Chorionic villi, 1465–1466
  formation of, 1051–1052, 1053*f*
Chorionic villus sampling (CVS), 1107–1108, 1108*f*
Chorionicity, in multifetal pregnancy, 1115–1116, 1116*f*
  sonographic determination of, 1117–1119, 1118*f*, 1119*t*, 1120*f*–1121*f*
  triplets and, 1122*f*
Choroid plexus
  fetal
    fetal brain and cysts of, 1170, 1173*f*
    sonographic view of, 1024*f*
    spina bifida and cysts of, 1233
    trisomy 18 and cyst of, 1103*f*, 1104
    trisomy 21 and cysts of, 1101
  neonatal/infant
    in coronal imaging, 1514–1515, 1514*f*
    cysts of, 1565, 1566*f*
    development of, 1522–1523, 1522*f*–1523*f*
    papillomas of, 1562, 1565*f*
  papillomas of
    Aicardi syndrome and giant pigmented nevi in, 1209
    in neonatal/infant brain, duplex Doppler sonography of, 1588*f*
    VM with, 1177–1178
Choroid(s)
  asymmetry of, in VM, 1178
  separation of, from medial ventricle wall, in VM evaluation, 1176, 1176*f*
Chromosomal abnormalities. *See also* Aneuploidy; Triploidy; Trisomy 13; Trisomy 18; Trisomy 21
  diagnostic testing for, 1107–1109, 1108*f*
  Ebstein anomaly with, 1286
  fetal, IUGR and, 1455
  fetal hydrops from, 1429–1430, 1430*f*
  maternal age-related risks of, 1088, 1089*f*
  primary amenorrhea in, 1887
  teratologic hip dislocation and, 1932
  triploidy as, 1104–1106, 1104*b*, 1105*f*
  trisomy 13 as, 1104
  trisomy 18 as, 1103–1104
  trisomy 21 as, 1097–1103
  Turner syndrome as, 1106–1107, 1106*f*
Chromosomal anomalies, in CHD, 1270
Chromosomal microarray analysis (CMA), 1097
Chromosome 11p13, hepatoblastomas and, 1746
Chronic allograft nephropathy, 1810, 1812*f*
Chronic autoimmune lymphocytic thyroiditis, 724, 725*f*–727*f*
Chronic epididymitis, 841, 843*f*
Chronic kidney disease (CKD), 1796–1798, 1797*t*, 1798*f*
Chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS), 389–390, 390*f*
Chronic sclerosing pancreatitis, 236
Chylothorax
  congenital, fetal, hydrops from, 1425–1426
  fetal
    in hydrops, 1413–1416
    primary, 1256
  neonatal, radiopaque hemithorax in, 1704*f*
Chylous ascites, 508
Ciliopathies, 1182, 1346
Cingulate sulcus, 1515
  neonatal/infant, development of, 1520–1521, 1521*f*
Circumscribed carcinomas, 786
Circumvallate placenta, 1479–1480, 1480*f*–1481*f*
Cirrhosis
  biliary, 92–93, 182
    pediatric, 1741
  gallbladder wall thickening and, 199*f*
  hepatic vein strictures in, 95, 95*f*
  in inborn errors of metabolism, 1738
  of liver, 92–96
    Doppler ultrasound characteristics of, 95, 95*f*
    HCC and, 122, 122*t*
    intrahepatic portal hypertension from, 96
    morphologic patterns of, 92–95, 94*f*
    pseudocirrhosis of, 125–128, 129*f*
    sonographic features of, 95*b*
    SWE and, 95–96
  macronodular and micronodular, 92–93
  pediatric, 1741, 1742*f*
    causes of, 1760*b*
    intrahepatic portal hypertension and, 1759–1762
  post necrotic, 1741
Cistern, as transtemporal approach landmark, 1592, 1593*f*
Cisterna magna
  fetal
    effacement of, in Chiari II malformation, 1183–1185, 1184*f*
    normal sonographic appearance of, 1168–1169
  neonatal/infant
    clot in, in intraventricular hemorrhage, 1545, 1546*f*
    development of, 1524
    mega, Dandy-Walker malformation differentiated from, 1531, 1534*f*
CKD. *See* Chronic kidney disease
Classic diagnostic triad, for renal cell carcinoma, 340
Clavicle, 878–879, 878*f*
  growth of, normal, 1378
Clear cell carcinoma, 581, 582*f*
Cleavage, neonatal/infant brain and disorders of, 1532–1536. *See also* Holoprosencephaly
Cleft lip/palate
  associated signs of, 1152*b*
  bilateral, 1152, 1156*f*–1157*f*
    hypertelorism and, 1144*f*
    Roberts syndrome and, 1401
  complete compared to incomplete, 1151, 1153*f*–1154*f*
  deviation of vomer in, 1151
  differential diagnosis of, 1151*b*
  isolated clefts of secondary palate in, 1153
  median, 1152
  as midface abnormality, 1151–1153
  patterns of, 1152*f*
  Tessier category of, 1152–1153, 1153*f*
  trisomy 13 and 18 in, 1151
  unilateral, 1152, 1155*f*
    midface hypoplasia with, 1149*f*
Cleidocranial dysplasia
  ribs in, 1382–1384
  wormian bones in, 1139
Clinodactyly, fetal, 1404–1405, 1406*f*
Cliopathies, 1182
Clitoris, fetal, enlarged, 1367
CLO. *See* Congenital lobar overinflation
Cloaca, 1337*f*, 1338, 1674
Cloacal exstrophy
  fetal abdominal wall and, 1328–1329, 1329*f*
  pediatric, risk of spinal dysraphism with, 1689
  sacral agenesis in, 1237
Cloacal malformation, 1310–1311
  fetal, lower urinary tract obstruction and, 1363, 1363*f*
  pediatric, risk of spinal dysraphism with, 1689
Clonorchiasis, biliary tree and, 178–179, 179*f*
Clopidogrel (Plavix), 598
Closed-loop obstruction, mechanical bowel and, 293, 295*f*
Cloverleaf-shaped skull, 1136
  craniosynostosis with, 1137*f*–1138*f*
  in skeletal dysplasias, 1382
  in thanatophoric dysplasia type 2, 1388–1389, 1389*f*
Clubfoot
  fetal, 1407, 1407*f*
    body stalk anomaly and, 1329
    campomelic dysplasia and, 1395
    in skeletal dysplasia, 1382
    spina bifida and, 1233
  pediatric, 1932
Clubhand, fetal, 1407
  in skeletal dysplasias, 1382
Clustered macrocysts, in breast, 779, 780*f*
Clustered microcysts, in breast, 782
CMA. *See* Chromosomal microarray analysis
CMV. *See* Cytomegalovirus infection
CNS. *See* Central nervous system
CNVs. *See* Copy number variants
Coagulation necrosis, from HIFU, 32
Coagulopathies, small bowel obstruction from, 1843
Coarctation
  of aorta, 1291, 1292*f*
    fetal, hydrops from, 1423–1424
    hypoplastic left heart syndrome with, 1287
  of frontal horn, 1522, 1522*f*
  of lateral ventricles, 1566
Coccygeal dimples, 1679, 1680*f*
Coccyx
  agenesis of, 1689
  development of, in infants, 1677, 1680*f*
Cogwheel sign, 587–588
Colitis
  infectious, pediatric, 1852
  pseudomembranous, 296–297, 298*f*
  tuberculosis, 287–288
  ulcerative, 266–267
Collagen bundles, 859
Collagen vascular disease, maternal, fetal AVB from, 1297
Coloboma, 1143, 1146*f*
Colon
  carcinoma of, 261–264, 263*f*–264*f*
    pediatric, 1880
  diverticula of, 290, 291*f*
  fetal, 1308–1316
    anorectal malformations and, 1310–1312, 1311*f*
    MMIHS and, 1362–1363
  pediatric, 1847–1848
    ectopic or imperforate anus and, 1847–1848, 1850*f*
    interventional sonography and anatomy of, 1950
    normal anatomy of, 1847, 1850*f*
    sonographic technique for, 1847
Color assignments, changing, in color Doppler, 933
Color Doppler ultrasound, 24, 25*b*
  aliasing in, 28, 29*f*, 966
  for breast assessment, 769–772, 770*f*–773*f*
  for carotid stenosis evaluation, 932–935
    advantages and pitfalls of, 934–935, 934*b*, 934*f*
    bruit from, 933, 934*f*
    optimal settings in, low-flow vessel evaluation, 933–934, 933*b*, 934*f*
  color assignments in, changing, 933
  for Crohn disease, 268*t*, 269, 272*f*
  Doppler beam in, vessel paralleling, 933
  for epididymitis, pediatric, 1896, 1896*b*
  in fetal heart assessment, 1275–1277, 1282*f*

Color Doppler ultrasound *(Continued)*
green-tag feature in, 932–933
interpretation of, 28, 28*f*–29*f*
interventional sonography, pediatric and, 1945
limitations of, 25*b*
for neonatal/infant brain, 1573–1574
operating modes in, 30–31
for pancreatic carcinoma, 241, 241*b*, 241*f*–243*f*, 241*t*
for percutaneous needle biopsies, 599
in placenta accreta diagnosis, 1471
in placenta blood flow assessment, 1468–1469
in pleural fluid imaging, 1709, 1710*f*
power compared to conventional, 25, 26*f*
PRF in, 28, 29*f*, 30–31
process of, 24, 26*f*
prostate cancer and, 404*f*, 406
slow-flow sensitivity settings on, 939
for testicular torsion, pediatric, 1895–1899, 1896*b*
for testicular tumors, pediatric, 1901–1902
in ureteral calculi detection, 337, 339*f*
for ureteral jets evaluation, 1781*f*
weighted mean frequency in, 28
Color gain, in renal artery duplex Doppler sonography, 449
Color streaking, breast cysts with, 775, 776*f*
Colpocephaly, 1202*f*
in Chiari II malformation, 1526, 1527*f*
in corpus callosum agenesis, 1528, 1530*f*
Column of Bertin, in kidney development, 1781, 1783, 1784*f*
Coma, brain death differentiated from, 1618–1620, 1620*f*
Comet-tail artifacts, 202, 695
in benign and malignant thyroid nodule differentiation, 712–713
in degenerative cysts of thyroid, 1646, 1647*f*
Common bile duct
anastomosis of, for liver transplantation, 625
dilation of, cylindrical or saccular, pediatric, 1735, 1736*f*
diverticula of, 1735
stones in, 173–174, 173*f*
acute pancreatitis and, 221
liver transplantation complications with, 629, 632*f*
Common femoral vein
as landmark for femoral hernias, 482, 485*f*
normal anatomy of, 500, 981*f*
Complete molar pregnancy, 1078, 1079*f*
Complete subclavian steal, 952–953, 953*b*, 953*f*
Complete TGA, 1289, 1289*f*
Complicated cysts, of breast, 775–780, 776*f*
Compression
of amplitudes, 9
ballottement and, 768
for breast sonography, 768, 772, 773*f*
of femoral vein, normal, 982*f*
maneuvers, for dynamic ultrasound of hernia, 474, 475*f*
for parathyroid gland adenomas detection, 739
soft tissue ganglia causing, 865
in sound wave, 2, 2*f*
Compression sonography, 258–260, 261*f*
Computed tomography (CT)
in abdominal aortic aneurysm
rupture evaluation and, 438, 439*f*
for screening and surveillance, 437
treatment planning with, 438
in interventional sonography, pediatric, 1943, 1943*t*
parathyroid adenomas and accuracy of, 748, 748*f*
Computed tomography (CT) *(Continued)*
pediatric chest, sonography compared to, 1709, 1710*f*–1711*f*
for percutaneous needle biopsies, 599
three-dimensional, in skeletal dysplasia evaluation, 1384–1385
Concentric hypertrophy, 1294–1295
Conceptual age, definition of, 1443–1444
ConfirmMDx test, 396
Congenital adrenal hyperplasia (CAH)
adrenal rests in, 832–833, 833*f*, 1824, 1900–1901
pediatric, 1822–1824, 1824*f*, 1900–1901
Congenital anomalies of kidney and urinary tract (CAKUT), 1336
Congenital bilateral absence of the vas deferens (CBAVD), 394
Congenital coxa vara, atypical hips and, 1932
Congenital cystic adenomatoid malformation (CCAM), 1246, 1248*t*
fetal, hydrops from, 1426
Congenital diaphragmatic hernia (CDH), 1248*t*, 1258–1264
anomalies associated with, 1263
bilateral, 1262
fetal lung size and, 1244
FETO for, 1264
left-sided, 1258–1259, 1260*f*
morbidity and mortality from, 1264, 1264*t*
prognosis of, 1261–1262, 1262*b*
right-sided, 1259, 1261*f*
survival predictors in, 1262, 1262*b*
in utero therapy for, 1264
Congenital heart block, fetal, 1297, 1297*f*
hydrops from, 1425
Congenital heart defects, thickened NT in, 1095–1097, 1096*f*
Congenital heart disease (CHD)
chromosomal anomalies in, 1270
extracardiac malformations in, 1270
fetal arrhythmia and, 1270–1273
hydrops and, 1270
IVF and, 1270–1273
MCDA twins and, 1270–1273
risk factors associated with, 1270, 1271*t*–1272*t*
recurrence, in offspring, 1273*t*
recurrence, in siblings, 1273*t*
Congenital high airway obstruction (CHAOS), 1248*t*, 1253–1255, 1254*f*
hydrops from, 1426
Congenital hypothyroidism, 694
pediatric ovarian cysts and, 1875
Congenital infantile myofibromatosis, 1664, 1665*f*
Congenital lobar emphysema, 1246
Congenital lobar overinflation (CLO), 1246, 1251–1252, 1253*f*
Congenital malformations, obstetric sonography and, 1041
Congenital myopathy, atypical hips and, 1932
Congenital nephrotic syndrome, CKD and, 1796–1798
Congenital pulmonary airway malformation (CPAM)
classification of, 1248
differential diagnosis of, 1248*t*
fetal, 1246–1252
hydrops development and, 1248–1249, 1426, 1427*f*
pediatric, 1715–1716, 1717*f*
pleuropulmonary blastoma differentiated from, 1252–1253
sonographic diagnosis of, 1248, 1249*f*
volume ratio of, 1248, 1250
Congestive heart failure
gallbladder wall thickening and, 199*f*
neonatal/infant, 1566
Conglomerate masses, Crohn disease and, 269
Conjoined tendon insufficiency
direct inguinal hernia and, 479–481, 483*f*–484*f*
sports hernia and, 485–486, 489*f*
Conjoined twins, 1115–1116
complications with, 1129–1130, 1130*f*
Conn syndrome, adrenal adenomas in, 419
Connatal cysts, 1566
Connective tissue, dense fibrous, homogeneous plaque and, 920–921
Conradi-Hünermann syndrome, 1399
Constrictive amniotic bands, 1182–1183
Continuous ambulatory peritoneal dialysis, 521
Continuous wave (CW) devices, 8
Continuous wave Doppler, 24, 25*f*
Continuous wave probes, with duplex pulsed Doppler, 939
Continuous wave ultrasound, 36
Contraceptive devices, intrauterine, 529, 552–554, 553*f*
Contraceptives, oral, hepatic adenomas and, 1746
Contrast, speckle effect on, 13–15, 14*f*
Contrast agents, 41–42. *See also* Blood pool contrast agents
acoustic cavitation and, 43, 44*b*
avoidance of, in obstetric sonography, 1038
blood pool, 55–56
disruption-replenishment imaging and, 66–67, 67*f*
echo enhancing, 57*f*
harmonic imaging with, 58–64
in hydrosonovaginography, 1870–1871, 1871*f*
intermittent harmonic power Doppler imaging and, 66, 66*f*
intermittent imaging with, 64–67, 66*f*
intravenous Doppler, 1749–1750
intravenous ultrasound, 1746
microbubbles as, 53–54, 54*f*
behavior of, incident pressure and, 56–58, 57*t*
disruption of, 64–67, 66*f*
FNH characterization with, 106, 106*f*, 108*t*, 109*f*
future of technology for, 68–69, 69*f*–70*f*
HCC characterization with, 106, 106*f*
hemangioma characterization with, 106, 106*f*–107*f*, 108*t*
inertial cavitation and, 67–68
lesional enhancement with, 105, 106*f*–107*f*, 109*f*
liver mass characterization with, 105–106, 106*f*–107*f*, 108*t*, 109*f*–110*f*
MI and, 58, 58*b*, 105
need for, 56–58, 57*f*
regulation of, 68
safety of, 67–68
in musculoskeletal interventions, 898
nonlinear echoes and, 58–64
amplitude and phase modulation imaging and, 64, 65*f*
harmonic B-mode imaging and, 60
harmonic spectral and power Doppler and, 60–61, 60*f*–62*f*
plane-wave contrast imaging and, 64
pulse inversion Doppler imaging and, 63–64
pulse inversion imaging and, 62–63, 62*f*–63*f*
temporal maximum intensity projection imaging and, 64, 65*f*
tissue harmonic imaging and, 61–62
perfluorocarbons in, 56
for liver mass detection, 107, 111*f*
requirements for, 54–56

Contrast agents *(Continued)*
triggered imaging and, 65
types of, 54–56
in water enema technique, 1870–1871, 1871*f*
Contrast effect, of steroid anesthetic mixture, 899, 899*f*
Contrast pulse sequence (CPS), 64
Contrast-enhanced ultrasound (CEUS)
adenoma diagnosis with, 116–117, 117*f*
backscatter increased with, 107, 111*f*
for breast lesions, 773–774
cavernous hemangioma characterization with, 111, 113*f*
for Crohn disease, 269, 273*f*
Crohn disease identification with, pediatric, 1853, 1854*f*
in fatty liver diagnosis, 91–92
FNH diagnosis with, 113–115, 115*f*
gut wall and, 261
HCC detection with, 120–122, 123*f*
Hilar cholangiocarcinoma assessment with, 188, 191*f*
liver metastases diagnosis with, 128–129, 130*f*
for pancreas, 251
for pancreas transplantation, 676
for prostate cancer, 406
for thyroid gland assessment, 692, 714–715
Contrast-to-noise ratio, spatial compounding and, 13–15, 15*f*
Conus medullaris
determining position of, 1677, 1679*f*
fetal, location of, 1218–1221, 1221*f*, 1673, 1673*f*
low and tethered, caudal agenesis type II and, 1689
Conus septum, TOF and, 1288
Cooper ligaments, 761, 761*f*–763*f*
Copy number variants (CNVs), 1088

AVF and malformation as, 366–367, 366*f*
renal vascular Doppler ultrasound and, 366
Germ cell tumors
ovarian, 582–585
pediatric, 1879
testicular, 822–825, 822*b*
mixed, 822–823, 825*f*
nonseminomatous, 823–824, 825*f*
regressed, 824–825, 825*f*–826*f*
thymus, 1723–1724

Germinal epithelium, 565
Germinal matrix hemorrhage, hypoxic-ischemic injury in premature infant and, 1541–1543, 1542*f*, 1543*b*, 1543*t*
Germinal matrix of, neonatal/infant, development of, 1524, 1524*f*
Gerota fascia, 314
Gestational age
  alpha-fetoprotein levels compared to, 1227*f*
  calculation of, 1049
  cervical length and, 1499–1500, 1499*f*
    spontaneous PTB prediction based on, 1500–1501, 1501*t*
  definition of, 1443–1444
  determination of
    accuracy of, 1449, 1450*t*
    composite formulas for, 1448–1449
    routine ultrasound screening in, 1022–1029
  estimation of
    CRL in, 1062
    in first trimester, 1061–1062
    gestational sac size in, 1061, 1061*f*
    MSD in, 1061, 1061*f*, 1444–1445, 1445*t*
    routine ultrasound screening in, 1022–1029
  extremity long-bone lengths and BPD at, 1379*t*
  fetal measurements for determining, 1016, 1016*b*, 1444–1449
    age assignment and, 1449, 1450*t*
    in first trimester, 1444–1445, 1445*f*–1446*f*, 1445*t*–1446*t*
    in second and third trimesters, 1446–1448, 1447*f*–1450*f*, 1447*t*–1449*t*
  fetal weight assessment in relation to, 1451–1453, 1452*t*, 1453*f*
  fetal weight estimation compared to, 1453, 1453*f*
  for heterozygous achondroplasia detection, 1381
  kidney length compared to, 1776–1778, 1780*f*
  PSV blood flow in MCA as function of, 1421, 1422*t*
  thermal effects of ultrasound and, 1037–1038
  thoracic circumference and length correlated with, 1247*t*
  usage of term, 1167
Gestational sac, 1017*f*
  abnormal size of, 1063
  chorionic bump in, 1065
  chorionic sac fluid of, 1054–1055, 1056*f*
  discriminatory level for seeing, 1056
  early pregnancy failure and
    appearance concerns in, 1065, 1066*f*
    no embryo in, 1063–1065, 1065*f*
    small MSD in relationship to CRL in, 1066, 1067*f*
  identification of, in gestational age determination, 1444, 1445*f*, 1446*t*
  mean diameter of
    CRL and, early pregnancy failure and, 1066, 1067*f*
    in gestational age determination, 1444–1445, 1445*t*
  normal sonographic appearance of, 1054–1055, 1055*f*–1056*f*
  size of, in gestational age estimation, 1061, 1061*f*
  threshold level for seeing, 1056
  transvaginal ultrasound for identification of, 1054–1055
  β-hCG levels and, 1056–1057
Gestational trophoblastic disease, 556, 1077–1084, 1479
  hydatidiform molar pregnancy and, 1078–1080
    complete, 1078, 1079*f*
    partial, 1078, 1080*f*
    vaginal bleeding and, 1078
Gestational trophoblastic disease *(Continued)*
  PTN and, 1078, 1080–1084, 1082*f*
    choriocarcinoma and, 1080–1082, 1083*f*
    diagnosis and treatment of, 1083–1084
    Doppler ultrasound for, 1083
    after hydatidiform molar pregnancy, 1080, 1081*f*
    invasive mole, 1080, 1081*f*
    PSTT and, 1082
    sonographic features of, 1082–1083
"Geyser sign", 889–891, 892*f*
GGTP. *See* Gamma-glutamyl transpeptidase
Ghost triad, biliary atresia and, 1737, 1738*f*
Giant pigmented nevi, choroid plexus papillomas in, 1209
Giant-cell tumors, in TSC, 1200*f*
Glenohumeral joint, 878–879, 878*f*
  effusion of, 893–894, 894*f*
Glenohumeral joint, injection of, 901, 901*f*
Glenoid fossa, 878–879, 878*f*
Glial scarring, in PVL, 1552–1553
Glioependymal cysts, cavum veli interpositi cysts differentiated from, 1170
Gliomas, hypothalamic, precocious puberty and, 1887
Glisson capsule, 77
Glomerulonephritis, 370, 371*f*
  CKD and, 1796–1798
Glomus, choroid plexus, neonatal/infant, development of, 1522–1523, 1523*f*
Glomuvenous malformation, in venous malformations of neck, 1657
Glucocorticoid, secretion of, 417
Glucose, plasma levels of, high, NTDs from, 1218
Glucose-6-phosphate dehydrogenase (G6PD) deficiency, 1431
Glutaric aciduria type 1, 1540–1541
Glycogen storage disease (GSD)
  inborn errors of metabolism and, 1738
  liver in, 92
  pediatric
    type I, adenomas in, 1746
    tyrosinemia and, 1740*f*
Goiter(s)
  adenomatous, sonographic appearance of, 727
  fetal, 1159–1163, 1162*f*
  multinodular, 711, 711*f*
    in children, 1648, 1648*f*
    parathyroid adenomas detection and, 746
    sonographic appearance of, 727
  in thyroid gland nodular disease, 695–697, 695*f*–699*f*
Goitrous hypothyroidism, 694
Goldenhar syndrome, clefts of secondary palate in, 1153
Gonadal dysgenesis, primary amenorrhea in, 1887
Gonadal stromal tumors, testicular, 826, 827*f*
Gonadal veins, anatomic variants of, 457
Gonadoblastoma(s), 826, 827*f*
  pediatric, 1880
    in dysplastic gonads, 1899–1901
Gonads
  differentiation of, 1887
  dysplastic, 1899–1901
Gonococcal perihepatitis, PID and, 1887
Gorlin syndrome, 585
Gout, rheumatoid arthritis and, 867–869, 868*f*
Graafian follicle, 1049
Graded compression sonography, 283
Graft infarction, pediatric renal transplantation and, 1807–1809, 1808*f*
Graft-dependent hyperparathyroidism, 742–744, 743*f*
Graft-versus-host disease, pediatric, intestinal wall thickening in, 1853–1854, 1855*f*
Granulocytic sarcomas, pediatric, neck, 1666, 1667*f*
Granuloma(s)
  of liver, pediatric, 1748
  silicone, in extracapsular breast implant rupture, 805–807, 806*f*
  sperm, 841, 843*f*
  splenic, pediatric, 1771*f*
  stitch, after herniorrhaphy, 494–496, 495*f*
Granulomatous cystitis, pediatric, 1908
Granulomatous disease, chronic, gastric mucosa thickening in, 1839–1840
Granulomatous mastitis, 803–804
Granulomatous peritonitis, 514
Granulomatous prostatitis, 390, 390*f*
Granulosa cell tumor, ovarian, 585
  pediatric, 1880
    pseudoprecocious puberty and, 1887
Graves disease
  fetal goiter in, 1159–1163
  thyroid gland and, 727, 727*f*
    pediatric, 1646, 1646*f*
Gray-scale median level, for echolucency of plaque, 922
Great arteries, transposition of, 1289–1290, 1289*f*–1290*f*
Great saphenous vein (GSV)
  acute DVT in, 984, 984*f*
  anatomy of, 981–982, 981*f*
  vein mapping of, 989–990
Great vessels, fetal, short-axis view of, 1275, 1278*f*
Green-tag feature, in color Doppler, 932–933
Groin
  definition of, 471
  hernias of, dynamic ultrasound of
    contents of, 472–473
    entities stimulating, 499–500, 501*f*
    key sonographic landmarks for, 474
    maneuvers for, 473–474, 474*f*–475*f*
    recurrent, 494–496
    report for, 471–472
    technical requirements for, 471
  pain, 470–471
Growth. *See* Fetus, growth of; Intrauterine growth restriction

fetal, 1206, 1207*f*
neonatal/infant brain and, duplex Doppler sonography of, 1580–1581, 1584*f*
intramural, pediatric, in Henoch-Schönlein purpura, 1853, 1855*f*
intraparenchymal
IUFD and, 1124*f*
neonatal/infant brain and, 1547–1548, 1547*f*–1549*f*
intraplacental, thick placenta in, 1466
intraplaque, in heterogenous plaque, 920–921
intraventricular
from germinal matrix hemorrhage, 1541
with hydrocephalus, 1545–1547, 1546*f*–1547*f*
neonatal/infant brain and, 1544–1545, 1544*f*–1546*f*, 1545*b*
signs of, 1545*b*
pediatric
ovarian cysts and, 1877, 1878*f*–1879*f*
spinal canal, 1695, 1695*f*–1696*f*
thyroid, 1646, 1647*f*
percutaneous needle biopsy complications with, 608, 609*f*
placental, 1474
posterior fossa, 1548–1550
postpartum, in fetal hydrops, 1436
subarachnoid, neonatal/infant brain and, 1550, 1550*f*
subchorionic
early pregnancy failure and, 1069, 1069*f*
fetal echogenic bowel and, 1315*f*
subdural, fetal, bilateral, 1207*f*
subependymal, neonatal/infant brain and, 1543–1544, 1543*f*–1544*f*
Hemorrhagic cholecystitis, 200
Hemorrhagic cystitis, pediatric, 1908, 1910*f*
Hemorrhagic ovarian cysts, 570–571, 571*f*, 575
Hemothorax, sonographic appearance of, 1702, 1707*f*
Henoch-Schönlein purpura, 845–846, 1842
pediatric, 1853, 1855*f*
scrotal and testicular involvement in, 1899
Heparin, 598
Hepatic alveolar echinococcus, 90
Hepatic artery
anastomosis of, for liver transplantation, 624
aneurysms of, after liver transplantation, 1768, 1769*f*–1770*f*
anomalies of, 80–81
liver circulation and, 78
after liver transplantation
normal appearance of, 625
occlusion of, 626–627
pseudoaneurysms of, 634, 636*f*
resistive index elevation in, 634
stenosis of, 631–634, 634*f*–635*f*, 1766
thrombosis of, 627, 628*f*, 631, 633*f*
pediatric, Doppler studies of, best approaches for, 1752–1754, 1755*f*
pseudoaneurysm of, 104
after liver transplantation, 634, 636*f*
Hepatic vein(s)
anatomic variants of, 457
anomalies of, 81–82
fetal liver calcifications and, 1316–1318
liver circulation and, 80
normal, 76, 76*f*, 77*t*
occlusion of, in Budd-Chiari syndrome, 100–102, 100*f*–101*f*
pediatric
anatomy of, 1733–1734, 1734*f*
Doppler studies of, best approaches for, 1752
thrombosis of, suprahepatic portal hypertension and, 1763, 1763*f*
stenosis of, after liver transplantation, 637, 643*f*
strictures of, in cirrhosis, 95, 95*f*
Hepatitis, 1203–1204

of ultrasonic power, 35
Interdigital neuromas, injection for, 904, 904*f*
Interhemispheric fissure, fetal, normal sonographic appearance of, 1168, 1169*f*
Intermittent harmonic power Doppler imaging, 66, 66*f*
Intermittent imaging, with contrast agents, 64–67, 66*f*
Internal echoes, in renal cysts, 357, 357*b*
Internal inguinal ring, as landmark for inguinal hernias, 474–475, 476*f*

Internal jugular vein (IJV)
acute DVT of, 994*f*
anatomy of, 990–991, 990*f*
as cerebral blood vessel, 955–956
monophasic venous waveforms of, stenosis and, 1006, 1009*f*
phlebectasia of, 1658, 1660*f*
sonographic technique for, 955, 955*f*
thrombosis of, 955–956, 956*f*–957*f*
central line placement causing, 1658, 1661*f*
ultrasound examination for, 991, 991*f*
Internal oblique aponeurosis, torn, in spigelian hernia, 483–484, 487*f*
Internal urethral sphincter, 384
International Society for Ultrasound in Obstetrics and Gynecology (ISUOG), 1041
Interphalangeal joint, injection of, short-axis approach to, 901
Intersegmental laminar fusion, pediatric, 1688
Interstitial ectopic pregnancy, 1073, 1074*f*
Interstitial line sign, 1073
Interventional sonography, pediatric
for abscess drainage, 1953
appendiceal, 1956, 1960*f*
transrectal, 1953–1954, 1954*f*
anatomy for, 1950
colon or bowel and, 1950
diaphragm and, 1950, 1950*f*
antibiotics for, 1951
for biopsy
devices for, 1950
mediastinal mass, 1956, 1959*f*
targeted organ lesion, 1961, 1961*f*–1962*f*
central venous access for, 1954
Chiba needle for, 1948
color Doppler ultrasound and, 1945
CT and, 1943, 1943*t*
for deep foreign body removal, 1961, 1965*f*
drainage catheters for, 1948
equipment for, 1943
freehand, 1945–1947
correcting needle angle in, 1947, 1949*f*
correcting off-target needle in, 1947
initial needle placement and localization in, 1945–1946, 1945*f*–1946*f*
locating needle after insertion in, 1946–1947, 1947*f*–1948*f*
mechanical guides compared to, 1945
training aids for, 1947
guidance methods in, 1943, 1943*t*
for head lesions, 1961, 1966*f*
initial puncture device for, 1949–1950
local anesthetic technique for, 1951, 1952*f*
multimodality interventional suites for, 1943, 1944*f*
for musculoskeletal procedures, 1961, 1963*f*–1964*f*
for neck lesions, 1961, 1967*f*
one compared to two operators for, 1943–1945
patient and, 1942–1943
for percutaneous cholangiography and drainage, 1956, 1959*f*
for peritoneal drainage, 1954–1956, 1958*f*
personnel for, 1943
for PICC, 1954, 1955*f*–1957*f*
for pleural drainage, 1954–1956, 1958*f*
principles of, 1942–1943
sedation for, 1950–1951
for steroid injection, 1961, 1964*f*
transducers in, 1943
locating needle after insertion and, 1946–1947, 1947*f*
typical procedures for, 1951–1953
aims and expectations in, 1952–1953
coagulation studies in, 1952
Interventional sonography, pediatric *(Continued)*
difficult catheter fixation for, in infants, 1953
initial ultrasound in, before sedation, 1953
postprocedural care and follow-up in, 1953
prior consultation and studies in, 1951–1952
Interventricular septum, viewed from right ventricle, 1283*f*
Intervillous spaces, 1465–1466
blood flow in, 1467–1468, 1468*f*
Intestinal hematomas, small bowel obstruction from, 1843
Intestinal inflammatory disease, pediatric, 1848–1862. *See also* Appendicitis, pediatric
appendicitis as, 1855–1860, 1857*b*, 1858*f*–1862*f*
ascariasis and, 1853, 1853*f*
Crohn disease and, 1853, 1854*f*
graft-versus-host disease and, 1853–1854, 1855*f*
Henoch-Schönlein purpura and, 1853, 1855*f*
HUS and, 1851*f*, 1853–1854
mucosal, 1851, 1851*f*
NEC and, 1854–1855, 1855*b*, 1856*f*
transmural, 1851, 1852*f*
Intestinal malrotation
with midgut volvulus, 1841–1842, 1843*f*–1844*f*
midline stomach and, 1307
Intestinal wall thickening, pediatric, causes of, 1851, 1851*b*, 1851*f*–1852*f*, 1853–1854, 1855*f*
Intestine(s), acoustic cavitation in, 43. *See also* Bowel; Gastrointestinal tract
Intima-media complex, in carotid wall, 918–919, 919*f*
Intima-media thickness, atherosclerotic disease and, 918–919
Intraamniotic bleeding, fetal echogenic bowel and, 1316
Intraatrial septum, embryologic development of, 1282*f*
Intracardiac focus, echogenic, in trisomy 21, 1100*f*, 1101
Intracranial hemorrhage
fetal, 1206, 1207*f*
neonatal/infant brain and, duplex Doppler sonography of, 1580–1581, 1584*f*
Intracranial pressure, increased, vasospasm differentiated from, 1609–1610
Intracranial tumors, neonatal/infant brain and, duplex Doppler sonography of, 1585, 1587*f*
Intradecidual sac sign, 1054, 1055*f*
Intraductal intrahepatic cholangiocarcinoma, 185, 186*f*–187*f*
Intraductal papillary mucinous neoplasm (IPMN), 245–247, 245*f*–246*f*
Intradural lipomas, pediatric, 1686, 1687*f*
Intrahepatic cholangiocarcinoma, 184–185, 186*f*
intraductal, 185, 186*f*–187*f*
Intrahepatic stones, in biliary tree, 173, 173*f*
Intramedullary lipoma, 1686
Intramural sinus tract, in Crohn disease, 269, 274*f*
Intraoperative ultrasound
for adrenal glands, 429
for liver, 133
Intraparenchymal hematomas, 638
Intraparenchymal hemorrhage
IUFD and, 1124*f*
neonatal/infant brain and, 1547–1548, 1547*f*–1549*f*
Intraperitoneal gas, free, in acute abdomen, 277–281, 282*f*
Intraperitoneal stomach, 218–219, 220*f*
Intrasubstance rotator cuff tears, 888, 890*f*
Intratesticular artery, 821, 821*f*
Intratesticular cysts, 829, 830*f*
Intratesticular variocele, pediatric, 1891–1892
Intratesticular vessels, pediatric, 1888
Intrauterine devices (IUDs), 529
PID and, 587
uterine sonographic techniques and, 552–554, 553*f*
Intrauterine fetal death (IUFD), 1123–1125, 1124*f*
Intrauterine growth restriction (IUGR), 1062
from CMV, 1204
diagnosis of, 1455
fetal monitoring in, 1455
in Miller-Dieker syndrome, 1195
multifetal pregnancy morbidity and mortality and, 1119–1123
ossification delayed in, 1091
risk factors for, 1455–1460
fetal and placental, 1456*b*
maternal, 1456*b*
with spina bifida, 1233
in triploidy, 1105*f*
in trisomy 18, 1077
Intrauterine pregnancy, 1052–1053
Intravaginal torsion, 844, 844*f*
Intravascular ultrasound, in plaque characterization, 943
Intravenous Doppler contrast agents, 1749–1750
Intravenous ultrasound contrast agents, 1746
Intraventricular hemorrhage
from germinal matrix hemorrhage, 1541
neonatal/infant brain and, 1544–1545, 1544*f*–1546*f*, 1545*b*
with hydrocephalus, 1545–1547, 1546*f*–1547*f*
signs of, 1545*b*
Intussusception
MBO from, 293, 296*f*
pediatric, 1843–1847
Doppler ultrasound for, 1849*f*
false-positive, 1843, 1846*f*
Henoch-Schönlein purpura complicated with, 1853
ileocolic, 1847*f*–1848*f*
small bowel, 1844–1845, 1849*f*
sonographic signs of, 1843*b*
Invasive fibrous thyroiditis, 727–728, 728*f*
Invasive mole persistent trophoblastic neoplasia, 1080, 1081*f*

Doppler ultrasound assessment of, 771–772, 772*f*
pediatric
age and causes of, 1660, 1662*t*
cervical, 1658, 1660–1663
mediastinal masses and, 1724
site of node and causes of, 1660, 1662*t*
supraclavicular, 1658
retroperitoneal, 464
in tuberculous peritonitis, 521
Lymphangiectasia, appearance of, 1412, 1413*f*
Lymphangioma(s)
abdominal, pediatric, 1862, 1864*f*
fetal, neck, hydrops from, 1425
paratesticular, 1903–1904
pediatric pancreas and, 1865
pelvic, mesenteric cysts in, 509–510, 510*f*
splenic, 148
Lymphatic dysplasia, congenital, hydrops from, 1428, 1436*f*
Lymphatic malformations. *See also* Cystic hygroma(s)
fetal neck abnormalities and, 1159, 1161*f*
macroglossia in, 1153, 1153*b*, 1158*f*
pediatric
of chest, 1723
chest wall, macrocystic, ultrasound-guided sclerotherapy of, 1726, 1727*f*
of neck, 1655–1657, 1657*f*
parotid gland, 1636, 1637*f*
submandibular space, 1639–1640
in Turner syndrome, 1159
Lymphedema, hereditary, fetal, 1403–1404, 1405*f*
Lymphocele(s)
pelvic, 591
after renal transplantation, 665–666, 673*f*–674*f*
pediatric, 1809, 1811*f*
Lymphocytic leukemia, acute, 1796
Lymphoma(s)
adrenal, 426–427, 427*f*
AIDS-related, 266, 266*f*
B-cell, AKI and, 1796
bladder, 353, 354*f*
Burkitt, pediatric, 1860
gastric, endosonographic identification of, 301
gastrointestinal, 264–266, 266*f*
pediatric, 1862
genitourinary tract tumors and, 352–353
Hodgkin, pediatric, neck, 1665, 1665*f*
Lymphoma(s) *(Continued)*
of liver, 125, 129*f*
lymphadenopathy from, 1724
mediastinal, pediatric, biopsy of, 1956
non-Hodgkin, 125, 264–266
pediatric, neck, 1665
splenic lesions in, 152–153, 154*f*
ovarian, 585
pediatric, 1880
pediatric
liver metastases from, 1746
neck, 1665, 1665*f*
paratesticular, 1903–1904
peritoneal, 513, 517*f*
renal, 333, 352–353, 353*b*
pediatric, 1820, 1823*f*
retroperitoneal, 464
salivary gland, pediatric, 1639
of small bowel, 266, 266*f*
splenic lesions in
nodular, 152, 154*f*
solid, 152–153
testicular, 826–827, 828*f*
pediatric, 1901
of thyroid gland, 708–709, 709*f*
pediatric, 1648
ureteral, 353
Lymphoplasmacytic sclerosing pancreatitis, 236
Lymphoproliferative disorder. *See* Posttransplant lymphoproliferative disorder
Lysosomal disorders, fetal hydrops from, 1432

M

Macrocephaly, 1135–1136
fetal brain and, 1194–1195
Macrocranium(ia)
in skeletal dysplasia, 1382
in thanatophoric dysplasia, 1387
Macrocysts, ovarian, pediatric, 1873–1875
Macroglossia, 1153, 1153*b*, 1158*f*
Macronodular cirrhosis, 92–93
Macrosomia, 1453
sonographic criteria for, 1454*t*–1455*t*
Maffucci syndrome, in venous malformations of neck, 1657
Magnetic resonance angiography (MRA), in carotid stenosis diagnosis, 916
Magnetic resonance imaging (MRI), 32–33
breast ultrasound correlation with, 810–811, 811*f*–812*f*
of CNS, 1166–1167
of fetal brain, 1166–1167, 1172*f*
for fetal spine, 1216
for fetal urinary tract abnormalities, 1342, 1342*f*
of fetus, 1031–1032, 1031*f*
musculoskeletal system ultrasound compared to, 856
parathyroid adenomas and accuracy of, 748, 749*f*
in pregnancy, 1031–1032, 1031*f*
shoulder ultrasound compared to, 877–878
in skeletal dysplasia evaluation, 1385
Mainzer-Saldino syndrome, 1395
Majewski syndrome, 1396
Malacoplakia, 333, 333*f*
Male pseudohermaphroditism, dysplastic gonads and, 1899
Malformations, definition of, 1399
Malignancies, childhood, obstetric sonography and, 1041
Malignant melanoma, splenic lesions in, 153, 155*f*
MALToma, pediatric, 1639

Mammary ducts
  normal sonographic appearance of, 762, 764*f*
  subareolar and intranipple, scanning of, 762, 765*f*
Mammary fascia, 761, 762*f*
Mammary zone, of breast, 761, 761*f*, 763*f*
Mandible, fetal, normal sonographic appearance of, 1135*f*
Mandibular nasal prominence, 1134, 1134*f*
MAP (minimal-access parathyroidectomy), 749, 750*f*
Marfan syndrome, 946
Marginal placental cord insertion, 1484–1485, 1487*f*
  multifetal pregnancy and, 1119
Massa intermedia, enlarged, in Chiari II malformation, 1526, 1527*f*
Masseter muscle, pediatric, chloroma of, 1641*f*
Massive splenomegaly, 145, 146*t*
Masticator space, pediatric, pathology of, 1640, 1641*f*
Mastitis
  granulomatous, 803–804
  periductal, 771, 771*f*
  sonography for, 803–804
Maternal age, chromosomal abnormalities risk and, 1088, 1089*f*
Maternal floor infarction, 1473–1474, 1476*f*
Mathias laterality sequence, spina bifida and, 1226
Matrix metalloproteinases (MMPs), 434
Maxilla, fetal, normal sonographic appearance of, 1135*f*
Maxillary nasal prominence, 1134, 1134*f*
Maximum vertical pocket, 1339
Maximum-intensity projection (MIP), 105–106
Mayer-Rokitansky-Küster-Hauser syndrome, 1881–1883, 1882*f*
May-Thurner syndrome, 456–457
MBO. *See* Mechanical bowel obstruction
MCA. *See* Middle cerebral artery
McCune-Albright syndrome, pediatric ovarian cysts and, 1875

MCMA. *See* Monochorionic monoamniotic twins
MDCT. *See* Multidetector computed tomography
Mean sac diameter (MSD)
  in gestational age estimation, 1061, 1061*f*, 1444–1445, 1445*t*
  of gestational sac
    for gestational age estimation, 1444–1445, 1445*t*
    small, in relationship to CRL, early pregnancy failure and, 1066, 1067*f*
  yolk sac and, 1057
Mechanical beam steering, 10–11
Mechanical bowel obstruction (MBO)
  afferent loop, 293
  closed-loop, 293, 295*f*
  gastrointestinal tract and, 293
  intussusception causing, 293, 296*f*
  midgut malrotation predisposing to, 293
  sonographic assessment of, 293, 294*f*
Mechanical index (MI)
  for acoustic cavitation, 44–45, 45*f*
  definition of, 58
  microbubbles as contrast agents and, 58, 58*b*, 105
  in obstetric sonography, 1035
Mechanical sector scanners, 11
Mechanical ventilation, in neonatal/infant brain, 1578, 1579*f*
Meckel diverticulum
  intussusception and, 1844–1845, 1849*f*
  pediatric appendicitis differentiated from, 1858–1860, 1862*f*
Meckel-Gruber syndrome
  Dandy-Walker malformation differentiated from, 1532
  fetal brain dorsal induction errors and, 1182
  fetal cystic kidneys and, 1351, 1351*f*
  spina bifida and, 1226
Meconium ileus, 1310
  fetal CF and, 1316
Meconium periorchitis, focal calcifications from, 1904, 1904*f*
Meconium peritonitis
  fetal
    CF and, 1316
    hydrops from, 1428, 1428*f*
    liver calcifications and, 1316–1318
    massive ascites in, 1418–1419, 1421*f*
    small bowel and, 1313, 1313*t*, 1314*f*
  pediatric
    cystic, 1842–1843, 1846*f*
    testicular torsion and, 1892–1893
Medial fibroplasia, renal artery stenosis and, 447
Medial gastrocnemius muscle, tear of, 858, 859*f*
Medial nasal prominence, 1134, 1134*f*
Median arcuate ligament syndrome, 453, 453*f*
Mediastinal shift, in unilateral pulmonary hypoplasia, 1246, 1247*f*
Mediastinum
  fetal, masses in, hydrops from, 1425
  pediatric, assessment of, 1702, 1703*f*–1704*f*
  pediatric, masses of, 1723–1724
    abnormal thymus location mimicking, 1723
    anterior, 1723–1724
    biopsy of, 1956, 1959*f*
    lymphadenopathy and, 1724
    posterior, 1724
    thymic index and, 1723, 1724*t*, 1725*f*, 1726*t*
Mediastinum testis, 819, 820*f*
  pediatric, 1888
Medical renal disease. *See* Kidneys, pediatric, medical diseases of
Medulla
  adrenal, functions of, 417
  cerebral, as foramen magnum approach landmark, 1592, 1595*f*
Medullary carcinoma, of thyroid gland, 701–707, 707*f*–708*f*
  pediatric, 1648
Medullary cystic kidney disease, 359
  pediatric, 1816, 1817*f*
Medullary nephrocalcinosis, 339, 340*f*
  pediatric, 1798–1799, 1799*f*
Medullary sponge kidney, 339, 340*f*, 359
  pediatric, 1799
Megacalices, congenital, 321
Mega-cisterna magna
  fetal, 1189
    arachnoid cysts differentiated from, 1192–1193
    normal sonographic appearance of, 1168–1169
  neonatal/infant, Dandy-Walker malformation differentiated from, 1531, 1534*f*
Megacystis, fetal, 1360, 1360*b*, 1360*f*
  megalourethra and, 1362*f*
Megacystis-microcolon-intestinal hypoperistalsis syndrome (MMIHS), 1362–1363
  pediatric hydronephrosis and, 1788–1791
Megacystitis, fetal, thickened NT and, 1096*f*
Megahertz, definition of, 2
Megalencephaly, 1194–1195
Megalourethra, fetal, urinary tract obstruction in, 1362, 1362*f*
Megaureter(s)
  congenital, 321, 322*f*
  fetal, 1358–1359
  primary, pediatric hydronephrosis and, 1786–1788, 1787*f*
Meigs syndrome, 585
Membranous glomerulonephritis, 369
Membranous VSDs, 1281
MEN. *See* Multiple endocrine neoplasia
Ménétrier disease, gastric mucosa thickening in, 1839–1840
Meningeal layer, in myelocystocele, 1233
Meningitis, neonatal/infant, 1560, 1561*f*–1562*f*
Meningocele
  atretic, tethered cord and, 1679
  fetal
    cranial, 1179
    definition of, 1225*t*
    pathogenesis of, 1226
    sonographic findings in, 1218
    spina bifida occulta and, 1226
  posterior, closed spinal dysraphism and pediatric, 1682–1683
Meningoencephalocele, 1218
Meningomyelocele, fetal cloacal exstrophy and, 1328
Menopause
  endometrial abnormalities after
    bleeding and, 545–546
    fluid and, 546–547, 546*b*, 547*f*
    hormone use and, 544–545, 544*b*, 545*f*
  ovaries after, 569
    cysts in, 569–570, 571*f*
Menstrual age
  definition of, 1443–1444
  usage of term, 1167
Menstrual cycle, interrelationships in, 1050*f*
Menstruating females, ovarian volume in, 1873, 1875*t*
Mesencephalon, formation of, 1077
Mesenchymal dysplasia, of placenta, 1479, 1479*f*
Mesenchymal tumors, intracranial, fetal, 1208
Mesenchyme, formation of, 1053
Mesenteric, adenopathy, in acute abdomen, 282
Mesenteric adenitis
  pediatric, 1858–1860, 1862*f*
  right lower quadrant pain in acute abdomen from, 288
Mesenteric adenopathy, in acute abdomen, 282
Mesenteric artery(ies), 451–455. *See also* Celiac artery
  anatomy of, 451, 452*f*
  celiac artery as, 451
  duplex Doppler sonography of, 453–455, 455*f*
    interpretation of, 454–455, 456*f*–458*f*
  inferior
    anatomy of, 451, 452*f*
    connections of, with superior mesenteric artery, 451
    duplex Doppler sonography of, 454
  ischemia of, 451–453
  in median arcuate ligament syndrome, 453, 453*f*
  stenosis of, turbulence after, 454, 456*f*
  superior
    anatomy of, 451, 452*f*
    connections of, with inferior mesenteric artery, 451
    duplex Doppler sonography of, 454
    occluded, 454–455, 458*f*
    stenosis of, 457*f*
Mesenteric cyst(s)
  fetal, ovarian cysts differentiated from, 1369
  gastrointestinal cysts differentiated from, 1860, 1863*f*
  pediatric, ovarian cysts differentiated from, 1875
  peritoneal, 509–510, 510*f*
Mesenteric vein(s)
  clots in, in acute pancreatitis, 224–225, 227*f*
  pediatric
    Doppler studies of, best approaches for, 1752
    flow direction in, in portal hypertension, 1752

Mesentery, small bowel, 505, 505*f*
Mesoblastic nephroma
  congenital, 1352–1353, 1353*f*
  pediatric, 1818–1820, 1821*f*
Mesocardia, 1273
Mesocolon, transverse, inflammation of, in acute pancreatitis, 224–225, 226*f*
Mesoderm layer, of trilaminar embryonic disc, 1216–1217, 1217*f*
Mesomelia, 1381, 1381*b*, 1382*f*
Mesonephric (wolffian) duct, 820–821
Mesonephros, 311, 312*f*, 1336–1338
Mesorchium, torsion of, pediatric, 1325
Mesosalpinx, 564–565
Mesothelioma(s)
  cardiac, in infants, 1293
  multicystic, 508–509
  pediatric, 1712*f*
  peritoneal, primary, 513, 516*f*
Mesovarium, 564–565
Metabolic disorders
  fetal hydrops from, 1432
  of liver, 91–96
  neonatal jaundice caused by, 1734
  neonatal/infant brain abnormalities from, 1538
Metabolic syndrome, fatty liver in, 91
Metabolism, inborn errors of, jaundice and, 1738–1740, 1739*b*, 1740*f*

Pancreatoblastoma, pediatric, 1865
Pancytopenia, Fanconi, 1400, 1402*f*
Panovarian cysts, 573
Pantaloon hernias, 493–494, 495*f*
Papillary apocrine metaplasia (PAM), 778*f*, 779, 780*f*–781*f*
mural nodules caused by, 782, 783*f*–784*f*
Papillary carcinoma
ethanol ablation of cervical nodal metastasis from, 720, 721*f*
of thyroid gland, 698–701, 701*f*–705*f*
cystic, sonographic features of, 705*f*, 713
pediatric, 1648, 1649*f*
Papillary cystadenomas, of epididymis, 840–841
Papillary microcarcinoma, of thyroid, 701, 706*f*
Papillary necrosis, 328–329, 329*b*, 329*f*
Papillary process, 75–76
Papilloma(s)
breast, 769–771, 770*f*
intracystic, 782, 783*f*
intraductal, 799, 799*f*–800*f*
peripheral, 799, 800*f*
choroid plexus
Aicardi syndrome and giant pigmented nevi in, 1209
neonatal/infant, 1562, 1565*f*
in neonatal/infant brain, duplex Doppler sonography of, 1588*f*
VM with, 1177–1178
transitional cell, lower urinary tract, pediatric, 1910–1912
VM with, 1177–1178
PAPP-A. *See* Pregnancy-associated plasma protein A
Paracentesis, 610, 610*f*
Paracoccidiomycosis, 423
Paradidymis, 820–821
Paragangliomas, carotid body tumors and, 947–948, 949*f*
Paralabral cysts, injection for, 907–909, 910*f*–911*f*
Parallel orientation, in breast sonography
not (taller-than-wide), 789–790, 792*f*
wider-than-tall, 797, 797*f*
Paralytic ileus, 294*f*, 295
Parameniscal cysts, 907–909
Paramesonephric duct cysts, pediatric. *See* Müllerian ducts
Parapelvic cysts, 359, 360*f*
Paraplegia, traumatic, neurogenic bladder in, 1907
Parapneumonic collections, in pediatric chest, 1710–1711
Pararenal spaces, inflammation in, in acute pancreatitis, 224–225, 225*f*
Parasagittal infarction, from hypoxic-ischemic injury in full-term infant, 1541
Parasites, fetal brain and, 1203–1204
Parasitic diseases
of genitourinary tract, 331
of liver, 87–90, 89*f*–90*f*
Paratenon, 859
Parathyroid glands. *See also* Hyperparathyroidism
adenomas of
carcinomas differentiated from, 735–736, 738*f*
carotid sheath/undescended, 740, 742*f*
combined modalities for accuracy with, 748
compression for detection of, 739
CT accuracy for, 748, 748*f*
echogenicity of, 735, 736*f*
ectopic locations of, 739–741
false-negative examination for, 745*b*, 746
false-positive examination for, 745–746, 745*b*
fine-needle aspiration biopsy accuracy for, 746
hypoechoic, 735
imaging accuracy with, 746–749
inferior, 738–739, 739*f*
internal architecture of, 735, 736*f*
intrathyroid, 740, 742*f*
localization of, 736–741
mediastinal, 740, 741*f*, 748
MRI accuracy in, 748, 749*f*
multiple gland disease in, 735, 738*f*
percutaneous needle biopsy of, 750–751, 753*f*
pitfalls in examination of, 745–746, 745*b*
Parathyroid glands *(Continued)*
retrotracheal/retroesophageal, 739–740, 740*f*
scintigraphy accuracy for, 747, 747*f*
shape of, 735, 735*f*
size of, 735, 737*f*
sonographic appearance of, 735–736
sonographic examination and typical locations in, 736–739, 739*f*
superior, 738–739, 739*f*
surgical removal of, 749, 750*f*
ultrasound accuracy for, 746–747, 748*f*
vascularity of, 735, 737*f*
anatomy of, 732–733, 733*f*
autotransplantation of tissue of, recurrent hyperparathyroidism from, 742–744, 743*f*
carcinoma of
adenomas differentiated from, 735–736, 738*f*
primary hyperparathyroidism from, 734
ectopic, 733, 739–741
embryology of, 732–733
enlarged, in secondary hyperparathyroidism, 745
eutopic, 733
inferior, 733
pediatric, 1650, 1650*f*
supernumerary, 733
Parathyroid hormone, chief cells in production of, 733
Parathyroidectomy, minimal-access, for primary hyperparathyroidism, 749, 750*f*
Parathyromatosis, in persistent hyperparathyroidism, 744, 744*f*
Paratubal cysts, 573
Paraumbilical hernias, 492
Paraumbilical veins, pediatric
flow direction in, in portal hypertension, 1752, 1757, 1758*f*
in intrahepatic portal hypertension, 1761
Paraurethral cysts, pediatric, 1883–1884
Parenchymal abscess, pediatric renal transplantation and, 1812
Parenchymal calcification, renal, 339–340, 340*f*
Parenchymal junctional defects, 313, 314*f*
Parietal peritoneal line, 510–511
Parinaud oculoglandular syndrome, 1633–1634
Parotid glands, pediatric
accessory, 1630
acinic cell carcinoma of, 1638, 1639*f*
anatomy of, 1630, 1630*f*
bacterial infections in, 1632–1633, 1632*f*
deep lobe of, 1630
hemangiomas of, 1636, 1637*f*
lipomas of, 1639
lymphatic malformation of, 1636, 1637*f*
nodal enlargement in, 1633–1634
peripheral nerve sheath tumors of, 1639
Parotid space, pediatric, 1629, 1630*f*
cystic lesions of, 1639, 1640*b*
Parotitis
HIV and, 1635, 1636*f*
juvenile, recurrent, 1634, 1634*f*
from mumps, 1632
Parovarian cysts, pediatric, 1875, 1876*f*
Paroxysmal supraventricular tachycardia, fetal, 1296, 1296*f*
Partial molar pregnancy, 1078, 1080*f*
Partial subclavian steal, 952–953, 953*b*, 953*f*
Partial-thickness rotator cuff tears, 887–888, 889*f*–890*f*
Particulate ascites, 507
Parvovirus infection, fetal
hydrops from, 1431–1432, 1431*f*
massive ascites in, 1418–1419
Pascals, 16

Patau syndrome. *See* Trisomy 13
Patellar dislocation, congenital, pediatric, 1934, 1935*f*
Patent ductus arteriosus, intracranial RI and, 1576
Patent urachus, 322
  pediatric, 1791
PCA. *See* Posterior cerebral artery
PCA3 score, 396
PCOS. *See* Polycystic ovarian syndrome
Peak end diastolic ICA/CCA ratio, in assessing degree of carotid stenosis, 930
Peak systolic ICA/CCA ratio

infarctions of, 1466, 1473–1474, 1476*f*–1477*f*
insertion of umbilical cord into, 1484, 1485*f*
low, 1469, 1470*f*
marginal sinus of, 1466, 1467*f*
masses of, 1474–1476
chorioangioma as, 1476, 1478*f*–1479*f*
malignant, 1476
mesenchymal dysplasia of, 1479, 1479*f*
in molar gestations, 1479, 1480*f*
morphologic abnormalities of, 1479–1481
in multifetal pregnancy, chorionicity and, 1119, 1120*f*
position of, sonographic determination of, 1469, 1470*f*
postpartum, 1487–1489, 1490*f*
RPOC and, 1487–1489, 1490*f*
size of, 1466–1467, 1467*f*–1468*f*
sonographic appearance of, 1466, 1467*f*
subamniotic hematomas of, 1474
subchorionic hematomas of, 1474
Placenta *(Continued)*
succenturiate lobes of, 1480–1481, 1481*f*
thickness of, 1466, 1467*f*
in third stage of labor, 1487
vascularity of, 1468*f*
Doppler ultrasound and, 1467–1469
vascularization of, 1052–1053
volume of
in first trimester, in early pregnancy evaluation, 1466–1467
second trimester, assessment of, 1466, 1468*f*
Placenta accreta, 1470–1471, 1472*f*–1473*f*
Placenta increta, 1470–1471
Placenta percreta, 1470–1471, 1473*f*
Placenta previa, 1469–1470
complete, 1469, 1470*f*
marginal, 1469, 1470*f*
placenta accreta with, 1471
Placental bed, subinvolution of, 556
Placental cord insertion, multifetal pregnancy and, 1119, 1122*f*
Placental lakes, 1466, 1467*f*
Placental shelf, 1479–1480
Placental villi, hydropic degeneration of, 1078, 1080*f*
Placental volume quotient, 1466–1467
Placental-site trophoblastic tumor (PSTT), 530–531, 1082
Placentation, multifetal pregnancy and, 1115–1116, 1116*f*
Placentomegaly, fetal, hydrops and, 1418, 1420*f*
Placodes
nasal, 1134
spinal dysraphism and, pediatric, 1680
Plagiocephalic heads, 1136–1138
Plane-wave contrast imaging, 64
Plantar fasciitis, injection for, 902, 904*f*
Plaque(s)
in atherosclerosis, 433
carotid
atheromatous, 919
atherosclerotic rupture of, 919–920
calcified, 920–921, 921*f*
carotid artery dissection and, 946
characterization of, 919–922, 920*f*–922*f*, 922*b*
heterogenous, 920–921, 922*f*
homogenous, 920–921, 920*f*–921*f*, 936–937, 938*f*
intraplaque hemorrhage and, 920–921
morphology of, ultrasound types of, 921, 922*b*
nonstenotic, 936–937, 938*f*
qualitative assessment of, in carotid stenosis, 924
tandem, in carotid stenosis, 923–924
types 1-4, 921, 922*b*
ulceration of, 923, 923*b*, 923*f*–924*f*
vulnerable, identification of, treatment decisions and, 943
Plasma protein A, pregnancy-associated, 1089–1090
Plasmacytoma, 827–829
Platelet-rich plasma, intratendinous injection of, 909–910
Platyspondyly
in skeletal dysplasias, 1382
in thanatophoric dysplasia, 1388–1389, 1390*f*
Plavix (clopidogrel), 598
PLCO (Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial), 397
Pleomorphic adenomas, salivary gland, pediatric, 1636–1638, 1638*f*
Pleural disease, pediatric, pulmonary disease differentiated from, sonography in, 1709, 1710*f*
Pleural drainage, fetal, hydrops from, 1426–1427

Pleural effusions
fetal, 1256–1258, 1257*f*
hydrops and, 1413–1416, 1417*f*, 1425
lung size and, 1244
primary, 1256
secondary, 1256
pediatric
drainage of, ultrasound-guided, 1724–1725
sonographic signs of, 1702–1711, 1704*f*–1708*f*
Pleural fluid, pediatric
aspiration of, ultrasound-guided, 1724–1725, 1726*f*
through hepatic window, 1707*f*
pneumonia with small amount of, 1706*f*
septated, 1702, 1708*f*
sonogram compared to CT scan for, 1709, 1711*f*
sonographic signs of
bare area sign in, 1709, 1709*f*
color Doppler ultrasound signal in, 1709, 1710*f*
diaphragm sign in, 1709
displaced-crus sign in, 1709
free movement in, with respiration, 1709, 1709*f*
septations in, 1709
sonographic signs of, 1709, 1709*b*
through splenic window, 1707*f*
Pleuropulmonary blastoma, 1252–1253
Plexiform neurofibroma, in intraoperative procedures, 1621*f*
Plicae palmatae, 533, 535*f*
PMPI. *See* Power modulation pulse inversion
Pneumatosis intestinalis
in acute abdomen, 277–281
in gastrointestinal tract, 297–299, 299*f*
pediatric, sonography for, 1854–1855
Pneumobilia
biliary tree and, 175–176, 176*f*
after liver transplantation, 625, 1767–1768, 1769*f*–1770*f*
Pneumocystis carinii, hepatic opportunistic infection by, 91, 91*f*
Pneumonia, pediatric, 1711–1714
air bronchograms from, 1702, 1703*f*, 1708*f*
chest radiograph compared to ultrasound for, 1712–1714, 1715*f*
on chest ultrasound, 1703*f*
empyema from, 1707*f*
round, 1711–1712, 1715*f*
with small amount of pleural fluid, 1706*f*
Pneumoperitoneum, 524–526, 525*f*
Pneumothoraces, sonographic detection of, 1725–1726
Poland syndrome, ribs in, 1382–1384
Polar arteries, 445–446
Polycystic kidney disease, 359–361
autosomal dominant, 83, 243, 361, 362*f*
pediatric, 1814–1815, 1815*f*
autosomal recessive, 359, 361*f*, 1799
pediatric, 1812–1813, 1814*f*
congenital hepatic fibrosis and, 1757–1759, 1762*f*
fetal pancreatic cysts and, 1320
Polycystic ovarian disease, pediatric, 1877–1878, 1879*f*
Polycystic ovarian syndrome (PCOS), 573–574, 574*f*
Polycythemia, dural sinus thrombosis from, 1205–1206
Polydactyly
definition of, 1399
fetal, 1405–1406
postaxial, in trisomy 13, 1104, 1105*f*
Polydactyly *(Continued)*
short-rib, syndromes associated with, 1382, 1383*f*, 1395–1396, 1397*f*
toe, fetal, 1406*f*
Polyhydramnios
anorectal malformations and, 1311–1312
cervical assessment in, 1505
diagnostic significance of, 1340–1341
esophageal atresia and, 1305–1306
fetal hydrops and, 1418, 1420*f*, 1432–1433
jejunoileal atresia and, 1310
in lethal skeletal dysplasias, 1386
meconium peritonitis and, 1313
with mesoblastic nephroma, 1352–1353
in trisomy 18, 1104
Polymicrogyria, 1196, 1198*f*
Polyorchidism, 838–839, 841*f*
pediatric, 1891
Polypoid intraluminal tumors, 261–264, 263*f*
Polyps
endometrial, 544, 548, 549*f*
tamoxifen and, 544–545
intussusception and, 1844–1845
urethral, posterior, pediatric, bladder outlet obstruction from, 1906, 1906*f*
Polysplenia, 159–161
in cardiosplenic syndrome, 1292, 1293*b*
fetal, 1320
univentricular heart with, 1287–1288
Polysplenia syndrome
biliary atresia in, 1737, 1738*f*
Doppler evaluation of liver transplant recipient with, 1764–1766
Polyvinyl chloride, 123
Pontocerebellar hypoplasia, 1190
Pontocerebellar syndrome, vermian dysplasia with, 1191
Popliteal artery, 966
aneurysms of, 972*f*
normal appearance of, 966–967
occlusion of, 968*f*
Popliteal cysts, pediatric, 1939
Popliteal vein
normal anatomy of, 980–981, 981*f*
ultrasound examination of, 982–983
Porcelain gallbladder, 202, 202*f*
Porencephalic cysts, neonatal/infant brain and, 1537, 1565
Porencephaly
from germinal matrix hemorrhage, 1541
HPE differentiated from, 1189
from intraparenchymal hemorrhage, 1547, 1548*f*
Porta hepatis, 77, 79*f*
Portal hypertension
duplex Doppler sonography in, 98
intrahepatic, from cirrhosis, 96
left sided, splenic vein thrombosis from, in chronic pancreatitis, 232–233, 234*f*–235*f*
liver vascular abnormalities and, 96–98, 96*f*–97*f*
portosystemic venous collaterals in, 96–98, 96*f*
presinusoidal, 96
splenomegaly and, 145, 147*f*
Portal hypertension, pediatric, 1756–1757
backward-flow theory of, 1760–1761
Doppler assessment of
abnormal flow patterns in, 1754–1756
abnormal hepatic arterial Doppler patterns in, 1755–1756
absent Doppler signal in, 1754, 1754*b*
arterialized flow patterns in, 1754
hepatofugal flow in, 1757
intrahepatic portal hypertension and, 1759–1762
in liver disease, 1752–1754, 1754*f*–1755*f*
Portal hypertension, pediatric *(Continued)*
of normal flow patterns in splanchnic vessels, 1750
paraumbilical veins flow direction in, 1757, 1758*f*
pelvic varices in, 1760*f*
possibilities and pitfalls of, 1750
in prehepatic portal hypertension, 1757–1759
reversed flow in, 1754–1755
sonographic technique for, 1750–1752
splenorenal shunts in, 1757, 1759*f*
in suprahepatic (posthepatic) portal hypertension, 1762–1764, 1763*f*
surgical portosystemic shunts and, 1764
to-and-fro flow in, 1754–1755, 1755*f*
Doppler ultrasound assessment of, 1748–1764
basic principles of, 1748–1750
forward-flow theory of, 1760–1761
thickened lesser omentum and, 1756, 1756*f*
Portal triad, 78
Portal vein(s)
anastomosis of, for liver transplantation, 624
aneurysms of, 103–104
after liver transplantation, 1768, 1769*f*–1770*f*
anomalies of, 81
cavernous transformation of, 98, 99*f*
clots in, in acute pancreatitis, 224–225, 228*f*
fetal liver calcifications and, 1316–1318
left, Doppler studies of, best approach for, 1752
liver circulation and, 78
main, Doppler studies of, best approach for, 1752
normal, 76, 77*t*, 78*f*
pediatric
anatomy of, 1731–1734, 1732*f*
cavernous transformation of, in prehepatic portal hypertension, 1757, 1761*f*
flow direction through, meals and, 1750
left, branches of, 1734
left, Doppler studies of, 1750
right, branches of, 1733*f*, 1734
thrombosis of, 1757, 1757*b*
pseudostenosis of, 636
stenosis of, after liver transplantation, 635–636, 638*f*, 1766, 1768*f*
thrombosis of, 98, 99*f*–100*f*
chronic pancreatitis and, 232–233, 235*f*
from HCC, 120, 121*f*
after liver transplantation, 635–636, 639*f*–640*f*, 1766
malignant, 98, 99*f*
pediatric, 1757, 1757*b*
Portosystemic shunts
intrahepatic, 104, 1761–1762
liver and, 130–132
in portal hypertension, 1757
portocaval, patency of, Doppler assessment of, 1764
surgical, 1764

"Sunburst sign," in corpus callosum agenesis, 1528, 1532*f*
Superb microvascular imaging (SMI), 1746
basic technique of, 1749–1750, 1752*f*
Superficial fascia, pediatric, 1628, 1629*f*
Superficial peritendinous and periarticular injections, 902–904
for foot and ankle, 902–904, 903*f*–904*f*
for hand and wrist, 904, 905*f*
Superficial venous insufficiency, 981–982
Superior mesenteric artery (SMA)
pancreatic body and, 211, 211*f*
small bowel obstruction and, 1308
Superior mesenteric vein (SMV), 211, 211*f*
Superior vena cava (SVC)
anatomy of, 991
catheter position for, pediatric, 1716–1721, 1722*f*
stenosis, with PICC line, 993*f*
thrombosis of, pediatric, 1721, 1721*b*, 1722*f*
ultrasound examination of, 991–992, 992*f*
Supernumerary glands, 733
Supernumerary kidneys, 319
Supernumerary testes, 838–839, 841*f*

Superoanteromedial ridge, 416–417
Supraclavicular lymphadenopathy, pediatric, 1658
Suprahyoid space, pediatric
  anatomy of, 1628–1640, 1629*f*
  cystic lesions of, 1639–1640, 1640*b*, 1640*f*–1641*f*
  masticator space of, pathology of, 1640, 1641*f*
  salivary glands in, 1629–1639
    anatomy of, 1630–1631
Supraspinatus fossa, 878–879
Supraspinatus tendon
  anatomy of, 878–879
  calcific tendinitis of, 891–892, 892*f*
  postoperative, 888, 891*f*
  tendinosis of, 886*f*
  ultrasound evaluation of, 881–883, 883*f*–884*f*
Supratentorial tumors, neonatal/infant brain and, 1562
Supraventricular tachycardia (SVTs)
  with Ebstein anomaly, 1286–1287
  fetal, 1296–1297, 1296*f*
    hydrops from, 1424, 1425*f*
Surface epithelial inclusion cysts, 569, 573
Surface epithelial-stromal tumors, 579–582, 580*f*–582*f*
SURUSS. *See* Serum, Urine and Ultrasound Screening Study
Surveillance
  of AAA, 435–437
    CT in, 437
    sonographic technique for, 436–437, 436*f*–437*f*
  active, for prostate cancer, 401
Suspensory (infundibulopelvic) ligament, 564–565
Sutures, cranial, premature fusion of, 1136–1139, 1138*b*, 1138*f*–1139*f*
SVC. *See* Superior vena cava
SVTs. *See* Supraventricular tachycardia
SWE. *See* Shear wave elastography
Swyer syndrome, 1887
Sylvian fissure, neonatal/infant, development of, 1514*f*–1515*f*, 1520–1521
Syncytiotrophoblast, 1049, 1051–1052, 1052*f*, 1466*f*
Syndactyly
  fetal, 1406, 1406*f*
  of fingers, in triploidy, 1105*f*, 1406
Synechia, amniotic band sequence and, 1401
Synovitis, 867, 869
  hip joint, pediatric, 1931*f*
Syntelencephaly, 1187, 1189, 1535–1536
Synthetic arteriovenous graft. *See* Arteriovenous graft, synthetic
Syphilis, 1203–1204
  fetal hydrops from, 1431–1432
Syringocele, 1683–1684
Syrinx, 1681
System setup, obstetric sonography and, 1035–1036, 1035*f*–1037*f*
Systemic lupus erythematosus, maternal, fetal AVB from, 1297
Systolic velocity, cerebral, factors changing, 1612*t*
Systolic-to-diastolic ratio (S/D ratio), 27, 27*f*

T

"T" sign, in monochorionicity, 1119, 1119*t*, 1121*f*
Tachyarrhythmias, fetal, hydrops from, 1424
Tachycardia
  fetal, 1296–1297, 1296*f*
  neonatal/infant, intracranial RI and, 1576
  supraventricular
    with Ebstein anomaly, 1286–1287
    fetal, 1296–1297, 1296*f*
    fetal, hydrops from, 1424, 1425*f*
  ventricular, 1296
Tactile sensation, in obstetric sonography, 1038
Tailgut cysts, 297, 298*f*
Takayasu arteritis
  aortic stenosis in, 444
  of common carotid artery, 944–946, 947*f*
Talipes equinovarus, fetal, 1406*f*, 1407
  campomelic dysplasia and, 1395
Talipomanus, fetal, 1407
TAMM. *See* Time-averaged mean of maximum velocity
Tamoxifen, 544–545, 545*f*
Tandem plaques, in carotid stenosis, 923–924
TAPS. *See* Twin anemia polycythemia sequence
Tardus-parvus waveform(s)
  arterial stenosis and, 969, 971*f*
  in hepatic artery thrombosis after liver transplantation, 631, 633*f*
  in internal carotid artery stenosis, 934*f*, 938
  pediatric renal artery stenosis and, 1809
  in peripheral artery stenosis, 965–966
  in popliteal artery occlusion, 968*f*
  in renal artery duplex Doppler sonography, 450, 450*f*
  in renal artery stenosis, 368, 368*f*
  in subclavian steal phenomenon, 953*b*, 954
Target pattern, in gut wall, 257, 260*f*
Targeted organ lesion biopsy, 1961, 1961*f*–1962*f*
TAS. *See* Transabdominal sonography
TASC. *See* Trans-Atlantic Inter-Society Consensus
TCC. *See* Transitional cell carcinoma
TCD. *See* Transcranial Doppler sonography
TDLUs. *See* Terminal ductolobular units
Teale femoral hernia, 482, 485*f*
Teen mothers, fetal gastroschisis and, 1322–1323
Tegmento-vermian angle, 1189–1190
Telangiectasia, hereditary hemorrhagic, 104
Telencephalon, formation of, 1077
"Telephone receiver" femur, 1380*f*
Temporal average intensity, 36
Temporal bone approach, for duplex Doppler ultrasound of neonatal/infant brain, 1574, 1575*f*
Temporal horns, of lateral ventricles, neonatal/infant, in coronal imaging, 1514–1515
Temporal maximum intensity projection imaging, 64, 65*f*
Temporal peak intensity, 36, 36*f*
Temporal tap, in external carotid artery identification, 918, 918*f*
Tendinitis, calcific
  injections for, 909, 911*f*
  of supraspinatus tendon, 891–892, 892*f*
Tendinosis, 859–861, 861*f*
  de Quervain, injection for, 904, 905*f*
  rotator cuff, 886, 886*f*
  in sports hernia, 486
  of supraspinatus tendon, 886*f*
Tendon(s)
  anatomy of, normal, 859, 860*f*
  anisotropy of, 859, 860*f*, 899
  calcification of, 859–861
  conjoined
    direct inguinal hernia and, 479–481, 483*f*–484*f*
    weakness/tear of, sports hernia and, 485–486, 489*f*
  inflammation of, 861–862, 862*f*
  injections of deep, 904–907
  injuries to, 859–861, 861*f*
  tears to, 861, 861*b*, 862*f*
  ultrasound techniques for, 859–862
Tenosynovitis, 861–862, 862*f*
  long head of biceps, 892–893, 893*f*
  stenosing, injections for, 902
Tenotomy, percutaneous, 909–910, 913*f*
Teratocarcinomas, pediatric, testicular, 1899
Teratogenic effects, from hyperthermia, 38
Teratogens, thermal effects of ultrasound and, 1037
Teratologic hip dislocation, pediatric, 1932
Teratoma(s). *See also* Sacrococcygeal teratomas
  cystic, ovarian, 582–584, 582*b*, 583*f*
  dacryocystocele differentiated from, 1143
  fetal
    cardiac, 1294
    cervical, 1159, 1161*f*
    intracranial, 1208–1209, 1209*f*
    intrapericardial, hydrops from, 1424
    neck, hydrops from, 1425, 1426*f*

adenomas of, 697, 700*f*
anatomy of, 692–694, 692*f*
aplasia of, 694, 694*f*
carcinoma of, 695, 698–708
anaplastic, 707–708, 708*b*, 709*f*
follicular, 701, 701*b*, 706*f*–707*f*, 1648
incidence of, 722, 722*f*–723*f*
medullary, 701–707, 707*f*–708*f*, 1648
papillary, 698–701, 701*f*–705*f*, 713, 1648, 1649*f*
papillary microcarcinoma, 701, 706*f*
CEUS for assessment of, 692, 714–715
congenital abnormalities of, 694, 694*f*
cysts, calcifications of, 695
diffuse disease of, 723–728, 723*b*
adenomatous goiter as, 727
Graves disease and, 727, 727*f*, 1646, 1646*f*
ectopic, 694
elastography for assessment of, 692, 714–715, 715*f*–716*f*
ethanol injection for nodular disease of
for autonomously functioning nodules, 719–720
for benign cystic lesions, 719, 719*f*
for solitary solid benign "cold" nodules, 720
fetal, normal sonographic appearance of, 1136*f*
hypoplasia of, 694, 694*f*
incidentally detected nodule and, 720–723, 722*f*–723*f*, 723*b*
instrumentation for, 691–692, 692*f*
lingual, pediatric, 1639
lobes of, 692
lymphoma of, 708–709, 709*f*
metastases to, 709, 710*f*
nodular disease of, 694–723
adenomas in, 697, 700*f*
carcinoma in, 698–708
fine-needle aspiration biopsy in, 709–710, 710*t*, 722
hyperplasia and goiter in, 695–697, 695*f*–699*f*
Thyroid gland *(Continued)*
lymphoma in, 708–709, 709*f*, 1648
metastases in, 709, 710*f*
parathyroid adenomas confused with, 745–746
pathologic features of, 695–709
sonographic correlates of, 695–709
sonographic evaluation of, 695*b*
pediatric
cancer of, 1648, 1648*b*, 1649*f*
congenital lesions of, 1642–1643
cysts of, 1646, 1647*f*
dimensions of, normal, 1642*t*
dysgenesis of, 1642–1643
ectopic, 1642–1643, 1644*f*
follicular adenoma of, 1646–1648, 1647*f*
hemiagenesis of, 1642–1643, 1643*f*
hemorrhage in, 1646, 1647*f*
inflammatory disease of, 1643–1646, 1645*f*–1646*f*
isthmus of, 1640–1642
lobes of, normal thickness of, 1643*t*
masses of, 1646–1648, 1647*f*–1649*f*, 1648*b*
normal anatomy of, 1640–1642, 1642*f*, 1642*t*–1643*t*
pseudonodule of, 1646
pyramidal lobe of, 1640–1642
retrosternal, 1723
volume of, normal, 1643*t*
sonographic applications in, 710–720
for benign and malignant nodule differentiation, 696*f*–699*f*, 712–714, 712*t*
CEUS for, 692, 714–715
elastography for, 692, 714–715, 715*f*–716*f*
incidentally detected nodule and, 720–723, 722*f*–723*f*, 723*b*
needle biopsy guidance for, 715–720, 718*f*–719*f*, 721*f*
for thyroid mass detection, 710–712, 711*f*–712*f*
TIRADS for, 714
sonographic technique for, 691–692, 692*f*
vascularity of, 693, 694*f*
volume of, measuring, 692–693, 693*f*
Thyroid Imaging Reporting and Data System (TIRADS), 714
Thyroid inferno, in Graves disease, 727, 727*f*
Thyroiditis, 723*b*
acute suppurative, 723–724
chronic autoimmune lymphocytic, 724, 725*f*–727*f*
de Quervain, 1645
focal, pediatric, 1645
Hashimoto, 724, 725*f*–727*f*
fetal goiter and, 1159–1163
pediatric, 1645, 1646*f*
invasive fibrous, 727–728, 728*f*
painless (silent), 725–727
subacute granulomatous, 724, 724*f*
Thyromegaly, fetal, 1159–1163
TI. *See* Thermal index
TIA. *See* Transient ischemic attack
TIB. *See* Thermal index for bone
Tibia, dislocation of, pediatric, 1934*f*
Tibial artery
anterior, 966
normal appearance of, 966–967
posterior, 966
sonographic technique for, 967
Tibial hemimelia, pediatric, 1933
Tibial tendons, posterior, injection of, 902, 903*f*
Tibial veins
anterior, 981, 981*f*
posterior, 981, 981*f*
Tibioperoneal trunk, 966, 981
Time gain compensation (TGC)
artifacts and settings of, 19–21
control of, 8–9, 8*f*
output control and, 50
Time-averaged mean of maximum (TAMM) velocity, 1593, 1605–1606
Time-averaged peak velocity, 1593
"Tip of the iceberg" sign, 582–583
TIPS. *See* Transjugular intrahepatic portosystemic shunts
TIRADS. *See* Thyroid Imaging Reporting and Data System
TIS. *See* Thermal index for soft tissue
Tissue harmonic imaging, 13, 13*f*–14*f*, 38, 61–62
Tissue heating
spatial focusing and, 35
temporal considerations in, 36, 36*f*
tissue type and, 36, 36*f*

Tissue vibration artifact, 973–974, 974*f*
T-lymphotropic virus, 1203–1204
TMPRSS2:ERG test, 396
Tobacco, fetal gastroschisis and, 1322–1323
Toe polydactyly, fetal, 1406*f*
Toes, sandal, 1406*f*, 1407
TOF. *See* Tetralogy of Fallot
Tongue, fetal, abnormally enlarged, 1153, 1153*b*, 1158*f*
TORCH infections, 1203–1204
neonatal/infant brain and, 1511, 1558
Torsion, testicular. *See* Testicular torsion
Torsion knot, 844, 845*f*
Toxemia, pediatric pregnancy and, 1884
Toxoplasmosis
fetal brain and, 1204
fetal hydrops from, 1432
prenatal, neonatal/infant brain and, 1558–1560
TPA. *See* Tissue plasminogen activator
Trabecula septomarginalis, moderator band of, 1274–1275
Trachea, fetal, CHAOS and, 1253
Tracheal webs, fetal, CHAOS and, 1253
Tracheoesophageal fistula, fetal
CHAOS and, 1254–1255
esophageal atresia and, 1305
Transabdominal scanning, for placenta previa, 1469
Transabdominal sonography (TAS), for pelvis, 564
Trans-Atlantic Inter-Society Consensus (TASC), 970
Transcranial Doppler (TCD) sonography
adult
functional, 1622
indications for, 1598–1623, 1598*b*
vasospasm and, 1608–1610, 1610*t*
for carotid artery examination, 948–950, 950*f*
pediatric
ACA collateral flow evaluation and, 1610, 1611*f*
angle correction for, 1607
asphyxia and, 1614, 1616*f*
AVM detection with, 1614, 1615*f*
brain death and, 1618–1620, 1618*b*, 1619*f*–1620*f*
in cardiopulmonary bypass, 1621–1622
in CEA, 1621
cerebral edema and, 1614, 1617*f*
contrast enhancement for, 1597
ECMO monitoring with, 1622
equipment types for, 1591–1592
factors changing indices in, 1612*t*
foramen magnum approach for, 1592, 1595*f*
functional, 1622
headaches and, 1610–1611, 1612*f*
hydrocephalus and, 1611–1614, 1613*f*
hyperventilation therapy and, 1614

Transcranial Doppler (TCD) sonography *(Continued)*
indications for, 1598–1623, 1598*b*
in intraoperative neuroradiologic procedures, 1620–1622, 1621*f*–1622*f*
limitations for, 1597, 1597*t*
orbital approach for, 1592, 1596*f*
pitfalls in, 1597, 1597*t*
power settings for, 1597
right-to-left shunt evaluation with, 1614–1618
for SCD, 1591, 1598–1608, 1599*b*, 1599*f*–1608*f*
sleep apnea and, 1611
submandibular approach for, 1592–1593
technique for, 1592–1596
TPA and, 1622
transtemporal approach for, 1592, 1593*f*–1594*f*
vascular malformations and, 1614, 1615*f*
vasospasm and, 1608–1610, 1609*f*, 1610*t*
velocity evaluation in, 1593, 1595–1596
Transducer(s), 7–8
arrays, 11–12, 12*f*
hand-held, for breast sonography, 788, 789*f*–790*f*
heating, in obstetric sonography, 1038
heeling and toeing of, 768
in interventional sonography, pediatric, 1943
locating needle after insertion and, 1946–1947, 1947*f*
for neonatal/infant brain imaging, 1512
output control and, 50
percutaneous needle biopsies and sterilization of, 600
second harmonic and, 105
selection of, 12
for obstetric sonography, 1035
Transfundal pressure, dynamic cervical change and, 1501–1503
Transfusion, fetomaternal, maternal serum alpha-fetoprotein elevation in, 1228. *See also* Twin-twin transfusion syndrome
Transhepatic cholangiography, 614–615
Transient double-bubble sign, 1309
Transient elastography, 1764
Transient ischemic attack (TIA), 916
carotid artery embolism causing, 919
Transitional cell carcinoma (TCC)
bladder, 347–348, 350*f*
genitourinary tract tumors and, 346–348
nonpapillary, 346
ovarian, 581–582, 582*f*
papillary, 346
renal, 346–347, 346*f*–349*f*
synchronous, 346
ureteral, 347
Transitional cell papilloma, lower urinary tract, pediatric, 1910–1912
Transjugular intrahepatic portosystemic shunts (TIPS), 131–132, 132*b*, 132*f*–133*f*, 463, 1764
Translabial ultrasound
of cervix, 1497
of female urethra, 315, 316*f*
Transmediastinal artery, 820*f*, 821
Transmitter, 7
Transorbital approach, for duplex Doppler ultrasound of neonatal/infant brain, 1574, 1575*f*
Transperineal biopsy, TRUS-guided, 411
Transperineal scanning, in Crohn disease, 276
Transperineal ultrasound
cervix in, 1497, 1497*f*
in ureteral calculi detection, 337
Transplantation, organ, 623–624. *See also* Liver transplantation; Pancreas transplantation; Posttransplant lymphoproliferative disorder; Renal transplantation
Transposition of great arteries (TGA), 1289–1290, 1289*f*–1290*f*
Transrectal ultrasound (TRUS)
biopsy guided by, 407–411, 408*f*
analgesia and, 407
antibiotic prophylaxis and, 407, 408*f*
anticoagulation and, 407–408
bowel preparation and, 407
indications and sampling for, 409, 409*b*, 410*f*
in men with absent anus, 411
mpMRI-TRUS fusion, 410–411
other applications of, 411–412
preparation for, 407–408
after radical prostatectomy, 411, 411*f*
side effects and complications in, 409
technique for, 408–409, 408*f*
transperineal, 411
brachytherapy guided by, 401, 402*f*
for drainage of pelvic abscesses, 612
for hematospermia, 394
infertility and, 392–394, 393*f*
of male urethra, 315, 316*f*
probes for, 386–387, 386*f*
of prostate, 381–382
prostate cancer, mpMRI fusion with, 406–407, 410–411
prostate cancer and, 302, 302*f*, 403–406, 403*f*–405*f*, 406*b*
in rectal carcinoma staging, 301
rectal cleansing prior to, 387
Transtemporal window
for TCD sonography, 1592, 1593*f*–1594*f*
for transcranial Doppler sonography, 948
Transurethral resection of ejaculatory ducts, 393
Transurethral resection of prostate (TURP), 385*f*–386*f*, 388
Transvaginal sonography, in peritoneal disease evaluation, 506, 506*f*–507*f*
Transvaginal ultrasound
for acute appendicitis diagnosis, 283, 285*f*
for adnexa assessment, 566
cervical abnormal findings on, 1503*b*
for cervix, 1497–1498, 1497*f*–1498*f*
diagnostic value of, 258
for drainage of pelvic abscesses, 612, 613*f*
endometrial thickness assessment with, 545–546
in gestational sac identification, 1054–1055
for pediatric pelvis, 1870–1871
for placenta previa, 1469
in pregnancy, safety of, 1049
thermal effects of, 38
in ureteral calculi detection, 337, 338*f*
for uterus, 529, 529*b*
in yolk sac identification, 1057
Transventricular valvotomy, 1292
Transverse abdominis tendon, torn, in spigelian hernia, 483–484, 487*f*
Transverse mesocolon, 219, 220*f*
Transverse myelitis, pediatric, neurogenic bladder in, 1907
Transverse testicular ectopia, 1890
Transverse waves, 2–3
TRAP. *See* Twin reversed arterial perfusion
Trauma
biliary, hemobilia from, 174, 175*f*
bladder, 366
cervical, carotid artery damage from, 946, 948*f*
dural sinus thrombosis from, 1205–1206
focused abdominal sonography for, 508
to genitourinary tract, 365–366
Trauma *(Continued)*
to liver, 129–132, 131*f*
to lower urinary tract, pediatric, 1912
to musculoskeletal system pediatric, 1938–1939, 1939*f*
pediatric
epididymitis following, 1897
scrotum and, 1897–1898, 1898*f*
renal, 365–366, 366*f*
scrotal, 847–851, 850*f*
splenic, 158, 159*f*–160*f*
testicular, 847–851, 850*f*
ureteral, 366
Treacher Collins syndrome
clefts of secondary palate in, 1153
midface hypoplasia in, 1148
Triangular cord sign, in biliary atresia, 1734–1735, 1737, 1738*f*
Trichobezoars, 300, 1840, 1841*f*
Tricuspid atresia
fetal, hydrops from, 1423–1424
hypoplastic right ventricle with, 1287
Tricuspid insufficiency, fetal, spectral Doppler assessment of, 1281*f*
Tricuspid regurgitation
in aneuploidy screening, 1095
in Ebstein anomaly, 1286
neonatal/infant, cardiac pulsations in veins and, 1578, 1578*f*
"Trident hand" configuration, achondroplasia and, 1407, 1408*f*
Triggered imaging, 65
Trigone, 314
neonatal/infant, in coronal imaging, 1515
pediatric, identification of, 1871, 1872*f*
Triorchidism, 1891
Triphalangeal thumb, in Aase syndrome, 1401
Triphasic waveform, 966–967
Triplets, amnionicity and chorionicity and, 1122*f*
Triploid karyotype, partial molar pregnancy and, 1078
Triploidy, 1078
common sonographic findings in, 1104–1106, 1104*b*, 1105*f*
Dandy-Walker malformation in, 1105*f*
fetal hydrops from, 1429–1430
IUGR in, 1105*f*
omphalocele in, 1105*f*
ovarian cysts in, 1105*f*
skeletal findings in, 1408–1409
syndactyly of fingers in, 1105*f*, 1406
Triradiate cartilage
of hip, 1923
in sonogram of hip from transverse/neutral view, 1927
Trisomy 9, horseshoe kidney in, 1345–1346
Trisomy 13 (Patau syndrome)
common sonographic findings in, 1104, 1104*b*, 1105*f*
facial clefts in, 1151
fetal hydrops from, 1429–1430
fetal omphalocele and, 1325
fetal pentalogy of Cantrell and, 1329
HPE in, 1104, 1105*f*
hyperechogenic kidneys in, 1351
NT in, 1093
polydactyly in, 1104, 1105*f*
proboscis in, 1104, 1105*f*
skeletal findings with, 1408, 1408*b*
umbilical cord cysts in, 1483
Trisomy 17, biliary atresia and, 1737
Trisomy 18 (Edwards syndrome)
biliary atresia and, 1737
CDH and, 1263

Trisomy 18 (Edwards syndrome) *(Continued)*
choroid plexus cyst in, 1103*f*, 1104
clenched hands in, 1103, 1103*f*
common sonographic findings in, 1103–1104, 1103*b*, 1103*f*
congenital heart defects in, 1103
ectopia cordis and, fetal, 1329
facial clefts in, 1151
fetal hydrops from, 1429–1430
fetal pentalogy of Cantrell and, 1329
horseshoe kidney in, 1345–1346
hydrocephalus in, 1103
IUGR and, 1104
mega-cisterna magna and, 1168–1169
NT in, 1093
omphalocele in, 1103, 1103*f*
fetal, 1325
polyhydramnios in, 1104
skeletal findings with, 1408, 1408*b*
umbilical cord cysts in, 1103*f*, 1483
Trisomy 21 (Down syndrome)
absent nasal bone in, 1150
adjunct features of, 1101
A-V canal, 1098*f*
AVSD and, 1101, 1284
β-hCG concentration in, 1089–1090
choroid plexus cysts and, 1101
congenital heart defects in, 1097, 1098*f*
duodenal atresia in, 1097, 1098*f*
ear length in, 1101
echogenic bowel in, 1100*f*, 1101

cysts of, 842*f*
Vasa aberrantia, 820–821
Vasa previa, 1480, 1485–1487, 1488*f*–1489*f*
Vascular abnormalities, in liver. *See* Liver, vascular abnormalities in
Vascular anomalies, of neck, pediatric, 1654–1655, 1655*b*
malformations, 1655–1658, 1655*b*, 1657*f*, 1659*f*
tumors, 1655, 1655*b*, 1656*f*
Vascular malformations
fetal, 1204–1208, 1206*f*
dural sinus thrombosis as, 1205–1206, 1206*f*
hydranencephaly as, 1208, 1208*f*
intracranial hemorrhage as, 1206, 1207*f*
pediatric
in masticator space, 1640, 1641*f*
in neck, 1655–1658, 1655*b*, 1657*f*, 1659*f*
Vasculitis
acute, gut edema and, 295, 297*f*
autoimmune, Henoch-Schönlein purpura and, 1853
mesenteric ischemia from, 453
renal artery stenosis and, 447
Vasectomy, epididymis changes following, 841, 843*f*
Vasodilation, 27
Vasospasm, 950
pediatric, TCD sonography for, 1608–1610, 1609*f*, 1610*t*
VATER syndrome
fetal renal anomalies in, 1341
spina bifida and, 1226
Vein mapping
before hemodialysis, 996–1000
upper extremity, 996–998, 998*f*–1000*f*
of lower extremity peripheral veins, 989–990
Vein of Galen
aneurysms of, 1204, 1206*f*
arachnoid cysts differentiated from, 1192–1193
in neonatal/infant brain, duplex Doppler sonography of, 1583–1584, 1585*f*–1586*f*
cavum veli interpositi cysts differentiated from aneurysm of, 1170

Vein of Galen *(Continued)*
malformations of, neonatal/infant brain and, 1566, 1567*f*
Vein of Markowski, 1180
fetal brain and, 1204
Velamentous umbilical cord insertion, 1484–1485, 1486*f*
multifetal pregnancy and, 1119, 1122*f*
Velocardiofacial syndrome, clefts of secondary palate in, 1153
Velocity
arterial stenosis and, 969, 970*f*
diastolic, end, in assessing degree of carotid stenosis, 930
in Doppler spectral analysis of carotid artery, 925
stroke and SCD indications with, 1605–1607
systolic
cerebral, factors changing, 1612*t*
peak, in determining carotid stenosis, 929–930
TCD sonography evaluation of, 1593, 1595–1596
time-averaged mean of maximum, 1593, 1605–1606
time-averaged peak, 1593
Velocity range, in obstetric Doppler sonography, 1036
Velocity ratios, in carotid artery stenosis evaluation, 937
Venography
in IJV, 955–956
wedge hepatic, 1764
Veno-occlusive disease, hepatic, 103
Venous drainage, in pancreas transplantation, 672
Venous insufficiency
deep, causes of, 989, 990*f*
superficial, 981–982
Venous malformations, pediatric
of neck, 1657
of salivary gland, 1636
Venous occlusive disease, hepatic, small-vessel, 1762–1763
Venous venous (VV) anastomoses, 1125, 1125*f*
Ventilation, mechanical, in neonatal/infant brain, 1578, 1579*f*
Ventral hernias, 488–494
Ventral induction errors, fetal brain and, 1186–1203
arachnoid cysts as, 1192–1193, 1193*f*
in cerebellum, 1189–1192
Dandy-Walker malformation as, 1190, 1190*f*
HPE as, 1186–1189, 1187*b*, 1188*f*, 1189*b*
mega-cisterna magna as, 1192, 1193*f*
in posterior fossa, 1189–1192
rhombencephalosynapsis as, 1192
vermis hypoplasia or dysplasia as, 1190–1192, 1192*f*
Ventricle(s)
cardiac
double-outlet right, fetal, 1288–1289, 1289*f*
echogenic foci, significance of, 1294, 1294*f*
hypoplastic left, fetal, 1292
hypoplastic right, fetal, 1287, 1287*f*
neonatal/infant, left, dysfunction of, intracranial RI and, 1576
cerebral, fetal, sonographic view of, 1024*f*
fourth
cisterna magna clot of, 1546*f*
trapped, in intraventricular hemorrhage, 1545–1547
Ventricle(s) *(Continued)*
lateral, neonatal/infant
coarctation of, 1566
in coronal imaging, 1513–1515, 1514*f*–1515*f*
in sagittal imaging, 1515–1517, 1517*f*
measurement technique for, 1174–1176, 1175*f*
medial wall of, separation of choroid from, in VM evaluation, 1176, 1176*f*
persistent terminal, pediatric, 1685
third
in corpus callosum agenesis, 1528, 1531*f*
fetal, normal sonographic appearance of, 1168
Ventricular aneurysms, congenital, 1294
Ventricular diverticula, 1294
Ventricular septal defects (VSDs), 1270, 1281–1284, 1283*f*–1284*f*
with spina bifida, 1233
in trisomy 21, 1098*f*, 1101
Ventricular tachycardia, fetal, 1296
Ventriculitis
chemical, 1206
in intraventricular hemorrhage, 1545–1547
neonatal/infant brain and, 1560, 1563*f*
Ventriculoarterial discordance, in TGA, 1289
Ventriculomegaly (VM)
CDH and, 1263
conditions associated with, 1178*b*
fetal brain and, 1174–1178
hydrocephalus differentiated from, 1611–1612
isolated, 1176
IUFD and, 1124*f*
marked, 1176, 1177*f*
measurement technique for, 1174–1176, 1175*f*
mild, 1176, 1177*f*
neonatal/infant hydranencephaly compared to, 1538*f*
pathogenesis of, 1177–1178
in rhombencephalosynapsis, 1192
in spina bifida, 1184*f*, 1230–1232
in trisomy 21, 1098*f*
ultrasound evaluation of, 1177*f*, 1178
Ventriculus terminalis
formation of, 1673, 1673*f*
normal anatomy of, 1674, 1677*f*
Verma-Naumoff syndrome, 1396
Vermian agenesis, 1190
Vermian dysplasia, Dandy-Walker malformation differentiated from, 1190
Vermis
abnormalities of, 1192
cerebellar, 1167, 1515, 1516*f*, 1524
dysplasia of, 1190–1192, 1192*f*
embryology of, 1167
hypoplasia of, 1190–1192, 1192*f*
inferior, arachnoid cysts differentiated from, 1192–1193
hypoplasia/dysgenesis/agenesis of, 1190–1191
keyhole-shaped defect in, 1191–1192
neonatal/infant
in coronal imaging, 1514–1515, 1514*f*
development of, 1524
trapezoidal vermian defect in, 1191–1192
Vertebral artery, 950–955
anatomy of, 951, 951*f*
occlusion of, 954–955
stenosis of, 954–955, 955*f*
subclavian steal phenomenon and, 952–954, 953*b*, 953*f*–954*f*
subclavian steal with transient flow reversal in, 979*f*
technique and normal examination of, 951–952, 951*f*–952*f*
Vertebral vein, 951*f*, 952
Vertebrobasilar insufficiency, symptoms of, 950–951
Vertical talus, congenital, 1932–1933, 1932*f*
Verumontanum, 382*f*–383*f*, 384
Vesicoamniotic shunts, for lower urinary tract obstruction, 1363–1365, 1364*f*, 1365*t*

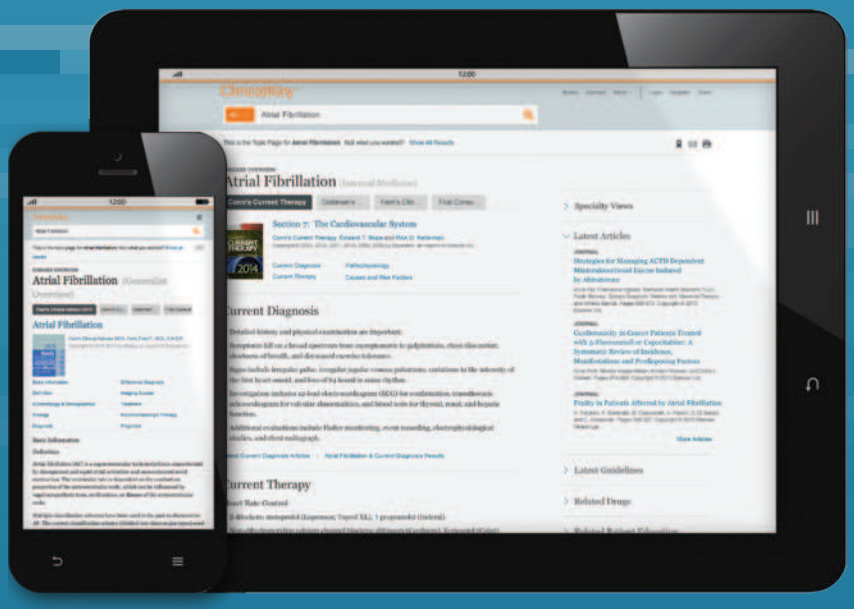
ClinicalKey®

Fast answers and trusted evidence



Drive better outcomes with a clinical search engine that makes it easier to find and apply relevant knowledge.

Fast
Anticipates your query, recognizing concepts and offering shortcuts

Complete
Draws relevant answers from a wide range of current, comprehensive content across 30+ medical and surgical specialties

Convenient
Accessible at the patient's bedside or on the go, making it easy to discover, share, and apply content anywhere

Trusted
Content from Elsevier, the name healthcare professionals worldwide rely on

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

ABOUT THE EDITORS

Carol M. Rumack, MD, FACR, is Professor of Radiology and Pediatrics at the University of Colorado School of Medicine in Denver, Colorado. Her clinical practice is based at the University of Colorado Hospital. Her primary research has been in neonatal sonography of high-risk infants, particularly the brain, on which she has published and lectured widely. She is a Fellow, previous Chair of the Ultrasound Commission, past president of the American College of Radiology, and American Association for Women Radiologists, and a Fellow of both the American Institute of Ultrasound in Medicine and the Society of Radiologists in Ultrasound. She and her husband, Barry, have two children, Becky and Marc, and five grandchildren.

Deborah Levine, MD, FACR, is Professor of Radiology at Beth Israel Deaconess Medical Center, Boston, and Harvard Medical School. At Beth Israel Deaconess Medical Center she is Vice Chair of Academic Affairs of the Department of Radiology, Co-Chief of Ultrasound, and Director of Ob/Gyn Ultrasound. Her main areas of clinical and research interest are obstetric and gynecologic imaging. She is a Fellow and past Vice President of the American College of Radiology and a Fellow (and 2016-2017 President) of the Society of Radiologists in Ultrasound. She and her husband, Alex, have two children, Becky and Julie.

PREFACE

The fifth edition of *Diagnostic Ultrasound* is a major revision. Previous editions have been very well accepted as reference textbooks and have been the most commonly used reference in ultrasound education and practices worldwide. The text and references have all been updated and are now all available online. We are pleased to provide over 2500 new/revised images (with over 5800 images total) and over 380 new videos (with 480 total videos). The display of real-time ultrasound has helped to capture those abnormalities that require a sweep through the pathology to truly appreciate the lesion as well. Daily we find that cine or video clips show important areas between still images that help to make certain a diagnosis or relationships between lesions. Now we rarely need to go back to reevaluate a lesion with another scan, making patient imaging more efficient. Another new offering in this textbook is a completely online "virtual" chapter on artifacts. PowerPoint videos explain many of the artifacts that are linked to images and videos in the text.

The fifth edition was a major change for our editorial team, as we said a fond farewell to Stephanie Wilson and Bill Charboneau. Their expertise is still felt in this edition, as they have contributed chapters on gastrointestinal ultrasound (liver, biliary tree, and gastrointestinal tract, which are all some of Stephanie's passions) and thyroid and interventional ultrasound (just some of Bill's areas of expertise).

Nearly 100 outstanding new and continuing authors have contributed to this edition, and all are recognized experts in the field of ultrasound. As in prior editions, we have emphasized the use of collages to show many examples of similar anatomy and pathology. These images reflect the spectrum of sonographic changes that may occur in a given disease, instead of the most common manifestation only.

The book's format has been redesigned with key points in addition to the outline at the beginning of each chapter. There are again colored boxes to highlight the important or critical features of sonographic diagnoses. Key terms and concepts are emphasized in boldface type. To direct the readers to other research and literature of interest, comprehensive reference lists are provided.

Diagnostic Ultrasound is again divided into two volumes. Volume I consists of Parts I to III. Part I contains chapters on physics and biologic effects of ultrasound and includes descriptions of elastography and contrast agents. Part II covers abdominal sonography and includes two completely revised chapters on pelvic sonography, along with chapters on interventional procedures (including those in the thorax) and organ transplantation. Part III presents small parts imaging, including thyroid, breast, scrotum, carotid, a completely revised chapter on imaging of the extracranial vessels, and two completely revised musculoskeletal imaging chapters, as well as an updated chapter on musculoskeletal intervention.

Volume II begins with Part IV, with obstetric ultrasound, which has important updates in first-trimester scanning and screening for aneuploidy including cell-free DNA. Part V comprehensively covers pediatric sonography, including pediatric interventional sonography. Completely revised chapters on the pediatric spinal canal and pediatric kidney are replete with new images and scanning techniques.

Diagnostic Ultrasound is for practicing physicians, residents, medical students, sonographers, and others interested in understanding the vast applications of diagnostic sonography in patient care. Our goal is for *Diagnostic Ultrasound* to continue to be the most comprehensive reference book available in the sonographic literature, with a highly readable style and superb images.

Carol M. Rumack, MD, FACR
Deborah Levine, MD, FACR

ACKNOWLEDGMENTS

We wish to express our deepest appreciation and sincerest gratitude:

To all of our outstanding authors, who have contributed extensive, newly updated, and authoritative text and images and videos. We cannot thank them enough for their efforts on this project.

To Alexander Jesurum, PhD, whose outstanding efforts kept the references updated for all of our authors and who helped in author contact and communication.

To Lisa Napolitano, RDMS, who spent hours finding and cropping videos to supplement our online edition.

To Robin Carter, Executive Content Strategist at Elsevier, who has worked closely with us on this project from the very beginning of the fifth edition.

To Taylor Ball and Dan Fitzgerald at Elsevier, who kept us on track for the process of updating and copyediting the entire manuscript.

