Propolis (bee glue)	Hands	Violin
Chromium	Hands	Harp, violin
Paraphenylenediamine	Chin	Violin, viola

Table 88.17 Allergic contact dermatitis associated with musical instruments[94–98].

remedies for the treatment of fiddler's neck include astringents, benzoyl peroxide, keratolytics, tretinoin, topical erythromycin and application of French brandy.

Treatment of excess salivation with a transdermal scopolamine patch has been reported. Remedies for hyperhidrosis include topical aluminum-based drying agents, iontophoresis, β-adrenergic blocking agents (especially if the hyperhidrosis is due to "stage fright"), calcium channel blockers, botulinum toxin A and ganglionectomy (see Ch. 39). Anticholinergic therapy is not useful for many musicians because of the frequent side effects of dry mouth and blurred vision[94–96]. If allergic contact dermatitis is suspected, patch testing can be performed (see Ch. 14).

89 Signs of Drug Abuse

Josep L Genebriera de Lamo, Mark R Pittelkow and Miguel Sanchez

INTRODUCTION

According to the Diagnostic and Statistical Manual of Mental Disorders (DSM-4), drug abuse is a non-conforming pattern of drug practice in a manner that deviates from medically recommended or socially accepted standards. Repeated drug abuse can progress to drug addiction, the result of drug-induced central nervous system (CNS) changes that lead to maladaptive alterations in spontaneous behavior and in the behavioral response to subsequent exposures to the drug. Physical dependence is associated with drug addiction, which denotes a constellation of cognitive, behavioral and physiologic symptoms manifested by compulsive drug use, tolerance, and withdrawal symptoms upon discontinuation of a drug (Table 89.1).

Drug abuse is a global problem and is directly responsible for minor to life-threatening and fatal illnesses and injuries, as well as adverse sociologic consequences (loss of occupational productivity and higher rates of poverty, crime, prison occupancy, domestic violence, child abuse or neglect) which increase the risk of infirmity and disability. According to the Office of National Drug Control Policy, the overall economic cost of drug abuse to American society during 2007 was estimated to be $193 billion.

Illicit drug use may be suspected or diagnosed on the basis of cutaneous findings. In fact, the skin is the tissue most evidently affected by intravenous drug addiction[1]. The wide spectrum of complications result from local or systemic effects (including toxic or allergic) of the drug itself, adulterants or infectious agents. Polydrug use, especially involving the consumption of alcohol and drugs, is common among drug addicts[1].

Amphetamines

Amphetamines were initially sold as a non-prescription appetite suppressant and rapidly became a favorite street drug ("pep pills", "Bennies"). Crystallized methamphetamine ("ice", "crystal", "glass", "tina"), an addictive stimulant with a high potential for abuse and dependence, produces an even stronger "rush" or "flash" when injected intravenously or inhaled. Oral ingestion of tablets ("speed", "meth", "chalk") or snorting powder merely produces a profound sense of euphoria. Smoking the base form ("snot") extends the duration of the "high" for up to 24 hours. Amphetamines can lead to reduced appetite, restlessness, insomnia and increased or distorted sensations; on physical examination, there may tachypnea, tachycardia and hypertension as well as flushing, sweating and even uncontrollable movements or shaking. Speed freaks (high-intensity abusers) progressively use the drug to remain euphoric, and with high doses or chronic use, xerostomia, xerosis, pruritus, acne excoriée and formication can occur, along with dental caries and loss of teeth ("meth mouth"). "Tweaking", continuous drug use without sleep for 3 to 15 days, is often associated with irritability, paranoia, violence and frustration due to inability to recreate the euphoric high.

Methylenedioxymethamphetamine (MDMA), also known as "ecstasy", "Adam", "XTC", "hug", "beans", or "love drug", is a synthetic stimulant and hallucinogen with a chemical structure similar to methamphetamine. MDMA causes a reduction in the concentration of serotonin transporters (SERTs) within the brain[2], and brain damage caused by heavy, prolonged use of MDMA may be long-lasting[3]. High doses can cause malignant hyperthermia, leading to rhabdomyolysis, renal failure and cardiovascular collapse. A staple at raves and PNP ("party and play") parties because of the associated increase in energy and reduction of sexual inhibition, crystallized methamphetamine and MDMA have been associated with unprotected, promiscuous sexual activity and especially high risk of contracting sexually transmitted diseases. More recently, "bath salts" (e.g. "Ivory Wave", "Cloud 9", "Vanilla Sky") that contain mephedrone, methylenedioxypyrovalerone (MDPV), or other cathinone or ampthetamine type stimulants have become popular and they can be injected, snorted, smoked or ingested orally.

FEATURES OF DRUG DEPENDENCE
• Recurrent and excessive drug use which may result in tolerance and withdrawal
• Recurrent social, occupational, psychological or physical problems as a result of excessive drug use
• Failed attempts to control substance use

Table 89.1 Features of drug dependence.

Benzodiazepines

Benzodiazepines are among the most frequently prescribed medications in the US, as they are in the UK, where surveys indicate that approximately 10% of the population take benzodiazepine sedatives regularly. Although they are only mild euphoriants, benzodiazepines are commonly misused by polydrug addicts (especially temazepam and flunitrazepam [Rohypnol®; "roofies"]), alcoholics and recreational drug users. Benzodiazepines are ingested (often with alcohol), snorted or, occasionally, injected. The most common side effects of benzodiazepines are related to their sedating and muscle-relaxing properties, e.g. decreased alertness and concentration and lack of coordination, respectively. Other side effects include depression, disinhibition, blurred vision and confusion, and with intravenous use, hypotension and hypoventilation.

Cannabis

Cannabis ("marijuana", "pot", "herb", "weed", "ganja", "Mary Jane") is the most frequently self-administered illicit drug. It is a mixture of dried shredded leaves and flowers of the *Cannabis sativa* plant, which contains the chemical delta-9-tetrahydrocannabinol (THC), and is usually smoked as a cigarette or through a pipe or bong. Marijuana cigarettes may be laced with other drugs, such as crack or heroin. The minimal amount of THC required to produce a perceptible psychoactive effect is ~10 mcg/kg body weight. A subjective change in perception may be accompanied by an impairment of concentration, psychomotor coordination and/or short-term memory. Arteritis has also been reported[4], and it may represent a particular form of Buerger's disease, with cannabis acting as a co-factor in young smokers. In a number of countries, there has been an increase in the use of synthetic cannabinoids ("Spice").

Cocaine

Cocaine ("coke", "blow", "toot", "flake", "snow") is an alkaloid stimulant and topical anesthetic which is extracted from the leaves of the *Erythroxylon coca* shrub. Crack ("base", "rock", "hubba", "gravel"), a freebase form of cocaine, is more addictive than heroin. It is produced by dissolving cocaine in water and baking soda and then heating the mixture until it crystallizes. Cocaine is injected or snorted, while crack is smoked.

In addition to Raynaud's phenomenon, cocaine use has been associated with small vessel vasculitis (leukocytoclastic vasculitis), necrotizing granulomatous vasculitis, acute generalized exanthematous pustulosis, and Stevens-Johnson syndrome[5,5a]. Its use can also lead to a number of cardiovascular side effects – Buerger's disease, hypertensive crisis, myocardial or cerebral infarction, and ventricular arrhythmias.

More recently, cocaine adulterated with levamisole has been associated with the development of neutropenia and ischemic vasculopathy with necrotizing purpura and ulceration (see below).

Gamma-Hydroxybutyrate

Gamma-hydroxybutyrate (GHB; "liquid ecstasy", "liquid X", "liquid G", "fantasy"), a "party drug", is a rapid-acting CNS depressant popular among revelers for its relaxant, euphoric and purported aphrodisiac properties. GHB can mentally and physically paralyze a person as well as induce memory loss, and it is used more often than flunitrazepam as a "rape drug". Because it reportedly promotes muscle mass and has been shown to elevate human growth hormone *in vivo*, GHB is commonly misused by bodybuilders.

Lysergic Acid Diethylamide

Lysergic acid diethylamide ("LSD", "acid"), an hallucinogen, is manufactured from the lysergic acid found in ergot, a fungus that grows on rye and other grains. It is often sold in single-dose (20 to 80 mcg) squares of blotter paper. LSD causes an altered experience of time, senses and memories, usually within 30–90 minutes after ingestion. Changes in auditory and visual perception (e.g. moving geometric patterns) are typical. In addition to pupil dilation and tachycardia, patients may develop sweating, sialorrhea, piloerection and a strong metallic taste.

Opiates

Also known as diacetylmorphine, heroin ("junk", "smack", "horse", "scag"), the fastest acting of all opiates, is three times more potent than morphine and still accounts for much of the illicit opiate abuse in the US. Because of its increased lipid solubility, it crosses the blood–brain barrier more rapidly, prompting a "rush" within 7 to 8 seconds after intravenous injection or 10–15 minutes after being snorted or smoked. There has been a growing tendency to sniff, snort ("shabbang") or smoke ("chase the dragon") heroin rather than inject it intravenously ("shoot up") or subcutaneously ("skin pop"). Opiate addicts may alternate injections of heroin and cocaine (crisscrossing) or inject highly addictive "speedballs" of the two drugs together. Methadone, an oral synthetic opioid with a half-life between 24 and 48 hours, is widely used as a substitute for heroin in narcotic treatment programs and for chronic pain.

Opiates remain the leading cause of fatal overdoses, with methadone, which is increasingly being obtained via the Internet, becoming a significant problem. Fentanyl, a narcotic analgesic that is 50 to 100 times more potent than morphine, is particularly prone to overdosing. Buprenorphine, a more potent and longer-lasting analgesic than morphine, appears to act as a partial agonist of μ and κ opioid receptors, but tolerance with chronic use may not develop, presumably due to the lack of δ-agonist activity.

Pentazocine is an oral benzomorphan opiate antagonist with a lower risk of drug dependence than opiates, but ingestion of pentazocine may precipitate withdrawal symptoms in persons physically dependent on opiates. However, when tablets are crushed, diluted and then injected in combination with the antihistamine tripelennamine (Pyribenzamine®), the euphoric effects are similar to those produced by heroin. The side effects are similar to those of morphine, but pentazocine may be associated with a greater risk of hallucinations. Severe necrosis and secondary infection of the skin and subcutaneous tissue, including underlying muscle, may develop at repeated injection sites of pentazocine.

Anabolic Steroids

Anabolic steroids promote the growth of skeletal muscle and the development of male sexual characteristics. They are ingested (oxandrolone, oxymetholone, stanozolol) or injected (nandrolone, testosterone, boldenone) intramuscularly by bodybuilders to increase muscle mass and by athletes to boost physical performance. Physical and psychological dependence can develop after habitual use. Higher risks for cardiovascular disease, hepatic disorders (e.g. peliosis hepatis, hepatic adenomas), infectious diseases (due to needle sharing) and perhaps mood disorders are among the long-term complications of anabolic steroid misuse. The cutaneous side effects are outlined in Table 89.3.

PATHOPHYSIOLOGY OF ADDICTION

Administration of addictive drugs, directly or indirectly, leads to an increase in dopamine activity within the mesolimbic system (reward circuit) as well as the frontal cortex, anterior cingulate and hippocampus. This is thought to play a role in incentive salience and craving. In addition, MRI studies have documented progressive loss of frontal lobe volume in both cocaine- and heroin-dependent addicts and this may lead to unrestricted behaviors.

EPIDEMIOLOGY

Approximately 5% of the world's population (i.e. 200 million people) uses illicit drugs and approximately 14 million of them inject drugs[6]. Drug abuse is a problem is both high- and low-income countries (Table 89.2; Fig. 89.1), and in 2009–2010, the United Nations Office of Drugs and Crime estimated that 2.8–4.5% of the global population (ages 15–64 years) misused cannabis, followed by amphetamines (0.3–1.3%)

SELF-REPORTED ALCOHOL AND ILLICIT DRUG USE AMONG HIGH SCHOOL SENIORS IN THE US (2008)

Drug	Use within the past year (%)
Alcohol	65
Marijuana	32
Opiates (other than heroin)	9
Stimulants	7
Tranquilizers	6
Hallucinogens	6
Sedatives	6
Cocaine	4
Inhalants	4
Anabolic steroids	1.5
Heroin	0.7

Table 89.2 Self-reported alcohol and illicit drug use among high school seniors in the US (2008). *From the US Department of Justice, Bureau of Justice Statistics (http://bjs.ojp.usdoj.gov/content/dcf/du.cfm).*

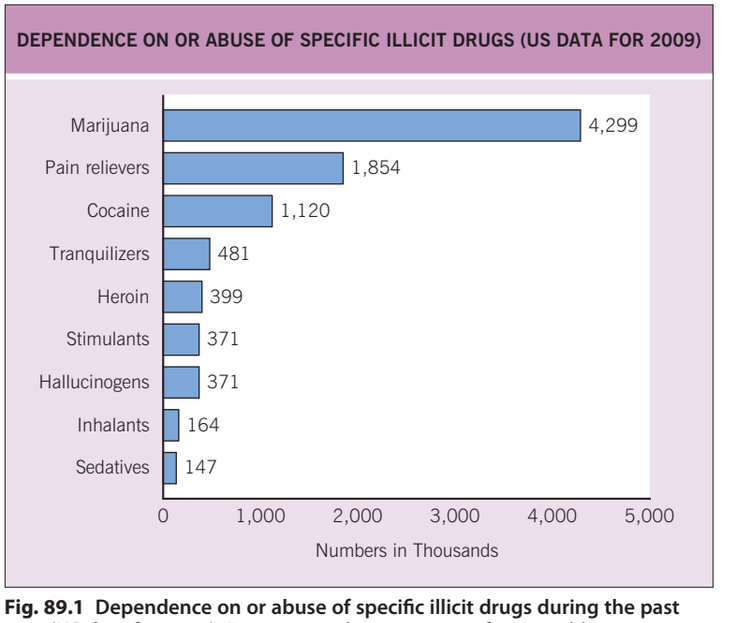

Fig. 89.1 Dependence on or abuse of specific illicit drugs during the past year (US data for 2009). Estimates in those 12 years of age or older. Hallucinogens include ectasy, lysergic acid (LSD) and phencyclidine (PCP). *Results from the 2009 National Survey on Drug Use and Health: Volume I. Summary of National Findings, U.S. Department of Health and Human Services Substance Abuse and Mental Health Services Administration Office of Applied Studies. www.oas.samhsa.gov/NSDUH/2k9NSDUH/2k9results.htm.*

Fig. 89.2 Injection sites ("skin tracks") in an intravenous drug user. There is overlying hyperpigmentation and scarring of veins due to inflammation from repeated non-sterile injections as well as injections of irritating drugs and adulterants.

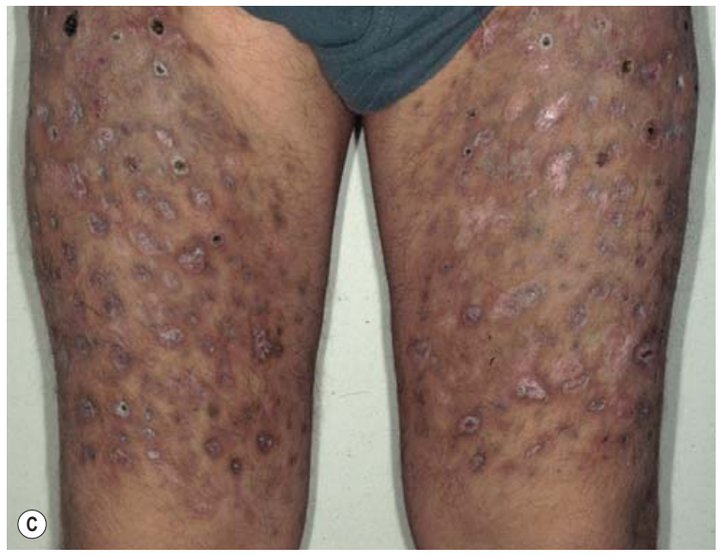

Fig. 89.3 "Skin popping" scars. A–C Multiple circular depressed scars, some with rims of postinflammatory hyperpigmentation, admixed with circular hemorrhagic crusts overlying ulcerations. Cocaine was injected into the thighs.

and opioids (0.5–0.8%)[3]. According to the National Survey on Drug Use and Health, in 2009, an estimated 21.8 million Americans 12 years of age or older were current (during the past month) illicit drug users.

CLINICAL FEATURES

Scars

Intravenous drug users have a number of recognizable stigmata, which identify their habit to anyone with experience in illicit drug use[7]. The most prominent of these are "skin tracks", which represent overlying hyperpigmentation and scarring of veins due to inflammation from repeated non-sterile injections as well as injections of irritating drugs and adulterants (Fig. 89.2). Early lesions in intravenous drug users consist of trails of punctures, crusted lesions and ecchymoses along the veins of an extremity[5]. Usually, the veins of the arms are initially used for injection, and when these become scarred, drug is injected into the vessels of the hand, digits, wrist, lower extremities, neck, axillae and eventually into any visible vein or palpable artery[7]. Increasingly, parenteral drug users are injecting themselves in the legs, feet and groin in order to avoid the presence of scars on exposed parts of the body which can persist for years.

Tissue injury also occurs from intradermal or subcutaneous injections and from accidental extravasation after intended injection into veins[5]. Drugs are injected subcutaneously and intradermally when patent vessels cannot be found. The resulting "skin popping" scars are depressed, irregular, circular and often dyschromic (Fig. 89.3). In some users, indurated, hypertrophic or keloidal scars form at these sites[7]. Drug users who cannot find intact veins may also rub powdered drugs into lacerations created with razor blades or knives.

Adulterants such as lactose, mannitol, dextrose, baking soda and flour are used to dilute ("cut") heroin and other powder drugs[7]. Many adulterants, especially quinine and dextrose, are highly sclerosing and more damaging to tissue than pure heroin[1]. Quinine is a popular adulterant because it has a bitter taste similar to heroin and it accentuates the narcotic euphoria. It is destructive to lymphatics and repeated injections can lead to chronic, non-pitting hand edema. More recently, levamisole-adulterated cocaine has been associated with the development of retiform purpura and cutaneous necrosis (see below).

The risk of thrombophlebitis and skin necrosis from injections of propoxyphene is so high that even the most determined addict ceases use of the drug after only a few weeks (Table 89.3)[5]. Highly vasoconstrictive, cocaine produces tissue ischemia, especially when extravasated. In fact, skin and muscle infarction have developed after inhalation of freebase cocaine. Due to their alkalinity, barbiturates, when injected into the skin, cause tender, erythematous, indurated plaques, which break down into deep ulcers and frequently become infected. Injection of the antihistamine tripelennamine, usually injected in combination with pentazocine or another opioid, also induces tissue necrosis and ulceration. Pentazocine injection may cause brawny, sclerodermatous skin thickening and large, irregularly shaped, deeply penetrating ulcers that may extend to muscle and then heal with significant atrophy (Fig. 89.4)[8]. Pentazocine-related cutaneous sclerosis develops more commonly in addicts with diabetes mellitus[8].

CUTANEOUS SIGNS OF DRUG ABUSE		
Lesion type	**Route(s)/associated drug(s)**	**Other associated signs**
Skin tracks	IV	Lymphedema
Skin popping scars	sc or dermal	Lymphedema
Ulcerations	IV/propoxyphene IV/cocaine sc/barbiturates sc, IM/pentazocine (± tripelennamine)	Circumferential pigmented bands (IV administration)
Retiform purpura with ulceration	Snorting, IV/cocaine adulterated with levamisole Smoking/crack cocaine adulterated with levamisole	Neutropenia
Sclerosis	sc, IM/pentazocine sc/barbiturates sc/cocaine	
Palmar and digital hyperkeratosis	Smoking/crack cocaine	Madarosis Linear and circular black plaques on the fingers and palms Cuts and blisters on the lips
Nasal verrucae	Snorting/cocaine or heroin	Nasal irritation Septal perforation
Pseudoaneurysm	Arterial injection	Petechiae/purpura Reduced peripheral pulses
Cellulitis	IV, sc, intradermal	Osteomyelitis and pyogenic arthritis
Cutaneous *Pseudomonas* infection	IV, sc, intradermal/heroin sc/pentazocine ± tripelennamine	Folliculitis
Wound botulism (*Clostridium botulinum*, especially type A)	IM, sc/black tar heroin or quinine-adulterated heroin	Lymphedema Skin popping scars
Excoriations & self-induced ulcers	Methamphetamine	Dry leathery skin Red dry nose Dental caries/loss of teeth Weight loss Paranoia
Formication or delusions of parasitosis	Cocaine Methamphetamine	
Pruritus	Heroin Cocaine (chronic) Methamphetamine	With heroin: Flushing Pseudoacanthosis nigricans
Papulopustular acneiform eruption	MDMA (ecstasy)	
Acne vulgaris	Anabolic steroids Methamphetamine Marijuana	Coarse skin Hirsutism Male and female pattern alopecia Increased hair growth in women Gynecomastia (in men) Testicular atrophy Clitoral enlargement Excoriations
Perinasal and perioral irritant dermatitis	Sniffing of volatile solvents and inhalants	

Table 89.3 Cutaneous signs of drug abuse. IM, intramuscular; IV, intravenous; MDMA, methylenedioxymethamphetamine; sc, subcutaneous.

Fibrous myopathy, joint restriction, muscle contractures, brachial plexus neuropathy, inflexible ankylosis and suppurative tenosynovitis are musculoskeletal and neurologic complications from intracutaneous and intravenous injections[1].

Bacterial Infections

Unless they participate in needle exchange programs, hardcore parenteral drug users rarely use sterile techniques and they may share needles, which predisposes them to frequent infections (Table 89.4). Skin and soft tissue infections are the most common diseases for which drug addicts seek healthcare or are hospitalized[9–11]. Among 127 intravenous drug users, 41% developed cellulitis, 32% an abscess with cellulitis, 16% an abscess alone, 10% infected skin ulcers, 7% necrotizing fasciitis and 5.5% septic phlebitis with cellulitis[11]. The most common presentation of cellulitis is an erythematous, tender, warm, edematous, indurated plaque (Fig. 89.5); however, only tenderness and edema may be apparent initially, and in more darkly pigmented skin, erythema may be difficult to appreciate. In contrast to the general population, cellulitis more frequently involves the upper extremity.

Lymphangitis associated with skin infection is common. In addition, underlying osteomyelitis and septic arthritis should be considered in cutaneous infections associated with injections. In some reports, up to one-third of hospitalized addicts with skin and soft tissue infections have an associated culture-proven bacteremia[7,11]. In a smaller subset, bacterial endocarditis develops, which is the most common systemic bacterial infection in intravenous drug users and accounts for 5% to 8% of hospitalizations[12] (see the discussion below).

The flora spectrum of street heroin does not correlate with the spectrum of bacteria causing infections in intravenous drug users[13]. Cellulitis is most frequently caused by *Staphylococcus aureus* and less often by streptococci (commensal flora)[11,12]. However, bacterial cultures and sensitivity testing are indicated in order to identify those cutaneous infections due to methicillin-resistant *Staphylococcus aureus* (MRSA), Gram-negative bacteria, anaerobes or unusual organisms and to determine the most effective antibiotic regimen[13]. The combination of

Fig. 89.4 Atrophic depressions of the thighs and extensive calcification from multiple pentazocine injections.

Fig. 89.5 Cellulitis of the lower extremity in an intravenous drug user.

INFECTIOUS COMPLICATIONS OF DRUG ABUSE	
Type of infection	**Organisms and/or associated features**
	BACTERIAL
Abscesses and cellulitis	• *Staphylococcus aureus* > *Streptococcus* spp. > Gram-negative bacilli, anaerobes • Often polymicrobial • Lymphangitis is common • *Clostridium* infection (e.g. *C. botulinum* type A) with adulterated heroin (e.g. black tar skin popping) • *Pseudomonas aeruginosa* with pentazocine ± tripelennamine or heroin injections • *Eikenella corrodens* with methylphenidate injections (esp. into the femoral triangle)
Necrotizing fasciitis	• Polymicrobial in 60–85% of cases • Includes anaerobes in ~10%
Pyomyositis	
Septic thrombophlebitis	• Associated with endocarditis or pulmonary emboli
Septic arthritis	• Increased likelihood of Gram-negative bacilli (esp. *Pseudomonas* spp.)
Osteomyelitis	• In *Pott's puffy tumor*, frontal sinusitis leads to frontal bone osteomyelitis and a subgaleal abscess; may be complicated by an epidural abscess
Endocarditis	• *S. aureus* > *Streptococcus viridans* > Gram-negative (esp. *Pseudomonas* spp.), polymicrobial • Often right-sided (e.g. tricuspid valve)
	FUNGAL
Candidiasis	• Disseminated candidiasis with pustular folliculitis; associated with injections of brown heroin • Septic arthritis, osteomyelitis, endocarditis (*C. parapsilosis, C. tropicalis*), septicemia ("fungemia syndrome")
Aspergillosis	• Pulmonary infections from contaminated marijuana • Dissemination and endocarditis may occur
Zygomycosis	• Cellulitic plaques or necrotic abscesses
	VIRAL
Hepatitis	• Hepatitis B viral infection may be associated with immune complex disease (e.g. arthritis, urticarial vasculitis) during the period of antigenemia • Syringe/needle sharing accounts for more than half of new cases of hepatitis C in the US
HIV	

Table 89.4 Infectious complications of drug abuse.

tripelennamine and pentazocine may promote the selective survival of *Pseudomonas aeruginosa*, and the use of quinine to adulterate heroin appears to predispose to *Clostridium* infection.

Wound botulism due to *Clostridium botulinum* type A occurs almost exclusively in drug addicts[14]. This particular infection is associated with parenteral injection, especially skin popping of black tar heroin, a form that derives its color from impurities during its manufacture and from adulterants. Black tar heroin is very hygroscopic and has a high water content, which supports the growth of organisms[15]. *C. sordelli* infection can present as toxic shock syndrome and *C. novyi* type A was responsible for an outbreak of severe infection with a high mortality rate in drug users who injected heroin extravascularly[16,17].

The spores of *C. botulinum* are not destroyed by heating the contaminated heroin and are inoculated into the subcutaneous tissue, where they germinate and produce toxin[15]. In the early stages, there is usually pain, tenderness and swelling, but a cellulitis or abscess may not be apparent. In cocaine snorters, the intranasal septum or paranasal sinuses may become infected. Botulism causes acute, usually descending and symmetric, flaccid paralysis with ophthalmoplegia, ptosis or other cranial nerve dysfunction. The diagnosis is supported by conventional electromyography. Treatment consists of high-dose penicillin, antitoxin and respiratory support.

In addition to injecting frequently and using non-sterile techniques (e.g. dirty needles), there are additional risk factors for the development of abscesses, including "skin popping", injecting speedballs (a mixture of cocaine and heroin that can induce ischemia within soft tissues)[18], HIV infection and "booting" (repeatedly flushing and pulling back during injection)[18a,18b]. Abscesses from subcutaneous drug injection are often multilobulated, deep and have extensive necrosis, requiring exploration and debridement. Superficial abscesses often rupture spontaneously, leaving punched-out ulcers. A single pathogen is cultured in over 50% of cases, and more than one organism is present in 33% to 45%[11]. Fever and leukocytosis are not particularly reliable measures of severity, as they are absent in 50% and 57% of cases, respectively[11]. Any type of bacteria may be cultured from these abscesses, but the more common are *Staphylococcus aureus* (20–60%), *Streptococcus* spp. (25%) and Gram-negative bacilli (up to 25%). Anaerobic bacteria are common as well, especially in polymicrobial infections. In one study, anaerobic bacteria were recovered from two-thirds of abscesses, and in one-third of these, they were the only cultured organism[19]. *Eikenella corrodens*,

an oral flora bacterium, has been cultured from some abscesses caused by injections of methylphenidate. Curiously, some abscesses develop months after a patient has ceased use of drugs.

Abscesses may be contiguous with underlying bone in the setting of associated osteomyelitis. In intravenous drug users, acute or chronic osteomyelitis develops from contiguous infection in surrounding soft tissue, hematogenous seeding of bacteria, or direct penetrating trauma from needles. The presence of osteomyelitis should be considered in anyone with continued pain after treatment of a soft tissue infection or with soft tissue infections that recur or respond slowly to appropriate treatment with antibiotics. Occasionally, septic arthritis can develop via these same mechanisms and may involve more unusual sites, e.g. the sternoclavicular joint in those who "shoot the pocket" (jugular vein)[20,20a].

Cervical abscesses usually occur in the anterior cervical triangle, and may cause life-threatening complications such as mediastinitis, pneumomediastinum, airway obstruction, internal jugular vein thrombosis, and extension into the carotid sheath. Abscesses in the groin may present with only tenderness and edema. These abscesses can be deep and extensive, especially if they originate in the femoral triangle. In general, the degree of pain usually exceeds that anticipated from the clinical findings.

MRI is superior to CT imaging in detecting the presence of fluid and purulent collections in skin, joints or tendon sheaths, but both are valuable in confirming the presence of deep and groin abscesses[21]. Sinography can be employed to delineate the extent of an abscess cavity or fistula. It is crucial to be aware that necrotizing fasciitis with or without myositis can present as erythema (77%), fluctuance (20%), edema (20%) or induration (43%), clinically resembling a non-fluctuant abscess yet requiring extensive subfascial debridement[22]. Fever and leukocytosis are often present. In some cases, only swelling or subtle cellulitis is apparent. However, severe pain, disproportionate to the physical findings, is present in 94% of cases[23]. If this complaint is disregarded or misinterpreted as a request for narcotics, the outcome can be devastating.

Notably, the classic cutaneous findings of necrotizing fasciitis, such as bullae (noted in 3% of patients), tissue crepitance (3%) and skin necrosis (10%), are usually absent, and only present in a small minority of patients[22]. For this reason, surgical exploration is mandatory in any parenteral drug user with cellulitis and unexplained severe pain[24]. Any necrotic tissue should be debrided surgically (Fig. 89.6), as the infection will progress in 75% of patients treated with only parenteral antibiotics[24]. Multiple organisms are cultured in 60% to 85% of cases, including anaerobes in 12% of patients. The presence of gas is not pathognomonic for *Clostridium* infection, as gas gangrene can also (but infrequently) be caused by other bacteria (e.g. usually mixed infections with *Enterococcus faecalis*, *Escherichia coli*, group G *Streptococcus*, *Klebsiella pneumoniae*, *Proteus vulgaris*, *Citrobacter diversus*, *Bacteroides bivius*, *Peptostreptococcus asaccharolyticus* or *Morganella morganii*).

Fig. 89.6 Necrotizing fasciitis of the upper extremity with extensive tissue necrosis in an intravenous drug user. Surgical debridement has been performed.

Fungal Infections

Dermatophytosis is very common in addicts. Disseminated candidiasis associated with injections of brown heroin was reported in the 1980s and found to be caused by an overgrowth of yeast in the lemon juice used to dissolve the heroin[25]. Initially, patients developed high fevers, rigors, headaches, myalgias and occasionally jaundice, but, at this stage, blood and urine cultures rarely demonstrated organisms. Usually after a week or so, up to 90% of the patients developed pustular folliculitis and painful nodules in hair-bearing areas (scalp, moustache and beard)[25]. The lesions resembled bacterial folliculitis but potassium hydroxide examination and lesional biopsy specimens demonstrated the presence of yeast. Other complications included ocular disease (chorioretinitis, uveitis, endophthalmitis, episcleritis), monoarthritis, painful costal osteochondritis and pleuritis[25].

Intravenous drug use is also a predisposing factor for zygomycosis. The characteristic cutaneous lesion is a cellulitic plaque or abscess with extensive necrotic tissue.

Granulomas

Injection of hydrous magnesium silicate (talc) or starch can produce granulomatous responses (Fig. 89.7) in the walls of veins as well as in the deep dermis and subcutaneous tissue, resulting in the formation of

Fig. 89.7 Foreign body granuloma formation leading to papules at the sites of injection of adulterated heroin.

firm, movable cutaneous nodules[26] (see Ch. 94). Talc is the main ingredient in some of the narcotic tablets that are crushed, diluted in liquid, and then injected. Talc granulomas may also develop in the lungs, liver, lymph nodes, spleen and bone marrow. Granulomas may not appear for up to 50 years after subcutaneous injection, because it is the conversion of silica to its colloidal form that stimulates the formation of granulomas[26]. When the inflammatory nodules ulcerate, they can heal with epidermal pigmentary changes, woody induration of the dermis and subcutaneous tissue, and retracted cicatrices.

Mucous Membrane Lesions

Snorting cocaine causes erythema of the nasal mucosa, nasal irritation, anosmia and rhinitis, and may lead to epistaxis, perforation of the nasal

Fig. 89.8 Tooth decay is a common physical finding in hardcore drug addicts (arrow). The term "meth mouth" is applied to those who abuse methamphetamines.

Fig. 89.9 Multiple excoriations in a cocaine addict. The patient felt "crawling" of his skin.

septum and osteolytic sinusitis. Nasal verrucae (snorters' warts) can also erupt in cocaine users. Less often, sniffing heroin causes these findings. A complex consisting of nasal collapse, septal perforation, palatal retraction and pharyngeal wall ulceration has been described in cocaine snorters. Cuts and blisters on the lips from glass or metal smoking pipes have been noted in addicts who smoke crack cocaine, while ageusia, halitosis and repeated lip smacking are additional signs of cocaine abuse. The labial mucosa may become dry in heroin or amphetamine users[7] and amphetamine use may also cause dysgeusia and xerostomia. There are reports of men applying cocaine powder on their glans penis to postpone ejaculation and of women rubbing cocaine on their genitals to enhance pleasure. These practices can lead to priapism, irritant dermatitis and even ulcerations. Penile ulcers have also developed after injections of heroin into the shaft veins.

Hardcore drug users frequently have marked dental and gingival disease due to poor hygiene (Fig. 89.8). Betel palm seeds (betel nuts) contain a narcotic stimulant and habitual chewing of these nuts, a practice in some areas of Southeast Asia, stains the teeth and is associated with the development of oral leukoplakia and submucosal fibrosis. The addictive habit of chewing *Catha edulis* tree leaves, which contain the narcotic Qat, is popular in several African and Middle Eastern countries and produces oral keratotic white plaques in approximately 20% of users.

Red or "bloodshot" eyes due to conjunctival vascular injection occurs with marijuana and sometimes with cocaine or phencyclidine (PCP) use. Repeated sniffing of volatile solvents and inhalants, such as butane gas, paint thinner, aerosol sprays, cleaning fluids and glues, can cause nasal, labial, perioral and perinasal irritant dermatitis (sniffer's rash). The skin lesions may be discrete papules or erosions that are often confused with acne.

Burns

Burns are common in addicts with an altered state of mind, including burns from lit matches, cigarettes, paraphernalia, and contact with fire during cooking. Cigarette burns typically occur on the digits and sternum as the cigarette was being held or smoked prior to loss of consciousness[7]. The necklace sign is produced by cigarette ashes, which fall on the neck when the smoking addict falls asleep. Singeing of the eyelashes and eyebrows, resulting in madarosis, may be caused by rising hot vapors during the smoking of crack cocaine. Crack addicts may also have linear or circular black plaques on the fingers and palms.

Ulcers

As has been previously described, ulcers can be caused by direct drug-related cutaneous, deep tissue or vascular injury, by accidental or incidental trauma, or by infection. When other venous accesses have been exhausted, drug users may attempt to inexorably maintain the granulation tissue of the ulcer (with its rich vascular network of capillaries) for injection of heroin or other drugs, resulting in chronic non-healing ulcers called "shooter's patches"[27].

Formication

Prolonged use of cocaine may lead to the development of formication, tactile hallucinations during which the patients sense that insects are crawling on or under their skin ("coke bugs")[5]. Repetitive, stereotypical skin picking leading to excoriations and disfiguring skin ulcers on the face and extremities is a common finding in methamphetamine abusers. Not uncommonly, these individuals also feel that bugs are crawling under their skin, and cocaine or crystal methamphetamine use should be considered in anyone who presents with delusions of parasitosis as well as neurotic excoriations (Fig. 89.9). Other signs of methamphetamine abuse are dry skin, pruritus with lichenification, unpleasant body odor, a red dry nose, sweating, premature aging, rotting teeth, aggressive behavior and paranoia. Acne, especially the excoriée type, has been described.

Additional Cutaneous Findings

Circumferential, pigmented bands due to pressure from tourniquets are common in intravenous drug users with darkly pigmented skin. "Soot tattoos" are produced by injections of residual carbon on the needle after flaming[5]. Self-induced tattoos have been considered a sign of drug abuse; however, the current popularity of tattoos and their pervasive presence in persons with present or past connections to street gangs have diminished the reliability of this sign[5]. Hyperkeratosis of the fingers and palms is common in heavy users of crack cocaine. Traumatic bullae at the site of injection are occasionally observed. Pressure erythema, bullae and ulcers develop in comatose patients after an overdose with barbiturates or other sedative drugs (Fig. 89.10) (see Ch. 35).

The combination of chronic cocaine use coupled with marijuana inhalation often leads to very pruritic skin. Also, the feeling of euphoria induced by heroin is frequently accompanied by skin flushing and itching, as well as a dry mouth, watery eyes and rhinorrhea. Generalized or focal, especially genital, itching during the euphoric stage following heroin administration has been named "high pruritus".

Fig. 89.10 Coma bulla. Large bulla with subsequent erosion on the medial ankle due to prolonged coma from barbiturate overdose.

Hyperhidrosis is a common adverse effect of amphetamines or LSD. Within 30 to 90 minutes of LSD ingestion, the user feels a wide range of emotions, accompanied by sweating, increased body temperature, dry mouth, tremors and dilated pupils. Piloerection, paresthesias and flushing are manifestations of the somatic phase of LSD intoxication, while pseudohallucinations and synesthesias occur during the perceptual phase. Delusions and visual hallucinations occur at higher doses. Hypoesthesia is a common manifestation of low-dose exposure to PCP.

There have been scattered reports in habitual MDMA (ecstasy) users of a papulopustular (acneiform) facial eruption, which may indicate a higher risk of severe adverse effects, such as hepatic damage. In some cases, the eruption responded to topical metronidazole[28]. Acne and other skin eruptions are anecdotally worsened by cannabis. Acne ranging from mild to cystic, especially on the trunk, is common among users of anabolic steroids. Other cutaneous effects of anabolic steroid abuse include oily hair and skin, male and female pattern alopecia, hirsutism in women and coarse skin (see Table 89.3). Most are reversible if the abuser stops taking the drugs, but some are permanent.

Drug-Induced Reactions

As expected, hypersensitivity reactions to drugs, especially morbilliform eruptions, urticaria (opiates, barbiturates, amphetamines, marijuana), bullous eruptions, fixed drug reactions, small vessel vasculitis, Stevens–Johnson syndrome and toxic epidermal necrolysis occur more frequently in illicit drug users than in the general population (Table 89.5). In one study, dermatographism was found in a quarter of patients comatose from a drug overdose. Angioedema due to barbiturates and heroin can cause eyelid as well as labial edema. Pigmented circular patches on the skin and mucous membranes may be extensive in addicts with fixed drug eruptions.

Vascular Lesions

The most common vascular lesions are ecchymoses and even hematomas over injected vessels. Petechiae may form distal to the placement of a tourniquet. *Vascular compromise* of the hands is common and is characterized by discoloration, edema and a cold temperature. Intense burning pain is often experienced after self-administered intra-arterial injection of drugs. This is followed within hours by edema of the affected limb. Although the peripheral pulses usually remain strong, cyanosis and patches of livedo reticularis can develop followed by distal ischemia and even necrosis. Ischemia and ulceration can appear after intra-arterial injection of a number of drugs, including temazepam (as high as 100% when injected into the radial artery), barbiturates, cocaine, heroin, pentazocine, diazepam, amphetamine and sodium thiopental[13]. Other manifestations reported after accidental or intentional drug

injections into the radial artery include purpuric and pustular nodules, presumably as a result of embolization, as well as palmar cyanosis and edema with or without ulceration.

Septic thrombophlebitis results in tender, swollen extremities with or without erythema. A tender cord may be present when the affected vein is superficial, but deep vein thrombophlebitis is easily misdiagnosed as cellulitis or an abscess, either of which may be an associated complication. Deep vein thromboses are diagnosed via Doppler ultrasonography.

Pseudoaneurysms result from infected injuries to arteries (arterial wall or perivascular tissue) during intra-arterial injection of drugs ("hitting the pinkie"). They are most commonly seen in the groin, followed by the extremities, with the close proximity of the femoral artery to the femoral vein one possible explanation for those arterial injections that are inadvertent[29]. The typical lesion is a tender, diffusely indurated, pulsatile mass with an associated bruit (50–60% of cases) and decreased peripheral pulses (25%). Local suppuration and petechiae and purpura are often present. Half will resolve with antibiotics alone, but expanding lesions require proximal ligation of the vessel, resection of the pseudoaneurysm, and appropriate drainage. Otherwise, there is a risk of rupture due to necrosis. Mycotic aneurysms also occur in 15–25% of patients with infective endocarditis, most frequently in the femoral artery.

Infective endocarditis should be excluded in all injection-drug users with bacteremia. It is most commonly due to *S. aureus* and the tricuspid valve is involved in 70% of patients. Symptoms may include cough, dyspnea, fever and pleuritic chest pain. The mortality rate is <5%, but can be higher in HIV-infected individuals[30,31]. When left-sided, complications include brain and splenic abscesses due to septic emboli. Infective endocarditis associated with injection-drug use is also one of the rare settings in which polymicrobial endocarditis is encountered[20,30,31].

In addition to arterial disease (see above), cocaine can produce *superficial or deep venous thromboses*. Treatment consists of parenterally administered antibiotics, bed rest, elevation of any involved extremity, and anticoagulation; however, care must be taken to exclude a mycotic aneurysm, which can bleed, especially in the setting of anticoagulation. Distal thrombosis with extensive infarctive thigh lesions and associated hepatitis and glomerulonephritis has been reported with cocaine use, as has aortic thrombosis or dissection, acute arterial insufficiency and intestinal ischemia[29]. Most recently, levamisole-adulterated cocaine has been associated with the development of neutropenia and retiform purpura that can become necrotic (Fig. 89.11)[32–34]. Histologic examination demonstrates microvascular thromboses within the dermis, sometimes accompanied by leukocytoclastic vasculitis. Patients may also have antineutrophil cytoplasmic antibodies, decreased levels of protein C and S, or anti-phospholipid antibodies. Of note, levamisole can be detected in the serum, urine or crack pipes.

Arteriovenous fistula-associated angiomatoid nodules (pseudo-Kaposi sarcoma) in a patient with hepatitis B viral infection was reported as a possible complication of heroin use[35]. In addition, palpable purpura and tender nodules may appear as cutaneous manifestations of small and medium-sized vessel vasculitis due to hepatitis B or C viral infections or specific drugs. Repeated vascular injury and infection of the digits can cause irreversible contractures (camptodactyly) that resemble Dupuytren's disease.

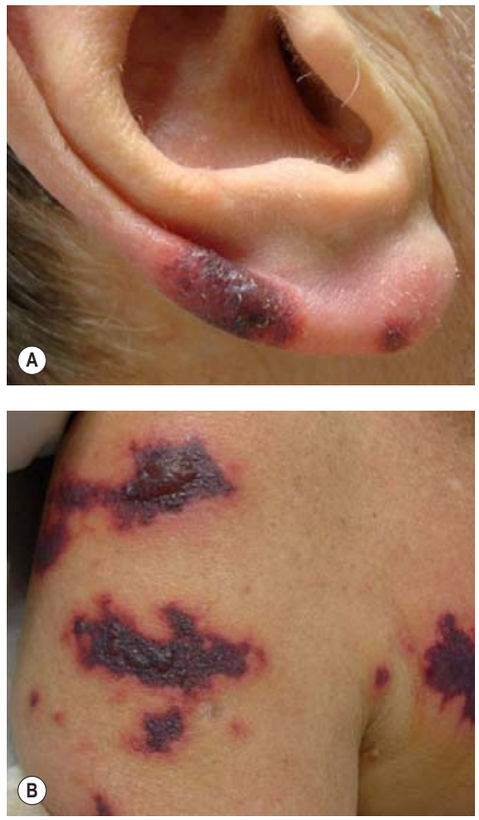

Fig. 89.11 Retiform purpura due to levamisole-adulterated cocaine. A, B The earlobe is a common site of involvement and purpuric lesions of the earlobe had been described previously as a side effect of levamisole. Up to 70% of the cocaine in the US at the time of writing contained levamisole but <3% of the heroin supply. *Courtesy, Jeffrey Callen, MD.*

Systemic Complications

Drug abuse may indirectly contribute to congenital cutaneous malformations and domestic violence (see Ch. 90). The estimated incidence of infective endocarditis (see above), a major cause of mortality in this population, is 1.5 to 3.3 cases per 1000 injection-drug users per year[20]. Several cutaneous signs (arterial emboli, conjunctival hemorrhages, splinter hemorrhages, Janeway lesions and Osler nodes) may be present. The prevalence of HIV infection among intravenous drug users with infectious endocarditis is very high, ranging from 45% to 90%. The US Centers for Disease Control and Prevention estimates that 55–60% of AIDS cases among women and one-third of overall AIDS cases in the US are linked to injection-drug use or sex with partners who inject drugs.

Parenteral drug users are also at high risk for contracting other bloodborne viruses such as hepatitis B and C and human T-lymphotrophic virus types 1 and 2 (HTLV-1, HTLV-2). Approximately 60% of all new cases of hepatitis C infections in the US are attributed to syringe and needle sharing with an infected individual. In some user populations, transmission of hepatitis C occurs so rapidly that within 6 months of beginning drug use, one-third of users are infected, and within 2 years, up to 90% have contracted the infection[36].

Drug addicts have high prevalences of all sexually transmitted diseases, due to multiple partners, prostitution and failure to use condoms. However, narcotic abuse is a common cause of false-positive non-treponemal syphilis screening tests (e.g. VDRL, RPR). In these cases, treponemal tests (e.g. MHA-TP, FTA-ABS) will be non-reactive. In addicts who have had syphilis, both types of tests will be positive, but the titers of the non-treponemal test may not decrease rapidly after treatment.

Cocaine may initiate scleroderma in susceptible individuals or unmask it at an earlier age in those with subclinical disease. However, the localized cutaneous induration induced by cocaine injections is reversible. Cases of Henoch–Schönlein purpura, polyarteritis nodosa and necrotizing angiitis with renal and pulmonary disease have been associated with the use of heroin. Nephrotic syndrome from amyloidosis has been reported in heroin skin poppers and intravenous drug users with chronically draining skin lesions[37].

TREATMENT

A detailed discussion of the management of drug addiction is beyond the scope of this chapter. Approaches are summarized in Table 89.6 and discussed elsewhere in the literature[38]. When providing care to persons suspected of drug addiction, it should be remembered that even admission of illicit drug use is difficult, as patients risk disapproval and overt or concealed rejection even from medical professionals.

The selection of antibiotics to treat skin infections should be guided by antibiotic sensitivities of the cultured organisms. With the emergence of community acquired MRSA, appropriate cultures of lesions and wounds have become more imperative than ever. Broad-spectrum antibiotic regimens that cover *S. aureus* should be prescribed until antibiotic sensitivity results are available. Treatment of cellulitis consists of splinting, limb elevation and intravenous antibiotics. Inclusion of vancomycin or linezolid (for MRSA) and clindamycin (for anaerobes) in the antibiotic regimen has been recommended for hand

TREATMENT OF DRUG ADDICTION	
Drug	**Treatments**
Opiates	• Drug detoxification – Office-based – Inpatient – Ultra-rapid under general anesthesia using naltrexone (plus clonidine, benzodiazepines and antiemetics) • Maintenance therapy – Agonist (methadone, levomethadyl*) – Partial agonist (long-acting buprenorphine) – Antagonist (naltrexone) • Pharmacologic therapy for withdrawal (e.g. clonidine, lofexidine, guanfacine) • Additional measures (counseling, psychotherapy, acupuncture)
Cocaine	• Drug rehabilitation • Anticonvulsants (e.g. topiramate, tiagabine), dopamine agonists/reuptake inhibitors† (e.g. amantadine, bromocriptine, pergolide, vanoxerine), antidepressants (e.g. bupropion), CNS stimulants (e.g. modafinil), $GABA_B$ receptor agonists (e.g. baclofen), N-acetylcysteine
Amphetamines	• Drug rehabilitation • Antidepressants (e.g. fluoxetine, imipramine, desipramine, mirtazapine), modafinil, antipsychotics (e.g. chlorpromazine, haloperidol, thioridazine)
*Withdrawn from the US market due to risk of cardiac arrhythmias. †To date, no statistical evidence of benefit for dopamine agonists.

infections and should also be considered in infections that may result in loss of limb or life[13]. Hand infections must be aggressively treated, recognizing that amputation of the digits or the hand occurs in 10% of patients[13].

Even with surgical plus aggressive medical treatment, the mortality rate of necrotizing fasciitis in drug addicts is approximately 20% and limb amputation is necessary in another 18%[22]. A decrease in mortality from 27% to 7% was reported with a protocol consisting of aggressive diagnosis, intense intravenous broad-spectrum antimicrobial therapy, supportive care, early subfascial debridement, and follow-up debridement of the wound in 8 to 12 hours until no further necrotic tissue had formed. Between two and four debridements were required[23].

Skin grafting of large ulcers may be necessary when healing does not occur with compression and appropriate dressings. Some substance abusers may deliberately sabotage the skin graft by injecting through it or into the vacuum (VAC) dressing tubing[39]. Recovered parenteral drug users often wear long-sleeved shirts and other garments to hide the stigmata of their past addiction and may seek help in diminishing the appearance of these signs. Hypertrophic scars improve with intralesional injections of corticosteroids and pulsed dye laser treatments (see Ch. 98). Hyperpigmented scars require the use of pigment-specific lasers and bleaching agents, including hydroquinone. Tissue augmentation with hyaluronic acid or fat can improve the appearance of depressed scars. Such scars may also respond to low-fluency treatments with visible light lasers, which stimulate fibroblast proliferation.

Skin Signs of Abuse 90

Sharon S Raimer, Lauren Raimer-Goodman and Ben G Raimer

Chapter Contents

Child abuse 1521
Elder abuse 1525

Physical and psychological abuse are problems that may occur in any cultural environment. Although abuse is not limited to particular age groups, this chapter will focus on abuse inflicted upon children and elders – individuals who are often least able to defend themselves or escape their situation without recognition of the abuse by others.

CHILD ABUSE

Synonym: ■ Battered child syndrome

Key features

- Signs of physical abuse include: unexplained bruises; injuries of the thorax, abdomen, buttocks, genitals, chin, ears or neck; curvilinear marks; and cigarette burns or other well-demarcated burns
- Signs of sexual abuse include attenuation, fresh tears or scars of the hymen and/or the anal margin extending out onto perianal skin

Introduction

Child abuse is a term used to encompass the broad spectrum of non-accidental maltreatment of children, including physical, emotional and sexual abuse as well as neglect. Physical abuse is defined as a non-accidental injury of a child; the injury may be the result of a single abusive episode or occur over a longer period of time. Two out of every 100 infants under 1 year of age are victims of abuse or neglect[1]. In 2010, 11% of childhood injuries reported to the National Trauma Data Bank were due to intentional assault, and 6% of assault-related injuries resulted in death of the child[2]. Abused children are generally younger and more likely to sustain serious intracranial, thoracic and abdominal injuries than children who are injured accidentally[3]. Younger children are at greater risk because they are demanding, non-verbal and defenseless.

Parents may describe abused children as "difficult", which in fact may be true; however, the parents' attempts to intervene in an excessive and inappropriate manner constitute abuse. Premature infants, disabled children, and children with behavioral problems appear to be at increased risk of abuse. Parents who abuse their children were often themselves abused as children. They are frequently immature, dependent individuals who are socially isolated. Often, they do not handle stress well, and a personal or family crisis may trigger an abusive episode. It is important that all physicians recognize signs of physical abuse in children, as it tends to be repeated, and an intentionally injured child should be considered at high risk for the future occurrence of a severe physical injury.

Physical neglect is a failure to provide the necessities of life for a child, including nutrition, clothing, housing, medical care and a safe, supervised environment. Emotional abuse or neglect results when parents fail to provide a nurturing environment that permits the child to grow and reach his or her full potential.

Sexual abuse can be defined as engaging a child in a sexual activity that the child cannot comprehend, for which the child is developmentally unprepared and cannot give informed consent, and/or that violates the social and legal taboos of society[4]. The child's involvement may be coerced with physical threats, rewarded through bribes, or induced via misrepresentation of moral values. Sexual abuse can be assaultive or non-assaultive. Non-assaultive sexual abuse probably occurs frequently and often goes unreported since there is usually little or no physical injury to the child. Assaultive sexual abuse, on the other hand, is characterized by physical injury and violence. Both types of sexual abuse may result in severe emotional trauma to the child.

History

Maltreatment of children has always existed, but in 1946, Dr John Caffey, a pediatric radiologist, initiated medical concern about child abuse by reporting six children who presented with skeletal fractures and associated subdural hematomas that were clearly related to trauma[5]. The immense importance of this problem was not generally recognized until 1962, when Kempe et al.[6] coined the term *battered child syndrome*, the findings of which include inadequately explained signs of trauma, multiple fractures at different stages of healing, and/or failure to thrive that responds to either nutritional therapy or placing the child in an emotionally supportive environment.

Epidemiology

Child abuse is a worldwide problem that occurs among all ethnic and racial groups and in families of all socioeconomic and educational levels. In the US, single-parent families with incomes below 200% of the poverty threshold have much higher probabilities of violence[7]. Child abuse occurs more frequently when other problems such as unemployment, substance abuse, unplanned pregnancies or discord between parents increase the stress on individuals within the family. Boys are at greater risk for serious injury than are girls, and infant boys have the highest fatality rate[1].

The perpetrator of sexual abuse is often a person well known to the child, in most cases the natural father, followed in frequency by a stepfather or another close relative. Although reports of abuse are about three times more likely in girls than in boys[8], sexual abuse in boys may be more likely to go undetected and/or unreported. Epidemiologic studies have shown that the risk for sexual abuse rises during preadolescence[8]. Features related to family structure that have been associated with a small, but statistically significant, increase of sexual abuse are the presence of a stepfather in the household, children living without one or both of their natural parents, and children whose mothers are disabled, ill or extensively out of the home[8].

Clinical Features

Physical abuse

Physical abuse is frequently identified by *bruises* (ecchymoses) (Fig. 90.1) that may be located in areas not normally prone to accidental injury, most commonly the head and neck (particularly the face) followed by the buttocks, trunk and arms[9]. They often are large, multiple and occur in clusters. The shape of the bruises may help to identify the object with which the child was struck. Linear bruising is produced when an object such as a rod, stick or strap is used to strike a child. Hematomas and traumatic fractures of underlying bone may be present.

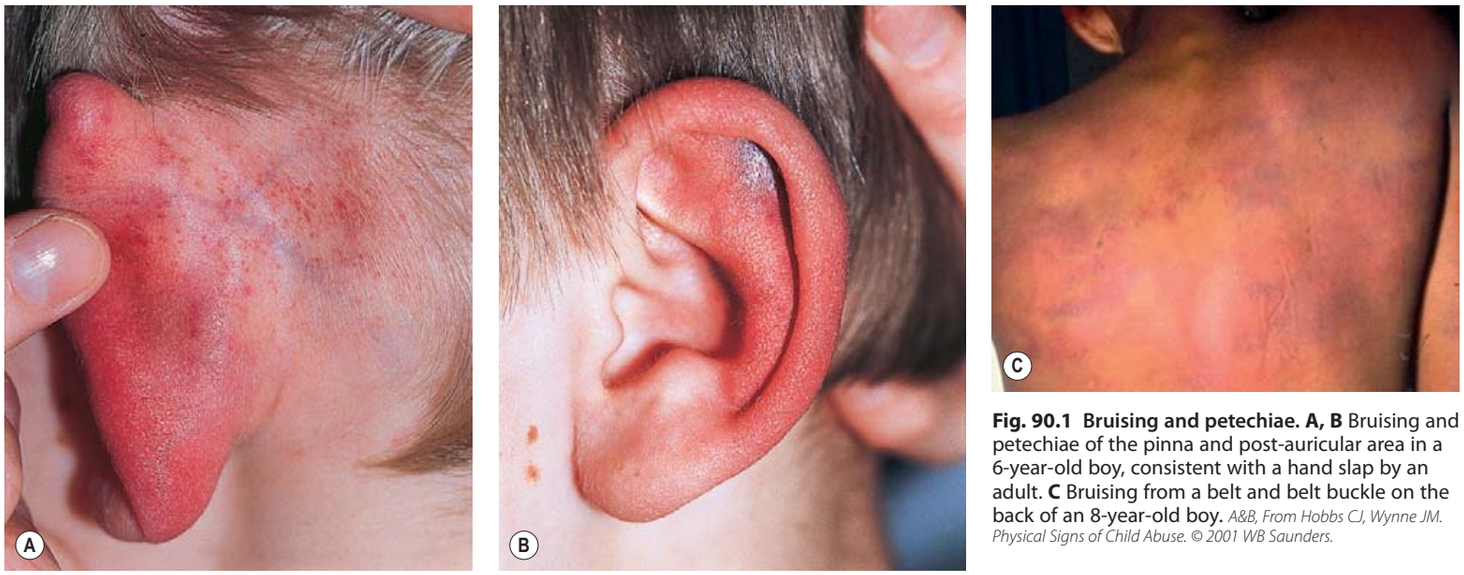

Fig. 90.1 Bruising and petechiae. A, B Bruising and petechiae of the pinna and post-auricular area in a 6-year-old boy, consistent with a hand slap by an adult. **C** Bruising from a belt and belt buckle on the back of an 8-year-old boy. *A&B, From Hobbs CJ, Wynne JM. Fig. 90.2 Curvilinear mark on the cheek of a child from assault with an electric cord. A corneal abrasion was also present.

Fig. 90.3 Healing injury due to binding around the ankles.

Loop marks are perhaps the single most characteristic finding in child abuse (Fig. 90.2). Such curvilinear marks are produced by small ropes, cords, electrical cords or belts and appear randomly over the body as a result of striking a struggling child[10].

Buckle imprints from belts can often be matched to the particular belt buckle used to strike the child. Buckles produce deep ecchymoses (see Fig. 90.1C) and can result in injury to underlying organs and bones.

Pinch marks, particularly on the ears or in the genital region of boys, should alert the examining physician to the possibility of abuse. Male toddlers rarely sustain bruises on the genitalia secondary to a fall.

Blunt trauma can be a very severe form of abuse that may or may not result in cutaneous lesions. Blunt trauma to the abdomen can lead to severe injury or even death of a child. Soft intra-abdominal organs are injured when they are slammed against the vertebral column by a kick or severe blow delivered to the abdomen. Blunt trauma in the form of slapping injury causes capillaries to break between the digits, producing linear bruises that outline the fingers. This often leaves the imprint of a hand on the child's skin, which can frequently be matched to the perpetrator.

Binding injuries are more likely to occur when the perpetrator is emotionally disturbed or psychotic. Acute binding injuries cause edema of the soft tissue around the wrists and ankles that may resemble rope burns with redness and warmth or abrasions (Fig. 90.3). Chronic binding injuries may result in bands of postinflammatory hyperpigmentation.

Traumatic alopecia results from forcefully pulling out the scalp hair. The occipital region is the most common location. When a large tuft of hair is abruptly pulled out, the underlying scalp may hemorrhage with subsequent hematoma formation.

Human bite marks leave the indelible mark of the perpetrator and may serve to identify the abuser. Adult human bite marks, which can be identified by the width of the dental arch (>4 cm), must be distinguished from those of a child, since toddlers may be bitten by their peers. Human bites produce a crushing type of injury, whereas animal bites typically result in puncture wounds.

Thermal burns constitute an especially traumatic form of injury to the young child, and the abuser in such cases is likely to be suffering from a psychiatric disturbance. Cigarette burns represent a frequent form of thermal injury and tend to be randomly distributed (Fig. 90.4). Branding injuries take the shape of the heated object (Figs 90.5 & 90.6). Dunking scald injuries occur most often in infants and toddlers, and scalds on the buttocks may be associated with attempts to toilet train an infant. "Donut-type sparing" on the child's buttocks may be apparent when the buttocks are held against the cooler tub or basin while the surrounding hot water scalds the remaining immersed skin. Dunking scalds of the extremities leave a characteristic "stocking and

Fig. 90.4 Injury produced by a cigarette burn.

Fig. 90.5 Branding injury on the thigh from a fork.

Fig. 90.6 Burn injury from an iron.

Fig. 90.7 Burn injury due to dunking in hot water. Note the sharp line of demarcation of the burn on the arm (arrow).

glove" distribution with a very sharp demarcation of the burn (Fig. 90.7). In non-accidental burns, the adults responsible for the child (and possibly the burn) frequently claim not to have witnessed the burning incident, and other relatives commonly bring the child to the hospital[11]. A delay between the injury and seeking medical care often occurs with inflicted burns.

A child may present with skin signs of multiple types of physical abuse. Such a child may be severely injured at the time of presentation or, if not, should be considered at high risk for the future occurrence of a severe injury. Both acute and healing injuries are frequently present in chronically abused children.

Physical neglect

Physical neglect usually results in a constellation of relatively obvious findings, including signs of poor nutrition, hygiene and, at times, general health. Children may have old untreated injuries, dermatitis, and infestations of the skin and hair, and they typically have not received required childhood immunizations.

Emotional deprivation

Emotional neglect or deprivation accounts for at least one-half of the children in high-income countries placed under the pediatric diagnostic term *failure to thrive*. These children fail to grow and develop in their home environment despite adequate caloric intake, while they thrive with food and stimulation in a hospital setting or foster home. There are no characteristic physical findings or diagnostic laboratory tests for these children. The diagnosis can be rendered only after other potential causes of failure to thrive have been excluded, and it is usually confirmed when the child demonstrates "catch-up" growth and development outside the disturbed home environment.

PHYSICAL SIGNS OF CHILDHOOD SEXUAL ABUSE
DIAGNOSTIC
• Attenuation of the hymen with loss of tissue • Fresh tears or scars of the hymen • Anal margin extending out onto perianal skin
SUGGESTIVE
• Gaping hymenal opening • Notch or concavity in posterior half of hymen • Notch in anterior half of hymen (if asymmetric and associated with other abnormalities) • Anal fissures • Gaping of anal sphincter with mucosal prolapse • Laxity of anal sphincter with edema ("tire sign") • Dilated perianal veins • Reflex anal dilatation

Table 90.1 Physical signs of childhood sexual abuse.

Sexual abuse

The diagnosis of child sexual abuse is based on a combination of findings in the patient's history, physical examination and, when indicated, laboratory evaluation. Children rarely fabricate reports of sexual abuse, and any such description by a child should be thoroughly investigated. Unfortunately, false accusations by parents involved in custody disputes do occasionally occur and are a burden to the medical and legal systems.

Physical signs that are diagnostic or suggestive of childhood sexual abuse are described in Table 90.1. However, physical findings may be

absent following sexual abuse. Many types of sexual molestation, such as fondling and oral sodomy, do not usually leave physical signs. Even when mild or moderate injuries occur (e.g. petechiae, ecchymoses, abrasions, superficial lacerations), healing in the anogenital area often takes place within days, resulting in very subtle or undetectable physical findings[12,13]. Acute findings that should alert the physician to the possibility of abuse include fresh genital (Fig. 90.8) or anal injuries without an adequate explanation. In the absence of a history of trauma or severe constipation, anal fissures or scarring may be suggestive of abuse. Pierce[14] reported that among 50 children with a strong history of anal abuse, 41 (82%) had anal fissures or scars. In contrast, only 2 of 81 children with no history of sexual abuse had fissures and none had scars.

It is important to be aware of normal physical findings in the genital area of female children. Studies of newborn girls have noted that a hymen is invariably present and anterior hymenal clefts are common, but posterior clefts are not normally seen[12]. Anatomic features that are suggestive of penetration include narrowing of the posterior hymenal rim to less than 1 mm and complete hymenal clefts located between 4 and 8 o'clock[13]. The presence of semen (detected via testing for prostatic acid phosphatase) or sperm is indicative of abuse, and non-perinatally acquired syphilis, gonorrhea[12] or (if other modes of acquisition are also excluded) HIV infection confirms mucosal contact (most likely sexual) with infective bodily secretions. Perinatally acquired infections with *Chlamydia trachomatis* have been documented to persist as long as 28 months; therefore, infections with this organism in children younger than 3 years of age are not as suggestive of abuse.

Anogenital warts in children (see Ch. 79) may be perinatally acquired, transmitted during the routine care of children, autoinoculated from other sites of infection, or acquired as a result of sexual abuse. In most studies, proven abuse is uncommon in children with anogenital warts who are younger than 3 years of age[15].

Differential Diagnosis

Although it may be difficult to differentiate abuse from accidental injury in a child, the distribution of injuries is often helpful. Abused children have significantly more soft tissue injuries on the cheeks, trunk, genitalia and upper legs than accidentally injured children[9]. Labbe and Caouette[16] performed over 2000 skin examinations in 1467 normal children to determine the type and location of recent skin injuries. The majority of children over 9 months of age had at least one injury, usually a bruise, but 15 or more injuries was rare. The lower limbs were the most commonly involved sites. Less than 2% of the children had injuries to the thorax, abdomen, pelvis or buttocks, and less than 1% to the chin, ears or neck. Bruises were rare in infants who were not yet independently mobile. Therefore, injury in infants or in the locations mentioned above should arouse suspicion of the possibility of abuse.

There are several cutaneous disorders that can mimic child abuse (Table 90.2; Fig. 90.9). In addition, normal anatomic variants are sometimes mistaken for signs of childhood sexual abuse. For example, 25% of newborn girls have a white line (linea vestibularis) in the posterior vestibule that could be confused with scar tissue produced by sexual abuse. Other conditions that are occasionally misdiagnosed as sexual abuse are listed in Table 90.3.

Evaluation and Management

When any lesion suspicious for abuse is present, the entire cutaneous surface of the child as well as the oral, anal and genital mucosae should be examined. Child abuse should be suspected if parents lack an explanation for a child's injuries, relate circumstances not compatible with the physical findings, describe activities for which a child is developmentally incapable, give differing accounts or change their stories. A summary of recommended steps in the evaluation and management of suspected child abuse is provided in Table 90.4. Most countries (including the US) require physicians to report suspected physical abuse, neglect and sexual abuse of children. Legal protection is generally given to healthcare providers who make such reports in good faith.

When a child gives a history of sexual abuse or has physical findings highly suggestive of abuse, an immediate referral should be made to a child protective services agency. If the history and physical findings are less certain, it may be most appropriate for experienced medical personnel to make the decision of whether sexual abuse is likely and referral to child protective services is warranted, since the potential negative impact of misdiagnosis on the family structure is substantial[17]. Whenever feasible, any child suspected of being sexually abused should be examined by a pediatrician or gynecologist experienced in evaluating children for signs of abuse. Anogenital examination by multiple

CONDITIONS THAT CAN MIMIC CHILD ABUSE

Condition	Comments
Bleeding into the skin (ecchymoses, purpura)	
• Multiple bruises due to platelet or clotting disorders	• Areas most commonly traumatized by children (e.g. shins, knees)
• Ehlers–Danlos syndrome, especially the vascular type (type IV)	• Common sites of trauma, especially shins
• Bruising due to "cupping" or cao gio (coin rubbing)	• Primarily children from SE Asia (see Ch. 133)
• Vasculitis, particularly Henoch–Schönlein purpura (HSP) and acute hemorrhagic edema of infancy	• Favors lower extremities as well as the buttocks in HSP and the face in acute hemorrhagic edema; associated edema and arthritis
Blue discoloration of skin mistaken as bruising	
• Dermal melanocytosis	• Lack of progression of color to green or yellow; favors presacrum and back
• Infantile hemangioma (deep) or vascular malformation	
Linear hyperpigmentation	
• Phytophotodermatitis	
• Sock-line or mitten-line hyperpigmentation	
Vesicles, bullae or erosions mistaken as non-accidental burns or other intentional injuries	
• Impetigo, ecthyma, blistering distal dactylitis	
• Erythema multiforme, fixed drug eruption	
• Bullous mastocytosis	
• Irritant contact dermatitis	• e.g. laxative-induced irritant contact dermatitis mimicking an immersion burn
• Arthropod bite reaction	
• Moxibustion	• Primarily children from SE Asia (see Ch. 133)
• Burn from a hot car seat or seat-belt buckle	
• Genetic disorders of skin fragility, e.g. forms of epidermolysis bullosa (see Ch. 32) or porphyria (see Ch. 49)	
Other	
• Osteogenesis imperfecta	• Multiple fractures, blue sclerae
• Hair tourniquet	
• Self-inflicted injury	

Table 90.2 Conditions that can mimic child abuse.

Fig. 90.9 Cutaneous disorders that may be misdiagnosed as physical or sexual abuse. A Linear hyperpigmented streaks on the back of a 2-year-old girl due to phytophotodermatitis; the parent had lime juice on her hand and touched the child. **B** Genital lichen sclerosus may have associated purpura or hemorrhagic bullae. **C** A perianal pyramidal protrusion in the typical location, just anterior to the anus in the midline. This finding is most common in infant girls. *A, Courtesy, Anthony J Mancini, MD. C, Courtesy, Julie V Schaffer, MD.*

physicians should be avoided if possible, given the potential trauma this may impose on the child. Lastly, because physical signs of sexual abuse may resolve within a few days, children should be evaluated by an experienced provider as soon as possible[13].

When the history and/or physical findings suggest the possibility of oral, genital or rectal contact, cultures and serologic tests to evaluate for sexually transmitted diseases are indicated. If the abuse occurred within 24 hours of the examination, samples should also be collected for forensic evidence[13].

Victims of all types of abuse may suffer long-term psychologic consequences. Some children withdraw and develop feelings of worthlessness, helplessness, hopelessness and depression. Others exhibit aggressive and impulsive behavior and are at risk for delinquency, substance abuse, absenteeism from school or work, adolescent pregnancy, sexual promiscuity and prostitution. Abused children are more likely as adults to be abusive to their own children and spouses. Thus, long-term psychologic support for abused children is desirable.

In summary, the dermatologist may be the first physician to encounter the abused child, so it is important to be alert for possible abuse, perform the appropriate documentation and testing, and report it to the proper authorities. It is often necessary to enlist the help of a primary care physician or gynecologist experienced in the evaluation of abuse. An atlas by Hobbs and Wynne[18] provides additional information and many color illustrations.

CONDITIONS OCCASIONALLY MISDIAGNOSED AS CHILDHOOD SEXUAL ABUSE

• Congenital anomalies
• Accidental injury
• Perianal streptococcal infection
• Lichen sclerosus (may be associated with purpura or hemorrhagic bullae)
• Genital vitiligo
• Localized vulvar bullous pemphigoid or other bullous diseases
• Crohn's disease
• Entities misdiagnosed as genital or perianal warts
  • Perianal pyramidal protrusion
  • Molluscum contagiosum
  • Pseudoverrucous papules and nodules due to fecal or urinary incontinence
  • Perianal papillomatous lesions of Goltz syndrome

Table 90.3 Conditions occasionally misdiagnosed as childhood sexual abuse.

EVALUATION AND MANAGEMENT OF SUSPECTED CHILD ABUSE
• Examine the entire cutaneous surface as well as oral, anal and genital mucosae; estimate the ages of individual traumatic lesions and identify any associated injuries • Detail all traumatic lesions in the medical record • Photograph injuries whenever possible • Funduscopic examination to assess for retinal hemorrhages* • Otoscopic examination to exclude hemotympanum • Skeletal survey to assess for unsuspected fractures, especially in children under 6 years of age • Treat acute injuries or infections • Report suspected abuse, initially by telephone and subsequently in writing, to the local child protective services agency • Protect the child from further injury while suspected abuse is being investigated • Long-term counseling for proven abuse
*Can occur secondary to head trauma or severe shaking; the presence of extensive, bilateral retinal hemorrhages in a child <3 years of age is strongly suggestive of abuse.

Table 90.4 Evaluation and management of suspected child abuse.

ELDER ABUSE

Key features

- Elder abuse may involve intentional actions that cause harm or create a serious risk of harm
- Failure by a caretaker to satisfy the basic needs of an elder or to protect the elder from harm also constitutes elder abuse

TYPES AND PREVALENCES OF ELDER ABUSE	
Type of elder abuse	**One-year prevalence rate (%)***
Physical abuse	1.6
Psychological abuse	4.6
Sexual assault	0.6
Material exploitation	5.2
Neglect	5.1

*Among 5777 adults aged 60 years or older in the US who were randomly selected to participate in a telephone interview-based study[21].

Table 90.5 Types and prevalences of elder abuse.

Introduction

The establishment in 1997 of the International Network for the Prevention of Elder Abuse, with representatives from countries throughout the world, demonstrated that there is international concern about elder abuse[19]. Key features (noted above) of elder abuse have been defined by a panel convened by the US National Academy of Sciences[20]. In most countries, both the healthcare system and legal statutes recognize the types of elder abuse listed in Table 90.5. Approximately one in four elders is at risk of abuse, and 6% have experienced significant abuse in the past month[21,22].

Risk Factors for Elder Abuse

Because of increased opportunities for contact and thus for conflict and tension, a shared living arrangement is a major risk factor for elder abuse[23]. Abuse also occurs in residential and nursing care facilities, and nearly one-third of such facilities have been cited for an abuse violation that caused or had the potential to cause harm to a resident[24]. Elderly individuals living alone are more likely to be victims of financial abuse, but they are at lower risk for other forms of abuse[25]. Physical abuse is reported to occur more frequently in elders with dementia, especially those with a history of aggressive behavior[26]. Social isolation has also been identified as a risk factor, with victims more likely to be isolated from friends and family (other than the person with whom they are living) than are non-victims[19]. Pathologic characteristics of perpetrators of elder abuse include mental illness, particularly depression and alcohol abuse[27]. Additionally, people who abuse elders may actually be dependent (e.g. financially) on the person they are abusing. In some cases, abuse stems from attempts by relatives (particularly adult offspring) to obtain the victim's resources[28].

Clinical Features and Assessment

In recent years, more data have become available on the clinical features of elder abuse. Lachs and Pillemer[19] proposed guidelines for medical assessment when elder abuse is suspected (Table 90.6), and Reis and Nahmiash[29] developed and validated the Indicators of Abuse screening tool for practitioners. Unfortunately, abused elders may not always have findings clearly attributable to abuse. Conversely, older individuals may have findings that mimic abuse but which are actually a result of accidental injuries or chronic disease[19].

If elder abuse is suspected, a comprehensive assessment should be done by a provider who has substantial experience with the clinical and psychosocial aspects of elder abuse. The patient should not be examined in the presence of the suspected abuser. The presence of other healthcare staff should also be minimized, since many patients are ashamed to admit that they are victims of elder abuse[19]. Although direct questions about abuse are appropriate, the interviewer may prefer to begin with general questions about safety issues and the home environment. Attempts to elicit details about the nature, frequency and provoking factors of abuse are recommended[19].

The physician must use considerable caution in interacting with a suspected abuser. One of the risks of confronting an alleged abuser is that access to the elderly person may be lost. If the physician deems it necessary to interview a suspected abuser, an empathetic nonjudgmental approach may be helpful[19].

POTENTIAL FINDINGS IN ELDER ABUSE	
Behavior observations	• Withdrawal • Absence of eye contact with interviewer • Infantilizing of patient by caregiver • Functionally impaired patient who presents without designated caregiver
General appearance	• Hygiene, cleanliness and appropriateness of dress
Skin and mucous membranes	• Skin turgor, other signs of dehydration • Multiple abrasions in various stages of evolution • Wrist or ankle lesions suggestive of restraint use • Bruises (shape may suggest implement used) • Decubitus ulcers • Lack of care provided for established skin lesions • Infestations • Immersion burn (stocking/glove distribution)
Head and neck	• Traumatic alopecia (distinguishable from androgenetic alopecia on basis of distribution) • Scalp hematomas, lacerations, abrasions
Genitourinary	• Rectal or vaginal bleeding could indicate sexual abuse
Musculoskeletal	• Examination for occult fracture, pain • Observe gait • Fractures that are not explained by mechanisms of reported injury

Table 90.6 Potential findings in elder abuse. *Adapted from Lachs MS, Pillemen K. Elder abuse. Lancet 2004;364:1263–72.*

INTERVENTIONS FOR ELDER ABUSE	
Context of elder abuse	**Potential interventions**
Abuse potentially related to stress from caring for impaired family member	Respite services Adult daycare Caregiver education programs (e.g. on what constitutes abuse) Recruitment of other family, informal, or paid caregivers to share burden of care Psychotherapy for caregiver Treatment for depression Social integration of caregiver to reduce isolation
Violence related to substance or alcohol misuse	Referral to alcohol or drug misuse rehabilitation programs as appropriate
Violence related to behavioral problems associated with mental health	Treatment referral
Spousal violence (often longstanding)	Marital counseling Support groups Shelter Orders of protection Victim advocacy
Abuse by aggressive dementia patient	Geriatric medical assessment of causes of underlying behavior
Financial exploitation by family members	Guardianship proceeding, power of attorney (transfer of legal authority) Protective services
Financial exploitation by paid caregiver	Referral to legal services Involvement of law enforcement Protective services

Table 90.7 Interventions for elder abuse. *From Lachs MS, Pilleman K. Elder abuse. Lancet 2004;364:1263–72.*

Management

Because elder abuse is multifactorial, Lachs and Pillemer[19] suggested potential interventions based on the context of abuse (Table 90.7). A multidisciplinary team involving physicians, nurses, social workers, elder care attorneys, and, when appropriate, adult protection agencies

and law enforcement officials is helpful when dealing with elder abuse. If the abused person is competent to make medical decisions and willing to accept intervention, education regarding elder abuse can be provided, a safety plan implemented (e.g. placement in a safe home, giving emergency phone numbers), and the patient as well as family members referred to appropriate services. If the patient's competency is in question and/or intervention is refused, the physician must determine if the individual has the mental capacity to make medical decisions. If not, conservatorship and an order of protection may be required.

In summary, dermatologists should remain vigilant in looking for physical signs of abuse in elderly patients, especially those who are dependent on caregivers. Patients suspected of being abused should be evaluated, wherever possible, by physicians with expertise in elder abuse. However, dermatologists who encounter or recognize the signs of elder abuse are responsible for initiating the evaluation process that protects these fragile members of society.

Histiocytoses 91

Warren T Goodman and Terry L Barrett

Chapter Contents

Langerhans cell histiocytosis *1529*
Non-Langerhans cell histiocytoses..... *1535*
Malignant histiocytic disorders *1545*

Key features

- LCH is a clonal proliferative disorder
- LCH cells are S100-, CD1a-, and Langerin (CD207)-positive
- Ultrastructurally, intracytoplasmic Birbeck granules are seen
- Osteolytic bone lesions are common
- Diabetes insipidus is common

OVERVIEW

The histiocytoses represent a group of proliferative disorders with a common CD34-positive progenitor cell in the bone marrow. Three "histiocytes" of cutaneous importance are: (1) the Langerhans cell, which migrates to and from the epidermis and functions as a potent antigen-presenting cell (APC); (2) the mononuclear cell/macrophage (sometimes called the "true" histiocyte), which migrates to and from the dermis and has both phagocytic and APC properties; and (3) the dermal dendrocyte/dendritic cell, of which there are two subtypes. Type 1 dermal dendrocytes are factor XIIIa-positive and generally reside within the papillary dermis, whereas type 2 dermal dendrocytes are CD34-positive and are generally found within the reticular dermis. Type 1 dermal dendrocytes may be involved in phagocytosis, antigen presentation, inflammation, collagen production and wound healing, while the function of type 2 dermal dendrocytes is less certain.

Dysfunction of these various histiocytes has led to a group of well-known but poorly understood disorders. For years, many of the histiocytoses were known by numerous names, reflecting the lack of understanding and agreement regarding their origin. Electron microscopy and the development of immunohistochemical stains have provided insight into these conditions. It is now clear that the histiocytoses are closely related entities, with Langerhans cell histiocytosis (LCH) representing one group of disorders and non-Langerhans cell histiocytosis (non-LCH) representing another. Of note, each group represents a spectrum of disease, with overlap between entities.

This chapter covers the most common and several of the rarer histiocytic disorders in detail. In addition, the key features of the hemophagocytic syndromes (Table 91.1), the rare malignant histiocytic disorders (class III histiocytosis; see Table 91.3), and the even rarer dendritic cell hamartomas (see Table 91.4) are presented.

LANGERHANS CELL HISTIOCYTOSIS

Synonyms:

- Langerhans cell histiocytosis (LCH; class I histiocytosis, histiocytosis X), comprising:
  - Letterer–Siwe disease
  - Hand–Schüller–Christian disease
  - Eosinophilic granuloma
  - Congenital self-healing reticulohistiocytosis (Hashimoto–Pritzker disease)

Introduction

Langerhans cell histiocytosis (LCH) is a clonal proliferative disease of Langerhans cells that express an immunophenotype positive for S100, CD1a and Langerin (CD207), and which contain cytoplasmic Birbeck granules. LCH represents a disease spectrum with four prominent but overlapping syndromes:

- Letterer–Siwe disease
- Hand–Schüller–Christian disease
- eosinophilic granuloma
- congenital self-healing reticulohistiocytosis (Hashimoto-Pritzker disease).

Disease expression ranges from mild, sometimes asymptomatic, single-organ involvement to severe, progressive multisystem disease.

History

Letterer–Siwe disease, Hand–Schüller–Christian disease and eosinophilic granuloma were described in the early twentieth century. In 1953, Lichtenstein[2] grouped the three disorders into a single entity which he called *histiocytosis X*. In 1973, Hashimoto and Pritzker[3] described the entity congenital self-healing reticulohistiocytosis. Immunologic and ultrastructural studies confirmed the relationship of the pathologic cells in histiocytosis X and congenital self-healing reticulohistiocytosis to Langerhans cells, providing a basis for the Writing Group of the Histiocyte Society[4], in 1987, to reclassify them as "Langerhans cell histiocytoses".

Epidemiology

LCH occurs worldwide and most commonly develops in children ages 1–3 years, though disease can develop at any age. The reported incidence of LCH varies widely. However, an annual incidence of at least five per million children is often quoted, with the adult incidence suspected to be less than one-third that of children. LCH is more common in boys, with a male : female ratio of nearly 2 : 1. In adults, there may be a slight female predominance.

Some cases of LCH appear to be familial. One study described simultaneous development of LCH in four of five monozygotic twin pairs and in one of three dizygotic pairs[5]. Additionally, in two families with affected non-twin siblings, parental consanguinity was known in one and possible in the other.

Pathogenesis

Until recently, the pathogenesis of LCH was unknown. Viral and immunologic etiologies had long been considered, although to date no studies have demonstrated a primary immune abnormality in patients with LCH and there has been no consistent detection of viral genomes in LCH tissue[6]. In 2010, a significant percentage (57%) of LCH specimens were shown to harbor the *BRAF* V600E mutation[6a], as has been described in cutaneous melanomas. This finding strongly suggested that LCH is neoplastic and raised the possibility of the therapeutic use of *BRAF* inhibitors in the future.

CLINICAL FEATURES OF THE HISTIOCYTOSES			
Histiocytosis	**Usual age**	**Most common mucocutaneous sites**	**Other findings**
LANGERHANS CELL HISTIOCYTOSES			
Letterer–Siwe disease	0–2 years	Scalp, flexural areas, trunk	Visceral and bone lesions
Hand–Schüller–Christian disease	2–6 years	Scalp, flexural areas, trunk, gingival	Diabetes insipidus, bone lesions, exophthalmos
Eosinophilic granuloma	7–12 years	Skin lesions rare	Bone lesions primarily
Congenital self-healing reticulohistiocytosis (Hashimoto–Pritzker disease)	Congenital	Widespread, localized, or single lesion	Spontaneous resolution, but children should be followed longitudinally
NON-LANGERHANS CELL HISTIOCYTOSES			
Primarily cutaneous, usually self-resolving			
Juvenile xanthogranuloma	0–2 years	One to a few lesions >> numerous & widespread Head and neck > upper trunk > extremities	Rare eye and visceral lesions; spontaneous resolution; association with CALM, NF-1, and/or juvenile myelomonocytic leukemia
Benign cephalic histiocytosis	0–3 years	Face and neck > trunk and extremities	Usually none (diabetes insipidus rare); spontaneous resolution
Giant cell reticulohistiocytoma	Adults	Head (solitary lesion)	None; spontaneous resolution
Generalized eruptive histiocytoma	<4 and 20–50 years	Widespread (axial)	Recurrent crops; spontaneous resolution
Indeterminate cell histiocytosis	Any	Solitary or generalized Trunk & extremities > head & neck, genitalia	Uncommon visceral and bone lesions; possible association with B-cell lymphoma and leukemia
Primarily cutaneous, often persistent/progressive			
*Papular xanthoma	Any	Generalized (discrete yellow papules and papulonodules with relative sparing of flexural sites)	Mucous membrane involvement can occur occasionally
*Progressive nodular histiocytoma	Any	Generalized (discrete yellow papules and nodules, sometimes with prominent facial involvement)	May represent same entity as the progressive form of papular xanthoma[1]; mucous membrane involvement can occur
*Hereditary progressive mucinous histiocytosis	Childhood/ Adolescence	Generalized (skin-colored to erythematous papules and nodules)	Usually occurs in female patients; histologically, abundant dermal mucin in addition to histiocytes
Cutaneous, with frequent systemic involvement			
Necrobiotic xanthogranuloma	17–60 years	Periorbital > other face, trunk, extremities	Paraproteinemia due to plasma cell dyscrasia or lymphoproliferative disorder, hepatosplenomegaly
Multicentric reticulohistiocytosis	30–50 years	Head; hands, elbows (over joints); mucosa (oral, nasopharyngeal)	Arthritis (often destructive); up to 30% with internal malignancy
Rosai–Dorfman disease	10–30 years	Eyelids and malar area	Massive lymphadenopathy in a subset of patients, fever, hypergammaglobulinemia; skin-limited form increasingly recognized
Xanthoma disseminatum	Any	Flexural areas to widespread > mucosa (oral, nasopharyngeal)	Diabetes insipidus
Systemic, with skin involvement rare to unusual			
Erdheim–Chester disease*	Any	Skin involvement ~25% of patients: eyelids, scalp, neck, trunk, axillae (red–brown to yellow nodules and indurated plaques)	Fever, bone lesions, exophthalmos, diabetes insipidus; involvement of the lungs, kidneys, adrenals, heart, CNS, retroperitoneum and testes; high mortality rate
Sea-blue histiocyte syndrome (sea-blue histiocytosis)* • Inherited • Acquired	Usually adolescence/ young adulthood (inherited form)	Skin involvement rare (inherited form): facial (macular hyperpigmentation and nodules)	Histiocytes contain cytoplasmic granules that stain azure blue with May–Gruenwald stain; multiple organs involved; can be fatal

*Not covered in the body of the text.

Table 91.1 Clinical features of the histiocytoses. CALM, café-au-lait macule; NF, neurofibromatosis.

Continued

As mentioned previously, at least a small subset of LCH appears to be hereditary[5]. In addition, several studies by different investigators have demonstrated clonal $CD1a^+$ histiocytes in all LCH tissue tested[7,8]. Based upon these results, as well as the presence of oncogenic *BRAF* mutations, LCH is now best regarded as a clonal neoplastic disorder.

While several studies have demonstrated elevated levels of cytokines in lesions of patients with LCH, including TNF-α, interferon-γ, granulocyte–monocyte colony-stimulating factor (GM-CSF) and interleukin (IL)-1, IL-2, IL-4 and IL-10, these cytokines and interleukins are thought to promote various disease-related symptoms and morbidity, rather than being responsible for the development of disease.

Clinical features

The four well-described variants of LCH have significant clinical overlap. As a result, many clinicians no longer attempt to differentiate

CLINICAL FEATURES OF THE HISTIOCYTOSES			
Histiocytosis	**Usual age**	**Most common mucocutaneous sites**	**Other findings**
Hemophagocytic lymphohistiocytosis (HLH; hemophagocytic syndrome)* • Primary (genetic; see Table 60.5) – Familial HLH‡, Chédiak–Higashi syndrome, Griscelli syndrome type 2, and X-linked lymphoproliferative syndrome • Secondary (acquired) – Infection-associated (e.g. EBV, CMV)§ – Malignancy-associated (e.g. NK/T-cell lymphoma) – Macrophage activation syndrome associated with autoimmune connective tissue disease (e.g. Still's disease, systemic lupus erythematosus)	Primary: 0–2 years Secondary: any	Generalized (purpuric macules and papules, morbilliform eruptions, erythroderma, keratotic nodules) or acral (erythematous macules)†; malignancy-associated forms may present with lesions of cutaneous or subcutaneous T-cell lymphoma	Fever, hepatosplenomegaly, cytopenias, hypertriglyceridemia, hypofibrinogenemia, histologic evidence of hemophagocytosis (e.g. in the bone marrow, lymph nodes or spleen), low natural killer cell activity, hyperferritinemia, elevated soluble CD25 (plus evidence of infectious agent, malignancy or autoimmune connective tissue disease in secondary forms)

*Not covered in the body of the text.
†Skin biopsy specimens rarely demonstrate hemophagocytosis.
‡In the US, most commonly due to mutations in the gene that encodes perforin
§A list of infectious agents associated with HLH is available at www.cdc.gov/ncidod/eid/vol6no6/fisman_refs.htm.

Table 91.1 Clinical features of the histiocytoses (cont'd). EBV, Epstein-Barr virus; CMV, cytomegalovirus.

between the various syndromes that comprise LCH, recognizing that LCH is one disease with a wide clinical spectrum and a highly varied course. For historical context, the three classically described variants and the more recently recognized congenital self-healing reticulohistiocytosis are discussed here.

Letterer–Siwe disease is the acute diffuse form of LCH. It is a multisystem disease that nearly always develops prior to age 2 years, and commonly presents in children less than 1 year of age. Cutaneous involvement occurs in most patients as 1–2 mm pink to skin-colored papules, pustules and/or vesicles in the scalp, flexural areas of the neck, axilla and perineum, and on the trunk (Fig. 91.1A–C). Scale and crust with secondary impetiginization are common changes, as is the development of petechiae and purpura (Fig. 91.1D). The lesions tend to coalesce and become tender, especially when fissures develop in intertriginous zones (Fig. 91.1E). Palmoplantar and nail involvement can occur, as can soft tissue nodules (Fig. 91.1F). In patients with darkly pigmented skin, the lesions may appear relatively hypopigmented (Fig. 91.1G). The eruption is most often confused with seborrheic dermatitis, various forms of diaper dermatitis (see Ch. 13) or intertrigo, arthropod bites (including scabies), and varicella.

During the course of the disease, many organs can become infiltrated by clonal LCH cells. However, only if the key functions of the organ are affected is such involvement of prognostic significance. Lung, liver, lymph node and bone involvement commonly occur at some point during the illness. Osteolytic bone lesions are painful, usually multiple, and most frequently affect the cranium. Occasionally, the hematopoietic system can be involved, with thrombocytopenia and anemia portending a poor prognosis.

Classically, Hand–Schüller–Christian disease represents the triad of diabetes insipidus, bone lesions and exophthalmos. These patients tend to have a chronic progressive course. For most, Hand–Schüller–Christian disease begins between the ages of 2 and 6 years. Patients with the complete triad are rare, as exophthalmos is uncommon and often a late finding. Approximately 30% of patients develop skin or mucous membrane lesions. While early cutaneous lesions are similar to those seen in Letterer–Siwe disease, older lesions can become xanthomatous. Ulcerative nodules may develop in the oral and genital areas, with premature loss of teeth possible secondary to gingival lesions.

At least 80% of patients with Hand–Schüller–Christian disease develop bone lesions, the cranium being preferentially involved. Chronic otitis media occurs commonly in these patients and in patients with all forms of LCH. Diabetes insipidus, secondary to infiltration of the posterior pituitary by LCH cells, develops in approximately 30% of patients and is more common in those patients with cranial bone involvement. The chances of reversing the diabetes insipidus with radiation or chemotherapy are remote once symptoms develop. However, symptomatic treatment with vasopressin is effective.

Eosinophilic granuloma is a localized variant of LCH that generally affects older children, boys more than girls. Skin and mucous membrane lesions are rare, with a single asymptomatic granulomatous lesion of the bone the most common manifestation. The cranium is most frequently affected, though lesions can also develop within the ribs, vertebrae, pelvis, scapulae and long bones. A spontaneous fracture or otitis media may be the first sign of disease.

Congenital self-healing reticulohistiocytosis (Hashimoto–Pritzker disease) is a variant of LCH which is generally limited to the skin and rapidly self-healing. It presents at birth or in the first few days of life with a characteristic eruption of widespread red to purplish-brown papulonodules. After several weeks, the lesions crust and involute. Solitary papules or nodules (often eroded or ulcerated) and disseminated vesicular eruptions have also been observed (Fig. 91.2; see Ch. 34). Mucous membrane lesions are rare, although systemic involvement has been reported. While congenital self-healing reticulohistiocytosis is considered a benign, self-resolving disorder, its relationship to other LCH variants suggests a cautious approach with respect to prognosis.

Adults rarely develop LCH, but, when they do, the most commonly involved sites are the skin, lung and bone (see Fig. 91.1E). Diabetes insipidus can also develop and, as in children, is more likely when bony involvement of the skull is present. Severe multisystem disease, classically referred to as Letterer–Siwe disease, is rare in adults. However, LCH can be a progressive disease in adults, especially when both bone and extraskeletal sites are involved.

Two patterns of associations between LCH and malignancy have been noted[9]. First, an increased incidence of solid tumors and leukemia has been noted in patients previously treated for LCH. In 20 of 21 reported cases of acute lymphoblastic leukemia (ALL) or acute myelogenous leukemia occurring following treatment for LCH, the therapeutic regimens had included chemotherapy, radiotherapy, or both. It was suspected that the increased incidence of leukemias in this group was treatment-related. In addition, a few patients developed skin or solid tumors (e.g. basal cell carcinoma, osteosarcoma) within the fields of radiotherapy for their LCH.

Second, there may be an increased incidence of LCH developing in patients with ALL or solid tumors[9]. In 7 of 12 reported patients with both LCH and ALL, the leukemia preceded the LCH. There may also be an association between retinoblastoma and LCH. Of nine reported cases of solid tumors preceding LCH or developing concurrently with LCH, four were retinoblastomas[9].

The prognosis of patients with LCH varies dramatically. A high mortality rate is associated with multisystem disease, especially in children less than 2 years of age, and in any patient with multiorgan disease if the hematopoietic system, liver, lungs or spleen is involved. Even with

Fig. 91.1 Langerhans cell histiocytosis – clinical spectrum. A Scalp involvement may initially be diagnosed as seborrheic dermatitis; however, there are usually more discrete papules and crusting. **B** Pink, thin plaques with fissuring along the inguinal crease can also resemble seborrheic dermatitis. **C** Advanced disease with coalescence of papules into large plaques and prominent inguinal lymphadenopathy. **D** The presence of petechiae and purpuric papules is a clue to the diagnosis. **E** In an adult, the clinical presentation of inguinal involvement is similar to that of infants. **F** This subcutaneous nodule on the scalp involved the skull and represented the initial manifestation of multisystem Langerhans cell histiocytosis in an infant. **G** In patients with darkly pigmented skin, the papules can be hypopigmented. *B, Courtesy, Richard Antaya, MD. D, F, G, Courtesy, Julie V Schaffer, MD.*

aggressive treatment, mortality in this group of patients ranges from 35% to 55%[10]. Patients not falling into this category tend to do better. Nevertheless, progression or persistence of disease is common.

Pathology

Just as the clinical appearance of LCH is variable, so is the histologic appearance. In a typical papule, a proliferation of LCH cells is present in the papillary dermis (Fig. 91.3). These cells are large, 10–15 μm in diameter, with a reniform (kidney-shaped) nucleus. Usually, some epidermal infiltration by Langerhans cells is present, as well as interface changes. The dermal LCH cells are often admixed with eosinophils, neutrophils, lymphocytes and plasma cells. Mast cells may be present in large numbers. Secondary features such as crusting, pustule formation, hemorrhage or necrosis may obscure the characteristic LCH cell infiltrate. Older lesions that are no longer proliferative may appear granulomatous, xanthomatous or fibrous.

Table 91.2 Antigenic markers of the histiocytoses. Classic results are provided and results may vary in specific cases. Staining for other classic macrophage/monocyte markers (e.g. HAM56) is variable.

In nodular lesions of congenital self-healing reticulohistiocytosis, the histology may be identical to other variants of LCH. However, lesions with sheets of histiocytes with abundant eosinophilic cytoplasm, so-called "reticulohistiocytes", intermixed with LCH cells and giant cells, have also been described. The cytoplasm of the reticulohistiocytes and the giant cells may have a "ground glass" appearance, as in multicentric reticulohistiocytosis.

In soft tissue nodules or bone lesions, LCH cells are readily identifiable, especially during the proliferative phase of the process, as the aggregates tend to be larger. In these lesions, sheets of LCH cells may be found, and a few mitoses may be seen. Older bone lesions, on the other hand, may show only xanthomatous or fibrous changes. Early lesions should be biopsied when possible.

Langerhans cells are of bone marrow origin (see Ch. 4). Clonal LCH cells have a similar though not identical immunophenotype to Langerhans cells. Like Langerhans cells, LCH cells show positive immunostaining for CD1a, Langerin (CD207) and S100 (Table 91.2), and do not characteristically express factor XIIIa (a marker for type 1 dermal dendrocytes) or classic macrophage/monocyte markers such as CD68 or HAM56 (Fig. 91.4). ATPase, peanut lectin and α-D-mannosidase are positive in LCH cells, but staining for these is less often performed, as CD1a staining is more specific. Langerin, a transmembrane C-type lectin that serves as an endocytic receptor, is a highly specific Langerhans cell marker. Because Langerin is the major protein of Birbeck granules, Langerin immunostaining can be used as a substitute for demonstration of Birbeck granules by electron microscopy. Both Langerin and CD1a have important roles in the uptake, processing and presentation of non-peptide (e.g. lipid) antigens by Langerhans cells.

Electron microscopy demonstrates Birbeck granules, which are rod- or racquet-shaped cytoplasmic structures pathognomonic for Langerhans cells and LCH cells (Fig. 91.5). On average, approximately 50%

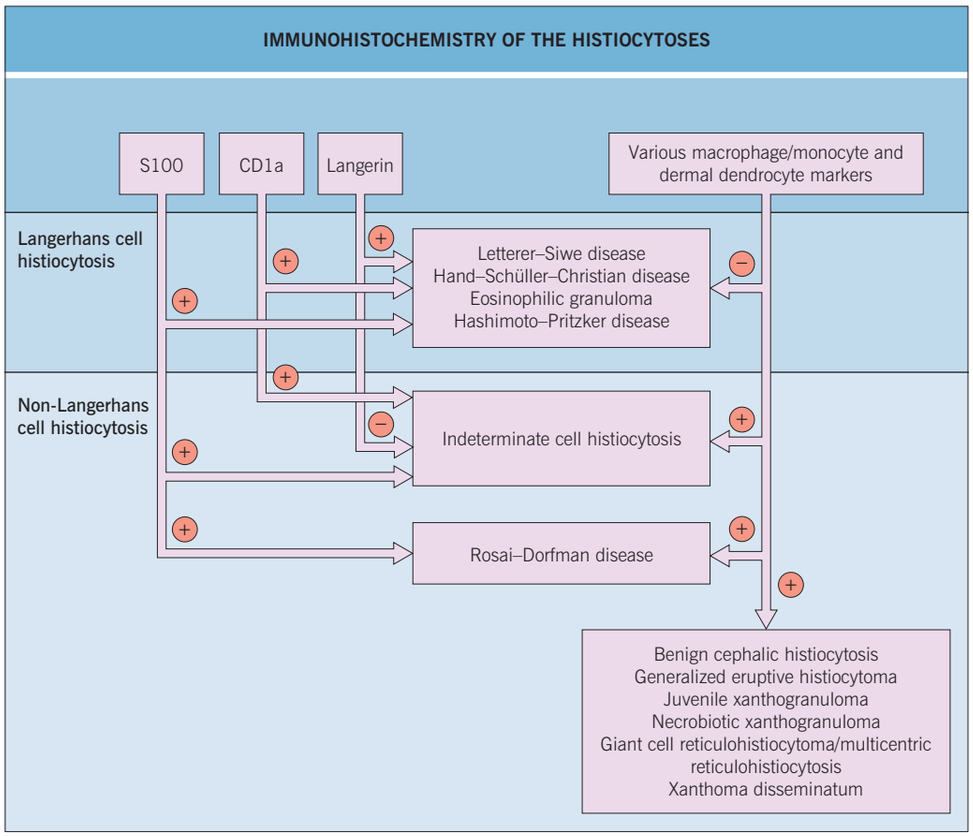

Fig. 91.4 Immunohistochemistry of the histiocytoses. Examples of classic macrophage/monocyte markers are CD68 and HAM56; an example of a classic dermal dendrocyte marker is factor XIIIa.

Fig. 91.5 Langerhans cell histiocytosis (Birbeck granules). Electron micrograph demonstrates classic racquet-shaped Birbeck granules in the cytoplasm of an LCH cell.

of cells will demonstrate Birbeck granules. With the availability of CD1a and Langerin staining, electron microscopy is performed less frequently today than in the past.

Differential diagnosis

The clinical differential diagnosis is vast and includes seborrheic dermatitis, various forms of diaper dermatitis (see Ch 13), and arthropod bites (including scabies), as well as leukemia, B- and T-cell lymphomas, multiple myeloma (bony lesions), urticaria pigmentosa and the non-Langerhans cell histiocytoses (see Table 91.1). However, the characteristic histologic features of LCH will lead one to suspect the diagnosis, which is confirmed with the combination of positive immunostaining for CD1a, S100 and Langerin (CD207; Fig. 91.6) or demonstration of Birbeck granules on electron microscopy.

Treatment

All patients diagnosed with LCH should undergo evaluation of the hematologic, pulmonary, hepatosplenic, renal and skeletal systems to determine the extent of disease. Further evaluation of the CNS and the bone marrow may be required. Treatment of LCH is dependent on the number of body systems involved and the severity of involvement.

For mild single-system skin disease (if treatment is required), topical corticosteroids, topical antimicrobials, narrowband UVB, PUVA, and topical nitrogen mustard (mechlorethamine) have been reported to be effective in case series, although potential side effects must be considered. For more extensive disease, thalidomide may be effective.

Localized bone lesions can be treated effectively with curettage. Symptomatic recurrent or new lesions, or those with a significant risk of fracture, cosmetic defect or functional abnormality, may require treatment with radiation. Treatment options for less problematic bone tumors include oral nonsteroidal anti-inflammatory drugs (NSAIDs) and intralesional corticosteroid injections.

Multisystem disease has traditionally been treated with systemic therapy. The LCH-1 clinical trial compared the effectiveness of vinblastine versus etoposide (in combination with a single dose of methylprednisolone)[10]. The vinblastine- and etoposide-based regimens were found to be equivalent with regard to disease response (58% vs. 65%, respectively), reactivation (61% vs. 55%), toxicity (47% vs. 58%) and survival (76% vs. 83%), as well as in prevention of disease-related permanent consequences such as diabetes insipidus, endocrinopathies (e.g. growth hormone deficiencies), orthopedic problems, hearing impairment, liver and lung failure, and CNS disease.

While it was also noted that a failure to respond to treatment at 6 weeks was a predictor of poor outcome, those patients who had multisystem disease but were over 2 years of age at diagnosis *and* had no involvement of the hematopoietic system, liver, lungs or spleen, had a 100% probability of survival. Perhaps the most significant shortcoming of treatment with either the vinblastine- or etoposide-based regimen, as shown in LCH-1, was the high rate of reactivation of disease (58% ± 6%). For these patients, multidrug chemotherapy is an option.

Information on current trials for multisystem disease as well as for adults with single-system disease are available at the website for the Histiocyte Society (www.histiocytesociety.org). Anecdotally, small

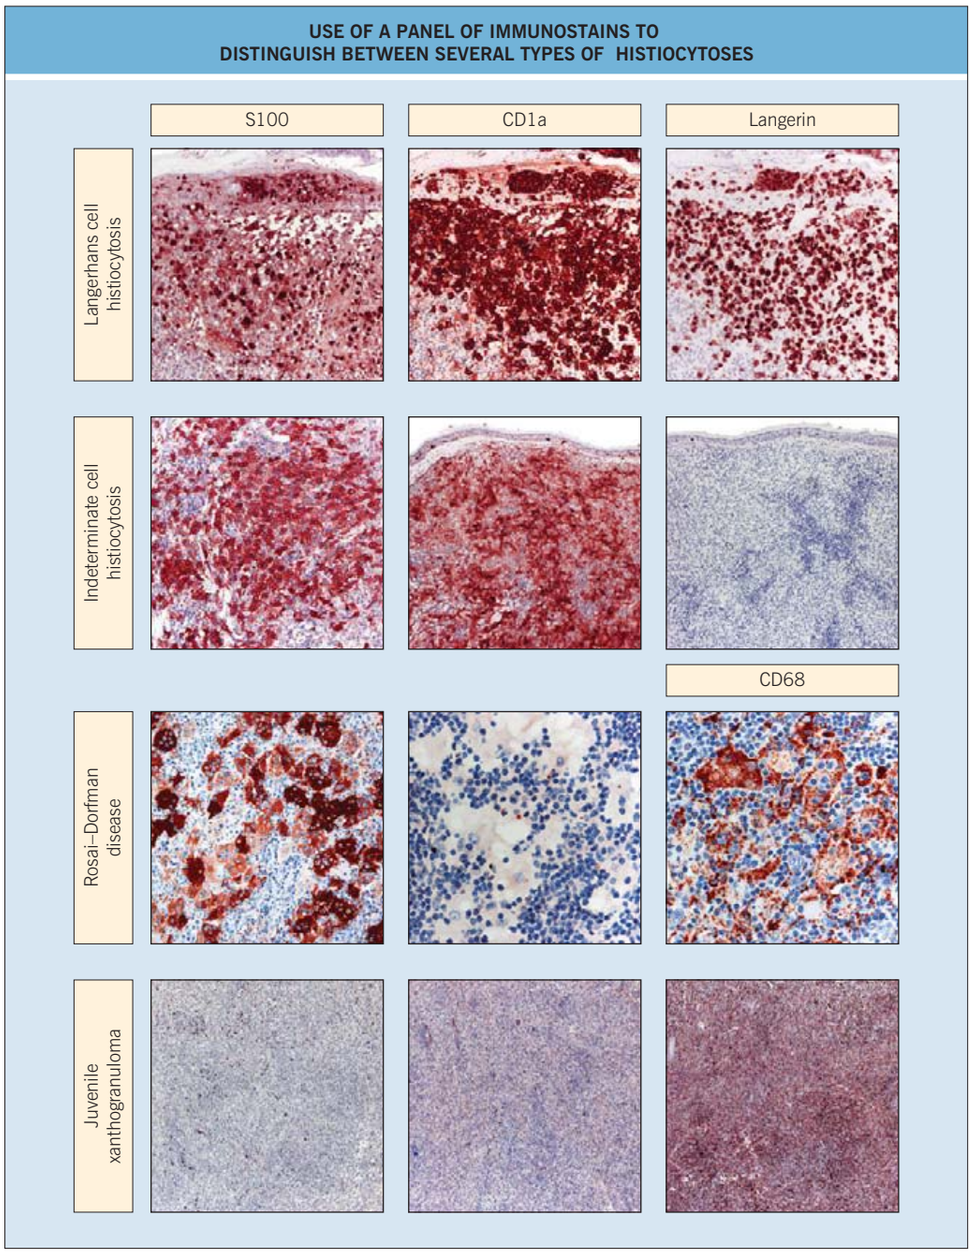

Fig. 91.6 Use of a panel of immunostains to distinguish between Langerhans cell histiocytosis and several types of non-Langerhans cell histiocytosis. See Table 91.2 for staining patterns. *Courtesy, Lorenzo Cerroni, MD.*

numbers of patients with reactivation of LCH have benefited from etanercept, cyclosporine or 2-chlorodeoxyadenosine (2-CdA), and there is currently an ongoing trial of 2-CdA plus cytosine arabinoside (ara-C). Imatinib mesylate was also reportedly beneficial in a case of multisystem LCH involving the brain which was unresponsive to radiation. For those with the most severe disease, hematopoietic stem cell, liver or lung transplantation may be required.

NON-LANGERHANS CELL HISTIOCYTOSES

Synonyms: ■ Class II histiocytosis ■ Non-X histiocytosis ■ Histiocytoses of mononuclear phagocytes other than Langerhans cells

Benign Cephalic Histiocytosis

Synonym: ■ Histiocytosis with intracytoplasmic worm-like bodies

Key features

- Infants <1 year of age most commonly affected
- Red to brown macules and papules of the face and neck
- Self-limiting disease, so no treatment required
- Ultrastructural finding: worm-like bodies

Introduction

Benign cephalic histiocytosis is a rare, self-limited histiocytic proliferative disorder of young children, primarily affecting the face.

History

Gianotti et al.[11], in 1971, described the condition as "infantile histiocytosis with intracytoplasmic worm-like bodies", based upon findings of comma-shaped structures by ultrastructural studies. The disorder was renamed "benign cephalic histiocytosis", based upon typical clinical findings, when it became clear that many histiocytic disorders had similar ultrastructural findings.

Epidemiology

Benign cephalic histiocytosis is rare, with approximately 40 cases having been described to date. The disorder typically begins by the age of 1 year and always within the first 3 years of life. There appears to be no gender predilection[12]. One adult patient with T-cell lymphoma was noted to have developed lesions similar to benign cephalic histiocytosis.

Pathogenesis

The pathogenesis of benign cephalic histiocytosis is not known. However, given a similar histopathology, ultrastructural appearance and immunohistochemical profile to juvenile xanthogranuloma and generalized eruptive histiocytoma, several investigators have suggested that benign cephalic histiocytosis may represent a variant of juvenile xanthogranuloma or generalized eruptive histiocytoma. Gianotti et al.[13], on the basis of a blinded histopathologic comparison that found great similarity between 14 benign cephalic histiocytosis, 25 juvenile xanthogranuloma, and 4 generalized eruptive histiocytoma specimens, believe that these three non-LCH self-healing histiocytoses should be viewed as a single disease with a spectrum of clinical features.

Clinical features

The eruption of benign cephalic histiocytosis is characterized by the evolution of 2–5 mm, red to red–brown macules and papules, first on the face (Fig. 91.7), with subsequent appearance on the ears and neck. Occasionally, lesions may develop on the trunk and arms, with infrequent involvement of the buttocks and thighs. The lesions spontaneously resolve after months or years. The papules flatten, become briefly hyperpigmented, and often disappear completely. Most children are otherwise healthy without involvement of the mucous membranes or internal organs. However, diabetes insipidus has been reported in a young girl with benign cephalic histiocytosis[14]. The course can be marked by exacerbations.

Pathology

Gianotti et al.[13] described three histologic patterns in benign cephalic histiocytosis: a papillary dermal pattern, a diffuse pattern, and a lichenoid pattern. In the papillary dermal pattern, the most common form, the infiltrate is well defined and closely approaches the epidermis. The histiocytes are pleomorphic and have abundant eosinophilic cytoplasm, with hyperchromatic, sometimes indented nuclei and large nucleoli. There are scattered lymphocytes and a few eosinophils. In the diffuse pattern, pleomorphic histiocytes are rare, with most histiocytes being round and regular with minimal cytoplasm. The infiltrate is dispersed throughout the dermis. In the lichenoid pattern, small regular histiocytes and occasional lymphocytes are seen perivascularly and in the superficial dermis. In all forms, Touton cells are absent and foamy cells are rare or absent.

The histiocytes in benign cephalic histiocytosis express CD11b, CD14b, CD68, HAM56 and factor XIIIa (see Fig. 91.4, Table 91.2)[15,16]. Typically, however, only immunostains for CD68 and occasionally factor XIIIa are performed. Ultrastructural studies have demonstrated cytoplasmic comma-shaped bodies, worm-like particles, and desmosome-like junctions between histiocytes. The comma-shaped bodies and worm-like particles are also found in LCH, juvenile xanthogranuloma, generalized eruptive histiocytoma and Rosai–Dorfman disease, so they are not as helpful diagnostically as originally thought.

Differential diagnosis

The differential diagnosis includes LCH and the non-LCH disorders, in particular juvenile xanthogranuloma and generalized eruptive histiocytoma (see Table 91.1). However, benign cephalic histiocytosis has characteristic clinical features, and the dome-shaped papulonodules of juvenile xanthogranuloma are usually few in number or occasionally numerous and widespread. Additionally, juvenile xanthogranuloma is often easily differentiated from benign cephalic histiocytosis by histopathology. Even in early juvenile xanthogranuloma, where foamy cells are few to none, Touton cells can be found on step sections[13]. Touton cells are reportedly not seen in benign cephalic histiocytosis.

Treatment

Benign cephalic histiocytosis is generally a self-limiting disorder and no treatment is usually needed. However, careful regular examinations of all patients with benign cephalic histiocytosis is recommended, as both exacerbations of the disease and diabetes insipidus can occur.

Generalized Eruptive Histiocytoma

Synonyms: ■ Eruptive histiocytoma ■ Generalized eruptive histiocytosis

Key features

- Adults affected more commonly than children
- Recurrent crops of numerous, small, red to brown papules
- Widespread axial distribution
- Self-limiting disease, so no treatment required

Introduction

Generalized eruptive histiocytoma is a very rare disorder, characterized by recurrent crops of small papules, axially distributed, which heal with hyperpigmented macules.

History

In the initial description of generalized eruptive histiocytoma in 1963, three adult patients were described by Winkelmann and Muller[17]. The disorder has also been described in children.

Epidemiology

Generalized eruptive histiocytoma is a very rare disease. Approximately 42 cases have been reported to date, with about one-quarter being children. There may be a male predilection. Onset in adults is from the third to sixth decade. In children, onset is usually before age 4 years.

Pathogenesis

The cause of generalized eruptive histiocytoma is unknown. As discussed in the section on benign cephalic histiocytosis, several authors have suggested that generalized eruptive histiocytoma, benign cephalic histiocytosis, and juvenile xanthogranuloma may represent different expressions of the same disorder. Generalized eruptive histiocytoma-like presentations have been seen early in the course of other non-LCH

Fig. 91.7 Benign cephalic histiocytosis. Multiple brown papules on the face of a young child.

Fig. 91.8 Generalized eruptive histiocytoma. Multiple firm red papules on the trunk.

disorders, leading some investigators to suggest that generalized eruptive histiocytoma may be an early, indeterminate stage of non-LCH[18].

Clinical features

The eruption is characterized by recurrent crops of red to brown papules. At each occurrence, hundreds of papules, less than 1 cm, are distributed on the trunk, proximal extremities, and occasionally the face (Fig. 91.8). The papules are usually arranged symmetrically, and mucosal surfaces are occasionally involved. Within several months, the lesions resolve completely or leave behind hyperpigmented macules or small scars. In some children, there may be a less symmetric distribution pattern and papules can become xanthomatous. Internal involvement has not been observed and the affected individuals are otherwise healthy.

Pathology

The superficial and mid dermis typically contain a nearly uniform infiltrate of histiocytes with a few lymphocytes. Rarely, a lichenoid pattern has been observed[13]. Xanthomatous cells are rare, but spindled cells can be seen; to date, giant cells have been reported in one case[19]. The histiocytes stain for lysozyme, α_1-antitrypsin, CD11b, CD14b, CD68 and factor XIIIa (see Fig. 91.4, Table 91.2)[20,21]. In practice, however, immunostains for only CD68 and occasionally factor XIIIa are performed. Ultrastructural studies demonstrate prominent cytoplasmic dense bodies, occasional worm-like bodies, and concentric laminated bodies.

Differential diagnosis

The differential diagnosis includes LCH, urticaria pigmentosa, eruptive syringomas, widespread papular granuloma annulare, and other non-LCH disorders. Of the latter, juvenile xanthogranuloma, xanthoma disseminatum, benign cephalic histiocytosis, indeterminate cell histiocytosis and papular xanthoma (see Table 91.1) can be the most difficult to differentiate from generalized eruptive histiocytoma. However, benign cephalic histiocytosis occurs in children and is most often localized to the head and neck, while the generalized lesions of papular xanthoma are yellow because of lipid accumulation and patients with xanthoma disseminatum have the tendency for plaque formation, a flexural distribution pattern, and the development of diabetes insipidus in addition to laryngeal, oral and eye lesions. By routine histology and immunostaining, generalized eruptive histiocytoma can be distinguished from indeterminate cell histiocytosis ($S100^+$, $CD1a^+$) and juvenile xanthogranuloma (Touton giant cells).

Treatment

No treatment is usually required as the disorder is self-limited and without systemic symptoms. There are, however, scattered reports of the use of isotretinoin, cryotherapy and PUVA. Careful follow-up of all patients with generalized eruptive histiocytoma is recommended, as more serious forms of non-LCH, including xanthoma disseminatum, have been reported to develop in patients with generalized eruptive histiocytoma.

Indeterminate Cell Histiocytosis

Key features

- Adults and children affected
- Both generalized and solitary variants exist
- Immunophenotypic profile – antigenic markers of both LCH ($S100^+$, $CD1a^+$) and non-LCH ($CD68^+$, etc.), but not Langerin (CD207)
- Primarily a cutaneous disorder, but visceral involvement and development of leukemia has occurred in a few patients

Introduction

Indeterminate cell histiocytosis is a very rare and somewhat controversial proliferative disorder of histiocytes which displays both LCH and non-LCH immunophenotypic features. There are two clinical variants – solitary and generalized.

History

Indeterminate cells were described in 1963, and a patient with features first recognized as indeterminate cell histiocytosis was reported by Wood et al.[22] in 1985. Fewer than 50 cases have been reported to date in the literature. Originally, indeterminate cell histiocytosis was thought to be closely related to LCH as the lesional cells were positive for S100 and CD1a, but they did lack Birbeck granules. However, it was later shown that the lesional cells also expressed macrophage/monocyte markers, leading to the proposal that indeterminate cell histiocytosis represented a disorder with overlap between LCH and non-LCH. Most recently, it has been noted that indeterminate cell histiocytosis primarily displays features of non-LCH (with the exception of the routine expression of S100 protein), and the suggestion has been made that most patients diagnosed with indeterminate cell histiocytosis actually have some variation of another non-LCH disorder[23].

Epidemiology

Indeterminate cell histiocytosis is extremely rare and has no apparent sexual predilection. The disorder occurs in adults, adolescents and infants, and a congenital form has also been reported.

Pathogenesis

The pathogenesis of indeterminate cell histiocytosis is unknown. As noted above, the question has been raised as to whether this disorder is actually a separate entity or represents a variation of one of the other non-LCH disorders[23].

Clinical features

While the majority of patients with indeterminate cell histiocytosis have involvement of the trunk and extremities, lesions have also been observed on the genitalia and in the head and neck region, including the eyelids and ears. Both a generalized form and a solitary form have been documented. In the generalized form, cutaneous lesions usually begin as firm red to brown papules, each less than 1 cm. In the solitary form, there is a single soft erythematous lesion, approximately 1 cm in diameter. Ulceration can occur. As lesions age, they become brown to yellow. The clinical course is variable and may wax and wane. Many patients may experience a partial or complete regression of lesions, while some have a progressive course.

Although mucous membrane involvement is rare, both corneal and conjunctival lesions have been reported. Patients are usually healthy, but visceral involvement and death have been reported in three instances. One infant developed an aggressive form of indeterminate

cell histiocytosis with a fatal course; the disease initially presented in the bone and then eventually spread to visceral organs and the skin[24]. To date, two cases have been associated with leukemia, one with mast cell leukemia and the other with acute myelogenous leukemia. The latter patient also had non-Hodgkin lymphoma prior to developing indeterminate cell histiocytosis.

Pathology

Histology often reveals a predominantly monomorphous infiltrate of histiocytes, either well circumscribed or more diffusely distributed within the dermis. Epidermotropism is less common than in LCH. Histiocytes often have an oncocytic appearance, with occasional spindled, scalloped or vacuolated cell variants. Touton giant cells can be present. Lymphocytes are commonly present and eosinophils are occasionally observed.

The immunophenotype of indeterminate cell histiocytosis demonstrates characteristics of *both* LCH and non-LCH. Lesional cells show expression of S100, CD1a, HAM56, CD68, lysozyme, α_1-antitrypsin, HLA-DR, CD11c, CD14b and factor XIIIa (see Fig. 91.4, Table 91.2)[19,24,25]. However, Langerin (CD207) is not expressed (see Fig. 91.6). The ultrastructural features of the histiocytes in indeterminate cell histiocytosis are similar to those seen in Langerhans cells except that no Birbeck granules are found.

Differential diagnosis

The clinical appearance of the cutaneous lesions of indeterminate cell histiocytosis is not unique. Similar-appearing papules in the same distribution can be found in generalized eruptive histiocytoma, juvenile xanthogranuloma and congenital self-healing reticulohistiocytosis (see Table 91.1). When lesions of indeterminate cell histiocytosis are limited to the head and neck, benign cephalic histiocytosis also must be considered. The diagnosis of indeterminate cell histiocytosis can be suspected based upon histopathology. However, confirmation requires the histiocytic infiltrate to demonstrate immunophenotypic features of both LCH (but without Langerin expression) and non-LCH disorders, and to lack Birbeck granules ultrastructurally.

Treatment

Treatment of cutaneous lesions is not usually required as the condition is often either self-limited or non-progressive, and the lesions are asymptomatic. A single lesion can be removed surgically. Several patients have been described with extensive disfiguring cutaneous disease who were treated with systemic chemotherapy (e.g. vinblastine, 2-chlorodeoxyadenosine, cyclophosphamide, and/or etoposide). The use of PUVA has also been reported. Because visceral involvement and leukemia can occur, careful follow-up of all patients with indeterminate cell histiocytosis is recommended.

Juvenile Xanthogranuloma

Key features

- Most common histiocytosis
- Usually infants and young children with involvement of the head and neck region and upper body
- Small and large nodular forms which acquire a yellow color as they mature
- Ocular lesions can cause blindness
- Rare association with both neurofibromatosis type 1 and juvenile myelomonocytic leukemia
- Touton giant cell characteristic histologic finding

Introduction

Juvenile xanthogranuloma is a fairly common non-LCH, most often affecting infants and young children. Cutaneous lesions usually resolve and most patients have an otherwise unremarkable course. Ocular juvenile xanthogranuloma can lead to blindness and there is an association of juvenile xanthogranuloma with neurofibromatosis type 1 (NF1) and juvenile myelomonocytic leukemia.

History

The term "juvenile xanthogranuloma" was suggested by Helwig and Hackney[26] in 1954 based upon histologic findings of xanthomatous histiocytes and giant cells. However, multiple cases of juvenile xanthogranuloma, under different names, had been reported during the first half of the twentieth century. The first case of juvenile xanthogranuloma was reported in 1905 by Adamson[27], who named the disorder "congenital xanthoma multiplex".

Epidemiology

Juvenile xanthogranuloma is a fairly common disorder and the most common histiocytic disease of childhood[28]. However, the true incidence may be underestimated, as many lesions, especially those which are solitary and small, may go unrecognized. In children, there is a male predominance of approximately 1.5:1; no sex predilection is noted in adults. A significant majority of reported patients are Caucasian. Almost 75% of cases appear during the first year of life, with over 15% being noted at birth. Juvenile xanthogranuloma is rare in adults, in whom its peak incidence is in the late twenties to early thirties, though lesions have been reported in the elderly. Most adult patients have solitary lesions.

Pathogenesis

The cause of juvenile xanthogranuloma is not known; however, it is often suggested that the condition is reactive with histiocytes possibly responding to a traumatic or infectious stimulus. The reason for the progressive lipidation of histiocytes in the absence of hyperlipidemia is not clear. However, it has been shown that in adult patients with xanthogranuloma, the uptake of low-density lipoprotein and the synthesis of cholesterol within macrophages is increased[29]. As discussed in the section on benign cephalic histiocytosis, several authors have suggested that generalized eruptive histiocytoma, benign cephalic histiocytosis, and juvenile xanthogranuloma may represent different expressions of the same disorder.

Clinical features

Gianotti and Caputo[30] described two common clinical variants of juvenile xanthogranuloma: a small nodular form and a large nodular form. Patients with the small nodular form, also known as the micronodular form, can present with many pink to red–brown, dome-shaped papules, 2–5 mm in diameter. The lesions are widely scattered on the upper part of the body and rapidly become yellow. In contrast, the more common large nodular form is characterized by one or a few nodules 1–2 cm in diameter. Both forms may coexist.

The most common location for juvenile xanthogranuloma is the head and neck (Fig. 91.9), followed by the upper torso, the upper extremities and the lower extremities. Oral juvenile xanthogranuloma is rare and usually presents as a solitary yellow nodule on the lateral aspect of the tongue or the midline of the hard palate. Unusual morphologic presentations include keratotic, pedunculated, subcutaneous, clustered, plaque-like and giant lesions.

Extracutaneous lesions have been reported in many organs, the eye being most commonly affected. Visceral, bone and CNS involvement (e.g. diabetes insipidus) is rare, although to date three deaths have been attributed to the disease[31]. The lung is the second most frequent extracutaneous site of disease. Ocular juvenile xanthogranuloma is almost always unilateral and develops in less than 0.5% of patients with cutaneous lesions. However, approximately 40% of patients with ocular juvenile xanthogranuloma have cutaneous lesions, always multiple, at the time of diagnosis[32]. Ocular involvement usually occurs before 2 years of age and often affects the iris. Hyphema (hemorrhage into the anterior chamber) and glaucoma are serious complications which can result in blindness. Early referral to an ophthalmologist for evaluation and possible treatment is important.

A well-recognized association exists between juvenile xanthogranuloma and café-au-lait macules. Some of these patients have a family history of NF1, while others fulfill the clinical criteria for NF1. Another well-known association is that of juvenile xanthogranuloma and juvenile myelomonocytic leukemia. Patients with NF1 also have an increased risk of developing juvenile myelomonocytic leukemia. A so-called "triple association" consisting of juvenile xanthogranuloma, NF1 and juvenile myelomonocytic leukemia has been observed in

Fig. 91.9 Juvenile xanthogranuloma. **A** Pink nodule with a few telangiectasias representing an early lesion. **B** Well-developed yellow–brown papulonodule on the chin, with the color reflecting the accumulation of lipid within histiocytes. *Courtesy, Julie V Schaffer, MD.*

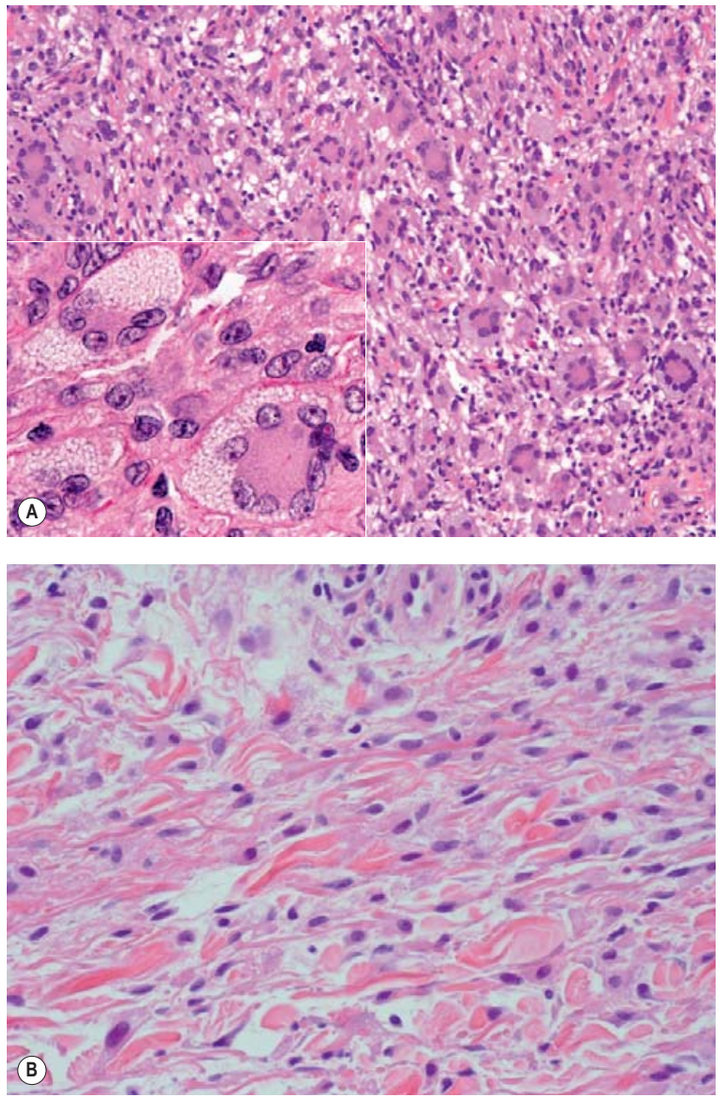

Fig. 91.10 Juvenile xanthogranuloma. **A** Dermal histiocytic infiltrate mixed with lymphocytes and scattered Touton giant cells. Insert, Touton giant cells have a "wreath-like" arrangement of nuclei within the cell. **B** In some cases, the histiocytes can be spindled.

several patients, and patients with juvenile xanthogranuloma and NF1 have at least a 20-times increased risk of developing juvenile myelomonocytic leukemia[33]. Other forms of leukemia have also been reported in association with juvenile xanthogranuloma, e.g. chronic lymphocytic leukemia in adults with multiple lesions.

In the majority of patients with disease limited to the skin, the course is self-limited and benign. These patients are otherwise in good health and lesions usually regress within 3–6 years. Hyperpigmentation, mild atrophy or anetoderma may remain.

Pathology

Typically, nodules demonstrate a well-demarcated dense infiltrate of histiocytes in the superficial dermis in small lesions, extending into the subcutis in larger lesions. There is often loss of the rete ridges, and ulceration occurs in some cases. Early lesions usually demonstrate monomorphous histiocytes with abundant eosinophilic cytoplasm. In mature lesions, the histiocytes develop lipid in their cytoplasm, creating a foamy "xanthomatous" appearance. Touton giant cells are a characteristic finding (Fig. 91.10). Lymphocytes, eosinophils and plasma cells are also scattered throughout the infiltrate. Variants without Touton giant cells or with many spindle cells have been reported, but serial sections typically reveal rare giant cells[13]. A rare lichenoid pattern has also been reported[13].

Juvenile xanthogranuloma histiocytes stain positively for HAM56, CD68 and factor XIIIa (see Fig. 91.6, Table 91.2)[34]. Some cases have shown expression of S100; CD1a is usually negative and Langerin (CD207) is always negative. By electron microscopy, comma-shaped bodies, lipid vacuoles, cholesterol clefts and myeloid bodies have been observed in the histiocytes.

Differential diagnosis

The major diagnostic dilemmas occur with the other non-LCH disorders and LCH, although the initial clinical differential diagnosis of a single lesion can be broad (e.g. molluscum contagiosum, Spitz nevus). Some examples of adult xanthogranuloma have been reported to have a similar clinical presentation, histology and immunophenotype as giant cell reticulohistiocytoma[35]. In general, the constellation of clinical and histopathologic features allows a distinction between juvenile xanthogranuloma and benign cephalic histiocytosis or generalized eruptive histiocytoma, the two most closely related non-Langerhans cell disorders. LCH can always be differentiated from juvenile xanthogranuloma by the use of immunostains.

Treatment

Due to the self-limiting nature of the eruption, no treatment is required. Occasionally, lesions are removed for cosmetic concerns, despite the anticipated spontaneous resolution. While ocular lesions often require intervention (e.g. topical corticosteroids for iris lesions, excision for limbal lesions), sites of systemic involvement can be followed without treatment unless their location interferes with normal function. For patients in the latter group, various chemotherapeutic regimens, radiotherapy, high-dose systemic corticosteroids, and cyclosporine have been tried in isolated case reports[36]. Given the possibility of spontaneous involution, however, it is difficult to gauge response to treatment.

Necrobiotic Xanthogranuloma

Synonym: ▪ Necrobiotic xanthogranuloma with paraproteinemia

Key features

- Average age of onset is the sixth decade
- Firm nodules and plaques with a yellow hue; may develop ulceration
- Most common site of involvement is the periorbital region
- Multisystem disease that includes hepatosplenomegaly and ocular involvement
- An IgG monoclonal gammopathy is seen in at least 80% of patients
- Paraproteinemia is due to plasma cell dyscrasias or lymphoproliferative disorders

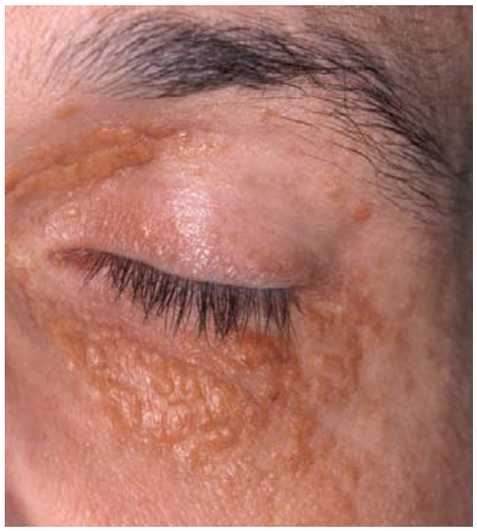

Fig. 91.11 Necrobiotic xanthogranuloma. Yellow–brown papules and plaques in a periorbital distribution in a patient with chronic lymphocytic leukemia. Such lesions may initially be mistaken for xanthelasma. *Courtesy, Kalman Watsky, MD.*

Introduction

Necrobiotic xanthogranuloma is a rare, progressive multisystem histiocytic disease characterized by destructive cutaneous and subcutaneous lesions. The vast majority of patients have a monoclonal gammopathy due to either a plasma cell dyscrasia or a lymphoproliferative disorder (see Ch. 119).

History

Necrobiotic xanthogranuloma was characterized in 1980 by Kossard and Winkelmann[37]. Their original eight patients demonstrated yellowish plaques, subcutaneous nodules, and an associated dysproteinemia. These authors also noted several reports published prior to 1980 representing unrecognized cases of necrobiotic xanthogranuloma.

Epidemiology

Necrobiotic xanthogranuloma is a rare disorder. In 1992, Mehregan and Winkelmann[38] reported their 32 patients with necrobiotic xanthogranuloma and reviewed the 16 reported cases from the world literature. Men and women are affected approximately equally. The average age of onset is the sixth decade.

Pathogenesis

While the pathogenesis of necrobiotic xanthogranuloma is as yet unknown, its strong association with monoclonal gammopathies has led to several hypotheses. The paraprotein may act either as a primary inciting agent or as a cofactor in eliciting a giant cell granulomatous reaction. In a recent study, there was no evidence of a monoclonal proliferation of plasma cells within the inflammatory infiltrate of skin lesions[39].

Clinical features

Cutaneous lesions, typically multiple, have appeared in all cases. The classic skin lesion is an asymptomatic indurated papule, nodule or plaque with a yellow "xanthomatous" hue (Fig. 91.11). Other reported features include telangiectasias, atrophy, ulceration of lesions and scarring, with scars being common sites for the development of new lesions.

The periorbital region is the most common site of involvement. The trunk, remainder of the face, and proximal extremities are also frequently involved. Approximately 50% of patients have ophthalmic manifestations, which include orbital masses, ectropion, ptosis, conjunctival lesions, keratitis and scleritis, episcleritis, anterior uveitis, and proptosis[40].

A hallmark feature of necrobiotic xanthogranuloma is the associated paraproteinemia, an IgG monoclonal gammopathy, which is found in at least 80% of cases. The paraproteinemia can be detected by serum protein electrophoresis and/or the more sensitive immunofixation electrophoresis. Other common findings include hepatomegaly, splenomegaly, an increased ESR, leukopenia, hypocomplementemia, and an underlying plasma cell dyscrasia (including myeloma). Less commonly, cryoglobulinemia and/or an underlying lymphoproliferative disorder are observed. Of the 48 patients described by Mehregan and Winkelmann[38], a plasma cell dyscrasia was found in 17 patients (with eight fulfilling the criteria for multiple myeloma) and lymphoproliferative disorders in two patients. Postmortem examination has demonstrated involvement of multiple organ systems, with endocardial necrobiotic xanthogranuloma found in most cases.

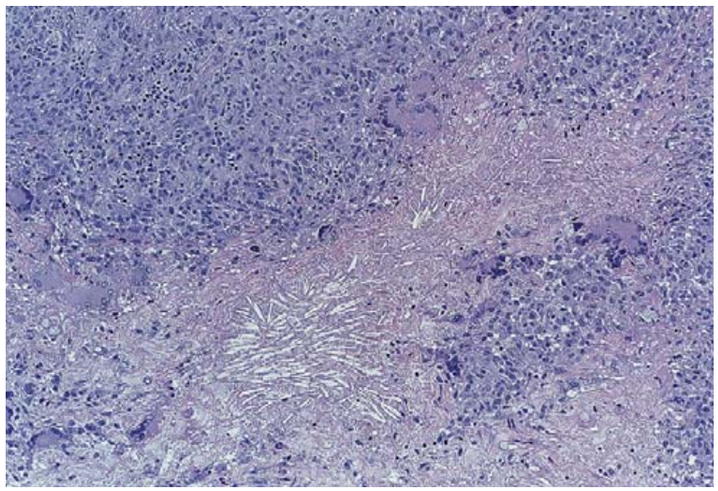

Fig. 91.12 Necrobiotic xanthogranuloma. A necrobiotic area contains cholesterol clefts. Surrounding this area are many bizarre multinucleated giant cells.

Ugurlu et al.[41] examined the outcomes in 26 patients with ocular and systemic manifestations of necrobiotic xanthogranuloma. Ten of their patients developed a plasma cell dyscrasia (including myeloma) or a lymphoproliferative disorder. The associated malignancy often developed after the onset of cutaneous manifestations and did not tend to be aggressive. Overall survival was 100% at 10 years and 90% at 15 years. A poorer survival rate was noted in a study of 22 patients by Finan and Winkelmann[42]. Two patients died of multiple myeloma within 10 years, and three others died of various solid tumor malignancies.

Pathology

Classic, non-ulcerated lesions have a normal epidermis and superficial dermis. A palisading xanthogranuloma is found in the middle dermis extending through the panniculus (Fig. 91.12). The granulomas consist of histiocytes, foam cells, lymphoid follicles, plasma cells and giant cells with zones of necrobiosis. Cholesterol clefts are found in areas of "necrobiosis" (altered collagen, in which there appears to be necrosis, loss of collagen bundle integrity, and nuclear debris). A prominent feature is the presence of both Touton giant cells and large, bizarre foreign body giant cells. These cells are found scattered within the granuloma and often at the margins of areas of necrobiosis. Histiocytic

cells stain positively for lysozyme, CD68 and CD11b (see Fig. 91.4, Table 91.2)[38,41,43].

Differential diagnosis

The clinical differential diagnosis includes necrobiosis lipoidica, normolipemic plane xanthomas, xanthelasma, non-LCH disorders (xanthoma disseminatum, multicentric reticulohistiocytosis, juvenile xanthogranuloma, Erdheim–Chester disease), foreign body granulomas, and sarcoidosis. Subcutaneous nodules also need to be distinguished from the nodules of rheumatoid arthritis and subcutaneous granuloma annulare. However, most of these disorders can be excluded on the basis of morphology, distribution pattern, histologic features and associated systemic manifestations (if any).

Treatment

No controlled clinical studies are available regarding the treatment of necrobiotic xanthogranuloma. Resolution or improvement of skin lesions has been seen in some patients treated with low-dose chlorambucil, melphalan or cyclophosphamide (± systemic corticosteroids), radiation therapy, CO_2 laser, and plasmapheresis. With rare exceptions, topical and locally injected corticosteroids have been tried with minimal or no benefit; in case series, systemic corticosteroids (including pulsed high-dose dexamethasone) have resulted in improvement in some patients. Ugurlu et al.[41] noted a 42% recurrence rate following surgical excision of lesions, and recommended against this intervention, if possible.

Reticulohistiocytosis

Synonyms for giant cell reticulohistiocytoma: ■ Solitary reticulohistiocytosis ■ Solitary reticulohistiocytoma

Key features

- Clinical spectrum ranges from a single lesion to multicentric reticulohistiocytosis with systemic involvement
- All forms are seen primarily in adults
- Papules and nodules favor the head, hands and elbows; periungual papules have been likened to "coral beads"
- 50% of patients develop mucous membrane lesions (oral and nasopharyngeal)
- Multicentric reticulohistiocytosis is associated with a destructive arthritis and, in some patients, solid organ malignancies
- Histiocytes have a characteristic "ground glass" appearance

Introduction

The reticulohistiocytoses are a rare group of closely related non-Langerhans cell histiocytoses which most commonly affect adults. The spectrum of disease ranges from a solitary cutaneous form to multicentric reticulohistiocytosis, a disease with both cutaneous and systemic features. Well-developed lesions demonstrate a classic histopathology consisting of mononucleated and multinucleated giant cells with a "ground glass" appearance.

History

Giant cell reticulohistiocytoma, an isolated cutaneous tumor sometimes referred to as a solitary reticulohistiocytoma, was first reported in 1950 by Zac[44]. The term multicentric reticulohistiocytosis was introduced by Goltz and Laymon[45] in 1954 to define those cases with both cutaneous and systemic manifestations. Familial histiocytic dermatoarthritis, described in 1973, is a very rare variant of multicentric reticulohistiocytosis, characterized by a familial occurrence and associated glaucoma, uveitis and cataracts[46].

Epidemiology

All forms of reticulohistiocytoses occur predominantly in Caucasian adults, with pediatric cases being exceptionally rare. Multicentric reticulohistiocytosis is uncommon, occurring most frequently in women during the fourth decade. Giant cell reticulohistiocytoma occurs in young adults and has no sexual predilection.

Pathogenesis

The pathogenesis of the reticulohistiocytoses is unknown. However, it has been speculated that it represents an abnormal histiocytic response to various stimuli. Mycobacteria have been suggested as a possible trigger for multicentric reticulohistiocytosis. In one old study, 56% of multicentric reticulohistiocytosis patients had a positive tuberculin skin test[47]. Multicentric reticulohistiocytosis has also been reported to respond to antituberculosis treatment. However, confirmation of mycobacteria within skin nodules is lacking. Others have suggested that the histiocytic response in multicentric reticulohistiocytosis is an immunologic process related to an underlying autoimmune or neoplastic disorder or even that the multicentric reticulohistiocytosis represents a systemic osteoclastic disease.

The cause of giant cell reticulohistiocytoma is even less clear. Some lesions are believed to occur after trauma. Cerio et al.[35] referred to giant cell reticulohistiocytoma synonymously with the solitary or eruptive adult form of xanthogranuloma.

Clinical features

Giant cell reticulohistiocytoma presents as a single, asymptomatic, yellow to red nodule. It can develop at any cutaneous site but is thought to favor the head. The patients are otherwise healthy and lesions tend to spontaneously resolve. Rarely, multiple cutaneous lesions develop without any evidence of systemic disease. Nodules are generally less than 1 cm in diameter.

Multicentric reticulohistiocytosis is a disease characterized by cutaneous and mucous membrane reticulohistiocytomas and severe arthropathy. There is an association with hyperlipidemia, a positive tuberculin skin test, systemic vasculitis, and autoimmune disease. Up to 28% of multicentric reticulohistiocytosis patients have reportedly had an associated malignancy, with bronchial, breast, stomach and cervical carcinomas being most common. An elevated ESR and anemia have been noted in approximately half of patients, and one-third demonstrate hypercholesterolemia. Rarely, monoclonal hypergammaglobulinemia and cryoglobulinemia have been observed. Fever and weight loss can occur.

Cutaneous lesions range from a few millimeters to 2 cm and are skin-colored to pink, red–brown or yellow. Lesions tend to be acrally distributed. Favored sites include the head, hands, fingers, ears, and articular regions of the limbs (Fig. 91.13). Small papules aligned along the periungual regions result in a characteristic "coral bead" appearance. Approximately one-half of patients develop papules and nodules of the oral, pharyngeal and nasal mucosa. Less common findings include a "leonine facies" secondary to severe facial involvement, periarticular rheumatoid-like nodules, an initial photodistribution, and secondary nail changes.

A 6–8-year course of symmetric, erosive arthritis of multiple joints is common and there is progression to arthritis mutilans in 45% of cases. The joints of the fingers and hands, as well as the knees and wrists, are most commonly involved, although any joint may be affected. Cartilaginous destruction of the nose and ears can lead to facial disfigurement. Rarely, there is histiocytic involvement of the heart, eye, lungs, thyroid, liver, kidney, muscle, salivary gland and/or bone marrow. For most, the disease spontaneously remits within 5–10 years, though patients are often left with significant disability. Fatal disease has been rarely reported in patients with widespread systemic involvement.

Pathology

Many believe that the histopathology of giant cell reticulohistiocytoma and multicentric reticulohistiocytosis is identical. Well-developed lesions demonstrate a dermal infiltrate of lymphocytes and histiocytes, with occasional plasma cells and eosinophils. The histiocytes have a characteristic appearance. They are both mononuclear and multinuclear, with abundant eosinophilic, homogenous and finely granular cytoplasm, creating a "ground glass" effect (Fig. 91.14). Multinucleated cells demonstrate nuclei arranged haphazardly, aligned at the periphery, or clustered in the center.

Giant cell reticulohistiocytoma and multicentric reticulohistiocytosis histiocytes stain positively for lysozyme and α_1-antitrypsin and also

Fig. 91.13 Multicentric reticulohistiocytosis. A Grouped firm red–brown papules on the dorsal surface of the fingers, hand and wrist in this 73-year-old African-American woman. **B** Grouped pink papulonodules on the elbow in a second patient. **C** A more subtle presentation in a third patient, with small pink papules and thin plaques that favor the skin overlying the small joints of the hands; this is the form that can initially be confused with dermatomyositis. *A, Courtesy, Susan D Laman, MD; B, Courtesy, Jean L Bolognia, MD; C, Courtesy, Kalman Watsky, MD.*

express CD68, CD11b, CD14 and HAM56 (see Fig. 91.4, Table 91.2)[35,48]. S100 is most often negative. Several case reports have shown positive staining for factor XIIIa, though Zelger et al.[49] found that factor XIIIa was positive in cases of giant cell reticulohistiocytoma and negative in multicentric reticulohistiocytosis lesions.

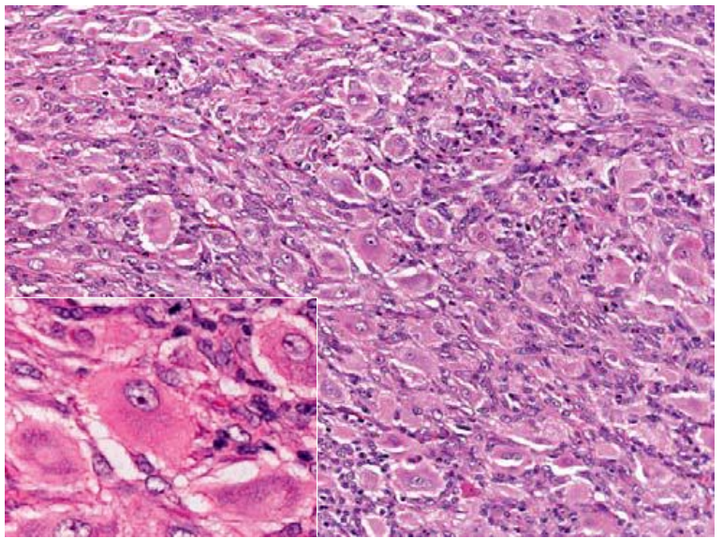

Fig. 91.14 Reticulohistiocytosis. Numerous mononucleated and multinucleated histiocytes extending throughout the dermis. These histiocytes have abundant eosinophilic, finely granular cytoplasm, creating a "ground glass" appearance (insert). *Courtesy, Lorenzo Cerroni, MD.*

Differential diagnosis

The nodule of giant cell reticulohistiocytoma is not distinctive, and the clinical differential diagnosis is broad (e.g. adnexal tumor, foreign body granuloma). Some examples of adult xanthogranuloma have been reported to have a similar clinical presentation, histology and immunophenotype to giant cell reticulohistiocytoma[35].

Multicentric reticulohistiocytosis must be differentiated from rheumatoid arthritis, dermatomyositis (especially when lesions are photodistributed), and the other histiocytoses, with juvenile xanthogranulomas, generalized eruptive histiocytosis, and cutaneous Rosai–Dorfman disease presenting the greatest challenge. While the constellation of clinical and histopathologic findings will eventually lead to the correct diagnosis, several biopsies over time may be required in some patients.

Treatment

Surgical excision of giant cell reticulohistiocytoma is curative. Most systemic therapy for multicentric reticulohistiocytosis has not been effective. Although not in controlled clinical trials, NSAIDs, oral corticosteroids, azathioprine, cyclophosphamide and chlorambucil have been tried, but with limited or no benefit. However, there are multiple case reports of substantial benefit with methotrexate, either alone or in combination with cyclophosphamide and corticosteroids[50]. Alendronate and inhibitors of TNF-α have recently been shown to be of value in isolated cases.

Rosai–Dorfman Disease

Synonyms: ■ Sinus histiocytosis with massive lymphadenopathy ■ Destombes–Rosai–Dorfman syndrome

Key features

- Children and young adults are most commonly affected
- Although massive, painless bilateral cervical lymphadenopathy is characteristic, extranodal sites, including the skin, can be the sole manifestation of the disease
- Skin-limited form is increasingly being recognized
- In the systemic form, cutaneous lesions occur in a minority of cases (~10%), are usually multiple, and are clinically nonspecific
- Fever and polyclonal hypergammaglobulinemia are often seen
- In the lymph nodes and the skin, emperipolesis is a common histologic feature

Introduction

Rosai–Dorfman disease is an uncommon, often protracted, histiocytic proliferative disorder. It is characterized by massive but painless bilateral cervical lymphadenopathy, fever, anemia, elevated ESR, neutrophilia and a polyclonal hypergammaglobulinemia. Cutaneous lesions occur in a minority of patients with systemic disease, are usually multiple, and are clinically nonspecific.

History

Sinus histiocytosis with massive lymphadenopathy was described as a distinct entity by Rosai and Dorfman[51] in 1969. However, the eponymous designation "Rosai–Dorfman disease" is more appropriate as some patients have extranodal lesions as the sole manifestation of the condition[52].

Epidemiology

For a time, there was a repository for cases of Rosai–Dorfman disease, rather than a registry in the true sense. In 1990, the repository contained 423 patients, and by 1995, almost 600 cases had been reported[53,54]. Rosai–Dorfman disease has a widespread geographic distribution, although there is a higher incidence in the West Indies. The systemic form occurs most commonly in children and young adults and is more frequently seen in male patients. In 1990, an equal percentage of white and black patients, 44% of each, were in the repository[53]. On the other hand, the skin-limited form occurs primarily in adults and favors women.

Pathogenesis

The etiology of Rosai–Dorfman disease has not been identified, though a viral pathogenesis has been postulated. HHV-6 sequences have been detected in involved lymph nodes[55], but this finding is nonspecific given the presence of HHV-6 in many reactive and infectious disorders of lymphoid tissue[56]. More recently, it has been suggested that Rosai–Dorfman disease may be closely related to autoimmune lymphoproliferative syndrome, an inherited disorder associated with defects in Fas-mediated apoptosis (see Table 60.5)[57].

Clinical features

While Rosai–Dorfman disease is often an indolent, self-limited disease, a protracted course marked by remissions and exacerbations occurs in many patients. The characteristic clinical feature is massive, painless, bilateral cervical lymphadenopathy. However, any nodal site may be involved, unilateral involvement may occur, and an absence of lymph node involvement has been reported in multiple patients. Fever is a frequent occurrence and most cases demonstrate an elevated ESR and polyclonal hypergammaglobulinemia. A common finding is mild anemia, though severe anemia has occurred. Neutrophilia is occasionally seen. There are multiple reports of non-Hodgkin lymphoma occurring in association with Rosai–Dorfman disease.

Immune disorders occur in approximately 15% of patients with Rosai–Dorfman disease. Anti-red blood cell autoantibodies and joint disease are the most common findings. Patients with immunologic abnormalities have an unfavorable prognosis. In one analysis, 10 of 14 fatal cases were noted to have some form of immune dysfunction[58]. Other unfavorable prognostic signs include disseminated nodal disease or involvement of the liver, kidney or lower respiratory tract.

Over 40% of patients with Rosai–Dorfman disease have at least one extranodal site of involvement. The most common extranodal sites are the skin and soft tissue, the eyelid and orbit, the upper respiratory tract, major salivary glands, CNS and bone. However, virtually any organ can be involved.

Cutaneous involvement occurs in approximately 10% of patients with the systemic form. The skin may be the only organ involved, with skin-limited disease increasingly being recognized. Cutaneous lesions are often multiple and appear as nonspecific red to red–brown or xanthomatous macules, papules, nodules or plaques (Fig. 91.15); in the skin-limited form, there may be a single lesion. Panniculitis has also been reported. The eyelids and malar regions are frequent sites of involvement.

Pathology

Rosai–Dorfman disease, or sinus histiocytosis with massive lymphadenopathy, is a disease which had been characterized by specific findings in the affected lymph nodes. However, consistent and unique histopathologic and immunohistochemical findings in the skin make diagnosis possible even in cases without lymph node involvement.

Affected lymph nodes demonstrate dilated sinuses containing neutrophils, lymphocytes, plasma cells, and histiocytes with large vesicular nuclei and abundant cytoplasm. A characteristic though not unique feature is emperipolesis, or the taking up of intact lymphocytes and plasma cells by the histiocytes. Neutrophils and red cells can also be internalized in a similar fashion.

Cutaneous lesions demonstrate a dense dermal infiltrate of histiocytes with scattered lymphocytes, plasma cells and neutrophils. The histiocytes have large vesicular nuclei, small nucleoli, and abundant foamy, eosinophilic cytoplasm with feathery borders (Fig. 91.16). Emperipolesis is a constant finding. Occasional findings include foamy histiocytes within dilated lymphatics, thick-walled venules with surrounding plasma cells, lymphoid aggregates, fibrosis and multinucleate histiocytes.

In Rosai–Dorfman disease, the histiocytes stain positively for S100, CD11c, CD14, CD68, laminin 5 and lysozyme (see Fig. 91.6, Table 91.2)[59]. Examples of positive staining for factor XIIIa have been reported. With the exception of one study from 1994[60], CD1a expression in Rosai–Dorfman disease has been shown to be negative.

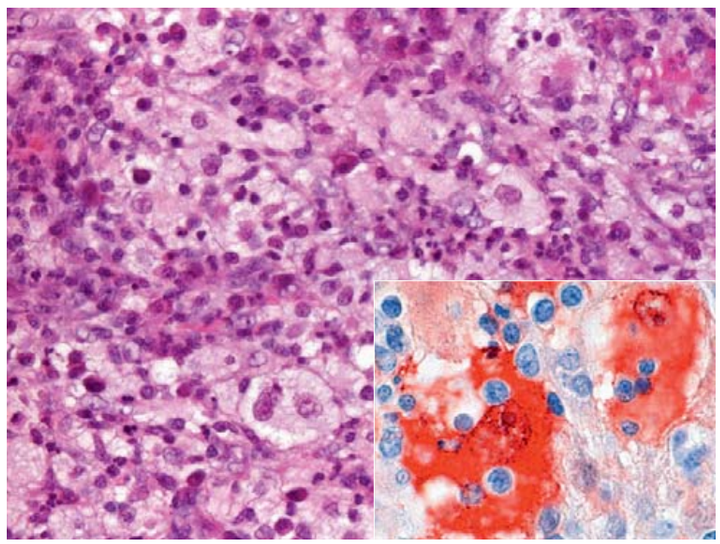

Fig. 91.16 Rosai–Dorfman disease. Large histiocytes with clear cytoplasm admixed with small lymphocytes and plasma cells. The large cells stain positively for S100 (insert), and the immunostain highlights lymphoid cells within the cytoplasm of large histiocytes (emperipolesis). *Courtesy, Lorenzo Cerroni, MD.*

Differential diagnosis

Given the clinically nonspecific cutaneous lesions found in Rosai–Dorfman disease, the differential diagnosis includes the other histiocytoses, sarcoidosis, infectious processes, and other infiltrative disorders. The diagnosis of cutaneous Rosai–Dorfman disease is based upon the combination of characteristic histologic and immunohistochemical findings. The differential diagnosis of massive lymphadenopathy includes Hodgkin lymphoma, non-Hodgkin lymphoma, chronic lymphocytic leukemia, metastases, infectious lymphadenopathies, and Kikuchi's disease (a histiocytic necrotizing lymphadenitis that often affects young Asian women). Rosai–Dorfman disease is differentiated by a typical combination of clinical and laboratory findings plus confirmatory histology and immunohistochemistry.

Treatment

Many lesions are asymptomatic and heal spontaneously, thus not requiring treatment. When treatment is indicated due to destructive lesions, disseminated disease or lesions causing physical compromise, radiotherapy, surgical excision, systemic corticosteroids and alkylating agents have been used with some success[61]. There are also a few isolated reports of improvement with thalidomide. However, due to the rarity of the disorder, there have been no controlled trials.

Fig. 91.17 Xanthoma disseminatum. Symmetric involvement of the major flexures is a characteristic finding. Note the yellow discoloration of some of the coalescing papulonodules. *Courtesy, David Wetter, MD.*

Xanthoma Disseminatum

Synonym: ■ Disseminated xanthosiderohistiocytosis

Key features

- Classic triad of cutaneous xanthomas, mucous membrane xanthomas, and diabetes insipidus
- Symmetric distribution
- Flexural and intertriginous involvement
- Upper airway lesions

Fig. 91.18 Xanthoma disseminatum. Sclerotic form of xanthoma disseminatum in a patient who developed multiple myeloma.

Introduction

Xanthoma disseminatum is a rare, normolipemic, histiocytic proliferative disorder affecting the skin, mucous membranes and, frequently, the hypothalamus and pituitary, leading to transient diabetes insipidus.

History

Four cases of "xanthomatosis disseminata" were described by Montgomery and Osterberg[62] in 1938. A review and characterization of the disorder was provided by Altman and Winkelmann[63] in 1962.

Epidemiology

Xanthoma disseminatum is a rare condition, with approximately 100 cases reported by 1995[64]. Men are more commonly affected than women. Age of onset ranges from 8 months to 85 years, though more than 60% of patients develop the disease before age 25 years.

Pathogenesis

The etiology of xanthoma disseminatum is unknown. As most patients have normal lipid levels, it has been suggested that xanthoma disseminatum represents a reactive proliferative disorder of histiocytes with secondary accumulation of lipid.

Clinical features

Patients with xanthoma disseminatum may demonstrate the triad of cutaneous xanthomas, xanthomas of mucous membranes, and diabetes insipidus. The primary xanthomatous lesion is a yellow, red or brown papule. The onset of disease is marked by the eruption of hundreds of papules, symmetrically arranged, on the face and in the flexural and intertriginous areas of the trunk and proximal extremities (Fig. 91.17). The lesions tend to cluster into well-formed, potentially disfiguring plaques (Fig. 91.18). Older lesions may become atrophic.

Mucous membrane lesions are found in 40–60% of patients with xanthoma disseminatum, the upper airway and oral mucosa being commonly involved. Corneal and conjunctival lesions can threaten vision. CNS involvement of the hypothalamus and pituitary stalk results in diabetes insipidus in 40% of patients. This is usually mild, transient and sensitive to vasopressin. Rare associations with xanthoma disseminatum have included monoclonal gammopathies due to plasma cell dyscrasias and thyroid disorders.

Caputo et al.[64] have suggested that patients follow one of three clinical courses: (1) a rare, self-healing form with spontaneous resolution of lesions; (2) the common persistent form in which lesions may never resolve; and (3) the very rare progressive form with organ dysfunction and CNS involvement. Disease-related mortality has been reported in a few cases, including one with associated CNS involvement outside the pituitary and hypothalamus[65].

Pathology

In the early stages, there is a dense dermal infiltrate of histiocytes with few foamy cells or other inflammatory cells. Fully developed lesions, however, demonstrate many foam cells with histiocytes, and scattered

CLINICAL AND IMMUNOPHENOTYPIC FEATURES OF THE MALIGNANT HISTIOCYTIC DISORDERS (HISTOCYTOSIS III)				
Disorder	**Epidemiology**	**Most common initial site**	**Immunophenotype**	**Prognosis**
Langerhans cell sarcoma	Adults > children; F > M	Skin	+ S100, CD1a, Langerin	Aggressive; > 50% mortality
Histiocytic sarcoma	Adults > children	GI, skin, soft tissue	+ CD68, CD163, lysozyme	Aggressive; 60–80% mortality
Interdigitating dendritic cell sarcoma	Adults > children	Solitary lymph node > skin	+ S100, vimentin, fascin; weakly + CD68, lysozyme, CD45	Aggressive; ~ 50% mortality
Follicular dendritic cell sarcoma	Adults > children	Cervical lymph node	+ CD21, CD35, CD23, clusterin; +/– S100, CD68	Indolent; 10–20% mortality

Table 91.3 Clinical and immunophenotypic features of the malignant histiocytic disorders (histiocytosis III). F, female; M, male.

THE DERMAL DENDROCYTE HAMARTOMAS					
	Epidemiology*	**Most common site**	**Clinical presentation**	**Pathology**	**Immunophenotype**
Medallion-like dermal dendrocyte hamartoma†	Congenital > acquired 13 pts, mostly female	Chest	Single, 2–16 cm erythematous, atrophic (wrinkled) patch or plaque	Dermal spindle cell proliferation	Majority + for both CD34 & factor XIIIa
Fat-storing hamartoma of dermal dendrocytes	Congenital 1 pt (male)	Lumbar‡	Single, reddish-brown plaque with nodularity	Lipidized histiocytes between collagen bundles within reticular dermis	+ Factor XIIIa (CD34 was not performed)
Dermal dendrocyte hamartoma with stubby white hair	Congenital 1 pt (female)	Back‡	Single, soft, red nodule with short white hairs	Spindle cells	+ CD34; – factor XIIIa
Congenital CD34+ granular cell dendrocytosis	Congenital 1 pt (male)	Face and extremities‡	Numerous skin-colored papules and plaques	"Granular cells" interstitially arranged, primarily within superficial dermis	+ CD34; – factor XIIIa

*To date.
†May require analysis for the *COL1A1-PDGFB* fusion gene (e.g. via fluorescence in situ hybridization [FISH]) to exclude an atrophic dermatofibrosarcoma protuberans, which can have similar clinicopathologic features (see Ch. 116)
‡Based on only one reported patient.

Table 91.4 The dermal dendrocyte hamartomas.

lymphocytes, plasma cells and Touton cells. Xanthoma disseminatum histiocytes stain for lysozyme and α_1-antitrypsin and also express CD68, CD11b, CD14, CD11c and factor XIIIa (see Fig. 91.4, Table 91.2)[64,66]. Typically, only CD68 and occasionally factor XIIIa immunostains are performed.

Differential diagnosis

The disorders most likely to be confused with xanthoma disseminatum include juvenile xanthogranuloma, eruptive xanthoma (see Ch. 92), generalized eruptive histiocytoma, papular xanthoma, and multicentric reticulohistiocytosis. Most often, these can be fairly easily differentiated based on clinical and histopathologic bases.

Treatment

As xanthoma disseminatum is a rare disease, there are no controlled trials for systemic therapy. Radiotherapy has been used to control airway obstructive disease. For cutaneous and mucosal lesions, oral corticosteroids have not been of value, while the effectiveness of clofibrate has been mixed. Cyclophosphamide has been effective in the control of mucosal lesions[65]. Cutaneous lesions have been treated by CO_2 laser, dermabrasion, radiotherapy, electrocoagulation, intralesional corticosteroids, cryotherapy and surgical excision.

MALIGNANT HISTIOCYTIC DISORDERS

Synonym: ■ Class III histiocytosis

The malignant histiocytic disorders are all very rare tumors (Table 91.3). Because most cases previously diagnosed as being of histiocytic origin have subsequently been shown to be either high-grade B-cell or T-cell lymphoid malignancies, their true incidence is uncertain. Nonetheless, the most recent WHO classification of tumors of hematopoietic and lymphoid tissues includes several true malignant histiocytic tumors[67].

DERMAL DENDROCYTE HAMARTOMAS

Synonyms: ■ $CD34^+$ dermal dendrocytomas ■ Plaque-like $CD34^+$ dermal fibroma

The dermal dendrocyte hamartomas are exceptionally rare and most cases are of recent description (Table 91.4)[68–71]. As the name implies, they are thought to be derived from dermal dendrocytes/dendritic cells, in particular $CD34^+$ dermal dendrocytes. The most common of these entities is the medallion-like dermal dendrocyte hamartoma[68].

Xanthomas 92

W Trent Massengale, Kafele T Hodari, Erin E Boh and Lee T Nesbitt Jr

Key features

- Cutaneous xanthomas can signal the presence of an underlying hyperlipidemia or monoclonal gammopathy
- An understanding of basic lipid metabolism provides insight into the underlying hyperlipoproteinemias as well as the formation of xanthomas
- The major forms of xanthomas associated with hyperlipidemia are: eruptive, tuberous, tendinous and plane (including xanthelasma)
- Normolipemic plane xanthomas occur in association with monoclonal gammopathies
- Histologically, lipid-laden macrophages (foam cells) are seen in the dermis
- Prompt recognition and proper treatment can lead to xanthoma resolution as well as prevention of potentially life-threatening complications

INTRODUCTION

Cutaneous xanthomas develop as a result of intracellular and dermal deposition of lipid. One of the major distinguishing clinical features of xanthomatous tissue is a characteristic yellow to orange hue. Xanthomas may present with a variety of morphologies, from macules and papules to plaques and nodules. As discussed below, the morphology and anatomic location of the lesions can suggest the type of underlying lipid disorder or the presence of a paraproteinemia.

Xanthomas can develop in the setting of primary or secondary disorders of lipid metabolism. Early recognition of these lesions can make a significant impact on the diagnosis, management and prognosis of patients who suffer from an underlying disease. It is therefore important for dermatologists to become familiar with the basic concepts of lipid metabolism and the associated disease states, as well as be able to recognize the often pathognomonic cutaneous findings.

EPIDEMIOLOGY

Hyperlipidemia is quite common in the general population. In North America alone, it is estimated that over 100 million people currently have an elevated serum cholesterol level >200 mg/dl. Despite the large number of people who suffer from hyperlipidemia, only a minority will develop cutaneous xanthomas. It is not always possible to predict who will develop xanthomas, because the exact mechanism by which they form is not yet fully understood. It is believed they result from the permeation of circulating plasma lipoproteins through dermal capillary blood vessels followed by phagocytosis of the lipoproteins by macrophages, forming lipid-laden cells known as foam cells[1]. However, the precise steps and their regulation are still an area of investigation.

PATHOGENESIS

There is strong evidence to support the theory that the lipids found in the various xanthomas are the same as those in the circulation[2]. The majority of plasma lipids are transported in complex structures known as lipoproteins. The basic structure of the lipoprotein allows the delivery of triglycerides and cholesterol to peripheral cells for their metabolic needs. This structure consists of a hydrophilic outer shell and a hydrophobic core. The outer shell consists of phospholipids, free cholesterol, and non-covalently linked specialized proteins known as apolipoproteins or apoproteins (apo). The inner core contains triglycerides and cholesterol esters.

Lipoproteins differ in their core lipid content. Triglycerides are the major core lipids in chylomicrons and very-low-density lipoproteins (VLDLs), while cholesterol esters dominate the core of low-density lipoproteins (LDLs), high-density lipoproteins (HDLs), and remnants of chylomicrons and VLDLs. The apoproteins found in the outer shell can also differ amongst the various lipoproteins (Table 92.1). These proteins serve several important functions, such as mediating the binding of lipoproteins to their respective receptors in target organs and activating enzymes involved in their metabolism.

There are two major pathways of lipoprotein synthesis (Fig. 92.1A). The exogenous pathway begins with dietary fat intake. Through the action of pancreatic lipase and bile acids, dietary triglycerides are degraded to fatty acids and monoglycerides. After absorption by the intestinal epithelium, the triglycerides are reformed and packaged with a small amount of cholesterol esters into the central core of a chylomicron. The outer shell of the chylomicron consists of phospholipids, free cholesterol, and several apoproteins, including B-48, E, A-I, A-II and C-II.

Chylomicrons then enter the lymphatics and eventually the systemic circulation via the thoracic duct. Once in the circulation, hydrolysis of the core triglycerides occurs, releasing free fatty acids to the peripheral tissues. This is mediated through the action of the enzyme lipoprotein lipase that is bound to capillary endothelium. The activation of the lipoprotein lipase system is complex and involves not only hormones such as insulin, but also apoproteins such as C-II, located on the lipoprotein outer surface.

After hydrolysis of approximately 70% of the original triglyceride content, a chylomicron "remnant" exists. The central core now contains predominantly cholesterol ester that has been acquired from circulating HDL molecules. The chylomicron remnant is taken up in the liver by specialized high-affinity apo B-100/E receptors that recognize the apoproteins E_3 or E_4 on its outer shell. Once in the liver, the remaining lipids enter hepatic storage and apoproteins such as B-48 are degraded.

IMPORTANT APOPROTEINS

Apoprotein	Lipoprotein association	Function and comments
A-I	Chylomicrons, HDLs	Major protein of HDL; activates *l*ecithin:cholesterol *a*cyltransferase (LCAT)
B-48	Chylomicrons, chylomicron remnants	Unique marker for chylomicrons
B-100	VLDLs, IDLs and LDLs	Major protein of LDL; binds to LDL receptor
C-II	Chylomicrons, VLDLs, IDLs and HDLs	Activates lipoprotein lipase
E (at least 3 alleles [E_2, E_3, E_4])	Chylomicrons, chylomicron remnants, VLDLs, IDLs and HDLs	Binds to LDL receptor

Table 92.1 Important apoproteins. HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

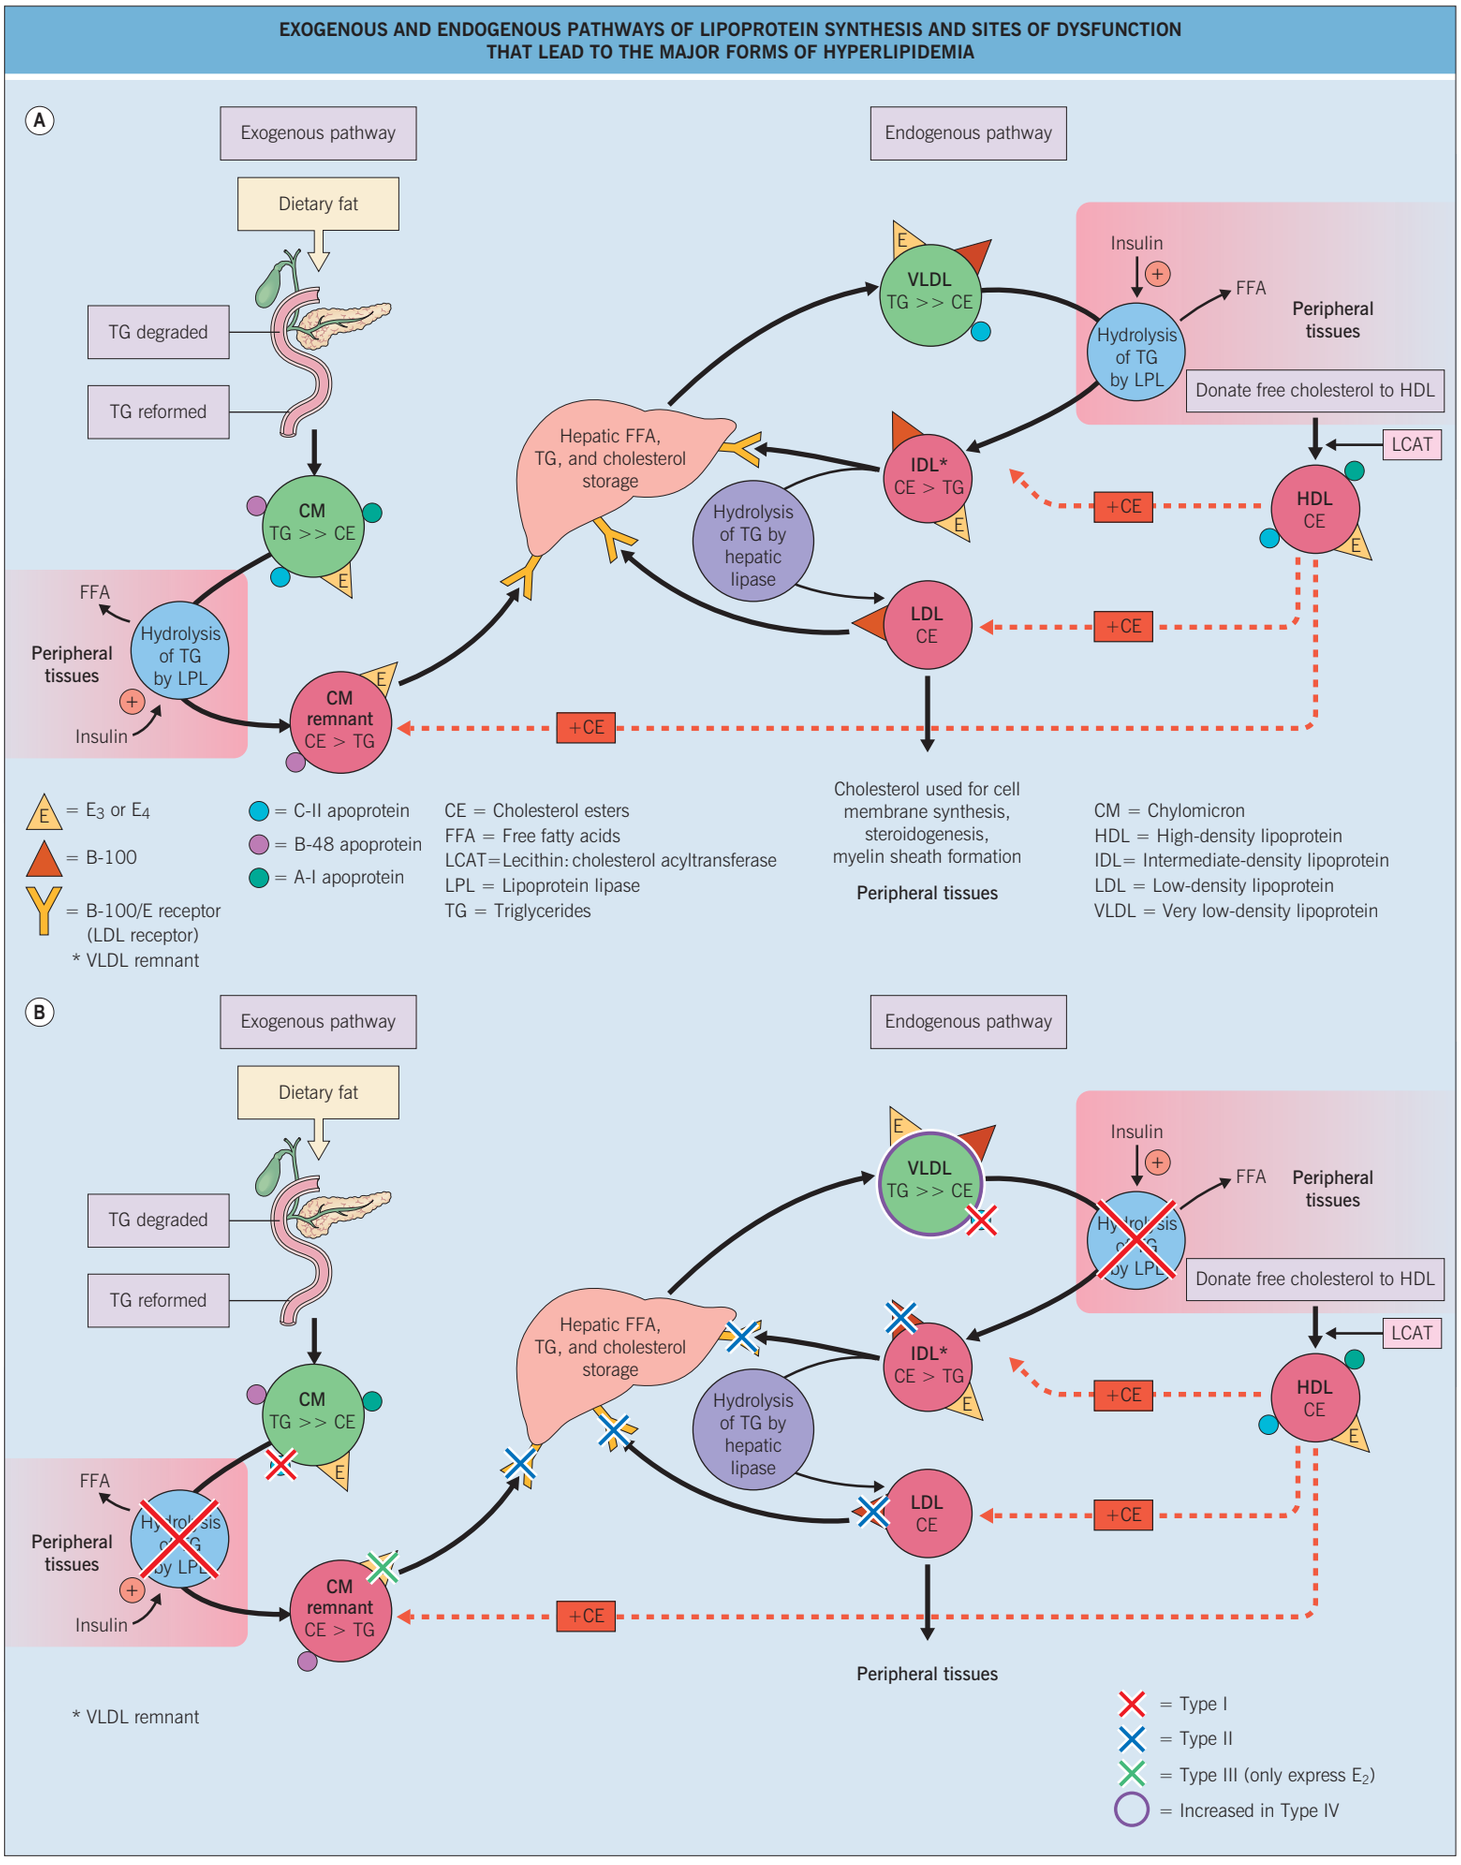

Fig. 92.1 Exogenous and endogenous pathways of lipoprotein synthesis (A) and sites of dysfunction that lead to the major forms of hyperlipidemia (B). Lipoprotein lipase (LPL) is activated by the C-II apoprotein.

IMPORTANT HYPERLIPOPROTEINEMIAS				
Type	**Pathogenesis**	**Laboratory findings**	**Clinical findings**	
			Skin (types of xanthoma)	**Systemic**
Type I (familial LPL deficiency, familial hyperchylomicronemia)	(a) Deficient or abnormal LPL (b) Apo C-II deficiency (c) Deficient glycosyl-phosphatidylinositol-anchored HDL-binding protein	Slow chylomicron clearance Reduced LDL and HDL levels Hypertriglyceridemia	Eruptive	No increased risk of coronary artery disease
Type II (familial hypercholesterolemia or familial defective apo B-100)	(a) LDL receptor defect (b) Reduced affinity of LDL for LDL receptor due to dysfunction of apo B-100 (ligand) (c) Accelerated degradation of LDL receptor due to missense *PCSK9* mutations* (d) Defective LDL receptor adaptor protein 1 (required for receptor internalization)	Reduced LDL clearance Hypercholesterolemia	Tendinous, tuberoeruptive, tuberous, plane (xanthelasma, intertriginous areas, interdigital web spaces†)	Atherosclerosis of peripheral and coronary arteries
Type III (familial dysbetalipoproteinemia, remnant removal disease, broad beta disease, apo E deficiency)	Hepatic remnant clearance impaired due to apo E abnormality; patients only express the apo E_2 isoform that interacts poorly with the apo E receptor	Elevated levels of chylomicron remnants and IDLs Hypercholesterolemia Hypertriglyceridemia	Tuberoeruptive, tuberous, plane (palmar creases) – most characteristic Tendinous	Atherosclerosis of peripheral and coronary arteries
Type IV (endogenous familial hypertriglyceridemia)	Elevated production of VLDL associated with glucose intolerance and hyperinsulinemia	Increased VLDLs Hypertriglyceridemia	Eruptive	Frequently associated with type 2 non-insulin-dependent diabetes mellitus, obesity, alcoholism (see Fig. 92.4)
Type V	Elevated chylomicrons and VLDLs; subset related to apo A-V defect	Decreased LDLs and HDLs Hypertriglyceridemia	Eruptive	Diabetes mellitus

*Gain-of-function mutations cause autosomal dominant hypercholesterolemia[4], whereas loss-of-function mutations (most prevalent in African-Americans) result in low LDL levels[5].
† Said to be pathognomonic for homozygous state.

Table 92.2 Important hyperlipoproteinemias. Apo, apolipoprotein; HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LPL, lipoprotein lipase; PCSK9, proprotein convertase subtilisin/kexin type 9; VLDL, very-low-density lipoprotein.

The endogenous pathway begins with the hepatic formation of VLDL particles. The central core of the VLDL consists primarily of triglycerides. The triglycerides are derived from circulating free fatty acids and hepatic triglyceride stores. Important apoproteins found on the outer shell include B-100, E and C-II. In a fashion similar to the chylomicron, lipoprotein lipase mediates hydrolysis of the VLDL molecule, removing the majority of its triglyceride content, and cholesterol esters are acquired from HDL molecules. Lipoprotein lipase activation requires the presence of apo C-II on the VLDL outer shell. After removal of the majority of the triglyceride content, the VLDL "remnant", also known as an intermediate-density lipoprotein (IDL), can then be taken up in the liver by apo B-100/E receptors and degraded. IDLs that escape uptake by the hepatocyte are stripped of their remaining core triglycerides by extracellular hepatic lipases and enter the circulation as LDLs.

The LDL contains predominantly cholesterol ester in its central core and expresses B-100 on its surface. LDL delivers the cholesterol ester to peripheral tissues, where it can be converted to free cholesterol. Cholesterol has several important functions in the body, such as being an essential component of cell membrane bilayers. It is also important in the production of the myelin sheath of nerves, adrenal and gonadal steroidogenesis, and the production of bile acids. Hepatocytes play the major role in the catabolism of LDLs. Their uptake is mediated through the high-affinity apo B-100/E receptor found on the cell surface of the hepatocytes. Free cholesterol in excess of metabolic needs is re-esterified for storage.

HDLs serve several important functions in cholesterol metabolism. One of the primary functions of HDLs is the removal of cholesterol from the peripheral tissues. During this process, free cholesterol and phospholipids are transferred from the cell membranes of peripheral cells to the HDL molecules. The free cholesterol is then esterified by the enzyme *l*ecithin:*c*holesterol *a*cyl*t*ransferase, or LCAT. This enzyme requires the presence of the HDL apoprotein A-I. HDL molecules then transfer the cholesterol esters to other lipoproteins such as LDLs and remnants of chylomicrons or VLDLs for transportation back to the liver.

The liver plays the central role in the overall cholesterol economy. Hepatic intracellular cholesterol levels have a direct impact on the activity of HMG-CoA reductase, the rate-limiting enzyme of cholesterol synthesis, and on the expression of the high-affinity apo B-100/E receptor. When intracellular cholesterol levels are low, HMG-CoA reductase becomes activated and high-affinity apo B-100/E receptor expression increases. The increase in high-affinity receptors leads to increased uptake of cholesterol-containing lipoproteins such as chylomicron remnants, IDLs and LDLs. This is followed by the lowering of plasma cholesterol levels. As discussed later, this mechanism will be the basis for many of the pharmacologic interventions aimed at lowering cholesterol levels.

CLINICAL FEATURES

Due to the complexity of cholesterol homeostasis, there are several possible ways in which hyperlipidemia may occur. Genetic mutations can affect important enzymes, receptors or receptor ligands, with such defects leading to the overproduction of lipoproteins or the inhibition of their clearance (Fig. 92.1B). Each possible defect would lead to a different abnormal lipid profile.

In 1965, Lees and Frederickson[3] published a system for classifying various disorders of lipid metabolism based upon the electrophoretic migration of the serum lipoproteins present. This system for phenotyping hyperlipoproteinemias is used today in a modified form (Table 92.2). In the next section, descriptions of underlying lipid disorders will reference not only the Frederickson classification system, but also the specific molecular defects when possible.

With the exception of the homozygous form of familial hypercholesterolemia (type II), most cutaneous xanthomas do not appear until adulthood. Once the diagnosis is established, treatment of associated disorders (e.g. metabolic syndrome [see Table 53.5]) should reduce the incidence of potential systemic sequelae such as myocardial infarctions, cerebrovascular accidents and hepatitic steatosis.

Fig. 92.2 Eruptive xanthomas due to hypertriglyceridemia. The lesions favored the extensor surface of the lower extremities, in particular the knees.

Fig. 92.3 Eruptive xanthomas. Note the yellowish hue and the clustering of some of the lesions.

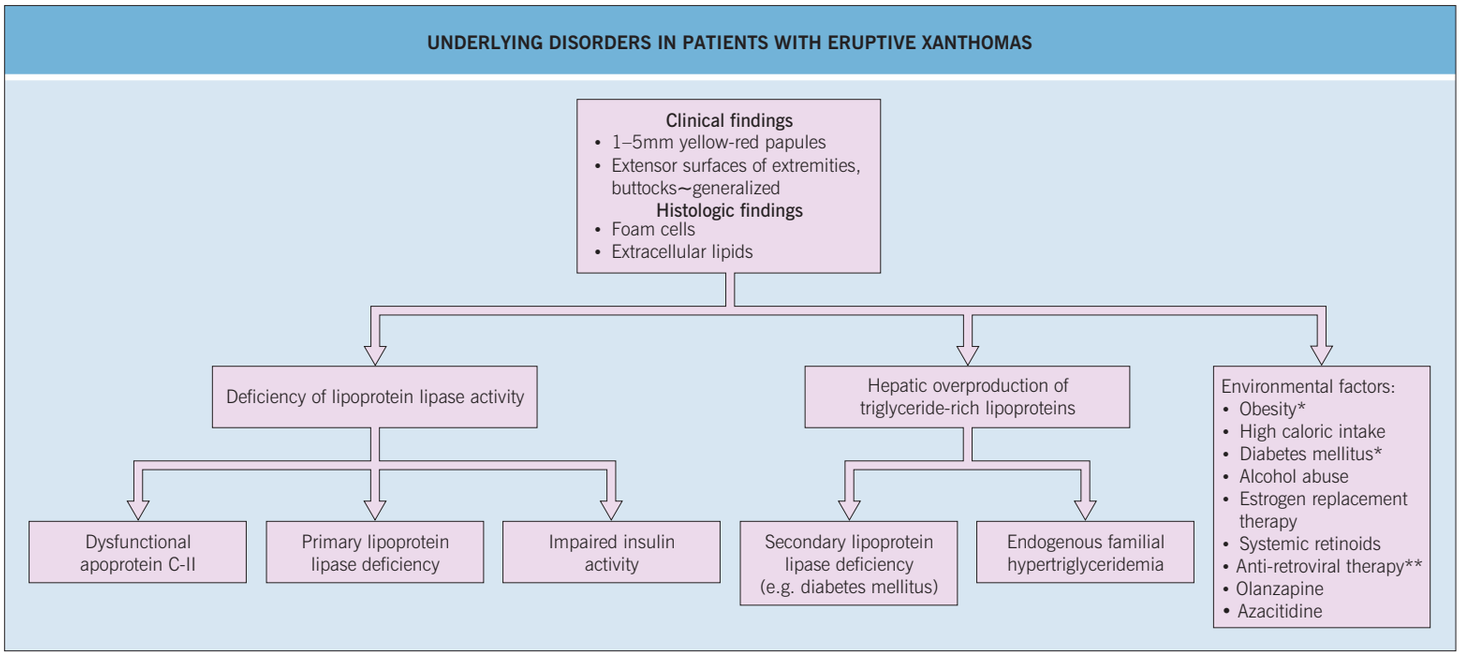

Fig. 92.4 Underlying disorders in patients with eruptive xanthomas. *Components of the metabolic syndrome[9] (see Table 53.5). **Examples include ritonavir, indinavir and stavudine.

Eruptive xanthomas

Eruptive xanthomas appear as erythematous to yellow papules, approximately 1 to 5 mm in diameter (Figs 92.2 & 92.3). They are usually distributed on the extensor surfaces of the extremities, buttocks and hands. Early in their development, lesions may have an inflammatory halo (likely due to their triglyceride component), which may be accompanied by tenderness and pruritus. The Koebner phenomenon has been reported to occur with eruptive xanthomas[6].

Eruptive xanthomas can be seen in the setting of primary or secondary hypertriglyceridemia. Triglyceride levels in patients with eruptive xanthomas often exceed 3000 to 4000 mg/dl. In the Frederickson classification of hyperlipidemias, hypertriglyceridemia can be seen in type I (elevated chylomicrons), type IV (elevated VLDLs) and type V (elevated chylomicrons and VLDLs).

One reason for elevated triglyceride levels is failure to remove such lipids from the circulation. Deficient activity of lipoprotein lipase will lead to accumulation of triglyceride-rich chylomicrons and VLDLs (see Fig. 92.1B). This can be related to abnormalities in the enzyme itself, as in *lipoprotein lipase deficiency* (*chylomicronemia syndrome*), or in other controlling factors such as *dysfunctional apoprotein C-II* or *impaired insulin activity* (Fig. 92.4)[7,8].

Another reason for increased triglyceride levels is hepatic overproduction of triglyceride-rich lipoproteins via the endogenous pathway. In *endogenous familial hypertriglyceridemia*, a genetic defect exists that causes the liver to respond abnormally to dietary carbohydrates and insulin, with overproduction of hepatic VLDLs. The result is a Frederickson type IV pattern of hypertriglyceridemia. Secondary acquired defects in lipoprotein lipase activity, such as those due to diabetes mellitus, are not uncommon in these patients. With this second insult, the lipoprotein lipase system can become saturated and, as a result, no longer handles dietary lipids, leading to chylomicron elevations as well. This pattern is classified as a Frederickson type V phenotype.

Environmental factors and underlying diseases commonly exacerbate genetic defects of triglyceride metabolism, leading to worsening of the hypertriglyceridemia with eruptive xanthoma formation. Such factors include obesity, high caloric intake, diabetes mellitus, alcohol abuse, oral estrogen replacement, and systemic medications that can lead to

Fig. 92.5 Tuberoeruptive xanthomas on the elbow of a child with homozygous familial hypercholesterolemia. Note the yellowish hue. *Courtesy, Julie V Schaffer, MD.*

Fig. 92.6 Nodular tuberous xanthoma of the elbow. *Courtesy, Lorenzo Cerroni, MD.*

hypertriglyceridemia (e.g. retinoids, protease inhibitors, olanzapine). The resultant pattern usually leads to a Frederickson type IV phenotype. Oral retinoid therapy (especially bexarotene) can elevate triglyceride levels through the elevation of hepatic VLDL secretion. With isotretinoin, this finding seems to be more prevalent in genetically predisposed individuals and may signal an increased risk for future metabolic syndrome[10]. Two of the five criteria for the clinical diagnosis of metabolic syndrome are lipid abnormalities – elevated triglycerides and reduced HDLs (see Table 53.5).

The treatment of eruptive xanthomas involves the identification and treatment of the underlying causes of the hypertriglyceridemia (see Fig. 92.4). Failure to recognize and treat the patient with hypertriglyceridemia could lead to complications such as acute pancreatitis. Pharmacologic and dietary lowering of the circulating triglycerides to reasonable levels will result in the prompt resolution of the eruptive lesions.

Tuberous/tuberoeruptive xanthomas

Tuberoeruptive and tuberous xanthomas are clinically and pathologically related and often described as being on a continuum. Tuberoeruptive xanthomas present as pink–yellow papules or nodules on extensor surfaces, especially the elbows and knees (Fig. 92.5). Tuberous lesions are noted to be larger than tuberoeruptive lesions and may exceed 3 cm in diameter (Fig. 92.6). Together, these lesions can be seen in hypercholesterolemic states such as *dysbetalipoproteinemia* (Frederickson type III) and *familial hypercholesterolemia* (Frederickson type II; see below). In contrast to eruptive xanthomas, tuberous xanthomas are usually slow to regress following institution of appropriate therapy.

Dysbetalipoproteinemia, or broad beta disease, is a genetic disorder of lipid metabolism that is inherited in an autosomal dominant fashion. It is caused by the presence of an isoform of apo E, mainly apo E_2, that is a poor ligand for the high-affinity apo B-100/E receptor (see Fig. 92.1B). This results in the poor hepatic uptake of chylomicron and VLDL remnants. As a result, the serum levels of both cholesterol and triglycerides are elevated. The cutaneous lesions that are most characteristic of this disease are tuberous or tuberoeruptive xanthomas (present in 80% of patients) and plane xanthomas of the palmar creases (*xanthoma striatum palmare*), which are present in two-thirds of patients[11].

Tendinous xanthomas

Tendinous xanthomas are firm, smooth, nodular lipid deposits that can affect the Achilles tendons (Fig. 92.7) or the extensor tendons of the hands (Fig. 92.8), knees or elbows. The overlying skin is normal in appearance. Ultrasound can aid in the diagnosis of subtle lesions of the Achilles tendon by demonstrating hypoechoic nodules or an increase in the anteroposterior diameter of the tendon[12]. The presence of tendinous xanthomas is almost always a clue to an underlying disorder of lipid metabolism. Lipid disorders that have been associated with this type of xanthoma include familial hypercholesterolemia, dysbetalipoproteinemia, and hypothyroidism (Table 92.3).

Fig. 92.7 Tendinous xanthoma. Linear swelling of the Achilles area, representing a tendinous xanthoma in a patient with dysbetalipoproteinemia.

Tendinous xanthomas are most frequently seen in the setting of *familial hypercholesterolemia*. This disorder results from a deficiency of normal LDL receptors on cell membranes, which leads to the poor hepatic clearance of circulating LDLs and, therefore, elevated LDL cholesterol levels (Frederickson type II). This condition is inherited in an autosomal dominant fashion with a high degree of penetrance. Homozygotes can have LDL cholesterol levels of 800 to 1000 mg/dl with widespread atherosclerosis and the appearance of xanthomas during the first decade of life. Heterozygosity for the disorder is more common and is estimated to occur in 1 in 500 individuals in the US. The types of xanthomas seen in this disorder include tendinous, tuberous, tuberoeruptive, and plane (including xanthelasma). Because of its relatively common occurrence, patients with tendinous xanthomas are more likely to have the heterozygous form of the disease than the rare homozygous state. Plane xanthomas of the intertriginous web spaces

Fig. 92.8 Tendinous xanthomas of the fingers in a patient with homozygous familial hypercholesterolemia. Note intertriginous plane xanthomas of the web spaces.

Fig. 92.9 Plane xanthomas of the antecubital fossae. This young patient had dysbetalipoproteinemia.

SECONDARY HYPERLIPIDEMIA – UNDERLYING DISORDERS
• Diabetes mellitus*
• Cholestasis
– Primary biliary cirrhosis (often plane xanthomas, including palmar)
– Alagille syndrome (elbows/knees, flexures, fingers, palms, helices)*,†
• Biliary atresia*
• Hypothyroidism*
• Nephrotic syndrome*
• Type I glycogen storage disease (von Gierke)*
*Xanthomas can develop during childhood.
†Autosomal dominant disorder due to *JAG1* or (in a small subset of patients) *NOTCH2* mutations, with cholestasis (due to paucity of intrahepatic bile ducts), elevated LDL (cholesterol) levels, cardiac defects, peculiar facies, growth retardation and posterior embryotoxon; xanthomas within body folds may become very firm[13–15].

Table 92.3 Secondary hyperlipidemia – underlying disorders.

Fig. 92.10 Plane xanthomas of the palmar creases (arrows) in a patient with dysbetalipoproteinemia. They are seen in approximately two-thirds of patients with this disorder. Plane xanthomas are also seen in the setting of cholestasis, e.g. biliary atresia or primary biliary cirrhosis.

of the fingers are thought to be pathognomonic for the homozygous condition (see Fig. 92.8)[16]. A closely related disorder, known as *familial defective apolipoprotein B-100*, has been described. In this dominantly inherited genetic disorder, the LDL receptor is normal. However, there is decreased affinity of LDL for the LDL receptor because the mutation affects its ligand, apo B-100. Patients may present with identical clinical findings as in familial hypercholesterolemia, although usually not as severe[17]. From a therapeutic standpoint, distinguishing this disorder from dysfunction or accelerated degradation of the LDL receptor (see Table 92.2) would become more important in the future should treatments aimed at correcting LDL receptor function become available.

Rarely, tendinous xanthomas can develop in the absence of a lipoprotein disorder. Two examples are *cerebrotendinous xanthomatosis* and *β-sitosterolemia*. In cerebrotendinous xanthomatosis, an enzymatic defect exists in the bile acid synthetic pathway, leading to the abnormal accumulation of an intermediate known as cholestanol. This intermediate is deposited in most tissues, including the brain, and can also form tendinous xanthomas[18]. In β-sitosterolemia, an abnormal accumulation of plant sterols occurs, leading to tendinous xanthoma formation.

Plane xanthomas and xanthelasma

Plane xanthomas are seen as yellow to orange, non-inflammatory macules, papules, patches and plaques. They can be circumscribed or diffuse. Their location can vary and the site often serves as a clue to the particular underlying disease state. For example, intertriginous plane xanthomas may occur in the antecubital fossae (Fig. 92.9) or the web spaces of the fingers (see Fig. 92.8), where they are almost pathognomonic for homozygous familial hypercholesterolemia[16]. Plane xanthomas of the palmar creases, or *xanthoma striatum palmare* (Fig. 92.10), are almost diagnostic for dysbetalipoproteinemia, especially when accompanied by tuberous xanthomas[19].

Xanthelasma, or *xanthelasma palpebrarum*, are commonly observed plane xanthomas of the eyelids (Fig. 92.11). Although the presence of xanthelasma warrants investigation for hyperlipidemia, the latter is present in only about one-half of the patients with these lesions. Younger patients with xanthelasma, or those with a strong family history of hyperlipidemia and xanthelasma, are more likely to have an underlying lipid disorder and should be appropriately screened.

Plane xanthomas of cholestasis may occur as a complication of diseases such as biliary atresia or primary biliary cirrhosis. In these conditions, unesterified cholesterol begins to accumulate in the blood, leading to plane xanthoma formation. The lesions often begin as localized plaques of the hands and feet, but can become generalized.

Plane xanthomas can also occur in a normolipemic patient, where they may signal the presence of an underlying monoclonal gammopathy (Fig. 92.12), usually due to a plasma cell dyscrasia, but occasionally secondary to a lymphoproliferative disorder such as B-cell lymphoma or Castleman's disease (see Ch. 119). This type of xanthoma can also be seen in patients with chronic myelomonocytic leukemia. In gammopathy-associated plane xanthomas, monoclonal IgG is thought to bind to circulating LDL, rendering the antibody–LDL complex more

Fig. 92.11 Xanthelasma palpebrarum with typical yellowish hue.

susceptible to phagocytosis by macrophages[20]. Favored locations include the neck, upper trunk, flexural folds and periorbital region.

Verruciform xanthomas

Verruciform xanthomas are asymptomatic, planar or verrucous solitary plaques averaging 1 to 2 cm in diameter. They occur primarily in the mouth (Fig. 92.13), but sometimes in anogenital (including the scrotum) or periorificial sites. There is usually no associated hyperlipidemia and the lesions persist for years. Histologically, there is usually hyperkeratosis, acanthosis, papillomatosis and foamy macrophages limited to the submucosa or dermal papillae.

These lesions are also seen in the setting of lymphedema, epidermolysis bullosa, pemphigus, discoid lupus erythematosus and GVHD, as well as within cutaneous lesions of the X-linked dominant disorder *c*ongenital *h*emidysplasia with *i*chthyosiform erythroderma and *l*imb *d*efects (CHILD) syndrome. The latter is due to mutations in the *NSDHL* gene, which encodes 3β-hydroxysteroid dehydrogenase, an enzyme involved in cholesterol biosynthesis (see Ch. 57). In a recent molecular study of sporadic verrucous xanthomas, two of nine lesions were found to have a missense somatic mutation in exon 6 of the *NSDHL* gene (only exons 4 and 6 were examined) which differed from the mutations seen in CHILD syndrome[21]. The possibility was raised that enzymatic dysfunction leads to an excess formation and accumulation of lipid storage droplets, followed by formation of lipid-laden dermal macrophages.

Another hypothesis suggests that the foam cells could be due to damage to the epithelium much in the same way as the amyloid deposits within the dermal papillae in lichen amyloidosis. The few foam cells beneath the epithelium may be subtle and easy to miss, in which case verruciform xanthomas may be confused histologically with warts and other papillomatous conditions. Surgery is generally curative.

PATHOLOGY

The characteristic histologic finding in xanthomas is the foam cell. Foam cells consist of macrophages that contain imbibed lipid within their cytoplasm (Fig. 92.14). All xanthomas contain dermal infiltrates of lipid, but they may vary in the degree of lipid content, the inflammatory infiltrate, the amount and location of the infiltrate, and the presence of extracellular lipid. The histologic appearance of xanthomas is somewhat altered by routine processing, as formalin fixation can remove deposits of lipid and leave artifactual clefting. Polarized microscopy can be used to detect lipid material in the dermal infiltrates, as cholesterol esters are doubly refractile.

Eruptive xanthomas contain lipid deposits in the reticular dermis. Of note, early in lesion development, foam cells are relatively small in number and size. The initial inflammatory infiltrate is mixed, containing both neutrophils and lymphocytes. As increased lipidization occurs, the appearance of the lesion becomes more typical of a xanthoma, but foam cells remain fewer in number compared with other types of xanthomas. Extracellular lipids are present in the dermis, which are seen as artifactual clefts filled with a wispy faint blue–gray material.

Tuberous xanthomas demonstrate large aggregates of foam cells in the dermis, often accompanied by fibrosis but without a large number of inflammatory cells. Tendinous xanthomas have a similar histology but the foam cells are even larger in size. Cholesterol esters are present in these lesions and can be seen with polarized microscopy.

Plane xanthomas such as xanthelasma can have a unique histologic appearance. The foam cells in this type of xanthoma are more superficial than in other types of xanthomas. Small aggregates of foam cells are often present in the superficial dermis. The lesions are non-inflammatory and have minimal fibrosis. With xanthelasma, there are often clues as to the location of the lesion, such as a thin epidermis, fine vellus hair follicles, and striated muscle fibers that are characteristic of the eyelid.

DIFFERENTIAL DIAGNOSIS

A selection of the diseases included in the differential diagnosis of xanthomas is listed in Table 92.4.

TREATMENT

The treatment of xanthomas associated with hyperlipidemia requires the identification of the underlying lipoprotein disorder and other possible exacerbating factors. In addition to dietary measures, there are several lipid-lowering pharmacologic agents available to help lower lipid levels in patients with primary and secondary hyperlipidemia. Table 92.5 outlines their mechanisms of action, clinical effects and side effects. Correction of the underlying lipid disorder leads to the eventual resolution of the xanthomas in many patients. Xanthomas that have grown slowly over years, such as tendinous and tuberous xanthomas, are often slow to regress, whereas eruptive xanthomas may disappear within weeks of aggressive therapy.

Dietary measures are important components of successful lipid-lowering therapy, in addition to oral medications (see Table 92.5). Decreasing total caloric intake and the achievement of ideal body weight alone can make a significant impact on lipid levels in some patients. Dietary fat restriction to less than 30% of total caloric intake should be attempted. Mono-unsaturated fats such as olive oil should comprise the majority of the fat intake. Alcohol avoidance is essential, especially in patients with hypertriglyceridemia.

Xanthomas, particularly xanthelasma, can be treated surgically by excision or destructive methods. When xanthelasma excision is performed, it may be followed by suture or second intention healing[28]. Reported destructive methods for xanthelasma include laser surgery (CO_2, pulsed-dye or erbium:YAG lasers), chemical agents such as trichloroacetic acid, and cryosurgery[29–32]. Despite the initial success of the chosen method, the lesions often recur. Surgical excision has also been employed in the management of tendinous xanthomas. This can be technically difficult however, as the lipid deposits may be intertwined with the involved tendon[33].

DIFFERENTIAL DIAGNOSIS OF XANTHOMAS
• Eruptive xanthomas
– Non-Langerhans cell histiocytoses
Xanthoma disseminatum
Papular xanthoma
Generalized eruptive histiocytomas
Indeterminate cell histiocytosis
Rosai–Dorfman disease
Juvenile xanthogranuloma (micronodular form)
– Xanthomatous lesions of Langerhans cell histiocytosis
– Disseminated granuloma annulare
• Tuberous xanthomas
– Erythema elevatum diutinum
– Multicentric reticulohistiocytosis
• Tendinous xanthomas
– Giant cell tumor of the tendon sheath
– Rheumatoid nodule
– Subcutaneous granuloma annulare
• Xanthelasma
– Syringomas
– Necrobiotic xanthogranuloma
– *A*dult-onset *a*sthma and *p*erio*c*ular *x*anthogranuloma (AAPOX)
– Sebaceous hyperplasia
– Palpebral sarcoidosis

Table 92.4 Differential diagnosis of xanthomas.

LIPID-LOWERING MEDICATIONS				
Class of drug	**Mechanism of action**	**Clinical effects**	**Side effects/Interactions**	**Comments**
HMG-CoA reductase inhibitors ("statins")	• Competitive inhibition of the rate-limiting enzyme of hepatic cholesterol synthesis, with depletion of hepatocellular stores of cholesterol • Upregulation of hepatic LDL receptors (bind LDL & IDL; see Fig. 92.1) • Decreased endogenous VLDL production	• 25–45% decrease in LDL levels • 25% decrease in VLDL levels • 10% increase in HDL levels	• Elevations in hepatic transaminases • Myopathy (risk may be increased with co-administration of other medications, e.g. cyclosporine, nicotinic acid, fibrates) • Drug-induced dermatomyositis • May increase warfarin levels	• Useful for many lipid disorders, including *heterozygous* familial hypercholesterolemia, hypercholesterolemia due to diabetes • Not effective in *homozygous* familial hypercholesterolemia (LDL receptor function is lacking)
Bile acid-binding resins	• Bind to bile acids in the small intestine, preventing their reabsorption in the terminal ileum • Because of enhanced bile acid secretion, the liver must increase its synthesis of bile acids from cholesterol • Decrease in hepatic cholesterol stores leads to upregulation of hepatic LDL receptors (also increased HMG-CoA reductase activity)	• 10–35% decrease in LDL levels (even with increase in hepatic cholesterol synthesis)	• Elevation of triglyceride levels, especially if dysbetalipoproteinemia or pre-existing hypertriglyceridemia • GI upset & gritty texture of resin • Affect absorption of medications such as digitalis, thyroxine, warfarin	• Lowering of LDL levels can be further enhanced by the addition of an HMG-CoA reductase inhibitor or nicotinic acid • Effective in *heterozygous* familial hypercholesterolemia • Not effective in *homozygous* familial hypercholesterolemia

Table 92.5 Lipid-lowering medications. GI, gastrointestinal; HDL, high-density lipoprotein; HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very low-density lipoprotein. Based on refs 22–27.

Continued

LIPID-LOWERING MEDICATIONS				
Class of drug	**Mechanism of action**	**Clinical effects**	**Side effects/Interactions**	**Comments**
Nicotinic acid (niacin)	• Lowers VLDL synthesis (and subsequently lowers LDL levels) • Enhances lipoprotein lipase activity (and subsequently lowers triglyceride levels)	• 20–80% decrease in triglyceride levels (rapid) • 10–15% decrease in LDL levels (slower) • 20–30 mg/dl increase in HDL	• Intense flushing and pruritus are common • Hepatic dysfunction • Worsening of glucose intolerance • Acanthosis nigricans, hyperpigmentation, xerosis • Increased risk of myopathy & rhabdomyolysis when administered with HMG-CoA reductase inhibitors	• Can be used in combination with HMG-CoA reductase inhibitors or bile acid-binding resins • Combination therapy for familial hypercholesterolemia • Treatment of severe hypertriglyceridemia refractory to fibric acid derivatives (to prevent pancreatitis)
Probucol	• Antioxidant • Presumably, lipid-lowering mechanism is independent of LDL receptors	• Lowers LDL levels • *Lowers* HDL levels • Dramatic resolution of tendon & plane xanthomas	• Lowers HDL levels	• No effect on triglyceride levels • Only agent (on market) that can lower cholesterol levels in *homozygous* familial hypercholesterolemia
Fibric acid derivatives (e.g. gemfibrozil, fenofibrate, clofibrate)	• Activation of lipoprotein lipase in peripheral tissues (e.g. muscle) • Decreases VLDL synthesis by suppression of the endogenous lipid pathway	• Dramatic improvement in lipid levels, with resolution of tuberous & palmar xanthomas (patients with dysbetalipoproteinemia) • Lowers triglyceride levels; prevents pancreatitis & eruptive xanthoma formation (patients with severe hypertriglyceridemia & chylomicronemia syndrome)	• Because of inhibition of the cytochrome P450 3A4 system, possibility of dermatologic drug interactions (e.g. increased plasma levels of bexarotene or cyclosporine) • Increased risk of myopathy when administered with HMG-CoA reductase inhibitors	• Treatment of hypertriglyceridemia
CETP inhibitors (e.g. anacetrapib)	• Inhibition of cholesteryl ester transfer protein (CETP) • CETP transfers cholesterol from HDLs to VLDLs or LDLs	• 40% decrease in LDL-C levels • Marked increase in HDL levels	• Increase in aldosterone and systolic blood pressure (torcetrapib) • Increase in transaminases and CPK	• Not FDA-approved • Another CTEP inhibitor (torcetrapib) was withdrawn from the market because of an increase in mortality

Table 92.5 Lipid-lowering medications (cont'd). CPK, creatine phosphokinase; HDL, high-density lipoprotein; HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A; LDL, low-density lipoprotein; VLDL, very low-density lipoprotein. Based on refs 22–27.

Chapter Contents

Sarcoidosis 1557
Granuloma annulare 1563
Necrobiosis lipoidica 1566
Annular elastolytic giant cell granuloma 1568
Cutaneous Crohn's disease 1570

INTRODUCTION

The diseases discussed in this chapter are unified by similar histologic findings despite having disparate, often unknown, causes. Granulomatous dermatitis may be defined as having an inflammatory cutaneous infiltrate in which histiocytes are the preponderant inflammatory cells. While numerous non-infectious cutaneous disorders fall within this broad definition, cutaneous sarcoidosis is the prototype of granulomatous dermatitis. Many conditions mimic the appearance of sarcoidosis, including cutaneous Crohn's disease as well as certain foreign body reactions (see Ch. 94). Granuloma annulare, the closely related annular elastolytic giant cell granuloma (actinic granuloma), and necrobiosis lipoidica are the best-known examples of palisaded granulomatous dermatitis. Each of these entities will be reviewed in this chapter (Fig. 93.1 & Table 93.1). Additional non-infectious granulomatous disorders are covered in other chapters, including granulomatous cheilitis in Chapter 72, rheumatoid nodules and interstitial granulomatous dermatitis in Chapter 45, and primary immunodeficiency-associated sterile granulomatous dermatitis in Chapter 60.

SARCOIDOSIS

Synonyms/subsets: ■ Löfgren's syndrome – erythema nodosum, hilar adenopathy, fever, arthritis ■ Heerfordt's syndrome – parotid gland enlargement, uveitis, fever, cranial nerve palsy ■ Darier–Roussy disease – subcutaneous sarcoidosis

Key features

- A systemic granulomatous disorder of unknown origin that most commonly involves the lungs
- Cutaneous manifestations of sarcoidosis are seen in up to one-third of patients, and they may be the first clinical sign of the disease
- Red–brown to violaceous papules and plaques appear most often on the face, lips, neck, upper back and extremities
- Variants of sarcoidosis include lupus pernio, subcutaneous, ichthyosiform, angiolupoid and ulcerative
- Erythema nodosum is a nonspecific inflammatory skin finding associated with subacute, transient sarcoidosis
- Histologically, sarcoidosis is characterized by non-caseating epithelioid granulomas, usually without surrounding lymphocytic inflammation (i.e. "naked" granulomas)

History

Sarcoidosis was described initially by Sir Jonathan Hutchinson in 1875 and cutaneous sarcoidosis (lupus pernio) by Besnier in 1889. Caesar Boeck first coined the term "multiple benign sarkoid" in 1899.

Epidemiology

Sarcoidosis, which occurs in patients of all races and ages as well as both sexes, is characterized by a bimodal age distribution, with peaks between 25 and 35 years and then again between 45 and 65 years in women. In the US, there is an increased incidence of sarcoidosis in African-Americans, ranging from 35 to 64 per 100 000. Sarcoidosis in African-Americans tends to be more acute and severe than in other populations. African-American women in the fourth decade of life have the highest incidence, occurring with a rate of 107 per 100 000. In comparison, the incidence in Caucasians in the US ranges from 10 to 14 per 100 000. Worldwide, the incidence of sarcoidosis is highest in Sweden (64 per 100 000) and the UK (20 per 100 000) and lowest in Spain and Japan (both 1.4 per 100 000). A greater number of patients with new-onset sarcoidosis are reported in the winter and spring[1].

Pathogenesis

Sarcoidosis is a multisystem granulomatous disease characterized by hyperactivity of the cell-mediated immune system. Specifically, upregulation of $CD4^+$ T-helper cells of the Th1 subtype occurs following antigen presentation by monocytes bearing MHC class II molecules, which initiates formation of epithelioid granulomas in a variety of tissue types[2]. In the lung, an oligoclonal α/β T-cell population has been described, suggesting that antigenic triggers of sarcoidosis favor a progressive accumulation and activation of specific T-cell clones[3].

Increased production of Th1 cytokines, including interleukin (IL)-2 and interferon (IFN)-γ, as well as release of tumor necrosis factor (TNF)-α by macrophages, leads to B-cell stimulation and hypergammaglobulinemia. IL-12 is also thought to play a role in sarcoidosis as are $CD4^+$ T cells of the Th17 subtype[3a].

Monocyte chemotactic factor (MCF), produced by activated T-helper cells, attracts monocytes from the circulation into peripheral tissues. Compartmentalization of granuloma-forming T lymphocytes and monocytes within peripheral tissues leads to lymphopenia and decreased delayed-type hypersensitivity to common antigens (anergy), most pronounced during the initial stages of sarcoidosis. In addition, T regulatory cells may play a role in the anergic state. Perhaps the observation that IFN-α, especially when administered for hepatitis C viral infections, can induce cutaneous sarcoidosis will provide further insights into the immunopathogenesis.

The identity of the antigen responsible for the cascade of events leading to granuloma formation in patients with sarcoidosis remains uncertain. Some investigators have proposed an autoimmune etiology, while others have searched for an infectious cause. The latter is suggested by the observation that sarcoidal granulomas have developed in patients receiving organ transplants from donors with sarcoidosis. Mycobacterial DNA sequences have been identified in lung tissue, peripheral blood, skin, and cerebrospinal fluid in some studies of patients with sarcoidosis but not in others[4]. Sarcoidosis patients do not develop fulminant infectious symptoms when placed on immunosuppressive agents, which argues against a purely infectious etiology. In addition, mycobacteria have not been cultured from sarcoidal tissues. Possible viral causes of sarcoidosis, including human herpesvirus-8, have been postulated but not proven[5]. Sarcoidal lesions have been reported in HIV-infected patients upon immune restoration when given antiretroviral therapy. However, no evidence of infection with

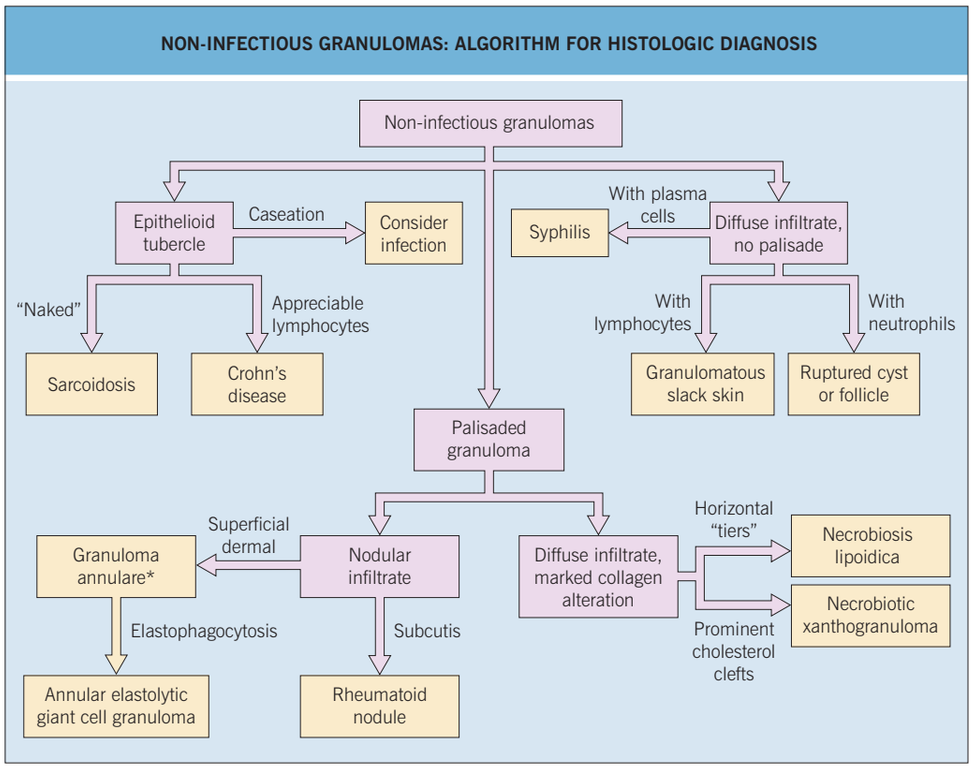

Fig. 93.1 Non-infectious granulomas: algorithm for histologic diagnosis. Interstitial granulomatous dermatitis and palisaded neutrophilic and granulomatous dermatitis may represent an additional diagnostic consideration (see Table 93.2). *May also have a patchy dermal interstitial pattern without palisades, or subcutaneous palisades with more mucin than rheumatoid nodules.

CLINICAL FEATURES OF THE MAJOR GRANULOMATOUS DERMATITIDES

	Sarcoidosis*	Classic granuloma annulare†	Necrobiosis lipoidica	AEGCG	Cutaneous Crohn's disease	Rheumatoid nodule
Average age (years)	25–35, 45–65	<30	30	50–70	35	40–50
Sex predilection	Female	Female	Female	None	Female	Male‡
Racial/ethnic predilection in US	African-American	None	None	Caucasian	Ashkenazi Jews	None
Sites	Symmetric on face, neck, upper trunk, extremities	Hands, feet, extensor aspects of extremities	Anterior and lateral aspects of distal lower extremities	Face, neck, forearms (sites of chronic sun exposure)	Genital areas, lower > upper extremities	Juxta-articular areas, especially elbows, hands, ankles, feet
Appearance	Red to red–brown papules and plaques; occasionally violaceous or annular	Papules coalescing into annular plaques	Plaques with elevated borders, telangiectasias centrally	Annular plaques	Dusky erythema and swelling, ulceration	Skin-colored, firm, mobile subcutaneous nodules
Size of lesions	0.2 to >5 cm	1–3 mm papules, annular plaques usually <6 cm	3 to >10 cm	1–6 cm	Variable	1–3 cm
No. of lesions	Variable	1–10	1–10	1–10	1–5	1–10
Associations	Systemic manifestations of sarcoidosis; interferon-α therapy for hepatitis C viral infection >> melanoma	Rare diabetes mellitus, HIV infection, malignancy	Diabetes mellitus	Actinic damage	Intestinal Crohn's disease	Rheumatoid arthritis
Special clinical characteristics	Occasional central atrophy and hypopigmentation; development within scars	Central hyperpigmentation	Yellow–brown atrophic centers, ulceration	Central atrophy and hypopigmentation	Draining sinuses and fistulas	Occasional ulceration, especially at sites of trauma

*Clinical variants include lupus pernio and subcutaneous (Darier–Roussy), psoriasiform, ichthyosiform, angiolupoid and ulcerative sarcoidosis.
†Clinical variants include generalized, micropapular, nodular, perforating, subcutaneous and patch granuloma annulare.
‡Although rheumatoid arthritis has a female:male ratio of 2–3:1.

Table 93.1 Clinical features of the major granulomatous dermatitides. AEGCG, annular elastolytic giant cell granuloma; HIV, human immunodeficiency virus.

Mycobacterium tuberculosis could be identified in these sarcoidosis-like lesions[6].

Genetic susceptibility to sarcoidosis has been associated with HLA-1, HLA-B8 and HLA-DR3 alleles[7], and, more recently, HLA-DRB1 and DQB1[8]. Polymorphisms in the gene encoding angiotensin-converting enzyme (ACE) have also been identified in patients with sarcoidosis. An environmental trigger for the disease is suggested by seasonal clustering of sarcoidosis with erythema nodosum in the spring. Occupational associations have been recorded in healthcare workers, firemen, and navy personnel on aircraft carriers[4].

While the etiologic agent clearly remains elusive, investigation of the immunopathogenesis of the disease (see above) has been aided by examining the cutaneous reaction produced by injection of a tissue suspension prepared from sarcoidal spleen. The suspension (Kveim-Siltzbach antigen) causes characteristic non-caseating granuloma formation in the skin of patients with sarcoidosis, and although this skin test is rarely performed nowadays, it was used in the past to help confirm the diagnosis. Immunohistochemical studies of the Kveim skin test have demonstrated a predominance of $CD4^+$ helper T cells and a paucity of $CD8^+$ suppressor T cells, B cells, and immunoglobulin deposition in the cutaneous granulomas. Peripheral blood monocytes are present in the skin for the first several days, but then transform into epithelioid histiocytes and multinucleated giant cells[2].

Clinical Features

Up to a third of patients with systemic sarcoidosis develop skin lesions, which may be the first or only clinical manifestation of the disease. Cutaneous sarcoidosis most commonly manifests as papules and plaques, often red–brown in color (Fig. 93.2A). Papules may be flat-topped in appearance. Sarcoidal lesions favor the face, lips, neck, upper trunk and extremities (Figs 93.2B–D), and are fairly symmetric in distribution. Classically, the cutaneous lesions lack secondary changes, but occasionally scale or ulcerations can develop. Less common presentations include hypopigmentation (Fig. 93.3A), subcutaneous nodules, acquired ichthyosis (Fig. 93.3B), alopecia and discrete micropapular lesions; erythroderma, erythema multiforme and verrucous plaques are rare manifestations. A classic finding is the development of cutaneous sarcoidosis within pre-existing scars or at sites of prior trauma (Fig. 93.2E).

Although many lesions are red–brown in color, they can vary from yellow–brown to erythematous (especially in lightly pigmented skin) to

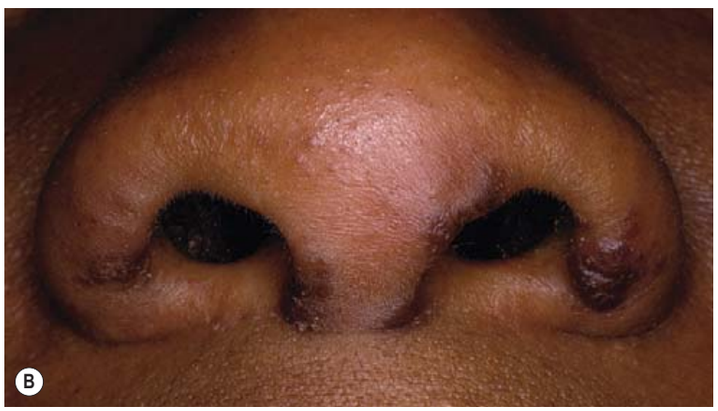

Fig. 93.2 Sarcoidosis. **A** Cutaneous sarcoidosis usually consists of papules and plaques with a typical reddish-brown color. **B, C** Lesions often favor the nose, lips and perioral region. **D** Hyperpigmented plaques, some of which have scale. **E** Papules of cutaneous sarcoidosis arising within a tattoo; the differential diagnosis includes foreign body reaction. *B, Courtesy, Louis A Fragola, Jr, MD.*

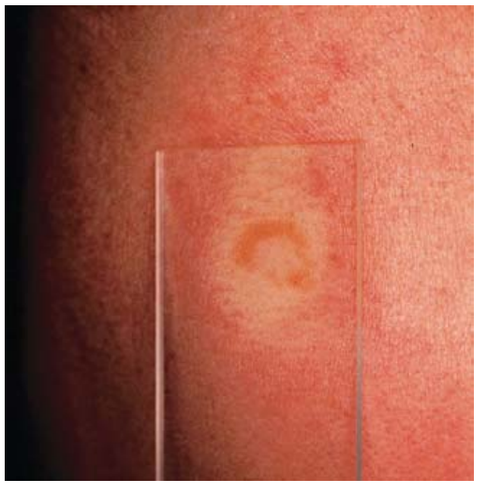

Fig. 93.4 Sarcoidosis. With diascopy, a yellow–brown, "apple jelly" color is seen.

Fig. 93.5 Erythema nodosum in a patient with sarcoidosis. These patients often have hilar lymphadenopathy. *Courtesy, Louis A Fragola, Jr, MD.*

violaceous; the latter color is often associated with lupus pernio. Upon diascopy, in which pressure induces blanching, the lesions are said to have the color of "apple jelly" (Fig. 93.4); this finding is usually easier to appreciate in lightly pigmented skin. Individual plaques can develop central clearing leading to an annular configuration or they can contain prominent telangiectasias (angiolupoid sarcoidosis). By dermoscopy, translucent yellow to orange globular-like or structureless areas associated with linear vessels may be seen in lesions of sarcoidosis.

Variants of sarcoidosis include Darier–Roussy disease and lupus pernio. Patients with Darier–Roussy sarcoidosis present with painless, firm, mobile nodules without epidermal changes. This variant represents sarcoidosis limited to the subcutaneous tissue. Lupus pernio is characterized by papulonodules and plaques, primarily involving areas most affected by cold (i.e. pernio), including the nose, ears and cheeks; there is often a beaded appearance along the nasal rim (Fig. 93.3C). Recognition of lupus pernio is important because of its association with chronic sarcoidosis of the lungs (approximately 75% of patients) and of the upper respiratory tract (approximately 50% of patients). In addition, cystic lesions within the bones of the distal phalanges are seen more frequently. Although most skin lesions of sarcoidosis are asymptomatic and, with treatment, resolve without scarring, lupus pernio is often the exception[9].

The most important nonspecific cutaneous manifestation of sarcoidosis is erythema nodosum (Fig. 93.5). Erythema nodosum is associated with subacute, transient sarcoidosis that usually resolves spontaneously and typically does not require systemic corticosteroid therapy. In general, there are no additional cutaneous manifestations. Biopsy specimens from erythema nodosum lesions show a granulomatous septal panniculitis (see Ch. 100). Sarcoidosis manifesting as erythema nodosum with hilar adenopathy, fever, migrating polyarthritis, and acute iritis is termed Löfgren's syndrome.

Nail changes can be seen in sarcoidosis, including clubbing, subungual hyperkeratosis, and onycholysis. Oral sarcoidosis may affect the soft mucosa, gingival tissue, tongue, hard palate, and major salivary glands. Heerfordt's syndrome (uveoparotid fever) includes parotid gland enlargement, uveitis, fever, and cranial nerve palsies, usually of the facial nerve.

