous deletion of the *SNAI2* gene (the expression of which is regulated by MITF) has also been identified as a cause of WS2. SNAI2 is a zinc finger transcription factor that has an essential role in the development of neural crest-derived cells, and its complete absence leads to both auditory and pigmentary abnormalities[71].

The SOX10 transcription factor plays an essential role in the development of melanoblasts and ganglion cells, and mutations in this gene can cause WS4 or (if milder) WS2[72]. WS4 can also be caused by mutations in the genes encoding the endothelin B receptor and its endothelin-3 ligand[73]. The endothelin B receptor is found on melanoblast-ganglion cell precursors in the developing neural crest, and its binding to endothelin-3 is essential for the generation of these cell types (see Fig. 65.3).

Clinical features

Waardenburg syndrome type 1 (WS1)

A white forelock, generally similar to that of piebaldism, is the most frequently observed pigmentary abnormality in WS (20–60% of patients). Although the forelock is usually white, patches of red, brown or black hair have been described. A few patients have additional areas of poliosis (e.g. frontoparietal or occipital scalp). Premature graying can involve the scalp hair, eyebrows and body hair, and the onset may be as early as the teens. Areas of leukoderma with an appearance, distribution pattern and natural history similar to piebaldism have been observed in approximately 15% of patients. The prevalence of hearing impairment ranges from 9% to more than 37%[74], and it may be bilateral or unilateral and severe or moderate.

Fig. 66.14 Waardenburg syndrome type 2. Heterochromia irides in the absence of dystopia canthorum. The white forelock is seen in the upper left corner. *Courtesy, Daniel Albert, MD.*

Heterochromia irides, partial (sectorial) or complete, is found in >20% of patients (Fig. 66.14). Complete heterochromia irides gives rise to irides of different colors, one being whitish blue. Bilateral involvement results in bilateral pale blue eyes (isohypochromia). Hypomelanotic fundi may be present.

The eyebrows may be confluent (synophrys) or show hyperplasia of their medial portions (15–70% of patients). The characteristic dystopia canthorum represents an increase in the distance between the inner canthi, with normal distances between the pupils and between the outer canthi. This is accompanied by a shortening in the length of the palpebral fissure (blepharophimosis) and a lateral displacement of the inferior lacrimal points, which are then situated in front of the cornea. The dystopia is usually symmetric but may be asymmetric. Dystopia canthorum is a characteristic feature of WS1 and WS3.

Waardenburg syndrome type 2 (WS2)
WS2 differs from WS1 primarily by the absence of dystopia canthorum. In addition, deafness is probably more common in patients with WS2.

Klein–Waardenburg syndrome (WS3)
WS3 is similar to WS1 but is also associated with upper limb abnormalities (e.g. hypoplasia, syndactyly).

Shah–Waardenburg syndrome (WS4)
In WS4, the characteristic findings of WS occur in association with Hirschsprung disease. In many patients, a white forelock, amelanotic macules and heterochromia irides are present. Deafness is fairly common, but dystopia canthorum and a broad nasal root are uncommon. Additional rare manifestations (associated with *SOX10* mutations) include central nervous system dysfunction, neonatal hypotonia and arthrogryposis.

Tietz syndrome
Tietz syndrome is a rare autosomal dominant disorder characterized by diffuse pigmentary dilution of the skin and hair together with deafness and hypoplasia of the eyebrows. Although the eyes are blue, affected individuals do not have photophobia or nystagmus and the fundi are normal. The clinical phenotype is significantly different from WS2, despite being allelic.

Pathology
As in piebaldism, the areas of involvement in WS have an absence or minimal number of melanocytes when examined by light or electron microscopy.

Diagnosis
In patients with the complete WS phenotype, the diagnosis is clear. However, there is significant clinical heterogeneity, and in some forme fruste cases the diagnosis can be difficult to establish. Examination of family members can be helpful as they may have other features of the disease.

Treatment
No specific treatment is available. However, early diagnosis permits appropriate management of the deafness.

Disorders of Melanosome Biogenesis
Melanosomes are considered members of the lysosome-related organelle family, which includes platelet dense granules and the lytic granules of cytotoxic lymphocytes and natural killer (NK) cells. When the biogenesis of these organelles is disrupted, affected individuals present with the clinical findings of OCA due to their defective melanosomes together with additional symptoms (e.g. bleeding diathesis, immunodeficiency) that reflect abnormalities in other lysosome-related organelles[75,76]. These genetic diseases include Hermansky–Pudlak syndrome (HPS) and Chédiak–Higashi syndrome (CHS).

Hermansky–Pudlak syndrome
To date, nine subtypes of HPS have been identified, each of which is inherited in an autosomal recessive manner (Table 66.6)[77].

Pathogenesis
Most forms of HPS result from mutations in genes that encode components of the *b*iogenesis of *l*ysosome-related *o*rganelles *c*omplexes 1–3 (BLOC1/2/3; see Table 66.6 & Fig. 65.8). These complexes are involved in the formation of lysosome-related organelles, including melanosomes, by a mechanism distinct from that of the adaptor protein 3 (AP-3) complex. The exception is HPS2, which is caused by mutations in the *AP3B1* gene. *AP3B1* encodes the β3A subunit of the AP-3

DISORDERS OF MELANOSOME TRANSPORT AND TRANSFER				
Human disease	**Mouse model**	**Gene mutated**	**Protein function**	**Patient population**
			HERMANSKY–PUDLAK SYNDROME (HPS)	
HPS1	Pale ear	*HPS1*	Trafficking of organelle-specific proteins; component of BLOC-3 (see Fig. 65.8)	Puerto Rico, Arecibo region
HPS2	Pearl	*AP3B1*	β3A (also known as β1) subunit of adaptor protein 3 (AP-3); formation of vesicles from the trans-Golgi network and protein trafficking (see Fig. 65.8)	
HPS3	Cocoa	*HPS3*	Component of BLOC-2	Puerto Rico
HPS4	Light ear	*HPS4*	Component of BLOC-3	
HPS5	Ruby eye 2	*HPS5*	Component of BLOC-2	
HPS6	Ruby eye	*HPS6*	Component of BLOC-2	
HPS7	Sandy	*DTNBP1*	Encodes dysbindin*, a component of BLOC-1	
HPS8	Reduced pigmentation	*BLOC1S3*	Component of BLOC-1 (subunit 3)	
HPS9	Pallid	*PLDN*	Encodes pallidin, a component of BLOC-1	
			CHÉDIAK–HIGASHI SYNDROME (CHS)	
CHS	Beige	*LYST*	Lysosomal trafficking regulator protein that controls fission/fusion of lysosome-related organelles	
			GRISCELLI SYNDROME (GS)	
GS1	Myosin Va dilute	*MYO5A*	Captures melanosomes when they reach the cell periphery within dendrites and attaches them to the actin cytoskeleton; also expressed in neurons	
GS2	Rab27A	*RAB27A*	Melanosomal membrane GTPase that binds to melanophilin and takes part in melanosome attachment at the cell periphery; also functions in granule secretion from cytotoxic T-cells	
GS3	Leaden	*MLPH*	Links myosin Va to Rab27a, enabling docking of melanosomes at the cell periphery	
		Deletion of the *MYO5A* F-exon	The F-exon of myosin Va is only expressed in melanocytes	

*Dysbindin also binds to α- and β-dystrobrevins, components of the dystrophin-associated protein complex in both muscle and non-muscle cells.

Table 66.6 Disorders of melanosome transport and transfer. BLOC, biogenesis of lysosome-related organelles complex; CTL, cytotoxic T lymphocytes; *DTNBP1*, dystrobrevin binding protein 1.

complex, which is involved in protein sorting to lysosomes and lysosome-related organelles (see Fig. 65.8). AP-3 also functions in CD1b-associated antigen presentation and secretion of lytic granules from cytotoxic T cells, explaining the additional clinical feature of immunodeficiency in patients with HPS2.

Clinical features

Compared to unaffected first-degree relatives, patients with HPS have pigmentary dilution of the skin, hair and eyes. The degree varies, depending upon the underlying mutations and the patient's ethnic origin. With age, an increase in pigmentation is usually seen, but patients still have difficulty tanning. Ocular manifestations of albinism, such as nystagmus and reduced visual acuity, are also present.

Systemic manifestations due to organelle dysfunction include a bleeding tendency (e.g. with tooth extraction or childbirth) as well as interstitial pulmonary fibrosis and granulomatous colitis secondary to ceroid lipofuscin accumulation within lysosomes. Less often, renal failure and cardiomyopathy develop, usually during adulthood. Patients with HPS2 experience recurrent bacterial infections due to neutropenia and abnormal cytotoxic T-cell function.

Laboratory findings and pathology

Laboratory evaluation is notable for the presence of hair bulb tyrosinase as well as stage I to III (rarely stage IV) melanosomes and macromelanosomes by electron microscopy. Although the platelet count is normal, the bleeding time and platelet function analyzer (PFA)-100 time are prolonged due to platelet dysfunction. Ultrastructurally, there is an absence of dense bodies within platelets. Ceroid deposits, derived from the degradation of lipids and glycoproteins, are found within lysosomes in affected internal organs, including the lungs and gastrointestinal tract. Presumably, this reflects a defect in lysosomal function.

Treatment

The development of progressive pulmonary fibrosis often leads to premature death in patients with HPS, who have an average lifespan of only 30–50 years. Although the antifibrotic agent pirfenidone appeared to slow the progression of pulmonary fibrosis in HPS1 patients in an initial controlled study, a more recent controlled trial found no benefit of this agent in HPS1 patients with mild to moderate pulmonary disease[78]. Platelet transfusions can be administered prior to surgical procedures in HPS patients.

Cross syndrome

Cross syndrome is characterized by diffuse pigmentary dilution, silvery hair, ocular anomalies, and neurologic abnormalities (e.g. psychomotor retardation, ataxia and spasticity). A family with overlapping features of HPS and Cross syndrome has raised the possibility that this latter syndrome may be a clinical variant of HPS[79].

Chédiak–Higashi syndrome

Chédiak–Higashi syndrome (CHS) is a rare autosomal recessive disorder characterized by OCA with a silvery-gray cast to the hair, photophobia, nystagmus and ocular hypopigmentation; an admixture of hyper- and hypopigmentation may be evident in chronically sun-exposed skin, especially in patients with relatively dark constitutive pigmentation. Additional findings include a bleeding diathesis due to diminished function of platelet dense granules, progressive neurologic dysfunction, and severe immunodeficiency due to abnormal lytic granules in lymphocytes, NK cells and neutrophils (see Ch. 60). A hallmark of the disorder is the presence of giant lysosome-related organelles, including melanosomes, platelet dense granules and neutrophil granules. Examination of a peripheral blood smear for the latter represents a simple method of screening for this condition. CHS is caused by mutations in the *lys*osomal *t*rafficking regulator gene (*LYST*), which encodes a cytoplasmic protein that regulates fission/fusion of lysosome-related organelles[80].

Tricho-hepato-enteric syndrome (phenotypic diarrhea of infancy)

This autosomal recessive disorder caused by mutations in the tetratricopeptide repeat domain 37 gene (*TTC37*) can present with diffuse pigmentary dilution of the skin and hair, platelet defects (including abnormal granules) and immunodeficiency. Unlike CHS, it is also characterized by brittle hair with trichorrhexis nodosa, intractable diarrhea during infancy, primary liver disease, facial dysmorphism and cardiac defects.

Disorders of Melanosome Transport and/or Transfer

Identification of the defective proteins in various forms of Griscelli syndrome (GS) has led to better understanding of processes of melanosome transport.

Epidemiology

Griscelli syndrome and the related Elejalde syndrome (neuroectodermal melanolysosomal disease) are rare autosomal recessive disorders.

Pathogenesis

On the basis of molecular genetics (as well as clinical findings), GS has been separated into three entities, GS1, GS2 and GS3 (see Table 66.6). GS1 is due to mutations in the gene that encodes myosin Va[81]. One end of the myosin Va protein binds the actin cytoskeleton, while the other can bind an organelle, e.g. a melanosome. This linkage plays a key role in the transfer of melanosomes from melanocytes to keratinocytes. GS2 is associated with mutations in *RAB27A*[82], which encodes a small Ras-like GTPase (belonging to the Rab family) that is present in melanosomes. GS3 is due to mutations in *MLPH*, whose protein product, melanophilin, serves to link myosin Va to Rab27a[83] (see Fig. 65.10). Because *MLPH* is expressed only in melanocytes, the associated phenotype is limited to diffuse pigmentary dilution and silvery hair. On the other hand, expression of *MYO5A* in neurons explains the associated neurologic abnormalities in GS1, and expression of *RAB27A* in hematopoietic cells accounts for the immunodeficiency and hemophagocytic syndrome observed in GS2. Elejalde syndrome may represent a variant of GS1, but its molecular basis is not yet known.

Clinical features

All three types of GS are characterized by pigmentary dilution of the skin and silvery-gray hair due to pigment clumping within melanocytes. As noted above, patients with GS1 exhibit primarily neurologic impairment[81], while those with GS2 have immune abnormalities due to defective release of cytotoxic lysosomal contents from hematopoietic cells. A hemophagocytic syndrome can also occur in GS2, with uncontrolled T-lymphocyte and macrophage activation leading to death[82]; this process can involve the CNS in a secondary manner.

Elejalde syndrome presents with the pigmentary findings of GS plus severe neurologic dysfunction.

Treatment

Hematopoietic stem cell transplantation is indicated for the treatment for GS2 (but not GS1 or GS3).

Tuberous Sclerosis Complex

The tuberous sclerosis complex (TSC) represents an autosomal dominant disorder characterized by hamartomas in multiple organs, most commonly the skin, brain, eye, heart and kidney (see Ch. 61).

Clinical features

The classic TSC triad of facial angiofibromas ("adenoma sebaceum"), seizures and mental deficits is preceded by the appearance of white macules. In one study utilizing Wood's lamp examination, hypomelanotic macules were found in 64 of 65 patients with TSC (although this high figure may be an artifact of referral selection).

Hypomelanotic macules are often evident at birth or during the neonatal period. In fact, all lesions are probably present at birth, but they may be inapparent, particularly in lightly pigmented infants, until the skin is exposed to UV light or the patient is examined with a Wood's lamp. The number of lesions varies from one to >100 per patient. The great majority of patients have 2–20 hypomelanotic macules, with 50% having fewer than six and 50% having six or more macules. Lesions may be polygonal, lance-ovate, "thumbprint-like", guttate ("confetti-like") or (rarely) segmental (Fig. 66.15). The most characteristic, but not the most frequent, configuration is lance-ovate

Fig. 66.15 Tuberous sclerosis. Two types of hypomelanotic macules – lance-ovate and confetti (idiopathic guttate hypomelanosis-like). *Courtesy, Dr Strobel.*

DIFFERENTIAL DIAGNOSIS OF GUTTATE LEUKODERMA
Idiopathic guttate hypomelanosis
Pityriasis lichenoides chronica
Lichen sclerosus
Achromic verrucae plana*
Leukoderma punctata (after PUVA therapy)
Vitiligo ponctué
Darier disease (usually admixed with keratotic lesions)
Confetti-like lesions of tuberous sclerosis
Xeroderma pigmentosum
In association with punctate palmoplantar keratoderma
In association with chromosomal abnormalities
Disseminated hypopigmented keratoses (after PUVA therapy)*
Frictional lichenoid dermatitis*
Pityriasis alba
Pityriasis versicolor (especially on the face of children)
Clear cell papulosis*
*Minimally elevated flat-topped papules.

Table 66.7 Differential diagnosis of guttate leukoderma. Guttate hypopigmentation may also be seen in the setting of dyschromatoses (see Table 67.8). *Adapted from Bolognia JL, Shapiro PE. Albinism and other disorders of hypopigmentation. In: Arndt KA, et al (eds). Cutaneous Medicine and Surgery. Philadelphia: WB Saunders, 1995.*

(rounded at one end, pointed at the other), which resembles the leaflet of the mountain ash tree, hence the name "ash leaf spot".

Hypomelanotic macules are usually found on the trunk, particularly posteriorly, but they can be found on any cutaneous surface. They occur more commonly on the lower extremities than on the upper extremities or the head and neck; lesions on the scalp are often associated with more lightly pigmented hairs. The long axis of the lance-ovate (ash leaf) macules is predominantly in the cephalocaudal direction on the extremities and in the transverse direction on the trunk. The margins of the lesions are usually smooth but may be irregular. The macules and patches are a dull white color (hypomelanotic), not the "pure-white" color (amelanotic) of vitiligo. As a result, they may be inapparent on casual examination of lightly pigmented skin. Wood's lamp examination reveals a reduction, but not an absence, of pigmentation. The relative size and number of hypomelanotic macules do not change with age, and spontaneous disappearance does not occur. Café-au-lait macules are seen in some patients.

Pathogenesis

Circumscribed hypomelanosis in TSC does not appear to result from a reduction in the number of melanocytes but rather from decreased size and poor melanization of melanosomes, which (regardless of racial background) are grouped within the lysosomes of keratinocytes (see Table 65.3). Of note, decreased melanosome size is not a feature of other circumscribed congenital hypomelanoses. TSC is caused by mutations in two tumor suppressor genes, *TSC1* and *TSC2*, which encode the hamartin and tuberin proteins, respectively (see Ch. 61). These proteins associate physically *in vivo*, functioning together to negatively regulate mammalian target of rapamycin (mTOR) signaling.

Diagnosis

If an infant has three or more hypopigmented macules, a diagnosis of TSC should be considered and (if there is no history of seizures) echocardiography performed as an initial investigation (see Fig. 61.21). The presence of three or more hypomelanotic macules, especially if lance-ovate in shape, raises the possibility of TSC. The combination of white macules and seizures increases the likelihood of TSC. Although the presence of only one or two hypopigmented macules or patches in an otherwise healthy infant does not completely exclude TSC, the diagnosis of nevus depigmentosus is much more likely.

It is usually fairly easy to distinguish vitiligo, given its characteristic distribution pattern and the pure-white color. Postinflammatory hypopigmentation is typically easily excluded by the lack of preceding or concurrent inflammatory or trauma-induced lesions. Nevus anemicus is readily distinguished by its "disappearance" upon diascopy; in addition, vigorous rubbing or application of ice produces erythema in the hypopigmented lesions of TSC but not in nevus anemicus. Hypomelanotic macules may be observed in patients with ataxia telangiectasia (likely reflecting "pigmentary mosaicism"). Westerhof syndrome is characterized by hypo- and hyperpigmented macules, possibly in association with growth retardation; autosomal dominant inheritance has been proposed, but the etiology is not known. Familial progressive hyper- and hypopigmentation, which also has autosomal dominant inheritance and features lesions ranging from small macules to large patches, was recently found to be caused by heterozygous activating mutations in the KIT ligand gene (*KITLG*)[83a].

Rarely, the hypopigmentation in TSC has a segmental pattern, for which the differential diagnosis includes segmental vitiligo (which progresses over a few months to 2 years and is amelanotic) and "pigmentary mosaicism" (see below). Idiopathic guttate hypomelanosis (IGH) may resemble the confetti lesions of TSC, but IGH is an acquired disorder that usually develops in adults. The diagnosis of TSC should be considered in any child or infant with a guttate leukoderma. Other causes of a guttate leukoderma are outlined in Table 66.7.

"Pigmentary Mosaicism": Hypomelanosis of Ito, Segmental Pigmentation Disorder and Nevus Depigmentosus

Hypomelanosis of Ito (HI) is a descriptive term for hypopigmentation along Blaschko's lines (also referred to as "linear nevoid hypopigmentation"), which reflects mosaicism characterized by a clone of skin cells with a decreased ability to make pigment ("pigmentary mosaicism"; see Ch. 62). Although cytogenetic data are less substantial, "segmental pigmentation disorder" and nevus depigmentosus are also considered to represent manifestations of cutaneous mosaicism[84].

Clinical features

HI may be apparent at birth or become evident during infancy or early childhood. The characteristic pattern of streaks and whorls (Table 66.8) can occur unilaterally or bilaterally and is seen most commonly on the trunk and limbs (Fig. 66.16)[84]. Abnormalities of the CNS, eye or musculoskeletal system are found in approximately 30% of patients with hypopigmentation along Blaschko's lines who present to a pediatric dermatologist at a tertiary referral center.

Nevus depigmentosus occurs in 1 in 50–75 individuals. The name is a bit of a misnomer, as the areas of leukoderma are actually hypomelanotic rather than amelanotic. Most lesions measure a few centimeters in diameter and have irregular but well-defined borders, often breaking apart into smaller macules at the periphery (Fig. 66.17). A block-like variant of nevus depigmentosus, also referred to as the hypopigmented form of the "segmental pigmentation disorder", typically features midline demarcation and less distinct lateral borders[85].

Phylloid hypomelanosis is a distinctive pattern of hypomelanosis that occurs in patients with mosaic forms of trisomy (or tetrasomy) 13 or 13q. The hypomelanosis consists of: (1) round or oval lesions; (2) large

DISORDERS WITH LINEAR HYPOPIGMENTATION
LESIONS USUALLY FOLLOW BLASCHKO'S LINES
• Hypomelanosis of Ito/"linear nevoid hypopigmentation"*
• Lichen striatus
• Focal dermal hypoplasia (Goltz syndrome)
• Menkes kinky hair disease (female carrier)
• Conradi–Hünermann–Happle syndrome
• Epidermal nevus
• In association with nevus comedonicus
• Linear lichen sclerosus
• Guttate macules in linear keratosis follicularis and linear basaloid follicular hamartoma
LESIONS MAY FOLLOW BLASCHKO'S LINES
• Segmental vitiligo
• Segmental ash leaf spot
• Fourth stage of incontinentia pigmenti
LESIONS DO NOT FOLLOW BLASCHKO'S LINES
• Linear hypopigmentation secondary to intralesional corticosteroids
• Pigmentary demarcation lines, type C
*Block-like hypopigmentation represents another pattern of "pigmentary mosaicism" and may coexist with linear lesions; overlaps with a "systematized" nevus depigmentosus with a linear configuration.

Table 66.8 Disorders with linear hypopigmentation. *Adapted from Bolognia JL, Shapiro PE. Albinism and other disorders of hypopigmentation. In: Arndt KA, et al (eds). Cutaneous Medicine and Surgery. Philadelphia: WB Saunders, 1995.*

Fig. 66.16 Hypomelanosis of Ito. Note the S-shaped pattern of the hypopigmented streaks along Blaschko's lines on the flank and abdomen.

asymmetric areas reminiscent of the leaves of a begonia; and (3) pear-shaped or oblong macules. Additional features may include telangiectatic macules, hypertrichosis, CNS defects (especially absence of the corpus callosum), conductive hearing loss, choroidal and retinal colobomas, craniofacial anomalies and digital malformations[86].

Pathology

Light and electron microscopy of involved skin in HI may reveal a decreased number of melanocytes and melanosomes[87]. A wide variety of cytogenetic abnormalities in lymphocytes and/or lesional fibroblasts have been detected in patients with HI (see Ch. 62).

Diagnosis

The differential diagnosis of linear leukoderma is presented in Figure 66.18. Diagnostic considerations for the common type of nevus depigmentosus are discussed above (see TSC).

Fig. 66.17 Nevus depigmentosus. Hypomelanotic patch with a decrease, but not absence, of pigmentation.

OTHER GENETIC FORMS OF HYPOMELANOSIS

Albinism–deafness syndrome, also called Ziprkowski–Margolis syndrome or Woolf syndrome, is an X-linked disorder that has been mapped to Xq26.3–q27.1[88]. Affected boys have congenital sensorineural deafness and a severe piebald-like phenotype with extensive areas of hypopigmentation.

NUTRITIONAL HYPOMELANOSIS

In *kwashiorkor*, which is due to severe protein deficiency, the skin initially becomes erythematous to red–brown in color with marked desquamation (see Ch. 51). Both hypomelanosis and patchy postinflammatory hypermelanosis can be seen, with striking pigmentary changes in florid cases. The hypomelanosis usually begins on the face. The hair is dry and lusterless, and it may become light red–brown in color. Upon resumption of dietary protein intake, the skin repigments slowly. Diffuse pigmentary dilution due to *deficiencies of copper* or *selenium* have also been reported (see Fig. 66.11).

POSTINFLAMMATORY HYPOMELANOSIS

Epidemiology

Postinflammatory hypomelanosis (PIH) represents a very common skin disorder that is more obvious in darkly pigmented or tanned individuals. A large number of dermatoses can lead to PIH[89], including psoriasis, seborrheic dermatitis, atopic dermatitis, sarcoidosis, lichen sclerosus, lichen striatus, pityriasis lichenoides chronica, mycosis fungoides and lupus erythematosus (Fig. 66.19). In some patients, repeated examinations are required to identify primary inflammatory lesions.

Pathogenesis

The various steps that determine skin color, including melanogenesis, are controlled by multiple factors (e.g. growth factors, cytokines) that exert their actions directly or indirectly on keratinocytes and melanocytes. Dysregulation of these processes can induce abnormal melanocyte–keratinocyte interactions. Cutaneous inflammation, for example, is able to alter melanosome biogenesis, melanin production, melanosome transport, and especially transfer of melanosomes to keratinocytes. Severe local inflammation can lead to a loss of functional melanocytes or even melanocyte death.

Clinical features

Hypomelanosis usually follows or coexists with inflammatory lesions, but, occasionally, only hypopigmented lesions are seen, e.g. in sarcoidosis or mycosis fungoides. PIH, either localized or widespread, is usually associated with a decrease, but not absence, of pigment.

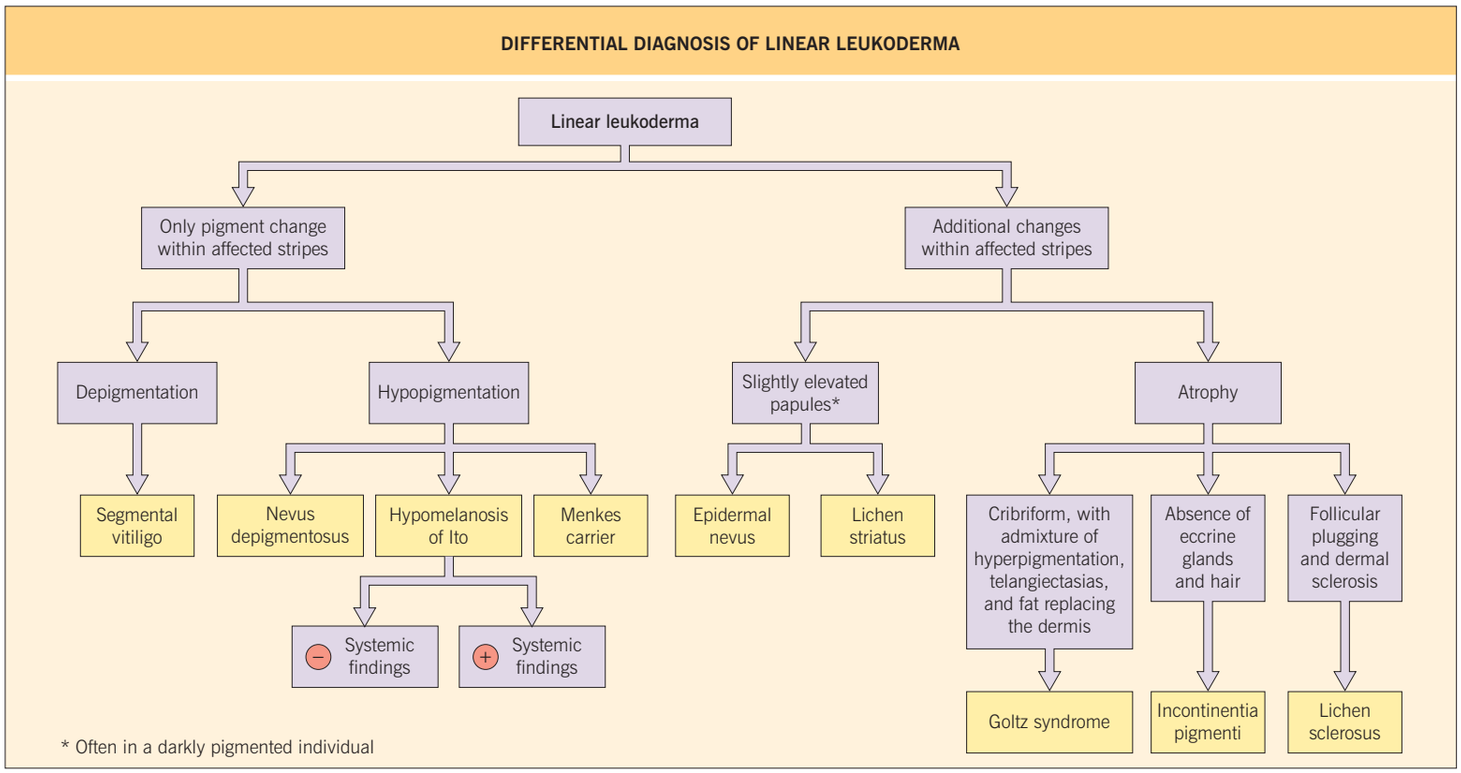

Fig. 66.18 Differential diagnosis of linear leukoderma.

Complete depigmentation is most commonly seen in the setting of severe atopic dermatitis and discoid lupus erythematosus (see Fig. 66.19E,F). Whether this lack of pigment represents koebnerization of vitiligo into areas of inflammation versus the consequence of severe inflammation is debatable.

Pathology

In certain forms of PIH (e.g. sarcoidosis, mycosis fungoides), histologic examination of hypopigmented lesions can aid in establishing the diagnosis, whereas in others (e.g. pityriasis lichenoides chronica) the findings are often nonspecific.

Treatment

Once the underlying inflammatory disorder is effectively treated, the PIH usually gradually resolves. Sun exposure or UVB phototherapy may be helpful. In amelanotic lesions with complete loss of melanocytes, epidermal or melanocyte grafting may be considered (see above).

Pityriasis Alba

Pityriasis alba is a very common condition, consisting of slightly scaly, round to oval, ill-defined macules and patches with mild to moderate hypopigmentation (see Ch. 12). Although it occurs in all races, pityriasis alba is more noticeable in darkly pigmented individuals. It is generally a disorder of childhood and adolescence, and it becomes more apparent during the summer months when the surrounding skin is tanned. The lesions usually vary in size from 0.5 to 3 cm, but larger lesions can also occur.

The earliest lesions may be pink in color, but after a few weeks, the erythema fades and the cutaneous surface assumes a whitish, dry, powdery appearance, sometimes with a slightly raised, pinkish border. The face, especially the malar region, is the most frequent site of involvement. Occasionally, lesions of pityriasis alba are seen on the neck, trunk and extremities. This dermatosis is generally asymptomatic, but some patients complain of itching and burning. With Wood's lamp examination, more lesions may become apparent and a decrease in pigment is confirmed (as opposed to an absence of pigment as in vitiligo). Although the patches of hypomelanosis often remain stationary and unchanged for several years, they usually (but not always) clear spontaneously after puberty.

Light and electron microscopy reveal reduced numbers of active melanocytes and a decrease in the number and size of melanosomes in the affected skin.

The differential diagnosis includes pityriasis versicolor, vitiligo (see above) and other forms of PIH, in particular pityriasis lichenoides chronica when the lesions are extrafacial.

Topical hydrocortisone may be helpful, but emollients seem to be equally effective.

Sarcoidosis

The true incidence of leukoderma in sarcoidosis is unknown. In one series, hypopigmentation was observed in 6% of sarcoidosis patients. The female-to-male ratio is ~2:1. The lesions are described as circumscribed or poorly marginated papules or plaques that vary from one to a few centimeters in diameter, and they may or may not be indurated. In addition, dermal nodules surrounded by hypomelanosis may be seen[90]. The lesions appear most commonly on the extremities, are asymptomatic, and have no other secondary changes. They appear to carry no specific prognostic significance, and spontaneous repigmentation may occur.

Histologically, non-caseating granulomas are seen in the dermis. By electron microscopy, some melanocytes appear normal, while others have abnormalities such as cytoplasmic vacuolation, dilation of the rough endoplasmic reticulum, and degenerative changes within mitochondria. The melanosomes appear morphologically normal, but their number within keratinocytes is decreased. The clinical and histologic features of leprosy differ enough to allow a distinction.

Hypopigmented Mycosis Fungoides

Hypomelanotic mycosis fungoides (MF) is a variant of early-stage MF that is most frequently observed in darkly pigmented individuals (Fig. 66.20), probably because it is more clinically obvious in darker skin. The hypomelanotic lesions occur on the trunk or extremities and may be pruritic. Erythema and slight infiltration are usually, but not always, present. Although the most common age range at the time of diagnosis is 30–40 years, it can develop in children and adolescents. Treatment with photo(chemo)therapy or topical nitrogen mustard (mechlorethamine) can result in repigmentation. Routine histology shows the typical features of MF and electron microscopy demonstrates decreased

Fig. 66.19 Postinflammatory hypomelanosis. Hypopigmentation secondary to psoriasis (**A**), seborrheic dermatitis in an infant (**B**), pityriasis lichenoides chronica (**C**), and lichen striatus (**D**). G, Courtesy, Julie V Schaffer, MD.*

numbers of melanosomes within epidermal keratinocytes. Numerous morphologically normal melanosomes are present in melanocytes. These observations suggest a defect in melanosomal transfer, a change seen in most postinflammatory hypomelanoses.

Scleroderma and Lichen Sclerosus

Patients with scleroderma can develop diffuse hypermelanosis[91] with accentuation in sun-exposed sites, a mixture of hypo- and hyperpigmentation in areas of chronic sclerosis (e.g. the hands), and a characteristic leukoderma in both sclerotic and non-sclerotic skin. The latter features circumscribed areas of complete pigment loss except for perifollicular and supravenous retention of pigment (Fig. 66.21). When this peculiar leukoderma is seen, scleroderma must be excluded, as it is only known to occur in two other settings: overlap syndromes (i.e. those that include scleroderma) and scleromyxedema. The origin and pathogenesis of the pigmentary disturbances in scleroderma are unknown.

Genital and extragenital lesions of lichen sclerosus are often hypomelanotic. Additional changes include epidermal atrophy, follicular plugging and, in the anogenital region, purpura. Occasionally, extragenital lichen sclerosus presents as a guttate leukoderma (see Table 66.7; Fig. 66.22). Electron microscopy reveals a loss of pigment cells or decreased number of melanocytes with degenerative changes.

Lupus Erythematosus

In discoid lupus erythematosus (DLE), hypomelanosis or amelanosis is almost always associated with cutaneous atrophy and scarring (see Fig. 66.19F). Hypomelanosis favors the center of the lesions, and it is often accompanied by a rim of hyperpigmentation. In chronic scarring DLE, the pigmentary changes are persistent. Histologically, in addition to a decreased number of epidermal melanocytes, there is epidermal atrophy, vacuolar degeneration of the basal layer, pigmentary incontinence and fibrosis, changes that help to establish the correct diagnosis.

Fig. 66.20 Hypopigmented mycosis fungoides. This condition is most often observed in individuals with darkly pigmented skin.

Fig. 66.21 Leukoderma of scleroderma. Uniform retention of perifollicular pigment within areas of leukoderma. Hyperpigmentation is also seen overlying a superficial vein.

Hypomelanosis is also frequently seen in the center of annular lesions of subacute cutaneous LE, but this is usually reversible.

INFECTIOUS AND PARASITIC HYPOMELANOSIS

Pityriasis (Tinea) Versicolor

The primary lesion is round to oval, hypomelanotic, and usually measures several millimeters to 1–3 cm in diameter (Fig. 66.23). Within the areas of involvement, the lesions are often coalescent centrally. Associated fine scale may be obvious or only apparent upon scratching or stretching the skin. The distribution is usually symmetric and favors the upper trunk and shoulders; lesions sometimes develop on the lower trunk, neck and face (see Ch. 77). While the contrast between the hypomelanotic infected skin and the surrounding normal skin is striking in darkly pigmented patients, or following a tan in lightly pigmented patients, Wood's lamp examination may be required to locate all the lesions.

Fig. 66.22 Guttate lichen sclerosus involving the areola.

Fig. 66.23 Pityriasis (tinea) versicolor. A Hypopigmented variant with obvious scale. **B** Guttate hypopigmented lesions on the cheek; note the classic scaly lesions in the posterior auricular area. *B, Courtesy, Julie V Schaffer, MD.*

Fig. 66.24 Tuberculoid leprosy. Large, thin hypopigmented plaque on the elbow with a raised light pink border.

Fig. 66.25 Onchocerciasis (leopard skin). Depigmentation of the shin with follicular repigmentation or retention of perifollicular pigment, a common site for the associated leukoderma.

In the hypopigmented skin, there is a decreased density of melanosomes within keratinocytes, but no change in the melanocyte density. Abnormal melanosome production, decreased melanin synthesis, and a partial block in melanosome transfer to keratinocytes have all been suggested as underlying defects. Azelaic acid, a competitive inhibitor of tyrosinase produced by *Malassezia furfur*, may play a role in the decreased melanin synthesis. Although the differential diagnosis includes postinflammatory hypopigmentation (e.g. secondary to parapsoriasis), progressive macular hypomelanosis or early vitiligo, the diagnosis of pityriasis versicolor is easily confirmed by examination of the associated scale in a potassium hydroxide preparation.

Hypomelanosis without any scaling may remain for months after spontaneous or treatment-induced eradication of the hyphal form of the organism.

Leprosy

Hypomelanotic macules may be the earliest expression of *lepromatous leprosy*. The lesions are usually small, multiple, subtle and ill-defined; they may be difficult to recognize, particularly in lightly pigmented skin. The face, extremities and buttocks are favored, and the warmer parts of the body are usually spared. There is little or no anhidrosis or loss of sensation. Later, plaques, nodules or diffuse infiltration of the skin appear (see Ch. 75).

The hypopigmented patches of *tuberculoid leprosy* are much different from those of lepromatous leprosy. Tuberculoid lesions have discrete edges and can be quite large, up to 30 cm in diameter (Fig. 66.24). A raised border, uniform infiltration or a characteristic pebbled appearance may be observed. The surface can be slightly scaly, dry or minimally atrophic. The lesions are asymmetrically distributed on the posterolateral aspects of the extremities, back, buttocks and face. There is associated alopecia, anhidrosis, and loss of tactile and heat sensations.

In *borderline (dimorphous) leprosy*, plaques and annular lesions are more common than hypomelanotic macules; the latter, if present, have ill-defined borders. A "Swiss cheese" appearance with erythematous annular lesions and hypomelanotic areas, all bound by vague outer borders, characterizes this form of leprosy. In *indeterminate leprosy*, the macules are usually hypomelanotic, but they may also be erythematous; hypoesthesia may be present. They are asymmetrically distributed and favor exposed sites.

The mechanism of hypopigmentation in leprosy is unknown, and there are no histologic or ultrastructural alterations in the melanocytes. Treatment usually, but not always, results in repigmentation of the hypomelanotic macules.

Treponematoses

In *pinta*, hypomelanotic lesions occur during the late phase of the disease, a few months to several years after the appearance of secondary lesions. Irregular, vitiligo-like areas of depigmentation favor skin overlying bony prominences and are often surrounded by brown to blue–gray hyperpigmentation. Atrophy, xerosis and alopecia may be evident. Longstanding amelanotic lesions do not typically repigment.

Hypomelanosis occasionally develops in untreated tertiary *yaws*. Symmetric hypomelanotic macules enlarge until an entire area is affected. The most common sites are the dorsal aspects of the wrists and hands and over the metacarpophalangeal and interphalangeal joints.

Hypomelanosis may occur in the late stages of *bejel (endemic syphilis)*. Hypomelanotic macules have well-defined borders and may be admixed with pigmented macules. The lesions are usually symmetrically distributed on the extremities, genitalia, areolae and trunk. Early penicillin G treatment results in satisfactory repigmentation.

In *secondary syphilis*, hypomelanosis is an occasional finding that is called "leukoderma syphiliticum". In the "necklace of Venus", small (1–2 mm) hypomelanotic macules are scattered within a larger area of hyperpigmentation on the neck. Hypopigmentation may also develop at sites of previous inflamed lesions, which favor the neck, proximal extremities, upper trunk, abdomen, axillae and groin. Leukoderma syphiliticum regresses with treatment and usually disappears completely within several months to a year.

Onchocerciasis

Initially, small (punctate), yellow–brown hypomelanotic macules appear on the middle third of the shin medial to the tibial crest. Later, the macules enlarge, coalesce and undergo progressive lightening until there is amelanosis (Fig. 66.25). Pigmented macules persist within the hypopigmented patches, hence the designation "leopard skin" (see Ch. 83). Other sites of involvement may include the lateral aspects of the legs, groin and skin overlying the bony prominences of the pelvis.

Post-kala-azar Dermal Leishmaniasis

Small hypomelanotic macules in a symmetric distribution that favors the upper trunk and arms constitute the prenodular stage of the disease. The lesions become elevated over a period of months to years. Total repigmentation following systemic treatment with antimonials is almost impossible to achieve.

Herpes Zoster

Hypo- or depigmentation is sometimes seen in the sites of previous herpes zoster. Amelanosis can result from melanocyte destruction during the inflammatory and healing process, which may also lead to atrophy and fibrosis.

HALO NEVUS AND MELANOMA-ASSOCIATED LEUKODERMA

Halo Nevus

The halo nevus phenomenon (see Ch. 112) most often occurs in children and young adults with multiple melanocytic nevi; it is unusual in

adults over 40 years of age. A central melanocytic nevus is surrounded by a round or oval amelanotic annulus. The lesions are asymptomatic and the most common site is the trunk, particularly the back. There are four stages in the evolution of a halo nevus: (1) appearance of the halo; (2) loss of pigment within the central nevus; (3) disappearance of the nevus; and (4) disappearance of the halo.

Some patients develop multiple halo nevi and/or associated vitiligo. The exact relationship between halo nevi and vitiligo has been the subject of controversy.

Both nevus cells and epidermal melanocytes in the surrounding skin are destroyed, as demonstrated by histologic and ultrastructural studies. Both $CD4^+$ and $CD8^+$ T cells infiltrate halo nevi. Peripheral T cells from a patient with halo nevi were shown to lyse *in vitro* melanocytes obtained from normal nevus, implicating T cells in the pathogenesis of halo nevi. Oligoclonality of the T-cell response in patients with halo nevi further suggests that the destruction of melanocytes could represent the lysis of a distinctive cell type through an immune process mediated by a limited number of T-cell clones[92].

The clinical diagnosis of halo nevus is usually fairly straightforward, but Wood's lamp examination may occasionally be required to detect the halo. The halo phenomenon can occur with a variety of types of melanocytic nevi (e.g. neurotized, blue, congenital) and melanoma. Careful examination of the central lesion is therefore required. Typical halo nevi require no treatment other than reassurance. Individuals beyond 40 years of age with halo nevi should be examined carefully for melanoma (ocular and cutaneous).

Melanoma-Associated Leukoderma

Vitiligo-like depigmentation can occur in patients with cutaneous or ocular melanoma. At least three types of leukoderma are associated with melanoma: hypomelanosis within tumors (primary or metastatic) due to regression (see Ch. 113), amelanosis around tumors (see above; Fig. 66.26), and vitiligo-like depigmentation remote from the tumors. In the latter, involvement of ocular melanocytes (e.g. uveitis, retinopathy, VKH-like changes) has also been reported.

Increasing evidence suggests that melanoma-associated, vitiligo-like leukoderma results from an immune reaction directed against antigenic determinants shared by normal and malignant melanocytes. Although antibodies to pigment cells are commonly found in patients with melanoma, growing evidence points towards an important role for cellular immune responses (Fig. 66.27). Vitiligo-like lesions have been observed in melanoma patients following successful immunotherapy with anti-cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4) antibodies (e.g. ipilimumab) (Fig. 66.28); IL-2; tumor-infiltrating lymphocytes specific for tyrosinase-, gp100- or TYRP1-derived antigens; or peptide vaccines based upon these antigens. In addition, cytotoxic T-lymphocyte clones derived from melanoma patients efficiently lyse cultured human melanocytes.

Clonally expanded T cells with identical Vp regions have been identified in a primary melanoma and a depigmented halo surrounding the tumor, again suggesting a role for a T-cell-mediated antitumoral

response in the development of melanoma-associated, vitiligo-like leukoderma. Melan-A/MART-1-specific $CD8^+$ T cells have been identified in inflammatory hypomelanotic skin lesions following the infusion of Melan-A/MART-1-specific $CD8^+$ T-cell clones in a patient with metastatic melanoma[93]. Thus, in melanoma patients, "vitiligo" may be a visible effect of a spontaneous (or therapy-induced) antitumoral immune response against melanocyte differentiation antigens (see Ch. 113). Several studies using mouse models have shown that vitiligo-like depigmentation and rejection of B16 melanomas can be accomplished via vaccine strategies targeting melanocyte differentiation antigens. This, plus the occasional observation of spontaneous resolution of metastatic melanoma following the development of vitiligo-like leukoderma, holds hope for the future of immunotherapy.

CHEMICAL AND PHARMACOLOGIC HYPOMELANOSIS

A large number of chemical and pharmacologic agents can cause hypomelanosis of skin and hair[94,95]. The three major groups of depigmenting compounds (Table 66.9) are:

- phenols/catechols
- sulfhydryls
- miscellaneous.

Hydroquinone (HQ) and its derivatives (MMEH, MBEH) are the most widely used "bleaching" agents. HQ induces a reversible hypopigmentation of the skin, and it is used to treat disorders such as melasma. In contrast, depigmentation from MBEH is often permanent and occurs not only in the areas of application but also in distant sites; as a result, its only indication is as depigmentation therapy for widespread vitiligo (see above). Of note, MMEH and MBEH were identified as depigmenting agents after outbreaks of occupational leukoderma in workers exposed to these chemicals in rubber products.

Hypomelanosis can follow the use of either topical or intralesional corticosteroids, particularly in darkly pigmented individuals. Potent topical corticosteroids are unfortunately widely used as lightening agents in many areas of the world (especially Africa and Asia). In most cases, the hypomelanosis is incomplete, but the risk of significant side effects (e.g. acne, atrophy, striae) is high. Hypomelanosis induced by intralesional or intra-articular corticosteroids can be stellate or linear, has an irregular outline, and is often ill-defined (Fig. 66.29). The

SELECTED CHEMICALS ASSOCIATED WITH LEUKODERMA

cutaneous hypopigmentation appears several weeks to months after the injection. In most instances, repigmentation occurs within 1 year after discontinuation of the injections.

In any patient, particularly adults, presenting with new-onset "vitiligo" (Fig. 66.30), a detailed history to detect exposure to known depigmenting agents (see Table 66.9) is mandatory. Patch testing can be useful for confirming the diagnosis of chemical leukodermas, but delayed readings are essential (e.g. at 2 weeks, then again at 4–6 weeks). Spontaneous repigmentation may occur following avoidance of the causative agent, but treatment, as for vitiligo, is usually required (see above).

In chemical leukoderma induced by HQ and its derivatives, melanocytes are decreased in number or absent. Other depigmenting agents inhibit tyrosinase (thus blocking melanogenesis) or prevent melanosome transfer.

Patients treated with imatinib mesylate (Gleevec®) have been noted to develop various forms of hypomelanosis, including generalized lightening of the skin, hypopigmentation of the distal digits, difficulty in maintaining a suntan, and progression of vitiligo. These changes appear to be reversible and potentially dose-dependent, and they have been observed more commonly in darkly pigmented individuals[96]. Imatinib mesylate is a tyrosine kinase inhibitor that targets the bcr-abl fusion protein that is characteristic of chronic myelogenous leukemia; it also inhibits three other tyrosine kinases – platelet-derived growth factor (PDGF) receptor-α, PDGF receptor-β and the KIT receptor. Imatinib mesylate-induced inhibition of the KIT receptor, which is involved in melanogenesis and melanocyte homeostasis, is the most likely explanation for the hypopigmentation. Loss of hair color has been noted in patients receiving sunitinib malate, another inhibitor of tyrosine kinase receptors (including the KIT receptor). Sunitinib-induced hair depigmentation appears to be reversible with cessation of treatment[97].

HYPOMELANOSIS FROM PHYSICAL AGENTS

Various types of physical injuries can induce cutaneous hypomelanosis or amelanosis, including thermal burns, freezing, UV radiation, lasers, ionizing radiation, and physical trauma from surgical procedures. The combination of the history of an insult, the shape of the hypopigmentation, and associated findings usually makes the diagnosis relatively straightforward.

Repigmentation is based on a host of factors, including the type and depth of the insult or injury, the anatomic location, and the presence of hair follicles and pigmented hairs.

MISCELLANEOUS

Idiopathic Guttate Hypomelanosis

Idiopathic guttate hypomelanosis (IGH) is a very common disorder, the incidence of which increases with age. It is seen in up to 80% of patients over the age of 70 years. IGH occurs in all races and skin types, but it is more striking in darkly pigmented skin. In Caucasians, IGH may favor those with brown eyes and brown hair. An apparent female predominance is probably the result of heightened perception of a cosmetic problem.

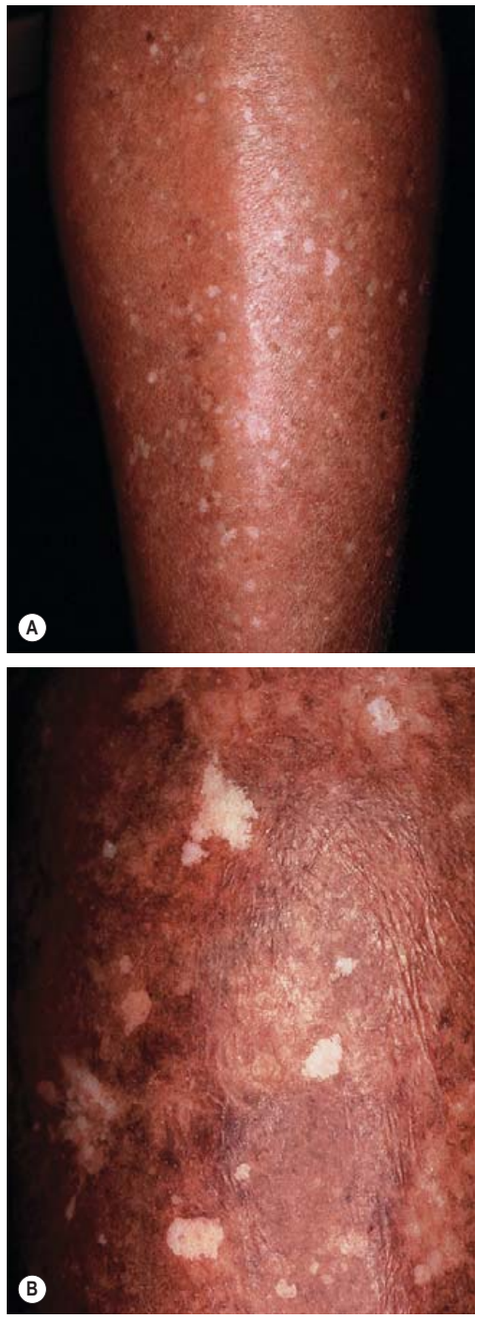

Fig. 66.31 Idiopathic guttate hypomelanosis. **A** Typical 1–5 mm macules on the shin. **B** Occasionally there is admixture of larger lesions.