It has been an intense year for everyone, and we are very proud of this superb edition of *Diagnostic Ultrasound.*

CONTENTS

VOLUME I

PART I Physics

1 **Physics of Ultrasound,** 1
Christopher R.B. Merritt

2 **Biologic Effects and Safety,** 34
J. Brian Fowlkes and Christy K. Holland

3 **Contrast Agents for Ultrasound,** 53
Peter N. Burns

PART II Abdominal and Pelvic Sonography

4 **The Liver,** 74
Stephanie R. Wilson and Cynthia E. Withers

5 **The Spleen,** 139
Patrick M. Vos, John R. Mathieson, and Peter L. Cooperberg

6 **The Biliary Tree and Gallbladder,** 165
Korosh Khalili and Stephanie R. Wilson

7 **The Pancreas,** 210
Thomas Winter and Maryellen R.M. Sun

8 **The Gastrointestinal Tract,** 256
Stephanie R. Wilson

9 **The Kidney and Urinary Tract,** 310
Mitchell Tublin, Deborah Levine, Wendy Thurston, and Stephanie R. Wilson

10 **The Prostate and Transrectal Ultrasound,** 381
Ants Toi

11 **The Adrenal Glands,** 416
Christina Marie Chingkoe, Olga R. Brook, and Deborah Levine

12 **The Retroperitoneum,** 432
Raymond E. Bertino and Elton Mustafaraj

13 **Dynamic Ultrasound of Hernias of the Groin and Anterior Abdominal Wall,** 470
Deborah Levine, Lisa Napolitano, and A. Thomas Stavros

14 **The Peritoneum,** 504
Anthony E. Hanbidge, Korosh Khalili, and Stephanie R. Wilson

15 **The Uterus,** 528
Douglas Brown and Deborah Levine

16 **The Adnexa,** 564
Rochelle Filker Andreotti and Lori A. Deitte

17 **Ultrasound-Guided Biopsy of Chest, Abdomen, and Pelvis,** 597
Theodora A. Potretzke, Thomas D. Atwell, J. William Charboneau, and Carl Reading

18 **Organ Transplantation,** 623
Derek Muradali and Tanya Punita Chawla

PART III Small Parts, Carotid Artery, and Peripheral Vessel Sonography

19 **The Thyroid Gland,** 691
Luigi Solbiati, J. William Charboneau, Vito Cantisani, Carl Reading, and Giovanni Mauri

20 **The Parathyroid Glands,** 732
Bonnie J. Huppert and Carl Reading

21 **The Breast,** 759
Jordana Phillips, Rashmi J. Mehta, and A. Thomas Stavros

22 **The Scrotum,** 818
Daniel Sommers and Thomas Winter

23 **Overview of Musculoskeletal Ultrasound Techniques and Applications,** 856
Colm McMahon and Corrie Yablon

24 **The Shoulder,** 877
Colm McMahon and Corrie Yablon

25 **Musculoskeletal Interventions,** 898
Ronald S. Adler

26 **The Extracranial Cerebral Vessels,** 915
Edward I. Bluth, Stephen I. Johnson, and Laurie Troxclair

27 **Peripheral Vessels,** 964
Mark E. Lockhart, Heidi R. Umphrey, Therese M. Weber, and Michelle L. Robbin

VOLUME II

PART IV Obstetric and Fetal Sonography

28 **Overview of Obstetric Imaging,** 1015
Deborah Levine

29 **Bioeffects and Safety of Ultrasound in Obstetrics,** 1034
Jacques S. Abramowicz

30 **The First Trimester,** 1048
Elizabeth Lazarus and Deborah Levine

31 **Chromosomal Abnormalities,** 1088
Bryann Bromley and Beryl Benacerraf

32 **Multifetal Pregnancy,** 1115
Mary C. Frates

33 **The Fetal Face and Neck,** 1133
Ana P. Lourenco and Judy A. Estroff

34 **The Fetal Brain,** 1166
Ants Toi and Deborah Levine

35 **The Fetal Spine,** 1216
Elizabeth Asch and Eric Sauerbrei

36 **The Fetal Chest,** 1243
Dorothy Bulas

37 **The Fetal Heart,** 1270
Elizabeth R. Stamm and Julia A. Drose

38 **The Fetal Gastrointestinal Tract and Abdominal Wall,** 1304
Nir Melamed, Anne Kennedy, and Phyllis Glanc

39 **The Fetal Urogenital Tract,** 1336
Katherine W. Fong, Julia Eva Kfouri, and Kirsten L. Weind Matthews

40 **The Fetal Musculoskeletal System,** 1376
Phyllis Glanc, David Chitayat, and Sheila Unger

41 **Fetal Hydrops,** 1412
Deborah Levine

42 **Fetal Measurements: Normal and Abnormal Fetal Growth and Assessment of Fetal Well-Being,** 1443
Carol B. Benson and Peter M. Doubilet

43 **Sonographic Evaluation of the Placenta,** 1465
Thomas D. Shipp

44 **Cervical Ultrasound and Preterm Birth,** 1495
Hournaz Ghandehari and Phyllis Glanc

PART V Pediatric Sonography

45 **Neonatal and Infant Brain Imaging,** 1511
Carol M. Rumack and Amanda K. Auckland

46 **Duplex Sonography of the Neonatal and Infant Brain,** 1573
Thierry A.G.M. Huisman and Andrea Poretti

47 **Doppler Sonography of the Brain in Children,** 1591
Dorothy Bulas and Alexia Egloff

48 **The Pediatric Head and Neck,** 1628
Rupa Radhakrishnan and Beth M. Kline-Fath

49 **The Pediatric Spinal Canal,** 1672
Ilse Castro-Aragon, Deborah Levine, and Carol M. Rumack

50 **The Pediatric Chest,** 1701
Chetan Chandulal Shah and S. Bruce Greenberg

51 **The Pediatric Liver and Spleen,** 1730
Sara M. O'Hara

52 **The Pediatric Urinary Tract and Adrenal Glands,** 1775
Harriet J. Paltiel and Diane S. Babcock

53 **The Pediatric Gastrointestinal Tract,** 1833
Susan D. John and Martha Mappus Munden

54 **Pediatric Pelvic Sonography,** 1870
William L. Simpson, Jr., Humaira Chaudhry, and Henrietta Kotlus Rosenberg

55 **The Pediatric Hip and Other Musculoskeletal Ultrasound Applications,** 1920
Leslie E. Grissom and H. Theodore Harcke

56 **Pediatric Interventional Sonography,** 1942
Neil Johnson and Allison Aguado

Appendix: Ultrasound Artifacts: A Virtual Chapter
Korosh Khalili, Hojun Yu, Alexander Jesurum, and Deborah Levine
Index, I-1

VIDEO CONTENTS

4 The Liver
Stephanie R. Wilson and Cynthia E. Withers

Video 4.1 **Normal liver, sagittal sweep**
Video 4.2 **Normal liver, subcostal sweep**
Video 4.3 **Focal fat in the liver**
Video 4.4 **Geographic fatty infiltration of the liver**
Video 4.5 **CEUS of FNH with classic enhancement features**
Video 4.6 **CEUS of the flash-filling hemangioma shown in Fig. 4.47**
Video 4.7 **CEUS of focal nodular hyperplasia**
Video 4.8 **CEUS of focal nodular hyperplasia**
Video 4.9 **CEUS of hepatic adenoma in a young woman**
Video 4.10 **CEUS of small hepatocellular carcinoma**
Video 4.11 **CEUS of hepatocellular carcinoma**
Video 4.12 **Classic colorectal metastasis**
Video 4.13 **CEUS of liver metastasis**
Video 4.14 **CEUS of liver metastasis**

5 The Spleen
Patrick M. Vos, John R. Mathieson, and Peter L. Cooperberg

Video 5.1 **Normal spleen in sagittal plane**
Video 5.2 **Normal spleen in transverse plane**
Video 5.3 **Contrast study of lymphoma manifesting as a hypoechoic solitary splenic lesion**

6 The Biliary Tree and Gallbladder
Korosh Khalili and Stephanie R. Wilson

Video 6.1 **Distal common bile duct and ampulla of Vater**
Video 6.2 **Intrahepatic bile duct stones**
Video 6.3 **Distal common bile duct stone**
Video 6.4 **Choledochoduodenal fistula**
Video 6.5 **Primary sclerosing cholangitis**
Video 6.6 **Primary sclerosing cholangitis**
Video 6.7 **Cholangiocarcinoma complicating primary sclerosing cholangitis**
Video 6.8 **Cholangiocarcinoma complicating primary sclerosing cholangitis**
Video 6.9 **Cholelithiasis**
Video 6.10 **Acute cholecystitis**
Video 6.11 **Perforated cholecystitis with liver abscess**

7 The Pancreas
Thomas Winter and Maryellen R.M. Sun

Video 7.1 **Normal pancreas**
Video 7.2 **Acute pancreatitis**
Video 7.3 **Acute pancreatitis**
Video 7.4 **Chronic pancreatitis**
Video 7.5 **Chronic pancreatitis**
Video 7.6 **Pancreatic pseudocyst**
Video 7.7 **Pancreatic carcinoma**
Video 7.8 **Pancreatic carcinoma**
Video 7.9 **Intraductal papillary mucinous neoplasm**
Video 7.10 **Mucinous cystic neoplasm**

8 The Gastrointestinal Tract
Stephanie R. Wilson

Video 8.1 **An incidentally detected neuroendocrine tumor (carcinoid) of the small bowel**
Video 8.2 **Classic features of Crohn disease on a sweep through the terminal ileum**
Video 8.3 **Loss of stratification of the bowel wall layers in severe subacute inflammation of the sigmoid colon in a patient with Crohn disease**
Video 8.4 **Stricture in Crohn disease**
Video 8.5 **Color Doppler shows hyperemia in thickened bowel wall in Crohn disease**
Video 8.6 **Contrast-enhanced longitudinal image of Crohn disease**
Video 8.7 **Contrast-enhanced cross-sectional image of Crohn disease**
Video 8.8 **Severe fixation and acute angulation of the ileum with stricture and enteroenteric fistula**
Video 8.9 **Incomplete small bowel obstruction in patient with Crohn disease**
Video 8.10 **Dysfunctional and excess peristalsis**
Video 8.11 **Localized perforation with a phlegmonous inflammatory mass**
Video 8.12 **Enteroenteric fistula**
Video 8.13 **Normal appendix**
Video 8.14 **Perforated appendix**
Video 8.15 **Acute diverticulitis in second trimester of pregnancy**
Video 8.16 **Paralytic ileus**
Video 8.17 **Incomplete bowel obstruction due to an inflammatory stricture from Crohn disease seen only on endovaginal scan**

9 The Kidney and Urinary Tract
Mitchell Tublin, Deborah Levine, Wendy Thurston, and Stephanie R. Wilson

Video 9.1 **Doppler jet**
Video 9.2 **Renal cell carcinoma**
Video 9.3 **Transitional cell carcinoma of the bladder**
Video 9.4 **Bladder diverticula**

11 The Adrenal Glands
Christina Marie Chingkoe, Olga R. Brook, and Deborah Levine

Video 11.1 **Normal adrenal gland**
Video 11.2 **Adrenal adenoma**
Video 11.3 **Adrenal adenoma**
Video 11.4 **Adrenal gland with calcification**

12 The Retroperitoneum
Raymond E. Bertino and Elton Mustafaraj

Video 12.1 **Type 2 endoleak from inferior mesenteric artery–aorta**
Video 12.2 **Type 2 endoleak on enhanced computed tomography scan**
Video 12.3 **Type 3 endoleak, transverse image**
Video 12.4 **Type 3 endoleak, longitudinal image**
Video 12.5 **Aortic pseudoaneurysm (contained rupture), longitudinal image**
Video 12.6 **Restenosis of stented accessory left renal artery**
Video 12.7 **Angiogram of restenosis of stented accessory left renal artery**

Video 12.8 **Angiogram of stented accessory left renal artery restenosis after restenting**
Video 12.9 **Normal right renal artery**
Video 12.10 **Left renal artery stenosis with color bruit and aliasing throughout cardiac cycle**
Video 12.11 **Nutcracker syndrome**
Video 12.12 **Nutcracker syndrome after stent placement**
Video 12.13 **Prominent arcuate veins**
Video 12.14 **Mildly prominent arcuate veins**
Video 12.15 **Angiogram of left ovarian vein during coil placement**

13 Dynamic Ultrasound of Hernias of the Groin and Anterior Abdominal Wall
Deborah Levine, Lisa Napolitano, and A. Thomas Stavros

Video 13.1 **Fat-containing indirect inguinal hernia**
Video 13.2 **Direct inguinal hernia with intraperitoneal and preperitoneal fat**
Video 13.3 **Note bowel peristalsis in this inguinal hernia**
Video 13.4 **Large fat-containing direct inguinal hernia**
Video 13.5 **Change in hernia contents during Valsalva maneuver**
Video 13.6 **Completely reducible large wide-necked fat-containing ventral hernia**
Video 13.7 **Partially reducible indirect inguinal hernia containing fat and bowel**
Video 13.8 **Nonreducible fat-containing epigastric linea alba hernia**
Video 13.9 **Large bowel-containing indirect inguinal hernia extending into scrotum**
Video 13.10 **Fat-containing femoral hernia**
Video 13.11 **Moderate-sized fat-containing nonreducible left spigelian hernia**
Video 13.12 **Large fat- and bowel-containing incompletely reducible spigelian hernia**
Video 13.13 **Diastasis recti abdominis**
Video 13.14 **Fat-containing ventral hernia**
Video 13.15 **Small fat-containing nonreducible epigastric linea alba hernia**
Video 13.16 **Two adjacent moderate-sized fat-containing incompletely reducible epigastric linea alba hernias**
Video 13.17 **Mesh with strong shadow makes evaluation for recurrent hernia difficult**
Video 13.18 **Two adjacent moderate-sized fat-containing incisional hernias in patient after transverse rectus abdominis myocutaneous (TRAM) flap breast reconstruction**
Video 13.19 **Fat-containing incisional hernia**
Video 13.20 **Moderate-sized fat-containing reducible incisional hernia**
Video 13.21 **Moderate-sized fat-containing reducible recurrent inguinal hernia at the edge of mesh**
Video 13.22 **Pantaloon hernias**
Video 13.23 **Strangulated right femoral hernia**
Video 13.24 **Round ligament and inguinal canal (canal of Nuck) in a female with hydrocele**

14 The Peritoneum
Anthony E. Hanbidge, Korosh Khalili, and Stephanie R. Wilson

Video 14.1 **Tumor infiltration of the omentum**
Video 14.2 **Tumor implant in the pouch of Douglas**
Video 14.3 **Tumor implant in the pouch of Douglas**
Video 14.4 **Peritoneal carcinomatosis—parietal peritoneum**
Video 14.5 **Peritoneal carcinomatosis—visceral peritoneum**
Video 14.6 **Peritoneal carcinomatosis—visceral peritoneum**
Video 14.7 **Peritoneal mesothelioma**
Video 14.8 **Endometrioma in the pouch of Douglas**
Video 14.9 **Endometriotic plaque**
Video 14.10 **Endometriotic plaque**

15 The Uterus
Douglas Brown and Deborah Levine

Video 15.1 **Unicornuate uterus**
Video 15.2 **Bicornuate uterus**
Video 15.3 **Fibroid with cystic necrotic change**
Video 15.4 **Adenomyosis**
Video 15.5 **Prolapsing polyp**
Video 15.6 **Endometrial polyp**
Video 15.7 **Endometrial polyp**
Video 15.8 **Endometrial carcinoma**
Video 15.9 **Endometrial carcinoma with hematometra**
Video 15.10 **Synechia**
Video 15.11 **Low position of intrauterine device (IUD)**
Video 15.12 **Vascularized retained products of conception**
Video 15.13 **Bladder flap hematoma and sutures after cesarean section**

16 The Adnexa
Rochelle Filker Andreotti and Lori A. Deitte

Video 16.1 **Bowel peristalsis**
Video 16.2 **Hemorrhagic cyst**
Video 16.3 **Endometrioma**
Video 16.4 **Atypical endometrioma**
Video 16.5 **Deep infiltrating endometriosis**
Video 16.6 **Ovarian torsion**
Video 16.7 **Clear cell carcinoma in endometrioma**
Video 16.8 **Yolk sac tumor**
Video 16.9 **Hydrosalpinx in 70-year-old woman with adnexal cyst**
Video 16.10 **Hydrosalpinx in 35-year-old with complex left adnexal cyst**
Video 16.11 **Pelvic inflammatory disease caused by *Neisseria Gonorrhoeae***

17 Ultrasound-Guided Biopsy of Chest, Abdomen, and Pelvis
Theodora A. Potretzke, Thomas D. Atwell, J. William Charboneau, and Carl Reading

Video 17.1 **Ultrasound-guided omental core biopsy**
Video 17.2 **Ultrasound-guided liver core biopsy**
Video 17.3 **Ultrasound-guided liver mass biopsy using "freehand" technique**
Video 17.4 **Ultrasound-guided liver mass biopsy using "freehand" technique**
Video 17.5 **Power Doppler imaging improving drain conspicuity**
Video 17.6 **Transvaginal adnexal cyst local anesthesia**
Video 17.7 **Transvaginal adnexal cyst aspiration**

18 Organ Transplantation
Derek Muradali and Tanya Punita Chawla

Video 18.1 **Normal renal transplant, sagittal**
Video 18.2 **Normal renal transplant, transverse**
Video 18.3 **Arteriovenous malformation renal transplant**
Video 18.4 **Partially thrombosed pseudoaneurysm in hilum of renal transplant**
Video 18.5 **Normal pancreas transplant, sagittal**
Video 18.6 **Normal pancreas transplant, transverse**

19 The Thyroid Gland
Luigi Solbiati, J. William Charboneau, Vito Cantisani, Carl Reading, and Giovanni Mauri

Video 19.1 **Colloid cysts**
Video 19.2 **Honeycomb pattern of benign nodule**
Video 19.3 **Adenoma**
Video 19.4 **Papillary carcinoma: fine calcifications**
Video 19.5 **Papillary carcinoma: coarse and fine calcifications**
Video 19.6 **Fine-needle aspiration (FNA)**
Video 19.7 **Hashimoto thyroiditis**

20 The Parathyroid Glands
Bonnie J. Huppert and Carl Reading

Video 20.1 **Cystic and solid parathyroid adenoma**
Video 20.2 **Small parathyroid adenoma**
Video 20.3 **Multiple gland parathyroid hyperplasia**
Video 20.4 **Multiple gland parathyroid hyperplasia**
Video 20.5 **Superior parathyroid adenoma**
Video 20.6 **Superior parathyroid adenoma**
Video 20.7 **Inferior parathyroid adenoma**
Video 20.8 **Inferior parathyroid adenoma**
Video 20.9 **Ectopic superior parathyroid adenoma**
Video 20.10 **Intrathyroid parathyroid adenoma**
Video 20.11 **Intrathyroid parathyroid adenoma**
Video 20.12 **Ectopic parathyroid adenoma**
Video 20.13 **Parathyromatosis in the postoperative neck**
Video 20.14 **Parathyroid adenoma**
Video 20.15 **Small inferior parathyroid adenoma and multinodular goiter**
Video 20.16 **Small inferior parathyroid adenoma and multinodular thyroid**
Video 20.17 **Ectopic intrathyroid parathyroid adenoma biopsy**
Video 20.18 **Ectopic parathyroid adenoma biopsy**
Video 20.19 **Ethanol ablation of recurrent graft-dependent hyperparathyroidism**

21 The Breast
Jordana Phillips, Rashmi J. Mehta, and A. Thomas Stavros

Video 21.1 **Importance of light pressure for color Doppler examination**
Video 21.2 **Importance of light pressure for color Doppler examination**
Video 21.3 **Normal cyst**
Video 21.4 **Intraductal papilloma**
Video 21.5 **Percutaneous biopsy using spring-loaded biopsy device**

22 The Scrotum
Daniel Sommers and Thomas Winter

Video 22.1 **Atrophic testis with seminoma**
Video 22.2 **Epidermoid cyst**
Video 22.3 **Varicocele in patient performing a Valsalva maneuver, with gray-scale and color Doppler sonography**
Video 22.4 **Postvasectomy appearance of epididymis and vas deferens**
Video 22.5 **"Dancing sperm" postvasectomy image of scrotum**
Video 22.6 **Acute orchitis**
Video 22.7 **Inferior traumatic tunica albuginea rupture, hematoma in testis, and extrusion of seminiferous tubules**

23 Overview of Musculoskeletal Ultrasound Techniques and Applications
Colm McMahon and Corrie Yablon

Video 23.1 **Normal biceps muscle and distal tendon**
Video 23.2 **Normal Achilles tendon**
Video 23.3 **Normal finger flexor tendons—dynamic imaging**
Video 23.4 **Dynamic ulnar nerve subluxation**
Video 23.5 **Short-axis imaging of a Baker cyst**

24 The Shoulder
Colm McMahon and Corrie Yablon

Video 24.1 **Dynamic assessment for subcoracoid impingement**
Video 24.2 **Illustration of imaging the supraspinatus in long axis and the transition to infraspinatus posteriorly**
Video 24.3 **Dynamic assessment for subacromial impingement**
Video 24.4 **Dynamic imaging showing increased prominence of glenohumeral effusion on external rotation**
Video 24.5 **Short-axis imaging of the supraspinatus tendon**

25 Musculoskeletal Interventions
Ronald S. Adler

Video 25.1 **Intraarticular injection of a hip under ultrasound guidance**
Video 25.2 **Biceps tendon sheath injection using a rotator interval approach**
Video 25.3 **Aspiration of a spinoglenoid notch cyst**
Video 25.4 **Injection of calcific tendinosis**
Video 25.5 **Autologous blood injection of 50-year-old woman with lateral epicondylitis**
Video 25.6 **Depiction of Tenex procedure**
Video 25.7 **Posthydrodissection of sural nerve in a 59-year-old female patient**

26 The Extracranial Cerebral Vessels
Edward I. Bluth, Stephen I. Johnson, and Laurie Troxclair

Video 26.1 **Minimal homogeneous plaque at carotid bulb (gray-scale)**
Video 26.2 **Considerable homogenous plaque at ICA (gray-scale)**
Video 26.3 **Type 3 homogeneous plaque with less than 50% sonolucency (gray-scale)**
Video 26.4 **Type 3 homogeneous plaque with low-grade stenosis of the ICA (gray-scale)**
Video 26.5 **Calcified plaque in the CCA (gray-scale)**
Video 26.6 **Heterogeneous plaque in the left ICA (type 1) (gray-scale)**
Video 26.7 **Heterogeneous plaque (type 1) with greater than 50% sonolucency within the plaque of the left ICA (gray-scale)**
Video 26.8 **Heterogeneous plaque (type 2) in the ICA (gray-scale)**
Video 26.9 **High-grade stenosis in the proximal right ICA (color Doppler)**
Video 26.10 **Heterogeneous plaque in the ICA (color Doppler)**
Video 26.11 **Heterogeneous plaque in the left ICA (power Doppler)**
Video 26.12 **High-grade stenosis in the ICA (power Doppler)**
Video 26.13 **High-grade stenosis of the ICA (power Doppler)**
Video 26.14 **Low-grade stenosis in the ICA (color Doppler)**
Video 26.15 **Normal spectral waveform of the proximal ICA**
Video 26.16 **Normal spectral waveform of the mid ICA**
Video 26.17 **Normal spectral waveform of the distal ICA**
Video 26.18 **Normal spectral waveform of the right distal CCA**
Video 26.19 **High-grade stenosis in the ICA (power Doppler)**

Video 26.20 **High-grade stenosis in the ICA (color Doppler)**
Video 26.21 **High-grade stenosis with spectral broadening (color and spectral Doppler)**
Video 26.22 **Color and spectral Doppler of low-grade stenosis in the ICA**

27 Peripheral Vessels
Mark E. Lockhart, Heidi R. Umphrey, Therese M. Weber, and Michelle L. Robbin

Video 27.1 **Acute thrombus in the superficial femoral artery**
Video 27.2 **Occlusion of the superficial femoral artery with a large collateral exiting proximal to the occlusion**
Video 27.3 **Severe calcification of the superficial femoral artery limits ability to see within the artery lumen with gray-scale imaging**
Video 27.4 **Common femoral artery pseudoaneurysm**
Video 27.5 **Common femoral artery to common femoral vein arteriovenous fistula (AVF)**
Video 27.6 **Arterial bypass graft stenosis on grayscale and color Doppler**
Video 27.7 **Large radial artery pseudoaneurysm with rent in arterial wall**
Video 27.8 **Large radial artery pseudoaneurysm**
Video 27.9 **Subclavian steal**
Video 27.10 **Normal femoral vein compression during study to assess for deep venous thrombosis**
Video 27.11 **Acute common femoral vein (CFV) thrombus**
Video 27.12 **Nonocclusive slightly mobile thrombus within the great saphenous vein (GSV) with extension into the common femoral vein (CFV)**
Video 27.13 **Acute deep venous thrombosis in right lower extremity**
Video 27.14 **Chronic vein occlusion with collaterals**
Video 27.15 **Chronic common femoral vein (CFV) occlusion with normal antegrade flow in the femoral vein, and flow reversal in the profunda femoral vein**
Video 27.16 **Slow flow in patent, compressible vein without deep venous thrombosis, longitudinal cine clip**
Video 27.17 **Slow flow in patent, compressible vein without deep venous thrombosis, transverse cine clip**
Video 27.18 **Thrombus in one of paired femoral veins**
Video 27.19 **Normal femoral vein valve**
Video 27.20 **Normal internal jugular vein (IJV) on gray scale compression cine clip**
Video 27.21 **Acute internal jugular thrombus**
Video 27.22 **Nonocclusive thrombus in one brachial vein in the paired brachial veins**
Video 27.23 **Acute thrombus around peripherally inserted central catheter (PICC) line in the basilic vein**
Video 27.24 **Acute thrombus around peripherally inserted central catheter (PICC) line in the basilic vein**
Video 27.25 **Thick-walled cephalic vein with chronic thrombus**
Video 27.26 **Large hematoma adjacent to arteriovenous fistula (AVF)**
Video 27.27 **Small AVF basilic vein pseudoaneurysm**
Video 27.28 **Graft wall irregularity and degeneration from repeated punctures**
Video 27.29 **Graft venous anastomosis stenosis with peak systolic velocity measuring 6.1 m/sec in highest velocity portion of jet**

28 Overview of Obstetric Imaging
Deborah Levine

Video 28.1 **Normal 6-week embryo with cardiac activity**
Video 28.2 **Normal first-trimester embryo with rhombencephalon appearing as a fluid collection in the region of the head**
Video 28.3 **Sagittal view of uterus with 17-week gestational age fetus in cephalic presentation and anterior placenta**
Video 28.4 **Normal intracranial anatomy at 19 weeks' gestation**
Video 28.5 **Four-chamber view of beating fetal heart**
Video 28.6 **Scan through the heart**
Video 28.7 **Normal kidneys and lumbosacral spine**
Video 28.8 **Transverse fetal spine**
Video 28.9 **Bladder and umbilical arteries**

30 The First Trimester
Elizabeth Lazarus and Deborah Levine

Video 30.1 **Early embryonic cardiac activity**
Video 30.2 **Early pregnancy failure at 7 weeks**
Video 30.3 **Expanded amnion in nonviable pregnancy**
Video 30.4 **Ten-week demise with calcified yolk sac**
Video 30.5 **Small subchorionic hemorrhage**
Video 30.6 **Right ectopic pregnancy with adnexal mass separating from the ovary with manual pressure**
Video 30.7 **Ruptured ectopic pregnancy**
Video 30.8 **Cesarean section implantation in retroflexed uterus**
Video 30.9 **Normal rhombencephalon**
Video 30.10 **Persistent trophoblastic neoplasia**
Video 30.11 **Choriocarcinoma**

31 Chromosomal Abnormalities
Bryann Bromley and Beryl Benacerraf

Video 31.1 **Nuchal translucency**
Video 31.2 **Cystic hygroma**
Video 31.3 **Nasal bone in first trimester**
Video 31.4 **Echogenic bowel**
Video 31.5 **Amniocentesis needle being withdrawn from amniotic fluid cavity**

32 Multifetal Pregnancy
Mary C. Frates

Video 32.1 **Quintuplets, 9 weeks' gestational age**
Video 32.2 **Conjoined embryos, 7 weeks' gestational age**
Video 32.3 **Monochorionic monoamniotic twins, 26 weeks' gestational age**
Video 32.4 **Three separate placentas in a trichorionic triplet pregnancy at 13 weeks' gestational age**
Video 32.5 **Velamentous cord insertion in a twin, 34 weeks' gestational age**
Video 32.6 **Growth and fluid discrepancies in dichorionic twins, 24 weeks' gestational age**
Video 32.7 **Twin-twin transfusion syndrome, 22 weeks' gestational age**
Video 32.8 **Twin reversed arterial perfusion sequence, 16 weeks' gestational age**
Video 32.9 **Monochorionic monoamniotic twins, 12 weeks' gestational age**
Video 32.10 **Monochorionic monoamniotic twins, 28 weeks' gestational age**
Video 32.11 **Monochorionic monoamniotic conjoined twins, 35 weeks' gestational age**

33 The Fetal Face and Neck
Ana P. Lourenco and Judy A. Estroff

Video 33.1 **Left 2 complete cleft lip, cleft alveolus, and cleft palate in sagittal plane in 20-week gestational age fetus**
Video 33.2 **Left unilateral complete cleft lip, cleft alveolus, and cleft palate in axial plane in 20-week gestational age fetus**
Video 33.3 **Left unilateral complete cleft lip, cleft alveolus, and cleft palate in coronal plane in 20-week gestational age fetus**
Video 33.4 **Micrognathia at gestational age 20 weeks**

34 The Fetal Brain
Ants Toi and Deborah Levine

Video 34.1 **Normal brain, axial**
Video 34.2 **Normal brain, coronal**
Video 34.3 **Normal brain, sagittal**
Video 34.4 **Choroid plexus cysts**
Video 34.5 **Bilateral ventriculomegaly**
Video 34.6 **Chiari malformation in fetus with spinal neural tube defect**
Video 34.7 **Holoprosencephaly**
Video 34.8 **Second trimester agenesis of corpus callosum**
Video 34.9 **Agenesis of corpus callosum in coronal plane**
Video 34.10 **Agenesis of corpus callosum in sagittal plane**
Video 34.11 **Agenesis of corpus callosum in axial plane with midline cyst**
Video 34.12 **Absence of septal leaflets**

35 The Fetal Spine
Elizabeth Asch and Eric Sauerbrei

Video 35.1 **Normal transaxial spine**
Video 35.2 **Normal longitudinal spine**
Video 35.3 **Myelomeningocele**
Video 35.4 **Closed neural tube defect: transaxial**
Video 35.5 **Closed neural tube defect: longitudinal**
Video 35.6 **Sacrococcygeal teratoma**

36 The Fetal Chest
Dorothy Bulas

Video 36.1 **Congenital pulmonary adenomatoid malformation**
Video 36.2 **Small pleural effusion at 16 weeks' gestational age**
Video 36.3 **Left-sided congenital diaphragmatic hernia at 32 weeks' gestational age (transverse view)**
Video 36.4 **Left-sided congenital diaphragmatic hernia at 32 weeks' gestational age (sagittal view)**
Video 36.5 **Large left-sided congenital diaphragmatic hernia with large amount of liver in chest**
Video 36.6 **Right-sided congenital diaphragmatic hernia**

37 The Fetal Heart
Elizabeth R. Stamm and Julia A. Drose

Video 37.1 **Normal apical four-chamber view**
Video 37.2 **Normal sub-costal four-chamber view**
Video 37.3 **Normal appearance of the aorta and pulmonary artery**
Video 37.4 **Color Doppler of the aorta and pulmonary artery**
Video 37.5 **Short-axis view of the color Doppler of the ventricles and great arteries**
Video 37.6 **Three-vessel and trachea view**
Video 37.7 **Aortic arch**
Video 37.8 **Aortic arch**
Video 37.9 **Atrioventricular septal defect**
Video 37.10 **Hypoplastic left heart syndrome**
Video 37.11 **Hypoplastic right heart**
Video 37.12 **Ebstein anomaly**
Video 37.13 **Tetralogy of Fallot**

38 The Fetal Gastrointestinal Tract and Abdominal Wall
Nir Melamed, Anne Kennedy, and Phyllis Glanc

Video 38.1 **Esophageal atresia**
Video 38.2 **Gastric debris**
Video 38.3 **Gastric debris**
Video 38.4 **Duodenal atresia**
Video 38.5 **Jejunal atresia**
Video 38.6 **Duplication cyst**
Video 38.7 **Meconium peritonitis**
Video 38.8 **Echogenic bowel**
Video 38.9 **Normal gallbladder**
Video 38.10 **Annular pancreas**
Video 38.11 **Splenic cyst**
Video 38.12 **Gastroschisis**
Video 38.13 **Omphalocele**
Video 38.14 **Bladder exstrophy**
Video 38.15 **Cloacal exstrophy**

39 The Fetal Urogenital Tract
Katherine W. Fong, Julia Eva Kfouri, and Kirsten L. Weind Matthews

Video 39.1 **"Lying down" adrenal sign due to unilateral renal agenesis**
Video 39.2 **Bilateral renal agenesis**
Video 39.3 **Pelvic kidney**
Video 39.4 **Cross-fused renal ectopia**
Video 39.5 **Horseshoe kidney**
Video 39.6 **Autosomal recessive polycystic kidney disease**
Video 39.7 **Perinephric urinoma**
Video 39.8 **Primary megaureter**
Video 39.9 **Megalourethra**
Video 39.10 **Cloacal dysgenesis**
Video 39.11 **Ovarian cyst**

40 The Fetal Musculoskeletal System
Phyllis Glanc, David Chitayat, and Sheila Unger

Video 40.1 **Thanatophoric dysplasia**
Video 40.2 **Clubfeet at 21 weeks**

41 Fetal Hydrops
Deborah Levine

Video 41.1 **Fetal abdomen at 30 weeks gestational age in fetus with a small amount of ascites and polyhydramnios**
Video 41.2 **Bilateral pleural effusions, left greater than right**
Video 41.3 **Large unilateral pleural effusion inverts the hemidiaphragm and is associated with ascites**
Video 41.4 **Small pericardial effusion in fetus with poorly contractile and echogenic heart**
Video 41.5 **Anasarca in fetus with congenital pulmonary airway malformation**
Video 41.6 **Middle cerebral artery Doppler**
Video 41.7 **Poorly contractile heart abnormal appearing heart, bilateral pleural effusions, and marked anasarca**

42 Fetal Measurements: Normal and Abnormal Fetal Growth and Assessment of Fetal Well-Being
Carol B. Benson and Peter M. Doubilet

Video 42.1 **Early embryonic heartbeat**
Video 42.2 **Fetal movement**
Video 42.3 **Fetal breathing movements**

43 Sonographic Evaluation of the Placenta
Thomas D. Shipp

Video 43.1 **Placental lake**
Video 43.2 **Thick placenta**
Video 43.3 **Placenta accreta**
Video 43.4 **Placenta increta**
Video 43.5 **Placenta percreta**
Video 43.6 **Abruption**
Video 43.7 **Abruption**
Video 43.8 **Preplacental hematoma**
Video 43.9 **Preplacental hematoma**
Video 43.10 **Placental infarction**
Video 43.11 **Placental infarction**
Video 43.12 **Circumvallate placenta**
Video 43.13 **Circumvallate placenta**
Video 43.14 **Bilobed placenta**
Video 43.15 **Velamentous cord insertion and two-vessel cord**
Video 43.16 **Umbilical cord insertion into placenta**
Video 43.17 **Vasa previa**

44 Cervical Ultrasound and Preterm Birth
Hournaz Ghandehari and Phyllis Glanc

Video 44.1 **Open cervix with large funnel and bulging membranes**
Video 44.2 **Closed cervix with mobile debris at the internal os**
Video 44.3 **Open cervix with mobile debris in the dilated cervical canal and adjacent to the external os**

45 Neonatal and Infant Brain Imaging
Carol M. Rumack and Amanda K. Auckland

Video 45.1 **Normal coronal sweep**
Video 45.2 **Normal sagittal sweep**
Video 45.3 **Normal mastoid sweep**
Video 45.4 **Chiari II malformation**
Video 45.5 **Ventriculomegaly in association with Chiari II malformation (seen in Video 45.4)**
Video 45.6 **Chiari II malformation, pointed frontal and large occipital horn; partial absence of corpus callosum (same neonate as in Videos 45.4 and 45.5)**
Video 45.7 **Tethered cord in patient with Chiari II malformation, sagittal scan**
Video 45.8 **Absence of cavum septi pellucidi, coronal scan**
Video 45.9 **Right subacute subependymal, intraventricular, and right frontal intraparenchymal hemorrhages, coronal scan**
Video 45.10 **Right subependymal, caudothalamic groove, and hemorrhage and intraventricular hemorrhage, sagittal scan**
Video 45.11 **Cisterna magna clot**
Video 45.12 **Acute intraventricular echogenic blood**
Video 45.13 **Bilateral intraventricular hemorrhage and intraparenchymal hemorrhage**
Video 45.14 **Acute highly echogenic hemorrhage**
Video 45.15 **Intraventricular hemorrhage**
Video 45.16 **Cystic periventricular leukomalacia**
Video 45.17 **Cytomegalovirus with punctate calcifications**
Video 45.18 **Multiple focal calcifications**
Video 45.19 **Ventricular septation**

47 Doppler Sonography of the Brain in Children
Dorothy Bulas and Alexia Egloff

Video 47.1 **Normal color Doppler of circle of Willis in 6-year-old**
Video 47.2 **Spectral wave form of the right middle cerebral artery**
Video 47.3 **Normal spectral Doppler of right bifurcation**
Video 47.4 **Four-year-old pending brain death after fall from second story**
Video 47.5 **Eight-year-old pending brain death after motor vehicle accident postcraniectomy for hematoma**

48 The Pediatric Head and Neck
Rupa Radhakrishnan and Beth M. Kline-Fath

Video 48.1 **Wharton duct stone**
Video 48.2 **Multinodular goiter**
Video 48.3 **Infantile hemangioma**
Video 48.4 **Lymphatic malformation**

49 The Pediatric Spinal Canal
Ilse Castro-Aragon, Deborah Levine, and Carol M. Rumack

Video 49.1 **Normal cauda equina**
Video 49.2 **Normal filum terminale**
Video 49.3 **Skin dimple and hypoechoic tract in subcutaneous tissues extending to normal coccyx**
Video 49.4 **Lipomyelocele in sagittal view**
Video 49.5 **Sagittal lipomyelocele**
Video 49.6 **Lipomyelocele in transverse view**
Video 49.7 **Lipomyelomeningocele**
Video 49.8 **Segmental spinal dysgenesis in sagittal view**
Video 49.9 **Segmental spinal dysgenesis patient with fatty filum**

50 The Pediatric Chest
Chetan Chandulal Shah and S. Bruce Greenberg

Video 50.1 **Moving septations within pleural fluid**
Video 50.2 **Hemidiaphragmatic motion in an infant**
Video 50.3 **Hemidiaphragmatic movement in healthy 31-month-old child**
Video 50.4 **Hemidiaphragmatic paralysis in an infant after cardiac surgery**

51 The Pediatric Liver and Spleen
Sara M. O'Hara

Video 51.1 **Normal porta hepatis showing portal vein, hepatic artery, and common bile duct**
Video 51.2 **Neonatal hepatitis**
Video 51.3 **Steatosis from obesity**
Video 51.4 **Multiple cutaneous hemangiomas in a 1-month-old infant**
Video 51.5 **Multiple cutaneous hemangiomas in a 1-month-old infant**
Video 51.6 **Hepatic abscess**
Video 51.7 **Normal flow in the main portal vein**
Video 51.8 **Normal branching vessels in the liver**
Video 51.9 **Normal third- and fourth-order branches in the liver**
Video 51.10 **Cavernous transformation of the portal vein**
Video 51.11 **Pneumobilia, an expected finding following portoenterostomy**

52 The Pediatric Urinary Tract and Adrenal Glands
Harriet J. Paltiel and Diane S. Babcock

Video 52.1 **Crossed renal ectopia**
Video 52.2 **Contrast-enhanced urosonography depicts a normal bladder**
Video 52.3 **Contrast-enhanced urosonography demonstrates vesicoureteral reflux**
Video 52.4 **Contrast-enhanced urosonography shows a normal male urethra**
Video 52.5 **Inflammatory pseudotumor**
Video 52.6 **Laceration of the mid-lateral aspect of the left kidney and perirenal hematoma**
Video 52.7 **Multicystic dysplastic kidney**
Video 52.8 **Burkitt lymphoma involving kidney**
Video 52.9 **Neuroblastoma**

54 Pediatric Pelvic Sonography
William L. Simpson, Jr., Humaira Chaudhry, and Henrietta Kotlus Rosenberg

Video 54.1 **Water vaginogram**
Video 54.2 **Normal postpubertal ovary**
Video 54.3 **Polycystic ovarian morphology**
Video 54.4 **Normal postpubertal testis**
Video 54.5 **Testicular microlithiasis**

55 The Pediatric Hip and Other Musculoskeletal Ultrasound Applications
Leslie E. Grissom and H. Theodore Harcke

Video 55.1 **Normal coronal/flexion view, midacetabulum**
Video 55.2 **Normal coronal/flexion view, posterior lip**
Video 55.3 **Subluxation, coronal/flexion view, midacetabulum**
Video 55.4 **Dislocatable hip, coronal/flexion view, midacetabulum**
Video 55.5 **Dislocatable hip, coronal/flexion view, posterior lip**
Video 55.6 **Normal transverse/flexion view**
Video 55.7 **Subluxation, transverse/flexion view**
Video 55.8 **Dislocation, transverse/flexion view**

56 Pediatric Interventional Sonography
Neil Johnson and Allison Aguado

Video 56.1 **Peripherally inserted central catheter (PICC) line placement**
Video 56.2 **Video loops showing debris attached to and obstructing the drainage catheter during diagnostic and therapeutic aspiration of heavily bloodstained abdominal fluid with floating debris**
Video 56.3 **Video loops showing debris attached to and obstructing the drainage catheter during diagnostic and therapeutic aspiration of heavily bloodstained abdominal fluid with floating debris**
Video 56.4 **Appendiceal abscess with catheter touching fecalith**
Video 56.5 **Gaucher disease patient rib biopsy**
Video 56.6 **Gaucher rib osteomyelitis drain catheter being advanced**
Video 56.7 **Gaucher rib prebiopsy showing pus and displaceable rib**
Video 56.8 **Juvenile rheumatoid arthritis tendon sheath steroid injection**

Appendix: Ultrasound Artifacts: A Virtual Chapter
Korosh Khalili, Hojun Yu, Alexander Jesurum, and Deborah Levine

Video A.1 **Propagation velocity artifact**
Video A.2 **Attenuation-related artifacts**
Video A.3 **Shadowing**
Video A.4 **Showing in region of cauda equina**
Video A.5 **Increased through transmission**
Video A.6 **Path of sound assumption**
Video A.7 **Mirror image artifact**
Video A.8 **Comet-tail artifact**
Video A.9 **Comet-tail artifact in adenomyomatosis**
Video A.10 **Refraction from the anterior abdominal wall**
Video A.11 **Anisotropy**
Video A.12 **Anisotropy at supraspinatus tendon insertion**
Video A.13 **Reverberation artifact from free intraperitoneal gas**
Video A.14 **Ring-down artifact**
Video A.15 **Ring-down artifact from air in bile ducts**
Video A.16 **Dirty shadowing**
Video A.17 **Side lobe artifact**
Video A.18 **Partial volume averaging explanation**
Video A.19 **Tissue vibration artifact**
Video A.20 **Tissue vibration artifact from left renal artery stenosis with color bruit and aliasing**
Video A.21 **Aliasing seen in common femoral artery to common femoral vein arteriovenous fistula**
Video A.22 **Twinkle explanation**
Video A.23 **Twinkle**

DIAGNOSTIC ULTRASOUND

This page intentionally left blank

CHAPTER 28

Overview of Obstetric Imaging

Deborah Levine

SUMMARY OF KEY POINTS

- Ultrasound allows for accurate prediction of gestational age.
- The appropriate training and skills are necessary for safely performing and accurately interpreting obstetric ultrasound
- There are many options for screening pregnant women, most of which include ultrasound.
- Routine obstetric ultrasound has specific recommended views that allow for depiction of many, but not all, fetal anomalies.
- Three-dimensional ultrasound, fetal Doppler examinations, and fetal magnetic resonance imaging may be used when additional information is needed beyond that available with routine gray-scale ultrasound.

CHAPTER OUTLINE

TRAINING, PERSONNEL, AND EQUIPMENT
ULTRASOUND GUIDELINES

CONCLUSION

There were more than 3.9 million live births in the United States in 2013.[1] Ultrasound is the most frequently used imaging modality for assessment of pregnancy. With care being taken to keep exposure to ultrasound limited to medically needed information, and with imaging performed at the appropriate power settings, ultrasound is safe for use in pregnancy.

Indications for ultrasound during the **first trimester** include pregnancy dating, assessment of women with bleeding or pain, and assessment of nuchal translucency in screening for aneuploidy. In the **second trimester,** ultrasound is used for pregnancy dating, assessment of interval growth, assessment of patients with abnormal pain or bleeding, assessment of size-to-dates discrepancy, routine survey of fetal anatomy, and assessment of maternal complications due to conditions such as age, drug use, or history of previous abnormalities.

In cases of multiple gestations, ultrasound is used to assess growth and complications of twinning. In women with history of cervical incompetence, ultrasound is used to screen for cervical changes that put a patient at risk for preterm delivery. In the **third trimester,** ultrasound is predominantly used to assess fetal growth and well-being. Ultrasound is increasingly used for fetal procedures such as testing for aneuploidy, drainage of abnormal fetal fluid collections, and guidance for fetal surgery. Ultrasound is well recognized as the screening modality of choice, but additional information may be needed beyond that available with ultrasound. In many of these cases, especially those with fetal central nervous system abnormalities, fetal magnetic resonance imaging (MRI) can help clarify the diagnosis.

Part IV of this textbook focuses on obstetric ultrasound and reviews specific fetal organ system anatomy and pathology, with chapters also on safety of ultrasound in pregnancy, assessment of twins, and growth. Fetal magnetic resonance (MR) and three-dimensional (3D) ultrasound images are added throughout to illustrate the benefit of these techniques in select cases.

TRAINING, PERSONNEL, AND EQUIPMENT

Obstetric ultrasound diagnosis is critically dependent on examiner training and experience.[2,3] Physicians and sonographers performing obstetric ultrasound examinations should have completed appropriate training and should be appropriately credentialed and/or boarded. Accreditation of ultrasound laboratories improves compliance with published minimum standards and guidelines.[4] Ultrasound practitioners should be knowledgeable regarding the basic physical principles of ultrasound, equipment, record-keeping requirements, indications, and safety of using ultrasound in pregnancy. Studies should be conducted with real-time scanners

Indications for First-Trimester Ultrasound

- Confirmation of the presence of an intrauterine pregnancy
- Suspected ectopic pregnancy
- Vaginal bleeding
- Pelvic pain
- Estimation of gestational age
- Diagnosis or evaluation of multiple gestations
- Confirmation of cardiac activity
- Adjunct to chorionic villus sampling, embryo transfer, and localization, and removal of an intrauterine device
- Assessment for certain fetal anomalies, such as anencephaly, in high-risk patients
- Measurement of nuchal translucency when part of a screening program for fetal aneuploidy
- Suspected ectopic pregnancy
- Suspected hydatidiform mole
- Maternal pelvic masses and/or uterine abnormalities

Modified from Collaborative Subcommittee. ACR–ACOG–AIUM–SRU practice parameter for the performance of obstetrical ultrasound. American College of Radiology; 2014.[5]

using a transabdominal and/or transvaginal approach, depending on the gestational age and the region of interest. The choice of transducer frequency is a trade-off between beam penetration and resolution. In general, a 3- to 5-MHz transducer frequency provides sufficient resolution with adequate depth penetration in all but the extremely obese patient. During early pregnancy, a 4- to 7-MHz abdominal transducer or a 5- to 10-MHz vaginal transducer can provide superior resolution while still allowing adequate penetration. Higher-frequency transducers are most useful in achieving high-resolution scans of anatomy close to the probe, and lower-frequency transducers are useful when increased penetration of the sound beam is necessary and when a wider field of view is needed. Use of Doppler ultrasound and 3D imaging depends on the specific indication. As in all imaging studies, complete documentation of the images and a formal written interpretation are essential for quality assurance, accreditation, and medicolegal issues.

ULTRASOUND GUIDELINES

First Trimester

The current guidelines of the American College of Radiology (ACR) and American Institute of Ultrasound in Medicine (AIUM) for the performance of first-trimester obstetric ultrasound examination include documentation of the location of the pregnancy (intrauterine vs. extrauterine), documentation of the appearance of the maternal uterus and ovaries (Fig. 28.1), and assessment of **gestational age,** either by measurement of mean sac diameter (before visualization of embryonic pole; Fig. 28.2) or by embryonic/fetal pole crown-rump length[5] (Fig. 28.3). Another important structure to assess is the **yolk sac.** An image of the heart rate is taken using M-mode ultrasound. It is important to use M-mode rather than spectral Doppler ultrasound on the embryo to limit power deposition. Late in the first trimester,

Indications for Second- and Third-Trimester Ultrasound

- Estimation of gestational (menstrual) age
- Evaluation of fetal growth
- Evaluation of fetal anatomy and fetal well-being
- Vaginal bleeding
- Abdominal or pelvic pain
- Cervical insufficiency
- Determination of fetal presentation
- Suspected multiple gestation
- Adjunct to amniocentesis or other procedure
- Evaluation of discrepancy between uterine size (as measured by fundal height) and clinical dates
- Pelvic mass
- Suspected hydatidiform mole
- Adjunct to cervical cerclage placement
- Suspected ectopic pregnancy
- Suspected fetal death
- Suspected uterine abnormality
- Suspected amniotic fluid abnormalities
- Suspected placental abruption
- Adjunct to external cephalic version
- Premature rupture of membranes and/or premature labor
- Previous abnormal screening exams
- Follow-up evaluation of placental location for suspected placenta previa or accreta
- Previous congenital anomaly
- Screening for or follow-up of fetal anomalies

Modified from Collaborative Subcommittee. ACR–ACOG–AIUM–SRU practice parameter for the performance of obstetrical ultrasound. American College of Radiology; 2014.[5]

dating can be performed with measurement of the biparietal diameter and head circumference rather than crown-rump length.

Videos 28.1 and 28.2 show normal first-trimester findings of an early embryo with cardiac activity (Video 28.1) and normal findings of rhombencephalon (Video 28.2).

In the first trimester it is important to not only establish the location of the pregnancy (intrauterine versus extrauteruine) but when intrauterine, to carefully determine if it is a potentially viable pregnancy or if it is a nonviable pregnancy.[6-9] Due to the

General Survey Guidelines for First-Trimester Ultrasound

- Gestational sac
  - Location of pregnancy: intrauterine vs. extrauterine
- Gestational age (as appropriate)
  - Mean sac diameter
  - Embryonic pole length or crown rump length
- Yolk sac
- Cardiac activity on M-mode ultrasound
- Embryo/fetal number (amnionicity/chorionicity)
- Maternal anatomy: uterus and adnexa

Modified from Collaborative Subcommittee. ACR–ACOG–AIUM–SRU practice parameter for the performance of obstetrical ultrasound. American College of Radiology; 2014.[5]

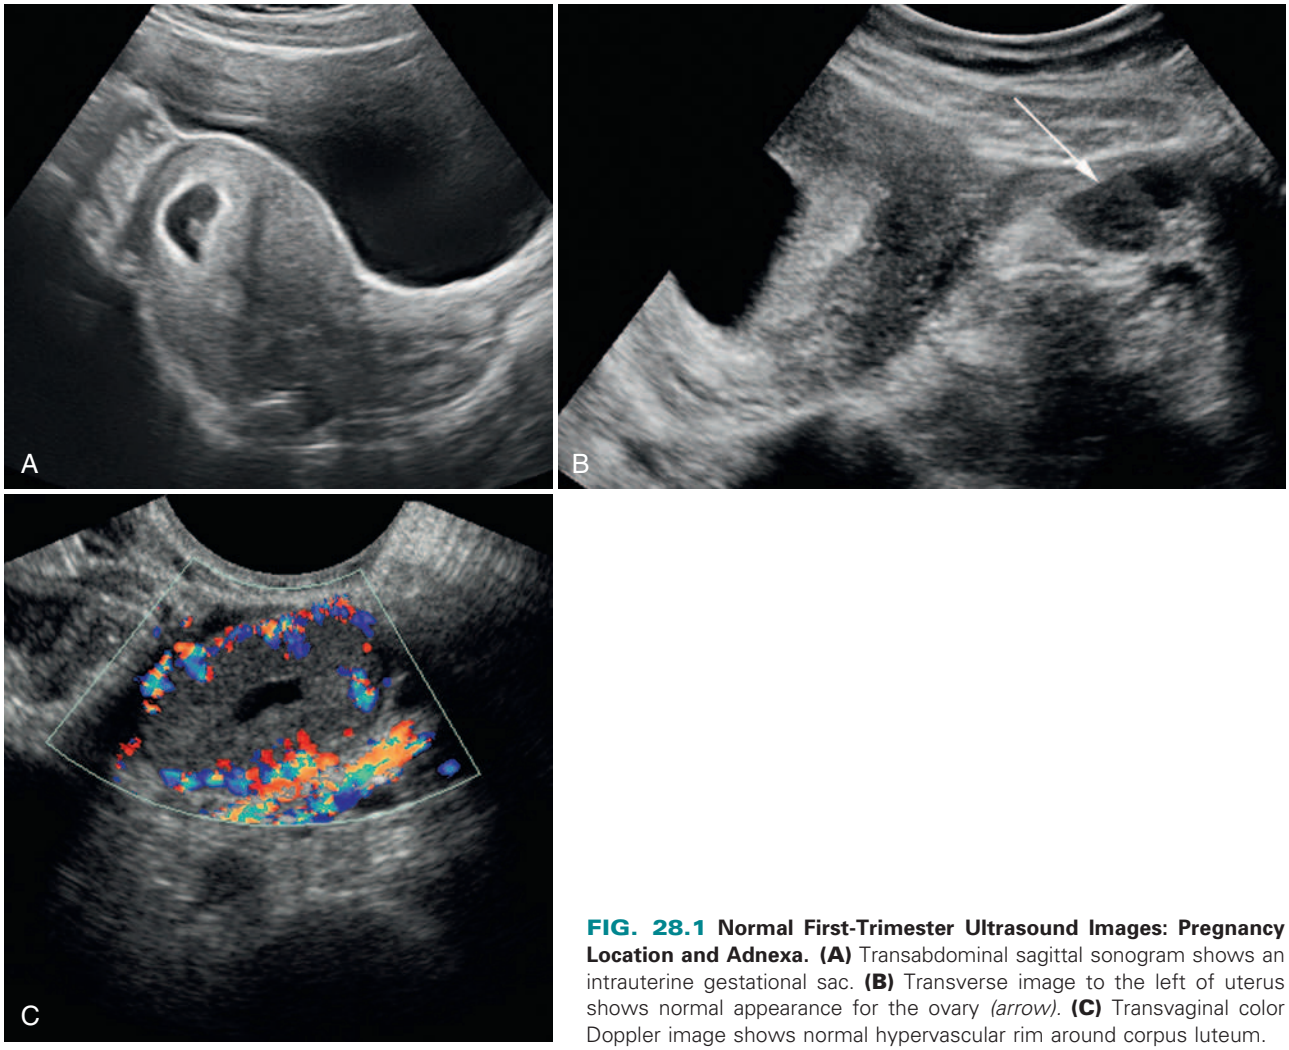

FIG. 28.1 Normal First-Trimester Ultrasound Images: Pregnancy Location and Adnexa. (A) Transabdominal sagittal sonogram shows an intrauterine gestational sac. **(B)** Transverse image to the left of uterus shows normal appearance for the ovary *(arrow)*. **(C)** Transvaginal color Doppler image shows normal hypervascular rim around corpus luteum.

FIG. 28.2 Normal First-Trimester Measurement of Sac Diameter. Transvaginal sagittal image shows sagittal measurement of sac diameter *(calipers)*. Measurements in three orthogonal planes are averaged to calculate the mean sac diameter. Note yolk sac within the gestational sac.

variety of medical professionals performing and interpreting ultrasound in a variety of clinical settings, thresholds for the diagnosis of a failed pregnancy have been increased in order to not misdiagnose a potentially viable pregnancy. These issues are discussed in detail in Chapter 30.

In cases of multiple gestation, first-trimester scans should document the fetal number as well as the amnionicity and chorionicity (Fig. 28.4). Chapter 32 discusses the assessment of multifetal pregnancies.

In addition, the American College of Obstetricians and Gynecologists (ACOG) recommends that prenatal testing for aneuploidy be offered to all pregnant women.[10] Clinicians must understand current screening options (and the tradeoffs between them), including traditional serum analysis (with or without nuchal translucency ultrasonography) or cell-free DNA so that they can discuss these options appropriately with the patient. Cell-free DNA testing uses DNA from the placenta to assess the risk of the fetus having a chromosomal abnormality; it does not assess risk for fetal anomalies such as neural tube defects or ventral wall defects. Management decisions, including termination of the pregnancy, should not be based on the results of the cell-free

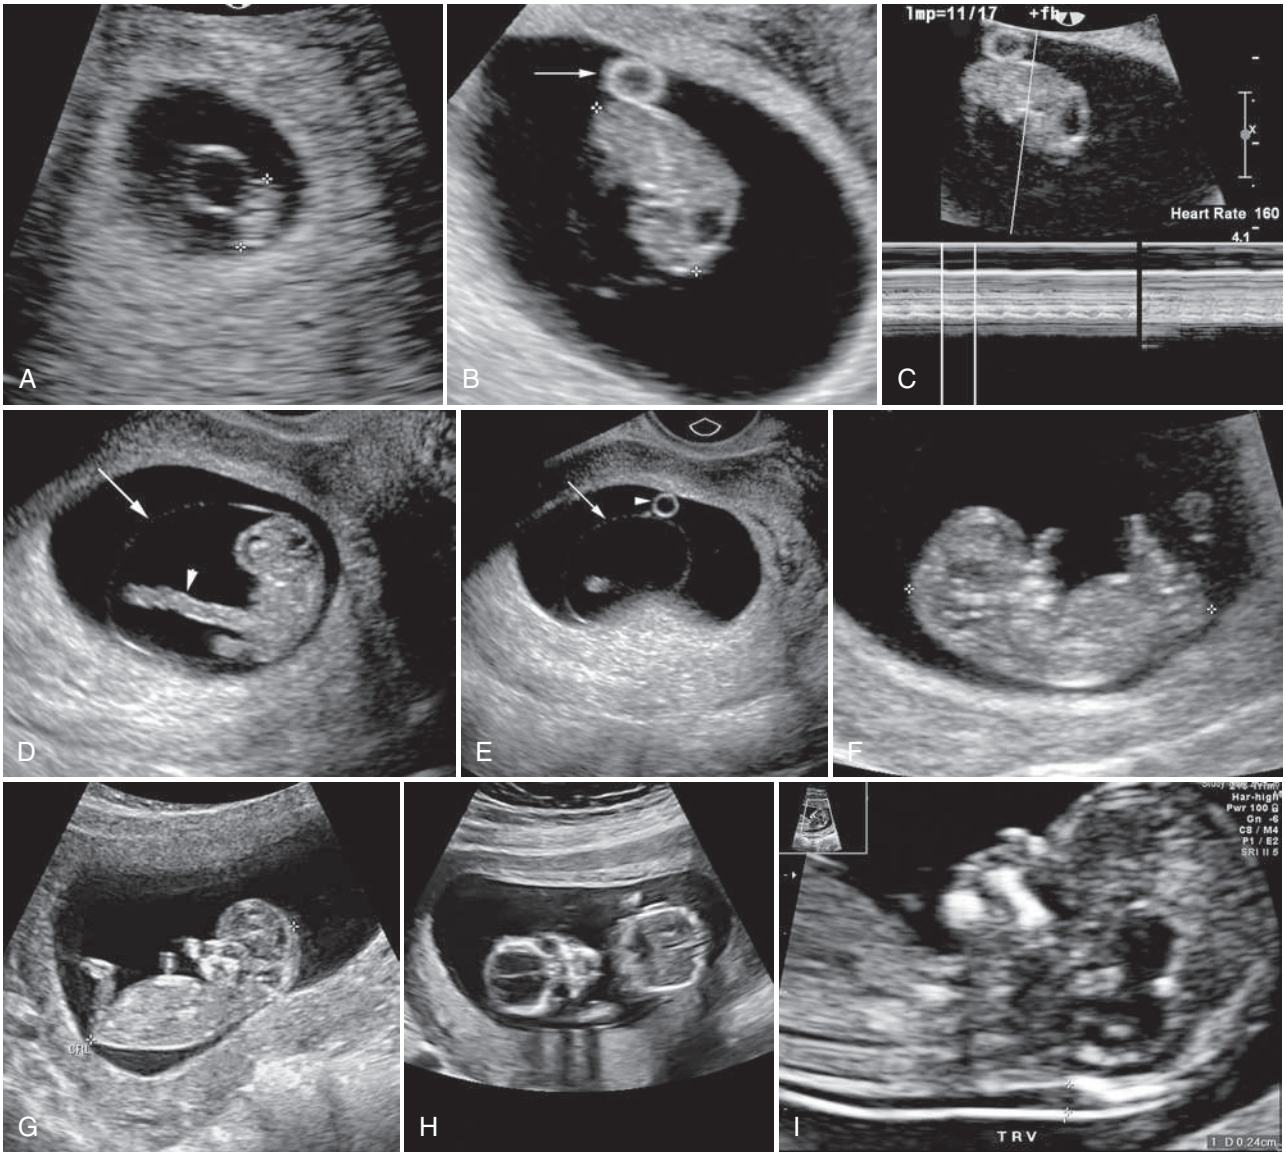

FIG. 28.3 First-Trimester Ultrasound Images: Embryo and Fetus. **(A)** Normal embryo at 6.5 weeks' gestation. Note embryonic pole *(calipers)* adjacent to yolk sac. **(B)** Normal embryo at 8 weeks' gestation. Note embryo *(calipers)* and adjacent yolk sac *(arrow)*. **(C)** M-mode ultrasound from same embryo as in **B.** Note normal heart rate of 160 beats/min. **(D)** Normal embryo at 9 weeks' gestational age. Note embryo within amnion *(arrow)* and umbilical cord *(arrowhead)*. **(E)** Just lateral to image in **D,** note yolk sac *(arrowhead)* is located outside the amnion *(arrow)*. **(F)** Sagittal ultrasound at 10.5 weeks' gestation. **(G)** Sagittal ultrasound at 11.5 weeks' gestation. **(H)** Coronal view of face at 13 weeks' gestation. **(I)** Sagittal ultrasound of nuchal translucency *(calipers)* at 13 weeks' gestation. See also Videos 28.1 and 28.2.

DNA screening alone.[10] Patients should be counseled that a negative cell-free DNA test result does not ensure an unaffected pregnancy. According to a 2015 ACOG committee opinion, "Given the performance of conventional screening methods, the limitations of cell-free DNA screening performance, and the limited data on cost-effectiveness in the low-risk obstetric population, conventional screening methods remain the most appropriate choice for first-line screening for most women in the general obstetric population."[10]

Thus despite increased use of cell-free DNA testing, ultrasound screening is still being performed by measuring **nuchal translucency** between 11 and 14 weeks of gestation (see Fig. 28.3I). This measurement, in conjunction with maternal age and serology, can be used to determine an individualized risk of fetal aneuploidy (see Chapter 31). Increased use of maternal serum screening, as well as first- and second-trimester ultrasound have reduced the number of interventional procedures to detect aneuploidy while increasing the number of prenatal diagnoses of aneuploidy.[11] Given the increased scanning late in the first trimester, it is also increasingly common for a limited anatomic survey to be conducted in the late first trimester. Anomalies that should be detected this early include **anencephaly** (Fig. 28.5) and **omphalocele** (Fig. 28.6). Although substantial information can be obtained at this time, the first-trimester anatomic survey is unlikely to replace the second-trimester anatomic survey, since many structures are difficult

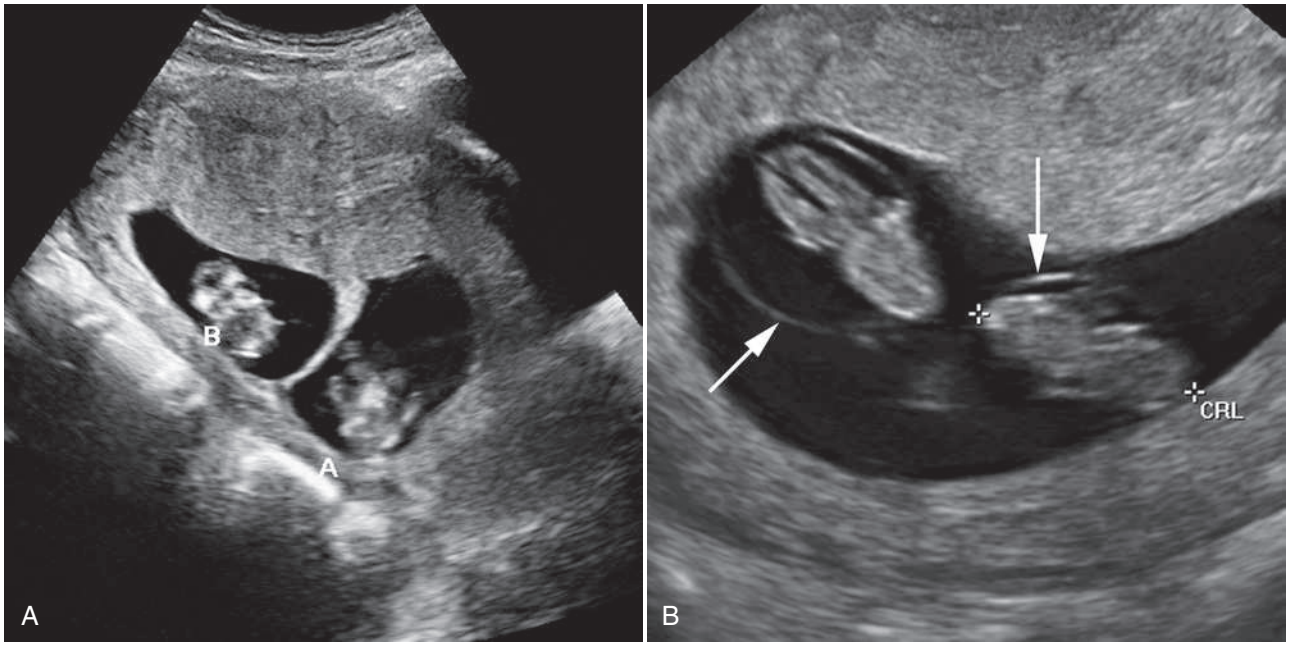

FIG. 28.4 Multiple Gestations. The entire gestational sac should be examined to identify multiple gestations. **(A)** Transabdominal image of **diamniotic dichorionic twins.** Note the thick, dividing membrane that separates twin A *(A)*, the presenting twin, from twin B *(B)*. **(B)** Transvaginal image of **diamniotic monochorionic twins** at 8 weeks' gestational age (*calipers* denote crown rump length *[CRL]*) with two thin membranes (*arrows,* amnion) still close to embryonic poles.

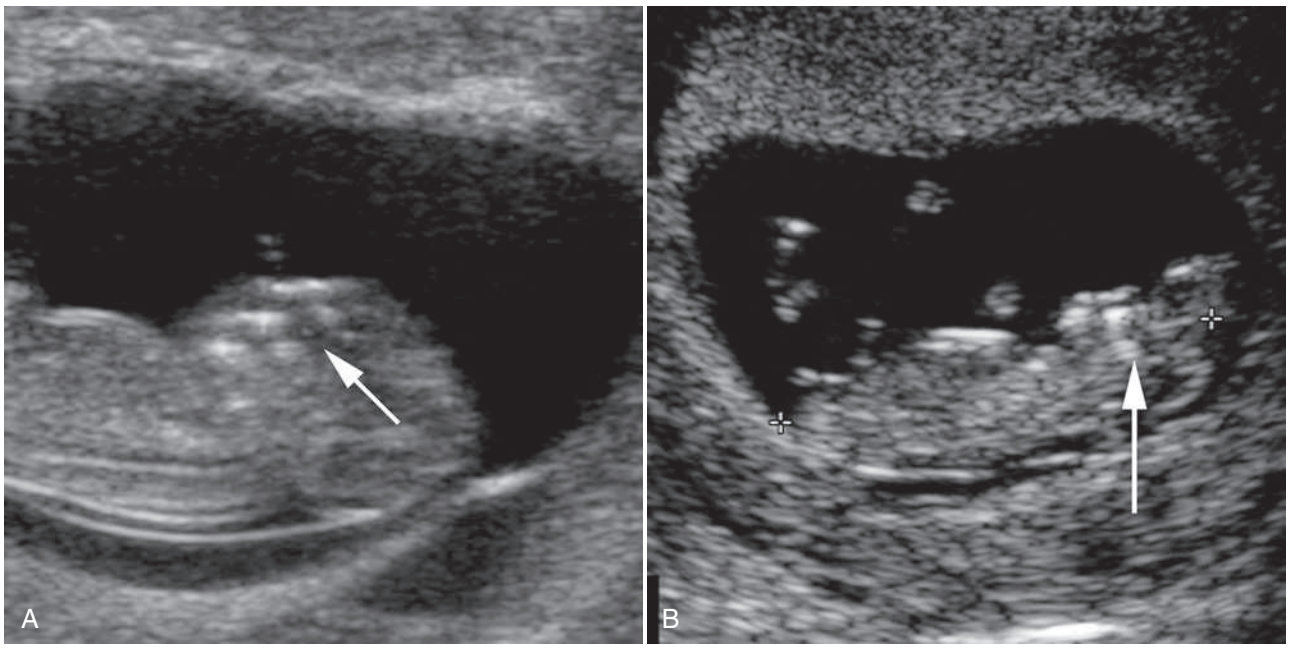

FIG. 28.5 Anencephaly. (A) Sagittal ultrasound at 10 weeks' gestation. **(B)** Sagittal ultrasound in a different fetus at 12 weeks' gestation. Note the orbits *(arrow)* with absent ossified cranium above this level with angiomatous stroma. The *calipers* mark the estimate of the crown rump length, made difficult due to angiomatous stroma above the orbits.

to visualize completely early in the second trimester, particularly the heart, cardiac outflow tracts, posterior fossa, and distal spine.

Second and Third Trimesters

The current ACR/AIUM guidelines for the performance of the second- and third-trimester obstetric ultrasound examinations describe the **standard sonographic examination.**[5] It is important to understand that the guidelines were written to maximize detection of many fetal abnormalities but are not expected to allow for detection of all structural abnormalities.

The terminology **level I** and **level II** examinations refer to "standard" or "routine" (level I) and "high risk," "specialized," or "detailed" (level II) obstetric ultrasound. The concept of these

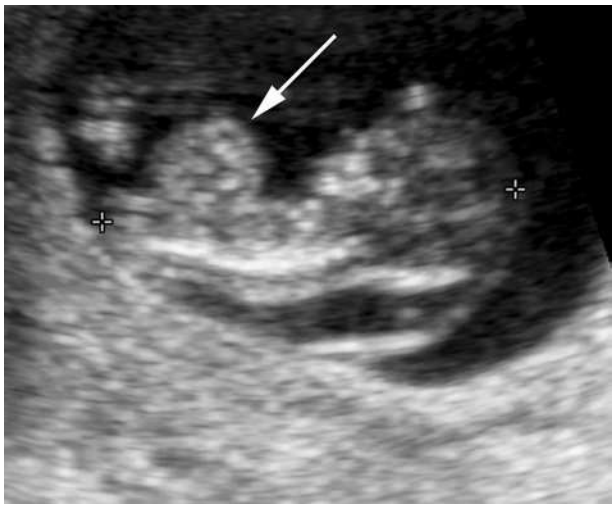

FIG. 28.6 Omphalocele at 11 Weeks' Gestational Age. Sagittal view of fetus *(calipers)* shows a large, abdominal wall defect *(arrow).*

two levels of scanning is that the standard, basic, routine, or level I examination is performed routinely on pregnant patients (Figs. 28.7 to 28.15, Videos 28.3) to 28.9. The methods to obtain all the required images are described in detail in subsequent chapters. This chapter provides a collage of figures as a guide for the anatomic survey and common additional views obtained during a fetal survey.

In general, the "standard fetal anatomic survey" refers to the **second-trimester scan,** typically performed between 16 and 22 weeks of gestation. When anatomic surveys are performed at 20 to 22 weeks' gestational age, there is less need for repeat scans to document normal anatomy compared to studies performed earlier in pregnancy.[12] However, there are practical considerations when determining the optimal timing of studies. In well-dated pregnancies in women who are unlikely to want amniocentesis, a survey at 20 to 22 weeks' gestation is optimal. However, if a pregnancy is not well-dated, an earlier scan may be needed both to establish accurate dates for the pregnancy and to assess the anatomy. Some centers offer the scan at 16 weeks' gestation to coincide with performance of genetic amniocentesis and/or midtrimester quadruple serum screening.

The level I examination consists of investigation of the maternal uterus and ovaries, the cervix, and placenta (Fig. 28.7, Video 28.3), as well as a systematic review of fetal anatomy. **Adnexal cysts** are common in pregnant women. In early pregnancy a cyst is most likely the corpus luteum. If a cyst appears atypical or enlarges beyond the middle second trimester, it should be further assessed. Leiomyoma position and size should be documented. If the myometrium appears thin in the lower uterine segment (e.g., <3 mm in a woman with prior cesarean section), the myometrium should be measured with transvaginal sonography and should be followed later in pregnancy because the thin myometrium puts the woman at risk for **uterine dehiscence** and/or **rupture.** It is helpful to begin the examination with a sagittal midline view to assess the cervix. If the cervix appears abnormally short or if placenta previa is suspected, a vaginal scan can then be performed.

Survey Guidelines for Second- and Third-Trimester Ultrasound

GENERAL SURVEY
Cardiac activity: document with M-mode
Presentation: cephalic, breech, transverse, variable
Fetal number: for multiples, amnionicity/chorionicity, concordance with size, amniotic fluid
Maternal anatomy: uterus, adnexa, and cervix
Gestational age and fetal weight assessment
- Biparietal diameter
- Head circumference
- Abdominal circumference
- Femur length

Amniotic fluid
- Estimate as normal
- If abnormal, quantify if high or low

Placenta: position

FETAL ANATOMIC SURVEY

Head, Face, and Neck
Cerebellum
Choroid plexus
Cisterna magna
Lateral cerebral ventricles
Midline falx
Cavum septi pellucidi
Upper lip

Chest
Four-chamber view
Outflow tracts

Abdomen
Stomach (presence, size, and situs)
Kidneys, bladder
Umbilical cord insertion site into fetal abdomen
Umbilical cord vessel number

Spine

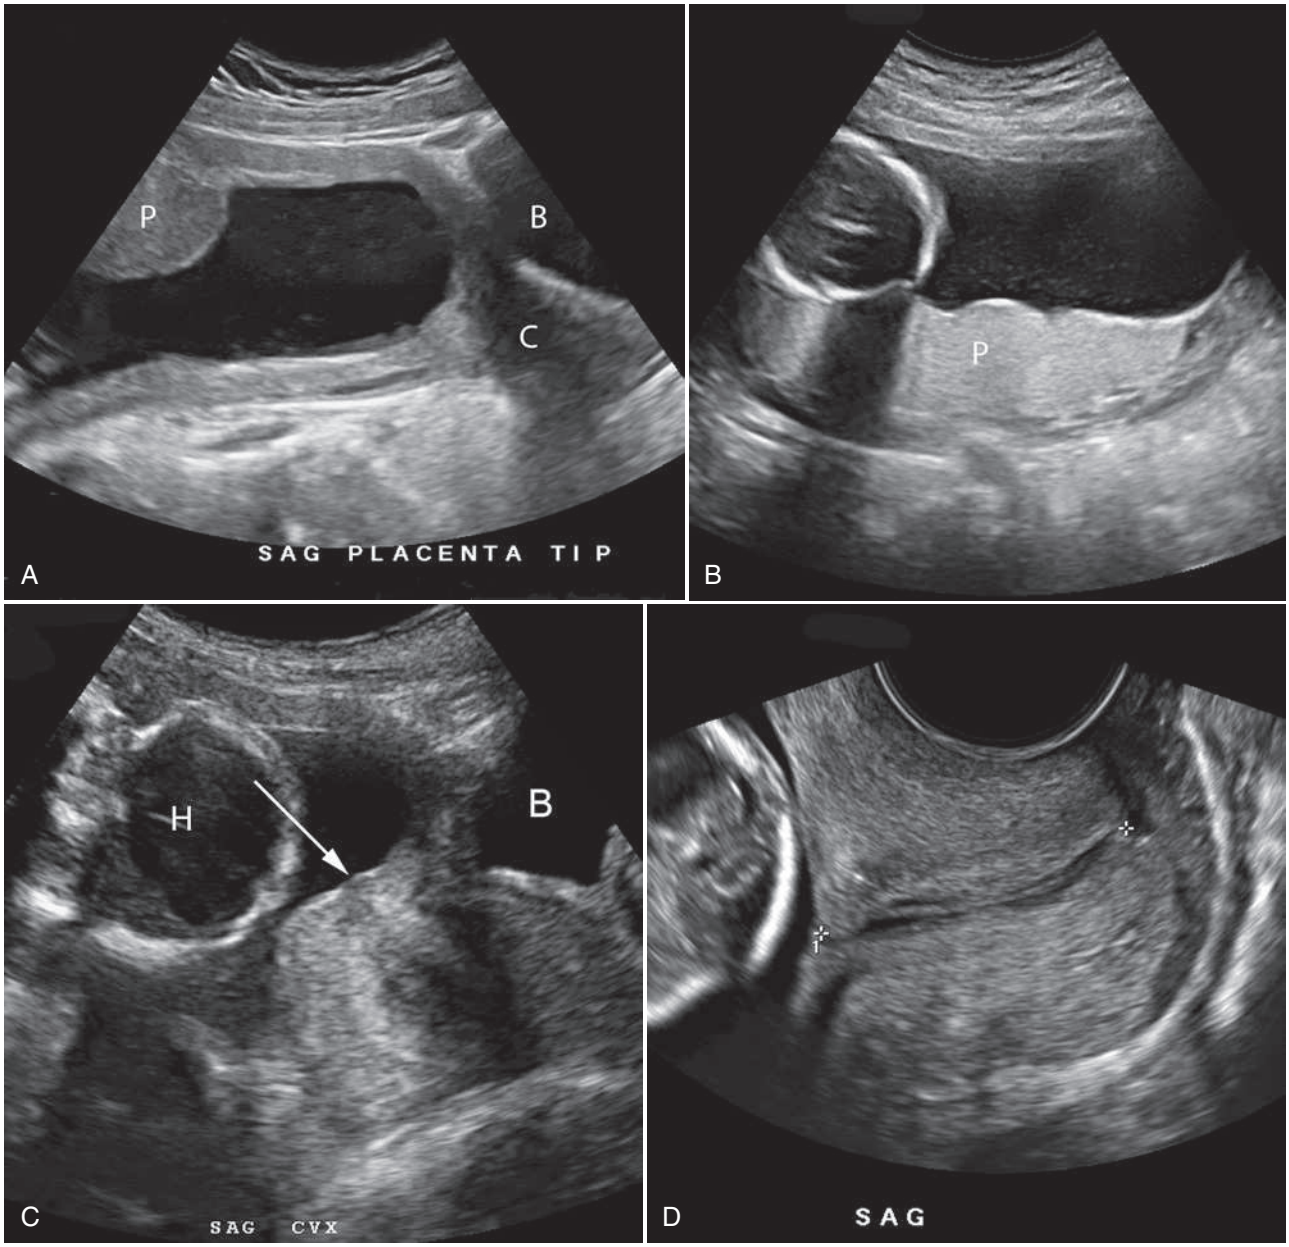

FIG. 28.7 Overview of Uterus, Cervix, and Fetal Position. (A) Sagittal sonogram of uterus shows a normal-appearing cervix *(C)* and an anterior placenta *(P),* with the placental tip far away from the internal cervical os. *B,* Bladder. **(B)** Transverse sonogram of posterior placenta *(P).* **(C)** Transabdominal image of normal-appearing cervix (*arrow* on internal os). Note bladder *(B)* and fetal head *(H).* With the head as the presenting part, the fetus is in cephalic position. **(D)** Transvaginal sonogram of normal-appearing cervix *(calipers).* See also Video 28.3.

Transverse and longitudinal scans of the entire uterine cavity are then performed for assessment of **fetal cardiac activity,** amniotic fluid volume, localization of the placenta, and determination of **fetal presentation** and **situs** (Fig. 28.8). Knowledge of the plane of section across the maternal abdomen, combined with the position of the fetal spine and right-sided and left-sided structures within the fetal body, allows accurate determination of fetal position and identification of normal and pathologic anatomy. Some congenital anomalies, such as dextrocardia, will be recognized only if a structure is identified as "abnormal" by virtue of its atypical position related to the position of the fetus.

Biometry is performed to estimate gestational age and fetal weight (Fig. 28.9). Assessment of gestational age in the second and third trimesters is discussed in more detail in Chapter 42. Additional views in routine obstetric sonography include the head and face (Fig. 28.10, Video 28.4), heart (Fig. 28.11, Videos 28.5 and 28.6), abdomen and pelvis (Fig. 28.12, Video 28.7), spine (Fig. 28.13, Video 28.8), extremities (Fig. 28.14), and umbilical cord (Fig. 28.15, Video 28.9).

Other specialized sonographic examinations include fetal Doppler sonography, biophysical profile, fetal echocardiography, and additional biometric measurements.

The high-risk, targeted, detailed, or level II scan should have a specific indication that requires a detailed fetal sonogram, performed by a clinician with expertise in obstetric imaging.[13,14] This high-risk scan is performed when an anomaly is suspected

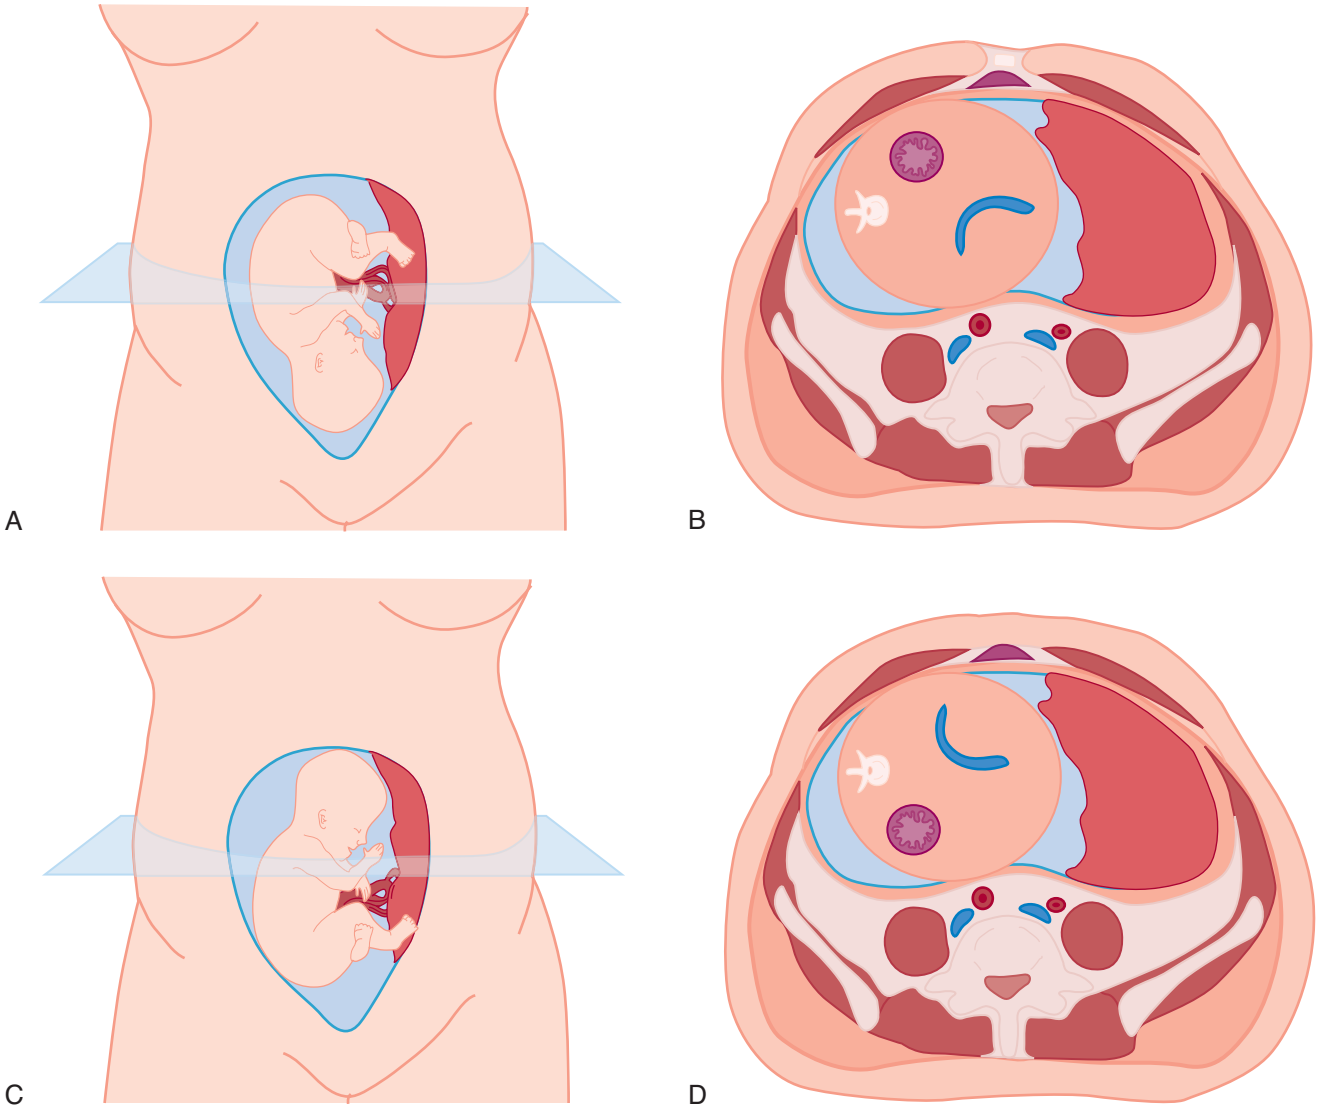

FIG. 28.8 Determination of Situs. (A) Scan plane and **(B)** transverse scan diagram. With fetus in cephalic position and spine on the maternal right side, the left-sided stomach is "up" on the side closest to the transducer. **(C)** Scan plane and **(D)** with the fetus in breech position and spine on the maternal right side, the left-sided stomach is "down" on the side farthest away from the transducer.

because of maternal medical or family history, or if abnormal results are suspected on a routine scan. These high-risk scans include detailed views of fetal anatomy beyond those obtained in the routine exam. Wax et al.[14] provide a more complete description of these anomalies.

ROUTINE ULTRASOUND SCREENING

Estimation of Gestational Age

Determination of the **expected date of delivery** (EDD) is especially important in obstetric practice because it is used to intervene in pregnancies considered to be "growth restricted" and in postterm pregnancies. Multiple studies have demonstrated that routine use of ultrasound results in more accurate assessment of the EDD than does last menstrual period (LMP) dating or physical examination, even in women with regular and certain menstrual dates.[15-18] **Pregnancy dating** is most accurately performed in the first half of pregnancy. **Fetal growth** should be assessed by comparison to earlier scans in pregnancy whenever possible. In a Cochrane review of nine trials of routine ultrasound in early pregnancy, routine use of early ultrasound and the subsequent adjustment of the EDD led to a significant reduction in the number of postterm pregnancies.[19]

A rule of thumb is that in the first trimester, LMP dating should be maintained unless ultrasound yields an EDD more than 7 days off; in the second trimester, ultrasound should be used to change EDD if it is off by more than 2 weeks (and follow-up is then needed to ensure appropriate interval growth); and in the third trimester, a 3-week discrepancy between LMP and ultrasound dating is allowed but needs to be taken into the clinical context, with assessment for growth restriction or

Text continued on p. 1029.

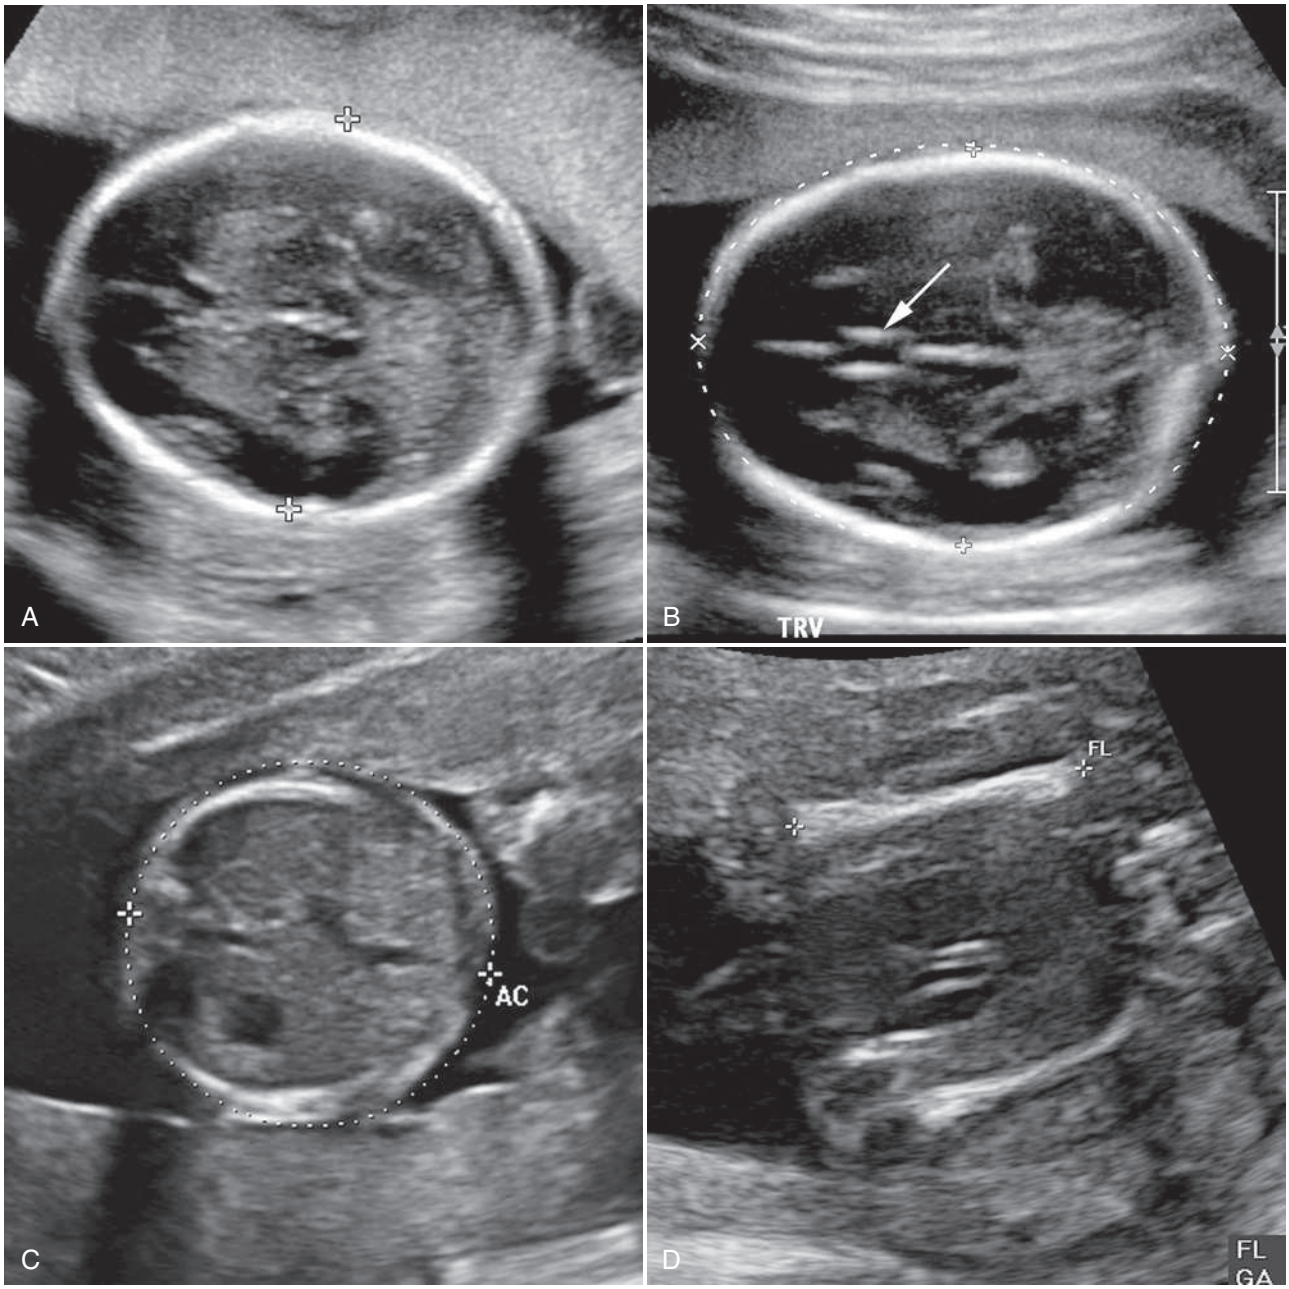

FIG. 28.9 Second-Trimester Biometry. (A) Biparietal diameter. Note the level of this ultrasound image at the thalamus and third ventricle. The calipers are placed from the outer skull in the near field to the inner skull in the far field. **(B) Head circumference.** Note how circumference is measured around the outside of the skull. Arrow depicts cavum of the septum pellucidum. **(C) Abdominal circumference** *(AC).* Note the curve of the portal vein and stomach on this transverse image, with circumference drawn around the outside of the skin. **(D) Femur length** *(FL).* Note that the "upside" femur should be measured, with the shaft of the bone as near to perpendicular to the scan plane as possible, excluding the distal femoral epiphysis.

Indications for Detailed Fetal Anatomic Survey

- Previous fetus or child with a congenital, genetic, or chromosomal abnormality
- Known or suspected fetal anomaly or known growth disorder in the current pregnancy
- Fetus at increased risk for a congenital anomaly, such as maternal diabetes, pregnancy conceived via assisted reproductive technology, high maternal body mass index (≥35 kg/m^2), multiple gestation, abnormal screening results, teratogen exposure
- Fetus at increased risk for a genetic or chromosomal abnormality, such as parental carrier of a chromosomal or genetic abnormality, maternal age 35 years or older at delivery, abnormal screening results
- Other conditions affecting the fetus, including congenital infections, maternal drug dependence, isoimmunization, abnormalities of amniotic fluid

Modified from Wax J, Minkoff H, Johnson A, et al. Consensus report on the detailed fetal anatomic ultrasound examination: indications, components, and qualifications. J Ultrasound Med. 2014;33(2):189-195.[14]

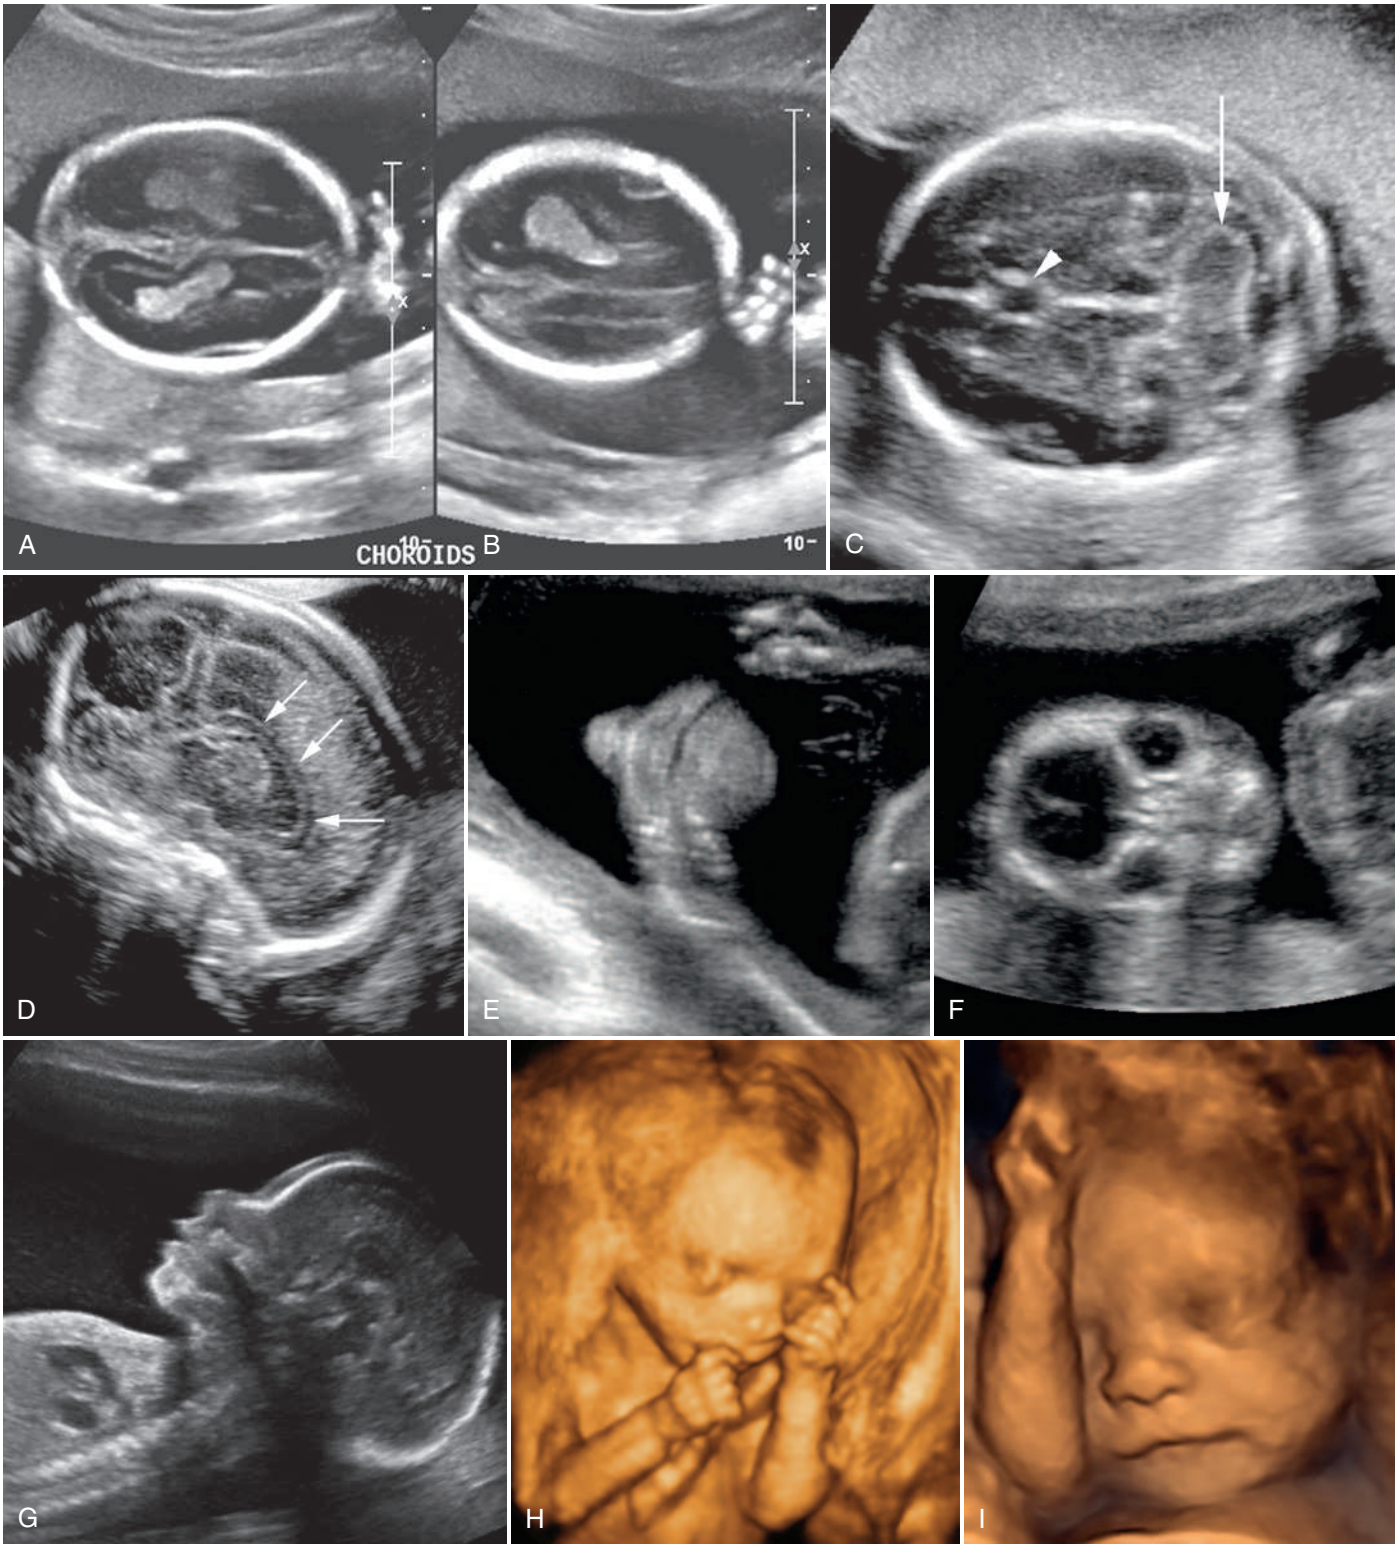

FIG. 28.10 Sonographic Views of Fetal Head and Face. In addition to the biparietal diameter and head circumference, required views of the head include images of the **cerebral ventricles, cerebellum, cavum of the septum pellucidum, midline falx, and nose and lips.** Additional views that can be obtained are angled views to demonstrate both sides of the choroid plexus and views through the anterior fontanelle or midline sutures to demonstrate the corpus callosum as well as views of the orbits and profile. **(A)** Axial and **(B)** oblique axial images show cerebral ventricles filled with **choroid plexus. (C)** Axial image shows cerebellum *(arrow)* and cavum of the septum pellucidum *(arrowhead).* **(D)** Transvaginal sagittal view of the corpus callosum *(arrows).* Required view of the face is of the nose and lips. Additional views include orbits and profile. **(E)** Coronal view of nose and lips. **(F)** Coronal view of orbits. **(G)** Sagittal view of facial profile. **(H)** and **(I)** Three-dimensional images of fetal face. See also Video 28.4. (**A** and **B** courtesy of Dr. A. Toi.)

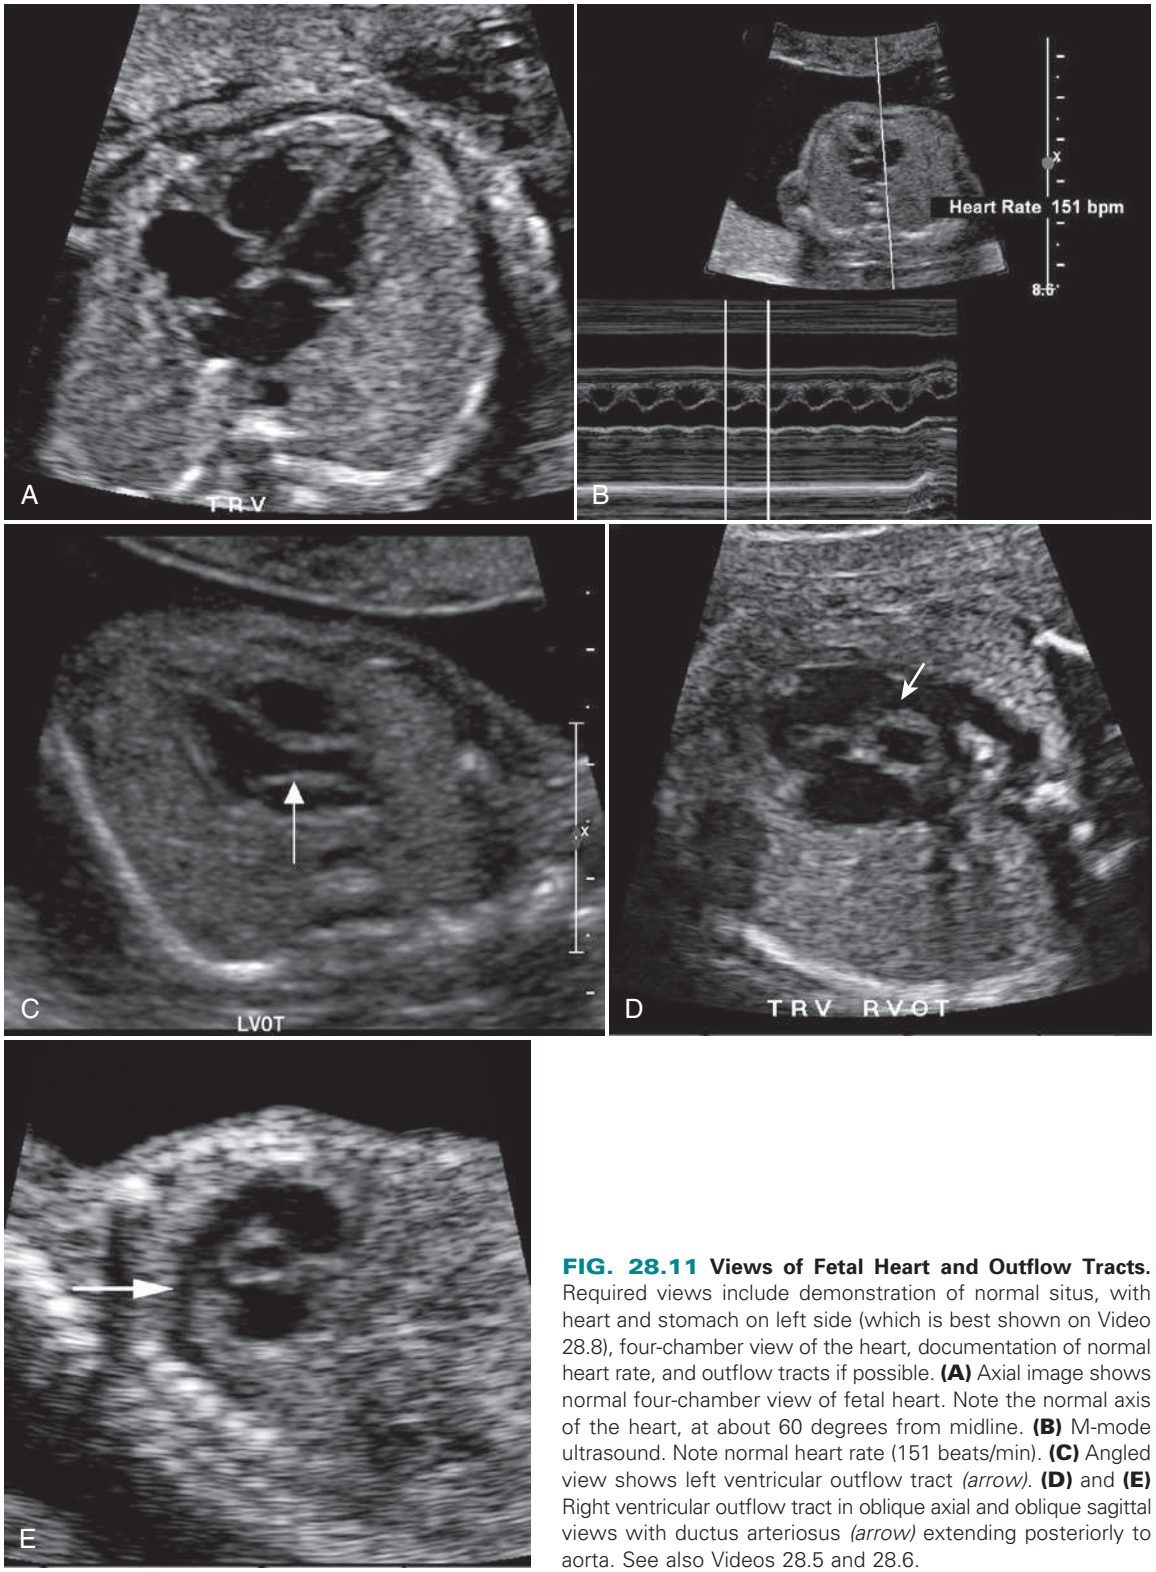

FIG. 28.11 Views of Fetal Heart and Outflow Tracts. Required views include demonstration of normal situs, with heart and stomach on left side (which is best shown on Video 28.8), four-chamber view of the heart, documentation of normal heart rate, and outflow tracts if possible. **(A)** Axial image shows normal four-chamber view of fetal heart. Note the normal axis of the heart, at about 60 degrees from midline. **(B)** M-mode ultrasound. Note normal heart rate (151 beats/min). **(C)** Angled view shows left ventricular outflow tract *(arrow)*. **(D)** and **(E)** Right ventricular outflow tract in oblique axial and oblique sagittal views with ductus arteriosus *(arrow)* extending posteriorly to aorta. See also Videos 28.5 and 28.6.

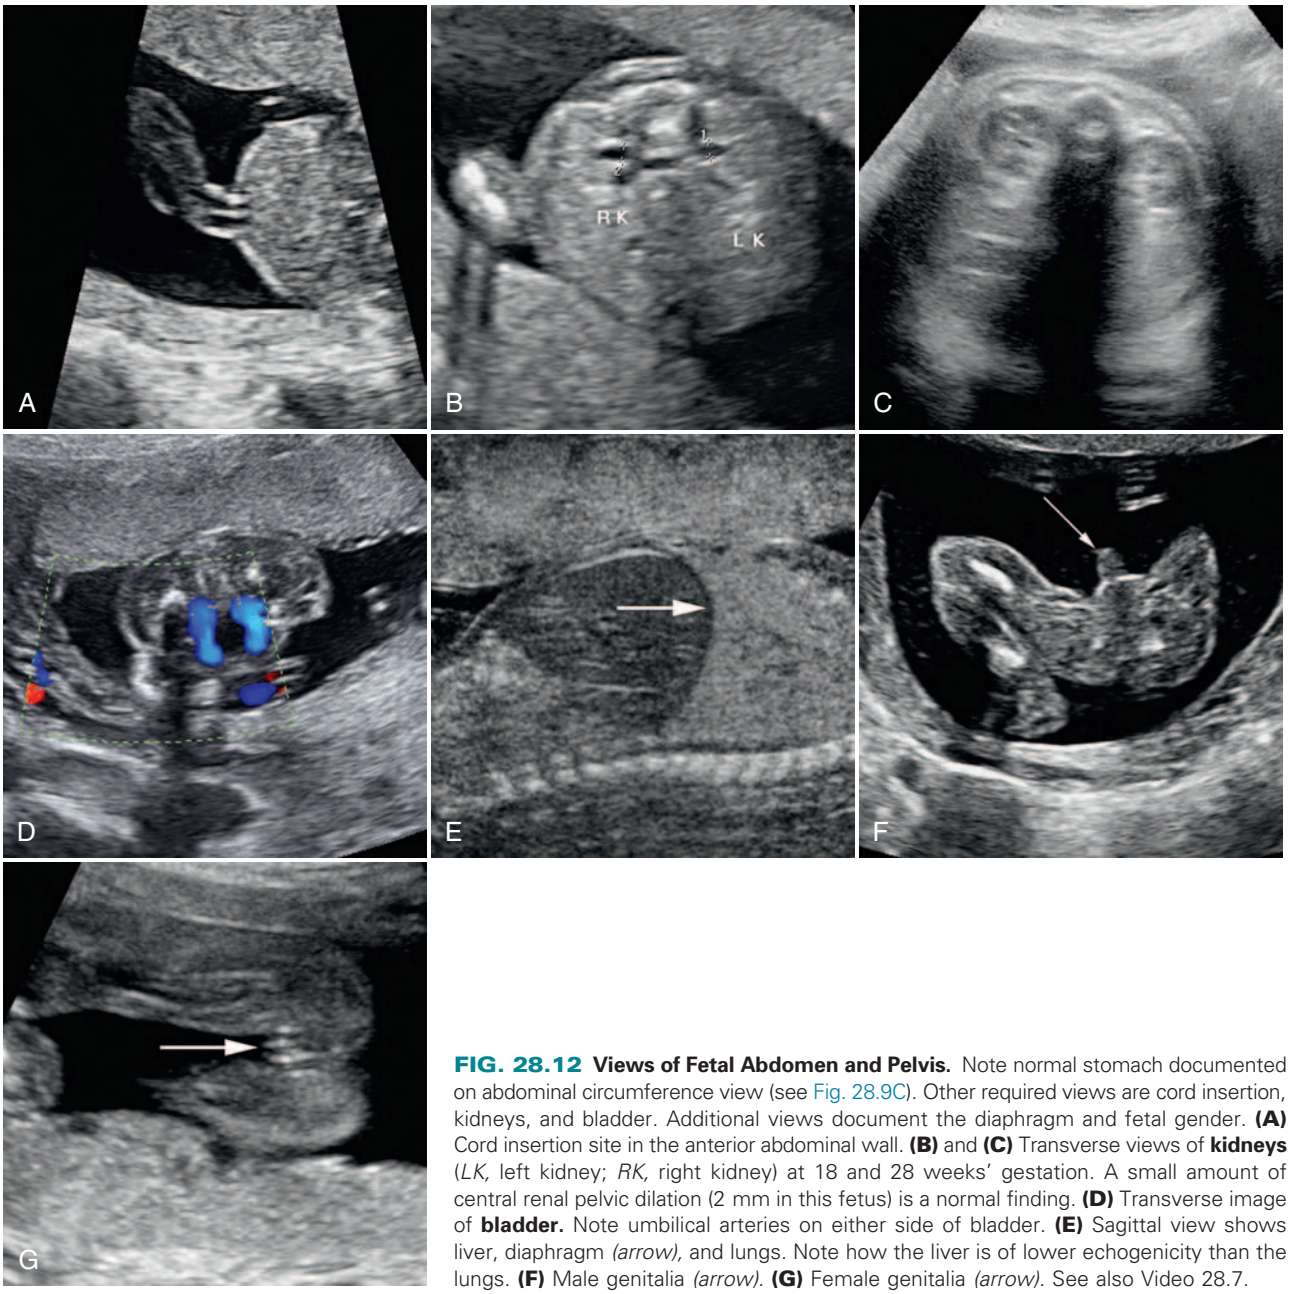

FIG. 28.12 Views of Fetal Abdomen and Pelvis. Note normal stomach documented on abdominal circumference view (see Fig. 28.9C). Other required views are cord insertion, kidneys, and bladder. Additional views document the diaphragm and fetal gender. **(A)** Cord insertion site in the anterior abdominal wall. **(B)** and **(C)** Transverse views of **kidneys** (*LK,* left kidney; *RK,* right kidney) at 18 and 28 weeks' gestation. A small amount of central renal pelvic dilation (2 mm in this fetus) is a normal finding. **(D)** Transverse image of **bladder.** Note umbilical arteries on either side of bladder. **(E)** Sagittal view shows liver, diaphragm *(arrow),* and lungs. Note how the liver is of lower echogenicity than the lungs. **(F)** Male genitalia *(arrow).* **(G)** Female genitalia *(arrow).* See also Video 28.7.

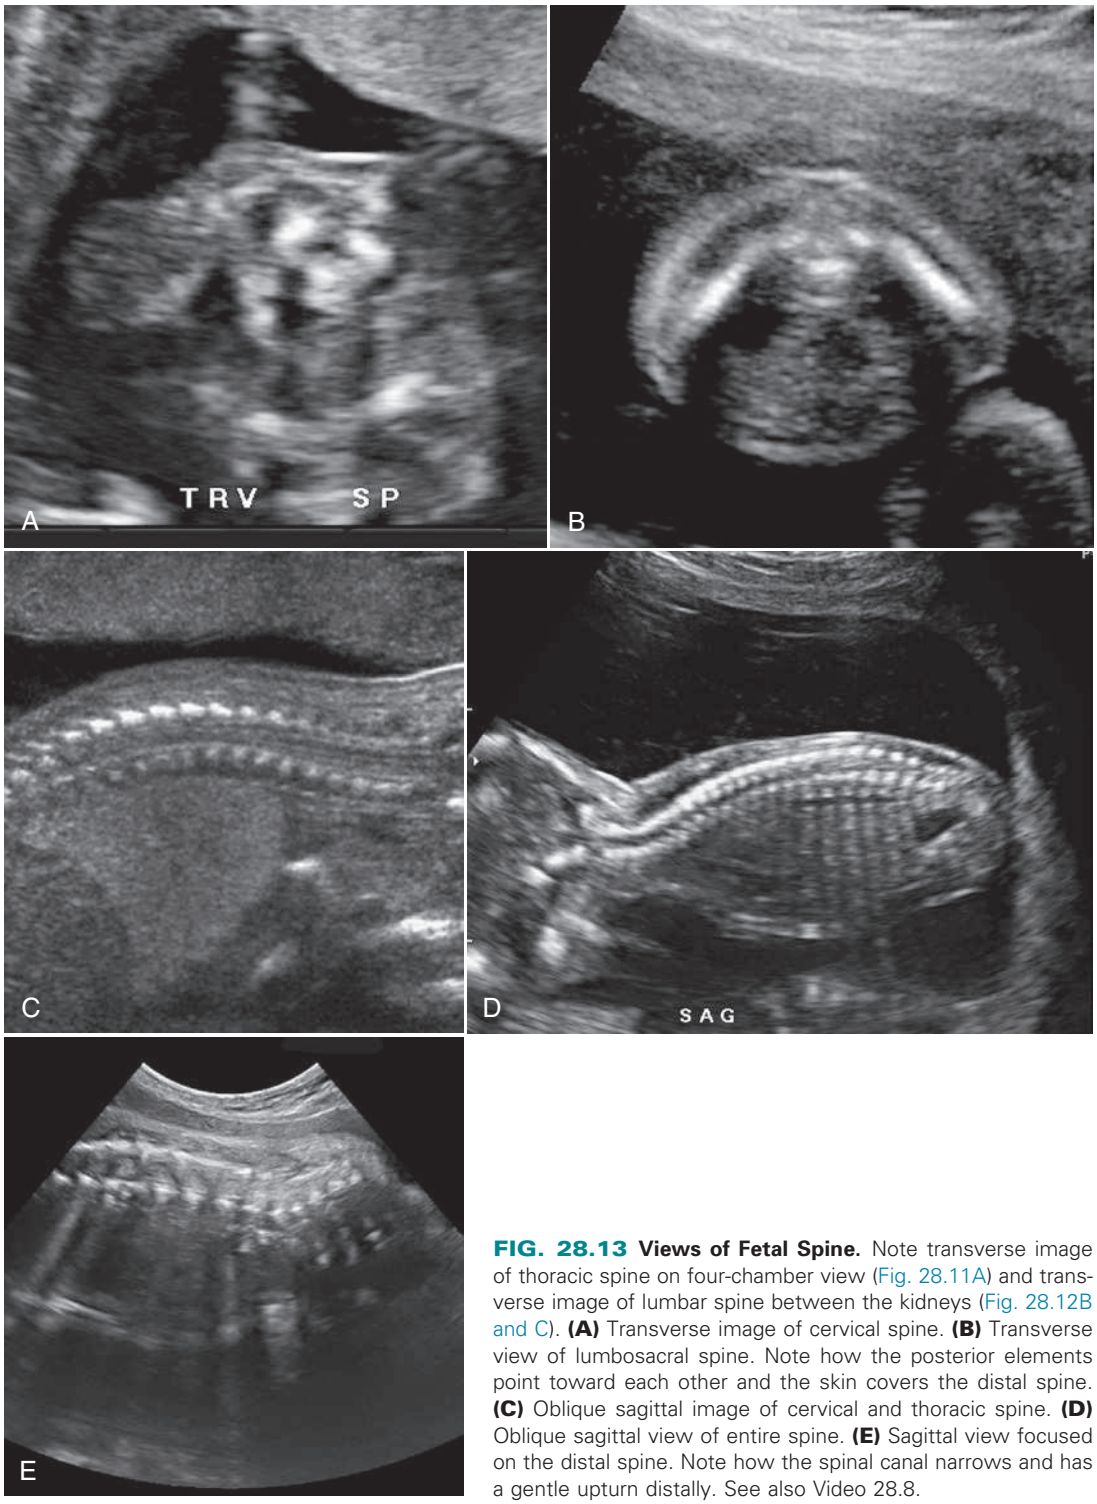

FIG. 28.13 Views of Fetal Spine. Note transverse image of thoracic spine on four-chamber view (Fig. 28.11A) and transverse image of lumbar spine between the kidneys (Fig. 28.12B and C). **(A)** Transverse image of cervical spine. **(B)** Transverse view of lumbosacral spine. Note how the posterior elements point toward each other and the skin covers the distal spine. **(C)** Oblique sagittal image of cervical and thoracic spine. **(D)** Oblique sagittal view of entire spine. **(E)** Sagittal view focused on the distal spine. Note how the spinal canal narrows and has a gentle upturn distally. See also Video 28.8.

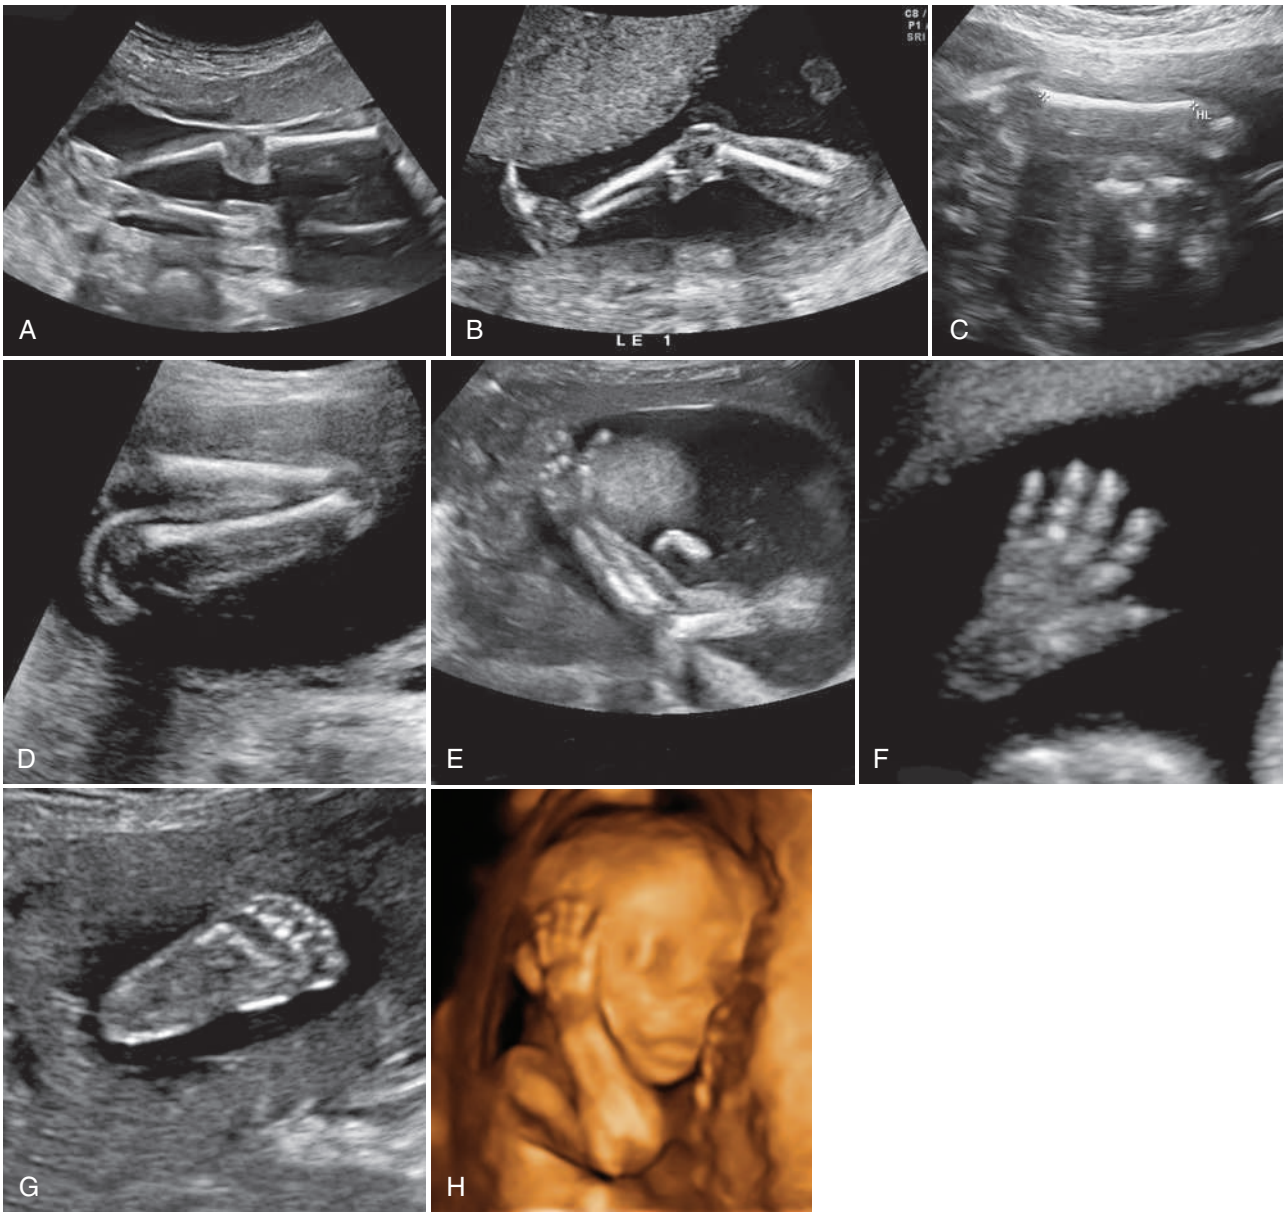

FIG. 28.14 View of Fetal Extremities. Required views include documentation of all four extremities. Additional views include measurements of all the long bones and demonstration of the fingers and toes. **(A)** and **(B)** Lower extremities. **(C)**-**(E)** Upper extremities. **(F)** Hand. Note four fingers with thumb partially out of the field of view. **(G)** Foot. **(H)** Three-dimensional view of upper extremity. (See also Fig. 28.10H for 3D view of hands.)