Systemic manifestations of sarcoidosis are protean. Lung disease occurs in approximately 90% of patients, ranging from alveolitis to granulomatous infiltration of the alveoli, blood vessels, bronchioles,

pleura and fibrous septa[10]. The end stage of pulmonary sarcoidosis is fibrosis with bronchiolectasis and "honeycombing" of the lung parenchyma. Hilar and/or paratracheal lymphadenopathy, which is usually asymptomatic, occurs in 90% of patients.

Granulomatous inflammation also occurs in the liver, spleen and bone, as well as the kidney, gastrointestinal tract (upper and lower) and peripheral lymph nodes. Additional sites include the central and peripheral nervous systems, muscle, heart, endocrine glands (e.g. pituitary, thyroid) and bone marrow. Occasionally, there is involvement of the ear, breast, and male and female reproductive systems. Ocular sarcoidosis may present with granulomatous inflammation of the uveal tract (iris, ciliary body, choroid), retina, optic nerve, conjunctivae or lacrimal glands.

Childhood sarcoidosis is rare, and it usually presents with a triad of arthritis, uveitis and cutaneous lesions along with constitutional symptoms. Peripheral lymphadenopathy is frequently present, but pulmonary involvement is less common than in adults. Sarcoidosis should be considered in the differential diagnosis of any childhood illness with arthritis, especially if ocular symptoms are present.

Hypercalcemia is present in up to 10% of patients, and it is believed to be due to increased calcitriol synthesis by sarcoidal histiocytes. Subsequent hypercalciuria and nephrocalcinosis may lead to renal failure. Lymphopenia, leukopenia and an elevated ESR can be seen in up to 40% of patients.

Pathology

The histopathologic hallmark of sarcoidosis is the presence of superficial and deep dermal epithelioid cell granulomas devoid of prominent infiltrates of lymphocytes or plasma cells ("naked tubercles") (Fig. 93.6). Central caseation is usually absent, although fibrinoid deposition may be observed in up to 10% of cases. Multinucleated histiocytes ("giant cells") are usually of the Langhans type, with nuclei arranged in a peripheral arc or circular fashion. The giant cells may contain eosinophilic stellate inclusions known as asteroid bodies (Fig. 93.7) or rounded laminated basophilic inclusions known as Schaumann bodies. Asteroid bodies represent engulfed collagen, whereas Schaumann bodies likely represent degenerating lysosomes. Neither finding is specific for sarcoidosis.

A range exists within the histologic spectrum of sarcoidosis, from the characteristic tubercles with minimal or no surrounding lymphocytic inflammation to unusual cases with dense lymphocytic and plasmocytic infiltrates around and within the nodular histiocytic aggregates. Occasionally, these aggregates may extend into the subcutaneous fat, producing the clinical features of Darier–Roussy sarcoidosis and fibrosing panniculitis[11].

Diagnosis and Differential Diagnosis

Sarcoidosis is a diagnosis of exclusion, both clinically and histologically. In order to establish the diagnosis, a supportive clinical history must be accompanied by the histologic presence of non-caseating granulomas in at least one organ system. Radiologic findings include hilar and/or paratracheal lymph node enlargement with or without pulmonary infiltrates on chest radiography. High-resolution CT scans of the chest are more sensitive than radiographs in detecting parenchymal and nodal disease and may be used to delineate active inflammation from fibrosis. Pulmonary function tests reveal restrictive lung disease, with decreased vital capacity, residual volume, total lung capacity and diffusing capacity. Musculoskeletal radiographs may show joint effusions and cystic lesions in the small bones of the hands and feet. Histologically, the granulomatous lesions of the gastrointestinal tract can be indistinguishable from Crohn's disease or Whipple's disease.

Serologically, elevated antinuclear antibody titers occur in ~30% of patients. The serum angiotensin-converting enzyme (ACE) level is elevated in ~60% of patients; it has a false-positive incidence of 10%, making it a more useful test for monitoring disease progression than for establishing the diagnosis. Most patients exhibit lymphopenia, with a decreased $CD4^+$:$CD8^+$ ratio of circulating lymphocytes. Five percent of patients have non-hemolytic anemia, and one-quarter have eosinophilia. Both an elevated ESR and hypercalcemia may be present (see above).

Like syphilis, sarcoidosis is a great mimic and the clinical differential diagnosis depends upon the type of presenting clinical lesions. For example, a list of other disorders, in addition to sarcoidosis, that can present with annular lesions is provided in Table 19.1. Papules, nodules and plaques may be nonspecific in clinical appearance, dictating biopsy,

and then the differential diagnosis rests upon the histopathologic findings. It is important to exclude the possibility of drug-induced cutaneous sarcoidosis (e.g. IFN-α for hepatitis C viral infection, TNF-α inhibitors).

The histologic differential diagnosis is broad, and includes multiple infections that lead to granulomatous inflammation. Special stains for acid-fast and fungal organisms should be obtained. When clinically appropriate, tissue culture should be performed. In tuberculoid leprosy, clues to the diagnosis include inflammation within and around peripheral nerves (where acid-fast *Mycobacterium leprae* occasionally may be demonstrated with a Fite stain), elongated tubercles (reflecting nerve involvement), and denser collections of lymphocytes and plasma cells around the tubercles. Lupus vulgaris is the form of cutaneous tuberculosis that is most difficult to distinguish from sarcoidosis histologically, due to the difficulty in demonstrating organisms in this variant. Histologic features of lupus vulgaris include caseation necrosis within the central portion of tubercles, denser collections of peripheral lymphocytes, and epidermal changes such as ulceration or pseudoepitheliomatous hyperplasia; this constellation usually allows its distinction from sarcoidosis. A QuantiFERON®-TB Gold test may provide additional information. It is especially important to exclude infectious etiologies before initiating immunosuppressive agents (e.g. TNF-α inhibitors).

Other histologic mimics include foreign body reactions to zirconium, beryllium, silica, tattoo ink or soft tissue fillers. Special laboratory techniques, including histochemical, microincineration or spectrophotometric examinations, may be required to identify the causative agents in zirconium and beryllium granulomas (see Table 94.3). Specimens should be polarized to exclude birefringent foreign material as a causative agent, although up to 20% of known sarcoidal granulomas will have foreign material present within them. This observation is particularly common in lesions from the elbows and knees. Therefore, the dermatologic diagnoses of foreign body granuloma and sarcoidosis are not mutually exclusive[12].

In addition, granulomatous mycosis fungoides, Hodgkin disease, granulomatous rosacea, cutaneous Crohn's disease, Blau syndrome (see Ch. 55), cheilitis granulomatosa, and the sarcoidal reaction to an underlying lymphoma can have histologic appearances similar to sarcoidosis. The histologic differences between sarcoidosis, granuloma annulare, necrobiosis lipoidica, annular elastolytic giant cell granuloma, rheumatoid nodule and interstitial granulomatous dermatitis are outlined in Table 93.2.

Treatment

Corticosteroids, in either topical, intralesional or systemic form, are the mainstay of therapy for systemic sarcoidosis (Table 93.3). Therapy is guided by disease severity and progression. The typical oral prednisone dose for systemic disease is 1 mg/kg/day for 4–6 weeks, followed by a slow taper over months to years as dictated by the pulmonary disease, sarcoidosis of the upper respiratory tract, ocular disease or other internal manifestations. Cutaneous sarcoidosis that is major in terms of disfigurement may respond to lower doses of prednisone, including every-other-day regimens. Hydroxychloroquine (200–400 mg/day) or chloroquine (250–500 mg/day) can be effective in controlling skin manifestations of sarcoidosis, particularly chronic disease. Other reported therapeutic agents for cutaneous disease include minocycline (200 mg/day), methotrexate (10–25 mg weekly), thalidomide (50–300 mg/day), isotretinoin (1 mg/kg/day for 3–8 months), and allopurinol (100–300 mg/day)[13–17]. Improvement of systemic and cutaneous sarcoidosis has been observed with TNF-α inhibitors, including infliximab, adalimumab and etanercept, but these agents may also trigger sarcoidosis[18,19]. One phase II trial of etanercept was terminated early due to adverse events (e.g. lymphoproliferative disorders). Benefit from leflunomide has also been reported[20].

Other treatments for cutaneous disease include superpotent topical corticosteroids with or without occlusion, intralesional triamcinolone (3–10 mg/ml every month), and PUVA[21,22]. Pulsed dye and CO_2 laser treatments and photodynamic therapy may be effective for lupus pernio, but there is also a report of laser therapy worsening the disease[23,24]. Surgical excisions with grafting have been performed for ulcerative sarcoidosis[25]. A treatment algorithm, based upon evidence-based methodology, has been proposed[26].

HISTOLOGIC FEATURES OF THE MAJOR GRANULOMATOUS DERMATITIDES

can degrade connective tissue[31]. One ultrastructural study found that the main alteration in GA is elastic fiber degeneration and suggested that this disease is primarily a disorder of elastic tissue injury[32]. Familial cases of GA have been reported, including cases in identical twins, and an association may exist between generalized GA and HLA-Bw35[33]. Vessel-based mixed inflammatory cell infiltrates with endothelial swelling are sometimes detected in routine histopathologic specimens, and direct immunofluorescence studies of GA may show vessel-based deposits of immunoreactants, but a role for these findings in the pathogenesis of this disease has not been established.

Clinical Features

GA is a benign, usually self-limited, cutaneous disease that classically presents as arciform to annular plaques located on the extremities of young people (Fig. 93.8A)[28]. In general, the distribution of GA is: 60% isolated to the hands and arms, 20% on the legs and feet, 7% on both upper and lower extremities, 5% on the trunk, and 5% on the trunk plus other areas[34]. Facial lesions are rare. The plaques may be skin-colored, pink or violaceous in color, and, upon close inspection, are found to be composed of individual small papules measuring a few millimeters in diameter (Fig. 93.8B). These lesions are usually asymptomatic. Solitary umbilicated papules or nodules may also occur, especially on the fingers.

Generalized (disseminated) GA, which occurs in a minority of patients, is characterized by myriad, small, skin-colored to pink–violet

GRANULOMA ANNULARE

Synonyms: ■ Pseudorheumatoid nodule – subcutaneous granuloma annulare variant ■ Generalized granuloma annulare – disseminated granuloma annulare

Key features

- Small grouped papules assuming an annular configuration, often in a symmetrical and acral distribution
- Seen primarily in children and young adults
- Clinical variants include localized, generalized, micropapular, nodular, perforating, patch and subcutaneous forms
- A possible association with diabetes mellitus is controversial
- Histopathologically, there is an infiltrative or palisading granulomatous dermatitis with focal degeneration of collagen and elastin and deposition of mucin

History

Calcott Fox first described "ringed eruption of the fingers" in 1895. Radcliffe-Crocker called this entity granuloma annulare in 1902.

Epidemiology

Two-thirds of patients with granuloma annulare (GA) are less than 30 years of age. The female-to-male ratio is approximately 2:1 in this common disease.

Pathogenesis

The etiology of GA is unknown. Trauma, insect bite reactions, tuberculin skin testing, sun exposure, PUVA therapy, and viral infections have all been proposed as inciting factors[27,28]. Based on the T-cell subpopulations identified in GA lesions, a delayed-type hypersensitivity reaction to an unknown antigen has been postulated as the precipitating event[29]. Morphologic similarities to tuberculosis suggest that GA is caused by a Th1 inflammatory reaction, with IFN-γ-producing lymphocytes eliciting matrix degradation[30]. These lymphocytes release cytokines, including macrophage inhibitory factor, that cause monocytes to accumulate in the dermis and release lysosomal enzymes that

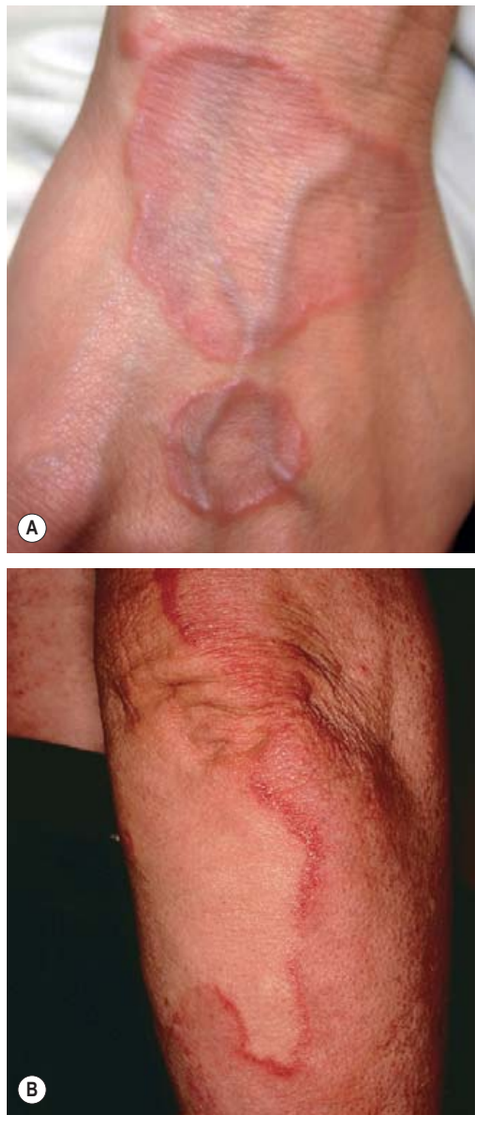

Fig. 93.8 Granuloma annulare. A Annular plaques on the dorsal aspect of the hand, a common location. **B** Larger lesion on the arm with a figurate border composed of coalescing papules. Note the red–brown color of previously involved skin.

Fig. 93.9 Disseminated granuloma annulare. Numerous papules and small annular plaques.

Fig. 93.10 Perforating granuloma annulare. Papules can have a central keratotic plug or umbilication. *Courtesy, Ronald P Rapini, MD.*

papules in a symmetric distribution on the trunk and extremities. Some of these papules may coalesce to form small annular plaques (Fig. 93.9). Generalized GA has a later age of onset, poorer response to therapy, and an increased prevalence of the HLA-Bw35 allele. In one study of 100 patients with generalized GA, 45% had lipid abnormalities, including hypercholesterolemia, hypertriglyceridemia or both[35].

Perforating GA presents clinically as small papules with central umbilication, scale-crust or focal ulceration, primarily on the dorsal hands and fingers (Fig. 93.10). This variant occurs up to 5% of patients with GA, and it exhibits transepidermal elimination of degenerating collagen histologically[36].

Deep dermal or *subcutaneous* GA manifests as large, painless, skin-colored nodules which may be mistaken for rheumatoid nodules, leading to the term pseudorheumatoid nodule. It has a predilection for children less than 6 years of age. Typical locations include the palms, hands, anterior tibial surfaces and feet, as well as the buttocks, scalp and, rarely, the eyelids[28]. As many as 50% of individuals with deep GA lesions also have associated classic lesions.

Patch GA is a distinct variant that is characterized by patches of erythema on the extremities and trunk. Symmetrical lesions on the dorsum of the feet often present as macular (i.e. "patch") disease. Although an annular configuration may be absent, presence of the classic histopathologic findings of interstitial GA (see below) allow for the diagnosis to be made microscopically.

GA has been described as a paraneoplastic granulomatous reaction to solid organ tumors, Hodgkin disease, non-Hodgkin lymphoma and granulomatous mycosis fungoides[37–40]. In these patients, the clinical pattern is frequently atypical, with painful lesions in unusual locations, including the palms and soles.

Many reports either supporting or refuting the association of GA with diabetes mellitus have been published. In a retrospective study of 84 patients, 12% were found to have diabetes mellitus, and these patients were more likely to suffer from chronic relapsing GA than were non-diabetic patients[41]. In a larger retrospective study of 1383 patients, diabetes mellitus was diagnosed in 21% of patients with generalized GA, compared with ~10% of patients with localized GA[35].

Classic GA and perforating GA may occur in herpes zoster scars (see Table 80.6)[42]. Atypical variants of GA, including photodistributed, have been associated with HIV infection[43].

Pathology

GA is a granulomatous dermatitis characterized by focal degeneration of collagen and elastic fibers, mucin deposition, and a perivascular and interstitial lymphohistiocytic infiltrate in the upper and mid dermis. The key to the histopathologic diagnosis of GA is the identification of histiocytes in one of three patterns. The most common (accounting for ~70% of cases) is the interstitial or infiltrative pattern (Fig. 93.11), in which scattered histiocytes are distributed between collagen fibers. Degeneration of collagen fibers is minimal, but granular, basophilic mucin deposition between collagen bundles can be highlighted with Alcian blue and colloidal iron stains[31]. The second pattern (25% of cases) is more obvious and is easier to diagnose. It consists of one to several palisading granulomas with central connective tissue degeneration surrounded by histiocytes and lymphocytes (Fig. 93.12). Mucin is abundant in the center of the palisaded granuloma, and fibrin, neutrophils and nuclear dust may also be present. The final pattern is rare, and it consists of epithelioid histiocytic nodules that can resemble cutaneous sarcoidosis.

Increased mucin can be detected in approximately 70% of biopsy specimens from GA lesions. The sensitivity of detection is increased by using at least two different mucin stains, such as colloidal iron and Alcian blue. Elastic tissue is reduced or absent within the histiocytic aggregates in approximately 20% of generalized GA and 35% of localized GA cases[44].

Ultrastructurally, degeneration of elastic and collagen fibers is seen; the latter consists of collagen fiber swelling, loss of periodic banding, fragmentation, and dissolution of fiber structure with replacement by a granular and finely fibrillar material. Collagen degeneration is more common in localized GA than in generalized GA[44]. Elastophagocytosis is occasionally noted, but is not a prominent histopathologic feature.

As noted previously, vascular changes in GA are variable, but include fibrin, C3 and IgM deposition in vessel walls (detected by direct immunofluorescence) and occlusion of vascular lumina[45]. One study found that the presence of leukocytoclastic or granulomatous vasculitis or a thrombotic vasculopathy within the lesions of GA was predictive of associated systemic disease[46], and the possibility of palisading neutrophilic and granulomatous dermatitis as a reflection of disorders such as rheumatoid arthritis needs to be considered (see Ch. 45).

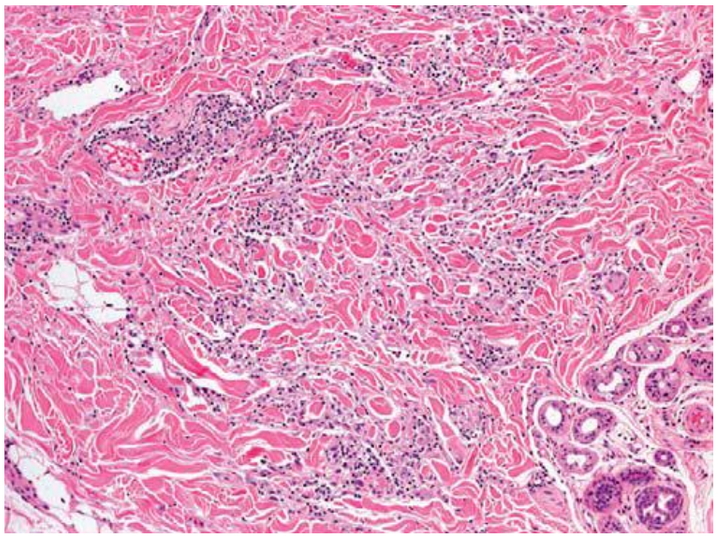

Fig. 93.11 Granuloma annulare, interstitial pattern. Infiltration of histiocytes between the dermal collagen fibers, with scant mucin. *Courtesy, Lorenzo Cerroni, MD.*

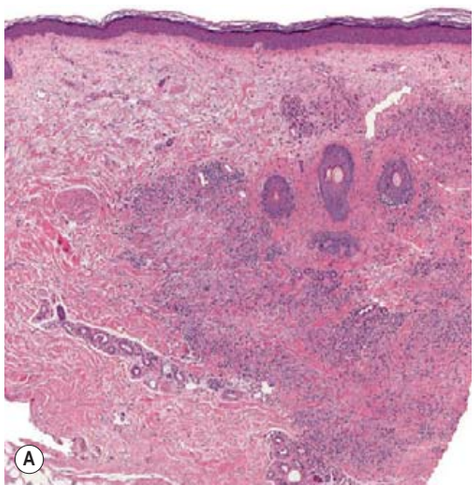

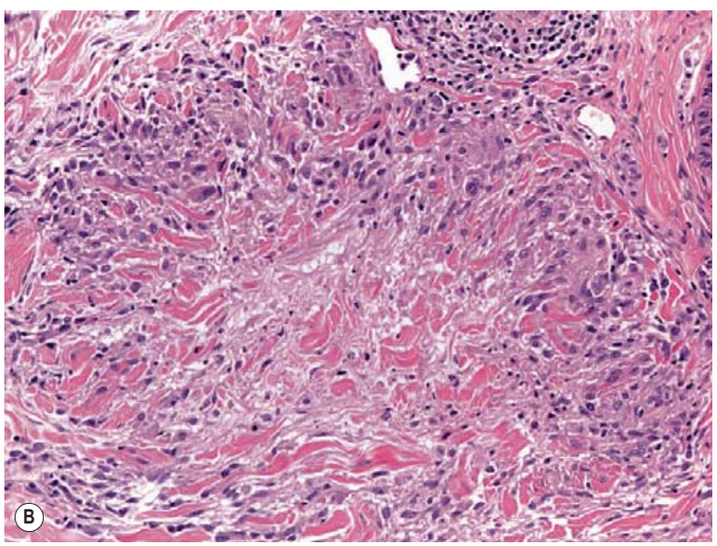

Fig. 93.12 Granuloma annulare, palisaded pattern. A Multiple palisaded granulomas within the dermis. Degenerative collagen and mucin deposition are present in the central portion of the granulomas. **B** A palisaded granuloma with epithelioid histiocytes surrounding an anuclear dermis characterized by altered collagen and pallor due to deposition of acid mucopolysaccharides/glycosaminoglycans (mucin). *Courtesy, Lorenzo Cerroni, MD.*

In deep GA, the histologic findings are usually of the palisaded granulomatous type and extend into the deep dermis or subcutaneous fat. In perforating GA, there is a superficial histiocytic infiltrate with transfollicular and/or transepidermal elimination of granulomatous inflammation.

Differential Diagnosis

GA is diagnosed based on its clinical and histopathologic features – there are no laboratory tests which aid in confirming the diagnosis. When the diagnosis of deep GA versus rheumatoid nodule is in question, a rheumatoid factor level identifies patients at risk for the latter. Rheumatoid nodules also demonstrate fibrin rather than mucin histologically.

The clinical differential diagnosis for conventional GA includes the annular entities listed in Table 19.1, including annular sarcoidosis and annular elastolytic giant cell granuloma. A clue to the latter is central hypopigmentation and/or atrophy. Arcuate and annular plaques of mycosis fungoides or borderline leprosy may also simulate GA, requiring biopsy for definitive diagnosis.

Papular GA (Fig. 93.13) can simulate flat warts, secondary syphilis, early eruptive xanthomas, and the non-X-histiocytoses (see Ch. 91). *Subcutaneous* GA can be clinically similar to rheumatoid nodules, the nodules of rheumatic fever, tendinous xanthomas, epithelioid sarcoma, subcutaneous sarcoidosis, and deep granulomatous infections. *Perforating* GA must be differentiated from primary perforating disorders (see Ch. 96) and, occasionally, perforating calcinosis cutis, perforating gout or molluscum contagiosum, based on histopathologic findings[28].

The clinical and histologic differences between GA, sarcoidosis, necrobiosis lipoidica, annular elastolytic giant cell granuloma, rheumatoid nodule and interstitial granulomatous dermatitis are outlined in Tables 93.1 and 93.2. The histopathologic differential diagnosis of GA also includes morphea, cutaneous T-cell lymphoma, xanthomas, epithelioid sarcoma and, rarely, scleromyxedema.

Treatment

Given the self-limited and benign nature of GA, reassurance and clinical observation may be the treatment of choice for localized, asymptomatic disease. High-potency topical corticosteroids with or without occlusion and intralesional corticosteroid injections are the usual first-line local therapies. Other treatment options include cryosurgery, PUVA or UVA1 therapy, and CO_2 laser treatment (Table 93.4)[47–49]. In a small series, multiple intralesional injections of recombinant human IFN-γ led to improvement[50]; however, side effects and cost may make this treatment difficult to justify.

Systemic agents are reserved for severe cases, and include oral niacinamide (nicotinamide; 500 mg three times daily)[51], isotretinoin (0.5–0.75 mg/kg/day)[52], antimalarials (chloroquine 3 mg/kg/day or hydroxychloroquine 6 mg/kg/day)[35,53], dapsone (100 mg/day)[54] and pentoxifylline[55]. In one series of six patients, a combination of three antibiotics (rifampin, ofloxacin and minocycline) administered monthly for 3 months led to improvement (see Table 93.4)[56].

TREATMENT OF GRANULOMA ANNULARE
Topical corticosteroids (3)
Intralesional corticosteroids (2)
Topical calcineurin inhibitors (3)
Topical imiquimod (3)
Cryosurgery (2)
Hydroxychloroquine or chloroquine (2)
Niacinamide (nicotinamide) (3)
Minocycline + ofloxacin + rifampin* (3)
Pentoxifylline (3)
Intralesional interferon (3)
5-lipoxygenase inhibitor (zileuton) plus vitamin E† (3)
Dapsone (3)
Isotretinoin (3)
PUVA (psoralen plus UVA) or UVA1 (2)
Cyclosporine (3)
TNF-α inhibitors (adalimumab, infliximab) (3)
Methotrexate (3)
Fumaric acid esters (3)
Chlorambucil (3)
Photodynamic therapy with topical 5-aminolevulinic acid (3)
CO_2 laser (3)
Surgical excision (3)

*Administered monthly: minocycline (100 mg), ofloxacin (400 mg) and rifampin (600 mg) × 3 months
†Doses of 2400 mg po daily (zileuton) and 400 IU po daily (vitamin E).

Table 93.4 Treatment of granuloma annulare. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

Use of more toxic and/or expensive therapies are controversial, but reports exist for cyclosporine (3–4 mg/kg/day for 3 months)[57], chlorambucil[58], etretinate[59] and photodynamic therapy[60] being beneficial in individual or small groups of patients. With regard to TNF-α inhibitors, there are multiple case reports of adalimumab and infliximab being effective for generalized GA[61,62], with variable results for etanercept[63]. However, no large, randomized, double-blind, placebo-controlled studies have been performed to support the use of these systemic medications.

Spontaneous resolution of GA occurs within 2 years in 50% of patients, but there is a 40% recurrence rate. The recurrent lesions tend to occur at the original sites, but clear more rapidly (80% within 2 years). The duration of untreated lesions has been reported to range from a few weeks to several decades[64].

NECROBIOSIS LIPOIDICA

Synonym: ■ Necrobiosis lipoidica diabeticorum

Key features

- Plaques with violaceous to red–brown, palpable peripheral rims and yellow–brown atrophic centers with telangiectasias
- The most common site is the shins
- Ulceration can occur following trauma
- The proportion of patients with diabetes mellitus varies from 15% to 65%
- Pathogenesis is unknown
- Pathology shows palisading granulomatous dermatitis with a "layered" appearance, often with perivascular plasma cells

History

First called "dermatitis atrophicans diabetica" by Oppenheim in 1929, the condition was renamed necrobiosis lipoidica diabeticorum (NLD) by Urbach in 1932. The first non-diabetic patient with NLD was described in 1935 by Goldsmith, generating the more general term necrobiosis lipoidica, which is currently preferred. Nonetheless, the abbreviation NLD is ingrained in our lexicon.

Epidemiology

In a study of 171 patients, Muller and Winkelmann found that diabetes mellitus, usually type 1, was present in approximately 65% of patients with NLD[65]. An additional 12–15% of patients with NLD demonstrated abnormal glucose tolerance tests. Also, over half of the patients with no evidence of diabetes and a normal glucose tolerance test reported a positive family history of glucose intolerance[65,66]. However, a more recent retrospective study of 65 patients with NLD seen in a dermatology outpatient clinic found that only 11% had diabetes mellitus at the time of presentation. An additional 11% were later diagnosed with impaired glucose tolerance or diabetes[67].

There is no proven connection between a patient's level of glycemic control and the likelihood of developing NLD lesions, but diabetic patients with NLD do appear to have a higher rate of diabetes-related complications such as peripheral neuropathy, retinopathy and limited joint mobility[68]. Only 0.03% of patients with diabetes have NLD. The female-to-male ratio is approximately 3:1.

Pathogenesis

The cause of NLD remains unknown. There is no HLA linkage. Immunologically mediated vascular disease has been suggested as the primary cause of the altered collagen seen in NLD, and this hypothesis is supported by the presence of immunoreactants deposited in vessel walls of lesional as well as uninvolved skin in patients with NLD[69]. Previous immunofluoresence studies had also found evidence for immune complex vasculitis in NLD[70]. It is has also been postulated that the microangiopathic vessel changes seen in diabetic patients could contribute to the development of collagen degeneration and subsequent dermal inflammation. Elevated plasma levels of fibronectin, factor VIII-related antigen, and α_2-macroglobulin have been detected in patients with NLD, but the significance of these findings has not been determined[71]. Theories regarding abnormally elevated platelet adhesion, increased thromboxane A_2 production, and increased blood viscosity within NLD lesions remain speculative.

Some investigators consider NLD to be primarily a disease of collagen, with inflammation occurring as a secondary event. Anticollagen antibodies have been detected in patients with both NLD and GA, but no significant increase in antibody levels as compared with control patients has been demonstrated[72]. The concentration of collagen is decreased in NLD lesions, and electron microscopy reveals a loss of the cross-striations of collagen fibrils and significant variation in the diameter of individual fibrils. Fibroblasts cultured from NLD lesions synthesize less collagen than their counterparts from unaffected skin[73]. Overhydration of collagen due to hyperglycemia can lead to increased collagen cross-linking and stiffness, but it is unclear if this phenomenon occurs in NLD.

From central Europe, there was a report of the detection of *Borrelia* spp. via focal floating microscopy in NLD[74], but these findings need to be confirmed.

Clinical Features

Clinically, NLD is characterized by yellow–brown, atrophic, telangiectatic plaques with an elevated violaceous rim, typically present in the pretibial region (Fig. 93.14). The plaques are usually multiple and bilateral. Lesions start as small, firm, red–brown papules that gradually enlarge and then develop central epidermal atrophy. Ulceration occurs in approximately a third of lesions (see Fig. 53.21), usually following minor trauma. Less typical anatomic locations for NLD include the upper extremities, face and scalp, where the lesions may be more annular or serpiginous in configuration and are less atrophic. As a result, there is significant overlap with annular elastolytic giant cell granuloma.

Decreased sensation to pinprick and fine touch, hypohidrosis and partial alopecia can be found within NLD plaques. Decreased S100 staining within the cutaneous nerves of inflammatory plaques has been

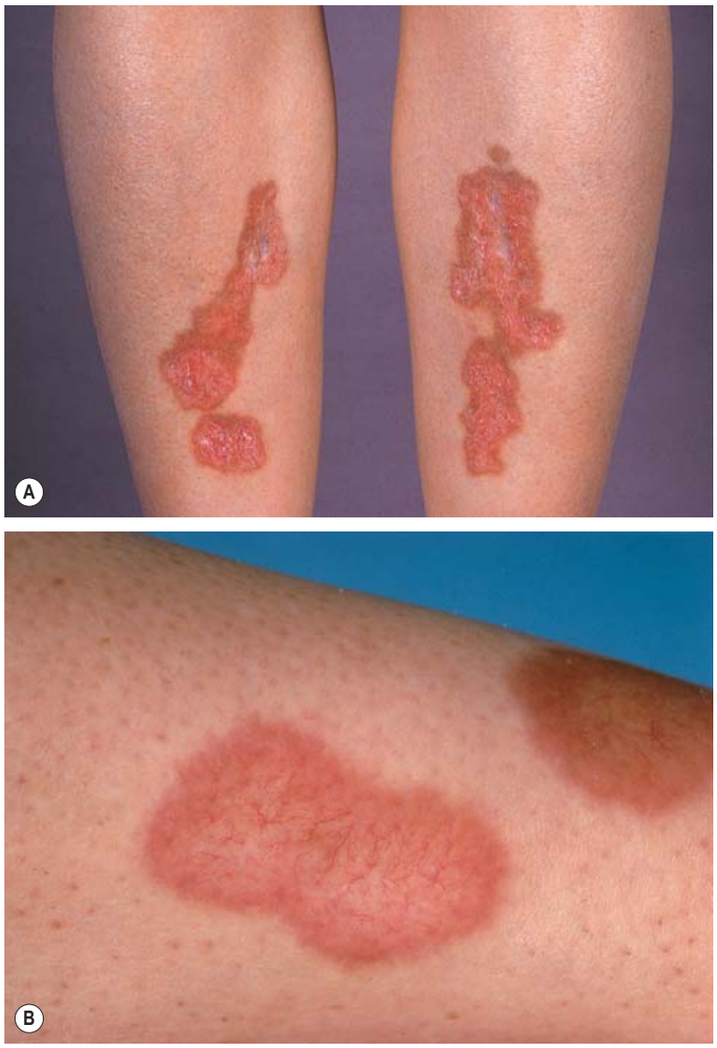

Fig. 93.14 Necrobiosis lipoidica. A Pink–brown atrophic plaques on the shins. **B** Annular plaques with central telangiectasias.

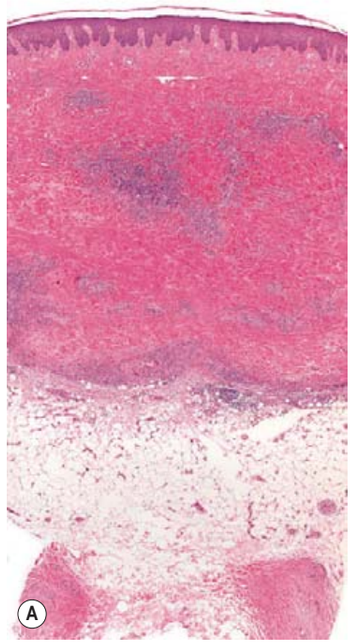

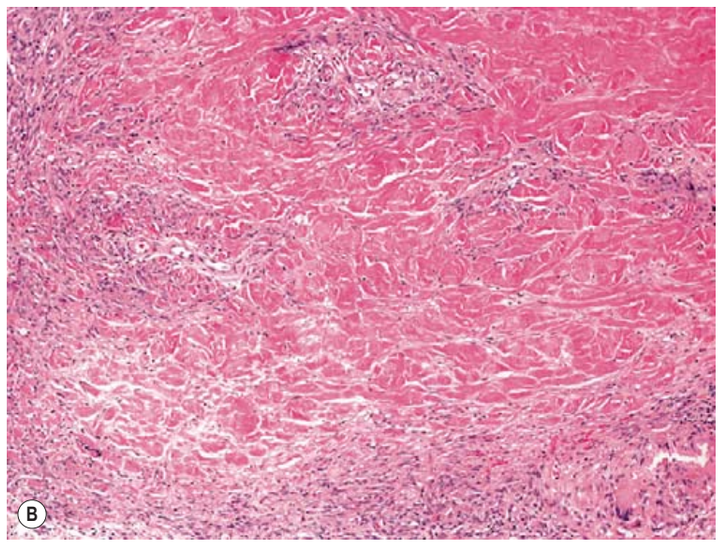

Fig. 93.15 Necrobiosis lipoidica – histologic features. A Multiple granulomas within the entire dermis extending into the subcutaneous fat. Note the layered tiers of granulomatous inflammation aligned parallel to the skin surface. **B** Palisaded granuloma composed of epithelioid histiocytes with altered collagen centrally. *Courtesy, Lorenzo Cerroni, MD.*

observed, with degenerative neural changes possibly accounting for the loss of sensation[68]. Of note, the cutaneous nerves in GA demonstrate normal S100 staining patterns. Although the lesions of NLD are typically asymptomatic, some patients report pruritus, dysesthesia or pain. Lesions that ulcerate after trauma or from transepidermal elimination of altered collagen and elastic fibers can be very painful. Rarely, squamous cell carcinoma has been reported to develop within lesions of NLD[75].

Pathology

Biopsy specimens, particularly from the palpable inflammatory border, reveal a diffuse palisaded and interstitial granulomatous dermatitis (Fig. 93.15), with "layered" tiers of granulomatous inflammation aligned parallel to the skin surface involving the entire dermis and extending into the subcutaneous fat septae. The epidermis is normal or atrophic. There is a superficial and deep perivascular infiltrate that is predominantly lymphocytic but also contains plasma cells and occasionally eosinophils. The granulomatous inflammation includes multinucleated histiocytes but no asteroid bodies.

Focal loss of elastic tissue can be demonstrated in areas of connective tissue sclerosis. Between the layers of inflammatory cells, there are horizontal tiers of degenerated collagen, with fibers of irregular size and shape. Extracellular lipid deposition in these foci can be identified only via staining frozen tissue sections with an oil red O stain. However, this is seldom done from a practical standpoint. In contrast to GA, there is no significant mucin deposition in the center of the palisading granulomas.

Early lesions of both NLD and GA may have foci of leukocytoclasia, but NLD shows more prominent endothelial cell swelling, fibrosis and hyalinization; the latter can lead to blood vessel wall thickening or even endarteritis obliterans. The vessel walls often contain a PAS-positive, diastase-resistant material suggesting neutral glycosaminoglycans[71].

NLD occasionally presents with less sclerotic collagen and more typical epithelioid cell granulomas rather than the horizontally tiered pattern of altered collagen and palisaded granulomatous inflammation described above. Vascular changes are rare, and this form of NLD is felt to have a weaker association with diabetes mellitus than the classic lesions[71].

Immunofluorescent studies of NLD lesions have yielded conflicting results, and are not performed routinely. Deposits of C3, IgM and IgA have been noted around dermal blood vessels (lesional skin)[70] as has vascular deposition of C3, fibrin and IgM (both lesional and non-lesional skin)[69]. However, in another study, positive immunofluorescence was detected in only 4 of 14 lesional skin biopsies[76]. Fibrin is consistently found deposited in areas of altered collagen[77].

Differential Diagnosis

Clinically, the differential diagnosis of NLD includes primarily GA, necrobiotic xanthogranuloma, sarcoidosis, diabetic dermopathy and lipodermatosclerosis. Other entities in the differential diagnosis include additional forms of panniculitis (see Ch. 100), granulomatous infections (e.g. leprosy, tertiary syphilis, dimorphic fungal infections), morphea, lichen sclerosus and sclerosing lipogranuloma.

Lesions of GA and sarcoidosis generally do not exhibit the same degree of atrophy, telangiectasias or yellow–brown color as NLD lesions, although prominent telangiectasias can be present in angiolupoid sarcoidosis and can occur following injections of triamcinolone. However, there are reports of NLD and sarcoidosis coexisting in the same patient[78]. Necrobiotic xanthogranuloma is characterized by yellow, indurated, often periorbital (among other sites) plaques, and it is associated with a paraproteinemia. The lesions of diabetic dermopathy are located on the shins, but they are macular and hyperpigmented. Injection of substances such as paraffin, cottonseed oil, sesame oil or beeswax may cause plaque-like indurations with ulcerations mimicking NLD, but the ensuing lesions of sclerosing lipogranuloma are rarely located on the legs.

The major entity in the histopathologic differential diagnosis for NLD is GA. Whereas the inflammation in NLD is diffuse and involves the entire dermis extending into subcutaneous fat septae, GA is patchy with discrete foci of granulomatous inflammation amid areas of uninvolved dermis. There is usually deposition of mucin within areas of granulomatous inflammation in GA but not in NLD. In general, NLD has more giant cells, plasma cells, vascular changes, collagen degeneration, and extracellular lipid deposition than GA.

Necrobiotic xanthogranuloma can be differentiated from NLD histologically by the presence of abundant cholesterol clefts in necrobiotic xanthogranuloma. One case report did describe NLD with prominent cholesterol clefts and transepithelial elimination of cholesterol crystals via hair follicles[79]. Transepidermal elimination of elastic fibers has also been observed and should not be misconstrued with entities such as elastosis perforans serpiginosa[80].

Treatment

No treatment for NLD has proven to be effective in large, double-blind, placebo-controlled studies. In patients with diabetes mellitus, control of blood glucose levels usually does not have a significant effect on the course of NLD. Spontaneous remission after an average of 8 to 12 years was observed in only 17% of 171 patients with NLD in one study[65].

First-line therapy includes potent topical corticosteroids for early lesions and intralesional corticosteroids injected into the active borders of established lesions. Because the histologic changes can extend well into normal-appearing skin in clinically active NLD lesions[68], some authors advocate the injection of intradermal corticosteroids into a rim of clinically normal skin around expanding plaques in an effort to halt disease progression. In addition, 5-week courses of systemic corticosteroids were found to be effective in a series of six patients with an average follow-up period of 7 months, but this can elevate serum glucose levels[81].

Other therapies are directed at increasing fibrinolysis or decreasing platelet aggregation and thromboxane A_2 synthesis in order to decrease the microangiopathy and vascular thrombosis seen in lesions of NLD. Stanozolol, inositol niacinate (inositol nicotinate), nicofuranose, ticlopidine hydrochloride and pentoxifylline are all agents that have been used towards this end in anecdotal reports or uncontrolled case series. The use of stanozolol is limited by its potential hepatotoxicity and ticlopidine can cause agranulocytosis. A 16-patient controlled trial of aspirin (40 mg/day) versus placebo showed no significant difference between the groups[82]. A 12-patient controlled trial of aspirin (300 mg three times daily) plus dipyridamole (75 mg three times daily) versus placebo also showed no significant effects of treatment[83]. Perilesional heparin injection has been reported in the Russian literature[84].

Niacinamide (500 mg three times daily) has been used with some success in both NLD and GA, and it is postulated to inhibit the release of lymphokines and decrease macrophage migration[71]. Small series of patients have also been treated successfully with antimalarials[85], with the proposed mechanism of action being inhibition of antigen presentation and decreased production of several cytokines (e.g. TNF-α, IL-6, IFN-γ). There are reports of TNF-α inhibitors (etanercept, infliximab) leading to improvement of NLD, including recalcitrant ulcerated lesions[86]. In a limited number of patients, systemic cyclosporine also improved severe, ulcerating NLD on the lower legs[87,88].

Other reported topical therapies include granulocyte–macrophage colony-stimulating factor or bovine collagen[89] for ulcerations and tretinoin gel (0.025% twice daily) to decrease lesional atrophy[90]. In addition, improvement with topical PUVA[91,92], UVA1 phototherapy[93], mycophenolate mofetil (500 mg twice daily)[94] and thalidomide[95] has been described.

If surgical therapy becomes necessary for severe ulcerations that are refractory to medical treatment, excision to deep fascia or periosteum must be performed to minimize the chance of recurrence. Split-thickness skin grafting is performed following excision.

ANNULAR ELASTOLYTIC GIANT CELL GRANULOMA

Synonyms: ■ Actinic granuloma ■ Giant cell elastophagocytosis ■ Miescher's granuloma of the face ■ Atypical (annular) necrobiosis lipoidica of the face and scalp

Key features

- Asymptomatic annular plaques, predominantly on the head and neck and other chronically sun-exposed sites
- The border of each plaque is elevated and erythematous, while the center is slightly atrophic and hypopigmented
- Histopathologically, non-palisading granulomas with histiocytes, foreign body type multinucleated giant cells and lymphocytes
- Elastic fibers are absent within the central portion of the lesion, and some elastic fibers are found within giant cells (elastophagocytosis)
- No collagen alteration, mucin or lipid deposition, or vascular changes are seen histopathologically

History

O'Brien[96] described the entity known as actinic granuloma in 1975 but attributed the first description of this disease to Georgouras in 1964. O'Brien used "actinic" in the name of this disorder because he believed that its etiology was linked to ultraviolet and infrared radiation. This nosologic theory was rejected by Hanke et al.[97] whose patients did not all demonstrate significant solar elastosis histologically but otherwise fit O'Brien's clinical and histopathologic descriptions. These authors coined the descriptive term "annular elastolytic giant cell granuloma" in 1979. Upon review of the literature, both O'Brien and Hanke realized that the diseases they were describing had previously been reported under other names, including atypical necrobiosis lipoidica of the face and scalp[98], Miescher's granuloma of the face[99], and possibly granuloma multiforme[100].

Epidemiology

Annular elastolytic giant cell granuloma (AEGCG) is an uncommon disease that occurs predominantly in middle-aged women, at least 30 years of age but usually over 40. Patients have been reported from several regions of the world, including Australia, the UK, the US, the Caribbean basin and Africa.

Pathogenesis

Debate exists as to whether annular elastolytic giant cell granuloma is a distinct clinical entity or a variant of GA[101,102]. Its pathogenesis is not understood, but it may be related to inflammation precipitated by

Fig. 93.16 Annular elastolytic giant cell granuloma. The border resembles granuloma annulare but the central portion is hypopigmented and/or atrophic (**A, B**). A biopsy specimen that includes the area outlined in **A** would contain the three characteristic histologic zones: absence of elastic fibers, granulomatous inflammation, and normal skin. Longitudinal sectioning of the surgical specimen is preferred. *B, Courtesy, Kalman Watsky, MD.*

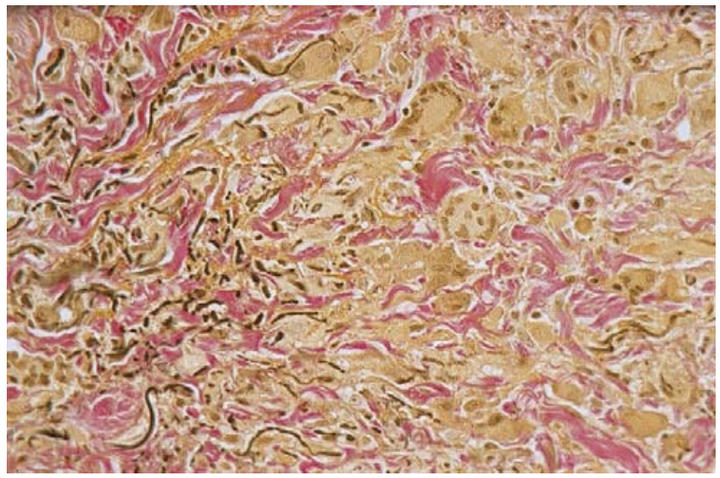

Fig. 93.17 Annular elastolytic giant cell granuloma – histologic features. Loss of elastic fibers (black) is seen amid the granulomatous infiltrate (yellow). The remaining collagen is stained red (Verhoeff–van Gieson stain). *Courtesy, Ronald P Rapini, MD.*

actinic damage. Specifically, O'Brien postulated that "a state of autoaggression develops in relation to the damaged [elastic] fibers", in an attempt to repair or remodel damaged skin[96]. T lymphocytes involved in AEGCG are predominantly of the helper-inducer subset, suggesting that the pathogenesis may involve a cell-mediated immunologic response to a weakly antigenic determinant on altered elastotic fibers[102]. However, destruction of elastic tissue has also been observed in classic GA and NLD, leading to the argument that this finding may be a secondary event caused by the granulomatous inflammation rather than a precipitating one[97]. A few patients with AEGCG as well as diabetes mellitus, NLD and/or sarcoidosis have been reported, as have rare patients with lymphoma or leukemia[103,104].

Clinical Features

Patients with AEGCG have large annular plaques with a raised erythematous border (3–5 mm) and a slightly atrophic, hypopigmented center, distributed mainly in chronically sun-exposed areas (Fig. 93.16). The sites of predilection include the neck, face, upper trunk and arms. Early on, skin-colored or pink papules may appear, singly or in small groups, before they coalesce into annular plaques. Scale is rarely observed. In contract to NLD, there is no yellow color, telangiectasias or associated alopecia. Individual lesions measure 1–10 cm in diameter, and the total number of lesions is generally fewer than 10. Patients are usually asymptomatic, although pruritus has been reported. A single plaque lasts for months to years, after which spontaneous remission may occur, leaving mottled dyspigmentation or normal-appearing skin[96].

Pathology

Sections through the raised border of an AEGCG lesion show a nonpalisading granulomatous infiltrate of histiocytes, foreign body type multinucleated giant cells (with haphazardly arranged nuclei), and lymphocytes within the mid to upper dermis; there is an absence of altered collagen or mucin or lipid deposition[105]. Elastic fibers are identified adjacent to and within the giant cells, giving rise to the term elastophagocytosis. Asteroid bodies that stain with acid orcein (like elastic fibers) are observed within the multinucleated giant cells. These findings are not specific for AEGCG, but they are seen less frequently in other granulomatous disorders such as GA and NLD. Elastic tissue stains, such as the Verhoeff–van Gieson stain, show a characteristic complete absence of elastic fibers in the areas affected (or previously affected) by granulomatous inflammation (Fig. 93.17). Normal quantities of elastin are seen in the deeper dermis. Sections from previously involved skin show normal elastic and elastotic fibers surrounding a well-demarcated zone of dermis that remains free of elastic tissue staining.

There are no vascular changes other than a sparse perivascular lymphocytic infiltrate. Basophilic solar elastosis may be present, and was observed in all of O'Brien's patients with actinic granuloma. The epidermis may be normal or slightly thinned. Direct immunofluorescence studies for fibrin, C3, IgG, IgM and IgA are negative.

Occasionally, histiocytes and epithelioid cells form tubercles that are indistinguishable from sarcoidal granulomas.

Differential Diagnosis

The diagnosis of AEGCG is based on the characteristic clinical appearance and histopathologic findings outlined above. There are no helpful laboratory tests. The clinical differential diagnosis includes the annular variants of the diseases outlined in Table 93.1, as well as erythema annulare centrifugum (different distribution), annular lichen planus and secondary syphilis (central hyperpigmentation), tinea corporis and granulomatous infections. Granuloma multiforme (Mkar disease) clinically resembles AEGCG, but it occurs in Africa and histologically has prominent collagen alteration surrounded by palisading granulomas. Therefore, it may be a variant of GA rather than AEGCG.

Other entities in the histologic differential diagnosis include granulomatous slack skin, mid-dermal elastolysis, anetoderma and acquired cutis laxa. Special stains for acid-fast bacilli and fungal organisms should be performed to exclude an infectious granulomatous process such as tuberculosis, leprosy or deep fungal infections. Culture and/or PCR of tissue can be performed, depending upon the clinical situation.

Treatment

AEGCG is a persistent condition that responds poorly or inconsistently to topical or intralesional corticosteroids, PUVA therapy and antimalarial drugs[106]. There are case reports of improvement following 8 weeks of cyclosporine (5 mg/kg/day) or 16 weeks of chloroquine therapy (200–400 mg/day)[107,108]. Excision of lesions followed by partial-thickness

skin grafting has been performed with no recurrence at 15 months of follow-up[109], but this would rarely be required. In individual patients, cryotherapy, cauterization and methotrexate were reported to be ineffective.

CUTANEOUS CROHN'S DISEASE

Synonym: ■ Metastatic Crohn's disease

Key features

- Erythematous plaques, often on the buttocks and genital skin
- Cutaneous non-caseating granulomatous lesions that are not contiguous with intestinal Crohn's disease have been referred to as "metastatic"
- Approximately 20% of patients with cutaneous lesions have no preceding diagnosis of gastrointestinal Crohn's disease

History

Crohn's disease, first described in 1932, is characterized by segmental granulomatous inflammation of the intestinal tract and frequently involves cutaneous tissues as well.

Epidemiology

Crohn's disease usually begins between the second and fourth decades of life. Mucosal and skin findings occur in 20–45% of patients[110], and include distant cutaneous (metastatic) Crohn's disease, contiguous perianal Crohn's disease, oral Crohn's disease, reactive dermatologic disorders (e.g. erythema nodosum, pyoderma gangrenosum) and nutritional skin changes[111].

Cutaneous Crohn's disease is relatively rare, with fewer than 100 cases reported in the literature. Two-thirds of the patients are women, and the mean age of onset is 35 years. Fewer than 20 cases have been reported in children. Approximately 20% of the reported cases had skin disease that preceded the diagnosis of intestinal Crohn's disease by 3 months to 8 years.

Pathogenesis

Cutaneous Crohn's disease occurs in association with or precedes intestinal Crohn's disease. A number of genetic abnormalities which can lead to an exaggerated T-cell response to certain commensal enteric bacteria and defective microbial clearance, including after breaks in the mucosal barrier or an alteration in the balance in gut flora (dysbiosis), have been linked to Crohn's disease. The protein products of these genes have several functions, including regulation of NF-κB function (e.g. *NOD2* [*CARD15*]) and autophagy (*ATG16L1*). Like psoriasis, Crohn's disease is a predominantly Th1- and Th17-mediated disease, and elevated levels of IL-23 and IL-17 are present within involved tissues[112].

Clinical Features

Cutaneous Crohn's disease may be either genital or extragenital, with genital involvement found in approximately two-thirds of children and one-half of adults. Labial or scrotal erythema and swelling are the usual presenting signs[113] (Fig. 93.18). Non-genital disease presents with dusky erythematous plaques, often followed by the development of ulceration with undermined edges, draining sinuses and fistulas, and scarring. These lesions have been observed on the lower extremities and soles (38%), abdomen and trunk (24%), upper extremities and palms (15%), face and lips (11%), flexural areas (8%), and in a generalized distribution (4%)[111,114].

Perianal lesions, which may extend to the adjacent perineum, buttocks or abdomen, consist of ulcers, fissures, sinus tracts or vegetating plaques[115]. These are seen in approximately one-third of patients with intestinal Crohn's disease. Abdominal surgical sites, such as laparotomy scars, colostomies and ileostomies, may also be sites of granulomatous inflammation. For semantic purposes, these lesions are considered to be "contiguous" Crohn's disease rather than "metastatic" Crohn's disease, but show the same histopathologic features.

Fig. 93.18 Cutaneous Crohn's disease. Note the swelling and violaceous discoloration of the labia majora in this prepubescent girl. *Courtesy, Joseph L Jorizzo, MD.*

Oral lesions occur in 5–20% of patients with Crohn's disease, and these may consist of cobblestoning of the buccal mucosa, tiny gingival nodules, small aphthae-like ulcers, linear ulcerations, angular cheilitis and ulceration, pyostomatitis vegetans, gingival hyperplasia, cheilitis granulomatosa, diffuse oral swelling, or indurated fissuring of the lower lip. Histologically, 90% of oral lesions associated with Crohn's disease contain granulomas[115]. Other reactive cutaneous manifestations of Crohn's disease include cutaneous polyarteritis nodosa, erythema nodosum, erythema multiforme, finger clubbing, leukocytoclastic vasculitis, epidermolysis bullosa acquisita, palmar erythema, a pustular response to trauma (pathergy), and pyoderma gangrenosum. Zinc deficiency may cause an acrodermatitis enteropathica-like syndrome in patients with severe Crohn's disease[111].

There is no consistent correlation between the appearance of skin lesions and intestinal Crohn's disease activity. Cutaneous Crohn's disease is more commonly associated with colorectal rather than small intestinal disease.

Pathology

In both cutaneous and oral lesions of Crohn's disease, nodular, non-caseating epithelioid tubercles with surrounding lymphocytes are found in the superficial and deep dermis, sometimes extending into the subcutaneous fat. There are a few scattered multinucleated Langhans-type giant cells and a sparse perivascular lymphohistiocytic infiltrate. The histopathologic changes are the same as those seen in intestinal lesions.

Differential Diagnosis

Clinically, the differential diagnosis of cutaneous Crohn's disease includes other granulomatous disorders such as cutaneous sarcoidosis, mycobacterial infections, deep fungal infections and foreign body reactions. Other infections, such as actinomycosis or cellulitis, may mimic cutaneous Crohn's disease. Ulcerated lesions may be misdiagnosed as pyoderma gangrenosum. In the case of genital swelling and ulcerations, one must consider granuloma inguinale, schistosomiasis, hidradenitis suppurativa, and chronic lymphedema due to obstruction[114].

The histologic picture of cutaneous Crohn's disease is, at times, indistinguishable from other granulomatous diseases with tuberculoid features, including lupus vulgaris. In the latter, central necrosis within tubercles is a helpful distinguishing clue. Differentiating cutaneous Crohn's disease from sarcoidosis can also be challenging, although Crohn's disease usually has denser collections of lymphocytes. Zirconium and beryllium granulomas, other foreign body granulomas, and infectious granulomas must all be considered in the histologic differential diagnosis. Special stains for acid-fast bacilli and fungal organisms

should be obtained, and all skin biopsies should be polarized to look for foreign bodies.

Treatment

Cutaneous Crohn's disease tends to be chronic, and its severity is not related to the activity of the patient's intestinal disease. Oral metronidazole is an effective treatment (250 mg three times daily), and is frequently paired with topical or intralesional corticosteroids. Systemic agents reported for the treatment of cutaneous Crohn's disease include oral corticosteroids, sulfasalazine, azathioprine, 6-mercaptopurine, and TNF-α inhibitors (e.g. infliximab, adalimumab)[116]. Surgical excision of lesions is often complicated by wound dehiscence and disease recurrence.

FOREIGN BODY GRANULOMAS (see Ch 94)

Key features

- The most common cause of a foreign body granuloma is rupture of a follicle or cyst
- Inflammation may be either a suppurative and diffuse granulomatous dermatitis or a nodular mononuclear granulomatous dermatitis
- Clues to the inciting foreign body should be sought by polarizing the specimen and searching for cornified cells, tattoo pigment, suture remnants, splinter material, etc.

94 Foreign Body Reactions

MA Abdallah, MMA Abdallah and Marwa A-R Abdallah

Chapter Contents

Foreign body reactions to inorganic and metallic compounds.. *1575*
Reactions to organic and biologic products..... *1579*
Injectable soft tissue fillers *1580*

Key features

- Foreign body reactions represent inflammatory responses to inorganic and high-molecular-weight organic materials that have been introduced into the skin and are variably resistant to degradation
- Routes of introduction can vary from accidental or self-inflicted to surgical procedures and topical application of medications
- The most common clinical presentation is red to red–brown papules, nodules or plaques (with or without ulceration) that are due to granulomatous inflammation
- Less common presentations of foreign body reactions include lichenoid or pseudolymphomatous, or a fistula or draining wound
- Histologic findings vary from granulomas (foreign body, sarcoidal, palisading) to lichenoid, eczematous or pseudolymphomatous patterns
- Diagnosis of foreign body reactions requires a high index of suspicion, thorough history, recognition of distinctive distribution patterns, and histologic examination (including polarized microscopy)

GENERAL CONSIDERATIONS

Definition

Literally, any material – living or non-living – introduced into the body is a "foreign body" and is treated by our immune system as "non-self" in order to elicit an appropriate response. Such a broad definition also includes infectious agents, but they are covered elsewhere (see Chs 74–85). This chapter will focus on non-living materials that have been introduced into the dermis or subcutis[1–3]. They represent inorganic compounds or organic material of high molecular weight that resist degradation by the body's inflammatory cells or their products. Foreign bodies reported to elicit skin reactions are listed in Table 94.1.

Routes of Entry

Accidental

Inoculation with foreign bodies may occur unintentionally during various activities such as gardening (wood splinters, cactus spines) and swimming and diving (coelenterate envenomation, sea urchin spines), or it may result accidentally, such as in a blast injury (silica particles) or motor vehicle accident.

Surgical procedures

Contamination of wounds by talc or starch powders used for lubrication of surgical gloves may incite a foreign body reaction. Surgical sutures can also cause a foreign body response. Histologically, suture granulomas are commonly seen in excisional specimens of previously sampled cutaneous tumors. More recently, foreign body reactions have been observed in association with 2-octyl cyanoacrylate, a tissue adhesive used for small superficial wounds and lacerations, as well as a copolymer-containing lubricating agent used for liposuction[3a,3b].

Iatrogenic

Foreign material implanted into the skin for the purpose of tissue augmentation, e.g. injectable soft tissue fillers, can induce reactions in some individuals (Fig. 94.1). Paraffin is still being used illegally for tissue augmentation, and a paraffin foreign body reaction can also occur after the application of paraffin-containing materials such as nasal packs[4].

Tattooing

Tattooing is the introduction of an exogenous pigment into the dermis, either deliberately or accidentally, resulting in permanent discoloration of the skin.

Topical application

Deodorants and antipruritic preparations containing zirconium oxide applied to the skin surface may cause foreign body reactions. Of note, zirconium lactate was generally banned in 1978.

Self-inflicted

Self-administered intravenous injections, a common practice among drug addicts, may lead to the introduction of foreign material into the skin.

Pathogenesis

The initial tissue response to most foreign substances involves an accumulation of neutrophils which usually fail to properly deal with the foreign body. Its persistence attracts monocytes and local tissue macrophages that engulf the foreign material and become activated. Engulfed material may resist degradation and remain sequestered within the macrophages. Activated macrophages secrete a variety of specific biologically active substances, e.g. cytokines, that attract additional macrophages and blood monocytes. The formation of a chronic granuloma represents an attempt by the body to sequester a persistent indigestible material. Individual macrophages may become larger (epithelioid histiocytes) or fuse to form multinucleated foreign body giant cells. The infiltrate also contains T lymphocytes and fibroblasts. The pathogenesis of other patterns of reactions, e.g. lichenoid, pyogenic granuloma-like, pseudolymphomatous, remains speculative.

Clinical Features

The host response and, consequently, the clinical presentations of foreign body implantation are variable (Tables 94.2 & 94.3). An acute inflammatory response occurs shortly after the entry of the foreign material. This may resolve, to be followed weeks, months or even years later by a chronic inflammatory response. Although the latter may have a variety of clinical presentations, red to red–brown papules, nodules and plaques (with or without ulceration) are most commonly observed.

CLASSIFICATION OF FOREIGN BODIES ACCORDING TO THEIR ORIGINS AND ROUTES OF ENTRY		
Origin		**Route of entry**
	NON-BIOLOGIC (INORGANIC/METALLIC COMPOUNDS)	
	Tattoo inks	Decoration Cosmetic Accidental Iatrogenic
	Paraffin	Tissue augmentation Topical paraffin-containing preparations
	Silicone (polydimethyl siloxane) liquid or gel	Tissue augmentation
	Silica	Wound contamination Blast injuries
	Talc	Surgical procedures Wound contamination Umbilical stump contamination Intravenous injection of self-prepared drugs
	Zirconium	Topical application: deodorants, antipruritic medications
	Beryllium	Laceration by broken fluorescent lamps (historical) Inhalation
	Aluminum	Subcutaneous injection of aluminum-containing vaccines
	Zinc	Subcutaneous injection of insulin–zinc preparations
	Other synthetic fillers, e.g. poly-L-lactic acid, calcium hydroxylapatite, polymethylmethacrylate	Tissue augmentation
	BIOLOGIC	
Produced in the skin but normally isolated from body's defense mechanisms	Hair keratin (see Ch. 38)	Ruptured follicle or cyst* Ingrown hair Barber's sinus
	Nail keratin	Ingrown nail Accidental
Produced by other living organisms	Starch	Surgical procedures
	Cactus spines	Accidental Occupational
	Jellyfish and corals	Accidental Swimming or diving
	Sea urchin spines (see Ch. 85)	Accidental Swimming or diving
	Silk sutures	Surgical procedures
	Hyaluronic acid	Tissue augmentation
	Bovine collagen	Tissue augmentation
Miscellaneous	Corticosteroids	Intralesional injection
	Sutures, primarily absorbable (rarely nylon or polypropylene)	Surgical procedures
	Polyamide synthetic "hair" fibers	Scalp "hair" restoration
	2-octyl cyanoacrylate	Tissue adhesive for small, superficial wounds and lacerations

*Most common cause of a foreign body reaction in the skin.

Table 94.1 Classification of foreign bodies according to their origins and routes of entry.

Over time, the lesions may become firmer due to fibrosis. The pattern and arrangement of the cutaneous lesions will correspond to the route of inoculation, and observation of this patterning, in association with relevant patient history, is crucial.

In addition to nodules and plaques, other forms of foreign body reaction include pyogenic granuloma-like lesions[5], lichenoid lesions[6,7], and a chronic draining fistula or wound[8].

Pathology

Apart from the acute reaction to the trauma that accompanies the introduction of the foreign body, a chronic reaction is the usual response. Although different patterns of chronic local tissue reactions have been described, including lichenoid[6], chronic inflammatory and pseudolymphomatous[9], the most common is the granulomatous type of reaction[10,11] (see Table 94.3). Granulomas that develop as a reaction to foreign bodies are of two major types:

- allergic (immunologic)
- non-allergic ("foreign body").

The allergic type is characterized by the presence of collections of individual epithelioid histiocytes associated with variable numbers of lymphocytes and fewer multinucleated Langhans-type giant cells[11]. In the non-immunologic type, the foreign body giant cell (Fig. 94.2) is the most conspicuous component of the infiltrate, which also contains histiocytes, lymphocytes and other inflammatory cells.

A histologic decision as to whether a granuloma is of the foreign body type or of the allergic type is not always possible and different patterns may be seen in the same section. It is noteworthy that foreign body reactions in HIV-infected patients are different, with abundant

CLINICAL PRESENTATIONS OF FOREIGN BODY REACTIONS	
Clinical presentation	**Foreign substance**
Erythema, induration, papules, nodules (with or without ulceration)	Tattoo inks, paraffin, silicone*, silica, beryllium (local), starch, soft tissue fillers (e.g. hyaluronic acid)
Sarcoidosis-like granulomatous papules	Tattoo inks, talc, zirconium, beryllium (systemic), soft tissue fillers (e.g. bovine collagen, hyaluronic acid)
Pyogenic granuloma-like lesions	Talc, keratin (ingrown nail)
Pseudofolliculitis barbae, "ingrown" hairs of the pubic region and upper thighs	Keratin
Pruritic lichenoid papules and plaques (often in an irregular linear pattern)	Tattoo inks, jellyfish and coral stings
Abscess	Keratin (e.g. pilonidal disease), zinc, paraffin, soft tissue fillers
Sinus tract/fistula	Suture, keratin (pilonidal disease, barber's sinus)
Persistent subcutaneous nodules at injection site	Aluminum, soft tissue fillers containing synthetic particles (see Table 94.4)
Photoallergic eczematous reaction	Tattoo ink containing cadmium sulfide (yellow), cadmium selenide (red) or azo dyes (yellow, red)
*Often a delayed onset (years).	

Table 94.2 Clinical presentations of foreign body reactions.

Fig. 94.1 Granulomatous reaction to bovine collagen injection.

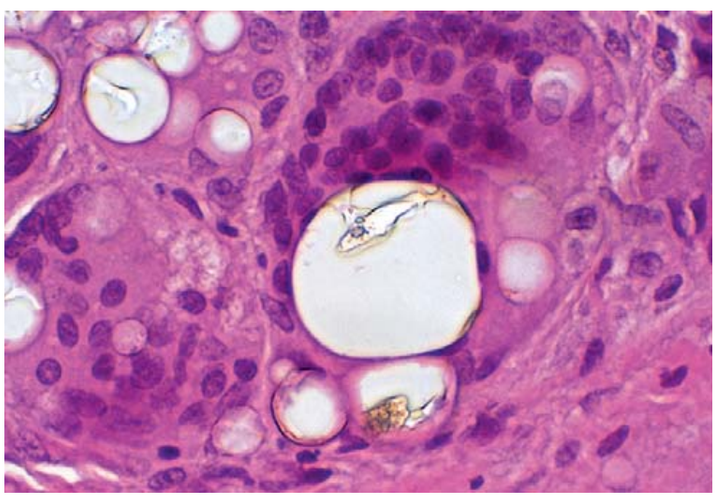

Fig. 94.2 Birefringent foreign body is engulfed by a foreign body-type giant cell with the typical haphazard array of nuclei. *Courtesy, Thomas D Horn, MD.*

individual macrophages, but no giant cells, suggesting an immunologic dysfunction[12]. The foreign material inciting a reaction may be detected in conventional H&E-stained sections or may require special procedures for its identification (see Table 94.3).

Diagnosis

Foreign body reactions should be considered in the differential diagnosis of localized inflammatory nodules and plaques, especially when there is a persistent draining wound or sinus. Occasionally, they appear as pyogenic granulomas or localized lichenoid papules. Clinical morphology is usually not distinctive, but there may be a suggestive distribution pattern, and a thorough history is indispensable for arriving at the correct diagnosis.

Histologic examination confirms the granulomatous nature of the lesion and occasionally foreign bodies may show distinctive microscopic features in H&E-stained sections (Fig. 94.3). However, special procedures are usually required for an accurate diagnosis, particularly microscopic examination with polarized light (Fig. 94.4). Imaging techniques such as plain radiography, ultrasonography, CT scanning and MRI are of little practical value in visualizing small cutaneous foreign bodies, even if the foreign body is radio-opaque.

Identification of the chemical nature of the foreign body requires sophisticated physicochemical procedures that necessitate special processing of the tissue sample and are available in only a few research centers. Energy dispersive X-ray analysis (EDXA), electron energy loss spectroscopy (EELS), laser microprobe mass analysis, and infrared spectrophotometry are examples (see Table 94.3).

To summarize, accurate identification of a foreign body reaction depends on a high index of suspicion, thorough history-taking, and histologic examination, including polarized microscopy.

FOREIGN BODY REACTIONS TO INORGANIC AND METALLIC COMPOUNDS

Tattoo

A tattoo may occur accidentally or deliberately for cosmetic and decorative purposes. Accidental tattooing results from unintentional deposition of exogenous pigmented substances such as asphalt, graphite or carbon within injured skin (Fig. 94.5). Automobile, bicycle and skating accidents as well as puncture wounds are the most common causes of traumatic tattoos. In decorative tattooing, the pigment is introduced into the dermis via needles or a tattoo gun to create various designs, group-identity symbols, or writings. Cosmetic tattoos are also done to define lip contours, replace eyeliner, or hide an abnormality in skin color. An iatrogenic tattoo may remain after the use of ferrous subsulfate (Monsel's solution) for hemostasis.

CLINICAL AND HISTOPATHOLOGIC FEATURES OF FOREIGN BODY REACTIONS					
Foreign body	**Clinical presentations**	**Histologic reaction patterns**	**Other distinctive features**	**Birefringent**	**Other detection methods**
Tattoo inks	Erythema, induration, papules, nodules Lichenoid papules and plaques Eczematous dermatitis (including photoallergic reactions)	Foreign body or (with certain dyes) sarcoidal granulomas Lichenoid dermatitis Spongiotic dermatitis Pseudolymphoma	Pigment granules scattered throughout the infiltrate, extra- and intracellular (macrophages)		EDXA
Silica	Nodules, indurated plaques within scar Disseminated papules (blast injuries) Prolonged incubation period	Granulomas (sarcoidal > foreign body)	Colorless crystals, extra- and intracellular	√	IRS or EDXA
Talc	Sarcoid-like papules Thickening and erythema of an old scar Involvement of intertriginous zones, iv injection sites Umbilical stumps Pyogenic granuloma-like	Sarcoidal or foreign body granulomas Pyogenic granuloma-like	Needle-shaped or round talc crystals: clear, blue–green or yellow–brown	√	EDXA
Zirconium	Persistent, soft, brownish papules Involvement of axillary skin	Sarcoidal granulomas			EDXA
Beryllium, local skin reaction	Nodule, ulcer	Caseating granulomas			EELS
Beryllium, systemic	Widely scattered papules (<1% of cases)	Sarcoidal granulomas			Bronchoalveolar lavage
Aluminum	Persistent subcutaneous nodules at injection site	Granulomas with peripheral lymphocytes and eosinophils Pseudolymphoma			EDXA
Zinc	Furuncles at injection sites	Early: dense neutrophilic infiltrate Late: granulomas and fibrosis	Rhomboidal crystals	√	EDXA
Starch	Papules, nodules	Foreign body granulomas	Ovoid basophilic starch granules PAS-positive	√	
Cactus	Dome-shaped, skin-colored papules with a central black dot	Early: neutrophils Late: sarcoidal or foreign body granulomas	Spines, extra- and intracellular (giant cells) PAS-positive	√	
Jellyfish, corals, sea urchin spines	Pruritic lichenoid papules and plaques (onset 2–3 weeks after exposure) Linear, zig-zag and whip-like (flagellate) patterns of erythema/edema (early), hyperpigmentation or lichenoid papules (late)	Lichenoid dermatitis	Calcite crystals (sea urchin spines)	√ (sea urchin spines)	
Keratin	Pseudofolliculitis/acne keloidalis Pyogenic granuloma-like lesions, ingrown nails Pilonidal disease	Foreign body granulomas	Other inflammatory cells	√	
Intralesional corticosteroids	Skin-colored to yellow–white papules or nodules develop at the site of a previous intralesional injection of corticosteroid The incubation period varies between weeks to months	Foreign body granulomas	Pale bluish material on H&E		
Suture	Wound appears inflamed, red, edematous (or develops papules or nodules) and opens to form a fistula	Foreign body granulomas		√	

Table 94.3 Clinical and histopathologic features of foreign body reactions. The order of the entities in this table corresponds to that in the text. Injectable soft tissue fillers are reviewed in Table 94.4. EDXA, energy dispersive X-ray analysis; EELS, electron energy loss spectroscopy; IRS, infrared spectrophotometry; iv, intravenous.

Decorative tattoos often contain a number of pigments that are combined to create different hues. These may be inorganic salts of metals, such as mercury in cinnabar (red, becoming historical), cobalt (blue), chromium (green), cadmium (yellow, red), ferric hydrate (sienna) and manganese (purple), or organic preparations, such as sandalwood, brazilwood and carmine[10]. The red color is most commonly associated with nodular reactions (Fig. 94.6).

Clinical features

Delayed reactions may occur within a few weeks of the tattoo placement, but have been reported over 15 years later[13]. Most commonly, erythematous nodules or plaques are seen, but there may be lichenoid or eczematous lesions. The reactions are usually confined to the site of the tattoo (see Fig. 94.6). Tenderness and erythema vary according to the degree of inflammation and may be absent. Rarely, a photoallergic reaction, presenting as pruritic inflamed nodules, occurs in red or yellow tattoos containing cadmium sulfide following exposure to UV light[13].

Tattoo pigments may migrate to the regional lymph nodes and at the time of lymph node sampling may clinically mimic metastatic melanoma.

Pathology

Different patterns of an inflammatory response can be elicited, including sarcoidal, foreign body granulomatous, lichenoid and pseudolymphomatous[9]. In non-inflamed tattoos, the dermis shows granules of different sizes, shapes and colors, located both within macrophages and extracellularly in the absence of an inflammatory infiltrate[14]. Most tattoo pigments appear black with H&E staining, regardless of the clinical color, but sometimes red or yellow colors are apparent histologically.

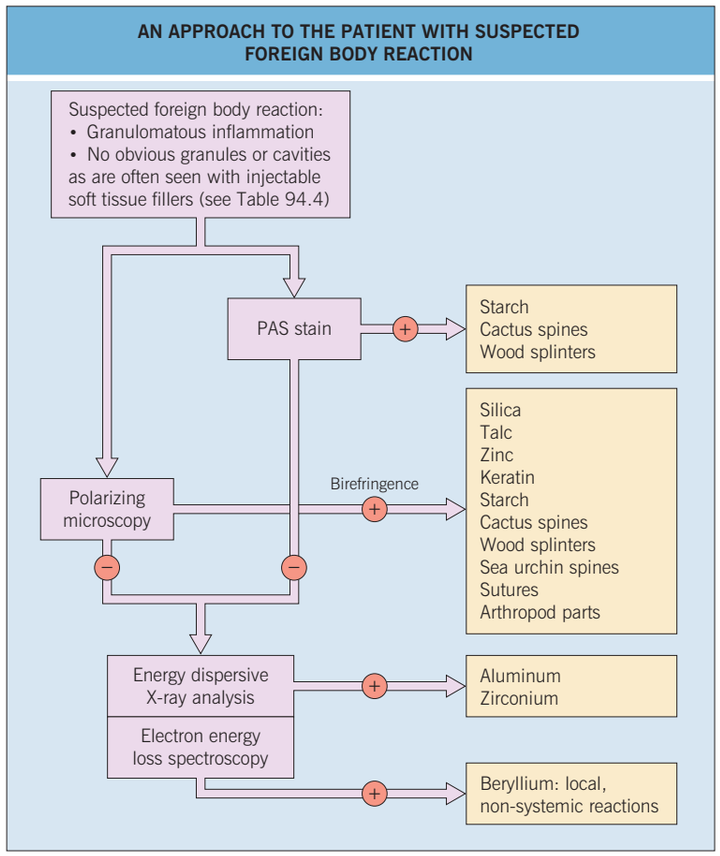

Fig. 94.4 An approach to the patient with suspected foreign body reaction.

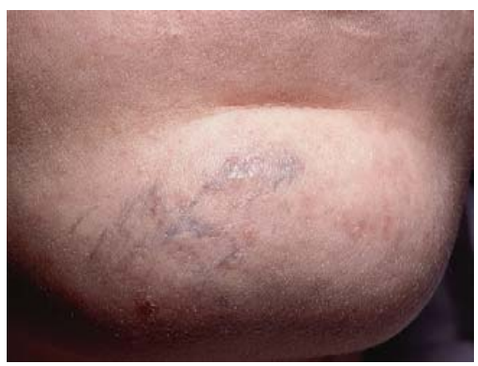

Fig. 94.5 Traumatic tattoo of the chin. Bluish discoloration and slight erythema, predominantly due to silica. *Courtesy, Ronald P Rapini, MD.*

Diagnosis and differential diagnosis

The presence of inflammatory lesions confined to the site of a tattoo suggests the diagnosis. The differential diagnosis includes other inflammatory disorders that may arise in tattoos, e.g. sarcoidosis. Inoculation of certain infectious agents (e.g. atypical mycobacteria) may mimic pigment-induced inflammation within a tattoo. Identification of the causative pigment is generally unnecessary unless further tattooing is anticipated. Other causes of dermal pigmentation include melanin, hemosiderin, lipofuscin, silver, gold, minocycline, amiodarone and chlorpromazine. Special stains to identify melanin and iron (hemosiderin) may be useful (see Ch. 0).

Treatment

Although many therapeutic modalities for tattoo removal have been used, some of them can result in significant scarring. Nowadays, lasers (e.g. Q-switched ruby, alexandrite, Nd:YAG) represent the primary treatment modality, allowing for selective destruction of chromophores while leaving adjacent collagen intact. The specific type of laser chosen depends on the tattoo ink colors and the wavelengths to which they best respond[15] (see Ch. 137). Several wavelengths are required to treat multicolored tattoos optimally.

Surgical excision can be considered for the treatment of inflamed tattoos. Topical corticosteroids are often ineffective, but intralesional

Fig. 94.6 Granulomatous reaction to the red (cinnabar) portions of a tattoo. Over the past several years, cinnabar (mercuric sulfide) has been gradually replaced by cadmium selenide (cadmium red), ferric hydrate (sienna) and organic compounds. *Courtesy, Ronald P Rapini, MD.*

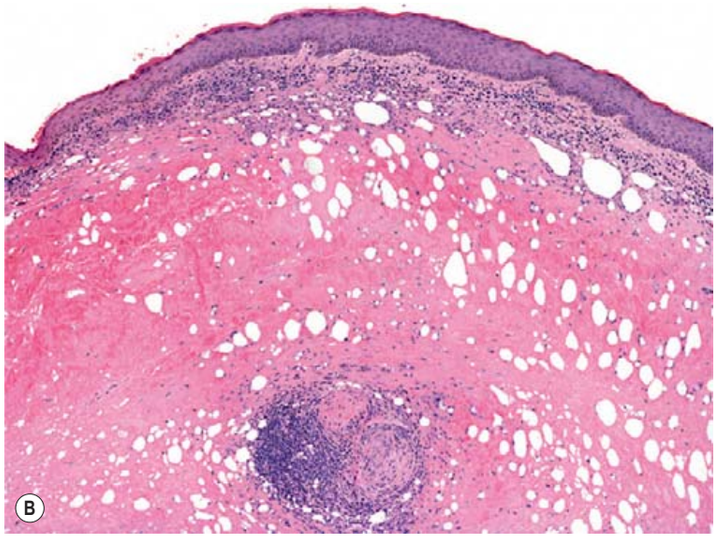

Fig. 94.7 Sclerosing lipogranuloma of the penis. A The penis was injected in order to relieve urinary retention following a motorbike accident, and an ulcerated, indurated yellow plaque with telangiectasias developed at the site. **B** Histologic examination showed sclerosis as well as multiple circular and oval empty spaces within the dermis. *Courtesy, Glen Foxton, MD, and Clare Tait, MD.*

corticosteroids may lead to improvement; laser therapy is not advised because of the risk of inducing a systemic reaction, following release of pigment from macrophages, in an already sensitized patient[15].

Paraffin (Sclerosing Lipogranuloma)

Paraffin, being a mineral oil, is not hydrolyzed by tissue lipases and is treated by the body as a foreign substance. Augmentation of body contour by local injection of paraffin, although banned in most countries, is still performed in some regions of the world and is mostly done by non-medical personnel. Accidental paraffinoma of the orbit and palpebra has been reported following intraoperative placement of paraffin-impregnated gauze packs within the nasal cavity.

Clinical features

In those cases due to injected paraffin, the genitalia and breast are the most common sites of involvement (Fig. 94.7A). Clinically, non-tender firm nodules and indurated plaques are seen, sometimes with ulceration or abscess formation and involvement of subcutaneous tissue (see Ch. 100). The interval between the time of injection and the development of lesions may span many years.

Pathology

The dermis shows a characteristic "Swiss cheese" appearance due to the presence of numerous ovoid or round cavities where the paraffin resided prior to processing (Fig. 94.7B). Between the cavities, there is fibrotic connective tissue and a cellular infiltrate composed of macrophages, variable numbers of multinucleated foreign body giant cells, and lymphocytes. Some of the macrophages have foamy cytoplasm. In specially processed tissue, the foreign material stains with fat stains[16], although less intensely than neutral fats, helping to differentiate paraffinoma from reactions to silicone, which also have numerous cavities but negative fat stains.

Treatment

Excision with appropriate tissue reconstruction is the only means of therapy.

Silicone

Silicone (polydimethyl siloxane), either in its liquid form or as silicone gel-filled implants, is used for tissue augmentation, and, in some patients, its use has been followed by foreign body reactions.

Clinical features

Silicone gel-filled implants are widely used for breast augmentation and reconstruction after mastectomy and may be followed, usually after months or years, by the formation of cutaneous nodules and plaques at the site. Silicone is also employed to correct HIV-related lipoatrophy. Silicone reaches the dermis if the implant capsule ruptures as a result of trauma or there is leakage from the capsule[17]. Nodular foreign body granulomatous reactions evolve some years after rupture or leakage[17], and can slowly progress, resulting in sclerosis and ulceration of involved skin. Spread of the leaked gel from the implant down into the arm or abdominal wall has been reported and leads to the development of nodules distant from the site of the implant.

Similar nodules and indurated plaques, sometimes with ulceration, have been seen following injections of liquid silicone into the subcutaneous tissue[18].

In the literature, there are anecdotal reports of patients in whom autoimmune connective tissue diseases such as scleroderma and systemic lupus erythematosus developed after breast augmentation with silicone-filled prostheses. However, carefully controlled epidemiologic studies have not supported a causal link.

Pathology

A biopsy specimen is critical to establishing the diagnosis. Histologic sections have a "Swiss cheese" appearance due to the presence of silicone-filled cavities surrounded by histiocytes, lymphocytes and eosinophils. The histiocytes may be foamy or multinucleated. Fibrous tissue within the areas separating the cavities is also seen. In contrast to paraffinomas, the cavity contents do not stain with lipid stains.

Treatment

Excision of persistent symptomatic lesions is recommended.

Silica

Wounds or penetrating injuries accidentally contaminated with silica (silicon dioxide) contained in sand, soil, rocks and glass may be followed some years later by the formation of a foreign body reaction. The period between inoculation and development of a reaction may be as long as 25 years. This extended "incubation" period is due to the very slow release of colloidal silica (the only form capable of inciting a reaction) from the large particles of silica introduced into the body[19]. Reactions to silica are thought to be due to a delayed-type hypersensitivity response.

Clinical features

At first, the wound heals, but then papules, nodules or indurated plaques develop within the scar years later. Multiple disseminated lesions may follow trauma produced by the explosion of land mines and bombs[19]. Macrocheilitis was described following a road accident that occurred 25 years prior to the development of the foreign body reaction[20].

Pathology

The dermis contains multiple nodular aggregates of granulomas, usually sarcoidal and less often foreign body, separated by strands of

connective tissue. Langhans- and foreign body-type giant cells are usually numerous in both types of granuloma. Colorless crystals may be observed within the cytoplasm of the giant cells or lying free in the interstitium. These bodies are birefringent when examined with polarized microscopy.

Differential diagnosis

Granulomatous lesions occurring at the site of an old scar may mimic systemic sarcoidosis clinically and histologically[21]. The presence of foreign material within a sarcoidal granuloma does not exclude sarcoidosis, since some granulomas of sarcoidosis appear to be attracted to old scars. Examination under polarized light will identify silica crystals, but by-products of histiocyte metabolism are known to crystallize rarely.

Treatment

Excision of persistent symptomatic lesions is recommended. Spontaneous resolution of silica granuloma, although reported, is exceptional.

Talc

Talc (hydrous magnesium silicate) that contaminates wounds, erosions, umbilical stumps or intravenous puncture sites is another important cause of foreign body reactions. Because of its widespread use, it is a common cause of foreign body granulomas. Talc is a component of many dusting powders and antibiotic powders and is still preferred by some surgeons as a lubricant for surgical gloves.

Despite repeated warnings in the medical literature, dusting of raw umbilical stumps with antibiotic powders containing talc was reported to be the most frequent cause of umbilical granulomas[5]. Talc may also enter the skin through abrasions and fissures, particularly in intertriginous areas in obese persons who apply talc powder liberally[22]. Tablet forms of medications contain, in addition to the pharmacologically active material, talc as a filler to hold the tablet together. Tablets are frequently crushed and then suspended in solutions by drug addicts prior to intravenous injection[23], and foreign body reactions may develop at intravenous injection sites. Talc may also reach the lungs via inhalation (usually occupational) or through injections of self-prepared drugs.

Clinical features

As with reactions to other forms of silica, the lesions usually take a long time to appear. The clinical appearance is varied: it may take the form of erythematous papules or nodules suggestive of sarcoidosis, or appear as thickening and erythema of an old scar. Despite the long latency period, the diagnosis should be considered, especially when lesions appear in certain sites, e.g. the umbilicus in infants, inguinal area in patients with a history of intertrigo, injection sites in intravenous drug addicts.

Pathology

The histologic features may be similar to those of sarcoidosis or noncaseating tuberculosis. Alternatively, there may be granulomatous inflammation consisting of histiocytes and foreign body giant cells. A few of these cells may contain clear, blue–green or yellow–brown, needle-shaped or round crystals. Under polarized light, talc crystals appear as white birefringent particles[5]. A picture simulating a pyogenic granuloma plus giant cells has also been described[5].

Treatment

Excision of persistent symptomatic lesions is recommended.

Zirconium

Some zirconium salts are components of antiperspirant preparations as well as over-the-counter preparations used in the treatment of allergic contact dermatitis. Sodium zirconium lactate was the first salt incriminated as a cause of foreign body reactions and was banned in the late 1970s. Subsequently, zirconium oxide and aluminum–zirconium complex have also been shown to be capable of producing the same reaction. Development of the granulomas represents a delayed-type hypersensitivity reaction to zirconium[24].

In sensitized individuals, persistent, soft, red–brown papules appear in areas to which zirconium-containing preparations were applied. The axillary skin is the most frequently affected site.

Histologically, non-caseating granulomas resembling a sarcoidal reaction are seen[24]. The small size of the zirconium particles does not allow their detection with polarized light microscopy; however, energy dispersive X-ray analysis can prove their presence (see Table 94.3).

Beryllium

In the past, beryllium-containing compounds were widely used in the manufacture of fluorescent light tubes, and industrial exposure resulted in serious systemic and local complications. As a result, their use was discontinued.

Occupational inhalation of beryllium particles results in systemic berylliosis, in which the primary pathology is in the lung and skin involvement is rare (<1%). The cutaneous granulomas of systemic berylliosis consist of widely scattered papules with no secondary changes. Laceration or puncture of the skin by broken fluorescent tubes used to result in local cutaneous berylliosis. Wounds heal slowly and are followed by persistent erythema, swelling, induration and possible ulceration.

Histologically, cutaneous lesions of systemic berylliosis are indistinguishable from sarcoidosis. Local berylliosis, on the other hand, has a caseating tuberculoid pattern[11]. In systemic berylliosis, bronchioalveolar lavage is recommended for diagnosis.

Aluminum

Rare hypersensitivity reactions to the aluminum adjuvant in vaccines and hyposensitization immunotherapy do occur. Persistent subcutaneous granulomatous nodules appear at the site of injection several months after vaccination[25]. Histologically, granuloma formation with central granular debris surrounded by a histiocytic mantle is seen. A dense lymphoid infiltrate with eosinophils is present at the periphery[25]. Of note, *topical* application of aluminum chloride for hemostasis produces a stippled appearance within macrophages in the healing wound.

Zinc

A zinc-induced granuloma at the site of an injection is a rare complication of zinc-containing insulin[26]. Sterile furuncles develop at the injection sites and eventually heal with atrophic scars. Histologically, an initial stage characterized by a dense neutrophilic infiltrate is followed by granuloma formation that ends in fibrosis. By polarizing microscopy, birefringent rhomboid crystals are seen.

Zirconium, beryllium, aluminum and zinc granulomas may be surgically excised if they are symptomatic.

REACTIONS TO ORGANIC AND BIOLOGIC PRODUCTS

Starch

Granulomas may result from the contamination of wounds with starch used as a lubricant for surgical gloves.

Pathology

Foreign body granulomas with multinucleated giant cells are seen. Starch granules appear as ovoid basophilic structures. They react with PAS and are birefringent in polarized light[27].

Cactus spines

Accidental implantation of cactus spines into the skin results from contact with cacti in gardens and fields. Occupational exposure occurs in persons peeling and selling prickly pear fruit, especially in the Middle East and Latin America. Most of the reported cases are due to contact with the genus *Opuntia*[28].

At the time of injury, acute inflammation occurs and then in some patients, eventually evolves into a typical foreign body reaction. The lesions occur primarily on the hands and fingers as clusters of dome-shaped, skin-colored papules with a central black dot, sometimes called sabra dermatitis. This often resembles scabies or fiberglass dermatitis.

Pathology

Two types of granulomatous reaction have been described: an allergic reaction consisting of epithelioid cells and Langhans- and foreign

body-type giant cells[28], as well as foreign body-type granulomas[11]. The granulomas occupy the entire dermis, surrounding spine fragments which stain intensely red with PAS stain. Wood splinters and thorns of other plant origin have a similar suppurative or granulomatous reaction. However, most splinters appear brown with a rectangular pattern of cell walls (see Fig. 94.3A). Fungal hyphae may be present within the plant material, but they seldom invade the surrounding dermis in the healthy host.

Cnidaria (Coelenterata) – Jellyfish, Corals

Members of the phylum Cnidaria (Coelenterata) include jellyfish, corals and sea anemones (see Ch. 85). Almost all cnidarians possess nematocysts, or stinging capsules. Each nematocyst contains toxins and a coiled thread-like apparatus with a barbed end that functions as a flexible syringe. When the nematocyst comes into contact with the victim, the barbed end of the thread-like organ is discharged and the toxin is injected into the skin.

Clinical features

Jellyfish and coral stings elicit similar cutaneous reactions: an early primary irritant toxic reaction in all exposed persons, and a delayed-type hypersensitivity reaction in a small percentage. A sharp burning pain is felt and, within minutes, the affected area becomes erythematous and edematous and may form blisters. The acute response may be accompanied by an immediate-type hypersensitivity reaction including urticaria, angioedema and even anaphylaxis. The lesions resolve, leaving postinflammatory hyperpigmentation in a streaky flagellate fashion corresponding to where the coral or jellyfish brushed the skin. In some individuals, new lesions appear a few weeks later at previously involved sites (average 3 weeks)[7]. The latter are severely pruritic, shiny, lichenoid papules and plaques and are arranged in a number of patterns, including linear, zig-zag and whip-like (Fig. 94.8).

Pathology

The lesions that comprise the delayed response have a lichenoid tissue reaction.

Treatment

First aid includes soaking the site in hot, but not scalding, water (denatures proteins). Subsequent use of topical potent corticosteroids, antihistamines and systemic corticosteroids is controversial. Treatment of acute reactions is reviewed in Chapter 85. Intralesional corticosteroids are the most effective therapy for delayed-type hypersensitivity reactions.

Fig. 94.8 Coral envenomation. Delayed lichenoid reaction on the calf. The patient accidentally came into contact with a coral reef and developed acute dermatitis that resolved, to be followed 3 weeks later by this severely itchy eruption that responded favorably to intralesional triamcinolone injection.

Keratin

In addition to ruptured epidermoid cysts, dermatologic foreign body reactions to keratin are involved in three common, distressing conditions that occur in otherwise healthy young persons: pseudofolliculitis, ingrown nails, and sacrococcygeal pilonidal sinus disease.

Keratin, normally sequestered from the body's immune surveillance by the surrounding epithelium, is treated as foreign if it directly contacts the dermis. This may occur as a result of ruptured hair follicles, epidermoid cysts or acne lesions, or because of external keratin sources (e.g. ingrown hairs or nails), or through accidental entry of hairs into the interdigital skin, especially of barbers and dog groomers.

Pseudofolliculitis barbae and acne keloidalis nuchae

In pseudofolliculitis barbae, there is a foreign body inflammatory reaction surrounding a hair that has been previously shaved or plucked (see Ch. 38). This condition affects mainly those with curly hair, with an incidence of more than 50% amongst blacks. Certain inherent properties of the hairs in affected individuals, in particular a curled flattened elliptical shape, play an important pathogenetic role. Because the shaft is curved, it grows back toward the skin surface. The flattened elliptical hair shaft when shaved develops a pointed tip, which facilitates re-entry of the hair into the skin. A foreign body reaction to keratin results in the development of inflammatory papules and pustules that result in hyperpigmentation or small keloidal scars[8].

Pseudofolliculitis also affects women who regularly remove hair from the pubic region, axillae and legs by plucking or shaving. Papules containing embedded hairs, pustules and cysts develop in affected areas, often resolving with significant postinflammatory hyperpigmentation.

Treatment

Apart from cessation of shaving or laser epilation of the affected areas, nearly all therapeutic modalities are unrewarding. For further details, see Chapters 38 and 137.

Pilonidal sinus

Most cases of pilonidal sinus occur in the sacrococcygeal region (see Fig. 38.15). Much less often, it is seen in the umbilical region[8], and, rarely, interdigitally in barbers[29].

Sacrococcygeal pilonidal sinuses may be asymptomatic (debris-filled pit) or present as a draining sinus or an acute abscess. The condition is more common in young men. There is often an underlying cyst with associated granulation tissue, fibrosis and frequently tufts of hairs. Excisional specimens reveal a sinus tract extending into the subcutaneous tissue and dermis, surrounded by chronic inflammation. Hairs are found in the sinuses in three-quarters of the cases[30].

Small, asymptomatic or slightly tender, openings in the interdigital web spaces of the hands have been observed in barbers. The lesions are caused by the penetration of short hairs into the interdigital spaces, inciting an inflammatory foreign body granuloma. The clinical course is usually self-limited but can be complicated by repeated infections, which may require surgical excision of the involved area[29]. Histologically, a sinus tract lined by epidermis and containing one or several hairs is seen. Hairs extending deeper than the sinus tract incite a foreign body reaction.

INJECTABLE SOFT TISSUE FILLERS

With the exception of autologous fat, all injectable soft tissue fillers, resorbable or non-resorbable, represent foreign bodies and therefore have the potential to cause foreign body reactions (Fig. 94.9). Depending upon the particular filler, these reactions can range from relatively common (e.g. paraffin) to rare (e.g. hyaluronic acid)[31]. Paraffin and silicone are discussed above and the histopathologic features of inflammatory reactions to various fillers are outlined in Table 94.4[32].

Hyaluronic Acid

Currently, hyaluronic acid is the most commonly utilized injectable soft tissue filler, in part because the incidence of foreign body reactions is much lower (0.42%) than that reported for bovine collagen (3–4%)[31]. When a reaction does occur, the injected site becomes firm, tender, edematous and erythematous, and abscess formation may occur. The foreign body reaction begins approximately 6 to 8 weeks after hyaluronic

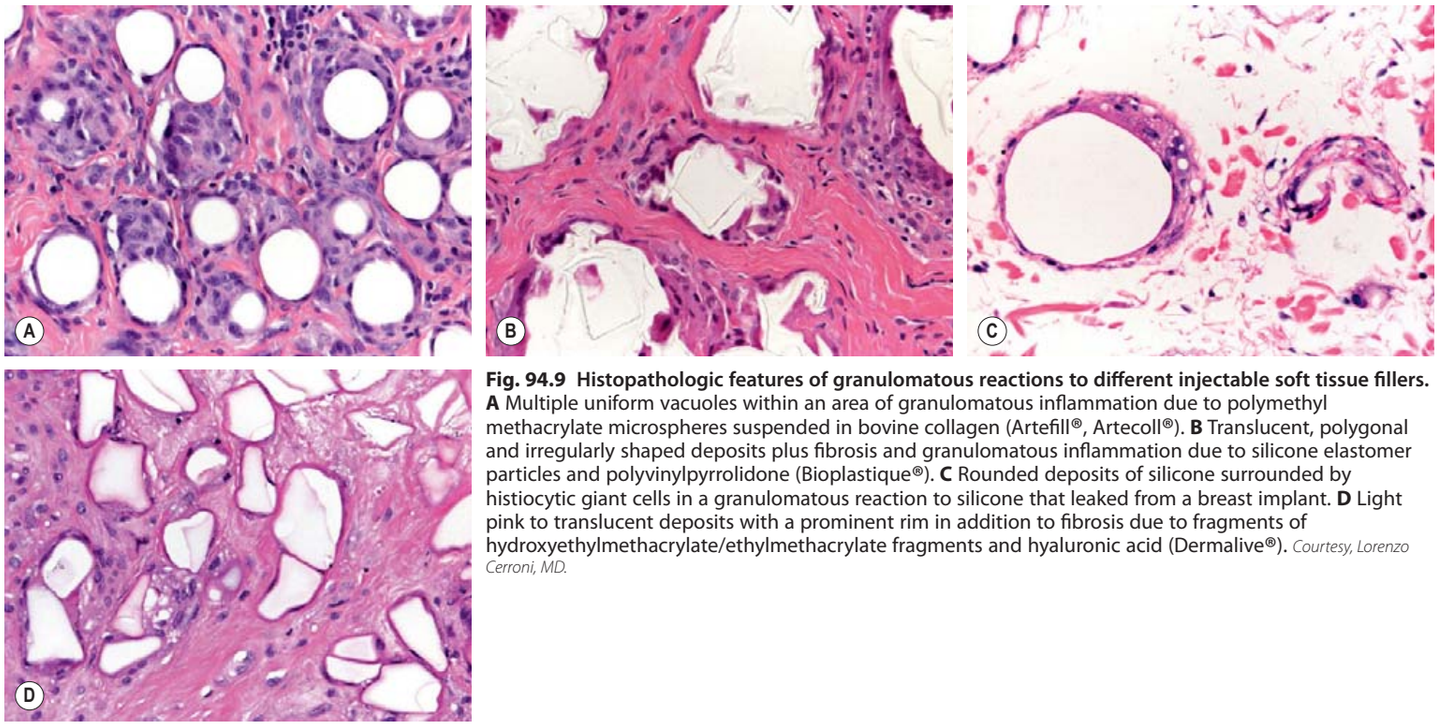

Fig. 94.9 Histopathologic features of granulomatous reactions to different injectable soft tissue fillers. **A** Multiple uniform vacuoles within an area of granulomatous inflammation due to polymethyl methacrylate microspheres suspended in bovine collagen (Artefill®, Artecoll®). **B** Translucent, polygonal and irregularly shaped deposits plus fibrosis and granulomatous inflammation due to silicone elastomer particles and polyvinylpyrrolidone (Bioplastique®). **C** Rounded deposits of silicone surrounded by histiocytic giant cells in a granulomatous reaction to silicone that leaked from a breast implant. **D** Light pink to translucent deposits with a prominent rim in addition to fibrosis due to fragments of hydroxyethylmethacrylate/ethylmethacrylate fragments and hyaluronic acid (Dermalive®). *Courtesy, Lorenzo Cerroni, MD.*

HISTOPATHOLOGIC FEATURES OF INJECTABLE SOFT TISSUE FILLERS

Category	Chemical composition	Trade names®,™	Histopathologic features
Resorbable within months	Bovine collagen	Zyderm, Zyplast	Palisading granulomas with foreign body giant cells; eosinophilic bovine collagen at the center of the granulomas; immunoperoxidase staining with anti-bovine collagen type I antibodies
	Human collagen – Bioengineered – Cadaveric – Autologous	Cosmoderm, Cosmoplast Cymetra	Granulomatous reaction
	Hyaluronic acid	Hylaform, Restylane, Juvéderm, Perlane, Captique, Prevelle Silk, Elevess, Bolotero, Macrolane	Irregular clusters of basophilic material surrounded by histiocytes and giant cells; positive Alcian blue stain
Resorbable within years	Hyaluronic acid plus dextranomer microparticles	Matridex, Reviderm intra	Suppurative granuloma surrounding bluish-grey filamentous material and round, bluish, spherical particles
	Poly-L-lactic acid microspheres plus sodium carboxymethyl-cellulose	Sculptra, New-Fill	Foreign body granuloma around fusiform or oval, translucent particles, birefringent under polarized light
	Calcium hydroxylapatite plus carboxymethylcellulose	Radiance, Radiesse	Foreign body granuloma surrounding bluish, rounded particles
Permanent	Paraffin*		Foreign body granuloma with "Swiss cheese" appearance (Fig. 94.7B); positive fat stains (e.g. oil red O); detected by IRS
	Silicone oil or silicone gel	Silikon 1000†, SilSkin, MDX 4-4011, Adatosil 5000	Foreign body granuloma with "Swiss cheese" appearance (Fig. 94.9C); histiocytes may be foamy; negative fat stains; detected by EDXA; radio-opaque on X-ray
	Silicone particles (100-600 microns) suspended in polyvinylpyrrolidone	Bioplastique	Foreign body reaction with translucent, irregular, non-birefringent particles dispersed in a sclerotic stroma (Fig. 94.9B)
	Polymethylmethacrylate microspheres plus bovine collagen	Artefill, Artecoll, Arteplast	Granulomatous infiltrates around vacuolar structures of homogenous shape and size (Fig. 94.9A)
	Hydroxyethylmethacrylate/ethylmethacrylate fragments in hyaluronic acid	Dermalive, Dermadeep	Foreign body granuloma around polygonal, irregular, translucent pink structures (Fig. 94.9D)
	Polyacrylamide hydrogel	Aquamid, Interfall, Formacryl, Amazingel, Argiform, Bio-Formacryl, OutLine, Royamid, Kosmogel	Foreign body granuloma surrounding a basophilic, multi-vacuolated material
	Polyalkylimide gel	Bio-Alcamid	Basophilic, amorphous, granular material surrounded by inflammatory infiltrates
	Polyvinylhydroxide microspheres suspended in polyacrylamide gel	Evolution	No reports of side effects to date; limited local reactions at test sites in volunteers

*Banned in most countries; also seen after application of paraffin-impregnated gauze packs.
†FDA-approved for intraocular use.

Table 94.4 Histopathologic features of injectable soft-tissue fillers. EDXA, energy dispersive X-ray analysis; IRS, infrared spectrophotometry (non-processed tissue). Adapted from ref. 32.

acid injection, and spontaneous resolution occurs over 6 to 24 weeks. This reaction responds to intralesional injections of corticosteroid or hyaluronidase (see Ch. 158)[33].

Bovine Collagen

As the first FDA-approved injectable soft tissue filler for facial rhytides, bovine collagen implants have been widely used. However, bovine collagen has been largely replaced by less antigenic fillers, in particular hyaluronic acid (see above).

Despite negative skin testing (which is required prior to treatment), a small proportion of treated patients still develop a local reaction after injection. Two types of reactions have been reported: non-immunogenic and immunogenic. The former is characterized by localized tissue necrosis, which occurs shortly after implantation, and such reactions are probably the result of local vascular interruption; two-thirds of local necrotic events have occurred in the glabellar area[34]. The most common hypersensitivity reaction is the development of induration and erythema at the treatment site. It usually resolves spontaneously in less than a year. Rarely, abscesses ensue as a manifestation of hypersensitivity to bovine collagen (4 in 10 000 cases) and they may persist for several weeks. Periods of remission and exacerbation may occur, ranging from 1 to more than 24 months[34].

Intralesional corticosteroids are recommended for inflammatory reactions. Abscesses may be drained prior to injection.

Fig 94.10 Foreign body reactions to polyamide synthetic "hair" implantation. In addition to multiple perifollicular granulomas, there is evidence of chronic folliculitis. *Courtesy, Marwa Abdallah, MD.*

MISCELLANEOUS

Intralesional Corticosteroids

Foreign body reactions to intralesional corticosteroids are quite rare despite the widespread use of this treatment modality. Reactions result from failure of the injected material to disperse in the usual manner or from incomplete absorption, leaving a small residuum that evokes a foreign body reaction[35].

Histologically, pools of granular, lightly stained material surrounded by a histiocytic and foreign body granulomatous infiltrate are seen in the dermis. Cellular reactions are absent around sites of recent injections[35].

Sutures

Nylon and polypropylene sutures used in contemporary surgery are relatively inert (see Ch. 144), but most other materials regularly produce chronic inflammation and granuloma formation. The incubation period varies from weeks[36] to years[37].

The incision site may appear inflamed, red and edematous. A fistula may develop, through which the suture material is extruded. Inflammation persists until the suture material is totally removed.

Histologically, granulomatous inflammation of various types is seen surrounding suture material: foreign body, histiocytic, palisading, or a combination thereof[36,37]. Transepidermal elimination of the suture material occurs[36].

Polyamide "Hair" Implants

In patients with androgenetic alopecia in whom autologous hair transplantation is not feasible (e.g. inadequate donor sites), polyamide "hair" fibers have been used for synthetic scalp hair restoration. Although some authors have reported complications in only ~1% of patients, foreign body reactions are a real risk (Fig. 94.10)[38]. Polyamide fiber hair restoration is not approved in the US.

Mesotherapy

Although this technique usually involves the subcutaneous injection of phosphatidylcholine plus a detergent solvent (e.g. deoxycholic acid) and leads to the dissolution of fat cells, there is no standardization of injected materials. Therefore, in addition to irritant cutaneous necrosis and atypical mycobacterial infections, granulomatous reactions have been observed[39].

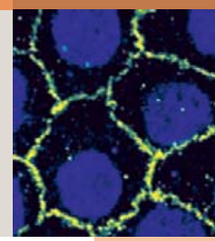
Biology of the Extracellular Matrix

95

Leena Bruckner-Tuderman



Key features

- Extracellular matrices (ECMs) represent specifically organized networks of collagens, elastin, glycoproteins and proteoglycans that have distinct structural roles and specific functional properties in all tissues
- ECMs are biologically active, interact with cells, and regulate cellular functions during development, regeneration and normal tissue turnover
- Mutations in genes encoding ECM proteins cause a broad spectrum of human diseases, from Ehlers–Danlos syndrome to epidermolysis bullosa, and components of the ECM are targeted in autoimmune diseases such as bullous pemphigoid, epidermolysis bullosa acquisita and lichen sclerosus
- The collagen family contains 28 different subtypes. All collagens consist of three polypeptide α-chains, which are folded into a triple helix. In each chain, every third amino acid is glycine (Gly), and thus a sequence of an α-chain can be expressed as $(Gly\text{-}X\text{-}Y)_n$. A hallmark of collagens is the presence of hydroxyproline (Hyp) in the Y position of this repeat sequence. Collagens are expressed in all tissues of the human body, and distinct sets of collagens co-polymerize into highly organized suprastructures, e.g. fibrils and filaments, in a tissue-specific manner
- Elastin provides tissues with their elasticity. Elastin monomers contain repetitive hydrophobic sequences and are highly cross-linked. The cross-links between several individual molecules provide for both elasticity and insolubility of the elastic fibers, which can be stretched by 100% or more and still return to their original form. In addition to elastin, elastic fibers in the dermis also contain a microfibrillar component that attaches the fibers to the surrounding structures

INTRODUCTION

The different types of extracellular matrix (ECM) represent specifically organized assemblies of the macromolecules listed in Table 95.1. The macromolecules have characteristic patterns of aggregation into insoluble suprastructures with a high degree of order at successive hierarchic levels[1]. Each of these structures is tissue-specific and adapted to the particular needs of a given tissue. At first glance, the major constituents are often similar in functionally diverse ECMs. However, different types of quantitatively minor molecular components associate with major elements in tissue-specific suprastructural arrays determined by their relative compositions. The matrix suprastructures may be likened to alloys, each having metallurgic properties that differ from each other and those of the pure metals (Fig. 95.1).

Individual ECM macromolecules are usually oligomers composed of one or several polypeptides. Intimate contacts between the subunits are formed by coiled-coil structures, such as the collagen triple helix or supercoiled α-helices comprised of three or more polypeptides. In addition, large matrix macromolecules can be regarded as linear sequences of structural modules that are similar in a large variety of proteins[1]. The modules can be recognized by several cellular receptors, but receptor clustering is determined in a tissue-specific manner and the response may be different in different tissues.

Our knowledge of ECM macromolecules has expanded dramatically in recent years due to the great power of both molecular genetics and proteomics. A multitude of molecules have been characterized and their expression, regulation, tissue specificity and functions discerned[2]. The assembled ECM structures are generally adhesive, enabling the attachment of tissue-specific cells, leukocytes, tumor cells, and even microorganisms. Through integrin-mediated interactions with cells, matrix molecules control cell proliferation, differentiation and migration, especially during development and regenerative processes. Without contact with the ECM, many cells undergo apoptosis. Furthermore, the ECM can function as a reservoir of information; certain proteoglycans and proteins bind growth factors (e.g. transforming growth factor [TGF]-β) and release and activate them as needed to control cellular functions[2]. To date, mutations in approximately 50 different genes encoding ECM molecules have been found to underlie heritable disorders in humans and mice.

STRUCTURE AND FUNCTION OF THE EXTRACELLULAR MATRIX

Collagens

The collagen family of proteins plays an important role in maintaining the integrity of most tissues. The family currently includes 28 proteins formally defined as collagens[3] (Table 95.2). These proteins contain at least 43 distinct polypeptide chains, each encoded by a different gene, and more than 15 other proteins have a collagen-like domain (e.g. macrophage scavenger receptor 1 and 2, ectodysplasin, pulmonary surfactant proteins).

Collagen triple helix

All collagens consist of three polypeptide chains, known as α-chains, which are folded into a triple helix. In some collagens, the α-chains are identical (homotrimers), while others contain two or three different α-chains (heterotrimers). In each polypeptide chain, every third amino acid is glycine (Gly), and the sequence of an α-chain can be expressed as $(Gly\text{-}X\text{-}Y)_n$, where X and Y represent other amino acids and n varies according to the length of the α-chain. A high number of proline (Pro) and hydroxyproline (Hyp) residues are in the X and Y positions, respectively, and hydrogen bonds between the hydroxyl groups of Hyp contribute to the stability of the helix. The prototype collagen (type I) has an uninterrupted Gly-X-Y repeat sequence that is almost 1000 amino acid residues in length. This forms a rigid, rod-like structure with a diameter of 1.5 nm and length of 300 nm. In some collagens, the $(Gly\text{-}X\text{-}Y)_n$ repeats are interrupted by one or more amino acids. The interruptions may be numerous and longer than the $(Gly\text{-}X\text{-}Y)_n$ repeats, and they provide the molecule with flexibility, which is important for the specific functions of a given collagen type[3].

Biosynthesis of collagens

Collagen biosynthesis involves a number of post-translational modifications (Fig. 95.2). Some collagens are first synthesized as procollagens that have propeptide extensions at their N-terminus, their C-terminus, or both termini. The main intracellular steps in collagen biosynthesis include the following:

- cleavage of signal peptides
- hydroxylation of certain Pro and lysine (Lys) residues to 4-Hyp, 3-Hyp, and hydroxylysine (Hyl)

COMPONENTS OF THE EXTRACELLULAR MATRIX	
Collagens (28 types)	Laminins (18)**
Elastin	Proteoglycans (Table 95.3)
Fibrillins (3 types)	Glycoproteins (Table 95.4)
LTBPs (4 types)	Integrins
Fibulins* (7 types)	Modifying enzymes

*Fibulins are believed to function as intra-molecular bridges that stabilize ECM structural networks (e.g. elastic fibers, microfibrils or basement membrane structures).
**15 of which are well characterized.

Table 95.1 Components of the extracellular matrix (ECM). These belong to several protein superfamilies. The molecules assemble into mixed fibrils and networks in a tissue-specific manner. Several enzymes are involved in the biosynthesis and modification of ECM assemblies. Integrins are the main cellular receptors for the ECM. LTBP, latent TGF-β binding protein.

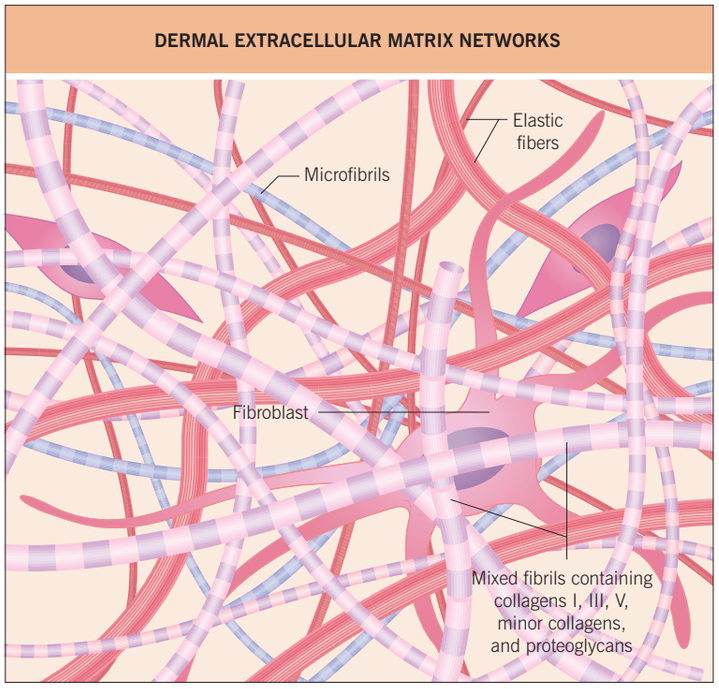


Fig. 95.1 Dermal extracellular matrix networks. Different molecules polymerize into distinct fibril networks and, within the mesh of the networks, cells are embedded in the amorphous extrafibrillar matrix. The fibril networks interact with each other, with the extrafibrillar matrix and with the cells. These networks have a dual function: support of the tissue and regulation of cellular functions.

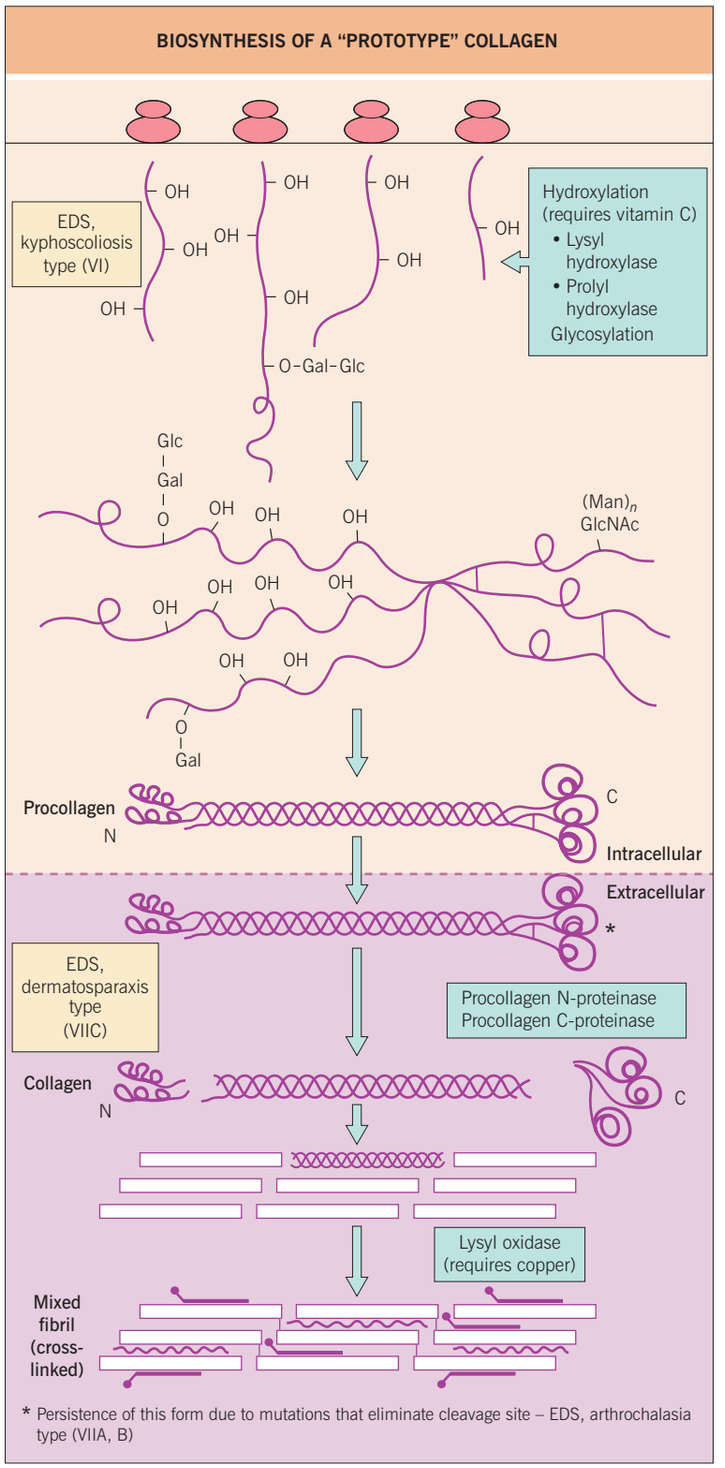

Fig. 95.2 Biosynthesis of a "prototype" collagen. The procollagen α-chains are synthesized in the rough endoplasmic reticulum. During its synthesis, certain prolyl and lysyl residues on the nascent polypeptide are hydroxylated and modified by glycosylation. Three α-chains associate to form a trimer and fold into a triple helix. The newly formed triple helical procollagen is secreted into the extracellular space, where the N- and C-terminal propeptides are cleaved by specific proteases. The mature collagen molecules assemble to form mixed fibrils with other collagens and non-collagenous molecules. The suprastructures are stabilized by covalent cross-links. EDS, Ehlers–Danlos syndrome. *Adapted from Myllyharju J, Kivirikko KI. Collagens, modifying enzymes and their mutations in humans, flies and worms. Trends Genet. 2004;20:33–43.*

- glycosylation of some of the Hyl residues to galactosyl-Hyl and glucosylgalactosyl-Hyl
- glycosylation of certain asparagine residues
- association of the α-chains in a specific manner
- formation of intra- and interchain disulfide bonds
- folding of the triple helix.

After the chains have become associated and sufficient Hyp residues have been formed in each chain, a nucleus of the triple helix forms (usually in the C-terminal region) and propagates towards the other end of the molecule in a zipper-like fashion[4]. The procollagen molecules are then transported from the endoplasmic reticulum across the Golgi apparatus without leaving the lumen of the Golgi cisternae. During this transport, the molecules begin to aggregate laterally and form early fibrils ready for secretion[5]. The *extracellular* steps in biosynthesis typically include cleavage of the N- and/or C-terminal propeptides, assembly into suprastructures with other collagens and non-collagenous components, and formation of covalent cross-links.

The specific enzymes involved in the biosynthesis of collagens include prolyl-4-hydroxylase and prolyl-3-hydroxylase, which hydroxylate Pro residues to Hyp, and lysyl hydroxylases, which hydroxylate Lys residues to Hyl. These enzymes require O_2, Fe^{2+}, α-ketoglutarate and ascorbate (vitamin C) as cofactors for the reactions. In the rough endoplasmic reticulum, glycosyltransferases add glucosylgalactosyl disaccharides onto the α-chains. The same intracellular enzymes modify all collagen

Table 95.2 The collagen family of proteins. The names of types found in the skin are in bold italics. Multiplexins are collagens with multiple triple helix domains and interruptions. ECM, extracellular matrix; FACITs, fibril-associated collagens with interrupted triple helices.

THE COLLAGEN FAMILY OF PROTEINS			
Type	**Chains**	**Gene**	**Tissue distribution**
FIBRIL-FORMING COLLAGENS			
Collagen I	α_1(I), α_2(I)	*COL1A1*, *COL1A2*	Skin, most ECM
Collagen II	α_1(II)	*COL2A1*	Cartilage, vitreous humor
Collagen III	α_1(III)	*COL3A1*	Skin (including fetal skin), lung, vasculature
Collagen V	α_1(V), α_2(V), α_3(V)	*COL5A1*, *COL5A2*, *COL5A3*	Skin, with collagen I heterotypic fibrils
Collagen XI	α_1(XI), α_2(XI), α_3(XI)	*COL11A1*, *COL11A2*, *COL11A3*	With collagen II heterotypic fibrils
Collagen XXIV*	α_1(XXIV)	*COL24A1*	Developing bone and cornea
Collagen XXVII*	α_1(XXVII)	*COL27A1*	Cartilage, eye, ear, lung
FACITS			
Collagen IX	α_1(IX), α_2(IX), α_3(IX)	*COL9A1*, *COL9A2*, *COL9A3*	With collagen II heterotypic fibrils
Collagen XII	α_1(XII)	*COL12A1*	Skin, tissues containing collagen I
Collagen XIV	α_1(XIV)	*COL14A1*	Skin, tissues containing collagen I
Collagen XVI	α_1(XVI)	*COL16A1*	Skin, many tissues
Collagen XIX	α_1(XIX)	*COL19A1*	Basement membranes, fetal muscle
Collagen XX	α_1(XX)	*COL20A1*	Skin, cornea, cartilage, tendon
Collagen XXI	α_1(XXI)	*COL21A1*	Many tissues, including skin
Collagen XXII*	α_1(XXII)	*COL22A1*	Tissue junctions (including between the anagen hair follicle and dermis)
Collagen XXVI*	α_1(XXVI)	*COL26A1*	Testis, ovary
BASEMENT MEMBRANE COLLAGENS			
Collagen IV	α_1(IV), α_2(IV), α_3(IV), α_4(IV), α_5(IV), α_6(IV)	*COL4A1*, *COL4A2*, *COL4A3*, *COL4A4*, *COL4A5*, *COL4A6*	All basement membranes, isoforms vary Skin: α_1(IV), α_2(IV), α_5(IV) and α_6(IV)
MICROFIBRILLAR COLLAGENS

chains[4]. The *extracellular* processing enzymes have a higher substrate specificity. Procollagen I N-proteinase cleaves the N-propeptide of procollagens I and II. This enzyme is a member of the disintegrin and metalloproteinase (ADAM) proteinase family and is also designated as ADAM with thrombospondin type 1 motif (ADAMTS)-2. Procollagen C-proteinase cleaves the C-propeptide of collagens I, II, III, V and VII. It is a member of the tolloid proteinase family and is also called bone morphogenetic protein (BMP)-1, since it was initially co-purified with other BMPs from bone extracts. Cross-linking between collagen molecules involves the ε-amino groups of Lys and Hyl and is catalyzed by lysyl oxidase, a copper-requiring enzyme[4]. Another enzyme that catalyzes cross-linking of at least some collagens is tissue transglutaminase. Collagen VII-containing anchoring fibrils in the upper dermis appear to be transaminated, and collagen VII serves as a substrate for tissue transglutaminase-2 *in vitro*[6].

The collagen family of proteins

The length and continuity of the triple helical domains vary among the collagen types. For practical purposes, the collagens have been divided into groups according to their ability to form supramolecular aggregates, which are depicted in Figure 95.3. The types and tissue distributions of the collagens in each group are listed in Table 95.2, and those found in the skin are discussed below. More detailed information on all the collagen types is available in recent reviews[1,3–5].

Collagens of the skin

Collagens account for 75% of the dry weight and 20–30% of the volume of the dermis. Different collagens polymerize into distinct suprastructures and have specific functions in the dermis as well as in epidermal and vascular basement membranes. "Pure" collagen fibrils do not exist; these fibrils are always mixtures of several collagens and other molecules, e.g. proteoglycans[1]. Classic, ultrastructurally recognizable, cross-banded fibrils in the dermis contain collagens I, III, V, XII and XIV. The characteristic cross-banding (Fig. 95.4) with periodicity of 64 nm results from precise lateral packing of the different collagens within the fibrils (see Fig. 95.3). Collagen I is the major component of the fibrils, and the amount of other collagens varies. For example, during embryonic development and wound repair, the content of collagen III is higher than in the steady-state situation. Of note, collagen III is also an important component of the vasculature, in particular arterial walls. Collagen VI, a highly glycosylated and disulfide-bonded collagen, is a component of almost all tissues, including the skin. *In vitro*, it polymerizes to form beaded filaments (see Fig. 95.3), but *in vivo* in the dermis, the ultrastructure of the collagen VI fibrils is reminiscent of microfibrils.

The collagen IV molecules in different basement membranes are composed of six genetically distinct but structurally homologous α-chains, which form three major networks: (1) α_1/α_2-containing; (2) $\alpha_3/\alpha_4/\alpha_5$-containing; and (3) $\alpha_1/\alpha_2/\alpha_5/\alpha_6$-containing[3]. In the skin, the α_1/α_2-containing collagen IV network dominates within the dermal–epidermal junction (see Ch. 28), but the $\alpha_1/\alpha_2/\alpha_5/\alpha_6$-containing network is also thought to be present[3]. The chain composition is determined by the carboxy-terminal non-collagenous (NC1) domains; covalent interactions between these domains link α-chains to each other and have a role in the formation of collagen IV dimers (composed of two triple-helical protomers). In addition, connections between amino-terminal 7S domains lead to formation of collagen IV tetramers (composed of four triple helical protomers; see Figs 28.5 and 95.3).

Two collagens are essential for the cohesion of the epidermis and dermis (see Ch. 28). Collagen VII is the major, if not sole, component of the anchoring fibrils that attach the basement membrane to the dermal ECM. Collagen XVII (also known as bullous pemphigoid antigen 2) is a component of the anchoring filaments that bind the basal keratinocytes to the lamina densa (basement membrane proper). It is a transmembrane collagen in type II orientation with a long extracellular C-terminal region containing a multiply-interrupted triple helix referred to as collagenous domains 1–15 (see Fig. 31.9). The ectodomains can be shed from the cell surface by transmembrane proteases[7], a process important for regulation of cell adhesion and migration. Basal

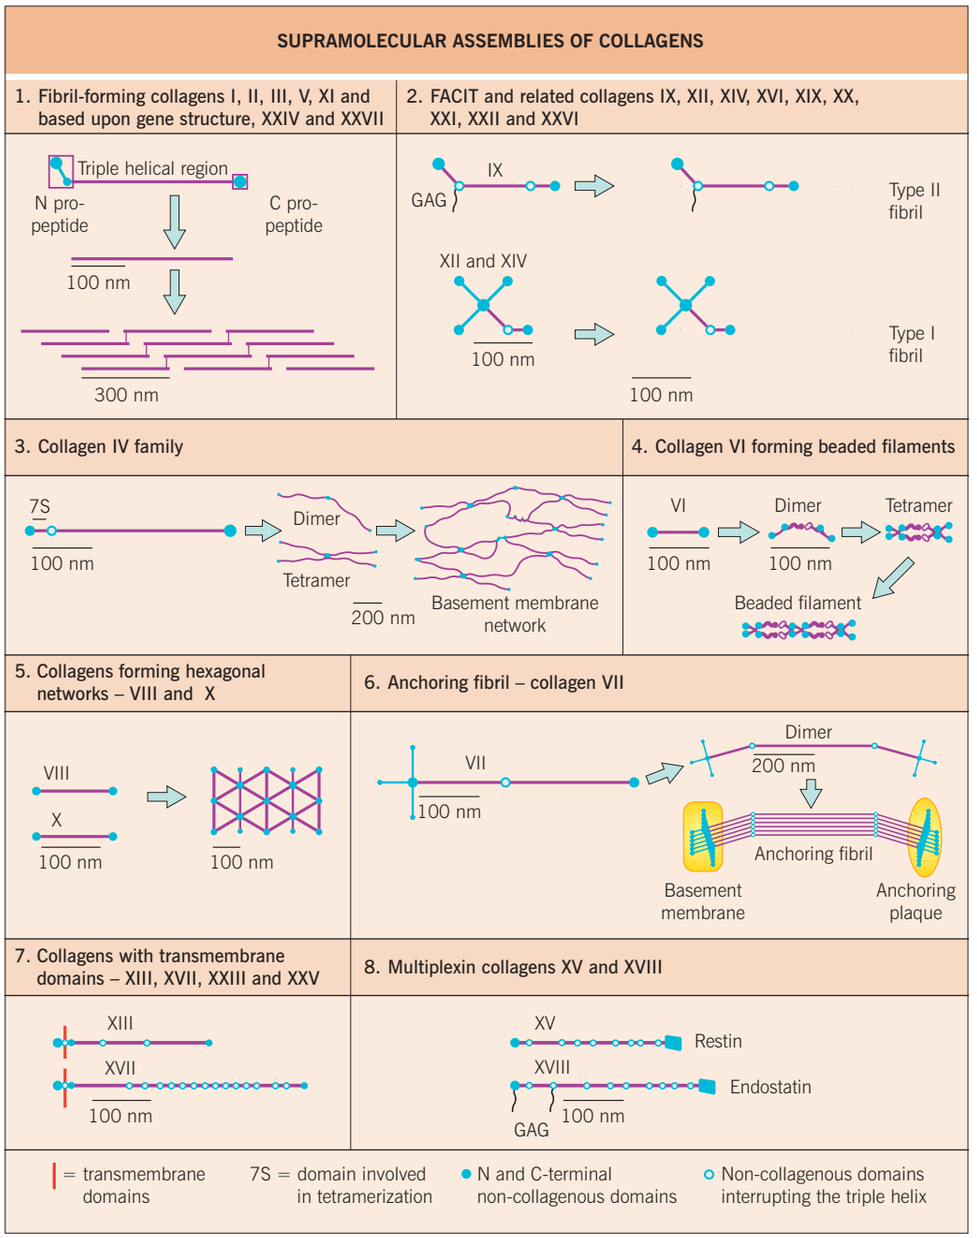

Fig. 95.3 Supramolecular assemblies of collagens. The suprastructures formed by different collagens are shown. Non-collagenous components also interact with the fibrils and networks. The suprastructural organization of the transmembrane collagens XIII and XVII and the multiplexin collagens XV and XVIII is not known yet (panels 7 and 8). These collagens are in close vicinity to basement membranes and are likely to participate and/or interact with the different basement membrane networks. FACIT, fibril-associated collagens with interrupted triple helices; GAG, glycosaminoglycans. *Adapted from Myllyharju J, Kivirikko KI. Collagens, modifying enzymes and their mutations in humans, flies and worms. Trends Genet. 2004;20:33–43.*

keratinocytes also express a second transmembrane collagen, type XIII, which is a component of focal contacts.

The vascular basement membranes in the skin contain yet other collagens – namely, collagens VIII and XVIII. Collagen VIII builds hexagonal networks below the endothelial basement membranes (see Fig. 95.3) and, thus, structurally strengthens the vascular wall. Collagen XVIII is localized at the dermal side of vascular basement membranes. Its C-terminal fragment, endostatin (see Fig. 95.3), is proteolytically released from the collagen molecule and has independent biological functions that include inhibition of angiogenesis[3].

Most collagens in the skin are products of dermal fibroblasts. Exceptions include: (1) collagen XVII, a surface component of epidermal keratinocytes; (2) collagen VII, which can be synthesized by both keratinocytes and fibroblasts; and (3) collagens VIII and XVIII, which are produced by endothelial cells. Several genetic and acquired diseases are associated with abnormalities of skin collagens or the enzymes that process them (see Tables 95.5 & 95.6, and discussion below).

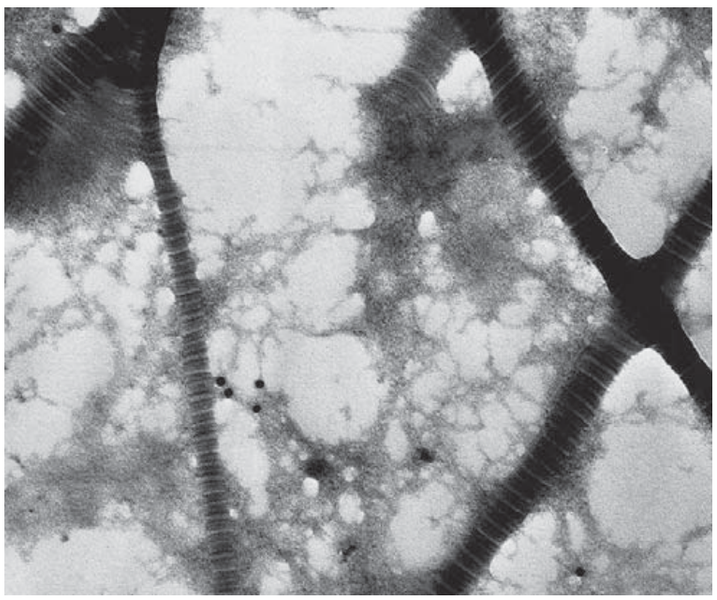

Fig. 95.4 Fibrillar and filamentous networks extracted from human skin. The large cross-banded fibrils represent dermal mixed fibrils containing collagens I, III and V; other minor collagens; and decorin (a proteoglycan). The cross-banding has a characteristic periodicity of 64 nm. The filamentous network in the background contains microfibrillar and basement membrane components. In this immunoelectron photomicrograph, the black dots are colloidal gold particles coupled to anti-collagen IV antibodies, indicating that basement membrane networks are strongly associated with the dermal fibrillar networks. *Courtesy, Uwe Hansen, MD.*

Elastic Fibers

The elasticity of many tissues, including the skin, depends upon the structure of elastic fibers, which can have variable compositions. A characteristic property of these fibers is that they can be stretched by 100% or more and still return to their original form. The main components of elastic fibers are elastin and microfibrils.

Elastin

Elastin is a highly cross-linked protein[8]. Its monomer, tropoelastin, contains repetitive modules of hydrophobic amino acids (Val-Gly-Val-Pro-Gly)$_n$ and exists in several tissue-specific splice variants. Ala- and Lys-rich repeats form critical cross-linking domains and may interrupt the basic repetitive structure. Lysyl oxidase, the same copper-dependent enzyme that catalyzes collagen cross-linking (see above), catalyzes the formation of desmosine cross-links between elastin molecules, which account for both the elasticity and insolubility of elastic fibers. Although elastin makes up the bulk of mature elastic fibers, the precise interactions between microfibrils and elastin that occur during elastic fiber assembly are not currently known. A current model based on coordinated, spatially and temporally regulated assembly is presented in Figure 95.5.

Microfibrils

Microfibrils (10 to 12 nm in diameter) insert into the basement membrane in a perpendicular orientation (classically referred to as "oxytalan fibers") and extend into the papillary dermis (Fig. 95.6), where they gradually merge with elastic fibers that contain a relatively small amount of elastin and form a plexus parallel to the dermal–epidermal junction (classically referred to as "elaunin fibers"). Such fibers appear to be continuous with the elastic fibers within the reticular dermis, which contain more abundant elastin. Microfibrils consist mainly of fibrillins[9], but they also contain and associate with other proteins, such as microfibril-associated glycoproteins (MAGPs), latent TGF-β binding proteins (LTBPs), fibulins, elastin microfibril interfacer (EMILIN)-1 and, in the papillary dermis, collagen XVI[8,9]. Fibrillins 1–3 are large glycoproteins that contain both epidermal growth factor (EGF) and cysteine (Cys) repeats. The EGF repeats bind calcium, which is required for stabilization of the protein. Fibrillin-1 interacts with perlecan in the epidermal basement membrane to attach the microfibrils to the dermal–epidermal junction.

A new paradigm has emerged from recent investigations demonstrating that, in addition to guiding elastic fiber assembly and providing structural support, fibrillins function together with LTBPs to regulate cell signaling[10]. The four members of the LTBP family are high-molecular-weight glycoproteins characterized by EGF-like and 8-Cys repeats, and they all associate with the small latent complex of TGF-β

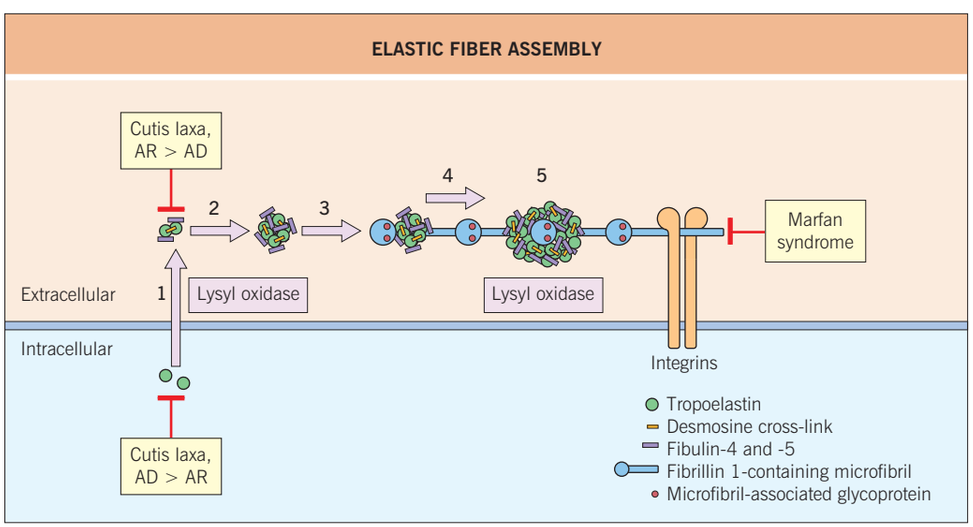

Fig. 95.5 Elastic fiber assembly. This model is based on current knowledge of interactions between elastin, microfibrillar proteins and cells in generating a functional elastic fiber. Tropoelastin is secreted and cross-linked by lysyl oxidase on the cell surface (**1**). Additional elastin is added to the aggregates (**2**), which are then transferred onto pre-existing fibrillin-1-containing microfibrils (**3**) that bind to the cell surface via integrins. Fibulin-4 and -5 interact with the elastin aggregates, enhance cross-linking and bind to fibrillin-1, thus augmenting the transfer of elastin aggregates to the microfibrils. The elastin aggregates and the microfibrils develop into larger structures (**4**) and are further cross-linked by lysyl oxidase (**5**) to form a functional elastic fiber. *Adapted from Wagenseil JE, Mecham RP. New insights into elastic fiber assembly. Birth Defects Res C Embryo Today. 2007;81:229–40.*

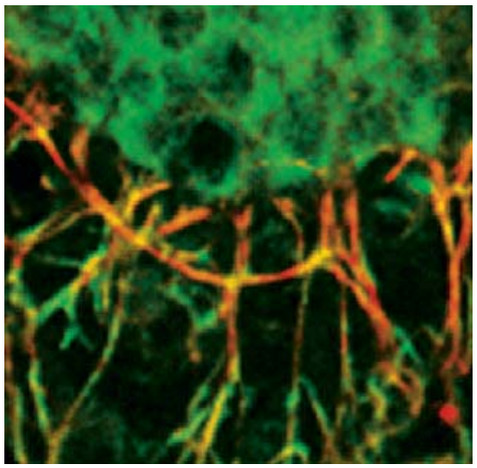

Fig. 95.6 Microfibrils in the papillary dermis. Confocal scanning microscopy of microfibrils, which emerge from the epidermal basement membrane and traverse the papillary dermis perpendicularly. The immunostaining is with antibodies to fibrillin-1 (red) and latent TGF-β complex (green). The orange–yellow color demonstrates co-localization of both proteins on the microfibrils.

(see below; Fig. 95.7). The LTBP-1/latent TGF-β complex (referred to as the large latent complex) binds to fibrillin-containing microfibrils. Together, they control bioavailability of TGF-β in the skin and other tissues. LTBPs contain multiple proteinase-sensitive sites, providing the means to solubilize the large latent complex from ECM structures, and both soluble and ECM-associated forms are known to exist. Another group of signaling molecules that can bind to fibrillins are the bone morphogenetic proteins (BMPs)[10]. These are secreted as cross-linked dimeric complexes that are associated through their prodomains, which interact directly with the amino-terminus of fibrillin. Fibrillins and LTBPs therefore have important roles in targeting latent, activatable TGF-β and BMPs into different ECMs. Thus, microfibrils serve not only as a force-bearing element and scaffolding for elastin deposition in the dermis, but also as an important repository for signaling molecules in the skin[2,9,10].

The Extrafibrillar Matrix

The dermal fibril networks and cells are embedded in an amorphous extrafibrillar material that binds water and provides the hydrated consistency of the skin. Previously, this amorphous material was presumed to be biologically unstructured and inert and was called the "ground substance". This prediction turned out to be incorrect – the extrafibrillar matrix is molecularly and structurally diverse, highly organized, and biologically active. It contains a number of proteoglycans and glycoproteins as well as hyaluronic acid and water. The functions of the extrafibrillar matrix are adapted to the biologic needs of each tissue. For example, during embryonic development, water-binding proteoglycans and glycosaminoglycans (GAGs) form a hydrated milieu for cell migration and proliferation. During development and tissue remodeling, glycoproteins of the extrafibrillar matrix are essential for formation of the correct tissue architecture.

GAGs are polysaccharides composed of sulfated and acetylated sugars with negative charges that can bind large amounts of ions and water. The most prominent and ubiquitous *protein-free* GAG is hyaluronic acid, a giant polysaccharide composed of thousands of N-acetylglucosamine/glucuronic acid disaccharides. Other GAGs, however, bind to proteins with a serine hydroxyl group, forming a proteoglycan (Fig. 95.8)[11]. Proteoglycans differ remarkably in their protein content and the number, type and length of their GAG side chains (Table 95.3). Four different *proteoglycan-bound* GAGs are known: chondroitin sulfate, dermatan sulfate, keratan sulfate and heparan sulfate[11]. Versican is the most important proteoglycan in the dermis (see Fig. 95.8). It is associated with the elastic fiber system and forms huge complexes with hyaluronic acid, which provide the skin with its tautness. Versican can be synthesized by fibroblasts, smooth muscle cells and epithelial cells.

Perlecan is a major heparan sulfate proteoglycan found in all basement membranes, including the epidermal basement membrane[12]. Small leucine-rich proteoglycans (SLRPs) are characterized by a protein core of Leu-rich repeats and Cys-bonded loops, with only one or two GAG chains. SLRPs that are found in the skin include decorin, biglycan, fibromodulin, lumican and keratocan[11]. Decorin has multiple functions; for example, it binds to collagen fibrils and TGF-β. Biglycan is a cell surface proteoglycan that also binds to TGF-β, and fibromodulin regulates formation of collagen-containing fibrils. Syndecans are transmembrane heparan sulfate proteoglycans that regulate cell adhesion to the ECM and subsequent cytoskeletal organization. Syndecans 1, 2 and 4 are expressed in the skin and can be found in keratinocytes, dendritic cells and fibroblasts, where they are thought to mediate "outside-in" cell signaling[11].

Laminins and Other Glycoproteins

Laminins, a family of basement membrane glycoproteins with 18 members (three of which are not yet well characterized), are expressed in all tissues. Each laminin isoform is a trimer consisting of an α-, β- and γ-chain[13,14]. The current laminin nomenclature (revised in 2005) is based on the chain composition, e.g. the laminin isoform that is composed of α_3-, β_3- and γ_2-chains is referred to as laminin 332 (formerly known as laminin 5)[15]. In the skin, the epidermal basement membrane contains laminins 332, 311 (formerly known as laminin 6) and 511 (formerly known as laminin 10), and the vascular basement membrane contains laminins 411 (formerly laminin 8) and 511. The structure, biologic functions and sequelae of genetic defects of laminins expressed in the skin are discussed in more detail in Chapters 28 and 32.

Other glycoproteins with important functions in the skin are listed in Table 95.4.

Functions of the Extracellular Matrix

Structural role of the extracellular matrix

In the past, the ECM was regarded as a structural scaffold that gave organs their shape and consistency. Over the past decade, considerable progress has been made in our understanding of the broad spectrum of distinct ECM suprastructures and their specific functions[1,2]. For example, corneal stroma contains stacked sheets of parallel fibrils with a uniform and small diameter. In each consecutive layer, the fibrils are oriented almost perpendicularly to the adjacent layers, rendering the tissue resistant to high tensile forces in two dimensions and, at the same time, allowing undisturbed penetration of visible light. Basement membranes are sheets with limited tensile strength but important tissue-specific properties that allow for particular cell attachments and regulate morphogenesis, differentiation and barrier functions. In the dermis, various ECM networks are embedded in the water-binding extrafibrillar matrix, maintaining the elasticity, resilience and tautness of the skin. At the dermal–epidermal junction, specific basement membrane-associated aggregates ensure strong adhesion of the epidermis and the dermis and, as a result, provide resistance against external shearing forces (see Ch. 28).

Regulation of cellular functions

In addition to their structural roles, ECMs are biologically active. *In vitro* studies and transgenic and knockout mouse models (see Ch. 3) have demonstrated the importance of ECMs as potent regulators of cellular functions during development, regeneration, wound healing, inflammation and tumorigenesis. ECM macromolecules can influence a multitude of cellular processes and events, such as adhesion, migration, cytoskeletal organization, determination of cell shape and polarization, division, differentiation and apoptosis.

Cells use a variety of receptors, such as integrins and cell surface proteoglycans, to recognize signals from the ECM[2]. The family of β_1 integrins represents the most common class of matrix receptors. The α-subunit of the integrin determines the specificity for individual matrix protein ligands, but the affinity and degree of specificity vary. Some integrins recognize only one ligand, while others can bind to several matrix proteins.

Signals from the ECM can have different effects on the cell[16]. For example, they can induce clustering of integrins on the cell surface and lead to formation of protein complexes between the cytoplasmic domains of the integrins and the cytoskeleton, thereby influencing cell shape. Alternatively, activation of integrins by the ECM can stimulate signal transduction pathways involving focal adhesion kinase (protein tyrosine kinase 2), paxillin and tensin. ECM–integrin interaction may also induce mitogen-activated protein kinase-mediated regulation of transcription,

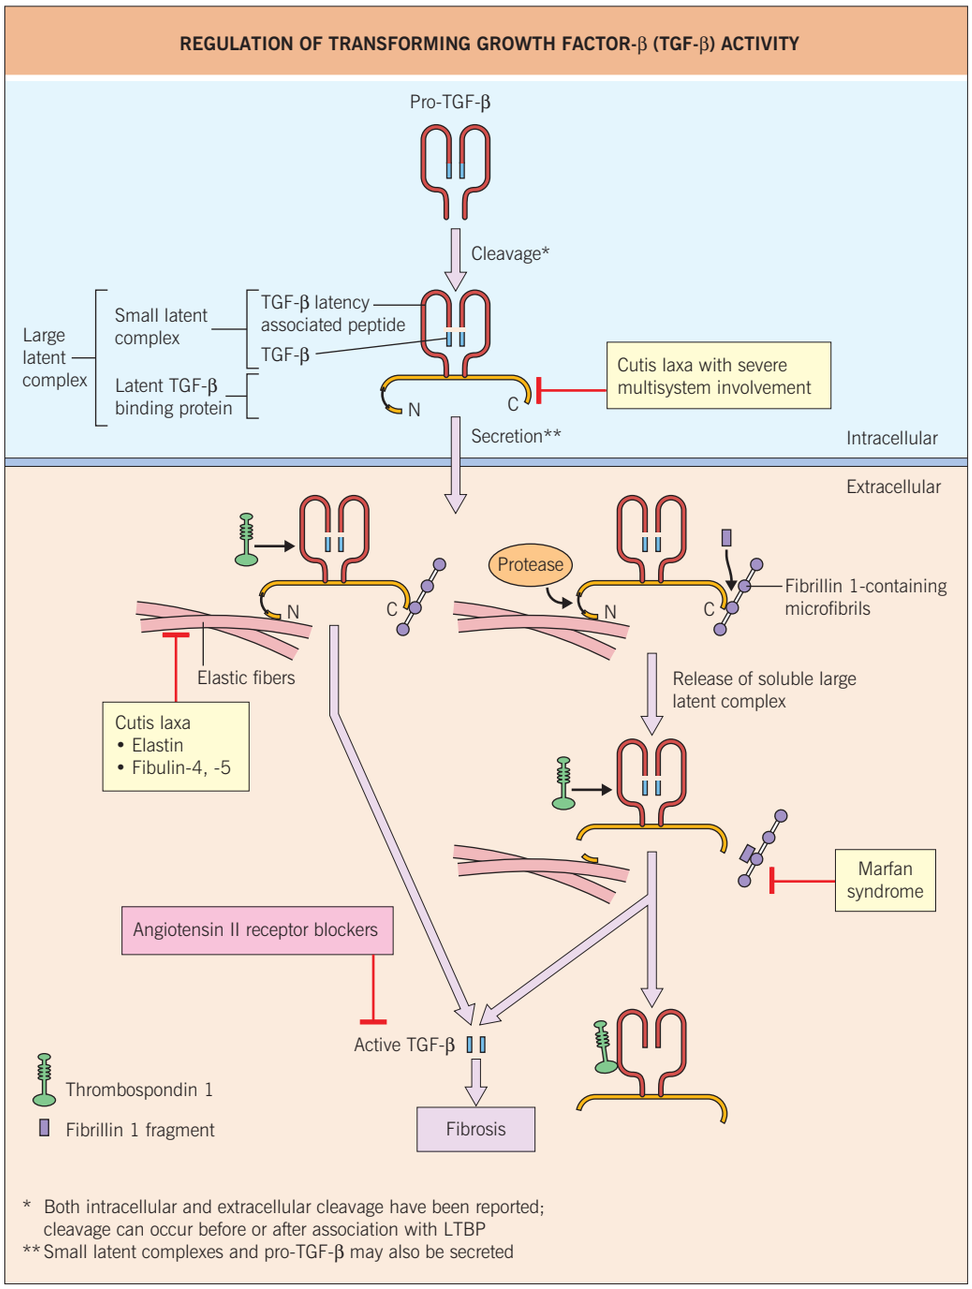

Fig. 95.7 Regulation of transforming growth factor-β (TGF-β) activity. TGF-β is synthesized as an inactive homodimeric propeptide, pro-TGF-β. After cleavage, mature TGF-β is sequestered in an inactive form via its continued association (now non-covalent) with the latency-associated peptide (LAP; forming the small latent complex) and covalent linkage of the LAP to the latent TGF-β binding protein (LTBP; forming the large latent complex). In addition, the large latent complex becomes attached to the extracellular matrix (ECM) via covalent linkage of the LTBP N-terminus with ECM proteins and non-covalent association of the LTBP C-terminus with fibrillin-1 (a member of the LTBP/fibrillin superfamily). Solubilization of the large latent complex from the ECM can occur via proteolytic cleavage of susceptible hinge regions within the LTBP and disruption of the fibrillin-1–LTBP interaction by fibrillin-1 fragments. Binding of ECM glycoproteins such as thrombospondin 1 to the LAP results in the release of active TGF-β that can bind to its receptors and promote fibrosis. *Adapted from August P, Suthanthiran M. Transforming growth factor beta signaling, vascular remodeling, and hypertension. N Engl J Med. 2006;354:2721–3.*

cell proliferation and differentiation. A further level of regulation of integrin-mediated ECM signaling results from the regulation of integrin activation through divalent cations, phospholipids and other agents[17].

Growth factors of the TGF-β family are potent regulators of ECM formation, in addition to their immunomodulatory functions and regulatory roles in cell growth[2]. They are secreted from cells as latent complexes containing TGF-β and its propeptide latency-associated peptide (LAP). In most cells, LAP is covalevntly linked to LTBP, forming the large latent complex (see above and Fig. 95.7). The secreted large latent complexes associate covalently with the ECM proteins via the N-termini of the LTBPs. TGF-β can be released from the complexes by various matrix-degrading proteinases originating from fibroblasts or inflammatory cells. In addition to the LTBPs, several other ECM molecules can bind to TGF-β and modulate its activity, such as thrombospondin and the core proteins of the proteoglycans decorin, biglycan and fibromodulin[2].

DISEASES RELATED TO ECM DEFECTS

Molecular studies of the genes and proteins involved in diseases of the ECM have produced a wealth of information regarding the normal biology of the ECM[18–21]. Putative functions for many matrix macromolecules were found for the first time, or confirmed, when mutations in their genes were shown to cause diseases. For example, functions of the minor fibrillar collagens V, IX and XI in controlling the collagen fibril diameter have been ultimately proven via studies of animal or human genetic disorders[3]. The fundamental roles of collagens VII and XVII in dermal–epidermal adhesion became clear when mutations in the corresponding genes were discovered in patients with hereditary epidermolysis bullosa (EB)[18]. Genetic ECM diseases with cutaneous manifestations are listed in Table 95.5, and the molecular mechanisms and pathophysiology of selected conditions are delineated below. Ehlers–Danlos syndrome (EDS), cutis laxa and pseudoxanthoma elasticum (PXE) are covered in more depth in Chapter 97, and EB is discussed in Chapter 32.

Ehlers–Danlos syndrome

The quantitatively major components of the collagen fibrils found in the ECMs of many tissues (e.g. skin, tendon, bone, cartilage) are collagens I, II (absent from the skin) and III. Smaller amounts of other "minor" collagens (e.g. types V, IX, XI, XII, XIV) are expressed in a tissue-specific manner[3]. Mutations in the genes encoding major or minor collagens can result in distinct constellations of

PROTEOGLYCANS OF THE SKIN			
Proteoglycan	**Gene**	**Size of the core protein (kDa)**	**Glycosaminoglycan (GAG) side chains (number)**

Table 95.4 Glycoproteins of the skin.

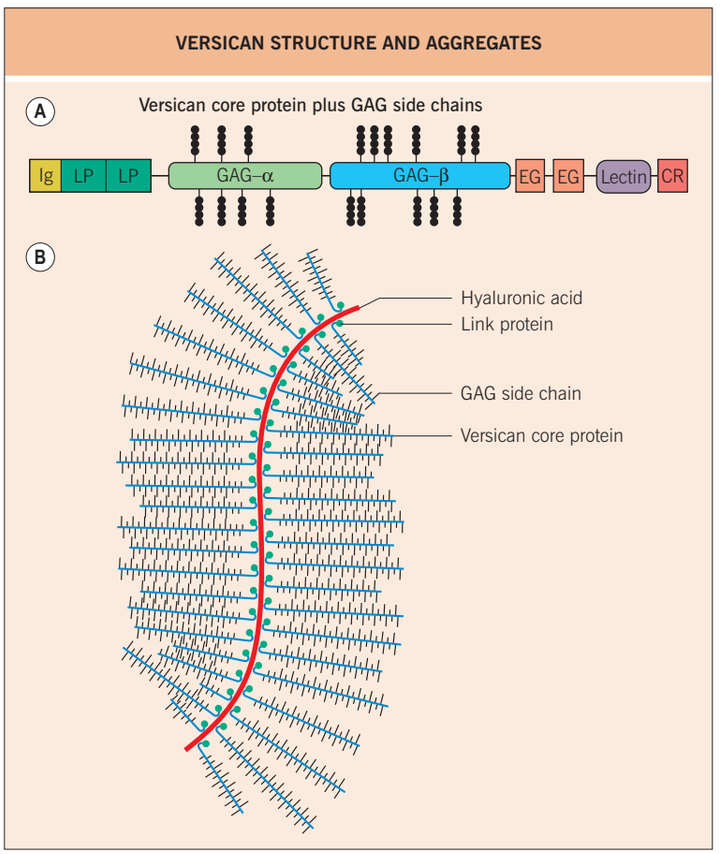

Fig. 95.8 Versican structure and aggregates. A The core protein contains several structural motifs important for glycosaminoglycan (GAG) and ligand binding. The N-terminal immunoglobulin-type repeat (Ig) is followed by two consecutive link-protein type modules (LP), which are involved in mediating the binding of the core protein to hyaluronic acid. The GAG binding domain, which comes in tissue-specific alternative splice variants, GAG-α and/or GAG-β, carries the GAG side chains. It is followed by structural motifs, including two epidermal growth factor-like repeats (EG), a C-type lectin domain (Lectin), and a complement regulatory protein-like module (CR). **B** In the dermis, versican can form huge aggregates with hyaluronic acid (red). The core protein (blue), which carries a number of GAG side chains (black), is bound to hyaluronic acid via its link-protein domain (green; LP module in the scheme in panel A). The aggregates can bind large amounts of water, and thus provide for the tautness of the skin. *Adapted from Iozzo RV. Matrix proteoglycans: from molecular design to cellular function. Ann Rev Biochem. 1998;67:609–52.*

abnormalities in different organs, including several types of EDS (see Ch. 97)[19]. For example, defects in the *COL3A1* gene encoding collagen III are responsible for the vascular type of EDS (type IV), an autosomal dominant condition that presents with thin translucent skin, excessive bruising, and life-threatening arterial, gastrointestinal and uterine ruptures. Mutations in the *COL3A1* gene have also been found in a subset of patients with arterial aneurysms as the primary clinical manifestation.

Alterations in several genes encoding minor fibrillar collagens can also cause severe connective tissue diseases, suggesting pivotal functions for these quantitatively minor components. The α_1- and the α_2-chains of collagen V co-polymerize with collagens I and III and have a role in the control of fibrillogenesis. They limit the solubility of macromolecules in the fibrils and regulate the geometry of lateral aggregation as well as the overall shapes and sizes of the collagen aggregates. Consistent with this concept, the classic type of EDS (types I & II) rarely results from mutations in the *COL1A1* gene encoding the α_1-chains of collagen I, whereas mutations in the *COL5A1* and *COL5A2* genes encoding the α_1- and α_2-chains of collagen V account for approximately 50% of patients[21]. Patients with this form of EDS exhibit variable degrees of skin hyperelasticity and fragility, atrophic scarring and joint hypermobility (Fig. 95.9A). Since collagen V is a heterotrimeric molecule consisting of α_1(V) and α_2(V) with or without α_3(V) chains, *COL5A3* is another candidate gene for EDS (although mutations in this gene have not been identified to date). Mutations in the gene encoding tenascin-X, a glycoprotein in the extrafibrillar matrix, can cause a recessive form of EDS with similar clinical findings of hyperextensible skin and joint hypermobility[21].

Mutations in genes that encode proteins involved in the post-translational modification of collagen (see above and Fig. 95.2) have been found to underlie other forms of EDS. For example, loss-of-function mutations in the lysyl hydroxylase 1 gene lead to abnormal lysyl hydroxylation and glycosylation of collagens in patients with the kyphoscoliosis type of EDS (type VIA), a recessive disease characterized by hyperextensible and fragile skin as well as hypermobile joints, scoliosis and ocular fragility. Recently, mutations in the gene encoding dermatan-4-sulfotransferase 1 (required for biosynthesis of dermatan sulfate) have been identified in patients with musculocontractural EDS (type VIB), which presents with craniofacial abnormalities, joint contractures and wrinkled palms together with the findings of the kyphoscoliosis type.

GENETIC EXTRACELLULAR MATRIX DISEASES OF THE SKIN				
Protein	**Gene**	**Inheritance**	**Disease**	**Phenotypic features in the skin* and other organs**
Collagen I (α1- and α2-chains)	*COL1A1*	AD	EDS, arthrochalasia (type VIIA)	***Skin hyperextensibility and fragility,*** joint hypermobility, congenital hip dislocation†
		AD	EDS, classic (type I; rare cause of this EDS type)	See below
	COL1A2	AD	EDS, arthrochalasia (type VIIB)	See above
		AR	EDS, cardiac valvular	Cardiac valve defects, otherwise similar to classic EDS (see below)
Collagen III	*COL3A1*	AD	EDS, vascular (type IV)	***Translucent, fragile skin with extensive bruising;*** arterial fragility, intestinal and uterine rupture‡
Collagen V (α1- and α2-chains)	*COL5A1* *COL5A2*	AD	EDS, classic (type I – severe; type II – milder)	***Skin hyperextensibility and fragility,*** joint hypermobility
Collagen VI	*COL6A1* *COL6A2* *COL6A3*	AD, AR	Ullrich disease	***Puffy skin,*** distal joint hypermobility, muscular dystrophy
Collagen VII	*COL7A1*	AD, AR	Dystrophic epidermolysis bullosa	***Skin fragility and blistering***
Collagen XVII	*COL17A1*	AR	Junctional epidermolysis bullosa	***Skin fragility and blistering***
Fibrillin-1	*FBN1*	AR	Marfan syndrome	***Striae,*** characteristic body habitus, aortic dilation/dissection‡
		AD	Congenital stiff skin syndrome	***Diffusely thick and hard skin, nodules on fingers,*** joint contractures, short stature, entrapment neuropathy
Elastin	*ELN*	AD > AR	Cutis laxa, AD > AR	***Lax, redundant skin***
Fibulin-4	*FBLN4*	AR	Cutis laxa, AR type I	***Lax, redundant skin;*** emphysema and arterial anomalies
Fibulin-5	*FBLN5*	AR > AD	Cutis laxa, AR type I > AD	***Lax, redundant skin;*** emphysema and arterial anomalies (AR form)
Latent TGF-β binding protein-4	*LTBP4*	AR	Cutis laxa with severe pulmonary, gastrointestinal and urinary abnormalities	***Lax, redundant skin;*** features in name of disorder, dysmorphic facies, joint hyperextensibility, hypotonia
TGF-β receptors 1 & 2	*TGFRB1* *TGFRB2*	AD	Loeys–Dietz syndrome (types I and II)‡	Aortic aneurysms, arterial tortuosity, skeletal anomalies, joint hypermobility; primarily in type II: ***translucent skin, easy bruising, atrophic scarring;*** primarily in type I: craniofacial anomalies
Tenascin-X	*TNXB*	AR	EDS, AR due to tenascin-X deficiency	***Skin hyperextensibility,*** joint hypermobility
		AD	EDS, hypermobility (type III)	***Variable skin hyperextensibility,*** joint hypermobility with recurrent dislocations
Extracellular matrix protein-1	*ECM1*	AR	Lipoid proteinosis	Hyalin deposition in the dermis and submucosal tissues, hoarse voice, intracranial calcifications
ABCC6 transporter	*ABCC6*	AR	Pseudoxanthoma elasticum (PXE)	***Yellowish papules, lax skin,*** retinal angioid streaks, cardiovascular disease
ATPase, $Cu2^{+}$-transporting, α-polypeptide	*ATP7A*	X-R	Occipital horn syndrome	***Lax skin,*** tortuous arteries, joint hypermobility, occipital calcifications
Solute carrier family 2, member 10 (a glucose transporter)	*SLC2A10*	AR	Arterial tortuosity syndrome	***Lax skin, ± telangiectasias on the cheeks,*** tortuous arteries, joint hypermobility
Solute carrier family 39, member 13 (a zinc transporter)	*SLC39A13*	AR	EDS-like spondylocheirodysplasia	***Skin hyperextensibility and fragility, atrophic scarring, wrinkled palms,*** joint hypermobility, growth retardation
Lysyl hydroxylase 1	*PLOD1*	AR	EDS, kyphoscoliosis (type VIA)	***Skin hyperextensibility and fragility,*** ocular fragility, joint hypermobility, scoliosis
Lysyl hydroxylase 3	*PLOD3*	AR	Bone fragility with contractures, arterial rupture and deafness	Features in name of disorder, acral ***blistering, easy bruising,*** dysmorphic facies, hypoplastic nails, osteopenia, cataracts, delayed growth and development
		AD	Epidermolysis bullosa simplex-like phenotype	***Skin fragility and blistering***
ADAMTS-2 (procollagen N-proteinase)	*ADAMTS2*	AR	EDS, dermatosparaxis (type VIIC)	***Sagging, doughy, fragile skin;*** characteristic facies

*Elastosis perforans serpiginosa can also develop in patients with EDS and pseudoxanthoma elasticum.
† A phenotype with features of both EDS and osteogenesis imperfecta has also been reported.
‡ The phenotype of Loeys–Dietz syndrome can mimic Marfan syndrome (type I) or vascular EDS (type II).

Table 95.5 Genetic extracellular matrix diseases of the skin. Diseases and phenotypic features are colored based on the primary cutaneous manifestation (when applicable) as follows: ***orange***, hyperextensible skin (as in classic EDS); ***pink***, extensively bruised skin (as in vascular EDS); ***peach–tan***, skin fragility with blistering (as in epidermolysis bullosa); ***light blue***, lax skin (as in cutis laxa); ***dark blue***, yellowish papules ± lax skin (as in pseudoxanthoma elasticum). ABCC6, ATP-binding cassette subfamily C member 6; AD, autosomal dominant; ADAM, a disintegrin and metalloproteinase; AR, autosomal recessive; EDS, Ehlers–Danlos syndrome; TGF, transforming growth factor; X-R, X-linked recessive.

GENETIC EXTRACELLULAR MATRIX DISEASES OF THE SKIN				
Protein	**Gene**	**Inheritance**	**Disease**	**Phenotypic features in the skin* and other organs**
Dermatan-4-sulfotransferase 1	*CHST14*	AR	EDS, musculocontractural[§]	***Skin hyperextensibility and fragility, wrinkled palms,*** ocular fragility, joint contractures and hypermobility, scoliosis, craniofacial abnormalities
Galactosyltransferase-I	*B4GALT7*	AR	EDS, progeroid	***Skin hyperextensibility,*** joint hypermobility, progeroid facies, osteopenia, mental and growth retardation
Vacuolar H^+-A2 subunit	*ATP6V0A2*	AR	Cutis laxa, AR type IIA Wrinkly skin syndrome	***Lax skin,*** facial dysmorphism, large fontanelles, microcephaly, delayed development ± growth, strabismus, joint hypermobility
Pyrroline-5-carboxylate reductase 1	*PYCR1*	AR	Cutis laxa, AR type IIB De Barsy syndrome (DBS)	***Lax skin,*** facial dysmorphism, large fontanelles, microcephaly, delayed development and growth, joint hypermobility; corneal opacities, cataracts & athetosis in DBS
Pyrroline-5-carboxylate synthetase	*ALDH18A1*	AR	Mental retardation, joint hypermobility and ***skin laxity***	Features in name of disorder, with or without hyperammonemia
γ-glutamyl carboxylase	*GGCX*	AR	PXE-like disorder with multiple coagulation factor deficiency	***Yellowish papules, lax skin,*** retinal angioid streaks, cardiovascular disease, bleeding diathesis
Golgin, RAB6-interacting	*GORAB*	AR	Gerodermia osteodysplastica	***Lax skin (primarily on dorsal hands and feet),*** progeroid facies with prognathism, short stature, osteoporosis
Ras and Rab interactor 2	*RIN2*	AR	Macrocephaly, ***alopecia, cutis laxa*** and scoliosis (MACS)	Features in name of disorder, facial dysmorphism, gingival hypertrophy, joint hyperextensibility
Filamin A (actin-binding protein 280)	*FLNA*	X-D	EDS, periventricular nodular heterotopia variant	***Variable skin hyperextensibility,*** aortic dilation, periventricular nodular heterotopia, joint hypermobility

*Elastosis perforans serpiginosa can also develop in patients with EDS and pseudoxanthoma elasticum.
[§]Exists on a spectrum with adducted thumb-clubfoot syndrome, which is caused by mutations in the same gene.

Table 95.5 Genetic extracellular matrix diseases of the skin (cont'd). Diseases and phenotypic features are colored based on the primary cutaneous manifestation (when applicable) as follows: ***orange***, hyperextensible skin (as in classic EDS); ***light blue***, lax skin (as in cutis laxa); ***dark blue***, yellowish papules ± lax skin (as in pseudoxanthoma elasticum). *ALDH18A1*, aldehyde dehydrogenase 18 family, member A1; AR, autosomal recessive; *CHST14*, carbohydrate sulfotransferase 14; EDS, Ehlers–Danlos syndrome; X-D, X-linked dominant.

Failure to cleave the N-propeptide from procollagen I causes the arthrochalasia type of EDS (types VIIA & VIIB), a dominant disorder that features severe joint hypermobility, including dislocations. The persistence of this propeptide on collagen I molecules drastically alters fibrillogenesis, and the fibrils that form are thin and highly irregular in diameter. Affected individuals typically have a splice-site mutation in the *COL1A1* or *COL1A2* gene that causes exon skipping and elimination of the cleavage site for ADAMTS-2 (procollagen I N-proteinase) in the proα_1(I) or proα_2(I) chain[21]. Loss-of-function mutations in the *ADAMTS2* gene itself cause another form of EDS, the dermatosparaxis type (type VIIC; Fig. 95.9B), in which (similar to collagen I in the arthrochalasia type), procollagen N-propeptides persist and sterically disturb polymerization of the collagen fibrils in the skin and other tissues[21]. This recessive condition has a distinct, severe phenotype that includes characteristic facies and sagging, fragile skin with a doughy consistency.

Cutis laxa

Cutis laxa is an uncommon ECM disease characterized by genetic heterogeneity and clinical variability (see Ch. 97); acquired variants also exist[19]. In all cases, the primary diagnostic feature is loose, hyperextensible skin with decreased resilience and elasticity, leading to an appearance of "too large skin" and premature aging (Fig. 95.9C). The skin changes are often accompanied by extracutaneous manifestations, including pulmonary emphysema, bladder diverticula and pulmonary artery stenosis. Histologically, there is marked fragmentation or diminution of elastic fibers.

Multiple genes are involved in the pathogenesis of recessive and dominant forms of cutis laxa (see Table 95.5), including those that encode the elastic fiber components elastin, fibulin-4 and fibulin-5[19,22,23]. A severe developmental syndrome featuring cutis laxa and extensive pulmonary, gastrointestinal and urinary abnormalities is caused by mutations in the latent TGF-β binding protein-4 gene (*LTBP4*), demonstrating that the role of TGF-β signaling in ECM assembly is essential for proper development[24].

Other inherited disorders are characterized by secondary effects on elastic fiber deposition or degradation[19]. For example, elastic fibers are calcified and fragmented secondary to decreased activity of anti-mineralization proteins in PXE (see below and Ch. 97), and elastic fibers are prematurely degraded due to unregulated elastase activity in patients with α_1-antitrypsin deficiency and some forms of acquired atrophoderma. Decreased or aberrant deposition of elastic fibers in certain tissues is also characteristic of Marfan syndrome.

Marfan syndrome

Fibrillin-1 is the major component of microfibrils and has an important structural role in elastic fibers. The highly homologous fibrillin-2 exhibits different spatial and temporal expression during development, and the functional relationship between the two molecules is not fully understood. Fibrillin-1 mutations underlie Marfan syndrome, an autosomal dominant disorder with variable connective tissue weakness of the skin as well as skeletal, ocular and cardiovascular systems[10,19,21]. The cutaneous manifestations can include striae and elastosis perforans serpiginosa. In addition to structural disturbances in elastic fibers and microfibrils due to mutant fibrillin, emerging data suggest that fibrillin mutations preclude or decrease the sequestration of latent TGF-β complexes (see above), thus rendering them more prone to activation. This leads to unproductive tissue remodeling, abnormal cell behavior and loss of ECM integrity[10]. Mutations in the gene encoding fibrillin-2 lead to a Marfan syndrome-like condition called congenital contractural arachnodactyly, which is characterized by skeletal abnormalities in the absence of ocular and cardiovascular features[21].

Heterozygous mutations in the genes encoding the TGF-β receptors 1 and 2 underlie Loeys–Dietz syndrome. Type I Loeys–Dietz syndrome is characterized by aortic aneurysms, generalized arterial tortuosity, craniofacial malformations (e.g. bifid uvula, cleft palate, hypertelorism), skeletal anomalies and joint laxity. Type II Loeys–Dietz syndrome has less craniofacial involvement and also features cutaneous manifestations similar to those of the vascular type of EDS, including translucent

Fig. 95.9 Phenotypic manifestations of genetic extracellular matrix defects. A Classic Ehlers–Danlos syndrome (type II) with slightly overstretchable skin results from mutations in the collagen V genes. **B** Dermatosparaxis showing fragile skin with purpura and a "doughy" texture due to mutations in the gene for ADAMTS-2. **C** Cutis laxa can be caused by mutations in several different genes, including those encoding the elastic fiber components elastin, fibulin-4 and fibulin-5. **D** Junctional epidermolysis bullosa with skin blisters after minimal friction can be caused by mutations in the collagen XVII gene. *B, Courtesy, Julie V Schaffer, MD. C, Courtesy, Thomas Schwarz, MD.*

skin, easy bruising and atrophic scarring[20,21]. The phenotypic overlap with Marfan syndrome and vascular EDS is not surprising considering the association between fibrillin and latent TGF-β and the role of TGF-β in regulating collagen expression.

Pseudoxanthoma elasticum

PXE (see Ch. 97) is a heritable disorder characterized by cutaneous, vascular and ocular (classically angioid streaks) involvement that results from the accumulation of fragmented and calcified elastic fibers in the dermis, arterial walls and Bruch's membrane, respectively. The skin findings – laxity and yellowish papules and plaques – are the most common and often the earliest manifestations of PXE.

Although PXE has traditionally been considered as a prototypic heritable ECM disorder, it is caused by mutations in the gene that encodes the ATP-binding cassette (ABC) subfamily C member 6 (ABCC6) transmembrane transporter, which is primarily expressed in the liver[25]. Mutations in the γ-glutamyl carboxylase gene (*GGCX*) can also lead to a PXE-like phenotype together with deficiency in vitamin K-dependent coagulation factors. GGCX catalyzes the vitamin K-dependent γ-glutamyl carboxylation that activates the matrix gla protein (MGP), which functions as an inhibitor of pathologic mineralization, as well as coagulation factors. Although the substrates of ABCC6 remain to be determined, it is speculated that this transporter may export a GGCX cofactor (e.g. a vitamin K–glutathione conjugate) from the liver into the circulation, with loss of ABCC6 function resulting in reduced activation of MGP and, as a consequence, connective tissue calcification[25].

Epidermolysis bullosa

EB represents a diverse group of hereditary diseases characterized by mechanical fragility of the skin that results in cutaneous blister formation (see Ch. 32)[18,26]. Mutations in the collagen VII gene (*COL7A1*) cause both dominant and recessive forms of dystrophic EB[27]. Because collagen VII is a component of the anchoring fibrils, cleavage occurs at the level of these fibrils in the uppermost dermis (just below the lamina densa). Patients with severe forms of recessive dystrophic EB are nullizygotes harboring mutations that lead to premature termination codons[27]. As a consequence, anchoring fibrils and collagen VII are absent from the skin. Milder forms of dystrophic EB are associated with missense mutations in one or both copies of the *COL7A1* gene. When heterozygous, such mutations often exert dominant-negative effects, since structurally aberrant collagen VII molecules are assembled and incorporated into the anchoring fibrils, rendering them functionally inadequate.

Mutations in the *COL17A1* gene encoding the α_1(XVII) chain of collagen XVII, a homotrimeric transmembrane collagen localized to the hemidesmosome-anchoring filament complex of basal keratinocytes[7], can cause junctional EB. This recessive EB subtype is characterized by

cleavage within the lamina lucida of the epidermal basement membrane. Patients with two null alleles of *COL17A1* tend to have widespread blistering (generalized non-Herlitz junctional EB; Fig. 95.9D), whereas those with two missense mutations and some preservation of collagen XVII function exhibit milder clinical phenotypes (localized non-Herlitz junctional EB)[28].

Laminin 332 (formerly known as laminin 5) is a major structural component of the lamina densa, where it secures epidermal adhesion by linking $\alpha_6\beta_4$ integrin on the cell surface to collagen VII of the anchoring fibrils. Like defects in collagen XVII, mutations in the genes encoding the three polypeptide chains of laminin 332 cause junctional EB. The most severe form, Herlitz junctional EB, is often fatal during infancy; it results from null mutations and a complete lack of laminin 332 in the skin. Missense mutations are associated with milder forms of the disease (e.g. generalized non-Herlitz junctional EB)[28].

Other hereditary matrix diseases with skin symptoms

Muscular dystrophies (Ullrich disease [more severe], Bethlem myopathy [milder]) can be caused by mutations in the *COL6A1, COL6A2* and *COL6A3* genes encoding the α_1(VI), α_2(VI) and α_3(VI) chains of collagen VI[19]. This collagen forms beaded filaments/microfibrils in several tissues, including the muscle and skin. Extramuscular manifestations – a puffy consistency of the skin and joint hyperlaxity – likely reflect abnormalities of the microfibrillar networks in the dermis and synovia.

Mutations in the extracellular matrix protein-1 gene (*ECM1*) cause lipoid proteinosis, a recessive multi-organ disease characterized by the accumulation of hyalinized material in many tissues, including the dermis (see Ch. 48)[29]. ECM-1 is a 85 kD glycoprotein that binds to fibulins, perlecan and laminin 332[30].

Loss-of-function mutations in both copies of the *PLOD3* gene encoding lysyl hydroxylase 3, an enzyme with important roles (including glucosyltransferase and galactosyltransferase activities) in the post-translational modification of collagens[31], have been found to underlie a severe, multi-organ connective tissue disease which features fragile skin that is prone to blistering as well as bruising (see Table 95.5). *PLOD3* haploinsufficiency has also been documented in a family with a phenotype limited to skin blistering. *In vitro* studies have demonstrated that even a moderate decrease in lysyl hydroxylase 3 activity has deleterious consequences for the deposition and organization of the ECM[32].

Extracellular matrix components as autoantigens

Several ECM components are targeted in autoimmune diseases affecting the kidney, cartilage and skin (Table 95.6). Autoantigens in these conditions include the α_3- and α_5-chains of collagen IV in Goodpasture disease[33], collagen II in relapsing polychondritis, and collagens VII and XVII in the autoimmune blistering diseases EB acquisita and bullous pemphigoid, respectively[34]. The autoantigen in p200 pemphigoid, a novel autoimmune subepidermal blistering disease, was recently identified as the γ1-chain of laminin located at the dermal–epidermal junction[35].

Antibodies to fibrillin-1 have been described in patients with systemic sclerosis (especially individuals of Choctaw Native American or Japanese descent) and morphea (especially those with linear and generalized subtypes). The mutated protein in lipoid proteinosis, ECM-1, is the target of autoantibodies in patients with lichen sclerosus, which also features dermal hyalinization[29].

The immunodominant epitopes in autoimmune disorders are often localized to one or several distinct structural domains and, therefore, recombinant domains can be employed for precise diagnostic testing. It is thought that binding of autoantibodies to ECM components disturbs their supramolecular aggregation or ligand binding, which in turn leads to functional deficiency and corresponding clinical symptoms.

EXTRACELLULAR MATRIX COMPONENTS AS TARGETS IN AUTOIMMUNE DISEASES

Disease(s)	Autoantigen(s)	Biologic and clinical features
Goodpasture disease	Collagen IV, α_3- and α_5-chains	Glomerulonephritis, pneumonitis with hemoptysis
Relapsing polychondritis, arthritis	Collagen II; collagen IX	Chondritis of ear, larynx and trachea; arthritis
Pemphigoid (various subtypes)	Collagen XVII (BP, PG, MMP)*; laminin 332 (MMP); laminin-γ1 chain (p200 pemphigoid)	Skin blistering
Epidermolysis bullosa acquisita	Collagen VII	Skin blistering, fragility
Bullous eruption of systemic lupus erythematosus (SLE)	Collagen VII	Skin blistering with underlying SLE
Scleroderma†	Fibrillin-1; PDGF receptor	Skin fibrosis
Lichen sclerosus	Extracellular matrix (ECM) protein-1	Inflammation, epidermal atrophy, hyalinization of the dermis

*Also the autoantigen in linear IgA bullous dermatosis.
†Not confirmed in large patient cohorts.

Table 95.6 Extracellular matrix components as targets in autoimmune diseases. BP, bullous pemphigoid; PDGF, platelet-derived growth factor; MMP, mucous membrane (cicatricial) pemphigoid; PG, pemphigoid gestationis.

Skin aging and other acquired ECM abnormalities

Changes in the dermal ECM contribute to both chronologic and photoinduced skin aging. Morphologic hallmarks of aged skin include reduced microfibrils in the papillary dermis, disorganized elastic fibers, and reduction and weakening of other ECM fibril networks. Although the molecular details of these ECM changes are not fully understood, it is generally accepted that the structurally perturbed dermal networks cannot bind adequate amounts of hyaluronic acid and, consequently, water, which leads to lax and wrinkled skin. The biosynthetic activity of all cells diminishes during aging, but reduced synthesis of dermal collagens by fibroblasts is a particularly prominent feature. This has been shown to be mediated by decreased TGF-β and connective tissue growth factor (CTGF) signaling[36]. Increased degradation of ECM components also occurs and destabilizes network structures. The deleterious effects of UV irradiation include release of cytokines from the epidermis and generation of reactive oxygen species. These mediators induce inflammatory processes and stimulate expression and activation of a spectrum of matrix metalloproteinases and serine proteinases such as elastase, which can degrade ECM networks[37].

Weakened ECMs lead to disturbed wound healing and a bruising tendency in scurvy, a disease resulting from an insufficient supply of ascorbic acid (vitamin C). This vitamin is an essential cofactor for prolyl and lysyl hydroxylases, which modify collagens during their biosynthesis and are required for cross-linking[4].

In fibrotic disorders such as scleroderma (systemic sclerosis) and keloids, thickened skin reflects excessive ECM in the dermis. The reasons for the accumulation are not fully understood; inflammation-mediated upregulation of ECM synthesis (e.g. collagen, fibrillins, proteoglycans) via TGF-β and CTGF are believed be causative mechanisms in scleroderma (see Ch. 43). A keloid is an overgrowth of dense fibrous tissue in the skin as a result of trauma. The cellularity of keloids is increased, and the ECM shows abnormal thin fibrils that are haphazardly organized in dense nodules. Various abnormalities of ECM biosynthesis have been measured in keloid fibroblasts *in vitro*, and matrix assembly is perturbed[38]. Gene profiling studies indicated a role for multiple fibrosis-related pathways in the pathogenesis of keloids[39], but the regulatory mechanisms leading to excessive ECM accumulation still remain unclear. A genetic predisposition for keloid formation seems to exist. Among Caucasians, 5–10% of individuals with keloids have a positive family history; among Africans, the prevalence is much higher.

Animal Models

Mouse models for ECM diseases have produced new insights into pathomechanisms, allowed further assessment of abnormalities observed in human diseases, and enabled testing of novel therapeutic approaches[40]. For example, mice with a targeted mutation in one

collagen V gene were noted to have thin, fragile skin with disorganized and loosely packed fibrils, which pointed to collagen V genes as candidates for EDS prior to the detection of human mutations. Likewise, a tenascin-X-deficient mouse reproduced the symptoms of human recessive EDS, i.e. greatly disturbed biomechanical properties of the skin but milder joint abnormalities.

For fibrillin-1, transgenic mouse models have been used to discern genotype–phenotype correlations. Analyses of different models revealed an association between fibrillin-1, microfibril assembly and TGF-β signaling, showing that a defect in the latter is central to Marfan syndrome pathogenesis and phenotypic variability[9,10].

Targeted ablation of the elastin gene in mice leads to fatal obstructive arterial disease characterized by subendothelial cell proliferation and reorganization of smooth muscle, suggesting that elastin has a role in regulating cellular proliferation[8]. The phenotype of heterozygous mice suggested that human supravalvular aortic stenosis may be caused by functional hemizygosity of the elastin gene, which was confirmed by mutational analysis in humans. Of note, while loss-of-function elastin mutations that lead to haploinsufficiency are associated with supravalvular aortic stenosis, cutis laxa can result from dominant-negative missense mutations in the elastin gene.

Collagen VII-deficient mice recapitulate the clinical, genetic, immunohistochemical and ultrastructural characteristics of recessive dystrophic EB in humans[19]. Collagen VII knockout mice die during the first 2 weeks of life, while mice with hypomorphic mutations have a severe phenotype but live into adulthood[41]. These mice have provided significant information regarding the molecular pathogenesis of recessive dystrophic EB, and they have become useful for testing cellular and molecular approaches to therapy[42]. Mice lacking collagen XVII exhibit a moderately severe form of junctional EB[43] and are also being used to study novel therapeutic approaches.

Mice harboring disrupted proteoglycan genes have demonstrated the importance of these molecules for cutaneous tautness and integrity[11]. The decorin knockout mouse has fragile skin with markedly reduced tensile strength, associated with coarser, irregular ECM fibers in the skin and tendons; these findings established the fundamental role for decorin in regulating collagen fibrillogenesis *in vivo*. Mice with a disrupted syndecan 4 gene have a significant wound-healing defect and impaired angiogenesis within granulation tissue, suggesting that this cell surface proteoglycan has an important role in wound healing and angiogenesis.

Abnormalities in collagen-processing enzymes also occur spontaneously in animals. Bovine dermatosparaxis is a recessively inherited connective tissue disorder that, like the human form of this disease, features extreme fragility and droopiness of the skin as well as joint laxity. Both human and bovine dermatosparaxis result from mutations in the gene encoding ADAMTS-2, which excises the N-propeptide of procollagens I and II[19].

Potential for Biologically Valid Molecular Therapies

Clarification of the molecular mechanisms underlying ECM disorders forms a basis for novel therapeutic approaches. Diseases well suited for such therapies include recessive forms of EB caused by a lack of collagen VII, collagen XVII or laminin 332. Currently, preclinical and clinical pilot trials on gene-, cell- and protein-based therapies are ongoing for recessive dystrophic and junctional EB (reviewed in refs 44 & 45).

Gene therapy with delivery of gene-corrected stem cells or vectors directing the expression of the missing protein has the advantage of continuous protein biosynthesis in the skin but may carry a risk of oncogenesis. Retroviruses, lentiviruses and non-viral transposon-mediated gene transfer have been successfully used to restore collagen VII or laminin 332 synthesis in keratinocytes *in vitro*. In the first human pilot study on EB, laminin-β3-deficient skin of an adult patient was corrected by transplantation of stem cell-enriched epidermal grafts transduced *ex vivo* with a retroviral vector expressing normal *LAMB3* cDNA. The treatment resulted in sustained synthesis and proper assembly of functional laminin 332 and, clinically, an absence of blistering in the corrected epidermis.

For recessive dystrophic EB, cell- and protein-based therapies have also shown promise. Murine and human studies have demonstrated that intradermal injection of allogeneic fibroblasts leads to increased deposition of collagen VII at the dermal–epidermal junction and clinical improvement for several months. Intriguingly, a systemic approach using bone marrow transplantation after total or partial myeloablation has resulted in substantial proportions of donor cells in the skin, increased collagen VII deposition at the dermal–epidermal junction and variably decreased blistering in children with recessive dystrophic EB. Protein therapy with intradermal injection of recombinant human collagen VII (which has a long half-life) has been shown to result in correct protein deposition within anchoring fibrils and reduced blistering in mouse models of dystrophic EB.

For the treatment of dominant disorders, strategies to silence expression of the mutated allele (preventing dominant-negative effects) or to supplement with normal protein (correcting haploinsufficiency) hold promise[46].

Better understanding of molecular and cellular disease mechanisms disclosed an unexpected pharmacologic approach to the treatment of Marfan syndrome[47]. Since excessive TGF-β signaling contributes to the development of aortic aneurysms in individuals with this condition, it was hypothesized that TGF-β antagonists might prevent or partially reverse this disease manifestation. Indeed, angiotensin II receptor blockers are now successfully employed to prevent aortic root dilation in patients with Marfan syndrome[48].

Future development of successful therapies for connective tissue disorders will also depend on the progress in our understanding of "alloy" formation by matrix macromolecules. This endeavor will be facilitated not only by the analysis of aggregate formation by matrix macromolecules or their mixtures *in vitro*, but also by the elucidation of further genetic defects and their consequences in animal or human diseases, as well as the generation of transgenic animals as models for human disorders. This combined information will help us to understand and treat not only inherited ECM diseases but also many common disorders currently considered as acquired.

96 Perforating Diseases

Ronald P Rapini

Synonyms: ■ Hyperkeratosis follicularis et parafollicularis in cutem penetrans: Kyrle disease ■ Acquired perforating dermatosis: acquired reactive perforating collagenosis, acquired reactive perforating dermatosis, perforating disorder of uremia

Key features

- Group of disorders with transepidermal elimination of collagen, elastic tissue or necrotic connective tissue
- Papules or nodules with keratotic plugs
- Elastosis perforans serpiginosa is associated with genetic diseases or penicillamine administration and involves elastic tissue; lesions are typically annular and most commonly occur on the neck
- Reactive perforating collagenosis occurs after minor trauma, involves collagen, and often involves the upper extremities
- Acquired perforating dermatosis is almost always associated with diabetes mellitus or the pruritus of renal failure; it favors the lower extremities of adults
- Broadband or narrowband UVB phototherapy appears to be the most effective treatment for acquired perforating dermatosis

INTRODUCTION

The perforating diseases (Table 96.1) are a group of papulonodular skin disorders characterized by keratotic plugs or crusts in which dermal connective tissue "perforates" or is eliminated through the epidermis. There are two prototypic perforating diseases, both of which can be inherited. They are reactive perforating collagenosis (RPC), in which primarily collagen fibers perforate the epidermis[1], and elastosis perforans serpiginosa (EPS), in which primarily elastic fibers perforate. The third major perforating disease is acquired perforating dermatosis, which usually develops during adulthood in association with diabetes mellitus and/or the pruritus of renal failure[2]. Many textbooks traditionally list "perforating folliculitis" as the fourth perforating disease[3], but, in the opinion of the author, this seems unjustified. It does not appear to be a specific entity, since perforation or rupture of follicles occurs in a wide variety of diseases classified as folliculitis, regardless of whether the pathogenesis involves bacteria, fungi, *Demodex* mites, physical trauma or other mechanisms.

Some authorities have expanded the concept of the preceding so-called "primary" perforating diseases to include a variety of unrelated "secondary" perforating disorders in which transepidermal elimination of a substance occurs as a secondary component of a primary dermatosis (Table 96.2). As in most of the preceding perforating disorders, the epidermis often becomes hyperplastic, eventually surrounds the material to be extruded, and subsequently causes the material's elimination via normal keratinocyte maturation. Some of these disorders are discussed elsewhere in this text and involve perforation of endogenous substances, exogenous foreign material, infectious organisms, granulomas, and even neoplastic cells[4].

HISTORY

In 1916, Kyrle reported a diabetic woman with generalized hyperkeratotic nodules, which he called "hyperkeratosis follicularis et parafollicularis in cutem penetrans". Lutz first described EPS as "keratosis follicularis serpiginosa" in 1953, and, in 1955, Miescher described the histologic findings, naming it "elastoma intrapapillare perforans verruciforme". Mehregan, Schwartz and Livingood reported the first child with RPC in 1967. Mehregan and Coskey expanded the concept of perforating disease to include perforating folliculitis in their article in 1968.

EPIDEMIOLOGY

The perforating diseases are found worldwide, without any clear racial predilection. The very rare childhood-onset form of RPC is commonly familial, and childhood-onset EPS is occasionally familial. Although the exact inheritance pattern for both is still uncertain, isolated inherited EPS may have an autosomal dominant pattern. EPS affects nearly four times more men than women, but the sex distribution is about equal in RPC and acquired perforating dermatosis. Perforating folliculitis is said to be more common in women. In patients receiving maintenance hemodialysis, acquired perforating dermatosis is observed in an estimated 4.5% to 11%[5].

PATHOGENESIS

The precise pathogenesis for the perforating disorders is unknown. As it is unlikely that dermal connective tissue or hair shafts actively perforate into the epithelium, some have argued that "transepidermal elimination" is a more accurate term. The term "perforating" is embedded in the dermatologic lexicon, however, and is easier to say. Epithelium becomes hyperplastic and eventually surrounds the abnormal connective tissue, just as it appears to do with wood splinters or other foreign bodies. In acquired perforating dermatosis, pruritus probably leads to chronic scratching, which results in epithelial hyperplasia, as in prurigo nodularis. Indeed, many of the patients have common prurigo nodules in addition to classic perforating lesions. The possibility has been raised that enlargement of a hyperkeratotic plug could lead to penetration through the base of the hyperplastic epidermis, i.e. the perforation is caused by the plug above rather than being due to the abnormal connective tissue below.

Primary perforating diseases may be due to either genetic or acquired abnormalities of collagen or elastic fibers. In EPS, as well as some cases of acquired perforating dermatosis in which elastic fibers were perforating, enhanced expression of elastin receptors was detected in the epidermis surrounding the elastic material[6]. Recently, it was proposed that scratching exposes keratinocytes to *a*dvanced *g*lycation *e*nd product (AGE)-modified extracellular matrix proteins, in particular collagen types I and III. This would then lead to terminal differentiation of keratinocytes via the AGE receptor (CD36), followed by upward movement of keratinocytes along with glycated collagen[7].

Fibronectin levels have been shown to be increased in the serum of patients with diabetes mellitus and uremia, and fibronectin has also been found to be increased within the skin at sites of transepidermal elimination[8]. This may be significant, since fibronectin plays a role in epithelial cell signaling, locomotion and differentiation. It binds to type IV collagen (the type found in basement membranes) and to keratinocytes, and may incite epithelial proliferation and perforation. In one study of RPC, the investigators demonstrated that it was type IV collagen that was being transepidermally eliminated[9]. Increased expression of transforming growth factor-β_3 (TGF-β_3), matrix metalloproteinase-1 (MMP-1), and tissue inhibitor of metalloproteinase-1 (TIMP-1) has been observed in lesional skin of acquired RPC[10], but this enhanced expression may be a reflection of concurrent wound healing.

MAJOR PERFORATING DISEASES					
Disease	**Incidence**	**Time of onset**	**Most common location**	**Perforating substance**	**Associations**
Familial reactive perforating collagenosis (RPC)	Very rare	Childhood	Arms, hands, sites of trauma	Collagen	None
Elastosis perforans serpiginosa (EPS)	Rare, M > F	Childhood, early adulthood; variable with penicillamine-induced EPS	Neck, face, arms, other flexural areas	Elastic tissue	Genetic diseases (see Fig. 96.13), penicillamine
Perforating folliculitis	Common	Early adulthood	Trunk, extremities	Necrotic material	May simply be ordinary folliculitis with follicular rupture, i.e. not a specific entity
Acquired perforating dermatosis, includes acquired RPC, Kyrle disease* and, rarely, acquired EPS	Common (10% of dialysis patients)	Adulthood	Legs or generalized	Necrotic material, collagen or, uncommonly, elastic tissue	Diabetes, renal disease, pruritus, rarely liver disease; may be end stage of perforating folliculitis
Perforating calcific elastosis	Very rare, more common in black women	Adulthood	Abdomen, periumbilical	Calcified elastic tissue	Multiparity, obesity, hypertension

*In the opinion of some authors.

Table 96.1 Major perforating diseases. F, female; M, male.

SECONDARY PERFORATING DISEASES
ENDOGENOUS SUBSTANCES
Chondrodermatitis nodularis helicis Hematomas Perforating pseudoxanthoma elasticum Perforating calcinosis Gout (urate crystals) Papular mucinosis (mucin)
GRANULOMAS
Perforating granuloma annulare (Fig. 93.10) Necrobiosis lipoidica Sarcoidosis Rheumatoid nodule
EXOGENOUS FOREIGN MATERIAL
Silica Wood splinters
INFECTIOUS DISEASES
Chromomycosis Leprosy Schistosomiasis
TUMOR CELLS
Melanoma Paget's disease Mycosis fungoides Pilomatricoma Nevus sebaceus

Table 96.2 Secondary perforating diseases. For a more extensive list, see ref. 4.

Fig. 96.1 Reactive perforating collagenosis. This keratotic papule on the upper extremity followed minor trauma in a healthy man who had developed similar papules since childhood.

Other proposed pathomechanisms include abnormal vitamin A or D metabolism, enzyme release from neutrophils[11], and microangiopathy related to diabetes. Deposition of substances such as uric acid, hydroxyapatite or silicon[12] has also been implicated in the pathogenesis of perforating disorders.

CLINICAL FEATURES

Reactive Perforating Collagenosis

Familial RPC is a rare disorder that begins during childhood[1,13]. After superficial trauma, patients develop keratotic papules that reach a size of 5–8 mm over the following 3–4 weeks (Fig. 96.1). The Koebner phenomenon may occur, in which injury to the skin results in the formation of new lesions, often in a linear distribution. Koebnerization is more commonly observed with RPC than with the other perforating disorders, but it has been reported with all of them. Arms and hands are the most common sites of involvement in RPC. The papules tend to spontaneously resolve over 6–10 weeks. Verrucous perforating collagenoma (*collagenome perforant verruciformé*) is a very rare nonfamilial variant of RPC in which severe trauma to the skin results in verrucous papules with transepidermal elimination of collagen[14]. Acquired RPC that begins during adulthood usually occurs in association with diabetes mellitus or renal insufficiency, and these cases are best classified as acquired perforating dermatosis, even though the histopathology can be identical to the inherited form of RPC.

Elastosis Perforans Serpiginosa

EPS is a rare disorder beginning during childhood or early adulthood. About 40% of cases occur in association with other genetic disorders, including Down syndrome, Ehlers–Danlos syndrome, osteogenesis imperfecta, Marfan syndrome (Fig. 96.2), pseudoxanthoma elasticum (PXE), Rothmund–Thomson syndrome, and acrogeria. In a survey of pediatric dermatologists, the majority performed a detailed history and careful physical examination, but did not embark upon an extensive search for these genetic disorders in an otherwise healthy child or adolescent with EPS[15].

Fig. 96.2 Elastosis perforans serpiginosa in the setting of Marfan syndrome. Annular papules and plaques developed on the ear.

Fig. 96.3 Elastosis perforans serpiginosa. Papules arranged in an annular configuration on the neck.

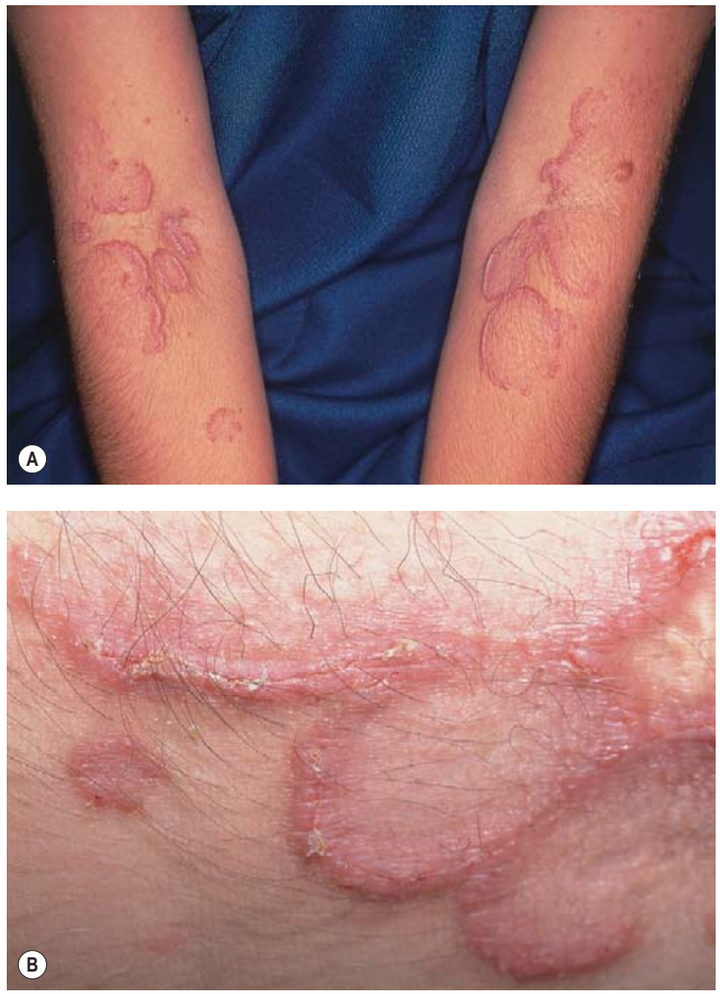

Fig. 96.4 Penicillamine-induced elastosis perforans serpiginosa. A Multiple annular plaques favoring the antecubital fossae. **B** Closer view with foci of hyperkeratosis at sites of transepidermal elimination.

Very rare cases of EPS associated with renal failure (clearly more rarely encountered than the acquired form of RPC) are best classified as acquired perforating dermatosis. EPS has also been reported to be induced by the drug penicillamine, which disrupts desmosine cross-links within elastin (see Ch. 97)[16]. Because penicillamine is used to treat Wilson disease, the possibility of copper metabolism playing a role in the pathogenesis of EPS has been raised, but EPS is also seen in patients with cystinuria or rheumatoid arthritis who have received penicillamine.

Lesions of EPS are keratotic, 2–5 mm papules that tend to be arranged in a serpiginous or annular pattern, most commonly on the lateral neck (Fig. 96.3), but also on the face, arms (Fig. 96.4) or other flexural areas. The rings of papules may reach several centimeters in diameter. Most patients experience no symptoms or only mild pruritus. Like RPC, the lesions may spontaneously resolve, but they tend to persist longer, often for several years.

Acquired Perforating Dermatosis and Kyrle Disease

Acquired perforating dermatosis has been used as a catch-all term for those examples of perforating disease arising in adults, usually in association with diabetes mellitus and/or the pruritus of renal failure[2]. The majority of the patients with chronic renal failure are receiving dialysis, and most of those with diabetes have associated nephropathy[17]. This disorder can also occur in conjunction with other causes of pruritus, from insect bites and scabies to lymphoma and hepatobiliary diseases, including primary biliary cirrhosis and malignancies. In addition, acquired perforating dermatosis may arise in sites of trauma (e.g. healing herpes zoster) or following exposure to several classes of drugs (e.g. TNF-α inhibitors, bevacizumab, sirolimus, indinavir). While an association with hypothyroidism and hyperparathyroidism has been reported, most of these patients also had established risk factors (e.g. diabetes, nephropathy). In a series of 22 patients with acquired perforating dermatosis, three were healthy and had no known associated illnesses and two were renal transplant recipients[17].

Acquired perforating dermatosis occurs most commonly on the legs (Fig. 96.5), but generalized or widely scattered papules or nodules can be seen (Figs 96.6 & 96.7). Extensor surfaces are favored over flexures and the mucous membranes are spared. A clue to the diagnosis is the presence of a central keratotic core, which is sometimes physically removed by the patient. Occasionally, a giant variant is observed, where lesions are up to 2 cm in diameter[18]. Rarely, secondary infections due to bacteria (e.g. *Staphylococcus aureus*), atypical mycobacteria (e.g. *Mycobacterium abscessus*) or fungi (e.g. *Mucor* spp.) have been reported.

Largely on the basis of their histologic findings, patients with acquired perforating dermatosis have been variably designated in the literature as having RPC, EPS[2], perforating folliculitis[13] or perforating PXE. Since the pathologic findings vary from lesion to lesion in the same patient, it seems unwise to subclassify patients in this way. Since some, but not necessarily all, of these lesions appear to be follicular, and since manipulation of the lesions by patients frequently alters the histologic changes, the term "acquired perforating dermatosis" was proposed to

Fig. 96.5 Acquired perforating dermatosis. Numerous papules and nodules on the legs in a patient with both renal failure and diabetes mellitus.

Fig. 96.7 Acquired perforating dermatosis. Note the linear arrangement of the keratotic papules (Koebner phenomenon).

Fig 96.6 Acquired perforating dermatosis. Keratotic papules on the arm of a diabetic woman on hemodialysis. Note the central keratotic core which is sometimes dislodged by the patient.

Fig. 96.8 Perforating calcific elastosis. When a biopsy was performed from the elevated edge of this supraumbilical plaque in a multiparous African-American woman, resistance was felt, as well as a grinding sound.

encompass all of these cases. Furthermore, since Kyrle had used the phrase "follicularis et parafollicularis" to emphasize that not all lesions were proved to be centered on follicles, the eponym Kyrle disease has been used synonymously with acquired perforating dermatosis by some authorities[2]. However, others do not consider Kyrle disease to be an entity, or prefer to define it as merely representing the presence of end-stage excoriated hyperplastic nodules of folliculitis[2].

Perforating Calcific Elastosis

This disorder is characterized by plaques that favor the abdomen, especially the periumbilical region of middle-aged, obese, hypertensive, multiparous black women (Fig. 96.8)[19]. Involvement of the breast in patients with renal disease has also been observed. The plaques may be verrucous or have keratotic papules at their periphery. In histologic sections stained with H&E or von Kossa or Verhoeff-van Gieson stains, calcified elastic fibers (identical to those in PXE) are seen undergoing transepidermal elimination. However, affected patients do not have the other clinical findings of PXE. Similar transepidermal elimination has been observed in patients who treated their dermatitis with a commercially available calcium salt water normally used for making bean curd[20] or had their dermatitis exposed to calcium chloride contained in ice-melting salt.

PATHOLOGY

In all the perforating diseases, there is a plug of crusting or hyperkeratosis, with variable parakeratosis, depending upon the stage of the lesion (Fig. 96.9A). As the plug enlarges, epithelial hyperplasia develops, sometimes with dyskeratosis of keratinocytes. At the site of perforation, the epithelial hyperplasia often resembles an elephant snout or crab claw. However, sections from multiple levels through the tissue may need to be examined to find the site of perforation. Some lesions may have aggregates of neutrophils in the dermis, while older lesions, particularly those of EPS, tend to have lymphocytes, macrophages or multinucleated giant cells in the dermis at the site of perforation.

In RPC, collagen fibers are seen within the plug or within the epidermis (Figs 96.9B & 96.10), whereas in EPS, elastic fibers are seen

A Hyperplastic epidermis clutches the increased dermal elastic fibers like a claw. **B** Transepidermal elimination of neutrophils and elastic fibers from the dermis through a channel in the epidermis.

Fig. 96.10 Reactive perforating collagenosis. Transepidermal elimination of red collagen fibers through the spinous layer and into the stratum corneum (Verhoeff–van Gieson stain).

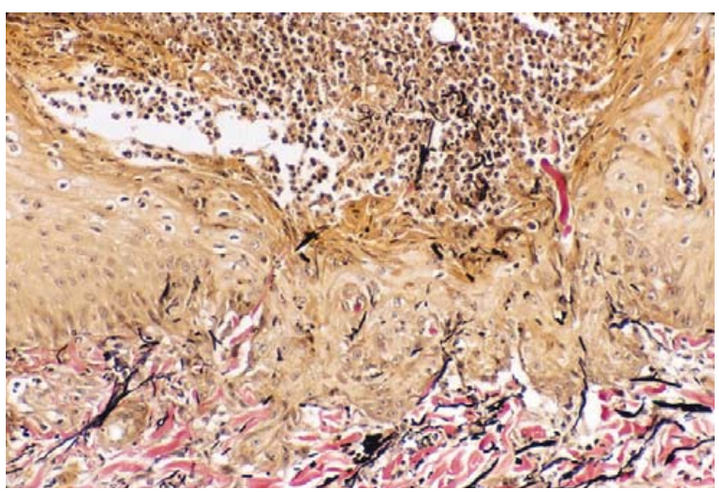

Fig 96.12 Acquired perforating dermatosis. Transepidermal elimination of both collagen (red) and elastic fibers (black) into a crust with many neutrophils is seen (Verhoeff–van Gieson stain).

DIFFERENTIAL DIAGNOSIS OF PERFORATING DISEASES
REACTIVE PERFORATING COLLAGENOSIS AND ACQUIRED PERFORATING DERMATOSIS
Excoriations from a variety of causes (prurigo simplex)
Prurigo nodularis
Folliculitis
Arthropod bites
Perforation of exogenous foreign material
Perforation of endogenous substances
Multiple keratoacanthomas
Dermatofibromas
If Koebner phenomenon: psoriasis, lichen planus, verrucae
ELASTOSIS PERFORANS SERPIGINOSA (RESEMBLES OTHER ANNULAR DISEASES; SEE CH. 19)
Granuloma annulare, Tinea — Common annular diseases
Sarcoidosis
Actinic granuloma (annular elastolytic giant cell granuloma)
Perforating pseudoxanthoma elasticum
Porokeratosis
Discoid lupus erythematosus

instead (in the same location; Fig. 96.11). In RPC, the dermal connective tissue adjacent to the plug appears unremarkable, while in EPS, an increased amount of brightly eosinophilic elastic tissue is often present in the superficial dermis. The Verhoeff–van Gieson stain is most helpful, because collagen fibers appear red and elastic fibers appear black (Fig. 96.12). However, in EPS, the elastic fibers higher up in the epidermis may lose their ability to stain black. In penicillamine-induced EPS, characteristic "lumpy-bumpy" elastic fibers with lateral buds resembling a "bramble bush" are seen in both lesional and non-lesional skin.

Biopsy findings in acquired perforating dermatosis vary according to the stage of evolution of the lesion. The histology may be identical to childhood RPC or EPS, or perforating folliculitis. In other cases, it may be less specific, with amorphous degenerated material within the perforations. This material often cannot be clearly identified as collagen or elastic fibers, but sometimes both are present (see Fig. 96.12)[2].

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes other disorders characterized by papules or nodules with central keratotic plugs or crusts (Table 96.3). When the Koebner phenomenon occurs, other disorders that can also arise in a linear pattern should be considered, e.g. psoriasis, lichen planus and verrucae. EPS may be confused with other disorders that are annular or serpiginous (see Ch. 19), but usually the individual keratotic plugs within the ring make it distinctive. Histologically, elastic fibers are commonly observed within the epidermis at the base of keratoacanthomas or any condition that leads to pseudoepitheliomatous hyperplasia, especially healing wounds.

Since many patients with acquired perforating dermatosis have coexisting folliculitis and prurigo nodularis, it is important to realize that these patients may have multiple different types of lesions at different stages of development and that a biopsy of just one lesion may not be representative of the entire process. Figure 96.13 provides an algorithm for the approach to the patient with a primary perforating disorder.

TREATMENT

Table 96.4 summarizes the various treatments that have been reported, most of which are anecdotal or based upon small case series. There

TREATMENT OF PERFORATING DISEASES
TOPICAL
Retinoids (e.g. tretinoin, tazarotene)[21] (3)
Corticosteroids (3)
Menthol (3)
Salicylic acid (3)
Sulfur (3)
Benzoyl peroxide (3)
Emollients (3)
Imiquimod (3)
SYSTEMIC
Antihistamines (e.g. doxepin) (3)
Corticosteroids (intralesional, intramuscular, oral) (2)
Retinoids (vitamin A, acitretin, isotretinoin)[16] (2)
Antibiotics (e.g. doxycycline, clindamycin, erythromycin, tetracycline, rifampin)[22,23] (3)
Methotrexate (3)
Charcoal (3)
Allopurinol[18] (3)
OTHER
Avoid trauma and scratching (wearing gloves, trimming of fingernails, behavior modification, transcutaneous nerve stimulator[24]) (3)
Cellophane-tape stripping (for EPS) (3)
Phototherapy (broadband or narrowband UVB; PUVA)[25] (2)
Cryotherapy (3)
Electrosurgical destruction (3)
Laser ablation (e.g. CO_2, Er:YAG, pulsed dye)[26] (3)
Excision of larger bothersome lesions (3)
Renal transplantation, if kidney failure[12] (3)

Table 96.4 Treatment of perforating diseases. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. EPS, elastosis perforans serpiginosa.

have been no well-designed, placebo-controlled studies of therapeutic interventions. The inherited forms of RPC and EPS generally remain mild and localized and are therefore not so problematic. Local measures may be successful, but some authors have declared treatment to be largely ineffective. The patient with mild RPC may be satisfied simply to avoid trauma and wait for lesions to resolve spontaneously.

EPS may be treated with local cryotherapy, tangential excision, electrosurgical destruction, lasers (e.g. pulsed dye, Er:YAG) or cellophane tape stripping. However, aggressive treatment is more likely to result in scarring. As with RPC, spontaneous resolution of lesions makes it difficult to evaluate therapies.

Treatment of generalized acquired perforating dermatosis or extensive perforating folliculitis is often difficult. Sedating antihistamines and other typical "anti-itch" treaments (see Ch. 6) are often prescribed in an attempt to reduce the associated pruritus. Phototherapy (broadband or narrowband UVB or PUVA) is a particularly good choice for patients with renal disease, since it often relieves their coexisting pruritus. Other therapies that are sometimes helpful include intralesional corticosteroids and oral[14] or topical retinoids. Anecdotally, some patients have attributed rapid improvement to a change in the type of dialysis tubing or equipment employed, or even an alteration in the methods used during the actual dialysis procedure (personal observation). Occasional dialysis patients with acquired perforating dermatosis have been cured after renal transplantation[12].

Heritable Disorders of Connective Tissue 97

Franziska Ringpfeil and Jouni Uitto

Chapter Contents

Ehlers–Danlos syndrome *1607*
Pseudoxanthoma elasticum *1612*
Cutis laxa *1615*

Key features

- Heritable connective tissue disorders with skin involvement comprise a phenotypically diverse group of conditions
- Recognition of characteristic skin findings is often critical to establishing the diagnosis and identifying associated internal involvement, which may include life-threatening cardiovascular disease (e.g. in the vascular type of Ehlers–Danlos syndrome and pseudoxanthoma elasticum)
- Heritable connective tissue disorders can be caused by mutations in genes encoding structural extracellular matrix (ECM) proteins (e.g. collagens, components of elastic fibers), enzymes that modify these structural proteins, and other proteins with effects on the ECM (e.g. via transport or regulatory functions)

Introduction

Heritable connective tissue diseases manifest with a broad range of phenotypic abnormalities, and the relative degrees of cutaneous and extracutaneous involvement vary considerably. At one end of the spectrum, the clinical findings are mild and limited to a single organ such as the skin, while at the other end of the spectrum, the cutaneous manifestations may be part of multi-organ pathology causing considerable morbidity and even mortality[1,2]. Tremendous progress has been made toward understanding the molecular bases of heritable disorders of connective tissue. This has led to improved classification and prognostication, with better recognition of phenotypic spectrums and relationships among disorders.

The connective tissue meshwork is critical for organogenesis during embryonic development and homeostatic maintenance of tissues, with complex protein assembly and cell-matrix interactions. The principal fibrillar components of the extracellular matrix (ECM) of the skin are networks consisting of collagen and elastic fibers (see Ch. 95). Recognition of the complex interactions among the various types of collagen, elastic fibers (which consist of elastin and a number of associated microfibrillar proteins) and other ECM components has allowed the identification of critical metabolic as well as structural features that are a prerequisite for normal physiologic functions. The study of heritable disorders of connective tissue has demonstrated the considerable impact of disruption of various individual components of the ECM and related proteins.

Classic, "primary" heritable disorders of connective tissue caused by mutations in the genes encoding collagen and structural components of elastic fibers include several forms of Ehlers–Danlos syndrome (EDS) and cutis laxa (CL), respectively. In addition to primary defects in the genes for structural components themselves or enzymes modifying these proteins, the ECM can be perturbed by seemingly unrelated pathologic processes. Examples of the latter, which can be considered as "secondary" connective tissue disorders, include pseudoxanthoma elasticum (PXE) and homocystinuria.

This chapter provides detailed discussions of EDS, PXE and CL. In addition, Marfan syndrome, homocystinuria, osteogenesis imperfecta and Buschke–Ollendorff syndrome are presented in Table 97.1. These and other genetic diseases that affect the ECM of the skin are also summarized in Table 95.5.

EHLERS–DANLOS SYNDROME

Synonym: ■ Cutis hyperelastica

Key features

- Clinically and genetically heterogeneous group of connective tissue disorders caused by defective function of various collagens, collagen-processing enzymes and tenascin-X (a collagen-associated protein)
- Autosomal dominant and autosomal recessive inheritance patterns
- Cutaneous features include hyperextensible and fragile skin, easy bruising and poor wound healing
- Extracutaneous features include joint hypermobility, scoliosis and, particularly in the vascular type, a significant risk of spontaneous arterial, intestinal or uterine rupture

History

A survey of the literature reveals descriptions of patients with features of Ehlers–Danlos syndrome (EDS) as early as the mid-1600s. The first comprehensive report of the systemic nature of this condition was published in 1892 by Tschernogobow[3]. Drs Ehlers and Danlos, Danish and French dermatologists, respectively, contributed to a comprehensive clinical description in the early 1900s, and this constellation of findings became known as the Ehlers–Danlos syndrome in 1936. The genetic nature of EDS was noted in 1949, and soon thereafter it was suggested that the phenotype resulted from defects in the collagen meshwork. The genetic heterogeneity of EDS became evident in the 1960s, and molecular defects in collagen synthesis were first described in 1972.

In the past, EDS was divided into as many as 11 subtypes (numbered I–XI) based primarily upon clinical features. In 1997, a consensus conference was held and a revised nosology was proposed[4] (Table 97.2). Currently, the molecular basis of most major forms of EDS is known[5,6].

Epidemiology

Features suggestive of EDS (e.g. loose-jointedness) are present in a relatively large number of individuals in the general population especially in certain African groups. However, more stringent diagnostic criteria that include findings in the skin and joints, at a minimum, limit the incidence of EDS to approximately 1 in 5000. Although all forms of EDS can cause considerable morbidity, only one variant, the vascular type (previously type IV), typically causes premature demise of affected individuals[7].

Pathogenesis

EDS is a clinically and genetically heterogeneous group of connective tissue disorders caused by defective function of the collagen meshwork (Fig. 97.1). The collagen family is now known to consist of 28 distinct proteins that differ in their tissue distributions and functions[8] (see Ch. 95). Each collagen consists of three α-chain polypeptides, which

ADDITIONAL HERITABLE DISORDERS OF CONNECTIVE TISSUE WITH CUTANEOUS FINDINGS

Disease	Cutaneous findings	Extracutaneous manifestations	Inheritance	Associated gene/protein product
Marfan syndrome	Striae, elastosis perforans serpiginosa, decreased subcutaneous fat on extremities	Skeletal abnormalities (e.g. disproportionately long limbs, arachnodactyly, scoliosis), lens subluxations (upward), cardiovascular abnormalities (e.g. dilation/dissection of ascending aorta*)	AD	*FBN1*/fibrillin-1 defects (the major component of microfibrils)†
Homocystinuria	Malar flush, livedo reticularis, diffuse pigmentary dilution, tissue paper-like scars	Marfanoid habitus, lens subluxations (downward), venous and arterial thrombosis‡, mental retardation	AR	*CBS*/cystathionine synthase enzyme deficiency (resulting in increased plasma homocysteine§); rarely, methylenetetrahydrofolate reductase, 5-methyltetrahydrofolate-homocysteine methyltransferase, or 5-methyltetrahydrofolate-homocysteine methyltransferase reductase deficiency (enzymes that convert homocysteine back to methionine)
Osteogenesis imperfecta	Thin skin	Bone fragility, blue sclerae, dentinogenesis imperfecta (in a subset of patients)	AD	*COL1A1*, *COL1A2*/type I collagen defects
Buschke–Ollendorff syndrome	Connective tissue nevi (dermatofibrosis lenticularis disseminata); occasionally cutaneous sclerosis associated with melorheostosis	Osteopoikilosis ("spotted" bones); occasionally melorheostosis (sclerotic bone resembling "dripping candle wax" on radiographs; reflects a postzygotic "second hit" in the *LEMD3* gene); rarely otosclerosis	AD	*LEMD3*/LEM domain-containing 3, an antagonist of bone morphogenic protein (BMP) and TGF-β signaling

*In addition to traditional treatment with β-blockers, angiotensin II receptor blockers (e.g. losartan), which antagonize pathogenic transforming growth factor (TGF)-β signaling, can prevent aortic root dilation in patients with Marfan syndrome; administration of doxycycline, which inhibits metalloproteinases-2 and -9, may also be of benefit.
†Mutations in the genes encoding TGF-β receptors 1 and 2 can lead to a phenotype that mimics Marfan syndrome.
‡Methionine-restricted, cysteine-supplemented diet plus pyridoxine recommended.
§Elevated plasma homocystine and homocysteine can be detected in patients with homocystinuria (but only homocysteine in hyperhomocysteinemia).

Table 97.1 Additional heritable disorders of connective tissue with cutaneous findings. Other rare genetic diseases of the extracellular matrix are listed in Table 95.5. AD, autosomal dominant; AR, autosomal recessive.

are synthesized as precursor molecules, pro-α-chains; a trimeric collagen molecule may be either a homotrimer or heterotrimer (i.e. consisting of the same versus two or three genetically different kinds of polypeptides, respectively). There are 43 different pro-α-chains, each encoded by a distinct gene[8].

The pathogenesis of EDS can involve mutations in genes for collagen-processing enzymes as well as those encoding collagen α-chains. The latter result in either dominant-negative effects (e.g. disruption of trimers and fibrils due to incorporation of mutant collagen α-chains) or haploinsufficiency. The precise phenotype depends upon the nature of the mutation(s) and the type of collagen or other protein that is affected.

Lysyl hydroxylase deficiency, caused by mutations in the corresponding gene, *PLOD*, results in reduced hydroxylysine content of collagen polypeptides and an altered cross-linking profile of collagen fibrils. This leads to the recessively inherited kyphoscoliosis type of EDS (previously known as type VIA). Mutations affecting another collagen-processing enzyme, the procollagen I N-peptidase (encoded by the *ADAMTS2* gene) that is responsible for the cleavage of amino-terminal propeptides from triple-helical type I procollagen, result in the formation of irregular and thin collagen fibrils with reduced mechanical properties. The collagen fibrils appear "hieroglyphic" in cross-section and contain type I collagen with an intact N-propeptide, termed pN-collagen. Procollagen I N-peptidase deficiency leads to the recessively inherited dermatosparaxis type of EDS (previously known as type VIIC).

Dominant-negative effects leading to EDS are caused by mutations in different collagen genes, including those encoding α-chains of type I (*COL1A1, COL1A2*), type III (*COL3A1*) and type V (*COL5A1, COL5A2*) collagens. Characteristically, these types of genetic lesions are splice site mutations resulting in an in-frame deletion of a single exon, or missense mutations resulting in a glycine substitution in the collagenous domain. Since the expression levels of these "mutated" polypeptides is the same as for the normal chains and they are incorporated into the polymeric collagen molecules, they affect the triple helix formation and/or thermal stability of the collagen triple helices by a dominant-negative mechanism. The presence of the mutant chains typically results in defective secretion of collagen molecules, and, as a consequence, the collagen fibrils are often reduced in amount as well as structurally abnormal.

Haploinsufficiency is caused by a heterozygous loss-of-function mutation, usually associated with a premature termination codon. These types of mutations often result in unstable mRNA that undergoes accelerated decay, leading to an absence of the corresponding polypeptide. Haploinsufficiency can also be caused by a missense mutation encoding a polypeptide that cannot be incorporated into collagen triple helices. Haploinsufficiency occurs when the synthesis of only 50% of the normal amount of the collagen is not enough to form fully functional fibrils, thus resulting in a disease phenotype.

Both dominant-negative mutations in *COL3A1* and haploinsufficiency of type III collagen can cause the vascular type of EDS (previously known as type IV). Collagen III is an important component of arterial and intestinal walls and a less abundant component of dermal connective tissue. However, a reduced amount of type III collagen leads to small or variably sized dermal collagen fibrils and thinning of the dermis, emphasizing the pivotal role of type III collagen in fibrillogenesis. A decreased amount of collagen III in the dermis has also been detected in some patients with the periodontitis (previously known as type VIII) and kyphoscoliosis types of EDS (which, unlike vascular EDS, are not caused by *COL3A1* mutations).

The classic type of EDS (previously known as types I and II) can be caused by dominant-negative mutations in *COL5A1* and *COL5A2* or (in 30–50% of cases) haploinsufficiency of type V collagen (*COL5A1*). The role of type V collagen in collagen fibrillogenesis is to limit fibril diameter, explaining the approximately 25% increase in fibril diameter that is observed by electron microscopy in affected individuals. Mutations in the genes encoding the pro-α-chains of type I collagen (*COL1A1*, *COL1A2*) that correspond to the cleavage site of procollagen N-peptidase result in the dominantly inherited arthrochalasia type of EDS (previously known as types VIIA and VIIB), while procollagen I N-peptidase deficiency leads to dermatosparaxis, a recessively inherited condition.

Complete tenascin-X deficiency (i.e. via biallelic null mutations) leads to an autosomal recessive form of EDS with features similar to those of classic EDS[9]. Tenascin-X is an ECM protein that is thought to have a role in reinforcing associations among collagen fibrils. The

CLASSIFICATION OF EHLERS–DANLOS SYNDROME				
EDS type*	**Traditional classification†**	**Clinical features**	**Inheritance**	**Mutated gene/protein**
Classic	I, II	Hyperextensible skin, joint hypermobility, atrophic scars, easy bruising, absence of the inferior labial and lingual frenula	AD, AR‡	*COL5A1*, *COL5A2*/α_1- and α_2- chains of type V collagen; *TNXB*/tenascin-X Rarely, *COL1A1*/α_1-chain of type I collagen
Hypermobility	III	Joint hypermobility, pain and dislocations; absence of inferior labial and lingual frenula	AD	*TNXB*/tenascin-X (~10% of affected individuals, predominantly female)
Vascular	IV	Thin, translucent skin; arterial, gastrointestinal and uterine rupture; excessive bruising, small joint hypermobility, characteristic facies	AD	*COL3A1*/α_1-chain of type III collagen
Kyphoscoliosis	VIA	Hyperextensible and fragile skin, neonatal hypotonia, joint hypermobility, congenital scoliosis, ocular fragility	AR	*PLOD1*/lysyl hydroxylase§
Musculocontractural	VIB	Hyperextensible and fragile skin, wrinkled palms, joint contractures and hypermobility, scoliosis, ocular fragility, craniofacial abnormalities	AR	*CHST14*/dermatan-4-sulfotransferase 1 (allelic with adducted thumb–clubfoot syndrome)
Arthrochalasia	VIIA, VIIB	Hyperextensible and fragile skin, severe joint hypermobility with congenital bilateral hip dislocation, scoliosis	AD	*COL1A1*, *COL1A2*/α_1- and α_2-chains of type I collagen
Dermatosparaxis	VIIC	Severe skin fragility, sagging and redundant skin that is soft and doughy, easy bruising, hernias, distinctive facies	AR	*ADAMTS2*/procollagen I N-peptidase
EDS, cardiac valvular		Cardiac valve defects, otherwise similar to classic EDS (see above)	AR	α_2-chain of type I collagen
EDS, progeroid		Skin hyperextensibility, joint hypermobility, progeroid facies, osteopenia, mental and growth retardation	AR	*B4GALT7*/galactosyl transferase-1
EDS, periventricular nodular heterotopia variant		Variable skin hyperextensibility, aortic dilation, periventricular nodular heterotopia, joint hypermobility	X-D	*FLNA*/filamin A (actin-binding protein 280)
EDS-like spondylocheirodysplasia		Skin hyperextensibility and fragility, atrophic scarring, wrinkled palms, joint hypermobility, growth retardation	AR	*SLC39A13*/solute carrier family 39, member 13 (a zinc transporter)

*According to the 1997 Villefranche Consensus Meeting[4].
†Replaced by the Consensus classification[4].
‡The classic forms due to type V collagen mutations are inherited in an autosomal dominant (AD) fashion, while those caused by tenascin-X deficiency are autosomal recessive (AR).
§Analysis of the urine for an increased deoxypyridinoline:pyridinoline ratio can be used as a screening test for kyphoscoliosis-type EDS.