The typical IGH lesion is a circumscribed, sharply defined, asymptomatic porcelain white macule[98]. The lesions are usually 0.5–6 mm in diameter and often delineated by the skin furrows; occasionally, lesions are up to 2.5 cm in size (Fig. 66.31). Once present, they do not change in size or coalesce; their surface is smooth but not atrophic. Spontaneous repigmentation has not been reported. Hairs within the lesions usually retain their pigment. In most patients, there are multiple lesions on the extensor forearms and shins; the remainder of the extremities can be affected, but rarely the face.

The most consistent histologic features of IGH are a flattening of the dermal–epidermal junction, moderate to marked reduction or focal absence of melanin granules in the basal and suprabasal layers, and a basket-weave hyperkeratosis. There is a moderate to relatively marked reduction in the number of DOPA-positive epidermal melanocytes (10–50% compared with normal skin), but these cells are never totally absent. At the ultrastructural level, some melanocytes have normal melanogenic activity, while others lack mature melanosomes. The

Fig. 66.32 Disseminated hypopigmented keratoses. Over 200 guttate minimally elevated hypopigmented papules developed after several months of PUVA therapy. Histologically, there was no evidence of verruca plana. *Courtesy, Jean L Bolognia, MD*

Fig. 66.33 Clear cell papulosis. Multiple hypopigmented, barely elevated flat-topped papules and macules in the suprapubic area and on the abdomen along the "milk lines" in a 2-year-old boy. Histologically , these lesions are characterized by large clear cells in the lower epidermis that have a pattern of immunohistochemical staining similar to clear cells of Toker and extramammary Paget's disease. *Courtesy, Julie V Schaffer, MD.*

keratinocytes show marked variation in their content of melanin, which may be absent or markedly decreased.

The diagnosis of IGH is usually made clinically; the differential diagnosis of guttate leukoderma is shown in Table 66.7 and includes achromic verrucae plana, pityriasis lichenoides chronica, disseminated hypopigmented keratoses that follow PUVA therapy (Fig. 66.32) and clear cell papulosis (Fig. 66.33). Although lesions of atrophie blanche favor the distal shins and ankles, these porcelain white scars are usually depressed and encircled by papular telangiectasias. The cause of IGH is unknown, but sun exposure probably plays a role.

Cryotherapy with liquid nitrogen has been described as a possible therapy for IGH. As sunlight is most likely a precipitating factor, use of sunscreens and physical barriers should be recommended.

Vagabond's Leukomelanoderma

This skin disorder occurs in older persons in whom dietary deficiency is combined with lack of cleanliness and heavy infestation with *Pediculus humanus* var. *corporis*. These patients have small macules of hypomelanosis (related to scratching) superimposed on a background of diffuse hypermelanosis, especially of the wrists, axillae, groin, inner thighs and posterior neck.

Fig. 66.34 Progressive macular hypomelanosis. Note the coalescence of the non-scaly hypopigmented macules on the center of the back.

DISORDERS ASSOCIATED WITH PREMATURE GRAYING OF SCALP HAIR

- Piebaldism
- Waardenburg syndrome
- Vitiligo
- Sudden whitening of hair
- Hereditary premature canities
- "Bird-headed" dwarfism
- Progeria
- Werner syndrome
- Ataxia telangiectasia
- Rothmund–Thomson syndrome
- Fisch syndrome
- Myotonic dystrophy
- Prolidase deficiency (also in Table 66.11)
- Oasthouse disease

Table 66.10 Disorders associated with premature graying of scalp hair.

Progressive Macular Hypomelanosis

Progressive macular hypomelanosis (PMH) is a fairly common skin disorder, observed more frequently in young women with darkly pigmented skin who originate from or reside in tropical climates. The disorder is characterized by poorly defined, nummular, non-scaly hypopigmented macules and small patches on the trunk, with rare extension onto the proximal extremities or head and neck region; confluence of lesions may occur centrally (Fig. 66.34)[99]. Another variant of PMH features large circular lesions. There is no associated pruritus or preceding inflammation, and patients are sometimes misdiagnosed as having residual hypopigmentation related to pityriasis versicolor. Histologically, there is decreased pigment in the epidermis and a normal-appearing dermis. Electron microscopy demonstrates a shift from large melanosomes in uninvolved skin to small aggregated membrane-bound melanosomes in hypopigmented skin. *Propionibacterium acnes* residing within hair follicles may play a role in PMH. One proposed treatment regimen consists of topical 1% clindamycin and 5% benzoyl peroxide plus UVA irradiation (three times per week for 12 weeks).

Hair Hypomelanosis

Poliosis refers to a circumscribed hypomelanosis of hair (see Table 66.4), whereas canities implies a more generalized depigmentation of hair. Graying of hair, localized or generalized, is characterized by an admixture of normally pigmented, hypomelanotic and amelanotic hairs. Whitening of hair is the endpoint of canities and graying of hair. The graying and whitening of human hair that occurs with aging is due to defective maintenance of melanocyte stem cells[100,101].

A number of genetic disorders are associated with premature graying of hair (Table 66.10), while there are both hereditary and acquired causes of diffuse hypomelanosis of hair (Table 66.11). In Chédiak-Higashi, Griscelli and Elejalde syndromes, the scalp hairs have a silvery hue due to pigment clumping.

DISORDERS ASSOCIATED WITH DIFFUSE HYPOMELANOSIS OF SCALP HAIR

- Fanconi syndrome
- Book syndrome
- Down syndrome
- Hallerman–Streiff syndrome
- Treacher–Collins syndrome
- Prolidase deficiency (also in Table 66.10)
- Hyperthyroidism
- Chronic protein loss or deficiency (e.g. due to kwashiorkor, nephrosis, ulcerative colitis, malabsorption)
- Vitamin B_{12} deficiency
- Tyrosine kinase inhibitors
- Antimalarials (chloroquine > hydroxychloroquine)

Table 66.11 Disorders associated with diffuse hypomelanosis of scalp hair. See also Figure 66.11.

Leukodermas without Hypomelanosis

Woronoff's ring

Woronoff's ring is a blanched halo of fairly uniform width surrounding psoriatic lesions after phototherapy or topical treatments. There is an element of vasoconstriction, but it is uncertain whether there is any decrease in pigmentation.

Nevus anemicus

Nevus anemicus (see Ch. 106) presents as a pale area of variable size (often 3–6 cm) with an irregular, "broken up" outline. It is usually unilateral and located on the trunk. Present since birth, the lesion is most commonly detected later in life, and it is most noticeable when there is surrounding vasodilation due to heat or emotional stress. On diascopy, the lesion becomes indistinguishable from surrounding skin. Histologically, there are no abnormalities in the melanocytes or melanin content. Nevus anemicus is caused by decreased blood flow through the capillaries in the dermal papillae, due to a localized hypersensitivity of the blood vessels to catecholamines.

Cutaneous edema and anemia

Cutaneous edema and anemia also produce lightening of the skin and mucous membranes. In the case of anemia, it is due to decreased hemoglobin levels in the skin.

Angiospastic macules (Bier spots)

Pale macules, usually 3–6 mm in diameter, are seen on the extremities (often more noticeable on the legs) (see Ch. 106). They are due to localized vasoconstriction and are seen most often in young women. Their appearance may be induced by a dependent position or placing a tourniquet on the limb.

Chapter Contents

Diffuse and circumscribed hyperpigmentation 1049
- Postinflammatory hyperpigmentation 1049
- Erythema dyschromicum perstans 1050
- Lichen planus pigmentosus 1052
- Melasma 1052
- Drug-induced hyperpigmentation or discoloration 1055

Linear hyperpigmentation 1058
- Pigmentary demarcation lines 1058
- Linear postinflammatory hyperpigmentation 1059
- Flagellate pigmentation from bleomycin 1061
- Flagellate mushroom dermatitis 1062
- Hyperpigmentation along the lines of Blaschko 1062

Reticulated hyperpigmentation 1064
- Prurigo pigmentosa 1064
- Dyskeratosis congenita 1066
- Naegeli–Franceschetti–Jadassohn syndrome 1068
- Dermatopathia pigmentosa reticularis 1069
- X-linked reticulate pigmentary disorder 1069
- Dowling–Degos disease 1070
- Reticulate acropigmentation of Kitamura 1071

Dyschromatoses 1071
- Dyschromatosis symmetrica hereditaria 1073
- Dyschromatosis universalis hereditaria 1073
- Acquired brachial cutaneous dyschromatosis 1074

The color of the skin depends upon the amount and distribution of melanin and other chromophores such as hemoglobin, with factors including their effects on light absorption, reflection and scattering. Disorders of hyperpigmentation usually result from an increase in melanin production and, on occasion, from an increase in the density of active melanocytes. Discoloration of the skin may also be caused by deposition of exogenous substances such as drugs, drug complexes (e.g. with melanin or iron) or heavy metals within the dermis.

To aid in the clinical approach, disorders of hyperpigmentation can be divided into diffuse, circumscribed, linear and reticulated subsets. A review of each of these categories is followed by a discussion of dyschromatoses, disorders characterized by both hypo- and hyperpigmentation. Benign melanocytic neoplasms are covered in Chapter 112.

DIFFUSE AND CIRCUMSCRIBED HYPERPIGMENTATION

Introduction

Diffuse and circumscribed hyperpigmentation are discussed together because both postinflammatory hyperpigmentation (PIH) and reactions to systemic drugs, two major causes of hyperpigmentation, can assume either of these patterns. PIH most often presents as circumscribed lesions, and the size, shape and distribution pattern provide clues to the etiology. Melasma is another common cause of circumscribed hypermelanosis. Additional causes of diffuse hyperpigmentation include metabolic diseases, sclerodermoid disorders, nutritional deficiencies and, occasionally, HIV infection.

POSTINFLAMMATORY HYPERPIGMENTATION

Synonym: ■ Postinflammatory hypermelanosis

Key features

- Extremely common, especially in individuals with more darkly pigmented skin
- Develops after inflammation or injury to the skin, but preceding inflammation may be transient or subclinical
- The increased melanin may be primarily within the dermis (e.g. following lichen planus) or in the epidermis (e.g. following acne or atopic dermatitis)
- Epidermal hyperpigmentation fades more readily than dermal hyperpigmentation

Introduction

PIH represents an acquired excess of melanin pigment following cutaneous inflammation or injury. It can occur anywhere on the skin surface, including the mucous membranes and the nail unit. PIH is extremely common and can have significant cosmetic and psychosocial consequences.

Epidemiology

PIH can occur at any age and there is no gender preference. Individuals with darkly pigmented skin tend to have a greater frequency, severity and duration of PIH than those with lighter complexions.

Pathogenesis

In the *epidermal* form of PIH, there is increased melanin production and/or transfer to keratinocytes. Inflammatory mediators (e.g. prostaglandins E_2 and D_2) that enhance pigment production may play a role in this process. In *dermal* hyperpigmentation, melanin enters ("falls into") the dermis via a damaged basement membrane, where it is phagocytosed by and subsequently resides within dermal macrophages (referred to as melanophages). Macrophages may also migrate into the epidermis, phagocytose melanosomes, and then return to the dermis[1]. Melanin within dermal melanophages tends to persist for long periods of time (e.g. years).

Clinical Features

Asymptomatic hyperpigmented macules and patches range in color from either tan to dark brown (epidermal melanin) or gray–blue to gray–brown (dermal melanin). Primary lesions of the underlying inflammatory disorder may or may not be evident admixed with the hyperpigmentation or elsewhere. When primary lesions are absent, the size, shape and distribution pattern of the hyperpigmented lesions can provide clues to the underlying etiology (Table 67.1). PIH can be exacerbated by continued inflammation, trauma or exposure to ultraviolet (UV) irradiation.

DISORDERS ASSOCIATED WITH POSTINFLAMMATORY HYPERPIGMENTATION	
Inflammatory disease	**Clinical clues**
	COMMON
Acne vulgaris	Head/neck region, upper trunk; <1 cm; perifollicular
Atopic dermatitis	Atopic diathesis; face and extensor extremities in infants, then later flexural involvement; excoriations; atopic pleats; xerosis; lichenification; transverse nasal crease ("allergic salute")
Lichen simplex chronicus	Common locations: posterior neck, ankle, scrotum
Transient neonatal pustular melanosis	Black newborns; pustules precede pigmentation
Impetigo	Favors face; most common in children
Insect bites	Favor exposed areas; usually <1 cm; lower extremities common with flea bites; clustered and sometimes linear patterns ("breakfast–lunch–dinner")
	LESS COMMON
Irritant and allergic contact and photocontact dermatitis	Sites determined by etiologic agent and form of exposure; phytophotodermatitis associated with linear hyperpigmentation in sun-exposed areas
Pityriasis rosea	Favors trunk and proximal extremities; lesions follow skin cleavage lines; oval-shaped
Psoriasis	Scalp/nail involvement; knees/elbows most common sites
Polymorphous light eruption	Extensor upper extremities, mid upper chest, face; seasonal (e.g. spring or early summer)
Discoid lupus erythematosus	Face and conchal bowls, with follicular plugging in latter site; oral lesions; in scarred lesions, central hypopigmentation with rim of hyperpigmentation
Lichen planus	Wrists, shins, presacral; nail/oral involvement
Erythema dyschromicum perstans (ashy dermatosis)	Neck, proximal upper extremities, trunk; round or oval in shape with gray–brown to blue–gray color; long axis can follow skin cleavage lines (similar to pityriasis rosea); less commonly observed in fair-skinned individuals
Fixed drug eruption	Circular; favors perioral, acral and genital sites; recurrence at same site(s) with repeated exposure
Morbilliform drug eruption	Widespread; usually discrete lesions, history of drug exposure
Viral exanthem	Widespread; usually discrete lesions; history of associated symptoms
Morphea	Trunk or extremities; large-sized except in guttate variant; may be linear; associated induration and later dermal atrophy
Atrophoderma of Pasini and Pierini	Trunk; large-sized; depressed with "cliff sign" at periphery no induration
Neurotic (psychogenic) excoriation, acne excoriée	Favors face, scalp, extensor surface of arms, upper back (reachable areas); linear or angular shapes; multiple stages of evolution, from erosions/ulcerations to scars

Table 67.1 Disorders associated with postinflammatory hyperpigmentation. *Adapted from Bolognia JL. Disorders of hypopigmentation and hyperpigmentation. In: Harper J, Oranje A, Prose N (eds). Textbook of Pediatric Dermatology, 2nd edn Oxford: Blackwell Science, 2006;997–1040.*

Disorders that commonly lead to epidermal PIH include acne, insect bites, pyodermas, atopic dermatitis, psoriasis and pityriasis rosea (Fig. 67.1). In contrast, dermal PIH is associated with dermatoses characterized by degeneration of the basal layer of the epidermis and inflammation at the dermal–epidermal junction, such as lichen planus, lichenoid drug reactions, lupus erythematosus and fixed drug eruptions. Upon treatment of the underlying disorder, epidermal PIH generally resolves over time, although fading may require months or years in darkly pigmented individuals. Dermal melanosis tends to persist longer and is sometimes permanent.

Pathology

As noted above, epidermal PIH is characterized by increased pigment in keratinocytes and dermal PIH by melanophages within the dermis.

Differential Diagnosis

As discussed previously, the size, shape and distribution of the hyperpigmented lesions can provide clues to the inflammatory disease or injury that preceded PIH (see Table 67.1), and a thorough skin examination may detect active primary lesions. A history of prior inflammatory lesions and medication use (including prescription, over-the-counter and alternative products) should be obtained. Disorders such as erythema dyschromicum perstans, melasma, pityriasis versicolor and atrophoderma of Pasini and Pierini should be considered in patients without evidence of preceding inflammation by history or on examination. Occasionally, a biopsy may assist in making the diagnosis.

Treatment

Provided that the underlying dermatosis is successfully treated, PIH eventually improves in most patients, especially those with epidermal hypermelanosis. Sun protection, including daily application of a broad-spectrum sunscreen, can help to prevent accentuation of the pigmentation by UV exposure. Topical hydroquinone (2–4%) may lead to lightening over 3–6 months if the increase in pigmentation is limited to the epidermis. As with melasma (see below), use of a topical retinoid and corticosteroid together with hydroquinone may be more effective than monotherapy. Topical azelaic acid and α-hydroxy acids are additional therapeutic options. Laser therapy has limited benefits, especially for individuals with darkly pigmented skin, and it may lead to hypopigmentation. Q-switched ruby, alexandrite and Nd:YAG lasers are variably successful in removing dermal pigment (see Ch. 137).

ERYTHEMA DYSCHROMICUM PERSTANS

Synonyms: ■ Ashy dermatosis ■ Dermatosis cenicienta (Cinderella dermatosis)

Key features

- Most common in individuals with skin phototypes III–IV
- Gray–brown to blue–gray macules and patches in a symmetric distribution
- Favors the neck, trunk and proximal extremities
- A consistently effective treatment is not currently available

Introduction

Ramirez first described erythema dyschromicum perstans (EDP) in 1957, referring to affected individuals as *los cenicientos* (ashen ones).

Fig. 67.1 Epidermal postinflammatory hyperpigmentation. The lesions were due to pemphigus foliaceus (**A**), contact dermatitis from a contraceptive patch (**B**), insect bites (**C**) and transient neonatal pustular melanosis (**D**). Note the residual inflammation and "breakfast–lunch–dinner" configuration in C. *A, C & D, Courtesy, Julie V Schaffer, MD. B, Courtesy, Andrew Alexis, MD MPH.*

This is an asymptomatic, slowly progressive eruption that is characterized by circumscribed areas of dermal pigmentation[2].

Epidemiology

Although there have been reports of this entity worldwide, the majority of patients with EDP are from Latin America. There is no gender preference. The disorder usually presents during the second to third decade, but it occasionally develops in younger children or older adults.

Pathogenesis

The etiology of EDP is not known. Although it has been postulated that a cell-mediated immune reaction to an ingestant, contactant or microorganism underlies the discrete areas of pigmentary incontinence, no causal agent has consistently identified[2]. In most patients, a trigger is never found. However, there have been reports of EDP developing in association with the ingestion of ammonium nitrate, oral X-ray contrast media, and medications (e.g. benzodiazepines, penicillin); exposure to various pesticides, fungicides or toxins; endocrinopathies such as thyroid disease; and whipworm and HIV infections. The presence of the HLA-DR4 allele may represent a risk factor for EDP in Mexican patients.

Clinical Features

Oval, circular or irregularly shaped macules and patches that are 0.5 to 3 cm in diameter and slate-gray to blue–brown in color develop gradually in a symmetric pattern (Fig. 67.2). The initial site of involvement is often the trunk, with subsequent spread to the neck, proximal upper extremities, and sometimes the face. The mucous membranes are spared, and the palms, soles and scalp are rarely affected. Occasionally, early stage lesions have a thin, raised, erythematous border, which tends to resolve over a few months, and the long axis of lesions may follow skin cleavage lines. Peripheral hypopigmentation may be seen in older lesions.

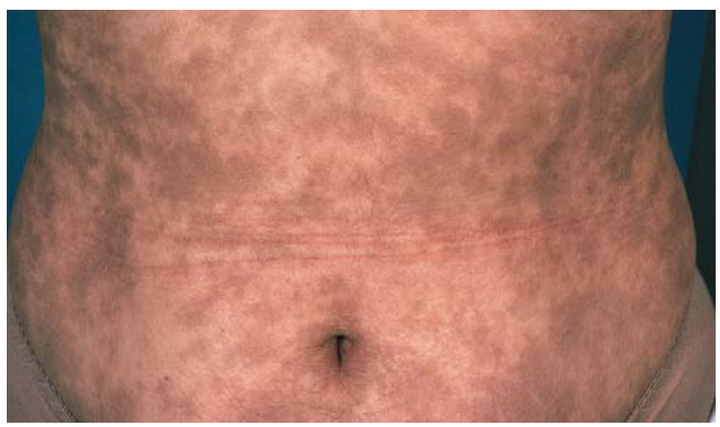

Fig. 67.2 Erythema dyschromicum perstans (ashy dermatosis). Multiple gray–brown macules and patches on the abdomen. The "ashy" color is characteristic.

EDP is usually asymptomatic but can be mildly pruritic. The disease progresses slowly and usually does not regress in adults. However, in one study of 33 prepubertal children, the majority of whom were

Caucasian, the disease spontaneously resolved in two-thirds of the patients, with no recurrences over the ensuing 2–3 years[3].

Pathology

In early ("active") lesions, vacuolar degeneration of the basal cell layer, a perivascular mononuclear cell infiltrate in the upper dermis, and increased epidermal melanin and dermal melanophages are seen. Colloid bodies and dermal hemosiderin may be present. Immunohistochemical findings include expression of cell adhesion and lymphocyte activation molecules (e.g. CD36, intercellular adhesion molecule-1 [ICAM-1], CD69, CD94) that are associated with inflammation and activation of cytotoxic T cells[4]. In later ("inactive") lesions, the number of dermal melanophages is increased but hydropic changes within the basal cell layer are absent and the dermal mononuclear cell infiltrate is minimal.

Differential Diagnosis

The differential diagnosis of EDP includes a lichenoid drug eruption (see Ch. 11), lichen planus (especially lichen planus pigmentosus), a generalized fixed drug eruption, other dermal forms of PIH, macular urticaria pigmentosa, and (less often) infectious diseases such as leprosy or pinta. Of note, the PIH that follows pityriasis rosea is usually epidermal.

Treatment

There is no consistently effective therapy for EDP. Topical corticosteroids and hydroquinone are generally of no benefit. Oral corticosteroids, antibiotics, antimalarials, isoniazid and griseofulvin, as well as UV light therapy, have produced variable results. Successful treatment with dapsone and clofazimine has been reported in small series.

LICHEN PLANUS PIGMENTOSUS

Key features

- Variant of lichen planus most commonly described in adults with skin phototypes III-V
- Gray–brown to dark brown macules and patches in either a photodistribution or an inverse (intertriginous) pattern

Lichen planus pigmentosus (LPP) is an uncommon variant of lichen planus that favors young to middle-aged adults with skin phototypes III–V, including those from India[5,6], Latin America and the Middle East. It presents as irregularly shaped or oval, brown to gray–brown macules and patches in either sun-exposed areas (especially the forehead, temples and neck) or intertriginous zones (Fig. 67.3). It is usually asymptomatic, but some patients describe mild pruritus or burning. In contrast to EDP, early lesions with an erythematous border are not a feature of LPP. While the distribution is symmetric in the vast majority of patients, a unilateral linear variant has also been described.

Fig. 67.3 Lichen planus pigmentosus. Multiple coalescing brown to gray–brown macules in the axilla of a middle-aged woman.

Occasionally, a reticulated or follicular pattern is observed. The palms, soles, nails and oral mucosa are usually not involved. In one series of 124 patients with LPP, 19 were noted to also have typical lesions of lichen planus[6]. LPP is a chronic disorder with exacerbations and remissions. Histologic findings include basal cell degeneration, a mild perivascular or band-like infiltrate in the upper dermis, and dermal melanophages.

The etiology of LPP is unknown. The photodistribution in some patients suggests that UV can play a pathogenic role, and topical application of mustard oil (which contains allyl isothiocyanate, a potential photosensitizer) and amla oil have been proposed as possible inciting agents[6]. The differential diagnosis includes the actinic and inverse variants of lichen planus (see Ch. 11), a lichenoid drug eruption, EDP, melasma, the entities listed in Table 67.2, PIH and cutaneous T-cell lymphoma. In one uncontrolled study, lightening of the pigmentation occurred in 54% (7/13) of patients treated with topical tacrolimus for 12–16 weeks[7].

MELASMA

Synonyms: ■ Chloasma ■ Mask of pregnancy

Key features

- At least 90% of patients are women
- Increased prevalence in individuals who are Hispanic, or of Asian or African descent
- Most common location is the face, followed by the forearms
- Symmetric patches of hyperpigmentation with irregular borders due to increased melanin within the epidermis and/or dermis

Introduction and Epidemiology

Melasma is a common acquired disorder characterized by symmetric, hyperpigmented patches with an irregular outline, occurring most commonly on the face. It is most prevalent among young to middle-aged women who are Hispanic or of Asian, African or Middle Eastern descent (i.e. those with more darkly pigmented skin). Exacerbating factors include pregnancy, use of oral contraceptives and sun exposure.

Pathogenesis

Although the exact pathogenesis of melasma is unknown, it is hypothesized that following exposure to UV irradiation (or another inducer), hyperfunctional melanocytes within involved skin produce increased amounts of melanin[8,9]. The key role of UV irradiation is supported by fading of lesions during winter months and a distribution pattern demonstrating involvement of sun-exposed regions and sparing of relatively sun-protected sites such as the philtrum. Additional important pathogenic factors include the skin phototype (favoring individuals with more darkly pigmented skin) and estrogens (predilection for women and association with pregnancy and oral contraceptive use). Other medications (e.g. phenytoin, phototoxic drugs) and disorders (e.g. autoimmune thyroid disease) also have the potential to aggravate melasma. Increased expression of KIT and stem cell factor within the lesional epidermis and dermis, respectively, may play a role in the hyperpigmentation of melasma.

Clinical Features

Light to dark brown or brown–gray patches with irregular borders appear primarily on the face (Fig. 67.4). The areas of hypermelanosis are distributed symmetrically in three classic patterns: (1) *centrofacial* (most common), involving the forehead, cheeks, nose, upper lip (sparing the philtrum) and chin; (2) *malar*, affecting the cheeks and nose; and (3) *mandibular*, along the jawline. Less common sites include the extensor aspect of the forearms and mid upper chest. Lesions often first appear or are accentuated following exposure to UV irradiation or during pregnancy. In lightly pigmented individuals, this "mask of pregnancy" frequently diminishes or disappears after parturition, but it tends to persist in women with more darkly pigmented skin.

DIFFERENTIAL DIAGNOSIS OF MELASMA	
Disorder	**Key differences from melasma/comments**
Drug-induced hyperpigmentation or discoloration	• History of medication use (e.g. doxycycline, amiodarone; see Table 67.3) • Hyperpigmentation less patterned and less irregular in outline • Discrete oval or round shape of fixed drug eruption rarely confused with melasma • May follow phototoxic drug reaction • Oral contraceptives and phenytoin may exacerbate melasma
Postinflammatory hyperpigmentation, e.g. due to cutaneous lupus erythematosus, photosensitivity reactions, contact dermatitis (e.g. irritant contact dermatitis to hydroquinone or tretinoin) or other forms of dermatitis	• History of inflammatory phase with erythema, scale and possible pruritus or burning • Primary lesions – may be admixed or elsewhere on body
Actinic lichen planus	• Fine scale overlying violaceous lesions if inflammatory phase still present • Histologic features: hydropic degeneration of basal layer, lichenoid infiltrate
Lichen planus pigmentosus	• Often begins on the temples/in the preauricular area and involves the neck ± intertriginous sites • Coexistent classic lichen planus (~20% of patients) • Histologic features: vacuolar degeneration of basal layer; variable lichenoid infiltrate and epidermal atrophy
Pigmented contact dermatitis (Riehl's melanosis)	• Favors sites of application of contactants, especially cosmetics • May be reticulated • Brown–grey color due to dermal melanin deposits • Histologic features: vacuolar degeneration of basal layer and lichenoid infiltrate in early lesions
Exogenous ochronosis	• History of hydroquinone application to areas of hyperpigmentation followed by progressive darkening • Superimposed small pigmented papules may also be seen • Histologic features: banana-shaped, yellow–brown deposits in the dermis
Acquired bilateral nevus of Ota-like macules (Hori's nevus)	• Asian women, usually during the fourth or fifth decade of life • Multiple brown–gray to brown–blue macules, primarily in the malar region • Less common sites: lateral forehead, temples, upper eyelids, nasal root or alae • Lack of ocular or mucosal involvement • Histologic features: pigment-producing dermal melanocytes
Erythema dyschromicum perstans	• Inflammatory phase with rim of erythema occasionally seen • Lesions slate-gray to blue–brown • Distribution includes sun-protected areas
Poikiloderma of Civatte	• Presence of atrophy and telangiectasias • Favors lateral and inferior aspects of anterior neck; sparing of perifollicular skin and submental region
Erythromelanosis follicularis faciei et colli	• Red–brown patches on lateral cheeks and neck • Superimposed tiny pale follicular papules
Cutaneous mercury deposits	• History of use of mercury-containing soaps or creams • Dermatitis often present • Histologic features: brown–black granules free in dermis, in association with elastic fibers and within macrophages

Table 67.2 Differential diagnosis of melasma.

Melasma has also been subdivided into four types based upon the primary location of the pigment: epidermal, dermal, mixed or indeterminate (e.g. in patients with very dark skin pigmentation). In theory, lesions with increased epidermal melanin are accentuated and those with increased dermal melanin become less obvious (i.e. blend with uninvolved skin) with Wood's lamp examination. However, clinicopathologic studies utilizing adjacent uninvolved skin as controls have shown that Wood's lamp examination does not correlate with histologic findings[9,10]. In addition, no completely dermal form of melasma was observed histologically when bilateral nevus of Ota-like macules (a form of dermal melanocytosis sometimes misdiagnosed as melasma; see Table 67.2) were excluded. Further studies are needed to determine the clinical utility and prognostic significance (considering that epidermal pigmentation is more likely to respond to topical therapies) of Wood's lamp examination.

Pathology

Compared to uninvolved adjacent skin, increased melanin deposition is observed in all layers of the epidermis. An increased number of melanophages may also be seen. Epidermal melanocytes are normal to increased in number, and they are enlarged with prominent dendrites[9,10].

Ultrastructurally, lesional melanocytes contain an increased number of melanosomes. In addition, the mitochondria, Golgi apparatus and rough endoplasmic reticulum are increased in number or amount. These findings support the theory of hyperfunctional melanocytes, presumably stimulated by UV irradiation or hormones (see Pathogenesis above).

Differential Diagnosis

The differential diagnosis of melasma is reviewed in Table 67.2. These disorders are distinguished from melasma based upon historical aspects (e.g. drug ingestion, previous inflammation), color, distribution pattern, histologic features and (if present) primary inflammatory lesions.

Treatment

Diligent sun protection – including hats, clothing (if extrafacial), broad-spectrum sunscreens and avoidance – and patient motivation are necessary for any treatment regimen for melasma to be successful. Wood's lamp examination helps to delineate the extent of involvement and may distinguish between increased melanin primarily within the epidermis versus within both the epidermis and dermis (see above). Whereas epidermal pigmentation is somewhat amenable to topical therapies and chemical peels, dermal pigmentation is notoriously difficult to treat. In darkly pigmented individuals (e.g. those with indeterminate melasma), a skin biopsy is occasionally performed before treatment is initiated.

Fig. 67.4 Various forms of melasma and melasma-like hyperpigmentation. A Malar variant. **B** Mild centrofacial type with sparing of the philtrum. **C** Extension of the hyperpigmentation onto the mandible. **D** Involvement of the extensor forearm; note the same irregular outline as is seen on the face. **E** Melasma-like appearance in a patient with previous acute cutaneous lupus erythematosus. *C–E, Courtesy, Jean L Bolognia, MD.*

The most common topical regimen is a combination of hydroquinone (2–4%), tretinoin (0.05–0.1%) and a corticosteroid (class V–VII)[11]. For epidermal melasma, 2 months of therapy are typically required to initiate lightening and 6 months of treatment are often needed to achieve satisfactory results.

The mechanisms of action of hydroquinone include: (1) competing with tyrosine as a substrate for tyrosinase, the initial enzyme in the melanin biosynthetic pathway that converts tyrosine to dopaquinone (see Ch. 65); and (2) selective damage to melanosomes and melanocytes[12]. Side effects include irritant and allergic contact dermatitis, postinflammatory hyperpigmentation, and exogenous ochronosis (see below). The latter side effect is uncommon and is usually caused by prolonged use of hydroquinone at a concentration >2%.

Topical tretinoin as a monotherapy can be helpful, but the required treatment period is often 24 weeks or longer. Other topical agents that have been reported to lighten melasma include glycolic acid, kojic acid and azelaic acid, with the latter two agents acting as tyrosinase inhibitors. Salicylic acid and glycolic acid peels can be used as adjunctive therapy (see Ch. 154). Deeper chemical peels, laser therapy (e.g. Q-switched ruby, 1550 nm fractional) and dermabrasion have variable results and can cause scarring and dyspigmentation. Cosmetic camouflage is helpful for patients with recalcitrant melasma.

ADDITIONAL FORMS OF CIRCUMSCRIBED HYPERPIGMENTATION

Segmental Pigmentation Disorder

This term was coined by Metzker et al. in 1983 and re-introduced by Hogeling and Frieden in 2010[13]. It is a form of "pigmentary mosaicism" (i.e. a postzygotic genetic alteration leading to a regional change in pigment production potential) characterized by a block-like or "checkerboard" pattern of hyper- or (less often) hypopigmentation that usually becomes apparent in infancy. The hyperpigmented patches favor the trunk, with midline demarcation more often evident ventrally than dorsally and less distinct lateral borders. There are usually no associated extracutaneous anomalies.

Familial Progressive Hyperpigmentation

Familial progressive hyperpigmentation is an autosomal dominant disorder characterized by hyperpigmented patches in a widespread distribution including the palms, soles, lips and conjunctiva. The lesions begin to develop in infancy and increase in size, number and confluence with age. This condition can be caused by heterozygous gain-of-function mutations in the KIT ligand gene (*KITLG*)[14].

Primary (Localized) Cutaneous Amyloidosis

Macular and lichenoid forms of primary (localized) cutaneous amyloidosis (see Ch. 47) are associated with hyperpigmentation. The most common locations are the upper back (macular amyloidosis) or the extensor surface of the lower extremities (lichen amyloidosis), and there is a characteristic rippled pattern with parallel bands or ridges of hyperpigmentation. Areas of involvement are often pruritic, and rubbing plays a key role in the production of lesions. Histologically, melanophages as well as amyloid deposits that stain positively with antikeratin antibodies are seen within the upper dermis.

Mastocytosis

Cutaneous mastocytosis consists of a spectrum of disorders characterized by the accumulation of normal mast cells within the skin, and sometimes in other organs (see Ch. 118). The form of mastocytosis classically associated with hyperpigmentation is urticaria pigmentosa, where patients develop a few to several hundred brown to red–brown papules. However, solitary mastocytomas can also have a light brown color. Lesions of cutaneous mastocytosis typically urticate after they are stroked (Darier's sign), and an increased number of mast cells is seen in biopsy specimens. The cause of the pigmentation in this disorder may involve stem cell factor or mast cell-derived pro-opiomelanocortin

(POMC) peptides, e.g. α-melanocyte-stimulating hormone[15]. Somatic activating mutations in the gene that encodes the KIT receptor often underlie urticaria pigmentosa in both children and adults. Whereas the prognosis for childhood-onset urticaria pigmentosa is excellent, with spontaneous resolution over months to years, adult-onset disease is frequently persistent (see Ch. 118).

Pityriasis (Tinea) Versicolor

Pityriasis versicolor is a superficial skin infection caused by the yeast *Malassezia furfur* (see Ch. 77). Hypo- or hyperpigmented macules or very thin papules and plaques covered with fine scale are usually found on the upper trunk and proximal upper extremities but may also appear in other sites such as the neck, face and groin. There is often coalescence of lesions centrally, especially on the trunk. In light and electron microscopy studies, a similar number of melanocytes was noted in uninvolved skin as in hypo- and hyperpigmented lesions; the latter had a thickened stratum corneum that contained more organisms. The clinical differential diagnosis for the hyperpigmented form of pityriasis versicolor may include PIH and confluent and reticulated papillomatosis, but a KOH preparation of the scale distinguishes pityriasis versicolor from these entities.

Atrophoderma of Pasini and Pierini

Atrophoderma of Pasini and Pierini (see Ch. 99) is usually seen in young adults and has been postulated to represent an atrophic form of morphea. Most often, several oval hyperpigmented patches measuring 4–10 cm in diameter appear on the posterior trunk. There is a subtle depression of the entire lesion, but no induration or secondary changes. The depression can be appreciated by palpation of the edge of the lesion, with a characteristic "cliff sign" at the peripheral margin.

PIGMENTED LESIONS

Lentigines

Lentigines are reviewed in Chapter 112.

Café-au-Lait Macules

Café-au-lait macules (CALMs) are hyperpigmented macules or patches two to three shades darker than uninvolved skin (see Ch. 112). They are found in at least 10% of the population. Although often evident at birth (~3% of all neonates, up to 30% of black neonates), CALMs may not become apparent until infancy or early childhood in lightly pigmented individuals. The presence of multiple CALMs raises the possibility of neurofibromatosis type 1 or another genetic syndrome (see Table 61.4); Figure 61.10 outlines an approach to a young child with multiple CALMs. A CALM is usually easily distinguished from a fully developed congenital melanocytic nevus, but in infants there may be overlap in the clinical appearance of these two entities. The differential diagnosis also includes the earliest stage of a nevus spilus (before the "speckles" appear), a Becker's nevus or smooth muscle hamartoma, and a mastocytoma; segmental CALMs and "pigmentary mosaicism" have significant overlap. Although laser treatment of CALMs has been reported (see Ch. 137), responses vary and recurrence of pigmentation is common.

DRUG-INDUCED HYPERPIGMENTATION OR DISCOLORATION

Key features

- Localized or generalized hypermelanosis or discoloration may be seen
- Although several classes of drugs are known to induce hyperpigmentation or discoloration, the most common are minocycline, antimalarials, chemotherapeutic agents and zidovudine
- Longitudinal, transverse or diffuse melanonychia may also be present

A wide range of medications (most commonly chemotherapeutic agents, antimalarials, minocycline and zidovudine) and chemicals can lead to cutaneous hypermelanosis or discoloration (Table 67.3, Figs 67.5–67.8). The underlying mechanisms vary from induction of melanin production to deposition of drug complexes or heavy metals within the dermis. The pigmentation can be circumscribed or generalized. Although it usually resolves with discontinuation of the offending drug, the course may be prolonged[16]. Melanonychia (longitudinal, transverse or diffuse) and oral mucosal pigmentation may also be observed.

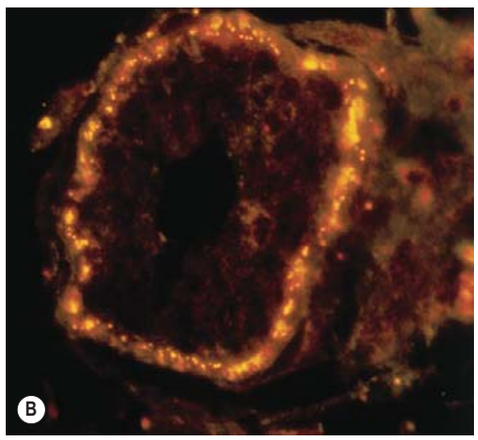

Fig. 67.5 Argyria. **A** Diffuse slate-gray discoloration of the palms. **B** Darkfield microscopy of an eccrine gland. Note the refractile nature of the granules and their location in the membrana propria. *A, Courtesy, Mary Beth Cole, MD, and Michael L Smith, MD.*

DRUGS AND CHEMICALS ASSOCIATED WITH HYPERPIGMENTATION OR DISCOLORATION		
Drug or chemical	**Clinical features**	**Histopathology/comment**
	CHEMOTHERAPEUTIC AGENTS	
BCNU (carmustine)	• Hyperpigmentation at sites of topical application (not with parenteral administration)	• Hyperplasia of basal melanocytes • Increased melanin within the epidermis
Bleomycin (intravenous or intralesional)	• Linear, flagellate bands that favor the trunk and may be associated with minor trauma (see text) • Transverse melanonychia • Hyperpigmentation overlying joints/pressure points or localized to striae and palmar creases • Sclerodermoid changes	• Increased epidermal melanin but no increase in the number of melanocytes • Usually relatively few dermal melanophages
Busulfan	• Generalized hyperpigmentation resembling Addison's disease; sometimes associated with drug-induced pulmonary fibrosis	• Increased melanin within basal keratinocytes and dermal macrophages
Cyclophosphamide	• Diffuse hyperpigmentation of the skin and mucous membranes • Pigment localized to the nails (transverse, longitudinal or diffuse melanonychia), palms and soles, or teeth	• Cutaneous hyperpigmentation usually regresses within 6 to 12 months after therapy is discontinued
Dactinomycin	• Generalized hyperpigmentation, most prominent on the face	• Pigmentation fades after treatment is discontinued
Daunorubicin	• Hyperpigmentation of sun-exposed areas • Transverse brown–black melanonychia	
Doxorubicin	• Hyperpigmentation overlying the small joints of the hands and involving the palms (especially the creases), soles and oral mucosa (buccal, tongue) • Transverse melanonychia	• Increased epidermal melanin • Increased number of melanocytes
5-Fluorouracil	• Hyperpigmentation in sun-exposed areas (~5% of patients treated systemically; often follows an erythematous photosensitivity reaction) • Increased pigmentation of skin overlying veins in which the drug was infused • Other sites include the dorsal aspects of the hands, palms/soles and radiation ports • Transverse or diffuse melanonychia; lunular pigmentation	• Postinflammatory hyperpigmentation
Hydroxyurea	• Reversible hyperpigmentation over pressure points and on the back • Longitudinal, transverse or diffuse melanonychia; lunular pigmentation	• Lichenoid eruption with postinflammatory hyperpigmentation can also occur
Mechlorethamine (nitrogen mustard)	• Topical use for cutaneous T-cell lymphoma may result in generalized hyperpigmentation • More intense in lesional skin	• Disaggregation of melanosomes within keratinocytes • Increased number of melanocytes
Methotrexate	• Uniform hyperpigmentation in sun-exposed areas (occasionally follows an erythematous photosensitivity reaction)	• Uncommon
	ANTIMALARIALS	
Chloroquine, hydroxychloroquine, quinacrine	• Gray to blue–black pigment, usually pretibial, with (hydroxy)chloroquine; face, hard palate, sclerae and subungual areas may be involved • Diffuse yellow to yellow–brown discoloration with quinacrine • Discoloration affects up to 25% of patients	• Dermal deposition of melanin-drug complexes; hemosiderin around capillaries • May fade after discontinuation of drug, but rarely resolves completely
	HEAVY METALS	
Arsenic	• Areas of bronze hyperpigmentation ± superimposed "raindrops" of lightly pigmented skin; favors axillae, groin, palms, soles, nipples and pressure points • Dyspigmentation appears 1–20 years after arsenic exposure, with a strong dose-response relationship • Palmoplantar keratoses and squamous cell carcinoma typically develop after dyspigmentation (see Chs 58 & 88)	• Dermal and epidermal deposition of arsenic • Increased epidermal melanin synthesis
Bismuth	• Generalized blue–gray discoloration of the face, neck and dorsal hands • Oral mucosa and gingivae may be involved	• Bismuth granules in the papillary and reticular dermis
Gold (chrysiasis)	• Permanent blue–gray discoloration in sun-exposed areas, mostly around the eyes	• Gold particles within lysosomes in dermal macrophages, especially in perivascular and perieccrine areas
Iron	• Permanent brown pigment at injection sites or in areas of application of ferric subsulfate (Monsel's) solution as a hemostatic agent • Dermal hemosiderin deposits (due to lysis of extravasated red blood cells and release of their iron stores) are commonly observed in the setting of venous hypertension, in pigmented purpuric dermatoses and as a side effect of sclerotherapy of superficial veins	• Pigment coats collagen fibers and is deposited in dermal macrophages
Lead	• "Lead line" in gingival margin • Nail discoloration	• Lead line is due to subepithelial deposition of lead granules
Mercury	• Slate-gray discoloration, particularly in skin folds	• Brown–black granules free in dermis, in association with elastic fibers and within macrophages
Silver (argyria)	• Diffuse slate-gray discoloration (Fig. 67.5A), increased in sun-exposed areas; occurs in settings of occupational exposure, alternative medications or systemic absorption from use of silver sulfadiazine on extensive burns/wounds • The nail unit (diffuse or localized to the lunulae) and sclerae may also be affected • Sites of topical application (e.g. of silver sulfadiazine to burns or ulcers)	• Silver granules in the basement membrane and the membrana propria of eccrine glands; highlighted by darkfield illumination (Fig. 67.5B)

Table 67.3 Drugs and chemicals associated with hyperpigmentation or discoloration. BCNU, 1,3-bis (2-chloroethyl)-1-nitrosourea. *Adapted from Kang S, Lerner EA, Sober AJ, Levine N. In: Levine N (ed.). Pigmentation and Pigmentary Disorders. Boca Raton: CRC Press. 1993;417–31.*

Continued

DRUGS AND CHEMICALS ASSOCIATED WITH HYPERPIGMENTATION OR DISCOLORATION		
Drug or chemical	**Clinical features**	**Histopathology/comment**
	HORMONES	
Oral contraceptives	• Melasma; increased pigmentation of nipples and nevi	• Increased melanocytes and increased melanin synthesis
ACTH/MSH (ACTH is rarely used; [Nle4-D-Phe7]-α-MSH currently not FDA-approved)	• Diffuse brown or bronze hyperpigmentation, accentuated in sun-exposed sites	• Increased melanin synthesis
	MISCELLANEOUS COMPOUNDS	
Amiodarone	• Slate-gray to violaceous discoloration of sun-exposed skin, especially the face (less common than erythema from photosensitivity) • Fair-skinned patients after long-term, continuous therapy	• Yellow–brown granules in dermal macrophages, mostly in a perivascular distribution • By EM, lysosomal inclusions composed of a lipid-like substance • Usually fades completely over months to years after discontinuation of drug, but sometimes persists
Azidothymidine (zidovudine, AZT)	• Longitudinal > transverse and diffuse melanonychia (up to 10% of patients); blue lunulae • Mucocutaneous hyperpigmentation (e.g. widespread diffuse, acral, oral macules); most common in patients with darkly pigmented skin, and may be accentuated in areas of friction or sun exposure	• Skin biopsy shows increased melanin in the epidermis and dermal melanophages • Fades gradually after drug is discontinued
Clofazimine	• Diffuse red to red–brown discoloration of skin, conjunctivae • Violet–brown to blue–gray (Fig. 67.6) discoloration, especially of lesional skin	• Red color secondary to drug in fat (highly lipophilic) • Blue–violet color secondary to brownish granular pigment within dermal macrophages • By EM, phagolysosomes contain amorphous granular material and lamellar structures characteristic of lipofuscin • Fades gradually after discontinuation of drug
Diltiazem	• Slate-gray to gray–brown discoloration of sun-exposed skin in patients with skin phototypes IV–VI; perifollicular accentuation and a reticular pattern may be observed	• Sparse lichenoid infiltrate and numerous dermal melanophages
Dioxins	• Hyperpigmentation may occur in sun-exposed areas • Chloracne is a more common skin finding	• Rare, except in accidental exposure
Hydroquinone	• Hyperpigmentation in areas of application due to irritant contact dermatitis (i.e. postinflammatory) or exogenous ochronosis; the latter may also result in small "caviar-like" papules	• In exogenous ochronosis, yellow–brown banana-shaped fibers in papillary dermis (Fig. 67.7)* • Presumed mechanism is metabolism by melanocytes of hydroquinone into ringed structures that serve as precursors of ochronotic fibers • May fade upon discontinuation of hydroquinone; variable improvement with pigment-directed Q-switched lasers
Imatinib	• Localized or diffuse hyperpigmentation (<5% of patients) • Diffuse melanonychia, repigmentation of gray hair, and pigmentation of the gingiva and teeth	• Localized or diffuse hypo- or depigmentation is more common (40–60% of darkly pigmented patients)
Minocycline	• *Type I*: blue–black discoloration in sites of inflammation and scars, including those due to acne (Fig. 67.8C) • *Type II*: blue–gray macules/patches (1 mm–10 cm in size) within previously normal skin, most often on the shins (Fig. 67.8A,B); sometimes misdiagnosed as ecchymoses • *Type III*: diffuse "muddy brown" pigmentation that is most prominent in sun-exposed areas • Blue-black discoloration may also involve nails, sclerae, oral mucosa, bones, thyroid and teeth	• Iron-containing (types I, II) or melanin-containing (type II) pigment granules within the dermis; the former can be intra- or extracellular and may represent hemosiderin and/or a minocycline derivative plus chelated iron • Increased melanin within the basal epidermis and/or dermal melanophages (type III) • Minocycline is a highly lipid-soluble, yellow, crystalline material that turns black with oxidation • Fades after discontinuation of medication, but may take months or even years; for types I and II, treatment with Q-switched pigment-directed lasers (similar to tattoo removal) may decrease the discoloration
Psoralens	• Diffuse hyperpigmentation after exposure to UVA light following oral administration (PUVA) • Circumscribed or linear streaks of hyperpigmentation can be seen with topical exposure (e.g. topical PUVA or phytophotodermatitis [exposure to psoralen-containing plants plus sunlight])	• Proliferation of follicular melanocytes, with increased synthesis and transfer of melanin • Singly dispersed melanosomes within keratinocytes • Psoralens are furocoumarin compounds originally derived from plants
Psychotropic drugs (chlorpromazine, thioridazine, imipramine, desipramine, amitriptyline)	• Slate-gray discoloration in sun-exposed areas	• Golden-brown granules in the upper dermis • Electron-dense inclusion bodies

*Similar histologic findings are seen in alkaptonuria (also referred to as ochronosis), an autosomal recessive disease caused by deficiency in homogentisic acid oxidase, which results in accumulation of homogentisic acid in the tissues; this insoluble pigment binds to collagen and leads to blue–black discoloration (e.g. of the helices and sclerae; see Ch. 63).