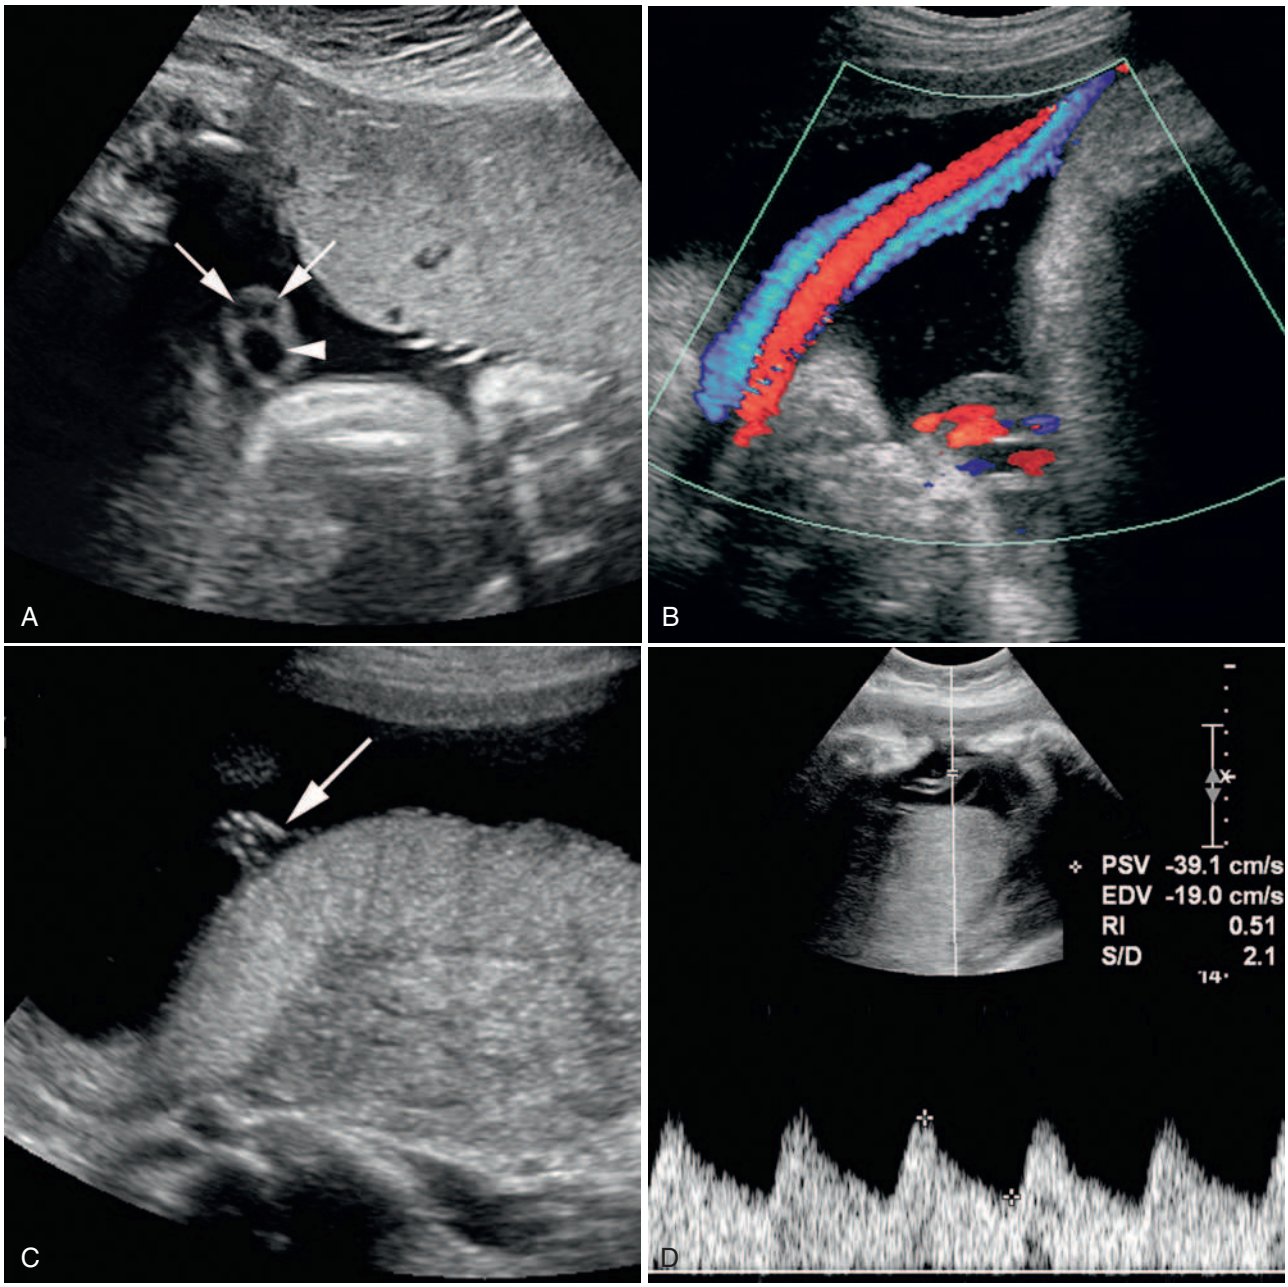

FIG. 28.15 Views of Umbilical Cord. Required views include cord insertion site into the anterior abdominal wall (see Fig. 28.12A) and documentation of number of vessels in the umbilical cord. Additional views include cord insertion site into the placenta and Doppler examination of the cord. **(A)** Transverse image of **three-vessel umbilical cord.** Note two arteries *(arrows)* that are smaller than the single vein *(arrowhead)*. See also Video 28.9 and Fig. 28.12D. **(B)** Color Doppler longitudinal image of three-vessel cord. **(C) Cord insertion site** *(arrow)* into the placenta. **(D)** Spectral Doppler image documents normal umbilical arterial systolic-to-diastolic ratio in third-trimester fetus.

macrosomia if appropriate. It is important to recognize that if a pregnancy is redated after the first trimester, follow-up is needed to assess for appropriate interval growth (see Chapter 42).

Identification of Twin/Multiple Pregnancies

A major benefit of routine ultrasound screening is early identification of multiple gestations.[3,16,20-22] Randomized clinical trials comparing routine second-trimester ultrasound examination with sonography performed for clinical indications have shown that a substantial number of twin pregnancies are not recognized until the third trimester or delivery in women who do not undergo routine ultrasound. The improved diagnosis of twins leads to improved perinatal outcome because of a reduced incidence of low birth weight, smallness for gestational age, prematurity, low Apgar scores, and stillbirths.[20]

Screening and Perinatal Outcomes

The value of a routine second-trimester scan in apparently normal pregnancies to identify those at high risk for unsuspected problems is controversial. Many countries perform one, two, or even three sonograms as part of routine obstetric care.[21,23,24]

Benefits of Routine Second-Trimester Ultrasound Screening

- More accurate gestational age
- Detection of major malformations before birth
- Earlier detection of multiple pregnancy
- Fewer low-birth-weight singleton births
- Lower incidence of induction for postterm pregnancy
- Early detection of placenta previa
- Reassurance of a normal pregnancy

It can be difficult to interpret the results of studies designed to assess the impact of routine screening.[3,16,21] Not only do anomalies need to be detected by ultrasound, but to show the benefit of ultrasound there must be a documented difference in outcome, either in termination of pregnancies (potentially leading to decreased perinatal mortality from loss of anomalous fetuses) or in improved perinatal care. Because these studies do not necessarily control for these outcomes, the benefits of screening—in particular the importance of parental understanding of fetal anomalies when pregnancies with fetal anomalies are continued—are difficult to demonstrate.

The Helsinki Ultrasound Trial reported a significant decrease in perinatal mortality among the ultrasound-screened group, from 9 to 4.6 per 1000.[21] This was attributed to the relatively high rate of detection of fetal anomalies in that study (58% of major malformations were detected before 24 weeks) with subsequent termination of fetuses with anomalies.

In the Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) trial, the investigators did not find a significant difference in "adverse perinatal outcome" (defined as fetal death, neonatal death, or neonatal morbidity) in the screened versus control groups. The explanation for the lack of improved outcome was the limited sensitivity of routine sonography in the detection of congenital abnormalities (16.6% before 24 weeks and 34.8% before 40 weeks) coupled with a low rate of pregnancy termination once the diagnosis had been made.[3] A subsequent meta-analysis based on four randomized clinical trials with data on 15,935 women (7992 were allocated to routine sonography vs. 7943 to selective scanning) found the perinatal mortality rate was significantly lower in patients allocated to routine scanning, again because of the early detection of fetal abnormalities that led to induced abortions.[25] The authors concluded that routine ultrasound scanning is effective and useful as a screening test for malformations.

Fetal Malformations: Diagnostic Accuracy

The incidence of major congenital abnormalities at birth in the general population is 2% to 3%, yet these abnormalities are responsible for 20% to 25% of perinatal deaths and an even higher percentage of perinatal morbidity. Prenatal detection of an anomaly increases the options for pregnancy management, and in select cases the disorder may be amenable to intrauterine treatment. For these reasons, offering routine ultrasound as a screening test for congenital abnormalities is an attractive concept. However, the performance of screening ultrasound in detecting abnormalities in the low-risk population is variable, with sensitivity and specificity ranging from 14% to 85% and 93% to 99%, respectively.[3,24,26-32] The wide range in sensitivity can be partially explained by what authors used as the definition of an "anomaly" and the experience of the individuals performing and interpreting the studies.[24,31] Another factor is the type of anomaly. In the Eurofetus study,[33] the best detected abnormalities were of the urinary system (88.5%) and central nervous system (88.3%). Cardiac abnormalities were not well detected, whether major (38.8%) or minor (20.8%), and the lowest rates of detection were for minor abnormalities of the musculoskeletal system (18% vs. 73.6% for major defects) and cleft lip and palate (18%).[33] Another important issue is the gestational age when the study is performed. In the Eurofetus Study, for example, 38.5% of the anomalies were diagnosed after 29 weeks' gestation. Other factors influencing sensitivity of prenatal sonography include the quality of equipment, prevalence of a particular defect, maternal body habitus, and examination protocol.[24,33,34]

Many of the benefits of ultrasound are nonquantifiable. Having time to adjust prenatally to information about an anomaly can improve both the clinician's and the parents' approach to the pregnancy and birth, as well as their abilities to make decisions about prenatal and postnatal treatment.[35] It is important for patients and their physicians to understand the limitations of ultrasound. Not all abnormalities can be detected. The accuracy of prenatal ultrasound is variable and often depends on where and by whom it is being performed.

Three-Dimensional Ultrasound

In addition to two-dimensional (2D) images, 3D imaging allows for reconstructed images in planes that were not previously available. This allows for improved visualization of facial anomalies[36] and anomalies of the hands, feet, and spine.[37] In addition, 3D images may be more comprehensible to the patient, promoting better understanding of the abnormality.[36,37] 4-dimensional imaging is just viewing the 3D images over time and rarely adds additional diagnostic value. Cervical assessment is also thought to be more complete with volume imaging.[38] **Volume imaging** can be used to assess the lungs,[39,40] which is used in fetuses with suspected pulmonary hypoplasia. Reconstructed images can be helpful to image portions of the brain.[41] Subsequent chapters integrate 3D images as appropriate.

Prudent Use of Ultrasound

The AIUM, ACR, and ACOG collaborative guidelines on performance of obstetric ultrasound state, "This diagnostic procedure should be performed only when there is a valid medical indication, and the lowest possible ultrasonic exposure setting should be used to gain the necessary diagnostic information under the 'as low as reasonably achievable' (ALARA) principle."[5] Although there is no reliable evidence of physical harm to human fetuses from diagnostic ultrasound imaging using current technology, public health experts, clinicians, and industry representatives agree that casual use of sonography, especially during pregnancy, should be avoided. The U.S. Food and Drug Administration (FDA) views the promotion, sale, or lease of ultrasound equipment for making "keepsake" fetal videos as an unapproved use of a

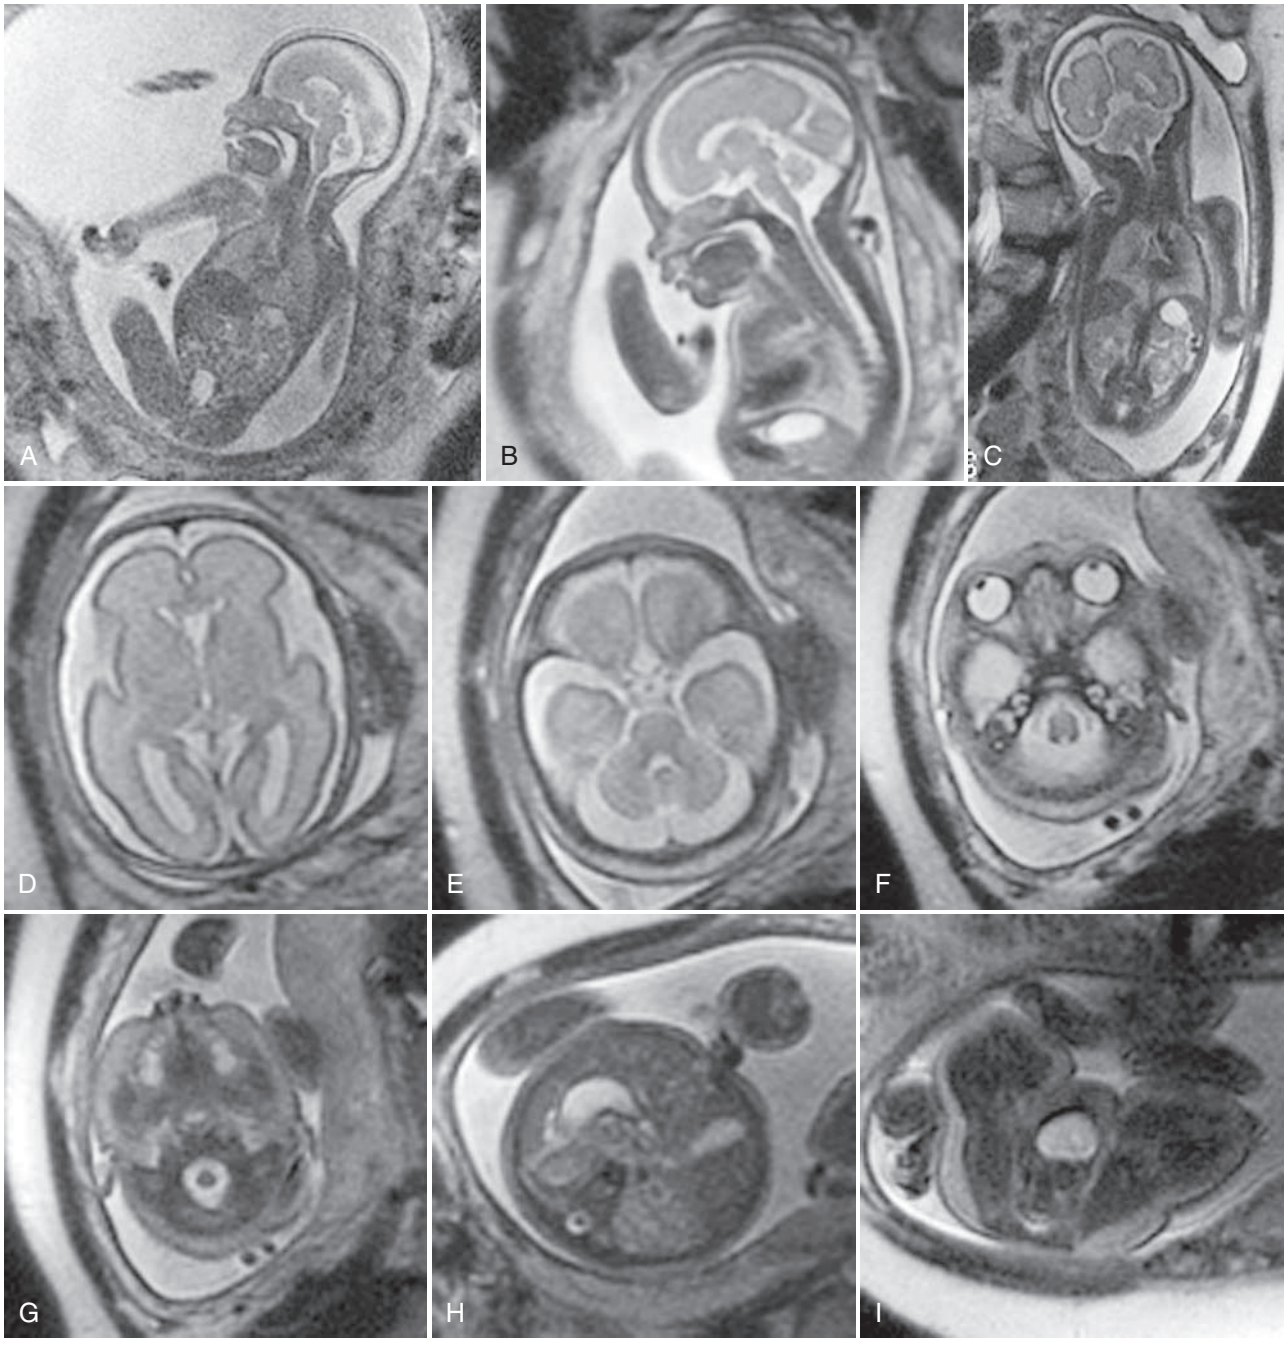

FIG. 28.16 Normal Fetal MRI: Representative T2-Weighted Images. (A) Sagittal view of fetal head with fetal body in coronal plane. **(B)** Sagittal view of fetal head. Note normal appearance of corpus callosum and soft palate, with fluid outlining the soft palate above the tongue. **(C)** Coronal view of the brain, chest, and abdomen. Note normal appearance to the lungs, diaphragm, stomach, and kidneys. **(D)** Axial view of brain with normal-appearing lateral ventricles. **(E)** Oblique axial view of brain shows normal cerebellar hemispheres and vermis. **(F)** Axial view at level of globes. Note the dark lens in each globe. **(G)** Axial view at level of palate. Note that majority of the alveolar tooth-bearing ridge is well depicted. **(H)** Axial view at level of stomach and gallbladder. Note spinal cord outlined by fluid in thecal sac. **(I)** Axial view at level of bladder.

medical device.[42] Medically indicated obstetric imaging can easily integrate making copies of key images for parents who want an early view of their baby.

MAGNETIC RESONANCE IMAGING

Ultrasound is the screening modality of choice for fetal imaging. However, when additional information regarding fetal anatomy or pathology is needed, fast MRI is increasingly being used as a correlative imaging modality in select cases (Fig. 28.16). MRI is useful in these cases because it has no ionizing radiation, provides excellent soft tissue contrast, has multiple planes for reconstruction, and has a large field of view, allowing for improved depiction of many complex fetal abnormalities.

It is important to tailor the examination to answer specific questions raised either by patient history or by previous

sonographic examination. In the past decade, software and hardware have allowed for fetal MR images to be obtained in about 400 milliseconds. This allows for fetal imaging to be performed without maternal or fetal sedation. The ease of performing these examinations and the superb contrast resolution afforded by T2-weighted MRI have popularized the use of this imaging tool to improve prenatal diagnosis.

There are no known biologic risks from MRI. The MR procedure is not believed to be hazardous to the fetus.[43-55] No delayed sequelae from MR examination have been encountered, and it is expected that the potential risk for any delayed sequelae is extremely small or nonexistent.

However, most studies on fetal risk have been performed at 1.5 Tesla. Heating has been shown in animal studies at 3.0 Tesla.[56] Therefore when possible fetal studies should be done at 1.5T.

Gadolinium is the contrast typically used for MRI, but it is not recommended for fetal examination. Gadolinium crosses the placenta and appears within the fetal bladder soon after intravenous administration. The contrast is excreted from the fetal bladder into the amniotic fluid, where it is then swallowed and potentially reabsorbed from the gastrointestinal tract. Because of this reabsorption, the half-life of gadolinium in the fetal circulation is not known.[57] This drug has been shown to have adverse effects on the fetus in animal models. **Gadopentetate dimeglumine** has been shown to impair development slightly in rats (at 2.5 times the human dose, 0.1 mmol/kg), and in rabbits (at 7.5 times the human dose).[58,59] It is considered a **pregnancy category C** drug, meaning that it should be given only if potential benefit outweighs the risk; animal studies have revealed adverse effects, but no controlled studies have been performed in humans.[58] Therefore we do not use contrast for fetal examinations at our institution.

CONCLUSION

Ultrasound is a readily available, noninvasive, and safe means of evaluating fetal well-being, determining gestational age, and assessing the intrauterine environment. It is an indispensable tool for the practice of obstetrics. Ultrasound is also a screening test, yielding results that must be interpreted and integrated in a knowledgeable manner. As with physical examination, the ultrasound study is most helpful when performed in a consistent and reproducible fashion, carefully documenting positive and negative findings important in clinical decision making. The information gained from routine obstetric ultrasound may provide reassurance, guide therapy, or identify a pathologic condition that merits further investigation.

CHAPTER 29

Bioeffects and Safety of Ultrasound in Obstetrics

Jacques S. Abramowicz

SUMMARY OF KEY POINTS

- Obstetric ultrasound should only be performed with a clear indication, with calibrated machines, and by proficient professionals.
- Know the specific machine being used (what causes increase in output power).
- Keep the examination as short as possible and use the lowest possible output power but compatible with arriving at the correct diagnosis (as low as reasonably achievable [ALARA] principle).
- Keep track of the onscreen thermal index (TI) and mechanical index (MI).
- Keep the TI under 1.
- Keep the MI under 1.
- Start the scan at low power output and increase power only if necessary.
- It is preferable to use gain compensation over increasing output power.
- Be very cautious when using Doppler in the first trimester or in the immediate vicinity of bone.

SAFETY GUIDELINES
CONCLUSION

More than half a century of extensive use in clinical obstetric and radiologic practice has shown that diagnostic ultrasound does not cause major abnormalities in the fetus. Ultrasound, however, is a form of energy and clinicians must consider whether subtle effects are possible when such energy penetrates living tissues. Although some effects have been described in animals, no immediate human correlation can be made. Conversely, "no effects detected so far" does not necessarily means "no effect." Only large, epidemiologic studies can solve this problem. In the United States, most women who receive prenatal care are referred for at least one ultrasound scan; in many other countries, almost 100% of these women are exposed to ultrasound. In reproductive endocrinology, numerous scans are performed on the ovaries (and the follicles) and the very early developing embryo or fetus.[1] Furthermore, multiple examinations are often performed during pregnancy, with or without clear indication. Because of this near-universal exposure of pregnant women and their unborn children to ultrasound, given its tremendous diagnostic value,[2] the issues of possible effects and safety need to be addressed. The issue of whether short-term or long-term adverse bioeffects to the fetus may result from exposure to ultrasound has been raised since the beginning of the clinical use of this modality.[3,4]

It is well established that under certain conditions, ultrasound can have undesirable side effects. This and the issue of safety have been discussed extensively in the literature.[3,5-24] Two conflicting points need clarification: (1) to date, no evidence has been found of harmful effects of ultrasound in humans at clinical exposure levels, but (2) all available published epidemiologic data are from before 1992. Since then, acoustic output of diagnostic systems for fetal use was increased by a factor of almost 8, from 94 mW/cm^2 to 720 mW/cm^2, and, in reality, a factor of 16 (from 46 mW/cm^2) based on earlier regulations.[25] Additional concerns follow:

- An increasing number of fetuses in the first trimester, a time of maximal susceptibility to external insults, are exposed to ultrasound, particularly spectral Doppler.[26]
- "Entertainment" ultrasound, scanning to obtain pictures or videos of the fetus (fetal "keepsake" videos) without a medical indication has burgeoned[27] despite calls for avoidance of unnecessary exposure.[10,28,29]
- Clinical users of obstetric ultrasound appear to have limited knowledge and awareness of bioeffects and safety.[30]

Thus the main goals of this chapter are as follows:

1. Summarize the literature on bioeffects in experimental settings as well as the available knowledge on bioeffects in the human fetus.
2. Analyze changes that occurred over time in energy levels of ultrasound machines and the regulations involved.
3. Describe how manipulation of many instrument controls alters acoustic energy and thus exposure.
4. Educate sonographers and physicians on how best to minimize fetal exposure without sacrificing diagnostic quality.

INSTRUMENT OUTPUTS

Over the years, output of ultrasound instruments has increased.[31,32] Furthermore, many machine controls can alter the output, and various machines can behave differently when manipulating similar controls. For example, keeping in mind that the degree of temperature elevation is proportional to the product of the amplitude of the sound wave times the pulse length and the pulse repetition frequency, it becomes immediately evident why any change (augmentation) in these characteristics can add to the risk of elevating the temperature, a potential mechanism for bioeffects. Three important parameters under end-user control are the (1) scanning/operating mode (including transducer choice), (2) system setup and output control, and (3) dwell time.

Scanning Mode

When comparing modes, the spatial peak temporal average intensity (ISPTA) increases from B-mode (average, 34 mW/cm^2) to M-mode to color Doppler to spectral Doppler (average, 1180 mW/cm^2).[33] Average ISPTA values are 1 W/cm^2 in Doppler mode but can reach 10 W/cm^2. Caution is therefore recommended when applying this mode. Color Doppler has higher intensities than B-mode but is still much lower than spectral Doppler, mainly because of the mode of operation: sequences of pulses, scanned through the area of interest ("box"). High pulse repetition frequencies are used in pulsed Doppler techniques, generating greater temporal average intensities and power than B-mode or M-mode and thus greater heating potential. Also, because the beam needs to be held in relatively constant position over the vessel of interest in spectral Doppler ultrasound, temporal average intensity may further increase. This is particularly concerning in first-trimester applications. In addition, **transducer choice** is important because it will determine frequency, penetration, resolution, and field of view.

System Setup

Starting or **default output power** is another important ultrasound parameter. Some manufacturers "boot" their machines with high power, which supposedly produces a better image, and the sonographer must act to decrease that power. Other systems boot up with low power and, only if judged necessary, the sonographer will increase that power. In, For example, the Doppler signal in Fig. 29.1A was obtained with a high power, as reflected by an elevated TI of 2.9, whereas in Fig. 29.1B the power was greatly reduced (TI = 0.6), and the image is still diagnostic. Also, the examiner fine-tunes to optimize the image, influencing output but with no visible effect, except to change **thermal index** (TI) and **mechanical index** (MI), as discussed in Chapter 2.

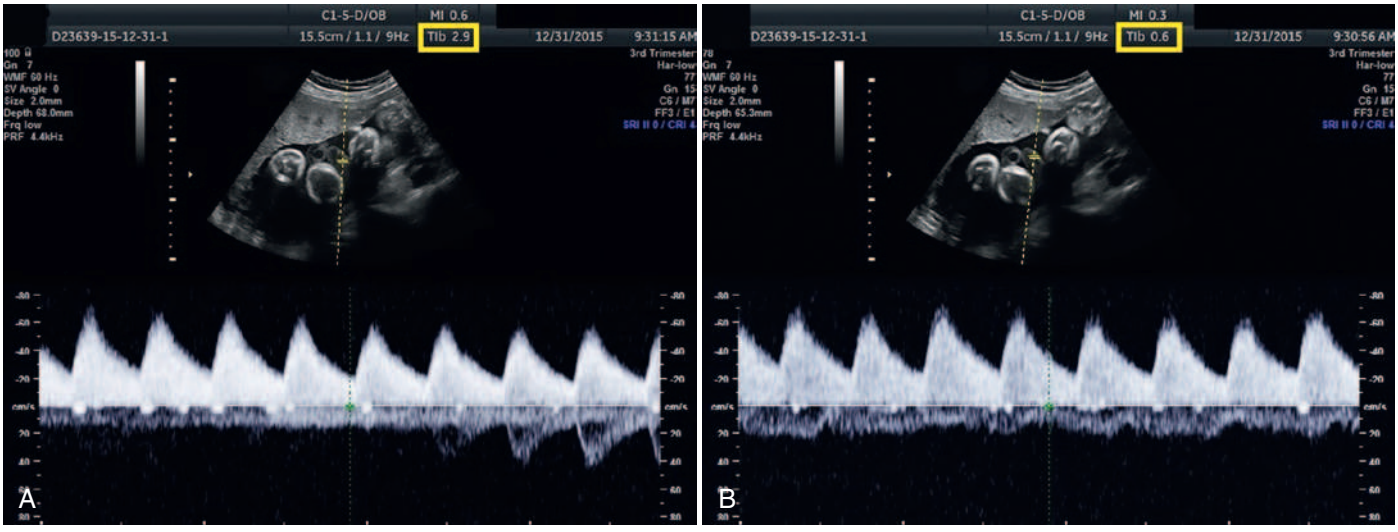

FIG. 29.1 Effect of Changing Power Setting on Thermal Index of Bone (TIB) During Spectral Doppler Velocity Measurements of Umbilical Artery. (A) The output power is high, and the thermal index (TI) is 2.9 *(yellow box)*. **(B)** The power has been lowered; the TI is now 0.6, and the tracing is still diagnostic.

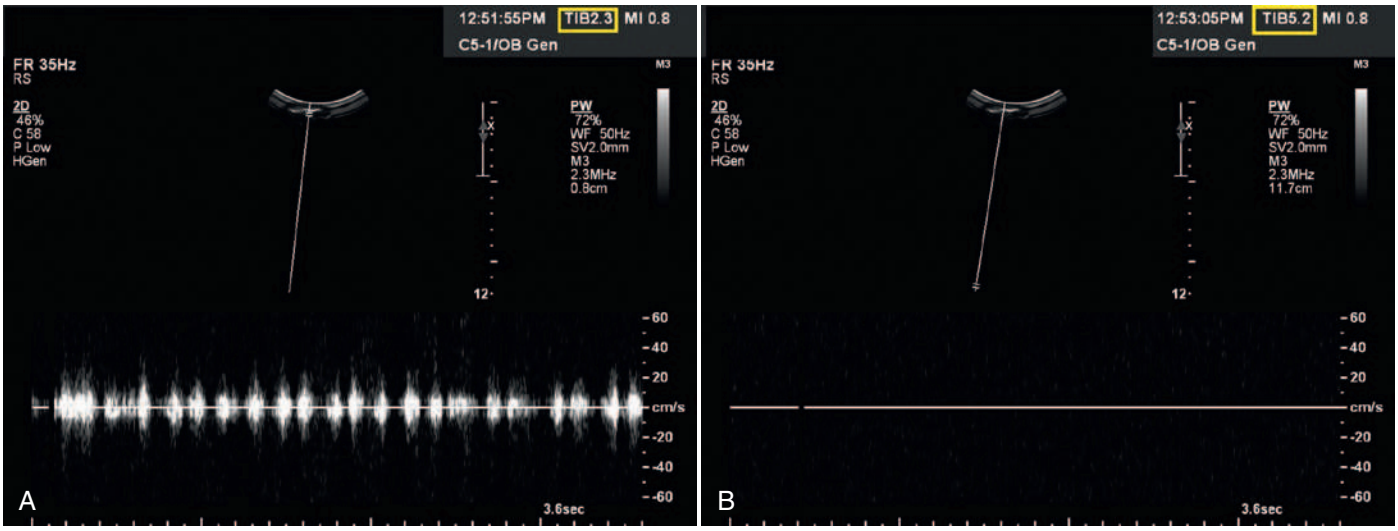

FIG. 29.2 Effect of Changing Focal Area on Thermal Index of Bone (TIB) During Spectral (Pulsed) Doppler Examination. Changing the focal area from **(A)** near field to **(B)** far field changes the thermal index *(yellow box)* from 2.3 to 5.2.

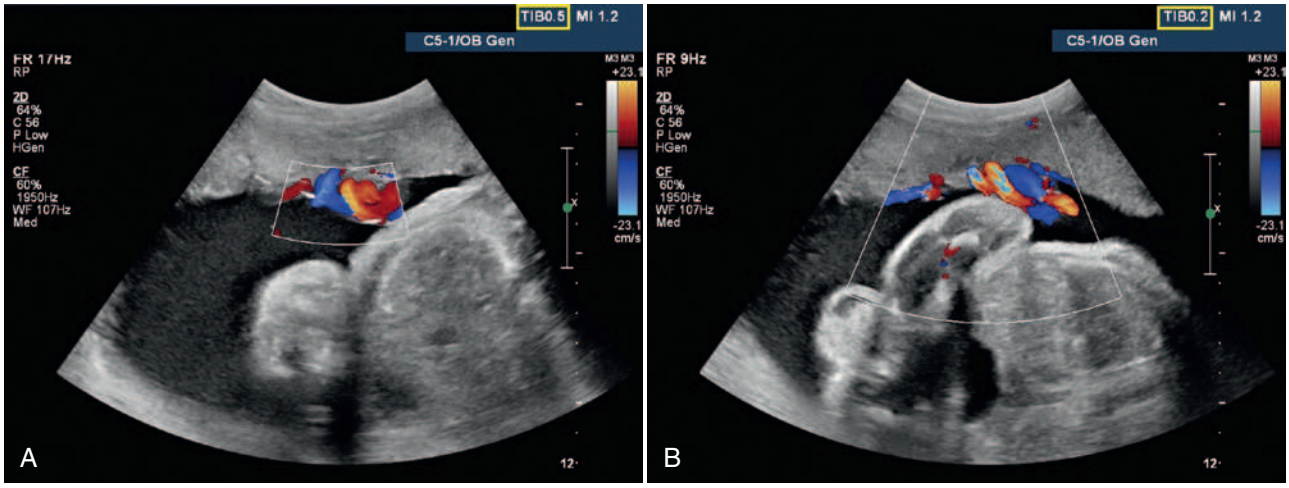

FIG. 29.3 Effect of Changing Size of Color Box on Thermal Index of Bone (TIB) During Color Doppler Examination of Umbilical Cord. Changing the size of the box from **(A)** large to **(B)** small changes the thermal index *(yellow box)* from 0.2 to 0.5.

Controls that regulate output include **focal depth,** usually with greatest power at deeper focus (Fig. 29.2) but occasionally with highest power in the near field; **increasing frame rate;** and **limiting the field of view,** as by high-resolution magnification or certain zooms. In Doppler mode, changing **sample volume** and **velocity range** (to optimize received signals) will change output. In Fig. 29.3, only the size of the color box is smaller, which caused increased TI on the output. It should be remembered that **receiver gain** often has similar effects as these controls on the recorded image (postprocessing), but no effect on the output of the outgoing beam (preprocessing), and therefore it is completely safe to manipulate. In Fig. 29.4A, the output power is high. In Fig. 29.4B, the output power has been greatly reduced (as reflected by a very low TI) and the image is much less diagnostic. In Fig. 29.4C, the receiver gain has been greatly increased, resulting in an image that looks identical to that in Fig. 29.4A but there were no changes in acoustic power, as reflected by unchanged TI and MI or power percentage. In other words, the receiver gain should be maximized before output is increased, which will rarely, if ever, be necessary.

Dwell Time

Dwell time is the **actual scanning time** and thus directly under control of the examiner. Dwell time is not taken into account in the calculation of the safety indices and generally is not reported in clinical or experimental studies. However, it takes only one pulse to induce cavitation and about a minute to raise temperature to its peak. Directly correlated with dwell time is **examiner experience,** that is, the examiner's knowledge of anatomy, bioeffects, instrument controls, and scanning techniques.

THERMAL EFFECTS

That diagnostic ultrasound can induce thermal changes in various animals has been demonstrated.[34] In addition, hyperthermia has clearly been shown to be teratologic to many species.[35-43] Elevated

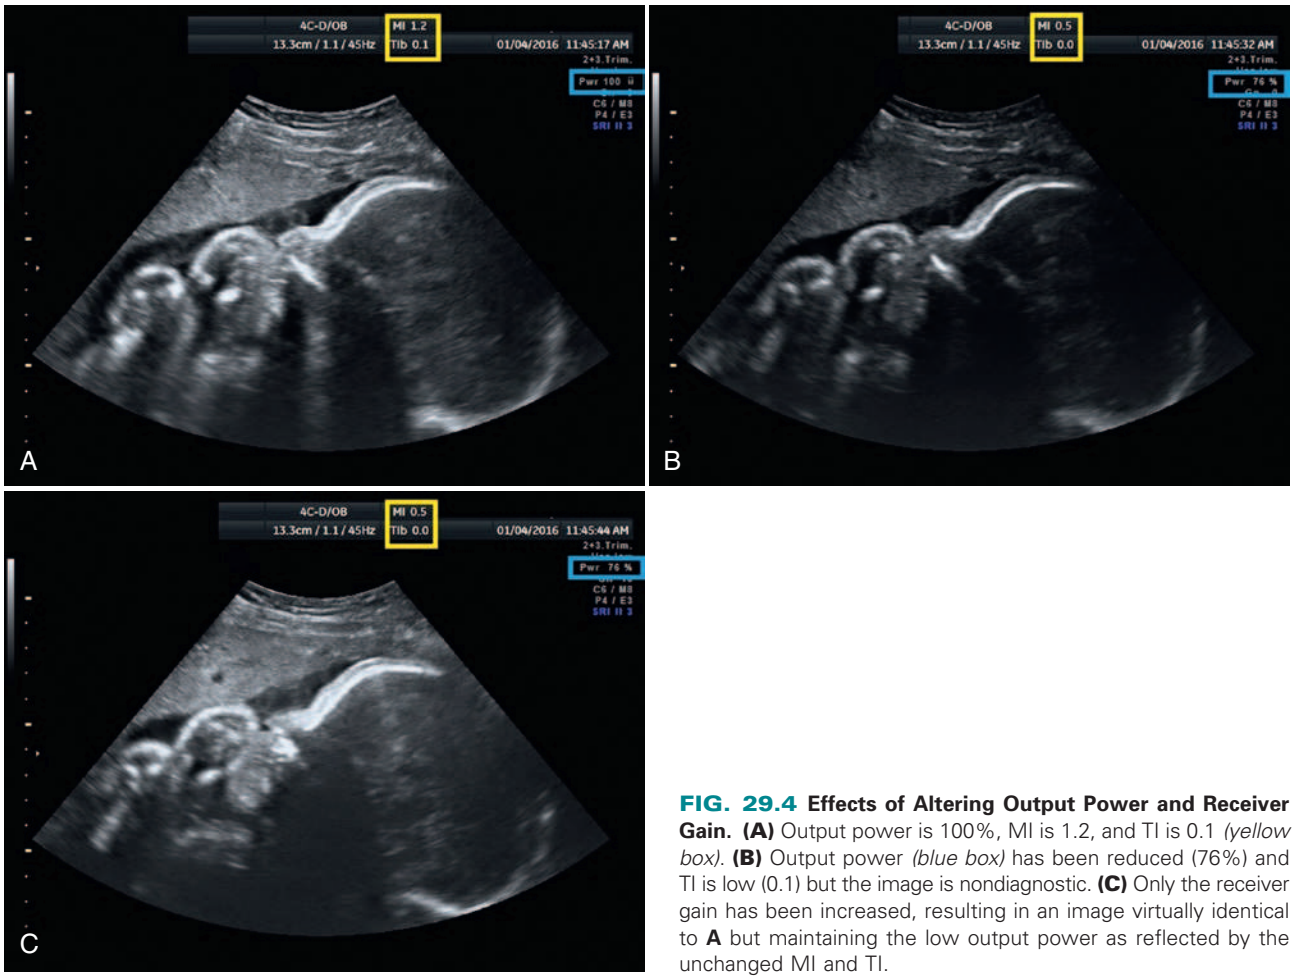

FIG. 29.4 Effects of Altering Output Power and Receiver Gain. (A) Output power is 100%, MI is 1.2, and TI is 0.1 *(yellow box).* **(B)** Output power *(blue box)* has been reduced (76%) and TI is low (0.1) but the image is nondiagnostic. **(C)** Only the receiver gain has been increased, resulting in an image virtually identical to **A** but maintaining the low output power as reflected by the unchanged MI and TI.

maternal temperature, whether from illness or exposure to heat, can produce teratogenic effects.[20,37,38,41-56] A rise less than 2°C is thought to be safe,[57] although any temperature increase for any amount of time may have some effect,[46,58] and a rise of 2.5°C may be considered significant.[59] A major question is whether diagnostic ultrasound can induce a rise in temperature in the fetus that could reach dangerous levels.[13,57,60] Temperature elevation in the human fetus cannot be exactly measured but can be estimated fairly accurately.[61,62] For prolonged ultrasound exposures, temperature elevations of up to 5°C have been obtained.[57] Thus *any* temperature increment for *any* period of time has *some* effect; the higher the temperature differential or the longer the temperature increment, the greater is the likelihood of producing an effect. Although these assumptions cannot be demonstrated in diagnostic ultrasound and no human data exist, clinicians should keep these facts in mind when performing obstetric ultrasound. This also forms part of the argument against nonmedical or nonindicated ultrasound examinations.

As with any external influence on the pregnancy, **gestational age** is a vital factor. **Milder** (in time or intensity) exposures during the preimplantation period (very early gestational age) could have similar or worse consequences than **more severe** exposures during embryonic and fetal development and could result in fetal demise and abortion or structural and functional defects. Such a dose analysis is not available. As for many other **teratogens,** the central nervous system (CNS) is most at risk because of a lack of compensatory growth by undamaged neuroblasts. In experimental animals the most common defects associated with temperature increase are of the neural tube **(anencephaly, microencephaly)** and the eyes **(microphthalmia, cataract).** Associated with CNS defects are functional and behavioral problems.[45] Other organ defects secondary to hyperthermia include defects of craniofacial development (e.g., clefts) and anomalies of the axial and appendicular skeleton,[63] the body wall, teeth, and heart.

Gestational age is critical when considering heat dispersion. In midterm, there was no significant difference when guinea pig fetal brains were exposed, alive (perfused) or postmortem (nonperfused), in the focal region of the ultrasound beam. However, a significant cooling effect of vascular perfusion was observed when the fetuses reached the stage of late gestation near term, when the cerebral vessels were well developed.[64] In early human pregnancy, less than 6 weeks, the minimal fetal perfusion may reduce heat dispersion.[65] The increased sensitivity of Doppler devices suggests evidence of blood flow within embryonic vesicles after heart formation, with the simultaneous development of a uterine circulatory pathway in the developing placenta. The flow is often referred to as "nonpulsatile" or

"percolating"[66,67] with near-minimal Doppler-measured velocities, as opposed to later in pregnancy. At about week 12 of gestation, the plugs of the spiral arteries are "loosened" and allow for freer blood circulation.[68,69]

Thus perfusion status is far from approaching that for normal tissue levels (as assumed in the TI algorithm) for much of the first trimester. Only later, when "free circulation" is established (about week 11 or 12 of gestation), does the tissue become normally perfused, when the embryonic circulation actually links up with the maternal circulation.[69] This absence of perfusion may result in underestimation of the actual ultrasound-induced temperature in early gestation. This warrants extreme caution in first-trimester scanning, particularly with the recent increase in utilization of Doppler in the first trimester.[70-73]

Also, the issue of **transducer heating** may be particularly relevant in the first trimester, if performing endovaginal scanning.[72,74] A mitigating factor is motion (even very small) of the examiner's hand, as well as the patient's breathing and body movements (in obstetric ultrasound, both mother and fetus), which tend to spread the region being heated. However, for spectral (pulsed) Doppler studies, it is necessary to have the transducer as steady as possible. Because the intensity and acoustic power associated with Doppler ultrasound are the highest of all the general-use categories, time spent scanning with Doppler ultrasound mode is crucial. Ziskin[75] reported that average duration of 15,973 Doppler ultrasound examinations was 27 minutes (longest, 4 hours!). It is clear that temperature increases of 1°C are easily reached in routine scanning.[76] Elevation of up to 1.5°C were obtained in the first trimester and up to 4°C in the second and third trimesters, particularly with the use of pulsed Doppler.[77] In many clinical machines, TI values of 5 or 6 can be obtained in Doppler mode.

MECHANICAL EFFECTS

Although effects have been described in neonates or adult animals, because gas bubbles are not present in fetal lung or bowel, it is assumed that the risk from mechanical effect secondary to cavitation is minimal.[78] Several other mechanical effects do not appear to involve cavitation, such as **tactile sensation** of the ultrasound wave, **auditory response, cell aggregation,** and **cell membrane alteration. Hemolysis** has also been reported,[79] although some cavitation nuclei must be present for hemolysis to occur. Such microbubbles would be provided by the introduction of ultrasound **contrast agents** to the area under ultrasound examination. However, there is currently no clear clinical indication for the use of these agents in fetal ultrasound.[80,81] In addition, fetal stimulation caused by pulsed ultrasound insonation has been described, with no apparent relation to cavitation.[82] This effect may be secondary to radiation forces associated with ultrasound exposures. No harmful effects of diagnostic ultrasound secondary to nonthermal mechanisms have been reported in human fetuses. However, because of these known mechanical effects of ultrasound in living tissues, and because pressures in Doppler propagation are much higher than in B-mode imaging, further caution is recommended in the use of ultrasound, particularly in the first trimester.[83]

BIOEFFECTS OF ULTRASOUND

Animal Research

Multiple studies have shown effects of ultrasound in a wide variety of species.[84-87] Studies of gross effects on the brain and liver of cats showed well-defined lesions and demyelination in the brain[88] and tissue damage in the liver[89] resulting from ultrasound exposure of a few seconds at 1 and 3 MHz, respectively. Other observed effects include limb paralysis, as a result of spinal cord injury in the rat,[90,91] as well as lesions in the liver, kidney, and testes of rabbits.[92] Changes in fertility were demonstrated in male mice after in utero ultrasound exposure of the testes.[93] Although some effects are likely caused by mechanical processes, very high temperature elevations (much higher than with diagnostic ultrasound) may be more directly involved with the tissue damage. It took acoustic pressures generated by lithotripsy to obtain effects in muscles,[94] as well as hemorrhage in bowel[95] and lungs.[96] These intensities are much higher than in diagnostic ultrasound but are helpful in understanding the mechanisms involved with possible bioeffects of ultrasound.

Several major clinical end points for bioeffects in animals that could have direct relevance to human studies include fetal growth and birth weight, effects on brain and CNS function, and change in hematologic function. High-level exposures were associated with decreased body weight at birth in exposed monkeys compared with controls, but all showed catch-up growth when examined at 3 months of age.[97] Decreased birth weight after prenatal exposure to ultrasound has also been reported in mice[98,99] but not convincingly in rats.[100] Clear species differences therefore seem to exist,[101] making it difficult to extrapolate to the human. In a report of 30 pregnancies in monkeys, half were exposed to ultrasound.[97] The scanned fetuses had lower birth weights and were shorter than the control group. No significant differences were noted in rate of abortions, major malformations, or stillbirths. Moreover, all showed catch-up growth when examined at 3 months of age. In situ intensities were higher than routinely used in clinical obstetric imaging in the human. Studies in mice have shown increased mortality and decreased body weight after in utero exposure to diagnostic ultrasound.[102,103] Gross lesions have been described in the CNS[104] and the spine[91] in mammals.

Neurologic or behavioral findings may be sensitive markers of teratogenic effect.[84,105] Pregnant Swiss albino mice were exposed to diagnostic ultrasound for 10, 20, or 30 minutes on day 14.5 (fetal period) of gestation and compared with sham-exposed controls.[106] Significant behavioral alterations in the exposed groups included decreased locomotor and exploratory activity and more trials needed for learning. No changes were observed in physiologic reflexes or postnatal survival. The authors concluded that ultrasound exposure during the early fetal period can impair brain function in the adult mouse.[106] In another study, the same authors found increased anxiolytic activity and learning latency in ultrasound-treated animals.[107] Pregnant Swiss albino mice were exposed to similar diagnostic levels of ultrasound for 10 minutes on day 11.5 or 14.5. Behavioral tests at 3 and 6 months post partum showed more pronounced effects in the 14.5-day than in the 11.5-day group. The authors concluded that exposure

to diagnostic ultrasound during the late organogenesis period or early fetal period in mice may cause changes in postnatal behavior.[107]

An intriguing paper was published on memory changes in chicks after being insonated in ovo with various levels of Doppler ultrasound.[108] Exposure was to 5 or 10 minutes of B-mode, or to 1, 2, 3, 4, or 5 minutes of pulsed Doppler ultrasound. Two hours after hatching, chicks were trained to recognize certain colors in relation to some feeding procedures. B-mode exposure on day 19 (of a 21-day gestation) did not affect memory. However, significant memory impairment occurred after 4 and 5 minutes of pulsed Doppler exposure, as expressed by the inability to discern the colors. Short-, intermediate- and long-term memory was equally impaired, suggesting an inability to learn. The chicks were still unable to learn with a second training session. Although there are major differences in terms of length of gestation, amount of "energy received," and other technical issues when compared with human fetal exposure, these findings raise important questions on the potential effect of pulsed Doppler ultrasound in utero exposure on cognitive function.

As mentioned previously, ultrasound induces thermal changes in various animals, and hyperthermia clearly is teratogenic to many species.[35-43,64,109] In guinea pigs, mean temperature increases of 4.9°C close to parietal bone and 1.2°C in the midbrain were recorded after 2-minute ultrasound exposures, although at exposure conditions higher than usually employed in clinical examinations.[64] After only 2 minutes of insonation with an ISPTA of 2.9 W/cm^2 (about four times higher than the current U.S. Food and Drug Administration allowance for diagnostic use), mean maximum temperature increases varied from 1.2°C at 30 days to 5.2°C at 60 days. Importantly, 80% of the mean maximum temperature increase occurred within 40 seconds. This rapid rate of heating is relevant to the safety of clinical examinations in which the dwell time may be an important factor. Because maximal ultrasound-induced temperature increase occurs in the fetal brain near bone, worst-case heating will occur later in pregnancy, when the ultrasound beam impinges on bone, and less will occur earlier in pregnancy, when bone is less mineralized. This is one of the justifications to utilize **thermal index for bone** (TIB) late in pregnancy and **thermal index for soft tissue** (TIS) earlier.

In 2006 Ang et al.[110] evaluated the effect of ultrasound insonation in pregnant mice on neuronal position within the embryonic cerebral cortex of the fetuses. Neurons generated at embryonic day 16 that normally migrate to the superficial cortical layers were chemically labeled. A small but statistically significant number of neurons remained scattered within inappropriate cortical layers and in the subjacent white matter, failing to acquire their proper position when exposed to ultrasound for a total of 30 minutes or longer during their migration. However, several major differences exist between this experimental setup and clinical ultrasound in humans,[111] most notably the length of exposure (up to 7 hours). No real mechanistic explanation was given for the findings, there was no real dose-response effect, and scans were performed over a short period of several days. The experimental setup was such that embryos received whole-brain exposure to the beam, which is rare in humans (although possible very early in pregnancy), and the small brains of mice develop over days. Thus, although the study merits repeating, the applicability to human embryology is questionable.[111]

These animal studies suggest precaution with obstetric ultrasound. However, the animal studies to date do not implicate ultrasound used at daily clinical exposure levels with major adverse fetal effects.

Human Studies

Among the published epidemiologic studies on obstetric ultrasound exposure,[14,49,112-115] some have serious limitations, such as lack of a testable hypothesis for causation of the studied effect, small samples, poorly matched controls, and, most often, lack of information on acoustic output and exact quantification of exposure (number of episodes, duration of exposure, and inability to calculate "dose"). These limitations are a major problem in the analysis of published data,[116] particularly with new imaging modalities that have potentially high energy levels and new applications of existing modalities. Typical examples are spectral Doppler ultrasound analysis of the tricuspid artery at 11 to 14 weeks' gestation in screening for Down syndrome[26] and studies of the fetal heart anatomy and function during the first trimester.[71,117-120] There is no epidemiologic or other information on levels of exposure or possible effects at these early, particularly susceptible gestational ages. Several "epidemiologic" reports are actually case-control studies and require caution in their interpretation. The effects being studied (e.g., low estimated fetal weight) may be the same as the clinical indication for performing the ultrasound examination ("suspected intrauterine growth delay"). Thus an association, but not a causal relationship, may exist between the ultrasound and the growth delay.

A further crucial confounding factor is that major congenital anomalies occur in 3% to 5% of the general human population. An increment of 1% to 2% over this "background" incidence would be a major clinical effect but might go undetected as an individual finding in routine clinical practice and would be detectable only after prolonged observation in large populations. Also, some underreporting occurs; for example, a certain number of birth defects is expected in any ultrasound study in relatively large (>1000) populations. Often, however, these studies describe no anomalies in the study group or in the control population; in a survey of more than 121,000 patients among 68 examiners, combining 292 institute-years of experience, 3000 to 5000 anomalies would be expected as background rate, but none were reported.[121]

In fact, rigorous epidemiologic studies of the adverse bioeffects of ultrasound are scarce. Several biologic end points have been analyzed in the human fetus or neonate to determine whether prenatal exposure to diagnostic ultrasound had observable effects: intrauterine growth restriction and low birth weight,[122] delayed speech,[123] vision and hearing,[124] dyslexia,[125] neurologic and mental development or behavioral issues,[126,127] malignancies,[128] and nonright-handedness.[129,130] Most findings have never been duplicated, and the majority of studies have been negative for any association, with the possible exception of low birth weight.

There are no epidemiologic studies related to the output display standard (thermal and mechanical indices) and clinical

outcomes. Only a few clinical studies describe routine scan,[131] first-trimester scan,[132] particularly, **nuchal translucency** screening,[133] as well as Doppler[132] and three-dimensional (3D)/four-dimensional (4D) ultrasound.[134] Furthermore, although some studies address the issue of repeat scans,[135,136] it was not as an analysis of potential cumulative effects for which no information is available.

Birth Weight

In one often-quoted study of more than 2000 infants, a small (116 g at term) but statistically significant lower mean birth weight was found in the half exposed to ultrasound compared with the nonexposed group.[137] However, information was collected several years after exposure, with no indications known and no exposure information available. Moreover, in a later study, the authors concluded that the relationship of ultrasound exposure to reduced birth weight may be caused by shared common risk factors, which lead to both exposure and a reduction in birth weight,[138] an association but not a causal relationship.

A twice-greater risk of low birth weight was reported in another retrospective study after four or more exposures to diagnostic ultrasound.[14] These results were not reproduced in another retrospective study with a large population, originally of 10,000 pregnancies exposed to ultrasound matched with 500 controls and with 6-year follow-up.[139] No increased congenital malformations, chromosomal abnormalities, infant neoplasms, speech or hearing impairment, or developmental problems were observed in this latter study.

In a randomized controlled trial of more than 2800 pregnant women, about half received five ultrasound imaging and Doppler flow studies at 18, 24, 28, 34, and 38 weeks of gestation, and half received a single ultrasound imaging at 18 weeks.[122] An increased risk of intrauterine growth restriction was detected in those exposed to frequent Doppler ultrasound examinations, possibly through effects on bone growth. However, when children were examined at 1 year of age, there were no differences between the study and control groups. In addition, after examining their original subjects after 8 years, the investigators found no evidence of adverse neurologic outcome.[136] Similarly, other randomized studies found no harmful effect of one or two prenatal scans on growth.[140,141] Curiously, in some studies, birth weight was slightly higher in the scanned group, but not significantly, except in one group of newborns exposed to ultrasound in utero who weighed on average 42 g (75 g in reported smokers) more than the control group.[141] Thus ultrasound exposure in utero does not appear to be associated with reduced birth weight, although Doppler ultrasound exposure may have some risks.[114]

Delayed Speech

To determine if an association exists between prenatal ultrasound exposure and delayed speech in children, Campbell et al.[123] studied 72 children with delayed speech and found a higher rate of ultrasound exposure in utero compared with the 144 control subjects. However, this retrospective study used records more than 5 years old, with neither a dose-response effect nor any relationship to time of exposure. A much larger study of more than 1100 children exposed in utero and 1000 controls found no significant differences in delayed speech, limited vocabulary, or stuttering.[142]

Dyslexia

Dyslexia has been extensively studied. Stark et al.[125] compared more than 4000 children (ages 7-12 years) exposed to ultrasound in utero to matched controls, analyzing outcome measures at birth (Apgar scores, gestational age, head circumference, birth weight, length, congenital abnormalities, neonatal/congenital infection) or in early infancy (hearing, visual acuity/color vision, cognitive function, behavior). No significant differences were found, except for a significantly greater proportion of dyslexia in children exposed to ultrasound. Given the design of the study and the presence of several possible confounding factors, the authors indicated that dyslexia could be incidental.

Subsequently, long-term follow-up studies of more than 600 children with various tests for dyslexia (e.g., spelling, reading) were performed.[143-147] End points included evaluation for dyslexia along with examination of nonright-handedness, said to be associated with dyslexia. No statistically significant differences were found between ultrasound-exposed children and controls for reading, spelling, arithmetic, or overall performance, as reported by teachers. Specific dyslexia tests showed similar incidence rates among scanned children and controls in reading, spelling, and intelligence scores and no discrepancy between intelligence and reading or spelling. Therefore the original finding of dyslexia was not confirmed in subsequent randomized controlled trials. It is considered unlikely that routine ultrasound screening can cause dyslexia.

Nonright-Handedness

A possible link between prenatal exposure to ultrasound and subsequent nonright-handedness at age 8 to 9 years in children exposed to ultrasound in utero was first reported in 1993 from Norway.[146] According to the authors, however, the difference was "only barely significant at the 5% level" and was restricted to boys.[148] A second group of researchers (including Salvesen, main author of the first study), studying a new population of more than 3000 children from Sweden, reported similar findings of a statistically significant association between ultrasound exposure in utero and nonright-handedness in males.[129] An intriguing recent study showed that fetuses self-touched their faces more often with the left hand than the right, as observed by ultrasound, in correlation to stress levels of the mother.[149] Furthermore, laterality is, mostly, genetically determined[150] but could, naturally, be modified by external factors. Evidence is insufficient to infer a direct effect on brain structure or function, or even that nonright-handedness is an adverse effect.

Neurologic Development and Behavioral Issues

Neurons of the cerebral neocortex in mammals, including humans, are generated during fetal life in the brain proliferative zones and then migrate to their final destination by following an inside-to-outside sequence. This neuronal migration occurs in the human fetal brain mainly from 6 to 11 weeks of gestation[151] but continues until 32 weeks. It has long been theorized that

external factors such as ultrasound could affect this process.[152] In another study, only 2 of 123 variables were found to be disturbed at birth, but not at 1 year of age, in children exposed in utero; these variables are **grasp reflex** and **tonic neck reflex.**[153] The significance was not elaborated, and some doubts exist regarding statistical validity. Stark et al.[125] reported that vision and intelligence scores were identical among 425 exposed infants and 381 controls. A large report found no association between routine exposure to prenatal ultrasound and school performance (deficits in attention, motor control, perception, vision, and hearing).[154] In more than 4900 children age 15 to 16 years, no differences were found in school performance between exposed and nonexposed children, except for a lower score for exposed boys in physical education.[155]

Behavioral changes may be a more sensitive marker of subtle brain damage than obvious structural alterations.[156] Such changes have been described in animals,[84,105] although often transient.[97] An interesting study in mice was recently published.[157] As detailed earlier, there may be male preponderance of nonright-handedness after in utero ultrasound exposure. Furthermore, an increased prevalence of autism exists in males and there are reports of excess nonright-handedness in this population. Pregnant mice were exposed to 30 minutes of diagnostic ultrasound at embryonic day 14.5. Social behavior of their male pups was analyzed 3 weeks after birth. Ultrasound-exposed pups were significantly ($P < .01$) less interested in social interaction than sham-exposed pups and demonstrated significantly ($P < .05$) more activity relative to the sham-exposed pups (only in the presence of an unfamiliar mouse). These results suggest that social behavior in young mice was altered by in utero exposure to diagnostic ultrasound. The authors' conclusions are that this may be relevant for autism but that major differences between the exposure of diagnostic ultrasound of mice and humans preclude conclusions regarding human exposure and require further studies. Indeed, no such changes have been reported in humans. In particular, schizophrenia and other psychoses have not been found to be associated with prenatal ultrasound exposure.[158] The question has been raised about the increased rate of autism observed over the past few years and its relation to the greatly increased use of ultrasound in obstetrics. Although a major upsurge in both have occurred, there is no cause and effect demonstrable between the two.[159]

Congenital Malformations

In humans, prenatal ultrasound has not been shown to result in an increased incidence of congenital anomalies, as found in animals.

Childhood Malignancies

No association has been found between ultrasound exposure in utero and the later development of leukemia[160,161] or solid tumors in children.[128,162-166]

Again, although some of these studies were published in 2007 or 2008, the populations studied were exposed to ultrasound in utero 20 to 30 years ago, that is, with instruments generating lower outputs and with minimal or no information available on exposure conditions.

IS DOPPLER DIFFERENT?

Spectral (pulsed) Doppler uses high pulse repetition frequencies, generating greater temporal average intensities and powers than B- or M-mode, and hence greater heating potential (see "Thermal Effects").[75] Adequate diagnostic information may be obtained with low output levels (as documented by values of the TI), as demonstrated in Fig. 29.1. This has been reported in the literature, specifically for Doppler, the mode with the highest output, both in early and later pregnancy.[167,168] In fact, under pressure from bioeffects and safety committees of various professional organizations (American Institute of Ultrasound in Medicine [AIUM], European Federation of Societies of Ultrasound in Medicine and Biology [EFSUMB], International Society for Ultrasound in Obstetrics and Gynecology [ISUOG], and World Federation for Ultrasound in Medicine and Biology [WFUMB]), several manufacturers have changed their default settings, specifically for pulsed Doppler in fetal mode, from very high (as it was originally, presumably in an attempt to obtain better images) to very low, with the end user capable of raising the output, if desired. Because acoustic output is high in Doppler, special precaution is recommended, particularly in early gestation.[169]

SAFETY GUIDELINES

It is difficult to issue precise safety recommendations because of the multitude of ultrasound instruments, each with a selection of transducers and used in a variety of applications. Patient characteristics further complicate the task.[170] Safety guidelines are very important, however, given the very low level of knowledge about bioeffects and safety of ultrasound among clinical end users. In a questionnaire distributed to ultrasound active end users (of which 82% were obstetricians), only 17.7% gave the correct answer of the definition of the TI. Approximately 96% did not know the proper definition for MI. Almost 80% of respondents did not know the correct answer to the multiple choice question of where to find the acoustic indices; answer options were the machine documentation, a textbook, a complicated calculation or in real time on the ultrasound monitor (the correct answer).[171] Similar results were recorded in surveys abroad, performed in Europe, Asia, or the Middle East,[172-174] indicating that clinical end users worldwide show poor knowledge regarding safety issues of ultrasound during pregnancy.[30] More recently, knowledge among residents in obstetrics and gynecology was also found to be grossly lacking.[175] Similar results were obtained in a survey of sonographers, and years of experience made no difference.[176]

In another study, compliance with the **ALARA** (as low as reasonably achievable) principle by practitioners seeking credentialing for nuchal translucency (NT) measurement between 11 and 14 weeks' gestation was evaluated. Only 5% of the providers used the correct TI type (TIB) at lower than 0.5 for all submitted images, 6% at lower than 0.7, and 12% at 1.0 or lower. A TI (TIB or TIS) higher than 1.0 was used by almost 20% of the providers. Proficiency in NT measurement and educational background (physician or sonographer) did not influence compliance with ALARA. The authors concluded that clinicians seeking

credentialing in NT do not demonstrate compliance with the recommended use of the TI in monitoring acoustic output.[177] An easy way to reduce exposure is to reduce the TI and MI, using the appropriate controls, and/or reduce the dwell time. The 1999 statement of the British Medical Ultrasound Society, reconfirmed in 2009, declares[178]:

> *For equipment for which the safety indices are displayed over their full range of values, the TI should always be less than 0.5 and the MI should always be less than 0.3. When the safety indices are not displayed, T_{max} should be less than 1°C and MI_{max} should be less than 0.3. Frequent exposure of the same subject is to be avoided.*

The British Medical Ultrasound Society has strict recommendations for maximum allowed exposure time (T_{max}), depending on the TI (Table 29.1).

Miller and Ziskin[57] demonstrated a logarithmic relationship between exposure duration and temperature elevation in producing harmful bioeffects in animal fetuses. For temperatures below 43°C, the exposure time necessary for every 1°C increase in temperature was decreased by a factor of 4. Using a maximum "safe" exposure time of 4 minutes for a temperature elevation of 4°C, based on these calculations, the following maximal exposure times are allowable with no apparent obvious risks: 128 minutes at 1°C, 64 at 2°C, 16 at 3°C, and only 4 minutes at 4°C. Precautions are, naturally, of particular importance in early gestation[179,180] and for Doppler exposure.[181]

General recommendations from major professional organizations follow. It is strongly recommended to consult various safety statements published on these organizations' websites.[182-192]

1. A diagnostic ultrasound exposure that produces a maximum in situ temperature rise of no more than 1.5°C above normal physiologic levels (37°C) may be used clinically without reservation on thermal grounds.[193]
2. A diagnostic ultrasound exposure that elevates embryonic and fetal in situ temperature above 41°C (4°C above normal temperature) for 5 minutes or more should be considered potentially hazardous.[193,194] In this regard, maternal temperature elevation (e.g., from viral disease) should be considered because body temperature of the fetus will also be increased above normal.[48]
3. The risk of adverse effects is increased with the duration of exposure (dwell time).[195]
4. Based on available information, there is no reason to withhold scanning in B-mode for medical indications. The risk of thermal damage secondary to heating appears to be negligible.[193]
5. M-mode ultrasound appears to be safe and not to cause thermal damage (Fig. 29.5).[48]
6. Spectral Doppler ultrasound may produce high intensities, and routine Doppler examination during the embryonic period is rarely indicated.[196]
7. Three-dimensional (3D) and four-dimensional (4D) ultrasound are based on two-dimensional (2D) B-mode imaging with multiple 2D planes obtained and assembled (reconstructed) into a volume. Hence the exposure is really to B-mode and is, most likely, safe. Time of exposure has to be watched to avoid long episodes of scanning to obtain the "ideal" 3D volume (Fig. 29.6).
8. Education of ultrasound operators is crucial; the responsibility for the safe use of ultrasound devices is shared between the users and the manufacturers, who should ensure the accuracy of the output display.[196]
9. The AIUM advocates the responsible use of diagnostic ultrasound and strongly discourages the nonmedical use of ultrasound for "entertainment" purposes. The use of ultrasound without a medical indication to view the fetus, obtain a picture of the fetus, or determine the fetal gender is inappropriate and contrary to responsible medical practice. Ultrasound should be used by qualified health professionals to provide medical benefit to the patient.[28]
10. Examinations should be kept as short as possible and with as low MI and TI outputs as possible, but without sacrificing diagnostic accuracy. Follow the **as low as reasonably achievable** (ALARA) principle.[197]

TABLE 29.1 Duration of Obstetric Ultrasound as a Function of Thermal Index

Thermal Index (TI)	Recommended Upper Limit
0.7	60 min
1	30 min
1.5	15 min
2	4 min
2.5	1 min

Modified from British Medical Ultrasound Society (BMUS) Safety Group. Guidelines for the safe use of diagnostic ultrasound equipment. Ultrasound. 2010;18:52-59.[178]

CONCLUSION

Diagnostic ultrasound has been used in medicine in general and obstetrics and gynecology in particular for more than half a century. No confirmed biologic effects have been described in patients as a result of exposure to diagnostic ultrasound. Such effects, however, have been described in animals, often at exposure levels higher than, but also occasionally equivalent to, those used in clinical practice. Epidemiologic information available is from studies performed on instruments with acoustic output much lower than current machines. Often, exposure data are insufficient and number of subjects too small. Furthermore, "no reported effects" does not mean "no effects," and such biologic effects may be identified in the future. Prudent use of ultrasound in fetal scanning, following the ALARA principle, is therefore recommended. Based on known mechanisms, there is no contraindication to the use of B-mode, M-mode, 3D/4D, and color Doppler ultrasound, when clinically indicated. However, special precaution is necessary when applying pulsed Doppler ultrasound, particularly in the first trimester.

CHAPTER 30

The First Trimester

Elizabeth Lazarus and Deborah Levine

SUMMARY OF KEY POINTS

- First-trimester development follows a predictable pattern on first-trimester ultrasound.
- Some ultrasound findings are definitive for early pregnancy failure, whereas others are suggestive and require follow-up.
- Ultrasound is vital in the diagnosis of ectopic pregnancy in typical and atypical locations.
- Gestational trophoblastic disease is composed of four entities, and ultrasound is helpful in their diagnosis and management.

CHAPTER OUTLINE

MATERNAL PHYSIOLOGY AND EMBRYOLOGY
SONOGRAPHIC APPEARANCE OF NORMAL INTRAUTERINE PREGNANCY
Gestational Sac
β-hCG and Early Pregnancy Ultrasound
Yolk Sac
Embryo and Amnion
Embryonic Cardiac Activity
Umbilical Cord and Cord Cyst
ESTIMATION OF GESTATIONAL AGE
Gestational Sac Size
Crown-Rump Length
EARLY PREGNANCY FAILURE
Diagnostic Findings of Early Pregnancy Failure
Crown-Rump Length 7 mm or Greater and No Heartbeat
Gestational Sac Mean Sac Diameter 25 mm or Greater and No Embryo
Worrisome Findings of Early Pregnancy Failure
Embryos With Crown-Rump Length Less Than 7 mm and No Heartbeat
Gestational Sac With Mean Sac Diameter 16 to 24 mm and No Embryo
Gestational Sac Appearance
Small Mean Sac Diameter in Relationship to Crown-Rump Length
Abnormally Large Amnion With Respect to Embryo Size
Yolk Sac Size and Shape
Embryonic Bradycardia
Subchorionic Hemorrhage
ECTOPIC PREGNANCY
Clinical Presentation
Sonographic Diagnosis
Heterotopic Gestation
Serum β-hCG Levels
Specific Sonographic Findings
Nonspecific Sonographic Findings
Adnexal Mass
Free Fluid
Endometrium
Implantation Sites
Pregnancy of Unknown Location
Management
EVALUATION OF THE EMBRYO
Normal Embryologic Findings

Abnormal Embryos
GESTATIONAL TROPHOBLASTIC DISEASE
Hydatidiform Molar Pregnancy
Complete Molar Pregnancy
Partial Molar Pregnancy
Coexistent Hydatidiform Mole and Normal Fetus
Persistent Trophoblastic Neoplasia
Invasive Mole
Choriocarcinoma
Placental-Site Trophoblastic Tumor
Sonographic Features of Persistent Trophoblastic Neoplasia
Diagnosis and Treatment
CONCLUSION

The first trimester of pregnancy is a period of rapid change that spans fertilization, formation of the blastocyst, implantation, gastrulation, neurulation, the embryonic period (weeks 6-10), and early fetal life.[1] First-trimester sonographic diagnosis traditionally focused on evaluation of growth by serial examination to differentiate normal from abnormal gestations. This has changed since the advent of transvaginal sonography (TVS), which affords enhanced resolution over transabdominal sonography (TAS), with earlier visualization of the gestational sac and its contents,[2] earlier identification of embryonic cardiac activity,[3] and improved visualization of embryonic and fetal structures.

Despite these technologic improvements, it is important to set clinically relevant and realistic goals for first-trimester sonographic diagnosis. Most examinations are requested because the patient has vaginal bleeding or pain, or a palpable mass has been identified on physical examination. Ultrasound in the first trimester is often requested to diagnose early pregnancy failure or an ectopic pregnancy.

The goals of first-trimester sonography include (1) visualization and localization of the gestational sac (intrauterine or ectopic pregnancy) and (2) early identification of embryonic demise and other forms of nonviable gestation. It also seeks to identify those pregnancies that are at increased risk for early pregnancy failure. First-trimester ultrasound accurately dates the duration or menstrual/gestational age of the pregnancy and assists in early diagnosis of fetal abnormalities, including identification of embryos more likely to be abnormal, based on secondary criteria (e.g., abnormal yolk sac). In multifetal pregnancies, first-trimester ultrasound can be used to determine the number of embryos and the chorionicity and amnionicity.

Current trends in ultrasound late in the first trimester focus on **nuchal translucency** screening combined with maternal age and maternal serum screening to determine the risk of chromosomal abnormalities and structural anomalies. Associated with the increased emphasis on late first-trimester ultrasound and first-trimester screening, there is an opportunity to visualize fetal anomalies earlier than at the time of the standard 18- to 20-week scan. First-trimester diagnosis of specific anomalies is discussed in the chapters covering those organ systems.

As experience with early first-trimester ultrasound evolves, reliable sonographic indicators of ectopic pregnancy and embryonic demise have been established.[4-6] The accuracy of some sonographic signs used as indicators of the presence of a live embryo or of embryonic demise depends on the use of modern, high-resolution ultrasound equipment and the operator's expertise. Published values in the literature based on data using high-frequency transducers cannot be applied to lower-resolution 5.0-MHz transducers.[7,8] The TVS signs listed in this chapter assume the use of modern equipment with a transducer frequency of at least 7 to 8 MHz, with meticulous scanning technique. Transducers with frequencies of 10 MHz or higher can provide improved spatial resolution, identifying abnormal and normal features at even earlier points in pregnancy.[9] Nyberg and Filly[6] emphasize that experienced physicians who interpret ultrasound rarely rely on a single parameter and simultaneously consider multiple variables to create a diagnostic impression.

MATERNAL PHYSIOLOGY AND EMBRYOLOGY

All dates presented in this chapter are in **menstrual age** or **gestational age,** in keeping with the radiologic and obstetric literature, rather than in embryologic age, as used by embryologists. This can be counted as follows:

$$\text{Gestational age} = \text{Conceptual age} + 2 \text{ weeks}$$

Early in the menstrual cycle, the pituitary secretes rising levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which cause the growth of 4 to 12 primordial follicles into **primary ovarian follicles**[10] (Fig. 30.1). When a fluid-filled cavity or antrum forms in the follicle, it is referred to as a **secondary follicle.** The primary oocyte is off to one side of the follicle and surrounded by follicular cells or the **cumulus oophorus.** One follicle becomes dominant, bulges on the surface of the ovary, and becomes a "mature follicle" or **graafian follicle.** It continues to enlarge until ovulation, with the remainder of the follicles becoming atretic. The developing follicles produce estrogen. The estrogen level remains relatively low until 4 days before ovulation, when the dominant or active follicle produces an estrogen surge, after which an LH and prostaglandin surge results in ovulation. Ovulation follows the LH peak within 12 to 24 hours. Actual expulsion of the oocyte from the mature follicle is aided by several factors, including the intrafollicular pressure, possibly contraction of the smooth muscle in the **theca externa** stimulated by prostaglandins, and enzymatic digestion of the follicular wall.[11]

Ovulation occurs on approximately day 14 of the menstrual cycle with expulsion of the secondary oocyte from the surface of the ovary. In women with a menstrual cycle longer than 28 days, this ovulation occurs later, so that the secretory phase of the menstrual cycle remains at about 14 days. After ovulation, the follicle collapses to form the **corpus luteum,** which secretes progesterone and, to a lesser degree, estrogen. If a pregnancy does not occur, the corpus luteum involutes. In pregnancy, involution of the corpus luteum is prevented by **human chorionic gonadotropin** (hCG), which is produced by the outer layer of cells of the gestational or chorionic sac **(syncytiotrophoblast).**

Before ovulation, **endometrial proliferation** occurs in response to estrogen secretion (Fig. 30.1). After ovulation, the endometrium becomes thickened, soft, and edematous under the influence of progesterone.[12] The glandular epithelium secretes a glycogen-rich fluid. If pregnancy occurs, continued production of progesterone results in more marked hypertrophic changes in the endometrial cells and glands to provide nourishment to the **blastocyst.** These hypertrophic changes are referred to as the **decidual reaction** and occur as a hormonal response regardless of the site of implantation, intrauterine or ectopic.

Oocyte transport into the fimbriated end of the fallopian tube occurs at ovulation as the secondary oocyte is expelled with the follicular fluid and is "picked up" by the fimbria. The sweeping movement of the fimbria, the currents produced by the action of the cilia of the mucosal cells, and the gentle peristaltic waves from contractions of the fallopian musculature all draw the oocyte into the tube.[13]

The mechanism of **sperm transport** is regulated to maximize the chance of fertilization and ensure the most rigorous sperm will be available.[14] From 200 to 600 million sperm and the ejaculate fluid are deposited in the vaginal fornix during intercourse. Sperm must move through the cervical canal and its mucous plug, up the endometrial cavity, and down the fallopian tube to meet the awaiting oocyte within the distal third or ampullary portion of the fallopian tube. Sperm were thought to move primarily using their tails, although they travel at 2 to 3 mm per minute, which would take about 50 minutes to travel the 20 cm to their destination. Settlage et al.[13] found motile sperm within the ampulla between 5 and 10 minutes after deposition near the external cervical os. If inert particles such as radioactive macroaggregates or carbon particles are placed near the external os, they too will be picked up and transported up the uterus and down the tubes. Contractions of the inner layer of myometrium are believed to create a negative pressure strong enough to suck up particles and move them up the endometrial canal. These contractions

have been demonstrated in nonpregnant women and increase in strength and frequency to peak at 3.5 contractions per minute at ovulation.[15]

Fertilization occurs on or about day 14 as the mature ovum and sperm unite to form the **zygote** in the outer third of the fallopian tube (Fig. 30.2). Cellular division of the zygote occurs during transit through the fallopian tube. By the time the conceptus enters the uterus, about day 17, it is at the 12- to 15-cell stage **(morula).** By day 20, the conceptus has matured to the **blastocyst stage.** The blastocyst is a fluid-filled cyst lined with trophoblastic cells that contain a cluster of cells at one side called the **inner cell mass.** On day 20, the blastocyst at the site of the inner cell mass burrows through the endometrial membrane into the hyperplastic endometrium, and implantation begins[16] (Fig. 30.3A).

Implantation is completed by day 23 as the endometrial membrane re-forms over the blastocyst (Fig. 30.3B). During implantation, the **amniotic cavity** forms in the inner cell mass. A bilaminar embryonic disk separates the amniotic cavity from the exocoelomic cavity. The **primary (primitive) yolk sac** forms at about 23 days of gestational age as the blastocyst cavity becomes lined by the exocoelomic membrane and hypoblast. As the extraembryonic coelom forms, the primary yolk sac is pinched off and extruded, resulting in the formation of the **secondary yolk sac** (Fig. 30.4). Standard embryology texts indicate that the secondary yolk sac forms at approximately 27 to 28 days of menstrual age, when the mean diameter of the gestational sac is approximately 3 mm. It is the secondary yolk sac, rather than the primary yolk sac, that is visible with ultrasound. For the remainder of this chapter, the term **yolk sac** is used to refer to the *secondary* yolk sac. The extraembryonic coelom becomes the **chorionic cavity.**

Later, because of differential growth, the yolk sac comes to lie between the amnion and chorion. During week 4, there is rapid proliferation and differentiation of the **syncytiotrophoblast,** forming primary **chorionic villi.** Traditional thinking that the syncytiotrophoblastic cells invade the maternal endometrial vessels, leaving maternal blood to bathe the trophoblastic ring, has been challenged. Hustin[16] compared TVS to hysteroscopy of the placenta, chorionic villous sampling tissue, and

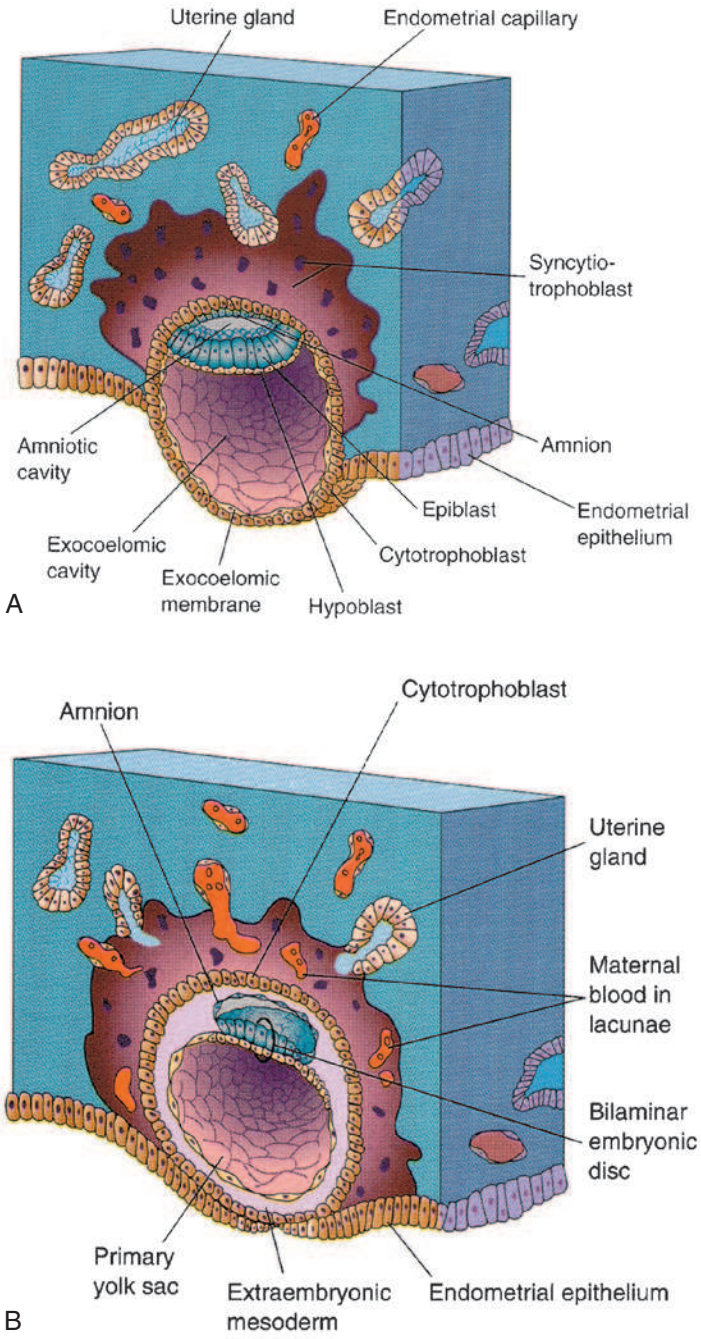

FIG. 30.3 Implantation of the Blastocyst Into Endometrium. Entire conceptus is approximately 0.1 mm at this stage. **(A)** Partially implanted blastocyst at approximately 22 days. **(B)** Almost completely implanted blastocyst at about 23 days. (With permission from Moore KL. The developing human: clinically oriented embryology. 10th ed. Philadelphia: Elsevier; 2016.[1])

hysterectomy specimens with an early pregnancy in situ. Before 12 weeks, the intervillous space contains no blood, only clear fluid, and on histologic examination, the villous tissue is separated from the maternal circulation by a continuous layer of trophoblastic cells. Only after the third month does the trophoblastic shell become broken and the maternal circulation become continuous with the intervillous space. Furthermore, at weeks 8 and 9 of gestation, the trophoblastic shell forms plugs within the spiral arteries, allowing only filtered plasma to permeate the placenta.[17] In two-thirds of abnormal pregnancies, the trophoblastic shell is thinner and fragmented, and the trophoblastic invasion of the spiral arteries is reduced or absent.[18]

Vascularization of the placenta occurs at the beginning of the fifth week. Oh et al.[19] showed significant increases in sac size from 5 weeks onward in normal **intrauterine pregnancy** (IUP) versus pregnancy failure. The rationale for placental vascularization was based on early work by Folkman,[20] who showed that tumors can grow to a size of 3 mm being nourished only by diffusion. To exceed this size, cells must recruit host blood vessels, or the cells at the center will receive inadequate nutrition.

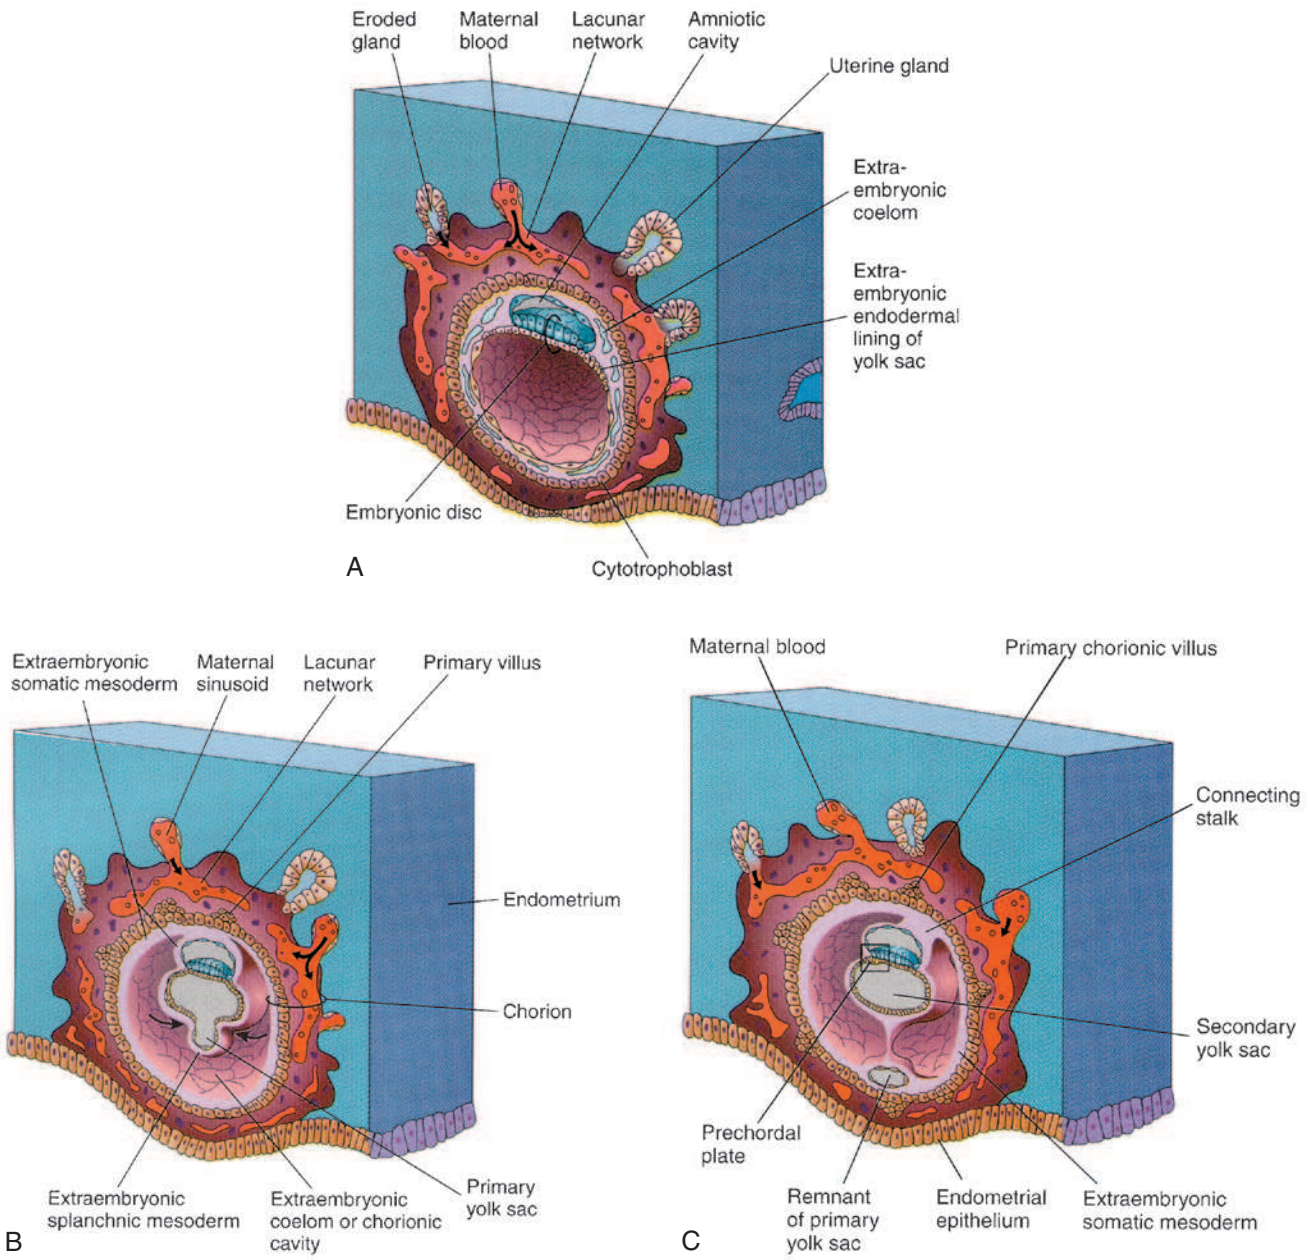

FIG. 30.4 Formation of Secondary Yolk Sac. (A) Approximately 26 days: formation of cavities within extraembryonic mesoderm. These cavities will enlarge to form extraembryonic coelom. **(B)** About 27 days and **(C)** 28 days: formation of secondary yolk sac with extrusion of primary yolk sac. Extraembryonic coelom will become chorionic cavity. (With permission from Moore KL. The developing human: clinically oriented embryology. 10th ed. Philadelphia: Elsevier; 2016.[1])

Similarly, the rapidly growing embryonic implantation must be vascularized by the 3-mm stage that occurs at 5 weeks' gestation.

During the fifth week, the embryo is converted by the process of **gastrulation** from a bilaminar disk to a trilaminar disk with the three primary germ cell layers: ectoderm, mesoderm, and endoderm. During gastrulation, the primitive streak and notochord form. The primitive streak gives rise to the **mesenchyme,** which forms the connective tissue of the embryo and stromal components of all glands.

The formation of the neural plate and its closure to form the neural tube is referred to as **neurulation.** This process begins in the fifth week in the thoracic region and extends caudally and cranially, resulting in complete closure by the end of the sixth week (day 42). Failure of closure of the neural tube results in neural tube defects.

During the fifth week, two cardiac tubes (the primitive heart) develop from splanchnic mesodermal cells. By the end of the fifth week, these tubes begin to pump into a primitive paired vascular system. By the end of the fifth week, a vascular network develops in the chorionic villi that connect through the umbilical arteries and vein to the primitive embryonic vascular network.

Essentially all internal and external structures appear in the adult form during the **embryonic period,** which ends at 10

menstrual weeks. By the end of the sixth week, blood flow is unidirectional, and by the end of the eighth week, the heart attains its definitive form. The peripheral vascular system develops slightly later and is completed by the end of the tenth week. The primitive gut forms during week 6. The midgut herniates into the umbilical cord from week 8 through the end of week 12. The rectum separates from the urogenital sinus by the end of week 8, and the anal membrane perforates by the end of week 10. The **metanephros,** or primitive kidneys, ascend from the pelvis, starting at approximately week 8, but do not reach their adult position until week 11. Limbs are formed with separate fingers and toes. Almost all congenital malformations except abnormalities of the genitalia originate before or during the embryonic period. External genitalia are still in a sexless state at the end of week 10 and do not reach mature fetal form until the end of week 14.

Early in the **fetal period,** body growth is rapid and head growth relatively slower, with the **crown-rump length (CRL)** doubling between weeks 11 and 14.

SONOGRAPHIC APPEARANCE OF NORMAL INTRAUTERINE PREGNANCY

Gestational Sac

Implantation usually occurs in the fundal region of the uterus between day 20 and day 23.[21] In a study of early implantation sites in 21 patients, it was found that implantation occurs most frequently on the uterine wall ipsilateral to the ovulating ovary and least often on the contralateral wall.[21] In addition, in a study of predominant sleeping positions in the peri-implantation period, Magann et al.[22] found that the 33% of women who slept prone were most likely to have a high or fundal implantation than those who slept on their back or side. The latter groups predominantly had implantations corresponding to their resting posture.

At 23 days, the entire conceptus measures approximately 0.1 mm in diameter and cannot be imaged by TAS or TVS techniques. The earliest sonographic sign of an IUP was described by Yeh et al.,[23] who identified a focal echogenic zone of decidual thickening at the site of implantation at about 3½ to 4 weeks of gestational age. This sign is nonspecific and of limited diagnostic value.

The first reliable gray-scale evidence of an IUP is visualization of a small (1-2 mm fluid collection surrounded by an echogenic rim) **gestational sac** within the thickened decidua. Yeh et al.[23] originally identified this sign, referred to as the **intradecidual sign,** which is seen at about 4.5 weeks' gestation. An intradecidual gestational sac should be eccentrically located within the endometrium. It is important to ensure that the sac abuts the endometrial canal to distinguish an intrauterine gestational sac from a **decidual cyst.**

The intradecidual sign was originally described on TAS,[23] with a sensitivity of 92%, specificity 100%, and overall accuracy of 93% for distinguishing between early IUP and ectopic pregnancy. Chiang et al.[24] looked at this sign using TVS and found overall sensitivity of 60% to 68%, specificity of 97% to 100%, and overall accuracy of 67% to 73%, indicating that the sign, when present, is useful for diagnosing an IUP. When absent, it does not reliably exclude an IUP. It is usually possible to demonstrate an early IUP as a small intradecidual sac between 4½ and 5 weeks' gestational age using TVS (Figs. 30.5 and 30.6). Using a high-frequency (7.5-10 MHz) TVS, Oh et al.[19] were able to identify a gestational sac in all 67 patients scanned between 28 and 42 days' gestational age (**mean sac diameter** [MSD] between 28 and 35 days was 2.6 mm).

The **double-decidual sign** (also called double decidual sac sign) was described by Bradley et al.[25] and Nyberg et al.[26] as a method for distinguishing between an early IUP and an endometrial fluid collection of other origin, such as the pseudosac of an ectopic pregnancy. A well-defined double-decidual sign is an accurate predictor of the presence of an IUP. A vague or absent double-decidual sign should be considered nondiagnostic because it does not reliably exclude an IUP.[27]

The endometrium in the pregnant state is called the **decidua capsularis, decidua vera,** and **decidua basalis.** The double-decidual sign is based on visualization of the gestational sac as an echogenic ring formed by the decidua capsularis and chorion laeve eccentrically located within the decidua vera (Fig. 30.6), forming two echogenic rings. The outer ring is formed by the echogenic endometrium of the lining of the uterus. The **decidua basalis–chorion frondosum** (future placenta) may also be visualized as an area of eccentric echogenic thickening. The double-decidual sign was initially described, and is considered most useful, on TAS. It can usually be identified by about 5.5 to 6 weeks' gestational age and is useful in establishing an intrauterine gestation prior to TAS ability to visualize the yolk sac. It is almost always resolvable by the time the gestational sac reaches 10 mm, at which point the yolk sac is typically visible by TVS, thus diminishing the usefulness of this finding.[28]

Parvey et al.[29] found a double-decidual sign in only 53% of early pregnancies with no yolk sac or embryo present. They also assessed visualization of the echogenic chorionic rim alone as a sign of IUP and found its presence in 64% of cases. It was more clearly defined in later pregnancies with a higher β-hCG level (mean, 16,082 mIU/mL) and thin, less clearly defined, or even absent in the earliest pregnancies. Using a higher-frequency 10-MHz transvaginal transducer to scan patients who had a positive pregnancy test and only a small (<1 cm) intrauterine "fluid collection" seen with a 6- to 7-MHz transducer, Benacerraf et al.[9] were able to improve their diagnostic confidence in eight patients with an IUP. This demonstrates the need to scan TVS with a high-frequency transducer when an early pregnancy is in question. Even with use of modern TVS equipment, the double-decidual sign is absent in at least 35% of intrauterine gestational sacs.[30]

The **normal gestational sac** is round in the very early stages and implants immediately beneath the thin, echogenic endometrial stripe (see Fig. 30.5). As it enlarges, the sac often has a somewhat oval shape because of the pressure exerted by the muscular uterine walls (Fig. 30.7). It can be distorted during TVS by compressing the uterus with the vaginal probe. The gestational (or chorionic) sac is filled with extracoelomic or **chorionic sac fluid,** which is normally weakly reflective and more echogenic than the amniotic

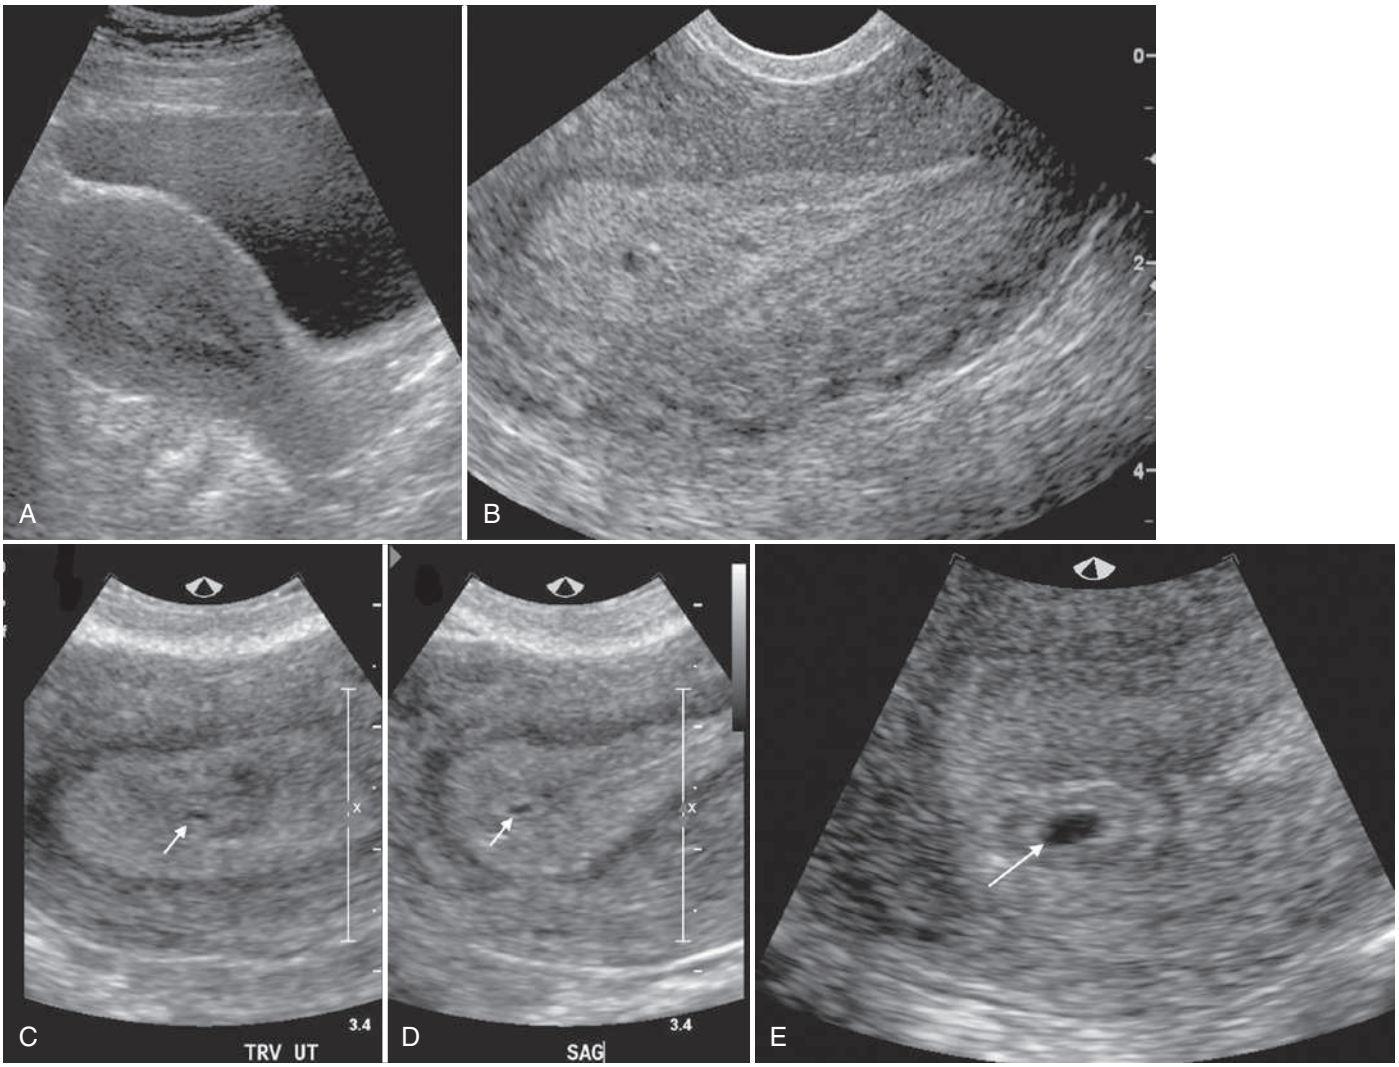

FIG. 30.5 Intradecidual Sac Sign at 32 Days. (A) TAS fails to show the gestational sac. **(B)** TVS shows the echogenic ring of the sac implanted just below the endometrial stripe. In another woman **(C)** transverse and **(D)** sagittal TVS show an early gestational sac *(arrow)*. The sac *(arrow)* slightly displaces the endometrial stripe posteriorly and has a slightly echogenic rim, seen best on **(E)** high-resolution image.

fluid. This difference is best appreciated if the system gain is increased. The low-level echoes within the chorionic fluid are accentuated, and yet the amniotic fluid remains echo free[31] (Fig. 30.8). The low-level echoes are likely caused by the relatively thick proteinaceous material in chorionic fluid.[32]

Some researchers have investigated using **color flow Doppler sonography** to help identify the presence of an early IUP. Emerson et al.[33] found that the detection of peritrophoblastic flow of high velocity and low impedance increased the sensitivity of detection of IUP from 90% to 99%. Parvey et al.[29] found this flow pattern in only 15% of IUPs without a visible yolk sac or embryo. They considered that combining the Doppler findings with the sonographic identification of inner chorionic rim would yield a high sensitivity and specificity of over 90%. However, this exposes the early **IUP** to the increased power deposition of Doppler scanning (see Chapter 29). Therefore Doppler should not be routinely performed when assessing the early IUP.[34] However, when scanning in the adnexal region, use of Doppler and associated power deposition is not a concern, because the first-trimester pregnancy (if ectopic) is nonviable (and because any IUP would be out of the field of insonation).

β-hCG and Early Pregnancy Ultrasound

Serum hCG levels perform an important complementary role with ultrasound in the evaluation of early pregnancy. Levels using the serum beta subunit of human chorionic gonadotropin **(β-hCG)** provide a reproducible value that can help guide management in clinical practice.

A negative serum β-hCG level excludes pregnancy in a young woman with pain or bleeding. The serum β-hCG test yields positive results at approximately 23 days of gestational age,[35] before a normal intrauterine gestational sac may be imaged with TVS. A disproportionately lower than expected β-hCG level is an indicator of a poor prognosis.[36] The World Health Organization (WHO) has issued several sets of standards for β-hCG, calibrated in International Units (IU). Over the years, β-hCG levels have

been measured using the first International Reference Preparation (IRP), the Second International Standard (IS), the Third IS, and the Fourth IS. The Second IS produces values that are approximately half that of the First IRP and Third and Fourth IS. The WHO recommends that the Third and Fourth IS should be used for calibration of immunoassays.[37]

In a literature review, Nyberg and Filly[6] noted the importance of the appropriate use of a threshold level and a discriminatory level of β-hCG for the appearance of a gestational sac. The **threshold level** identifies the earliest one can expect to see a sac, and the **discriminatory level** identifies when one should always see the sac. Although the menstrual history provides useful information early in a woman's obstetric care, because of the variability in the timing of ovulation and the unreliability of menstrual history, discriminatory levels based on history are of limited clinical use.

A gestational sac can often be visualized sonographically at low serum β-hCG levels. As TVS has improved, threshold values

FIG. 30.6 Double-Decidual Sign. have dropped to as low as 390 mIU/mL.[38] Extensive efforts have been made to identify a discriminatory level for the serum β-hCG, defined as the level of serum β-hCG above which sonographers should always visualize an intrauterine sac on ultrasound to be considered normal. Work by Barnhart indicated that this level, using TVS, should be set at 1000 to 2000 mIU/mL.[38-40] However, additional studies have shown that a single value of β-hCG is of limited value. Mehta at el.[41] showed that although the absence of a visible sac at a β-hCG level of 2000 mIU/mL is suggestive of an abnormal outcome, it is not diagnostic, as 33% (17 of 51 in her series) of such early pregnancies went on to have normal outcomes.

Discriminatory levels can be used to guide management but cannot be used as absolute indicators that the absence of a sonographically demonstrable gestation sac is abnormal. Serial β-hCG measurements are usually more helpful than a single measurement in identifying abnormal from normal pregnancy, and ultrasound can document important diagnostic features regardless of the exact β-hCG value.[5]

Barriers to Use of Strict β-hCG Thresholds in Determination of Pregnancy

Resolution of the ultrasound scanner
Patient body habitus
Position of the uterus
Type of hormonal assay
Experience of the sonographer
Masses such as fibroids
Multiple gestations

Yolk Sac

At 4 weeks' menstrual age, the primary yolk sac begins to regress and the secondary yolk sac develops. The secondary yolk sac is the first structure to be seen normally within the gestational sac. Using TAS, it is often seen when the MSD is 10 to 15 mm and should typically be visualized by an MSD of 20 mm.[42] TVS allows earlier and more detailed visualization of the yolk sac (Figs. 30.6 and 30.9), which is typically visualized by an MSD of 8 mm.[28] However, the visualization of a yolk sac without an embryonic pole occurs only for a brief period of time. In patients being scanned for pregnancy of unknown viability, the MSD of 25 is used as the threshold, with need to visualize an embryo at this time.

The demonstration of a yolk sac may be critical in differentiating an early intrauterine gestational sac from a pseudosac.[28] Although the double-decidual sign is not 100% specific for presence of an IUP, the identification of a yolk sac within the early gestational sac is diagnostic of IUP. The yolk sac plays an important role in human embryonic development.[10] While the placental circulation is developing, the yolk sac plays a role in **transfer of nutrients** to the developing embryo in the third and fourth weeks. **Angiogenesis** occurs in the wall of the yolk sac in the fifth week. The mesenchymal cells or angioblasts aggregate to form "blood islands"; a cavity forms within these islands, which fuse with others to form networks of endothelial channels. Vessels extend into adjacent areas by endothelial budding and fusion with other vessels. This vascular network in the wall of the yolk sac eventually joins the embryonic circulation via the paired **vitelline arteries and veins** through a stalk called the **vitelline duct. Hematopoiesis** occurs first in the well-vascularized extraembryonic mesoderm covering the yolk sac wall in the fifth week, in the liver in the eighth week, and later in the spleen, bone marrow, and lymph nodes. The dorsal part of the yolk sac is incorporated into the embryo as **primitive gut** (foregut, midgut, and hindgut) in the sixth week. The yolk sac remains connected to the midgut by the vitelline duct (Fig. 30.10).

Lindsay et al.[43] reported that the yolk sac grows at a rate of 0.1 mm per millimeter of MSD growth when the MSD is less than 15 mm, then slows to 0.03 mm. The upper limit of normal for yolk sac diameter between 5 and 10 weeks of gestational age is 5.6 mm.

The number of yolk sacs present can be helpful in determining **amnionicity** of a multifetal pregnancy (Fig. 30.11). In general, the number of yolk sacs and the number of amniotic sacs are the same. In a **monochorionic monoamniotic** (MCMA) twin gestation, there will be two embryos, one chorionic sac, one amniotic sac, and one yolk sac. Levi et al.[44] examined four MCMA twin pregnancies, all with a single yolk sac. One was a conjoined twin and one a twin ectopic, with both pregnancies terminated. The other two pregnancies delivered normally at 34 weeks. Of the four cases, two had a larger-than-normal yolk sac (>5.6 mm), and one yolk sac was irregular in contour. Therefore in MCMA twins, a single, large, or normal-sized yolk sac with two live embryos can result in a normal twin delivery.

Embryo and Amnion

Visualization of the amnion in the absence of an embryo usually occurs in intrauterine embryonic death as a result of resorption of the embryo[45] (Fig. 30.12).

Amniotic fluid is a colorless, fetal dermal transudate; as the skin cornifies and the kidneys begin to function, at about 11 weeks, it becomes pale yellow. The amnion becomes visible when the embryo has a CRL of 2 mm at 6 weeks. The cavity becomes almost spherical by about 7 weeks, likely a result of the more rapid increase in fluid volume relative to the growth of the sac membrane to accommodate it. The actual rate of fluid increase is more rapid after about 9 weeks (Fig. 30.13), when urine is produced. Fluid accumulates at about 5 mL per day at 12 weeks. The amniotic cavity expands to fill the chorionic cavity completely by week 16. It is therefore normal to identify the amnion as a separate membrane or sac within the chorionic cavity before 16 weeks (Fig. 30.14). Occasionally, the amnion and chorionic membranes may fail to be juxtaposed at week 16 (so-called **unfused amnion**), and separation of these membranes may persist for a short time.[46]

Iatrogenic or spontaneous rupture of the amniotic membrane in the first trimester is a rare occurrence and even more rarely results in the **amniotic band sequence.** This rupture may result in retraction of the amnion in part or in whole, up to the base of the umbilical cord where the amnion and chorion are adherent. More often, the floating amniotic membranes do not adhere to the fetus, and no fetal anomalies occur.

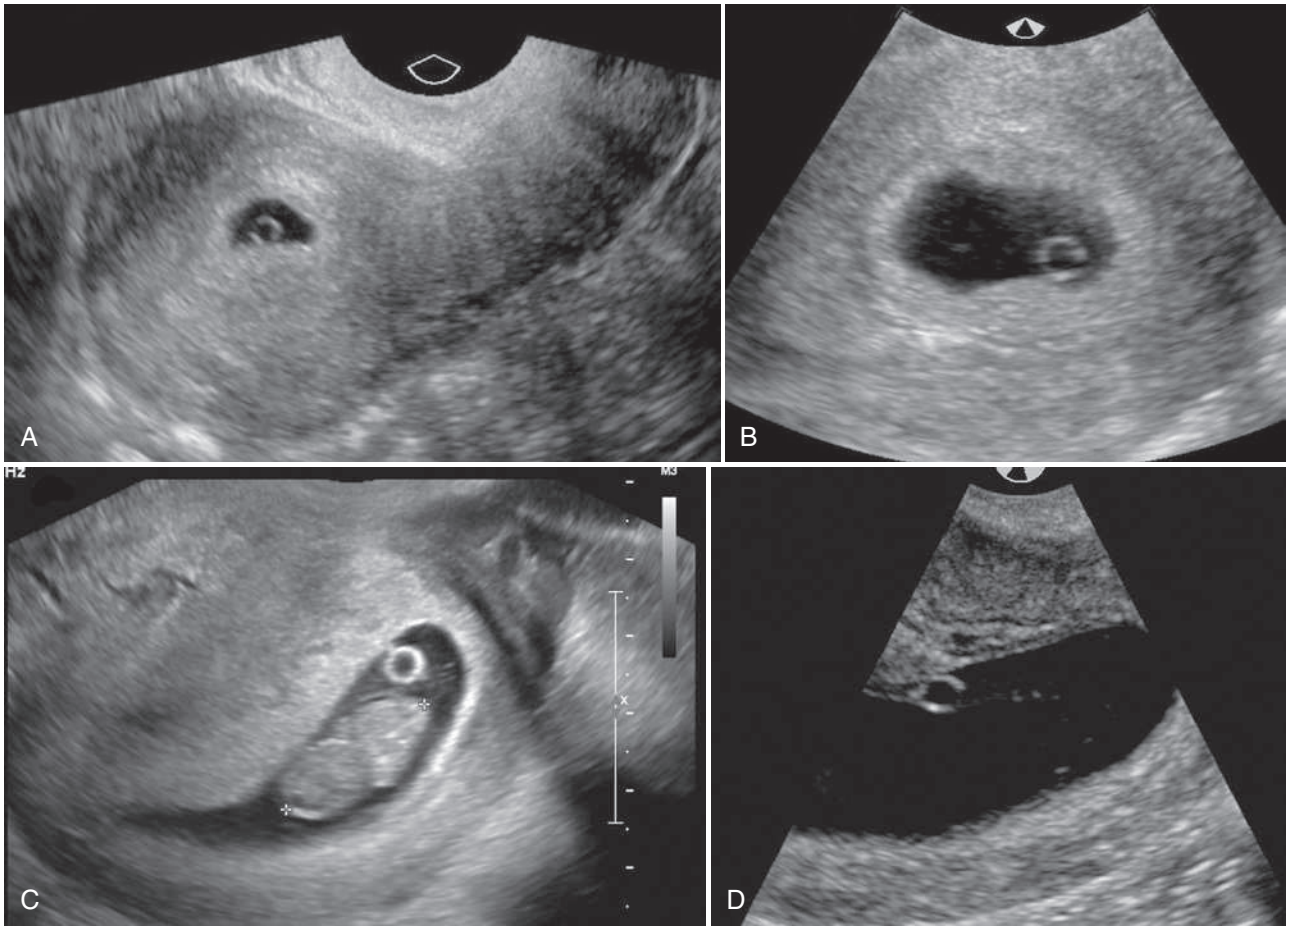

FIG. 30.9 Normal Yolk Sac. (A) Sagittal and **(B)** transverse TVS of the early IUP demonstrates the yolk sac at 5 weeks 5 days. **(C)** Yolk sac is seen separate from embryo *(calipers)* at 9 weeks. **(D)** At 11 weeks, yolk sac lies at edge of chorionic sac outside of early amnion.