Table 97.2 Classification of Ehlers–Danlos syndrome (EDS). The traditional EDS types V (X-linked), VII (periodontitis) and X (fibronectin) have unknown molecular bases and are not included in the current nosology. Previous EDS types IX and XI have been reclassified as occipital horn syndrome (see Table 97.6) and familial joint hypermobility syndrome, respectively. AD, autosomal dominant; ADAMTS2, *a d*isintegrin-like *a*nd *m*etalloprotease domain with *t*hrombospondin type 1 motifs 2; AR, autosomal recessive; COL, collagen; PLOD1, *p*rocollagen-*l*ysine 1, 2-*o*xoglutarate 5-*d*ioxygenase 1; X-D, X-linked dominant.

pathogenic consequences of tenascin-X deficiency have been substantiated by the observation of hyperextensible skin with reduced tensile strength in *Tnx*-null mice[10] ("knockout mice"; see Ch. 3).

Clinical Features

The general features of EDS include hyperextensible, fragile skin and joint hypermobility[4] (Fig. 97.2A,B). However, different subtypes of EDS have additional manifestations, both clinical and molecular, which allow their classification into six major categories (defined by the 1997 consensus conference[4]) (Fig. 97.3); several other novel variants of EDS have also been recognized (see Table 97.2). Typical skin findings are present, to a varying degree, in all subtypes of EDS[11]. The skin tends to be fragile, splitting readily as a result of trauma, particularly on the knees, elbows, shins and forehead. The wounds present with a gaping, "fish-mouth" appearance, and the resulting scars are typically atrophic and widen over time (Fig. 97.2C). Wound healing may be delayed and dehiscence is common. Sites of repeated trauma develop a variety of secondary lesions such as molluscoid pseudotumors, which are fleshy nodules of redundant skin and fibrous tissue that favor the knees and elbows. Another frequent finding is subcutaneous spheroids (Fig. 97.2D), which appear over bony prominences as multiple small, hard, mobile nodules that are thought to represent calcified fat globules. Easy bruising is commonly observed, reflecting the fragility of small blood vessels. Dermatologic disorders that are occasionally associated with (but not specific to) EDS include elastosis perforans serpiginosa and piezogenic papules.

The *classic type of EDS* (previously types I and II) represents the most common variant and is usually inherited in an autosomal dominant fashion. Rarely, this phenotype has an autosomal recessive pattern of inheritance, sometimes in association with congenital adrenal hyperplasia due to deletion of the contiguous genes encoding tenascin-X and 21-hydroxylase. The major clinical features of classic EDS include hypermobile joints and hyperextensible skin that heals with widened, atrophic scars, which often have a "cigarette paper" appearance. The skin also tends to be soft, velvety and prone to bruising. At least half of affected individuals can touch the tip of their nose with their tongue (Gorlin's sign), compared to 10% of the general population (Fig. 97.2E). Although classic EDS may be associated with mild aortic root dilation and mitral valve prolapse (each in ~5% of patients), these findings are rarely of clinical significance[12]. Other frequent musculoskeletal manifestations include pes planus, hypotonia and temporomandibular joint dysfunction.

The *hypermobility type of EDS* (previously type III) has an autosomal dominant inheritance pattern. The primary clinical features are generalized joint hypermobility and hyperextensible, smooth and velvety skin. Other manifestations include recurrent joint dislocations, which can cause chronic joint and limb pain as well as eventual osteoarthritic changes.

The *vascular type of EDS* (previously type IV) is inherited in an autosomal dominant fashion. These patients have thin, translucent skin with extensive bruising and are at high risk for arterial, intestinal and uterine ruptures[13]. Spontaneous arterial rupture has the highest incidence in the third and fourth decades of life but may occur earlier.

COLLAGEN BIOSYNTHESIS, SECRETION AND FIBRIL ASSEMBLY – RELATIONSHIP OF PATHOLOGY TO THE MAJOR SUBTYPE OF EHLERS-DANLOS SYNDROME

Physiology	Pathology	EDS subtype (mode of inheritance)
 Synthesis, hydroxylation and glycosylation of pro-α polypeptides of type I, III and V collagens	**Lysyl hydroxylase** deficiency results in reduced hydroxylysine content and altered cross-linking profile	Kyphoscoliosis (AR)
Formation of interchain S-S bonds at the carboxyl ends followed by triple helix formation	Dominant-negative mutations or haploinsufficiency in ***COL3A1*** affect triple helix formation, thermal stability, and secretion of type III collagen molecules	Vascular type (AD)
Secretion of procollagen	Dominant-negative mutations in the recognition sites for procollagen N-peptidase in ***COL1A1*** and ***COL1A2*** prevent cleavage of amino-terminal propeptides	Arthrochalasia (AD)
Removal of propeptides by specific proteases	Loss-of-function mutations in **procollagen-N-peptidase** result in the formation of only thin collagen fibrils	Dermatosparaxis (AR)
Fibril assembly	Dominant-negative mutations in ***COL5A1*** and ***COL5A2*** or haploinsufficiency in ***COL5A1*** result in abnormal or reduced amount of collagen fibrils	Classical type (AD)
Stabilization of fibrils by intermolecular cross-linking	Absence of **tenascin-X** leads to reduced collagen fibril density	Classical type (AR)

Fig. 97.1 Collagen biosynthesis, secretion and fibril assembly – relationship of pathology to the major subtype of Ehlers–Danlos syndrome. AD, autosomal dominant; AR, autosomal recessive; Glc-Gal, glucosyl-galactosyl residue attached to the hydroxyl group (OH) of lysine residues; S-S bonds, disulfide bonds.

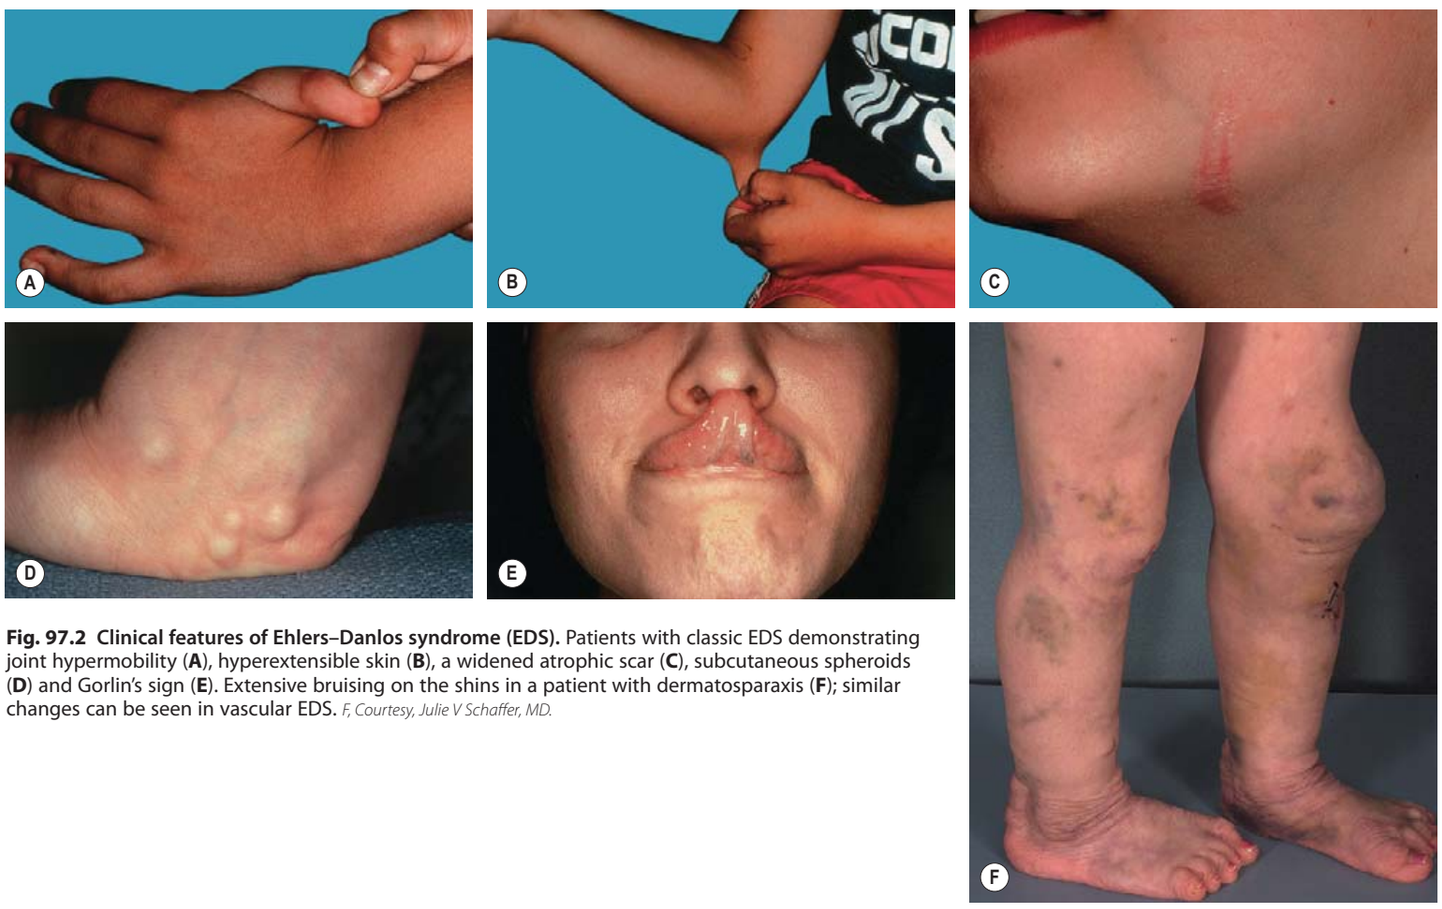

Fig. 97.2 Clinical features of Ehlers–Danlos syndrome (EDS). Patients with classic EDS demonstrating joint hypermobility (**A**), hyperextensible skin (**B**), a widened atrophic scar (**C**), subcutaneous spheroids (**D**) and Gorlin's sign (**E**). Extensive bruising on the shins in a patient with dermatosparaxis (**F**); similar changes can be seen in vascular EDS. *F, Courtesy, Julie V Schaffer, MD.*

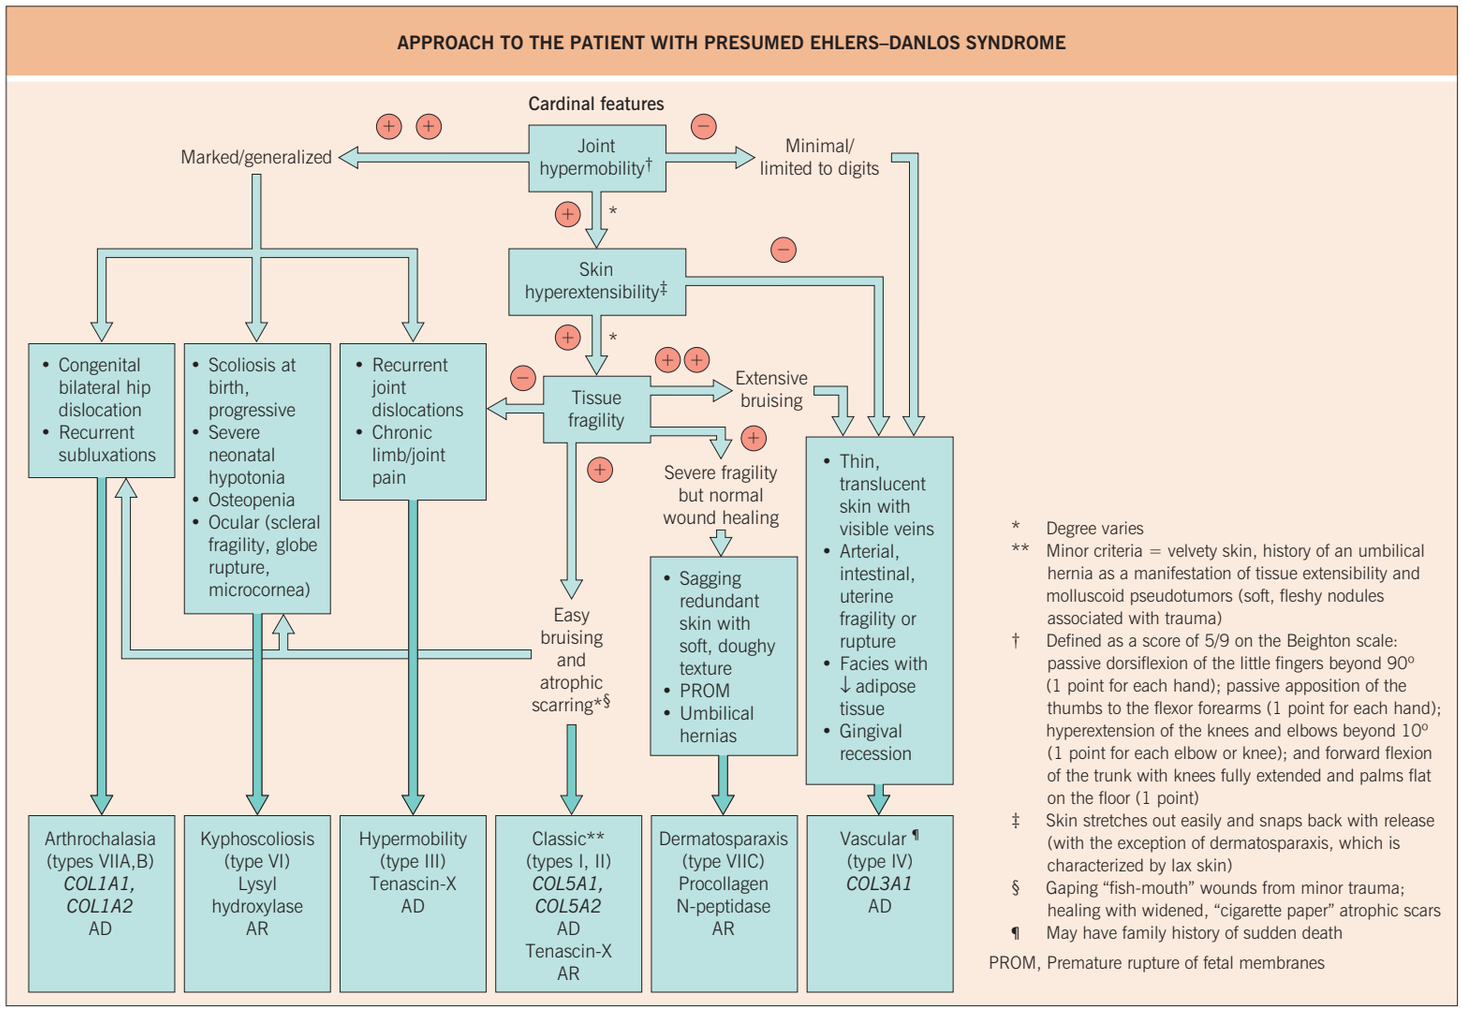

Fig. 97.3 Approach to the patient with presumed Ehlers–Danlos syndrome. AD, autosomal dominant; AR, autosomal recessive.

Affected individuals often have a characteristic facial appearance, with a "pinched" nose, thin lips, hollow cheeks and prominent "staring" eyes due to decreased periorbital adipose tissue.

The *kyphoscoliosis type of EDS* (previously type VIA) is inherited in an autosomal recessive fashion. Major features are skin hyperextensibility, generalized joint hypermobility, severe hypotonia at birth (leading to delayed gross motor development), progressive congenital scoliosis, and scleral fragility that can lead to rupture of the ocular globe. Additional findings may include atrophic scars, easy bruising, fragility of other tissues (rarely arterial rupture), a marfanoid habitus, microcornea and osteopenia.

The *arthrochalasia type of EDS* (previously types VIIA and VIIB) is inherited in an autosomal dominant fashion. The major clinical features include severe generalized joint hypermobility with recurrent subluxations and congenital bilateral hip dislocation. Patients may also present with hyperextensible skin, atrophic scars, easy bruising, hypotonia, scoliosis and mild osteopenia.

The *dermatosparaxis type of EDS* (previously type VIIC) is an autosomal recessive disorder that, unlike other forms of EDS, presents with skin that is sagging and redundant as well as extremely fragile. The skin has a highly characteristic soft, doughy consistency, and it tears and bruises easily (Fig. 97.2F). Additional findings include premature rupture of fetal membranes, large umbilical or inguinal hernias, delayed closure of the fontanelles, distinctive facies with puffy eyelids and micrognathia, blue sclerae, gingival hyperplasia, abnormal dentition and short limbs.

Pathology

Histopathologic examination of the skin may suggest or support the presence of a connective tissue disorder when a thin reticular dermis with reduced and/or disorganized collagen fibrils is seen. However, in general, the histopathologic findings are not diagnostic. Nonspecific increases in elastic fibers have been reported, particularly in areas of repeated trauma or molluscoid pseudotumors.

Electron microscopy often shows the presence of collagen fibrils with variable diameters and occasional large "cauliflower" fibrils with an irregular contour. Characteristic hieroglyphic fibrils can be encountered in the dermatosparaxis type of EDS. Immunohistochemical demonstration of intracellular accumulation of type III collagen may be helpful in pointing to the vascular type of EDS.

In general, the diagnosis of EDS is clinical. Protein electrophoresis of collagens extracted from cultured dermal fibroblasts can be helpful in demonstrating specific collagen defects (see Fig. 97.1), particularly in the vascular, arthrochalasia and dermatosparaxis types of EDS[13]. Analysis of the urine for an increased deoxypyridinoline : pyridinoline ratio may be used as a screening test for kyphoscoliosis-type EDS, and tenascin-X deficiency can be demonstrated by an ELISA of a serum sample[9]. Genetic testing is available for all of the major forms of EDS except the hypermobility type.

Differential Diagnosis

Several previously described rare subtypes of EDS, including type V (X-linked variant), type VIII (periodontitis type) and type X (fibronectin type), have been excluded (at least for the present) from the EDS nosology due to a lack of clear descriptions of their clinical features and unknown molecular bases. The previous EDS type IX, an X-linked recessive condition known as occipital horn syndrome, is now considered to represent a form of cutis laxa (see Table 97.6) rather than EDS. In contrast to cutis laxa, which is characterized by loose and sagging skin with decreased resilience, the skin of patients with EDS (with the exception of the dermatosparaxis type) retains its elasticity and recoil. Although some patients with EDS (in particular the kyphoscoliosis

COMPARISON OF SELECTED CLINICAL FEATURES IN EHLERS–DANLOS SYNDROME AND MARFAN SYNDROME

type) have a marfanoid body habitus, they do not typically exhibit other findings of Marfan syndrome (Table 97.3), a distinct heritable connective tissue disorder due to mutations in the fibrillin-1 gene (*FBN1*) (see Table 97.1).

The phenotype of Loeys–Dietz syndrome type II can mimic that of vascular EDS, with overlapping features including translucent skin, easy bruising, atrophic scarring, joint hypermobility and arterial rupture (see Table 95.5). Patients with vascular EDS and other types that result in extensive bruising are often suspected to have a bleeding disorder, and they may present to a dermatologist after a hematologic evaluation fails to reveal any abnormalities. In addition to the major forms of EDS discussed above, other uncommon variants should also be considered (see Table 97.2).

Treatment

Currently, no specific treatment is available for any of the subtypes of EDS. The most important intervention is prevention of trauma to the skin, such as the use of shin guards and avoidance of contact sports. Use of sutures with prolonged tensile strength may improve healing and the appearance of surgical scars. In the vascular type of EDS, affected individuals are at high risk of arterial and bowel ruptures, and pregnancies may be complicated by uterine rupture. Early diagnosis of this type of EDS is critical to enable prompt recognition and optimal management of complications as well as to provide reproductive counseling and close monitoring during pregnancies[13].

PSEUDOXANTHOMA ELASTICUM

Synonym: ■ Grönblad–Strandberg syndrome

Key features

- An autosomal recessive disorder characterized by clumped and distorted elastic fibers with deposits of calcium
- Cutaneous features include yellowish papules, "cobblestoning" and redundant folds in flexural areas
- Calcification of elastic fibers in the walls of medium-sized arteries can lead to luminal narrowing and clinical sequelae such as claudication, renovascular hypertension, angina and myocardial infarctions
- Angioid streaks reflect breaks in the calcified elastic lamina of Bruch's membrane; choroidal neovascularization and hemorrhage can result in loss of visual acuity
- Gastrointestinal hemorrhage represents another possible complication

History

The French dermatologist Balzer first described the skin manifestations of PXE and associated elastic degeneration in the skin and heart in 1884[14], which was followed 5 years later by a similar case report by Chauffard[15]. Based on these two cases, Darier coined the name "pseudo-xanthome élastique" in 1896 to differentiate this condition from xanthomas (hence pseudoxanthoma)[16]. In the late 1920s, Grönblad[17] and Strandberg[18] recognized the association of the characteristic skin manifestations with angioid streaks, and the cardiovascular manifestations were better defined two decades later. More recently, the molecular defects that underlie PXE were identified, clarifying the mode of inheritance (which had previously been the subject of much debate)[19,20].

Epidemiology

PXE is an autosomal recessive disease, with estimates of prevalence ranging from 1 in 25 000 to 1 in 100 000. It occurs in all races without geographic predilection and appears to have a slight female preponderance[21]. Skin changes of PXE usually appear during childhood, but the diagnosis is frequently not made until serious systemic or ocular complications develop in the third or fourth decade of life. Mild cutaneous and ocular findings have also been observed in heterozygous carriers[22].

Pathogenesis

Loss-of-function mutations in both copies of the *ABCC6* gene can be identified in most patients with PXE. *ABCC6* encodes an ABC-cassette transporter with a high degree of homology to the multidrug resistance-associated proteins. ABCC6 is predominantly expressed in the basolateral membrane of hepatocytes, where it serves as an efflux pump. Unlike other members of this protein family, ABCC6 does not seem to confer any significant chemotherapy resistance; however, there may be some functional overlap considering that ABCC6 is believed to play a role in cellular detoxification.

Mutations in both copies of the γ-glutamyl carboxylase gene (*GGCX*) have recently been found to cause PXE-like skin changes plus deficiency in vitamin K-dependent coagulation factors[23]. A combination of heterozygous mutations in *GGCX* and *ABCC6* has also been identified in patients with cutaneous findings of PXE[24]. The GGCX enzyme catalyzes the vitamin K-dependent γ-glutamyl carboxylation that is necessary for activation of both coagulation factors in the liver and the matrix gla protein in peripheral connective tissues. When carboxylated (activated), matrix gla protein prevents ectopic mineralization.

Although the physiologic and pathologic substrates of ABCC6 are still unknown, it has been speculated that it exports a GGCX cofactor (e.g. a vitamin K–glutathione conjugate) from the liver into the circulation. In addition, serum levels of fetuin A, a major anti-mineralization protein that is secreted from the liver into the blood, are significantly reduced in PXE[25]. An ABCC6 defect could therefore result in decreased plasma anti-mineralization capacity due to reduced matrix gla protein and/or fetuin-A activity, allowing progressive mineralization of elastic fibers in target organs[26] (Fig. 97.4). Calcification of elastic fibers in the mid and deep dermis, the media and intima of mid-sized arteries, and Bruch's membrane of the eye produces the characteristic clinical and histopathologic changes of PXE.

Clinical Features

PXE primarily affects the elastic fiber networks of the skin, eyes and cardiovascular system. There is tremendous variability in severity even among siblings, and sometimes only one or two of these organ systems show signs of the disease.

PXE owes its name to the characteristic cutaneous findings, which bear some resemblance to xanthomas and represent the most frequent manifestation of the condition. Thin, yellowish papules typically appear in flexural areas during the first or second decade of life. The lateral neck is usually affected first (Fig. 97.5A,B). Over time, the papules coalesce to form cobblestone-like plaques, giving rise to a "plucked chicken skin" appearance (Fig. 97.5C). Other flexural sites that may be affected include the antecubital and popliteal fossae, wrists, axillae, groin and periumbilical area in multiparous women (not to be confused with *perforating periumbilical calcifying elastosis*, a localized, acquired,

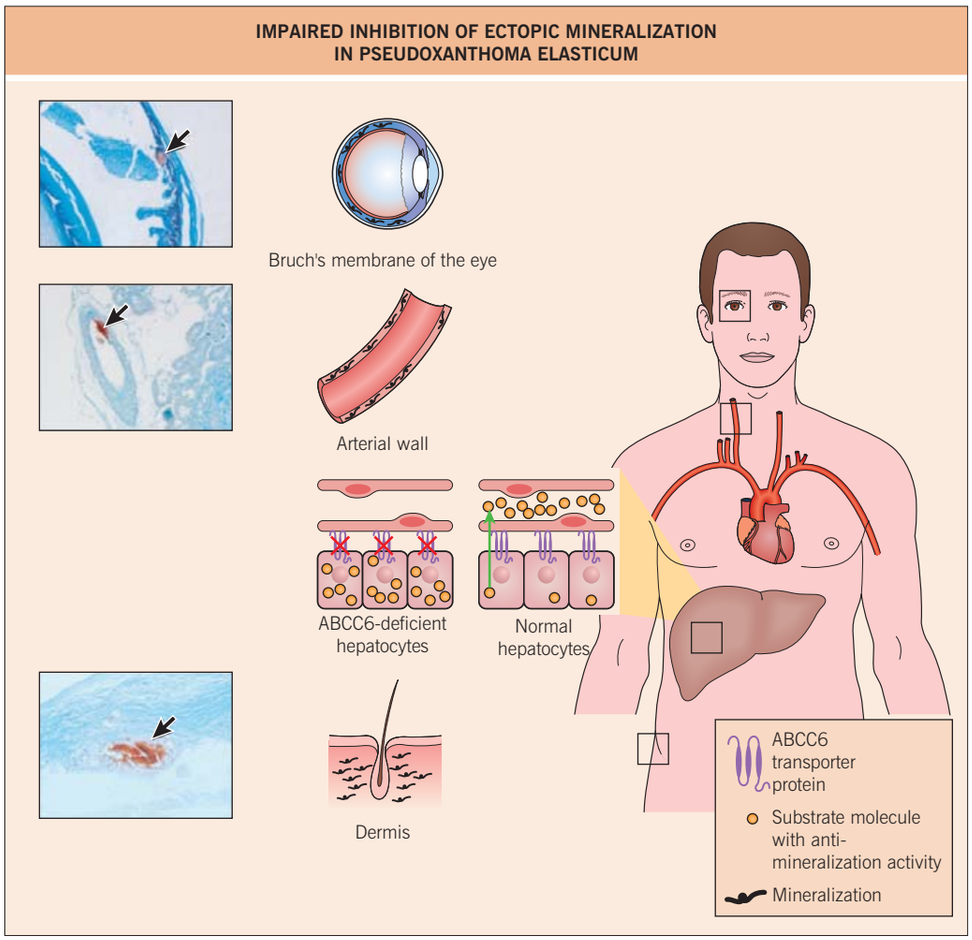

Fig. 97.4 Impaired inhibition of ectopic mineralization in pseudoxanthoma elasticum. The normal liver expresses high levels of the ABC-binding cassette subfamily C member 6 (ABCC6) protein, which serves as an efflux pump on the basolateral surface of hepatocytes, transporting molecules from inside these cells to the circulation. In patients with pseudoxanthoma elasticum (PXE), an absence of ABCC6 transporter activity in the liver results in reduced circulating concentrations of molecules that serve as physiologic anti-mineralization factors. This leads to calcification of connective tissues in the eye, arterial walls (media and intima) and dermis. The presence of calcium is evident on histopathological examination of these tissues (Alizarin red staining; see arrows in left panels) in ABCC6-/- mice, which recapitulate the features of human PXE. *Redrawn from Uitto J, Li Q, Jiang Q. Pseudoxanthoma elasticum: molecular genetics and putative pathomechanisms. J Invest Dermatol. 2010;130:661–70.*

Fig. 97.5 Clinical features of pseudoxanthoma elasticum. Yellowish papules and "cobblestoned" plaques on the neck (**A, B**) and in the antecubital fossa (**C**). Thickened, yellowish sagging skin in the axilla (**D**). *C, D, Courtesy, Julie V Schaffer, MD.*

purely cutaneous PXE-like condition [Table 97.4; see Ch. 96]). Involvement of non-flexural sites may occur in patients with more extensive disease.

With advanced disease, firm papules or plaques may develop as a result of increased dermal calcium deposition, and extrusion of this yellowish material through the epidermis as "perforating PXE" occasionally occurs. Loss of recoil due to impaired function of the elastic fiber network often leads to sagging of the skin, which is most notable in the axillae (Fig. 97.5D) and groin. Mucosal involvement presents as yellow papules, which are most often apparent on the lower lip (Fig. 97.6). Prominent creases develop on the chin in two-thirds of affected individuals <30 years of age and the vast majority of older patients.

DIFFERENTIAL DIAGNOSIS OF PSEUDOXANTHOMA ELASTICUM			
Disorder	**Patient characteristics**	**Clinical features**	**Histologic features**
Actinic elastosis	History of chronic sun exposure; lightly pigmented skin; middle-aged and older adults	Yellow to gray, thickened, lax, finely to coarsely wrinkled skin; photodistribution on the lateral forehead, neck, dorsal aspect of the forearms	Masses of basophilic, amorphous, degenerated elastic fibers in the papillary and upper reticular dermis
Late-onset focal dermal elastosis	7th–9th decades	Multiple 1–3 mm yellow papules; may coalesce; neck, axillae, groin, antecubital and popliteal fossae	*Increased* normal-appearing elastic fibers in the mid and deep reticular dermis
Elastoderma	3rd–4th decades	Localized areas of lax, pendulous skin; neck, trunk, arm	*Increased* normal- and abnormal-appearing elastic fibers throughout the dermis, extending into the subcutis
Perforating periumbilical calcific elastosis*	Multiparous black women; 5th–8th decades†	Plaque composed of coalescing keratotic papules (most apparent at the periphery); periumbilical area‡	Transepidermal elimination of calcified, distorted elastic fibers
PXE-like papillary dermal elastolysis§	6th–9th decades; primarily women	Multiple 2–3 mm yellow or skin-colored papules coalescing to form plaques with a cobblestone appearance; neck, flexor forearms, axillae, lower abdomen, inframammary folds	*Decreased* elastic tissue in a band-like distribution in the papillary dermis, with fragmentation and clumping of elastic fibers
White fibrous papulosis of the neck§	5th–9th decades; Japanese men, Caucasian women	Multiple 2–3 mm whitish papules; neck > upper trunk	*Decreased* elastic fibers in the papillary and mid reticular dermis; thickened collagen bundles

*Also referred to as periumbilical perforating PXE.
†Occasionally associated with an increased calcium–phosphate product in the setting of chronic renal failure.
‡Similar lesions have been reported on the breasts.
§Within the spectrum of fibroelastolytic diseases of the skin.

Table 97.4 Differential diagnosis of pseudoxanthoma elasticum (PXE). The differential diagnosis also includes PXE-like skin lesions in patients receiving D-penicillamine, after local exposure to saltpeter, and in longstanding end-stage renal disease. In addition, the possibility of underlying β-thalassemia or sickle cell anemia needs to be considered.

Fig. 97.6 Mucosal lesions in pseudoxanthoma elasticum. Yellow papules on the inner aspect of the lower lip.

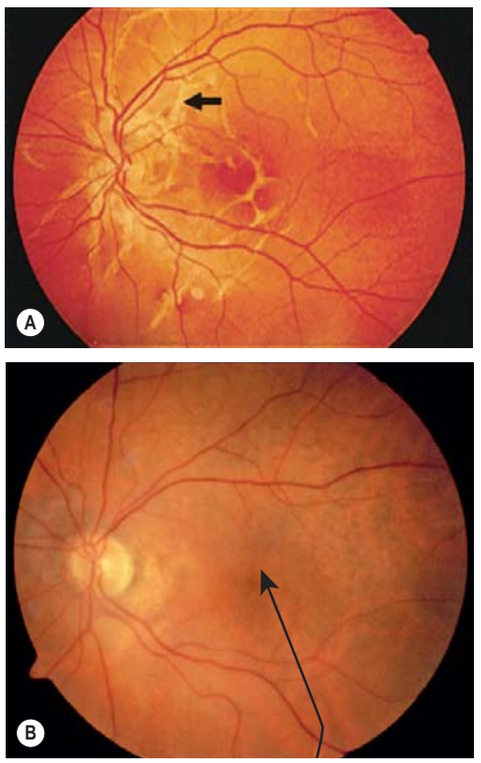

Fig. 97.7 Funduscopic findings in pseudoxanthoma elasticum (PXE). **A** Broad, lightly colored streaks (arrow) represent angioid streaks. **B** Mottling with "peau d'orange" color changes (arrow) over the entire retinal pigment epithelium, which may precede the onset of angioid streaks and represents the most common ophthalmologic finding in PXE.

The classic ocular finding in PXE is angioid streaks (Fig. 97.7A), which may be evident as early as the first decade of life and can be found in virtually all PXE patients by 30 years of age[21]. Angioid streaks are usually asymptomatic and reflect breaks in the calcified elastic lamina of Bruch's membrane, which is derived from the retina and choroid plexus. These fractures can lead to choroidal neovascularization, and the newly formed vessels are prone to hemorrhage with subsequent scarring. This process ultimately results in progressive loss of vision (especially in central fields), which usually becomes apparent after 40 years of age and occasionally leads to legal blindness.

Angioid streaks are highly characteristic but not pathognomonic of PXE. They can be encountered in a variety of metabolic and heritable disorders, including Paget's disease of the bone, sickle cell anemia, thalassemia, EDS and lead poisoning, as well as in the setting of age-related degeneration of Bruch's membrane. Mottling of the retinal pigment epithelium (referred to as "peau d'orange" changes) (Fig. 97.7B) is actually the most prevalent ophthalmologic finding in PXE and may precede the development of angioid streaks. Less commonly, macular degeneration, optic drusen and "owl's eyes" (paired hyperpigmented spots) may be detected.

Cardiovascular manifestations of PXE often cause significant morbidity and may even result in early death. PXE affects primarily mid-sized arteries, especially of the extremities, and progressive calcification of the elastic media and intima leads to the formation of atheromatous plaques. Sequelae may include intermittent claudication, loss of peripheral pulses, renovascular hypertension, angina pectoris, myocardial infarction and stroke, which typically occur at a much younger age than in the general population. Calcified blood vessels of the gastric and intestinal mucosa have an increased propensity for hemorrhage, and patients frequently present with gastrointestinal bleeding, particularly from the stomach[21]. Patients with PXE also have an increased prevalence of mitral valve prolapse.

Individuals with *GGCX* mutations have cutaneous, ocular and cardiovascular findings similar to those of classic PXE. The skin manifestations tend to be more extensive (affecting non-flexural areas of the trunk and extremities) and severe, with redundant folds of skin that resemble cutis laxa. Loss of visual acuity secondary to ocular

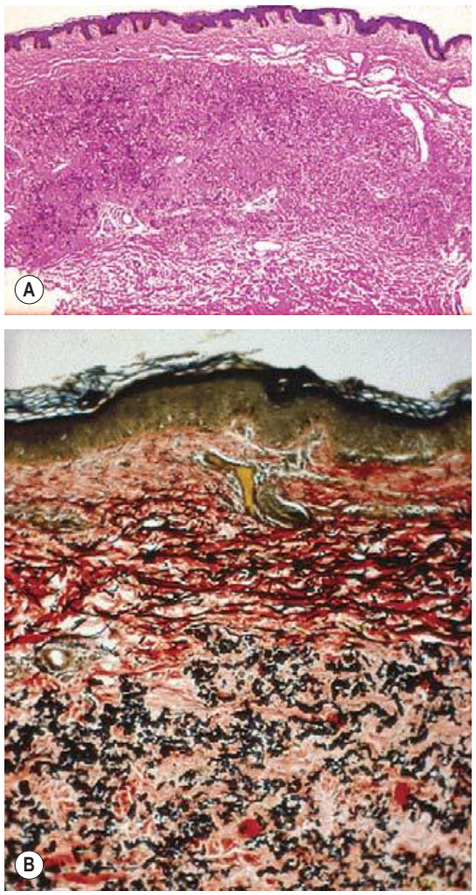

Fig. 97.8 Histopathology of pseudoxanthoma elasticum (PXE). **A** Purple clumps in the mid and deep reticular dermis in H&E-stained sections represent calcium deposits on elastic fibers in advanced PXE. **B** Verhoeff–van Gieson elastic stain can reveal black-staining, irregularly clumped elastic fibers in earlier disease.

involvement has not been described. Additional hemorrhagic complications may occur secondary to the associated coagulation factor deficiency, including epistaxis, gingival bleeding, menorrhagia and intracranial hemorrhage.

A MULTIDISCIPLINARY APPROACH TO MANAGEMENT OF PSEUDOXANTHOMA ELASTICUM

SKIN
No specific treatment is available Surgical intervention for excessive skin folds[39]
EYES
Prevention and early detection • Biannual funduscopic examination • Regular use of an Amsler grid to assess for central visual field defects • Use of sunglasses • Diet/vitamins rich in antioxidants • Avoidance of head trauma, heavy straining and smoking
Treatment • Laser photocoagulation or photodynamic therapy with verteporfin for choroidal neovascularization related to angioid streaks in patients with visual symptoms (recurrence rate 65% for laser therapy)[40] • Intravitreal injections of VEGF antagonists (e.g. bevacizumab)[41] • Macular translocation (only for extensive neovascularization)[42]
CARDIOVASCULAR SYSTEM
Prevention and early detection • Baseline electrocardiogram and echocardiogram • Annual cardiac examination • Healthy lifestyle with balanced diet, regular exercise, weight control, and avoidance of smoking and excessive alcohol intake • Magnesium supplementation* (e.g. magnesium carbonate-containing phosphate binders)[43] • Moderate calcium intake (as appropriate for age) • Low-dose therapy with acetylsalicylic acid if not contraindicated
Treatment • Correction of hyperlipidemia and hypertension • Low-dose acetylsalicylic acid, pentoxyfylline, cilostazol or clopidogrel for intermittent claudication
*A diet high in magnesium was shown to reduce connective tissue mineralization in a mouse model of PXE[43].

Table 97.5 A multidisciplinary approach to management of pseudoxanthoma elasticum. VEGF, vascular endothelial growth factor.

Pathology

Characteristic light microscopic changes in the skin consist of distorted, fragmented elastic fibers in the mid and deep reticular dermis. In advanced cases, calcium deposits on these altered elastic fibers are visible in routinely stained sections as purple clumps (Fig. 97.8A). Similar changes are observed in the media of mid-sized arteries. In early disease, stains for elastin (Verhoeff–van Gieson; Fig. 97.8B) and calcium (von Kossa) are sometimes necessary to visualize the characteristic alterations in the elastic fibers. In some patients without skin manifestations who are suspected to have PXE because of other findings, such as angioid streaks, a diagnosis may be confirmed by biopsy of a pre-existing scar[27].

Increased deposition of matrix proteins with a high degree of affinity for calcium is observed on an ultrastructural level; these proteins include osteonectin, fibronectin and vitronectin, as well as alkaline phosphatase and bone sialoprotein[28]. Serum levels of calcium and phosphate are normal[21].

Differential Diagnosis

Although the characteristic skin lesions of PXE are easily diagnosed in younger patients, actinic damage within chronically sun-exposed sites in older individuals can clinically mimic the yellowish, lax plaques of PXE. However, the latter involves the neck but not the axillae or groin. The differential diagnosis may also include late-onset focal dermal elastosis, elastoderma, perforating periumbilical calcific elastosis, and fibroelastolytic skin disorders (PXE-like papillary dermal elastolysis and white fibrous papulosis of the neck) (see Table 97.4)[29,30].

Skin lesions with the same morphology and distribution as PXE and similar histologic features have been observed in patients receiving D-penicillamine (which interferes with desmosine cross-linking in elastin; see below)[31], after local exposure to saltpeter[32,33], in longstanding end-stage renal disease[34] and (historically) in L-tryptophan-induced eosinophilia myalgia syndrome[35]. In patients with penicillamine-induced PXE-like skin changes, the von Kossa stain is negative, indicating no calcification of the abnormal fibers, whereas in saltpeter exposure and end-stage renal disease, calcification occurs and this stain is positive. Ophthalmologic and cardiovascular findings are absent and the skin lesions may resolve after cessation of the causative exposure or (in patients with renal disease) normalization of the serum calcium–phosphate product.

A PXE-like phenotype is present in up to 20% of the patients with β-thalassemia (Mediterranean populations) or sickle cell anemia[36]. Affected individuals may have characteristic cutaneous involvement as well as angioid streaks and vascular stigmata, but none of their siblings without a hematologic disorder have signs of PXE, and mutations in *ABCC6* have not been detected. Interestingly, down-regulation of ABCC6 expression in the liver has been observed in a mouse model of β-thalassemia, suggesting a possible pathogenic mechanism[37]. PXE-like skin lesions have also been encountered in amyloid elastosis, which typically occurs in the setting of primary systemic amyloidosis; histologic examination reveals amyloid deposits that encase dermal elastic fibers, which may be short and fragmented[38].

Treatment

An approach to the multidisciplinary management of PXE is presented in Table 97.5[39–43].

CUTIS LAXA

Synonyms: ■ Dermatochalasia ■ Dermatomegaly ■ Generalized elastolysis ■ Generalized elastorrhexis

Key features

- Group of conditions characterized by sparse and fragmented elastic fibers
- Both heritable (autosomal dominant or recessive) and acquired forms
- Features loose, sagging skin with reduced elasticity and resilience
- Extracutaneous manifestations include emphysema, hernias and diverticula

History

The clinical differences between cutis laxa (CL) and EDS were delineated in 1923 by F Parkes Weber[3], and the generalized nature of the elastolysis and potential for internal involvement were recognized by Goltz and co-workers in 1965[44].

Epidemiology

The heritable forms of CL are relatively rare and no precise estimate of their prevalence is available. There appears to be no racial or ethnic predilection, and inheritance can be autosomal dominant or autosomal recessive. Heritable CL is typically apparent at birth or during early childhood, but the development of lax skin is occasionally delayed until early adulthood in autosomal dominant forms. Acquired CL frequently has later onset.

Pathogenesis

CL represents a disorder of the elastic fiber network and can involve multiple tissues, including internal organs as well as the skin. Recent insights into the molecular bases of inherited forms of CL have refined the classification of this group of conditions (Table 97.6). Mutations in the elastin gene (*ELN*) that lead to qualitative as well as quantitative abnormalities in this protein have been identified as the cause of an autosomal dominant form of CL[45]. Defects in several genes can underlie autosomal recessive CL (ARCL), which tends to be more severe and is divided into two groups with different patterns of extracutaneous involvement. ARCL type I features potentially fatal involvement of the lungs, vascular abnormalities and gastrointestinal/genitourinary diverticula, whereas ARCL type II is characterized by craniofacial anomalies and delayed growth and development (see Table 97.6).

Initially, fibulin-5 "knockout" mice (see Ch. 3) were noted to develop a phenotype remarkably similar to human CL. In these mice, disorganization of elastic fibers resulted in loose skin, vascular abnormalities and emphysema. Fibulin-5 is a calcium-dependent elastin-binding protein that localizes to the surface of elastic fibers *in vivo*. Subsequently, homozygous fibulin-5 mutations were described in families with ARCL type I, and a heterozygous duplication within the fibulin-5 gene was also found in a sporadic case of CL[46,47]. Mutations in the fibulin-4 gene have also been identified in patients with ARCL type I, suggesting that fibulin-4 is necessary for elastic fiber formation[48]. Recently, mutations in the latent TGF-β binding protein-4 gene (*LTBP4*) were reported to underlie a lethal AR form of CL associated with severe pulmonary, gastrointestinal and genitourinary malformations[49]. The absence of LTBP4, an ECM protein that binds to fibrillin and controls the bioavailability of TGF-β, leads to aberrant TGF-β activity and defective elastic fiber assembly in many types of tissues.

Genetic defects in several intracellular proteins have been found to underlie ARCL type II. For example, mutations in both alleles of the *ATP6V0A2* gene, which encodes the A2 subunit of the vacuolar H^+-ATPase, produce a phenotypic spectrum that ranges from primarily "wrinkly skin" to severe CL in association with facial dysmorphism, microcephaly, joint laxity, and delayed growth and development[50]. ATP6V0A2 defects result in impaired N- and O-glycosylation, vesicular transport and secretion of tropoelastin, thereby reducing production of functional elastin. Interestingly, mutations in the pyrroline-5-carboxylate reductase 1 and pyrroline-5-carboxylate synthetase genes (*PYCR1* and *P5CS*, respectively) cause similar ARCL type II phenotypes[51]. These genes encode mitochondrial enzymes that are critical for the biosynthesis of proline, which is a major component of collagen and plays a role in an oxidative cycle important to cellular metabolism. PYCR1 deficiency causes abnormal mitochondrial morphology and increased apoptosis upon oxidative stress in fibroblasts, and it has been suggested that mitochondrial dysfunction is involved in the pathogenesis of these forms of CL, especially their progeroid and neurodegenerative manifestations (see Table 97.6).

An alternate pathogenic mechanism for CL, in particular acquired variants, is enhanced degradation of elastic fibers[52]. Sagging of the skin, usually with little or no associated internal organ involvement, can develop in the weeks to months following the onset of an inflammatory skin condition (e.g. a drug reaction, chronic urticaria, Sweet's syndrome). In these cases, release of elastases into the extracellular milieu by inflammatory cells (e.g. neutrophils, monocytes-macrophages) may lead to proteolytic degradation of elastic fibers[53]. Individuals with α_1-antitrypsin deficiency are especially susceptible to excessive proteolysis, and both generalized and localized (the latter following Sweet's syndrome [Marshall syndrome]) CL has been reported in these patients. Immunopathogenic mechanisms may play a role in some cases of acquired CL, as evidenced by the occurrence of acral or generalized CL in association with monoclonal gammopathies and observation of IgG, IgA or amyloid deposition on elastic fibers in lesional skin[54]. In addition, there may be an underlying genetic susceptibility for the development of CL, e.g. polymorphisms or "mild" mutations in the elastin and/or fibulin-5 genes[55].

Finally, CL-like cutaneous changes as well as elastosis perforans serpiginosa and PXE-like findings have been observed in patients treated for a prolonged period with high-dose D-penicillamine for conditions such as Wilson disease or cystinuria. D-Penicillamine can interfere with elastin cross-linking by two mechanisms. First, D-penicillamine is a copper chelator and can lower serum copper levels, which reduces the activity of lysyl oxidase, an enzyme required for elastin cross-linking (see Ch. 95)[56]. Second, D-penicillamine can chemically block the allysine and lysine residues that come together to form desmosine cross-links. As a result of these actions, newly synthesized elastin molecules do not become stably cross-linked. Instead, they are subject to rapid proteolysis, thus precluding the synthesis of functional elastic fibers.

Clinical Features

All forms of CL are characterized by loose, sagging skin with reduced elasticity and resilience. This often gives the affected patient an "aged" facial appearance with down-slanting palpebral fissures and a long philtrum (Fig. 97.9). Cutaneous findings are present at birth in most heritable forms of CL but may develop later in life in autosomal dominant as well as acquired variants. The laxity and wrinkling usually progress over time, although improvement of the skin with age has been noted in ARCL type II. Skin involvement is frequently generalized; however, it can be primarily acral in ARCL type II or acquired CL.

In some patients with CL, clinical manifestations are limited to the skin, and the phenotype is primarily of cosmetic concern. In other patients, the cutaneous findings are associated with prominent extracutaneous features, which can include emphysema, umbilical and inguinal hernias, gastrointestinal and genitourinary tract diverticula, cardiac or arterial abnormalities, skeletal or joint involvement, and delayed growth and development. The extracutaneous manifestations, particularly pulmonary complications, can cause considerable morbidity and mortality[44]. Association with congenital hemolytic anemia has also been reported[57]. The cutaneous and extracutaneous features of specific types of heritable CL are summarized in Table 97.6.

Generalized acquired CL without an identifiable trigger may be clinically indistinguishable from milder heritable forms of CL (e.g. late-onset autosomal dominant CL). Generalized or localized forms of acquired CL can also occur in association with a plasma cell dyscrasia (see Fig. 97.9B), as a consequence of drug intake (particularly penicillamine), and subsequent to a systemic or cutaneous inflammatory disorder (Table 97.7). In the latter situation, the inflammatory reaction is followed by progressive sagging of the skin, which can become extensive and lead to a prematurely aged appearance. Acquired CL most commonly develops in adults and presents with generalized skin involvement (often beginning on the face and neck), which can be associated with internal manifestations (e.g. emphysema, gastrointestinal and genitourinary diverticula). Occasionally, localized CL is found predominantly around the eyes (blepharochalasis) or on the distal extremities,

HERITABLE FORMS OF CUTIS LAXA AND RELATED CONDITIONS

AR cutis laxa type I[†]	AR	*FBLN4 (EFEMP2)*	Fibulin-4	Generalized	• Arterial/aortic tortuosity, aneurysms and stenoses • Emphysema (often severe/fatal) • GI and GU diverticula, hernias[‡] • Joint laxity, arachnodactyly, fractures (variable)
		FBLN5	Fibulin-5		
Cutis laxa with severe pulmonary, GI and GU abnormalities	AR	*LTBP4*	Latent TGF-β binding protein-4	Generalized	• Pulmonary malformations/emphysema (severe/fatal) • GI and GU malformations (diverticula, stenoses) • Facial dysmorphism[§], large fontanelles • Joint laxity, hypotonia
AR cutis laxa type IIA (including some patients with wrinkly skin syndrome)	AR	*ATP6V0A2*	Vacuolar H^+-ATPase A2 subunit	Generalized; improves over time	• Translucent skin with prominent veins (especially IIB) • Ocular abnormalities (strabismus & high myopia in IIA; corneal opacities & cataracts in DBS) • Facial dysmorphism[§], large fontanelles • Microcephaly • Partial pachygyria (IIA), absent corpus callosum (IIB) • Developmental delay ± neurologic degeneration; dystonia (DBS) • Congenital hip dislocation, joint laxity, hypotonia • Osteopenia, short stature (especially IIB) • Dental caries • O- and N-glycosylation defect (IIA[‖]) • Hyperammonemia (in a subset of the *ALDH18A1* type)
AR cutis laxa type IIB (including some patients with De Barsy syndrome [DBS] or a gerodermia osteodysplastica-like phenotype)	AR	*PYCR1*	Pyrroline-5-carboxylate reductase 1	Generalized, especially on dorsal hands and feet; improves over time	
		ALDH18A1 (rare variant)	Pyrroline-5-carboxylate synthetase		
Gerodermia osteodysplastica (geroderma osteodysplasticum)	AR	*GORAB (SCYL1BP1)*	Golgin, RAB6-interacting	Primarily on dorsal hands and feet	• Malar hypoplasia, prognathism, oblique furrow lateral to eyebrows • Joint laxity • Osteoporosis, fractures, dwarfism
Macrocephaly, alopecia, cutis laxa and scoliosis (MACS)	AR	*RIN2*	RAS and RAB interactor 2	Generalized, most pronounced on face	• Sparse hair • Gingival hypertrophy, facial dysmorphism • Macrocephaly • Scoliosis, joint laxity
Occipital horn syndrome	X-R	*ATP7A*	ATPase, Cu^{2+}-transporting, α-polypeptide	Generalized, most pronounced on face and neck	• Easy bruising, coarse hair (variable) • Arterial tortuosity • Chronic diarrhea; bladder diverticula • Long face, high forehead, hooked nose • Developmental delay • Wedge-shaped occipital calcifications • Joint laxity
RELATED HERITABLE CONDITIONS THAT FEATURE LAX AND/OR REDUNDANT SKIN					
Arterial tortuosity syndrome	AR	*SLC2A10*	Solute carrier family 2, member 10 (a glucose transporter)	Generalized	• Telangiectasias on cheeks (variable) • Arterial tortuosity • Long face, micrognathia, high-arched palate • Joint laxity and contractures

*A genetic defect has not been established for all patients classified in these subtypes.
[†]A recessive form of cutis laxa due to homozygous mutations in the elastin gene has been reported in a single family to date.
[‡]E.g. inguinal, umbilical, diaphragmatic.
[§]Features may include a broad forehead and midfacial hypoplasia as well as findings related to the lax skin (e.g. down-slanting palpebral fissures, long philtrum).
[‖]Can be assessed via analysis of the glycosylation of serum transferrin ± apolipoprotein C-III.

Table 97.6 Heritable forms of cutis laxa and related conditions. "Neonatal cutis laxa with a marfanoid phenotype" was described in an infant who lacked immunohistochemical evidence of laminin-β1 in the skin and had a heterozygous chromosomal break involving the *LAMB1* locus (which is near the *ELN* locus). Rare, autosomal recessive syndromes that can present with cutis laxa include transaldolase deficiency (also features hypertrichosis, hepatosplenomegaly, hemolytic anemia and GU malformations) and congenital disorders of glycosylation due to mutations in component of oligomeric Golgi complex 7 (*COG7*; fatal due to multiple-system malformations) or steroid 5-α-reductase 3 (*SRD5A3*; also features ichthyosis, ocular colobomas and midline brain malformations). AD, autosomal dominant; *ALDH18A1*, aldehyde dehydrogenase 18 family, member A1; AR, autosomal recessive; *EFEMP2*, EGF-containing fibulin-like extracellular matrix protein 2; GI, gastrointestinal; GU, genitourinary; TGF, transforming growth factor; X-R, X-linked recessive.

Continued

HERITABLE FORMS OF CUTIS LAXA AND RELATED CONDITIONS					
Disorder	**Inheritance**	**Gene***	**Protein**	**Distribution of cutis laxa**	**Additional features**
Costello syndrome	AR	*HRAS*	HRAS	Variable, especially on hands and feet	• Deep palmoplantar creases, acanthosis nigricans, periorificial papillomas • Curly or sparse hair, coarse facies • Cardiac malformations • Mental and growth retardation • Risk of malignancies, e.g. rhabdomyosarcoma
Donohue syndrome ("leprechaunism"; see Ch. 101)	AR	*INSR*	Insulin receptor	Variable	• Generalized lipodystrophy, hypertrichosis, acanthosis nigricans • Insulin resistance • Distinctive "elfin" facies • Severe growth retardation
Finnish-type amyloidosis	AD	*GSN*	Gelsolin	Generalized	• Corneal dystrophy • Polyneuropathy
"Michelin tire baby" syndrome (may represent multiple disorders with similar phenotypes; variant with extracutaneous findings also known as "circumferential skin creases Kunze type")	AD	?	?	Multiple circumferential creases/folds of skin on the extremities > neck > trunk (excess rather than lax skin)	• Affected skin may have excess fat or smooth muscle, and the latter is often associated with hypertrichosis; elastic fibers are usually normal (fragmentation noted in only one report) • Skin creases often resolve over time • Subset of patients has extracutaneous findings, most frequently cleft palate, thick/overfolded helices, dysmorphic facies (e.g. epicanthal folds, small eyes), and delayed growth and development

*A genetic defect has not been established for all patients classified in these subtypes.

Table 97.6 Heritable forms of cutis laxa and related conditions (cont'd). "Neonatal cutis laxa with a marfanoid phenotype" was described in an infant who lacked immunohistochemical evidence of laminin-β1 in the skin and had a heterozygous chromosomal break involving the *LAMB1* locus (which is near the *ELN* locus). Rare, autosomal recessive syndromes that can present with cutis laxa include transaldolase deficiency (also features hypertrichosis, hepatosplenomegaly, hemolytic anemia and GU malformations) and congenital disorders of glycosylation due to mutations in component of oligomeric Golgi complex 7 (*COG7*; also features ichthyosis, ocular colobomas and midline brain malformations) or steroid 5-α-reductase 3 (*SRD5A3*; fatal due to multiple-system malformations). AD, autosomal dominant; AR, autosomal recessive.

ACQUIRED CUTIS LAXA: ASSOCIATED CONDITIONS
SKIN DISORDERS
• Urticaria and/or angioedema • Drug eruptions (e.g. due to penicillin or an SSRI) • Sweet syndrome-like eruptions (Marshall syndrome*) • Arthropod bite reactions • Erythema multiforme • Dermatitis herpetiformis • Lupus panniculitis • Interstitial granulomatous dermatitis • Cutaneous mastocytosis • Cutaneous lymphoma
EXTRACUTANEOUS INFLAMMATORY DISORDERS
• Rheumatoid arthritis • Systemic lupus erythematosus • Nephrotic syndrome • Celiac disease • Sarcoidosis
HEMATOLOGIC DISORDERS
• Monoclonal gammopathy (especially acral CL; underlying plasma cell dyscrasia) • Congenital hemolytic anemia
INFECTIOUS DISEASES
• Febrile viral syndrome • *Borrelia burgdorferi* infection • Syphilis
DRUG INTAKE (ALSO SEE DRUG ERUPTIONS ABOVE)
• Penicillamine • Isoniazid (single report)
*Referred to as type II acquired CL, with other forms of acquired CL classified as type I.

Table 97.7 Acquired cutis laxa (CL): associated conditions. Generalized or localized CL (including Marshall syndrome) can occur in the setting of α_1-antitrypsin deficiency. SSRI, selective serotonin reuptake inhibitor.

particularly the palms and soles. Marshall syndrome refers to CL in association with a Sweet syndrome-like neutrophilic dermatosis, and it occurs primarily in infants and young children[58].

Pathology

In the skin of patients with CL, the characteristic histologic feature is sparse and/or fragmented elastic fibers (Fig. 97.10). This ranges from virtual absence of elastic fibers in a newborn with severe CL (e.g. ARCL type I) to fragmentation but a normal density of fibers in late-onset autosomal dominant CL. Electron microscopy shows irregular fragmentation of the elastic fiber structure. In some patients, elastic fiber abnormalities are accompanied by alterations in collagen fibers, which likely reflect a general perturbation of the ECM and mechanical properties of the skin due to the primary elastic fiber defect.

Differential Diagnosis

Clinical findings consistent with CL can develop as a consequence of the normal aging process of the skin. In contrast to CL, the hyperextensible skin of patients with EDS retains its elasticity and recoil, with the exception of lax as well as "doughy" and extremely fragile skin in the rare dermatosparaxis type of EDS. As in other forms of EDS, the primary pathology in dermatosparaxis resides in the collagen meshwork, and a diagnosis of CL should be reserved for conditions characterized by abnormalities in the structure or quantity of elastic fibers. In PXE and the related PXE-like disorder associated with coagulation factor deficiency, the skin can be loose and sagging without recoil; however, the primary papular lesions at the predilection sites distinguish these conditions from CL.

Mid-dermal elastolysis (see Ch. 99) is an acquired disorder with a predilection for young and middle-aged women that is characterized by circumscribed or diffuse areas of fine wrinkling, most often in sun-exposed sites on the upper trunk, lateral neck and upper arms[59]. It features the pathognomonic histopathologic finding of a band-like loss of elastic fibers in the mid dermis. Anetoderma presents as focal areas of flaccid skin (e.g. 1 to 2 cm in diameter) with loss of elastic tissue

Fig. 97.9 Clinical features in cutis laxa. **A** Loose skin and drooping jowls in an infant with heritable cutis laxa. **B** Sagging folds of skin giving a prematurely aged appearance to a man with acquired cutis laxa associated with multiple myeloma. *A, Courtesy, Thomas Schwarz, MD. B, Courtesy, Jeffrey P Callen, MD.*

and may have an antecedent inflammatory process. It is histologically and ultrastructurally identical to CL and may be regarded as a variant of acquired localized CL with smaller, circumscribed lesions.

Several rare syndromes can present with lax skin and elastic fiber abnormalities characteristic of CL (see Table 97.6)[60]. The features of gerodermia osteodysplastica, wrinkly skin syndrome and De Barsy syndrome overlap considerably with those of ARCL type II, and many of the patients recently reported to have the latter condition (based on molecular testing as well as clinical findings) had previously been diagnosed with one or more of the former disorders. "Michelin tire baby" syndrome (see Table 97.6) presents with congenital circumferential skin creases on the extremities that may be reminiscent of CL, but the folds reflect excess tissue rather than cutaneous laxity.

Treatment

The redundant and sagging skin may be of major cosmetic concern to patients with CL, and reconstructive surgery can provide a dramatic improvement with significant psychosocial benefit. Surgical wounds heal with scars that have a normal appearance and tensile strength. However, sagging may reoccur, necessitating additional surgical procedures. The associated internal organ involvement requires appropriate care through a multidisciplinary approach.

Elastic tissue-related disorders 1628

This chapter will discuss disorders in which there are increased amounts of collagen within the skin, followed by those with increased elastin.

HYPERTROPHIC SCARS AND KELOIDS

Key features

- Normal scars are preceded by injury, immediate in onset, flat and asymptomatic
- Hypertrophic scars are raised and confined to the wound margin. Sometimes they improve spontaneously and tend to have a good response to treatment
- Keloids extend beyond the wound margin and are delayed in onset. They seldom resolve spontaneously, and their response to treatment is often poor
- Compared to normal skin and normal scars, both hypertrophic scars and keloids have increased cellularity, vascularity and connective tissue

Introduction

Hypertrophic scars and keloids represent two forms of abnormal wound healing. Both are characterized by local fibroblast proliferation and excessive collagen production in response to cutaneous injury. However, their clinical and histopathologic features differ, as well as proposed pathogeneses. While keloids are often more elevated above the skin surface than hypertrophic scars, the key difference is that keloids extend beyond the original wound margin into adjacent normal skin, often with claw-like extensions resembling the pincers of a crab. Hypertrophic scars, on the other hand, remain confined to the site of the original injury. Both keloids and hypertrophic scars favor sites of increased tension, but keloids can also appear in sites such as the earlobe, where there is minimal tension.

Epidemiology

There is a higher incidence of keloids in darkly pigmented individuals of African ancestry. From 4.5% to 16% of predominantly black and Hispanic populations have keloids, with an incidence of up to 16% in black Africans[1]. Although the incidence of hypertrophic scars is probably higher than that of keloids, precise data are lacking. There is often a familial tendency to develop hypertrophic scars and keloids and possibly an autosomal dominant mode of inheritance with incomplete clinical penetrance and variable expression.

Keloids may occur at any age, but they tend to form in individuals between 10 and 30 years of age. Younger individuals are more frequently subjected to trauma and younger skin possesses greater tension, whereas older skin is less elastic and has more redundancy. The rate of collagen synthesis is also greater in younger persons[2].

Pathogenesis

Factors that play a major role in keloid development include genetic predisposition, typically coupled with some form of skin injury[3]. The latter include lacerations, burns, surgical excisions, skin piercings and injections (vaccines, tattoo inks) as well as cutaneous inflammation (e.g. acne vulgaris, insect bites). Whether the latter play a role in spontaneous keloids is a matter of debate.

Wound or skin tension has also been implicated as a critical factor in the formation of keloids and hypertrophic scars[4]. When there is loss of tissue as in a surgical excision, the attempt to close the wound creates tension. In addition, constant tension is transmitted to the skin from the underlying musculoskeletal structures. The possibility of hormonal influences has been raised[5] to provide an explanation for the appearance of keloids at or after puberty and their resolution following menopause, in addition to reports of the onset or enlargement of keloids during pregnancy.

Insight into the normal sequence of wound healing is important in understanding the pathophysiology of hypertrophic scars and keloids. Normal wound healing occurs in three phases: the inflammatory phase, the proliferative or granulation phase, and the maturation or remodeling phase (see Ch. 141). During the normal maturation phase, the nodularity and redness of the wound soften and flatten due to simultaneous collagen synthesis and degradation. In keloids, collagen

DIFFERENCES IN ADULT VERSUS FETAL WOUND HEALING		
	Adult	**Fetal**
Fluid environment	No	Yes
Sterile environment	No	Yes
Inflammation	Yes	No
Scar formation	Yes	No
pO_2 (mmHg)	>60	20

Table 98.1 Differences in adult versus fetal wound healing.

synthesis is ~20 times and 3 times greater than in normal non-injured skin and hypertrophic scars, respectively. This collagen overproduction is attributed in large part to the activity of keloidal fibroblasts.

The influence of various growth factors on scar and keloid formation has been the subject of more recent studies[6]. As in systemic sclerosis, both transforming growth factor (TGF)-β and platelet-derived growth factor (PDGF) have been shown to play an integral role (Fig. 98.1). For example, the majority of cells involved in wound healing express TGF-β in an initially inactive form (which becomes active following its release from the latency associated protein; see Fig. 95.7) that strongly promotes the chemotaxis of fibroblasts to the site of injury. In keloidal tissue, TGF-β, which is known to play a critical role in fibroblast proliferation and collagen production, is overproduced and poorly regulated via autocrine signaling pathways. At the same time, keloidal fibroblasts have increased expression of growth factor receptors, including for TGF-β and PDGF, and therefore respond more intensely to these growth factors. Decreased production of molecules that promote matrix breakdown (e.g. matrix metalloproteinases [MMPs]) may also be occurring within keloids. Lastly, in comparison to normal dermal fibroblasts, keloidal fibroblasts exhibit a reduced rate of apoptosis[7].

Especially interesting is the observation that fetal wounds (prior to the third trimester) heal *without* scarring[8]. Scrutiny of the differences between adult and fetal wound healing suggests that both inflammation and cytokines unique to adult wound healing are likely to play a prominent role in the development of hypertrophic scars and keloids (Table 98.1).

Clinical Features

Both keloids and hypertrophic scars have a smooth surface and are firm to palpation. They may be pruritic or painful and can even inhibit normal motion of adjacent tissues. The color can vary from pink–purple (early lesions) to skin-colored to hypo- or hyperpigmented. While keloids may be more elevated above the skin surface than hypertrophic scars, the key difference is that keloids extend beyond the original wound margin into adjacent normal skin, often with claw-like extensions resembling the pincers of a crab (in Greek, *chelè* means claw; Figs 98.2 & 98.3). Hypertrophic scars, on the other hand, remain confined to the site of the original injury (Figs 98.4 & 98.5). Both keloids and hypertrophic scars favor sites of increased wound tension (e.g. upper trunk, deltoid region), but keloids can also appear in sites such as the earlobe, where there is minimal tension (Fig. 98.6). Additional clinical features are outlined in Table 98.2.

Scar assessment

Assessment of any scar begins with a determination of its extent, i.e. surface area or volume, based upon measurement of the maximum dimensions and thickness. In addition, subjective scales, such as the Vancouver Scar Scale (VSS), have been developed to provide an overall impression of the quality of the scar (Table 98.3)[9]. While the VSS is widely accepted, some authors have questioned its reliability and validity[10], and scales that incorporate both patient and observer scar assessments have subsequently been developed and shown to be reliable[11,12].

Non-invasive techniques can be used to measure scar color, blood flow, transcutaneous oxygen tension, skin hardness, elasticity and hydration[13]. In addition, skin imaging techniques such as dedicated scar photography, high-frequency ultrasound, laser Doppler perfusion imaging, confocal microscopy and magnetic resonance imaging can be employed to objectively evaluate scars[14]. However, the eventual goal is to create an easy-to-use and inexpensive system that monitors the qualitative and quantitative evolution of scars[15].

Pathology

In hypertrophic scars, there is an increase in both the number of fibroblasts and density of collagen fibers within the dermis (Fig. 98.7). The orientation of both the cells, which are spindle-shaped, and the collagen becomes parallel to the skin surface[16,17]. Dermal blood vessels are vertically oriented (i.e. perpendicular to the skin surface; see Fig. 98.7B), and there may be a sparse perivascular inflammatory infiltrate. Elastic tissue is diminished or absent. Keloids are characterized by the presence of thick hyalinized collagen bundles in a haphazard array with mucinous

ground substance and an increased number of fibroblasts. In general, the overlying epidermis and papillary dermis are uninvolved. Early on, there are abundant deposits of fibrillary collagen within the reticular dermis, while mature keloids often have strikingly thick, glassy, homogeneous collagen bundles; the latter are composed of multiple densely packed fibrils and are oriented *haphazardly* throughout the dermis (Fig. 98.8). In longstanding keloids, there may be a return to the earlier fibrillary pattern. There are fewer, if any, vertically oriented blood vessels, compared with hypertrophic scars[18]. Both keloids and hypertrophic scars have an absence of subepidermal adnexal structures.

Because keloidal collagen is not always present (absent in up to 45% of lesions, depending upon the series[16]), additional histologic findings may prove helpful in distinguishing keloids from hypertrophic scars. These include (in keloids) a tongue-like advancing edge as the scar tissue extends through the reticular dermis; a broad cellular fibrous band occupying the upper reticular dermis with a sharp demarcation from the normal-appearing papillary and reticular dermis; and fascia-like fibrous bands primarily in the deeper portion of the scar[16]. Occasionally, immunohistochemical stains are also employed, such as the α-smooth muscle actin (α-SMA) stain to identify myofibroblasts[17]. In one study, nodules of α-SMA-positive cells were observed only in hypertrophic scars[19].

To distinguish keloids and hypertrophic scars from spindle cell tumors, immunohistochemical stains may also be performed. In contrast to dermatofibrosarcoma protuberans, immunostaining for CD34 is negative in these scarring processes[20]. Staining for factor XIIIa, which highlights dermal dendrocytes, is also negative, allowing distinction from dermatofibromas, including the keloidal variant[21]. While there is little or no S100-staining in scars (<10% of cells in 2 of 25 cases[17]; 0% in 16 scars[22]), negative staining does not completely exclude desmoplastic melanoma; additional criteria such as cellular atypia and proliferation of atypical melanocytes within the epidermis need to be considered.

Differential Diagnosis

Perhaps the greatest difficulty lies in distinguishing hypertrophic scars, which may become enormous, from keloids (Fig. 98.9). By convention, a keloid extends into adjacent tissue, whereas a hypertrophic scar remains within the confines of the original injury. The sclerotic form of xanthoma disseminatum may be confused with keloids clinically but not histologically (see Fig. 91.18) – as may lobomycosis (keloidal blastomycosis; lacaziosis), which is due to infection with *Lacazia loboi* (see Ch. 77). There are also keloidal forms of scleroderma and morphea, in addition to the rare presentation of carcinoma *en cuirasse* as keloidal nodules and the keloidal plaques that can develop on the lower extremities of patients with type IV Ehlers–Danlos syndrome. Lastly, formation of keloids can be a clinical clue to rare inherited syndromes such as Rubenstein–Taybi and Goeminne syndromes. The histologic differential diagnosis is discussed in the Pathology section.

Treatment

The management of keloids and hypertrophic scars continues to challenge clinicians, for there is no universally accepted treatment protocol. Obviously, prevention remains the best strategy, with predisposed patients avoiding non-essential surgery. Potential treatments are outlined in Table 98.4[23–25]. Silicone elastomer sheeting, a simple intervention, is thought to work by increasing the temperature, hydration (reduces water vapor loss), and perhaps the oxygen tension of the occluded scar, which may decrease capillary activity, leading to a reduction in collagen deposition[26]. This sheeting is also used as a preventative measure immediately after healing in patients at risk for developing hypertrophic scars or keloids.

Keloids are thought to be best treated by a combination of surgery plus postoperative radiation therapy, although to date there have been no randomized controlled trials. Typically, a median cumulative dose of 28 Gy (range, 4–40 Gy) over a period of days (most often 2 or 3 consecutive days) is administered immediately following excision; complete flattening (68% of keloids) and flattening to <2 mm in height (an additional 11%) were observed in a retrospective series of 126 keloids in 83 patients[27]. In a recent literature review that focused on patients who had received radiation therapy for keloids, five radiotherapy-associated carcinomas were identified[28]. The authors concluded that the risk of inducing a malignancy is very low, especially when

Radiofrequency treatment was found to have no effect (3). HS, hypertrophic scars; K, keloids.

surrounding tissues (e.g. thyroid, breasts) are adequately shielded, particularly in children.

Although TGF-β plays a key role in collagen production, research into mechanisms of skin scarring identified TGF-β_3 as a potential anti-scarring therapy; for example, in non-scarring fetal skin, the ratio of TGF-β_3: TGF-β_1 and -β_2 is high. In three double-blind, placebo-controlled studies, intradermal injections of avotermin (recombinant human TGF-β_3) along both margins of 1 cm, full-thickness skin incisions led to improvement of scar scores[29]. The injections were performed before wounding and 24 hours later and the assessment time points varied from week 6 to month 12. Erythema and edema were observed more frequently with avotermin than with placebo, and at the time of writing, avotermin is not an FDA-approved biologic agent. Lastly, in controlled trials, topical onion gel extract was not effective in reducing scar-associated erythema or pruritus[25].

DUPUYTREN'S CONTRACTURE

Synonyms: ■ Palmar fibromatosis ■ Dupuytren's disease/diathesis

Key features

- Thickening of the palmar and digital fascia
- Flexion contracture of affected digits
- Myofibroblast proliferation followed by excess collagen synthesis
- Treatments include injections of collagenase and surgical fasciectomy

History

In 1777, Henry Cline discovered that thickening of the palmar fascia produced this characteristic contracture, and, 2 years later, proposed palmar fasciotomy as a cure.

Epidemiology

Dupuytren's contracture is common in Caucasians of northern European ancestry, and it is rare in darkly pigmented populations. The prevalence approaches 30% in individuals over 60 years of age in Norway. This condition affects middle-aged to older individuals of both sexes, although men are affected about a decade earlier than women. Familial associations suggest an autosomal dominant inheritance, but sporadic cases are common. The lesion is associated with other fibromatoses, including Peyronie's disease, plantar fibromatosis (Ledderhose's disease), and knuckle pads (see Ch. 116). The condition has also been associated with alcoholism and diabetes mellitus.

Fig. 98.10 Dupuytren's contracture. There is greater involvement of the fifth finger than the fourth finger. Fibrotic cords can be felt and are accentuated by extension of the digits. Eventually, flexion contractures develop. *Courtesy, Jean L. Bolognia, MD.*

Pathogenesis

Fibrogenic cytokines (e.g. TGF-β_1 and TGF-β_2) are thought to be involved in the genesis of Dupuytren's contractures. They are able to induce the growth of fibroblasts and their differentiation into myofibroblasts, in addition to stimulating the production of extracellular matrix. In a recent genome-wide association study involving nearly 1000 individuals with Dupuytren's contracture, 9 different susceptibility loci were detected, with 6 of the 9 loci harboring genes that encode proteins in the Wnt-signaling pathway[29a]. This led the authors to conclude that aberrations in this signaling pathway will provide insights into the pathophysiology of this fibromatosis.

Clinical Features

Patients often present late in the course of their disease with flexion contractures of the affected digits. Most often, lesions develop in an ulnar distribution, and the ring finger is most commonly affected. The disorder begins with a nodule in the fascia of the palm, which grows at varying rates to produce a cord, and then it contracts, producing a flexion contracture (Fig. 98.10). Complications of Dupuytren's contracture include nerve injury, loss of joint mobility, and the development of reflex sympathetic dystrophy[30].

Pathology

Histologically, the nodular lesion consists of a proliferation of myofibroblasts, which subsequently align along lines of tension. As the cord develops, there is collagen thickening and myofibroblasts disappear.

Differential Diagnosis

Although usually a straightforward diagnosis, one must consider ganglion cysts, giant cell tumors of the tendon sheath, soft tissue sarcomas, calluses and tenosynovitis.

Fig. 98.11 Cutis verticis gyrata. Cerebriform folding of the skin of the scalp. Erythema in the posterior grooves is related to a previous superinfection.

CUTIS VERTICIS GYRATA – DISEASE ASSOCIATIONS
PRIMARY ESSENTIAL
• None
PRIMARY NON-ESSENTIAL
• Neurologic abnormalities (e.g. mental retardation, seizures) • Ophthalmologic abnormalities (e.g. cataracts, optic atrophy)
SECONDARY
• Acromegaly, pseudoacromegaly • Myxedema (including cretinism)* • Insulin resistance • Turner and Noonan syndromes (following resolution of intrauterine lymphedema)* • Fragile X syndrome • Klinefelter syndrome • Hereditary neuralgic amyotrophy • Tuberous sclerosis • Hyper-IgE syndrome • Graves' disease* • Paraneoplastic due to metastatic carcinoma
*Increased dermal mucin may also be observed.

Table 98.5 Cutis verticis gyrata – disease associations.

Treatment

Surgical approaches are the mainstay of therapy, with fasciectomy releasing the joint contracture in most patients. Postoperative splinting and range-of-motion exercises are important for a good outcome, and recurrences are common. Recently, injectable collagenase (from *Clostridium histolyticum*) was FDA-approved for the treatment of Dupuytren's contractures; up to three monthly injections are done per cord, followed by a finger-extension procedure the following day. In two placebo-controlled trials, reduction in the contracture (to 0–5°) was seen in 44% and 64% of collagenase-treated cords, compared to 5% and 7% in the placebo groups[31]. Possible complications include tendon, ligament or nerve injury, as well as urticaria and angioedema.

CUTIS VERTICIS GYRATA

Key features

- Hypertrophy and folding of the scalp
- Primary (idiopathic) form seen almost exclusively in males, with an onset at puberty
- Face not affected as in pachydermoperiostosis
- Underlying disorders in the secondary form include acromegaly, Turner syndrome and myxedema

Clinical Features

In primary cutis verticis gyrata, overgrowth of the scalp develops at puberty and progresses to produce symmetric gyrate or cerebriform folding of the skin (Fig. 98.11). The folds are usually aligned in an anterior–posterior direction on the crown and vertex and are soft to spongy on palpation. Terminal hair density may be reduced on the folds, but not in the furrows. *Primary* cutis verticis gyrata can be subdivided into essential (isolated) and non-essential (associated with neurologic and/or ophthalmologic abnormalities) forms, both of which have a male predominance. *Secondary* cutis verticis gyrata is less common and has a more equal sex distribution. Onset of the latter varies from birth to adulthood and secondary forms may be asymmetric, depending on the underlying etiology (Table 98.5).

Pathology

Biopsy specimens from cutis verticis gyrata typically show increased dermal collagen in otherwise normal-appearing skin.

Differential Diagnosis

An extensive congenital cerebriform melanocytic nevus of the scalp can have the appearance of cutis verticis gyrata. One must also differentiate the latter from pachydermoperiostosis, which is associated with facial involvement and thickening of the skin on the hands and feet, as well as clubbing of the digits[32]. Furrowed skin on the scalp, forehead, preauricular areas, neck, trunk, palms and soles in association with acanthosis nigricans, craniosynostosis and a prominent umbilical stump characterizes Beare–Stevenson cutis gyrata syndrome, an autosomal dominant condition caused by mutations in the fibroblast growth factor receptor 2 (*FGFR2*) gene. Dissecting cellulitis of the scalp, Darier disease or extensive AL amyloid deposition can lead to cerebriform folds of skin resembling cutis verticis gyrata. Less often, cutis verticis gyrata might be confused with a plexiform neurofibroma, nevus lipomatosus, connective tissue nevus, aggregated cylindromas, acanthosis nigricans or cutaneous leukemic infiltrates.

Treatment

This unusual morphologic syndrome is generally asymptomatic, and it requires no treatment. Occasionally, surgical excision is performed[33,34].

JUVENILE HYALINE FIBROMATOSIS AND INFANTILE SYSTEMIC HYALINOSIS

Synonyms: ■ Hyaline fibromatosis syndrome ■ Murray–Puretic–Drescher syndrome ■ Fibromatosis hyalinica multiplex juvenilis ■ (Juvenile) systemic hyalinosis

Key features

- Rare, allelic autosomal recessive disorders with clinical overlap
- Usually present during infancy or early childhood
- Clinical features include papulonodular lesions (favoring the ears, scalp, neck, hands and periorificial areas), gingival hypertrophy and flexion contractures of large joints; infantile systemic hyalinosis represents a more severe variant with internal organ involvement
- Mutations in the gene that encodes capillary morphogenesis protein-2 (CMG2) are responsible for both disorders
- Treatment consists of excision of nodules and gingivae as needed, but lesions often recur

Introduction

Both juvenile hyaline fibromatosis (JHF) and infantile systemic hyalinosis (ISH) are rare autosomal recessive genodermatoses characterized by hyaline accumulation in the dermis. They are allelic disorders, i.e. due to mutations in the same gene, but can differ with regard to severity and involvement of internal organs (Table 98.6). It has been suggested that JHF and ISH exist within a continuum of disease with varying phenotypic expression[35] and the encompassing term "hyaline fibromatosis syndrome" has been proposed.

History

As early as 1873, Murray had described a condition which he termed "molluscum fibrosum". In 1972, Kitano et al.[36] renamed the disorder "juvenile hyaline fibromatosis".

Epidemiology

Both JHF and ISH are rare disorders that present during infancy or early childhood. As expected given the autosomal recessive inheritance pattern, both sexes are equally affected.

Pathogenesis

The gene that encodes capillary morphogenesis protein-2 (CMG2) resides on chromosome 4q21. CMG2 is an integrin-like cell surface receptor that binds laminins and type IV collagen (as well as the anthrax toxin), and in the skin it is thought to play a role in cell–matrix interactions and basement membrane integrity[37]. Mutations in *ANTXR2* (*CMG2*) can lead to both JHF and ISH. Missense and other in-frame mutations that affect the cytoplasmic domain tend to cause JHF, whereas truncating mutations and missense mutations that affect the extracellular protein-binding domain tend to cause ISH[38]. However, the exact pathophysiology is still unclear.

Clinical Features

Initially, firm papules and nodules develop on the scalp, ears (Fig. 98.12), neck and face (particularly perinasal and perioral regions) as well as the perianal area; papulonodules also favor the hands. Affected children are of normal intelligence, but often suffer severe physical handicap from joint contractures and tumors. Gingival hyperplasia and osteolytic bone lesions may also occur. Infantile systemic hyalinosis is a more severe variant that is characterized by hyaline deposits in multiple internal organs, recurrent infections and, in most cases, death during early childhood.

Pathology

An increased number of fibroblasts are embedded in a hyalinized connective tissue stroma that is homogeneous, amorphous and acidophilic (stains positively with PAS)[36]. Mononuclear cells and $CD68^+$, osteoclast-like giant cells are also present in a perivascular location. Additional findings include intracytoplasmic and extracellular eosinophilic globules; over time, the lesions tend to become more paucicellular[39]. There is an accumulation of type VI collagen within the fibromas in JHF.

Differential Diagnosis

Winchester syndrome and nodulosis–arthropathy–osteolysis (NAO) syndrome share clinical features with JHF and ISH (e.g. nodules, joint contractures, osteopenia)[39]. The former are allelic autosomal recessive disorders due to mutations in the gene that encodes matrix metalloproteinase-2 (MMP2). Additional findings include coarse facies and hypertrichosis. Painful nodules on the palms and soles are observed in NAO syndrome, whereas thickened, hyperpigmented skin and gingival hypertrophy characterize Winchester syndrome. Histologically, both conditions feature a proliferation of fibroblasts and thickened col-

CLINICAL FEATURES OF JUVENILE HYALINE FIBROMATOSIS VERSUS INFANTILE SYSTEMIC HYALINOSIS

	Juvenile hyaline fibromatosis	Infantile systemic hyalinosis
Age of onset	Childhood (<5 years old)	Infancy
Cutaneous findings:		
• Firm, pearly papules (favoring the perinasal area and ears)	+	+
• Verrucous perianal nodules	+	+
• Firm nodules/tumors (favoring the scalp, neck, hands and trunk)	+	–
• Reddish-blue to brown plaques overlying extensor surfaces of joints	–	+
• Diffusely thickened skin	–	+
Gingival hypertrophy	+	+
Joint contractures	+	+
Osteopenia	+	+
Persistent diarrhea	–	+
Recurrent infections	–	+
Visceral involvement	–	+
Normal mental development	+	+
Survival into adulthood	+	–

Fig. 98.12 Juvenile hyaline fibromatosis. Firm pearly papules favor the ears.

DISORDERS CHARACTERIZED BY INCREASED ELASTIC TISSUE FIBERS			
Disorder	**Clinical features**	**Histopathologic features**	**Comments**
Late-onset focal dermal elastosis	Multiple 1–3 mm yellow papules that may coalesce Favors the neck, axillae, groin, antecubital and popliteal fossae	Increased normal-appearing elastic fibers in the mid and deep reticular dermis	See Ch. 97
Linear focal elastosis (elastotic striae)	Multiple yellow, palpable, striae-like bands of the lumbosacral region	Focal increase in number of elongated or fragmented elastic fibers (thickened > thinned) within the mid dermis; the ends of the elastic fibers may be split with a "paintbrush" appearance	May represent an excessive regenerative process of elastic fibers, perhaps to repair striae distensae (see Ch. 99)
Elastoderma	Localized areas of lax, pendulous skin; neck, trunk, arm	Increased normal- and abnormal-appearing elastic fibers throughout the dermis	See Ch. 97
Elastofibroma dorsi	Large mass in the deep subcutaneous tissue of the infrascapular area	Arises within the fascia Increased elastic fibers with a globular and beaded morphology admixed with plump collagen bundles, fibroblasts and mature fat cells (Fig. 98.13)	Favors older women > men and Japanese Possibly related to chronic mechanical stress
Elastoma (nevus elasticus)	Firm, skin-colored to yellowish papule(s) which may be clustered Favors the trunk	Accumulation of broad, partially fragmented, branching elastic fibers within the mid and lower dermis	Type of connective tissue nevus (see Ch. 116) Associated with Buschke–Ollendorf syndrome
Elastosis perforans serpiginosa	Annular and polycyclic plaques composed of keratotic papules Favors the neck, face, antecubital fossae and other flexural areas	Perforating disorder with transepidermal channel that contains fragments of elastotic material Increased number of coarse elastic fibers in the superficial dermis	Associated with penicillamine (lumpy-bumpy fibers*), Down syndrome and connective tissue disorders (e.g. Ehlers–Danlos syndrome, Marfan syndrome; see Ch. 96)

*By electron microscopy

Table 98.7 Disorders characterized by increased elastic tissue fibers[41–51]. Actinic elastosis has masses of degenerated elastic fibers within the upper dermis, and when it forms a localized plaque, the term elastoma of Dubreuilh may be applied. Papillary dermal elastosis is considered a variant of papillary dermal elastolysis. Special stains for elastic fibers include Verhoeff–Van Gieson and orcein (acid orcein–Giemsa; see Ch. 0).

lagen bundles extending from the deep reticular dermis to the subcutaneous fat.

Treatment

Unfortunately, treatment options for JHF and ISH are limited. Surgical excision of nodules and gingival hypertrophy, as well as release of contractures, can be performed, but lesions often recur. Physiotherapy may slow the progression of joint contractures[39]. Injections of corticosteroids into fibromas have met with limited success. Systemic interferon-α-2b therapy was reported to improve the skin lesions, gingival hypertrophy and joint contractures in one patient.

ELASTIC TISSUE-RELATED DISORDERS

In general, mechanisms which lead to increased dermal elastic tissue are unknown, and the nosology of the elastic tissue-related disorders can be confusing[40]. There are several acquired disorders whose clinical appearance can overlap and their clinical as well as histologic features are outlined in Table 98.7.

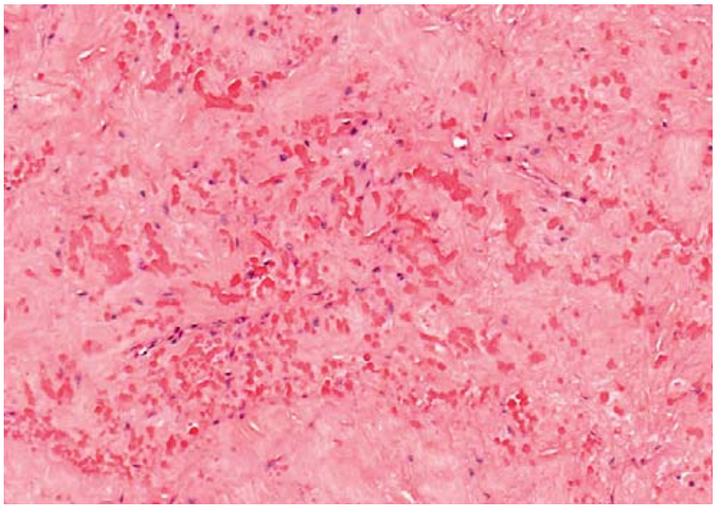

Fig. 98.13 Elastofibroma dorsi. Eosinophilic, irregular, partly fragmented elastic fibers admixed with swollen collagen bundles. *Courtesy, Lorenzo Cerroni, MD.*

Chapter Contents

Mid-dermal elastolysis 1631
Anetoderma 1632
Striae 1635
Idiopathic atrophoderma of Pasini and Pierini 1636
Follicular atrophoderma 1637
Atrophia maculosa varioliformis cutis 1639
Piezogenic pedal papules (piezogenic papules) 1639

Atrophies of the skin that are due to a diminution or loss of collagen and/or elastic fibers are discussed in this chapter. The areas of involvement can be quite large, as in mid-dermal elastolysis, or punctate, as in follicular atrophoderma. In most disorders, the underlying pathogenesis remains to be discovered.

MID-DERMAL ELASTOLYSIS

Key features

- Uncommon disorder with areas of fine wrinkling
- Usually affects Caucasian middle-aged women
- Selective loss of elastic tissue in the mid dermis

Introduction

Mid-dermal elastolysis is a rare acquired disorder of elastic tissue. It is characterized clinically by diffuse fine wrinkling, most often located on the trunk, neck and arms. Histologically, a clear band of elastolysis is present in the mid dermis.

History

In 1977, Shelley and Wood reported the first case of "wrinkles due to idiopathic loss of mid-dermal elastic tissue". Their patient, a 42-year-old woman, had circumscribed areas of fine wrinkles that gave her an inappropriately aged appearance[1].

Epidemiology

To date, approximately 80 cases have been reported in the literature. The vast majority of patients are Caucasian women between the ages of 30 and 50 years[2,3].

Pathogenesis

The cause of the acquired elastic tissue degeneration in mid-dermal elastolysis is still unclear. Exposure to UV light is thought to be a major contributing factor in the degeneration of elastic fibers[4] (as in annular elastolytic giant cell granuloma). There are reports of mid-dermal elastolysis developing after significant UV exposure, including natural sunlight, UVA (tanning salon) and narrowband UVB phototherapy[5].

Other possible mechanisms include defects in the synthesis of elastic fibers, autoimmunity against elastic fibers, and damage to elastic fibers via the release of elastase by inflammatory cells or fibroblasts. More recent studies have suggested that an altered balance between matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs) may be playing a role, in addition to $CD34^+$ dendritic fibroblasts[6].

Clinical features

Mid-dermal elastolysis is characterized by well-circumscribed or larger diffuse areas of fine wrinkling (Fig. 99.1), usually in a symmetric distribution pattern (type I). The wrinkles themselves tend to follow cleavage lines. Discrete perifollicular papules can be seen in some patients (type II), with the site of the central hair follicle being indented. Inconstant features include erythematous patches, telangiectasias and reticulated erythema (type III)[3]. Although in the majority of cases there is no history of a prior inflammatory dermatosis, some patients do report previous mild to moderate erythema and, rarely, the elastolysis is preceded by episodes of urticarial lesions or granuloma annulare.

The sites of predilection are the trunk, lateral neck and upper extremities. Once the patches of wrinkling have appeared, they usually remain stationary. They are asymptomatic and give the skin a prematurely aged appearance. The affected areas usually have normal pigmentation and no associated scaling, induration or herniation. There is neither associated systemic involvement nor a family history of similar lesions.

Pathology

The epidermis is normal in appearance and, occasionally, a mild perivascular infiltrate is noted in the dermis. Elastic tissue stains, such as Verhoeff–van Gieson or Weigert's stain, reveal a selective loss of elastic fibers in the mid dermis (Fig. 99.2). There is preservation of normal elastic tissue in the superficial papillary dermis above, in the reticular dermis below, and along adjacent hair follicles. The preservation of elastic tissue around the hair follicles explains the perifollicular papules that can be seen in some cases.

By electron microscopy, phagocytosis of normal as well as degenerated elastic fiber tissue by macrophages has been described[7]. Elastophagocytosis by macrophages is also occasionally observed by routine histology.

Differential diagnosis

Mid-dermal elastolysis must be differentiated from the other disorders of elastic tissue such as anetoderma, pseudoxanthoma elasticum (PXE), PXE-like papillary dermal elastolysis, elastoderma and cutis laxa, especially the acquired form (Table 99.1).

Clinically, anetoderma is characterized by smaller soft macules and papules that herniate upon palpation, as opposed to diffuse wrinkling. Histologically, elastolysis can occur in the papillary and/or mid-reticular dermis in anetoderma (see below). Patients with cutis laxa have loose, redundant skin, hanging in folds, and histologic examination shows elastolysis that frequently involves the entire dermis. There is also a form of postinflammatory elastolysis and cutis laxa that was originally described in young girls of African descent. An inflammatory phase consisting of indurated plaques or urticaria, malaise and fever preceded the diffuse wrinkling, atrophy and severe disfigurement. Insect bites may be the trigger for the initial inflammatory lesions[8].

Less often, mid-dermal elastolysis is confused with solar elastosis or perifollicular elastolysis that is usually seen on the trunk in association with acne vulgaris. Solar elastosis differs by its onset in an older age group, restriction to only sun-exposed areas, yellowish color and coarser wrinkling, as well as by hyperplasia of abnormal elastic fibers and basophilic degeneration of the collagen in the papillary dermis. Perifollicular elastolysis leads to a selective and almost complete loss of the

DISORDERS OF ELASTIC TISSUE			
Condition	**Clinical findings**	**Site of predilection**	**Pathology**
Anetoderma	Multiple circumscribed areas of flaccid skin; lesions are often elevated (protruding), but can be macular or depressed	Usually on trunk	Focal or complete loss of elastic tissue in the papillary and/or mid-reticular dermis
Mid-dermal elastolysis	Diffuse areas of fine wrinkling and occasional perifollicular papules in middle-aged women	Trunk, arms and lateral neck	Selective loss of elastic fibers within the mid dermis in a band-like pattern
Pseudoxanthoma elasticum (PXE; see Ch. 97)	Yellowish coalescing skin papules, "cobblestoning", and redundant folds in flexural sites; associated ocular and cardiovascular involvement	Lateral neck, axillae, and groin; scars	Calcified and clumped elastic fibers in the mid dermis
Cutis laxa (see Ch. 97)	Loose, sagging skin folds resulting in prematurely aged appearance. Hereditary or acquired. Internal organ involvement, e.g. pulmonary, in hereditary form and generalized acquired form	Eyelids, cheeks, neck, shoulder girdle and abdomen	Diminished and fragmented elastic fibers throughout the dermis
PXE-like papillary dermal elastolysis	Multiple 2–3 mm yellow or skin-colored papules that can coalesce into cobblestoned plaques	Neck, flexor forearms, axillae, lower abdomen, inframammary folds	Decreased elastic tissue in the papillary dermis (band-like pattern); clumping and fragmentation of elastic fibers

Table 99.1 Disorders of elastic tissue. For additional entities, see Tables 95.5, 97.4 and 97.6.

elastic fibers that surround hair follicles, compared with preservation of elastic fibers around follicles in mid-dermal elastolysis. In one report, elastase-producing *Staphylococcus epidermidis* was found within the hair follicles and postulated to be playing a role[9].

Treatment

Currently, there is no effective treatment for mid-dermal elastolysis. Sunscreens, colchicine, chloroquine, vitamin E and topical agents (retinoic acid, corticosteroids) have been tried without success[2].

ANETODERMA

Synonyms: ■ Macular atrophy ■ Anetoderma maculosa ■ Anetoderma maculosa cutis ■ Atrophia maculosa cutis

Key features

- Circumscribed 1–2 cm areas of flaccid skin, which may be elevated, macular or depressed
- *Primary* anetoderma has classically been divided into inflammatory and non-inflammatory
- *Secondary* anetoderma is associated with infectious and inflammatory cutaneous disorders as well as tumors and autoimmune disorders (e.g. antiphospholipid antibody syndrome)
- Focal dermal defect of elastic tissue

Introduction

The term "anetoderma" is derived from *anetos*, the Greek word for slack, and *derma* for skin. Anetoderma is an elastolytic disorder characterized by localized areas of flaccid skin, which may be depressed, macular or papular; the latter can reflect herniation of the subcutaneous tissue. Anetoderma may be idiopathic or associated with an inflammatory disorder of the skin.

History

The first case of primary inflammatory anetoderma was reported by Jadassohn in 1892, and it occurred in a 23-year-old woman who had depressed pink-to-red lesions on her elbows that were noted to have an atrophic, wrinkled appearance[10]. A year previously, Schweninger and Buzzi described a 29-year-old woman with multiple sac-like tumors that demonstrated herniation upon palpation; the lesions were located on the trunk and upper extremities but lacked inflammation[11].

Epidemiology

Several hundred cases of anetoderma have been reported in the world literature since the original report. Primary anetoderma favors young adults between 15 and 25 years of age and occurs more frequently in women than men. The epidemiology of secondary anetoderma reflects that of the underlying etiologies (see Table 99.3).

Pathogenesis

The pathogenesis of anetoderma is not known. These lesions could be considered unusual scars, since scars also have decreased elastic tissue. The loss of dermal elastin may reflect an impaired turnover of elastin, caused by either increased destruction or decreased synthesis of elastic fibers. There are a number of proposed explanations for the focal elastin destruction, e.g. the release of elastase from inflammatory cells, the release of cytokines such as interleukin-6, an increased production of progelatinases A and B[12], and the phagocytosis of elastic fibers by macrophages. In addition, immunologic mechanisms may play a role in anetoderma and may explain the occasional associated findings of antiphospholipid antibodies, antinuclear antibodies, false-positive serologic testing for syphilis or *Borrelia* spp., and positive direct immunofluorescence (see below).

True primary anetoderma occurs when there is no underlying associated disorder, and it arises within clinically normal skin. It can be classified into two major forms: those with preceding inflammatory lesions (the Jadassohn–Pellizzari type) and those without preceding inflammatory lesions (the Schweninger–Buzzi type) (Table 99.2). This clinical classification is primarily of historical interest, since the two types of lesions can coexist in the same patient and their histopathology is often the same (i.e. inflammation has been observed in both types of lesions); the presence or absence of clinical inflammation at the onset of the disease is not related to prognosis[13].

Secondary anetoderma can arise in the setting of a primary inflammatory dermatosis, skin infection or cutaneous tumor, as well as in patients with systemic disorders (e.g. autoimmune). Over the past decade, an association with antiphospholipid antibody syndrome has been highlighted. Although the vast majority of cases are sporadic, familial anetoderma has been described and is usually not associated with pre-existing lesions[14].

Clinical features

The characteristic lesions are flaccid circumscribed areas of slack skin that are a reflection of a marked reduction or absence of dermal elastic fibers; they can appear as depressions, wrinkling or sac-like protrusions (Fig. 99.3). These atrophic lesions can vary in number from a few to hundreds, and they typically measure 1–2 cm in diameter and are skin-colored to blue–white in color. The skin surface can be normal in appearance or wrinkled, and a central depression may be seen. Coalescence of smaller lesions can give rise to larger herniations.

The examining finger sinks into a distinct pit with sharp borders as if into a hernia ring. The bulge reappears when the pressure from the finger is released. This clinical finding is referred to as the "buttonhole" sign and is similar to that observed in neurofibromas.

Predilection sites for these asymptomatic lesions are the chest, back, neck and upper extremities. They usually develop in young adults, and new lesions often continue to form for many years as the older lesions fail to resolve.

CLASSIFICATION OF ANETODERMA	
Primary anetoderma	• Jadassohn–Pellizzari type: preceding inflammatory lesions • Schweninger–Buzzi type: no preceding inflammatory lesions
Secondary anetoderma	• Associated with a primary dermatosis or cutaneous tumor • Associated with a systemic disease (autoimmune, infectious) or drug
Familial anetoderma	

Table 99.2 Classification of anetoderma.

True secondary anetoderma implies that the characteristic atrophic lesion has appeared in the same site as a previous specific skin lesion (see Fig. 99.3D,E). Some authors also consider lesions associated with an underlying disease (e.g. HIV infection, antiphospholipid antibody syndrome) as secondary anetoderma; however, in this instance, the atrophic areas do not necessarily develop within areas of known inflammation. Evaluation for the presence of antiphospholipid antibodies should be performed before patients with idiopathic anetoderma are labeled as having true primary anetoderma[15]. The range of heterogeneous conditions associated with secondary anetoderma are outlined in Table 99.3. With the exception of distribution (and perhaps size), the clinical features are the same as those of primary anetoderma.

Anetoderma has also been described in premature infants. In some cases, it may have been related to the use of cutaneous monitoring leads or adhesives[16].

In patients with anetoderma, a variety of systemic abnormalities have been reported, including ocular, endocrinologic, skeletal, cardiac, pulmonary and gastrointestinal. Because there has been no consistency with regard to these associated abnormalities, they are probably coincidental, although the possibility exists that they may reflect a more generalized elastolytic disorder that has yet to be defined.

Pathology

In routinely stained sections, the collagen within the dermis of affected skin appears normal. Perivascular lymphocytes are often present but do not correlate with clinical findings of inflammation. Monoclonal antibody studies have shown that the majority of lymphocytes in these infiltrates are helper T cells.

The predominant abnormality (as revealed by elastic tissue stains) is a focal, more or less complete loss of elastic tissue in the papillary and/or mid-reticular dermis. There are usually some residual abnormal, irregular and fragmented elastic fibers (Fig. 99.4)[17]. Plasma cells and histiocytes with occasional granuloma formation can be seen.

SECONDARY ANETODERMA – ASSOCIATED CONDITIONS	
Infectious	• Varicella • Folliculitis • Syphilis (cutaneous) • Molluscum contagiosum • Tuberculosis (cutaneous) • Lepromatous leprosy • HIV infection • Acrodermatitis chronica atrophicans • Post-hepatitis B immunization
Drugs	• Penicillamine
Inflammatory	• Acne vulgaris • Mastocytosis • Lichen planus • Granuloma annulare • Juvenile xanthogranuloma • Cutaneous sarcoidosis • Cutaneous lymphoid hyperplasia (lymphocytoma cutis) • Prurigo nodularis • Insect bites
Autoimmune	• Discoid and systemic lupus erythematosus • Antiphospholipid syndrome • Primary Sjögren's syndrome • Addison's disease • Graves' disease
Tumors and depositions	• Involuted infantile hemangioma • Pilomatricoma • Melanocytic nevus • Dermatofibroma • Dermatofibrosarcoma protuberans • Primary cutaneous marginal zone B-cell lymphoma (primary cutaneous plasmacytoma or immunocytoma) • Nodular amyloidosis • Xanthoma

Table 99.3 Secondary anetoderma – associated conditions.

Fig. 99.3 Anetoderma – primary and secondary. Lesions can range from soft, skin-colored papules that herniate upon palpation (**A**) to flaccid papules that have a central depression (**B**). The upper trunk and neck is a common location for primary anetoderma (**C**). Wrinkling of the skin from secondary anetoderma due to sarcoidosis (**D**) and lepromatous leprosy (**E**). *A, Courtesy, Ronald P Rapini, MD; C, Courtesy, Thomas Schwarz, MD; E, Courtesy, Louis A Fragola, Jr, MD.*

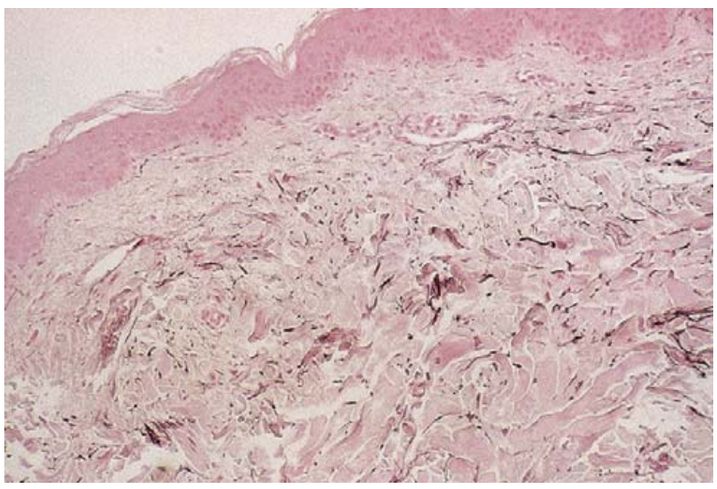

Fig. 99.4 Histology of anetoderma. A decrease of elastic fibers in both the papillary and reticular dermis (Weigert's stain).

Direct immunofluorescence sometimes shows linear or granular deposits of immunoglobulins and complement along the dermal–epidermal junction or around the dermal blood vessels in affected skin[18]. However, these findings are not helpful diagnostically.

Electron microscopy demonstrates that the elastic fibers are fragmented and irregular in shape and occasionally they are engulfed by macrophages.

Differential diagnosis

Anetoderma must be differentiated from other disorders of elastic tissue such as mid-dermal elastolysis (see Table 99.1) as well as atrophoderma (see below). However, the major differential diagnosis consists of post-traumatic scars and papular elastorrhexis. The latter is an acquired disorder characterized by firm, white, non-follicular papules that measure 2–5 mm in diameter and are evenly scattered on the trunk. The lesions usually appear during adolescence or early adulthood. Histology demonstrates focal degeneration of elastic fibers and normal collagen. There are no associated extracutaneous abnormalities. This disorder is believed by some authors to be a variant of connective tissue nevi[19] or an abortive form of the Buschke–Ollendorff syndrome[20], while others think that these lesions represent papular acne scars[21]. They are differentiated from anetoderma by being firm and non-compressible.

Less often, anetoderma is confused with perifollicular elastolysis (see above), nevus lipomatosus or focal dermal hypoplasia (Goltz syndrome). Nevus lipomatosus superficialis of Hoffman and Zurhelle presents as a clustered group of soft, skin-colored to yellow nodules, usually located on the lower trunk and present since birth (see Ch. 117). Histology shows ectopic mature lipocytes located within the dermis. The lesions of Goltz syndrome (including telangiectasias, vermiculate dermal atrophy, hypopigmentation, hyperpigmentation, and fatty herniations/hamartomas) are in a linear array along the lines of Blaschko (see Ch. 62). Histologically, a decrease in dermal content is seen as well as extension or deposition of subcutaneous fat into the dermis.

Treatment

Various therapeutic modalities have been tried, but have not resulted in improvement of existing atrophic lesions; these include intralesional

injections of triamcinolone and systemic administration of aspirin, dapsone, phenytoin, penicillin G, vitamin E and inositol niacinate. Some authors have reported improvement with hydroxychloroquine. Surgical excision of limited lesions may be helpful, with the patient aware of the possibility of scar formation.

STRIAE

Synonyms: ■ Striae distensae ■ Striae atrophicans ■ "Stretch marks" ■ Linear atrophy

Introduction

Striae are a very common condition in all age groups. They are linear atrophic depressions of the skin that form in areas of dermal damage produced by stretching of the skin. They are associated with various physiologic states, including puberty, pregnancy, growth spurts, rapid weight gain or loss, obesity[22], and disorders that lead to hypercortisolism.

History

Striae were first described by Roederer in 1773, and the first histologic descriptions were made by Troisier and Menetrier in 1889.

Epidemiology

Striae are very common and usually develop between the ages of 5 and 50 years. They are seen more commonly in Caucasians, and striae occur about twice as frequently in women as in men. They commonly develop during puberty, with an overall incidence of 25–35%[23], or during pregnancy, with an incidence of approximately 75%[24].

Pathogenesis

Factors leading to the development of striae have not been fully elucidated. Striae distensae are a reflection of "breaks" in the connective tissue that lead to dermal atrophy. A number of factors, including hormones (particularly corticosteroids), mechanical stress and genetic predisposition, appear to play a role.

Clinical features

Striae are usually multiple, symmetric, well-defined linear atrophic lesions that often follow the lines of cleavage. They are usually more of a cosmetic concern, but rarely they can ulcerate. Initially, striae appear as red-to-violaceous elevated lines that can be mildly pruritic and are called striae rubra (Fig. 99.5). Over time, the color gradually fades, and the lesions become atrophic, with the skin surface exhibiting a fine wrinkled appearance. These striae alba are usually permanent, but they may fade somewhat over time[23]. The striae can measure several centimeters in length and a few millimeters to a few centimeters in width.

During puberty, striae appear in areas where there is a rapid increase in size. In girls, the most common sites are the thighs, hips, buttocks and breasts, whereas in boys, they are seen on the shoulders, thighs and lumbosacral region (Fig. 99.6). Other less common sites include the abdomen, upper arms, neck and axillae.

Striae distensae are a common finding on the abdomen, and less so on the breasts and thighs, of pregnant women, especially during the last trimester. They are more common in younger primigravidas than in older pregnant women, in those who gained more weight during pregnancy, and/or those who had babies with a higher birth weight. One study showed that striae gravidarum are statistically significant predictors of lacerations during vaginal delivery[25]. More recently, the presence of striae was found to be a risk factor for the development of pelvic relaxation and clinical prolapse[26].

The striae associated with systemic corticosteroid therapy and Cushing's syndrome can be larger and more widely distributed (see Ch. 53). Flexural and intertriginous areas are particularly at risk for developing striae from the use of topical corticosteroids.

Atrophic striae may become elevated and even "worm-like" in the setting of severe edema, including lymphedema. In addition, there are diseases such as polymorphic eruption of pregnancy in which initial lesions arise within striae.

Fig. 99.5 Striae. A Linear erythematous lesions on the abdomen (striae rubra). **B** Atrophic linear lesions of striae alba in a teenager. **C** Large axillary striae in a patient receiving chronic, high-dose systemic corticosteroids. *B, Courtesy, Kalman Watsky, MD.*

Pathology

Histologic findings depend upon the stage of evolution of the striae at the time the biopsy is performed. The epidermis can be normal during

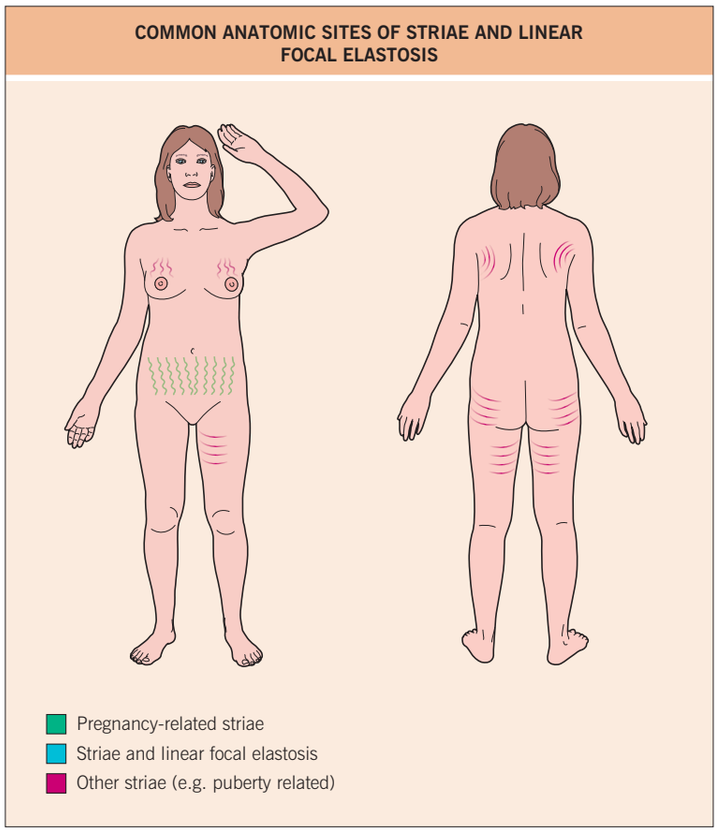

Fig. 99.6 Common anatomic sites of striae and linear focal elastosis. Striae associated with pregnancy are in green and lesions of linear focal elastosis are in blue.

the early stages, but eventually it becomes flattened and atrophic with blunted rete ridges. The dermal thickness is decreased, as is the collagen in the upper dermis. The collagen bundles are thinned and lie parallel to the epidermis, but they are also arranged transversely to the direction of the striae. Alterations in elastic fibers are variable, but dermal elastin can be fragmented, and specific elastin staining can demonstrate a marked reduction in visible elastin content compared with adjacent normal dermis[27]. There is an absence of both hair follicles and other adnexal structures.

Differential diagnosis

The diagnosis of striae distensae is usually straightforward, but the differential diagnosis does include linear focal elastosis (elastotic striae), an entity first described by Burket et al.[28] in 1989. Linear focal elastosis is characterized by rows of yellow, palpable, striae-like bands on the lower back. Unlike striae, the lesions are raised and yellow rather than depressed and white. Elderly men are most commonly affected, although such lesions have been described in teenagers. Linear focal elastosis is probably not an uncommon condition. Histologically, there is a focal increase in the number of elongated or fragmented elastic fibers as well as a thickened dermis. It is postulated that linear focal elastosis may represent an excessive regenerative process of elastic fibers and could be viewed as a keloidal repair of striae distensae[29].

Treatment

Striae distensae have no medical consequences, but they are frequently distressing to those afflicted. As stretch marks tend to improve spontaneously over time, the usefulness of treatments that have been tested without case controls is difficult to assess. Treatment of early-stage striae with tretinoin 0.1% cream can improve their appearance, and its application has been shown to decrease the length and width of striae[30]. Other topical treatments, including 0.05% tretinoin/20% glycolic acid and 10% L-ascorbic acid/20% glycolic acid, may also improve the appearance of stretch marks[31]. Several lasers have been used to treat striae: the 585 nm pulsed dye laser has been shown to lead to some improvement in the appearance of striae rubra, but it has no effect on striae alba; secondary pigmentary alterations in darker skin are a potential complication[32]. Improvement in the leukoderma of striae alba was noted with the 308 nm excimer laser, but maintenance treatment was required to sustain the cosmetic benefit[33]. Currently, there is no specific therapy that results in a complete response. Perhaps advances in laser technologies will provide better options in the future.

IDIOPATHIC ATROPHODERMA OF PASINI AND PIERINI

Synonyms: ■ Sclérodermie atrophique d'emblée ■ Morphea plana atrophica ■ Dyschromic and atrophic variation of scleroderma

Key features

- Depressed patches, usually on the posterior trunk and brown in color
- "Cliff-drop" or abrupt transition from normal to diseased skin
- Lesions are asymptomatic and lack induration
- Disorder lasts for many years but has a benign course

Introduction

Idiopathic atrophoderma of Pasini and Pierini is a form of dermal atrophy that presents as one or several sharply demarcated depressed patches, usually on the back of adolescents or young adults. Whether atrophoderma represents an atypical, primarily atrophic form of morphea or "burnt-out" morphea or a separate distinct entity is still debated.

History

In 1923, Pasini described atrophic cutaneous lesions on the trunk of a 21-year-old woman that he referred to as progressive idiopathic atrophoderma[34]. In 1936, and over the subsequent years, Pierini and associates extensively studied and defined the condition and its possible link to morphea. This prompted Canizares et al.[35] in 1958 to rename this entity "idiopathic atrophoderma of Pasini and Pierini".

Epidemiology

This disorder is more frequently encountered in women than in men, with a ratio of 6:1 in adults[36]. It usually starts insidiously in young individuals during the second or third decade of life. However, a number of cases have been described in children younger than 13 years of age. Recently, a rare congenital case was reported[37].

Pathogenesis

The etiology of atrophoderma of Pasini and Pierini remains as yet unknown. Some authors have suggested the possible role of infection with *Borrelia burgdorferi*, as in acrodermatitis chronica atrophicans, since a positive serology can be found in up to 40–50% of European patients[38]. However, false-positive results can occur, and results have varied widely. Given some overlap between atrophoderma and morphea, perhaps insights into the pathogenesis of the latter will provide clues to the former.

Clinical features

Lesions usually appear on the trunk, especially on the back and lumbosacral region, followed in frequency by the chest, arms and abdomen[38]. The face, hands and feet are usually spared. The distribution is often symmetric and bilateral, but a linear pattern along Blaschko's lines has been described (atrophoderma of Moulin; see Ch. 67).

The lesions are single or multiple and usually round or ovoid, ranging in size from a few centimeters to patches covering large areas of the trunk. They are usually asymptomatic and lack inflammation. When

lesions coalesce, they can form large irregular patches. The patches usually have a brown color (Fig. 99.7), but some are more blue to violet in color or even hypopigmented[39]. The surface of the skin is normal in appearance, as is the consistency upon palpation. There is a lack of cutaneous induration or sclerosis.

The borders or edges of these lesions are sharply defined, and they are usually described as abrupt "cliff-drop" borders ranging from 1 to 8 mm in depth, although they can have a gradual slant[35]. These depressed patches have a characteristic appearance and give the impression of inverted plateaus, or, if multiple lesions are present, they can have the appearance of Swiss cheese. The lesions are even more apparent when present on the back, because the dermis is thicker in this area. Occasionally, deep blood vessels may be seen running through the depressed patches.

The skin surrounding the patches is normal in appearance, and there is no erythema or lilac ring as in morphea. However, typical lesions of morphea, lichen sclerosus and atrophoderma have been observed to occur simultaneously in the same patient (but in different areas), supporting the view that these conditions are related[40]. In addition, sclerodermatous changes can occasionally appear years later in the center of the depressed lesions, leading to a white, shiny induration[35]. In a series of 139 patients, 17% had a white induration in the central portions of their atrophic lesions, and, in 22%, superficial plaques of morphea coexisted in sites separate from the atrophic foci[36].

Fig. 99.7 Atrophoderma of Pasini and Pierini. **A,B** Multiple light brown patches on the back; note the subtle depression of the lesions with a "cliff-drop" edge. In B, dermal blood vessels are easily seen within a few patches; the white papule is a healed biopsy site. *A, Courtesy, Catherine C McCuaig, MD; B, Courtesy, Julie V Schaffer, MD.*

The course of this benign disease is progressive, and lesions can continue to appear for decades before reaching a standstill. Transformation to generalized morphea has not been observed.

Pathology

In general, the histologic picture is not diagnostic, so the diagnosis is primarily a clinical one. The epidermis is usually normal or slightly atrophic. Pigmentation of the basal layer may be increased. A perivascular infiltrate consisting of T cells and histiocytes may be seen. Collagen bundles in the reticular dermis show varying degrees of homogenization and clumping. Dermal thickness is eventually reduced when compared with adjacent normal skin[41]. Dermal atrophy is difficult to evaluate on a punch biopsy, but it can be more easily demonstrated if an elliptical biopsy is taken in an area that includes the cliff-drop border and is then sectioned longitudinally to show the transition between normal and lesional skin. MRI performed in one patient with atrophoderma of Pierini and Pasini showed that the clinical depression was not secondary to subcutaneous atrophy[42]. In most series, no abnormality has been observed with elastic tissue stains[36,38]; however, a recent retrospective study described a spectrum of changes, ranging from normal to severe diminution and fragmentation of the elastic fiber network[39]. The diagnostic value of elastic tissue changes is still debatable. The adnexal structures are usually preserved.

If sclerodermatous changes appear in pre-existing patches, the histology reveals varying degrees of collagen sclerosis resembling morphea. Direct immunofluorescence may show nonspecific IgM and C3 staining in the dermal papillary blood vessels in early lesions or at the dermal–epidermal junction[43].

Differential diagnosis

Since the original description, there has been much discussion over whether idiopathic atrophoderma of Pasini and Pierini is a distinct entity or an atrophic, non-indurated, perhaps "burnt-out" variant of morphea (see Ch. 44). Active lesions of morphea present as indurated, often hyperpigmented plaques with a characteristic peripheral lilac rim.

Although atrophoderma of Pasini and Pierini lacks sclerosis[36,38,40,43], its relationship to morphea is favored by its striking clinical and histologic similarities to the atrophy seen at sites of regressing plaques of morphea. To some, the different course and outcome of atrophoderma of Pierini and Pasini as compared with morphea justifies preservation of a distinct name.

Anetoderma, also an atrophic dermal process, is easily differentiated by palpation and histology, which consistently shows a loss of elastic fibers in the dermis (as opposed to a loss of collagen).

Treatment

The natural course of the disease is often protracted (10–20 years) but self-healing, making the evaluation of therapy difficult. No treatment has been proven effective. In view of the possibility of an underlying *Borrelia* infection, penicillin has been used to treat atrophoderma of Pasini and Pierini, but the results have been inconclusive. A retrospective evaluation of 25 patients treated with oral penicillin (2 million IU/day) or oral tetracycline (500 mg three times daily) for 2–3 weeks reported clinical improvement and no evidence of new active lesions in 20 of the 25 patients. In the same study, four of six patients who did not receive treatment also had no evidence of progressive disease[38]. A dramatic response to oral hydroxychloroquine was recently reported in one patient[44], and three treatment sessions with the Q-switched alexandrite laser was effective in diminishing hyperpigmentation by 50% in another patient[45].

FOLLICULAR ATROPHODERMA

Follicular atrophoderma refers to dimple-like depressions at the follicular orifices. It can occur as an isolated defect of limited extent, in association with a variety of disorders in which hair follicles are plugged with keratin, or with rare genodermatoses.

In 1944, Miescher described follicular atrophoderma in an 8-year-old girl with atypical chondrodystrophy[46]. Six years later, Curth also used

the term follicular atrophoderma (although there was no evidence of follicular atrophy but rather follicular agenesis) and further reported in 1978 on the genetics of follicular atrophoderma[47].

Clinical features

Distinctive ice-pick depressions around hair follicles can be seen most commonly on the back of the hands and feet or on the cheeks. These pitted scars are often present at birth or during childhood. A family history may be present. Follicular atrophoderma can be associated with Bazex–Dupré–Christol syndrome or with Conradi–Hünermann–Happle syndrome. When the lesions are found exclusively on the cheeks, the term "atrophoderma vermiculatum" applies. Atrophoderma vermiculatum can in turn be associated with various disorders discussed in the next section.

Atrophoderma Vermiculatum

Atrophoderma vermiculatum, a disorder limited to the face, has been described under a variety of names, including ulerythema acneiforme, acne vermoulante, atrophoderma reticulata symmetrica faciei, folliculitis ulerythema reticulata, folliculitis ulerythemosa, and honeycomb atrophy ("ulerythema" means scar plus redness and "vermiculatum" means worm-eaten).

Atrophoderma vermiculatum is a condition that can: (1) occur sporadically; (2) be inherited as an autosomal dominant disorder; (3) be part of a group of related diseases that are referred to as "keratosis pilaris atrophicans" (see Table. 38.2); or (4) be associated with various syndromes.

Multiple symmetric inflammatory papules on the cheeks, presumably centered around hair follicles, may precede the atrophic lesions. These papules then go on to become pitted, atrophic and depressed scars in a reticulated or honeycomb pattern (Fig. 99.8). The severity of erythema varies, as does the presence of milia and horny follicular plugs. These lesions can extend to the forehead and preauricular regions. This condition usually has its onset during childhood or, less often, around puberty. Both sexes appear to be equally affected[48]. It usually has a slow progressive course.

Atrophoderma vermiculatum can be associated with a group of closely related disorders referred to as keratosis pilaris atrophicans (see Table. 38.2)[49]. This group also includes keratosis follicularis spinulosa decalvans and ulerythema ophryogenes. These conditions are characterized by keratotic follicular papules, variable degrees of inflammation, and secondary atrophic scarring. Ulerythema ophryogenes (or keratosis pilaris atrophicans faciei) differs from atrophoderma vermiculatum by affecting primarily the lateral portion of the eyebrows (ophryogenes) in the form of erythema, follicular papules and alopecia. The inheritance pattern is autosomal dominant with incomplete penetrance, and progression usually ceases after puberty. Keratosis follicularis spinulosa decalvans begins during childhood as keratotic follicular papules on the malar area and progresses to involve the eyebrows, scalp and extremities, with associated scarring alopecia. In most patients, this disorder is inherited in an X-linked recessive fashion.

The underlying pathogenesis in atrophoderma vermiculatum as well as the other disorders in the keratosis pilaris atrophicans group appears to be abnormal follicular hyperkeratinization. The latter occurs in the upper third of the hair follicle, leading to obstruction of the growing hair shaft and production of chronic inflammation. The end result is scarring below the level of obstruction.

Histopathology is usually not very helpful and shows dilated follicles, sometimes associated with plugging, inflammation and sclerosis of dermal collagen.

The various syndromes that include atrophoderma vermiculatum are Rombo syndrome (milia, telangiectasias, basal cell carcinomas [BCCs], hypotrichosis, acral cyanosis, and, rarely, trichoepitheliomas), Nicolau–Balus syndrome (syringomas and milia), Tuzun syndrome (fissured [scrotal] tongue), and, finally, the Braun–Falco–Marghescu syndrome (palmoplantar hyperkeratosis and keratosis pilaris).

The differential diagnosis of atrophoderma vermiculatum includes atrophia maculosa varioliformis cutis, keratosis pilaris rubra of the cheeks, and, in older adults, erythromelanosis faciei.

This disorder is primarily a cosmetic problem. Various topical treatments, including emollients, corticosteroids, tretinoin and keratolytics, have shown no consistent benefit. In some instances, systemic isotretinoin has been shown to stop progression and to induce remission[49]. Dermabrasion, laser therapy (e.g. CO_2 and 585 nm pulsed dye) and fillers (e.g. hyaluronic acid, autologous fat) are other options for improving the appearance of the atrophic scars[50].

Fig. 99.8 Atrophoderma vermiculatum. Multiple small pitted scars on the cheek of a young girl. Note the honeycomb pattern on the lower inner cheek; the skin is said to appear "worm-eaten". *Courtesy, Robert Hartman, MD.*

Bazex–Dupré–Christol Syndrome

Bazex, Dupré and Christol first described this genodermatosis in 1964, not to be confused with the other disease called Bazex syndrome (acrokeratosis paraneoplastica) in which hyperkeratotic plaques of the ears, nose, cheeks, hands, feet and knees are associated with carcinomas of the upper aerodigestive tract (see Ch. 53).

Bazex–Dupré–Christol syndrome is characterized by follicular atrophoderma, milia, multiple BCCs, hypotrichosis, and localized hypohidrosis (above the neck)[51]. It is inherited in an X-linked dominant fashion, and the gene has been linked to Xq24–q27[52]. Additional reported findings include facial hyperpigmentation, hair shaft anomalies and multiple trichoepitheliomas. Systemic manifestations are absent. Recently, it was suggested that this syndrome might better be classified as an ectodermal dysplasia[53].

The follicular atrophoderma, described as multiple ice-pick marks or patulous follicles, is found most commonly on the dorsal aspect of the hands, but can also be seen on the feet, lower back, elbows and, rarely, the face; it may be present at birth or appear later during childhood. No abnormalities of the elastic fibers have been found (nor any evidence of atrophy of the epidermis, hair or dermis), making the term "follicular atrophoderma" a misnomer. The histopathology usually shows hair follicles that are abnormally wide, plugged and surrounded by an inflammatory cell infiltrate and clusters of basaloid cells. Sweat glands can be absent.

The BCCs develop in about 40% of patients (primarily on the face) and they can resemble melanocytic nevi; the age of onset varies from 9 to 50 years of age. To date, approximately 20 families with this syndrome have been described.

The differential diagnosis includes other genodermatoses with multiple BCCs: nevoid basal cell carcinoma syndrome (Gorlin syndrome), an autosomal dominant disorder due to mutations in the *PTCH* gene, and Rombo syndrome, an autosomal dominant disorder characterized by BCCs, atrophoderma vermiculatum, milia, hypotrichosis, acrocyanosis, and, occasionally, trichoepitheliomas.

Conradi–Hünermann–Happle Syndrome (X-Linked Dominant Chondrodysplasia Punctata, CDPX2)

Conradi–Hünermann–Happle syndrome is an X-linked dominant disorder that occurs almost exclusively in girls, since it is usually lethal in hemizygous males. This form of chondrodysplasia punctata results from mosaicism for mutations in the gene on the X chromosome that

Fig. 99.9 Atrophia maculosa varioliformis cutis. Multiple linear scar-like depressions (between and above arrows) with no history of trauma. *Courtesy, Jean L Bolognia, MD.*

Fig. 99.10 Pedal papules of infancy. Soft nodules on the medial and plantar surfaces of the foot. *Courtesy, Julie V Schaffer, MD.*

encodes the emopamil-binding protein[54]. The clinical manifestations include ichthyosiform streaks (composed of erythema plus feathery, adherent scale) patterned along the lines of Blaschko; they usually resolve during the first year of life and are replaced by bands of follicular atrophoderma[55]. Hyperpigmentation, cataracts, scarring alopecia, saddle-nose deformity, asymmetric limb reduction defects, and stippled calcifications of the epiphyses can be seen (see Ch. 57). Within the ichthyosiform areas in newborns, keratotic follicular plugs containing dystrophic calcification is a distinctive histopathologic feature[54].

ATROPHIA MACULOSA VARIOLIFORMIS CUTIS

Atrophia maculosa varioliformis cutis was first described by Heidingsfeld in 1918[56] and is not as rare as the number of published cases would suggest. It consists of small round "varioliform" and linear facial depressions that are asymptomatic (Fig. 99.9)[57]. It occurs spontaneously on the cheeks and occasionally involves the forehead or chin. There is a gradual increase in the number of lesions, but in the absence of preceding trauma, acne or inflammatory lesions. A familial variant has been described. Pachydermodactyly and extrahepatic biliary atresia have been associated findings, but this association is probably fortuitous. The pathogenesis is unknown.

The histologic changes include a depression of the epidermis and normal collagen fibers, but a slightly decreased number of elastic fibers. There is usually little or no inflammation. The differential diagnosis includes simple scars, which can be differentiated by history and the presence histologically of dermal fibrosis, and atrophoderma vermiculatum. The latter is harder to differentiate, but it can present with inflammatory papules that are followed by pitted scars, and atrophoderma vermiculatum usually has a honeycombed (rather than sharply linear) pattern and is usually centered on hair follicles. There is no known treatment to prevent the occurrence of these lesions.

PIEZOGENIC PEDAL PAPULES (PIEZOGENIC PAPULES)

Piezogenic pedal papules were first described by Shelley and Rawnsley in 1968[58]. This term is somewhat of a misnomer as piezogenic means "producing pressure", when in fact these lesions are produced by pressure. It is postulated that pressure induces herniation of fat through connective tissue in the dermis of the heels.

These papules are common enough in the general population to be considered normal and have also been described in association with Ehlers–Danlos syndrome and Prader–Willi syndrome. An infantile variant characterized by larger nodules on the medial aspect of the heel (present without weight-bearing) has recently been reported (Fig. 99.10)[59].

Skin-colored papules and nodules are seen on the sides of the heels (see Ch. 88); they are induced by weight-bearing and disappear when the leg is raised. The lesions are usually asymptomatic, but pain has been described during weight-bearing, and, in these cases, an orthopedic shoe or surgical excision may help. Similar lesions have been described on the wrists[60].

OTHER ATROPHIES OF THE CONNECTIVE TISSUE

Many systemic conditions (scleroderma, lupus erythematosus, dermatomyositis) and genodermatoses (poikiloderma congenitale, dyskeratosis congenita, Cockayne syndrome, Hallermann–Streiff syndrome) have cutaneous atrophy (epidermal, dermal and/or subcutaneous) as an associated finding. Lichen sclerosus is discussed in Chapter 44, progeria in Chapter 63, Ehlers–Danlos syndrome and cutis laxa in Chapter 97, and acrodermatosis chronica atrophicans in Chapter 74. Cutaneous atrophy is also a well-known complication of prolonged use of either systemic or topical corticosteroids (see Ch. 125).

INTRODUCTION

Panniculitis is a diagnostically challenging arena for dermatologists and pathologists. Terminology is difficult, partly because various names have been applied to the same disorder (e.g. nodular vasculitis and erythema induratum), and partly because new discoveries have resulted in the introduction of new terms and the abandonment of others. For example, cases that might have previously been classified as Weber–Christian disease may now be categorized as α_1-antitrypsin deficiency panniculitis, lupus panniculitis, or pancreatic panniculitis. From a clinical standpoint, many forms of panniculitis with diverse etiologies closely resemble one another, presenting as tender, erythematous subcutaneous nodules. Some panniculitides can be a manifestation of different disease processes (erythema nodosum is the classic example), and, even if the type of panniculitis is correctly identified, this is only the first step in a series of clinical and laboratory investigations required to determine the underlying cause. From a pathologic standpoint, the subcutaneous fat responds to a variety of different insults in a limited number of ways, and, therefore, histopathologic differences among the various forms of panniculitis may be subtle. Management can also be difficult, since there are often at least two therapeutic desiderata:

- specific treatment of the panniculitis
- treatment of the underlying illness.

In this chapter, these issues will be addressed by introducing a schema for the classification of these disorders, recommending an approach to the histopathologic diagnosis, and providing information about the specific forms of panniculitis and their management.

Table 100.1 provides a working classification for the multiple forms of panniculitis. The categories are determined partly by clinical characteristics such as location (Fig. 100.1), partly by histopathology, and partly by etiology. A word should be said about *septal* versus *lobular* panniculitis. These are largely artificial constructs, since there is no purely septal or purely lobular panniculitis. Certain forms of panniculitis can be characterized as having predominantly septal involvement, and this finding can provide a useful clue to diagnosis when combined with other clinical and histopathologic features.

CLASSIFICATION OF THE PANNICULITIDES
PREDOMINANTLY SEPTAL PANNICULITIS
• Erythema nodosum
Erythema nodosum migrans (subacute nodular migratory panniculitis)

• Lipodermatosclerosis
• Infection-induced panniculitis
• Malignancy-related panniculitis-like infiltrates
Subcutaneous panniculitis-like T-cell lymphoma (see Ch. 120)
Other lymphomas with involvement of subcutaneous tissues
*Descriptions vary; some authors regard this as a lobular or mixed septal–lobular panniculitis.

Table 100.1 Classification of the panniculitides. The categories for classification of panniculitis are determined partly by clinical characteristics such as location and associated diseases and partly by histopathology. This classification scheme does not include Weber–Christian disease as cases initially assigned this designation have subsequently been reclassified as other forms of panniculitis, including α_1-antitrypsin deficiency, lipodermatosclerosis, lupus panniculitis and traumatic panniculitis.

Table 100.2 provides an approach to the histopathologic diagnosis of an unknown case of panniculitis. When performing a biopsy in a patient with panniculitis, it is absolutely critical that the specimen include a generous portion of subcutaneous fat. Therefore, excisional biopsies extending through the subcutis or narrow incisional biopsies that incorporate a broad expanse of subcutaneous fat are generally preferable to punch biopsies.

ERYTHEMA NODOSUM

Synonyms: ■ Erythema contusiformis ■ Erythema nodosum migrans (variant form)

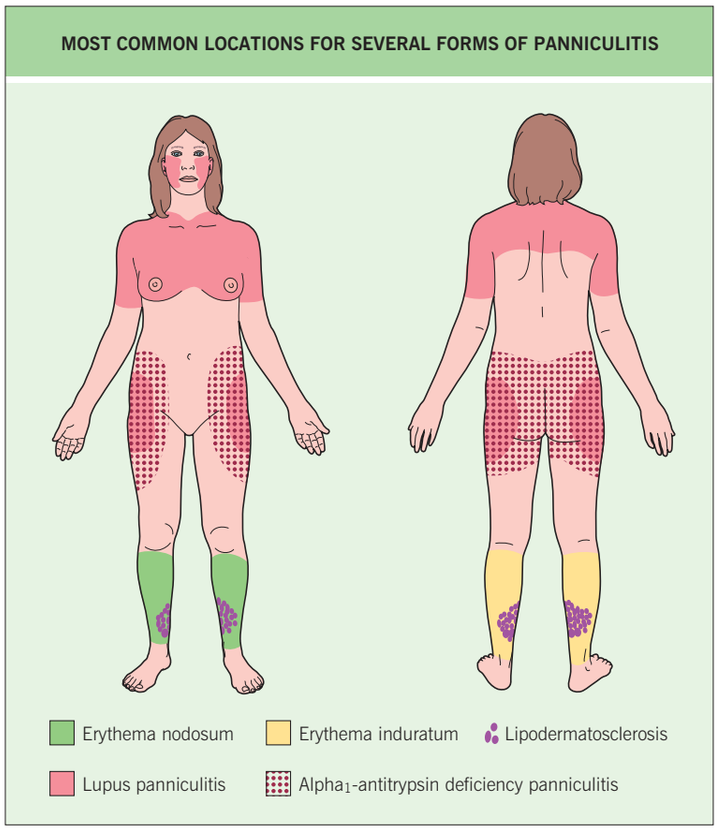

Fig. 100.1 Most common locations for several forms of panniculitis. Classification of panniculitis depends upon multiple factors, including clinical characteristics such as location and ulceration as well as histopathology and etiology.

Key features

- Tender, erythematous subcutaneous nodules
- Usually distributed symmetrically over pretibial areas; occasionally elsewhere
- In later stages, lesions acquire a bruise-like appearance
- May be accompanied by fever, arthralgias and malaise
- Associated with a wide variety of systemic disorders

Introduction

Erythema nodosum is probably the best known of the various forms of panniculitis, as well as the most common. It typically presents as an acute eruption of tender, erythematous subcutaneous nodules over the pretibial areas bilaterally. It is widely regarded as a delayed hypersensitivity response to a variety of antigenic challenges[1], although the mechanisms of its development are more complex than this statement would indicate. Histopathologically, it is the prototype of a "septal" panniculitis. Identification and treatment of the underlying disorder, if found, is of primary importance, but therapy directed toward the lesions themselves is also an option.

History

At the beginning of the eighteenth century, Robert Willan gave the first clear description of erythema nodosum, and he provided its name in his famous work, *On Cutaneous Disease*[2,3].

Epidemiology

Erythema nodosum can occur at any age, in both sexes, and in all racial groups. It is more common among women and is more frequently observed during the second through fourth decades of life[4,5]. The relative ranking of underlying causes may vary according to geographic location, for example, in areas where *Coccidioides immitis* is endemic and regions where Behçet's disease is more prevalent.

Pathogenesis

Erythema nodosum has been considered a delayed hypersensitivity response to a variety of antigenic stimuli, including bacteria, viruses and chemical agents[1,6]. Llorente et al.[7] observed expression of mRNA for Th1 cytokines (interferon-γ, interleukin-2) in the skin lesions and peripheral blood of patients with erythema nodosum, and a Th1 pattern of cytokine synthesis is associated with delayed-type hypersensitivity reactions. However, a complex series of intermediate steps is most assuredly involved in the development of these lesions. A variety of adhesion molecules and inflammatory mediators appear to be associated with erythema nodosum. For example, vascular cell adhesion molecule-1 (VCAM-1; CD106), platelet endothelial cell adhesion molecule-1 (PECAM-1; CD31), HLA-DR and E-selectin are expressed on endothelial cells (see Ch. 102), while intercellular adhesion molecule-1 (ICAM-1; CD54), very late antigen-4 (VLA-4), L-selectin and HLA-DR are expressed by inflammatory cells in erythema nodosum lesions[8].

Neutrophils are frequently numerous in early lesions, and it has been shown that a higher percentage of circulating neutrophils in patients with erythema nodosum leads to the production of reactive oxygen intermediates; these intermediates, in turn, may provoke inflammation and tissue damage[9]. Support for a pathogenic role for these cells and molecules is provided by studies of the effects of colchicine. This inhibitor of neutrophil chemotaxis is useful in treating inflammatory lesions of Behçet's disease and non-Behçet's-related erythema nodosum[10]. Among other effects, colchicine has been shown to diminish L-selectin expression on the neutrophil surface, inhibit E-selectin-mediated endothelial adhesiveness for neutrophils, and diminish stimulated expression of ICAM-1 on the endothelium[8].

Additional indirect evidence for the role of inflammatory cells and mediators includes reports of erythema nodosum following treatment with granulocyte colony-stimulating factor[11], and improvement (as well as flares) of erythema nodosum lesions with administration of tumor necrosis factor (TNF) inhibitors[12]. Erythema nodosum, especially in its chronic phase, is characterized by granuloma formation and TNF is known to play a role in granuloma formation. A link between deregulation of TNF-α production and granuloma formation is further supported by the strong correlation of a polymorphism in the promoter region of the gene that encodes TNF-α and the development of sarcoidosis-associated erythema nodosum[13].

A wide range of precipitating factors has been linked with erythema nodosum. Infectious causes are common, particularly upper respiratory infections (both streptococcal and non-streptococcal). Other commonly reported causes include sarcoidosis, inflammatory bowel disease, and certain medications. Table 100.3 lists the most well-known causes or associations as reported in several clinical series[4,5,14].

Clinical features

Erythema nodosum presents with bilateral, tender erythematous nodules. These arise in crops and clearly the most common sites are the shins (Fig. 100.2). Other locations are occasionally involved, particularly the thighs and forearms[4]. Nodules may appear on the trunk, neck and face[3], but this is sufficiently rare that development of lesions in these locations should prompt consideration of other diagnoses. Unlike other forms of panniculitis, ulceration is not a feature of erythema nodosum. Systemic symptoms may occur that are not necessarily related to a specific coexisting systemic disorder; these include arthritis, arthralgia, fever and malaise[3].

Because of its close association with a variety of disorders and infections, erythema nodosum is an important skin sign of systemic disease. For example, its development may precede or accompany a flare of inflammatory bowel disease[15]. It may also have some value as a prognostic indicator in certain disorders. For example, erythema nodosum is associated with a protective effect against disseminated disease in patients with coccidioidomycosis, and it is closely associated with a more benign and self-limited form of sarcoidosis[1,16]. Nevertheless, a significant percentage of cases – more than one-third – have no known disease association, even when followed for a year or more[5]. Clinical or laboratory data that tend to predict that a case of erythema nodosum may be secondary to a systemic disease are listed in Table 100.4.

AN APPROACH TO THE HISTOPATHOLOGIC DIAGNOSIS OF PANNICULITIS	
Histopathologic aspects to consider	**Conclusions**
Look for the "center of gravity" of the infiltrate	Recommended originally by Pinkus, the purpose is to determine whether or not the inflammatory process is centered in the subcutis (favoring a primary panniculitis), in the dermis, or in the fascia (in which case the panniculitis may be a secondary manifestation of a deeper inflammatory process)
Determine if the panniculitis is predominantly septal, predominantly lobular, or mixed	Generally, a predominantly septal panniculitis narrows the diagnostic considerations (see Table 100.1). If the panniculitis is lobular or mixed, look for other distinguishing features
Determine if there is vasculitis involving a medium-sized vessel, in the face of a lobular or mixed panniculitis	This is characteristic of **erythema induratum (nodular vasculitis);** caveat: deeper levels are often required in order to demonstrate the involvement of vessels
Look for fat necrosis with saponification and "calcium soap" formation	This is a feature of **pancreatic panniculitis**
Look for needle-shaped clefts within lipocytes	Their presence favors a diagnosis of **sclerema neonatorum, subcutaneous fat necrosis of the newborn**, or **post-steroid panniculitis**
Determine if the panniculitis has a lymphoplasmacytic predominance	This tends to be a feature of **panniculitis due to connective tissue disease**, including lupus erythematosus; beware of lymphocytic predominance in cases of subcutaneous panniculitis-like T-cell lymphoma
Check for a "central nidus" of inflammation or evidence of a needlestick injury. Look for vacuolated spaces or foreign material	These are clues to **traumatic panniculitis including factitial panniculitis**. Polarization microscopy can be helpful
Look for membranocystic changes in the subcutis	This change is characteristic of (though not pathognomonic for) **lipodermatosclerosis;** it can be observed in any panniculitis with prominent degenerative changes
Determine if the panniculitis is associated with substantial cellular necrosis, vascular proliferation, hemorrhage, sweat gland necrosis, or neutrophilic aggregates	These changes are often encountered in **infection-induced panniculitis**. Tissue cultures and special stains for organisms may be indicated
Determine if the infiltrating cells are particularly monotonous or atypical in appearance	Consider subcutaneous panniculitis-like T-cell lymphoma and other lymphomas with involvement of the subcutaneous fat. Rarely, non-hematologic malignancies mimic panniculitis. Immunohistochemical stains are mandatory for a precise diagnosis
Determine if there are large cells with cytophagic activity	Cytophagic activity (hematophagocytosis) observed primarily in subcutaneous infiltrates of primary cutaneous γ/δ T-cell lymphoma. This finding was previously termed "cytophagic histiocytic panniculitis"

Table 100.2 An approach to the histopathologic diagnosis of panniculitis.

Fig. 100.2 Erythema nodosum. Erythematous, tender nodules located bilaterally on the shins. *Courtesy, Kenneth E Greer, MD.*

Erythema nodosum lesions usually last a few days or weeks and then slowly involute, without scar formation. Discoloration suggestive of a bruise may be seen as erythema subsides. More chronic forms do occur, some of which show a tendency toward migration or centrifugal spread; the latter have been termed *subacute nodular migratory panniculitis* or *erythema nodosum migrans (*see below). Up to one-third of cases of erythema nodosum recur. Annual recurrences are particularly common among idiopathic cases[14].

Pathology

Erythema nodosum is the prototypic septal panniculitis, but this should not be taken to imply that histopathologic changes are entirely confined to subcutaneous septa[17]. Biopsy specimens of early lesions tend to show edematous septa and mild lymphocytic infiltrates (Fig. 100.3). Neutrophils may predominate in early lesions[8], and a variant with a predominance of eosinophils has been reported[18]. True vasculitis of the type seen in leukocytoclastic vasculitis is not demonstrable, and erythema nodosum is not generally regarded as a vasculitic process. However, "secondary" vasculitis may be observed in lesions when they contain relatively heavy, mixed or neutrophil-rich inflammatory infiltrates. Thrombophlebitis has been reported, and this change is apparently more frequent in erythema nodosum lesions associated with Behçet's disease[6,8].

In early lesions, one may also find Miescher's microgranulomas, a characteristic if not pathognomonic feature of erythema nodosum. These are small collections of macrophages, found within septa or at a septal–lobular interface, that tend to surround neutrophils or small cleft-like spaces[3]. Reported variations in the frequency of these granulomas in erythema nodosum[3,19] may result in part from differences in definition, in the acceptance of subtle changes, and in the rigor of the search. Miescher's microgranulomas can also be observed in older lesions, at which point the constituent cells have evolved into the appearance of epithelioid and multinucleated giant cells (Fig. 100.4).

As lesions progress, the septa become widened and contain a mixed, partly granulomatous infiltrate. These cells infiltrate the periphery of fat lobules in a lace-like configuration. The extent of lobular involvement may vary, and in some cases can be prominent[8]. Nevertheless, in the case of a lobular panniculitis without the characteristic septal changes, a diagnosis of erythema nodosum should be made with caution. There is also frequently a mild to moderate perivascular lymphocytic infiltrate in the overlying dermis. In later stages, the septa become fibrotic, partly replacing the fat lobules. Residual granulomas and lipophages can be observed, and a degree of vascular proliferation may be present[3]. Over the long term, a remodeling process takes place that usually results in minimal residual scarring[3].

CAUSES OF ERYTHEMA NODOSUM		
Incidence	**Cause**	**Comments**
Most common	Idiopathic	Still the largest single category, accounting for a third to a half of cases
	Streptococcal infections, especially of the upper respiratory tract	The largest single infectious cause
	Other infectious associations: Bacterial gastroenteritis – *Yersinia* > *Salmonella, Campylobacter* Viral upper respiratory tract infections	Overall, infection may account for a third or more of cases
	Coccidioidomycosis	Erythema nodosum is associated with a lower incidence of disseminated disease
	Drugs	Especially estrogens and oral contraceptive pills; also sulfonamides, penicillin, bromides, iodides; occasionally, TNF inhibitors
	Sarcoidosis*	10–20% of cases in some series
	Inflammatory bowel disease	Crohn's disease has a stronger association with erythema nodosum than does ulcerative colitis
Uncommon	Less common infectious associations: Brucellosis *Chlamydophila*† *pneumoniae* *Chlamydia trachomatis* *Mycoplasma pneumoniae* Tuberculosis Hepatitis B‡ Histoplasmosis	
	Neutrophilic dermatoses: Behçet's disease Sweet's syndrome	"Erythema nodosum" in Behçet's disease more closely resembles erythema induratum (nodular vasculitis)
	Pregnancy	
Rare	Rare infectious associations: Gonorrhea Meningococcemia *Escherichia coli* Pertussis Syphilis Cat scratch disease HIV infection Blastomycosis Giardiasis	*Erythema nodosum leprosum* is a different disease that is characterized by a cutaneous small vessel vasculitis
	Malignancy, most often acute myelogenous leukemia, Hodgkin disease	May overlap with Sweet's syndrome

*Löfgren's syndrome is an acute, spontaneously resolving form of sarcoidosis characterized by erythema nodosum, hilar lymphadenopathy, fever, polyarthritis and uveitis.
†Previously referred to as *Chlamydia*.
‡Erythema nodosum secondary to the hepatitis B vaccine has also been reported.

Table 100.3 Causes of erythema nodosum. TNF, tumor necrosis factor.

FINDINGS SUGGESTIVE OF A SYSTEMIC CAUSE FOR ERYTHEMA NODOSUM
• Synovitis • Diarrhea • Abnormal chest X-ray • Preceding upper respiratory tract infection • Elevated antistreptolysin O and/or anti-DNase B titers • Positive tuberculin skin test or QuantiFERON®-TB Gold test

Table 100.4 Findings suggestive of a systemic cause for erythema nodosum.

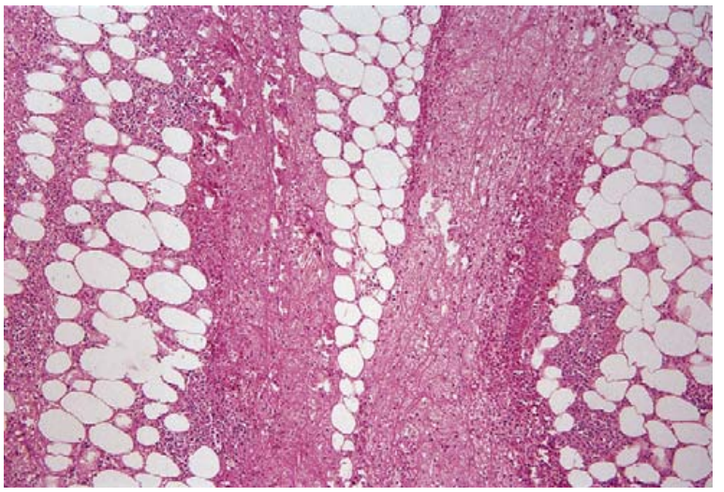

Fig. 100.3 Erythema nodosum. Septa are widened and edematous, and infiltrated by lymphocytes and neutrophils.

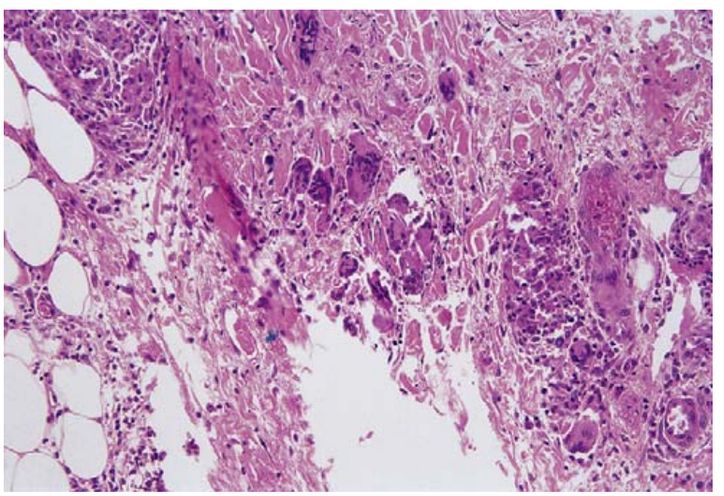

Fig. 100.4 Erythema nodosum. Miescher's microgranulomas within septa. Note the many multinucleated giant cells.

Differential diagnosis

The clinical picture of an acute eruption of tender subcutaneous nodules over both shins of a young person is highly characteristic of erythema nodosum. However, when lesions are few in number, are located in sites other than the lower legs, or are of longer duration (>6 weeks), erythema nodosum can be difficult to distinguish from other forms of panniculitis. Lesions of erythema induratum (nodular vasculitis) can resemble those of erythema nodosum, but they tend to occur on the posterior aspect of the lower legs and may ulcerate. Ulceration is also a feature of pancreatic panniculitis, which occurs more frequently in other locations (although still favoring the lower legs), is more likely to be accompanied by arthritis and serositis, and is associated with elevated serum amylase and lipase levels.

Histopathologically, the picture of a predominantly septal panniculitis usually limits the differential diagnosis and tends to exclude those conditions that are chiefly lobular or mixed. Pancreatic panniculitis may show predominantly septal changes in its earliest stages[20], but, eventually, these lesions exhibit the characteristic fat necrosis, with saponification and "ghost cell" formation. Infection-induced panniculitis can sometimes mimic erythema nodosum, but there are often

more extensive neutrophilic infiltrates, cellular necrosis (including sweat gland necrosis), vascular proliferation, and hemorrhage[21]. Special staining for organisms and microbiologic studies may be helpful if infection is a serious consideration.

Treatment

Treatments most often recommended for uncomplicated erythema nodosum include bed rest, salicylates, and nonsteroidal anti-inflammatory drugs (NSAIDs; Table 100.5)[2,15]. Potassium iodide has been used with success, with adult dosages ranging from 300 to 1500 mg/day (Table 100.6)[22]. Improvement may be seen within 2 weeks. Potassium iodide may work through inhibition of cell-mediated immunity, as well as via inhibition of neutrophil chemotaxis and suppression of neutrophil-generated oxygen intermediates[2]. In light of this treatment response, reports of erythema nodosum *triggered* by potassium iodide seem contradictory.

Treatment of erythema nodosum is influenced by underlying conditions. Thus, colchicine is useful in management of erythema nodosum that accompanies Behçet's disease[8]. Various treatments for inflammatory bowel disease are also effective in managing coexistent erythema nodosum[12]. Agents that have been employed in these circumstances include systemic corticosteroids, hydroxychloroquine, cyclosporine, thalidomide and infliximab[23]. Both etanercept and infliximab have been reported to be effective in treating erythema nodosum[24], but paradoxically both have been reported to produce erythema nodosum as a cutaneous side effect[25,26]. NSAIDs are to be avoided in treating the erythema nodosum of inflammatory bowel disease, since these may trigger a flare of the bowel disease or compromise maintenance therapy[15].

THERAPEUTIC LADDER FOR ERYTHEMA NODOSUM
Discontinue possible causative medications
Treatment of underlying infectious diseases
Bed rest and leg elevation
Nonsteroidal anti-inflammatory drugs (NSAIDs) (3)
Potassium iodide (2)
Colchicine (3) (esp. in the setting of Behçet's disease)
Prednisone (3)
Dapsone (3)
Hydroxychloroquine (3)
Mycophenolate mofetil (3)
Infliximab (3) (esp. in the setting of inflammatory bowel disease)
Thalidomide (3) (esp. in the setting of inflammatory bowel disease)*
Cyclosporine (3) (esp. in the setting of Behçet's disease)
*May transiently exacerbate erythema nodosum associated with Behçet's disease.

Table 100.5 Therapeutic ladder for erythema nodosum. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective trial or large case series; (3) small series or individual case reports.

USE OF POTASSIUM IODIDE (KI)
SATURATED SOLUTION OF POTASSIUM IODIDE (SSKI)
• 1000 mg/ml
• Droppers are supplied with calibrations for: 0.3 ml (300 mg)* 0.6 ml (600 mg)
• In adults and older children, common dose = 300 mg tid po with starting dose = 150–300 mg tid
• In infants and young children, common dose = 150 mg tid
• SSKI should be diluted in water or juice to try to minimize the bitter aftertaste
• Crystallization may occur with cold temperatures, but rewarming and shaking dissolves the crystals; discard if solution turns yellow–brown
SIDE EFFECTS OF SSKI
• Acute – nausea, bitter eructation, excessive salivation, urticaria, angioedema, cutaneous small vessel vasculitis
• Chronic – enlargement of salivary and lacrimal glands, acneiform eruption, iododerma, hypothyroidism, hyperkalemia, occasionally hyperthyroidism
*0.3 ml = 10 drops from the calibrated dropper supplied with SSKI.

Table 100.6 Use of potassium iodide (KI).

Subacute Nodular Migratory Panniculitis

Synonyms: ■ Erythema nodosum migrans ■ Chronic erythema nodosum

Key features

- Nodules on the lower extremities that migrate or undergo centrifugal spread, with central clearing
- Often unilateral
- Most cases are idiopathic; occasionally associated with streptococcal infection or thyroid disease
- More chronic course than typical erythema nodosum

Clinical features

This condition was first described by Bafverstedt in 1954[27] and was named *subacute nodular migratory panniculitis* by Vilanova and Piñol Aguade in 1956[28]. Some of its clinical and microscopic characteristics are similar to chronic erythema nodosum, and it is believed by many to represent a variant of the latter[3,27]; however, others consider it to be a separate disorder[29]. Subacute nodular migratory panniculitis is seen predominantly in women, is often unilateral, and is characterized by nodules that migrate or expand in a centrifugal manner (with central clearing)[3] and may assume a yellowish or morpheaform appearance[30]. Lesions tend to be less tender than those of classic erythema nodosum. There may be few, if any, associated systemic symptoms[27], though arthralgias have been reported and the ESR may be elevated[28]. Most cases are idiopathic, but some are associated with streptococcal infection (as evidenced by elevated antistreptolysin O and anti-DNase B titers) or thyroid disease[29].

Pathology

Microscopically, the changes are those of a chronic septal panniculitis[30]. However, in contrast to more classic forms of chronic erythema nodosum, subacute nodular migratory panniculitis shows greater septal thickening, more prominent granulomatous inflammation along the borders of widened subcutaneous septa, absence of phlebitis, and rare hemorrhage[29].

Treatment

Untreated, subacute nodular migratory panniculitis can last for months or years. However, treatment with potassium iodide is usually effective, resulting in clearing of lesions within several weeks[30].

MORPHEA/SCLERODERMA PANNICULITIS

(See also Chs 43 & 44)

Clinical features

Both morphea and scleroderma (systemic sclerosis) can affect the subcutaneous fat (Table 100.7), which is the primary site of involvement in deep morphea (morphea profunda)[36]. Subcutaneous extension also occurs in variants such as disabling pansclerotic morphea of childhood, generalized morphea, and linear morphea. In addition, eosinophilic fasciitis can involve the subcutaneous fat as well as the fascia[31]. These syndromes may be associated with peripheral eosinophilia, polyclonal gammopathy and serologic abnormalities[31,37]. Fleischmajer et al.[32] have proposed that the sclerosing process in scleroderma is initiated by the changes that take place in the subcutis.

Pathology

Table 100.7 outlines the microscopic changes in morphea and scleroderma. These conditions are associated with septal panniculitis (Fig. 100.5). Lymphocytes and plasma cells predominate[31,33,38], though macrophages and eosinophils may be present. In some cases, the number

CLINICAL AND MICROSCOPIC FEATURES OF CONNECTIVE TISSUE PANNICULITIS				
Disorder	**Clinical presentation**	**Lesion distribution**	**Relation to systemic disease**	**Histopathology of panniculitis**
Morphea and scleroderma	Indurated plaques	Extremities, trunk	Occurs in scleroderma, but usually more pronounced in morphea	Septal, with thickening and sometimes mucin deposition; inflammation especially at dermal–subcutaneous interface; lymphocytes and plasma cells; lymphoid follicles in morphea*
Lupus panniculitis	Tender subcutaneous nodules and plaques; may have overlying lesions of discoid LE	Face (especially cheeks), upper arms, shoulders, hips, breasts, trunk	Only minority of cases associated with systemic LE	Lobular or mixed lobular/septal; mucin deposition; hyaline necrosis of lobules; lymphocytes and plasma cells, sometimes with prominent nuclear dust; nodular lymphocytic aggregates or lymphoid follicles
Dermatomyositis	Indurated, painful plaques and nodules; may ulcerate	Buttocks, abdomen, thighs, arms	Can arise in patients with established dermatomyositis or precede other disease manifestations	Lobular or mixed septal/lobular; fat necrosis; lipomembranous changes; sometimes calcification; lymphocytes and plasma cells; sometimes nodular lymphocytic aggregates
Annular atrophic connective tissue panniculitis of the ankles	Subcutaneous atrophy, which may be preceded by induration and tenderness	Circumferential bands around the ankles	Patients often have antinuclear antibodies and/or autoimmune conditions such as thyroiditis or rheumatoid arthritis	Lobular or mixed septal/lobular lymphohistiocytic panniculitis with areas of fat necrosis
Atrophic connective tissue panniculitis	Erythematous, indurated plaques that resolve with subcutaneous atrophy	Favors extremities; may be widespread	As above	As above

*Less often than in lupus panniculitis.

Table 100.7 Clinical and microscopic features of connective tissue panniculitis. Based on refs 31–35. LE, lupus erythematosus.

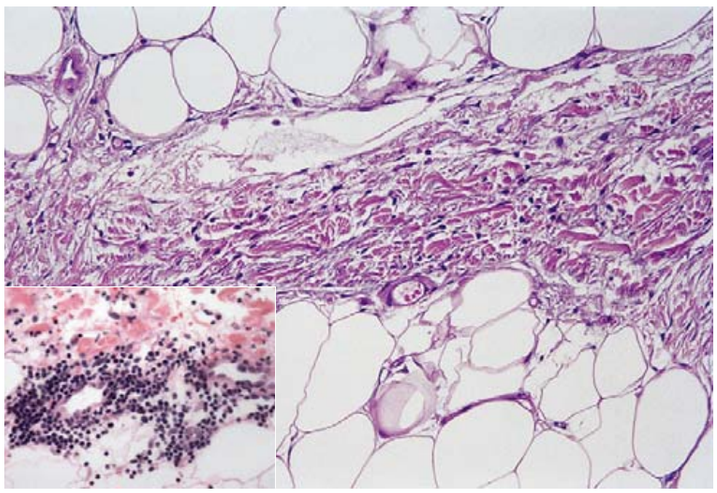

Fig. 100.5 Morphea panniculitis. Septal thickening, mucin deposition and mild lymphocytic infiltrate. Lymphoplasmacytic infiltrates concentrate at the dermal–subcutaneous interface (insert).

of plasma cells is striking[33]. In late stages of morphea, the subcutis is largely replaced by hyalinized connective tissue, quite often accompanied by changes of lipoatrophy.

Differential diagnosis

The combination of septal panniculitis with lymphoplasmacytic predominance and dermal and subcutaneous sclerosis is unique, and this helps to separate morphea/scleroderma panniculitis from other septal forms of panniculitis. Differentiation among the several variants outlined above is more difficult, requiring clinical data for accurate classification. Sclerosis with lesser degrees of subcutaneous inflammation characterizes scleroderma, while a predominance of fascial involvement with extension into the subcutis is more typical of eosinophilic fasciitis.

ALPHA$_1$-ANTITRYPSIN DEFICIENCY PANNICULITIS

Synonym: ■ Alpha$_1$-protease (proteinase) deficiency panniculitis

Key features

- Erythematous, painful subcutaneous nodules or plaques that often ulcerate and drain
- Associated with α_1-antitrypsin deficiency; patients with the most severe disease are homozygotes for the Z allele of the *SERPINA1* gene (PiZZ)
- A characteristic histologic finding is liquefactive necrosis of the dermis and subcutaneous septa, but lobular or mixed septal–lobular changes with neutrophils may occur

Introduction

Alpha$_1$-antitrypsin deficiency is a well-established but uncommon cause of panniculitis. The most severely affected individuals, with markedly decreased levels of the protease inhibitor, are most prone to the development of ulcerating neutrophilic panniculitis. Recognition of the disorder is important not only in the selection of appropriate therapy, but also in addressing other manifestations of the disease and in dealing with its genetic aspects.

History

Alpha$_1$-antitrypsin deficiency is an inborn error of metabolism that was first delineated by Eriksson and others in the early 1960s[39]. In 1972, Warter and colleagues identified members of a family with α_1-antitrypsin deficiency and "Weber–Christian syndrome". Subsequent investigations linked the clinical and microscopic findings to known effects of proteinase inhibitor deficiency.

Epidemiology

No apparent racial or geographic prevalence has been noted for α_1-antitrypsin deficiency panniculitis. The incidence of the disease is approximately equal in men and women[40,41]. Age of onset ranges from infancy to the eighth decade of life[41].

Pathogenesis

Alpha$_1$-antitrypsin, a glycoprotein produced in the liver, is the most abundant circulating *ser*ine *p*rotease *in*hibitor (serpin). The more than 120 different alleles of the gene that encodes this protein (SERPINA1;

formerly known as PI) are divided into categories based upon the electrophoretic mobility of their protein products (M = medium, S = slow, Z = very slow). The most common protease inhibitor (Pi) phenotype is MM (homozygous for M alleles), which is associated with normal serum levels of α_1-antitrypsin (120–200 mg/dl)[42]. Heterozygotes with one copy of the S or Z allele have mild to moderate deficiencies of the inhibitor (PiMS and PiMZ; prevalences of 1–3% in Caucasian populations). Patients who are homozygous for the Z allele (PiZZ; prevalence of 1:1500 – 1:5000 in Caucasian populations) have severe α_1-antitrypsin deficiency, with serum levels in the range of 20–45 mg/dl. In these individuals, most of the aberrant α_1-antitrypsin protein accumulates in the endoplasmic reticulum of hepatocytes, and the small amounts that enter the circulation have decreased function and a tendency to form inactive polymers that may stimulate neutrophil chemotaxis[43]. Of note, Z-type polymers have been detected in the skin of a patient with α_1-antitrypsin deficiency panniculitis, further suggesting a possible proinflammatory role[44].

Alpha$_1$-antitrypsin acts upon a wide range of proteolytic enzymes that play a direct role in degradation of tissues, including trypsin, collagenase, and elastase[45]. It also has important effects on immune function, e.g. inhibition of membrane-bound serine proteases involved in the activation of lymphocytes and macrophages[46]. It may also inhibit complement activation, both through a direct effect on complement-related proteases[47] and by inhibiting the neutrophil proteases that activate enzymes of the complement system[48].

In addition to panniculitis, the consequences of α_1-antitrypsin deficiency include chronic liver disease with cirrhosis (resulting from retention of the aberrant protein within the liver), emphysema, pancreatitis, membranoproliferative glomerulonephritis, rheumatoid arthritis, C-ANCA (cytoplasmic antineutrophil cytoplasmic antibody)-positive vasculitis, other cutaneous vasculitides, and angioedema (resulting from deficiency of the protease inhibitor)[40,48]. The initiating event in individuals who develop panniculitis is not always clear; trauma appears to play a role in some cases. Postpartum flares of the disease have been reported in genetically susceptible individuals. This is attributed to the estrogen-promoted increase in proteinase inhibitor levels during pregnancy, followed by a precipitous decline to subnormal levels postpartum[49]. Absence of the α_1-antitrypsin protease inhibitor results in activation of lymphocytes and macrophages, lack of restraint upon the complement cascade, release of chemotactic factors, accumulation of neutrophils with release of their proteolytic enzymes, and consequent attack upon fat and nearby connective tissues[43,45]. The subcutis may be particularly vulnerable to this process, since fatty acids make nearby elastin more susceptible to proteolytic degradation[48].

Clinical features

Large, erythematous to purpuric, tender nodules or plaques appear in a variety of sites (Fig. 100.6), especially the lower trunk and proximal extremities (flanks, buttocks and thighs)[40,43,45]. Ulcers develop that may be deep and necrotic, accompanied by an oily discharge[41,43,45]. Migration of lesions has been reported[40]. A history of antecedent trauma can be elicited in approximately one-third of cases[41]. Some patients with panniculitis also have fever, pleural effusions and pulmonary emboli[41]. The clinical course of the panniculitis is often prolonged, and lesions are resistant to therapy. Healing is accompanied by scarring and subcutaneous atrophy[41]. The most severe manifestations arise in those with profound proteinase inhibitor deficiency (PiZZ), although the panniculitis can also occur in heterozygotes[40].

Fig. 100.6 Alpha$_1$-antitrypsin deficiency panniculitis. Purpuric nodules on the ankle. *Courtesy, Kenneth E Greer, MD.*

Pathology

Descriptions of the pathology of α_1-antitrypsin deficiency panniculitis have varied. Early, there is a neutrophilic panniculitis, followed rapidly by necrosis and destruction of fat lobules[45]. Splaying of neutrophils between collagen bundles in the reticular dermis has been described as an early clue to the diagnosis[50]. Dissolution of dermal collagen, with resultant liquefactive necrosis and separation of fat lobules from adjacent septa, is a principal change in most cases[51]. Another characteristic feature is the presence of "skip areas" of normal fat adjacent to foci of severe necrotizing panniculitis[45]. Chronic inflammation and hemorrhage may be present at the periphery of areas of involvement[45]. Most authors have not found evidence for *primary* leukocytoclastic vasculitis, although there may be evidence for lymphocytic vasculitis, *secondary* vasculitis in areas of heavy neutrophilic infiltration, or thrombosis[45]. In individuals with intermediate levels of protease inhibitor deficiency, lipophage and giant cell accumulation may be prominent[45]. Lesions heal with scarring and obliteration of fat lobules.

Views differ on whether α_1-antitrypsin deficiency panniculitis should be regarded as a primarily septal or lobular panniculitis. Clearly, involvement of fat lobules can be significant, and, as a result, some authors have labeled the process a lobular panniculitis. On the other hand, some descriptions have emphasized early septal inflammation, collagenolysis of the fibrous septa[51], and the prominent septal fibrosis in late-stage lesions[50].

Differential diagnosis

Clinically, the degrees of inflammation, ulceration and drainage associated with α_1-antitrypsin deficiency panniculitis may actually raise a differential diagnosis more focused upon ulcerative skin disorders. The presence of ulcers with geometric patterns supports a diagnosis of factitial panniculitis. Ulcers associated with α_1-antitrypsin deficiency generally lack the necrotic, "undermined" borders associated with pyoderma gangrenosum[45].

Su et al.[45] have extensively reviewed the microscopic differential diagnosis for this disorder. Entities that are of particular importance for consideration include traumatic (factitial) panniculitis, infection-induced panniculitis, pancreatic panniculitis, and erythema induratum (nodular vasculitis). Each of these can be associated with infiltrates that include neutrophils and varying degrees of necrosis, yet each has other distinct findings (see below). In the appropriate clinical setting, subcutaneous Sweet's syndrome and neutrophilic panniculitis in patients with rheumatoid arthritis or inflammatory bowel disease may represent additional diagnostic considerations.

Treatment

Treatments that are usually ineffective include corticosteroids, immunosuppressants, cytotoxic agents, colchicine, danazol and hydroxychloroquine[40,45]. Doxycycline is sometimes effective, particularly in mild cases; one suggested dosage schedule is 200 mg twice daily for 3 months[47,52]. Dapsone may also be beneficial in mild cases, by suppressing neutrophil migration and inhibiting oxidation reactions induced by myeloperoxidase[40]. Reduction of alcohol intake has also been recommended, since ethanol (as a hepatotoxin) may precipitate α_1-antitrypsin-associated hepatitis[48].

The most effective therapeutic measure is replacement of α_1-antitrypsin via intravenous infusions. Dosages are generally 60 mg/kg per week, administered over a period of 3 to 7 weeks[40,41]. Improvement is relatively rapid, and clearing of the panniculitis can occur after three weekly doses[40]. Recurrences are possible when α_1-antitrypsin levels fall below 50 mg/dl[40], but these typically respond to further replacement therapy. Other successful therapies have included plasma exchange and liver transplantation (in appropriate clinical circumstances). In the future, autophagy-enhancing drugs such as carbamazepine may reduce systemic manifestations such as hepatic fibrosis[52a].

ERYTHEMA INDURATUM

Synonyms: ■ Nodular vasculitis ■ Erythema induratum of Bazin or Bazin's disease (tuberculous etiology) ■ Erythema induratum of Whitfield (non-tuberculous etiology)

Key features

- Erythematous nodules or plaques, usually on the posterior lower legs of young to middle-aged women
- Ulceration and drainage may occur
- Microscopic features of lobular or mixed panniculitis with evidence for vasculitis involving arteries or veins
- Classically associated with tuberculosis, but similar lesions can be idiopathic or induced by other infectious agents or drugs

Introduction

Erythema induratum is a condition characterized by nodules on the lower extremities, which may ulcerate and drain. Originally regarded as a tuberculid, its relationship to tuberculosis in a subset of patients has been solidified by several more recent studies detecting mycobacterial DNA in cutaneous lesions.

History

Erythema induratum was first described by Ernest Bazin in 1861. It was generally regarded as a tuberculid because of a strong association with tuberculosis, though Koch's postulates could not be fulfilled. In 1945, Montgomery and colleagues proposed the term *nodular vasculitis* for cases with similar clinical and pathologic features that were not of tuberculous origin. Since the early 1970s, erythema induratum and nodular vasculitis have generally been considered as synonyms referring to a clinicopathologic entity with several possible causes, one of which is tuberculosis. The detection of mycobacterial DNA in cutaneous lesions has confirmed a tuberculous origin in some patients[53]. There are some clinicians, however, who prefer to use the term nodular vasculitis when referring to individuals with a non-tuberculous etiology.

Epidemiology

In erythema induratum, an overwhelming female predominance is observed, but men can also develop the disease[54]. There is no apparent racial predilection, and although there is a wide age range among affected patients, the mean is between 30 and 40 years[54]. Erythema induratum of tuberculous etiology occurs more frequently in populations with a high prevalence of tuberculosis.

Pathogenesis

As mentioned, there has been a strong association of some cases with tuberculosis. This has now been substantiated by the detection of mycobacterial DNA in skin lesions by PCR[53,55,56]. Specific primers can be used to distinguish *M. tuberculosis* complex DNA from that of other mycobacterial pathogens[56]. Non-tuberculous cases have been related to other infectious agents (e.g. *Nocardia*[21]) or to drugs (e.g. propylthiouracil[57]). An example of erythema induratum in association with "red fingers" syndrome was described in a patient with chronic hepatitis C infection[58].

Although it has been suggested that erythema induratum results from an immune complex-mediated vasculitis[54], most investigators believe that the process represents a type IV, cell-mediated response to an antigenic stimulus[59]. Biopsy specimens show a predominance of T lymphocytes, macrophages and dendritic cells, including Langerhans cells[54,60,61]. One study of peripheral blood mononuclear cells from a patient with erythema induratum and active tuberculosis showed a high proliferative response to purified protein derivative (PPD) and marked production of interferon-γ, suggesting a pathogenic role for these PPD-specific T cells in a delayed hypersensitivity response to mycobacterial antigens[62].

Clinical features

Erythema induratum is characterized by tender, erythematous to violaceous nodules and plaques that most often develop on the lower legs, especially the calves[60,61]. Lesions have also been reported on the feet, thighs, buttocks and arms[54]. Annular arrangements of nodules have been described in *M. tuberculosis*-related cases[63]. Ulceration can occur (Fig. 100.7). Lesions are persistent, tend to heal with scarring, and are prone to recurrence[54,60,64]. In erythema induratum associated with *M. tuberculosis*, there may be clinical and radiographic evidence for active tuberculosis, positive skin tests to PPD or a positive QuantiFERON®-TB Gold test. Clinical differences between tuberculous and non-tuberculous cases are minor.

Pathology

Erythema induratum is generally described as a lobular or mixed septal/lobular panniculitis. Inflammation is mixed, and can include neutrophils, lymphocytes, macrophages and multinucleated giant cells. Vasculitis is identifiable in the vast majority of cases, and most frequently involves veins or arteries of connective tissue septa and small venules of the fat lobules[65] (Fig. 100.8). It may be predominantly neutrophilic[60], lymphocytic[64] or granulomatous. Necrosis with a coagulative or caseous appearance may be present, sometimes with palisading granulomas[60] (Fig. 100.9). Necrosis has been described in both tuberculous and non-tuberculous cases, and the incidence and degree of

necrosis are greater in those cases that are positive for *M. tuberculosis* DNA by PCR methods[55]. However, this finding is absent in over half of cases.

Differential diagnosis

Infection-induced panniculitis tends to show a more prominent neutrophilic component, granular basophilic necrosis, sweat gland necrosis and proliferation of small vessels, and organisms may be identified on special staining. Lupus panniculitis tends to be less granulomatous, has a prominent lymphoplasmacellular infiltrate, may show mucin deposits, and sometimes has overlying epidermal and dermal changes typical for lupus erythematosus. Both polyarteritis nodosa and thrombophlebitis tend to show inflammation limited to the immediate perivascular zone, in contrast to the extensive lobular panniculitis often encountered in erythema induratum. Histologically, perniosis can be difficult to distinguish from erythema induratum, but there is typically a history of cold exposure[60], and on microscopic examination the vessels often show "fluffy edema" of their walls.

Treatment

Treatment should be directed at the underlying cause, if found. This includes multi-drug antituberculous therapy for those cases associated with *M. tuberculosis*[63] (see Ch. 75). Appropriate antimicrobial therapy is indicated for other infection-related cases, and possible inciting medications should be discontinued. Other helpful therapies have included corticosteroids, NSAIDs, potassium iodide, tetracycline, gold[64] and mycophenolate mofetil[66]. Supportive care includes bed rest, bandages, gradient support hose, and avoidance of aggravating factors such as smoking.

PANCREATIC PANNICULITIS

Synonyms: ■ Pancreatic fat necrosis ■ Enzymatic panniculitis

Key features

- Subcutaneous nodules, sometimes accompanied by fever, arthritis or abdominal pain
- Associated with pancreatic disorders, including acute and chronic pancreatitis and pancreatic carcinoma
- Mixed septal/lobular panniculitis featuring "ghost cell" formation and the deposition of basophilic material due to saponification of fat by calcium salts
- Treatment primarily directed towards the underlying pancreatic disorder

Introduction

Pancreatic panniculitis is an uncommonly reported complication of pancreatic disease. In addition to the symptoms associated with fat necrosis, its chief importance is as a sign of a significant systemic disorder, particularly because the panniculitis may be recognized prior to detection of the underlying pancreatic disease.

History

Chiari first described pancreatic panniculitis in 1883. By 1999, fewer than 100 cases had been reported[67,68].

Epidemiology

Panniculitis develops in up to 2% of patients with pancreatic disorders[69]. No geographic, racial or sex predilections have been reported.

Pathogenesis

There is considerable evidence that the enzymes lipase, amylase and trypsin are involved in producing the lesions of pancreatic panniculitis[67]. Elevated enzyme levels have been detected in the blood[68,69], urine[67] and skin lesions, even in the absence of detectable pancreatic disease. Lipase has the clearest relationship with the panniculitis, with a number of cases showing elevated serum lipase levels but normal amylase levels[68]. Amylase levels tend to peak 2–3 days after eruption of the skin lesions and return to normal 2–3 days after regression of the lesions. Trypsin and perhaps amylase may act by promoting increased permeability of vessel walls, thereby permitting lipase to hydrolyze neutral fat to form glycerol and free fatty acids, with resulting fat necrosis and inflammation[68,69]. Venous stasis may promote this process, possibly explaining the predilection for the lower extremities. Elevated enzyme levels may not be the complete explanation for the changes of pancreatic panniculitis[70]. Immunologic factors probably also play a role.

Clinical features

Subcutaneous nodules develop in association with acute or chronic pancreatitis, pancreatic carcinoma (acinar cell > other types [e.g. neuroendocrine carcinomas]), pancreatic pseudocysts, pancreas divisum, or traumatic pancreatitis[68,71]. Panniculitis developing in individuals with chronic pancreatitis is often associated with a pancreaticoportal fistula, and, in some of these patients, an acinar cell carcinoma can be found. Panniculitis may precede detection of pancreatic disease by 1–7 months[69], and in the case of pancreatic carcinoma, its onset may signal the presence of metastatic disease[68,69].

In pancreatic panniculitis, subcutaneous nodules develop, frequently on the legs (Fig. 100.10), but also on the abdomen, chest, arms and scalp[68,69]. Erythematous, edematous, sometimes painful lesions arise singly or in crops, and they may migrate. They can become fluctuant and ulcerate, discharging an oily material[68]. Panniculitis may also involve visceral fat, including the omentum and preperitoneal fat[68]. Associated findings include fever, abdominal pain, inflammatory polyarthritis, ascites and pleural effusions[68]. The association of subcutaneous nodules, polyarthritis and eosinophilia is known as Schmid's triad, and it is associated with a poor prognosis. Some patients have radiographic evidence of multiple lytic areas involving cortical bone near large joints. Cutaneous lesions may involute within a period of weeks, leaving hyperpigmented scars. In acute pancreatitis, the panniculitis resolves as the acute inflammatory phase passes[68]. However, lesions may also persist and expand until the underlying pancreatic abnormality has been treated.

Pathology

Pancreatic panniculitis may begin as a septal panniculitis[20], but with progression, the lesion takes on the appearance of a lobular or mixed septal/lobular process. Even in early stages, fat necrosis with liquefaction and microcyst formation is observed[67,70]. Lipocytes lose their nuclei and develop thick, shadowy walls, forming the characteristic "ghost cells". Saponification of fat by calcium salts results in deposition of granular or homogeneous basophilic material (Fig. 100.11). Neutrophils, occasional eosinophils, macrophages, and multinucleated giant cells are sometimes present and may encroach upon the septa. Fibrosis and lipoatrophy are seen in late stages as the process resolves.

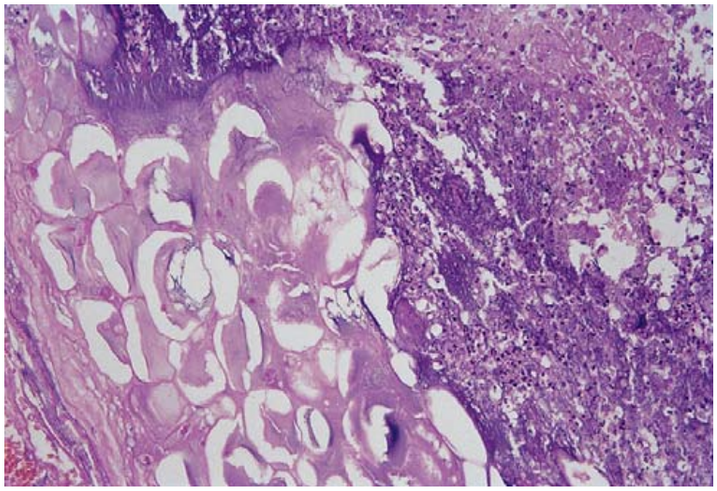

Fig. 100.11 Pancreatic panniculitis. Neutrophilic inflammation, cellular necrosis, and deposition of homogeneous basophilic material due to saponification of fat by calcium salts.

Differential diagnosis

Clinically, the nodules of pancreatic panniculitis can resemble those of a number of other forms of panniculitis. Ulceration and discharge would argue against erythema nodosum, and an association with fever, polyarthritis and/or abdominal pain should raise suspicion of associated pancreatic disease. Serum amylase and lipase levels, if elevated, may also be helpful. Histologic evidence of "ghost cell" formation and saponification of fat distinguishes pancreatic panniculitis from other panniculitides. Eosinophilic "hyaline necrosis" is seen in lupus panniculitis, rather than granular or homogeneous basophilic necrosis typical of pancreatic panniculitis.

Treatment

Although supportive measures such as compression and elevation can be helpful, effective management of pancreatic panniculitis is dependent upon treatment of the underlying pancreatic disease. In chronic pancreatitis, a pancreatic duct stent can be used to relieve obstruction, or, if a fistula or cyst is involved, biliary bypass surgery can be undertaken if simple drainage measures are unsuccessful. Octreotide, a synthetic somatostatin-like polypeptide, can be used to inhibit pancreatic enzyme production[68]. Resection of pancreatic cancer may be followed by regression of the panniculitis.

SCLEREMA NEONATORUM, SUBCUTANEOUS FAT NECROSIS OF THE NEWBORN, AND POST-STEROID PANNICULITIS

There are three entities – sclerema neonatorum, subcutaneous fat necrosis of the newborn, and post-steroid panniculitis – that are characterized histologically by formation of needle-shaped clefts within lipocytes. In contrast to adult fat, the subcutaneous fat of infants is thought to be prone to crystal formation because of a higher content of saturated fatty acids, including palmitic and stearic acids, and a relatively lower content of unsaturated fatty acids, such as oleic acid[72]. This increased saturated to unsaturated fatty acid ratio results in a higher melting point for stored fat and promotes crystallization under certain conditions. Microsized crystals (type A) apparently do not produce an inflammatory response; they are actually common (in a widely dispersed form) in healthy infants 6 months of age or less, but are more numerous in sclerema neonatorum. Larger, type B crystals that tend to be arranged in rosettes are capable of eliciting a granulomatous response; these larger crystals are most often seen in subcutaneous fat necrosis of the newborn and post-steroid panniculitis[72]. Crystallization and defects in fat mobilization account for the clinical findings in these disorders.

Sclerema Neonatorum

Key features

- Arises in premature infants
- Skin is diffusely cold, rigid, and board-like
- Microscopically, needle-shaped clefts are present within lipocytes with minimal inflammation
- Affected infants are often hypothermic and may have a variety of other medical problems; early death is common

History

Sclerema neonatorum was first recognized in 1722 by Uzembenzius, although the classic description is usually attributed to Underwood (1784). Ballantyne provided an early description of the histopathologic changes, and Knopfelmacher noted the presence of needle-shaped crystals in subcutaneous tissue in 1897.

Epidemiology

Sclerema neonatorum presents most often in premature, debilitated infants, usually during the first week of life. There is a slight male predominance, with no substantial difference in death rates between the sexes[73].

Pathogenesis

In infants who develop sclerema, crystallization and hardening of fat occur in the setting of an increased saturated:unsaturated fatty acid ratio and a defective ability to mobilize fatty acids. Precipitating factors, which may include subcutaneous ischemia due to perinatal asphyxia as well as hypothermia, are listed in Table 100.8[72].

Clinical features

The clinical features are outlined in Table 100.8[72–74]. Rapid hardening of the subcutaneous tissues leads to firm, rigid skin over most of the body. Low admission weight and temperature as well as hemorrhagic phenomena portend a particularly poor prognosis[73].

Pathology

Table 100.8 outlines the microscopic features. Inflammation is usually sparse, and most of the needle-shaped clefts are found within lipocytes rather than within giant cells (Fig. 100.12)[72,74]. At a later stage, thickened connective tissue bands may be the only histologic finding[74].

Differential diagnosis

In contrast to sclerema neonatorum, subcutaneous fat necrosis of the newborn is a localized process with a favorable prognosis; histologically,

PANNICULITIDES WITH NEEDLE-SHAPED CLEFTS IN THE SUBCUTIS						
Condition	**Patient characteristics**	**Onset**	**Cutaneous findings**	**Associated systemic findings**	**Histopathology**	**Possible precipitating factors**
Sclerema neonatorum	Severely ill premature neonates	First week of life	Widespread, diffuse hardening, sparing only the genitalia, palms and soles; cool, waxy, rigid and board-like skin with livid, mottled discoloration	Respiratory difficulties, congestive heart failure, intestinal obstruction, diarrhea; death, usually from septicemia, in three-quarters of cases	Needle-shaped clefts in lipocytes; septal thickening; inflammation sparse to absent (few neutrophils, eosinophils, macrophages or multinucleated giant cells may be seen)	Hypothermia, perinatal asphyxia, defective complement activity, dehydration
Subcutaneous fat necrosis of the newborn	Full-term neonates	First 2–3 weeks of life	Circumscribed, erythematous, indurated subcutaneous nodules favoring the cheeks, shoulders, back, buttocks, thighs; may become fluctuant	Hypercalcemia (onset may be delayed for several months), thrombocytopenia, hypertriglyceridemia	Lobular panniculitis with neutrophils, lymphocytes, macrophages; needle-shaped clefts in a radial array within lipocytes and giant cells; sometimes foci of calcification, hemorrhage	Hypothermia, hypoglycemia (e.g. due to gestational diabetes), perinatal hypoxemia (e.g. due to meconium aspiration, placenta previa, umbilical cord prolapse, pre-eclampsia), birth trauma
Post-steroid panniculitis	Children (ages 1–14 years)	1–40 days* after cessation of high-dose systemic corticosteroid therapy	Firm red plaques on cheeks, arms, trunk; small and discrete or large and confluent lesions; pruritic, tender or asymptomatic	Underlying conditions treated with systemic corticosteroids have included leukemia, cerebral edema, nephrotic syndrome, secretory diarrhea, acute rheumatic fever	Lobular panniculitis with lymphocytes, macrophages, multinucleated giant cells; needle-shaped clefts in lipocytes and giant cells	Follows rapid corticosteroid withdrawal

*Usually within 10 days.

Table 100.8 Panniculitides with needle-shaped clefts in the subcutis.

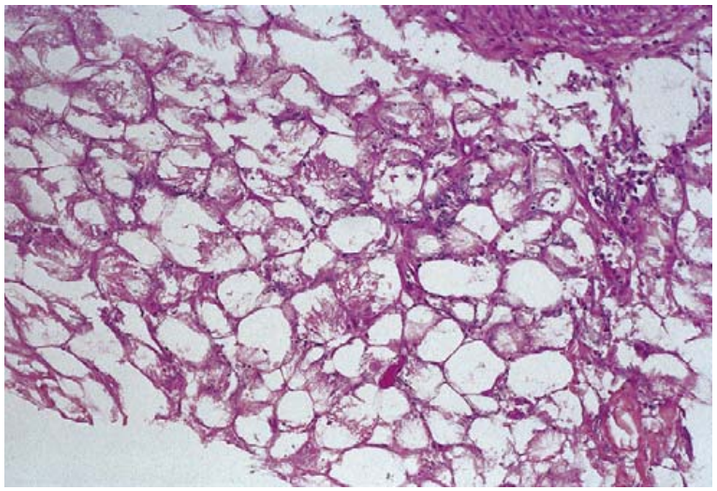

Fig. 100.12 Sclerema neonatorum. Needle-shaped clefts within lipocytes, in the absence of inflammation.

the latter is distinguished by more prominent inflammation and localization of needle-shaped clefts within giant cells. Scleredema neonatorum is a condition seen in premature infants with congenital heart disease. In this disorder, the skin is distended and wax-like, and on biopsy the dermis appears edematous, with increased amounts of mucin[72]. Other conditions that can present with diffusely indurated skin in the neonatal period include stiff skin syndrome (usually favoring the trunk, buttocks and thighs), restrictive dermopathy, and Hutchinson–Gilford progeria.

Treatment

Attempts to treat this disorder are disappointing[73]. Management includes treatment of sepsis, ventilatory support, correction of fluid and electrolyte imbalances, and maintenance of body temperature[72,75]. Exchange transfusions may be of value in selected instances[72,75]. Systemic corticosteroids are of questionable value[72,73].

Subcutaneous Fat Necrosis of the Newborn

Key features

- Development of one or more mobile, firm, subcutaneous nodules or plaques during the newborn period
- Sometimes associated with hypercalcemia or thrombocytopenia
- Granulomatous lobular panniculitis with needle-shaped clefts within lipocytes and giant cells
- Prognosis is usually favorable; spontaneous resolution is common

Introduction

In contrast to sclerema neonatorum, subcutaneous fat necrosis is a localized process. Although complications can arise, particularly in relation to hypercalcemia, most cases resolve spontaneously.

History

At the beginning of the twentieth century, Fabyan described "abscesses" that spontaneously resorbed, and provided the first microscopic description of subcutaneous fat necrosis.

Epidemiology

Subcutaneous fat necrosis of the newborn typically occurs in full-term neonates during the first 2 to 3 weeks of life[76].

Pathogenesis

It is believed that a variety of stresses imposed upon fetal fat, with its high ratio of saturated to unsaturated fatty acids, results in crystallization, adipocyte injury and granulomatous inflammation. Hypothermia is one potential eliciting factor, as illustrated by a case of subcutaneous fat necrosis that developed as a complication of hypothermic cardiac surgery[77]. Other proposed causes are listed in Table 100.8[72,76,78]. The role of birth trauma has been questioned, since many cases have occurred in infants delivered by cesarean section[76].

Clinical features

The clinical features are outlined in Table 100.8. Smooth, circumscribed, mobile, red to violaceous, subcutaneous nodules or plaques develop, sometimes in a symmetrical fashion[72,76] (Fig. 100.13). The areas of fat necrosis have been detected by CT[79] and MRI[80].

Some cases are associated with hypercalcemia or thrombocytopenia, and the former may develop 1–4 months after the onset of the skin lesions[78]. It is believed that the hypercalcemia results from extrarenal production of 1,25-dihydroxyvitamin D_3 (calcitriol) by activated macrophages (expressing 1-α-hydroxylase) within areas of granulomatous panniculitis, which stimulates calcium absorption from the gut and mobilization from the bones[76,81]. The mechanism for thrombocytopenia may be local sequestration in the subcutis, as studies have shown normal bone marrow findings and resolution of the platelet abnormality as the inflammatory process resolves[82]. Spontaneous resolution of lesions is the rule, sometimes in association with lipoatrophy. Deaths have been reported in patients with associated hypercalcemia[82].

Pathology

The microscopic changes are outlined in Table 100.8. Needle-shaped clefts are observed within both lipocytes and giant cells (Fig. 100.14). The crystals are doubly refractile and stain with oil red O[72]. Occasionally, however, needle-shaped clefts are not evident in otherwise typical cases. Eosinophilic granules are sometimes found within multinucleated giant cells; their origin is not entirely certain, but they may be derived from degranulating eosinophils[83].

Fig. 100.13 Subcutaneous fat necrosis of the newborn. Indurated plaques on the trunk.

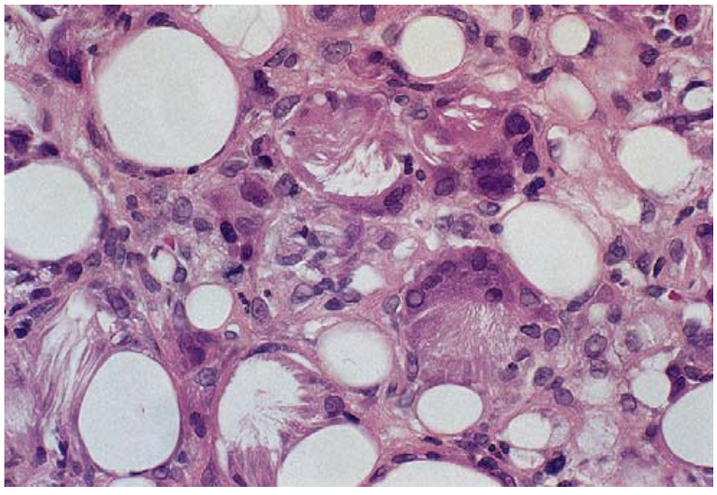

Fig. 100.14 Subcutaneous fat necrosis of the newborn. Needle-shaped clefts in a radial configuration are present within giant cells. Similar findings are seen in post-steroid panniculitis.

Differential diagnosis

The extensive cutaneous involvement in sclerema neonatorum is usually distinguishable from the localized, self-limited process of subcutaneous fat necrosis; histologically, inflammation in sclerema is minimal. Post-steroid panniculitis is microscopically indistinguishable from subcutaneous fat necrosis, but it arises in a different clinical setting (see below).

Treatment

Since many lesions resolve spontaneously, the emphasis is on supportive care. Systemic corticosteroids may be indicated to control the inflammation in severe cases[72]. Serial monitoring of calcium levels (for at least 4 months) is important. Hypercalcemia is managed by hydration, dietary restriction of both calcium and vitamin D, calcium-wasting diuretics (e.g. furosemide), calcitonin and bisphosphonates (e.g. etidronate, pamidronate)[76,78,84]. Corticosteroids may be helpful in managing hypercalcemia, by interfering with the metabolism of vitamin D to calcitriol, and by inhibiting calcitriol production by macrophages[78].

Post-steroid Panniculitis

Key features

- A rare complication of rapid systemic corticosteroid withdrawal
- Subcutaneous nodules develop on the cheeks, arms and trunk
- Lesions resolve spontaneously, or when corticosteroids are readministered
- Pathology consists of granulomatous lobular panniculitis with needle-shaped clefts within both lipocytes and giant cells

History

In 1956, Smith and Good[85] reported 11 children with acute rheumatic fever who were treated with large doses of corticosteroids that were rapidly tapered. Five children developed pruritic, erythema nodosum-like lesions.

Epidemiology

Post-steroid panniculitis is a disorder of children. It occurs in an older age group than either sclerema neonatorum or subcutaneous fat necrosis of the newborn, with reported ages ranging from 20 months to 14 years[86].

Pathogenesis

Post-steroid panniculitis occurs after rapid withdrawal of systemic corticosteroids that have been administered either orally or intravenously. For patients who had received prednisone, cumulative dosages ranged from 2000 to 6000 mg[86]. The precise mechanism by which the panniculitis arises is not known.

Clinical features

Patients who have developed this form of panniculitis received corticosteroid therapy for a variety of conditions[85–87], including those listed in Table 100.8. Lesions appear 1 to 40 days after rapid corticosteroid withdrawal and disappear spontaneously over a period of months to a year[87].

Pathology

Microscopic changes are outlined in Table 100.8[87]. Needle-shaped clefts, some with a "starburst" pattern, can be identified within lipocytes or giant cells.

Differential diagnosis

A less nodular presentation involving the cheeks can mimic non-panniculitic disorders such as erythema infectiosum, atopic dermatitis, lupus erythematosus or facial cellulitis. The microscopic changes in these conditions would be quite different from those of post-steroid panniculitis. Cold panniculitis has clinical and microscopic similarities, but the history of cold exposure and the lack of needle-shaped

clefts on biopsy permit distinction. The microscopic changes of post-steroid panniculitis are virtually identical to those of subcutaneous fat necrosis of the newborn, although calcification and hemorrhage are more commonly observed in the latter condition. Clinical history is decisive.

Treatment

Since spontaneous resolution is the rule, treatment is usually unnecessary. Readministration of corticosteroids followed by a more gradual taper may be helpful[87].

LUPUS ERYTHEMATOSUS PANNICULITIS (LUPUS PANNICULITIS)

Synonyms: ■ Lupus profundus ■ Subcutaneous lupus erythematosus

Key features

- Tender subcutaneous nodules and plaques arising on the face, proximal extremities and trunk
- Associated with discoid lupus erythematosus in at least one-third of patients; less often associated with systemic lupus erythematosus (10–15% of patients)
- Often precedes onset of other manifestations of lupus erythematosus
- Characteristic microscopic changes include lobular panniculitis with hyaline necrosis and a predominantly lymphoplasmacytic infiltrate; nodular aggregates of lymphocytes are common
- Overlying epidermal or dermal changes of lupus erythematosus are frequently present

History

Kaposi first described the clinical characteristics of lupus panniculitis in 1869. In 1940, it was recognized as a manifestation of lupus erythematosus (LE) by Irgang. Lupus panniculitis was firmly established as a specific subtype of LE in a 1956 paper by Arnold[88].

Epidemiology

Lupus panniculitis constitutes a small subset of all cases of cutaneous LE, representing 2–3% of this group[89]. It usually occurs in adults, with a median age of onset of 30–40 years[90]. Children can also develop lupus panniculitis, and an association with neonatal lupus has been described[88]. There is a predominance among women, with a female : male ratio ranging from 2 : 1 to 4 : 1[37,90]. Sometimes there is a family history of either LE or another autoimmune connective tissue disease[89].

Pathogenesis

The autoimmune basis of lupus panniculitis is thought to be similar to that of other types of LE (see Ch. 41). The cells comprising the infiltrates of lupus panniculitis are T lymphocytes and macrophages[91]. Lupus panniculitis (often with a childhood onset and widespread distribution) has been described in patients with partial C4 deficiency[92]. This complement deficiency causes defective opsonization of immune complexes, which may play a role in the pathogenesis of the disease[92]. Immunohistochemical analysis has shown an interferon-driven Th1-biased immune response in active lesions of lupus panniculitis; this may result in recruitment of cytotoxic CXCR3-positive lymphocytes[93].

Clinical features

Lupus panniculitis is characterized by tender subcutaneous nodules and plaques that may arise in crops (see Table 100.7). A history of trauma can sometimes be elicited. Lesions tend to develop on the face, upper arms, hips and trunk (Fig. 100.15). The lack of involvement of the distal extremities is noteworthy[90]. Changes in the overlying skin range from a light pink color to those of chronic cutaneous (discoid) LE (e.g. scaling, follicular plugging, dyspigmentation, telangiectasias, atrophy and scarring). At times, findings of discoid LE are too subtle to be recognized clinically but can be seen on microscopic examination of biopsy specimens. The overlying skin may also be "tethered" to the subcutaneous nodule or plaque, creating a surface depression, and ulceration occasionally occurs. Lupus panniculitis has a chronic, relapsing clinical course[94]. It usually eventuates in subcutaneous atrophy, which can be disfiguring (see Chs 41 & 101).

Fig. 100.15 Lupus panniculitis. Red–brown plaques on the upper outer arm. Note the significant subcutaneous atrophy and overlying lesions of discoid lupus erythematosus. *Courtesy, Kenneth E Greer, MD.*

Lupus panniculitis often occurs prior to other manifestations of LE and in the absence of other autoimmune connective tissue diseases[90]. For example, lesions of discoid LE have developed up to 10 years after the appearance of the panniculitis. However, manifestations of systemic LE or discoid LE can also occur long before (or at the same time as) the panniculitis[37]. There is a closer relationship of lupus panniculitis to other forms of chronic cutaneous LE (e.g. discoid LE) than to systemic LE. Coexistent discoid lesions are observed in at least one-third of patients, whereas only 10–15% meet the diagnostic criteria for systemic LE[34,90]. Most individuals in the latter group have relatively mild systemic manifestations, usually arthralgias or Raynaud's phenomenon[89]. It is common for patients to have low-titer antinuclear antibodies; they can also have other circulating autoantibodies (including those targeting double-stranded DNA or extractable nuclear antigens), leukopenia, hypocomplementemia, and an elevated ESR[89].

Pathology

Lupus panniculitis is a predominantly lobular process with a variable degree of inflammation (Fig. 100.16). The characteristic microscopic changes (e.g. hyaline necrosis of the fat lobules) are outlined in Table 100.7. Granulomas can occur and tend to encroach upon the septa, but they are usually not prominent. Other features include lymphocytic vasculitis and mucin or calcium deposition.

The subcutaneous findings alone are considered sufficiently characteristic to permit a diagnosis of lupus panniculitis. However, overlying epidermal or dermal changes of discoid LE occur in one-half to two-thirds of cases and are also helpful diagnostically[34,91,95]. With direct immunofluorescence, a positive lupus band can be identified in the overlying skin in a high percentage of cases, even in those where the histopathologic changes are nonspecific[95].

Differential diagnosis

Clinically, lesions of lupus panniculitis can resemble other forms of panniculitis. The rarity of involvement of the distal extremities helps to distinguish it from conditions such as erythema nodosum and

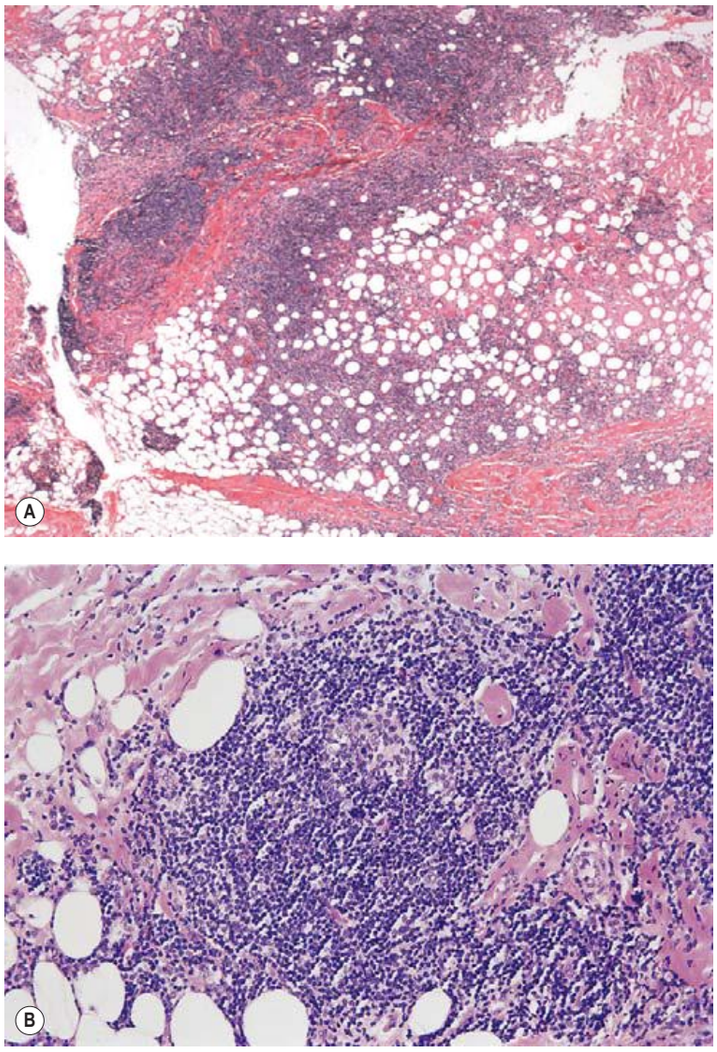

Fig. 100.16 Lupus panniculitis. A Septal and lobular panniculitis with hyaline necrosis of fat lobules. **B** Nodular aggregate of lymphocytes in the subcutis with lymphoid follicle formation.

erythema induratum. It should also be remembered that other forms of subcutaneous inflammation may occur in patients with LE, including erythema nodosum, thrombophlebitis, pancreatic panniculitis, and juxta-articular, rheumatoid nodule-like lesions.

Microscopically, lupus panniculitis can resemble the panniculitis associated with morphea and dermatomyositis (see Table 100.7), traumatic panniculitis (which often has evidence of foreign material) and, in its later stages, localized lipoatrophy due to other etiologies[89,94]. Overlying epidermal or dermal changes of LE, when present, can be of help in excluding other forms of panniculitis. However, a vacuolar interface dermatitis and abundant dermal mucin together with a lobular lymphocytic infiltrate have been described in cases of subcutaneous panniculitis-like T-cell lymphoma[96]. A lack of prominent $CD8^+$ T cells or cytophagia as well as the presence of lymphoid follicles with reactive germinal centers, a mixed infiltrate with conspicuous plasma cells, and polyclonal T-cell receptor gene rearrangement can help to establish a diagnosis of lupus panniculitis in patients lacking additional cutaneous or systemic manifestations of LE[35].

Treatment

Antimalarials are frequently used to treat lupus panniculitis, and they produce improvement in most patients[90]. Addition of a second antimalarial may prove useful in patients who do not respond to a single agent[94]. In view of the chronic, relapsing nature of the disease, treatment may be required for several years[89].

Systemic corticosteroids, when used, are often restricted to initial phases of the disease[89]. Other systemic therapies include dapsone, mycophenolate mofetil, cyclophosphamide, thalidomide and IVIg[90,92,97]. Overlying discoid lesions, if present, can be treated with potent topical or intralesional corticosteroids.

PANNICULITIS OF DERMATOMYOSITIS

Key features

- An uncommon manifestation of dermatomyositis
- Incidental microscopic changes of panniculitis (in the absence of clinical lesions) are seen more often
- Can precede or follow other manifestations of dermatomyositis
- Microscopically, it is a lobular or mixed panniculitis with lymphoplasmacytic predominance
- Usually responds well to therapy

Introduction

Panniculitis is a rare but established clinical manifestation of dermatomyositis. However, there is some evidence that microscopic involvement of subcutaneous fat without overt clinical features of panniculitis is more common.

Clinical features

The characteristic lesions are persistent, indurated, painful plaques and nodules that may ulcerate and lead to lipoatrophy (see Table 100.7)[98]. They can arise in the setting of established dermatomyositis[98] or represent the first manifestation of the disease[99]. The other clinical and laboratory features and the incidence of malignancy in affected individuals appear to be similar to those of dermatomyositis patients without panniculitis[98]. It has been suggested that panniculitis is a favorable prognostic sign, as good responses to therapy have generally been reported[100]. However, partial or generalized lipoatrophy without preceding clinical lesions of panniculitis (occasionally accompanied by increased abdominal fat) occurs in up to one-quarter of patients with juvenile dermatomyositis, and it is often associated with metabolic abnormalities such as hypertriglyceridemia and insulin resistance (see Ch. 101).

Pathology

The microscopic features are outlined in Table 100.7. Lymphocytic vasculitis has been described, and fat necrosis has been noted in several reports[98]. Lipomembranous changes have been observed in some cases (see section on lipodermatosclerosis), and lesions with these changes may be particularly resistant to therapy[98]. Calcification is variable and is an expected finding in cases of dermatomyositis associated with calcinosis of deep soft tissues and skeletal muscle[31]. Vacuolar alteration of the basal layer of the overlying epidermis has been described[98], and the dermis may be edematous or mucinous with perivascular lymphocytic inflammation[100]. Direct immunofluorescence is reported to be negative for deposits along the dermal–epidermal junction[98], although immunoreactants have been detected in vessel walls[100].

Differential diagnosis

Lupus panniculitis is more likely to show hyaline necrosis and lymphoid nodules, but clinical and laboratory findings may be needed to make a distinction. Overlying poikilodermatous changes can occur in both diseases, but lupus is more likely to show appendageal involvement and is associated with positive basement membrane zone fluorescence.

Treatment

Treatments include prednisone, methotrexate, azathioprine, cyclosporine and IVIg[98–100]. Panniculitis lesions have shown variable responses to hydroxychloroquine.

TRAUMATIC PANNICULITIS

Key features

- Inflammation in the subcutis resulting from external injury
- The injurious event may be accidental, purposeful or iatrogenic, and it may be a manifestation of an underlying psychiatric disturbance
- A variety of histopathologic changes are observed, depending upon the inciting agent
- Identification of foreign material is of greatest help in diagnosis

Introduction

Extrinsic injury of varying types can produce panniculitis. There are four broad categories: cold panniculitis (Haxthausen's disease), sclerosing lipogranuloma, panniculitis due to other injectable substances or therapies, and panniculitis due to blunt trauma.

History

Cold panniculitis was reported by Lemez in 1928, when he noted that newborns and infants up to 6 months of age were particularly susceptible to cold injury, as demonstrated by the production of a subcutaneous nodule following application of an ice cube[101]. In 1941, Haxthausen described a condition occurring in small children a few days after exposure to cold, consisting of firm infiltrated nodules of the cheeks and chin. A similar type of cold injury due to popsicles was reported by Epstein and Oren in 1970[102].

Injection of foreign lipid material into the skin for cosmetic or other purposes has been performed for centuries[103]. In 1950, Smetana and Bernhard reported 14 cases of what they termed *sclerosing lipogranuloma* of the male genitalia. They believed it was an endogenous process, but subsequent studies demonstrated the presence of mineral oil in similar cases[103].

Epidemiology

Infants and small children are most at risk for cold panniculitis. A form of the disease also occurs on the thighs of young women who are equestrians[104]. Sclerosing lipogranuloma of the male genitalia is seen mostly in young adults[105]. A sclerosing, pseudosclerodermatous panniculitis has been reported following megavoltage radiation for metastatic carcinoma[106] and as a radiation recall reaction after cyclophosphamide therapy[107].

Pathogenesis

Cold injury to fat favors small children, due in part to a higher ratio of saturated to unsaturated fatty acids that results in a higher solidification point for infantile fat[108]. Cold injury is also related to fluctuations in blood flow that occur with declining temperatures (the "hunting phenomenon"), ice crystal formation, and the changes that occur with thawing[108]. Injections of oils (and associated impurities) are known for producing subcutaneous inflammation. Substances include mineral oil (paraffin) as well as camphor, cottonseed and sesame oils. Even medical grade silicone may contain impurities, and, since encapsulation of this material is desirable when used for cosmetic purposes, fibrosis-inducing substances such as olive oil or castor oil are often added[103]. Injected substances responsible for factitial panniculitis have included milk and feces.

Panniculitis has been produced by numerous therapeutic agents, such as meperidine, morphine, tetanus antitoxoid, pentazocine, phytonadione (vitamin K)[109], povidone[110], aurothioglucose[111], interleukin-2 (IL-2)[112], and substances used for tissue augmentation such as bovine collagen[113] or poly-L-lactic acid. More recently, panniculitis due to "mesotherapy" (involves injection of substances such as phosphatidylcholine to treat localized fat accumulations; see Ch. 156)[114] and electroacupuncture[115] have been described. In addition to the foreign body response elicited by many of these agents, other immune mechanisms may also be involved. With blunt trauma, granulomas contain material that may be derived from the breakdown of erythrocyte membranes[116].

Clinical features

In cold panniculitis (including popsicle panniculitis), erythematous, firm nodules develop, particularly on the cheeks and chin[108]. In equestrian cold panniculitis, erythematous to violaceous, tender plaques appear on the thighs following exposure to cold while wearing tight-fitting clothing[104] (Fig. 100.17).

In lipogranuloma, nodules are sometimes migratory and can be accompanied by varying degrees of swelling, erythema, abscess formation, lymphangitis and fibrosis[103]. The term *sclerosing lipogranuloma* often refers to lesions arising on the male genitalia due to self-injection of oily materials (see Ch. 94). There has also been a report of a sclerosing lipogranuloma that apparently resulted from topical application of vitamin E cream[117]. In several Japanese patients, Y-shaped induration of the scrotum (in which exogenous lipids could not be detected) was described as eosinophilic sclerosing lipogranuloma[118]. Patients with sclerosing lipogranuloma frequently deny self-injection, making diagnosis difficult. Another variant of lipogranuloma is the *grease gun granuloma*, which results from accidental firing of the grease gun used by mechanics. This results in formation of a verrucous nodule, often on the dorsum of the hand[119].

Inflamed nodules with varying degrees of pain and fibrosis have been observed in other forms of panniculitis due to injection, with the distribution of lesions sometimes providing a clue to their cause. A dramatic example of this is *Texier's disease*, a panniculitis due to phytonadione (vitamin K) injections. In this disorder, sclerotic lesions with lilac-colored borders form on the buttocks and thighs, in a configuration resembling a "cowboy gunbelt and holster"[109]. Lesions due to blunt trauma often have an ecchymotic character and involve locations such as the arm or hand[116].

Pathology

Table 100.9 outlines the microscopic changes in various forms of traumatic panniculitis[105–107,119–122]. In addition, sclerosing lipogranuloma is discussed in Chapter 94.

Differential diagnosis

In cold panniculitis, the absence of needle-shaped clefts in lipocytes and location of the most intense inflammation near the dermal–subcutaneous interface help to distinguish this condition from subcutaneous fat necrosis of the newborn. In sclerosing lipogranuloma and related lipogranulomas, the large vacuoles found in the dermis and subcutis are distinctive (Fig. 100.18). Radiographs are sometimes useful in differentiating lipogranulomas from silicone granulomas, since only the latter are radio-opaque[123]. Mineral oil in non-processed tissue can be identified by infrared spectrophotometry[119].

MICROSCOPIC FEATURES OF TRAUMATIC PANNICULITIS		
Condition	**Microscopic features**	**Special considerations**
Cold panniculitis	Septal/lobular inflammation, especially at the dermal–subcutaneous border and periadnexally; lymphocytes, neutrophils, foamy macrophages, poorly developed granulomas; mucin, adipocyte necrosis, microcysts	Needle-shaped clefts are not observed
Lipogranuloma	*Sclerosing lipogranuloma* – granulomatous lobular panniculitis with marked fibrosis and numerous round or oval vacuoles of various sizes in the dermis and subcutis, producing a "Swiss cheese" appearance (Fig. 100.18); nodular aggregates of lymphocytes, plasma cells, eosinophils, macrophages or giant cells often present *Grease gun granuloma* – also pseudoepitheliomatous hyperplasia	Exogenous oils within the vacuoles can be identified in frozen sections stained with oil red O, silver bromide and osmium tetroxide
Injection-induced panniculitis	Central nidus of subcutaneous inflammation; sometimes fibrosis* or polarizing foreign material	*Povidone panniculitis* – gray–blue material within macrophages on routine staining that also stains with Congo red and chlorazol-fast pink *Cancer vaccines* – eosinophils may be numerous
Panniculitis due to aluminum in hyposensitization vaccines	Nonspecific lobular panniculitis with fibrosis; formation of numerous lymphoid follicles; may resemble lupus panniculitis, pseudolymphoma	Macrophages display greyish to violaceous, granular cytoplasm due to lysosomes that contain aluminum salts; can be identified using X-ray microanalysis or possibly aluminum staining
Panniculitis due to injectable aesthetic microimplants	Diffuse granulomatous infiltrate that may involve dermis and subcutis; focal areas of collagen degeneration	Different "fillers" can have specific histopathologic features (see Table 94.4)
Blunt trauma	Organizing hematoma, focal granuloma	Deposits of mucopolysaccharides and iron can be seen
Postirradiation or radiation recall panniculitis	Deep fibrosis, mixed inflammation	Inflammation includes lymphocytes, plasma cells, macrophages, eosinophils

*Especially with phytonadione (vitamin K) and pentazocine injections; lipid-containing vacuoles, fat necrosis, foam cells, thrombosis and endarteritis are also observed in the latter.

Table 100.9 Microscopic features of traumatic panniculitis.

Panniculitis due to injectable substances can be diagnosed when foreign material (often identified by polarization microscopy) is present. Cases with acute inflammation and necrosis may resemble infection-induced panniculitis, and, in fact, infection may accompany injection panniculitis[124]; special stains and cultures for organisms (including atypical mycobacteria) are useful in this regard. Sclerosing traumatic panniculitis (e.g. that due to phytonadione or pentazocine injections) may resemble morphea clinically, but would not present as a septal panniculitis histologically.

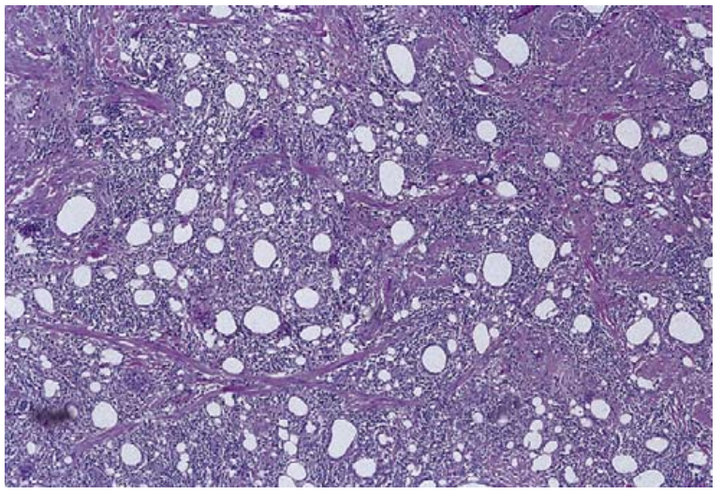

Fig. 100.18 Oil granuloma. Numerous vacuolated spaces, in this case due to grease gun injury.

Treatment

Treatment of these disorders mainly involves removal of the inciting stimulus and eradication of any associated infection. Intralesional or systemic corticosteroids can be helpful in controlling the inflammation, and they have been used in the management of sclerosing lipogranuloma[103] and granulomatous panniculitis due to bovine collagen injections[113]. Surgical excision may also be an option for sclerosing lipogranuloma[103].

LIPODERMATOSCLEROSIS

Synonyms: ■ Sclerosing panniculitis ■ Hypodermitis sclerodermiformis ■ Chronic panniculitis with lipomembranous changes

Key features

- Favors the medial aspect of the lower extremities above the malleolus
- Acute phase with erythema, warmth and tenderness, which may be misdiagnosed as infectious cellulitis
- Chronic phase with induration and red–brown to violet–brown discoloration
- Usually develops in the setting of chronic venous insufficiency
- Both septal and lobular panniculitis; lipomembranous changes are common, particularly in chronic lesions

Introduction

Erythema, induration and pigmentary changes have been known for many years to be associated with venous insufficiency. Because of the variety of clinical appearances and histopathologic findings that can occur at different stages of the disease, a number of diagnostic terms have been employed to explain the changes. Recently, the various manifestations of this panniculitis have been consolidated under the heading of *lipodermatosclerosis* or *sclerosing panniculitis*.

History

The cutaneous signs of venous insufficiency have long been recognized. In 1955, Huriez drew attention to a related indurated lesion, which he termed *hypodermitis sclerodermiformis*[125].

Epidemiology

Most patients are women over the age of 40 years, but cases appearing after the age of 75 years have also been reported[126,127].

Pathogenesis

There is considerable evidence for venous insufficiency in patients with lipodermatosclerosis[128], and fibrinolytic abnormalities are also present in these individuals. Venous hypertension leads to a compromised ability to reduce foot vein pressure during exercise. This results in increased capillary permeability, which causes leakage of fibrinogen, its polymerization to form fibrin cuffs around vessels, impedance of oxygen exchange, and tissue anoxia (see Ch. 105)[127]. Pericapillary fibrin deposits can be seen in uninvolved, clinically normal extremities of patients with healed venous ulcers of the opposite extremity, suggesting that this abnormality precedes the clinical changes of lipodermatosclerosis[129].

There may also be an abnormal regulation of angiogenesis within lesions of lipodermatosclerosis. In particular, increased expression of vascular endothelial growth factor receptor 1 (VEGFR-1), which can act as a negative regulator of VEGF-mediated angiogenesis, has been observed, along with increased expression of angiopoietin-2 (Ang-2)[130]. Additional factors contributing to the pathogenesis of lipodermatosclerosis may include protein C and S deficiencies[131], local stimulation of collagen synthesis[127], and obesity.

Clinical features

The acute phase of lipodermatosclerosis presents with pain, warmth, erythema and some induration (Fig. 100.19A), most often located on the medial lower leg above the malleolus. Other dependent sites such as the lower aspect of the abdominal pannus can also develop lipodermatosclerosis. At this point, the changes are relatively diffuse[127]. In the chronic phase, there is marked sclerosis of the dermis and subcutis, resulting in induration that is more sharply demarcated from the adjacent normal skin (Fig. 100.19B). Hyperpigmentation due to hemosiderin deposition may also be present[126]. These features give the affected leg the appearance of an inverted wine bottle[132].

Fig. 100.19 Lipodermatosclerosis. **A** Acute phase with tender erythematous plaques on both lower extremities. **B** Chronic phase with sclerotic red–brown plaque on the lower medial leg. *B, Courtesy, Kenneth E Greer, MD.*

Pathology

Early lesions show mid-lobular ischemic necrosis, a lymphocytic infiltrate in the septa that rims the fat lobules, variable degrees of capillary congestion and thrombosis, and hemorrhage with hemosiderin deposition. With progression, septal thickening, hyaline sclerosis involving lipocytes, lipophage formation, and mixed inflammatory cell infiltrates[126] appear. Advanced lesions show marked septal sclerosis and lipomembranous change in the face of markedly reduced inflammation.

Lipomembranous change has been emphasized as a key feature in lipodermatosclerosis[133]. This consists of thickened, undulating membranes that form cysts and papillary configurations (Fig. 100.20). The membranes are believed to result from degenerated cell membranes of lipocytes and/or macrophages. The material comprising the membranes is ceroid, an oxidation product of unsaturated fatty acids[134].

Pericapillary fibrin can be demonstrated in lesions of lipodermatosclerosis with phosphotungstic acid–hematoxylin stain or by immunofluorescent methods[133]. Dermal changes include fibrosis, tortuous thick-walled veins, and superficial and deep perivascular inflammation[126]. Biopsy should be avoided if the diagnosis is obvious, since poor wound healing and ulceration frequently result. When necessary, a thin elliptical excision should be obtained from the margin of a lesion.

Differential diagnosis

Difficulties in clinical diagnosis arise most often in early lesions, when the process is more diffuse and erythematous. At this stage, consideration is often given to cellulitis, erythema nodosum, or erythema induratum[126,127,132]. Persistence of a lesion, association with stasis changes, and lack of response to antimicrobials suggest the correct diagnosis, perhaps aided by studies of venous function[128].

As induration develops and progresses, differentiation from morphea and scleromyxedema may be necessary. In morphea, subcutaneous involvement is predominantly septal, and lipophagic and lipodystrophic changes are not as prominent as they are in lipodermatosclerosis[126]. Lipomembranous changes, when present, can be of great diagnostic help; however, these findings can occur in a variety of other conditions, including lupus and dermatomyositis panniculitis, liposarcoma, erythema nodosum, and diabetic dermopathy[134].

Treatment

Leg elevation and consistent compression therapy are the mainstays of treatment for lipodermatosclerosis[127]. Traditional anti-inflammatory therapies are usually ineffective in this condition[126], although intralesional corticosteroids (e.g. triamcinolone 5–10 mg/cc) may be of benefit when used in conjunction with compression therapy. Good results were reported with the anabolic steroid stanozolol[127], especially in the earlier phases of the disease, but this medication is no longer commercially available. As a result, danazol has been used (successfully) as a substitute[135]. Anabolic steroids enhance fibrinolysis, and they can reduce

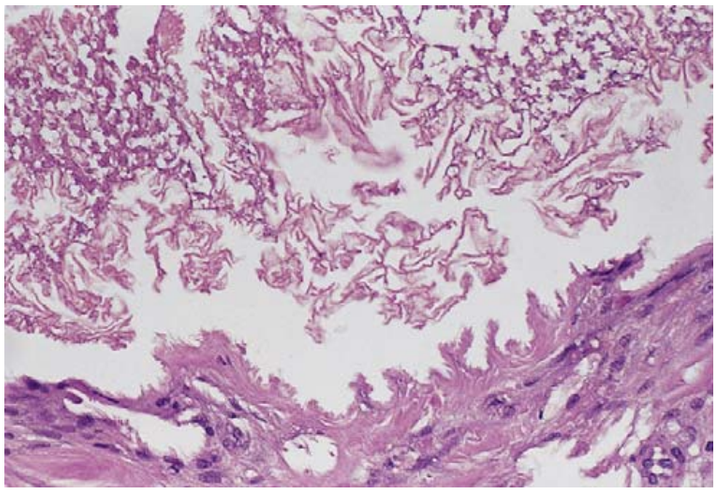

Fig. 100.20 Lipodermatosclerosis. Lipomembranous change, consisting of cystic formation with elaborate papillary configurations.

pain, extent of involvement, and induration of the skin. However, side effects of sodium retention, lipid profile abnormalities, hepatotoxicity, and virilization in women do limit their use. Oxandrolone, an anabolic steroid with less hepatotoxicity and fewer androgenic effects, represents another therapeutic option[132]. Other reported treatments include ultrasound, pentoxifylline, fasciotomy and phlebectomy[127,136].

INFECTION-INDUCED PANNICULITIS

Synonym: ■ Infective panniculitis

Key features

- A wide variety of infectious agents has been reported to produce panniculitis
- Some degree of immunosuppression is common, but not invariable
- Histopathologic findings vary, but often include mixed septal/lobular panniculitis, neutrophilic infiltration, hemorrhage and necrosis
- Special staining and culture studies can provide a definitive diagnosis

Introduction

Panniculitis can result from a distant focus of infection (a classic example being erythema nodosum) or panniculitis can be *directly* induced by an infectious agent. The latter can produce a variety of clinical and microscopic appearances, although there are some features that infection-induced lesions have in common, regardless of the etiologic agent.

History

Multiple case reports of panniculitis directly caused by infectious agents have been published[137,138], but most early studies of deep skin infections did not focus upon the changes in the subcutaneous fat. In 1989, Patterson et al.[21] studied 15 cases of infection-induced panniculitis, with an emphasis upon the histopathologic features in the subcutis. Since that time, additional reports of panniculitis due to infection have appeared.

Epidemiology

There appears to be no age, sex or racial predilection among cases of infection-induced panniculitis. Many of these patients are immunosuppressed[21] or have predisposing medical conditions such as diabetes mellitus[137].