ADDITIONAL FORMS OF DIFFUSE HYPERPIGMENTATION

In addition to medications, diffuse hyperpigmentation can be caused by metabolic abnormalities, nutritional deficiencies, and several inherited and acquired syndromes. An approach to the patient with diffuse hyperpigmentation is provided in Figure 67.9.

LINEAR HYPERPIGMENTATION

Linear hyperpigmentation can have a variety of etiologies, including postinflammatory changes, drug reactions and mosaic genetic alterations that result in hypermelanosis along the lines of Blaschko (see Ch. 62). Pigmentary demarcation lines represent normal dorsal–ventral patterning of the skin. In the evaluation of a patient with linear hyperpigmentation, an initial step is to determine whether or not the hypermelanosis follows the lines of Blaschko.

PIGMENTARY DEMARCATION LINES

Synonyms: ■ Futcher's lines ■ Voight's lines ■ Ito's lines

Key features

- Lines of demarcation between dorsal surfaces (which are relatively hyperpigmented) and ventral surfaces
- Physiologic pattern of human pigmentation
- More often apparent in individuals with darkly pigmented skin
- Most commonly seen on the anterolateral upper arm and posteromedial thigh

Introduction

In all skin types, the dorsal skin surfaces are relatively hyperpigmented compared to the ventral surfaces. In individuals with darkly pigmented skin, visible lines of demarcation between dorsal and ventral surfaces are more conspicuous, especially on the anterolateral portion of the upper arm (Fig. 67.10A). These demarcation lines are bilateral, symmetric and present from infancy through adulthood. Additional lines occur on the posteromedial aspect of the thighs (Fig. 67.10B), upper chest (Fig. 67.10C) and paraspinal region of the back (Table 67.4; Fig. 67.11).

FIVE MAJOR FORMS OF PIGMENTARY DEMARCATION LINES

Type	Description
A	A vertical line along the anterolateral portion of the upper arm that may extend into the pectoral region (most commonly observed type)
B	A curved line on the posteromedial thigh that extends from the perineum to the popliteal fossa and occasionally to the ankle
C	A vertical or curved hypopigmented band on the mid chest that results from two parallel pigmentary demarcation lines
D	A vertical line in a pre- or paraspinal location
E	Bilateral chest markings (hypopigmented macules and patches) in a zone that runs from the mid third of the clavicle to the periareolar skin

Table 67.4 Five major forms of pigmentary demarcation lines.

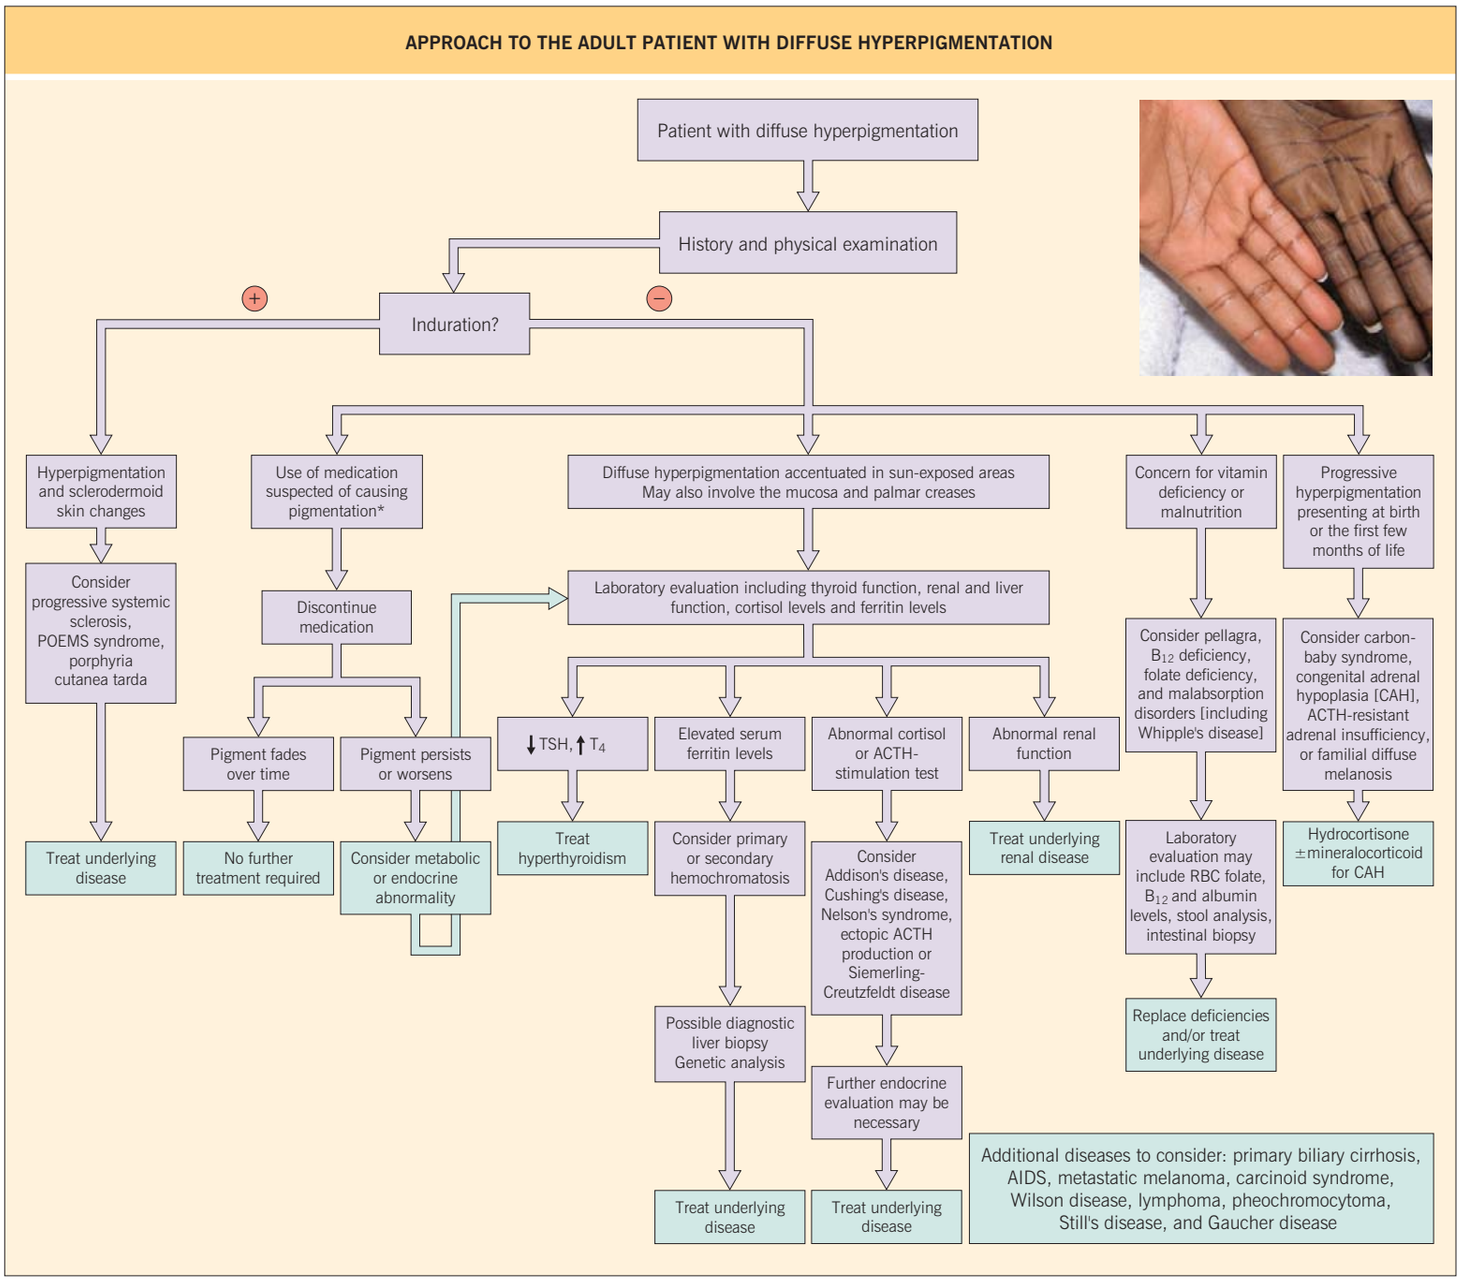

Fig. 67.9 Approach to the adult patient with diffuse hyperpigmentation. The palm on the right in the inset photograph shows diffuse hyperpigmentation in a patient with POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal gammopathy and *s*kin lesions). ACTH, adrenocorticotropic hormone; T_4, thyroxine; TSH, thyroid-stimulating hormone. *See Table 67.3 for a list of drugs and chemicals associated with diffuse hyperpigmentation.

Differential Diagnosis

PIH may occasionally be confused with pigmentary demarcation lines types A, B and D. However, in the latter there is no preceding inflammation or injury and the lines are perfectly symmetric and stable over time. Types C and E pigmentary demarcation lines may be confused with linear nevoid hypopigmentation. Linea nigra, the linear hyperpigmentation that extends from the umbilicus to the pubis in pregnant women (see Fig. 27.10B), is easily distinguished from a pigmentary demarcation line.

Treatment

These are normal pigmentation patterns, and no treatment is indicated.

LINEAR POSTINFLAMMATORY HYPERPIGMENTATION

PIH is the most common cause of acquired hyperpigmentation, with the circumscribed variant (see above) seen more often than diffuse or linear forms. In general, PIH is more clinically apparent in individuals with darkly pigmented skin than in those with lightly pigmented skin.

Clinical Features

Linear PIH occurs when there has been a preceding contact dermatitis with a linear pattern (e.g. phytophotodermatitis [Fig. 67.12] or due to poison ivy; see Ch. 17), another linear inflammatory dermatosis (e.g. koebnerized psoriasis), linear trauma (e.g. burns, abrasions, dermatitis

Fig. 67.10 Pigmentary demarcation lines (PDLs). A The most common PDL (type A) is on the upper arm, with relative hypopigmentation on the ventral surface. **B** Type B PDLs on the posterior thighs, with relative hypopigmentation medially. **C** Type C PDL (composed of parallel lines) may be confused with linear nevoid hypopigmentation. *A, C, Courtesy, Jean L Bolognia, MD. B, Courtesy, Justin Finch, MD.*

artefacta; Fig. 67.13) or chemical phlebitis. Less often, PIH follows the lines of Blaschko because the antecedent inflammatory dermatosis did so, e.g. linear lichen planus. The color ranges from brown (epidermal) to brown–gray (dermal). PIH slowly fades over time, provided that further injury to the skin does not occur. However, resolution may not occur for months to years, especially in more darkly pigmented individuals and when the melanin is primarily dermal. The pathogenesis, histology and treatment of linear PIH are similar to those of the circumscribed form (see above).

Differential Diagnosis

Linear PIH is relatively easy to recognize when there is a history of preceding cutaneous injury or inflammation, but it is more difficult if the preceding event was transient or unnoticed. The differential diagnosis includes rare conditions such as flagellate pigmentation due to bleomycin or mushroom dermatitis (see below) as well as the common phenomenon of black dermographism. The latter occurs when metals, including those in jewelry (nickel, gold, silver), are abraded by harder substances such as powders that contain zinc oxide. The color varies from dark grey to black, and the deposits of metallic powder can be easily removed. Black lacquer deposits associated with poison ivy dermatitis can also result in linear pigmentation, but the color is jet black (see Ch. 17).

FLAGELLATE PIGMENTATION FROM BLEOMYCIN

Synonym: ■ Scratch dermatitis

Key features

- Occurs in 10–20% of patients treated with systemic bleomycin
- Linear hyperpigmented streaks are most often seen on the chest and back
- Reversible once the drug is discontinued
- Additional findings may include circumscribed hyperpigmentation of the skin overlying joints, transverse melanonychia and sclerodermoid changes

Introduction

Bleomycin is a cytotoxic antibiotic used to treat malignancies such as Hodgkin disease and testicular carcinoma. It is also occasionally used intralesionally for sclerotherapy of vascular malformations or treatment of warts. Flagellate or "streaked" hyperpigmentation due to bleomycin was first recognized in 1970[17].

Epidemiology

Flagellate hyperpigmentation is a fairly common side effect, occurring in 10–20% of patients treated with systemic bleomycin and occasionally in those who receive intralesional bleomycin.

Pathogenesis

The pigmentation appears to be dose-dependent, but the pathogenesis is poorly understood. The pigmentation may represent a form of PIH, and preceding flagellate erythema is observed in a subset of patients. The configuration of the lesions is suggestive of a relationship to scratching. However, attempts to reproduce the lesions by scratching the skin of patients receiving bleomycin have often been unsuccessful, and some patients deny pruritus or previous scratching[18]. Other hypotheses include a bleomycin-induced local increase in melanogenesis or alteration of "pigment maturation"[17].

Clinical Features

Bleomycin-associated pigmentation can be circumscribed, diffuse or flagellate. Circumscribed lesions are typically found over joints or in other pressure points, but hyperpigmentation can also be localized to the palmar creases, striae, or sites of adhesive electrode pads. Flagellate pigmentation usually occurs after cumulative doses of 100–300 mg; however, it has been reported after doses as low as 15 to 30 mg (including intralesional injections of warts or vascular malformations)[17,18]. Flagellate pigmentation appears from 1 day to 9 weeks after administration of the drug. Some patients have pruritus (ranging from mild to severe) or linear urticarial lesions preceding the pigmented streaks, but others have neither associated symptoms nor antecedent lesions. The linear bands or streaks are brown in color and are most commonly seen on the chest and back (Fig. 67.14).

Additional cutaneous side effects of bleomycin include painful nodules on the fingers, verrucous plaques on the knees and elbows, sclerodermoid changes, and digital gangrene due to Raynaud's phenomenon. Nail changes can include melanonychia (typically transverse) as well as Beau's lines, onychomadesis and onycholysis.

Pathology

Varying histologic findings have been reported in bleomycin-induced flagellate hyperpigmentation, from basal layer hypermelanosis to spongiosis confined to the basal layer in association with a perivascular lymphohistiocytic infiltrate and pigmentary incontinence. By electron microscopy, an increased number and size of melanosomes within the basal keratinocytes may be seen; the melanocytes sometimes contain enlarged mitochondria[19].

Differential Diagnosis

Linear forms of PIH should be considered in the differential diagnosis (see above). However, a history of systemic bleomycin administration coupled with the characteristic clinical picture usually points to the correct diagnosis. Shiitake mushroom dermatitis (see below) can also present as flagellate lesions, but a history of ingestion of or occupational exposure to raw shiitake mushrooms allows a distinction to be made, as does the presence of a prominent papular component. Flagellate erythema can occur in patients with dermatomyositis, and fixed reddish-brown plaques and hyperpigmented streaks in bizarre linear arrays have been observed in patients with adult-onset Still's disease; histologically, these eruptions are characterized by an interface dermatitis (in dermatomyositis) and necrotic keratinocytes in the upper epidermis plus a dermal neutrophilic infiltrate (in Still's disease).

Treatment

While there is no specific therapy, recognition that bleomycin is the culprit is important as these patients are usually receiving multiple medications. Pruritus can be treated with topical corticosteroids and oral antihistamines. The pigmentation usually fades over 3 to 4 months, once the course of chemotherapy is complete and the bleomycin is discontinued.

FLAGELLATE MUSHROOM DERMATITIS

Synonyms: ■ Shiitake mushroom dermatitis ■ Shiitake-induced toxicoderma ■ Mushroom worker's disease

Key features

- Occurs after eating large amounts of raw or partially cooked shiitake mushrooms
- A second form occurs in persons who cultivate shiitake mushrooms
- Flagellate streaks initially composed of papules or petechiae are seen on the face, scalp, trunk and proximal extremities

Introduction

Shiitake mushroom dermatitis occurs in individuals who have ingested significant amounts of raw shiitake mushrooms or in those who cultivate these mushrooms. It can result in linear streaks of papules or petechiae that may be confused with the flagellate pigmentation of bleomycin[20].

History

Toxicoderma caused by shiitake mushrooms was first described in the Japanese literature in 1977. Since then, over 100 cases of "shiitake dermatitis" have been reported from Japan and Europe.

Epidemiology

Shiitake dermatitis from the ingestion of raw or partially cooked mushrooms occurs most often in Japan. Mushroom worker's disease is seen most frequently in Japan, Finland and elsewhere in Europe, and less commonly in the US.

Pathogenesis

A thermolabile toxin in shiitake mushrooms is probably responsible for this dermatosis. Prick and patch tests using shiitake mushroom extract are negative in patients who have ingestion-related dermatitis and even oral rechallenge can be negative. A phototoxic mechanism has also been proposed[20]. In mushroom worker's disease, an allergic alveolitis has been described, but specific IgE antibodies are lacking. Skin testing is positive in some patients with the occupational form of the disease.

Clinical Features

In shiitake mushroom dermatitis, pruritic papules, vesicles and edema develop on the face, scalp, trunk and proximal extremities. Scratching leads to long, flagellate streaks composed of petechiae or papules on the trunk and extremities. This can be followed by a linear pattern of either discoloration due to hemosiderin or PIH. Erythematous photoinduced skin lesions have been observed in half of the Japanese cases of shiitake mushroom dermatitis, and fever and malaise are occasional associated findings[20].

In mushroom worker's disease, fever, chills and cough are associated symptoms.

Pathology

Spongiosis and necrotic keratinocytes are seen within the epidermis in addition to a lymphocytic dermal infiltrate[20].

Treatment

The acute dermatitis can be treated with topical corticosteroids and oral antihistamines. Resolution occurs within 1 to 8 weeks if the mushrooms are avoided. Thoroughly cooking shiitake mushrooms will prevent the disorder in those individuals who are unable to tolerate eating raw mushrooms. However, patients with respiratory or skin symptoms due to occupational exposure should completely avoid shiitake mushrooms[21].

HYPERPIGMENTATION ALONG THE LINES OF BLASCHKO

The lines of Blaschko are characterized by a V-shape on the posterior midline, an S-shape on the abdomen, and spirals on the posterior scalp[22,23] (see Ch. 62). Dermatoses that follow the lines of Blaschko result from mosaicism.

Linear and Whorled Nevoid Hypermelanosis

Synonyms: ■ Linear nevoid hyperpigmentation ■ Reticulate hyperpigmentation of Iijima, Naito and Uyeno ■ Zebra-like hyperpigmentation in whorls and streaks ■ Reticulate and zosteriform hyperpigmentation ■ Progressive cribriform and zosteriform hyperpigmentation

Key features

- Hyperpigmentation in whorls and streaks following the lines of Blaschko
- Usually becomes apparent within the first year of life
- Associated systemic findings occur in a minority of affected individuals
- Increased melanin within the epidermis and few melanophages

Introduction

Linear and whorled nevoid hypermelanosis (LWNH), first described in the 1970s, is characterized by swirls and streaks of macular hyperpigmentation along the lines of Blaschko[24]. Occasionally, there are associated systemic abnormalities.

Epidemiology

LWNH is a sporadic disorder with no gender preference. It is viewed as an uncommon disorder but is probably under-recognized.

Pathogenesis

LWNH is a genetically heterogeneous mosaic skin condition characterized by a clone of skin cells with increased pigment production[25]. A variety of underlying mosaic chromosomal anomalies have been reported.

Clinical features

Swirls and streaks of brown pigmentation usually appear early during the first year of life (Fig. 67.15). The full extent of skin involvement is

Fig. 67.15 Linear and whorled nevoid hypermelanosis on the trunk. This young African-American girl had developmental delay. Note the distribution along the lines of Blaschko. *Courtesy, Julie V Schaffer, MD.*

typically apparent by the time the child is 2–3 years of age[24]. The linear hyperpigmentation tends to persist indefinitely. Occasionally, patients with "pigmentary mosaicism" will develop both hypo- and hyperpigmented streaks, which may be referred to as "linear nevoid pigmentation".

Up to a quarter of patients with LWNH who present to a pediatric dermatologist have extracutaneous findings, which typically become apparent during infancy and may be neurologic, musculoskeletal or (less often) cardiac in nature[25]. However, the exact incidence of extracutaneous abnormalities in LWNH is unknown.

Pathology

LWNH is characterized by increased melanin within basal keratinocytes and, in some cases, a slight increase in the density of melanocytes. There are few dermal melanophages.

Differential diagnosis

The differential diagnosis includes other disorders characterized by hyperpigmentation along the lines of Blaschko (Table 67.5; Figs 67.16 & 67.17). The hyperpigmented stage (stage 3) of incontinentia pigmenti (IP) is distinguished by its grayish-brown color, a predominance of melanophages rather than epidermal pigment (Fig. 67.18), fading over time and (in most patients) a history of previous inflammatory vesicular and verrucous stages (1 and 2, respectively). Some epidermal nevi initially have minimal or no palpable component, but they eventually become elevated. Of note, a mother and child previously reported as an example of "familial LWNH" (with histologic findings of increased epidermal melanin but no pigment incontinence in affected skin) were subsequently found to have hypohidrotic ectodermal dysplasia with immunodeficiency due to a hypomorphic *NEMO* mutation[26].

Treatment

There is currently no effective treatment, although future developments in laser therapy may hold promise. Camouflage cosmetics may be helpful.

Incontinentia Pigmenti

A full discussion of IP can be found in Chapter 62. This X-linked dominant multisystem disorder is characterized by skin lesions distributed along the lines of Blaschko, including vesicles (stage 1), verrucous lesions (stage 2), hyperpigmentation (stage 3) and, eventually, hypopigmentation (stage 4). The third stage usually presents within the first year of life and is characterized by gray to gray–brown streaks and whorls along the lines of Blaschko (Fig. 67.19). The trunk is a common

DISORDERS WITH HYPERPIGMENTATION THAT CAN FOLLOW BLASCHKO'S LINES
INHERITED AND/OR EARLY ONSET
• Linear and whorled nevoid hypermelanosis (a form of "pigmentary mosaicism")
• Third stage of incontinentia pigmenti
• Chimerism
• Early epidermal nevus
• X-linked reticulate pigmentary disorder*
• Focal dermal hypoplasia (Goltz syndrome; usually hyperpigmented macules in a linear array)
• Conradi-Hünermann-Happle syndrome
• Café-au-lait macules of McCune–Albright syndrome†
• Seckel syndrome‡
ACQUIRED
• Hyperpigmentation secondary to linear lichen planus or lichen planus pigmentosus
• Linear fixed drug eruption
• Linear atrophoderma of Moulin (Fig. 67.17)
• Linear biphasic cutaneous amyloidosis‡
*Female patients.
†Most often in broad bands or with a block-like configuration.
‡Single case.

Table 67.5 Disorders with hyperpigmentation that can follow Blaschko's lines.

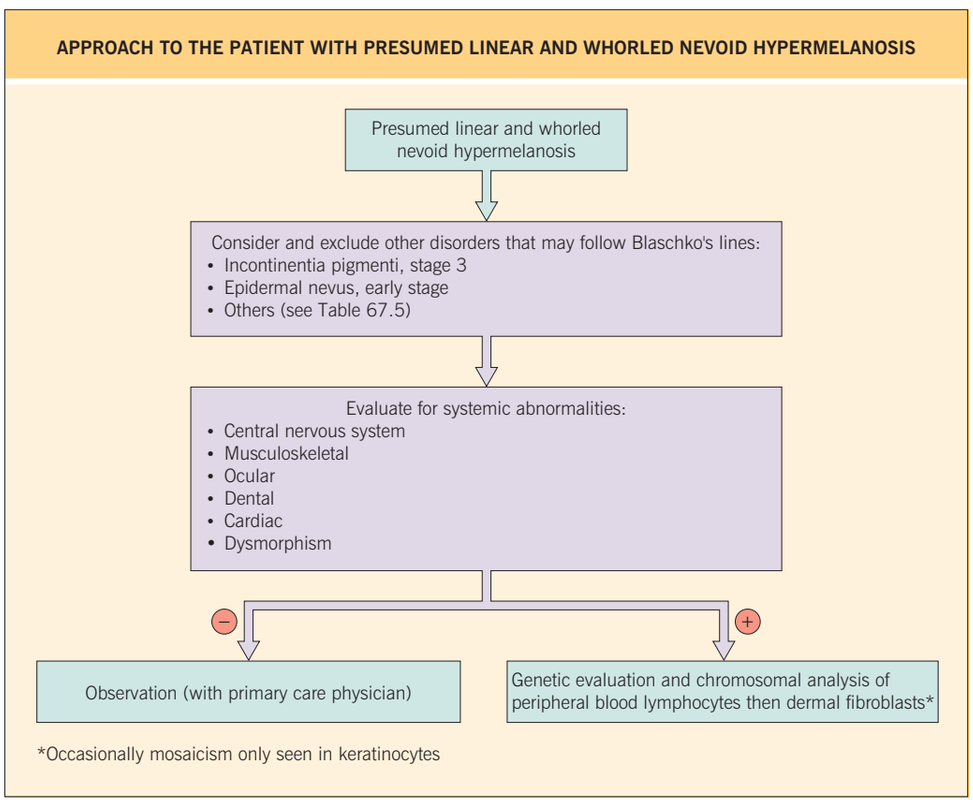

Fig. 67.16 Approach to the patient with presumed linear and whorled nevoid hypermelanosis. In general, the initial evaluation is clinical, with additional studies only as indicated based on abnormalities that are evident. Genetic abnormalities are currently detected primarily at the chromosomal (not gene) level; decisions regarding performance of conventional chromosomal analysis and/or array comparative genomic hybridization are made on a case-by-case basis.

Fig. 67.17 Linear hyperpigmentation due to atrophoderma of Moulin. Note the subtle depression of the lesions on the upper lateral thigh. *Courtesy, Jean L Bolognia, MD.*

Fig. 67.19 Stage 3 incontinentia pigmenti in a 2-year-old child. Note the characteristic gray–brown color, and the distribution along the lines of Blaschko.

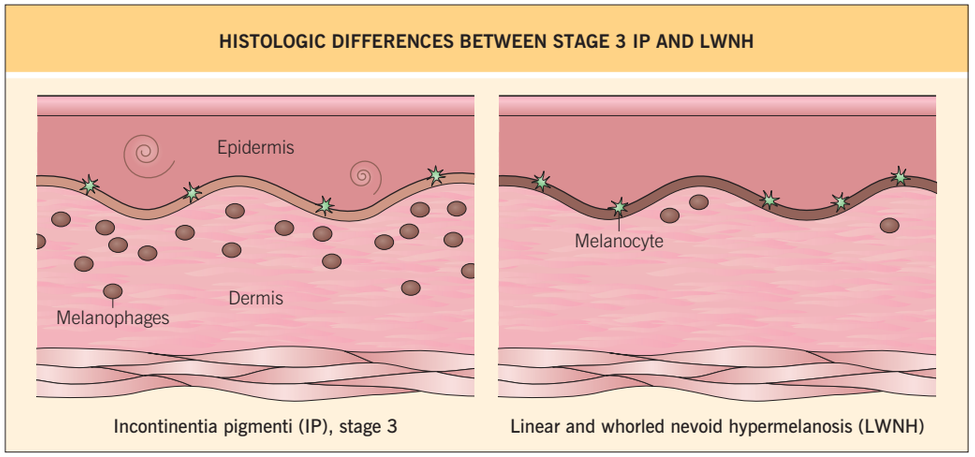

Fig. 67.18 Histologic differences between stage 3 incontinentia pigmenti (IP) and linear and whorled nevoid hypermelanosis (LWNH).

area of involvement. The pigmentation fades gradually during late childhood to adolescence. IP is due to mutations in the *NEMO* gene. The gradual fading of stage 3 lesions reflects increased apoptosis within the affected streaks, followed by replacement with normal skin.

RETICULATED HYPERPIGMENTATION

Disorders characterized by true reticulated macular hyperpigmentation are rare. Initial evaluation should exclude other more common entities such as confluent and reticulated papillomatosis of Gougerot and Carteaud (see Ch. 109), where the lesions are elevated and favor the neck and upper trunk (Fig. 67.20), and the hyperpigmentation of erythema ab igne, which has a widely spaced net-like pattern corresponding to the arrangement of the cutaneous venous plexus (see Ch. 88). A similar violaceous to brown-colored net-like pattern can also be seen on the lower extremities of patients with livedo reticularis. Reticulated hyperpigmentation is an occasional feature of other skin disorders, such as its occurrence on the anterolateral neck in patients with atopic dermatitis ("atopic dirty neck") and in association with epidermolysis bullosa herpetiformis.

When a true reticulated pigmentary disorder exists, the family history should be reviewed and the patient carefully examined for associated abnormalities. The following section discusses prurigo pigmentosa and six genodermatoses associated with reticulated hyperpigmentation. Additional entities that feature reticulated hyperpigmentation are listed in Table 67.6.

PRURIGO PIGMENTOSA

First described by Nagashima in 1971[27], this idiopathic disorder is characterized by a markedly pruritic eruption of erythematous papules and papulovesicles on the back, neck and chest. Crops of inflammatory lesions develop rapidly and then involute within a week, leaving macular reticulated hyperpigmention. Recurrences tend to occur at the same site, and lesions in multiple stages are often evident. The condition favors young adults, with a female : male ratio of ≥2 : 1; the majority of reported patients have been from Japan. Three histopathologic stages have been identified: (1) neutrophilic exocytosis, spongiosis, papillary dermal edema and a superficial perivascular infiltrate of neutrophils; (2) intra-/subepidermal vesiculation, necrotic keratinocytes and a patchy lichenoid infiltrate of predominantly lymphocytes; (3) parakeratosis and dermal melanophages[28]. Treatment with oral minocycline, doxycycline or dapsone is usually effective for the inflammatory component of prurigo pigmentosa. The condition does not respond to corticosteroids (topical or systemic) or antihistamines.

Fig. 67.20 Confluent and reticulated papillomatosis of Gougerot and Carteaud. **A** On the neck and back of a teenage girl. **B** On the chest of an older woman. *A, Courtesy, Seth Orlow, MD PhD.*

DISORDERS CHARACTERIZED BY RETICULATED PIGMENTATION	
Disorder	**Key features**
Confluent and reticulated papillomatosis of Gougerot and Carteaud	Elevated with rough texture; favors neck and upper trunk; responds well to minocycline
Erythema ab igne	Widely spaced net that corresponds to vascular pattern; due to heat injury (see Ch. 88)
Atopic dirty neck	Anterolateral neck
Dyskeratosis congenita*	X-linked recessive (XLR) form more common than autosomal dominant (AD) and autosomal recessive (AR) forms; pterygium, leukoplakia, pancytopenia, mucosal squamous cell carcinoma, leukemia (see Table 67.7); mutations in the genes that encode dyskerin (XLR), the TERC (AD) or TERT (AD, AR) subunit of telomerase, TINF2 (AD), NOP10 (AR), NHP2 (AR) or TCAB1 (AR)
Fanconi's anemia*	Autosomal recessive; more often diffuse hypermelanosis; radial ray bony defects, pancytopenia, leukemia (see Table 67.7)
X-linked reticulate pigmentary disorder	X-linked recessive (only males have generalized reticulated pigmentation); neonatal colitis, recurrent pneumonia, hypohidrosis, photophobia; amyloid deposits in adults
Dowling–Degos disease (DDD)	Autosomal dominant; reticulated hyperpigmentation of major flexures (may be composed of or admixed with discrete hyperpigmented macules and papules), comedones on the back and neck, pitted facial scars; due to loss-of-function mutations in keratin 5 gene
Galli–Galli disease	Acantholytic variant of DDD
Haber syndrome	Rosacea-like facial eruption plus the clinical features of DDD
Pigmentatio reticularis faciei et colli	Possible variant of DDD; hyperpigmentation of the face and neck plus multiple epidermoid cysts
Epidermolysis bullosa simplex (EBS) herpetiformis (Dowling–Meara) and EBS with mottled pigmentation*	"Mottled" appearance due to mutations in the genes that encode keratin 5 and 14 (with a specific P25L keratin 5 mutation usually underlying EBS with mottled pigmentation) (see Ch. 32)
Prurigo pigmentosa	Typically young Japanese women; favors the back, neck and chest; recurrent crops of pruritic papulovesicles that resolve with a reticulated pattern of hyperpigmentation
Mendes da Costa disease*	Traumatic bullae and hyperpigmentation, usually acral; dwarfism, atrichia
Dermatopathia pigmentosa reticularis	Autosomal dominant; persistent reticulated hyperpigmentation, alopecia, nail dystrophy; palmoplantar keratoderma and hypoplastic dermatoglyphics in some patients; mutation in the keratin 14 gene
Naegeli–Franceschetti–Jadassohn syndrome	Autosomal dominant; fading reticulated hyperpigmentation, dental anomalies, hypohidrosis, palmoplantar keratoderma, hypoplastic dermatoglyphics, nail dystrophy; mutations in the keratin 14 gene
Reticulate acropigmentation of Kitamura	Primarily autosomal dominant; atrophic acral lentigo-like lesions, palmoplantar and dorsal phalangeal pitting
Reticulate genital hyperpigmentation associated with localized vitiligo*	Affected individuals had congenital or acquired reticulate hyperpigmentation of the genitalia, which was followed by the development of vitiligo in the same region
Cantu syndrome	Reticulated pigmentation of face, forearms and feet; palmoplantar keratoderma
Mitochondrial disorders	Sun-exposed areas (e.g. cheeks, dorsal aspects of the forearms and hands); additional cutaneous findings include hypertrichosis, hair shaft abnormalities and acrocyanosis (see Ch. 63)
Postinflammatory	Lichenoid dermatoses (e.g. lichen planus pigmentosus); contact dermatitis (e.g. due to benzoyl peroxide)
Drug-induced	Diltiazem (sun-exposed areas); chemotherapeutic agents such as 5-fluorouracil and bleomycin (see Table 63.7)

*Also dyschromatosis.

Table 67.6 Disorders characterized by reticulated pigmentation. TERC, telomerase RNA component; TERT, telomerase reverse transcriptase; TCAB1, telomerase Cajal body protein-1; TINF2, telomere repeat binding factor 1-interacting nuclear factor 2.

DYSKERATOSIS CONGENITA

Synonym: ■ Zinsser–Engman–Cole syndrome

Key features

- 90% of patients are male, as the most common form is X-linked recessive
- Triad of reticulated hyperpigmentation, nail dystrophy (e.g. pterygium) and leukoplakia
- Continuous lacrimation (epiphora) due to lacrimal duct atresia
- Bone marrow dysfunction (thrombocytopenia, anemia, pancytopenia)
- Predisposition to malignancy, especially mucosal squamous cell carcinoma, leukemia and Hodgkin disease

Introduction

First described in 1906 by Zinsser, dyskeratosis congenita (DKC) is a genodermatosis characterized by progressive bone marrow failure and the mucocutaneous triad of reticulated hyperpigmentation, nail dystrophy and leukoplakia. In addition, affected individuals have an increased risk of developing squamous cell carcinoma (especially mucosal), acute myelogenous leukemia and Hodgkin disease[29].

Epidemiology

The most common form of DKC has an X-linked recessive pattern of inheritance. As a result, as many as 90% of patients are male. However, autosomal dominant and autosomal recessive forms of DKC also exist.

Pathogenesis

The X-linked recessive form of DKC is caused by mutations in the *DKC1* gene, which encodes the dyskerin protein that interacts with the telomerase enzyme[30] (Fig. 67.21). Telomerase is composed of two subunits, TERC (telomerase RNA component) and TERT (telomerase reverse transcriptase). Heterozygous mutations in the genes that encode these subunits or the telomere repeat binding factor 1-interacting nuclear factor 2 (TINF2), a component of the shelterin complex that plays an integral role in telomere structure and function, can lead to autosomal dominant forms of DKC[31,32]. In addition, biallelic mutations in the genes that encode TERT, telomerase Cajal body protein-1 (TCAB1; also known as WRAP53), or the NOP10 and NHP2 ribonucleoprotein analogs that associate with the telomerase complex have been found to underlie autosomal recessive forms of DKC[33,34]. Heterozygous mutations in the gene encoding TERT can also result in familial adult-onset pulmonary fibrosis without the skin findings or other manifestations of DKC[35].

Telomerase prevents the progressive shortening of chromosomes that would otherwise occur with DNA replication. Tissues with high replication rates (e.g. the bone marrow and skin) are particularly vulnerable when telomerase is not functioning properly. Telomerase dysfunction also leads to chromosome instability, which can result in tumorigenesis. DKC may also be considered as a premature aging syndrome, since short telomeres lead to early senescence in affected individuals.

Clinical Features

A lacy reticulated pattern of hyperpigmentation develops during the first decade of life. This occurs primarily on the neck (Fig. 67.22A&B), upper chest and upper arms and may be admixed with macules of hypopigmentation. In some areas, telangiectasias and epidermal atrophy are also seen, i.e. poikiloderma. Additional cutaneous features include wrinkled skin on the extremities, dorsal aspects of the hands,

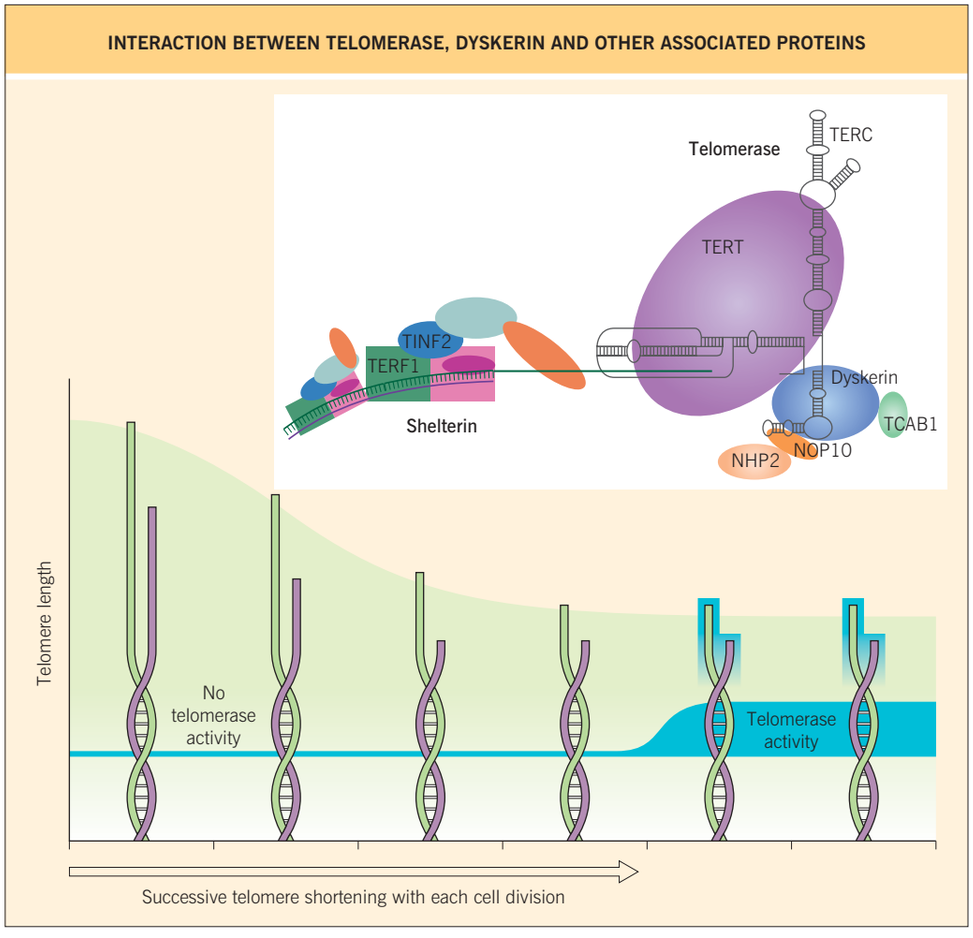

Fig. 67.21 Interaction between telomerase, dyskerin and other associated proteins. Telomerase, the enzyme that protects against progressive shortening of the chromosomes with each successive cell division, is composed of two subunits: an RNA component (TERC) and reverse transcriptase (TERT). Dyskerin, the protein that is dysfunctional in patients with X-linked recessive dyskeratosis congenita, interacts with telomerase and plays a role in its proper function. Autosomal dominant DKC can result from dysfunction of the TERC subunit, the TERT subunit or the telomere repeat binding factor 1 (TERF1)-interacting nuclear factor 2 (TINF2); the latter is a component of the shelterin complex that plays an essential role in telomere structure and function. Autosomal recessive DKC can be caused by mutations in the genes encoding the TERT subunit; telomerase Cajal body protein-1 (TCAB1), which associates with dyskerin; or the NOP10 and NHP2 ribonucleoprotein analogues that associate with the telomerase complex.

and genitalia; palmoplantar hyperhidrosis and hyperkeratosis; frictional bullae; and acrocyanosis.

Nail involvement is present in the vast majority of patients, typically appearing during early childhood. Initial changes include longitudinal ridging and splitting, followed by pterygia formation (Fig. 67.22C) and occasionally complete nail loss. Premalignant leukoplakia occurs in most patients, usually manifesting during early adolescence. White plaques on the oral mucosa are observed most commonly, with a predilection for the lateral portions of the tongue. Involvement of the urethra, vagina and anus may also be seen. The teeth may be malformed, missing, or have aberrant spacing or extensive caries. Epiphora (continuous lacrimation) due to lacrimal duct atresia is common[29].

Bone marrow failure occurs in 50–90% of patients and is a major cause of mortality. It presents during the second or third decade with anemia, thrombocytopenia or pancytopenia. Malignancies tend to develop during the third or fourth decade, most notably squamous cell carcinomas of the mouth, anus, cervix, vagina, esophagus and skin. There is also an increased risk of myelodysplasia, acute myelogenous leukemia, Hodgkin disease and gastrointestinal carcinomas[29].

Other systemic manifestations that have been described include testicular atrophy, pulmonary fibrosis, liver cirrhosis, developmental delay, and immunologic dysfunction leading to opportunistic infections. Of note, increased severity in successive generations (anticipation) due to progressive telomere shortening characterizes autosomal dominant forms of DKC, and *TINF2* mutations tend to result in severe DKC with onset in early childhood. However, family members who are asymptomatic carriers of *TERT* mutations have also been described. *Hoyeraal–Hreidarsson syndrome* is an allelic condition characterized by bone marrow failure, immunodeficiency, microcephaly, cerebellar hypoplasia and growth retardation. Also caused by *DKC1* mutations, it typically leads to death in early childhood. *Revesz syndrome* is another related disorder that features progressive neurologic deterioration, intracranial calcifications and exudative retinopathy together with the manifestations of DKC; it is caused by heterozygous mutations in the *TINF2* gene.

Pathology

Histologically, the features of poikiloderma vasculare atrophicans are seen, with telangiectasias and epidermal thinning as well as foci of increased pigment within the basal layer. In the early stage, hydropic degeneration of basilar keratinocytes and a band-like inflammatory infiltrate in the upper dermis may be evident. In the late stage, the epidermis is markedly thinned and flattened and melanophages are present in the upper dermis.

Short telomere length can be detected in leukocytes from patients with DKC by flow fluorescence *in situ* hybridization[36].

Differential Diagnosis

Fanconi's anemia is also associated with pigmentary abnormalities, pancytopenia and an increased risk of neoplasia (e.g. leukemia); this disorder is compared to DKC in Table 67.7. Naegeli–Franceschetti–Jadassohn (NFJ) syndrome and dermatopathia pigmentosa reticularis (DPR) differ by their lack of leukoplakia and bone marrow involvement (see below). Patients with chronic GVHD may develop poikilodermatous skin changes and lacy white patches of the oral mucosa. However, GVHD is usually easily distinguished by the history of a hematopoietic stem cell transplant (or, rarely, a solid organ transplant). Additional entities associated with poikiloderma are discussed in Chapter 63.

Treatment

Management of DKC patients requires multidisciplinary care. Longitudinal surveillance of all mucosal surfaces is indicated to monitor for the development of squamous cell carcinoma within areas of

COMPARISON OF DYSKERATOSIS CONGENITA AND FANCONI'S ANEMIA		
	Dyskeratosis congenita	**Fanconi's anemia (FA)**
Pigmentation	Lacy reticulated hyperpigmentation favoring the neck and upper chest, with onset during the first decade of life Sometimes admixed with hypopigmented macules Poikiloderma may be present (telangiectasias and epidermal atrophy)	More generalized, diffuse hyperpigmentation; less often reticulated Sometimes admixed with hypopigmented macules Multiple café-au-lait macules may be present
Hematologic abnormalities	Anemia, leukopenia, thrombocytopenia, pancytopenia Onset typically in 2nd decade	Anemia, leukopenia, thrombocytopenia, pancytopenia Onset typically in 1st decade
Associated malignancies	Increased risk, in particular SCC (esp. mucosal), acute myelogenous leukemia, Hodgkin disease	Increased risk, in particular SCC (esp. of head & neck), acute myelogenous leukemia, hepatocellular cancer; increased risk of breast and pancreatic cancer with *heterozygous* mutations in some FA genes*
Additional clinical findings	Nail abnormalities (e.g. pterygium), leukoplakia, hyperhidrosis, palmoplantar hyperkeratosis, frictional bullae, acrocyanosis, epiphora (continuous lacrimation)	Radial ray bony defects involving the thumb, short stature, renal and cardiac malformations, hypogonadism and other endocrinopathies
Exposure of lymphocytes to mitomycin C or diepoxybutane	No chromosomal breakage	Enhanced chromosomal breakage and rearrangement
Inheritance	Most common form is X-linked recessive (~90% of patients are male); occasionally autosomal dominant or autosomal recessive	Autosomal recessive (at least 11 complementation groups); rarely X-linked recessive (1 complementation group; ~1% of patients)

*For example, *BRCA2* (*FAD1*).

Table 67.7 Comparison of dyskeratosis congenita and Fanconi's anemia. SCC, squamous cell carcinoma.

leukoplakia. Sun and cigarette avoidance are advisable. Bone marrow failure can be treated with supportive transfusions of blood products and the use of androgens (e.g. oxymetholone), erythropoietin and granulocyte colony-stimulating factor. Although hematopoietic stem cell transplantation can potentially cure bone marrow failure and leukemia in patients with DKC, it has historically been associated with a high rate of complications and poor long-term survival.

NAEGELI–FRANCESCHETTI–JADASSOHN SYNDROME

Key features

- Autosomal dominant disorder due to heterozygous mutations in the keratin 14 gene
- Reticulated hyperpigmentation beginning by 2 years of age and often fading during adolescence
- Hypohidrosis and heat intolerance
- Dental anomalies, including early loss of teeth
- Palmoplantar keratoderma, with absent or hypoplastic dermatoglyphics

Introduction

NFJ syndrome is a rare autosomal dominant genodermatosis that is characterized by reticulated hyperpigmentation as well as ectodermal dysplasia (primarily dental anomalies and hypohidrosis) and hypoplastic dermatoglyphics.

History

First described by Naegeli in 1927, NFJ was initially confused with incontinentia pigmenti. In 1954, Franceschetti and Jadassohn re-examined the original family and noted the autosomal dominant pattern of inheritance.

Epidemiology

Affected families have been of Swiss and British descent.

Pathogenesis

NFJ syndrome is caused by truncating mutations in the non-helical head domain of the keratin 14 gene (*KRT14*) (see Fig. 56.5) that result in haploinsufficiency[37]. This leads to increased susceptibility of keratinocytes to tumor necrosis factor-α (TNF-α)-induced apoptosis, which explains the hyperpigmentation secondary to pigment incontinence observed in affected individuals and points to a role of the N-terminal portion of keratin 14 in regulating apoptosis during morphogenesis of cutaneous appendages.

Clinical Features

Brown or gray–brown reticulated hyperpigmentation develops by the age of 2 years, without a preceding inflammatory stage. The pigmentary changes are most often observed on the abdomen and periocular and perioral regions, with variable involvement of the neck, trunk, proximal extremities, axillae and groin. The hyperpigmentation often fades after puberty and may eventually disappear. Some infants have bullae on their feet during the newborn period. Decreased sweat gland function with lifelong heat intolerance is a problem for many patients. Other cutaneous manifestations include absent or hypoplastic dermatoglyphics, palmoplantar keratoderma (diffuse or punctate), and onychodystrophy (onycholysis, subungual hyperkeratosis and congenital malalignment of the great toenails). Dental anomalies are common and include abnormally shaped teeth, supernumerary teeth, and yellow spotted tooth enamel. Early total loss of teeth may occur.

Pathology

Histologically, the hyperpigmented skin demonstrates pigment incontinence, i.e. melanophages.

Differential Diagnosis

The lack of leukoplakia, bone marrow failure or an increased risk of malignancies in patients with NFJ syndrome differentiates it from DKC. Although NFJ syndrome lacks the prominent alopecia and more persistent hyperpigmentation that characterize DPR, there is significant overlap between these allelic disorders. The hyperpigmentation of stage 3 IP follows Blaschko's lines and is usually preceded by an inflammatory stage (see above). X-linked reticulate pigmentary disorder often presents with hypohidrosis and dental anomalies as well as reticulate hyperpigmentation, but additional systemic manifestations as well as the inheritance pattern distinguish it from NFJ. Hypohidrosis, onychodystrophy, dental anomalies, and hypoplastic or absent dermatoglyphics can be seen in other forms of ectodermal dysplasia. Reticulated hyperpigmentation and palmoplantar keratoderma may

develop in patients with epidermolysis bullosa simplex due to mutations in keratin 5 or 14, but blistering is more prominent. In addition, patients with Kindler syndrome may have absent or hypoplastic dermatoglyphics, but they develop poikiloderma rather than reticulated hyperpigmentation (see Ch. 63).

Treatment

Treatment is supportive. Genetic counseling should be offered to affected individuals planning future children.

DERMATOPATHIA PIGMENTOSA RETICULARIS

Key features

- Autosomal dominant disorder due to mutations in the keratin 14 gene
- Persistent reticulated hyperpigmentation with truncal predominance
- Non-scarring alopecia of the scalp, eyebrows and axillae
- Onychodystrophy
- Absent dermatoglyphics and punctate keratoderma in some patients

Introduction and Pathogenesis

DPR is a rare genodermatosis that was recognized as a distinct entity in the 1970s. Like NFJ (see above), a heterozygous truncating mutation in the non-helical head domain of the keratin 14 gene has been shown to cause DPR[37].