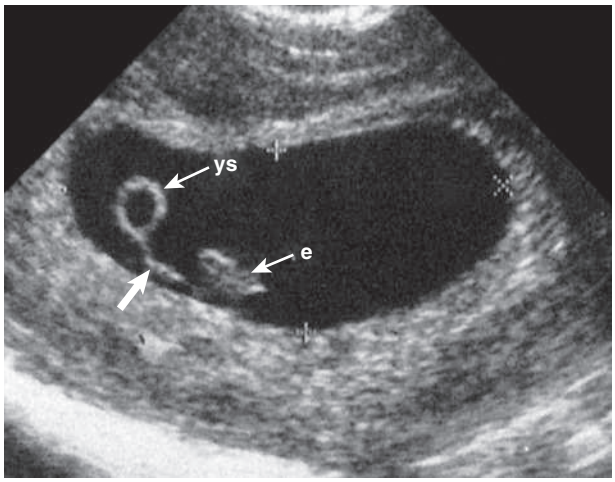

FIG. 30.10 Normal Embryo at 8 Weeks. TVS shows vitelline duct *(thick arrow),* yolk sac *(ys),* and embryo *(e).*

FIG. 30.11 Early Monochorionic Diamniotic (MCDA) Twins. Two separate yolk sacs are seen within a single chorion at 5 weeks 5 days. It is too early to visualize the two amnions.

Embryonic Cardiac Activity

Using TVS, an embryo with a CRL as small as 1 to 2 mm may be identified immediately adjacent to the yolk sac (Fig. 30.15). In normal pregnancies the embryo can be identified in gestational sacs as small as 10 mm and should always be identified when the MSD is equal to or greater than 25 mm with optimal scanning parameters and high-resolution TVS.[4,5]

Embryologic data suggest the tubular heart begins to beat at 36 to 37 days' gestational age.[10] Cadkin and McAlpin[47] described cardiac activity adjacent to the yolk sac before the embryo can

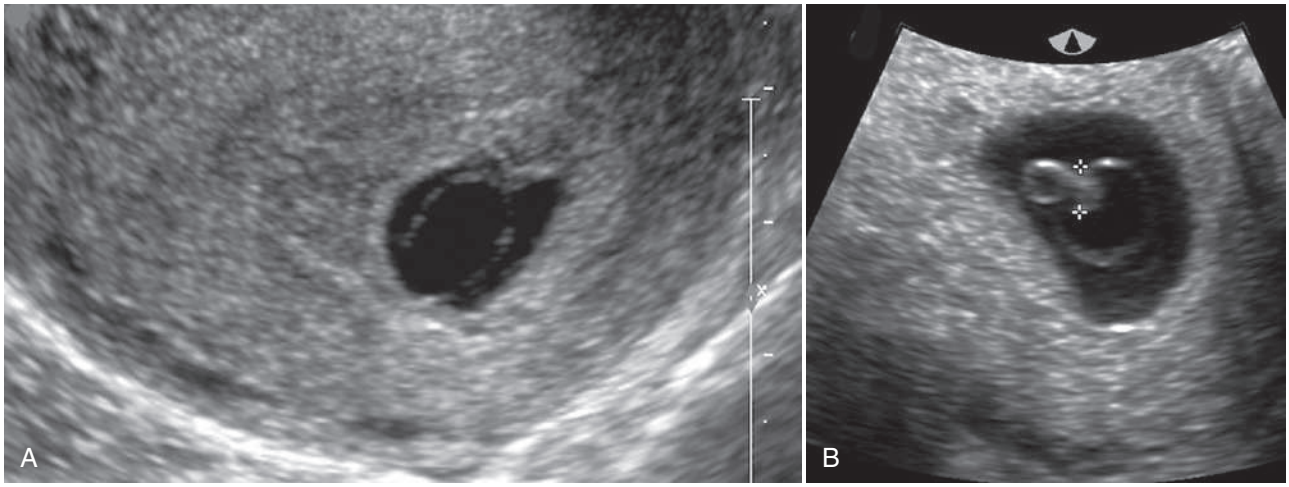

FIG. 30.12 Abnormal Amnion. (A) TVS at 9 weeks demonstrates an **empty amnion** within the gestational sac. This pregnancy eventually failed. **(B) Expanded amnion** at 7 weeks. Note how the amnion is much larger than would be expected for an embryo *(calipers)* of this size. This pregnancy did not progress.

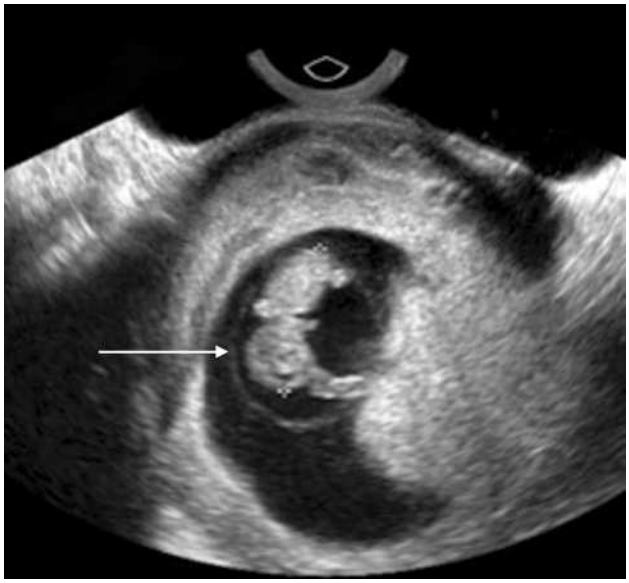

FIG. 30.13 Normal 9-Week 4-Day Gestation. TVS shows the embryo *(calipers)* and the amnion *(arrow)* separate from the surrounding chorion.

be fully visualized at the end of the fifth week. Ragavendra et al.[48] placed a 12.5-MHz endoluminal catheter transducer into the endometrial canal adjacent to the gestational sac. They identified cardiac activity in an embryo with a CRL of 1.5 mm and resolved the two walls of the heart, seen only as a tube. Using TVS, cardiac activity is typically seen by the time an embryo is 2 mm in size, and is almost always seen by 5-mm CRL. However, for strict diagnosis of nonviable pregnancy the threshold is set at 7 mm CRL.[4,5] Normal embryonic cardiac activity is greater than 100 beats per minute (bpm) (Video 30.1) when the embryo is less than 6.3 weeks and 120 bpm at or beyond 6.3 weeks.[49] When embryonic cardiac activity is visualized and the rate is less than 100 bpm, then follow-up should be obtained. We have seen pregnancies with small embryos of 1–2 mm in size with heart rates of 80–99 bpm with normal follow-up (see Fig. 30.15).

Umbilical Cord and Cord Cyst

The umbilical cord is formed at the end of the sixth week (CRL = 4.0 mm) as the amnion expands and envelops the connecting stalk, the yolk stalk, and the allantois. The cord contains two umbilical arteries, a single umbilical vein, the allantois, and yolk stalk (also called the **omphalomesenteric duct** or **vitelline duct**), all of which are embedded in **Wharton jelly.** The **umbilical arteries** arise from the internal iliac arteries and in the newborn become the superior vesical arteries and the medial umbilical ligaments. The **umbilical vein** carries oxygenated blood from the placenta to the fetus. The oxygenated blood is shunted through the ductus venosus into the inferior vena cava and the heart. The single left umbilical vein in the newborn becomes the ligamentum teres, which attaches to the left branch of the portal vein. The ductus venosus becomes the ligamentum venosum.

The **allantois** is associated with bladder development and becomes the urachus and the median umbilical ligament. It extends into the proximal portion of the umbilical cord. The **yolk stalk** connects the primitive gut to the yolk sac. The paired **vitelline arteries and veins** accompany the stalk to provide blood supply to the yolk sac. The arteries arise from the dorsal aorta to supply initially the yolk sac, then the primitive gut. The arteries remain as the celiac axis, superior and inferior mesenteric arteries supplying the foregut, midgut, and hindgut, respectively. The vitelline veins drain directly into the sinus venosus of the heart. The right vein is later incorporated into the right hepatic vein. The portal vein is also formed by an anastomotic network of vitelline veins.

The length of the umbilical cord has a close linear relationship with gestational age in normal pregnancies. Hill et al.[50] found they could reliably measure the cord lengths in 53 embryos at 6 to 11 weeks' gestational age. Also, the cord lengths in 60% of dead embryos were more than two standard deviations (2 SD) below the value for that expected gestational age.

The width of the umbilical cord has also been measured sonographically, and Ghezzi et al.[51] found a steady increase from 8 to 15 weeks. There was a significant correlation between cord

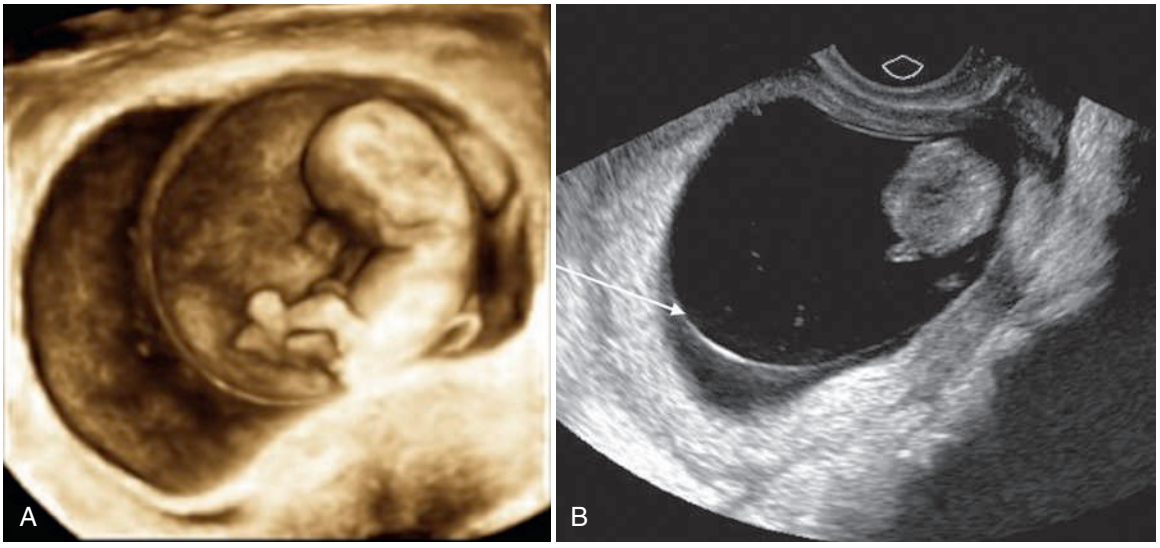

FIG. 30.14 Normal 12-Week Gestation. (A) Surface rendering image from three-dimensional TVS shows the embryo within the amnion. **(B)** Two-dimensional TVS shows the amnion *(arrow)* approaching, but not fused with, the chorionic sac.

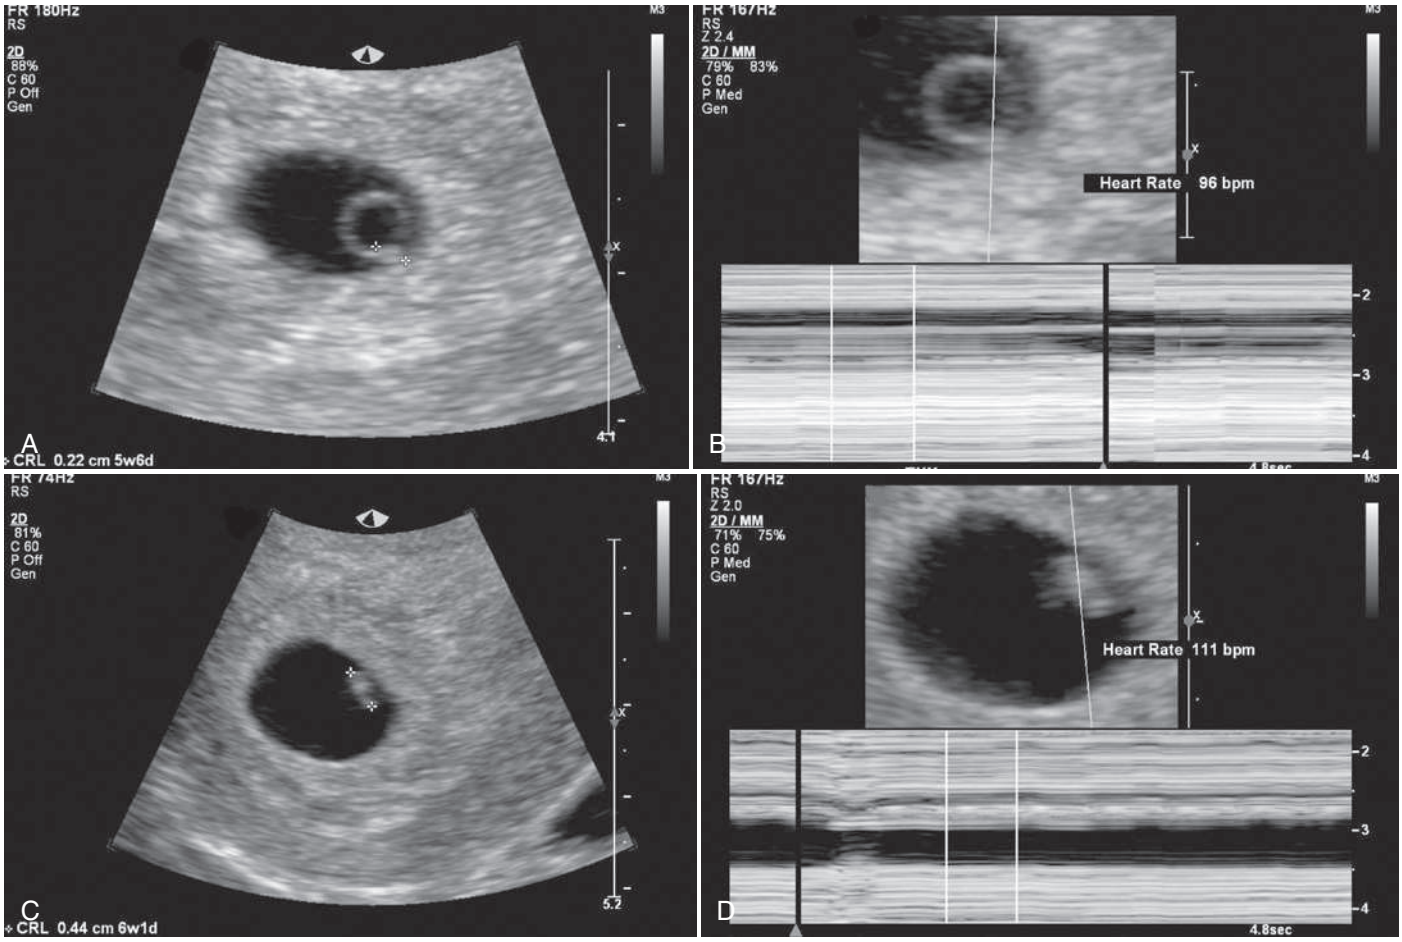

FIG. 30.15 Normal Embryo With Early Cardiac Activity. (A) Image shows 5-week 6-day embryo *(calipers)* adjacent to the yolk sac. **(B)** M-mode ultrasound shows a heart rate of 96 beats/min. **(C)** Two days later, the embryonic pole *(calipers)* has grown and **(D)** the heart rate has increased to 111 beats/min. See also Video 30.1.

diameter and gestational age ($r = 0.78$; $P < .001$), CRL ($r = 0.75$; $P < .001$), and biparietal diameter ($r = 0.81$; $P < .001$) but no correlation with birth weight or placental weight. The cord diameter was significantly smaller by at least 2 SD in patients who developed preeclampsia or had a miscarriage.

Cysts and pseudocysts within the cord have been described in the first trimester.[52] Cysts are usually seen in the eighth week and usually resolve by the 12th week. They are singular, closer to the embryo/fetus than the placenta, with a mean size of 5.2 mm (Fig. 30.16). Cysts may originate from remnants of the allantois or omphalomesenteric duct and characteristically have an epithelial lining.[53] It is hypothesized that the cyst is an **amnion inclusion cyst** that occurs as the amnion was enveloping the umbilical cord. In a series of 1159 consecutive patients scanned between 7 and 14 weeks, Ghezzi et al.[54] found 24 cord cysts at a prevalence of 2.1%. Single cysts in the first trimester were associated with a normal outcome and a healthy infant, whereas multiple or complex cysts were associated with an increased risk of miscarriage or aneuploidy. Thus although umbilical cord cysts have been associated with chromosomal abnormalities if seen in the second and third trimesters, those seen in the first trimester typically resolve and are not associated with poor outcome.

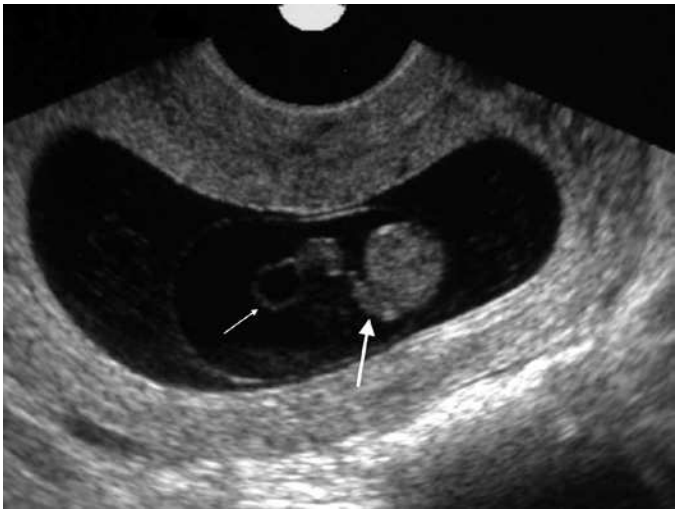

FIG. 30.16 Umbilical Cord Cyst at 10 Weeks. TVS shows a cyst *(small arrow)* arising from the cord *(large arrow)*. On subsequent examination (not shown) the cyst was no longer seen.

ESTIMATION OF GESTATIONAL AGE

During the first trimester, gestational age can be estimated sonographically with greater accuracy than at any other stage of pregnancy. As pregnancy progresses, biologic variation results in wider variation around the mean for all sonographic parameters at a given gestational age.

Gestational Sac Size

The MSD offers an opportunity to date an early pregnancy before the embryo can be visualized. The MSD is an average of the diameter of the sac, obtained by adding the anteroposterior and craniocaudad diameters on the sagittal view of the uterus to the transverse diameter obtained on the transverse view and dividing by three (Fig. 30.17). The gestational age can be predicted by MSD using the following formula: menstrual age in days = MSD in mm + 30.[55] The MSD increases in size at a rate of 1.1 mm per day.[56] If MSD is very small, about 2 mm, gestational age is 4 to 4½ weeks, and MSD of about 5 mm is 5 weeks. At 5½ weeks, a yolk sac appears (see Fig. 30.9A and B). At 6 weeks, an embryo first appears adjacent to the yolk sac (see Fig. 30.15A). When the embryo is first seen, cardiac activity is appreciated as a consistent flicker[40] (Fig. 30.15B and Video 30.1).

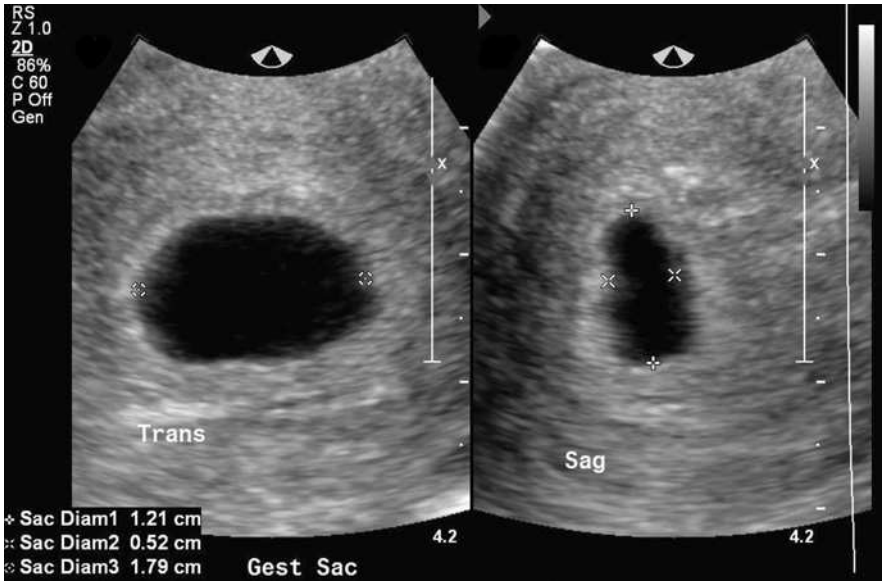

FIG. 30.17 Gestational Age Established by Mean Sac Diameter (MSD). Gestational age can be estimated measuring the sac in three dimensions. Average of three measurements is used to correlate with gestational age prior to visualization of the embryonic pole. MSD of 12 mm is consistent with gestational age of 6 weeks 0 days. However, these data are not used to formally establish pregnancy dating. Sonographic dating of the pregnancy is done with the crown-rump length when cardiac activity is present.

Crown-Rump Length

Once the embryonic pole is visualized (just before 6 weeks), measurement of the CRL of the embryo is considered the most accurate method to date the pregnancy.[57,58]

EARLY PREGNANCY FAILURE

One of the most important roles of ultrasound in the first trimester is to identify early pregnancies that have failed or that are more likely to fail. Studies have demonstrated a 20% to 31% rate of early pregnancy loss after implantation in normal healthy volunteers.[59,60] Many pregnancies abort before the pregnancy is confirmed by either ultrasound or a chemical pregnancy test. Approximately 50% of miscarriage is caused by chromosomal abnormalities.[61] Early pathologic studies of Hertig and Rock,[60] also showed a high frequency of morphologic abnormalities in preimplantation embryos. Loss rates are increased with increased maternal age and prior history of early pregnancy failure.[62]

Although the etiology of first-trimester pregnancy loss is still not fully understood, there are many known and suspected causes. In a study of 232 first-trimester patients (normal, healthy women, positive urinary pregnancy test, and no vaginal bleeding) with TVS at the first visit, Goldstein[57] determined the incidence of subsequent pregnancy loss by following all to delivery or spontaneous abortion. This group had an overall pregnancy loss rate of 11.5% in the embryonic period, (i.e., <70 days from last menstrual period). The loss rate diminished as the pregnancy progressed. The loss rate was 8.5% when a yolk sac was seen, 7.2% with an embryo of CRL less than 5 mm, 3.3% with CRL 6 to 10 mm, and 0.5% with CRL greater than 10 mm. The loss rate leveled off at 2% from 14 to 20 weeks. Therefore under the best circumstances, the pregnancy loss rate will be 11.5% overall, from 5 weeks onward. Once the embryo reaches a CRL of 10 mm, there is about a 98% chance of a successful outcome. Westin et al. confirmed that after 12 weeks menstrual age, the miscarriage rate decreases to 0.5% in low-risk women.[63]

A patient who is in the process of a spontaneous abortion will often present with brownish spotting, a decrease in the symptoms of pregnancy (breast tenderness, nausea), and on examination, a uterus smaller than expected. The latter sign is subjective and not reliable in early gestation. Bleeding is a common complication in early pregnancy, affecting approximately 25% of women with documented pregnancies.[42] Women who present with bleeding have a much higher incidence of pregnancy loss. In women who present with a closed cervical os and uterine bleeding in the first trimester, 50% will eventually abort. Using TVS, Falco et al.[64] studied 270 patients with first-trimester bleeding at 5 to 12 weeks' gestation; 45% were diagnosed initially as a nonviable pregnancy or empty gestational sac. Of the remaining singletons with demonstrable fetal cardiac activity, 15% (23/149) subsequently aborted. In a later prospective study of 50 patients with MSD of 16 mm or less, no embryo, and first-trimester bleeding, Falco et al.[65] found that 64% eventually miscarried; 13/18 (72%) of those who continued to delivery had a yolk sac seen; and 13/32 (40%) went on to fail even though a yolk sac was present. Advanced maternal age (>35) and low serum β-hCG (<1200 mIU/mL IRP) were associated with increased risk of pregnancy failure.

Table 30.1 summarizes the rate of spontaneous abortion in women with and without bleeding in early pregnancy.[57,64,66,67]

One theorized cause of early pregnancy failure is chromosomal anomaly in the early embryo. Sorokin et al.[68] performed chorionic villous sampling in 795 first-trimester pregnancies and found that 35 had a nonviable pregnancy before the procedure; 19 of the 35 women had subsequent chorionic villous sampling, and all were aneuploid. Ten cases had chromosomal abnormalities, virtually always lethal in the embryonic period, and nine had defects with moderate potential for viability. Gestations with low viability potential had a larger discrepancy (23.4 ± 8.3 days) in estimated minus observed gestational age, which was significantly greater than that of gestations with moderate viability potential (8.9 ± 4.3 days; $P < .001$). The absence of an embryonic pole was more common in the first group. This demonstrates that the more severe the anomaly is, the more likely that very early embryonic demise or **intrauterine growth restriction** will occur.

Another cause of early pregnancy failure is **luteal phase defect,** thought to be failure of the corpus luteum to support the conceptus adequately once implantation has occurred. This may result from a shortened luteal phase in cases of ovulation induction and *in vitro* fertilization (IVF), or from luteal dysfunction, more frequently seen in obese women or women older than 37 years of age.[69] Luteal phase defect has been defined as a delay of more than 2 days in histologic development of the endometrium relative to the day of the cycle. The underlying cause may be decreased hormone production by the corpus luteum, decreased levels of

TABLE 30.1 Rate of Spontaneous Abortion in Early Pregnancy

Study	Age (Wk)	Number	Indication	Abortion Rate (%)
Goldstein[57]	5-10	232	Routine	11.5
Pandya et al.[66]	10-13	17,870	Routine	2.8
Stabile et al.[67]	5-16	624	Bleeding	45
Falco et al.[64]	5-12	270	Bleeding	51.5
Falco et al.[64]	5-12	149	Bleeding + live embryo/fetus	15
Pandya et al.[66]	10-13	17,870	Bleeding	15.6

FSH or LH or abnormal patterns of secretion, or a decreased response of the endometrium to progesterone.

Angiogenesis of the corpus luteum may be needed for the regulation of progesterone production. Kupesic et al.[70] found that the resistive index (RI) in intraovarian arteries in normal nongravid women dropped below 0.47 in the luteal phase compared to a group with luteal phase defect who had a high resistance throughout the menstrual cycle, with RI always above 0.50. They suggest that Doppler sonography may predict functional capacity of the corpus luteum, at least in the nongravid state. Blumenfeld and Ruach[69] were successful in treating luteal phase defect in a group undergoing ovulation induction and in patients with previous abortions, using hCG administration twice weekly in the sixth and tenth weeks. This reduced the rate of miscarriage from 49% to 17.8% ($P < .01$).

Currently, as medical management for a failed pregnancy may include intervention with misoprostol that may harm a potentially viable pregnancy, a false positive diagnosis of early pregnancy failure can lead to negative consequences. This has led to a philosophy espoused by the Society of Radiologists in Ultrasound of using conservative criteria on ultrasound for early pregnancy failure that would eliminate a false positive result.[5,27] Early pregnancy failure may not always be able to be diagnosed or excluded on the basis of a single ultrasound, and follow-up studies may be necessary for conclusive diagnosis.

Diagnostic Findings of Early Pregnancy Failure

Diagnostic Findings of Early Pregnancy Failure

CRL of 7 mm without a heartbeat
MSD of 25 mm without an embryonic pole

Crown-Rump Length 7 mm or Greater and No Heartbeat

In patients with a sonographically demonstrable embryo, no cardiac activity is one of the most important factors in predicting pregnancy outcome. The absence of cardiac activity does not necessarily indicate embryonic demise, however, because TVS can identify a normal, very early embryo without cardiac activity.

Many studies have demonstrated that cardiac activity is expected when CRL is greater than 5 mm. Levi et al.[3] reviewed a series of 96 patients with CRL of less than 5 mm to assess the predictive value of the presence or absence of cardiac activity using TVS. Of 71 patients available for follow-up, 46 embryos had cardiac activity, 35 progressed to at least the late second trimester, and 11 ended as first-trimester demise. Of the 25 embryos without demonstrable cardiac activity, 5 (20%) were normal and 20 (80%) ended as first-trimester embryonic deaths. Of the five normal embryos without demonstrable cardiac activity on initial TVS, three had initial CRL of less than 1.9 mm. Standard embryology texts indicate that the embryonic heart begins to beat at the beginning of the sixth week, when the CRL is 1.5 to 3 mm. Thus it is not surprising that cardiac activity may or may not be identified in normal embryos with CRL less than 2 mm. In the study by Levi et al., initial TVS assessment failed to identify cardiac activity in 2 of 25 normal embryos with CRL of 2 to 4 mm. TVS enabled correct identification of cardiac activity in 100% of normal embryos with CRL of 4 to 4.9 mm.[3] Pennell et al.[71] found that 16 of 18 embryos with CRL less than 5 mm had no cardiac activity on initial TVS assessment but demonstrated cardiac activity on follow-up TVS. Cardiac motion was seen on TVS in all pregnancies with CRL greater than 5 mm.

The combination of vaginal bleeding and absent cardiac activity in embryos of CRL less than 5 mm on TVS is associated with a very poor prognosis. Aziz et al.[72] reviewed outcomes in embryos of CRL of 5 mm or less with absent cardiac activity on TVS, in women presenting with vaginal bleeding; all resulted in pregnancy failure.

Before making a diagnosis of embryonic demise, it is critical to ensure that the examination is of high quality, performed with modern equipment and an appropriate transducer frequency, and that the entire embryo is visualized. A high frame rate must be used, and the frame-averaging mode must be turned off. If there is any doubt in the diagnosis, follow-up examination should be performed. There is interobserver variability in measurement, even by experienced sonographers. In a prospective cross-sectional study on 1060 women, Abdullah et al. demonstrated that changing the CRL cutoff to greater than 7 mm would minimize the risk of a false positive diagnosis of miscarriage. A generous cutoff ensures that a desired pregnancy would not be mistakenly terminated by the administration of medication for chemical miscarriage or dilation and curettage to remove products of conception[4,5] (Fig. 30.18, Video 30.2). It is also imperative that transmitted maternal pulsations are not mistaken for embryonic cardiac pulsations, especially when evaluating a static M-mode image to verify embryonic cardiac activity (Figs. 30.18B and 30.19).

Gestational Sac Mean Sac Diameter 25 mm or Greater and No Embryo

In many patients the embryo is not visualized on the initial sonogram, and the diagnosis of pregnancy failure cannot be made on the basis of lack of cardiac activity. In these patients the diagnosis of pregnancy failure may be made based on gestational sac characteristics. The most reliable indicator of abnormal outcome based on gestational sac features is **abnormal size.**[2,42]

Using TVS, an MSD of 8 mm or more without a demonstrable yolk sac, or 16 mm with no demonstrable embryo, are not typical and are suggestive of pregnancy failure.[5,43] However, recent studies have documented gestational sacs up to 21 mm with initially no visible embryos that went on to be viable pregnancies.[4] Most authors allow a few millimeters of leeway in MSD measurements as a margin of error, and many do not use the absent yolk sac as a sign of pregnancy failure. This is partly due to interobserver variability in measurements. Given these variables, the Society of Radiologists in Ultrasound recently advocated diagnosing early pregnancy failure by gestational sac size only for sacs with MSD of 25 mm or greater with no embryo[5] (Fig. 30.20).

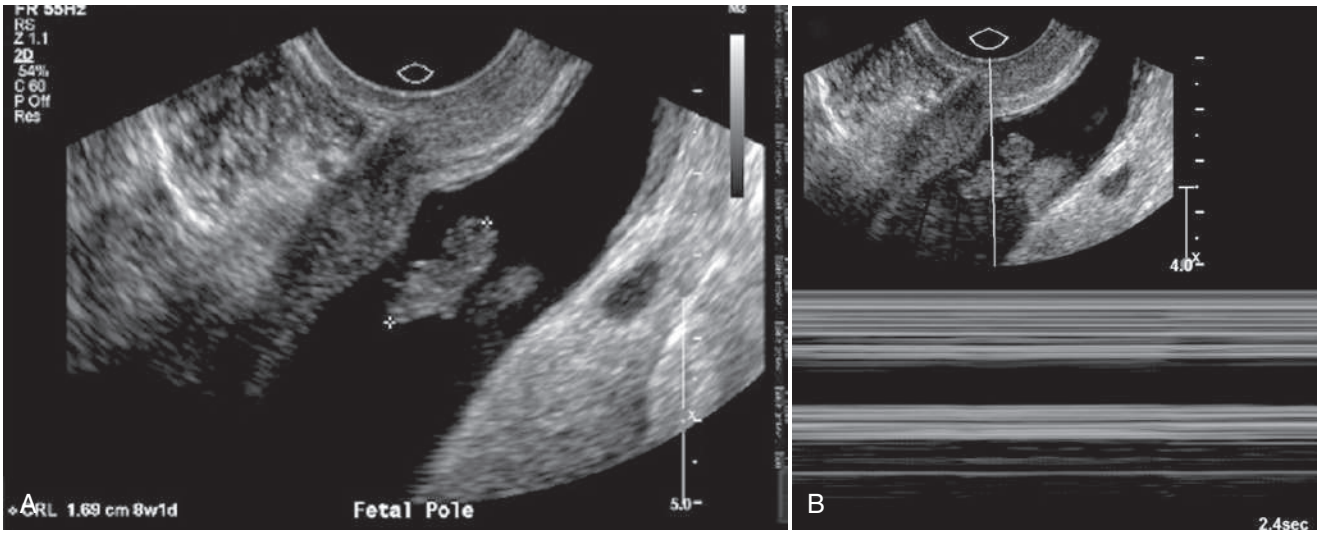

FIG. 30.18 Ultrasound Findings Diagnostic of Early Pregnancy Failure. (A) TVS shows an embryo *(calipers)* measuring larger than 7 mm without cardiac activity. **(B)** M-Mode confirms no fetal cardiac activity. See also Video 30.2.

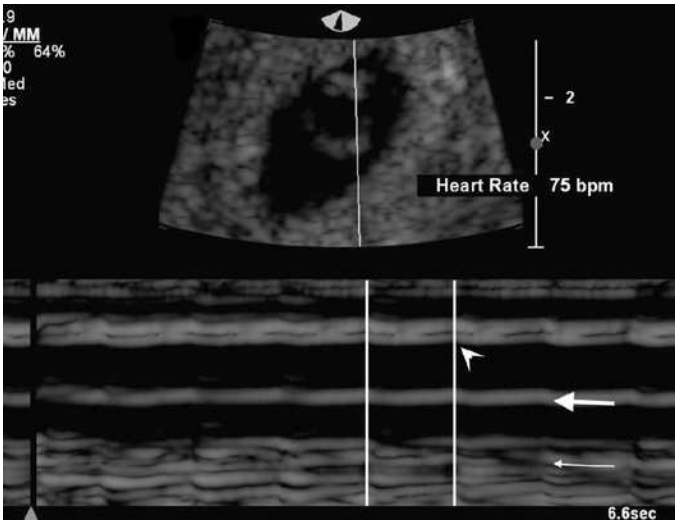

FIG. 30.19 M-Mode Documenting Transmitted Maternal Uterine Arterial Pulsations Mistaken for Fetal Cardiac Pulsations. Maternal uterine pulsations *(small arrow)* are transmitted to the inferior portion of the yolk sac *(large arrow)* and embryo *(arrowhead)* and mistakenly measured as a slow embryonic cardiac activity at 75 beats/min. Key to transmitted pulsation is noting the same rate throughout the different depths of tissue insonated.

Furthermore, these parameters only apply to high-resolution TVS and cannot be used for examinations performed with a 5-MHz TVS probe. Rowling et al.[73] studied early pregnancies with lower-frequency TVS probes (5 MHz) as well as higher-frequency probes (9-5 MHz broadband). The gestational sac was first seen at 6.4 mm in size with the lower frequency but at 4.6 mm with higher frequencies. A yolk sac was always seen in normal pregnancies with a gestational sac greater than 5 mm, and an embryo was always seen with a sac of 13 mm, using frequencies above 5 MHz.

Worrisome Findings of Early Pregnancy Failure

Additional sonographic features may suggest an abnormal outcome but lack the specificity in isolation to diagnose early pregnancy failure. These include findings involving the gestational sac, yolk sac, amnion, yolk sac, and embryo (Table 30.2).

Embryos With Crown-Rump Length Less Than 7 mm and No Heartbeat

If on initial imaging, an embryo is seen measuring less than 7 mm and lacking cardiac activity, the findings are worrisome but not entirely diagnostic of early pregnancy failure. As previously stated, findings on ultrasound follow a typical pattern with an embryo with a heartbeat demonstrable at 6 weeks.[40] Small embryos usually demonstrate measurable cardiac activity, but lack of a heartbeat in a small embryo of less than 7 mm may still result in a normal pregnancy. Follow-up sonography should be performed in these cases. Given the reliable pattern of growth, early pregnancy failure can also be verified on ultrasound by lack of visualization of an embryo with cardiac activity on follow-up scans. Embryonic cardiac activity should be documented by 11 days after a scan demonstrating a gestational sac with a yolk sac or by 14 days after a scan demonstrating a gestational sac without a yolk sac. If the pregnancy does not meet these milestones in this time interval, early pregnancy failure can be reliably diagnosed.[5]

Gestational Sac With Mean Sac Diameter 16 to 24 mm and No Embryo

As mentioned earlier, using TVS findings of either an MSD of 8 mm or more without a demonstrable yolk sac, or 16 mm with no demonstrable embryo, is not typical and is suggestive of pregnancy failure. Normal gestational sac growth is 1.1 mm/day. Nyberg et al.[56] found that patients with early pregnancy failure had MSD growth rates of less than 0.7 mm/day. This growth rate is

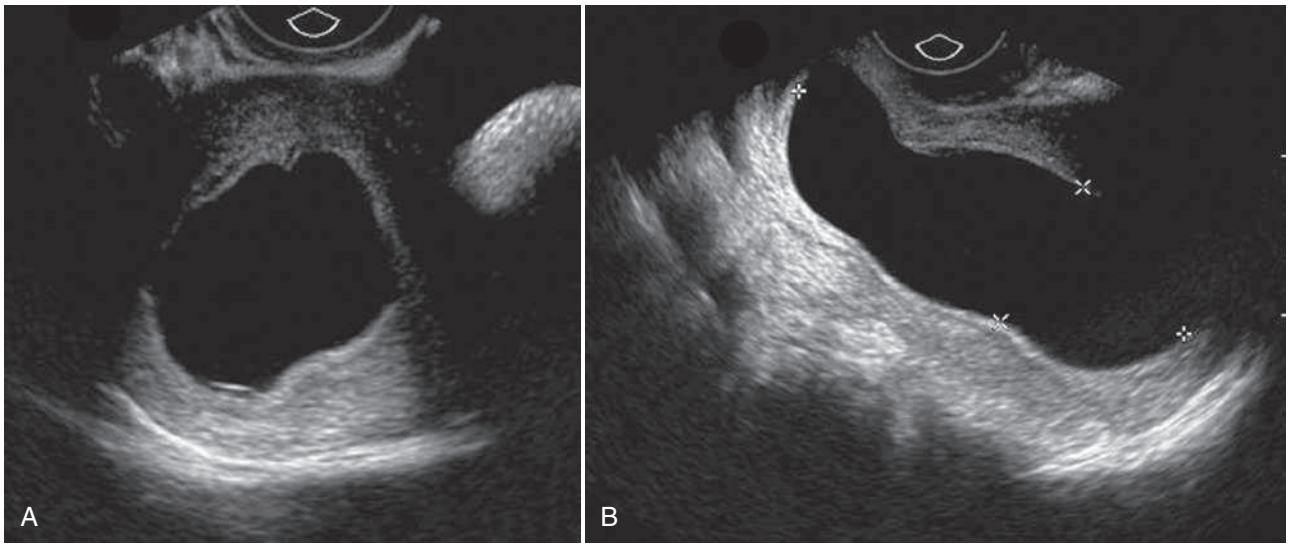

FIG. 30.20 TVS Findings Diagnostic of Early Pregnancy Failure With Large, Empty Sac. (A) Transverse and **(B)** sagittal images of an empty gestational sac with MSD *(calipers)* greater than 25 mm. No yolk sac or embryonic pole is visualized.

TABLE 30.2 Worrisome Findings for Early Pregnancy Failure

Finding	Comment
Embryo with CRL < 7 mm and no heartbeat	Embryo 2-6 mm without cardiac activity is a worrisome finding. Follow-up is needed to assess for cardiac activity in 1 week to ensure 100% specificity in diagnosis of miscarriage.
Gestational sac with MSD 16-24 mm and no embryo	Embryo is typically seen by the time the MSD is 16 mm. Follow-up in 10-14 days is needed to ensure 100% specificity in diagnosis of miscarriage.
Gestational sac appearance	Irregular shape of sac, low position of sac, and weak decidual reaction are associated with miscarriage, but the size of the embryo and presence or absence of cardiac activity guides the diagnosis of miscarriage.
Small MSD in relationship to CRL	Low fluid is associated with poor outcome. If MSD-CRL < 5, follow-up is recommended.
Abnormal amnion size	Expanded amnion or empty amnion as evaluated by an experienced sonologist is diagnostic of miscarriage. If any uncertainty is present, then follow-up should be obtained.
Yolk sac > 6 mm Calcified yolk sac	Findings are associated with miscarriage, but the size of the embryo and presence or absence of cardiac activity guides the diagnosis.
Embryonic bradycardia	Heart rate (HR) < 100 may be seen with 1- to 2-mm embryo and be a normal finding. In general, when HR is <100, follow-up is recommended.
Large subchorionic hemorrhage	Large hemorrhage is associated with miscarriage, but the size of the embryo and presence or absence of cardiac activity guides the diagnosis of miscarriage.

useful information in assessing the normal development in serial examinations. With an expected growth rate of 1.1 mm/day, one should see an appropriate increase in sac size and, if normal, the appearance of a yolk sac or an embryo. If the growth is less than expected, it becomes more suggestive of early pregnancy failure. On follow-up imaging, absence of an embryo with a heartbeat 7 to 13 days after a scan showing a gestational sac without a yolk sac or 7 to 10 days after a scan showing a gestational sac with a yolk sac remains suspicious. Given the remaining small chance that such pregnancies may still progress, longer time intervals between examinations are necessary for confident diagnosis.[5]

Gestational Sac Appearance

The following gestational sac criteria are not reliable in isolation but indicate a pregnancy at increased risk for early failure: distorted gestational sac **shape,** thin **trophoblastic reaction** (<2 mm), weakly echogenic **trophoblast,** and **abnormally low position** of the gestational sac within the endometrial cavity[42] (Fig. 30.21).

A **"chorionic bump,"** a focal irregular convexity or bulge in the surrounding choriodecidual reaction into the gestational sac, is associated with a guarded prognosis with a live birth rate for these pregnancies of less than 50%. The bulge likely represents a small hematoma.[74]

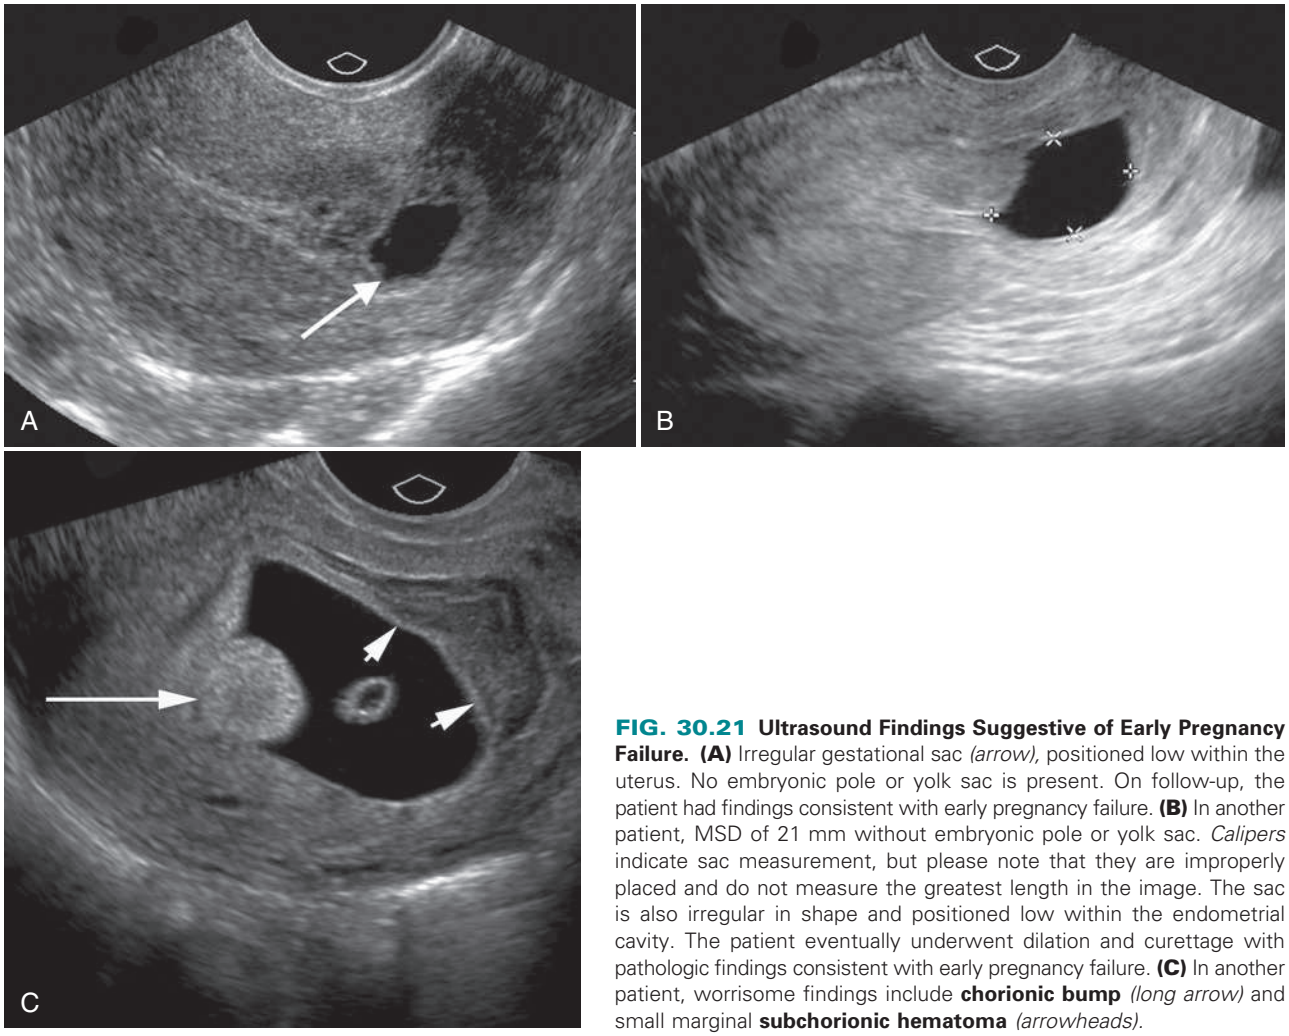

FIG. 30.21 Ultrasound Findings Suggestive of Early Pregnancy Failure. (A) Irregular gestational sac *(arrow),* positioned low within the uterus. No embryonic pole or yolk sac is present. On follow-up, the patient had findings consistent with early pregnancy failure. **(B)** In another patient, MSD of 21 mm without embryonic pole or yolk sac. *Calipers* indicate sac measurement, but please note that they are improperly placed and do not measure the greatest length in the image. The sac is also irregular in shape and positioned low within the endometrial cavity. The patient eventually underwent dilation and curettage with pathologic findings consistent with early pregnancy failure. **(C)** In another patient, worrisome findings include **chorionic bump** *(long arrow)* and small marginal **subchorionic hematoma** *(arrowheads).*

Small Mean Sac Diameter in Relationship to Crown-Rump Length

An additional feature that portends a higher likelihood of early pregnancy failure is a small sac size in relationship to CRL. Bromley et al.[75] found that in 16 patients at 5½ to 9 weeks' gestational age with an MSD less than 5 mm greater than the CRL (i.e., MSD − CRL = <5 mm), sometimes termed **early oligohydramnios,** 15 (94%) had spontaneous first-trimester abortion despite a normal heart rate for age (Fig. 30.22). As noted by Giacomello, this is not truly "oligohydramnios" as the small sac size is due to reduction of chorionic fluid, outside of the amnion.[76] A later study by Rowling demonstrated that this finding may not be as ominous as originally thought, with at least 35% of such cases progressing to the second trimester or to a normal delivery.[73]

Abnormally Large Amnion With Respect to Embryo Size

The amnion is usually visualized *after* the embryo, so it should not be visualized in the absence of an embryo.[45] In normal pregnancies, the amnion is not usually visible until the CRL of the embryo is greater than approximately 7 mm.[77,78] A large visible amniotic sac compared to the CRL is suggestive of abnormal outcome.[45,79] Horrow[77] demonstrated that the difference between the CRL and the amniotic sac diameter is 1.1 ± 2.0 mm in normal embryos but 8.6 ± 3.8 mm in abnormal pregnancies. In abnormal early pregnancies, the chorionic cavity remained appropriate in size relative to the embryonic CRL, indicating that the increased difference in CRL compared to amnion diameter is caused by enlargement of the amnion rather than a small embryo. This finding is especially useful in early embryos before visualization of cardiac activity. As with other predictors of abnormal outcome, patients with abnormal amnion appearance, either the "empty amnion"[45] (Fig. 30.23) or "expanded amnion"[78,79] (Fig. 30.24, Video 30.3) where the amnion is too large for an embryo of a particular size, should be considered to have a nonviable pregnancy. However, the expertise of the individual interpreting the exam is important. If any question remains about viability of the pregnancy, a follow-up ultrasound examination is prudent.[78] At times the clinician may see two sacs within the gestational sac. Although it may be a monochorionic diamniotic pregnancy (see Fig. 30.11), it may also be a failed pregnancy with an empty amnion (or very small embryo with respect to the size of the amnion) and a yolk sac (see Figs. 30.12B and 30.25).

Yolk Sac Size and Shape

Studies have attempted to characterize the normal sonographic appearance of the yolk sac and to identify abnormal morphologic features that may predict poor fetal outcome.[80] In general, a yolk sac diameter greater than 5.6 mm between 5 and 10 weeks is associated with an abnormal outcome in singleton pregnancies.[43] However, a yolk sac greater than 5.6 mm may be seen normally in MCMA twins.[44] Kucuk et al.[80] found that yolk sac shape alone had a sensitivity of 29% and specificity of 95% in predicting an abnormal outcome. An abnormally **large yolk sac** is often the first sonographic indicator of pathology and is often associated with subsequent embryonic demise. Even if the pregnancy survives the first trimester, the fetus may still be abnormal. Although the number of cases is small, large yolk sacs have been associated with abnormalities such as trisomy 21, partial molar pregnancy,[81] and omphalocele; thus follow-up anatomic surveys for the finding of an abnormal appearing yolk sac are recommended.

A **calcified yolk sac** appears as a shadowing echogenic mass in the absence of any other identifiable yolk sac. A calcified yolk sac will usually be seen with a dead embryo and may calcify within 36 hours after demise (Fig. 30.26, Video 30.4).

The yolk sac can be filled with **echogenic material** and is not the same as one that is calcified. This can be seen in live pregnancies. Szabo et al.[82] followed such cases alone and in conjunction with **nuchal lucency** in 3620 first-trimester pregnancies. They found 39 cases (1.0%) of echogenic yolk sacs 1.8 to 4.0 mm in diameter in pregnancies at 9 to 11 weeks' menstrual age; 19 of the 39 (49%) had both a nuchal lucency greater than 3 mm and

FIG. 30.22 Small Sac Size in Relationship to Embryo (MSD – CRL = <5 mm). The gestational sac containing a yolk sac and embryonic pole is smaller than expected. This pregnancy eventually failed.

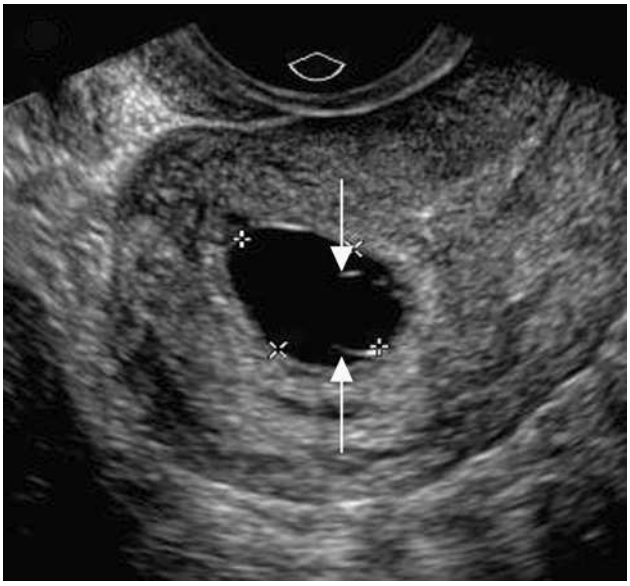

FIG. 30.23 Empty Amnion. TVS at 6 weeks by dates shows gestational sac *(calipers)* with an abnormally large empty amnion *(arrows)*. Early pregnancy failure was later confirmed.

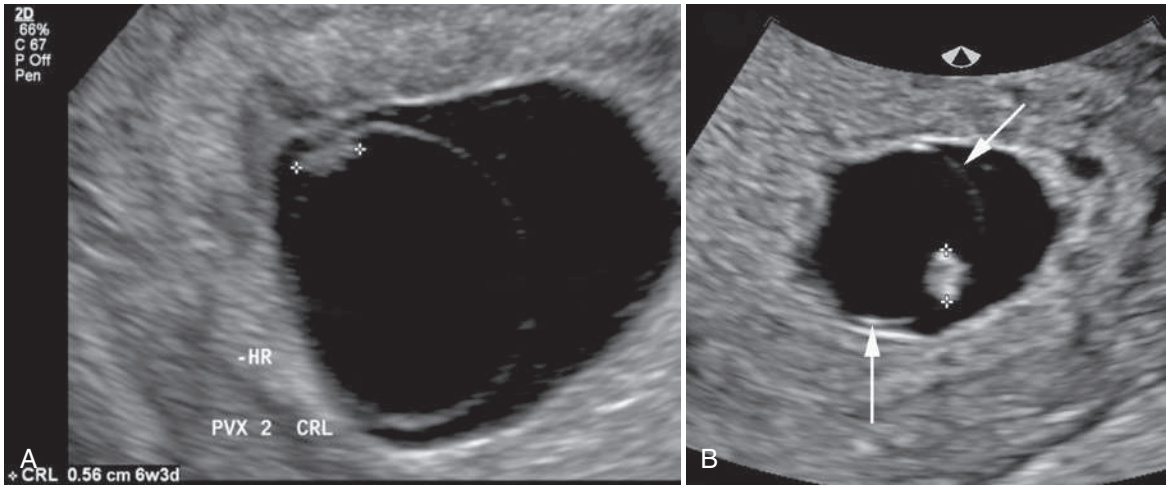

FIG. 30.24 Expanded Amnion in Nonviable Pregnancy. Two different examples **(A)** and **(B)** show a small embryo *(calipers)* with amnion (*arrows* in Figure **B**) that is too large for an embryo of this size. No cardiac activity was documented in either embryo. See also Video 30.3.

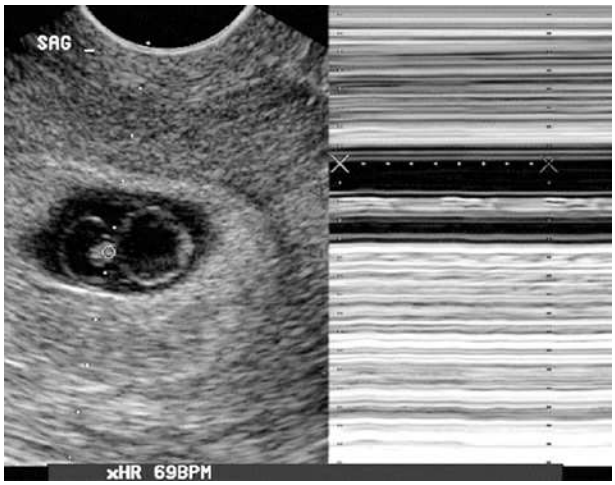

FIG. 30.25 Embryonic Bradycardia. A small embryo in a 10-week by dates pregnancy with a heart rate of 69 beats/min. This embryo later was found to not have cardiac activity. A round amniotic sac is seen on the left and the large yolk sac is seen to the right of the embryo.

an echogenic yolk sac, with all 19 chromosomally abnormal, and the other 20 (51%) had an echogenic yolk sac as the only unusual finding, with all delivered normally.

Embryonic Bradycardia

Although embryonic cardiac activity indicates that the embryo is alive at examination, an abnormally slow heart rate may predict impending demise. The embryonic heart rate increases between 6 and 9 weeks' gestation. At 6 weeks' menstrual age, the mean embryonic heart rate ranges from 90 to 133 bpm, and at 9 weeks' gestation it ranges from 144 to 170 bpm. The lower the heart rate is, the greater the chance is of miscarriage. Doubilet and Benson[49] found that a heart rate less than 80 bpm in embryos with a CRL less than 5 mm was universally associated with subsequent embryonic demise. A rate of 80 to 90, 90 to 99, and 100 bpm were associated with risk of demise of 64%, 32%, and 11%, respectively. Rates below 100 bpm before 6.3 weeks' gestation and below 120 bpm between 6.3 and 7 weeks' gestation are associated with a high risk of miscarriage.[49,83] Additionally, even

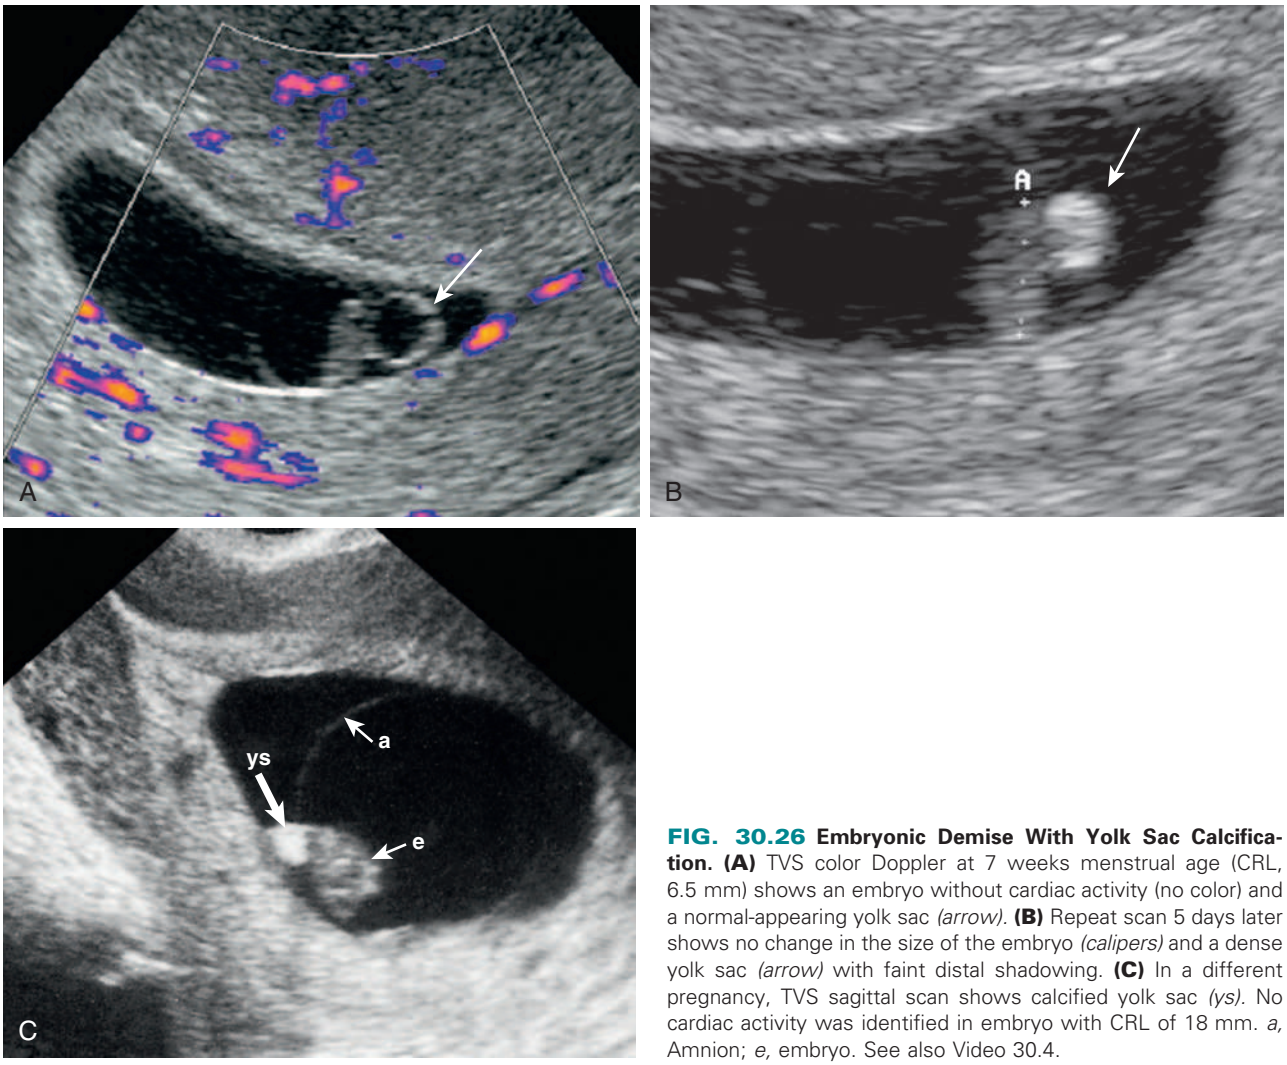

FIG. 30.26 Embryonic Demise With Yolk Sac Calcification. (A) TVS color Doppler at 7 weeks menstrual age (CRL, 6.5 mm) shows an embryo without cardiac activity (no color) and a normal-appearing yolk sac *(arrow)*. **(B)** Repeat scan 5 days later shows no change in the size of the embryo *(calipers)* and a dense yolk sac *(arrow)* with faint distal shadowing. **(C)** In a different pregnancy, TVS sagittal scan shows calcified yolk sac *(ys)*. No cardiac activity was identified in embryo with CRL of 18 mm. *a,* Amnion; *e,* embryo. See also Video 30.4.

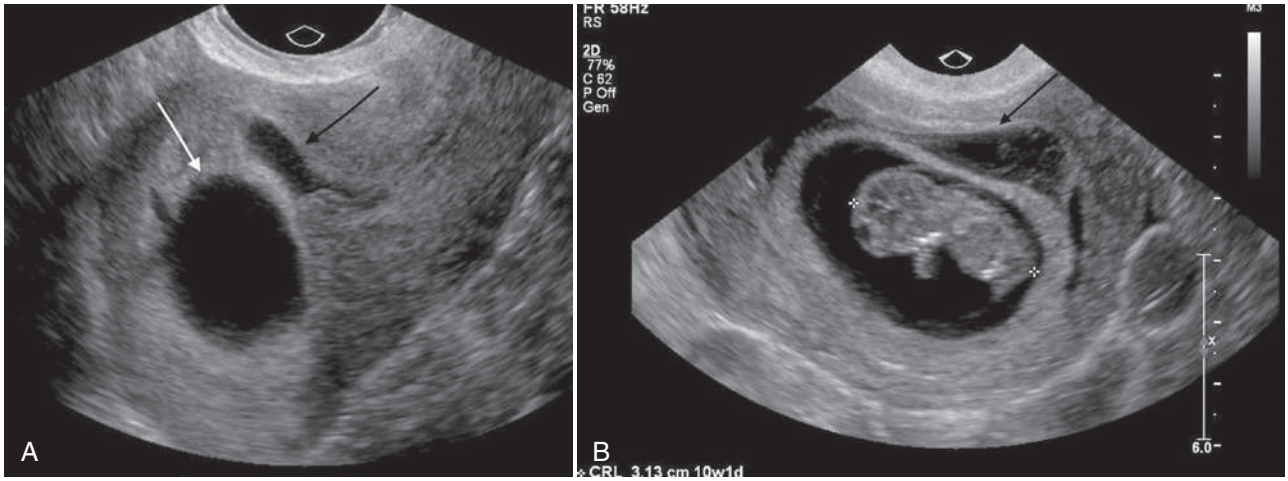

FIG. 30.27 Subchorionic Hematoma. (A) Sagittal TVS at 7 weeks' gestation shows a small hypoechoic collection *(black arrow)* adjacent to the gestational sac *(white arrow)*. The live embryo was not in the field of view. The bleed resolved and pregnancy continued uneventfully. **(B)** In another patient, sagittal transverse TVS at 10 weeks' gestation shows a large subacute hemorrhage *(black arrow)* with a lacy appearance to the clot. A live embryo *(calipers)* is present. See also Video 30.5.

if normal cardiac activity is documented on a follow-up study after 8 weeks, the rate of subsequent first-trimester demise remains elevated if a slow embryonic heart rate is detected at 6 to 7 weeks.[83] Embryos with slow heart rates documented before 7.0 weeks of gestation may also be associated with an increase in cardiac, chromosomal, and other structural anomalies.[84]

Arrhythmia is also an indicator of first-trimester loss.[85] In a group of 950 patients, Vaccaro et al.[85] found four arrhythmias, with three having ventricular bradycardia, all of which were dead on follow-up scan within 2 weeks.

Embryos with abnormally rapid heart rates, above 135 bpm before 6.3 weeks or at least 155 bpm at 6.3 to 7.0 weeks have a good prognosis, with a high likelihood of normal outcome.[86]

Subchorionic Hemorrhage

Subchorionic hemorrhage, or a hematoma resulting from elevation of the placental margin or marginal sinus rupture,[87] causes elevation of the chorionic membrane (Fig. 30.27, Video 30.5). **Acute hemorrhage** is usually hyperechoic or isoechoic relative to the decidua. The hemorrhage gradually becomes sonolucent in 1 to 2 weeks.

This finding may be associated with vaginal bleeding. The incidence of subchorionic hematomas early in pregnancy ranges from 1.3% to 18%.[88] The association of subchorionic hematomas with early pregnancy failure is variable, but most studies support that worse outcomes are seen in "large" hematomas extending 50% or more of the circumference of the gestational sac and in hematomas diagnosed earlier in the first trimester (Fig. 30.27B).

Pedersen and Mantoni[89] studied 342 pregnant women from 9 to 20 weeks' gestation presenting with vaginal bleeding and found subchorionic hematomas in 18%, averaging 20 mL (range, 2-150) in size. This study found no difference in the rate of miscarriage (10%) or premature delivery (11%) between the patients with and without subchorionic hematomas.

In a retrospective study of 516 patients with first-trimester bleeding, Bennett et al.[90] found an overall pregnancy loss rate of 9.3%. Pregnancy loss increased with increasing maternal age and decreasing gestational age. For women over age 35, the rate is 13.8% (vs. 7.3 for those younger than 35 years), and for those presenting at or before 8 weeks, it is 13.7% (vs. only 5.9% for those later in gestation). The most important predictor for pregnancy loss was the presence of a large subchorionic hemorrhage.[90] The small or medium-sized hemorrhages (i.e., ≤50% the sac circumference) had a miscarriage rate of 9%, versus 18.8% for the larger subchorionic hemorrhages. In a study involving patients from 5 to 14 weeks' gestation, Leite et al. found that patients with very large hematomas were associated with adverse outcome in 46% of pregnancies. In their study, vaginal bleeding was not associated with a poor prognosis, but diagnosis at early gestational age was associated with a worse outcome.[91]

ECTOPIC PREGNANCY

Ectopic pregnancy remains one of the leading causes of maternal death in the United States. It accounts for 1.4% of all pregnancies and approximately 15% of maternal deaths. Although the incidence of ectopic pregnancy is increasing, the mortality rate has declined to less than 1 in 1000 cases compared with 3.5 in 1000 in 1970.[92,93] The increased incidence is likely caused by increased prevalence of the risk factors as well as earlier diagnosis, whereas heightened awareness and improved diagnostic capabilities have led to a decrease in the mortality rate.

Clinical Presentation

The classic clinical triad of pain, abnormal vaginal bleeding, and a palpable adnexal mass is present in approximately 45% of patients with ectopic pregnancy.[94] In addition, the positive predictive value of this triad is only 14%. Other presenting signs and symptoms include any combination of the classic triad, as well as amenorrhea, adnexal tenderness, and cervical motion tenderness. Schwartz and Di Pietro[94] found that only 9% of patients with clinically suspected ectopic pregnancy actually had an ectopic pregnancy, whereas 17% had symptomatic ovarian cysts, 13% had pelvic inflammatory disease, 8% had dysfunctional uterine

bleeding, and 7% had spontaneous abortions. The clinical presentation is thus nonspecific. In addition, even in retrospect, 8.7% of proven ectopic pregnancies are sonographically normal at the time of initial evaluation.[95]

The **prevalence** of ectopic pregnancy varies according to the patient population and their inherent risk factors. Nevertheless, all patients in the reproductive age group are at risk. Factors that increase the **risk** of ectopic pregnancy include tubal abnormality preventing passage of the zygote or resulting in delayed transit; previous ectopic pregnancy,[96,97] cesarean section, or tubal reconstructive surgery; pelvic inflammatory disease; chlamydial salpingitis[98]; intrauterine contraceptive devices; and increased age or parity.

There is an association between **infertility** and ectopic pregnancy, likely because of the shared tubal abnormalities in both conditions. The risk factors for ectopic pregnancy are therefore present in patients who undergo ovulation induction or IVF and embryo transfer. The increased incidence of multiple pregnancies with ovulation induction and IVF further increases the risk for both ectopic and **heterotopic** (coexistent intrauterine and ectopic) gestation. The hydrostatic forces generated during **embryo transfer** may also contribute to the increased risk.[99] The frequency of heterotopic pregnancy was originally estimated on a theoretic basis to be 1 in 30,000 pregnancies. More recent data indicate that the rate is approximately 1 in 7000 pregnancies.[100,101]

Risk of Ectopic Pregnancy

Any tubal abnormality that may prevent passage of zygote or result in delayed transit
Previous tubal pregnancy
History of tubal reconstructive surgery
Pelvic inflammatory disease
Intrauterine contraceptive device
Increased maternal age
Increased parity
Previous cesarean section

Sonographic Diagnosis

Because any woman of child-bearing age is at risk for ectopic pregnancy, determining the location of a pregnancy is required for any pregnant woman who has a pelvic ultrasound. The differential diagnosis for pelvic pain in early pregnancy is vast, including ectopic pregnancy, early pregnancy failure, tubo-ovarian torsion, degenerating fibroids, and ovarian cysts.

A limited TAS is recommended in all cases of suspected ectopic pregnancy in which the TVS does not provide a clear diagnosis, looking for findings that may be outside the range of the transvaginal probe. Although a full bladder is preferred, in the emergent setting patients should not be required to fill their bladder prior to imaging.[102] The TAS exam should include views of the uterus and adnexa in the sagittal and transverse orientations. When fluid is seen in the pelvis, it is helpful to look higher in the abdomen for the extent of fluid to provide a sense of the degree of blood loss. With a large volume of blood loss, the patient could decompensate rapidly. Fluid seen in the upper abdomen should impart a greater sense of urgency to the clinical setting (Figs. 30.28 and 30.29).

TVS assessment of the uterus, ovaries, and adnexal regions should almost always be performed, as it is superior to TAS in evaluating the endometrial contents and adnexa, providing a diagnosis more often and earlier. Views of the uterus in the sagittal and transverse planes should be performed to assess for a small gestational sac. The adnexa should be imaged with documentation of the ovaries as well as the space between the ovaries and uterus as this is the most common location of an ectopic adnexal mass.[103] During the TVS, it may be helpful to perform a gentle bimanual examination with the probe and a hand providing gentle pressure to move a questionable mass away from the ovary. If the mass moves separately from the ovary (Video 30.6), it is more likely to be an ectopic mass rather than an ovarian mass, most commonly a corpus luteal cyst. A suspected ectopic mass should be assessed during the TVS for local tenderness. The probe is used to apply light pressure on the mass. This pressure almost always elicits pain similar to the

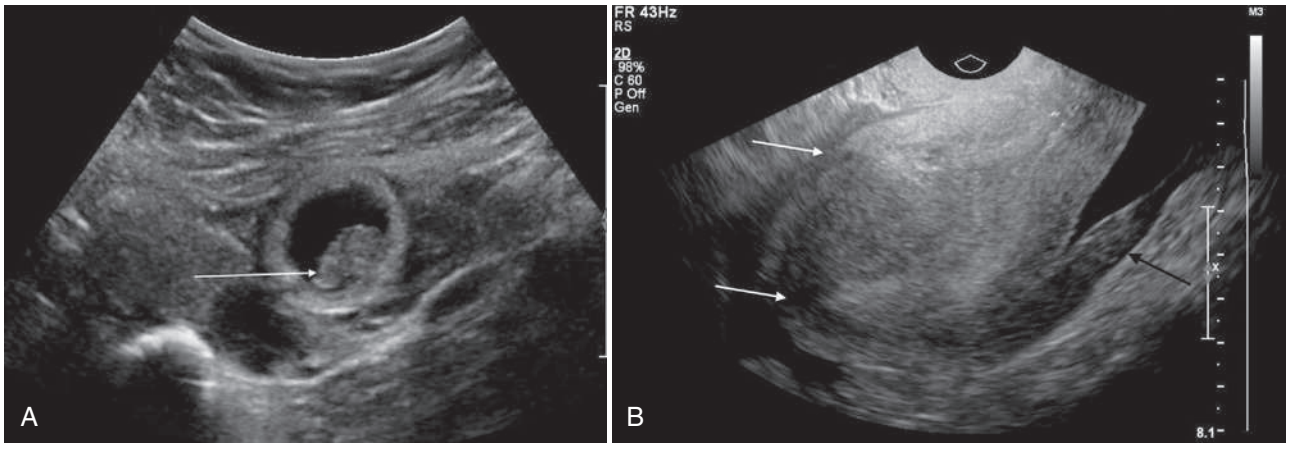

FIG. 30.28 Live Ectopic Pregnancy. A 33-year-old woman with left lower quadrant pain at 9 weeks' gestation. **(A)** Transverse TAS of the right adnexa shows a gestational sac with an embryo. Cardiac activity was seen at real-time imaging. **(B)** TVS shows the uterus *(white arrows)* and some clot in the cul-de-sac *(black arrow)*. However, the ectopic pregnancy was only seen on the TAS.

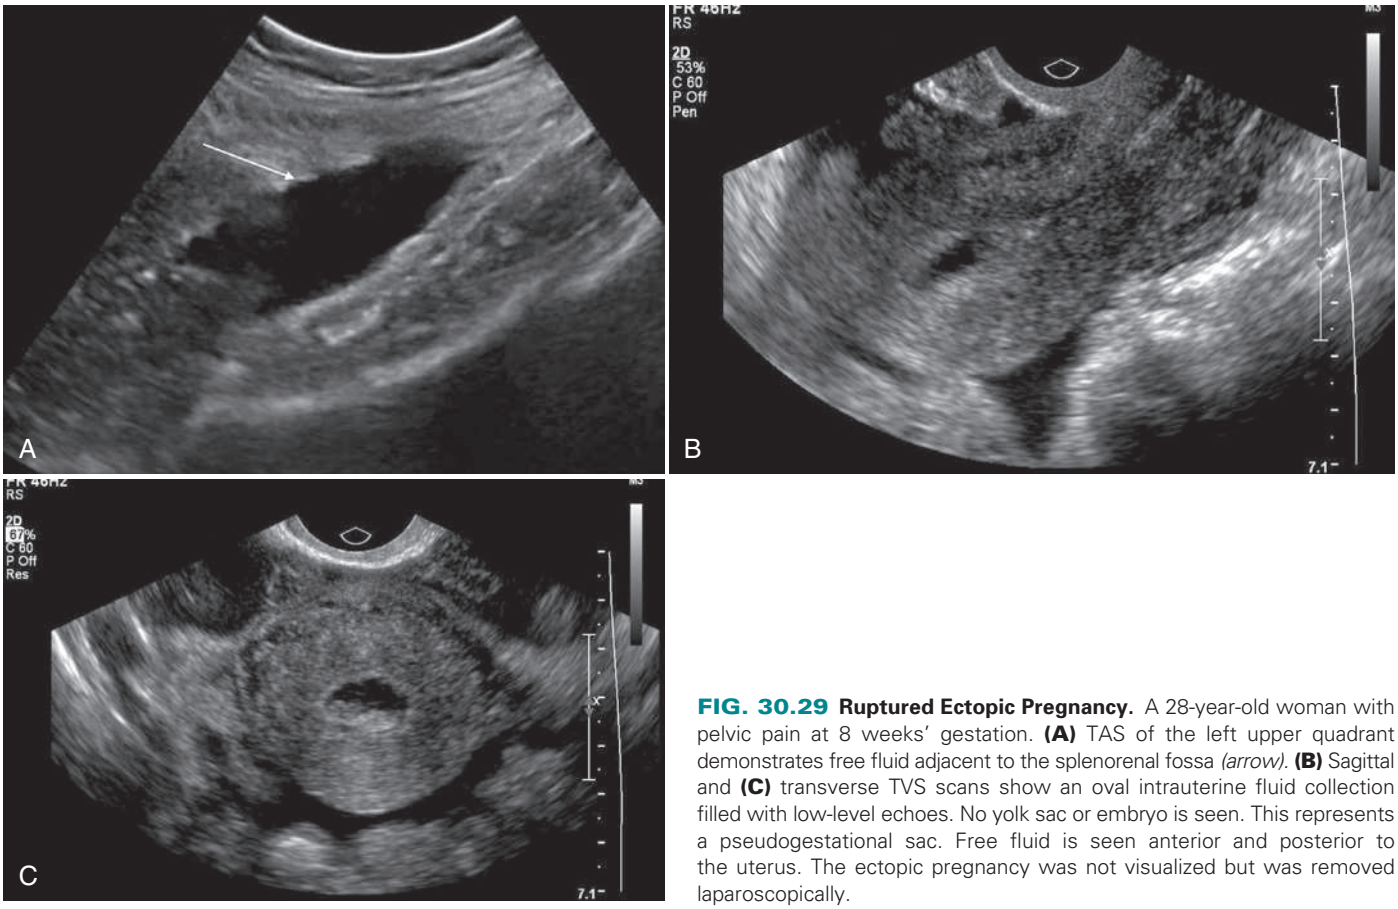

FIG. 30.29 Ruptured Ectopic Pregnancy. A 28-year-old woman with pelvic pain at 8 weeks' gestation. **(A)** TAS of the left upper quadrant demonstrates free fluid adjacent to the splenorenal fossa *(arrow)*. **(B)** Sagittal and **(C)** transverse TVS scans show an oval intrauterine fluid collection filled with low-level echoes. No yolk sac or embryo is seen. This represents a pseudogestational sac. Free fluid is seen anterior and posterior to the uterus. The ectopic pregnancy was not visualized but was removed laparoscopically.

sensation that brought the patient to hospital initially. Pain can also be felt with other inflammatory or expanding masses, such as a hemorrhagic corpus luteum. The pelvis and cul-de-sac should be examined for fluid.

TVS ultrasound may miss an ectopic pregnancy located high out of the field of view of the probe or when a pelvic mass such as a fibroid or bowel gas is located between the vagina and the adnexa.[104-106] In 5% of cases, findings may be present that only TAS can identify[107] (see Fig. 30.28).

Heterotopic Gestation

If a normal IUP is identified, the likelihood of ectopic pregnancy is drastically reduced. In the presence of an IUP, the risk of coexistent ectopic pregnancy **(heterotopic gestation)** lies between 1 in 4000 and 1 in 7000.[100,108] However, even in the presence of an IUP, evaluation of the adnexa should be performed to screen for a possible coexistent ectopic pregnancy, especially in women who present with adnexal pain and women with a history of assisted reproduction techniques such as IVF.[109] The risk for heterotopic pregnancy may be as high as 1% to 3% in women undergoing ovulation induction[110] (Fig. 30.30).

Serum β-hCG Levels

Serum β-hCG levels play an important adjunctive role in the early diagnosis of ectopic pregnancy. A negative β-hCG level excludes the possibility of live pregnancy in a woman presenting with pain whereas a negative ultrasound does not. As previously stated, the WHO recommends that the Third IS and the identical Fourth IS should be used for calibration of immunoassays.[37] In general, we expect to visualize a gestational sac when the β-hCG level is greater than 2000 mIU/mL (IRP). Discriminatory levels such as this can be used to guide management but cannot be used as absolute indicators that the absence of a sonographically demonstrable gestation sac with this level of β-hCG is abnormal. A 2013 study by Connolly found that of 366 patients with first-trimester pain and bleeding, whose pregnancies ultimately were shown to be viable, a hCG level of 3510 mIU/mL was needed for a gestational sac to be seen 99% of the time.[111] Serial β-hCG measurements are usually more helpful than a single measurement in identifying abnormal from normal pregnancy, and ultrasound may document important diagnostic features regardless of the β-hCG value.[5] The β-hCG level in a normal pregnancy has a doubling time of approximately 2 days, whereas patients with a failed or failing gestation have a falling β-hCG level. Patients with ectopic pregnancy usually have a slower increase in β-hCG levels, although they occasionally show patterns similar to a normal pregnancy or spontaneous abortion.

Specific Sonographic Findings

The most specific sonographic sign of ectopic pregnancy is documentation of a live embryo in an extrauterine location (Fig.

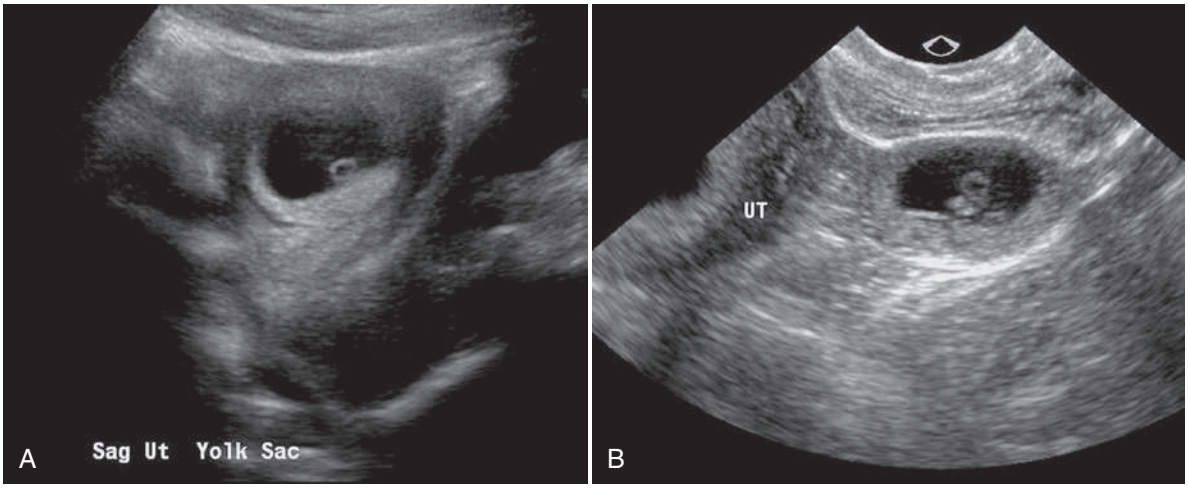

FIG. 30.30 Heterotopic Pregnancy at 6 Weeks. (A) Sagittal TAS demonstrates an intrauterine gestational sac containing a yolk sac. **(B)** Transverse TVS shows an extrauterine gestational sac in the left adnexa. The left ectopic pregnancy was treated surgically and the patient went on to have an otherwise uneventful pregnancy. *UT,* Uterus.

30.30). This finding is 100% specific but a has a low sensitivity of 15% to 20%.[104,112]

Nonspecific Sonographic Findings

Adnexal Mass

The most common location for ectopic pregnancy to occur is in the fallopian tube, with 75% to 80% in the ampullary portion, 10% in the infundibular, 5% in the fimbria, and 2% to 4% in the interstitial segment. Ectopic pregnancies in a tubal location often produce a mass in the adnexa, which is the most common ultrasonographic finding.[107,113] The mass may be solid or heterogeneous and is comprised mostly of blood products from bleeding into the wall and lumen of the fallopian tube. Adnexal masses containing a tubal ring with or without central identifying features such as yolk sac or embryo increases the specificity of the finding.[103]

Using TVS Fleischer et al.[114] found an **ectopic tubal ring** in 49% of patients with ectopic pregnancy and in 68% of unruptured tubal pregnancies. The tubal ring can usually be differentiated from a corpus luteum cyst because the cyst is eccentrically located with a rim of ovarian tissue. A tubal ring is a concentric ring created by the trophoblast of the ectopic pregnancy surrounding the chorionic sac. This ring is often within a hematoma that may be confined to the fallopian tube or that may extend outside it (Fig. 30.31). Frates et al.[115] found that an ectopic tubal ring was more echogenic than ovarian parenchyma, in contrast to the corpus luteum, which typically is as echogenic or less echogenic than ovarian parenchyma. The wall of the corpus luteum is usually less echogenic than the endometrium, whereas Stein et al.[116] found that the tubal ring of an ectopic pregnancy was more echogenic than the endometrium in 32% of cases, a finding that can be helpful in distinguishing between a tubal ring and a corpus luteum cyst.

The ectopic tubal ring may be obscured or replaced by a mass that is often echogenic (Fig. 30.31) but may be of mixed echogenicity. Easily overlooked or mistaken for fat or bowel, these masses will be found only with a high index of suspicion and careful TVS of the adnexa, looking for the tubal ring or mass that is focally tender. Color Doppler can be helpful in finding the mass, which may be hyperemic (Fig. 30.31B). However, the corpus luteum also is hyperemic and is much more common than ectopic pregnancy, so merely seeing a "ring of fire" around an adnexal lesion is not sufficient for diagnosis of ectopic pregnancy. Other entities can cause an adnexal mass such as hemorrhagic corpus luteum cyst, endometriosis, and abscess and is therefore not diagnostic.[114]

Free Fluid

TVS is extremely sensitive in detecting **free pelvic fluid.** Small amounts of free fluid can be seen in both ectopic and intrauterine pregnancies. The presence of echogenic free fluid (Figs. 30.28B and 30.31B, Video 30.7) or blood clots in the posterior cul-de-sac in pregnant patients, without sonographic evidence of an IUP and especially when found in high quantities or in association with an adnexal mass, indicates a high risk of ectopic pregnancy but can also be seen in cases of ruptured corpus luteum cyst. Echogenic fluid correlates with hemoperitoneum at surgery.[117] Thus if there is a large amount of blood in the pelvis and an ectopic pregnancy is not visualized, whether the diagnosis is ruptured ectopic pregnancy or ruptured ovarian cyst is not as important as the hemodynamic stability of the patient. Unstable patients are treated surgically with either diagnosis.

Endometrium

There is no specific endometrial appearance or thickness that can be used to distinguish a patient with ectopic pregnancy from those with an early IUP.[118] The most common appearance of the endometrium in ectopic pregnancy is normal or a generalized increased echogenicity due to decidual reaction. Pseudogestational sacs are endometrial fluid collections surrounded by echogenic endometrium from a prominent decidual reaction. These fluid collections are present in 5% to 10% of ectopic pregnancies. They tend to be lenticular in shape (Fig. 30.29B) with internal

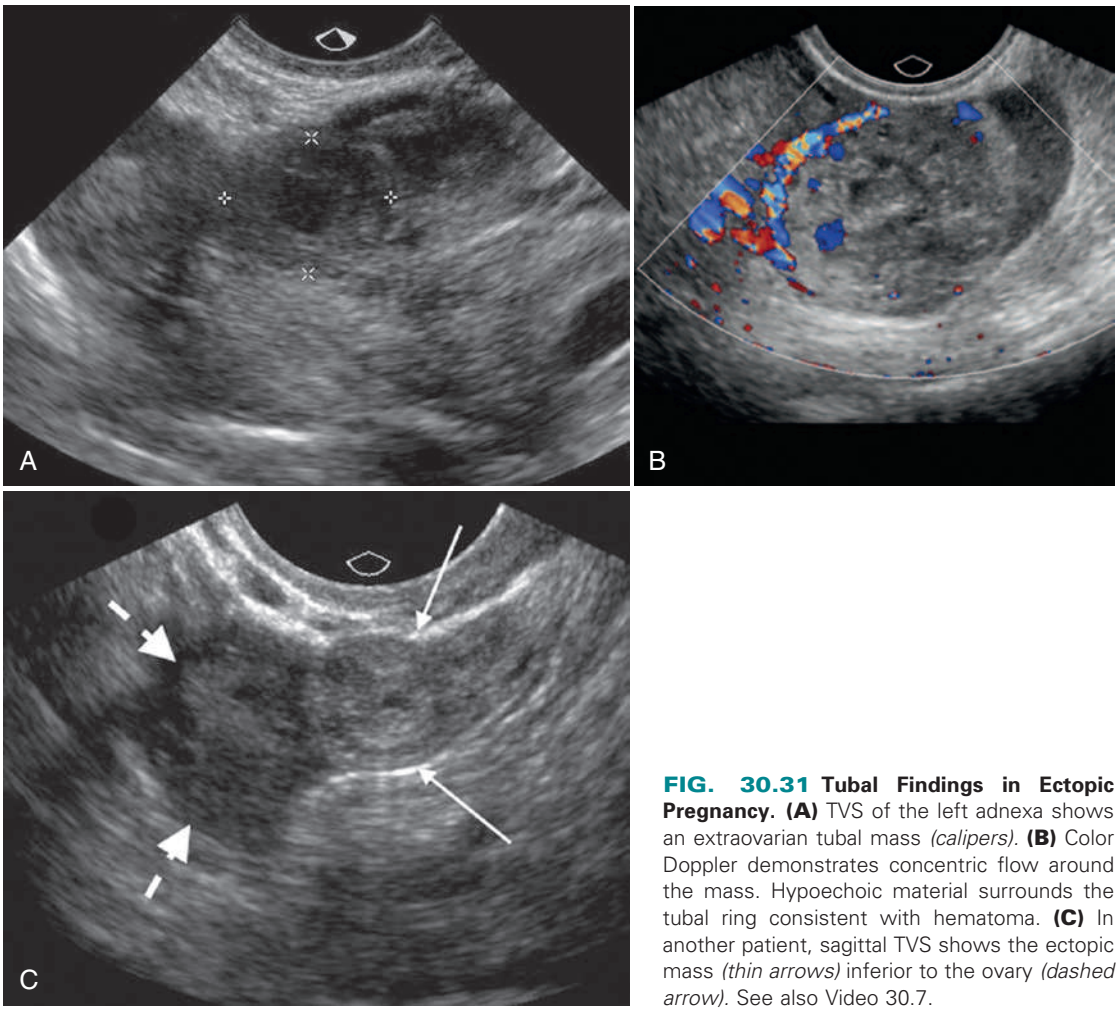

FIG. 30.31 Tubal Findings in Ectopic Pregnancy. (A) TVS of the left adnexa shows an extraovarian tubal mass *(calipers).* **(B)** Color Doppler demonstrates concentric flow around the mass. Hypoechoic material surrounds the tubal ring consistent with hematoma. **(C)** In another patient, sagittal TVS shows the ectopic mass *(thin arrows)* inferior to the ovary *(dashed arrow).* See also Video 30.7.

echoes due to blood, but they can be smooth and rounded with debris that could be mistaken for products of conception.[104,109]

Implantation Sites

Ectopic pregnancy may occur in several sites. Approximately 95% of ectopic pregnancies occur in the ampullary or isthmic portions of the fallopian tube. The second most common site, about 2% to 4% of all ectopic pregnancies, is an interstitial pregnancy occurring in the intramural portion of the tube, where it traverses the wall of the uterus to enter the endometrial canal[103] (Fig. 30.32).

Implantation in the superior lateral portion of the endometrial canal but not within the intramural portion of the tube is normal and is not an ectopic pregnancy. This is often mistaken for an ectopic pregnancy, but echogenic endometrium can be seen around the sac (double-decidual sign), and if followed even for 1 week, the sac grows and attains a more typical appearance in the endometrial canal. Three-dimensional ultrasound can add in the confidence of the diagnosis of both interstitial ectopic and eccentric intrauterine pregnancy.[119]

Because of the distensibility of this portion of the fallopian tube, **interstitial ectopic pregnancies** may present and rupture later than other tubal gestations, often causing massive intraperitoneal hemorrhage from the dilated arcuate arteries and veins, which lie in the outer third of the myometrium between the thin outer myometrium and the thick intermediate layer.[119] The mortality of interstitial pregnancy is twice that of other ectopic pregnancies. Ackerman et al.[120] found that the two currently used sonographic signs of myometrial thinning and sac eccentricity are unreliable and described the more useful **interstitial line sign.** The interstitial line is a thin, echogenic line extending from the endometrial canal up to the center of the interstitial sac or hemorrhagic mass. It was seen in 92% of interstitial ectopic pregnancies. The line is the nondistended, empty endometrial canal. The interstitial ectopic pregnancy is usually surrounded by trophoblast but should not have a double-decidual sign. Treatment historically was surgical with cornual resection, but now less invasive therapy with local injection of potassium chloride or with local or intramuscular injection of methotrexate is performed to avoid uterine surgery. Occasionally this type of ectopic pregnancy is mistakenly called a **"cornual pregnancy."** However this term should be reserved for a gestational sac lying within a rudimentary horn or within one horn of a bicornuate uterus.[119]

Cervical ectopic pregnancies are to the result of implantation in the endocervical canal (Fig. 30.33). They are rare, accounting

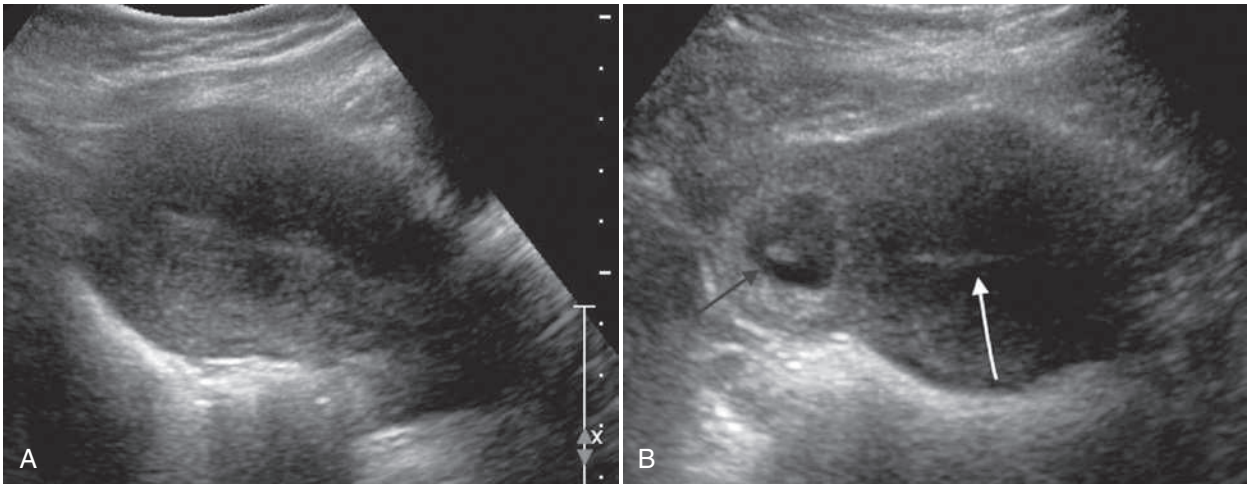

FIG. 30.32 Interstitial Ectopic Pregnancy. (A) Sagittal TAS demonstrates an unremarkable endometrial stripe. **(B)** Transverse TAS shows a gestational sac containing an embryo *(black arrow)* eccentrically positioned within the uterus, separate from the endometrial stripe *(white arrow)*. The pregnancy was terminated with direct injection of methotrexate within the gestational sac, avoiding uterine surgery.

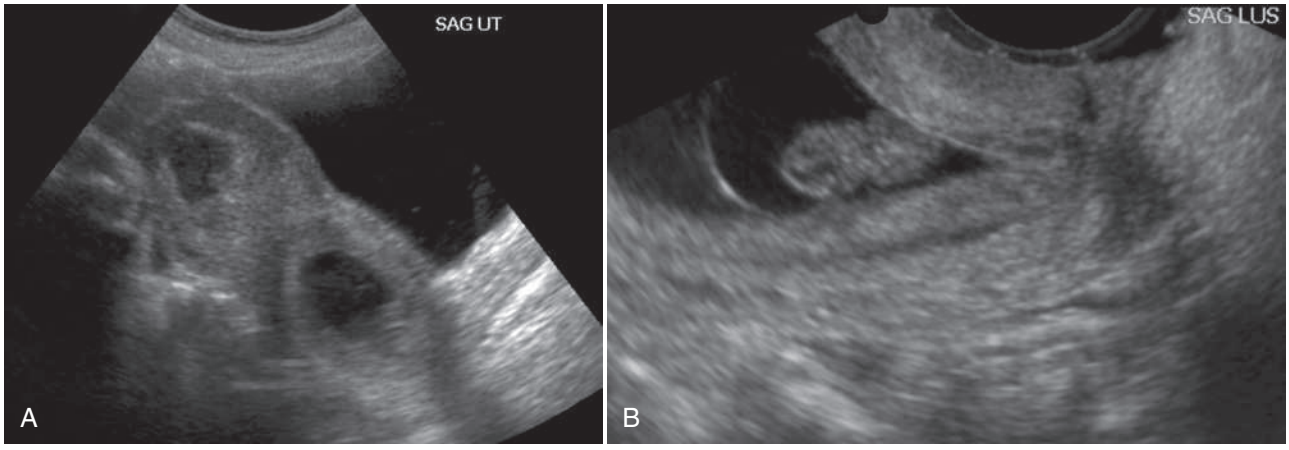

FIG. 30.33 Cervical Ectopic Pregnancy. (A) TAS sagittal view of the uterus shows a pseudogestational sac in the endometrium. A second fluid collection is seen in the cervix secondary to the gestational sac. **(B)** Sagittal TVS of the cervix shows a gestational sac containing an embryo.

for less than 1% of all ectopic pregnancies, and can be confused with abortion in progress. Ultrasound can help to distinguish an intracervical ectopic pregnancy by documenting an embryo with a heartbeat or color Doppler–documented peritrophoblastic flow. Remember that an aborting gestational sac may present in the lower uterine segment and cervix on its way out of the uterus. Sonographically in an aborting gestation, the sac will be oblong, the embryo (if present) will not have a heartbeat, and there will be no trophoblastic vascularity because it has detached from the uterine wall. Clinically, both situations are associated with vaginal bleeding, but the abortion will more likely produce crampy pain as well. Occasionally an abortion in progress will still show flow when being scanned, but follow-up imaging will show lack of flow. Therefore before any interventional procedure for a cervical ectopic is performed, we always check to see if cardiac activity is still present.

Cesarean scar implantation appears to be increasing, with more cases appearing in the literature.[121] The patient may present with painless vaginal bleeding and a history of one or more cesarean sections. An early sonogram will show a sac implanted in the lower uterine segment, with local thinning of the myometrium (Fig. 30.34, Video 30.8). There is usually prominent vascularity at the implantation site. Catastrophic hemorrhage may result, with the need for complete hysterectomy. Treatment of a scar implantation is often protracted. A dilation and curettage procedure is seldom advised because the thin lower segment may be perforated. Medical therapy is more common, with methotrexate taken systemically and often injected locally as well. Presence of a live embryo may require careful injection of potassium chloride into the embryo to stop cardiac activity.

Abdominal pregnancies are also rare. These pregnancies often result from uterine rupture from an interstitial ectopic pregnancy (Fig. 30.35) but may also more rarely occur from direct implantation. When diagnosed in the first trimester, these pregnancies are typically treated in a similar way to tubal ectopic pregnancies. When diagnosed in the third trimester, abdominal pregnancies may result in a viable neonate.

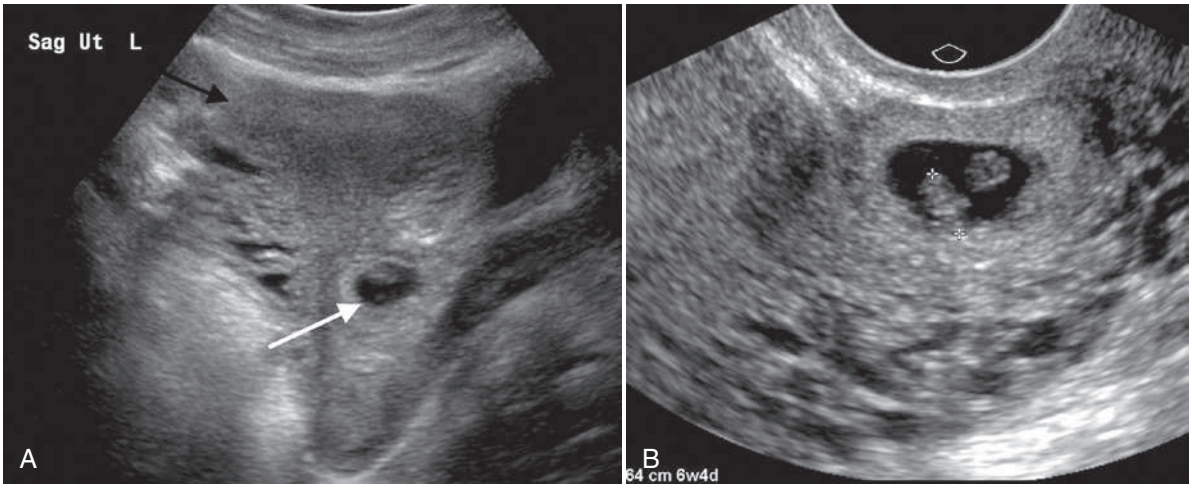

FIG. 30.34 Cesarean Scar Implantation. (A) TAS at 7 weeks' gestation shows a sac *(white arrow)* in the anterior lower uterine segment, far from the uterine fundus *(black arrow).* **(B)** TVS shows the sac in the region of the c-section scar with an embryo *(calipers)* and yolk sac. No myometrium is visualized anterior to the sac. See also Video 30.8.

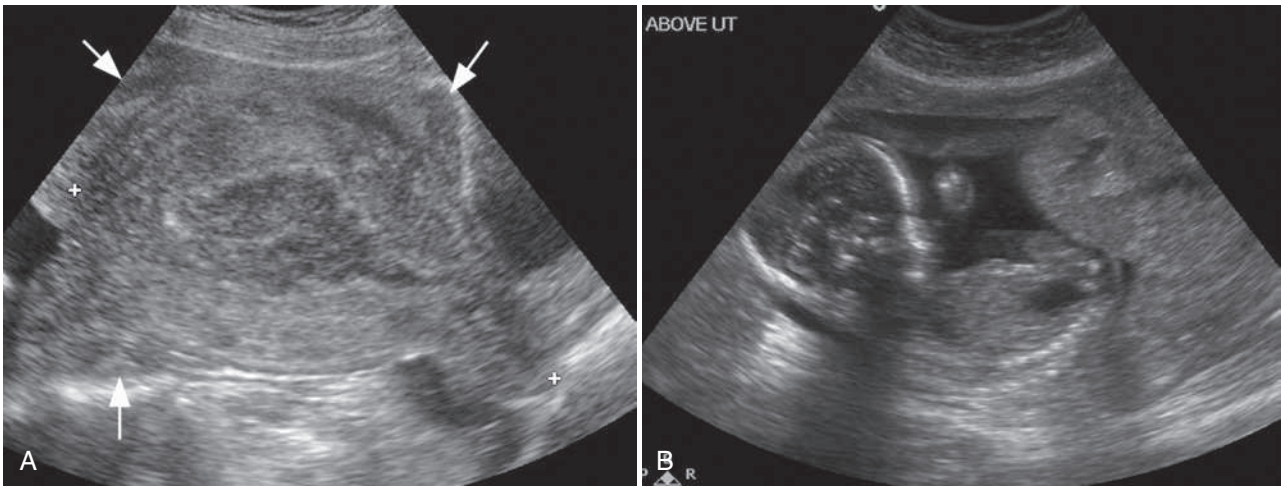

FIG. 30.35 Abdominal Ectopic Pregnancy. A 19-year-old woman with acute abdominal pain and syncope. **(A)** Sagittal TAS demonstrates a mildly enlarged uterus with an endometrial cavity distended with blood. Blood is also seen surrounding the uterus *(arrows).* **(B)** TAS superior to the uterine fundus demonstrates a 15-week abdominal ectopic pregnancy. Surgical treatment confirmed abdominal ectopic secondary to uterine rupture caused by an interstitial ectopic pregnancy.

Pregnancy of Unknown Location

In first-trimester patients, the initial TVS correctly identifies the site of in over 90% of patients.[106] In the absence of a well-defined IUP, or in the absence of an ectopic pregnancy, other findings can suggest the location of the implantation but are nonspecific and can result in diagnostic error. Recently, women with a positive pregnancy test who have no evidence of either an IUP or ectopic pregnancy on TVS have been categorized as having **pregnancy of unknown location** (PUL).[122,123] The differential diagnosis for PUL includes a very early IUP, an abnormal IUP, spontaneous miscarriage, and ectopic pregnancy.[124] The proportion of patients categorized as PUL depends on gestational age at examination (and of course depends on the quality of the scan and expertise of the imager).

In a series of 5318 unselected women in the first trimester, 456 (8.7%) were classified as PUL.[106] Of the 456 patients classified as PUL, 31 (6.8%) had ectopic pregnancies. The PUL group benefits from close follow-up because of their high incidence of ectopic pregnancy. Kirk et al.[106] showed that a single TVS examination correctly diagnosed ectopic pregnancy in 96.1% of patients undergoing surgical management. Therefore 3.9% of patients diagnosed with ectopic pregnancy and treated nonsurgically could have normal or abnormal IUPs. Thus it is important to consider the clinical history and presentation before using nonspecific parameters in the management of patients with ectopic pregnancy.

Management

The conventional management of ectopic pregnancy has been surgical, with resection of the diseased tube. Improved diagnostic capabilities, including TVS, allow for earlier diagnosis and the potential for a more conservative approach to treatment. The

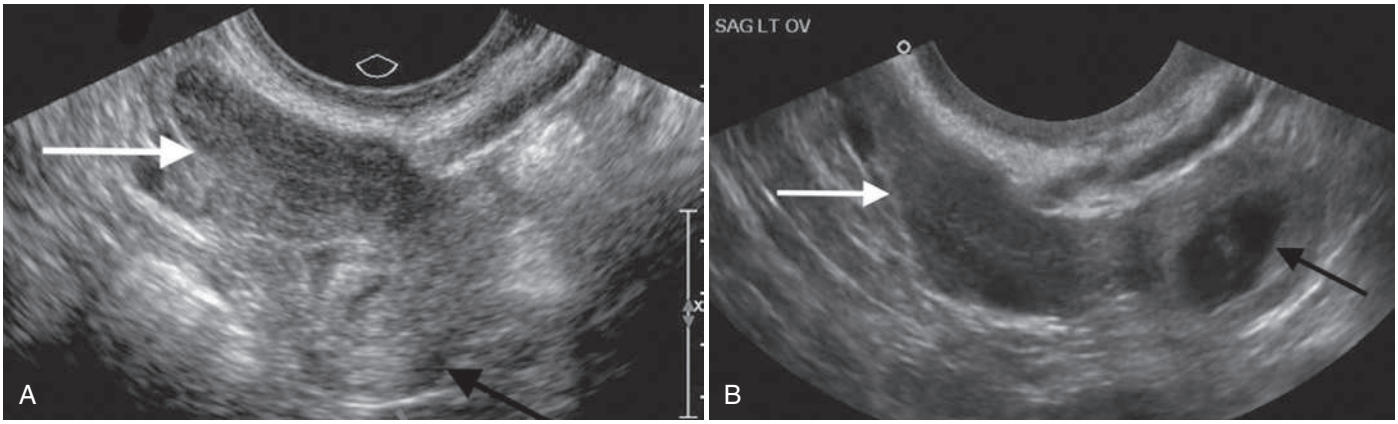

FIG. 30.36 Left Ectopic Pregnancy Failed Medical Management. A 38-year-old woman with pain and bleeding from left ectopic pregnancy treated with methotrexate. **(A)** At initial diagnosis, left extraovarian ectopic mass *(black arrow)* was found adjacent to the left ovary *(white arrows).* HCG levels continued to rise. **(B)** Repeat scan 2 weeks later shows growth of adnexal mass now containing a gestational sac with embryonic pole. The ectopic pregnancy was then treated successfully with salpingectomy.

ultimate goal is to diagnose the ectopic pregnancy before tubal rupture and to treat it so as to minimize tubal scarring while maintaining tubal patency.

Laparoscopy is often used for definitive diagnosis in ectopic pregnancy and for the more conservative surgical procedures such as salpingotomy.[125] The diseased tube is incised and microdissection used to remove the gestational sac. The incision is then left to heal by secondary intention. The rate of subsequent IUP in these surgical patients is 61.4%, with a 15% rate of recurrent ectopic pregnancy.[126]

Medical management has also been successful in the treatment of early ectopic pregnancy. Cell growth inhibitors such as methotrexate are injected systemically (intravenous, intramuscular, or oral administration) and the serum β-hCG levels followed closely. The methotrexate kills the rapidly dividing trophoblastic cells, which are then reabsorbed, resulting in falling β-hCG levels and, ideally, preservation of the tubal lumen.[127] Success rates range from 61% to 93% for local injection[128] and from 65% to 94% for intramuscular treatment.[129] The rate of side effects is 21% with parenteral administration and 2% with local injection under ultrasonic guidance.

Medical treatment is most successful in tubal pregnancies (vs. interstitial ectopic pregnancy or cervical ectopic pregnancy), those cases with smaller ectopic masses, less free fluid, and those without embryonic cardiac activity.

Barnhart et al.[130] reviewed studies of multidose and single-dose regimens of methotrexate and found an overall success rate of 89% (1181 of 1327 women). The single dose was used more often but was associated with a significantly greater chance of failure than multidose therapy, although it had fewer side effects. Hajenius et al.[128] compared treatment options of laparoscopy, laparotomy, methotrexate (local vs. systemic, single vs. multiple dose), and expectant management (where patients are monitored without treatment). Multidose intramuscular methotrexate is most cost-effective in patients with low serum β-hCG than laparoscopic salpingostomy. In all cases, both therapies had similar results, with laparoscopy having a higher cost and longer hospital stay.

Nazac et al.[129] studied 137 women with an unruptured ectopic pregnancy and hematosalpinx seen on TVS. They found that in cases with an hCG level less than 1000 mIU/mL, local injection of methotrexate (1 mg/kg) directly into the sac after first aspirating the contents had a 92.5% success rate compared with 67% for intramuscular administration. The local injection was performed vaginally using the same technique as for follicle aspiration during oocyte retrieval in IVF.

A common complication of methotrexate therapy is a rupture of the ectopic pregnancy, with increased pelvic pain and tenderness and the appearance of a hemorrhagic mass. Usually these will resolve with conservative management but occasionally will require surgical intervention. Even with successful treatment of an ectopic pregnancy, an adnexal mass may increase in size as a result of edema and hemorrhage. However, any evidence of further continuation of growth of the ectopic pregnancy is evidence of failure of the therapy (Fig. 30.36).

Conservative management is becoming more common for the stable patient with low or declining levels of β-hCG. Success rates of up to 69.2% have been reported.[126]

EVALUATION OF THE EMBRYO

The diagnosis of specific fetal anomalies in the first trimester is discussed in the chapters pertaining to the involved organ system. Nuchal translucency screening is discussed in the Chapter 31. This discussion is limited to general principles of assessment of the embryo in the first trimester. Current trends in first-trimester diagnosis, including widespread acceptance of TVS, nuchal translucency screening, maternal serum markers, and cell free DNA testing, combined with improved sonographic resolution, have resulted in the potential diagnosis of a wide range of defects in the first trimester. As the resolution of ultrasound equipment improves, visualization of embryologic structures becomes possible. It is critical that incorrect decisions are not made on the basis of incomplete understanding of normal and abnormal embryonic and fetal anatomy in the first trimester. Therefore if any uncertainty surrounds the findings in an early scan,

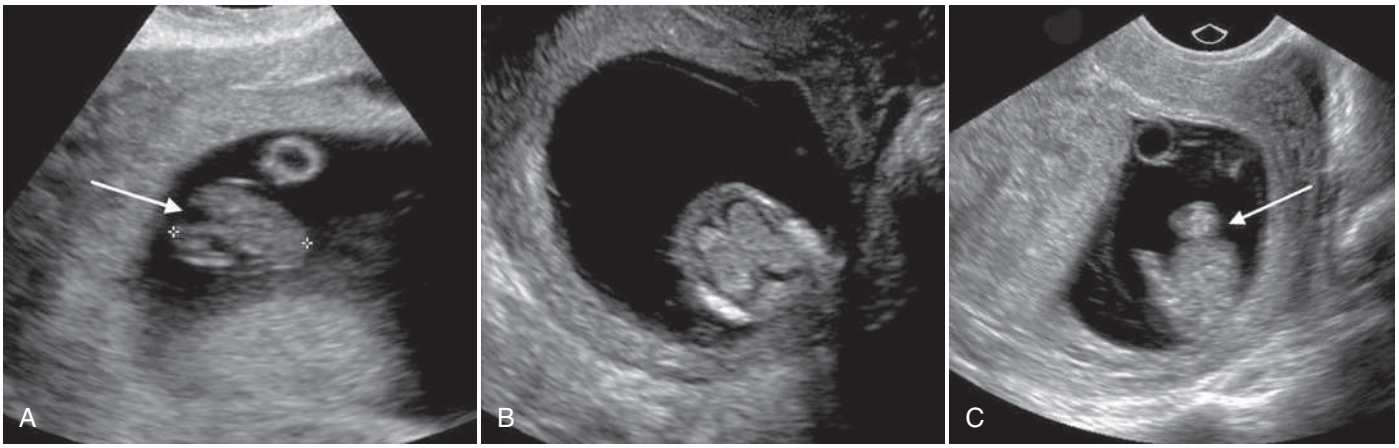

FIG. 30.37 Normal First-Trimester Anatomy. (A) Embryo *(calipers)* at 7 weeks 6 days demonstrates a cystic appearance in the cranial region *(arrow)* representing the normal **rhombencephalon.** See also Video 30.9. **(B)** Transverse scan of a 12-week fetus shows normal **lateral ventricles with choroid plexus** filling most of the lateral ventricles. **(C)** Ten-week embryo has the typical echogenic bowel herniated into the base of the umbilical cord *(arrows)* due to **physiologic midgut herniation.**

a follow-up sonographic examination may be indicated for evaluation of fetal morphologic characteristics in the second trimester.

Three major points should be considered: (1) normal embryologic/fetal development may mimic pathology, (2) abnormal embryos/fetuses may appear normal early in pregnancy, and (3) discrepancies between dates and embryo size may be the only visible manifestation of pathology in some first-trimester examinations.

Normal Embryologic Findings Mimicking Pathology

Normal embryologic development in the first trimester may mimic pathologic changes more often seen in the second and third trimesters.

Rhombencephalon

During the sixth week, three primary brain vesicles form: the **prosencephalon** (forebrain), the **mesencephalon** (midbrain), and the **rhombencephalon** (hindbrain).[10] Small cystic structures can be seen normally in the posterior aspect of the embryonic head. The earliest cystic structure seen at 6 to 8 weeks' gestation represents the normal embryonic **cystic rhombencephalon,** which later forms the normal fourth ventricle and should not be mistaken for a posterior fossa cyst of pathologic importance[131] (Fig. 30.37A, Video 30.9). The prosencephalon divides into an anterior portion known as the **telencephalon** and a posterior **diencephalon.** The telencephalic vesicles later form the lateral ventricles, and the diencephalon (and to a lesser degree the telencephalon) forms the third ventricle. After approximately 9 weeks, the lateral ventricles can be identified sonographically as two small cystic spaces in the embryonic head at 11 weeks and are more evident with the large choroid plexus almost filling them at 13 weeks (Fig. 30.37B). By 12 weeks the lateral ventricles extend almost to the inner table of the skull, and on sonography, only a small rim of cerebral cortex can be demonstrated to surround them. The choroid plexus is echogenic and fills the lateral ventricles completely except for the frontal horns.