INFECTION-INDUCED PANNICULITIS – REPORTED CAUSATIVE AGENTS
BACTERIA
Staphylococcus aureus
Group A *Streptococcus*
Pseudomonas aeruginosa
Nocardia asteroides
MYCOBACTERIA
M. tuberculosis
M. marinum
M. avium-intracellulare
M. chelonae
M. fortuitum
M. ulcerans
COXIELLA
C. burnetii
BORRELIA
B. burgdorferi
FUNGI
Blastomyces dermatitidis
Histoplasma capsulatum
Microsporum spp. (including *M. canis*)
Candida spp. (including *C. albicans*)
Cryptococcus neoformans
Fusarium spp.
Aspergillus spp. (including *A. flavus*)
Aureobasidium pullulans
HELMINTHS
Nematodes (*Gnathostoma* spp.)
Trematodes (*Fasciola hepatica*)

Table 100.10 Infection-induced panniculitis – reported causative agents.

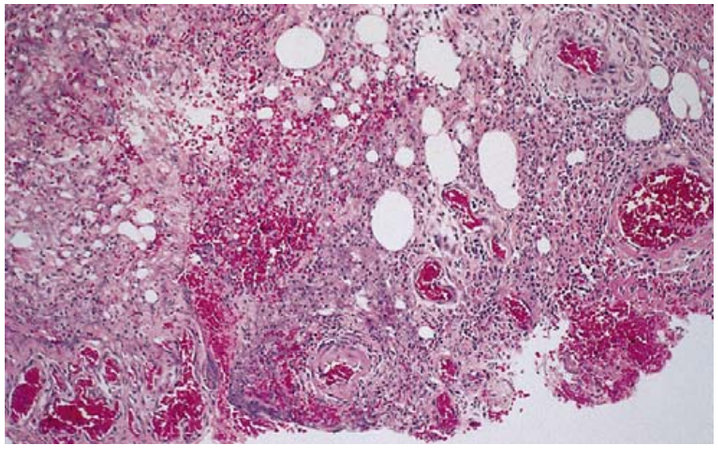

Fig. 100.21 Infection-induced panniculitis. Bacterial panniculitis, showing heavy neutrophilic infiltration, basophilic necrosis, vascular proliferation and hemorrhage.

Pathogenesis

In this group of disorders, infectious agents are considered to be directly responsible for the panniculitis. Examples of reported microorganisms to date are listed in Table 100.10[21,137–145].

Involvement of the subcutis can result from direct inoculation or septicemia. Other potential modes of spread include transfascial from an enteric source, in the case of abdominal panniculitis[144], or via "persorption", a proposed mechanism by which *Candida* migrates across intact endothelium from the gut to a subcutaneous site[145]. Immunosuppression is common, but not invariable, among individuals with infection-induced panniculitis.

Clinical features

Patients develop local swelling and erythema. There may be one or more fluctuant nodules that ulcerate and drain. Lesions on the legs and

Fig. 100.22 Cytophagic histiocytic panniculitis. Subcutaneous nodules with purpura. *Courtesy, Kenneth E Greer, MD.*

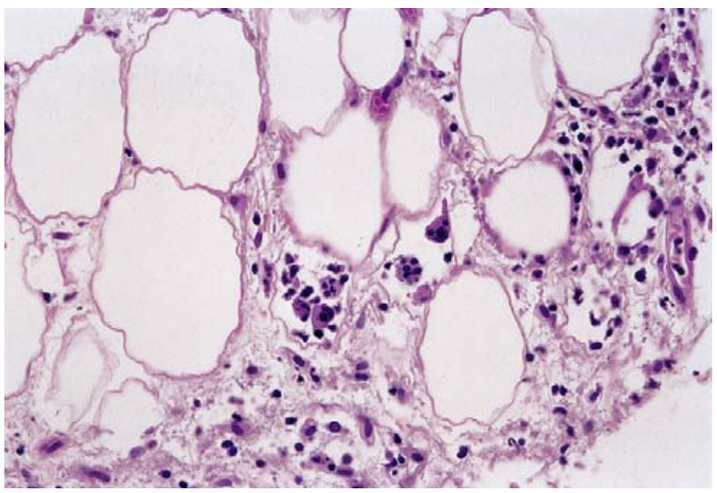

Fig. 100.23 Cytophagic histiocytic panniculitis. Macrophages engaged in cytophagic activity. Some of them have the appearance of "bean bag cells".

feet are common, but other sites of involvement include the gluteal region, abdomen, axillae, arm or hand. Underlying conditions include diabetes mellitus, leukemias or solid tumors, autoimmune connective tissue disease, AIDS and organ transplantation.

Pathology

Individual cases can mimic other primary forms of panniculitis. Common changes (regardless of the infectious agent) include a mixed septal/lobular panniculitis, neutrophilic infiltration, vascular proliferation, hemorrhage, and necrosis that involves lipocytes, inflammatory cells and eccrine sweat coils[21] (Fig. 100.21). In Q fever due to *Coxiella burnetii*, there may be a "doughnut-like" granulomatous lobular panniculitis, in which fibrin and inflammatory cells form a ring around a central clear space; similar changes have been found in the liver and bone marrow of patients with Q fever[140].

Differential diagnosis

Fluctuant, ulcerating nodules also occur in pancreatic panniculitis, traumatic panniculitis, and α_1-antitrypsin deficiency panniculitis. Clinical and laboratory data can usually permit distinction. Of note, traumatic panniculitis may be accompanied by infection. Examples of infection-induced panniculitis with predominantly septal involvement or with large vessel vasculitis could be confused with acute erythema nodosum or erythema induratum, respectively. Special stains for organisms and cultures are keys to the diagnosis. In one study, special stains were positive for organisms in 14 of 15 cases[21].

Treatment

Treatment consists of appropriate antimicrobial therapy. Surgery may be indicated for isolated lesions caused by grain-forming fungi or bacteria, such as mycetoma or botryomycosis[139]. A more radical surgical approach has been used successfully in treating abdominal panniculitis due to enteric bacteria[144].

CYTOPHAGIC HISTIOCYTIC PANNICULITIS

The term "cytophagic histiocytic panniculitis" has been used to describe subcutaneous nodules or plaques that on histiologic examination show infiltrates of macrophages containing erythrocytes, lymphocytes and/or karyorrhectic debris, i.e. exhibiting hematophagocytosis (Figs 100.22 & 100.23)[146]. These macrophages with cytophagic activity have been referred to as "bean bag" cells. With the advent of immunophenotyping and genetic techniques, it has become apparent that the vast majority of patients have lymphoma, with atypical lymphoid cells also present within the panniculus[147]. In general, the lymphomas represent subcutaneous involvement of primary cutaneous γ/δ T-cell lymphoma or EBV-associated extranodal NK/T-cell lymphoma, nasal type (see Ch. 120)[148]. Occasionally, patients have subcutaneous panniculitis-like T-cell lymphoma, and, rarely, no lymphoma[149]. Individuals in the latter group may still have a fatal course due to a hemophagocytic syndrome that involves the liver, spleen and bone marrow (leading to pancytopenia). Recently, a heterozygous nonsense mutation in the gene that encodes perforin, leading to a decrease in the expression of perforin by cytotoxic T cells, was reported in a child with these histologic findings (but no evidence of lymphoma)[150].

MALIGNANT SUBCUTANEOUS INFILTRATES

Malignant infiltrates may involve the subcutis, mimicking the clinical and microscopic appearance of panniculitis. The best known of these is subcutaneous panniculitis-like T-cell lymphoma (see Ch. 120). While cytophagia can be seen in the latter disorder, it is particularly characteristic of subcutaneous involvement of primary cutaneous γ/δ T-cell lymphoma and EBV-associated extranodal NK/T-cell lymphoma, nasal type. Other lymphomas (e.g. B-cell), leukemias, and metastatic solid tumors may infiltrate the subcutis. For example, a case of melanophagic panniculitis that obscured foci of metastatic melanoma has been reported[151]. Obviously, clinical information is crucial in such cases.

Histopathologic clues include the recognition of significant pleomorphism or monotony among infiltrating cells in the subcutis, infiltration between collagen bundles of the dermis or around adnexal structures, and supporting immunohistochemical studies. Of note, the diagnosis of subcutaneous panniculitis-like T-cell lymphoma can sometimes be elusive as the initial impression may be lupus panniculitis or even a nonspecific panniculitis with lipomembranous changes[152].

UNUSUAL OR NEWLY DESCRIBED FORMS OF PANNICULITIS

Table 100.11 lists several newly described or unusual forms of panniculitis[141,153–162]. When a patient presents with panniculitis that is not readily classifiable, it may be worthwhile to consider these alternative diagnoses. Several of them probably do not actually represent distinct entities, but rather represent overarching terms that include established forms of panniculitis. For example, plasma cell panniculitis could include not only morphea and postirradiation pseudoscleroderma tous

UNUSUAL OR NEWLY DESCRIBED FORMS OF PANNICULITIS			
Type of panniculitis	**Clinical features**	**Microscopic findings**	**Comments**
Crystal deposition panniculitis	Red nodules, sometimes with necrosis; may have drainage; legs and elsewhere	Necrotizing and/or granulomatous panniculitis; calcium oxalate crystals in subcutaneous vessels; subcutaneous deposits of sodium urate crystals	Oxalosis: primary (inherited) or secondary (chronic renal failure) Urate deposition: may be an isolated cutaneous finding in gout
Idiopathic palmoplantar hidradenitis	Sudden onset of painful erythematous nodules; soles > palms Self-limited	Neutrophilic eccrine hidradenitis	Precipitated by trauma (mechanical, thermal) Mimicked by erythema nodosum, cold panniculitis, pseudomonas hot-foot syndrome
Sweet's panniculitis (subcutaneous Sweet's syndrome)	Erythematous nodules that may be painful; extremities; associated with leukemias (e.g. AML, hairy cell leukemia), treatment of acute promyelocytic leukemia with all-*trans*-retinoic acid, and, rarely, solid tumors	Predominantly neutrophilic lobular panniculitis, without vasculitis; immature myeloid forms have been described	Must exclude other neutrophil-rich forms of panniculitis, such as α_1-antitrypsin deficiency and pancreatic panniculitis
Panniculitic bacterid	Sudden onset of tender subcutaneous nodules; lower extremities; polyclonal hypergammaglobulinemia, cold agglutinins, cryofibrinogens	Lobular panniculitis, predominantly neutrophils with microabscesses; angiopathy; extravascular granulomas	Triggered by non-tuberculous infections; underlying disorders include atopy, antiphospholipid antibody syndrome
Plasma cell panniculitis	Hyperpigmentation and induration; trunk and extremities	Sclerosis of subcutaneous septa; plasma cells prominent component of infiltrate	Not a single entity; manifestation of morphea profunda, other autoimmune connective tissue disorders, and post-irradiation pseudosclerodermatous panniculitis
Panniculitis of Lyme disease	Tender nodules or diffuse fasciitis; fever, chills, photophobia, polyarthritis	Acute septal panniculitis; may contain eosinophils, plasma cells; lymphocytic vasculopathy	Detection of *Borrelia* spp. in tissues; positive serologies confirm the diagnosis
Fasciitis–panniculitis syndrome	Subcutaneous induration, sometimes with regional pain	Chronic inflammation, accompanied by replacement of fat lobules by fibrous tissue; thickening of fascia	Term used primarily in the rheumatologic literature; encompasses several autoimmune connective tissue diseases; also described as a paraneoplastic syndrome with hematologic, pancreatic and gastrointestinal malignancies
Atypical lymphocytic lobular panniculitis	Recurrent, infiltrative plaques; lower extremities, abdomen	Interstitial subcutaneous infiltrate with well-differentiated lymphocytes; no significant fat necrosis	Molecular studies show clonal or oligoclonal profile; no progression to lymphoma; considered T-cell dyscrasia
Infantile-onset panniculitis with uveitis and systemic granulomatosis	High fever, anemia, hepatosplenomegaly, uveitis, arthritis	Histiocytic lobular panniculitis, with lymphocytes and neutrophils initially; granulomas in later stage	Resemblance to Blau syndrome, but lack *NOD2/CARD15* mutations; may respond to TNF inhibitors

Table 100.11 Unusual or newly described forms of panniculitis. AML, acute myelogenous leukemia; TNF, tumor necrosis factor.

panniculitis but also other autoimmune connective tissue diseases or infectious diseases. The fasciitis–panniculitis syndrome is a term that has appeared from time to time, primarily in the non-dermatology literature. While sometimes discussed as if it were a single entity, fasciitis–panniculitis syndrome has been used to include eosinophilic fasciitis, morphea profunda, lupus panniculitis, lipodermatosclerosis, and a variety of other conditions. Sweet's syndrome and Lyme disease are established entities that can occasionally have panniculitis as a significant finding. Two other recently described conditions, atypical lymphocytic lobular panniculitis and panniculitic bacterid, may require further study and experience before being widely accepted as distinct entities. No doubt this list will change as disease mechanisms are better understood and disorders are reclassified or absorbed into other classification schemes.

101 Lipodystrophies

Suat Hoon Tan, Priya Sen and Mark Tang

Synonyms: ■ Lipodystrophy: lipoatrophy, lipohypertrophy

Key features

- Lipodystrophies are inherited or acquired disorders characterized by a paucity or complete absence of fat that may be generalized, partial or localized; lipohypertrophy may accompany the lipoatrophy
- Though the terms lipodystrophy and lipoatrophy are often used interchangeably, lipoatrophy should be used specifically for selective loss of fat, with lipodystrophy implying a redistribution of fat, in part due to a hypertrophic compensation of the non-atrophic fat
- Lipodystrophy syndromes represent a heterogeneous group of disorders that are characterized by lipoatrophy and fat accumulation in characteristic body distribution patterns
- Fat is a metabolically active organ, thus fat loss is associated with metabolic derangements, which parallel the extent and duration of lipoatrophy
- Patients with lipodystrophy typically develop the metabolic syndrome, which includes insulin resistance, diabetes mellitus, hyperinsulinemia, hypertriglyceridemia, cardiovascular disease and hepatic steatosis. This association has provided insights into the pathogenesis of coronary artery disease and diabetes mellitus
- Systemic manifestations of generalized and partial lipodystrophy syndromes include medical complications of the metabolic syndrome, hormonal abnormalities, organ dysfunction, anabolic syndrome, glomerulonephritis and autoimmune disorders
- A distinct syndrome of peripheral lipoatrophy, central obesity, breast hypertrophy, dorsocervical fat pad enlargement, hyperlipidemia and insulin resistance occurs in patients with HIV infection undergoing treatment with antiretroviral therapy (ART)
- Isolated or localized lipoatrophy can occur at the site of medication injection, trauma or pressure, in association with autoimmune connective tissue disease, or following certain panniculitic inflammatory or neoplastic processes
- Microscopically, there may be a complete absence of subcutaneous fat or a decrease in adipocyte size and number. An inflammatory panniculitis may be seen in early disease

Introduction

Lipodystrophy is the term that describes a heterogeneous group of diseases characterized by a selective fat loss and secondary fat accumulation in a characteristic body distribution pattern in all but the more localized variants. Adipose tissue has crucial metabolic and endocrine functions, in addition to having a role in mechanical protection. The loss of peripheral subcutaneous fat and a compensatory accumulation of visceral fat is closely associated with insulin resistance, diabetes mellitus, dyslipidemia, hypertension and coronary artery disease. These metabolic abnormalities and their sequelae are now referred to as the metabolic syndrome and they underscore the important metabolic and endocrine functions of fat, in its role as a diverse and crucial body organ.

More than a century after the first description of lipodystrophy[1] and then delineation of generalized lipodystrophy into congenital and acquired forms[2], the genetic basis of several of the inherited lipodystrophies has now been elucidated. Mutations have been found in genes ranging from those encoding proteins essential for adipocyte differentiation to those encoding nuclear lamins (see below).

Clinically, lipodystrophy can be broadly classified into inherited or acquired forms and then further subclassified based on the extent of fat loss, in conjunction with genetic mutations, age of onset and systemic manifestations (Fig. 101.1 & Table 101.1). Based upon the distribution pattern, lipodystrophy may be subdivided into three major groups: (1) generalized; (2) partial (extensive, but not generalized); and (3) localized (limited to an isolated area).

Localized lipodystrophy is a commonly encountered form of lipoatrophy, which may be due to injections of medications or vaccines, pressure, previous surgery, trauma or panniculitis (see Ch. 100). Nowadays, lipodystrophy associated with antiretroviral therapy (ART; formerly referred to as highly active antiretroviral therapy [HAART]) for HIV infections has emerged as the most common non-localized form of acquired lipodystrophy[3]. It is important for dermatologists to recognize this drug effect and the associated metabolic syndrome, as there are profound social, psychological and medical implications. The dermatologist is also likely to occasionally encounter partial lipodystrophy that may be associated with glomerulonephritis or with autoimmune diseases such as dermatomyositis or lupus erythematosus. Finally, there are several rare genetic syndromes that will be discussed (see Table 101.1).

Pathogenesis

Adipose tissue functions as an endocrine organ via its secretion of hormones and adipocytokines, such as leptin, TNF-α, interleukin (IL)-6 and adiponectin. Altered expression and activity of these factors play a role in the development of insulin resistance and other metabolic changes seen in lipodystrophic syndromes, which are similar to those observed with obesity and the metabolic syndrome[4,5].

There appears to be a final common pathway of defective adipocyte triglyceride storage in conditions characterized by fat loss as well as fat excess. This defect can result from impaired triglyceride synthesis due to an enzyme deficiency (e.g. AGPAT2); defective adipocyte development caused by mutations in genes critical to adipocyte differentiation (e.g. *seipin, PPARG, AKT2, LMNA*); adipocyte apoptosis; or autoimmune- or drug-mediated adipocyte destruction. All of these processes can impair normal adipocyte differentiation, development, lifespan and/or function[6].

The destruction or impaired differentiation of adipocytes leads to a cascade of hormonal and metabolic consequences. Adiponectin, a product of the *apM1* gene, is expressed in and secreted exclusively by differentiated adipocytes. It plays a positive role in regulating insulin sensitivity and glucose and lipid homeostasis. Plasma adiponectin levels are inversely correlated with fasting insulin levels and insulin resistance[7]. Serum adiponectin and leptin levels are *reduced* both in murine models of lipoatrophy with insulin resistance and in humans with congenital and acquired lipodystrophies[8] as well as HIV/ART-related lipodystrophy[9,10]. As an example, the hyperphagia, reduced leptin levels, and deficiency in leptin signaling associated with generalized lipodystrophy results in an increased carbohydrate load, triglyceride accumulation in the muscle and liver, and, ultimately, insulin resistance, diabetes and hepatic steatosis. Of note, infusion of leptin reverses insulin resistance in mouse models with deficient messenger RNAs encoding leptin[11].

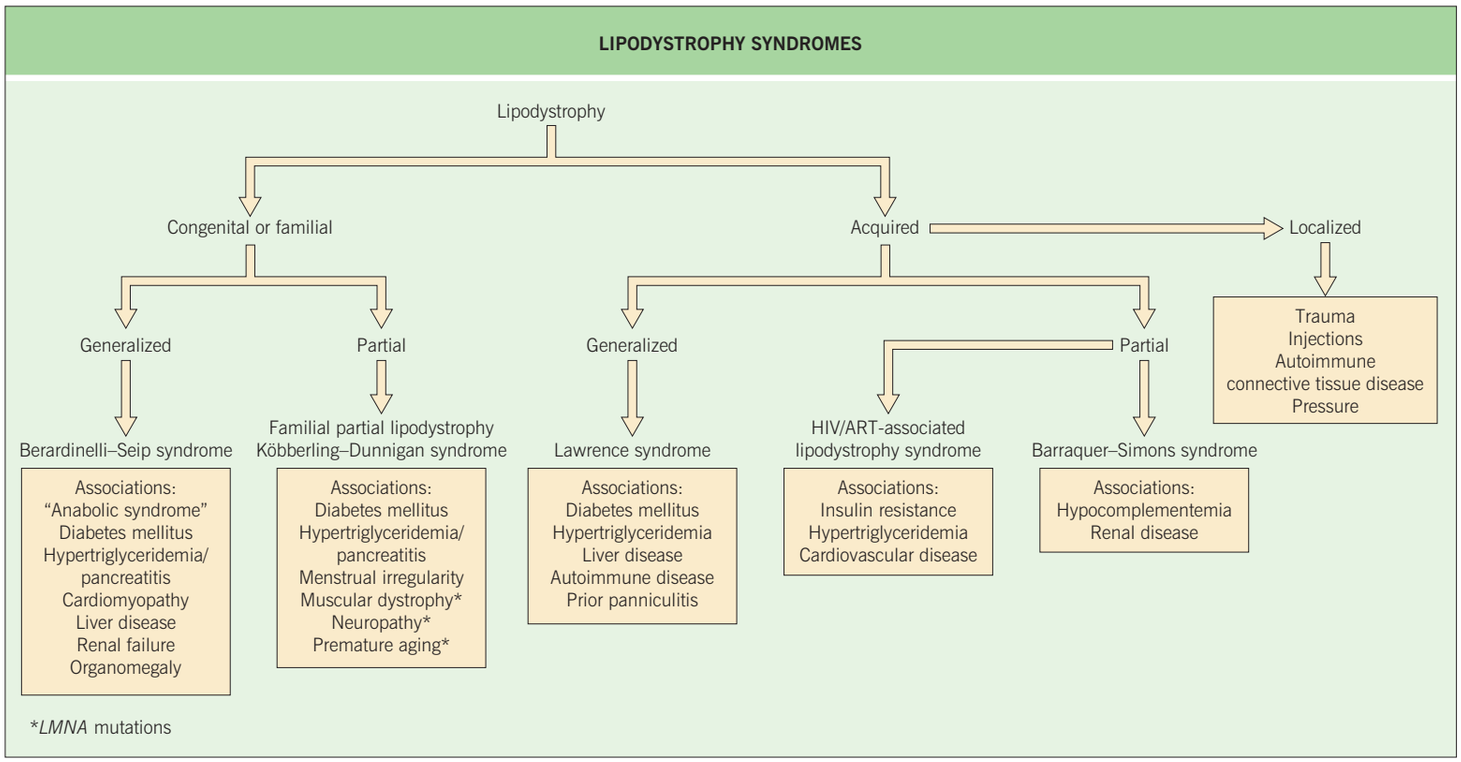

Fig. 101.1 Lipodystrophy syndromes.

adipose tissue exhibits features of generalized lipodystrophy (see below)[12].

Congenital generalized lipodystrophy (Berardinelli–Seip syndrome)

Congenital generalized lipodystrophy (CGL) is an autosomal recessive disorder, and two major genetic subtypes have been described – Berardinelli–Seip congenital lipodystrophy (BSCL) type 1, due to mutations in the gene that encodes 1-acylglycerol-3-phosphate *O*-acyltransferase 2 (*AGPAT2*), and BSCL type 2, due to mutations in *BSCL2/seipin* (see Table 101.1). It has been postulated that these genes cause lipodystrophy primarily by affecting adipocyte differentiation or lipid droplet formation in adipose tissue. In type 1, aberrant AGPAT2 enzyme activity causes a marked reduction in triglyceride and phospholipid synthesis, resulting in abnormal adipocyte function[13]. In type 2, *BSCL2* mutations affect the endoplasmic reticulum membrane protein seipin which is critical for lipid droplet morphology.

In some patients who do not have mutations in either gene, molecular screening has recently identified mutations in the gene that encodes caveolin 1 (*CAV1*). CAV1 is a key structural component of plasma membrane caveolae, which play an important role in human adipocyte function[14].

Differences in the molecular basis of CGL may account for the phenotypic heterogeneity[15]. *AGPAT2* has been found to be highly expressed in human omental adipose tissue, which may explain the preferential loss of metabolically active intra-abdominal adipose tissue but preservation of mechanical palmoplantar adipose tissue in patients with type 1 BSCL. *BSCL2* has been found to also be highly expressed in the brain[16], which may account for the higher prevalence of mental retardation in type 2 BSCL patients.

Familial partial lipodystrophy (including Dunnigan variety, Köbberling variety)

Familial partial lipodystrophy (FPLD) is a heterogeneous group of autosomal dominantly inherited disorders. The most prevalent subtype is the Dunnigan variety, which is due to mutations in *LMNA*[17,18]. *LMNA* encodes lamins A and C, and missense mutations in *LMNA* occur in patients with FPLD. Lamins belong to the intermediate filament family of structural proteins that compose the nuclear lamina. *LMNA* mutations lead to disruption of nuclear function, resulting in apoptosis and premature cell death of adipocytes. These mutations also alter plasma levels of leptin, with heterozygotes (mutation in one copy of *LMNA*) having decreased plasma leptin and increased fasting plasma insulin and C-peptide levels[19]. Of note, *LMNA* mutations are also responsible for a group of laminopathies that includes muscular dystrophy, cardiomyopathy, neuropathies, and syndromes of premature aging (see Table 63.9). The clinical phenotype/syndrome is determined by the site and type of *LMNA* mutations[20].

Another subtype of FPLD results from heterozygous missense mutations of the gene that encodes peroxisome proliferator-activated receptor-γ (*PPARG*)[21]. The PPAR-γ protein plays an essential role in adipogenesis (see Fig. 101.14), but the entire pathogenesis remains unclear. Although this subtype has a milder phenotype than the Dunnigan variety, with a later age of onset and involvement confined to the distal extremities, metabolic disturbances are more severe, suggesting that *PPARG* mutations may have additional direct effects.

Recently, FPLD due to heterozygous missense mutations in the gene that encodes v-AKT murine thymoma oncogene homolog 2 (*AKT2*) was described. AKT2, also known as protein kinase B, is involved in post-receptor insulin signaling and its dysfunction may lead to lipodystrophy secondary to abnormal adipocyte differentiation[22]. In addition, in three families with lipodystrophy (primarily of the lower extremities) as well as hypertension, insulin resistance, hypertriglyceridemia and acanthosis nigricans, heterozygous loss-of-function mutations were described in the gene that encodes perilipin (*PLIN1*)[22a]. Perilipin is responsible for the formation, maturation and function of lipid droplets within adipocytes.

Partial lipodystrophy may also be seen in association with mandibuloacral dysplasia (MAD), an autosomal recessive syndrome associated with mutations in the *LMNA* gene (type A), or with mutations in the gene *ZMPSTE24* which encodes a zinc metalloproteinase involved in post-translational proteolytic processing of prelamin A (type B)[23,24]. The latter has been associated with severe mandibuloacral dysplasia, premature aging and generalized lipodystrophy.

Mesangiocapillary glomerulonephritis type 2 (MCGN II) has been reported in a case of partial lipodystrophy due to a mutation in the *LMNA* gene, suggesting that partial lipodystrophy of both the sporadic and familial subtypes may predispose to this condition and the observed renal and complement abnormalities may be secondary to other factors associated with lipodystrophy[25].

LIPODYSTROPHY SYNDROMES							
Syndrome	**Age of onset**	**Sex**	**Genetics (chromosome)**	**Distribution of fat changes**	**Metabolic derangements**	**Systemic associations**	**Systemic complications**
INHERITED							
Congenital generalized lipodystrophy (Berardinelli–Seip syndrome)	Birth	F=M	AR Type 1: *AGPAT2* (9q34) Type 2: *BSCL2/seipin* (11q13) Type 3: *CAV1* (7q31)	↓ Fat: face, trunk, extremities, viscera Types 1 & 3: loss of metabolically active adipose tissue in the skin and viscera, but preservation of mechanical adipose tissue (palmoplantar, retro-orbital) Type 2: both metabolically active and mechanical adipose tissue are lost	+++: IR, DM, ↑ TG; anabolic syndrome; ↑ metabolic rate	Type 3: associated with vitamin D resistance	Hypertrophic cardiomyopathy, liver failure/cirrhosis, organomegaly, acute pancreatitis, proteinuric nephropathy (see Table 101.3) More severe disease in type 2, with higher incidence of mental retardation and cardiomyopathy
Familial partial lipodystrophy (Köbberling–Dunnigan syndrome)	Puberty	F>M	AD Dunnigan type: *LMNA* (lamin A/C; 1q21.2) *PPARG* (3p25) *AKT2* *PLIN1*	Dunnigan type: ↓ fat on extremities ± trunk, ↑ fat on face/neck (double chin), muscular hypertrophy *PPARG*-associated: ↓ fat on extremities/buttocks (less severe than Dunnigan type); trunk/viscera spared	IR, DM, ↑ TG, ↓ HDL (more severe in *PPARG*-associated type than Dunnigan type)	None preceding	Acute pancreatitis, hepatic steatosis/cirrhosis, menstrual abnormalities Clinical findings and metabolic complications more severe in women
Familial partial lipodystrophy with mandibuloacral dysplasia (MAD)	Childhood or puberty	M>F	AR Type A: *LMNA* Type B: *ZMPSTE24*	↓ fat on extremities Type B – may have generalized lipodystrophy	IR, DM, ↑ TG, ↓ HDL in some patients	None preceding	Premature aging, hypoplasia of mandible, clavicles and terminal digits, short stature, scleroderma-like skin lesions with mottled skin pigmentation
ACQUIRED							
Acquired generalized lipodystrophy (Lawrence syndrome)	Childhood or adolescence	F>M 3:1	None known	↓ Fat: face, trunk, extremities Preservation of fat within the bone marrow	++: IR, DM, ↑ TG (correlates with the degree of lipodystrophy)	1/3 have a preceding autoimmune disease (e.g. juvenile dermatomyositis, Sjögren's syndrome) or infection; 25% have a preceding panniculitis	Liver failure/cirrhosis, proteinuric nephropathy
Acquired partial lipodystrophy (Barraquer–Simons syndrome)	Childhood or adolescence Rarely adults	F>M 3:1	Sporadic or AD: *LMNB2* (Lamin B2; 19p13.3)	↓ Fat: face, upper extremities, trunk, with spread in a cephalocaudal direction Spares lower extremities ↑ Fat: hips and legs Hemilipodystrophic variants	Rare IR, DM, ↑ TG	Often preceded by a febrile illness; 1/5 have mesangiocapillary glomerulonephritis Almost all have low levels of C3 and presence of circulating C3 nephritic factor Autoimmune disease associations include SLE, dermatomyositis	Sequelae of renal abnormalities
HIV/ART-associated lipodystrophy syndrome	2 months–2 years after initiation of combination antiretroviral therapy Adults>children	M=F overall, F>M central adiposity	None known	↓ Fat: face, extremities ↑ Fat: central (trunk/viscera), dorsocervical ("buffalo hump"), breasts Lipomas (e.g. pubic)	++: IR, ↑ TG, ↑ LDL, ↓ HDL; ± DM	HIV infection	Cardiovascular disease

Table 101.1 Lipodystrophy syndromes. *AGPAT2*, 1-acylglycerol-3-phosphate O-acyltransferase-2 gene; AR, autosomal recessive; AD, autosomal dominant; *AKT2*, v-AKT murine thymoma oncogene homolog 2; *BSCL2*, Bernardinelli–Seip congenital lipodystrophy 2 (Seipin) gene; *CAV1*, caveolin 1 gene; DM, diabetes mellitus; ART, antiretroviral therapy; HDL, high-density lipoproteins; HIV, human immunodeficiency virus; LDL, low-density lipoproteins; IR, insulin resistance; PI, protease inhibitor; *PPARG*, peroxisome proliferator-activated receptor-γ; SLE, systemic lupus erythematosus; TG, triglycerides; *ZMPSTE24,* gene that encodes a zinc metallo-protease.

Acquired generalized lipodystrophy (Lawrence syndrome)

There is no known genetic defect. A third of patients have an antecedent autoimmune disease or viral or bacterial infection, but a causal relationship with the latter has not been established. Twenty-five percent of cases of acquired generalized lipodystrophy are heralded by panniculitis (see Table 101.1)[26].

The preceding panniculitis and the frequent association of autoimmune disease imply immunologically mediated fat cell lysis. Autoantibodies against the adipocyte membrane have been reported in one patient with this condition[27]. As with the other forms of lipodystrophy, most patients have low serum levels of leptin and adiponectin.

Acquired partial lipodystrophy syndrome (Barraquer–Simons syndrome)

This occurs sporadically or may be autosomal dominant. Subcutaneous fat is often lost acutely after a viral illness. The exact pathogenesis is not known, but it may be related to adipsin, a protein produced by adipocytes which is identical to factor D (a component of the alternative complement pathway; see Ch. 60), as well as C3 nephritic factor (C3NeF), an IgG autoantibody against an alternative pathway enzyme. There is dysregulated activation of the alternative pathway, associated with C3NeF binding to the rate-limiting C3 convertase enzyme (C3bBb). This results in unopposed activation of the alternative complement pathway, excessive consumption of C3, and complement-dependent lysis of adipocytes. Regional differences in factor D expression parallel the regional distribution of adipocyte loss in partial lipodystrophy, which may explain the cephalocaudal distribution of fat. Renal cells also express complement components, and a similar mechanism of complement-mediated injury may be responsible for the MCGN II seen in these patients[28].

Recently, mutations in *LMNB2* were described in four patients with acquired partial lipodystrophy[29].

Localized lipoatrophy

The pathogenesis of localized lipoatrophy is heterogeneous. Lipoatrophic plaques may be the result of direct sequelae of pyogenic abscesses, various lobular panniculitides, localized autoimmune connective tissue diseases such as lupus profundus and morphea, or panniculitic lymphoma. Atrophic connective tissue disease panniculitis is associated with systemic evidence of various autoimmune disorders such as systemic lupus erythematosus or dermatomyositis, implying an immunologic mechanism.

Iatrogenic causes include complications of injected medications (Table 101.2). The causes may be multifactorial, such as inflammatory responses to the injected medicines and/or trauma. In the case of insulin lipoatrophy, it may be induced by impurities and is significantly associated with the presence of anti-insulin antibodies[30]; perivascular mononuclear infiltrates and vascular immunoreactants near insulin injections suggest a localized immune response. Because repeated use of the same injection site increases the risk of lipoatrophy, the latter can be largely prevented by regular rotation of injection sites. Of note, lipoatrophy is rare with the use of human insulin and insulin pump therapy. Growth hormone injections may lead to lipoatrophy via a direct lipolytic effect. Panniculitis at the injection site may precede localized lipoatrophy due to glatiramer, and subcutaneous injections of methotrexate may cause semicircular lipoatrophy.

Lipoatrophia semicircularis may represent repetitive trauma or pressure-induced changes (Fig. 101.2), due to constant or intermittent pressure such as leaning against a desk or chair edge, basin, bathtub or counter, or from tight-fitting jeans or girdles. Support for microtrauma is demonstrated by resolution of the lesions when trauma is avoided, and the occurrence of similar lesions in multiple employees in the same workplace[31]. Others have implicated local hyperproduction of TNF-α by macrophages[32]. Localized lipoatrophy of the upper and lateral calf due to pressure is commonly observed in women who cross their legs when seated (Fig. 101.3).

Up to 60% of involutional lipoatrophy (see below) may be associated with prior local injections, suggesting a trauma-related phenomenon[33]. Lipophagocytizing macrophages seen by electron microscopy suggest an initial stimulation by injectable material; typically, an active foreign body reaction is absent.

Lipodystrophia centrifugalis abdominalis infantalis is usually idiopathic, but has been reported to be associated with mechanical trauma or focal infection. Predominance of this condition in East Asia is notable and reports in twins and siblings point to the possibility of an HLA predisposition. In one patient with lipodystrophia centrifugalis abdominalis infantilis, positive immunohistochemical staining for Fas, bcl-2 and p53 and terminal transferase-mediated dUTP nick end-labeling (TUNEL) in degenerating fatty tissue suggested apoptosis as a possible factor[34].

INJECTED MEDICATIONS THAT CAN CAUSE LOCALIZED LIPOATROPHY
MOST COMMON
Insulin • Non-human form primarily
Corticosteroids
LESS COMMON
Antibiotics • Benzathine penicillin
Growth hormone
Heparin
Iron
Immunomodulatory drugs • Glatiramer acetate (multiple sclerosis) • Methotrexate*
Vaccines • Diphtheria–pertussis–tetanus vaccine
Exogenous material
*Semicircular lipoatrophy.

Table 101.2 Injected medications that can cause localized lipoatrophy.

Clinical Features

Congenital generalized lipodystrophy (CGL)

CGL (BSCL types 1 and 2) is rare, with an estimated prevalence of less than 1 case in 10 million[35]. As an autosomal recessive disorder, there is often consanguinity. All subtypes are characterized by generalized loss or absence of metabolically active subcutaneous fat from birth, resulting in a cadaveric facies and distinctive muscular-appearing body habitus (Fig. 101.4). Features of anabolic syndrome are evident in early childhood (Table 101.3). There is also a deficiency of bone marrow and visceral fat. Type 2 BSCL also lacks mechanical fat, in addition to metabolically active fat. The inability to store sufficient fat in the adipocytes results in the metabolic syndrome (see Ch. 53), which becomes more profound during puberty[35]. Hepatosplenomegaly is typical, and may be associated with umbilical herniation. Diabetes mellitus is evident by adolescence, but the hyperinsulinemia can be detected as early as infancy. Enlarged genitalia are seen especially in women, and may be associated with polycystic ovarian syndrome and infertility. Dermatologic sequelae (see Table 101.3) include acanthosis nigricans, which is noted by adolescence and may be extensive. Serious medical complications and metabolic derangements include cirrhosis from fatty liver, premature atherosclerosis, sequelae of diabetes, pancreatitis from hypertriglyceridemia, and a high mortality rate from hypertrophic cardiomyopathy. The mean age of death is 32 years. Type 2 appears to be a more severe disorder that is associated with mental retardation, hypertrophic cardiomyopathy and a higher incidence of premature death.

Familial partial lipodystrophy

Familial partial lipodystrophy (FPLD) was first described by Dunnigan and Köbberling[36], who outlined the clinical characteristics of large Scottish and German pedigrees with familial syndromes of partial lipodystrophy. Nowadays, FPLD is classified based upon genetic mutations and clinical phenotype (see Table 101.1). This group of disorders differs from other forms of *inherited* lipodystrophy by a later onset (after puberty) and fat loss predominantly affecting the extremities, with sparing of the face[35,37]. FPLD is a rare disorder, with a prevalence of less than 1 in 15 million[35].

In *LMNA*-associated FPLD, a normal childhood is followed by a progressive, symmetric loss of subcutaneous fat; the latter uniformly involves the extremities and variably extends to the trunk (anterior > posterior). Compensatory accumulation of excess fat occurs and results in a fat head and neck, with a round face, as well as increased supraclavicular fat. Acromegalic facies with a double chin is characteristic. As a result of the loss of fat in the limbs, there is an accentuation of subcutaneous veins and an appearance of muscular hypertrophy

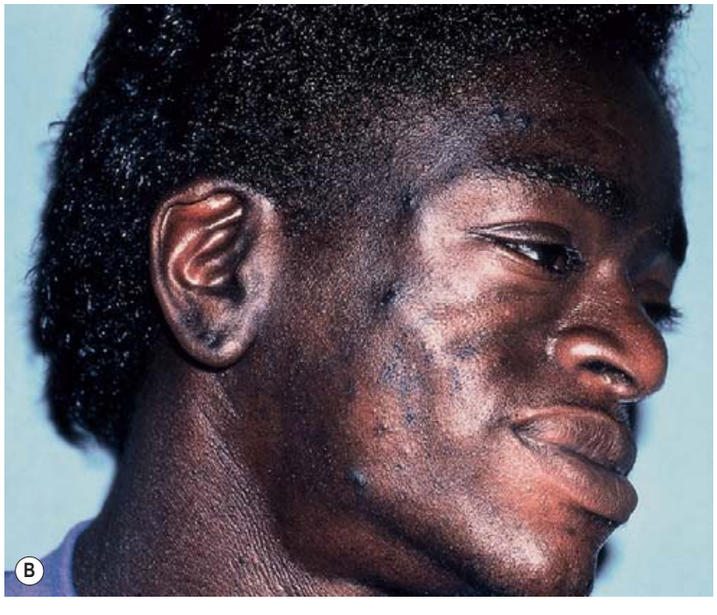

Fig. 101.4 Congenital generalized lipodystrophy syndrome. A Extensive acanthosis nigricans, facial and extremity lipodystrophy, and muscular habitus. **B** Close-up view demonstrating loss of Bichat's fat pad and buccal fat. *Courtesy, Kenneth E Greer, MD.*

FEATURES OF CONGENITAL GENERALIZED LIPODYSTROPHY
LIPODYSTROPHIC FEATURES
• Lack of Bichat's fat pad in the preauricular region, resulting in a cadaveric facies • MRI studies show near total absence of subcutaneous fat and other metabolically active adipose tissues • Preservation of fat deposits in "mechanical" sites (type 1): orbit, palms, soles, tongue, breasts, vulva and in periarticular and epidural regions • Muscular body habitus due to the extreme paucity of subcutaneous fat
ANABOLIC SYNDROME
• Muscular hypertrophy with prominent superficial veins • Acromegalic facial and acral features • Voracious appetite • Increased basal metabolic rate • Heat intolerance • Accelerated growth with a normal to slightly increased adult height • Advanced bone and dental age • Osteosclerotic and lytic skeletal changes • Masculine features in females (clitoromegaly rare) • Enlarged genitalia (usually limited to infancy and childhood)
METABOLIC DISTURBANCES
• Insulin resistance and severe fasting or postprandial hyperinsulinemia from early infancy • Insulin levels may decrease after several years, due to exhaustion of pancreatic β cells • Very insulin-resistant diabetes mellitus: noted at puberty with growth cessation • Impaired glucose tolerance is noted around age 8–10 years • Hypertriglyceridemia and sequelae (chylomicronemia, pancreatitis) • Hyperlipidemia accelerates at puberty (with growth cessation) • Low HDL-cholesterol levels (accurate assessment may be hindered by the increased TGs) • Low plasma leptin levels, corresponding to decreased body fat
DERMATOLOGIC MANIFESTATIONS
• Acanthosis nigricans (AN), often early onset and widespread • Hypertrichosis, including increased (often curly) scalp hair at birth • Hyperhidrosis • Coarse skin on the upper body • Hyperkeratotic epidermal papillomatosis (may represent an exaggerated form of AN) • Xanthomas
GYNECOLOGIC DISTURBANCES
• Oligomenorrhea • Polycystic ovaries • Infertility (females)
ORGANOMEGALY AND ORGAN DYSFUNCTION
• Hypertrophic cardiomyopathy (often fatal) • Fatty liver, hepatomegaly, cirrhosis, liver failure • Organomegaly: tonsils and adenoids, lymph nodes, spleen, kidneys, adrenals, pancreas, ovaries • Central nervous system abnormalities: hypothalamic–pituitary dysfunction, ventricular dilation, below average intelligence, +/– mild mental retardation • Proteinuric nephropathy

Table 101.3 Features of congenital generalized lipodystrophy[2,35]. HDL, high-density lipoprotein; TG, triglyceride.

Fig. 101.5 Lipoatrophy of the lower extremities, leading to the appearance of muscular hypertrophy. *Courtesy, William D James, MD.*

(Fig. 101.5). Although FPLD associated with mutations in *PPARG* has milder clinical features and an onset after the second decade of life, the metabolic disturbances may be more severe[35].

Metabolic disturbances in FPLD are similar to those in the generalized lipodystrophy syndromes. Glucose intolerance, ranging from mild to severe, develops during young adulthood. Acute pancreatitis and hepatic steatosis and cirrhosis may occur, with complications from diabetes mellitus, atherosclerotic cardiovascular disease or hypertrophic cardiomyopathy leading to premature death. When compared to men, affected women have been reported to have more severe triglyceride elevations. Dermatologic manifestations include tuberous xanthomas, acanthosis nigricans and hirsutism, while gynecologic findings include menstrual irregularities, polycystic ovaries, and fat hypertrophy within the labia majora.

Familial partial lipodystrophy with mandibuloacral dysplasia is a rare variant of partial lipodystrophy characterized by mandibular and clavicular hypoplasia, short stature, a high-pitched voice, and ectodermal abnormalities of the skin, teeth, nails and hair[23,35]. There are multiple craniofacial defects, including dental overcrowding and a bird-like facies with prominent eyes and a beaked nose. Skeletal abnormalities include osteolysis of the clavicles, acro-osteolysis, delayed closure of cranial sutures and joint contractures. Mottled hyperpigmentation, alopecia, atrophy of extremity skin and nail dysplasia are the characteristic cutaneous findings. Less common clinical features include sensorineural hearing loss, delayed puberty, a high-arched palate and cutaneous calcinosis. Features of the metabolic syndrome may be present (see Ch. 53).

Acquired generalized lipodystrophy

To date, approximately 80 cases of acquired generalized lipodystrophy (AGL; Lawrence or Lawrence–Seip syndrome) have been reported in the English literature. New diagnostic criteria for AGL have been proposed, as well as a subclassification into three subtypes (Table 101.4).

In approximately one-third to one-half of patients, there is a preceding systemic illness, in particular a viral or bacterial infection or an autoimmune disorder (e.g. a connective tissue disease, thyroiditis)[35]. Clinical features of AGL are similar to those of the congenital variant, but are of later onset and milder. The lipoatrophy typically does not become apparent until childhood or adolescence and rarely develops during adulthood; the disorder is approximately three times more common in women. Large areas of the face, trunk and extremities have fat loss (Fig. 101.6), and the palms and soles may even be involved. Loss of peripheral fat as well as perinephric and intra-abdominal fat can be documented by MRI scans, whereas bone marrow fat is preserved; the latter feature may be helpful in differentiating AGL from CGL.

Tender subcutaneous nodules of panniculitis may precede the lipoatrophy in the type 1 variant and there may be an overlap in the panniculitic and autoimmune varieties. Progression may occur rapidly or over an extended period. When the lipodystrophy becomes generalized, the systemic abnormalities become manifest. The extent of fat loss is closely related to the severity of insulin resistance and hypertriglyceridemia.

The associated metabolic syndrome is generally less severe than with CGL, in contrast to the liver sequelae, which are often lethal. The latency before the development of frank diabetes is shorter than with the congenital variant, that is, approximately 4 years after the loss of fat. If preceded by panniculitis, there may be less severe fat loss and a lower prevalence of diabetes and hypertriglyceridemia than with the other two varieties (see Table 101.4)[26]. The anabolic syndrome is

ACQUIRED GENERALIZED LIPODYSTROPHY: PROPOSED DIAGNOSTIC CRITERIA AND SUBTYPES

ESSENTIAL CRITERION

Selective loss of fat involving large regions of the body beginning during childhood or adolescence

SUPPORTIVE CRITERIA

Clinical
- Loss of subcutaneous fat from the palms and soles
- Acanthosis nigricans
- Hepatosplenomegaly
- Panniculitis prior to onset (by clinical history and/or histologic confirmation; see below)
- Associated autoimmune diseases (see below)

Laboratory
- Diabetes mellitus or impaired glucose tolerance
- Severe hyperinsulinemia (fasting and/or postprandial)
- Increased serum triglyceride and/or decreased HDL-cholesterol levels
- Reduced serum leptin and/or adiponectin levels
- Anthropometric or MRI evidence of large regions of fat loss
- MRI evidence of preserved bone marrow fat

SUBTYPES

Panniculitic variant (type 1)
- Panniculitis precedes the onset of lipoatrophy, which may be noted in the center of expanding annular lesions or at distant sites
- Mean age of onset is 7 years; slight female predominance (~1.5-fold)
- Associated symptoms include low-grade fever, malaise, arthralgias and abdominal pain
- May be associated with autoimmune diseases (see below)
- Relatively mild metabolic derangements and leptin abnormalities
- Histopathologic evaluation reveals a lymphohistiocytic subcutaneous infiltrate ± granulomatous foci

Autoimmune variant (type 2)
- Concurrent or prior autoimmune disease without preceding panniculitis; associated with juvenile dermatomyositis, Sjögren's syndrome, juvenile idiopathic arthritis, vitiligo, chronic urticaria/angioedema and autoimmune thyroiditis, hepatitis or hemolytic anemia
- Mean age of onset is 15 years; female predominance (~3-fold)
- Hepatomegaly is invariably present; hypertriglyceridemia and diabetes mellitus occur in most patients
- Laboratory abnormalities may be observed without clinical evidence of autoimmune disease, including antinuclear, anti-smooth muscle, anti-glomerular basement membrane, anti-salivary duct, antimitochondrial and anti-adrenal/ovary/placenta/testis antibodies

Idiopathic (type 3)
- No evidence of panniculitis or autoimmune disease
- Mean age of onset is 20 years (range, <2–60 years); female predominance (~3-fold)

Table 101.4 Acquired generalized lipodystrophy: proposed diagnostic criteria and subtypes. Adapted from reference 26.

variable and less prominent; its severity is less striking when the condition starts in later childhood or adulthood. Hepatic steatosis is commonly present in affected children, leading to a higher incidence of hepatomegaly, cirrhosis and liver-related mortality in AGL than in CGL. Gynecologic abnormalities include true or pseudo-clitoromegaly (the latter due to fat loss), polycystic ovarian syndrome, and menstrual irregularities. Premature coronary artery disease and carotid or peripheral vascular disease may occasionally be seen. Renal and central nervous system abnormalities are usually absent. Dermatologic features, in addition to panniculitis and lipoatrophic areas, include acanthosis nigricans, localized or generalized hyperpigmentation, eruptive xanthomas, telangiectases, mild palmar/plantar keratoderma, and hair abnormalities, including mild hirsutism, curly hair and occasional alopecia. The acanthosis nigricans begins in childhood and involves the neck, axillae, groin, umbilicus and nipples. Associated autoimmune diseases include juvenile dermatomyositis, Sjögren's syndrome, vitiligo, chronic urticaria and angioedema (see Table 101.4).

Fig. 101.6 Acquired generalized lipodystrophy. There is loss of subcutaneous fat, resulting in a muscular appearance of the legs and accentuation of the tendons. *Courtesy, Jacqueline Junkins-Hopkins, MD.*

Acquired partial lipodystrophy

Acquired partial lipodystrophy (Barraquer–Simons syndrome, progressive lipodystrophy, cephalothoracic lipodystrophy) is the most common type of non-localized lipodystrophy other than HIV/ART-related lipodystrophy. It has been reported worldwide, with more than 250 patients described in the literature[35,38].

Three phenotypic subtypes have been noted: (1) fat loss in the upper half of the body; (2) fat loss in the upper half of the body, with hypertrophy of adipose tissue in the lower half; and (3) hemilipodystrophy, where one half of the face or body is affected.

Lipodystrophy begins during childhood or pre-puberty (median age of diagnosis, 8–10 years), at times after a viral illness; it is characterized by a symmetric and insidious but progressive loss of subcutaneous fat in a cephalocaudal fashion starting on the face (Fig. 101.7) and scalp, and extending down to the pelvic girdle and mid thighs. Progression usually occurs within a 1–2-year period, but can occur over many years. Physical findings may be apparent by the teen years, although the onset may be delayed until 40 years of age. Women are affected three times more often than men.

The face is usually affected first, with sunken eyes due to loss of retro-orbital and periorbital tissue as well as loss of the preauricular (Bichat's) fat pads, resulting in a progeria-like or cadaveric appearance (Fig. 101.8). The hips and legs tend to be spared, and often demonstrate fat hypertrophy, especially in women. Growth delay or stunted growth is not characteristic of this disorder.

MCGN II with nephritic syndrome, seen in approximately one-fifth of patients, may occur many years, usually about eight, after the onset of lipodystrophy. Almost all patients with acquired partial lipodystrophy have low levels of C3 in addition to circulating C3 nephritic factor (C3NeF), composed of polyclonal IgG. This leads to unopposed activation of the alternative complement pathway (see above) and C3NeF-induced lysis of adipocytes. The low C3 level also predisposes these patients to recurrent *Neisseria meningitidis* infections and prophylactic antibiotics may be required.

Other autoimmune associations include systemic lupus erythematosus, juvenile dermatomyositis, scleroderma, Sjögren's syndrome, pernicious anemia, hypothyroidism, celiac disease, dermatitis herpetiformis, temporal arteritis and small vessel vasculitis. An association of acquired

partial lipodystrophy with chronic sclerodermatous GVHD, POEMS syndrome and extrinsic allergic alveolitis have also been reported. CNS abnormalities such as mental retardation, epilepsy, and sensorineural deafness have been observed.

Metabolic syndrome is less common than in other lipodystrophies, but acanthosis nigricans, menstrual abnormalities, hirsutism, insulin resistance, type 2 diabetes mellitus, and hyperlipidemia may be seen.

Localized lipoatrophy

Localized lipoatrophy presents as one or multiple depressed areas (i.e. indentations), usually on the proximal extremities, ranging from under a few centimeters to greater than 20 cm in diameter. *Drug-induced lipoatrophy* is most commonly due to injections of corticosteroids and non-human insulin (see Table 101.2); it may be accompanied by local lipohypertrophy. Of note, multifocal lipoatrophy due to intravenous corticosteroid use has been described. *Involutional lipoatrophy* is an idiopathic lipoatrophy characterized clinically by non-inflammatory focal loss of fat. Based upon reported cases, there is a strong predominance of women. Focal oval areas of lipoatrophy, 2 to 8 cm in diameter, occur predominantly on the buttocks and proximal extremities, especially the upper arm, corresponding to locations frequently used as injection sites. Although it is estimated that up to 60% of cases of involutional lipoatrophy may be associated with prior local injections (see above), this type of lipoatrophy may occur without prior injections.

Atrophic connective tissue panniculitis is rare, and it often occurs on the upper or lower extremities. In "pure" cases of this condition, there is no prior clinical inflammation although there is evidence histologically of lymphocytic panniculitis. In other patients, the lipoatrophy may be the direct result of clinical panniculitis. The latter is common on the head and neck or proximal extremities if associated with lupus panniculitis (also referred to as lupus profundus; Fig. 101.9). Other associated autoimmune diseases include dermatomyositis, thyroiditis, juvenile idiopathic arthritis, vitiligo, and insulin-dependent diabetes mellitus.

Lipoatrophia semicircularis (semicircular lipoatrophy) has been reported primarily in women in their 20s to 30s and rarely in children. It presents as symmetric, asymptomatic, 4–8 cm linear horizontal depressions on the anterolateral thighs (see Fig. 101.2). Infrequent presentations include two or three parallel depressions, a unilateral distribution, or symptoms of cramps, pain after sports, heavy legs, or a burning sensation. The lesions usually appear over a few weeks and spontaneously resolve between 9 months to 4 years. The lipoatrophy may recur. MRI can assist in differentiating this from an inflammatory panniculitis.

Annular lipoatrophy presents with a deep, persistent, pseudosclerotic band approximately 9–11 cm in length that encircles the arm or ankle[39]. More extensive lesions have recently been reported that were 14–16 cm in length. It may be preceded by tenderness and swelling of the limb, or associated with discomfort and arthritis. This entity may represent a variant or end-stage presentation of atrophic connective tissue disease panniculitis. Thus, there may be patients with associated autoimmune diatheses.

Lipodystrophia centrifugalis abdominalis infantalis (centrifugal lipodystrophy) has largely been reported from East Asia, in particular Japan[40]. Onset is usually before 3 years of age, with more than 90% of patients presenting by age 5 years. In Koreans, there is a fourfold female predominance[41]. Although lipodystrophia centrifugalis abdominalis infantalis affects primarily Asian children, it may occasionally occur in Caucasians and in adults. There is a well-demarcated area of lipoatrophy with a periphery of erythema and scale on the trunk or abdomen, associated with regional lymphadenopathy. The lipoatrophy begins on the lower abdomen or in the groin region (and may include the genitalia) in about 80% of patients, and in the axillary region in about 20% of patients; it spreads onto the abdomen or chest, respectively, in a centrifugal fashion (Fig. 101.10). The underlying blood vessels become visible and ulceration may occur within the depressed areas. Contrary to its original name, this condition can affect non-abdominal sites such as the face, neck and lumbosacral region, and it is not limited to infants (Fig. 101.11). The lesions progress slowly over several years and spontaneous resolution has been observed in over 50% of patients by their teens[40]. Rarely, the disorder persists into adulthood.

Progressive hemifacial atrophy (Parry–Romberg syndrome) may be considered a form of severe morphea (see Ch. 44), and may be accompanied by atrophy of the underlying cartilage and bone, with potential ophthalmologic and dental consequences.

Non-progressive late-onset linear hemifacial lipoatrophy occurs on the malar cheek, primarily in elderly individuals.

The most common location for lipodystrophia centrifugalis infantalis is the abdomen (see Fig. 101.10). *Courtesy, National Skin Centre, Singapore.*

Inflammatory reactions due to material injected for cosmetic purposes or due to self-inflicted injections of foreign material can lead to lipoatrophy which may be associated with scarring and dyschromia.

Lipohypertrophy

Lipohypertrophy remains a frequent complication of insulin therapy, irrespective of the insulin source and mode of administration[42]. As with insulin lipoatrophy, anti-insulin antibodies are associated with lipohypertrophy in children and adolescents with type 1 diabetes. The clinical consequence is that injection of insulin into a site of lipohypertrophy, while painless, may lead to erratic absorption of the insulin, with the potential for poor glycemic control. Injection of pegvisomant, a growth hormone receptor antagonist used to treat acromegaly, is another cause of lipohypertrophy (Table 101.5).

Pathology

Generally speaking, the histologic picture of the various lipodystrophy syndromes (see Table 101.1) is non-inflammatory. In *generalized lipodystrophy*, there is complete or near-complete loss of subcutaneous fat, with the dermis and fascia in direct apposition. Less often, biopsy specimens appear to have no overt abnormalities, except for an increased amount of collagen, which has replaced the subcutaneous fat. In contrast, biopsies of *acquired generalized lipodystrophy*, in particular type 1, may show a lobular panniculitis (Fig. 101.12; see Table 101.4).

In *acquired generalized lipodystrophy* and areas of lipoatrophy in some forms of *partial lipodystrophy*, two histologic patterns have been recognized: (1) non-inflammatory with involutional changes of the fat; and (2) inflammatory in the form of a lobular panniculitis with lymphocytes, lipophages and plasma cells[43]. Whether these two patterns are stage-related remains to be clarified, as even in patients without panniculitis clinically, biopsies of early lesions may show inflammation, but it is usually mild.

Involutional changes of the subcutaneous fat are characterized by small fat lobules with a reduction in the size and number of adipocytes (Fig. 101.13). *Involutional lipoatrophy* can be further divided into two histologic subtypes[33]. In the first type, the lobules may be composed of faintly acidophilic, small fat cells that retract from one another as well as the surrounding connective tissue, leading to an appearance similar to embryonic fat; the lobules often have an eosinophilic appearance. These histologic findings are more prominent at the periphery of the clinically depressed area, with tiny acidophilic fat cells present more centrally. Inflammation is absent to sparsely mononuclear. The second type, with indistinguishable clinical features, shows small atrophic adipocytes with a normal fat cell membrane surrounded by prominent vasculature. At scanning magnification, the lobules are collapsed (with an orientation parallel to the skin surface) and surrounded by numerous capillaries. Acid mucopolysaccharide deposition within the fat lobules and fibrosis of the septae may be seen, as well as occasionally lipomembranous changes.

Although birefringent non-crystalline foreign material may be observed, foreign body giant cells and lipophages are typically absent in both subtypes of involutional lipoatrophy. $CD68^+$ macrophages can be demonstrated with immunohistochemical staining. Ultrastructural studies have shown that these are lysosomally active macrophages

CAUSES OF LIPOHYPERTROPHY
Insulin therapy – risk factors include duration of therapy, frequent injections, failure to rotate sites of injections, and poor injection technique
Pegvisomant (growth hormone receptor antagonist) injections*
Growth hormone injections
Excess corticosteroids – includes Cushing's disease (excessive ACTH production by the pituitary gland) and Cushing's syndrome (iatrogenic, adrenal tumors, nodular adrenal hyperplasia, ectopic ACTH production)
HIV/ART-associated – risk factors include extended exposure to nucleoside reverse transcriptase inhibitors, exposure to protease inhibitors, age ≥40 years, longer duration of therapy, higher body mass index before onset of therapy, and presence of metabolic derangements (elevated serum triglyceride and insulin levels; depressed serum testosterone levels)
*Used to treat acromegaly.

Table 101.5 Causes of lipohypertrophy.

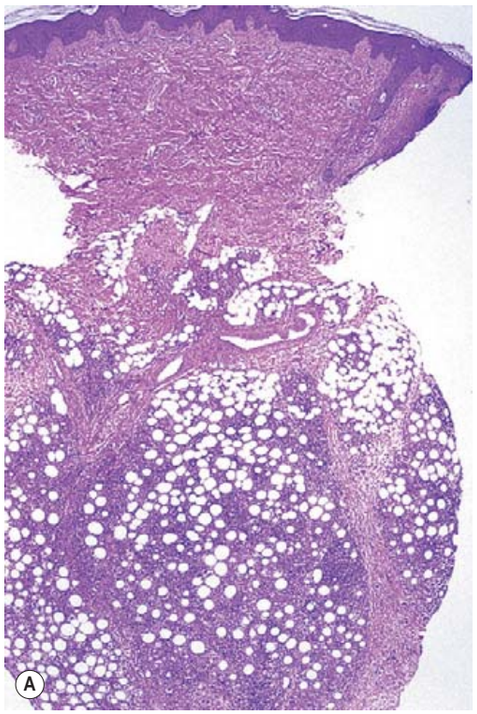

Fig. 101.12 Histopathologic features of the preceding panniculitis in type 1 acquired generalized lipodystrophy.

adjacent to lipocytes, and they may contain degenerated lipid[33]. In *localized lipodystrophy*, a loss of fatty tissue is seen, along with a variable degree of fibrosis. There is usually no inflammatory infiltrate, although panniculitis has been reported in a few cases. Deposits of immunoreactants can be seen within blood vessel walls or the basement membrane, particularly in the inflammatory type.

Histologically, well-developed areas of *lipodystrophia centrifugalis abdominalis infantilis* show a diminution of subcutaneous fat with scant or absent inflammation. The erythematous rim tends to correspond to a moderate or marked lymphohistiocytic infiltrate in the subcutaneous fat; a deep dermal and peri-eccrine lymphocytic infiltrate is an uncommon finding. There may be fibrosis and thickening of the septae within the subcutis. The few adipocytes that are present may have myxoid changes.

Other localized variants such as *lipoatrophia semicircularis* (semicircular lipoatrophy) and *drug-induced lipoatrophy* usually show a loss of fatty tissue and replacement by collagen, with no features of panniculitis. There are often scattered lipophages. Lastly, HIV/ART-associated lipodystrophy resembles the non-inflammatory pattern of lipodystrophy.

Differential Diagnosis

There are a variety of other complex syndromes that present with lipoatrophy along with a number of other physical and systemic features (see below). A detailed discussion of these syndromes is beyond the scope of this chapter.

The excessive fat accumulation seen in patients with familial partial lipodystrophy (Dunnigan variety) and HIV/ART-associated lipodystrophy could be confused with Cushing's syndrome. Acromegaly can have overlapping features with generalized lipodystrophy.

In an infant with generalized lipodystrophy, the following conditions should also be considered:

- *Leprechaunism* (Donohue syndrome) is included in some lipodystrophy classifications, as the patients present with generalized lipodystrophy, severe insulin resistance, acanthosis nigricans and hirsutism. In contrast to CGL, these patients have a distinct elfin facies, severe intrauterine growth retardation, prominent nipples, loose skin, a mutation in the insulin receptor gene, and death during infancy.
- *SHORT syndrome* (*s*hort stature, *h*yperextensible joints, *o*cular depression, *R*ieger anomaly [iridocorneal mesodermal dysgenesis], and *t*eething delay) is also included in some lipodystrophy classifications, as there is congenital lipoatrophy of the face and upper body. This is distinguished by the above-outlined associated abnormalities, intrauterine growth retardation, delayed bone age, and a dysmorphic facies which includes a triangular shape, micrognathia, deep-set eyes and anteverted ears. Carbohydrate metabolic abnormalities are rare to absent.
- *Progeria-type syndromes* are characterized by limb lipoatrophy, cardiovascular disease and diabetes, but they are accompanied by muscle wasting, sclerodermatous changes, cataracts and other signs of premature aging. Some of the progeric syndromes have

LMNA mutations similar to those associated with FPLD, and may be considered as part of a broader group of disorders, termed laminopathies (see Table 63.9).
- In *Cockayne syndrome*, lipoatrophic changes are accompanied by growth delay, retinal abnormalities, photosensitivity and defects in DNA repair (see Chs. 63 & 87).
- *AREDYLD syndrome*: congenital generalized lipoatrophic diabetes is associated with an acrorenal field defect and ectodermal dysplasia.

Localized lipodystrophies should be differentiated from initial phases of progressive lipodystrophy, morphea, lupus panniculitis, and atrophoderma of Pasini and Pierini. Although there is overlap amongst the various types of localized lipodystrophy, the distribution and morphology combined with a history of injections, the presence clinically or histologically of panniculitis, and associated autoimmune disorders may aid in the diagnosis.

Poland syndrome is a rare congenital disorder consisting of unilateral partial or total absence of a breast and/or pectoralis major muscle, and ipsilateral symbrachydactyly, which may simulate lipoatrophy. Lastly, MRI can help to differentiate loss of fat from other causes of localized depressions of the skin.

Treatment

Management issues for lipodystrophy syndromes are threefold: (1) cosmetic concerns; (2) metabolic derangements; and (3) systemic associations. Also, with better elucidation of the genetic basis of the various inherited lipodystrophy syndromes (see Table 101.1), determination of the underlying genetic mutation can have important implications for prognosis and genetic counseling.

Treatment options for the physical aspects of lipodystrophy are limited (see below). Localized lipodystrophy may resolve spontaneously, depending on the etiology and/or subtype. In trauma-induced cases, in particular lipoatrophia semicircularis, the depressions may normalize over a period of weeks. Switching to purified human insulin may improve insulin lipoatrophy, but it may take 1–3 years[42].

Surgical treatment has had variable and limited success. Persistent facial lipoatrophy may be amenable to flaps. Soft tissue augmentation using a variety of permanent and non-permanent fillers may be helpful (see Ch. 158). Solid synthetic volumetric midfacial implants, constructed using computer-aided design and manufacturing technology[44], may offer a more durable correction of the defects. A thoughtful assessment of possible long-term complications of permanent fillers is always mandatory prior to treatment. Fat transplantation via lipoinjection may also help facial defects[45].

While medical therapy is directed predominantly at the metabolic derangements in order to reduce the associated morbidity and mortality, it may also offer some benefit for the lipodystrophic features. Thiazolidinediones (TZDs; also referred to as glitazones), which are PPAR-γ agonists, have been used to increase insulin sensitivity, increase body fat, improve adipocytokine levels and lower triglyceride levels[46]. However, there have been concerns regarding the adverse side effects of this group of drugs, e.g. troglitazone was withdrawn from the market due to hepatotoxicity. In the US, prescribing the newer TZD rosiglitazone requires enrollment in a controlled access program and pioglitazone may exacerbate heart failure and increase the risk of bladder cancer. Fibrates are PPAR-α agonists that increase fatty acid oxidation and have been used to treat hypertriglyceridemia. Omega-3 polyunsaturated fatty acids can also lower circulating triglyceride levels by reducing hepatic triglyceride synthesis via competitive inhibition. To date, controlled trials supporting the efficacy of these various drugs in inherited lipodystrophies are lacking.

Therapy has also been targeted at the adipokine abnormalities, such as leptin deficiency. Treatment with recombinant methionyl human leptin (r-metHuLeptin) for generalized lipodystrophy, both congenital and acquired forms, has resulted in an improvement of glycemic control, hyperlipidemia, hepatomegaly, and diabetic complications such as proteinuria. The therapy is generally well tolerated, with no notable serious adverse effects[47,48]. Improvement has been documented after only 4 months of therapy[49]. In addition to correcting the metabolic derangements, leptin replacement may improve appetite regulation. With long-term treatment, benefits have been shown to persist[47].

Nutritional alteration (e.g. low-fat diet), exercise, and a weight-management program can further improve the hyperlipidemia and hyperglycemia. Management by an endocrinologist is recommended.

Acquired partial lipodystrophy

Management of patients with acquired partial lipodystrophy should include initial evaluation and continued monitoring for autoimmune disease (such as lupus and dermatomyositis), thyroid disease and renal disease. The latter should include evaluation for proteinuria, low C3, and C3 nephritic factor (C3NeF), and, if necessary, renal biopsy to exclude MCGN.

The presence of neutralizing antibodies against C3NeF in IVIg has led to treatment of a patient with MCGN II and C3NeF with IVIg, with encouraging results[50].

Genetic counseling should be considered for the familial variants.

Insulin lipodystrophy

While the incidence of insulin lipoatrophy has decreased significantly with the advent of purified human insulin, some patients may be injecting other forms. Switching to human insulin and changing the mode of delivery are helpful interventions (see above). For prevention, constant rotation of injection sites, such that the same site is not used more often than once a month, is recommended. Liposuction may lead to improvement in the hypertrophic form.

HIV/ART-ASSOCIATED LIPODYSTROPHY

HIV/ART-associated lipodystrophy has become the most common form of non-localized lipodystrophy. It is linked in particular to protease inhibitors (PI) and nucleoside analogue reverse transcriptase inhibitors (NRTIs), affecting up to 40% of patients within 1 to 2 years of initiation of ART[51].

The clinical findings in HIV/ART-associated lipodystrophy include:
- lipoatrophy of peripheral sites, primarily the face, limbs, heel pads, and buttocks
- central lipohypertrophy or adipose tissue accumulation, especially dorsocervical, supraclavicular, within the breasts, intra-abdominal and visceral (e.g. liver)
- metabolic abnormalities – insulin resistance, type 2 diabetes, dyslipidemia, hypertension, lactic acidosis.

The progressive body changes resulting from a combination of lipoatrophy and lipohypertrophy can be disfiguring and potentially stigmatizing, resulting in a loss of adherence to ART[52].

Pathogenesis

The etiology of HIV/ART-associated lipodystrophy is multifactorial and includes multiple sites of drug actions in metabolic pathways and within different tissues, all in a complex interplay with host-specific factors such as age, genetics, severity of HIV infection, and inflammatory states[52]. Proposed mechanisms for ART-induced subcutaneous fat loss include:
- impaired pre-adipocyte differentiation and increased adipocyte apoptosis[53,54]
- impaired insulin-stimulated lipogenesis and increased lipolysis[53], leading to decreased adipocyte size
- mitochondrial toxicity[55] (see Table 101.6 & Fig. 101.14).

HIV/ART-related lipodystrophy was initially considered a PI-mediated disease, but exposure to thymidine analogue NRTIs has been identified as an independent and significant risk factor for its development. In particular, stavudine, didanosine and zidovudine were more strongly associated with lipoatrophy[55,58].

Inhibition of DNA polymerase-γ within mitochondria is the proposed major site of action of NRTIs, leading to the mitochondrial dysfunction that has been observed in several tissues, including adipose tissue[55]. Of note, the latter has a high concentration of mitochondria. When the NRTI-induced mitochondrial DNA depletion reaches a threshold, this results in decreased adipocyte size[54] and increased adipocyte death, culminating in the development of lipoatrophy. Interference with the function of the respiratory chain complexes leads to impaired fatty acid

MECHANISMS OF ANTIRETROVIRAL THERAPY (ART)-ASSOCIATED LIPOATROPHY			
	HIV drugs implicated	**Drug-induced effect**	**Cellular response**
↓ Adipocyte differentiation*	PIs, NRTIs	Defect in lamin A/C processing and/or RXR-PPAR-γ heterodimer activation decreases function of SREBP-1c & other downstream transcription factors	↓ Production of new mature fat cells → ↓ fat cell number
↑ Adipocyte apoptosis*	PIs, NRTIs	↑ TNF-α signaling (as well as mechanism described above for ↓ differentiation)	↑ Fat cell death → ↓ fat cell number
↑ Lipolysis*	PIs, NRTIs	↓ Expression of perilipin	↑ Release of stored TGs as FFAs and glycerol into circulation → ↓ fat cell size
↓ Lipogenesis	PIs, NRTIs	↓ Expression and function of lipogenic SREBP-1c	↓ FFA uptake by adipocytes → ↓ fat cell size
Mitochondrial toxicity	NRTIs	Inhibition of mitochondrial DNA polymerase-γ	↑ Catabolic pathways (lipolysis), altered production of hormones and cytokines (↓ adiponectin, ↑ TNF-α), ↓ adipocyte differentiation, ↑ adipocyte apoptosis
*Also represent sequelae of mitochondrial toxicity.			

Table 101.6 Mechanisms of antiretroviral therapy (ART)-associated lipoatrophy. From refs 53–57. FFA, free fatty acids; HIV, human immunodeficiency virus; NRTI, nucleoside reverse transcriptase inhibitor; PI, protease inhibitor; PPAR-γ, peroxisome proliferator-activated receptor-γ; RXR, retinoid X receptor; SREBP-1c, sterol regulatory element-binding protein-1c; TG, triglycerides; TNF-α, tumor necrosis factor-α.

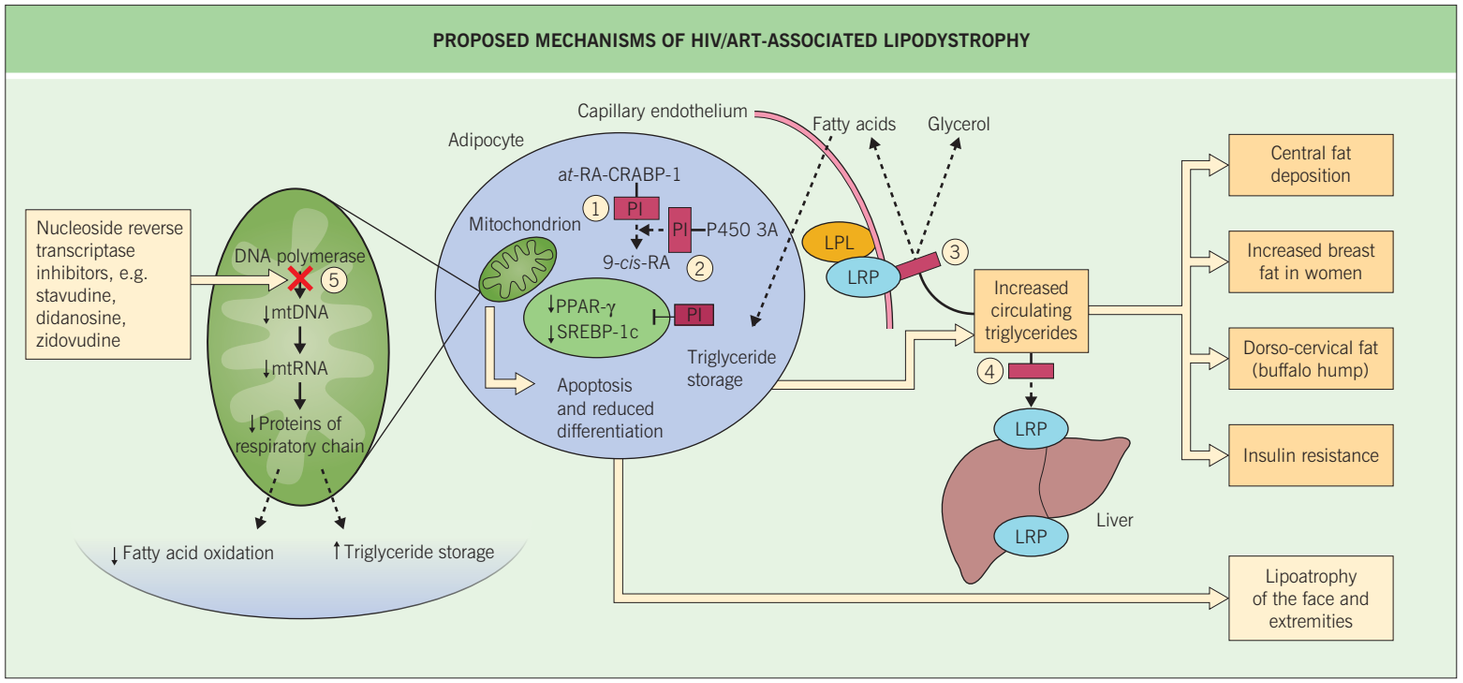

Fig. 101.14 Proposed mechanisms of HIV/ART-associated lipodystrophy. The combination of decreased PPAR-γ expression and decreased fatty acid oxidation capacity resulting from drug exposure could explain how these drugs cause adipocyte toxicity and lipoatrophy. ART, anti-retroviral therapy; *at*-RA, all-*trans*-retinoic acid; CRABP-1, cytoplasmic retinoic acid binding protein type 1; LPL, lipoprotein lipase; LRP, low-density lipoprotein receptor-related protein; mtRNA, mitochondrial RNA; mtDNA, mitochondrial DNA; PPAR-γ, peroxisome proliferator-activated receptor-γ; PIs, protease inhibitors; RXR, retinoid X receptor; SREBP-1c, sterol regulatory element-binding protein-1c. *Adapted from Carr A. HIV protease inhibitor-related lipodystrophy syndrome. Clin Infect Dis. 2000;30:S135–42.*

oxidation and intracellular accumulation of triglycerides and lactate, which can then enter the systemic circulation (see Fig. 101.14).

PIs cause adipose toxicity via their effects on *s*terol *r*egulatory *e*lement-*b*inding *p*roteins (SREBP) which function as transcription factors. In part, PIs prevent the cellular maturation of the SREBP-1c isoform to its active form in adipocytes[56], resulting in impairment of intracellular fatty acid and glucose metabolism as well as adipocyte differentiation (see Table 101.6). In addition, PIs decrease the expression of peroxisome proliferator-activated receptor-γ (PPAR-γ) and this can also lead to a reduction in differentiation of adipocytes[57]. These regulators of lipid metabolism, SREBP-1 and PPAR-γ, are linked through PPAR-γ coactivator-1. Decreases in PPAR-γ expression correlate with decreases in mitochondrial RNA expression, again providing a link between NRTI-induced mitochondrial toxicity and lipoatrophy. PPAR-γ expression is also decreased by the HIV viral protein R (vpr), lending support to a direct role of HIV itself in the pathogenesis of lipodystrophy.

Clinical Features

As in hereditary lipodystrophy syndromes, fat redistribution may precede the development of metabolic complications. HIV/ART-associated lipodystrophy usually has its onset during the first 6 to 12 months after commencing therapy. In cross-sectional studies using DEXA scans and computed tomography, a 14–65% prevalence of central lipohypertrophy was noted within 1 to 2 years of initiation of ART[60].

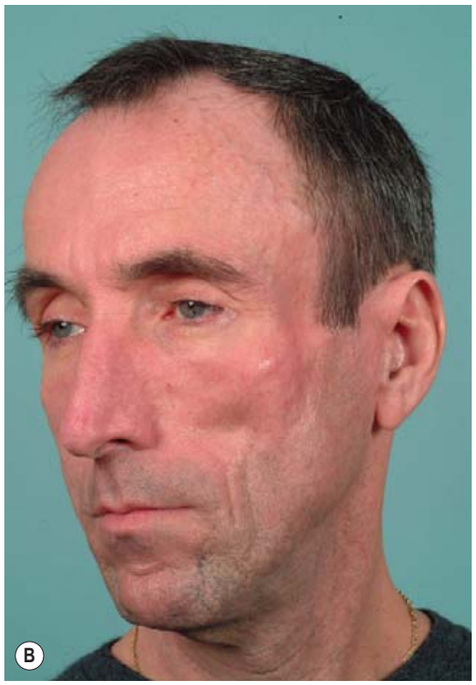

Fig. 101.15 HIV/ART-associated lipodystrophy. **A** There is symmetric loss of buccal, parotid and preauricular (Bichat's) fat pads, resulting in prominent zygomata, sunken eyeballs, and a cachectic appearance. **B** The side view highlights the loss of temporal fat. *Courtesy, Ken Katz, MD.*

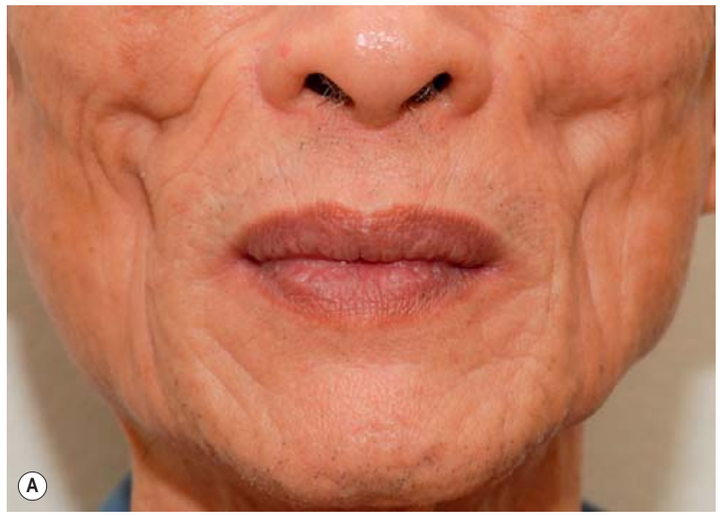

Fig. 101.16 HIV/ART-associated lipodystrophy. A Marked indentation of the medial cheeks in an older patient, with redundant melolabial folds. **B** Lower extremities with prominent veins and defined musculature. *A, Courtesy, Priya Sen, MD.*

However, patient self-report, in concert with physician examination, still remains the earliest and best indicator of body shape change.

Peripheral lipoatrophy occurs primarily in the face (Figs 101.15 & 101.16A), limbs (Fig. 101.16B), buttocks and heel pads. The loss of subcutaneous facial fat, in particular within the buccal, parotid and preauricular (Bichat) fat pads, results in prominent zygomata, sunken eyes, deepened and redundant melolabial folds, and a cachectic facies. Central lipohypertrophy presents as: (1) an accumulation of intra-abdominal fat (omental, mesenteric, retroperitoneal), resulting in abdominal protrusion ("protease paunch"; "Crix belly"); and/or (2) increased fat deposition within the dorsocervical fat pad ("buffalo hump"), breasts (gynecomastia in men, larger breasts in women), anterior neck and/or lateral mandibular region, and the muscles and liver. Lipoma formation has also been noted, and the presence of a "buffalo hump" has been shown to be associated with insulin resistance and diabetes mellitus. Of note, the cross-sectional Fat Redistribution and Metabolic Change in HIV Infection (FRAM) study found no correlation between changes in central fat and peripheral fat in HIV-infected men[59].

The use of different combinations of drugs in ART may lead to distinct clinical syndromes of fat redistribution. For example, PIs are more frequently associated with central fat hypertrophy and metabolic derangements, whereas treatment with NRTIs (stavudine in particular) is a stronger independent risk factor for the development of peripheral fat wasting and lipoatrophy. In addition, multiple NRTI-induced complications related to mitochondrial toxicity, including myopathy, polyneuropathy, liver steatosis, pancreatitis, hyperlactatemia, bone marrow toxicity and a Fanconi-like syndrome, can also develop.

HIV-related lipodystrophy is clearly associated with metabolic abnormalities[61], including insulin resistance, diabetes, dyslipidemia (hypertriglyceridemia, decreased high-density lipoproteins), and bone disorders, e.g. osteopenia, osteoporosis and avascular necrosis. Insulin resistance in HIV/ART-associated lipodystrophy arises via direct effects

of PIs on insulin-mediated whole-body glucose uptake as well as the indirect effects of dyslipidemia, mitochondrial toxicity, and changes in body composition on whole-body insulin sensitivity. Adipocytokines, in particular leptin and adiponectin, affect insulin sensitivity and low levels of both factors have been observed in HIV/ART-associated lipodystrophy[5,9]. In HIV-infected patients receiving ART, the prevalence of metabolic syndrome has been reported to be 16–24%, resulting in an increased risk for cardiovascular disease[62]. The Data Collection on Adverse Events of Anti-HIV Drugs (DAD) study found a 26% increase in the rate of myocardial infarction per year of ART during the first 4–6 years of exposure[63].

The most common significant risk factors for the development of lipoatrophy or lipohypertrophy are age (>40 years), disease severity at the onset of therapy (CD4 count <200/μl; higher nadir viral load), and longer duration of therapy with either PIs and/or NRTIs[60,64]. The risk of developing lipoatrophy appears higher in individuals with less subcutaneous fat pre-ART, whereas fat accumulation is more likely in those with more fat at baseline. Combination therapy consisting of two NRTIs and a PI has a strong association with severe lipoatrophy, and HIV-infected men have a lower risk of presenting with lipohypertrophy than do women[51]. In summary, the body fat changes in HIV/ART-associated lipodystrophy reflect an interplay of multiple influences: type of ART prescribed, viral-induced effects, and other host factors.

Treatment

The use of ART has significantly reduced HIV morbidity and mortality; however, the morphologic changes of lipodystrophy are quite stigmatizing and can cause pain, disability and psychosocial distress. Unfortunately, this can result in reduced compliance or even discontinuation of an effective therapeutic regimen. Lipoatrophy, once established, is largely irreversible in the majority of patients and it remains the most difficult manifestation of the lipodystrophy syndrome to manage.

HIV/ART-associated lipoatrophy

In antiretroviral therapy-naïve patients, selection of initial regimens that are less frequently associated with lipoatrophy can reduce the incidence of lipodystrophy. When initial regimens include tenofovir/emtricitabine as opposed to zidovudine/lamivudine, there is less lipoatrophy[65]. In both the RAVE[66] and MITOX[67] studies, switching from a thymidine analogue to either tenofovir or abacavir significantly improved peripheral lipoatrophy of the limbs, although there was no difference in visceral adipose tissue or buffalo hump development. Metabolic parameters improved following a switch to tenofovir, with modest reductions in serum levels of total cholesterol, low-density lipoproteins and triglycerides.

In general, the use of systemic medications to reverse the lipoatrophy has been disappointing. For example, even though the thiazolidinedione rosiglitazone, a PPAR-γ agonist, can reverse *in vitro* the block in adipocyte differentiation induced by PIs, randomized controlled studies have shown that rosiglitazone did not improve fat mass in HIV/ART-associated lipoatrophy. It actually worsened the dyslipidemia, despite an improvement in insulin sensitivity and adiponectin levels[68].

This lack of a beneficial effect on lipoatrophy was independent of background therapy. Use of pioglitazone, which unlike rosiglitazone is metabolized by cytochrome P450 3A4 enzymes, has shown some increase in limb fat. In vitro, uridine supplementation can abrogate thymidine analogue-induced adipocyte toxicities. Pilot studies have shown increases in fat mass in patients who take uridine supplements while continuing the thymidine analogues[69].

Particularly stigmatizing is the emaciated facies of facial lipoatrophy, and injectable fillers can help restore the facial fullness that has been lost. In 2004, the FDA approved poly-L-lactic acid fillers for this indication. Even though the lipoatrophic process is ongoing, facial volume can be restored by increasing the thickness of the dermis and the effects may last up to 2 years. Injectable calcium hydroxylapatite has also been FDA-approved for the treatment of HIV/ART-associated lipoatrophy. Its effects last up to 12 months. These fillers are generally safe and well tolerated, with nodule formation being a possible long-term complication. The transfer of autologous fat to the face also leads to improvement, but a donor site may be lacking in patients with significantly reduced body fat.

HIV/ART-associated lipohypertrophy

Switching from a PI to an alternative antiretroviral regimen has not been shown to reverse visceral abdominal fat accumulation. Diet and exercise modifications reduce overall and truncal fat, but as in the general population, adherence to these lifestyle changes is difficult. Use of thiazolidinediones, metformin and testosterone has not shown any beneficial effect on visceral adipose tissue.

Patients with central lipohypertrophy have reduced growth hormone secretion, reduced response to growth hormone-releasing hormone, and increased somatostatin tone (which inhibits growth hormone secretion). As a result of these findings and the known fat-oxidizing and lipolytic properties of growth hormone, the use of daily subcutaneous injections of recombinant growth hormone was investigated. There was some evidence of a reduction in both visceral adipose tissue and abdominal subcutaneous fat; however, its use was associated with a loss of peripheral limb fat and insulin resistance. There was no clear reduction in cardiovascular risk[70]. Liposuction may be beneficial, especially for dorsocervical and submental fat accumulation.

Metabolic derangements

The metabolic derangements in HIV/ART-associated lipodystrophy may be severe and unresponsive to intervention. Patients should be screened and assessed for dyslipidemia, diabetes mellitus, hypertension and change in body shape at regular intervals. Diet, exercise and cessation of smoking may improve metabolic parameters and reduce cardiovascular risk. Serum low-density lipoprotein (LDL) levels are used to monitor the need for further interventions. The latter include switching to antiretroviral drugs with no adverse effect on circulating lipid levels and the initiation of lipid-lowering medication(s). Statins are recommended as first-line therapy for reducing elevated LDL-cholesterol levels. Fibrates (gemfibrozil, fenofibrate) are recommended when there is an elevation in both LDL-cholesterol and triglyceride levels. Metformin and glitazones are used to manage type 2 diabetes[70].

Structure and function of cutaneous blood vessels *1679*
Vascular development *1681*
Structure and function of the cutaneous lymphatic system *1685*
Related diseases *1687*
Current trends in antiangiogenesis *1688*

Key features

- Cutaneous blood vessels and lymphatic vessels play important roles in skin inflammation and tumor progression
- Vascular endothelial growth factor (VEGF) and placental growth factor (PlGF) are major skin angiogenesis factors
- Expression of VEGF and PlGF by keratinocytes is upregulated in psoriasis, healing wounds and cutaneous squamous cell carcinomas
- VEGF-C and VEGF-D induce skin lymphangiogenesis via interaction with VEGF receptor-3 on lymphatic endothelium. Inactivating VEGF receptor-3 mutations have been found in congenital lymphedema
- Cutaneous lymphatic vessels can be specifically visualized in skin sections due to their selective expression of the glycoprotein podoplanin and of the hyaluronan receptor LYVE-1

INTRODUCTION

The blood vessels of the skin are involved in the control of body temperature and provide a conduit for the supply of nutrients and oxygen to the skin and for the rapid disposal of metabolic waste products. Recent scientific progress in the field of vascular biology has provided ample evidence that both blood vessels and lymphatic vessels also play essential roles in the development and progression of skin tumors, in the mediation and perpetuation of cutaneous inflammation, as well as in physiologic processes such as tissue repair and hair follicle growth. An increased knowledge about markers for specific types of vessels, together with the identification of key molecules that control vascular growth and function, has led to an in-depth understanding of the mechanisms that control the function of the cutaneous vascular system in health and disease, with important implications for the development of novel therapeutic strategies for the treatment of skin diseases.

STRUCTURE AND FUNCTION OF CUTANEOUS BLOOD VESSELS

Blood vessels are essential in order to: supply sufficient oxygen and nutrients to the skin, maintain normal tissue homeostasis and function, and meet the increased nutritional needs of the skin in various pathologic conditions. Blood flows from arteries and arterioles through capillary loops to postcapillary venules and veins. For practical and didactic purposes, the vascular system of the skin has been divided into a superficial and a deep vascular plexus (Fig. 102.1), with additional vascular networks surrounding sweat glands and hair follicles. The architecture of the cutaneous vascular system varies in different areas of the body. In the presence of pronounced epidermal rete ridges, such as in the skin overlying the extensor aspects of the joints or on the palms and soles, straight capillary loops extend into the elongated dermal papillae. In contrast, rete ridge formation and papillary loop formation are less pronounced in the abdominal skin. In fact, it appears that the shape of the papillary microvessels exactly reflects the three-dimensional architecture of the epidermal rete ridges, with only one loop within each papilla[1]. The inner diameter of papillary blood vessels averages between 5 and 10 microns. In contrast to the idealized architectural model of the cutaneous vascular system, vascular perfusion studies (Fig. 102.2) and immunofluorescent studies (Fig. 102.3) reveal a rather continuous, sometimes irregular meshwork of interconnecting cutaneous blood vessels. Consistently, blood vessels are found immediately below the non-vascularized epidermis and surrounding anagen hair follicles.

It has been thought that hair follicles and other skin appendages are predominantly supplied from the lower vascular plexus, whereas the papillary vessels originate from the superficial vascular plexus. Immunohistochemical and perfusion studies suggest that while the frequently single blood vessel within the mesenchymal hair papilla is derived from the lower vascular plexus, the dense vascular network surrounding the hair follicle is predominantly derived from the upper vascular plexus (Fig. 102.4). The relatively small blood vessels that are found during the telogen resting phase of the follicle elongate and enlarge during the anagen growth phase, and then extend towards the subcutis together with the growing hair follicle. During the catagen phase, hair follicle involution is associated with regression of perifollicular blood vessels and with increased rates of endothelial cell apoptosis[2]. Whereas the richness of the follicular blood supply depends on the size of the hair follicles, recent studies suggest that, conversely, the extent

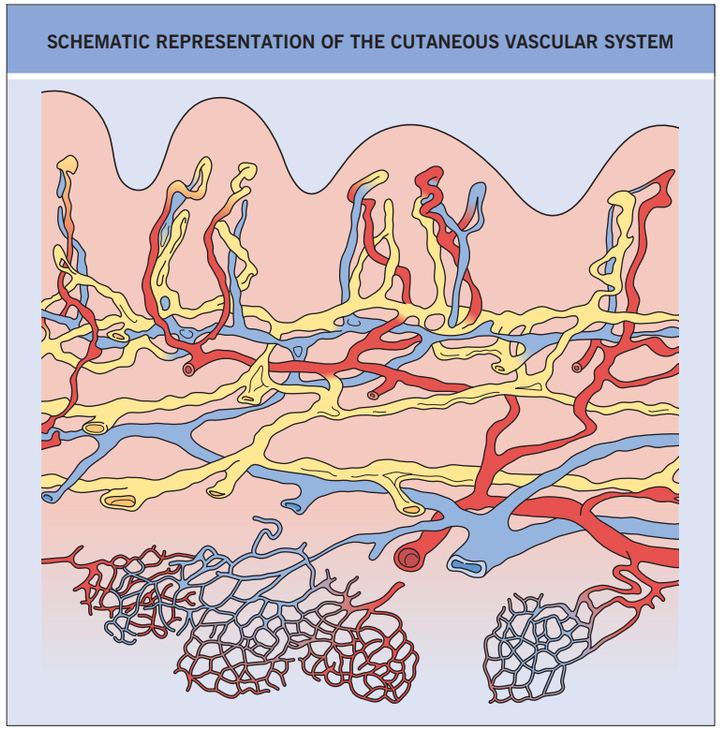

Fig. 102.1 Schematic representation of the cutaneous vascular system. The superficial vascular plexus feeds vessels in the dermal papillae; arteries (red) and veins (blue) are closely associated with lymphatic vessels (yellow). The capillary networks of the subcutaneous adipose tissue are depicted at the base of the schematic.

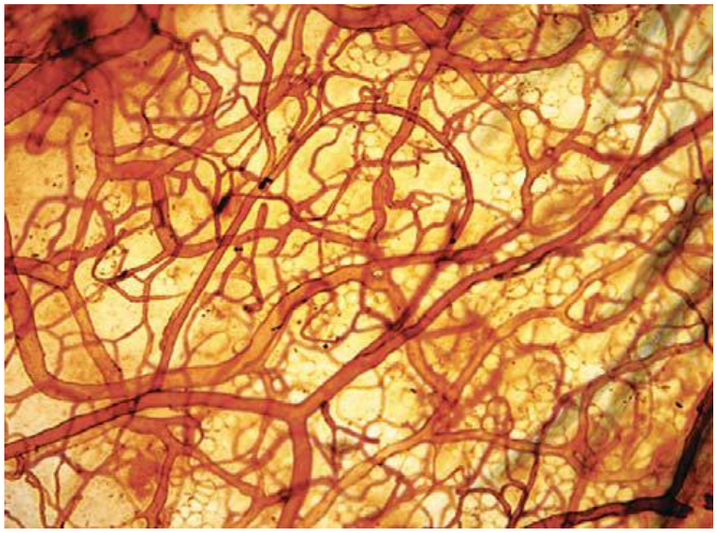

Fig. 102.2 Intravascular perfusion of murine skin with the lectin *Leucopersicon esculentum*. The perfusion highlights dense irregular vascular networks.

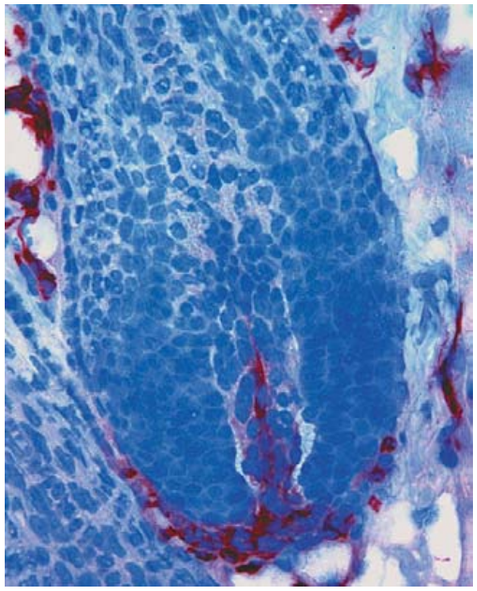

Fig. 102.4 Blood supply of the hair follicle. A single vascular loop extends into the dermal papilla of the hair follicle, while a mesh of blood vessels surrounds the anagen hair follicle (CD31 immunohistochemical stain).

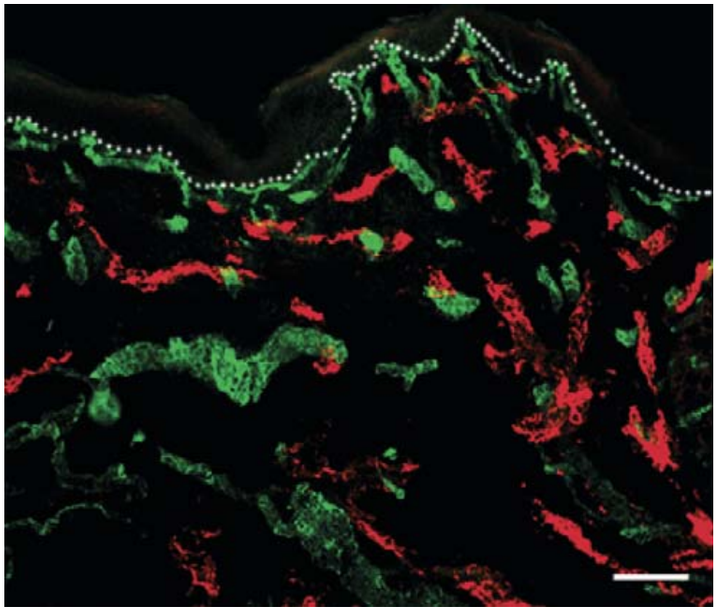

Fig. 102.3 Distinct staining of cutaneous blood vessels (PAL-E; green) and lymphatic vessels (LYVE-1; red) in human neonatal foreskin. The dotted line indicates the approximate location of the basement membrane. The white bar represents 50 microns.

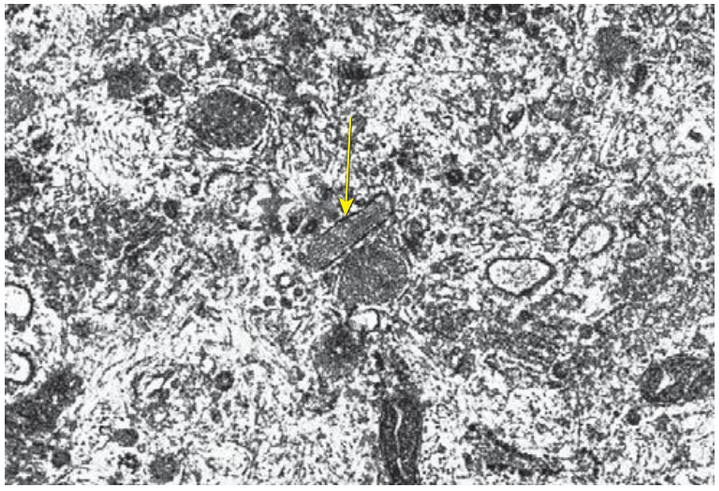

Fig. 102.5 Ultrastructural visualization of a rod-shaped Weibel–Palade body (WPB; arrow) within the cytoplasm of a human endothelial cell.

of perifollicular vascularization may directly influence the size of the hair follicles[2].

In addition to its importance for the nutritional support of the skin, the cutaneous vasculature also plays a systemic role in regulating body temperature and blood pressure. Arterioles possess precapillary muscular sphincters that, upon contraction, can shunt the blood via arteriovenous anastomoses directly to venules, thereby bypassing the capillary networks. Arteriovenous anastomoses are frequently found in the fingertips, where they form the glomi or glomus bodies[1]. Glomi have autonomous innervation and are able, via modulation of their muscular contraction levels, to control peripheral blood flow. The density and importance of arteriovenous anastomoses in other body areas remains unclear.

All blood vessels contain a continuous inner monolayer of flat endothelial cells that are surrounded, on the external side, by a continuous basement membrane. Smaller vessels contain a second, sometimes discontinuous, layer of perivascular cells, called pericytes, which are also surrounded by a basement membrane. Pericytes play an important role in the maintenance of mature blood vessels, and detachment of pericytes from endothelial cells is an early event during sprouting angiogenesis (outgrowth of new capillaries from pre-existing blood vessels). Arterioles and venules are also surrounded by pericytes, which can be visualized by staining for α-smooth muscle actin and desmin. The walls of most arterioles and larger venules and veins contain contractile smooth muscle cells that are surrounded by a basement membrane. Vascular basement membranes contain collagen types IV, XV and XVIII, laminin, fibronectin, and other extracellular matrix proteins. Electron microscopy studies have shown that the basement membrane of endothelial cells in the arterial side of the cutaneous vasculature is rather homogeneous, whereas multilayered basement membranes have been described surrounding venous capillaries[3].

At the ultrastructural level, vascular endothelial cells are characterized by tight junctions between neighboring cells and by a specialized organelle, the rod-shaped Weibel–Palade body (Fig. 102.5), which serves as a storage organelle for the coagulation factor von Willebrand factor, also known as factor VIII-related antigen. Weibel–Palade bodies also contain P-selectin, tissue plasminogen activator, angiopoietin-2 and endothelin-1. Activation of endothelial cells by proinflammatory cytokines or pro-angiogenic factors readily leads to translocation of these storage organelles to the cell membrane, with consecutive enhanced membrane expression of P-selectin and release of von Willebrand factor. Other characteristic ultrastructural features include caveolae (minute invaginations) of the membrane surface, pinocytotic vesicles, and the formation of vesiculo-vacuolar organelles (VVOs)[4]. Circulating macromolecules cross the endothelium through interendothelial cell gaps and transendothelial cell pores, some of which arise

from VVOs. Endothelial cell fenestrations, areas with direct apposition of the endothelial cell membranes without intervening cytoplasm, are rarely seen in normal skin except in angiogenic perifollicular blood vessels during the growth phase of the hair follicle. However, fenestrated endothelial cells are frequently seen in skin diseases with pronounced angiogenesis and vascular hyperpermeability, including psoriasis.

Several markers for blood vascular endothelial cells have been identified (see Table 102.3). However, some of these markers (e.g. CD31, CD34) can also be detected on other dermal cells such as lymphatic endothelial cells (CD31) or fibrocytes (CD34). In normal skin, the most specific markers for cutaneous blood vessels appear to be CD34 and PAL-E (see Fig. 102.3). Double immunofluorescence stains for both the pan-endothelial cell marker CD31 (PECAM-1) and for the lymphatic vascular endothelium-specific hyaluronan receptor LYVE-1 also allow for the selective visualization of LYVE-1-negative blood vessels in the skin (see Fig. 102.15). In addition, differential immunostains for CD31 as well as vascular basement membrane markers (e.g. laminin, collagen IV, collagen XVIII) can be used to visualize cutaneous blood vessels[5].

VASCULAR DEVELOPMENT

During embryogenesis, the first blood vessels are formed through *vasculogenesis*, the differentiation of undifferentiated angioblasts into endothelial cells that form a primitive vascular network. Angioblasts originate from blood islands in the extraembryonic mesoderm of the yolk sac. Blood islands are clusters of epithelioid cells; the outer cells differentiate into angioblasts, whereas the inner cells differentiate into primitive hematopoietic cells, suggesting that both cell types originate from a common embryonic precursor cell, the hemangioblast[6], which is formed from earlier precursor cells under the influence of fibroblast growth factors (Fig. 102.6). Hemangioblasts already express the high-affinity receptor for vascular endothelial growth factor (VEGF), vascular endothelial growth factor receptor-2 (VEGFR-2; KDR [human]; Flk-1 [murine]; see Fig. 102.8); under experimental conditions, early VEGFR-2-positive cells can give rise to both endothelial cells and blood cells[7].

Angioblasts develop under the influence of stimulation by VEGF and express several vascular endothelial cell markers, including the Tie-1 and Tie-2 receptors, vascular endothelial (VE)-cadherin, and the high-affinity VEGF receptors 1 (Flt-1), 2 (KDR) and 3 (Flt-4). Angioblasts within the embryo appear along the anterior intestinal portal and along the lateral edges of the somites, later coalescing to form the dorsal aorta and the large vessel primordia of the body. Angioblasts are highly migratory "prevascular" endothelial cells and are found throughout the embryo with the exception of tissues such as cartilage and epithelia[6].

When angioblasts form a lumen, they become endothelial cells with a polarized phenotype and production of a basal lamina. Interactions of integrin receptors on the endothelial surface with the basement membrane are of paramount importance for the formation of the primordial vascular plexus, and establishment of interendothelial adherence junctions requires the vascular endothelial (VE)-cadherin. The early vascular system consists of sinusoidal capillaries that are arranged in a polygonal honeycomb pattern (see Fig. 102.6). The primordial vascular plexus then becomes surrounded by mesenchymal cells that give rise to pericytes and vascular smooth muscle cells. In a next step, under the influence of VEGF, angiopoietins (see Fig. 102.7) and ephrins, profound remodeling of the primordial vascular plexus takes place. Remodeling involves both the formation and the regression of blood vessels and apoptosis of vascular endothelial cells.

Angiogenesis, the sprouting of new blood vessels from existing primordial vessels, represents the major mechanism for new blood vessel formation. In addition, intussusception, the non-sprouting generation of new blood vessels, involves the formation of intravascular endothelial pillars, leading to the division of the vascular lumen and to the formation of a new vascular space. The Tie-2 receptor tyrosine kinase, expressed on vascular endothelial cells, plays a crucial role in vascular sprouting and remodeling during early embryonic angiogenesis. Pericyte-derived angiopoietin-1 (Ang-1) activates the Tie-2 receptor, whereas Ang-2 can act as an inhibitor of Ang-1 (Fig. 102.7).

Ephrin–Eph receptor interactions, via bidirectional signaling, also play an important role in vascular remodeling and in the determination of vascular identity. Ephrin B2 is specifically expressed by arterial endothelium, whereas its receptor, Eph-B4, is expressed by venous endothelium. Both molecules are involved in the definition of boundaries between arterial and venous endothelial cells. Additional molecules are involved in the control of embryonic angiogenesis and vascular remodeling, including transforming growth factor-β (TGF-β), its low-affinity receptor endoglin, and activin receptor-like kinase-1. Of note, dysfunction of the latter two proteins is seen in hereditary hemorrhagic telangiectasia (see below). Platelet-derived growth factor-β (PDGF-β), secreted by endothelial cells, plays a critical role in the recruitment and differentiation of pericytes and periendothelial smooth muscle cells that contribute to the stability of mature blood vessels[8].

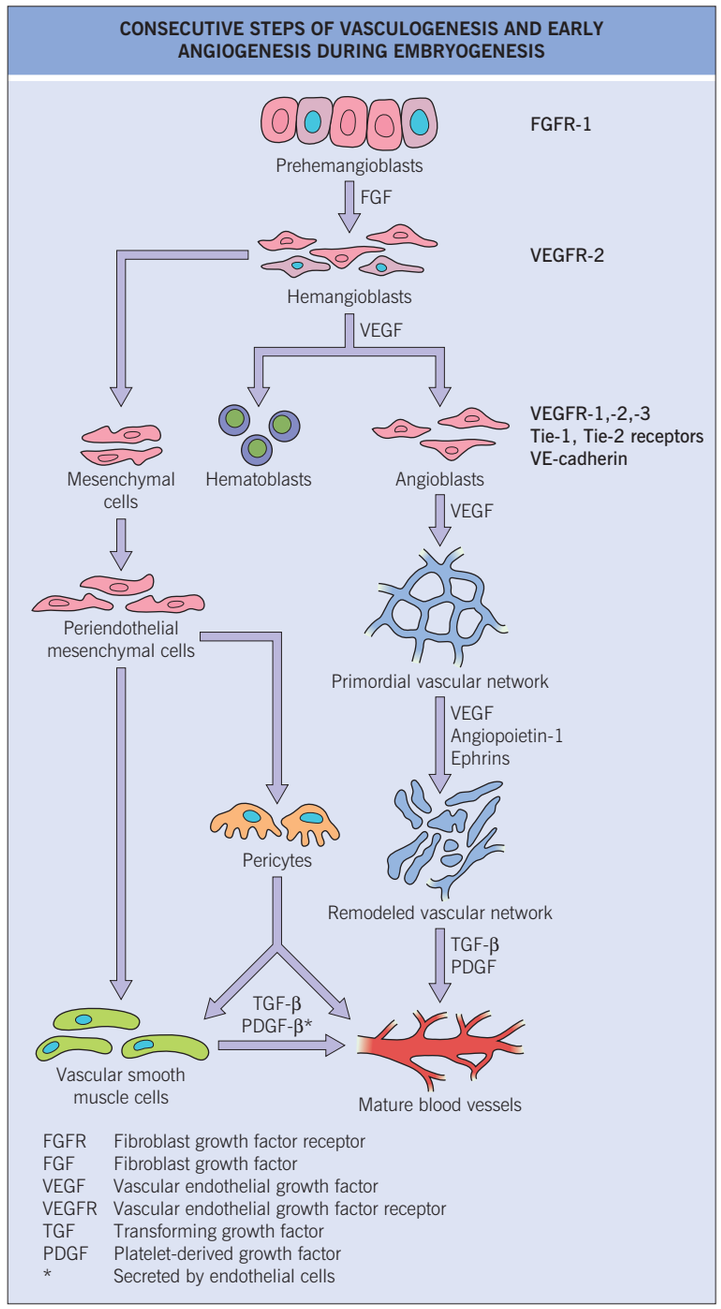

Fig. 102.6 Consecutive steps of vasculogenesis and early angiogenesis during embryogenesis: formation and remodeling of primordial vascular networks.

Regulation of Skin Angiogenesis

Angiogenesis is a common feature of developing skin during embryogenesis. In contrast, the blood vessels in healthy adult skin are predominantly quiescent, with the exception of the cyclic expansion and involution of perifollicular blood vessels during the hair cycle[2]. However, adult skin retains the capacity for brisk initiation of angiogenesis during

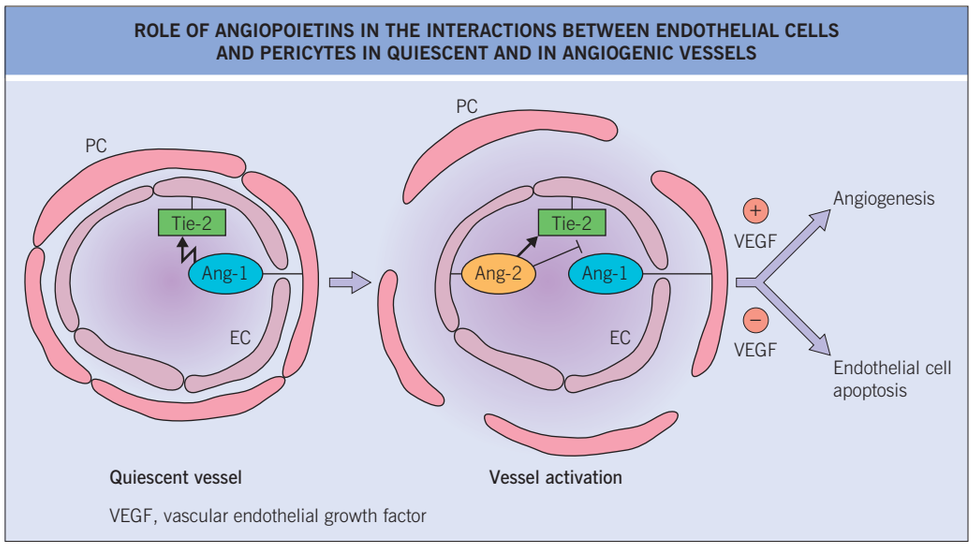

Fig. 102.7 Role of angiopoietins in the interactions between endothelial cells and pericytes in quiescent and in angiogenic vessels. Activation of the endothelial Tie-2 receptor by pericyte (PC)-derived angiopoietin-1 (Ang-1) is thought to result in vessel maturation. Upregulation of angiopoietin-2 (Ang-2) in angiogenic endothelial cells (EC) blocks the vessel-stabilizing effect of pericyte-derived Ang-1 via the endothelial Tie-2 receptor. Both VEGF and Ang-2 expression are upregulated in angiogenic skin diseases, including psoriasis.

THE STEPWISE INDUCTION OF ANGIOGENESIS
1. Induction of microvascular hyperpermeability
2. Enzymatic degradation of vascular basement membrane and interstitial matrix
3. Endothelial cell migration via integrin receptors on activated endothelial cells interacting with native or degraded matrix molecules
4. Endothelial cell proliferation
5. Formation of mature blood vessels

Table 102.1 The stepwise induction of angiogenesis.

wound healing, in the setting of inflammation, and during neoplastic growth. Angiogenesis occurs as: (1) the sprouting outgrowth of new capillaries from pre-existing postcapillary venules; or (2) non-sprouting remodeling of pre-existing blood vessels either through circumferential growth/vascular enlargement or through the formation of intravascular endothelial cell pillars (intussusception). Angiogenesis is a multistep process (Table 102.1) that often involves as a first step the induction of microvascular hyperpermeability, i.e. increased vascular leakage, leading to extravasation of plasma proteins such as fibrinogen and prothrombin. Fibrinogen is then further processed to fibrin and serves as a provisional matrix for migrating endothelial cells, whereas the generation of thrombin acts as an initiator of the extrinsic coagulation cascade, leading to cleavage and activation of several matrix proteins[9]. Together, these processes lead to the generation of a highly angiogenic stroma.

The distinct biologic functions of pericytes during angiogenesis have not been completely elucidated. Although in some experimental angiogenesis models pericytes may lead endothelial cells in the formation of vascular sprouts, a major function of pericyte coverage appears to be the maintenance of mature and quiescent blood vessels (a function which is interrupted during tumor angiogenesis). In normal adult skin, pericytes secrete Ang-1, which leads to phosphorylation of the Tie-2 receptor (a receptor exclusively expressed on vascular endothelial cells) and maintenance of the mature vascular architecture (see Fig. 102.7). In turn, endothelial cells secrete growth factors that mediate the recruitment of pericytes, including PDGF (see above). During the early stages of angiogenesis, endothelial cells express high amounts of Ang-2, a functional antagonist of Ang-1, thereby blocking the maturation-inducing effect of Ang-1 and leading to detachment of pericytes from vascular endothelial cells[10]. In the presence of VEGF, endothelial cells then undergo the consecutive steps of angiogenesis, whereas in the absence of VEGF, vascular endothelial cells undergo apoptosis (see Fig. 102.7). Both VEGF and Ang-2 expression are upregulated in angiogenic skin diseases, including psoriasis, and keratinocyte-derived VEGF and placental growth factor (PlGF; see below) both potently induce the expression of Ang-2 in dermal microvascular endothelial cells. There is evidence that bone marrow-derived progenitor cells also contribute to the angiogenic response. Most of these cells differentiate into perivascular macrophages that secrete angiogenic factors including VEGF, whereas some progenitor cells might adopt endothelial cell differentiation and become incorporated into the vessel wall.

The vascular basement membrane serves as a natural barrier that prevents sprouting of endothelial cells from quiescent, non-angiogenic vessels, with pericytes assisting in the maintenance of the quiescent state. An early step in the angiogenic response involves the degradation of vascular basement membrane components such as collagen type IV through the concerted action of activated proteases, including matrix metalloproteinase (MMP)-2 and MMP-9. Integrin receptors on the surface of activated endothelial cells, in particular the $\alpha_1\beta_1$, $\alpha_2\beta_1$ and $\alpha_v\beta_3$ integrins, then interact with either native or degraded matrix molecules (e.g. collagen type I, fibronectin) in order to facilitate endothelial cell migration[11]. The migration of endothelial cells in the skin is directed towards a gradient of angiogenesis factors that are most commonly produced by the epidermis, but that can also be secreted by macrophages. Endothelial cells then undergo a series of cell divisions, promoted by potent angiogenesis factors such as VEGF and basic fibroblast growth factor (bFGF). Finally, endothelial cells form vascular lumina and mature new blood vessels with basement membrane and pericyte coverage.

In normal skin, vascular quiescence is maintained by the dominant influence of potent endogenous angiogenesis inhibitors over angiogenic stimuli, whereas angiogenesis is induced by increased secretion of angiogenic factors and/or by down-regulation of angiogenesis inhibitors. Several factors that control angiogenesis within the skin have been identified. The major skin angiogenesis factor, VEGF, was originally discovered as vascular permeability factor (VPF), due to the activity of tumor cell-conditioned media to induce accumulation of ascites fluid[12]. VEGF is a homodimeric, heparin-binding glycoprotein occurring in at least four isoforms of 121, 165, 189 and 201 amino acids, due to alternative splicing. VEGF binds to two type III tyrosine kinase receptors that are expressed predominantly on vascular endothelial cells, Flt-1/VEGF receptor-1 (VEGFR-1) and KDR/Flk-1/VEGFR-2 (Fig. 102.8). In addition, VEGF165 also binds to the neuropilin-1 receptor on endothelial and other cells.

In vitro, VEGF acts as a specific mitogen for human dermal microvascular endothelial cells and also induces endothelial cell migration towards several extracellular matrices. *In vivo*, VEGF enhances microvascular permeability and angiogenesis. VEGF is expressed at low levels in normal epidermis, whereas healing wounds and skin diseases associated with angiogenesis and vascular hyperpermeability, particularly psoriasis, show prominent upregulation of VEGF expression by epidermal keratinocytes[13]. The expression and biologic activity of VEGF are controlled by several distinct molecular mechanisms. Hypoxia and low intracellular glucose concentrations result in transcriptional activation (via hypoxia-inducible factors) and stabilization of VEGF mRNA. Skin

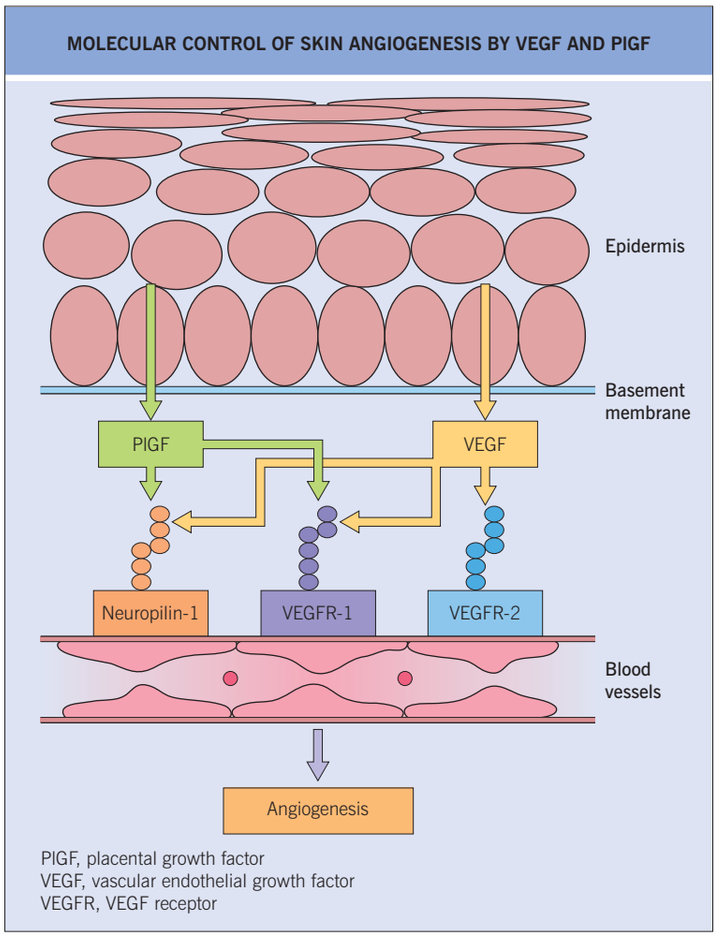

Fig. 102.8 Molecular control of skin angiogenesis by vascular endothelial growth factor (VEGF) and placental growth factor (PlGF).

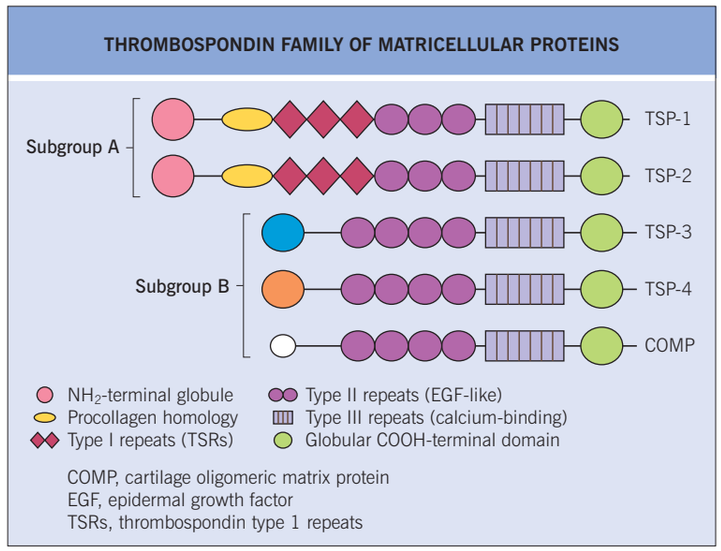

Fig. 102.9 The thrombospondin (TSP) family of matricellular proteins. TSP-1 and TSP-2 are potent endogenous inhibitors of skin angiogenesis.

hypoxia directly leads to upregulation of VEGF expression by epidermal keratinocytes, dermal fibroblasts and dermal endothelial cells. This mechanism is likely important in the induction of epidermal VEGF expression during wound healing and in areas of skin cancers adjacent to tumor necrosis.

Keratinocyte VEGF expression is also induced by several growth factors that mediate epidermal hyperplasia. In psoriasis, healing wounds and squamous cell carcinomas, TGF-α and other ligands of the epidermal growth factor receptor (EGFR) are released by suprabasal keratinocytes. In an autocrine loop, these growth factors induce hyperplasia of the epidermis. Simultaneously, they induce VEGF gene expression and protein secretion by epidermal keratinocytes, which lead to paracrine induction of angiogenesis through interaction with VEGF receptors on cutaneous microvessels (see Fig. 102.8). This mechanism links epidermal hyperplasia with increased vascularization, thereby providing enhanced vascular support to meet the enhanced nutritional needs of proliferating keratinocytes[13]. It also provides a molecular explanation for the reported association of thickened acanthotic epidermis with elongated capillary vessels[1]. Several other growth factors that stimulate keratinocyte proliferation, including keratinocyte growth factor (KGF), bFGF and hepatocyte growth factor (HGF), have recently joined the group of VEGF-inducing molecules.

The biologic importance of epidermis-derived VEGF for cutaneous angiogenesis *in vivo* has been confirmed in transgenic mouse models, using the keratin 14 promoter to selectively target expression of murine VEGF164 to basal epidermal keratinocytes and to keratinocytes of the outer root sheath of the hair follicle. VEGF transgenic mice are characterized by elongated and tortuous dermal blood vessels that are hyperpermeable to circulating plasma proteins[14]. VEGF-overexpressing mice are unable to down-regulate experimentally induced cutaneous inflammation and develop chronic inflammatory skin lesions that closely resemble those of human psoriasis[15].

The majority of human cancers studied thus far are characterized by overexpression of VEGF by tumor cells and by overexpression of VEGF receptors on tumor-associated blood vessels; blocking of VEGF function inhibits angiogenesis and suppresses tumor growth *in vivo*. However, in humans, the responses have ranged from none to modest (see below). VEGF also promotes skin carcinogenesis, since selective transgenic overexpression of VEGF in epidermal keratinocytes resulted in enhanced tumor development and metastasis[16].

Placental growth factor (PlGF) is a more recently identified member of the VEGF family of angiogenesis factors, with considerable sequence homology with VEGF. PlGF occurs in at least three different isoforms of 149 (PlGF-1), 170 (PlGF-2) and 221 (PlGF-3) amino acids. Both PlGF-1 and PlGF-2 are expressed in human skin. Similar to VEGF, the expression of PlGF is upregulated in cutaneous squamous cell carcinomas, in epidermal keratinocytes at the advancing wound edge, and in the hyperplastic psoriatic epidermis. In contrast to VEGF, PlGF does not activate VEGFR-2 (KDR), but selectively binds to VEGFR-1 (see Fig. 102.8). In addition, the heparin-binding isoform PlGF-2, but not PlGF-1, binds to the neuropilin-1 receptor. Evidence from genetic mouse models indicates that PlGF and VEGF act in synergy to induce both angiogenesis and vascular leakage and PlGF exerts proinflammatory effects[17,18]. A number of additional pro-angiogenic molecules are upregulated in angiogenic skin conditions, including interleukin-8, PDGF, FGF and angiogenic chemokines. However, the distinct contributions of each of these factors to the cutaneous vascular response remain to be characterized in more detail.

Thrombospondin (TSP)-1 and TSP-2 are major endogenous inhibitors of skin angiogenesis and are expressed in normal human skin. Thrombospondins are matricellular proteins that mediate interactions between extracellular matrix molecules and cellular integrin receptors (Fig. 102.9). TSP-1, a 450 kD modular, homotrimeric glycoprotein, contains a procollagen homology region, three properdin-like type I repeats, three epidermal growth factor-like repeats, and seven Ca^{2+}-binding repeats. TSP-1 is involved in a large number of biologic processes, including proliferation, migration and differentiation of various cell types; moreover, TSP-1 inhibits endothelial cell proliferation *in vitro* and angiogenesis *in vivo*. In normal human skin, TSP-1 is expressed by dermal cells and by epidermal keratinocytes, and it is deposited within the dermo-epidermal basement membrane zone, contributing to the barrier that prevents ingrowth of blood vessels into the epidermis. In contrast, TSP-1 expression is down-regulated in squamous cell carcinomas of the skin. Reintroduction of the *TSP-1* gene into squamous cell carcinomas inhibits tumor growth in mice, associated with inhibition of tumor angiogenesis and enhanced tumor cell necrosis[19]. The potential mechanisms by which TSP-1 inhibits skin angiogenesis include the induction of endothelial cell apoptosis through specific interactions with the endothelial CD36 receptor, the activation

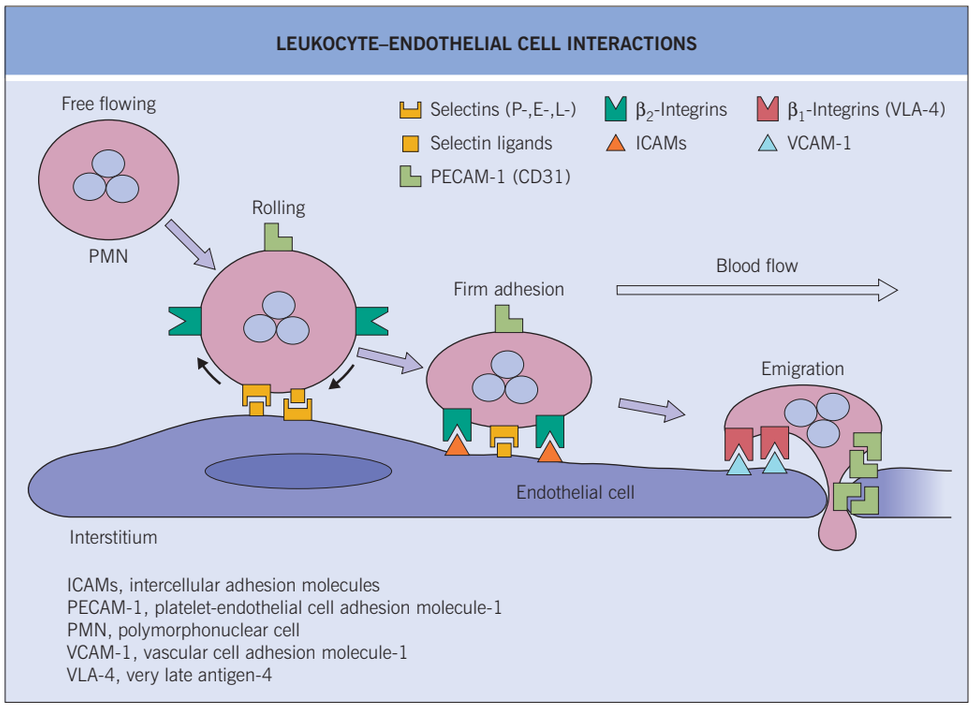

Fig. 102.10 The multistep process of leukocyte–endothelial cell interactions that leads to leukocyte recruitment into inflamed skin. Examples of selectin ligands on leukocytes are cutaneous lymphocyte-associated antigen (CLA) and P-selectin glycoprotein ligand (PSGL).

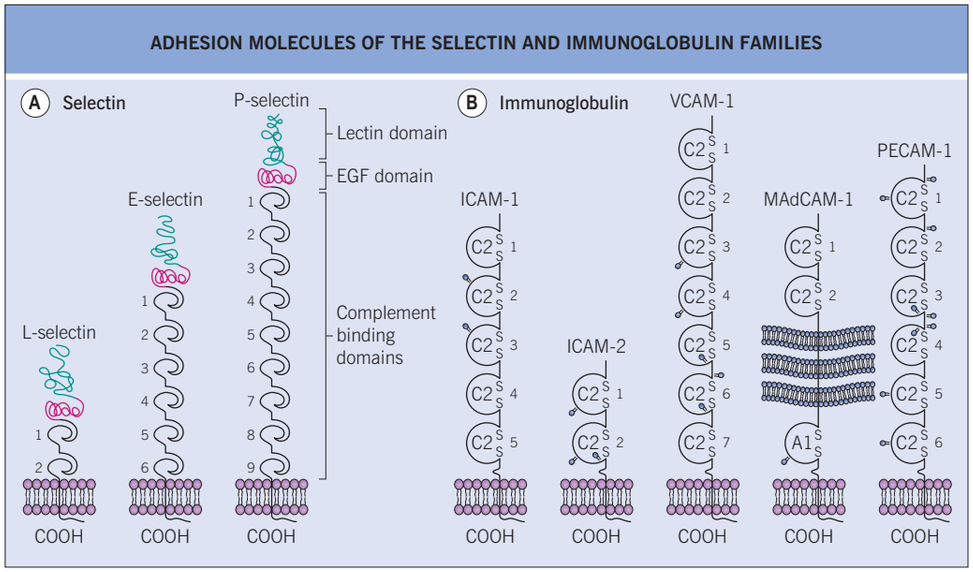

Fig. 102.11 Adhesion molecules of the selectin (A) and immunoglobulin (B) families. EGF, epidermal growth factor; MAdCAM, mucosal addressin cell adhesion molecule; ICAM, intercellular adhesion molecule; PECAM, platelet–endothelial cell adhesion molecule; VCAM, vascular cell adhesion molecule.

of latent TGF-β, and the inhibition of matrix metalloproteinase activity[19]. Overexpression of TSP-1 in the skin of transgenic mice results in impaired granulation tissue formation and wound vascularization, delayed and reduced skin carcinogenesis, and diminished photodamage induced by chronic UVB irradiation of the skin[20].

A second member of the thrombospondin family, TSP-2, is also expressed in normal human skin and acts as an endogenous inhibitor of angiogenesis. The expression of TSP-2 is down-regulated in epithelial squamous cell carcinoma cells, whereas a strong upregulation of TSP-2 is found in the mesenchymal stroma during skin carcinogenesis, representing a natural tumor defense mechanism[21]. Mice that are deficient in TSP-2 show increased skin vascularization, enhanced and prolonged inflammatory reactions, and enhanced skin carcinogenesis, confirming the important role of endogenous TSP-2 in the control of skin angiogenesis. Accordingly, targeted overexpression of TSP-2 within murine epidermis protects from skin cancer development and inhibits the growth of established skin cancers[19].

A number of additional endogenous inhibitors of angiogenesis are likely involved in the maintenance of normal vascular quiescence in the skin, most prominently interferons. Moreover, antiangiogenic activity has been reported for several cleavage products of molecules that are expressed in the vascular basement membrane, including fragments of collagens type IV (tumstatin), XV, and XVIII (endostatin).

Regulation of Leukocyte–Endothelial Cell Interactions

Accumulation of leukocytes in the skin is a prominent feature of acute and chronic inflammatory skin diseases and represents a rate-limiting step in the inflammatory response. Leukocyte recruitment is a multistep process that is controlled by the sequential activation of a number of adhesion molecules on both leukocytes and vascular endothelial cells, as well as by several inflammatory cytokines and chemokines. Predominantly, leukocyte extravasation occurs in the postcapillary venules of the skin that are particularly sensitive to the induction of adhesion molecules. As a first step, relatively weak adhesive leukocyte–endothelial cell interactions, involving distinct selectins and their ligands, result in the tethering and rolling of leukocytes on the vessel wall (Fig. 102.10). In a second step, leukocytes become firmly attached to the vessel wall, mainly mediated through the interaction of adhesion molecules of the immunoglobulin superfamily and their ligands. Finally, leukocytes migrate into the dermis through spaces between adjacent endothelial cells, involving interactions between junctional adhesion molecules. The molecular structure of the major adhesion molecules involved in leukocyte–endothelial cell interactions is shown in Figure 102.11, and the localization, ligand binding specificity, and function of each adhesion molecule are summarized in Table 102.2.

MAJOR ADHESION MOLECULES INVOLVED IN LEUKOCYTE–ENDOTHELIAL CELL INTERACTIONS: CELL-TYPE-SPECIFIC EXPRESSION, LIGANDS AND FUNCTION			
Adhesion molecule	**Cell type**	**Ligands**	**Function**
		INTEGRIN FAMILY	
LFA-1 (CD11a/CD18)	Leukocytes	ICAM-1, ICAM-2	Adhesion, emigration
Mac-1 (CD11b/CD18)	Granulocytes, monocytes	ICAM-1, iC3b	Adhesion, emigration
VLA-4 (CD49d/CD29)	Lymphocytes, monocytes, eosinophils, basophils	VCAM-1	Adhesion
		SELECTIN FAMILY	
E-selectin (CD62E)	Endothelial cells	L-selectin, CLA, SSEA-1	Rolling
P-selectin (CD62P)	Endothelial cells	L-selectin, PSGL-1	Rolling
L-selectin (CD62L)	Leukocytes	E-selectin, CD14, P-selectin, GlyCAM, MAdCAM	Rolling
		IMMUNOGLOBULIN SUPERGENE FAMILY	
ICAM-1 (CD54a)	Endothelial cells, monocytes	LFA-1, Mac-1, CD43	Adhesion, emigration
ICAM-2 (CD102)	Endothelial cells	LFA-1	Adhesion, emigration
VCAM-1 (CD106)	Endothelial cells	VLA-4	Adhesion
PECAM-1 (CD31)	Endothelial cells	PECAM-1	Adhesion, emigration

Table 102.2 Major adhesion molecules involved in leukocyte–endothelial cell interactions: cell-type-specific expression, ligands and function. CLA, cutaneous lymphocyte-associated antigen; Gly-CAM, glycosylation-dependent cell adhesion molecule; ICAM, intercellular adhesion molecule; LFA, lymphocyte function-associated antigen; MAdCAM, mucosal addressin cell adhesion molecule; PECAM, platelet–endothelial cell adhesion molecule; PSGL, P-selectin glycoprotein ligand; SSEA, stage-specific embryonic antigen; VCAM, vascular cell adhesion molecule; VLA, very late activation antigen.

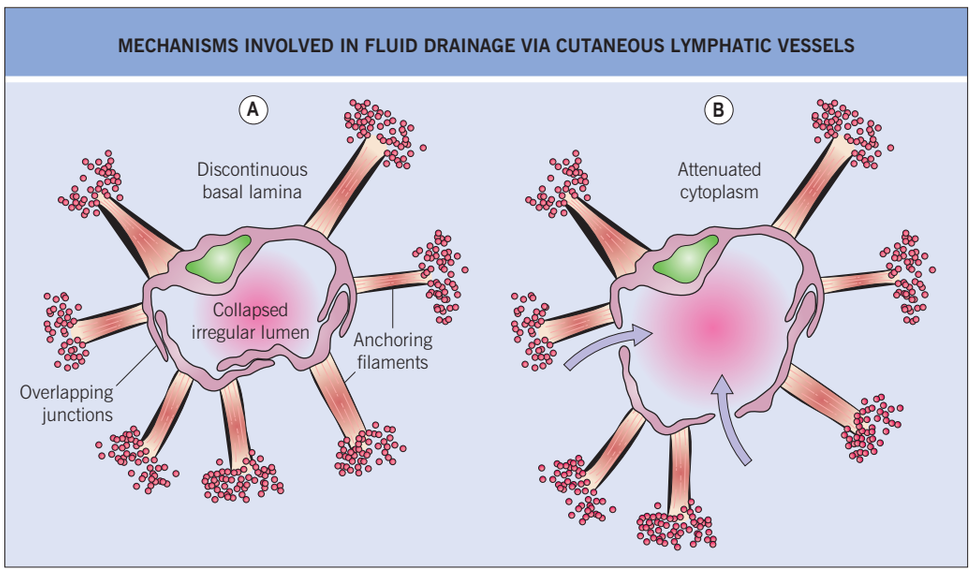

Fig. 102.12 Mechanisms involved in fluid drainage via cutaneous lymphatic vessels. A Normal skin. **B** Skin with increased interstitial fluid content.

STRUCTURE AND FUNCTION OF THE CUTANEOUS LYMPHATIC SYSTEM

Lymphatic vessels were first described in the seventeenth century by Gasparo Aselli as "lacteae venae" (milky veins). The cutaneous lymphatic system develops in parallel with the blood vascular system through a process termed lymphangiogenesis, and lymphatic vessels are not present in avascular structures such as epidermis, hair and nails[22]. The lymphatic system is composed of a vascular network of thin-walled capillaries that drain protein-rich lymph from the extracellular space and play a crucial role in the maintenance of normal tissue pressure. Lymphatic vessels also play an important role in mediating the trafficking of immune cells from the skin to the regional lymph nodes, and in the metastatic spread of cutaneous malignancies[22].

Lymphatic capillaries are lined by a continuous single-cell layer of overlapping endothelial cells and lack a continuous basement membrane. In initial lymphatics, overlapping flaps at the borders of oak leaf-shaped endothelial cells lack junctions at their tips but are anchored on the sides by discontinuous button-like junctions; the latter differ from the conventional, continuous, zipper-like junctions found in larger collecting lymphatics and blood vessels[23]. Lymph returns to the venous circulation via larger lymphatic collecting vessels, which contain a muscular and adventitial layer as well as numerous valves, and the thoracic duct.

The lymphatic vessels of the skin form two horizontal plexuses. The superficial plexus collects lymph from lymphatic capillaries that can extend into the dermal papillae and is located in close vicinity to the superficial cutaneous arterial plexus. Vertical lymphatic vessels connect the superficial plexus with the larger collecting vessels in the lower dermis and upper subcutis, whereas few lymphatics are found within the subcutis (see Fig. 102.1). The deep lymphatic vessels are located below the deep arterial system and contain valves to ensure unidirectional fluid transport.

The structure of the cutaneous lymphatics is dependent on the structure of the skin at a particular site and can vary significantly. Lymphatic vessels have a regular, uniform shape where the skin is firm and thick, whereas the shapes are more variable in regions where the skin is thin and loose. Certain areas, such as the fingers, the palms and soles, the scrotum and the foreskin, appear to have a more abundant lymphatic network.

Lymphatic capillaries respond to increased tissue fluid content by widening their lumina (Fig. 102.12), an action mediated by anchoring

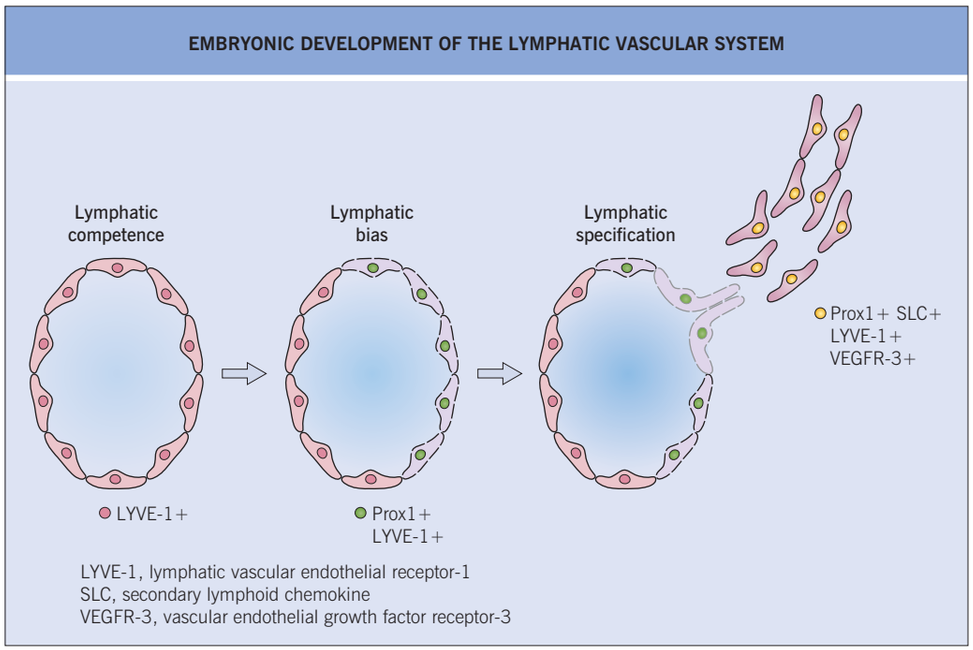

Fig. 102.13 Embryonic development of the lymphatic vascular system.

filaments that connect the lymphatic endothelial cells with the surrounding interstitium. In normal skin, the majority of lymphatic vessels are collapsed. Whereas elevation of the interstitial pressure up to + 2 mmHg results in distention of lymphatic vessels and in increased lymph flow, higher interstitial fluid pressure results in edema formation. The detection of enlarged lymphatics in the skin, however, does not allow predictions about their function, because overextended lymphatics can be dysfunctional, as in some types of lymphedema.

The first concept of lymphatic development was hypothesized by Florence Sabin, who proposed, based upon ink injection experiments, that isolated primitive lymph sacs originate from endothelial cells that bud from veins during early development. The peripheral lymphatic system originates from the primary lymph sacs and spreads by endothelial sprouting into the surrounding tissues and organs, where local capillaries are formed. As an alternative, it has been proposed that the primary lymph sacs arise in the mesenchyme, independent of the veins, and secondarily establish venous connections. Recent experimental evidence has supported the venous origin of the lymphatic system in mammals. The homeobox gene *Prox1* is a specific marker for lymphatic endothelial cells and is first expressed, during embryonic development, in a polarized manner by a subset of venous endothelial cells that consequently bud off from the cardinal veins, migrate through the tissues, and finally form lymphatic vessels (Fig. 102.13). Of note, Prox1 deficiency results in complete absence of a lymphatic system in mice, among other defects[24], and Prox1 activity is needed to maintain the lymphatic vessel phenotype after birth[25].

Until recently, studies of the lymphatic system were hampered by the lack of specific markers that reliably distinguish lymphatic from blood vascular endothelial cells. The endothelial marker PECAM-1 (platelet–endothelial cell adhesion molecule-1, CD31) is expressed by both blood vessel and lymphatic endothelial cells, although the expression levels are lower in lymphatics. Because of the absence or only rudimentary formation of a basement membrane, lymphatic vessels can be visualized by differential immunostaining for both CD31 and basement membrane components, such as collagen types IV and XVIII or laminin. Similarly, double stains for CD31 plus either the specific blood vascular marker PAL-E (only detectable on frozen sections; see Fig. 102.3) or the blood vascular marker CD34 can be used to specifically detect lymphatic vessels in the skin.

More recently, several new markers have been identified that are predominantly expressed by lymphatic endothelial cells in the skin (Table 102.3)[22]. *VEGFR-3* (vascular endothelial growth factor receptor-3, Flt-4) is expressed on lymphatic vessels in normal skin and serves as a receptor for the lymphangiogenesis factors VEGF-C and VEGF-D (Fig. 102.14). In addition, *podoplanin*, a surface glycoprotein, is a novel marker for the cutaneous lymphatic vasculature. The antibody D2-40 recognizes podoplanin and reliably and specifically stains lymphatic vessels (but not blood vessels) in normal and diseased human skin[26]. Of note, podoplanin deficiency results in congenital lymphedema formation as well as abnormal connections between lymphatic and blood vessels in mice[27,28].

The *lymphatic vascular endothelial hyaluronan receptor* (LYVE-1), a CD44 homologue, has been recently identified as a specific cell surface protein of lymphatic endothelial cells[22]. Although some specialized blood vascular endothelial cells that are involved in hyaluronic acid metabolism (e.g. sinusoidal endothelial cells in the liver, vascular endothelium in the lung) also express LYVE-1, its expression is highly specific for lymphatics in most organs, including the skin (Fig. 102.15). One has to keep in mind, however, that several of the markers discussed here, including

MARKERS FOR LYMPHATICS AND FOR BLOOD VESSELS

Marker	Lymphatics	Blood vessels
CD31 (PECAM-1)	+	++
CD34	–	+
PAL-E	–	+
Collagen type IV	–	+
Collagen type XVIII	–	+
Laminin	(+)	++
VEGFR-1	–	+
VEGFR-2	+	+
VEGFR-3	+	–
Podoplanin	++	–
LYVE-1	++	–
SLC/CCL21	+	–
Prox1	++	–

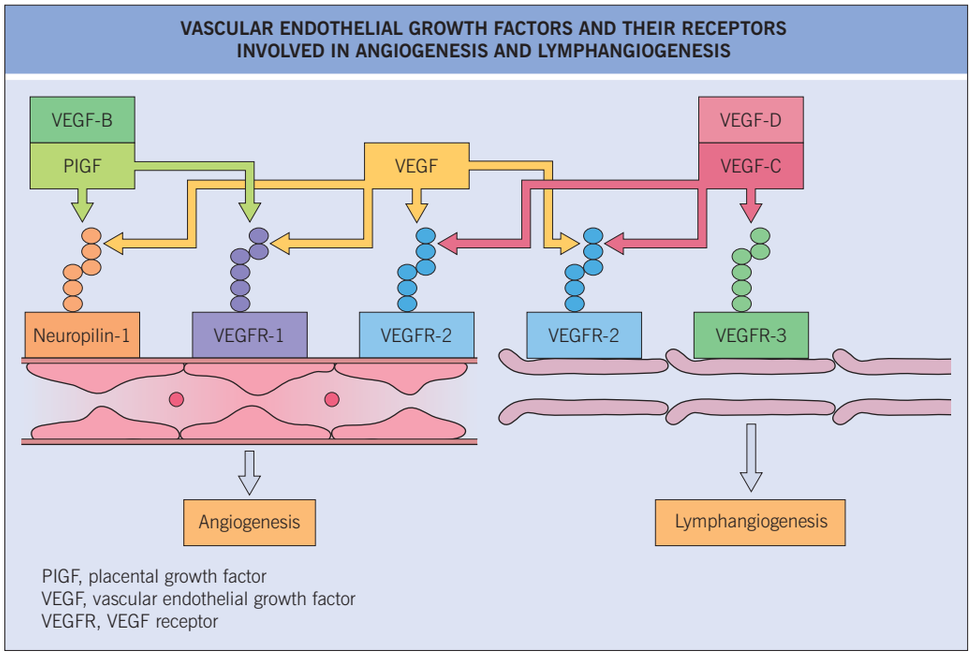

Fig. 102.14 Vascular endothelial growth factors and their receptors involved in angiogenesis and lymphangiogenesis. VEGF is also known as VEGF-A. Heterozygous inactivating missense mutations of the gene encoding VEGFR-3, the receptor for the lymphangiogenesis factors VEGF-C and VEGF-D, have been found in families affected by primary lymphedema (Milroy disease), which is characterized by chronic swelling of the extremities.

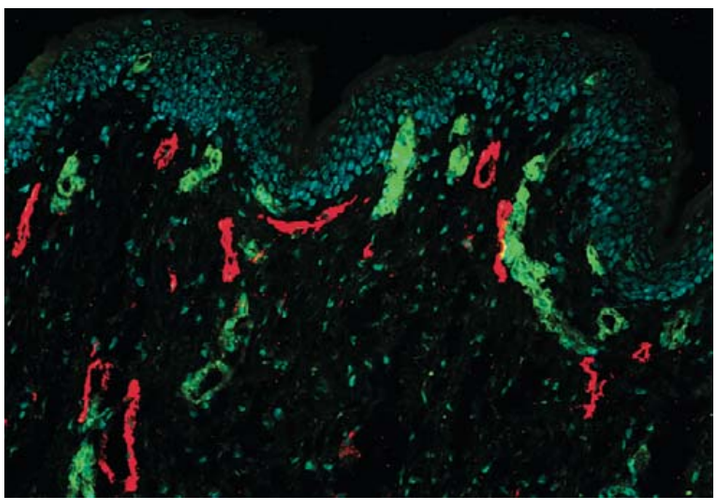

Fig. 102.15 Specific immunofluorescence staining of CD31-positive blood vessels (green) that are LYVE-1-negative and of CD31-positive/LYVE-1-positive lymphatic vessels (red) in human foreskin. Nuclei are stained blue.

VEGFR-3 and LYVE-1, can also be expressed by distinct subsets of leukocytes such as dermal dendritic cells and/or macrophages.

Secondary lymphoid chemokine (SLC; also termed CCL21) is specifically produced by lymphatic endothelial cells in the skin and binds to the CC chemokine receptor-7 (CCR-7) on dendritic cells and lymphocytes[22]. It serves an important role as a guidance molecule for the migration of dendritic and other cells via the lymphatics to the lymph nodes. Expression of CCR-7 in human melanoma cells resulted in increased lymph node metastasis of experimental melanomas in mice, suggesting that tumor cells may be able to take advantage of natural immune response mechanisms to further their metastatic spread[29]. The *chemokine receptor D6* – a receptor for several pro-inflammatory chemokines – has also been detected on lymphatic vessels, but not on blood vessels. Lastly, the homeobox gene *Prox1* is the earliest marker for lymphatic endothelial cells during embryonic development and its specific expression is maintained by cutaneous lymphatic endothelial cells in the adult. Prox1 appears to be the most specific marker for lymphatic vascular differentiation in the skin[22].

Until recently, the molecules regulating growth and function of lymphatic vessels have remained unknown. Over the past decade, two new members of the VEGF family of angiogenesis factors have been identified that are distinguished by their capacity to stimulate lymphangiogenesis. Both VEGF-C and VEGF-D activate the receptor tyrosine kinase VEGFR-3 (Flt-4) on lymphatic endothelial cells and, after cleavage, the receptor tyrosine kinase VEGFR-2 (KDR) that is expressed on blood vessels and lymphatic endothelium (see Fig. 102.14). Transgenic mice with targeted overexpression of either VEGF-C or VEGF-D in the skin were characterized by hyperplastic cutaneous lymphatic vessels, whereas no major abnormalities of blood vessels were found[30]. Conversely, blockade of both VEGF-C and VEGF-D by transgenic overexpression of a soluble VEGFR-3 in the skin has been shown to result in absence of a cutaneous lymphatic system and in the development of lymphedema[31]. Recently, additional lymphangiogenesis factors have been identified, including VEGF-A, angiopoietin-1, bFGF and hepatocyte growth factor (HGF)[32].

RELATED DISEASES

Angiogenesis is a characteristic feature of tissue repair and of numerous diseases, including inflammatory skin disorders such as psoriasis and contact dermatitis, cutaneous neoplasias including squamous cell carcinoma, melanoma and Kaposi sarcoma, and infantile hemangiomas. Moreover, several other diseases are characterized by prominent visible blood vessels, including rosacea and basal cell carcinomas. Genetic mutations that lead to dysfunction of the vascular Tie-2 receptor have been associated with vascular malformations (see Ch. 104), and mutations in the genes that encode the low-affinity TGF-β receptor endoglin and activin receptor-like kinase (ALK)-1 lead to the formation of vascular malformations in patients with hereditary hemorrhagic telangiectasia types I and II. Lastly, VEGF-C has been identified as a growth factor for HIV-associated Kaposi sarcomas that strongly express Flt-4/VEGFR-3, and infection of blood vascular endothelial cells with the Kaposi sarcoma-associated herpesvirus leads to their genetic reprogramming and to the adoption of a lymphatic endothelial cell phenotype[33].

Impairment of lymphatic function leads to the development of a number of diseases, most prominently to lymphedema of the skin, with associated impaired immune function and fibrotic changes[22,34]. Heterozygous inactivating missense mutations of the gene encoding VEGFR-3, the receptor for the lymphangiogenesis factors VEGF-C and VEGF-D, have been found in families affected by primary lymphedema (Milroy disease), which is characterized by chronic swelling of the extremities[35]. *VEGFR-3* mutations were also found in *Chy* mutant mice, the murine equivalent of Milroy disease, and both virus-mediated VEGF-C gene therapy and delivery of VEGF-C protein have been shown to induce

generation of functional lymphatic vessels in injured skin, indicating possible novel therapeutic strategies for congenital or acquired lymphedemas[30].

In lymphedema–distichiasis, lymphatic vessel function fails because of mutations affecting the function of the forkhead transcription factor FOXC2[36], and mutations in the transcription factor gene *SOX18* underlie recessive and dominant forms of hypotrichosis–lymphedema–telangiectasia[37]. Finally, tumor-associated lymphangiogenesis has been found to promote sentinel lymph node metastasis and to reduce overall survival in human melanomas and in a number of other carcinomas[38,39].

In summary, the recent progress in our understanding of the molecular mechanisms that control blood vascular and lymphatic development and function have led to novel insights into the pathogenesis of a number of skin diseases with vascular involvement, as well as to the development of novel therapeutic approaches to treat these diseases.

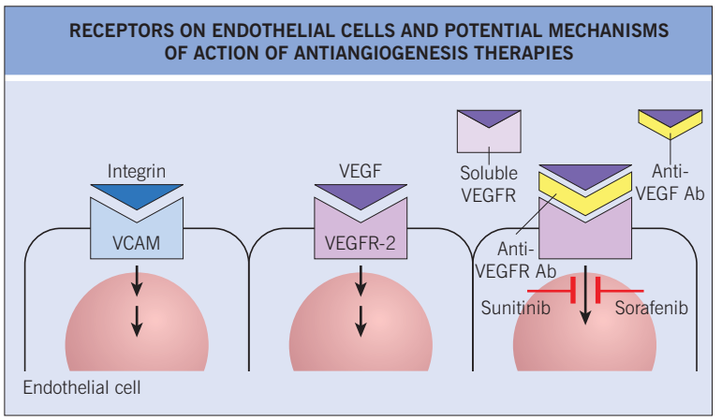

Fig. 102.16 Receptors on endothelial cells and potential mechanisms of action of antiangiogenesis therapies.

CURRENT TRENDS IN ANTIANGIOGENESIS

A large number of experimental studies have shown that the induction of angiogenesis is essential for tumor progression and that inhibition of blood vessel growth inhibits malignant tumor growth and metastasis in mice. Based upon these findings, inhibition of tumor angiogenesis has become a main target of anticancer strategies[40]. Despite the identification of several distinct tumor angiogenesis factors, including interleukin-8 and bFGF, the majority of current antitumor angiogenesis therapies are aimed at inhibiting the bioavailability or the receptor signaling of VEGF-A, generally considered to represent the major angiogenic factor in the majority of solid tumors.

The anti-VEGF-A antibody bevacizumab (Avastin®) – combined with chemotherapy – has shown modest beneficial effects in patients with metastatic colon cancer. However, in metastatic breast cancer, there are several studies that have failed to demonstrate a significant survival benefit with bevacizumab. Side effects include gastrointestinal perforation, delayed wound healing and hemorrhage (e.g. gastrointestinal, CNS). Additional clinical trials in human cancer patients are currently investigating the anticancer activity of VEGF receptor-blocking antibodies, PlGF-blocking antibodies and soluble VEGF receptor molecules, as well as small molecule tyrosine kinase inhibitors that block VEGF receptor signaling (Fig. 102.16).

Endogenous inhibitors of angiogenesis, including thrombospondin-1-derived peptides, are also under investigation in clinical trials. Several drugs that are already in clinical use have been found to exert mild antiangiogenic activities, including thalidomide and interferon-α and -β. The first two agents, for example, are used as second-line therapy for extensive Kaposi sarcoma. "Metronomic" or low-dose chemotherapy (e.g. with paclitaxel or vinblastine) has been proposed to exert antiangiogenic effects, and experimental tumor studies in mice have shown additive or synergistic effects of low-dose chemotherapy combined with angiogenesis inhibitors[41]. Unfortunately, there appears to be a number of potential mechanisms that lead to resistance to antiangiogenic therapy.

The recent discovery of active tumor- and lymph node-associated lymphangiogenesis, and its correlation with enhanced cancer metastasis, suggests that, at least in some types of cancer, anti-lymphangiogenic therapy might provide a novel strategy[5,38,39,42]. Moreover, *in vivo* imaging of tumor-induced lymphangiogenesis might provide a sensitive method for the early detection of lymph node metastases.

Although the efficacy of antiangiogenic therapy in the treatment of advanced melanoma or cutaneous squamous cell carcinoma still remains unclear, an increasing number of non-malignant skin diseases have emerged as potential targets for treatments aimed at vascular endothelium. For example, prior to the discovery of the efficacy of propranolol, steroid-unresponsive infantile hemangiomas were treated with interferon-α; additional vascular lesions that might respond to antiangiogenic treatment include angiokeratomas and kaposiform hemangioendotheliomas. Psoriasis is characterized by vascular enlargement and activation, and recent experimental data suggest that blockade of VEGF might represent a novel therapeutic strategy[43]. In fact, pulsed dye laser therapy has been used to effectively treat psoriatic skin lesions, predominantly by targeting cutaneous blood vessels. Similarly, telangiectasias, in particular in rosacea, would appear to represent prime targets for antiangiogenic therapy.

Blockade of angiogenesis and vascular activation might also represent a novel approach for preventing UVB-induced skin damage[44] as well as multistep skin carcinogenesis, indicating the potential use of angiogenesis inhibitors for chemoprevention. Of note, in solid organ transplant recipients, substituting sirolimus (rapamycin; an mTOR inhibitor) for cyclosporine has led to improvement of immunosuppression-associated Kaposi sarcoma, and in those transplant patients with multiple basal cell and squamous cell carcinomas, use of sirolimus may lead to a decrease in their formation.

Because systemic inhibition of angiogenesis might cause considerable side effects, including hypertension, proteinuria and interference with reproductive functions, the challenge and opportunity for dermatology will be to develop topical angiogenesis inhibitors that will be able to penetrate the skin but not reach potentially toxic systemic levels. Recent experimental data indicate the feasibility of this approach[45].

In addition to these potential dermatologic applications, antiangiogenesis has become a promising new therapeutic approach in ophthalmology. Diabetes mellitus is frequently associated with intraocular neovascularization, and new blood vessel growth is the principal cause of visual loss in the wet form of age-related macular degeneration, the most common cause of blindness in Western countries. Intravitreal injection of VEGF inhibitors has been successfully used to prevent progression of this disease and has been approved for clinical use by the Food and Drug Administration (FDA). Other potential therapeutic applications of antiangiogenesis include diseases of the female reproductive tract, such as polycystic ovary syndrome, endometriosis and ovarian hyperstimulation syndrome. The potential side effects of chronic, systemic angiogenesis inhibition are at present not well characterized and, therefore, it is difficult to predict whether systemic antiangiogenic therapies will be used for non-malignant conditions in the future.

Infantile Hemangiomas 103

Anita N Haggstrom and Maria C Garzon

Synonyms: ■ Hemangioma of infancy ■ Hemangioma

Key features

- The most common soft tissue tumor of infancy
- Benign endothelial cell neoplasms
- Demonstrate a typical growth pattern characterized by early proliferation followed by gradual, spontaneous involution
- Distinct histopathologic and immunohistochemical features that differentiate them from other vascular anomalies in children
- May be associated with extracutaneous findings when occurring at certain anatomic sites, e.g. the face, neck and lumbosacral area
- Treatment choice, if any, depends on multiple factors and must be tailored to each individual patient

INTRODUCTION

Infantile hemangiomas are benign proliferations of endothelial tissue and represent the most common tumors arising in the neonatal period. They are characterized by significant growth during the first several months of life, followed by slow spontaneous involution over the ensuing years. This natural history differentiates them from vascular malformations (Table 103.1; see Fig. 104.1). During the past decade, elucidation of mechanisms governing growth and regulatory pathways of normal vascular development has led to new insights into the pathophysiology of infantile hemangiomas.

HISTORY

The terms "infantile hemangioma" and "hemangioma of infancy" are now used to describe a specific group of vascular tumors that arise during infancy and demonstrate characteristic clinical and histologic features. Infantile hemangiomas have been recognized in the medical literature for centuries, and they have been given various names such as *nevus maternus*, *angioma simplex*, *angioma cavernosum*, *angiodysplasia*, *strawberry nevus* and *capillary hemangioma*[1]. Despite early attempts to make distinctions among different types of vascular lesions of infancy, the term "hemangioma" was frequently applied in a generic manner to a wide variety of congenital and acquired vascular anomalies including vascular malformations, without consideration of differences in their biologic behavior.

One of the most important developments in the study of vascular "birthmarks" (including lesions that become apparent during early infancy) was the suggestion and acceptance of a biologic classification scheme. In 1982, Mulliken and Glowacki[2] first proposed that vascular birthmarks should be categorized according to their biologic and clinical behavior. The International Society for the Study of Vascular Anomalies modified this classification system slightly in 1996 (Table 103.2)[3].

Under this organization scheme, vascular birthmarks are divided into two broad categories: *vascular tumors* and *vascular malformations*. Vascular tumors are characterized by cellular proliferation and include infantile hemangiomas, the later-onset pyogenic granuloma, and less common neoplasms that may arise during infancy or early childhood, including tufted angioma and kaposiform hemangioendothelioma (see Table 103.2; see Ch. 114). Vascular malformations, on the other hand, are believed to represent errors in vascular morphogenesis. They are frequently noted during the neonatal period, but, unlike infantile hemangiomas, they do not rapidly proliferate in the first year of life nor do they resolve spontaneously (see Table 103.1). Vascular malformations are characterized by the type of dysplastic vessels they contain and their flow properties (see Ch. 104).

Adopting specific terminology has allowed investigators to better categorize vascular birthmarks and predict their clinical behavior and prognosis. The biologic classification was expanded to include histopathologic and immunohistochemical features that aid in distinguishing infantile hemangiomas from other vascular tumors (see Table 103.1). Despite the wide acceptance of the biologic classification scheme, nosologic confusion still persists in the medical community as well as in the literature. Even within the past decade, a review of genetic reference texts found the term "hemangioma" to be used imprecisely with great frequency[4].

EPIDEMIOLOGY

Infantile hemangiomas arise during the first year of life and are the most common tumor of infancy. They develop in 4–5% of infants, with the majority of lesions noted within the first several weeks of life[5]. Infantile hemangiomas may occur more commonly in Caucasian infants than in other racial groups, but this predilection has not been consistently observed[6]. This vascular tumor is clearly more common in girls than in boys, with a female : male ratio of 2–5 : 1 overall[7–9] and approximately 7 : 1 for severe, complicated lesions[10]. Infantile hemangiomas also develop more frequently in premature infants, affecting 23–30% of infants with birthweights less than 1000 g and 15% of those with birthweights between 1000 and 1500 g[6,11]. There is a threefold increased incidence in infants born following chorionic villus sampling compared to those born following amniocentesis or without a history of prenatal instrumentation[12]. A multicenter, prospective cohort study of over 1000 infants from the US with infantile hemangiomas found several important epidemiologic and demographic differences compared to US National Vital Statistics data for children born in the same period. Infants with hemangiomas were more likely to be female, Caucasian, low birthweight, premature, products of multiple gestation pregnancies, and born to older mothers[13].

Infantile hemangiomas typically arise sporadically, although Margileth and Museles[14] reported a 10% incidence of familial cases in their 1965 series. The frequent occurrence of hemangiomas in the general population makes it difficult to assess the true familial incidence. Autosomal dominant segregation of infantile hemangiomas was described in six kindreds, some of which included members who also had vascular malformations, and genetic mapping was performed (see below)[15,16].

PATHOGENESIS

Infantile hemangiomas represent localized or regional areas of abnormal vascular development and proliferation. Several hypotheses have been proposed to explain their pathogenesis, but no single theory accounts for all of their features. It is likely that several mechanisms under the control of multiple genes, in addition to local effects, play a role in the development, growth and involution of hemangiomas.

Hemangioma Endothelial Cells: Origin, Defects and Signaling

Recent evidence suggests that hemangiomas may be derived from endothelial progenitor cells or multipotent stem cells[17–19]. This implies

VASCULAR "BIRTHMARKS" IN CHILDREN		
	Infantile hemangioma	**Vascular malformation**
Clinical	• Usually absent at birth or subtle precursor lesion present (only occasionally well formed) • Rapid proliferation • Spontaneous involution over years	• Usually evident at birth • Slow expansion, proportionate with growth • Persists into adulthood
Epidemiology	More common in: • girls (2–5 : 1) • premature and/or low-birthweight infants • infants whose mothers were older or who underwent chorionic villus sampling	No gender or gestation predilection
Pathology	**Proliferating**: endothelial cell hyperplasia, lobule formation, mast cells, prominent basement membrane **Involuting**: fibrofatty tissue replacement, decreased mast cells when fully involuted	Dependent upon type, often irregular vascular channels
Immunohistochemistry	Positive for GLUT-1, Lewis Y antigen, merosin and FcγRII	Negative for GLUT-1, Lewis Y antigen, merosin and FcγRII

Table 103.1 Vascular "birthmarks" in children.

BIOLOGIC CLASSIFICATION OF VASCULAR BIRTHMARKS
VASCULAR TUMORS
• Infantile hemangioma • Congenital hemangioma (rapidly involuting or non-involuting variants) • Kaposiform hemangioendothelioma • Tufted angioma • Pyogenic granuloma • Congenital hemangiopericytoma • Spindle cell hemangioma
VASCULAR MALFORMATIONS
• Capillary malformations (slow flow) • Venous malformations (slow flow) – Typical – With glomus cells • Lymphatic malformations (slow flow) – Macrocystic – Microcystic • Arteriovenous malformations (fast flow) • Combined malformations (slow and/or fast flow)

Table 103.2 Biologic classification of vascular birthmarks.

that vasculogenesis (*de novo* formation of vessels from progenitor/stem cells) as well as angiogenesis (formation of new vessels from existing ones) might occur during hemangioma formation.

Hemangiomas have been shown to represent clonal expansions of endothelial cells[20], and *somatic* mutations in genes that encode proteins involved in vascular endothelial growth factor (VEGF) signaling (e.g. VEGF receptors [VEGFRs]; see Ch. 102) and other pathways that affect vascular development (e.g. dual-specificity phosphatase 5 [DUSP5]) have been identified in hemangioma tissue[18,21,22]. Heterozygous *germline* mutations in *VEGFR2* and *TEM8* (encodes an integrin-like receptor in endothelial cells) genes have also been found in a small subset of hemangioma patients and may represent hemangioma predisposition factors (Fig. 103.1)[23]. In addition, familial hemangiomas in several kindreds have been linked to chromosome 5q[16] and loss of heterozygosity (see Ch. 54) of 5q has been noted in sporadic hemangiomas[24], suggesting that gene(s) at this locus may be involved in hemangioma formation.

Recent studies have confirmed the importance of the VEGF pathway in infantile hemangiomas and provided evidence of a shift from VEGFR1 (which binds VEGF without transmitting a signal) to VEGFR2 (which stimulates endothelial cell proliferation upon VEGF binding) expression in hemangioma endothelial cells (see Fig. 103.1)[23]. Hemangiomas also have increased expression of the endothelial cell-specific Tie-2 tyrosine kinase receptor and dysregulated production of angiopoietin-2 (see Ch. 102)[25].

Placental Hypothesis

The shared immunohistochemical phenotype of hemangioma cells and human placental endothelium implies that hemangioma cells are either of placental origin (e.g. via embolization) or undergo differentiation toward a placental microvascular phenotype. North and co-workers[26,27] reported that glucose transporter protein-1 (GLUT-1) is expressed by infantile hemangiomas during all phases of their development (proliferating, involuting, involuted) as well as by the placenta, but not by other vascular tumors or malformations. Other placenta-associated vascular antigens, including merosin, FcγRII and Lewis Y antigen, are present in hemangioma specimens and placental chorionic villi but absent in microvessels of the normal skin and subcutis[27]. However, hemangiomas do not express placental *trophoblastic* markers (e.g. human placental lactogen)[28].

Hypoxia and Other Extrinsic Factors

A role for hypoxia in the pathogenesis of hemangiomas is supported by their association with hypoxic placental changes, prematurity/low birthweight (often caused by placental insufficiency), retinopathy of prematurity (GLUT-1-positive, hypoxia-induced neovascularization) and regional arterial insufficiency (e.g. PHACE[S] and LUMBAR syndromes; see below)[29,30]. Hypoxia upregulates expression of GLUT-1 and VEGF, leading to mobilization of endothelial progenitor cells. Moreover, the combination of hypoxia and estrogen (pertinent considering the predilection of hemangiomas for female infants) has a synergistic effect on hemangioma endothelial cell proliferation *in vitro*[29].

Other cell types in the hemangioma's environment, including monocytes, fibroblasts, mesenchymal cells, adipocytes and mast cells, can influence endothelial cell proliferation and may have a role in hemangioma formation and/or involution.

Factors Influencing Natural History

Hemangiomas have been studied during different phases of their clinical course to gain insights into the mechanisms that govern their growth and involution. In the proliferative phase, hemangiomas express markers of proliferation (e.g. proliferating cell nuclear antigen [PCNA]) and increased levels of pro-angiogenic molecules such as VEGF and basic fibroblast growth factor (bFGF)[31–33]. In addition, other angiogenesis mediators, proteins found within the perivascular extracellular matrix, and enzymes involved in matrix remodeling are produced at higher levels during proliferation (Table 103.3)[31,34–41].

The factors that govern the transition of hemangiomas from proliferation to involution, which is associated with decreased production of pro-angiogenic factors, are not fully understood[31,36,37]. Indoleamine 2,3-dioxygenase (IDO), an enzyme that degrades tryptophan and (through tryptophan starvation and immunosuppressive effects of its metabolites) inhibits T-cell activation, is highly expressed by macrophages, dendritic cells, the placenta (where it is believed to protect the fetus from rejection) and *proliferating* hemangiomas. It has been hypothesized that increased IDO activity protects proliferating hemangiomas from immune surveillance, and subsequent downregulation of IDO production may therefore have a role in involution[18,42]. Increased expression of angiogenesis inhibitors and apoptosis promoters has been observed in involuting hemangiomas (see Table 103.3)[31,43–46]. Loss of DUSP5 function increases apoptosis in human umbilical vein endothelial cells, leading to speculation that somatic mutations in this gene (recently found in hemangiomas; see above) may contribute to hemangioma involution as well as proliferation[22].

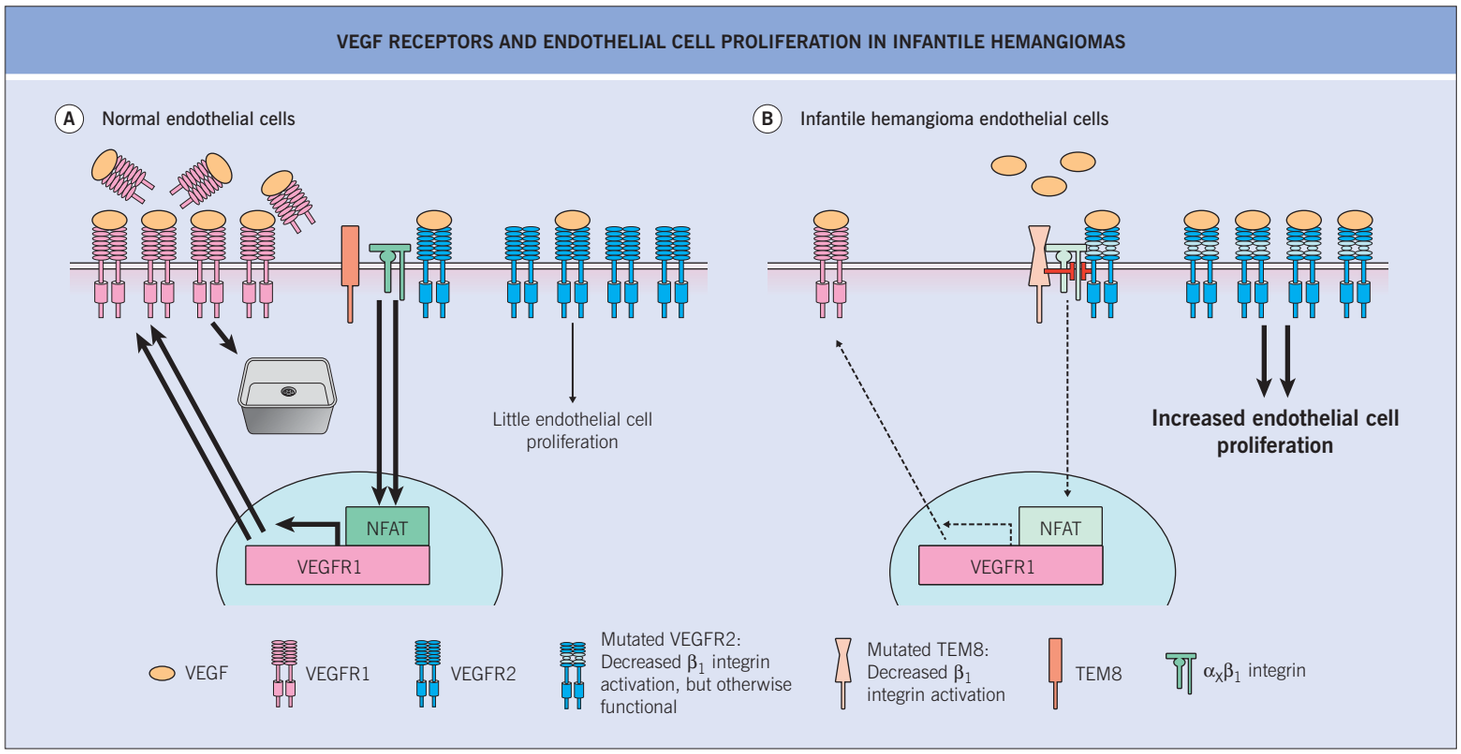

Fig. 103.1 VEGF receptors and endothelial cell proliferation in infantile hemangiomas. A In normal endothelial cells, β_1-integrin (which forms a complex with the integrin-like receptor TEM8 and VEGFR2) increases transcription of VEGFR1 via activation of NFAT. Binding of VEGF to VEGFR2 stimulates endothelial cell proliferation, but VEGF binding to VEGFR1 (which exists in soluble and transmembrane forms) is of higher affinity and does not transmit a signal. VEGFR1 thereby acts as a VEGF "sink" or decoy receptor that decreases the amount of VEGF available to activate VEGFR2. **B** Hemangioma endothelial cells have decreased β_1-integrin activity and, as a consequence, markedly reduced expression of VEGFR1. This leads to increased VEGF-dependent activation of VEGFR2 and enhanced endothelial cell proliferation. In a subset of hemangioma patients, the low β_1-integrin activity can be explained by a germline mutation in the *VEGFR2* or *TEM8* gene; such mutations result in increased interactions among β_1-integrin, TEM8 and VEGFR2 as well as inhibition of β_1-integrin function. NFAT, nuclear factor of activated T cells; TEM8, tumor endothelial marker 8; VEGF, vascular endothelial growth factor; VEGFR, VEGF receptor.

MARKERS OF PROLIFERATING AND INVOLUTING HEMANGIOMAS

PROLIFERATIVE PHASE

- General markers of proliferation, e.g. proliferating cell nuclear antigen (PCNA)
- Vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF)*,†
- Monocyte chemoattractant protein-1†
- Adhesion molecules on endothelial cells – E-selectin, ICAM-3†
- Matrix metalloproteinase-2 and -9 (extracellular matrix remodeling)‡
- Vitronectin (found in the perivascular extracellular matrix)
- Indoleamine 2,3-dioxygenase (inhibits T-cell activation)
- Apoptosis inhibitors

INVOLUTION

- Interferon-regulated gene products (interferons are known to inhibit angiogenesis)
- bFGF (early in involution)
- Increased mast cells (early in involution)
- Tissue inhibitor of matrix metalloproteinases-1 (inhibits angiogenesis)
- Apoptosis promoters

*VEGF and bFGF (but not the angiogenesis inhibitor interferon-β) are also expressed by the hyperplastic epidermis overlying proliferating hemangiomas.
†Angiogenesis mediators.
‡Increased levels also found in blood and urine.

Table 103.3 Markers of proliferating and involuting hemangiomas. Lymphatic vessel endothelial hyaluronan receptor (LYVE)-1 has been identified in perivascular dendritic cells in hemangiomas of various stages. ICAM, intercellular adhesion molecule.

CLINICAL FEATURES

Presentation

Most infantile hemangiomas have a typical presentation and growth pattern. Lesions usually become apparent during the first few weeks of life, although the proportion of hemangiomas that were "congenital" in published series has ranged from 15% to 60%[9,47]. There are several distinct subgroups of hemangiomas evident in the immediate newborn period: (1) infantile hemangioma precursor lesions; (2) occasional typical infantile hemangiomas that are relatively well formed at birth and subsequently demonstrate a natural history (variable proliferation then slow involution) similar to those that arise later; and (3) an uncommon subset of congenital hemangiomas that demonstrate intrauterine proliferation, little if any postnatal growth, and then either early rapid involution in postnatal life or minimal to absent involution. The third group includes the rapidly involuting congenital hemangioma (RICH) and the non-involuting congenital hemangioma (NICH), which are considered as separate entities from infantile hemangiomas and are discussed below.

Reports of significant numbers of hemangiomas being noted at birth probably included precursor lesions. Telangiectasias surrounded by a vasoconstricted halo, areas of pallor, pink macules, and blue bruise-like patches are the most common precursor lesions (Fig. 103.2). Pink macules and patches may mimic a capillary malformation, and repeat examination over the ensuing weeks is essential to determine the diagnosis (Fig. 103.3). Rarely, an area of ulceration on the lip or perineum may herald the onset of an infantile hemangioma, and in a newborn infant these lesions may be confused with bacterial or viral infections. Biopsy of the ulcerated lesion may not be clearly diagnostic of an infantile hemangioma, but continued observation of the site usually clarifies the diagnosis[48].

Hemangiomas may occur anywhere on the skin and mucosal surfaces, with approximately 50% of those in infants who present to a pediatric dermatologist being located on the head and neck[13]. The clinical appearance of a hemangioma is determined by its location within the skin and subcutaneous tissues. Superficial hemangiomas are situated in the superficial dermis and are bright red in color during their proliferating phase. The surface is finely lobulated, and the term "strawberry hemangioma" has been used to describe them[2]. The majority of superficial hemangiomas are focal lesions (Fig. 103.4A,B). Less common

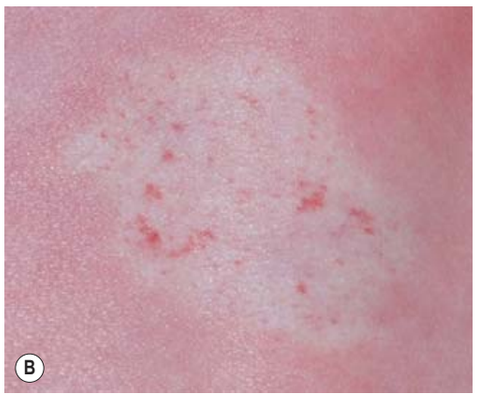

Fig. 103.2 Hemangioma precursors. These premonitory lesions can have a "bruised" (**A**) or blanched (**B**) appearance. *B, Courtesy, Julie V Schaffer, MD.*

Fig. 103.3 Superficial hemangioma mimicking a capillary malformation. This lesion's segmental configuration would warrant a consideration of PHACE(S) syndrome.

Fig. 103.4 Superficial hemangioma. Lesions can be focal (**A**, **B**) or have a broader segmental distribution (**C**). Note the bright red color and finely lobulated surface, irrespective of size. Involvement may be diffuse or broken-up. *Courtesy, Julie V Schaffer, MD.*

and more worrisome is the larger plaque-type or segmental pattern of superficial hemangiomas (Fig. 103.4C). These lesions may begin as broad erythematous patches that are confluent, reticulated or telangiectatic. Within a few weeks, bright red papules and plaques arise on the surface.

Deep hemangiomas are located in the deep dermis and/or subcutis. They usually are not apparent in the immediate newborn period, often becoming evident after a few weeks of age. They present as warm, ill-defined, light blue–purple masses with minimal or no overlying skin changes (Fig. 103.5), making them more difficult to diagnose than superficial or mixed hemangiomas[49]. The presence of dilated veins or telangiectasias overlying a deep hemangioma provides a clue that the lesion is of vascular origin. Larger deep hemangiomas often have significant arterial blood supply during their peak growth phase. A thrill may be felt or a bruit auscultated, and high flow can be documented by Doppler ultrasonography. Mixed hemangiomas have both superficial and deep components, often presenting during the proliferative phase as a well-delineated red vascular plaque overlying a larger, poorly circumscribed light blue nodule.

Superficial hemangiomas are the most common type, accounting for approximately 50–60% of infantile hemangiomas. An additional 25–35% of hemangiomas are mixed and 15% are deep[7]. Approximately 25% of patients have multiple lesions, which are occasionally associated with visceral hemangiomatosis (see below).

Several studies have characterized hemangiomas based upon the pattern of involvement in the skin and subcutaneous tissues, and these features may be useful for predicting prognosis[50,51]. Pattern subtypes include: (1) *focal* lesions that appear to arise from a single localized nidus; and (2) *segmental* lesions that cover a broad area or developmental unit (the terms "plaque-like" or "diffuse" are also used to describe this group). Lesions that are difficult to classify are designated as *indeterminate*. Segmental hemangiomas are more likely to be associated with regional extracutaneous anomalies, including PHACE(S) and LUMBAR syndromes (see below)[51]. The distribution patterns of segmental hemangiomas on the face correlate somewhat with classic embryonic facial prominences, differing the most on the upper face. Investigators have identified four primary segments for facial hemangiomas, S1 to S4 (Fig. 103.6)[52]. Involvement of these segments may be incomplete, and some hemangiomas encompass more than one segment.

Natural History

Studies have documented the typical growth pattern of infantile hemangiomas. The phases include *early proliferation* (rapid increase in size), *late proliferation* (continued growth at a slower rate), *plateau* (existence as a distinct phase debated), and *involution*[53]. Hemangiomas tend to "mark out their territory" early on, subsequently

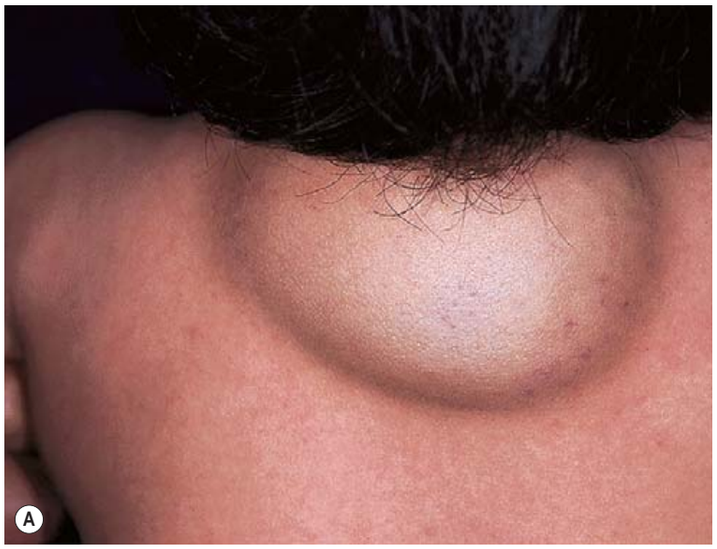

Fig. 103.5 Deep hemangiomas. Note the skin-colored to bluish hue with scattered telangiectasias. *A, Courtesy, Anthony J Mancini, MD.*

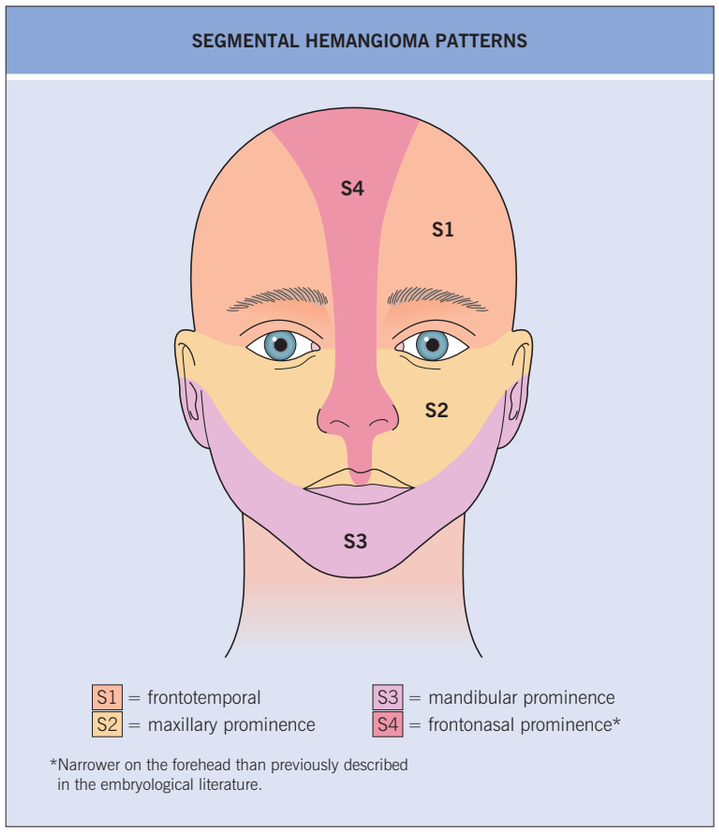

Fig. 103.6 Segmental hemangioma patterns. Based upon a prospective study (n = 165) of image analyses of hemangiomas. Adapted with permission from ref. 52.

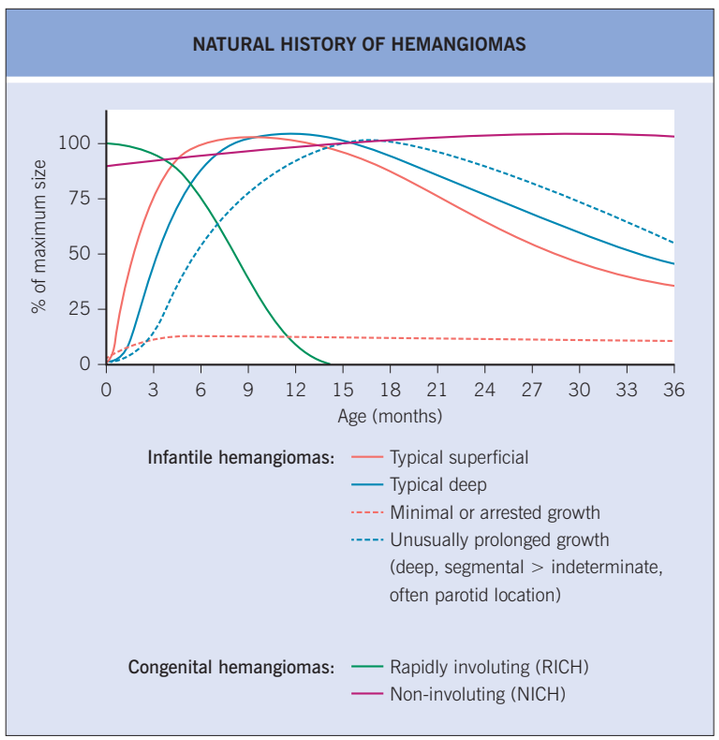

Fig. 103.7 Natural history of hemangiomas.

undergoing primarily volumetric rather than centrifugal growth[53]. During the proliferative phase, hemangiomas frequently become warmer and firmer in texture, and the surface of superficial hemangiomas may appear tense. Mixed and deep hemangiomas in the proliferative phase often feel firmer with crying or activity. Deep hemangiomas tend to proliferate for approximately a month longer than superficial hemangiomas, and the deep component of mixed lesions often continues to grow even after the superficial component has plateaued (Fig. 103.7).

A recent large prospective cohort study found that, on average, hemangiomas achieved 80% of their final size by the end of the early proliferative phase, which occurred at a mean age of 3.2 months (standard deviation ±1.7 months)[53]. Less than 5% of hemangiomas in this study had documented growth after 9 months of age, and most of these lesions had a deep component (70%) and a segmental or indeterminate morphology (70%)[53]. A retrospective series of 23 infants with hemangiomas exhibiting growth beyond 9 months of age (mean age of 17 months at last documented growth) showed that such lesions often have a location near the parotid gland (39%) as well as a deep component and segmental morphology[54].

A small subset of infantile hemangiomas (referred to as "*minimal or arrested growth*", "*abortive*" or "*reticular*") has little or no growth beyond patches of reticulated erythema with coarse and/or fine telangiectasias, often superimposed on a background of pallor (Fig. 103.8)[55,56]. They are GLUT-1-positive and involute at a pace similar to classic infantile hemangiomas (although larger ectatic vessels may persist), but a proliferative component is absent or accounts for <25% of the surface area, often presenting as small red papules at the periphery[55]. These hemangiomas favor the lower body and may develop recalcitrant ulceration or (if larger and segmental) be associated with LUMBAR syndrome (see below)[57].

Involution of infantile hemangiomas may begin as early as the first year of life and continues for several years. A color change from bright red to gray–purple (Fig. 103.9) and flattening of the surface are often the earliest signs of involution. Superficial plaques often break apart into smaller islands before clearing. As the tumor involutes, the mass becomes less firm and assumes a fatty consistency. During involution,

Fig. 103.8 Minimal/arrested growth (reticular) infantile hemangiomas. Telangiectasias and larger ectatic vessels are evident. Note the focal crusting (**A**) and small bright red papules behind the ear (**B**, arrow). Presence of the latter (which may be subtle or absent), reticulated erythema and characteristic telangiectasias (often both fine and coarse) help to distinguish these lesions from capillary–venous malformations. *B, Courtesy, Julie V Schaffer, MD.*

Fig. 103.9 Hemangioma during involution. Note the lightening (gray color) and softening of the hemangioma during involution.

larger lesions demonstrate less change in consistency and size with crying and activity[6,58].

Natural history studies of untreated hemangiomas demonstrate that 30% of lesions involute fully by 3 years of age, 50% by 5 years, 70% by 7 years, and over 90% by 9 years[6,9,58]. Some hemangiomas involute completely, while others may leave atrophic, fibrofatty or telangiectatic residua (Fig. 103.10). Predicting whether the residual lesion will be of cosmetic significance is one of the most challenging aspects of hemangioma management.

Complications

The majority of hemangiomas are small lesions that require little or no intervention. However, certain hemangiomas are problematic owing to their size, location or association with other anomalies. The age of the patient and the growth pattern of the hemangioma are crucial factors in predicting complications.

Ulceration

Ulceration occurs in up to 10% of all infantile hemangiomas and represents the most common complication[59]. Although hemangiomas in any location can be affected, those on the lip and in the anogenital region or other skin folds (e.g. the neck) have the greatest tendency to ulcerate (Fig. 103.11). Ulceration appears to develop more commonly within large, mixed (superficial and deep; see Fig. 103.11C) and segmental hemangiomas[59]. In addition, infantile hemangiomas with minimal or arrested growth are prone to ulceration (see Figs 103.8A & 103.11A), which may be recalcitrant. Although overall the median age at ulceration is 4 months[59], whitish discoloration of hemangiomas in infants younger than 3 months of age may be a sign of impending ulceration[60]. In addition to causing pain, ulcers increase the risk of infection and result in scarring with textural change. The management of ulcerated hemangiomas can be challenging (see below)[61]. Of note, significant bleeding is a rare complication of proliferating hemangiomas, including ulcerated lesions. Most bleeding episodes are minor and can be controlled with firm pressure.

Disfigurement and interference with function because of large size

Large hemangiomas can distort tissues, interfere with function, and lead to significant long-term sequelae. In addition, high-output congestive heart failure (which is most frequent in the setting of visceral hemangiomatosis) and regional extracutaneous abnormalities (especially for broad segmental lesions) may complicate the course of large hemangiomas.

Disfigurement and interference with function because of location

Even small lesions may cause complications if they arise in vulnerable locations[62]. *Periocular* hemangiomas are often associated with ophthalmologic complications (Fig. 103.12). Most commonly, periocular hemangiomas cause astigmatism by compressing the globe and deforming the cornea, which results in asymmetric refractive errors. They may also cause visual abnormalities by obstructing the visual axis as they proliferate or by invading the orbital musculature, which can lead to light-deprivation amblyopia and strabismus. Lesions located on the upper lid are most problematic, but visual obstruction can complicate lesions on the lower lid as well. Proptosis is a rare presentation of an orbital hemangioma and may develop gradually or suddenly. In these cases, the diagnosis of hemangioma may be difficult to establish clinically when a cutaneous lesion is not present. Infantile hemangiomas associated with proptosis may cause corneal exposure even after the mass has involuted. All infants with periocular hemangiomas should be evaluated by an ophthalmologist at baseline and closely thereafter during the proliferative stage[63–65].

Hemangiomas located on the *nasal tip* are particularly challenging. Deep and mixed hemangiomas can distort the underlying cartilage and leave significant fibrofatty residua. The resultant "Cyrano-nose" deformity may require reconstructive surgery. In rare cases, superficial hemangiomas located along the *columella* may ulcerate and lead to destruction of underlying cartilage, which may be heralded by the appearance of a horizontal crease in the inferior columella.

Lip hemangiomas are often superficial or mixed lesions; painful ulceration is common as they proliferate, which leads to feeding difficulties. Local factors, including recurrent trauma and the commensal bacterial flora, may increase the incidence of this complication. Even small hemangiomas crossing the vermilion border (Fig. 103.13) can leave significant cosmetic residua.

Hemangiomas located on the *pinna* may ulcerate and become infected, increasing the risk of scarring and distortion of normal structures. Conductive hearing loss can result from obstruction of the external auditory canal by a hemangioma[6].

Hemangiomas located on the *breast* pose a particular challenge in girls. These lesions may affect the underlying breast bud, and residual masses may lead to the appearance of breast asymmetry. Early surgical

intervention is ill advised as it may ultimately affect normal breast development.

Anogenital hemangiomas are often complicated by ulceration (associated with painful urination and defecation; see Fig. 103.11A) and infection. Wound care may be difficult in this region. Large hemangiomas of the *limbs* may also be complicated by ulceration, and when they resolve, residual excess tissue and rarely limb-length discrepancy can remain.

Systemic involvement

Large facial hemangiomas, specifically segmental lesions, can pose challenges beyond the complications noted above. They are often

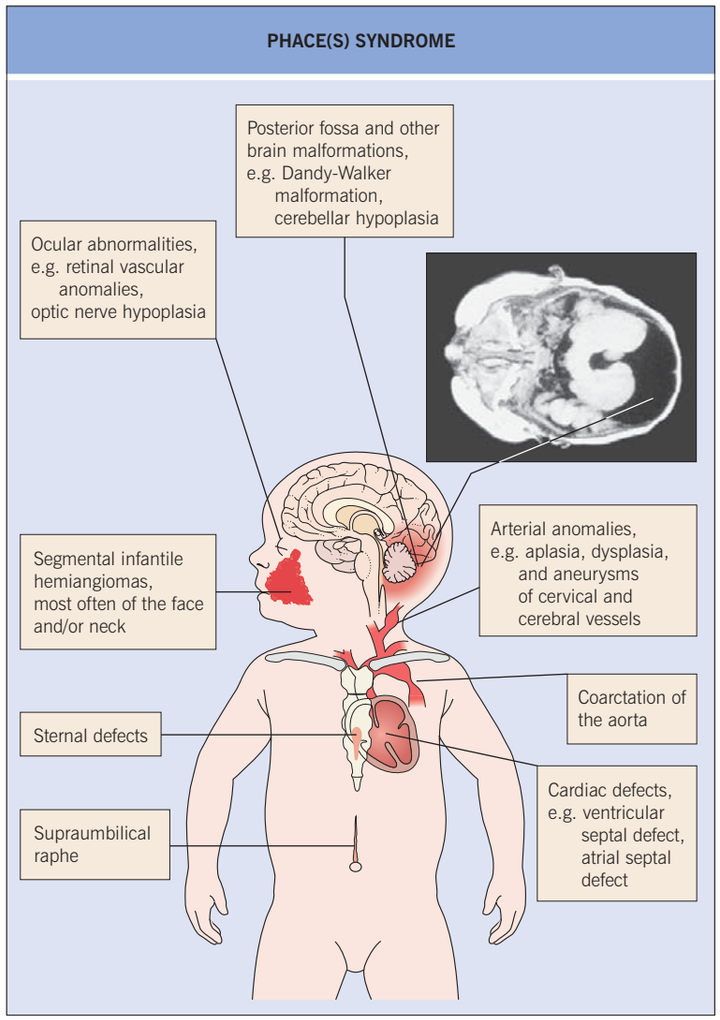

Fig. 103.14 PHACE(S) syndrome. Major clinical features are illustrated.

associated with extracutaneous anomalies, especially in female infants (~6:1 female:male ratio in PHACE[S] syndrome; see below)[66]. These hemangiomas may present as segmental telangiectatic patches (e.g. "minimal growth" lesions), vascular plaques or deep masses. A relationship between facial hemangiomas and CNS anomalies (structural and vascular) was recognized over 30 years ago[67]. Since then, other associated congenital anomalies have been identified. In 1996[68], the acronym ***PHACE(S)*** *syndrome* was coined for this spectrum of findings: ***P****, p*osterior fossa and other structural brain malformations; ***H****, h*emangioma; ***A****, a*rterial anomalies of cervical and cerebral vessels; ***C****, c*ardiac defects (especially *c*oarctation of the aorta); ***E****, e*ye anomalies; ***S****, s*ternal defects and *s*upraumbilical raphe (Fig. 103.14). Recently, diagnostic criteria for PHACE(S) syndrome were established by a multidisciplinary group of specialists[69] (Table 103.4).

In a prospective study of 108 infants (age <1 year; mean age 3 months) with large facial hemangiomas (≥22 cm^2), 31% had PHACE(S) syndrome. The vast majority (91%) of those with this syndrome had more than one extracutaneous manifestation (major ± minor criteria), and the most common findings were cerebrovascular (91%), cardiovascular (67%) and structural brain (52%) anomalies[66]. Recommendations for evaluation of infants at risk for PHACE(S) syndrome are presented in Figure 103.15. Cerebrovascular and cardiovascular changes may be progressive, with potential complications including ischemic stroke, and affected infants should be followed by neurologists and cardiologists as clinically appropriate[70].

Lower facial or "beard" hemangiomas often serve as markers of laryngeal hemangiomatosis, and the risk can be estimated by the extent of cutaneous involvement in this region (Fig. 103.16)[71]. However, airway hemangiomas are occasionally associated with segmental hemangiomas that primarily involve the upper face or small hemangiomas in the "beard" area[72]. Airway hemangiomas are typically subglottic. The onset of symptoms, which include noisy breathing and biphasic stridor, ranges from a few weeks to several months of age[71]. Infants with lower facial hemangiomas of concern should be referred for otolaryngologic evaluation.

Hemangiomas located in the *midline lumbosacral area* (Fig. 103.17) are a marker for occult spinal dysraphism. The risk of spinal dysraphism in an infant or child with an isolated midline lumbosacral hemangioma (or residuum of an involuted hemangioma) >2.5 cm in diameter is approximately 35%[73]. Factors that further increase the risk include a larger or ulcerated hemangioma and the presence of additional cutaneous markers (e.g. a deviated gluteal cleft, lipoma or skin appendage; see Ch. 64)[73].

Large hemangiomas on the lower body, especially extensive segmental lesions with "minimal growth", have been associated with a broad spectrum of regional extracutaneous abnormalities (analogous to those of the upper body in PHACE[S] syndrome). Several acronyms have been proposed for this group of findings (see Fig. 103.15), and the most

DIAGNOSTIC CRITERIA FOR PHACE(S) SYNDROME

Definite PHACE(S): Facial hemangioma >5 cm in diameter plus 1 major criterion or 2 minor criteria
Possible PHACE(S):
- Facial hemangioma >5 cm plus 1 minor criterion; *or*
- Hemangioma of the neck or upper torso plus 1 major criterion or 2 minor criteria; *or*
- 2 major criteria in the absence of a hemangioma

Organ system	Major criteria	Minor criteria
Cerebrovascular	• Anomalies of major cerebral arteries* (e.g. dysplasia, hypoplasia, stenosis, aneurysm, aberrant origin/course) • Persistent trigeminal artery	• Persistent embryonic arteries (other than trigeminal artery) • Intracranial hemangioma
Structural brain	• Posterior fossa anomalies (e.g. Dandy–Walker complex, cerebellar hypoplasia/dysplasia)	• Midline anomalies • Neuronal migration disorder
Cardiovascular	• Aortic arch anomalies • Anomalous origin of subclavian artery ± vascular ring	• Ventricular septal defect • Right aortic arch
Ocular	• Posterior segment anomalies (e.g. retinal vascular anomalies, optic nerve hypoplasia)	• Anterior segment anomalies (e.g. sclerocornea, cataract, coloboma)
Ventral or midline	• Sternal defect • Supraumbilical raphe	• Hypopituitarism • Ectopic thyroid

*Major cerebral arteries include: internal carotid artery; middle, anterior, or posterior cerebral artery; and vertebrobasilar system.

Table 103.4 Diagnostic criteria for PHACE(S) syndrome[69].

recent and inclusive is ***LUMBAR*** *syndrome*: ***L***, *l*ower body/*l*umbosacral hemangioma and *l*ipomas or other cutaneous anomalies (e.g. "skin tags"); ***U***, *u*rogenital anomalies and *u*lceration; ***M***, *m*yelopathy (spinal dysraphism); ***B***, *b*ony deformities; ***A***, *a*norectal and *a*rterial anomalies; and ***R***, *r*enal anomalies[74]. Recommendations for evaluation of infants with hemangiomas with a midline lumbosacral location and/or a segmental distribution on the lower body are summarized in Figure 103.15.

Multiple lesions are found in 10–25% of infants with hemangiomas and may be associated with visceral hemangiomatosis[75]. Most infants with both internal and skin involvement have many small, superficial cutaneous hemangiomas (Fig. 103.18) that range from a few millimeters to a few centimeters in diameter. Evaluation for visceral involvement is recommended when five or more skin lesions are present. Historically, the terms *"diffuse"* and *"benign" neonatal hemangiomatosis* were used for infants who had multiple cutaneous hemangiomas with or without visceral lesions, respectively[76–78]. However, some cases reported as diffuse neonatal hemangiomatosis actually represented other entities such as multifocal lymphangioendotheliomatosis with thrombocytopenia (see Ch. 114). To avoid further confusion, it has been recommended that patients simply be categorized as having *multiple cutaneous hemangiomas with or without systemic hemangiomas*.

The liver is the most common site of visceral hemangiomas in patients with multiple skin lesions (Fig. 103.19)[76,78]. Although they may be asymptomatic, hepatic hemangiomas can result in significant morbidity from complications such as high-output cardiac failure due to arteriovenous or arterioportal shunts (most often with multifocal hepatic lesions), abdominal compartment syndrome related to massive hepatomegaly (typically with diffuse hepatic involvement) and hypothyroidism (see below)[79–81]. Gastrointestinal tract hemangiomas (which may be associated with bleeding) have been described in patients with multiple or segmental skin lesions, but some reported cases might represent other types of multifocal vascular anomalies. True infantile hemangiomas within the CNS are rare, affecting only 1% (15/1454) of patients seen at a vascular anomalies referral center over a 10-year period[82]. Most of these cases represented intracranial or intraspinal extension of an overlying infantile hemangioma (some of which were segmental lesions); a few patients had hydrocephalus, but invasion into the CNS parenchyma was not observed[82]. Hemangiomas may also develop in a variety of other sites, including mucosal surfaces and the eyes.

In addition to their association with multiple small cutaneous lesions, visceral hemangiomas sometimes occur in infants with solitary large cutaneous hemangiomas, most often segmental facial lesions (with or without associated PHACE[S] syndrome). In such patients, hepatic, gastrointestinal, CNS and mediastinal hemangiomas have been observed[10,83,84]. However, no hepatic hemangiomas were found via ultrasound in a recent prospective study of 60 infants with at least one large (>30 cm^2) hemangioma and fewer than five lesions in total[85]. Of note, visceral hemangiomas occasionally occur in the absence of cutaneous lesions.

Increased levels of type 3 iodothyronine deiodinase, an enzyme that deactivates thyroid hormone, have been identified in tissue from proliferating hemangiomas. This can lead to hypothyroidism in infants with large-volume proliferative-phase lesions[86]. The consumptive nature of the hypothyroidism often makes it difficult to correct, but it resolves as the tumor regresses. Screening for hypothyroidism in the immediate neonatal period is inadequate, as hemangiomas are typically only beginning to develop at that time. Although most reported cases have been associated with hepatic hemangiomatosis, type 3 iodothyronine deiodinase activity has been noted in cutaneous hemangiomas. Consequently, it has been recommended that evaluation for hypothyroidism be considered in infants with large cutaneous hemangiomas or hepatic hemangiomatosis[86,87].

Infants with multiple cutaneous hemangiomas should be monitored for signs or symptoms of visceral involvement with periodic physical examinations. Radiologic evaluation, most often abdominal ultrasonography to screen for hepatic lesions[88], may be indicated to assess for systemic involvement in some patients (e.g. those with five or more cutaneous lesions) (see Fig. 103.15). Infants with hepatic hemangiomatosis should be followed closely with serial ultrasounds, clinical assessments and laboratory evaluation for hypothyroidism, with potential additional investigations including a cardiac evaluation (especially if high-flow shunting is identified) and further imaging with CT and/or MRI[89]. Not all infants with hepatic hemangiomatosis require treatment, but it is often difficult to determine those who will at initial presentation[88]. Typically, infantile hemangiomas located within the viscera follow the same course of proliferation and involution as cutaneous lesions.

Rapidly Involuting and Non-involuting Congenital Hemangiomas

Infrequently, infants present with a fully developed "hemangioma" in the immediate newborn period. These congenital hemangiomas have features that are clinically, histologically and immunohistochemically distinct from infantile hemangiomas (Table 103.5), most notably that they are GLUT-1-negative[47,90–92].

One subset of such tumors is referred to as the *rapidly involuting congenital hemangioma (RICH*; also reported as *congenital nonprogressive hemangioma* in a series where the lesions were excised during early infancy). RICHs are characterized by significant intrauterine growth, little if any postnatal growth, and rapid involution within the first year of life[47,91]. They are equally common in boys and girls. Intrauterine growth may be noted by prenatal ultrasonography as early as 12 weeks' gestation, and prenatal Doppler ultrasonography may reveal high vascularity and fast flow[90,91]. This tumor can appear at birth as a raised violaceous mass with prominent radiating veins, a hemispheric nodule with coarse telangiectasias surrounded by a pale rim, or a firm, pink to violaceous plaque that is often located on the lower extremity. Small, firm, violaceous papules may be present on the surface, and superimposed milia or hypertrichosis are occasionally noted. Ulceration, hemorrhage and necrosis can occur within the tumor, and rapid regression is evident within the first year of life[3,90] (Fig. 103.20). Transient thrombocytopenia may develop during the neonatal period[93].

Another type of congenital hemangioma is the *non-involuting congenital hemangioma (NICH)*[92]. These lesions occur slightly more often in male infants. They typically present at birth as well-circumscribed,

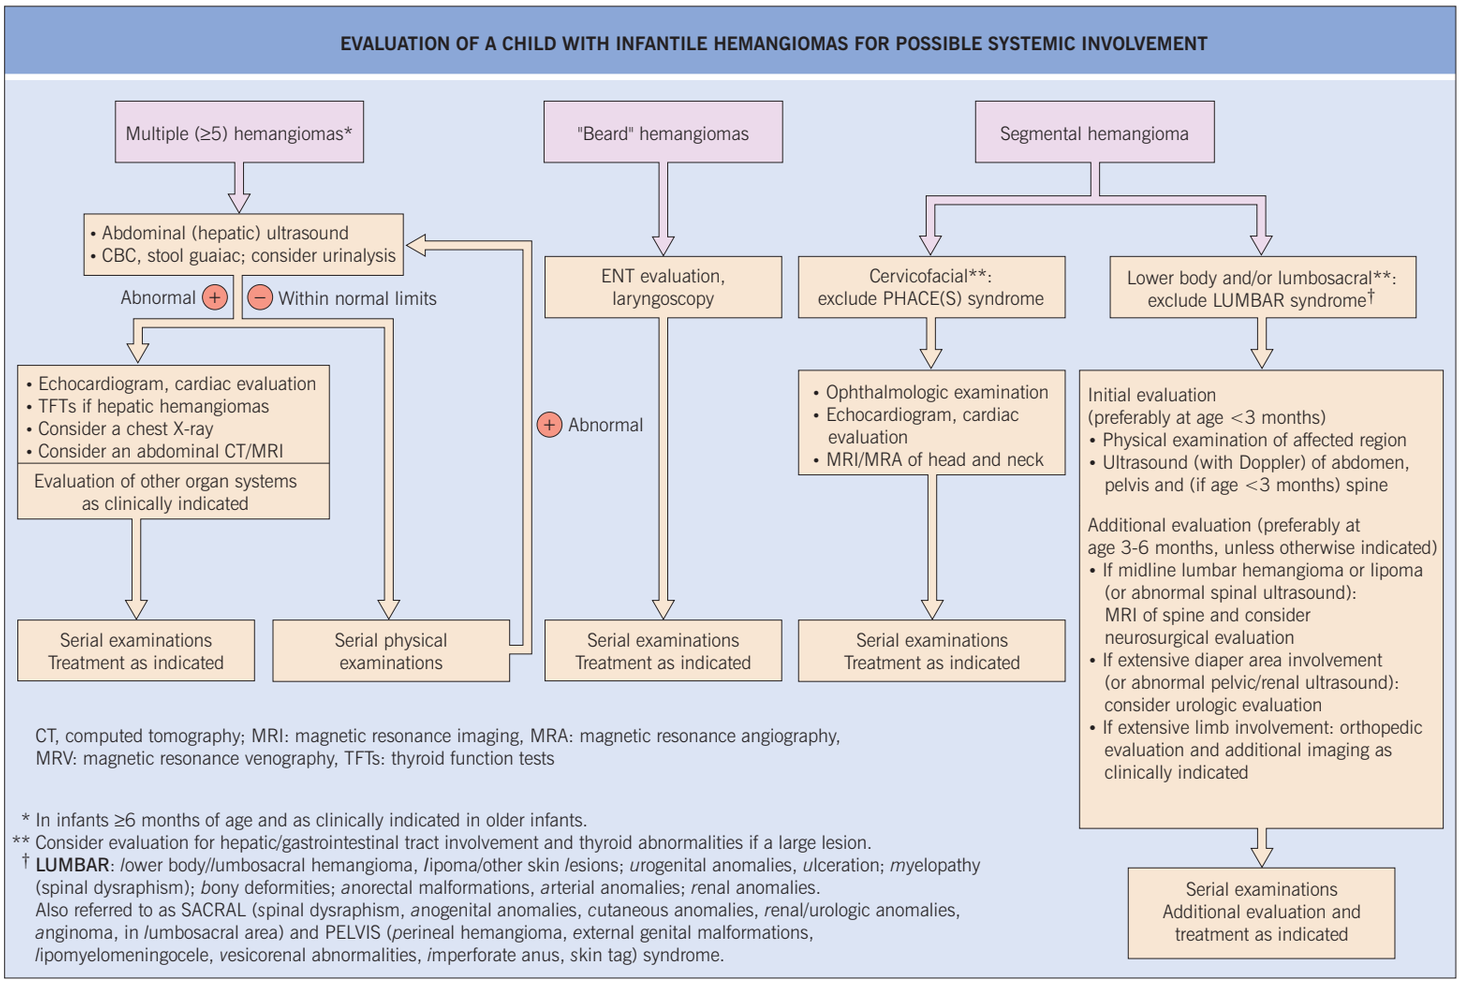

Fig. 103.15 Evaluation of a child with infantile hemangiomas for possible systemic involvement.

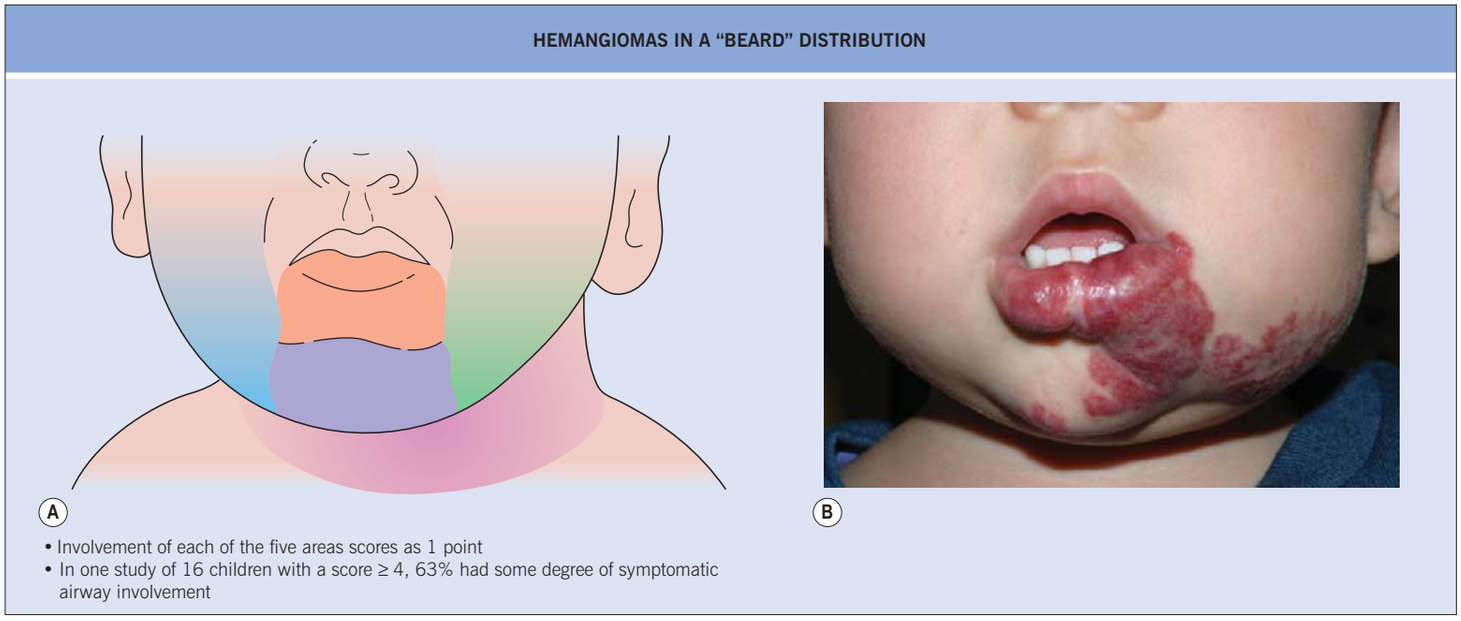

Fig. 103.16 Hemangiomas in a "beard" distribution. A Anatomic sites associated with risk of an airway hemangioma. **B** Infant with a laryngeal hemangioma in addition to cutaneous lesions in a "beard" distribution. *A, Adapted, with permission, from ref. 71. B, Courtesy, Julie V Schaffer, MD.*

pink to blue–violet masses or plaques with overlying coarse telangiectasias, surrounded by a pale or bluish rim (Fig. 103.21). NICHs are warm to palpation and, unlike infantile hemangiomas, grow proportionately with the child. The lesions may worsen with maturity and do not involute spontaneously. The diagnosis is often established retrospectively after the lesion is excised because involution fails to occur. Whether NICH and RICH represent distinct entities or exist on a spectrum remains unclear, and patients with coexistent congenital hemangiomas and common infantile hemangiomas have been described[91,94].

KEY FEATURES OF INFANTILE AND CONGENITAL HEMANGIOMAS		
Infantile hemangioma	**Rapidly involuting congenital hemangioma (RICH)**	**Non-involuting congenital hemangioma (NICH)**
Usually absent or precursor lesion at birth	Fully developed at birth	Fully developed at birth
Rapid postnatal proliferation	Intrauterine proliferation	Intrauterine proliferation then proportionate postnatal growth
Slow spontaneous involution	Rapid involution during the first year*	Do not involute spontaneously
More common in girls	Equal prevalence or slightly more common in girls	Slightly more common in boys
Lobular endothelial proliferation during proliferative phase; fibrofatty tissue during involution	Capillary lobules within fibrotic stroma containing thin-walled vessels, hemosiderin	Lobules of small, thin-walled vessels with large central vessel; dilated, dysplastic veins between lobules; "hobnailed" endothelial cells lining intralobular vessels
Positive GLUT-1 and Lewis Y antigen	Negative GLUT-1 and Lewis Y antigen	Negative GLUT-1

*Occasionally associated with thrombocytopenia during the neonatal period.

Table 103.5 Key features of infantile and congenital hemangiomas.

Kasabach–Merritt Phenomenon

Kasabach–Merritt phenomenon (KMP) is the association of a vascular tumor with a thrombocytopenic coagulopathy. Kasabach and Merritt reported the first case in 1940 and classified the tumor as a "capillary hemangioma". For decades thereafter, it was assumed that thrombocytopenic coagulopathy was a rare complication of typical hemangiomas[95]. However, data have shown that the tumors linked with this life-threatening complication are not true infantile hemangiomas. Rather, the histopathologic features of the tumors most commonly associated with KMP are those of kaposiform hemangioendothelioma (KHE) and tufted angioma (see Ch. 114)[96,97].

KMP typically presents during the first months to year of life with a rapidly enlarging, ecchymotic mass (Fig. 103.22) associated with thrombocytopenia and a consumptive coagulopathy. This syndrome is equally common in boys and girls. The clinical appearance of the tumor prior to the development of KMP is variable. Some patients have skin-colored, red or violaceous plaques, while others have masses that resemble lymphatic malformations or deep lesions within the neck, mediastinum or retroperitoneum. Many of these tumors are evident at birth. When the coagulopathy develops, the tumor becomes indurated as well as enlarged, and petechiae and purpura appear locally or (less commonly) in a widespread distribution.

Tumors associated with KMP do not typically respond well to treatment, and the coagulopathy may continue for months to years. Residual masses often persist after the coagulopathy resolves and occasionally worsen with maturity. Residual lesions frequently have a port-wine stain-like appearance with superimposed papules and a fibrotic texture upon palpation[98]. Telangiectatic streaks with associated swelling and irregular firm subcutaneous masses may also remain. Residual involvement of muscles and joints can impair mobility and cause painful contractures. Histologic examination of residual lesions has revealed features of tufted angioma and/or KHE with prominent fibrosis[98].

RADIOLOGIC FEATURES

Ultrasonography, CT and MRI can play important roles in the diagnosis and evaluation of infantile hemangiomas. Most superficial and mixed infantile hemangiomas are diagnosed based upon their clinical

Fig. 103.21 Non-involuting congenital hemangioma (NICH) in a school-aged child. This lesion was fully formed at birth and remained warm and firm to palpation. Note the coarse telangiectasias and pallor. *Courtesy, Julie V Schaffer, MD.*

Fig. 103.22 Kaposiform hemangioendothelioma associated with Kasabach–Merritt phenomenon in a 5-week-old boy. Progressive induration and ecchymosis developed rapidly over a 24-hour period. An eczematous eruption is also evident. *Courtesy, Julie V Schaffer, MD.*

features. However, imaging may be useful for defining the extent and depth of the deep component of mixed lesions. Radiologic evaluation is particularly helpful for confirming the diagnosis of deep infantile hemangiomas that lack superficial changes. It is important to consider the phase of growth when assessing hemangiomas radiographically, because proliferating hemangiomas demonstrate different characteristics than their involuting and involuted counterparts. The findings from MRI, Doppler sonography and CT of the various phases of hemangiomas as well as in KMP are presented in Table 103.6.

MRI is the most useful imaging technique for helping to define the extent and tissue characteristics of vascular tumors, and the use of contrast can help to differentiate an infantile hemangioma from other tumors. If MRI does not confirm the diagnosis of infantile hemangioma or there are concerns regarding a possible malignancy, histologic examination of the tumor is recommended. MRI and/or MR angiography (MRA) can also be used to determine the presence of hemangiomas within internal organs and to detect other structural anomalies, including CNS malformations and arterial anomalies[99].

A RICH may demonstrate distinct radiographic features. Although they can be recognized by prenatal ultrasonography during the second and third trimester, misdiagnosis as other vascular anomalies such as lymphatic or arteriovenous malformations is common[100]. Postnatal ultrasonographic evaluation of a RICH reveals uniformly hypoechoic lesions mostly confined to the subcutaneous fat. Diffuse vascularity is typical, with vessels showing venous or low-resistance arterial flow[101]. Doppler evaluation of a NICH demonstrates fast-flow vessels, and MRI reveals features similar to infantile hemangiomas[92].

MRI of vascular tumors associated with KMP shows diffuse soft tissue masses that enhance after contrast administration (see Table 103.6). Ill-defined margins, involvement of multiple tissue planes, overlying cutaneous thickening, edema, subcutaneous stranding and signal voids caused by hemosiderin deposits may help to differentiate KHEs from infantile hemangiomas[97].

PATHOLOGY

The histopathologic features of infantile hemangioma correlate with the stage of hemangioma development (see Tables 103.1 & 103.5). Infantile hemangiomas may extend from the superficial dermis to the deep subcutaneous tissue, and in some locations there may be involvement of surrounding tissues such as salivary glands and muscle. Biopsy

IMAGING FINDINGS IN SELECTED PEDIATRIC VASCULAR TUMORS						
Lesion	**Magnetic resonance imaging**				**Doppler sonography**	**Computed tomography**
	T1-weighted	**Contrast enhancement**	**T2-weighted**	**Gradient**		
Infantile hemangiomas:

specimens obtained from superficial and deep lesions show the same features. Well-defined non-encapsulated masses composed of proliferating plump endothelial cells and pericytes characterize proliferating hemangiomas (Fig. 103.23). Small vascular lumens may be noted focally throughout the tumor, but lumen formation may be more difficult to appreciate in early proliferating lesions.

Later in the proliferating stage, lobules of endothelial masses separated by fibrous septae become more prominent. Larger feeding and draining vessels are noted within the septae, and mitotic figures and apoptotic bodies may be present within the tumor mass. Although abnormal mitotic figures are not typical of proliferating hemangiomas, some authors have noted that mitotic activity and mild nuclear pleomorphism may be present in infantile hemangiomas and should not be a cause for concern if other typical histopathologic features are also present. An increased number of mast cells is often present within proliferating hemangiomas, and some studies have found even higher numbers of mast cells during early involution[39].

As the lesion matures, proliferation ceases and involution progresses; in some lesions, histologic features of both phases may be evident. The involuting phase is marked by flattening of the endothelium and reduced numbers of mitotic figures. Eventually, the vessels decrease in number and lose their tightly packed appearance, with fibrofatty tissue separating the vessels within and between lobules. The feeding and draining vessels within the septae may persist, but mast cells decrease in number. Fully involuted lesions display fibrofatty tissue and a few persistent vessels at sites where tumor lobules and septae previously existed.

Immunohistochemical analysis is useful for confirming the diagnosis of infantile hemangioma. As noted above, GLUT-1 expression is normally restricted to vessels with blood–tissue barrier functions, such as the brain and placenta. A high level of GLUT-1 immunoreactivity is present in the endothelia within infantile hemangiomas of all phases[25]. GLUT-1 staining is absent in other types of vascular tumors and vascular malformations. In addition, other placenta-associated vascular proteins, including FcγRII, merosin and Lewis Y antigen, are present in infantile hemangiomas but absent in vascular malformations and pyogenic granulomas. These placental markers are also absent in normal vessels of the skin and subcutis[26,39].

Histologically and immunophenotypically, congenital hemangiomas have several features that are distinct from infantile hemangiomas (see Table 103.5). These include striking lobularity with densely fibrotic stroma, stromal hemosiderin deposits, focal thrombosis and sclerosis of capillary lobules, lack of infiltration of surrounding tissues, fewer mast cells, and the coexistence of proliferating vasculature with multiple thin-walled vessels. Moreover, congenital hemangiomas lack immunoreactivity to GLUT-1 and Lewis Y antigen[47,91]. Some tumors do, however, demonstrate zones of involution[91].

DIFFERENTIAL DIAGNOSIS

Superficial and mixed hemangiomas are usually diagnosed based upon their characteristic clinical features. Hemangioma precursors and early proliferating lesions may sometimes be misdiagnosed as capillary malformations or telangiectasias. Deep lesions provide a greater challenge, and radiographic evaluation may be helpful. The differential diagnosis of a deep hemangioma may include a vascular malformation (particularly venous, lymphatic or combined venous–lymphatic malformations; see Ch. 104) and kaposiform hemangioendothelioma. Pyogenic granulomas occur commonly in children and may mimic a superficial hemangioma. They typically arise after the first few months of life and are pedunculated. Other vascular lesions of infancy that may represent diagnostic considerations include tufted angioma, multifocal lymphangioendotheliomatosis with thrombocytopenia, infantile hemangiopericytoma, spindle cell hemangioma, verrucous "hemangioma" and eccrine angiomatous hamartoma.

A congenital fibrosarcoma may mimic a hemangioma because the former are often firm and blue–purple in color and can have ectatic superficial veins. In addition, some patients with this malignancy present with disseminated intravascular coagulation, which further confuses the clinical picture. Rhabdomyosarcoma, neuroblastoma, primitive neuroectodermal tumor, lymphoblastic lymphoma and dermatofibrosarcoma protuberans are other neoplasms that may have a vascular appearance due to overlying telangiectasias or a blue to red color. Additional entities that may be mistaken for a hemangioma include: infantile myofibromatosis, which can present as solitary or multiple red to pink plaques or nodules; lipoblastoma, which presents as an enlarging skin-colored or (less often) erythematous mass; and

REASONS TO CONSIDER SYSTEMIC THERAPY FOR INFANTILE HEMANGIOMAS
Threatened vital functions
• Vision
• Airway
Potential for disfigurement
• Nasal tip/columella
• Lip, especially if the lesion crosses the vermilion border
• Large/rapidly growing lesion, especially if on the face
Severe/recalcitrant ulceration
High-output cardiac failure

Table 103.7 Reasons to consider systemic therapy for infantile hemangiomas.

nasal glioma, often presenting as a congenital blue–red mass on the bridge of the nose. Radiographic studies, especially MRI, may be useful in differentiating these tumors from a hemangioma. However, if the diagnosis is not clarified by clinical and radiographic examinations, or if the lesions are atypical, then histologic examination is indicated.

TREATMENT

Infantile hemangiomas manifest with a wide spectrum of clinical severity, and their management needs to be individualized. Most therapeutic recommendations are based on anecdotal experience. In the last few decades, upon identification of subgroups of infantile hemangiomas with a greater risk of developing complications, indications for active intervention have been proposed (Table 103.7)[102]. The major goals of management include: (1) preventing or reversing life- or function-threatening complications; (2) treating ulcerations; (3) preventing permanent disfigurement; (4) minimizing psychosocial distress to patients and their families; and (5) avoiding overly aggressive, potentially scarring procedures for lesions that have a strong probability of involuting without significant residua[103].