Clinical Features

DPR presents by the second year of life with the triad of reticulated hyperpigmentation, non-scarring alopecia and onychodystrophy[38]. The reticulated hyperpigmentation has a predilection for the trunk but also occurs on the proximal extremities, and it persists during adulthood (Fig. 67.23). The nail involvement may result in pterygia formation. Variable features include absent dermatoglyphics, hypo- or hyperhidrosis, and a punctate palmoplantar keratoderma.

Pathology

Histologically, the hyperpigmented skin demonstrates pigment incontinence, i.e. melanophages.

Fig. 67.23 Dermatopathia pigmentosa reticularis. Persistent hyperpigmentation in a reticulated pattern extending from the lower abdomen to the thigh in a young man. *Courtesy, Julie V Schaffer, MD.*

Differential Diagnosis

There is clinical overlap with the NFJ syndrome (e.g. reticulated hyperpigmentation, nail dystrophy, punctate keratoderma, absent dermatoglyphics), but the latter lacks alopecia and has less persistent hyperpigmentation. Additional diagnostic considerations are as discussed above for NFJ.

X-LINKED RETICULATE PIGMENTARY DISORDER

Synonyms: ■ Partington syndrome type II ■ Familial cutaneous amyloidosis ■ X-linked reticulate pigmentary disorder with systemic manifestations

Key features

- Reticulated hyperpigmentation along the lines of Blaschko in women and in a generalized pattern in men
- Recurrent infections and multiple systemic manifestations in male patients
- Some adult patients have amyloid deposits within the dermis

Introduction

This rare genodermatosis is characterized by reticulated brown hyperpigmentation that is generalized in male patients and along the lines of Blaschko in female patients. Affected males have severe systemic complications that often lead to premature death. The disorder was first described by Partington et al. in 1981[39], and several additional families have subsequently been identified[40–42]. The pathogenesis is unknown, but the disorder has been mapped to Xp21.11–p21.3.

Epidemiology

Partington's original kindred had English and Scottish heritage[39]. Other reported families (all unrelated) had Maltese, Lebanese, Spanish and mixed Dutch, French and German ancestries[40–42].

Clinical Features

In *female* patients with this X-linked disorder, manifestations appear to be limited to the skin. At birth or within the first few weeks of life, female infants develop lacy or reticulated areas of hyperpigmentation in streaks that follow the lines of Blaschko. Although the lesions are reminiscent of stage 3 IP, there are no preceding vesicular or verrucous stages. The hypermelanosis may fade during adulthood.

In *male* patients, the reticulated hyperpigmentation is generalized (Fig. 67.24), initially developing on the inner thighs, buttocks or cheeks between 4 months and 5 years of age. Affected boys often have severe systemic manifestations, including a low birthweight, neonatal colitis, failure to thrive during infancy, seizures and hemiplegia, as well as gastroesophageal reflux, urethral strictures and inguinal hernias. Recurrent pneumonias and chronic obstructive pulmonary disease are nearly always present in male patients and can lead to premature death. Intelligence may be normal or development delayed. Additional features include dental anomalies, hypohidrosis, xerosis, photophobia, corneal clouding, and skeletal changes such as delayed bone age and shortened metacarpals. Blonde unruly hair with a frontal upsweep is a notable clinical finding; in fair-skinned patients, the hair may become silver-gray[39–41].

Pathology

Although the histologic features of the cutaneous hyperpigmentation are similar in male and female patients, they are fairly nonspecific. Findings include increased epidermal melanin, pigment incontinence with dermal melanophages, and dyskeratosis[39]. Amyloid deposits in the upper dermis (keratin-positive as in macular amyloidosis) were also noted in adults (but not children) from the original Canadian family and a recently reported kindred[39,42]. As with macular amyloidosis, deposits were not found in other tissues.

Fig. 67.24 X-linked reticulate pigmentary disorder. There is reticulated hyperpigmentation of the face and neck in this 11-year-old boy, as well as blond, coarse hair. *Courtesy, K Robin Carder, MD.*

Fig. 67.25 Dowling–Degos disease. Hyperpigmented macules forming a reticulated pattern in the axilla. *Courtesy, Thomas Schwarz, MD.*

Differential Diagnosis

In boys, other entities with reticulated hyperpigmentation should be considered (see Table 67.6), particularly DKC and NFJ syndrome, especially when there are recurrent infections (DKC), hypohidrosis (NFJ syndrome) or dental anomalies (both DKC and NFJ syndrome). In female carriers, the differential diagnosis includes the disorders listed in Table 67.5.

Treatment

Treatment is supportive. Genetic counseling is indicated for families planning future pregnancies.

DOWLING–DEGOS DISEASE

Synonyms:
- Reticular pigmented anomaly of the flexures
- Reticulated pigmented anomaly of the flexures

Key features

- Reticulated hyperpigmentation in flexural sites
- Comedone-like lesions on the back and neck
- Pitted facial scars
- Autosomal dominant with variable penetrance
- Caused by loss-of-function mutations in the gene that encodes keratin 5

Introduction

Dowling–Degos disease (DDD) is an uncommon autosomal dominant condition characterized by acquired reticular hyperpigmentation in intertriginous sites.

Epidemiology

There is no racial or sex predilection, and it has been reported worldwide.

Pathogenesis

DDD is caused by loss-of-function mutations in the non-helical head domain of the keratin 5 gene (*KRT5*) (see Fig. 56.5) that lead to haploinsufficiency[43]. Interestingly, a missense mutation in the same region of *KRT5* underlies epidermolysis bullosa simplex with mottled pigmentation (see Ch. 32). The head domain of keratin 5 has been found to interact with Hsc70, a chaperone involved in vesicle uncoating, and it has been postulated that keratin 5 has a role in melanosome trafficking.

Clinical Features

Onset is typically during the third to fourth decade of life. The reticulated hyperpigmentation is admixed with and sometimes composed of lentigo-like brown macules; small brown papules with variable hyperkeratosis may also develop. These findings progressively increase over time, initially appearing in the axillae (Fig. 67.25) and groin with later involvement of the intergluteal and inframammary folds, neck, trunk and inner aspects of the arms and thighs. Some patients report pruritus of the affected flexural areas. Comedone-like lesions on the back or neck, pitted perioral scars, epidermoid cysts and hidradenitis suppurativa represent additional features in some patients.

Pathology

Histologically, there is increased pigmentation of the basal layer and finger-like rete ridges with thinning of the suprapapillary epithelium. This results in an "antler-like" pattern arising from the under surface of the epidermis and hair follicles. Dermal melanophages and a mild perivascular lymphohistiocytic infiltrate are also observed[44]. *Galli–Galli disease* represents a variant of DDD (also caused by *KRT5* mutations) with prominent suprabasal non-dyskeratotic acantholysis in biopsy specimens of lesional skin in addition to the usual clinical and histologic features[45].

Differential Diagnosis

Acanthosis nigricans is distinguished clinically by velvety plaques and histologically by less pronounced elongation of the rete ridges. In addition, there is no follicular involvement. Patients with neurofibromatosis type 1 develop lentigines (oftentimes referred to as "freckles") in the axillae and groin, but this disorder is usually easy to distinguish from DDD.

The spectrum of DDD-like disorders that feature reticulate pigmentation include reticulate acropigmentation of Kitamura (see below) and Haber syndrome. Patients with *Haber syndrome* develop a photosensitive rosacea-like facial eruption during adolescence, which is followed by the appearance of keratotic papules, comedone-like lesions, pitted

scars and reticulate hyperpigmentation on the trunk and proximal extremities as well as in the axillae.

Treatment

Topical hydroquinone, tretinoin, adapalene and corticosteroids have been used with varying success. Improvement following treatment with the erbium:YAG laser has also been reported[46].

RETICULATE ACROPIGMENTATION OF KITAMURA

Synonym: ■ Kitamura reticulate acropigmentation

Key features

- Atrophic reticulated or lentigo-like hyperpigmentation that favors the dorsal aspects of the hands and feet and appears during childhood
- Pits on the palms, soles and dorsal phalanges
- Autosomal dominant inheritance pattern

Introduction

Reticulate acropigmentation of Kitamura is a rare genodermatosis characterized by atrophic hyperpigmented macules that appear during childhood and initially have an acral distribution. Two-thirds of reported patients have been Japanese, but the condition has been described in individuals with other ethnic backgrounds.

Clinical Features

During childhood, slightly depressed lentigo-like hyperpigmented macules develop on the dorsal aspects of the hands and feet and often assume a reticulated pattern. These macules slowly darken over time and subsequently may spread to other sites of the body during adulthood. Sunlight may aggravate the condition. Pits are found on the palms, soles and dorsal phalangeal surfaces, and breaks in the dermatoglyphics are also evident.

Pathology

Examination of the hyperpigmented macules shows epidermal atrophy and elongated rete ridges that contain an increased amount of melanin. An increased number of DOPA-positive melanocytes are seen in the basal layer of the epidermis.

Differential Diagnosis

In contrast to the more common solar lentigines, the hyperpigmented macules of acropigmentation of Kitamura are slightly atrophic and develop at an earlier age. Unlike dyschromatosis symmetrica hereditaria (see below), white macules are not admixed with the brown macules. Reticulate acropigmentation of Kitamura may represent a variant of Dowling–Degos disease (see above) with a different distribution pattern.

Treatment

Treatment options are similar to those listed above for Dowling–Degos disease.

DYSCHROMATOSES

Dyschromatoses are characterized by the presence of both hypo- and hyperpigmentation (Figs 67.26–28). Often, at least one component of the dyspigmentation is guttate. The two classic dyschromatoses, dyschromatosis symmetrica hereditaria and dyschromatosis universalis hereditaria, are discussed in this section. A more recently recognized entity, acquired brachial cutaneous dyschromatosis, is also described. Additional dyschromatoses are listed in Table 67.8.

Fig. 67.26 Dyschromic amyloidosis cutis. An admixture of reticulated hyperpigmentation and guttate hypopigmentation are evident. *Courtesy, Seth J Orlow, MD PhD.*

Fig. 67.27 Dyschromatosis symmetrica hereditaria. An admixing of multiple hypo- and hyperpigmented macules on the hands more so than on the forearms. *Courtesy, Peter Ehrnstrom, MD.*

Fig. 67.28 Dyschromatosis universalis hereditaria. Both hypo- and hyperpigmentation were present in a widespread distribution. *With permission from Urabe K, Hori Y. Dyschromatosis. Semin Cutan Med Surg. 1997;16:81–5.*

DYSCHROMATOSES	
Disorder	**Key features**
GENETIC DISORDERS	
Dyschromatosis symmetrica hereditaria	Symmetrical dyschromatosis of distal extremities, especially dorsal aspects of hands and feet; palms, soles and mucous membranes spared Usually presents by age 6 years Caused by heterozygous mutations in *ADAR* (*DSRAD*) gene (encodes double-stranded RNA-specific adenosine deaminase) Vast majority of patients are Japanese or Chinese (see text)
Dyschromatosis universalis hereditaria	Truncal or generalized hyper- and hypopigmented macules; can occur on palms and soles, but not mucous membranes Usually presents by age 6 years, often becoming apparent in the first year of life Majority of patients are Japanese (see text)
Xeroderma pigmentosum (XP)	Lentigines and hypopigmented macules on dorsal aspects of hands and feet, face and other chronically sun-exposed sites Actinic damage beginning in infancy and early childhood, with skin cancers often developing during the first decade of life Autosomal recessive disorder caused by defective nucleotide excision repair (complementation groups A–G) or error-free bypass (XP-variant) of UV-induced DNA damage
Dyskeratosis congenita	Reticulated hyperpigmentation can be admixed with macules of hypopigmentation; nail dystrophy and leukoplakia Predisposition to malignancies (see Table 67.7) Most common form is X-linked recessive
Epidermolysis bullosa simplex with mottled pigmentation	Acral blistering early in childhood, mottled pigmentation, punctate keratoses of the palms and soles, and dystrophic, thickened nails Typically due to a specific keratin 5 mutation (P25L; see Ch. 32)
Wende–Bauckus/Pegum syndrome	At 1 year of age, background hyperpigmentation (gray–brown) develops on the trunk > extremities Tiny white macules on the trunk with confluence in flexures
Ziprkowski–Margolis syndrome	Diffuse pigmentary dilution of the hair and skin, sparing the buttocks and genital region Later, multiple hyperpigmented macules appear, giving the skin a leopard-like appearance Congenital sensorineural deafness, heterochromia irides X-linked recessive inheritance
Chédiak-Higashi syndrome (CHS) and Griscelli syndrome (GS)	In addition to pigmentary dilution of the skin, patients may develop diffuse hyperpigmentation with superimposed guttate hypopigmentation in sun-exposed areas Silvery hair with clumps of melanin, bleeding diathesis (CHS), neurologic abnormalities (CHS, GS1), immunodeficiency (CHS, GS2) (see Ch. 66 and Table 60.4)
Syndromes with ectodermal dysplasia	
• Berlin syndrome	Generalized grayish-brown hyperpigmentation with superimposed guttate hypopigmented macules Sparse eyebrows with absent lateral aspect, delayed dentition/hypodontia, short stature, sexual underdevelopment in male patients, mental retardation Described in one family (Iranians living in Israel; four affected siblings; consanguineous parents)
• Lucky/Winter syndrome	Generalized hyperpigmentation with superimposed guttate hypopigmented macules (latter most prominent in flexural sites) Scant lightly pigmented hair, enamel hypoplasia (single central incisor in one patient), "digitalized" thumbs, short stature Likely autosomal dominant inheritance
• Acromelanosis albo-punctata	Diffuse hyperpigmentation with superimposed guttate hypopigmentation affecting acral and flexural areas, with atrophic skin on the dorsal aspects of the hands and feet Keratotic follicular papules on the legs, pili torti, platonychia
EXPOSURES	
Arsenic	From systemic ingestion of inorganic arsenic Background of bronze hyperpigmentation with superimposed "raindrop"-like guttate hypopigmented macules Palmoplantar keratoses, Bowen's disease, basal cell carcinoma and squamous cell carcinoma Increased risk of certain internal malignancies
Diphencyclopropenone (DPCP)	Used for topical immunotherapy for alopecia areata of the scalp Hyperpigmented patches with superimposed confetti-like hypopigmented macules occurring mainly on treated areas of the scalp, sometimes at remote untreated sites Described in four patients among 243 patients treated with DPCP
Monobenzyl ether of hydroquinone	Dyschromia with confetti-like hyper-, hypo- or depigmented macules occurring following topical application; typically used for depigmentation therapy in patients with severe vitiligo
Betel leaf (*Piper betle*)	Contact leukomelanosis on the face following application of betel leaves (used as a home remedy for hyperpigmentation) Initially described in Taiwanese patients
Photoleukomelanodermatitis of Kobori	Dyschromic drug eruption that occurs after ingestion of afloqualone, thiazides or tetracyclines, followed by exposure to sunlight
INFECTIONS	
Secondary syphilis (necklace of Venus)	Background hyperpigmentation with superimposed white macules on neck (see Ch. 82)
Pinta	During late phases, copper-colored and slate-blue macules become admixed with depigmented macules and patches (see Ch. 74)

Table 67.8 Dyschromatoses. See Table 67.7 for Fanconi's anemia.

Continued

DYSCHROMATOSES	
Disorder	**Key features**
OTHER	
Dyschromic amyloidosis cutis	Generalized guttate leukoderma plus reticulated macules of hyperpigmentation (see Fig. 67.26), primarily in sun-exposed skin Onset before puberty; may have autosomal dominant inheritance Small foci of amyloid deposits in the papillary dermis
Kwashiorkor	Protein malnutrition, usually in an infant or young child Small hypopigmented macules in diaper area and on thighs, lower abdomen and back in addition to hyperpigmented areas "Flaky paint" dermatosis

Table 67.8 Dyschromatoses (cont'd). See Table 67.7 for Fanconi's anemia.

DYSCHROMATOSIS SYMMETRICA HEREDITARIA

Synonyms: ■ Acropigmentation of Dohi ■ Symmetrical dyschromatosis of the extremities

Key features

- Small, irregular hypopigmented and hyperpigmented macules on the dorsal aspects of the distal extremities, especially the hands and feet
- Autosomal dominant disorder caused by mutations in the *ADAR* (*DSRAD*) gene, which encodes an RNA-specific adenosine deaminase

Introduction

Dyschromatosis symmetrica hereditaria (DSH) was first reported by Toyama in 1929. It is characterized by both hyper- and hypopigmented macules of varying size on the dorsal surfaces of the distal extremities. The vast majority of reports have come from Japan, China, and Korea, but DSH has also been described in European, Afro-Caribbean and Indian patients[47]. The prevalence in Japan is approximately 1.5 per 100 000[48].

Pathogenesis

DSH has an autosomal dominant inheritance pattern with high penetrance. It is caused by mutations in the *ADAR (DSRAD)* gene, which encodes the double-stranded RNA-specific adenosine deaminase[48–50].

Clinical Features

Hyper- and hypopigmented macules arise in infancy or early childhood. The macules often increase in size and number until adolescence, when they stabilize; darkening after sun exposure may be observed. This dyschromatosis favors the distal extremities (see Fig. 67.27) and is usually most marked on the dorsal aspects of the hands and feet; it spares the palms, soles and mucous membranes. Spontaneous clearing has not been described. A few patients with dystonia and neurologic deterioration associated with a particular *ADAR* mutation have been reported.

Pathology

In the hyperpigmented macules, there is increased melanin within basal keratinocytes, while the hypopigmented macules demonstrate a decrease in the density of DOPA-positive melanocytes.

Differential Diagnosis

Reticulate acropigmentation of Kitamura lacks hypopigmented macules, while vitiligo lacks hyperpigmented macules. Patients with xeroderma pigmentosum also develop hyper- and hypopigmented macules during childhood, but the lesions are in a photodistribution that includes the face and upper trunk. In dyschromatosis universalis hereditaria (see below), the dyschromic lesions have a similar clinical appearance, but they may be present at birth in some patients and, more importantly, the primary distribution is truncal (see Table 67.8).

Treatment

Current treatments are unsatisfactory. Strict sun avoidance may decrease the contrast between the hypo- and hyperpigmented macules[50].

DYSCHROMATOSIS UNIVERSALIS HEREDITARIA

Key features

- Hyperpigmented and hypopigmented macules in a generalized distribution, with onset in early childhood
- Most reported patients have been Japanese

Introduction and Pathogenesis

Dyschromatosis universalis hereditaria (DUH) is a rare disorder characterized by hypo- and hyperpigmented macules in a generalized distribution. Initially described in 1933, this condition is most common in Japan but has also been reported in patients from other parts of Asia and Europe. Its relationship to dyschromatosis symmetrica hereditaria is unclear. Autosomal dominant and recessive forms of DUH have been linked to 6q24.2–q25.2 and 12q21–q23, respectively. Interestingly, familial progressive hyper- and hypopigmentation, which is characterized by autosomal dominant inheritance with reduced penetrance and lesions ranging from small macules to large patches, was recently found to be caused by heterozygous activating mutations in the KIT ligand gene (*KITLG*) at 12q22[51]. Whether the form of DUH associated with this locus is due to *KITLG* mutations remains to be determined.

Clinical Features

Over 80% of DUH patients develop dyschromia by 6 years of age, and approximately 20% have dyspigmentation at birth. Numerous hyperpigmented and hypopigmented macules of various sizes develop on the head, neck, trunk (see Fig. 67.28) and extremities, including the dorsal aspects of the hands and feet. Hyperpigmented macules on the face can resemble ephelides or lentigines. The dyschromia may involve the palms and soles, but it spares the mucous membranes. There is no seasonal change or spontaneous regression with age[52]. Extracutaneous abnormalities reported in isolated cases of DUH include short stature and high-frequency deafness; abnormalities in erythrocytes, platelets and tryptophan metabolism; bilateral glaucoma and unilateral cataract; and seizures[53].

Pathology

A focal increase or decrease in the melanin content of the basal layer is seen in the hyperpigmented and hypopigmented areas, respectively[53].

Differential Diagnosis

Xeroderma pigmentosum may have similar dyspigmentation, but it is in a photodistribution and associated with premature actinic damage (see Ch. 86). Additional causes of dyschromatosis are outlined in Table 67.8.

Treatment

There is no satisfactory treatment.

ACQUIRED BRACHIAL CUTANEOUS DYSCHROMATOSIS

This acquired dyschromatosis was described in 2000[54] and primarily affects Caucasian women in the fifth to seventh decades of life. It is characterized by chronic, asymptomatic gray–brown patches with geographic borders interspersed with hypopigmented macules on the dorsal aspect of the forearms[54]. Affected individuals often have evidence of chronic sun exposure clinically (e.g. poikiloderma of Civatte) or histologically (e.g. solar elastosis).

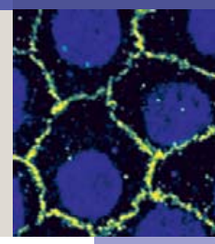
Biology of Hair and Nails 68



David de Berker, Claire A Higgins, Colin Jahoda and Angela M Christiano

Key features

- The pilosebaceous unit and nail apparatus are epidermal derivatives that produce two of the hardest epithelial structures known in mammalian biology
- The hair follicle is the only continuously regenerating organ in the mammalian body
- Hair and nails serve multiple functions, including protection, sensation and social communication
- Hair shafts and nail plates largely consist of dead, terminally differentiated keratinocytes (trichocytes and onychocytes) whose durability is based on the presence of abundant keratin intermediate filaments
- While hairs grow in a cyclic fashion, nail production is continuous
- The hair cycle includes phases of growth (anagen), regression (catagen), resting (telogen) and hair shaft shedding (exogen)
- The hair follicle is a major reservoir for epithelial and melanocyte stem cells; it also represents a site of immune privilege
- The nail apparatus consists of the nail plate (a fully cornified structure) and other specialized epithelial tissues, including the nail matrix (which produces the nail plate), nail bed and nail folds (proximal and lateral)

PRINCIPLES OF APPENDAGE MORPHOGENESIS

In mammals, the development of skin appendages occurs through evolutionarily conserved mechanisms. In all cases, appendages form as a result of interactions between two adjacent tissue layers, the ectoderm (epidermis) and underlying mesoderm (dermis). Appendage morphogenesis is characterized by key inductive events that ultimately lead to formation of the final structure, whether it be a hair, nail, feather, mammary gland or (in oral mucosa) tooth (Fig. 68.1). For example, the hair follicle first arises as a small epithelial bud, subsequently progressing to a complex, multi-cylindrical structure with associated sebaceous and apocrine glands (Fig. 68.2).

The basic principles of appendage development were generated from a series of classic homo- and heterospecific tissue recombination experiments performed in the 1970s, which have served as the foundation for research in this field[1,2]. These experiments demonstrated that the initial "message" for the development of all types of skin appendages is from the dermal mesenchyme (stage 0), which does not itself change morphologically but rather signals the overlying epithelium to thicken and form a placode (stage 1) (Fig. 68.3). The type of appendage that develops is determined within the epidermis. Canonical (β-catenin-dependent) WNT (*w*ingless-type *int*egration site) signals are candidates for the dermal message, and it is thought that they precede other activators and regulators of appendage development[3].

BIOLOGY OF HAIR

Hair Follicle Morphogenesis

WNT signaling plays key roles in hair follicle development. In mice, lack of WNT signaling through overexpression of the WNT inhibitor Dickkopf homolog 1 (DKK1) prevents hair follicle formation[3], while overexpression of β-catenin (which acts downstream of WNT; see Fig. 55.8) in the epidermis converts interfollicular epidermis to a placode fate[4]. Loss-of-function mutations in the *WNT10A* gene, which encodes an activator of WNT signaling, cause autosomal recessive forms of ectodermal dysplasia in humans, including odonto-onycho-dermal dysplasia and Schöpf–Schulz–Passarge syndrome (see Ch. 63). The spectrum of cutaneous findings that can result from *WNT10A* mutations includes hypotrichosis, nail dystrophy, palmoplantar keratoderma with eccrine syringofibroadenomatosis, and apocrine hidrocystomas[5]. In addition, heterozygous missense mutations in the adenomatosis polyposis coli down-regulated 1 gene (*APCDD1*) can cause hereditary hypotrichosis simplex, which manifests with progressive, generalized hair loss and thinning of the hair shaft (miniaturization). The APCDD1 protein normally inhibits WNT/β-catenin signaling by binding to WNT and low-density lipoprotein receptor-related proteins (LRPs) upstream of β-catenin (see Fig. 55.8), and mutations in APCDD1 lead to dysregulation of this pathway[6].

In normal mouse hair follicle development, WNT and β-catenin expression is observed in the presumptive placode following the initial dermal signal. This directly increases transcription of the ectodysplasin A receptor gene (*Edar*), which leads to augmented nuclear factor-κB (NF-κB) signaling[7]. Expression of EDAR within the primary follicle placode also suppresses placode inhibitory signals from the surrounding epidermis, which refines WNT/β-catenin expression within the placode. A reaction-diffusion mechanism involving WNT and DKK signaling within the epidermis is believed to modulate hair follicle spacing, with competing gradients of placode-promoting (WNT) and placode-inhibiting (DKK) morphogens[8,9]. These gradients demarcate the placode border and establish regular intervals between follicles.

After the determination of placode fate, reciprocal signaling cascades between the mesenchyme and overlying epithelium continue to drive hair follicle morphogenesis. This communication results from a complex interplay among secreted signaling molecules, which include WNT and NF-κB pathway components and other proteins (see Fig.

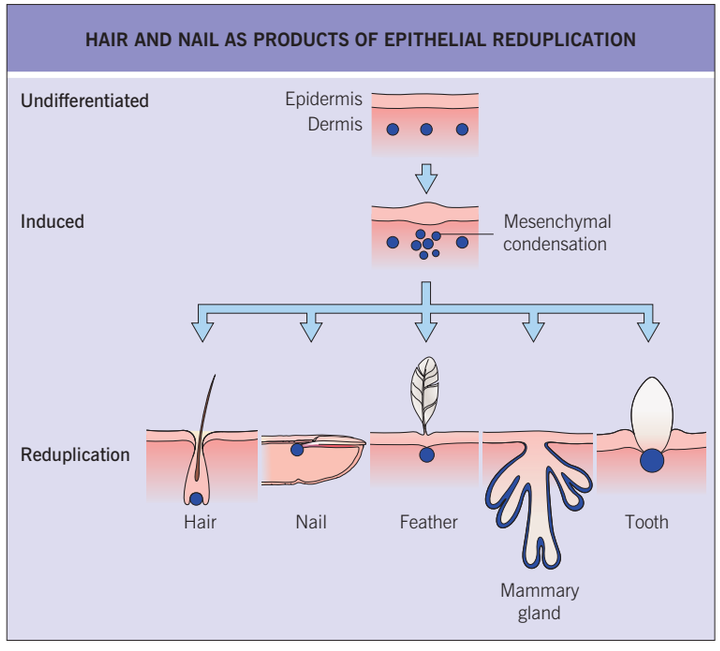


Fig. 68.1 Hair and nail as products of epithelial reduplication. *Reproduced with permission from: Chuong C-M. Morphogenesis of epithelial appendages: variations on top of a common theme and implications in regeneration. In: Chuong C-M, ed. Molecular Basis of Epithelial Appendage Morphogenesis. Austin: R.G. Fig. 68.2 Fetal development of the hair follicle.

68.3). After placode formation, an epithelial signal leads to clustering of the underlying mesenchyme and formation of a dermal condensate. A second dermal signal then leads to proliferation of the epidermis and epidermal invasion of the dermis by a column of epithelial cells that forms the hair germ (stage 2), followed by the hair peg (stage 3–4) and subsequently the bulbous peg (stage 5–8) (see Fig. 68.3)[10]. In the placode stage, activated WNT and EDAR control the localized accumulation of sonic hedgehog (SHH), which is essential for the downgrowth of the hair germ[11]. Primary cilia located on dermal cells within the condensate coordinate the signaling activities of SHH. In mice that lack SHH or have abnormal cilia assembly, the dermal condensate forms but subsequent proliferation and downgrowth of the epithelium are arrested[12,13]. Hemidesmosomal integrins also have a physical role in hair germ invagination, and mice with deficient β1 or β4 integrins have evaginated hair germs that cannot physically move downward into the dermis[14,15]. In addition, there is evidence that microRNAs have important roles in skin and hair follicle development. For example, mice with ablation of Dicer, a microRNA processing enzyme, display evagination of the hair germ but (since hemidesmosomes are intact) no physical severing of the papilla–hair germ interface[16].

During normal follicle invagination, the mesenchymal condensate is progressively engulfed by the epidermal cells, and it eventually becomes the enclosed dermal papilla of the follicle. Although epithelial growth is initially downward, it reverses in response to WNT and bone morphogenic protein (BMP) signaling from the newly formed dermal papilla. As a result, the overlying matrix in the hair bulb initiates a program of upward differentiation, giving rise to the layers of the hair shaft and inner root sheath. Epithelial cell fate depends upon the relative position of a matrix cell with respect to the dermal papilla, resulting in production of the concentric layers of the hair follicle[17]. An early effector of this signaling within the matrix is the distal-less homeobox 3 (DLX3) transcription factor, which directly regulates the expression of hair keratin genes in the hair shaft and inner root sheath[18]. A dominant frameshift mutation in the *DLX3* gene results in tricho-dento-osseous syndrome[19], a form of ectodermal dysplasia that features defects in hair, teeth and bone.

The generation of mouse models has increased our understanding of hair biology and facilitated the identification of genes that are expressed in the hair follicle[20]. Mutations in many of these genes have been found to underlie human diseases, including non-syndromic hair disorders and syndromes with manifestations that involve other skin appendages and/or extracutaneous tissues (see Table 69.7). Determining how these genetic defects lead to specific disease phenotypes has helped to elucidate the function of the encoded proteins in normal hair follicle morphogenesis and cycling.

Complex neural networks develop in conjunction with hair follicle morphogenesis. Nerve fibers arrive at the skin first and are located at presumptive follicular sites, running parallel to a dense network of blood vessels (Fig. 68.4). Developing follicles become innervated around stage 5, with nerve fibers encircling the isthmus and bulge regions[21]. Neurotrophins released from the follicular epithelium stimulate and determine the density of the innervation. Similarly, signaling proteins that promote angiogenesis, such as vascular endothelial growth factor (VEGF), are released from the epithelium and increase the vascular network surrounding follicles[22].

Hair follicle patterning

Although the basic architectural principles are similar in all hair follicles and shafts, different types of hairs can be produced in a single organism. In the dorsal skin of mice, hair follicle development occurs in three successive waves: (1) large, straight primary (guard or tylotrich) hairs, which comprise 1–3% of total hairs and have two sebaceous glands, on embryonic day 14.5; (2) secondary awl (straight, comprise ~30% of the coat) and auchene (one bend, only 0.1% of the coat) hairs on day 16.5; and (3) tertiary (zigzag) hairs, which account for ~70% of the coat and have several bends, on day 18.5. The mouse coat therefore contains four distinct hair types, in addition to specialized hairs such as the vibrissae (whiskers) and tail hairs[23]. EDAR is necessary for placode development in primary hair follicles[24] but not for induction of secondary hair follicles, which utilize signaling pathways that involve Noggin and (SRY-box 18) SOX18 expression within the dermal papillae[25,26]. In humans, hypohidrotic ectodermal dysplasia with abnormal morphogenesis of scalp hair, sweat glands and teeth results from mutations in the genes encoding components of the EDAR/NF-κB signaling pathway, including EDAR, its ligand ectodysplasin A and the downstream effector EDAR-associated death domain[27]. In addition, a non-synonymous single nucleotide polymorphism (SNP) within the *EDAR* gene is associated with increased hair thickness in Asian populations[28]. These clinical observations underscore the importance of the EDAR/NF-κB signaling pathway in human appendage development. However, whether EDAR affects the patterning of human hair follicles is not yet known. Interestingly, mutations in the human *SOX18* gene cause lymphedema and telangiectasias as well as hypotrichosis[29].

All of the hairs of the mouse dorsal coat have anterior–posterior polarity along the body axis, and they are formed parallel to one another to form a sleek coat. Several proteins, including SHH and neural cell

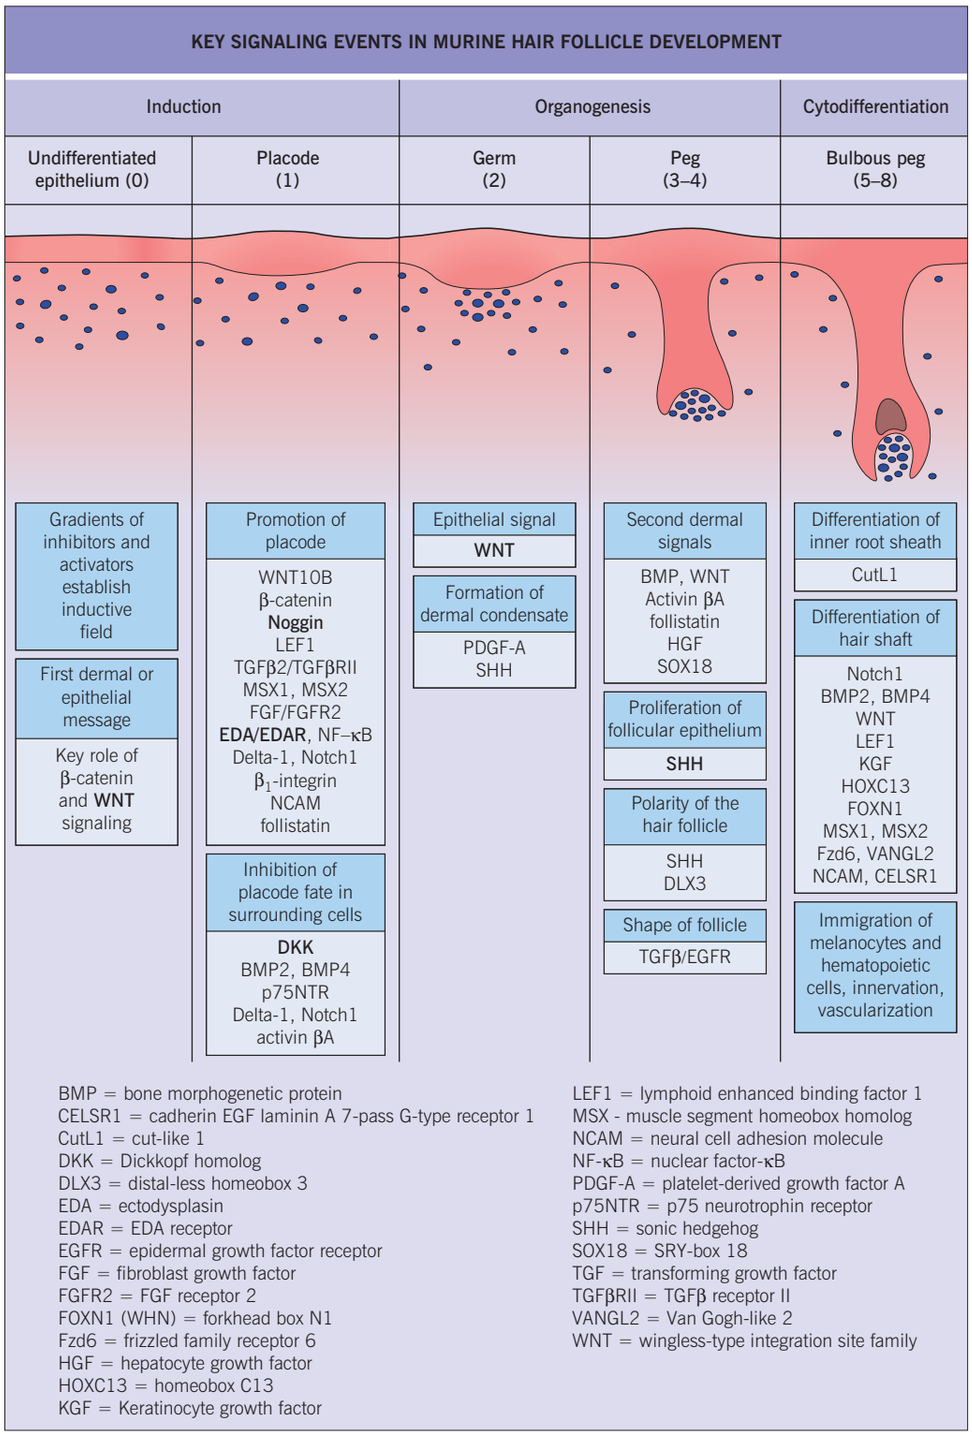

Fig. 68.3 Key signaling events in murine hair follicle development. *Adapted from Millar SE. Molecular mechanisms regulating hair follicle development. J Invest Dermatol. 2002;118:216–25.*

adhesion molecule (NCAM), have an asymmetric distribution within the follicle. This pattern is established by a conserved planar cell polarity (PCP) pathway during hair germ development[30]. PCP proteins Van Gogh-like 2 (VANGL2) and cadherin epidermal growth factor laminin A seven-pass G-type receptor 1 (CELSR1) respond to directional cues and are necessary for the correct polarization of follicles within the skin[30,31]. Mutations in *Vangl2* or the frizzled family receptor 6 (*Fzd6*) affect the early global alignment of hair follicles, resulting in hair germs that initially grow directly down. However, over time the follicles reorient themselves in competing patterns, with local alignment producing characteristic whorls on the back of the mouse[32,33]. Hair whorls are frequently observed in mammals, such as on the occipital scalp in humans, between the eyes in horses and cattle, and on the upper chest in dogs[32].

Under physiologic conditions, human hair follicle morphogenesis occurs only once. Lanugo, vellus and terminal hairs (Table 68.1) follow the same basic architectural principles. The first "coat" that is formed is fine, long, variably pigmented lanugo hair, which is shed in an anterior to posterior wave during the seventh and eighth months of gestation. A second coat of fine, shorter, unpigmented lanugo hair then grows in all areas except the scalp and is shed 3–4 months after birth, leading to almost complete alopecia on the body; pigmented hairs on the scalp (which have variable lengths and diameters) are also shed postnatally in an anterior to posterior wave. After these first two cycles, hair starts to grow in an asynchronous "mosaic" pattern rather than in waves. In prepubertal children, hair is typically terminal on the scalp, eyelashes and eyebrows, while it is vellus on the face, trunk and extremities. During puberty, vellus hairs in some sites come under the influence of androgens and start to enlarge, becoming terminal hairs. Conversely, terminal hairs on the scalp can revert to miniaturized vellus-like hairs in postpubertal individuals with androgenetic alopecia. Congenital generalized hypertrichosis (Ambras syndrome) is characterized by a disruption in the patterning of hairs, with terminal hairs growing at sites that normally have

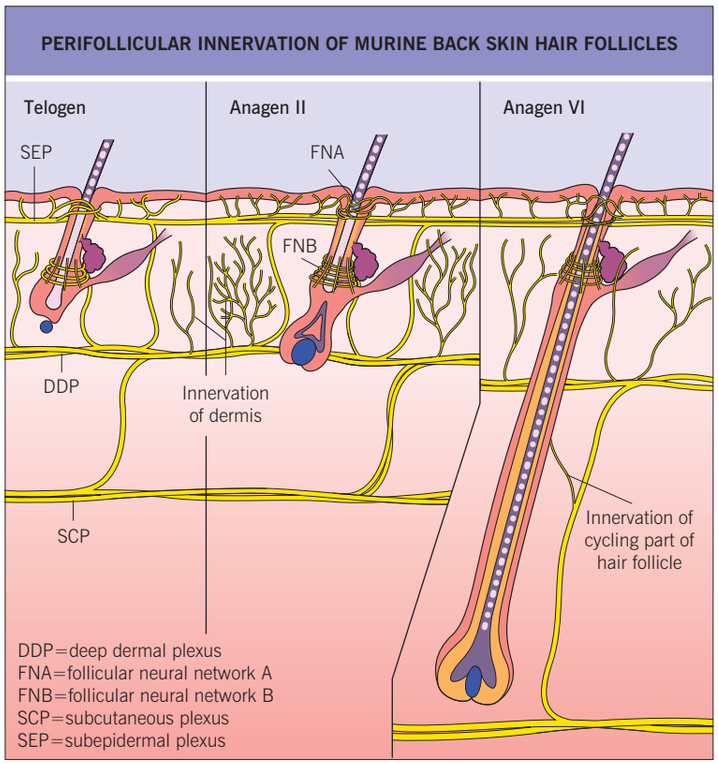

Fig. 68.4 Perifollicular innervation of murine back skin hair follicles. *Adapted from Paus R, Peters EM, Eichmüller S, Botchkarev VA. Neural mechanisms of hair growth control. J Invest Dermatol Symp Proc. 1997;2:61–8.*

vellus follicles[34]. Recently, a position effect that down-regulates the expression of the trichorhinophalangeal syndrome I gene (*TRPS1*) was found to underlie this hypertrichosis phenotype in both humans and mice[35]. A position effect caused by copy number variations affecting the transcription factor SOX9 has been linked to hypertrichosis with or without gingival hyperplasia[36].

In most mammals, there are differences in the hair pattern in different body sites, for example on dorsal skin, ventral skin and the face. While the ectoderm involved in skin and hair development is non-neural and relatively homogeneous, the mesenchyme has various origins that may explain the regionalization of different hair types. The dorsal dermis is derived from the somite dermomyotome, the ventral dermis has a somatopleural origin, and the craniofacial dermis arises from the neural crest[37–39]. The dermal progenitors at each of these sites are specified by different signaling pathways. Mice display regional differences in skin thickness as well as hair color and type. The postnatal identity of their skin is acquired by embryonic day 12.5, with the T-box 15 (TBX15) transcription factor appearing within dorsal skin to demarcate the dorsal ventral boundary[40].

In humans, androgen dependence is a feature that varies in the follicles at different body sites. Follicles in the frontal scalp are normally androgen-dependent, whereas occipital scalp follicles are hormonally insensitive and therefore less susceptible to androgenetic alopecia. When hair follicles from the occipital scalp are transplanted to the frontal scalp, they typically retain the pigmentary characteristics, androgen sensitivity and growth rate of the donor site[41]. However, in other instances, transplanted hairs take on characteristics of the recipient site, such as scalp hairs moved into the eyebrow region. It remains to be established exactly which characteristics are more influenced by the recipient site versus the donor site following transplantation.

Postnatal hair follicle development

Although hair follicle formation in general occurs prior to birth, adult mammalian skin retains the capacity for hair follicle morphogenesis. In adult mouse and rabbit skin, WNT-dependent *de novo* hair follicle formation occurs after wounding[42,43]. It is therefore reasonable to view therapeutic intervention to initiate *de novo* hair follicle formation on the human scalp as an achievable goal. Trans-species end-bulb formation and hair fiber growth has been demonstrated after the implantation of intact dermal papillae from human donors onto amputated vibrissa follicles[44]. In addition, allogeneic transplantation of hair follicle dermal sheath tissue can induce new follicle formation in the recipient, with protection from rejection due to its immune privileged status[45]. In addition to hair papillae transplants, cultured tooth mesenchymal papilla cells from humans and rats have been shown to induce hair fiber formation in an amputated follicle, highlighting the level of conservation among appendage papillae[46]. Papilla cells in rodents show much more inductive potency than those in humans. Rodent hair follicle papilla cells can reprogram differentiated glabrous epidermis to make a *de novo* hair follicle, and they are also capable of initiating trans-differentiation of amnion or even differentiated adult corneal epithelium into epidermis complete with hair follicles[47–49]. This represents a classic example of simple epithelial reprogramming, which was recently demonstrated in a broader context by the reprogramming of thymic epithelium into skin and hair follicles[50].

The Mature Hair Follicle: Cycling and Anatomy

Once the mature follicle is generated during embryogenesis and early postnatal life, it begins to cycle and continues to do so throughout its lifetime. The phases of the hair cycle include active growth (anagen), regression (catagen) and rest (telogen) (Fig. 68.5). As noted above, mouse follicles cycle in a wave along the anterior to posterior axis, while human follicles cycle in a mosaic pattern. Hair follicle cycling is an autonomous phenomenon that continues even when hair follicle units are isolated from the skin to grow in culture[51]. Distinct morphologic changes occur as the follicle transitions through the different stages of the hair cycle. The lower portion of the follicle undergoes growth and regression, while the upper region of the follicle (including the sebaceous gland, isthmus, infundibulum and hair canal) remains permanent.

The process of cycling makes the hair follicle a dynamic structure, enabling animals to change their coats depending on the season (e.g. for camouflage and insulation; Table 68.2) and for the lengths of hairs to vary depending on the site. Coat changes involve two processes: (1) shedding of the old coat, which (inclusive of signals and structural changes preceding fiber loss) has been referred to as a fourth stage of the hair cycle termed "exogen"; and (2) initiation of the new hair fiber growth[52]. Another term that has been introduced is "kenogen", which refers to a telogen follicle that has lost its club fiber but has not yet transitioned to anagen. Androgenetic alopecia is characterized by an increased proportion of follicles in kenogen[53].

Anagen

The duration of anagen, the period of active hair fiber production, depends on the species, body site and other factors (Table 68.3). Anagen is subdivided into six substages (anagen I–VI); in mice it has a duration of 1–3 weeks[54], compared to the human scalp where anagen can last several years[55]. The start of anagen (as observed in mouse skin) is associated with an increase in the dermal papilla cell number, due mainly to an influx of cells from the surrounding dermal sheath. The cells of the dermal sheath that surround the base of the follicle are also progenitors in dermal papilla regeneration after removal of the lower follicle[56,57]. The increase in cell number at the start of anagen is accompanied by an increase in extracellular matrix material. This doubles the size of the dermal papilla[58], the width of which is directly proportional to the thickness of the hair shaft produced by the follicle. The degree of axial symmetry within the hair bulb determines the curvature of the final hair structure[59].

The dermal papilla signals to the surrounding matrix cells, whose proximity to the dermal papilla specifies their fate[17]. As the matrix cells begin to differentiate, they form precursor cells of the different follicle lineages. Migrating upwards, these cells undergo specialized programs of differentiation, expressing defined sets of keratins to form seven concentric epithelial lineages of the follicle (Fig. 68.6). The outer root sheath is the outermost layer of the epidermal portion of the follicle. In contrast to the other epithelial components of the follicle, the outer root sheath does not originate from upward growth of matrix cells, but rather directly from the bulge, a stem cell niche in the permanent portion of the follicle (see below)[60].

Catagen

Following completion of hair fiber growth, the follicle enters catagen, which is divided into eight substages (catagen I–VIII) that take the

TRICHOLOGY TERMS	
Hair (follicle) cycle	Autonomous, rhythmic transformation of fully developed hair follicles through phases of growth, regression and resting; essentially controlled by the follicle itself (by an as yet enigmatic "hair cycle clock"), yet modulated by numerous systemic/extrafollicular factors
Anagen	Growth stage of the hair follicle cycle
Catagen	Involution of the lower two-thirds of the hair follicle by massive keratinocyte apoptosis
Telogen	Resting phase of the hair follicle cycle
Exogen	Phase of active hair shaft shedding (during anagen IV)
Kenogen	Telogen follicle with no club hair present
Hair bulb	Lowermost portion of the hair follicle
Hair matrix	Rapidly proliferating keratinocytes that terminally differentiate to produce the hair shaft
Club hair	Fully keratinized proximal tip of hair shaft, formed during late catagen and telogen; brush-like appearance; characteristic of telogen follicles
Vellus hair (follicle)	Very short, non-pigmented, and usually non-medullated; absence of arrector pili muscle; tiny vellus follicles can display extremely large sebaceous glands (face); undergo full hair cycle, yet much shorter than terminal hair
Terminal hair	Large, usually pigmented and medullated hair
Lanugo hair	Fine hair on the fetal body; shed *in utero* or during the first weeks of life
Vibrissae	Special sensory hair follicles with unique anatomy and biology, found on the upper lips/snout region of rodent skin, but not in humans; largest and most densely innervated hair follicles with special sinusoid blood supply; first hair follicles to develop
Tylotrich hair follicle	Large sensory hair follicles interspersed within truncal skin, most notably in rodents; extra large, long hair shaft, typically associated with double sebaceous gland and an innervated epidermal Merkel cell complex (Pinkus' Haarscheibe); second type of hair follicle to develop
Non-tylotrich pelage hair	Majority of all hair follicles, last to develop
Effluvium	Excessive shedding of hair shafts (=process)
Alopecia	Abnormal hair loss (=result)
Hirsutism	Excessive vellus-to-terminal hair conversion in androgen-dependent areas in women
Miniaturization	Terminal-to-vellus hair conversion (e.g. on the balding scalp during androgenetic alopecia); these miniaturized follicles still have an arrector pili muscle (unlike true vellus hairs)
Infundibulum of follicle	Region extending from the junction with the interfollicular epidermis to the opening of the sebaceous gland; displays cornification similar to that of the interfollicular epidermis
Isthmus of follicle	Region located between the opening of the sebaceous gland and the site of insertion of the arrector pili muscle; displays trichilemmal keratinization
Arrector pili muscle	Inserts at the level of the bulge; pulls up hair ("goose bumps")
Bulge	Segment of the outer root sheath located at the level of arrector pili muscle insertion; major seat of epithelial stem cells of the hair follicle
Secondary hair germ	Additional seat of epithelial and also of melanocyte stem cells; located between club hair and dermal papilla in telogen hair follicle
Connective tissue sheath (CTS)	Special mesenchymal follicular sheath that is tightly attached to the hair follicle basement membrane and is continuous with the follicular dermal papilla
Follicular dermal papilla (DP)	Onion-shaped, closely packed, specialized fibroblast population with inductive and morphogenic properties; hair cycle-dependent fibroblast trafficking occurs between CTS and DP; volume of DP determines size of hair bulb and, thus, hair shaft diameter
Inner root sheath (IRS)	Packages and guides the hair shaft; cornifies
Outer root sheath (ORS)	Merges distally into the epidermis and proximally into the hair bulb; provides slippage plane, nutrition, regulatory molecules, and stem cells
Follicle pigmentary unit	Melanin-producing hair follicle melanocytes located above and around the upper one-third of the DP; transfer eu- or pheomelanosomes to differentiating hair follicle keratinocytes in the precortical matrix; goes largely into apoptosis during each catagen phase, regenerated from melanocyte stem cells in hair germ (and from non-melanogenic ORS melanocytes?) during anagen

Table 68.1 Trichology terms. *Courtesy, John P Sundberg, DVM, PhD.*

follicle from late anagen to telogen[61]. Catagen lasts approximately 2 weeks in humans, regardless of the site and follicle type[62]. The initiation of catagen is characterized by a nearly 50% reduction in the volume of the dermal papilla, due to loss of extracellular matrix as well as migration of dermal papilla cells into the surrounding dermal sheath[58]. Melanocytes in the hair bulb also begin to down-regulate melanogenesis. Later, there is cessation of mitotic activity within the matrix cells of the bulb, and the remaining hair precursor cells differentiate to form the base of the hair shaft, now termed the "club fiber".