Physiologic Anterior Abdominal Wall Herniation

During embryogenesis, the midgut normally herniates into the umbilical cord at the beginning of the eighth week of gestation. The midgut rotates 90 degrees counterclockwise and then returns to the abdomen during the 12th week. As the midgut returns to the abdomen, further rotation occurs, completing the normal rotation of the midgut.

Schmidt et al.[132] describe the normal physiologic appearance of the anterior abdominal wall during this period. The herniated bowel appears as a small, echogenic mass (6-9 mm) protruding into the cord at approximately 8 weeks (CRL, 17-20 mm). The echogenic mass decreases to 5 to 6 mm at 9 weeks (CRL, 23-26 mm). The size of the mass of herniated bowel varies. Follow-up examinations reveal reduction of the hernia between 10 and 12 weeks. In up to 20% of normal pregnancies, the herniated bowel may still be found outside the fetal abdomen at 12 weeks (Fig. 30.37C).

Abnormal Embryos

Many embryonic abnormalities may not be sonographically visible in the first trimester. In the first trimester, abnormal embryos may appear normal. Ultrasound in the first trimester is best at detecting abnormalities of the neurologic system, such as anencephaly; abdominal wall defects, such as omphalocele; and severe abnormalities of the urologic system, such as megacystis. These are illustrated in the chapter on chromosome abnormalities (Chapter 31, see Fig. 31.6) where first trimester screening for chromosome abnormalities is described. Individual first-trimester anomalies are discussed in the chapters regarding their specific organ systems.

GESTATIONAL TROPHOBLASTIC DISEASE

Gestational trophoblastic disease is a spectrum of cellular proliferations stemming from the placental villous trophoblast encompassing four main types: hydatidiform mole (complete

and partial), invasive mole, choriocarcinoma, and placental trophoblastic tumor.[133]

Hydatidiform Molar Pregnancy

Hydatidiform molar pregnancy is the most common and benign form of gestational trophoblastic disease, with an incidence of 1 in 1000 pregnancies in North America.[134] The incidence is much higher in the Asian population. There is an increased risk in teenagers, in women older than 35 years of age, and in women with a previous molar pregnancy. The risk also increases with the number of previous spontaneous abortions.[135] Molar pregnancy is characterized histologically by cystic (hydatidiform) degeneration of chorionic villi, with absent or inadequate vascularization and abnormal trophoblastic proliferation. Embryos or fetuses are either absent or abnormal.

The most frequent presenting symptom is **vaginal bleeding,** which occurs in more than 90% of cases. Passage of vesicles (hydropic villi) through the vagina occurs frequently and is considered specific for the diagnosis of molar pregnancy.[136] The uterus may be enlarged for dates, and there may also be rapid uterine enlargement. Medical complications include pregnancy-induced hypertension, hyperemesis gravidarum, preeclampsia, and hyperthyroidism. The routine use of ultrasound for any woman with bleeding in pregnancy allows for early diagnosis, and few women in current practice show the classic features of hyperemesis and preeclampsia.[137]

Serum β-hCG levels in molar pregnancy are abnormally elevated, usually greater than 100,000 mIU/mL. The ovaries may be greatly enlarged in complete molar pregnancy by multiple, bilateral theca lutein cysts. These are large, usually multilocular, and may undergo hemorrhage or torsion and can be a source of pelvic pain. Theca lutein cysts are most marked when trophoblastic proliferation is severe, and when hCG is elevated. They are seen much less often in the first trimester.[138,139]

Molar pregnancy is treated by uterine evacuation, which is adequate in most patients. Approximately 80% of complete moles and 95% of partial moles will subsequently follow a benign course.[136,140] However, accurate diagnosis and classification of molar pregnancy are important because of the risk of persistent trophoblastic neoplasia (PTN). The American College of Obstetrics and Gynecology currently recommends follow-up testing for hCG for 6 months after levels become undetectable.[141]

Hydatidiform molar pregnancy is classified as either complete molar pregnancy or partial molar pregnancy on the basis of cytogenetic and pathologic features.

Complete Molar Pregnancy

Complete molar pregnancy is characterized by a **diploid karyotype** of 46,XX in 80% to 90% of cases, with the chromosomal DNA being exclusively paternal in origin.[142] This occurs when an ovum with absent or inactive maternal chromosomes is fertilized by a normal haploid sperm. Occasionally, fertilization of an empty ovum by two haploid sperm results in a 46,XY pattern.[135] As the embryo dies at an early stage, no fetal parts are seen.[142] The placenta is entirely replaced by abnormal, hydropic chorionic villi with excessive trophoblastic proliferation.

The classic sonographic features of complete molar pregnancy include an enlarged uterus with a central heterogeneous echogenic mass that expands the endometrial canal. The mass contains multiple cystic spaces of varying size, representing the hydropic villi (Fig. 30.38). These cystic spaces may vary in size from a few millimeters to 2 to 3 cm. In the second trimester, TAS diagnosis is highly accurate. The second trimester appearance typically presents as an echogenic mass containing multiple tiny cysts due to the hydropic villi in what used to be termed a "snowstorm" pattern. However, with the higher frequencies now used the "snowstorm" has become a "bunch of grapes."

In the first trimester, molar pregnancies have a variable appearance on ultrasound, sometimes appearing as a predominantly solid, echogenic mass or even as an intrauterine fluid collection because tiny hydropic villi may not be adequately resolved (Fig. 30.39). In these cases, a molar pregnancy may not be able to be differentiated from a miscarriage.

Partial Molar Pregnancy

Partial molar pregnancy has a **triploid karyotype** of 69,XXX, 69,XXY, or 69,XYY and is also referred to as "triploidy." Most partial moles have one set of maternal chromosomes and two sets of paternal chromosomes, resulting from fertilization of a normal ovum by two haploid sperm. Triploidy of maternal origin is not associated with gestational trophoblastic disease.[143] Pathologically, partial molar pregnancy has well-developed but generally **anomalous (triploid) fetal tissues. Hydropic degeneration of placental villi** is focal, interspersed with normal placental villi (Fig. 30.40).

Triploidy is discussed in more detail in Chapter 31.

Placental **hydropic degeneration** (unrelated to trophoblastic neoplasia) may also show similar sonographic features. Hydropic degeneration occurs frequently in first-trimester abortion of any cause. The associated cystic spaces may be difficult or impossible to differentiate from an early mole. Therefore in cases with equivocal ultrasound features, the products of conception should be carefully evaluated to avoid missing a hydatidiform mole.

Recent studies have shown that **sonography is much more accurate in diagnosing complete molar pregnancy than partial molar pregnancy.** Kirk et al.[144] evaluated sonography in the first trimester and found an accuracy of 95% for the diagnosis of complete mole and 20% for partial mole, with an overall accuracy for hydatidiform mole of 44%. In 859 pathologically diagnosed hydatidiform moles, Fowler et al.[145] found that sonography performed in the first and early second trimester had a similar 44% overall accuracy and an accuracy of 79% and 29% for complete and partial moles, respectively. Also, the sonographic detection rate improved after 14 weeks' gestation.

Coexistent Hydatidiform Mole and Normal Fetus

In complete moles, an embryo or fetus is absent except in the rare event of a coexistent twin pregnancy. These twin pregnancies with an apparently normal fetus and a hydatidiform mole are uncommon, with an estimated incidence of 1 in 20,000 to 100,000 pregnancies.[146,147] It is differentiated from a partial molar pregnancy by identifying a normal-appearing fetus with a corresponding normal placenta adjacent to a mass of placental tissue that

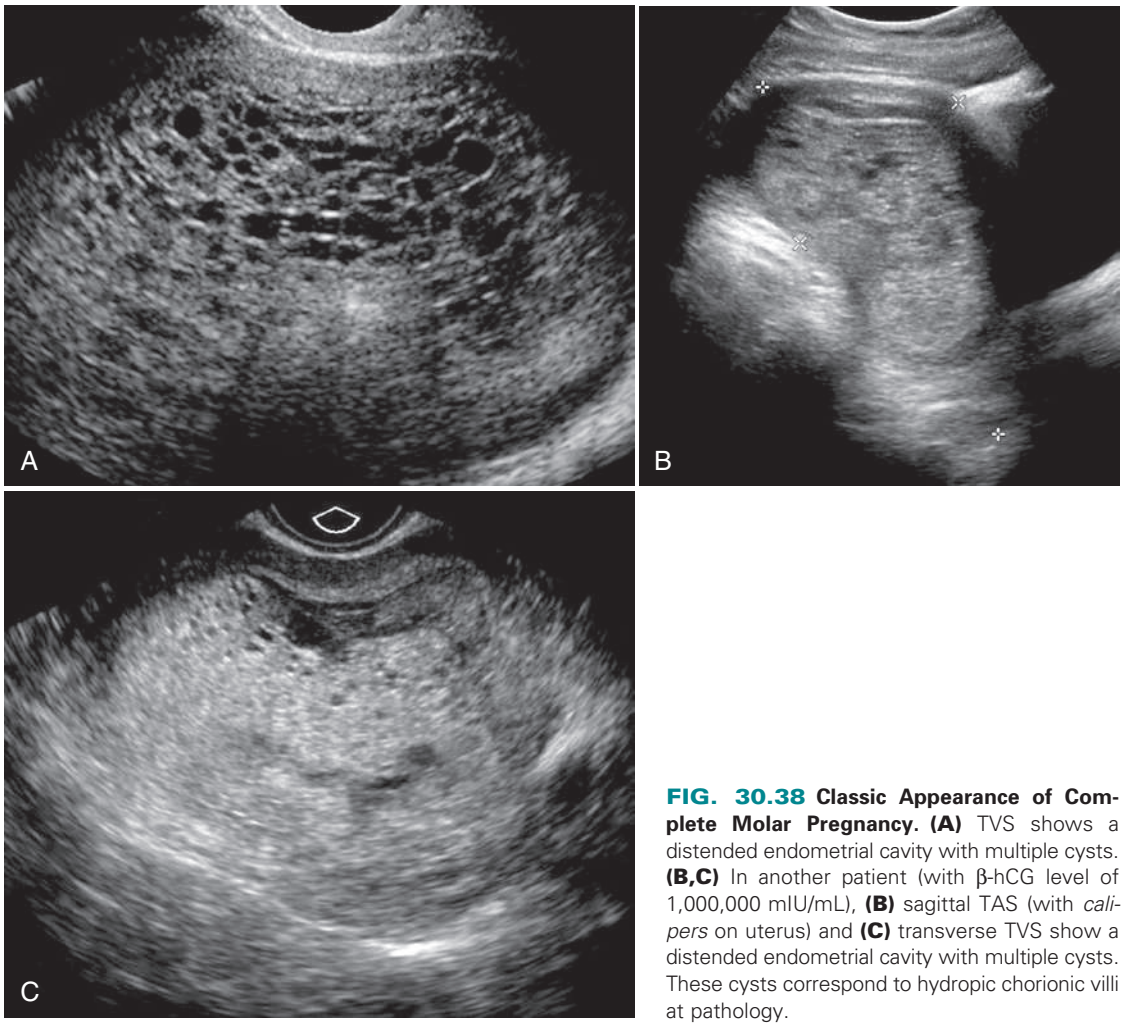

FIG. 30.38 Classic Appearance of Complete Molar Pregnancy. (A) TVS shows a distended endometrial cavity with multiple cysts. **(B,C)** In another patient (with β-hCG level of 1,000,000 mIU/mL), **(B)** sagittal TAS (with *calipers* on uterus) and **(C)** transverse TVS show a distended endometrial cavity with multiple cysts. These cysts correspond to hydropic chorionic villi at pathology.

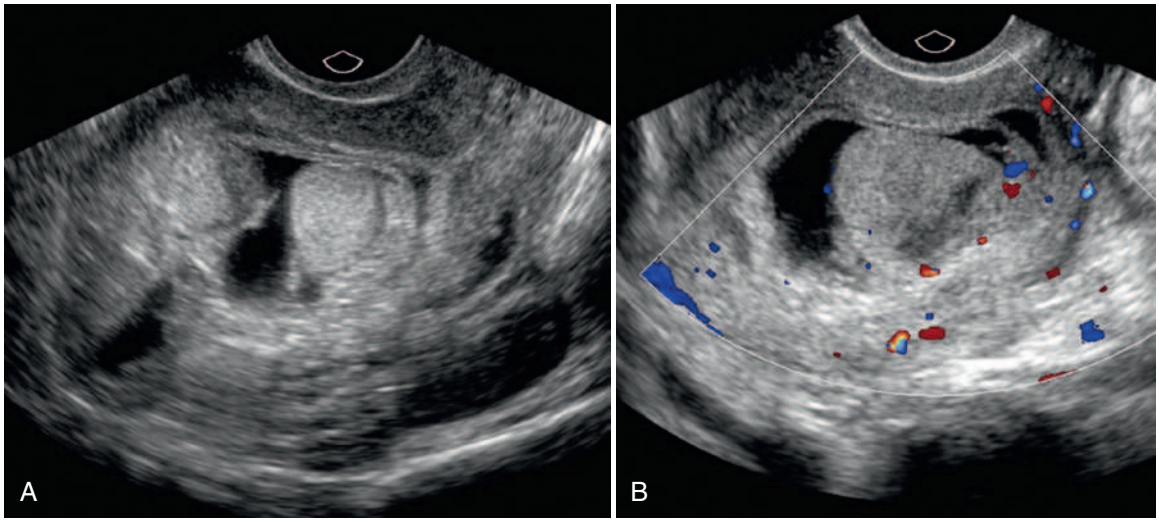

FIG. 30.39 Atypical Appearance Complete Molar Pregnancy. A 33-year-old at 8 weeks' gestation with β-hCG level of 73,000 mIU/mL. Sagittal TVS **(A)** without and **(B)** with color Doppler demonstrate irregular soft tissue masses protruding into the gestational sac.

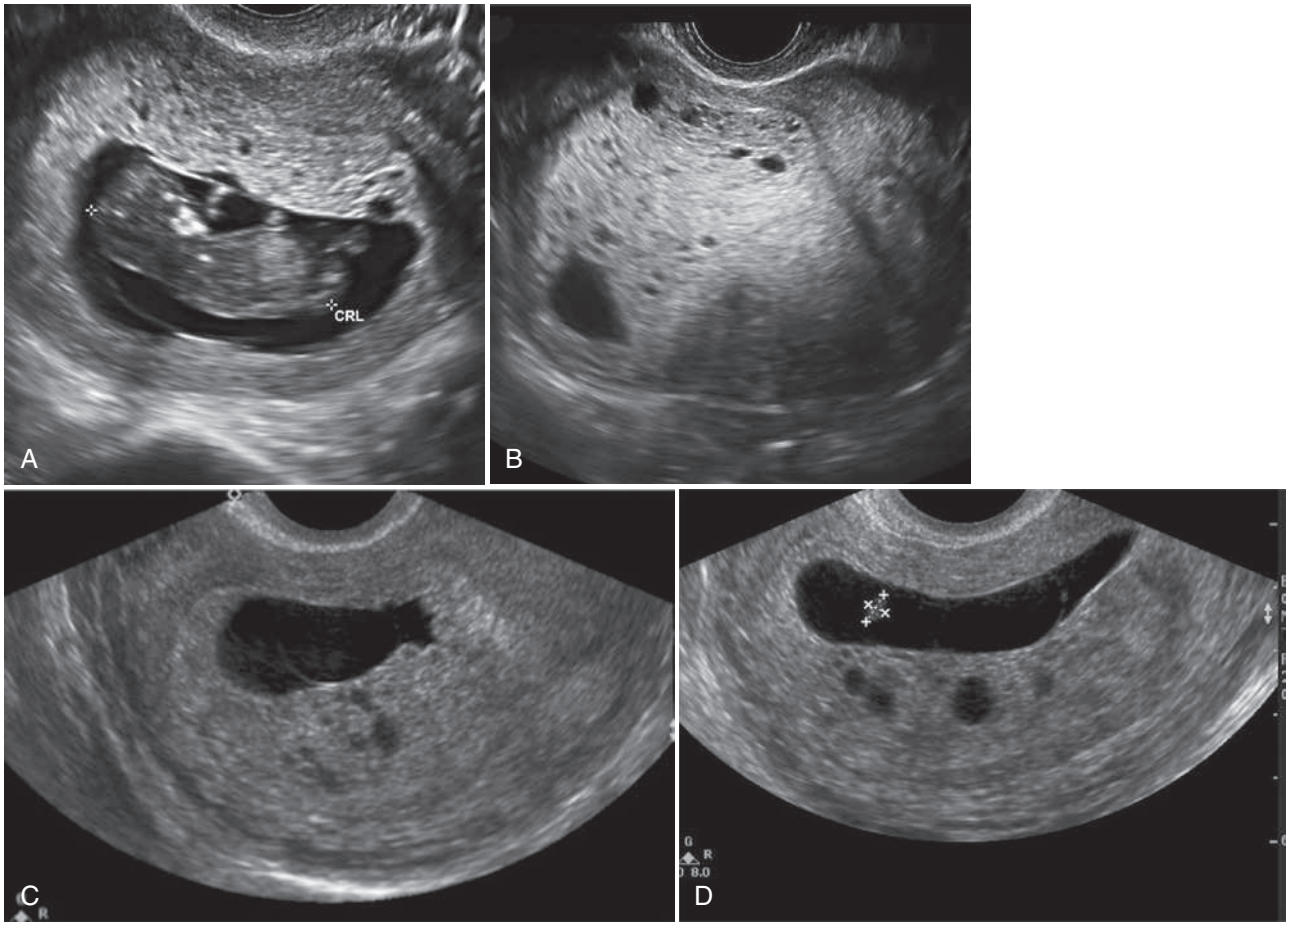

FIG. 30.40 Partial Molar Pregnancy. (A) and **(B)** TVS images show a fetus with a large thick cystic placenta. *CRL,* Crown-rump length. In another patient at 14 weeks' menstrual age (history of bleeding and β-hCG of 32,117 mIU/mL), **(C)** transverse and **(D)** sagittal TVS scans demonstrate an intrauterine gestational sac containing a smaller than expected embryonic pole *(calipers)* without a heartbeat. Multiple small cystic spaces are seen in the placenta.

demonstrates molar changes (Fig. 30.41). Initial studies suggested that these patients were at high risk for developing PTN.[146] However, a larger study of 77 cases showed that the risk of PTN was similar to that after a singleton complete mole and was not increased by continuing the pregnancy.[147] The 53 women who decided to continue the pregnancy had an increased risk of pregnancy complications, but 20 (38%) delivered a live baby, usually after 32 weeks.

Persistent Trophoblastic Neoplasia

PTN is a life-threatening complication of pregnancy that includes invasive mole, choriocarcinoma, and the extremely rare placental-site trophoblastic tumor. PTN occurs most often after molar pregnancy (Figs. 30.42 and 30.43, Video 30.10); up to 20% of complete moles develop persistent disease requiring additional therapy.[134,136] Complete moles with severe degrees of trophoblastic proliferation are at the highest risk, with persistent disease developing in 50% or more of these patients.[140] The risk is also increased in patients older than 40 years of age and in women who have had multiple molar pregnancies.[142] The risk of persistent disease after partial molar pregnancy is much lower, occurring in approximately 5%.[136,142] Less often, PTN develops after a normal term delivery, spontaneous abortion, or, in rare cases, an ectopic pregnancy.[134]

Invasive Mole

Invasive mole is the **most common form of PTN,** accounting for 80% to 95% of cases.[148] Patients usually present with vaginal bleeding and persistent elevation of serum hCG within 1 to 3 months after molar evacuation.[149] Histologically, invasive mole is characterized by the presence of formed chorionic villi and trophoblastic proliferation deep in the myometrium (see Fig. 30.42). It is considered biologically benign and is usually confined to the uterus; in rare cases, molar tissue can penetrate the whole thickness of the myometrium, leading to uterine perforation, which may cause severe hemorrhage.[150] Lesions can invade beyond the uterus to parametrial tissues, adjacent organs, and blood vessels. Rarely, invasive molar villi may embolize to distant sites, including the lungs and brain.

Choriocarcinoma

Choriocarcinoma is an extremely rare malignancy with an incidence of 1 in 30,000 pregnancies. Although it may occur after any pregnancy, the most important risk factor for

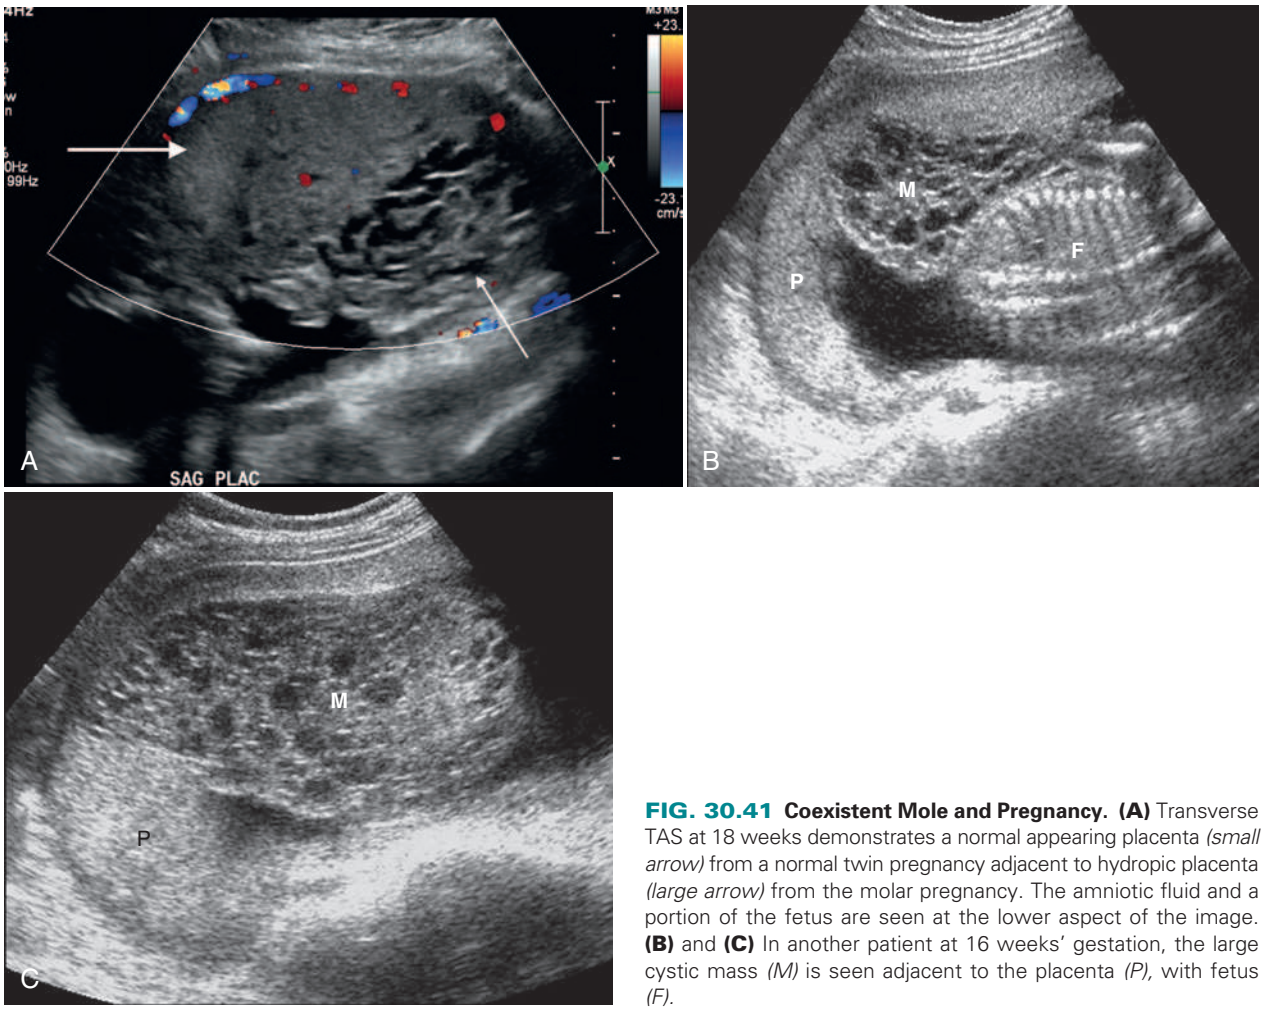

FIG. 30.41 Coexistent Mole and Pregnancy. (A) Transverse TAS at 18 weeks demonstrates a normal appearing placenta *(small arrow)* from a normal twin pregnancy adjacent to hydropic placenta *(large arrow)* from the molar pregnancy. The amniotic fluid and a portion of the fetus are seen at the lower aspect of the image. **(B)** and **(C)** In another patient at 16 weeks' gestation, the large cystic mass *(M)* is seen adjacent to the placenta *(P),* with fetus *(F).*

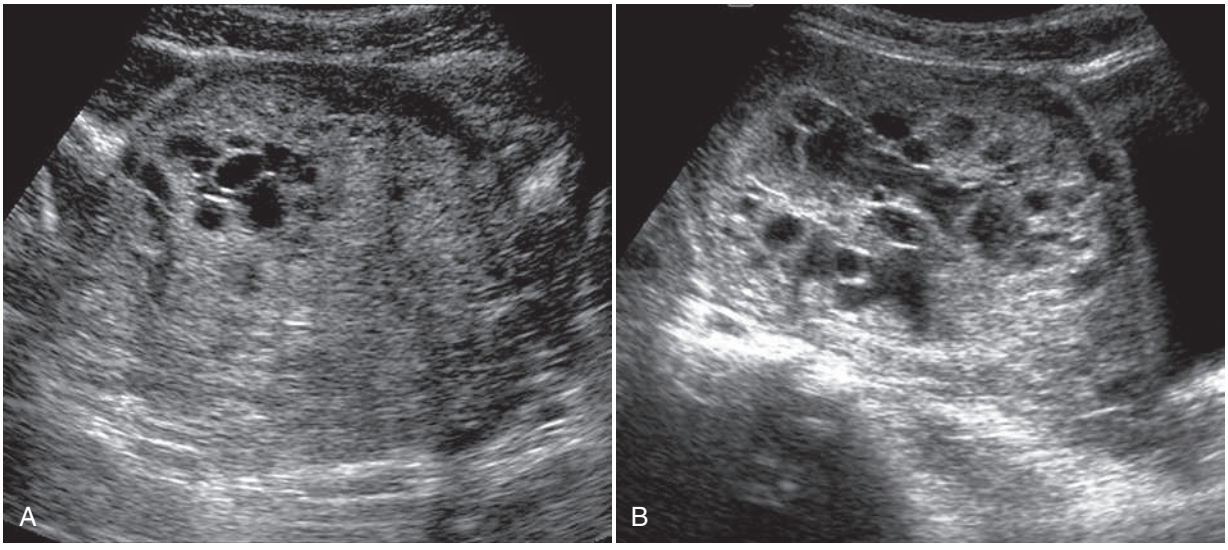

FIG. 30.42 Invasive Mole 6 Weeks After Evacuation of Complete Mole. (A) Transverse and **(B)** sagittal TAS images show large mass filled with multiple cystic spaces extending deep into the myometrium on the right side.

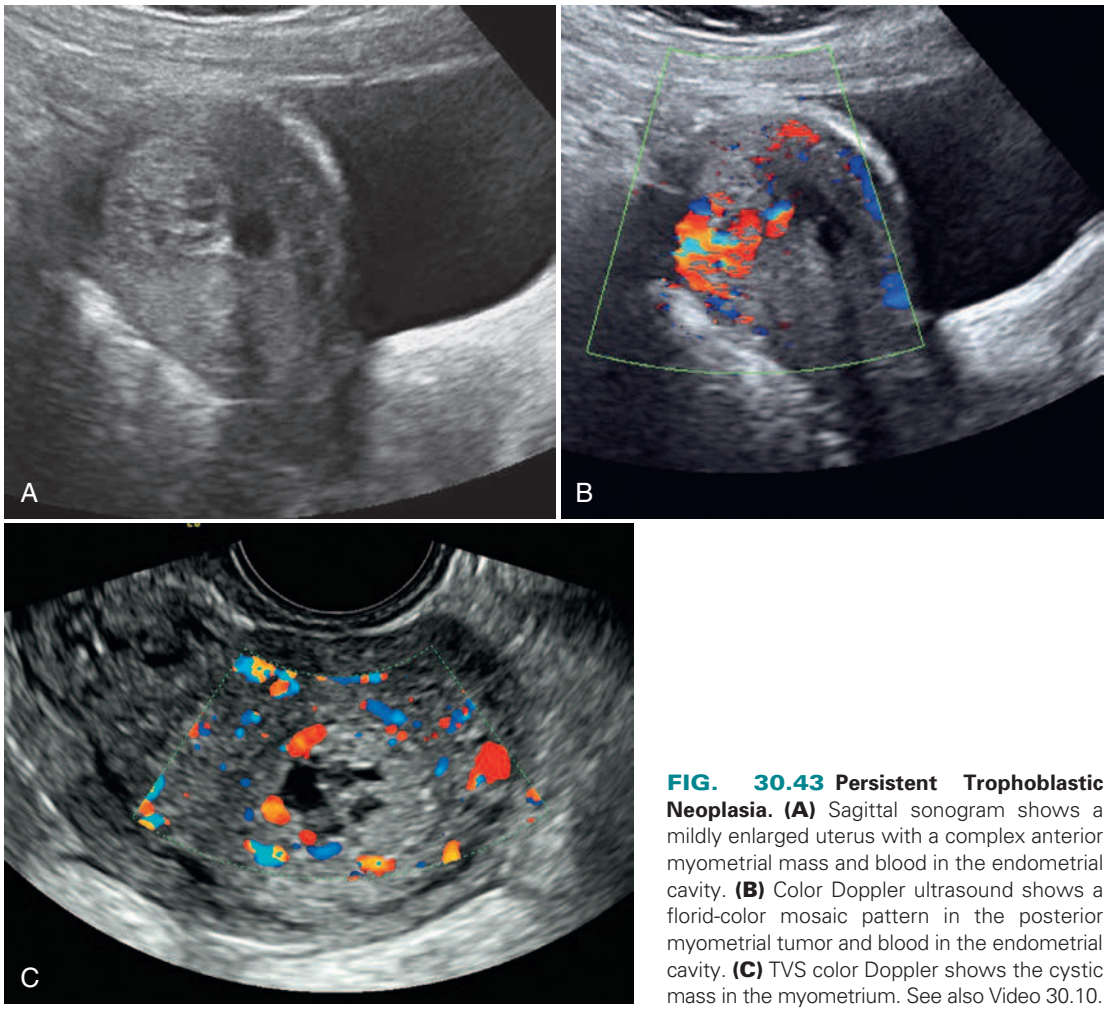

FIG. 30.43 Persistent Trophoblastic Neoplasia. (A) Sagittal sonogram shows a mildly enlarged uterus with a complex anterior myometrial mass and blood in the endometrial cavity. **(B)** Color Doppler ultrasound shows a florid-color mosaic pattern in the posterior myometrial tumor and blood in the endometrial cavity. **(C)** TVS color Doppler shows the cystic mass in the myometrium. See also Video 30.10.

choriocarcinoma is molar pregnancy (Fig. 30.44, Video 30.11). Molar gestations precede 50% to 80% of cases, and 1 in 40 molar pregnancies gives rise to choriocarcinoma. Choriocarcinoma is a purely cellular lesion characterized histologically by the invasion of the myometrium by abnormal, proliferating trophoblast and the absence of formed villi. Hemorrhage and necrosis are prominent features.[135] Early vascular invasion is common, resulting in distant metastases, most frequently affecting the lungs, followed by the liver, brain, gastrointestinal tract, and kidney. Respiratory compromise may be the initial presentation.[151] Venous invasion and retrograde metastases to the vagina and pelvic structures are also common.[151]

Placental-Site Trophoblastic Tumor

Placental-site trophoblastic tumor (PSTT) is the **rarest and most fatal form of PTN.**[152] As with choriocarcinoma and invasive mole, PSTT can follow any type of gestation, but in more than 90% of cases it develops after a normal term delivery.[150] The tumor may occur from as early as 1 week to many years after pregnancy. Vaginal bleeding is the most common symptom, although some women may present with amenorrhea. Histologically, PSTT is distinct from other forms of trophoblastic neoplasia. It arises from nonvillous "intermediate" trophoblast that infiltrates the decidua, spiral arteries, and myometrium at the placental bed. PSTT may be confined to the uterus, may be locally invasive in the pelvis, or may metastasize to the lungs, lymph nodes, peritoneum, liver, pancreas, or brain. Serum hCG is not a reliable marker for PSTT; it is usually negative or only mildly elevated. Histochemical staining of intermediate trophoblast for hCG is weak or absent, whereas staining for human placental lactogen is strongly positive. Unfortunately, serum human placental lactogen is not a reliable predictor of tumor behavior.[152] Surgical therapy is recommended because these lesions tend to resist chemotherapy and have a high risk of metastasis.

Sonographic Features of Persistent Trophoblastic Neoplasia

Sonography plays an important role in detecting and staging PTN and in monitoring response to therapy. The small, myometrial lesions typical of this condition may not be apparent on TAS.[153] Invasive mole, choriocarcinoma, and PSTT may appear similar sonographically.[154,155] The most frequently described sonographic abnormality in PTN is a focal, echogenic myometrial nodule.[151,153-155] The lesion usually lies close to the endometrial cavity, but it may be found deep in the myometrium. Lesions may appear solid and uniformly echogenic, hypoechoic, or

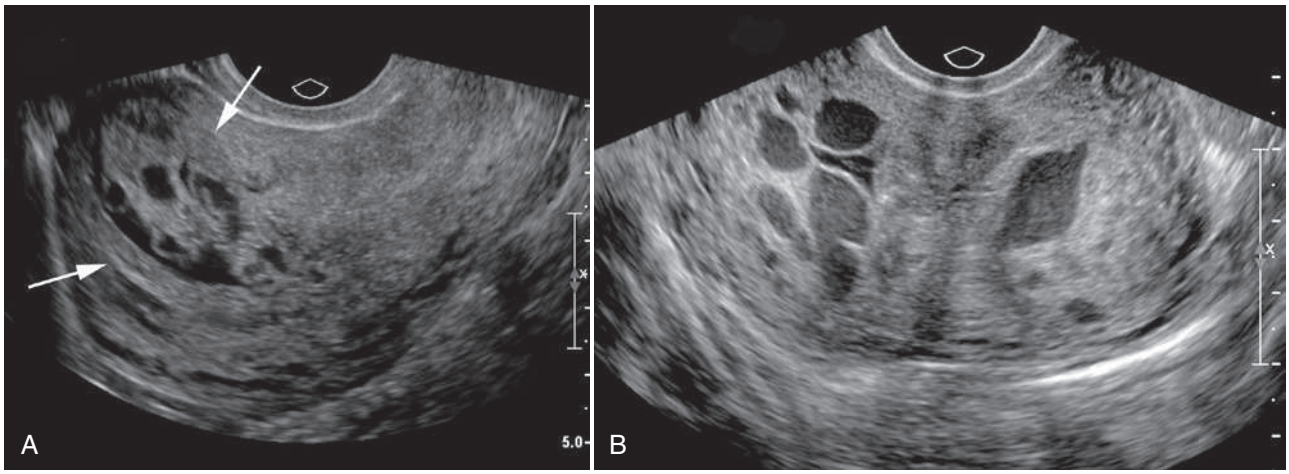

FIG. 30.44 Choriocarcinoma After Normal Pregnancy. (A) Sagittal and **(B)** transverse TVS images show an ill-defined endometrium *(arrows)* with multiple large cystic spaces. See also Video 30.11.

complex and multicystic, similar to molar tissue. Thick-walled, irregular anechoic areas may be seen, resulting from tissue necrosis and hemorrhage.[153-155] In other cases, anechoic areas within lesions represent vascular spaces. When tumor replaces the entire myometrium, the uterus is enlarged, with the myometrium appearing heterogeneous and lobulated. The tumor may extend beyond the uterus to the parametrium, pelvic side wall, and adjacent organs. In extreme cases, PTN appears as a large, undifferentiated pelvic mass. Sonography can be diagnostic in the correct setting (e.g., recent molar pregnancy, rising serum hCG, previously documented normal sonogram).

After effective therapy, sonographic lesions become progressively more hypoechoic and smaller in size. Eventually, no residual abnormality is apparent in many cases. However, up to 50% of patients will have persistent abnormalities after therapy that may be difficult to distinguish from active lesions sonographically.

Duplex and color Doppler ultrasound features of PTN reflect the marked hypervascularity of invasive trophoblast.[156,157] Uterine spiral arteries feed directly into prominent vascular spaces, which then communicate with draining veins. These **functional arteriovenous shunts** produce abnormal uterine hypervascularity and high-velocity, low-impedance blood flow on duplex interrogation.[156] **Trophoblastic blood flow** has characteristic, high PSV and low RI. PSV is usually greater than 50 cm/sec and is often over 100 cm/sec. RI is usually less than 0.5 and is often well below 0.4. In contrast, normal myometrial blood flow usually has a PSV of less than 50 cm/sec and an RI in the range of 0.7. Color Doppler sonographic features typical of PTN include extensive color aliasing, admixture of color signals, loss of discreteness of vessels, and chaotic vascular arrangement. Regions of abnormal color Doppler ultrasound frequently appear larger than corresponding sonographic abnormalities.

Trophoblastic signals on spectral Doppler ultrasound are not unique to PTN. They are seen in all conditions with functioning trophoblast, including failed pregnancy, retained products of conception, and ectopic pregnancy. These potential pitfalls are distinguished from PTN by clinical findings, sonographic morphology, and pathology. However, PSTT should remain a consideration even with a normal hCG level. In most patients the diagnosis of PTN is fairly straightforward, and additional information provided by Doppler ultrasound is supportive but not critical. However, when PTN is not suspected clinically, duplex and color Doppler sonography may provide the first indication of trophoblastic disease by showing marked hypervascularity and typical trophoblastic blood flow within lesions. Doppler ultrasound also improves diagnostic specificity by showing normal uterine waveforms when PTN is absent and sonography is abnormal, as when other uterine lesions mimic the appearance of PTN, or persistent nonspecific abnormalities remain after effective therapy.[157]

Diagnosis and Treatment

Because PTN arises most often after a molar pregnancy, the diagnosis is usually based on abnormal regression of hCG after uterine evacuation. A histologic diagnosis is not considered mandatory because curettage risks uterine perforation and does not significantly alter management or outcome.[151,158] Patients are treated on the basis of clinical staging that includes computed tomography of the brain, chest, abdomen, and pelvis.

With the exception of PSTT, hCG level is a sensitive and specific marker for detecting and monitoring PTN. Normal mean disappearance time of hCG in benign moles ranges from 7 to 14 weeks (median, 11 weeks) but can be as long as a year. Contraception is recommended for 6 months after a normal hCG has been attained in order to distinguish a rising hCG resulting from persistent or recurrent disease from that due to pregnancy.[133]

PTN is broadly classified as **nonmetastatic** or **metastatic** on the basis of staging computed tomography of the brain, chest, abdomen, and pelvis.[151,158] Nonmetastatic PTN has an excellent prognosis. Single-agent therapy with methotrexate achieves sustained remission in virtually 100% of cases.[158] Metastatic PTN is subdivided into **low-risk** and **high-risk** groups. Virtually all patients with low-risk metastatic disease are cured with simple chemotherapy.[151] In contrast, patients with high-risk disease have a substantially worse prognosis and a high likelihood of failure

with single-agent therapy. High-risk, poor-prognosis disease is indicated by duration of disease for more than 4 months, pretreatment hCG levels greater than 40,000 mIU/mL, presence of brain or liver metastases, antecedent term pregnancy, and prior history of failed chemotherapy. These patients are treated aggressively with appropriate combinations of intense multiagent chemotherapy, adjuvant radiotherapy, and surgery. By tailoring therapy in this way, even high-risk patients have cure rates of 80% to 90%.[151,159]

CONCLUSION

First-trimester sonography plays an important role in establishing the location of a pregnancy and determining if the pregnancy is potentially viable (cardiac activity seen). Knowledge of the landmarks with respect to the appearance of the gestational sac, yolk sac, and embryo are important in the appropriate triage of patients who present with pain and bleeding in the first trimester.

CHAPTER 31

Chromosomal Abnormalities

Bryann Bromley and Beryl Benacerraf

SUMMARY OF KEY POINTS

- Screening for aneuploidy using the nuchal translucency (NT) measurement should be performed by a credentialed provider participating in an ongoing quality-monitoring program.
- In chromosomally normal fetuses with an increased NT, normal anatomy and no identifiable genetic syndromes, there does not appear to be a higher risk of developmental delay than in the general population.
- A "marker" identified during a second-trimester sonogram should prompt a detailed evaluation of the fetus and correlation with a priori risk estimates for aneuploidy.
- The constellation of sonographic findings seen in the second trimester may lead physicians to suspect a specific chromosomal abnormality.
- Cell-free DNA screening with reportable results has superior test performance metrics compared with traditional screening for targeted aneuploidies; however, false-positive and false-negative results occur. Positive results should be confirmed by a diagnostic test. Negative results do not ensure a normal outcome.

CHAPTER OUTLINE

FIRST-TRIMESTER SCREENING FOR ANEUPLOIDY
Nuchal Translucency and Trisomy 21
Serum Biochemical Markers
Combined First-Trimester Screening
Integrated and Sequential Screening
Standardization of Nuchal Translucency Measurement Technique
Nuchal Translucency and Other Aneuploidies
Cystic Hygroma
Nasal Bone
Other Markers for Aneuploidy
Reversed Flow in Ductus Venosus
Tricuspid Regurgitation

PRENATAL SCREENING FOR ANEUPLOIDY WITH CELL-FREE DNA
DIAGNOSTIC TESTING
CONCLUSION

The current standard of obstetric care in the United States is to offer prenatal screening for aneuploidy to all women who present for care before 20 weeks' gestation.[1] If a woman chooses to have a prenatal risk assessment for aneuploidy, multiple sonographic markers and biochemical parameters are available in both the first and the second trimester. Recently, the paradigm for prenatal screening has included the evaluation of **cell-free DNA** in the maternal plasma and diagnostic testing has expanded beyond the basic karyotype to include microarray analysis that can detect small deletions and duplications in the genome, known as "copy number variants" (CNVs).[2,3] The choices available depend on the gestational age of the fetus at presentation for obstetric care and the availability of resources within the local demographic area. Screening algorithms are becoming progressively more diverse with varying trade-offs.[4] Counseling by an experienced provider is recommended.[5]

Background risk for **aneuploidy** (deviation from exact multiple of haploid number of chromosomes) depends on maternal age, fetal age, family history, and previously affected pregnancy. Whereas trisomies 21, 18, and 13 increase in frequency as maternal age increases, monosomy X and triploidy remain at a constant rate[6] (Fig. 31.1).

Trisomy 21 (Down syndrome) is the most common aneuploidy to result in a live birth and is the most frequently identifiable genetic cause of mental retardation. The estimated prevalence has increased over the past 20 years because of trends in advancing maternal age and is estimated to be 1 in 504 in the second trimester.[7] Trisomies 18 and 13 are rarer, with a prevalence of 1 in

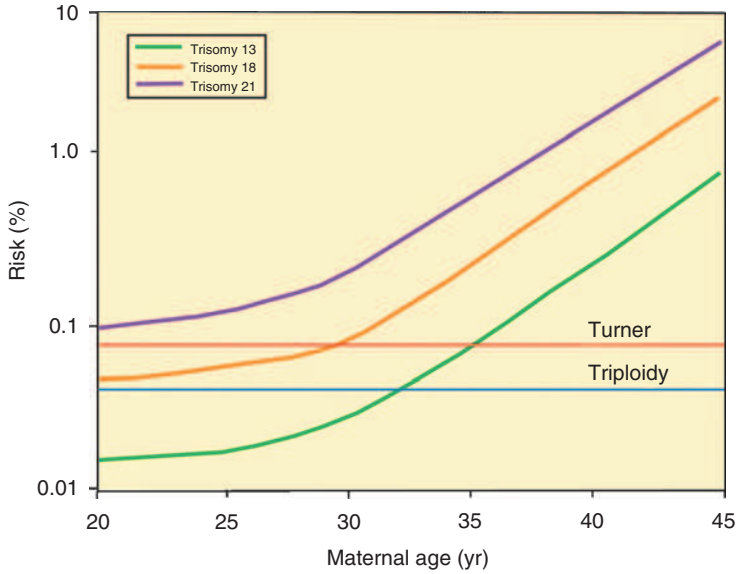

FIG. 31.1 Maternal Age–Related Risk for Chromosomal Abnormalities.

5000 and 1 in 10,000, respectively.[8] The frequency of aneuploidy is higher earlier in gestation because of the fetal loss rate associated with chromosomal abnormalities as gestation progresses. Fetal death with trisomy 21 between the first or second trimester and birth is 30% and 20%, respectively. Fetal death between the first trimester and birth with trisomies 18 and 13 is approximately 80%.[6,9]

FIRST-TRIMESTER SCREENING FOR ANEUPLOIDY

First-trimester screening for aneuploidy that incorporates ultrasound provides a patient-specific numeric risk estimate of trisomy 21, 18 and 13. It may also be a clue for other chromosomal conditions.[10] Most pregnancies are normal, so most women can be reassured early in gestation that their risk of aneuploidy is low. Others may find that the risk estimate is high enough that to undergo a secondary **screening with cell-free DNA** or diagnostic testing (chorionic villous sampling) to obtain a karyotype or microarray analysis. If the results are abnormal, the patient has time to obtain additional information and explore resources that are available before making a decision about continuing or terminating a pregnancy. The decision to terminate can be made with privacy and at a time in pregnancy when safe methods of pregnancy interruption are available.[11]

Nuchal Translucency and Trisomy 21

In 1866, Dr. Langdon Down reported a classification of individuals with developmental delay who had similar physical characteristics. He described the skin as "deficient in elasticity, giving the appearance of being too large of the body."[12] Fetuses with trisomy 21 as well as other aneuploidies often have excess fluid in the subcutaneous tissue behind the fetal neck (Fig. 31.2A, Video 31.1). Sonographically, this appears as an echolucent fluid collection between the soft tissue over the cervical spine and an echogenic line representing the skin edge. This fluid space is called the **nuchal translucency** (NT)[13] (Fig. 31.2B). The lucency is thought to represent mesenchymal edema and is often associated with distended jugular lymphatics (Fig. 31. 2C). The prevailing theory suggests an alteration in lymphangiogenesis and delayed lymphatic development. Other possible causes include cardiac failure and abnormal extracellular matrix, but these do not explain the localized and transient nature of the NT. Most likely, the cause is a complex interaction of factors.[14] NT normally increases with advancing gestational age, and therefore the measurement is compared to **crown-rump length** (CRL, Fig. 31.2D). An NT greater than 95% for CRL is considered thickened. An NT greater than 99% does not change significantly with CRL and is approximately 3.5 mm[15] (Fig. 31.2E).

In 1992, Nicolaides et al.[13] reported that an NT of 3 mm or greater in the first trimester was associated with a 35% risk of chromosomal abnormality. The association between chromosome anomalies and a thickened NT was subsequently confirmed in a large, prospective multicenter trial of 20,804 pregnancies. The risk of trisomy 21 can be calculated by multiplying the a priori (presumptive) risk by a **likelihood ratio** derived from the degree of deviation in NT from the expected NT. This methodology, in conjunction with a risk cutoff of 1 in 300, resulted in the identification of 80% of fetuses with trisomy 21, with a **false-positive rate** (FPR) of 5%.[16] Snijders et al.[17] evaluated the use of NT and maternal age to detect trisomy 21 in a multicenter trial that included 22 different sites and 306 trained sonographers. Using a threshold of 1 in 300, the sensitivity for the detection of trisomy 21 was 82% for an FPR of 8%. If the FPR was set at 5%, the sensitivity for the detection of trisomy 21 was 77%.

Serum Biochemical Markers

A variety of serum biochemical markers have different concentrations in pregnancies with trisomy 21 compared with euploid

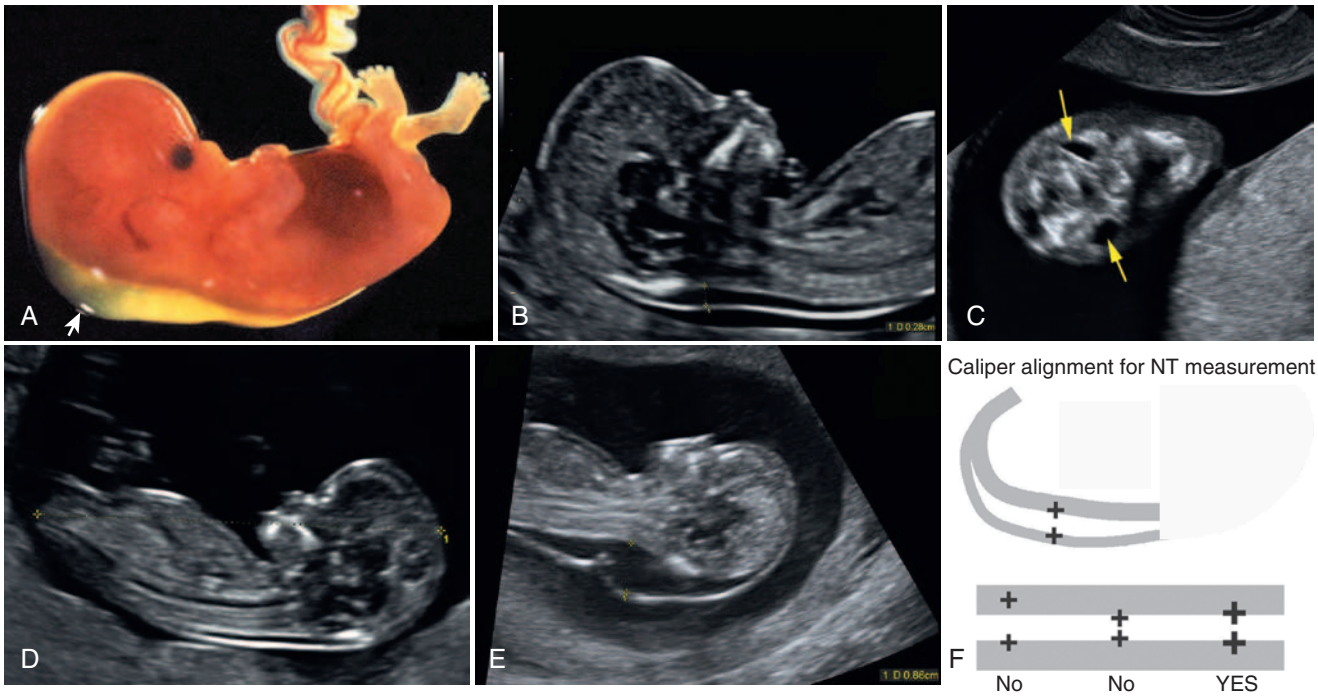

FIG. 31.2 Nuchal Translucency. (A) Gross pathology image of a fetus with trisomy 21 demonstrating the fluid collection at the back of the neck known as the "nuchal translucency" (NT; *arrow*). pregnancies. The maternal serum of women carrying fetuses with trisomy 21 has a higher concentration of **free beta human chorionic gonadotropin** (free β-hCG) and lower concentration of **pregnancy-associated plasma protein A** (PAPP-A) compared with the serum of women carrying euploid fetuses. The use of these serum markers, in conjunction with maternal age, results in identification of 62% of fetuses with trisomy 21 at an FPR of 5%.[18]

Combined First-Trimester Screening

There is no association between NT measurement and serum levels of free β-hCG or PAPP-A in euploid fetuses or in those with trisomy 21. This independence allows the combination of NT screening and biochemical screening, resulting in a more effective method of risk assessment than either method individually.[19,20] Wald et al.[21] demonstrated that the combination of NT measurement with maternal serum PAPP-A and free β-hCG, known as the **combined first-trimester screening** test, results in the detection of 85% of trisomy 21 fetuses at an FPR of 5%.

First-trimester screening using NT measurement and serum biochemical measurement has been further validated in four large studies. The One-Stop Clinic to Assess Risk (OSCAR) screening trial in the United Kingdom studied 12,339 women with singleton pregnancies between 10 and 14 weeks' gestation. First-trimester screening was accepted by 97.5% of the women, and if they screened positive (risk ≥ 1:300), 77% underwent invasive diagnostic testing. There were 25 cases of trisomy 21, of which 23 (92%) were detected, with an FPR of 5%. The detection rates of both trisomy 13 and 18 were 100%.[22]

A multicenter trial in North America (BUN study) similarly evaluated 8514 patients with singleton pregnancies between 74 and 97 days' gestation. A screening result was considered positive if the risk of trisomy 21 was 1 in 270 or higher or the risk of trisomy 18 was 1 in 150 or higher. There were 61 cases of trisomy 21; detection rate was 79% with a 5% FPR. The detection rate of trisomy 18 was 90% with a 2% FPR.[23]

The Serum, Urine and Ultrasound Screening Study (SURUSS) evaluated the efficacy, safety, and cost-effectiveness of first- and second-trimester screening for trisomy 21. This prospective study was conducted primarily in the United Kingdom on 47,053 pregnancies between 9 and 13 weeks' gestation. In the first trimester the combined test had a sensitivity of 85% for the detection of trisomy 21 with an FPR of 6%.[24]

The First and Second Trimester Evaluation of Risk (FASTER) was the largest trial based in the United States and was designed to determine how best to screen pregnant women for trisomy 21. This multicenter trial included 36,120 patients with complete first-trimester data, of whom 92 fetuses had trisomy 21. The trial included NT measurements as well as serum biochemistry in both the first and the second trimester, revealing the results to patients only in the second trimester, after both serum screens.

The detection rate of trisomy 21 was 87%, 85%, and 82% at 11, 12, and 13 weeks' gestation, respectively, at a 5% FPR. For a detection rate of 85%, NT alone (without biochemical data) had an unacceptably high FPR of 20%. If the FPR was set at the more acceptable level of 5%, the sensitivity for detection of trisomy 21 fell to 68%.[25]

Screening for aneuploidy in twin gestations is less robust than in singleton gestations and is hampered by nuances of placentation. Determination of amnionicity and chorionicity is crucial. Sebire et al.[26] studied a series of 448 twin pregnancies and identified 88% of trisomy 21 fetuses (FPR 7%) using an NT less than 95%. The prevalence of a thickened NT is higher in euploid monochorionic twins than in euploid dichorionic twins, which may relate to placental structure or fetal anomalies. Discordance of NT measurements in monochorionic twins may predict twin-to-twin transfusion syndrome.[27,28] Additionally, the contribution of biochemical markers increases the complexity of risk assessment in twin gestations because the concentration of markers relates to the pregnancy (as opposed to the individual fetus). Spencer and Nicolaides[29] identified 75% of trisomy 21 fetuses (FPR of 7%) using biochemical markers and NT measurement. Wald and Rish[30] reported that at a set FPR of 5%, the estimated detection rate of trisomy 21 was 84% in monochorionic twins and 70% in dichorionic twins. This compares to an 85% estimated detection rate in singletons. Recently, it has been reported that the risk of trisomy 21 in twins may not be as high as previously thought, especially in monozygotic twins; these data add to the complexity of risk assessment. In a large population study based in Europe examining the prevalence of Down syndrome among monozygotic and dizygotic twins, the adjusted risk ratio (RR) of Down syndrome was 0.58 (95% CI, 0.53-0.62) for twins compared with singletons. This was most pronounced in monozygotic twins where the adjusted RR was 0.34 (95% CI, 0.25-0.44). In dizygotic twins the adjusted RR was 1.34 (95% CI, 1.23-1.46).[31]

A major question is whether an NT measurement exists above which there is no benefit to additional biochemical screening. Results of the FASTER trial were evaluated with specific attention to this question. An NT of 4 mm or greater was identified in 32 patients (0.09 %). In this group the lowest combined risk assessment for trisomy 21 in euploid fetuses was 1 in 8 and for aneuploid fetuses was 7 in 8. There were 128 patients with NT of 3 mm or greater. The lowest risk of trisomy 21 among euploid fetuses using combined screening was 1 in 1479, and the lowest risk among those with aneuploidy was 1 in 2. Only 10 patients (8%) had the risk lowered below 1 in 200, all of whom had normal outcome. These authors concluded that there is minimal benefit in waiting for combined screening results in fetuses with NT of 3 mm or larger and no benefit for those with NT of 4 mm or larger.[32]

Integrated and Sequential Screening

Wald et al.[33] introduced the concept of **integrated screening,** in which first- and second-trimester evaluation is used to provide a *single* risk estimate for trisomy 21.

The FASTER trial compared screening strategies across the first and second trimesters. There were 33,546 patients with complete first- and second-trimester data available, including 87 fetuses with trisomy 21. The fully integrated screen that included first-trimester NT measurement along with PAPP-A and a second-trimester quad screen resulted in the detection of 95% of fetuses with trisomy 21 at a 5% FPR or 87% if the FPR was set at 1%.[25] A disadvantage of integrated screening is that the patient does not have any screening results in the first trimester, and fetuses at high risk of trisomy 21 are not identified until the midtrimester.[34] Compounding this, as many as 20% of patients may not comply with the second-trimester screen.[24,35]

Two alternative approaches have been proposed in response to the criticism of late notification of patients at "high risk" of aneuploidy. Each of these sequential protocols discloses first-trimester results to patients above a specific "high-risk" threshold.[35,36] Women above the threshold and therefore considered at highest risk can be referred for genetic counseling and diagnostic testing early in gestation. In the *step-wise protocol,* those not identified in the high-risk group undergo second-trimester biochemical screen. In the *contingent protocol,* only those women at intermediate risk (≥1:50 and <1:1500) go on to the second-trimester biochemical screening while those at low risk (<1:1500) are not offered additional screening. In each protocol the results of first- and second-trimester screening are **integrated** and reported as a single number because if they are independently interpreted, the FPR is unacceptably high.[1,37] Those with a risk of 1 in 270 or higher were offered genetic counseling and diagnostic testing.

Cuckle et al.[35] retrospectively calculated the midtrimester risks of trisomy 21 from the FASTER trial data. In this study, patients were categorized as "high risk" (>1:30), "borderline risk" (1:30-1:1500), and "low risk" (<1:1500) based on the results of the first-trimester evaluation. Only patients in the borderline category underwent recalculation of risk based on second-trimester biochemical screening. The initial detection of trisomy 21 (>1:30) after first-trimester screening was 60% with an FPR of 1.2%. Of the remaining population, 23% were at borderline risk and calculated as having additional screening. Contingent screening identified 91% of fetuses with trisomy 21, with a 4.5% FPR. Stepwise screening, in which all women other than those at highest risk had calculated first- and second-trimester testing, had a detection rate of 92% with an FPR of 5.1%. Integrated screening, in which all women had both first-semester and second-trimester testing, had a detection rate of 88% with an FPR of 4.9%. This study showed that **contingent screening,** in which only 23% of the population went on to the second-trimester biochemical serum screen, had a similar detection rate of trisomy 21 as the protocols in which most if not all patients had recalculation of risk with second-trimester biochemistry.

Standardization of Nuchal Translucency Measurement Technique

For NT screening to be accurate, standardization of technique, training, and ongoing monitoring are crucial. This education, validation, and ongoing quality assurance has been

supported by two organizations: the Nuchal Translucency Quality Review program based in the United States and the Fetal Medicine Foundation based in the United Kingdom. The criteria and caliper placement for measuring the NT are illustrated in Fig. 31.2 (see also Video 31.1 for real time scanning without measurement). The specific details for credentialing can be found at www.ntqr.org or www.fetalmedicine.org.

The fetal CRL must be between 45 and 84 mm although variations exist among laboratories that perform the biochemical component. The accuracy of the NT measurement and the CRL is critical because the NT measurement is converted into multiples of the median (MoM) based on the CRL. An adequate sonographic image to measure the CRL requires the fetus to occupy a majority of the image space and be in a neutral position. The longest straight line between the fetal crown and rump is measured at least three times and the average of three good measurements is used.

Haddow et al.[38] showed that accuracy is critical when obtaining an NT measurement. They studied 4412 women who underwent first-trimester screening with biochemistry and NT in which no specific training in NT measurement was required although the method for measuring NT was a standard protocol. Measurement of the NT varied considerably between centers and could not be reliably incorporated into risk calculations. Furthermore, the center with the highest success rate in obtaining an NT measurement (100%) had the lowest sensitivity (0%) for identifying trisomy 21. Results from the BUN trial revealed that after training, measurements were initially smaller than expected compared with normative values developed by Fetal Medicine Foundation. With increasing experience, the measurements of the BUN trial were in concordance with published norms.[23,39]

Criteria for an Accurate Crown-Rump Length

ALARA: Thermal Index BONE < 0.7[40]

MAGNIFICATION
The fetus fills the majority of the image space available

MIDSAGITTAL VIEW
Fetal spine midsagittal
Profile, spine, and rump are visible

NEUTRAL POSITION
The spine is in line with the head
Fluid is visible between the fetal chin and chest

MEASUREMENT
Angle of insonation perpendicular to fetus
Fetus horizontal on image
Calipers are placed on the outer border of the skin at crown and rump

Fetal Nuchal Translucency (NT) Measurement Technique

ALARA: Thermal Index BONE < 0.7[40]

CLEAR NT MARGINS
Thin NT line
Angle of insonation perpendicular to NT space
Fetus horizontal on image
TIPS for optimal imaging:
1. Optimize your focal zone
2. Reduce your dynamic range
3. Reduce the gain
4. Review harmonics. Possible edge enhancement optimized with harmonics off
5. Avoid post freeze zoom
6. Narrow your sector

FETUS IN MIDSAGITTAL PLANE
Fetal spine midsagittal in thoracic and cervical region
Tip of nose in profile
Third and fourth ventricles in brain demonstrated

FETUS OCCUPIES MAJORITY OF IMAGE
Head, neck, and upper thorax fill image
Fetus occupies more than 50% of image space; a second fetus of the same size would not fit in the image space

HEAD IN A NEUTRAL POSITION
Head in line with the spine, angle of neck and chest is less than 90 degrees
Pocket of fluid should be visible between chin and neck

AMNION SEEN SEPARATELY FROM NT LINE
Fetus is seen away from uterine wall and separate from the amnion

MEASUREMENT
Calipers (cursors) must be + (plus/positive)
Crossbar of caliper is on the NT line at the inner border adjacent to the lucency
Measurement is perpendicular to long axis of fetus
Measurement is taken at the WIDEST part of the lucency (If nuchal cord, measure above and below the cord and average)

A poorly done NT measurement has a negative impact on detection of aneuploidy, and inaccuracy of 0.5 mm decreases sensitivity by 18%.[41] Training an inexperienced examiner to obtain reliable reproducible NT measurements takes 80 to 100 scans.[42]

Screening using an NT measurement is not always possible because of limited availability of this specialized ultrasound in certain areas and a variety of maternal conditions, including large myomas and high maternal body mass index, which may hamper the ability to obtain a reliable measurement. Initial studies suggested that an NT value was obtainable in 99% of cases, but clinical studies report an 80% initial success rate.[43,44]

If an accurate NT measurement is not possible, a serum-only version of the integrated test should be offered. The performance of the serum integrated test with no ultrasound component has

approximately an 85% detection rate for Down syndrome at a 5% FPR.[22,25,33]

Nuchal Translucency and Other Aneuploidies

A thickened NT has been used to detect fetuses with trisomy 18. These fetuses have an abnormal biochemical pattern with very low β-hCG and very low PAPP-A. The BUN trial of 8514 screened pregnancies, using a risk cutoff of 1 in 150, identified 91% of fetuses with trisomy 18 with a 2% FPR. Additionally, four in five fetuses with trisomy 13 were identified.[23] These trisomies result in fetuses that have multiple congenital malformations and rarely survive beyond the first year of life. The FASTER trial reported a detection rate of 78% for all nontrisomy 21 aneuploidies at FPR of 6% when first-trimester screening included those cystic hygroma or combined screening.[45] Spencer and Nicolaides[46] developed an algorithm for the detection of trisomy 18 and 13 that included maternal age, NT, free β-hCG, and PAPP-A. Using a risk cutoff of 1 in 150, they predicted a 95% detection rate for these chromosomal defects with FPR of 0.3%. In a population-based study of 452,901 women with singleton gestations, the detection rates of aneuploidy based on first-trimester and sequential screening was 81.6% at a FPR of 4.5%. The detection rates of trisomy 21, 18, and 13 were 92.9%, 93.2%, and 80.4% respectively. The detection of monosomy X and triploidy were 80.1% and 91.0%.[47] In a recent prospective validation study the first-trimester combined test detected 90%, 97%, and 92% of trisomies 21, 18, and 13, respectively, as well as >90% of cases of monosomy X, >85% of triploidies, and >30% of other chromosomal abnormalities, at FPR of 4%.[48]

Cystic Hygroma

The distinction between a first-trimester cystic hygroma and a thick NT is controversial. Historically, a cystic hygroma has been diagnosed when the hypoechoic space at the back of the neck extends down the fetal back and contains septations (Fig. 31.3, Video 31.2). Malone et al.[49] reported on 134 cases of cystic hygroma identified in the FASTER trial from 38,167 screened pregnancies. Chromosomal abnormalities were present in 51% of these patients and major structural anomalies were identified in 34% of those without karyotypic anomaly. Survival with normal outcome was confirmed in 17% of cases. These investigators reported an increased risk of aneuploidy, cardiac malformations, and fetal death in fetuses with cystic hygroma compared with those who had a simple, thickened NT.[49] Other investigators have reported that septations are seen in all thickened NTs if examined in the transverse suboccipitobregmatic plane and that the incidence of adverse outcome is related to NT thickness rather than appearance.[50,51]

Nasal Bone

Dr. Down, in his original essay describing the physical features of a category of developmentally delayed individuals, identified the nose as being small.[12] Not surprisingly, many fetuses with trisomy 21 have a small or absent nasal bone. The fetal nasal bone can be seen by ultrasound starting at approximately 11 weeks' gestation. The first-trimester nasal bone evaluation is technically challenging, and competency in assessing nasal bone reportedly takes an average of 80 scans.[52] The criteria for a nasal bone evaluation are shown in Fig. 31.4 and Video 31.3. Initial first-trimester screening studies report that the nasal bone is absent in 73% of fetuses with trisomy 21 and 0.5% of euploid fetuses.[53] Cicero et al.[54] studied 5918 fetuses between 11 and 14 weeks and obtained a fetal profile in 99%. An absent fetal nasal bone in euploid fetuses varied by ethnicity. A nasal bone was not identified in 2.2% of Caucasian fetuses, 9% of African Caribbean fetuses, and 5% of Asian fetuses. Younger fetuses also have a higher incidence of nonvisualization of the nasal bone. Absence of the nasal bone was seen in 4.7%, 3.4%, 1.4%, and 1% of euploid fetuses with CRL of 45 to 54 mm, 55 to 64 mm, 65 to 74 mm, and 75 to 84 mm, respectively.

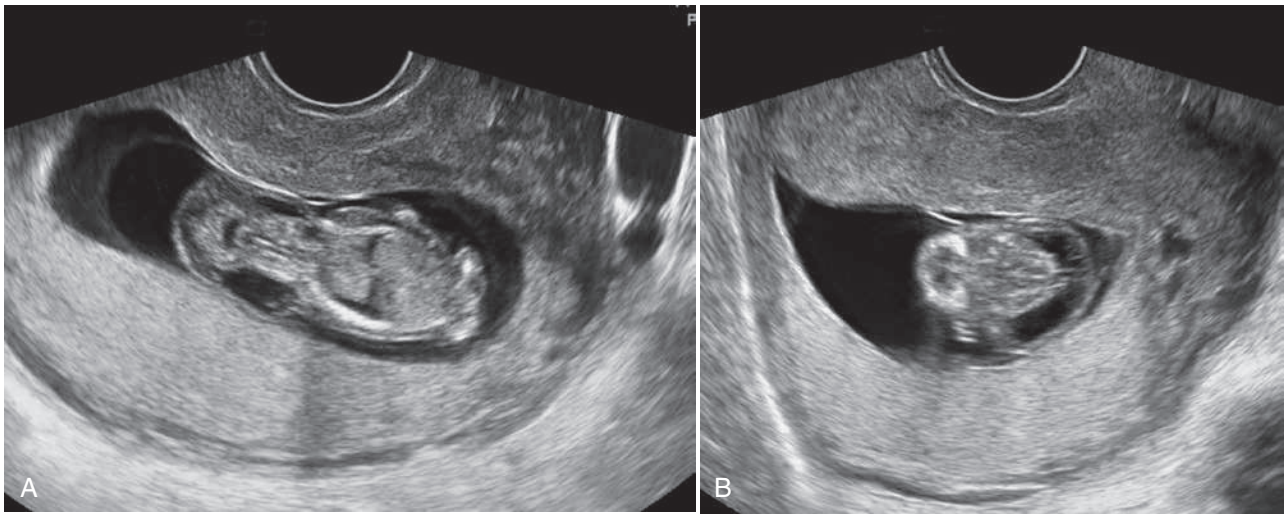

FIG. 31.3 Cystic Hygroma. (A) First-trimester fetus with skin thickening that extends around the entire body, consistent with cystic hygroma, and bilateral distended jugular lymphatic sacs. Note the bilateral **pleural effusions,** indicating **hydrops. (B)** Axial scan through the head of the same fetus shows septations within the nuchal thickening. See also Video 31.2.

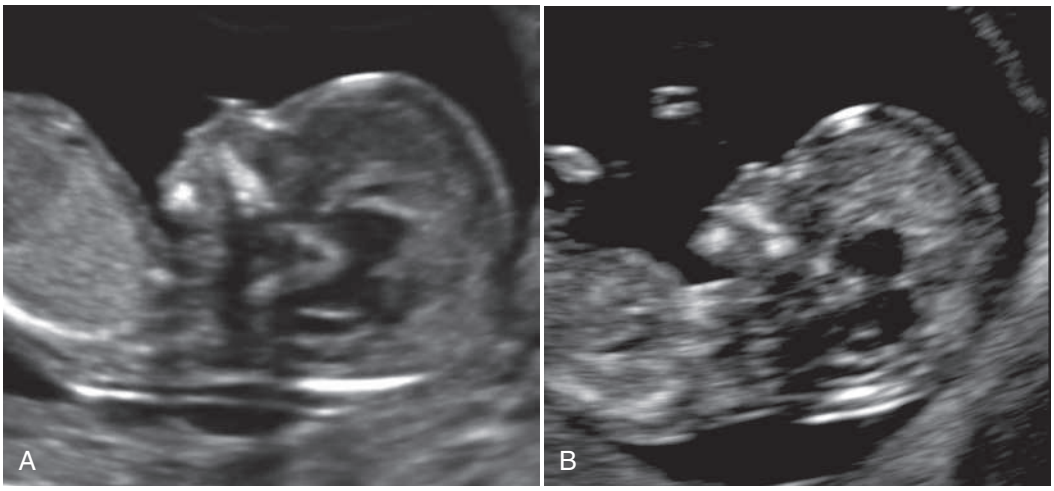

FIG. 31.4 First-Trimester Nasal Bone Assessment. (A) Midsagittal profile of a fetus shows the correct method of assessing the nasal bone. Note that the nasal bone is more echogenic than the overlying skin and they form an equal (=) sign. **(B)** Midsagittal profile of a fetus with trisomy 21 shows the echogenic overlying skin but **absent nasal bone.** See also Video 31.3.

Criteria for Nasal Bone (NB) Evaluation

ALARA: Thermal Index BONE < 0.7[40]
Margins of fetal anatomy clear without ambiguity in nasal anatomy
Fetus in midsagittal plane
- Fetal spine midsagittal in thoracic and cervical region
- Tip of nose clearly seen in profile and the skin edge over the nasal bridge is identified
- Care must be taken to demonstrate the skin edge separately from the NB so that an equal (=) sign is apparent
- Third and fourth ventricle are identified in the brain

Fetus occupies majority of image
- Head, neck, and upper thorax fill image
- Fetus occupies more than 50% of width and length of image

Angle of insonation 45 degrees to fetal profile, perpendicular to NB
Echogenicity of NB is comparable to other bony structures and similar or brighter than the overlying skin.

Nonvisualization of the nasal bone increases with thickened NT measurements. In fetuses with an NT below the 95th percentile, 1.6% had a nonvisualized nasal bone, compared with 2.7% for NT above the 95th percentile of 3.4 mm, 5.4% for NT 3.5 to 4.4 mm, 6% for NT 4.5 to 5.4 mm, and 15% for NT of 5.5 mm or greater. In this same study, an absent nasal bone was seen in 69% of trisomy 21 fetuses and in 32% of fetuses with other chromosomal defects.[54]

No significant association exists between the biochemical markers free β-hCG and PAPP-A and the fetal nasal bone; therefore these can be combined to refine the first-trimester risk assessment for trisomy 21.[55] Cicero et al.[56] prospectively evaluated 20,418 singleton fetuses between 11 and 14 weeks. The fetal nasal bone was absent in 238 (1.2%), was present in 19,937 (97.6%), and could not be evaluated in 243 (1.2%). A fetal nasal bone was absent in 113 in 20,165 (0.6%) of chromosomally normal fetuses and in 87 in 140 (62.1%) of fetuses with trisomy 21. The combination of NT and biochemical markers in the first trimester (combined first-trimester screening) resulted in the identification of 90% of fetuses with trisomy 21 at an FPR of 5%. Inclusion of the nasal bone resulted in the same rate of detection of trisomy 21 but with the FPR decreasing to 2.5%. These statistics held true if all fetuses underwent screening with a nasal bone evaluation performed at the time the NT was measured or if the nasal bone was evaluated in a two-stage approach in which only those at intermediate risk based on combined screening results underwent nasal bone evaluation. Orlandi et al.[57] used a simplified method for assessing the presence or absence of the nasal bone in which the nasal bone was considered absent only if there was no line below the nasal bridge at all. They found that using this strategy resulted in fewer cases being classified as absent while maintaining a high detection rate for aneuploidy.

Not all investigators have been as successful using the fetal nasal bone to assess for aneuploidy. Sepulveda et al.[58] reported on 1287 consecutive fetuses being evaluated for NT and presence or absence of a nasal bone. Overall, 110 fetuses (8.5%) had an NT at or above 95% and 25 (1.9%) had an absent nasal bone. Of the 31 trisomy 21 fetuses, 28 had an NT above 95% and 13 had an absent nasal bone. The detection rate of trisomy 21 was 90.3% using NT and 41.9% using an absent nasal bone. All but one fetus with an absent nasal bone had a thickened NT, and only two normal fetuses had an absent nasal bone. These authors concluded that although an absent nasal bone is highly predictive of trisomy 21, it is less useful as a sonographic marker than the NT. Malone et al.[59] reported that the nasal bone evaluation was not a useful test for population screening.

It is evident that the issues surrounding nasal bone screening in the first trimester are complex. The identification of the nasal bone as present or absent is a specialized skill that is attained

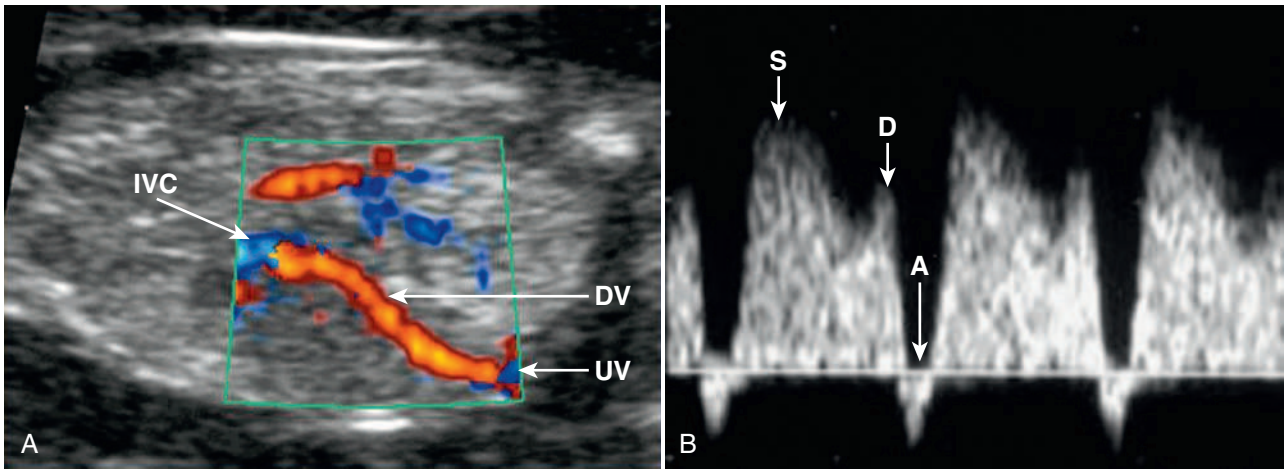

FIG. 31.5 Reversed Flow in Ductus Venosus. (A) Color Doppler anatomy of vessels at oblique sagittal view of fetal trunk. *DV,* Ductus venosus; *IVC,* inferior vena cava; *UV,* umbilical vein. **(B)** Abnormal ductus venosus sonogram shows a **reversed *a* wave.** Absent or reversed a-wave flow can occur in cardiac failure, with or without cardiac defects, and in chromosomally abnormal fetuses. *D,* Diastole; *S,* systole.

with experience, even for competent imagers. It has been recommended that the nasal bone be considered a contingency marker in patients whose first-trimester risk based on NT and biochemistry is in an intermediate-risk category between 1 in 101 and 1 in 1000.[56,60,61]

Other Markers for Aneuploidy

Reversed Flow in Ductus Venosus

The ductus venosus directs well-oxygenated blood from the umbilical vein to the coronary and cerebral circulation. Abnormal blood flow demonstrated as a reversed *a* wave in the ductus venosus is seen in 80% of fetuses with trisomy 21 and in 5% of euploid fetuses[9,62] (Fig. 31.5).

Tricuspid Regurgitation

Tricuspid regurgitation has also been proposed as a method of risk assessment. Falcon et al.[63] compared 77 fetuses with trisomy 21 and 232 chromosomally normal fetuses from singleton pregnancies at 11 to 14 weeks of gestation. Tricuspid regurgitation was identified in 57 (74%) of trisomy 21 fetuses and in 16 (7%) of euploid fetuses. No relationship between tricuspid regurgitation and the levels of maternal serum free β-hCG and PAPP-A was identified. The authors concluded that an integrated sonographic and biochemical test can identify about 90% of trisomy 21 fetuses for a 2% to 3% FPR.

First-trimester sonographic screening using NT and maternal age (without biochemistry) is enhanced by using additional ultrasound markers of nasal bone, tricuspid and ductus venosus flow. Detection rates of Down syndrome of 80%, 87%, and 94% are reported when using one, two, or three additional ultrasound markers while maintaining the FPR at 3%.[64]

Thickened Nuchal Translucency With Normal Karyotype

A thickened NT is associated with an increased risk of structural fetal anomalies including **congenital heart defects** (CHDs). In a study of 29,154 euploid fetuses between 10 to 14 weeks' gestation, Hyett et al.[65] identified 50 with CHDs; 56% of the fetuses were from a group of 1822 with an NT thickness greater than 95%. In a meta-analysis evaluating the screening performance of increased first-trimester NT for the detection of major CHDs, eight independent studies with 58,492 patients were reviewed. An NT greater than 99% had a sensitivity of 30% for the detection of CHDs. If an NT greater than 99% is used as an indication for a fetal echocardiogram, 1 in 16 referred cases would have CHDs. If the threshold was lowered to fetuses with an NT greater than 95%, 1 in 33 referred cases would have a major CHD.[66] Data from the FASTER trial confirmed that the incidence of major CHD increased with increasing NT, although the sensitivity for CHD detection was only 9.6%. These investigators concluded that NT lacked the qualities of a good screening test for heart disease; however, an NT of 2.5 MoM (99%) or greater is considered an indication for fetal echocardiography.[67] A population-based study evaluating the performance of a first-trimester thickened NT in the detection of critical CHDs in euploid liveborn infants demonstrated that an NT of greater than 99% had a 5-fold increased risk while an NT of 3.5 mm or larger had a 12-fold increased risk compared with fetuses whose NT measured less than 90% for CRL.[68]

Fetuses with a thick NT are at increased risk for a variety of major congenital abnormalities in addition to CHDs (Fig. 31.6). In combined data from 28 studies of 6153 euploid fetuses with thick NT, the prevalence of major anomalies was 7.3% (range, 3%-50%). The prevalence of major anomalies increased from 1.6% in those with an NT less than 95% to 2.5% in those with an NT 95% to 99%, 10% in those with an NT of 3.5 to 4.4 mm, and increasing dramatically thereafter to 46% in those with an NT greater than 6.5 mm.[15] Anomalies demonstrated included facial clefts, diaphragmatic hernia, abdominal wall defects as well as a multitude of other structural abnormalities. Timmerman et al. demonstrated an increased risk of oral facial cleft in chromosomally normal fetuses with a thick NT.[69] In a large population-based study of euploid infants examining the relation

of an increased NT and major noncardiac structural defects, an NT measurement of 95% or greater or NT of 3.5 mm or larger was associated with an increased risk compared with those having an NT less than 90% for CRL. The most commonly identified anomalies were hydrocephalus, agenesis/hypoplasia/dysgenesis of the lung, atresia or stenosis of the small intestine, osteodystrophies, and diaphragmatic anomalies. In this study, the association with orofacial clefts seen by Timmerman was not noted; however, the populations studied were quite different.[47] A fetus with a thickened NT should be evaluated for other structural abnormalities as extensively as possible at the time of the first-trimester scan.[70-72] In ongoing pregnancies, a detailed structural evaluation with meticulous attention to fetal cardiac imaging in the second trimester is warranted.

In chromosomally normal fetuses, the risk of intrauterine demise increases with increasing NT. In a study of 6650 pregnancies undergoing NT screening, the prevalence of miscarriage, fetal death, or termination for an anomaly was 1.5% in euploid fetuses with an NT below the 95th percentile compared with 18% in those with an NT above the 99th percentile.[73] Westin et al.[74] reported on 16,260 euploid fetuses from an unselected population to determine how well NT measurements predicted adverse outcome. The overall rate of adverse outcome was 2.7%. The risk of adverse outcome increased with higher NT measurements. An NT of 3 mm or greater was associated with a 6-fold increase in adverse outcome, 3.5 mm or greater with a 15-fold increased risk, and 4.5 mm or greater with a 30-fold increased risk. These authors concluded that likelihood ratios could be used to calculate an individual's risk of adverse outcome but could not reliably distinguish between normal and adverse outcome.

Not all fetuses with a thick NT have an abnormal outcome. In 2001, Souka et al.[75] reported on 1320 euploid singleton pregnancies with an NT of 3.5 mm or greater. These fetuses underwent sonographic evaluation at 14 to 16 weeks and 20 to 22 weeks. The chance of a live birth with no defect was 86% in the group with an NT of 3.5 to 4.4 mm, 77% for NT of 4.5 to 5.4 mm, and 67% for NT of 5.5 to 6.4 mm. In fetuses with an NT of 6.5 mm or greater, the chance of normal outcome was 31%. In total, there were 200 fetuses (15.5%) with abnormalities, 80% of which were diagnosed prenatally. There were 1080 (82%) survivors, 60 (6%) of whom had abnormalities requiring medical or surgical care or were developmentally delayed. In a group of 82 fetuses with persistent nuchal thickening but an otherwise normal scan, 19% had an adverse outcome. In the group of 980 euploid fetuses with a normal second-trimester scan, there were 22 (2%) with adverse outcome. Severe developmental delay was seen in 1 in 82 (1%) with isolated persistent nuchal thickening, compared with 4 in 980 (0.4%) with a normal scan.[75]

Bilardo et al.[76] reviewed the outcome of 675 pregnancies with an increased NT, known karyotype, and known pregnancy outcome. Of the study group, 451 (67%) had a normal karyotype, and 19% of these euploid pregnancies had an adverse outcome. The range of abnormal outcome varied with the degree of NT thickening, from 8% with NT between the 95% and 3.4 mm to 80% with NT of 6.5 mm or greater. Second-trimester sonography

was performed on 425 euploid fetuses, and an abnormality was identified in 50 fetuses (12%). Of fetuses with a suspicious or abnormal scan, 86% had an adverse outcome. A normal second-trimester ultrasound was reported on 375 (88%) of fetuses, and 96% of those were alive and well. Of fetuses with a thickened NT in the first trimester, normal karyotype, and normal second-trimester scan, 4% had an adverse outcome, which included intrauterine demise, structural defects, and genetic syndromes. The most frequently missed anomalies on ultrasound were cardiac defects, underscoring the need for detailed fetal echocardiography in fetuses with a thick NT.

Senat et al.[77] prospectively evaluated long-term outcome in children with a normal karyotype and a NT at or greater than 99%. The study population consisted of 179 fetuses that underwent midtrimester sonography as well as fetal echocardiography. There were 17 fetal losses, including 10 malformations, 5 intrauterine demises, 1 miscarriage, and 1 termination. At 2 years of age, 89% (of 162 liveborns evaluated) of children had no malformations and normal developmental testing. Eleven percent of children had a structural abnormality noted after birth. Two children (1.2%) had neurologic delay. In one child, the delay was isolated, and in the other it was associated with an unidentified syndrome. These authors concluded that when the karyotype is normal and the sonogram is normal with resolution of the NT, the outcome is not adversely affected at 2 years of age. This was supported by Miltoft et al. in a prospective study of chromosomally normal fetuses with NT of at least 99% and normal ultrasound findings who were evaluated by an Ages and Stages Questionnaire and found no increased risk of developmental delay at 2 years of age when compared with a control group.[78] Sotiriadis et al. in a review of the literature concluded that there does not appear to be a higher risk of developmental delay than the general population in chromosomally normal fetuses with an increased NT, normal anatomy, and no identifiable genetic syndromes.[79]

The finding of a thickened NT should prompt a comprehensive conversation concerning genetic associations by an experienced provider. Advances in diagnostic testing include chromosomal microarray analysis (CMA), which can detect chromosomal abnormalities that are too small to be detected by standard karyotype. The benefit of CMA in fetuses with a thickened NT is controversial. Schou et al. did not detect any chromosomal aberrations of clinical importance in 100 fetuses with an NT of 99th percentile or greater.[80] Similarly, Huang et al. did not find additional pathogenic CNVs in fetuses with an NT between 3 and 4 mm without other detectable abnormalities.[81] Leung et al. reported that 8.3% of fetuses with an NT greater than 3.5 mm and a normal karyotype had a pathologic submicroscopic chromosomal abnormality. In those fetuses with additional sonographic findings, pathogenic CNVs were identified in 20% compared with 5.3% in those without additional sonographic findings.[82] In a prospective series of patients with an NT of at least 3.5 mm and normal quantitative fluorescence–polymerase chain reaction for aneuploidy, CMA identified pathogenic CNVs in 12.8% of fetuses and variants of uncertain significance in 3.2 %.[83] In a recent meta-analysis, Grande et al. reported that genomic microarray provides incremental yield in 5% of fetuses with an increased NT and normal karyotype. The pooled prevalence of variants of uncertain significance was 1%.[84] A thickened NT has been associated with myriad genetic disorders, the most common being Noonan syndrome.[9,15,85]

SECOND-TRIMESTER SCREENING FOR TRISOMY 21

Although first-trimester risk assessment allows a patient the benefit of time in using the information to make decisions regarding pregnancy, not all women present for prenatal care early enough in gestation to take advantage of this benefit.

Ultrasound is an integral part of risk assessment for aneuploidy in the second trimester.[86-94] Approximately 25% of fetuses with trisomy 21 have a major congenital anomaly, such as cardiac defect or duodenal atresia[90,91] (Fig. 31.7). The cornerstone to identifying fetuses with trisomy 21 has been the recognition of sonographic **"markers,"** which are variations in anatomy that are usually associated with normal outcome but carry a statistically increased risk of aneuploidy. Some of these markers are well-known physical entities such as the thickened nuchal fold and the small nasal bone.[12] Others are findings specific to prenatal sonography, such as an echogenic intracardiac focus, urinary tract dilation, slightly short femoral and humeral length, and echogenic bowel. The identification of a marker should prompt a comprehensive fetal sonographic examination to look for other markers and structural abnormalities. The presence or absence of a marker and the associated clinical significance must be interpreted in the setting of the patient's a priori risk for aneuploidy (Figs. 31.8-31.10 and Tables 31.1-31.3).

Nuchal Fold

Early studies showed that the presence of a thickened nuchal fold identified 40% of fetuses with trisomy 21 with FPR of 0.1%.[95-98] This measurement is obtained using an axial view through the

TABLE 31.1 Likelihood Ratios (LRs) of Isolated Markers for Trisomy 21

Marker	LR[90]	LR[91]	LR[94]	LR[109a]
Nuchal fold	11.0	—	17	3.79

fetal head, across the thalami and angled posteriorly to include the cerebral peduncles, cerebellar hemispheres, and cisterna magna as well as the occipital bone. The measurement is made from the surface of the occipital bone to the surface of the skin edge (Fig. 31.8). Care must be taken not to angle below the occiput because this will lead to spuriously large measurements. Initially, a measurement of 6 mm or greater was considered abnormal; however, 5 mm was later determined to be a more sensitive threshold, with little change in the specificity.[99] Interobserver variability for this measurement is small (1 mm), establishing

the nuchal fold as a highly reproducible measurement.[100] More recently, some have suggested that because the nuchal fold measurement fits a log gaussian distribution, it should be evaluated as a continuous variable and interpreted in the context of gestation-specific norms, to allow a more refined method of risk analysis.[101,102] Numerous investigators have confirmed that a thickened nuchal skin fold is an important marker for detecting trisomy 21, and after more than 30 years, it remains one of the most important second-trimester markers.[103-109]

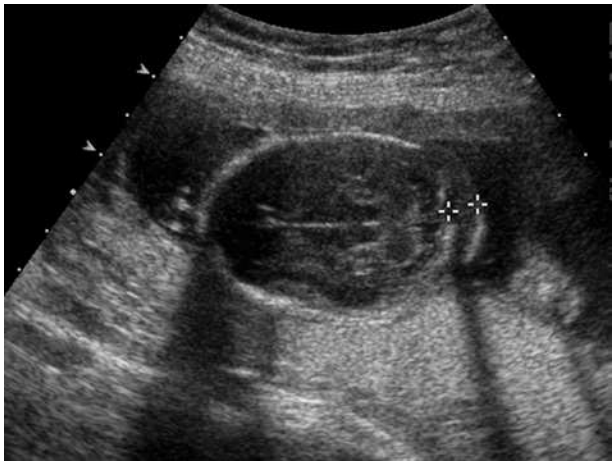

FIG. 31.8 Nuchal Fold. Axial scan through the fetal head of a second-trimester fetus demonstrating a thickened nuchal fold *(calipers),* measuring 6 mm.

Trisomy 21: Common Second-Trimester Sonographic Markers

Nuchal fold
Absent or hypoplastic nasal bone
Short femur
Short humerus
Echogenic bowel
Echogenic intracardiac focus
Urinary tract dilation
Mild ventriculomegaly

Facial Profile (Nasal Bone)

The appearance of the fetal nasal bone is an important sonographic marker utilized for identifying fetuses at increased risk for trisomy 21[110] (Fig. 31.9). The fetal nasal bone is evaluated on a midsagittal view of the fetal profile. The angle of insonation should be 90 degrees to the longitudinal axis of nasal bone although a slightly oblique angle (45 or 135 degrees) helps to define the edges of the nasal bone more sharply. If the nasal bone is viewed "on end" (0 or 180 degrees), it will appear erroneously as absent.[111] In 239 fetuses referred for amniocentesis because of a risk of trisomy 21 of 1 in 270 or greater, Bromley et al.[112] reported that 6 in 16 (37%) fetuses with trisomy 21 did not have a detectable nasal bone. Of the fetuses with a detectable nasal bone, the mean length was shorter in those with trisomy 21 than in euploid

Modified from Agathokleous M, Chaveeva P, Poon LC, et al. Meta-analysis of second-trimester markers for trisomy 21. Ultrasound Obstet Gynecol. 2013;41(3):247-261.[109]

fetuses. A receiver-operator characteristic curve for the prediction of trisomy 21 based on biparietal diameter (BPD)/nasal bone length (NBL) reveals that a cutoff of 11 or greater identifies 69% of trisomy 21 fetuses with a 5% FPR. Other authors recommend measurement of less than 5th percentile or an absolute measurement of less than 2.5 mm as thresholds to predict aneuploidy.[113-116]

Vintzileos et al.[117] retrospectively evaluated the significance of the nasal bone ossification in fetuses referred for genetic sonogram; 29 fetuses with trisomy 21 were compared to 102 euploid fetuses. Absence of the nasal bone was seen in 41% of fetuses with trisomy 21 and none of the euploid fetuses. The absence of the fetal nasal bone is as powerful a marker for trisomy 21 as the thickened nuchal fold.[118]

Odibo et al.[119] suggested that evaluating the NBL as a multiple of the median is the optimal method of using this marker. These investigators examined 3634 women at increased risk for aneuploidy and nasal bone assessment was possible in 3197 women (88%), 23 of whom had fetuses with trisomy 21. An NBL of less than 0.75 MoM provided the best definition of nasal bone hypoplasia and had a sensitivity and specificity of 49% and 92%, respectively, compared with 61% and 84% for BPD/NBL greater than 11. These investigators favor the incorporation of absent nasal bone as a major marker for trisomy 21 in the second-trimester genetic sonographic screening because of its ease of identification and better specificity compared with MoM of less than 0.75.

There is variation in the prevalence of a hypoplastic or absent nasal bone depending on ethnicity. Cicero et al.[115] reported that 8.8% of patients of African Caribbean ancestry had an absent or hypoplastic nasal bone, compared with 0.5% of Caucasian fetuses, thus limiting the utility of this marker in patients of African Caribbean heritage.

Three-dimensional ultrasound has been used to evaluate the presence or absence of the fetal nasal bone. In 20 fetuses with trisomy 21, Benoit and Chaoui[120] found 9 had either an absent or a hypoplastic nasal bone on two-dimensional ultrasound. The three-dimensional evaluation showed bilateral nasal bone absence in six fetuses and unilateral nasal bone absence in three. Prenasal thickness (PT) has recently been reported as a useful marker for the detection of trisomy 21 in the second and third trimester. In a retrospective evaluation of 159 fetuses with trisomy 21, Vos et al. reported on the NBL and PT as well as ratios of NBL/PT and prefrontal space ratios to identify fetuses with trisomy 21.[121] These ratios were not gestational age related and at least one of these four findings was identified on 95.3% of fetuses with trisomy 21. The NBL/PT and prefrontal space ratios individually identified 86% and 80% of fetuses with trisomy 21. In the setting of a normal karyotype and otherwise normal detailed imaging, the outcome for an isolated absent nasal bone is favorable.[122]

Femur Length

A short femur was one of the earliest recognized features in the sonographic detection of trisomy 21.[123] The expected femoral length (FL = –9.645 + 0.9338 × BPD) accounts for 94% of variation in normal length.[124] Based on BPD, a measured-to-expected

femur length ratio of 0.91 or less identifies 40% of fetuses with trisomy 21, with a 5% FPR.[125] Although all agree that fetuses with trisomy 21 have shorter femurs than euploid fetuses, the difference is quite small, and the clinical utility of this finding remains controversial.[126] Additionally, femur length varies among fetuses of different ethnicity. Asian fetuses tend to have shorter femurs and black fetuses longer femurs compared with white fetuses.[127] Such differences may be sufficient to question the usefulness of the femur as a marker in many populations.

Humerus Length

The length of the humerus is a more sensitive and specific marker for trisomy 21 than the femoral length.[128] Benacerraf et al.[129] found that the measured humeral length was shorter than the expected humeral length in fetuses with trisomy 21, with a measured-to-expected humeral length ratio of less than 0.90 the optimal criterion for detecting affected fetuses (expected humeral length = −7.9404 + 0.8492 × BPD). The use of this ratio identified 50% of the fetuses with trisomy 21, with a 6.2% FPR.[129]

Urinary Tract Dilation

In the second trimester, mild urinary tract dilation is considered present if the maximal anteroposterior diameter of the intrarenal pelvis measures 4 mm or more[130] (Fig. 31.10A). Among fetuses with trisomy 21, 17% to 25% have urinary tract dilation, compared with 2% to 3% of euploid fetuses.[130,131]

Echogenic Bowel

Echogenic bowel is seen in 0.2% to 0.8% of fetuses in the second trimester.[132-134] To be considered echogenic, the bowel must appear as a well-delineated homogeneous area that is as bright as the adjacent bone when the operator is using a transducer with a frequency of 5 MHz or less (Fig. 31.10B, Video 31.4). The incidence of chromosomal abnormalities in the setting of echogenic bowel ranges from 3% to 27%.[132-137] The cause of echogenic bowel seen in association with aneuploidy may be related to poor bowel motility and decreased water content of meconium.[137] In addition to aneuploidy, echogenic bowel is associated with cystic fibrosis, infectious causes such as cytomegalovirus, primary bowel abnormalities, and severe growth restriction. It has also been associated with fetal ingestion of blood and impending fetal demise.[132-137]

Echogenic Intracardiac Focus

An echogenic intracardiac focus (EIF) is a discrete, bright white dot that appears as bright as bone in the region of the papillary muscle of the heart (Fig. 31.10C). An EIF is usually located within the left ventricle but can be seen in either or both cardiac ventricles. Most are seen as a single focus, but they may occur as multiple foci. This sonographic finding is caused by mineralization of the papillary muscle and is seen in 16% of fetuses with trisomy 21 as well as 5% of euploid fetuses.[138,139]

An EIF is the most common marker to occur as an isolated entity both in fetuses with trisomy 21 and in euploid fetuses.[90,91] An EIF carries a twofold to fourfold increased risk of trisomy 21.[90,91,94,139,140] This marker cannot be used reliably in patients of Asian ancestry because of the high prevalence of the EIF in the euploid Asian population.[141]

The identification of an EIF is confounded by technical considerations such as cardiac position.[142] When the interventricular septum is pointing directly toward or away from the transducer beam in an apical or basal view, an EIF is detected more often than when the septum is imaged perpendicular to the transducer beam in a lateral view. To be convinced that an EIF is present, it must be as bright as bone and seen in several planes. Other normal specular reflectors in the fetal heart, such as the moderator band in the right ventricle, can be mistaken for an EIF. Winn et al.[143] evaluated 200 patients scanned between 18 and 22 weeks' gestation. The rate of "true" echogenic intracardiac foci was 11 in 200 (5.5%). The rate of "false" echogenic foci was 34 in 200 (17%). The most common locations for a false EIF were the moderator band, endocardial cushion, and tricuspid valve annulus.

Recently, an aberrant right subclavian artery has been reported as a useful prenatal ultrasound marker for the detection of trisomy 21.[144] A recent meta-analysis reported the prevalence of aberrant right subclavian artery in fetuses with trisomy 21 is 23.6% compared with 1.02% in euploid fetuses. The identification of an aberrant right subclavian artery should prompt genetic sonography including fetal echocardiography and correlation with a priori risk estimates.[145]

Structural Anomalies

Approximately 25% of fetuses with trisomy 21 are identified as having a structural anomaly, including cardiac defects, duodenal atresia, ventriculomegaly, and hydrops[90,91,132,146] (see Fig. 31.7). Cardiac defects are seen in approximately 50% of newborns with trisomy 21 and include atrioventricular septal defects and ventriculoseptal defects. With meticulous technique, these can be found prenatally in 80% to 90% of fetuses with trisomy 21.[147]

Adjunct Features of Trisomy 21

Adjunctive features that may be seen on occasion in fetuses with trisomy 21 but are not robust enough to adjust the risk of aneuploidy include iliac angle measurements, ear length, clinodactyly, hypoplasia of the middle phalanx of the fifth digit, sandal gap toe, and frontothalamic distance. These features are difficult to standardize, and there is substantial overlap between those with and without trisomy 21. The identification of an adjunctive feature should prompt a genetic sonogram in which markers with established likelihood ratios are evaluated and correlated with a priori risk estimates.[148-154]

Cases of trisomy 21 have been reported in fetuses with choroid plexus cysts.[155] However, this is believed to result from the population incidence of choroid plexus cysts rather than from trisomy 21.[156]

Combined Markers

The finding of individual sonographic markers can be used to estimate a risk of aneuploidy.[156-163] In the early years of genetic sonography, a scoring index was utilized that rated the markers as "major" (score of 2 for thickened nuchal fold or major anomaly) and "minor" (score of 1 for each finding, such as short femur, short humerus, pyelectasis, echogenic bowel, and EIF).[157,158] A cumulative score of 2 or more identified 73% of fetuses with trisomy 21, with an FPR of 4%. Nyberg et al.[90,162] suggested integrating these markers into risk assessment by using Bayes

theorem and likelihood ratios. They showed that likelihood ratios could be calculated for each isolated marker, then applied to the patient's a priori (presumptive) risk using Bayes theorem. This resulted in a revised risk of aneuploidy based on the presence or absence of specific markers. Table 31.1 shows a comparison of four studies that computed likelihood ratios for trisomy 21 using isolated markers.

Clusters of markers, even minor ones, confer more risk than individual markers alone[90,91] (Table 31.2). Winter et al.[89] demonstrated that the genetic sonogram scoring index and the method of ultrasound risk assessment using likelihood ratios were essentially equivalent in the detection rate of trisomy 21. The advantage of using likelihood ratios is that a patient's specific risk of aneuploidy can be calculated and balanced against the risk of pregnancy loss associated with an invasive procedure. Even in the largest studies, the number of fetuses with an isolated marker is small, leading some to recommend that a revised risk estimate for aneuploidy is statistically more robust if the overall likelihood ratio is calculated by the product of the positive and negative likelihood ratios for each marker.[109,164]

Trisomy 21: Revised Risk Ratio Calculations

Revised risk = a priori risk × likelihood ratio (LR)

EXAMPLE 1: METHOD USING ISOLATED LR

A 25-year-old woman with a priori risk of trisomy 21 of 1:500 based on quad screen.

Detailed ultrasound shows an isolated echogenic intracardiac focus (EIF) (LR ≈ 2).

Revised risk = 1:500 × 2 = 1:250

EXAMPLE 2: METHOD USING "CLUSTER OF MARKER" LR

A 39-year-old woman with a priori risk of trisomy 21 of 1:1000 based combined screen.

Detailed ultrasound shows EIF and urinary tract dilation (LR ≈ 6 from two markers).

Revised risk = 1:1000 × 6 = 1:166

EXAMPLE 3: METHOD USING POSITIVE AND NEGATIVE LRS FOR EACH MARKER

Short humerus not used in calculation

A 28-year-old woman with a priori risk of trisomy 21 of 1:1000 based combined screen.

Detailed ultrasound shows EIF and short femur. Negative for nuchal fold, urinary tract dilation, echogenic bowel, nasal bone, and ventriculomegaly.

Revised Risk: 1:1000 × LR for combination of positive/negative = 4.41 (5.83 × 3.72 × 0.92 × 0.90 × 0.80 × 0.46 × 0.94) = 1/226

Likelihood ratios in examples 1 and 2 are with permission from Bromley B, Lieberman E, Shipp TD, Benacerraf BR. The genetic sonogram: a method of risk assessment for Down syndrome in the second trimester. J Ultrasound Med. 2002;21(10):1087-1096.[91]
Likelihood ratios in example 3 are with permission from Agathokleous M, Chaveeva P, Poon LC, et al. Meta-analysis of second-trimester markers for trisomy 21. Ultrasound Obstet Gynecol. 2013;41(3):247-261.[109]

Agathokleous et al. performed a meta-analysis of second-trimester markers for Down syndrome using data published after 1995. Weighted independent estimates of detection rates, FPRs, and positive and negative likelihood ratios for each marker was calculated.[109]

Genetic sonography is best used in conjunction with a priori risk estimates based on an accepted screening protocol.[163,165-169] Souter et al.[167] demonstrated that serum biochemical marker analytes and sonography are independent and therefore can be used in conjunction with each other to modify the risk of aneuploidy. Several investigators have shown that patients of advanced maternal age who had a normal genetic sonogram and reassuring serum screen are at a lower risk for trisomy 21.[90,91,166,169] The absence of markers has been shown to reduce the risk of trisomy 21 by (60%-90%).[90,91,109,164] This may be even more dramatic as many studies were published before the nasal bone was recognized as an important marker in second-trimester risk assessment. In a recent meta-analysis, the absence of markers conferred a 7.7-fold reduction in risk of Down syndrome[109] (Table 31.3).

Most studies on genetic sonography were performed in the time period prior to the use of first-trimester risk assessment, whether by combined screening or integrated screening. The clinical utility of the genetic sonogram after first-trimester risk assessment for Down syndrome is controversial. Rozenberg et al.[170] performed a multicenter interventional study in an unselected population to evaluate the performance of first-trimester combined screening followed by second-trimester ultrasound. First-trimester combined screening identified 80% of fetuses with trisomy 21 at a screen-positive rate of 2.7%. Using a thickened nuchal fold or the presence of a major anomaly on a second-trimester ultrasound increased the detection rate to 90%, with a screen-positive rate of 4.2%.

Krantz et al.[171] performed a simulation study to assess genetic sonography as a sequential screen for trisomy 21 after first-trimester risk assessment. First-trimester combined screening resulted in a detection rate of 88.5% with a 4.2% FPR. A follow-up with genetic sonography using individual marker likelihood ratios to modify the first-trimester risk for screen-negative patients detected an additional 6.1% of trisomy 21 cases for an additional 1.2% FPR, giving a total detection rate of 94.6% and a total FPR of 5.4%. If a contingent protocol were adopted in which only patients with a first-trimester risk between 1 in 300 and 1 in 2500 were evaluated, the additional detection rate would be 4.8% with FPR of 0.7%, giving a total detection rate of 93% and a total FPR of 4.9%. These authors concluded that second-trimester genetic sonography, if used properly, can be an effective sequential screen after first-trimester risk assessment.

The clinical utility of genetic sonography after prior screening for Down syndrome was studied on 7842 pregnancies, including 59 with Down syndrome, who participated in the FASTER trial.[164] At a set FPR of 5%, adding genetic sonography to the combined screen or the integrated test increased the detection rate of Down syndrome from 81% to 90% and 93% to 98% respectively. A smaller increase in detection rate was noted for the stepwise or contingent protocols, from 97% to 98% and 95% to 97%, respectively. Other studies have suggested that genetic sonography after combined screening or sequential screening may decrease the

FPR with no significant change in detection rate of Down syndrome.[172,173] It has been cautioned that the use of genetic sonography after first-trimester risk assessment may result in increased patient anxiety without increasing the detection rate of trisomy or false reassurance.[173,174] While historically the finding of an isolated marker would potentially result in a diagnostic test that came with an associated risk of fetal loss, the recent incorporation of cell-free DNA provides a secondary level of screening that does not carry a risk of pregnancy loss. A negative cell-free DNA analysis makes the identification of a marker of unlikely clinical importance with respect to aneuploidy screening.[175] Certain markers such as short femur, echogenic bowel, or urinary tract dilation may be associated with other concerning clinical situations.

TRISOMY 18 (EDWARDS SYNDROME)

Trisomy 18 is the second most common autosomal trisomy, with a prevalence of 4.8 per 10,000 total births.[176] With improving prenatal diagnosis and associated high termination rates, the live birth prevalence has decreased to 0.1 in 1000.[177] Individuals with this disorder have a limited capacity for survival, with 44% of those identified in utero dying before birth.[178] About 50% of affected newborns die within the first week, and only 5% to 10% survive beyond the first year of life. Those who survive are severely intellectually disabled and physically handicapped.[179]

Fetuses with trisomy 18 have a plethora of anomalies. Sonographically, 77% to 97% of fetuses with trisomy 18 can be identified by the presence of these structural malformations.[180-184] The more common structural anomalies in fetuses with trisomy 18 include **congenital heart defects, central nervous system anomalies, hydrocephalus, diaphragmatic hernia, omphalocele** (70% of which only contain bowel), and **abnormally clenched hands** (with overlapping index fingers)[180-184] (Fig. 31.11). In our experience, cases of trisomy 18 not identified by prenatal ultrasound have been scanned early in the second trimester, when a complete structural survey was not feasible or when other factors such as surgical scarring or maternal body habitus precluded optimal visualization of the fetus.[157,158]

Trisomy 18: Common Sonographic Findings

Choroid plexus cyst
Strawberry-shaped skull
Abnormal cerebellum, cisterna magna
Neural tube defects
Cardiac defects
Omphalocele
Esophageal atresia
Diaphragmatic hernia
Clenched hands, overlapping index fingers
Radial ray anomalies, limb reduction defects
Clubfeet, rocker-bottom feet
Intrauterine growth restriction (especially with polyhydramnios)

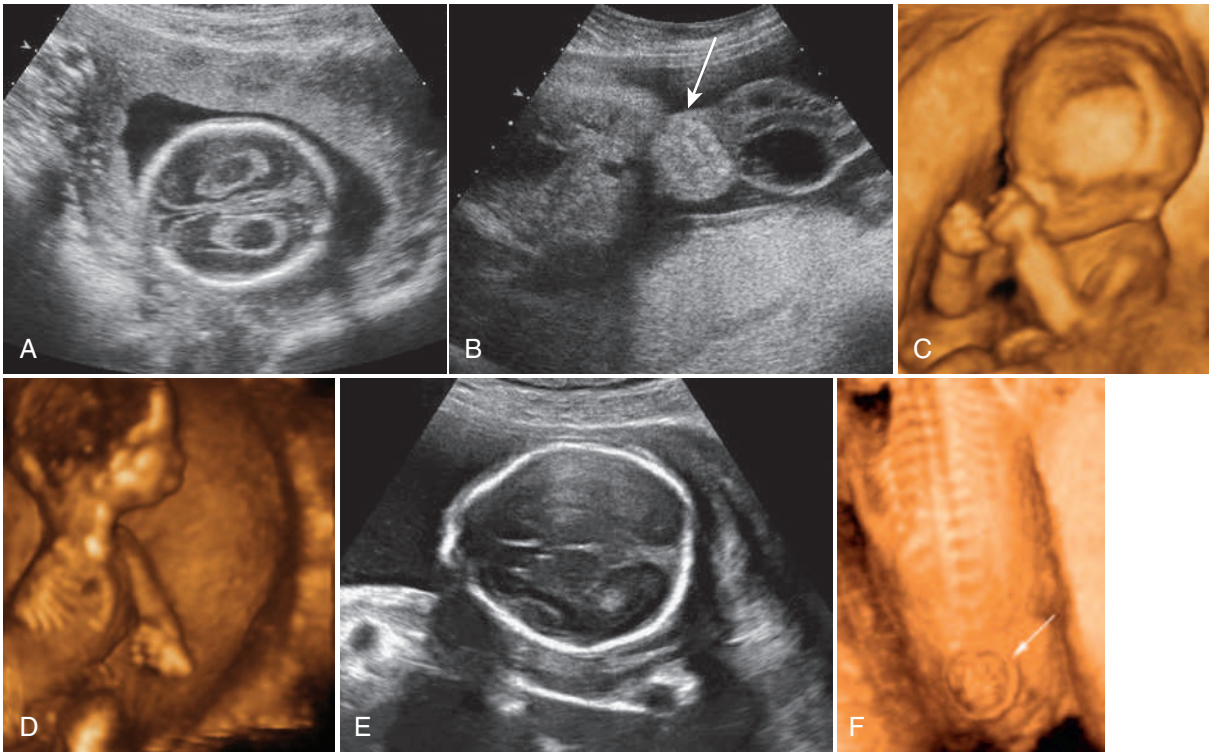

FIG. 31.11 Second-Trimester Sonographic Findings in Trisomy 18. (A) Choroid plexus cyst. Scan through the fetal head at 18 weeks shows bilateral choroid plexus cysts. **(B) Omphalocele.** Scan of the fetal lower abdomen shows a bowel-containing omphalocele *(arrow)* as well as an **umbilical cord cyst. (C) Clenched fists.** Three-dimensional scan of a midtrimester fetus shows characteristic clenching of the hands and overlapping fingers. **(D) Radial ray anomaly.** Three-dimensional scan demonstrates a radial ray anomaly. Note the **micrognathia** as well. **(E) Strawberry-shaped skull. (F)** Three-dimensional scan of the fetal spine at 18 weeks demonstrating a **neural tube defect** *(arrow)*.

The sonographic findings observed in fetuses with trisomy 18 vary with gestational age. As expected, anomalies such as cystic hygromas are seen more frequently in the late first and early second trimester, whereas cardiac defects and growth restriction tend to be later findings. In a review of 47 fetuses with trisomy 18, Nyberg et al.[183] identified cardiac defects in 14% before 24 weeks' gestation and in 78% scanned after 24 weeks. **Intrauterine growth restriction** (IUGR) was seen in 28% of affected fetuses scanned at less than 24 weeks and in 89% of those evaluated in the third trimester. IUGR, in combination with **polyhydramnios,** is an ominous observation highly predictive of trisomy 18.[183,185] In addition to those mentioned earlier, other findings, such as radial ray defects, rocker-bottom feet, clubfeet, strawberry-shaped skull (flattening of occiput with pointing of frontal bones), and abnormal-appearing cerebellum and cisterna magna, have been reported.[179-190]

Choroid Plexus Cysts

Choroid plexus cysts (CPCs) are discrete echolucencies within the choroid plexus that result from the folding of the neuroepithelium, trapping secretory products and desquamated cells[191] (Fig. 31.11A). CPCs are seen in 1% to 2% of the normal fetuses and are most common in the second trimester, usually resolving by 28 weeks' gestation.[180-182] About 30% of fetuses with trisomy 18 have CPCs.[182,183] The majority of fetuses with trisomy 18 also have other structural anomalies to suggest aneuploidy.[180-183] Cyst number, size, and laterality are not useful in distinguishing affected fetuses from normal fetuses.[192-194] Additionally, resolution of CPCs does not necessarily reflect a normal karyotype.[195]

The predictive value of isolated CPCs for aneuploidy is low when no other abnormalities are seen.[155,182] Therefore after a CPC is seen, a detailed ultrasound assessment of the fetus should be performed. In the setting of an isolated CPC, correlation with a priori risk of trisomy 18 based on an accepted screening protocol is recommended.[155,196] Cheng et al.[197] reported on the significance of isolated CPCs in a population previously screened with NT and found that the likelihood ratio for trisomy 18 was not increased in those with normal NT measurements. Noninvasive prenatal screening with cell-free DNA can be considered. Invasive testing is not warranted in the setting of an isolated CPC.[185,193,194,198-202]

TRISOMY 13 (PATAU SYNDROME)

Trisomy 13 is the third most common autosomal trisomy with a prevalence of 1.9 in 10,000 total births.[176] With improving prenatal diagnosis and associated high termination rates, the live birth prevalence has decreased to 0.03 in 1000.[177] Individuals with trisomy 13 have numerous structural abnormalities and are severely intellectually disabled. Anomalies often seen include forebrain defects, ocular malformations, facial clefts, heart defects, and abnormal extremities. In fetuses that are not terminated, there is a 46% intrauterine fetal death rate and 93% early neonatal mortality rate.[203] Rarely, survival is more long term.[204] Sonographic detection of fetuses with trisomy 13 is 90% to 100% (Fig. 31.12).[157,158,205-209]

Trisomy 13: Common Sonographic Findings

- Holoprosencephaly
- Microcephaly
- Neural tube defects
- Facial clefts, ocular anomalies
- Cardiac defects
- Echogenic intracardiac focus
- Congenital diaphragmatic hernia
- Omphalocele
- Echogenic kidneys
- Postaxial polydactyly
- Intrauterine growth restriction

Cardiac and central nervous system defects are the most frequently identified anomalies. The most common central nervous system malformations identified in trisomy 13 are **holoprosencephaly, ventriculomegaly, microcephaly,** and posterior fossa malformations. **Alobar holoprosencephaly** is often associated with severe midline facial defects, including **hypotelorism, microphthalmia, anophthalmia, cyclopia,** and **proboscis.** In addition, fetuses with trisomy 13 often have postaxial **polydactyly,** abnormal hand configuration, **echogenic kidneys,** atypical calcifications, and **IUGR.**[205-209]

TRIPLOIDY

Triploidy is the result of a complete extra set of chromosomes (69 chromosomes) and is not related to maternal age.[210] The extra set of chromosomes may be paternally derived (diandric), usually from a double fertilization, or maternally derived (digynic) from fertilization of a diploid egg.[211] The frequency of the parental origin has been widely disparate with diandric cases in 20% to 85%.[212] Triploidy occurs in 1% to 3% of conceptions, and most are spontaneously aborted.[213,214] The prevalence of triploidy at 11 to 14 weeks is 1 in 6614 and survival of a fetus with triploidy beyond 20 weeks' gestation is unusual.[48,210] Paternal triploid origin is often associated with a large placenta filled with cystic spaces and moderate growth restriction. Triploidy on the basis of an extra maternal chromosomal complement is usually associated with a small placenta and asymmetric IUGR.[211,213] Fetuses with triploidy have a multitude of structural malformations, most often involving the central nervous system, heart, and hands[214,215] (Fig. 31.13).