Active Non-intervention

Small hemangiomas that carry an excellent prognosis for spontaneous resolution with a good cosmetic outcome are usually managed with active non-intervention. Physicians should recognize that small, seemingly trivial lesions may be troubling to parents and cause significant distress. Parents of children with facial hemangiomas demonstrate reactions similar to those seen in parents of children with permanent deformities. They may feel that their concerns about the hemangioma have been inadequately addressed and express dissatisfaction with their child's medical care[104]. Use of the internet has increased parental access to information (albeit of variable quality) about hemangiomas and their treatment.

Active non-intervention includes discussing information that parents have learned about hemangiomas. Indications for treatment, types of therapy, and why they are or are not appropriate for their child must be reviewed. Close observation with periodic photography to monitor the hemangioma is essential. Reviewing photographic examples of the evolution of hemangiomas is helpful for families. Many parents are fearful of bleeding and ulceration; therefore, reviewing the care for superficial bleeding (along with reassurance that it is rarely problematic) or ulceration in anticipation of these potential complications, is worthwhile.

Management of Ulceration

Ulceration is the most frequent complication of infantile hemangiomas (see Fig. 103.11). Management should be directed at healing the ulceration, preventing infection and reducing pain. A review of 60 infants with ulcerations found that multiple modalities were often used concurrently, and that no single therapy proved most effective[61]. Components of management include local wound care, treatment of infection (relatively uncommon), specific therapies (e.g. pulsed dye laser, β-blockers, corticosteroids) and pain management. Superficial ulcerations can frequently be managed with local wound care. Saline or Burow's solution compresses may be used to gently debride thick crusts, and topical antibiotics such as mupirocin and bacitracin ointments are applied, followed by occlusive dressings.

In open trials, metronidazole gel has been useful for ulcers in intertriginous and moist areas such as the perineum. Although the safety of metronidazole gel has not been established in young children, systemic metronidazole has been used safely to treat parasitic infections in this age group. Kim et al.[61] calculated that it would require relatively large amounts of topical gel to reach systemic levels of the drug or toxicity from its propylene glycol vehicle; nonetheless, they recommended limited application of small amounts of metronidazole gel when it is used in this setting. Oral antibiotics are often prescribed to treat presumed infections of ulcerated hemangiomas. Antibiotics that cover staphylococci and streptococci, such as first-generation cephalosporins, are commonly employed (see Ch. 127). A bacterial culture should be obtained from the wound. Occlusive dressings such as Duoderm®, Duoderm Extra Thin®, Vigilon® or Omniderm® can be applied after application of the topical antibiotic at sites that are amenable (see Ch. 145). Thin hydrocolloid dressings are often favored because of the ease of application and the ability to leave them in place for a few days. Petrolatum-impregnated gauze may also be used for perineal ulcers but needs to be changed frequently. Compression dressings such as Coban® elastic bandage are useful for extremity hemangiomas, and parents should be instructed in their proper application.

A variety of modalities that are used to treat hemangiomas for other indications (see below) may be helpful for treating ulcerated lesions. Pulsed dye laser has been widely used for the treatment of ulcerated hemangiomas. Some uncontrolled studies demonstrated healing of ulcerations and resolution of pain after two to three treatments with the pulsed dye laser performed at 2-week intervals[105–108]. However, others observed mixed results, with 50% showing improvement and 5% experiencing worsening of the ulceration[61]. Excisional surgery may be considered as a means to manage small or pedunculated ulcerated lesions.

Improvement of chronically ulcerated, treatment-resistant facial and diaper-area hemangiomas was observed after application of becaplermin (recombinant platelet-derived growth factor) 0.01% gel[109,110]. This preparation is FDA-approved, but only for the treatment of diabetic ulcers in adults; in these patients, use of three or more 15 g tubes of becaplermin gel was associated with increased mortality from (but not incidence of) malignancy. Becaplermin's mechanism of action includes promotion of angiogenesis, which raises questions regarding the potential for stimulation of growth and worsening of hemangiomas. Further studies are indicated to determine the effectiveness and safety of this modality.

An important consideration in the treatment of ulcerated hemangiomas is pain, which is a commonly associated symptom. Local wound care, and especially occlusive dressings, can provide some pain relief. Oral acetaminophen and topical lidocaine ointment may also help to alleviate the discomfort, although the latter must be used sparingly to prevent systemic lidocaine toxicity. In some patients, narcotic analgesics (e.g. acetaminophen with codeine) may be necessary for short periods of time. Eutectic mixture of local anesthetics is not recommended for the treatment of ulcerated hemangiomas because it should not be applied to eroded or ulcerated skin[61].

Local Medical Therapies

Intralesional corticosteroids

Intralesional corticosteroids are usually used to treat localized lesions, such as small lip hemangiomas. Systemic absorption likely occurs, but it is believed to be less than with oral corticosteroids when small lesions are treated. As with oral corticosteroids, there is no well-established dosage regimen. Concentrations of triamcinolone acetonide between 5 and 40 mg/ml have been reported in the literature[61,111,112]. Shorter-acting corticosteroid preparations, such as dexamethasone or betamethasone acetate, are sometimes administered in combination with triamcinolone. It is recommended that the total maximum dose of triamcinolone not exceed 3–5 mg/kg per treatment session[62], thereby reducing the chance of HPA axis suppression and excessive exposure to the preservative benzyl alcohol. The interval between treatment sessions is also not well established. Some patients require repeat treatments at approximately monthly intervals, while others respond after a single treatment. The need for repeat therapy will depend upon the stage of proliferation of the hemangioma.

The use of intralesional corticosteroids to treat periorbital hemangiomas is controversial[113]. When the injection pressure exceeds the systemic arterial pressure, there can be retrograde arterial flow and presumably embolization of corticosteroid particles into the ocular circulation. Reports of serious complications, including retinal and ophthalmic artery occlusion leading to permanent vision loss, as well as local atrophy and necrosis, have limited the use of this modality in the periorbital area[112,114,115].

Topical corticosteroids

In a few case reports and one series of 34 patients, an ultrapotent class 1 topical corticosteroid was utilized to treat periocular hemangiomas and other lesions with a superficial component[116,117]. Cessation of growth, decreased size/thickness and/or lightening of the color of the hemangioma was observed in ~75% of the patients, and there were no significant side effects. Further studies are needed to assess the effectiveness of this modality and to identify the subset of hemangiomas (likely thinner superficial lesions) with the best response to such treatment.

Topical β-blockers

There have been anecdotal reports of improvement of superficial facial hemangiomas with topical application of timolol 0.5% gel or solution[118,118a]. Additional studies are needed to determine the potential benefits of this topical non-selective β-blocker (similar to the systemic agent propranolol; see below) in the treatment of superficial and ulcerated hemangiomas, with increased potential for systemic absorption in the latter setting (Fig. 103.24).

Topical imiquimod

There are a few case series and one small prospective study of 5% imiquimod cream (which has antiangiogenic as well as immune-modifying activity) for the treatment of proliferating hemangiomas[119,120]. Although improvement of the superficial component (fading of the color more than decreased volume) is often observed, an inflammatory reaction that may include erosion of the hemangioma surface frequently occurs[119,120]. Controlled studies are needed to further assess the risks and benefits of this modality.

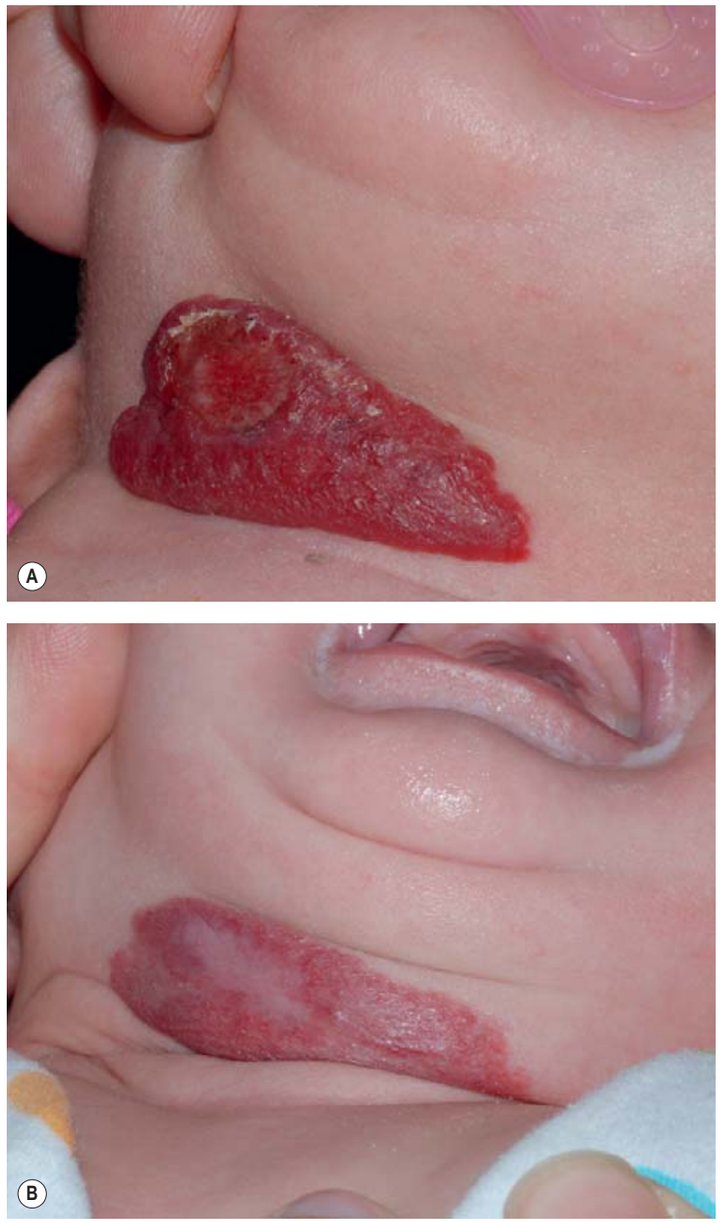

Fig. 103.24 Ulcerated superficial hemangioma treated with topical timolol. **A** An ulcerated superficial infantile hemangioma on the neck of a 10-week-old girl. **B** Four weeks after institution of topical timolol 0.5% gel, with one small drop applied twice daily. Note the healing of the ulcer, which occurred within two weeks, as well as the lighter color and decreased thickness of the hemangioma. *Courtesy, Julie V Schaffer, MD.*

Systemic Therapies

Systemic corticosteroids

Systemic corticosteroids, usually prednisolone or prednisone, have traditionally been the mainstay of treatment for life- or function-threatening hemangiomas (see Table 103.7). They are also used to treat hemangiomas that are highly likely to cause disfigurement and those that are persistently ulcerated. Corticosteroids have been shown to suppress VEGF production by hemangioma-derived stem cells and to inhibit vasculogenesis in a murine model[121].

Dosage recommendations, duration of therapy, tapering schedules and monitoring guidelines vary widely and no single standard exists. Initial dosages of prednisone (or its equivalent) of 2–3 mg/kg/day are most commonly used[62]. However, some authors have advocated higher dose regimens of 3–5 mg/kg/day because it is speculated that larger doses result in higher response rates[122]. Treatment is usually maintained at these doses until cessation of growth or shrinkage occurs, followed by a gradual taper. The taper schedule is determined by a variety of factors, including the age of the patient, hemangioma growth rate, reason for treatment, presence of adverse effects and rebound growth. The latter may occur if steroids are discontinued while the hemangioma is still in its proliferating phase; this should not be interpreted as a treatment failure but, rather, underscores the importance of recognizing the growth pattern of the hemangioma when making therapeutic decisions.

A literature review used strict inclusion and exclusion criteria to assess the effectiveness of systemic corticosteroids in proliferating infantile hemangiomas[123]. A mean dose of 2.9 mg/kg/day was used over a mean period of 1.8 months before tapering, with a response rate of 84%; cessation of growth was observed more often than shrinkage of the hemangiomas. Doses exceeding 3 mg/kg/day resulted in a response rate of 94% but with a greater incidence of adverse effects. Both this systematic review and a retrospective series of 62 children who received prednisone or prednisolone at an initial dosage of 2–3 mg/kg/day tapered over a mean period of 7.9 months found a low incidence of serious side effects[124]. Adverse reactions in children receiving systemic corticosteroids can include cushingoid facies, irritability, disruption of sleep, gastrointestinal symptoms, and a decreased growth rate (height and weight); however, the majority of children experience catch-up growth after cessation of therapy. In a series of 22 children with hemangiomas who were treated with systemic corticosteroids for a mean of 7 months, hypertension and hypothalamic–pituitary–adrenal (HPA) axis suppression (assessed via morning cortisol levels measured after tapering to a physiologic dose) were frequently observed[125]. However, in another study, only 1 of 16 infants whose hemangiomas were treated with systemic corticosteroids for a mean of 7 months had adrenal insufficiency (assessed with the more specific low-dose corticotropin stimulation test) following completion of therapy[126].

Immunosuppression is another potential side effect of systemic corticosteroid therapy for hemangiomas, although serious infections have

rarely been reported. *Pneumocystis jiroveci (carinii)* pneumonia has been described in a few infants receiving systemic corticosteroids for hemangiomas[127], leading some clinicians to recommend trimethoprim–sulfamethoxazole prophylaxis in this setting. The administration of live-virus vaccines (see Ch. 128) is a concern in children receiving systemic corticosteroids for more than 2 weeks at a dose equivalent to prednisone ≥2 mg/kg/day or ≥20 mg/day in those weighing more than 10 kg. The American Academy of Pediatrics' Committee on Infectious Disease recommends that the administration of live-virus vaccines (see Table 128.9) be avoided while an infant is receiving corticosteroids at these doses and until they have been discontinued for at least 1 month[128].

Recently, concerns have been raised about neurotoxicity in very premature infants treated with corticosteroids for other indications[129]. There is currently no evidence of similar effects in term infants, but this finding raises questions about long-term side effects. Controlled studies are needed to determine the optimal corticosteroid dosage regimen to achieve the desired response with the lowest incidence of adverse effects.

Systemic β-blockers

The non-selective β-blocker propranolol has recently been shown in a randomized controlled trial, several large series and multiple additional case reports to represent an effective systemic treatment for severe infantile hemangiomas[130,131,131a]. Hemangioma endothelial cells express β_2-adrenergic receptors, and effects of propranolol include vasoconstriction, decreased expression of pro-angiogenic factors (e.g. VEGF, bFGF), and induction of endothelial cell apoptosis. The original report in 2008 described the serendipitous discovery of rapid improvement of a hemangioma in an infant who was treated with propranolol for cardiac complications of corticosteroid therapy; this prompted the authors to initiate propranolol therapy in 10 additional infants with function-threatening or disfiguring proliferative-phase hemangiomas (some of whom had previously failed corticosteroid treatment), and marked improvement was again observed[130]. A more detailed follow-up study of these patients and 21 additional children treated with propranolol was subsequently published[131]. The infants in this uncontrolled series received 2–3 mg/kg/day (usually 2 mg/kg/day) of propranolol, divided into two or three oral doses. A color change from red to purple and softening of the hemangiomas were typically noted within a few days of initiating therapy, followed by progressive flattening and reduction in size over a period of weeks to months. Treatment was continued for an average of 6 months, with regrowth (sometimes requiring retreatment) in several hemangiomas when propranolol was stopped before age 12 months.

Additional case series and reports have described similar responses of infantile hemangiomas, including those involving the airway and liver, to treatment with propranolol[132,133]. Benefit for hemangiomas in the late proliferative phase or involution has also been noted[131]. The side-effect profile of propranolol is overall more favorable than that of systemic corticosteroids, and possible adverse reactions include hypotension, bradycardia, hypoglycemia (early signs blunted; can potentially lead to seizures), bronchospasm and sleep disturbances[134,135]. There have also been reports of β-blockers that do not cross the blood-brain barrier (i.e. are hydrophilic rather than lipophilic like propranolol) and/or are β_1-selective (e.g. atenolol) having efficacy for infantile hemangiomas, but controlled trials comparing different β-blockers have not yet been performed[135a].

There are currently no consensus guidelines regarding the use of propranolol for the treatment of infantile hemangiomas. Ongoing studies will help to determine optimal dosing (initial, escalation and tapering) and appropriate monitoring procedures; considerations regarding these issues are summarized in Table 103.8. Many experts advise a baseline cardiac assessment (including examination, electrocardiography, and, in some cases, echocardiography), often involving referral to a pediatric cardiologist, prior to propranolol therapy[134,135]. If clinically indicated (see above), patients should undergo evaluation for PHACE(S) syndrome (especially cardiovascular and cerebrovascular anomalies) or other potential extracutaneous involvement, before beginning propranolol, and its use in infants with PHACE(S) syndrome should be individualized based on consideration of potential complications. Following initiation of therapy and dose escalation, patients should be monitored for signs of bradycardia, hypotension and hypoglycemia[134]. Gradual tapering is recommended, in part to prevent rebound tachycardia.

Other systemic therapies

Vincristine is a chemotherapeutic agent that has been widely used for the treatment of childhood neoplasms. It is a vinca alkaloid that interferes with microtubule formation during mitosis, inducing apoptosis of tumor and endothelial cells[136]. There are reports of its use to treat life- or function-threatening infantile hemangiomas and other vascular tumors that are unresponsive to corticosteroids, as well as the Kasabach–Merritt phenomenon. Toxicities include peripheral neuropathy, constipation, jaw pain, and (uncommonly) anemia and leukopenia. Placement of a central venous catheter is required to administer vincristine, and participation of a pediatric oncologist/hematologist is advisable. Further studies are needed to determine its effectiveness, the incidence of adverse reactions, and optimal dosage regimens for the treatment of infantile hemangiomas[136–140].

Recombinant interferon-α (2a and 2b) can inhibit angiogenesis and was used in the past to treat life- or function-threatening infantile hemangiomas that were resistant to corticosteroid therapy[141–143]. Adverse effects include fever, irritability, diarrhea, neutropenia, elevated transaminases and skin necrosis[142–144]. The most worrisome potential side effect of interferon-α in infants is spastic diplegia, which has been reported in up to 20% of those undergoing treatment for hemangiomas[144,145]. Neurotoxicity does not appear to be dose-related and is potentially (but not always) reversible upon discontinuation of therapy. Because of this concerning possible complication, interferon is now rarely used for the treatment of infantile hemangiomas. When it is administered to infants, baseline neurologic assessment and serial examinations are essential.

Surgical and Laser Therapy

Pulsed dye laser (PDL) therapy (585–600 nm wavelength, usually 0.45–1.5 ms pulse duration) is effective for the treatment of capillary malformations. In the case of proliferating infantile hemangiomas, laser therapy appears to have the most benefit for superficial lesions[146–148]. Hemangiomas with deep dermal or subcutaneous involvement may show lightening of the superficial portion, but PDL therapy does not appear to alter the growth pattern of the deeper component[149]. Multiple treatment sessions, usually every few weeks, are required during the proliferating phase to improve the lesion and prevent rebound growth. Treatments are generally well tolerated, but adverse reactions can include pigmentary alteration, ulceration and atrophic scarring.

A randomized controlled study of early PDL treatment of uncomplicated infantile hemangiomas found no significant difference in the number of children with complete clearance of their hemangiomas at 1 year of age compared to the untreated control group. In the PDL-treated infants, redness was improved, but they were more likely to develop cutaneous atrophy and hypopigmentation than were the untreated cohort[150]. In addition, severe ulceration and scarring have been reported in young infants with large superficial hemangiomas following early laser treatment[151].

The PDL is effective for the treatment of telangiectasias on the surface of involuting and involuted hemangiomas. The Nd:YAG laser has also been used to treat infantile hemangiomas and may have greater efficacy than the PDL for deeper lesions, although there appears to be a higher risk of scarring. Percutaneous treatment utilizing bare fiber Nd:YAG has been reported for deep hemangiomas.

Surgical excision is usually employed to treat involuted or partially involuted lesions in order to remove fibrofatty tissue and redundant skin. The optimal timing for surgery depends upon many factors, including the location and size of the lesion. Surgical excision during the proliferating phase is controversial and reserved for specific situations, such as a function-threatening periorbital hemangioma that has failed to respond to pharmacologic therapy or in which pharmacologic therapy is believed to pose a greater risk to the patient than surgical excision. Other settings where early surgery may be appropriate include pedunculated lesions for which resection will be inevitable and small, persistently ulcerated lesions that have failed more conservative therapy. Excision can be considered in preschool children for involuting lesions when they are located in a cosmetically sensitive area (e.g. nasal tip,

ADMINISTRATION OF PROPRANOLOL FOR INFANTILE HEMANGIOMAS: CONSIDERATIONS REGARDING PRETREATMENT EVALUATION, DOSING AND MONITORING
PRETREATMENT EVALUATION
• In conjunction with a pediatrician and/or pediatric cardiologist: cardiac examination, heart rate, manual blood pressure, electrocardiogram (ECG), ± echocardiogram*
• If abnormalities on cardiac examination/ECG, at risk of PHACE(S) syndrome† or presence of hepatic hemangiomas, refer to a pediatric cardiologist and obtain echocardiogram ± Holter monitoring
• Consider blood glucose level (e.g. via fingerstick)
• Determine if history of bronchospasm/reactive airway disease (usually considered a contraindication to propranolol therapy)
• If at risk for PHACE(S) syndrome†, MRI/MRA of head and neck to exclude vascular anomalies (see Fig. 103.15 for additional information); if abnormal findings, obtain evaluation by a neuroradiologist familiar with PHACE(S) and consider referral to a pediatric neurologist
• If multiple (e.g. ≥5) hemangiomas, abdominal ultrasound to assess for hepatic hemangiomas (see Fig. 103.15 for additional information)
DOSING AND COURSE
• Initial: 0.5–1 mg/kg/day divided into 2 or 3 doses
• Increase as tolerated, usually with a goal of 2 mg/kg/day‡ divided into 2 or 3 doses§
• For a proliferating hemangioma, treatment is typically continued until 9–15 months of age (depending on the clinical setting and course)
– Based on the response to treatment and other characteristics of the hemangioma, dose increases as the child grows to maintain the same goal dose/kg may or may not be needed
– Dose should be lowered or therapy temporarily suspended during intercurrent illnesses, especially if decreased oral intake or vomiting
• Taper over ~2–4 weeks before discontinuing (primarily to prevent rebound tachycardia)
MONITORING
• Risks of propranolol include bradycardia, hypotension, hypoglycemia, sleep disturbances and bronchospasm‖
• Consider a brief *inpatient* stay (e.g. 1–2 days) with telemetry for initiation of treatment, especially if <2–3 months of age, history of preterm birth and/or complications (e.g. associated cardiovascular anomalies)
• Outpatient initiation of therapy with assessment of heart rate, blood pressure and blood glucose *in-office* or by a *visiting nurse* may otherwise be appropriate*
– Within one day of the first dose or a dose escalation (ideally 0.5–2 hours after administration)
– Every 3–6 weeks while on a stable dose
– Normal ranges for pediatric vital signs are available at: www.emedicinehealth.com/pediatric_vital_signs/article_em.htm
• Educate parents about signs of hypoglycemia (early¶: sweating, rapid heart rate, shakiness, fussiness; late: lethargy, poor feeding, hypothermia, seizures)
– Encourage parents to feed the infant before each dose and do not administer before bedtime without feeding
– Feed at least every 3–4 hours in younger infants and every 4–5 hours in older infants
*Holter monitoring can also be considered at baseline and/or periodically during treatment.
†Segmental cervicofacial hemangioma ≥5 cm in diameter.
‡Occasionally need to increase to 3 mg/kg/day, and doses as low as 1 mg/kg/day may be effective.
§An example protocol is an initial dose of 0.5 mg/kg/day divided into 2 or 3 doses (0.25 or 0.17 mg/kg/dose, respectively), then doubling of the dose every 3–7 *days* in an *out*patient setting or every 1–3 *doses* in an *in*patient setting until reaching 2 mg/kg/day.
‖To date there has been a single case report of hyperkalemia associated with treatment of a large, ulcerated hemangioma with propranolol.
¶May be masked with the β-adrenergic blockade.

Table 103.8 Administration of propranolol for infantile hemangiomas: considerations regarding pretreatment evaluation, dosing and monitoring. Practices vary widely, and some pediatric dermatologists/pediatric cardiologists recommend more or less intensive evaluation and monitoring. The patient's age, hemangioma-related issues, and medical comorbidities also affect management.

lip). The ultimate management goal is to achieve as normal an appearance as possible, considering the expected surgical scar as well as the predicted time course and outcome of involution. Therefore, just as with other treatment modalities, the surgical management of infantile hemangiomas needs to be individualized.

Arterial embolization has been used to treat life-threatening hemangiomas that are causing high-output congestive heart failure. It may be used concurrently with other modalities and prior to surgical resection in some cases[152].

Cryosurgery has also been used to treat infantile hemangiomas[153,154]. Contact cryosurgery is the method most commonly employed, and it is used mostly in Europe and Latin America. Adverse effects include scarring and pigmentary alteration.

Management of Kasabach–Merritt Phenomenon

KMP is a life-threatening disorder that represents a medical emergency. The associated vascular tumors respond less consistently to treatment than do infantile hemangiomas. Systemic corticosteroids, interferon-α, chemotherapeutic agents including vincristine and cyclophosphamide, ticlopidine and aspirin have been used alone and in combination, with a variable response rate[98]. A retrospective case series suggested that some patients may be successfully managed with vincristine[155]. Surgical excision, embolization and radiation have also been utilized[136,156], and supportive care is mandatory. Platelet transfusions may lead to enlargement of the tumor and worsening of the coagulopathy, possibly due to pro-angiogenic factors present in blood products[157].

Vascular Malformations 104

Odile Enjolras

Synonyms: ■ Mature angiomas [misnomer]; angiodysplasias; vascular birthmarks ■ Capillary malformation (CM): port-wine stain, nevus flammeus, telangiectasia ■ Venous malformation (VM): cavernous angioma [misnomer], cavernous hemangioma [misnomer], phlebectasia ■ Lymphatic malformation (LM): lymphangioma, lymphangioma circumscriptum, lymphangioma simplex, cystic hygroma, cavernous lymphangioma ■ Arteriovenous malformation (AVM): cirsoid aneurysm, cirsoid hemangioma

Key features

- Although both were once called "angiomas", vascular malformations clearly differ from the vascular tumors seen in infants and children
- In slow-flow malformations, capillaries, veins and/or lymphatic channels are anomalous; most lesions are either apparent at birth or become evident within the first few months or years of life
- In fast-flow malformations, there is arteriovenous shunting; some lesions are apparent at birth, but the majority become evident later in childhood or adulthood
- All vascular malformations are lifelong and may worsen, creating cosmetic consequences and functional impairment
- Vascular malformations are occasionally found together with other abnormalities as a part of a complex syndrome

INTRODUCTION

According to the classification system adopted by the International Society for the Study of Vascular Anomalies (ISSVA), there are two types of vascular anomalies: vascular tumors (most commonly the infantile hemangioma) and vascular malformations[1] (Table 104.1). Vascular malformations are localized defects of vascular morphogenesis, likely caused by dysfunction in pathways regulating the formation of vascular channels during embryonic development. True angiogenesis may occur in some of these lesions, potentially explaining their propensity to thicken and even expand over time. However, in general, vascular malformations have a quiescent endothelium, and they do not exhibit the markers of endothelial cell proliferation seen in infantile hemangiomas during their proliferative phase (Fig. 104.1)[2,3]. Because vascular malformations are not truly proliferating lesions with cellular hyperplasia, the suffix "oma" (meaning "tumor") has been deemed inaccurate. Thus, the terms "angioma", "lymphangioma" and "hemangioma" should no longer be used for vascular malformations.

Vascular malformations are subcategorized depending on the predominant anomalous channels and flow characteristics: slow-flow or fast-flow[2,3]. A slow-flow vascular malformation may be:

- capillary (CM), i.e. port-wine stain (PWS)
- venous (VM): a misnomer for this entity is "cavernous hemangioma", a term with a long history of use to describe deep infantile hemangiomas
- lymphatic (LM): this category includes microcystic and macrocystic lesions (formerly termed lymphangioma and cystic hygroma, respectively).

A fast-flow vascular malformation combines arterial anomalies and arteriovenous shunting, creating the nidus of an arteriovenous malformation (AVM).

Complex-combined vascular malformations are designated as capillary–venous (CVM), capillary–lymphatic (CLM), capillary–lymphatic–venous (CLVM), lymphatic–venous (LVM), capillary–arteriovenous (C-AVM) or lymphatic–arteriovenous (L-AVM), depending on the vessels involved. A few scenarios provide evidence of overlap (e.g. spindle cell hemangiomas and VMs in patients with Maffucci syndrome; pyogenic granulomas superimposed on a CM or AVM) or coexistence (e.g. familial co-segregation of infantile hemangiomas and vascular malformations) of vascular tumors and vascular malformations.

Vascular malformations may occur in any body part or organ system. They are most easily identified in the skin and mucous membranes, with some of these lesions invading deep into underlying muscles, bones or joints. Others are found in visceral locations. Vascular malformations can appear as localized lesions of varying sizes, occur within a segmental distribution, or be dispersed as multifocal or disseminated lesions. Vascular malformations are occasionally found together with other abnormalities as part of a complex syndrome, which may be referred to by an eponym (e.g. Klippel–Trenaunay syndrome; KTS).

Vascular malformations are persistent and tend to worsen over time if not treated. Categorizing a lesion as a CM, LM, VM or AVM is important, since diagnostic modalities as well as treatment will differ depending on the type of vessels involved[1]. In many patients, a multidisciplinary team is required to provide optimal management. Cure is rarely achievable. A realistic aim is improvement and minimization of cosmetic or functional consequences. Many patients require longitudinal care from infancy through adulthood[1].

HISTORY

In the medical literature addressing vascular malformations, lesions and syndromes were originally delineated based on clinical features. Many authors played a major role in their description, including Virchow, Trélat, Monod, Klippel, Trenaunay, Weber, Sturge, Bockenheimer, Maffucci, Bell and Malan. Unfortunately, pathologists and clinicians did not work together. Consequently, multiple nomenclatures became an obstacle to communication among physicians treating these patients. In 1976, John B Mulliken (a plastic surgeon in the US), Anthony E Young (a vascular surgeon in the UK) and Jean-Jaques Merland (a neurointerventional radiologist in France) joined forces to convene the first of many Workshops on Vascular Anomalies. The ISSVA, created in 1992, is dedicated to analyzing the clinical, radiologic, biologic and pathologic characteristics of vascular lesions and improving diagnosis and treatment via multidisciplinary and international collaboration[2].

EPIDEMIOLOGY

Little is known regarding the exact prevalence of vascular malformations in the general population. The most common types are CMs, then VMs. The least common are AVMs. Vascular malformations have no gender predilection. They appear to be less frequent in individuals of African and Asian descent.

PATHOGENESIS

An initial embryologic process, vasculogenesis, creates the primitive vascular plexus. Then angiogenesis, the secondary sprouting of mesoderm-derived endothelial cells, forms new vessels from existing ones, thereby generating most blood and lymphatic vessels. Endothelial

DIFFERENCES BETWEEN VASCULAR MALFORMATIONS AND INFANTILE HEMANGIOMAS		
Characteristics	**Vascular malformations**	**Infantile hemangiomas**
Clinical features	CM: red, macular during infancy VM: blue, compressible, fills with dependency LM: vesicles or large cysts AVM: four stages: stage 1 – dormant: red, warm; macular (mimics CM) or slightly infiltrated (mimics late involuting infantile hemangioma) stage 2 – expansion: warm mass with thrill/throbbing, dilated draining veins stage 3 – destruction: pain, ulceration; occasional bone lysis and fracture stage 4 – cardiac decompensation; high-output cardiac failure; also signs of stage(s) 2 ± 3	Premonitory markers at birth in 50%: red telangiectatic, bluish "bruise-like" or white "anemic" macules Superficial hemangioma: bright red, "strawberry"-like papules and plaques (during proliferative phase) Deep hemangioma: warm, rubbery mass under normal-colored or bluish skin
Sex prevalence	Female : male ratio 1 : 1	Female : male ratio 3 : 1 to 6 : 1
Natural history	Usually evident at birth Lifelong persistence, with commensurate growth during childhood and often slow worsening over time AVM: may worsen with puberty, trauma and pregnancy	Precursor lesion or no evidence at birth Postnatal proliferation over 6–12 months, then slow involution over years Reach stable involuted stage
Radiology	VM or LM (slow flow): hypersignal on MRI T2-weighted sequence VM: thrombi and phleboliths (MRI, CT); gadolinium enhancement on MRI AVM (fast flow): flow voids on MRI T1- and T2-weighted sequences; arteriovenous shunts on Doppler ultrasound	Well-defined mass Some flow voids on MRI T1-weighted sequences (high-flow vessels)
Pathology (see Fig. 104.22)	CM: ectatic capillaries VM or LM: distorted, interconnected malformed channels AVM: AV fistulae and increased capillaries Typically no increase in cellular turnover	Dense lobular proliferation of endothelial cells forming capillaries with tiny lumens Increased cellular turnover in proliferating lesions can be demonstrated by elevated levels of markers of proliferation (PCNA, Ki-67), ECM remodeling (collagenase, urokinase), and vascular growth (bFGF, VEGF)
Immunophenotype	GLUT-1-negative	GLUT-1-positive
Hematology	VM or LVM: chronic LIC, occasional DIC Treatment of flares with low-molecular-weight heparin Possible benefit of low-dose aspirin as prophylaxis	(Kasabach–Merritt syndrome is not linked to infantile hemangiomas, but to other vascular tumors such as kaposiform hemangioendotheliomas and tufted angiomas, both of which are GLUT-1-negative; see Ch. 114)
Molecular biology	Sporadic VMs: somatic *TEK* mutation in 50% Familial vascular malformations: see Table 104.2	Rare families with autosomal dominant inheritance linked to 5q, and *somatic* loss of heterozygosity of 5q in some hemangiomas *Germline* mutation in *VEGFR2* or *TEM8* in some patients *Somatic* mutation in *VEGFR2* or *FLT4/VEGFR3* (5q34) in some hemangiomas Clonality in some hemangiomas

Table 104.1 Differences between vascular malformations and infantile hemangiomas. AVM, arteriovenous malformation; bFGF, basic fibroblast growth factor; CM, capillary malformation; CT, computed tomography; DIC, disseminated intravascular coagulation; ECM, extracellular matrix; *FLT4*, fms-related tyrosine kinase 4; LIC, localized intravascular coagulation; LM, lymphatic malformation; MRI, magnetic resonance imaging; PCNA, proliferating cell nuclear antigen; *TEM8*, tumor endothelial marker 8; VEGF, vascular endothelial growth factor; VM, venous malformation.

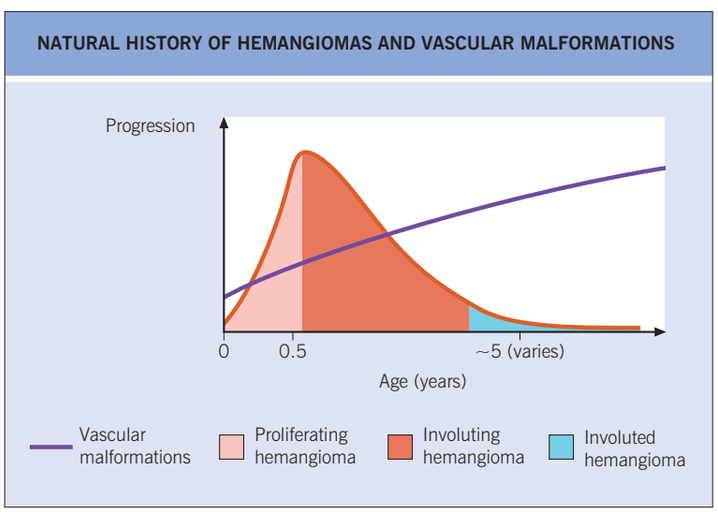

Fig. 104.1 Natural history of infantile hemangiomas and vascular malformations.

differentiation, recruitment of smooth muscle cell precursors to ensheathe endothelial cells and build vessel walls, and, finally, changes in channel size, morphology and rheology create capillaries, veins and arteries.

Vascular malformations constitute a heterogeneous group of disorders that result from alterations in formation of blood or lymphatic channels. Dysfunction in signaling processes that regulate migration, differentiation, maturation, adhesion and survival of the cells of vascular walls is thought to have a pathogenic role. Markers of cellular proliferation are not elevated in vascular malformations[3]. In the cephalic region of the embryo, mural cells associated with endothelial cells come from the neural crest; therefore, a vascular malformation complex such as Sturge–Weber syndrome (SWS) is likely caused by a somatic mutation in the embryo's anterior neural crest or adjacent cephalic mesoderm. Rare familial transmission of vascular malformations has allowed mapping of susceptibility to certain inherited lesions to precise chromosomal locations, identification of the associated gene(s) and disease-causing mutations, discovery of the function of the encoded proteins, and clarification of the role the dysfunction plays in regulatory pathways (Table 104.2). It remains to be determined if sporadic vascular malformations, which are far more frequent than familial ones, are caused by the same gene mutations. Some data support this hypothesis. For example, mutations in the *TEK* gene causing constitutive activation

VASCULAR ANOMALIES FOR WHICH THE MOLECULAR BASIS IS KNOWN				
Vascular malformation	**Mode of inheritance**	**Mutated gene(s)**	**Type of mutation**	**Protein and function**
CAPILLARY AND/OR ARTERIOVENOUS MALFORMATIONS				
Ataxia–telangiectasia	AR	*ATM* (11q22–23)	Loss-of-function	ATM protein is similar to phosphoinositol-3 kinase – regulates cell cycle, DNA repair, p53
Capillary malformation–arteriovenous malformation	AD	*RASA1* (5q13)	Loss-of-function	p120-Ras-GAP protein – involved in signaling by growth factor receptors
Cerebral capillary malformations (CCM; familial cerebral cavernomas)*	AD	CCM1: *KRIT1* (7q21–22) CCM2: *MGC4607* (7p15–13) CCM3: *PDCD10* (3q25.2–27)	Loss-of-function	KRIT-1 interacts with KREV-1, RAP-1A and malcavernin (the *CCM2* gene product) – roles in MAPK and integrin signaling
Hereditary hemorrhagic telangiectasia (HHT; Osler–Weber–Rendu)	AD	HHT1: *ENG* (9q3) HHT2: *ACVRL1/ALK1* (12q13) HHT3: (5q31–32) HHT4: (7p14)	Loss-of-function	Endoglin and activin receptor-like kinase 1 (ALK1) – two TGF-β receptors with roles in vessel wall integrity
Juvenile polyposis with HHT	AD	*SMAD4* (18q21.1)	Loss-of-function	SMAD4 tumor suppressor protein – role in TGF-β signaling
VENOUS MALFORMATIONS				
Cutaneous and mucosal venous malformations (VMCM)	AD; sporadic (with somatic mutations in lesional tissue)	*TEK* (9p21)	Gain-of-function	TIE-2, an endothelial cell-specific tyrosine kinase receptor that binds angiopoietins
Glomuvenous malformations (glomangiomatosis)	AD/"paradominant"	*GLMN* (1p21–22)	Loss-of-function (germline plus second hit within lesions)	Glomulin protein is a component of a multiprotein complex – role in vascular morphogenesis
LYMPHATIC ANOMALIES				
Milroy disease (familial congenital lymphedema)	AD†	*FLT4* (5q34)	Loss-of-function	VEGFR-3 – a tyrosine kinase receptor in lymphatic vessels
Lymphedema–distichiasis syndrome	AD	*FOXC2* (16q22–24)	Loss-of-function	Forkhead family transcription factor C2
Hypotrichosis–lymphedema–telangiectasia	AR, AD	*SOX18* (20q13.33)	Loss-of-function	SRY-box 18 transcription factor
Hennekam lymphangiectasia–lymphedema syndrome‡	AR	*CCBE1* (18q21)	Loss-of-function	Collagen & calcium-binding EGF domain-containing protein 1
Hereditary lymphedema	AD	*GJC2* (1q42.13)	Loss-of-function	Connexin 47 in gap junctions of lymphatic vessels
Lymphedema-choanal atresia	AR	*PTPN14* (1q32)	Loss-of-function	Protein tyrosine phosphatase that may interact with VEGFR-3
ARTERIOPATHY				
CADASIL	AD	*NOTCH3* (19q12)	Loss-of-function in a subset of cases	Accumulation of NOTCH-3 protein in vascular smooth muscle cells

Cutaneous vascular malformations, including hyperkeratotic capillary–venous malformations (associated with *KRIT1* mutations) and venous malformations (less common), occur in ~10% of patients.
†An autosomal *recessive* form of congenital lymphedema caused by hypomorphic *FLT4* mutations has also been described.
‡Presents with generalized lymphedema, lymphangiectasias (intestinal and pulmonary), facial anomalies (flat face, depressed nasal bridge, hypertelorism) and mental retardation.

Table 104.2 Vascular anomalies for which the molecular basis is known. Vascular malformations also occur in patients with PTEN hamartoma tumor syndrome (typically fast-flow lesions) and Proteus syndrome (due to mosaic activating *AKT1* mutations) (see text). AD, autosomal dominant; AR, autosomal recessive; CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; *FLT4*, fms-related tyrosine kinase 4; MAPK, mitogen-activated protein kinase; *PDCD10*, programmed cell death 10; TGF-β, transforming growth factor-β; VEGFR-3, vascular endothelial growth factor receptor-3; VM, venous malformation.

of the endothelial cell tyrosine kinase receptor TIE-2 are found in lesional tissues but not the peripheral blood (indicative of a *somatic* mutation) in half of patients with sporadic VMs as well as in the *germline* of patients with familial cutaneous and mucosal VMs (VMCM)[4]. Such research brings hope of gene therapy or currently unimaginable novel treatment strategies[4–6].

CLINICAL FEATURES

With the expertise of multidisciplinary vascular clinics, >90% of vascular malformations can be correctly categorized on the basis of their clinical features. This helps in the selection of the best investigative tools (Table 104.3), avoiding redundant and unnecessary diagnostic imaging procedures.

Capillary Malformations

Two major types of CM exist: PWSs and telangiectasias. These lesions can represent the most obvious sign of a complex syndrome. An approach to the evaluation of a patient with a presumed CM of the head and neck region is shown in Figure 104.2.

Port-wine stain

PWSs typically present at birth as well-demarcated red macules and patches. PWS is *not* the correct term for the common congenital capillary stains located on the mid-face (forehead, glabella, tip of the nose and philtrum), eyelids, and nape or occiput (Fig. 104.3A&B). Such lesions are referred to as a *nevus simplex* or *salmon patch*; they are also known as an "angel kiss" or "aigrette" on the forehead and a "stork bite" on the neck. Many fade spontaneously between 1 and 3 years of age, the facial ones more often than those in the nape area.

The growth of PWSs is commensurate with the child's growth. They can be localized or have a segmental pattern, but they do not follow the lines of Blaschko. Some are multifocal and widespread. Facial PWSs are frequently distributed according to what has classically been considered the sensory trigeminal nerve dermatomes, with three areas recognized: V1 (ophthalmic region: forehead and upper eyelid), V2 (maxillary region; Fig. 104.3C) and V3 (mandibular region).

INVESTIGATIVE TOOLS FOR VASCULAR MALFORMATIONS				
Tool	**Vascular lesion**			
	Capillary malformation	**Lymphatic malformation**	**Venous malformation**	**Arteriovenous malformation**
Ultrasonography	+/–	++++	+++	++++
CT with contrast	–*	++	++	++
MRI with gadolinium	–*	+++ (no gadolinium enhancement)	++++ (gadolinium enhancement)	+++
3D-angio CT or 3D-angio MRI	–	–	++	++++
Arteriography	–	–	–	++++
Phlebography	–	–	+/–	–
Lymphography (isotopic)	–	+/–	–	–
Biopsy	+/–	+/–	–	–

*Brain studies are useful in the evaluation of possible Sturge–Weber syndrome (SWS); specific MRI techniques that may provide additional information in patients with SWS include dynamic contrast bolus MR perfusion imaging, susceptibility-weighted imaging (SWI), and MR diffusion tensor imaging (see text for details).

Table 104.3 Investigative tools for vascular malformations. A larger number of +'s indicates increased utility. CT, computed tomography; MRI, magnetic resonance imaging.

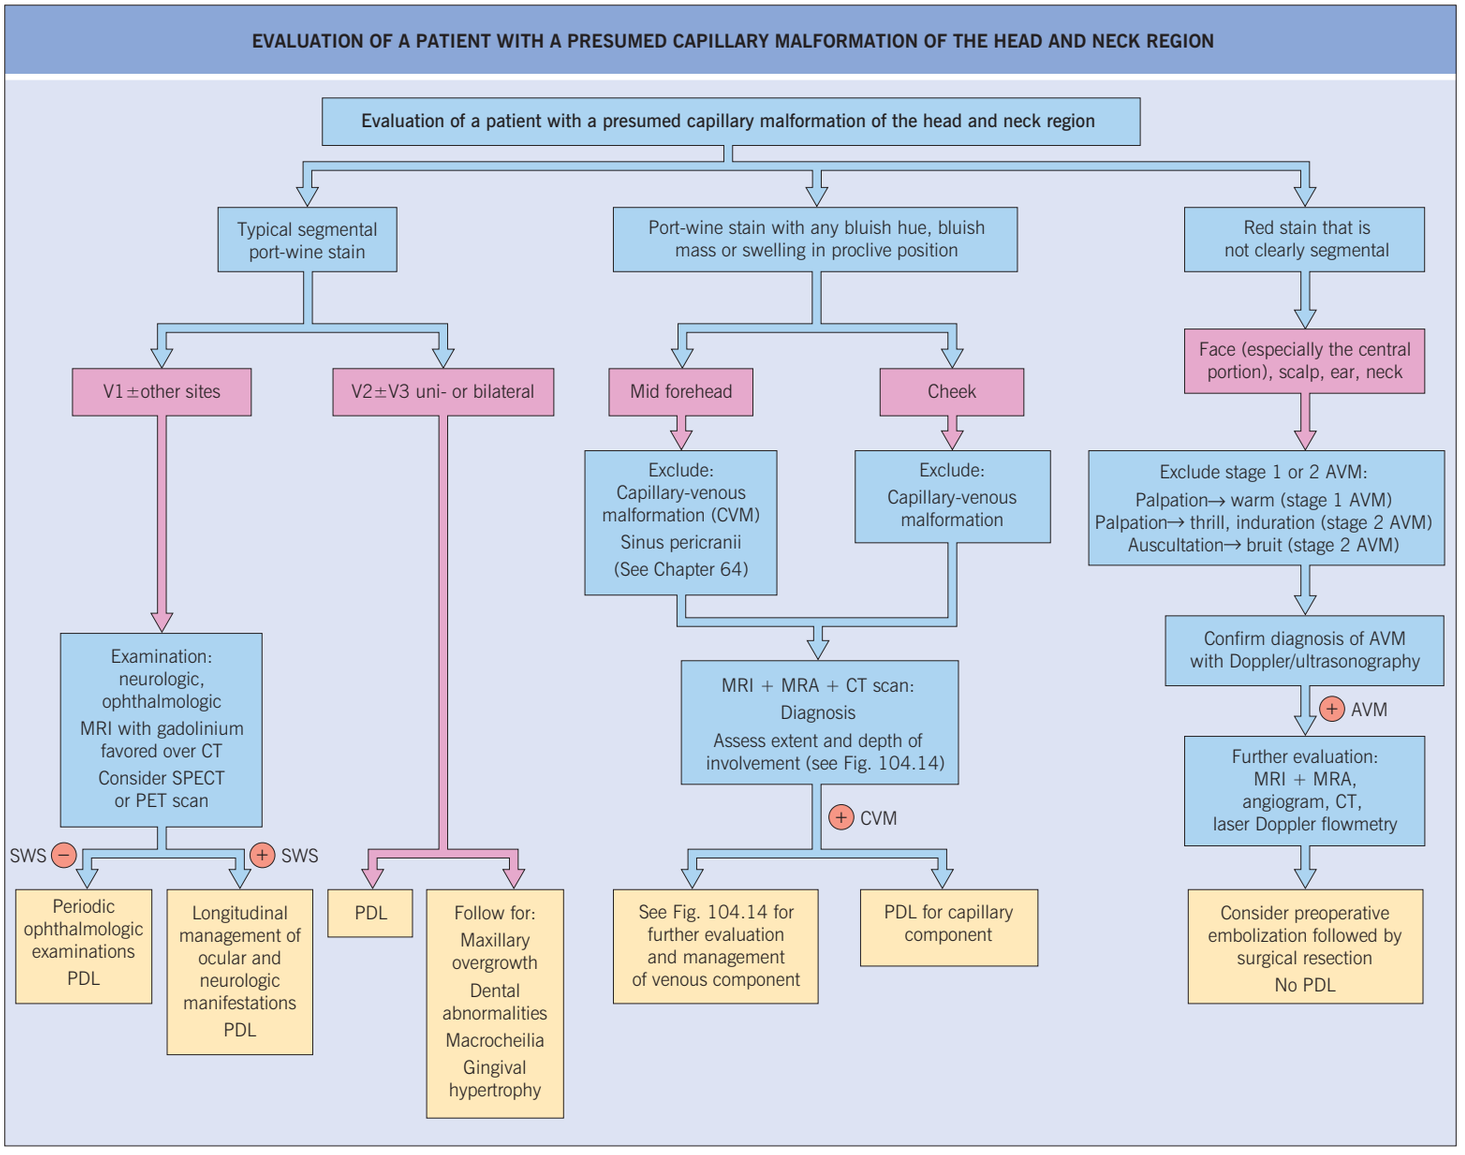

Fig. 104.2 Evaluation of a patient with a presumed capillary malformation of the head and neck region. AVM, arteriovenous malformation; CT, computed tomography; CVM, capillary venous malformation; PDL, flashlamp-pumped pulsed dye laser; MRA, magnetic resonance arteriography; MRI, magnetic resonance imaging; PET, positron emission tomography; SPECT, single photon emission computed tomography; SWS, Sturge-Weber syndrome.

Fig. 104.3 Salmon patches versus port-wine stain (PWS) in V2 distribution. A Involvement of the central face in a symmetric pattern is typical of a salmon patch; such lesions usually fade over the first few years of life but are sometimes misdiagnosed as a PWS. **B** Salmon patches in the nape area ("stork bites") tend to be more persistent. **C** In this young infant with a PWS, the skin is smooth. This lesion will be persistent. *B, Courtesy, Julie V Schaffer, MD.*

Over time, PWSs (especially those affecting the V2 and V3 areas) often develop a deeper red hue, changing from pinkish-red (at birth) to purplish-red (in adulthood). Affected skin may thicken and become nodular (Fig. 104.4), and superimposed pyogenic granulomas occasionally appear. In a study of 173 patients with PWSs, thickening was observed in 11% (median age 32 years), nodularity in 24% (median age 44 years), and both in 6% (median age 45 years)[7]. Overgrowth of the maxilla (Fig. 104.5) and other facial bones underlying a PWS can also occur, creating problems such as an open-bite deformity. Affected gums and lips may enlarge, potentially resulting in epulides, gingival bleeding, macrocheilia and lip incompetence. Hypertrophic skin changes are rare in PWSs on the trunk and limbs. Interestingly, when a child with a PWS has atopic dermatitis, eczematous lesions may have a predilection for areas of skin affected by the CM.

PWSs are congenital in the vast majority of patients. However, *acquired PWSs* have been described in adolescents and adults, and onset of such lesions may be precipitated by trauma. Of note, early morphea (especially the linear variant) occasionally presents with a red vascular patch that mimics an acquired PWS[7a].

A CM can be admixed with a network of blanched macules representing a nevus anemicus (Fig. 104.6), a phenomenon referred to as vascular twin spotting. The association of a CM with aberrant Mongolian spots (dermal melanocytosis) (Fig. 104.7) or a nevus spilus (speckled lentiginous nevus) is another example of twin spotting, which is referred to as *phakomatosis pigmentovascularis (PPV)* (Table 104.4)[8,9].

A dorsal midline PWS (e.g. of the lumbosacral area) is occasionally a hallmark for *occult spinal dysraphism*, particularly if the stain is associated with other cutaneous markers of dysraphism (see Ch. 64). In patients with clinically suspected dysraphism, ultrasound may be useful in infants <2–4 months of age, but MRI is a more sensitive study.

Fig. 104.4 Port-wine stain in V2 distribution in an adult. Hyperplasia and nodularity are prominent.

Fig. 104.5 Port-wine stain in V2 distribution. Note the enlarged gingiva on the right and overgrowth of the right maxilla.

Syndromic capillary malformations

Sturge–Weber syndrome

SWS is a sporadic neurologic disorder in which a facial CM is associated with ipsilateral ocular and leptomeningeal/brain anomalies. The facial PWS typically involves the V1 region (forehead and upper eyelid)[1], and it often extends unilaterally or bilaterally over more of the face (Fig. 104.8). Some SWS patients also have PWSs on the extremities and trunk, which may be associated with KTS (see below). In addition, SWS occasionally occurs in the setting of PPV.

Ocular involvement is more frequent when the PWS affects both the V1 and V2 regions. It may be detected at birth because of buphthalmos (congenital glaucoma). Acute glaucoma with a cloudy cornea can be an infantile emergency. Usually, however, increased eye pressure develops slowly. Glaucoma may become obvious only in late childhood; thus, periodic lifelong assessment of visual function and eye pressure is

Fig. 104.6 Phakomatosis pigmentovascularis type 2b (cesioflammea; associated with Sturge–Weber syndrome). A port-wine stain and nevus anemicus are intermingled on the shoulder of this man.

Fig. 104.7 Phakomatosis pigmentovascularis type 2a (cesioflammea). A large port-wine stain and extensive dermal melanocytosis are seen.

PHAKOMATOSIS PIGMENTOVASCULARIS (PPV)				
Type	**Descriptive name**	**Proportion of reported cases**	**Major cutaneous components**	**Other reported cutaneous components**
Ia/b	*	<5%*	Epidermal nevus + **PWS**	
IIa/b	Phakomatosis cesioflammea	75%	Dermal melanocytosis (aberrant Mongolian spots) + **PWS**	Nevus anemicus, hypotrichosis, lipohypoplasia, hypoplastic nails
IIIa/b	Phakomatosis spilorosea	10%	Nevus spilus (macular type) + **PWS/"nevus roseus"**†	Nevus anemicus, lymphedema, hypotrichosis
IVa/b	Phakomatosis pigmentovascularis, unclassifiable	10%	Variable, sometimes with features of II + III or II + V	Nevus anemicus, nevoid hyper- or hypopigmentation, nevus sebaceus
Va/b	Phakomatosis cesiomarmorata	<5%	Dermal melanocytosis + **cutis marmorata telangiectatica congenita**	

*Existence as a type of PPV has been challenged considering that epidermal nevi are not melanocytic lesions; epidermal nevi can occur together with vascular malformations in Proteus, *PTEN* hamartoma tumor and CLOVES syndromes (see text), which are not generally considered as PPV.
†Capillary malformation with a pale pink color; "rosé-wine" rather than port-wine stain.

Table 104.4 Phakomatosis pigmentovascularis (PPV). a = cutaneous abnormalities only; b = cutaneous and extracutaneous abnormalities (e.g. of Sturge–Weber syndrome, Klippel–Trenaunay syndrome, or ocular as well as cutaneous nevus of Ota). PWS, port-wine stain.

Fig. 104.8 Infant at risk for Sturge–Weber syndrome. Port-wine stain with involvement of V1 as well as V2 and V3.

mandatory to recognize and treat glaucoma before it results in loss of vision. A choroidal vascular malformation may also be detected in the affected eye.

Neurologic symptoms are due to the presence of a CVM within the pia mater ipsilateral to a V1 PWS; over time, cerebral hemiatrophy and calcifications may develop in association with the leptomeningeal vascular malformation. The occipital region of the brain is the most common location. Neurologic consequences can include seizures, either affecting the side of the body opposite to the vascular anomaly or generalized. Epilepsy typically develops in the first year of life, and the seizures may be difficult to control with anticonvulsants, especially early on. Additional findings can include contralateral hemiparesis or hemiplegia, developmental delays (e.g. in motor and cognitive skills), emotional and behavioral problems, attention deficits and migraine headaches.

The risk of ocular and neurologic manifestations of SWS is ≤10% when a unilateral PWS affects the full V1 region; it is lower when the PWS involves only a portion of the V1 area and much higher (>50%) for a bilateral PWS covering the forehead and both upper eyelids[1,10]. In a study of 55 patients with the leptomeningeal vascular anomalies of SWS, the associated cutaneous CM was unilateral in 63.5%, bilateral in 31%, and absent in 5.5%[11]. All three tissues involved in SWS – namely, all the cellular components of the V1 facial skin (except for the endothelial cells), the ocular choroid and the pia mater – are cephalic neural crest derivatives, originating from a common precursor in the anterior neural primordium. An early somatic mutation, prior to

migration of embryonic neural crest derivatives, has been hypothesized. Regionalization of the cephalic neural crest cells to specific areas of the face is not strict, explaining some fluidity in the distribution of the facial CM, especially at the internal and external eyelid canthi (V1–V2 watershed).

Early neuroimaging can identify and delineate the extent of central nervous system (CNS) abnormalities in infants with a V1 PWS. CT with iodinated contrast and MRI with gadolinium can detect pial and brain lesions as well as enlargement of the ipsilateral choroid plexus. Before 6 months of age, MRI may demonstrate advanced myelination in the involved hemisphere. Gyriform calcifications develop during childhood in SWS patients and are visible by various neuroimaging modalities. MRI may also reveal developmental venous anomalies of the brain (see cephalic VM section below).

Some infants and children with SWS have cognitive deficits that are more severe than anticipated based upon their limited cortical involvement on conventional MRI studies. Functional cerebral imaging, such as SPECT (single photon emission computed tomography, which evaluates regional cerebral blood flow) or PET (positron emission tomography, which shows the metabolism of glucose), can permit early and more precise evaluation of the location of brain lesions and their consequences. Newer, less invasive MRI techniques also enable early evaluation of brain anomalies. Susceptibility-weighted imaging (SWI), which detects deoxygenated blood with extremely high sensitivity, provides detailed assessment of venous abnormalities without contrast injection. In children with SWS, SWI also shows a gyriform pattern of cortical signal intensity loss that correlates well with hypometabolic areas on PET scans[12]. MR diffusion tensor imaging can identify microstructural changes in the white matter in children with SWS[12]. Lastly, dynamic contrast bolus magnetic resonance perfusion imaging can visualize cerebral perfusion defects in SWS patients[13].

Endocrine dysfunction may occur due to effects of SWS on the hypothalamic–pituitary axis. Examples include growth hormone deficiency in 0.5% (9/1653) of patients from a SWS registry (compared to 0.03% in the general population) and central hypothyroidism in ~2% (2/84) of patients evaluated at a SWS referral center[14].

Klippel–Trenaunay syndrome

Klippel–Trenaunay syndrome (KTS) is defined as a limb CVM or CLVM associated with progressive overgrowth of the affected extremity. Additional findings can include extension of the vascular malformation to the truncal skin, lipomatosis, lymphedema, and vascular lesions of the gastrointestinal (GI) and urinary tracts (which may bleed intermittently). The cutaneous CM presents either as: (1) a pink-to-red, blotchy stain in an apparently haphazard distribution over the affected extremity; or (2) a red-to-purple, sharply demarcated geographic stain that tends to affect the lateral aspect of the thigh, knee and leg (Fig. 104.9). Geographic stains often have a lymphatic component, and superimposed purple or clear vesicles (representing angiokeratomas or microcystic LMs) frequently develop[15]. KTS patients with a geographic stain have an increased risk of complications such as massive limb overgrowth and cellulitis[15]. Like "pure" VMs (see below), the anomalous venous network in KTS may be associated with a chronic intravascular coagulopathy with high D-dimer and low fibrinogen levels, and patients are at risk of deep vein thrombosis, chronic thromboembolic pulmonary hypertension or even life-threatening pulmonary embolism[16]. Foot and hand malformations in KTS are usually associated with deep venous system anomalies[17].

Duplex ultrasonography is useful in investigating the vascular anomalies underlying KTS, and MRI can delineate the extent of soft tissue and bone involvement (see Table 104.3). Lymphoscintigraphy is occasionally indicated. In patients with GI bleeding, colonoscopy or capsule endoscopy may reveal capillary patches, extensive dilated venous channels and microcystic LM in the intestines.

Fig. 104.9 Klippel–Trenaunay syndrome. Geographic capillary stain on the thigh associated with lymphatic vesicles, dilated incompetent veins and enlarged lower limb.

Fig. 104.10 Plantar cerebriform connective tissue nevus in a man with Proteus syndrome.

Proteus syndrome

Proteus syndrome is characterized by progressive worsening over time and a mosaic distribution of anomalies (see Ch. 62)[18]. It was recently found to be caused by mosaic activating mutations in the *AKT1* gene, which encodes a protein that positively regulates cellular growth and proliferation[18a]. Asymmetric, disproportionate overgrowth leads to severe deformity and disabling orthopedic consequences (e.g. hyperostoses that distort the skull and other bones, megaspondylodysplasia with scoliosis). Cutaneous features include epidermal nevi, cerebriform connective tissue nevi of the palms and soles (Fig. 104.10), patchy dermal hypoplasia, dysregulated adipose tissue (lipomas, regional absence of fat) and slow-flow vascular anomalies (CMs, VMs, LMs). Pulmonary cysts and a distinctive facial phenotype (e.g. a long face, ptosis, anteverted nares) represent additional manifestations. The differential diagnosis of Proteus syndrome includes the next three entities.

CLOVES syndrome

This "Proteus-like" syndrome is characterized by asymmetric ***C***ongenital ***L***ipomatous ***O***vergrowth (infiltrative, typically truncal), ***V***ascular anomalies (slow- or fast-flow), ***E***pidermal nevi and ***S***coliosis/other ***S***keletal abnormalities (especially broad hands and feet)[19,20].

CLAPO syndrome

CLAPO syndrome features ***C***Ms and ***L***Ms (particularly of the lower lip, tongue and neck) together with ***A***symmetry and ***P***artial ***O***vergrowth of the face and extremities[21].

Macrocephaly–capillary malformation

Macrocephaly–CM, previously known as macrocephaly–cutis marmorata telangiectatica congenita (CMTC), manifests with pinkish-red, finely reticulated or confluent PWSs (Fig. 104.11) rather than true CMTC (see below). Additional features include persistent mid-facial capillary stains (especially on the philtrum), developmental delay, neurologic anomalies (e.g. ventriculomegaly, acquired cerebellar tonsillar herniation), asymmetric overgrowth, syndactyly (especially 2nd–3rd toes), polydactyly, joint laxity and hyperelastic skin[22].

Telangiectasias

Telangiectasias (see Ch. 106) are dilated capillary-type blood vessels. These punctate, stellate, or linear red lesions may have a localized, segmental or widespread distribution. In some disorders they tend to affect particular anatomic sites. For example, *angioma serpiginosum* features clusters of tiny punctate telangiectasias in serpiginous patterns with a predilection for the extremities, whereas *unilateral nevoid telangiectasia* has a segmental configuration favoring the face, neck, chest and arms. The lesions of *hereditary benign telangiectasia* (HBT) may mimic those of hereditary hemorrhagic telangiectasia (HHT; see below), but the former is not associated with epistaxis or visceral hemorrhage. In addition, some kindreds initially reported as having HBT actually had capillary malformation–arteriovenous malformation (CM-AVM; see below)[23].

Cutis marmorata telangiectatica congenita

Cutis marmorata telangiectatica congenita (CMTC) is characterized by a dark purple to red–purple, broad reticulated vascular pattern intermingled with telangiectasias and (occasionally) prominent veins (Fig. 104.12). It commonly affects one or more limbs and the corresponding quadrant(s) of the trunk. Unlike cutis marmorata, CMTC persists upon warming the affected infant. Atrophic depressions may be evident within the net-like pattern, especially over joints, and can result in ulceration and scarring. CMTC often lightens after the first year of life, but some residual violaceous network is common[1,24]. Up to 50% of patients have associated abnormalities, most often hypoplasia (girth > length) of the affected limb(s) and additional vascular malformations. Other skeletal (e.g. syndactyly), ocular (e.g. glaucoma associated with facial CMTC) and neurologic defects are occasionally observed, especially in patients with generalized CMTC. *Adams–Oliver syndrome* combines distal transverse limb defects, scalp skin and skull defects (aplasia cutis congenita; see Ch. 64) and variable cardiac malformations with CMTC or a reticulated CM. Macrocephaly–CMTC has been reclassified as *macrocephaly–CM* (see above). Lastly, relatively short-lived "pseudo"-CMTC has been described in infants with neonatal lupus erythematosus.

Hereditary hemorrhagic telangiectasia

Hereditary hemorrhagic telangiectasia (HHT; Osler–Weber–Rendu disease) is an autosomal dominant disorder characterized by mucocutaneous telangiectasias (which actually represent small AVMs) and

Fig. 104.11 Reticulated port-wine stain (PWS) in a patient with macrocephaly–capillary malformation syndrome. This boy has hemihypertrophy of the side of the body *opposite* to the PWS. *Courtesy, Julie V Schaffer, MD.*

Fig. 104.12 Cutis marmorata telangiectatica congenita (CMTC) with atrophy of the affected limb. The color of the broad vascular network can be red–purple (**A**) or, as seen in this infant of Caribbean descent, brownish-purple (**B**).

visceral AVMs that have a propensity to bleed. Phenotypes vary considerably, even within a given family[25–27]. The first manifestation of HHT is usually epistaxis during childhood or adolescence (mean age of onset = 12 years)[27]. Telangiectasias of the skin and oral mucosa typically appear after puberty and may not be noticed until adulthood. They most commonly affect the face, lips, tongue, palms and fingers (including periungual areas and the nail bed). These dark red lesions are either round, slightly elevated papules or ill-defined, stellate macules.

It is important to screen individuals suspected to have HHT for visceral AVMs (Table 104.5). In particular, AVMs in the lungs and brain are often asymptomatic prior to the sudden development of life-threatening complications[25–27]. Pulmonary AVMs can result in hypoxemia, hemorrhage, and (because of the lack of capillary bed filtering) cerebral abscesses or strokes due to paradoxical emboli. Transcatheter embolotherapy of pulmonary AVMs is recommended[27]. Lethal intracranial hemorrhage from cerebral AVMs can occur as early as infancy[26], and acute paraplegia due to spinal AVMs has also been described in children with HHT. Treatment strategies for AVMs of the CNS include embolization, microsurgery and stereotactic radiation. Gastrointestinal or (less often) genitourinary tract bleeding typically occurs in mid adulthood and often presents as iron deficiency anemia. Lastly, hepatic AVMs may lead to high-output heart failure, portal hypertension and biliary disease.

Mutations in two different genes are known to cause classic HHT: *ENG* (endoglin; HHT1) and *ALK1* (activin receptor-like kinase 1, also known as *ACVRL1*; HHT2). Both genes encode glycoprotein components of endothelial transforming growth factor-β (TGF-β) receptors. A genotype–phenotype correlation has been established, with a higher risk of pulmonary (especially in women) and cerebral AVMs in HHT1 and a higher risk of liver AVMs in HHT2. Two other HHT loci have been described, but the associated genes have not yet been identified (see Table 104.2). In addition, mutations in the *SMAD4* gene (which encodes a protein that transmits signals from the TGF-β receptor) underlie a disorder that features juvenile gastrointestinal polyposis and HHT. Genetic testing can establish the diagnosis of HHT in children and young adults who do not yet meet clinical criteria (see Table 104.5). Information on medical centers and laboratories that specialize in HHT is available at www.hht.org.

Ataxia–telangiectasia

Ataxia–telangiectasia is an autosomal recessive disorder that occurs in approximately 1 in 40 000 births and is due to mutations in the *ATM* gene (see Ch. 60). Ataxia is the initial symptom and usually presents in toddlers. Telangiectasias typically begin to appear at 4–6 years of age, primarily on the conjunctivae, face and ears. Immunoglobulin deficiencies (e.g. IgA, IgG) and defective cell-mediated immunity explain the frequent sinopulmonary infections. Patients are at high risk for the development of lymphoma and leukemia. Elevated levels of circulating α-fetoprotein are found in affected individuals. Heterozygote carriers of a mutated *ATM* gene also have an increased risk of breast cancer and hematologic malignancies.

Angiokeratomas

Angiokeratomas (see Ch. 114) consist of ectasias of dermal capillaries associated with an acanthotic and hyperkeratotic overlying epidermis. These dark red-to-purple, papular vascular anomalies can vary considerably in size, depth and location[1]. The two most common types are *solitary papular angiokeratoma* and *angiokeratomas of the scrotum and vulva*. The former is often found on the lower extremity, and it may be mistaken for a melanoma. In *angiokeratoma circumscriptum*, clusters of ectasias form a plaque or linear array, usually on an extremity, that is often present at birth. Congenital hyperkeratotic vascular anomalies resembling angiokeratoma circumscriptum but with a deeper dermal component consisting of small, thick-walled blood vessels

STUDIES RECOMMENDED TO SCREEN FOR SYSTEMIC INVOLVEMENT AND ASSIST IN THE DIAGNOSIS OF HEREDITARY HEMORRHAGIC TELANGIECTASIA (HHT)

Study	Indication(s)	Purpose of study	Intervention(s) if positive study
Transthoracic contrast echocardiography (bubble study)*	Suspected or confirmed HHT†	Detect **pulmonary** AVMs, which lead to right-to-left shunting (15–50% of HHT patients)	• Confirmation with unenhanced multidetector CT of the thorax with thin-cut reconstructions • Transcatheter embolotherapy for all adults and symptomatic children (and on a case-by-case basis for asymptomatic children) • Antibiotic prophylaxis for procedures with risk of bacteremia, precautions to avoid air bubbles during intravenous access, and avoidance of SCUBA diving
Brain MRI with and without gadolinium‡	Suspected or confirmed HHT†	Detect **cerebral** AVMs and other vascular malformations (~25% of HHT patients)	• Consideration of invasive testing and treatment • Referral to a center with neurovascular expertise
Annual hemoglobin and hematocrit testing	HHT patients >35 years of age	Detect substantial bleeding related to **gastrointestinal** AVMs (~25% of HHT patients; rare before age 40 years)	• Upper endoscopy if anemia disproportionate to epistaxis • Iron supplementation • Treatment considerations include endoscopic cauterization and systemic hormonal or antifibrinolytic therapy
Doppler ultrasonography or triphasic spiral CT of liver	(1) HHT patients with signs/symptoms of heart failure or hepatobiliary disease; or (2) an uncertain HHT diagnosis†	Detect **hepatic** AVMs (present in 30–80% but symptomatic in <10% of HHT patients)	• Additional testing and treatment (directed by findings) in symptomatic patients; liver biopsy should be avoided • Further screening for systemic involvement if diagnosis established
Genetic analysis of *ENG* and/or *ACVRL1* (then *SMAD4* if negative)	(1) "Index case" in HHT family (2) Patients who do not meet HHT criteria† but are at risk because of an affected first-degree relative§ or clinically suspected to have HHT	Detect underlying *ENG* or *ACVRL1* mutation (~75% of HHT patients) or, rarely, *SMAD4* mutation (1–3% of HHT patients)	• Identification of a specific mutation facilitates genetic analysis in family members (including prenatal testing) • Further screening for systemic involvement if diagnosis established

*If negative, repeat screening should be considered after puberty, within the 5 years preceding a planned pregnancy, after pregnancy, and otherwise every 5–10 years.
†Clinical diagnostic criteria are: spontaneous recurrent epistaxis, characteristic mucocutaneous telangiectasias, visceral telangiectasias/AVMs, and HHT in a first-degree relative; definite HHT if ≥3 criteria (met by ≥90% of HHT patients by age 40 years) and possible/suspected HHT if 1–2 criteria (especially for children and young adults).
‡Some authors have recommended omission of gadolinium in the initial MRI screening of children (especially those <2 years of age), and repeat screening with gadolinium at ~age 18 can be considered for children with negative studies; MRI screening for spinal AVFs can also be considered in children.
§The causative mutation should first be identified in an "index case" from the family.

Table 104.5 Studies recommended to screen for systemic involvement and assist in the diagnosis of hereditary hemorrhagic telangiectasia (HHT). Based on 2009 international guidelines[27]. AVF, arteriovenous fistula; AVM, arteriovenous malformation; CT, computed tomography; MRI, magnetic resonance imaging.

(larger than normal capillaries) have been referred to as "*verrucous hemangiomas*" but behave clinically as vascular malformations. Grouped tiny lesions are also seen in *angiokeratoma of Mibelli*, which favors the toes, fingers, knees and elbows. *Angiokeratoma corporis diffusum* is characterized by more widespread lesions, often in a bathing trunk distribution, and it can be associated with several hereditary lysosomal storage disorders such as *Fabry disease* (an X-linked recessive condition due to deficiency of α-galactosidase A) and *α-fucosidase deficiency* (see Table 63.6). Angiokeratomas (as well as microcystic lymphatic lesions) may develop on the surface of geographic CMs in KTS (see above).

Cerebral capillary malformation and hyperkeratotic cutaneous capillary–venous malformation

A distinctive hyperkeratotic cutaneous capillary–venous malformation (HCCVM) occurs in a subgroup of patients with inherited cerebral capillary malformations (CCMs), also referred to as familial cerebral cavernomas[28,29]. Neurologic manifestations, which develop at a mean age of 30 years (range, 2–72 years), may include headaches, seizures and cerebral hemorrhage[28]. This autosomal dominant disorder can be caused by mutations in three different genes (see Table 104.2): *KRIT1* (*CCM1*), *MGC4607* (malcavernin; *CCM2*) and *PDCD10* (*CCM3*). Among the ~10% of familial CCM patients who have *cutaneous* vascular malformations, ~90% have a *KRIT1* mutation[29]. HCCVMs have thus far been described exclusively in patients with *KRIT1* mutations. These irregularly shaped, dark crimson or reddish-purple plaques with surrounding bluish discoloration are typically congenital and located on the extremities. Smaller reddish-brown macules with peripheral telangiectatic puncta have also been observed[29]. Less frequently, children and adults with mutations in any of the three genes develop dark blue cutaneous papules and nodules reminiscent of blue rubber bleb nevus syndrome (BRBNS), which represent VMs[29].

Venous Malformations

VMs are commonly confused with deep infantile hemangiomas or, when they involve a large portion of an extremity, KTS. VMs are recognized clinically by their blue hue, softness, compressibility and tendency to fill with dependency (Fig. 104.13). They can occur in a focal, segmental or (especially in forms with autosomal dominant inheritance) widespread distribution. VMs are best imaged using T2-weighted MRI (see Table 104.3)[1]. Figure 104.14 provides an approach to the evaluation and management of patients with VMs.

Cephalic venous malformation

These lesions frequently lead to cosmetic and functional problems that worsen over time[1]. In addition to the skin, they may affect the lips, oral mucosa, and deeper structures such as muscles, the infratemporal fossa and the orbit (see Fig. 104.13). Cephalic VMs expand when the head is in dependent position. With time, distortion of facial features often becomes conspicuous. Patients with parapharyngeal and laryngeal VMs should be monitored for sleep apnea, which can put them at risk of sudden death during sleep. Approximately 20% of patients with extensive cephalic VMs have defects of the underlying skull[1], which must be identified before performing sclerotherapy, to avoid embolization through the defect.

In the author's experience, 25% of patients with extensive cephalic VMs have developmental venous anomalies (previously referred to by the misnomer "venous angiomas"), compared to <1% of the general population[1]. These are uncommon functional trajectories of venous

Fig. 104.13 Venous malformations (VMs). **A** Distortion of the tongue and lower lip has lead to an open bite. **B** The skin and muscles of the entire arm are affected, with soft bluish nodules and obvious swelling in the dependent position. **C** This VM has a segmental distribution on the right trunk and involvement of the ipsilateral arm.

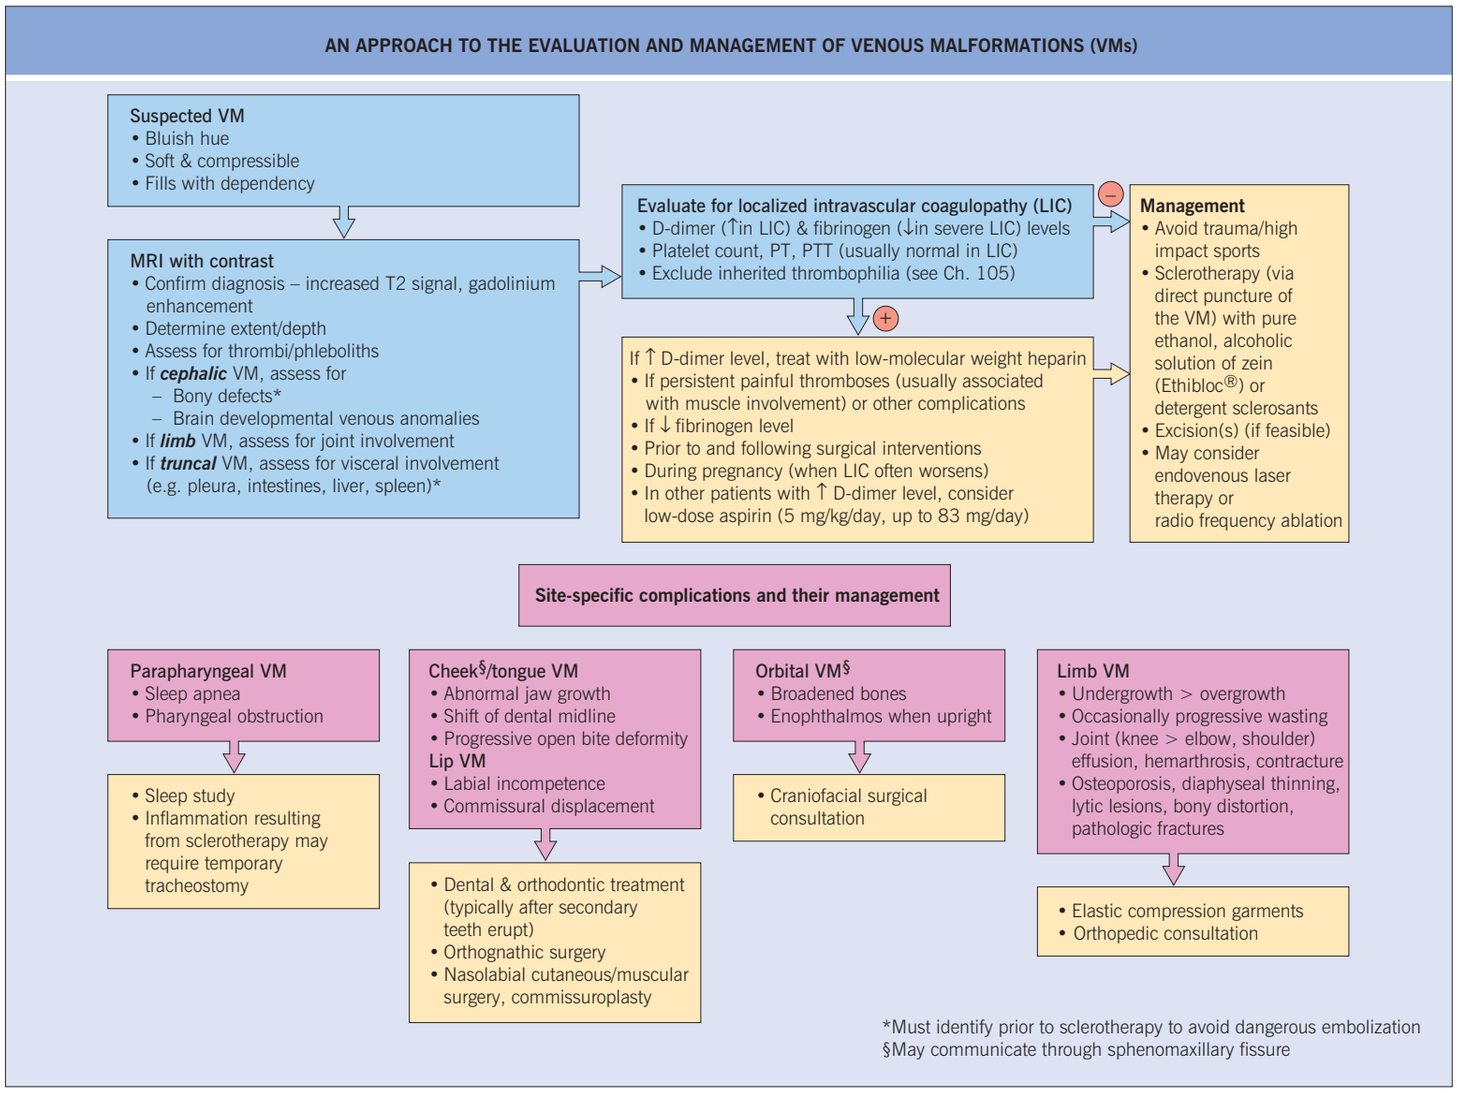

Fig. 104.14 An approach to the evaluation and management of venous malformations (VMs). In the inset, T2-weighted magnetic resonance imaging (MRI) clearly shows VM in the neck (white hypersignals); black dots within the white areas represent phleboliths.

drainage from the brain, usually with enlarged deep venous channels. Developmental venous anomalies may cause headaches, but they do not confer risk of cerebral hemorrhage and treatment is not needed. Of note, patients with cephalic VMs are not at increased risk of CCM-type cerebral vascular malformations (see above).

Trunk and limb venous malformation

VMs of the trunk and limbs often have cosmetic and functional consequences (see Fig. 104.14). VMs form spongy masses of saggy ectatic venous channels, which are easily emptied by elevating and massaging the affected region (see Fig 104.13). However, permeation deep into muscles, joints and bones is common[1]. Muscle involvement is associated with episodes of pain after motion and in the morning. The pain is linked to thromboses inside the low-flow channels, leading to phlebolith formation (round calcifications). Half of patients with large VMs have a chronic localized intravascular coagulopathy with elevated D-dimer levels[30,31]. Joint involvement usually becomes symptomatic before 10 years of age with complications such as effusions and hemarthrosis. Limb VMs are commonly misdiagnosed as KTS. However, the latter does not have muscle or joint involvement (other than that related to an associated VM), and undergrowth of a limb affected by a pure VM is more common than overgrowth.

Sinusoidal hemangioma

Sinusoidal "hemangioma" (see Ch. 114) is a misnomer for a distinctive vascular malformation that typically presents in adults (especially middle-aged women) with deep bluish nodules, often on the breast or extremities. Diagnosis is based on histologic features: well-circumscribed lobules composed of densely packed, large, thin-walled, blood-filled venous channels. Sinusoidal patterns have also been observed in congenital VMs.

Syndromes associated with venous malformations

Familial cutaneous and mucosal venous malformation (VMCM)

Familial VMCM is an autosomal dominant condition in which multiple VMs affect the skin, oral mucosa and muscles. Visceral VMs (e.g. of intestines, lungs, CNS) and cardiac malformations have been observed in a few families[32]. The disorder is caused by heterozygous germline mutations in the *TEK* gene that result in hyperphosphorylation and constitutive activation of TIE-2, a vascular endothelium-specific tyrosine kinase receptor; the downstream signaling of this receptor is also altered[5,32]. Interestingly, approximately half of *sporadic* VMs have *somatic* activating mutations in the *TEK* gene within lesional tissue[5].

Blue rubber bleb nevus syndrome (BRBNS; Bean syndrome)

BRBNS is a sporadic disease characterized by widely distributed dark blue papules and nodules and skin-colored compressible protuberances ("rubber blebs") as well as larger VMs (Fig. 104.15) or LVMs affecting the skin and muscle. Gastrointestinal lesions bleed and result in iron deficiency anemia. Other sites of visceral involvement (CNS, lungs, heart) are uncommon. To date, *TEK* mutations have not been identified in patients with classic BRBNS.

Fig. 104.15 Blue rubber bleb nevus syndrome. Small blue venous nodules are superimposed on a large subcutaneous venous malformation in this girl.

Fig. 104.16 Plaque-type glomuvenous malformation on the distal lower extremity.

Fig. 104.17 Maffucci syndrome. A Both nodular venous malformations and enchondromas distort the hand. **B** A radiograph demonstrates an enchondroma and multiple phleboliths.

Glomuvenous malformation

Glomuvenous malformations (GVMs; previously known as glomangiomas) represent a variant of VM with rows of glomus cells around distorted venous channels (see Ch. 114). They occur as small solitary lesions, widely scattered blue–purple nodules, or (less commonly) large segmental plaques (Fig. 104.16). GVMs may be evident at birth (especially plaque-type lesions) or appear during childhood or adolescence, and they often worsen over time[33,34]. In contrast to classic VMs, GVMs tend to be painful when palpated, partially (rather than fully) compressible, and hyperkeratotic (especially on the extremities) with a cobblestone-like appearance. GVMs do not typically affect viscera or joints; mucosal involvement (deep intraoral lesions) or superficial invasion of muscles occasionally occurs. Approximately two-thirds of patients with glomuvenous malformations, but only 1% of those with classic VMs, have a family history of similar lesions. GVMs have a dominant (sometimes referred to as paradominant) mode of inheritance that results from heterozygous germline mutations in the glomulin (*GLMN*) gene passed from generation to generation plus a somatic "second hit" in this gene within lesional skin (see Table 104.2)[35].

Maffucci syndrome

Maffucci syndrome features a combination of VMs (blue to skin-colored nodules) and enchondromas (similar to those of Ollier disease), leading to orthopedic and cosmetic consequences (Fig. 104.17). It most commonly affects the extremities; however, cephalic lesions with severe neuro-ophthalmologic complications may also occur. Histologically, the cutaneous nodules demonstrate features of both a VM and a vascular tumor, the spindle cell hemangioma (see Ch. 114). Maffucci syndrome is a sporadic condition that is distinct from Ollier disease, with mutations in the *PTHR1* gene identified in the latter but not the former disorder.

Lymphatic Anomalies

Lymphedema results from hypoplasia, aplasia or disruption of lymphatic channels, whereas LMs are due to hyperplasia of the lymphatic network. LMs may be microcystic, macrocystic or combined. They can have superficial (skin and mucous membranes), deep (e.g. muscles, bone), or visceral (<10% of patients) involvement[1]. Lymphedema is divided into primary (abnormal development of the lymphatic system) and secondary (acquired disruption of lymphatic channels) forms (see Ch. 105).

Primary lymphedema

Patients with primary lymphedema usually accumulate lymph fluid in the extremities (lower > upper); cephalic and genital involvement occasionally occurs. Affected individuals are at risk for bacterial infections and septicemia. Generalized lymphedema may be associated with intestinal or pulmonary lymphangiectasias, exudative enteropathy, and pleural effusions.

Genetic forms of lymphedema (see Table 104.2) manifest at birth or later in life (ranging from childhood to adulthood). Congenital or childhood-onset lymphedema can occur in the setting of *Turner syndrome* (see Ch. 55) and *Noonan syndrome*. *Milroy disease*, which

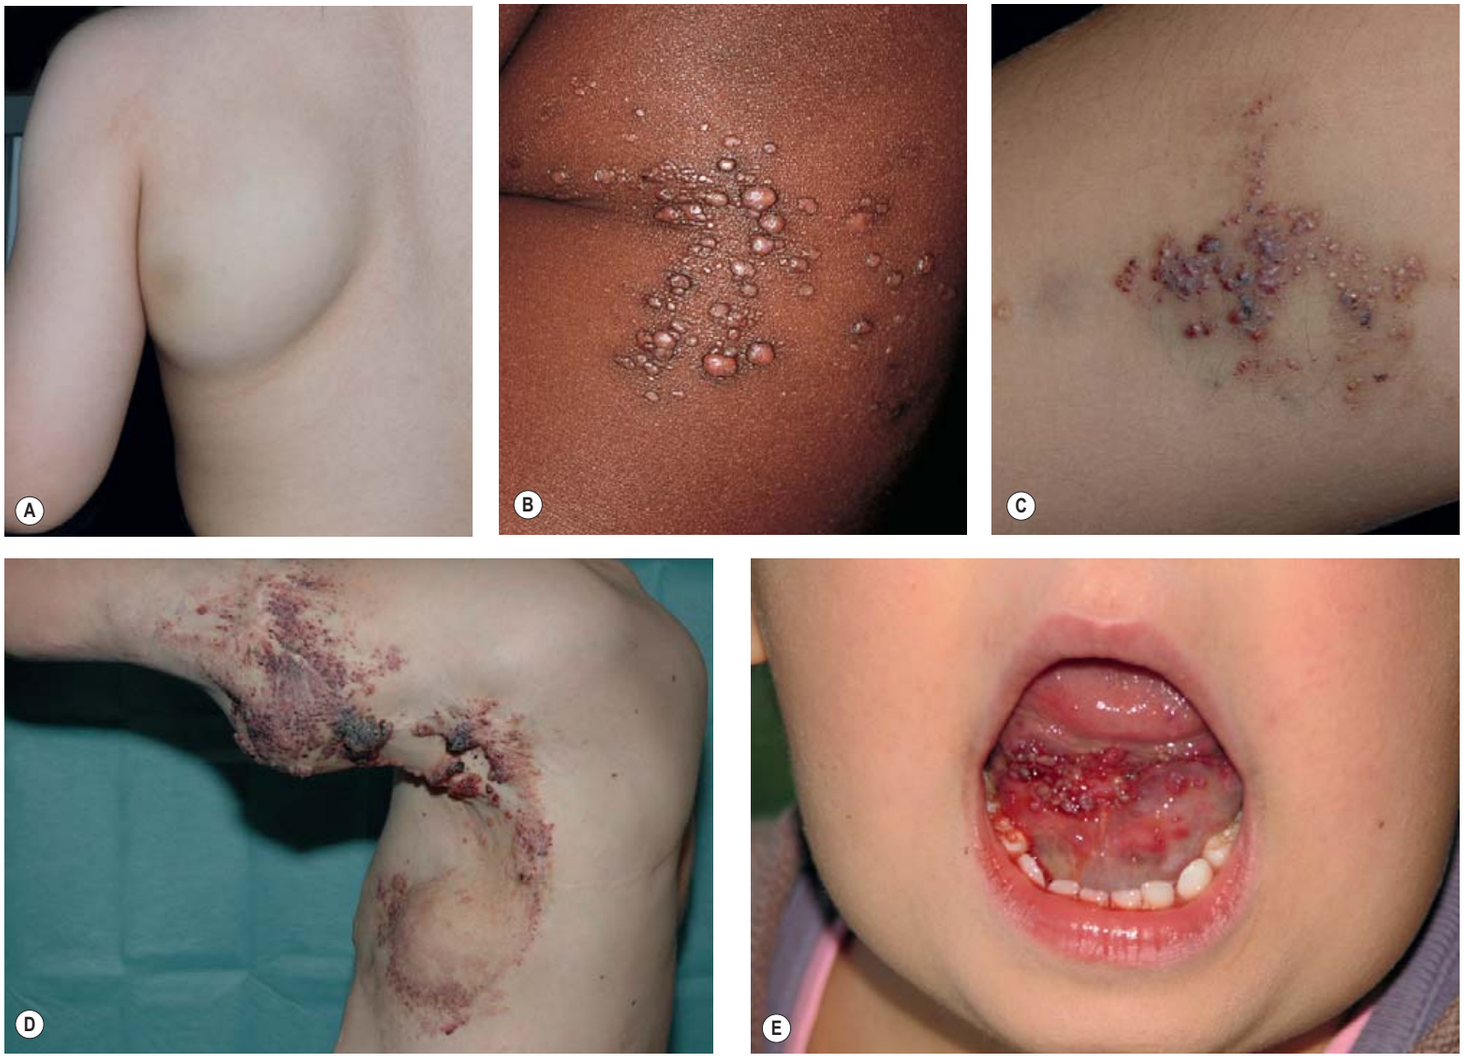

Fig. 104.18 Lymphatic malformations (LMs). A Macrocystic LM on the lateral trunk. The mass was soft except for a focal firm area of hemorrhage associated with bruise-like discoloration of the overlying skin. **B–E** Microcystic LMs presenting as clusters of clear or hemorrhagic vesicles, with active bleeding from lesions in the mouth (**E**). The crops of vesicles in (**D**) recurred years after surgical resection (utilizing grafting and linear closure) of a large microcystic LM affecting the skin and deeper structures of the arm and thorax. *A, C, Courtesy, Julie V Schaffer, MD.*

presents with congenital lymphedema of the lower extremities (especially below the knees), is an autosomal dominant disorder caused by mutations in the *FLT4* gene that encodes vascular endothelial growth factor receptor-3 (see Ch. 102). Autosomal dominant inheritance of lymphedema with peripubertal onset occurs in *Meige disease* (the etiology of which is currently unknown) and *lymphedema–distichiasis syndrome*. The latter also features congenital distichiasis (aberrant eyelashes arising from the meibomian glands) and venous varicosities, and it is caused by mutations in the *FOXC2* gene. *Aagenaes syndrome* is an autosomal recessive disorder that manifests with infantile cholestasis and childhood-onset lymphedema. Other familial lymphedema syndromes with a known molecular basis are presented in Table 104.2.

Macrocystic lymphatic malformation ("cystic hygroma")

Macrocystic LMs represent collections of large, interconnected lymphatic cysts lined by a thin endothelium. The most common locations are the neck, axilla and lateral chest wall (Fig. 104.18A). Prenatal detection by ultrasound is possible as early as the first trimester of pregnancy. Some patients who are diagnosed prenatally have malformation syndromes caused by chromosomal abnormalities or other genetic defects (Down syndrome, Turner syndrome, Noonan syndrome). A macrocystic LM appears as a large, soft, translucent mass under normal skin. The diagnosis can be confirmed by ultrasound, CT or MRI (see Table 104.3) as well as by direct puncture and cytologic analysis of the fluid. Hemorrhage inside a cyst can create sudden swelling, with the mass becoming tense, firm, purple or yellowish in color, and tender.

Microcystic lymphatic malformation ("lymphangioma circumscriptum")

These ill-defined aggregates of relatively small, abnormal lymphatic channels are the most common type of LMs. They can occur anywhere on the skin (favoring the proximal limbs and chest) or in the mouth (including the buccal mucosa, lips, tongue and oral floor). Plaques with crops of clear or hemorrhagic vesicles scattered on their surface (Fig. 104.18B–E) vary in size and appearance (e.g. the number and color of superimposed vesicles) over time. Additional clinical findings are intermittent swelling, hemorrhage and leakage of lymph from superficial vesicles. Lesions are often much more extensive than clinically expected from the number of vesicles. Complications include erysipelas-like reactions following minor injuries, other inflammatory flares and infections.

Combined microcystic and macrocystic lymphatic malformation

Extensive cervicofacial combined LMs commonly have bony involvement. This can lead to mandibular overgrowth and prognathism, resulting in a long or asymmetric face, bite deformities and abnormal occlusal planes[36]. Intraoral combined LMs are frequently complicated

by inflammatory flares or spontaneous bleeding in the setting of upper respiratory or dental infections. This can result in sudden expansion of the lesions, particularly those in the tongue. Local infections can lead to cellulitis or even septicemia. In some patients with massive oropharyngeal combined LMs, airway compromise (extrinsic or intrinsic) requires tracheostomy. Hypersalivation and dental caries are common, with the potential for loss of teeth. Speech, mastication and swallowing may be impaired. In addition to swelling, pain and infections, specific complications of combined LMs in the orbital region include chemosis, strabismus, amblyopia, proptosis and visual loss[37].

On the trunk and limbs, combined LMs tend to worsen as the child grows. When a minor wound on the affected extremity becomes infected, the inflammatory reaction results in expansion of the LM (just as in patients with limb lymphedema). Perineal and gluteal cleft LMs, which are particularly prone to fluid leakage and infection, severely impair quality of life. Rare multifocal abdominal and thoracic LMs that extend into viscera (often categorized as "lymphangiomatosis") may have a lethal outcome due to expansion and visceral complications. In *Gorham–Stout (disappearing bone) disease*, an LM creates progressive radiolucent bone lesions and eventually massive osteolysis, which results in pathological fractures and deformity; involvement of the thoracic skeleton may be associated with pulmonary lymphangiectasia. Lastly, patients with extensive combined LMs, in particular those that have a venous component, may have a chronic localized intravascular coagulopathy with elevated D-dimer levels.

Arteriovenous Malformations

AVMs are fast-flow vascular malformations with direct communications (AV shunting) between arteries and veins creating a nidus (AV nidus). They are rare and constitute the most dangerous group of vascular anomalies. Schobinger's staging was adopted by the ISSVA in order to classify AVMs according to their clinical severity[1,2,38]. The stages are: (1) *quiescent/dormant* – macular or slightly infiltrated, red, warm lesions mimicking a PWS (Fig. 104.19A&B); (2) *expansion* – warm masses with throbbing and thrills over dilated draining veins (Fig. 104.19C); (3) *destruction* – necrosis, hemorrhage, ulceration and (occasionally) lytic bone lesions (plus findings of stage 2) (Fig. 104.19D); (4) *cardiac decompensation* (plus findings of stage 2 ± 3). Initial evaluation with ultrasonography and MRI studies can confirm the diagnosis and delineate the extent of the lesion (see Table 104.3).

In 40% of patients, AVMs are visible at birth; the remainder appear later in life. The most frequent location is cephalic (~70% of patients in the author's experience; Fig. 104.20)[38]. Puberty (75% of patients), pregnancy (25% of women) and trauma may result in worsening of AVMs[38]. In an analysis of 65 patients with cephalic AVMs (unpublished personal data), 39 were centrofacial and 7 were hemifacial; 10 affected the forehead, 10 the ear and 4 the scalp. Stage 3 cephalic AVMs are disfiguring and function- or even life-threatening lesions, and those on an ear or extremity may lead to amputation[39]. Multifocal AVMs affecting an extremity can lead to cardiac overload and distal ischemia.

Fig. 104.19 Arteriovenous malformations (AVMs). A, B Dormant (stage 1) AVMs mimicking a port-wine stain (**A**) and infantile hemangioma (**B**). **C** Expanding (stage 2) centrofacial AVM associated with AVMs of the retina and brain in a boy with Bonnet–Dechaume–Blanc syndrome. **D** Destructive (stage 3) AVM that has led to cutaneous necrosis.

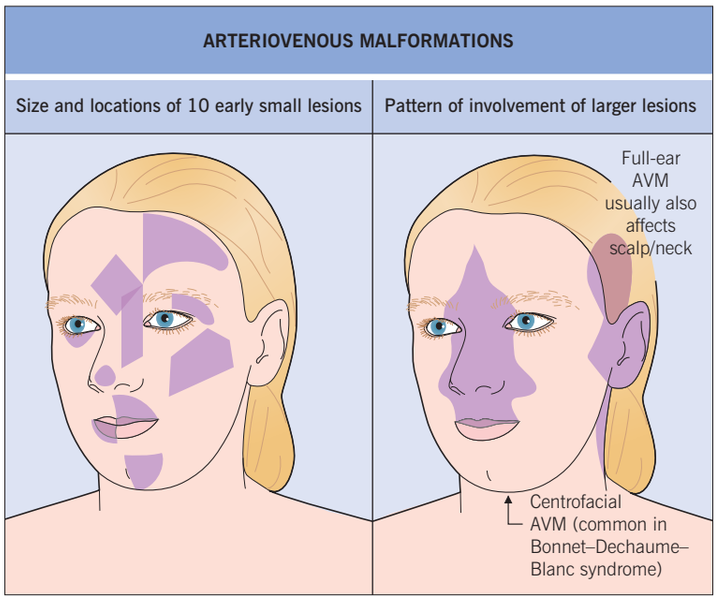

Fig. 104.20 Arteriovenous malformations – size, locations and patterns.

Fig. 104.21 Cobb syndrome. This stain on the nape has an appearance reminiscent of a salmon patch, but it was warm and superimposed darker red macules progressively appeared. Doppler ultrasonography, MRI and arteriography confirmed the presence of a metameric arteriovenous malformation of the skin and spine.

Attempted treatment with arterial or venous ligatures, partial excision, or proximal (rather than selective distal) embolization often precipitates complications. *Stewart–Bluefarb syndrome* represents *acroangiodermatitis* (pseudo-Kaposi sarcoma; see Ch. 105) occurring in association with an AVM of the lower extremity.

Syndromes associated with arteriovenous malformations

Cobb syndrome

This rare sporadic condition features cutaneous, intraspinal (intramedullary ± meningeal), and vertebral AVMs in the same metamere. Congenital red or red–brown vascular stains mimicking a PWS (actually a stage 1 AVM) (Fig. 104.21) or throbbing masses with dilated veins (stage 2 AVM) are present in 20% of patients with spinal AVMs. Neurologic deficits typically develop during young adulthood due to a mass effect of the expanding AVM on the spinal cord and subarachnoid hemorrhage. Neurologic signs range from back pain and radiculalgia to rectal and bladder dysfunction to paraparesis and paraplegia. MRI and angiography establish the presence of the spinal AVM. Endovascular embolization of the spinal AVM may improve the prognosis.

Bonnet–Dechaume–Blanc syndrome (BDBS; Wyburn–Mason syndrome)

This rare metameric AVM extends from the craniofacial region to the orbit and brain. Incomplete forms of the disease also exist. The brain AVM may remain asymptomatic or manifest as seizures or hemiparesis/hemiplegia. In 12 BDBS patients (personal observations) between 5 to 51 years of age, their facial AVMs (stage 1, 2 or 3) were midfacial in 3 (see Fig. 104.19B–D), hemifacial in 3, and both midfacial and hemifacial in 6. The presence of an orbital AVM was an inconsistent finding (4 patients), but brain AVMs (of the chiasm, choroid plexus, or thalamus) were present in all 12 individuals and led to cerebral hemorrhage in 4 patients. In a second series of 15 patients with BDBS[40], orbital AVMs were present in 14 and frequently affected the optic nerve (13 patients) and retina (11 patients); symptoms in this group included reduced visual acuity or fields, blindness, recurrent epistaxis, nasal obstruction and gingival hemorrhage.

Parkes Weber syndrome

In this rare *fast-flow* vascular malformation syndrome, limb overgrowth (in length and girth) occurs secondary to arteriovenous fistulae (AVF); this must be differentiated from the purely *slow-flow* malformations of KTS. A diffuse red CM, excess fat, and lymphatic anomalies may also be observed in Parkes Weber syndrome. Lytic bone lesions and cardiac failure often develop, and prognosis is poor after puberty. Parkes Weber syndrome can occur in association with multifocal CMs as a component of the familial CM-AVM syndrome (see below)[6,22].

Capillary malformation–arteriovenous malformation (CM-AVM)

This autosomal dominant disorder is caused by mutations in the *RASA1* gene (see Table 104.2). Multiple small cutaneous CMs are evident at birth or appear during childhood, presenting as pink to red–brown macules (often with a narrow blanched border) in a haphazard distribution. Approximately 30% of affected individuals also have high-flow lesion(s)[6,22]. Among 140 patients from 50 families with CM-AVM, 90% had multifocal small CMs, 6% had a solitary "atypical" CM, 12% had Parkes Weber syndrome, 11% had an AVM of the skin/subcutaneous tissue (most often a solitary facial lesion), and 7% had a cerebral AVM/AVF[22].

PTEN hamartoma tumor syndrome (PHTS)

PHTS, which encompasses Bannayan–Riley–Ruvalcaba and Cowden syndromes, is an autosomal dominant condition caused by mutations in the *PTEN* gene (see Ch. 63)[41,42]. Affected individuals are often macrocephalic, and they are predisposed to the development of malignancies (especially of the breast and thyroid). Cutaneous manifestations with onset at birth or in childhood include genital pigmented macules, segmental excess of hypervascularized fat, and vascular malformations. The latter are typically multifocal, intramuscular fast-flow lesions that are associated with ectopic fat and focal segmental dilatation of draining veins[43]. Cerebral developmental venous anomalies are also common in PHTS patients.

PATHOLOGY

The histologic characteristics of the four major types of vascular malformations are illustrated in Figure 104.22[1].

Capillary Malformations

A CM is composed of ectatic capillaries within the papillary and reticular dermis, lined by a flat continuous endothelium. Thickening of affected skin can occur over time due to a progressive increase in the diameter of the capillaries, involvement of the dermis and subcutis, fibrosis of the dermis, and, occasionally, venous channels in the subcutis.

Venous Malformations

Large convoluted and interconnected anomalous venous channels dissect the normal connective tissues and muscles. Organized thrombi,

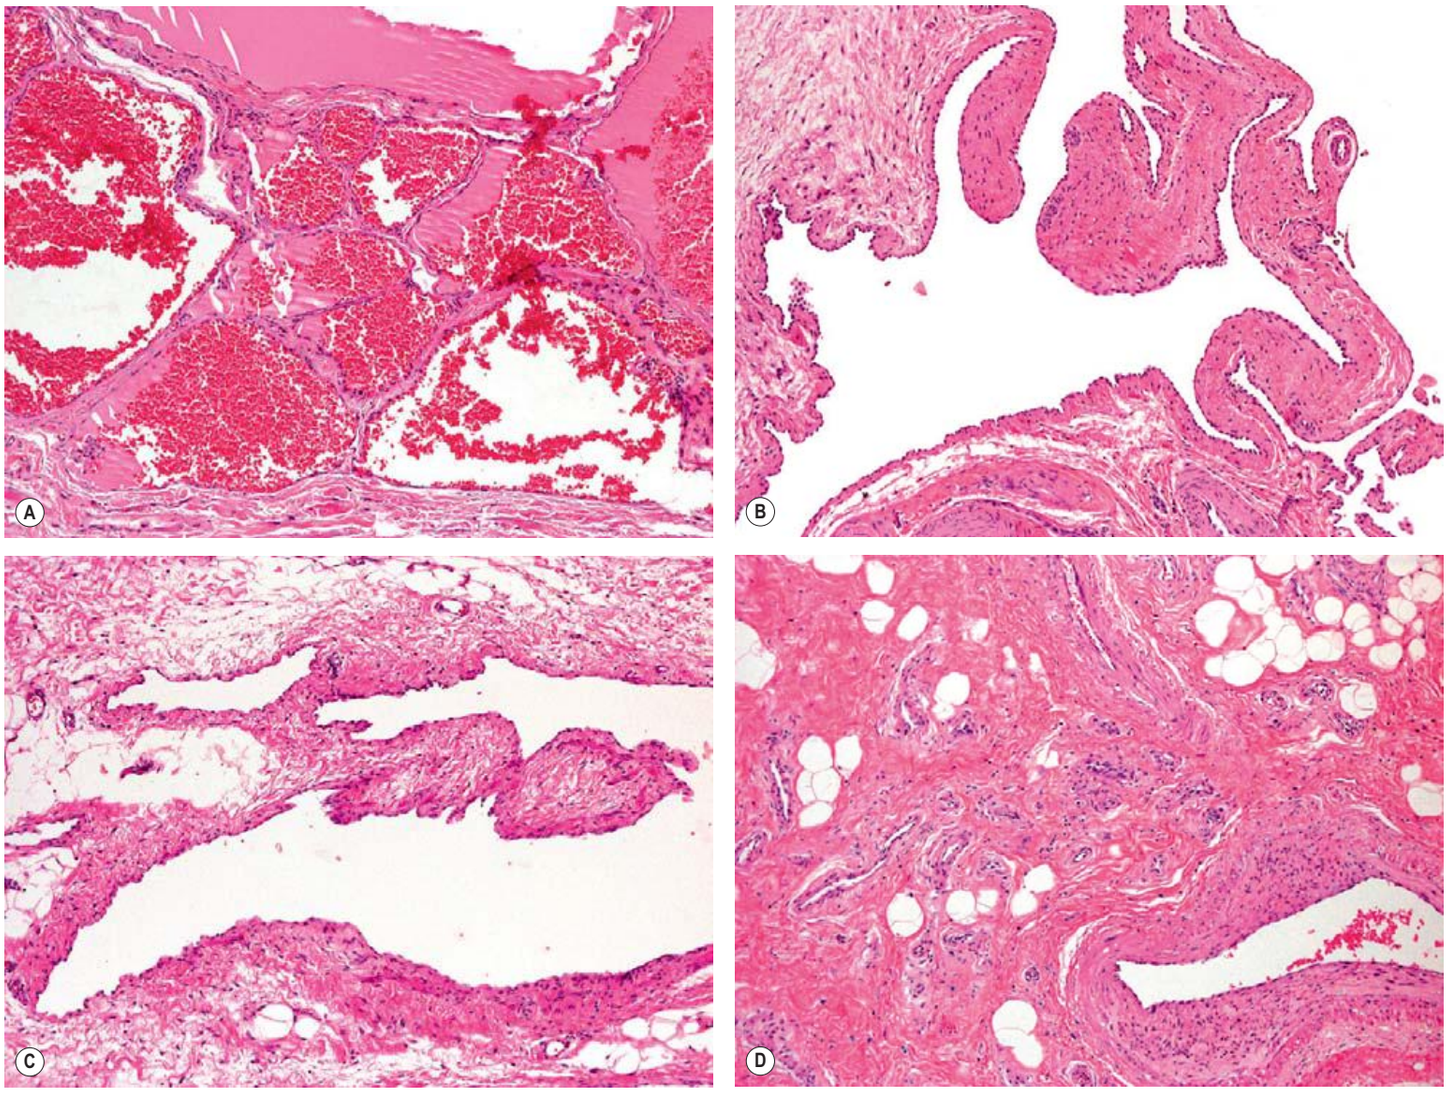

Fig. 104.22 Histologic features of vascular malformations. A Capillary malformation in an adult that was thickened and nodular. An increased number of dilated capillaries are present in the dermis. **B** Venous malformation composed of large, irregularly shaped, thin-walled channels. **C** Lymphatic malformation with large, irregularly shaped channels. **D** Arteriovenous malformation demonstrating an area of intense capillarogenesis near the AV nidus. This finding is sometimes misinterpreted as a "capillarovenous" malformation. *A–D, Courtesy, Lorenzo Cerroni, MD.*

phleboliths (round calcifications) and Masson's papillary endothelial hyperplasia are frequently observed. Anomalous vessels of a VM have a continuous flat endothelium and a thin basement membrane. Their walls have discontinuous media due to foci with a relative lack or absence of smooth muscle cells.

Lymphatic Malformations

LMs of the microcystic type ("lymphangioma") exhibit enlarged, distorted, irregular lymphatic channels with varying numbers of smooth muscle cells in their walls and a very thin endothelium, sometimes barely visible. Larger polyhedral lymphatic vessels may exhibit valves, and they are usually separated by fibrous septa. Lymphatic clefts dissect the host connective tissues. Hyperkeratotic epidermis may overlie some clusters of dermal lymphatic vesicles. LMs of the macrocystic type ("hygroma") are composed of large lymphatic cisterns, often interconnected with thinner channels. Vesicles and large cysts in LMs usually contain watery fluid, lymphocytes, and macrophages; hemorrhage can also be seen.

Arteriovenous Malformations

AVMs have irregularly thickened walls and are usually randomly distributed in the dermis and other involved tissues. Direct communications between vessels with different elastic components, typically arteries and veins, may be evident. A capillary component is often obvious in the overlying papillary dermis, and it may have a lobular architecture.

DIFFERENTIAL DIAGNOSIS

Vascular malformations must be distinguished from vascular neoplasms. Early or "arrested growth" ("abortive") superficial infantile hemangiomas may resemble CMs, whereas deep infantile hemangiomas and other vascular tumors (e.g. kaposiform hemangioendothelioma, infantile hemangiopericytoma) can mimic VMs, LMs and LVMs (see Chs 103 & 114). Multifocal lymphangioendotheliomatosis with thrombocytopenia should be considered in patients with multiple vascular malformations, especially when associated with gastrointestinal bleeding (see Ch. 114).

Occasionally, other neoplasms and inflammatory disorders are misdiagnosed as vascular anomalies. A red or blue color and/or a mass underneath normal skin can represent potentially misleading clinical signs. For example, erythematous lesions of lupus erythematosus, plaque-type angiofibromas, telangiectasia macularis eruptiva perstans and other telangiectatic conditions (see Ch. 106) can mimic CMs. Dermal melanocytosis (e.g. nevus of Ota, Mongolian spot) has a deep blue color that may lead to misdiagnosis as a VM. Masses beneath normal skin that may be erroneously diagnosed as a macrocystic LM in infants and children include a lipoblastoma, teratoma, bronchogenic

CAUSES OF ACQUIRED CUTANEOUS LYMPHANGIECTASIA
INFLAMMATORY CAUSES
Crohn's disease (favors perineal area) Morphea profunda Systemic sclerosis
INFECTIOUS CAUSES
Tuberculosis (e.g. scrofuloderma) Recurrent erysipelas/cellulitis
NEOPLASTIC CAUSES
Intralymphatic metastases (e.g. breast carcinoma, melanoma)
IATROGENIC CAUSES
Surgical resection, lymphadenectomy, and/or radiotherapy for cancer (e.g. of the breast, prostate, bladder, cervix) Amputations Corticosteroid-induced atrophy ± photoaging Penicillamine-induced dermopathy
OTHER CAUSES
Pregnancy (vulvar) Cirrhotic ascites (abdominal) Porphyrias (e.g. porphyria cutanea tarda, variegate porphyria; centrofacial) Spontaneous development in elderly patients (genital)

Table 104.6 Causes of acquired cutaneous lymphangiectasia.

cyst, branchial cleft cyst, thyroglossal duct cyst, myofibroma, rhabdomyosarcoma and fibrosarcoma.

Acquired cutaneous lymphangiectasia imitating a LM can develop in several settings (Table 104.6).

TREATMENT

No single treatment exists for this heterogeneous group of lesions.

Capillary Malformations

PWSs and telangiectasias are currently best treated with a flashlamp-pumped pulsed dye laser (PDL; see Ch. 137)[44–46]. This treatment of PWSs, which is typically initiated early in life (especially for facial lesions) to decrease potential psychosocial distress and avoid lesional thickening, is often very effective. However, not all lesions respond well; PWSs on the central face and distal limbs tend to be more resistant to therapy than those in other sites. PDL treatment is safe, producing temporary purpura but a low risk of hypo- or hyperpigmentation and scarring[45]. Although the latter side effects are more common in individuals with darkly pigmented skin (e.g. skin type V), these patients may have a good response and should not be excluded from PDL treatment.

Intervention during infancy with modified PDL therapy using a longer wavelength, increased pulse duration, higher fluence (11–12 J/cm^2) and dynamic cooling spray can maximize lightening or clearing of PWSs[46]. Use of a topical anesthetic (see Ch. 143), together with the anesthetic effect of the cryogen spray, helps to reduce the need for general anesthesia in children. In a longitudinal study of 51 patients whose facial CM was treated with classic PDL, redarkening was evident in one-third of the lesions after a median follow-up period of 10 years[47]. Relapses may be less common in patients treated at a younger age. If treatment is delayed, facial and gingival PWSs may develop hyperplastic changes that require additional dermatologic (e.g. dermabrasion prior to PDL treatment) as well as orthodontic and surgical interventions (e.g. to correct open-bite deformities and macrocheilia).

Multidisciplinary care is necessary for patients with SWS. Anticonvulsants are the mainstay of treatment for seizures, although selected patients with severe, uncontrolled seizures may benefit from surgical management. Glaucoma usually responds to medical or surgical treatment. As discussed above, PDL therapy for PWSs can begin during infancy. Psychological counseling may be helpful for patients and families affected by SWS, and support is also available through the Sturge–Weber Foundation (www.sturge-weber.org).

Venous Malformations

Satisfactory treatment of a cephalic VM typically requires multiple sclerotherapy procedures over a period of years (often spanning from childhood to adulthood) combined with surgical excisions (see Fig. 104.14)[1]. The aims are to maintain facial symmetry, preserve muscular functions and restore the dynamics of the smile. Limb VMs may also benefit from sclerotherapy and resection; however, many are too extensive and invasive for such interventions to be advisable. Use of elastic compression garments helps to reduce swelling and pain in the affected extremity. Treatment with low-molecular-weight heparin can control chronic coagulopathy associated with VMs, especially before surgery and during painful thrombotic events[30,31]. Low-dose aspirin (5 mg/kg/day, up to 83 mg/day) may be of some benefit in patients with a mild coagulopathy.

Lymphatic Malformations

The choice and outcome of treatment depend on the type and extent of the LM[36,37]. Macrocystic LMs are best treated with percutaneous sclerotherapy utilizing agents such as killed bacteria (picibanil/OK-432), alcoholic solution of zein (Ethibloc®), sodium tetradecyl sulfate, pure ethanol, doxycycline and bleomycin. This creates an inflammatory reaction with subsequent fibrosis and shrinkage of the treated cyst; repeated procedures are usually necessary. Surgical therapy is employed if sclerotherapy fails or gives incomplete results.

Surgical excision is the treatment of choice for microcystic LMs, either with direct closure or (for large lesions) use of skin grafts or tissue expanders. However, incomplete excisions are a common problem, whether because of concern regarding functional consequences of extensive surgeries or underestimation of the extent of the LM (see Fig. 104.18D). Other techniques (often used in combination) to reduce the extent of these lesions include laser therapy (e.g. CO_2, surface application or intralesional bare fiber Nd:YAG, diode), radiofrequency ablation, cryoablation and sclerotherapy[48–50]. Microcystic LMs of the tongue and floor of the mouth are particularly difficult to treat, and careful dental hygiene is important. Transient inflammatory swelling of LMs usually responds to therapy with nonsteroidal anti-inflammatory drugs, corticosteroids and/or antibiotics.

Arteriovenous Malformations

In general, stage 2 and 3 AVMs of the head and neck should be excised completely after careful preoperative embolization (using arterial ± direct puncture approaches) to prevent excessive intraoperative bleeding. Reconstruction often requires techniques such as skin grafting, preoperative tissue expansion, and free tissue transfer[1,38]. Subtotal excision frequently results in subsequent progression of the AVM, with recruitment of adjacent vessels and apparent angiogenesis. Stage 1 and early stage 2 AVMs are often managed conservatively if postsurgical cosmetic results might be worse than the lesion itself. However, resection of early-stage AVMs can prevent further progression.

Embolization alone usually cannot cure a superficial AVM. The most effective embolic agent, pure ethanol, poses substantial risks (especially at higher doses) that include renal or pulmonary toxicity and cardiac arrest. For AVMs that begin to hemorrhage, embolization may be lifesaving. Distal hand or foot AVMs are rarely controlled long-term by embolotherapy, and ischemic complications resulting in extreme pain, necrosis and bleeding may require amputation. In one report, treatment of a diffuse AVM in the arm of a young girl using a metalloproteinase inhibitor (Marimastat®) with antiangiogenic effects produced sustained improvement (including reconstruction of affected bones) over a 12-year period without adverse effects[51].

Complex-Combined Malformations

A complex-combined vascular malformation of a limb requires an individualized management plan. Longitudinal orthopedic evaluation is essential for lower extremity lesions in growing children. Carefully timed epiphysiodesis (before the end of the growth period) can potentially correct a leg-length discrepancy in KTS, but it may worsen vascular disease in Parkes Weber syndrome. Treatment of a component of the vascular malformation (e.g. surgery for varicose veins in KTS or embolization of the AV nidus in Parkes Weber syndrome) often has suboptimal results. Elastic support garments and a compensatory shoe-lift are indispensable conservative interventions.

105 Ulcers

Ariela Hafner and Eli Sprecher

Chapter Contents

Venous ulcers 1729
Lymphedema 1737
Arterial ulcers 1738
Diabetic (and neuropathic) ulcers 1740
Ulcers due to physical factors 1741
Other causes of skin ulceration 1744

Synonyms: ■ Ulcer – wound, sore ■ Venous ulcer – ulcer due to venous insufficiency/venous hypertension ■ Arterial ulcer – ulcer due to atherosclerosis ■ Neuropathic ulcer – mal perforans ■ Livedoid vasculopathy – atrophie blanche, livedoid vasculitis ■ Pressure ulcer – decubitus ulcer, pressure sore, bed sore

Key features

- The history should include onset, course, symptoms, exacerbating and alleviating factors, past medical history, family history, social history, travel and medications
- Important aspects of the physical examination include location, size and shape of the ulcer, characteristics of the ulcer edge and base, and associated physical findings
- Helpful laboratory evaluation includes vascular studies, blood tests, cultures and biopsy
- A biopsy of non-healing chronic ulcers is indicated to exclude carcinoma or other underlying diseases
- In addition to local care, therapy of ulcers should aim to correct or treat the underlying cause:
  - Venous insufficiency: compression
  - Arterial insufficiency: surgery
  - Neuropathic or pressure ulcer: relief of pressure
  - Infection: antibiotics
  - Neoplasm: surgery, chemotherapy, radiotherapy
  - Vasculopathy: treat the underlying cause of the occlusive disorder
  - Vasculitis or other inflammatory process (e.g. pyoderma gangrenosum): corticosteroids, immunosuppressive agents
- A key factor in therapy is the promotion of wound healing:
  - Debridement: mechanical, enzymatic, autolytic
  - Dressings: maintain a moist wound environment
  - Infection control: antibiotics
  - Skin grafting or skin substitutes
  - Growth factors

INTRODUCTION

A chronic wound is defined as one that fails to progress through a normal orderly and timely sequence of repair or a wound that passes through the repair process without restoring a functional result[1]. An ulcer is a wound that is associated with loss of both epidermal and dermal tissues, and chronic ulcers, which are due to a variety of systemic and/or local factors, represent a diagnostic and therapeutic challenge to the dermatologist. The majority of ulcers occur on the lower extremities, and most are related to venous hypertension and insufficiency, peripheral artery disease or peripheral neuropathy (Table 105.1). Less common causes are outlined in Figure 105.1 and sites other than the legs may be involved (e.g. pressure-induced ulcers).

Wound therapy has advanced considerably over the past few decades with the advent of innovative dressings and technologies, but the key factor in the management of chronic ulcers remains proper patient evaluation and correction of the underlying cause, once identified. This chapter addresses both common and unusual causes of cutaneous ulceration as well as appropriate evaluation and management.

VENOUS ULCERS

Chronic venous disease is a common problem in adults, with its prevalence increasing with age. However, the prevalence varies considerably amongst studies, i.e. from <1% to 17% in men and from <1% to 40% in women. This variability is due in large part to a lack of standardized diagnostic criteria[2].

Risk factors for chronic venous disease include family history, age, female gender, obesity, pregnancy, prolonged standing and height[3]. Venous hypertension and venous insufficiency represent the most common cause of chronic leg ulcerations. Venous ulcers tend to recur, are sometimes painful, and clearly have an impact on quality of life[4]. Because of their prevalence and chronicity, there are significant healthcare costs, estimated to be approximately $3 billion per year in the US[3].

Pathogenesis

The venous system of the lower extremities consists of an interconnected network of superficial veins, deep veins, and perforator or communicating veins which connect the superficial and deep systems[5] (see Ch. 155). Throughout the superficial, communicating and deep veins, one-way bicuspid valves ensure unidirectional flow toward the deep system, thus allowing blood to flow in a cephalad direction and preventing reflux (Fig. 105.2A). It is primarily the contraction of calf muscles that drives blood from the leg toward the heart[4].

During standing, as leg muscles relax, venous pressure in the legs may reach up to 80 to 90 mmHg[3]. Calf muscle contractions, as during ambulation, transiently increase pressure within the deep leg veins, propelling blood towards the heart. When pressure rises within the deep system, the valves close, preventing retrograde flow and transmission of high pressure to the superficial system[4]. When the deep system empties, the deep vein pressure abruptly falls to <30 mmHg and the valves open, enabling flow from the superficial into the deep system[3,4].

In the absence of competent valves, however, the decrease in venous pressure with leg movements is attenuated, and high pressures generated in the deep veins by calf muscle contraction are transmitted to the superficial venous system and to the microcirculation within the skin[3]. A sustained elevation in venous pressure is responsible for the typical clinical picture seen in chronic venous disease and is termed *venous hypertension* or *venous insufficiency*.

In most patients, venous hypertension is caused by reflux through incompetent valves (Fig. 105.2B), whether primary (congenital) or secondary to deep vein thromboses or recurrent trauma. Additional causes of venous hypertension include venous outflow obstruction and failure of the calf muscle pump due to obesity or leg immobility[3].

Although venous hypertension appears to be central to the skin changes seen in chronic venous disease, the exact pathogenic cascade

COMPARISON OF CLINICAL FINDINGS IN THE THREE MAJOR TYPES OF LEG ULCERS			
	Venous	**Arterial**	**Neuropathic/mal perforans***
Location	Medial malleolar region	Pressure sites Distal points (toes)	Pressure sites
Morphology	Irregular borders Yellow fibrinous base	Dry, necrotic base Well-demarcated ("punched out")	"Punched out"
Surrounding skin	Yellow–brown to brown discoloration due to hemosiderin deposits Pinpoint petechiae ("stasis purpura") Lipodermatosclerosis	Shiny atrophic skin with hair loss	Thick callus
Other physical examination findings	Varicosities Leg/ankle edema ± Stasis dermatitis ± Lymphedema	Weak/absent peripheral pulses Prolonged capillary refill time (>3–4 seconds) Pallor on leg elevation (45° for 1 min) Dependent rubor	Peripheral neuropathy with decreased sensation ± Foot deformities
*Most commonly due to diabetes mellitus.			

Table 105.1 Comparison of clinical findings in the three major types of leg ulcers. *Adapted from Phillips TJ, Dover JS. Leg ulcers. J Am Acad Dermatol. 1991;25:965–87.*

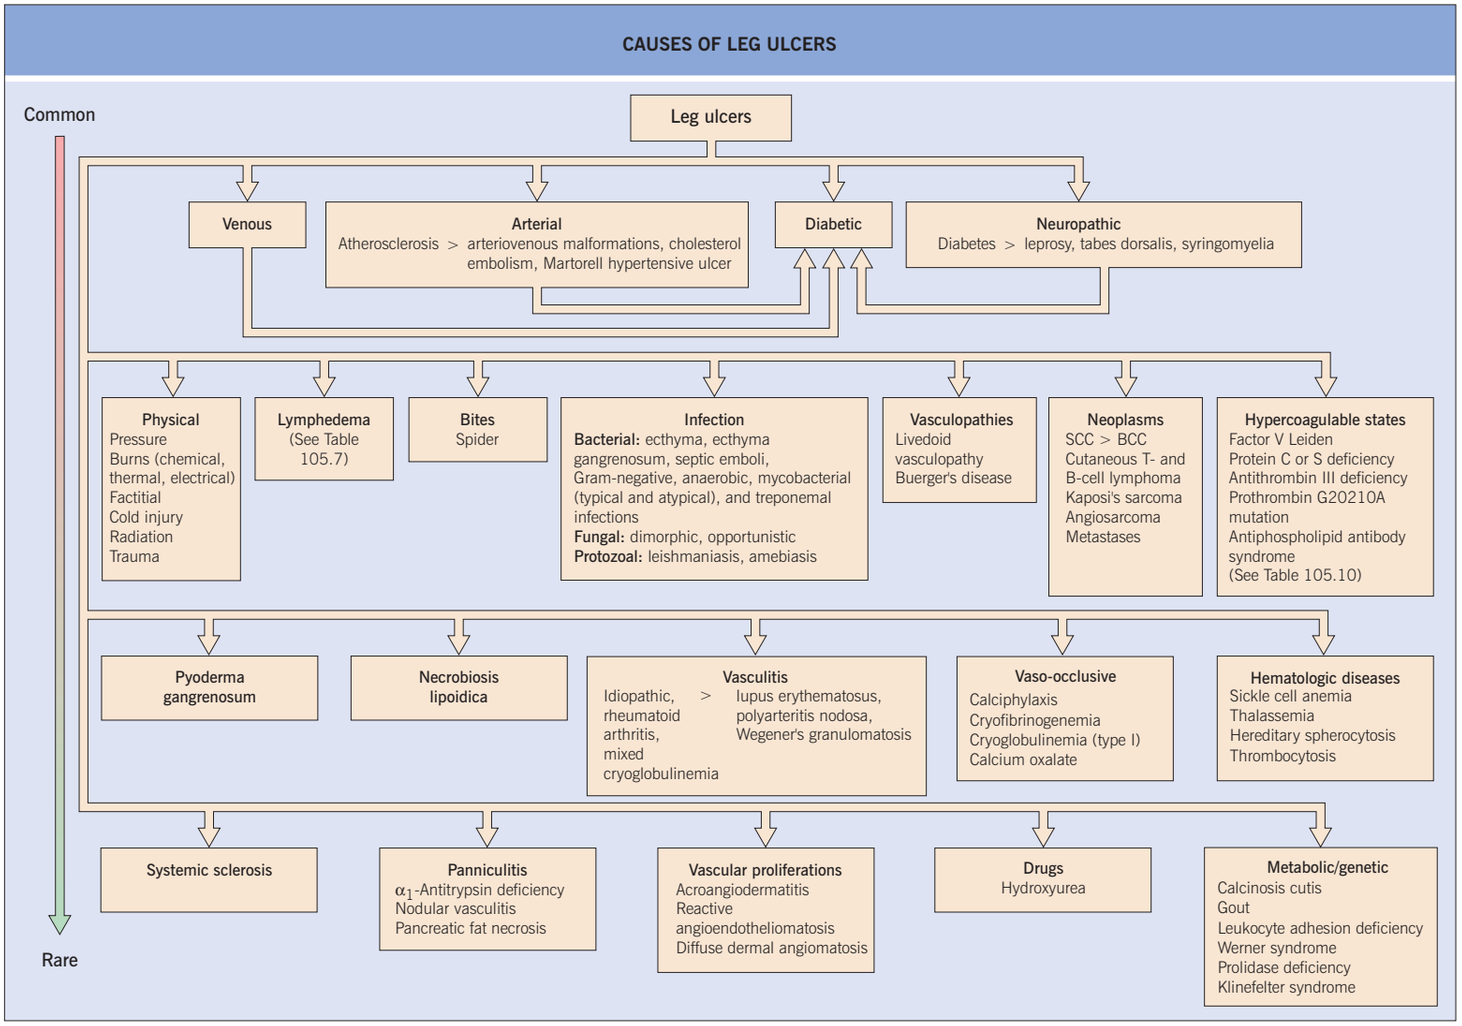

Fig. 105.1 Causes of leg ulcers. Patients with Behçet's disease also develop lower extremity ulcers due to vasculitis and/or venous insufficiency related to deep vein thromboses, and, occasionally, erosive pustular dermatosis is a cause of leg ulcers. Hydroxyurea-induced leg ulcers are often on the malleolus or tibial crest, exceedingly painful and surrounded by atrophic skin. Additional genetic syndromes associated with ulceration are listed in Table 105.10.

from valvular incompetence to frank ulceration remains obscure. A few pathomechanisms have been suggested, but it is still unclear whether they represent causative factors or epiphenomena[6]. For example, Browse and Burnand[7] proposed that cuffs of fibrin around dermal capillaries (due to leakage of fibrinogen) could impede the diffusion of oxygen and nutrients to surrounding tissues and lead to degenerative skin changes. Falanga and Eaglstein[8] postulated that venous pooling induced inter-endothelial space widening and deposition of fibrin and other macromolecules that then "trapped" growth factors, rendering them unavailable for wound repair.

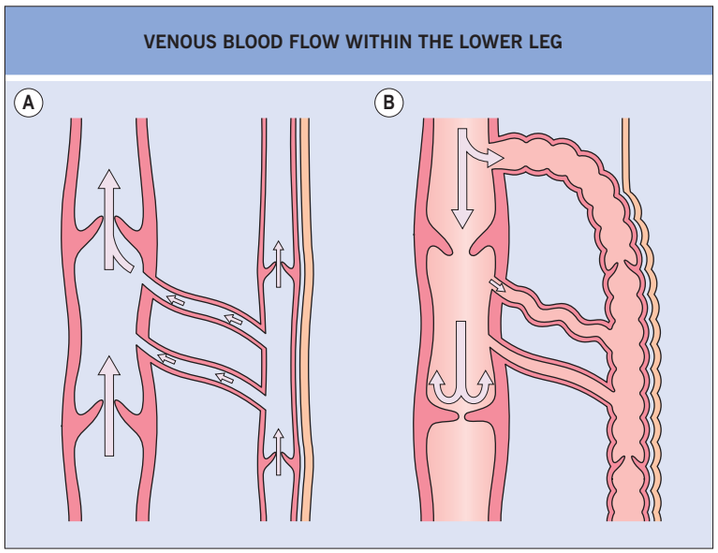

Fig. 105.2 Venous blood flow within the lower leg. A Under normal circumstances, blood is pumped against gravity towards the heart by the calf muscles. Blood flows from the superficial veins to the deep venous system via the perforating veins. Bicuspid valves ensure the unidirectionality of the blood flow. **B** When the valves are incompetent and/or hydrostatic pressure is elevated, blood flows back into the superficial venous system, leading to the formation of varicose veins.

Nowadays, however, the predominant theory is that chronic inflammation plays a key role in chronic wounds[3]. In the setting of elevated venous pressure, there is entrapment of leukocytes within small blood vessels and the skin of the lower extremity (referred to as the microvascular leukocyte-trapping hypothesis; Fig. 105.3)[9]. These trapped leukocytes become activated and they initiate an inflammatory response that leads to cellular and tissue dysfunction, resulting in the dermal changes often observed in patients with chronic venous insufficiency.

Expression of specific adhesion molecules on endothelial cells attracts various leukocytes (e.g. macrophages, T lymphocytes, mast cells) into the dermis via diapedesis (see Ch. 102), where they further promote inflammatory responses via the release of cytokines and activated proteinases[10]. Specifically, increased expression and activity of matrix metalloproteinases (MMPs) contribute to the breakdown of the extracellular matrix, which promotes the formation of ulcers and impairs healing. Elevated levels of cytokines such as transforming growth factor-beta (TGF-β) and vascular endothelial growth factor (VEGF) translate into increased dermal fibrosis and proliferation of dermal capillaries, respectively. Capillary hyperpermeability and extravasation of red blood cells lead to deposition of ferric iron within affected skin, resulting in brown discoloration. A persistent inflammatory response can eventually give rise to ulcer formation, as continued production of MMPs and cytokines (e.g. interleukin-1 and tumor necrosis factor-alpha [TNF-α]) leads to impaired fibroblast function and increased degradation of growth factors necessary for wound healing. In addition, oxidative stress-induced premature aging and dysfunction of wound fibroblasts contribute to the chronicity of venous ulcers[11,12].

Clinical Features

Chronic venous disease is associated with a wide spectrum of clinical findings, ranging from uncomplicated telangiectasias and varicose veins to lipodermatosclerosis and large chronic ulcerations[5]. Patients with

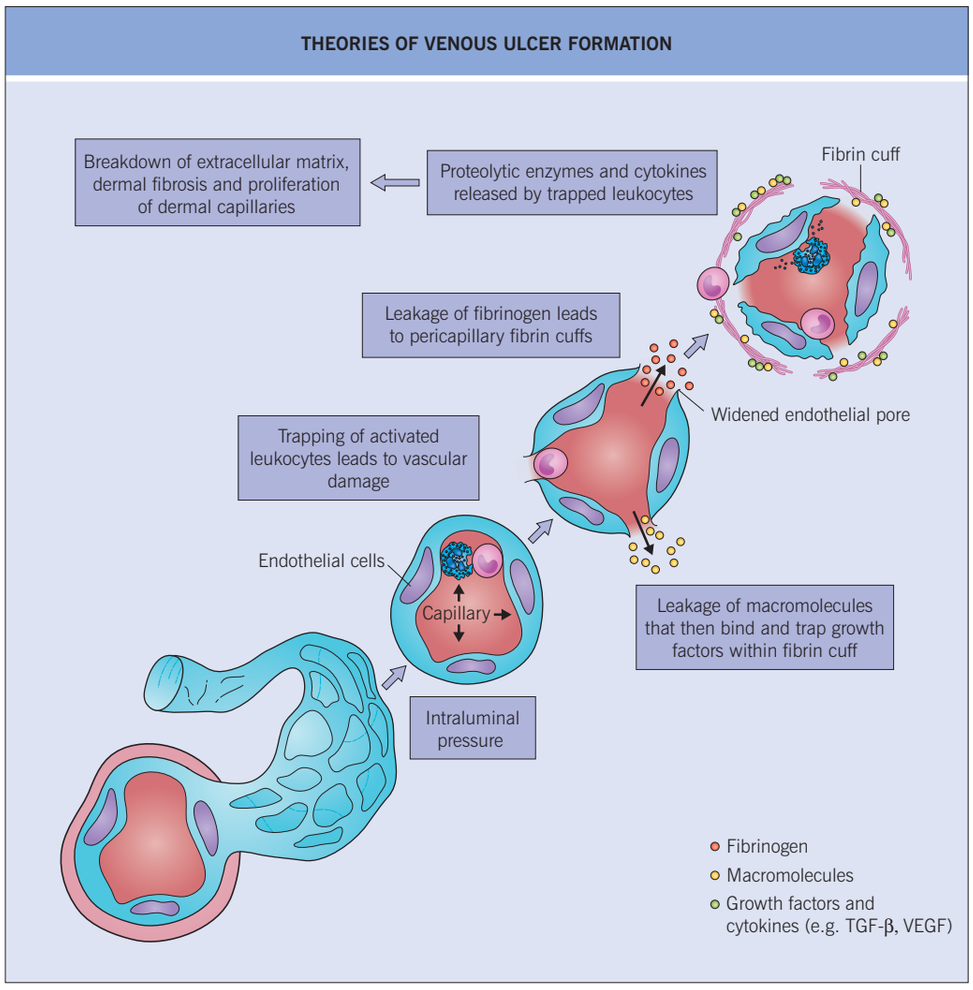

Fig. 105.3 Theories of venous ulcer formation. The theories include the presence of pericapillary cuffs due to leakage of fibrinogen, binding of growth factors by leaked molecules, and the trapping of leukocytes with subsequent chronic inflammation, dermal changes and ulcer formation. TGF, transforming growth factor; VEGF, vascular endothelial growth factor.

venous ulcers often complain of swelling and aching of the legs, typically worsened by dependency and prolonged standing but improved by leg elevation, use of gradient support stockings or walking, all of which decrease venous pressure. Additional symptoms sometimes ascribed to chronic venous disease include muscle cramps, pruritus and restless legs[4,5].

Most commonly, venous ulcers are located above the medial malleolus (Fig. 105.4). The ulcer is usually shallow with a border that is typically irregular; the wound bed is often covered by a yellow, fibrinous exudate. If the latter is appropriately debrided, a base of healthy, non-ischemic granulation tissue is usually seen. When untreated, venous ulcers tend to become larger than most other chronic wounds and can even become circumferential on the lower extremity[4]. Pedal pulses are usually palpable. If they are not palpable because of induration or edema, an ankle–brachial index (see below) should be obtained to exclude concomitant peripheral artery disease[5].

Characteristic associated features include (Fig. 105.5): (1) varicose veins of varying severity (see Ch. 155); (2) pinpoint petechiae superimposed on a yellow–brown discoloration due to extravasation of red blood cells and deposition of hemosiderin within macrophages (see Fig. 22.5), which is sometimes accompanied by hyperpigmentation; (3) edema; and (4) stasis dermatitis with pruritus, erythema, scaling and weeping (see Ch. 13). Of note, stasis dermatitis is sometimes aggravated by allergic contact dermatitis to topically applied medications, e.g. neomycin. The smooth, ivory-white, sclerotic plaques of atrophie blanche that are often surrounded by punctate telangiectasias and/or brown discoloration are observed in up to 40% of patients with chronic venous insufficiency[13] (Fig. 105.6).

Patients with longstanding venous hypertension and insufficiency may develop chronic lipodermatosclerosis (sclerosing panniculitis) with induration and fibrosis that begins on the lower medial aspect of the leg above the malleolus (see Fig. 105.5C, D). Eventually, the entire

Fig. 105.4 Venous ulcer and stasis dermatitis. Note the erythema, crusting and scaling of the skin surrounding the ulcer of the medial malleolus. There is a yellowish fibrinous exudate and granulation tissue is seen in approximately 15% of the ulcer bed.

Fig. 105.5 Associated findings in patients with venous hypertension and venous insufficiency. A Venulectasias of the instep. **B** Brown discoloration of the foot and ankle due to hemosiderin deposits within dermal macrophages in addition to hyperpigmentation. Note the cut-off at Wallace's line. **C** Lipodermatosclerosis with violet–brown discoloration, tenderness and induration that typically begins above the medial malleolus.

Continued

Fig. 105.5 Associated findings in patients with venous hypertension and venous insufficiency (cont'd). **D** Stasis dermatitis and chronic lipodermatosclerosis with serous crusts and the "inverted champagne bottle" or "bowling pin" configuration. **E** Acroangiodermatitis (pseudo-Kaposi sarcoma). Violaceous plaque in a patient with venous hypertension. Histologically, these lesions can resemble Kaposi sarcoma.

Fig. 105.6 Livedoid vasculopathy. A Multiple hemorrhagic crusts and small, very painful ulcers associated with brown discoloration due to hemosiderin deposits. **B** Stellate, porcelain-white atrophic scars with peripheral telangiectatic papules, referred to as atrophie blanche.
B, Courtesy, Julie V Schaffer MD.

lower third of the leg may become involved, leading to an appearance that has been likened to an "inverted champagne bottle". Some authors believe the degree of lipodermatosclerosis correlates with delayed wound healing. Chronic lipodermatosclerosis may be preceded by an acute inflammatory stage characterized by warm, erythematous, firm plaques that are tender and painful and are often misdiagnosed as cellulitis or another type of panniculitis, especially erythema nodosum[4].

Lipodermatosclerosis, along with ulcerations, is not limited to the lower extremities, as these changes can be seen in other sites such as the most dependent portion of the pannus (Fig. 105.7).

Laboratory Evaluation

Standardized evaluation of patients with chronic venous disease is based on the CEAP classification system which generates scores derived from objective clinical signs (C), etiology (E), anatomical (A) location of the affected veins, and pathophysiology (P) (reflux, obstruction or both)[14]. Table 155.1 outlines the details of the CEAP classification system.

Duplex ultrasonography, preferably performed with the patient in a standing position, is useful for assessing both reflux and obstruction within the deep, superficial and perforating veins, from the inferior vena cava to the calf veins. It provides information that is necessary for determining the CEAP score. In general, venography is performed if an intervention is planned. *Ascending* venography is recommended for patients with post-thrombotic disease as it gives a detailed anatomic map of the venous return of the lower extremity, whereas *descending* venography is helpful in assessing valvular disease and estimating reflux severity. Experience with high-resolution magnetic resonance venography and computed tomography venography is still limited, but should increase over the next decade[5,14].

Fig. 105.7 Lipodermatosclerosis, chronic ulceration and lymphedema of the dependent portion of the pannus. The changes are similar to those seen on the distal lower extremities.

POINTS TO INCLUDE IN THE HISTORY AND PHYSICAL EXAMINATION OF PATIENTS WITH A LEG ULCER

History	Physical examination
• Onset and clinical course of ulcer • Symptoms, including those of vascular disease or neuropathy • Alleviating factors • Exacerbating factors • Past medical history, e.g. diabetes mellitus, ASCVD, autoimmune CTD • Family history • Medications, topical and systemic • Personal habits (e.g. smoking, alcohol intake)	General, emphasizing the following: • Ulcer characteristics – Location and size – Morphology, including depth, shape, border and base – Surrounding skin, e.g. edema, dermatitis, fibrosis, cellulitis, necrosis • Peripheral pulses • Capillary refill time • Evidence of peripheral neuropathy • Deep tendon reflexes

Table 105.2 Points to include in the history and physical examination of patients with a leg ulcer. ASCVD, atherosclerotic cardiovascular disease; CTD, connective tissue disease. *Adapted from Kanj LF, Phillips TJ. Management of leg ulcers. Fitpatrick's J Clin Dermatol. 1994;Sept/Oct:52–60.*

Pathology

Within the dermis surrounding the ulceration, there is fibrosis, a proliferation of capillaries, and deposits of hemosiderin within macrophages. Extravasation of red blood cells may also be seen.

Differential Diagnosis

A significant number of patients may have a combination of venous and arterial insufficiency, so before treatments such as compression stockings are prescribed, the latter should be excluded (see below). In patients with livedoid vasculopathy or recurrent deep vein thromboses, the possibility of hypercoagulability as a contributing factor needs to be considered (see Table 105.9 & Ch. 23). Additional clues from the history, e.g. rate of expansion, or physical examination aid in narrowing the differential diagnosis (Table 105.2) Histologic examination of a longstanding or recalcitrant ulcer is recommended to exclude other diagnoses, such as squamous cell carcinoma[13] or atypical mycobacterial infection (see Fig. 105.1), and the biopsy specimen should include surrounding non-ulcerated skin.

Treatment

Most of the therapeutic principles described in the following sections can be applied to the care of other types of cutaneous ulcers, unless otherwise specified. In general, normal wound healing requires adequate perfusion, good nutritional and immune status, and avoidance of deleterious mechanical forces[15]. The initial step in the approach to an ulcer should be to address all systemic and local factors that may impair healing.

Moisture and occlusion

In the past, the mainstay of wound management was to dry the wound bed with absorptive gauzes. A major breakthrough in the management of chronic wounds was the realization that a moist environment is critical for wound healing and occlusive dressings do not increase the risk of infection[16]. Moist retentive wound dressings stimulate collagen synthesis, promote angiogenesis by creating an hypoxic environment, encourage re-epithelialization, and decrease pain. By serving as a barrier against external contamination and by lowering wound pH, occlusive dressings actually decrease wound infection rates[15].

Dressings should be changed based on their potential for absorbency and the amount of exudate, with attention to the delicate balance between overhydration and excessive dryness. For example, occlusive dressings applied to highly exudative wounds may cause maceration and erosion of the surrounding skin, possibly leading to further deterioration of the wound. In addition, chronic wound fluid can perpetuate cytokine and MMP production (see above), thereby affecting the function of fibroblasts and growth factors and contributing to chronicity. It is therefore important to protect the skin surrounding the wound bed with an ointment in order to preserve barrier integrity[15].

Debridement

Debridement consists of the removal of necrotic, non-viable or infected tissue from the wound bed in order to promote healing. In a sense, debridement is an attempt to shift the wound from a chronic state (with a milieu characterized by an abnormal extracellular matrix, an excess of proteolytic enzymes and senescent cells) into an acute state. Debridement can be surgical (sharp debridement), mechanical (wet to dry), autolytic, chemical (enzymatic) and biologic (maggot therapy)[17].

Sharp debridement with surgical instruments represents the most rapid method for debriding a wound and is most appropriate for large necrotic and/or infected wounds. It also enables the clinician to estimate the extent and severity of a wound. Although damage to viable tissue is possible, sharp debridement performed by a skilled physician is usually highly selective[17]. Caution is advised in the case of arterial ulcers because of the potential risk for tissue desiccation and ulcer enlargement[15]. Sharp debridement may be associated with bleeding and pain and may necessitate analgesia.

Wet-to-dry (mechanical) debridement consists of placing gauze moistened with saline over the wound, allowing the gauze to dry, and then removing the dry gauze along with adherent non-viable tissue. It is relatively fast and easy to perform, but is painful and does not discriminate between viable and non-viable tissue. It is indicated for wounds with large amounts of necrotic tissue.

Autolytic debridement is the process by which the body uses its own proteolytic enzymes and phagocytic cells to clear necrotic debris. The process is enhanced by moist retentive wound dressings and may require weeks to accomplish. Autolytic debridement is selective, painless, and suited primarily for wounds with minimal debris. It is contraindicated if the wound is infected[17].

Enzymatic (chemical) debridement utilizes topically applied proteolytic enzyme preparations such as papain–urea or collagenase to digest necrotic tissue, collagen, fibrin and wound exudate. Chemical debridement is a gradual process. The papain–urea preparation contains papain, which is derived from the plant *Carica papaya* and is a non-selective cysteine protease. It is active over a broad pH range and is associated with an intense inflammatory response and digestion of viable tissue; local pain or a burning sensation is often described. Therefore, the product should be applied only to the wound bed and not to the surrounding intact skin. Collagenase preparations are derived from *Clostridium histolyticum*; they specifically target native collagen and are active within a narrow pH range of 6 to 8. These preparations are highly selective and do not harm viable cells[16]. Prior to application, it is advisable to cross-hatch the eschar, if present, in order to increase penetration[15].

For therapy-resistant, chronic ulcers with marked necrosis and slough, *maggot debridement* therapy can be considered. Essentially, it

exploits the ability of maggots to decompose necrotic tissue (benign myasis), but the debridement is done in a controlled manner so as to avoid undesirable effects on healthy tissues[18]. Degradation via proteinases that are in larval excretory/secretory products is thought to contribute to wound debridement[19]. It is important to select larval strains that feed preferentially on necrotic tissue and to avoid applying too many larvae to a wound. The flies most often employed are facultative calliphorids, in particular the green bottle blowfly, *Lucilia sericata*[18].

Maggots are used to treat various types of chronic ulcers, including pressure ulcers, venous ulcers, neurovascular diabetic ulcers, and traumatic and postsurgical wounds. In a recent multicenter, randomized, open study that compared the clinical effectiveness of larval therapy to a standard debridement technique (hydrogel) for "sloughy" or necrotic leg ulcers, larval therapy did not improve the rate of healing or reduce bacterial load, but it did significantly reduce the time to debridement and increase ulcer pain[20].

Wound dressings

The ideal wound dressing should: (1) provide a moist retentive environment; (2) absorb excess exudate without causing maceration of surrounding skin; (3) protect against bacteria; (4) leave no residual debris but cause no trauma when removed; (5) decrease odor; and (6) relieve pain. In addition, the ideal wound dressing should be cost-effective, easy to handle, and be neither irritating nor allergenic. Obviously, there is no single dressing that can fulfill all these criteria throughout the entire healing process. A vast array of dressings exists and the choice of a dressing depends upon the wound type and its characteristics at a given time (Table 105.3)[15,16].

Management of wound infection

The presence of a microbial infection is always detrimental to wound healing. However, all chronic open wounds are colonized with bacteria and it is important, although often difficult, to distinguish true infection from bacterial colonization. Of note, colonization is defined by the presence of replicating bacteria and adherent microorganisms, but without evidence of tissue damage.

Critical colonization is a relatively new concept in which the bacterial burden within a chronic wound does not elicit the typical symptoms or signs of an infection, but does delay healing. The presence of 10^6 or more colony-forming units of bacteria per gram of tissue predicts delayed wound healing and a high risk for developing an infection[16]. Recent studies have demonstrated that in many chronic wounds, bacteria persist in the form of biofilms. The latter represent communities of bacteria protected by an adhesive polymeric matrix cover that communicate with each other via water channels. Through these communication channels, bacteria are able to regulate the transcription of genes and protein products in a manner that is beneficial to them, but which can delay healing (quorum sensing)[16]. Biofilms are particularly resistant to antimicrobial therapy.

Wounds become clinically infected when host defenses are overwhelmed. Signs and symptoms of infection include an increased exudate, purulent discharge, pain, and surrounding erythema and swelling. However, sometimes an increase in ulcer size and malodorous or friable granulation tissue are the only clues to the presence of an active infection within a chronic wound. Systemic signs of infection such as fever, chills, tachycardia and leukocytosis may suggest that the infection has progressed to a bacteremia or septicemia, although the former may be subtle in elderly patients, necessitating a high index of suspicion.

Most chronic wounds have a polymicrobial flora. Bacterial cultures usually grow aerobic Gram-positive cocci, which are often mixed with Gram-negative bacilli and sometimes anaerobes[21]. Clinically infected wounds should be cultured and treated initially with broad-spectrum systemic antibiotics. The antibiotic regimen is then adjusted based on the results of sensitivity testing.

In properly treated, non-healing wounds that demonstrate critical colonization, topical antimicrobials should be considered. Topical

TYPES OF WOUND DRESSINGS

Dressing type	Properties	Disadvantages	Indications
Gauzes	• Good absorption • Can be impregnated with: – NaCl to become highly absorbent, discourage bacterial overgrowth and prevent formation of excess granulation tissue – petrolatum so less drying and adherent, but then less absorbent – iodine or silver as an antiseptic	• Adhere to wound bed and promote desiccation • Can cause pain and trauma, including removal of epithelium, upon removal	• Wet wounds with heavy exudate • May serve as a secondary dressing
Films	• Semi-occlusive, thin polyurethane membranes • Maintain moisture • Permeable only to vapors, not to liquids • Transparency enables wound visualization	• Non-absorbent • Can cause maceration if applied to wounds with heavy exudate	• Wounds with minimal exudate • As a secondary dressing
Hydrogels	• Maintain a moist environment • Promote autolytic debridement • Non-adhesive • Relieve pain	• Can lead to maceration of skin surrounding wound if used in exudative wounds	• Dry wound • Wound with minimal exudate
Hydrocolloids	• Adhesive, occlusive dressings that absorb exudates with the formation of hydrophilic gel • Provide a moist environment	• Not suitable for wounds with heavy exudate or infected wounds • May produce a brown, malodorous exudate • May be traumatic on removal	• Wounds with a mild to moderate exudate
Alginates	• Fibrous dressings derived from brown seaweed • Highly absorbent and require moisture to function • Ion exchange between calcium in the alginate and sodium in the wound fluid leads to the formation of a moist retentive gel • Hemostatic	• May adhere to dry wounds • May leave fibrous debris in the wound • Can lead to maceration around the wound unless cut to the size of the wound bed	• Wounds with a moderate to heavy exudate • Undermined or tunneling wounds
Foams (polyurethane)	• Good absorbance capacity • Non-traumatic upon removal • Provide thermal and shear protection	• May produce malodorous drainage • Maceration around wound possible	• Wounds with a moderate to heavy exudate
Collagens	• Collagen matrix that physically entraps MMPs and facilitates growth factor activity	• Nonspecific inhibition of MMPs	• Clean, non-infected, recalcitrant chronic wounds

Table 105.3 Types of wound dressings. For additional details, see Chapter 145. MMPs, matrix metalloproteinases.

antimicrobial agents are divided into two major categories: antiseptics and antibiotics. Antiseptics have a broad antimicrobial spectrum as well as multiple microbial targets, but they are often toxic to host tissues. Topical antibiotics have specific cellular targets and a narrower spectrum of activity; they are not toxic to human cells but are more likely to induce bacterial resistance. Commonly used topical antibiotics include bacitracin, neomycin, mupirocin, retapamulin, gentamicin and fusidic acid. Topical antibiotics can cause allergic contact dermatitis, in particular neomycin and bacitracin. It is also preferable to avoid topical antimicrobials that have a systemic counterpart[21].

Commonly used antiseptics include hydrogen peroxide, chlorhexidine, iodine-based preparations (e.g. povidone-iodine, cadexomer iodine), and silver-releasing agents. Hydrogen peroxide and povidone-iodine have a broad antimicrobial spectrum with minimal resistance but may be cytotoxic. Cadexomer iodine is a complex of 0.9% elemental iodine plus cadexomer microbeads which are composed of a modified starch-based polymer. Upon absorption of exudate, the cadexomer beads swell and slowly release iodine into the wound bed, thus maintaining non-toxic iodine concentrations[22].

Silver is an effective antiseptic agent with broad-spectrum activity, including against methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), and extended-spectrum β-lactamase producers. Resistance has rarely been reported, primarily with Gram-negative species[21]. Only the ionized form of silver (Ag^+) has antimicrobial properties, so exposure to wound fluid or exudate is required if the source is metallic silver[23]. Silver ions kill bacteria by damaging bacterial cell walls and intracellular and nuclear membranes as well as denaturing bacterial DNA, RNA and key enzymes (e.g. respiratory enzymes)[15,23]. Silver may also promote cellular proliferation and re-epithelialization by inducing the production of metallothionein by epidermal cells. Metallothionein increases zinc- and copper-dependent enzymes required for cellular proliferation and matrix remodeling[23]. Silver has been incorporated into various dressing products (e.g. gauzes, hydrocolloids, alginates, foams) in addition to creams, gels and barrier protectants which differ in their solubility and the rate at which silver ions are released into the wound bed[15]. Disadvantages of silver products include potential irritation, permanent blue–gray discoloration (localized argyria) and cost. Topical silver sulfadiazine has induced neutropenia in children which was reversible once the cream was discontinued[16].

Lastly, as chronic wounds may serve as a portal of entry for *Clostridium tetani*, it is recommended that the tetanus immune status of patients with chronic leg ulcers be assessed[23a].

Adjuncts to wound care

Compression

Compression therapy is a mainstay in the treatment of venous insufficiency. Compression stockings improve venous return, reduce edema, stimulate healthier granulation tissue within venous ulcers[15] and improve quality of life[15]. A Cochrane meta-analysis of 39 randomized controlled trials concluded that compression therapy increased ulcer healing rates as compared to no compression[24].

Elastic stockings, preferably with graduated compression, are available in a wide range of compressive pressures (15 to 60 mmHg), lengths and materials (Table 105.4). Lower levels of compression (20 to 30 mmHg) are sufficient for preventing mild edema, whereas higher levels of compression (30 to 40 mmHg) are required to control stasis dermatitis or lead to the healing of ulcers. Compression stockings also prevent the recurrence of venous ulcers once healed. Therefore, life-long use of compression is recommended for patients with a history of venous ulcers[5]. In addition to stockings, there are other forms of compression such as bandages and wraps, as outlined in Tables 105.5 and 105.6. Of note, surgical correction of superficial venous reflux (plus compression) does not improve ulcer healing but does reduce the recurrence of ulcers[25].

It is important to remember that compression therapy in patients with undiagnosed arterial insufficiency can lead to ulcer worsening, gangrene or even limb amputation. As many patients with venous disease have concomitant arterial insufficiency, clinically significant arterial disease must be excluded before prescribing compression therapy. The latter is also relatively contraindicated in patients with uncompensated congestive heart failure[15].

CLASSES OF COMPRESSION STOCKINGS

Class	Pressure at the ankle	Indication
I	20–30 mmHg	Simple varicose veins Mild edema Leg fatigue
II	30–40 mmHg	Moderate edema Severe varicosities Moderate venous insufficiency
III	40–50 mmHg	Severe edema Severe venous insufficiency Post-thrombotic lymphedema
IV	50–60 mmHg	Elephantiasis

Table 105.4 Classes of compression stockings. *Adapted from Phillips TJ. Current approaches to venous ulcers and compression. Dermatol Surg. 2001;27:611–21.*

Manual lymph drainage

Edema is a significant cause of delayed healing of venous ulcers. Identifying the cause of the edema is instrumental in choosing the appropriate therapy, which in turn is critical for ulcer resolution. However, even with identification and treatment of contributing factors (e.g. afterload reduction, diuretics), edema may be persistent.

Manual lymph drainage is a massage technique in which lymph conduits are contracted more frequently and lymphatic fluid is moved away from affected lymphedematous regions toward more centrally located, functioning lymph basins, thereby reducing edema volume. This manual drainage is employed during the early, intensive phase of lymphedema therapy and is combined with short-stretch compression bandaging applied immediately after treatment. The regimen also includes a series of exercises to increase lymphatic flow through functioning collateral pathways, skin care, and sometimes the use of intermittent pneumatic compression. This intensive, short-term therapy is referred to as "complete decongestive physiotherapy" and is followed by a maintenance phase that consists of skin care, elastic compression and exercise[26,27].

Topical negative pressure therapy

In topical negative pressure therapy, ideally performed using a vacuum-assisted closure (VAC) system, negative pressure is applied to hasten wound healing. It is used primarily for ulcers that are due to venous disease or diabetes. The system includes an open pore foam conduit (cut to the wound size) sealed with a semi-occlusive drape which is then attached to a vacuum source via a tube. When subatmospheric pressure (100–125 mm Hg) is applied to the foam–wound interface (continuously or intermittently), accumulated fluid is transferred to a canister. Topical negative pressure therapy promotes wound healing by creating mechanical forces that stimulate a biological response while maintaining a moist environment. It also removes exudate, reduces edema, increases local perfusion, decreases the bacterial count and enhances granulation tissue formation[15,28].

Before application, the wound must be debrided of necrotic tissue in order to prevent infection. Topical negative pressure therapy is contraindicated for ischemic wounds and ulcerated malignancies because it may cause necrosis of the wound edges and tumor growth, respectively. The foam should be changed every 48 to 72 hours. Sometimes, new granulation tissue grows into the foam, which can result in pain during foam changing. If this occurs, then the foam should be changed more frequently or a denser foam employed. In up to 25% of patients, there are complications such as pain, odor, periwound irritation or maceration, infection, bleeding and necrosis; most of these problems can be avoided with careful patient selection and skilled management[28,29].

Skin substitutes

Patients with recalcitrant chronic ulcers can sometimes benefit from autologous skin grafting, especially when the ulcers are due to venous disease (see Ch. 148). However, there has been an increase in the use of biological dressings and synthetic skin substitutes in such patients. Living skin substitutes are tissue-engineered products that contain a cellular component of autologous or allogeneic origin plus a biodegradable scaffold, and they serve as a replacement for the epidermis, dermis

TYPES OF COMPRESSION THERAPY		
Bandage	**Advantages**	**Disadvantages**
Elastic wraps	Inexpensive Can be reused	Often applied incorrectly by the patient Tend to unravel Do not maintain sustained compression Lose elasticity after washing
Self-adherent wraps	Self-adherent Maintain compression	Expensive Cannot be reused
Unna boot	Comfortable Protects against trauma Full maintenance of ambulatory outpatient status Minimal interference with regular activities Substitutes for a failing pump	Pressure changes over time Needs to be applied by well-trained physicians and nurses Does not accommodate highly exudative wounds
Four-layer bandage	Comfortable Can be left in place for 7 days Protects against trauma Maintains a constant pressure for 7 days because of the overlap and elasticity of the bandages Useful for highly exudative wounds	Needs to be applied by well-trained physicians and nurses Expensive
Graduated compression stockings	Reduce the ambulatory venous pressure Increase venous refilling time Improve calf pump function Different types of stockings accommodate different types of leg disorders Dressings underneath can be changed frequently	Often cannot monitor patient compliance Difficult to put on
Orthotic device	Adjustable compression Sustained pressure Easily put on and removed Comfortable	Expensive Bulky appearance
Compression pump	Augments venous return Improves hemodynamics and microvascular functions Enhances fibrinolytic activity Prevents postoperative thromboembolic complications in high-risk patients	Expensive Requires immobility for a few hours per day

Table 105.5 Types of compression therapy. *Adapted from Choucair M, Phillips TJ. Compression therapy. Dermatol Surg. 1998;24:141–8.*

CLASSES OF COMPRESSION BANDAGES	
Class	**Properties**
Class I	Lightweight and conforming Stretch and simple dressing retention properties
Class II	Also known as short stretch bandages Act like rigid, non-elastic bandages Used for light support
Class III • Class IIIA • Class IIIB • Class IIIC	 Light compression bandages Moderate compression bandages Extra-high performance Achieve 40 mmHg at the ankle Useful for: • Severe varicosities • Severe edema • Postphlebitic syndrome

Table 105.6 Classes of compression bandages.

or both. These skin mimetics provide temporary wound coverage, but serve primarily as a source for growth factors and extracellular matrix. Although effective in wound repair, their clinical use is still limited due to their high cost and complex technology (see Ch. 145)[30]. In general, these living skin substitutes are indicated for venous and diabetic ulcers.

There are also biological dressings that consist of just an extracellular matrix (i.e. they have no cellular component). Structural extracellular matrix components, such as collagen, fibronectin and proteoglycans, provide a temporary scaffold that supports cellular proliferation and migration. In addition, they contain cytokines, e.g. TGF-beta and bFGF, which promote wound healing. These dressings are also used for diabetic and venous ulcers.

Another approach is a bio-inspired artificial hydrogel matrix that utilizes natural enzymatic reactions to become bioactive. It is able to incorporate and then deliver biomolecules (e.g. MMPs, growth factors) and at the same time be degraded and remodeled by them, ultimately being replaced by newly formed tissue.

Topical and oral medications

Daily, short-contact application of topical tretinoin solution (0.05%) was reported to stimulate granulation tissue formation and healing of chronic leg ulcers[31]. Fonder et al.[15] also reported that application of small amounts of 0.025% tretinoin cream can induce neovascularization in ischemic wound beds.

Pentoxifylline, a drug that targets inflammatory cytokine release, leukocyte activation and platelet aggregation at the microcirculatory level, is occasionally a component of the treatment regimen for chronic venous insufficiency. Although evidence of a beneficial effect when the drug is used as monotherapy is largely lacking, pentoxifylline has been shown (at a dose of 1200 mg per day), in conjunction with compression therapy, to modestly improve ulcer healing as compared to compression plus placebo[32]. This effect has been attributed to the drug's fibrinolytic properties, antithrombotic effects, and/or ability to inhibit the production of proinflammatory cytokines.

LYMPHEDEMA

Lymphedema is the accumulation of lymph fluid within the interstitium that is due to a reduction in lymph drainage in the presence of *normal* capillary filtration. Lymphedema should be differentiated from edema which results from an imbalance between capillary filtration and lymph drainage.

Lymphedema can be primary or secondary (Table 105.7). Primary lymphedema can be further subdivided based on age at time of clinical presentation[33]. *Congenital lymphedema* usually appears before 1 year of age and is sporadic or familial (e.g. Nonne–Milroy disease; Fig. 105.8). Meige disease, a type of *lymphedema praecox*, is the most common form of primary lymphedema and it usually presents around puberty and more often affects girls. *Lymphedema tarda* usually presents after 35 years of age and is probably the result of an environmental

CAUSES OF LYMPHEDEMA	
Primary lymphedema	**Secondary lymphedema**
Congenital lymphedema (presents at birth or within first 1–2 years of life) • Congenital aplasia of the thoracic duct • Hypoplasia of peripheral lymphatics • Congenital abnormalities of the abdominal or thoracic lymphatics • Hereditary (Nonne–Milroy disease; type 1A) – AD; caused by *VEGFR3 (FLT4)* mutations in some families • Turner syndrome • Noonan syndrome	• Recurrent lymphangitis and cellulitis • Parasitic infections, e.g. filariasis • Lymph node dissection, e.g. for melanoma or breast cancer • Malignant obstruction, e.g. lymphoma, Kaposi sarcoma, retroperitoneal sarcoma • Radiation injury • Obesity • Surgical excisions, e.g. mastectomy, prostatectomy • Podoconiosis (exposure to mineral microparticles in volcanic soils) • Acne vulgaris and acne rosacea (midface) • Granulomatous disease
Lymphedema praecox (presents around puberty) • Meige disease (type II); lymphedema – distichiasis syndrome; yellow nail syndrome – AD; caused by *FOXC2* mutations in some families • Hypotrichosis–lymphedema–telangiectasia syndrome – AD or AR; caused by *SOX18* mutations	
Lymphedema tarda (presents after age 35 years)	

Table 105.7 Causes of lymphedema. In distichiasis, there is abnormal growth of eyelashes from the orifices of meibomian glands, leading to a double row of eyelashes. AD, autosomal dominant; AR, autosomal recessive.

Fig. 105.8 Bilateral primary lymphedema due to Nonne–Milroy disease.

trigger such as trauma or infection superimposed on inherently weakened lymphatics.

Common causes for secondary or acquired lymphedema are malignancy, radiation and surgical lymph node dissection, as well as chronic venous insufficiency, trauma, recurrent cellulitis, filariasis and obesity (Fig. 105.9). Filariasis, due to infection of the lymphatics by the nematode *Wuchereria bancrofti*, is the most common cause of lymphedema in low-income tropical and subtropical countries.

Clinically, lymphedema begins as painless pitting edema of the dorsal aspect of the foot which then progresses proximally. Over time, the skin becomes indurated due to fibrosis, and the affected areas are prone to ulceration and secondary infection. Recurrent infections lead to worsening of the lymphedema and a vicious cycle is established[26].

Elephantiasis nostras verrucosa is a complication of chronic lymphedema and most commonly affects the feet and distal lower extremities. In addition to profound non-pitting edema and progressive fibrosis of the dermis and subcutaneous tissue, there are verrucous changes with papillomatosis and hyperkeratosis (Fig. 105.10). The skin acquires a mossy or cobblestone appearance and discrete firm fibrous papules may develop. Colonization with bacteria and fungi often results in ulcers becoming crusted and malodorous[34].

Elephantiasis nostras verrucosa is difficult to treat. Compression stockings, pneumatic pumps and massage are used to decrease lymph

Fig. 105.9 Lymphedema secondary to morbid obesity associated with myxedema.

Fig. 105.10 Elephantiasis nostras verrucosa. The patient had both lymphedema and venous insufficiency.

accumulation. Topical keratolytics or humectants, such as salicylic acid and urea, may improve the hyperkeratosis[34]. Oral retinoids have been reported to be of benefit for both the verrucous changes and the lymphedema[35]. Surgical debridement can be considered for patients who do not respond to more conservative therapies[36].

The differential diagnosis includes lipedema[37], in which there is an abnormal deposition of subcutaneous fat with sparing of the feet (Fig. 105.11), and obesity-associated lymphedematous mucinosis, where there can be dermal mucin deposition in the absence of thyroid disease.

ARTERIAL ULCERS

Peripheral arterial disease (PAD) is a common manifestation of atherosclerosis. Cigarette smoking and diabetes mellitus are the strongest risk factors for the development of PAD, with hypertension, dyslipidemia and hyperhomocysteinemia representing additional risk factors[38]. Up to 25% of patients with leg ulcers have PAD, and a significant number of patients have a combination of arterial and venous insufficiencies[15].

Pathogenesis

A lack of blood perfusion decreases tissue resilience and leads to tissue necrosis; it also impedes wound healing by reducing the supply of oxygen, nutrients and soluble mediators involved in the repair process. Although PAD alone infrequently precipitates ulceration, arterial insufficiency plays a major role in delayed wound healing and complications

Fig. 105.11 Lipedema. This middle-aged woman has bilateral "stovepipe" enlargement of the legs and minimal involvement of the feet. Note the sharp demarcation between normal and abnormal tissue at the ankle, referred to as the "cuff sign". *Courtesy, Jean L Bolognia, MD.*

DETERMINATION AND INTERPRETATION OF THE ANKLE–BRACHIAL INDEX

- With the patient in a supine position, the systolic blood pressure is measured in the:
  - brachial arteries (right and left)
  - dorsalis pedis and posterior tibial arteries (right and left)
- The ABI is determined by:

$$\frac{\text{the highest of the systolic pressures from the dorsalis pedis or posterior tibial arteries}}{\text{the higher of the brachial artery systolic pressures}}$$

- Interpretation of the ABI:
  - 0.91–1.30 = normal range
  - >1.30 = suggests incompressible tibial arteries due to medial calcification (diabetes mellitus, chronic renal insufficiency)
  - <0.9 = indicative of peripheral artery disease (PAD)
  - 0.41–0.90 = mild to moderate PAD
  - 0.00–0.40 = severe PAD

Table 105.8 Determination and interpretation of the ankle–brachial index (ABI).

Fig. 105.12 Arterial ulcer. The punched-out appearance and surrounding smooth shiny skin are common features.

Fig. 105.13 Cholesterol emboli. Ischemia of the toes and necrosis with early ulcer formation.

including gangrene. Ischemic foot ulcers are often precipitated by trauma in a patient with relatively mild symptoms of arterial insufficiency. In such an individual, the degree of skin perfusion is sufficient to maintain cutaneous integrity, but is not adequate enough to support proper wound healing. In such a setting, the ulcer will inevitably progress into a chronic wound or gangrene unless perfusion is restored[39].

Clinical Manifestations

Although most patients with significant PAD are symptom-free, intermittent claudication, defined as leg pain induced by ambulation and relieved by resting, is the earliest and the most common presenting symptom of PAD of the lower extremities. With disease progression, patients begin to complain of pain at rest, especially when the legs are elevated in bed at night, which is ameliorated by dependency. While symptoms of claudication are usually localized to the calf or the thigh, pain at rest is often felt in the feet. In advanced stages of PAD, the reduction in cutaneous blood supply may lead to ischemic ulceration and gangrene, and this may necessitate amputation[40].

Arterial ulcers are usually round with a sharply demarcated border and are characterized by an absence of bleeding (Fig. 105.12). These wounds typically occur on the distal lower extremities, often over bony prominences (e.g. the first and fifth metatarsal heads). The surrounding skin may be hairless, shiny and atrophic. Wound pain is often significant and is exacerbated by limb elevation. Additional manifestations of impaired arterial perfusion to the foot include diminished or absent pedal pulses, cool feet, pallor of the foot with elevation of the leg and then subsequent redness with lowering (dependent rubor), sluggish refilling of toe capillaries, thickened nails and absence of toe hair (see Table 105.1)[15,39].

Laboratory Evaluation

The ankle–brachial pressure index, more commonly referred to as the ankle–brachial index (ABI), is a simple, non-invasive test that is widely used for diagnosis of PAD and to assess its severity. The ABI is calculated by dividing the systolic blood pressure in the ankle by the systolic blood pressure in the arm while the patient is in a resting supine position (Table 105.8). A decrease in arterial blood pressure at the ankle (relative to the central blood pressure) implicates arterial stenosis at any point between the aorta and the ankle[41]. The normal range for the ABI is 0.91 to 1.30, with a reading <0.9 being indicative of PAD[42].

Depending on the patient's presentation and symptoms, further non-invasive imaging techniques may be employed, including duplex ultrasound, computed tomography angiography (CTA), and magnetic resonance angiography (MRA). Both CTA and MRA produce images of vascular structures in cross-sectional slices that can be reconfigured into three-dimensional angiographic images. CTA is less expensive than MRA, with higher spatial resolution. However, CTA involves ionizing radiation and the use of iodinated contrast material. The gold standard for diagnosis and evaluation of PAD is invasive digital subtraction angiography, which can also be used to guide endovascular intervention[38].

Differential Diagnosis

Patients with PAD can also develop cutaneous ulcers due to cholesterol emboli (Fig. 105.13) and risk factors include arterial or coronary catheterization and anticoagulation (see Ch. 23). In Buerger's disease, ulcers occur distally on both the upper and lower extremities, with

smoking as a risk factor. Additional disorders to consider are in Figure 105.1, including diffuse dermal angiomatosis (see below).

Treatment

Arterial ulcers can benefit from restoration of peripheral arterial blood flow, either by surgical reconstruction (e.g. femoral popliteal bypass) or by less invasive endovascular interventions (e.g. femoral angioplasty)[15]. In principle, local treatment of arterial ulcers is similar to that of other types of skin ulcers, with two major exceptions: (1) sharp debridement should be performed very cautiously or avoided in order to prevent further necrosis and ulcer enlargement; and (2) VAC therapy should be avoided as it can lead to worsening of the ulcer.

DIABETIC (AND NEUROPATHIC) ULCERS

Patients with diabetes mellitus have a 12–25% lifetime risk of developing a foot ulcer. These foot ulcers constitute a major medical and economical burden, with a substantial morbidity and impaired quality of life. Approximately 15% of diabetic patients with foot ulcers will eventually undergo a lower extremity amputation. The rising incidence of both type 1 and type 2 diabetes has made diabetic foot ulcers the most important risk factor for lower extremity amputation in high-income countries[43,44].

Pathogenesis

The etiology of diabetic ulcer formation is multifactorial. Although ischemia, trauma and infection have traditionally been incriminated as underlying pathogenic factors, nowadays diabetic neuropathy is considered to be the major cause of foot ulcers in diabetic patients[45].

Diabetic neuropathy typically involves the sensory, motor and autonomic nerves, with *sensory* neuropathy substantially impairing the patient's perception of touch, deep pressure, temperature and joint position. With the loss of protective sensation, foot trauma is unrecognized and this can lead to ulceration. Peripheral *motor* neuropathy results in weakness and atrophy of the intrinsic muscles of the feet, producing altered biomechanics and structural deformities that, in the presence of sensory neuropathy, increase the risk for skin injury and ulceration from repetitive mechanical stress. Continuous pressure to the skin overlying bony prominences typically results in the formation of a thick, keratotic plaque (callus), which eventually breaks down and ulcerates[15,45]. *Autonomic* neuropathy also plays a role because it can lead to a loss of sweating, with the resultant dry skin being susceptible to cracks and fissures that serve as a portal of entry for bacteria[45]. In addition, a potential consequence of autonomic neuropathy is arteriovenous shunting within the skin microcirculation which results in decreased cutaneous perfusion and oxygen saturation, thus contributing to ulceration and an impaired response to infection[44]. Moreover, this abnormal vascular autoregulation, coupled with sensory neuropathy, contributes to the development of Charcot joints (degenerative arthropathy), further adding to the risk of ulceration from an abnormal distribution of pressure forces and foot deformities[46].

Diabetes is also associated with an increased risk of developing PAD, which characteristically affects vessels between the knee and the ankle[43]. Although microcirculatory dysfunction occurs early on in the course of diabetes, it is primarily atherosclerotic macrovascular disease that accounts for ischemic complications in these patients[44]. In general, diabetic foot ulcers are not purely related to vascular occlusion; rather, mechanical damage that typically occurs to the insensate foot, in the presence of a decreased blood supply, rapidly results in ischemic ulcers. PAD also contributes to an altered response to foot infections and poor wound healing. The combination of a depressed immune response plus a decrease in cutaneous blood supply plays a key role in the development of cellulitis, abscesses and osteomyelitis, all of which increase the risk of limb amputation[46].

Occasionally, patients with diabetes develop ulcerations within lesions of necrobiosis lipoidica as well as ulcers due to streptococcal infections.

Clinical Features

Diabetic ulcers are usually located on pressure points and bony prominences such as the metatarsal heads, great toes and heels. They often arise within exuberant, moist, malodorous calluses (mal perforans) (Fig. 105.14). In the absence of peripheral atherosclerotic disease, the diabetic foot is warm, with good color and palpable pulses, but with decreased sensation. Foot deformities are frequently present, e.g. hammer toes, claw toes, and a high or flattened arch (Charcot foot).

Fig. 105.14 Neuropathic ulcers (mal perforans) in patients with diabetes mellitus and peripheral neuropathy. Common locations are the plantar surface of the heel (**A**) and the great toe (**B**). Note the thick rim of callus.

Laboratory Evaluation

Because diabetic ulcers are heterogeneous in nature, a thorough evaluation of the patient is crucial in determining the underlying causes. More specifically, peripheral neuropathy can be detected via a neurologic examination of the lower extremities that includes the use of a 10 g monofilament to test for sensation[47]. More invasive testing, i.e. nerve conduction studies/electromyography, is sometimes required. The degree to which vascular perfusion is compromised can be assessed via determination of the ABI (see above).

A complete blood count, ESR, C-reactive protein level and blood glucose level are obtained when assessing for a possible associated infection. Of note, sometimes an elevated blood glucose level is the only sign of infection. Microbial cultures (bacterial, mycobacterial and fungal) should be obtained from the wound bed. Although swabs are often used, deep tissue specimens, obtained aseptically, are preferable[47].

Diagnostic imaging, including plain radiographs of both feet, bone scintigraphy, MRI, CT and sometimes ultrasound, is used to better define the presence or absence of a bone or deep soft tissue infection. Of these, MRI is the most accurate test for diagnosing osteomyelitis. If osteomyelitis is suspected, a bone biopsy processed for culture and histology is the gold standard[43,45].

Treatment

Conservative treatment of diabetic foot ulcers consists of providing a proper wound healing environment, eradication of infection, and avoidance of repetitive trauma by alleviating the mechanical load on ulcers

(off-loading). Methods of off-loading include bed rest and the use of a wheelchair, crutches, total contact casting, cast walkers, felted foam, half-shoes or therapeutic shoes. Total contact casting is considered the best approach as it enables pressure redistribution and continuous off-loading of the ulcer area. The inability of the patient to remove the cast ensures compliance and reduces the level of activity[47,48]. However, total contact casting is somewhat impractical because it is expensive and requires skill and experience. In addition, as the edema subsides, cast changing and size adjustments are often required (usually twice a week or more often). Total contact casting is contraindicated if the wound is infected or has a significant exudate and it can lead to new ulcerations over bony prominences[45].

Another approach to off-loading is the use of specialized shoes that reduce pressure about the forefoot and heel and multilayered insoles that enhance shock absorption[45]. Half-shoes assist in off-loading forefoot plantar ulcers as they support only the rear and mid foot, while the forefoot is left suspended in the air[47].

Initial wound management consists of cleansing the wound and proper debridement of any necrotic material, including the callus; the latter can contribute to increased pressure on the insensate foot. In addition, debridement promotes wound healing at the cellular level by removing excess extracellular matrix, thus liberating trapped growth factors and facilitating cell migration[46]. Moist wound healing is recommended as with other types of chronic ulcers but avoidance of maceration of surrounding skin is of particular importance.

Apart from standard therapies (see above), hyperbaric oxygen has been shown to be of specific benefit to patients with diabetic foot ulcers. While it is unclear to what extent it benefits other types of ulcers[49], hyperbaric oxygen therapy has been shown to be effective in the treatment of diabetic foot ulcers, with a decrease in healing time and amputation rate. Oxygen (100%) at supra-atmospheric pressures is intermittently inhaled, either in a full-body (monoplace) chamber or in a multiplace chamber via a gas mask. In theory, tissue hypoxia impairs wound healing and hyperbaric oxygen therapy leads to an increase in the blood oxygen level within the wound. In addition, there is reallocation of blood flow to hypoxic areas due to hyperoxic vasoconstriction of surrounding normal tissue[50]. Side effects include oxygen toxicity to the brain (e.g. seizures) and lungs and barotrauma to the lungs, ears, sinuses and eyes (transient myopia)[15].

As endogenous growth factors are often degraded or trapped within chronic wounds, genetically engineered exogenous growth factors have been used to try to enhance wound healing. Becaplermin gel (Regranex®) is recombinant platelet-derived growth factor whose biologic activity is similar to its endogenous counterpart, with stimulation of granulation tissue production and release of other growth factors important to wound repair. It is the only growth factor approved for use in chronic neuropathic diabetic ulcers[15]. In the setting of best wound care, becaplermin gel has been shown to increase healing rates and shorten healing time of diabetic ulcers[51]. However, in routine clinical practice, becaplermin has not been as successful and it has an FDA black box warning of an increased risk of cancer mortality (when exposed to three or more tubes). More recently, strategies have focused on improving growth factor activity and protecting these factors from degradation[30].

Living skin equivalents (e.g. Apligraf™, Dermagraft™) are bioengineered products that act as delivery systems for growth factors and extracellular matrix (see Ch. 145)[52–54]. Both are indicated for recalcitrant diabetic foot ulcers that have no exposed muscle, bone or tendon, are not infected and have had aggressive debridement.

Prevention

Preventing wound recurrence is of critical importance. The risk of ulceration and/or amputation is increased in patients who have had diabetes for ≥10 years, are male, have poor glucose control, or have target organ complications. Foot-related conditions that are associated with an increased risk of amputation are peripheral neuropathy, altered biomechanics, evidence of increased pressure, foot deformity, PAD, history of an ulcer or previous amputation, and severe nail pathology[55]. Tight control of glucose levels is required in order to prevent diabetic complications that are due to microvascular changes, as the latter predispose the patient to neuropathy, ischemia and infection. Lower HgbA1c values are associated with a decrease in healing times for leg and foot ulcers[56]. Smoking cessation and control of low-density lipoprotein (LDL) and total cholesterol levels are also important in the prevention of atherosclerotic vascular disease.

All diabetic patients should receive an annual foot examination to assess neurologic and vascular status, biomechanics, skin integrity, and the presence and types of foot deformities. Patients with significant risk factors for ulcer formation should be evaluated more frequently. Education regarding daily foot care that includes inspection for any scratch, blister or erythema, daily washing in warm water, appropriate footwear selection (e.g. avoiding pointed shoes), skin moisturizing, and treatment of nail and foot fungal infection should be provided.

ULCERS DUE TO PHYSICAL FACTORS

Any form of mechanical trauma to the skin can result in the formation of an ulcer if factors that compromise the skin's ability to recover from physical insults are present. The most common form of physical injury which leads to ulceration is prolonged pressure due to immobilization. The resultant ulcer is commonly referred to as a *pressure ulcer* or *decubitus ulcer* (decubitus means lying down in Latin). These ulcers are caused by unrelieved pressure to soft tissues compressed between a bony prominence and an external surface. The most common bony prominences involved are the sacrum, ischial tuberosities, greater trochanters, heels and lateral malleoli[57] (Fig. 105.15).

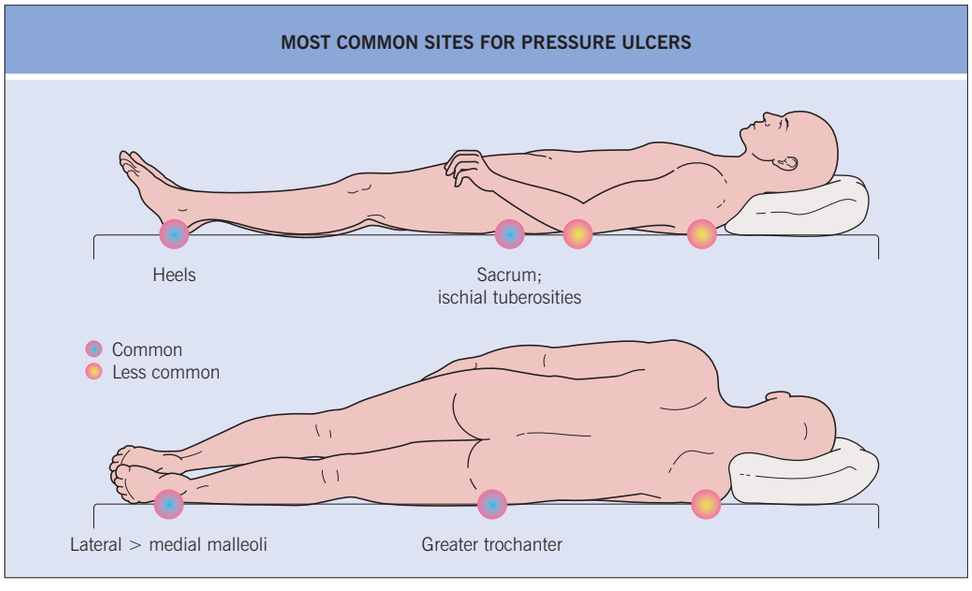

Fig. 105.15 Most common sites for pressure ulcers.

Fig. 105.16 Pressure ulcer (stage III) over the sacral area.

Fig. 105.17 Black eschar of the heel at site of pressure necrosis.

Approximately 1.5–3 million people in the US have pressure ulcers with an annual cost of treatment of up to $5 billion[57]. It has also been estimated that 10% of hospitalized patients and 25% of nursing home residents have pressure ulcers, with most developing during the first few weeks of hospitalization. An estimated 70% of pressure ulcers occur in patients over 70 years of age; 95% are located on the lower portion of the body: 65% in the pelvic girdle area (Fig. 105.16) and 30% on the lower limbs (Fig. 105.17). Risk factors that predispose to the development of pressure ulcers include prolonged immobility, sensory deficit, circulatory disturbance and poor nutrition[57].

Pathogenesis

Four major etiologic factors have been identified as playing an important role in the development of pressure ulcers: external pressure, shearing forces, friction and moisture.

Interstitial pressures >32 mmHg (normal capillary pressure range = 12–32 mmHg) usually compromise oxygenation and microcirculation. There is an inverse time–pressure curve, with slow ulcer formation at low pressures and rapid ulcer formation at high pressures (≥70 mmHg). The length of continuous exposure of the skin to pressure is also of critical importance, thus explaining why intermittent relief of the pressure can prevent ulcer formation. Because subcutaneous tissues are most susceptible to the damaging effects of prolonged exposure to pressure, deep tissue trauma can occur with relatively little superficial damage that would alert caregivers to the extent of tissue injury[57].

Shearing forces result from the sliding and relative displacement of two apposing surfaces. Although externally applied pressure is more effective than shearing forces alone in reducing skin arteriolar blood flow, these two factors can combine to enhance vascular occlusion. When the head of a supine patient is raised more than 30°, shearing forces occur in the sacral and coccygeal areas. Sliding of the torso transmits pressure to the sacrum and deep fascia, as the outer sacral skin is fixed because of friction with the bed. Vessels within the deeper portion of the superficial fascia angulate and thrombose, which manifests clinically as undermining of the ulcer[57].

Friction is often associated with shearing and it reflects the degree of resistance generated when two surfaces move across each other. When a bedridden patient is dragged across the bed sheets, friction is produced. Damage to the protective stratum corneum enhances ulcer formation by compromising the skin barrier.

Moisture results from perspiration due to fevers and from urine and feces. It has been shown to increase the risk of pressure ulcer formation fivefold[57].

Clinical Features

Pressure ulcers are usually classified according to a four-stage system designed by the National Pressure Ulcer Advisory Panel (NPUAP) (Fig. 105.18). Of note, the ulcers do not necessarily progress sequentially from stage I to stage IV, nor do they necessarily heal from stage IV to stage I[58].

- *Stage I*: non-blanchable erythema of intact skin which heralds skin ulceration. For darker-skinned individuals, warmth, edema, discoloration of the skin and induration may serve as indicators of impending ulceration[57,58].
- *Stage II*: partial-thickness skin loss involving the epidermis, dermis or both. This superficial lesion presents as an erosion, blister or shallow ulcer[57,58].
- *Stage III*: full-thickness skin loss with damage to the subcutaneous tissue, extending down to (but not including) the underlying fascia. This deep lesion presents as a crater-like ulcer and sometimes involves adjacent tissue[57,58].
- *Stage IV*: full-thickness skin loss and extensive tissue necrosis with destruction extending to muscle, bone, or supporting structures such as tendons or joint capsules. Undermining or sinus tracts can be present[57,58].

As mentioned previously, a major limitation in the clinical classification of pressure ulcers stems from the fact that extensive deep tissue damage may be accompanied initially by minimal superficial manifestations. Adequate evaluation may also be hampered by the presence of an eschar, which should be debrided for full assessment[57].

Pathology

When the diagnosis is in doubt or when a secondary malignancy is suspected in the setting of a longstanding lesion, histologic examination is indicated. When there is *blanchable* erythema clinically, the superficial dermal capillaries and venules are dilated. Mild to moderate edema within the papillary dermis is seen in association with a mild perivascular lymphocytic infiltrate. The epidermis, pilosebaceous structures and reticular dermis remain normal. At the stage of *non-blanchable* erythema, engorgement of capillaries and venules with red blood cells, platelet thrombi, and hemorrhage are observed in the papillary dermis. Although the epidermis still appears normal, sweat gland and subcutaneous fat degeneration is often present[57]. Subepidermal separation can occur with formation of a subepidermal bulla. In early ulcers, the epidermis is lost and acute inflammation of the papillary and reticular dermis is seen. Chronic ulcers have a diffusely fibrotic dermis with a loss of adnexa. The surface may have a hemorrhagic crust containing acute inflammatory cells or a thin zone of coagulation necrosis. In the black eschar stage, full-thickness destruction of the skin occurs. General dermal architecture is preserved, but there is obliteration of cellular details.

Treatment

As a rule, pressure ulcers are preventable. The mainstay of prevention is relief of pressure on the skin. This can be accomplished by frequent

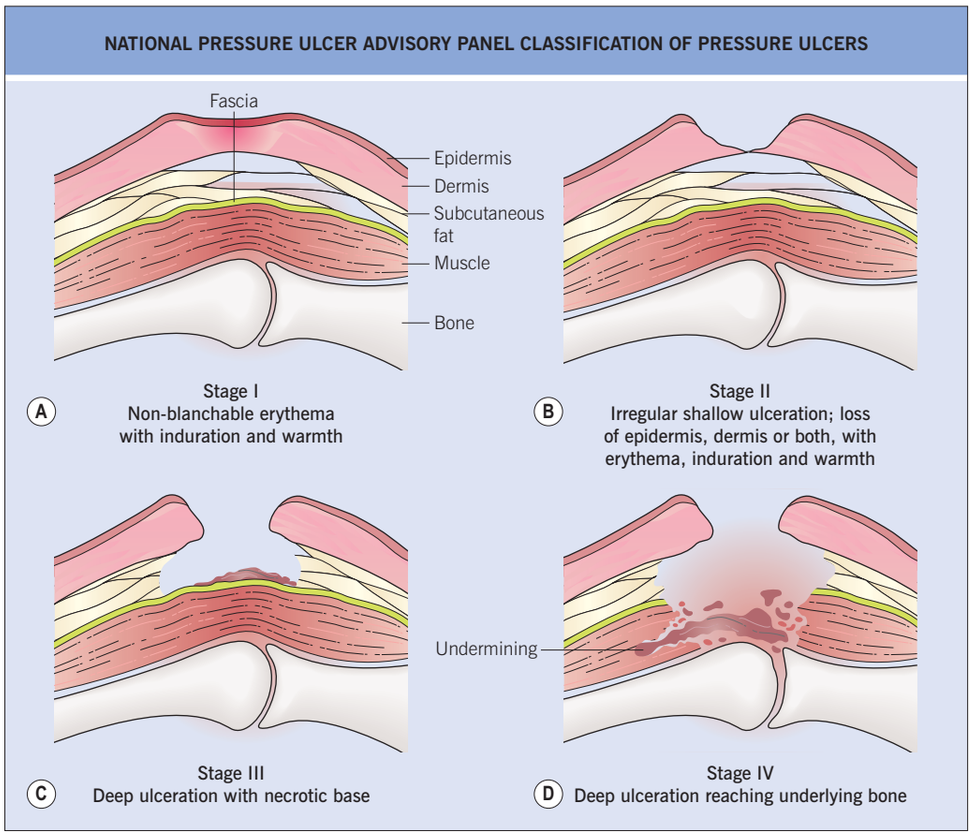

Fig. 105.18 National Pressure Ulcer Advisory Panel classification of pressure ulcers. A Stage I: non-blanchable erythema of intact skin. This lesion is the heralding sign of impending skin ulceration. For darker-skinned individuals, other signs may be indicators and include warmth, edema, discoloration of the skin, and induration. **B** Stage II: partial-thickness skin loss involving the epidermis, dermis or both. This superficial lesion presents as an abrasion, blister or shallow crater. **C** Stage III: full-thickness skin loss, in which subcutaneous tissue is damaged or necrotic and may extend down into, but not including, the underlying fascia. This deep lesion presents as a crater and sometimes involves adjacent tissue. **D** Stage IV: full-thickness skin loss and extensive tissue necrosis, destruction to muscle, bone, or supporting structures such as a tendon or joint capsule. Undermining or sinus tracts can be present.

Fig. 105.19 Additional causes of ulcers. A Systemic sclerosis with an ulcer of the fingertip. **B** Multiple ulcers secondary to sickle cell anemia.

position changes in addition to use of a variety of support surfaces to relieve pressure; the latter include air- or liquid-filled flotation devices, foam products, and pillows or foam wedges as positioning devices. Adequate nutrition, education, pain management and psychosocial support are also important interventions. Causes of immobility and systemic conditions that interfere with wound healing or decrease tissue perfusion must be addressed, including congestive heart failure, diabetes and/or spastic paresis.

The general principles of ulcer and chronic wound care discussed previously also apply to pressure ulcer management. Briefly, debridement may be accomplished via mechanical, enzymatic and/or autolytic means. Wounds should be cleansed as non-traumatically as possible, and normal saline for irrigation is preferred rather than cytotoxic agents such as hydrogen peroxide or povidone-iodine. As always, bacterial colonization and infection must be controlled. Dressings should provide a moist, but not macerated, environment and occlusive dressings are often utilized.

In general, stage I, II and III pressure ulcers are more likely to heal with local therapy, whereas stage IV ulcers, particularly those over the ischial tuberosities, often require surgical intervention. Adjuvant therapies such as laser, ultrasound, hyperbaric oxygen, and UV irradiation are investigational and to date cannot be considered as standard of care. The

EVALUATION FOR HYPERCOAGULABILITY			
Disorder	**%***	**Screening tests**	**Potential confounding conditions**
		INHERITED

Table 105.9 Evaluation for hypercoagulability. Shaded areas represent first-tier screening tests. The initial laboratory evaluation should also include a complete blood count with differential and platelet count, examination of a peripheral blood smear, ESR, activated partial thromboplastin time (PTT), and hepatic and renal function panels. Testing for antineutrophil cytoplasmic antibodies (ANCA) can be considered for patients with retiform purpura, as ANCA-positive vasculitides occasionally present with minimally inflammatory lesions. Additional inherited causes of hypercoagulability include polymorphisms in the genes encoding the endothelial protein C receptor, the protein Z-dependent protease inhibitor, and E-selectin. AD, autosomal dominant; CBS, cystathionine β-synthase; MTHFR, methylenetetrahydrofolate reductase; ND, not determined; OCP, oral contraceptive pills; RVVT, Russell viper-venom time.

application of growth factors, cultured keratinocyte grafts and skin substitutes is promising, but these are also still in the investigational stage.

OTHER CAUSES OF SKIN ULCERATION

Diffuse Dermal Angiomatosis

Diffuse dermal angiomatosis is a rare manifestation of vascular atherosclerosis. There is rapid development of one or several violaceous, ill-defined plaques, often with central ulceration. The lesions are typically painful and are usually located on the lower extremities, but they may appear elsewhere (e.g. breast, forearm). Histologically, a diffuse interstitial proliferation of CD31-positive endothelial cells is present within the papillary and reticular dermis, with focal formation of small vascular channels. Cytologic atypia and atypical mitoses are absent.

Interventions to correct the underlying PAD, such as femoral popliteal bypass surgery or femoral artery angioplasty, lead to rapid resolution. Less often, lesions resolve without therapy[59].

Hematologic Disorders

Anemia is a major and often unrecognized cause for delayed wound healing. It prevents proper tissue oxygenation. In addition, some forms of anemia are associated with a marked tendency for ulcer formation, such as the hemoglobinopathies (Fig. 105.19)[60]. Hematologic malignancies are also associated with ulcerative processes including pyoderma gangrenosum, vasculitis and cryoglobulinemia (type I). Clotting abnormalities can play a direct role in the formation of ulcers (e.g. antiphospholipid antibody syndrome)[57,58], as well as serving as a predisposing factor for more common types of cutaneous ulcerations such as venous ulcers[61,62]. Table 105.9 summarizes the recommended evaluation when hypercoagulability is suspected.

Additional Causes

A variety of physical, inflammatory, infectious, metabolic and inherited disorders are also associated with cutaneous ulceration and they are discussed elsewhere in the textbook (Table 105.10).

ADDITIONAL CAUSES OF CUTANEOUS ULCERATION		
Cause	**Favored anatomic site**	**Location of review**
	PHYSICAL	
Burns – thermal, electrical, chemical	Site of exposure	Chapters 15, 16, 88
Cold injury (e.g. frostbite)	Acral	Chapter 88
Radiation (e.g. orthovoltage)	Site of exposure	Chapter 139
	INFLAMMATORY	
Vasculitis (small and medium-sized vessels, primary and secondary)	Lower extremities	Chapter 24; Fig. 105.1
Pyoderma gangrenosum	Lower extremities, sites of trauma	Chapter 26
Behçet's disease	Lower extremities	Chapter 26
	VASCULAR	
Raynaud's phenomenon and systemic sclerosis	Digital, extensor surface of joints	Chapter 43
	INFECTIOUS	
Bacterial (e.g. *Streptococcus* spp., *Treponema* spp.), mycobacterial, viral (e.g. chronic HSV), fungal, parasitic	Exposed sites Pressure sites in the case of leprosy and tertiary syphilis*	Chapters 74–83; Fig. 105.1
	BITES AND STINGS	Chapter 85
	NEOPLASTIC	
BCC, SCC > metastases or other primary cutaneous carcinomas	For BCC and SCC, sites of chronic sun exposure For SCC, chronic ulcers, scars, sites of chronic inflammation or oncogenic HPV infection	Chapters 108, 120, 122
	METABOLIC	
Examples: calcinosis cutis, calciphylaxis, gout	Varies from juxta-articular (calcinosis cutis, gout) to "fatty" areas (calciphylaxis)	Chapters 48, 50
	GENODERMATOSES	
Examples: Adams–Oliver syndrome, prolidase deficiency, laryngo-oculo-cutaneous syndrome, familial tumoral calcinosis, Werner syndrome, Flynn–Aird syndrome, chilblain lupus (*TREX1* mutations), Klinefelter syndrome	Varies from scalp due to aplasia cutis congenita to lower extremity	Chapters 41, 50, 63, 64; Fig. 105.1
	DRUGS	
Examples: hydroxyurea, methotrexate, interferon (IFN), anticoagulants	Varies from lower extremities (hydroxyurea) to sites of injection (IFN) to "fatty" areas (warfarin)	Chapters 21, 23
	PHOTODAMAGE	
Erosive pustular dermatosis	Usually hairless scalp, but occasionally lower extremity	Chapter 87
*Due to neuropathy.		

Table 105.10 Additional causes of cutaneous ulceration. In addition to lower extremity ulcers, patients with prolidase deficiency develop diffuse telangiectasias, dermatitis, lymphedema and manifestations of systemic lupus erythematosus. BCC, basal cell carcinoma; HPV, human papillomavirus; HSV, herpes simplex virus; SCC, squamous cell carcinoma.

INTRODUCTION

This chapter will cover several disorders of the skin vasculature, including livedo reticularis, flushing and erythromelalgia, as well as vascular ectasias such as telangiectasias and venous lakes. Some of the diseases described here are important skin signs of systemic disease, while others are incidental findings. Additional disorders of blood vessels are covered elsewhere, e.g. infantile hemangiomas (Ch. 103), vascular malformations (Ch. 104), and vascular neoplasms and proliferations (Ch. 114).

LIVEDO RETICULARIS

Key features

- A common physiologic finding consisting of a mottled reticulated vascular pattern
- May occur secondarily due to an underlying disease, e.g. autoimmune connective tissue disease, antiphospholipid antibody syndrome
- The pattern varies depending on the underlying cause
- Appropriate investigations depend on the clinical context and associated findings

Introduction

Livedo reticularis (LR) is an extremely common finding and usually results from a physiologic vasospastic response to cold exposure. Among normal healthy individuals, the predisposition to LR will vary. It can also be a reflection of a number of underlying systemic diseases. LR resulting from any cause can vary to some degree with changes in external temperature. Physiologic LR will usually disappear with warming and reappear with cooling. Other variants may persist to varying degrees with warming.

History

The term "livedo reticularis" was first used by Hebra over a century ago to describe a violaceous skin discoloration caused by an abnormality of the cutaneous circulation. Renault (1883) and later Unna (1896) and Spalteholz (1927) suggested that a cone arrangement of the cutaneous microvasculature served as an explanation for the occurrence and pattern of LR[1].

Pathogenesis

LR results from alterations in blood flow through the cutaneous microvasculature system (Fig. 106.1). The latter consists of arterioles that are oriented perpendicularly to the skin surface. The vessels then divide into capillary beds that in turn drain into a subpapillary plexus. It has been proposed that this arrangement of vessels gives rise to a series of 1 to 3 cm cones with the ascending arteriole at the apex of each cone. At the edge of the cone, the venous plexus is more prominent and the arterial bed is diminished. Any process that either reduces blood flow to and through the skin or reduces drainage of blood out of the skin will result in the accumulation of deoxygenated blood in the venous plexus, leading to the clinical appearance of LR[1–3].

There are a number of causes of LR (Table 106.1) and the clinical pattern of LR can vary with the nature of the underlying cause. A complete fine network is indicative of alterations in blood flow caused by vasospasm or by factors within the blood that alter the viscosity and the flow through the vessels. Vessel wall pathology and intraluminal obstruction are more likely to result in a patchy distribution of LR, depending on the distribution of the underlying pathology.

Livedo racemosa (Fig. 106.2) refers to a distinct pattern of LR consisting of a large branching pattern that is usually situated on the trunk and proximal limbs. It is generally indicative of Sneddon syndrome, which is associated with multiple strokes that lead to progressive neurologic impairment[4]. Similar findings may also be seen in the antiphospholipid antibody syndrome (APS)[5].

Clinical Features

Congenital livedo reticularis

Cutis marmorata telangiectatica congenita

Cutis marmorata telangiectatica congenita (CMTC) is characterized by a persistent reticulated vascular pattern that is often limited to one extremity (see Ch. 104), but can be more widespread. Lesions are usually noted at birth, and, when the trunk is involved, there may be a sharp cut-off at the midline. Associated anomalies include other vascular malformations, limb asymmetry and, occasionally, neurologic or ocular abnormalities[6,7]. Cutaneous vascular changes can improve during the first few years of life, with 20% of patients showing complete resolution.

Acquired livedo reticularis

Livedo reticularis without systemic associations

Physiologic livedo reticularis/cutis marmorata

These terms are synonymous and refer to a normal pattern of LR that occurs in response to cold (Fig. 106.3A). It is often more marked in neonates, infants and young children[2,3]. In adults, it may be associated with a tendency towards acrocyanosis and chilblains.

Primary/idiopathic livedo reticularis

This refers to a persistent fine network of LR that is often widespread, particularly on the lower extremities. While there is some fluctuation with temperature, the LR will usually persist with warming (Fig. 106.3B). It is due to persistent vasospasm of arterioles and is not secondary to any underlying cause. However, primary LR is a diagnosis of exclusion and it is important to consider secondary causes (see Table 106.1). This is especially true when the LR is extensive[2,3].

Livedo reticularis secondary to systemic disease

Livedo reticularis due to vasospasm

Vasospasm is the most common cause of LR, including that seen in association with autoimmune connective tissue diseases (CTD; Fig.

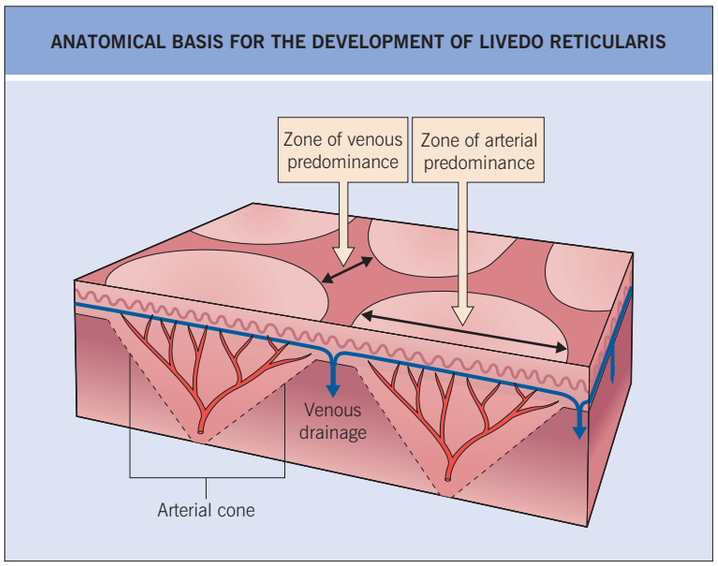

Fig. 106.1 Anatomical basis for the development of livedo reticularis.

106.3C). Reflecting a vasospastic tendency, it occurs more commonly in patients with Raynaud's phenomenon.

Livedo reticularis due to vessel wall pathology

Vasculitis is the most common cause of vessel wall pathology associated with LR. In general, LR will only occur if medium-sized arterioles at the dermal–subcutaneous border or in the deep dermis are affected. Cutaneous polyarteritis nodosa (PAN) always involves these vessels and is therefore invariably associated with LR[8]. Systemic PAN, cryoglobulinemic vasculitis and autoimmune CTD-related vasculitis may also affect these arterioles. The pattern of LR seen is usually a larger network that may be continuous or patchy depending on the distribution of vessel involvement.

Calciphylaxis consists of calcium deposition in the walls of blood vessels (see Ch. 50). It is most commonly seen in the setting of chronic renal failure complicated by hyperparathyroidism. Calciphylaxis may initially commence with LR that then becomes purpuric and subsequently necrotic (Fig. 106.4).

Sneddon syndrome is a rare syndrome consisting of widespread livedo racemosa (Fig. 106.5A) in conjunction with multiple cerebral ischemic episodes leading to progressive neurologic impairment[4,5] (see Ch. 23). It remains uncertain as to whether the vascular pattern results from vasculopathy, vasculitis or coagulopathy, but characteristic changes are seen within affected vessels (Fig. 106.5B; see below).

Livedo reticularis due to intraluminal pathology

LR can result either from factors (e.g. within the blood) that slow intravascular blood flow or from complete obstruction of the vessel lumen. Altered blood flow due to an increase in blood viscosity may be secondary to abnormal circulating proteins (e.g. cryoglobulins[9], cryofibrinogens, cold agglutinins, paraproteins) or an increase in normal blood components (e.g. polycythemia vera[10], thrombocytosis). A fine, evenly distributed pattern of LR is usually seen. Hypercoagulable states can also be associated with LR, including the APS[11] and protein C[12], protein S or antithrombin III deficiencies[13]. LR of the lower extremities is often seen in patients with neurologic conditions that lead to immobility of the lower limbs and stasis.

Complete obstruction of the vessel lumen can result from either emboli (e.g. cholesterol emboli derived from atheromata[14]) or thromboses within vessels (e.g. APS, heparin or warfarin necrosis). Intracellular crystal deposition is seen in hyperoxaluria and this also gives rise to luminal obstruction and LR[15]. A patchy, discontinuous-pattern LR is seen with intraluminal obstruction and it may subsequently become purpuric with areas of infarction and necrosis.

A combination of intraluminal obstruction and vessel wall pathology is seen in livedoid vasculopathy. This is an uncommon condition that is sometimes associated with LR. It consists of multiple, recurrent, painful ulcers on the lower extremities that heal slowly with residual atrophie blanche. Histologically, vessel lumina are filled with hyaline

CAUSES OF LIVEDO RETICULARIS
CONGENITAL LIVEDO RETICULARIS
• Cutis marmorata telangiectatica congenita
ACQUIRED LIVEDO RETICULARIS
Vasospasm
• Cutis marmorata/physiologic livedo reticularis • Primary (idiopathic) livedo reticularis • Autoimmune connective tissue diseases (e.g. SLE) • Raynaud's phenomenon/disease
Vessel wall pathology
• Vasculitis – Cutaneous polyarteritis nodosa – Systemic polyarteritis nodosa – Cryoglobulinemic vasculitis – Autoimmune connective tissue disease-associated vasculitis (e.g. rheumatoid arthritis, SLE, Sjögren's syndrome) • Calciphylaxis • Sneddon syndrome • Livedoid vasculopathy (also intraluminal obstruction)
Intraluminal pathology
• Increased normal blood components – Thrombocythemia – Polycythemia vera • Abnormal proteins – Cryoglobulinemia – Cryofibrinogenemia – Cold agglutinins – Paraproteinemia • Hypercoagulability (see Table 105.9) – Antiphospholipid syndrome – Protein S and C deficiencies – Antithrombin III deficiency – Factor V Leiden mutation – Homocystinuria, hyperhomocysteinemia – Disseminated intravascular coagulation • Thrombotic thrombocytopenic purpura • Embolic – Cholesterol emboli – Septic emboli – Atrial myxoma – Nitrogen (decompression sickness) – Carbon dioxide arteriography • Hyperoxaluria
Other
• Medications (e.g. amantadine, norepinephrine, interferon) • Infections (e.g. hepatitis C [vasculitis], *Mycoplasma* spp. [cold agglutinins], syphilis) • Neoplasms (e.g. pheochromocytoma) • Neurologic disorders (e.g. reflex sympathetic dystrophy, paralysis) • Moyamoya disease

Table 106.1 Causes of livedo reticularis. SLE, systemic lupus erythematosus.

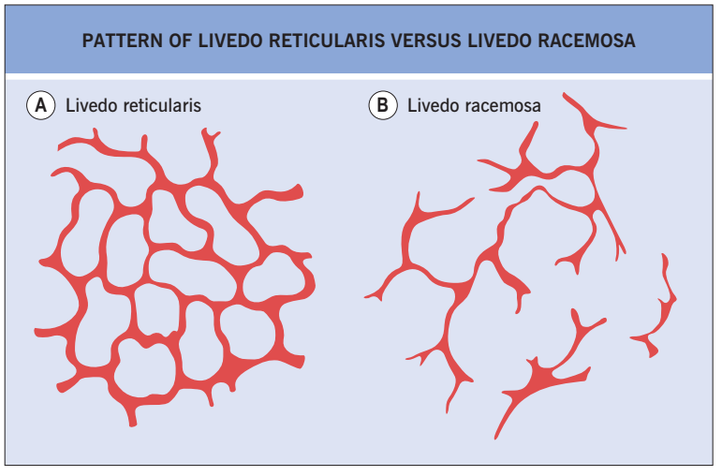

Fig. 106.2 Pattern of livedo reticularis (A) versus livedo racemosa (B).

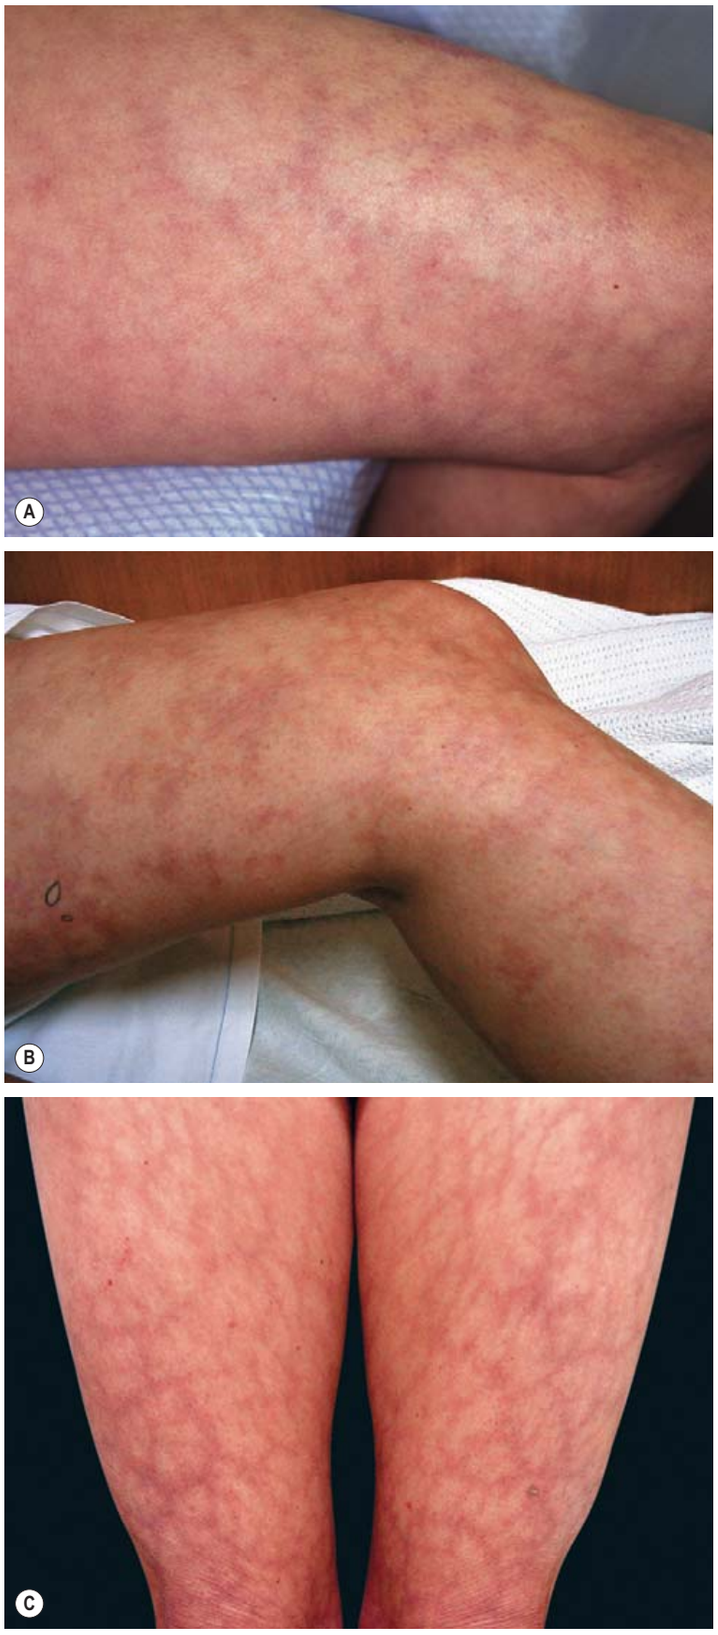

Fig. 106.3 Livedo reticularis. A An even, net-like pattern is seen on the thigh in physiologic livedo reticularis. **B** In primary (idiopathic) livedo reticularis, the pattern persists with warming. **C** Livedo reticularis in a patient with systemic lupus erythematosus. *C, Courtesy, Jeffrey Callen, MD.*

thrombi, and fibrinoid material is also present in the walls of these vessels and in the perivascular stroma[16].

Other causes of livedo reticularis

There are numerous causes of LR cited in the literature, and, in most, one of the above mechanisms can generally be implicated. The other causes include drugs such as amantadine[17] and norepinephrine (noradrenaline), as well as infections. The latter can lead to: the production of cryoglobulins, cold agglutinins or antiphospholipid antibodies; the induction of immune vasculitis; or septic vasculitis or septic emboli. Neoplasms may also be associated with LR via hypercoagulability or paraproteinemia as well as vasospasm (e.g. pheochromocytoma). Lastly, LR may be seen in several neurologic conditions (e.g. reflex sympathetic dystrophy) as a result of vasospasm or vasodilation (this is in addition to stasis arising from immobility).

Fig. 106.4 Reticulate purpura and cutaneous necrosis due to calciphylaxis. These patients also often have patchy areas of livedo reticularis. *Courtesy, Norbert Sepp, MD.*

Differential Diagnosis

Erythema ab igne is a heat-induced skin disease that begins as a reversible LR, then, with continued heat exposure, evolves into a fixed reticulated hyperpigmentation in the same pattern. When present on the anterior thighs, the possibility of direct contact with a laptop computer should be considered. Various cutaneous eruptions may have a reticulated pattern and might be confused with LR, including reticulated erythematous mucinosis (favors mid central trunk) and some viral exanthems (e.g. erythema infectiosum). Poikilodermatous conditions may also have a reticulate pattern (e.g. dermatomyositis, mycosis fungoides); however, the presence of epidermal changes and telangiectasias will help distinguish these conditions from LR.

Pathology

The histology of LR varies depending on the underlying cause. In idiopathic or physiologic forms resulting from vasospasm, no abnormality will be evident. With secondary causes of LR, a number of abnormalities may be seen, including vasculitis, calcium deposition within vessel walls (calciphylaxis), intravascular eosinophilic plugging (monoclonal cryoglobulinemia), intraluminal thromboses (hypercoagulable states), cholesterol clefting (cholesterol emboli) and crystal deposition (oxalosis). In Sneddon syndrome, vessel walls demonstrate endothelial inflammation and subendothelial myointimal hyperplasia with partial or complete occlusion of affected arterioles (see Fig. 106.5B). In order to locate the histopathologic changes, it is necessary to sample the affected arterioles. A moderately large elliptical biopsy from the non-discolored skin in the center of the net pattern is necessary and serial sectioning may be required.

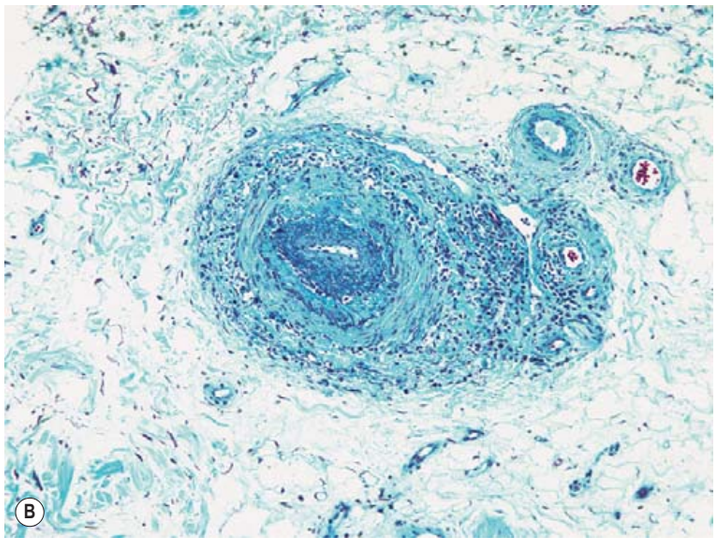

Fig. 106.5 Sneddon syndrome. A The characteristic irregular, broken, branching pattern of livedo racemosa is seen on the back and arms. **B** A connective tissue stain highlights a subcutaneous artery with subendothelial proliferation of smooth muscle, leading to almost complete luminal occlusion.

Treatment

LR is a clinical sign and does not require treatment per se. It is unresponsive to treatments such as vascular laser therapy or vasodilatory medications. Underlying causes require identification and appropriate treatment.

FLUSHING

Key features

- Flushing is a physiologic response, but in an exaggerated form causes clinical symptoms
- Common triggers (e.g. heat, emotion, exercise and some foods) will exacerbate flushing of any cause
- Causes of excessive flushing include exogenous medications, menopause, neurologic disorders and systemic diseases (e.g. carcinoid syndrome)

Introduction

Flushing is the term used to describe transient and episodic reddening of the skin, most commonly of the face, and less often the neck, ears and upper chest. It is the visible sign of a generalized increase in cutaneous blood flow. The greater visibility and capacitance of the superficial cutaneous vasculature of the face and adjacent areas accounts for the limited distribution[18]. In the evaluation of an affected patient, there are a number of causes to consider, including underlying systemic disorders (Table 106.2).

CAUSES OF FLUSHING
• Physiologic
• Exogenous agents (see Table 106.3)
• Menopause
• Neurologic disorders
– Anxiety
– Autonomic dysfunction
– Tumors (e.g. hypogonadal pituitary tumors)
– Migraine
– Frey's syndrome (auriculotemporal syndrome)
• Systemic diseases
– Carcinoid syndrome
– Mastocytosis
– Pheochromocytoma
– Medullary carcinoma of the thyroid
– Thyrotoxicosis
– POEMS syndrome
– Pancreatic tumors (e.g. VIPomas)
– Prostaglandin-secreting renal cell carcinoma

Table 106.2 Causes of flushing. POEMS, *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-protein (monoclonal gammopathy), *s*kin changes; VIP, vasoactive intestinal polypeptide.

EXOGENOUS AGENTS THAT CAN CAUSE FLUSHING
• Alcohol
• Drugs
– Angiotensin-converting enzyme (ACE) inhibitors
– Calcium channel blockers
– Calcitonin
– Chlorpropamide*
– Cholinergic agonists (e.g. pilocarpine)
– Cyclosporine
– Disulfiram*
– Fumaric acid esters
– Gold ("nitritoid reactions")
– Hydralazine
– Nicotinic acid
– Nitrates (e.g. glyceryl trinitrate)
– Opiates
– Prostaglandins
– Sildenafil, tadalafil, vardenafil
– Tamoxifen
• Foods
– Spoiled scombroid fish
• Foods additives
– Monosodium glutamate (MSG), sodium nitrite, sulfites
*With alcohol intake.

Table 106.3 Exogenous agents that can cause flushing.

Pathogenesis

An increase in cutaneous blood flow occurs with relaxation of vascular smooth muscle. This may occur via the autonomic nervous system[19] (usually leading to active vasodilation), endogenous vasoactive agents (such as histamine and serotonin) or exogenous agents (Table 106.3). Alcohol-induced flushing may result from the direct effect of alcohol as well as cutaneous vasodilation from elevated blood levels of acetaldehyde; the latter occurs in those with alcohol dehydrogenase deficiency (prevalent in Asians) and in the "disulfiram reaction" induced by some medications. Flushing from fermented alcoholic drinks may be caused by vasoactive substances such as tyramine[20]. Vasodilation mediated by the autonomic nervous system is often accompanied by eccrine

SIGNS AND SYMPTOMS OF THE CARCINOID SYNDROME
• Cutaneous – Flushing – Vascular rosacea-like changes – Pellagra – Edema and induration of the face > extremities • Bronchospasm • Diarrhea • Cardiac dysfunction (right-sided) • Hypotension • Peptic ulcers

Table 106.4 Signs and symptoms of the carcinoid syndrome.

sweating due to a direct effect on both sweat glands and blood vessels (wet flush)[21]. Direct vasodilation by vasoactive agents is usually not associated with increased sweating (dry flush).

Clinical Features

Blushing is a common emotionally triggered form of flushing associated with embarrassment and anxiety and is considered an exaggerated physiologic response. *Physiologic flushing* also occurs as part of normal thermoregulation in response to heat or exercise. *"Hot flashes"* refer to flushing associated with menopause, which lasts for a few minutes and is usually associated with sweating[22]. Flushing of any cause may be exacerbated or triggered by a number of common factors such as heat, hot drinks, exercise, anxiety, food additives (e.g. sulfites) and alcohol. Affected patients often report a feeling of heat and burning of the skin during episodes and find the color change a social hindrance. Some patients become anxious that they will flush at inopportune times and this further exacerbates the problem. Repeated flushing may lead to fixed erythema and telangiectasias.

Those carcinoid tumors that secrete vasoactive agents (e.g. serotonin) are associated with the carcinoid syndrome (Table 106.4). Flushing, often severe, is present in the majority of patients with carcinoid syndrome[23] and it may be precipitated by the common triggers of flushing. The classic "carcinoid flush", seen with approximately 10% of *midgut* tumors (small intestine, appendix, proximal colon), lasts minutes and consists of erythema and pallor as well as a cyanotic hue. Of note, liver metastases are required. Type III *gastric* carcinoid tumors are associated with a pruritic, patchy, bright red flush admixed with white patches and probably mediated by histamine. *Bronchial* tumors are associated with a prolonged (hours to days), intensely red to purple flush. Hindgut tumors (distal colon, rectum) are rarely, if ever, associated with the carcinoid syndrome and flushing, even with liver metastases.

An approach to the clinical assessment of flushing and relevant investigations are listed in Table 106.5.

Differential Diagnosis

Fixed erythema, and sometimes telangiectasia, of the face and neck are seen in fair-skinned individuals with photodamage as well as patients with seborrheic dermatitis, photosensitivity disorders or autoimmune CTD. Affected individuals may complain of the persistent redness and burning of the skin rather than actual flushing. Rosacea may be associated with pronounced flushing, but, usually, fixed erythema, papulopustules, edema and/or telangiectasia are present to some degree.

Treatment

The clinician should consider and eliminate any suspected exogenous cause (see Table 106.3). Underlying systemic causes, although rare, should be considered (see Table 106.2). Triggers of flushing are likely to be clinically relevant in most patients and should be avoided where possible. Non-selective β-blockers (e.g. nadolol, propranolol) or clonidine may be effective in idiopathic flushing. Anxiolytics may be helpful, particularly if emotional symptoms or anxiety are evident. Menopausal flushing may respond to hormone replacement therapy, clonidine or selective serotonin reuptake inhibitors (SSRIs). In troublesome cases unresponsive to these measures, transthoracic endoscopic sympathectomy may be considered.

CLINICAL APPROACH TO THE EVALUATION OF FLUSHING
1. Identify provocative factors • Direct questioning • Patient diary (food, medications, activities) 2. Check for associated symptoms • Sweating • Urticaria • Diarrhea • Bronchospasm 3. Investigation Not required in all cases Indicated if flushing: • Of sudden or recent onset • Severe • Associated with systemic symptoms Investigations to consider: • Complete blood count with differential and platelets • Thyroid function tests • Serum tryptase, histamine and/or chromogranin A levels; plasma free metanephrines • 24-hour urine collection for – Serotonin metabolites such as 5-hydroxyindole acetic acid (5-HIAA) – Fractionated metanephrines – Histamine metabolites such as methylimidazole acetic acid (MIAA) • CT/MRI scans; somatostatin receptor scintigraphy (using radiolabeled analogue of somatostatin) 4. Elimination • Exclude suspected drugs and food additives

Table 106.5 Clinical approach to the evaluation of flushing.