The club fiber migrates up the follicle, and a germ capsule termed the trichilemmal sac forms around the fiber's base. The club fiber itself is formed from cortical and cuticle cells only, and it is characterized by a lack of pigmentation. The electron-dense, non-nucleated layer of trichilemmal keratin around its proximal end has a characteristic "brush" structure that protrudes outwards and between the outer root sheath cells surrounding the club[63]. Abundant desmosomes between the trichilemmal keratin and surrounding tissue are thought to physically anchor the club fiber within its trichilemmal sac until it receives the correct signal for release[64].

As the club fiber moves up the follicle, the dermal papilla (which is initially still in the subcutaneous fat) becomes separated from the club by an epithelial strand that is surrounded by a thickened, convoluted basement membrane (the glassy membrane)[65]. Apoptosis in the epithelial strand creates an "apoptotic force" that draws the dermal papilla up to just beneath the club fiber in the dermis, leaving behind a trailing dermal sheath called the streamer or stele[52]. Loss-of-function mutations in the hairless gene (*HR*) can result in atrichia with papular lesions (APL)[66,67], a rare autosomal recessive disease characterized by complete hair loss early in life and later eruption of papular lesions. Hairless is required for apoptosis in the epithelial strand, which brings the dermal papilla up beneath the club fiber and secondary hair germ in a position to activate the start of the next anagen phase. This explains why individuals with APL are born with hair, which is then lost and never grows back. More recently, activating mutations in the

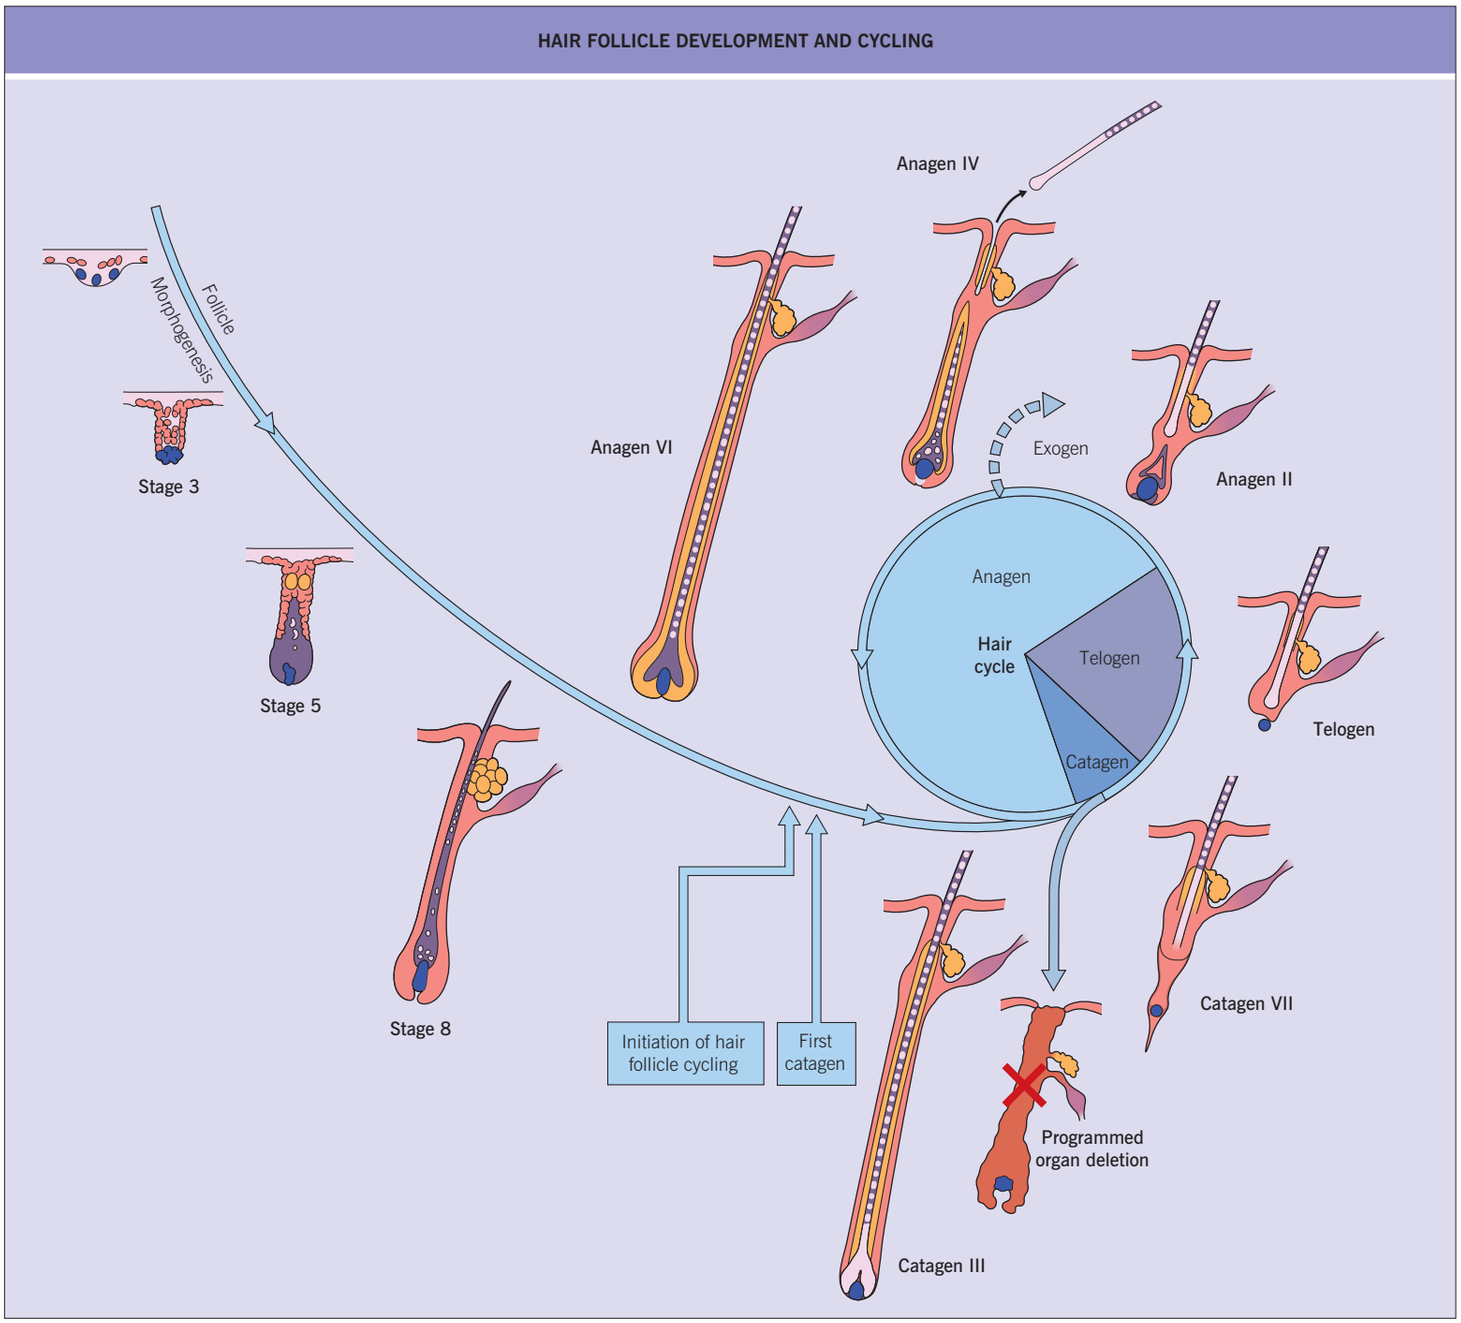

Fig. 68.5 **Hair follicle development and cycling.**

upstream open reading frame of *HR* were found to underlie a different form of sparse hair known as Marie Unna hypotrichosis[68].

Telogen

Once apoptosis in the epithelial strand draws the dermal papilla upward so it is adjacent to the club fiber and secondary hair germ, the follicle has entered telogen. The duration of telogen can be as short as 2 days in mice, compared to approximately 3 months for human scalp hairs. The hair germ is derived from the bulge during the catagen to telogen transition and lies adjacent to it, separating the bulge from the dermal papilla[69]. As in hair follicle morphogenesis, epithelial–mesenchymal cross-talk is required to activate the new anagen phase. Indeed, anagen progression recapitulates the middle and later stages of hair follicle development, and many factors that drive follicle morphogenesis (e.g. WNT, SHH, noggin) also play important roles in telogen to anagen transition (Fig. 68.7). The bulge is relatively quiescent during telogen, which is often referred to as the resting phase. However, the hair germ (which is biochemically distinct from the bulge) is responsive to anagen-initiating signals from the dermal papilla and starts to show enhanced proliferative and transcriptional activity in late telogen, leading to the initiation of anagen[69].

The macro-environment surrounding the hair follicle also takes part in regulating cycle transitions. BMPs in the subcutaneous fat are capable of maintaining follicles in a "refractory" telogen, and cessation of this inhibitory activity by BMPs enables the follicle to progress to a "competent" telogen with a hair germ that is responsive to anagen-initiation signals and capable of entering a new anagen phase[70]. Fluctuations of microRNA levels (e.g. microRNA-31) in the follicle and its macro-environment may also silence certain gene expression patterns, promoting a switch from telogen to anagen[71]. After secondary hair germ activation, the germ cells begin to contribute to the hair matrix and concentric layers of the follicle via an upward movement, while bulge cells generate the outer root sheath in a downward movement[72]. In follicles with a longer anagen duration, the proliferative capacity of the matrix is not enough to sustain growth. The "stem cell trafficking theory" proposes that a continuous migration of precursor cells from the bulge down the outer root sheath prevents exhaustion of the germinative matrix during anagen[73].

FUNCTIONS OF HAIR AND NAILS
FUNCTIONAL PROPERTIES OF HAIR SHAFTS
• Social and sexual communication • Camouflage • Protection against chemical and physical damage • Protection against insects • Provide sensory "antennae" • Insulation against heat loss, overheating and desiccation • Removal from the skin surface of parasites, dirt, debris and squames by the outward-moving hair shaft • Facilitation of sebum, apocrine sweat and pheromone secretion • Organ of scavenging and excretion via the melanized hair shaft, which serves to deposit and extradite unwanted molecules • Hair shaft medulla can serve as a fiber-optic device for conversion of UV light into heat (polar bear)
FUNCTIONAL PROPERTIES OF PILOSEBACEOUS UNITS
• Production, extrusion, containment and mooring of pigmented hair shafts • Crucial stem cell reservoir (e.g. for keratinocytes, melanocytes) • Reservoir for Langerhans cells • Highly sensitive tactile organs that sense hair shaft movements • Generate sebum, apocrine sweat and pheromones
FUNCTIONAL PROPERTIES OF NAILS
• Social and sexual communication (color, shape, length) and aesthetic appearance • Protection of the distal phalanges of the digits from mechanical, chemical and biological trauma • Contribute to the tactile discrimination and fine motor capacities of the fingertips • Provide the ability to scratch and groom • Rudimentary natural weapons • Contribute to pedal biomechanics essential for full motor functioning of the feet

Table 68.2 Functions of hair and nails. *Courtesy, John P Sundberg, DVM, PhD.*

Exogen

The stimulus for entry into catagen, and hence the formation of a club hair, typically occurs several months before the hair is shed in humans[74,75]. Shedding of overhair is loosely coupled with anagen in mouse pelage follicles[76], while club fiber release is a very predictable event in rat whisker follicles. In the latter instance, the club fiber is retained in its own silo through the following anagen and then cast off prior to the onset of catagen in a regulated manner[77]. In humans, the club fiber is not usually retained through subsequent anagens; instead, it is believed to be shed in the telogen to anagen transition. The term "exogen" was introduced into the literature in 1998 to represent the shedding of the club fiber from its silo as well as the preceding signals and structural changes in the follicle[52]. Exogen is considered to be an active event rather than a passive process where the club fiber is dislodged due to mechanical forces from the new growing fiber. A gradual decrease in the adhesion of the club fiber within its epithelial silo has been observed prior to its programmed release from the follicle[77].

Structure of the hair fiber

In response to signaling from the dermal papilla, the matrix cells at the base of the follicle proliferate and then differentiate during anagen, forming the different layers of the follicle. The three central lineages (medulla, cortex and hair cuticle) form the hair fiber, which fulfills the primary function of the anagen follicle – hair production. Surrounding the hair fiber are the three concentric layers that compose the inner root sheath (IRS): the IRS cuticle, Huxley's layer and Henle's layer. The IRS undergoes a complex program of differentiation in the anagen follicle, with Henle's layer terminally differentiating shortly after formation. The IRS cuticle differentiates further up the follicle, followed by Huxley's layer; all three layers undergo desmosomal remodeling during terminal differentiation[78]. The IRS forms a mechanically supportive tube around the hair fiber, but it is degraded by proteolytic enzymes within the follicle at the level of the isthmus[79], allowing the hair shaft to enter the hair canal and emerge from the skin surface without an associated IRS.

The seventh concentric layer that originates from the matrix in line with the hair fiber and IRS is the companion layer, which is a single cell thick. Regarded as the "slippage plane" between the inner root sheath and the surrounding outer root sheath during anagen, the companion layer enables directional hair growth. It is attached to the IRS through "Flugelzellen" structures that extend from Huxley's layer through Henle's layer and link to the companion layer via numerous desmosomes[80,81]. A "barrel" of transversely orientated intermediate filaments on the inner side of the companion layer are thought to provide support for the inner root sheath, protecting it from the compressive forces of the expanding outer root sheath.

Hair Keratins

The 54 functional keratin genes that have been identified to date (see Table 56.2) encode 28 type I and 26 type II keratins, which form heterodimeric pairs containing one keratin of each type. There are 11 type I hair keratins, designated K31–K40 (previously known as Ha1–Ha8, Ka35 and Ka36), and six type II hair keratins, designated K81–K86 (previously known as Hb1–Hb6) (see Ch. 56); the remainder are epithelial keratins[82–84]. Compared to epithelial keratins, hair keratins possess more sulfur in their head and tail domains, which allows them to form tight cross-links with associated proteins[85].

Different hair and epithelial keratins are expressed in the various concentric layers of the hair follicle, with hair keratins found primarily in the cortex and hair cuticle (see Fig. 56.6)[86]. Autosomal dominant monilethrix, which features fragile "beaded" hairs and follicular hyperkeratosis, is caused by mutations in the helix termination and initiation motifs of several type II hair keratins: K81, K86 and (less commonly) K83[87,88]. These keratins are highly expressed within the hair cortex and are critical to its development[87,88]. Mutations in the gene encoding K85, another type II hair keratin that is important for hair follicle development, underlie autosomal recessive pure hair and nail ectodermal dysplasia. K85 is primarily expressed in the matrix of the follicle, which may explain the relatively severe phenotype (total alopecia) observed in these patients[89,90].

Some epithelial keratins exhibit hair follicle specificity (Fig. 68.8). The type I keratins K25, K27 and K28 and the type II keratin K71 are expressed within the IRS (cuticle, Huxley's layer and Henle's layer). In addition, K74 is restricted to Huxley's layer, while K73 and K72 are found in the IRS cuticle[85,91]. Mutations in the gene encoding K71 (the only type II keratin expressed in Henle's layer) have been linked to hair disorders in mice and dogs but not yet in humans. However, mutations in the gene encoding K74 can cause autosomal dominant woolly hair, which is characterized by slowly growing, short hair that (unlike autosomal recessive forms of woolly hair) has a normal density[92]. To date, none of the type I hair or epithelial keratins have been linked to human disease.

The companion layer contains only one keratin, the type II epithelial K75. K75 is also expressed in the medulla of the hair shaft and in fungiform papillae of the tongue. Pseudofolliculitis barbae and loose anagen hair syndrome have been linked to defects in K75[82,85,93]. Although the outer root sheath expresses several keratins, including K5/K14, K6a/K16 and K6b/K17 (see Fig. 68.8), patients with pachyonychia congenita due to mutations in the latter keratin pairs only occasionally exhibit hair abnormalities such as pili torti (primarily with K17 defects)[94].

Desmosomes in the Hair Follicle

Desmosomes are specialized adhesive structures that couple neighboring cells together in a variety of tissues, with particular importance in epithelia and the myocardium[95,96]. Each desmosome is connected to the intermediate filament cytoskeletons of the interacting cells, which imparts resilience and resistance to mechanical stress (see Ch. 56). Desmogleins (Dsg1–4) and desmocollins (Dsc1–3) are desmosome-specific cadherin family members that interact in the intercellular space to couple the two halves of the desmosome; they are connected to intermediate filaments via the linker cytoplasmic plaque proteins plakoglobin, plakophilins (Pkp1–3) and desmoplakin (see Fig. 56.8)[97]. Mutations in genes encoding desmosomal components can result in diseases affecting the hair (woolly or fragile hair, hypotrichosis) as well as the skin (e.g. palmoplantar keratoderma, fragility/blistering) and heart (cardiomyopathy), producing multisystem disorders such as Naxos disease, Carvajal syndrome and ectodermal dysplasia/skin fragility syndrome (see Fig. 56.8 and Ch. 58).

BASIC INFORMATION ON HUMAN HAIR FOLLICLES	
Total number	~5 000 000 (mostly vellus)
Number of scalp hair follicles	~100 000 Blondes: + 20% Redheads: – 20%
Average density of hairs on the scalp	Terminal + vellus: 1135/cm^2 (newborn)* 615/cm^2 (20–30 years)* 485/cm^2 (30–50 years)* 435/cm^2 (70–80 years)* African-Americans, Asians: lower density Terminal only: ~250/cm^2 Bald scalp (45–70 years): 330/cm^2* Highest density: cheek + forehead*
Hair embryology	Development progresses at fixed intervals in cephalocaudal direction, becoming first visible in eyebrow, upper lip and chin regions (9th week) At 16 weeks, hair shafts are formed in these regions Hair follicles are formed in sequential waves of interspersed follicles
Hair cycle distribution for terminal scalp hair	Anagen: 85–90% Telogen: 10–15% Catagen: <1%
Duration of hair cycle phases	Anagen: 2–6 years Catagen: 2–3 weeks Telogen: 3 months } Terminal scalp hair There are substantial variations in anagen duration: Terminal mustache: 4–14 weeks Terminal on arms: 6–12 weeks Terminal on legs: 19–26 weeks Vellus: 6–12 weeks Premature anagen induction is induced by plucking of telogen hair shafts (depilation) Estrogens prolong anagen Thyroxine promotes growth, corticosteroids retard anagen onset
Number of lifetime cycles per scalp follicle	10–20
Physiologic hair shedding rate (scalp)	~100–200/day (substantial interindividual and seasonal variations)
Hair shaft production rate (scalp)	~0.35 mm/day, 1 cm/month Hair production is not influenced by cutting/shaving Estrogens reduce hair growth rate Androgens increase hair growth rate and hair diameter in androgen-dependent sites (e.g. beard)
Hair shaft diameter and length	Vellus: <0.03 mm; 1–2 mm Terminal: >0.06 mm; 1–50 cm Average diameter: Asian hair (circular): 120 µm Caucasian (elliptic): 50–90 µm
Hair shaft structures	Cuticle (outside), cortex, medulla (center) Cuticle maintains hair fiber integrity Cortex contains bulk of hair keratins and keratin-associated proteins Hair fiber strength is largely due to disulfide bonding Medulla consists of loosely connected trichocytes with large intercellular air spaces; provides insulation (animals)
Hair shaft pigmentation	Dark hair: predominance of eumelanin Blond/red hair: predominance of pheomelanin Melanosomes of hair cortex larger than those of epidermis
Hair graying (canities)	Generally commences in the third to fourth decade of life on the temples, spreading later to crown and occiput; by the age of 50 years, 50% of the population has at least 50% grey hair
Hair patterns	Pubic hair: horizontal (90% of women, 20% of men), acuminate (10% of women, 50% of men) Diffuse chest hair: normally grows only in men, after puberty (until 6th decade) Axillary: appears about 2 years after first pubic hairs, more sparse in Asians than Caucasians; frequently absent in older individuals Trichoglyphics: single, clockwise parietal whirl present in 95% of individuals

*Data from Giacometti L. The anatomy of the human scalp. In: Montagna W (ed). *Advances in Biology of Skin, Vol VI: Aging*. Oxford: Pergamon Press, 1965:97–120.

Table 68.3 Basic information on human hair follicles.

All four desmogleins are found in the hair follicle, with differentiation-specific expression patterns[98,99]. Dsg4 is the only desmosomal cadherin that is highly expressed in the hair shaft cortex, including the keratinizing zone in which hair keratins are abundant. Dsg4 is also present in the precortex, lower hair cuticle, upper IRS cuticle and interfollicular epidermis (granular and cornified layers)[98,100]. Several transcription factors (e.g. lymphoid enhancer-binding factor 1 [LEF1], homeobox C13 [HOXC13], forkhead box N1 [FOXN1]) regulate the expression of both Dsg4 and hair keratins in differentiating trichocytes[101]. Dsg4 is a key mediator of keratinocyte adhesion in the hair follicle, where it coordinates the transition from proliferation to differentiation[100]. Mutations in *DSG4* can cause localized autosomal recessive hypotrichosis and autosomal recessive monilethrix[100,102–104].

Although hair shedding and alopecia result when Dsg3 is disrupted in mice, showing its importance in the development and maintenance of the murine hair follicle[105,106], to date, similar hair phenotypes have

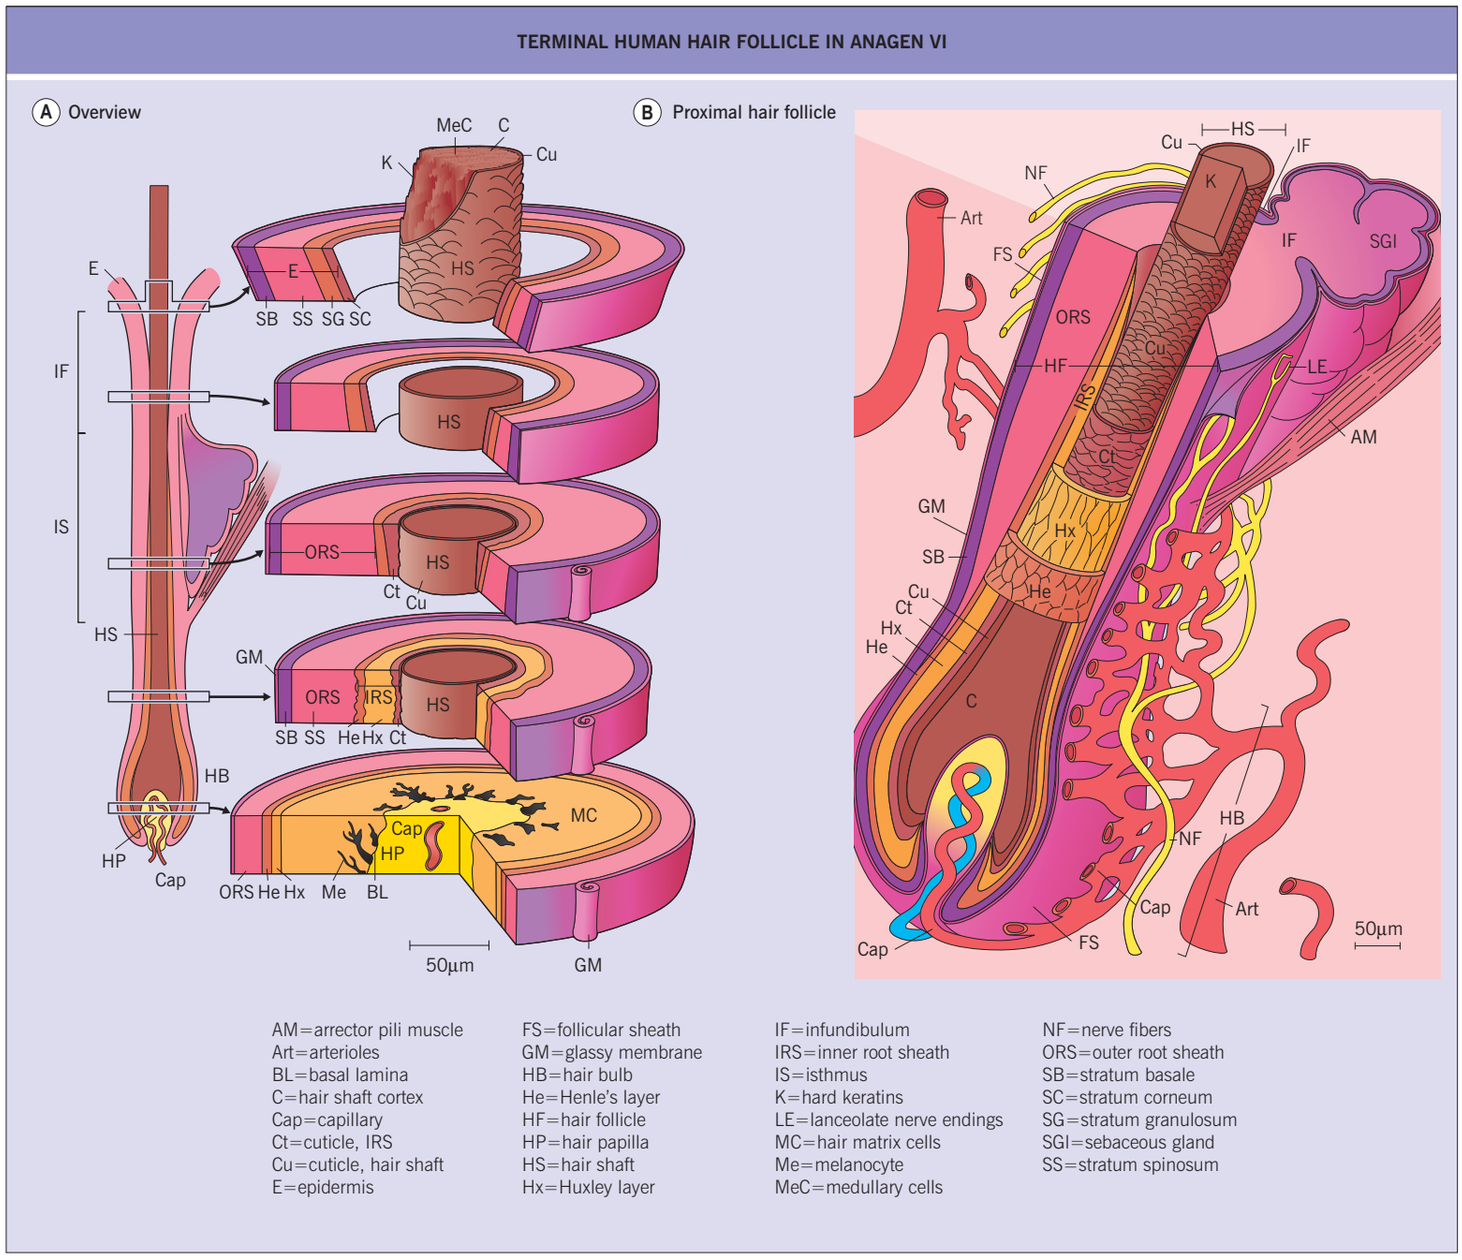

Fig. 68.6 Terminal human hair follicle in anagen VI. A Overview. **B** Proximal hair follicle.

not been identified in humans with Dsg3 defects. However, abnormal hair can represent the primary manifestation of mutations in the genes encoding Dsc3 (autosomal recessive hypotrichosis and recurrent skin "vesicles") and corneodesmosin (*CDSN*; autosomal dominant hypotrichosis simplex of the scalp)[107,108]. In addition, loss-of-function *CDSN* mutations underlie an autosomal recessive inflammatory peeling skin syndrome[109]. Corneodesmosin is a secreted glycoprotein that is present in later stages of differentiation of the IRS as well as within modified desmosomes in the stratum corneum (where its proteolysis has a role in desquamation)[110]. Similar to the observations in humans, *Cdsn*-knockout mice die soon after birth due to severe epidermal barrier defects[111], and grafting of corneodesmosin-deficient skin onto nude mice leads to the initial growth of thin, slightly curly hair with subsequent hair loss. These findings highlight the importance of corneodesmosin for hair growth and epidermal barrier function.

Hair Follicle Stem Cells

Adult stem cells have the ability to self-renew and to regenerate tissues, both in homeostasis and during wound repair. Given the dynamic remodeling seen with the cyclic regeneration of the hair follicle, it has long been postulated that it contains one or more stem cell niche(s) (see Ch. 2). Studies in the 1990s showed that slow-cycling, label-retaining cells (characteristics of stem cells) are localized in the bulge area of the follicle (named for the swelling evident at this site in rodents)[60].

Although the bulge architecture in mice is not pronounced until 3 weeks after birth, slow-cycling bulge cells can be identified during early stages of murine hair follicle morphogenesis by the marker SOX9[112]. During anagen in adult mouse skin, bulge stem cells express distinctive markers, including SOX9 as well as S100A4, CD34, transcription factor 3 (TCF3), LIM homeobox 2 (LHX2), nuclear factor of activated T cells calcineurin-dependent 1 (NFATc1), leucine-rich repeat-containing G-protein-coupled receptor 5 (LGR5), and keratin 15[113–117]. Bulge stem cells also share gene expression patterns with hematopoietic, neural and embryonic stem cells[117]. The molecular architecture of the bulge is not identical in mice and humans, and until relatively recently the location of the bulge in human follicles was unclear as it is not a morphologically distinct entity. However, laser capture microdissection and microarray-based analysis of human anagen hair follicles identified distinctive human bulge cells with clonogenic potential that express CD200 but (in contrast to bulge cells in mice) not CD34 (see Table 2.3)[118].

When follicles cycle through telogen in mice, a secondary hair germ is formed just above the dermal papilla but below the bulge. Bulge cell

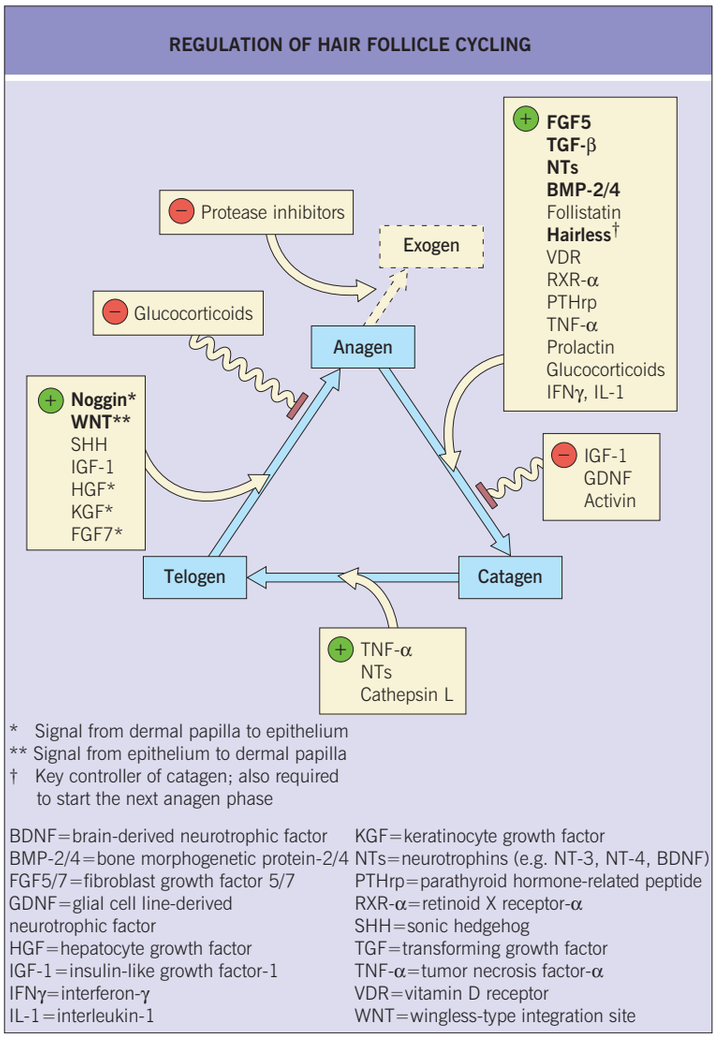

Fig. 68.7 Regulation of hair follicle cycling.

progeny that migrated out of the niche during the previous anagen (en route to becoming transit amplifying cells) are capable of migrating back again and regaining stem cell characteristics[119]. Some markers are expressed in both the secondary hair germ and the bulge, including keratin 15, LHX2, TCF3 and (at low levels) SOX9[69]; in addition, LGR5 is expressed in the germ but only the lower bulge cells[116]. Markers highly expressed in the secondary hair germ but not the bulge include P-cadherin and LEF1[69]. Following wounding, bulge and hair germ cells can both contribute to the interfollicular epidermis[120]; however, this does not occur under homeostatic conditions. There are other stem cell niches located in the follicle above the bulge that contribute to both the hair follicle and interfollicular epidermal lineages in mice. An LGR6-positive population is found in the central isthmus[121], while leucine-rich repeats and immunoglobulin-like domains 1 (LRIG1)- and Blimp1-positive populations are present in the upper isthmus[122,123], with these cells maintaining the sebaceous glands and interfollicular epidermis. There is also a stem cell antigen-1 (SCA1)-positive cell population in the infundibulum that is thought to contribute to skin homeostasis[124].

The dermal papilla and dermal sheath represent a mesenchymal stem cell niche within the follicle. Under homeostatic conditions, dermal papilla cells rarely divide after formation of the initial condensate during morphogenesis, yet their gene expression profile is dynamic throughout development and the hair cycle. If removed from their niche, dermal papilla cells have the ability to differentiate into osteogenic, myogenic and adipogenic lineages[125–127]. Dermal papilla cells can also show hematopoietic activity both *in vitro* and *in vivo*, where they are capable of reconstituting the entire hematopoietic system of an irradiated mouse[128]. In addition to their ability to transdifferentiate, a major function of dermal papilla cells is related to their inductive potential. Isolated and cultured dermal cells from adult follicles are capable of stimulating a range of committed epithelia to form follicles, inclusive of progenitor stem cells[47,49,129,130]. Understanding how dermal papilla cells are capable of inducing *de novo* follicle formation would provide answers to many intriguing questions related to adnexal development.

The Hair Follicle and the Immune System

The hair follicle represents an immune privileged site, which is defined as a location in the body where foreign tissue grafts can survive for

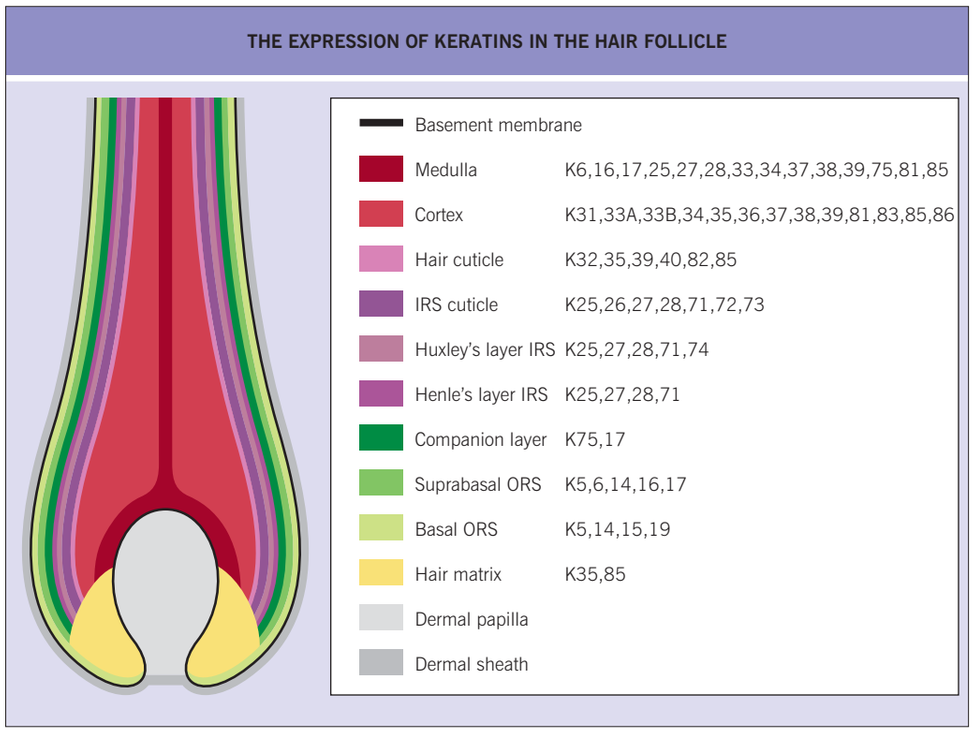

Fig. 68.8 The expression of keratins in the hair follicle.

extended periods of time without immune rejection[131]. Other immune privileged sites include the anterior chamber of the eye, testis, brain and placenta. The immune privileged status of the hair follicle underscores its evolutionary importance. Functions of the hair in different species include maintaining an adequate internal body temperature and providing protection against other environmental changes, toxins and infectious agents (see Table 68.2).

Initial evidence regarding the immune protection of the hair follicle came from the classic "Billingham experiment" in 1971[132], in which skin from black guinea pigs was transplanted onto an immunologically incompatible strain of white guinea pigs. The color of the grafted skin changed to white, reflecting the expected immune response against the foreign epidermal melanocytes. However, pigmented hairs grew within the grafts, showing that the foreign hair follicle melanocytes survived. Later experiments demonstrated that application of the contact allergen picryl chloride to mouse skin during the early anagen phase of the hair cycle led to a significant decrease in sensitization compared to application during the telogen phase[133], suggesting that the immune system around the hair follicles is suppressed specifically during the anagen phase. Features of the human anagen hair bulb that protect it from an immune response are summarized in Table 68.4.

Until recently, the immune privilege of the hair follicle was thought to be restricted to the matrix region during the anagen phase. However, evidence has accumulated that the immune privilege of the hair follicle extends to the bulge region and is present at this site during the entire hair cycle[142]. Because the bulge represents the hair follicle stem cell niche, sustained immune privilege in this region may be essential for the survival of the follicle.

Insights into the basis of hair follicle immune privilege (see Table 68.4) have begun to emerge in the past decade through the study of autoimmune hair disorders, but our understanding of this phenomenon is far from complete. Two mechanisms can underlie an immune reaction directed against the hair: (1) a primary attack of the immune system against the hair follicle; or (2) a breakdown in hair follicle immune privilege leading to a secondary attack by the immune system[131,134,135]. The latter hypothesis is favored, but definitive evidence for this process is still lacking. Because the hair matrix immune privilege is mainly restricted to the anagen phase[135], it has been postulated that an autoantigen from melanocytes, which are active during the anagen phase, could be responsible for initiating the immune response against the hair follicle that occurs in alopecia areata. Indeed, antibodies against melanocyte-associated antigens have been found in patients with this condition[143,144].

It is thought that collapse of hair follicle immune privilege begins with induction of major histocompatibility complex (MHC) class I molecule expression, which allows presentation of autoantigens to the immune system, on the follicular epithelium[145]. In hair follicles affected by alopecia areata, there is increased expression of MHC class I polypeptide-related sequence A (MICA). $CD8^+$ T cells and natural killer (NK) cells accumulate around affected hair follicles and exhibit increased expression of the NKG2D activating receptor, but decreased expression of inhibitory receptors such as killer cell immunoglobulin-like receptor three domains long cytoplasmic tail 1 (KIR3DL1) and heterodimeric CD94/NKG2A[131,135,136]. UL16 binding protein 3 (ULBP3), a NKG2D ligand, was recently shown to be upregulated in the dermal sheath and papilla of hair follicles affected by alopecia areata[136]. These observations indicate that hair follicles in patients with alopecia areata lose their immune privilege and express danger signals in their outermost layer, leading to self-destruction. There is also down-regulation of immunosuppressant molecules such as transforming growth factor (TGF)-β1, α-melanocyte stimulating hormone (MSH), indoleamine 2,3-dioxygenase (IDO)-1, and the IK cytokine (which inhibits the functions of interferon [IFN]-γ) in the setting of alopecia areata[131,134,135,142]. IFN-γ plays a pivotal role in the pathogenesis of alopecia areata by inducing the expression of MHC class II antigens (normally absent in the hair follicle matrix and dermal sheath), thereby propagating the immune response and contributing to destruction of the hair follicle[131,134].

A recent genome-wide association study (GWAS) in patients with alopecia areata implicated genes that are involved in immune regulation, in particular the function of regulatory T cells (e.g. cytotoxic T lymphocyte-associated protein 4 [CTLA4], interleukin [ILs]-2 and -21, the IL-2 receptor A [CD25], ULBPs, Eos [an Ikaros transcription factor]), as well as those expressed in the follicle (e.g. syntaxin 17, peroxiredoxin 5)[136]. Such studies may provide insights into potential therapeutic targets. For example, treatment with an CTLA4–Ig fusion protein that inhibits costimulation of T cells was shown to prevent disease onset in a mouse model of alopecia areata[146].

MECHANISMS CONTRIBUTING TO THE IMMUNE PRIVILEGE OF THE HAIR FOLLICLE

Mechanism of immune evasion	Function of the molecules affected
Down-regulated expression of MHC class I, MICA and β_2-microglobulin	Required for presentation of autoantigens to the immune system
Down-regulated expression of MHC class II	Required for functioning of antigen-presenting cells
Upregulated expression of IL-10, transforming growth factor-β1 (TGF-β1) and α-melanocyte stimulating hormone (α-MSH)	Immunosuppressive actions
Increased production of Fas-ligand (FasL)	Induces apoptosis of activated T cells; known to be crucial for maintenance of immune privilege in the eye, brain and fetus
Low expression of heterodimeric CD94/NKG2C and NKG2D receptors on NK cells and $CD8^+$ cytotoxic T cells as well as of the NKG2D ligand UL16 binding protein 3 (ULBP3)	These receptors activate NK cells and $CD8^+$ cytotoxic T cells upon ligand binding; NKG2D has been implicated in the immune attack on the hair follicle in alopecia areata
High expression of killer cell immunoglobulin-like receptors (KIRs) and heterodimeric CD94/NKG2A receptors on NK cells	These receptors inhibit NK cells
Increased production of indoleamine 2,3-dioxygenase (IDO)-1	Inhibits lymphocyte proliferation
Increased production of IK cytokine	Inhibits interferon-γ-induced expression of MHC class II antigens
Lack of lymphatic vessels around the hair follicle	Recruit immune cells

Table 68.4 Mechanisms contributing to the immune privilege of the hair follicle[134–141]. IL, interleukin; MHC, major histocompatibility complex; MICA, MHC class I polypeptide-related sequence A; NK, natural killer.

BIOLOGY OF NAILS

Like its phylogenetic ancestors (e.g. claws, hoofs), the nail protects the distal phalanges and contributes to a variety of motor and sensory functions (see Table 68.2). Two key aspects of nail biology are how nails grow and from what part of the nail apparatus they arise. The composition of nails and the characteristics of the surrounding soft tissues are other important considerations, including their natural constituents and features as well as potential exogenous or "biomarker" elements that may indicate an individual's environment or state of health[147,148]. An understanding of these aspects of the nail unit, in addition to its anatomy and development, can maximize the clinician's ability to accurately assess, correctly diagnose and effectively treat patients with nail disorders. However, our current knowledge of the regulation of nail development and growth on a molecular level is relatively poor, and acquisition of data has been hampered by the difficulty in obtaining nail-producing tissues and growing nails and/or nail matrix keratinocytes in culture. Tools such as mouse models (considering the substantial homology between murine claws and human nails), improved methods for organ-culturing microdissected components of the human nail apparatus, and the development of nail-equivalent *in vitro* systems will hopefully help to better elucidate the molecular mechanisms of nail biology in the future.

Nail Unit Anatomy

An understanding of nail biology and disease requires knowledge of the local anatomy (Fig. 68.9)[149,150]. The first distinction is between the nail

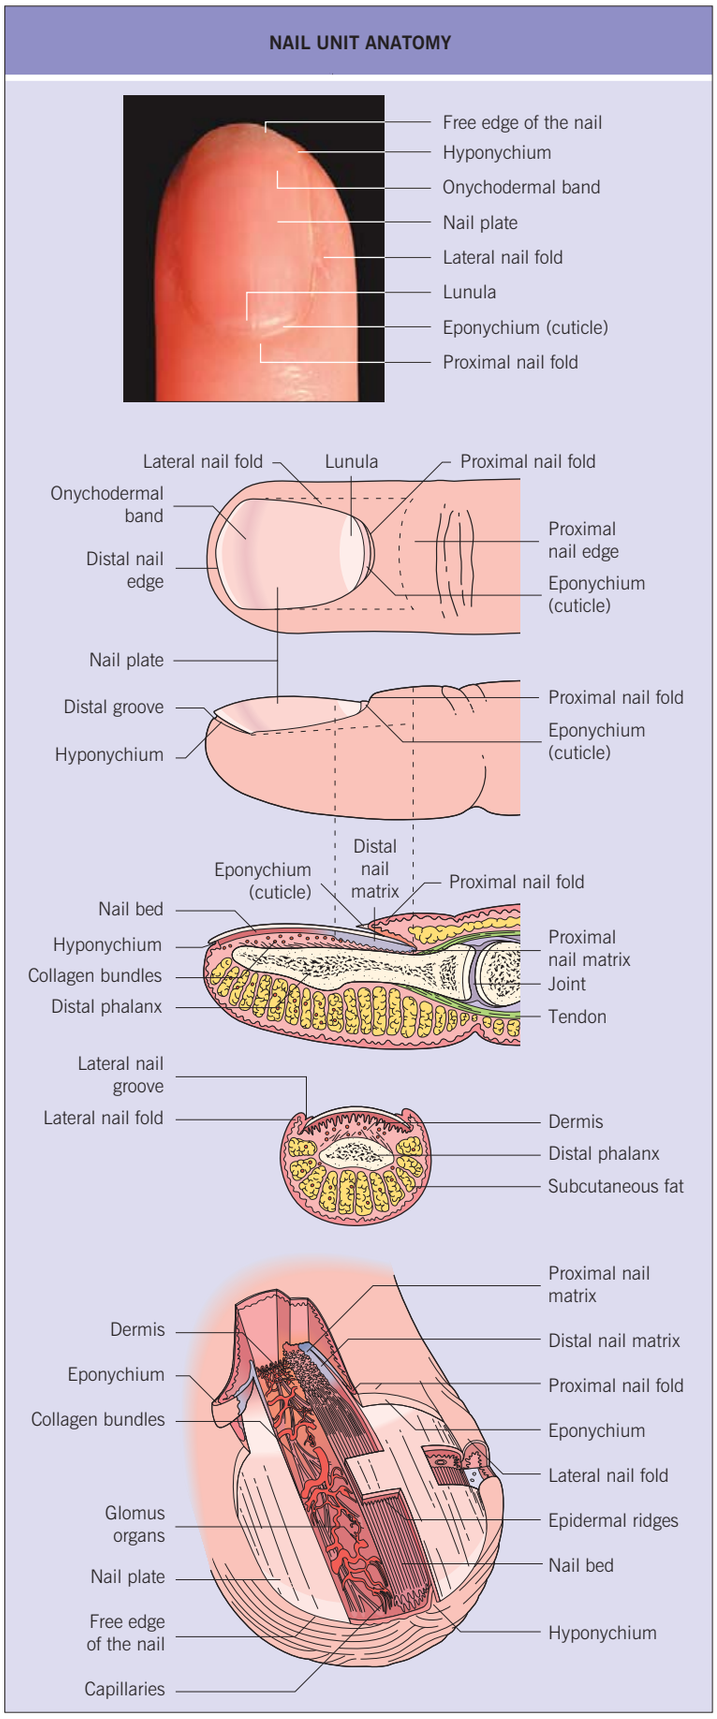

Fig. 68.9 Nail unit anatomy.

plate and the soft tissues supporting it. The nail plate is a hard, semitransparent, slightly convex sheet comprised of tightly packed corneocytes termed onychocytes. It contains abundant "hard" hair-type keratins, which are embedded in a matrix of sulfur-rich high-cysteine and high-glycine/tyrosine proteins (see below). The dermis of the nail apparatus (beneath its epithelial structures) is a fibrocollagenous network that is "sandwiched" between the hard tissues of the nail plate and the underlying bone, lacking associated subcutaneous soft tissues or pilosebaceous units. As a result, bacterial infections in this region have a higher risk of spread to the adjacent bone (i.e. osteomyelitis of the distal phalanx) than in most other sites of the body.

The nail plate is surrounded on three edges by nail folds (one proximal and two lateral). The proximal nail fold, a double layer of skin overlying the proximal part of the nail, protects this area from trauma, solvents and infectious agents that might otherwise alter nail shape and structure. The dorsal layer of the proximal nail fold is continuous with the skin of the digit, while the ventral layer is continuous with the nail matrix. The cuticle (eponychium) is a thin strip of cornified epithelium that adheres to the nail at the edge of the proximal nail fold and acts as a seal against ingress. Damage to the cuticle results in a predisposition to inflammation of the nail fold; conversely, inflammation of the nail folds disrupts normal maturation of the epithelium and cuticle formation. Nail fold inflammation can also disturb the underlying matrix and alter nail plate production, most often manifesting as transverse ridging. The proximal nail fold may also help to mold the emerging nail, forming a relatively thin structure that grows obliquely from its point of origin in the matrix.

The longitudinal axis of nail growth is also guided by the lateral nail folds, which compress the nail plate from each side and contribute to its transverse curvature. The lateral margins of the nail bed form deep sulci that follow the curve of the distal phalanx and then fold back on themselves to produce the lateral nail folds. These sulci help to attach the nail to the soft tissues and, similar to the proximal nail fold and cuticle, provide a seal at the nail margin.