Triploidy: Common Sonographic Findings

- Neural tube defects
- Ventriculomegaly
- Posterior fossa anomalies
- Micrognathia
- Cardiac anomalies
- Omphalocele
- Renal anomalies
- Talipes equinovarus
- 3-4 Syndactyly
- Asymmetric growth restriction
- Abnormal placenta (hydropic changes or small)
- Oligohydramnios

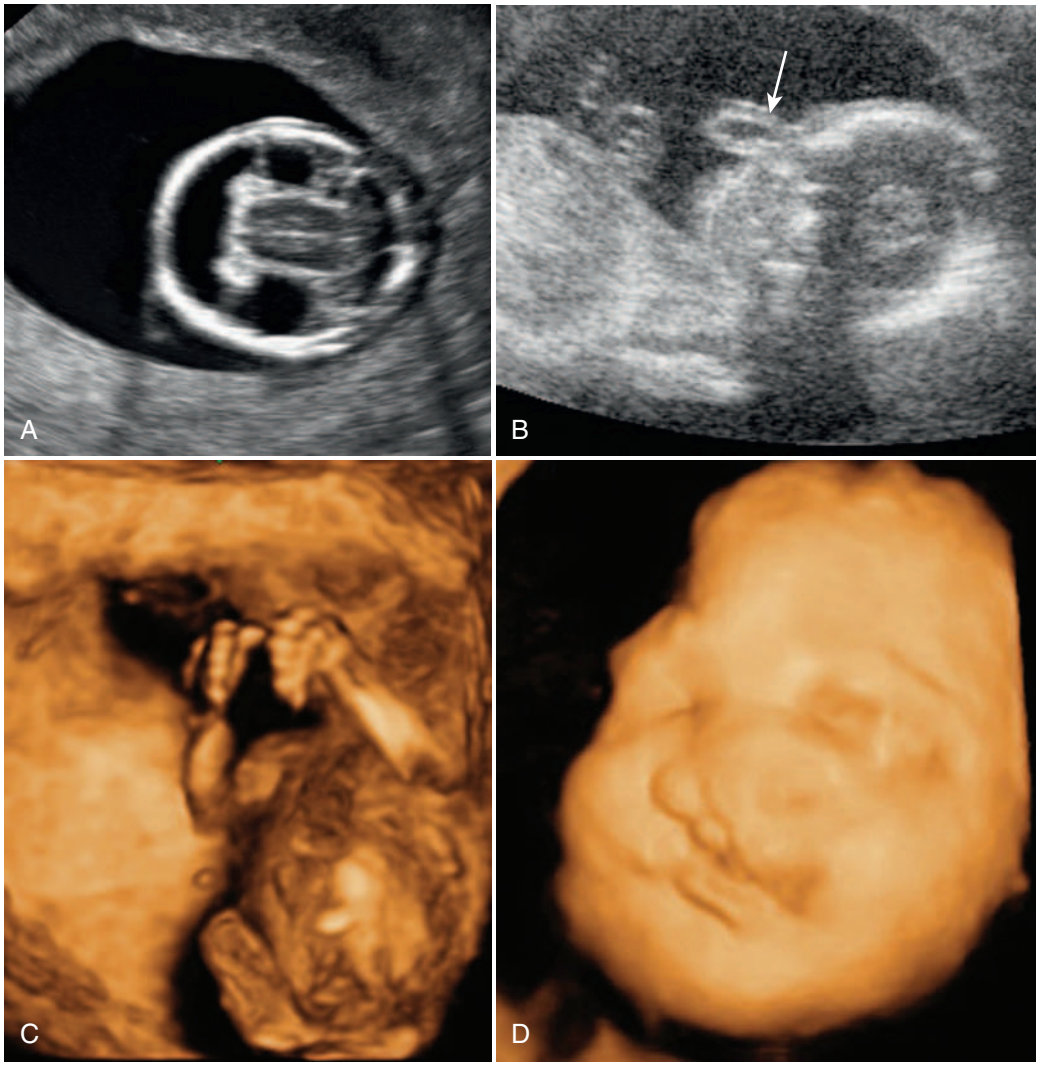

FIG. 31.12 Sonographic Findings in Trisomy 13. (A) Alobar holoprosencephaly at 11 weeks. **(B) Proboscis** *(arrow)*. **(C)** Postaxial **polydactyly** on three-dimensional image at 14 weeks. **(D)** Three-dimensional scan of a third-trimester fetus shows a large, midline **facial cleft.**

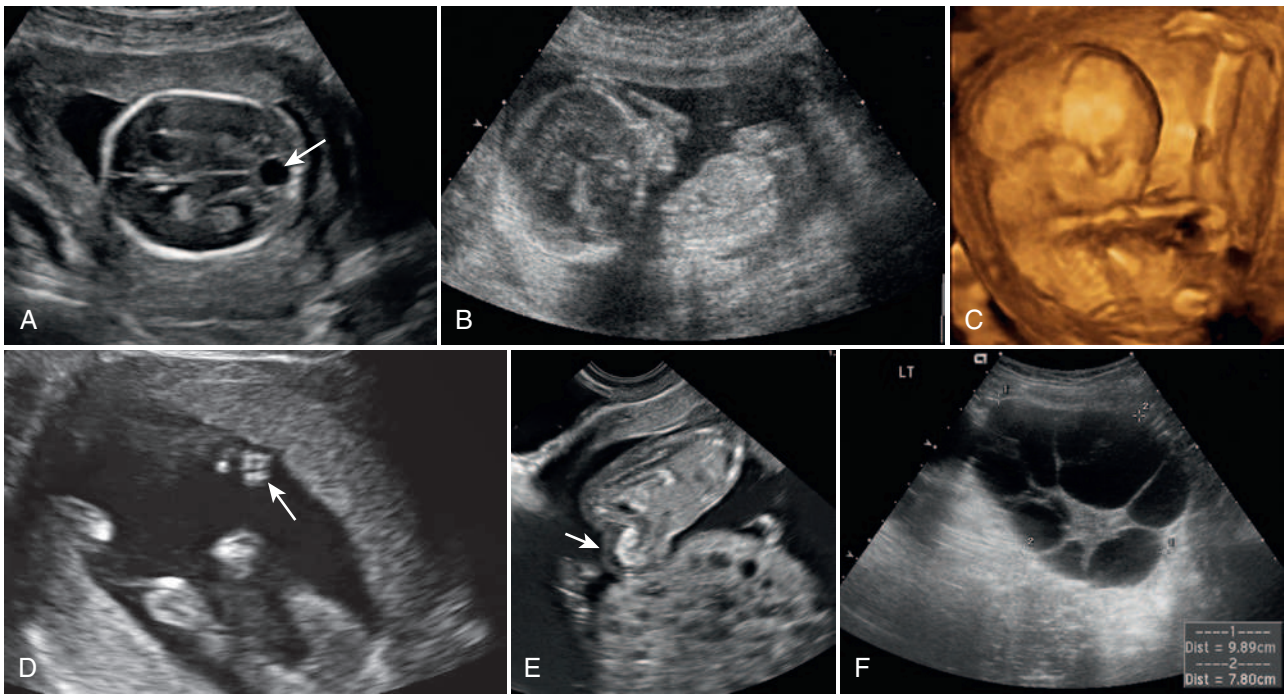

FIG. 31.13 Second-Trimester Sonographic Findings in Triploidy. (A) Dandy-Walker malformation *(arrow)*. **(B)** and **(C)** Asymmetrical IUGR. Note the discrepancy in size of the head and body. **(D) Syndactyly** of the fingers *(arrow)*. **(E)** Scan through the placenta showing multiple lucencies as well as an omphalocele *(arrow)*. **(F)** Maternal ovaries with multiple cysts characteristic of theca lutein cysts.

Triploidy can be associated with maternal complications, including early-onset preeclampsia, bilateral multicystic ovaries, hyperemesis gravidarum, and persistent trophoblastic disease.[216,217]

Jauniaux et al.[214] described 70 cases of triploidy scanned between 13 and 29 weeks' gestation. Anatomic defects were found in 93% of cases, with abnormalities of the hands (predominantly 3-4 syndactyly) the most frequent finding (52%). Cerebral ventriculomegaly was identified in 37%. Cardiac defects, primarily atrioventricular septal defects, were detected in 34% of fetuses. Micrognathia affected 26% of fetuses. Placental molar changes were seen in 29%, and amniotic fluid volume was decreased in 44%. Asymmetrical growth restriction was noted in 72% of cases, and each of these fetuses had a sonographically normal–appearing placenta.[214]

MONOSOMY X (TURNER SYNDROME)

Turner syndrome is the result of a 45,X chromosomal complement, usually caused by loss of the paternal X chromosome, and is unrelated to maternal age. About 95% of conceptuses are spontaneously aborted. Turner syndrome occurs in 1 in 2000 to 1 in 5000 live births.[218-221] The lethal type of Turner syndrome seen in the midtrimester of pregnancy generally presents with large septated cystic hygromas, total body **lymphedema, pleural effusions, ascites,** and cardiac defects[218,219] (Fig. 31.14).

Cystic hygromas are malformations of the lymphatic system and appear as saccular septated fluid collections, most often surrounding the back of the fetal head and neck. Azar et al.[220] reported that 75% of fetuses with bilateral dorsal septated nuchal

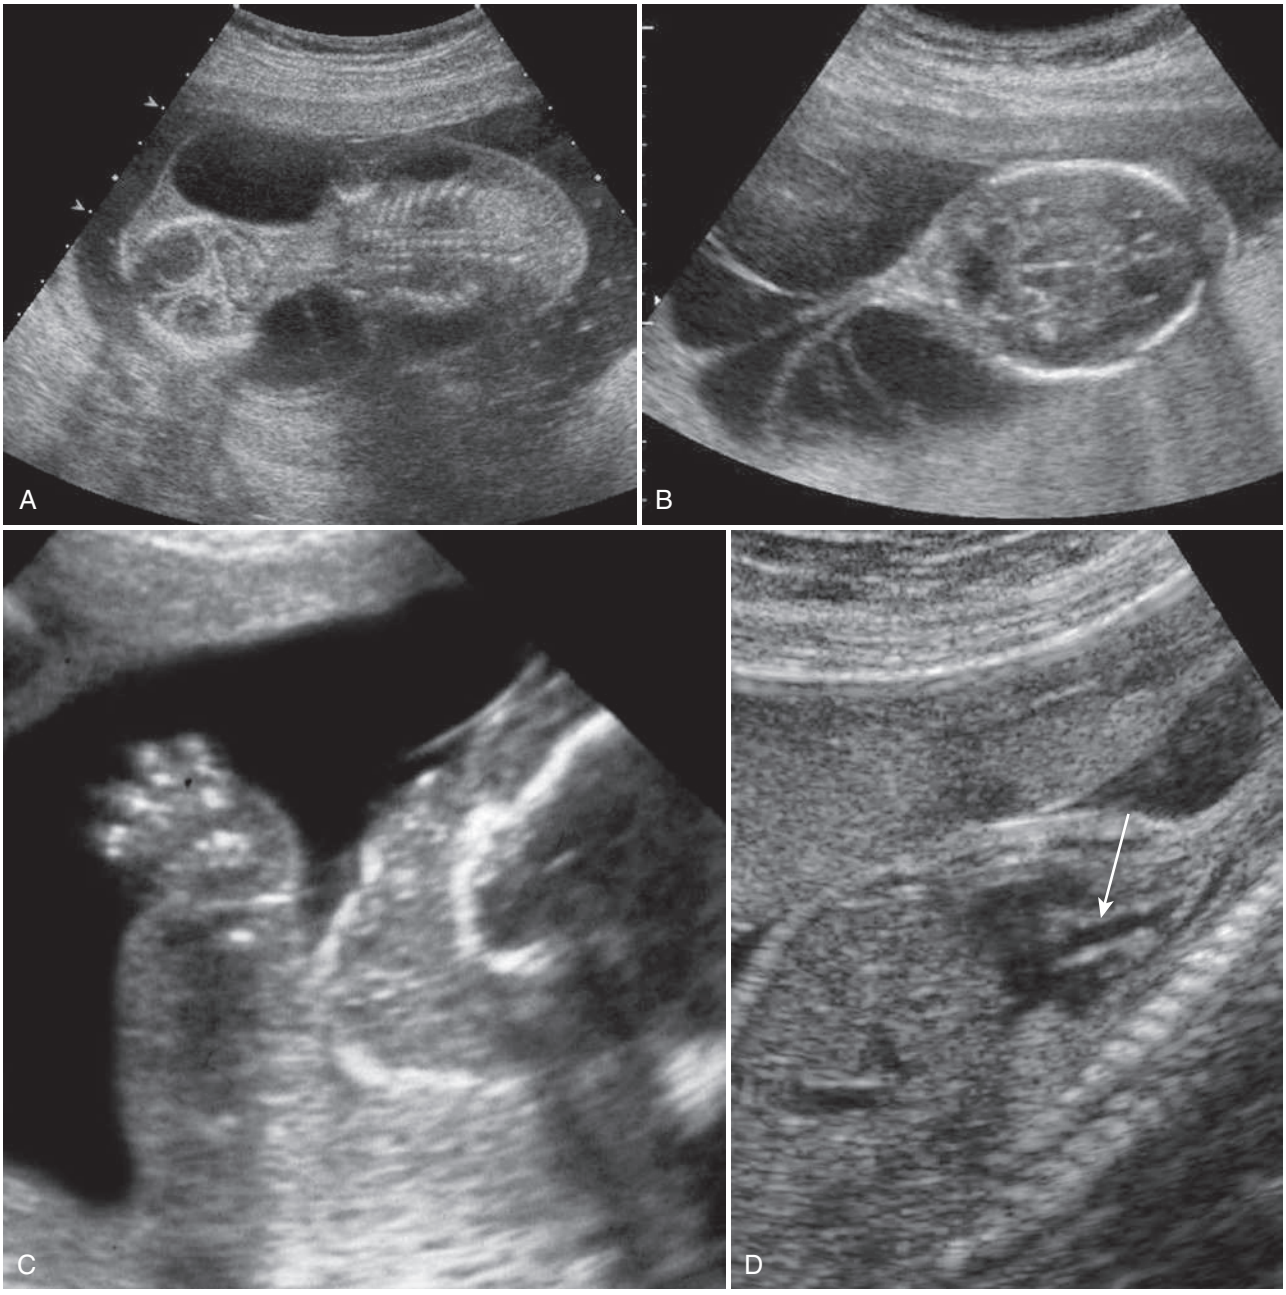

FIG. 31.14 Second-Trimester Sonographic Findings in Monosomy X (Turner Syndrome). (A) and **(B)** Large septated **cystic hygromas. (C)** Hydropic fetal arm in a fetus with severe lymphangiectasia. **(D)** Small aorta *(arrow)* in fetus with **interrupted aortic arch.**

cervical cystic hygromas had chromosomal anomalies, the most common being Turner syndrome (94%). Although many second-trimester fetuses with cystic hygromas have Turner syndrome, other karyotypic abnormalities, including trisomies 21, 18, and 13 and triploidy, have also been reported. In general, cystic hygromas in fetuses with Turner syndrome are larger than those seen with other karyotypic abnormalities, and fetuses with Turner syndrome may also have generalized lymphedema extending down the torso and extremities.

Cardiac abnormalities, most often left-sided defects such as coarctation of the aorta, may be identified in 10% to 48% of fetuses with Turner syndrome. However, this may be an underestimation because many fetuses are identified late in the first semester or early in the second trimester, when optimal cardiac evaluation is not likely.[218-221] Baena et al.[218] reported on 125 cases of Turner syndrome from an unselected population and noted that 67% were identified prenatally. The most common sonographic findings were cystic hygromas (59%) and hydrops (19%).

PRENATAL SCREENING FOR ANEUPLOIDY WITH CELL-FREE DNA

Recently the incorporation of **cell-free DNA** analysis into screening for aneuploidy has revolutionized the paradigm of risk assessment. The option for aneuploidy screening by cell-free DNA has been supported by the American College of Obstetricians and Gynecologists (ACOG) for women at increased risk for this condition.[222] Cell-free DNA from placental origin makes up 10% to 15% of circulating cell-free DNA in maternal plasma and is used to screen for trisomy 21, 18, and 13 as early as 10 weeks' gestation. Sex chromosome analysis may be requested. The relative proportion of fetal to maternal origin of circulating cell-free DNA is termed the fetal fraction and is essential for an accurate test result. Three different methods of cell-free DNA analysis have been described—massively parallel shotgun sequencing, chromosome-selective sequencing, and single nucleotide polymorphism–based analysis—each with high sensitivity and specificity for trisomy 21 and 18.[223-225] Sensitivity for trisomy 13 and monosomy X is somewhat lower although specificity remains high. Gil et al. in a recent meta-analysis reported weighted pool detection rates and FPRs of 99.2% and 0.09% for trisomy 21, 96.3 and .13% for trisomy 18, and 91% and .13% for trisomy 13.[226] For monosomy X, the weighted pool detection rate was 90.3% with a FPR of .23%. Accuracy for sex determination generally exceeds 98%.[222] Although cell-free DNA with reportable results has excellent performance metrics for the detection of common chromosomal trisomies, it remains a screening test. False-positive results may occur as a result of confined placental mosaicism, true fetal mosaicism, maternal chromosomal abnormality, a demised second twin, or maternal malignancy.[222,227] False-negative results may occur with low-level fetal mosaicism, low fetal fraction of circulating cell-free DNA, insufficient depth of sequencing, or sample error. Of note, between 1% and 8% of the population may have unreportable findings or a "no call" result. This situation is most likely to occur when there is a lower fetal fraction of cell-free DNA or results that are "too close" to call.[228,229] A low fetal fraction is associated with early gestational age, aneuploidy, and high maternal body mass index.[229,230] Patients with unreportable results should be referred for genetic counseling and offered detailed ultrasound evaluation and diagnostic testing.[222] Performance of cell-free DNA screening on living twin gestations is feasible, but early data suggest that the detection rate for trisomy 21 and 18 is slightly lower and that test failure is higher compared with singletons.[231] Recommendations for the use of cell-free DNA are regularly updated, and cell-free DNA screening currently is not recommended by ACOG in women with multiple gestations.[222]

Performance metrics on the general population are excellent although the positive predictive value of the test is lower than in a high-risk population. There is no argument when a result is reported, that cell-free DNA screening has a higher sensitivity and specificity, lower FPR, and higher PPV for the detection of trisomy 21 and 18 than combined screening, but it does not detect other conditions that are important to the health and well-being of the fetus.[228,232] It must be kept in mind that although cell-free DNA is an excellent screening test for targeted chromosomal abnormalities, both appropriate pretest counseling and confirmation of positive results before any irreversible decisions concerning the pregnancy are undertaken is critical.[222] Patients should be counseled that a negative result does not ensure an unaffected pregnancy as there is a residual risk of a targeted trisomy as well as other chromosomal abnormalities or genetic conditions. Cell-free DNA may not detect 16.9% to 23.4% of chromosomal abnormalities that may be identified by traditional screening algorithms.[233,234] Cell-free DNA screening is of limited utility in patients with sonographic abnormalities and they should be offered diagnostic testing. Benachi et al. report that in women with fetal abnormalities detected through use of ultrasonography, the rate of pathogenic chromosome abnormalities missed by cell-free DNA is at least 8%.[235] Shani et al., in a retrospective cohort study of 3140 invasive diagnostic procedures in singletons, reported clinically significant chromosomal abnormalities were present in 220 (7%).[236] Based on current published detection rates for cell-free DNA, including "nonreportable" results, these authors calculated that cell-free DNA would not have detected 99 in 220 (45%) of chromosomal abnormalities.

DIAGNOSTIC TESTING

Diagnostic testing can be performed by chorionic villus sampling in the late first trimester or by amniocentesis in the second trimester. Diagnostic testing options are rapidly expanding beyond conventional karyotype and may include CMA, which identifies microalterations known as CNVs on a genomic scale. These CNVs may be pathogenic, benign, or of unknown significance.[237] In 4% to 10% of fetuses with a structural anomaly and a normal karyotype, CMA may detect abnormal CNVs.[237,238] Whole exome sequencing may provide further insight into prenatal diagnosis.[239]

Chorionic villus sampling is performed between 10 and 13 weeks' gestation. Placental villi are obtained either through a transabdominal or transvaginal approach under ultrasound guidance depending on placental location. For transabdominal approach an 18- or 20-gauge needle is advanced into the placenta

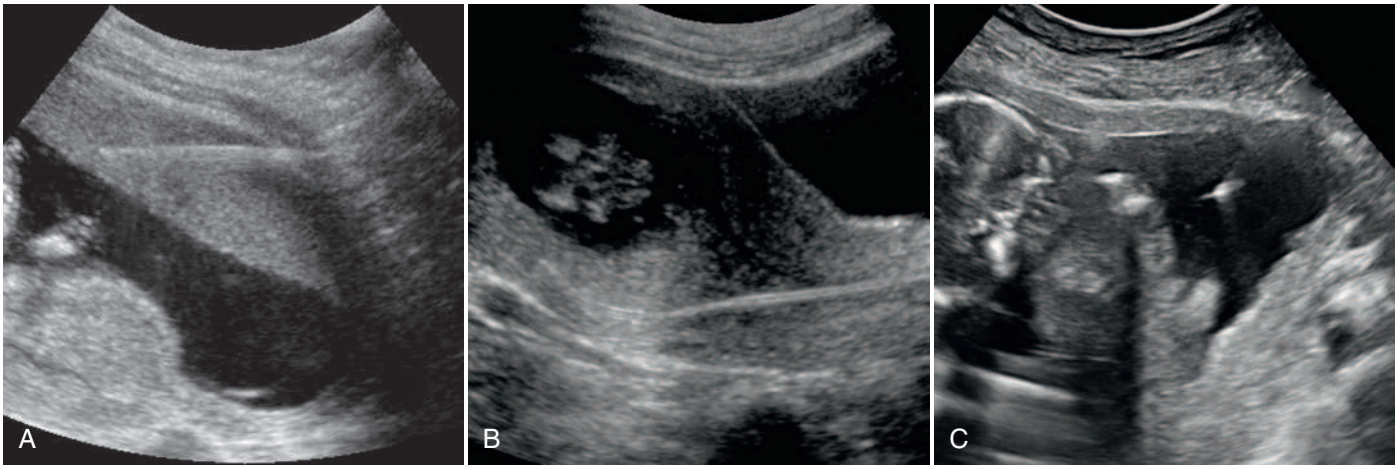

FIG. 31.15 Diagnostic Procedures. (A) Transabdominal **chorionic villus sampling.** Transverse image of needle entering the placenta. **(B)** Transcervical chorionic villus sampling. Sagittal image shows a catheter passing through the cervix and into the placenta. Note the full bladder and amniotic cavity. **(C) Amniocentesis.** Transverse ultrasound image shows needle entering the amniotic fluid. See also Video 31.5.

and the stylet removed (Fig. 31.15A). A 20-mL syringe with about 2 mL of cell-transport medium is connected to the needle. The needle is then guided back and forth through the placenta while suction is intermittently applied to the syringe. The needle is withdrawn and the cell-transport medium is drawn though the needle to clear any remaining villi. The specimen is examined under a dissecting microscope for adequacy. For transcervical CVS (Fig. 31.15B), a 5.7-Fr flexible CVS cannula with a rigid metal introducer is guided into the cervix under direction visualization, and then into the placenta under sonographic guidance (Fig. 31.15B). The introducer is withdrawn and a 20-mL syringe with about 2 mL of transport medium is connected to the cannula. Suction is intermittently applied to the cannula as it is slowly withdrawn from the placenta. As with all fetal procedures, the fetal heart rate is documented after the procedure. Women who are Rh negative and who have an Rh-positive partner are given RhoGAM.

The CVS specimen can then be tested with fluorescent in situ hybridization (FISH), direct cytogenetic analysis, or cultured villi for numerous conditions.[240,241] One concern with CVS is that there is a discrepancy between the prenatal cytogenetic diagnosis from placental source and the fetal karyotype. The U.S. Collaborative Study on CVS and other large registries have found that a successful genetic diagnosis can be obtained in 99.7% of cases, with an FPR of 11 per 10,000 pregnancies.[242,243] There were no diagnostic errors involving trisomy 13, 18, or 21 in these studies.[242] Maternal cell contamination occurs in 0.8% to 2.2% of cases.[242,244] Approximately 0.5% of CVS samples will have an ambiguous finding that needs confirmation by amniocentesis.[245] **Confined placental mosaicism** is seen in 0.7% to 1.6% of cases[242-244] and may be caused by meiotic errors with subsequent "trisomy rescue" or by mitotic errors in the developing morula.[246] Confined placental mosaicism can also cause a false-positive cell-free DNA result and, in some cases, diagnostic testing by amniocentesis is suggested.[247]

A recent meta-analysis reports a weighted pooled procedure–related miscarriage at less than 24 weeks for CVS as 0.22% (95% CI, −0.71%-1.16%).[248] The Canadian Collaborative CVS-Amniocentesis Clinical Trial group recruited women at less than 12 weeks' gestational age and randomized them to CVS in the first trimester or amniocentesis at 15 to 17 weeks' gestational age. No significant differences were seen in fetal loss rates.[249] Caughey et al.[250] compared CVS, amniocentesis, and control groups of women at similar gestational ages who declined intervention and found no significant differences in the adjusted loss rates between the CVS and amniocentesis groups in the most recent study period reported. Early concerns about an increased risk of oromandibular-limb hypogenesis syndrome[251] have been not been upheld.[252] A report by the World Health Organization on the safety of CVS found that the risk of limb reduction defects by week was comparable to that of the general population, except at 8 weeks' gestational age, when it was elevated with CVS.[253]

Genetic amniocentesis is typically performed between 15 and 20 weeks' gestation (Fig. 31.15C). Sonographic guidance is used for location of a fluid pocket. Most often a 22-gauge 3.5-inch long spinal needle is used (Fig. 31.15C, Video 31.5). For larger patients a longer needle may be required. The placenta is avoided if possible, but performing the procedure through the placenta is thought to be safe. Typically 15 to 20 mL of fluid is removed (with a rule of thumb being 1 mL per week of gestation). When amniocentesis is performed in multiple gestations, care is taken to approach each sac separately. The reported procedure-related loss rate before 24 weeks' gestation in a recent meta-analysis was 0.11% (95% CI, −0.04%-0.26%).[248] The heterogeneity of studies on diagnostic testing limits a precise estimation of procedure-related loss for CVS or amniocentesis; however, the added procedure-related risk following is quite low (0.2% and 0.1%).[254] The commonly quoted procedure loss rate is "less than 1 in 300 to 500 procedures."[254] Leakage of amniotic fluid may occur after a genetic amniocentesis, although favorable pregnancy outcomes are seen in more than 90% of women with expectant management.[255,256] Amniocentesis between 11 and 13 weeks' gestation has been associated with increased pregnancy loss rates,

membrane rupture, and talipes equinovarus as well as higher amniotic fluid culture failures and therefore is not recommended.[254] As with all fetal procedures, the fetal heart rate is documented after the procedure. Women who are Rh negative and have an Rh-positive partner are given RhoGAM.

CONCLUSION

Over the past three decades, risk assessment for aneuploidy has progressed to the point that maternal age alone or NT width alone is no longer considered adequate for determining the risk of having a chromosomally abnormal offspring. Obstetric sonography, in conjunction with maternal serum analytes, has become a powerful tool in the assessment aneuploidy risk in both the first and the second trimester. In the second trimester the diverse sonographic patterns seen with the different aneuploidies allow clinicians to guide patients to a presumptive diagnosis. Recent advances in cell-free DNA analysis provide exceptional screening performance targeted specifically for trisomies 21 and 18 and, to a slightly lesser degree, for trisomy 13; however, other chromosomal abnormalities that are potentially detected by combined screening or diagnostic testing are not identified. Karyotype has been the standard for fetuses with structural anomalies; however, microarray analysis to determine CNV abnormalities will augment the detection of clinically significant disorders, most notably in fetuses with structural abnormalities. When considering all detectable chromosome problems, multiple marker screening including NT, with the option of diagnostic testing for screen positive results, is the optimal strategy for most women. For pregnant women aged 40 years or older, cell-free DNA as a primary screening tool is optimal.[4]

CHAPTER 32

Multifetal Pregnancy

Mary C. Frates

SUMMARY OF KEY POINTS

- Multifetal pregnancies have higher rates of perinatal morbidity and mortality than singletons.
- Chorionicity is the major determining feature for the inherent unique complications faced by multiple gestations.
- Fetal growth differences and congenital malformations are increased in all types of multiple gestations.
- In monochorionic twins with a single demise, there is a high risk of severe cerebral and other injuries in the survivor.
- Sonography permits the diagnosis of syndromes unique to monochorionic twins, including twin-twin transfusion syndrome, twin anemia polycythemia sequence, twin reversed arterial perfusion sequence, and conjoined twins.

CHAPTER OUTLINE

ZYGOSITY/CHORIONICITY
DETERMINATION OF CHORIONICITY
GENERAL ISSUES
LOSS OF A TWIN
COMPLICATIONS OF MONOCHORIONICITY
Twin-Twin Transfusion Syndrome
Twin Anemia Polycythemia Sequence
Twin Reversed Arterial Perfusion Sequence
MONOAMNIOTIC TWINS
CONJOINED TWINS

Pregnancies with more than one fetus have become an increasingly common obstetric occurrence, primarily as a result of assisted reproductive technologies. Most **multifetal** pregnancies are **twins,** with higher-order multiples also possible. The rate of twins occurring naturally is 1 in 80 births,[1] yet the rate of twin births continues to rise. According to the Center for Disease Control Vital Statistics,[2] whereas the number of overall births in the United States was stable to slightly decreased in 2013 compared with 2012, the rate of twins reached a new high of 33.7 per 1000 births. The rate of triplet or higher births has been dropping since 1998, with a 2013 rate of 119.5 per 100,000 births. Modifications of assisted reproductive techniques are in part responsible for the declining rate of triplet and higher-order multiple gestations since the peak in 1998.[3] Multifetal pregnancies are subject to all the same considerations of singleton pregnancies but are also at particular risk for premature delivery and growth restriction. In 2013, more than one of every two twins and more than 9 of every 10 triplets was born preterm or with low birth weight.[2] In addition, there are unique issues that arise in multiple gestations, and it is critical for imagers to have a full understanding of these possible complications.

ZYGOSITY/CHORIONICITY

Twins are either **dizygotic** (fraternal) or **monozygotic** (identical). Among spontaneous twins, approximately two-thirds are dizygotic and one-third are monozygotic. Dizygotic twins occur when two separate ova are fertilized by two separate sperm. The rate of dizygotic twinning varies with maternal age (increased with older mothers), race, and family history. Monozygotic twins occur when a single ovum is fertilized by a single sperm and the embryo then divides from 2 to 14 days after fertilization. The timing of the division will dictate the type of twin. Spontaneous monozygotic twinning is uniform across the world (3.5/1000), and historically is not affected by maternal age, race, or other known factor.[1] However, there is currently an increased incidence of monozygotic twins from 2 to 12 times the expected rate following *in vitro* fertilization.[4-6] It has been reported that in patients undergoing assisted reproduction, the timing of single embryo transfer can affect the rate of monozygotic twins, with a higher rate seen following a 5- to 6-day transfer as compared to a 2- to 3-day transfer and a higher rate in patients who have undergone assisted hatching.[7,8] Higher-order multiples may have any combination of zygosity.

For management of a twin pregnancy, the type of twin is characterized by chorionicity rather than zygosity. Chorionicity is the major determining feature for the inherent unique complications faced by multiple gestations, with monochorionic pregnancies at the highest risk.[9] Therefore accurate determination of chorionicity is critical to ensure appropriate obstetric management of a twin pregnancy.[10]

Dizygotic twins are always **dichorionic diamniotic,** meaning that each twin has its own placenta (chorion), amnion, and amniotic fluid. Each twin exists in a separate intrauterine

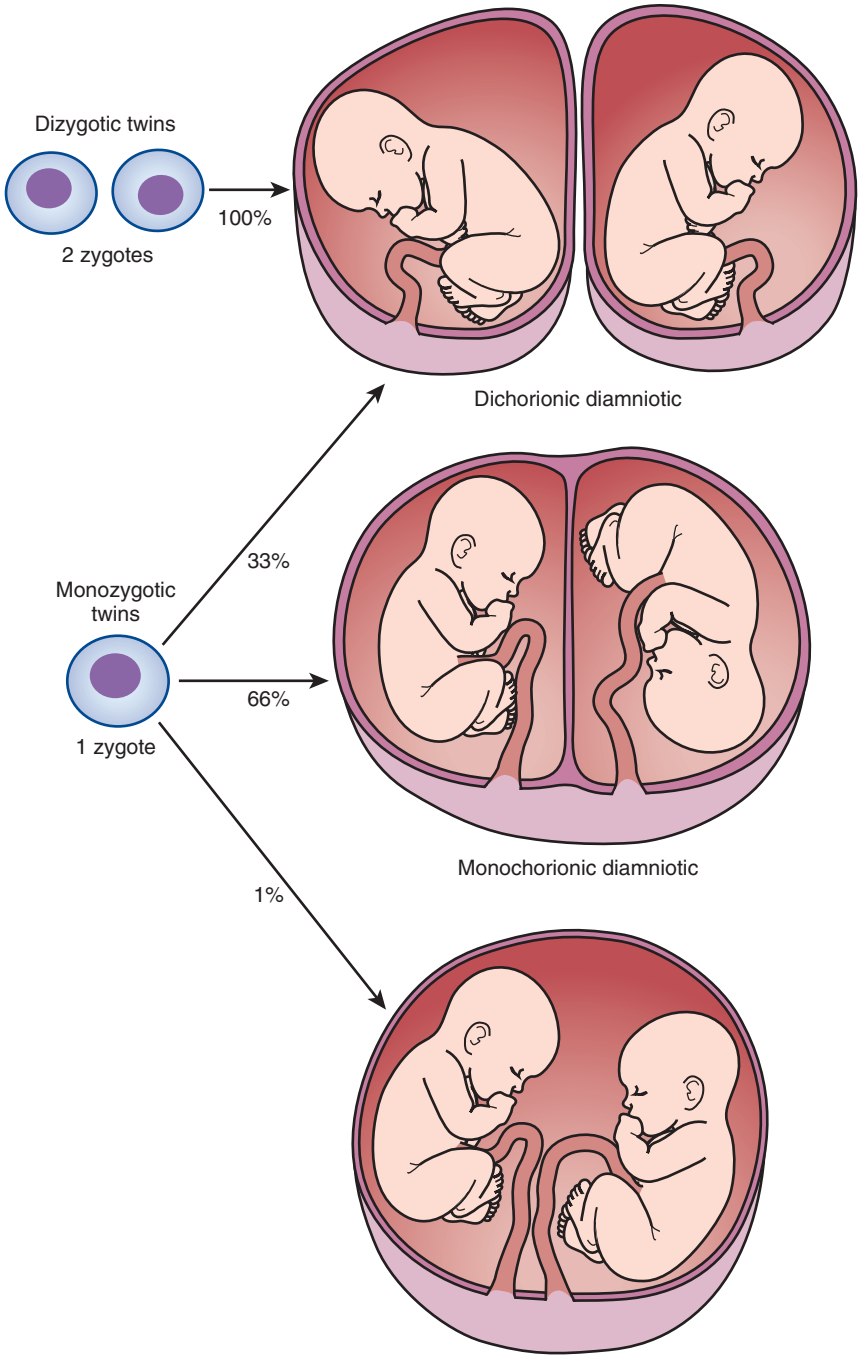

FIG. 32.1 Diagram Illustrating Zygosity and Placentation in Twins. Of twin gestations, two-thirds are dizygotic and one-third are monozygotic. All dizygotic twins result in diamniotic dichorionic pregnancies. Monozygotic twins can be dichorionic (33%), monochorionic diamniotic (66%), or monoamniotic monochorionic (approximately 1%).

environment, and the twins are genetically different. In contrast, there are three possible variations of chorionicity for monozygotic twins, who are genetically identical. Twins that occur when a single zygote divides within the first 4 days after fertilization have their own placenta (chorion), amnion, and amniotic fluid (dichorionic diamniotic, seen in one-third of cases). Monozygotic twins that occur from a later division share a placenta (chorion), but each has its own amnion (**monochorionic diamniotic,** seen in two-thirds). When the division occurs between days 7 and 14, the twins will share a placenta (chorion), amnion, and amniotic fluid (**monochorionic, monoamniotic,** seen in approximately 1%) (Fig. 32.1). Any later time of division will result in **conjoined** twins.[11] The increased risks associated with multiple gestations are related to chorionicity rather than zygosity, and ultrasound plays a critical role in the determination of twin type. Chorionicity is most easily and accurately determined via sonography in the first trimester. Both chorionicity and amnionicity must be established for each embryo.

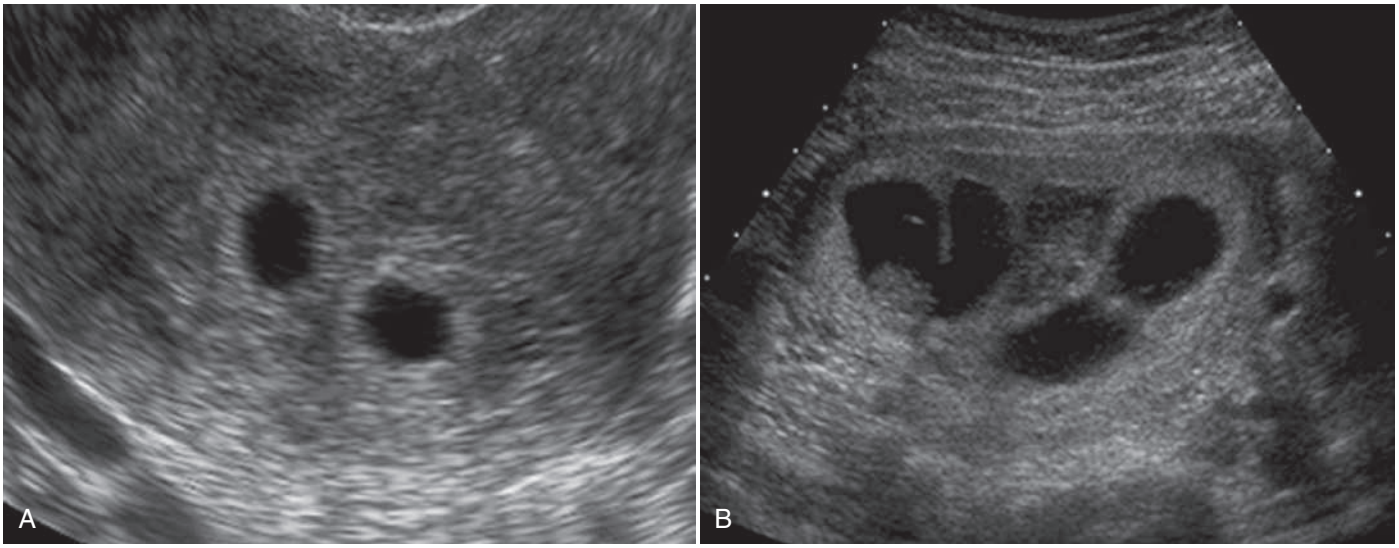

FIG. 32.2 The Number of Gestational Sacs Corresponds to Chorionicity. (A) Early dichorionic twins. Two separate gestational sacs are seen. **(B)** Quintuplets following assisted reproduction. Five separate gestational sacs are visible, with a single live embryo within each sac. See also Video 32.1.

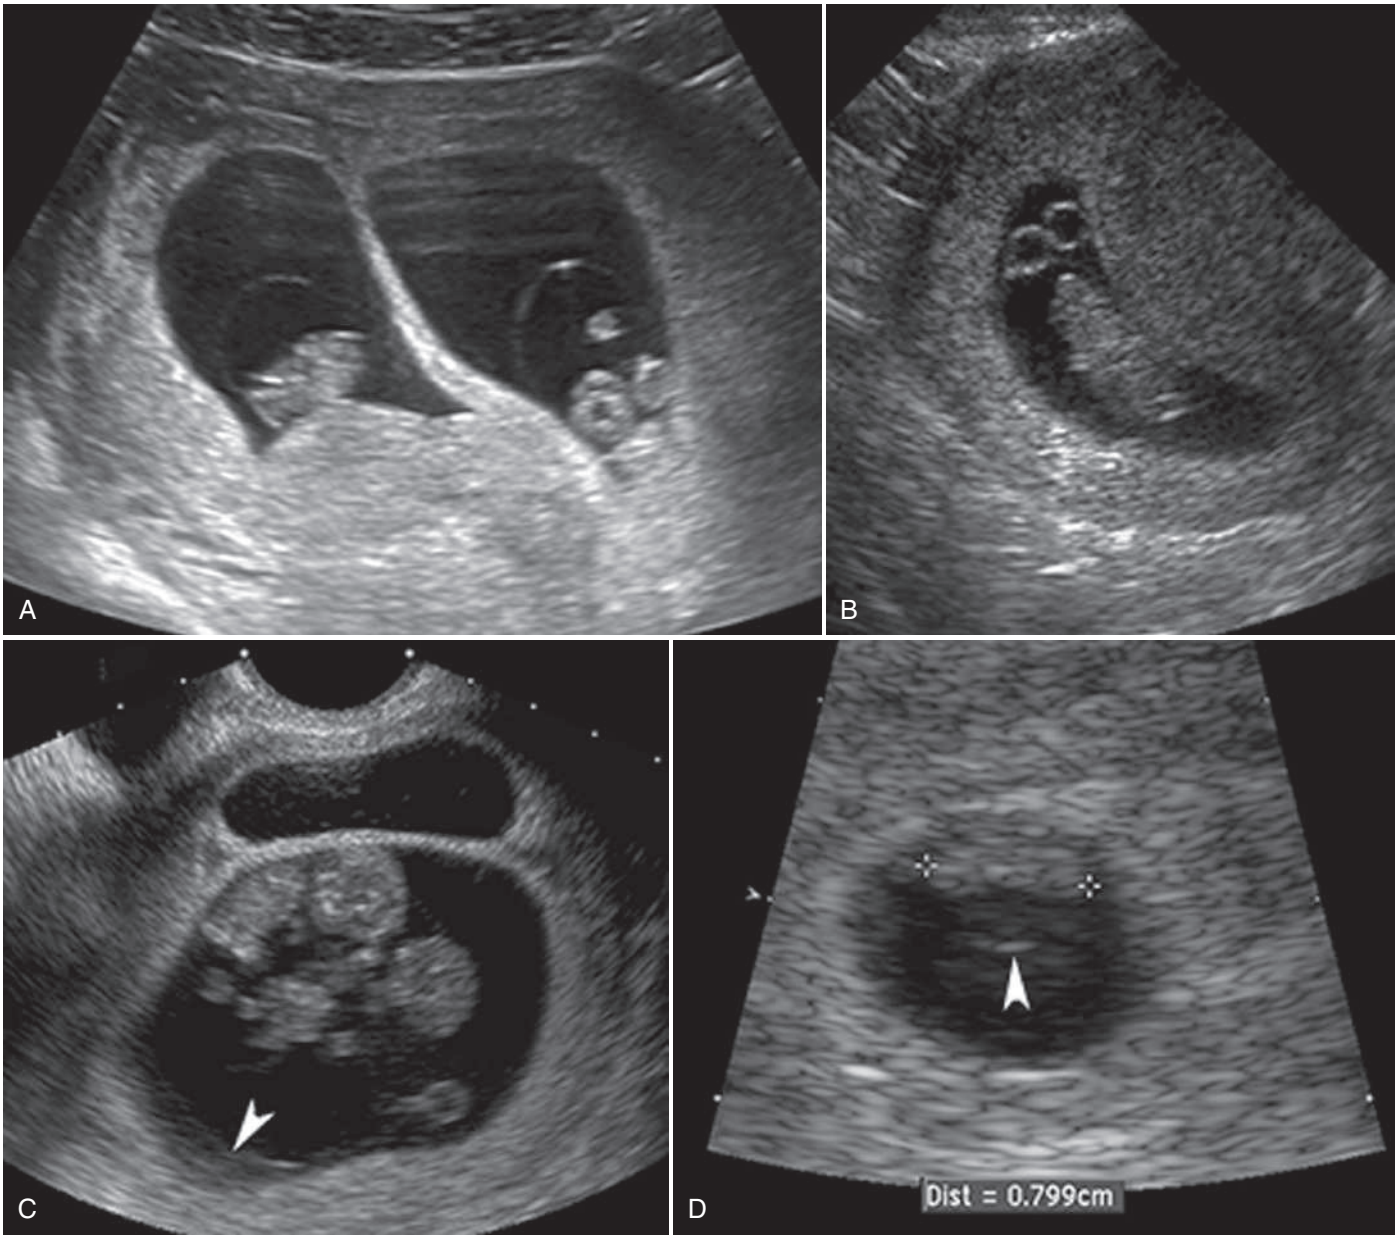
DETERMINATION OF CHORIONICITY

Ultrasonography plays a vital role in the evaluation of multiple gestations, beginning with the first-trimester study. It is at this examination that the possibility of a twin or higher-order gestation will first be raised. A transvaginal approach is standard for early pregnancy (<8 weeks' gestational age) and may be useful later in the first trimester if transabdominal imaging is not definitive.[12] Determination of chorionicity is best performed very early in gestation, when the gestation sac size is small and the number of distinct sacs can be clearly established. The number of sacs will determine the number of chorions (Fig. 32.2, Video 32.1). Each sac should be evaluated for the presence of a yolk sac, embryo, and cardiac activity. To successfully identify monochorionic twins or higher-order multiples, careful evaluation of the contents of each sac is critical, to search for more than one yolk sac or embryo. In addition to accurately determining chorionicity, first-trimester ultrasound is also highly accurate at dating pregnancy,[13] which is particularly important for multiple gestations. The initial ultrasound report must clearly define the type of gestation, including chorionicity for each embryo, and should provide a single gestational age, as the first sonogram will be used for dating and for directing management of the pregnancy. In patients who have conceived via *in vitro* fertilization, the embryo transfer date should be used to establish the gestational age. For spontaneous multiples, if the size of the embryos is similar, an average of crown-rump lengths will provide an accurate gestational age. If the embryos are significantly different in size, the pregnancy should be dated based on the crown-rump length of the largest embryo, as any size discrepancy in the first trimester is likely related to an abnormality of the smaller embryo.

A potential pitfall in the early assessment of multiple gestations is the "appearing twin." At very early gestational ages (<7 weeks), the number of gestational sacs in the uterus may be undercounted, and the content of each sac is indeterminate.[14] A second or third gestational sac may appear, or a second embryo may be seen within a single sac. In contrast, because of the high background loss rate in the first trimester, twins may also "vanish."[15,16] Loss of a twin before 8 weeks' gestational age has minimal, if any, effect on the surviving twin, regardless of the chorionicity.[17,18]

Two distinct gestational sacs within the endometrial cavity indicates dichorionic twins. A single gestational sac containing two yolk sacs is a monochorionic pregnancy, and amnionicity then needs to be determined. The number of yolk sacs within a sac was historically thought to accurately predict the number of amnions[19]; that is, two yolk sacs in a single gestational sac corresponds with monochorionic diamniotic twins while one yolk sac with two embryos indicates monochorionic monoamniotic twins. However, more recently there have been reports of two yolk sacs leading to two embryos within a single amnion, as well as a single yolk sac leading to two embryos and two separate amniotic sacs.[20,21] It is clear that early multiples require close follow-up before assigning the amnionicity. The amnion can first be appreciated around the embryo just after 7 weeks' gestation; however, it may be very subtle, and scanning at 8 or 9 weeks' gestation or later may be more straightforward. Ultrasound has been shown to be highly accurate in assigning chorionicity during the first trimester,[22] in particular with the high resolution provided with a transvaginal transducer (Fig. 32.3, Video 32.2). In one large multicenter study, assignment of chorionicity with ultrasound was correct in 93.6% of twin gestations when performed before 20 weeks, with the most accurate classification occurring in pregnancies less than 14 weeks.[10] In this cohort, the likelihood of misclassification rose with each week of gestational age.

As the gestational sacs begin to grow and fill the endometrial cavity, the sacs begin to impress on each other, and it may be less obvious whether there are two separate sacs. At this time in the late first trimester and beyond, other methods can be used to determine chorionicity with sonography[23] (Table 32.1).



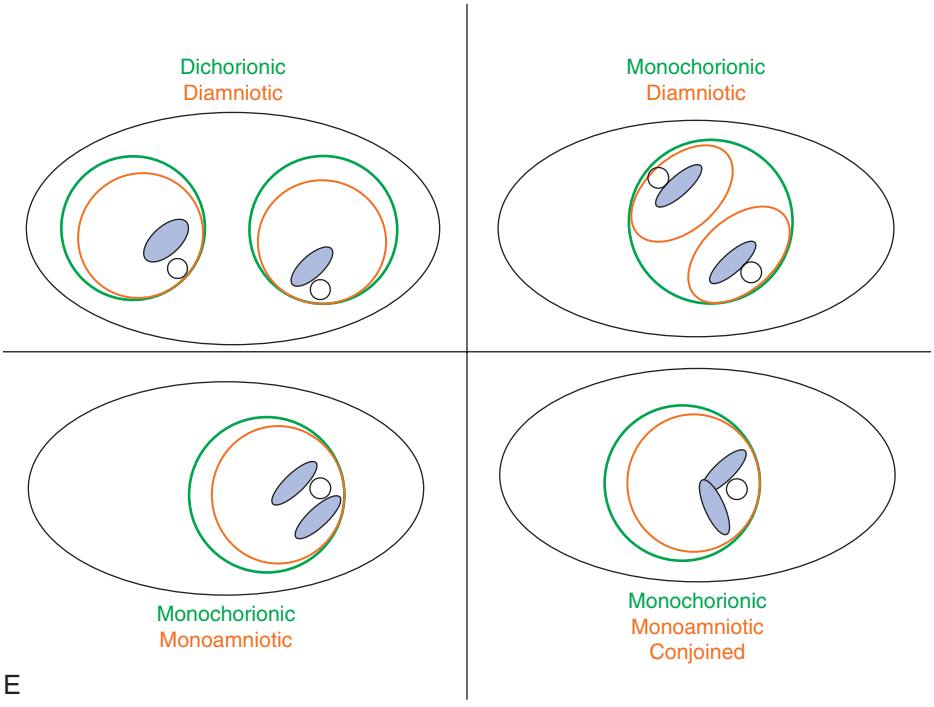


FIG. 32.3 First-Trimester Twins. (A) Dichorionic diamniotic twins. Two separate gestational sacs, each with embryo and yolk sac. Note the thin amnion separated from the chorion in each sac. **(B)** Monochorionic diamniotic twins. Single gestational sac with two yolk sacs and two embryos (only one is shown). **(C)** Monochorionic monoamniotic twins. Single gestational sac with two separate embryos and a single surrounding amnion *(white arrowhead).* **(D)** Monochorionic monoamniotic **conjoined twins.** Single gestational sac with a single amnion *(white arrowhead),* and a single large embryo that contains two heart beats. See also Video 32.2. **(E)** Corresponding line diagram of first-trimester pregnancies. *Blue,* Embryo; *brown,* amnion; *green,* chorion; *small black,* yolk sac.

TABLE 32.1 Sonographic Findings Used to Assign Chorionicity and Amnionicity in the Second and Third Trimesters

Dichorionic	Monochorionic Diamniotic	Monochorionic Monoamniotic
Two separate placentas or can merge to appear as a single placenta	Single placenta	Single placenta
Twin peak sign	T sign	—
Different or same fetal sex	Same sex	Same sex
Thick membrane	Thin membrane	No membrane
—	—	Entangled cords

As a first step, the placental locations should be determined. Two separate placentas indicate a dichorionic pregnancy.[1] However, approximately 50% of dichorionic placentas can appear fused at sonography.[24] If only a single placenta is seen, the fetal surface of the placenta should be searched for a twin peak or delta sign,[25-27] indicating a dichorionic gestation. This sign is a triangular extension of placenta into the intertwin membrane. Two layers of amnion and two layers of chorion form the intertwin membrane of a dichorionic gestation, and proliferating chorion frequently extends between the two chorionic membranes and separates the amnions, thus forming the peak or triangle (Fig. 32.4). This appearance is not continuous across the entire membrane, but rather occurs in patches that can be difficult to identify as the gestational age increases.

In a monochorionic gestation, the separating membrane is composed of two layers of amnion only, without chorion. The two-amnion membrane meets the placenta/single chorion in a T-shaped manner (Fig. 32.5). Because of the presence of four layers (in dichorionic twins with the two thicker chorions and two thin amnions) versus two layers of membranes (in monochorionic twins with two thin amnions) between sacs, the membrane is subjectively thicker in dichorionic gestations than in monochorionic gestations, but this method is less reliable for chorionicity determination than the others described earlier. When the fetus is large enough to assess anatomy, fetal sex can assist in differentiating twin types. Two different sexes are obviously dichorionic, whereas same-sex twins can be either dichorionic or monochorionic. Monoamniotic twins can be accurately identified when there is entanglement of either fetal parts or the cord (Fig. 32.6, Video 32.3). For higher-order multiples, any combination of chorionicity and amnionicity is possible, and more than one means of determining the type of gestation may be needed (Fig. 32.7, Video 32.4).

GENERAL ISSUES

Multiple gestations require the full sonographic evaluation appropriate for singleton pregnancies but have additional unique issues. One important role of the ultrasonologist is to establish which fetus is which, in a way that will allow continuous identification of each fetus until delivery. This determination is made on the first ultrasound in the second trimester or in the late first trimester at the time of nuchal translucency measurement. The fetus whose anatomic part is presenting (i.e., is closest to the cervix) is termed fetus 1 (or A). This fetus should remain fetus 1 for the rest of the pregnancy, even if it moves out of the presenting position at some point. Although a change in position is unlikely to happen if the initial determination was correct, it might occasionally occur, particularly when the intertwin membrane inserts near the cervix. The nonpresenting fetus is labeled twin 2 (or B). In larger-order multiples, the location in the uterus is used as an identifying characteristic—triplet 2 is upper right, triplet 3 is upper left, or vice versa. There is no standard method of labeling higher-order births beyond the presenter as number 1. Whichever method is chosen needs to be clearly reported and reproducible for all follow-up studies. In addition to proximity to the cervix, other clues for identifying which fetus is which are placental location, sex, discordant growth, and any potential anomaly. For higher-order multiples, the placentation/chorionicity should be reported at every exam, and this will help the sonographer with labeling—for example, dichorionic triamniotic triplets: triplet 1 is presenting with an anterior placenta, triplets 2 (upper right) and 3 (upper left) share a posterior placenta.

Good visualization of the intertwin membrane is essential and can be challenging at later gestational ages and in monochorionic gestations. The majority of monochorionic pregnancies are diamniotic, and lack of membrane visualization is typically due to oligohydramnios or overlapping fetal parts. Assessment of the amniotic fluid volume is performed for each fetus individually. Fluid volume is assessed either subjectively by an experienced examiner or using the deepest vertical pocket (see Chapter 42). Cutoffs of greater than 8 cm and less than 2 cm within one sac are generally accepted values to define polyhydramnios and oligohydramnios, respectively.[28] Occasionally, separation of the intertwin membrane can be appreciated, with amniotic fluid tracking between the membranes. This appearance has not been shown to be associated with an adverse outcome.[29]

The umbilical cord of each fetus should be evaluated for the presence of three vessels, as both monochorionic and dichorionic pregnancies have a higher incidence of single umbilical artery than do singletons.[30] In multiple gestations 17% to 22% have an abnormal placental cord insertion with its associated adverse outcomes as compared with 8% of singletons.[31,32] The abnormal cord insertions include both **marginal** (11% of twins) and **velamentous** (6%) insertions[31] and the placental cord insertion of each fetus should be documented (Fig. 32.8, Video 32.5). A velamentous cord insertion in one or both twins is more common in pregnancies conceived with assisted reproductive technology, as well as in twins with intrauterine growth restriction.[33-35]

Twin pregnancies are known to have higher rates of perinatal morbidity and mortality than singletons,[36-38] and the risk is closely related to chorionicity.[39,40] Greater-order multiples have still higher risks. The primary complications are premature delivery, intrauterine growth restriction, and intrauterine demise of one or

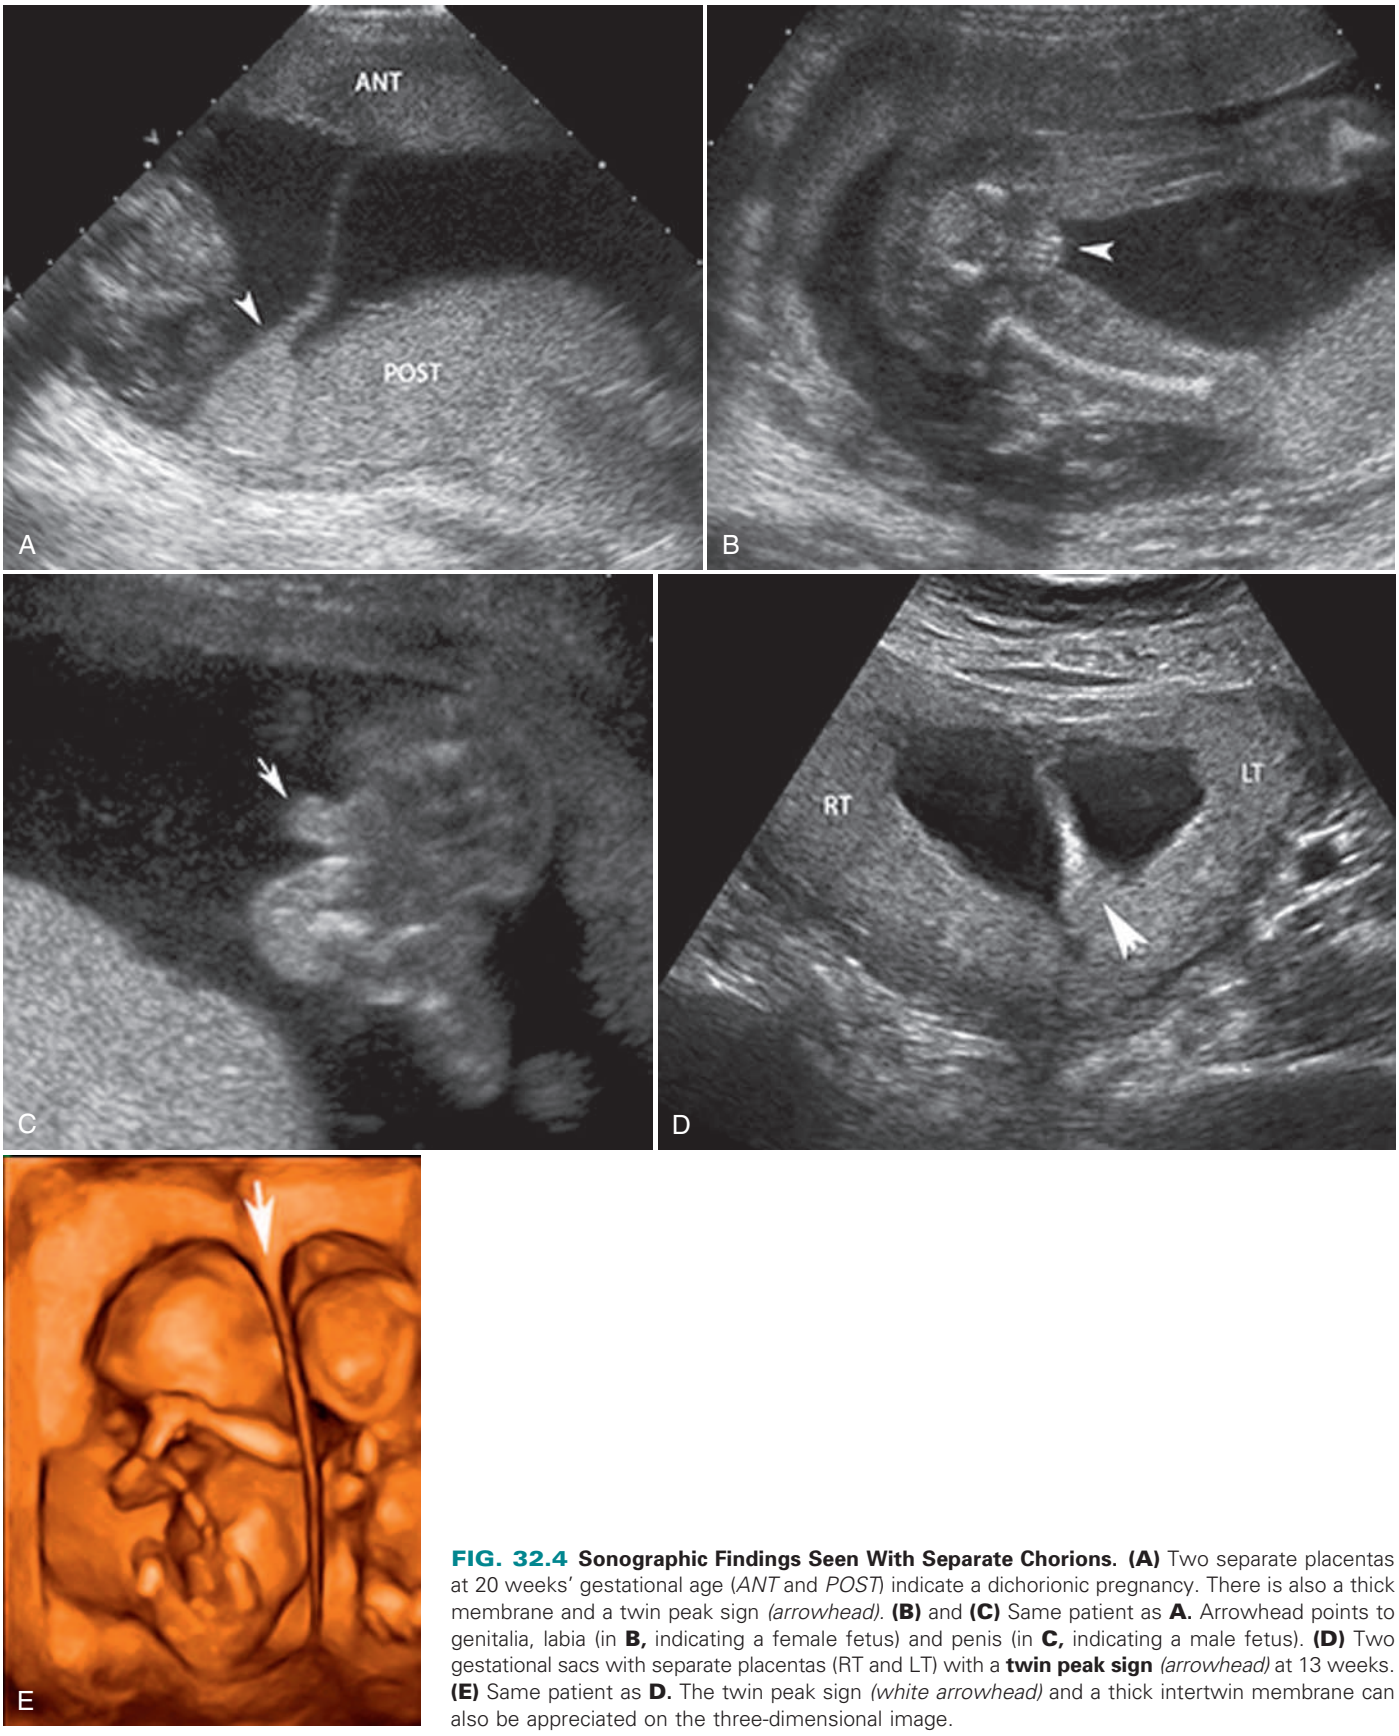

FIG. 32.4 Sonographic Findings Seen With Separate Chorions. (A) Two separate placentas at 20 weeks' gestational age (*ANT* and *POST*) indicate a dichorionic pregnancy. There is also a thick membrane and a twin peak sign *(arrowhead).* **(B)** and **(C)** Same patient as **A.** Arrowhead points to genitalia, labia (in **B,** indicating a female fetus) and penis (in **C,** indicating a male fetus). **(D)** Two gestational sacs with separate placentas (RT and LT) with a **twin peak sign** *(arrowhead)* at 13 weeks. **(E)** Same patient as **D.** The twin peak sign *(white arrowhead)* and a thick intertwin membrane can also be appreciated on the three-dimensional image.

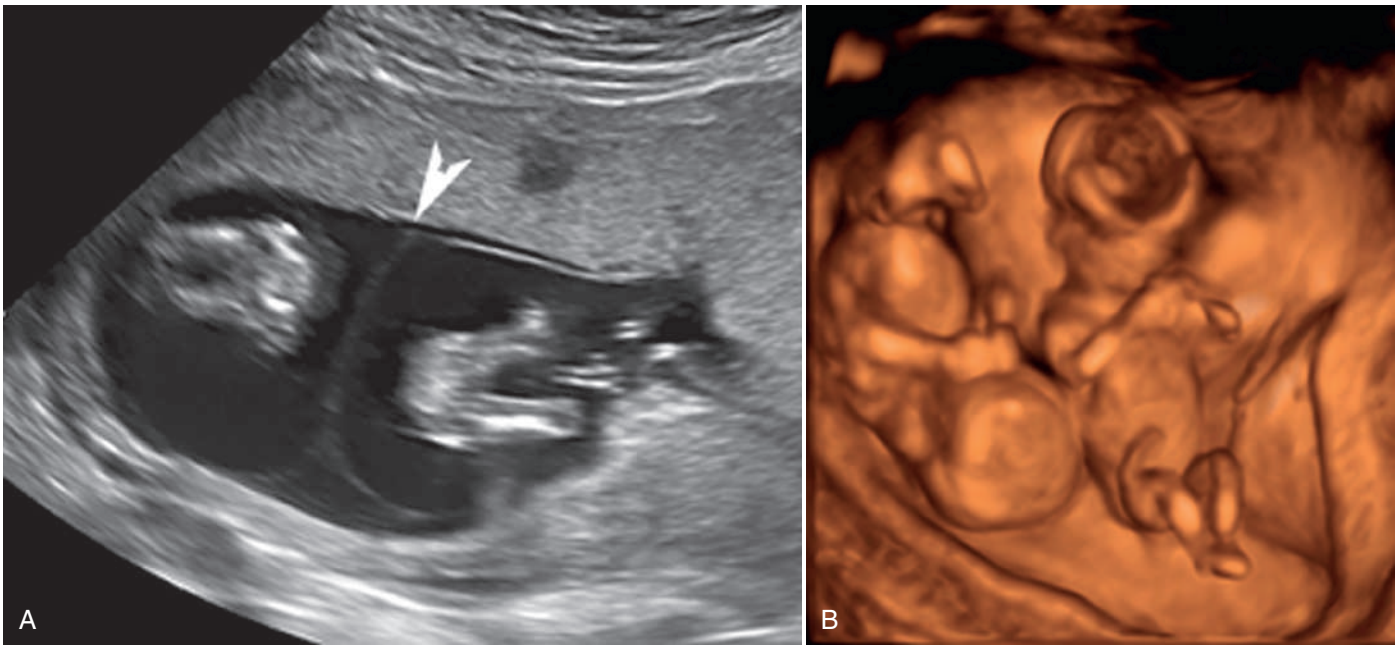

FIG. 32.5 Sonographic Findings Seen With Monochorionic Twins. (A) Monochorionic diamniotic twin gestation at 12.5 weeks' gestational age. There is an amnion visible around each fetus, which meets the anterior placenta in a T configuration *(white arrowhead)*. **(B)** Same patient as **A.** The thin membrane is not visible on the three-dimensional image of the twins.

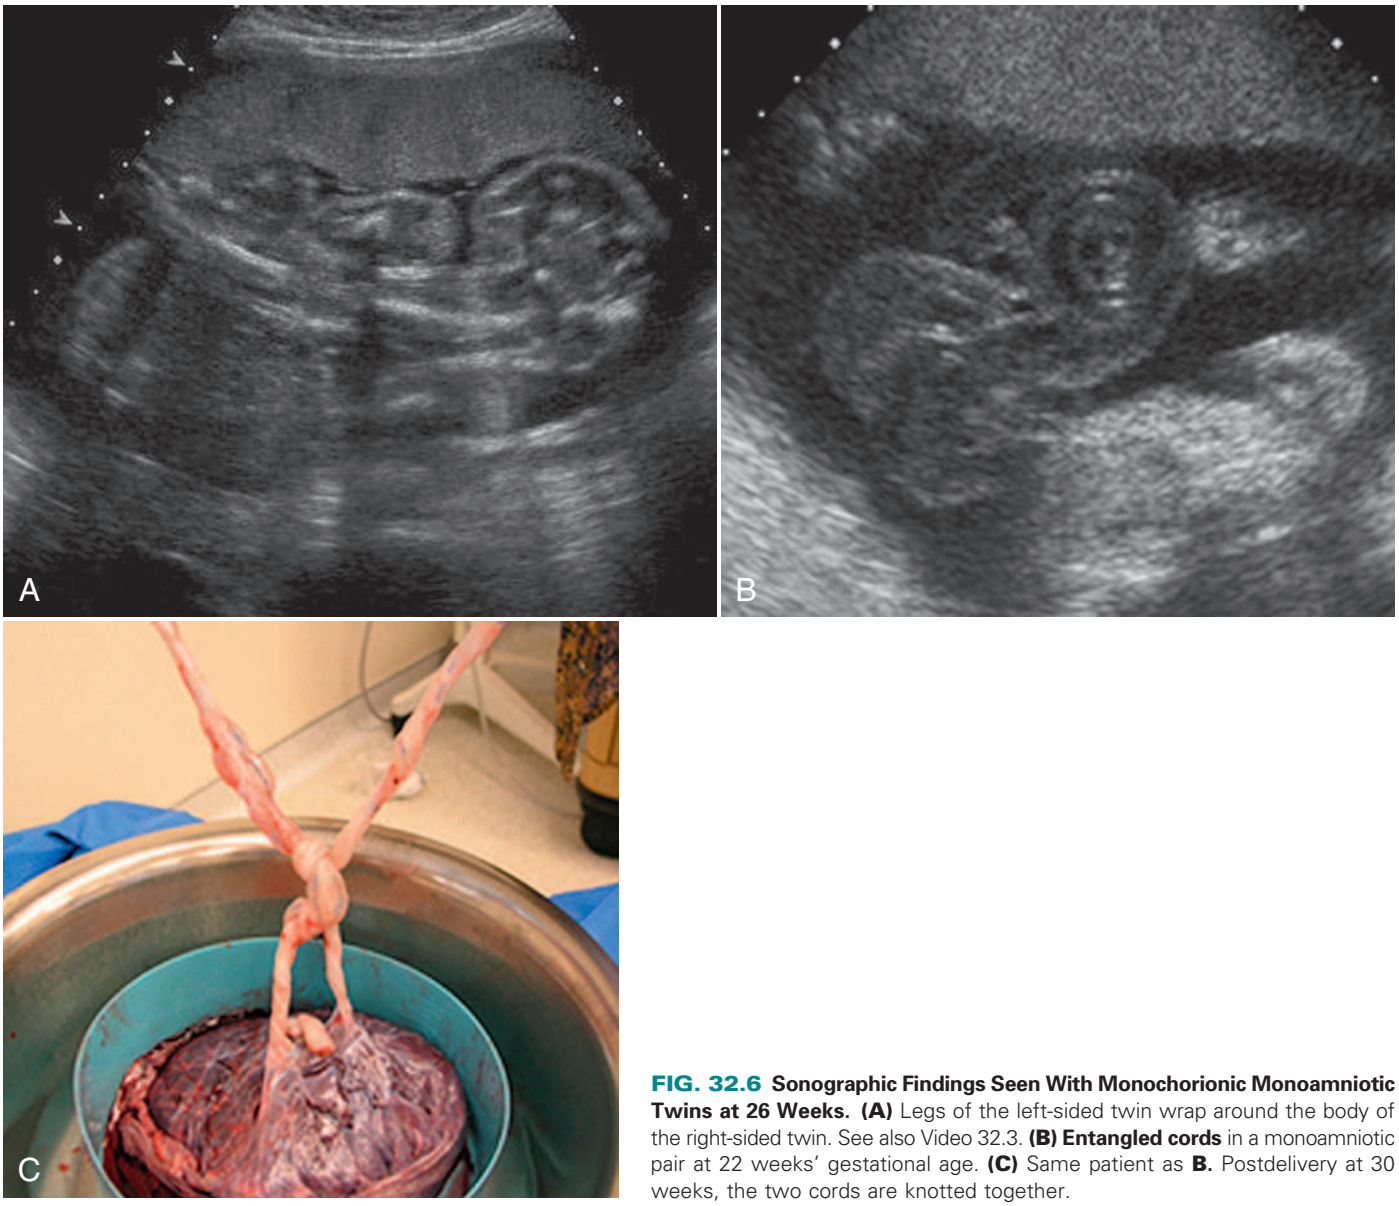

FIG. 32.6 Sonographic Findings Seen With Monochorionic Monoamniotic Twins at 26 Weeks. (A) Legs of the left-sided twin wrap around the body of the right-sided twin. See also Video 32.3. **(B) Entangled cords** in a monoamniotic pair at 22 weeks' gestational age. **(C)** Same patient as **B.** Postdelivery at 30 weeks, the two cords are knotted together.

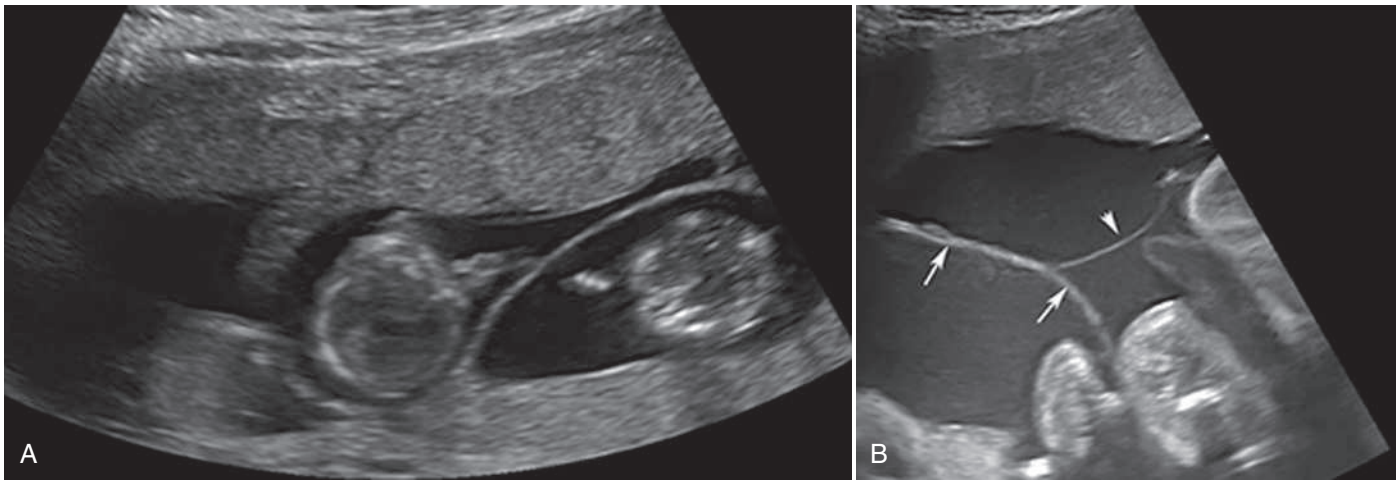

FIG. 32.7 Triplet Pregnancy Categorization. Each triplet needs amnionicity and chorionicity assigned accurately; analysis of more than one characteristic might be needed. **(A)** Three separate placentas in a trichorionic triplet pregnancy at 13 weeks. There is a posterior placenta on the left. The two anterior placentas appear merged, but a **twin peak sign** is present. See also Video 32.4. **(B) Triplet pregnancy** at 26 weeks' gestational age. There is both a thin *(white arrowhead)* and a thick *(white arrows)* membrane, consistent with triamniotic dichorionic twins.

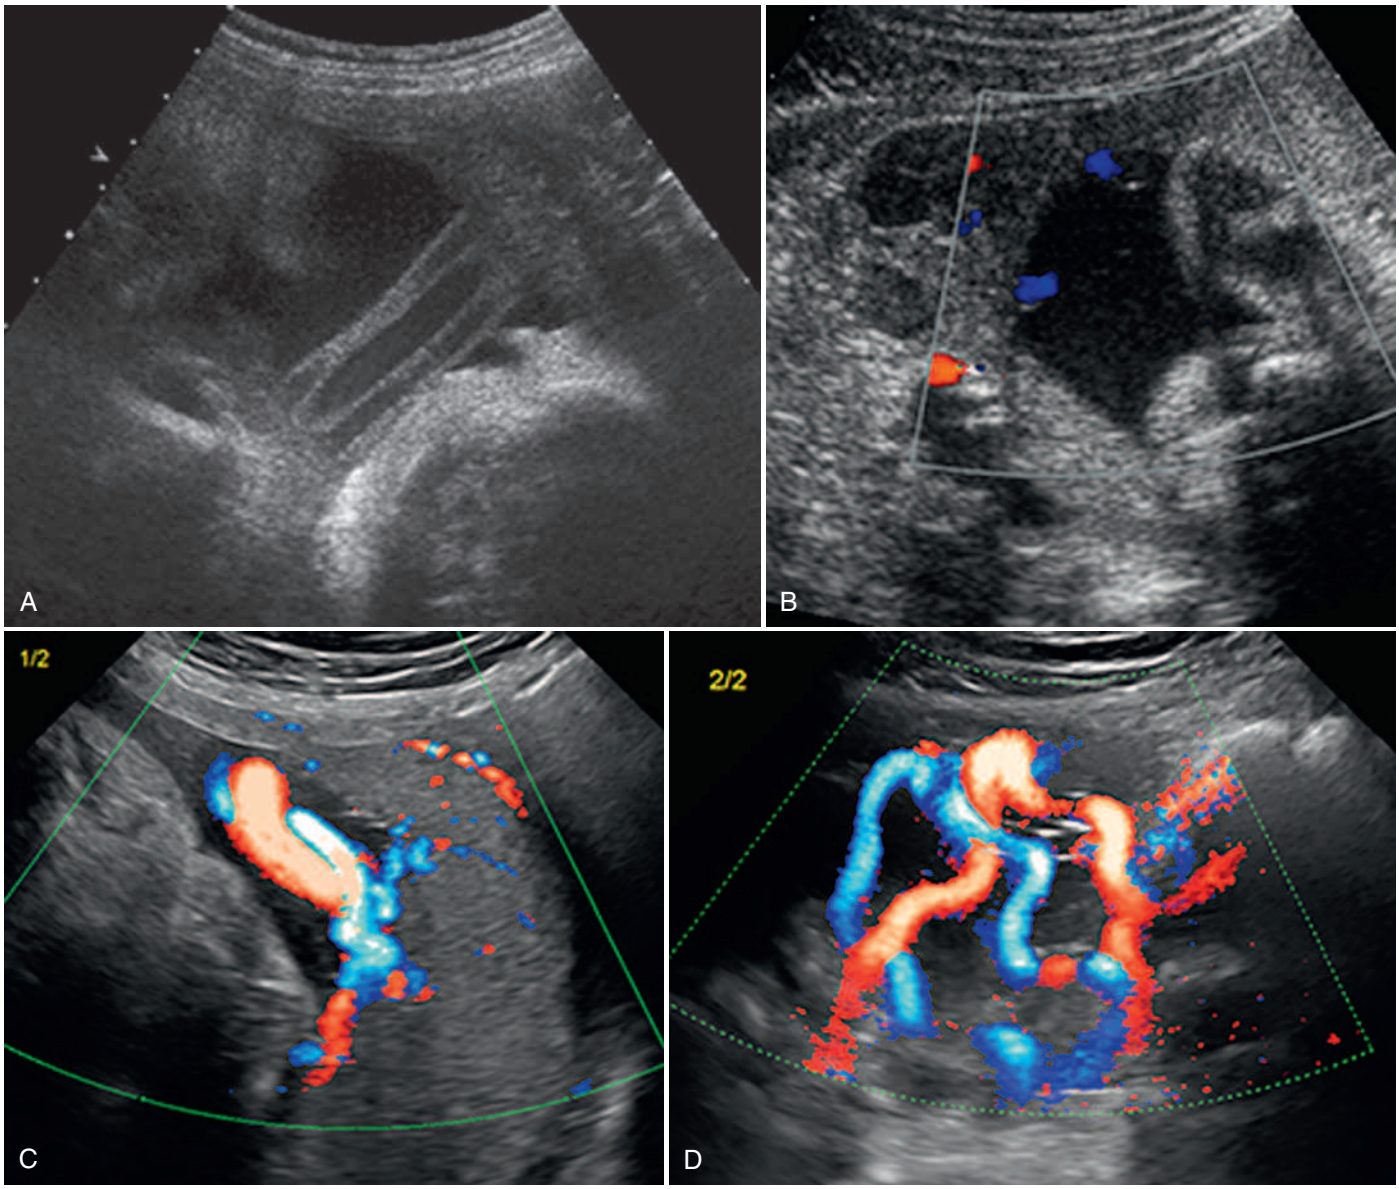

FIG. 32.8 Velamentous Cord Insertion. Up to one-quarter of twin gestations have an abnormal placental cord insertion. **(A)** Straight separate vessels are seen approaching the placenta in a 34-week twin. See also Video 32.5. **(B)** Same patient as **A.** Separate vessels *(blue)* can be seen on the surface of the placenta with color Doppler. **(C)** Power Doppler image of a normal placental cord insertion in twin 1 of a monochorionic gestation at 29 weeks' gestational age. **(D)** Same patient as **C.** Power Doppler image of a velamentous placental cord insertion in twin 2.

more fetuses. In a study of more than 3600 twin pregnancies, 2 liveborn infants occurred in 96% of dichorionic pregnancies, 86% of monochorionic diamniotic twins, and 67% of monochorionic monoamniotic twins. Before 22 weeks' gestation, the risk of spontaneous loss of both fetuses is significantly higher in monochorionic twins than dichorionic twins, and in monochorionic monoamniotic twins than in monochorionic diamniotic twins.[39,41,42] It is interesting to note that another large study of multiples found that when anomalous fetuses and intrauterine losses are excluded, the neonatal outcome for multiple gestation infants is similar to that of singletons who are born at similar gestational ages.[43] It is clear that premature delivery is an important influencing factor on the poor outcomes of multiple gestations.

Fetal growth differences in multiple gestations are well recognized. Twin fetuses are smaller than singletons, and monochorionic twins are more affected.[44] The growth differences are most profound after 30 weeks' gestation. Altered growth patterns in monochorionic twins are related to unequal placental sharing, whereas a discrepancy in dichorionic twin growth may potentially be due to a more or less favorable uterine implantation site[33] (Fig. 32.9, Video 32.6). Ultrasound estimation of fetal weight in twins and triplets has been shown to be accurate, and it is an important means of monitoring multiple gestations, as there is an increased risk of fetal loss with discordant fetal weights.[45-48] Fetal weights are considered discordant when there is a 15% to 25% weight difference, as determined by the following formula: (Larger twin estimated weight – smaller twin estimated weight)/larger twin estimated weight × 100.[49,50] The North American Fetal Therapy Network recommends ultrasound measurements to assess fetal growth every 4 weeks.[51] Others agree with a 4-week interval for dichorionic twins but suggest a 2-week interval for monochorionic twins from 16 weeks until delivery, because of the higher intrinsic risk associated with monochorionicity.[13,52,53] There is evidence to suggest that ultrasound surveillance, including measurements every 2 weeks, is appropriate for both monochorionic and dichorionic twins,[54] and more frequent monitoring is appropriate in any multiple gestation when there is weight discordance or other complication.[13,51] In general, umbilical artery Doppler is not recommended without an indication, such as growth restriction, unexplained oligohydramnios, or maternal hypertension.[13] When Doppler studies are performed without a definitive indication, abnormal results may lead to unnecessary interventions such as antenatal hospitalization and increased surveillance, which do not improve outcome.[55,56]

All types of twins have an increased risk of a congenital malformation.[57-59] A congenital anomaly occurs in singleton pregnancies at a rate of 2% to 3%, and this rate is doubled in all types of twins, with monochorionic twins twice as likely as dichorionic twins to have an anomaly.[60] This increased risk includes all types of congenital anomalies except for chromosomal abnormalities. A complete fetal anatomic survey is therefore recommended for all twin gestations at 18 to 22 weeks' gestational age.[13,61] Monochorionic twins are at increased risk in particular for congenital heart disease, with a rate as high as 7.5%,[62-64] and the rate is highest in twins affected with twin-twin transfusion syndrome. A monochorionic gestation is considered an indication for fetal echocardiography.[51,65]

LOSS OF A TWIN

Single intrauterine fetal death (IUFD) occurs in approximately 4% to 7% of twin pregnancies.[17,42] In a recent large study of twin outcomes with two live fetuses after 12 weeks' gestation, the rate of intrauterine fetal demise of one twin after 22 weeks was twice as high for monochorionic diamniotic as compared to dichorionic twins.[39] Higher losses are also seen with higher degrees of weight discordance between fetuses.[66] Loss of a single twin is therefore not uncommon and typically occurs in the third trimester. In a small number of these pregnancies, there is subsequent demise

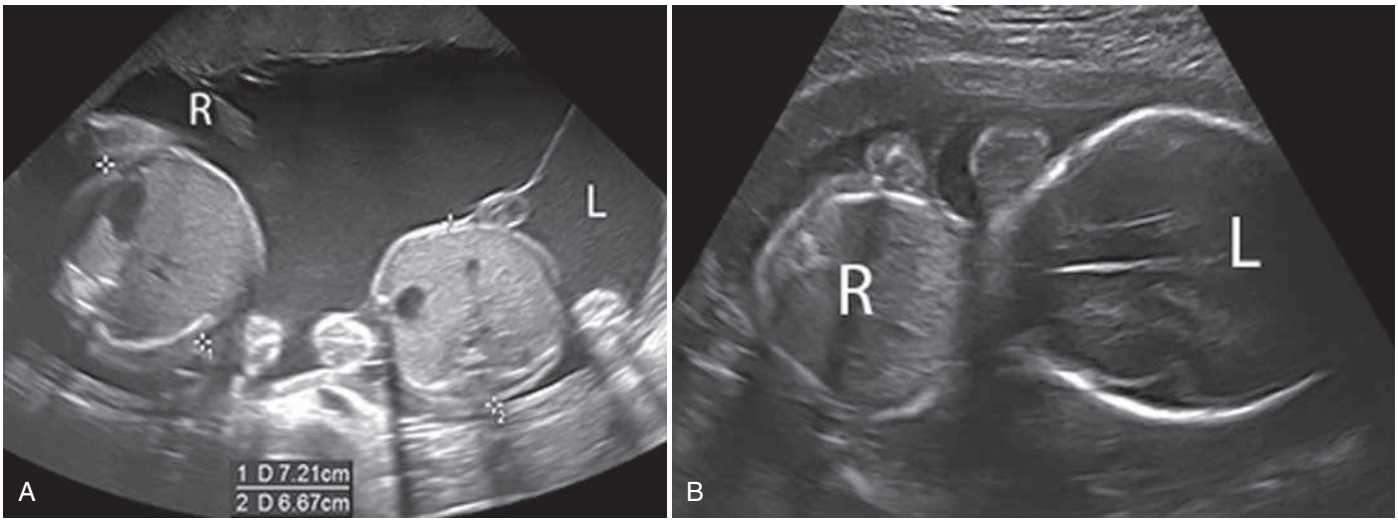

FIG. 32.9 Growth Discrepancy in Twins. (A) Monochorionic diamniotic twins at 28 weeks' gestational age. The twin on the maternal right *(R)* is larger with more amniotic fluid. The left-sided twin *(L)* is smaller and has less fluid. **(B)** Diamniotic dichorionic twins at 24 weeks. The abdomen of the twin on the right *(R)* is markedly smaller in comparison to the head of the twin on the left *(L),* and there is oligohydramnios. The right-sided twin measures approximately 19 weeks; the left-sided twin is normally grown. See also Video 32.6.

of the second twin,[42,67,68] which is also more likely in monochorionic twins, and the risk is particularly high for monoamniotic twins.[39] After loss of one twin, the surviving twin is at increased risk for adverse outcome, and the risk is again associated with chorionicity, as a result of the vascular anastomoses in a shared placenta.

In a dichorionic gestation with a single IUFD, there is no significant risk of injury to the surviving fetus, but there is an increased rate of preterm delivery.[67] However, in monochorionic twins with a single demise, risk of severe cerebral injury in the survivor may be as high as 25% to 34%.[68,69] In these cases, fetofetal hemorrhage is thought to be responsible. When the first fetus expires, there is a sudden drop in vascular resistance across the placental anastomoses and blood is shunted away from the survivor, with subsequent anemia, hypotension, and hypoperfusion of vital organs. This mechanism has been confirmed with in utero documentation of anemia in surviving fetuses.[17,70,71] The developing central nervous system is at highest risk for significant injury, and the consequences of the insult may not be apparent immediately. The sonographic manifestations of cerebral ischemia are similar to those seen in premature infants, namely, intracranial hemorrhage, middle cerebral artery infarction, and periventricular white matter injury with subsequent leukomalacia (Fig. 32.10). Renal injury can result in cortical necrosis, and limb reduction

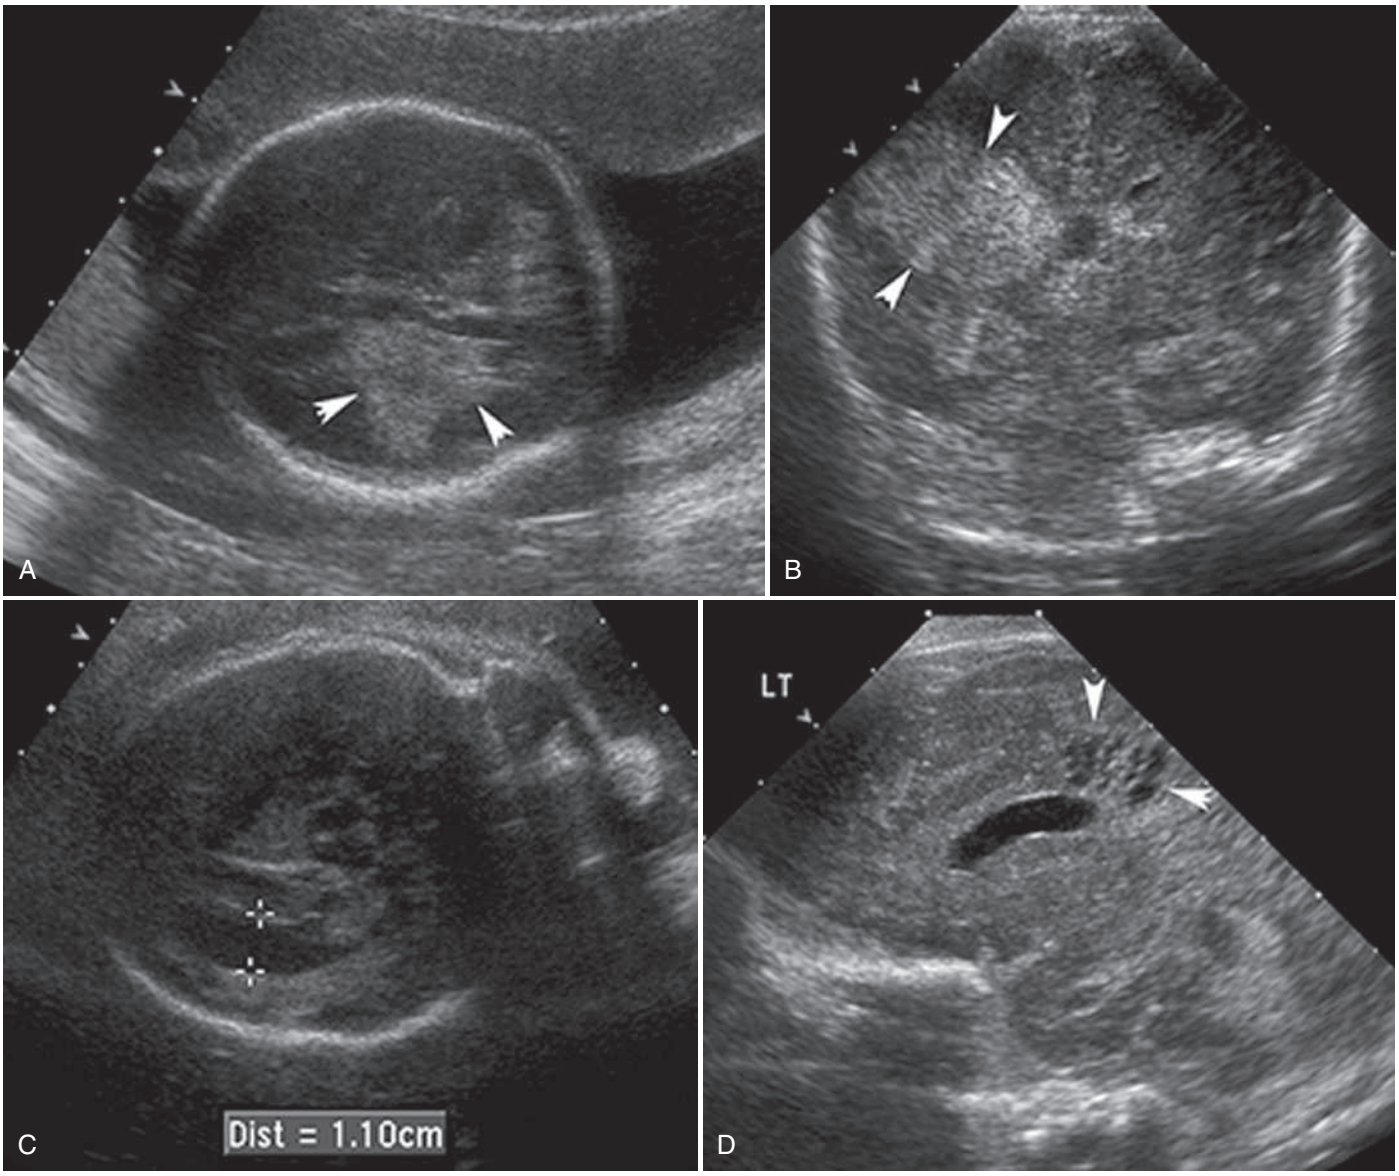

FIG. 32.10 Sequelae of Intrauterine Fetal Demise in Monochorionic Twin Gestations. (A) Axial image of the fetal head 24 hours after **amnioreduction** of 1800 mL from the gestational sac of this fetus. There is an echogenic lesion inseparable from the dependent lateral ventricle consistent with intraparenchymal hemorrhage *(arrowheads).* **(B)** Same patient as **A.** Postnatal head ultrasound of the same twin, day of life 1, 48 hours after amnioreduction. There is a large **intraparenchymal hemorrhage** on the right *(arrowheads).* **(C)** Monochorionic twin at 30 weeks' gestational age, following an IUFD of its twin 3 weeks ago. There is new **ventriculomegaly** of the survivor. **(D)** Same patient as **C,** 1 week later. Postnatal head ultrasound on day of life 3 shows cystic changes *(arrowheads)* in a parietal periventricular location consistent with **periventricular leukomalacia,** the result of the intrauterine fetal demise 4 weeks earlier.

injuries are possible.[69] The combination of twin-twin transfusion syndrome and single IUFD places the survivor at increased risk for cerebral injury.[69]

COMPLICATIONS OF MONOCHORIONICITY

The increased risks of abnormal growth, prematurity, and intrauterine demise seen in monochorionic gestations are all related to the single placental mass that is shared between the two fetuses. The majority of monochorionic placentas have vascular connections that cross back and forth between the two fetal-placental circulations, allowing minute amounts of blood exchange between twins. The anastomoses can be superficial or deep, and there are three distinct types: arterial/arterial (AA), arterial venous (AV), and venous venous (VV)[33] (Fig. 32.11). AA anastomoses are usually bidirectional and small and are found in 87% of placentas. AV anastomoses are unidirectional, deep, and found in 94% of monochorionic placentas. VV anastomoses are bidirectional, superficial, and found in a minority of placentas.[33,72,73] Within a monochorionic placenta, the degree and direction of flow across a combination of the three types of anastomoses are responsible for the unique complications of monochorionicity described in this section, as well as the general issues of growth and survival.[74,75]

Twin-Twin Transfusion Syndrome

This common complication (Table 32.2) affects between 10% and 23% of monochorionic twins. It is defined by oligohydramnios (deepest vertical pocket < 2 cm) with a small or empty bladder in the donor and polyhydramnios (deepest vertical pocket > 8 cm) with a distended bladder in the recipient in a monochorionic pregnancy.[52,57,72,76] Twin-twin transfusion syndrome (TTTS) was initially thought to include both amniotic fluid and fetal hematocrit differentials; however, it is now known that no in utero transfusion occurs with this syndrome, as hematocrits are often similar in both fetuses,[77] and the process could therefore be termed "twin oligohydramnios/polyhydramnios syndrome." Fetuses with TTTS have the same number of AV as, and more VV anastomoses than, fetuses without TTTS; however, it is the presence of more AA anastomoses that appears to be protective.[74,78,79] The unequal anastomoses allow a net transfer of volume from one fetal circulation to the other, creating a volume overloaded fetus (the recipient) and a hypovolemic fetus with poor renal perfusion and decreased urine output (the donor).[80]

The syndrome is usually first identified between 16 and 26 weeks' gestation (Fig. 32.12, Video 32.7). Serial ultrasounds of all monochorionic gestations are recommended to monitor for the development of TTTS, with fluid and bladder checks every 2 weeks.[52,53,81] A useful staging system proposed in 1999 (Table 32.3) can help diagnose the syndrome early in its progression.[76]

The syndrome begins with unequal amniotic fluid and bladder volumes and can advance to severe oligohydramnios (stuck twin), hydrops of either twin, and potential fetal demise. A stuck twin occurs when there is such a tiny amount of amniotic fluid around the donor fetus that the intertwin membrane cannot be identified because it is so closely applied to that fetus. The fetus in the sac with low fluid is restricted in movement and seems adherent to the wall of the uterus, often appearing suspended or "stuck" in comparison with the freely moving co-twin with its surrounding

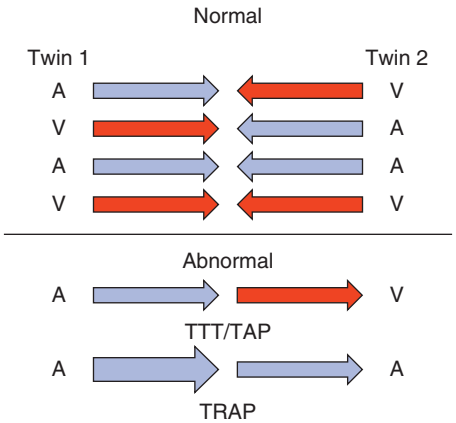

FIG. 32.11 Patterns of Vascular Anastomoses in Monochorionic Placentas. Monochorionic placentas contain arterial/arterial (AA), arterial venous (AV), and venous venous (VV) anastomoses. Unequal flow can lead to the unique complications of TTTS, TAPS, and TRAP. *Blue,* Arterial/deoxygenated flow; *red,* venous/oxygenated flow.

TABLE 32.2 Complications of Twin-Twin Transfusion Syndrome

Donor	Recipient
Oligohydramnios, may be "stuck"	Polyhydramnios
IUGR, small size	Possible hydrops
Small/nonvisualized bladder	Dilated bladder ± dilated renal pelves
	Large size
	Cardiomegaly
If live born, has better outcome	Struggles postnatally

IUGR, Intrauterine growth restriction.

TABLE 32.3 Quintero Staging of Twin-Twin Transfusion Syndrome

Stage	Findings
I	Amniotic fluid differential (oligohydramnios in donor and polyhydramnios in recipient)
II	Nonvisualized bladder in donor
III	Absent or reversed umbilical artery diastolic flow in donor
IV	Hydrops in either fetus
V	IUFD of one fetus

IUFD, Intrauterine fetal death.
Modified from Quintero R, Morales W, Allen M, et al. Staging of twin-twin transfusion syndrome. J Perinatol. 1999;19(8):550-555.[76]

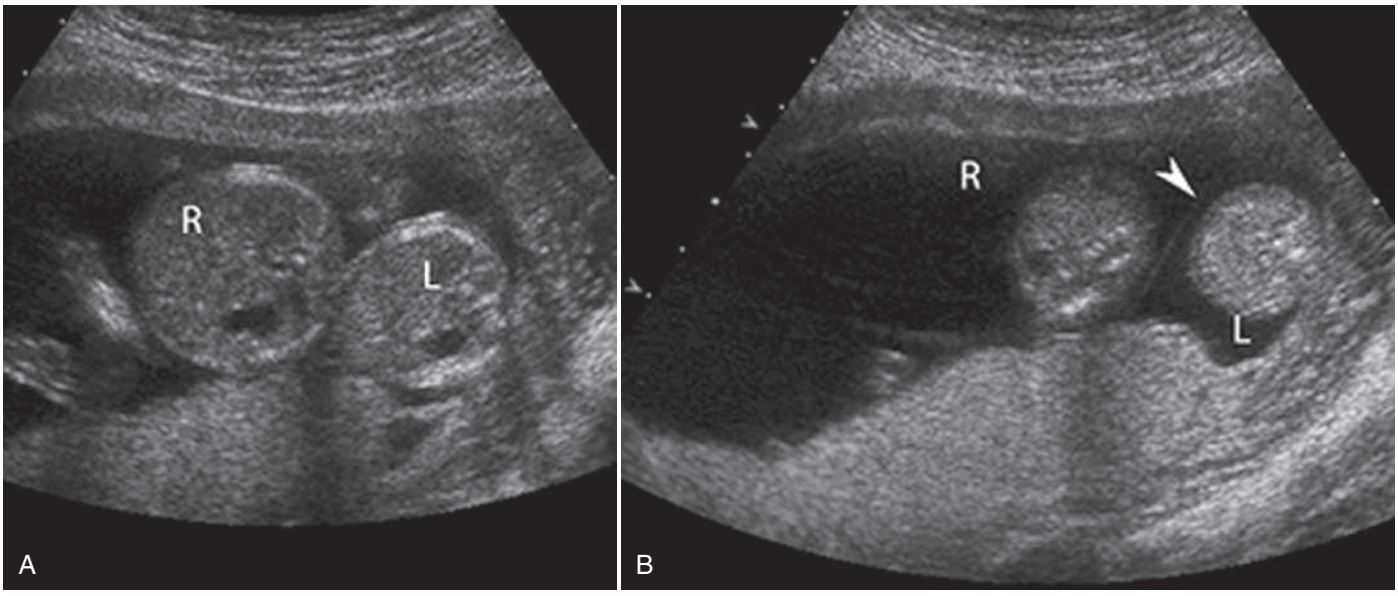

FIG. 32.12 Early Twin-Twin Transfusion Syndrome; Stage I. (A) and **(B)** Monochorionic twins at 16 weeks' gestational age. A discrepancy in abdominal diameters is apparent. The smaller twin on the maternal left *(L)* has much less amniotic fluid than the larger twin on the maternal right *(R)*. The very thin separating amnion is visible between the twins *(arrowhead)*. See also Video 32.7.

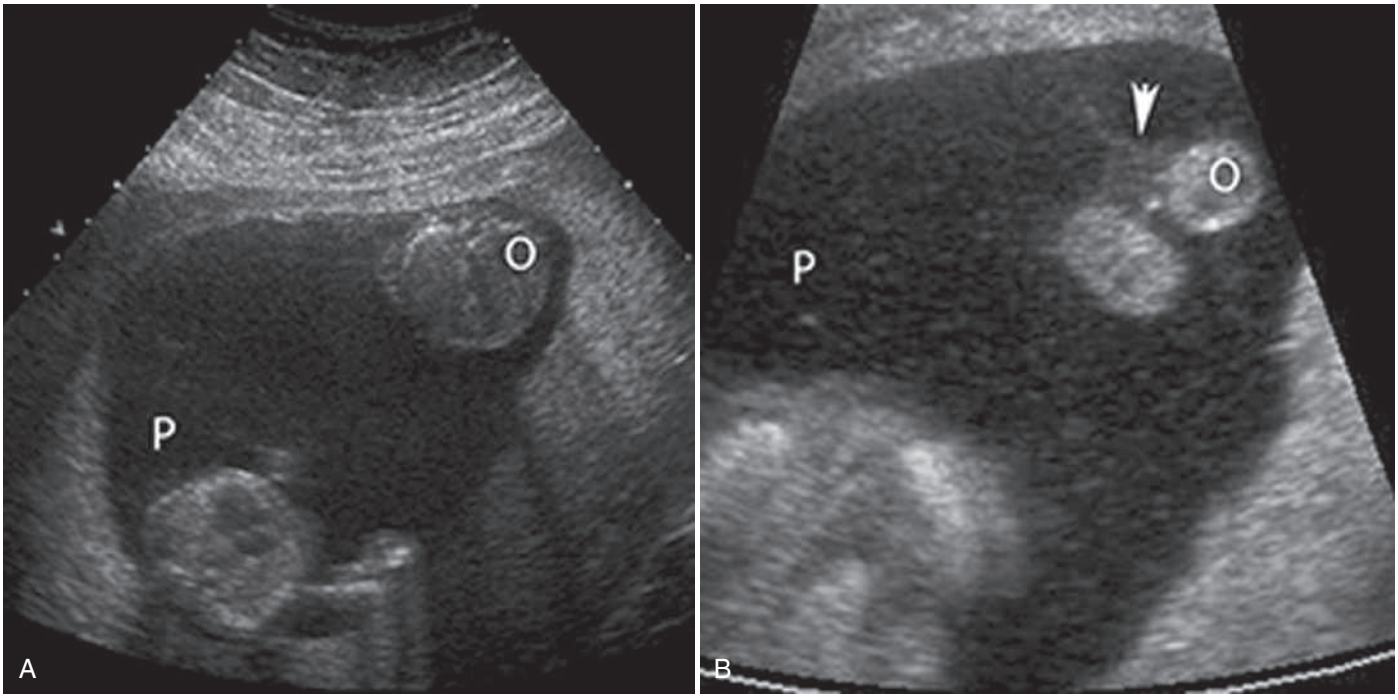

FIG. 32.13 Twin-Twin Transfusion; Stuck Twin. (A) and **(B)** Monochorionic twins at 16 weeks' gestational age. One twin *(O)* is "stuck" to the anterior uterine wall as a result of severe oligohydramnios. Its twin *(P)* is far posterior, freely moving in a large amount of amniotic fluid. The membrane *(arrowhead)* is barely visible surrounding a tiny amount of echogenic amniotic fluid between the legs of the "stuck" twin.

polyhydramnios (Fig. 32.13). In addition to fluid discrepancies, findings can include growth discordance (>20% difference in estimated fetal weight, with the donor smaller than the recipient), growth restriction of the donor, and cardiomegaly caused by volume overload in the recipient.[80] Untreated, approximately three-quarters of stage I fetuses remain stable or regress, whereas the perinatal loss rate for stage III or higher is between 70% and 100%.[52] A treatment option for TTTS is fetoscopic laser surgery performed at specialized centers worldwide; a less invasive alternative is serial amniocentesis to equalize fluid volumes and decrease the risk of preterm labor.[82,83]

Twin Anemia Polycythemia Sequence

The twin anemia polycythemia sequence (TAPS) was first described in 2007 by Lopriore et al., who presented two cases of presumed TTTS without associated amniotic fluid

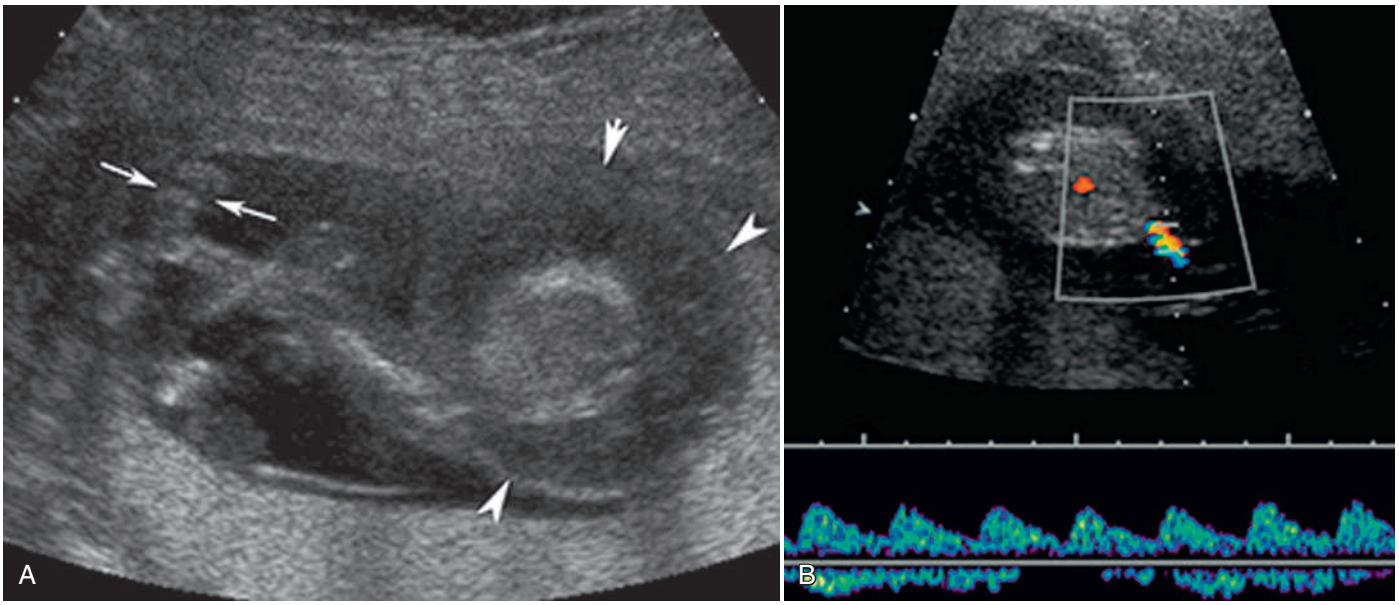

FIG. 32.14 Twin Reversed Arterial Perfusion Sequence. (A) Acardiac twin at 16 weeks. There is marked soft tissue edema around the trunk of the twin *(arrowheads)* and a club foot *(arrows)*. Despite the absence of a heart or upper body, there is active movement of the fetus. See also Video 32.8. **(B)** Same patient as **A.** Reversed flow in the acardiac twin umbilical artery, with pulsatile arterial flow entering at the umbilicus.

discordance.[84] TAPS occurs when there is sufficient unequal passage of red cells via the placental anastomoses such that one twin becomes anemic (the donor) and one becomes polycythemic (the recipient). The transfusion occurs extremely slowly via tiny unidirectional AV anastomoses, over a long period of time.[33,72] TAPS occurs in approximately 5% of monochorionic twins,[85] although this rate is higher following laser treatment for TTTS when all of the anastomoses have not been ablated.[86] Although amniotic fluid discordance is often seen as part of the TAPS sequence, the discordance is not as great as seen in TTTS. The diagnosis of TAPS is made prenatally with Doppler interrogation of the middle cerebral artery in each fetus. Doppler imaging of the middle cerebral artery has been shown to be an accurate noninvasive method for determining the presence of anemia in utero, nearly replacing percutaneous umbilical blood sampling in many centers.[87] Optimal technique is critical because incorrect technique can lead to false-positive diagnoses of anemia.[88] The anemic fetus will demonstrate elevated peak systolic velocity in the middle cerebral artery (>1.5 multiples of the median), while the polycythemic fetus demonstrates decreased velocities (<1.0 multiples of the median)[72,89] (see Chapter 41, Table 41.2). An additional sonographic finding occasionally seen in TAPS is two different placental echogenicities, with each region corresponding to a different fetal circulation.[90,91] Because TAPS typically occurs at a later gestational age than TTTS, the morbidity and mortality rates are much lower than those for TTTS.[92] However, late-onset TAPS can be associated with growth discordance and even intrauterine demise, and assessments of middle cerebral artery velocities are recommended every 2 weeks in the third trimester in monochorionic twins.[72,90]

Twin Reversed Arterial Perfusion Sequence

The twin reversed arterial perfusion (TRAP) sequence is a rare condition that occurs when one twin has an absent or severely malfunctioning heart and there is a large unbalanced AA anastomosis within a monochorionic placenta.[72] Blood flow is directed from the umbilical artery of one twin (pump twin with a normal heart) through the placenta and into the umbilical artery in the second twin, thus reversing flow in that umbilical artery. Flow is then directed inferiorly down the iliac arteries to the lower extremities of the second fetus and then out of the umbilical vein in a reversed direction back to the placenta. VV anastomoses allow that blood to then return to the pump twin. Flow in the recipient twin is deoxygenated, and its circulation exists only inferior to the diaphragm. The recipient is often grossly malformed above the diaphragm with an absent or malformed heart, head, and upper extremities, but can be remarkably intact inferior to the diaphragm, and has been termed an "acardiac twin" or "acardiac monster." This fetus retains the ability to move independently, as the spinal cord and lower extremities can be normally developed (Fig. 32.14, Video 32.8). The exact mechanism that creates the TRAP process is unclear, but it may be related to demise of the recipient twin with continued growth and development in the absence of a beating heart from the reversed circulation. Alternatively, the recipient fetus could be anomalous from conception. The TRAP sequence can be missed at first- or early second-trimester sonography when it is mistaken for a fetal demise because of the lack of cardiac activity. Color and pulsed Doppler interrogation will identify reversal of flow in the umbilical arteries and vein of the acardiac twin (Fig. 32.15). There is a high risk of IUFD of the donor twin related to high

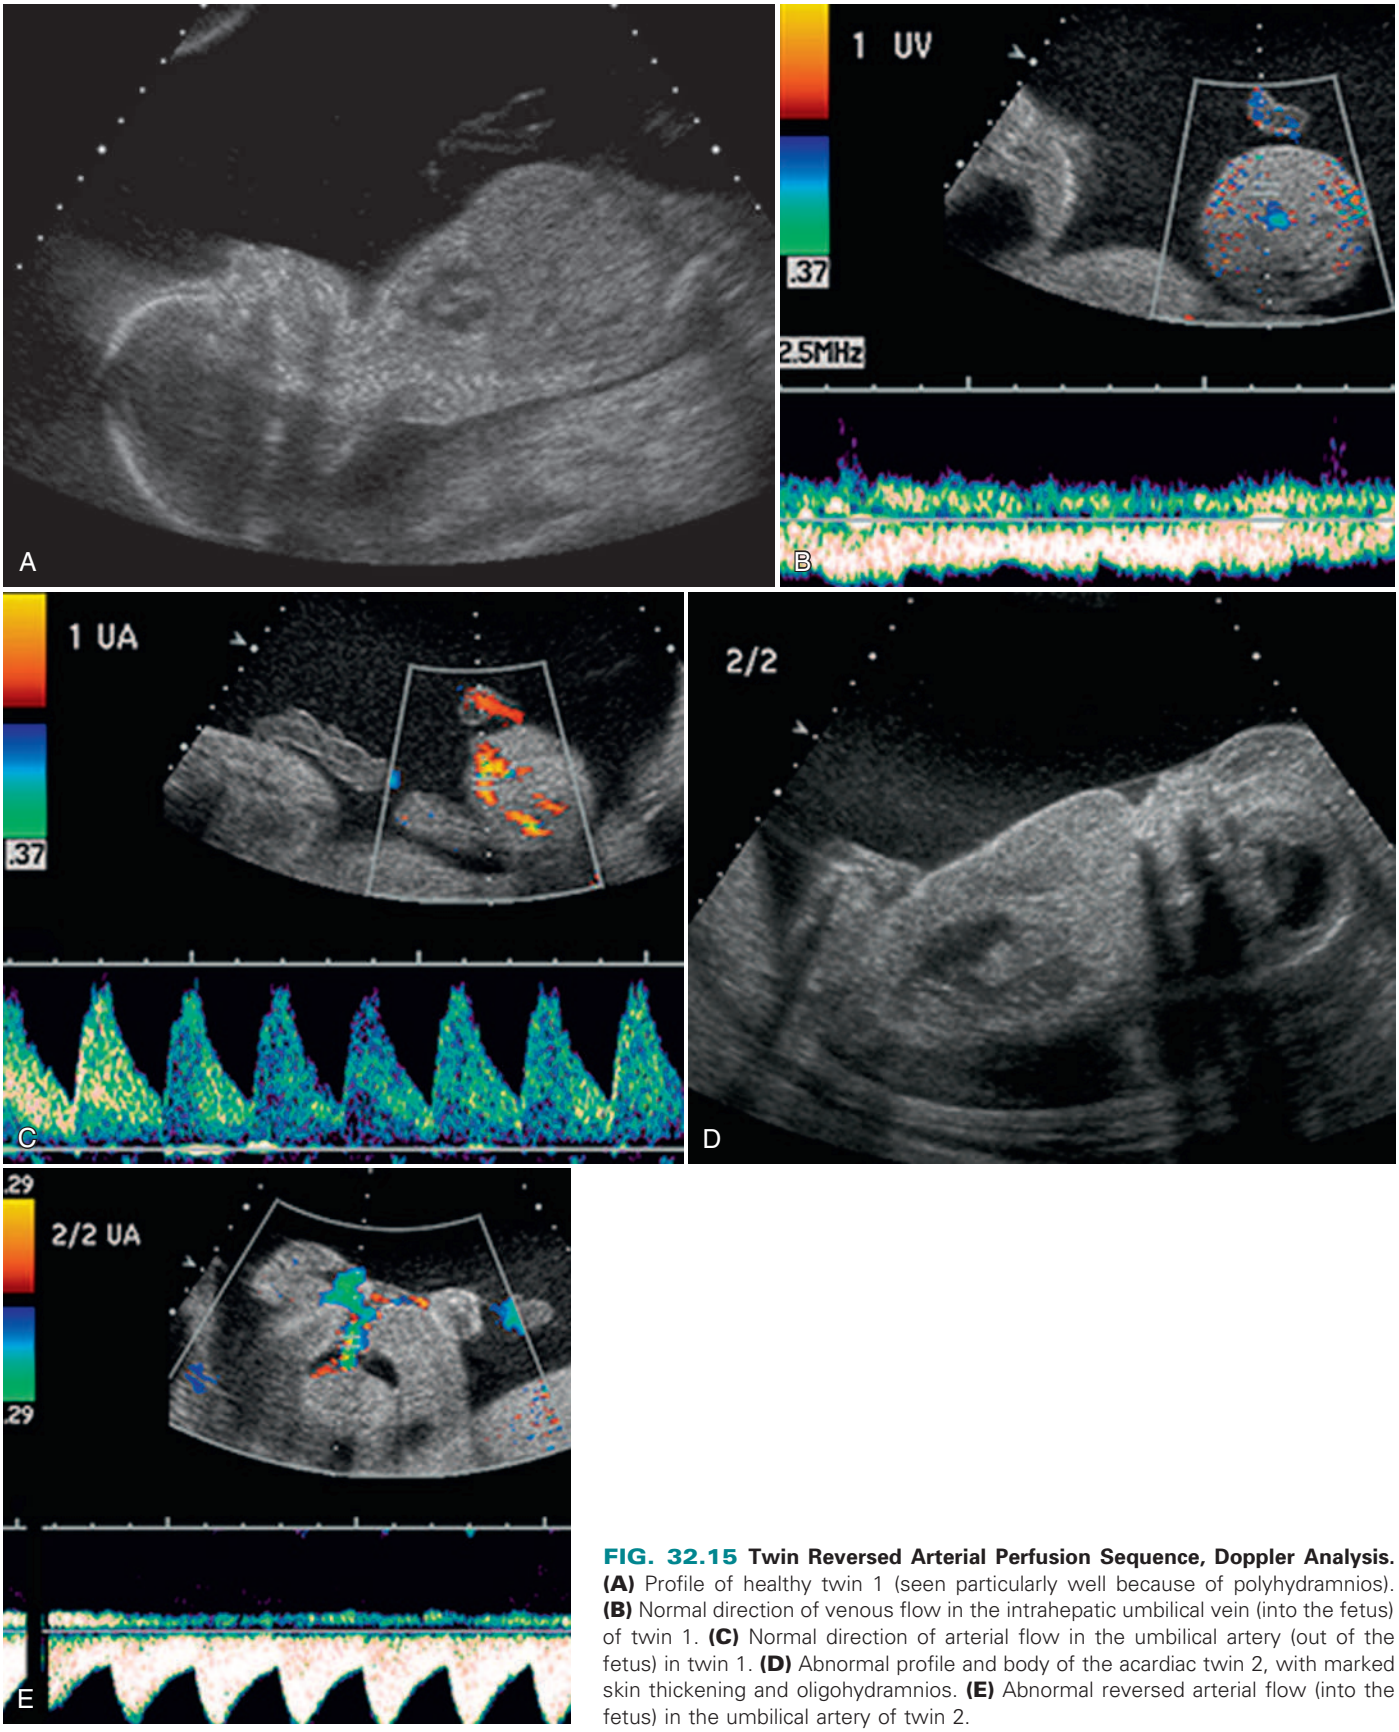

FIG. 32.15 Twin Reversed Arterial Perfusion Sequence, Doppler Analysis. **(A)** Profile of healthy twin 1 (seen particularly well because of polyhydramnios). **(B)** Normal direction of venous flow in the intrahepatic umbilical vein (into the fetus) of twin 1. **(C)** Normal direction of arterial flow in the umbilical artery (out of the fetus) in twin 1. **(D)** Abnormal profile and body of the acardiac twin 2, with marked skin thickening and oligohydramnios. **(E)** Abnormal reversed arterial flow (into the fetus) in the umbilical artery of twin 2.