ERYTHROMELALGIA

Synonyms: ■ Erythermalgia ■ Erythralgia

Key features

- Characterized by painful burning and erythema of the distal extremities (lower > upper)
- Precipitated by heat and relieved by cooling
- May be idiopathic, familial or arise secondarily due to an underlying condition (e.g. thrombocythemia)

Introduction

Erythromelalgia (EM) is an episodic condition characterized by a burning sensation, erythema and increased skin temperature. It affects acral sites, particularly the lower extremities. Classically, there are three major forms, including:

- type 1 associated with thrombocythemia
- type 2 primary or idiopathic form
- type 3 associated with underlying causes other than thrombocythemia.

History

The term "erythromelalgia" was first coined by Mitchell in 1878. It was used to describe redness (erythos), involvement of extremities (melos), and pain (algos). The diagnostic criteria were established by Thompson[24] in 1979: (1) burning pain in the extremities; (2) pain aggravated by warming; (3) pain relieved by cooling; (4) erythema of affected skin; and (5) increased temperature of affected skin.

Epidemiology

In Norway, the estimated incidence of EM is 0.25/100 000 with a prevalence of 2/100 000[25]. While types 1 and 3 usually appear during adulthood, type 2 may appear in childhood and may be familial. The female : male incidence varies from 2 : 1 to almost 3 : 1. In one study,

the mean age of onset was 56 years (range, 5–91 years) with 4% having their symptoms begin in childhood.

Pathogenesis

While the discovery of *SCN9A* mutations in patients with primary familial EM has provided insights into this disorder, in general, the pathogenesis of EM is not entirely understood. Firstly, it may vary depending on the underlying cause and between different patient subgroups. In patients with thrombocythemia, the pathophysiology is likely to be related to both increased numbers of platelets as well as abnormalities in platelet function. Of note, one explanation for why type 1 EM does not respond to heparin or warfarin is that the microthrombi that form do not require thrombin activation[26].

In other types of EM, changes in vascular dynamics may be a factor. It has been proposed that hyperemia results from increased blood flow through arteriovenous shunts with a resultant reduction in blood flow within nutritional vessels, thus leading to cutaneous hypoxia[25,27]. Another proposed mechanism is vasoconstriction (as occurs in Raynaud's phenomenon), but in EM this is followed by a prolonged phase of hyperemia[28]. A temperature-triggered release of vasoactive substances and chemical pain mediators may also play a role.

In 2004, gain-of-function missense mutations in *SCN9A*, which encodes the voltage-gated sodium channel alpha subunit Na(v)1.7, were first described in patients with primary familial EM[29]. Na(v)1.7 produces threshold currents and is expressed primarily within dorsal root ganglia of sensory neurons (especially nociceptors) and sympathetic ganglion neurons. Mutations lead to lowered thresholds and "overexcitability" of pain-signaling sensory neurons[30] while at the same time producing "under-excitability" of sympathetic neurons. Certain mutations that produce a lesser effect on sodium channel activation and subsequent neuron excitability are associated with a later onset of clinical signs and symptoms[31].

Interestingly, another dominantly inherited pain syndrome, paroxysmal extreme pain disorder, has also been found to be due to gain-of-function mutations in *SCN9A*, whereas loss-of-function mutations in both copies of this gene lead to a recessively inherited insensitivity to pain[32]. Lastly, there exist additional families that are not linked to chromosome 2q31–32 (*SCN9A* locus), suggesting genetic heterogeneity[33].

Associations in secondary EM include myelodysplastic syndromes, diabetes mellitus, peripheral vascular disease, vasculitis, systemic lupus erythematosus and other autoimmune CTDs.

Clinical Features

EM is characterized by burning, erythema and warmth of acral sites (Fig. 106.6). Attacks most commonly occur late in the day, last through the night, and frequently impair sleep. The symptoms are usually episodic, though occasionally they may be continuous. The feet are involved in 90% of patients, whereas the hands are affected in 25%. Less commonly, there is also involvement of the head and neck. Type 1 EM may be unilateral and is more frequently associated with progression to ischemic necrosis. In contrast, the idiopathic type is more likely to be bilateral. The pain is precipitated by minor elevations in temperature (between 32°C and 36°C). Other exacerbating factors include exercise, standing, walking, fever, and limb dependency. Cooling and limb elevation generally reduce the symptoms.

The affected areas will often appear red and swollen. Other findings include acrocyanosis, livedo reticularis, facial flushing, cutaneous necrosis and ulceration. In up to 40% of patients, the limb may appear normal between attacks. Prolonged immersion in water can lead to extensive maceration and contribute to ulcer formation.

Prognosis is variable. In one long-term study, approximately 30% of patients fell into each of three categories: worsening, no change, and improvement. A further 10% had complete resolution of their symptoms[34].

Pathology

In type 1 EM, vessels may show intimal proliferation and occlusive thrombosis. In general, however, biopsies are not required and histology is nonspecific.

Fig. 106.6 Erythromelalgia. Red hot painful hand (**A**) and legs (**B**) in two patients with erythromelalgia.
A, Courtesy, Agustin Aloma, MD.

Differential Diagnosis

Complex regional pain syndrome (CRPS; reflex sympathetic dystrophy) may sometimes have features similar to EM (see Ch. 6). Abnormal warmth, erythema and burning pain may be seen in both, but CRPS does not have the characteristic close relationship to temperature and tends to be constant rather than episodic. Peripheral neuropathy may also cause tingling and burning and may require differentiation by nerve conduction studies. Calcium channel blockers, autonomic dysfunction, acrodynia and mushroom poisoning, as well as occlusive vascular diseases such as thromboangiitis obliterans, may be associated with EM-like symptoms. It is important to consider underlying causes of EM – in particular, chronic myeloproliferative disorders – as EM may be the first sign of the latter.

Treatment

Although numerous treatments have been reported as possible therapies for EM, no single therapy is consistently effective and many cases can prove difficult to control. The assistance of a specialist pain clinic can be valuable. Various methods of cooling the limbs during attacks, such as fans, wet dressings, and ice packs wrapped in towels, should be explored and have often already been tried by the time of presentation. Frequent periods of leg elevation can be helpful in reducing both discomfort and leg edema, whereas prolonged periods of leg dependency should be avoided. Simple oral analgesia is also important.

Aspirin can be effective for type 1 EM and treatment for the thrombocythemia with medications such as hydroxyurea should also be considered. Topical therapies include 10% capsaicin cream, 1%

amitriptyline/0.5% ketamine gel and lidocaine patches, while possible oral medications include SSRIs (e.g. venlafaxine), tricyclic antidepressants (e.g. amitriptyline), anticonvulsants (e.g. gabapentin, carbamazepine), calcium channel blockers (e.g. diltiazem), the prostaglandin analogue misoprostol, and, especially in primary inherited EM, sodium channel blocking agents (e.g. mexiletine, flecainide)[35,36]. With the report of functional expression studies (based upon a specific mutation) correlating with clinical responsiveness to carbamazepine, the possibility exists of utilizing such assays in the future to guide therapy.

Several intravenous therapies have been used for more severe cases, including nitroprusside, prostaglandin E1, and lidocaine (combined with oral mexiletine). More invasive approaches include epidural infusions of bupivacaine and opiates, lumbar sympathetic blocks and bilateral lumbar sympathectomies[37]. Oral medications should be tried initially, but more invasive procedures may be necessary for more severe cases.

TELANGIECTASIAS

Key features

- Telangiectasia is due to persistently dilated dermal vessels and not angiogenesis
- Can occur as a primary process, a result of cutaneous damage, or secondary to systemic disease

Introduction

Telangiectasia refers to abnormal, small, persistently dilated blood vessels visible in the skin (Fig. 106.7). Individual vessels can be discerned and range in color from light red to deep purple and will usually empty with pressure. They occur as a result of vascular dilation rather than new vessel growth and are thought to arise from capillaries, venules or small arteriovenous malformations. Telangiectasias are seen in a range of clinical settings (Table 106.6).

Treatment is often not required; however, options include cosmetic camouflage, light or fine wire diathermy, injection sclerotherapy, and laser or intense pulsed light therapies.

Spider Telangiectasia

Synonyms: ■ Nevus araneus ■ Spider nevus ■ Spider angioma

This localized lesion has a slightly raised central red papule (which often becomes more prominent with time) and multiple small, radiating, dilated vessels ("legs")[38] (Fig. 106.8). The lesion can vary from several millimeters to more than a centimeter in diameter. They are commonly located on the face, neck, upper trunk and hands.

Spider telangiectasias represent a form of telangiectasia with a central feeding arterial vessel. They are usually seen in otherwise healthy individuals, especially women and children. Lesions, often multiple, commonly occur with pregnancy, liver disease and oral contraceptive pills (OCPs). Spontaneous resolution may occur, especially after pregnancy. Treatment options include electrosurgery or vascular lasers.

Generalized Essential Telangiectasia

This is a primary disorder that typically affects adult women but may commence during childhood. Initially, the limbs are affected, especially the distal lower extremities, with sheets of asymptomatic blanchable telangiectasias[39,40]. The involvement is usually symmetric. Over time, there is often a progression proximally such that the telangiectasias become more widespread. Although the telangiectasias are persistent, patients do not have associated systemic illnesses.

The differential diagnosis includes cutaneous collagenous vasculopathy; typically it is not confused with telangiectasia macularis eruptiva perstans. While improvement with vascular lasers is possible, the progressive nature must be considered and the cost of treating extensive involvement may prove prohibitive.

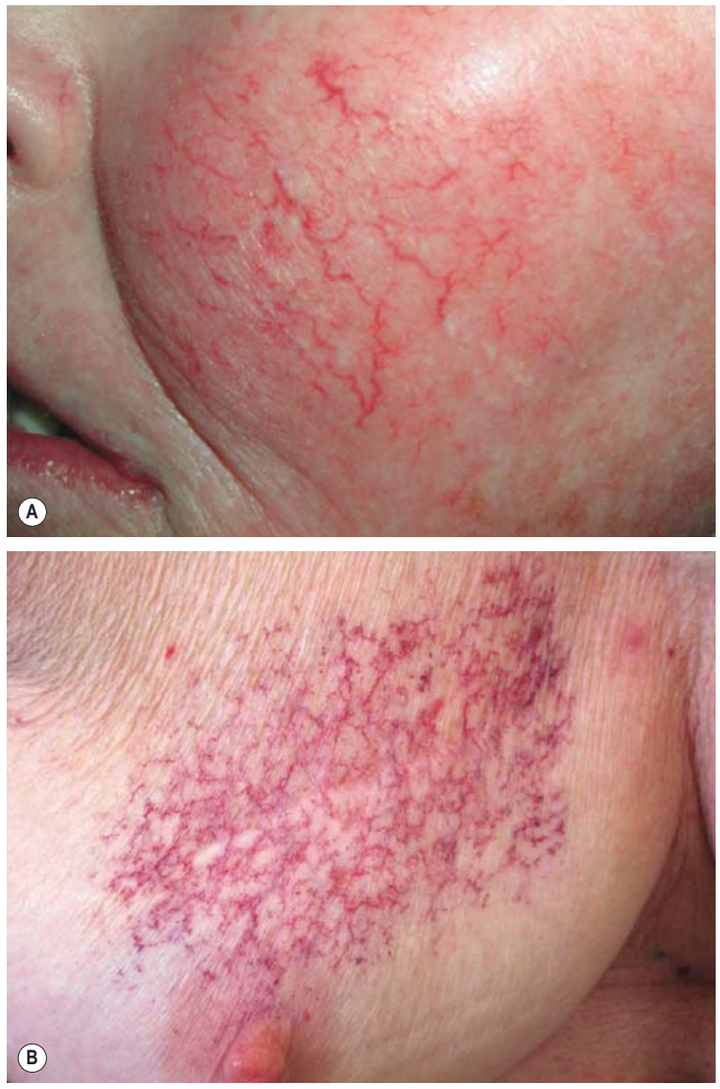

Fig. 106.7 Telangiectasias. A Sun-induced telangiectasias on the cheek. **B** Prominent telangiectasias on the breast following radiation therapy.

Cutaneous Collagenous Vasculopathy

Cutaneous collagenous vasculopathy (CCV) was first described in 2000[41]. Clinically, it can resemble generalized essential telangiectasia (GET). However, based upon the limited number of reported cases, there is not a female predominance, the telangiectasias may involve just the trunk and/or proximal extremities (Fig. 106.9A), and history of an "upward march" of lesions is lacking[42]. The etiology is unknown and there is no clear association with any underlying systemic illness or medication.

CCV does have unique histologic findings consisting of ectatic superficial blood vessels with hyalinized and laminated, concentric concretions surrounding the basement membrane of affected vessels. With special staining, this material is PAS-positive and diastase-resistant, and by immunohistochemistry, it reacts with antibodies against collagen type IV (Fig. 106.9B). Ultrastructurally, the deposits have been shown to consist of collagen with abnormal banding patterns (Luse bodies)[42].

This condition, like GET, is benign in nature. To date, responsiveness to vascular laser therapy has not been reported.

Unilateral Nevoid Telangiectasia

Telangiectasias in this condition are usually confined to the trigeminal or upper cervical dermatomes (Fig. 106.10) and may follow Blaschko's lines[43,44]. Congenital and acquired forms are recognized. It has been proposed that an increase in estrogen receptors on blood vessels in affected areas and/or an increase in estrogen levels is causative.

CAUSES OF TELANGIECTASIAS
PRIMARY
• Spider telangiectasias (also associated with estrogen excess) • Hereditary benign telangiectasia* • Costal fringe • Angioma serpiginosum • Unilateral nevoid telangiectasia • Generalized essential telangiectasia • Cutaneous collagenous vasculopathy
SECONDARY TO PHYSICAL CHANGES OR DAMAGE
• Photodamage • Post radiation therapy • Traumatic • Venous hypertension
SKIN DISEASE
• Telangiectatic rosacea • Incipient or involuted infantile hemangiomas
HORMONAL/METABOLIC
• Estrogen-related – Liver disease – Pregnancy – Exogenous estrogens • Corticosteroids
SYSTEMIC CONDITIONS
• Carcinoid syndrome • Mastocytosis (telangiectasia macularis eruptiva perstans) • Autoimmune connective tissue diseases – Lupus erythematosus – Dermatomyositis – CREST syndrome/systemic sclerosis • Mycosis fungoides, including poikilodermatous • B-cell lymphomas • Angiolupoid sarcoidosis • GVHD (in the context of poikiloderma) • HIV infection (anterior chest)
CONGENITAL MALFORMATIONS AND GENODERMATOSES
• Cutis marmorata telangiectatica congenita • Klippel–Trenaunay syndrome • Hereditary hemorrhagic telangiectasia • Ataxia–telangiectasia • Hypotrichosis–lymphedema–telangiectasia syndrome • Rombo syndrome • Bloom syndrome • Rothmund–Thomson syndrome • Poikiloderma with neutropenia • Dyskeratosis congenita • Xeroderma pigmentosum • Goltz syndrome (in Blaschko's lines) • GM1-gangliosidosis (also associated with angiokeratoma corporis diffusum) • Prolidase deficiency
*Childhood onset of multiple punctate, linear or arborizing telangiectasias favoring sun-exposed areas of the face and upper extremities; the vermilion lips and palate are occasionally affected, but there is no visceral involvement.

Table 106.6 Causes of telangiectasias. GVHD, graft-versus-host disease.

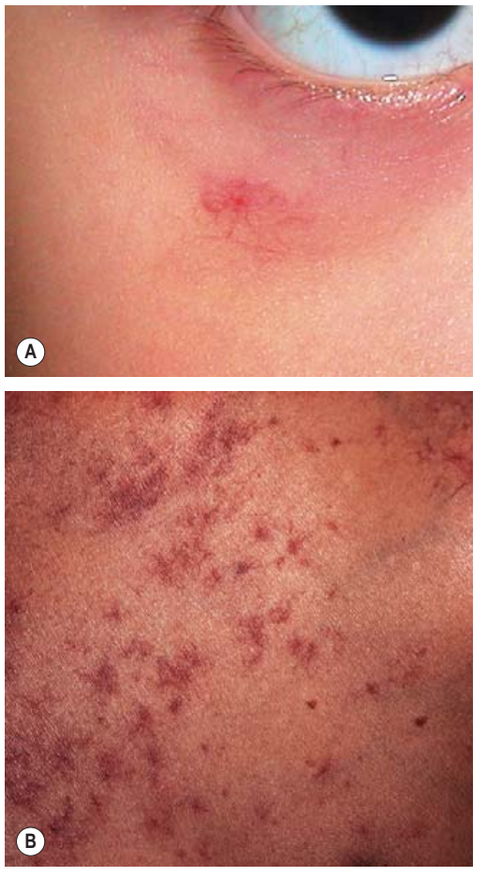

Fig. 106.8 Spider telangiectasias. **A** Central arteriole with radiating telangiectatic "legs" on the cheek of a young child. **B** Multiple lesions in a jaundiced patient with liver disease. *A, Courtesy, Phillip Bekhor, MD. B, Courtesy, Ronald P Rapini, MD.*

Situations of relative estrogen excess such as pregnancy, puberty and liver disease are associated with the acquired form.

Angioma Serpiginosum

Angioma serpiginosum is a rare vascular disorder with a characteristic appearance[45,46]. It is usually sporadic, but familial cases have been reported. Typically, the condition affects female patients and commences during the first two decades of life. Multiple, small, asymptomatic, non-palpable, deep-red to purple puncta occur in small clusters and sheets (Fig. 106.11). The arrangement and extension of the lesions may produce a serpiginous pattern. The extremities are most commonly affected, initially with a unilateral distribution; over months to years, the involvement may become more widespread. The palms, soles and mucous membranes are not involved.

The puncta represent dilated non-inflamed capillaries within the dermal papillae. These can be seen with dermoscopy. Incomplete blanching occurs with pressure, but lesions are not purpuric. The differential diagnosis includes pigmented purpuric eruptions, particularly the Majocchi's variant (purpura annularis telangiectoides), which is more likely to be bilateral and on biopsy has perivascular lymphocytes and extravasated erythrocytes. Treatment is not necessary, but lesions can be improved with the pulsed dye laser.

Hereditary Hemorrhagic Telangiectasia

Synonym: ▪ Osler–Weber–Rendu disease

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant condition in which there are multiple mucocutaneous and gastrointestinal telangiectasias (which are actually arteriovenous malformations) as well as variable visceral involvement (lung, liver and CNS). The diagnosis may first be suspected in children who have repeated episodes of epistaxis; however, the initial presentation can occur during the second or third decades of life. The characteristic mat-like and papular telangiectasias on the mucous membranes are first seen during adolescence[47]. Cutaneous lesions usually appear after puberty or even later in life.

Lesions, which increase in size and number as the patient ages, are most commonly seen on the face, tongue, lips, nasal mucosa, hands and fingertips. They frequently occur throughout the gastrointestinal tract and may result in obvious hemorrhage or iron deficiency anemia. Hemorrhage from vascular lesions in the lung, liver, CNS, spleen and urinary tract may occur, as well as paradoxical emboli due to pulmonary arteriovenous malformations.

HHT can result from mutations in several genes, most commonly *HHT1* and *HHT2* which encode endoglin and ALK-1, respectively (see

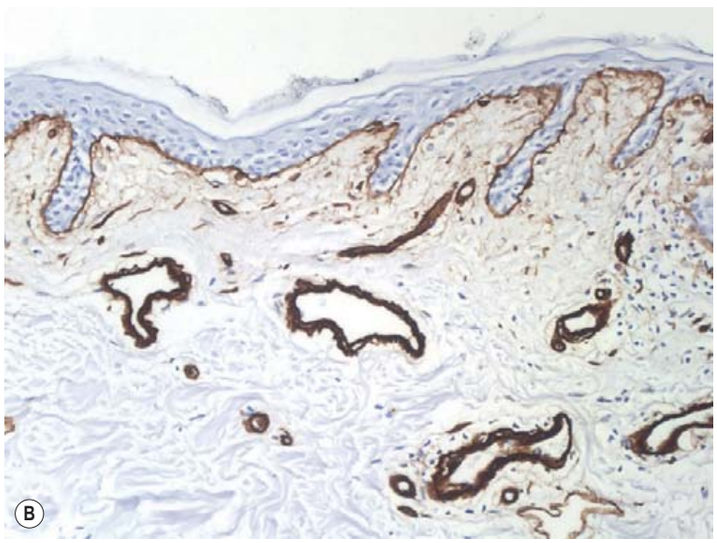

Fig. 106.9 Cutaneous collagenous vasculopathy – clinical and histologic features. A Multiple blanchable telangiectasias of the abdomen; the patient also had involvement of the thighs, back and hands. **B** Immunohistochemical staining with antibodies to collagen type IV demonstrating focal splitting and reduplication of the basement membrane zone surrounding dilated blood vessels. *Courtesy, Artur Zembowicz, MD. Fig. 106.11 Angioma serpiginosum. Grouped dark red puncta on the arm in a serpiginous pattern.

Table 104.2). Both of these glycoproteins are TGF-β receptors expressed by vascular endothelium, and they are thought to play a role in angiogenesis and vessel wall integrity.

Treatment of the mucocutaneous vascular lesions may not be required. Destructive treatments such as diathermy, cautery or laser may be used to treat individual lesions. Surgical management or embolization may be required for uncontrolled hemorrhage from mucosal lesions or complications arising from visceral lesions. Initial and longitudinal evaluation of patients with HHT is outlined in Table 104.5.

Ataxia–Telangiectasia

Synonym: ■ Louis-Bar syndrome

Ataxia–telangiectasia was first described by Louis-Bar in 1941. It is an autosomal recessive disorder characterized by cerebellar ataxia, chromosomal instability (frequent translocations between chromosomes 7 and 14), growth retardation, oculocutaneous telangiectasias, pulmonary infections (including bronchiectasis), immunodeficiency and the development of lymphomas[48].

It is covered in more detail in Chapter 60. Linear telangiectasias first appear on the bulbar conjunctivae between 4 and 6 years of age. Cutaneous telangiectasias favor the head and neck region, and they are most common on the malar prominences, ears and eyelids in addition to the popliteal and antecubital fossae. Patients may have poikiloderma (hypopigmentation, hyperpigmentation, atrophy, telangiectasia), premature hair graying, and decreased subcutaneous fat.

VENOUS LAKES

Venous lakes are small, dark-blue, slightly elevated, soft lesions that are predominantly localized on the lips (Fig. 106.12), ears or face of older adults. They can usually be emptied of most of their blood content by persistent pressure[49,50]. Pathologically, venous lakes represent telangiectasias in the dermis. Either one great, dilated venule or several communicating dilated spaces that contain erythrocytes are seen. Thrombosis is sometimes present. Optional treatment with electrosurgery or a hemoglobin-targeting laser is usually effective.

NEVUS ANEMICUS

Nevus anemicus is a congenital pale area of skin, most commonly found on the upper to mid trunk. These patches have an irregular border and an average diameter of 5–10 cm (Fig. 106.13). Within the body of the lesion, local blood vessels are very sensitive to endogenous catecholamines and are permanently vasoconstricted[51]. The border and extent of the lesion become imperceptible with pressure (or diascopy)

Fig. 106.12 Venous lake on the lip. The lesion is soft and, with compression, can be emptied of most of its blood content. *Courtesy, Ronald P Rapini, MD.*

Fig. 106.13 Nevus anemicus. Pale area of vasoconstriction with irregular borders on the back.

sufficient to cause blanching of surrounding skin. Conversely, application of heat or an ice cube will often accentuate the lesion; the border becomes hyperemic during warming, while the lesion stays pale. The pale appearance of the lesion (rather than an absence of pigmentation) and the results of the above clinical maneuvers allow nevus anemicus to be differentiated from vitiligo and nevus depigmentosus, respectively. Interestingly, islands of sparing may be present within the lesion, and skin transplanted within the nevus anemicus retains the characteristics of the donor site (donor dominance). No histologic abnormalities have been reported. No treatment is required or effective.

Fig. 106.14 Angiospastic macules (Bier spots). Multiple pale spots with an erythematous background on the forearm.

ANGIOSPASTIC MACULES (BIER SPOTS)

These were first described by Bier in 1898 and represent a pattern of vascular mottling consisting of white macular areas surrounded by a red to occasionally blue cyanotic background. Bier spots most commonly occur on the arms and legs of young adults (Fig. 106.14), but may also occur on the trunk. They are more noticeable in patients with lightly pigmented skin. Angiospastic macules may be induced by venous congestion and can be elicited by placing a limb in a dependent position or by placing a tourniquet around a limb. The spots disappear with limb elevation or release of the tourniquet. As with nevus anemicus, the border of the lesions becomes imperceptible with pressure (diascopy). The vascular pattern is thought to result from a benign physiological response consisting of vasoconstriction. Bier spots have also been associated with pregnancy and cryoglobulinemia.

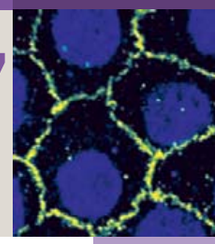
Principles of Tumor Biology and Pathogenesis of BCCs and SCCs

107



Edel A O'Toole, Fredrik Pontén, Joakim Lundeberg and Anna Asplund

Chapter Contents

Structure and function of p53 ..... *1764*
Structure and function of Patched *1765*
Pathogenesis of BCC *1768*
Pathogenesis of SCC *1769*

Key features

- Oncogenes act in a dominant fashion and gain-of-function results in increased proliferation
- Tumor suppressor genes act in a recessive fashion and loss of normal function results in uncontrolled growth
- The *p53* gene, the single most frequently mutated gene in human cancer, controls signaling pathways involved in cell division and apoptosis
- Mutations in either apoptosis- or senescence-regulating genes are considered "driver" mutations and are uniformly present in cancers.
- The *PTCH* gene controls proliferation and differentiation, and disruption of normal function is required for the development of basal cell carcinoma (BCC)
- BCCs, the most frequent cancer in humans, grow in skin that contains hair follicles, arise without precursors, and show no sign of progression
- BCCs are stroma-dependent and are locally invasive without producing metastasis (with rare exceptions)
- Squamous cell carcinomas (SCCs) arise in chronically sun-exposed skin and originate from epidermal keratinocytes
- SCC develops through a series of progressive stages, including actinic keratosis, invasive cancer and eventual metastasis

INTRODUCTION

No definition of cancer is entirely satisfactory from a cell biology point of view, despite the fact that cancer is essentially a cellular disease, characterized by a transformed cell population with autonomous cell growth and invasive behavior. Microscopic evaluation of a tissue section taken from an excised skin tumor remains the gold standard for determining the diagnosis of skin cancer. Analysis of genomic DNA, transcribed genes and expressed proteins adds important information to the histologic features detected by light microscopy. In the future, diagnosis and prognostic information and choice of treatment will most likely be based upon a synoptic evaluation of morphology in conjunction with an analysis of nucleic acids and proteins. Even today, evolving knowledge based on the human genome sequence and biochemical pathways, including signaling within and between cells, enables us to dissect some of the mechanisms that underlie different stages in tumor formation as well as the variation of phenotypes which define the different types of cancer.

Carcinogenesis

Malignant transformation represents the transition to a malignant phenotype and is based on the progressive accumulation of genetic alterations. Although not formally proven, malignant transformation takes place in one cell from which a subsequently developed tumor originates (the clonality of cancer dogma). Carcinogenesis is the process by which cancer is generated and is generally accepted to include multiple events which ultimately lead to growth of a malignant tumor[1]. This multistep process includes several rate-limiting steps, representing the addition of mutations and epigenetic events, which eventually lead to the formation of cancer (after various stages of precancerous proliferation).

The most common forms of cancer arise in somatic cells and are predominantly of epithelial origin (skin, prostate, breast, colon and lung), followed by cancers originating from hematopoietic lineage (leukemia and lymphoma) and mesenchymal cells (sarcomas). The stepwise changes involve an accumulation of errors (mutations) in vital regulatory pathways that control cell division, apoptosis, senescence, cell–cell and cell–matrix interactions, and cell death. Each of these changes provides a selective Darwinian growth advantage compared to surrounding cells, resulting in a net growth of the tumor cell population. A certain degree of genomic instability is probably required to attain a sufficient number of mutations. The spontaneous mutation rate is not high enough to explain the speed with which a cancer develops and thus tumor cells display a "mutator phenotype" with a higher mutation rate compared to neighboring normal cells. Decreased efficiency in DNA repair systems is one important mechanism leading to a "mutator phenotype"[2].

Knowledge of the events involved in carcinogenesis has been obtained from experimental cell culture and animal studies, as well as from clinicopathologic studies in humans. Information regarding cellular, molecular and genetic changes that represent tumor initiation and progression can be linked to histopathologic correlations. Primary genetic alterations leading to initiation of cancer can be identified and validated in experimental systems, but in clinical investigations this is not feasible. Progression is ascribed to the events that occur after malignant transformation and can in part be defined by histology. This multistep model includes defined stages of tumor development accompanied by features that include multiple genetic and epigenetic events involving different signalling pathways. Specific changes in DNA, signifying different steps in cancer development, were first described for colorectal cancer[3]. This model illustrates distinct genetic hits acquired during the passage from normal epithelium to metastatic cancer and provides support for the multi-hit carcinogenesis hypothesis.

The hallmarks of cancer have also been described from a functional perspective and consist of a number of molecular, biochemical and cellular traits that are shared by most human cancers. Six traits have been proposed and include self-sufficiency with regard to growth signals, insensitivity to antigrowth signals, evasion of apoptosis, limitless replicative potential, sustained angiogenesis, and tissue invasion/metastasis[4]. Self-sufficiency with regard to growth signals can be achieved by activation of oncogenes. Loss of function of tumor suppressor genes results in uncontrolled proliferation due to insensitivity to antigrowth signals. Evasion of apoptosis can be accomplished via inactivation of the *p53* tumor suppressor gene and production of survival factors. Constitutively active telomerase can render limitless replicative potential. The production of vascular endothelial growth factors results in sustained angiogenesis, and inactivation of cellular adhesion molecules, e.g. E-cadherin, facilitates the cell migration necessary for tissue invasion and metastasis. The order in which these capabilities are acquired is not static and varies between different forms of cancer.

Several traits can be achieved through a single genetic change, whereas a certain trait may require several genetic alterations. For example, inactivation of the *p53* tumor suppressor gene can result in insensitivity to antigrowth signals, resistance to apoptosis and increased

angiogenesis. In addition, impairment of cell cycle control and apoptotic pathways contributes to the "mutator phenotype". In individuals predisposed to cancer at an early age, certain traits result from alterations in the germline and are thus carried in every cell. Xeroderma pigmentosum ("mutator phenotype"; mutations in nuclear excision repair genes; Ch. 86), familial melanoma (defect in cell cycle control; *CDKN2A [INK4A]* mutations), Li–Fraumeni syndrome (defect in cell cycle control/apoptosis; *p53* mutations) and Gorlin syndrome (defect in control of proliferation/differentiation; *PTCH* gene mutations) are examples of how mutations within single genes in the germline promote development of cancer.

The Cell Cycle

Normal cell growth and cell mass are influenced by several internal factors, including signals which regulate proliferation, differentiation and cell death. These factors are in part triggered by blood supply and the external environment, including soluble molecules as well as matrix–cell and cell–cell contacts. Proliferation involves DNA replication and mitosis in a series of events termed the cell cycle (Fig. 107.1). Three primary checkpoints (G1, G2 and M), which act to ensure successful cell division, have been identified in the cell cycle[5]. Regulation of these G1, G2 and M transitions involves three major protein families: cyclins, cyclin-dependent kinases (CDKs) and cyclin-dependent kinase inhibitors (CKIs). CDKs regulate the phosphorylation of key proteins involved in cell cycle progression, e.g. the retinoblastoma (Rb) protein. The concentration and balance of cyclins versus CKIs in turn regulate CDK activity. CDKs are activated by mitogenic growth factors and are removed by ubiquitin-mediated proteolysis in a cyclic manner correlating to the different phases of the cell cycle.

The G1 transition is a critical one and is regulated by a complex interplay of macromolecules influenced by growth factors, hormones and cell contacts. The key factor is the degree of phosphorylation of Rb. If, at the G1 checkpoint, Rb is underphosphorylated, then cell proliferation is blocked and the cell is arrested in G1. The repression can be reversed by CDK-mediated phosphorylation. This phosphorylation/dephosphorylation cycle can thus reversibly regulate cell cycle progression and rate of proliferation (see Fig 107.1).

There are two major families of CKIs, and both are involved in the G1 checkpoint. The family of inhibitors of CDK4, also referred to as INK4, consists of p15, p16, p18 and p19; these inhibitors specifically bind to CDK4 and CDK6. The other family of CKIs is less specific with respect to the type of CDK they bind and includes the general CDK–cyclin complex inhibitors p21, p27 and p57. Expression of these CKIs is in part tissue-specific.

The *CDKN2A (INK4A)* gene locus, which is involved in familial melanoma (see Ch. 113), has an extraordinary feature; it encodes two different mRNAs by shifting the reading frame (hence the term ARF or alternative reading frame) and these two mRNAs are independently regulated. As a result, the two protein products (p16 and $p14^{ARF}$) have different amino acid sequences and different functions. p16 is a CKI that blocks Rb phosphorylation, whereas $p14^{ARF}$ binds MDM2, resulting in an increase in p53 through interference with the p53–MDM2 feedback loop. Thus, both p16 activation and $p14^{ARF}$ activation lead to cell cycle arrest through different pathways and their dysfunction can lead to cell proliferation. In carcinomas, cyclin and CKI alterations are common, whereas activating mutations in CDKs are rare, e.g. only a few families with familial melanoma have been described with mutations in *CDK4*. p53 and Rb alterations are also common events in human cancer.

Cancer Genes – Oncogenes and Tumor Suppressor Genes

With advances in technology, it is now possible to catalogue genome-wide changes in DNA, at unparalleled resolution. In breast and colon cancer, sequencing the exomes (coding exons) of tumors has revealed an average of 50 to 100 somatic mutations in "cancer genes" in each tumor[6]. Are these all significant? The answer is, probably, no. Somatic alterations in tumor DNA are called either *driver mutations* that confer a selective growth advantage to the cancer cells or *passenger mutations* that have no effect on tumorigenesis. Somatic copy number alterations can also occur[7,8]. Increase of gene function (oncogenes) as well as loss of gene function (tumor suppressor genes) will affect cell proliferation and can lead to uncontrolled growth. These two categories of genes,

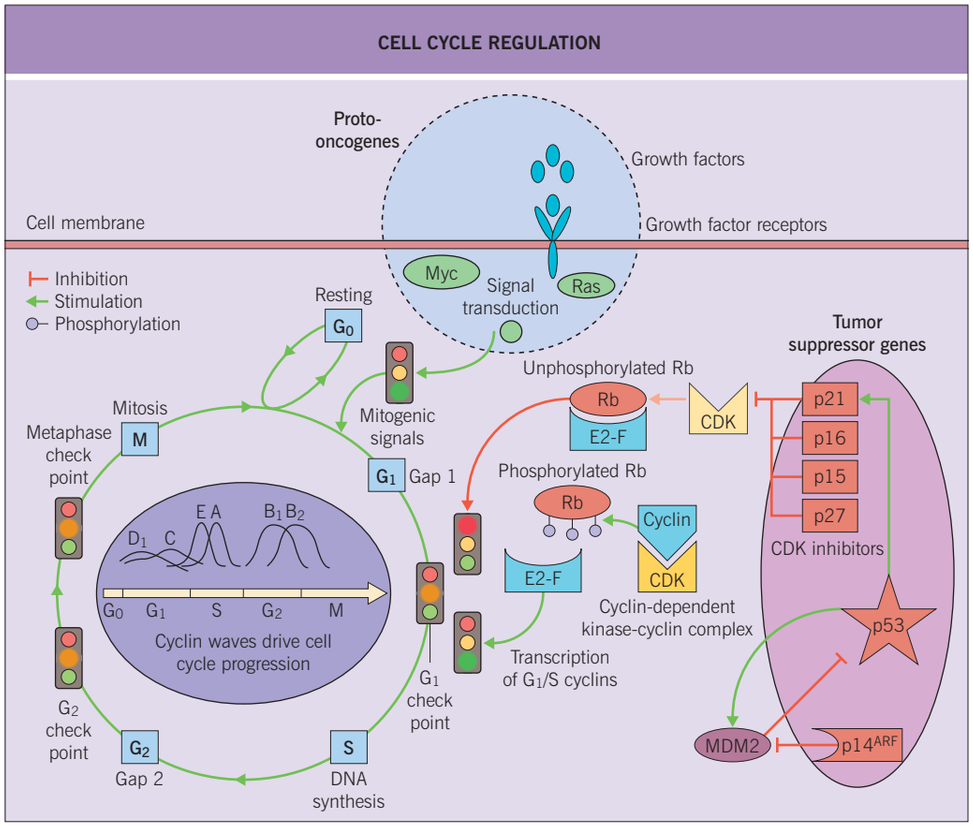


Fig. 107.1 The cell cycle. In normally dividing cells, the first gap (G1 phase, 8–30 h) prepares the cell for DNA synthesis (S phase, 8 h). The G1 gap includes a connection to a resting state (G0 phase) representing quiescent cells capable of entering into G1 after appropriate stimuli. Certain cells that exit the cell cycle and enter G0 phase are destined for terminal differentiation or senescence, irreversibly locked out of the cell cycle. After S phase, reorganization of the chromatin occurs in a second gap (G2 phase, 3 h) prior to mitosis (M, 1 h). Differentiation, which has a reciprocal correlation to proliferation, takes place in G0 after exit from G1. Cyclin waves, an underlying mechanism for cell cycle progression, are illustrated inside the cell cycle. Proto-oncogenes acting as driving forces on the cell cycle (green traffic lights), are depicted in green. Tumor suppressor genes, regulating the G1 checkpoint (red traffic light) of the cell cycle, are depicted in red. Yellow traffic light symbols represent checkpoints in the cell cycle. CDK, cyclin-dependent kinase; E2-F, a transcription factor that controls transcription of cyclins; Rb, retinoblastoma protein.

EXAMPLES OF ONCOGENES AND TUMOR SUPPRESSOR GENES IMPLICATED IN CARCINOGENESIS				
Gene			Protein product	
Name	Function	Chromosome	Location	Function
sis	Oncogene	22	Extracellular	Platelet-derived growth factor (PDGF)
ras	Oncogene	11	Membrane	GTPase
src	Oncogene	20	Cytoplasm/ membrane	Tyrosine kinase
raf	Oncogene	3	Cytoplasm/ membrane	Serine/threonine kinase
myc	Oncogene	8	Nucleus	Transcription factor
fos	Oncogene	14	Nucleus	Transcription factor
Rb	Suppressor gene	13	Nucleus	Cell cycle regulator
p53	Suppressor gene	17	Nucleus	DNA repair, apoptosis
bcl-2	Suppressor gene	18	Mitochondria	Apoptosis

Table 107.1 Examples of oncogenes and tumor suppressor genes implicated in carcinogenesis. A non-mutated oncogene is often referred to as a "proto-oncogene" and it encodes a protein that is part of the necessary network for cellular regulation.

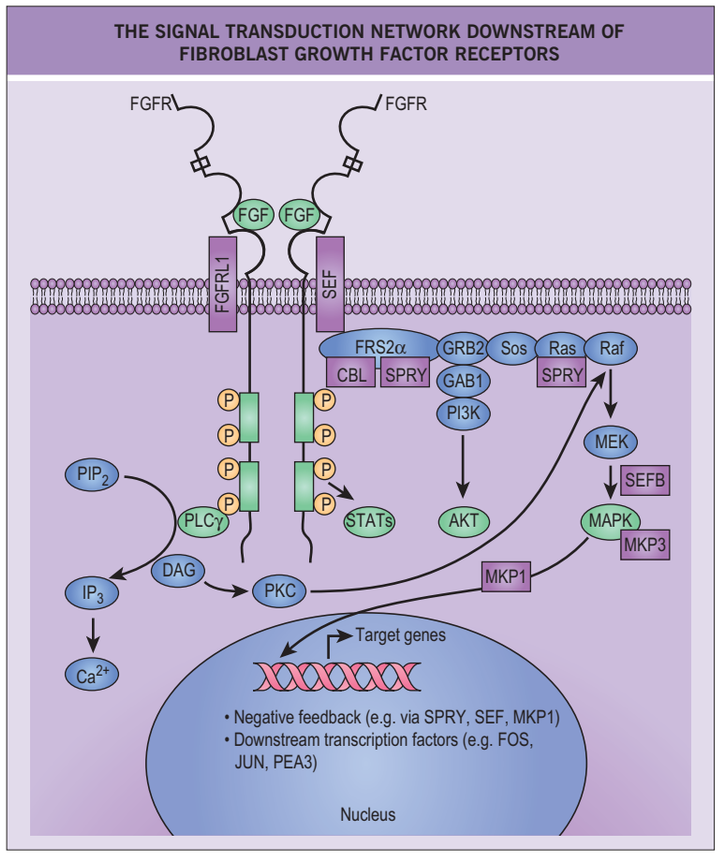

Fig. 107.2 The signal transduction network downstream of fibroblast growth factor (FGF) receptors (FGFRs), along with negative regulators. Following ligand binding and receptor dimerization, the kinase domains transphosphorylate each other, leading to the docking of adaptor proteins and the activation of four key downstream pathways: (1) RAS–RAF–MAPK; (2) PI3K–AKT; (3) signal transducer and activator of transcription (STAT); and (4) phospholipase Cγ (PLCγ) (all shown in green). Negative regulators are shown in purple, e.g. Sprouty (SPRY) and similar expression to FGF (SEF). DAG, diacylglycerol; FGFRL1, fibroblast growth factor receptor-like 1; FRS2α, FGFR substrate 2α; GAB1, GRB2-associated binding protein 1; GRB2, growth factor receptor-bound 2; IP_3, inositol triphosphate; MAPK, mitogen-activated protein kinase; MEK, MAPK kinase; MKP1/MKP3, MAPK phosphatase 1/3; P, phosphorylation; PI3K, phosphatidylinositol-3-kinase; PIP_2, phosphatidylinositol-4, 5-biphosphate; PKC, protein kinase C; Sos, son of sevenless. The abbreviations AKT, CBL and Raf are related to viral-associated nomenclature. *Adapted with permission from MacMillan Publishers Ltd: Turner N, Grose R. Nat Rev Cancer. Fibroblast growth factor signalling: from development to cancer. 2010;10:116–29.*

and their encoded proteins, represent the functional features that drive carcinogenesis at a molecular level. Oncogenes, described by a three-letter code (*ras, myc, src, fos*), are genes that gain oncogenic or transforming potential as a result of genetic changes[9]. More than 400 "cancer genes" have been identified that participate in diverse regulatory pathways that control cell fate (see examples in Table 107.1).

Extracellular signals such as growth factors and extracellular matrix components determine if cells move from a quiescent state into a proliferative state. These signals are transmitted into the cell through transmembrane structures that have distinct features (e.g. receptors) and the signals are then propagated into the nucleus by a multitude of interacting pathways (i.e. signal transduction). Increased production of growth factors and growth factor receptors is frequently observed in cancer cells and this results in an autocrine loop leading to enhanced cell proliferation[10]. Upon ligand binding, growth receptors mediate signals via tyrosine kinases or serine/threonine kinases on the cytosolic side of the membrane. As an example, the fibroblast growth factor signaling pathway is depicted in Figure 107.2. Cancer cells can also alter receptor activity via "activating" mutations in the genes that encode the receptors, thus generating constitutively active, ligand-independent receptor molecules (e.g. KIT in acral melanoma).

The *ras* proto-oncogene, which is mutated in approximately 40% of human cancers, plays a key role in signal transduction pathways between the cell membrane and the nucleus, communicating signals to a number of effector pathways. The ras family members are *H-ras, K-ras* and *N-ras*, and the 21 kDa Ras protein is a GTP-binding protein with latent GTPase activity, active when bound to GTP and inactive when GTP is hydrolyzed to GDP. The *ras* oncogene acts as a multifunctional modulator capable of redirecting input signals from growth receptors to alternative pathways. The end result of the signal cascade following Ras activation is increased transcription due to an alteration in the quantity or function of nuclear transcription factors.

For oncogenes, a change in one of the two inherited alleles leads to a gain-of-function that is dominant (over that of the unaffected allele). In contrast, tumor suppressor genes act in a recessive manner, i.e. a mutation in one allele has no effect (see Fig. 107.3). The biologic consequence of a recessive mutation becomes apparent when the second, normal (wild-type) allele is lost. Loss of this allele is termed loss of heterozygosity (LOH) and represents alteration from a heterozygous to a homozygous state for a gene (Fig. 107.4).

The tumor suppressor genes are of critical importance in human carcinogenesis. In contrast to the diverse interactions of oncogenes converging to stimulate growth, tumor suppressor genes act by inhibiting proteins that control cell cycle progression. Inactivation of both alleles of a suppressor gene (one of which may be inherited in an inactivated state as in familial cancer syndromes) is required to inactivate the normal repressive function. In normal cells, inactivation of the protein products of tumor suppressor genes is achieved via binding to other proteins or by phosphorylation. In tumor cells, inactivation is often due to mutations, insertions and/or deletions (allelic loss).

The Rb protein serves as a classic example for examining the functions of tumor suppressor genes. Underphosphorylated Rb protein blocks proliferation in normal cells by binding to, and thereby inactivating, a transcription factor (E2F) necessary for propagation of the cell cycle (see Fig. 107.1). Serine/threonine phosphorylation of the Rb protein disrupts this binding, releasing E2F and enabling cell cycle progression. Genes that control the levels of Rb phosphorylation (e.g. *CDKN2A*) act as tumor suppressor genes and are often inactivated in cancer by mutation or promoter methylation.

The *p53* gene is frequently inactivated by a point mutation, and as opposed to classic tumor suppressor genes (that act in a recessive manner), *p53* mutations can act in a dominant-negative manner (see Ch. 54 & Fig. 107.4). This is because the p53 protein is a tetrameric protein and oligomerization of a mutant allele product and a normal allele product results in an inactive protein.

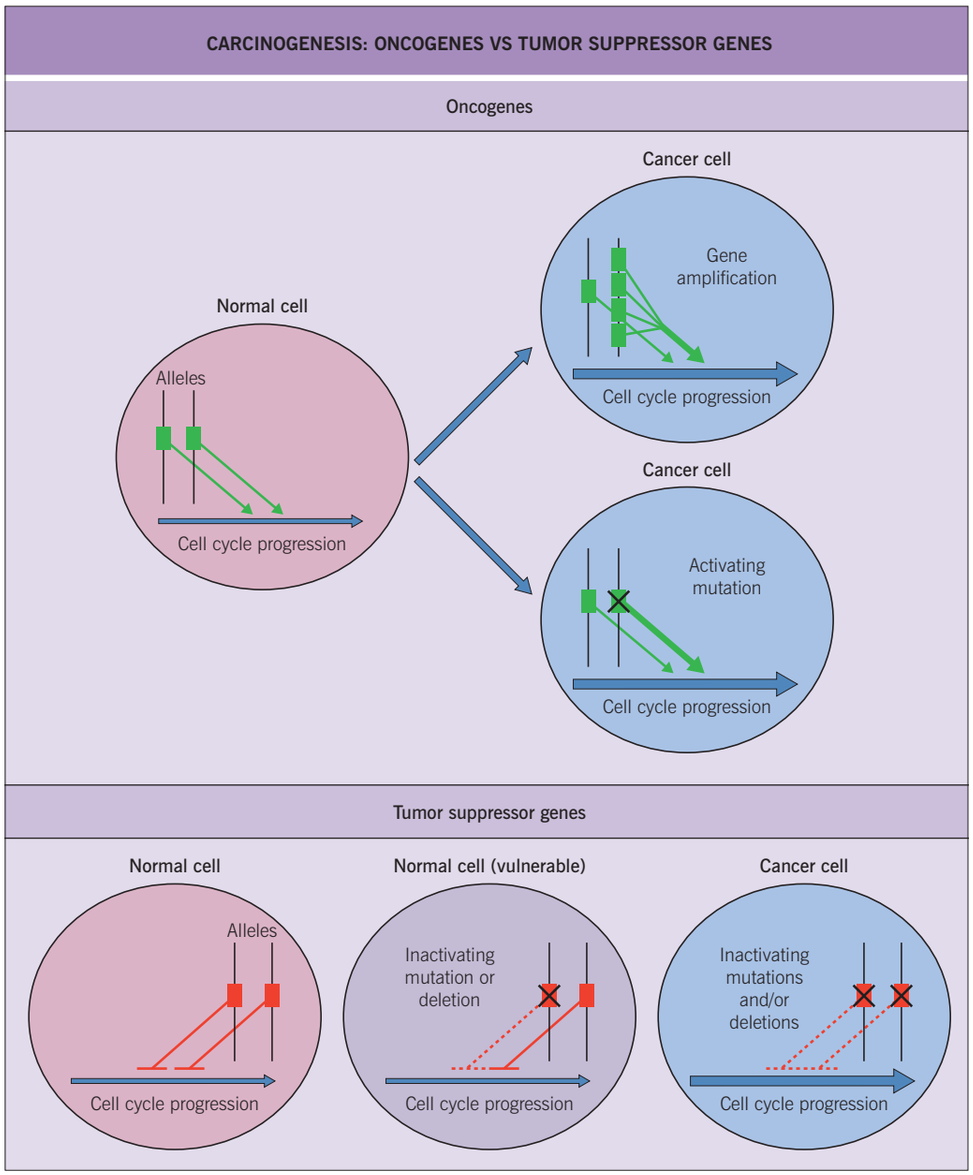

Fig. 107.3 Carcinogenesis: oncogenes vs tumor suppressor genes. An oncogene acts as an accelerator on the cell cycle, increasing cell proliferation. Oncogenes are proto-oncogenes that have acquired activating mutations or gene amplifications. Oncogenes function in a dominant fashion, meaning that activating alterations in only one allele are sufficient for the gene to gain oncogenic potential. A tumor suppressor gene acts as a brake on the cell cycle, decreasing cell proliferation. Tumor suppressor genes are inactivated by mutations in both alleles. Tumor suppressor genes function in a recessive manner, meaning that a mutation in only one allele is not sufficient for loss of gene function. Fig. 107.4 demonstrates the various mechanisms by which the "second hit" occurs in tumor suppressor genes.

MicroRNA (miRNA) is non-coding RNA that regulates translation and degradation of specific mRNAs (see Fig. 3.15). Dysregulation of miRNA expression has been associated with oncogenic transformation and miRNAs whose actions mimic oncogenes or tumor suppressors have been identified in human cancer. For example, miRNA-31 has been identified as a metastasis suppressor[11].

Epigenetic change is a modification to DNA or associated histone proteins, without variation in DNA sequence. There are two major mechanisms of epigenetic modification, DNA methylation (addition of a methyl [CH_3] group) and chromatin or histone modification. DNA methylation occurs in cytosines that precede guanines, known as dinucleotide CpGs or CpG islands, which occur in the promoter regions of many genes and generally results in gene silencing. However, changes in methylation may also occur in non-CpG-island regions, usually in close proximity to CpG islands. In cancer, methylation of cancer genes is more common than loss-of-function mutations or deletions[12].

Apoptosis

An equilibrium between proliferation and cell death is essential for normal homeostasis, and an imbalance can lead to abnormal growth. Cell death is important for tissue remodeling during embryogenesis and for maintaining homeostasis in normal adult tissues. Cell death is equally crucial for the removal of damaged cells, and this can occur via two different mechanisms – necrosis or apoptosis[13]. Necrosis involves poor nutrient supply leading to membrane disruption and cell lysis without *de novo* protein synthesis.

In contrast, apoptosis is regulated and requires mRNA and protein synthesis. Microscopically, apoptosis is characterized by the appearance of apoptotic bodies composed of cell membrane remnants and condensed chromatin. Apoptosis-related proteases, termed caspases, become activated and affect signal transduction pathways by activation of: (1) enzyme precursors that digest genomic DNA into 200 base pair (bp) units; and (2) proteases that degrade structurally important proteins such as lamins and actin (Fig. 107.5). Apoptosis can be induced by several different stimuli, including DNA damage (e.g. due to radiation, chemicals), withdrawal of growth cytokines (e.g. EGF, TGF-α, IGF, PDGF) and death-promoting agents (e.g. TNF) (see Fig. 107.5). Conflicts between different signaling pathways can also provoke apoptosis.

Independent of triggering apoptotic stimuli, apoptosis converges into a common series of molecular events that lead to irreversible morphologic changes and ultimately cell death. The regulation of apoptosis is under the strict control of proteins, including Bcl-2, BAX and Bad families that are capable of regulatory cross-talk by heterodimerization of protein subunits. The mitochondrial membranes contain proteins that either activate apoptosis (BAX, Bad) or inhibit apoptosis (Bcl-2). Overexpression of the survival factor Bcl-2 blocks apoptosis and thus protects the cells against radiation and chemotherapeutic agents. The p53 protein activates transcription of BAX and inhibits transcription of

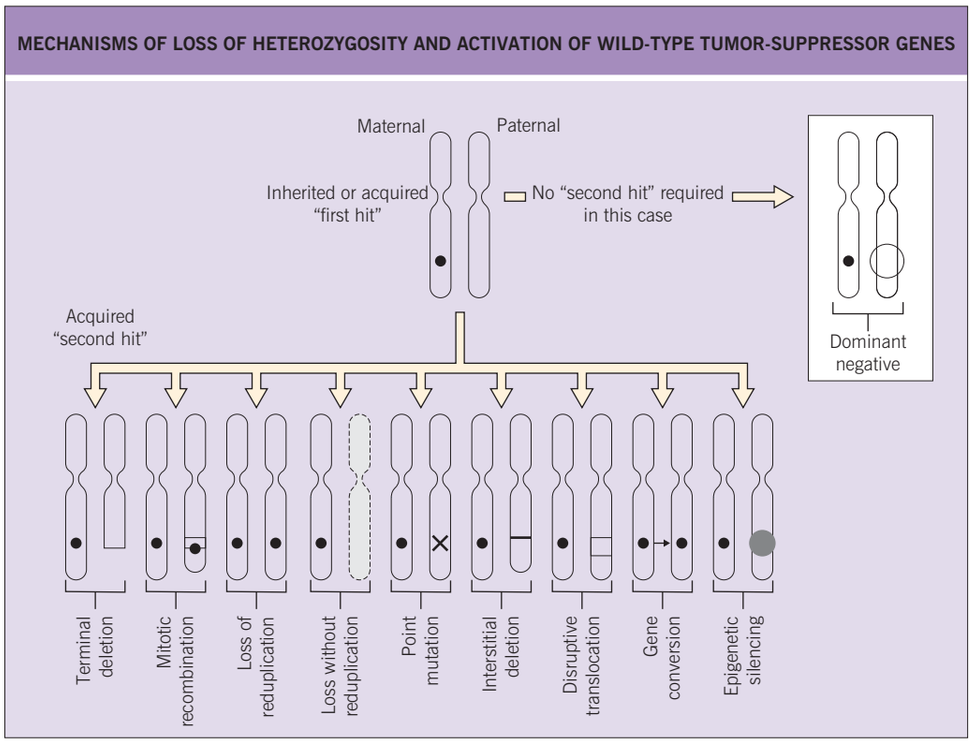

Fig. 107.4 Mechanisms of loss of heterozygosity and inactivation of wild-type tumor suppressor genes. Mechanisms depicted by which both copies of a gene can be inactivated (bottom). With loss of heterozygosity (LOH), the resultant changes are best explained by the absence of wild-type protein. While translocations usually activate oncogenes or generate new fusion proteins, they can also be associated with microdeletions. A common mechanism of epigenetic silencing is methylation of the promoter region of a gene. An alternative mechanism exists (right) in which the wild-type allele is rendered non-functional. That is, some mutations can lead to expressed truncated proteins, and the latter may have dominant negative effects or may be partially functional. An example would be the p53 protein. *Adapted and redrawn from Foulkes WD, Inherited susceptibility to common cancers, N Engl J Med. 2008;359:2143–53.*

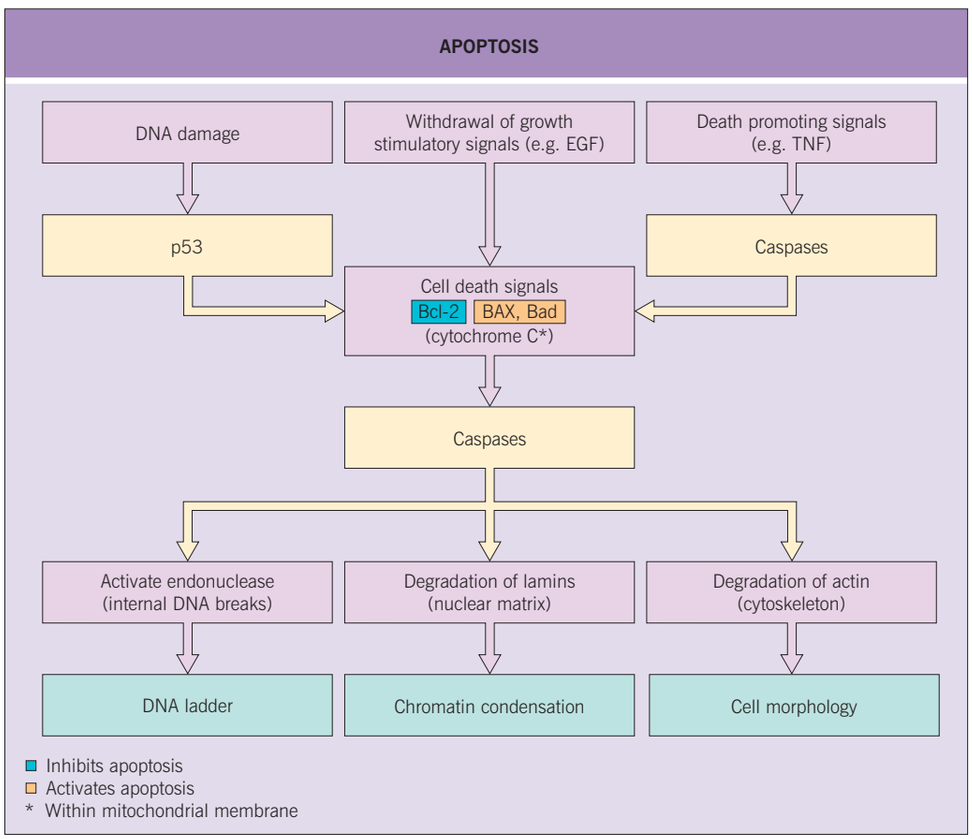

Fig. 107.5 Apoptosis. Various triggering events are depicted above the factors involved in the apoptotic pathways. Consequences of induced apoptosis are shown at the bottom of the figure. Fragmentation of genomic DNA by endonucleases results in a discrete ladder of DNA fragments of decreasing lengths. EGF, epidermal growth factor; TNF, tumor necrosis factor.

bcl-2, the net result favoring apoptosis. Thus, the p53 protein is a key factor for integrating pathways regulating DNA synthesis, DNA repair and apoptosis.

Limitless Replicative Potential

The number of mutations in a cell increases with time and partially explains the increasing risk for acquiring cancer as we age. The increased number of mutations is evident in normal cultured cells, which undergo approximately 60–70 doublings before reaching senescence and then death as a consequence of accumulating mutations and telomere shortening. Senescent cells are viable, but they are incapable of proliferation. During senescence, abnormal chromosomes accumulate and the telomere sequences diminish, eventually resulting in a crisis that leads to apoptosis.

The progressive erosion of telomere sequences (50–100 bp per mitosis) through successive cycles of replication eventually precludes protection of the ends of the chromosomes (see Fig. 67.21). This

facilitates end-to-end chromosomal fusions, resulting in karyotypic disarray and then apoptosis. Carcinogenesis involves disruption of these normal apoptotic events, yielding limitless replicative potential for the tumor cells. Up to 90% of all cancers exhibit increased levels of telomerase, the enzyme required for maintenance of telomere sequences in normal cells; this leads to retention of telomeres irrespective of the number of cell divisions[14].

Cancer cell populations also contain a subpopulation of self-renewing cells called cancer stem cells. These latter cells can increase in number as tumors enlarge and they can give rise to progeny that have the ability to invade locally as well as metastasize to distant sites, referred to as tumor-propagating cells (TPCs)[15]. Markers such as CD133, CD44 and ALDH (aldehyde dehydrogenase) are expressed by TPCs, and this population can be expanded within tumors by symmetrical division of TPCs and by cancer cells undergoing epithelial–mesenchymal transition.

Angiogenesis

Formation of new blood vessels (angiogenesis) is essential for tumor mass expansion, in order to provide adequate levels of oxygen and nutrients[16]. Endothelial cells are normally quiescent, with low proliferation rates and mitoses rarely being observed (aside from the setting of wound healing). Angiogenesis is initiated by growth factors, e.g. fibroblast growth factor (FGF) and vascular endothelial growth factor (VEGF), acting in a paracrine fashion and stimulating local endothelial proliferation (see Ch. 102). Sprouts from surrounding vasculature migrate toward the tumor via protease-mediated remodeling of extracellular matrix (e.g. serine proteases and metalloproteinases) and thereby establish new matrix–cell contacts. Of note, cancer cells express increased levels of VEGF and FGF. Inhibitors of angiogenesis, e.g. angiostatin, endostatin and thrombospondin, have been identified in plasma and extracellular matrix. Because thrombospondin is activated by p53, inactivation of p53 facilitates angiogenesis.

Invasion/Metastasis

Cell–cell interactions and extracellular glycoprotein matrix recognition are achieved by four classes of membrane-bound receptors, consisting of integrins, cadherins, selectins and members of the immunoglobulin family. All of these cellular adhesion molecules have an extracellular domain that binds ligands, leading to a conformational change in the cytoplasmic tail of the receptor. Upon ligand binding, internal regions of the receptors bind to specific cytoplasmic proteins influencing various pathways involved in proliferation, cell migration, differentiation and apoptosis. The extracellular ligands for integrins are matrix components composed of collagen, fibronectin or laminin (see Fig. 141.11) and immunoglobulin family members (see Table 102.2). Cadherins bind to cadherins present on adjacent cells and selectins bind to carbohydrate chains.

Disruption of tissue organization is a hallmark of cancer and is the result of alterations in cellular adhesion receptors resulting in selective growth advantage. In cell cultures, dysregulation of cell adhesion pathways underlies anchorage-independent growth. Metastases from epithelial cancers often lose E-cadherin expression, facilitating the escape of cells from the primary site to other locations. E-cadherin expression can be inactivated by hypermethylation of regulatory regions as well as mutations in the coding sequence. Alternatively, inactivation occurs through proteolysis of the extracellular domain of E-cadherin or mutations in the gene encoding E-cadherin's intracellular ligand, β-catenin.

Signaling from normal neighboring cells, e.g. fibroblasts and endothelial cells, appears to be equally important for the growth of a tumor and is often induced by signals from the tumor cells. Reciprocal release of abundant growth-stimulating signals creates amplifying loops enabling growth of both the tumor and its cognate stroma. Inflammatory cells have also been shown to be involved in a similar cross-talk between normal and malignantly transformed cells[17].

In humans, the most common cancers are basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), often termed "non-melanoma skin cancer". Although BCCs and SCCs possess many similar features, there are fundamental biologic differences, justifying a distinction between the two and rendering "non-melanoma skin cancer" a poor conceptual term. In the remainder of this chapter, BCC and SCC will be described with an emphasis on the similarities and the differences between their tumor biology. Disruption of the Hedgehog–Patched signaling pathway is closely linked to development of BCC and the *p53* gene is often mutated in both BCC and SCC. The *Patched (PTCH)* and *p53* genes will serve as a model to illustrate some of the basic features of epithelial skin carcinogenesis.

STRUCTURE AND FUNCTION OF *p53*

Background

The *p53* tumor suppressor gene was first described in 1979 and was initially erroneously classified as an oncogene due to its ability to transform cells. The wild-type p53 protein is involved in a multitude of cellular events and illustrates the complex molecular machinery within a cell[18]. The p53 protein is regarded as the "guardian of the genome" as it protects DNA integrity in response to cytotoxic stress, including radiation. Protection is achieved by management of signaling pathways that regulate cell cycle progression, DNA repair and apoptotic cell death. The ability of p53 to induce apoptosis by transactivation of target genes is critical for its function as a tumor suppressor gene. Aside from genomic alterations, p53 protein can also be inactivated by binding to other proteins, such as the viral proteins adenovirus E1B, human papillomavirus E6 and the SV40 T-antigen.

The *p53* Gene, Protein and Regulation

The *p53* gene is located on the long arm of chromosome 17 and contains 11 exons spanning some 20 000 bp of genomic sequence. The gene encodes a 53 kDa nuclear phosphoprotein of 393 amino acid residues. Four functional domains involved in the regulation of transcription, DNA binding, oligomerization and auto-inhibition are recognized (Fig. 107.6). Transcription is indirectly regulated within the transactivation domain (42 amino acid residues) either by binding to other proteins or by phosphorylation. For example, the nuclear protein Mdm2 is capable of inactivating wild-type p53 protein by binding to the transactivation domain. Subsequent to binding to Mdm2, p53 is degraded via the ubiquitin-mediated proteolysis pathway. In normal cells containing latent p53 protein bound to Mdm2, the half-life of p53 is approximately 2 minutes.

Interaction between Mdm2 and the p53 protein is dependent upon phosphorylation of the p53 transactivation domain as well as interactions with other proteins. Upon DNA damage, serine protein kinases are activated that readily phosphorylate p53 and release it from Mdm2 binding. Up to a 100-fold increased cellular content of functional p53

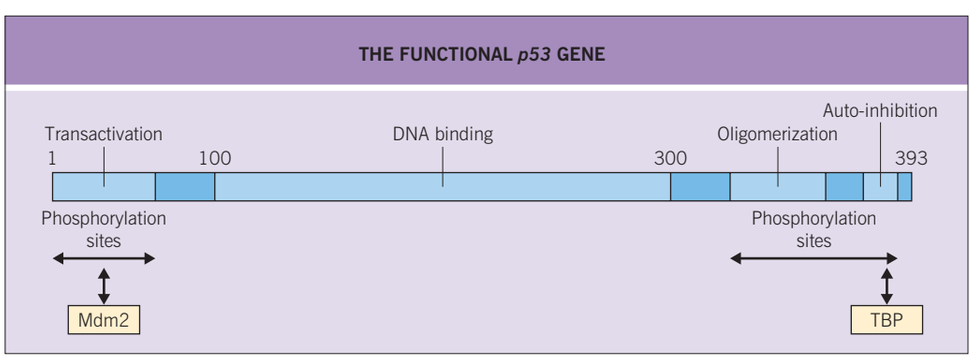

Fig. 107.6 The functional *p53* gene. There are four functional domains and they are involved in transactivation, sequence-specific DNA binding, oligomerization and auto-inhibition. Binding sites for Mdm2 and TBP proteins are noted. TBP, TATA box-binding protein.

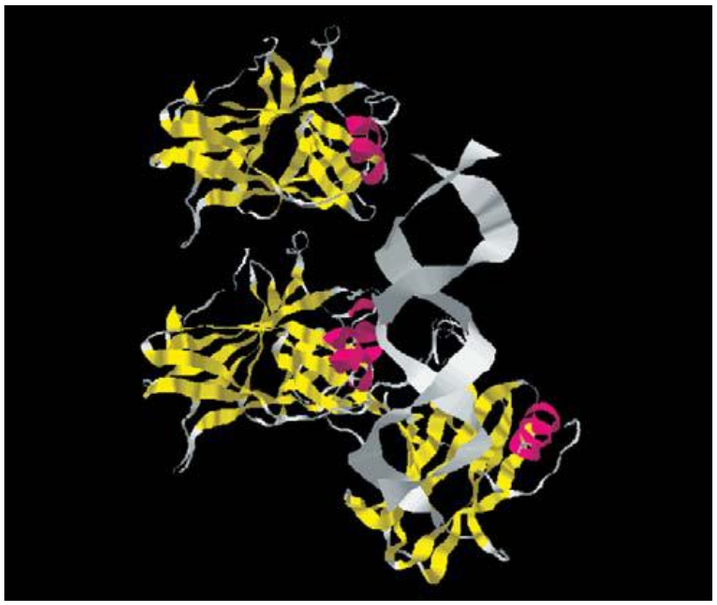

Fig. 107.7 Three-dimensional view of the p53 protein. Three units of the normally tetramerized active p53 are shown surrounding the DNA double helix (gray). The β-sheets are shown in yellow and α-helices are depicted in red. *From Sayle RA, Milner-White EJ. RASMOL: biomolecular graphics for all. Trends Biochem Sci. 1995;20:374; Cho Y, et al. Crystal structure of a p53 tumor suppressor-DNA complex: understanding tumorigenic mutations. Science. 1994;265:346–55.*

is thus obtained without a requirement for protein synthesis. p53 protein is a transcription factor for Mdm2, thus creating a feedback loop between p53 and Mdm2. Mdm2 protein levels are further regulated by binding to the $p14^{ARF}$ protein (see Fig. 107.1), which translocates Mdm2 to the nucleolus and thus prevents Mdm2–p53 interaction.

The structure of the DNA-binding domain has been shown to consist of a scaffold with three loops (Fig. 107.7). The first loop binds to the major groove of the target DNA sequence. The second loop has contact with the minor groove, and the third loop stabilizes the second loop via a zinc atom. The majority (80–90%) of detected *p53* mutations involve the sequence-specific DNA-binding domain. The distribution of reported mutations is shown in Figure 107.8 and depicts a number of hot spots within this region.

The p53 protein requires a tetramer configuration for DNA binding. The oligomerization domain is responsible for assembly of the protein. Because both normal and mutant allele products can be assembled together, this leads to the dominant-negative phenotype (see Ch. 54) that is characteristic of the mutant p53 protein. The auto-inhibitory domain of 30 basic amino acid residues is thought to block the DNA-binding domain and can be removed by phosphorylation or binding to other proteins such as TATA box-binding proteins (TBP). The p53 protein exerts its effects predominantly (but not exclusively) at the level of transcription. Genes that increase their transcription due to interaction with p53 contain a promotor (response) element for binding to the p53 tetramer (Table 107.2). The transactivation domain of p53 can also recruit additional transcription factors required for transcription.

The Cellular Response to DNA Damage

p53 is a general sensor of cytotoxic stress and can be activated by several types of DNA insults that create single- and double-strand breaks as well as cyclobutane pyrimidine dimers and 6-4 photoproducts, e.g. chemicals or gamma and UV radiation (see Ch. 86). In response to DNA damage, the level of p53 protein increases rapidly within the cell and exerts multiple, complex functions, including protection of DNA integrity and cellular proofreading[18]. The former involves cell cycle arrest at G1 in order to facilitate the repair of damaged DNA prior to cell division. The pathway downstream of p53 involves upregulation of p21, which, in turn, inhibits cyclin-dependent kinases and subsequent phosphorylation of Rb protein (see Fig. 107.1). Underphosphorylated Rb protein binds the transcription factor E2F and prevents the cell from entering into the S phase. Cellular proofreading involves apoptosis as a response to irreversible damage of genomic DNA and prevents survival of cells with severe genetic alterations. Sunburn cells in the epidermis represent apoptotic keratinocytes and can frequently be observed in normal skin subjected to sunburn.

EXAMPLES OF GENES WHERE TRANSCRIPTION IS INFLUENCED BY THE p53 TETRAMER

Gene (protein)	Regulation	Function
p21 (p21)	Activation	Proliferation
GADD45 (GADD45)	Activation	Proliferation
bax (Bax)	Activation	Apoptosis
thrombospondin (Thrombospondin)	Activation	Angiogenesis
mdm2 (Mdm2)	Inhibition	Regulatory
bcl-2 (Bcl-2)	Inhibition	Apoptosis
fos (Fos)	Inhibition	Proliferation
jun (Jun)	Inhibition	Proliferation

Table 107.2 Examples of genes where transcription is influenced by the p53 tetramer.

Mutated *p53*

The *p53* gene is the most frequently altered gene in human cancer. A majority of *p53* mutations are missense mutations leading to an altered amino acid sequence. Missense mutations are primarily found in the DNA-binding domain between codons 112 and 286 (see Fig. 107.8). Mutations in the DNA-binding domain do not affect oligomerization; thus, mutant p53 can still form tetramers with normal p53 protein derived from the intact *p53* allele. The formed heterodimers are, however, incapable of binding to promotor sequences.

The addition of small peptides (corresponding to the C-terminal domain) can potentially disrupt the auto-inhibitory binding of the C-terminal region to the DNA-binding domain of the mutant heterodimers and thereby reactivate the function of mutated p53. This observation may eventually translate into a therapeutic intervention. At the time of writing, drugs that disrupt p53–Mdm2 or p53–Mdm4 interactions are in clinical trials[19].

Clandestine proliferations of keratinocytes overexpressing p53 protein are evident in normal, chronically sun-exposed skin of Caucasians[20]. The pattern and degree of overexpression are distinctly different from the dispersed pattern of p53-immunoreactive keratinocytes following a single exposure to UV irradiation (Fig. 107.9). A recent study, using next-generation sequencing of sun-exposed versus shielded mid-life skin, revealed that persistent *p53* mutations had accumulated in 14% of epidermal cells in phenotypically normal skin, with no apparent evidence of a growth advantage[21]. Six percent of the mutated cells encoded for a truncated p53 protein. The authors estimated the accumulation of ~35 000 protein-altering *p53* mutations annually in the sun-exposed skin of a single individual, suggesting that UV-induced *p53* mutations are tolerated and not as hazardous as previously thought.

STRUCTURE AND FUNCTION OF PATCHED

Background

The Hedgehog signaling pathway plays a critical role during normal development, regulating both proliferation and cell fate. Initially, *patched* and *hedgehog* genes were identified in *Drosophila melanogaster*, where members of this complex signaling pathway were found to act as segment polarity genes involved in embryonic development. In recent years, it has become evident that Hedgehog is also involved in driving tumorigenesis[22]. When screening candidate genes for the hereditary nevoid basal cell carcinoma syndrome (Gorlin syndrome), the human homologue of the *patched* gene, *PTCH1*, was identified as a tumor suppressor gene associated with this syndrome[23]. The *PTCH1* gene encodes a receptor that mediates Hedgehog signaling (Fig. 107.10). Later studies have shown that inactivating mutations in the *PTCH1* gene are also common events in sporadic BCC. The significant cellular effects of Hedgehog signaling are mediated by proteins encoded by the *GLI* gene family.

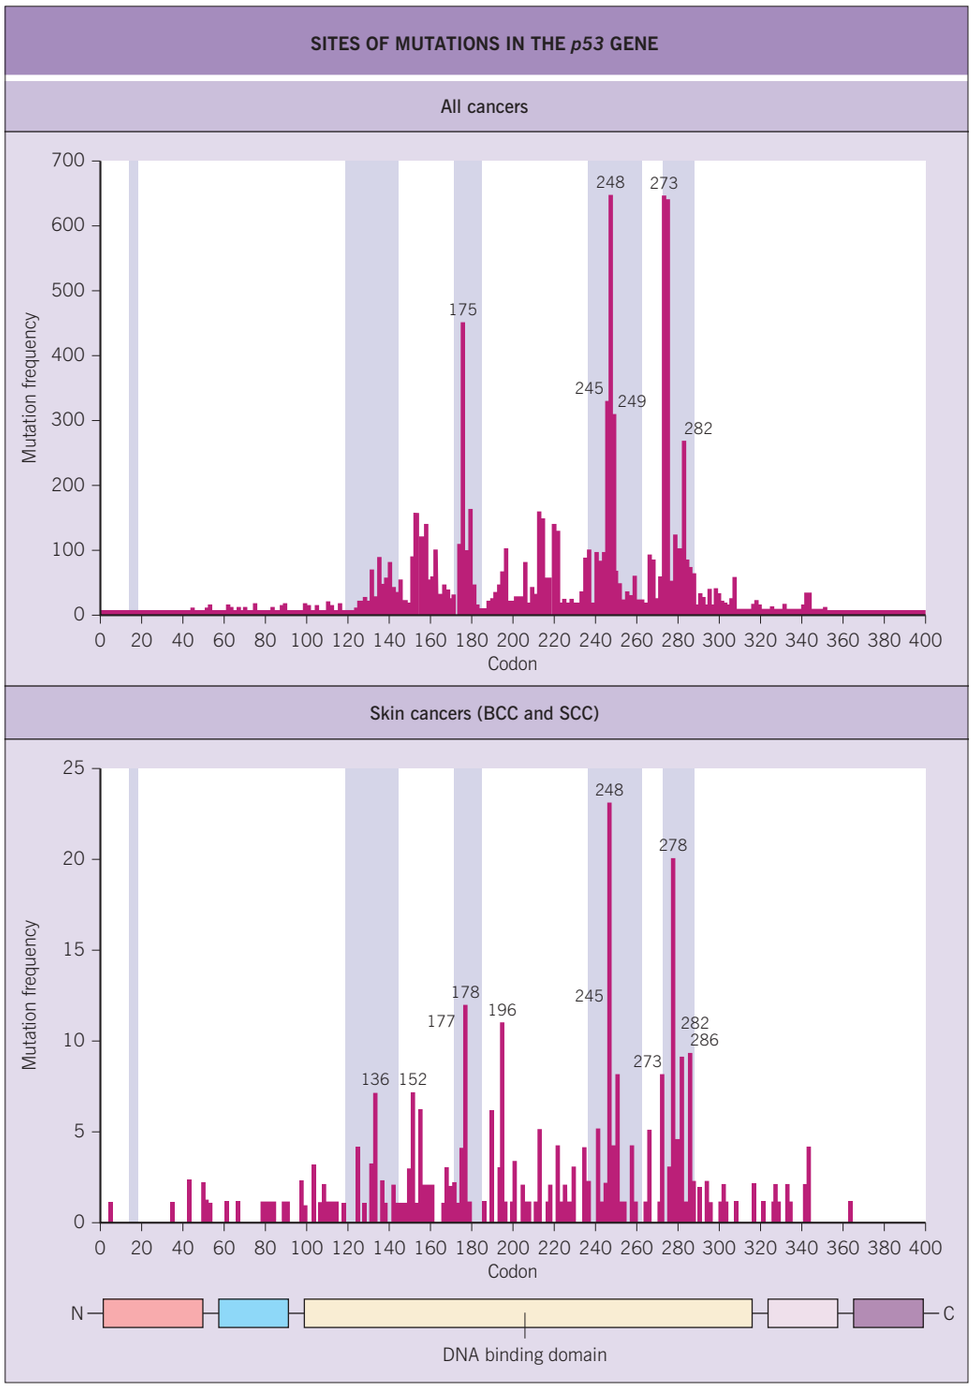

Fig. 107.8 Sites of mutations in the *p53* gene. The frequencies of mutations are shown with respect to specific codons within the *p53* gene in all cancers (top panel) and skin cancer (basal cell carcinoma + squamous cell carcinoma; bottom panel). Numbers represent hotspots for *p53* mutations. The gray bars represent evolutionary conserved regions of the *p53* gene. *From Hernandez-Boussard T, et al. IARC p53 mutation database. Hum Mutat. 1999;14:1–8.*

The human Hedgehog signaling pathway is complex, with three identified *hedgehog* genes (*sonic hedgehog* [*SHH*], *Indian hedgehog* [*IHH*] and *desert hedgehog* [*DHH*]), two *PTCH* genes (*PTCH1* and *PTCH2*) and three *GLI* genes (*GLI1*, *GLI2* and *GLI3*). The encoded proteins within these families are similar, although they display variations in expression levels in different cells and tissues as well as slightly different modes of interactions. In the skin, the SHH pathway is responsible for maintaining the stem cell niche and controlling development of sebaceous glands and hair follicles[24]. In the next section, a simplified scheme using Hedgehog, Patched and Gli as common denominators will be used to illustrate interactions and effects in this important pathway.

PTCH Gene

The human *PTCH1* gene was cloned and identified in 1996. Positional cloning was used to search the region within 9q22.3 in order to identify the gene responsible for Gorlin syndrome. The gene is 35 kb in length and consists of 23 exons. The first exon has three splice variants, 1, 1A and 1B. The different transcripts have been identified in human epidermis.

PTCH Protein Product (Patched)

The protein product of the human *PTCH* gene is the sonic hedgehog (SHH) receptor, which is an integral membrane protein with 12 predicted transmembrane regions and two large extracellular loops as well as a putative sterol-sensing domain. Patched protein normally binds and inhibits a seven-pass transmembrane G-protein receptor named Smoothened (SMO). SMO has been shown to be constitutively active when not bound to Patched (see Fig. 107.10).

Normal Function of Patched

By controlling proliferation, differentiation and cell fate, the SHH–Patched signaling pathway is critical for early embryologic development, including formation of the neural tube, musculoskeletal system, hematopoietic cells, skin and teeth. Mutations in the SHH pathway cause

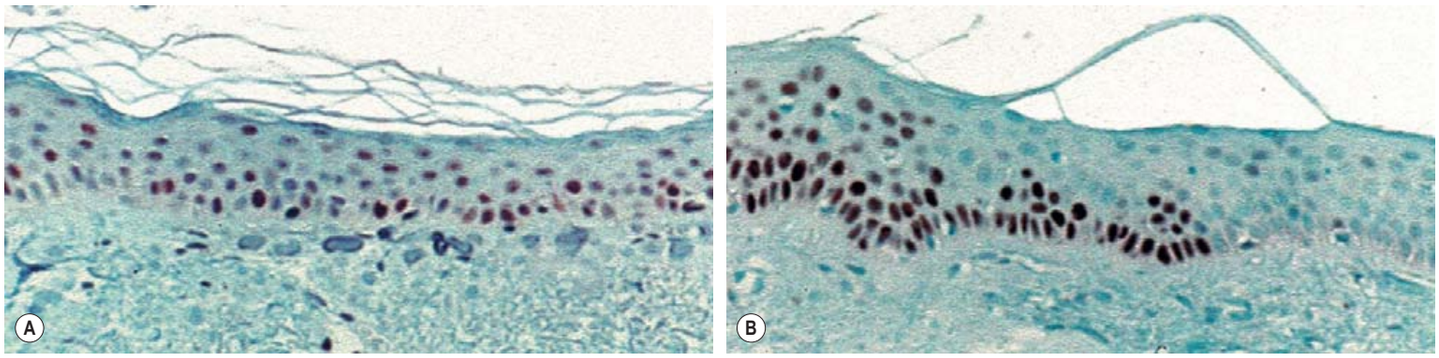

Fig. 107.9 p53 immunoreactivity. Photomicrographs of two different patterns of p53 immunoreactivity found in normal skin. **A** Dispersed pattern of p53 positivity representing a normal reactive response to DNA damage (e.g. single exposure to UVB). **B** Epidermal p53 clone representing a clonal expansion of morphologically normal keratinocytes with a *p53* mutation. The latter is seen in chronically sun-exposed skin. Of note, mutated p53 protein has an extended half-life as compared to wild-type protein (due to a less efficient MDM2/ubiquitin degradation pathway) and this property is used as a semiquantitative surrogate marker for altered p53 in immunohistochemical examination of tissue.

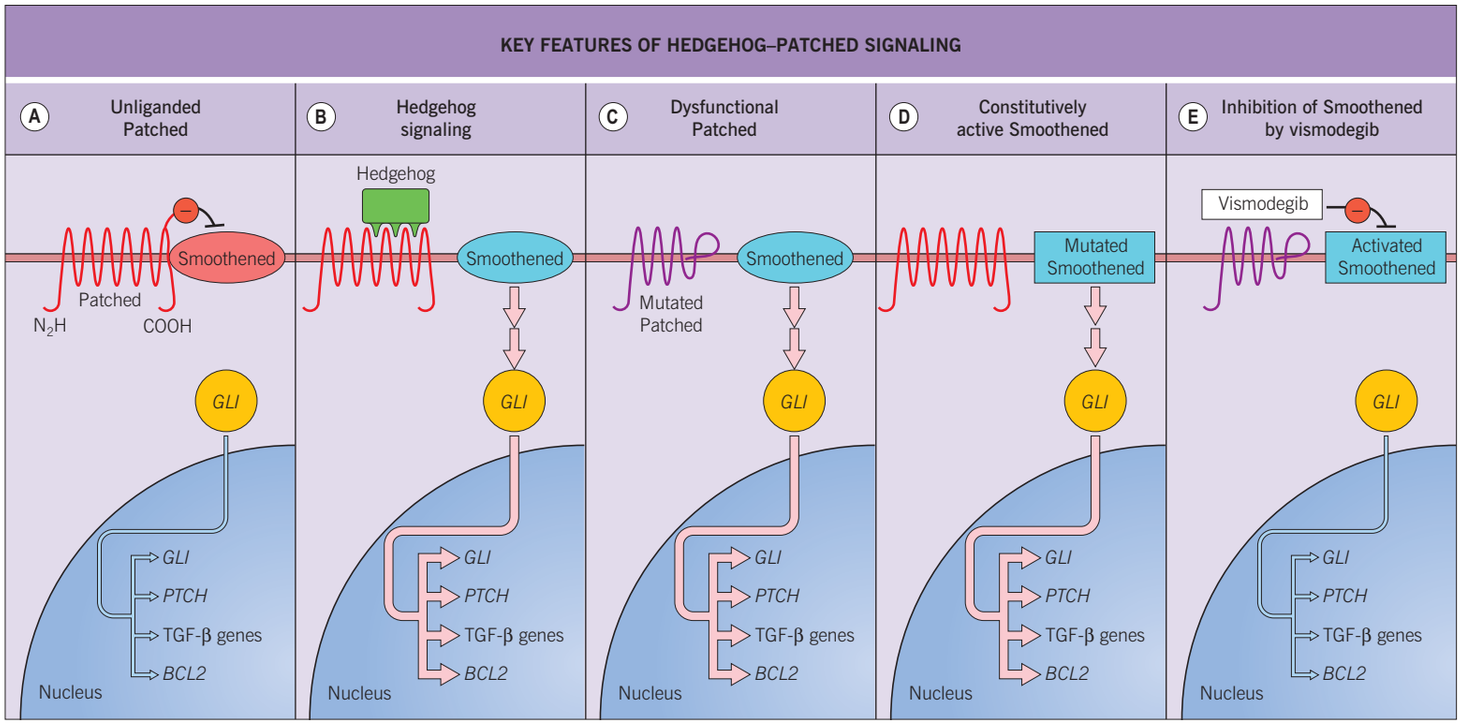

Fig. 107.10 Key features of Hedgehog–Patched signaling. A Unbound Patched silences Smoothened (SMO) signaling. **B** As Hedgehog binds to its receptor (Patched), the repression of SMO is removed and signals are transduced via Gli to the nucleus. **C** Inactivating mutations in *PTCH* simulate Hedgehog binding and result in constitutive activation of Gli and downstream target genes. **D** An activating mutation in *SMO* results in constitutive signaling to Gli and downstream target genes. **E** Vismodegib is an inhibitor of SMO that has been used to treat patients with nevoid BCC syndrome as well as metastatic or locally advanced BCCs (see Ch. 108).

holoprosencephaly, a Cyclops-like phenotype with severe congenital abnormalities.

Patched function is mediated via release of suppression of SMO. SMO signaling is then transduced and executed through the transcription factor Gli (see Fig. 107.10). Active Gli serves as a transcription factor for *GLI* itself as well as inducing transcription of *PTCH1*, thus creating a negative feedback loop. Other genes induced via the SHH–Patched signaling pathway include those that encode platelet-derived via factor-α (PDGFRA), the DNA-binding protein MYCN, β-catenin, members of the forkhead box (FOX) family, cyclins and runt-related transcription factor 3, a nuclear effector of the TGF-β family.

Regulation of Patched

Knowledge about genes and molecules involved in SHH–Patched signaling has been obtained mainly by genetic analyses in *Drosophila*. The signaling pathway is well conserved, although with increasing complexity, from insects to vertebrates, including humans. The SHH–Patched signaling pathway induces transcription of *PTCH* itself, creating a negative feedback loop for *PTCH*. Unliganded Patched interacts with and suppresses signaling by the co-receptor SMO. SHH signaling accordingly induces transcription of target genes by opposing the repressive activity of Patched. In other words, when SHH binds to the receptor Patched, repression of SMO is relieved and downstream target genes are induced. In a simplified scheme (see Fig. 107.10B), secreted SHH proteins bind to the receptor protein Patched and upon binding to the ligand, Patched dissociates from its co-receptor Smoothened.

Inactivating mutations of *PTCH1* simulate SHH signaling due to the failure of mutated Patched protein to suppress SMO (see Fig. 107.10C). The loss of negative autoregulation leads to increased transcription of non-functional PTCH mRNA. In carcinogenesis, several lines of evidence (including experiments using transgenic mice) suggest that the critical cellular effect is stimulation of proliferation as opposed to differentiation, and that this effect is mediated by upregulation of Gli.

PTCH Mutations

An early onset of multiple BCCs is a hallmark of Gorlin syndrome (also known as nevoid BCC syndrome), a rare autosomal dominant disease. The *PTCH* gene is mutated in patients with Gorlin syndrome and thus

strongly linked to the development of BCCs. Additional features that constitute Gorlin syndrome include skeletal abnormalities, jaw cysts, macrocephaly and palmoplantar pits. A majority of the germline mutations in *PTCH* are truncating, suggesting that haploinsufficiency underlies the developmental abnormalities. Both alleles of *PTCH* are often inactivated in both familial and sporadic cases of BCC, as would be expected for a classic tumor suppressor gene. Most tumors where *PTCH* is inactivated display a truncating mutation in one allele and deletion of the other allele, i.e. loss of heterozygosity (LOH). Alternatively, point mutations in both alleles can occur in tumors without LOH in the *PTCH* locus.

Constitutive activation of SHH signaling by inactivating mutations in *PTCH* or activating mutations in *SMO* appear to be required, and possibly also sufficient, for development of BCC. Disruption of the SHH–Patched pathway has also been found in other tumors such as medulloblastoma, as well as ovarian and cardiac fibromas, which are common in patients with Gorlin syndrome. In addition, *PTCH* mutations have been found in sporadic trichoepitheliomas, bladder carcinoma and SCC of the esophagus. Mutational analysis has shown that two-thirds of reported mutations were truncating or affected splicing.

PATHOGENESIS OF BCC

Sun exposure and anatomic site appear to be of etiologic importance in the development of BCC. Intermittent, recreational sun exposure, more so than cumulative UV radiation, is a significant risk factor[25]. The development of BCCs is restricted to skin containing pilosebaceous units. The fact that BCCs commonly develop on the face, and in particular on the nose, suggests that anatomic site, i.e. specific areas of skin that contain a higher number of target progenitor cells, plays an important role. Analogous to other malignancies, BCC appears to have a capacity for infinite growth and spontaneous regression is not a feature. Sophisticated studies of tumor biology have been sparse due to difficulties in establishing good experimental models, and *in vitro* culture of BCC cells from explanted tumors has in general been unsuccessful. Transplantation of BCC into athymic mice has been more successful, although extensive studies of long-term effects have been sparse. The development of transgenic mice as a model to study BCC has been rewarding, especially with regard to elucidating the role of different components of the SHH–Patched signaling pathway[26]. A recent study suggested that BCCs arise from interfollicular epidermis or the follicular infundibulum rather than the hair follicle bulge, as had been previously proposed[27].

Precursors

Perhaps the most striking feature of BCCs is that tumors virtually never develop metastases. Although tumors can grow for many years in the setting of sustained exposure to mutagenic UV radiation, the tumors remain indolent. Non-aggressive forms of BCC, such as superficial and nodular BCC, appear to develop *de novo* and continue to grow without progressing to more aggressive forms of BCC. Aggressive forms of BCC, e.g. morpheaform BCC, also show an unusual genomic stability, with a persistent pattern of locally invasive growth and tissue destruction, but without progression to metastatic disease. This also holds true for BCCs that develop in xeroderma pigmentosum patients, where there is a high number of unrepaired mutations. It is unclear why BCC cells are resistant to acquiring additional genetic hits leading to more autonomous growth.

Cancer

BCC is a tumor with unique growth characteristics. It is dependent on a specific loose connective tissue stroma for its continued growth, and one hypothesis for the inability of a BCC to transform into a metastasizing tumor is an unconditional dependence on a stroma produced by dermal fibroblasts. In an experiment where autotransplantation of BCC with and without its cognate stroma was performed, it became evident that BCC devoid of its stroma failed to proliferate and instead differentiated into keratin-filled cysts[28].

The loose connective tissue stroma that characteristically surrounds nests of BCC cells consists of dermal fibroblasts and thin collagen fibers. The cross-talk between tumor cells and mesenchymal cells of the cognate stroma simulates the epithelial–stromal interactions found in normal developing and adult cycling hair follicles. For example, the growth factor receptors for PDGF are upregulated in BCC stroma whereas the ligand, PDGF, is expressed primarily in tumor cells. In morpheic or infiltrative BCCs, the stroma is myofibroblast-rich as compared with nodular BCCs. These myofibroblasts secrete hepatocyte growth factor which promotes invasion of epithelial cells via its binding to c-Met, a tyrosine kinase receptor expressed in the epithelium of morpheic BCCs[29]. The invasive nature of BCCs can be explained in part by proteolytic activity of the tumor. Increased expression of enzymes such as metalloproteinases and collagenases, which degrade pre-existing dermal tissue and facilitate spread of tumor cells, can be found in both BCC cells and stromal cells.

Microscopically, BCCs often appear as multicentric tumors. In superficial BCCs, nests of tumor cells connected to the basal cell layer of the overlying epidermis appear as discontinuous buds of tumor cells. More recent studies based on microdissection, gene amplification and gene sequencing have shown that BCCs develop as a monoclonal proliferation consistent with a unicellular origin. Interestingly, BCCs often consist of subclones (Fig. 107.11). Using *p53* mutations as a marker for clonality, it was shown that different parts of a tumor share a common mutation but differ with respect to second, third or even fourth mutations within the two alleles of the *p53* gene[30].

Although BCC appears as a tumor with extraordinary genomic stability, a large number of tumors are aneuploid. Analyses of LOH have shown allelic loss of chromosome 9q, while LOH involving other chromosomes was observed infrequently[31]. Of note, the gene most often altered in BCCs is the *PTCH* gene, which is located on chromosome 9q. Two out of three BCCs show LOH and/or truncating mutations in the *PTCH* gene. In tumors where the *PTCH* gene is intact, other mutations such as activating mutations in *SMO* (up to 20%) have been detected. Accumulating data suggest that a sufficiently elevated expression level of Gli, by homozygous inactivation of *PTCH* or by activating mutations of *SMO*, in a responding cell is necessary and perhaps also sufficient to drive the formation of BCC. Constitutive SHH signaling has also been demonstrated to be required for growth of *established* BCCs (see Fig. 107.10)[32].

The second most common genetic alteration found in BCCs is point mutations in the *p53* gene. *p53* mutations appear early during carcinogenesis and at least 50% of BCCs have a mutated *p53* gene. The vast majority of *p53* mutations are missense mutations that carry a UV signature (see Ch. 86)[33]. In many BCCs, both *p53* alleles are affected by point mutations, unlike the more common combination of a point mutation and a deletion (LOH) observed in most other solid tumors. The role of *p53* mutations in the carcinogenesis of BCCs could be based on the expansion of the number of target cells, i.e. epidermal p53 clones, susceptible to transformation.

Mutations in the *CDKN2A (INK4A)* locus, which encodes both p16 and $p14^{ARF}$ (see above), have also been detected in a smaller number of sporadic BCCs. In contrast to tumor suppressor genes (e.g. *PTCH*, *p53*), oncogenes appear to play a lesser role in the development of BCC. *ras* genes are the most studied oncogenes and the frequency of *ras* mutations in BCC has varied between 0 and 30%, usually within the *H-ras* gene. Alterations in other oncogenes and tumor suppressor genes have only sporadically been recorded. Genome-wide association studies in the Icelandic population have revealed genetic susceptibility variants in the keratin 5 gene in patients with BCC[34].

Limitless replicative potential is essential for the malignant phenotype, and telomere maintenance is also evident in BCCs, due to high telomerase activity. Interestingly, BCCs express equal or higher levels of telomerase when compared to high-grade malignancies. The presence of intact DNA repair genes is also of critical importance. The detrimental effect of insufficient repair of UV-induced DNA damage is well illustrated in patients with xeroderma pigmentosum, who develop numerous BCCs at an early age.

Metastasis

Although BCCs virtually never metastasize, there have been a few reports in the literature of BCCs that developed metastases, and the incidence has been estimated to be 1:1000 to 1:35 000. It appears as if these rare cases represent aggressive tumors with perineural spread of tumor cells. Lymph node metastasis followed by lung and bone metastasis is the most common progression. The diagnosis has been

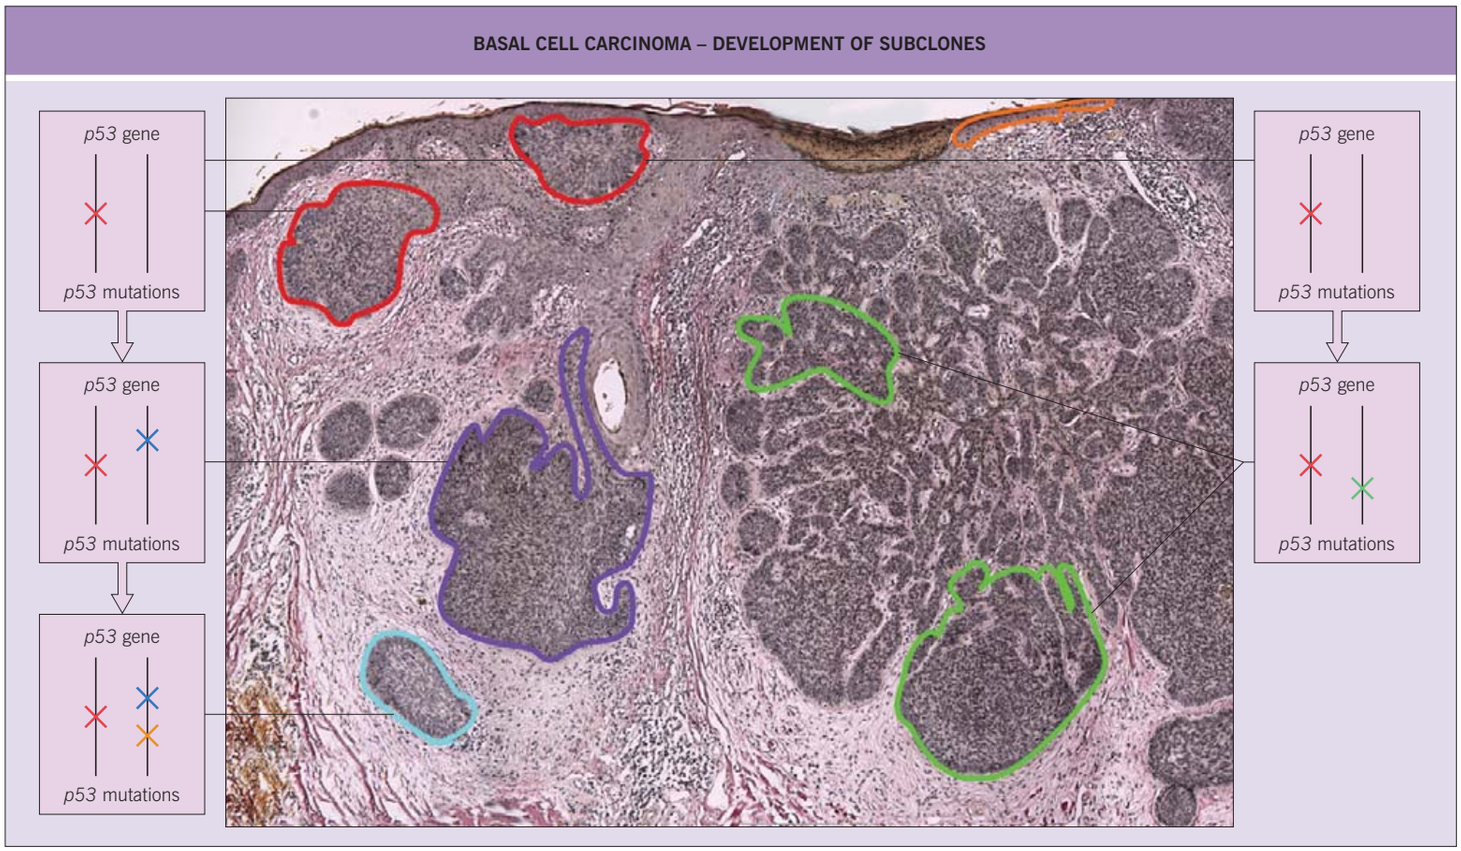

Fig. 107.11 Basal cell carcinoma (BCC) – development of subclones. A common *p53* mutation (red cross) is found in different parts of the tumor. Despite indistinguishable morphology, different parts of individual BCCs have acquired additional mutations in the *p53* gene (blue, orange and green crosses). Boxes illustrate the two *p53* alleles. Note normal *p53* status (outlined in orange) in overlying epidermal keratinocytes.

based on morphology, and the possibility that some of these cases represent poorly differentiated variants of SCCs cannot be excluded.

In summary, BCC is a common, locally invasive tumor of the skin, for which UV radiation and alterations in the *PTCH* gene are important etiologic factors. BCC is stroma-dependent for its growth, arises without precursors, and shows continuous growth without progression to metastatic disease.

PATHOGENESIS OF SCC

UV solar radiation is also a major etiologic factor in the development of cutaneous SCC. The cumulative dose of UV radiation received over time is a significant risk factor, in contrast to the more complex relationship between BCC and sun exposure early in life or cutaneous melanoma and sunburns[25]. SCC of the skin is a "classic cancer", as it has precursor lesions, tumor progression and the potential to develop metastatic disease. SCC can develop in different regions of the skin as well as other sites lined by squamous epithelia, e.g. mouth, esophagus, vagina. The biology of cutaneous SCC differs in part from that of SCCs that arise in other tissues. In particular, SCC in areas of chronically sun-exposed skin exhibits a relatively indolent behavior and the development of metastases is infrequent (less than 5% overall). There is a strong correlation between tumor thickness and metastasis (2.1–6 mm, 4% metastasize; >6 mm, 16% metastasize)[35]. Secondary risk factors for metastasis include immunosuppression and location on the lips or the ear. Desmoplastic SCCs have a higher recurrence rate. SCCs arising on the genitalia and perianal area are also more aggressive, with a higher risk of metastasis.

Precursors

The current opinion regarding cutaneous SCC is that the cancer is derived from a single transformed cell of keratinocytic lineage. The precise genetic events and number of mutations required for malignant transformation are unknown. However, cutaneous SCC develops through the addition of genetic alterations leading to a selective growth advantage. In this scheme of events, several stages can be defined. An attractive model (supported by studies in hairless mice) includes epidermal p53 clones as forerunners to squamous cell dysplasia (Fig. 107.12)[36]. According to the dogma, slight dysplasia precedes moderate and severe dysplasia (which is seen in SCC *in situ*) and invasive SCC then develops from carcinoma *in situ*. Further genetic alterations and selection leads to the final stage, where a locally invasive SCC gives rise to metastases in regional lymph nodes and distant organs.

Clinical precursor lesions associated with cutaneous SCC include actinic keratoses and Bowen's disease. Microscopically, actinic keratoses display signs of chronic sun damage, i.e. solar elastosis and a slight to severe grade of squamous cell dysplasia within the epidermis, especially in its lowermost portions. Bowen's disease also displays squamous cell dysplasia, which is full-thickness and often high-grade. Actinic keratoses are exceedingly common in chronically sun-exposed skin of older Caucasians. Lesions occur primarily on the face, hairless scalp, dorsal aspects of the hands, and helices of the ears (primarily in men). The risk for an individual actinic keratosis to progress into an invasive cancer is low, probably less than 1 in 1000 per year. The risk of SCC *in situ* progressing to invasive cancer is considered to be higher.

Cancer

UV solar radiation is accepted as a major risk factor for SCC. Numerous experiments using chemical multistage carcinogenesis models have been performed in mice, yielding SCC-like tumors. A typical protocol consists of a single application of an initiating compound, e.g. 7,12-dimethylbenz[a]anthracene (DMBA), which leads to irreversible activating mutations in *H-ras* genes within basal cells of the epidermis. In a second step, repetitive doses of a tumor-promoting agent, e.g. 12-O-tetradecanoylphorbol 13-acetate (TPA), induces a hyperproliferative response. Through partly epigenetic mechanisms, this leads to the development of squamous cell papillomas. Conversion of benign papillomas into malignant SCCs then involves a number of chromosomal and genetic alterations required for the acquisition of the

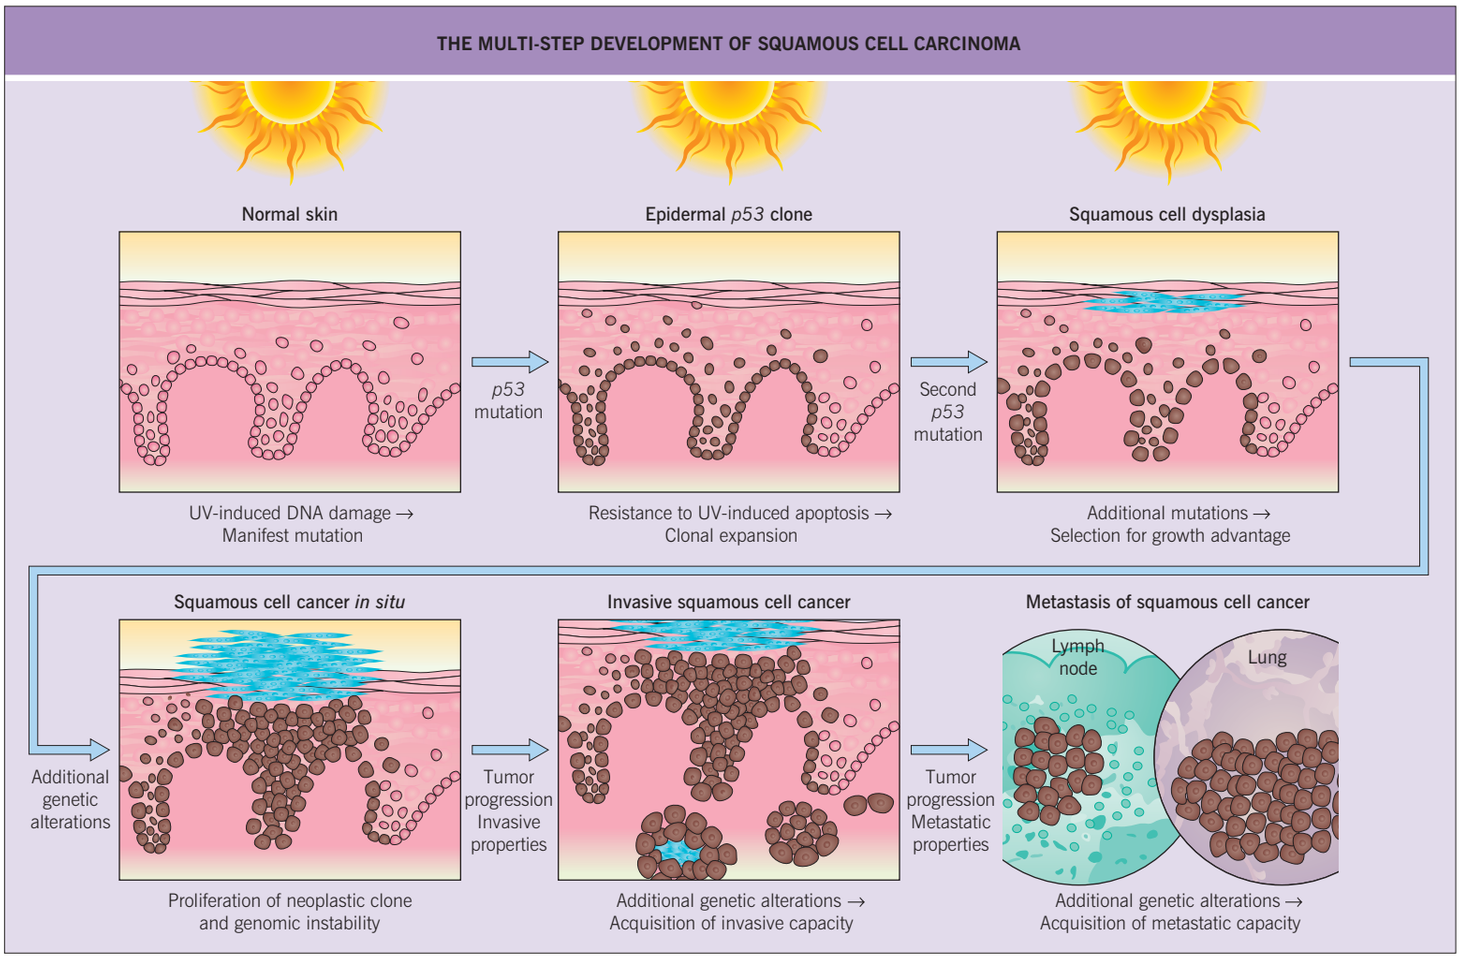

Fig. 107.12 The multistep development of squamous cell carcinoma. UV irradiation of normal skin induces mutations in keratinocytes and facilitates clonal expansion of keratinocytes with a mutated *p53* gene. Additional mutations (including a second *p53* mutation) that affect genes controlling proliferation, cell migration and cell death provide for selective growth advantage and cause genomic instability. The final result is metastatic tumor cells, capable of growing in regional lymph nodes and internal organs.

malignant phenotype. A limitation of the chemical carcinogenesis model is that it is different from UV-induced carcinogenesis, in particular *H-ras* is not implicated as a key oncogene in human SCC. A second murine skin carcinogenesis model is UVB-induced SCC in the hairless, SKH-1 mouse. Skin tumors in this model have a high frequency of *p53* mutations and low incidence of *Ras* mutations.

Invasive SCCs can have different degrees of differentiation. Highly differentiated tumors show features of keratinization and often invade the dermis with a broad rounded tumor margin. Papillomatous extensions and cords of slightly atypical squamous epithelia grow down into the dermis. Verrucous SCC, which very rarely metastasizes, is considered a special variant of highly differentiated SCC. Poorly differentiated SCCs show more anaplastic cytologic features and the squamous cell phenotype can sometimes only be verified via immunohistochemistry with antikeratin antibodies.

In general, poorly differentiated desmoplastic SCC exhibits a higher grade of malignancy[35]. However, biologic behavior can rarely be predicted by the degree of differentiation alone. SCC is dependent on a supportive stroma, as are all other solid tumors, and a vasculature induced by angiogenic signals is needed for the tumor to enlarge. Unlike the stroma surrounding a BCC, the SCC stroma is considered nonspecific and cell–cell interactions between tumor cells and stromal cells are not well characterized. SCC thus has the potential to grow at sites distant from the primary tumor.

Alterations in the *p53* gene are the most common genetic abnormalities found in actinic keratoses, SCC *in situ* and invasive SCC, and dysregulation of p53 pathways appears to be an early event in carcinogenesis of SCC. In typical cases, one allele contains a missense point mutation with a UV signature at dipyrimidine sites, while the remaining *p53* allele is deleted. Studies utilizing *p53* mutations as a clonality marker have suggested a direct relationship between actinic keratoses, SCC *in situ* and invasive SCC. By studying individual patients with lesions (e.g. SCC) adjacent to various morphologic entities (e.g. actinic keratoses), a genetic link has been found between coexisting lesions. The conclusion from these studies is that coexisting lesions represent different stages in SCC development.

One possible role for early *p53* mutations in SCCs (analogous to the situation in BCCs) is resistance to apoptosis, allowing for clonal expansion at the expense of neighboring keratinocytes containing a normal (wild-type) *p53* gene. Another common genetic aberration is mutation or epigenetic silencing of the *CDKN2A* locus. The most common mechanism of inactivation is promoter methylation[37]. The frequency of activating mutations in the oncogene *ras* ranges from 10% to 50%, depending on the experimental technique used and the site of the tumors analyzed. Amplification of the *c-Myc* oncogene has been reported in up to 50% of SCCs from immunosuppressed patients, often as a result of amplification of the chromosomal locus[38].

Loss of heterozygosity has been studied in different chromosomes, and unlike the case in BCC, where LOH is mainly restricted to chromosome 9q, actinic keratoses and SCCs demonstrate a more widespread LOH pattern with deletions in several chromosomes, e.g. 3p, 4p, 9p, 9q, 13q, 17p and 17q34 and gains of 3q, 8q and 20q. A recent study using high-resolution single nucleotide polymorphism microarrays of 60 SCC tumors showed that the most frequent aberrations were LOH at 3p and 9p, observed in 65% and 75% of tumors, respectively[39]. Three tumors had homozygous deletions within the fragile histidine triad (*FHIT*) gene at 3p14 and homozygous and heterozygous deletions were also found in the protein tyrosine phosphatase receptor type D (*PTPRD*) gene at 9p23 in 9 of 60 tumors. This study also revealed uniparental disomy (UPD) as a mechanism of copy number-neutral LOH in SCC.

Of note, UPD results in loss of one allele and subsequent duplication of the remaining allele (see Ch. 54). Poorly differentiated tumors had a greater number of chromosomal aberrations than well-differentiated tumors[39].

Recently, loss-of-function mutations in *NOTCH1* or *NOTCH2* were identified in 75% of cutaneous SCCs[39a]. These genes encode cellular receptors whose signalling pathways interact with that of the Wnt/β-catenin pathway (see Fig. 113.3).

Summary

In summary, SCC arising in chronically sun-exposed skin is a common tumor for which cumulative sun exposure is an important etiologic factor. SCC arises through a series of stages involving precursor lesions, such as actinic keratoses, and in high-risk cases results in metastasis to regional lymph nodes and elsewhere.

RELATED DISEASES

Adnexal Tumors

Tumors that mimic cutaneous adnexal differentiation display a multitude of different phenotypes (see Ch. 111). A majority of these tumors are benign, although malignant counterparts do exist. The degree of differentiation allows these tumors to be distinguished from BCC and SCC. An organoid nevus, e.g. nevus sebaceus of Jadassohn, represents a cutaneous malformation that includes pilosebaceous structures. Such lesions harbor an increased risk for the development of BCC and other adnexal tumors (e.g. trichoblastoma). The genetic background of a BCC arising in an organoid nevus is unclear, but one can speculate that such a developmental malformation contains an increased number of stem cells that could act as target cells for transformation into BCC.

Keratoacanthoma

Keratoacanthomas represent tumors characterized by the proliferation of atypical, highly differentiated squamous epithelia. Clinically, and even more so microscopically, keratoacanthomas resemble SCC. Clear distinction from a highly differentiated SCC is often impossible. However, the clinical course is usually benign and lesions are believed to undergo spontaneous regression if not excised. Sporadic cases with *p53* mutations and/or overexpression of p53 protein have been reported. Although microsatellite instability and LOH have been reported in keratoacanthomas from patients with the mismatch repair-deficient and cancer-prone Muir–Torre syndrome, sporadic keratoacanthomas appear to be more genetically stable. Ferguson–Smith syndrome, an autosomal dominant condition characterized by multiple keratoacanthomas, has recently been shown to be due to mutations in the *TGFBR1* gene[40].

Xeroderma Pigmentosum

Xeroderma pigmentosum (XP) represents a family of DNA repair syndromes, some of which are caused by inherited defects in nucleotide excision repair (NER) genes (see Ch. 86), resulting in a complex skin pathology including lentigines, epidermal hyperplasias, BCCs, SCCs and cutaneous melanomas triggered by exposure to the sun. Due to the deficient DNA repair, the rate at which skin cancers develop in young XP patients is increased at least 1000-fold. The variant form of XP is caused by mutations in DNA polymerase eta (Poleta) which has been recently shown to act like a "molecular splint" to stabilize damaged DNA[41].

Li–Fraumeni Syndrome

The Li–Fraumeni syndrome is a rare familial cancer syndrome where germline mutations of the *p53* gene play an important role. The syndrome is characterized by an autosomal dominant inheritance pattern and affected individuals display an early onset of various tumors, including breast cancer, brain tumors, osteosarcoma and leukemia. Excessive genomic DNA copy number variation has recently been described in this syndrome, accounting for variation in phenotypes in affected families[42]. However, skin cancer is not a typical feature of Li–Fraumeni syndrome, despite the fact that *p53* mutations are frequently observed in BCCs and SCCs.

Gorlin Syndrome

The most common inherited disorder associated with BCCs is the Gorlin syndrome (see above); it is transmitted in an autosomal dominant fashion. Affected individuals have a wide range of developmental anomalies, including skeletal abnormalities, craniofacial dysmorphism and macrocephaly. Multiple BCCs with an early onset are a hallmark of the syndrome which also includes features such as odontogenic keratocysts, palmoplantar pits and calcification of the falx cerebri. In addition to BCCs, patients have an increased incidence of medulloblastomas, meningiomas, ovarian fibromas and ovarian cancer, as well as cardiac fibromas. Germline mutations in the *PTCH* gene are found in the vast majority of patients with this syndrome.

Bazex Syndrome

Bazex syndrome is a rare genodermatosis characterized by follicular atrophoderma and the early onset of multiple BCCs. The responsible gene has been linked to Xq24–q27 and there is no male-to-male transmission. It should not be confused with acrokeratosis paraneoplastica, also known as Bazex syndrome, which occurs most commonly in the setting of carcinomas of the upper aerodigestive tract (see Ch. 53).

Chapter Contents

Actinic keratosis and squamous cell carcinoma *1777*
Basal cell carcinoma *1784*

Synonyms: ■ Solar keratosis and senile keratosis are non-preferred synonyms for actinic keratosis (solar keratosis is abbreviated to SK, causing confusion with seborrheic keratosis) ■ Bowen's disease – squamous cell carcinoma *in situ* ■ Basal cell epithelioma and rodent ulcer are antiquated synonyms for basal cell carcinoma ■ Basal cell nevus syndrome is a non-preferred synonym for nevoid basal cell carcinoma syndrome (Gorlin syndrome)

Key features

- Non-melanoma skin cancer (NMSC) represents the most frequently observed malignancy amongst Caucasians
- The major risk factor for NMSCs is UV light exposure; other factors include exposure to ionizing radiation, arsenic or organic chemicals, human papillomavirus infection, immunosuppression, and genetic predisposition
- Prevention efforts are aimed at lowering incidence and mortality via educational programs and sun protection campaigns
- NMSC, if neglected or inappropriately managed, can cause significant morbidity and even death
- Surgery is the mainstay of treatment, but promising new modalities include immunomodulators, photodynamic therapy, and drugs that address genetic defects

INTRODUCTION

Non-melanoma skin cancer (NMSC), specifically basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), represents the most frequently observed malignancy amongst Caucasians. In individuals with fair skin, approximately 75–80% of NMSCs are BCCs and up to 25% are SCCs[1]. Because the incidence of NMSC continues to rise, these neoplasms represent a significant health problem from the standpoint of patients' well-being and from the perspective of healthcare expenditures.

HISTORY

In 1775, Sir Percivall Pott noted an etiologic relationship between SCC and chimney soot exposure in his short treatise *Chirurgical Observations Relative to the Cancer of the Scrotum*. During the Industrial Revolution, links to arsenic, coal tar, shale oil and creosote were also identified. In the late 1800s, Paul Unna noted a connection to UV light, when he described skin cancer development in chronically sun-exposed sites in sailors.

Evidence of the nevoid basal cell carcinoma syndrome, consisting of jaw cysts, syndactyly and bifid ribs, has been identified in Egyptian mummies almost 4000 years old. In the 1850s, H Lebert first used the term "rodent ulcer" to describe untreated BCCs of long duration. Several years later, Sir Jonathan Hutchinson published a review of 42 cases of BCCs, identifying the tumor as a single entity with many different clinical and histopathologic forms. Krompecher first suggested that a BCC arose from the cells of the basal layer of the epidermis, but there were additional theories regarding the site of origin of this tumor, including from the hair follicle and other adnexal structures. Some authors hypothesized that a BCC was not a carcinoma but rather a nevoid tumor or hamartoma or that a BCC was derived from immature pluripotential cells which formed continuously during one's lifetime.

EPIDEMIOLOGY

NMSC occurs worldwide in all races. It is estimated that more than 3.5 million NMSCs occurred in approximately 2.5 million individuals in the US in 2006[2]. There are more skin cancers in the US population than there are all other cancers combined and it is estimated that one in five Americans will develop skin cancer during their lifetime[3] (over 95% will be NMSC). The most important factor related to development of these neoplasms appears to be skin phenotype (Table 108.1)[4–11], but other factors also play a significant role. As an example, the incidence of NMSC is about ten times higher in white versus Hispanic men and five times higher in white versus Hispanic women[12].

The exact incidence of NMSC may be difficult to determine due to issues such as diagnostic accuracy and diagnostic criteria (e.g. differentiation between AKs and SCC *in situ*). In addition, deriving precise data on NMSC is hampered by the fact that these neoplasms are not routinely included in state cancer registries (which often rely upon hospital data). Even if NMSCs were included, they would still be significantly underreported, given the number treated in private offices.

The amount of average annual UV radiation correlates with the incidence of skin cancer. There is also a direct relationship between the incidence of NMSC and latitude (Table 108.2), in that the closer individuals are to the equator, the greater their exposure to UV radiation. In Australia, the cumulative risk by age 70 years of having at least one NMSC is 70% for men and 58% for women. Incidence of NMSC increases with age, with a sharp increase in BCCs in men after the age of 60 years. In those under 40 years of age, the majority of NMSC is found in women, but, by age 80, the incidence in men exceeds that in women by a 2–3 : 1 ratio[12].

Actinic keratoses (AKs) are most often found in fair-skinned individuals, but can be seen in all races. AKs are so common that it has been estimated that currently up to 12% of individuals in the US have them[14]. In the UK, incidence rates for AKs are approximately 15 times those for BCC and SCC. Over 80% of AKs occur on the head, neck and upper extremities (dorsal hands and forearms). AKs develop much more often in individuals with a prior history of AKs, with increasing age, and in men. AKs are also markers for an increased risk for developing invasive SCC[15].

The demographics of ***SCC*** are similar to those of AKs, with the majority of SCC occurring on the head, neck and upper extremities[16]. In light-skinned populations, the degree of UV exposure is related to SCC development. On the other hand, in darkly pigmented populations, the pathogenesis of SCC may be unrelated to sun exposure, but rather may relate to chronic irritation or injury. SCC is found more frequently in men (3 : 1 male : female) and the incidence increases significantly after age 60 years[12]. The incidence of SCC has been rising worldwide in all age groups over the last several decades at an estimated 3–10% per year, with over 250 000 cases of invasive SCC diagnosed annually in the US. Similar incidence trends have been noted worldwide.

Weinstock[17] reported an age-adjusted mortality rate for confirmed cases of SCC in Rhode Island of 0.26/100 000. SCC-associated

INFLUENCE OF SKIN COLOR ON EPIDEMIOLOGY OF NMSC		
Characteristic	**Lightly pigmented individuals**	**Darkly pigmented individuals**
NMSC incidence	230 per 100 000	3.4 per 100 000
BCC:SCC ratio	4:1	1.1:1
BCC male:female ratio	1.5:1	1.3:1
SCC male:female ratio	2:1–5:1	1.3:1
% of BCCs developing in the head and neck region	60–80	90
% of SCCs developing in the head and neck region	65	35
% of SCCs developing in scars and chronic non-healing ulcers	<2	30–40
NMSC incidence rates	Increasing	?
NMSC mortality rates	Decreasing	Decreasing
% of skin cancer deaths due to NMSC in persons <50 years of age	10*	70
% of skin cancer deaths due to NMSC in persons >85 years of age	55	60

*Majority due to cutaneous melanoma.

Finland (1999)	62° N	49/45	7/4	56/49

Table 108.2 Comparison of latitude and incidence (per 100 000) of basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). All these data refer to Caucasian populations. Adapted from ref. 13. NMSC, non-melanoma skin cancer.

mortality is higher in whites and older persons, and men have a 3:1 greater SCC mortality rate as compared to women[17]. SCCs located on the ear, lip and genitalia appear to have a higher risk of death. While melanoma among whites is responsible for 90% of skin cancer deaths before 50 years of age (see Table 108.1), in adults over 85 years of age, the majority of skin cancer deaths are attributable to SCC[5].

BCC is the most common skin cancer in humans, and men generally have higher rates of BCC than do women (1.5–2:1)[18]. Over the last 30 years, it is estimated that incidence rates have risen between 20% and 80%. In the US, a disproportionate increase has been observed in young women. Similar increases in incidence rates have been noted worldwide, with the incidence doubling in Finland and Switzerland and increasing in Wales by 50% over the past two decades.

Incidence rates for BCC also increase with age and the median age at diagnosis is 68 years. In Queensland, Australia, age-adjusted incidence rates for BCC in 1996 were 2074 and 1579 per 100 000 per year for men and women, respectively – the highest rates for any specific cancer ever reported. In this geographic location, SCC occurred at half the rate of BCC among men and at about one-third the rate among women (see Table 108.2).

Mortality from BCC is quite rare and occurs primarily in immunocompromised patients and individuals with nevoid basal cell carcinoma (NBCC) syndrome. Cases of metastatic BCC are more likely from tumors with aggressive histopathologic patterns (morpheaform, infiltrating, metatypical, basosquamous). Perineural growth may be an indicator of aggressive disease. Metastases often involve regional lymph nodes, lungs, bone and skin. The mean age at the time of death is higher than with SCC, and the age-adjusted mortality rate for BCC has been estimated at 0.12 per 100 000. Mortality risk is related to increasing age, Caucasian race and male gender (>2× compared to women).

PATHOGENESIS

See Chapter 107.

RISK FACTORS (Table 108.3)

Environmental Exposures

UV radiation

UV exposure is the predominant cause of BCC and cutaneous SCC as evidenced by migrant studies, the correlation of incidence to latitude, and animal studies. There is, however, a difference in the type of UV exposure (see Table 108.3). For BCCs, intermittent intense episodes of UV exposure and sunburns at any age appear to increase risk, whereas cumulative long-term UV exposure and childhood sunburns increase the risk for developing SCCs and AKs[13,19].

As outlined in Table 108.2, the incidence of NMSC is inversely related to latitude. In addition, sun exposure early in life appears to have a greater influence on subsequent skin cancer risk than at a later age. For example, individuals born in countries with high ambient UV radiation such as Australia have significantly higher incidence rates of NMSC as compared to those with a similar genetic background (e.g. British, northern Europeans) who migrated to these locales later in life from countries with lower ambient UV radiation[13,20,21].

Tanning lamp usage

Several studies have demonstrated an increased risk for the development of NMSC in those who are exposed to artificial sources of UV radiation. Intentional tanning has been shown to increase the risk of SCC development[22] and Karagas et al.[23] demonstrated that any use of tanning devices was associated with odds ratios of 2.5 for SCC and 1.5 for BCC, even after adjustment for history of sunburns, sunbathing and sun exposure. In one study, women with BCCs had on average twice as many visits to tanning beds than did matched controls[24].

Therapeutic UV exposure

Individuals with psoriasis have been shown to be at increased risk for the development of NMSC. While long-term follow-up of psoriasis patients who underwent UV plus tar (Goeckerman) therapy found no increase in NMSC risk, long-term PUVA therapy was associated with a significant, dose-related risk of SCC development (adjusted relative risk = 8.6 for an accumulated exposure of between 100 and 337 treatments)[25]. With prolonged therapy, a slightly increased risk for BCC development was noted as well. In addition to the direct effects of PUVA, PUVA-induced immunosuppression may also play a role.

Ionizing radiation

Exposure to ionizing radiation leads to a threefold increased risk of NMSC[26]. The risk is in proportion to the radiation dose. Larger fractionated doses (>12–15 Gy) are thought to be necessary to induce tumor

RISK FACTORS FOR THE DEVELOPMENT OF BASAL CELL CARCINOMAS (BCCS) AND SQUAMOUS CELL CARCINOMAS (SCCS)	SCC	BCC
ENVIRONMENTAL EXPOSURES		
Cumulative/occupational sun exposure	+	
Intermittent/recreational sun exposure		+
Other exposures to UV light (PUVA, tanning beds)	+	+

*Both SCCs (keratoacanthoma type) and BCCs typically have sebaceous differentiation.
†More often trichoblastomas.

Table 108.3 Risk factors for the development of basal cell carcinomas (BCCs) and squamous cell carcinomas (SCCs). HPV, human papillomavirus.

CHEMICALS ASSOCIATED WITH THE DEVELOPMENT OF NON-MELANOMA SKIN CANCER
Mineral oil
Coal tar
Soot
Polychlorinated biphenyls
Arsenic
4,4′ bipyridyl
Psoralen (plus UVA)
Nitrogen mustard

Table 108.4 Chemicals associated with the development of non-melanoma skin cancer. Based on ref. 30.

formation, so the risk with a given total dose may be less if a larger number of smaller fractionated doses are given. Most SCCs and BCCs that arise after exposure to ionizing radiation do so after a long latency period of up to several decades, with most tumors appearing ~20 years after the initial exposure.

Treatment of tinea capitis with radiation (prior to the discovery of effective systemic antifungal medications) has been linked to the development of multiple BCCs. In a study of 2224 children given X-ray therapy for tinea capitis (compared to a control group of 1380 tinea capitis patients given only topical medications), the relative risk for developing BCC of the head and neck among irradiated Caucasians was 3.6[27]. BCCs have been observed in radiation fields following treatment of port-wine stains and Hodgkin disease as well as after accidental exposure[28].

Occupational risk factors

Persons with outdoor occupations have a higher risk of developing NMSC. Airline pilots, who are exposed to ionizing radiation at flight altitudes, have been shown to have an elevated risk for both BCC and SCC[29]. Other occupations associated with an increased risk for NMSC include textile workers, sailors, locomotive engineers and agricultural workers.

Chemical exposures

Multiple organic chemicals have been associated with an increased risk for the development of NMSC[30] (Table 108.4). Occupational chemical exposures which can lead to skin cancer most commonly involve pesticides, asphalt, tar and polycyclic aromatic hydrocarbons, and they typically result in SCC. NMSCs induced by chemical exposures are usually localized, most often on the arms, and are usually multiple[31].

Arsenic is a well-defined cause of SCC (see Ch. 88). A clue to arsenic exposure is the presence of palmoplantar arsenical keratoses. The SCCs that arsenic induces are often multiple[28]. Increasing evidence indicates that arsenic acts as a tumor promoter by modulating the signaling pathways responsible for cell growth[32]. BCC has also been reported with extensive arsenic exposure. The typical latency period from exposure to clinical appearance of NMSC is 20–40 years[33].

Human papillomavirus infection

Human papillomaviruses (HPV) represent a large group of DNA tumor viruses that infect the epithelia of both skin and mucosae, inducing hyperproliferative lesions, most commonly warts. In addition to the association between HPV and anogenital SCCs, including in HIV-infected patients, individuals with epidermodysplasia verruciformis (EV) are known to have a significantly increased risk of developing SCCs, especially in sun-exposed sites (see below). Infection with the HPV types referred to as EV- or beta-types (see Table 79.1) is also observed in the general population, in particular in immunosuppressed organ transplant recipients[34]. Because specific HPV subtypes are thought to act as co-carcinogens in conjunction with UV in the early development of SCC[35], a current focus of research is the development of HPV vaccines that address this issue[36].

Immunosuppression

Organ transplantation

Organ transplant recipients have a markedly increased incidence of NMSC, primarily SCC. The incidence of BCC in organ transplant recipients is up to five to ten times greater than in the general population, while the incidence of SCC is 40–250 times greater. Risk factors include skin type, cumulative sun exposure, age at transplantation, and the degree and the length of immunosuppression.

SCC is a significant cause of morbidity and mortality in transplant recipients[37,38]. The pathogenesis of skin cancer in transplant recipients is multifactorial, involving decreased immunity, direct carcinogenic effects of immunosuppressive medications, HPV infection and UV light exposure. Transplant recipients are prone to develop numerous lesions and are more likely to suffer local and regional recurrences and metastases (Fig. 108.1)[37]. AKs and SCCs begin to appear with increasing frequency several years after transplantation. Lesions are often multiple, and usually develop in sun-exposed areas. HPV DNA is found in approximately 70–90% of transplant-associated SCCs. Tumors from transplant recipients contain HPV strains that occur in common benign cutaneous warts (HPV types 1 and 2), EV (HPV-5 and others), high-risk oncogenic warts (HPV types 16 and 18) and low-risk oncogenic genital warts (HPV types 6 and 11). Sometimes, several HPV types are detected within a single tumor.

In one series of renal transplant patients from the US, 5% of the patients died of skin cancer. In another series of heart transplant patients from Australia, 27% died of skin cancer. Two-thirds of these deaths were due to SCC. Patients who receive hematopoietic transplants do not experience this marked increase in skin cancer incidence (unless they have received long-term voriconazole), presumably because of a shorter duration of immunosuppression.

Fig. 108.1 Recurrent squamous cell carcinoma in a patient who had received a solid organ transplant. *Courtesy, John Carucci, MD.*

Immunosuppressive drugs

Use of immunosuppressive drugs, other than for organ transplantation as discussed previously, also increases the risk for the development of NMSC (particularly SCC). Risk of SCC development is directly related to length of immunosuppressive drug usage. In one study, the risk of SCC was significantly increased among recipients of oral glucocorticoids (odds ratio = 2.31) and the risk of BCC was also elevated (odds ratio = 1.49)[39].

HIV infection

Patients with HIV infection are at increased risk for the development of several cancers, including cutaneous SCC[40]. The incidence of HPV-related SCC of the anus is significantly increased in this population. Serial examinations and anal cytologies are recommended for surveillance. The biologic behavior of these SCCs can be aggressive.

Other risk factors

Other possible risk factors include residence at high altitudes, thermal burns, chronic ulcers and tobacco abuse[41]. While evidence from animal models suggested a relationship between fat intake and skin cancer incidence, results from subsequent epidemiologic studies were inconsistent and failed to show any strong evidence for either this association or for other dietary factors (e.g.vitamins, minerals)[34,42–44].

Genetic Risk Factors

Genetic predisposition

Phenotypic characteristics such as red hair, light skin, poor ability to tan and freckling have been identified as risk factors for melanoma as well as NMSC[13]. Pigmentation is a polygenic trait, with polymorphisms in several genes leading to the variation observed in the human race (see Table 65.5). A key gene encodes the human melanocortin-1 receptor (MC1R) which is expressed on the cell surface of melanocytes. Population-based studies in diverse ethnic groups have shown that the coding region of the human *MC1R* is remarkably polymorphic (see Fig 65.14). In Caucasians, there is a strong association between nine common *MC1R* variant alleles and the red hair/fair skin phenotype, thus placing these individuals at higher risk of photocarcinogenesis[45].

Genetic syndromes associated with increased NMSC risk

Xeroderma pigmentosum

Xeroderma pigmentosum (XP) consists of a group of autosomal recessive disorders characterized by defects in unscheduled DNA repair (see Ch. 86). A markedly increased incidence of NMSC and melanoma is observed in these individuals, if they are exposed to sunlight. NMSCs appear at an early age (median age, 8 years) and the risk of NMSC in affected individuals who are <20 years of age is 4800 times that of the general population. Strict UV avoidance can significantly decrease NMSC formation.

Oculocutaneous albinism

Oculocutaneous albinism encompasses a group of autosomal recessive disorders in which there is a variable degree of pigmentary dilution of the skin, eyes and hair (see Ch. 66). At a relatively early age, NMSC, especially SCC, and cutaneous melanoma develop with increased frequency. As in XP, strict sun avoidance for life can greatly minimize tumor development. However, metastatic cutaneous SCC is still a significant problem in areas of the world such as equatorial Africa.

Epidermodysplasia verruciformis

Epidermodysplasia verruciformis (EV) is a rare, usually recessively inherited disorder in which there is widespread colonization of the skin by HPVs of multiple subtypes (see Ch. 79). Evidence for an association between cutaneous HPV infection and SCC was first reported in these patients. One-third to one-half of patients will develop SCCs as adults, usually in sun-exposed regions, and several decades earlier than is typical for SCC development in the general population. Aggressive biologic behavior, including perineural spread, metastases and death, have been reported. HPV subtypes most frequently identified in the SCCs that arise in EV patients are 5 and 8.

Dystrophic epidermolysis bullosa

Dystrophic epidermolysis bullosa associated with significant scarring can result from both dominant and recessive mutations in the type VII collagen gene. SCCs more commonly appear in the recessive forms, where they are the most common cause of death. Tumors usually develop during the third to fifth decades of life, are frequently multiple, and demonstrate aggressive behavior in terms of recurrences and metastases. Whether this aggressive biologic behavior is due to tumor development within scars and chronic non-healing wounds, to specific mutations in the type VII collagen gene, or to elevated levels of basic fibroblast growth factor, is uncertain.

Nevoid basal cell carcinoma (NBCC) syndrome

Nevoid basal cell carcinoma syndrome (NBCC syndrome; Gorlin syndrome) is a rare, autosomal dominant disorder due to a mutation in the human *PTCH* gene[46].

Manifestations of the syndrome include multiple or early-onset BCCs, odontogenic keratocysts of the jaw, palmoplantar pits, calcification of the falx cerebri, and skeletal anomalies (Table 108.5). Affected individuals may develop specific neoplasms such as medulloblastomas, meningiomas, (bilateral) ovarian fibromas and cardiac fibromas. Of note, the medulloblastomas usually arise during early childhood, so suspicion of NBCC syndrome at early age allows screening of at-risk individuals[46].

BCCs usually appear after puberty, but they may develop during childhood. The number of BCCs in a single patient varies from a few to more than a thousand (Fig. 108.2). The BCCs favor the sun-exposed areas of the face, neck and upper trunk, but may occur in sun-protected sites. As in the general population, nodular BCCs usually occur on the face, while superficial BCCs are found primarily on the torso. Individual lesions may be papulonodular, pedunculated, pigmented, eroded, ulcerated, or have a combination of these features. The BCCs are sometimes mistakenly diagnosed clinically as melanocytic nevi, angiomas or even skin tags. The clinical course of the cutaneous tumors is usually indolent prior to puberty, after which they enlarge and eventually ulcerate, as in the general population. Individuals with NBCC syndrome are exquisitely sensitive to ionizing radiation, and hundreds of tumors can develop in children within radiation ports following radiotherapy for medulloblastoma. Additional cutaneous findings include epidermoid inclusion cysts and facial milia.

Bazex syndrome and Rombo syndrome

Bazex syndrome is a rare condition, consisting of follicular atrophoderma (usually occurring as circumscribed areas on the dorsal aspect of the hands and feet), hypotrichosis, localized hypohidrosis, milia, epidermoid cysts, and multiple, primarily facial, BCCs. Genetic transmission in most families appears to occur in an X-linked dominant fashion. Sometimes a source of confusion is the completely different

DIAGNOSTIC CRITERIA FOR NEVOID BASAL CELL CARCINOMA (NBCC) SYNDROME
MAJOR CRITERIA
1. More than two BCCs or one BCC before the age of 20 years
2. Odontogenic keratocysts of the jaw (proven by histology)
3. Three or more palmar or plantar pits
4. Bilamellar calcification of the falx cerebri
5. Bifid, fused or markedly splayed ribs
6. First-degree relative with NBCC syndrome
MINOR CRITERIA
1. Macrocephaly (determined after adjustment for height)
2. Congenital malformations: cleft lip or palate; frontal bossing; "coarse face"; moderate or severe hypertelorism
3. Other skeletal abnormalities: Sprengel deformity*; marked pectus deformity; marked syndactyly of the digits
4. Radiographic abnormalities: bridging of the sella turcica; vertebral anomalies such as hemivertebrae and fusion or elongation of the vertebral bodies; modeling defects of the hands and feet; flame-shaped lucencies of the hands or feet
5. Bilateral ovarian fibroma
6. Medulloblastoma
*Unilateral elevation of smaller-sized scapula.

Table 108.5 Diagnostic criteria for nevoid basal cell carcinoma (NBCC) syndrome. The diagnosis of NBCC syndrome requires ***two major or one major and two minor criteria***. BCC, basal cell carcinoma. Adapted from ref. 46.

Fig. 108.2 Nevoid basal cell carcinoma (NBCC) syndrome. A Numerous small and several large nodular BCCs on the face. **B** Three superficial BCCs and one large nodular BCC on the chest of a younger man.

Bazex syndrome (acrokeratosis paraneoplastica), in which psoriasiform plaques of the fingers, toes, ears and nose are often associated with SCC of the upper aerodigestive tract. In the follicular atrophoderma form of Bazex syndrome, BCCs develop in the second decade of life and frequently have a trichoepithelioma-like histopathologic appearance.

The so-called Rombo syndrome has many of the features of Bazex syndrome. Patients have an atrophoderma vermiculatum-like appearance on the cheeks, with evidence of sweat duct proliferation histologically. In addition, they often have hypotrichosis, blepharitis, peripheral (facial/acral) telangiectatic erythema, milia, trichoepitheliomas, and BCCs.

Risk of Additional Cancers

Individuals who have had a BCC or SCC are at increased risk for the development of additional BCCs and SCCs[47], compared to the general population. Patients with NMSC are also at increased risk for developing cutaneous melanoma[48]. In addition, persons with a history of NMSC are at increased risk for developing and dying from other (non-skin) cancers[49,50].

ACTINIC KERATOSIS AND SQUAMOUS CELL CARCINOMA

Clinical Features

Actinic keratosis

AKs were initially described as solar keratoses (due to their suspected cause) and senile keratoses (due to the age of onset). The term "actinic keratosis" is relatively recent. The latter term is preferred over solar keratosis, partly because the abbreviation SK also stands for seborrheic keratosis.

AKs have historically been characterized as being "precancerous" or "premalignant" because the atypical keratinocytes within these lesions are confined to the epidermis. There is no risk of metastasis until these lesions evolve into invasive carcinoma. An alternative minority view is that it is not accurate to deem them "premalignant" because they are malignant in the same sense as Bowen's disease (SCC *in situ*) or intraepithelial melanoma (melanoma *in situ*). The likelihood of an invasive SCC evolving from a given AK has been estimated to occur at a rate of 0.075–0.096% per lesion per year. For example, for a person with 7.7 AKs, the average number present on the skin of an affected individual, SCC would develop at a rate of 10.2% over 10 years. Other estimates are even higher, with rates of 13–20% over a 10-year period (if the lesions were left untreated). These rates are similar to those that have been determined for intraepithelial neoplasia of other sites. In the uterine cervix, approximately 15% of all untreated low- and moderate-grade cervical intraepithelial neoplasia lesions (CIN I and II) will progress to carcinoma *in situ* (CIN III) and to more advanced carcinoma involving deeper tissues, if left untreated. This process generally occurs over 10 to 20 years, although in some patients this interval may be as short as 6 months. Because of this continuum of progression of AKs in the skin, the analogous term keratinocytic intraepithelial neoplasia (KIN I, II and III) has been proposed, but has not gained widespread use. Possible explanations for this include the common phenomenon of spontaneous resolution of AKs, the very low rate of progression to invasive SCC, and concern regarding overaggressive therapies being employed.

AKs are amongst the most frequently encountered skin lesions in clinical practice. They present on sun-damaged skin of the head, neck, upper trunk and extremities (Fig. 108.3A). Individuals at higher risk of developing AKs include the elderly, those with lighter skin phototypes and those with a history of chronic sun exposure. The primary lesion

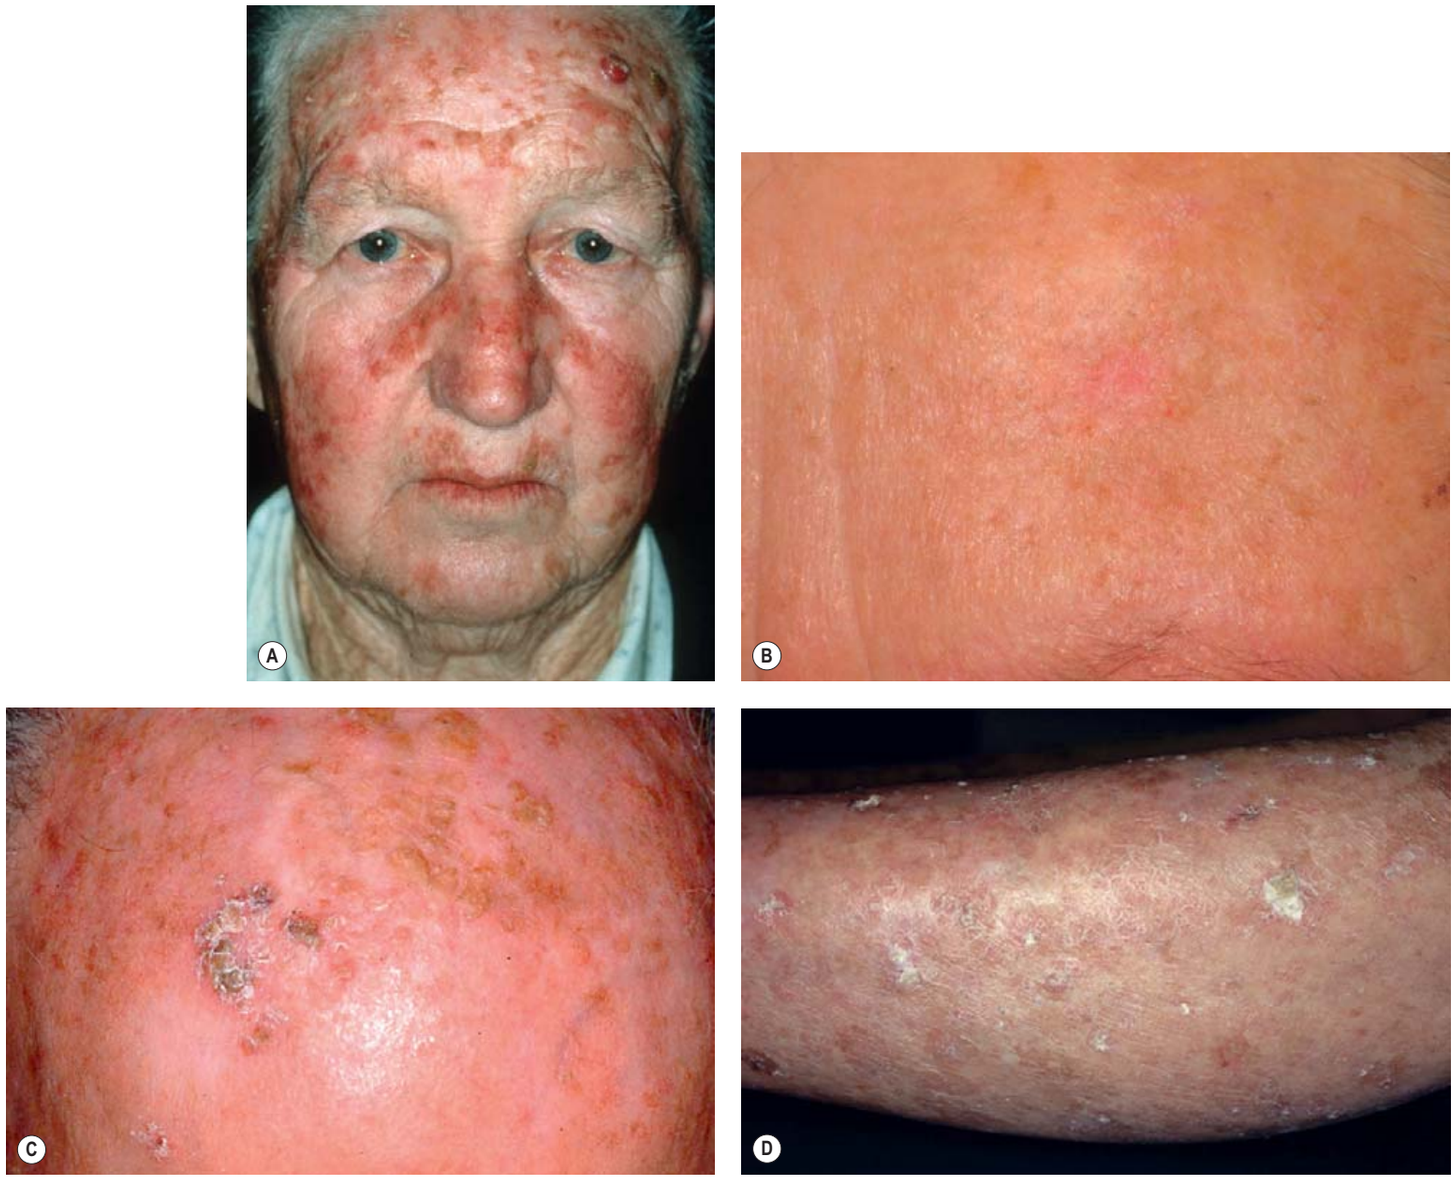

Fig. 108.3 Actinic keratoses (AKs). A Multiple AKs on the face of an elderly woman with fair complexion, blue eyes, and moderate to severe photodamage; the AKs vary in size from a few millimeters to over a centimeter. On the left forehead, the red nodule with slight scale-crust represents a well-differentiated SCC. **B** Pink-colored atrophic AK with minimal scale on the forehead. **C** Numerous hypertrophic AKs on the bald scalp with hypopigmentation at sites of previous treatment. **D** Multiple, large hypertrophic AKs on the shin of an elderly woman; note the thick scale. *B, Courtesy, Iris Zalaudek, MD; D, Courtesy, Jean L Bolognia, MD.*

is a rough erythematous papule with white to yellow scale. Patients may report tenderness. AKs can range in size from a few millimeters to large confluent patches several centimeters in diameter, especially in patients with severe photodamage. One of the earliest signs is slight erythema with almost imperceptible scale (Fig. 108.3B), although some lesions are devoid of visible erythema and present only as slight scale with indistinct borders. A clue to their presence is background photodamage, i.e. dyspigmentation, telangiectasia and wrinkling (see Ch. 87). Advanced lesions are typically thicker and well-defined with more visible hyperkeratosis and erythema. Lesions typically are clustered in areas of highest sun exposure, such as the superior helices of the ears, upper forehead, supraorbital ridge, nasal bridge, malar eminences, dorsal hands, extensor forearms, shins and the bald scalp (Fig. 108.3C).

Any region of the body can be affected if enough actinic damage has occurred. Visual inspection is best performed with simultaneous palpation to detect lesions that may not be readily apparent. This is especially true in individuals with significant background erythema from chronic sun exposure or rosacea. Tenderness on palpation should alert the clinician to the possibility that the lesion has evolved into carcinoma. Clinical subtypes of AKs include the classic variant already described, hyperplastic (or hyperkeratotic), pigmented, lichenoid, atrophic, bowenoid, and actinic cheilitis.

Hyperkeratotic (hypertrophic) AKs are easily identified on visual inspection as papules and plaques with scale or scale-crust and an erythematous base (Fig. 108.3D). The erythematous base often extends beyond the overlying hyperkeratosis. The hyperkeratotic scale can become white or yellow–brown over time (see Fig. 108.3C). Patients often find these lesions annoying due to their thickness. Sometimes, distinction from SCC can be difficult and biopsy is warranted. Occasionally, hyperkeratotic AKs may develop cutaneous horns which manifest as columns of thick cornified material that protrude above the skin. These should be biopsied to exclude the possibility of an underlying malignancy, as approximately 15% of cutaneous horns have invasive SCC at their bases[51].

Pigmented AKs, sometimes called superficial pigmented AKs (SPAKs), represent a subtype that often lacks associated erythema and has a hyperpigmented or reticulated appearance. These lesions can at times be difficult to distinguish from reticulated seborrheic keratoses, lentigines, or even the lentigo maligna subtype of cutaneous melanoma. Dermoscopy may be a useful adjunct in these situations. Clinical clues are the location on sun-exposed skin, background solar changes, and hyperkeratosis that is sometimes appreciable by palpation. In cases in which the diagnosis is questionable, a biopsy is required to exclude the possibility of melanoma.

Lichenoid AK is characterized histopathologically by the presence of a dense band-like inflammatory infiltrate. Clinically, this lesion is similar to the classic form of AK but has more erythema surrounding the base of the lesion. Patients may relate pruritus or tenderness that coincides with the onset of the lichenoid infiltrate in a pre-existing AK.

Atrophic AKs usually have minimal surface change but are appreciated as pink to red, slightly scaly macules or patches (see Fig. 108.3B) that are found by histopathologic examination to have an atrophic epidermis.

Actinic cheilitis is the term used to describe the characteristic changes that occur on the lower vermilion lip of individuals with moderate to severe photodamage. Actinic cheilitis may resemble the classic form of AK, with well-demarcated, erythematous papules or thin plaques with scale. In other patients, the erythema and especially the scale is more diffuse and can involve the entire lower vermilion lip; areas of leukoplakia may also be present. When clinical distinction between actinic cheilitis and SCC of the lip is not possible, a biopsy should be performed.

Squamous cell carcinoma in situ

SCC *in situ* is commonly called Bowen's disease. The most common presentation of SCC *in situ* is an erythematous scaly patch or slightly elevated plaque (Fig. 108.4) that arises within sun-exposed skin of an elderly individual. However, it can develop in younger individuals with significant photodamage. Bowen's disease may arise *de novo* or from a pre-existing AK. The head and neck, followed by the extremities and trunk, are the most common sites. Lesions can become crusted and in SCC *in situ* of anogenital mucosa, erosions may be prominent (Fig. 108.5).

Clinical distinction of SCC *in situ* from AK, superficial BCC, psoriasis or chronic eczema may at times be difficult (see Fig. 108.4D). Generally, AKs are smaller lesions and superficial BCCs often have a more translucent quality with slight elevation of the leading edge. Patients with psoriasis and diffuse actinic damage can pose a diagnostic dilemma, as concomitant psoriatic papules and plaques may clinically resemble AKs and Bowen's disease.

Arsenic-induced SCC *in situ* resembles the classic variety clinically but has a marked tendency to be multifocal and to arise on non-sun-exposed areas of the trunk. Associated findings include palmoplantar keratoses and guttate hypopigmentation superimposed on hyperpigmentation (see Ch. 88).

Bowenoid papulosis is a term used when histopathologic changes of SCC *in situ* are found within genital warts, usually due to infection with an oncogenic strain such as HPV-16 or -18. Dermatologists often prefer to use this term when multiple papules are present, as opposed to calling all of them SCC *in situ*, because the lesions rarely become invasive. The clinical appearance can vary from small brown papules of the penis to perianal pink papules to corrugated pink to brown plaques of

Fig. 108.4 Squamous cell carcinomas *in situ*, Bowen's type. A Scaly red plaque on the chest with skip areas. **B** Bright red, well-demarcated plaque on the proximal nail fold with associated horizontal nail ridging; the possibility of HPV infection needs to be considered. **C** Dermoscopic examination of a pink scaly plaque on the chest, with tiny dotted vessels in the upper half of the lesion. **D** Extensive involvement of the finger which is often misdiagnosed clinically as psoriasis or chronic eczema and therefore treated for years with corticosteroid creams (as was this patient). *C, Courtesy, Iris Zalaudek, MD.*

Fig. 108.5 Squamous cell carcinoma *in situ*, erythroplasia of Queyrat type. Large, eroded erythematous plaque with well-demarcated borders. The lesion began on the shaft of the penis.

the inguinal creases (see Chs 73 & 79). Whether this entity represents true SCC *in situ*, or is a histopathologic simulant, is a matter of debate.

Other variants of SCC *in situ* include a pigmented variant often seen in individuals with darker skin types and a verrucous form. Pigmented SCC *in situ* may be mistaken for a pigmented AK or a melanocytic lesion and verrucous SCC *in situ* may simulate a verruca clinically.

Invasive cutaneous squamous cell carcinoma

Invasive cutaneous SCC usually arises within a background of sun-damaged skin, most commonly on the bald scalp, face, neck, extensor forearms, dorsal hands and shins (Fig. 108.6A–D). The color usually varies from erythematous to skin-colored; rarely there are pigmented variants. SCCs are often papulonodular, but can be plaque-like, papillomatous or exophytic. The degree of associated scale varies, with some lesions becoming quite hyperkeratotic (see Fig. 108.6A); other secondary changes include crusting, erosions and ulcerations (Fig. 108.6E,F).

The natural history of SCCs also varies, from slowly enlarging to rapidly growing with significant tenderness and even pain. Of note, paresthesias, anesthesia and pain may be signs of perineural invasion.

Fig. 108.6 Clinical spectrum of cutaneous squamous cell carcinoma (SCC). A A large keratotic nodule of the supraorbital region in an elderly woman; note the coarse wrinkling and solar elastosis of the face. **B** Eroded and keratotic nodule that developed rapidly at the site of trauma on the shin. **C** Large, fungating nodule on the dorsum of the hand. **D** Multiple eroded superficial SCCs in association with hypertrophic AKs on the cheek and neck of an elderly man. **E** Erosive, slightly vegetating, thick plaque arising within lichen sclerosis of the vulva. **F** Firm, eroded, red plaque on the scrotum; histopathologically, the SCC was moderately differentiated. *B, Courtesy, Jean L Bolognia, MD.*

In general, invasive SCCs tend to have more "tumor volume" than classic AKs, but they can resemble hyperkeratotic (hypertrophic) AKs or inflamed seborrheic keratoses or verrucae.

Staging of SCC takes into account tumor volume as measured by diameter (≤2 cm vs >2 cm) and depth of invasion (>2 mm), and SCCs arising within sun-damaged skin are often early stage, i.e. T1/AJCC Stage I (Table 108.6). Anatomic sites with a greater risk of aggressive biologic behavior include the ear[52], the lips (Fig. 108.7), and mucosal sites including the vulva and penis (see Fig. 108.6E,F). Clinical examination of patients with invasive SCC includes palpation of regional lymph nodes for enlargement and firmness, followed by assessment of size if enlarged.

STAGING OF CUTANEOUS SQUAMOUS CELL CARCINOMA (SCC)

T, N, M			
	Primary tumor (T)		
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma *in situ*		
T1	Tumor ≤2 cm in greatest dimension with <2 high-risk features*		
T2	Tumor >2 cm in greatest dimension *or* Tumor any size with ≥2 high-risk features†		
T3	Tumor with invasion of maxilla, orbit or temporal bone		
T4	Tumor with invasion of skeleton (axial or appendicular) or perineural invasion of skull base		
	Regional lymph nodes (N)		
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension		
N2	Metastasis in a single ipsilateral lymph node, >3 cm but <6 cm in greatest dimension (2a); or in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension (2b); or in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension (2c)		
N3	Metastasis in a lymph node, >6 cm in greatest dimension		
	Distant metastasis (M)		
M0	No distant metastasis		
M1	Distant metastasis

	T4	N Any	M0
	T Any	N Any	M1

*High-risk features for the primary tumor (T) staging:
Depth/invasion: >2 mm thickness, Clark level ≥IV, perineural invasion
Anatomic location: primary site ear, primary site hair-bearing lip
Differentiation: poorly differentiated or undifferentiated
†Excludes cutaneous SCC of the eyelid.

Table 108.6 Staging of cutaneous squamous cell carcinoma (SCC). Adapted from American Joint Committee on Cancer, 2010.

Keratoacanthoma

Keratoacanthomas (KAs) are considered by some to be a variant of SCC and by others to represent benign tumors (i.e. pseudomalignancy). The exact nosology is still uncertain, although there are some data that support its differentiation from "conventional" SCC. Typically, a rapidly enlarging papule evolves into a sharply circumscribed, crateriform nodule with a keratotic core over a period of a few weeks (Fig. 108.8A,B), and then it may resolve slowly over months to leave an atrophic scar[53]. Most lesions occur on the head and neck or in sun-exposed areas of the extremities, with or without symptoms of pain or tenderness.

There are several distinct clinical presentations of KA, including solitary, multiple, grouped, keratoacanthoma centrifugum marginatum (Fig 108.8C), giant (Fig 108.8D), subungual, intraoral, multiple spontaneously regressing (Ferguson–Smith), multiple non-regressing, generalized eruptive (Grzybowski), KAs associated with Muir–Torre syndrome (may have sebaceous differentiation ["seboacanthoma"]; see Ch. 63), and KAs associated with chemical exposure, immunosuppression[30] and HPV infection[54].

By far the most common presentation is the solitary KA. While most of these tumors are small (5 to 15 mm), some KAs (e.g. keratoacanthoma centrifugum marginatum [see Fig. 108.8C]) may reach several centimeters in diameter, persist for months before resolution, and heal with prominent scarring. Grouped KAs may resolve more slowly than solitary KAs, while subungual KAs have been associated with underlying bony destruction.

The Ferguson–Smith syndrome is an autosomal dominant condition. Multiple KAs develop within sun-exposed areas, usually beginning in the third decade of life. Lesions typically regress over weeks to months, but rare examples of metastases have been reported.

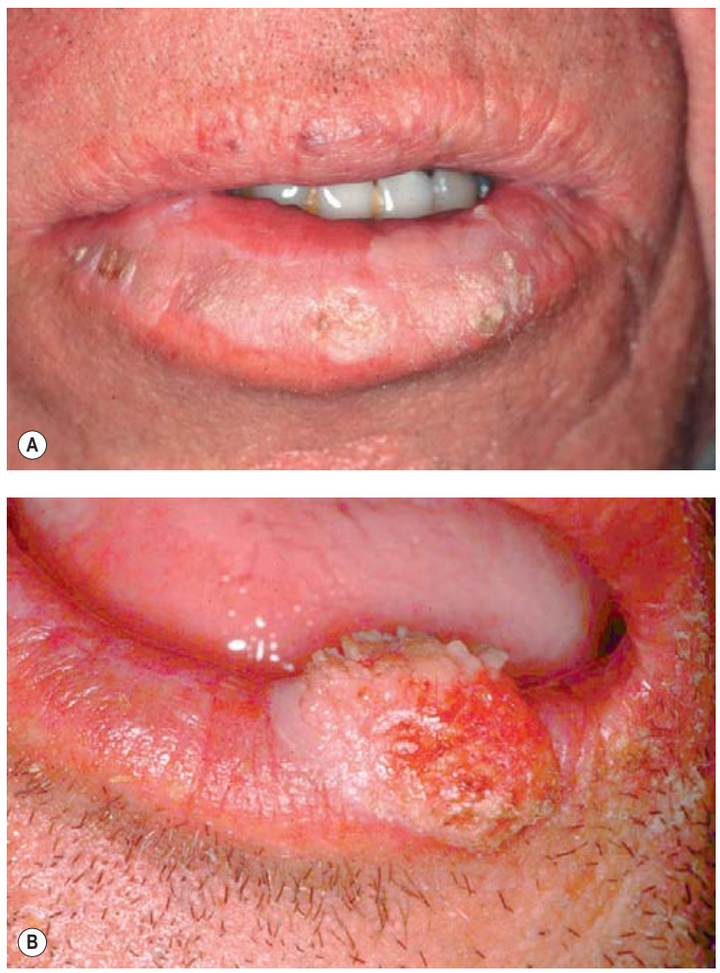

Fig. 108.7 Squamous cell carcinoma (SCC) of the lower lip. A Extensive hyperkeratosis and leukoplakia of the lower vermilion lip; histopathologically, the SCC was superficially invasive and well-differentiated. **B** Verrucous and eroded nodule on the lower vermilion lip in a heavy smoker.

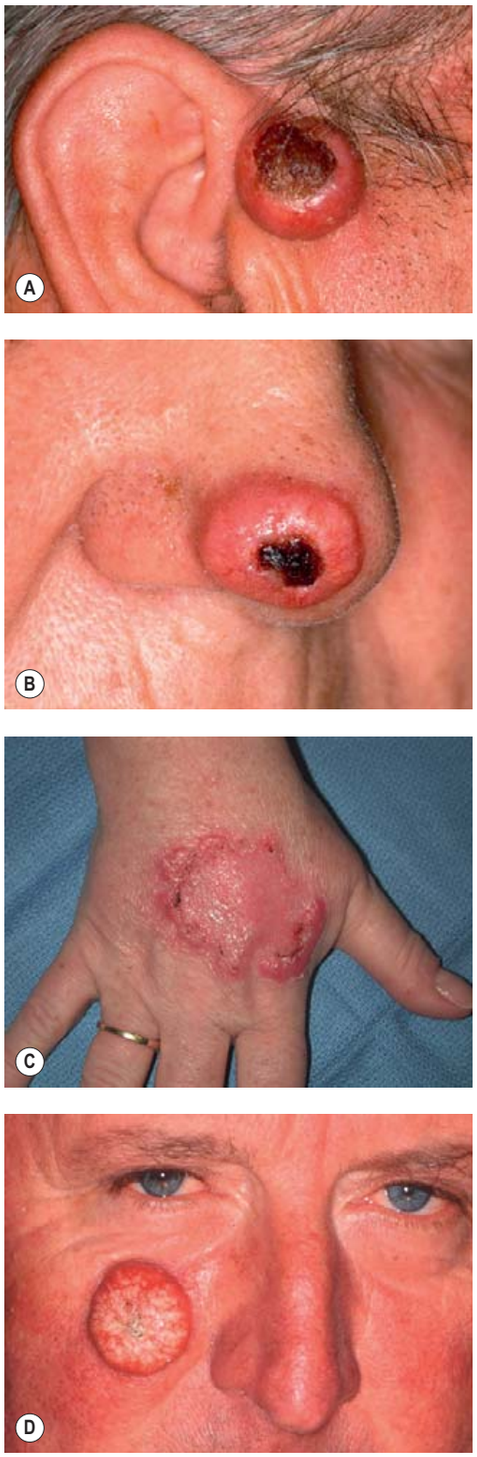

Fig. 108.8 Clinical spectrum of keratoacanthomas. **A, B** Rapidly growing, erythematous crateriform nodules with a rolled border and central keratotic core. **C** Progressive peripheral expansion and central involution with residual atrophy characterize keratoacanthoma centrifugum marginatum. **D** Giant keratoacanthoma with a yellow–red color and a history of rapid growth.

Fig. 108.9 Verrucous carcinoma. **A** Longstanding large nodule on the plantar surface with a rabbit burrow-like appearance; such a tumor is also referred to as an epithelioma cuniculatum. **B** Keratotic and ulcerated plaque on the ventromedial aspect of the great toe. **C** A classic location in an amputation stump. In general, these well-differentiated SCCs enlarge slowly.

Multiple KAs of the Grzybowski type present as thousands of papules resembling milia or early eruptive xanthomas. They develop rapidly and may slowly resolve over a period of months[53]. Patients often have scarring, ectropion and a mask-like facies.

Verrucous carcinoma

Verrucous carcinoma is a rare, well-differentiated variant of SCC which tends to occur in middle-aged and older adults. It is considered a low-grade malignancy with three major subtypes: (1) epithelioma cuniculatum (plantar surface of the foot); (2) giant condyloma acuminatum of the genitalia (also known as Buschke–Löwenstein tumor; see Ch. 79); and (3) oral florid papillomatosis (oral mucosa). Of note, the "cuniculatum" refers to the rabbit burrow-like appearance with crevices.

Clinically, verrucous carcinomas present as large (sometimes huge), exophytic tumors with a papillomatous or verrucous surface (Fig. 108.9A,B). They are commonly associated with HPV infection, and distinguishing between a verrucous carcinoma and a large wart or condyloma acuminatum can be difficult. Gradual penetration of verrucous carcinomas into underlying tissues can result in destruction of subcutis, fascia and bone. These tumors can arise within scars and amputation stumps (Fig. 108.9C) and in association with osteomyelitis fistulae and chronic venous insufficiency. Verrucous carcinomas often recur after attempted removal, but they usually do not metastasize, except for recurrent or irradiated tumors with anaplastic transformation.

Some authors consider subungual keratoacanthomas, proliferating tricholemmal cysts (proliferating pilar tumors) and papillomatosis cutis carcinoides to be subtypes of verrucous carcinoma.

Lymphoepithelioma-like carcinoma of the skin

Lymphoepithelioma-like carcinoma of the skin (LELCS) is an uncommon neoplasm that shows histopathologic similarities to lymphoepithelioma-like carcinoma (LELC), an undifferentiated

nasopharyngeal carcinoma associated with EBV infection. It has been suggested that LELCS has "the potential for both sweat glandular and follicular differentiation"[55]. Clinically, it presents as a dermal papule or nodule arising in the head and neck region[56]. In contrast to LELC, EBV genome integration is not found in LELCS, and metastases are rare. Evidence of HPV infection is also usually absent. LELCS is considered by some to be a variant of cutaneous SCC.

Histologically, LELCSs are localized within the dermis or subcutis; involvement of the overlying epidermis having been observed in only a few cases[57]. The tumor consists of clusters of epithelial cells (with large vesicular nuclei and prominent nucleoli) intermingled with lymphocytes and plasmacytoid cells. However, classic signs of squamous differentiation such as keratin "pearls", dyskeratotic cells or intercellular bridges are absent[56]. By immunohistochemistry, there is expression of cytokeratin and epithelial membrane antigen in the neoplastic cells; stromal lymphocytes express leukocyte common antigen (CD45). The histopathologic differential diagnosis includes cutaneous lymphadenoma, lymphocytoma cutis, follicle center lymphoma, and carcinoma with thymus-like differentiation.

In Vivo Imaging Methods

Dermoscopy

Dermoscopy of invasive SCC reveals linear-irregular vessels, elongated vessels resembling hairpins, dotted vessels or a combination of these findings (polymorphous or atypical vascular pattern). Typically, vessels are surrounded by a whitish halo; the latter is the dermoscopic hallmark of all keratinizing tumors and is also found in KAs and in seborrheic keratoses (see Table 0.38). Ulceration and hemorrhagic crusts appear as red-, brown- or black-colored surface blotches. Rare pigmented SCCs may have a scaly surface, diffuse or homogenous blue pigmentation and/or irregularly distributed blue–gray granular structures. AKs on the face demonstrate a so-called "strawberry pattern" (an erythematous pseudonetwork surrounding hair follicle orifices filled with yellowish keratotic plugs)[58], whereas in other body sites they often display surface scales and dotted vessels. Bowen's disease typically has a scaly surface and glomerular vessels.

Reflectance confocal microscopy

Reflectance confocal microscopy (RCM) is an imaging technique which allows non-invasive horizontal imaging of the epidermis and superficial dermis at almost the same resolution as routine histology. RCM (and dermoscopic) features of keratinizing tumors are often difficult to visualize due to the surface scaling which obscures underlying structures. Although to date, only a few publications have described the RCM features of AKs and SCCs, a recent study suggested that a disarranged pattern and/or an atypical honeycomb pattern, in conjunction with round nucleated cells at the level of the spinous/granular layer, were key features of SCC[59].

Pathology

Actinic keratosis

Several histopathologic variants of AK have been described, including pigmented, acantholytic, atrophic, bowenoid, lichenoid, hypertrophic (hyperkeratotic) and actinic cheilitis types. All are characterized by atypical keratinocytic proliferation, beginning in the basal layer and confined to the epidermis (Fig. 108.10).

Microscopic changes consist of partial-thickness atypical keratinocytes displaying nuclear pleomorphism (especially in the basal layer), and disordered maturation. The lesion may be acanthotic, often with an increased number of buds protruding into the papillary dermis, or atrophic with loss of rete ridges. Hyperkeratosis and parakeratosis are a constant finding. Acrosyringia and acrotrichia are often uninvolved, resulting in orthokeratosis at the ostia of these structures. This produces a characteristic pattern of alternating ortho- and parakeratosis, often referred to as the "flag" or "pink and blue" sign, since the color of the stratum corneum shows alternation of a more eosinophilic column (parakeratosis) with a basophilic one (orthokeratosis) (see Fig. 108.10A). AKs are associated with solar elastosis in the dermis (Fig. 108.10C).

The keratinocytic atypia of an AK is usually confined to the lower portion of the epidermis, as opposed to full-thickness atypia in SCC *in situ*. Diagnostic difficulty arises when the presence of small foci of full-thickness atypia occur in a lesion with otherwise characteristic features of an AK. Some pathologists may use the term "bowenoid AK" in this setting. A histopathologic grading system for AKs has been proposed as follows: grade 1, the presence of atypical cells within the basal or suprabasal layer only, without budding, involvement of the hair follicles or full-thickness atypia; grade 2, grade 1 plus budding and/or involvement of the hair follicles; and grade 3, characterized by full-thickness atypia (SCC *in situ*)[60].

In hyperkeratotic AKs, marked hyperkeratosis with associated parakeratosis is evident. If pronounced, this can lead to cutaneous horn formation. Pigmented AKs additionally show basilar pigmentation in a pattern similar to a solar lentigo (see Fig. 108.10C). Lichenoid lesions demonstrate a band-like infiltrate of lymphocytes in the papillary dermis directly beneath the dermal–epidermal junction. Actinic cheilitis arises on paramucosal skin, usually the lower vermilion lip, and may or may not show accompanying inflammation.

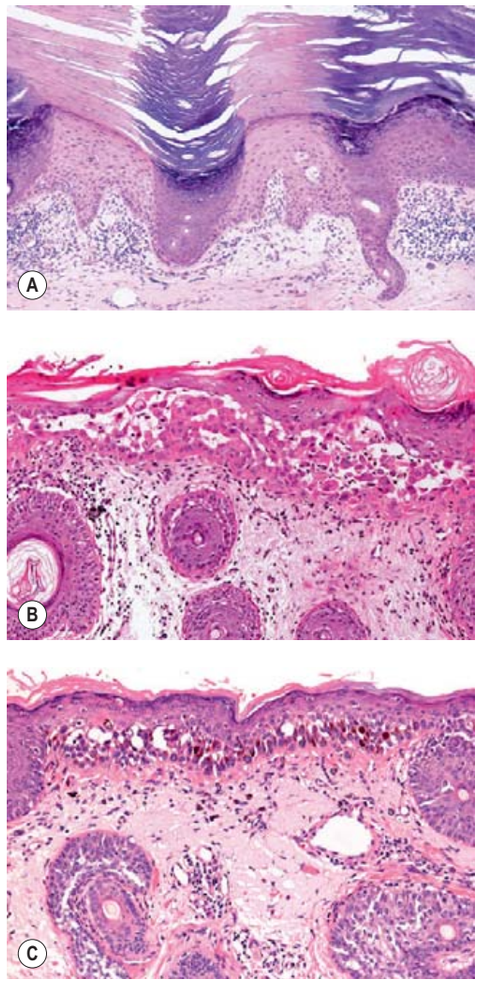

Fig. 108.10 Histopathology of actinic keratoses (AKs). **A** Hyperkeratotic AK with alternating pink and blue colors in the cornified layer; the pink-colored parakeratotic columns within the stratum corneum are located above the atypical keratinocytes in the spinous layer, while the blue-colored columns of orthohyperkeratosis are above the acrosyringia. Atypical epidermal keratinocytes also display a pinkish color that contrasts with the color of the basophilic, normal keratinocytes of the acrosyringia. **B** Acantholytic variant with clefts within the stratum spinosum. **C** Pigmented actinic keratosis with increased melanin pigmentation within the basal layer. Note the solar elastosis in the dermis.

Squamous cell carcinoma in situ

SCC *in situ* (Bowen's disease), by definition, demonstrates full-thickness atypia of the epidermis over a broad zone (Fig. 108.11). Nuclear pleomorphism and apoptosis are often more florid than in AKs, and mitoses are frequent. The epidermis commonly exhibits acanthosis. Atypical keratinocytes more commonly extend down the adnexa than in an AK. Diffuse confluent parakeratosis is also observed more often than the focal parakeratosis seen in an AK.

A number of different histopathologic variants have been described. The "pagetoid" variant demonstrates large keratinocytes with abundant, pale-staining cytoplasm scattered throughout the epidermis, simulating melanoma *in situ*, Paget's disease or extramammary Paget's disease (see Fig. 73.16). Immunohistochemistry may be necessary to make a distinction, although the location of the lesion on sun-damaged skin (as opposed to Paget's disease), the presence of desmosomal spines,

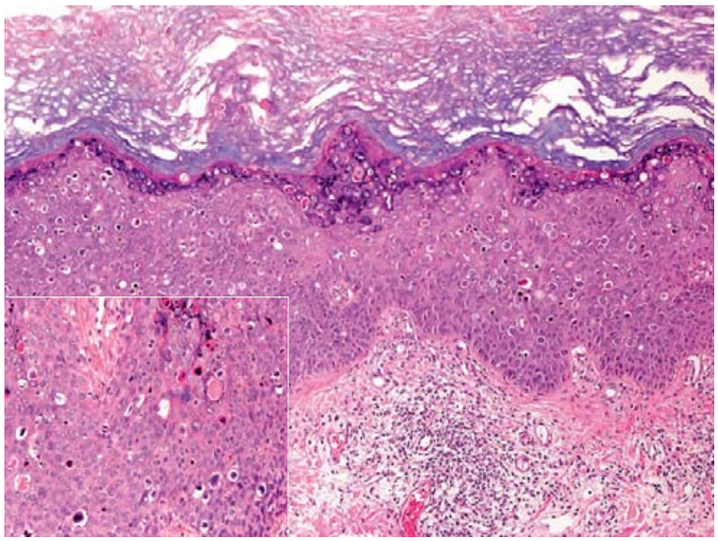

Fig. 108.11 Histopathology of Bowen's disease (squamous cell carcinoma *in situ*). Irregular epidermal hyperplasia with atypical pleomorphic keratinocytes throughout the entire epidermal thickness. Note several necrotic keratinocytes (insert).

and the presence of many apoptotic cells can be helpful. Another subtype is the pigmented variant, in which there is abundant melanin in the epidermis.

Invasive squamous cell carcinoma

Well-differentiated SCC generally arises in the setting of epidermal changes consistent with AK. In addition, there is a downward proliferation of lobules and detached aggregations of glassy, brightly eosinophilic keratinocytes containing nuclei with some degree of pleomorphism and mitoses (Fig. 108.12A). Nucleoli may be prominent. Intercellular bridges (desmosomes) are often apparent, along with keratin pearls and apoptotic cells. The degrees of nuclear atypia and cellular differentiation vary within and among tumors (Fig. 108.12B). The pink quality of the cytoplasm arises from abundant high-molecular-weight keratin. As a rule, aggregations of atypical keratinocytes are present within the dermis at varying levels. The inflammatory infiltrate varies considerably in intensity and consists primarily of lymphocytes and plasma cells. Invasive SCC arising from Bowen's disease is characterized by islands of tumor cells in the dermis that have a strikingly similar appearance to the atypical cells within the epidermis, i.e. a more basophilic appearance and an absence of clear-cut keratinization.

Poorly differentiated SCCs display progressive and overlapping features, ending in highly infiltrative tumors that lack overt keratinization and sometimes have a spindle cell morphology. Perineural infiltration (Fig. 108.12C) and desmoplastic or sclerotic stromal change become more common in these forms. Neurotropic SCCs behave in a more aggressive manner, with local recurrence rates approaching 50%[61]. Poorly differentiated tumors (cytokeratin-positive) generally require immunohistochemistry to distinguish them from spindle-cell melanoma (generally S100-positive), atypical fibroxanthoma (cytokeratin- and S100-negative, vimentin-positive) and leiomyosarcoma (smooth muscle actin- and desmin-positive).

There are several variants of SCC. The acantholytic type (Fig. 108.12D) and the related adenoid (pseudoglandular) SCC possibly have a worse prognosis. Other variants include bowenoid SCC, SCC with overlying cutaneous horn formation, and desmoplastic, mucinous, or pigmented SCC. Marjolin's ulcer is a SCC that occurs in a chronic wound or scar, including scars from a burn.

A recent large, prospective study focusing on risk factors that predict metastasis and local recurrence in cutaneous SCC reported overall rates of 4% for metastasis and 3% for local recurrence[52] . Only tumors >2 mm in vertical thickness had a significant risk of developing metastases. For SCCs whose thickness was between 2.1 and 6 mm, the metastatic rate was 4%, and it was 16% for lesions thicker than 6 mm. Other risk factors for metastasis included location on the ear, increased horizontal size, and immunosuppression (Table 108.7). Tumor thickness and the presence of a desmoplastic stroma were found to be risk factors for local recurrence. For example, of the 51 patients with desmoplastic SCC, 24% developed local recurrences, compared to 1% of the 564 patients with non-desmoplastic SCCs.

RISK FACTORS FOR METASTASIS OF INVASIVE SQUAMOUS CELL CARCINOMA
Tumor thickness >2 mm (high risk: tumor thickness >6 mm)
Diameter >2 cm
Location: ear, lips, mucosae including tongue, vulva, penis (perineural growth may be an additional risk factor in these locations)
Arising within a scar (e.g. burn, radiation)
Histopathologically, poorly differentiated or undifferentiated; acantholytic features; developing within Bowen's disease
Immunosuppression

Table 108.7 Risk factors for metastasis of invasive squamous cell carcinoma. Based in part upon ref. 52.

Keratoacanthoma

A KA typically has a "volcano-like" architecture. The tumor is comprised of well-differentiated keratinocytes with a brightly eosinophilic glassy cytoplasm, surrounding a core filled with cornified material (Fig. 108.13). An inflammatory infiltrate of lymphocytes, and often eosinophils, is usually present. Small intratumoral abscesses of neutrophils are common, and neurotropism may be observed. As the lesion regresses, the dome-shaped architecture flattens and fibrosis develops at the base of the lesion. Cytologic atypia is usually minimal in a KA. If hyperchromatic nuclei or abnormal mitoses are prominent, then the diagnosis of an invasive KA-like SCC should be rendered.

Verrucous carcinoma

Verrucous carcinoma is defined as a well-differentiated and distinct clinicopathologic variant of SCC. However, this term is not correctly used for any SCC that has a warty appearance. Cytologic atypia is minimal, and the tumor has a pushing border as opposed to an infiltrating invasive edge. Verrucous carcinoma can be associated with HPV infection, and histopathologic distinction from a large wart is often difficult and may be impossible if the entire tumor is not available for microscopic examination. The major distinguishing features of a verrucous carcinoma are the massiveness and depth of the lesion, as well as the more pronounced irregular architecture.

Histologic simulators of SCC

There are a number of histologic simulators of SCC, including irritated seborrheic keratosis, verruca vulgaris, warty dyskeratoma, inverted follicular keratosis, prurigo nodularis, hypertrophic lichen planus, hypertrophic lupus erythematosus, atypical mycobacterial or "deep" fungal infections, granular cell tumor, and pseudocarcinomatous hyperplasia (e.g. in a healing wound). Architectural pattern and recognition of cellular and nuclear features of malignancy are critical in establishing a diagnosis. In some cases, only clinical correlation allows a distinction between SCC and some of these conditions.

BASAL CELL CARCINOMA

Clinical Features

BCC is a tumor that arises within sun-damaged skin. It rarely develops on the palms and soles or mucous membranes. Currently, despite the description of more than 26 different subtypes of BCC, a universally accepted classification scheme is lacking[62]. In the view of the authors, there are four major distinctive clinicopathologic types, namely, nodular (Fig. 108.14), superficial (Fig. 108.15), morpheaform (Fig. 108.16), and fibroepithelial (also referred to as fibroepithelioma of Pinkus; Fig. 108.17)[63]. Combinations of the latter three types with nodular BCC may occur. While all types of BCC may ulcerate, ulceration is observed

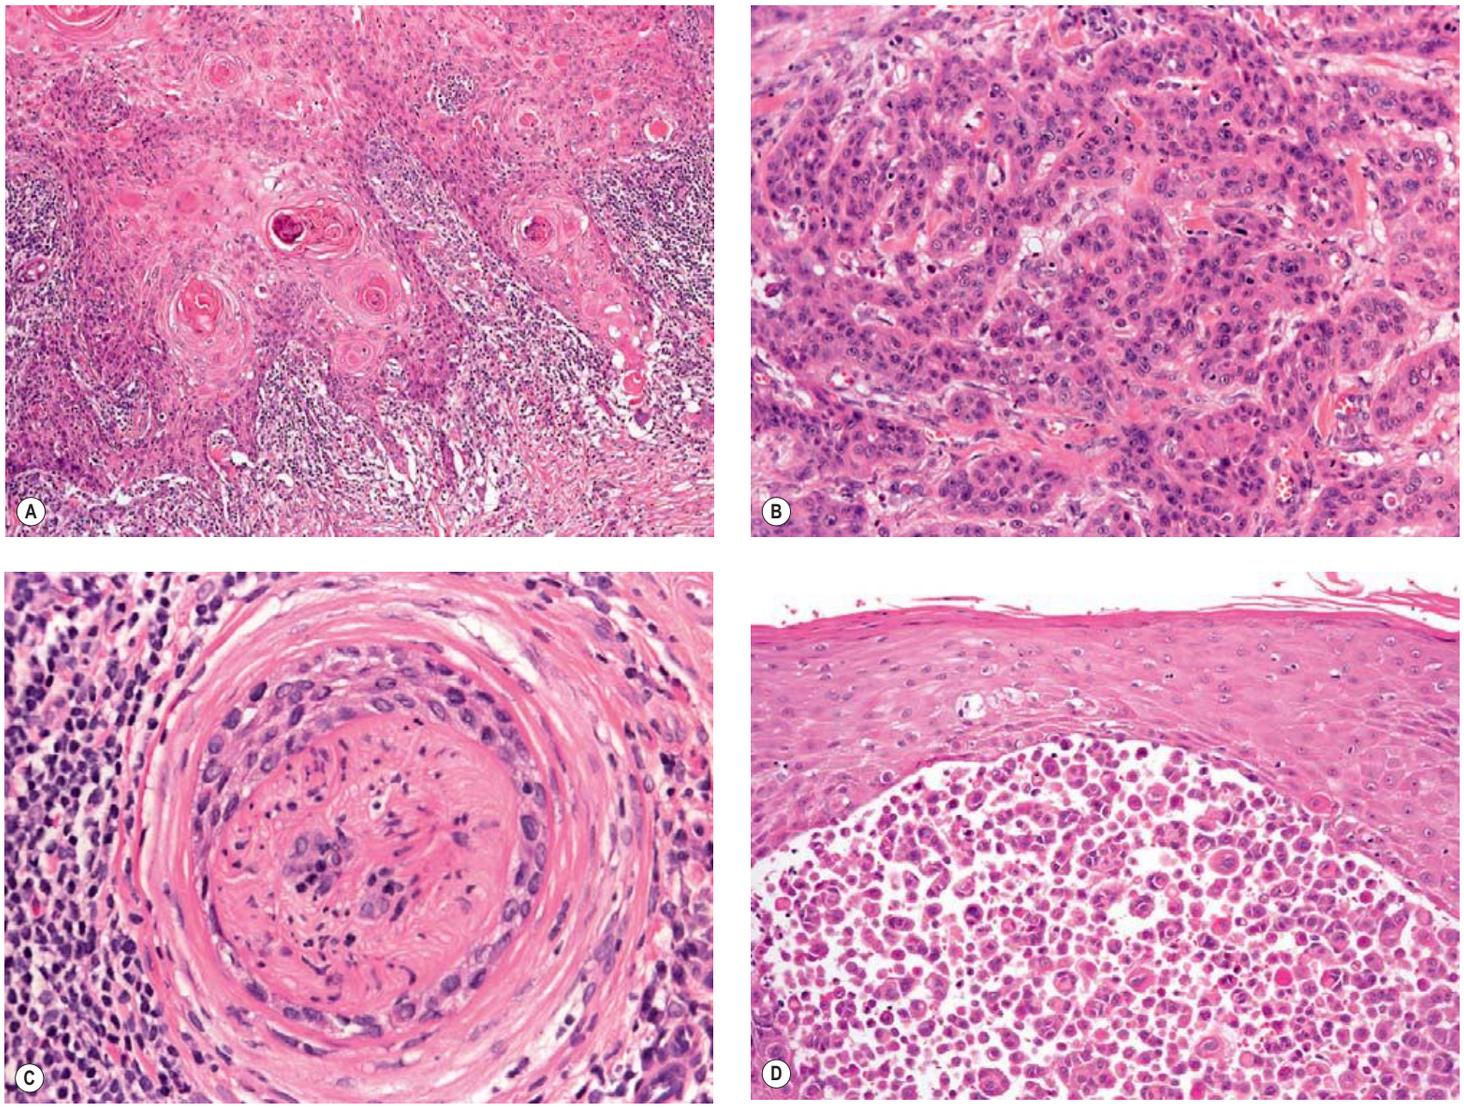

Fig. 108.12 Squamous cell carcinoma (SCC): range of histopathologic findings. A Well-differentiated SCC with numerous horn pearls (eosinophilic parakeratotic keratinization). **B** Poorly differentiated SCC with strands and cords of epithelial cells with prominent nuclear atypia and no signs of keratinization. **C** Perineural growth and neurotropism of a poorly differentiated SCC. **D** Acantholytic SCC characterized by epithelial aggregations composed of atypical keratinocytes with acantholysis. *Courtesy, Lorenzo Cerroni, MD*

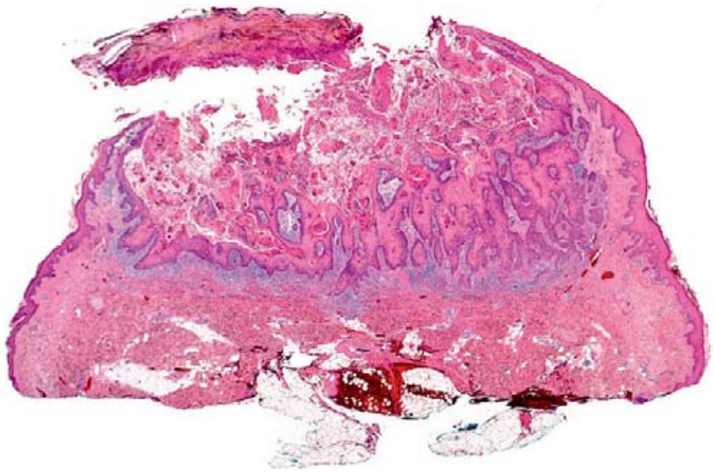

Fig. 108.13 Histopathology of keratoacanthoma. Scanning magnification of a stereotypical keratoacanthoma with a keratin-filled crater encompassed by epithelial lips.

more often in the nodular type. Also, variable amounts of melanin may be present within these tumors (Fig. 108.18), even though the majority of BCCs are amelanotic; pigmented BCCs are observed more commonly in those with darker skin phototypes[64]. A significant confounding factor when one attempts to classify BCCs is the number of different histopathologic patterns that become entwined with clinical subtypes. Examples are cystic, micronodular and basosquamous BCCs. A more complete list of histopathologic patterns is presented in Table 108.8. Although these patterns may be seen in all four major clinicopathologic types of BCC, they are observed more frequently in the nodular type.

Nodular basal cell carcinoma

Nodular BCC is the most common subtype, accounting for approximately 50% of all BCCs. Lesions typically present as a shiny, pearly papule or nodule with a smooth surface and the presence of arborizing telangiectasias (see Fig. 108.14A). With time, the tumor can enlarge and ulcerate (rodent ulcer, phagedenic ulcer), but an elevated rolled border usually remains and is a clinical clue to the diagnosis (see Fig. 108.14E). Sites of predilection are the face, especially the cheeks, nasolabial folds, forehead and eyelids, but nodular BCCs may arise in any hair-bearing area of the skin. They are rarely seen in non-hair-bearing sites, e.g. genital mucosa.

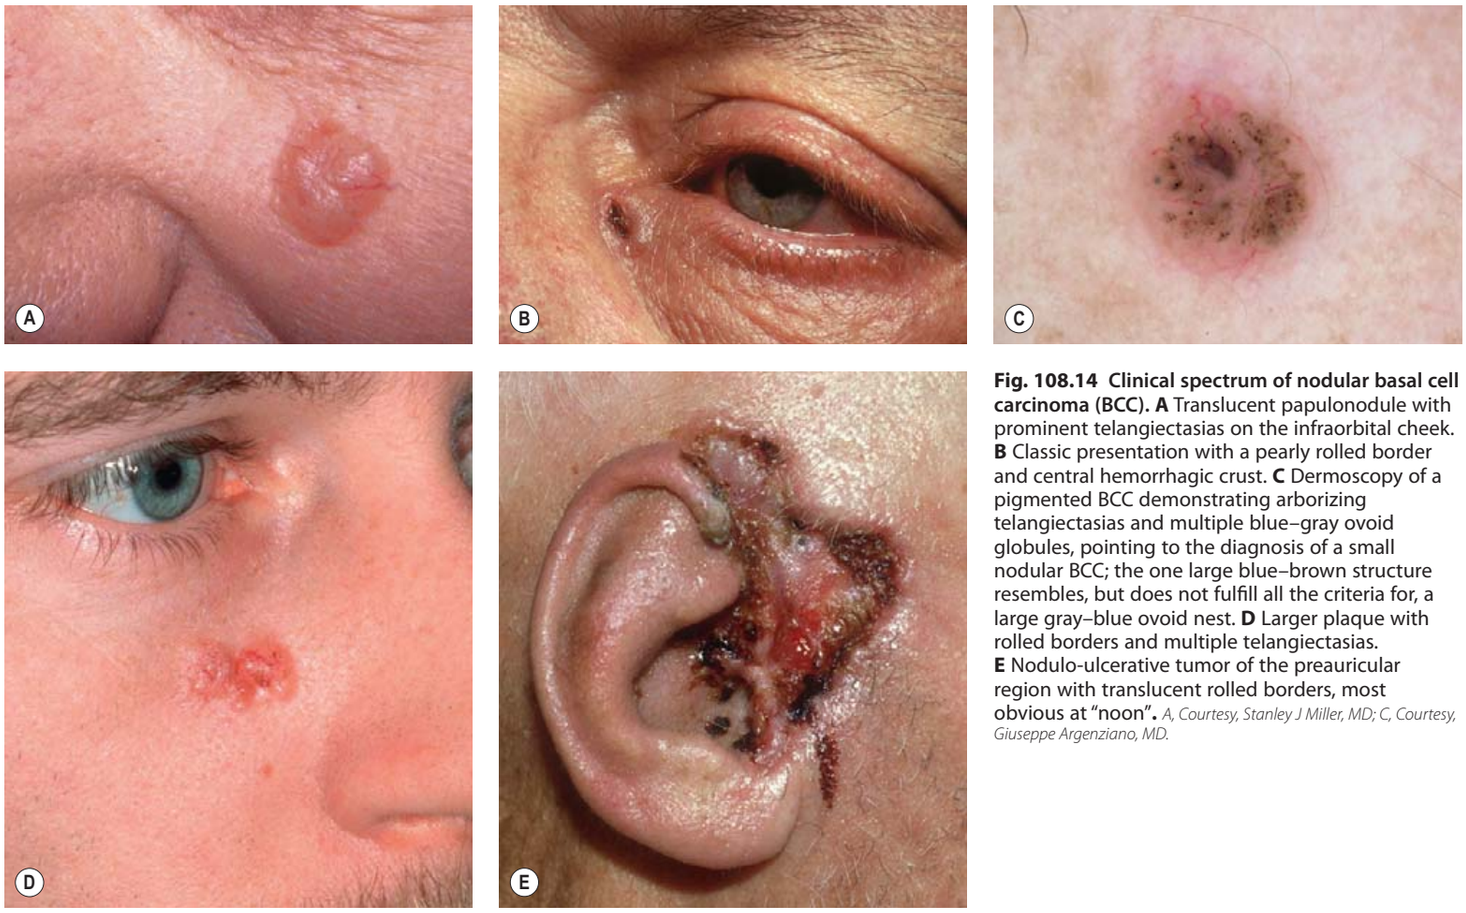

Fig. 108.14 Clinical spectrum of nodular basal cell carcinoma (BCC). A Translucent papulonodule with prominent telangiectasias on the infraorbital cheek. **B** Classic presentation with a pearly rolled border and central hemorrhagic crust. **C** Dermoscopy of a pigmented BCC demonstrating arborizing telangiectasias and multiple blue–gray ovoid globules, pointing to the diagnosis of a small nodular BCC; the one large blue–brown structure resembles, but does not fulfill all the criteria for, a large gray–blue ovoid nest. **D** Larger plaque with rolled borders and multiple telangiectasias. **E** Nodulo-ulcerative tumor of the preauricular region with translucent rolled borders, most obvious at "noon". *A, Courtesy, Stanley J Miller, MD; C, Courtesy, Giuseppe Argenziano, MD.*

Fig. 108.15 Superficial basal cell carcinoma. A Numerous erythematous patches and thin plaques on the back of a man with a history of arsenic exposure decades previously. **B** A solitary large, thin, dark pink plaque. There are scattered areas of fine scaling and small foci of brown pigment within the rolled border. As a rule, these lesions are neither pruritic nor tender.

The clinical differential diagnosis of non-ulcerated lesions includes adnexal neoplasms (see Ch. 109), intradermal melanocytic nevi (softer and comma vessels by dermoscopy), Merkel cell carcinoma, and cutaneous melanoma (amelanotic more often than melanotic); for ulcerated lesions, see Table 45.3 and Figure 105.1.

Superficial basal cell carcinoma

Superficial BCCs typically present as a well-circumscribed, erythematous, macule/patch or thin papule/plaque, with the diameter varying from a few millimeters to several centimeters (see Fig. 108.15). Additional findings include focal scale and/or crusts, a thin rolled border, and variable amounts of melanin; in larger lesions, areas of spontaneous regression may be present, characterized by atrophy and hypopigmentation. The mean age at diagnosis is 57 years, a younger age than for other types of BCC[43], and in younger age groups, superficial BCC is the most common subtype[65]. This BCC variant favors the trunk and extremities; less often, it occurs in the head and neck region. Multiple lesions may be present.

The growth pattern of superficial BCCs is primarily horizontal, but tumors may occasionally become deeply invasive, with induration, ulceration, and nodule formation. Extensive subclinical lateral spread accounts for the significant recurrence rate of these tumors after routine surgical treatment. The clinical differential diagnosis includes solitary lichenoid keratosis and Bowen's disease (more scale) as well as inflammatory diseases such as psoriasis, dermatitis and cutaneous lupus erythematosus.

Morpheaform basal cell carcinoma

This less common subtype of BCC frequently presents as a slightly elevated to even depressed area of induration that is usually light pink to white in color and has ill-defined borders (see Fig. 108.16); it often resembles a scar or plaque of morphea. The surface of the lesion is typically smooth, although crusts with underlying erosions or ulcerations as well as superimposed papules may be observed. While an elevated pearly border is typically absent, telangiectasias may be present.

Fig. 108.16 Morpheaform basal cell carcinoma (BCC). **A** Recurrent tumor 2 years after microscopically controlled surgery; note the scar-like appearance with superimposed glassy pink and brown papules. **B** Oval hypopigmented firm plaque that resembles a scar (e.g. post electrodessication and curettage). While there is a light pink color between 6 and 9 o'clock, no translucency or rolled border is present. **C** A classic example with indistinct borders and scar-like appearance. *A, Courtesy, Darrell S Rigel, MD.*

Fig. 108.17 Fibroepithelioma of Pinkus. This soft, skin-colored to light pink, broad, sessile nodule on the lower back representing a fibroepithelial BCC is adjacent to a classic nodular BCC.

The biologic behavior is usually more aggressive, with extensive local destruction.

Fibroepithelial basal cell carcinoma

This rare variant of BCC usually presents as a skin-colored or pink, sessile plaque or pedunculated papulonodule with a smooth surface (see Fig. 108.17). It favors the trunk, especially the lower back. Fibroepithelial BCCs often occur in individuals with multiple superficial BCCs. The clinical differential diagnosis includes a large fibroepithelial polyp (skin tag) or intradermal nevus.

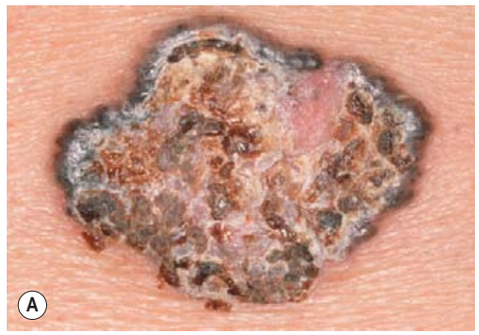

Fig. 108.18 Pigmented basal cell carcinoma. **A** In addition to the admixture of scale and hemorrhagic crusts centrally, there is a translucent and black rolled border superiorly. **B** The clinical differential diagnosis of this small nodular pigmented BCC includes nodular melanoma. However, the glassy translucency, in concert with characteristic dermoscopic features, will point to the diagnosis of pigmented BCC.

HISTOPATHOLOGIC PATTERNS OBSERVED IN NODULAR BASAL CELL CARCINOMAS

I. Epithelial patterns		II. Cytologic characteristics	
Adamantinoid	Labyrinthine	**Nuclear features**	**Cytoplasmic features**
Adenoid	Macronodular	Bowenoid	Basosquamous
Adenoid-cystic (adeno-cystic)	Micronodular	Cuboid	Clear
Anastomosing	Multimicrocystic	Oval	Granular
Arboriform	Nodular	Round	Signet-ring
Cribriform (sieve-like)	Petaloid	Spindle	Scant
Columnar	Racemiform	**III. Non-epithelial (stromal) findings**	
Cord-like	Retiform (reticulated)	Amyloid	Keloidal tissue
Comedo-like	Strand-like	Calcification	Mucin deposition
Cystic	Trabecular	Cartilaginous metaplasia	Osseous metaplasia
Frond-like	Tubular	Fibrosis (fibroplasia)	Sclerosis
Fenestrated		Granulation tissue-like	

Table 108.8 Histopathologic patterns observed in nodular basal cell carcinomas. Adapted from ref. 63.

Additional histopathologic subtypes of BCC

Basosquamous carcinoma

Basosquamous carcinoma (metatypical BCC) is a tumor that has histologic features of both BCC and SCC. These tumors may behave biologically more like a SCC than a BCC, i.e. have more aggressive behavior with a greater likelihood of recurring after treatment and metastasizing[66]. It has been estimated that this variant constitutes 1% of all NMSC. When metastases occur, they may have the same microscopic appearance as the original tumor or may resemble a poorly

differentiated SCC. The incidence of metastases with this variant of BCC has been estimated to be greater than 5%.

Micronodular basal cell carcinoma

This histopathologic term applies to BCCs in which smaller aggregations of basaloid cells infiltrate the dermis. Micronodular BCCs have a destructive behavior, with subclinical spread and high rates of recurrence. Clinically, they may present as macules, papules or slightly elevated plaques and may be difficult to differentiate from nodular BCC.

In Vivo Imaging Methods

Dermoscopy

Dermoscopy provides a demonstrated benefit in the diagnosis of non-pigmented and pigmented BCCs. The dermoscopic hallmark of BCC is the presence of well-focused arborizing vessels in conjunction with foci of microulceration. Additional dermoscopic findings with a high specificity for BCC include large blue-gray ovoid nests, multiple blue-gray globules, leaf-like structures and spoke-wheel areas (see Table 0.12). As expected, there is no pigment network[64]. In a recent publication, the presence of short, fine superficial telangiectasias as well as concentric structures and multiple, "in-focus" blue–gray dots was described (see Fig. 108.14C)[67].

Reflectance confocal microscopy

The following RCM features (see above for description of technique) have been described for all BCCs, regardless of subtype[68,69]: (1) variable architectural disarray of the epidermis; (2) a streaming pattern of elongated monomorphic nuclei that are polarized along the same axis; (3) tightly packed cells in the papillary dermis with a nodular/cord-like growth pattern; (4) palisading of tumor cell nuclei; (5) peri-tumoral dark cleft-like spaces (representing peri-tumoral mucinous edema); and (6) the presence of bright dendritic cells and melanophages (in pigmented BCC)[68].

Pathology

All types of BCC have as a least common denominator the presence of aggregations of basaloid keratinocytes within a variably fibromyxoid stroma (Fig. 108.19). A connection to the epidermis is usually observed, at least focally. The cells are characterized by large, relatively uniform nuclei and scant cytoplasm. Cellular borders are indistinct and desmosomes are inapparent. Apoptotic cells are common. The fibromyxoid stroma is intimately associated with the tumor islands, often showing increased cellularity. A characteristic feature of BCC is retraction of the stroma around the tumor islands, creating microscopically visible clefts (see Fig. 108.19B,D). Although this latter feature may not be seen in all instances, when present it is useful in differentiating BCCs from histopathologic simulators.

In nodular BCC (see Fig. 108.19D), large, round or oval aggregations of basaloid keratinocytes extend from the epidermis into the dermis. Overlying ulceration with an associated inflammatory response may be present. Peripheral palisading is usually prominent and peri-tumoral clefts are often conspicuous in nodular BCC. Centrally, the nuclei lack organization and are more randomly distributed. In larger tumor islands, central areas of necrosis may develop, leading to the formation of cystic spaces. True cystic or nodulocystic BCCs have mucin pools within the tumors (see Fig. 108.19E). Micronodular BCCs are composed of tumor islands much smaller than those of nodular BCC (see Fig 108.19I). The cellular features are similar.

Superficial BCCs are characterized by small, superficially located buds of basaloid cells extending no more deeply than the papillary dermis, with or without clefting (see Fig. 108.19A,B). In a given two-dimensional plane of section, there are skip areas along the epidermis, hence the synonym "superficial multifocal BCC". There is evidence that many of these multifocal buds connect in a net-like pattern, such that most tumors are not truly multifocal.

Keratotic BCCs or BCCs with follicular differentiation contain small keratinized cysts that lack a granular layer within the aggregates of neoplastic cells. These lesions display differentiation towards hair follicle structures. They can be difficult to differentiate from trichoepithelioma or other follicular adnexal neoplasms. Prominent clefting between the palisaded tumor islands and the stroma, as well as a myxoid (rather than a fibrocellular) stroma, characterize these BCCs. Infundibulocystic BCC is similar in appearance to the follicular variant of BCC, but usually has a more anastomosing pattern of tumor nests.

Pigmented BCCs usually have the overall architecture of a nodular BCC. They contain aggregates of melanin, often irregularly distributed, and melanocytes (see Fig. 108.19F). Melanophages are frequently dispersed within the dermis.

Morpheaform, sclerosing and infiltrative BCCs share similar histopathologic features. A common finding is a pattern of strands and cords of basaloid keratinocytes extending between collagen bundles (see Fig. 108.19J). These tumor islands may be composed of very few cells and may surround nerves. A peripheral palisaded pattern of tumor cells is absent and stromal retraction (cleft formation) is also frequently not evident.

Fibroepithelioma of Pinkus is a variant of BCC characterized by thin anastomosing strands and cords of tumor cells that project downward from the epidermis in a fenestrated pattern and are embedded in a fibrous stroma (see Fig. 108.19K). Both peripheral palisading and peritumoral retraction are less prominent. The differential diagnosis includes eccrine syringofibroadenoma and reticulated seborrheic keratosis.

The diagnosis of basosquamous carcinoma has been variably defined and applied. To some, these tumors are characterized by an admixture of typical BCC with zones of keratinization (positive for high-molecular-weight keratin), while to others, basosquamous carcinoma is characterized by histopathologic features of both BCC and SCC (see Fig. 108.19G). To some extent, use of the term may reflect diagnostic uncertainty between BCC and SCC. The diagnosis should be made sparingly, and not for any BCC that has some increased keratinization.

Histologic simulators of BCC

Of the other basaloid tumors that may simulate BCC (Table 108.9), adnexal neoplasms (see Ch. 111) cause the most difficulties, in particular trichoblastoma. In contrast to BCC, clefts in trichoblastoma are located within the stroma and not in direct proximity to the tumor, and follicular germs and papillae, simulating rudimentary hair follicles, are commonly found. Basaloid induction within dermatofibromas and nevus sebaceus may also simulate BCC histopathologically.

TREATMENT

The National Comprehensive Cancer Network (NCCN) has established guidelines of care for NMSCs. These guidelines are not strictly evidence-based, but developed through consensus by a working group of expert clinicians who review, interpret and synthesize the existing literature. For the most current version, see www.nccn.org/professionals/physician_gls/f_guidelines.asp.

Evaluation and risk assessment

Evaluation of a suspected NMSC requires a history, physical examination and biopsy of the suspicious lesion. The history should assess duration, rate of growth, and any prior therapy, as well as any personal or family history of prior skin cancers. Localized neurologic symptoms, although rare, may suggest the possibility of perineural involvement. Any history of prior radiation therapy to the area should be elicited. Current medical problems (e.g. chronic lymphocytic leukemia), medications (e.g. voriconazole) and allergies should be reviewed. Evidence of immunosuppression (i.e. organ transplantation, underlying hematologic malignancy, immunosuppressive medications or HIV infection) should be determined, and any of the risk factors listed in Table 108.3 identified.

Physical examination should include observation and palpation of the tumor to determine exact location and size, and whether it appears to have any connection to underlying structures such as muscle, cartilage or bone. How well or poorly defined the tumor borders are, whether there is physical evidence of prior surgery or other treatment modality (indicating the possibility of recurrence), and development within a site of chronic inflammation or scar should all be assessed. Careful inspection of the surrounding skin to exclude the presence of satellite lesions is necessary, as is examination of the draining lymph nodes, especially

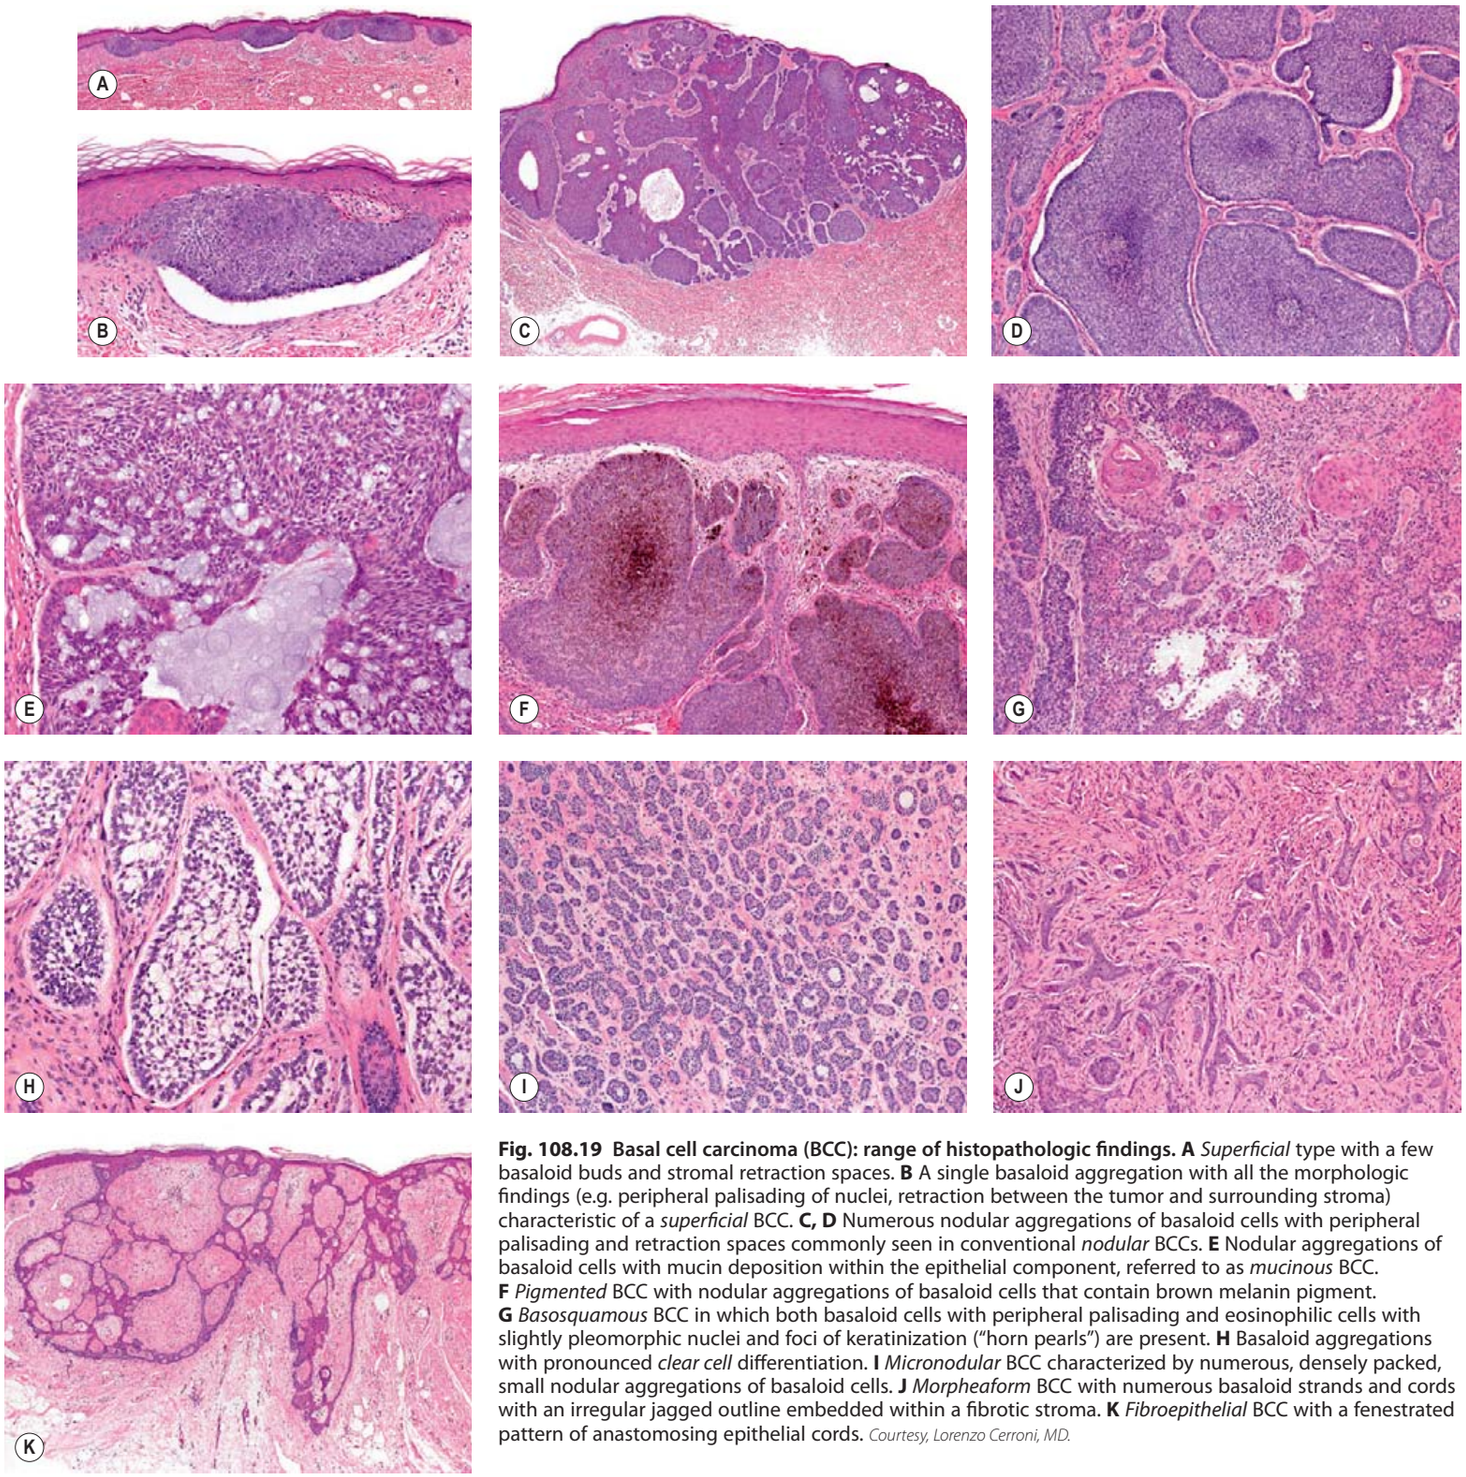

Fig. 108.19 Basal cell carcinoma (BCC): range of histopathologic findings. A *Superficial* type with a few basaloid buds and stromal retraction spaces. **B** A single basaloid aggregation with all the morphologic findings (e.g. peripheral palisading of nuclei, retraction between the tumor and surrounding stroma) characteristic of a *superficial* BCC. **C, D** Numerous nodular aggregations of basaloid cells with peripheral palisading and retraction spaces commonly seen in conventional *nodular* BCCs. **E** Nodular aggregations of basaloid cells with mucin deposition within the epithelial component, referred to as *mucinous* BCC. **F** *Pigmented* BCC with nodular aggregations of basaloid cells that contain brown melanin pigment. **G** *Basosquamous* BCC in which both basaloid cells with peripheral palisading and eosinophilic cells with slightly pleomorphic nuclei and foci of keratinization ("horn pearls") are present. **H** Basaloid aggregations with pronounced *clear cell* differentiation. **I** *Micronodular* BCC characterized by numerous, densely packed, small nodular aggregations of basaloid cells. **J** *Morpheaform* BCC with numerous basaloid strands and cords with an irregular jagged outline embedded within a fibrotic stroma. **K** *Fibroepithelial* BCC with a fenestrated pattern of anastomosing epithelial cords. *Courtesy, Lorenzo Cerroni, MD.*

for high-risk tumors, since in-transit[70] and distant metastases[71] are more common in these patients. In all patients, a full skin examination is required, to exclude other cutaneous malignancies.

Skin cancers are often identifiable visually by an experienced clinician. Nevertheless, a properly performed biopsy is essential to the diagnosis and management of any lesion. Numerous biopsy techniques, including excisional, incisional, shave, saucerization and punch, may be employed (see Ch. 146). For obvious skin cancers, especially in elderly patients, sometimes a tissue specimen can be obtained at the same time as definitive therapy. If a superficial process (such as a superficial BCC or SCC *in situ*) is suspected, or if shallow therapy (such as curettage and electrodesiccation) is being contemplated, a shave biopsy is usually adequate for establishing a diagnosis. In most other instances, a punch biopsy or deep saucerization that extends to subcutaneous fat is preferred. AKs, on the other hand, are often treated without prior biopsy unless invasive NMSC is suspected; clinical judgment determines which AKs require treatment and which can be left untreated.

The biopsy report should include an assessment of histopathologic subtype in both BCC and SCC, and degree of differentiation in SCC. Presence of ulceration and perineural or vascular involvement should be indicated. In SCC, histopathologic assessment of tumor depth, as either an anatomic estimate of depth or an actual measurement of tumor thickness in millimeters, appears to be prognostically useful[52].

Using these data, stratification of a specific tumor into a low- or high-risk category may be made (Table 108.10). High-risk tumors,

HISTOLOGIC SIMULANTS OF BASAL CELL CARCINOMA (BCC)	
	Major distinguishing features
Adenoid cystic carcinoma	Cribriform pattern, EMA-positive
Ameloblastoma	Location in mouth
Basaloid follicular hamartoma	Multiple small papules, positive family history
Cloacogenic carcinoma	Anal location
Dermatofibroma	Basaloid induction in overlying epidermis
Eccrine carcinoma	Small sweat ducts
Folliculocentric basaloid proliferation	Focal follicular budding
Merkel cell carcinoma	Punctate keratin (CK20-positive) in cytoplasm, expression of neuroendocrine markers
Metastatic breast carcinoma	History, single filing, expression of CK7, mammoglobulin, gross cystic disease fluid protein-15
Microcystic adnexal carcinoma	Small keratin cysts, absent stromal retraction, ductal differentiation
Mucinous carcinoma	Pools of mucin with floating basaloid islands
Nevus sebaceus	Basaloid induction; trichoblastomas and BCCs may arise within a nevus sebaceus
Sebaceous carcinoma	Oil red O-positive sebocytes on histochemical staining
Trichoblastoma	Clefts within the stroma; hair germs and papillae
Trichoepithelioma and desmoplastic trichoepithelioma	Horn cysts, absent stromal retraction, papillary mesenchymal bodies, peritumoral CD34 positivity; positive family history when multiple

Table 108.9 Histologic simulants of basal cell carcinoma (BCC). CK, cytokeratin; EMA, epithelial membrane antigen.

RISK FACTORS FOR RECURRENCE OF NMSC		
	Low risk	**High risk**
CLINICAL RISK FACTORS		
Location/size	Area L <20 mm	Area L ≥20 mm
	Area M <10 mm	Area M ≥10 mm
	Area H <6 mm	Area H ≥6 mm
Borders	Well defined	Poorly defined
Primary vs recurrent	Primary	Recurrent
Tumor at site of prior radiation therapy	Negative	Positive
Tumor at site of chronic inflammatory process (SCC only)	Negative	Positive
Rapidly growing tumor (SCC only)	Negative	Positive
Neurologic symptoms: pain, paresthesia, paralysis (SCC only)	Negative	Positive
Immunosuppression	Negative	Positive
PATHOLOGIC RISK FACTORS		
Perineural involvement	Negative	Positive
Subtype (BCC only)	Nodular, superficial	Micronodular, infiltrating, sclerosing
Degree of differentiation (SCC only)	Well differentiated	Moderately or poorly differentiated
Desmoplasia (SCC only)	Negative	Positive
Adenoid, adenosquamous or desmoplastic (SCC only)	Negative	Positive
Tumor thickness (SCC only)	<2 mm	≥ 2 mm (see text)

Area L: low risk for recurrence: trunk, extremities.
Area M: middle risk for recurrence: cheeks, forehead, neck, scalp.
Area H: high risk for recurrence: "mask areas" of face (central face, eyelids, eyebrows, periorbital, nose, lips, chin, mandible, preauricular and postauricular skin/sulci, ear, temple), genitalia, hands and feet.

Table 108.10 Risk factors for recurrence of non-melanoma skin cancer (NMSC). BCC, basal cell carcinoma; SCC, squamous cell carcinoma. Adapted from Miller SJ. The National Comprehensive Cancer Network guidelines of care for nonmelanoma skin cancers. Dermatol Surg. 2000;26:289–92 and Brantsch KD, Meisner C, Schonfisch B, et al. Analysis of risk factors determining prognosis of cutaneous squamous-cell carcinoma: a prospective study. Lancet Oncol. 2008;9:713–20.

particularly SCCs, need to be treated aggressively[72]. For larger and deeper tumors, the possible need for multispecialty collaboration or preoperative imaging studies should be considered. On the basis of this assessment, a rational therapeutic plan is designed. Because of the risk of post-therapeutic tumor recurrence and the elevated risk for subsequent NMSC and melanoma, patients with NMSC are typically followed regularly for life.

Standard excision

Standard surgical excision is effective for most primary BCCs; however, cure rates are inferior to those achieved with Mohs surgery in the case of recurrent BCC, infiltrative BCC, and BCC arising in high-risk (H) anatomic sites. It has been demonstrated that 4 mm margins are adequate for removal in 98% of cases of non-morpheaform BCC <2 cm in diameter. However, for facial lesions, simple excision with narrow margins is often not adequate for effective removal[73]. High-risk SCC requires 6 mm margins, with size >2 cm, poor differentiation, invasion to fat, and location in high-risk areas associated with a greater risk of subclinical tumor extension. Incompletely excised lesions, especially those involving high-risk sites or those involving the deep margin, should be re-treated. Re-excision or Mohs micrographic surgery are the treatments of choice in these cases[74].

Curettage with electrodesiccation

Curettage with electrodesiccation is frequently used by dermatologists to treat BCCs. Cure rates as high as 97–98% have been reported[75], but careful selection of appropriate lesions (e.g. those without extension into the deep dermis) is necessary. In terminal hair-bearing sites, extension of neoplastic cells down follicular structures could also lead to incomplete removal. Curettage and electrodesiccation can be used for small SCCs *in situ* and well-differentiated primary SCCs <1 cm in diameter. With a 4-year follow-up, Honeycutt and Jansen reported a 99% cure rate for 281 SCCs treated with this technique[76]; two recurrences were noted in lesions >2 cm in diameter.

Curettage alone

Barlow et al.[77] reported a 5-year cure rate of 96% for 302 biopsy-proven BCCs treated by a single investigator with curettage alone, with minimal complications (hypopigmentation, scarring). Tumors involving more than 50% of the deep edge of the shave biopsy specimen had an increased risk of recurrence.

Mohs micrographic surgery

Mohs surgery (see Ch. 150) for NMSC results in superior histopathologic verification of complete removal, can allow maximum conservation of tissue, and remains cost-effective when compared to either some excisions (such as those done in a surgical center or hospital operating room) or radiation therapy. Rowe and colleagues[78] reported a recurrence rate for BCC treated with Mohs surgery of only 1% over 5 years. This was superior to all other modalities, including excision (10%), curettage and desiccation (7.7%), radiation therapy (8.7%), and cryotherapy (7.5%). However, percentages do vary amongst studies, depending in part on the physicians involved and the types of lesions selected for inclusion. Although direct comparison of different studies is difficult, Mohs surgery clearly has the highest cure rate when all tumor types are included. In a similar study of treatment of recurrent BCC, Mohs surgery showed a long-term recurrence rate of 5.6%, superior to all other modalities, including excision (17.4%), radiation therapy (9.8%),

and curettage with electrodesiccation (40%). Mohs surgery is the preferred treatment for morpheaform, recurrent, poorly demarcated, high-risk (defined earlier), or incompletely removed BCC, and for those sites in which tissue conservation is paramount and there is a need for reliable clear margins. Mohs surgery is similarly indicated in cases of primary or recurrent SCC.

Radiation therapy

Radiation therapy (see Ch. 139) is a primary option for treating BCC or SCC if surgery is contraindicated. In choosing candidates for this therapy, consideration is given to function, cosmetic outcome and patient preference, but because of concerns regarding potential long-term sequelae, patients over the age of 60 years are preferred candidates. Advantages include avoidance of an invasive procedure in a patient who may not be able to tolerate or is unwilling to undergo surgery. Disadvantages include lack of margin control, poor cosmesis in some patients, prolonged course of therapy, and increased risk for future skin cancers. Radiation therapy is associated with higher recurrence rates than surgery for BCC[79]. Scars from radiation therapy tend to worsen with time, in contrast to surgical scars, which improve over time. Radiation is often used as an adjuvant modality following treatment of aggressive or high-risk SCC with surgery, especially when perineural involvement is identified, although to date no controlled studies have proven its usefulness[80]. Verrucous carcinomas, which are well differentiated and rarely metastasize, are usually not treated with radiation therapy, since there is concern that cellular transformation may result in a worse prognosis.

Cryosurgery

Cryosurgery (see Ch. 138) is a mainstay of treatment for AKs, but has also been used to treat NMSCs. It has the advantage of being fast (particularly in the case of AKs), and is advantageous for those patients wishing to avoid invasive surgery. Complications may include hypertrophic scarring and postinflammatory pigmentary changes. A serious potential adverse outcome is recurrent carcinoma that can become extensive because of concealment by the fibrous scar tissue.

Photodynamic therapy

Photodynamic therapy (see Ch. 135) is most often used for patients with multiple AKs and multiple small NMSCs. Reports of high recurrence rates[81,82] for NMSC suggest that this method may be best reserved for selected tumors when better-established methods are not feasible.

Laser

Laser surgery is an uncommon treatment for NMSCs, with limited data in the literature. One small study involving three patients with NBCC syndrome showed that carbon dioxide laser was effective in treating small, low-risk BCCs[83].

Medical treatment

Non-surgical treatment is employed primarily for AKs and superficial NMSCs. Topical 5-fluorouracil has been used for the treatment of AKs, superficial BCCs, and selected SCCs *in situ*[84]. Side effects are usually limited to local skin reactions (see Ch. 129). Topical diclofenac, a nonsteroidal anti-inflammatory drug (NSAID), is also an effective option for the treatment of AKs[85].

Imiquimod cream (see Ch. 128) has been used for the treatment of AKs and low-risk NMSC[86]. Imiquimod is a Toll-like receptor 7 (TLR7) agonist which induces interferon-α (IFN-α) and other cytokines and promotes Th1-type immunity. Cure rates for nodular BCC range from 53% to 75%, with higher rates for superficial BCC. The major advantage is a superior cosmetic result[87]. In general, adverse side effects are limited to local skin reactions. Topical imiquimod 5% cream has also proven to be a fairly effective treatment for cutaneous SCC *in situ*; in a placebo-controlled trial, 11 of 15 lesions resolved as compared to 0% in the placebo-treated group[88].