The structures bounded by the nail folds are the nail matrix proximally and the nail bed distally and medially. The half-moon-shaped lunula, which is most prominent on the thumb, demarcates the junction between the matrix and the nail bed. The lunula is less apparent, due in part to concealment by the proximal nail fold, with progression from the second to fifth finger. The lunulae of the toes are hidden by their relatively prominent proximal nail folds (which may serve a protective function) and (especially for the great toes) thicker nail plates[149,150].

The nail plate is in continuity with the matrix from which it arises, while the nail bed represents its underlying support structure and extends from the distal margin of the lunula to the onychodermal band (a thin pinkish transverse strip proximal to the whitish onychocorneal band; see Fig. 68.9). A longitudinal pattern of rugose rete ridges in the nail bed increases the surface area of its attachment to the ventral aspect of the nail, which has corresponding ridges. This enhances adhesion between these surfaces and enables the free edge of the nail to be used as a levering tool without lifting the nail or causing pain. Histologically, both the nail bed and matrix normally lack a granular layer. The presence of a granular layer in these sites is a sign of pathology, such as the altered nail bed behavior associated with subungual hyperkeratosis.

The nail is in close proximity to the underlying distal phalanx, and bone morphogenic proteins (BMPs) are thought to have roles in the morphogenesis of both structures. When the distal phalanx and/or interphalangeal joint are affected by an inflammatory disease such as psoriasis, involvement of the nail matrix (and hence nail plate) often occurs. Congenital absence of part of the distal phalanx is typically accompanied by a small or otherwise altered nail (e.g. congenital onychodysplasia of the index fingers), further illustrating the relationship between these two structures[151]. In the neonatal period, digit tip regeneration can occur in humans after partial amputation. This appears to require the presence of a residual nail unit and to involve the expression of BMP-4 and the muscle segment homeobox 1 (MSX1) transcriptional repressor[152]. In later life, regeneration does not occur upon partial amputation of the fingertip due to trauma or osteolysis in the setting of scleroderma, and secondary nail changes typically ensue.

The vascular supply of the digit is through two dorsolateral and two ventrolateral arteries that lack an internal elastic lamina and have a tortuous morphology that helps them to withstand flexion and other movements. There is substantial communication between these vascular networks, particularly distally via plexuses in the proximal nail fold and digital pulp. This provides the digit with a blood supply of more than one origin and direction, which ensures continued flow in the event of trauma or a sustained grip that decreases supply from the ventral vessels. The pulp plexus is located within a recess produced by

the gap between the ventral prominence of the distal phalanx and the rim of the distal interphalangeal joint[153].

In a cold environment, which leads to constriction of arterioles, arteriovenous anastomoses (Sucquet–Hoyer canals) within glomus bodies maintain sufficient blood supply to the distal digits. Glomus bodies are encapsulated oval structures containing modified smooth muscle cells that dilate upon exposure to the cold. These structures are most prominent in the subungual tissue, which represents the most common site of the glomus tumor, a benign proliferation of glomus cells[154] (see Ch. 114).

In the proximal nail fold, the dermal capillaries normally form a regular pattern of "hairpin" loops with a thin efferent limb and a more tortuous, thicker afferent limb. The organization of nail bed vessels is similar, although the hairpin turn is less evident. Dermatoscopic examination (capillaroscopy) of nail fold vessels can help to assess a patient's acral microvascular status. The pattern and/or patency of the capillaries in the proximal nail fold and nail bed is often altered in patients with an autoimmune connective tissue diseases (AI-CTD) or embolic disorder. The nail folds of patients with lupus erythematosus typically show dilated, tortuous capillaries of normal density, whereas scleroderma and dermatomyositis feature hemorrhages and decreased capillary density characterized by avascular areas alternating with dilated capillary loops. Acral infarction due to embolization (e.g. in the setting of endocarditis) can result in leakage of blood into the nail bed, referred to as splinter hemorrhages. These lesions can also develop secondary to trauma, psoriasis (which is associated with an increased number of papillary dermal vessels, disrupted nail integrity, and shearing forces with the nail bed) and AI-CTD.

The nerve supply of the digit follows the pattern of the vascular supply, with two dorsal and two ventral branches that have some overlap distally in their sensory territories[150]. Because the fingertips have an important role in sensory perception, nerve endings that transmit pain (type I fibers), touch (Meissner and Pacinian bodies) and temperature are all abundant. The function of these nerve endings may be compromised by pressure due to relatively minor trauma and edema within the fascial envelope that encloses a finger or toe.

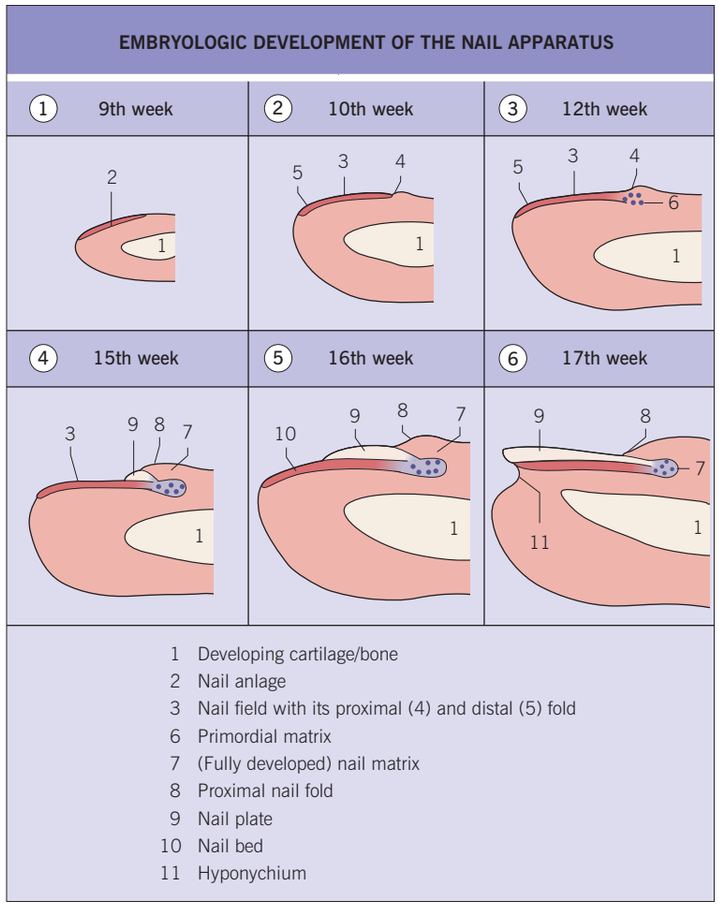

Fig. 68.10 Embryologic development of the nail apparatus.

Nail Embryology

The nail primordium becomes evident at 8 weeks' gestational age as a transverse ridge on the distal dorsal surface of the digit (Fig. 68.10) (see Ch. 2). Over the next 4 weeks, the ridge takes a more proximal position and eventually invaginates beneath the emerging proximal nail fold. The outline of the nail unit is established by 16 weeks' gestational age, and the nail plate completely covers the nail bed during the fifth month.

Study of inherited nail diseases has provided clues into some of the processes that regulate the formation of the nail unit. An autosomal recessive form of anonychia congenita is caused by loss-of-function mutations in the gene encoding R-spondin 4 (RSPO4) , which functions in the WNT signaling pathway[155]. Mouse studies have demonstrated expression of *Rspo4* in digit mesenchyme during embryogenesis, and it is thought to influence induction of the nail unit in the overlying epithelium.

Nail–patella syndrome is another genetic disorder that has contributed to our understanding of the organization of nail development. The nail changes in this autosomal dominant condition include triangular lunulae and absent or hypoplastic nails, with most prominent involvement of the thumbnail and other radial digits; however, an individual nail is usually more severely affected on its ulnar side. Extracutaneous manifestations include hypoplastic patellae, iliac horns, nephropathy and glaucoma. Nail–patella syndrome is caused by mutations in the gene encoding the LIM homeobox transcription factor 1β (LMX1B), which influences dorsoventral limb patterning[156,157]. In Clouston syndrome, a form of ectodermal dysplasia due to mutations in the gap junction β6 gene (*GJB6*) that encodes connexin 30, thickened nails with onycholysis occur in association with hypotrichosis and palmoplantar keratoderma (see Ch. 63)[158]. These genetic nail diseases illustrate the importance of communication between cells and tissues in the morphogenesis of the nails as well as other adnexal structures and organs. These messaging systems use the same "code" to initiate a variety of events in different tissues. Other genetic diseases affect the nails through alteration of their structural components, such as keratins or the constituents of the basement membrane.

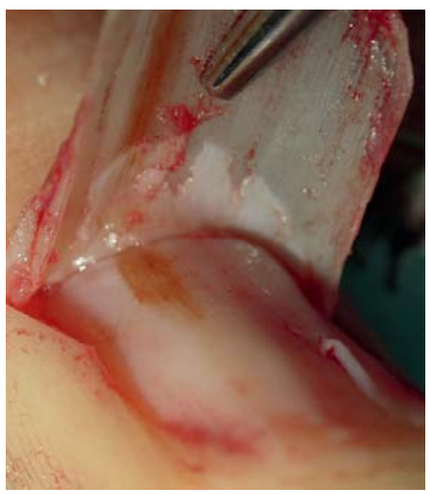

Fig. 68.11 Nail matrix biopsy to determine the etiology of longitudinal melanonychia. Note that the pigment in the nail extends to the proximal part of the matrix in the nail plate and (as seen when the nail is lifted) the matrix itself.

Nail Matrix

"Nail matrix" is a functional and anatomical term; although there is currently general consensus with regard to these definitions, disagreement about the precise functional role of the matrix (see below) can potentially lead to confusion about its exact anatomy.

Matrix anatomy

The anatomical boundaries of the "classical" matrix are most easily visible when the subungual tissues are seen during a surgical procedure in which the nail is avulsed and the proximal nail fold retracted (Fig. 68.11). This reveals two zones of tissues on which the nail rests, a proximal pale nail matrix and a distal pinker nail bed. Their arcuate junction is evident through the nail plate as the lunula (half moon).

The most lateral portion of the matrix may be "buried" in the sulcus of the lateral nail fold; because this can be difficult to access surgically, procedures designed to remove the lateral part of the nail matrix sometimes leave behind a small piece of matrix that produces a detached spicule of nail. Proximally, the matrix extends to the point of flexure of the proximal nail fold, where the latter structure turns back over and protects the proximal margin of the nail (see Fig. 68.9). Compared to epidermal keratinocytes, those in the nail matrix are larger and have a higher rate of proliferation.

Matrix function

For more than 50 years, anatomists and clinical scientists have investigated the relationship between the matrix and production of the nail (Fig. 68.12). Early work by Lewis[159] used static histology of silver-stained longitudinal sections of the nail unit to delineate three layers that he postulated were derived from separate epithelial surfaces within the nail unit: (1) the ventral aspect of the proximal nail fold (upper nail plate); (2) the "classical" matrix as defined above (mid nail plate); and (3) the nail bed (lower nail plate). This led to the misconception that there are three areas of matrix, dorsal, ventral and intermediate. Subsequent studies in squirrel monkeys (which have digits similar to those in humans) using *in vivo* autoradiography provided evidence that most, if not all, of the nail plate is generated from the "classical" matrix[160]. In these experiments, systemic injection of tritiated thymidine was followed by amputations at different time points, demonstrating that the thymidine reached the nail plate via the matrix. Injection of radiolabeled glycine into the nail unit of human volunteers who then had nail biopsies also showed that the matrix is the main source of the nail plate[161].

In the early 1990s, Johnson and colleagues[162,163] found that between the distal margin of the lunula and the end of the nail bed, the nail plate of the great toe increases in thickness by ~20%. They inferred from this observation that the nail bed contributes this proportion of the nail plate. Histologic assessment of nail plates obtained in a similar manner (avulsion) from the great toe confirmed this increase in thickness but showed that the number of cells in the vertical axis of the nail plate does not increase from the proximal to distal nail bed. These results suggested that the nail plate thickens because of compaction (e.g. due to distal-to-proximal compression) rather than an active contribution from the underlying nail bed[164]. Walking while wearing footwear produces low-grade, repetitive trauma to the free edge of the great toenail, which would explain such an effect[164].

Immunohistochemical staining with proliferating cell nuclear antigen or Ki-67 demonstrates minimal proliferative activity in the nail bed but substantial activity in the matrix, further supporting that the matrix is the source of the nail plate[165]. The correlation between anatomy and function explains the different patterns of nail disease that result from pathology affecting the matrix versus the nail bed (see Table 71.1). It also accounts for the potential for permanent nail deformity following surgical intervention or biopsy of the matrix, but not for similar interventions involving the nail bed. Because the proximal half of the matrix produces approximately 80% of the nail plate, surgeries or biopsies in this area are more likely to produce nail dystrophy than those of the distal matrix. Onychocytes migrate upward and distally along an oblique axis during their maturation and differentiation; as a result, the proximal part of the matrix produces the dorsal portion of the nail plate, while the distal part of the matrix synthesizes the ventral portion of the nail plate. Abnormalities in the proximal matrix underlie clinical findings such as pitting and longitudinal ridging/splitting, whereas disruption of the distal matrix can cause true leukonychia.

THEORIES ON THE ORIGIN OF THE NAIL PLATE

Origin of the nail plate	Evidence	Schematic, reference
Three portions of the nail matrix form three corresponding parts of the nail plate, which is characterized by a three-layer structure: Dorsal part = Proximal nail fold → Upper nail plate Intermediate part = Classical nail matrix → Intermediate nail plate Ventral part = Nail bed → Lower nail plate	Light microscopy and silver staining of human nails	 Lewis (1954)
Cells of the classical matrix are the origin of the whole nail plate	*In vivo* auto–radiography (with tritiated thymidine) in squirrel monkeys	 Zaias and Alvarez (1969)
Cells of the classical matrix produce nearly the total nail plate. Only a few cells of the nail bed in poorly defined locations take part in forming the nail plate	*In vivo* auto–radiography (with radiolabeled glycine) in human volunteers	 Norton (1971)
The regrowth of nail plates following traumatic avulsion of great toenails was investigated: approximately 20% of the nail plate's thickness was added when the nail grew over the nail bed, suggesting a nail bed contribution to the nail plate's growth	Changes in nail plate's thickness during nail growth in human volunteers	 Johnson et al. (1991,1993)
Cells of the proximal half of the matrix produce approximately 80% of the nail plate, whereas 1% or less of the nail plate is contributed by the nail bed. In psoriatic nails, the nail bed contribution may increase to over 25%	Immunohisto-chemical labeling in healthy human nails with antibodies to proliferating cell nuclear antigens and antigen Ki-67	 Healthy nail  Psoriatic nail de Berker and Angus (1996); de Berker et al. (1996)

Sites of origin and their contributions to the nail plate:

- Proximal matrix within nail fold (dorsal matrix)
- Nail bed
- Nail matrix
- Proximal half of nail matrix
- Distal half of nail matrix

Nail Unit Melanocytes

Melanocytes are found in the nail matrix but not in the normal nail bed. In general, foci of pigment in the nail bed that are separated from the nail folds and matrix are not melanocytic in origin[166], with possible exceptions including a metastatic melanoma and a partially amelanotic melanoma that is continuous with the matrix or nail fold. Nail matrix melanocytes are most abundant in the distal matrix and are found in suprabasal layers as well as the basal layer, which may reflect a distinct expression pattern of adhesion molecules (e.g. of α_2, α_3 and β_1 integrins) that regulate interactions between melanocytes and keratinocytes[166a].

The main distribution pattern of melanin in the nail plate is pigmented bands, referred to as longitudinal melanonychia, which vary in number, intensity and width depending on their etiology (see Ch. 71). Multiple streaks of longitudinal melanonychia due to active nail matrix melanocytes are commonly found in individuals with darkly pigmented skin, sometimes as a result of trauma or inflammation affecting the matrix. In contrast, nail matrix melanocytes in individuals with lightly pigmented skin are normally quiescent, and longitudinal melanonychia (especially an isolated band in an adult) in such patients usually requires a nail matrix biopsy (see Ch. 149) to exclude the possibility of melanoma.

Inadequate biopsy specimens (e.g. too small, non-representative) can lead to a delay in diagnosis and less favorable prognosis[167].

The Nail Immune System

The nail unit (in particular the proximal matrix) represents a site of relative immune privilege, with reduced expression of MHC class I and II antigens and decreased numbers of antigen-presenting cells. Although these features may be of benefit in preventing over-reactivity to environmental antigens, they could also increase vulnerability to human papillomavirus infections and their potential oncogenic effects, which can result in periungual squamous cell carcinomas[168].

Nail Keratins

Multiple types of keratins are expressed in the nail apparatus (Fig. 68.13), and they account for 80% of the dry weight of the nail plate. The nail plate and matrix contain "hard" hair-type keratins with a large number of sulfur-containing amino acids that facilitate cross-linking between keratin molecules. This reduces the amount of water associated with these proteins and makes them more rugged and resistant to chemical destruction compared with "soft" epithelial keratins[169].

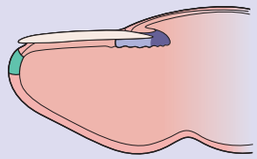
The pattern of keratin expression within the nail unit explains the involvement of this structure in several genodermatoses that are caused by keratin defects[170,171]. Pachyonychia congenita (PC) is an autosomal dominant disorder caused by mutations in the genes encoding keratins 6a or 16 (classically referred to as PC1) and 6b or 17 (classically referred to as PC2) (see Chs 58 & 71). These keratins are expressed in the nail bed, hair follicle and sebaceous gland as well as palmoplantar, injured (e.g. ulcer margins) and hyperproliferative epidermis. PC features thickening of the nail plate, much of which represents compaction of dense subungual hyperkeratosis, together with painful palmoplantar keratoderma, follicular keratoses and variable oral leukokeratosis and cysts (e.g. steatocystoma multiplex). Nail fragility as well as alopecia characterize the pure hair–nail ectodermal dysplasia that results from mutations in the gene for keratin 85. In these patients, keratin 85 lacks two cysteine residues, which may compromise nail integrity via diminished cross-linking of amino acids within keratins.

The nail bed does not express keratins 1 and 10, which characterize terminally differentiated stratified epithelia such as the epidermis. It has been postulated that the presence of the nail plate overlying the nail bed inhibits further differentiation of the latter structure. Indeed, if the nail plate is avulsed, the nail bed develops a cornified layer over the next 3 to 4 weeks.

Other Nail Plate Components

In addition to keratins, the nail plate contains structural proteins high in sulfur (with elevated cysteine content) or glycine and tyrosine (see Fig. 68.13). Other molecules and elements within the nail plate include water (normally ~10–15%, compared to ~15–25% for the epidermis), lipids (primarily cholesterol) and minerals (e.g. iron, zinc, calcium). The nail plate is relatively porous and ~1000-fold more permeable to water than is the epidermis; as a result, nails can be rapidly dehydrated and hydrated. Low water content in nails leads to brittleness, while nails composed of >30% water are soft and opaque. Although calcium is present in the nail plate, it does not influence the hardness of the nail.

DISTRIBUTION OF KERATINS AND NON-KERATIN PROTEINS IN THE NAIL APPARATUS



Anatomical region	Keratins (key examples)		Non-keratin proteins
	Soft keratins	Hard keratins	
Nail plate	K14, K16, K17, K5, K6	K31–K34 K81–K84	Ultra-high-sulfur proteins High-sulfur proteins High-glycine/tyrosine proteins Trichohyalin
Proximal nail matrix	K10, K14, K16, K17 K1, K5, K6		Actin, involucrin, filaggrin*, trichohyalin*, plasminogen activator inhibitor type II, laminin
Distal nail matrix	K10, K14, K20 K1, K5	K31	
Nail bed	K14, K16, K17, K5, K6, K7		Trichohyalin, plasminogen activator inhibitor type II, laminin
Hyponychium	K10, K14, K1, K5		Laminin
Tip	K16, K17 K6		
Embryonic nail unit	K19		*detected in monkey nails

Fig. 68.13 Distribution of keratins and non-keratin proteins in the nail apparatus. *Adapted fom Dawber RP, de Berker DA, Baran R. Science of the nail apparatus. In: Baran R, Dawber RP, de Berker DA, et al (eds). Diseases of the Nails and their Management. Oxford: Blackwell Science, 2001;1–47.*

THE NAIL APPARATUS: BASIC INFORMATION AND TERMINOLOGY	
Nail plate thickness	Toenails are usually thicker than fingernails Toenails: 1.4 mm in women, 1.65 mm in men Fingernails: 0.5 mm in women, 0.6 mm in men
Growth rate	Fingernails usually grow faster than toenails Fingernails: 2–3 mm/month Toenails: 1 mm/month Complete replacement of a nail requires 6 (fingernails) to 18 months (toenails)
Nail plate	Tightly packed cornified cells (onychocytes) arranged in a lamellar pattern (weakly eosin+, strongly acid-fast+); largest on the great toe (covers ~50% of the digit); fingernails have a longer longitudinal axis compared to the transverse axis, while toenails usually have a longer transverse axis
Nail matrix	Epithelium situated above the middle part of the distal phalanx of the digits; keratinizes without a granular layer and generates the nail plate; contains many melanocytes (up to 300/mm^2 in African-Americans), predominantly in suprabasal layers
Nail bed	Thin epithelium consisting of 2–5 cell layers with abrupt keratinization and no granular layer; typically no melanocytes
Proximal nail fold	Epithelium with a granular layer; its dorsal part corresponds to the skin of the dorsum of the digit and contains sweat glands but is devoid of pilosebaceous units; densely innervated; the ventral part is thinner and connects with the nail matrix epithelium
Hyponychium	An epithelium equivalent to the volar skin containing granular and thick cornified layers
Nail pigmentation	Banded pigmentation (longitudinal melanonychia) is common in Asians or African-Americans (seen in ~75% of African-Americans by 20 years of age and nearly 100% by 50 years of age); relatively uncommon in Caucasians

Table 68.5 The nail apparatus: basic information and terminology. *Courtesy, John P Sundberg, DVM, PhD.*

Likewise, the white "flecks" that are commonly seen in the nail plate (especially in children) have nothing to do with calcium but rather reflect small disturbances in the compaction of onychocytes, usually related to trauma.

The nail can also contain markers of various metabolic processes and exposures to exogenous substances (e.g. drugs, environmental pollutants). Biomarkers in the nail plate include glycosylated keratin in patients with diabetes mellitus[172], high sodium levels in those with cystic fibrosis[173], and increased amounts of lipids in hyperlipidemic individuals[174]. Exogenous substances that are found in the nail plate in settings of systemic exposure due to environmental contamination include arsenic, lead and other heavy metals[175,176]. Drugs taken for medical purposes or recreationally may also be present in the nail plate, depending on their binding properties and lipid solubility[177]. Analysis of nicotine in the toenails can be used to track exposure to cigarette smoke via inhalation[178], and a range of narcotics can be identified in nail clippings, either in deposits beneath the free edge of the nail plate due to recent direct contact or incorporated into the nail plate via systemic exposure over previous months[179]. For neonates, it is possible to measure *in utero* exposure to some drugs using nail analysis[180].

Nail Growth

Nail growth (Table 68.5) is typically measured in the longitudinal axis (e.g. using a vernier caliper) from a defined reference point to the free edge or by monitoring the movement over time of a transverse groove made at the peak of the lunula[181]; the mass of nail produced in clippings over a fixed period can also be determined. When a systemic event or local trauma disrupts nail growth for a brief period, a transverse groove (reflecting the contour of the proximal margin of the matrix) appears and grows outward with the affected nail, allowing the timing of the inciting phenomenon to be estimated. This clinical sign is known as Beau's lines, named after the Parisian cardiologist Justin Beau who described these bands in patients recovering from typhoid[182].

Multiple physiologic conditions, medical disorders and drug exposures can influence nail growth (Table 68.6). The appearance of decreased nail growth is occasionally explained by substantial thickening of the nail plate that deviates the axis of growth such that nail is accumulating upwards in the vertical axis as well as outward in the longitudinal axis. Examples include onychogryphosis and yellow nail syndrome[183] (see Ch. 71), which are both accompanied by retraction of the proximal nail fold that may normally have a role in molding and flattening the early nail. In these instances, measurement of nail bulk rather than length illustrates that the nails are actually growing, but in a different direction.

FACTORS THAT CAN INFLUENCE NAIL GROWTH

Factor/ condition	Reduction of growth	Acceleration of growth
Age	Elderly	Young
Time of day	Night	Day
Seasons	Winter	Summer
Anatomic location	Toes Thumb, little finger	Fingers Middle finger
Physiologic states		Pregnancy
Extracutaneous disorders	Fever Poor nutrition Denervation, immobilization Infections (e.g. mumps, tuberculosis)	Hyperthyroidism Arteriovenous shunting
Cutaneous disorders	Onychomycosis	Psoriasis, pityriasis rubra pilaris
Drugs	L-Dopa Calcium, vitamin D Methotrexate Azathioprine Etretinate/acitretin	Itraconazole Etretinate/acitretin (in psoriasis patients)

Table 68.6 Factors that can influence nail growth.

Alopecias 69

Leonard C Sperling, Rodney D Sinclair and Laila El Shabrawi-Caelen

Chapter Contents

Androgenetic alopecia *1093*
Telogen effluvium *1098*
Trichotillomania *1099*
Alopecia areata *1100*
Cicatricial (scarring) alopecias *1104*
Hair shaft abnormalities *1109*

Key features

- Genetically determined sensitivity of scalp hair follicles to adult levels of androgens
- Miniaturization of hairs in a symmetric "pattern" on the crown, vertex and frontal regions
- Antiandrogen medications can be used for successful treatment

INTRODUCTION

The pilosebaceous unit includes the hair follicle, the arrector pili muscle, the sebaceous gland and, where present, the apocrine gland (see Chs 35 & 68). The bulb is the lowest portion of the follicle and it contains the hair matrix epithelium and the mesenchymal dermal papilla. Whereas the bulb undergoes cyclical involution and regeneration, the infundibulum and isthmus represent the permanent part of the follicle.

Keratinocytes within the matrix rapidly proliferate and differentiate into six distinct cell lineages. Cells arising from the central matrix just above the dermal papilla give rise to the hair shaft, which consists of three components – the *medulla* (centrally), *cortex* and *hair shaft cuticle* (outermost). The outer aspects of the matrix give rise to the inner root sheath (IRS), a structure that is also composed of three layers: (1) the *IRS cuticle* (innermost), which interlocks with the hair shaft cuticle and anchors the shaft; (2) the *Huxley layer*; and (3) the *Henle layer* (outermost; see Ch. 68). Henle's layer then abuts the outer root sheath (ORS) epithelium.

The IRS is the first structure within the hair follicle to cornify, forming a hard cylindrical case around the emerging hair shaft; it also seals the lower portion of the pilosebaceous unit from the environment. Just below the entry of the sebaceous gland duct, the inner root sheath desquamates, creating a space between the shaft and the ORS, allowing for sebaceous gland excretory flow. Of note, the ORS is continuous with the overlying epidermis.

The arrector pili muscle attaches to the hair follicle at the *bulge*. Certain epithelial cells within the ORS bulge have stem cell-like properties and are involved in hair follicle regeneration and cycling[1] (see Chs 2 & 68). Theoretically, if this site is permanently injured, hair regrowth cannot occur.

In this chapter, the major non-cicatricial (non-permanent) alopecias will be reviewed first, followed by a discussion of cicatricial alopecias. This will be followed by a review of structural hair shaft abnormalities.

ANDROGENETIC ALOPECIA

Synonyms: ■ Male pattern and female pattern hair loss (MPHL and FPHL) ■ Common balding ■ Hereditary balding or thinning

Introduction

Androgenetic alopecia (AGA) is an androgen-dependent, hereditary physical trait resulting from the conversion of scalp terminal hairs into miniaturized vellus hairs in a characteristic pattern[1]. The frequency and severity increase with age, and at least 80% of Caucasian men and ~50% of women show evidence of AGA by age 70 years[2,3].

Pathogenesis

High concordance of MPHL amongst monozygotic twins indicates a strong genetic predisposition. The inheritance is polygenic and a

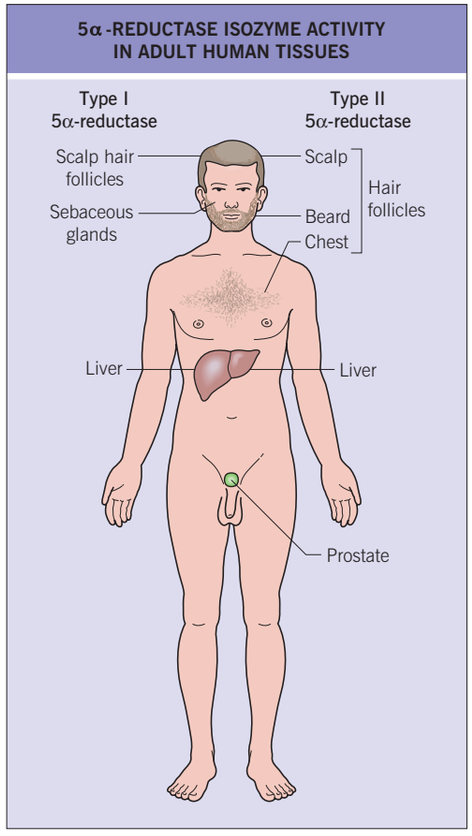

Fig. 69.1 5α-reductase isozyme activity in adult human tissues.

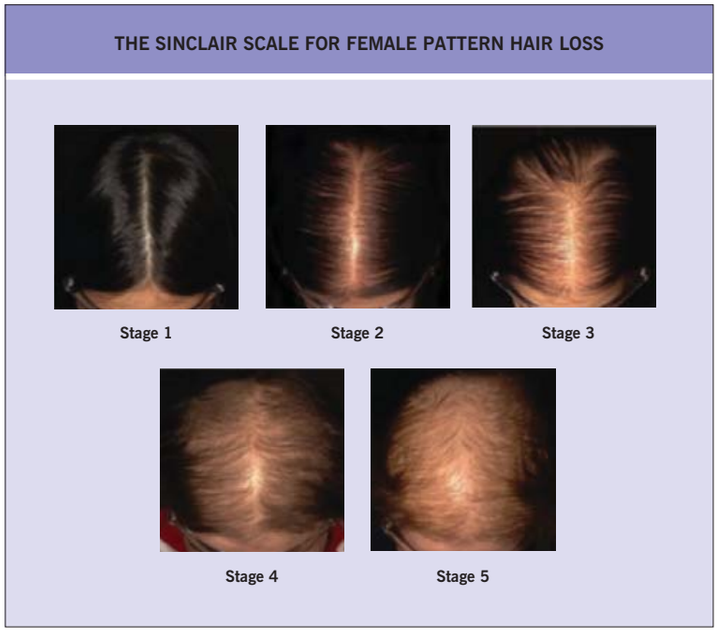

Fig. 69.3 The Sinclair scale for female pattern hair loss. Stage 1 – normal; Stage 2 – widening of the central part line; Stage 3 – widening of the part line with translucency of the hairs at its border; Stage 4 – development of a bald area anteriorly along the part line; and Stage 5 – advanced hair loss.

number of genetic loci have been implicated, including those that encode the androgen receptor (MPHL) and aromatase, which converts testosterone to estradiol (FPHL)[4,5]. Androgen hormones clearly initiate and promulgate MPHL in genetically susceptible individuals, and while inhibition of androgen biosynthesis or action will arrest the progression of MPHL, it will only partially reverse the miniaturization of hairs.

In men, the expression of AGA is related in particular to the androgen hormone dihydrotestosterone (DHT). Testosterone is converted to DHT by the enzyme 5α-reductase, of which there are two isoenzymes, type I and type II. Type I 5α-reductase is present predominantly in sebaceous glands and the liver, whereas type II 5α-reductase dominates in scalp, beard and chest hair follicles, as well as in the liver and the prostate gland (Fig. 69.1). The genetic absence of type II 5α-reductase prevents development of male AGA[1].

Investigators have localized androgen-metabolizing enzymes to various regions of the hair follicle (Fig. 69.2). In scalp biopsy specimens obtained from men with AGA, 5α-reductase activity and DHT levels are increased compared to non-balding scalp skin[6]. DHT is implicated in the appearance of miniaturized hair follicles and hair shafts, and decreased levels in both the skin and the blood have been associated with a reversal of miniaturization.

In women, a similar androgen-related pathophysiology is postulated[4]. Women who develop balding shortly after puberty often have a positive family history for pattern hair loss in both male and female family members. In women who develop pattern alopecia during the perimenopausal period and menopause, it may be due to a genetic predisposition as well as alterations in androgen metabolism at the level of the hair follicle and systemic hormonal changes[7].

Rarely, AGA develops in prepubertal children (ages 6–10 years)[8]. Affected boys and girls demonstrate a FPHL pattern without bitemporal recession, and they have a strong family history of AGA (present in at least one parent). No evidence has been found for abnormal circulating testosterone levels or precocious puberty.

Clinical features

MPHL is symmetric and progressive with some pattern variation. Hamilton[9] and then Norwood[10] first classified the patterns of male AGA based upon frontoparietal and frontal recession as well as vertex thinning (see Fig. 157.2). Occasionally, a "male type" pattern with frontotemporal and vertex thinning is seen in women, and then they too can be classified with the Hamilton or Norwood system.

However, the most common pattern of FPHL is diffuse central thinning of the crown with preservation of the frontal hairline. Often there is frontal accentuation of the hair loss, creating a "Christmas tree" pattern[11]. Examination of the central part width can be used to classify severity of FPHL via the Sinclair scale (Fig. 69.3)[12] and it can be compared to the occipital part width (Fig. 69.4)[1,13]. The findings by trichoscopy are shown in Figure 69.5.

Pathology

Scalp hairs exist as clusters (follicular units) composed of three to five shaft-producing follicles serviced by a single arrector pili muscle. One by one, as follicles miniaturize, the follicular units within thinning regions of the scalp begin to produce only one or two terminal hairs. Once all the follicles within a follicular unit miniaturize, baldness is observed[5]. Histopathologic findings of MPHL and FPHL are described in Table 69.1 and illustrated in Figure 69.10.

Fig. 69.4 Female androgenetic alopecia. Comparison of the part line on the crown (**A**) and the occiput (**B**).

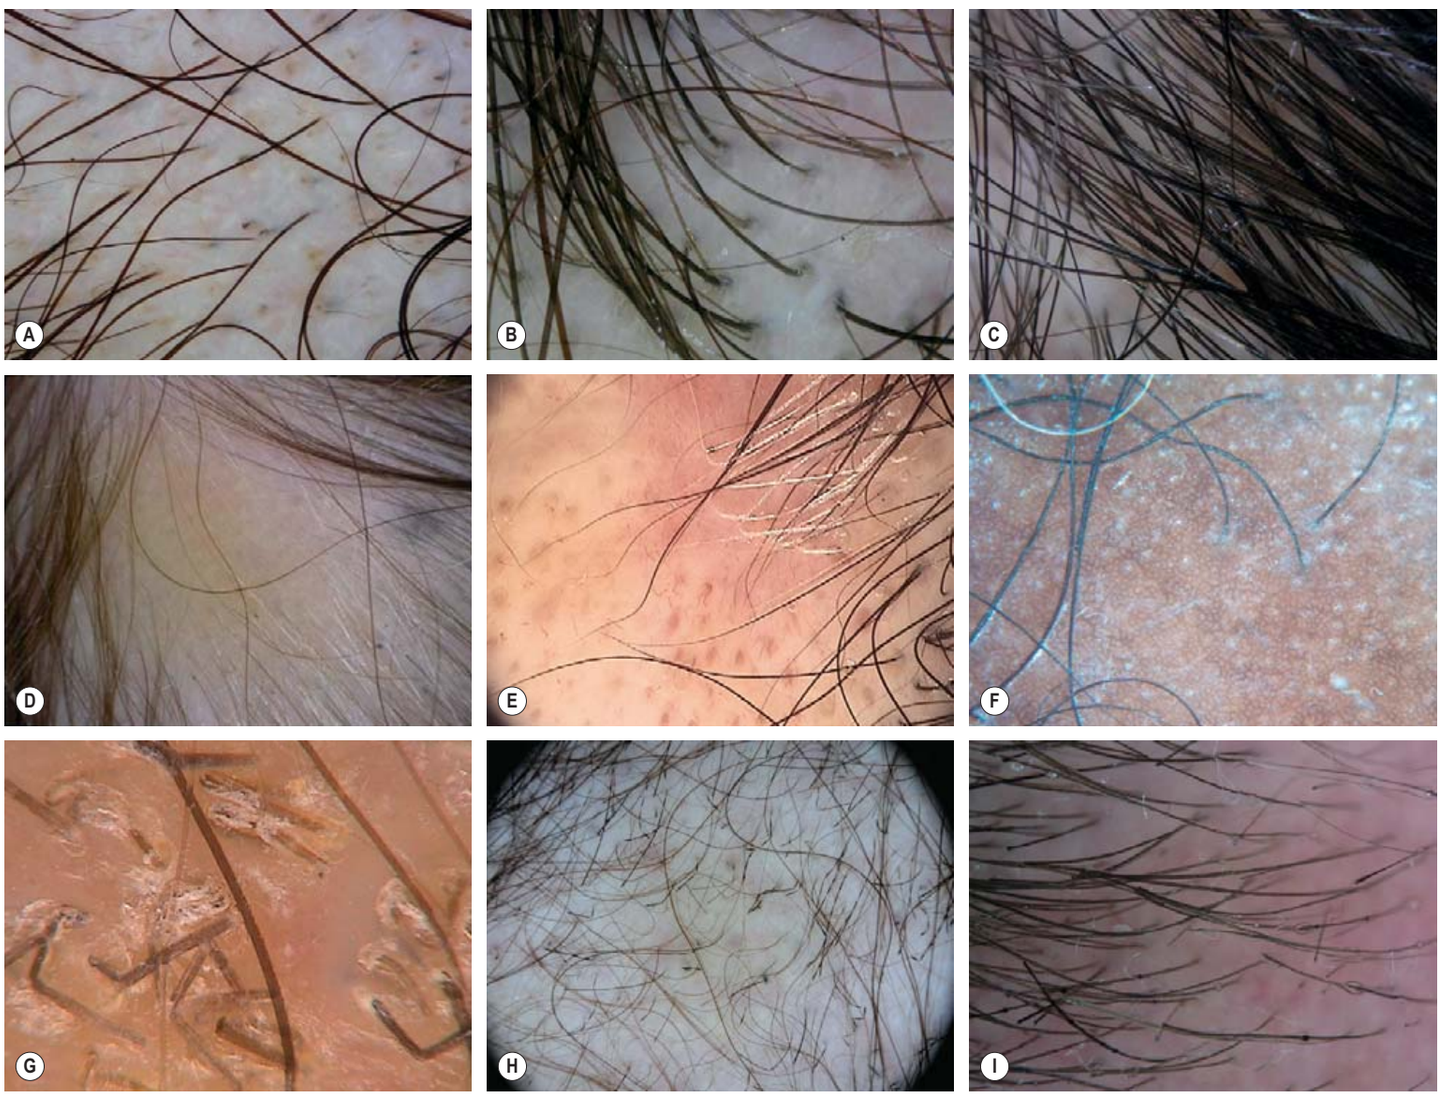

Fig. 69.5 Trichoscopy. A Alopecia areata (AA): yellow dots, exclamation point hairs and dystrophic hairs are characteristic features; the color of the yellow dots may vary from yellow to yellow–pink. Note some vellus-like hair shafts. **B** Androgenetic alopecia (AGA): a diversity of hair shaft diameters affects >20% of the hairs. Brown halos around hair shafts (peripilar sign) is a subtle clue. **C** Telogen effluvium: the hair shafts are of equal diameter (unlike AGA). **D** Temporal triangular alopecia: vellus-like, depigmented hair shafts, but no yellow dots or dystrophic hairs as are seen in AA. **E** Discoid lupus erythematosus (DLE): follicular red dots are a characteristic sign and they correspond histopathologically to dilated vessels, extravasated erythrocytes and keratin plugs. **F** Lichen planopilaris: discrete white dots due to loss of melanin over scarred fibrotic tracts and perifollicular fibrosis. The fibrosis in DLE is more diffuse. **G** Tinea capitis: comma hairs are a clue to the diagnosis. **H** Monilethrix: the presence of broken hair shafts plus hairs with a beaded appearance allows a bedside diagnosis. **I** Trichorrhexis invaginata (bamboo hairs) in a patient with Netherton syndrome: broken hair shafts and nodose swellings. *E–G, Courtesy, Antonella Tosti, MD.*

HISTOLOGIC FEATURES OF VARIOUS FORMS OF ALOPECIA
MALE AND FEMALE PATTERN HAIR LOSS (ANDROGENETIC ALOPECIA) (see Fig. 69.10)
• Normal *total* number of follicles and no significant inflammation • Increased number and percentage of vellus hairs • Numerous fibrous "streamers" • Slightly increased telogen count • Uninvolved scalp (e.g. occiput) appears normal
TELOGEN EFFLUVIUM
• Normal *total* number of hairs • Normal number of terminal (large) hairs • Increase in the telogen count to >20% (>15% is suggestive) • Absence of inflammation and scarring • Telogen count seldom exceeds 50%; >80% is inconsistent with telogen effluvium
TRICHOTILLOMANIA
• Follicles are normal size • Total number of hairs (both terminal and vellus) is normal • Incomplete, disrupted follicular anatomy • Increased number of terminal catagen and/or telogen hairs • Trichomalacia and pigment casts • No significant inflammation
ALOPECIA AREATA (see Fig. 69.10)
Early, progressive disease ("acute" and "subacute")[15]
• Normal *total* number of hairs • Peribulbar mononuclear cell infiltrate (with occasional eosinophils), predominantly affecting terminal anagen and catagen hair bulbs • Occasional exocytosis of inflammatory cells into bulbar epithelium • Degenerative changes of hair matrix • Increased number of terminal catagen and telogen hairs • Increased number of miniaturized hairs • Trichomalacia and marked narrowing of hair shafts
Longstanding and stable disease ("chronic")[15]
• Majority of hairs in catagen or telogen phases • Numerous miniaturized, "arrested", rapidly cycling hairs, referred to as *nanogen* hairs • Mild peribulbar mononuclear cell infiltrate around those nanogen hairs possessing anagen-like or catagen-like bulbs
POSTOPERATIVE (PRESSURE-INDUCED) ALOPECIA
• Early stage includes vascular thrombosis and inflammation within the dermis and superficial fat • Necrosis of the epidermis and eccrine coils when severe • In conjunction with alopecia, synchronized conversion of most or all of the terminal hair follicles to the catagen/telogen phase (*without* hair miniaturization) • Pigment casts, incontinent pigment within collapsed root sheaths, and trichomalacia (but not distorted follicular anatomy)
PSORIASIFORM ALOPECIA
• Psoriasiform epidermal changes may or may not be present • Marked increase in percentage of catagen/telogen hairs, associated with hair miniaturization • Occasional miniaturized follicle showing peribulbar chronic inflammation; plasma cells rare or absent • Marked diminution in number of sebaceous glands
TNF-α INHIBITOR-INDUCED PSORIASIFORM ALOPECIA
• Psoriasiform dermatitis often present • Increase in catagen/telogen hairs and miniaturization of hairs, similar to alopecia areata • Some peribulbar and superficial perivascular inflammation present, often with several eosinophils and plasma cells in the infiltrate
CENTRAL CENTRIFUGAL CICATRICIAL ALOPECIA
• Premature desquamation of the inner root sheath • Eccentric epithelial atrophy (thinning) with hair shafts in close proximity to the dermis • Concentric lamellar fibroplasia (onion skin-like fibrosis) of affected follicles • Variably dense lymphocytic perifollicular inflammation, primarily at the level of the upper isthmus and lower infundibulum • Occasional fusion of infundibula (polytrichia) • In advanced lesions, total destruction of the follicular epithelium with retained hair shaft fragments and granulomatous inflammation • In pustular lesions ("folliculitis decalvans"), intrafollicular and perifollicular infiltrates rich in neutrophils and lymphocytes
LICHEN PLANOPILARIS[15–24] (see Fig. 69.10)
• Band-like mononuclear cell infiltrate obscuring the interface between follicular epithelium and dermis; vacuolar alteration at the interface and hypergranulosis within affected infundibula is typical • Colloid or Civatte bodies are occasionally found as part of the interface alteration • Inflammation affects the *upper* portion of the follicle (infundibulum and isthmus) most severely • Occasionally, epidermal changes of lichen planus are found • Over time, perifollicular fibrosis becomes prominent and the lymphocytic infiltrate seems to "back away" from the follicle • An artifactual cleft between epithelium and stroma is often found, with epithelium "floating" within the cleft • Grouped globular immunofluorescence (usually IgM), adjacent to the follicular epithelium, is the characteristic pattern[25,26]

Table 69.1 Histologic features of various forms of alopecia.

Continued

HISTOLOGIC FEATURES OF VARIOUS FORMS OF ALOPECIA
DISCOID LESIONS OF LUPUS ERYTHEMATOSUS[15,18,23,24,27]
• Vacuolar interface alteration of the epidermis and follicular epithelium; epidermis may be spared • The interface change in follicles is usually vacuolar rather than lichenoid (less inflammation) • Chronic inflammation (often including plasma cells) of the eccrine sweat glands and arrector pili is sometimes present • Increased dermal mucin is often present • Granular deposits of IgG and C3 (less commonly IgM or IgA) at the dermal–epidermal junction and/or the junction of the follicular epithelium and dermis are typical
ACNE KELOIDALIS
• Perifollicular, chronic inflammation (lymphocytic and plasmacytic), most intense at the level of the isthmus and lower infundibulum • Lamellar fibroplasia, most marked at the level of the isthmus • Loss of sebaceous glands • Total follicular destruction in advanced disease
DISSECTING CELLULITIS OF THE SCALP
• Moderately dense, perifollicular lymphocytic inflammation affecting the lower half of the dermis and extending down into the subcutaneous fat • Numerous intact and seemingly undamaged follicles with intact sebaceous glands surrounded by an infiltrate of acute and chronic inflammation (early disease) • Increased percentage of catagen/telogen hairs • Initially, lymphocytes dominate the infiltrate, but eventually neutrophils become more numerous, especially in longstanding, fluctuant lesions • Vascular proliferation accompanies the infiltrate as the disease evolves, and the deep dermis and subcutaneous fat begin to exhibit the histologic findings of granulation tissue • Eventually, chronic abscesses become lined with squamous epithelium derived from the overlying epidermis, and true sinus tracts are formed • When inflammation subsides, there is dense fibrosis of the dermis and the superficial fat with loss of follicles
"END-STAGE" CICATRICIAL ALOPECIA[15]
• A decreased total number of hairs, especially terminal hairs • Loss of the sebaceous glands in zones of follicular loss • Residual, "naked" hair shafts surrounded by mild, granulomatous inflammation • Follicular streamers (stelae) without overlying follicles • Cylindrical columns of connective tissue representing the sites of former follicles
TRACTION ALOPECIA (END-STAGE)
• The total number of terminal hairs is markedly reduced • Distinct columns of connective tissue replace some follicles, leaving obvious "blank spaces" • The sebaceous glands associated with the remaining hair follicles are still intact and sebaceous glands often persist in follicular units that seem to have lost all of their hair-producing epithelium • No significant perifollicular inflammation • Rarely, retained "naked" hair shafts are seen in otherwise typical cases of end-stage traction alopecia; the significance of the finding is unclear

Table 69.1 Histologic features of various forms of alopecia (cont'd).

Differential diagnosis

The diagnosis of MPHL is straightforward unless it is coincidentally associated with other non-scarring hair diseases such as alopecia areata or telogen effluvium. Initial recognition of FPHL may coincide with a superimposed telogen effluvium. Early-onset or severe patterned hair loss in women should suggest the possibility of pathologic hyperandrogenism, and appropriate screening laboratory tests (total and free testosterone, dehydroepiandrosterone sulfate, and 17-hydroxy-progesterone) should be performed (see Ch. 70).

Treatment

A topical formulation, minoxidil (2% and 5%), and an oral drug, finasteride, have been approved by the US Food and Drug Administration (FDA) for the treatment of men with male AGA. Minoxidil is considered to be a biological response modifier and 1 ml is applied to the affected area twice a day. The most frequently reported adverse reactions are mild scalp dryness and irritation, and, rarely, allergic contact dermatitis. Minoxidil-induced hair growth is commonly associated with shedding of telogen hairs and a paradoxical worsening of hair loss approximately 4 to 6 weeks following initiation of treatment. This resolves with continued treatment.

Finasteride (1 mg daily; Fig. 69.6), a type II 5α-reductase inhibitor, has been found to be effective in the treatment of balding in men[28]. Patients should be informed that higher doses of finasteride (5 mg/day) have been associated with high-grade prostatic carcinomas in elderly men, although the overall incidence of prostatic carcinoma seems to be *reduced*[29]. With regard to the effects of finasteride (1 mg/day) on lowering serum concentrations of prostate-specific antigen (PSA), the recommendation is to adjust serum PSA concentrations by 40–50% when performing prostate cancer screening[30]. Finasteride therapy stops hair loss in 90% of men for at least 5 years, and hair can regrow in 65% of men. Continued use of the product is necessary to sustain regrowth, which is also true for topical minoxidil; halting the medication will be associated with resumption of hair loss. Surgical hair replacement, specifically hair transplantation and scalp reduction, are other alternatives for the treatment of male androgenetic alopecia (see Ch. 157). In the US, 2% and 5% topical minoxidil are approved for the management of FPHL. The latter may occur with hyperandrogenemia, and women may benefit from oral contraceptives (to suppress ovarian androgen production), spironolactone (Fig. 69.7), or, if appropriate, finasteride therapy[31–34]. If oral finasteride or spironolactone is used in women with childbearing potential, appropriate contraception should be utilized (given the risk of feminization of the male fetus), with oral contraceptives being the rational choice. While finasteride (1 mg per day) appears to be ineffective in postmenopausal women[35], when given at higher daily doses of 2.5 and 5 mg, it can improve FPHL[36,37].

Dutasteride is a combined type I and type II 5α-reductase inhibitor. A dose of 0.5 mg/day leads to a greater reduction in serum and scalp DHT levels than does finasteride at 5 mg/day. This suggests that dutasteride may be a more effective therapy. While there are emerging case reports of dutasteride leading to improvement of FPHL, the potential teratogenicity, prolonged biologic half-life preclude its use in women of childbearing age[38,39]. Hair transplantation can also be offered to women with severe FPHL.