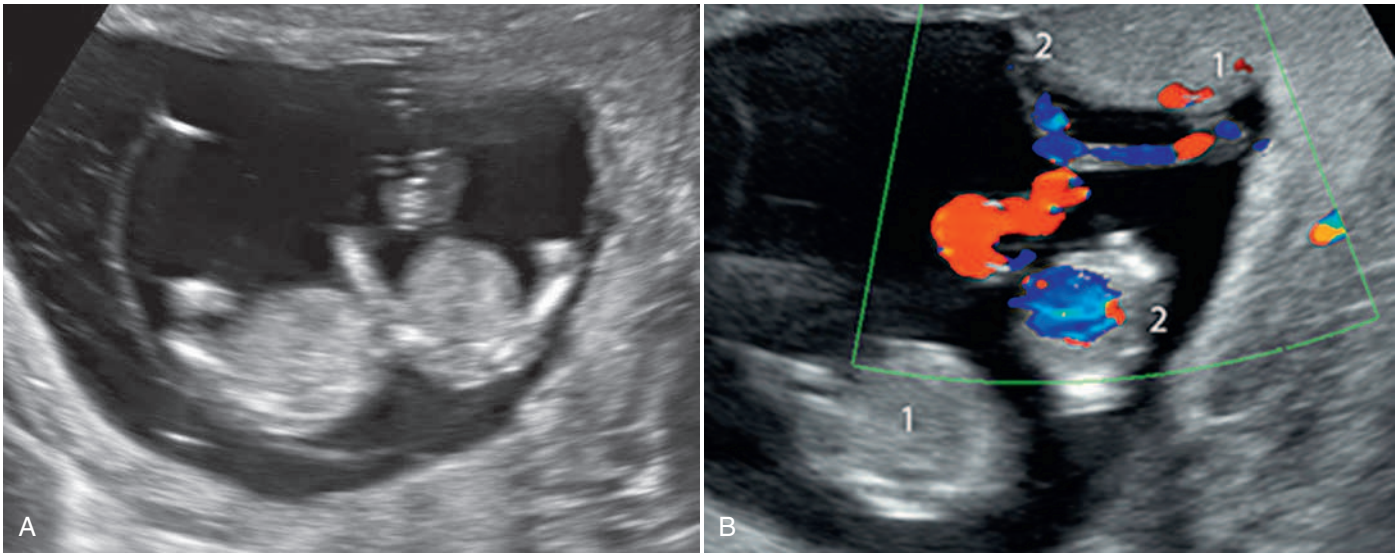

FIG. 32.16 Monochorionic Monoamniotic Twins, 12 Weeks' Gestational Age. (A) Transverse image of the fetal chests in a single gestational sac. The umbilical cords are entwined anteriorly. **(B)** Corresponding color Doppler image demonstrates the cords twisting together and then separating to insert into the anterior placenta. See also Video 32.9.

output cardiac failure and polyhydramnios,[93] particularly if the weight of the acardiac twin is more than 70% of the donor twin. In this situation, intervention to interrupt the abnormal circulation to the acardiac twin may be beneficial.[94-96]

MONOAMNIOTIC TWINS

In a monoamniotic pregnancy, both fetuses are located within a single amnion and therefore a single chorion. This rare type of twinning has the highest morbidity and mortality rate of any type of twin.[33] Monoamniotic twins should be suspected when no intertwin membrane is identified by 10 to 12 weeks' gestational age and can be confirmed at any age when the umbilical cords are seen to twist together or become entangled (Figs. 32.16 and 32.17, Videos 32.9 and 32.10). In the late first trimester, transvaginal imaging may provide better resolution to confirm the absence of a membrane. The monoamniotic placenta has the same three types of vascular anastomoses as found with diamniotic twins; however, there are more AA anastomoses, fewer AV anastomoses, and a similar number of VV anastomoses in monoamniotic twins when compared with diamniotic monochorionic twins. In addition to all of the potential complications of a monochorionic gestation, monoamniotic twins are at risk for cord knotting or entanglement at any gestational age, although the clinical significance of cord entanglement is unclear, as several studies have shown no improvement in outcome following ultrasound diagnosis of an entangled cord.[97,98] Discordant fetal anomalies can affect as high as 20% of monoamniotic pregnancies.[99] Monoamniotic twins are at high risk of unexpected and usually double intrauterine fetal demise, thought to be related to fetofetal hemorrhage via large AA anastomoses following cord compression.[72,100] Survival of monoamniotic twins may be as high as 80% with intensive surveillance and early delivery.[101,102]

CONJOINED TWINS

Conjoined twins are a rare type of monoamniotic twins that occur with late division of the embryo. The twins can be conjoined at any skin site and are diagnosed by demonstrating contiguous skin covering between two fetuses. The in utero rate of conjoined twins is estimated at 1 in 50,000 gestations, with an IUFD rate of 60% and an additional high loss rate after birth.[103] Conjoined twins are generally classified by the site of joining,[104] although the anatomy of each pair is unique. Careful sonographic evaluation of each fetus is imperative for a full assessment of the degree of sharing that exists, which will help with an accurate prognosis

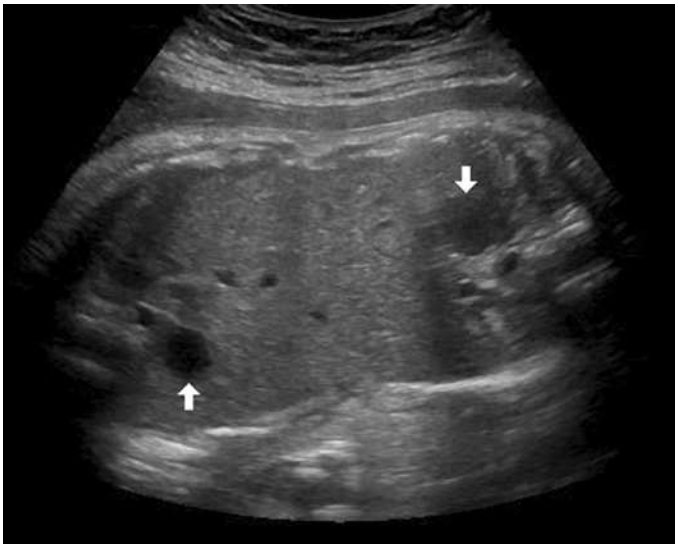

FIG. 32.18 Monochorionic Monoamniotic Conjoined Twins, 35 Weeks' Gestational Age. The twins share a liver (*arrows* mark the stomach of each twin) and the hearts are merged. See also Video 32.11.

for surgical separation.[105,106] Conjoined twins can be diagnosed in the late first trimester (see Fig. 32.3D); however, a detailed survey will be required by 18 to 20 weeks' gestation for the most accurate evaluation of the degree of visceral and vascular sharing (Fig. 32.18, Video 32.11). The umbilical cord may also be fused, with more than three vessels seen within a single cord.[106] Formal fetal echocardiography is indicated, as cardiac anomalies are highly related to outcome.[106]

CHAPTER 33

The Fetal Face and Neck

Ana P. Lourenco and Judy A. Estroff

SUMMARY KEY POINTS

- Ear and eye anomalies often accompany abnormalities of the skull and face.
- Abnormalities of fetal head size and shape may be associated with various syndromes and chromosomal anomalies.
- Hypoplastic or absent nasal bone may be seen in fetuses with trisomy 21.
- Cleft lip may be associated with cleft palate, and detailed description of the cleft is important to accurately counsel parents, predict postnatal outcome, and anticipate type of treatment.
- Isolated cleft palate is rarely diagnosed on prenatal ultrasound and is often associated with micrognathia and a variety of syndromes.
- Micrognathia is best assessed on sagittal midline views, can be associated with a variety of syndromes, and may lead to difficulties with feeding and airway management.
- Fetal neck masses are uncommon, and include lymphatic malformations, teratomas, hemangiomas, and thyromegaly. Evaluation of the fetal airway in relation to the mass is critical for delivery planning.

CONCLUSION
Acknowledgments

With technical advances in gray-scale and three-dimensional (3-D) imaging, sonographic evaluation of the fetal face and neck has become a routine part of the second-trimester fetal anatomic survey.[1] An increasing number of craniofacial anomalies are detectable in the first trimester. Abnormalities of the fetal face are particularly important because they are frequently associated with syndromes and chromosomal anomalies. This chapter reviews the embryology and normal development of the fetal face and neck and describes anomalies that can be detected sonographically.

EMBRYOLOGY AND DEVELOPMENT

Face

Fetal face development begins at approximately 4 weeks' gestation and rapidly progresses, with the completion of major events by 8 weeks' gestation (Fig. 33.1). In this complex process, ectoderm, mesoderm, endoderm, and neural crest cells all interact to develop the classic human facial features. Ectoderm surrounds the **stomodeum** (primitive mouth). The paired pharyngeal arches, or **branchial arches,** composed of central mesenchyme with outer

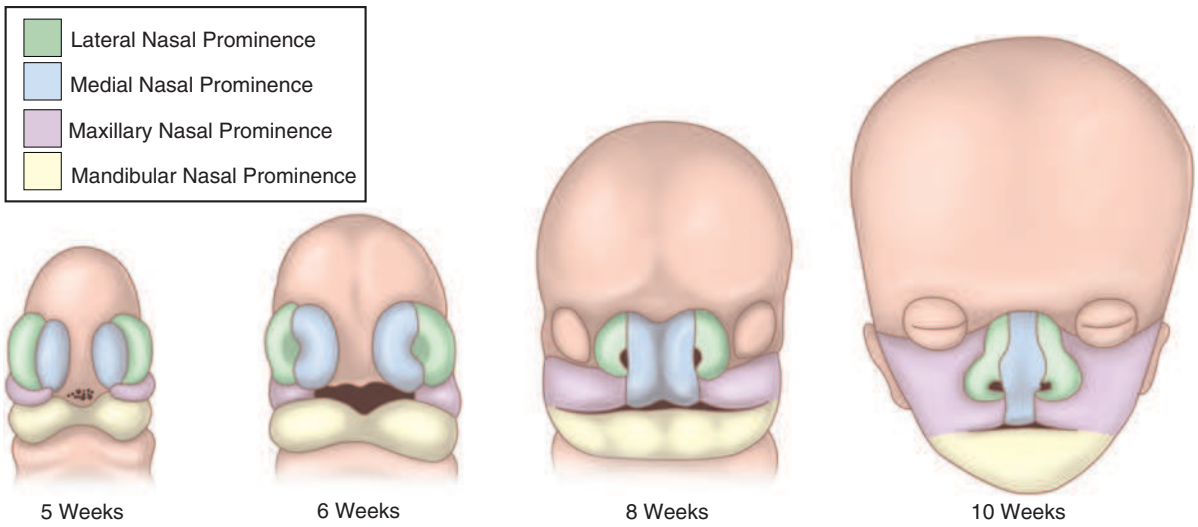

FIG. 33.1 Embryology of the Fetal Face at Gestational Ages 5 Through 10 Weeks. (Courtesy of Andrew S. Phelps, MD.)

ectoderm and inner endoderm coverings, progress to fuse in the midline. **Neural crest cells** give rise to connective tissues of the face (cartilage, bone, ligaments).

Five main tissue buds (called **prominences**) form the fetal face. The **frontonasal** prominence forms the forehead and dorsum apex of the nose. The **lateral nasal** prominences form the nasal ala. The **medial nasal** prominences form the nasal septum. **Maxillary** prominences form the upper cheeks and most of the upper lip. **Mandibular** prominences form the lower cheeks, lower lip, and chin. The maxillary and mandibular processes are derived from the first branchial arch. The remaining branchial arches go on to form the oropharynx.

During the fourth week of gestation, the frontal prominence forms at the cephalic end of the embryo. The two nasal **placodes** are present on the frontal prominence, and the optic discs are present posterolaterally. In the stomodeum, the buccopharyngeal membrane becomes fenestrated.

The fifth week brings development of nasal pits in the nasal placodes and differentiation of medial and lateral nasal prominences. The lens vesicles invaginate within the optic discs, and the caudal end of the medial nasal prominences begins to fuse with the maxillary prominences.

During the sixth week, six **auricular hillocks** (mesenchymal swellings) form and will become the pinna of the ears. Auricular pits may arise when these nodules do not fuse completely. Medial and lateral nasal prominences fuse, and the maxillary prominences begin to form the upper jaw. The nasal septum forms as the medial nasal prominences join in the midline. The edges of the optic fissures fuse, and the hyaloid vessels are present in the center of the optic stalk. These vessels will eventually form the retinal artery and vein.

By the seventh week, the tip of the nose is visible in profile, and the pinna of the ears is taking shape. The central axis of the nose and philtrum are formed as fusion of the medial nasal prominences is completed. Eyelids become prominent.[2-5] By the end of the eighth week, the developing eye is up to 2 mm in diameter.[6]

Neck

Development of the fetal neck is similarly complex, with extensive embryologic events contributing to development of vascular, neurologic, musculoskeletal, lymphatic, and endocrine systems. The laryngotracheal groove forms during the fourth week of gestation along the floor of the primitive mouth. After evagination of this groove, the laryngotracheal diverticulum forms. The distal end forms the lung bud. The endoderm of this diverticulum forms the epithelium of the larynx and trachea. The endothelium of the larynx proliferates and temporarily occludes its lumen. Recanalization occurs by the tenth gestational week, with formation of the laryngeal ventricle, vocal folds, and vestibular folds. The fourth and sixth pharyngeal arches form the surrounding cartilage and muscles.[2-4]

At 4 to 6 weeks' gestation, right and left jugular lymph sacs develop as diverticula of the subclavian veins. Lymphatic capillaries permeate the body and drain into these sacs. Abnormal connections between the lymphatic sacs and venous system are thought to contribute to lymphatic malformation and thickened nuchal translucency (NT) in the first trimester, as well as a thickened nuchal fold in the second trimester.[7]

SONOGRAPHY OF THE NORMAL FETAL FACE

Sonographic evaluation of the fetal face is part of the routine anatomic survey in midpregnancy, but little is actually required. According to the American Institute of Ultrasound in Medicine 2013 practice guidelines, only visualization of the fetal upper lip is mandatory during an anatomic survey.[1] Although not required, it is possible to obtain exquisite multiplanar two-dimensional (2-D), 3-D, and four-dimensional (4-D) views of the fetal face with state-of-the-art equipment.[8] Profile and 3-D[9] views (Fig. 33.2A) are helpful, especially when a true coronal view cannot be obtained because of fetal position. Sagittal 3-D volumes of the fetal face can often be obtained in these situations, and the

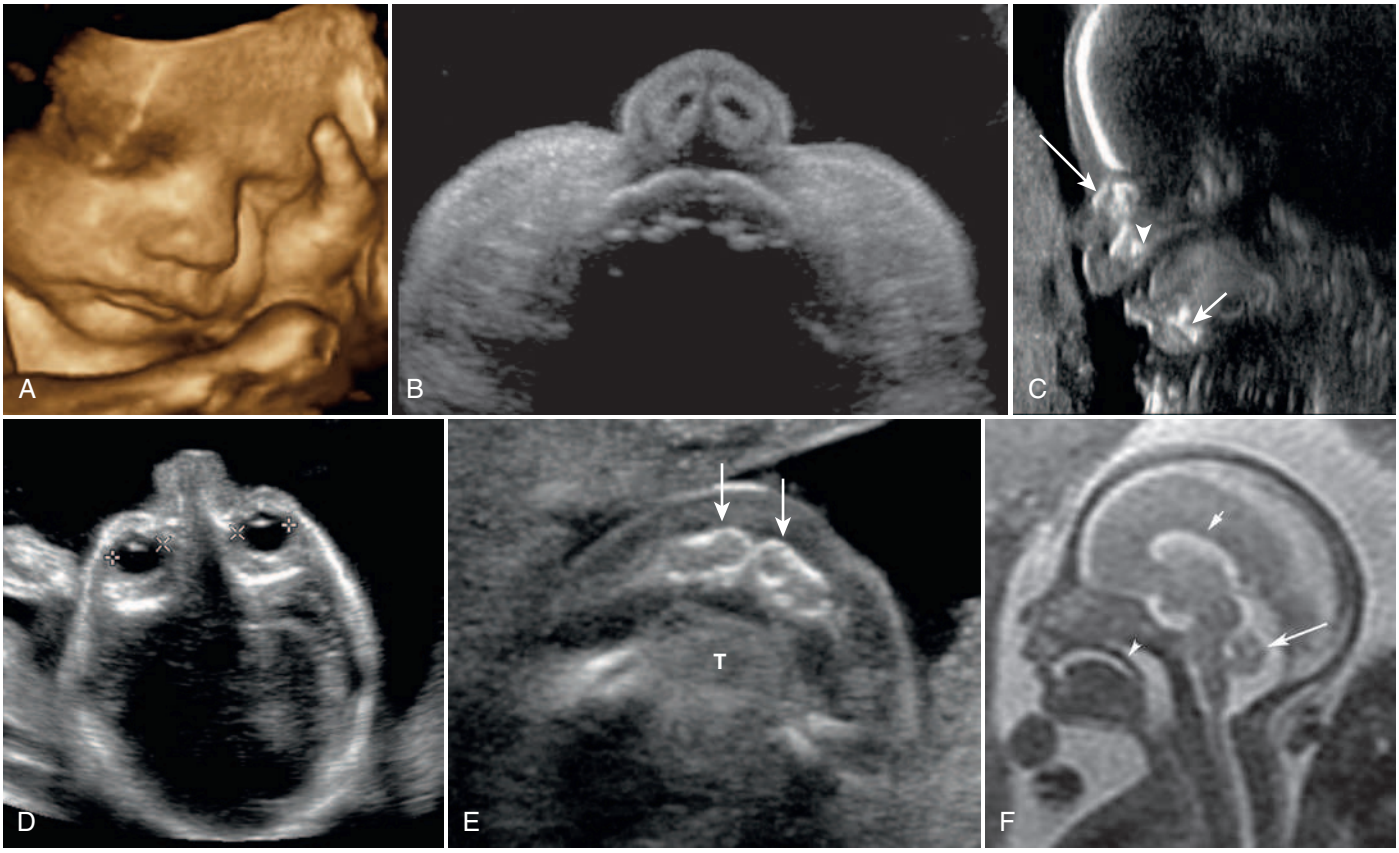

FIG. 33.2 Normal Fetal Face. (A) Three-dimensional (3-D) sonogram of a normal 30-week fetus. **(B)** Nose and lips. Coronal sonogram of normal nostrils and maxillary teeth of a different fetus at 33 weeks' gestation. **(C)** Profile of the face of a 17-week fetus shows a normal nasal bone *(long arrow),* maxilla *(arrowhead),* and mandible *(short arrow).* **(D)** Normal orbits in axial view (*cursors:* +, outer orbital distance; x, inner orbital distance). **(E)** Normal maxilla. Axial view of anterior aspect of the maxilla in a 17-week fetus shows the tongue *(T)* and tooth buds in the alveolus *(arrows).* **(F)** Sagittal T2-weighted magnetic resonance image of a normal fetal face at 27 weeks' gestation shows normal midline structures, such as corpus callosum *(short arrow),* cerebellar vermis *(long arrow),* and secondary palate *(arrowhead).*

image can then be rotated to show the upper lip and palate clearly. Coronal (see Fig. 33.2B) and axial views of the fetal nose and lips are obligatory in screening for fetal cleft lip.

The sagittal **facial profile** view is acquired whenever possible and should demonstrate the presence and normal configuration of the nasal bone, lips, chin, and forehead (see Fig. 33.2C). Three-dimensional volumes[10-13] can frequently be obtained and can be helpful for characterizing abnormalities. Axial views of the orbits can be obtained to verify that both globes are present, of normal size, and at a normal distance apart (see Fig. 33.2D). Axial images of the maxilla and alveolar ridge can be obtained to determine if a cleft primary palate is present (see Fig. 33.2E). The palate separates the nasal cavity from the oral cavity. The **secondary palate** is difficult to visualize on 2-D sonography but may be evaluated with special 3-D sonographic views[14-16] and is often readily visible on midline sagittal and coronal fetal magnetic resonance imaging (MRI; see Fig. 33.2F).

Images of the **fetal neck** are obtained in sagittal, axial, and coronal planes to evaluate the cervical spine and airway and to assess for masses (Fig. 33.3). The neck should also be evaluated for abnormal positioning, such as hyperextension, which can be present with anterior neck masses such as an enlarged thyroid or cervical teratoma. Thickening of the nuchal fold is evaluated at the second-trimester survey and is measured in the suboccipital bregmatic plane, where notable landmarks include the cavum septum pellucidum, cerebral peduncles, cerebellar hemispheres, and cisterna magna.

ABNORMALITIES OF THE HEAD

Abnormal Size

The fetal head is typically oval in configuration, and in this case, measurements of biparietal diameter (BPD) and head circumference will give similar estimates of gestational age. If sonographic head measurements are three standard deviations (SDs) below the mean, microcephaly is diagnosed.[17] If the measurements are greater than 3 SDs above the mean, macrocephaly is suggested.[5] Abnormalities of head size are important. **Microcephaly** may be associated with abnormalities of brain development and often leads to poor neurologic outcome. **Macrocephaly** may have a benign cause, such as a family history of a large head, or pathologic

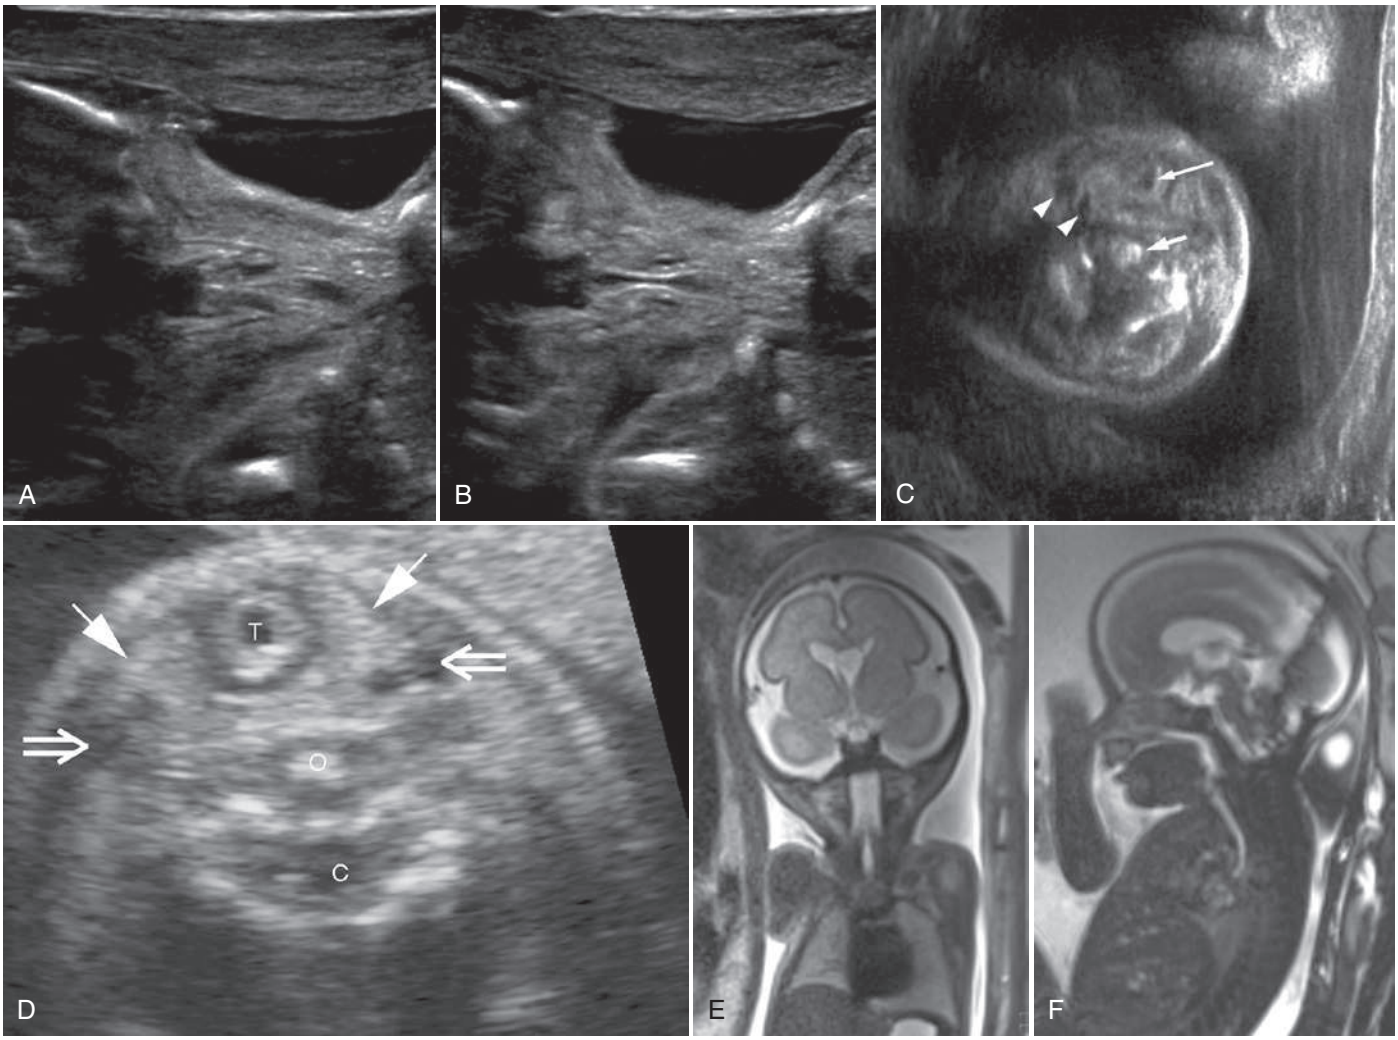

FIG. 33.3 Normal Neck. (A) Coronal sonogram of 21-week fetus showing pyriform sinuses, closed glottis, and subglottic trachea. **(B)** Coronal view showing open glottis. **(C)** Axial view of the neck showing carotid and jugular vessels *(arrowheads),* trachea *(long arrow),* and vertebral body *(short arrow).* **(D)** Axial view of neck shows thyroid *(arrows).* The carotids medially and the jugular veins laterally *(open arrows)* are posterior to the thyroid. The trachea *(T)* is in the midline, and behind it a vertebral body with a small central developing ossification center *(O).* The spinal cord *(C)* is in the vertebral arch. **(E)** and **(F)** Magnetic resonance imaging coronal **(E)** and sagittal **(F)** views of normal glottis, vocal cords, and subglottic trachea in a different, 27-week fetus.

causes such as underlying brain maldevelopment or injury or, rarely, a space-occupying lesion. If the fetal head is sufficiently large, cephalopelvic disproportion can occur at delivery, leading to failure of labor to progress and the need for cesarean delivery.

Abnormal Shape

Abnormal head shape takes many forms. An abnormally long and narrow (oblong) cranium is described as **dolichocephaly** and is more frequently seen in fetuses in breech position and in the setting of oligohydramnios. An abnormally round head is termed **brachycephaly,** which may be caused by premature fusion of the coronal sutures. A **lemon-shaped skull,** with indentation of the frontal bones, is often seen in association with open neural tube defects and the Chiari II malformation of the hindbrain, but it may also be seen in normal fetuses[18,19] (Fig. 33.4). A **strawberry-shaped skull**—flattening of the occiput and narrowing of the bifrontal portion of the cranium—may be seen in association with trisomy 18.[20] A **cloverleaf-shaped skull** is seen with some dwarfs, especially **thanatophoric dysplasia,** and in some fetuses with craniosynostosis.

Craniosynostosis

Craniosynostosis describes a heterogeneous group of disorders in which there is premature fusion of one or several of the cranial sutures. Although abnormal head shape may be diagnosed in utero, this diagnosis often does not become evident until after birth. It occurs in about 1 per 2500 births. Recent research suggests that the pathophysiology of craniosynostosis is related to abnormal molecular signaling by fibroblast growth factors,[21-23] leading to

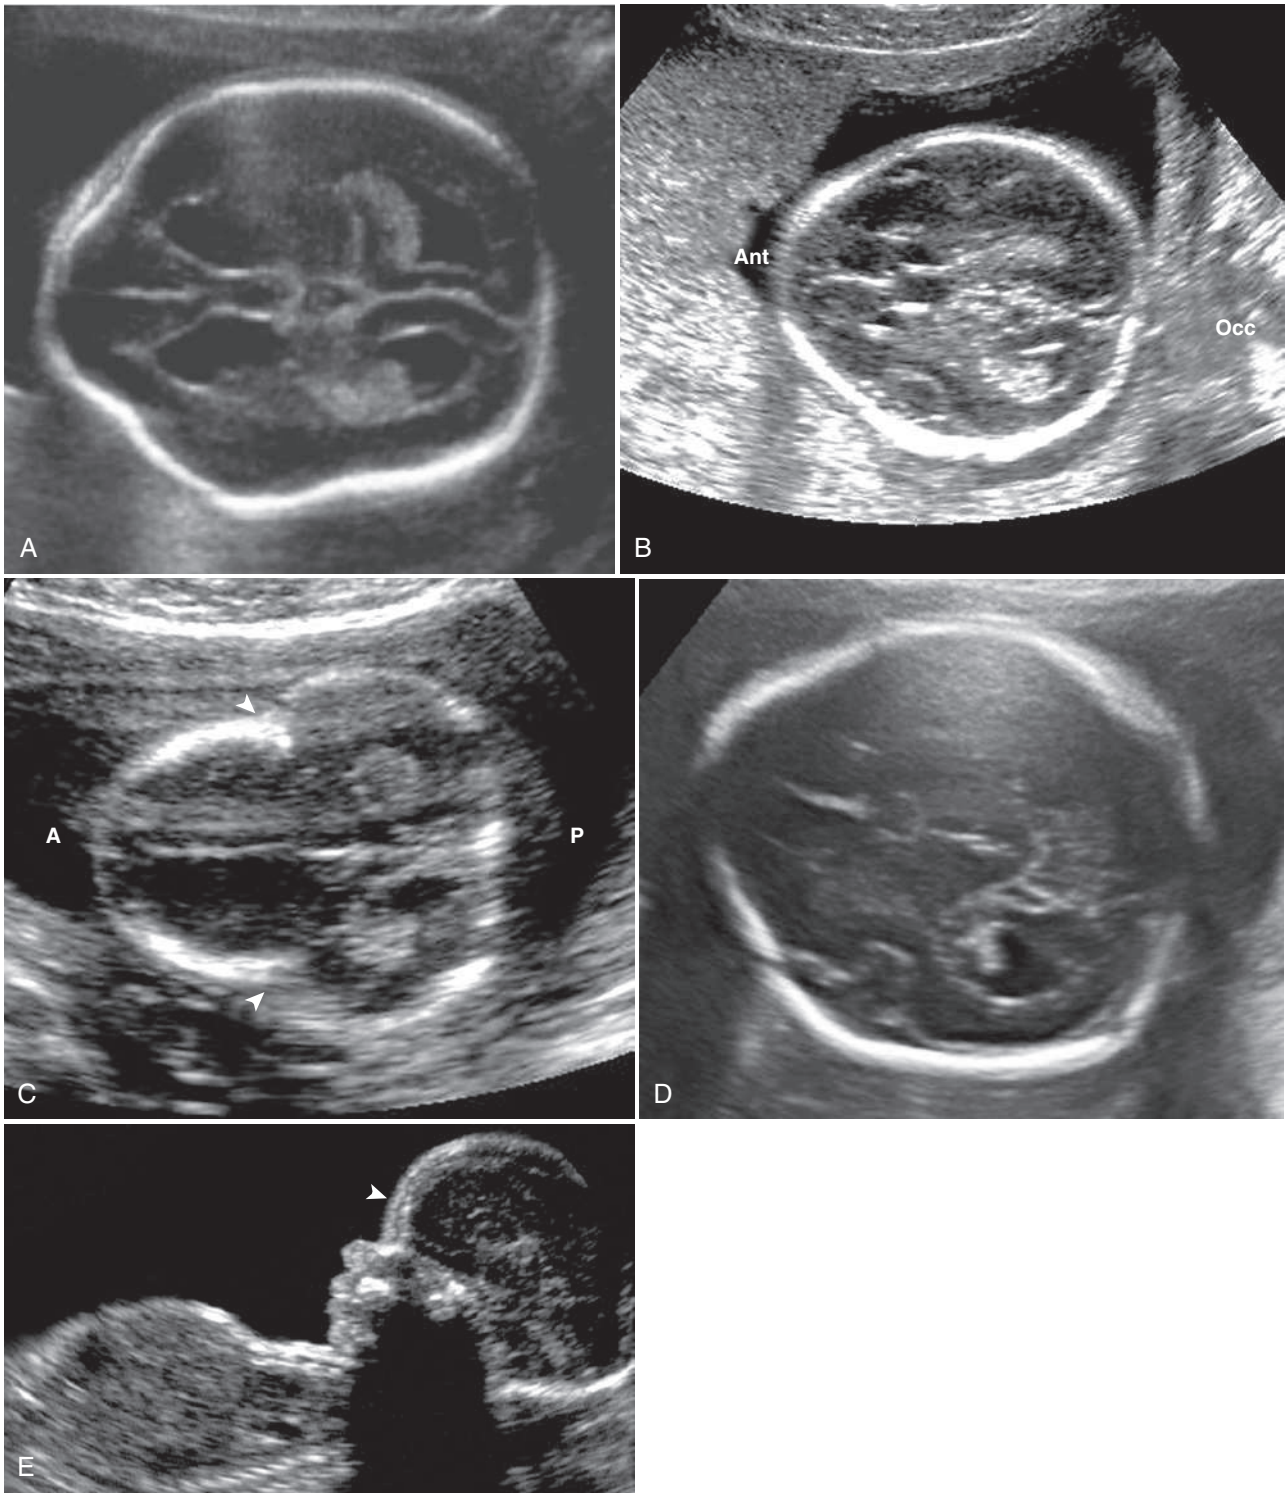

FIG. 33.4 Variety of Abnormal Head Shapes. (A) Lemon-shaped skull in association with neural tube defect. Axial sonogram shows concave deformity of the frontal bone as well as ventriculomegaly at 23 weeks' gestation. **(B) Brachycephaly and strawberry shape** (pointing anteriorly, flat occiput) at 20 weeks in a fetus with trisomy 18. Cephalic index is 96% (normal, 80%). *Ant,* Forehead; *Occ,* occiput. **(C) Craniosynostosis with cloverleaf skull.** Note the trilobite shape seen with craniosynostosis of the coronal *(arrowheads)* and other sutures except the squamosal in this fetus with **thanatophoric dysplasia.** *A,* Anterior; *P,* posterior. **(D) Metopic craniosynostosis.** Axial sonogram of a 27-week fetus with a pointed anterior skull secondary to metopic synostosis. **(E) Frontal bossing** *(arrowhead)* in a fetus with hypochondroplasia. Also note a "saddle nose," with the nasal bone meeting the frontal bone at an abnormal 90 degrees. A small thorax and a protuberant abdomen are present. (**B** and **C** courtesy of Ants Toi, MD.)

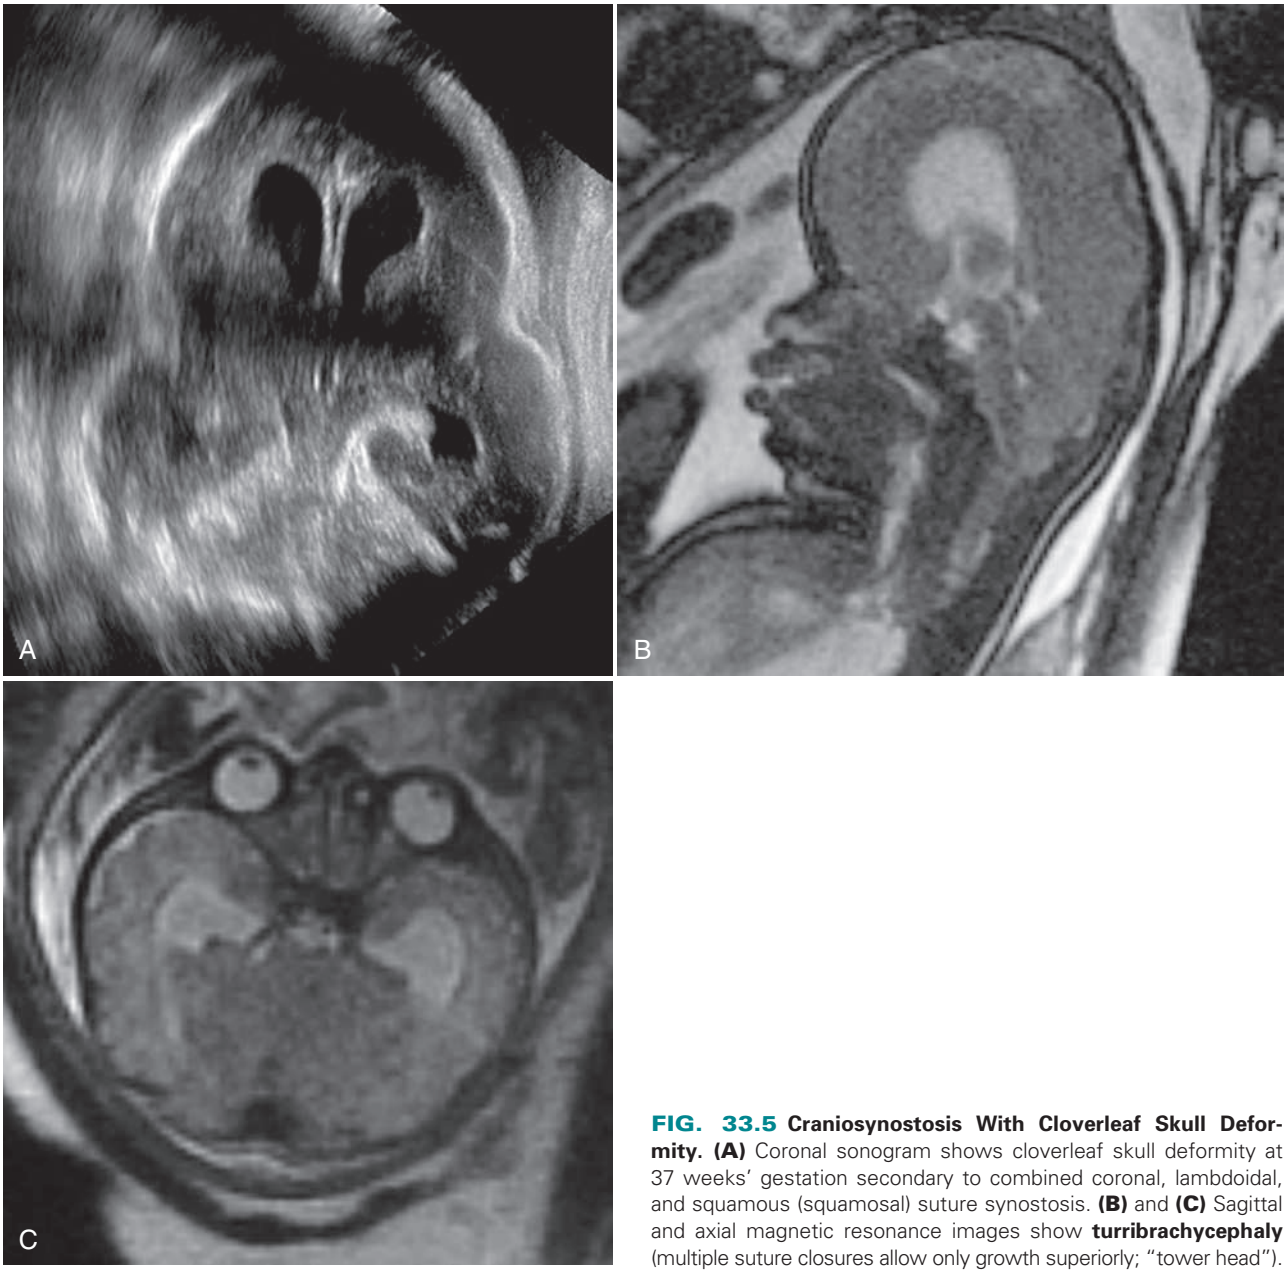

FIG. 33.5 Craniosynostosis With Cloverleaf Skull Deformity. (A) Coronal sonogram shows cloverleaf skull deformity at 37 weeks' gestation secondary to combined coronal, lambdoidal, and squamous (squamosal) suture synostosis. **(B)** and **(C)** Sagittal and axial magnetic resonance images show **turribrachycephaly** (multiple suture closures allow only growth superiorly; "tower head").

premature closure of cranial sutures (Fig. 33.5). About 85% of cases are isolated and about 15% syndromic. Craniosynostosis is associated with multiple syndromes, including **Apert, Crouzon, Pfeiffer, Antley-Bixler, Beare-Stevenson, Fetter,** and **Carpenter,** as well as **thanatophoric dysplasia.** The abnormal head shapes resulting from craniosynostosis can lead to facial abnormalities, including **hypertelorism, hypotelorism, exorbitism,** and **midface hypoplasia.** Dolichocephaly **(oblong head)** is the most common craniosynostosis condition and results from premature fusion of the sagittal suture. Asymmetrical heads are termed **plagiocephalic.**[24]

When fetal position is favorable, it is possible to trace the sutures sonographically and to evaluate their patency using high-frequency linear array probes.

Classification of Skull Deformities Based on Sutures Involved

Dolichocephaly/scaphocephaly: sagittal suture; most common synostosis
Anterior plagiocephaly: one coronal suture
Posterior plagiocephaly: one lambdoid suture
Brachycephaly: bilateral coronal suture; second most common synostosis
Trigonocephaly: metopic suture
Oxycephaly/turricephaly: all skull sutures and sutures at base of skull
Cloverleaf (kleeblattschädel): all but squamous (squamosal) suture

Prenatal diagnosis can be difficult; fetuses can appear normal in midtrimester but show changes in late pregnancy, when normal physiologic molding can be a confounder. In at-risk cases, head shape changes have been seen as early as 12 weeks. The fused sutures can be detected as absence of the sonolucent space normally seen between skull bones. The loss of hypoechoic suture appearance lags shape changes by 4 to 16 weeks. Three-dimensional multiplanar and surface rendering are helpful. Associated anomalies can allow differentiation among types.[25-27]

Additional problems can arise from the cranial deformity, including intracranial hypertension, obstructive apnea, proptosis, visual loss, dental malocclusion, and intellectual impairment. Learning disorders have been observed in 47% of school-age children.[26]

Fetuses prenatally suspected to have craniosynostosis should undergo detailed neurologic and anatomic sonography. MRI may be helpful. Postnatally, computed tomography (CT) surface rendering helps confirm the diagnosis and is needed for surgical treatment planning. Family history and molecular analysis for *FGFR* and *TWIST* mutations can help. Multidisciplinary counseling including craniofacial and neurosurgical specialists is important because therapy can involve molding helmets and surgery.[26,28,29]

Wormian Bones

Wormian bones are ossicles located in the sutures or fontanelles and may be associated with multiple conditions, such as **pyknodysostosis, osteogenesis imperfecta, cleidocranial dysplasia, hypothyroidism,** and **trisomy 21.** Three-dimensional views are particularly useful in the assessment of wormian bones (Fig. 33.6).

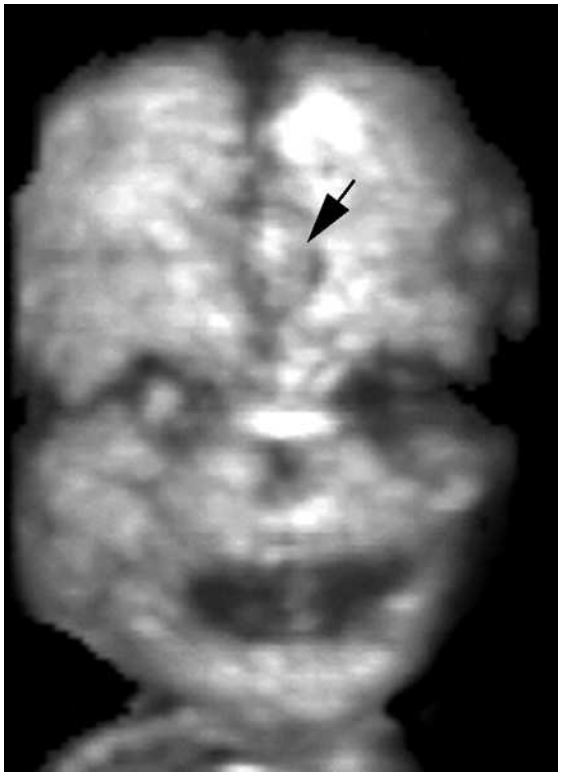

FIG. 33.6 Wormian Bone. An extra ossification center *(arrow)* is identified between the frontal bones of a fetus with trisomy 18.

Differential Diagnosis of Wormian Bones

Cleidocranial dysplasia
Congenital hypothyroidism
Hypophosphatasia
Osteogenesis imperfecta
Trisomy 21
Menkes kinky-hair syndrome
Progeria
Pyknodysostosis

Forehead Abnormalities

The forehead is best evaluated in the sagittal profile view, where the angle between the frontal and nasal bone can be assessed. **Frontal bossing** is abnormal prominence of the frontal bones and is a rare finding on fetal sonography. However, it has been reported in a variety of bony dysplasias and syndromes, including achondroplasia and thanatophoric dysplasia, and in syndromes with associated craniosynostosis.

Wolf-Hirschhorn ($4p^-$) syndrome has an abnormally sloped forehead, the "Greek warrior facies" (Fig. 33.7). The forehead can also be sloped in the settings of **microcephaly** and **encephalocele,** in which the forebrain is underdeveloped (Fig. 33.8).

Differential Diagnosis of Frontal Bossing

Achondroplasia
Acromegaly
Basal cell nevus
Cleidocranial dysostosis
Congenital syphilis
Crouzon syndrome
Fetal trimethadione
Pfeiffer syndrome
Russell-Silver syndrome
Thanatophoric dysplasia

Encephaloceles

An encephalocele or **cephalocele** is an abnormal protrusion of the brain and/or meninges through a defect in the skull and is considered a form of **spinal dysraphism.** In the United States and Western Europe, the occiput is the most common location for encephaloceles. Frontoethmoidal encephaloceles are more often found in Southeast Asia. Many encephaloceles are diagnosed during fetal sonography; they appear as abnormal defects in the calvaria with herniation of brain tissue or meninges. Fetal MRI is excellent for evaluating contents of the encephalocele and in assessing the appearance of the intracranial brain parenchyma.

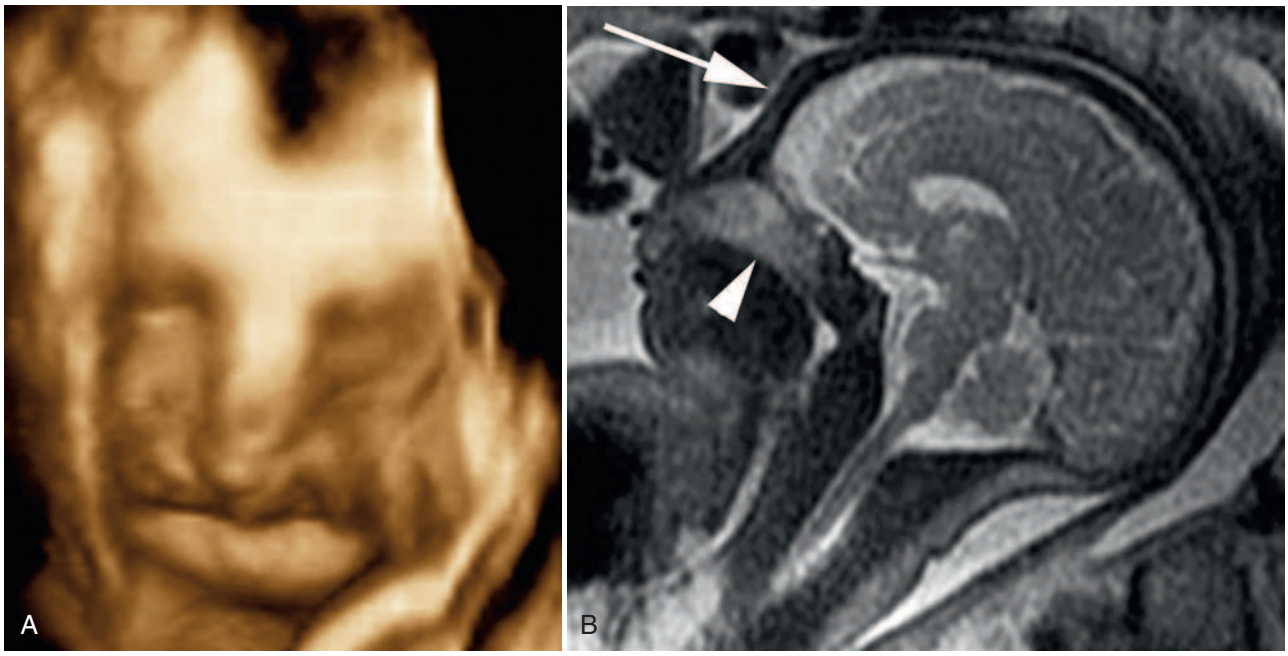

FIG. 33.7 Sloped Forehead in Fetus With Wolf-Hirschhorn Syndrome and Cleft Palate. (A) Coronal three-dimensional and **(B)** sagittal magnetic resonance images show a broad, flat nasal bridge and forehead at 34 weeks' gestation, the so-called "Greek warrior helmet" facies. Note sloped forehead (*arrow* in **[B]**) and absence of the secondary palate (*arrowhead* in **[B]** showing nasopharynx communicating with oropharynx).

Frontal encephaloceles can be seen during sonographic evaluation of the fetal face and are often associated with hypertelorism and midline facial clefting[30] (see Chapter 34).

ORBIT ABNORMALITIES

Sonographic evaluation of the fetal orbits is best obtained in axial or coronal views, in which one can confirm the presence of both orbits, evaluating their sizes and shapes and the distance between them. The sagittal view may help to evaluate abnormal anterior displacement of the globes (**proptosis** or **exorbitism**). The orbits should be symmetrical in size and the outer and inner interorbital distances within a normal range. Detailed nomograms are available for reference[31,32] (Table 33.1).

Hypotelorism

Hypotelorism is defined as an abnormally small distance between the orbits and is often associated with other anomalies[33,34] (Fig. 33.9). **Holoprosencephaly** (Fig. 33.10) can be associated with **cyclopia** (single midline eye with failed development of nose with or without a proboscis [Fig. 33.11]); **ethmocephaly** (hypotelorism with failed development of nose and a proboscis); or **cebocephaly** (hypotelorism and poorly developed nose with a single nostril).

Hypertelorism

Hypertelorism is defined as widely spaced eyes (Figs. 33.12 and 33.13). Given the embryologic development of the eyes and their migration from a lateral position to midline, hypertelorism may result from abnormalities that interfere with this normal migration. Large orbits can result in abnormal orbital measurements; Table 33.1 provides normal diameter of the globes.[35]

Conditions Associated With Hypotelorism

- Abnormalities of the brain
  - Holoprosencephaly
  - Microcephaly
- Chromosomal abnormalities
  - Trisomies 13, 18, and 21
  - Chromosome 5p deletion
- Head shape abnormalities
  - Trigonocephaly
- Syndromes
  - Langer-Giedion syndrome
  - Oculodentodigital dysplasia
  - Nasal maxillary dysostosis (Binder syndrome)
  - Myotonic dystrophy
  - Meckel-Gruber syndrome
  - Williams syndrome

Microphthalmia and Anophthalmia

Abnormally small orbits (microphthalmia) or absent orbits (anophthalmia) are rarely diagnosed on fetal sonography, but, when present, are frequently associated with chromosomal abnormalities or syndromes[36,37] (Fig. 33.14). Fetal karyotype analysis should be considered and a careful search for additional fetal abnormalities undertaken.

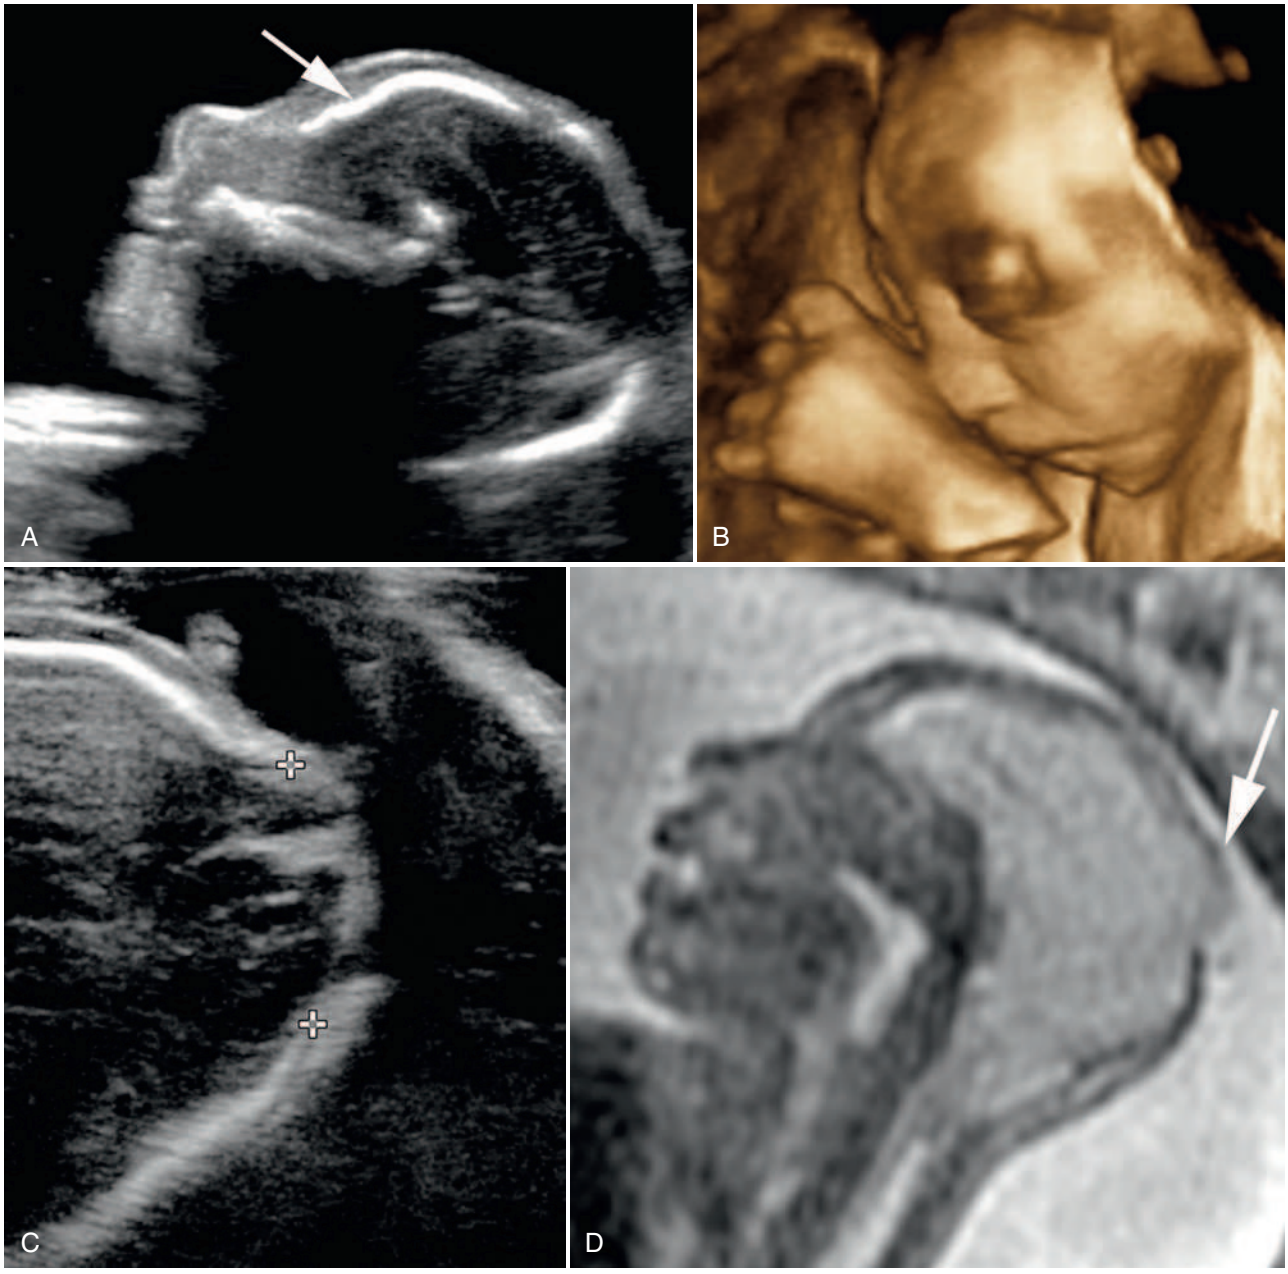

FIG. 33.8 Sloped Forehead in Fetus With Posterior Encephalocele. **(A)** and **(B)** Two-dimensional and three-dimensional sonographic profiles of a 28-week fetus with microcephaly and a small posterior encephalocele. The sloping forehead *(arrow)* is caused by a lack of forebrain development. **(C)** Axial sonogram shows high occipital defect *(calipers)* through which a small amount of dysplastic brain protrudes. **(D)** Sagittal magnetic resonance image shows microcephaly and the high occipital defect in the skull *(arrow)*.

Conditions Associated With Hypertelorism

- Chromosomal abnormalities
  - Trisomy 9p
  - 45,XO
- Single-gene disorders
  - Apert syndrome
  - Crouzon syndrome
  - Noonan syndrome
- Developmental abnormalities
  - Craniosynostosis
  - Anterior encephalocele
  - Median facial cleft
  - Megalencephaly
  - Agenesis of the corpus callosum
  - Orbital teratoma
  - Cleft lip
- Teratogens
  - Dilantin
  - Valproate

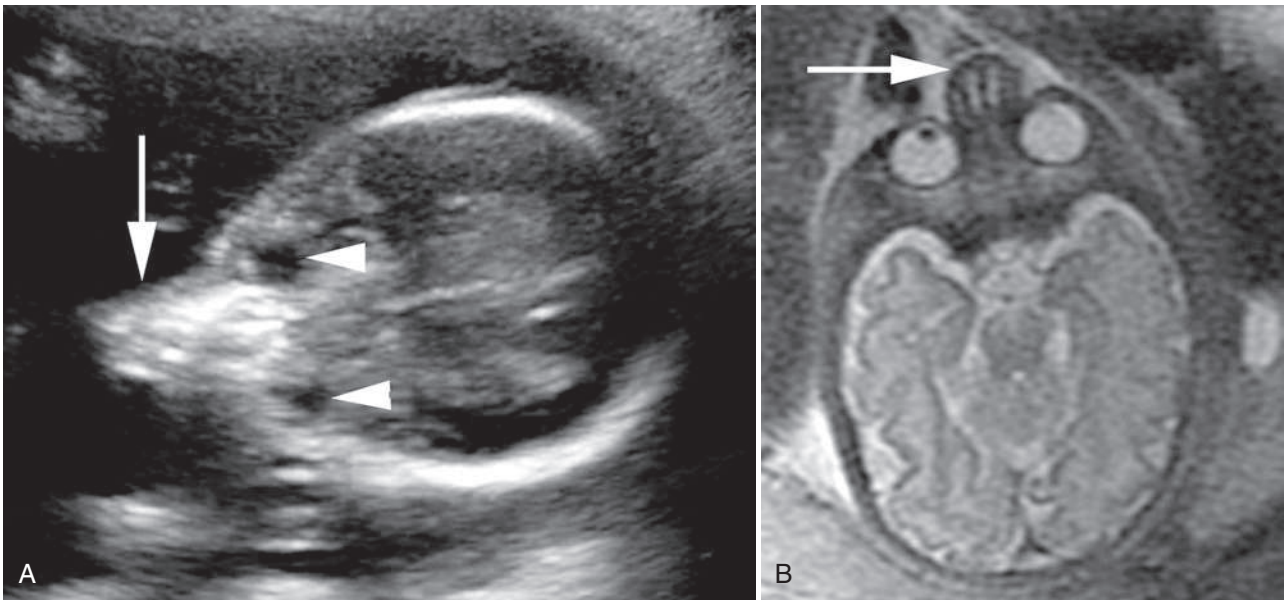

FIG. 33.9 Hypotelorism. (A) Microtia and **hypotelorism.** Axial sonogram shows small orbits *(arrowheads),* close together in the face, and the protuberant maxilla *(arrow).* The fetus also had agnathia and low-set ears (see Fig. 33.29). **(B) Hypotelorism** and abnormal nose *(arrow)* at 35 weeks' gestation. Axial magnetic resonance image of a 35-week fetus shows the relatively small intraorbital distance and an abnormal nose. The fetus was in deep vertex prone position, and the face could not be seen on fetal sonography before magnetic resonance imaging. This fetus was diagnosed postnatally with a complex Tessier cleft.

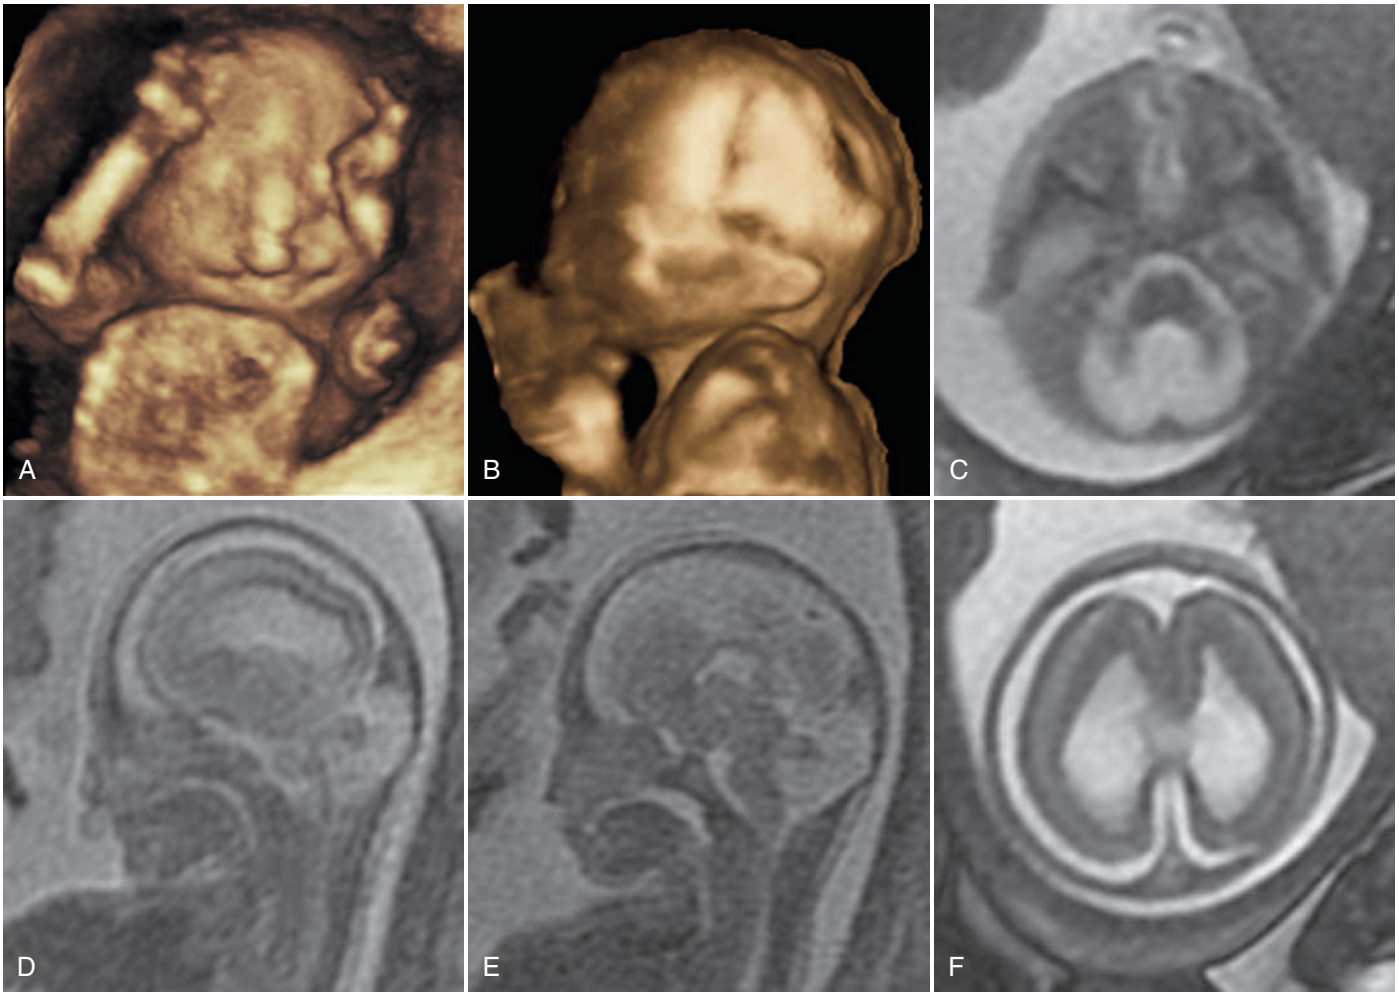

FIG. 33.10 Holoprosencephaly. Nineteen-week fetus with trisomy 13 including multiple anomalies. **(A)** Bilateral cleft lip and palate. **(B)** Low-set ears. **(C)** and **(D)** Proboscis and inferior vermian hypoplasia. **(E)** and **(F)** Semilobar holoprosencephaly.

Coloboma

Coloboma results from incomplete closure of the optic fissure and most often affects the **iris** inferiorly[6] (Fig. 33.15). However, it can affect any structure from the eyelid to the optic nerve or retina. Vision may or may not be affected, depending on the structures affected and the severity of the abnormality. Diagnosis in utero depends on visualization of a focal bulge in the posterior aspect of the globe. In cases where bones cause artifacts in this region and this assessment is crucial, 3-D ultrasound[38] or MRI[39] can be helpful. Coloboma is a rare diagnosis (0.2 per 1000)[40] and may be associated with other anomalies and syndromes, such as **CHARGE syndrome** (*c*oloboma, *h*eart defects, choanal *a*tresia, *r*estriction of growth and development, *g*enital and *e*ar anomalies).

Dacryocystocele

Dacryocystoceles result from obstruction of the **nasolacrimal ducts** (Fig. 33.16). These appear as cystic masses that may contain low-level internal echoes, located inferomedially to the orbit in the expected location of the nasolacrimal duct. There is usually no mass effect on the globe, and there is no increased vascular flow in or around these masses. Diagnosis is usually made after 30 weeks' gestation; the nasolacrimal ducts do not complete canalization until the third trimester.[41] The characteristic appearance and location of dacryocystoceles should allow differentiation from other facial masses, such as **teratomas** (often solid or mixed cystic and solid, and may contain calcifications) or **hemangiomas** (solid, echogenic sonographic appearance, with increased vascular flow). The natural history of dacryocystoceles is variable, with some resolving in utero, or postnatally with conservative measures such as massage and application of warm compresses, and others requiring probing or surgical intervention after birth.[42]

Congenital Cataracts

Congenital cataracts may be diagnosed on prenatal sonography, which will show a rounded echogenic mass in the anterior portion of the globe. Causes of congenital cataracts include genetic disorders, infection, syndromes, and microphthalmia.[5] Some cases are inherited by either autosomal dominant or autosomal recessive transmission. This is a rare disorder, with a reported incidence of approximately 3 per 10,000 births.[43]

Text continued on p. 1148.

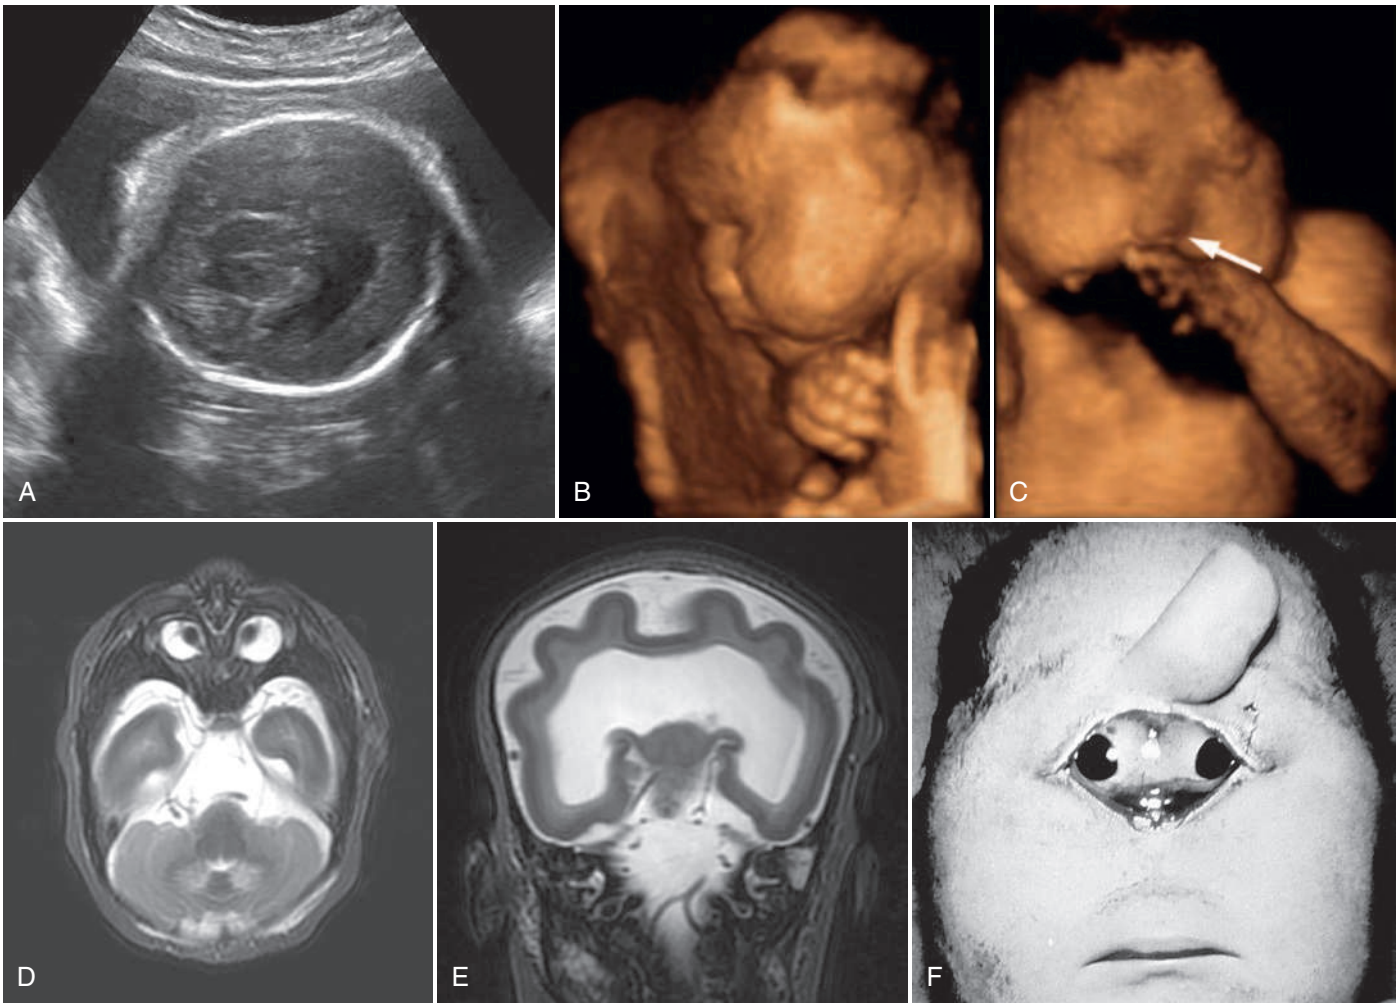

FIG. 33.11 Hypotelorism. Fetal sonography at 33 weeks showing fused thalami and holoprosencephaly on two-dimensional ultrasound **(A)** and hypotelorism, flat midface, and single nostril *(arrow)* on three-dimensional sonography (**B** and **C**). **(D)** and **(E)** Postnatal magnetic resonance imaging shows cyclopia **(D)**, and alobar holoprosencephaly **(E)**. **(F)** Postnatal photograph of a different infant, demonstrating cyclopia with fused globes, supraorbital proboscis, and absent nose. FIG. 33.12 Hypertelorism in Fetus at 25 Weeks With Bilateral Cleft Lip and Palate. (A) Axial sonogram shows hypertelorism (*cursors:* +, outer orbital diameter; x, inner orbital diameter). **(B)** Coronal magnetic resonance image shows hypertelorism and bilaterally absent palatal shelves. Note the absent secondary palate above the tongue *(T)* with communication of the amniotic fluid between the oropharynx and nasopharynx.

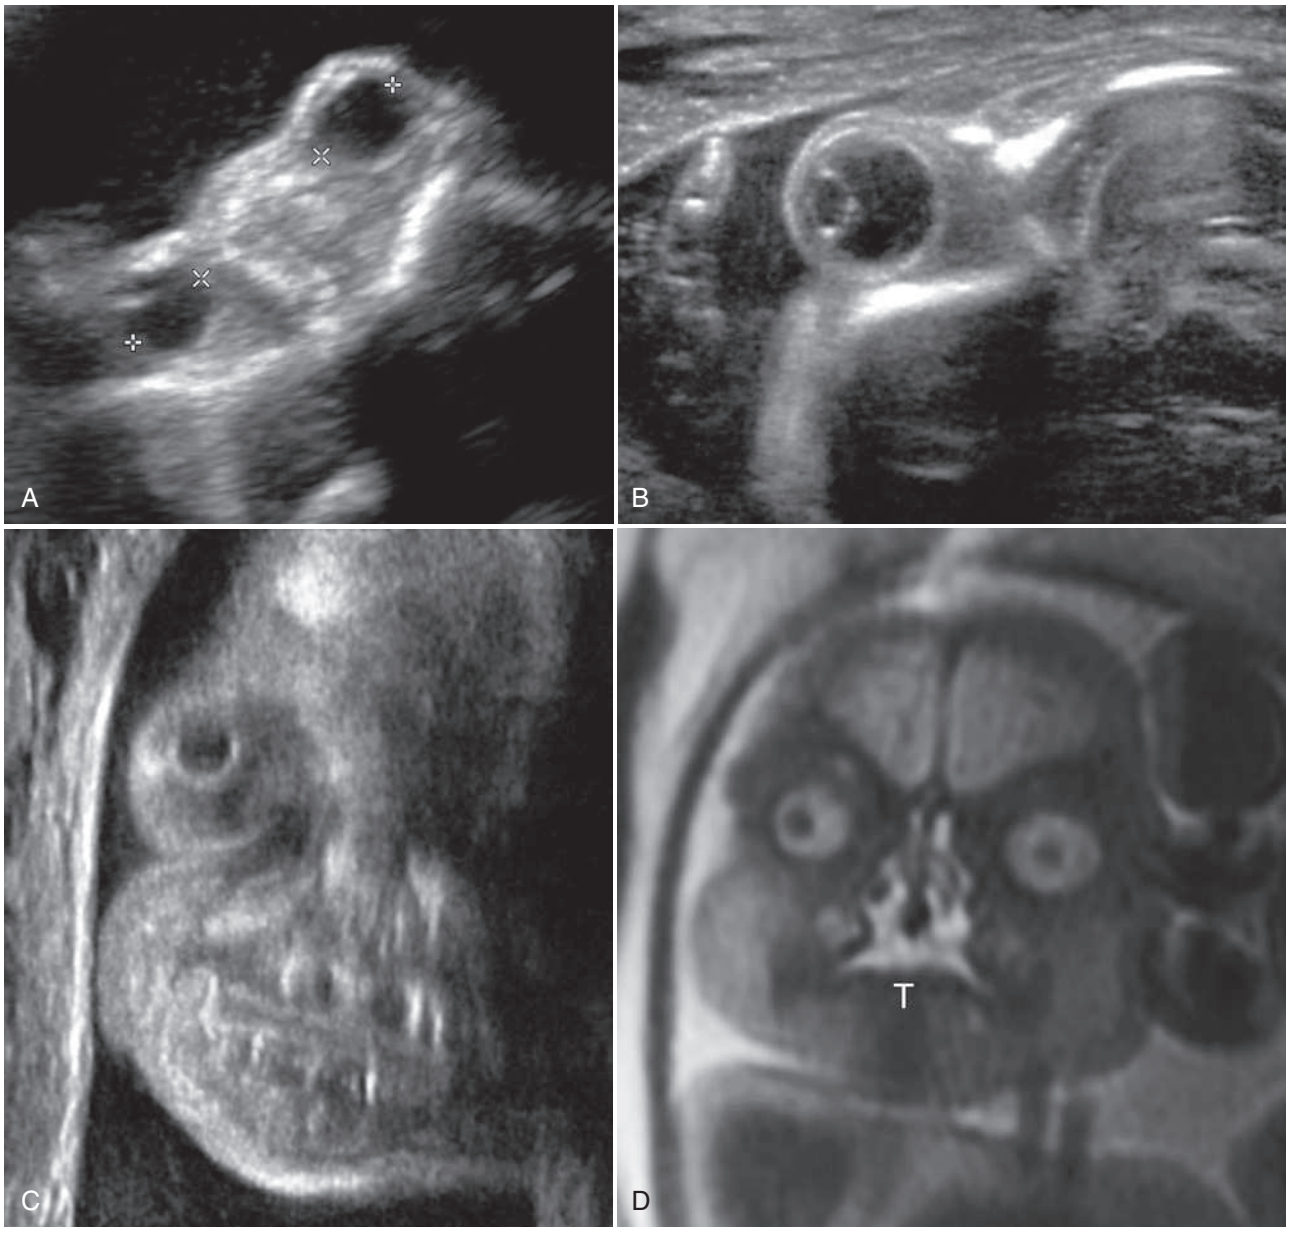

FIG. 33.13 Hypertelorism With Exorbitism in Fetus With Pfeiffer Syndrome. (A) Axial sonogram demonstrates hypertelorism (*cursors:* +, outer orbital diameter; x, inner orbital diameter) at 22 weeks' gestation. The outer orbital diameter was consistent with 25 weeks and 3 days (3 weeks greater than age by dates). **(B)** and **(C)** Axial and coronal sonograms show abnormally protuberant globe (exorbitism). **(D)** Coronal magnetic resonance image shows hypertelorism and bilateral cleft palate. Note the communication of the oropharynx with the nasopharynx, caused by defect in the palate above the tongue *(T).*

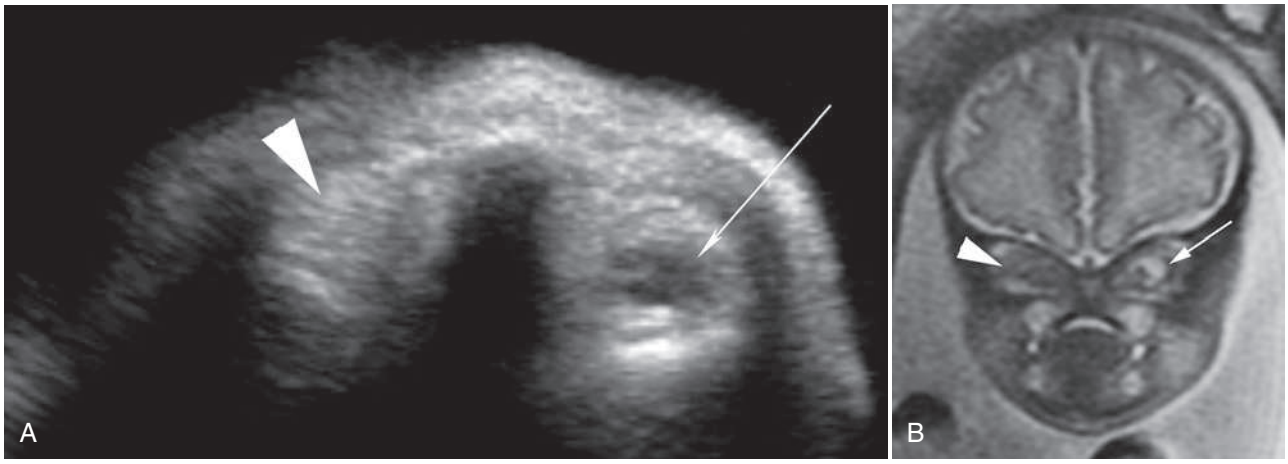

FIG. 33.14 Microphthalmia and Anophthalmia at 34 Weeks' Gestation. (A) Axial sonogram and **(B)** coronal magnetic resonance image show right anophthalmia *(arrowhead)* and left microphthalmia *(arrow).*

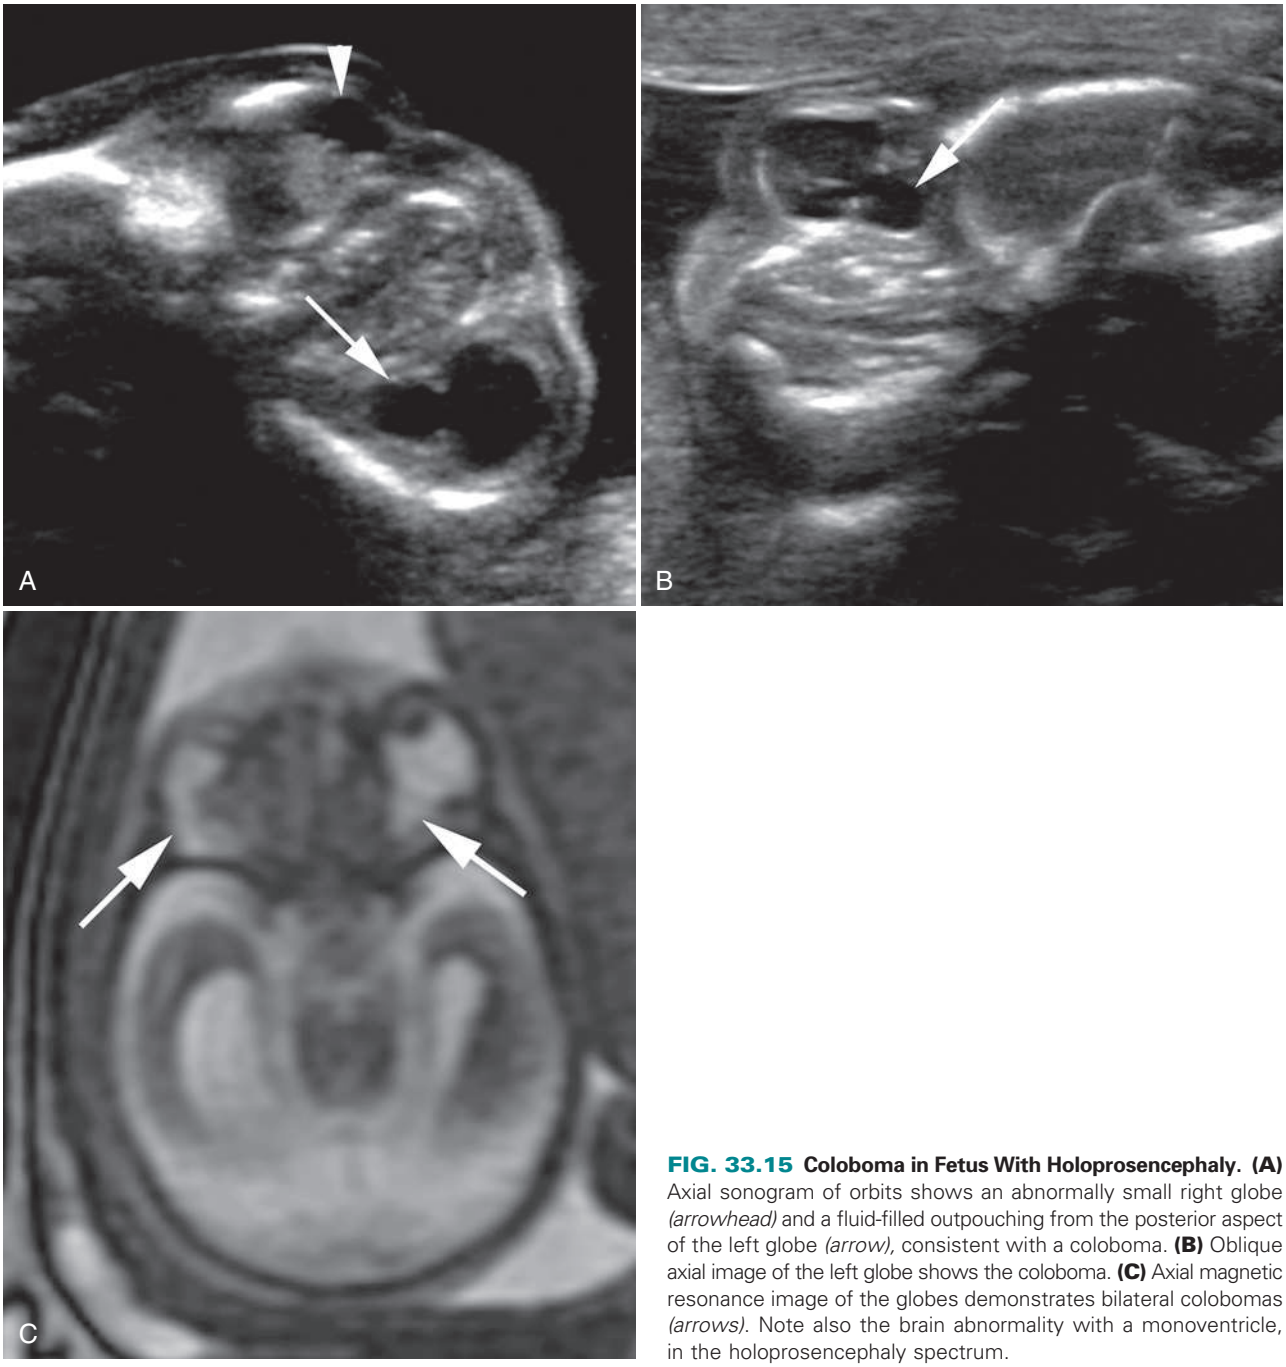

FIG. 33.15 Coloboma in Fetus With Holoprosencephaly. (A) Axial sonogram of orbits shows an abnormally small right globe *(arrowhead)* and a fluid-filled outpouching from the posterior aspect of the left globe *(arrow),* consistent with a coloboma. **(B)** Oblique axial image of the left globe shows the coloboma. **(C)** Axial magnetic resonance image of the globes demonstrates bilateral colobomas *(arrows)*. Note also the brain abnormality with a monoventricle, in the holoprosencephaly spectrum.

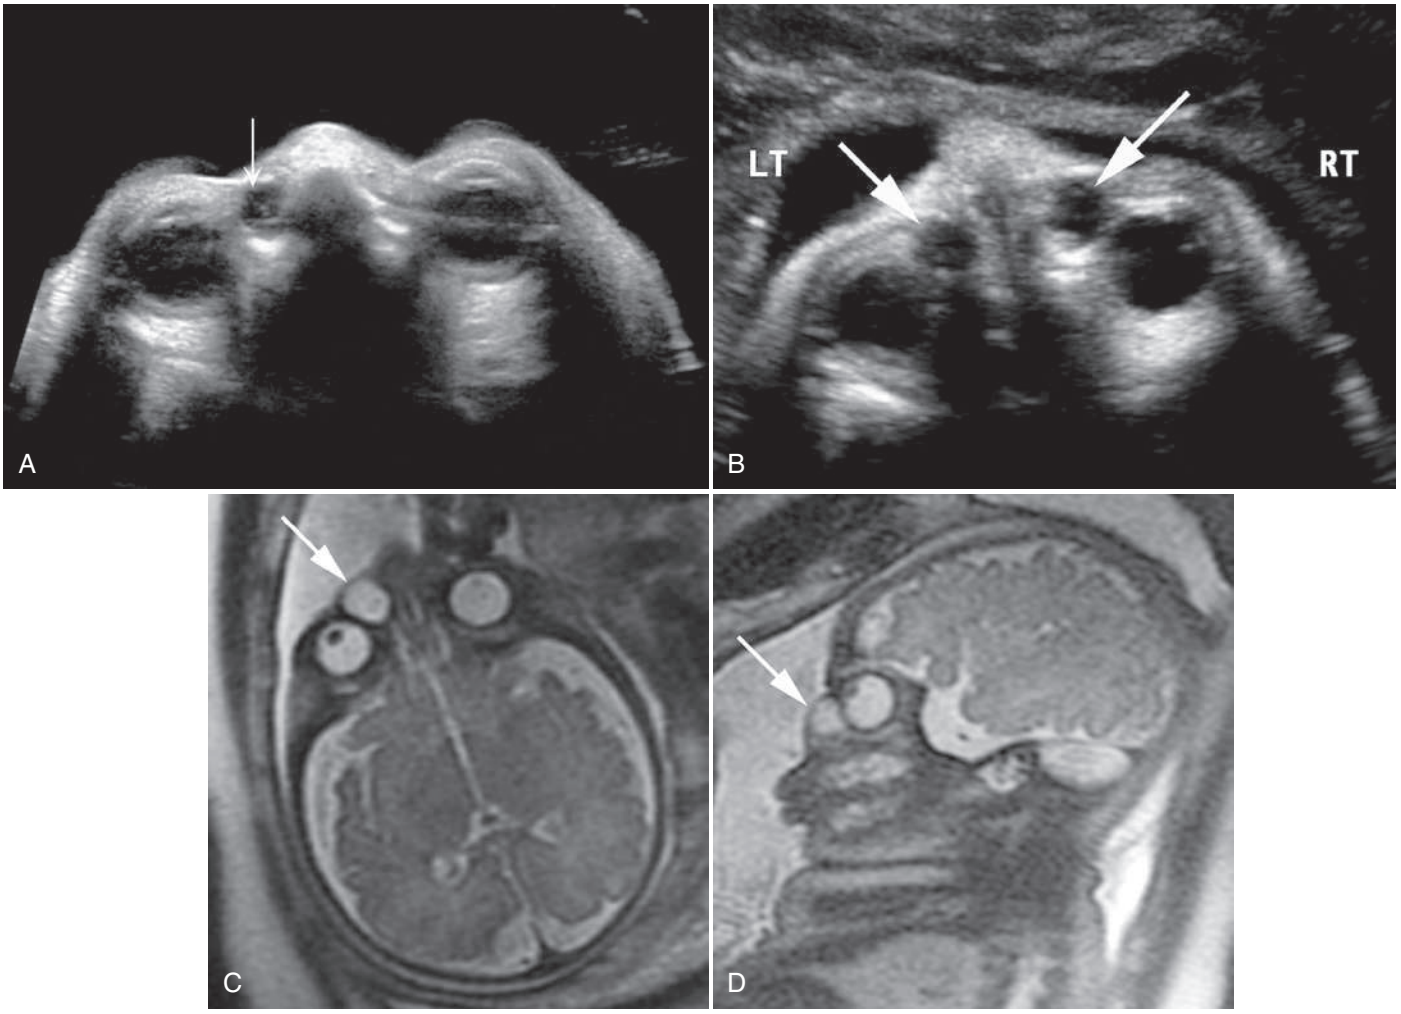

FIG. 33.16 Dacryocystocele. (A) Sonogram at 33 weeks shows unilateral dacryocystocele *(arrow)*. **(B)** Axial sonogram at 35 weeks shows fluid collections anteromedial to each orbit, consistent with bilateral dacryocystoceles *(arrows)*. **(C)** and **(D)** Axial and sagittal magnetic resonance images of a different 35-week fetus with a right dacryocystocele *(arrow)*.

Associations With Microphthalmos

- Single-gene disorders
  - Walker-Warburg syndrome
  - Fraser (cryptophthalmos) syndrome
  - Meckel Gruber syndrome
- Chromosomal abnormalities
  - Trisomy 13
  - Trisomy 18
- Drugs or irradiation
  - Ionizing radiation (4-11 weeks)
  - Ethanol
  - Thalidomide
  - Isotretinoin (retinoic acid)
- Maternal disease
  - Diabetes
  - Cytomegalovirus
  - Rubella
  - Toxoplasmosis
- Other
  - Encephalocele
  - Orbital tumors
  - CHARGE syndrome
  - VATER association

CHARGE, Coloboma, heart defects, choanal atresia, growth/development restriction, genital/ear anomalies; *VATER,* vertebral defect, imperforate anus, tracheoesophageal fistula, radial and renal dysplasia.

Differential Diagnosis of Congenital Cataracts

- Arthrogryposis
- Chondrodysplasia punctata
- Congenital aniridia
- Congenital ichthyosis
- Chromosomal abnormalities (21, 18, 13)
- G6PD deficiency
- Homocystinuria
- Hypochondroplasia
- Microphthalmia
- Infection
  - Rubella
  - Toxoplasmosis
- Syndromes
  - Marfan
  - Neu-Laxova
  - Smith-Lemli-Opitz
  - Walker-Warburg
- X-linked cataract (Hutterite)

G6PD, Glucose-6-phosphate dehydrogenase.

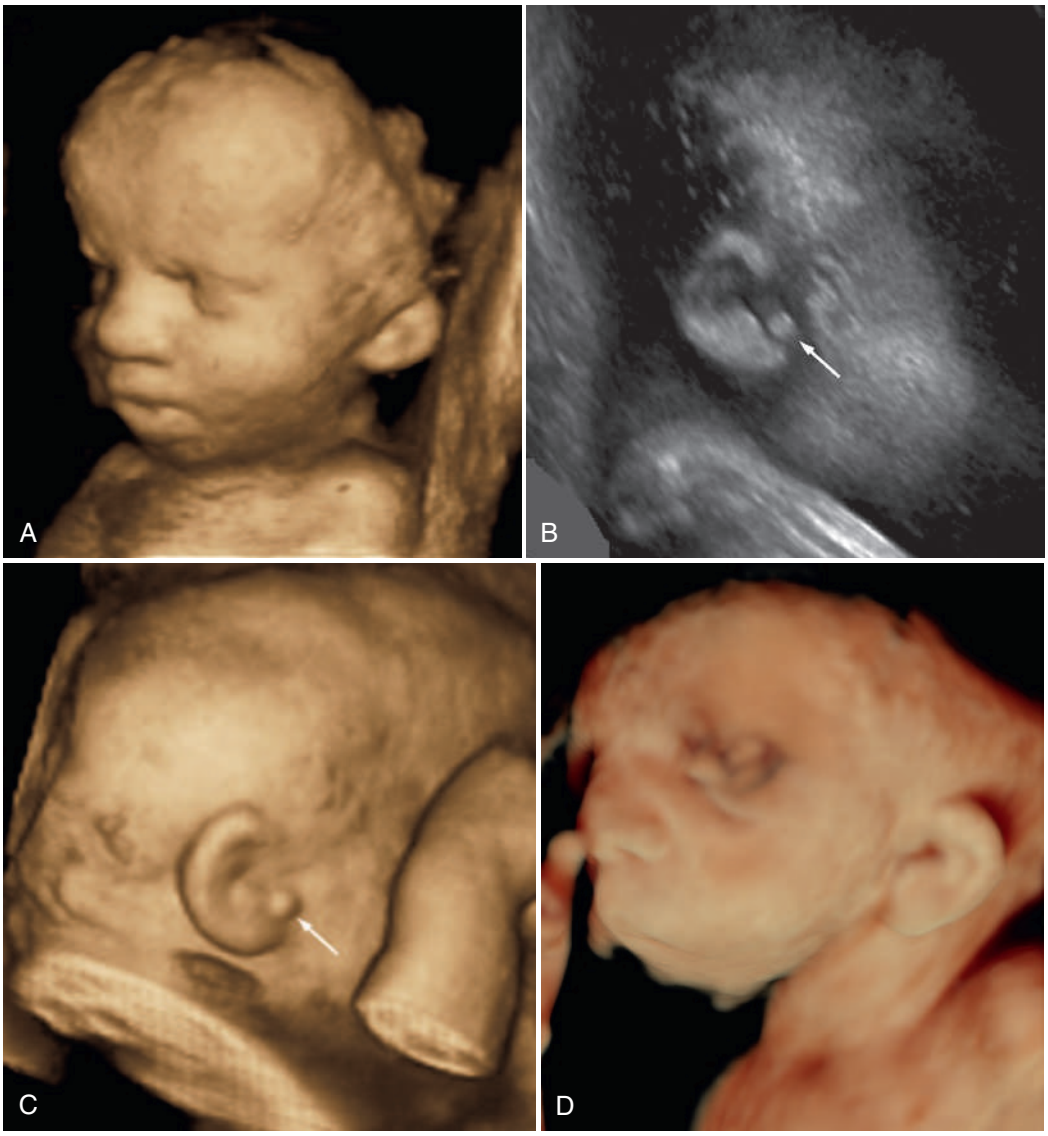

FIG. 33.17 Abnormal Ears. (A) Week 28 fetal sonography showing low-set ears and skin tag *(arrows)* on two-dimensional **(B)** and three-dimensional **(C)** images. **(D)** A different 27-week fetus with agnathia, microstomia, and low-set, abnormally turned ears.

EAR ABNORMALITIES

Abnormalities of the ears can be very difficult to diagnose on fetal sonography, but **low-set ears** are associated with multiple syndromes, including **Noonan syndrome** and certain trisomies. Low-set ears are described as the helix joining the cranium at a level below a horizontal plane through the inner canthi of the eyes. Ear anomalies may be more easily detected on 3-D sonography than on 2-D studies[44,45] (Fig. 33.17).

Microtia, or small ears, is a rare anomaly with an incidence of approximately 1 per 10,000 live births[46] and is often associated with syndromes and aneuploidy. Of 96 aneuploid fetuses, Yeo and colleagues[47] reported that 66% had small (<10th percentile) ears on sonography.

Otocephaly is a condition with union of the ears on the front of the neck and is caused by failure of ascent of the auricles during embryologic development. This is usually a fatal anomaly, often associated with agnathia or micrognathia, as well as holoprosencephaly. The most severe form of otocephaly may be associated with absence of the eyes, forebrain, and mouth.

MIDFACE ABNORMALITIES

Hypoplasia

The midface is the area between the upper lip and forehead. Midface hypoplasia can arise from a variety of causes, including syndromes such as **Apert, Crouzon, Treacher Collins,**[48] **Wolf-Hirschhorn,**[49] **Pfeiffer** (see Fig. 33.13), **Turner,** and **trisomy 21.** Midface hypoplasia may also result from facial clefts, craniosynostosis, and skeletal dysplasias. Midface hypoplasia is best demonstrated on sagittal midline views of the face, where one can see abnormal concavity of the midface, between the lower margin of the orbits and the upper jaw (Figs. 33.18 and 33.19).

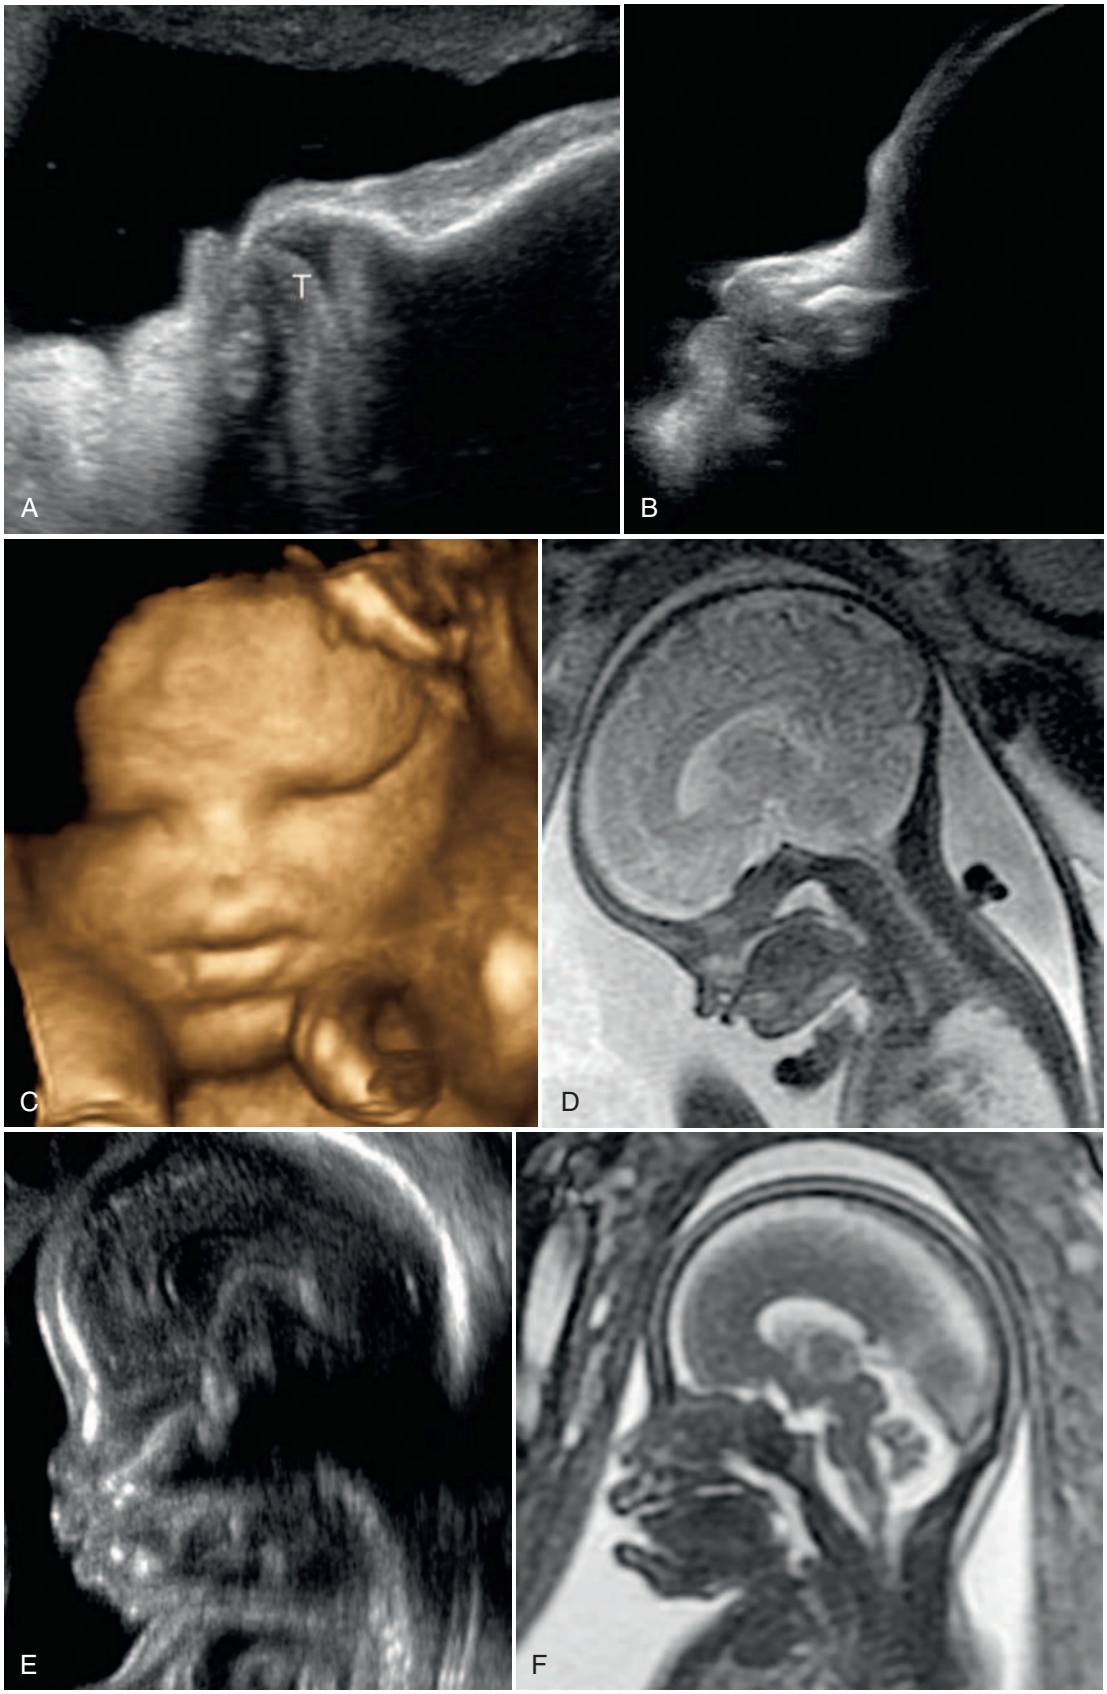

FIG. 33.18 Midface Hypoplasia. (A) Midface hypoplasia in association with **cleft lip and palate.** Sagittal view of the face shows midface retrusion in a 34-week fetus with unilateral complete left cleft lip and palate. Note the absent palate above the tongue *(T)*. **(B)**-**(D)** Midface hypoplasia in association with **microphthalmia** seen with sagittal ultrasound, three-dimensional ultrasound, and magnetic resonance imaging, respectively. **(E)** and **(F)** Midface hypoplasia in a fetus with **hypertelorism** (seen in same fetus as in Fig. 33.13). **(E)** Sagittal sonogram and **(F)** magnetic resonance image show an abnormally shaped skull and midface hypoplasia.

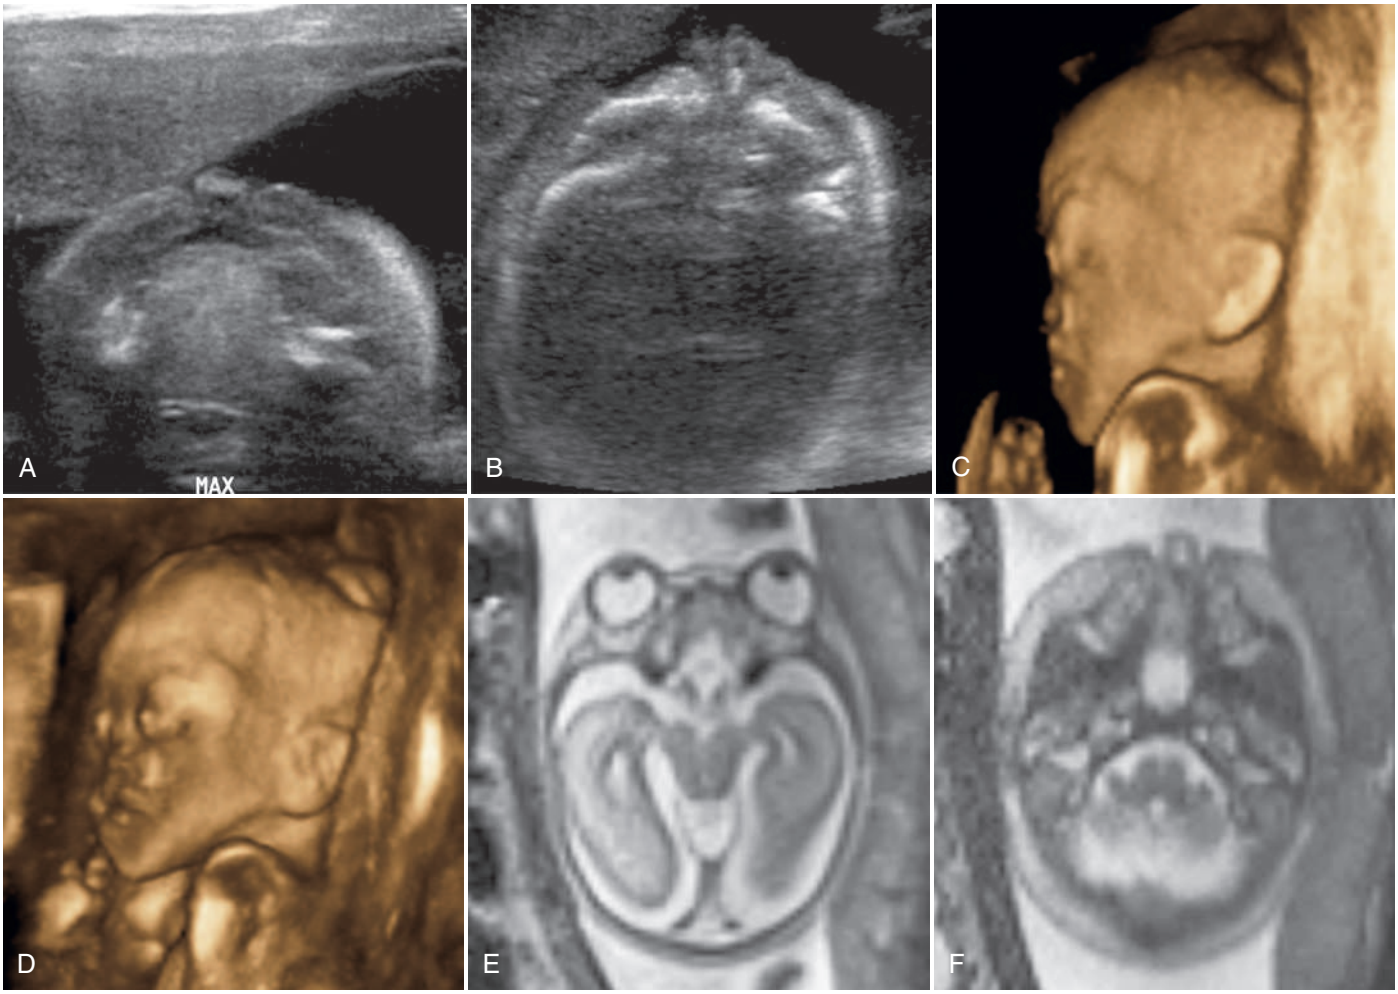

FIG. 33.19 Midface Hypoplasia. A 21-week fetal sonogram **(A-D)** and magnetic resonance images (**E** and **F**) show bilateral cleft lip and midline incisor. The flat profile of the fetus can be well appreciated on the three-dimensional views (**C** and **D**). Proptosis is evident in **(D)** and **(E)**.