Intralesional injection of interferon-α-2b may be used to treat BCC as an alternative to surgical or destructive methods. Tucker et al.[89] reported clinical cures in 95 of 98 BCCs (51 nodular and 44 superficial), with a mean follow-up period of 10.5 years. The main advantage is probably a superior cosmetic result, but the treatment is laborious, because usually nine injections are given (three times weekly for 3 weeks). Intralesional fluorouracil or methotrexate has been more commonly used for KA than for BCC or other forms of invasive SCC.

A new therapeutic concept for patients with advanced or metastatic BCC that cannot be treated with conventional therapeutic methods is the use of hedgehog pathway inhibitors. Mutations that lead to activation of the hedgehog-patched signaling pathway have been associated with the development of BCC (see Ch. 107). Vismodegib (GDC-0449), a selective inhibitor of hedgehog pathway activation via binding to the protein smoothened, was first reported to have antitumor activity in locally advanced or metastatic BCC in 2009[90]. Of the 33 patients with metastatic or locally advanced BCC in this phase I trial, 2 had a complete response while 16 had a partial response. In a randomized, placebo-controlled, phase II trial that enrolled 41 patients with NBCC syndrome, the number of new BCCs per month was 0.07 in those receiving 150 mg/day of oral vismodegib for at least a month, compared to 1.74 in the placebo group[90a]. Side effects included loss of taste, muscle cramps and weight loss, with 20% of patients discontinuing the medication because of side effects.

Combination therapy

Combining more than one therapeutic modality has the potential advantage of enhancing the cure rate while minimizing adverse effects and maximizing cosmetic results. Both topical 5-fluorouracil cream and 5% imiquimod cream have been used to pretreat BCC sites prior to Mohs surgery, leading to a decrease in wound size[91]. Imiquimod cream has also been used, in conjunction with topical fluorouracil cream, for the treatment of SCC *in situ* in transplant recipients. Excellent cosmetic results have been reported when BCCs were treated with just curettage followed by 6 weeks of topical 5% imiquimod cream (applied five times per week).

Metastatic NMSC

Cutaneous SCC of the head and neck most commonly metastasizes to parotid and cervical lymph nodes, and the development of metastases is associated with poor survival[92]. Aggressive local surgery, lymph node dissection, and postoperative radiation therapy are often needed. Chemotherapy for metastatic SCC is usually administered by oncologists and nowadays includes EGFR inhibitors. For metastatic BCC, the use of vismodegib can be considered (see above).

Prophylaxis

Retinoids have been used as prophylaxis against skin cancer development in solid organ transplant recipients, patients with multiple KAs or NBCC syndrome, and those with multiple NMSCs. Studies favor the use of acitretin over isotretinoin due to a better side-effect profile. Low-dose retinoid therapy (0.2–0.4 mg/kg/day) has been associated with lower rates of SCC[93]. Triglyceride levels and liver function should be monitored during therapy (see Ch. 126)[94].

A novel approach for chemoprevention of SCC in transplant patients is low-dose oral capecitabine, a prodrug of 5-flourouracil.

Reduction of immunosuppression in high-risk SCC

Reduction or cessation of immunosuppressive drug therapy has been associated with decreased numbers of future skin cancers and improved outcome in patients with pre-existing skin cancers[95]. This strategy may be useful in patients with many lesions or in cases of metastatic disease. Any alteration of the immunosuppressive regimen, including substitution with sirolimus, must be done in consultation with the primary physician.

Prevention and early detection

Primary prevention programs focused on lowering UV exposure appear to be having a positive effect in reducing the incidence of skin cancer. Consistent use of sunscreens (see Ch. 132) has been shown to decrease the incidence of SCC, but to have no effect or only a weak effect on the incidence of BCC in both immunocompetent individuals and immunocompromised organ transplant recipients[96]. As a side effect, sunscreens decrease pre-vitamin D_3 synthesis. Since vitamin D has been found to reduce non-skin cancer risk[97], the delicate balance between beneficial sun exposure that produces vitamin D and sun exposure that induces skin damage has become a controversial issue.

Marks[98] noted that the regular wearing of a hat with a 10 cm brim could lower lifetime NMSC rates by 40%, yet fewer than half of those watching outdoor sport events wear hats[99]. Other chemopreventive agents currently being evaluated are retinoids, difluoromethylornithine, T4 endonuclease V, polyphenolic antioxidants such as epigallocatechin gallate found in green tea and grape seed extract, silymarin, isoflavone genistein, curcumin, lycopene, vitamin E, beta-carotene, and selenium[100]. Use of NSAIDs did not significantly reduce the number of BCCs and SCCs[101].

Since fewer than 20% of medical students receive training in skin cancer examination[102], programs need to be developed to educate medical professionals in order to increase NMSC diagnostic skills. New non-invasive diagnostic techniques such as RCM may lead to enhanced diagnostic accuracy in the near future[102].

Warty dyskeratoma 1806
Acantholytic (dyskeratotic) acanthoma 1807
Epidermolytic acanthoma 1808
Large cell acanthoma 1808
Epidermal nevus 1809
Inflammatory linear verrucous epidermal nevus 1810
Nevus comedonicus 1811
Acanthosis nigricans 1812
Confluent and reticulated papillomatosis 1812
Clear cell papulosis 1813

The majority of the entities in this chapter can be further classified according to the algorithm in Figure 109.1.

SEBORRHEIC KERATOSIS

Key features

- Common benign lesions that typically begin to appear during the fourth decade of life
- Solitary or multiple, tan to black, macular, papular or verrucous lesions
- Often have a waxy or verrucous, "stuck-on" appearance
- May occur anywhere except mucous membranes, palms and soles
- Large variation in clinical appearance and may simulate melanocytic neoplasms
- In the very rare sign of Leser–Trélat, an abrupt increase in size or number of seborrheic keratoses is associated with an internal malignancy

Introduction

Seborrheic keratoses (SKs) are common benign skin lesions that are almost ubiquitous among older individuals. They only occur on hair-bearing skin, invariably sparing the mucosal surfaces and the palms and the soles. SKs can develop on the face, neck and trunk (especially the upper back), as well as the extremities.

Many clinical and histologic variants of SK have been described, and although they are usually easily recognized clinically, some lesions may prove difficult to diagnose by inspection alone, so biopsy for histopathologic examination may be required. This is especially true when there is a history of recent change or if there is inflammation. Larger dark lesions are sometimes biopsied when there is concern about the possibility of melanoma, but with the advent of dermoscopy, this occurs less frequently.

History

The date of the initial description of SKs is uncertain. In 1927, Fruedenthal delineated their clinical and histologic features.

Epidemiology

An apparent familial predisposition with a postulated autosomal dominant inheritance with incomplete penetrance has been described for the development of SKs. Despite their frequent occurrence, there are few statistics on prevalence, gender or racial predilection, or geographic distribution. Almost all epidemiologic studies have noted SKs as coincidental findings. They have been reported to be more common in Caucasian populations and to affect men and women with equal incidence[1]. Their appearance prior to the fourth decade is uncommon. Usually, additional lesions develop throughout the course of the life of the individual.

Pathogenesis

Although SKs are common in areas covered by clothing, sun exposure has been implicated in their development. Supporting evidence comes from the more frequent occurrence and earlier age of onset of SKs in individuals residing in tropical climates. An Australian study found a higher prevalence of SKs within sun-exposed areas such as the head and neck in contrast to non-sun-exposed areas in the same subjects. The authors also reported a more frequent occurrence and an earlier age of onset in their Australian study group population compared to a UK study group[2].

Based upon analysis of androgen receptor polymorphisms, a clonal origin was detected in over half of lesions evaluated, suggesting a neoplastic as opposed to hyperplastic origin[3]. An alteration in the distribution of epidermal growth factor receptors has also been observed. In irritated SKs, apoptosis within areas of squamous differentiation has been implicated as a cause of the irritation[4]. More recently, *somatic activating* mutations in *FGFR3* which encodes fibroblast growth factor receptor 3[5] and *PIK3CA* (whose protein product is the alpha subunit of phosphoinositide-3-kinase)[6] have been demonstrated within SKs.

Although SKs are often clinically verrucous, human papillomavirus (HPV) has been detected infrequently, except in lesions in the genital region. It is likely that these latter lesions actually represent condyloma acuminatum, as the two entities may appear similar both clinically and histologically[7].

Clinical Features

Occasionally solitary, SKs more commonly present as multiple, pigmented, sharply marginated lesions. They may be macules, papules or even plaques, depending on their stage of development (Fig. 109.2). Even within the same lesion there may be a great variation in color. They are usually light brown but may appear waxy yellow to brown–black in color. SKs typically evolve from a macule and may progress to become papular or verrucous. Keratotic plugging with follicular prominence, a velvety surface, a "stuck-on" appearance and/or hyperkeratotic scale are helpful features in distinguishing SKs from other pigmented

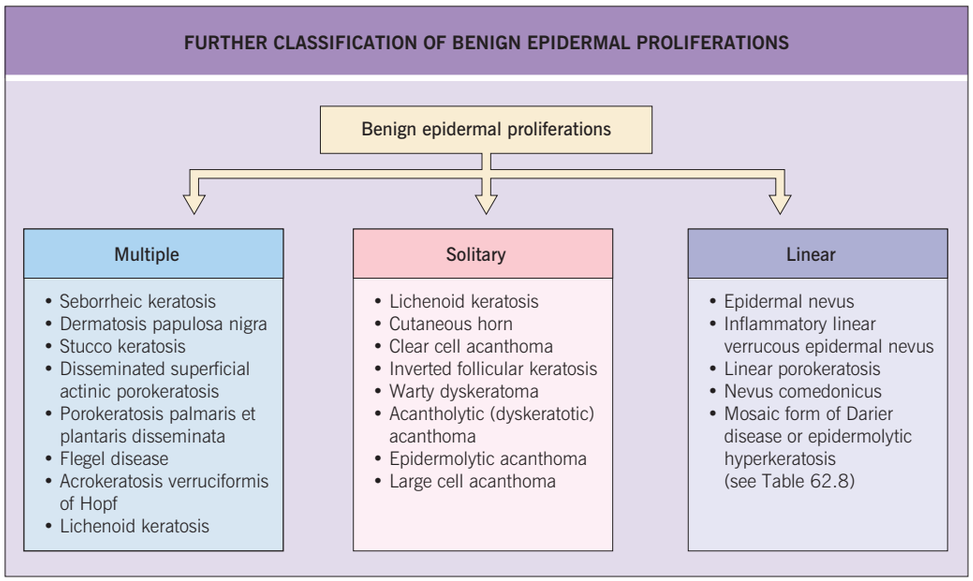

Fig. 109.1 Further classification of benign epidermal proliferations. Although the term solitary lichenoid keratosis is sometimes used, patients may develop multiple lesions, especially those with skin phototypes I or II and significant actinic damage.

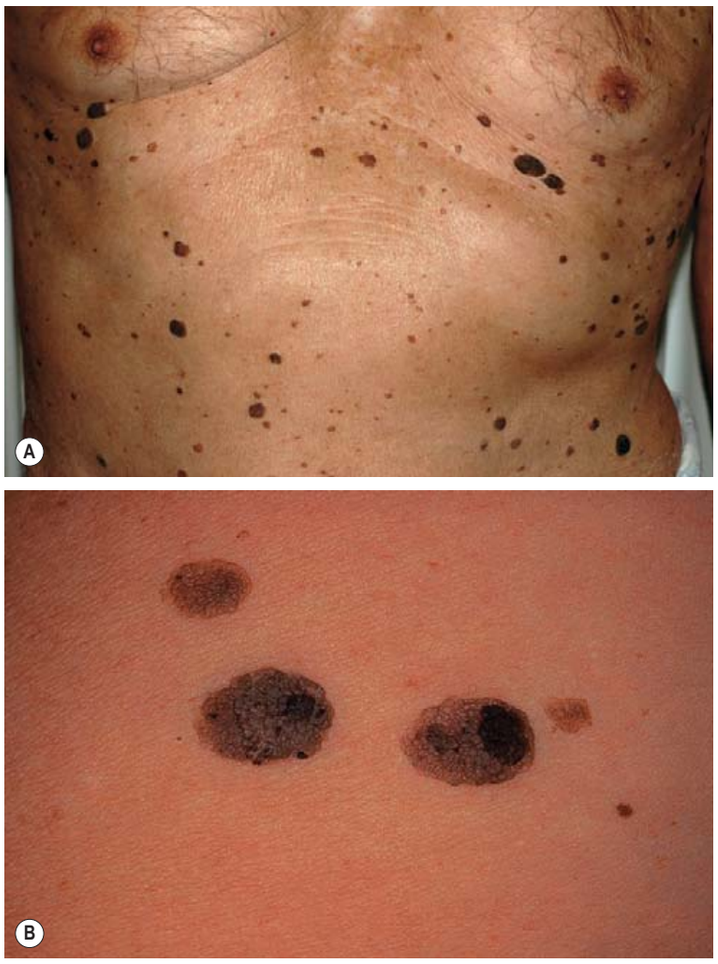

Fig. 109.2 Seborrheic keratoses. A Multiple seborrheic keratoses of the anterior trunk that vary in size and color. **B** Sharply demarcated, pigmented papule and plaques with a papillomatous surface and horn pseudocysts. Note the "stuck-on" appearance.

lesions. Individual lesions may be of any size but usually measure about 1 cm in diameter. They can become quite large, i.e. greater than 5 cm in diameter. Lesions may become inflamed due to rupture of the small pseudocysts they contain or from trauma, or rarely from infection with microorganisms such as *Staphylococcus aureus*. Although usually asymptomatic, traumatized or inflamed lesions may become tender, pruritic, erythematous, crusted and, rarely, pustular.

"Spontaneous regression", although observed, is not a common feature of SKs, even following inflammation. Conditions associated with an abrupt "flare" of lesions followed by regression include pregnancy, coexisting inflammatory dermatoses (in particular erythroderma) and malignancy[8].

Seborrheic Keratosis and Malignancy

Instances of malignant neoplasms arising within and adjacent to SKs were reported as early as 1932[9]. Invasive squamous cell carcinoma (SCC), cutaneous melanoma, basal cell carcinoma (BCC), keratoacanthoma, and SCC *in situ* have all been observed in association with SKs. This likely represents a coincidental neoplasm developing in adjacent skin, although it is possible that the various cell types present in an SK could develop into their respective neoplasms. In theory, the basaloid cells could give rise to BCC, the spinous cells to SCC, and melanocytes to melanoma[9]. BCC is thought to be the most frequent neoplasm seen in association with SKs[9–11], although one prospective study identified only SCC *in situ* when 4310 cases accessioned as SK clinically were evaluated histologically. SCC *in situ* was seen histologically in 60 of these specimens (1.4%)[12]. In another investigation, 4.6% of SCCs were clinically diagnosed as SKs, and in some of these, features of SK were seen in association with the SCC. The "collision" theory, when two distinct neoplasms develop separately at the same site, was entertained as a possible cause for this occurrence, especially given the prevalence of both of these lesions in the population at large[10]. Others believe that BCCs and SKs are both derived from the infundibular portion of the hair follicle, cells of which could evolve into either neoplasm, and in some cases, both concurrently.

The sign of Leser–Trélat is a rare cutaneous marker of internal malignancy (in particular gastric or colonic adenocarcinoma, breast carcinoma, and lymphoma). It is considered to be a paraneoplastic cutaneous syndrome characterized by an abrupt and striking increase in the number and/or size of SKs occurring before, during or after an internal malignancy has been detected[13–15]. Associated pruritus has been documented in over 40% of cases and the majority of the lesions are located on the back, followed by the extremities, face and abdomen[16,17]. Malignant acanthosis nigricans, another paraneoplastic syndrome, may appear at the same time or shortly after the sign of Leser–Trélat in approximately 20% of patients[16]. Rarely, in other conditions such as inflammatory dermatoses (see Ch. 10) and pregnancy[18,19], an abrupt appearance or increase in the number and size of SK lesions has also been reported.

The sign of Leser–Trélat was first described in 1900. Its validity as a reliable marker of internal malignancy has been challenged, given the frequency of both neoplasia and SKs in the elderly population, in whom

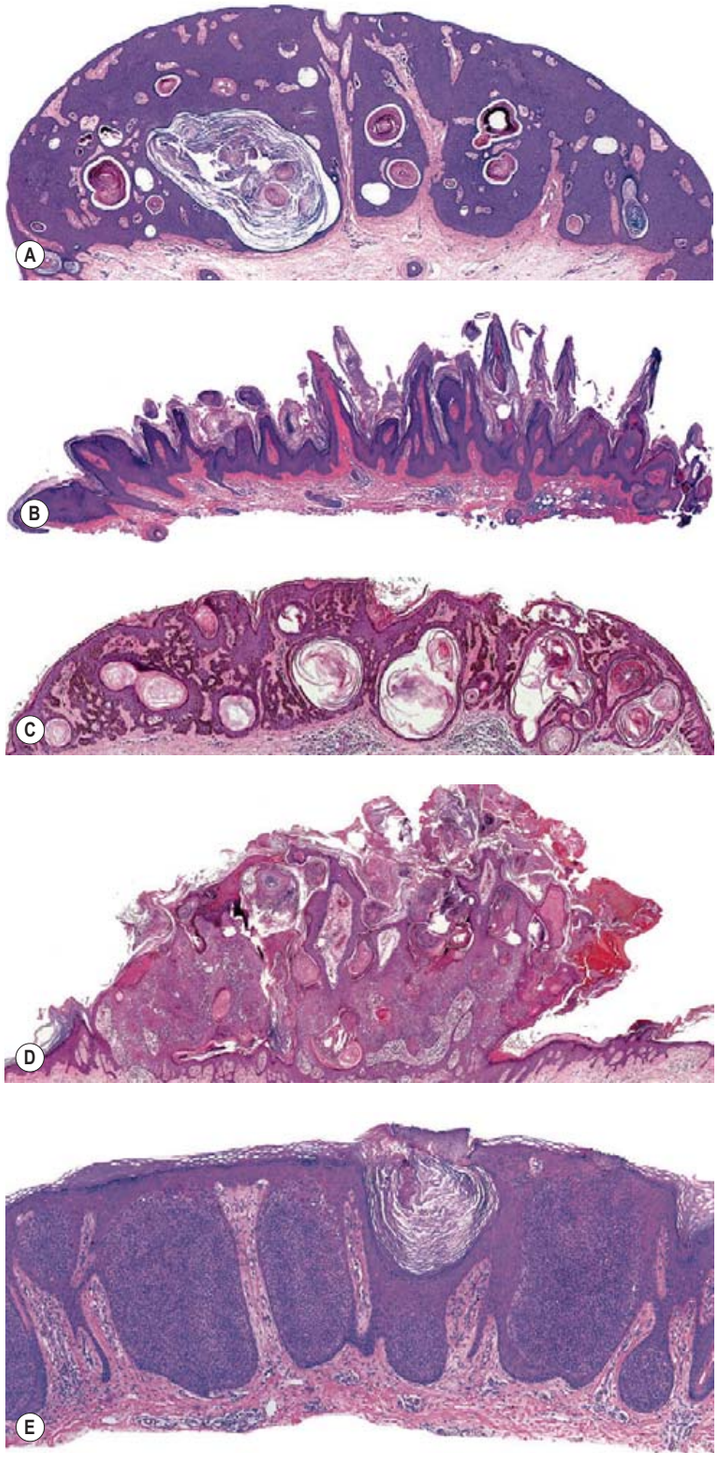

Fig. 109.3 Seborrheic keratoses – spectrum of histologic subtypes. the condition is usually observed[17]. Its description is also loosely defined, which is problematic as there are no standards that quantify the number of lesions required for the diagnosis. The few studies investigating SKs and their link with internal malignancy have largely been inconclusive. One retrospective review examined 1752 consecutive patients with the diagnosis of SK, and of these, 62 individuals were diagnosed with an internal malignancy within 1 year before or after the diagnosis of SK. Of those 62 patients, six patients presented with findings consistent with the sign of Leser–Trélat. However, an age- and sex-matched control group demonstrated similar findings[20].

The pathogenesis of the sign of Leser–Trélat is uncertain, but it is thought to be related to secretion of a growth factor by the neoplasm which leads to epithelial hyperplasia[16]. To qualify as a paraneoplastic process, the cutaneous findings need to coincide with the presence of the malignancy, resolving when the primary tumor is excised or successfully treated and reappearing with its recurrence or metastasis.

Pathology

There are at least six histologic types of SK: acanthotic, hyperkeratotic, reticulated, irritated, clonal and melanoacanthoma. Different histologic features are often present in the same lesion, resulting in diverse appearances. There are varying degrees of hyperkeratosis, acanthosis and papillomatosis. Horn pseudocysts, the product of cross-sectioned epidermal invaginations, are highly characteristic, though not invariably present. Generally, the base of an SK lies on a flat horizontal plane flanked by normal epidermis. The characteristic acanthosis is the result of an accumulation of benign squamous and basaloid keratinocytes, typically projecting outward and upward in an irregular fashion. The sharp demarcation at the base of most lesions has been called the "string" sign. The marked papillomatosis and hyperkeratosis are often likened to "church spires" with shadows of retained cornified material at their peaks.

The squamous cells of many SKs are representative of those found in the normal-appearing epidermis, but some SKs may contain basaloid cells that have a smaller size, uniform appearance and large oval-shaped nuclei. When slight intercellular edema is present, intercellular bridges are easily visualized. Cytologic atypia is usually not a feature of most SKs. Mild keratinocyte atypia and mitotic figures, when present, are usually associated with irritation and inflammation. The papillary dermis in most instances is unremarkable.

The *acanthotic* SK is the most common histologic type. It usually presents as a smooth-surfaced, dome-shaped papule. Slight hyperkeratosis and papillomatosis are often present, while the greatly thickened epidermis typically contains a preponderance of basaloid cells (Fig. 109.3A). Papillae may be narrow in some lesions, while others may be composed of interwoven aggregates of epithelial cells surrounding islands of connective tissue in a retiform pattern. Invaginated horn pseudocysts are most prevalent in this variant. Melanin is often increased in the acanthotic type of SK; it is primarily concentrated in keratinocytes and is transferred from neighboring melanocytes. Deeply pigmented lesions contain abundant melanin in basaloid cells.

The *hyperkeratotic* type of SK, also known as a digitated, serrated or papillomatous type, is almost the morphologic reverse of the acanthotic type. There is acanthosis but there is more prominent hyperkeratosis and papillomatosis (Fig. 109.3B). A preponderance of squamous cells relative to basaloid cells is seen. Abundant pigmentation is unusual, and keratinizing pseudocysts are observed less frequently than in acanthotic SKs. The hyperkeratotic type is the variant often described as having epidermal projections resembling "church spires", a finding also seen in acrokeratosis verruciformis.

The *reticulated* or *adenoid* type of SK is characterized histologically by delicate strands of epithelium that extend from the epidermis in an interlacing pattern (Fig. 109.3C). They are composed of a double row or more of basaloid cells that may be hyperpigmented. Horn pseudocysts, although less common than in the acanthotic variant, may be observed. Often, a solar lentigo is seen at the lateral margins of the lesion, supporting the notion that reticulated SK evolves from a solar lentigo.

A lymphoid infiltrate is often present in the dermis of *inflamed* or *irritated* SKs (Fig. 109.3D). It may be perivascular, diffuse or lichenoid. Spongiosis is often present and there may be necrosis of keratinocytes. Squamous eddies are common findings as well. These consist of whorls of eosinophilic keratinocytes. Irritated SKs often lack the sharply demarcated horizontal base seen with most SKs.

Clonal SKs are considered by some to represent a variant of irritated SK. The clonal, or nested, type of SK is characterized by having well-defined nests of loosely packed cells in the epithelium (Fig. 109.3E). The nests are composed predominantly of variably sized keratinocytes

that are often paler than adjacent cells and have a uniform appearance. They may also contain melanocytes.

Differential Diagnosis

Most SKs are easily identified clinically, although there are entities that may have a similar appearance. Conditions thought to be variants of SKs include dermatosis papulosa nigra, stucco keratoses and inverted follicular keratoses. They are discussed in this chapter under their respective headings. The clinical differential diagnosis includes acrochordon, verruca vulgaris, condyloma acuminatum, acrokeratosis verruciformis, tumor of the follicular infundibulum, eccrine poroma, Bowen's disease, SCC, solar lentigo, melanocytic nevus and melanoma.

Clinical differentiation between macular SKs, solar lentigines, and melanocytic neoplasms such as melanoma may at times be impossible. Solar lentigines are neither hyperkeratotic nor elevated and some are considered to represent an incipient reticulated type of SK. Over time, these lesions can develop into SKs as the buds of pigmented basaloid cells become thicker and there is greater acanthosis. Dermoscopy may be useful in distinguishing these entities (see Chs. 0 and 112).

A recent review of 20 cases of verrucous melanoma demonstrated how difficult it may be to distinguish between benign and malignant tumors. Of interest, 50% of these verrucous melanomas were thought to represent SKs clinically and a histopathologic diagnosis of a benign nevus was assigned to 10%. A broad spectrum of histopathologic findings, including hyperkeratosis, pseudoepitheliomatous hyperplasia, asymmetry and exophytic papillomatous growth pattern, were present in these cases[21].

Acanthotic and irritated types of SK should be delineated from eccrine poroma. On occasion, SKs may demonstrate "poroid" differentiation. Clinically, poromas are skin-colored, brown, pink or sometimes red papules or nodules that may be pedunculated and multilobular. Histologically, poromas are comprised of homogeneous, small basophilic cells with a delicate fibrovascular stroma and narrow ductal lumina with eosinophilic, PAS-positive, diastase-resistant cuticles (see Ch. 111).

Differentiation between an irritated SK, an SCC *in situ* (Bowen's disease) and SCC may require histopathologic examination. An irritated SK may be misdiagnosed as a carcinoma if atypia is present. Although squamous eddies may be abundant in both tumors, there should be no evidence of involvement of the dermis in irritated SKs. Bowen's disease demonstrates a preponderance of atypical keratinocytes with vacuolated cytoplasm, close crowding of nuclei, abundant mitoses and parakeratosis. The adnexal epithelium is also involved.

The Borst–Jadassohn pattern of clonal SK is also seen in some examples of Bowen's disease. In general, Bowen's disease with a clonal or nested pattern has greater atypia of the individual keratinocytes.

Melanoacanthoma was originally described by Bloch and named "non-nevoid melano-epithelioma, type 1"[22]. It is now regarded as a heavily pigmented SK by most authorities. In this variant, melanocytes are distributed throughout the lesion. While the keratinocytes contain melanin, the bulk of the pigment is present within melanocytes, many of which also have long dendrites[23]. Although the melanocytes are prominent, there is no significant increase in their number. The heavy pigmentation of melanoacanthoma has been explained by the blockage of transfer of melanin to keratinocytes, perhaps leading to an increase in the amount of melanin within melanocytes.

Intraoral melanoacanthoma or melanoacanthosis was first described in 1979. These lesions bear a striking clinical resemblance to the melanoacanthoma type of SK. Histologically, they are distinct from the cutaneous variant by having only minimal epithelial hyperplasia. Their histologic features are most like those of a heavily pigmented lentigo simplex, with a proliferation of dendritic melanocytes within the basal layer of the epithelium[24].

Verruca and condyloma acuminatum are hyperplasias caused by HPV. Both can clinically mimic SKs but differ in that they most frequently occur in younger individuals. Verrucae often present as rough papules with red or black dots that represent dilated or thrombosed capillary loops at the tips of the underlying dermal papillae. Verrucae favor acral locations, while condylomata acuminata occur in the genital region and rarely on the buccal mucosa. HPV has been reported in anogenital lesions with histologic features of SK[25] (see above). Koilocytic changes of perinuclear vacuolization with nuclear pyknosis in the superficial epidermis may not be present in some verrucae, but are helpful if present. An SK generally tends to be oriented in a more horizontal than vertical fashion, often has horn pseudocysts, and lacks koilocytes.

Tumor of the follicular infundibulum is distinguished from an SK by a superficial distinct plate-like epithelial proliferation. The latter consists of multiple slender epidermal connections composed of basaloid or pale cells, without as much hyperkeratosis as an SK. The reticulated type of SK has a similar pattern but lacks the distinct plate-like growth. Lightly pigmented SKs can easily be mistaken for an acrochordon, which has a pedunculated shape and is usually smoother and smaller in size.

Other conditions with papillated epidermal hyperplasia histologically are readily distinguished on a clinical basis. Some of these include acanthosis nigricans, epidermal nevus, and confluent and reticulated papillomatosis. Epidermal nevi tend to follow Blaschko's lines, appearing in a linear arrangement on the extremities and a whorled pattern on the trunk. Although histologic sections of epidermal nevi typically exhibit acanthosis and hyperkeratosis, they usually lack the pseudocysts seen in many SKs. Epidermal nevi are also usually apparent at birth or shortly thereafter, unlike SKs, which are seen in adults.

Acrokeratosis verruciformis of Hopf has a "church spire" configuration similar to that described for hyperkeratotic SK[26], but it is an autosomal dominant disorder (see Ch. 59) and lesions are usually limited to the distal extremities. Acanthoma fissuratum may clinically resemble a large SK, but histologic analysis reveals irregular epidermal hyperplasia.

Treatment

Treatment of asymptomatic SKs is largely performed for cosmetic reasons. Symptomatic lesions are usually removed by destruction, curettage or shave excision. The most common method of destruction is cryotherapy. Other methods include laser vaporization (pulsed CO_2, erbium:YAG) or electrodesiccation.

LICHENOID KERATOSIS

Synonyms: ■ Lichen planus-like keratoses (LPLK) ■ Solitary lichen planus ■ Solitary lichenoid keratosis (SLK) ■ Benign lichenoid keratosis (BLK)

Key features

- A solitary, pink to red–brown, scaly papule, most common on the upper chest or forearms
- Histologically, it appears almost identical to lichen planus, but is distinguished by clinical correlation
- Represents an inflammatory stage of a solar lentigo, actinic keratosis or SK

History

In 1966, two independent groups reported lesions with the histologic features of lichen planus but, unlike lichen planus, they occurred as solitary asymptomatic lesions. These two groups referred to these lesions as solitary lichen planus and solitary lichen planus-like keratosis.

Epidemiology

Eighty-five percent of lichenoid keratoses (LKs) develop between the ages of 35 and 65 years[27]. Women are diagnosed with the condition twice as frequently as men, and the vast majority of lesions are seen in Caucasians.

Pathogenesis

LKs have been thought to represent inflammation of a benign lentigo, actinic keratosis or SK. Because at least half of the lesions are related to "precancerous" actinic keratoses, the term lichenoid keratosis is preferred over the term benign lichenoid keratosis (BLK). Lesions are best referred to as lichenoid actinic keratosis when there is significant keratinocyte cytologic atypia or other classic features of an actinic keratosis, and as irritated SK when a lichenoid infiltrate is associated with other features of an SK. The authors prefer to use the term BLK only when the lesion is associated with a lentigo, with no evidence of actinic keratosis or SK.

Increased numbers of Langerhans cells have been observed in the epidermis of LKs. This has led to the suggestion that the lichenoid infiltrate of lymphocytes is secondary to a stimulus from Langerhans cells after their processing of an unidentified epidermal antigen. This mechanism is similar to that proposed for lichen planus. Constant pressure has been incriminated as an etiologic factor in some cases.

Clinical Features

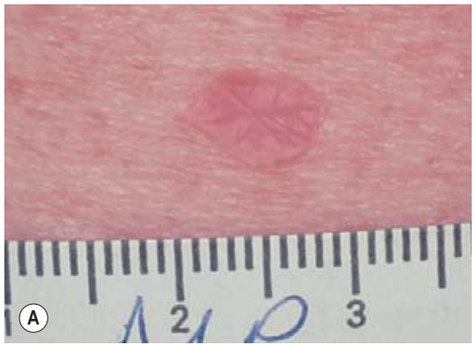
LKs occur primarily as solitary pink to red–brown, often scaly, papules ranging from 0.3 to 1.5 cm in diameter (Fig. 109.4A). An astute clinician can oftentimes suspect the diagnosis before the biopsy is performed. LK most closely resembles a BCC or Bowen's disease, and for this reason, these lesions are frequently biopsied. They are usually asymptomatic, although occasionally patients complain of slight pruritus or stinging[28]. The most common sites are the forearm and upper chest, with less frequent occurrence on the shins (in women) and other chronically sun-exposed sites.

Pathology

LK has a lichenoid infiltrate composed mainly of lymphocytes with scattered histiocytes (Fig. 109.4B). Eosinophils and plasma cells are sometimes present. All other elements of an interface dermatitis are observed, including basal vacuolar alteration, melanin incontinence, and colloid bodies. When melanin incontinence is prominent, and the lesion is clinically pigmented, sometimes the term pigmented lichenoid keratosis is used. Parakeratosis may be seen, unlike typical lichen planus. Sometimes there is frank separation of the epidermis from the infiltrate in the dermis, giving rise to a subepidermal blister or cleft. Basal cell proliferation is absent, and keratinocyte atypia is either mild or absent. Changes of a solar lentigo are often present at the periphery of the specimen. In some cases, a macular SK is observed.

Occasionally, lesions of LK may mimic mycosis fungoides, because of the presence of Pautrier-like microabscesses, alignment of lymphocytes along the basal layer and epidermotropism of the infiltrate. There are also atrophic and bullous variants, and sometimes the lesion may mimic lupus erythematosus or toxic epidermal necrolysis histopathologically[29].

LKs may undergo regression, and histologically, the appearance of a regressed keratosis may be confused with other regressing tumors, especially melanoma. The regressed LK usually displays a loosely fibrotic papillary dermis with scattered lymphocytes and melanophages. Regressed melanoma typically has a dense band of melanophages with lymphocytes and dilated blood vessels; there is also usually a thin epidermis overlying effaced rete ridges. In states of partial regression, remaining histologic clues to the proper diagnosis remain. The end stages of both tumors may not be distinguishable. Careful search for elements of superficial BCC is also advisable.



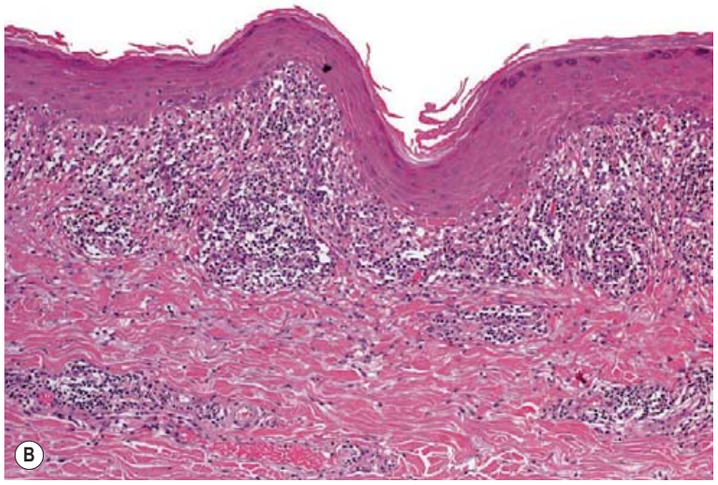


Fig. 109.4 Lichenoid keratosis. A Pink, flat-topped papule in a fair-skinned individual. **B** A lichenoid infiltrate beneath the epidermis with formation of Civatte bodies. Compact hyperkeratosis is also present. *A, Courtesy, Jean L Bolognia, MD. B, Courtesy, Lorenzo Cerroni, MD.*

Differential Diagnosis

Frequently cited clinical impressions include BCC, Bowen's disease, actinic keratosis, irritated SK, melanoma (including amelanotic), and nevus. A recent change in pigmentation of a lesion often leads the clinician to suspect an atypical melanocytic nevus or melanoma[27]. There is frequently melanin incontinence in the dermis associated with the vacuolar alteration of the basal cell layer and damage to melanocytes. The pathologist must take care to ensure that the lichenoid infiltrate is not obscuring melanoma *in situ* or even melanoma involving the superficial dermis, as these tumors may become heavily inflamed.

LK resembles other conditions with a band-like inflammatory (lichenoid) reaction pattern, including lichen planus, "lichenoid" lupus erythematosus, and lichenoid fixed drug reactions. Clinical correlation is very useful in excluding these conditions. Although lichen planus may be virtually identical to LK histologically, there is usually more wedge-shaped hypergranulosis and less parakeratosis in lichen planus. Clinically, in contrast to lichen planus, LK occurs as a single lesion in an overwhelming majority of patients.

Treatment

Once the diagnosis of LK is made, no further therapy is necessary. Any remaining lesion may be destroyed by any method.

DERMATOSIS PAPULOSA NIGRA

Key features

- Most common in individuals of African descent with darkly pigmented skin
- Multiple hyperpigmented papules on the face
- Considered to be a variant of SK
- Cryotherapy can result in hypopigmentation; best treatment is scissor snip, curettage or electrodesiccation, when desired

Introduction

Dermatosis papulosa nigra (DPN) is characterized by the presence of multiple, hyperpigmented, sessile to filiform, smooth-surfaced papules measuring from 1 to 5 mm, typically occurring on the face of darkly pigmented individuals (Fig. 109.5).

History

DPN was first described by Castellani in 1925 based on his observations during visits to Central America and Jamaica.

Fig. 109.5 Dermatosis papulosa nigra. Multiple hyperpigmented papules with typical location on the cheeks.

Epidemiology

DPN has a strong familial predisposition and has been reported to have an incidence in selected study populations ranging from 10% to 75%. This variability in incidence may be a reflection of sampling, as lighter-skinned blacks are affected less commonly[30]. In addition to those with African heritage, the condition has also been reported in Filipinos, Vietnamese, Europeans and Mexicans[30]. Rarely, it may be seen in children. Women are twice as likely to be affected as men. DPN is not related to any systemic disease or syndrome.

Pathogenesis

The cause of DPN is unknown. It tends to have an earlier age of onset than that of SKs, but otherwise is similar and probably is a variant of SK. Others view it as a variant of multiple fibroepithelial papillomata (acrochordons). There are ongoing molecular studies evaluating the potential role of circulating growth factors and receptor interactions in the development of DPN.

Clinical Features

Pigmented papules are distributed symmetrically across the malar eminences and forehead. Less often, lesions are on the neck, chest and back. The papules usually appear during adolescence, gradually increasing in size and number over time, and peaking in the sixth decade.

Pathology

DPN is characterized by acanthosis, papillomatosis and hyperkeratosis in a pattern quite similar to the acanthotic type of SK. Horn pseudocysts, however, are not a common feature.

Differential Diagnosis

The differential diagnosis of DPN includes primarily multiple SKs and acrochordons. Occasionally, melanocytic nevi, lentigines, verrucae, trichoepitheliomas, trichilemmomas, follicular hamartomas, syringomas and angiofibromas might be considered clinically.

Treatment

Treatment of DPN is generally performed only for cosmetic purposes, although individual lesions may be troublesome. Care should be exercised to avoid treatments that may result in dyspigmentation, so it may be best at first to only treat a small number of lesions. Snip excision with scissors, curettage and light electrodesiccation are the most common treatment modalities. Hypopigmentation after cryotherapy can be particularly problematic, since melanocytes are more sensitive to freeze damage than are keratinocytes.

Fig. 109.6 Stucco keratoses. Multiple gray–white keratotic papules on the ankle and dorsal foot. *Courtesy, Jean L Bolognia, MD.*

STUCCO KERATOSIS

Synonym: ■ Keratosis alba

Key features

- Gray–white papules or small plaques
- Typically on the lower extremities of older adults, especially the ankles
- Lesions are "stuck on", and when scraped off, there is minimal bleeding
- Probably is a white variant of SK

Introduction

Stucco keratoses are discrete gray–white papules and small plaques that are hard and opaque, with the latter reflecting focal accumulations of cornified material. They are usually distributed symmetrically below the knee, especially on the dorsal and lateral aspects of the foot and ankle (Fig. 109.6). Occasionally, they may also be noted on the thighs and the forearms.

History

Kocsard was the first to characterize stucco keratoses in 1958 based on his observations in 24 affected men in an Australian study group of 240 geriatric participants. The term stucco keratosis was coined by Kocsard in 1966, alluding to its "stuck-on" appearance. Although early accounts of stucco keratoses described elastotic changes in the upper dermis, this has been shown to represent solar elastosis.

Epidemiology

There is no familial predilection for stucco keratoses. They are noted more frequently during cold winter months, which is probably a manifestation of them being more overt with lower humidity and dry skin. They are seen most commonly in middle-aged to elderly individuals and are usually first observed after the age of 40. Men are four times more likely to be affected than women. Most patients are Caucasian, although information regarding racial or ethnic background is minimal. There are no known associated diseases or syndromes.

Pathogenesis

The cause of stucco keratosis remains unknown. Histochemical studies suggest an acquired focal abnormality of keratinization. Ultrastructural

examination has revealed no viral particles[31]. However, one immunocompetent patient with extensive stucco keratoses was shown to have multiple HPV types within various lesions using PCR technology[32]. The significance of this finding is not known, as HPV is purported to occur in about 20% of normal skin specimens[33].

Sun exposure has been proposed to be a factor in the formation of stucco keratosis, as most affected individuals present with manifestations of solar damage. However, this may be a reflection of the age and phototype of the patients. Heat and petroleum products such as tar have also been implicated.

Clinical Features

Gray–white papules or small plaques are typically present on the lower extremities of older adults. Lesions on the upper extremity are less common and the palms and soles are not involved. The papules may number in the hundreds. They are usually small, measuring from 1 to 4 mm, but rarely individual plaques may be as large as a few centimeters. Occasionally, brown, pink and deep yellow shades have been described. The lesions may be scraped or flicked off the skin surface with a fingernail and there is usually minimal, if any, bleeding. A collarette of dry scale may remain.

Pathology

Stucco keratoses display prominent orthokeratotic hyperkeratosis and papillomatosis, often imparting a peaked "church spire" pattern. Acanthosis is usually present, but to a lesser degree than in some SKs. The granular layer may be thickened. Horn cysts are usually absent and cytologic atypia is not a feature.

Differential Diagnosis

Stucco keratoses may resemble SKs, acrokeratosis verruciformis of Hopf, epidermodysplasia verruciformis, or verrucae plana. SKs tend to be larger and pigmented with a surface that appears "greasy", in contrast to stucco keratoses, which are smaller and have a dry, rough surface. Histologically, stucco keratoses resemble hyperkeratotic SKs and acrokeratosis verruciformis. All three may demonstrate papillomatosis and digitation, giving an appearance similar to "church spires" under the microscope. Acrokeratosis verruciformis differs from stucco keratoses in that it is an autosomal dominant disorder and involves the dorsal aspects of the hands (as well as the feet).

Treatment

As with SKs, treatment is generally for cosmetic reasons, although symptomatic lesions may require removal. Curettage, or local destruction with cryosurgery or electrodesiccation, are the usual forms of treatment. Some lesions soften with application of urea, lactic or α-hydroxy acids, or retinoid preparations, although these agents do not usually lead to their removal.

POROKERATOSIS

Key Features

- At least five clinical variants of porokeratosis are recognized
- The prototype, porokeratosis of Mibelli, is a plaque that appears during infancy or childhood
- Disseminated superficial actinic porokeratosis (DSAP) is the most common type, with multiple thin papules appearing most commonly on the legs of adult women
- Linear porokeratosis develops during infancy or childhood and follows the lines of Blaschko
- Punctate porokeratosis appears during or after adolescence as 1–2 mm papules of the palms and soles
- Porokeratosis palmaris et plantaris disseminata (PPPD) is a variation of punctate porokeratosis, with lesions also present on other areas of the body
- Some forms are inherited in an autosomal dominant fashion, but many patients have no family history
- A thread-like raised hyperkeratotic border is characteristic
- Histologically, a thin column of parakeratosis, the cornoid lamella, is seen in all variants and corresponds to the raised hyperkeratotic border seen clinically
- Development of SCC is possible but rare

Introduction

Porokeratosis presents as a hyperkeratotic papule or plaque, with an annular appearance due to its thread-like elevated border that expands centrifugally. The disorder was erroneously named porokeratosis because the column of parakeratosis known as the cornoid lamella was initially described as being present over a sweat pore, which of course is a fixed structure that cannot expand peripherally. At least five types of porokeratosis have been recognized. The different varieties of porokeratosis are likely related, as evidenced by reports of more than one type of porokeratosis developing in the same patient[34] and in multiple members of an affected family[35].

History

In 1893, Mibelli first described what is now considered classic porokeratosis: one to several discrete plaques that may occur anywhere on the skin or mucous membranes, usually appearing during infancy or childhood. That same year, Respighi reported a superficial and disseminated form of the disease. Descriptions of linear porokeratosis first appeared in 1918. Disseminated superficial actinic porokeratosis (DSAP) was detailed by Chernosky in 1966. Guss, in 1971, was the first to report porokeratosis palmaris et plantaris disseminata (PPPD). In 1977, Rahbari proposed that punctate porokeratosis be added to the group of diseases already classified as variations of porokeratosis.

Epidemiology

Porokeratosis is sometimes inherited as an autosomal dominant disorder, but most cases appear to be sporadic. Porokeratosis of Mibelli affects boys more than girls, but DSAP is more common in women. PPPD is inherited in an autosomal dominant manner yet is twice as common in males than in females, perhaps reflecting an environmental factor. DSAP is more common in Caucasians and is rare in blacks. Linear porokeratosis has been reported in monozygotic twins[36], and it has been seen in families with other types of porokeratosis (see below)[37], but a specific heritable pattern has thus far not been identified.

Pathogenesis

Although porokeratosis is thought to be a disorder of keratinization, the definitive pathogenesis remains unclear. In the case of DSAP, there are four possible genetic loci: 12q23.3 (DSAP1)[38], 15q25.1–26.1 (DSAP2)[39], and 1p31.3–p31.1 (DSAP3)[40], and 18p11.3 (DSAP4). For DSAP1, candidate genes include *SART3*[41] (encodes a tumor rejection antigen involved in the regulation of messenger RNA splicing), *SSH1*[42], and *ARPC3*[43]; the latter two are involved in polymerization and dynamics of actin filaments. The proposed genetic locus for PPPD1 is 12q24.1–q24.2.

An old hypothesis set forth by Reed proposes that lesions of porokeratosis represent an expanding mutant clone of keratinocytes. In Reed's view, the characteristic cornoid lamella, seen histologically, represents the border between normal epidermis and the mutant clone of cells. A dermal lymphocytic infiltrate beneath the cornoid lamella or in the central zone of the lesion is considered to be an immunologic response. Supporting this theory is the finding of abnormal DNA ploidy in keratinocytes of porokeratosis[44]. Triggering factors such as UV exposure[45] or immunosuppression due to AIDS[46] or organ transplantation[47] may induce porokeratosis in individuals who are genetically predisposed to developing abnormal clones of keratinocytes. A second, less accepted, theory suggests that the dermal lymphocytic infiltrate may be directed against an unidentified epidermal antigen and that this population of inflammatory cells releases mediators that provide a mitotic stimulus for epidermal cells[48]. A relationship between porokeratosis and HPV has not been established.

Clinical Features

Classic *porokeratosis of Mibelli* is a rare condition, beginning during infancy or childhood as an asymptomatic, small, brown to skin-colored keratotic papule that gradually enlarges over a period of years to form a plaque that may measure several centimeters in diameter. There is a raised, sharply demarcated, keratotic, thready border with a longitudinal furrow (Fig. 109.7A). The center of the lesion may be hyperpigmented, hypopigmented, atrophic and/or anhidrotic. Lesions may occur anywhere on the body, including mucous membranes, but the extremities are most frequently involved. Multiple lesions may appear, but they are almost always regionally localized and unilateral. It can be inherited in an autosomal dominant fashion.

Disseminated superficial porokeratosis and *disseminated superficial actinic porokeratosis* (DSAP) are actually more common than the Mibelli type. Small asymptomatic or mildly pruritic keratotic papules, usually ranging from 2 to 7 mm in diameter, appear during the third to fourth decades of life. They are often skin-colored to tan to pink or red in color. As the lesions progress, they expand radially, and the older, central area becomes atrophic while the well-demarcated border develops a thin, elevated, furrowed keratotic rim (Fig. 109.7C,D). Lesions occur in a more widespread pattern than other types of porokeratosis. Disseminated superficial porokeratosis usually involves the extremities bilaterally and symmetrically, sparing the palms, soles and mucous membranes, while the actinic form (DSAP) occurs exclusively in sun-exposed areas, most commonly the legs below the knees.

A majority of patients with DSAP report that the lesions become more prominent and erythematous during the summer[49]. Chernosky coined the term DSAP to distinguish this variant from the non-actinic disseminated superficial porokeratosis. He was able to induce lesions by exposing patients to UV light. Other investigators have not been able to reproduce these results and have questioned whether these lesions are really actinically induced. While many patients with DSAP have involvement of the shins and extensor forearms without involvement of other areas of sun damage (analogous to idiopathic guttate hypomelanosis), there are individuals with widespread involvement who clearly have sparing of non-sun-exposed sites. In addition, there are case reports of patients with psoriasis receiving UVB or PUVA treatments developing DSAP. DSAP may resemble and coexist with actinic keratoses, but, unlike actinic keratoses, DSAP almost always involves the legs and rarely the face whereas patients with actinic keratoses on the legs almost always have them on the face as well[50]. Rarely, DSAP has been reported in association with hepatitis C infection or systemic lupus erythematosus.

Linear porokeratosis arises in infancy or childhood, and it consists of one or more plaques that are similar in appearance to classic porokeratosis; however, the plaques follow the lines of Blaschko, most commonly on the extremities (Fig. 109.7E). Some patients have both DSAP and linear porokeratosis and the latter may represent loss-of-heterozygosity (i.e. type 2 mosaicism; see Fig. 62.2).

PPPD is uncommon and individual lesions resemble those of porokeratosis of Mibelli except they are smaller and have a less pronounced keratotic border. They may be asymptomatic or pruritic, and generally arise during childhood or adolescence. As the name suggests, the palms and soles are initially affected, but any surface, including mucous membranes, may be involved.

Fig. 109.7 Porokeratoses. A Porokeratosis of Mibelli on the hand of a child. **B** Actinic porokeratosis in a renal transplant patient with significant solar damage. Note the narrow, elevated rim. **C, D** Multiple lesions of disseminated superficial actinic porokeratosis (DSAP) with obvious peripheral keratotic rims; lesions can range in color from light brown to pink. **E** Several streaks of linear porokeratosis on the lower extremity. **F** Multiple keratotic papules of the plantar surface due to punctate porokeratosis. *B, C, D, Courtesy, Jean L Bolognia, MD. F, Courtesy, Kalman Watsky, MD.*

Punctate porokeratosis is the most difficult type to recognize clinically because of the small size of the lesions. It appears during adolescence or adulthood as small "seed-like" keratotic papules with a peripheral raised rim on the palms and/or soles[51] (Fig. 109.7F). It may clinically resemble punctate keratoderma, Darier disease, Cowden disease and arsenical keratoses, but a biopsy will usually confirm the diagnosis of punctate porokeratosis with its characteristic cornoid lamella. However, parakeratotic columns can be seen in spiny keratoderma in which the lesions resemble the spines of an old-fashioned music box.

Development of SCC in lesions of porokeratosis has been reported in all variants except the punctate form. Lesions in older patients, those of longstanding duration, and linear variants all have higher rates of malignant degeneration. DSAP has the lowest risk of malignant change[52]. SCC generally appears as a papule or plaque arising in contiguity with the individual lesion of porokeratosis, leading to asymmetry.

Other unusual or rare forms of porokeratosis include lesions that simulate porokeratosis of Mibelli, given their large diameter, but occur in immunocompromised adult patients (Fig. 109.7B). Porokeratosis can also develop within body folds, especially the gluteal cleft, termed porokeratosis ptychotropica.[53] Other uncommon clinical variants of porokeratosis include a reticular form[54] and a follicular variant[55]. In CDAGS syndrome, a very rare autosomal recessive disorder, patients develop erythematous plaques on the face and extremities that histologically resemble porokeratosis. *C*raniosynostosis and clavicular hypoplasia, *d*elayed closure of the fontanelle, *a*nal anomalies, and genitourinary malformations are additional findings to this *s*kin eruption[56].

Pathology

Identification of the cornoid lamella is the *sine qua non* for the histologic diagnosis of porokeratosis, although it may be seen in other conditions such as verruca vulgaris and actinic keratosis. It is characterized by a thin column of tightly packed parakeratotic cells extending from an invagination of the epidermis through the adjacent stratum corneum, often protruding above the surface of the adjacent skin (Fig. 109.8). Under the cornoid lamella, the granular layer is either absent or markedly attenuated, but it is of normal thickness in other areas of the lesion. Dyskeratosis and pyknotic keratinocytes with perinuclear edema are present in the spinous layer beneath the cornoid lamella. The superficial portion of the cornoid lamella trails toward the center of the lesion in a pattern that has been likened to smoke coming out of a moving train as the "clone" of epidermal cells advances centrifugally. The cornoid lamella corresponds to the clinically observed raised hyperkeratotic border. The clinician should include this portion of the lesion in the biopsy to establish the diagnosis. Sometimes, cornoid lamellae are found in multiple locations throughout the lesion in addition to the periphery. The invagination from which the cornoid lamella extends is less pronounced in varieties other than classic porokeratosis of Mibelli. Corresponding with the less prominent border seen in DSAP, the cornoid lamella in DSAP often does not protrude above the surface of the adjacent stratum corneum. The epidermis in the central portion of the porokeratotic lesion may be normal, hyperplastic or atrophic, with effacement of rete ridges. The dermis contains lymphocytes that may be perivascular, localized beneath the cornoid lamella, or lichenoid in the central portion of the lesion.

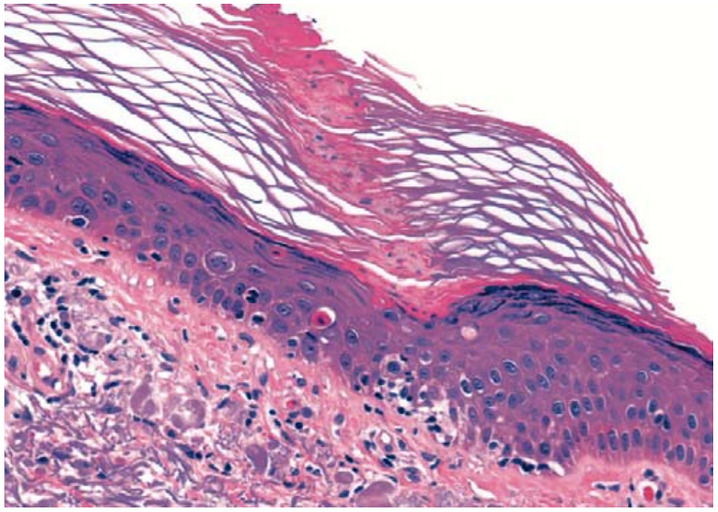

Fig. 109.8 Porokeratosis – histologic features. The cornoid lamella, a narrow column of parakeratotic cells, is the typical histologic feature of porokeratosis. Note both the absence of the granular layer and the vacuolar change at the dermo-epidermal junction beneath the cornoid lamella.

Differential Diagnosis

Porokeratosis can resemble other annular lesions (see Table 19.1) as well as actinic keratoses, but dermoscopy can assist in detection of the furrowed keratotic rim. Linear porokeratosis may be confused with other linear lesions (see Ch. 62) such as inflammatory linear epidermal nevus, incontinentia pigmenti (stage II) and linear lichen planus, none of which have a cornoid lamella. Cornoid lamellae can be found in actinic keratoses, but, in the latter, partial epidermal cytologic atypia is invariably present. Verruca vulgaris often has mounds of parakeratosis that are sometimes identical to cornoid lamellae, but koilocytosis is usually present along with other histologic features of warts. Porokeratotic eccrine ostial and dermal duct nevus is a separate entity (see Ch. 111).

Treatment

Cryotherapy[49], topical 5-fluorouracil (5-FU)[50], topical retinoids in combination with 5-FU, topical imiquimod, photodynamic therapy, CO_2 and other lasers, shave excision, curettage, linear excision[57], and dermabrasion[58] have all been used with variable degrees of success in treating porokeratosis. The abnormal clone of keratinocytes must be destroyed lest lesions recur. Porokeratosis is more difficult to eradicate than both actinic keratoses and SKs. In widespread or refractory lesions, administration of oral acitretin may be beneficial, although the disease will recur following its discontinuation[59]. Photoprotection should be recommended for patients who experience photoinduced aggravation.

FLEGEL DISEASE

Synonym: ■ Hyperkeratosis lenticularis perstans

Key features

- Very rare disorder, possibly autosomal dominant inheritance
- Multiple keratotic papules with a disc-like appearance in a symmetric distribution
- Predilection for the dorsal aspect of the feet and the distal extremities of adults

Introduction

In 1958, Flegel described this rare disorder in which asymptomatic, disc-shaped keratotic papules appear most commonly on the distal extremities of adults. The name hyperkeratosis lenticularis perstans refers to the disc or lens shape (lenticularis) of the papules and their persistent nature (perstans).

Epidemiology

Flegel disease is possibly inherited in an autosomal dominant pattern, although it also presents sporadically. Lesions are usually not evident until mid to late adulthood, but they have been described in individuals as young as 13 years of age[60,61]. No racial predilection has been reported.

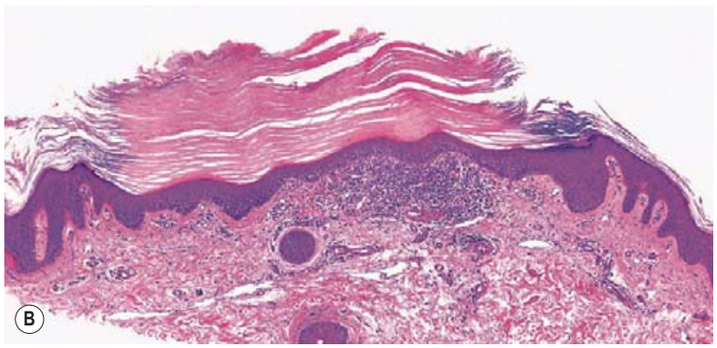

Fig. 109.9 Flegel disease. A Multiple symmetric hyperpigmented keratotic papules are present on the shins. **B** Thinned and flattened epidermis with overlying marked hyperkeratosis and an underlying patchy lichenoid infiltrate within the papillary dermis.

Pathogenesis

Lamellar granules (Odland bodies) have been shown to be either absent or altered on electron microscopic examination[62]. The lipid byproducts within lamellar granules influence stratum corneum desquamation, and, if they are absent or abnormal, hyperkeratosis may develop.

Clinical Features

Flegel disease is characterized by numerous symmetric keratotic papules (Fig. 109.9A). Lesions are most commonly observed on the dorsal aspect of the feet and the distal arms and legs, including the palms and soles. Lesions of the pinna and oral mucosa have also been documented. Individual papules are small, typically measuring from 1 to 5 mm in size. There is attached scale which may be more prominent at the peripheral margin. Removal of this scale can result in bleeding. Although most lesions are asymptomatic, patients occasionally complain of pruritus. While most lesions are small papules, those on the palms or soles often appear as fine pits. Flegel disease has been reportedly associated with endocrine disorders such as diabetes mellitus and hyperthyroidism[63].

Pathology

The papules consist of a discrete zone of ortho-hyperkeratosis, contrasting with the normal basket-weave cornified layer of the surrounding normal epidermis in most locations (Fig. 109.9B). There is often focal parakeratosis and hypogranulosis. The thin atrophic stratum spinosum is usually sharply indented or depressed at its lateral margin. A lichenoid infiltrate of lymphocytes is often present in the papillary dermis, along with dilated blood vessels[64]. A slight degree of hyperchromatism or nuclear infoldings, resembling Sézary cells, has been described in some cases of Flegel disease[65].

Differential Diagnosis

Stucco keratoses present as whitish-gray papules on the legs, but they typically do not bleed easily when scraped off and histologically there is papillomatosis not atrophy of the epidermis. There is no inflammation unless lesions have become irritated. Perforating disorders (see Ch. 96) have more prominent central keratotic plugs instead of disc-shaped hyperkeratosis, and there is a transepidermal elimination of connective tissue. With the exception of perforating granuloma annulare, perforating diseases rarely, if ever, occur on the palms or soles. Disseminated superficial actinic porokeratosis usually occurs on the legs, and a cornoid lamella is present. Other lichenoid diseases (see Ch. 11) can resemble the dermal changes in Flegel disease, but the clinical presentation allows differentiation. On a histopathologic basis, in the absence of clinical correlation, cases with lymphocyte atypia may be misdiagnosed as a cutaneous T-cell lymphoma.

Treatment

Treatment of Flegel disease is problematic as lesions tend to resist all but destructive therapy. Application of topical 5-fluorouracil cream is moderately effective, although it may not be well tolerated because of irritation. Other options include PUVA in combination with calcipotriol. Oral administration of retinoids has been attempted with inconsistent results.

ACROKERATOSIS VERRUCIFORMIS

Key features

- Multiple skin-colored, small, warty papules on the dorsal aspect of the hands and feet
- Rare autosomal dominant disorder of keratinization, often associated with Darier disease
- "Church spire" hyperkeratosis, papillomatosis and acanthosis

Clinical Features

Acrokeratosis verruciformis of Hopf is a rare autosomal dominant disorder, and it is often recognized during early childhood. Multiple skin-colored, small, warty papules appear on the dorsal aspect of the hands and feet and less commonly the extensor surfaces of the forearms and legs (see Fig. 59.14). It is often seen in patients with Darier disease, and patients with acrokeratosis verruciformis can have small, keratin-filled depressions on the palms and soles, as well as nail involvement. These observations are not surprising given that both Darier disease and acrokeratosis verruciformis can be due to mutations in the gene *ATP2A2* (see Fig. 59.1).

Pathology

There is hyperkeratosis, papillomatosis and acanthosis, often with hyperpigmentation. The hyperkeratosis may be quite prominent, and this lesion is often described as having a "church spire" configuration similar to that described for hyperkeratotic SK and stucco keratosis.

Differential Diagnosis

Histologic features similar to those of SK include hyperkeratosis, papillomatosis and acanthosis as well as some degree of hyperpigmentation. Clinicopathologic correlation is necessary to distinguish between these disorders. The name acrokeratosis verruciformis should not be confused with the unrelated epidermodysplasia verruciformis, a form of HPV infection (see Ch. 79) which usually has koilocytosis and cytologic atypia.

Treatment

Treatment is similar to that described for SKs and stucco keratoses.

CUTANEOUS HORN

Key features

- Clinical term for a firm, white to yellow, conical, markedly hyperkeratotic papule, plaque or nodule
- Most common in sun-exposed areas and arising from a hyperkeratotic actinic keratosis
- SCC is present at the base of the lesion in up to 20% of patients
- Other common causes include verruca and SK

Clinical Features

Cutaneous horn (cornu cutaneum) is a clinical term for a firm, white to yellow, conical, keratotic papule or plaque ranging from a few millimeters to several centimeters in size (Fig. 109.10A). These lesions result from abnormal accumulation of keratin in an elongated, vertically oriented column overlying an abnormality of the underlying spinous layer. Cutaneous horns may arise anywhere on the body, but sun-exposed areas are the most common locations. Men are affected more frequently than women. Individuals with a fair complexion and the elderly are particularly predisposed[66].

Pathology

A cutaneous horn consists of hyperkeratosis and parakeratosis associated with variable acanthosis (Fig. 109.10B), usually in association with the atypical keratinocytes of an actinic keratosis. Up to 20% of cutaneous horns arise over *in situ* or invasive SCCs[66]. Other lesions that may give rise to cutaneous horns include verrucae and SKs. Less common are other epithelial neoplasms, including tumors derived from follicular epithelium, especially trichilemmoma. A keratoacanthoma may produce a horn, but usually there is more of an endophytic keratinous plug.

Treatment

Shave excision with local destruction is the most common treatment. This must be done deeply enough to allow the pathologist to see the dermis beneath the horn in order to evaluate the possibility of dermal involvement by invasive carcinoma. Excision to adipose is best when invasion is suspected. In that case, induration of the dermis is detected, as opposed to the thickness related only to the horn. Treatment of malignant lesions is as described in Chapter 108. Cryotherapy alone may fail because the base may not be adequately treated unless the horn is pared first.

Fig. 109.10 Cutaneous horn. A This cutaneous horn arose from an actinic keratosis. **B** Striking column of hyperkeratosis with hyperplasia of the underlying epidermis.

CLEAR CELL ACANTHOMA

Synonym: ■ Degos' acanthoma

Key features

- Uncommon, usually solitary, papule or plaque on the leg
- Lesions are blanchable, erythematous and discrete; they may have attached "wafer-like" scale at their periphery
- Psoriasiform histology with well-demarcated zone containing clear to pale keratinocytes that stain positively with PAS

Introduction

First described by Degos in 1962, clear cell acanthoma is an uncommon red papule or plaque of the leg that may be suspected by astute clinicians, but usually a biopsy is required to establish the diagnosis.

Epidemiology

Clear cell acanthoma shows no sexual predilection and generally develops during middle-age, peaking in incidence by 50 to 60 years of age. It has not been described in children and neither an ethnic nor racial preference has been identified. Familial predisposition is rare, although there is one report of a French kinship with multiple affected family members having disseminated lesions[67].

Pathogenesis

The etiology of clear cell acanthoma is unknown. It was once thought to be induced by crude coal tar and UV light, although research has failed to demonstrate any link with environmental trauma, drugs, toxic substances or viruses. Given its abundant clear cytoplasm, it was originally thought to exhibit eccrine differentiation, although immunohistochemical and ultrastructural findings are more consistent with trichilemmal differentiation or features of the interfollicular epidermis[68,69]. It may be regarded as a variant of SK in which there are abundant glycogen-containing keratinocytes[70].

Others have proposed that clear cell acanthoma may actually be a localized, nonspecific, reactive inflammatory dermatosis. Several benign hyperproliferative dermatoses, including psoriasis, share a cytokeratin staining pattern similar to that seen in clear cell acanthoma. Furthermore, similarities in the histopathologic features between psoriasis and clear cell acanthoma suggest a common abnormality in the maturation of keratinocytes[71]. However, clear cell acanthomas do not develop following trauma and do not exhibit koebnerization, suggesting they are not simply a variant of localized psoriasis.

Clinical Features

Clear cell acanthoma presents as an erythematous, rounded papule or plaque that appears "stuck on" similar to an SK (Fig. 109.11A)[72]. A "wafer-like" scale is often appreciated, especially at the periphery[73]. The majority of clear cell acanthomas are solitary papules on the legs, but they may be found on the face, forearm, trunk and inguinal region. Lesions are almost always asymptomatic. Occasionally they are slightly eroded and a serous exudate may be present on the surface. There is often prominent vascularity that occasionally simulates a pyogenic granuloma, although the erythema can be blanched with application of pressure. By dermoscopy, the looped blood vessels within the dermal papillae create red dots in lines.

Clear cell acanthomas usually develop slowly, most commonly over a period of 2–10 years. They range in size from 0.3 to 2 cm in diameter,

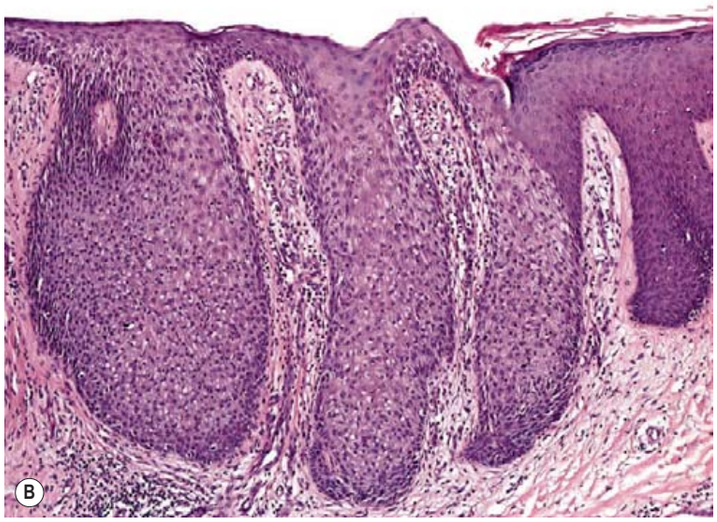

Fig. 109.11 Clear cell acanthoma. A Well-demarcated, dark red, shiny papule with a wafer-like collarette of scale. **B** Epidermal hyperplasia consisting of large pale keratinocytes. Note the sharp transition to normal skin. *B, Courtesy, Lorenzo Cerroni, MD.*

although larger lesions have been reported rarely, one of which had a diameter of 6 cm. Multiple lesions are rare, with only about 25 cases reported in the English literature, and these may either be few in number or numerous and widespread[74]. Disseminated forms have been categorized as either discrete (<12 lesions) or eruptive (>30 lesions)[75]. One patient had approximately 400 lesions[74]. Multiple lesions show a predilection for the lower extremities and may occur in conjunction with SKs, some forms of ichthyosis, and varicose veins[74]. Clear cell acanthomas with cystic, pigmented and polypoid features have been described, but these are uncommon. They have also been noted to develop in areas of pre-existing dermatoses, epidermal nevi, after trauma and following insect bites[76]. SCC *in situ* has also been rarely documented in association with clear cell acanthoma.

Pathology

Clear cell acanthoma displays a zone of sharply demarcated thickened epidermis with regular psoriasiform hyperplasia composed of enlarged pale keratinocytes (Fig. 109.11B). The epidermis is eroded and neutrophils extend from the papillary dermis into the stratum spinosum, aggregating in the overlying thin crust. The granular layer is diminished. PAS stains the pale cytoplasm of the keratinocytes red. The material that stains with PAS is diastase-sensitive, confirming it is glycogen. Electron microscopy also demonstrates abundant glycogen within the cytoplasm. Epidermal rete ridges are elongated. The dermis contains dilated blood vessels and sparse perivascular lymphocytes.

Differential Diagnosis

Clear cell acanthoma may be clinically confused with a pyogenic granuloma, traumatized hemangioma, dermatofibroma, verruca, BCC, SCC, amelanotic melanoma, inflamed SK, or psoriasis; dermoscopy can assist in making the diagnosis. Other clear cell neoplasms may occasionally cause confusion histologically, although the overall psoriasiform pattern of a clear cell acanthoma usually allows for distinction. Trichilemmomas usually appear on the face and consist of an inwardly growing lobule of pale keratinocytes lacking other features of psoriasis. The sebocytes of sebaceous neoplasms have a multiloculated cytoplasm containing lipid instead of glycogen, and are positive with oil red O, epithelial membrane antigen or adipophilin.

Treatment

Simple destruction or excision is adequate for removal. Shave excision or curettage combined with electrofulguration is a common form of treatment. Most lesions do not recur.

INVERTED FOLLICULAR KERATOSIS

Key features

- Asymptomatic, firm, white–tan to pink papule
- Typically solitary; most commonly on the face and neck of middle-aged and older adults
- Benign endophytic variant of irritated SK
- Histologically, squamous eddies and inflammation are common

History

Helwig was the first to delineate the features of inverted follicular keratosis (IFK) in 1955.

Epidemiology

IFK is seen most commonly in middle-aged to older Caucasian individuals. Men are affected twice as frequently as women.

Pathogenesis

In 1963, Duperrat and Mascaro proposed that the tumor was derived from the infundibulum of the hair follicle, although the cause is unclear.

Clinical Features

IFK is typically an asymptomatic, firm, white–tan to pink papule. It is found on the face in approximately 85% of cases, in particular on the cheek and upper lip. Other sites within the head and neck region are also affected. IFKs are usually less than 1 cm in diameter, but rarely they may reach up to 8 cm. They are typically stable and persistent lesions, but may regress.

Pathology

IFK exhibits an endophytic, somewhat bulbous proliferation of eosinophilic keratinocytes with basaloid or squamous differentiation (Fig. 109.12). The keratinocyte proliferation seems to surround one or several follicular canals that open to the surface. There may be inflammation. Squamous eddies are commonly seen.

Differential Diagnosis

The clinical differential diagnosis of IFK includes verruca, SK, trichilemmoma and other follicular adnexal tumors, BCC and SCC. Trichilemmoma has a predominance of clear cells, often with a palisade of basal cells and a thickened basement membrane. Rare mitotic figures may be appreciated in IFK, but overt cellular atypia as in SCC is absent.

WARTY DYSKERATOMA

Key features

- Uncommon, usually solitary papule or nodule with a central keratotic plug
- Usually located on the head or neck
- Acantholytic dyskeratosis seen at the base and sides of a cup-like epidermal invagination

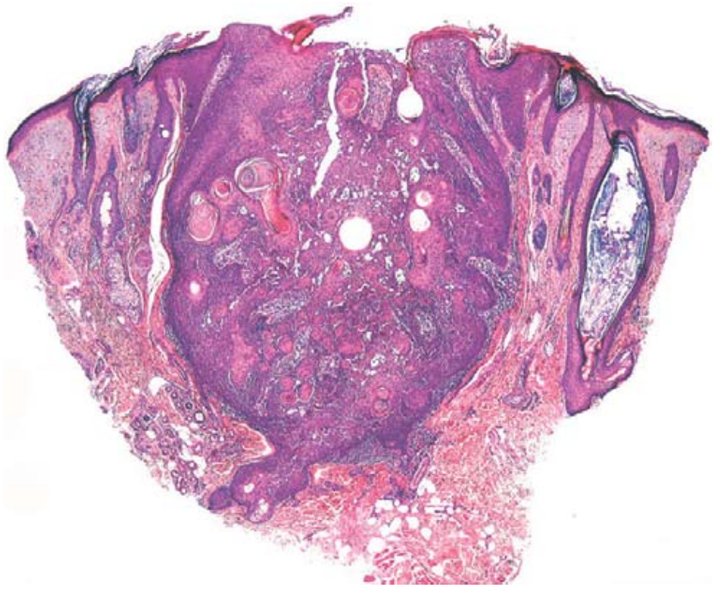

Fig. 109.12 Inverted follicular keratosis. An endophytic proliferation of keratinocytes with prominent squamous eddies is seen.

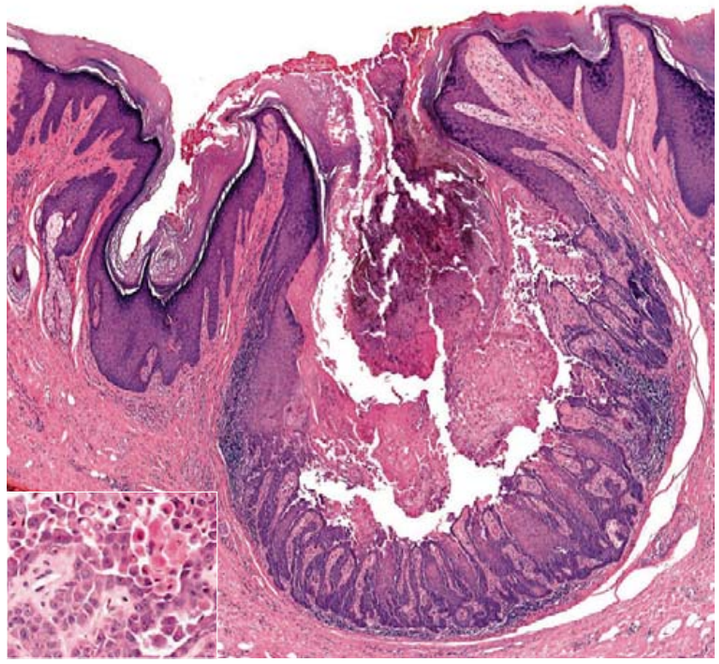

Fig. 109.13 Warty dyskeratoma. A cup-shaped invagination with a central keratotic plug. The lower portion of the wall has multiple villi. The epithelium demonstrates acantholysis and dyskeratosis (insert). *Courtesy, Lorenzo Cerroni, MD.*

Introduction

Warty dyskeratoma is an uncommon solitary papule or nodule usually found on the head or neck with a comedo-like plug and acantholysis with dyskeratosis histologically.

History

Helwig coined the term "isolated Darier's disease" in 1954. Three years later, the lesion was given the name warty dyskeratoma to indicate its solitary verrucous nature.

Epidemiology

Warty dyskeratoma is uncommon and demonstrates no genetic predisposition. It is more prevalent in men, usually appearing between the fifth and seventh decades of life. It is seen more commonly in Caucasians[77].

Pathogenesis

The pathogenesis of the acantholytic dyskeratosis in warty dyskeratomas has not been elucidated, although abnormal adhesion of keratinocytes has been demonstrated. Now that the gene responsible for Darier disease has been cloned, abnormalities in the function of its protein product could potentially be investigated in related entities like warty dyskeratoma.

Clinical Features

Warty dyskeratoma presents as a solitary, rarely multiple, verrucous, often crusted, skin-colored to red–brown papule or nodule with a central pore and a keratotic plug. Lesions grow slowly, and they are located most commonly on the scalp, cheek, temple, forehead, postauricular area and nose. Lesions have been found beneath the nail plate and in the mouth, especially on the hard palate and alveolar ridge. Warty dyskeratomas typically range in size from several millimeters to 2 cm in diameter.

Most warty dyskeratomas are asymptomatic, but patients may rarely complain of pruritus or burning. Bleeding and discharge of foul-smelling cornified material may occur. Warty dyskeratoma has been reported to coexist with other skin lesions, including verruciform xanthoma, actinic keratosis, SCC, BCC and adnexal carcinomas. Malignant degeneration in warty dyskeratoma has not been reported[77].

Pathology

Warty dyskeratoma is well circumscribed, and usually involves at least one dilated folliculosebaceous unit. There is a central cup-like invagination lined with epithelium displaying acantholysis and individual cell necrosis, corps ronds and grains, most closely resembling Darier disease (Fig. 109.13). The central crater is filled with cornified debris. Villous-like papillae, sometimes composed of only a single layer of basal cells, often project upward from the invaginated hyperplastic base.

Differential Diagnosis

Warty dyskeratoma may resemble other epithelial neoplasms and proliferations such as verruca, epidermal inclusion cyst, SK, hypertrophic actinic keratosis and SCC. Histologically, other conditions with suprabasilar acantholytic dyskeratosis must be excluded, such as Darier disease, Grover's disease, Hailey–Hailey disease, acantholytic acanthoma, familial dyskeratotic comedones, acantholytic actinic keratosis, and acantholytic SCC. Most of these are quite different clinically.

Treatment

Warty dyskeratoma is benign, so treatment depends upon the clinical situation. Most lesions are biopsied to exclude the possibility of a malignancy. Excision is curative.

ACANTHOLYTIC (DYSKERATOTIC) ACANTHOMA

Key features

- Often a solitary papule on the trunk of adults; may present as multiple lesions in the genital area
- Variant of a solitary keratosis with histopathologic findings of acantholysis with or without dyskeratosis in a hyperplastic epidermis with an overall flat architecture

Acantholytic (dyskeratotic) acanthoma is often a solitary papule on the trunk of adults, and biopsy is often performed to exclude a basal cell carcinoma. Occasionally, there are multiple lesions in the genital area. Histologically, there is acantholysis with or without dyskeratosis. Unlike warty dyskeratoma, there is neither a cup-shaped architecture nor an association with a hair follicle. In contrast to acantholytic actinic keratosis, there is not keratinocyte atypia.

EPIDERMOLYTIC ACANTHOMA

Key features

- Discrete keratotic papules in adults, with epidermolytic hyperkeratosis seen histologically
- Two varieties: an isolated form and a disseminated form

Epidemiology

Epidermolytic acanthomas may appear any time during adulthood. No particular race or gender is favored. There are no reports of familial epidermolytic acanthoma.

Pathogenesis

Because its clinical and histologic features may resemble those of verrucae, a viral origin was originally suspected, but HPV DNA has not been detected in skin lesions[78]. Gene mutations and exogenous factors such as UV light, other viruses[79], and trauma[80] have all been suggested as causes of acquired epidermolytic hyperkeratosis. Other theories include increased keratinocyte metabolic activity and aberrant keratin gene expression[81].

Clinical Features

Isolated epidermolytic acanthoma was initially described in 1970, while the disseminated form was described in 1973. Both the solitary and disseminated forms present as pigmented keratotic papules that may resemble verrucae or SKs (Fig. 109.14A). Individual lesions are generally 1 cm or less in diameter. Isolated epidermolytic acanthoma may appear on any body site. Lesions are discrete but they may occur in clusters and still be considered to represent the isolated variant. The disseminated form has a predilection for the trunk, especially the back[82]; it has also been reported in the genital region. Lesions are usually asymptomatic, but they may be pruritic.

Pathology

The histologic pattern of epidermolytic hyperkeratosis (Fig. 109.14B) consists of four components:

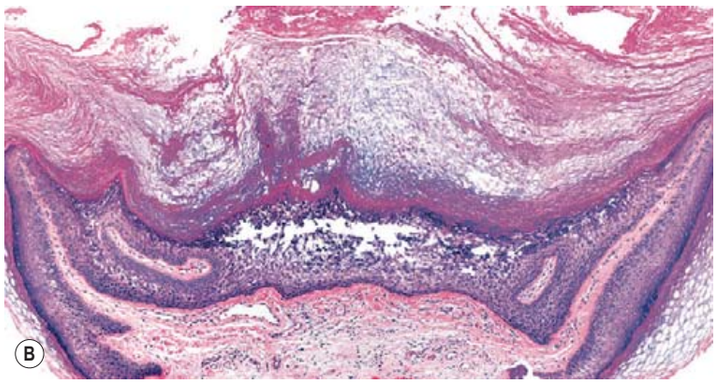

Fig. 109.14 Solitary epidermolytic acanthoma. A Keratotic papulonodule on the chest. **B** Marked hyperkeratosis and epidermolytic hyperkeratosis within the underlying epidermis.

- clear spaces of varying size surrounding nuclei in the stratum spinosum and stratum granulosum
- indistinct cellular boundaries consisting of reticulated, lightly staining material
- a markedly thickened granular zone containing an increased number of small and large, irregularly shaped, basophilic keratohyaline-like bodies
- compact hyperkeratosis.

The basal layer is normal. Epidermolytic acanthoma generally demonstrates more papillomatosis than is typically seen in other conditions with the histologic pattern of epidermolytic hyperkeratosis. There is often a slight superficial perivascular lymphocytic infiltrate in the dermis.

Differential Diagnosis

Conditions resembling epidermolytic acanthoma clinically include verrucae and SKs. Because the former does not have a characteristic clinical appearance, the diagnosis is not usually made until after a biopsy is performed. Epidermolytic hyperkeratosis is a histologic finding common to several conditions, including epidermolytic ichthyosis (bullous congenital ichthyosiform erythroderma), some epidermal nevi, and Vörner's palmoplantar keratoderma, and it is seen incidentally in normal skin and in lesions such as follicular cysts, SKs, atypical nevi, actinic keratoses and cutaneous horns[82].

Treatment

Treatment is not required as the lesions are benign. Destruction, shave excision or linear excision is successful, although recurrence may follow superficial removal.

LARGE CELL ACANTHOMA

Key features

- Small, skin-colored, hyper- or hypopigmented papule or plaque
- Located on sun-exposed skin of older individuals
- Likely a variant of solar lentigo or SK

Introduction

Large cell acanthoma is a benign keratinocytic lesion that is asymptomatic and often ignored[83,84]. Some dermatopathologists make the diagnosis frequently, while others do not believe that this is a specific entity.

History

Pinkus first described the lesion in 1967 during a lecture on benign epidermal neoplasms where he coined the term. He published his observations in 1970, noting its resemblance to solar keratosis[85].

Epidemiology

Large cell acanthoma is seen most commonly on sun-damaged skin of middle-aged to elderly individuals, with ages at diagnosis ranging from 28 to 89 years, and a mean age in the mid-60s. Women have a slightly higher incidence and most affected patients are Caucasian[85].

Pathogenesis

The pathogenesis of large cell acanthoma is unknown. Genetic studies have demonstrated low-grade aneuploidy, a finding typically associated with malignancy. Nevertheless, large cell acanthoma has generally been considered to be clinically benign. Some investigators have proposed that it is a variant of Bowen's disease[86]. Still others classify it as a variant of solar lentigo in a stage evolving into a reticulated SK or lichen planus-like keratosis[87].

Clinical Features

Large cell acanthoma characteristically presents as an asymptomatic, sharply demarcated, solitary, skin-colored, hyper- or hypopigmented papule or plaque (Fig. 109.15A) on the face or neck, including the

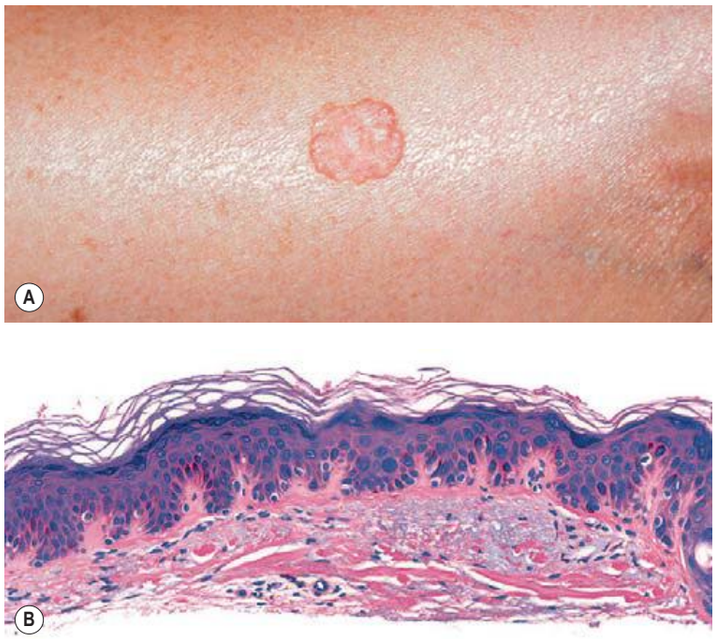

Fig. 109.15 Large cell acanthoma. A Well-demarcated, thin, pink–brown plaque. **B** Slight epidermal hyperplasia with foci of enlarged keratinocytes centrally.

eyelid[88]. It also may be found on the upper or lower extremities and the trunk[86]. Rarely, multiple lesions scattered on the extremities are observed.

As it is asymptomatic and often ignored, the time to diagnosis is quite variable, ranging from 3 months to 15 years[83,84].

Pathology

Histologically, large cell acanthomas are well demarcated, with uniform large keratinocytes with abundant cytoplasm and enlarged nuclei (Fig. 109.15B). Mild cytologic atypia may be appreciated. There is variable hyperkeratosis, epidermal rete ridge elongation, papillomatosis, or basal layer hyperpigmentation. Some lesions have minimal hyperkeratosis with flattened rete ridges and only small dermal papillae[86].

Differential Diagnosis

The differential diagnosis includes solar lentigo (histologically), solar keratosis, SK, Bowen's disease and melanoma.

Treatment

Shave or simple excision as well as destruction are options.

EPIDERMAL NEVUS

Synonym: ■ Nevus verrucosus

Key features

- Onset usually within the first year of life with "nevus" referring to a hamartoma of the epidermis and papillary dermis
- Most commonly, hyperpigmented papillomatous papules and plaques appear in a linear array along Blaschko's lines
- In nevus unius lateris (unilateral) and ichthyosis hystrix (bilateral), there are multiple lesions in streaks and whorls
- Patients with epidermal nevus syndrome have associated abnormalities, especially of the musculoskeletal and neurologic systems

Introduction

The word nevus (plural, nevi) is derived from Latin and, as currently used, has three definitions: (1) a congenital lesion (birthmark) or lesion arising early in life; (2) a benign tumor of melanocytes; or (3) a hamartoma. The latter is a benign malformation with an excess or deficiency of structural elements normally found in the affected area (e.g. epidermis, connective tissue, adnexa). In most hamartomas, one element is predominant.

Epidemiology

The incidence of epidermal nevus is estimated to be 1 in 1000 infants. The majority of epidermal nevi develop sporadically, although familial cases have been reported[89,90]. Males and females are equally affected.

Pathogenesis

Epidermal nevi are thought to originate from pluripotent cells in the basal layer of the embryonic epidermis. While mosaicism is thought to be responsible for most epidermal nevi (see Ch. 62), until recently only those nevi associated histologically with epidermolytic hyperkeratosis or acantholytic dyskeratosis had been shown to be due to genetic mosaicism (i.e. mutations in *KRT1* or *KRT10* versus *ATP2A2* that are limited to involved epidermis). In 2006, mosaicism for activating mutations in the gene that encodes fibroblast growth factor receptor 3 (*FGFR3*) were demonstrated in "common" epidermal nevi (i.e. those with acanthosis, papillomatosis and hyperkeratosis; see Table 62.8)[91]. Of note, similar germline mutations in *FGFR3* lead to skeletal dysplasia syndromes associated with acanthosis nigricans. As in SKs, activating mutations in *PIK3CA*, which encodes the alpha subunit of phosphoinositide-3-kinase which functions downstream of FGFR3, have been detected in epidermal nevi[6], in addition to an oncogenic mutation in *KRAS* in the latter[91a]. The possibility exists that additional genetic mutations in keratinocytes or fibroblasts within epidermal nevi may be detected in the future, including those that encode proteins involved in differentiation or other growth factor receptors.

While these lesions are classically referred to as "epidermal" nevi, the hamartomatous process also involves at least some portion of the dermis, especially the papillary dermis. This is evident when treatment directed purely at destruction of the epidermis fails to eradicate the lesion, which invariably recurs unless there is ablation or destruction of the upper dermis.

Clinical Features

In a review of 131 patients with epidermal nevi, the age of onset ranged from birth to 14 years, with 80% occurring within the first year of life[92]. They may occasionally appear during adulthood[93]. Epidermal nevi most commonly present as a single linear lesion, but sometimes multiple unilateral or bilateral linear plaques are seen. Most lesions consist of well-circumscribed, hyperpigmented, papillomatous papules or plaques that are usually asymptomatic (Fig. 109.16). The earliest lesions may be macular and confused with linear and whorled nevoid hypermelanosis. Rarely, epidermal nevi are hypopigmented. Once developed, the nevi may thicken and become more verrucous, especially over joints and in flexural areas such as the neck. Lesions occur most commonly on the trunk, extremities or neck[92] and their size and distribution are highly variable. Epidermal nevi follow Blaschko's lines (see Ch. 62) and may have an abrupt midline demarcation.

Nevus verrucosus is a term used for localized lesions that have a warty appearance. Nevus unius lateris, first named in 1863 by von Baerensprung, is a variant in which there are extensive unilateral plaques, often involving the trunk. Ichthyosis hystrix (systematized epidermal nevus) is a variant with extensive bilateral involvement, also usually on the trunk[94].

Epidermal nevus syndrome, a concept proposed by Solomon and Esterly in 1968, is diagnosed when epidermal nevi occur in combination with other developmental anomalies (see Ch. 62). These abnormalities most commonly involve the neurologic or musculoskeletal systems. Excluding cutaneous manifestations, a study of 119 patients with epidermal nevi found that 33% had abnormalities in one organ system, 6% in two, 5% in three, and 5% in five or more. Individuals with SOLAMEN and Proteus syndromes also develop epidermal nevi.

Fig. 109.16 Epidermal nevi. A, B Verrucous hyperpigmented plaques that follow the lines of Blaschko. Note the midline demarcation in B. *A, Courtesy, Kalman Watsky, MD. B, Courtesy, Kathyrn Schwarzenberger, MD.*

Pathology

At least ten histologic patterns have been observed in epidermal nevi, and more than one may be present in the same lesion[95,96]. Virtually all are characterized by epidermal hyperplasia, hyperkeratosis, acanthosis, papillomatosis, and variable parakeratosis (Fig. 109.17). Other findings such as epidermolytic hyperkeratosis and focal acantholytic dyskeratosis may be prominent features. Inflammatory linear verrucous epidermal nevus (ILVEN) may have clinical and histologic features very similar to psoriasis (see the following section).

Neoplasms such as BCC, SCC and keratoacanthoma may rarely develop in association with epidermal nevi. This malignant change occurs less commonly in epidermal nevus than in the closely related nevus sebaceus. Malignancy in epidermal nevus, when it does occur, typically develops after puberty[97]. Examples of BCC arising in epidermal and sebaceous nevi may actually be trichoblastomas, representing a manifestation of the hamartomatous nature of the neoplasm[98–100].

Differential Diagnosis

Nevus sebaceus (see Ch. 111), usually found on the head instead of the trunk or extremities, can be considered a subtype of epidermal nevus with additional hamartomatous components of sebaceous and apocrine glands accompanying the papillomatous epidermis. Organoid nevi combine features of both epidermal nevus and nevus sebaceus, with variation often depending upon anatomic site (e.g. head and neck versus trunk). Lichen striatus is an acquired lesion, has less papillomatosis and acanthosis as well as more dyskeratosis and spongiosis, and does not persist indefinitely. There are other nevoid conditions that are distributed along Blaschko's lines and therefore may simulate epidermal nevi, depending on the type and degree of epidermal proliferation.

Fig. 109.17 Epidermal nevus – most common histologic pattern. Epidermal hyperplasia with papillomatosis and hyperkeratosis.

Examples include porokeratotic eccrine ostial and dermal duct nevus, linear lichen planus and X-linked dominant chondrodysplasia punctata. Small lesions must be distinguished from SKs, verrucae vulgares and psoriasis, especially if there is Koebner phenomena.

Treatment

Infants and children with epidermal nevi, particularly multiple or extensive lesions, require a thorough evaluation for systemic abnormalities in conjunction with a pediatrician (see Ch. 62). Full-thickness surgical excision is curative, but recurrence is common when only the epidermis is removed (e.g. by shave excision or curettage). Surgical excision of larger lesions can be complicated by hypertrophic scars or keloid formation[101]. Topical therapies such as corticosteroids, retinoic acid, tars, anthralin, 5-fluorouracil and podophyllin have all been used, but they are of limited benefit. Chronic therapy with oral retinoids has been reported to be effective at decreasing the thickness of systematized epidermal nevi, although it does not result in resolution. Laser ablation may also be undertaken, but, to be effective, it must induce scarring and fibrosis of at least the papillary dermis. Therefore, this treatment is often not cosmetically acceptable to patients and test sites are recommended.

INFLAMMATORY LINEAR VERRUCOUS EPIDERMAL NEVUS

Synonym: ■ Dermatitic epidermal nevus

Key features

- Linear, psoriasiform papules or plaques, usually on one extremity
- 75% of nevi appear before the age of 5 years
- Four times more common in girls
- Usually persists for years despite attempts at treatment
- Histologically, psoriasiform hyperplasia with alternating parakeratosis and orthokeratosis

Introduction

Inflammatory linear verrucous epidermal nevus (ILVEN) is a relatively rare, linear, psoriasiform plaque that usually presents during childhood.

History

Altman and Mehregan are credited with the first description of ILVEN in 1971[102].

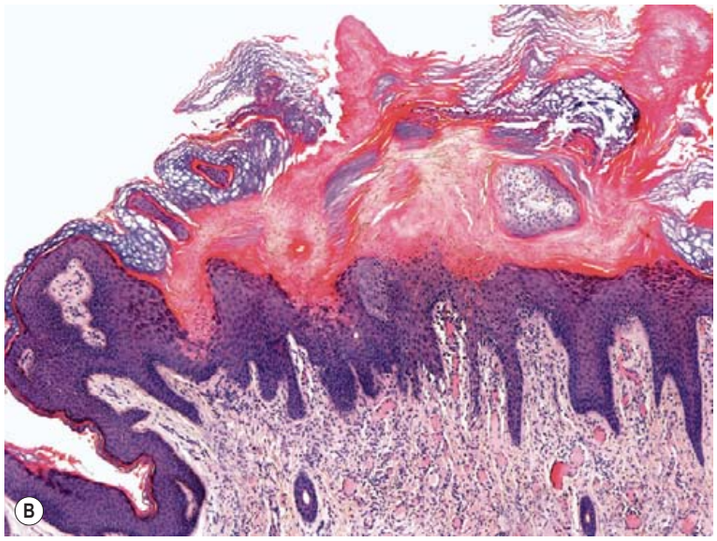

Fig. 109.18 Inflammatory linear verrucous epidermal nevus (ILVEN). A Linear erythematous scaly plaques on the medial aspect of the right thigh. Some of the lesions have a psoriasiform appearance. **B** Epidermal hyperplasia and broad zones of parakeratosis alternating with ortho-hyperkeratosis.

Pathogenesis

The definitive cause is unknown. As it bears some resemblance to psoriasis histologically, some believe that the two conditions share a common pathogenesis[103]. Involucrin, a structural component of mature squamous epithelium, is expressed in ILVEN in increased amounts within the orthokeratotic epithelium, but is minimally expressed within keratinocytes underlying areas of parakeratosis. However, in psoriasis, involucrin is expressed in all layers of the epidermis except the basal layer[104]. While there are similarities to psoriasis, others propose that ILVEN represents a clonal dysregulation of keratinocyte growth[103].

Clinical Features

ILVEN has a psoriasiform appearance and may be associated with significant pruritus. Scaly, erythematous papules coalesce to form a linear plaque, usually on a limb (Fig. 109.18A), although occasionally the trunk may be involved. Lesions are almost always unilateral. The left leg is reportedly more frequently affected than the right[102]. In 75% of patients, the age of onset is before the age of 5 years. Isolated instances of adult onset have been reported[105] and, rarely, there may be a familial predisposition. ILVEN has a 4:1 female-to-male predilection. Most lesions spontaneously resolve by adulthood[106]. A possible association of ILVEN with arthritis has been described[107].

Pathology

The psoriasiform histology of ILVEN correlates with its psoriasiform clinical appearance. Epidermal rete ridges are elongated, and broad zones of parakeratosis without an underlying granular layer alternate abruptly with depressed regions of orthokeratosis and hypergranulosis (Fig. 109.18B). There is often exocytosis of lymphocytes and neutrophils into the spongiotic papillomatous epidermis and occasionally Munro's microabscesses may be seen.

Differential Diagnosis

At least three other variants of epidermal nevi with inflammation have been described, including lichenoid epidermal nevus, psoriasis superimposed on an epidermal nevus, and epidermal nevi in *c*ongenital *h*emidysplasia with *i*chthyosiform nevus and *l*imb *d*efects (CHILD) syndrome (see Ch. 57). Lichenoid epidermal nevus is typically a verrucous plaque with a lichenoid lymphocytic dermal infiltrate. It is debatable whether lichenoid epidermal nevus truly represents linear lichen planus. The age of onset, distribution, lack of development of additional lesions of psoriasis over time, resistance to therapy, and lack of family history are all features of ILVEN. Patients with linear (nevoid) psoriasis can have or develop classic plaques of psoriasis elsewhere.

It has been suggested that ILVEN may be a form fruste of CHILD syndrome because rarely, ipsilateral skeletal anomalies are seen in patients with ILVEN. Also, although large areas of ichthyosiform erythema characteristically involve one-half of the body with an affinity for skin folds (ptychotropism), patients with CHILD syndrome can have linear keratotic plaques along Blaschko's lines that have an appearance similar to ILVEN. CHILD syndrome differs histologically from ILVEN in that it has features of verruciform xanthoma with elongated dermal papillae and cells with foamy cytoplasm in the upper papillary dermis[108], as well as vacuoles within the cells of the lower stratum corneum ultrastructurally.

Treatment

As with other epidermal nevi, ILVEN is difficult to treat. Treatments that are successful in psoriasis are only partially effective for ILVEN[107]. Surgical excision is effective but results in scarring. The pulsed dye laser (see Ch. 137) has been used successfully in some cases. Its mechanism of action is thought to involve destruction of small blood vessels in the papillary dermis that supply the overlying epidermis[109]. Combination therapy with topical tretinoin and 5-fluorouracil creams has also been employed with beneficial results, but long-term success can only be achieved with maintenance therapy[110]. Topical synthetic derivatives of vitamin D_3, such as calcipotriol, may also be partially effective[111,112]. There are anecdotal reports of improvement with etanercept.

Arthritis in association with ILVEN, although rare, can lead to significant morbidity. Early recognition is critical. Treatment is the same as for psoriatic arthritis[107].

NEVUS COMEDONICUS

Synonym: ■ Comedo nevus

Key features

- Benign hamartoma, usually arising before the age of 10 years
- Multiple grouped comedones in a linear array, most commonly on the face, trunk or neck
- Histologically, underdeveloped hair shafts and epidermal invaginations containing a keratin plug

Introduction

Nevus comedonicus is a rare hamartoma of the folliculosebaceous unit resulting in numerous dilated, keratin-filled comedones.

History

Kofmann, in 1895, was the first to delineate the features of nevus comedonicus. In 1914, White attempted to change the name to "nevus follicularis keratosis" as he considered the comedo-like lesions not to represent true comedones, as sebaceous glands were either rudimentary or absent in most cases.

Epidemiology

Approximately half of the cases of nevus comedonicus are evident at birth, with others appearing during childhood, usually before the age of 10 years. Onset in adulthood, albeit rare, is often associated with irritation or trauma. There is no racial or sexual predilection. Although most cases arise sporadically, familial clustering has been reported[113].

Pathogenesis

Nevus comedonicus is thought to represent growth dysregulation affecting the mesodermal portion of the pilosebaceous unit. The epithelial-lined invaginations, incapable of forming mature terminal hairs and sebaceous glands, accumulate a soft cornified ostial product resulting in a comedo-like plug. In 1998, *FGFR2* mutations were detected in a nevus comedonicus and not in the adjacent normal skin, providing evidence for genetic mosaicism (see Table 62.8)[114]. Of note, patients with Apert syndrome, sporadic or inherited in an autosomal dominant manner and due to mutations in *FGFR2*, may have comedones and severe cystic acne (see Table 62.8).

Clinical Features

There is usually a single circumscribed area (Fig. 109.19A) or linear streak composed of clusters of dilated follicular ostia that contain firm, darkly pigmented, cornified material. Occasionally, multiple linear plaques may be seen with midline demarcation. Their size is variable and they can range from a few centimeters in diameter to extensive lesions affecting half of the body. The site most commonly affected is the face, followed by the trunk, neck and upper extremity. These nevi may also arise in areas that are devoid of hair follicles such as the palms, soles and glans penis. When present on the elbows and knees, lesions can be verrucous in appearance. Inflammatory papules and cysts can be admixed with the comedones. Hormonal influences of puberty often worsen the condition.

Pathology

Nevus comedonicus consists of grouped undeveloped hair follicles, presenting as dilated invaginations filled with cornified debris devoid of hair shafts (Fig. 109.19B). Epidermolytic hyperkeratosis may sometimes be present in the follicular epithelium.

Differential Diagnosis

Many skin conditions present with comedones, and these must be differentiated from nevus comedonicus. Infantile acne typically presents on the face between the ages of 3 and 24 months. The comedones, pustules and papules in this disorder are not linear, and they are self-limited. Chloracne is associated with exposure to toxins that lead to the formation of comedones, generally located on both sides of the face and commonly behind the ears.

Familial dyskeratotic comedones is a rare autosomal dominant disorder in which comedones arise during childhood or adolescence and are widely scattered on the trunk and extremities without a linear configuration. Histologically, acantholytic dyskeratosis in the comedo wall is seen.

The dilated pore nevus resembles nevus comedonicus clinically but differs histologically by containing dilated follicular cysts. Porokeratotic eccrine ostial and dermal duct nevi also may be confused with nevus comedonicus, especially when the latter involves the palms or soles. These lesions are comprised of dilated eccrine ducts containing parakeratotic debris. The keratinocyte cytoplasm is typically vacuolated and the granular layer is absent.

Treatment

As with other epidermal nevi, treatment of nevus comedonicus is problematic. Localized lesions can be surgically excised, although it is often difficult to excise larger lesions. Manual comedo extraction, dermabrasion, and the use of keratolytic agents (e.g. salicylic acid, tretinoin and ammonium lactate[115]) may be helpful, but they are not curative. Isotretinoin is not usually recommended owing to the long-term treatment required, but it may be beneficial in preventing cyst formation. Antibiotics may be necessary to treat secondary infections.

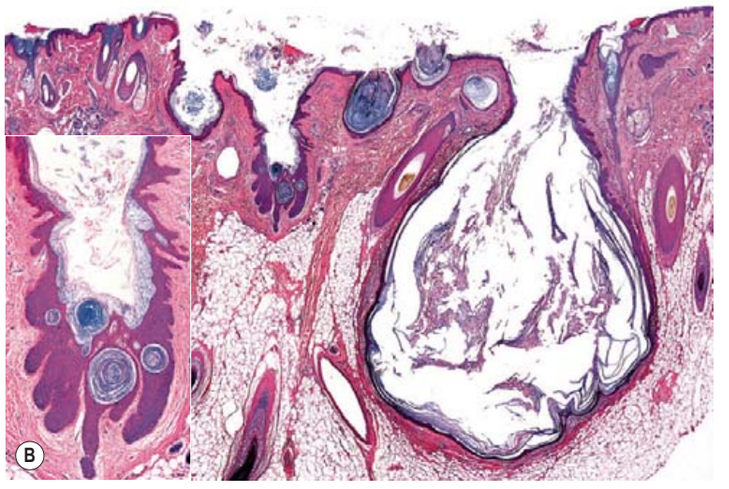

Fig. 109.19 Nevus comedonicus. **A** Numerous comedones within a broad streak along the lines of Blaschko. **B** Dilated infundibula filled with orthokeratotic keratin. Occasionally, the wall of the comedo will display epithelial hyperplasia (insert).

ACANTHOSIS NIGRICANS

Acanthosis nigricans is discussed in detail in Chapter 53. Histologically, it may be misinterpreted as SK, acrochordon, epidermal nevus, or confluent and reticulated papillomatosis, unless appropriate clinical correlation is provided.

CONFLUENT AND RETICULATED PAPILLOMATOSIS

Synonym: ■ Confluent and reticulated papillomatosis of Gougerot and Carteaud

Key features

- Onset typically during puberty
- Multiple brown verrucous papules or patches in a confluent and/or reticulated pattern, most commonly on the central chest and upper abdomen
- Oral minocycline is effective in approximately 50% of patients

History

Confluent and reticulated papillomatosis of Gougerot and Carteaud (CARP) was first described in 1927.

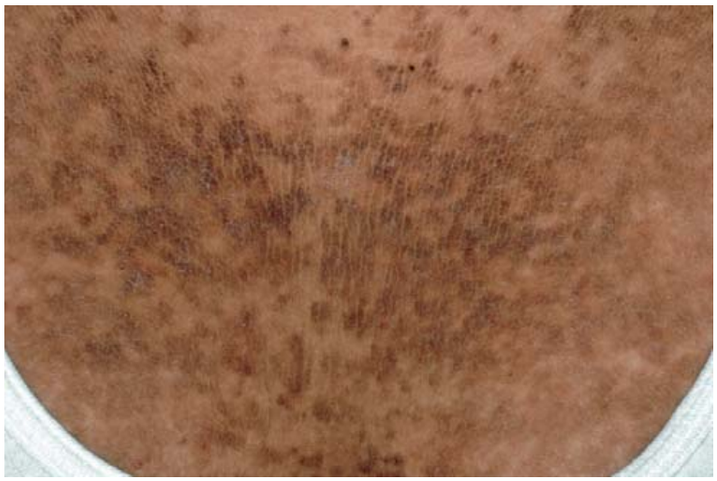

Fig. 109.20 Confluent and reticulated papillomatosis (CARP). Multiple hyperpigmented papules that are confluent centrally and assume a reticulated pattern laterally. *Courtesy, Julie V Schaffer, MD.*

Epidemiology

The typical onset of CARP is during puberty. Young women are affected 2.5 times more frequently than young men, and blacks are twice as likely to have CARP as whites. Occurrence of CARP is mostly sporadic, although familial cases have been reported[116].

Pathogenesis

Some think CARP may be caused by an endocrine imbalance, especially insulin resistance, because of its association with conditions such as obesity, menstrual irregularities and diabetes mellitus as well as pituitary and thyroid disorders. In addition, there is a clinical resemblance to acanthosis nigricans. However, most patients are otherwise healthy. Another hypothesis is that CARP is a disorder of keratinization. This theory arose because a number of patients have been successfully treated with topical and systemic retinoids[117]. An abnormal host response to *Malassezia furfur* has also been suggested, because this organism is sometimes prevalent within areas of involvement in its yeast (and, less often, hyphal) forms and because treatment with topical selenium sulfide has sometimes been successful[118]. The majority of cases, however, demonstrate no evidence of *M. furfur* proliferation.

Clinical Features

The initial lesions of CARP are 1–2 mm papules, first appearing in the intermammary area or less frequently the interscapular or epigastric regions. Lesions rapidly enlarge to 4–5 mm and become brown, hyperkeratotic, verrucous papules or patches. The papules coalesce and become confluent centrally and reticulated peripherally (Fig. 109.20). Involvement of the neck, shoulders and back can develop. Oral lesions have not been reported. The eruption is asymptomatic or, rarely, mildly pruritic.

Pathology

There is hyperkeratosis, acanthosis and papillomatosis. Sparse superficial perivascular lymphocytes are also seen. A characteristic feature is the club-shaped, bulbous epidermal rete ridges that protrude slightly into the papillary dermis with pigment at their bases ("dirty feet").

Differential Diagnosis

CARP can clinically resemble acanthosis nigricans, pseudoacanthosis nigricans, Darier disease and tinea versicolor. Acanthosis nigricans has thicker, more velvety plaques involving intertriginous areas; it also lacks the reticulated pattern of CARP. Although pseudoacanthosis nigricans, like CARP, has a predilection for darkly pigmented individuals, it is characteristically associated with weight gain and disappears with weight loss. Tinea versicolor may be related to CARP because of its brownish scale and association with *M. furfur*, but it is neither reticulated nor papillomatous.

Histologically, CARP may be misinterpreted as an SK, acrochordon, epidermal nevus, acanthosis nigricans, or other papillomatous epithelial proliferation, unless appropriate clinical information is provided.

Treatment

Treatment of CARP is often frustrating because it may not respond to therapeutic interventions or recurs after cessation of therapy. No single agent has been uniformly successful at providing long-term resolution. Temporary improvement has been reported with the use of various antibiotics, isotretinoin[119], etretinate[117] and acitretin as well as topical salicylic acid, hydroquinone, antifungals[118], and 5-fluorouracil[118]. Oral minocycline has been reported to be effective in about 50% of patients. Many reported no recurrences, while others experienced disease-free intervals for up to 18 months[120]. Oral retinoids are no more successful than oral antibiotics at maintaining a disease-free state, and, given their potential for causing hypertriglyceridemia and teratogenicity, they are generally considered to be second- or third-line agents.

CLEAR CELL PAPULOSIS

Key features

- Extremely rare condition, mainly described in Asian children
- Hypopigmented macules and papules arranged along the milk lines
- Histopathologically, large clear cells scattered along the basal layer of the epidermis and within the malpighian layer

Epidemiology

Clear cell papulosis (CCP) is an extremely rare condition that preferentially affects Chinese and other Asian children[121].

Pathogenesis

The pathogenesis of CCP is unknown. The arrangement of lesions along the so-called milk lines and the appearance of clear cells in lesional skin suggest a histogenetic relationship with Toker cells. Some authors have considered this process as the benign counterpart of extramammary Paget disease[122].

Clinical Features

CCP is characterized by multiple, asymptomatic, white macules or papules that are 2–10 mm in diameter, involving the anterior chest, abdomen and lumbar region. The lesions are often arranged along the milk lines. In rare cases, the face may be also involved.

Pathology

Lesions of CCP are mildly acanthotic and show a slightly disorganized arrangement of epidermal keratinocytes. Numerous clear cells are scattered primarily along the basal layer of the epidermis, but also within its upper layers. These clear cells are larger than adjacent keratinocytes and have cytoplasmic vacuolization due to abundant mucin contained within their cytoplasm; the latter may be better demonstrated with PAS, mucicarmine, alcian blue or colloidal iron stains. Immunohistochemically, clear cells of CCP express carcinoembryonic antigen, cytokeratins (CK7-, AE1/AE3-, and CAM5.2-positive), epithelial membrane antigen (EMA) and gross cystic fluid disease protein-15 (GCDFP-15), but are negative for expression of CD1a, S100 protein and HMB45[121].

Differential Diagnosis

Clinically, CCP should be differentiated from hypopigmented lesions of tinea versicolor, pityriasis lichenoides chronica, guttate lichen

sclerosus and confetti-type vitiligo (see Table 66.7). Histologically, CCP needs to be distinguished from extramammary Paget's disease and pagetoid dyskeratosis. Neoplastic cells of extramammary Paget's disease are more atypical and pleomorphic than those of CCP. Pagetoid dyskeratosis is a disorder of keratinization characterized by clear and pale eosinophilic keratinocytes scattered within the epidermis[123]; it is an incidental histopathologic finding without any clinical significance.

Treatment

CCP is a benign process and no treatment is necessary. Lesions may spontaneously resolve over time.

110 Cysts

Mary S Stone

Chapter Contents

Cysts with a lining of stratified squamous epithelium *1817*
Cysts lined with non-stratified squamous epithelium..... *1823*
Cysts without an epithelial lining *1826*

Key features

- Multiple types of cutaneous cysts have been described
- Cutaneous cysts present as circumscribed dermal or subcutaneous papules or nodules
- Histologic features of the cyst lining and the anatomic location determine the type of cyst
- Cysts may be lined by stratified squamous epithelium, non-stratified squamous epithelium, or no epithelium at all
- Treatment of cysts, when indicated, is primarily surgical

INTRODUCTION

Cysts are common cutaneous lesions. Patients with cysts may present to clinicians because of medical or cosmetic concerns, or due to discomfort from mechanical irritation or inflammation of the cyst. The definitive diagnosis of a cyst requires histologic examination, as many other dermal and subcutaneous tumors can form cyst-like nodules. Cysts can be classified by anatomic location (as they may occur in virtually any organ of the body), by embryologic derivation, or by histologic features. As the histologic features determine the definitive diagnosis, that scheme will be used in this chapter, which is limited to cutaneous cysts.

True cysts have an epithelial lining that may be composed of stratified squamous epithelium or other forms of epithelia. Some "cysts" have no epithelial lining at all. Cutaneous cysts can be divided into three main categories based on the presence or absence and composition of the cyst wall (Table 110.1; Fig. 110.1). Many non-dermatologists refer to epidermoid and pilar cysts as "sebaceous cysts", believing erroneously that the hydrated white keratinized contents of many epithelial-lined cysts is of sebaceous origin. The only true sebaceous cyst is the steatocystoma. Because of the confusion, the term "sebaceous cyst" is best avoided.

CYSTS WITH A LINING OF STRATIFIED SQUAMOUS EPITHELIUM

Epidermoid Cyst

Synonyms: ■ Epidermoid inclusion cyst ■ Infundibular cyst ■ Epidermal cyst ■ Epidermal inclusion cyst

Epidermoid cysts are the most common cutaneous cysts. They can occur anywhere on the skin, but are most common on the face and upper trunk. These lesions are well-demarcated, skin-colored to yellowish dermal nodules, and they may have a clinically visible punctum representing the follicle from which the cyst is derived (Fig. 110.2). These cysts range from a few millimeters to several centimeters in diameter. Tiny superficial epidermoid cysts are known as milia (see below). Epidermoid cysts derive from the follicular infundibulum (hence the synonym infundibular cysts; Fig. 110.3). They may be primary, or they may arise from disrupted follicular structures or traumatically implanted epithelium (hence the synonym epidermal "inclusion" cyst).

As follicular disruption is important in the pathogenesis of many epidermoid cysts, multiple epidermoid cysts may occur in individuals with a history of significant acne vulgaris. Multiple cysts may also occur in the setting of Gardner syndrome (familial adenomatous polyposis) and in nevoid basal cell carcinoma (BCC) syndrome[1,2]. Multiple scrotal cysts (Fig. 110.4) may lead to scrotal calcinosis via dystrophic calcification[3].

Non-inflamed epidermoid cysts are usually asymptomatic, but, with pressure, cyst contents may be expressed that may have an objectionable odor. Rupture of the cyst wall can result in an intensely painful inflammatory reaction, and this is a common reason for presentation to a physician (Fig. 110.5). Development of a BCC or squamous cell carcinoma (SCC) within an epidermoid cyst is a very rare event[4].

THE THREE MAIN CATEGORIES OF CUTANEOUS CYST

Category	Type	Most common location
Stratified squamous epithelium	Epidermoid cyst	Face; upper trunk
	Milium	Face
	Trichilemmal cyst	Scalp
	Proliferating trichilemmal cyst	Scalp (favors the elderly)
	Proliferating epidermoid cyst	Pelvic (anogenital)
	Vellus hair cyst	Trunk (chest)
	Steatocystoma	Trunk; axillae; groin
	Cutaneous keratocyst	No characteristic location
	Pigmented follicular cyst	Face (men)
	Dermoid cyst	Face along embryonic fusion planes, e.g. lateral eyebrow (infants)
	Verrucous cyst	Face, upper trunk (HPV-infected epidermoid cysts)
	Ear pit cyst	Preauricular
	Pilonidal cyst	Upper gluteal cleft; sacrococcygeal area
Non-stratified squamous epithelium	Hidrocystoma	
	• Eccrine	Face (lower eyelid, cheek)
	• Apocrine	Face (eyelid margin)
	Bronchogenic cyst	Suprasternal notch (infants)
	Thyroglossal duct cyst	Midline anterior neck
	Branchial cleft cyst	Lateral neck; preauricular; mandibular (teenagers, young adults)
	Cutaneous ciliated cyst	Lower extremities (young women)
	Ciliated cyst of the vulva	Labia majora
	Median raphe cyst	Ventral glans of penis
	Omphalomesenteric duct cyst	Umbilical; periumbilical
Absence of epithelium	Mucocele	Oral mucosa (lower labial)
	Digital mucous cyst	Dorsal aspect of distal phalanx of finger (occasionally toe)
	Ganglion	Wrist
	Pseudocyst of the auricle	Scaphoid fossa of the ear (adult men)
	Cutaneous metaplastic synovial cyst	Sites of surgical trauma

Table 110.1 The three main categories of cutaneous cyst.

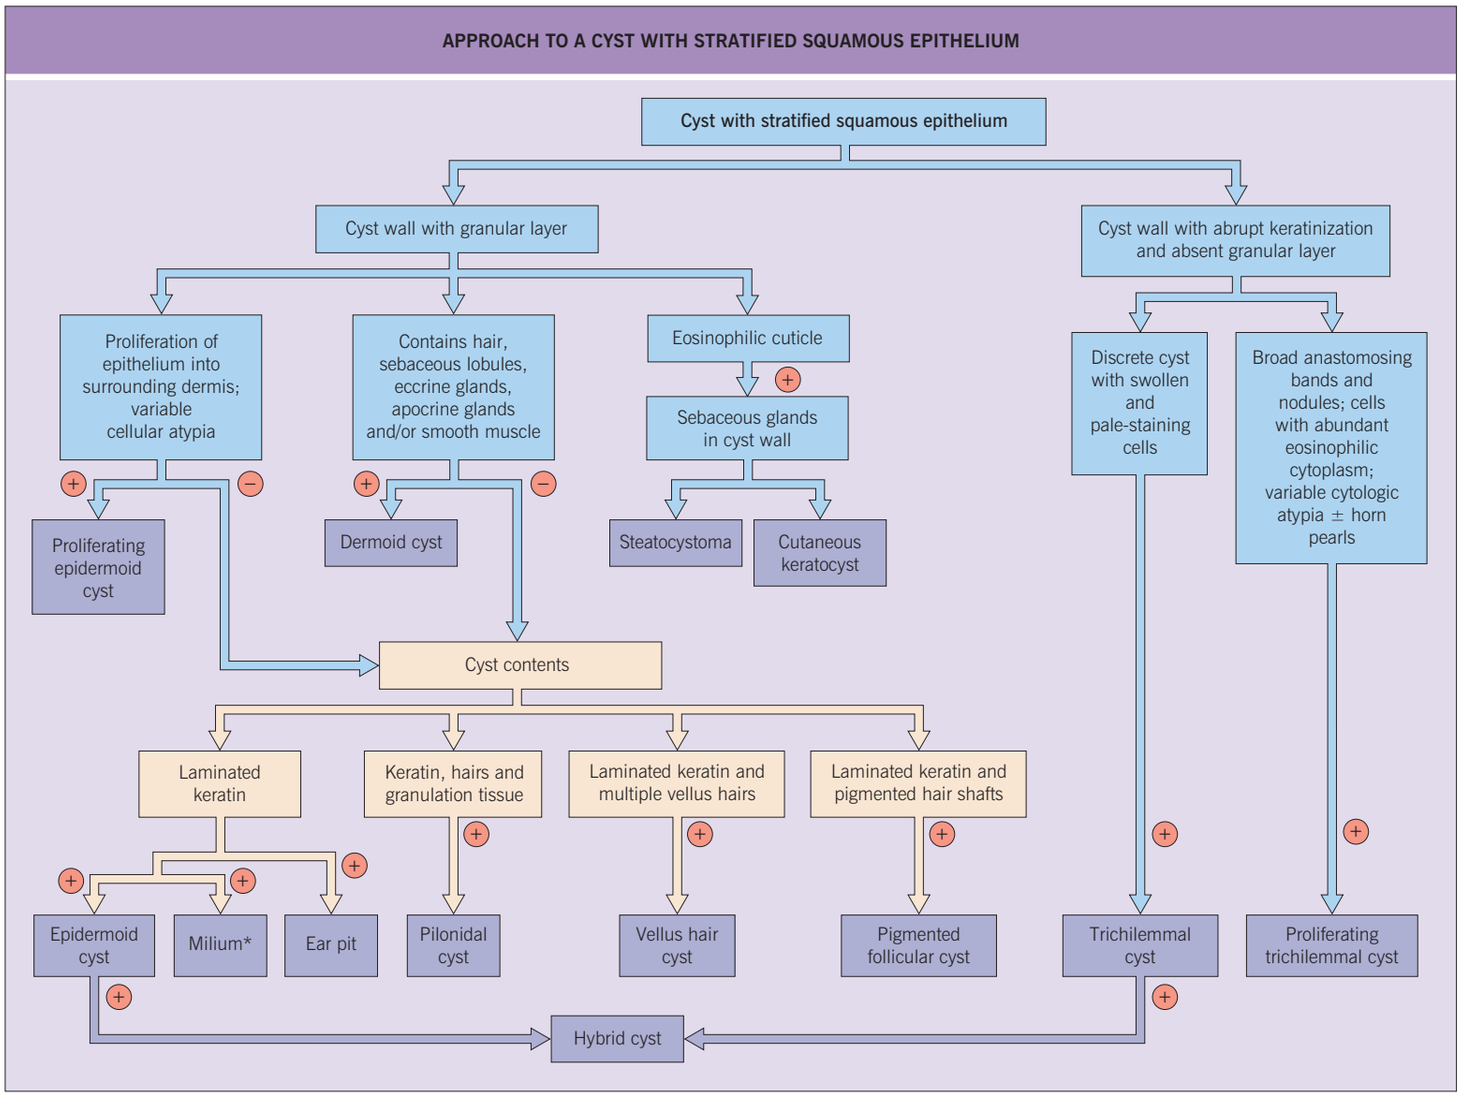

Fig. 110.1 Approach to a cyst with stratified squamous epithelium. *Diameter 1–2 mm.

Fig. 110.2 Epidermoid cyst. Typical clinical appearance of an epidermoid cyst with a yellowish hue. Two pores are present in this example.

Pathology

Histologic examination shows a cystic cavity filled with laminated keratin lined by a stratified squamous epithelium including a granular layer (Fig. 110.6). A surrounding inflammatory response with both acute and chronic granulomatous inflammation may be seen as evidence of prior rupture. In individuals with Gardner syndrome, some cysts show, as a characteristic feature, columns of pilomatricoma-like shadow cells projecting into the cyst cavity[1]. Infection of the cyst's epithelium with human papillomavirus can lead to irregular acanthosis with a verrucous appearance to the cyst wall ("verrucous cyst").

Treatment

If treatment is desired, excision is curative. Removal may be accomplished by simple excision, or incision and expression of the cyst contents and wall through the surgical defect. If the entire cyst wall is not removed, the cyst may recur. Inflamed epidermoid cysts may require incision and drainage, and, occasionally, antibiotic therapy. Intralesional triamcinolone may be helpful in speeding the resolution of the inflammation.

Dilated Pore of Winer and Pilar Sheath Acanthoma

Dilated pore of Winer and pilar sheath acanthoma are very similar lesions that present primarily on the face of adults (the upper lip in the case of pilar sheath acanthoma). While both have an obvious central keratin-filled opening ("pore"), the pilar sheath acanthoma has a more papular component. A large-pore BCC or large-pore trichoblastoma may have a similar appearance.

Pathology

Both lesions are cystic invaginations that are connected to the surface (like an open comedone) and have a stratified squamous epithelial lining. The wall is acanthotic with bulbous proliferations pushing into the surrounding dermis. Pilar sheath acanthoma has a more proliferative wall and a wider opening to the epidermis.

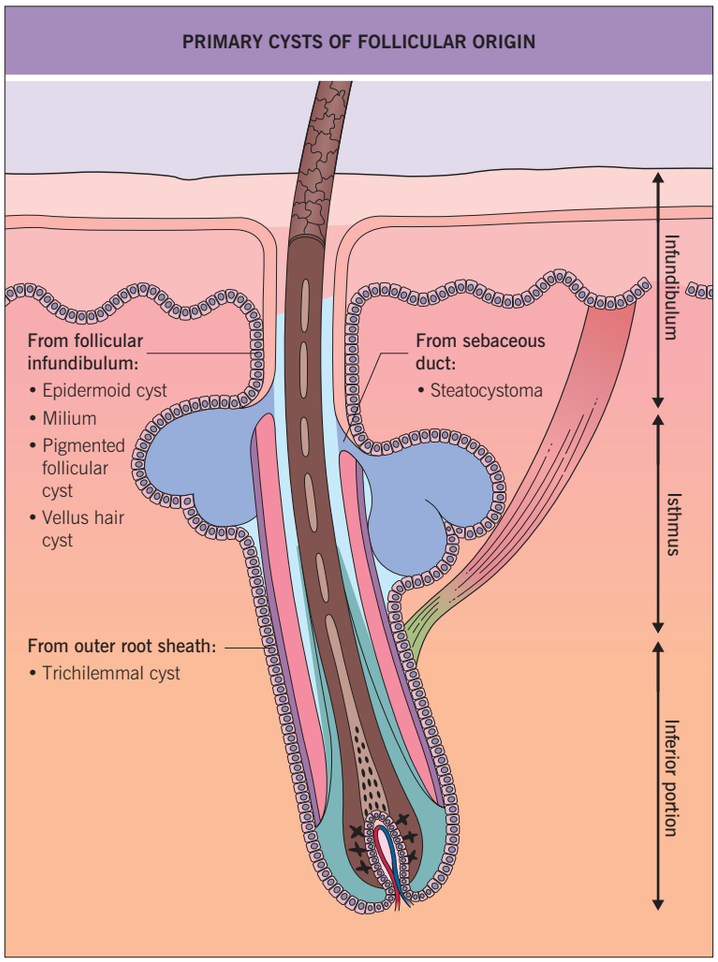

Fig. 110.3 Primary cysts of follicular origin. Anatomic origin of cysts derived from the pilosebaceous unit. *Adapted from Requena L, Sanchez Yus E. Follicular hybrid cysts. An expanded spectrum. Am J Dermatopathol. 1991;13:228–33.*

Fig. 110.4 Multiple scrotal cysts. They may be associated with dystrophic calcification. *Courtesy, Joyce Rico, MD.*

Treatment

If treatment is desired, excision is curative.

Milium

Milia are small epidermoid cysts and are quite common, occurring in individuals of all ages. Milia present as 1–2 mm white to yellow subepidermal papules (Fig. 110.7). Between 40% and 50% of infants will have milia, most commonly on the face. Most milia in newborns will resolve spontaneously during the first 4 weeks of life. Milia in newborns may also occur on the hard palate (Bohn's nodules) or on the gum margins (Epstein's pearls). These also resolve spontaneously. Milia may occur as a primary phenomenon, especially on the face, or as secondary phenomena following blistering processes or superficial ulceration from trauma or cosmetic procedures. Milia may also occur in areas of topical corticosteroid-induced atrophy[5].

Milia en plaque is characterized by multiple milia within an erythematous edematous plaque. Milia en plaque most often occurs in the postauricular area, but may also occur on or anterior to the ear. Persistent widespread milia in an infant may be a sign of hereditary trichodysplasia (Marie–Unna hypotrichosis) or oral–facial–digital syndrome type 1, an X-linked disorder that is lethal in males, in which milia are

Fig. 110.5 Inflamed epidermoid cyst. Such painful inflammatory reactions to cyst rupture are a frequent cause for presentation to a physician.

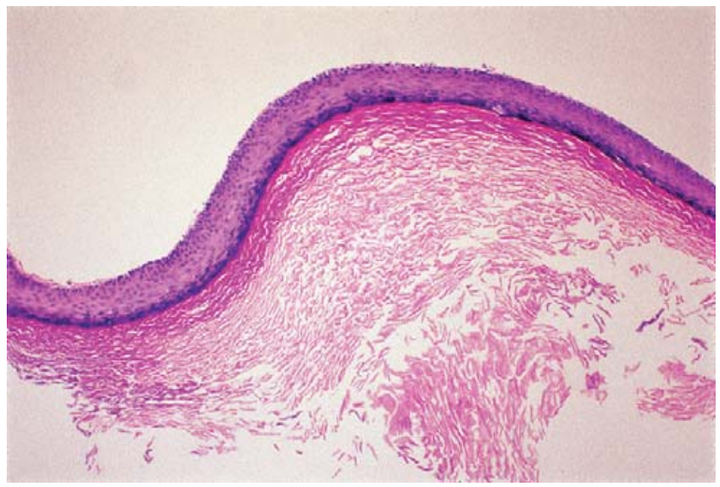

Fig. 110.6 Histology of an epidermoid cyst. The cyst wall shows epidermal keratinization including a granular layer. Laminated keratin cyst contents are seen.

Fig. 110.7 Milia. Tiny (1–2 mm), white, dome-shaped papules on the face.

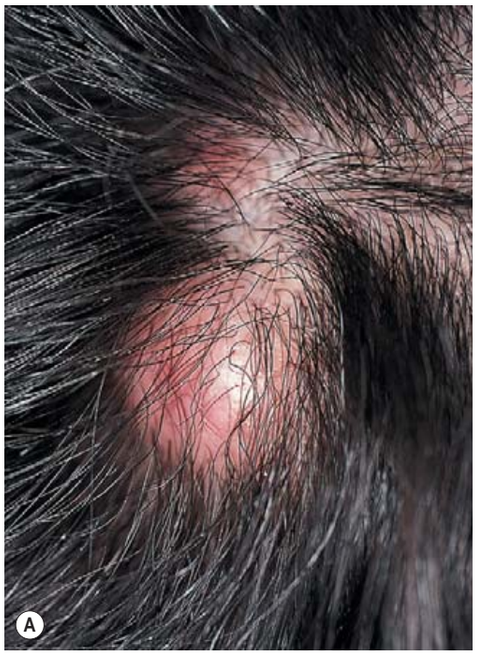

Fig. 110.8 Trichilemmal cyst versus proliferating trichilemmal cyst. A A non-inflamed trichilemmal cyst is skin-colored, mobile and has a smooth surface. **B** A proliferating trichilemmal cyst presenting as an enlarging cystic nodule in an elderly woman. Both types of cyst favor the scalp.

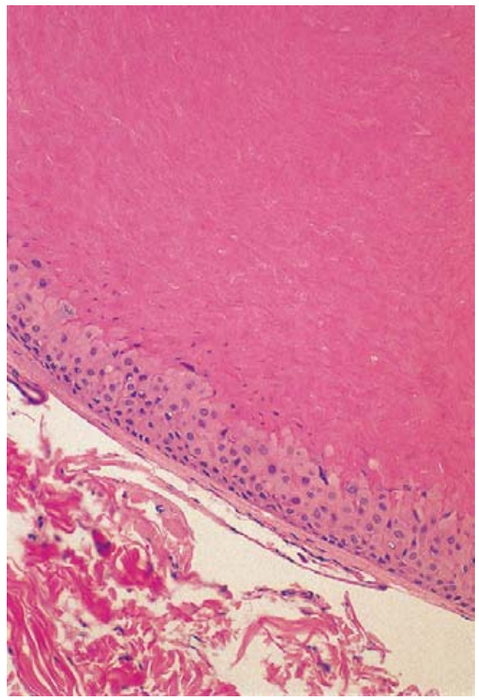

Fig. 110.9 Histology of a trichilemmal cyst. The cyst wall shows swollen keratinocytes with abrupt keratinization without formation of a granular layer. Homogeneous keratin fills the cyst.

associated with facial and skull malformations, cleft lip and palate, a lobulated tongue, mental retardation and polycystic kidneys; the associated alopecia follows the lines of Blaschko on the scalp. Milia are also seen in the setting of a number of other syndromes, including the BCC-associated syndromes, Rombo syndrome and Bazex syndrome.

Pathology

Histologic features are those of a small epidermoid cyst with a stratified squamous epithelial lining including a granular layer and laminated keratin cyst contents.

Treatment

Milia may be removed by incising the epidermis over the milium with a needle, scalpel or lancet and expressing the milium. The latter can be aided by the use of a comedo extractor. Laser ablation and electrodesiccation are also reported options. For multiple facial milia, topical retinoid therapy may be helpful in reducing the number of milia and aiding in the ease of removal.

Trichilemmal Cyst

Synonyms: ■ Pilar cyst ■ Wen ■ Isthmus–catagen cyst

Trichilemmal cysts are clinically indistinguishable from epidermoid cysts, but they are fourfold to fivefold less common. Ninety percent of trichilemmal cysts are located on the scalp (Fig. 110.8A). They may be solitary, but frequently they are multiple. Trichilemmal cysts may be inherited as an autosomal dominant trait.

Pathology

Trichilemmal cyst walls show keratinization analogous to that of the outer root sheath of the hair follicle at the isthmus *and* the sac surrounding catagen and telogen hairs (hence the synonym isthmus–catagen cyst). Trichilemmal cysts are lined by stratified squamous epithelial cells without visible intracellular bridges that become swollen and pale close to the cystic cavity and show abrupt keratinization without an intervening granular layer (Fig. 110.9). The cyst contents consist of homogeneous eosinophilic material that frequently shows foci of calcification. A foreign body giant cell response may surround the cyst if prior wall rupture has occurred.

Treatment

Treatment is by excision. Trichilemmal cysts typically "deliver" themselves through an incision without rupture more easily than do epidermoid cysts, and, therefore, the distinction between a trichilemmal cyst and an epidermoid cyst can often be correctly made at the time of excision.

Proliferating Trichilemmal Cyst

Synonyms: ■ Proliferating trichilemmal tumor ■ Proliferating pilar tumor ■ Proliferating follicular cystic neoplasm

A proliferating trichilemmal cyst classically occurs as a slow-growing nodule on the scalp in elderly women (see Fig. 110.8B). In fact, 90% occur on the scalp, and 84% occur in women with a median age of 63 years[6]. Proliferating trichilemmal cysts vary in size from a few millimeters to up to 25 cm in diameter. These tumors generally behave in a benign fashion, although, on occasion, aggressive local growth with

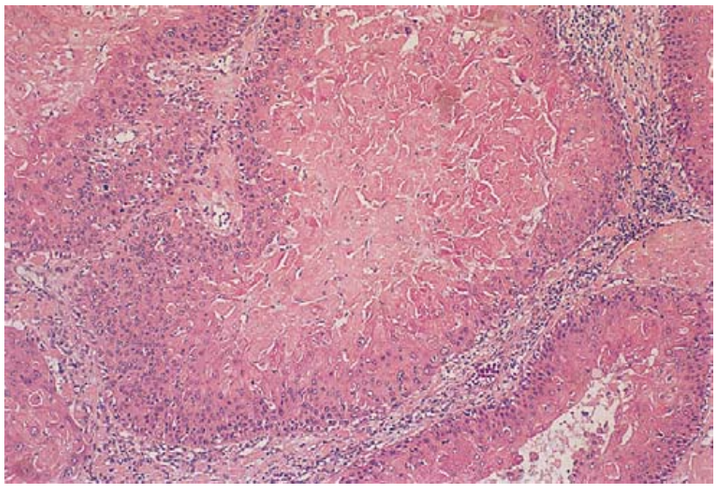

Fig. 110.10 Histology of a proliferating trichilemmal cyst. Irregular bands and nodules of squamous epithelium show central areas of abrupt keratinization.

Fig. 110.11 Eruptive vellus hair cysts. Pigmented small papules on the thigh of a young woman.

recurrences and metastases has been observed[6]. Extremely rarely, spindle cell carcinomas may develop within a proliferating trichilemmal cyst[7,8]. Distant metastases are rare in proliferating trichilemmal cysts, but over 30 such cases have been reported[9]. Whether a proliferating trichilemmal cyst represents a variant of SCC is an area of controversy[10].

Pathology

The histologic features of a proliferating trichilemmal cyst consist of broad anastomosing bands and nodules of squamous epithelium. The epithelium shows a proliferation of cells with abundant eosinophilic cytoplasm showing abrupt keratinization forming dense homogeneous keratin that fills cystic spaces. There may be areas of epidermoid keratinization with formation of horn pearls (Fig. 110.10) as well as areas of foreign body giant cell reaction. One-quarter of cases show an epidermal connection[6]. Cytologic atypia may vary markedly. Most tumors show well-circumscribed, pushing borders surrounded by compressed collagen. The lack of infiltrative growth into the surrounding stroma and abrupt trichilemmal keratinization helps in differentiation from SCC. Areas of marked atypia and infiltrative borders are features associated with a potential for aggressive behavior[11].

Treatment

Treatment is by complete surgical excision.

Proliferating Epidermoid Cyst

Synonym: ■ Proliferating epithelial cyst

Proliferating epidermoid cysts were first described in detail in 1995[6]. Unlike proliferating trichilemmal cysts, proliferating epidermoid cysts are observed more commonly in men and only 20% occur on the scalp. They range in size from 0.4 to 15 cm. In the 30 patients reported by Sau et al.[6] for whom follow-up was available, 20% of the cysts recurred, some multiple times, and one patient died of intractable local disease. None of the patients developed metastatic disease.

Pathology

Histologically, almost half of cases show an epidermal connection, usually with a narrow opening or connection to a dilated follicle. Most tumors show areas of typical epidermoid cyst wall. In addition, areas of squamous proliferation with squamous eddy formation are seen, with formation of a granular layer and production of loose laminated keratin. The epithelium tends to proliferate peripherally into the surrounding dermis, rather than centrally as seen in proliferating trichilemmal cysts. Degrees of cellularity and atypia are variable, and frank carcinomatous change with an infiltrative growth pattern may be seen.

Treatment

Treatment is by complete surgical excision.

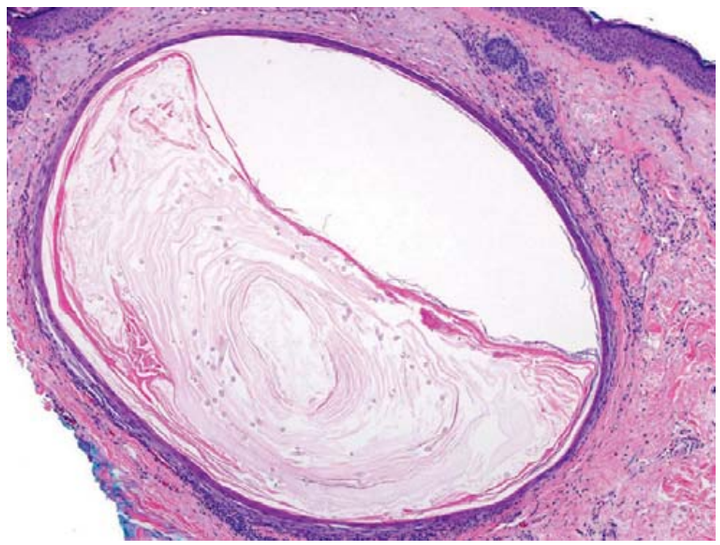

Fig. 110.12 Histology of a vellus hair cyst. A small cyst shows epidermoid keratinization of the cyst wall and numerous vellus hairs in the lumen.

Vellus Hair Cysts

Vellus hair cysts, described by Esterly, Fretzin and Pinkus in 1977[12], most commonly present as numerous, small, dome-shaped papules, ranging from skin-colored to darkly pigmented (Fig. 110.11). These cysts are most commonly located on the trunk, and they may be inherited in an autosomal dominant pattern. Multiple lesions are known as "eruptive" vellus hair cysts; occasionally, solitary cysts are seen. Although some lesions may resolve via transepidermal elimination of cyst products, most lesions persist indefinitely. Vellus hair cysts may become inflamed, but, in general, they are asymptomatic except for cosmetic concerns.

Eruptive vellus hair cysts may be seen in conjunction with steatocystoma multiplex, and both types of cysts have been reported in the setting of pachyonychia congenita (primarily type 2 [PC-2]; see Table 58.3). PC-2 can result from mutations in the genes that encode keratin 17 (*KRT17*) or keratin 6B (*KRT6B*)[13], whereas, to date, patients with inherited steatocystoma multiplex have been found to have mutations in *KRT17* (see below). Keratin 17 is expressed in the nail bed, hair follicles and sebaceous glands, but not in stratified squamous epithelium[14].

Pathology

Histologically, one sees a small cystic structure lined by stratified squamous epithelium with epidermoid keratinization. The cysts contain loose laminated keratin and numerous vellus hairs (Fig. 110.12). A follicle may be found entering the lower portion of the cyst.

Treatment

Vellus hair cysts may be treated by a number of modalities, including incision and drainage, needle evacuation, puncture followed by forceps-assisted extraction, topical retinoic or lactic acid, and laser ablation.

Steatocystoma

Steatocystomas occur as single (steatocystoma simplex) or multiple (steatocystoma multiplex) lesions. They tend to be a few millimeters to a centimeter in diameter and appear as cysts in the dermis that drain oily fluid if punctured (Fig. 110.13A,B). Steatocystomas are most numerous on the chest and in the axillae and groin. There are unusual facial and acral variants as well as a rare congenital linear form. Steatocystomas persist indefinitely, and they are usually asymptomatic except for cosmetic concerns.

Steatocystoma multiplex can be inherited as an autosomal dominant condition, and is due to mutations in the *KRT17* gene. It may occur in association with eruptive vellus hair cysts and pachyonychia congenita, primarily type 2 (see Table 58.3)[13,14]. Of note, all patients with pachyonychia congenita can develop epidermoid and pilar cysts, and there is a movement towards classifying patients based upon their *KRT* mutations, rather than clinical subtypes. For example, PC-2 is referred to as PC-6b/17.

Pathology

Biopsy specimens show a dermal cyst lined by a thin stratified squamous epithelium, without a granular layer and surmounted by a thin, irregular, corrugated eosinophilic cuticle (Fig. 110.13C). Small sebaceous lobules are found in or immediately adjacent to the cyst wall.

Treatment

Lesions can be excised or incised with removal of the cyst wall.

Cutaneous Keratocyst

Synonyms: ▪ Sebaceous duct cyst ▪ Isthmic-anagen cyst

Cutaneous keratocysts have been reported primarily in patients with the nevoid BCC syndrome. Their clinical appearance is similar to epidermoid cysts and there is no characteristic clinical location.

Pathology

These cysts have a stratified squamous epithelial wall without a granular layer and an eosinophilic cuticle, like a steatocystoma. However, no associated sebaceous lobules are seen[15].

Follicular Hybrid Cyst

Synonym: ▪ Hybrid cyst

Follicular hybrid cysts are not distinctive clinically, but rather represent a histologic variant of cysts with a stratified squamous lining in which there is transition in the cell wall between epidermoid keratinization and trichilemmal or pilomatrical keratinization[16,17]. They were originally described by Brownstein[17].

Pigmented Follicular Cyst

Pigmented follicular cysts, described by Mehregan and Medenica[18], are solitary and occur primarily on the face of men. They are often deeply pigmented and may be confused clinically with a nevus.

Histologically, these cysts have a pore-like connection to the epidermis, are lined by stratified squamous epithelium including a granular layer, and contain pigmented hair shafts. The clinical presentation, epidermal connection, and pigmented hair shafts distinguish the pigmented follicular cyst from vellus hair cysts.

Dermoid Cyst

Cutaneous dermoid cysts typically present in an infant along an embryonic fusion plane as a discrete, subcutaneous nodule. Dermoid cysts are usually 1–4 cm in diameter. The most common location is around the eyes (see Ch. 64).

Fig. 110.13 Steatocystoma multiplex. A,B Numerous cystic papules on the trunk and multiple cystic nodules on the neck. **C** Histology of steatocystoma. The cyst wall is characterized by an undulated, thin stratified epithelium lacking a stratum granulosum and lined by an eosinophilic cuticle. A search may be required to identify small sebaceous lobules in or immediately adjacent to the cyst wall (insert). *C, Courtesy, Lorenzo Cerroni, MD.*

Pathology

Histologically, dermoid cysts are lined by stratified squamous epithelium including a granular layer. They contain other normal cutaneous structures such as hair, sebaceous lobules, eccrine glands, apocrine glands, or smooth muscle.

Treatment

Treatment is by excision. However, as the differential diagnosis includes neural heterotopias, imaging studies may be appropriate prior to excision, to exclude a connection to the CNS (see Ch. 64).

Ear Pit

Synonyms: ■ Preauricular cyst ■ Congenital auricular fistula ■ Preauricular fistula

Ear pits are congenital defects, and they may present as a true cystic nodule or an invagination in the preauricular area (Fig. 110.14). During development, the ear is formed by the fusion of six tubercles: three each from the first two branchial arches. Preauricular cysts reflect defective embryologic fusion with epithelial entrapment. These defects are relatively common, occurring in approximately 0.5–1% of the normal population, and they may be transmitted in an autosomal dominant fashion[19]. Ear pits are usually unilateral and right-sided. Infection with tenderness and purulent drainage may prompt presentation to a physician.

Although ear pits are usually not associated with other significant abnormalities, they can occur in conjunction with deafness or with deafness plus renal anomalies in the branchio-otic syndrome and branchio-oto-renal dysplasia, respectively. Ear pits are also seen in a number of other congenital syndromes that are characterized by major morphologic anomalies, including Treacher Collins–Franceschetti syndrome, Goldenhar syndrome, Lowry–MacLean syndrome and cat-eye syndrome[20].

Pathology

Histologically, preauricular pits or cysts are lined by stratified squamous epithelium with a granular layer.

Treatment

If removal is desired, simple excision is curative. Although most ear pits are incidental findings, in a newborn, a physical examination to exclude one of the associated syndromes and an evaluation for hearing loss is indicated. Infected lesions may require antibiotic therapy.

Fig. 110.14 Ear pit.
Courtesy, Julie V Schaffer, MD.

Pilonidal Cyst

Synonyms: ■ Pilonidal sinus ■ Pilonidal disease ■ Barber's interdigital pilonidal sinus (when located in the interdigital spaces)

Pilonidal cysts typically present as an inflamed, painful cystic swelling in the upper gluteal cleft or sacrococcygeal area, but they have been described in many other locations. They are most common in men (at a ratio of 3–4 : 1) and in Caucasians. They occur most commonly in hirsute individuals[21]. Pilonidal cysts typically present near the end of the first decade of life and were a significant source of morbidity and hospitalization during World War II[21].

The etiology of pilonidal cysts and sinuses has been a controversial issue. Some authors have argued that they are congenital, essentially representing a dermoid cyst, whereas most authors now believe that the vast majority of lesions are acquired, representing a foreign body response to entrapped hair. A pilonidal cyst can be seen as part of the "follicular inclusion tetrad" which consists of acne conglobata, hidradenitis suppurativa, perifolliculitis capitis abscedens et suffodiens, and pilonidal cyst (see Ch. 38). Persistent exogenous hairs in the interdigital space of barbers or dog groomers may incite an encompassing epidermal proliferation, giving rise to a pilonidal cyst.

Pathology

Histologic features are those of an epidermal-lined cyst or sinus tract. Cyst cavities are lined with granulation tissue and mixed inflammation, with hair and keratin debris.

Treatment

Treatment is surgical and may include excision, marsupialization, or incision and curettage.

CYSTS LINED WITH NON-STRATIFIED SQUAMOUS EPITHELIUM

Hidrocystoma

Synonyms: ■ Cystadenoma ■ Sudoriferous cyst ■ Moll's gland cyst

Hidrocystomas typically present as translucent, skin-colored to bluish cysts on the face, although they may occur in other sites. Hidrocystomas are traditionally divided into apocrine and eccrine hidrocystomas by histologic features, and as solitary (Smith type) or multiple (Robinson type). Hidrocystomas may be associated with specific syndromes of ectodermal dysplasia, including Schöpf–Schulz–Passarge syndrome.

Apocrine hidrocystomas are usually solitary (Fig. 110.15), whereas eccrine hidrocystomas may be solitary or multiple and are occasionally quite numerous (Fig. 110.16). Eccrine hidrocystomas can enlarge with heat exposure or during the summer and regress with cooler temperatures. In general, eccrine hidrocystomas are thought to develop from cystic dilation of eccrine ducts due to retention of eccrine secretions,

Fig. 110.15 Apocrine hidrocystoma. A single, slightly bluish, translucent papule on the lower eyelid near the lateral canthus.

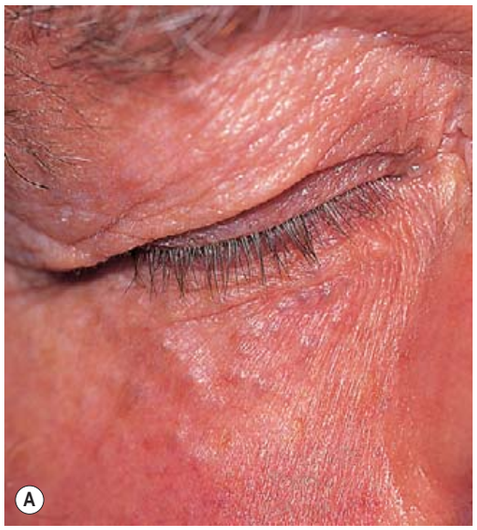

Fig. 110.16 Eccrine hidrocystomas. Numerous, tiny, translucent or bluish papules on the lower eyelid (**A**) or the cheek (**B**).

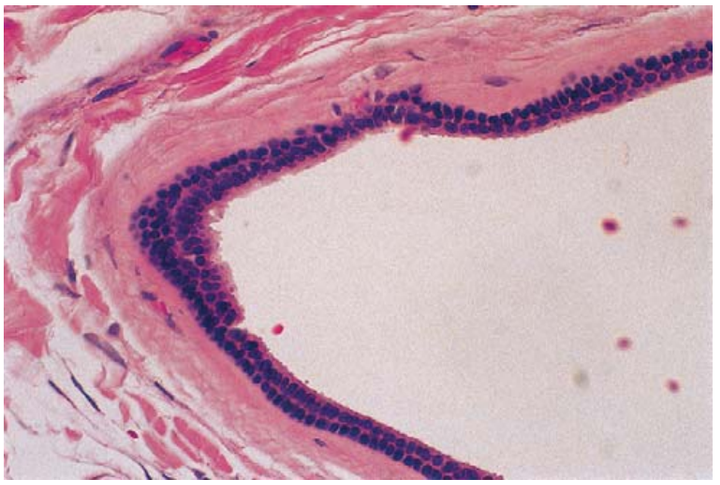

Fig. 110.17 Histology of apocrine hidrocystoma. The cyst wall shows typical apocrine decapitation secretion.

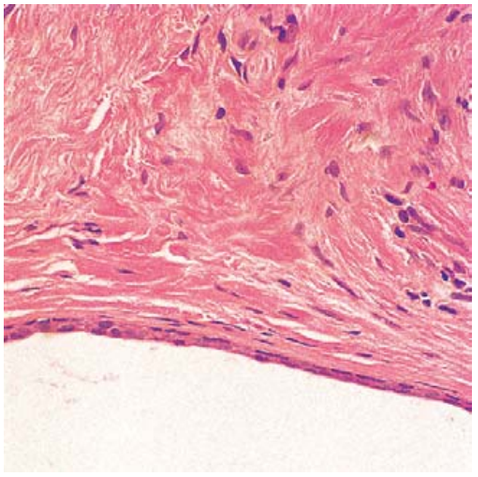

Fig. 110.18 Histology of eccrine hidrocystoma. Two layers of flattened epithelium form the cell wall.

while apocrine hidrocystomas are thought to represent adenomas of apocrine sweat gland coils[22]. Apocrine hidrocystomas are sometimes referred to as cystadenomas, although it has been recommended that this term be reserved for lesions with true papillomatous projections histologically[23]. Lesions along the lower eyelid margin are also known as Moll's gland cysts.

Pathology

Histologically, apocrine hidrocystomas are unilocular to multilocular dermal cysts lined by one to several layers of epithelial cells that show bulbous protrusions ("snouting") and luminal decapitation secretion (Fig. 110.17). Similarly lined papillary projections may extend into the cyst lumen. Histologic features of eccrine hidrocystomas are those of a uniloculate cyst containing clear fluid, lined by two layers of cuboidal to flattened epithelium (Fig. 110.18). Apocrine hidrocystomas express human milk-fat globulin antigen, while "true" eccrine hidrocystomas do not. Hidrocystomas that appear by light microscopy to be eccrine include a subset of lesions that mark immunohistochemically as apocrine hidrocystomas, despite a flattened wall[22].

Treatment

Hidrocystomas may be removed by simple excision, electrodesiccation or CO_2 laser. Multiple eccrine hidrocystomas may also be treated with daily application of topical 1% atropine in aqueous solution, although lesions reappear within days of discontinuing therapy[24]. Flattening after botulinum toxin A injections has been reported[25].

Bronchogenic Cyst

Cutaneous bronchogenic cysts are most commonly found in the suprasternal notch and, rarely, on the anterior neck or chin (see Fig. 64.2). A fistulous tract may connect to the epidermis. Rarely, they present as a pedunculated growth[26]. Bronchogenic cysts are solitary, and they are typically found at birth. Malignant transformation is very rare. They represent respiratory epithelium sequestered during embryologic development of the tracheobronchial tree.

Pathology

Bronchogenic cysts are lined by pseudostratified ciliated columnar epithelium with interspersed goblet cells. The cyst wall often contains smooth muscle and mucous glands, and, rarely, cartilage.

Treatment

Treatment is by excision.

Thyroglossal Duct Cyst

Thyroglossal duct cysts present as midline cystic nodules on the anterior neck in children or young adults (see Fig. 64.2). During development, the thyroid gland descends from the floor of the pharynx to the anterior neck. The tract it forms is known as the thyroglossal duct. Thyroglossal duct cysts arise from remnants of the thyroglossal duct. A tract connecting these cysts to the hyoid bone is frequently present, resulting in characteristic movement of the cyst with swallowing. Rarely, thyroid carcinoma may originate in a thyroglossal duct cyst[27].

Pathology

Histologically, thyroglossal duct cysts may be lined with cuboidal, columnar or stratified squamous epithelium and may contain some ciliated columnar cells. The characteristic histologic feature is the presence of thyroid follicles, characterized by low cuboidal cells surrounding homogeneous pink material, in the cyst wall (Fig. 110.19).

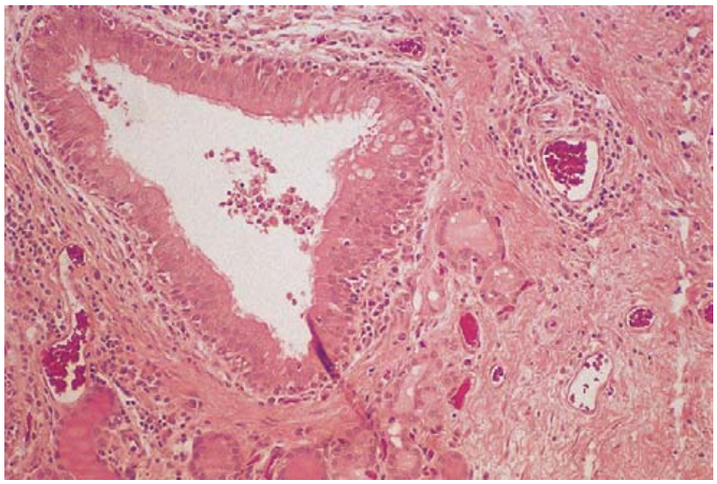

Fig. 110.19 Histology of thyroglossal duct cyst. Thyroid follicles are seen adjacent to a cyst lined by ciliated epithelium.

Treatment

Treatment is surgical, with excision of the cyst and any residual tract.

Branchial Cleft Cyst

Synonyms: ■ Lymphoepithelial cyst ■ Lateral cervical cyst

Branchial cleft cysts occur in the preauricular area, mandibular region, or along the anterior border of the sternocleidomastoid muscle (see Fig. 64.2). The origin of these cysts is controversial. There are two major theories regarding their origin:

- they arise from branchial cleft remnants
- they represent cystic alteration of embryologic epithelium or tonsillar epithelium within cervical lymph nodes[28].

Branchial cleft cysts most commonly present during the second or third decade of life. Infection of these cysts is a frequent cause of presentation to a physician.

Pathology

Histologically, these cysts are lined by stratified squamous epithelium or by pseudostratified ciliated columnar epithelium, and they are surrounded by lymphoid tissue.

Treatment

Treatment is by excision of the cyst and its associated tract after delineation of the extent of the lesion by CT or MRI[29].

Cutaneous Ciliated Cyst and Ciliated Cyst of the Vulva

Synonyms: ■ Cutaneous müllerian cyst ■ Cutaneous ciliated cystadenoma ■ Paramesonephric mucinous cyst of the vulva

Cutaneous ciliated cysts are uncommon cysts that typically occur on the lower extremities of young women, although a few cases have been reported in men. They are usually a few centimeters in diameter and, on rupture, drain clear to amber fluid. The histogenesis of these cysts is controversial. Most authors have suggested a müllerian duct origin. However, the few occurrences in men have led to the alternative hypothesis that some cases represent ciliated metaplasia of eccrine glands[30].

Ciliated cysts of the vulva are müllerian heterotopias, and they are located, as their name implies, on the vulva (most commonly on the labia majora). They usually measure between 1 and 3 cm in diameter. It has been suggested that both ciliated cyst of the vulva and the cutaneous ciliated cyst should be called cutaneous müllerian cysts, as their presumed origin is the same[31].

Fig. 110.20 Histology of a ciliated cyst of the vulva. The cyst wall is composed of columnar ciliated epithelium with papillary projections into the lumen.

Pathology

Cutaneous ciliated cysts may be unilocular or multiloculated. The cyst wall is composed of simple cuboidal to columnar ciliated epithelium that may have papillary projections into the cyst lumen (Fig. 110.20).

Treatment

Excision is curative.

Median Raphe Cyst

Synonym: ■ Apocrine cystadenoma of the penis

Median raphe cysts are solitary and usually only a few millimeters in diameter, although they may extend over several centimeters linearly. They occur in young men on the ventral aspect of the penis, most commonly on or near the glans. These cysts are thought to develop from aberrant urethral epithelium, but do not connect to the urethra[32].

Pathology

Histologically, median raphe cysts are lined by stratified columnar epithelium (one to four cell layers thick) without a connection to the overlying epithelium. Occasional mucin-containing cells are seen in the lining. Very rarely, a ciliated lining has been observed[33].

Treatment

Excision is curative.

Omphalomesenteric Duct Cyst

Synonyms: ■ Vitelline cyst ■ Omphalomesenteric duct remnant

Omphalomesenteric duct cysts represent a developmental defect in the closure of the omphalomesenteric duct. The omphalomesenteric duct is the fetal connection between the midgut and the yolk sac. It is usually obliterated and loses its intestinal attachment by 6 weeks of gestation[34]. Remnants of this duct may occur anywhere along its course between the intestines and the umbilicus. The spectrum of defects resulting from this faulty closure includes Meckel's diverticulum, umbilical–enteric fistulae, umbilical sinuses and omphalomesenteric duct cysts (internal or external); the latter can present as an umbilical polyp (Fig. 110.21).

Fig. 110.21 Omphalomesenteric duct cyst. This pink papule in the umbilicus of this infant showed gastrointestinal epithelium histologically. The clinical differential diagnosis includes an umbilical (pyogenic) granuloma and urachal cyst/remnant.

Pathology

These lesions are characterized histologically by ectopic gastrointestinal mucosa and must be distinguished from umbilical metastases of gastrointestinal adenocarcinomas.

Treatment

Management of omphalomesenteric duct cysts includes appropriate radiologic studies to exclude communication to the gastrointestinal tract prior to surgical excision.

Urachal Cyst

The urachus is a tube connecting the fetal bladder to the umbilicus and it normally closes during development, resulting in a fibrous tract. A persistent urachus presents during infancy with urine leakage from the umbilicus. A urachal cyst results from an incomplete urachal duct remnant. Urachal cysts are rare, and they usually present as a painful umbilical mass due to secondary infection. The diagnosis can be established by ultrasound in the majority of patients[35].

Pathology

These cysts are characterized by a urothelial lining of cuboidal or columnar cells.

Treatment

Excision is recommended to prevent secondary infections as well as late development of adenocarcinoma[35].

CYSTS WITHOUT AN EPITHELIAL LINING

Synonyms: ■ Mucous cyst of oral mucosa ■ Ranula (when located on the floor of the mouth)

Mucocele

Mucoceles most frequently develop on the lower labial mucosa, but they also occur on the floor of the mouth, buccal mucosa, and tongue. They appear as dome-shaped, bluish, translucent papules or nodules that range in size from a few millimeters to over a centimeter (Fig. 110.22). Mucoceles arise as a result of disruption of the ducts of minor salivary glands. This disruption leads to an accumulation of mucinous material, a reactive inflammatory response, and the development of surrounding granulation tissue.

A variant of mucocele, superficial mucocele, presents as a clear tense vesicle that is a few millimeters in diameter. Superficial mucoceles are most commonly found on the retromolar pad, posterior buccal mucosa, and soft palate. These lesions are short-lived, asymptomatic and recurrent. They may be confused clinically with an immunobullous or viral process.

Fig. 110.22 Mucocele. A bluish translucent papule on the lower mucosal lip.

Pathology

Biopsy specimens of mucoceles show one or several spaces within the connective tissue filled with mucinous material, but without an epithelial lining. The spaces are surrounded by chronic inflammation, mucin-containing macrophages, and granulation tissue. A salivary duct may be seen at the periphery of these findings. Adjacent minor salivary glands may show chronic inflammation and fibrosis. The mucinous material is sialomucin, and the latter contains both neutral and acid mucopolysaccharides, which stain with PAS (diastase-resistant) and with Alcian blue or colloidal iron, respectively.

Histologically, a superficial mucocele shows a subepithelial vesicle filled with mucin and a surrounding sparse to moderate mixed inflammatory infiltrate. Salivary gland ducts are seen opening into the vesicle or immediately adjacent to the vesicle.

Treatment

Mucoceles may resolve spontaneously. If they do not, treatment options include excision, marsupialization, electrodesiccation, intralesional corticosteroid injection, cryosurgery, and CO_2 laser therapy.

Digital Mucous Cyst

Synonyms: ■ Digital myxoid cyst ■ Cutaneous myxoid cyst

Digital mucous cysts most commonly occur on the dorsal surface of the distal phalanx of the finger. Toe lesions are less commonly observed. A characteristic depressed nail deformity may be seen distal to the cyst (Fig. 110.23). These cysts are skin-colored to bluish and drain clear gelatinous material when punctured. The etiology of digital mucous cysts is controversial, with some authors stating that they are degenerative in origin while others believe they extend from the distal interphalangeal joint space. A pedicle connecting the cyst to the adjacent joint space can usually be demonstrated[36].

Pathology

Histologically, clefts are seen in the dermis without an epithelial lining (Fig. 110.24). The clefts and the surrounding loose connective tissue contain abundant acid mucopolysaccharides, which can be highlighted by Alcian blue or colloidal iron stains.

Treatment

Resolution may be seen after intralesional injection of corticosteroids. Repeated puncture and drainage of a digital mucous cyst leads to resolution in up to 70% of patients[37]. Surgical excision may give even higher success rates. De Berker and Lawrence[36] reported a technique for identification and ligature of the connection to the joint capsule. This technique was curative in 94% of finger lesions and 57% of those on the toes.

Fig. 110.23 Digital mucous cyst. A translucent papule on the dorsal distal phalanx of the finger causing a depression in the nail plate.

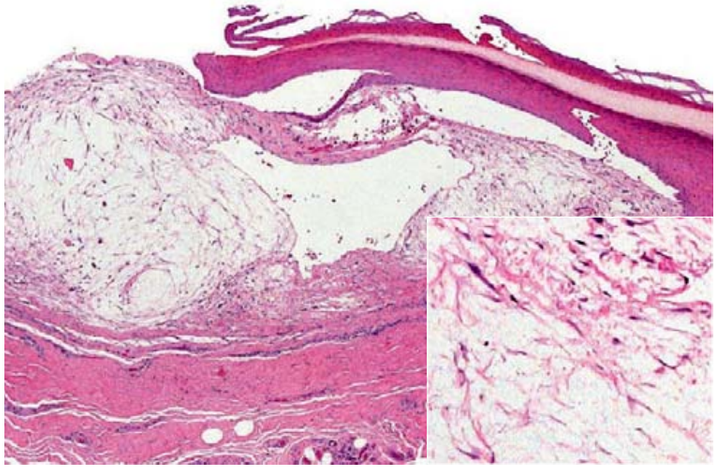

Fig. 110.24 Histology of a digital mucous cyst. A subepidermal cystic cavity is surrounded by mucin-rich dermis (insert). Note the prominent stratum lucidum of acral skin. *Courtesy, Lorenzo Cerroni, MD.*

Ganglion

Synonyms: ■ Ganglion cyst ■ Synovial cyst

Ganglia are soft cystic masses up to 4 cm in diameter that most commonly occur on the dorsal aspect of the wrist; they may also be found on the volar wrist or fingers, the dorsal aspect of the feet, or the knees. Ganglia rarely develop on the lateral elbow or anterior shoulder. They occur more commonly in women and may cause discomfort with activity, impairment of mobility, or cosmetic concerns. In the rare disorder cystic ganglionosis, multiple lesions appear during childhood or adolescence.

Ganglia are frequently attached to a tendon sheath or the joint capsule, but usually do not communicate with the joint space[38]. The mucin present within a ganglion is thought to be produced by local fibroblasts.

Pathology

Myxoid change is seen within the connective tissue that ultimately forms cystic spaces. These spaces coalesce into a dominant cystic space lined by fibrous tissue (Fig. 110.25), sometimes with a synovial lining.

Treatment

Early lesions may respond to several weeks of compression therapy[38]. Other options include aspiration plus intralesional corticosteroid injection or excision. Recurrences are common, even with excisional therapy.

Fig 110.25 Histology of a ganglion (cyst). A cystic space of acral skin is surrounded by fibrous tissue. *Courtesy, Lorenzo Cerroni, MD.*

Fig. 110.26 Pseudocyst of the auricle. Erythematous firm nodule on the ear.

Pseudocyst of the Auricle

Synonyms: ■ Endochondral pseudocyst ■ Cystic chondromalacia ■ Intracartilaginous cyst

Pseudocyst of the auricle usually arises in the scaphoid fossa of the ear in middle-aged men. Lesions are usually unilateral. They present as a painless swelling (Fig. 110.26), and they tend to arise over the course of a few weeks. The etiology of pseudocyst of the auricle is unknown, but chronic trauma as well as a developmental defect have been suggested.

Pathology

Biopsy specimens show a cavity within the auricular cartilage (without an epithelial lining) that contains clear fluid. Fibrous tissue and granulation tissue may be found in the cavity as well. The cartilage lining the cavity may show degenerative changes. No inflammation is seen within the cartilage, a feature that distinguishes a pseudocyst from relapsing polychondritis, which is frequently in the clinical differential diagnosis.

Treatment

Treatment options include aspiration, with or without intralesional injection of corticosteroids, as well as incision and drainage with

destruction of the cavity. Each of these modalities should be followed by pressure dressings[39].

Cutaneous Metaplastic Synovial Cyst

Cutaneous metaplastic synovial cysts typically present as a solitary tender subcutaneous nodule, although multiple lesions have been reported[40]. They occur primarily in areas of prior trauma, particularly prior surgical trauma. Frequently, the preoperative diagnosis is that of a suture granuloma.

Pathology

A cystic cavity is seen within the dermis that is not lined by epithelium. The cavity may communicate with the overlying epidermis via fistulas. Variably cellular villous structures mimicking hyperplastic synovium protrude into the cavity. These villi are covered with a fibrinous exudate. The base of the villi tends to merge with surrounding scar tissue.

Treatment

Excision is curative.

Adnexal Neoplasms 111

Timothy H McCalmont

Chapter Contents

Neoplasms and proliferations of follicular lineage *1829*
Neoplasms and proliferations with sebaceous differentiation .. *1839*
Neoplasms and proliferations with apocrine differentiation *1840*
Neoplasms and proliferations with eccrine differentiation..... *1847*

Key features

- Terminology and classification of adnexal tumors has varied considerably according to different authorities
- Combinations of follicular, sebaceous and apocrine differentiation occur commonly
- Many tumors historically classified as eccrine are probably apocrine

The nosology of adnexal neoplasms has been confused for decades, and a key problem has been the lack of a logical classification scheme. Postulated classifications and inferences regarding lineage have often been contradictory, a reflection of the fact that broad conclusions regarding lineage and classification were formerly based on enzyme histochemical attributes of dubious specificity[1,2].

The crucial principle to keep in mind when considering adnexal neoplasms is that the development of the eccrine apparatus is distinct from the folliculosebaceous-apocrine unit. Eccrine glands develop directly from the embryonic epidermis in early months of fetal development[3]. Follicles arise directly from the epidermis concurrently, but their development differs in that mesenchymal cells, precursors of the follicular papilla, descend jointly into the dermis with the developing follicle. Subsequently, sebaceous and apocrine glands and their ducts elaborate as secondary structures from bulges on the side of the developing follicle.

These ontogenetic relationships reflect relationships observed repeatedly in clinical disease[1]. As one would expect from ontogeny, follicular, sebaceous and apocrine differentiation occur conjointly, and combinations of eccrine and folliculosebaceous differentiation probably do not exist.

The topography of adnexal structures also offers insight into logical classification. There is striking variation in anatomic distribution among adnexal neoplasms, and some of these differences hold implications regarding lineage. Based on topography, it is nonsensical to pigeonhole spiradenoma, a tumor that commonly occurs within apocrine skin and rarely, if ever, develops acrally, as an eccrine tumor. In contrast, an acral predilection suggests that poroma is commonly of eccrine lineage[4].

Lastly, microscopy and morphology play a role in the assessment of lineage. For some lines of differentiation, the meaning ascribed to specific attributes is indisputable. Cells with coarsely vacuolated cytoplasm and scalloped nuclei signify sebaceous differentiation. Follicular differentiation is established by the presence of bulbar basaloid cells accompanied by mesenchymal cells resembling the follicular papilla. Follicular lineage is also connoted by matrical or outer sheath differentiation. In contrast, there are no specific attributes that permit recognition of eccrine or apocrine differentiation.

NEOPLASMS AND PROLIFERATIONS OF FOLLICULAR LINEAGE

Follicular and Folliculosebaceous-apocrine Hamartomas

Hamartomas are benign proliferations composed of cellular elements, native to a site, in aberrant proportion. A congenital hamartoma, such as nevus sebaceus, is properly referred to as a *nevus*. Hamartomas can be acquired and present in tumor-like fashion, although such lesions do not represent authentic neoplasms.

Proliferations of the folliculosebaceous-apocrine unit are commonly hamartoma-like. The folliculosebaceous-apocrine unit incorporates follicular epithelial, follicular mesenchymal, sebaceous and apocrine elements, and thus its microscopically diverse progeny is not surprising. Many follicular proliferations that we consider neoplastic, such as trichoblastoma, have integral stroma, and thus the distinction between follicular hamartoma and follicular neoplasm is sometimes blurred.

Hair follicle nevus

Introduction

Hair follicle nevi are authentic hamartomas, usually congenital, in which hairs and the follicles that ensheath them have abnormal morphology or size or are present in increased numbers.

Clinical features

Hair follicle nevus, also known as *vellus hamartoma*, presents as a small papule from which fine hairs protrude evenly from the surface. Lesions typically involve the face and commonly reside near the ear[5]. *Accessory tragus* overlaps with hair follicle nevus, and it has been suggested that the two entities are the same[6,7]. *Nevus pilosus* designates hamartomas characterized by closely set, non-vellus hairs.

Pathology

Microscopically, hair follicle nevi display a domed surface with an increase in normally formed vellus follicles. The configuration may resemble normal skin. Accessory tragi exhibit an identical pattern but are uniquely identifiable if deep subjacent hyaline cartilage can be found. Nevus pilosus is characterized by closely set terminal follicles.

Treatment

No therapy is required. Excision can be considered for cosmesis. In the evaluation of a hair follicle nevus or accessory tragus in a small child, parents can be counseled that the relative size of the lesion will diminish with time. The child will grow faster than the lesion, which may become inconspicuous by adolescence.

Trichofolliculoma

Introduction

Trichofolliculoma does not represent an authentic neoplasm. Rather, the term designates a group of follicular hamartomas in which fully formed follicular structures emanate from a central dilated infundibular space.

Clinical features

Trichofolliculoma presents as a papule or nodule involving the face, scalp or upper trunk. Many examples are not clinically distinctive. Sometimes, a central follicular ostium or punctum may be identifiable

Fig. 111.1 Trichofolliculoma. Wispy vellus hairs emerge from a skin-colored papule with a dilated central pore.

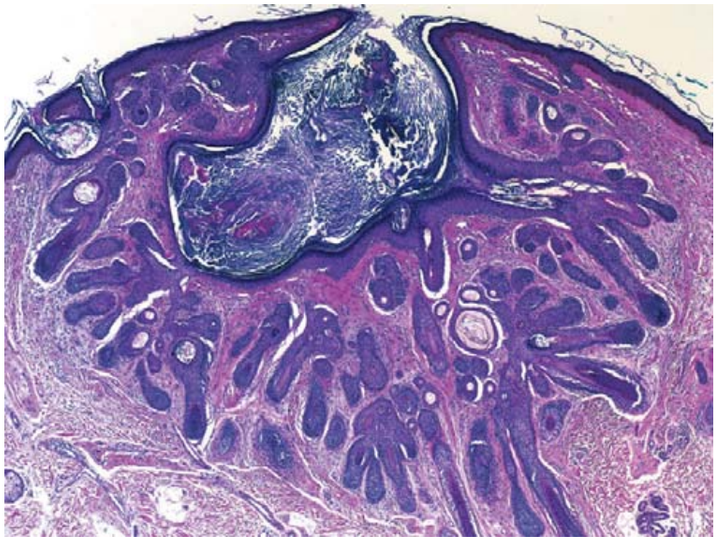

Fig. 111.2 Trichofolliculoma, viewed at scanning magnification. There is a central patulous follicular infundibulum, from which fully formed or nearly fully formed follicles radiate.

and it may harbor a small tuft of hairs (Fig. 111.1). Rarely, the clinical presentation will be as a large nodule or cyst.

Pathology

Prototypically, a trichofolliculoma consists of a central cystic space with infundibular cornification and central orthokeratin. Sometimes, cross-sections of hair shafts are identifiable within the cyst. Relatively well-developed and occasionally oddly formed vellus follicles protrude in radial fashion from the central structure (Fig. 111.2). The follicles usually display a bulb and papilla and exhibit inner and outer sheath and isthmic differentiation. The entire structure, including the central cyst and its associated radiating follicles, is enveloped by a vascularized fibrous (angiofibroma-like) stroma.

The radiating follicles are frequently cut on tangent, thus creating considerable microscopic variation, and deeper sections through the tissue block sometimes are required for diagnosis. If the radiating follicles are accompanied by sebaceous glands, the hamartoma can be termed a *sebaceous trichofolliculoma*[8]. This diagnostic embellishment is not of any clinical import.

The term *folliculosebaceous cystic hamartoma* has been applied to a group of nodular and cystic lesions described independently from trichofolliculoma[9–11]. Folliculosebaceous cystic hamartoma shows a central infundibular cyst from which follicular and sebaceous elements emanate, and the encompassing stroma may be fibrous or myxoid and often contains adipocytes. Rather than a unique entity, is seems likely that folliculosebaceous cystic hamartoma represents a large cystic sebaceous trichofolliculoma[9].

Treatment

Trichofolliculoma is wholly benign and no treatment is needed. If a trichofolliculoma is discovered by biopsy, no further intervention is required.

Fibrofolliculoma, perifollicular fibroma and trichodiscoma

Introduction

Fibrofolliculoma represents an adnexal hamartoma that includes both follicular epithelial and mesenchymal elements. Perifollicular fibroma and trichodiscoma were described independently but probably represent purely mesenchymal proliferations on the same spectrum as fibrofolliculoma. Some authorities consider perifollicular fibroma to be related to angiofibroma.

Clinical features

Fibrofolliculomas (Fig. 111.3), perifollicular fibromas and trichodiscomas are not clinically distinctive. All present as small, skin-colored to hypopigmented papules that involve the head and neck or upper trunk. The papules commonly present in multiplicity. In this context, strong consideration should be given to the possibility of the Birt–Hogg–Dubé syndrome (Fig. 111.4), an autosomal dominant disorder typified by multiple fibrofolliculomas, trichodiscomas and acrochordon-like lesions. Other associated phenomena include chromophobe renal cell carcinoma, colonic adenomas, pulmonary cysts and spontaneous pneumothoraces, medullary thyroid carcinoma, and connective tissue nevi.

Pathology

At low magnification, fibrofolliculoma displays slender strands of follicular mantle cells that emanate from a folliculosebaceous unit at the level of the isthmus. Usually, the strands are composed of cells with a slightly basaloid appearance, and sometimes, tiny integrated collections of mature sebocytes are identifiable. The epithelial component may assume a mitt-like morphology in some instances. The entire structure is encased by vascularized fibrous stroma.

Perifollicular fibroma consists almost exclusively of stroma that is identical to the stromal elements of fibrofolliculoma and angiofibroma. Lesions consist of spindled and stellate cells arrayed concentrically around follicles and distributed amongst thickened collagen bundles with a proportionate number of intervening small thin-walled vessels. Sometimes, a concurrent component of follicular epithelial hyperplasia is identifiable, although the epithelium tends to be inconspicuous in comparison to fibrofolliculoma. Trichodiscoma was thought by Pinkus to represent a unique proliferation with differentiation toward the *haarscheibe* (hair disk), which is probably a mythical structure. More recently, trichodiscomas have been interpreted as fibrofolliculomas or perifollicular fibromas with myxoid rather than fibrous stroma.

Treatment

Fibrofolliculomas, perifollicular fibromas and trichodiscomas are all benign and require no surgical treatment. Superficial electrodesiccation, carbon dioxide laser ablation, or dermabrasion can be utilized to ameliorate multiple lesions.

Nevus sebaceus

Introduction

Originally known as *organoid nevus*, nevus sebaceus is commonly thought of as a sebaceous lesion and historically has been the first entity discussed in chapters describing sebaceous tumors. In truth, nevus sebaceus is a non-neoplastic malformation that includes follicular, sebaceous and apocrine elements[12].

Clinical features

Nevus sebaceus represents a classic *nevus* or congenital malformation. At birth, lesions are only slightly raised and subtly discernible. Nevus sebaceus involves the scalp or face commonly, the neck occasionally, and the trunk rarely. Lesions that are linear are distributed along the lines of Blaschko, although this may be difficult to appreciate if small. On the scalp, a nevus will remain hairless, or mostly so, as the infant's hair grows around it. During childhood, the nevus thickens slightly and assumes a yellow or orange hue (Fig. 111.5). At adolescence, progressive thickening occurs and the surface becomes pebbly or verrucous.

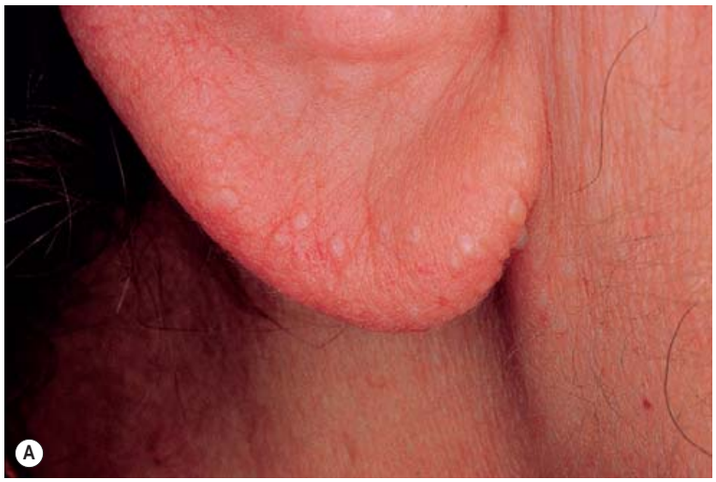

Fig. 111.3 Fibrofolliculomas in association with Birt–Hogg–Dubé syndrome. A Multiple small skin-colored to white papules on the ear. **B** Multiple smooth papules of the lateral cheek that are relatively hypopigmented and lack the telangiectasias of the background skin. **C** Histology from a patient with Birt–Hogg–Dubé syndrome showing a mitt-like configuration with a retiform array of isthmic keratinocytes flanked by delicate mucinous stroma.

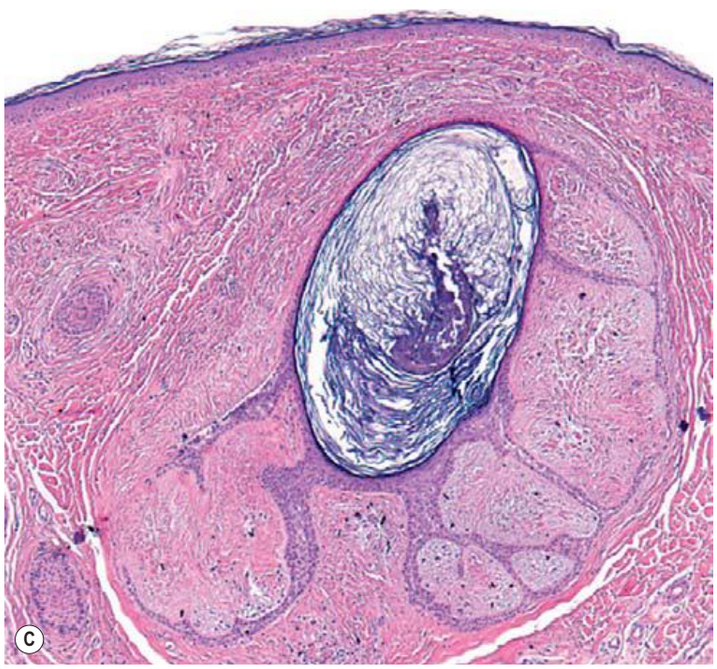

Especially when there is more extensive involvement with nevus sebaceus, the possibility of Schimmelpenning syndrome or phakomatosis pigmentokeratotica needs to be considered (see Table 62.8).

Nevus sebaceus represents a fertile field for the development of secondary adnexal neoplasms, commonly benign but occasionally malignant[13–15]. A past generation of dermatologists was taught that secondary carcinoma develops in 10% or more of these lesions over time, although this figure was poorly substantiated. The vast majority of secondary proliferations represent benign follicular germinative (trichoblastoma-like) foci (Fig. 111.6); the actual incidence of secondary basal cell carcinoma (BCC) is less than 1%[13,14]. Historically, syringocystadenoma papilliferum (papillary syringoadenoma) was believed to represent the most common secondary proliferation, but recent analysis indicates that trichoblastoma holds this role[13,14]. Other common secondary neoplasms include trichilemmoma, desmoplastic trichilemmoma, sebaceous adenoma, apocrine adenoma, and poroma. Only rarely does secondary sebaceous carcinoma or apocrine carcinoma arise in a nevus sebaceus. Malignancy probably develops only in longstanding or neglected lesions but exceptionally can be a source of mortality.

Pathology

In nevus sebaceus, the principal malformation is of individual folliculosebaceous units. An infantile nevus sebaceus can be microscopically subtle, particularly if the biopsy specimen includes only lesional skin, as the malformed follicular units are small and deviate little from normal. In an excisional specimen from the scalp during later childhood, tiny misshapen lesional follicles provide a stark contrast to normal terminal follicles at the periphery of the biopsy. Small apocrine glands may be identifiable in a specimen of sufficient depth. The epidermis also thickens and becomes progressively more papillated, gradually assuming a configuration akin to an epidermal nevus.

By late adolescence, nevus sebaceus displays an epidermal pattern identical to that of an epidermal nevus, typified by acanthosis and fibroplasia of the papillary dermis. There may be enlarged sebaceous glands in contiguity with the epidermal–dermal junction. Buds of follicular germinative cells may jut from the junction as well (Fig. 111.7). The underlying follicular units remain smallish and appear distorted but their sebaceous lobules increase in prominence. Dilated apocrine glandular structures with inspissated secretions are not uncommonly identifiable in the reticular dermis. This histopathology remains stable into adulthood.

Over time, some patients develop exaggerated verrucous epidermal hyperplasia much like a verruca vulgaris. It has been suggested that this represents a consequence of human papillomavirus infection[16]. Secondary neoplasms are common, and trichoblastoma, trichilemmoma and syringocystadenoma are frequently observed[13,14]. The strong association between syringocystadenoma and nevus sebaceus warrants careful scrutiny any time the diagnosis of syringocystadenoma is rendered, to ascertain whether a nevus sebaceus can be found in the same specimen.

Treatment

As carcinoma was formerly reputed to commonly develop within nevus sebaceus, the risk of transformation was used as justification for complete excision. In truth, the risk of development of secondary carcinoma is low[16]. However, the risk for the development of a secondary benign neoplasm, such as syringocystadenoma or trichoblastoma, is relatively high. In addition, it is clear that nevus sebaceus becomes increasingly verrucous and unsightly over time. In light of this, conservative complete excision in late childhood represents a commonly utilized approach. Lesions within the scalp may be difficult to follow clinically and extirpation will prevent the development of occult secondary changes. For facial lesions, consideration should be given to excision during childhood, before the development of secondary verrucous alteration, at a time when the risk of scarring is reduced compared to adulthood. The excisional margins can be minimal. Removal by shave or laser ablation is usually not successful.

Mixed tumor (chondroid syringoma)

Introduction

Cutaneous mixed tumor, also known as *chondroid syringoma*, represents an acquired hamartoma with folliculosebaceous-apocrine differentiation that has been interpreted as an adnexal adenoma since its description. Despite this legacy, mixed tumor is best pigeonholed as a hamartoma. The stroma of mixed tumor is always abundant and generally comprises half of the surface area of a given lesion in conventional sections, and the epithelial component is commonly heterogeneous[17].

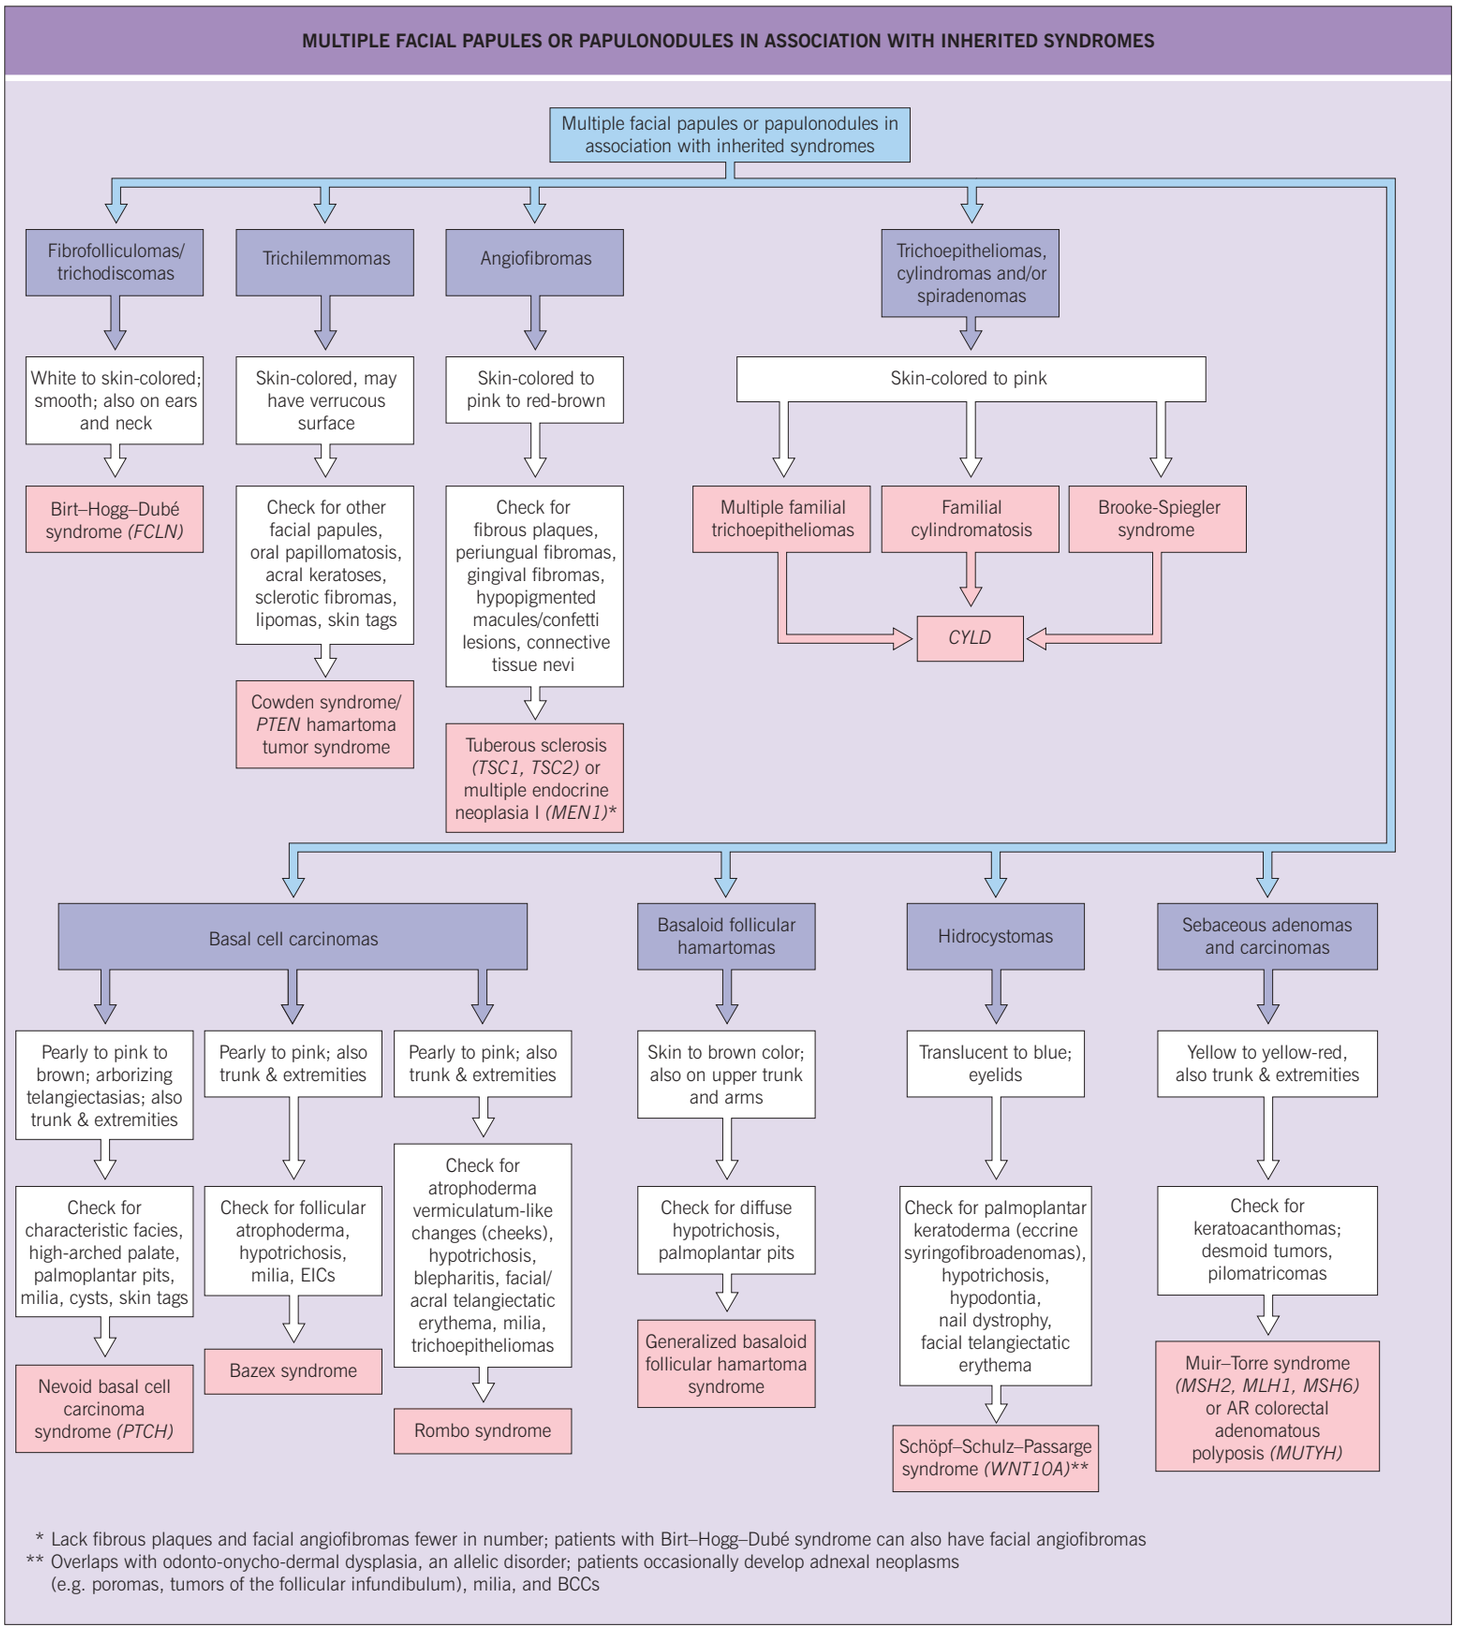

Fig. 111.4 Multiple facial papules or papulonodules in association with inherited syndromes. Patients with Gardner syndrome can develop multiple epidermoid inclusion cysts (sometimes with foci of pilomatrical differentiation) and osteomas in the head and neck region. AR, autosomal recessive; EICs, epidermoid inclusion cysts.

Fig. 111.5 Nevus sebaceus. An oval yellow-pink verrucous plaque on the scalp. Note the alopecia.

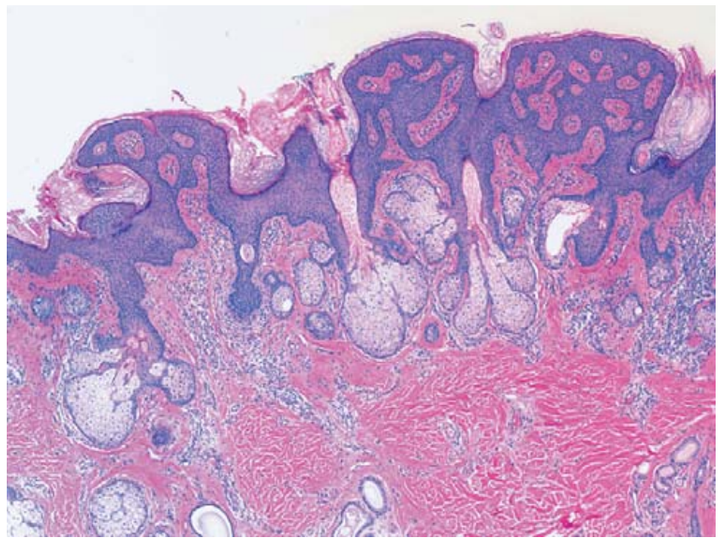

Fig. 111.7 Nevus sebaceus. Medium magnification reveals expansion of the epidermis in a papillated fashion, much like the pattern of an epidermal nevus. This is accompanied by adnexal malformation, with enlarged sebaceous lobules and clusters of follicular germinative cells positioned along the dermal–epidermal junction.

Fig. 111.8 Chondroid syringoma. Nodule on chin. *Courtesy, Ronald P Rapini, MD.*

An analogy has been drawn between cutaneous mixed tumor and mixed tumor (pleomorphic adenoma) of the salivary gland. While the comparison has some validity, it is important to note that pleomorphic adenoma of the salivary gland functions as a neoplasm in a biological sense, as it holds a tendency for local recurrence if incompletely extirpated as well as the potential for evolution to malignancy. In contrast, chondroid syringoma represents an indolent process virtually devoid of proliferative capacity. It rarely recurs after enucleation. Some authors consider chondroid syringoma and cutaneous myoepithelioma to represent two ends of a spectrum, and this concept is supported by the fact that some chondroid syringomata are particularly rich in myoepithelial (indeterminate) cells.

Clinical features

The clinical presentation of mixed tumor is indistinctive (Fig. 111.8). The lesions present as cutaneous nodules that are often misconstrued as cysts. Involvement of the head and neck is common and lesions may also develop on the trunk or within axillary or genital skin.

Pathology

Mixed tumor presents pathologically as a well-circumscribed nodule that resides within the deep reticular dermis or subcutis. Its biphasic morphology includes epithelial structures encompassed by ample varied stroma[17]. There is always a prominent collagenous component to the stroma, but myxoid and lipocytic zones can also be found. Despite its name, stromal hyaline cartilage is found in less than half of all chondroid syringomata.

The epithelial component of a mixed tumor displays two primary patterns. Most mixed tumors demonstrate large interanastomosing and branching tubules lined by columnar cells with decapitation secretion apparent at the luminal border; this configuration has been dubbed apocrine mixed tumor[18] (Fig. 111.9). Less commonly, mixed tumors show an epithelial component that includes many small rounded cuticulated ducts (Fig. 111.10). Such lesions have been interpreted by some as eccrine. Rather, it seems likely that all mixed tumors are hamartomas of folliculosebaceous-apocrine lineage and that the configuration of the epithelial component can vary.

The epithelial component of mixed tumor also commonly includes follicular and sebaceous elements[17,19]. Follicular differentiation can consist of small clusters of follicular germinative cells, lobules of outer sheath cells, cystic foci with isthmic or infundibular keratinization, and

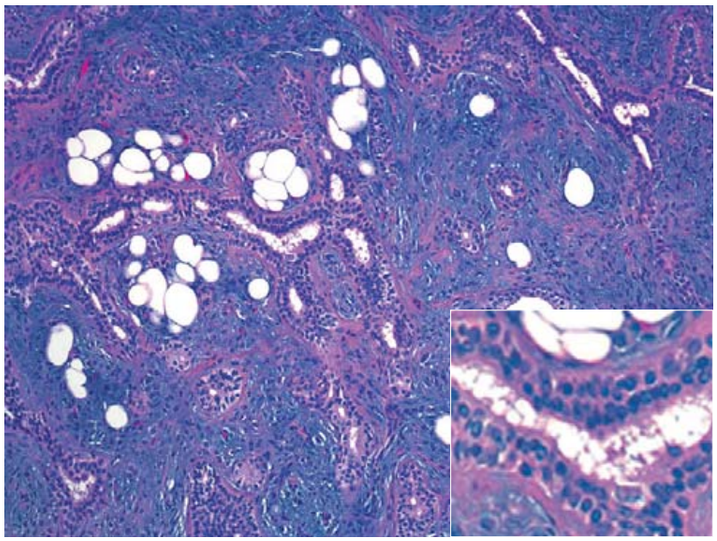

Fig. 111.9 Mixed tumor (chondroid syringoma) with overt apocrine differentiation. At medium magnification, there is a hamartomatous pattern, with large branching tubules arrayed within a mucinous stroma that contains lipocytes. Conspicuous apocrine differentiation with a "decapitation" pattern is evident in the insert.

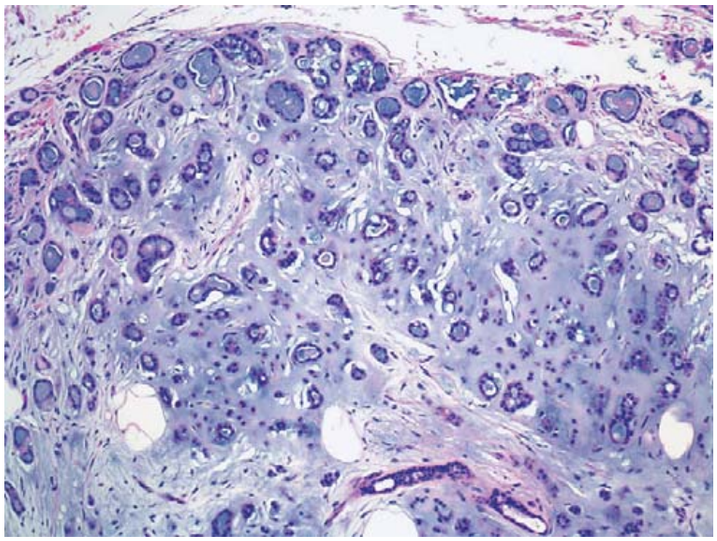

Fig. 111.10 Mixed tumor (chondroid syringoma) with ductal differentiation. This pattern, commonly referred to as the "eccrine" type of mixed tumor, shows small syringoma-like ducts positioned in ample stroma reminiscent of hyaline cartilage.

clusters of matrical cells. Small collections of sebocytes may also be found.

The number of myoepithelial cells in chondroid syringomas varies. Rare tumors composed exclusively of myoepithelial cells are classified as cutaneous myoepithelioma.

Treatment

Mixed tumor is benign and indolent. Most lesions are treated by simple enucleation, and the risk for persistence/recurrence is minimal. In contrast to mixed tumors of salivary origin, there is no need for excision with margins.

Neoplasms and Proliferations with Follicular Germinative Differentiation

Trichoepithelioma/trichoblastoma

Introduction

Trichoepithelioma and trichoblastoma are terms that refer to benign neoplasms with mostly follicular germinative differentiation[20]. Historically, the term *trichoepithelioma* is older and represents the name ascribed to a solitary lesion of the familial multiple form of trichoepithelioma (epithelioma adenoides cysticum), and thus the term trichoepithelioma is clinically useful in this context. The designation *trichoblastoma* was coined more recently and was originally applied to neoplasms that showed follicular bulbar differentiation almost exclusively. Although trichoepithelioma is still used, *trichoblastoma* has evolved to be an overarching label for benign proliferations with follicular germinative differentiation[20]. For many, in the current dermatopathologic lexicon, trichoepithelioma represents a variant of trichoblastoma.

Many authors have described subtle variations within the spectrum of follicular germinative neoplasms, thereby birthing terms such as trichogerminoma, trichoblastic fibroma, and lymphadenoma (adamantinoid trichoblastoma)[20]. For purposes of this discussion, these variants will be considered as falling within the larger spectrum of trichoblastoma.

Clinical features

Classic trichoepithelioma usually presents as a skin-colored papule or nodule on the face or upper trunk. Lesions have a predilection for the nose (Fig. 111.11). When in multiplicity, constituting epithelioma adenoides cysticum or Brooke's disease, lesional density is always greatest in the central face. The cylindromatosis (*CYLD*) gene, whose protein product functions as a tumor suppressor, underlies Brooke's disease. *CYLD* encodes a deubiquitinating enzyme that impedes the nuclear factor (NF)-κB and c-Jun N-terminal kinase (JNK) pathways[21]. Specifically, missense mutations lead to amino acid substitutions within the ubiquitin (Ub)-specific protease (USP) domain of the CYLD protein. Brooke's disease can be cosmetically troublesome and is associated with a risk of secondary BCC[22]. Patients can also develop cylindromas and spiradenomas (see Fig. 111.4). Lesions described historically as *trichoblastoma* were often larger and deeper than simple trichoepithelioma.

Pathology

All trichoepitheliomas and trichoblastomas have in common the architectural attributes of a benign neoplasm – namely, relative symmetry, circumscription and a lack of substantial cytologic atypicality. In addition, all are linked by prominence of follicular germinative cells with enveloping fibrocytic stroma that varies in degree[20,23]. In classic trichoepithelioma, the fibrocytic stroma is conspicuous and constitutes as much as half of the cellularity of the lesion in a given cross-section. In other lesions that simulate BCC, follicular germinative cells may be arrayed as either small or large nodules with only scant intervening sclerotic stroma. The coarse fibrous stroma typically maintains tightly adherent contact to the lesional follicular germinative cells[23]. This is in distinct contrast to the pattern of BCC, in which clefts between basaloid cells and stromal elements often serve as a diagnostic clue.

In classic trichoepithelioma, follicular germinative cells are often disposed as small clusters or as reticulate and cribriform cords (Fig. 111.12). There are usually foci of pronounced bulbar differentiation, emulating the follicular bulb and papilla; these structures have been termed *papillary mesenchymal bodies*[23,24]. Classic trichoepithelioma does not typically show follicular germinative differentiation exclusively. Rather, small cornifying cystic spaces with surrounding pinkish keratinocytes, reflecting concurrent infundibular or isthmic differentiation, are also apparent.

In small or large nodular trichoblastoma, follicular germinative cells comprise the majority of the surface area, papillary mesenchymal bodies may be inconspicuous, and superficial follicular differentiation may be absent. *Trichoblastic fibroma* is a designation used to characterize small nodular trichoblastomas with exaggerated fibrous stroma that often constitutes over half of the cross-sectional area of the lesion[25–27]. Papillary mesenchymal bodies may be conspicuous in trichoblastic fibroma. With close scrutiny, other modes of differentiation can occasionally be found in a trichoblastoma. There may be tiny collections of mature sebocytes, reflecting concurrent sebaceous differentiation, and (apocrine) ductal differentiation may also be noted.

Treatment

Trichoblastoma is benign and provokes no imperative for surgical treatment. Multiple facial trichoepitheliomas can be cosmetically disabling and many affected patients desire some type of intervention. Close

Fig. 111.11 Multiple familial trichoepitheliomas. Numerous skin-colored papules and nodules on the midface.

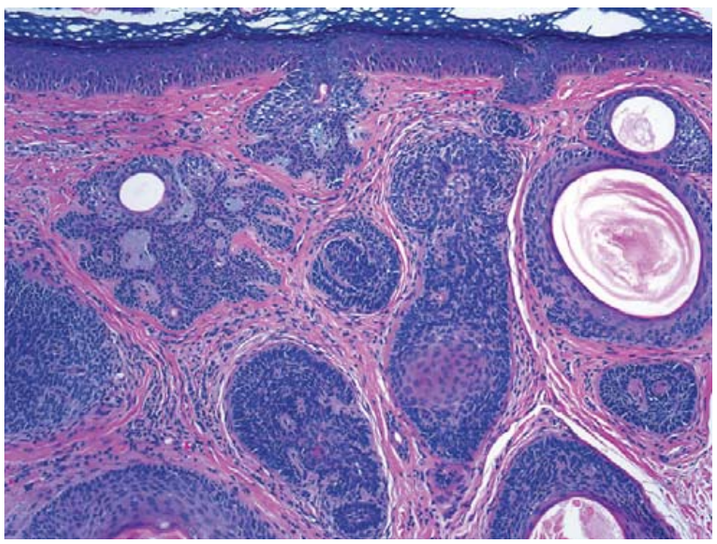

Fig. 111.12 Trichoepithelioma (trichoblastoma). This "classic" trichoepithelioma is composed mostly of clusters of follicular germinative cells but also shows superficial follicular differentiation, with small keratinizing cystic spaces. Note that clefts within the proliferation are between stromal elements, in contrast to the clefts between tumor and stroma that are characteristic of basal cell carcinoma.

followup for the possibility of secondary BCC is warranted[22]. Because of the number of lesions, conventional excision is not indicated. Other ablative approaches, including laser or electrosurgical destruction, have been employed with some success[28,29].

Desmoplastic trichoblastoma (desmoplastic trichoepithelioma)

Introduction

Originally termed *sclerosing epithelial hamartoma*, desmoplastic trichoepithelioma represents a variant of trichoblastoma with exaggerated stromal sclerosis (desmoplasia)[30]. It can easily be misinterpreted as morpheaform BCC by the uninitiated.

Clinical features

Desmoplastic trichoepithelioma commonly presents as a firm skin-colored to erythematous annular plaque with a central dell. The cheek of a woman represents a stereotypical context[30]. Most examples do not exceed 1 cm in diameter. Nearly all desmoplastic trichoepitheliomas are solitary. Multiplicity is a rarity.

Pathology

Desmoplastic trichoepitheliomas are composed of cords of basaloid cells, often two cells wide, arrayed interstitially amongst coarsened collagen bundles[20,30] (Fig. 111.13). The lesions are relatively circumscribed and are often confined to the upper two-thirds of the reticular dermis, although this is difficult to appreciate in biopsies *en parte*. Small cystic foci of isthmic or infundibular keratinization may be present, and if these cystic spaces are predominant, the designation *trichoadenoma* is apt. The cornifying cysts can rupture and elicit a granulomatous reaction, and small secondary foci of calcification may also be identified[20,30].

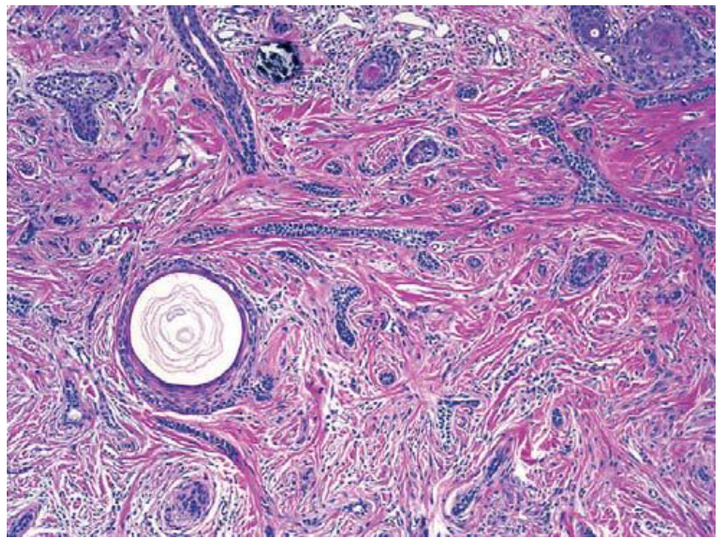

Fig. 111.13 Desmoplastic trichoepithelioma. It is composed of thin strands of basaloid (follicular germinative) cells, arrayed in sclerotic stroma. Much like conventional trichoepithelioma, there are foci of superficial follicular keratinization.

Treatment

Desmoplastic trichoepithelioma is benign. Small or partial biopsies may yield diagnostic uncertainty with respect to morpheaform BCC or microcystic adnexal carcinoma as a consideration in the differential diagnosis, and re-excision or resampling may be necessary when the interpretation is ambiguous.

Neoplasms and Proliferations with Matrical Differentiation

Pilomatricoma

Introduction

Pilomatricoma (pilomatrixoma, trichomatrioma, calcifying epithelioma) is a benign neoplasm or cyst typified by follicular matrical cornification. It has been demonstrated that mutations in *CTNNB1*, the gene that encodes β-catenin, a component of a key signaling pathway that influences cell differentiation and proliferation, are generally present in matrical neoplasms, including pilomatricomas[31]. Pilomatricomas also commonly demonstrate trisomy 18[32].

Clinical features

Pilomatricoma usually presents as a solitary skin-colored or bluish nodule (Fig. 111.14). Rarely, multiple lesions are evident, sometimes in association with myotonic dystrophy, Turner syndrome or Gardner syndrome (when cystic). Firmness is typical and reflects secondary calcification as well as accompanying fibrosis and granulomatous inflammation. Some lesions are "rock-hard" and plate-like on palpation. Pilomatricomas may occur on any hair-bearing surface, but most involve the head or upper trunk[33]. Most common in childhood and adolescence, pilomatricomas may develop at any age and can simulate BCC, clinically or microscopically, in later adulthood. Occasionally, the dermis overlying a pilomatricoma will develop anetoderma.

Pathology

Histopathologically, an early pilomatricoma frequently presents as a cyst with central matrical cornification. The cyst wall consists of basaloid matrical cells that show an abrupt transition to central eosinophilic cornified matrical cells in which barely discernible nuclear outlines remain. Sometimes, pink trichohyalin granules, illustrative of matrical cornification, are identifiable at the transition point. The

Fig. 111.14 Pilomatricoma. A nodule on the cheek of a child.

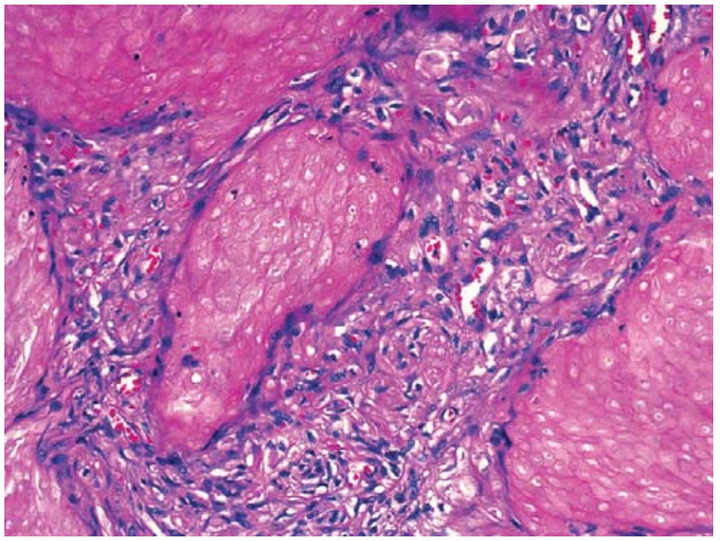

Fig. 111.15 Pilomatricoma. At high magnification, this longstanding example is notable for anucleate keratinized matrical cells ("shadow" cells) and a surrounding granulomatous reaction.

central anucleate cornified cells are commonly referred to as *ghost* or *shadow* cells.

In fully developed pilomatricomas, a cystic configuration is commonly lost. Solid collections of basaloid matrical cells and matrical corneocytes are present in varying degrees (Fig. 111.15). The cornified matrical cells elicit considerable fibrosis and a secondary granulomatous infiltrate, which can become predominant in longstanding lesions. Matrical cells have a proliferative capacity as high as any human tissue and can display numerous cells in mitosis. The designation *proliferative pilomatricoma* refers to a pilomatricoma with a high mitotic index. At times, such lesions can be misinterpreted as carcinoma[34]. In late lesions, basaloid matrical cells may be lacking. An involutional pilomatricoma at times can present with only a few shadow cells buried in a larger fibrosing granulomatous reaction. Calcification and ossification also ensue in late lesions.

Treatment

Pilomatricoma is a benign lesion that is usually treated by simple enucleation. A pilomatricoma may recur after limited excision. If multiple recurrences are observed, complete excision (with negative margins) should be performed to exclude pilomatrical carcinoma.

Pilomatrical carcinoma

Introduction

Pilomatrical (matrical) carcinoma is an uncommon malignancy that exhibits matrical cornification, much like pilomatricoma[35]. Mutations in the *CTNNB1* gene (coding for β-catenin) are common in matrical carcinoma[31]. This suggests a partial common pathogenesis for pilomatricoma and matrical carcinoma. Although on a practical basis no clear association exists, there is theoretical risk for the possibility of matrical carcinoma developing from conventional pilomatricoma.

Clinical features

Matrical carcinoma is typically a disease of adulthood. Lesions develop on the head and neck, often in the retroauricular area. Although a pathogenic link with ultraviolet irradiation has not been established, many matrical carcinomas develop within severely sun-damaged skin. If a diagnosis of matrical carcinoma is offered in a child or young adult at an age when the diagnosis is improbable, the case should be reassessed for the possibility of pilomatricoma.

Pathology

Much like pilomatricoma, matrical carcinomas include both basaloid matrical cells and anucleate matrical corneocytes. In contrast to pilomatricoma, the matrical carcinoma cells usually display nuclear pleomorphism. An infiltrative configuration or poor circumscription may be apparent, especially in an excisional biopsy. There may be considerable squamous cornification as well, and parts of a given lesion may resemble conventional squamous cell carcinoma (SCC).

Matrical carcinoma should be distinguished microscopically from BCC with matrical differentiation[36,37]. Histopathologically, the latter entity represents an otherwise conventional BCC in which small foci of matrical cornification are identifiable. The clinical behavior of this variant is thought to be identical to that of conventional BCC.

Treatment

Matrical carcinoma is a low-grade form of adnexal carcinoma that poses some risk for metastasis, although the risk is believed to be low[35]. Complete extirpation with negative margins represents standard care.

Neoplasms and Proliferations with Follicular Sheath (Trichilemmal) Differentiation

Trichilemmoma

Introduction

Trichilemmoma (tricholemmoma) constitutes a form of benign adnexal neoplasm with differentiation toward the follicular outer sheath[38]. Some have averred that trichilemmoma is merely a viral wart based upon conventional histopathology[20]. Generally, molecular analysis has failed to demonstrate intralesional papillomavirus DNA and thus viral causation seems unlikely[39].

Clinical features

Trichilemmomas may arise as simple or as multiple[38,40] papules that usually have similar coloration to surrounding normal skin (see Fig. 63.3). Individual lesions may display hyperkeratosis or a verrucous surface. Most are distributed on the central face, including the nose or upper lip, but any non-glabrous site may be affected. Trichilemmomas can also present on genital skin and simulate condylomata if multiple. Trichilemmoma may occur as a secondary neoplasm within nevus sebaceus. The variant *desmoplastic trichilemmoma* is especially common in this context[41].

Multiple trichilemmomas typically present on facial or genital skin. Multiple trichilemmomas are a common manifestation of Cowden syndrome (see Ch. 63 & Fig. 111.4)[38,42]. In addition to trichilemmomas, manifestations of Cowden disease include sclerotic fibromas, acral keratoses, and adenocarcinoma of the breast, thyroid gland or gastrointestinal tract[43].

Pathology

Microscopically, trichilemmomas present as small circumscribed lobular proliferations composed of pallid, glycogen-containing outer sheath cells. There is often a broad connection to the surface epidermis[38,40,42]. A papillated surface is common, and there may be verrucous hyperplasia with hypergranulosis, thereby simulating the pattern of a verruca in a superficial biopsy. Squamous eddies are not uncommon. There is a palisade of small, compact basal keratinocytes at the periphery of a lesional lobule, and a flanking thickened basement membrane that is PAS-D (periodic acid–Schiff with diastase)-positive is commonly present (Fig. 111.16). Outer sheath differentiation can also be recognized through use of CD34 immunostaining.

In desmoplastic trichilemmoma, small central angular clusters of outer sheath cells are arrayed in an infiltrative pattern with enveloping sclerotic stroma. This creates a configuration that at times simulates carcinoma[41,44,45]. Most commonly, a desmoplastic focus is accompanied

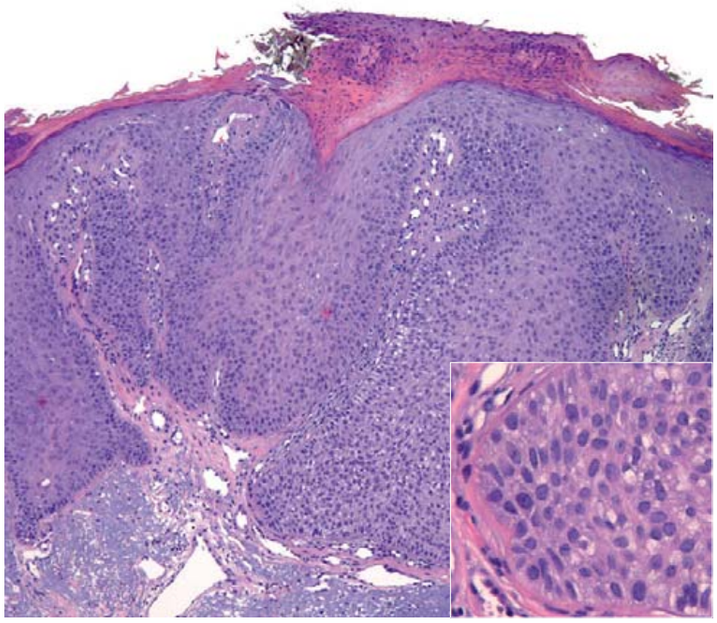

Fig. 111.16 Trichilemmoma. A benign neoplasm with a verrucous appearance arising within sun-damaged skin. Sometimes these lesions are misdiagnosed as actinic keratoses or superficial carcinomas. A thickened basement membrane flanks an area with follicular outer sheath differentiation (insert).

or surrounded by areas of conventional trichilemmoma that serve as the basis for accurate interpretation, but the diagnosis can be deceptive in partial or superficial biopsies.

Treatment

Trichilemmoma is a benign adnexal neoplasm with limited proliferative capacity. After recognition by biopsy, no further treatment is needed unless there is uncertainty regarding the diagnosis. If there is a desire for ablation, cryotherapy, electrosurgical destruction, shave, curettage or excision may be employed.

Trichilemmal carcinoma

This malignant analogue of trichilemmoma represents an invasive lesion composed in part of glycogen-containing clear cells, similar to cells of the follicular outer sheath. If a thickened, PAS-positive prominent basement membrane can be identified peripheral to areas of clear cell change, it is probably of considerable diagnostic significance. CD34 immunopositivity may also be of potential diagnostic value. Many of these carcinomas show accompanying keratinization and thus there is considerable overlap with lesions that have been pigeonholed as clear cell SCC.

Treatment

Trichilemmal carcinoma represents a carcinoma with limited metastatic potential. These lesions are probably best considered equivalent to SCC and treated as such.

Neoplasms and Proliferations with Superficial Follicular (Infundibular and Isthmic) Differentiation

Tumor of follicular infundibulum (isthmicoma)

Introduction

This benign lesion is commonly known as *tumor of follicular infundibulum (TFI)* or *infundibuloma*, but the designation *isthmicoma* is more apt, as the proliferation primarily shows follicular isthmic differentiation.

Clinical features

TFI prototypically presents clinically as a subtle macule, thin papule or plaque[46,47]. Lesions are skin-colored or sometimes slightly hypopigmented and may appear slightly atrophic[46]. Many examples are diagnosed incidentally within skin cancer excision specimens where no known clinical lesion was even identifiable. TFI may occur in multiplicity (Fig. 111.17A), and patients with this presentation may defy diagnosis for a time because of the subtlety of both the clinical and the microscopic findings[46–49]. Patients with multiple atrophic-appearing TFI may display a clinical pattern reminiscent of disseminated superficial porokeratosis or multiple actinic keratoses. TFI is occasionally present in Cowden disease.

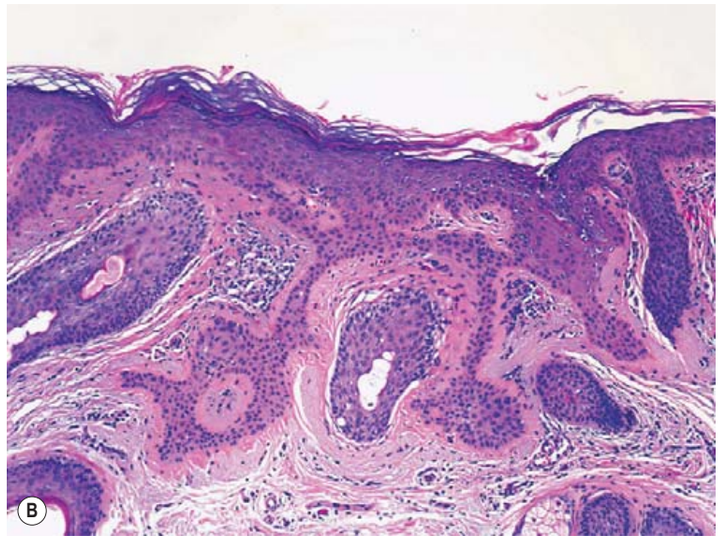

Fig. 111.17 Tumor of follicular infundibulum. A Multiple hypopigmented thin papules on the cheek. **B** The microscopic pattern is subtle, resembling a reticulated seborrheic keratosis. Strands of pale eosinophilic keratinocytes display multifocal attachment to the epidermal surface and also commonly interconnect with existent follicular structures.

Pathology

TFI consists of a plate-like proliferation of eosinophilic isthmic keratinocytes arrayed in reticulate fashion in the superficial dermis, in broad but intermittent continuity with both the surface epidermis and extant follicular structures[46]. Most of the constituent keratinocytes have cytoplasm similar to keratinocytes of the follicular isthmus, follicles in catagen phase, or the cells of an isthmic (pilar) cyst (Fig. 111.17B). The keratinocytes are paler than those of the surface epidermis, and sometimes a few scattered dyskeratotic keratinocytes are present. Some lesions will display trichilemmal foci in which pallid keratinocytes or a thickened basement membrane can be found, and occasionally a hybrid of TFI and trichilemmoma may be encountered. Additionally, small buds of follicular germinative cells may jut from the undersurface of a TFI.

Rarely, small clusters of sebocytes may be found within TFI[50]. Sebaceous or apocrine ducts have also been documented[49].

Treatment

TFI is a benign adnexal proliferation with negligible proliferative capacity. If desired, lesions may be removed by cryotherapy, shave, or electrosurgical destruction. For multiple lesions, superficial laser ablation can be considered[46].

Trichoadenoma (trichoadenoma of Nikolowski)

Introduction

The term *trichoadenoma* is a misnomer, as there are no adenomas of follicular lineage since the hair follicle is not a structure that exhibits glandular differentiation. Trichoadenoma represents a benign follicular neoplasm with sclerotic stroma that consists largely of small cystic spaces that exhibit infundibular and isthmic differentiation[51].

Clinical features

The clinical presentation of trichoadenoma is not distinctive. The neoplasm presents as a skin-colored papule or small plaque.

Pathology

Trichoadenoma is usually positioned in the superficial dermis. Cornifying cysts with infundibular or isthmic keratinization comprise the bulk of the proliferation[51]. The sclerotic stroma is often accompanied by thin strands of basaloid cells, similar to the cords observed in desmoplastic trichoepithelioma (Fig. 111.18). The degree of microscopic overlap between trichoadenoma and desmoplastic trichoepithelioma can be remarkable, and "pure" trichoadenomas may represent one pole of the spectrum of histopathologic findings that can be seen.

Treatment

Trichoadenoma is a benign adnexal neoplasm with negligible proliferative capacity. No further treatment is necessary unless the patient desires removal.

Proliferating pilar tumor (proliferating follicular-cystic neoplasm)

Introduction

Known for decades as *proliferating pilar tumor (PPT)* or *proliferating pilar cyst*, the designation *proliferating follicular-cystic neoplasm (PFCN)* was proposed by Ackerman as a more apt designation[20]. This term describes a group of nodular/cystic neoplasms characterized microscopically by abrupt keratinization akin to that of the follicular isthmus or in a follicle in catagen phase[52]. In the past, it was known that PPT could simulate SCC microscopically, but the entity was generally regarded as a benign process, although it was recognized that, occasionally, locally destructive behavior could occur[52].

Recently, this concept has been called into question, and a proposal has been issued that PFCN represents a mix of benign and malignant neoplasms grouped together under one rubric[20]. The proposal further iterates that a benign PFCN should be designated as *proliferating follicular-cystic acanthoma (PFCA)*, while a malignant PFCN should be designated as *proliferating follicular-cystic carcinoma (PFCC)*. As some examples of PFCN share features with carcinoma, including clinical characteristics such as locally destructive behavior, microscopic characteristics such as nuclear atypicality and molecular characteristics such as aberrations in ploidy, this proposal seems diagnostically practical[53–55].

Clinical features

PPT presents as a nodule, usually no more than a few centimeters in size, although there have been reports of lesions exceeding 20 cm in diameter. The lesions can develop in men but a female predominance is seen in most series. Roughly 90% of cases arise in the scalp, probably as a reflection of the density of follicles at that locale. The prototypical presentation is as a nodule on the scalp of an elderly woman. The lesions are usually well circumscribed but may be multinodular. Their circumscription is reflected in smooth borders and the fact that lesions generally shell out from adjacent tissues during surgical excision.