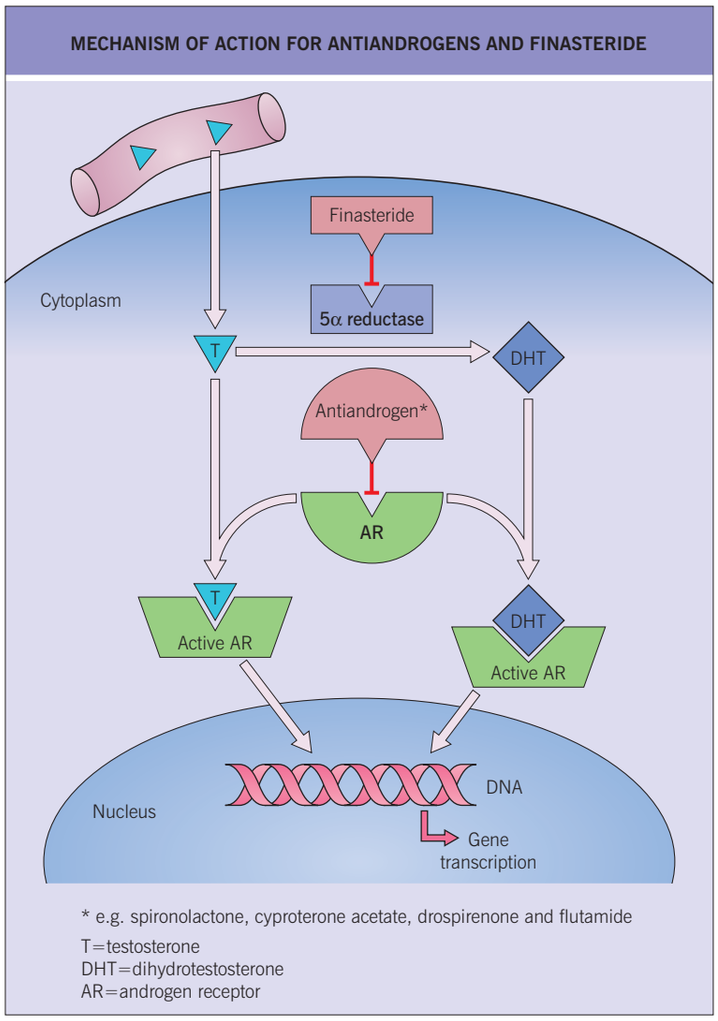

Fig. 69.6 Mechanism of action for antiandrogens and finasteride.

Fig 69.7 Female pattern hair loss in a 10-year-old girl. A Prior to treatment. **B** Obvious improvement following 5 years of therapy with oral spironolactone and topical minoxidil.

TELOGEN EFFLUVIUM

Key features

- Increased shedding of otherwise normal telogen hairs in response to a pathologic or normal physiologic change in health status
- A chronic form with no discernible precipitating factor is observed in some women
- Laboratory evaluation is directed by history, physical examination, and microscopic evaluation of shed or plucked hairs

CAUSES OF TELOGEN EFFLUVIUM

- Shedding of the newborn (physiologic)
- Postpartum (physiologic)
- Chronic telogen effluvium[42] (no attributable cause or illness)
- Postfebrile (extremely high fevers, e.g. malaria)
- Severe infection
- Severe chronic illness (e.g. HIV disease[43], systemic lupus erythematosus)
- Severe, prolonged psychological stress
- Postsurgical (implies major surgical procedure)
- Hypothyroidism and other endocrinopathies (e.g. hyperparathyroidism, hyperthyroidism)
- Crash or liquid protein diets; starvation/malnutrition
- Drugs:
  - discontinuation of oral contraceptives
  - retinoids (acitretin, isotretinoin) and vitamin A excess
  - anticoagulants (especially heparin)
  - antithyroid (propylthiouracil, methimazole)
  - anticonvulsants (e.g. phenytoin, valproic acid, carbamazepine)
  - interferon-α-2b
  - heavy metals
  - β-blockers (e.g. propranolol)

Table 69.2 Causes of telogen effluvium. For a complete list of associated drugs, see ref. 41.

Introduction

In the normal scalp, 90–95% of the follicles will be in the *anagen* phase and the remainder (5–10%) will be in the *telogen* phase (with about 50–100 hairs shed daily; see Fig. 68.5). Only a few follicles will be in the transitional or *catagen* phase. The biologic clock that determines the end of the anagen phase and the beginning of the catagen/telogen phase is a complex phenomenon whose molecular basis is beginning to be understood (see Ch. 68). The human hair can only grow for a few months to years before it becomes a telogen hair and is shed. Scalp hair grows longer than hair on other parts of the body because the length of its anagen phase is longer. Unlike mammals that molt, hair growth in humans is such that shedding of each follicle is independent of surrounding follicles. Consequently, a fairly uniform density of hair is maintained at all times. Various metabolic alterations such as pregnancy, malnutrition and other stresses are capable of adjusting the biologic clock within hair follicles, and it is possible for abnormally large numbers of hairs to enter the telogen phase simultaneously. When this happens, the hair loss is termed a *telogen effluvium*[40].

Pathogenesis

Depending on the cause of telogen effluvium, the period of excessive shedding can vary. Telogen effluvium is by far the most common form of hair loss seen as a side effect of medications or in association with systemic diseases or altered physiologic states. The causes of telogen effluvium are listed in Table 69.2. However, a fair number of women have been found to have a telogen effluvium without any discernible precipitating cause[42]. This chronic telogen effluvium primarily affects women between the ages of 30 and 60 years and is a diagnosis of exclusion.

If there is a definable precipitating event, hair loss begins approximately 3 months after this event. It takes that period of time for a hair follicle to progress through the telogen phase and to finally be shed. There is neither clinical nor histologic evidence of inflammation in a "pure" telogen effluvium.

Most drugs that have been associated with hair loss, with the exception of antineoplastic agents, cause hair loss via telogen effluvium. While numerous medications have been associated with hair loss, only a subset of these commonly causes telogen effluvium. The most prominent offenders are retinoids (acitretin and isotretinoin)[44], anticonvulsants, antithyroid medications, anticoagulants, lithium, interferons and β-adrenergic blocking agents. More complete lists of medications associated with alopecia are readily available[41].

Clinical features

Thinning of the hair involves the entire scalp and may also be noted on other hairy regions of the body (e.g. pubic and axillary hair). A gentle

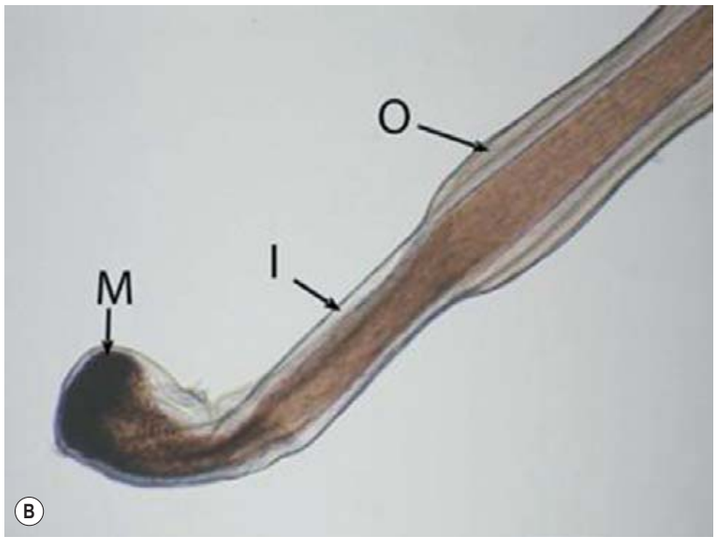

Fig. 69.8 Microscopic features of anagen and telogen hairs. A Telogen shaft showing a club-shaped bulb. **B** Anagen shaft with attached root sheaths, demonstrating a pigmented and distorted bulb; M, matrix; I, inner root sheath; O, outer root sheath. **C** Ruffled cuticle of loose anagen hair. *C, Courtesy, Julie V Schaffer, MD.*

hair pull may be positive for two or more normal telogen hairs (Fig. 69.8). A forcible hair pluck[45] (trichogram) will show a mixture of normal anagen and telogen hairs with the percentage of telogen in excess of 20%. While a telogen count of 15–20% is suggestive of abnormal shedding, >20% is diagnostic. In an active telogen effluvium, a 60-second timed hair count[45] will usually be in excess of 100 hairs (the mean normal value is 10 hairs)[46]. This method, which involves combing the hair forward for 60 seconds over cloth of a contrasting color before shampooing, can be used to follow the progression and eventual resolution of a telogen effluvium. The histopathologic findings in telogen effluvium are outlined in Table 69.1.

Eventually complete hair regrowth is expected. The prognosis for women with chronic telogen effluvium is relatively good, for although hair shedding can continue for many years, this does not appear to lead to baldness[47]. The prognosis for telogen effluvium associated with systemic disease is excellent if the precipitating cause is eliminated.

When the cause is unclear, the evaluation of a patient with telogen effluvium includes thyroid and chemistry panels, sedimentation rate, hematocrit and ferritin (as a reflection of total body iron storage). According to literature recommendations, ferritin levels should be at least 40 ng/dl, but the significance of abnormal values is uncertain[48]. In persistent cases of telogen effluvium, i.e. those lasting beyond 6 months, a scalp biopsy specimen submitted for horizontal sectioning can prove useful in excluding early AGA; the ratio of terminal to vellus hairs counted at the level of the isthmus allows distinction[49]. However, there is the possibility of the coexistence of the two disorders. Trichoscopy findings are shown in Figure 69.5.

TRICHOTILLOMANIA

Key features

- Self-induced plucking or breakage of hair
- Often associated with psychological stress or a personality disorder
- Incomplete and distorted follicular anatomy is a histologic hallmark

Introduction

The term "trichotillomania" is derived from the Greek *thrix*, hair; *tillein*, pulling out; and *mania*, madness. Trichotillomania is seen more commonly in females than in males, and in children more than adults. Onset of the disease is usually during early childhood to adolescence, and its prevalence is uncertain.

Pathogenesis

Trichotillomania is listed in the American Psychiatric Association's diagnostic classification system, DMS-4, and is grouped under the "impulse-control disorders not elsewhere classified causing clinically significant distress or impairment" (Table 69.3)[50]. However, many patients who chronically pull their hair do not meet all of the DSM-4 criteria for trichotillomania.

Individuals with trichotillomania may be a very heterogeneous group and include those with a mild habit as well as others who have an impulse-control disorder, personality disorder, body dysmorphic disorder, mental retardation or a psychosis[51]. Often the hair pulling that occurs during infancy and early childhood (boys>girls) resolves without treatment.

Clinical features

Individuals with trichotillomania usually pluck scalp hair, resulting in patchy or full alopecia of the scalp (see Ch. 7). Some patients may also pluck from other hair-bearing regions such as the eyebrows, eyelashes, face, extremities or pubic region. Patches of alopecia often have bizarre shapes, irregular borders, and contain hairs of varying lengths. Plucking may cause hair shaft fractures, and emerging shafts tend to feel "rough". In severe cases, hairs in the occiput tend to be spared. The clinical diagnosis can be supported by creating a "hair growth window" by repeatedly (weekly) shaving a small area of involved scalp to demonstrate normal, dense regrowth.

The histopathologic changes seen in trichotillomania are listed in Table 69.1. When incomplete or distorted follicular anatomy is found, suspected plucking is confirmed.

DSM-4 DIAGNOSTIC CRITERIA FOR TRICHOTILLOMANIA
1. Recurrent pulling out of one's hair resulting in noticeable hair loss
2. An increasing sense of tension immediately before pulling out the hair or when attempting to resist the behavior
3. Pleasure, gratification or relief when pulling out the hair
4. The disturbance is not better accounted for by another mental disorder and is not due to a general medical condition (e.g. a dermatologic condition)
5. The disturbance provokes clinically marked distress and/or impairment in occupational, social or other areas of functioning

Table 69.3 DSM-4 diagnostic criteria for trichotillomania.

The differential diagnosis includes tinea capitis, alopecia areata and monilethrix, which can be excluded by history, physical examination, trichoscopy, KOH examination, fungal culture and scalp biopsy. Trichoscopy findings are illustrated in Figure 69.5.

Treatment

No specific treatment approach has been established as effective in any large controlled study[52]. Hypnosis, behavioral modification therapy, insight-oriented psychotherapy and pharmacologic therapy have all been tried, but success rates are low. If a pharmacological therapy is considered, the recommended first-line medication is clomipramine. Selective serotonin reuptake inhibitors (SSRIs) have been tried without convincing success.

ALOPECIA AREATA

Key features

- Non-scarring patterned alopecia, most commonly presenting as circular areas of alopecia
- Organ-specific autoimmune disease involving T cells
- Can lead to total scalp hair loss (alopecia totalis) or complete scalp and body hair loss (alopecia universalis)

Introduction

Celsus is credited with describing patterns of hair loss using the Greek word *alopekia*, meaning fox mange, and Sauvages coined the term "alopecia areata". Alopecia areata is a non-cicatricial alopecia that is postulated to be a hair-specific autoimmune disease, with genetic factors involved in disease susceptibility and severity[53–55]. A concordance rate of 55% has been found in identical twin studies, implicating both genetic and environmental factors.

In the acute progressive stage of alopecia areata, lymphocytic infiltrates are seen around, and sometimes within, the hair bulb region of anagen follicles[31]. Despite the presence of this inflammatory infiltrate, the follicle retains its potential to produce hair, implying that the follicular stem cells remain viable.

The chronic relapsing nature of alopecia areata and its profound effect on physical appearance make the development of this condition a distressing and life-changing event for many affected individuals[56].

Epidemiology

The prevalence of alopecia areata in the US is approximately 0.1% to 0.2% of the population[57]. The average lifetime risk of developing alopecia areata is estimated to be 1.7%. Overall, one in five patients with alopecia areata reports that another family member has the disease.

Pathogenesis

T-lymphocyte interaction with follicular antigens (autoantigens) has been implicated in alopecia areata[53]. The importance of T cells in this disease has been demonstrated by several investigators. Sections of scalp skin from patients with alopecia areata will grow hair when engrafted onto congenitally athymic nude mice, and it is possible to transfer alopecia areata to human skin explants on SCID mice by the injection of scalp-infiltrating lymphocytes (both $CD4^+$ and $CD8^+$ T cells are required), but not with non-follicular scalp homogenates[58]. Melanocyte-associated antigens recognized by T cells might also function as possible autoantigens[59].

Normal anagen hair follicle keratinocytes typically lack expression of class I and class II major histocompatibility (MHC) antigens, suggesting immunologic privilege of the human hair follicle bulb[60]. In alopecia areata, human leukocyte antigens (HLA-A, -B, -C, -DR) become expressed by the hair follicle, allowing an interaction of cytotoxic T lymphocytes with hair matrix cells. In a recent genome-wide association study, single nucleotide polymorphisms were observed within the HLA region as well as in genes involved in the activation of regulatory T cells and natural killer cells (Table 69.4)[60a].

Clinical features

Alopecia areata commonly presents as round or oval patches of non-scarring hair loss (Fig. 69.9A). Short "exclamation point" hairs (i.e. distal end broader than the proximal end) can often be seen, particularly at the margins of areas of alopecia (Fig. 69.9B). Other presentations include alopecia totalis (loss of all scalp hair), alopecia universalis (loss of all scalp and body hair; Fig. 69.9C), and an ophiasis pattern (band-like pattern of hair loss along the periphery of the temporal and occipital scalp; Fig. 69.9D). The reticular variant is characterized by recurrent patchy disease, and patients experience hair loss in one area and, at the same time, spontaneous hair regrowth in another site. The rare diffuse variant of alopecia areata (see Fig. 69.9B) can manifest with widespread thinning or may primarily affect the top of the head. Non-pigmented hairs may initially be spared, and, as a result, some patients with diffuse involvement note rapid graying of the hair. With regrowth, the hairs may be initially gray or white, but usually repigmentation is observed within a few weeks or months[61].

In addition to the hair follicle, nails may be involved. The most common abnormality is nail pitting, but other changes described include trachyonychia (sandpaper-like roughness due to excessive longitudinal ridging; Fig. 69.9E), brittle nails, onycholysis, koilonychia and, rarely, onychomadesis[62] (see Ch. 71).

Disease associations are listed in Table 69.4. The histopathologic features of alopecia areata (Fig. 69.10) are described in Table 69.1, and trichoscopy findings are shown in Figure 69.5.

Differential diagnosis

Tinea capitis, trichotillomania, temporal triangular alopecia, traction alopecia, secondary syphilis and loose anagen syndrome need to be considered in the differential diagnosis of alopecia areata, in addition to pressure-related alopecia, aplasia cutis and "burnt-out" cicatricial alopecia. The diffuse variant may initially be confused with telogen effluvium and androgenetic alopecia. Usually, the history and clinical examination (including trichoscopy) is sufficient to distinguish between these conditions, but performing a scalp biopsy may prove useful.

Treatment

Treatment studies are difficult to perform because the disease has an unpredictable course and may improve on its own. To allow for the evaluation of treatments for alopecia areata, guidelines have been established to facilitate research[63].

Numerous therapies are available for the management of alopecia areata[53,64] (Table 69.5), and several can be utilized in combination. The treatment of patchy alopecia areata may include topical[65] or intralesional corticosteroids[66], topical minoxidil (2% or 5%), topical anthralin (0.5–1% cream applied daily; see Ch. 129), and combination therapy. The concentration of intralesional corticosteroid is usually 3–5 mg/ml of triamcinolone acetonide, and injections can be repeated every 4–8 weeks. This medication should be injected at the level of the mid dermis to target the diseased, miniaturized hair bulbs.

A dependable and safe treatment for extensive disease (totalis or universalis) has yet to be found, although spontaneous recovery is

Fig. 69.9 Alopecia areata. A Circular area of alopecia in a child. **B** Diffuse variant with multiple exclamation point hairs characterized by a distal end that is broader than the proximal end. **C** Total alopecia of the scalp, eyebrows and eyelashes in a patient with alopecia universalis. **D** Ophiasis with a band-like pattern of hair loss along the periphery of the temporal and occipital scalp. **E** Trachyonychia in a patient with alopecia areata. *B & E, Courtesy, Julie V Schaffer, MD.*

possible (albeit rarely), even in longstanding disease. Approximately 80% of patients will respond to high-dose systemic corticosteroids (e.g. 40 mg triamcinolone intramuscularly monthly, or daily oral prednisolone or dexamethasone tapered over 6–8 weeks); however ~50% will relapse with dose reduction or cessation of therapy[67]. Long-term maintenance therapy with oral corticosteroids is rarely justified and steroid-sparing agents such as azathioprine and methotrexate are unreliable.

Topical immunotherapy (with diphencyprone or squaric acid dibutyl ester) is the most promising treatment for extensive disease[62]. Clinicians interested in using topical immunotherapy should carefully review the published protocols[62] (Table 69.6). PUVA, potent topical corticosteroids under plastic occlusion, and systemic targeted immunomodulators ("biologics") have all been tried with less success. Of note, patients with the ophiasis pattern of hair loss are more resistant to therapy than are other patients with similar amounts of hair loss.

ALOPECIA AREATA: DISEASE AND GENETIC ASSOCIATIONS
• Associated diseases: – Atopy (allergic rhinitis, atopic dermatitis, asthma); >40% in some studies – Autoimmune thyroid disease (e.g. Hashimoto's thyroiditis), vitiligo, inflammatory bowel disease – Autoimmune polyendocrinopathy syndrome type 1 (autosomal recessive; due to mutations in the autoimmune regulator gene [*AIRE*]; up to 30% of patients have alopecia areata) – Type 1 diabetes increased in *relatives* of patients with alopecia areata • HLA associations: – HLA-DQB1*0301 (DQ7), HLA-DQB1*03 (DQ3), and HLA-DRB1*1104 (DR11); HLA-DQB1*03 appears to be a susceptibility HLA marker for all forms of alopecia areata, whereas the HLA alleles DRB1*0401 (DR4) and HLA-DQB1*0301 (DQ7) are considered markers for severe longstanding alopecia totalis/universalis[54,55] • Additional genome-wide associations[60a]: – Function of Treg cells: *CTLA4, IL-2/IL-21, IL2RA, Eos* – Expressed within the hair follicle: *PRDX5, STX17* – *ULBP* gene cluster - encodes activating ligands of NK cell receptor NKG2D

Table 69.4 Alopecia areata: disease and genetic associations. *PRDX5* encodes an anti-oxidant enzyme and *STX17* is associated with the gray hair phenotype in horses. CTLA4, cytotoxic T lymphocyte-associated antigen 4; IL, interleukin, IL-2RA, interleukin receptor A; ULBP, cytomegalovirus UL16-binding protein.

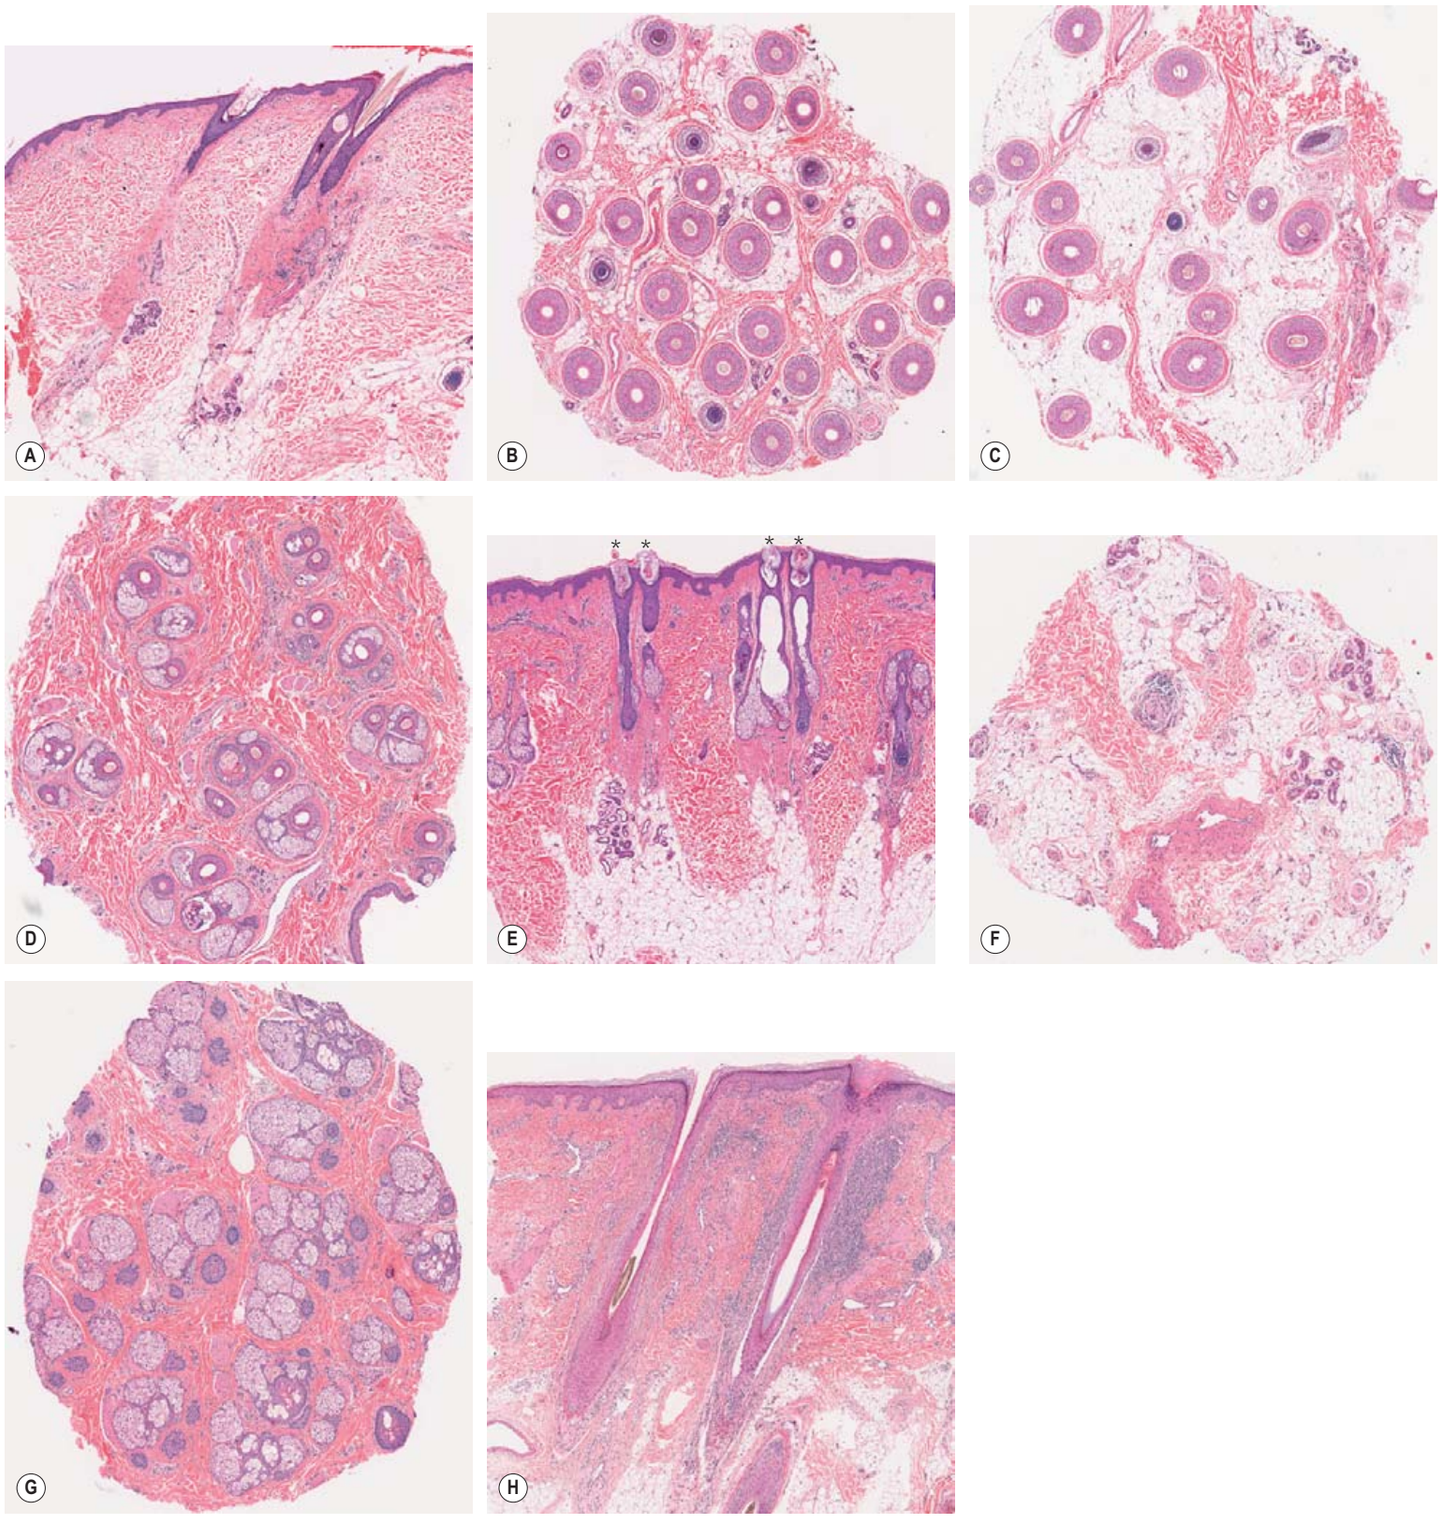

Fig. 69.10 Histologic features of androgenetic alopecia, alopecia areata and lichen planopilaris. A Androgenetic alopecia with the characteristic miniaturization of hair follicles (vertical section). **B** Normal scalp (horizontal section). **C** Androgenetic alopecia with variation in hair follicle size (horizontal section; compare to B). **D** Androgenetic alopecia at the level of the isthmus with miniaturized vellus-like hair follicles and no significant inflammation (horizontal section). **E** Alopecia areata with miniaturized, vellus-like hair follicles, one of which has a peribulbar lymphocytic infiltrate (vertical section). A clue to the diagnosis is the dilatation of the follicular infundibula which corresponds to the yellow dots by trichoscopy (asterisks)[14]. **F** Alopecia areata with the characteristic peribulbar lymphocytic infiltrates (horizontal section). **G** Alopecia areata at the level of the isthmus demonstrating exclusively telogen follicles (horizontal section). **H** Lichen planopilaris. Focal hypergranulosis at the acrotrichium and a dense perifollicular lymphocytic infiltrate. Note the Max-Joseph spaces between the hair follicle and the perifollicular sheath.

The treatment of eyebrows with intralesional corticosteroids is usually helpful, even in extensive cases. When eyelashes are absent, the wearing of eyeglasses can serve as a distracting cosmetic enhancement. All patients should be directed to the resources provided by the National Alopecia Areata Foundation (www.naaf.org) for a wealth of information about support groups, wigs, cosmetics and the latest research.

Lastly, two animal models, the *C3H/HeJ* mouse model and the Dundee rat model, are now available to investigators to help with the development, testing and analysis of new forms of therapy[68].

TREATMENT OPTIONS FOR THE MANAGEMENT OF ALOPECIA AREATA
Topical and intralesional corticosteroids (1) Topical irritants (e.g. anthralin, tazarotene, azelaic acid) (2) Topical minoxidil (2)
Topical immunotherapy (e.g. squaric acid dibutyl ester, diphencyprone) (1) Systemic corticosteroids, pulsed dosing* (especially if rapidly progressive) (2) Topical or oral photochemotherapy (PUVA) (2) Excimer laser (3) Photodynamic therapy (3)
Systemic corticosteroids, chronic (2) Systemic cyclosporine (3)
*e.g. oral prednisolone 300 mg (5 mg/kg for children) monthly for a minimum of three doses.

Table 69.5 Treatment options for the management of alopecia areata. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

TOPICAL IMMUNOTHERAPY FOR ALOPECIA AREATA
TREATMENT PROTOCOL FOR DIPHENCYPRONE (DPCP) OR SQUARIC ACID DIBUTYL ESTER (SADBE)*
• Sensitize with a 2% solution in acetone applied to a 4 × 4 cm area on one side of the scalp • After 1 week (2 weeks if the initial reaction is severe), a 0.001% solution is applied to all affected areas on the same side of the scalp • Each week, DPCP or SADBE is applied to the same side of the scalp – The *concentration* is titrated according to the severity of the reaction the previous week, with a goal of maintaining a low-grade, tolerable degree of erythema, scaling and pruritus for 24–36 hours after application – *Concentrations* are increased incrementally as follows: 0.001%, 0.01%, 0.025%, 0.05%, 0.1%, 0.25%, 0.5%, 1%, 2% • Once hair growth is established, the other side is also treated • Initial responses are usually seen after 12 weeks, and therapy is discontinued if there is no response by 24 weeks • Frequency of treatment can be decreased in the presence of full regrowth
ADDITIONAL INFORMATION
• Acetone solutions should be applied using a generous amount of cotton at the end of a wooden stick† • Following application: – The sensitizer is left on the scalp for 48 hours, then washed off – *Patients* should avoid touching the scalp for 6 hours – The *scalp* should be protected from light to avoid degradation of DPCP • SADBE must be refrigerated • Side effects include lymphadenopathy, severe or widespread eczematous reactions, and postinflammatory pigment alterations (particularly in patients with darkly pigmented skin)
CONTRAINDICATIONS
• Pregnancy (although teratogenicity has not been established) • Malignancies and blood dyscrasias
*Not FDA-approved. †Application by medical personnel is recommended.

Table 69.6 Topical immunotherapy for alopecia areata.

OTHER NON-CICATRICIAL (NON-SCARRING) ALOPECIAS

Postoperative (Pressure-Induced) Alopecia

This form of hair loss is seen most commonly in patients who have undergone lengthy surgical procedures under general anesthesia, and who had one portion of their scalp in prolonged contact with the operating table[69]. Less commonly, the condition is found in patients who sustain blunt trauma to the scalp[70,71].

Postoperative alopecia typically presents as a solitary, roughly oval patch at the site of greatest pressure, usually the upper occiput. Early on, erythema and induration are found in the central portion of the affected area. Nearly total hair loss with fairly sharp demarcation from the surrounding scalp occurs just a few weeks after the initial trauma. Usually, complete hair regrowth occurs, although several cases of permanent (i.e. cicatricial) hair loss have been reported.

The histologic findings in postoperative alopecia change as the lesion evolves (see Table 69.1)[15].

Temporal Triangular Alopecia

Also known as congenital triangular alopecia, temporal triangular alopecia may be present at birth or acquired during the first decade of life[72]. Rarely, lesions occur outside the temporal area or present during adulthood. The lancet-shaped lesions are a few centimeters in width, may be unilateral or bilateral, and are oriented so that that the tip of the "lancet" points superiorly and posteriorly (Fig. 69.11). Lesions appear hairless, but very fine vellus hairs can be seen with magnification and trichoscopy (see Fig. 69.5). Once present, the patches of alopecia persist for life.

Microscopically, there are *normal* numbers of follicles, but almost all are vellus hairs. All other features of the epidermis, dermis and other adnexa are entirely normal, and inflammation is absent.

Lipedematous Alopecia (Lipedematous Scalp)

This scalp disease does not fit well into any particular category. Coskey[73] first used the term "lipedematous alopecia" to describe a disorder of unknown cause characterized by a thick boggy scalp vertex and hair loss[73–75]. This disease has been described primarily in women with darkly pigmented skin and its coexistence in some patients with central vertex hair loss has raised the possibility of an association with central centrifugal cicatricial alopecia. The primary pathologic finding is an approximate doubling of scalp thickness as a result of edema and subsequent expansion of the subcutaneous fat layer. If there is prominent alopecia, histopathologic changes include not only a thickened adipose layer, but also replacement of hair follicles with fibrous tracts without discernible inflammation[76,77]. Surgery may be appropriate for small, well-circumscribed areas of alopecia[78].

In some instances, there is little or no alopecia[75], and so Lee and colleagues[79] have suggested that such cases be called lipedematous scalp, rather than lipedematous alopecia.

Fig. 69.11 Temporal triangular alopecia. The tip of the "lancet" points superiorly. *Courtesy, Jean L Bolognia, MD.*

Psoriasis of the Scalp and TNF-α Inhibitor-Induced Psoriasiform Alopecia

The occurrence of alopecia in the context of psoriasis is more common than expected. Usually, the alopecia is circumscribed (75%), rather than diffuse (25%)[80]. A specific finding is hair loss in tufts as thick psoriatic plaques are shed from the scalp. The latter can coincide with

antipsoriatic therapy[80]. Only rarely will psoriasis of the scalp lead to a scarring alopecia[81,82].

More recently, psoriasiform scalp alopecia has been observed in patients (with or without a history of psoriasis) receiving TNF-α inhibitors, in particular infliximab and adalimumab[83]. In protracted cases, scarring alopecia may ensue[83]. Histologically, the findings can vary (see Table 69.1).

Congenital Atrichia with Papules

This very rare condition is discussed because the genetic background of the disease has been well characterized[84]. Affected individuals fail to regrow nearly all their hair after shedding their initial growth of hair shortly after birth. Follicular cysts and milia-like lesions appear on the skin in later life[85]. This phenotype has been associated with mutations in two different genes: the *hairless* gene on chromosome 8p21 and the vitamin D receptor gene on chromosome 12q12–q14, explaining the associated vitamin D-dependent rickets. Additional inherited disorders with alopecia, in which the genetic bases are known, are outlined in Table 69.7.

CICATRICIAL (SCARRING) ALOPECIAS

Introduction

In this chapter, the terms *cicatricial alopecia* and *scarring alopecia* will be considered synonymous. "Cicatricial" or "scarring" implies that follicular epithelium has been replaced by connective tissue. The broadest definition of scarring alopecia might include all forms of alopecia

INHERITED DISORDERS WITH HYPOTRICHOSIS AND/OR HAIR SHAFT ABNORMALITIES			
Disorder	**Mode of inheritance**	**Gene or gene product**	**Gene symbol**
INHERITED DISORDERS WITH HYPOTRICHOSIS AND/OR HAIR SHAFT ABNORMALITIES			
Argininosuccinic aciduria*	AR	Argininosuccinate lyase	*ASL*
Atrichia with papular lesions	AR	Hairless (zinc finger transcription factor)	*HR*
Björnstad syndrome	AR	BCS1-like (mitochondrial membrane protein)	*BCS1L*
Cartilage–hair hypoplasia (Ch. 60)	AR	RNA component of mitochondrial RNA-processing endoribonuclease	*RMRP*
Giant axonal newuropathy with curly hair	AR	Gigaxonin	*GAN*
Hypohidrotic ectodermal dysplasia	X-linked AD	Ectodysplasin-A Ectodysplasin anhidrotic receptor gene or the EDAR-associated death domain gene	*EDA1* *EDAR or EDARADD*
Hypotrichosis, Mari type	AR	Lipase H	*LIPH*
Hypotrichosis, Marie Unna type	AD	5 prime upstream open reading frame of *HR* (hairless) gene	*HR*
Hypotrichosis simplex	AD	Adenomatosis polyposis down-regulated 1 gene	*APCDD1*
Hypotrichosis simplex of the scalp	AD	Corneodesmosin	*CDSN*
Hypotrichosis with juvenile macular dystrophy	AR	Cadherin 3 (P-cadherin)	*CDH3*
Keratosis follicularis spinulosa decalvans (KFSD)	XR	Membrane-bound transcription factor peptidase, site *2*	*MBTPS2*
Keratosis, ichthyosis and deafness	AD	Connexin-26	*GJB2*
Laron syndrome (pituitary dwarfism II)	AR	Growth hormone receptor	*GHR*
Localized autosomal recessive hypotrichosis	AR	Desmoglein 4	*DSG4*
Menkes disease†	XR	Cu^{2+}-transporting P-type ATPase 7A	*ATP7A*
Monilethrix	AD AD AD AR	Keratin 81 Keratin 83 Keratin 86 Desmoglein 4	*KRT81* *KRT83* *KRT86* *DSG4*
Netherton syndrome	AD	Serine protease inhibitor LEKTI	*SPINK5*
Pure hair nail ectodermal dysplasia	AD	Keratin 85, KRTHB5 gene	*KRT85*
T-cell immunodeficiency and congenital alopecia (Ch. 60)	AR	Forkhead box N1 (winged helix nude)	*FOXN1*
Trichothiodystrophy (TTD)	AR AR AR AR	XPB; TFIIH subunit, DNA helicase (functions in nucleotide excision repair and as a basal transcription factor) XPD; TFIIH subunit, DNA helicase (functions in nucleotide excision repair and as a basal transcription factor) General TFIIH, polypeptide 5 (TTDA; functions in nucleotide excision repair and as a basal transcription factor) Chromosome 7 open reading frame 11 (TTD-nonphotosensitive 1)	*ERCC3* *ERCC2* *GTF2H5* *C7orf11*
Vitamin D-dependent rickets with alopecia	AR	Vitamin D receptor	*VDR*

*Pili torti has also been observed in patients with other urea cycle defects such as citrullinemia.
†Allelic with occipital horn syndrome (see Table 55.5).

Table 69.7 Inherited disorders with hypotrichosis and/or hair shaft abnormalities. Hair and/or nail abnormalities can also be observed in patients with disorders of keratinization, epidermolysis bullosa and ectodermal dysplasias (see Tables 55.3, 32.1 & 55.5). AD, autosomal dominant; AR, autosomal recessive; ERCC, excision repair cross-complementing; mt, mitochondrial inheritance; TFIIH, transcription factor IIH; XP, xeroderma pigmentosum; XR, X-linked recessive. *Courtesy, Julie V Schaffer, MD.*

in which hair follicles are permanently lost. In most cases, it is assumed that *permanent injury of the follicular stem cell region has occurred*. In contrast, non-scarring alopecia is potentially reversible. A few hair diseases demonstrate a *biphasic* pattern, where non-scarring hair loss is seen *early* in the course of the disease, and permanent hair loss becomes apparent in the *later* stages of the disease[27]. Examples include androgenetic alopecia, alopecia areata and traction alopecia. These forms of alopecia are generally considered to be non-scarring. However, after many years or decades of continuous active disease, permanent dropout of follicles occurs.

In *primary* scarring alopecia, the target of inflammation appears to be the follicle. In *secondary* scarring alopecia, the follicle is merely an "innocent bystander" in the disease process. Examples of secondary scarring alopecia include deep burns, radiation dermatitis, cutaneous malignancies, cutaneous sarcoidosis, morphea, necrobiosis lipoidica, and certain chronic infections such as cutaneous tuberculosis. The various forms of secondary scarring alopecia should have distinctive clinical and histologic features typical of the underlying disease.

Performing a scalp biopsy may be helpful not only in establishing a diagnosis but also in assessing the degree of inflammation and injury to the stem cell region. Specimens should be at least 4 mm in diameter and extend into the fat. Ideally, two should be obtained – one for vertical sectioning, the other for horizontal sectioning. Recently, a HoVert technique was described in which a 4mm punch biopsy is transected ~1mm below the skin surface in order to create an epidermal disc (for vertical sections) and a lower portion (for horizontal sections)[85a].

The classification of primary cicatricial alopecia is both confusing and controversial[16,86]. Most of these diseases demonstrate some overlap in clinical and histologic features, blurring the distinction between disorders. In 2001, a North American Hair Research Society workshop developed a *provisional* classification (Table 69.8) to facilitate future discussion and research[86]. This scheme divides the entities into "lymphocytic", "neutrophilic", and "mixed lymphocytic and neutrophilic" forms[27,86–89].

Even advocates of this classification scheme, which is based on histologic findings, have found that it can fail to achieve reliable clinicopathologic correlation[88]. For the sake of simplicity, primary, inflammatory cicatricial alopecia can be divided into six diagnostic groups[15,16]. They are:

- central centrifugal cicatricial alopecia
- lichen planopilaris
- discoid lesions of lupus erythematosus
- acne keloidalis (folliculitis keloidalis, acne keloidalis nuchae)
- dissecting cellulitis (perifolliculitis abscedens et suffodiens)
- cicatricial alopecia, not otherwise classified.

Older terms such as pseudopelade, pseudopelade of Brocq, and folliculitis decalvans are poorly defined, and they are used in various ways by different authors and clinicians. Almost all of these older terms can be incorporated into one of the six categories already listed. However, some of the older terms (as well as some newer ones such as "tufted folliculitis") will be discussed in this section for the sake of clarity. End-stage traction alopecia will also be discussed in this section because it has many of the features of a cicatricial alopecia.

PROPOSED WORKING CLASSIFICATION OF PRIMARY CICATRICIAL ALOPECIA
GROUP 1: LYMPHOCYTIC
• Discoid lesions of lupus erythematosus (see Ch. 41) • Lichen planopilaris (LPP; see Ch. 11) – Classic LPP – Frontal fibrosing alopecia – Graham Little syndrome • Classic pseudopelade (*Brocq's alopecia* is the author's preferred term) • Central centrifugal cicatricial alopecia • Alopecia mucinosa (see Ch. 46) • Keratosis follicularis spinulosa decalvans (see Ch. 38) • Graft-versus-host disease
GROUP 2: NEUTROPHILIC
• Folliculitis decalvans • Dissecting cellulitis
GROUP 3: MIXED
• Acne keloidalis (see Ch. 38) • Acne necrotica • Erosive pustular dermatosis (see Ch. 87)
GROUP 4: NONSPECIFIC
• Cicatricial pemphigoid (see Ch. 30) • Busulfan-induced alopecia

Table 69.8 Proposed working classification of primary cicatricial alopecia. Adapted from ref. 86.

Central Centrifugal Cicatricial Alopecia

Synonyms: ■ Hot comb alopecia ■ Follicular degeneration syndrome ■ Pseudopelade of the central scalp ■ "Folliculitis decalvans" of the central scalp and vertex (for the highly inflammatory form)

Key features

- Slowly progressive, symmetric cicatricial alopecia centered on the crown or vertex
- Most often found in black women of African descent
- Early and mild disease can be effectively treated

Introduction

Over the years, central centrifugal cicatricial alopecia (CCCA) has been given several names because the condition is characterized by a spectrum in the degree and type of inflammation, resulting in some clinical variation[16,90–92]. All variants of CCCA have the following features in common:

- chronic and progressive disease, with eventual spontaneous "burn out" after years or decades
- disease predominantly centered on the crown or vertex
- disease that expands in a roughly symmetric fashion, with the greatest disease activity occurring in a peripheral zone of variable width, surrounding a central, alopecic zone
- clinical or histologic evidence of inflammation in the active, peripheral zone.

Epidemiology

CCCA is the most common form of scarring alopecia in any population that includes a significant number of black patients. Among African-Americans, CCCA is responsible for more cases of scarring alopecia than all other forms combined. The majority of black patients with CCCA are women, with a female: male ratio of about 3 : 1[91,92].

Pathogenesis

Caustic hair care products or the use of "hot combs" may aggravate the disease or hasten its progression, but cannot fully explain its pathogenesis. Virtually all African-American women with CCCA are using or have used chemical hair relaxers for styling purposes, but few men have used anything except pomades. Patients experience progression of the disease even after all chemical treatments (if any) are discontinued.

The current hypothesis is that patients are predisposed to follicular damage because of an anatomic abnormality, namely premature desquamation of the inner root sheath (IRS)[16,91,92]. Premature desquamation of the IRS can be observed in follicles that are otherwise normal, suggesting that it represents a very early phase of the disease. This change can occasionally be seen in other conditions in which follicles are subject to marked inflammation and degenerative changes. However, as a manifestation of *early* disease, premature IRS desquamation may be unique to CCCA and may predispose the affected follicles to injury or inflammation.

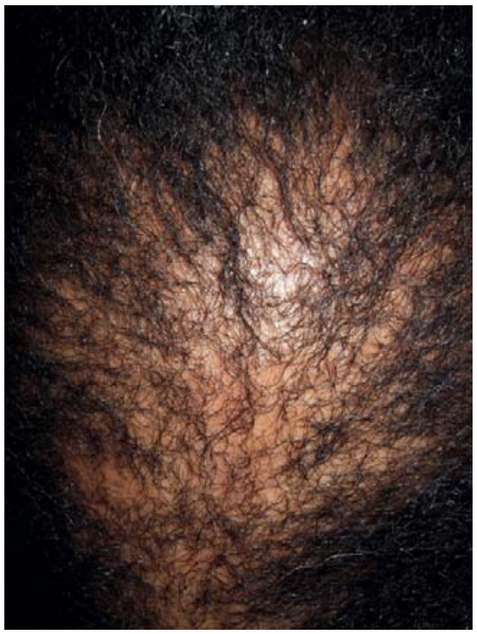

Fig. 69.12 Central centrifugal cicatricial alopecia in an African-American woman. Alopecia is most prominent on the crown and/or vertex.

Clinical features

The disease begins and remains most severe on the crown or vertex of the scalp, gradually expanding in a centrifugal fashion (Fig. 69.12). Symptoms may be mild or absent. Most patients note only mild, episodic pruritus or tenderness of involved areas. A few isolated hairs, some showing polytrichia (tufting as in "baby doll hair" or a hair brush), may be stranded in the otherwise denuded central zone. Longstanding or severe disease can result in hair loss covering the entire crown of the scalp.

Pustules and crusting may be found in the minority of patients who suffer from rapidly progressive disease or bacterial superinfection ("folliculitis decalvans")[93,94]. The pustules of CCCA are most likely a manifestation of bacterial superinfection and/or the immune response of the patient to degenerating follicular components[16]. However, some authors have argued that "folliculitis decalvans" is a primary staphylococcal infection[94]. In any case, a 2- to 3-week course of antibiotics or systemic corticosteroids can temporarily eliminate the purulent component of CCCA.

Pathology

The most productive area for biopsy is the peripheral, partially alopecic fringe, but even apparently "normal" scalp several centimeters from the clinically involved area may be diseased at the microscopic level. In most cases, transverse sections at several levels are required for a definitive diagnosis. Involved follicles will demonstrate some or all of the histopathologic features listed in Table 69.1.

Differential diagnosis

All conditions that can result in a progressive pattern of alopecia affecting the crown can mimic CCCA. These include male and female pattern alopecia, lichen planopilaris, and even unusual cases of chronic cutaneous lupus erythematosus. Other entities in the differential diagnosis are tinea capitis (kerion) and true bacterial infections of the scalp. Those who contend that "folliculitis decalvans" is a separate entity would add it to the list.

Treatment

For relatively non-inflammatory disease, a combination of a long-acting oral tetracycline (e.g. doxycycline or minocycline) plus a potent topical corticosteroid (e.g. clobetasol or fluocinonide) is usually sufficient to halt progression. Prolonged treatment for years is usually required for this chronic disease. For highly inflammatory cases ("folliculitis decalvans"), an initial 10-week regimen of oral rifampin and clindamycin (both at 300 mg twice daily) was very effective in a non-blinded, non-controlled study[94]. Maintenance therapy (such as oral doxycycline plus topical clobetasol) should follow.

Lichen Planopilaris

Key features

- Inflammatory, cicatricial alopecia with several different patterns of hair loss
- Most common cause of Brocq's alopecia (end-stage cicatricial alopecia)
- Frontal fibrosing alopecia is a distinctive clinical subset
- Can be very resistant to treatment

Introduction

Lichen planopilaris (LPP) affects women more often than men, and Caucasians are more often affected than dark-skinned individuals. Up to 50% of patients may develop lesions of the glabrous skin and mucous membranes or nail changes characteristic of lichen planus (see Ch. 11)[68]. Like lichen planus, the etiology of LPP is not known, but is presumably related to the cause(s) of lichen planus.

Clinical features

The clinical course of hair loss in LPP may be insidious or fulminant and the pattern highly variable. Patients with indolent scalp disease may be asymptomatic, but pruritus and tenderness are often present. Most commonly, there are several scattered foci of partial hair loss with associated perifollicular erythema, follicular spines and scarring (Fig. 69.13). A pattern of hair loss suggestive of central centrifugal cicatricial alopecia or Brocq's alopecia can also occur[17,95]. The diagnosis of LLP *cannot* be based on clinical features alone.