Pathology

PPT consists of a large and/or deep nodule that resides in the dermis or subcutis[52]. Because of its large size, the laboratory commonly receives fragmented specimens. Both solid and cystic patterns are usually evident at low magnification, with cystic areas exhibiting the pattern of an isthmic (pilar) cyst. The constituent keratinocytes are mostly isthmic keratinocytes with dense eosinophilic cytoplasm, and centrally there is an abrupt transition to compact keratin with little intervening granular layer (Fig. 111.19). Rarely, shadow cells, implying matrical keratinization, can be found. There may be focal necrosis and calcification.

The degree of cytologic atypicality varies among lesions and amongst different areas of a given lesion. Commonly, the neoplastic cells contain enlarged vesicular nuclei with prominent nucleoli and some degree of nuclear hyperchromasia, and mitotic figures are usually identified, but overt anaplasia is usually not present. Since some examples of PPT represent low-grade forms of carcinoma, tumors with marked cytologic atypicality, extensive necrosis, a lack of circumscription, or

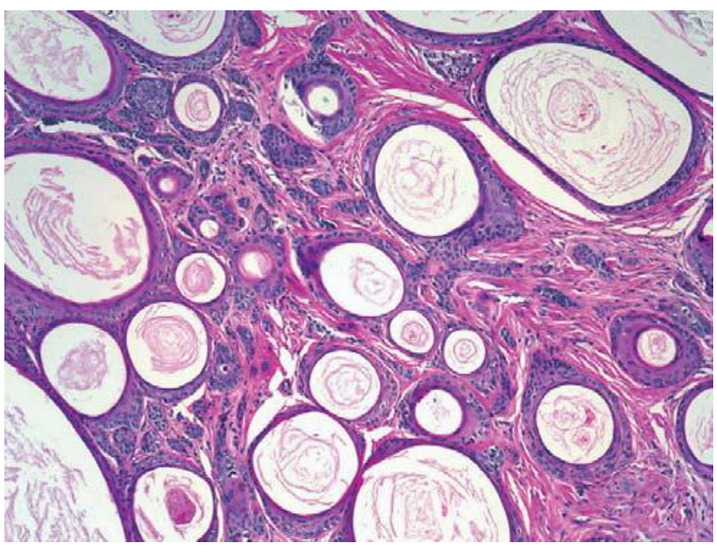

Fig. 111.18 Trichoadenoma. This lesion consists almost exclusively of small keratinizing cystic spaces. There are also a few strands of basaloid cells and sclerotic stroma, similar to the pattern observed in desmoplastic trichoepithelioma.

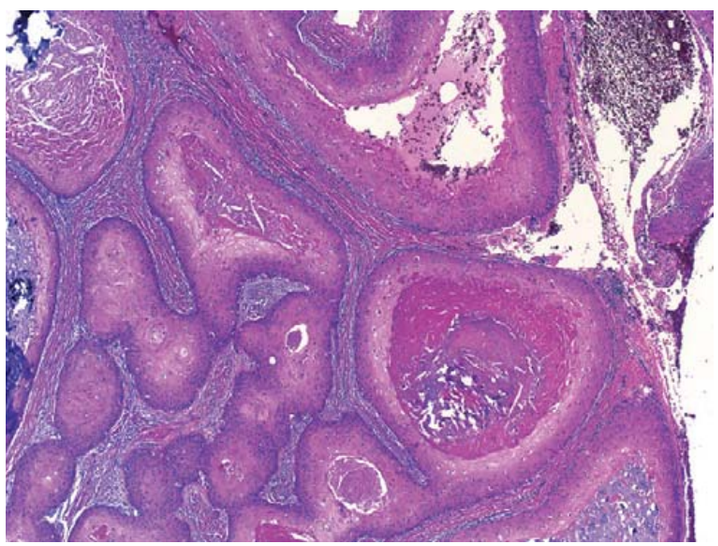

Fig. 111.19 Proliferating follicular-cystic neoplasm. This complex multicystic neoplasm shows abrupt keratinization, similar to the pattern exhibited at the follicular isthmus. Although it can be difficult to determine whether these lesions are benign or malignant, this example was well circumscribed and was eradicated by simple enucleation.

extraordinary numbers of mitotic figures warrant designation as PFCC[53,55].

Treatment

As noted, some examples of PPT may represent carcinoma. If a lesion has been enucleated in its entirety or near entirety, is circumscribed, and lacks substantial cytologic atypism, it can be interpreted as PFCA and additional surgical therapy is not necessary. If a given lesion lacks circumscription, shows substantial cytologic atypism or necrosis, or has been sampled *en parte*, then complete excision is warranted, as PFCC remains a concern.

NEOPLASMS AND PROLIFERATIONS WITH SEBACEOUS DIFFERENTIATION

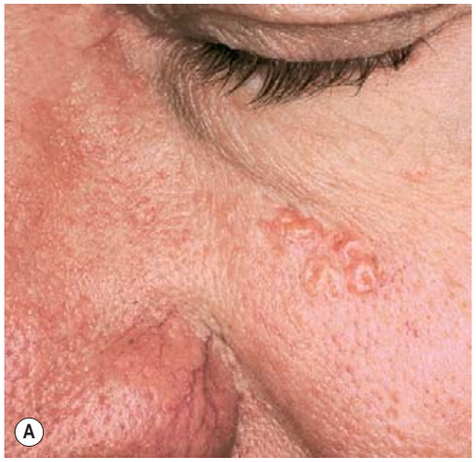
Sebaceous gland hyperplasia

Introduction

Sebaceous gland hyperplasia (SGH) does not represent a true neoplasm. It represents benign enlargement of sebaceous glands.

Clinical features

SGH is relatively common and presents with one or multiple yellowish, occasionally telangiectatic papules, usually on the central or upper face (Fig. 111.20) and sometimes on the upper trunk. Commonly, the clinical lesions display a central dell that corresponds to a central follicular infundibular ostium. *Beaded lines* represent a unique expression of SGH in which a linear array of hyperplastic sebaceous glands is present in the vicinity of the clavicle or on the neck[56]. Biopsy is occasionally indicated to exclude BCC.



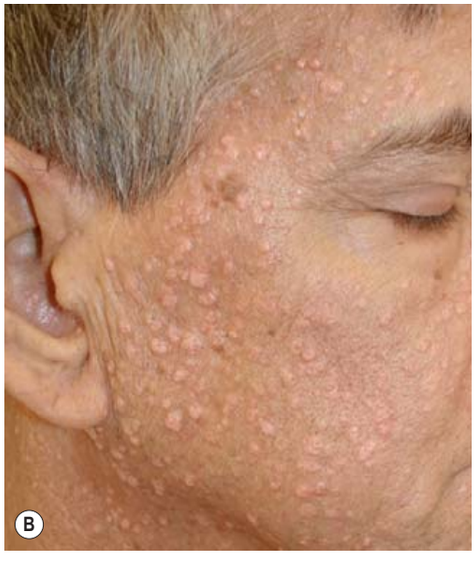


Fig. 111.20 Sebaceous hyperplasia. A Skin-colored to yellowish papules with a central dell. **B** Numerous lesions of sebaceous hyperplasia in a solid organ transplant recipient receiving long-term cyclosporine. *B, Courtesy, Oscar Colegio, MD, PhD.*

Pathology

The sebaceous gland in SGH shows normal morphology, with a thin rim of seboblasts surrounding the remainder of the gland, composed of mature sebocytes. The enlarged sebaceous lobules usually circumferentially surround a central infundibulum.

Treatment

If treatment is desired, lesions can be removed or diminished by shave, light electrosurgical destruction, cryotherapy, or laser ablation[57]. Long-term topical retinoid application may be beneficial. Oral isotretinoin has been utilized for patients with extensive disfiguring lesions.

Sebaceous adenoma, sebaceous epithelioma and sebaceoma

Introduction

The term *adenoma* designates a benign neoplasm with glandular differentiation, and any benign proliferation with predominance of sebaceous differentiation can be grouped under this rubric. Commonly, the term sebaceous adenoma has been applied to superficial benign sebaceous neoplasms with a predominance of mature sebocytes, while sebaceous epithelioma and sebaceoma have been applied to sebaceous neoplasms with a predominance of seboblasts. Troy and Ackerman[58] coined *sebaceoma* as an alternative to describe a group of benign sebaceous proliferations that were generally more deeply situated than superficial sebaceous adenomas and in which a vertically oriented microscopic pattern was identifiable.

The dated term sebaceous epithelioma is inherently confusing, as the diagnosis has been utilized differently by various authorities. To some, a sebaceous epithelioma represents a low-grade form of sebaceous carcinoma or BCC with sebaceous differentiation. Others have utilized the term to characterize sebaceoma or sebaceous proliferations of uncertain potential. We believe that the designation sebaceous epithelioma should be abandoned.

In this chapter, the term *sebaceous adenoma* is used in broad fashion to encompass both conventional sebaceous adenoma and sebaceoma.

Clinical features

Sebaceous adenomas present clinically as papules or nodules, usually less than a centimeter in diameter, distributed on the head or neck and sometimes on the upper trunk. The lesions are not clinically distinctive except when there is a yellowish color, which is often not apparent. Superficial sebaceous adenomas are usually relatively small and papular, while sebaceomas may present as a deep nodule[58,59]. Multiple sebaceous neoplasms, especially cystic ones, may serve as a presenting sign of the Muir–Torre syndrome (see Ch. 63 & Fig. 111.4), characterized also by multiple keratoacanthomas and visceral carcinomas, especially colonic adenocarcinoma[60,61].

Pathology

Conventional sebaceous adenoma is usually captured in continuity with the surface epidermis and is relatively small and circumscribed. The relative proportions of basaloid seboblastic cells and mature sebocytic cells varies, but sebocytes usually predominate. Seboblasts comprise a thin multilayer of cells at the periphery of each lobule. Mitotic figures can be found in seboblasts but are not conspicuous. Necrosis is not typically evident in an adenoma unless the lesion has been traumatized. Significant necrosis, whether of single cells or *en masse*, raises concern for the possibility of carcinoma.

Sebaceoma is usually more deeply situated, often involving the deep reticular dermis and sometimes the superficial subcutis[58]. The lesions are sharply circumscribed in an excisional specimen, but this may be difficult to fully appreciate in a biopsy *en parte*. Seboblasts predominate in sebaceoma and sebocytic differentiation may be only focal, yielding a microscopic pattern not unlike large nodular trichoblastoma (Fig. 111.21). If sebaceous differentiation is only focal, then epithelial membrane antigen (EMA) or adipophilin immunoperoxidase staining can be considered as a diagnostic supplement. EMA labels mature sebocytes in the normal sebaceous gland, while adipophilin labels fat-containing cells.

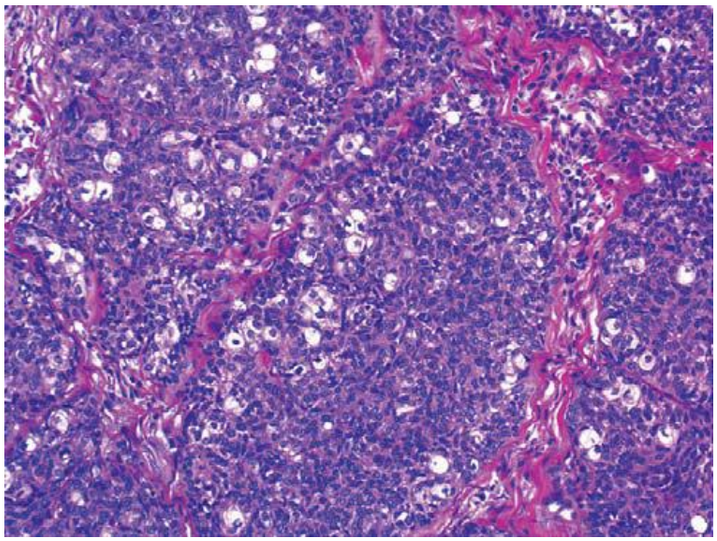

Fig. 111.21 Sebaceous adenoma (sebaceoma). This high-magnification view shows a background of basaloid seboblastic cells punctuated by scattered mature sebocytes with coarsely vacuolated cytoplasm. The neoplasm was large but sharply circumscribed at low magnification.

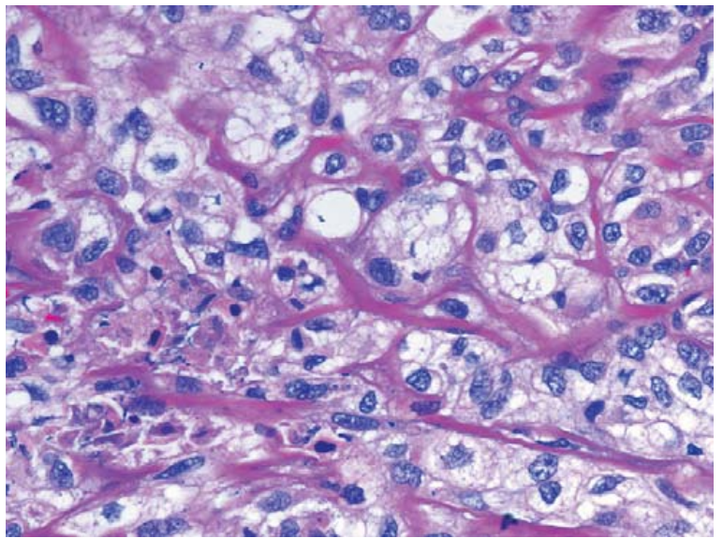

Fig. 111.22 Sebaceous carcinoma. At high magnification, there are cells with atypical nuclei and ample coarsely vacuolated cytoplasm. There are also many necrotic cells with pyknotic nuclei.

Treatment

Once a definite microscopic diagnosis has been achieved, no further treatment is obligatory. It is often difficult to establish the circumscription of lesions captured in superficial or partial biopsies. Complete excision of such lesions is appropriate to exclude the possibility of BCC with sebaceous differentiation or sebaceous carcinoma. Deeply situated lesions of Muir–Torre syndrome may be prone to rapid growth.

Sebaceous carcinoma

Introduction

The term sebaceous carcinoma designates an adenocarcinoma with sebaceous differentiation. By historical convention, these carcinomas have been separated into ocular and extraocular types. Extraocular sebaceous carcinoma is thought to hold a graver prognosis, although the data behind this belief are old and have been questioned[62].

Clinical features

The clinical presentation of sebaceous carcinoma is not distinctive. Typical clinical lesions include erythematous nodules or plaques that may be ulcerated or crusted and only occasionally display yellowish coloration. More commonly, the lesions display an erythematous or pearly morphology that is indistinguishable from common forms of non-melanoma skin cancer. Early in presentation, ocular lesions are very commonly misdiagnosed as blepharitis or ocular rosacea.

Sebaceous carcinomas commonly develop in the periorbital area but also occur elsewhere on the head and neck and less commonly on the trunk. Carcinomas from the trunk commonly display a nodular pattern, and superficial biopsies from such lesions may be deceptive and can be misinterpreted[62]. Sebaceous carcinoma can occur in patients with Muir–Torre syndrome, but the identification of a sebaceous carcinoma alone is not sufficient to diagnose the syndrome[60]. However, any unusual sebaceous neoplasm is probably sufficient provocation for consideration of the disease.

Pathology

Like many malignancies, sebaceous carcinoma often exhibits asymmetry, a lack of circumscription, and areas with an infiltrative pattern. In nodular sebaceous carcinoma, cells are arrayed as large nests and lobules. In infiltrative sebaceous carcinomas, jagged nests and thin strands are found. Sebaceous carcinoma can involve the surface epidermis or conjunctiva, in a pagetoid pattern, especially in ocular lesions[63,64]. This can be confused with Bowen's disease or melanoma.

The degree of sebaceous differentiation in sebaceous carcinoma varies greatly, as does the degree of nuclear atypicality (Fig. 111.22). Some carcinomas display obvious sebocytic differentiation, while other examples may be largely seboblastic or undifferentiated in appearance.

Stains for lipid, such as oil red O or Sudan black, have been utilized in the past as a tool to confirm sebaceous differentiation through labeling of cytoplasmic fat. However, such stains have little routine practical applicability as they require the use of frozen tissue substrate. EMA and adipophilin immunoperoxidase staining represent the best supplemental tests for confirmation of sebaceous differentiation. When authentic sebaceous differentiation is present, coarsely vacuolated cytoplasmic positivity can be seen with either stain.

Crateriform or cystic sebaceous neoplasms that display a clinical and microscopic pattern reminiscent of keratoacanthoma are uncommon lesions that probably represent low-grade carcinomas[60]. Sebaceous neoplasms with a keratoacanthoma-like pattern probably only occur in the context of Muir–Torre syndrome.

Treatment

Sebaceous carcinoma is an adnexal carcinoma with significant albeit variable metastatic potential. The primary treatment remains surgical extirpation. Although the risk of metastatic disease was formerly believed to be high, particularly for ocular carcinomas, the data contained within many older reports may be skewed by inclusion of carcinomas diagnosed late in their evolution. Extensive disease of the eye has been treated with ocular enucleation, especially when ocular conjunctival involvement was present. The metastatic potential of both superficial sebaceous carcinoma and sebaceous carcinoma with an infiltrative pattern may be limited, although additional study will be necessary to fully establish this.

NEOPLASMS AND PROLIFERATIONS WITH APOCRINE DIFFERENTIATION

In most textbooks, adnexal neoplasms with glandular and ductular differentiation have been rigorously separated into eccrine and apocrine neoplasms. Commonly, the distinction was based upon enzyme histochemistry, an imprecisely applied technique that is no longer available. Discrimination has also been based upon conventional microscopic assessment, a useful but imprecise tool, at least for the distinction of eccrine and apocrine attributes.

A few authorities have responded to this difficulty by grouping apocrine and eccrine neoplasms together, in recognition of the fact that it is impossible to determine whether a given lesion, such as a given syringoma, is of apocrine or eccrine lineage. In the sections that follow, the traditional categorization as apocrine or eccrine will be maintained, but areas of overlap will be expressly noted. For entities such as syringoma, poroma and hidradenoma, which can be of either apocrine or

eccrine lineage, the presentation will be included in the discussion of apocrine lesions.

Benign Neoplasms and Proliferations with Apocrine Ductular and Tubular Differentiation

Syringoma

Introduction

Syringoma represents a benign adnexal neoplasm with mostly ductal (syringeal) differentiation. Historically, syringomas have been interpreted as neoplasms of eccrine lineage[65,66]. The term syringoma can be used to describe neoplasms of either apocrine or eccrine lineage, and it is currently impossible to judge the lineage of any given lesion other than by its context[1,2].

Clinical features

A syringoma manifests clinically as a small, firm, skin-colored papule. Syringomas commonly present in multiplicity (Fig. 111.23) and may be eruptive[67,68]. The lesions are removed from women more commonly than men, although it is not clear that this represents authentic gender predilection. There is an increased incidence in Asian populations as well as an association with Down syndrome. Clear cell syringomas are associated with diabetes mellitus.

Syringomas may occur at any site on the body but are prone to occur in the periorbital area, especially the eyelids. Sometimes, lesions involve the upper trunk, favoring the ventral surface, or genital skin[67–69]. Eruptive syringomas most commonly involve the trunk but may involve the extremities, including the palms and soles. Acral syringomas, which are rare, are those that are most clearly of eccrine lineage, as the acini of glabrous (non-hair-bearing) skin are exclusively eccrine[70].

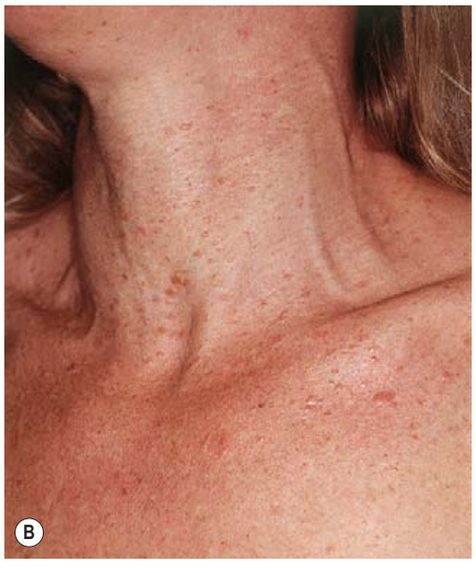

Fig. 111.23 Syringomas. **A** Aggregated skin-colored papules on the eyelids. **B** Multiple skin-colored to pink, smooth papules on the neck and upper chest. The lesions favor the ventral surface of the trunk, a distribution pattern referred to as *"en demicuirasse".* *B, Courtesy, Jean L Bolognia, MD.*

Pathology

From scanning magnification, a syringoma is small and circumscribed and is usually confined to the superficial dermis. The encompassing stroma is sclerotic. The epithelial component of the proliferation is composed of cells with pale or pinkish cytoplasm forming nests and tubules of relatively uniform size. Depending upon the exact plane of section, the nests of a syringoma vary in shape, and some nests may assume a morphology that resembles a comma or a tadpole (Fig. 111.24). Tubular areas exhibit ductular differentiation with central lumina lined by a compact eosinophilic cuticle. Typically, half or more of the nests in a given plane of section will show central ductal differentiation.

Usually, a syringoma lacks keratinization, although at times superficial cornification can be seen. Syringomas also typically lack evidence of follicular differentiation. If either follicular differentiation or keratinization is identified, other differential diagnostic possibilities should be strongly considered. The combination of superficial cornification, poor circumscription, and extension into the deep reticular dermis (or subcutis) favors microcystic adnexal carcinoma over syringoma. A lesion with strands of basaloid cells, focal superficial cornification and focal calcification probably represents desmoplastic trichoepithelioma rather than syringoma. If there are only cornifying cysts present and authentic ductal differentiation is lacking, then the most likely diagnosis is trichoadenoma.

Treatment

Syringoma is a benign adnexal neoplasm with negligible proliferative capacity. After definitive diagnosis, no further surgical intervention is needed unless adnexal carcinoma remains a clinicopathologic consideration. Syringomas may be treated with careful application of trichloroacetic acid, cryotherapy, punch excision, or electrosurgical destruction, with variable results. This can be difficult in the common situation in which multiple lesions are present on eyelids. Disseminated lesions can be cosmetically disabling and therapeutically challenging, and laser ablation might be the best choice[71].

Poroma

Introduction

Poroma designates a group of benign adnexal neoplasms with poroid (terminal ductal) differentiation. Like syringomas, poromas were widely interpreted historically as neoplasms of eccrine lineage because of dubious enzyme histochemistry[65,66]. The words *eccrine* and *poroma* became seemingly inextricably linked in the dermatologic lexicon, and thus poromas are often referred to as eccrine in reflexive fashion[2]. Poroma can be a proliferation of either apocrine or eccrine lineage[72–75]. Eccrine and apocrine poromas probably occur in nearly equal numbers.

The term *acrospiroma* is used by some authorities as a synonym for poroma and is used by other authorities as a broad designation that encompasses both poroma and hidradenoma.

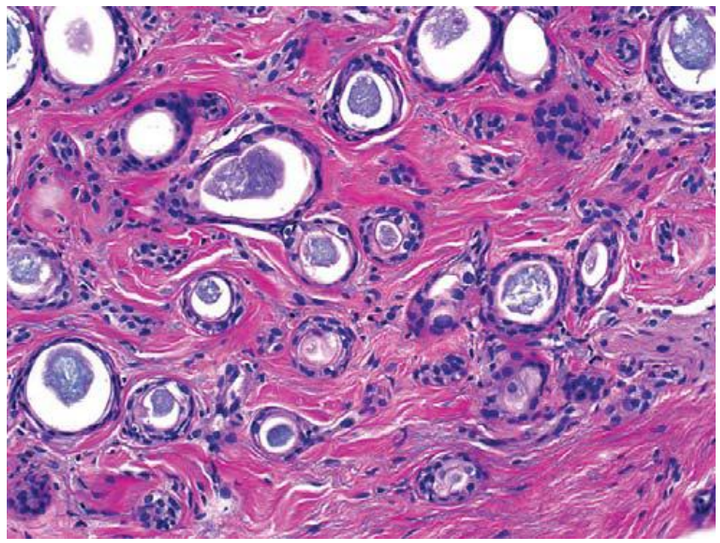

Fig. 111.24 Syringoma. This superficial adnexal neoplasm consists of nests of cells with pale cytoplasm positioned within sclerotic stroma. Many nests show central ductal differentiation with a compact eosinophilic cuticle.

Clinical features

Poromas usually present as solitary papules, plaques or nodules (Fig. 111.25)[4]. When sessile vascular plaques surrounded by thin indented moats appear on the palms and soles, an astute dermatologist can strongly suspect the diagnosis. They can appear on any cutaneous surface, where they are less readily identified with specificity. The scalp is another common site, with or without an associated nevus sebaceus[13]. Presumably, poromas arising secondarily within nevus sebaceus represent apocrine poromas. Occasionally, a poroma will be pigmented. Poromas commonly display highly vascularized stroma, and a clinical pattern suggestive of pyogenic granuloma is common, especially in poromas that involve acral skin. Rarely, multiple poromas will develop, either in an acral or in a widespread distribution, a clinical pattern referred to as poromatosis.

Pathology

The principal finding in all forms of poroma consists of a circumscribed proliferation of compact cuboidal keratinocytes with small monomorphous nuclei and scant eosinophilic cytoplasm. Poromas can be wholly intraepidermal, a pattern known historically as hidroacanthoma simplex; can occur in broad continuity with the epidermis (juxta-epidermal poroma; Fig. 111.26); or can develop wholly (or nearly so) within the dermis (intradermal poroma; Fig. 111.27), a pattern known historically as dermal duct tumor[3]. Accompanying stroma may be scant in association with intraepidermal poroma.

The degree of ductal differentiation varies greatly in individual neoplasms. Some poromas display innumerable foci in which poroid cells form small cuticulated ductal spaces. In other lesions, ducts may be difficult to identify, and a resemblance to seborrheic keratosis may ensue. Carcinoembryonic antigen (CEA) immunostaining, which labels the luminal surface of both apocrine and eccrine ducts, can be employed as a tool to confirm the presence of ductal differentiation. Poromas may occasionally display tubular (rather than ductular) foci in which a central cuticle is lacking. If such tubular foci are lined by columnar cells with holocrine secretion at the luminal border, a presumptive diagnosis of apocrine poroma can be offered.

At times, a poroma may display striking clear cell change. The constituent nuclei in such lesions are small but are surrounded by ample pale cytoplasm. Poromas are an exception to the rule that necrosis *en masse* is a clue to a malignancy. Curiously, poromas commonly display small collections of cells in coagulation necrosis. In malignant tumors, necrosis is usually a consequence of rapid growth (growth beyond the capacity of perfusion), but this is an unlikely explanation for necrosis in poroma, in which cellular proliferation is low. Poromas may occasionally display small foci of sebaceous differentiation, which usually consists of clusters of mature sebocytes near the lesion base[72,76,77].

Treatment

Poroma is a benign adnexal neoplasm and thus treatment is optional. Superficial lesions may be treated by shave or electrosurgical destruction. Superficial or deeper lesions may also be treated with simple excision.

Fig. 111.25 Poroma. A biopsy specimen is necessary to establish a definitive diagnosis.

Hidradenoma

Introduction

Hidradenoma is a form of benign adnexal neoplasm that is a close relative of poroma but is usually characterized by cells with ample cytoplasm, is never wholly intraepidermal, and does not commonly have a broad-based connection to the epidermis. As has been mentioned, some authorities use the broad designation *acrospiroma* to refer to both hidradenoma and poroma jointly. Although commonly classified as an eccrine neoplasm, hidradenomas are currently thought to be of either apocrine or eccrine lineage[65,66]. The vast majority of hidradenomas are believed to be of apocrine lineage[1,78].

Clinical features

Hidradenoma lacks any distinctive clinical attributes. The lesion presents as a solitary dermal or subcutaneous nodule; sometimes, a cystic quality or serous drainage can be detected.

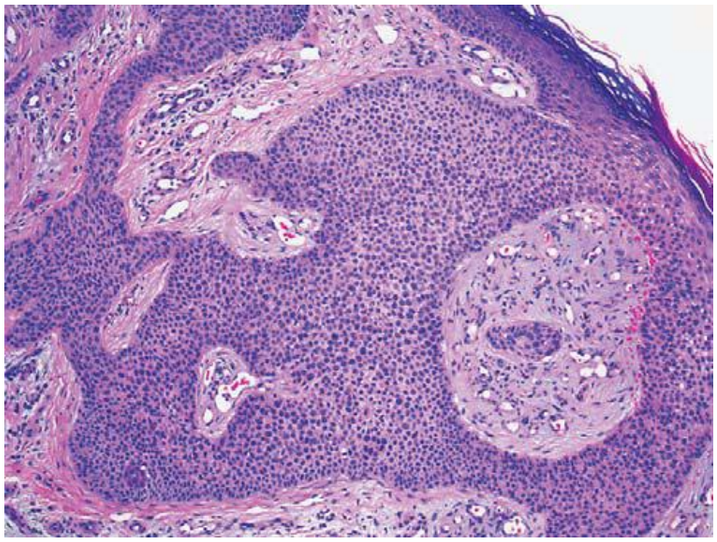

Fig. 111.26 Poroma, juxta-epidermal pattern. This poroma displays a pattern common to both eccrine and apocrine poroma. There are interanastomosing cords composed of small compact "poroid" cells, and the intervening stroma is highly vascularized and resembles granulation tissue.

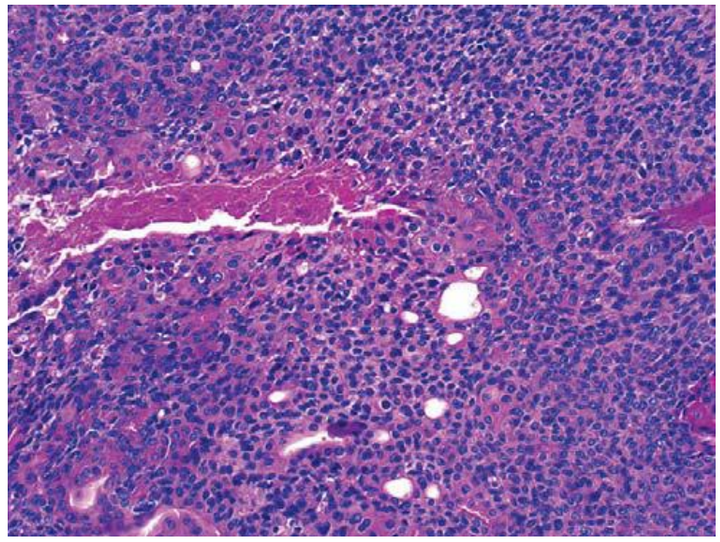

Fig. 111.27 Poroma, intradermal pattern. At low magnification, this lesion was a well-circumscribed dermal nodule. This high magnification shows conspicuous foci of ductal differentiation and also a focus of necrosis *en masse,* a finding common to poroma that is uncommon in other benign neoplasms.

Pathology

Hidradenomas are mostly dermal neoplasms with a nodular, sharply circumscribed pattern when viewed at low magnification. Some hidradenomas may display a juxta-epidermal pattern superficially with multifocal attachment to the epidermis, much like poroma. Although the stroma of hidradenoma is commonly sclerotic and may contain ectatic vessels, usually the granulation tissue-like quality that typifies the stroma of a poroma is not present. If desmoplastic stroma is conspicuous and exaggerated, the designation *desmoplastic hidradenoma* is recommended. The cells of hidradenoma are large with ample cytoplasm but uniform nuclei, which are generally somewhat larger than the nuclei of poroma. Overt clear cell change (clear cell hidradenoma) is common, as is cystic degeneration (solid-cystic hidradenoma)[79,80] (Fig. 111.28). Ductal differentiation can be found with scrutiny, although the degree observed may be minimal. Some lesions contain tubules lined by columnar cells with a decapitation pattern along their luminal border; such lesions can be designated as apocrine hidradenoma without question. Not surprisingly, hybrid lesions with features of both hidradenoma and poroma can be encountered, and the intermediate term *poroid hidradenoma* has been applied in this setting[81].

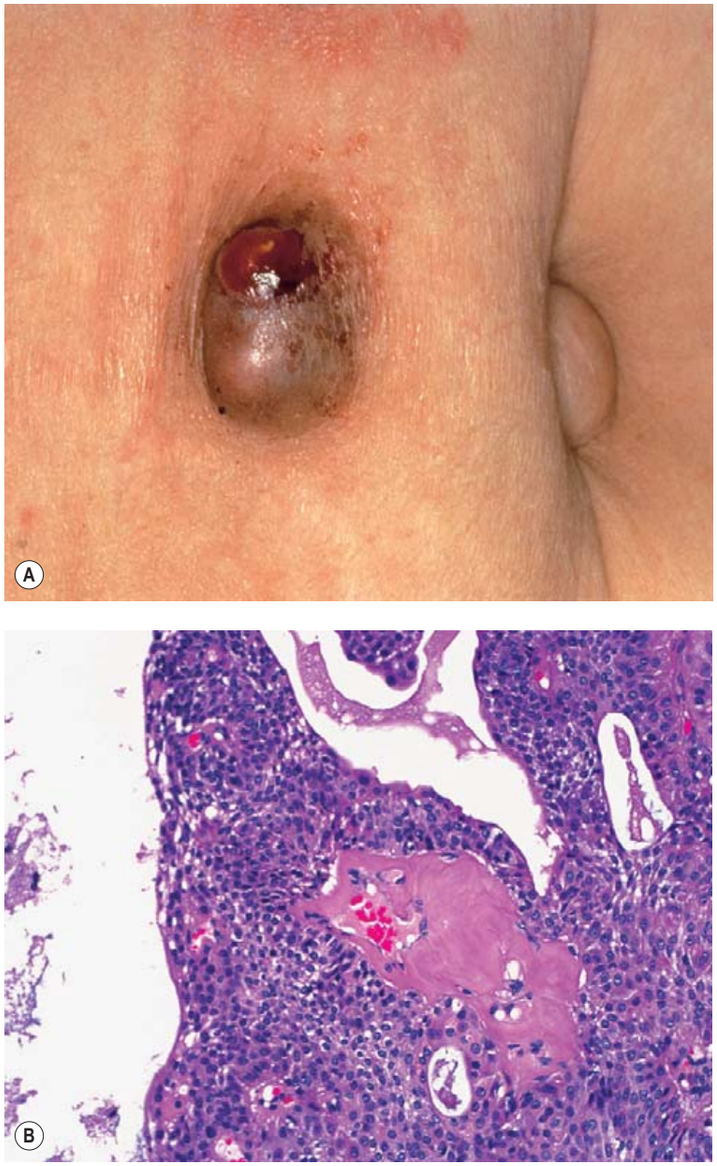

Fig. 111.28 Hidradenoma. A Solitary violaceous nodule on the abdomen with serous drainage. **B** This well-circumscribed nodule is composed of cells with small uniform nuclei and ample cytoplasm that often is pale or shows overt clear cell change. A cystic focus is present; lesions that display prominent cystic change have been referred to as "solid-cystic" hidradenoma.

Treatment

Hidradenoma is a benign adnexal neoplasm. Complete conservative excision is curative.

Apocrine adenoma

Introduction

Any benign neoplasm with apocrine differentiation, including poroma and hidradenoma, could be grouped under the broad roof of this rubric. On a practical basis, only adenomas with conspicuous glandular differentiation are included in this category. Usually, these proliferations exhibit abundant apocrine epithelium and conspicuous decapitation secretion, in which part of the cytoplasm pinches off into a lumen. Apocrine adenomas may present with a tubular or papillary microscopic pattern or a combination of the two. Entities within this conglomeration include *tubular adenoma, papillary adenoma, syringocystadenoma papilliferum* and *hidradenoma papilliferum*. The latter entity, also known as *papillary hidradenoma*, is a source of potential semantic confusion with conventional hidradenoma. Papillary hidradenoma (hidradenoma papilliferum) is an apocrine adenoma that usually exhibits a pronounced frond-like pattern with apocrine epithelium lining the constituent papillae. In contrast, conventional hidradenoma (acrospiroma) exhibits a mostly solid configuration.

Tubular, papillary or tubulopapillary adenomas with conspicuous apocrine differentiation may develop within the parenchyma or secretory apparatus of the breast. Apocrine adenomas in continuity with the nipple commonly exhibit a tubulopapillary pattern and have been referred to as *erosive adenomatosis*[82–84]. In addition to a tubulopapillary pattern, apocrine adenomas of the nipple may display small foci with solid and cribriform patterns, but usually necrosis is not identifiable. As such lesions are usually solitary, as erosion is commonly not present, and as the designation erosive adenomatosis is somewhat provocative, it is probably best to employ the simple term *nipple adenoma* in this context. The distinction between nipple adenoma and ductal adenocarcinoma can sometimes be challenging, and consultation with an experienced breast pathologist should be sought in difficult cases.

Clinical features

The presentation of tubular or papillary adenoma is not distinctive. These tumors present as smooth papules or nodules, and biopsy is required for diagnosis.

Syringocystadenoma papilliferum presents as a papule or plaque almost exclusively on the head or neck (Fig. 111.29). Syringocystadenomas usually exhibit a crusted surface that may ooze serosanguinous fluid; this is a reflection of the fact that the papillae of a syringocystadenoma are in continuity with the epidermal surface, permitting extrusion of secretory products. Most papillary syringoadenomas present on the scalp in association with nevus sebaceus[13,85].

Hidradenoma papilliferum usually presents as a smooth dermal or subcutaneous nodule, usually no more than a centimeter in diameter. Most papillary hidradenomas arise on the vulva, but development

Fig. 111.29 Syringocystadenoma papilliferum. Grouped papules and nodules with scale-crust. The possibility of an associated nevus sebaceus needs to be considered.

within skin of the breast, axilla, and inguinal or perianal areas has also been documented[86].

Pathology

At low magnification, tubular and papillary adenomas are usually well-circumscribed neoplasms positioned within the dermis, the superficial subcutis, or a combination of the two. Adenomas with a tubular pattern are composed mostly of rounded glandular spaces that vary in size and are lined by one or several layers of cuboidal cells with pale cytoplasm and small nuclei. Most spaces have small lumina and some display columnar apocrine cells apically. Papillary adenomas contain conspicuous tufts, with luminal cells that display an apocrine pattern. A combination of tubular and papillary patterns is not uncommon.

Papillary syringocystadenoma (syringocystadenoma papilliferum) is distinctive for its wide papillary fronds that are in continuity with the surface squamous epithelium. Syringocystadenomas are only rarely cystic. The fronds are lined by a bilayer, with basal cuboidal cells and apical columnar apocrine cells, and the cores of fronds virtually always contain a dense infiltrate of lymphocytes and plasmacytes (Fig. 111.30). A plasmacytic infiltrate commonly accompanies neoplasms of apocrine lineage, and thus the mere presence of plasma cells in a given lesion is not sufficient to confirm a diagnosis of syringocystadenoma.

At low magnification, papillary hidradenoma (hidradenoma papilliferum) consists of a well-circumscribed nodule within the dermis and usually lacks both a connection to the surface epithelium and the prominent plasmacytic infiltrate of syringocystadenoma papilliferum. Both tubules and papillary fronds are usually present, and broad elongated fronds with delicate fibrous cores are usually identifiable (Fig. 111.31). Both tubules and fronds are usually lined by a bilayer, with basal cuboidal myoepithelial cells and apical apocrine cells, and the apical cells usually display a conspicuous holocrine secretion. At least some of the basal layer cells represent authentic myoepithelial cells with contractile function, and labeling of the myoepithelial layer through immunoperoxidase staining for actin filaments can sometimes be of diagnostic value in the distinction from adenocarcinoma, which often lacks a complete myoepithelial layer.

Treatment

Apocrine adenomas are completely benign lesions. Complete conservative excision is curative.

Undifferentiated Neoplasms of Apocrine Lineage

Most adnexal neoplasms contain foci of differentiation that may be rudimentary but that are readily interpretable as representing normal structures. For example, while trichoblastoma is largely undifferentiated, it contains foci such as papillary mesenchymal bodies that clearly indicate follicular germinative lineage. In contrast, two closely-related entities, spiradenoma and cylindroma, display either a general lack of differentiation or display differentiation not readily identifiable as indicative of a normal structure. Both spiradenoma and cylindroma occasionally display tubular foci with a decapitation luminal pattern, suggesting apocrine lineage, but mostly these neoplasms display uninterpretable/unrecognizable differentiation.

Spiradenoma

Definition

The term *spiradenoma* connotes a benign adnexal neoplasm that has been historically designated as being of eccrine lineage, although reassessment indicates an apocrine process[1,65,66]. Spiradenoma not uncommonly occurs jointly with cylindroma and both occur jointly with trichoepithelioma/trichoblastoma (see Fig. 111.4); the most parsimonious explanation for this complex juxtaposition is that both spiradenoma and cylindroma are of folliculosebaceous-apocrine lineage[87,88]. Both spiradenoma and cylindroma occur jointly with trichoepithelioma in the Brooke–Spiegler syndrome that is due to mutations in *CYLD*, again implying kinship rather than disparate lineage. Spiradenoma has never been observed on glabrous (non-hair-bearing) skin. If spiradenoma were truly eccrine, occurrence on the palm or sole would be the rule and not the exception.

Clinical features

Spiradenoma typically presents as a dermal or subcutaneous papule or nodule on nearly any location; extraordinary lesions may achieve a diameter of several centimeters. Sometimes, spiradenomas are painful. The clinical lesions are not distinctive and biopsy is required for diagnosis, although an astute dermatologist can suspect the diagnosis in the setting of a painful nodule with a bluish hue. Spiradenomas may occur in multiplicity and in concert with cylindroma and trichoblastoma, and multiple lesions should prompt consideration of a diagnosis of Brooke–Spiegler syndrome.

Pathology

At low magnification, spiradenoma assumes a multinodular pattern with relatively large nodules positioned within the dermis and subcutis. Although the nodules may be asymmetrically distributed, each is sharply circumscribed. The nodules are composed of basaloid cells without obvious differentiation, although tubular apocrine foci can be observed on occasion. Upon close scrutiny, individual nodules exhibit a trabecular internal morphology, with compact basophilic cells lining the borders of trabeculae and larger cells with scant pale cytoplasm within their centers (Fig. 111.32). Usually, small lymphocytes

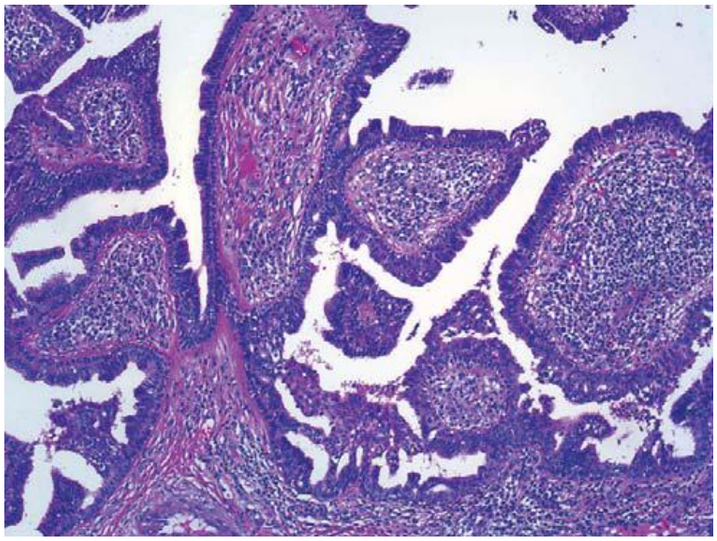

Fig. 111.30 Syringocystadenoma papilliferum. This neoplasm consists of papillary foci lined by columnar cells that usually display overt apocrine differentiation. The dermal cores of papillae are usually stuffed with lymphocytes and many plasma cells.

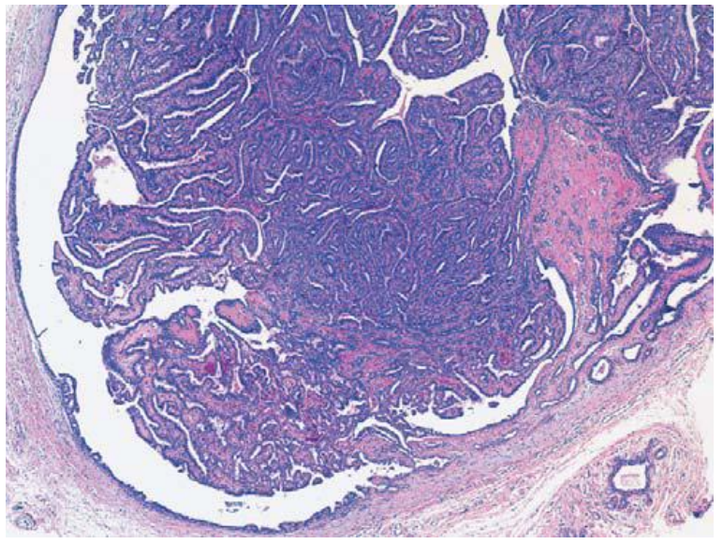

Fig. 111.31 Hidradenoma papilliferum. This well-circumscribed dermal nodule is composed of fronds and papillae with a connective tissue core lined by a bilayer of cells, with columnar apocrine cells positioned above a cuboidal monolayer of myoepithelial cells.

are scattered throughout trabecular areas. Some large (giant) spiradenomas develop cystic areas of degeneration or striking vascular ectasia as secondary events. Compact eosinophilic basement membrane material, arrayed either as tiny PAS-positive droplets or as circumferential bands, can occasionally be found within a spiradenoma, although such deposits are more commonplace in cylindroma. Spiradenoma can occur jointly with cylindroma, at least some of the time[87,88].

Treatment

Spiradenoma is a benign adnexal neoplasm. Despite its basaloid appearance, spiradenoma holds negligible proliferative capacity and recurrence is uncommon after simple enucleation or conservative excision.

Cylindroma

Introduction

The term *cylindroma* describes a form of benign adnexal neoplasm that is closely related to spiradenoma.

Clinical features

Cylindromas can present singly or in multiplicity and are not clinically distinctive; thus a biopsy is required for diagnosis. Solitary lesions commonly involve the head and neck area, especially the scalp (Fig. 111.33), and can also develop within skin of the trunk or genitalia. Multiple cylindromas may coalesce and form giant mosaic plaques on the scalp, which has been pejoratively referred to as turban tumor[89–91]. The recognition of multiple cylindromas should prompt consideration of the Brooke–Spiegler syndrome or multiple cylindromatosis (both autosomal dominant conditions), most examples of which are associated with *CYLD* gene mutations.

Pathology

At low magnification, cylindroma consists of sharply circumscribed nodules arrayed within the dermis and/or subcutis. The nodules are composed of nests of basaloid cells in close apposition, arrayed in a complex pattern that has been likened to a jigsaw puzzle. A rim of densely eosinophilic, PAS-positive basement membrane material commonly envelops the individual nests, and droplets of similar composition are often scattered in the centers of small nests (Fig. 111.34). Foci of ductular and apocrine tubular differentiation can sometimes be found but are inconspicuous.

Treatment

Cylindroma is a benign adnexal proliferation. Despite its basaloid appearance, cylindroma holds negligible proliferative capacity and recurrence is uncommon after complete excision.

Carcinomas of apocrine lineage

Introduction

Adnexal carcinomas with tubular and ductular differentiation (adnexal adenocarcinomas) are relatively uncommon, and their rarity has contributed to confusion with respect to diagnosis, classification and therapy. Adnexal carcinomas can develop *de novo* or they can arise in association with extant benign adnexal neoplasms. The semantics of carcinomas that arise in association with benign neoplasms has been problematic, as there has been a historical tendency to create an oxymoronic nomenclature by modifying the name of the benign analogue with the simple addition of the adjective *malignant*. Going forward, correct designations such as porocarcinoma and spiradenocarcinoma should be employed while the oxymoronic designations malignant poroma and malignant spiradenoma should be eschewed[2].

For certain types of adnexal carcinoma, such as spiradenocarcinoma or cylindrocarcinoma, the adenocarcinomas that develop from the benign neoplasm often lack a decisive pattern of differentiation and may only be specifically diagnosable through recognition of a remnant

Fig. 111.33 Cylindroma. While numerous tumors aggregated on the scalp are called turban tumors, solitary lesions usually present as smooth erythematous nodules.

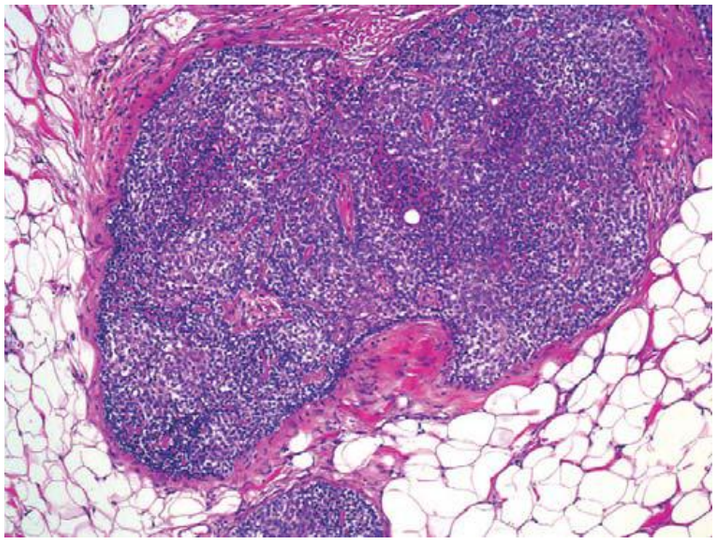

Fig. 111.32 Spiradenoma. This subcutaneous nodule shows multinodular basaloid aggregates with the typical trabecular pattern. Darkly staining cells line trabeculae and pale cells with pink cytoplasm are present in their centers, admixed with lymphocytes.

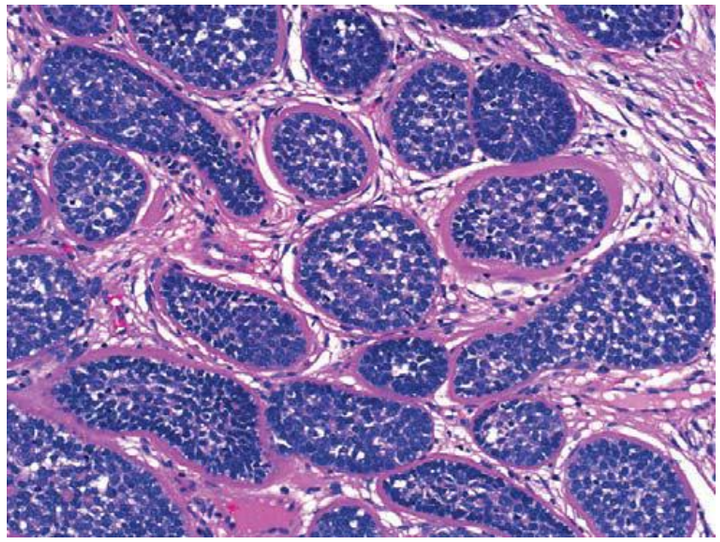

Fig. 111.34 Cylindroma. Nests of basaloid cells in a jigsaw puzzle-like pattern. Many nests are circumferentially enveloped by a dense eosinophilic cylinder of basement membrane material.

of the residual benign lesion. A spiradenocarcinoma in the absence of detectable spiradenoma will likely only be recognizable as poorly differentiated adenocarcinoma. Some forms of adnexal adenocarcinoma, such as porocarcinoma, display distinctive differentiation that is recognizable in a *de novo* lesion or in a carcinoma that developed within an existent tumor.

Clinical features

In general, the presentation of adnexal adenocarcinomas is not distinctive. Patients who develop adnexal carcinoma within an existent benign neoplasm often relate a history of recent rapid (or explosive) enlargement of a previously stable, longstanding plaque or nodule (Fig. 111.35). Ulceration and bleeding are common associated findings. Adnexal adenocarcinoma presents as a plaque or nodule, and biopsy and microscopy are required for diagnosis.

Perhaps the most is known about the presentation of *microcystic adnexal carcinoma* (MAC), a low-grade form of adnexal carcinoma (also known as *sclerosing sweat duct carcinoma*) that has been carefully evaluated in several large series[92]. MAC typically presents in young or middle-aged adults, most commonly in women and occasionally in children, and lesions slowly enlarge over years and are often misdiagnosed prior to the time of definitive recognition (Fig. 111.36)[92]. The most common location is the lip. Curiously, a left-sided predominance was noted in the largest series from the US, suggesting that UV light exposure (from driving) might be contributory to carcinogenesis, much like common forms of non-melanoma skin cancer.

Fig. 111.35 Porocarcinoma. Rapid growth and erosion or ulceration accompany this malignant adnexal tumor.

Fig. 111.36 Microcystic adnexal carcinoma. This tumor presents as a slowly expanding, firm plaque.

Pathology

All forms of adnexal adenocarcinoma share architectural attributes of malignancy, such as asymmetry, lack of circumscription, and an infiltrative configuration. There is considerable variability in the degree of cytologic atypicality, and no standard currently exists for the grading of these neoplasms. Some forms of adnexal carcinoma may display overtly anaplastic cytomorphology while other carcinomas, such as MAC or syringomatous carcinoma, display very subtle nuclear atypism.

Syringomatous carcinoma refers to a rare form of carcinoma with distal ductal differentiation[93,94]. Syringomatous carcinoma may be of either apocrine or eccrine lineage, and generally lineage cannot be discerned microscopically. Syringomatous carcinoma is characterized by poor circumscription, an infiltrative pattern at low magnification, and composition of small nests and tubules of pale cells with central cuticulated ducts. The degree of nuclear atypicality is usually modest, and thus a superficial biopsy, which hides the lack of circumscription, can lead to misinterpretation as syringoma. Syringomatous carcinoma has only been observed as a *de novo* malignancy.

MAC is a close relative of syringomatous carcinoma that is distinctive for biphasic or multiphasic differentiation. MAC displays a ductal component identical to that of syringomatous carcinoma coupled with follicular and (sometimes) sebaceous differentiation[92,95] (Fig. 111.37). The follicular component of MAC consists most notably of small cystic (microcystic) foci with follicular infundibular and isthmic keratinization, similar to the superficial follicular keratinization observed in desmoplastic trichoepithelioma or trichoadenoma. Areas resembling the follicular outer sheath may also be present. Extensive infiltration of the reticular dermis and perineural extension of tumor cells are common findings. Although desmoplastic trichoepithelioma and MAC exhibit overlapping features and both are characterized by foci of superficial follicular keratinization, follicular germinative (basaloid) cells are a hallmark of trichoepithelioma but are rarely, if ever, present in MAC.

Porocarcinoma may develop *de novo* or in association with an existent poroma[96]. Like poroma, porocarcinoma may be of apocrine or eccrine lineage, and it is generally impossible to determine the exact lineage of any given tumor. Some examples of porocarcinoma display little cytologic atypism and thus close attention must be paid to other attributes of malignancy, and small or partial biopsies may defy exact diagnosis. However, the degree of cytologic atypism is variable[94,97]. Porocarcinoma is composed of nests of eosinophilic or pallid cuboidal cells that infiltrate the dermis and perhaps subjacent deeper tissues, and ductal differentiation is usually conspicuous (Fig. 111.38). Porocarcinoma may display intraepidermal growth, with a pagetoid or nested pattern within the epidermis in some cases[94,97].

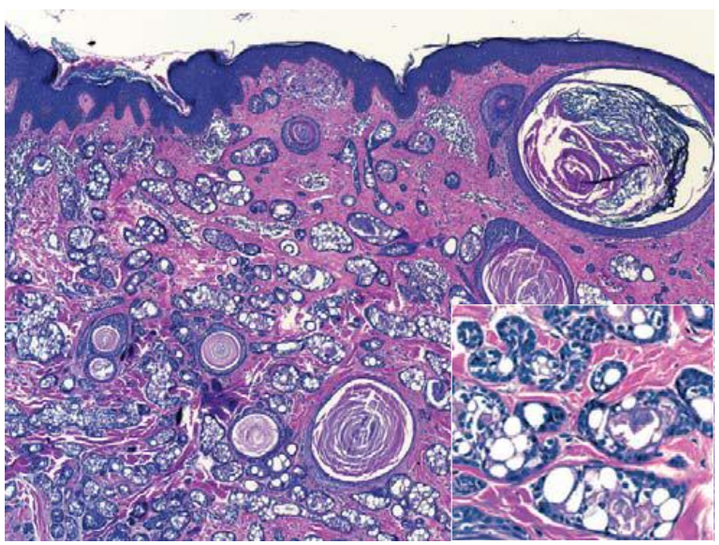

Fig. 111.37 Microcystic adnexal carcinoma. This deeply infiltrative carcinoma shows a biphasic microscopic pattern, with both ductular differentiation and superficial follicular keratinization. The high-magnification insert shows conspicuous ductal differentiation without cytologic atypism, which sometimes leads to misdiagnosis as a benign lesion.

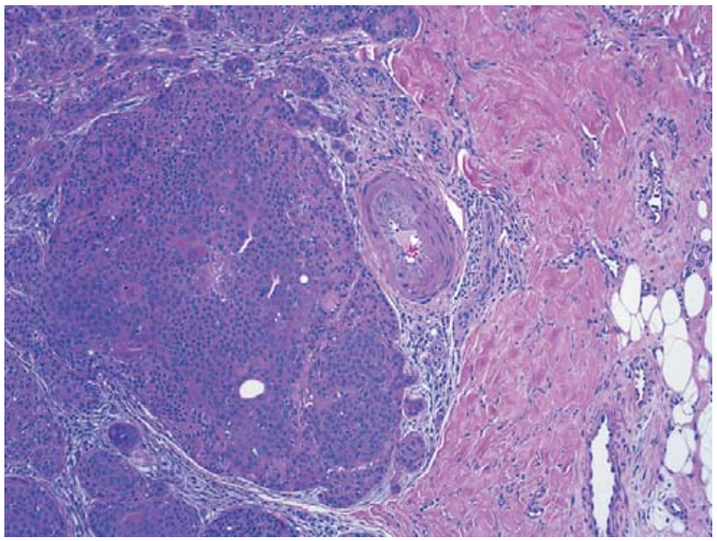

Fig. 111.38 Porocarcinoma. There are irregularly shaped nests of neoplastic cells that infiltrate deeply, with this image obtained at the level of the superficial subcutis. The largest nest shows central foci of ductular differentiation.

Hidradenocarcinoma may develop *de novo* or in association with an existent hidradenoma. Hidradenocarcinoma may be of apocrine or eccrine lineage. Cases reported in the older literature were notable for the presence of marked clear cell change, much like clear cell hidradenoma.

Spiradenocarcinoma and *cylindrocarcinoma* are usually poorly differentiated carcinomas that develop *de novo* or more commonly in association with an existent spiradenoma or cylindroma[98–100]. Both are extremely rare and may come to medical attention late in their course, as their evolution within longstanding stable lesions may contribute to a delay in pursuit of care by the patient.

Adenoid cystic carcinoma is a type of relatively undifferentiated adnexal carcinoma that resembles micronodular BCC but is generally distinctive for the presence of cribriform (net-like) glandular differentiation and a paucity of accompanying myxoid stroma. Primary cutaneous adenoid cystic carcinomas have been misinterpreted as metastatic lesions. Although initially postulated to represent a type of eccrine carcinoma, most authorities believe the entity represents a neoplasm of apocrine lineage. Adenoid cystic carcinoma tends to display considerable local invasiveness and most examples remain confined to the skin over years or even decades, but metastasis to lymph nodes and parenchymal organs can also rarely occur[101]. CD117 immunopositivity has been reported in association with adenoid cystic carcinoma and may be of value in providing additional diagnostic support.

Treatment

As a generality, the majority of adnexal adenocarcinomas are low-grade forms of carcinoma that are locally invasive but pose a low risk for metastasis. Many adnexal carcinomas that yield metastatic spread are large or were diagnosed late in their evolution. Surgical extirpation, including removal via Mohs micrographic surgery, remains the primary therapeutic modality. Careful microscopic classification is crucial to developing experience with larger groups of histopathologically homogeneous lesions to enable careful assessment of natural history as well as proper medical and surgical care.

NEOPLASMS AND PROLIFERATIONS WITH ECCRINE DIFFERENTIATION

Eccrine nevus (hamartoma)

Nevi or malformations with an eccrine glandular component are extremely uncommon. The clinical morphology of such lesions is not distinctive. Some lesions are alleged to maintain function of the eccrine apparatus. This can manifest clinically as mucinous discharge or localized hyperhidrosis.

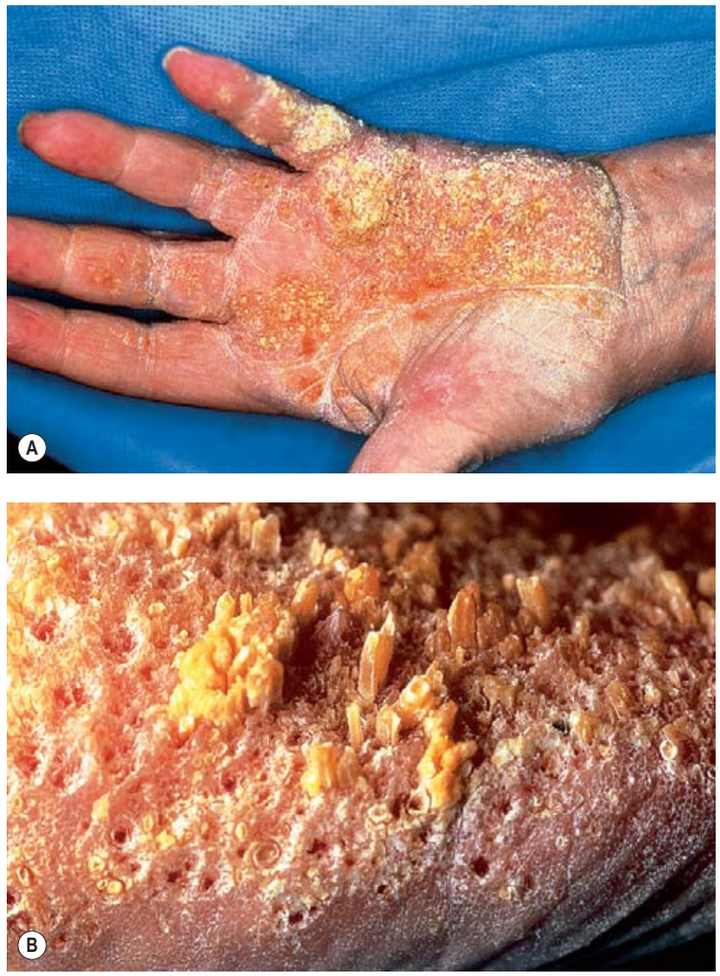

Fig. 111.39 Porokeratotic eccrine ostial and dermal duct nevus. Markedly hyperkeratotic spines arise from dilated eccrine ostia, corresponding to the histologic findings of coronoid lamellae.

Microscopically, the judgment as to whether eccrine glands are normal in number or increased can be difficult, especially in a partial biopsy. The absolute number of eccrine units is increased and the constituent units are of increased size in eccrine nevi. The surrounding stroma may be exclusively fibrotic or may include adipocytes. When the stroma also harbors an increase in small vascular channels, the designation eccrine angiomatous hamartoma can also be applied (see Fig. 39.5). For skin tag-like lesions on the coccygeal area, the term *coccygeal polypoid eccrine nevus* has been applied.

So-called porokeratotic eccrine ostial and dermal duct nevi are probably not eccrine nevi at all. These lesions are typically congenital and present as papules or plaques on the hands or feet, with punctate hyperkeratosis. The focal hyperkeratosis corresponds to cornoid lamellae that are often situated within acanthotic acrosyringia (Fig. 111.39). Eccrine acini are qualitatively and quantitatively normal in porokeratotic nevi, suggesting that these lesions should not be classified as a form of adnexal nevus. From the standpoint of nosology, these lesions probably fit best on the spectrum of epidermal nevi.

Treatment

Eccrine nevi are benign and require no treatment. Excision can be completed as an optional step.

Syringoma, poroma, hidradenoma, adnexal adenocarcinoma (see above)

Syringofibroadenoma

Syringofibroadenomas are rare tumors, usually located on the limbs. They may be associated with Clouston syndrome or Schöpf–Schulz–Passarge syndrome. They are characterized by an irregular

network of thin cords and strands of epithelial cells extending down from the epidermis. Ductal structures are usually present. A similar pattern may be observed in some cases of chronic stasis dermatitis. This has prompted some authorities to view syringofibroadenoma as a reactive process rather than an authentic neoplasm.

Papillary adenoma and adenocarcinoma

Introduction

The concept of *papillary adenoma* was originally put forth under the designation *aggressive digital papillary adenoma*[102–104]. These neoplasms are uncommon and commonly occur on acral skin of the fingers, toes, palms and soles, a topographic restriction that suggests that many or most are of eccrine lineage. Papillary adenoma was deemed aggressive because the neoplasms were prone to local recurrence if not completely excised, and some lesions were found to erode bone or infiltrate adjacent soft tissue[103]. Some neoplasms first classified as aggressive papillary adenoma have metastasized[104], and thus it appears this spectrum includes both adenomas and adenocarcinomas. It has also been suggested that all acral papillary lesions represent adenocarcinomas, but this seems biologically unlikely.

Clinical features

Papillary adenoma/adenocarcinoma presents as a solitary nodular lesion in an adult of any age. Lesions up to several centimeters in diameter have been observed. There is a male predilection. The lesions may be deeply situated and can impinge upon or erode underlying bone. The favored metastatic route appears to be hematogenous, and metastases involving the lung can occur.

Pathology

Papillary adenocarcinomas are extraordinarily cellular and display a combination of solid and papillary areas and are occasionally cystic[103]. A cribriform pattern can occasionally be found. For carcinomas with a largely cribriform or tubular configuration, the designation tubulopapillary carcinoma can be employed. Irrespective of the architecture of the lesion, its constituent cells have hyperchromatic nuclei and relatively little cytoplasm, and mitotic figures are usually readily identifiable (Fig. 111.40). There may be necrosis of individual cells or necrosis *en masse*. The enveloping stroma is commonly sclerotic. In overtly malignant lesions, vascular invasion or infiltration of bone may be observed.

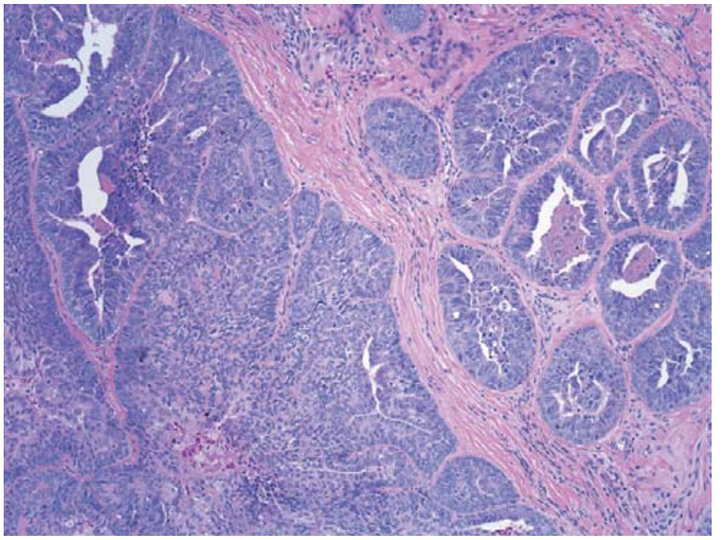

Fig. 111.40 Papillary adenocarcinoma of the digit. Solid, tubular and papillary foci, with small foci of necrosis. Mitotic figures are easily identified.

Treatment

It is difficult to predict the clinical course based upon the microscopic pattern. Complete surgical extirpation of papillary adenocarcinoma remains the standard of care. Because of diagnostic ambiguity, any papillary adenoma should also be fully excised.

EPHELIDES

Synonym: ■ Freckles

Key features

- Small, well-circumscribed, pigmented macules found only on sun-exposed skin of individuals with fair skin

Epidemiology and Pathogenesis

Ephelides are common in individuals with blond or red hair[1–6]. They are not present at birth, but usually appear during the first 3 years of life. Hyperpigmentation in ephelides is the result of increased sun-induced melanogenesis and transport of an increased number of fully melanized melanosomes from melanocytes to keratinocytes. Variants of the gene that encodes the melanocortin-1 receptor play a role in the development of red hair and ephelides (see Ch. 65)[7].

Clinical Features

Ephelides occur only on sun-exposed areas of the body, in particular the face, dorsal aspects of the arms, and upper trunk. They do not occur on mucous membranes. Ephelides are well demarcated and round, oval or irregular in shape. They are usually 1 to 3 mm in diameter, but are occasionally larger. Depending on the intensity of sun exposure, ephelides vary in color from light to dark brown, but almost never become as dark as lentigines or junctional nevi. They may increase in number and distribution and show a tendency for confluence, but they can fade over time with aging.

Ephelides are benign and show no propensity for malignant transformation[4]. While they are not a direct precursor of melanoma, ephelides are a marker of ultraviolet (UV)-induced damage and, hence, a marker for increased risk of UV-induced neoplasia[5]. In a study of 195 patients diagnosed with melanoma in England, the density of freckles on the face and arms was found to be more strongly associated with cutaneous melanoma than the number of melanocytic nevi. When adjusted for other factors (nevi, sunburns, skin type), those with a high freckle density had an odds ratio of 6.0 for developing melanoma compared with those without freckles. Some ephelides may represent a subtype of solar lentigo[5].

Pathology

The epidermis exhibits a normal configuration. The keratinocytes show an increase in melanin content, predominantly in the basal cell layer[6]. Occasionally, melanophages are seen in the papillary dermis. The density of melanocytes within ephelides does not differ significantly from normal. Compared to adjacent uninvolved epidermis, the melanocytes in ephelides are larger and have more branching of dendrites and a higher DOPA positivity, apparently indicating greater functional activity.

Differential Diagnosis

Ephelides must be distinguished from simple lentigines, solar lentigines, small café-au-lait macules and junctional nevi. In general, ephelides are lighter in color than simple lentigines, are confined to sun-exposed skin, and are responsive to solar exposure. In contrast, simple lentigines may occur on any site and are persistent. Table 112.1 compares ephelides and solar lentigines. Café-au-lait macules are usually solitary and larger than ephelides.

Treatment

Since darkening of ephelides depends on UV radiation, sun exposure should be minimized and use of sunscreens, hats and protective clothing recommended. Although topical retinoids and hydroquinone may lighten lesions, it is difficult to achieve an even clinical effect. Pigment-specific lasers and cryotherapy represent additional treatment options. Of note, any resulting dyspigmentation from these destructive therapies can be more disturbing to the patient than the original lesion.

CAFÉ-AU-LAIT MACULES

Key features

- Well-circumscribed, uniformly light to dark brown macules or patches that often range from 2 to 5 cm (in adults)
- Usually noted during infancy or early childhood
- Found in 10–20% of the normal population but can serve as a marker of an underlying genodermatosis, especially when multiple

COMPARATIVE CLINICAL FEATURES OF EPHELIDES AND SOLAR LENTIGINES		
	Ephelides (freckles)	**Solar lentigines**
EPIDEMIOLOGY		
Age of appearance	Early childhood	By 20–30 years (I, II)
Skin color	Light pigmentation	Light to dark pigmentation
Hair color	Often red or blond hair	Any type
Skin phototype	More common in I, II	More common in I and II, but also in III and IV
HISTORY		
Precipitating factors	Bursts of high-intensity sun exposure convert latent predetermined melanocytes to permanent freckles	Repeated sun exposure over time alters melanocytes within a circumscribed area to overproduce melanin
Duration of lesions	Fade without sun exposure	Persist for life
Relation to season	Much darker in summer, fade in winter and over time with aging	May darken in summer but do not fade in winter
Heredity	Probably AD; also AR when related to *MC1R* variants	No data
PHYSICAL EXAMINATION		
Type of lesion	Macule	Macule
Size	1–5 mm	5–15 mm or larger
Color	Light or medium brown	Medium or dark brown
Shape	Round to oval	Oval to irregular
Border	Smooth to jagged	Smooth to jagged
Distribution	Favor the face, forearms and back; rare on the dorsal aspect of the hands	Sites of chronic sun exposure, especially the face, arms (including dorsal aspect of the hands) and upper trunk
DERMOSCOPIC FEATURES		
	Uniform pigmentation and a moth-eaten edge	Diffuse light brown structureless areas, sharply demarcated and/or moth-eaten borders, fingerprinting, and a reticular pattern with thin lines that are occasionally short and interrupted

Table 112.1 Comparative clinical features of ephelides and solar lentigines. I, II, III, IV = skin phototypes (see Ch. 134); AD, autosomal dominant; AR, autosomal recessive; MC1R, melanocortin-1 receptor.

Fig. 112.1 Café-au-lait macule. Large tan patch in a geographic pattern on the lateral trunk. The patient did not have McCune-Albright syndrome.

Epidemiology

In an individual, the number of café-au-lait macules (CALM) can vary from one to more than a dozen. When multiple, the possibility of a genetic syndrome, such as neurofibromatosis 1 (NF1), needs to be considered[8,9] (see Table 61.4). Single CALM are found in 10% to 20% of the normal population, and up to 1% of healthy children have up to three CALM, especially African-American children. The lesions may be present at birth, but usually become clinically obvious during the first year of life and then increase proportionately in size with age.

Pathogenesis

The hyperpigmentation observed in CALM is due to increased melanogenesis and an increased melanin content within keratinocytes. While the underlying pathogenesis has not been elucidated in patients with isolated lesions, biallelic *NF1* inactivation has been identified in melanocytes from CALM in patients with NF1, and in McCune–Albright syndrome, affected skin contains an activating mutation in the gene that encodes $G_s\alpha$ (see Chs 61 & 65).

Clinical Features

The term café-au-lait refers to the lesion's characteristic homogeneous color of coffee with milk, which can be light to dark brown, depending upon the level of constitutive pigmentation. CALM are completely macular (Fig. 112.1), and they often have an overall oval morphology with margins that are well defined and regular ("typical" CALM)[10,11]. They may be located anywhere on the body, with the exception of the mucous membranes. CALM are usually 2–5 cm in diameter in adults, but may vary from freckle-like lesions (≤2 mm) to patches that are >20 cm in diameter. CALM enlarge proportionately with overall body growth and then remain stable in size during adulthood.

Compared with NF1, the CALM of McCune–Albright syndrome are typically fewer in number, larger, and have a midline demarcation; they usually have a segmental distribution pattern or present as broad bands along Blaschko's lines[12]. These CALM favor the head, neck, trunk and buttocks. They also tend to be unilateral, often involving the same side as the bone lesions and situated in proximity. They can, however, be indistinguishable both clinically and histologically from the CALM of neurofibromatosis. If present, superimposed lentigines (due to diffuse "freckling") can point to NF1-associated CALM.

Pathology

Light microscopy shows a normally configured epidermis with a slightly increased melanin content in the basilar keratinocytes. The adnexal epithelium is spared of hyperpigmentation, and melanophages are rarely found in the dermis. In DOPA-stained epidermis from most patients with neurofibromatosis, the density of melanocytes is higher in both CALM and normal adjacent skin, in comparison with healthy individuals. The melanocytic density in isolated CALM of otherwise normal persons, however, is usually less than in surrounding skin. Melanin macroglobules (large pigment particles) may be found in CALM but they are not specific for neurofibromatosis, as they are occasionally found in isolated CALM (without any underlying disease) and occur in several other conditions such as simple lentigines, Becker's melanosis, congenital melanocytic nevi, and sometimes even normal skin. By electron microscopy, the melanosomes are usually dispersed singly within melanocytes and are usually homogeneous, electron-dense, and ellipsoidal when fully melanized[9,13,14].

Differential Diagnosis

Hyperpigmented macules or patches that might be confused with CALM include linear nevoid hyperpigmentation (pigmentary mosaicism), early nevus spilus (before the "speckles" have appeared), Becker's

melanosis (without obvious hypertrichosis), mastocytomas, postinflammatory hyperpigmentation and phytophotodermatitis. Smaller lesions may resemble lentigines or acquired melanocytic nevi, while larger lesions may be confused with relatively flat congenital melanocytic nevi. Café-noir spots are hyperpigmented patches that have an even darker hue (relative to background skin) than CALM and are seen in LEOPARD syndrome and the Carney complex.

Treatment

CALM have never been reported to undergo malignant change. Topical agents (e.g. hydroquinone) and sun protection will have no effect on CALM. A variety of lasers have been used to treat CALM, with variable success[15,16]. The risks of laser surgery include transient hyperpigmentation or hypopigmentation, slight scarring, permanent hyperpigmentation, incomplete clearance, and especially recurrence. Typically, between 1 and 14 treatments are required, and responses are difficult to predict. For instance, of 12 CALM treated with a Q-switched ruby laser in one study, 50% developed repigmentation within 6 months. Responses to frequency-doubled Nd:YAG are also quite variable.

BECKER'S MELANOSIS

Synonyms: ■ Becker's nevus ■ Becker's pigmentary hamartoma ■ Nevoid melanosis ■ Pigmented hairy epidermal nevus

Key features

- Unilateral, hyperpigmented and often hypertrichotic patch or slightly elevated plaque
- Usually on the shoulder of male patients
- Onset during adolescence

Epidemiology

Becker's melanosis has been described in all races[17]. Although it is usually acquired, some cases are congenital. The lesions most often appear during the second and third decades of life and are six times more common in males than in females. Familial occurrence has been reported. In one study, the prevalence among 19 302 army recruits ages 17 to 26 years was 0.52%.

Pathogenesis

The pathogenesis of Becker's melanosis remains unclear. It is believed to be an organoid hamartoma of ectodermally and mesodermally derived tissues. An increase in androgen receptors and probable heightened sensitivity to androgens have been postulated. The latter characteristics would explain its onset during or after puberty, as well as its clinical and histologic manifestations, which include hypertrichosis, dermal thickening, acne and hypertrophic sebaceous glands. Androgen stimulation could also explain the accentuated smooth muscle elements often found in the dermis of Becker's melanosis[18].

Clinical Features

The onset of Becker's melanosis is usually noted during the second or third decade of life, sometimes following intense sunbathing. Lesions commonly have a unilateral distribution and involve an upper quadrant of the anterior or posterior chest plus the shoulder, but they also have been described on the forehead, face, neck, lower trunk, extremities (Fig. 112.2) and buttocks[17]. Normally, Becker's melanosis appears as a single lesion, but multiple lesions have occasionally been observed. The diameter ranges from a few centimeters to >15 cm, and the most common configuration is block-like, although linear patterns have been described.

The hyperpigmentation varies from uniformly tan to dark brown and the lesions are well demarcated, but the margins are usually irregular. The center of the lesion may show slight thickening and corrugation of the skin. Hypertrichosis usually develops after the hyperpigmentation, and the hairs become coarser and darker with time. Sometimes, the hypertrichosis is subtle and can only be appreciated by comparison with the contralateral side. The hypertrichosis and pigmentation may not overlap completely.

Fig. 112.2 Becker's melanosis (nevus). Large patch of hyperpigmentation on the leg which is medium brown in color. These lesions may be misdiagnosed as café-au-lait macules or congenital melanocytic nevi, especially when they do not occur on the upper trunk. *Courtesy, Jean L Bolognia, MD.*

Firmness to palpation may point to an associated smooth muscle hamartoma. In some patients, perifollicular papules may be a sign of coexistent proliferation of the arrector pili muscle. Acneiform lesions strictly limited to the area of hyperpigmentation have also been reported. Normally, Becker's melanosis is asymptomatic, but some patients report pruritus. After its initial appearance, the lesion may enlarge slowly for a year or two but then remains stable in size. The color can fade with time, but hypertrichosis usually persists.

Becker's melanosis is a benign lesion, and malignant transformation has not been reported. In contrast to the hyperplasia of the ectodermal and mesodermal tissues in Becker's melanosis, developmental anomalies that are generally hypoplastic in nature have occasionally been associated with Becker's melanosis. These abnormalities include hypoplasia of the ipsilateral breast, areola, nipple and arm, ipsilateral arm shortening, lumbar spina bifida, thoracic scoliosis and pectus carinatum, as well as enlargement of the ipsilateral foot. Accessory scrotum and supernumerary nipples have also been reported. In cases of Becker's melanosis with associated abnormalities (also referred to as "Becker's nevus syndrome"), the male:female ratio is reversed at 2:5 (in comparison to 6:1 in those without abnormalities)[19].

Pathology

There is variable papillomatosis, acanthosis and hyperkeratosis[17]. Regular elongation of the rete ridges and hyperplasia of the pilosebaceous unit may be observed. The melanin content of the keratinocytes is increased, whereas the number of melanocytes is normal or only slightly increased, without nesting. Melanophages may be found in the papillary dermis. A concomitant smooth muscle hamartoma is often, but not invariably, present in the dermis.

Differential Diagnosis

The differential diagnosis primarily includes CALM, congenital melanocytic nevus, plexiform neurofibroma and congenital smooth muscle hamartoma. The latter tends to be smaller in size but some authors consider Becker's melanosis and congenital smooth muscle hamartoma to be two ends of a clinical spectrum (see Ch. 117). A congenital melanocytic nevus, plexiform neurofibroma and congenital smooth muscle hamartoma can all have cutaneous hyperpigmentation and hypertrichosis. By dermoscopy, Becker's melanosis is less likely to have focal thickening of network lines, globules or homogeneous diffuse pigmentation, when compared to congenital nevi. The presence of

multiple CALM and axillary freckling can be helpful in establishing the diagnosis of neurofibromatosis, and unlike Becker's melanosis, CALM do not have corrugation on side-lighting. In an occasional patient, histologic evaluation is required to confirm the diagnosis, especially if the lesion is in an unusual location and there is an associated smooth muscle hamartoma.

Treatment

Patients with Becker's melanosis should be examined for possible soft tissue and bony abnormalities (see above). Electrolysis, waxing, camouflage makeup, and laser treatments may be recommended. The hyperpigmented component has been successfully treated with Q-switched ruby and frequency-doubled Nd:YAG[20], but recurrence rates are high. The hypertrichosis can be addressed with one of several lasers designed for this purpose (see Ch. 137).

SOLAR LENTIGINES

Synonyms: ■ Lentigo senilis ■ Liver spot ■ Old age spot ■ Senile freckle

Key feature

■ Tan to dark brown or black macules due to exposure to UV radiation

Epidemiology

Solar lentigines are found in 90% of the Caucasian population older than 60 years of age, and their incidence increases with advancing age[21,22]. They can also be found in younger individuals after acute or chronic sun exposure. Lentigines are more common in Caucasians, but also occur in Asians. Inherited patterned lentiginosis favors more lightly pigmented African-Americans, including those with mixed American Indian heritage.

Pathogenesis

Solar lentigines result from epidermal hyperplasia with variable proliferation of melanocytes and accumulation of melanin within keratinocytes in response to chronic UV radiation exposure. Associated mutations have not been elucidated. As with ephelides, variants in the melanocortin-1 receptor gene are linked to the development of solar lentigines[7].

Clinical Features

Solar lentigines are well-circumscribed, round, oval or irregularly shaped macules that vary in color from tan to dark brown or black. More lightly pigmented lesions are usually homogeneous (Fig. 112.3), whereas darker ones tend to have a mottled appearance. Solar lentigines almost always appear as multiple lesions. They usually vary from about 3 mm to 2 cm in diameter and can become confluent. Solar lentigines occur on sun-exposed areas, predominantly the dorsal aspects of hands and forearms, the face, the upper chest and back.

Solar lentigines have an irregular border and a reticulated pigment pattern when examined by tangential lighting and hand lens magnification. They may also be visible under Wood's lamp illumination when not apparent in normal light. The dermoscopic features of a solar lentigo may include the following: a diffuse light brown structureless area, sharply demarcated and/or moth-eaten borders, fingerprinting, and a reticular pattern with thin lines that are occasionally short and interrupted[23] (Fig. P1 [Appendix]). A particular variant that may be termed hypermelanotic or "ink spot" solar lentigo is characterized by a striking jet-black color and a stellate outline. By dermoscopy, a black branching pattern is seen.

Solar lentigines may develop at almost any age and may fade slightly with age or after the cessation of UV exposure. Most, however, persist indefinitely. The occasional development of melanocyte cytologic atypia in solar lentigines suggests a relationship of solar lentigines to lentigo maligna, but clear progression to lentigo maligna has not been established. Solar lentigines have been shown to be an independent risk factor for the development of melanoma. Histologic overlap suggests that solitary lichen planus-like keratosis and reticulated seborrheic keratosis can evolve from solar lentigines.

Fig. 112.3 Solar lentigines. Numerous light brown macules, some of which have an irregular border, on chronically sun-exposed skin.

Associated diseases and special forms

A *PUVA (psoralen + ultraviolet A)* lentigo is a well-defined hyperpigmented macule that commonly develops in individuals undergoing long-term PUVA chemotherapy (see Ch. 134). Up to 50% of PUVA-treated patients develop PUVA lentigines after an average of 5 to 7 years of photochemotherapy. The frequency and severity of the lesions are positively correlated with greater numbers of treatments, age of starting therapy, and male sex. There is a negative association with skin phototypes V and VI. In contrast to typical solar lentigines, PUVA lentigines also occur in sun-protected skin subjected to PUVA treatment. These lesions usually exhibit darker pigmentation and more of a stellate appearance in contrast to solar lentigines. PUVA lentigines often persist for years beyond the discontinuation of PUVA therapy. Histologically, the PUVA-induced lesions display lentiginous hyperplasia of large melanocytes that often exhibit mild cytologic atypia. On ultrastructural examination, the melanosomes in PUVA lentigines are usually larger in comparison with the melanosomes in solar lentigines[21]. Patients treated with PUVA should be monitored for the development of melanoma. Solar lentigines are also found in patients with *xeroderma pigmentosum* (see Ch. 87), a rare genetic disease in which clinical and cellular hypersensitivity to UV radiation and defective DNA repair are associated with skin malignancies.

Pathology

The rete ridges often have club-shaped or bud-like extensions and branching or fusing of rete ridges, forming a reticulated pattern (Fig. 112.4). The epidermis between the rete ridges may appear thinned. There is increased basal layer pigmentation, especially in the basaloid cells of the rete ridges. In some (but not all) cases, the melanocytes are increased in number. Melanocytes in dopa-stained sections of solar lentigines exhibit increased melanogenesis, and these cells have more numerous as well as longer and thicker dendritic processes than the melanocytes of normal skin. The superficial dermis often contains melanophages and occasionally a mild perivascular infiltrate of lymphocytes. Electron microscopic studies reveal abundant melanosome complexes in keratinocytes which appear to be larger than in normal surrounding skin[22].

Differential Diagnosis

The differential diagnosis of solar lentigines includes ephelides, macular seborrheic keratoses, simple lentigines, pigmented actinic keratoses, lentigo maligna, junctional melanocytic nevi and large cell acanthomas.

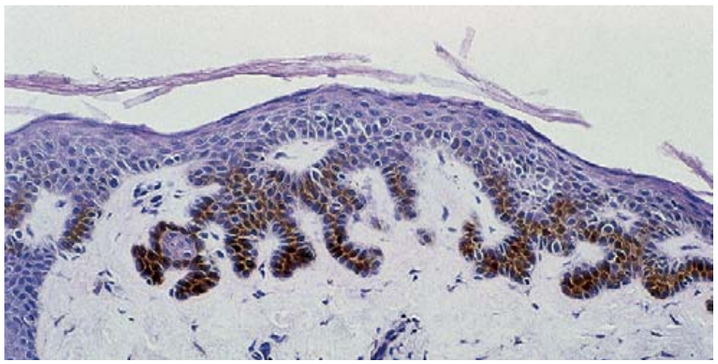

Fig. 112.4 Histology of a solar lentigo. Hyperpigmented elongated rete ridges with a diffuse increase in non-nested melanocytes, in addition to solar elastosis. *Courtesy, Ronald P Rapini, MD.*

Fig. 112.5 Anogenital lentiginosis. Biopsy of the darkest lesion (at 7 o'clock) showed no cellular atypia. Over a period of 10 years, several of the macules faded. *Courtesy, Jean L Bolognia, MD.*

Table 112.1 outlines the similarities and differences between solar lentigines and ephelides. There is essentially a continuum extending from solar lentigo to macular varieties of seborrheic keratosis. Demonstration of a keratotic surface with horn cysts is consistent with seborrheic keratosis. Pigmented actinic keratosis is more likely to have a scaly rough surface. Lentigo maligna often exhibits greater variation in pigmentation and irregularity of borders compared with solar lentigo, and by dermoscopy, rhomboid structures can be seen, in particular on the face. Simple lentigines are often smaller and more heavily pigmented than solar lentigines, and they arise during childhood with less relationship to UV exposure.

Treatment

Patients with PUVA lentigines should be monitored for the development of melanoma. Although a solar lentigo is a benign lesion of cosmetic concern only, it is an indication of chronic UV exposure which dictates monitoring of the patient for non-melanoma skin cancer and melanoma. Bleaching agents (e.g. hydroquinone) are not effective. Cryotherapy and laser surgery have been shown to be equally effective, but caution must be used to prevent post-treatment dyspigmentation. Preventive measures include sunscreens, physical barriers and limitation of sun exposure[22].

LENTIGO SIMPLEX AND MUCOSAL MELANOTIC LESIONS

Synonyms:
- Lentigo simplex: • Simple lentigo • Lentiginosis (multiple)
- Mucosal melanotic lesions: • Melanosis • Mucosal melanotic macules • Genital lentiginosis • Lentiginosis

Key feature

- A lentigo simplex is a brown macule with an early age of onset (as compared with a solar lentigo) and little or no relationship to sun exposure

Epidemiology

The frequency of lentigo simplex in children and adults is unknown. Lentigines are found in all races and seem to occur equally in both sexes. Isolated lesions may be present at birth, more commonly in darkly pigmented than lightly pigmented newborns. These lentigines may increase in number during childhood or puberty and sometimes occur in an eruptive form called lentiginosis with or without obvious precipitating factors. After melanocyte activation, lentigo simplex represents the next most common histology in matrix biopsies of longitudinal melanonychia (see Ch. 71). In darkly pigmented races, lentigo simplex is the most common histologic pattern for pigmented lesions in acral cutaneous sites.

Oral melanotic macules are found primarily in adults over 40 years of age. Some authors report a slight female predilection, whereas others describe both sexes being affected equally. The most common sites are the vermilion border, followed by the gingiva, the buccal mucosa and the palate. Up to 30% of melanomas in the oral cavity of Caucasians are preceded by melanosis for several months or years[23a]. In Japanese patients, two-thirds of infiltrative oral melanomas arise in association with oral melanosis. The labial (lip) melanotic macule usually appears between the second and fourth decades of life and has a strong predilection for Caucasian women.

The incidence of lentiginosis or melanosis of the female genital area is probably higher than reported. For example, 15% of 106 females between the ages of 16 and 42 years had genital "nevi", and in a study of 100 random autopsies, three cases showed melanosis of the genitalia, and all three were elderly women. Most lesions are found on the labia minora (Fig. 112.5), but they can also occur on the labia majora, the vaginal introitus, the cervix, the periurethral area and the perineum as well as perianally. In general, lentiginosis and melanosis of the female genitalia are benign conditions; atypia is uncommon and progression to melanoma has not been reported.

In a study of 10 000 men between 17 and 25 years of age, 14.2% were noted to have "pigmented nevi" of the genitalia[24]. It is uncertain what proportion represented penile lentiginosis or melanosis since no clinical descriptions or histologic studies were reported. In the literature, the ages of patients with penile lentiginosis or melanosis range from 15 to 75 years. The lesions occur on both the glans penis and penile shaft. Men can also develop lentigines perianally.

The incidence of conjunctival melanosis is unknown, but it can be assumed that primary acquired melanosis is a precursor lesion of melanoma in this area, since a significant number of conjunctival melanomas are associated with it. Lentigo simplex occasionally develops within scars following excision of cutaneous melanoma as do pigmented streaks due to basilar hyperpigmentation; the latter favors individuals with numerous solar lentigines.

Pathogenesis

An increased number of melanocytes within the basal layer of the epidermis leads to an increased production of melanin, resulting in hyperpigmented macules. To date, insights into lentigo formation have not been forthcoming despite the discovery of the genetic bases of several syndromes associated with lentiginosis (see Ch. 55). Some

penile lesions have been reported to follow injury, irritation or PUVA therapy. In women, hormonal factors are thought to play a role. Acral lentigines may be influenced by genetic factors, since they are frequently found in darkly pigmented individuals.

Clinical Features

Lentigines simplex are light brown to black, homogeneous pigmented macules occurring anywhere on the body, including mucous membranes and palmoplantar skin, without any predilection for sun-exposed areas. They are well circumscribed, round or oval, have regular borders, and are usually less than 5 mm (often <3 mm) in diameter. Lesions on the mucous membranes frequently have irregular, ill-defined borders and mottled non-homogeneous pigmentation with areas devoid of pigment (see Fig. 112.5). The latter may be several centimeters in diameter and may resemble early melanoma.

Lentigines simplex occur as solitary or multiple lesions. Generalized lentigines may be an isolated phenomenon without an underlying disease, either present at birth or appearing during childhood or adulthood, or it may be a sign of a genetic disorder (Table 112.2).

In contrast to lentigo simplex occurring on the skin, lesions on mucous membranes can slowly increase in size over months to years, with or without changes in the degree of pigmentation. The relationship between acral or anogenital lentigines and acrolentiginous melanoma requires more investigation.

Special forms and associated syndromes

Multiple lentigines may or may not be associated with other systemic manifestations. In *LEOPARD syndrome* (multiple lentiginosis syndrome, progressive cardiomyopathic lentiginosis, cardiocutaneous syndrome) the acronym refers to: *l*entigines, *e*lectrocardiographic conduction defects, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormalities of genitalia, *r*etardation of growth, and *d*eafness (see Table 112.2). Multiple lentigines are present at birth or appear during early infancy and may increase in number during childhood. The lesions are generalized, occurring in both sun-exposed and sun-protected sites, including genitalia, palms and soles.

The *Carney complex* is an autosomal dominant syndrome characterized by multiple lentigines and multiple neoplasias, including: myxomas of the skin, heart (atrial) and breast; psammomatous melanotic schwannomas; epithelioid blue nevi of skin and mucosae; growth hormone-producing pituitary adenomas; and testicular Sertoli cell tumors. Components of the Carney complex have been described previously as the *NAME (n*evi, *a*trial myxoma, *m*yxoid neurofibroma, *e*phelides) and *LAMB* (*l*entigines, *a*trial myxoma, *m*ucocutaneous myxoma, *b*lue nevi) syndromes.

Peutz–Jeghers syndrome is also an autosomal dominant disorder characterized by mucocutaneous lentigines which are present at birth or appear during childhood in combination with intestinal polyposis. The skin lesions have an acrofacial distribution pattern and favor the perioral region. Mucosal lesions may affect the palate, tongue, buccal mucosa and conjunctivae. The major entity in the differential diagnosis is Laugier–Hunziker syndrome (Fig. 112.6).

In *partial unilateral lentiginosis*, also referred to as segmental lentiginosis, there is unilateral clustering of lentigines, suggesting a developmental abnormality of melanocytes. The onset is often during childhood and the individual lentigines are well circumscribed, varying from 2 to 10 mm in diameter. There is no background hyperpigmentation (as in nevus spilus) and the lesion can expand in a wavefront-like manner. Patients with facial lesions may have ocular involvement and CALM may also be present. Partial unilateral lentiginosis may be associated with segmental NF1.

Pathology

Lentigo simplex exhibits increased numbers of melanocytes in the basal layer of elongated epidermal rete ridges. Increased melanin in the basal layer and sometimes even in the upper layers of the epidermis and stratum corneum is commonly observed. Melanophages and a mild inflammatory infiltrate are often present in the superficial dermis.

Lesions on mucous membranes, including the lips, show acanthosis with or without elongation of the rete ridges (Fig. 112.7). Slight melanocytic hyperplasia is usually observed, but may be absent. Hyperkeratosis, telangiectasia, activated fibroblasts, and large dendritic melanocytes have been described in labial melanotic macules. Some acral and mucosal lesions have been reported to exhibit cytologic atypia of the melanocytes. Ultrastructurally, melanin macroglobules have been observed within the melanocytes, as well as in keratinocytes and melanophages. These are not specific for lentigo simplex, since they have been described in other pigmented lesions (see above).

Fig. 112.6 Labial lentigines. Multiple hyperpigmented macules on the lower lip in a patient with Laugier–Hunziker syndrome. Additional lesions are present on the tongue. Peutz–Jeghers syndrome can have a similar clinical appearance.

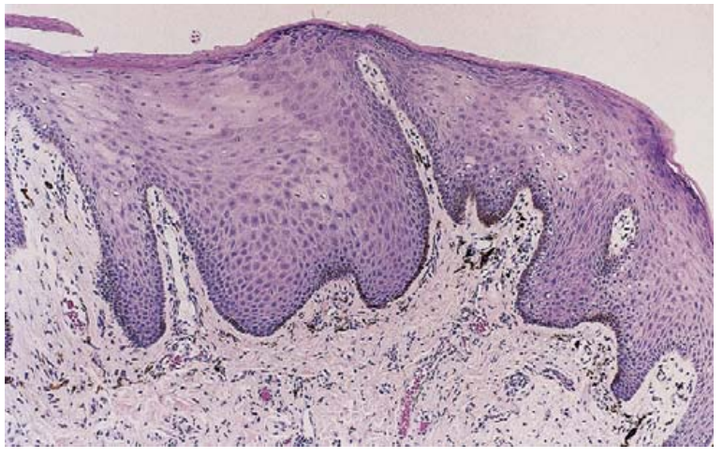

Fig. 112.7 Histology of a labial lentigo (melanotic macule). Hyperpigmented rete ridges are broader than in the typical lentigo.

Differential Diagnosis

The differential diagnosis of the solitary lentigo simplex involves primarily the junctional and relatively flat forms of compound melanocytic nevus, solar lentigo and ephelis. In some instances, cutaneous melanoma, pigmented spindle cell nevus, and cutaneous intracorneal hemorrhage might enter into the differential diagnosis.

Although there is a continuum from simple lentigo to junctional melanocytic nevus, the simple lentigo is distinguished from melanocytic nevi by the absence of distorted skin markings when viewed with side-lighting. Lentigo simplex is often smaller than a melanocytic nevus, but histopathologic examination may be required for discrimination. Lentigo simplex is usually distinguished from a solar lentigo by its smaller size, symmetry, uniform pigmentation, and lack of relationship to sun-exposed sites. However, this clinical distinction may not be possible in some instances.

Treatment

In general, there is no need to treat a benign-appearing lentigo simplex. Lesions on acral or mucous membranes should be evaluated carefully and, if clinically atypical, should be considered for biopsy to assess for

DISORDERS ASSOCIATED WITH MULTIPLE LENTIGINES			
Disorder	**Comments**	**Disorder**	**Comments**
GENERALIZED		**LOCALIZED**	
LEOPARD syndrome	• Autosomal dominant inheritance (high penetrance, variable expressivity); mutations in *PTPN11* gene • *L*entigines present in infancy/early childhood • Café-noir macules • *E*CG changes (conduction defects, hypertrophic cardiomyopathy), *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormal genitalia, growth *r*etardation and *d*eafness	**Head and neck (including oral mucosa) ± acral**	
		Peutz–Jeghers syndrome	• Autosomal dominant inheritance; mutations in *STK11* gene • Lentigines favor perioral region†, oral mucosa‡ and hands; longitudinal melanonychia • Multiple hamartomatous GI polyps • Pancreatic carcinoma; ovarian (adenoma malignum)/testicular tumors
Generalized lentigines	• Autosomal dominant inheritance; mapped to 4q21.1–q22.3 • Café-au-lait macules	Bandler syndrome*	• Autosomal dominant inheritance • Distribution of lentigines similar to Peutz–Jeghers • GI bleeding with small intestine hemangiomas rather than polyps
Deafness plus lentiginosis*	• ? Forme fruste of LEOPARD syndrome		
Carney complex (NAME/LAMB syndrome)	• Autosomal dominant inheritance; mutations in *PRKAR1A* gene • Lentigines, mucocutaneous myxomas, blue nevi (including epithelioid) • Psammomatous melanotic schwannomas • Atrial myxoma • Myxoid mammary fibroadenomas • Pigmented nodular adrenocortical disease; testicular (calcifying Sertoli cell), thyroid, and pituitary tumors	Laugier–Hunziker syndrome	• Similar distribution of lentigines as in Peutz-Jeghers, including lips, oral mucosa and digits • Longitudinal melanonychia and genital melanosis
		Cantú (hyperkeratosis–hyperpigmentation) syndrome	• Autosomal dominant inheritance • Punctate palmoplantar keratoderma • Multiple small (1 mm) macules on the face, forearms, hands/feet
Arterial dissection plus lentiginosis	• ? Inheritance pattern • Cutaneous lentigines with onset in childhood • Dissection of aortic, internal carotid and vertebral arteries	Cowden disease	• Autosomal dominant inheritance; mutations in *PTEN* gene • Periorificial and acral pigmented macules (see Table 63.3)
Gastrocutaneous syndrome*	• Autosomal dominant inheritance; see Table 61.4 for details	Centrofacial lentiginosis	• Autosomal dominant inheritance • Lentigines in a butterfly distribution on the nose, cheeks > forehead, eyelids, upper lip • Onset in infancy; increase in number in childhood • Possibly associated with neuropsychiatric illness and osseous anomalies
Tay syndrome*	• ? Autosomal recessive inheritance • Growth retardation, mental retardation; triangular face; cirrhosis; trident hands • Café-au-lait macules; premature canities; vitiligo		
Pipkin syndrome*	• Autosomal dominant inheritance • Nystagmus; strabismus	Inherited patterned lentiginosis	• Autosomal dominant inheritance • African-Americans with light brown skin • Pigmented macules appear in early childhood • Present on central face and lips > buttocks, elbows, hands/feet • Occasional oral mucosal involvement
		Cronkhite–Canada syndrome	• Typically affects older men • Lentigines of buccal mucosa, face, hands/feet • Alopecia (diffuse, non-scarring), nail dystrophy, intestinal polyposis
		Genital	
		Bannayan–Riley–Ruvalcaba syndrome	• Autosomal dominant inheritance; mutations in *PTEN* gene • Penile > vulvar pigmented macules (see Table 63.3)
		Lentiginosis perigenito-axillaris	• Genital and acral pigmented macules
		"Photodistribution"	
		Xeroderma pigmentosum	• Autosomal recessive inheritance; mutations in genes encoding proteins that repair UV-induced DNA damage • Lentigines favor, but are not limited to, chronically sun-exposed sites • Multiple skin cancers
		Segmental	
		Partial unilateral lentiginosis	• Multiple lentigines in a segmental distribution • Café-au-lait macules in same distribution

*To date, observed in a single family
†May fade.
‡Persists.

melanocytic atypia. Patients with both generalized and localized lentiginosis should undergo investigation to exclude systemic disease (see Table 112.2).

DERMAL MELANOCYTOSIS

Synonyms: ■ Congenital dermal melanocytosis ■ Mongolian spot

Key features

- Blue to blue–gray patch present at birth, whose primary location is lumbosacral
- More common in Asians
- Usually resolves during childhood
- Sparse dendritic melanocytes in the deeper dermis

Epidemiology

Dermal melanocytosis is usually present at birth or appears within the first weeks of life; rarely lesions appear after early childhood[25–27]. Both sexes seem to be affected equally. Dermal melanocytosis usually regresses during early childhood, but it can persist and was seen in 4.1% of 9996 Japanese males between 18 and 22 years of age. It occurs in all races, with a frequency in one study of 100% in Malaysians, 90–100% in Mongolians, Japanese, Chinese and Koreans, 87% in Bolivian Indians, 65% of blacks in Brazil, 17% of whites in Bolivia, but only 1.5% of whites in Brazil. The racial differences in the frequency of this abnormality suggest that genetic factors influence survival of dermal melanocytes (see Ch. 65). Microscopically, histologic findings consistent with dermal melanocytosis can be found in 100% of newborns, irrespective of race[25,26].

Pathogenesis

The blue color in dermal melanocytosis is secondary to melanin-producing melanocytes residing in the middle to lower dermis. Melanocytes appear in the dermis during the 10th week of gestation, and then either migrate into the epidermis or undergo cell death, except for melanocytes in the dermis of the scalp, extensor aspects of the distal extremities, and the sacral area. The latter is the most common site for dermal melanocytosis. The bluish coloration of dermal melanocytosis results from the Tyndall phenomenon: dermal pigmentation appears blue because of decreased reflectance of light in the longer-wavelength region compared with the surrounding skin. Longer wavelengths, such as red, orange and yellow, are not reflected, compared with the shorter wavelengths of blue and violet, which are reflected[27].

Clinical Features

The classic location is the sacrococcygeal and lumbar regions and the buttocks, followed by the back (Fig. 112.8). Dermal melanocytosis may consist of a single or multiple patches and usually involves <5% of the body surface area. The lesions are macular and have a round, oval or angulated shape. The size varies from a few to more than 20 cm. The color varies from light blue to dark blue to blue–gray. Extrasacral (aberrant) variants tend to be more persistent and there is overlap amongst persistent and adult-onset dermal melanocytoses, nevus of Ito and patch blue nevus. Extensive dermal melanocytosis should raise the possibility of phakomatosis pigmentovascularis types II and IV (see Ch. 104). When CALM and satellite congenital melanocytic nevi reside within areas of dermal melanocytosis, there may be a rim that lacks dermal melanocytes around each lesion (see Fig. 112.8).

Pathology

Bipolar dendritic melanocytes are dispersed singly in the lower half or two-thirds of the dermis. These melanocytes are DOPA-positive and lie parallel to the epidermis between the collagen bundles without disturbing the normal architecture of the skin. Occasionally, persistent dermal melanocytosis has the histology of a blue nevus with involvement of the subcutis, muscle and fascia by melanocytes. On electron microscopy, dermal melanocytosis shows fully developed melanocytes with exclusively mature, electron-dense melanosomes and very few premelanosomes.

Fig. 112.8 Dermal melanocytosis (Mongolian spots) in a child with neurofibromatosis 1. Surrounding each café-au-lait macule there is an absence of the characteristic blue discoloration.

Differential Diagnosis

The differential diagnosis of dermal melanocytosis includes primarily nevus of Ota (if there is facial involvement), nevus of Ito, and patch blue nevus. The latter has many names in the literature, including dermal melanocyte hamartoma, acquired dermal melanocytosis and acquired linear dermal melanocytosis; clearly there is overlap with the rare adult-onset dermal melanocytosis. The differential diagnosis also includes venous malformations or deep hemangiomas and a contusion. Although the distinctive clinical presentation of dermal melanocytosis generally allows easy distinction from these entities, there have been reports of the misdiagnosis of child abuse.

Treatment

Persistent lesions may be treated with cover-up cosmetics or lasers (see nevus of Ota).

NEVUS OF OTA AND RELATED CONDITIONS

Synonyms:
- Nevus of Ota: • Nevus fuscoceruleus ophthalmomaxillaris
- Oculodermal melanocytosis • Congenital melanosis bulbi
- Oculomucodermal melanocytosis
- Nevus of Ito: • Nevus fuscoceruleus acromiodeltoideus
- Nevus of Ota-like macules: • Hori's nevus

Key features

- Blue–brown unilateral or occasionally bilateral facial patch
- More common in Asians and blacks
- More dermal dendritic melanocytes than in congenital dermal melanocytosis, but less than in blue nevus

Epidemiology

Nevus of Ota occurs predominantly in more darkly pigmented individuals, especially in Asians and blacks, but has also been described in Caucasians as well[28,29]. Approximately 80% of all reported cases have been in women; however, this figure may be somewhat skewed as a result of greater cosmetic concerns in women. In Japan, nevus of Ota is seen in ~0.4–0.8% of all dermatologic patients. The lesion has two peaks of onset: the first (~50–60% of all cases) during infancy (before the age of 1 year), with the majority present at birth, and the second (40–50%) around puberty. Onset between the ages of 1 and 11 years and after 20 years is unusual. Although rare familial forms of nevus of Ota have been reported, the condition is generally not considered hereditary.

Pathogenesis

The blue to blue–gray color in nevus of Ota is due to melanin-producing melanocytes in the dermis. The larger concentration of melanocytes in nevus of Ota in comparison with congenital dermal melanocytosis is thought to indicate a hamartoma. The possibility of a hormonal influence in women has been raised. Somatic activating mutations in *GNA11* and *GNAQ* were detected in up to 15% of cases of nevus of Ota, as compared to 65–75% of blue nevi (primarily *GNAQ*) and 83% of primary uveal melanomas[30]. Both of these genes encode α-subunits of G proteins (see Ch. 65). In mice, germline mutations that increase the activity of closely related GTPases lead to an increase in dermal pigmentation.

Clinical Features

Nevus of Ota is usually characterized by a confluence of individual macules varying from pinhead-sized to several millimeters in diameter. The shape of the individual macules may be round, oval or serrated, whereas the overall appearance is that of an irregularly demarcated and often mottled patch. The overall size varies from a few centimeters to extensive unilateral and occasionally bilateral involvement (Fig. 112.9). The color varies from shades of tan and brown to gray, blue, black and purple.

Nevus of Ota is usually unilateral and favors the distribution of the first two branches of the trigeminal nerve. The periorbital area, temple, forehead, malar area, earlobe, pre- and retroauricular regions, nose and conjunctivae are the most common sites of involvement. A characteristic feature, which is seen in about two-thirds of patients, is the involvement of the ipsilateral sclera; rarely, nevus of Ota affects the cornea, iris, fundus oculi, retrobulbar fat, periosteum, retina and optic nerve. Iris mammillations and glaucoma (~10% of patients)[31] have been reported, but vision is usually not impaired. Other frequent sites of involvement are the tympanum (55%), nasal mucosa (30%), pharynx (25%) and palate (20%). Occasionally, the external auditory canal, mandibular area, lips, neck and thorax are involved. In 5% to 15% of patients, the lesion is bilateral.

Fig. 112.9 Nevus of Ota (oculodermal melanocytosis). Unilateral blue–gray discoloration of the face, which is either mottled or confluent. There is also involvement of the sclera.

Nevus of Ota may extend over time and it persists for life. Fluctuations in the intensity of the color have been described, especially in association with periods of hormonal flux such as menstruation, puberty or menopause.

Malignancies arising within nevi of Ota are rare, estimated at 1 in 400 in Caucasians. As of 2010, eleven cases of cutaneous melanoma arising within a nevus of Ota had been reported in the literature[32,33]. These typically presented in Caucasian patients as new subcutaneous nodules and did not adhere to the ABCD rules of melanoma. Other tumors such as atypical and borderline cellular blue nevi also have been described[33,34]. Multiple examples of primary melanoma of the choroid, orbit, iris, chiasma and meninges have been observed in association with nevus of Ota that exhibited eye involvement. It is one of the entities that can have associated neuromelanosis.

Related conditions

Nevus of Ito differs from nevus of Ota primarily in its area of involvement; the former corresponds to the distribution of the posterior supraclavicular and lateral cutaneous brachial nerves (which encompasses the supraclavicular, scapular and deltoid regions). The clinical and histologic picture is the same as in nevus of Ota. There is a mottled appearance with bluish and brownish macules. Nevus of Ito may occur as an isolated lesion or in association with an ipsilateral or bilateral nevus of Ota. *Acquired nevus of Ota-like macules* (Hori's nevus) are characterized by bilateral blue–gray to gray–brown macules of the zygomatic area (less often the forehead, upper outer eyelids and nose). Primarily Chinese or Japanese women ranging in age from 20 to 70 years have been reported with this condition. The eye and oral mucosa are not involved. It may also be misdiagnosed as melasma. A *patch blue nevus*, which overlaps with the rare adult-onset dermal melanocytosis, presents as a diffusely gray–blue area that may have superimposed darker macules. The age of onset and sites of involvement vary, with some lesions having a linear distribution.

Pathology

The non-infiltrated areas in nevus of Ota show pigmented, elongated, dendritic melanocytes scattered among the collagen bundles. In comparison with dermal melanocytosis, the cells are more numerous and are located in the upper third of the reticular dermis. Occasionally, cells are found in the papillary dermis or even deep in the subcutaneous fat.

Hypermelanosis of the lower epidermis and an increase in basilar melanocytes may occur. The DOPA reactivity of the melanocytes in nevus of Ota varies: slightly pigmented cells are often strongly reactive, whereas heavily pigmented melanocytes often are not reactive, indicating minimal residual enzymatic activity. Melanocytes can be found clustering around blood vessels and sweat and sebaceous glands; occasionally, they are seen within vessel walls or in sweat ducts. Raised or infiltrated areas show a larger number of dendritic melanocytes forming cellular aggregates or clumps resembling blue nevi histologically.

Differential Diagnosis

The differential diagnosis of nevus of Ota and related conditions includes congenital dermal melanocytosis (Mongolian spot), adult-onset dermal melanocytosis, blue nevus (patch or plaque), melasma, partial unilateral lentiginosis (when it involves the face), a nevus spilus that develops blue nevi, venous malformations and ecchymosis. Congenital dermal melanocytosis differs from nevus of Ota and other dermal melanocytoses due to its location in the lumbosacral region and its spontaneous regression during childhood.

Treatment

Nevus of Ota and nevus of Ota-like macules have been treated successfully by Q-switched ruby, alexandrite and Nd:YAG lasers[35,36]. Although malignant changes are rare in patients with nevus of Ota, patients with eye involvement should be followed more carefully by an ophthalmologist, since the majority of associated melanomas are ocular in origin and some patients develop glaucoma. Suspicious lesions, especially a new subcutaneous nodule, should be biopsied. Any complaint of neurologic symptoms requires further investigation.

BLUE NEVUS AND ITS VARIANTS

Synonyms: ■ Blue nevus of Jadassohn–Tièche ■ Nevus bleu ■ Blue neuronevus ■ Dermal melanocytoma

Key features

- Blue to blue–black firm papule, nodule or plaques, often with an onset during childhood or adolescence
- Aggregates of dermal, dendritic, heavily pigmented melanocytes

Epidemiology

Blue nevi are usually acquired with an onset during childhood or adolescence, although up to a quarter arise in middle-aged adults. A congenital common blue nevus is unusual but approximately 25% of cellular blue nevi are congenital.

Pathogenesis

Blue nevi represent benign tumors of dermal melanocytes[37–45]. In general, melanocytes disappear from the dermis during the second half of gestation, but some residual melanin-producing cells remain in the scalp, sacral region, and dorsal aspect of the distal extremities. These are the sites where blue nevi most commonly occur. The blue coloration of these nevi is the result of the Tyndall phenomenon (see above). As noted previously, somatic activating mutations in *GNA11* and *GNAQ* (primarily the latter) have been detected in 65–75% of blue nevi. As a consequence, the intrinsic GTPase activity of encoded α-subunits is blocked and the G protein becomes locked in a GTP-bound, constitutively active state[30].

Clinical Features

Common blue nevi

Common blue nevi are well-circumscribed, dome-shaped papules that are blue, blue–gray or blue–black in color (Fig. 112.10A). They are usually 0.5 to 1.0 cm in diameter, rarely larger. The lesions may occur anywhere, but about 50% are found on the dorsal aspect of the hands and feet, with the face and scalp being other common sites. Blue nevi have been described in the vagina, cervix, prostate, spermatic cord and lymph nodes. Over time, hypopigmentation can appear centrally within common blue nevi.

Usually, blue nevi are solitary, but they may be multiple or agminated or may arise with a nevus spilus or plaque blue nevus. Concentric, target-like lesions (target blue nevus) have been described as well. Dermoscopically, a blue nevus is characterized by homogeneous blue–gray to blue–black pigmentation (see Ch. 0).

Cellular blue nevi

Cellular blue nevi are blue to blue–gray or black nodules or plaques, generally 1 to 3 cm in diameter but sometimes larger (Fig. 112.11A)[37–39]. Their surface is often smooth but sometimes irregular. The most common sites are the buttocks, sacrococcygeal area and scalp, followed by the face and feet. Congenital cellular blue nevi, some with satellite lesions, have been reported, as have benign or malignant cellular blue nevi arising within congenital melanocytic nevi. The ratio of common blue nevus to cellular nevus is at least 5:1.

Epithelioid blue nevi

Epithelioid blue nevi were first reported as a feature of the Carney complex (see Table 112.2); however, they also may occur sporadically[46]. These lesions have a predilection for the trunk and extremities and rarely develop on orogenital mucosa. Histologically, they may be indistinguishable from pigmented epithelioid melanocytoma.

Pigmented epithelioid melanocytoma

This somewhat controversial term has been proposed as one that unifies epithelioid blue nevi (described above) and lesions previously reported as "animal-type", "melanophagic" or "pigment synthesizing" melanomas. The latter are characterized by marked melanin production and a resemblance to certain melanizing tumors in animals[47]. The lesions seem to have a low-grade potential for regional metastases, but rarely non-regional metastases; they almost never result in overt malignant behavior and death of patients. In one study, all eight epithelioid blue nevi that arose in patients with Carney complex (with confirmed *PRKAR1A* mutations) showed loss of expression of protein kinase

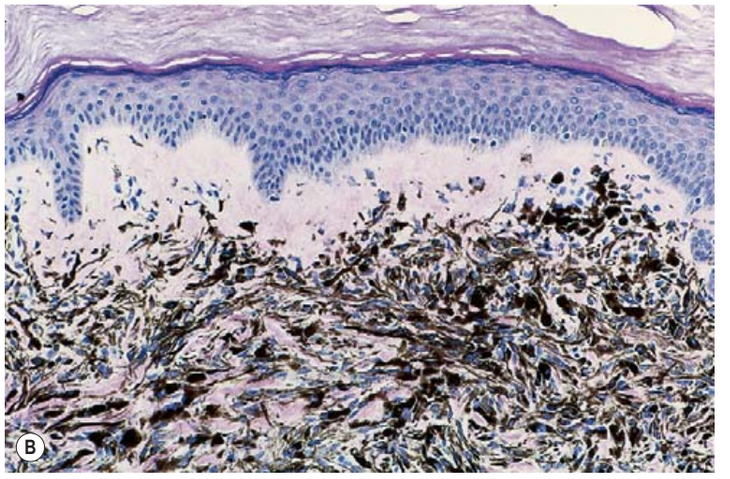

Fig. 112.10 Common blue nevus. **A** A well-circumscribed, blue, dome-shaped papule. **B** Histologically, there are heavily pigmented, spindle-shaped melanocytes as well as melanophages within the dermis; the melanocytes are denser than in dermal melanocytosis or nevus of Ota.

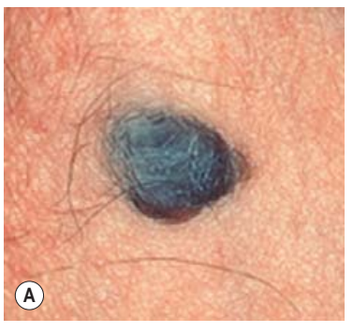

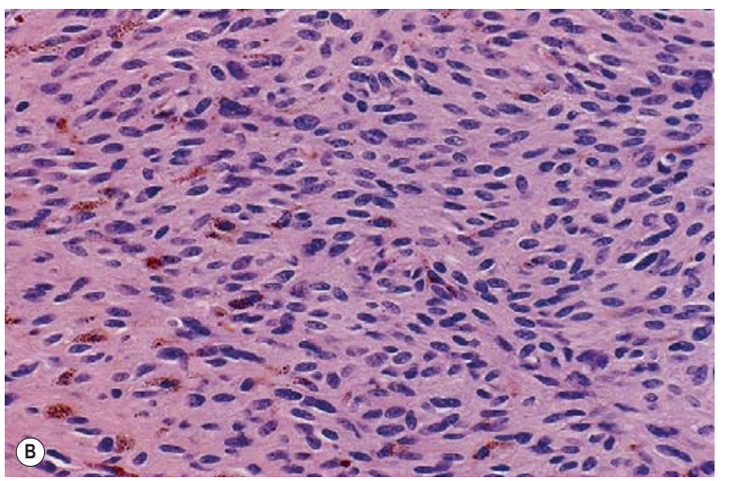

Fig. 112.11 Cellular blue nevus. **A** A firm blue plaque is a common presentation. **B** Histologically, there are plump spindled melanocytes devoid of melanin pigment and arranged within bundles. *A, Courtesy, Jean L Bolognia, MD.*

A regulatory subunit 1-α (the product of *PRKAR1A*) as did 28 (82%) of 34 sporadic pigmented epithelioid melanocytomas, suggesting a relationship[48].

Malignant blue nevi (cutaneous melanoma arising in or having features of blue nevus)

Malignant blue nevi are rare forms of cutaneous melanoma most commonly arising within cellular blue nevi[45,49]. They tend to show progressive enlargement, often measuring several centimeters in diameter, and have a multinodular or plaque-like appearance. The scalp is the most common site of occurrence and lymph nodes are the most common sites of metastasis. Malignant blue nevi can arise in a previously benign cellular blue nevus, in a nevus of Ota or Ito, or *de novo*.

Pathology

The *common* or *ordinary blue nevus* is composed of elongated and often slightly wavy melanocytes with long, branching dendrites (Fig. 112.10B). The melanocytes, with their long axes parallel to the epidermis, lie grouped or in bundles in the upper and mid dermis. Occasionally, they extend into the subcutaneous tissue or approach the epidermis, but do not alter it. Most of the melanocytes are filled with numerous fine melanin granules, often completely obscuring their nuclei as well as extending into their dendrites. Variable numbers of melanin-laden macrophages are also present. The amount of collagen is usually increased, giving the lesion a fibrotic appearance.

In the *cellular blue nevus*, one often observes deeply pigmented dendritic melanocytes (as in a common blue nevus) in addition to nests and fascicles of spindle-shaped cells with abundant pale cytoplasm containing little or no melanin (Fig. 112.11B). The aggregates of spindle cells may be arranged in intersecting bundles extending in various directions, a disposition resembling the storiform pattern of neurofibroma. Penetration of rounded, well-defined cellular islands into subcutaneous tissue is frequently noted. Some of the cells may appear atypical, with nuclear pleomorphism accompanied by multinucleated giant cells, rare mitoses and inflammatory infiltrates.

Occasionally, lymph nodes draining the anatomic site of a cellular blue nevus contain atypical cells. The foci, found either in the marginal sinuses or in the capsule, are usually small, discrete and peripherally located. They may result from passive transport or represent arrested migration from the neural crest. These "benign metastases" are found in 5% of the reported cases of cellular blue nevi. Electron microscopy reveals that the spindle-shaped cells in cellular blue nevi contain melanosomes with little or no melanization. Melanin production in these cells and a transition to bipolar dendritic nevus cells have been documented.

Atypical cellular blue nevi demonstrate one or more of the following features compared to conventional cellular blue nevi: larger size (e.g. >1–2 cm), asymmetry, ulceration, infiltrating features, cytologic atypia, mitoses and necrosis[50–52]. Such lesions have been associated with lymph node metastases and evolution to frank melanoma. These lesions require further study since their biologic potential is difficult to predict.

Epithelioid blue nevi and *pigmented epithelioid melanocytomas* are typified by dermal (and sometimes junctional) aggregates of enlarged epithelioid melanocytes often containing coarsely granular melanin pigment and prominent nucleoli. These cells are often admixed with heavily pigmented spindled and dendritic melanocytes as well as melanophages. Cytologic atypia and dermal mitoses may be present.

Differential Diagnosis

The differential diagnosis of a common blue nevus includes traumatic tattoo, combined nevus, vascular lesions including venous lake and angiokeratoma, sclerosing hemangioma, primary and metastatic melanoma, atypical nevus, pigmented spindle cell nevus, dermatofibroma, papular pigmented basal cell carcinoma and glomus tumor. For cellular blue nevus, especially with satellitosis, malignant blue nevus needs to be considered, and when the lesion is on the face, nevus of Ota. Blue nevi also need to be distinguished from a cutaneous neurocristic hamartoma, a complex proliferation of nevus cells, Schwann cells, and pigmented dendritic and spindled cells. Histologically, epithelioid blue nevi and pigmented epithelioid melanocytomas must be differentiated from primary or metastatic melanoma as well as tumoral melanosis due to complete or almost complete regression of melanoma.

Treatment

Blue nevi that are <1 cm in diameter, are clinically stable, do not have atypical features and are located in a typical anatomic site do not require removal. On the other hand, histologic evaluation should be strongly considered for lesions that appear *de novo*, are multinodular or plaque-like, or have undergone change. Atypical cellular blue nevi and pigmented epithelioid melanocytomas should be resected completely in order to prevent recurrence and because of their risk for malignant transformation or metastases. The approach to typical cellular blue nevi varies, but if observation is difficult (e.g. lesions on the scalp), excision can be considered.

COMMON ACQUIRED MELANOCYTIC NEVI

Synonyms: ■ Nevocellular nevus ■ "Mole"

Key features

- A junctional nevus is a brown to black macule with melanocytic nests at the junction of the epidermis and dermis
- An intradermal nevus is a skin-colored or light brown papule with nests of melanocytes in the dermis
- A compound nevus is a brown papule with combined histologic features of junctional and intradermal nevi

Epidemiology

The prevalence of melanocytic nevi is related to age, race, and perhaps genetic and environmental factors. A few nevi are present in early childhood, but their number then increases, reaching a peak during the third decade of life; thereafter, nevi tend to disappear with increasing age[53–55]. There is a period of particularly rapid development of nevi at puberty. A study in Scotland noted that, in the first decade of life, females had an average of three nevi and males two nevi. For the peak age interval 20 to 29 years, women and men had mean nevu counts of 33 and 22, respectively. Reflecting the progressive decline thereafter, women had a mean of six nevi and men four nevi in the seventh decade of life.

Caucasians in general have greater numbers of nevi than do darker-skinned populations, i.e. African-Americans and Asians. Furthermore, a greater prevalence of nevi is associated with lighter skin color in whites, with a peak in nevi number in those with skin phototype II. The frequency of melanocytic nevi (includes lentigines) on the palms and soles, nail beds and conjunctivae is also related to race; nevi on these surfaces are more prevalent in blacks and Asians than in whites. The mean acral nevus count for Africans in Uganda was 11, versus 2 to 8 for African-Americans.

Genetic factors may be operative in the prevalence of nevi: increased numbers of nevi have been shown to cluster in families, especially in those with familial melanoma. Although an autosomal dominant mode of inheritance has been postulated for clinically atypical nevi in hereditary melanoma families, the pattern of inheritance may be more complex. Environmental factors such as sun exposure influence the development of melanocytic nevi. However, genetic factors seem to directly determine an individual's potential for the development of melanocytic nevi, and the final expression of this potential is influenced by solar exposure. In addition, individuals appear to inherit different propensities for nevogenesis[55].

Pathogenesis

Melanocytic nevi are thought to originate from neural crest stem cells that migrate from the neural crest to the epidermis. Nevi are hypothesized to result from the proliferation of slightly altered melanocytes or "nevus cells" within the epidermis, producing junctional nevi. It is

TRIGGERS FOR THE DEVELOPMENT AND/OR GROWTH OF MELANOCYTIC NEVI
LIGHT EXPOSURE
• Sun exposure leading to multiple or severe sunburns* • Intermittent intense sun exposure (e.g. on sunny holidays) • Chronic moderate sun exposure (e.g. residence at lower latitudes) • Neonatal phototherapy
CUTANEOUS INJURY
Blistering processes (other than severe sunburns) • Toxic epidermal necrolysis/Stevens–Johnson syndrome* • Epidermolysis bullosa – junctional (particularly generalized atrophic benign) > recessive dystrophic > recessive simplex* • Bullae secondary to sulfur mustard (mustard gas) exposure*
Severe sunburn*
Scarring processes • Lichen sclerosus†
SYSTEMIC IMMUNOSUPPRESSION
• Chemotherapy, particularly for childhood hematologic malignancies*,†,‡ • Allogeneic bone marrow transplantation‡ • Solid organ transplantation, particularly renal*,‡ • HIV infection/AIDS* • Chronic myelogenous leukemia* • TNF inhibitor therapy*,‡ • Cyclosporine*
INCREASED HORMONE LEVELS
• Pregnancy*,§ • Growth hormone (increased size, not number, of nevi) • Addison's disease* • Thyroid hormone* • α-Melanocyte stimulating hormone analogue*
OTHER
• Sorafenib* • Atopic dermatitis in children (conflicting results in different studies) • Postoperative fever* • Seizures or electroencephalographic abnormalities*
*Eruptive nevi have been reported. †An increased number of atypical nevi may also be seen. ‡Nevi have a predilection for the palms and soles. §Relative immunosuppression may also play a role; an increase in the size or number of nevi has not been clearly demonstrated for pregnant women in general.

Table 112.3 Triggers for the development and/or growth of melanocytic nevi. TNF, tumor necrosis factor. *Adapted from Schaffer JV, Bolognia JL. The biology of melanocytic nevi. In: Nordlund JJ, Boissy RE, Hearing VJ, et al. (eds). The Pigmentary System: Physiology and Pathophysiology, 2nd edn. Oxford: Blackwell Publishing, 2006;1092–125.*

Fig. 112.12 Acquired melanocytic nevi. **A** Junctional nevus – dark brown macule with lighter brown rim. **B** Compound nevus – light to medium brown papule. **C** Intradermal nevus – soft light pink papule.

believed that such nevus cells subsequently migrate into the dermis, giving rise to compound nevi and ultimately dermal nevi when there are no longer residual nevus cells within the epidermis. Nevi are thought to be either developmental malformations (hamartomas) or benign proliferations with some growth advantage over surrounding basilar melanocytes. Of note, subclinical nests have been described in normal-appearing skin.

Factors leading to the onset of melanocytic nevi are poorly understood but could include the genetic influences alluded to earlier and environmental agents, principally UV exposure (Table 112.3). As in melanomas arising in sites of intermittent sun exposure, somatic mutations in *BRAF* are often detected in common acquired melanocytic nevi, including intradermal nevi, with *NRAS* mutations present in a small minority of acquired nevi[56]. In nevi, the *BRAF* mutations are thought to induce senescence.

Clinical Features

Melanocytic nevi are well-circumscribed, round to ovoid lesions, generally measuring from 2 to 6 mm in diameter. They appear orderly and symmetric overall. Although many nevi display slight asymmetry, the borders are usually regular and well defined. The junctional nevus is a macular lesion with slight accentuation of skin markings visible with side-lighting. Junctional nevi are also characterized by a uniform, medium to dark brown color (Fig. 112.12A). The dermoscopic features of a junctional nevus include a uniform pigment network thinning out towards the periphery (see Tables 0.12 & 0.13) (Fig. P2). Compound nevi show variable degrees of elevation and in general somewhat lighter shades of brown than do junctional nevi (Fig. 112.12B). Dermoscopically, they are characterized by a globular architecture with multiple round to ovoid globules sometimes forming a cobblestone pattern (see Ch. 0). Dermal nevi (Fig. 112.12C) are usually more elevated and show lighter shades of brown or even skin-colored tones compared with compound nevi. The dermoscopic features of an intradermal nevus predominantly consist of focal globules or globular-like structures. In addition, there may be pale to whitish structureless areas and fine linear or comma vessels (Fig. P3).

In addition to clinical and dermoscopic overlap amongst all three types of nevi, dermal nevi (and to a lesser degree compound nevi) may be papillomatous with pseudo-horn cysts. Nevi, especially acquired "congenital-appearing" nevi, contain hairs that are coarse and dark compared with those in surrounding skin. Nevi of the palms and soles are often macular or only slightly raised, have regular and well-defined borders, and show uniform or linear brown coloration (see below).

Melanocytic nevi of the nail matrix usually present as uniformly pigmented brown to dark brown longitudinal bands (melanonychia striata) with regular and distinct margins (see Ch. 71).

An important aspect of melanocytic nevi is their relationship to melanoma. A significant proportion of melanoma patients report the prior presence of a longstanding melanocytic nevus at the site of melanoma development. Histologic studies also have documented that approximately one-third of melanomas are associated with nevus remnants (but this figure is probably lower nowadays because of the increased incidence of lentigo maligna melanoma which rarely demonstrates an associated nevus). An increased number of melanocytic nevi correlates with increased melanoma risk.

Melanocytic nevi associated with epidermolysis bullosa

Distinctive melanocytic nevi termed "epidermolysis bullosa (EB) nevi" or "EB nevi" may develop at the sites of antecedent bullae or erosions primarily in patients with forms of EB that are recessively inherited[57]. These nevi can have a strikingly large size (up to 3 cm) as well as asymmetry, border irregularity, dark color, and satellitosis. Their development may be related to repetitive disruption of the basement membrane zone with the promotion of nevus cell proliferation or the dispersion of nevus cells into the blister cavity with their subsequent proliferation in its floor. To date, there are no reports of cutaneous melanoma developing at the sites of EB nevi, but longitudinal observation is warranted.

Melanocytic nevi associated with lichen sclerosus

Occasionally, melanocytic nevi develop in sites of genital lichen sclerosus[58,59]. The lesions are often dark brown to black in color, irregular in outline and can measure ≥6 mm. As a result, the possibility of melanoma is frequently considered and histologic distinction is not always simple.

Pathology

Melanocytic nevi contain intraepidermal or dermal collections of nevus cells or both (Fig. 112.13). The cells within the junctional nests have round, ovoid or fusiform shapes and are arranged in cohesive nests; with the exception of unusual amelanotic variants, these cells contain melanin. In the superficial dermis, the cells in general have epithelioid cell characteristics and contain amphophilic cytoplasm and, frequently, granular melanin. The nuclei have uniform chromatin with a slightly clumped texture. Deeper in the dermis, there is a diminished content of cytoplasm, such that the cells resemble lymphocytes; they are frequently arranged in linear cords. There may be a further transition to cells separated by fine connective tissue and assuming a spindled configuration, similar to fibroblasts or Schwann cells.

EB nevi are best considered exaggerated variants of recurrent/persistent melanocytic nevi (see below). Thus they usually exhibit asymmetry and considerable variation in the overall architecture of the nevus, including the junctional nests. Pagetoid melanocytosis and cytologic atypia may be present, as well as fibroplasia, a lymphocytic infiltrate, and melanophages.

In *melanocytic nevi associated with lichen sclerosus* (LS), the features of a genital nevus are superimposed on the changes of LS, which can vary from subtle to obvious. Irregular and confluent junctional nests are often accompanied by cytologic atypia. The changes of LS may suggest regression, and if the inflammatory component is significant, it may hinder assessment of the nevus cells. Findings that favor a genital nevus (rather than melanoma) include a diameter <5 mm, symmetry, sharp circumscription, nests predominantly at the dermal–epidermal junction, low-grade cytologic atypia of melanocytes, a conventional dermal nevus component, an absence of significant dermal mitoses, and limitation of the nevus to the area of LS.

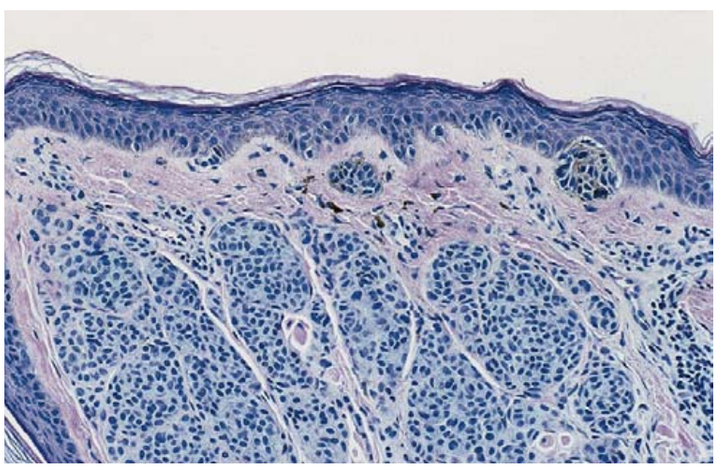

Fig. 112.13 Histology of a compound nevus. Nests of melanocytes within the dermis and at the dermal–epidermal junction. *Courtesy, Ronald P Rapini, MD.*

Differential Diagnosis

The differential diagnosis of melanocytic nevi includes the entire gamut of pigmented and skin-colored lesions (see Ch. 0). Raised nevi, potentially confused with seborrheic keratoses, are less likely to have a verrucoid surface and pseudo-horn cysts and dermoscopy can assist in the distinction. Dermatofibromas are usually differentiated from nevi by their very firm consistency, "dimpling" with lateral compression, preference for the lower extremities, and central white patch by dermoscopy. Both neurofibromas and fibroepithelial polyps may be indistinguishable from skin-colored or slightly pigmented, pedunculated dermal nevi. In general, typical melanocytic nevi are distinguishable from atypical nevi and melanoma by smaller size, overall symmetry and orderly appearance, homogeneous coloration, and regular, well-defined borders. Furthermore, red, blue, gray and black colors are not usually seen in common acquired nevi and should alert one to a potentially atypical lesion.

Treatment

Indications for removing melanocytic nevi are as follows: (1) a changing lesion; (2) atypical clinical appearance suspicious for melanoma; (3) repeated irritation; and (4) cosmetic concerns. Beyond these indications, there is no reason to remove nevi on a routine basis.

MELANOCYTIC NEVI OF GENITAL AND FLEXURAL SKIN

Key feature

- Nevi in "special sites", including genitalia, sometimes have atypical histologic changes, making distinction from melanoma difficult

Clinical Features

Melanocytic nevi occurring in genital sites, especially the vulva, are thought to have rather distinctive histopathologic features compared to most nevi from non-genital sites[60–62]. However, similar nevi may occur in other locations such as the scrotum, perineum, umbilicus or axilla[62]. In general, premenopausal women (ages 14 to 40 years) present with this type of vulvar lesion[60]. These nevi appear to be uncommon, perhaps accounting for <10% of nevi removed, but data could be biased by selection factors. In a series of 36 cases, more than half of the nevi were macular clinically, with the remainder elevated. These nevi are often larger in size (mean 5.9 mm, range of about 2–24 mm) than non-genital ordinary nevi, usually have fairly regular borders, and often have a complex mahogany color, i.e. an admixture of tan, brown and red[61].

Pathology

In general, these nevi are characterized by an overall symmetry and a frequent absence of lateral extension of intraepidermal melanocytic components beyond the dermal nevus elements (if present), and they are well circumscribed[60–62]. Many have a mushroom-like polypoidal morphology, with the rather distinctive junctional elements overlying a prominent dermal nevus component. Notably, there are architectural and cytologic features similar to atypical melanocytic nevi.

Differential Diagnosis

The differential diagnosis includes primarily melanoma, Spitz nevus, and nevi associated with genital LS (see above). Vulvar melanoma tends to occur in older women (average age ~65 years).

MELANOCYTIC NEVUS OF ACRAL SKIN

Synonyms: ■ Melanocytic nevus with intraepidermal ascent of cells (MANIACS) ■ Acral nevus

Key feature

- About one-third of acral nevi have intraepidermal upward migration of melanocytes and other architectural changes that can resemble melanoma

Clinical Features

Acral nevi are usually macular or only slightly elevated. They may display uniform brown or dark brown color, but often have linear striations (Fig. P4). The characteristic dermoscopic features of benign melanocytic nevi of the palms and soles are due to the unique anatomy of acral skin. The palms and soles consist of parallel ridges (mountains) and furrows (valleys). The intraepidermal eccrine ducts pass through the ridges (Fig. 112.14). In benign melanocytic nevi, the nests of nevus cells are situated around the furrows. The three major dermoscopic patterns seen in benign melanocytic nevi are the parallel furrow (Fig. 112.15), the lattice-like (see Fig. P4), and the fibrillar pattern (Table 112.4)[63].

Pathology

Acral nevi are usually relatively small (<5–6 mm), well-circumscribed and symmetric compound nevi. On occasion, the junctional nests are somewhat enlarged, but they usually have a fairly uniform round or oval shape and are similar in size and spacing. Lentiginous melanocytic proliferation and some degree of upward migration of melanocytes are features commonly observed in acral nevi [64–66]. One should be cautious in over-interpreting the latter changes unless prominent architectural disorder and cytologic atypia are also present. The dermal component of acral nevi is often characterized by round nests of type A cells.

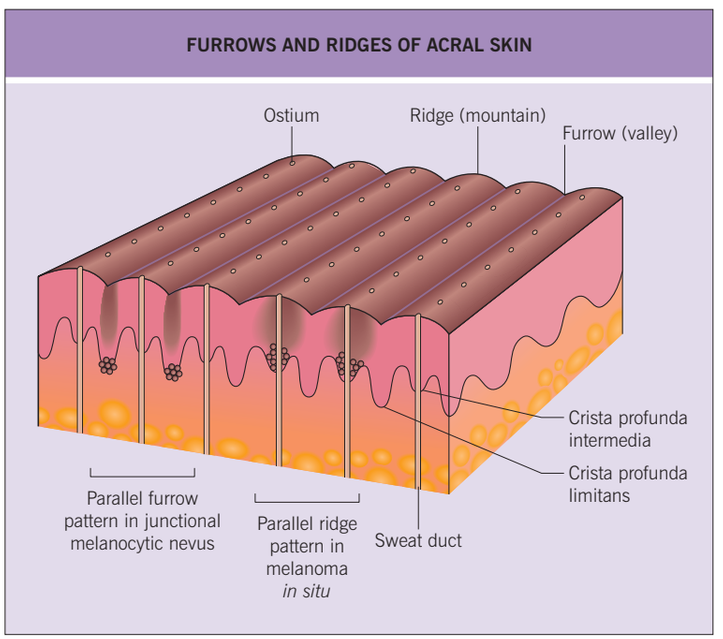

Fig. 112.14 Furrows and ridges of acral skin.

SPITZ (SPINDLE AND EPITHELIOID CELL) NEVUS/TUMOR

Synonyms: ■ Spitz's juvenile melanoma ■ Benign juvenile melanoma

Key features

- Red or pigmented papule or nodule, usually in children or young adults
- Prominent epithelioid and/or spindled melanocytes
- Mimic of melanoma histologically

Epidemiology

The prevalence of Spitz nevus in the general population has not been accurately documented[67,68]. However, among melanocytic lesions that have been surgically excised, approximately 1% exhibit the histologic characteristics of Spitz nevus. In data from Australia, it has been estimated that Spitz nevus accounts for 1.4 cases per 100 000 population, as compared with an annual incidence of 25.4 melanomas per 100 000 population. The vast majority of Spitz nevi are acquired, but up to 7% may be congenital. Spitz nevi occur in all age groups but are uncommon beyond 40 to 50 years of age. In the series of Weedon and Little[67], 36% of the individuals with Spitz nevi were under the age of 10 years, 33% were between the ages of 10 and 20 years, and 31% were older than 20 years of age. There is no gender predilection.

Pathogenesis

No particular etiologic factors that might account for the characteristic histologic changes found in Spitz nevi have been identified (see below regarding chromosome 11p). Widespread eruptive Spitz nevi have been associated with HIV infection, Addison's disease, chemotherapy, pregnancy, puberty and trauma, many of the same triggers as for common acquired nevi (see Table 112.3). The eruption of Spitz nevi with pregnancy and puberty suggests that dormant nevi may become hormonally activated. Many Spitz nevi, however, have no identified precipitating cause. To date, mutations in *BRAF* have not been detected in Spitz nevi,

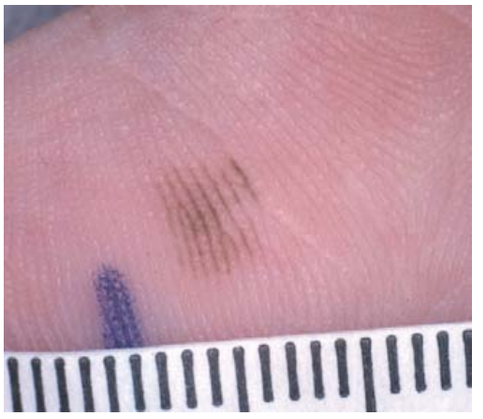

Fig. 112.15 Acral melanocytic nevus. The parallel furrow pattern is evident with a small focus of the lattice pattern. The ostia of the eccrine ducts within the epidermal ridges can also be seen, especially at the site of blue ink. *Courtesy, Jean L Bolognia, MD.*

ACRAL NEVI – COMMON DERMOSCOPIC PATTERNS	
Pattern	**Dermoscopy features**
Parallel furrow (most common)	Parallel rows of linear pigmentation along furrows/valleys (sulci of the surface skin markings; see Figs 112.14 & 112.15)
Lattice-like	Parallel furrows plus lines of pigmentation crossing the parallel lines (see Fig. P4)
Fibrillar	Densely packed, fine parallel lines of pigmentation, often set in a direction that crosses the skin markings

Table 112.4 Acral nevi – common dermoscopic patterns.

Fig. 112.16 Spitz nevus. Red dome-shaped papule on the ear of a child. *Courtesy, Ronald P Rapini, MD.*

Fig. 112.17 Agminated Spitz nevi. The grouped papules have arisen on normally pigmented skin.

in contrast to common melanocytic nevi (e.g. dermal). Recently, two families with multiple epithelioid and atypical nevi were found to have inactivating germline mutations in *BAP1*, which encodes a ubiquitin carboxy-terminal hydrolase[67a].

Clinical Features

Spitz nevi vary in size from 2 mm to >2 cm, with an average diameter of ~8 mm[67–70]. Typically, they are well-circumscribed, dome-shaped papules or nodules varying in color from pink to tan to dark brown (Fig. 112.16). Generally, the color is homogeneous and the margins are well defined. The surface topography may be smooth or, in some instances, verrucous. Relatively flat, polypoid and pedunculated morphologies have also been described. Occasional lesions may have erosions and scale-crust while others may be firm due to sclerosis and resemble dermatofibromas (i.e. desmoplastic)[71–73]. Telangiectasia is a frequent finding.

Although Spitz nevi may involve any part of the body, the head and neck area is probably the most common site, accounting for 42% of lesions in one series. There is a rather even distribution of lesions over the remainder of the body. In most instances, there is a history of recent onset, but a small percentage of Spitz nevi have been present for many years. Multiple Spitz nevi may occur in an agminated (grouped) or disseminated pattern[74,75]. *Disseminated* Spitz nevi can number in the hundreds, erupt suddenly, and involve the entire integument except for the palms, soles and mucous membranes. The papules tend to be polymorphous, affect adults, and spontaneously regress over several years. To date, no case reports of malignant degeneration of grouped or disseminated Spitz nevi have been published, although disseminated Spitz nevi have been associated with seizures.

Agminated (grouped) Spitz nevi are characterized by varying numbers of individual, raised nevi occurring in a localized or segmental distribution, and arising in otherwise clinically normal skin (Fig. 112.17). There has been some confusion in the literature where lesions arising with a CALM-like tan background have been referred to as agminated Spitz nevi; however, these lesions would be better termed Spitz nevi within a nevus spilus (speckled lentiginous nevus). Solitary or multiple spindle and epithelioid cell proliferations developing within a large congenital nevus exhibit the features of typical Spitz nevi.

Pigmented spindle cell nevus (see below) is classified by some authors as a subtype of Spitz nevi.

Atypical Spitz nevi refer to lesions demonstrating one or more (usually a constellation of) features that deviate from conventional Spitz nevi[76]. The features may include: large size (e.g. >1 cm in diameter); asymmetry; deep involvement of the dermis or subcutis; ulceration; easily found dermal mitoses (>2–3 mitoses/mm^2), especially deep; significant pagetoid spread; prominent confluence and high cellular density of melanocytes in the dermis; and lack of maturation. A grading protocol for atypical Spitz nevi in childhood and adolescence has been formulated (Table 112.5)[77]. Studies utilizing comparative genomic hybridization and fluorescence *in situ* hybridization techniques have identified copy number increases of chromosome 11p, sometimes accompanied by *HRAS* mutations (*HRAS* is located on 11p), in subgroups of Spitz nevi[78]. Additional chromosomal abnormalities (e.g. gain of 1p) have been found in atypical Spitz tumors[78a]. However, more studies are needed before the identification of such genetic alterations can be used to predict the biologic behavior of Spitz nevi.

ASSESSMENT OF ATYPICAL SPITZ NEVUS (TUMOR) IN CHILDREN AND ADOLESCENTS FOR RISK FOR METASTASIS	
Parameter	**Score**
AGE (YEARS)	
0–10 (pre-pubertal)	0
11–17 (post-pubertal)	1
DIAMETER (mm)	
0–10	0

ULCERATION	
Absent	0
Present	2
MITOTIC ACTIVITY (per mm^2)	
0–5	0
6–8	2
≥9	5

Table 112.5 Assessment of atypical Spitz nevus (tumor) in children and adolescents for risk for metastasis. Total score and risk for metastasis: 0–2, low risk; 3–4, intermediate risk; 5–11, high risk.

Malignant or metastasizing Spitz nevi are exceedingly rare lesions with features of atypical Spitz nevi that have been reported to result in a single regional lymph node metastasis, but no subsequent disease progression. Since such lesions are only rarely encountered, they have not been sufficiently studied to know their biologic nature and how (and if) they differ from conventional melanomas.

Pathology

Typically, these lesions display striking nests of large epithelioid cells, spindle cells or both, usually extending from the epidermis into the reticular dermis in an inverted-wedge configuration. The closely apposed nests of cells within a uniformly hyperplastic epidermis often contribute to a so-called "raining-down" appearance (Fig. 112.18). Both mononuclear and multinucleate giant epithelioid cells are frequently observed. These cells extend into the subjacent dermis both as single

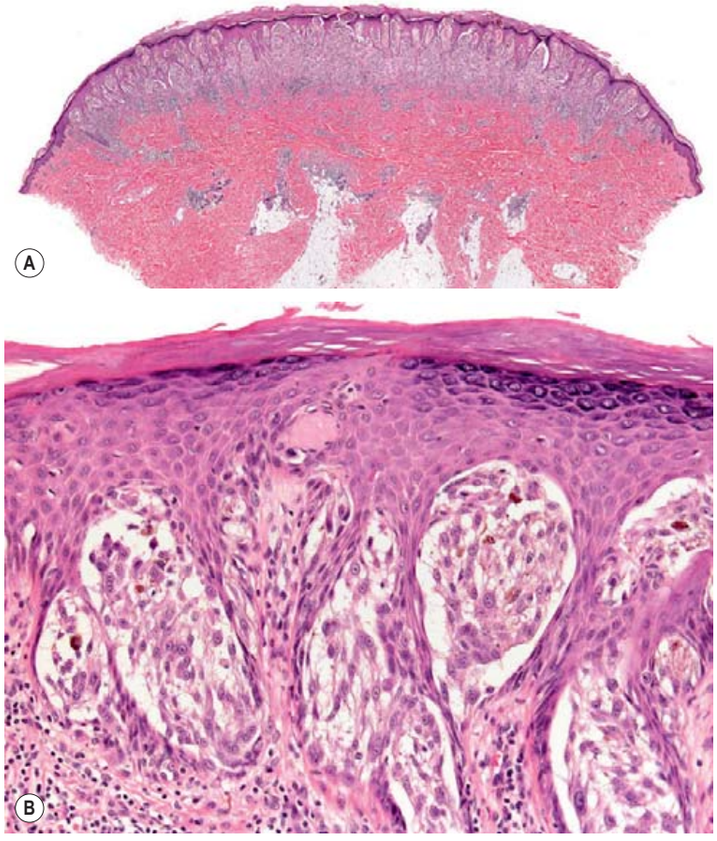

Fig. 112.18 Histology of Spitz nevus. A Dome-shaped with sharply demarcated and symmetric proliferation of spindled and epithelioid melanocytes at the dermo-epidermal junction and within the papillary dermis; there is also epidermal hyperplasia. **B** Nests of cohesive spindled and epithelioid melanocytes with clefts between the nests and the hyperplastic epidermis. *Courtesy, Lorenzo Cerroni, MD.*

cells and as nests or fascicles. In general, there is orderly infiltration of the dermal collagen by these nests or cells with so-called maturation, i.e. gradual diminution of nuclear and cellular sizes. The individual cells usually have abundant cytoplasm that stains slightly bluish or pink and nuclei with open chromatin patterns. Rather uniform nucleoli are usually also noted. Occasionally, bizarre cytologic features, necrotic cells and mitotic figures are found within even the most banal lesions.

Differential Diagnosis

The clinical differential diagnosis of Spitz nevi is wide and includes other melanocytic nevi, particularly dermal nevi, hemangiomas, pyogenic granuloma, verrucae, molluscum contagiosum, juvenile and adult xanthogranulomas, dermatofibroma, mastocytoma and adnexal tumors. The fundamental diagnostic problem is the histologic differentiation of Spitz nevus from cutaneous melanoma. The latter distinction is one of the most difficult problems in all of pathology and at present is subjective, based on the experience of the pathologist, and the careful weighing of a number of clinical and histopathologic parameters summarized in Table 112.6.

Treatment

Because of the frequent diagnostic difficulty in classifying these lesions, histologic evaluation of the entire lesion is highly recommended. Recurrence rates from 7% to 16% have been observed when lesions were incompletely excised. In the authors' opinion, complete excision with margins free of tumor is recommended for all Spitz nevi. However, there are clinicians, including pediatric dermatologists, who reserve this recommendation for lesions with any atypical features (clinically or histologically) or for Spitz nevi in adults. Margins of approximately 1 cm are advised for markedly atypical or histologically ambiguous variants. It is also advisable that patients with atypical lesions have periodic evaluations every 6 to 12 months. Although controversial, sentinel lymph biopsy may be considered on a case-by-case basis for markedly atypical lesions with a Breslow depth ≥1 mm. However, there is mounting evidence that sentinel lymph node involvement by Spitz tumors is not necessarily analogous to conventional metastatic melanoma[76], as almost all of the cases studied to date have not shown progression of

COMPARISON OF SPITZ NEVUS AND MELANOMA

Parameter	Spitz nevus	Melanoma
Age	Young age, especially <10 years, favors a benign process	Exceedingly rare under age 10 years (pre-pubertal); outnumber Spitz nevi in patients >30 to 40 years of age
Anatomic site	Head and neck > extremities (especially thighs) are preferential sites, but may occur anywhere	Most often on the trunk (back) in men and distal lower extremities in women; favor intermittently sun-exposed skin, but may occur anywhere
Size	Often <5–6 mm, usually <10 mm	Often >6 mm, but early lesions may be smaller; large size favors melanoma
Symmetry	Usually symmetric	Increasing asymmetry favors melanoma
Architecture	Dome-shaped, plaque-like, wedge-shaped in dermis, plexiform	Heterogeneous and complex (with exceptions)
Circumscription	Usually well demarcated with peripheral junctional nests	Often poorly demarcated ending in single-cell patterns
Maturation	Overall reduction in cellular density with depth; orderly dispersion and regular spacing of nests and cells among collagen bundles with depth; nests become progressively smaller, finally resulting in single melanocytes at the base of lesion; cells and nuclei also diminish in size with depth; maturation may be absent in a subset of Spitz nevi	Little or no maturation; confluence of melanocytes is not lost with depth; irregular spacing and disorderly arrangements of cells
Pagetoid spread	Less frequent than in melanoma; orderly; often confined to the epidermis over the central part of the lesion; nested patterns may be more frequent than single cells	Common; disorderly; the melanoma cells often reach the granular layer; higher cellular density
Zonation	Uniformity of cytologic features across horizontal strata of lesion	Heterogeneity of features
Mitotic figures in dermal component	Limited in number, superficial, usually not atypical	Greater in number, deeply located, atypical
Cytologic features	Abundant ground-glass or opaque cytoplasm; polyangular, rhomboidal; occasional dendrites	Variable amount of cytoplasm; often granular or "dusty" and abundant in epithelioid cells; scant cytoplasm in spindled cells
Nuclear features	Enlarged nuclei; uniform dispersed chromatin pattern; nucleoli may be prominent but usually uniform; reniform, multilobulated, multinucleate and giant bizarre forms occur	Pleomorphism; often high nuclear to cytoplasmic ratios; hyperchromatism; prominent variable nucleoli commonly multiple; thickened nuclear membranes

Table 112.6 Comparison of Spitz nevus and melanoma.

disease beyond the sentinel lymph nodes. In sum, further research into understanding and predicting the biologic behavior of atypical or ambiguous Spitz tumors is needed.

PIGMENTED SPINDLE CELL NEVUS

Synonyms: ■ Pigmented spindle cell tumor of Reed ■ Pigmented variant of Spitz nevus

Key features

- Dark brown to black macule or papule, usually <6 mm in diameter
- Found in children or young adults
- They are a spindle cell variant of Spitz nevus

Epidemiology

Pigmented spindle cell nevi occur less frequently than other forms of spindle and epithelioid cell nevi[79–82]. A few have been noted at birth; however, the mean age at diagnosis is 25 years (the age range in one series was 3 to 66 years). Women are affected more often than men. Pigmented spindle cell nevi are most commonly located on the extremities (70% of cases in one study), with the thigh being the most frequent site. About 20% of pigmented spindle cell nevi are found on the trunk, and 9% occur in the head and neck region.

Pathogenesis

As with other melanocytic nevi, pigmented spindle cell nevi are thought to be derived from cells migrating from the neural crest. The reasons for the prominent spindle cell features are not understood.

Clinical Features

The pigmented spindle cell nevus is usually a relatively flat or slightly raised, well-circumscribed lesion averaging about 3 mm in diameter (range 1.5 to 10 mm). The color is usually dark brown or black and is homogeneous. The most common dermoscopic patterns include the following: a dark structureless area almost to the periphery of the lesion, a central dark structureless area with symmetric pseudopods or radial streaming (starburst pattern), and/or a peripheral globular pattern (see Ch. 0). Irregularity of pigmentation is not common but may be found in atypical variants of pigmented spindle cell nevi. There is often a history of recent development or alteration. In one study, lesions had been present on average for about 6 months, although some were of longstanding duration. There is usually no family history of melanoma or atypical nevi.

The natural history is largely unknown. As has been mentioned, the vast majority of pigmented spindle cell nevi have been present for only a short time, usually less than a year. Congenital forms of pigmented spindle cell nevi, although uncommon, have been recognized. The occurrence of atypical varieties of pigmented spindle cell nevi and the presence of remnants of pigmented spindle cell nevi in association with cutaneous melanoma are circumstantial evidence that pigmented spindle cell nevi can undergo rare transformation to cutaneous melanoma. In a long-term (mean 8.8 years) follow-up of 15 patients with excised pigmented spindle cell nevi, there was no evidence of recurrence. In our experience, these lesions have almost never recurred. Thus, unless a lesion has been incompletely excised, recurrence strongly suggests an atypical process, possibly cutaneous melanoma.

Deep penetrating nevus (plexiform pigmented spindle cell nevus), which was previously thought to be a variant of cellular blue nevus by many, is more closely related to pigmented spindle cell nevi[83,84]. These lesions do not show *GNAQ* mutations typical of blue nevi. Pleomorphic spindle cells and variably present epithelioid cells extend vertically into the deep dermis or fat in plexiform aggregates.

Pathology

The pigmented spindle cell nevus displays a well-circumscribed and orderly appearance (Fig. 112.19A). The lesions are usually only slightly raised with nevus cells confined to the epidermis, but may involve the papillary dermis. The lesion is typified by fascicles of uniform, slender spindle cells that are closely aggregated (Fig. 112.19B). The cells usually contain fine, granular melanin. The nuclei contain delicate chromatin and small inconspicuous nucleoli and overall have a monotonous appearance. There may be clefting about the intraepidermal fascicles. Numerous melanophages are usually present in the papillary dermis. Upward migration of nevus cells throughout the epidermis is sometimes noted, but these cells are usually confined to the lower half of the epidermis. Atypical variants exhibit prominent single-cell hyperplasia extending peripherally along the basal layer of the epidermis and in a pagetoid pattern throughout the epidermis. Cytologic atypia also may be present in a varying degree in these atypical variants.

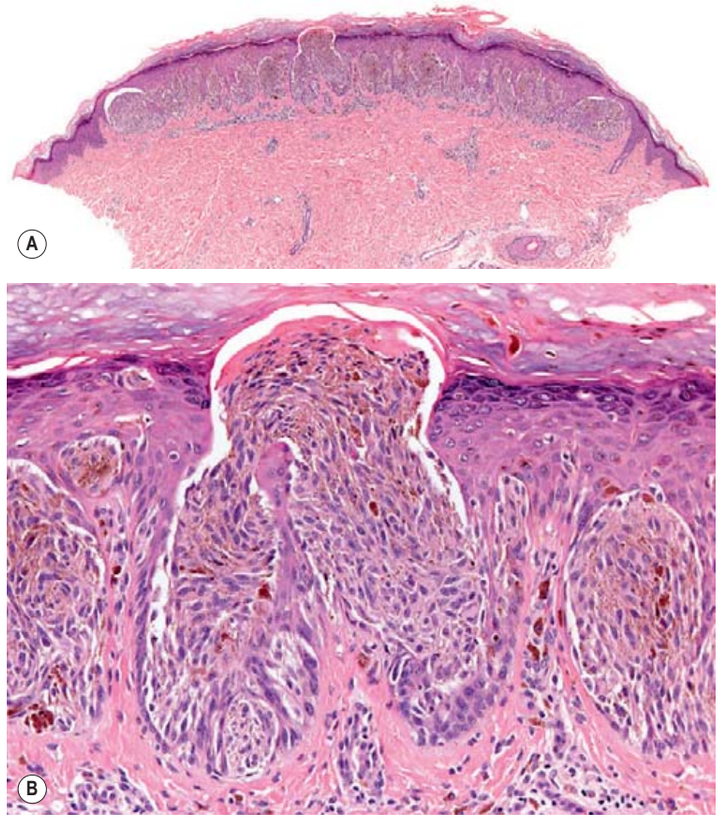

Fig. 112.19 Histology of a pigmented spindle cell nevus. A A predominantly junctional melanocytic proliferation that is characterized by well-defined margins, symmetry and an overall plate-like configuration. Several nests have a vertical configuration. **B** The melanocytes are spindle-shaped and heavily pigmented. *Courtesy, Lorenzo Cerroni, MD.*

Differential Diagnosis

The clinical differential diagnosis of pigmented spindle cell nevi includes early melanoma, atypical nevus, blue nevus, angiokeratoma and pigmented basal cell carcinoma. In general, the borders of pigmented spindle cell nevi are regular and well defined. The color is also homogeneous in most instances. However, atypical forms of pigmented spindle cell nevi may exhibit irregular borders and variation in color. Although spindle cell nevi have a characteristic dermoscopic pattern, histopathologic examination is required for diagnosis. It must be stressed, however, that the clinicopathologic presentation of typical pigmented spindle cell nevi is distinctive. Its history is that of a recently developed or changing, small, well-circumscribed, black lesion on the thigh of a young woman (usually in her 20s). These lesions are often conspicuous because of the dearth of pigmented lesions elsewhere on the body.

Treatment

The proper treatment of pigmented spindle cell nevi is complete excision with clear margins. The reason for this recommendation is to prevent recurrence, since the pathology of recurring lesions may be

alarming and difficult to distinguish from melanoma. For pigmented spindle cell nevi with atypical features, wider surgical margins are advised. For example, we advocate resection margins of 5 to 10 mm for markedly atypical forms of pigmented spindle cell nevus. Periodic follow-up, i.e. every 6 to 12 months, is also strongly advised for patients with atypical variants of pigmented spindle cell nevus.

ATYPICAL (DYSPLASTIC) MELANOCYTIC NEVUS

Synonyms: ■ Atypical nevus ■ Clark's nevus ■ Atypical mole ■ "Dysplastic" melanocytic nevus ■ Nevus with architectural disorder ■ B-K mole ■ The mole of FAMM (familial atypical mole and melanoma syndrome)

The US National Institutes of Health Consensus Conference held in January 1992 recommended that the histologic term "nevus with architectural disorder" replace dysplastic melanocytic nevus

Key features

- A controversial clinical designation for various nevi that have morphologic changes such as asymmetry, irregular borders and color variation
- Also a controversial pathologic term used for nevi with certain architectural changes and/or cytologic atypia
- The relationship to melanoma is complex

History

Since the description of atypical or "dysplastic" melanocytic nevi in the setting of melanoma-prone families over 30 years ago and subsequently in individuals outside such kindreds, these lesions have remained highly controversial[56,85–121]. This has largely resulted from the failure to reach a consensus regarding the nature of these lesions, an inability to formulate precise criteria for recognition, and, finally, a lack of understanding about their biologic significance. Specifically, this relates to criteria for individual lesions and for the so-called "dysplastic nevus syndrome", i.e. how many clinically atypical melanocytic nevi are needed and what are the minimal essential gross morphologic criteria required for diagnosis of an individual lesion? One particular problem, dating back to the original studies on atypical melanocytic nevi ("dysplastic nevi") in hereditary kindreds, has been the tendency to consider the histopathologic diagnosis of atypical melanocytic nevi ("dysplastic nevi") as the gold standard. However, it has been shown that the histopathologic features ascribed to atypical melanocytic nevi ("dysplastic nevi") lack specificity (see below).

Many studies have established that, irrespective of histology, melanoma risk is directly related to numbers of ordinary nevi (> 50 or 100 on the total skin surface) as well as the presence and number of atypical nevi, as defined by size (e.g. > 5, 6 or 8 mm), irregular or ill-defined borders, variation in color, macular component, etc. (Tables 112.7 & 112.8)[87–93]. Despite the seemingly logical conclusion that histopathologically atypical nevi should be associated with increased melanoma risk, only limited data thus far have shown such a relationship. Furthermore, studies examining the relationship between clinically atypical melanocytic nevi and histopathologically atypical melanocytic nevi have shown a poor correlation. Therefore, the "dysplastic" nevus cannot be considered a distinct clinicopathologic entity. At present, melanoma risk assessment of patients is based almost solely on gross morphologic parameters of nevi, i.e. total numbers of nevi on the skin surface and the presence and number of clinically atypical melanocytic nevi, along with other factors such as personal or family history of melanoma.

The term "atypical melanocytic nevus" undoubtedly encompasses a large and heterogeneous group of nevi including:

- nevi with atypical clinical features, which have been termed simply "atypical nevi"; in general, these atypical nevi can simulate melanoma clinically; this group of nevi includes not only "atypical" or "dysplastic" nevi, but also some congenital and combined melanocytic nevi, as well as Spitz/pigmented spindle cell nevi
- nevi with abnormal histopathologic features
- nevi with *both* abnormal clinical and histopathologic features
- nevi with histopathologic features that are equivocal or of unknown significance.

The latter group of nevi may demonstrate findings that may be reactive or proliferative in nature rather than neoplastic[85–121].

Epidemiology

Estimates of the incidence of atypical melanocytic nevi cover a wide range, as would be expected given the lack of consensus regarding definitions. Most estimates are in the 10% range, but estimates as high as 53% have been reported for the US population.

Atypical melanocytic nevi may be single or multiple. In the general population, atypical nevi may arise in a "sporadic" fashion, i.e. without a history of familial melanoma, versus in the context of a family history of atypical moles and/or melanoma. In both clinical settings, there is

MELANOCYTIC NEVUS PHENOTYPES		
	Common pattern	**Atypical pattern**
Number	None to few (<25) nevi	Many (>50) nevi
Size	<5 mm	Variable: small to large, often several >5 mm
Color	Uniform, homogeneous color	Some to many nevi with irregular or haphazard color, erythema
Borders	Well circumscribed	Irregular or ill-defined borders

Table 112.7 Melanocytic nevus phenotypes.

MELANOMA RISK ASSOCIATED WITH CLINICALLY ATYPICAL MELANOCYTIC NEVI: COMPARISON OF OCCURRENCE IN MELANOMA PATIENTS VERSUS CONTROLS					
Study	**Country**	**Definition**	**Melanoma patients (%)**	**Controls (%)**	**Relative risk**
Roush et al. & Nordlund et al.	Australia	>5 mm, irregular border, and haphazard pigmentation	34	7	7.7
MacKie et al.	Scotland	>5 mm and either irregular pigmentation or inflammation	38	20	2.1–4.5*
Holly et al.	US	At least 3 of 6 criteria: ill-defined border, irregular border, irregular pigmentation, >5 mm, erythema, accentuated skin margins	55	17	3.8–6.3†
Halpern et al.	US	>4 mm, macular component, variegation of color, and irregular or indistinct border	39	7	8.8
Garbe et al.	Germany	At least 3 of 5 criteria: >5 mm, irregular margins, ill-defined border, color variation, macular and papular components	45	5	7

*Relative risk for one or two atypical nevi, 2.1; for three or more atypical nevi, 4.5.
†Relative risk for one to five atypical nevi, 3.8; for six or more atypical nevi, 6.3.

Table 112.8 Melanoma risk associated with clinically atypical melanocytic nevi: comparison of occurrence in melanoma patients versus controls[87–93].

agreement that these nevi indicate some increase in melanoma risk[113]. More recently, objective evidence was presented that "dysplastic" nevi with moderate to severe atypia histologically represented a risk factor for the development of melanoma[121].

Sporadic atypical melanocytic nevi may occur at any time, while persons with a family history of atypical melanocytic nevi and/or melanoma usually manifest their atypical lesions by the end of the second decade. In contrast to common acquired moles that tend to appear in clusters around puberty, atypical melanocytic nevi may appear, even in an eruptive fashion, as late as the sixth decade. Histologic contiguity of atypical melanocytic nevi to melanomas was frequently observed in several studies of melanoma kindreds, but the development of melanoma in association with an individual atypical melanocytic nevus in the sporadic setting seems to be an uncommon event.

Clinical Features

Nevi as described below can occur anywhere on the cutaneous or mucosal surfaces of Caucasians as well as on the acral and mucosal surfaces of other races. Of note, other authors believe that distinct atypical melanocytic proliferations apart from atypical melanocytic nevi occur on acral and mucosal sites. Atypical nevi occupy an intermediate position on a continuum with common nevi at one end and cutaneous melanoma at the other end, and, as a result, they overlap with both. No single feature is diagnostic of atypical melanocytic nevi; rather, a constellation of clinical and dermoscopic findings is required for their recognition (see Figs P9, P10). However, the greater the number of clinical abnormalities present, the greater is the likelihood that the lesion will prove to be histologically atypical, but there are many exceptions.

The following gross morphologic features are commonly observed in atypical melanocytic nevi:

- *Asymmetry*: atypical melanocytic nevi often lack mirror-image symmetry. Greater asymmetry suggests greater likelihood of atypicality.
- *Size*: atypical melanocytic nevi may be of any size but generally range from 3 to 15 mm in greatest diameter. There is generally a positive correlation between increasing size and likelihood of atypia.
- *Borders*: atypical melanocytic nevi often exhibit irregular and ill-defined borders, but not typically the notched or scalloped borders of melanoma.
- *Coloration*: atypical melanocytic nevi often have many colors. They commonly exhibit irregularity of pigmentation with two or three shades of brown, e.g. tan, brown and dark brown (Fig. 112.20). They may also have areas that are skin-colored, pink, gray or brown–black. Of note, some atypical melanocytic nevi present with fairly uniform coloration and an erythematous appearance.

Fig. 112.20 Atypical melanocytic nevus. There is asymmetry as well as several shades of brown, simulating the clinical features seen in cutaneous melanoma.

Atypical melanocytic nevi most frequently involve the trunk and also show a striking (though less common) predilection for the scalp and for doubly covered areas of the body (breasts in women and bathing-trunk area in men). Their numbers may range from one or two to hundreds (Fig. 112.21). When multiple large lesions are present, their prominence is noteworthy, and while there may be variability, patients often have a "signature" nevus, clinically and histologically. Localized patterns such as linear tracts, clusters or figurate arrays may also be seen in patients with numerous nevi.

The overwhelming majority of atypical melanocytic nevi are clinically stable. However, there is definite evidence that some lesions eventuate in cutaneous melanoma. Progressive abnormalities in DNA content, cytogenetic alterations, and increased expression of melanocyte-associated antigens by immunohistochemistry have been correlated with progressive degrees of histologic atypia. Although these latter findings suggest a progression of atypical melanocytic nevi toward melanoma, atypical melanocytic nevi are not inevitable precursors to melanoma, and their presence can be viewed as a phenotypic marker of "skin at risk".

Pathology

Prototypic atypical melanocytic nevi are described as having several noteworthy architectural features (Fig. 112.22). Such nevi are often larger (commonly >5 to 6 mm in diameter), are more poorly circumscribed, are slightly more asymmetric, are relatively flat, particularly at the peripheries of the lesion, and often show heterogeneity as compared

Fig. 112.21 Atypical melanocytic nevi. Multiple pigmented macules and papules of varying sizes on the back.

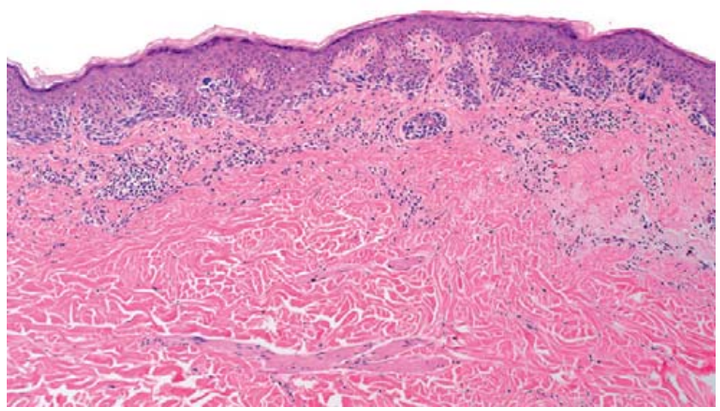

Fig. 112.22 Histology of an atypical melanocytic nevus. Note confluent nests of melanocytes at the dermo-epidermal junction and scattered solitary melanocytes in the lower portion of the epidermis. *Courtesy, Lorenzo Cerroni, MD.*

to ordinary nevi. In atypical melanocytic nevi, the junctional nests frequently extend beyond the dermal component (the "shoulder" phenomenon).

Of particular importance are abnormalities of the intraepidermal component. Architectural or organizational disorder occurs in two patterns that are often present simultaneously to a varying extent. The first is lentiginous melanocytic proliferation that is almost always associated with elongated epidermal rete ridges. In general, the basilar melanocytes are concentrated in the lowermost portions of the rete ridges, and the frequency of basilar melanocytes varies greatly, e.g. from one melanocyte per one to two keratinocytes to the melanocytes replacing the basilar keratinocytes and resulting in a confluent, clustered, or multilayered cellular appearance.

The second pattern includes nests of melanocytes irregularly disposed along and between the rete ridges in a more haphazard fashion as compared to ordinary nevi. These nests vary in size and shape, are frequently elongated, commonly have their long axes oriented along the dermal–epidermal junction, and contain variable numbers of cells. Colliding nests of melanocytes frequently fuse or "bridge". Dyscohesion of cells within these nests is also common; this feature contrasts with the cohesive appearance of junctional nests of melanocytes in ordinary nevi. Often, atypical nevi have a higher density or concentration of melanocytes in the intraepidermal component than do banal nevi, and this may be a helpful feature in their recognition.

Atypical melanocytic nevi with the latter two patterns usually exhibit cytologic atypia of their melanocytes. Such change is discontinuous and variable, from only a small percentage of cells demonstrating nuclear atypia to most cells being atypical. Cytologic atypia often has a general correlation with the degree of architectural abnormality present in a particular lesion. Pleomorphism of the nuclei (i.e. variation in size, shape and staining properties) is perhaps the most characteristic attribute of the nuclear changes in atypical melanocytic nevi. However, nuclear enlargement and hyperchromatism also occur. The cells are frequently typified by a perinuclear clear space resulting from cytoplasmic shrinkage, an artifact of tissue processing. Criteria for grading the degree of cytologic atypia and even architectural abnormality have been proposed, but there is currently no consensus.

Atypical melanocytic nevi may also contain a proliferation of atypical epithelioid melanocytes that resembles the epithelioid melanocytes in some forms of melanoma. This is characterized by prominent junctional nests of cells that are predominantly epithelioid in appearance, with round nuclei and finely granular melanin in their cytoplasm. The cells may also be disposed singly along the dermal–epidermal junction, with occasional pagetoid spread. Epithelioid cell proliferation may occur in a normal epidermis or in a hyperplastic epidermis, but the normal rete ridge pattern is retained. Cytologically, the melanocytes are enlarged and have variable degrees of nuclear enlargement, pleomorphism, hyperchromatism and, occasionally, prominent nucleoli. When these cells are in nests, they show some dyscohesion, but on the whole fill the nests completely. Mixtures of these intraepidermal patterns are common.

The dermal component of atypical melanocytic nevi may be composed of typical nevus cells, such as those in any acquired nevus, or of cells that may exhibit atypia. In addition to the abnormal proliferative patterns described above, other frequent alterations, in particular changes related to host response, characterize intermediate nevi. Two forms of collagenous change occur in the papillary dermis. Most common is a condensation of dense, acellular collagen around the elongated epidermal rete; this is known as concentric eosinophilic fibrosis. A less common pattern consists of delicately layered, or laminated, collagen subjacent to the rete tips with fibroblasts disposed along the laminated collagen fibers in a linear array. This pattern is referred to as lamellar fibroplasia. A mixture of the two collagen patterns is not uncommon.

Lymphocytic infiltrates, which usually are distributed in a perivascular fashion and less commonly in a band-like pattern, are also frequently observed in atypical melanocytic nevi. Finally, atypical melanocytic nevi usually have prominent vascularity throughout the papillary dermis, which is secondary to dilation and hypertrophy of existing vascular channels, rather than significant angiogenesis. The histopathologic criteria for atypical melanocytic nevi are still evolving, and, as already mentioned, many questions relating to the histopathology of these lesions are still unanswered.

Differential Diagnosis

The differential diagnosis of pigmented lesions approximately 4 to 15 mm in size includes both melanocytic and keratinocytic lesions. Among melanocytic proliferations, the principal diagnostic considerations lie among common acquired nevi, small congenital nevi, and cutaneous melanoma. The atypical melanocytic nevus is characterized by haphazard, irregular coloration, including hues of pink, tan, brown and even black, and irregularity in shape (features it shares with melanoma). The other nevic lesions either show symmetry and/or uniformity of coloration or, when irregularly colored, show orderly gradations or patterns of pigmentation.

Dermoscopy may also play an important role in evaluating atypical melanocytic nevi (Fig. P5). Although atypical melanocytic nevi can clinically resemble melanoma, many of these lesions fall into one of the benign dermoscopic melanocytic patterns (see Fig. P9). The features employed to evaluate a melanocytic nevus include colors, symmetry and organization. Benign melanocytic lesions tend to have few colors and are symmetric with regard to the distribution of colors and structures. Organization refers to the distribution of structures in a lesion. When these structures are symmetrically distributed and there are fewer than three colors (light brown, dark brown and black) noted, they create a pattern seen in many benign lesions. The most common benign patterns are reticular, globular and homogeneous. In addition, there are the subset patterns of reticular–homogeneous, reticular–globular and globular–homogeneous (see Fig. P9)[120].

Of particular note, a subset of atypical melanocytic nevi may demonstrate a "malignant" melanocytic dermoscopic pattern (see Fig. P10). These lesions often have many colors and are asymmetric and disorganized with respect to a non-uniform distribution of colors and structures. It is recommended that these lesions be biopsied.

Finally, another subset of atypical melanocytic nevi is characterized by uncertain melanocytic dermoscopic patterns. Just as the clinical and histologic features of atypical melanocytic nevi are a continuum, so too are the features with dermoscopy. These lesions should either be serially monitored or undergo biopsy.

Pigmented seborrheic keratoses, solar lentigines, lichen planus-like keratoses, pigmented actinic keratoses, pigmented Bowen's disease and basal cell carcinoma may exhibit pink, tan, brown or dark brown coloration.

Treatment

As within any area of medicine, the physician is first obliged to do no harm. Such an approach is particularly germane to patients with atypical melanocytic nevi, in order to avoid overly aggressive procedures, surgery and follow-up. Common sense should prevail at all times and consideration given as to whether the intervention will have any impact on potentially reducing mortality from melanoma. Treatment depends, on whether the patient presents with one or a few nevi or with numerous nevi and whether there is a personal history of melanoma, as well as on whether there exists a familial setting of atypical melanocytic nevi and/or melanoma. A gradient of melanoma risk has been clearly established for these various subsets of patients. Melanoma risk is probably continuous and increases with progressive increases in numbers of nevi, clinical atypia of nevi, and personal and familial occurrence of atypical nevi and melanoma.

Regardless of the risk group, any pigmented lesion suspicious for melanoma and any persistently and significantly changing lesion should, in the authors' opinion, be excised completely with approximately 2 mm margins for histopathologic examination. Some authors have advocated "deep" shave excision (saucerization) for superficial lesions, as long as the base of the lesion is removed. As opposed to partial punch biopsy, the latter allows for assessment of the overall architecture of the lesion and leads to less sampling error. A helpful rule of thumb in following patients with many atypical melanocytic nevi is to search for lesions that clearly stand out as different from the patient's other (baseline) nevi; such lesions should be examined carefully. It should be kept in mind that new nevi will continue to develop and nevi may enlarge and change with time, especially in young individuals. One must use common sense in assessing this normal evolution of nevi and not be overly aggressive in removing such nevi. It is not mandatory to remove clinically atypical nevi simply to confirm or exclude atypical melanocytic nevi histologically. An acceptable

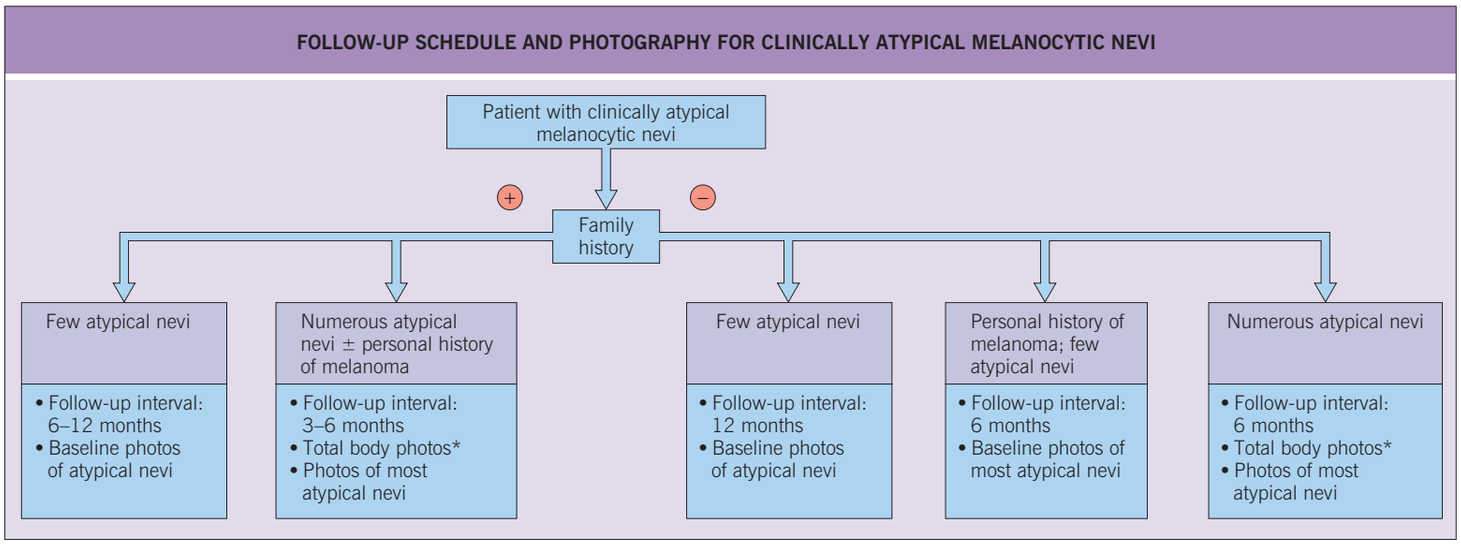

Fig. 112.23 Follow-up schedule and photography for clinically atypical melanocytic nevi. *Advocated by some authors, but not standard of care.

practice is to follow such patients on a regular schedule with a total body skin examination plus dermoscopy, baseline photography, and/or digital dermoscopy, as preferred by the clinician. The frequency of follow-up examinations is individualized and is based on the previously mentioned risk factors, i.e. numbers and clinical atypia of nevi, lesion stability, and personal and family history of melanoma (Fig. 112.23).

For patients having clinically suspicious lesions removed, narrow surgical margins are advised. If "severe" cytologic atypia is present in the lesion, re-excision is recommended because of frequent overlap with melanoma *in situ*. For atypical melanocytic nevi with lesser degrees of melanocytic atypia, the question of re-excision for a nevus not completely removed is controversial. One reason for the latter statement is that there is currently neither consensus about the grading of atypia in nevi nor sufficient data regarding the significance of melanocytic atypia in nevi. However, as with any melanocytic lesion, it is important to know if the lesion has been adequately sampled and also if the lesion was considered to be clinically atypical. If lesions are "slightly" atypical, no re-excision is recommended, as long as no residuum of the nevus is clinically apparent. If lesions are "moderately" atypical and present in the margins, even when no residual lesion is clinically obvious, a re-excision with clear margins might be considered, depending upon the degree of concern clinically, the site, the size of the nevus (versus the size of the biopsy), the patient's ability and interest in following the site, and color (more inclined with amelanotic lesions as assessing residuum is more difficult during healing phase).

In general, follow-up of patients with multiple atypical nevi, especially in the context of a personal or family history of melanoma, should be every 3 to 12 months, depending on the clinical situation. One should consider documentation of nevi by body charts and clinical photography as judged appropriate, with periodic updating. The authors have found that individual photographs of the most atypical or difficult-to-follow nevi are particularly helpful. Additional tools such as dermoscopy and/or digital imaging devices may be useful diagnostic aids.

Finally, individuals presenting with atypical melanocytic nevi should have a family history taken for the presence of atypical melanocytic nevi and/or melanoma. First-degree blood relatives should be examined both for documentation and to assess and potentially diminish their own risks of developing melanoma.

CONGENITAL MELANOCYTIC NEVUS

Synonyms: ■ Congenital nevomelanocytic nevus ■ Large congenital melanocytic nevi: • Giant pigmented nevus • Giant hairy nevus • Bathing trunk nevus • Garment nevus

Key features

- Small congenital nevi are <1.5 cm in diameter (in adults)
- Medium-sized congenital nevi are between 1.5 and 19.9 cm in diameter (in adults)
- Only the large (or giant) congenital nevi >20 cm in diameter (in adults) have a significantly higher risk for developing melanoma than do ordinary nevi

Introduction

Congenital melanocytic nevi are melanocytic nevi present at birth[122–141]. They consist of proliferations of benign melanocytes that may be intraepidermal, dermal, or both. Rarely, lesions appear after birth or within 2 years which are not otherwise remarkably different from congenital nevi and are therefore referred to as *congenital nevus tardive*. Some congenital melanocytic nevi may be just a few millimeters in size and appear clinically indistinguishable from common acquired nevi. In general, congenital melanocytic nevi are classified as small, intermediate- or medium-sized, and large or giant. For practical purposes, small congenital nevi are <1.5 cm in greatest diameter, medium-sized congenital nevi are from 1.5 to 19.9 cm, and large (or giant) congenital nevi are >20 cm (in adults; 9 cm on the scalp and 6 cm on the trunk in newborns). The latter often cover large areas of the body such as the arm, scalp, or even the entire dorsal surface from the scalp to the feet. Some authors base the distinction between small, intermediate and large congenital nevi on their ease of removal. In this scheme, small congenital nevi generally may be removed by simple excision, medium-sized nevi often require staged excisions for closure, and giant nevi often cannot be removed or require multiple staged excisions. A fourth category, garment nevus, is sometimes used to distinguish nevi that are >40 cm in diameter (in adults), given the greater risk for developing complications.

Neurocutaneous melanosis, also referred to as neurocutaneous melanocytosis, is a rare congenital syndrome characterized by: (1) the presence of either a large (>20 cm) congenital melanocytic nevus or multiple (more than three) usually smaller congenital melanocytic nevi (or both), in association with meningeal melanosis or melanoma; (2) an absence of cutaneous melanoma except in patients with histologically benign meningeal lesions; and (3) an absence of meningeal melanoma except in patients with histologically benign cutaneous lesions[137–140].

Epidemiology

Estimates of the incidence of congenital nevi are imprecise since distinctions between relatively "small" congenital melanocytic nevi and

acquired nevi are not well defined and histologic patterns vary considerably among congenital melanocytic nevi. When histologic confirmation is a criterion, the incidence may be as low as 0.6%; series based on clinical criteria have found an incidence as high as 2.5%. Giant congenital nevi are rare, with an estimated incidence of 0.005% (1 in 20 000). Patients with giant nevi often have multiple smaller (satellite) nevi as well, with greater numbers correlating with an increased risk of neurocutaneous melanosis. Familial aggregation of congenital nevi has occasionally been reported.

Pathogenesis

The precise pathogenesis of congenital melanocytic nevi has not been established. In one study of 32 truly congenital nevi, no *BRAF* mutations were detected, but 81% (26/32) harbored mutations in *NRAS*[142]. An origin from neural crest stem cells that have migrated to the skin appears almost certain. Individual melanocytes begin to appear in fetal skin before 40 days' gestation. Given the observation of congenital divided nevi of the eyelid and the fact that the eyelids open during the sixth month of gestation, it appears that congenital melanocytic nevi develop some time during this interval. Patients with either a large congenital nevus or multiple satellite-like lesions should be thought of as having a systemic disease, as nevus cells can be found in sites beyond the skin and central nervous system (CNS), such as the retroperitoneum.

Clinical Features

Small and medium-sized congenital melanocytic nevi are usually round or oval and fairly symmetric (Fig. P6). These lesions are usually slightly raised at birth and may be tan in color. They may or may not have associated hypertrichosis, and perifollicular hypo- or hyperpigmentation may be seen. Some congenital melanocytic nevi have rugose or pebbly surfaces (Fig. 112.24). Lesions that begin as slightly raised tend with age to become more elevated; color darkening and the assumption of a verrucous appearance are also common. After an initial darkening during the first year or so of life, some congenital melanocytic nevi may actually become lighter in color with aging, including satellites. In addition, congenital nevi can develop the halo phenomenon (see below), and occasionally, congenital nevi completely regress, even without forming a halo. As hamartomas, congenital nevi can exhibit asymmetry and variation in color, develop papules and nodules (e.g. proliferative nodules), and undergo change over time; however, histologic examination of any concerning areas is recommended (see Table 112.9).

The dermoscopic structures seen in congenital nevi may include the following: globules, diffuse background pigmentation (structureless), milia-like cysts, hypertrichosis, hyphae-like structures and perifollicular pigment changes. Congenital nevi have repeatable dermoscopic patterns. The most common patterns are the reticular, globular, reticular–globular (see Fig. P6), diffuse brown pigmentation, and multicomponent. The multicomponent pattern is often difficult to distinguish from melanoma and requires either monitoring or biopsy.

Varying numbers of so-called satellite congenital melanocytic nevi often accompany giant congenital melanocytic nevi (Fig. 112.25). In one study, at least 80% of patients with large congenital melanocytic nevi had satellite congenital melanocytic nevi. Such lesions typically resemble small or medium-sized congenital melanocytic nevi. Of note, some patients present with multiple satellite-like lesions in the absence of a large congenital nevus (see Fig. 112.25A), and these individuals are at greatest risk for neurocutaneous melanosis.

Neurocutaneous melanosis (melanocytosis)

In one series of 33 patients with neurocutaneous melanosis associated with large congenital melanocytic nevi (>20 cm), all nevi had a posterior axial location (involving the head, neck, back and/or buttocks); 31 of 33 patients had satellite nevi. In another study, 80% had posterior axis involvement and 55% had more than 20 satellite nevi. Neurocutaneous melanosis is divided into symptomatic and asymptomatic (noted on screening MRI). Symptomatic neurocutaneous melanosis presents with signs and symptoms of increased intracranial pressure, often due to hydrocephalus or mass effect, and it is associated with a poor prognosis. By MRI, there are several presentations of neurocutaneous melanosis, including: (1) multiple obvious postgadolinium-enhancing masses; (2) diffusely thickened leptomeninges noted by gadolinium enhancement; and (3) focal areas of increased signal on T1-weighted images. The first two forms are associated with a poor prognosis.

Melanoma

Although all sizes of congenital melanocytic nevi may be associated with melanoma, historical estimates of melanoma risk have been exaggerated because of referral bias and misdiagnosing the atypical melanocytic proliferations that develop in congenital melanocytic nevi as melanoma. The potential risk is probably related to size of the congenital melanocytic nevi, i.e. the larger the nevus, the greater the risk. At present it is thought that the melanoma risk associated with small congenital melanocytic nevi is low and probably not much more than that associated with acquired nevi. A prospective study of 230 medium-sized congenital melanocytic nevi in 227 patients, followed on average for 6.7 years, failed to document the development of a single case of

Fig. 112.24 Small congenital melanocytic nevus. Note the hypertrichosis and slight heterogeneity in pigmentation, reflecting its hamartomatous nature.

MANAGEMENT OF CHILDREN WITH GIANT CONGENITAL MELANOCYTIC NEVI
SURGICAL EXCISION VERSUS LONG-TERM CLINICAL EXAMINATION
• Consider surgical excision of the nevus (staged and/or with tissue expanders) in children at least 6 months of age in order to avoid the period of highest general anesthesia risk • If not excised or partial excision, lifelong examination of the nevus (including palpation) every 6 to 12 months plus baseline photography • Histologic examination of enlarging firm papulonodules and new areas of induration or ulceration*
MRI OF HEAD AND SPINE FOR THE DETECTION OF NEUROCUTANEOUS MELANOSIS† (NCM) AND OTHER CNS ABNORMALITIES‡
• Risk factors for NCM – multiple satellite lesions (>20)§, giant/"garment" nevus (>40 cm projected adult size), posterior axial location • In patients with no risk factors and no neurologic symptoms, MRI not necessary • In asymptomatic patients with at least one risk factor, MRI should be considered and it has a higher sensitivity prior to 4–6 months of age • In asymptomatic patients with intermediate risk (e.g. <10–20 satellites, 20–40 cm nevus as adult), MRI can be considered on a case-by-case basis • Repeat MRIs and neurodevelopmental evaluation performed based upon initial findings and neurologic symptoms • Patients with symptomatic NCM, in particular with multiple gadolinium-enhancing nodules, should not undergo surgical excision of the GCMN because of the associated poor prognosis
*Ulceration at birth or during the first week of life in areas prone to trauma may be due to immaturity of the skin but should heal over a few weeks. †Also referred to as neurocutaneous melanocytosis. ‡Need to check renal function given association with genitourinary malformations. §Highest risk of NCM in those with multiple satellite nevi but no giant congenital nevus.

Table 112.9 Management of children with giant congenital melanocytic nevi (GCMN). CNS, central nervous system; MRI, magnetic resonance imaging.

Fig. 112.25 Congenital melanocytic nevi. **A** Multiple medium-sized nevi. The patient had 25–30 such lesions. This presentation can be associated with neurocutaneous melanosis. **B** Large congenital nevus in an axial location with numerous satellite nevi, some of which have hypertrichosis. This patient died of intractable ascites due to the migration of melanocytes from the brain to the peritoneal cavity via his VP shunt. In the perianal region, the nevus was softer and somewhat "boggy" due to neurotization. *A, Courtesy, Jean L Bolognia, MD.*

melanoma. Similarly, in a longitudinal cohort study of 265 patients with medium-sized congenital melanocytic nevi, none developed melanoma. Thus, in general, the latter studies suggest that medium- (and small-) sized congenital melanocytic nevi are not associated with significantly increased risk for melanoma.

On the other hand, several studies have noted substantial melanoma risk linked to large or giant (>20 cm) congenital melanocytic nevi. In the same cohort study referred to above, Swerdlow, English and Qiao[128] estimated that patients with congenital melanocytic nevi >20 cm had a standardized morbidity ratio of 1224 for the development of melanoma. In a prospective study of 92 patients with large/giant congenital melanocytic nevi[134], three patients developed melanoma in extracutaneous sites (brain, CNS, retroperitoneum) during follow-up averaging 5.4 years. The latter authors calculated the cumulative 5-year life-table risk for melanoma to be 4.5%. The standardized morbidity ratio, which was calculated to be 239, was highly significant.

In a study of 289 patients with large congenital melanocytic nevi culled from the world literature[135], 34 patients (12%) developed primary cutaneous melanoma within their nevi. All of the patients developing these melanomas had congenital melanocytic nevi in an axial location, i.e. the head and neck and/or trunk. No melanomas were associated with an extremity or satellite congenital melanocytic nevus. The median age at diagnosis of melanoma was 4.6 years (range: birth to 52 years; average age: 13.2 years). Twenty-one patients developed primary melanomas in the CNS; all of the latter patients had neurocutaneous melanosis and large congenital melanocytic nevi in a posterior axial location. The median age at diagnosis was 3 years (range: 1 month to 50 years; average age: 11.6 years) for the latter group. An additional 10 patients presented with metastatic melanoma with unknown primary. All of the latter patients had axial congenital melanocytic nevi. A study based on a database of 1008 patients with large congenital melanocytic nevi or multiple medium-sized congenital melanocytic nevi found a significantly lower risk than in previous publications: 2.9% developed cutaneous melanoma associated with 0.8% deaths[141]. Recently, a comprehensive review of 14 studies that examined the development of melanoma in patients with congenital melanocytic nevi reported an overall risk of melanoma of 0.7% (in those with congenital melanocytic nevi of all types), with a risk of 2.5% and 3.1% in large and garment nevi, respectively[142a].

When a cutaneous melanoma develops in a relatively small congenital melanocytic nevus, it appears most commonly at the dermal–epidermal junction in a fashion similar to that of other conventional melanomas. However, up to two-thirds of cutaneous melanomas arising in larger congenital melanocytic nevi develop in the dermis, subcutaneous fat, or even deeper, as a distinct nodule. Rarely, other malignant tumors may arise in these lesions, including neurogenic sarcomas, fibrosarcomas, leiomyosarcomas, rhabdomyosarcomas, osteogenic sarcomas, and liposarcomas.

Leptomeningeal melanomas can arise in patients with neurocutaneous melanosis and most commonly involve the frontal and temporal lobes. As expected, these melanomas have a very poor prognosis.

Pathology

In contrast to common acquired nevi, which are confined to the papillary and upper reticular dermis, congenital nevi may exhibit infiltration of the lower reticular dermis, subcutaneous fat, fascia, and even deeper (Fig. 112.26). It is characteristic to observe nevus cells in a single-cell array throughout the middle or lower reticular dermis and even extending into the septa of the subcutis. Especially helpful is the presence of nevus cells surrounding (cuffing) and within the walls of blood vessels, within adnexal structures such as hair follicles and sweat glands, and within cutaneous nerves, particularly when observed in the lower half of the reticular dermis. Nevus cells may be found in the papillae and epithelium of hair follicles, in the sebaceous glands, in arrector pili muscles, and in the eccrine ducts of the lower dermis. There is often diminished cellularity (or maturation) with depth in the dermis. Uncommonly, congenital melanocytic nevi may show striking neural differentiation suggesting a peripheral nerve sheath tumor such as a neurofibroma. Structures resembling Meissner's corpuscles, Verocay bodies or neuroid tubules may be observed. Neurocutaneous melanosis is defined by the proliferation of benign "melanotic cells" (a term used to avoid a more precise designation such as melanocyte or melanoblast) in the meninges. This melanosis may involve the convexities and base of the brain, the ventral surfaces of the pons and medulla, as well as the upper cervical and lumbosacral spinal cord.

Differential Diagnosis

Although giant congenital melanocytic nevi are quite distinctive, occasionally they are confused with plexiform neurofibromas, as the latter can have both hyperpigmentation and hypertrichosis. The differential diagnosis of small congenital nevi includes congenital smooth muscle hamartoma, atypical nevus, and melanoma. For medium-sized congenital nevi, an additional entity to consider is Becker's melanosis. Of course, the possibility of melanoma exists for any clinically atypical area (e.g. darkening, nodularity) within a congenital nevus.

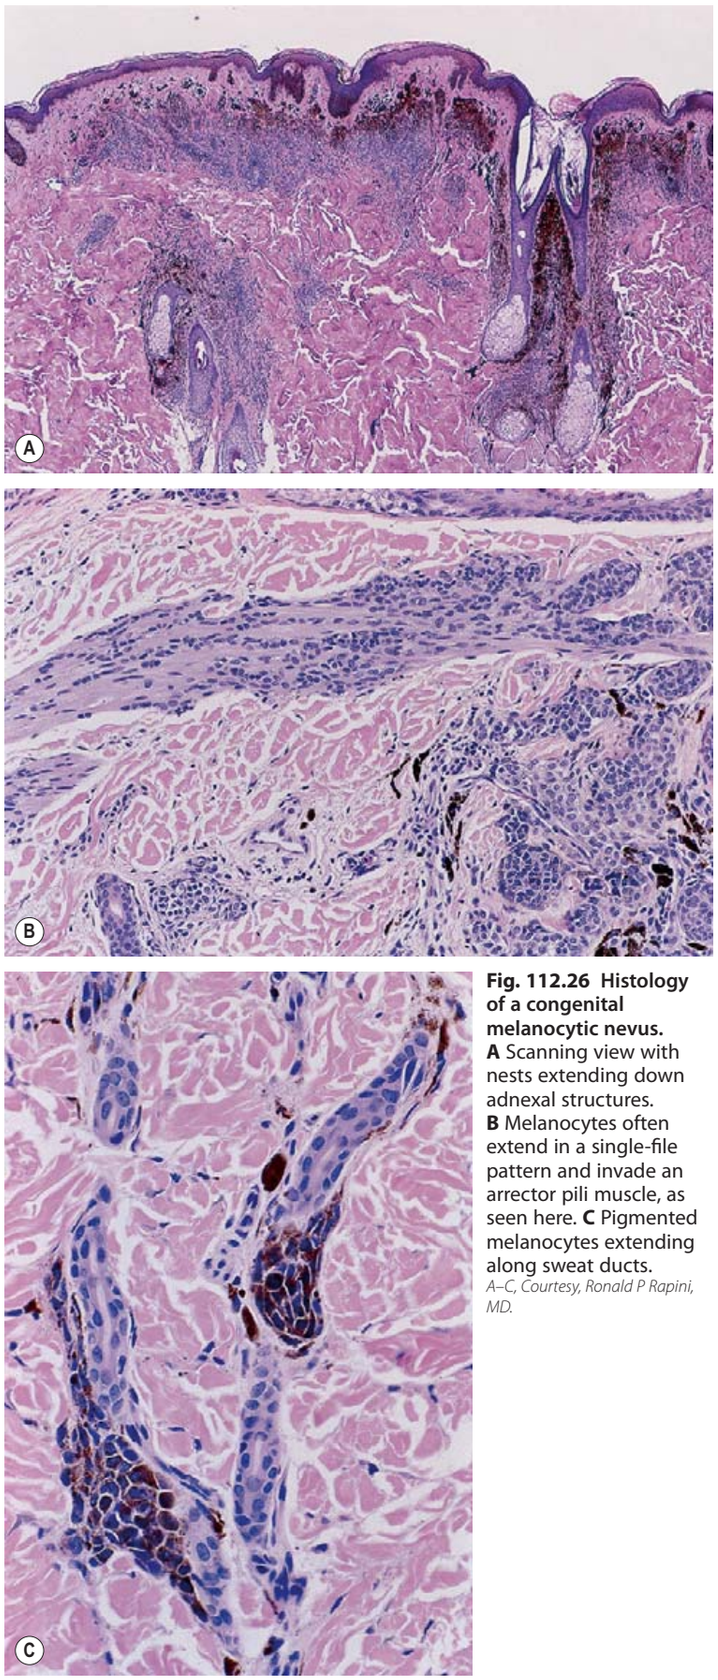

Fig. 112.26 Histology of a congenital melanocytic nevus. **A** Scanning view with nests extending down adnexal structures. **B** Melanocytes often extend in a single-file pattern and invade an arrector pili muscle, as seen here. **C** Pigmented melanocytes extending along sweat ducts. *A–C, Courtesy, Ronald P Rapini, MD.*

Treatment

The treatment of congenital melanocytic nevi is primarily related to two factors: their increased risk for progression to melanoma and their cosmetically disfiguring appearance. The decision to remove a congenital nevus is individualized and based on melanoma risk, age of the individual, anatomic location (proximity to vital structures), presence or absence of neurocutaneous melanosis, cosmetic outcome, and complexity of removal. The routine excision of uniform-appearing small and medium-sized congenital nevi no longer seems justified due to the low melanoma risk. An acceptable alternative to surgical excision is baseline photography, education and yearly examination.

The treatment of giant congenital nevi is more problematic, since melanoma risk is present from birth. If such giant nevi are to be excised, most authorities recommend delaying the procedure for at least 6 months so as to decrease the risk from general anesthesia (Table 112.9). Since the prognosis of patients with symptomatic neurocutaneous melanosis is so poor, surgical removal of large congenital melanocytic nevi should be delayed in such individuals. MRI of the CNS should be considered for neonates with large posterior axial congenital melanocytic nevi and with multiple satellite nevi, in order to screen for neurocutaneous melanosis. For patients with asymptomatic neurocutaneous melanosis, repeat scans and individualized care is indicated.

In the past, dermabrasion was sometimes performed, resulting in a more lightly pigmented and less elevated congenital nevus. More recently, especially in Europe, repeat curettage performed during the first few weeks of life (when there is a cleavage plane in the upper dermis) has led to similar results. Scarring and prolonged healing in the case of large lesions are the drawbacks. Lasers (e.g. Q-switched ruby, Q-switched alexandrite) have also been used to treat congenital nevi, but recurrence of pigmentation is an issue as is persistence of nevus cells[142b].

As mentioned previously, when melanoma supervenes in a large congenital nevus, it may involve the dermal or subcutaneous component and be difficult to detect early. Cutaneous melanoma arising in the smaller types of congenital melanocytic nevi usually begins in the epidermis and can be detected more readily.

NEVUS SPILUS

Synonyms: ■ Speckled lentiginous nevus ■ Zosteriform lentiginous nevus

Key features

- Tan patch with superimposed "speckles" that develop over time
- The darker macules and papules vary from lentigines and junctional and compound nevi to Spitz and blue nevi
- Occasionally, atypical nevi and small and medium-sized congenital nevi are seen within a larger nevus spilus
- There is a small risk of cutaneous melanoma

Epidemiology

There is some controversy as to whether nevus spilus is congenital or acquired and this is explained in part by the initial appearance of a nevus spilus – a uniformly tan-colored, CALM-like patch. There are several lines of evidence to suggest that nevus spilus is a type of congenital melanocytic nevus[143]. In one series, a nevus spilus was noted in approximately 2% of white adults. Males and females are equally affected.

Pathogenesis

A nevus spilus often has an oval shape, but it may have a block-like configuration or follow the lines of Blaschko (see Ch. 62); nevi in the latter patterns are sometimes referred to as zosteriform speckled lentiginous nevi and their configuration suggests a molecular event during embryogenesis. This type of nevus is thought to represent a localized "field defect" and has been likened to a garden of melanocytes in which any type of nevus can develop, simultaneously or sequentially[143].

Clinical Features

These lesions most commonly affect the trunk and extremities. The tan macular area typically ranges from 1 to 4 cm in diameter

Fig. 112.27 Nevus spilus (speckled lentiginous nevus) versus agminated nevi. A Multiple brown macules and papules superimposed upon a tan patch. **B** Grouped brown macules and papules in the absence of background hyperpigmentation. *B, Courtesy, Jean L. Bolognia, MD.*

(Fig. 112.27), but it may measure >20 cm and involve an entire extremity or half the trunk[143–145]. Although the darker speckles are usually macules or papules that are 1–6 mm in diameter, larger lesions that resemble small and medium-sized congenital nevi are occasionally seen.

A nevus spilus persists indefinitely and increased degrees of speckling over time have been documented by serial photography. There are reports of cutaneous melanoma arising within a nevus spilus[146] and on occasion melanocytic dysplasia has been noted in the nevus spilus adjacent to the site of melanoma development. As with conventional congenital melanocytic nevi, the risk of melanoma may be related to size[146], but it may also be related to the type of "speckles".

Nevus spilus is also seen in patients with phakomatosis pigmentovascularis types III and IV (see Ch. 104) as well as those with phakomatosis pigmentokeratotica. The latter patients also have organoid nevi, which combine features of epidermal nevi and sebaceous nevi. Patients with speckled lentiginous nevi may have ipsilateral dysesthesia, muscular weakness or hyperhidrosis, a combination referred to as the "speckled lentiginous nevus syndrome".

Pathology

The tan macule or patch of nevus spilus is characterized by lentiginous melanocytic hyperplasia associated with elongated epidermal rete ridges. The hyperpigmented macular foci are also characterized by lentiginous melanocytic hyperplasia or junctional nevi, whereas the papular foci represent compound, dermal, blue, Spitz, and/or atypical nevi. Histologic features associated with congenital melanocytic nevi can also be seen.

Differential Diagnosis

Agminated nevi (junctional, compound > Spitz, blue) and partial unilateral lentiginosis represent the major entities in the differential diagnosis. However, neither has an associated tan patch as a background and agminated nevi have less variation in the types of nevi present. Sometimes Wood's lamp examination is required to make the distinction.

Treatment

Because of reports of cutaneous melanoma developing within a nevus spilus, it seems advisable that patients be followed on a periodic basis (photography may be helpful). Individual pigmented lesions with atypical features or suspicious change should be evaluated histologically.

HALO NEVUS

Synonyms: ■ Leukoderma acquisitum centrifugum ■ Sutton's nevus ■ Perinevoid vitiligo

Key features

- White halo around a nevus
- Most common on the back in teenagers with an increased number of nevi
- Lymphocytes infiltrate the nevus

Epidemiology

Halo nevi generally affect individuals under the age of 20 years. Although the mean age is approximately 15 years, these nevi have been noted to appear from the first to the fifth decade of life[147]. The overall incidence of halo nevi in individuals under age 20 is probably <1%. There is no gender predilection, but those patients who develop halo nevi in general have an overall increased number of melanocytic nevi. Approximately 20% of individuals with halo nevi have vitiligo and they are less often associated with atypical features.

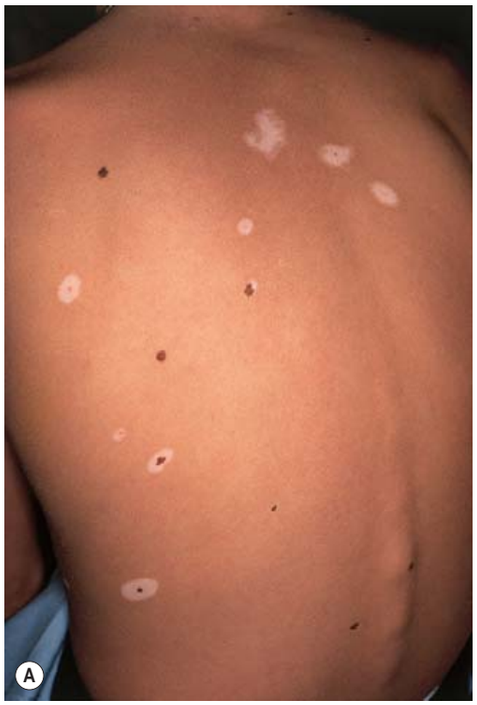
Pathogenesis

The basis for the development of a halo of depigmentation is thought to be either: (1) an immune response against antigenically altered nevus cells associated with tumor progression (dysplasia); or (2) a cell-mediated and/or humoral (antibody-mediated) reaction against non-specifically altered nevomelanocytes and possible cross-reactivity with nevomelanocytes at a distant site or sites. The first hypothesis holds that all halo nevi are atypical, but this has not been supported by histologic evaluations. The second theory holds that halo nevi are the result of a host response directed against non-specifically altered nevomelanocytes in response to a physical, chemical or other insult or perhaps result from an autoimmune pathogenesis, as in vitiligo. The second is favored nowadays.

The basis for nevus cell destruction in halo nevi is poorly understood, but both humoral and cellular immunologic factors have been implicated. Individuals with regressing halo nevi (but not other types of conventional nevi) have antibodies directed against melanoma cells, and lymphocytes isolated from patients with halo nevi and from melanoma patients are cytotoxic to melanoma cells in culture. However, it is not known whether the preceding observations are important in the pathogenesis of halo nevi or are merely epiphenomena. While the central nevus component of an active halo nevus is usually associated with a dense mononuclear cell infiltrate, the peripheral white halo has little or no such infiltrate. Perhaps destruction of melanocytes within the depigmented zone is secondary to the diffusion of a cytotoxic factor.

Clinical Features

Halo nevi are characterized by a central melanocytic nevus component that may be relatively flat or raised and dark brown to pink in color. The nevus may exhibit surface scale or crusting. Surrounding the central nevus is a well-circumscribed annulus of hypo- or depigmented skin (Fig. 112.28A). Erythema occasionally precedes the development of the depigmented halo, which is thought to appear over a period of weeks to months. In typical halo nevi, the central nevus often measures 3–6 mm in diameter, has smooth and well-defined borders, and has a homogeneous color. By dermoscopy, globular and/or homogeneous patterns that typify benign nevi in children and young adults are usually observed[148]. The white halo is often symmetric with a uniform width that may vary from a few millimeters up to several centimeters



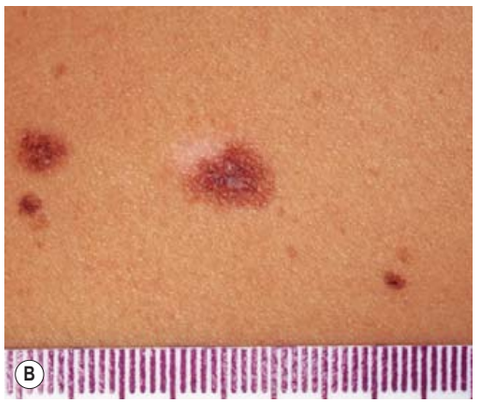


Fig. 112.28 Halo melanocytic nevi. **A** Stage I (central brown nevus), II (central pink nevus), III (depigmented macule), and early IV (partially repigmented) halo nevi are present. Multiple halo nevi are seen most commonly in children and young adults with numerous nevi. **B** A benign compound nevus with an asymmetric halo. *B, Courtesy, Jean L Bolognia, MD.*

(uncommon), but it can be asymmetric (Fig. 112.28B). A Wood's lamp may enhance or discern the halo. Dermoscopically, it is white and structureless (Fig. P7).

Halo nevi are most typically located on the upper back, but may be found in any location. Approximately 25% to 50% of affected individuals have two or more halo nevi. Rarely, large numbers of halo nevi occur, sometimes with a rapid onset. After the development of a halo nevus, its subsequent course is variable. Rarely, the central nevus persists indefinitely (and the halo repigments); usually the nevus regresses over months to years, leaving a white macule. The central nevus may first become irregular or pink in color. Complete repigmentation of the skin is seen in the vast majority of patients, but the process may take years.

A relationship to vitiligo, melanoma and atypical nevi has been well documented. A new onset of multiple halo nevi may be a sign of an ocular or cutaneous melanoma elsewhere, especially in older adults.

Pathology

The halo nevus may be junctional, compound or dermal. In the fully evolved stages, the central nevus is associated with a well-circumscribed, dense, somewhat band-like infiltrate of mononuclear cells, almost exclusively lymphocytes and histiocytes, which occupies the papillary dermis and penetrates nests of nevus cells. The latter change can be so prominent that nevus cells are difficult to distinguish from surrounding lymphoid cells without special stains. Degenerating nevus cells can sometimes be identified in this zone.

Differential Diagnosis

Common acquired melanocytic nevi with the halo phenomenon must be distinguished from: (1) other melanocytic proliferations with halos, such as congenital melanocytic nevi, atypical nevi, blue nevi, Spitz nevi, and primary melanomas or melanoma metastases; and (2) non-melanocytic lesions with halos, such as dermatofibromas, seborrheic keratoses, flat warts, molluscum contagiosum, basal cell carcinoma, lichen planus, psoriasis and sarcoidosis. An asymmetric, irregular halo may be seen with melanoma, as compared with the symmetry usually found in a halo nevus, but asymmetry does not equate with malignancy (see Fig. 112.28B). The clinical characteristics of the central melanocytic lesions determine whether a biopsy is performed, but halo nevi are exceedingly more common than halo primary melanomas, especially in adolescents.

Treatment

The approach to patients with halo nevi is individualized and depends upon the clinical setting. All persons with halo nevi should be questioned regarding a personal or family history of cutaneous melanoma, atypical nevi and vitiligo. Each halo nevus should be inspected carefully for features of an atypical melanocytic nevus or melanoma. The patient also should undergo a comprehensive skin examination for evidence of other halo nevi, atypical nevi, melanoma or vitiligo. If no atypical features are observed, the patient should be followed with periodic skin examinations. In general, clinically atypical halo nevi should be examined histologically. Halo nevi with a benign clinical appearance need not be removed. Individuals beyond 40 years of age with new-onset halo nevi should be examined carefully for melanoma (ocular and cutaneous).

COMBINED NEVUS

Synonyms: ■ Melanocytic nevus with phenotypic heterogeneity ■ One variant: • Clonal nevus • Inverted type A nevus

Key features

- Usually < 5–6 mm in diameter
- Frequently blue–gray in color when combination of blue nevus plus conventional nevus
- Another clinical presentation is the presence of a dark brown or black focus within a common nevus
- Presence of two or more distinct nevus components histologically

Introduction and Epidemiology

Combined melanocytic nevus refers to the simultaneous presence of at least two distinct nevus components in a single melanocytic neoplasm[149–153]. Any combination of conventional nevus, blue nevus or Spitz nevus may potentially be observed; however, one of the more common combinations is a conventional nevus plus a population of enlarged, pigmented, polygonal/epithelioid melanocytes and/or spindled melanocytes within the dermis, in association with melanophages. The incidence of combined nevi has been estimated to be ~1% of all melanocytic nevi sampled for histopathologic examination.

Clinical Features

The clinical features are directly related to the types of nevus components present. Combined nevi may arise at any site, but they have a predilection for the head and neck region (especially those with a blue nevus component), followed by the trunk. A smooth, blue–gray to blue–brown to blue–black papule or nodule is a common presentation, as is a discrete dark brown to black focus within an otherwise uniformly tan or brown banal nevus (Fig. 112.29). Some clinicians refer to the latter as a clonal nevus.

Fig. 112.29 One variant of combined melanocytic nevus. Dark brown to black papule within an otherwise uniformly pigmented light brown nevus. The differential diagnosis includes the possibility of a melanoma developing in a nevus. Some clinicians refer to nevi with this clinical appearance and the histologic features seen in Fig. 112.30 as clonal nevi. *Courtesy, Lorenzo Cerroni, MD.*

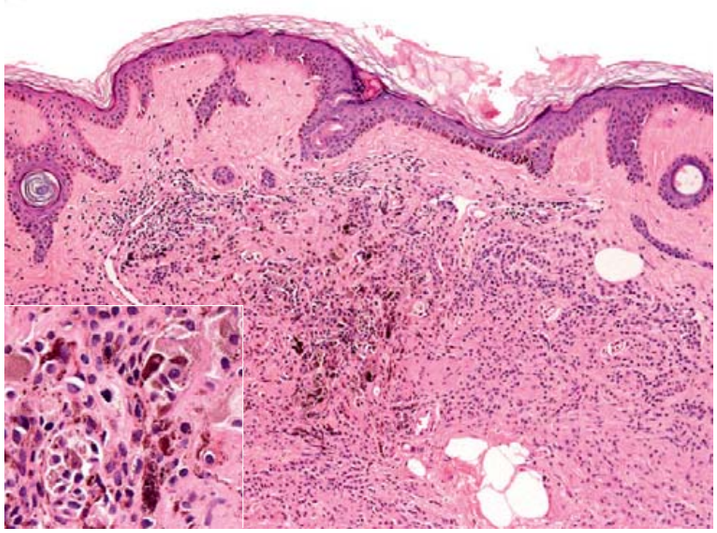

Fig. 112.30 Histology of a combined nevus. Within this intradermal nevus is a focal collection of pigmented dermal melanocytes and melanophages. The cells are benign in appearance (insert). Close examination of the focal proliferation of pigmented cells is recommended to exclude the possibility of melanoma. *Courtesy, Lorenzo Cerroni, MD.*

Pathology

The histologic features also vary depending on the types of nevi present. Most often, a banal compound or dermal nevus is either admixed with a dermal population of pigmented epithelioid or spindled melanocytes or it overlies a more discrete pigmented spindle and epithelioid component (Fig. 112.30). When there is extension into the deep dermis or subcutaneous fat, the term "deep penetrating nevus" or "plexiform pigmented spindle cell nevus" is sometimes applied.

Differential Diagnosis and Treatment

Both clinically and histologically, the presence of two or more components in a melanocytic lesion raises the possibility of melanoma, including one arising within a nevus. The clinical differential diagnosis also includes blue nevus, pigmented Spitz nevus, pigmented basal cell carcinoma, benign vascular tumor, the hemosiderotic variant of dermatofibroma, and melanoma metastasis. Careful histologic examination to exclude melanoma is required. If the lesion is sufficiently suspicious, a biopsy is performed.

RECURRENT MELANOCYTIC NEVUS

Synonyms: ■ Persistent melanocytic nevus ■ Pseudomelanoma

Key features

- Recurrent melanocytic nevi are fairly common following shave excision
- Heavily pigmented melanocytes proliferate within the epidermis, often with upward migration, and may resemble melanoma histologically

Epidemiology

In a series of 175 cases[154] recurrent nevi were most often noted in relatively young women, reflecting the greater number of nevi removed from women and a higher prevalence in younger patients. Recurrent nevi are most commonly observed on the trunk, followed by the head and neck region. Most of the recurrences have followed a shave excision, at an estimated rate of 10–30%. Approximately 50% of the recurrences were noted within 6 months of the surgical procedure[154].

Pathogenesis

The recurrence of melanocytic nevi reflects an intraepidermal proliferation of residual melanocytes, possibly originating from nearby sweat ducts, hair follicles or intraepidermal melanocytes. Trophic factors stimulating melanocyte migration, melanocyte proliferation, or both, may be related to mechanisms of wound healing or scar formation.

Clinical Features

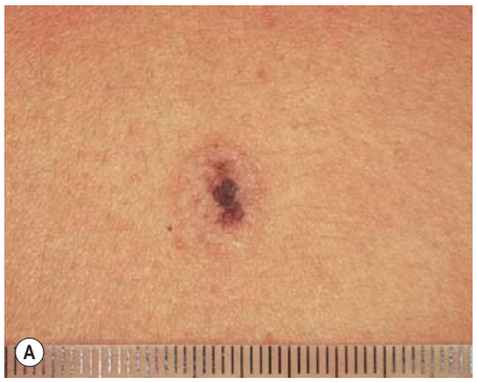
These lesions are characterized by circumscribed hyperpigmentation within a scar that is due to a previous surgical procedure for nevus removal (Fig. 112.31A). In most instances, the lesion is macular and exhibits variable irregularity of its border and pigment pattern. Stippling, mottling and a perifollicular distribution may be observed. Most recurrent nevi measure 2 to 5 mm in diameter. The dermoscopic features of persistent nevi are sometimes difficult to distinguish from melanoma. As a general rule, in recurrent nevi, the pigment will not extend beyond the white scar (Fig. P8). Most recurrent nevi are stable for years after development and then may fade. No increased melanoma risk has been associated with recurrent nevi.

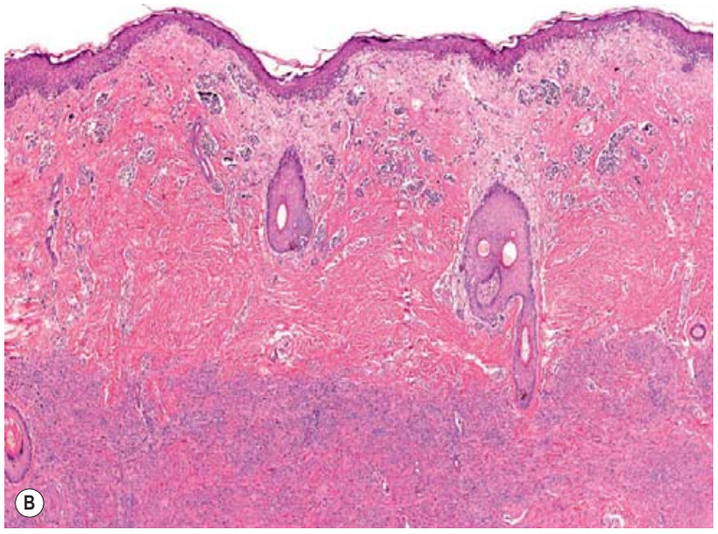
Pathology

Corresponding to the clinical features, one frequently observes intraepidermal melanocytic proliferation confined to the area above a dermal scar (Fig. 112.31B,C). The epidermis usually exhibits effacement of the rete pattern and variable lentiginous or nested proliferation of melanocytes. Often, the cells contain abundant melanin and have relatively uniform nuclei. However, occasionally, low-grade cytologic atypia is noted. Upward migration of epidermal melanocytes may also occur. Frequently, there are residual dermal nevus cells beneath the superficial dermal scar (see Fig. 112.31B).

Differential Diagnosis

The differential diagnosis of recurrent nevi includes the lentiginous melanocytic proliferations and the pigmented streaks due to basilar hyperpigmentation that can both develop in surgical excision scars (including those for melanoma). Additional entities to consider are traumatized nevi, recurrent atypical melanocytic nevi, and recurrent melanoma. In general, a recurrent melanocytic nevus is confined to the area of the surgical scar, appears within 6 months of surgery, and





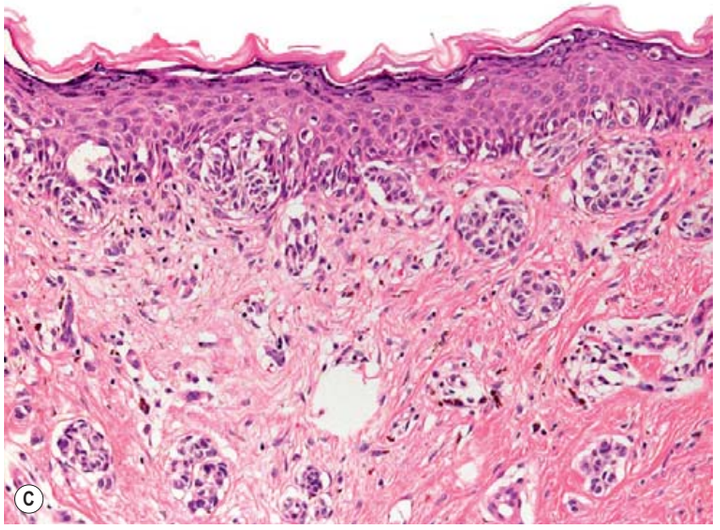


Fig. 112.31 Recurrent melanocytic nevus. A Dark brown pigmentation within the center of a circular scar; the pigmentation reflects the proliferation of melanocytes within the epidermis. **B** Histologically, an irregular junctional and superficial dermal melanocytic proliferation overlies a dermal scar and more deeply located residual dermal nevus. **C** At higher magnification, both junctional nests of melanocytes and single melanocytes are noted along the flattened dermal–epidermal junction. The melanocytes are enlarged polygonal cells and show some low-grade nuclear pleomorphism. *A, Courtesy, Jean L Bolognia, MD. B, C, Courtesy, Lorenzo Cerroni, MD.*

exhibits a banal histologic picture. Recurrent atypical nevi may have more disordered intraepidermal melanocytic proliferation (even a pagetoid pattern) and greater cytologic atypia than conventional recurrent nevi. Clinical features suggesting melanoma include irregular pigmentation, progressive enlargement, extension beyond the confines of the surgical scar, and a longer time interval before recurrence (>6 months).

Treatment

Establishing that a previous surgical procedure has occurred is integral to the diagnosis. Review of the previous biopsy specimen is mandatory if any atypicality is noted histologically. Excision of a recurrent nevus is not necessary unless abnormal clinical features are present, e.g. extension of the lesion beyond the surgical scar.