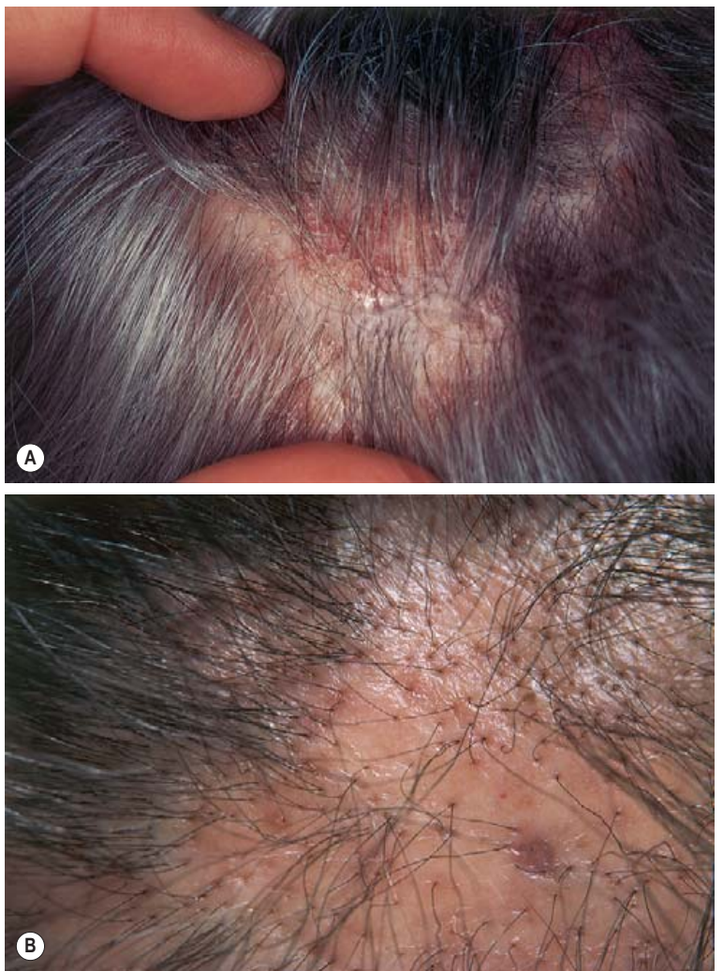

Fig. 69.13 Lichen planopilaris. A Perifollicular erythema in association with scale. **B** Later stage showing scarring with loss of follicular openings, but less erythema. *A, Courtesy, Jean L Bolognia, MD.*

Fig. 69.14 Frontal fibrosing alopecia. Progressive hair loss along the anterior hairline. *Courtesy, Kalman Watsky, MD.*

A condition termed "frontal fibrosing alopecia" was initially reported in several Australian, postmenopausal, Caucasian women[96,97]. Although most patients are elderly women (mean age in one series, 67 years), an identical pattern of hair loss has been observed in premenopausal women. There is progressive hair loss along the anterior hairline (Fig. 69.14) and the eyebrows. The histopathologic features are similar to those found in LPP. Frontal fibrosing alopecia appears to be just one of several clinical patterns of hair loss that can be seen in LPP. However, lesions of lichen planus are usually not found elsewhere in these patients and the lichenoid inflammation does not affect the interfollicular epidermis.

Possibly related to LPP is the Graham Little syndrome. This rare condition is characterized by patchy cicatricial alopecia of the scalp, non-scarring alopecia of the axillary and pubic areas, and grouped spinous follicular papules resembling lichen spinulosus or keratosis pilaris on the trunk and extremities (see Ch. 11)[89].

Pathology

The histopathologic features of LPP are listed in Table 69.1 and illustrated in Figure 69.10; the trichoscopy features are seen in Figure 69.5.

Treatment

LPP can be difficult to treat. Therapeutic recommendations include oral antimalarial drugs (e.g. hydroxychloroquine) and corticosteroids (topical, intralesional and oral)[89,97a,97b]. Recently, pioglitazone hydrochloride (a PPAR-γ agonist) was used with reported success[98]. Various other anecdotal or uncontrolled studies have reported that oral cyclosporine, oral mycophenolate mofetil, systemic retinoids or low-dose weekly oral methotrexate may be effective in some patients. These latter treatments should be used with caution, and they may themselves cause some degree of alopecia or potentially serious side effects. While some cases of LPP may burn out spontaneously, many others progress for years.

Discoid Lesions of Lupus Erythematosus

Synonym: ■ Scarring alopecia of lupus erythematosus

Key features

- Discoid lesions of lupus erythematosus occur most commonly on the face, ears and scalp
- Various clinical patterns of scalp involvement can be found
- Histopathologic findings can resemble those found in lichen planopilaris

Fig. 69.15 Late-stage chronic lupus erythematosus. Burnt-out discoid lesions of lupus erythematosus mimicking Brocq's alopecia.

Introduction

Discoid lesions are a form of cutaneous lupus erythematosus (LE) that can occur in patients with chronic cutaneous LE or systemic LE (see Table 41.2). Discoid lesions usually occur in adults, and are more common in women. Although discoid lesions are seen in patients with systemic LE, the majority of patients do not have systemic disease[99]. Among patients with skin disease only, about 50% will have scalp lesions, and very few of the patients with discoid lesions confined to the scalp will ever develop systemic LE[100].

Clinical features

The diagnosis of discoid lesions of LE requires histologic confirmation and cannot be based solely on the clinical appearance of scalp lesions. They may resemble classic discoid lesions elsewhere (see Ch. 41), with erythema, epidermal atrophy, and dilated, plugged follicular ostia in addition to alopecia. Central hypopigmentation and peripheral hyperpigmentation are commonly seen in dark-skinned individuals. However, the distribution and degree of clinical inflammation varies among patients, and the scalp lesions may resemble alopecia areata, lichen planopilaris, linear morphea, central centrifugal cicatricial alopecia or Brocq's alopecia (Fig. 69.15)[15]. Although pruritus or tenderness is common, the condition may be asymptomatic.

Pathology

The histopathologic findings are listed in Table 69.1 and trichoscopy findings in Figure 69.5.

Treatment

Discoid lesions usually respond to oral antimalarial drugs (e.g. hydroxychloroquine) and corticosteroids (topical, intralesional and oral) (see Ch. 41)[89]. If initiated early, a surprising amount of regrowth can occur. Various anecdotal or uncontrolled studies have reported that oral medications including cyclosporine, mycophenolate mofetil, retinoids, thalidomide and low-dose weekly methotrexate may be effective in some patients.

Acne Keloidalis

Synonyms: ■ Acne keloidalis nuchae ■ Folliculitis keloidalis

Key features

- Most common in black men, but can occur in women and Caucasians
- A primary form of cicatricial alopecia
- Often occurs in conjunction with central centrifugal cicatricial alopecia

Introduction

Acne keloidalis typically affects young black men and occasionally young black women[15,16,101,102]. It is at least 10 times more common in blacks than in whites and comprises nearly 0.5% of all dermatologic conditions in the black population[103]. However, this disorder can occur in white men and on rare occasion in white women.

Pathogenesis

The cause of acne keloidalis remains undetermined. The notion that lesions are caused by "ingrowing" hairs, analogous to the situation in pseudofolliculitis barbae, has been disproved[102]. Acne keloidalis is frequently found in association with central centrifugal cicatricial alopecia (CCCA), suggesting a common or related pathogenesis. Occasionally, the papular lesions and hair loss of acne keloidalis extend up onto the vertex of the scalp, producing a clinical "overlap" between this disorder and CCCA. In biopsy specimens, special stains for bacteria demonstrate relatively few organisms, suggesting that bacterial overgrowth is not of pathogenetic importance.

Clinical and histopathologic features

Acne keloidalis begins as small, smooth, firm papules admixed with occasional pustules on the occipital scalp and posterior neck (see Ch. 38). In a minority of patients, lesions are more numerous on the vertex and crown, and so it is best to use the term acne keloidalis without the modifier *nuchae*. With time, the papules resolve and leave small zones of alopecia within a field of papular lesions. In many patients, the papules coalesce and form firm, hairless, keloid-like protuberant plaques (hence the term *keloidalis*) that can be painful and cosmetically disfiguring. Abscesses and sinuses exuding pus may be present in advanced cases.

The histopathologic findings[102] are listed in Table 69.1.

Treatment

Treatment is easiest and most effective when instituted during the early (papular) phase. In the authors' experience, a regimen involving the chronic use of a potent topical corticosteroid such as clobetasol and a long-acting oral antibiotic such as doxycycline is effective in halting progression of the disease. Treatment of large keloidal lesions requires surgical excision below the level of the hair bulbs.

Dissecting Cellulitis of the Scalp

Synonym: ■ Perifolliculitis capitis abscedens et suffodiens

Key features

- A component of the "follicular occlusion tetrad"
- Early disease spares the hair follicles
- Inflammation is deep (subcutaneous fat and deep dermis)

Introduction

Dissecting cellulitis is an uncommon but distinctive and often debilitating disease. It is part of the "follicular occlusion triad" that includes hidradenitis suppurativa and acne conglobata (see Ch. 38) or tetrad that includes pilonidal sinus. However, isolated scalp disease is often seen. Dissecting cellulitis most commonly affects young adult men, especially black men, but can be seen (albeit rarely) in Caucasians and women[15,104–106]. Although follicular hyperkeratosis rather than infection is thought to play a primary role in pathogenesis, bacterial superinfection can occur.

Clinical and histopathologic features

Lesions begin as multiple, firm scalp nodules, most commonly on the mid and posterior vertex and upper occiput. The nodules rapidly develop into interconnecting, boggy, fluctuant, oval and linear ridges that eventually discharge purulent material (Fig. 69.16). There can be surprisingly little pain, and patients often seek help because of hair loss and a foul-smelling discharge.

Fig. 69.16 Dissecting cellulitis of the scalp and acne keloidalis in an African-American man.

The histopathologic findings are listed in Table 69.1.

Differential diagnosis

On rare occasions, tinea capitis can mimic dissecting cellulitis. Other highly inflammatory forms of cicatricial alopecia (particularly "folliculitis decalvans") can sometimes be confused with dissecting cellulitis.

Treatment

Various case reports indicate that isotretinoin (0.5–1.5 mg/kg daily until 4 months after achieving a clinical remission) may be an effective therapy for this condition[107], although relapses are common. Unfortunately, isotretinoin is not always effective. TNF-α inhibitors have been used with success[11,108] but to date have not been critically studied. Other treatment options include intralesional corticosteroids, oral antibiotics, and surgical approaches ranging from incision and drainage to excision with grafting.

Cicatricial Alopecia, Not Otherwise Classified

The diagnosis of "inflammatory cicatricial alopecia" or "burnt-out cicatricial alopecia" is preferable to coining a new or seemingly "specific" name for every puzzling clinical and histologic variation that is encountered.

"Burnt-out" or "end-stage" cicatricial alopecia

In patients with progressive hair loss, the diagnosis of "burnt-out cicatricial alopecia" invites additional biopsy specimens[15]. Although the patient's disease may truly be in remission, more often the histologic pattern of "end-stage" disease is due to sampling of an older, inactive portion of the lesion. The histologic findings are listed in Table 69.1.

Brocq's alopecia (Pseudopelade of Brocq)

In the authors' opinion, the term "pseudopelade of Brocq"[109,110] is a source of much confusion and should be abandoned. Brocq's alopecia is not a distinct disease but rather a clinical *pattern* of end-stage cicatricial alopecia. This pattern can be seen in lichen planopilaris, discoid lupus erythematosus and other forms of cicatricial alopecia[16,17,95]. If a definitive diagnosis of another form of cicatricial alopecia can be made, the term "Brocq's alopecia" cannot be used.

Brocq's alopecia is uncommon and usually affects Caucasian adults who discover discrete, asymptomatic areas of scalp hair loss. In some patients, the disease is slowly progressive, but in others it worsens in "spurts", with periods of activity followed by "dormant" periods. Brocq's alopecia results in irregularly shaped and often widely distributed and grouped bald patches on the scalp (Fig. 69.17)[111]. Patients with exclusive crown or vertex involvement may actually represent examples of "burnt-out" central centrifugal cicatricial alopecia (CCCA).

In most cases of Brocq's alopecia, the expected histologic findings are those of a "burnt-out" cicatricial alopecia.

Fig. 69.18 "Tufted folliculitis". Note the multiple hairs arising from a single follicular orifice within the area of scarring alopecia. *Courtesy, Kalman Watsky, MD.*

"Folliculitis decalvans"

"Folliculitis decalvans" is used in different ways by different authors, and so must be redefined each time the term is used. Usually, it is applied to highly inflammatory forms of cicatricial alopecia, where inflammatory, perifollicular papules and pustules dominate the clinical picture. Often (but not always) *Staphylococcus aureus* can be grown from pustular or crusted lesions. Some authors believe that a primary staphylococcal infection of the scalp is the cause of folliculitis decalvans[94].

The majority of these patients, especially African-American patients, prove to have CCCA if appropriate "early" lesions are selected for histologic evaluation[16]. However, a "folliculitis decalvans" clinical pattern can be seen in patients who eventually prove to have tinea capitis or lichen planopilaris.

Histologically, folliculitis decalvans presents as dense, perifollicular inflammation of the upper portion of follicles, with partial or complete epithelial destruction. Usually, both acute and chronic inflammation is present, but lymphocytic, neutrophilic or granulomatous inflammation may dominate the picture. Plasma cells are often part of the mix, but this is a common, nonspecific finding seen in chronic, inflammatory conditions of the scalp.

Mild cases can be managed with topical clindamycin and antiseptic shampoos, but treatment of severe disease is more complicated and may involve maintenance therapy with oral tetracyclines. In one series of patients, long-term remissions were observed with a combination of oral rifampin and clindamycin[102].

"Tufted folliculitis"

The "tufting" seen in this *pattern* of hair disease[112] is common to several forms of scarring alopecia. It is not a specific disease, but an end stage of several different conditions (Fig. 69.18). In the opinion of the authors, this diagnostic nomenclature should be abandoned[16].

Tufting occurs when the infundibular epithelia of damaged follicles heal with the formation of a large, common infundibulum. A zone of fibrosis separates individual clusters of damaged follicles. Another name for this phenomenon is *polytrichia*. Although tufting is fairly common in cases of CCCA, it can occasionally be seen in a wide variety of other disorders, including acne keloidalis, dissecting cellulitis, pemphigus and inflammatory tinea capitis.

Traction Alopecia (End-Stage)

Traction alopecia is a *biphasic* form of hair loss. Initially, the hair loss is temporary, hair regrowth can occur, and the condition behaves like a non-cicatricial form of alopecia. However, if excessive traction is maintained for years, the hair loss may eventually become permanent (end-stage or "burnt-out"). There may be a lag period of a decade or more between the period of traction and the onset of permanent hair loss. Patients with traction alopecia are usually African-American women who present in their 30s and 40s with a several-year history of persistent, bitemporal or frontal hair loss (Fig. 69.19)[113]. Occasionally, there also may be folliculitis within the areas of alopecia. Patients may deny having worn tight braids since childhood, but often other forms of traumatic styling (e.g. "curlers") have been employed. More recently, whether or not traction is the only, or even the major, causative factor has been questioned[114].

Fig. 69.19 Traction alopecia. Favors the frontotemporal area in African-American women and is due to traumatic types of hair styling.

The histologic findings in acute, reversible traction alopecia and permanent, longstanding, "burnt-out" traction alopecia are entirely different. The acute form resembles a mild form of trichotillomania[15,115]. End-stage disease, which is most commonly found in young African-American women, has the features listed in Table 69.1.

HAIR SHAFT ABNORMALITIES

Introduction

The hair shaft consists of three major regions: the medulla, cortex and cuticle (see Ch. 68). Epithelial and trichocyte (hair) keratins have been mapped to two keratin gene clusters – the acidic keratin cluster (type

I) at 17q12–q21 and the basic keratin gene cluster (type II) at 12q11–q13 – and so genetic studies of inherited hair abnormalities have focused on these regions. A few of the disorders listed in Table 69.7 do have underlying mutations in keratin genes, e.g. monilethrix.

This chapter will divide structural hair abnormalities (Fig. 69.20) into two broad categories – those associated with increased hair fragility and those *not* associated with increased hair fragility. In the analysis of hair shaft abnormalities with routine light microscopy, the best examinations are done by analyzing the proximal 1 to 2 inches of cut hair shafts. Shafts may also be examined by transmission or scanning electron microscopy, and amino acid analysis can be performed to detect low sulfur levels.

Structural Hair Abnormalities Associated with Increased Hair Fragility

"Bubble hair"

This distinctive hair shaft abnormality is usually seen in young women with a localized area of uneven, fragile hairs. The involved hair is straighter and stiffer than normal. By light microcopy, the hair shafts contain large, irregularly spaced "bubbles" that expand and thin the hair cortex (see Fig. 69.20). Hair fractures occur at the site of larger bubbles.

The problem is caused by traumatic hair care techniques involving heat, as from a malfunctioning hair dryer[116]. Once the damaged hair is trimmed, the condition resolves completely with gentle hair styling.

Monilethrix

Synonym: ■ Beaded hair

Monilethrix is a term of Greek and Latin derivation meaning "necklace hair". This disorder is inherited in an autosomal dominant fashion with variable expression. Monilethrix has been mapped to the epithelial keratin gene cluster on 12q11–q13, and point mutations have been found in the hair cortex-specific keratin genes *KRT86* (most often; previously referred to as *hHb6*) and *KRT81* (previously referred to as

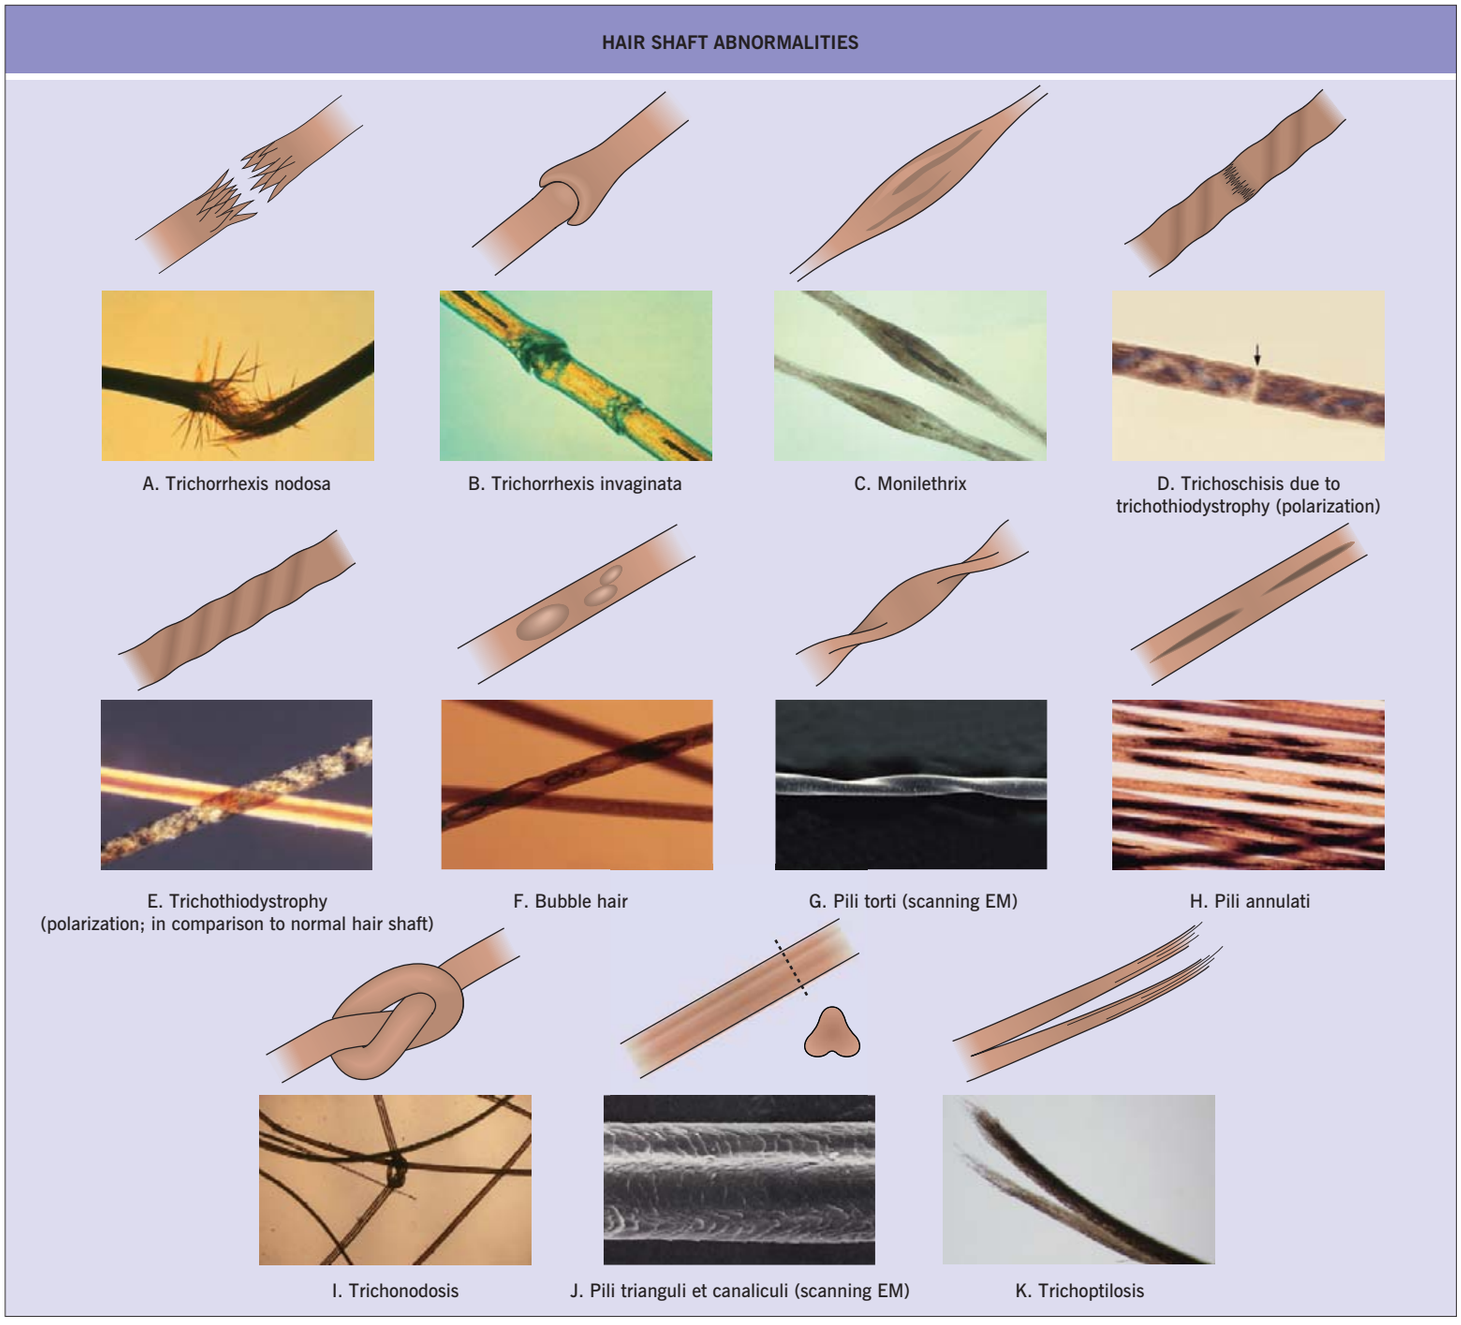

Fig. 69.20 Hair shaft abnormalities. EM, electron microscopy. *A & B, Courtesy, Maria K Hordinsky, MD; F, Courtesy, Jean L Bolognia, MD.*

Fig. 69.21 Monilethrix. Hypotrichosis due to breakage of fragile hairs. Note the small perifollicular papules with scale.

hHb1; see Ch. 56)[85]. In addition, mutations have been found in the genes that encode K83 and (in patients with an autosomal recessive form of monilethrix) desmoglein 4.

Affected individuals usually have normal-appearing hair at birth, but within the first few months of life these fibers are replaced by short, fragile, brittle hair (Fig. 69.21). Usually, the scalp is the only region involved, but in more extensive cases there may be eyebrow, eyelash and nail involvement (koilonychia most commonly). Perifollicular erythema and follicular hyperkeratosis are commonly observed. Hair fibers have uniform elliptical nodes of normal thickness and intermittent abnormal constrictions (see Fig. 69.20).

Pili torti

Pili torti is characterized by a flattened shaft and twisting of the hair fiber on its own axis (see Fig. 69.20). The twists are typically narrow and occur in groups of three to ten twists, giving the hair fiber a spangled appearance. Classic pili torti is part of a clinical syndrome associated with ectodermal abnormalities (keratosis pilaris, nail dystrophies, dental abnormalities). Hair may be sparse or abnormal from birth, or it may be normal at birth and then during infancy become replaced by brittle and fragile hair. Body hair also may be absent or sparse. Light microscopic examination reveals grouped twists of flattened hair.

In Björnstad syndrome, an autosomal recessive condition caused by mutations in the *BCS1L* gene, pili torti is associated with sensorineural hearing loss[117]; therefore, children with pili torti should have early testing for hearing loss. Other inherited diseases that can feature pili torti include Menkes disease (see below), Bazex–Dupré–Christol syndrome (see Ch. 99), hypotrichosis with juvenile macular dystrophy (due to P-cadherin mutations), Laron syndrome (primary growth hormone insensitivity), ectodermal dysplasias, mitochondrial disorders, and urea cycle defects (e.g. citrullinemia, argininosuccinic aciduria).

There is no treatment for pili torti, but it may improve at puberty. Although late-onset pili torti presents after puberty as patchy scalp alopecia, eyebrow and eyelash fibers may demonstrate fractures in childhood. Acquired pili torti-like hair shaft twisting has been reported in association with anorexia nervosa and oral retinoid therapy.

Menkes disease (trichopoliodystrophy or Menkes steely hair disease) is an X-linked recessive disorder of copper metabolism, with affected males having pili torti, severe psychomotor retardation, growth failure, seizures and other neurologic abnormalities[85]. Additional manifestations include a characteristic pudgy face with a "cupid's bow" upper lip, doughy skin and diffuse cutaneous hypopigmentation. Trichorrhexis nodosa can also affect the hair shafts in Menkes disease and is an additional source of hair fragility. The majority of patients die in early childhood. Features of the disease are the direct or indirect result of copper deficiency, and it is caused by mutations in *ATP7A*, a gene that encodes a copper-transporting ATPase. Clinically, hair is sparse in density, depigmented, lusterless, and looks and feels like steel wool. In suspected cases, the evaluation should include both the hair mount examination and serum copper and ceruloplasmin determinations. The presence of streaks of pili torti and/or hypopigmentation in mothers, sisters and maternal aunts of patients with Menkes disease may identify heterozygote female carriers.

Trichorrhexis invaginata

Trichorrhexis invaginata, also known as bamboo hair, is commonly seen in association with ichthyosis linearis circumflexa in patients with Netherton syndrome. The disorder results from pathogenic mutations in the *SPINK5* gene, which codes for a serine protease inhibitor termed LEKTI (see Ch. 57).

Atopy is commonly seen in affected individuals. The hair abnormality usually becomes evident in infancy with the development of short, sparse and very fragile hair. The breakage points consist of intussusceptions of the distal shaft ("ball") into the proximal shaft ("socket") due to defective cornification of the cortex (see Fig. 69.20). Fracture of the shaft may leave the proximal shaft with a golf tee-shaped end. In adults, the scalp hair tends to improve but bamboo defects in the eyebrow and body hair may persist.

Trichorrhexis nodosa

This is the most common of all the structural hair abnormalities and is characterized on light microscopic examination by a hair shaft fracture in which the individual cortical cells and their fragments splay out, appearing like the ends of two brushes pushed into one another (see Fig. 69.20). The abnormality is presumably caused by damage to the cuticular cells of the shaft and subsequently to the intercellular cement substance that normally binds cells together. Trichorrhexis nodosa may be a congenital or acquired abnormality. It may be seen in children with mental retardation and argininosuccinic aciduria or citrullinemia. Three variants of acquired trichorrhexis nodosa have been identified: (1) *proximal* trichorrhexis nodosa, which is commonly seen in patients after years of uncomplicated hair straightening; (2) *distal* trichorrhexis nodosa, which occurs as a result of acquired, cumulative, cuticular damage; and (3) *circumscribed* trichorrhexis nodosa, which may occur in the scalp, moustache or beard[118].

Trichothiodystrophy

Trichothiodystrophy is an autosomal recessive disorder characterized by sulfur-deficient hair. Vera Price and colleagues coined the term and recognized early on that trichothiodystrophy was a marker for a neuroectodermal symptom complex. Microscopic examination of hair fibers reveals transverse fractures (trichoschisis), alterations in the cuticle, and alternating light and dark bands under polarizing light[119] (see Fig. 69.20). Clinical features may vary greatly and range from an isolated hair abnormality to a constellation of findings (see Ch. 57). Several acronyms have been developed to describe the different clinical phenotypes seen. PIBIDS refers to a phenotype consisting of: P (photosensitivity), I (ichthyosis), B (brittle hair), I (intellectual impairment with low IQ), D (decreased fertility) and S (short stature). Some patients may also exhibit spasticity, tremors and ataxia, nail dystrophy, dental caries, cataracts, bony defects and immunodeficiency[85,120]. Approximately half of trichothiodystrophy patients are photosensitive (see Ch. 87).

Trichothiodystrophy is caused by several functionally related genetic defects involving the TFIIH/XPD-XPB complex (see Ch. 86). Current thinking is that transcription factor IIH has a dual function – transcription and DNA repair[85].

In order to diagnose trichothiodystrophy, it has been suggested that hairs demonstrate a low sulfur content *and* one of the following findings: trichoschisis, alternating light and dark bands by polarizing microscopy, or an absent or severely damaged hair cuticle by scanning electron microscopy[119,121].

Structural Hair Abnormalities *Not* Associated with Increased Hair Fragility

Acquired progressive kinking of the hair

The term encompasses several conditions characterized by acquired curling of the scalp hair. In the most common variant, young men develop curly, frizzy and lusterless hair in the frontotemporal region or vertex of the scalp, with subsequent progression to androgenetic

alopecia in the affected areas. Localized and diffuse forms of acquired hair kinking that are *not* associated with hair thinning have been described.

Loose anagen hair syndrome

The classic presentation of loose anagen hair syndrome is a young girl with fairly short blond hair that seldom needs cutting and who has diffuse or patchy alopecia without an increase in hair fragility. Boys and dark-haired children can also be affected. Anagen hair can be easily and painlessly pulled from the scalp, and microscopic examination reveals a ruffled proximal cuticle (see Fig. 69.8C), absence of the root sheath, and a bent matrix. Familial cases have been reported. The defect is thought to be a result of faulty cornification of the inner root sheath. This would then interfere with normal interdigitation of the inner root sheath cuticle with the hair cuticle, leading to poor anchoring. Improvement occurs with aging. The differential diagnosis includes telogen effluvium, alopecia areata and trichotillomania.

Pili annulati

Also known as ringed hair, this condition is characterized by hair shafts that have bright and dark bands when viewed by reflected light. The bright bands are related to light scattered from periodically occurring clusters of abnormal, air-filled cavities within the hair. The condition may be sporadic or seen as an autosomal dominant trait. On microscopic examination of a hair mount, the air-filled cavities are seen as dark regions (see Fig. 69.20).

Pili bifurcati

This hair fiber anomaly is characterized by bifurcation of the hair fiber at multiple irregular intervals along the shaft, forming separate rami, which then again fuse. Each ramus has its own cuticle.

Pili multigemini

The term pili multigemini is associated with multiple hair shafts arising from one papilla. Each hair fiber has its own inner root sheath but all the fibers are surrounded by a common outer root sheath. Multigeminate hairs are usually found in the beard region. The differential diagnosis includes trichostasis spinulosa and compound follicles.

Spun-glass hair (uncombable hair)

This entity is also known as pili trianguli et canaliculi and refers to a rare hair abnormality in which hair has a "spun glass" appearance due to the reflection of light from variably oriented, flattened hair surfaces. Hair is characteristically stiff and difficult to comb. Abnormal keratinization of the internal root sheath is postulated to cause the irregularly shaped hair shafts, which have a triangular shape on cross-section and a longitudinal groove that is best seen by scanning electron microscopy (see Fig. 69.20).

Woolly hair

Human hair may at times develop a woolly appearance. The presence of woolly hair may be congenital and can be inherited as either an autosomal dominant or recessive trait. Some patients present with a circumscribed patch of woolly hair (woolly hair nevus) (Fig. 69.22). Microscopic examination may reveal elliptical cross-sections, axial twisting and occasional trichorrhexis nodosa. Woolly hair is found in association with palmoplantar keratoderma (PPK) and cardiomyopathy in two autosomal recessive disorders – Naxos disease (diffuse non-epidermolytic PPK; due to plakoglobin mutations) and Carvajal syndrome (striate epidermolytic PPK; due to desmoplakin mutations). The triad of woolly hair, striate PPK and fatal cardiomyopathy has also been described in a family with a dominant-negative desmoplakin mutation. In addition, desmoplakin mutations underlie the autosomal recessive skin fragility/woolly hair syndrome. Woolly hair is occasionally observed in patients with Noonan syndrome and cardio-facio-cutaneous syndrome. Other conditions reported in association with woolly hair include ulerythema ophryogenes, keratosis pilaris, ichthyosis, osteoma cutis, abnormal teeth, nail dystrophy and intractable diarrhea during infancy. Kinky (but not truly woolly) hair is a feature of giant axonal neuropathy and tricho-dento-osseus syndrome.

Fig. 69.22 Woolly hair nevus. Circumscribed area where scalp hair is wavier and has a woolly appearance.

Alopecia of sites other than the scalp

While alopecia of the scalp is the primary focus of this chapter, alopecia can occur in any hair-bearing site. For example, in alopecia areata, there can be involvement of the eyebrows, eyelashes and even all the body hair. Occasionally, anagen effluvium will affect body hair as well as scalp hair. In addition, the presence of alopecia within an erythematous plaque may serve as a clue to the diagnosis of follicular (alopecia) mucinosis. There are also "patterned" alopecias of unknown etiology that can affect the anterolateral shin and thigh that are most obvious in men. Lastly, hypotrichosis of the lateral third of the eyebrows may serve as a clue to the presence of hypothyroidism.

Hypertrichosis and Hirsutism 70

Francisco M Camacho-Martínez

Key features

- Hypertrichosis represents the growth of hair in an excessive amount, whereas hirsutism is excessive growth of terminal hairs in a "male pattern" in a female patient
- Hypertrichosis may be generalized or localized, with etiologies ranging from genodermatoses to underlying hamartomas to repeated trauma
- Hirsutism is related to hormonal factors, in particular an increase in circulating androgen levels and/or enhanced end-organ sensitivity to androgens
- In women, the major sources of androgens are the adrenal glands and the ovaries; dysfunction of these organs must be considered when a patient presents with hirsutism
- If minimal or no hormonal abnormalities are found, the patient may be diagnosed as having constitutional hirsutism or familial hirsutism
- Depending on the origin of the hirsutism, treatment is based on administration of antiandrogens, glucocorticosteroids and/or contraceptives, combined with topical medications and physical measures

HYPERTRICHOSIS

Introduction

Hypertrichosis describes the growth of an excessive amount of hair on any area of the body. The term is frequently confused with *hirsutism*, which should only be applied to women with excessive growth of terminal hairs in a "male pattern" due to androgen overproduction or increased end-organ sensitivity to androgens[1,2]. Hypertrichosis can be classified based on its distribution (generalized versus localized), the age of onset (congenital or programmed from birth versus acquired), and the type of hair (lanugo or vellus versus terminal).

Clinical Features

Generalized hypertrichosis

Generalized hypertrichosis is the presence of lanugo hair, excess vellus hair, or terminal hair on much of the cutaneous surface, including an acquired transformation of terminal hair into lanugo hair (Fig. 70.1). Lanugo is the non-pigmented, non-medullated, fine hair that covers the fetus and can grow to several centimeters in length; it is normally shed *in utero* or during the first few weeks of life and replaced by vellus hair on the body and terminal hair on the scalp.

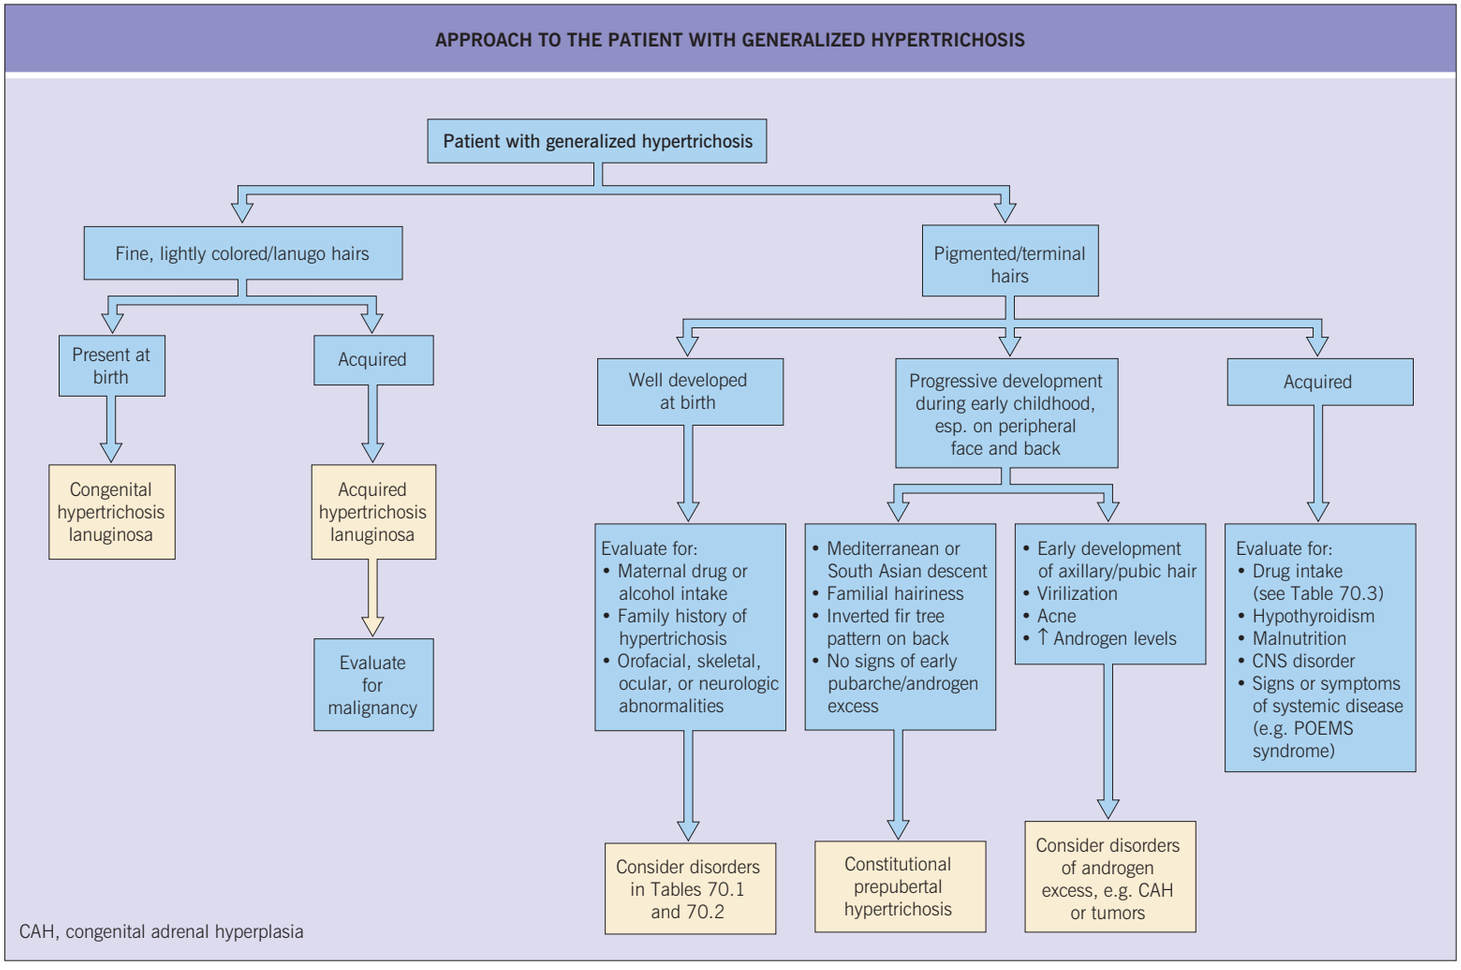

Fig. 70.1 Approach to the patient with generalized hypertrichosis. POEMS syndrome: *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal gammopathy, *s*kin lesions.

HEREDITARY DISORDERS CHARACTERIZED BY CONGENITAL GENERALIZED HYPERTRICHOSIS		
Disorder	**Inheritance (locus)**	**Other key features**
INCREASED HAIR IS THE MAJOR FEATURE		
Congenital hypertrichosis lanuginosa	AD	• Fine, downy, silvery-gray to blond lanugo hair • May be shed over the first year of life • Occasional dental anomalies; rarely other associations (see text)
Universal hypertrichosis	AD	• Thicker, longer hair most prominent on the frontal, temporal and preauricular areas of the face, the back and the proximal extremities* • Increases during infancy and tends to persist
Ambras syndrome	AD (8q22)	• Fine, silky, long hair (e.g. >10 cm) uniformly distributed on the face (including nose), ears and shoulders • Persists for life • Minor facial dysmorphism, dental anomalies, supernumerary nipples • Decreased expression of TRPS1*
X-linked hypertrichosis	XR† (Xq24–q27.1)	• Curly, shorter, dark hair most prominent on the face and upper body • Anteverted nostrils, prognathism; occasional dental anomalies, deafness
ASSOCIATED WITH GINGIVAL HYPERPLASIA, FACIAL DYSMORPHISM, SKELETAL DEFECTS, OCULAR ANOMALIES AND/OR MENTAL RETARDATION		
Gingival fibromatosis with hypertrichosis	AD (17q24.2–q24.3)	• Dark terminal hairs on the peripheral face, central back, and extremities • Gingival hyperplasia, coarse facies, MR, seizures
Cantú syndrome	AD	• Gingival hyperplasia, coarse facies, osteochondrodysplasia, macrosomia at birth, cardiomegaly
Zimmermann–Laband syndrome	AD (3p14.3)	• Gingival hyperplasia, coarse facies, hypoplastic nails and distal phalanges, joint hyperextensibility, macrosomia at birth, HSM, MR
Coffin–Siris syndrome	AR (7q32-q34)	• Sparse scalp hair, coarse facies, hypoplastic fifth fingernails and distal phalanges, GR, MR
Schinzel–Giedion syndrome	AR (18q12.3; *SETBP1*)	• Midfacial vascular stain, midfacial retraction, hyperconvex nails, hypoplastic distal phalanges and dermatoglyphs, GU anomalies, GR, MR
Gorlin–Chaudry–Moss syndrome	AR	• Craniofacial dysostosis with midfacial hypoplasia, hypoplastic distal phalanges, ocular and dental anomalies, genital hypoplasia, GR
Adducted thumbs syndrome	AR	• Arthrogryposis, craniosynostosis, myopathy
Barber–Say syndrome	AR	• Lax skin, ectropion, macrostomia, coarse facies, hypoplastic nipples, GR
Amaurosis congenita, cone–rod type, with hypertrichosis	AR	• Photophobia, visual impairment due to retinal dystrophy
CAHMR syndrome‡	AR	• *Ca*taracts, *h*ypertrichosis, *MR*
Acromegaly + hypertrichosis‡	AD	• Acromegaloid facies

*This pattern of distribution is also observed in prepubertal hypertrichosis (see text).
†Female carriers may manifest with nevoid hypertrichosis following Blaschko's lines.
‡Single family reported.

Table 70.1 Hereditary disorders characterized by congenital generalized hypertrichosis. AD, autosomal dominant; AR, autosomal recessive; GR, growth retardation; GU, genitourinary; HSM, hepatosplenomegaly; MR, mental retardation; TRPS1, tricho-rhino-phalangeal syndrome 1 protein; XR, X-linked recessive.

Congenital hypertrichosis lanuginosa

This is a rare autosomal dominant disease in which lanugo hair is not replaced by normal vellus hair. The fine, silvery-gray to blond hair continues to grow, reaching lengths of up to 10 cm and covering the entire body surface except for the palms, soles, dorsal surface of the distal phalanges, and prepuce. The hair growth is said to lead to a "dog" or "monkey" face. Associated dental abnormalities, malformations of the ear, glaucoma, pyloric stenosis, photophobia, and, rarely, physical and mental retardation have been reported.

Acquired hypertrichosis lanuginosa

This "paraneoplastic disease" is associated with a variety of internal malignancies, most often carcinoma of the lung, colon or breast. Acquired hypertrichosis lanuginosa can precede the diagnosis of the neoplasm, and it may also be associated with abnormalities of the tongue (e.g. burning pain) and other paraneoplastic dermatoses such as acanthosis nigricans, palmoplantar keratoderma, the sign of Leser–Trélat and acquired ichthyosis (see Ch. 53). The lanugo hair appears over the entire body within a short period of time, although in mild forms it may be localized to the face, leading to a "simian" appearance. Lanugo hair may even develop in areas of androgenetic alopecia.

Congenital generalized hypertrichosis

There are multiple rare inherited disorders that present with congenital generalized hypertrichosis, either as the sole manifestation or in association with gingival hyperplasia, facial dysmorphism, skeletal defects, mental retardation and other congenital anomalies (Table 70.1). A variety of additional hereditary diseases and syndromes can feature diffuse hypertrichosis (Table 70.2), which may be apparent at birth or develop early in life. Intrauterine exposure to medications such as minoxidil can also lead to congenital generalized hypertrichosis.

Prepubertal hypertrichosis

Prepubertal hypertrichosis is a relatively common finding in otherwise healthy infants and children, most often occurring in individuals of Mediterranean or South Asian descent. Pigmented hair is present in a widespread, diffuse distribution and becomes more obvious during childhood. There is involvement of the face (especially the forehead, temples and preauricular area), proximal extremities and back; hairs in the latter location assume an "inverted fir tree" pattern. Bushy eyebrows and a low anterior hairline represent additional features.

The facial distribution pattern of prepubertal hypertrichosis can overlap with that of familial hirsutism (see below), and there may be a family history of excessive hairiness. Mildly elevated serum levels of total and free testosterone have been observed in a subset of girls with prepubertal hypertrichosis, while others have a normal androgen profile[3]. These findings suggest multiple etiologies for this clinical pattern of hypertrichosis, including androgen excess as well as a greater constitutional propensity for hair growth.

HEREDITARY DISEASES AND CONGENITAL SYNDROMES ASSOCIATED WITH HYPERTRICHOSIS		
Disorder	**Sites of hypertrichosis**	**Other key features**
DYSMORPHIC SYNDROMES		
Cornelia de Lange syndrome	• Forehead, lateral face, shoulders, back • Low anterior hairline, synophrys, trichomegaly	• Distinctive facies, upper extremity anomalies, microcephaly, GR, MR, "growling cry" • AD; *NIPBL* mutations
Rubinstein–Taybi syndrome	• Lateral face, shoulders, back • Thick eyebrows, trichomegaly	• Midfacial vascular stains, keloids, pilomatricomas • Broad thumbs/halluces, beaked nose, high-arched palate, short stature, MR • AD; *CREBBP* mutations
DISORDERS WITH PRIMARY CUTANEOUS FEATURES		
Porphyrias	• Sun-exposed areas • Favors lateral face in PCT, HEP, VP • Face, trunk, extremities in CEP	• See Ch. 49
Lipodystrophy syndromes (e.g. Berardinelli–Seip syndrome, leprechaunism)	• Face, neck, extremities • Low hairline	• See Ch. 101
Erythrokeratodermia variabilis	• Trunk and extremities	• See Ch. 57
Dystrophic epidermolysis bullosa*	• Areas of previous blistering	• See Ch. 32
Ichthyosis bullosa of Siemens*	• Extremities	• See Ch. 57
METABOLIC DISORDERS		
Mucopolysaccharidoses†	• Trunk, extremities	• See Ch. 48
Congenital hypothyroidism	• Back, extremities	• See Ch. 46
MITOCHONDRIAL DISORDERS		
Leigh syndrome due to *SURF1* mutations	• Forehead, extremities	• Progressive neurodegeneration
MELAS syndrome	• Lower extremities	• *M*itochondrial *e*ncephalopathy, *l*actic *a*cidosis, and stroke-like episodes
INTRAUTERINE EXPOSURES‡		
Fetal hydantoin syndrome	• Face, back, extremities	• Gingival hyperplasia, coarse facies, hypoplastic nails and distal phalanges, GR
Fetal alcohol syndrome	• Face, back, extremities	• Midfacial hypoplasia, GR, CNS anomalies
MORPHEAFORM OR SCLERODERMOID DISORDERS		
Winchester syndrome	• Hypertrichosis and hyperpigmentation overlying areas of skin thickening	• Gingival hyperplasia, carpal/tarsal osteolysis, osteoporosis, coarse facies, GR • AR; matrix metalloproteinase-2 gene mutations
H syndrome§	• Lower trunk and lower extremities (in association with areas of *h*yperpigmentation & induration‖)	• Sensorineural *h*earing loss, short *h*eight, *h*eart anomalies, *h*epatosplenomegaly, scrotal masses, hypergonadotropic *h*ypogonadism, antibody-negative insulin-dependent diabetes mellitus, facial telangiectasias • AR; *SLC29A3* mutations (encodes nucleoside transporter hENT3)
Stiff skin syndrome	• Variable	• See Ch. 43
Linear melorheostosis¶	• Overlying affected skin and bone	• Hyperostosis ("candle wax" appearance) with overlying scleroderma • Due to *LEMD3* mutations

*Hypertrichosis is an uncommon feature.
†Hypertrichosis may also be observed in other lysosomal storage diseases, e.g. Krabbe disease and GM1-gangliosidosis, as well as sialuria.
‡Also minoxidil and diazoxide.
§Allelic with pigmented hypertrichotic dermatosis with insulin-dependent diabetes (PHID) syndrome.
‖Polyclonal perivascular lymphohistiocytic infiltration with numerous plasma cells in the dermis and subcutis.
¶Hypertrichosis has also been described overlying linear scleroderma in the absence of melorheostosis.