Absent Nasal Bone

Hypoplastic or absent nasal bone is seen with increased incidence in fetuses with **trisomy 21** and can be evaluated sonographically in the first trimester as part of early risk assessment. The fetal nasal bone is best evaluated in a midsagittal plane at sonography (Fig. 33.20). Some have found that combining data regarding the presence or absence of the fetal nasal bone with NT measurements improves the accuracy of detection of trisomy 21 at first-trimester screening.[50] Cicero's initial study on evaluation of the nasal bone in first-trimester examinations found that 73% of fetuses with trisomy 21 had an absent nasal bone.[50] Other studies have reported absent nasal bone in 50% to 67% of fetuses with trisomy 21.[51,52] The absence of a nasal bone at second-trimester sonography, or abnormally short nasal bone measurements in combination with other markers of aneuploidy, increases detection of aneuploidy.[53,54]

It is important to note, however, that accurate sonographic evaluation of the fetal nasal bone can be technically challenging. There are specific guidelines for nasal bone imaging.[55] Studies have shown that even experienced sonographers need to perform at least 80 supervised examinations that conform to specified

FIG. 33.20 Absent Nasal Bone. Profile of third-trimester fetus with trisomy 13 and absent nasal bone.

standards before they are proficient in sonographic nasal bone evaluation.[56]

Other Nasal Abnormalities

Fetal nasal masses are rare but can be identified with ultrasound. Differential considerations include glioma, dermoid, hemangioma, and encephalocele. Fetal MRI is often helpful in assessing for intracranial extension, which is seen with encephalocele and may be present with nasal gliomas. Nasal gliomas are composed of heterotopic neuroglial tissue, usually located on the bridge or side of the nose, and may be extranasal (60%), intranasal (30%), or both (10%).[57-60] Nasal gliomas, in contrast to hemangiomas, usually do not demonstrate significant vascular blood flow on Doppler. Dermoids are often solid and cystic, heterogeneous masses. Hemangiomas are frequently echogenic and demonstrate vascular flow on Doppler. Encephaloceles may contain only meninges and cerebrospinal fluid and thus appear cystic, or may contain brain tissue and appear heterogeneous.

Frontonasal dysplasia is a rare anomaly[61,62] involving abnormalities of the eyes, forehead, and nose and is defined by the presence of two or more of the following: hypertelorism, skin-covered gap in the bones of the forehead (anterior cranium bifidum occultum), broad nasal root, median facial cleft, nasal ala cleft, lack of formation of nasal tip, and V-shaped frontal hairline (widow's peak).[63]

Cleft Lip and Palate

Worldwide incidence of cleft lip, with or without cleft palate, is approximately 1 per 700 live births,[64] with an incidence in Caucasians of approximately 1 per 1000 live births. The incidence of facial clefting is lower in the African American population (0.3 per 1000), higher among Asians (2 per 1000), and highest in Native Americans (3.6 per 1000 live births). It is more common in males than females.[65] These abnormalities usually result from failure of fusion of the medial nasal prominences and maxillary prominences. Although facial clefts may occur as an isolated finding, they are present with increased frequency in chromosomal anomalies, including **trisomies 13 and 18,** and in other structural anomalies, especially those involving the heart and central nervous system.[66-68] Reports vary, with aneuploidy rates of 5% to 30% in association with facial clefts.[69-71] Thus identification of a facial cleft should prompt a detailed and complete evaluation of the fetus for additional anomalies. Some isolated facial clefts are familial, with the recurrence risk dependent on number of affected parents and siblings.[72]

Reported accuracy in the sonographic detection of fetal cleft lip and palate ranges from 16% to 93%.[73-78] Robinson and colleagues[77] found that sonography performed after 20 weeks' gestation had a significantly higher detection rate for cleft lip than did studies performed before 20 weeks, and they subsequently recommended that fetuses at high risk for cleft lip be evaluated after 20 weeks' gestation (Video 33.1, Video 33.2, Video 33.3). Using state-of-the-art equipment, high-frequency probes, and endovaginal sonography, detection is possible at earlier gestational ages. Some question the efficiency and usefulness of 3-D sonography in evaluating clefts,[79] but many have found 3-D applications to be extremely helpful.[8,80,81] Recent studies have described 3-D techniques for evaluating the primary and secondary palate during the first trimester.[82-84] Sommerlad and colleagues[85] found the 3-D reverse face view could be obtained in 90% of patients at 20 to 34 weeks' gestational age and correctly classified clefts of the lip, alveolar ridge, and palate in nearly 90% of patients. However, evaluation of the secondary palate remains challenging, even with 3-D flipped face techniques[86] and modifications[87] of this technique, with adequate views obtained in just over a third of patients imaged.

Differential Diagnosis of Cleft Lip and Palate

- Teratogens
  - Diphenylhydantoin (phenytoin)
  - Valproic acid
  - Retinoic acid
  - Carbamazepine
  - Diazepam
- Amniotic band syndrome
- Holoprosencephaly
- Ectodermal dysplasia
- Frontonasal dysplasia
- Robert syndrome
- Miller syndrome
- Trisomies 13, 18, and 21
- Triploidy

Fetal facial clefts should be described as completely as possible, using standard craniofacial terminology and including accurate description and classification of the cleft in relation to the lip, nostril, alveolus (maxillary tooth bearing arc), and secondary palate (Fig. 33.21). The secondary palate has an anterior, bony segment and a posterior, soft tissue segment. Both cleft lip and cleft palate may be unilateral or bilateral.

Information important to the surgeons for accurate parental counseling, postnatal repair planning, and prognosis includes whether the cleft is unilateral or bilateral and complete or incomplete (Fig. 33.22). A **complete cleft lip** is defined as a cleft that fully divides the lip and extends completely through the base of the ala of the nose and that usually is associated with a cleft of the underlying tooth-bearing alveolus as well. An **incomplete cleft lip** involves a portion of the lip, but at least a band of soft tissue spans the cleft. Incomplete cleft lip does not involve the ipsilateral underlying bony tooth-bearing alveolus (Fig. 33.23).

Associated sonographic signs of a cleft palate include an abnormally high position of the fetal tongue, hypertelorism, deviation of the **vomer** (a triangular bone in the nasal septum forming the posterior and inferior portion of the septum), and micrognathia.[71,88,89] To describe the type of cleft, two embryonic structures are considered: (1) the primary palate, formed by the prolabium, premaxilla, and columella, which includes the lip, nares, and alveolus, and (2) the secondary palate, which begins at the incisive foramen and is formed by a horizontal portion of the maxilla, the horizontal portion of the palatine bones, and the soft palate.

Cleft palate may interfere with fetal swallowing and result in polyhydramnios. Infants with cleft palate have difficulty with feeding, are at increased risk of otitis media, and may have difficulty with hearing and speech.[65]

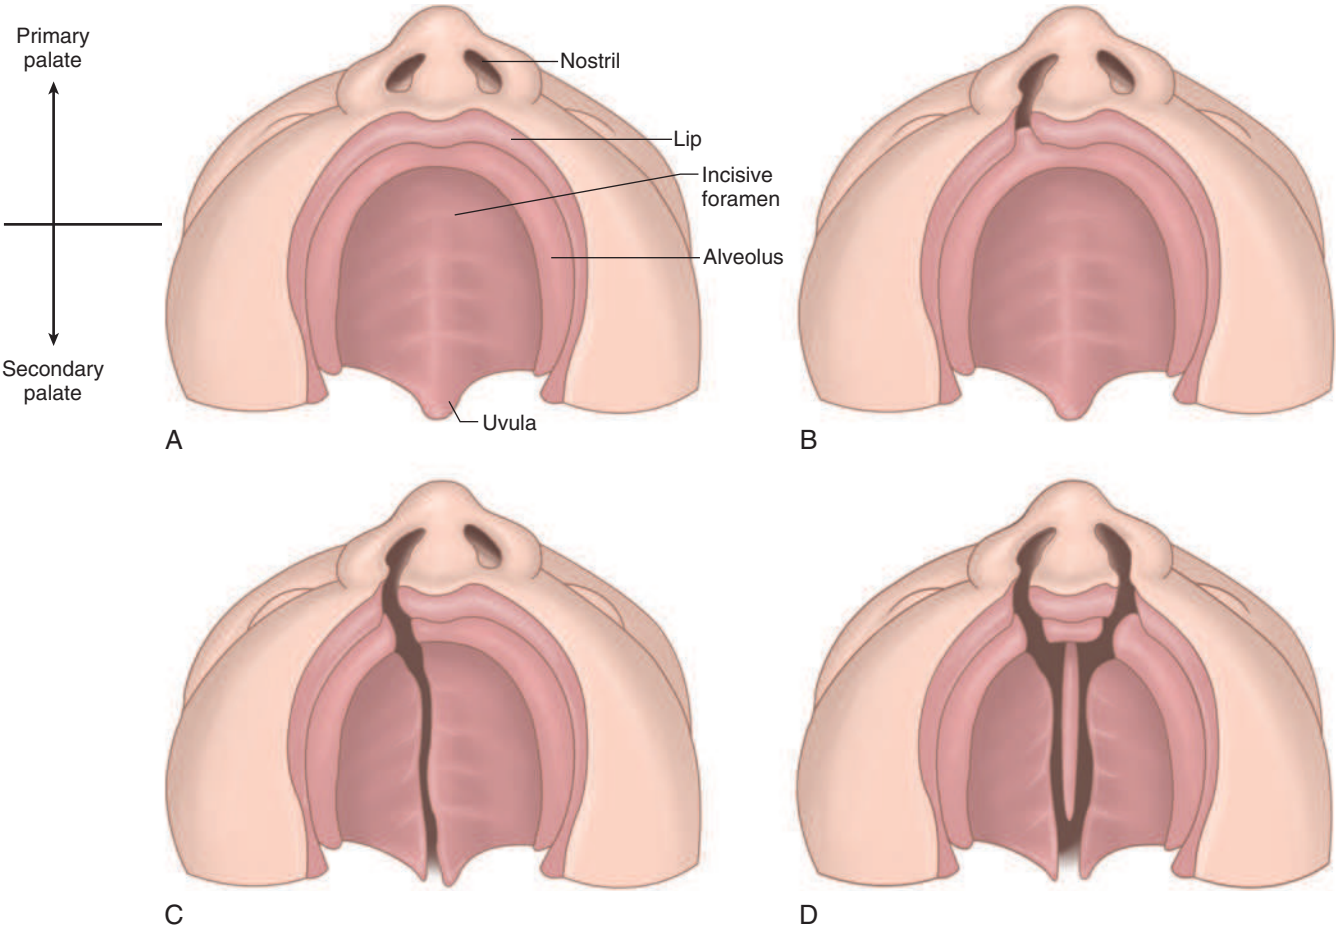

FIG. 33.21 Patterns of Clefting of Lip and Palate. (A) Normal anatomy of lip, primary palate, and secondary palate. The primary palate encompasses features anterior to the horizontal line, and the secondary palate is posterior to the blue line. **(B)** Isolated unilateral cleft lip involving the lip and nose. **(C)** Complete unilateral cleft lip and palate. The cleft lip extends through the primary palate, through the incisive foramen, and through the secondary palate. **(D)** Bilateral cleft lip and palate. This cleft extends on both sides through the nose, lip, primary and secondary palate (Courtesy of Andrew S. Phelps, MD.)

Associated Signs of Cleft Palate With Cleft Lip

AXIAL AND CORONAL VIEWS
Lips: cleft
Nares: flattened or deformed
Vomer: deviated away from side of cleft; often midline if bilateral cleft lip and palate
Maxilla: interrupted alveolus, wide gap
Orbits: hypertelorism

SAGITTAL VIEWS
Profile: midface retrusion
Tongue: high position in oropharynx

Unilateral Cleft Lip or Palate

Unilateral clefts occur more often on the left side. In a unilateral cleft lip or palate, there is often an offset between the two sides of the cleft, which are described as the "greater segment" on the side opposite the cleft, and the "lesser segment" on the side of the cleft (Fig. 33.24).

Bilateral Cleft Lip or Palate

Only about 10% of facial clefts are bilateral. In bilateral cleft lip or palate, the midsagittal view will often show an abnormal premaxillary protrusion of soft tissue anterior to and above the normal position of the upper lip (Fig. 33.25). Bilateral cleft lip and palate may be symmetrical or asymmetrical (Fig. 33.26).

Median Cleft Lip or Palate

Median cleft lip is a classic finding in **alobar holoprosencephaly.** In these cases, head size is small for menstrual dates and there is hypotelorism.[90] However, median cleft lip and palate can also be seen without holoprosencephaly. In these cases, head size and ocular diameters are normal.[90]

Unusual Facial (Tessier) Clefts

Asymmetrical clefts in unusual locations may be the result of **amniotic band syndrome** or may fall into the **Tessier cleft** category (see Fig. 33.22). Tessier clefts are rare, occurring in 1 to 5 per 100,000 live births.[91] These clefts are classified by the relationship of the cleft to the mouth, nose, and eye sockets and are numbered from 1 to 14, with the midline designated as 0.

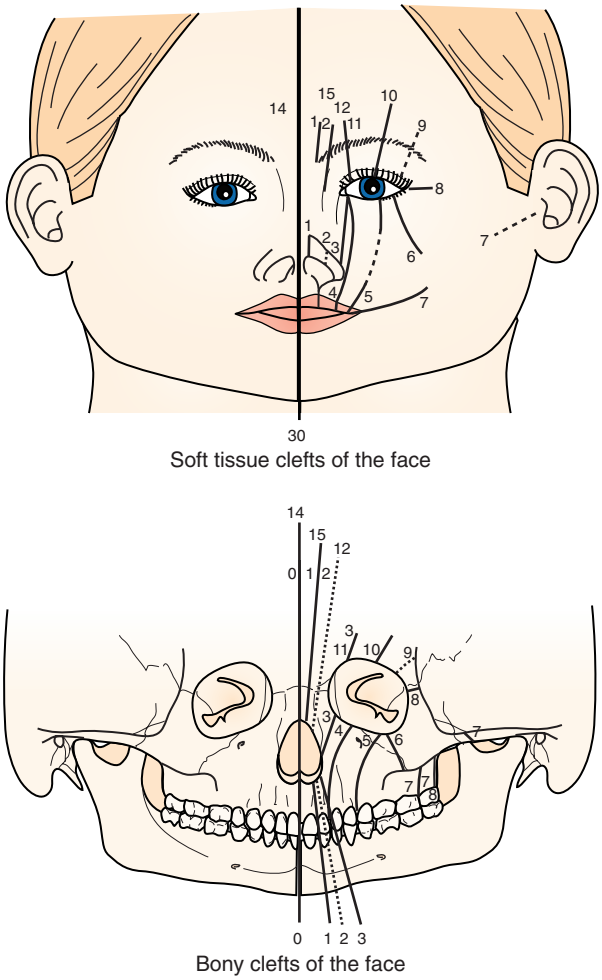

FIG. 33.22 Classification of Tessier Clefts. These clefts are classified by the relationship of the cleft to the mouth, nose, and eye sockets and are numbered from 1 to 14 with the midline designated as 0. Knowledge of these types of clefts is important for prenatal imaging, so that when unusual clefts are seen, they can be recognized as part of this spectrum. (Modified from Tessier P. Anatomical classification: facial, cranio-facial and latero-facial clefts. J Maxillofac Surg 1976;4:69-92.[92])

Tessier clefts can involve either the soft tissues (e.g., hairline, eyebrows, eyelids, nostrils, lips, ears) or the skeleton.[92] In some cases 3-D ultrasound has identified facial clefts not detectable on 2-D images.[93]

Isolated Cleft of Secondary Palate

Isolated clefts of the secondary palate are embryologically distinct from cleft lip or palate and are less common, occurring in approximately 1 per 2500 live births.[64] This abnormality is rarely[94] identified on prenatal sonography because of shadowing from overlying bony structures. Sonographic diagnosis is based on secondary signs, such as abnormal oropharyngeal fluid flow with color Doppler imaging[71] and high position of the tongue.[74,76,95] Cleft soft palate without cleft lip is more strongly associated with syndromes and chromosomal anomalies than cleft palate in concert with cleft lip.[76]

Syndromes associated with clefts of the secondary palate (without cleft lip) include **Goldenhar syndrome, Pierre-Robin sequence, Treacher Collins syndrome, Stickler syndrome,** and **velocardiofacial syndrome.** Three-dimensional sonography is often helpful in assessing the secondary palate, given a favorable fetal position and gestational age and adequate amniotic fluid.[14-16,96-99] Sagittal fetal MRI is helpful in delineating the normal soft tissues of the palate and in accurately characterizing palatal clefting, even when isolated to the posterior secondary (soft) palate.[88,89,100]

LOWER FACE ABNORMALITIES

Macroglossia and Oral Masses

Macroglossia, an abnormally enlarged tongue, has a variety of causes and can, at times, be identified on fetal sonography, visualized as the tongue protruding outside the oral cavity, typically on sagittal or axial views (Fig. 33.27). The etiology of macroglossia includes Beckwith-Wiedemann syndrome, trisomy 21, and vascular malformations such as lymphatic malformation or hemangioma.[101] If macroglossia is identified, a careful evaluation for the associated findings of **Beckwith-Wiedemann syndrome** and for markers of **trisomy 21** should follow.

Conditions Associated With Macroglossia

Beckwith-Wiedemann syndrome
Trisomy 21
Congenital hypothyroidism
Lymphangioma
Hemangioma
Inborn error of metabolism
Isolated autosomal dominant trait
Lingual thyroid
Neurofibroma
Epignathus

Micrognathia and Retrognathia

Micrognathia is a small chin, and retrognathia (retrognathism) is a posteriorly displaced chin. These are distinct abnormalities that frequently occur together. **Pierre-Robin sequence** is the clinical triad of micrognathia, glossoptosis (downward displacement of the tongue), and subsequent airway obstruction, often associated with cleft soft palate (Fig. 33.28). This finding is associated with syndromes (e.g., Stickler, velocardiofacial, Miller-Diecker, Beckwith-Wiedemann, Treacher Collins, Pfeiffer, femoral-facial); chromosomal anomalies (typically trisomy 18 or 13); and skeletal dysplasias (e.g., diastrophic, spondyloepiphyseal, congenital, camptomelic). If the abnormality is severe enough to interfere with fetal swallowing in utero, polyhydramnios may result. Micrognathia can lead to substantial feeding difficulties and problems with airway management after birth. Prenatal diagnosis is thus critical to delivery planning.

Micrognathia is best seen on midsagittal views of the fetal face and is identified by subjective assessment by the sonologist (Video 33.4). Although there have been attempts to standardize

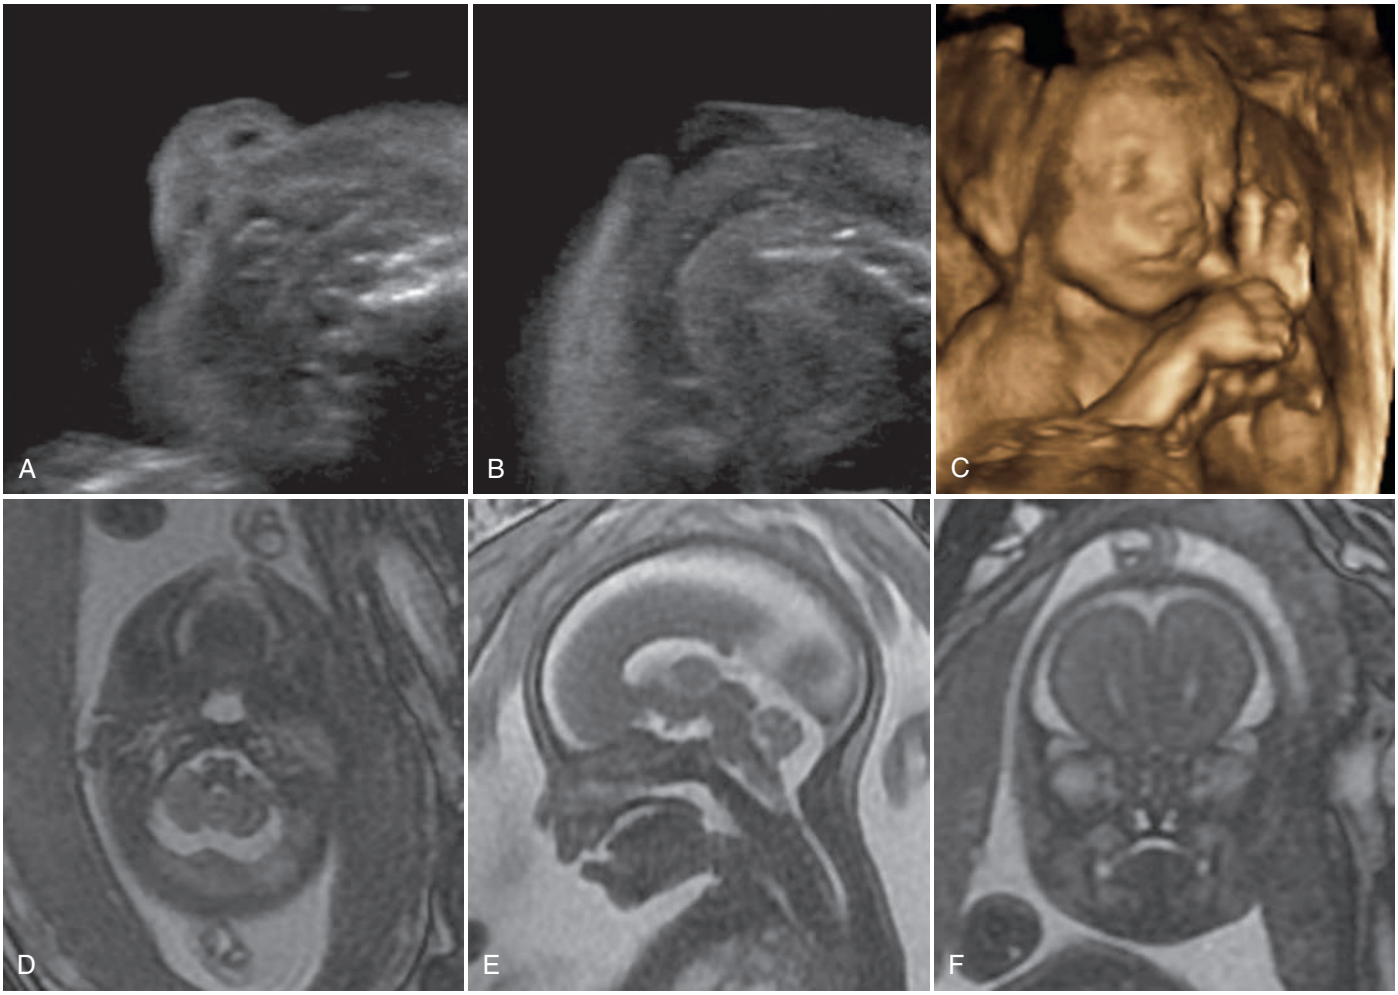

FIG. 33.23 Incomplete Cleft Lip. Two-dimensional (**A** and **B**) and three-dimensional **(C)** sonography of a 22-week fetus with unilateral incomplete left cleft lip. **(D)-(F)** Fetal magnetic resonance images showing intact alveolus **(D)** and intact secondary palate (**E** and **F**).

fetal jaw measurements[102-104] to identify micrognathia more objectively, there is no consensus on methodology. Three-dimensional sonography offers an additional method for the evaluation of micrognathia, because data can be manipulated to obtain a true sagittal view of the fetal face, which might otherwise not be possible.[105] Many fetuses with micrognathia have additional abnormalities,[106-108] so the physician should carefully search for associated anomalies, and fetal karyotyping is recommended. Fetal MRI may also be helpful. A recent study[107] showed that nearly all fetuses with moderate or severe micrognathia on prenatal MRI had Robin sequence. Although micrognathia is generally diagnosed in the second trimester and beyond, some[82] have reported findings of micrognathia identified in the first trimester.

Agnathia is total or partial absence of the lower jaw and is often associated with holoprosencephaly (Fig. 33.29). **Microstomia** is a small mouth, often associated with agnathia and otocephaly.[5]

SOFT TISSUE TUMORS

Soft tissue or bony tumors can cause alterations in head size or shape. A relatively common soft tissue lesion involving the face is a **hemangioma** (Fig. 33.30). Vascular anomalies such as hemangiomas are the most common tumors of infancy, and most are medically insignificant. On fetal sonography, hemangiomas often appear as echogenic, predominantly solid masses. These masses may contain detectable vascular channels with flow on Doppler ultrasound evaluation. Hemangiomas often increase in size during fetal life and can be infiltrative, affecting large areas. Classically, hemangiomas do not infiltrate bony structures. Hemangiomas can occur in any location and can involve the fetal face[109] or neck. With larger lesions, the risk of high-output cardiac failure increases owing to vascular shunting in the lesion. There may also be platelet trapping in the hemangioma, leading to thrombocytopenia (also referred to as "Kasabach-Merritt syndrome"). The adjacent skull may be thinner and may be associated with brain anomalies as in **Sturge-Weber syndrome.**[110-113]

NECK ABNORMALITIES

Nuchal Translucency and Thickening

The **nuchal translucency** (NT) is the fluid collection that forms posterior to the fetal neck during early development. Studies

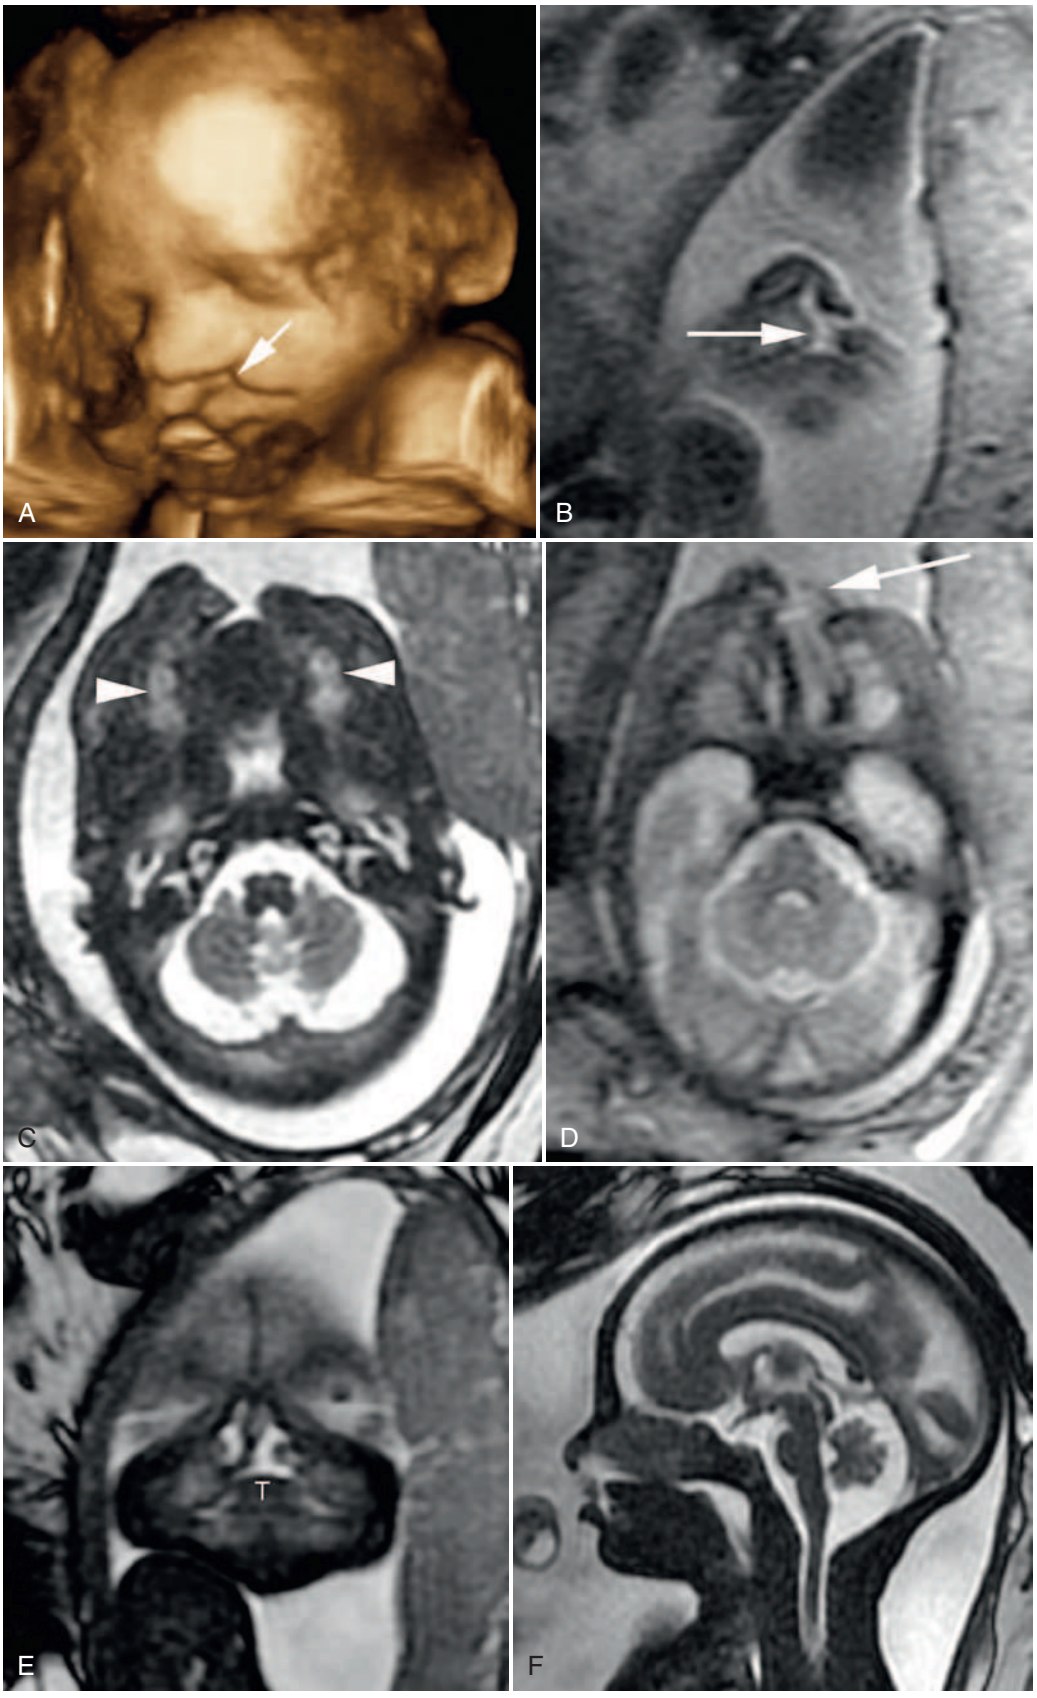

FIG. 33.24 Unilateral Complete Cleft Lip and Palate. (A) Coronal three-dimensional sonogram of the fetal lip and nose shows a normal right nostril and lip, cleft left lip *(arrow),* and a downward-sloping left nostril at 29 weeks' gestation. **(B)** Coronal magnetic resonance imaging (MRI) shows complete left cleft lip, with deformation of left nostril *(arrow).* **(C)** Axial MRI shows complete cleft left alveolus and lip (*arrowheads* indicate lateral margins of bony tooth-bearing alveolus), with greater segment on the right and lesser segment on the left. **(D)** Axial MRI shows deviation of the tip of the bony nasal septum (vomer) away from the side of the cleft *(arrow).* **(E)** Coronal MRI shows an intact right horizontal palatal shelf and absence of the left palatal shelf above the tongue *(T).* Note how a small amount of amniotic fluid in the oral cavity is helpful in making this determination. **(F)** Sagittal MRI shows an abnormally high position of the tongue, in keeping with a complete left cleft lip and palate. See also Videos 33.1, 33.2, and 33.3.

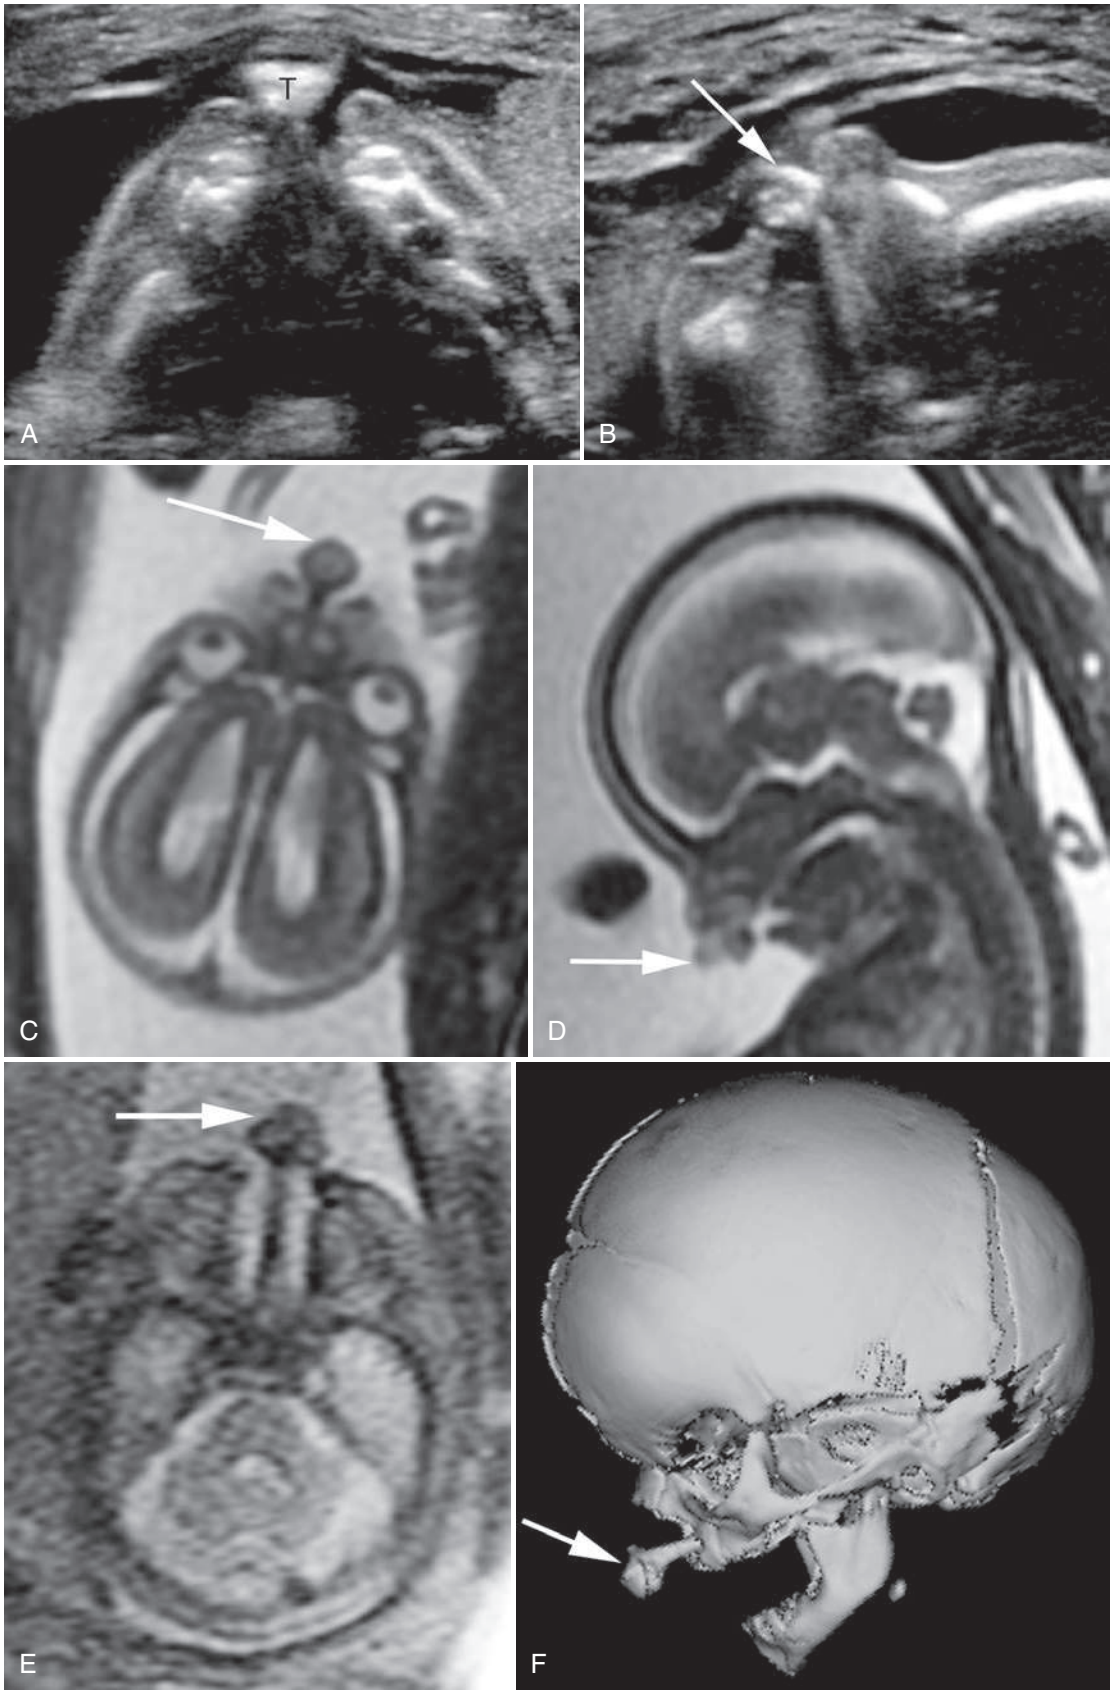

FIG. 33.25 Bilateral Complete Cleft Lip and Palate. (A) Axial sonogram of 18-week fetus with bilateral complete cleft lip and palate shows bilateral clefts in the tooth-bearing alveolus of the maxilla, with two tooth buds *(T)* displaced anteriorly in the intermaxillary segment. **(B)** Sagittal sonogram shows protrusion of the intermaxillary segment of the maxilla *(arrow)*. **(C)** and **(D)** Oblique axial and sagittal MR images show bilateral cleft lip and the anteriorly displaced intermaxillary segment of the maxilla *(arrow)*. **(E)** In a different fetus at 22 weeks with **Pfeiffer syndrome,** axial magnetic resonance imaging shows bilateral cleft palate with displaced intermaxillary segment of the maxilla *(arrow)* (see also Fig. 33.13). **(F)** Postnatal three-dimensional computed tomography reconstruction shows coronal craniosynostosis and the marked anterior position of the intermaxillary segment *(arrow)*.

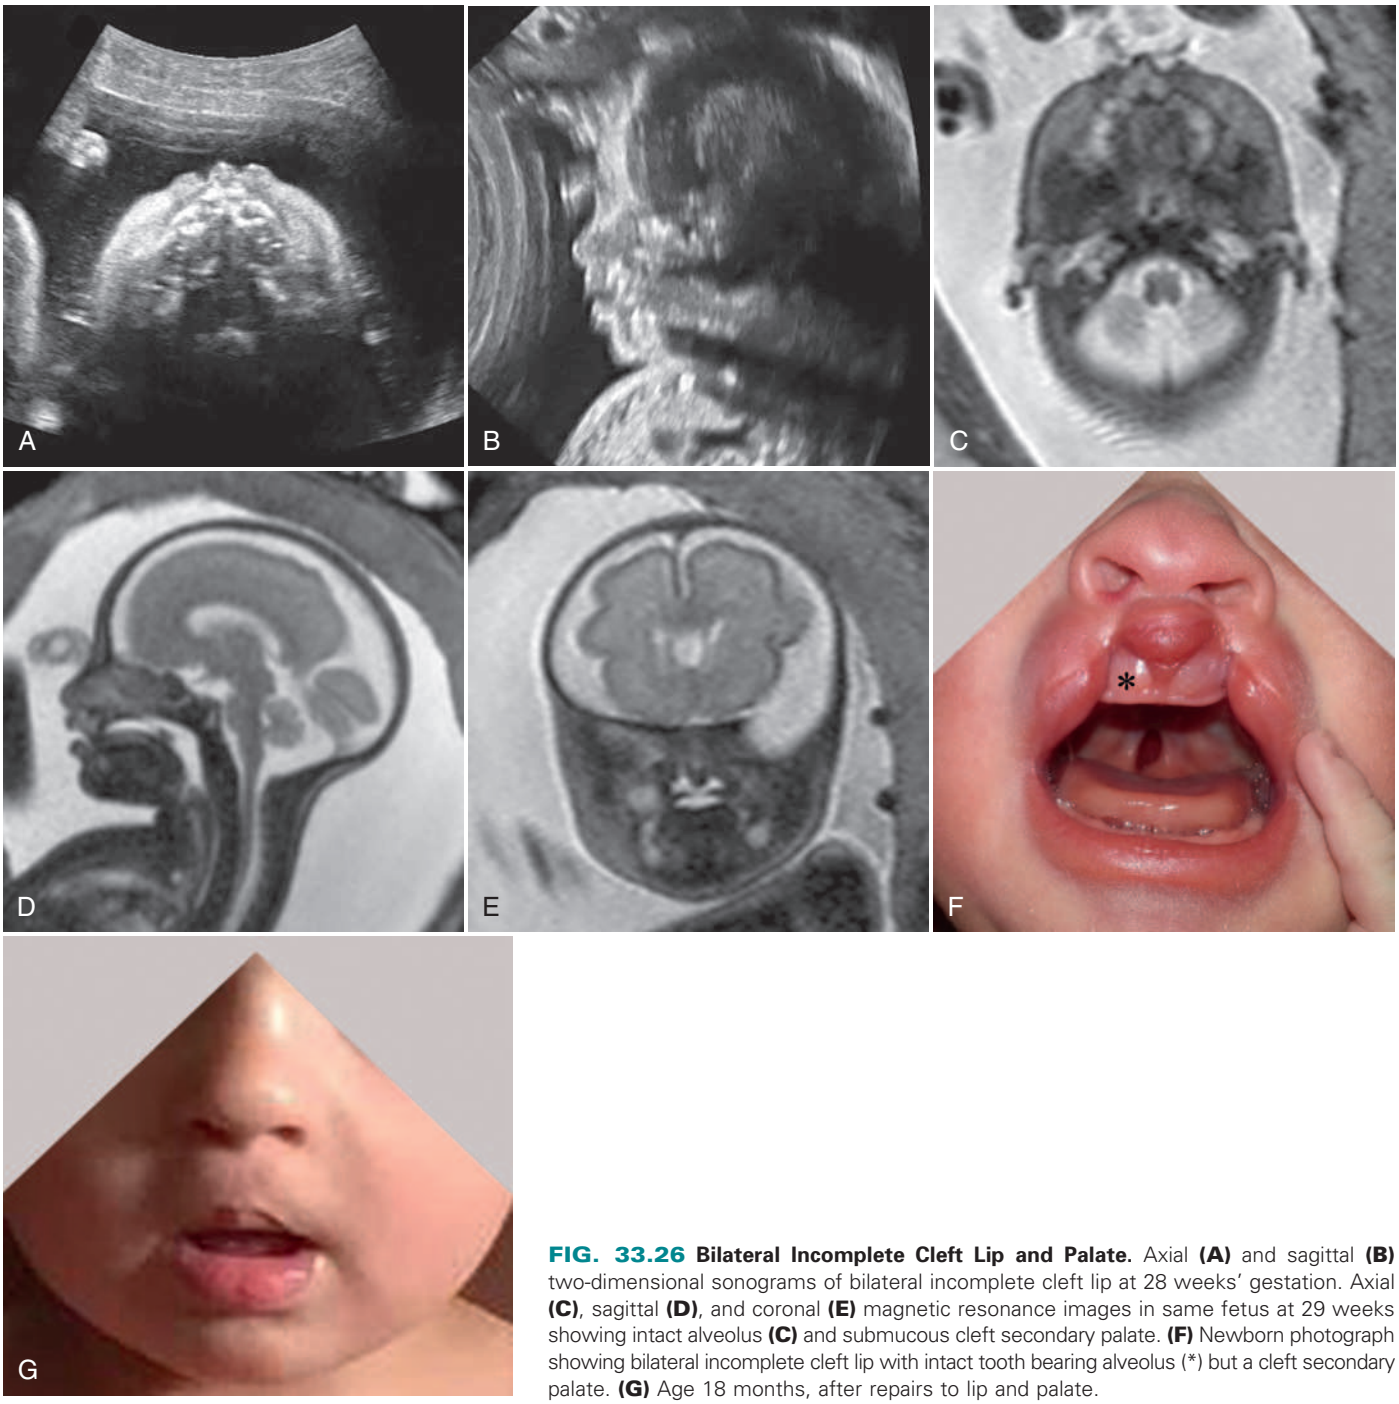

FIG. 33.26 Bilateral Incomplete Cleft Lip and Palate. Axial **(A)** and sagittal **(B)** two-dimensional sonograms of bilateral incomplete cleft lip at 28 weeks' gestation. Axial **(C)**, sagittal **(D)**, and coronal **(E)** magnetic resonance images in same fetus at 29 weeks showing intact alveolus **(C)** and submucous cleft secondary palate. **(F)** Newborn photograph showing bilateral incomplete cleft lip with intact tooth bearing alveolus (*) but a cleft secondary palate. **(G)** Age 18 months, after repairs to lip and palate.

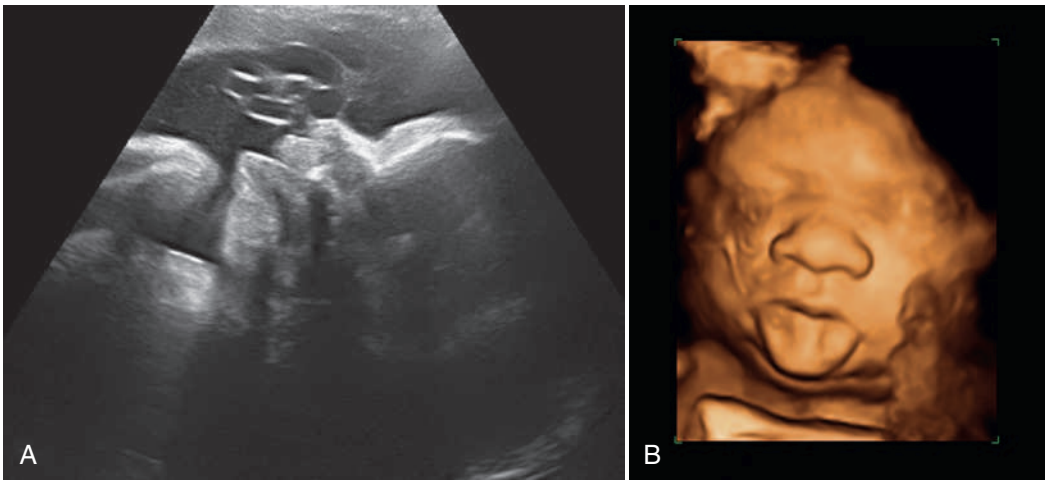

FIG. 33.27 Abnormal Tongue. Sagittal sonogram **(A)** and 3D ultrasound **(B)** showing macroglossia in a 33-week fetus with Beckwith-Wiedemann syndrome.

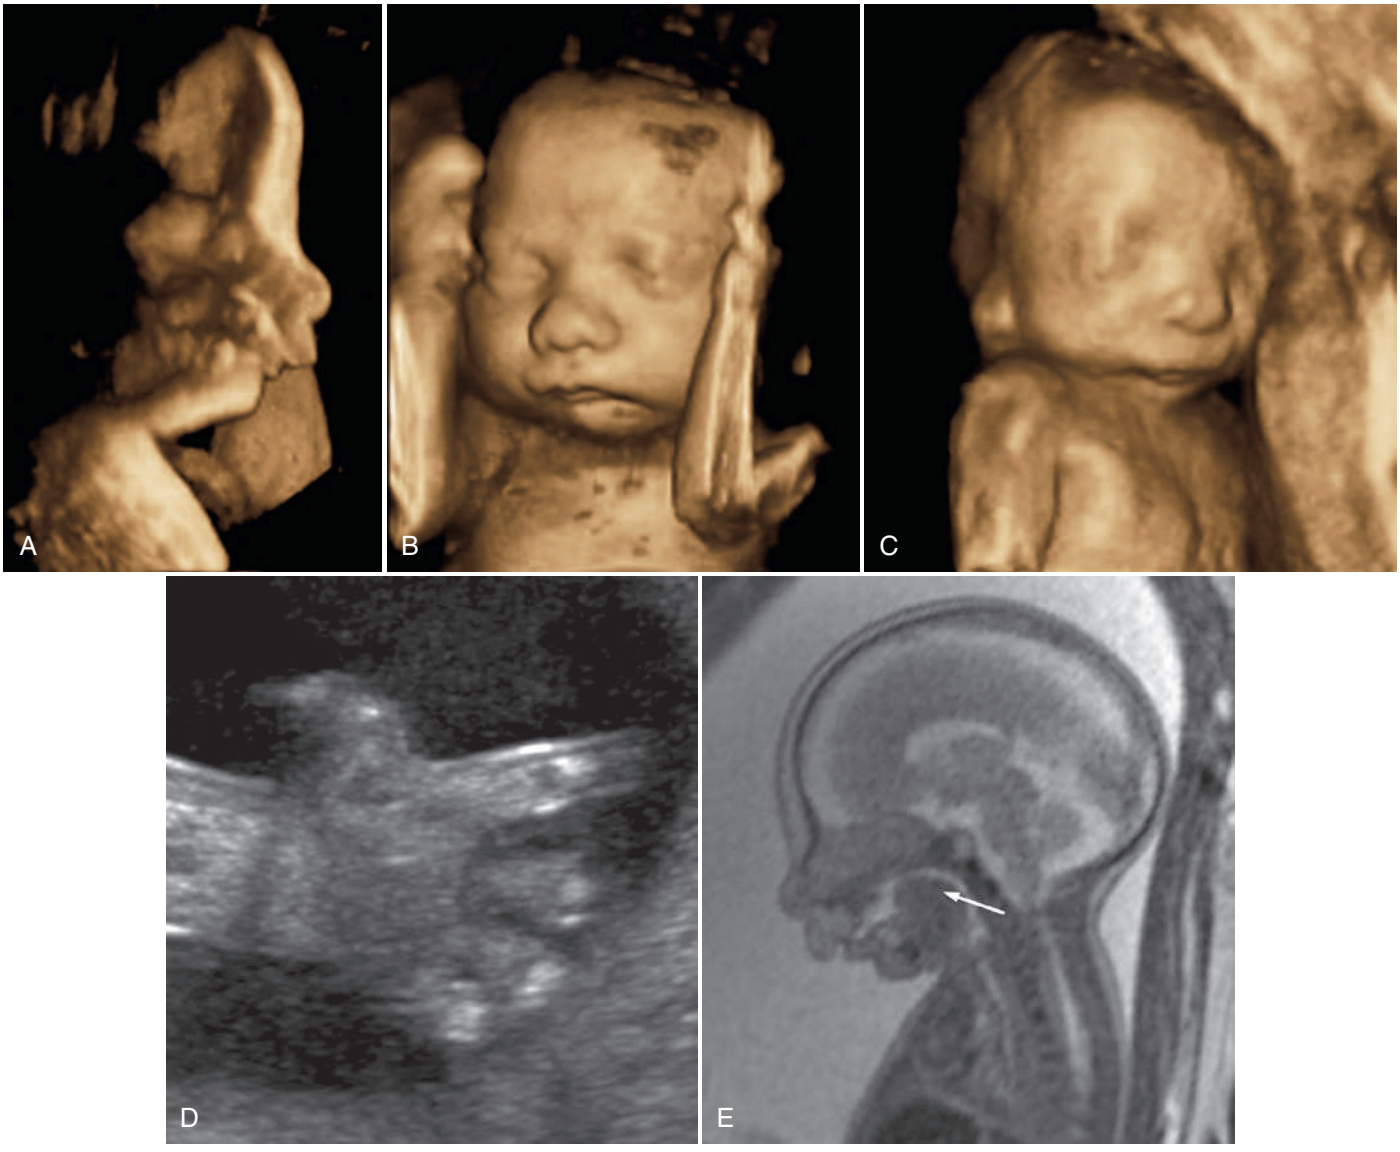

FIG. 33.28 Micrognathia. (A) and **(B)** Three-dimensional fetal sonogram at 33 weeks shows micrognathia; fetus also had high-riding posterior tongue, secondary palatal defect, left nasolacrimal duct cyst, and ventriculomegaly. **(C)-(E)** In a different fetus at 24 weeks. **(C)** Three-dimensional sonogram shows micrognathia. **(D)** Two-dimensional sonogram shows a hyperextended thumb, and **(E)** magnetic resonance imaging shows micrognathia and cleft secondary palate. Note high position of the tongue *(arrow)*. See also Video 33.4.

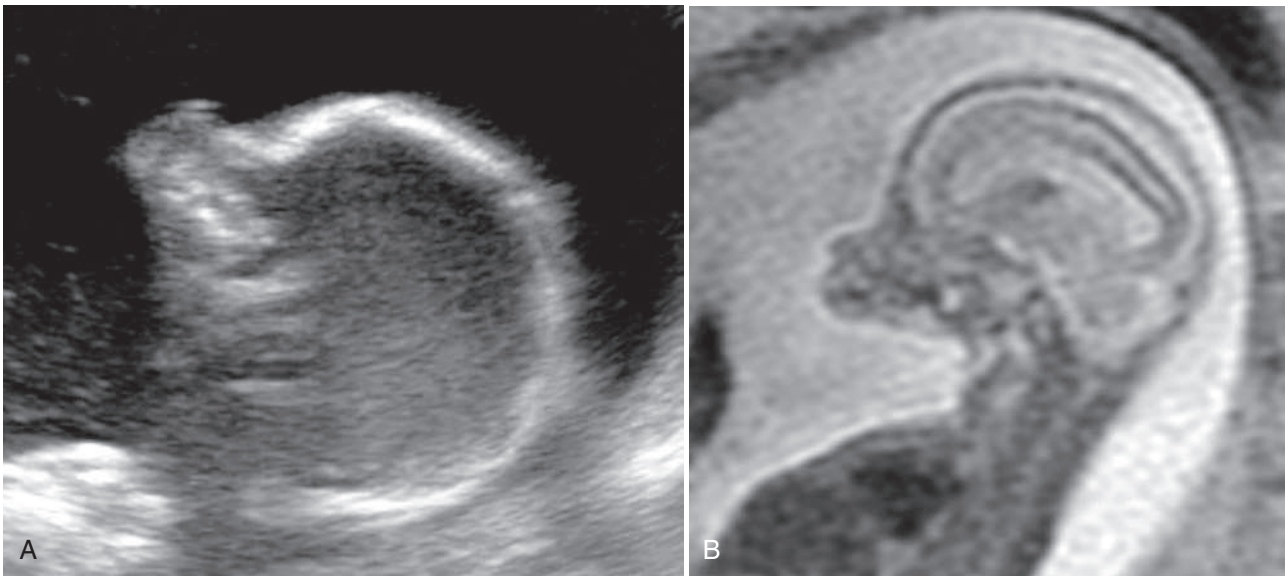

FIG. 33.29 Agnathia Microstomia. (A) Sagittal sonogram, and **(B)** magnetic resonance image show the absent mandible.

have shown that thickened NT measurements in the first trimester are associated with fetal aneuploidy, cardiac defects, other major malformations, and adverse pregnancy outcome.[114-118] Images must be obtained in midsagittal plane[119] by trained sonographers, and measurements are combined with patient age, gestational age, and serum testing to give a risk for aneuploidy (see Chapter 31). In the second trimester, the **nuchal fold thickness** is measured in the suboccipital bregmatic plane. A measurement of 6 mm or greater from 15 to 22 weeks is associated with an increased risk of trisomy 21.[120,121] The measurement is taken in the midline from the outer edge of the occipital bone to the outer edge of the skin.

Lymphatic Malformation (Cystic Hygroma)

Lymphatic malformation, known historically as "cystic hygroma," is a septated fluid collection behind the fetal neck, thought to result from early maldevelopment of the lymphatic system. This abnormality is highly associated with **Turner syndrome** (XO), other chromosomal anomalies, and cardiac structural abnormalities. When associated with hydrops, fetal mortality is very high. As with an increased NT, if a lymphatic malformation is diagnosed and chromosomes are found to be normal, the fetus should still be carefully evaluated for cardiac abnormalities.

Lymphatic malformations can occur elsewhere in the head and neck and may be microcystic or macrocystic. They are presumed to result from obstructed lymphatic sacs that do not communicate with main lymphatic channels. Although benign, morbidity is associated with mass effect on the fetal airway when such masses arise in the face and neck (Fig. 33.31). In this setting, fetal MRI is often useful for evaluation of the fetal airway and for delivery planning. Fluid-filled lymphatic malformations, even when large, are much more malleable than solid teratomas of the head and neck and are less likely to compromise the airway. When these malformations involve the tongue, cystic hygromas may interfere with swallowing and feeding after birth.

Cervical Teratoma

Teratoma is the most common tumor in neonates, with the majority located at the sacrum and coccyx. Approximately 5% of teratomas arise in the neck or oropharynx. Cervical teratomas occur equally in males and females.[122] Sonographically, teratomas are usually complex masses composed of both cystic and solid elements and are often associated with regions of calcification. There is usually vascular flow within the solid portions of the mass. In the neck, they are usually anterolateral in location and can become quite large, often involving the thyroid gland. When they arise in the neck, teratomas may impinge on the airway, interfere with fetal swallowing, and result in polyhydramnios. Evaluation of the fetal airway is particularly important to delivery planning and is often best accomplished with fetal MRI (Fig. 33.32).

When teratomas arise in the neck, there can be hyperextension of the fetal neck, best seen in sagittal views. Teratomas of the oropharynx **(epignathus)** often protrude from the mouth. Although most teratomas are histologically benign, prognosis depends on the degree of mass effect on the trachea and the ability to secure the infant's airway at delivery. If there is substantial mass effect on the airway, the **ex utero intrapartum treatment (EXIT) procedure** may be necessary. This complex procedure requires a team of specialists for the mother and fetus and involves cesarean delivery, with preservation of the maternal-fetal circulation through the placenta until the neonatal airway can be secured.[123-127]

Thyromegaly and Goiter

Fetal goiter is rare (1 per 30,000 to 50,000 live births)[128] and most often related to maternal thyroid disease, such as **Graves disease**[129] or **Hashimoto thyroiditis,** with antibodies that cross the placenta and lead to fetal thyroid dysfunction. Maternal use of **thyroid blocking agents** (e.g., propylthiouracil) may also result

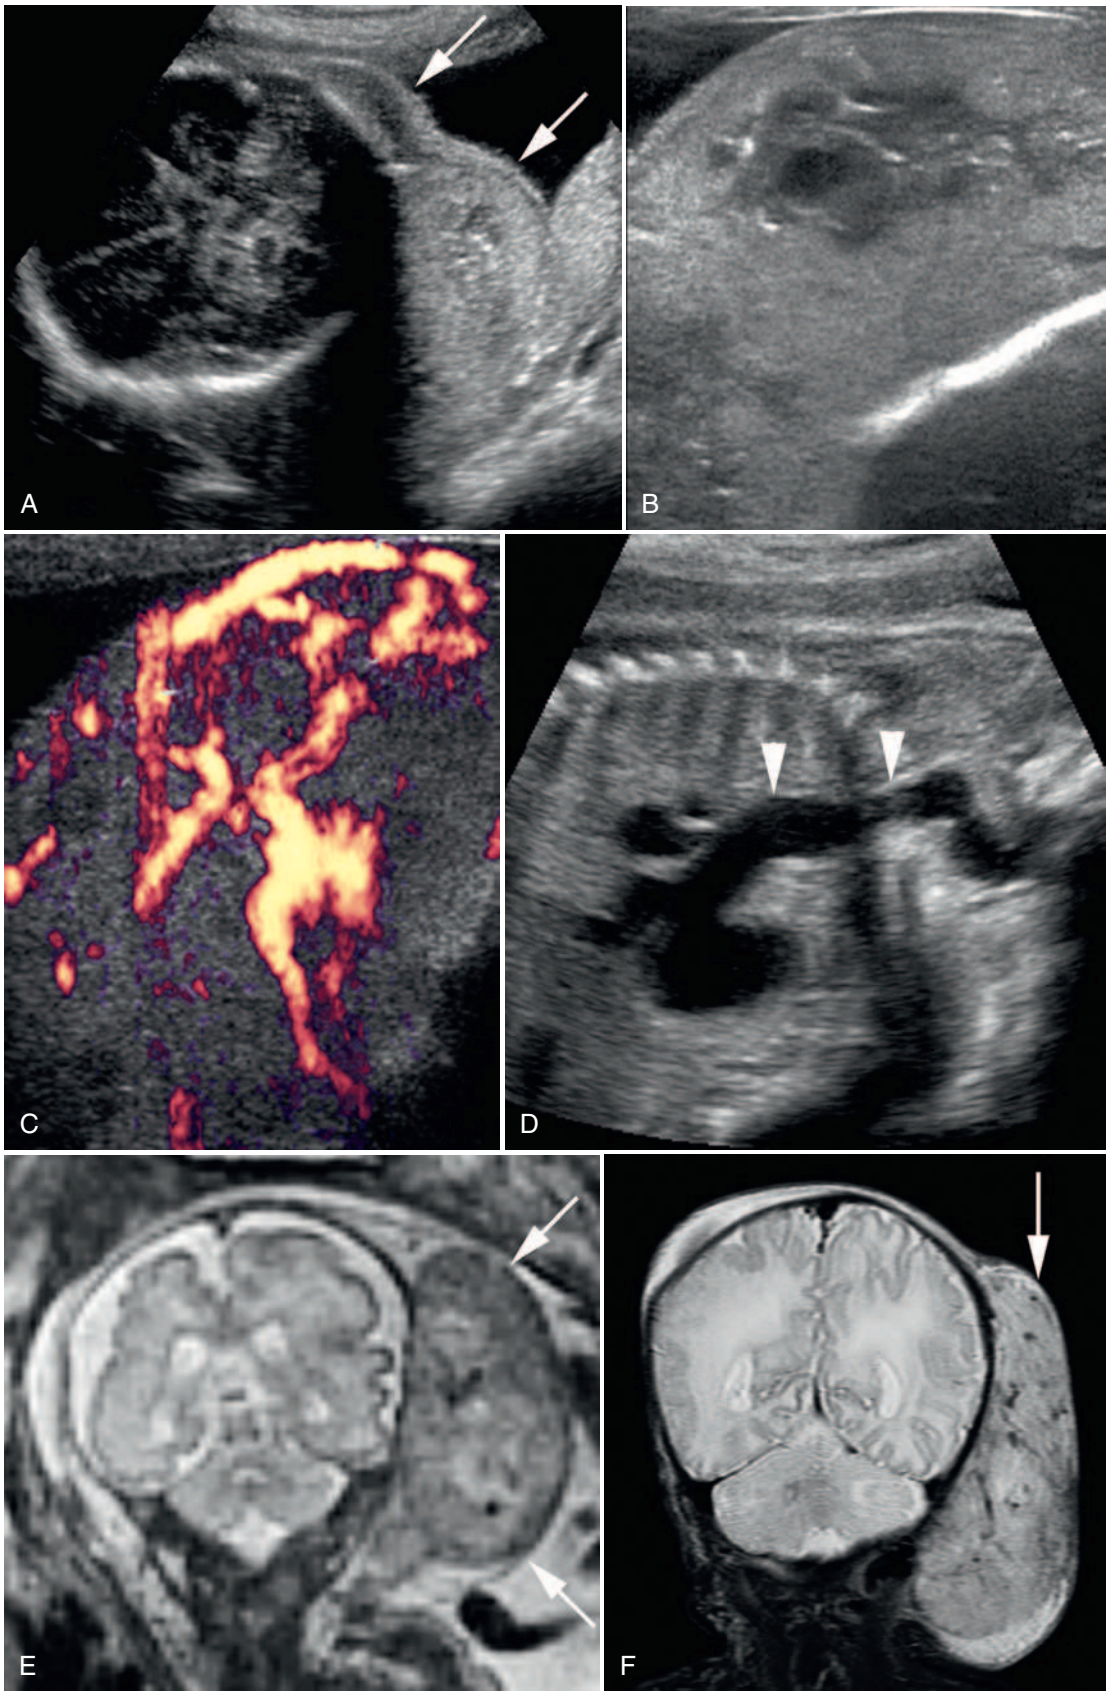

FIG. 33.30 Hemangioma at 30 Weeks' Gestation. (A) Axial sonogram shows a large, lateral and posterior soft tissue scalp mass *(arrows).* **(B)** High-frequency coned-down view illustrates the heterogeneous echogenicity of the mass. **(C)** Power Doppler view demonstrates the vascularity of the mass. **(D)** Oblique sonogram of the fetal chest and neck show a greatly enlarged superior vena cava *(arrowheads).* The heart was also enlarged, and the fetus was in heart failure from the volume of blood circulating through the scalp mass. **(E)** Coronal prenatal and **(F)** postnatal magnetic resonance images show the left scalp mass *(arrows).*

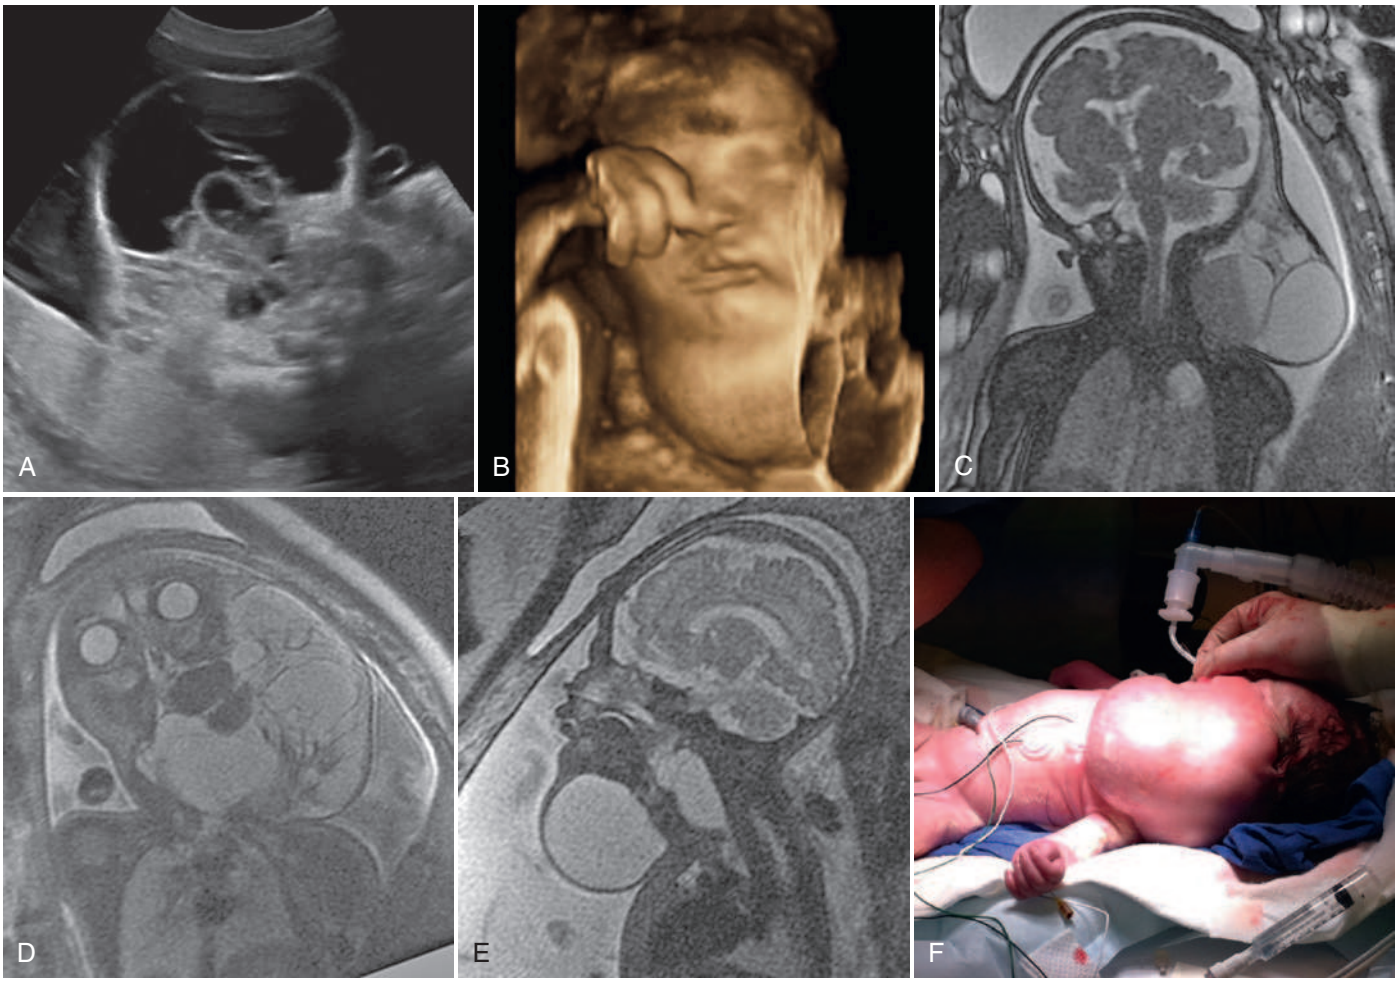

FIG. 33.31 Lymphatic Malformation. (A) Two-dimensional sonogram of left neck mass at 35 weeks showing complex cystic and solid appearance. **(B)** Three-dimensional sonogram showing left-sided mass. Coronal (**C** and **D**) and sagittal **(E)** fetal magnetic resonance images show the complex mass, potentially blocking the airway. **(F)** The newborn, with large left-sided neck mass, was successfully intubated during delivery by EXIT (ex utero intrapartum treatment) procedure.

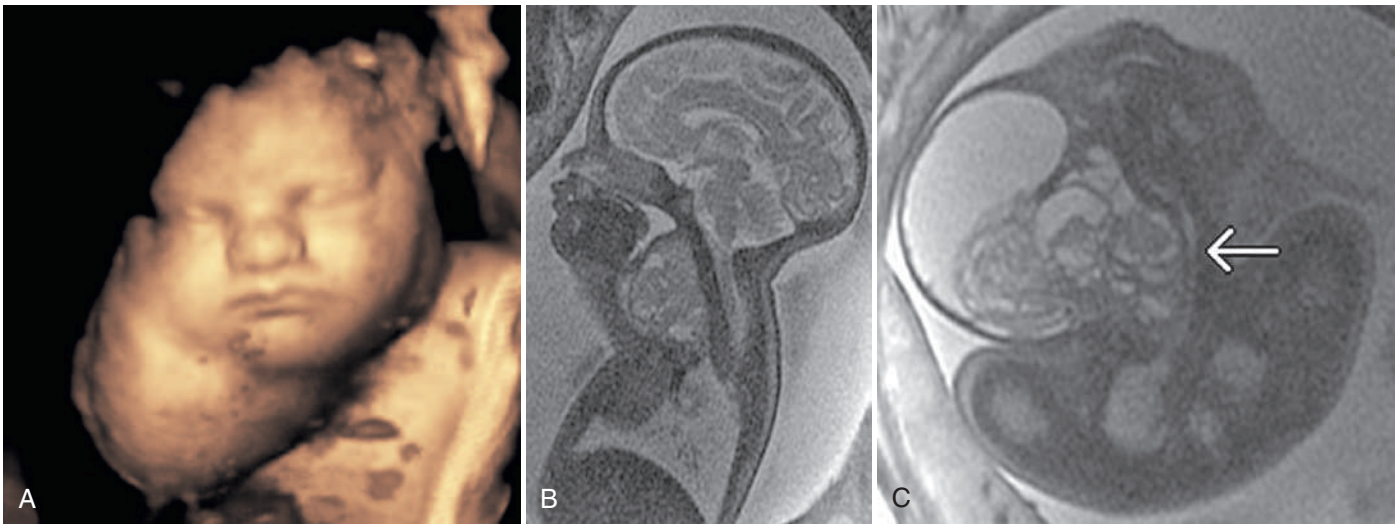

FIG. 33.32 Teratoma. (A) Three-dimensional sonogram at 34 weeks shows a right-sided cervical teratoma. Sagittal **(B)** and axial **(C)** T2-weighted fetal magnetic resonance images. Note visualization of the trachea *(arrow),* suggesting that the airway would likely be patent at birth.

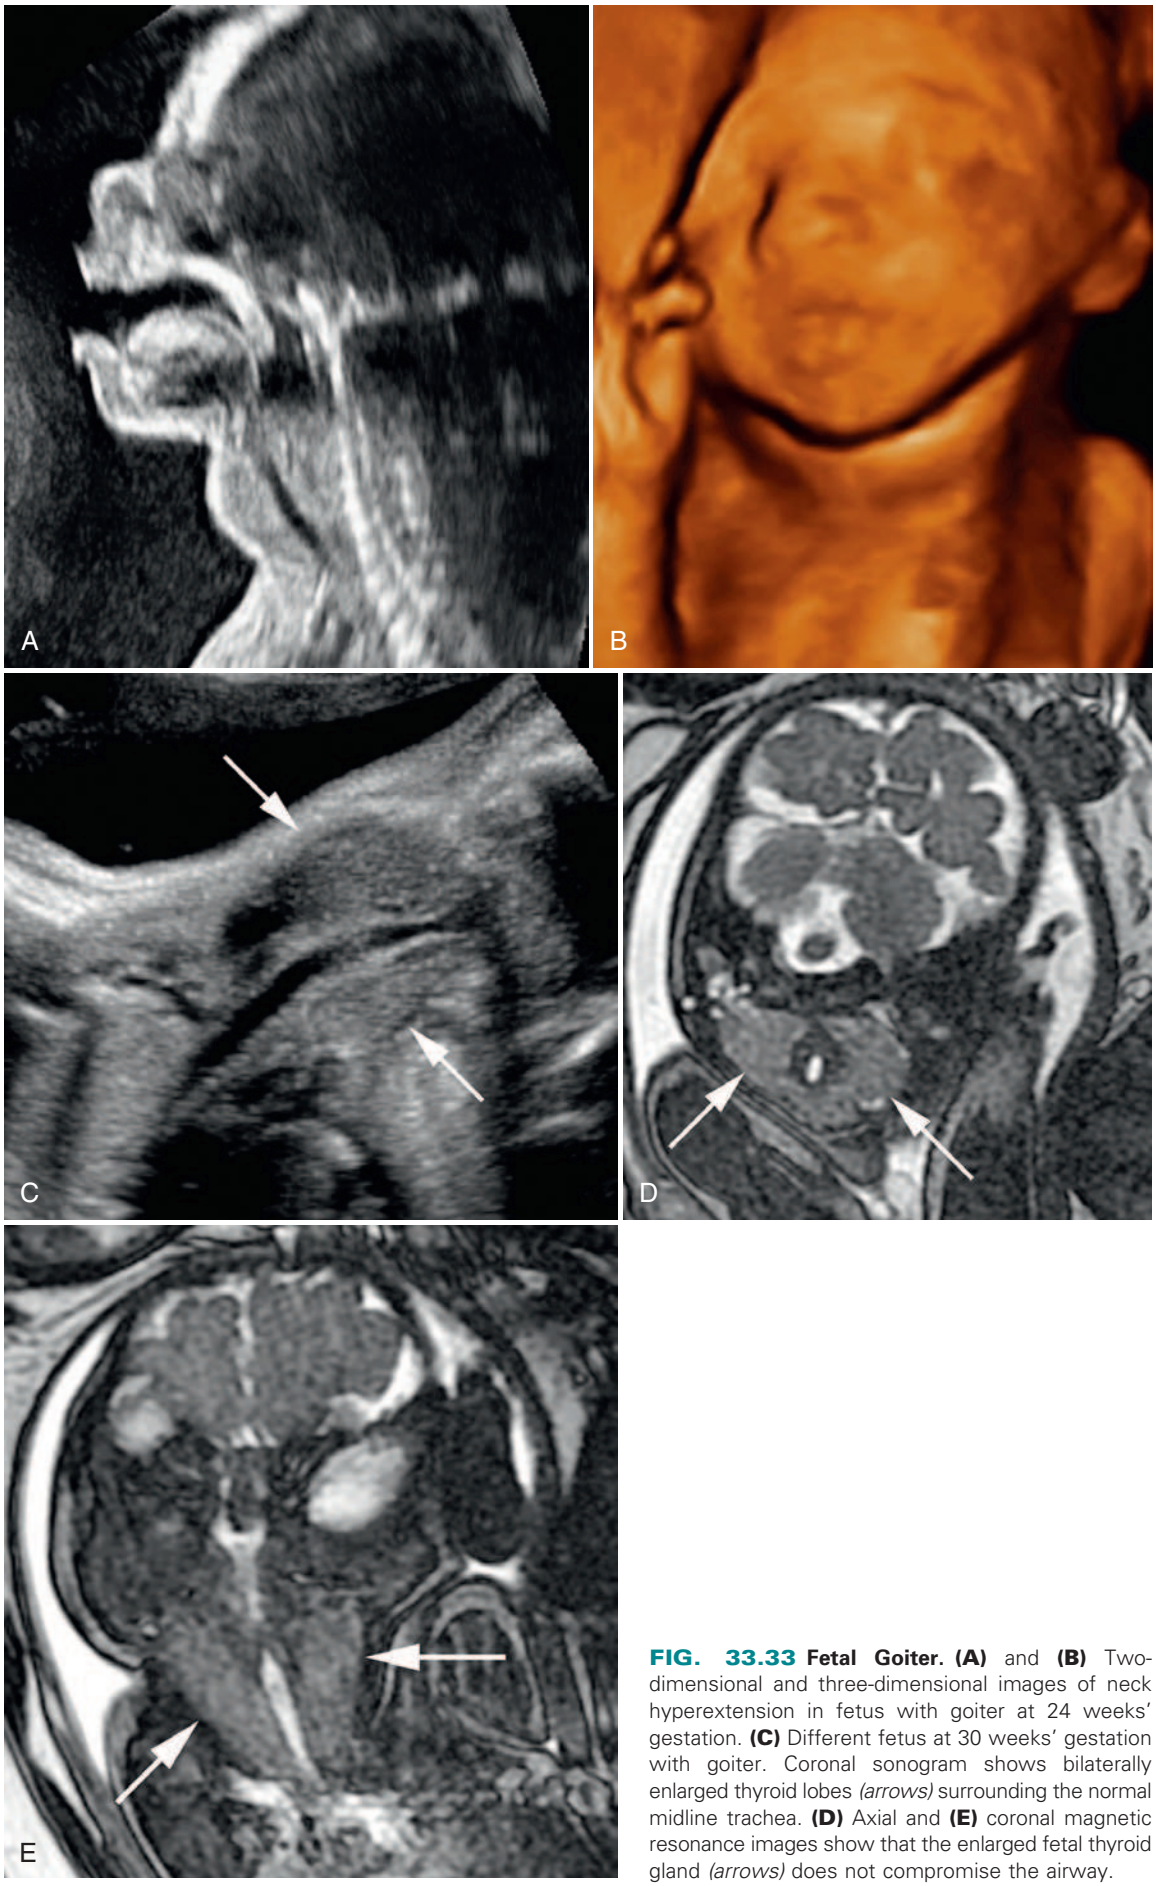

FIG. 33.33 Fetal Goiter. (A) and **(B)** Two-dimensional and three-dimensional images of neck hyperextension in fetus with goiter at 24 weeks' gestation. **(C)** Different fetus at 30 weeks' gestation with goiter. Coronal sonogram shows bilaterally enlarged thyroid lobes *(arrows)* surrounding the normal midline trachea. **(D)** Axial and **(E)** coronal magnetic resonance images show that the enlarged fetal thyroid gland *(arrows)* does not compromise the airway.

in fetal goiter. Primary fetal thyroid dysfunction may also cause goiter.

Fetal goiter appears as a midline homogeneous solid mass in the anterior neck surrounding the trachea (Fig. 33.33). There may be increased blood flow to the goiter. When large, fetal goiters cause hyperextension of the neck, leading to interference with fetal swallowing and resultant polyhydramnios. Neck hyperextension can lead to fetal malpresentation and can cause difficulties at delivery. Cordocentesis may be necessary to determine if there is fetal hypothyroidism or hyperthyroidism. In the setting of fetal **hypothyroidism,** treatment with intraamniotic thyroid hormone will often lead to a decrease in size of the fetal goiter.[130] After treatment with intrauterine thyroxine, fetal goiter may decrease in size, and hyperextension of the fetal neck may resolve. In cases of fetal **hyperthyroidism,** it is important to evaluate for fetal tachycardia and high-output cardiac failure.

CONCLUSION

Prenatal sonographic evaluation of the fetal face and neck offers an opportunity to identify many abnormalities. These observations are often essential to prenatal counseling and prognosis because of the association of many of these abnormalities with syndromes and chromosomal anomalies. Appropriate diagnosis of abnormalities allows for planning of the appropriate mode of delivery and therapy when the fetal airway is potentially compromised.

Acknowledgments

We would like to acknowledge with gratitude the assistance of librarians Alison Clapp and Miriam Geller and the administrative assistance of Susan Ivey, Department of Radiology, at Children's Hospital Boston. Special thanks also to Ants Toi, MD, for the discussion on craniosynostosis.

CHAPTER 34

The Fetal Brain

Ants Toi and Deborah Levine

SUMMARY OF KEY POINTS

- Protocol-based ultrasound carefully performed by a knowledgeable and experienced examiner following established guidelines is very sensitive in evaluating the central nervous system (CNS).
- Ventriculomegaly can be due to many underlying conditions, including obstruction, destruction, and dysmorphism, or a combination.
- In cases of brain abnormalities in which additional morphologic or functional information is needed beyond that available with ultrasound, magnetic resonance imaging can be helpful.
- Best results in assessment of complex CNS abnormalities are obtained when there is a multidisciplinary consultation and collaboration among specialists in imaging, genetics, and prenatal and postnatal care.

CHAPTER OUTLINE

DEVELOPMENTAL ANATOMY
Embryology
Sonographic Anatomy
Variants (Usually Normal)
Choroid Plexus Cysts
Blake Pouch Cyst
Cavum Veli Interpositi
VENTRICULOMEGALY AND HYDROCEPHALUS
Pathogenesis of Ventriculomegaly
Ultrasound Evaluation of Ventriculomegaly
SPECIFIC ABNORMALITIES
ERRORS OF DORSAL INDUCTION
Anencephaly and Exencephaly
Cephalocele and Encephalocele
Ciliopathies

CONCLUSION
Acknowledgments

Anomalies of the central nervous system (CNS) are the most common cause of referral for prenatal diagnosis and result in great anxiety for parents. CNS anomalies occur with a frequency of about 1.4 to 1.6 per 1000 live births but are seen in about 3% to 6% of stillbirths.[1] The increased use of maternal serum alpha-fetoprotein (MS-AFP) screening and first-trimester nuchal translucency (NT) screening has resulted in increased numbers of pregnancies being referred for evaluation of the CNS and suspected anomalies. Fortunately, protocol-based ultrasound carefully performed by a knowledgeable and experienced examiner following established guidelines is very sensitive in evaluating the CNS.[2-6] Routine scanning is currently recommended at 18 to 20 weeks of gestation. Although many cerebral anomalies are detectable in the first trimester and early second trimester, others develop or become apparent only later in pregnancy.[7-11]

Magnetic resonance imaging (MRI) has become an important supplement after initial ultrasound evaluation. Multiparametric MRI using special sequences allows evaluation of areas that are difficult to assess with ultrasound, can be used to evaluate tissue properties beyond morphology, and provides new insights into ischemia, tumor characteristics, bleeding, brain metabolism, and neural tracts, which can allow unprecedented clarification of suspected disorders.[12-15] Debate continues regarding the role of ultrasound versus MRI in evaluating the fetal CNS.[16,17] We believe that ultrasound will continue to be the initial screening modality and that MRI will increasingly be used to clarify findings. The

important issues for the examiner are familiarity with the strengths and limitations of all imaging modalities, expertise in their use, and collaboration with specialists in other disciplines.[15,18-20]

DEVELOPMENTAL ANATOMY

Embryology

Knowledge of fetal gestational age is particularly important when evaluating anatomy in early pregnancy. In this chapter we use **menstrual age** and **gestational age** as typically used clinically and with ultrasound studies to mean "age from last menses" or "postmenstrual weeks." For consistency will convert "fertilization age" or "conception age" used in publications to menstrual age by adding 2 weeks.

CNS development is controlled by numerous genes with functions not only in the CNS but also in the rest of the body, and the understanding of the molecular basis of development and malformations is occurring at an explosive rate.[21] Morphologic changes start at about the fifth menstrual week when cells destined to form the notochord infiltrate into the embryonic disc and induce the overlying embryonic tissue to thicken, fold over, and fuse as the neural tube. Zipperlike fusion starts in the midtrunk of the embryo and then extends to the cranial and caudal ends (Table 34.1). Final anterior closure, at the **rostral neuropore,** occurs by about 5½ menstrual weeks, and a few days later at the **caudal neuropore.** By the sixth week, the cephalic end enlarges and flexes to become the brain.[22,23] Transvaginal ultrasound and *in vitro* MRI can demonstrate many of the stages.[8,9,24] By 12 to 15 menstrual weeks, almost all structures and processes are in their final form except for the **corpus callosum, cerebellar vermis, neuronal migration** (from the periventricular germinal matrix), development of the **sulci** and **gyri,** and **myelination.** These latter structures and processes develop from about 15 weeks onward. The corpus callosum starts developing at about 12 weeks. Its development induces the formation of the two septi pellucidi and the intervening space, the **cavum septi pellucidi** (CSP) and **cavum Vergae** (after Andrea Verga in 1851).[8,25]

TABLE 34.1 Differentiation of Brain Regions From Primary Vesicles

Primary Vesicle	Secondary Vesicle	Mature Structure
Forebrain	Telencephalon	Cerebral hemispheres Basal ganglia Olfactory system
	Diencephalon	Thalamus Hypothalamus
Midbrain	Mesencephalon	Midbrain
Hindbrain	Metencephalon	Pons Cerebellum
	Myelencephalon	Medulla

Modified from Moore K. Essentials of human embryology. Toronto, Ontario: BC Decker; 1988.[26]

The dorsal aspect of the neural tube at the hindbrain **(rhombencephalon)** is very thin and membranous (**membranous area** or **area membranosa**). In the first trimester, the enclosed central neural canal, the rhombencephalic cavity, is very large and forms a conspicuous cystic cavity that should not be mistaken for an abnormality.[8] This space eventually becomes the fourth ventricle. The membrane is divided into an anterior rostral area (anterior membranous area or area membranosa rostralis) and posterior caudal area (posterior membranous area or area membranosa caudalis) by a fold, the plica choroidea, which will become the choroid of the fourth ventricle. The **cerebellum** and **vermis** develop as lateral and rostral proliferations into the anterior membranous area. The posterior membranous area eventually fenestrates to form the foramina of Magendie and Luschka. The posterior membranous area can bulge into the cisterna magna to a variable extent, forming the **Blake pouch.** With high-resolution equipment, the Blake pouch can be seen in most fetuses, where it is often mistaken for arachnoid strands.[27-29] The cerebellum and vermis are essentially formed by 22 weeks. Care must be taken before 22 weeks to avoid mistaking the incompletely developed early vermis for vermian dysplasia or hypoplasia.[30]

Cortex and neuron development starts at about 5 weeks and is complete by 28 weeks. There are three complex overlapping stages: proliferation, migration, and organization. Neurons proliferate and develop from glial stem cells at the surface of the ventricles and ganglionic eminence. Migration occurs via two pathways, projectional and tangential. In projectional migration, neurons follow a radially oriented glial scaffold directly to the cortical surface, with later-forming neurons passing through the earlier layers to the pial surface. From 17 to 34 weeks, this migration can be seen as bands or laminations that are visible on MRI and ultrasound as the ventricular zone, intermediate zone, subplate zone, and cortical plate. This regular pattern is disturbed with migrational disorders, malformations, and infections such as cytomegalovirus (CMV).[31-33] In tangential migration, GABAergic cells from the ganglionic eminence take a tangential route through the cortex and provide neurons with controlling functions. The ganglionic eminence overlying the thalamus is more evident on MRI than ultrasound.[34,35] The cortex undergoes folding into gyri to accommodate the extra cells. Finally, neurons in the cortex organize local connections and send axons remotely as large tracts such as the corpus callosum to connect the hemispheres. Development requires normally functioning genes and is easily disrupted by intrinsic and extrinsic insults such as fetal and maternal metabolic disorders, hypoxia, infections, and teratogens. Note that with teratogens, the final morphologic appearance reflects the gestational age and stage at which disruption occurred, rather than the specific agent.[21,36]

Sonographic Anatomy

The early embryo is best examined transvaginally. The cephalic end is identifiable by about 8 weeks. By 10 or 11 weeks, bones of the vault show mineralization. At this age, the brain mantle is very thin. The ventricles are large and filled with choroid, which provides nourishment for the developing brain.[37] A large, echo-free space behind the hindbrain represents the **rhombencephalic cavity,** which decreases in size as the cerebellum forms

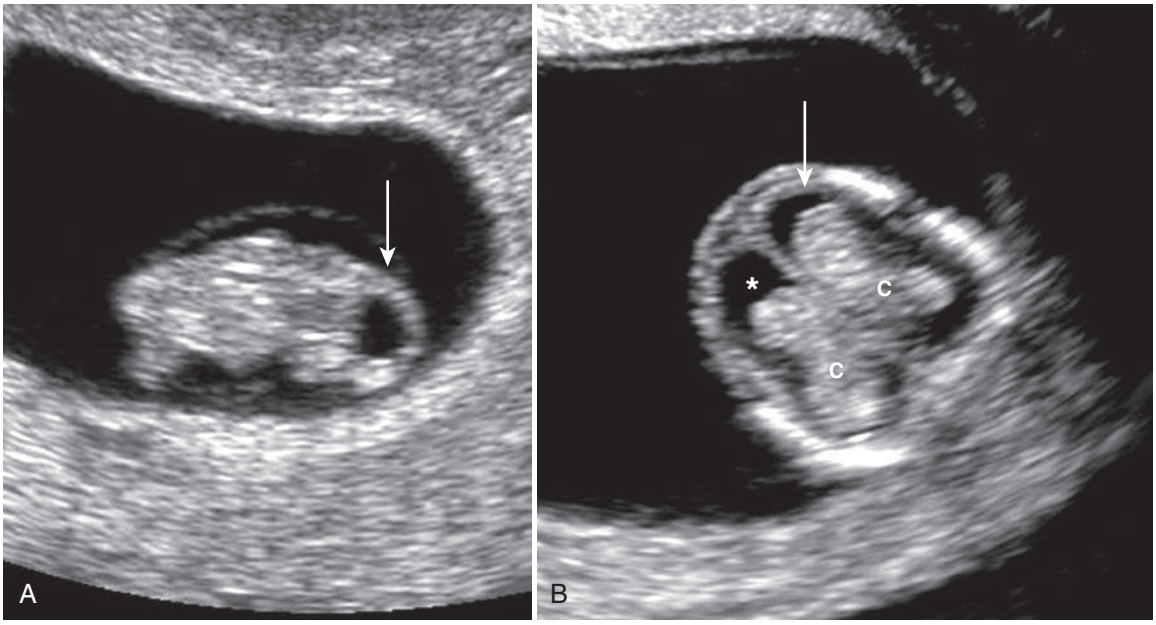

FIG. 34.1 Early Normal Fetal Head Images Obtained With Transvaginal Probe. (A) At 8 menstrual weeks the head is clearly differentiated from the trunk and limb buds. The intracranial cystic structure is the fetal rhombencephalic cavity *(arrow),* a normal space that eventually becomes the fourth ventricle. **(B) Scan at 12½ weeks.** Note that the cerebral cortex is very thin *(at tip of arrow).* The choroid plexuses *(C)* are very large and fill the ventricles (*) from side to side. Ossification is already visible in the skull bones.

and is destined to become the fourth ventricle. In the first trimester the normal rhombencephalic cavity appears especially large and prominent and should not be mistaken for an abnormality[8,38] (Fig. 34.1A).

After 13 or 14 weeks, most cerebral structures can be identified ultrasonographically (see Fig. 34.1B). In the second trimester, three standard transaxial planes or views (thalamic, ventricular, and cerebellar) can lead to the detection of more than 95% of sonographically detectable cerebral anomalies.[2,3,5,39] These three views (thalamic view, ventricular view, and cerebellar view) form the starting point for routine scanning. If abnormality is suspected, then additional views including transvaginal scan and the midline view to assess the corpus callosum and vermis are useful to clarify problems[5,20,40] (Fig. 34.2, Video 34.1, Video 34.2, and Video 34.3).

Cranial Structures to Note at Routine Anatomic Scan

Measurement of biparietal diameter and head circumference
Head shape
Bone density
Falx and interhemispheric fissure
Ventricle size and appearance
Cavum of the septi pellucidi (CSP)
Thalamus
Cerebellum and vermis
Cisterna magna
Nuchal fold
(Median view for corpus callosum and vermis—not part of routine scanning, but increasingly being done)

The **thalamic view** displays the **thalamus, third ventricle, fornices, basal ganglia, insula,** and **ambient cistern** and is used to measure the biparietal diameter (BPD), occipitofrontal diameter (OFD), and head circumference (HC) (see Fig. 34.2A). The smooth straight interhemispheric fissure is visible on this and the ventricular view. If the fissure appears irregular, then abnormalities of the corpus callosum and other cerebral structures should be suspected.[41,42] The **ventricular view** is slightly higher than the thalamic view and shows the bodies and, more important, the **atria of the lateral ventricles** as well as the **interhemispheric fissure** (see Fig. 34.2B).

Atrial width (occipital horn width) is the most useful and accepted measurement of ventricular size.[3,5,6] The atrium of the lateral ventricles is the site of confluence of the bodies, occipital horns, and temporal horns. Fortuitously, with abnormalities this is the part of the ventricle that undergoes the earliest and most marked enlargement. Ventricular measurement is a required element of routine scans and is easily performed during routine obstetric scanning. Usually only the distal ventricle is measured because the closer ventricle is obscured by artifact; it is assumed that the ventricles are symmetrical, but mild asymmetry is common (Fig. 34.3). Measurements should be performed in a very standardized manner on true axial views. Calipers should be placed touching the inner walls of the ventricles opposite the deepest part of the parieto-occipital fissure; a normal value is taken as below 10 mm.[39] Ventricular abnormality, especially enlargement, is a key finding in the initial detection of CNS abnormalities and is seen in about 88% of fetuses with cerebral abnormalities.[39,43]

The **cerebellar view** is obtained by rotating the transducer into a suboccipitobregmatic plane centered on the thalamus to show the **cerebellar hemispheres.** This view shows the cerebellum,

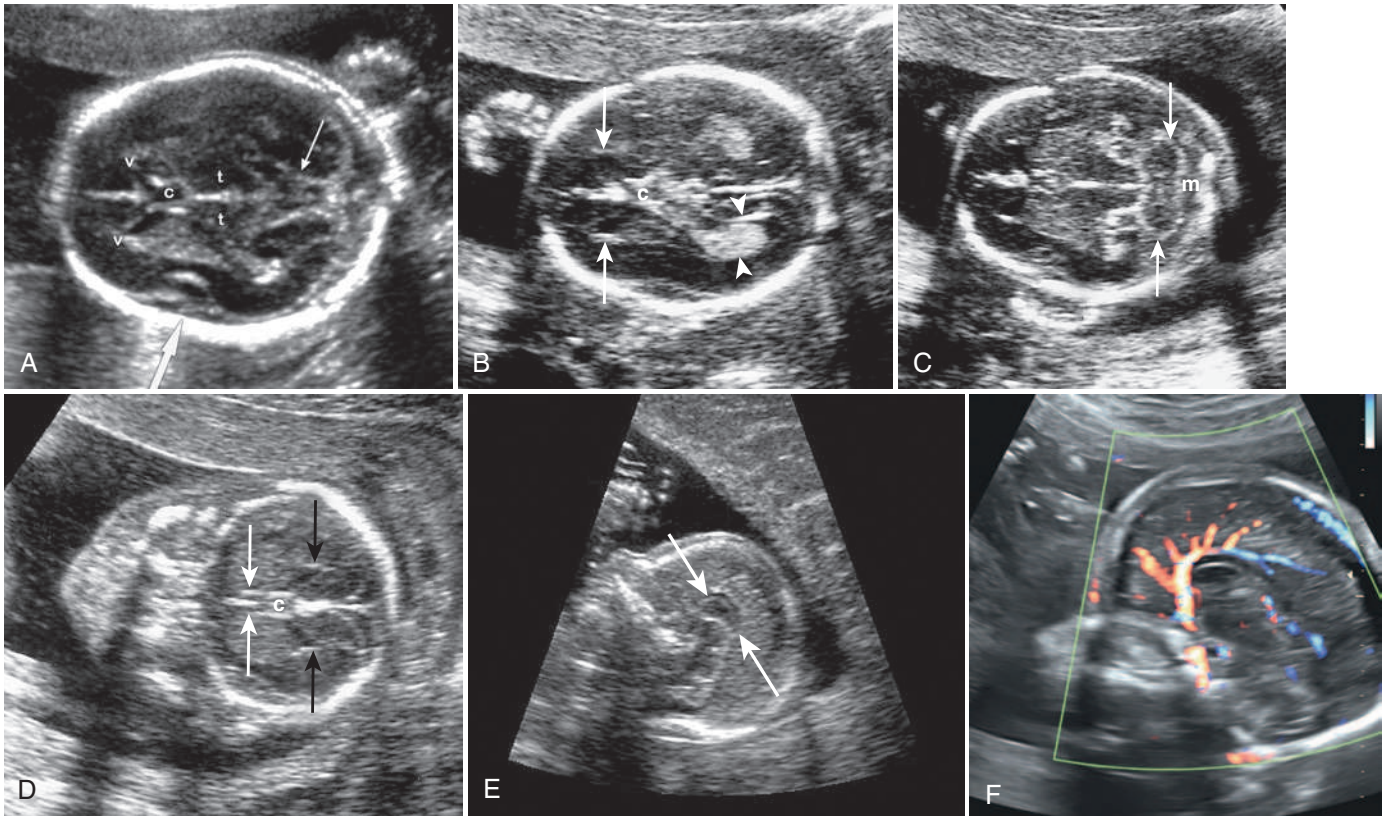

FIG. 34.2 Standard and Additional Planes for Viewing Cerebral Structures. (A) Thalamic view at 20 menstrual weeks. This transverse view at the level of the diamond-shaped thalamus-hypothalamus complex *(t)* contains the slitlike midline third ventricle. The echogenic triangular area behind the thalamus and between the occipital lobes is the ambient cistern *(arrow),* which contains cerebrospinal fluid (CSF) but is rendered echogenic because of strands of meninges supporting the brain structures. The insula is a short, brightly echogenic line *(thick arrow)* containing the pulsating middle cerebral artery branches. It is surrounded by normal white matter that is very hypoechoic and should not be mistaken for fluid. The echogenic band between thalamus and insula is the basal ganglia. Anteriorly are the tips of the anterior frontal horns of the lateral ventricles *(v),* and between them is the boxlike cavum septi pellucidi *(c).* **(B) Ventricular view at 18 weeks.** The atrium of the occipital horn is filled with echogenic choroid, and the ventricle measurement is indicated *(arrowheads).* Note that the choroid fills more than 60% of atrium width. The measurement between the medial ventricle wall and the choroid is less than 3 mm. The tips of the anterior frontal horns are visible *(arrows). c,* Cavum septi pellucidi. **(C) Cerebellar view at 18 menstrual weeks** is obtained by rotating the transducer from the thalamic view so that the cerebellar hemispheres *(arrows)* in the posterior fossa come into view, connected in the midline by the slightly more echogenic and narrower vermis. The cisterna magna *(m)* is visible between the cerebellum and the occipital bone. Also visible in this view are the thalamus, third ventricle, anterior horns, and cavum septi pellucidi. **(D) Coronal view at 19 weeks through the coronal suture** shows anterior frontal horns *(black arrows)* and large nerve trunks; the fornices *(white arrows)* are clearly visible below the cavum septi pellucidi *(c).* **(E) Midsagittal view through metopic suture at 19 weeks** shows normal corpus callosum *(arrows)* containing the cavum septi pellucidi in its arc below the corpus callosum. The echogenic cerebellar vermis is visible posteriorly. **(F) Sagittal color Doppler image shows the pericallosal artery.** Coronal and median views such as **(E)** and **(F)** are invaluable when there are concerns regarding midline structures.

cisterna magna, **cavum septi pellucidi** (CSP), and frequently the anterior horns of the lateral ventricles. Up to about 24 weeks, the transverse cerebellar diameter corresponds to gestational weeks. The **cisterna magna** is the cerebrospinal fluid (CSF) space behind the cerebellum and is measured between the cerebellar vermis and inner occipital bone on an axial plane that includes the anterior end of the CSP and the midplane of the cerebellum. It is normally 2 to 10 mm[5,44] (see Fig. 34.2C). Cisterna magna obliteration suggests **Chiari II malformation** and spina bifida. Excessive enlargement may be seen with **mega–cisterna magna, Blake pouch cyst, vermian dysplasia, Dandy-Walker syndrome,** and **arachnoid cysts.**[45-47]

Additional sonographic views and projections using the windows provided by the fontanelles and sutures can help to clarify brain anatomy and development. The **median (midsagittal) view** through the metopic suture–anterior fontanelle–sagittal suture shows midline structures such as the corpus callosum and occasionally the cerebellar vermis and brainstem[5] (see Fig. 34.2E-F). The posterolateral mastoid fontanelles can provide access to the cerebellum and occipital lobes and ventricles.

The **sulci** and **gyri** undergo predictable development patterns that can be assessed as early as 18 weeks. Special views to evaluate development of sulci and insula can be helpful in detecting abnormal development such as lissencephaly[48-50] (Fig. 34.4).

Multiplanar three-dimensional (3-D) imaging can be used to reconstruct axial and median views to assess the brain in any orientation. Midsagittal reconstructions are especially helpful in evaluating abnormalities of the corpus callosum and cerebellum.[40,51-53] Head shape and ossification should be noted with all these views (see Chapter 33). Although ultrasound is the mainstay

FIG. 34.3 Ventricular Measurement. Image at 20 weeks showing the appropriate position of calipers to measure the lateral ventricle.

of a prenatal examination, MRI has been proven to be valuable to further assess problems found with ultrasound. MRI provides excellent anatomic images after about 22 weeks' gestation and is superior in evaluating the character of brain tissue and the periphery of the brain, where ultrasound visibility is limited (Fig. 34.5). However, MRI has limitations in showing cerebral calcifications and small cysts.[18,54,55]

Variants (Usually Normal)

Choroid Plexus Cysts

Choroid plexus cysts (CPCs) are cystlike spaces in the choroid plexus and are due to entrapment of CSF within an infolding of neuroepithelium (Fig. 34.6, Video 34.4). It is suggested that only CPCs over 3 mm should be considered substantial enough to be termed "choroid plexus cyst." They are common and seen in 1% to 6% of fetuses between 14 and 24 weeks' gestation. Most are small and disappear without consequence by about 28 weeks. Rarely, large cysts may transiently dilate the lateral ventricles. They do not affect neurological development.[56]

The great majority of CPCs are found incidentally in normal fetuses, but they can be associated with trisomy 18. About 50% of trisomy 18 fetuses have CPC, and they are the only obvious initial finding in about 10% of trisomy 18 cases. Likelihood ratios of trisomy 18 with isolated CPC are about 7 (range 4-12) times the mother's background risk. Size and bilaterality of the cysts do not affect incidence of aneuploidy. Fetuses with trisomy 18 almost always have other detectable abnormalities. When CPCs are found, there should be a detailed search for features of trisomy 18, especially the hands, heart, and CNS. Other tests of aneuploidy risk should be reviewed, including maternal age, serum screening, and cell free fetal DNA testing (noninvasive prenatal testing [NIPT]) to ensure low aneuploidy risk. Many feel that patients with isolated CPC and low aneuploidy risk, especially with normal NIPT findings, do not warrant further counseling or testing.[20,57,58]

Blake Pouch Cyst

Blake pouch cyst, described by Robert Blake over 100 years ago, is a thin-walled cystic structure commonly seen in the midline of the posterior fossa behind the lower portion of the cerebellar vermis and brainstem. Because it contains CSF, this cyst is echo free, unlike the adjacent subarachnoid fluid, which is slightly echogenic owing to fine strands in the subarachnoid space (Fig. 34.7). Of note, this difference in appearance of the fluid and Blake cyst walls are not visible on MRI. With careful scanning, we have found that a Blake pouch cyst is visible in almost every fetus varying in size from tiny to large and conspicuous. A large Blake pouch can be associated with vermian rotation to 40 to 50 degrees with an intact vermis. Some feel this rotation results from delayed fenestration of the foramina of Magendie and Luschka and secondary cystic dilation of the inferior membranous area, which is the pouch and elevates the vermis. If isolated, the rotation typically decreases in later pregnancy and outcome is good.[28,59] When isolated, it should not be mistaken for abnormality. Three-dimensional ultrasound with midline reconstruction is especially helpful in this regard and can confirm vermian normality, as can MRI. We agree with those who feel that the mega–cisterna magna (MCM) is simply a large Blake pouch cyst, possibly resulting from delayed fenestration of the foramina; however, a few with isolated MCM may show developmental delay.[27,29,60]

Cavum Veli Interpositi

Cavum veli interpositi (CVI) is a small cystic collection in the midline, seen below the splenium of the corpus callosum, behind the upper brainstem and above the region of the pineal gland (Fig. 34.8). It represents fluid in the potential space in the telea choroidea above the third ventricle. Most CVIs are seen just below the splenium, but they can extend anteriorly above the third ventricle to the foramina of Monroe. Coronal, midsagittal, and 3-D scans to help to confirm the diagnosis and MRI and color Doppler exclude vascular abnormality such as vein of Galen aneurysm[61] (see Fig. 34.8C). Although infrequently described in the prenatal ultrasound literature, we have found small CVIs, with maximal diameter less than 8 mm, to be very common on axial scans at 18 to 20 weeks. The pediatric literature reports a CVI incidence of 5% to 34%.[62] Most CVIs are of no clinical consequence, and many recede spontaneously with normal long-term neurologic outcome.[62-65] Occasionally, however, large cysts can distort the brainstem and adjacent brain, causing obstructive hydrocephalus (HC), and need treatment by unroofing.

The physiologic CVI cysts tend to be isolated, unilocular, and small (<10 mm) and remain stable or recede over time. There is no known genetic association. The differential diagnosis includes cysts and cystlike conditions that occur in the midline, such as **dilated cavum Vergae, glioependymal cysts, arachnoid cysts, cystic tumors** (mainly cystic teratomas), **vein of Galen aneurysm, pineal cyst,** and **hemorrhage.** Pathologic cystic collections are generally larger, enlarge over time, and have associated abnormalities such as corpus callosum dysgenesis, ventriculomegaly (VM), or solid masses.[61,62,64,65]

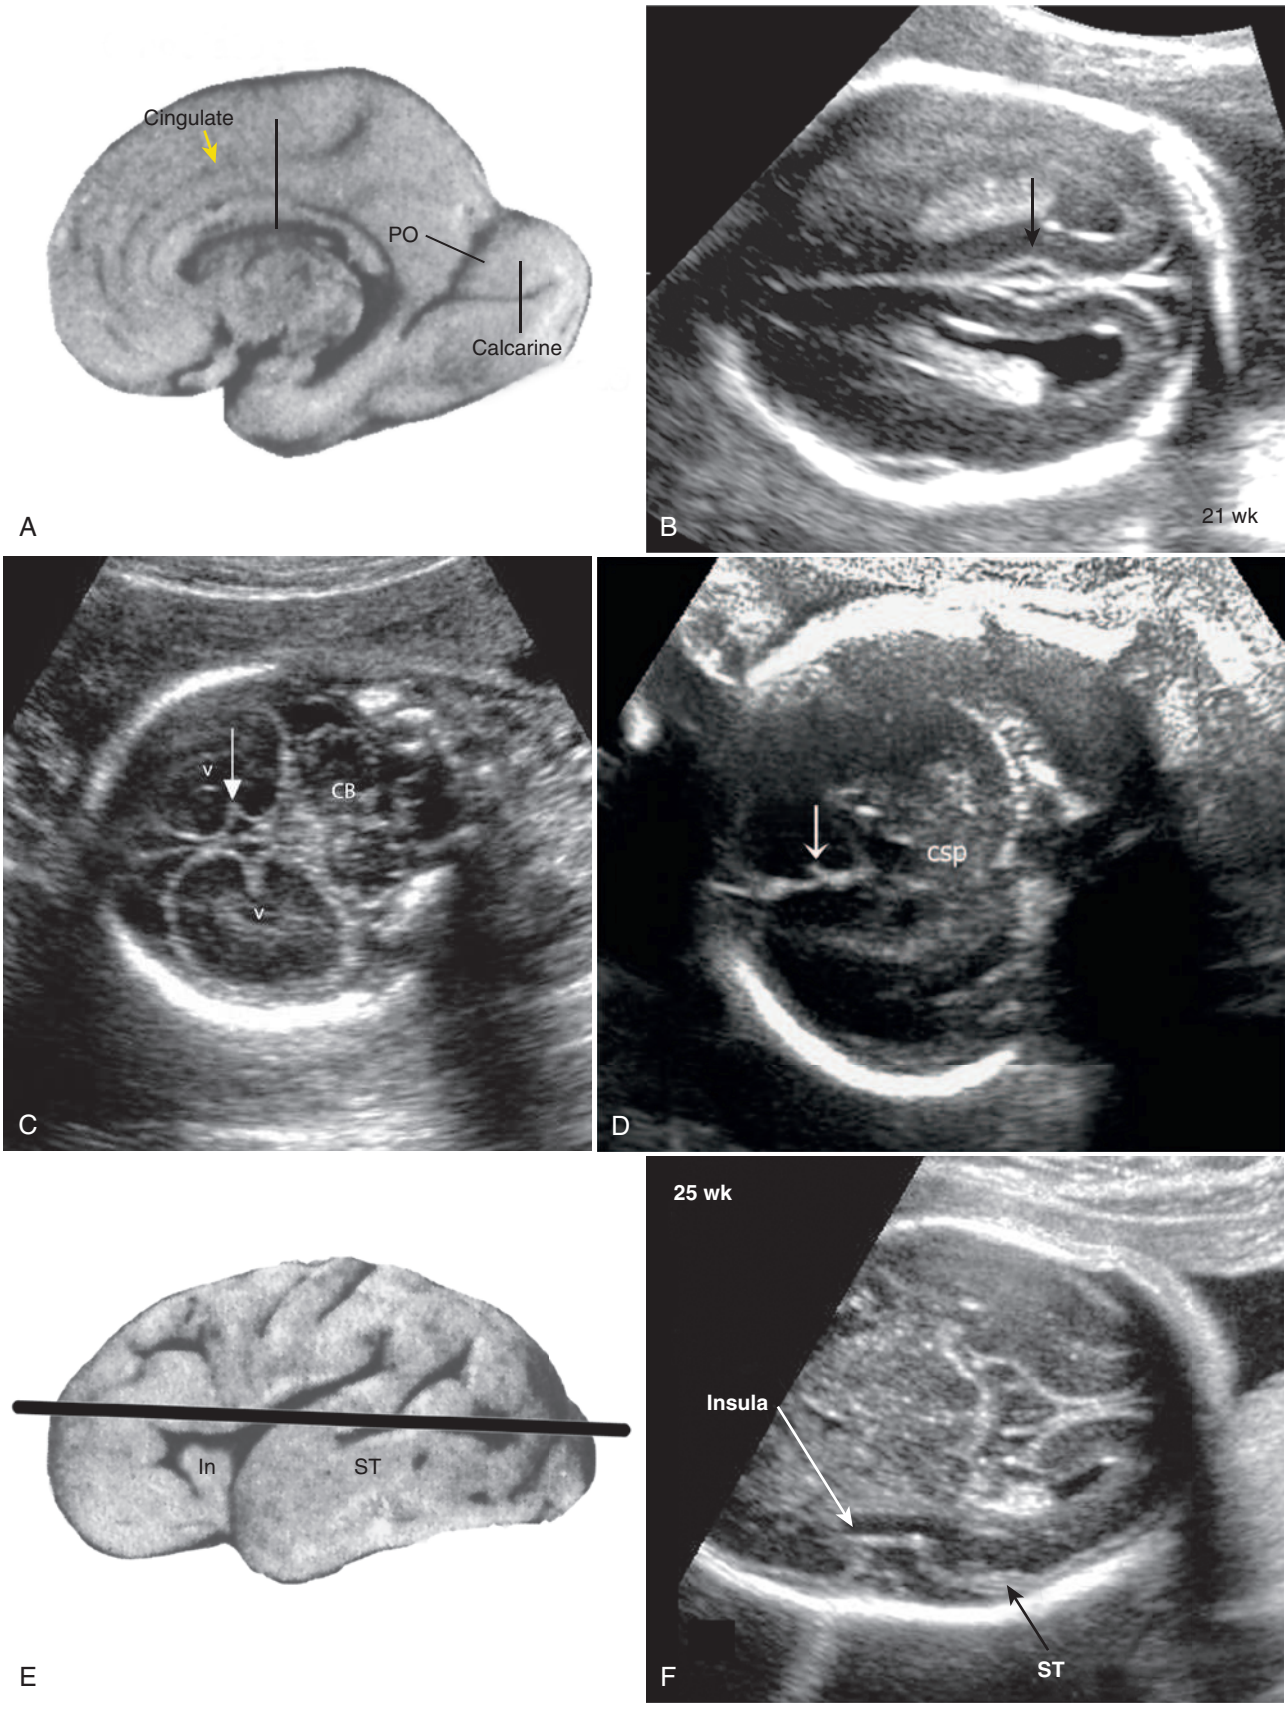

FIG. 34.4 Scan Planes *(Dark Lines)* Used to Assess Early-Appearing Sulci. Note that the scan planes are perpendicular to the direction of the sulcus being evaluated. **(A) Medial hemispheric surface at 26 weeks.** Coronal scan plane is best for cingulate sulcus *(yellow arrow)* and calcarine sulcus. Axial plane is best for parieto-occipital sulcus *(PO).* **(B) Axial view at 21 weeks** shows the diamond shape formed by the normal parieto-occipital sulci *(arrow).* **(C) Coronal view through the occipital lobes at 24 weeks** shows the calcarine sulcus *(arrow)* on the medial surface of the occipital lobe. Mild left-right asymmetry is normal. *CB,* Cerebellum; *V,* ventricles. **(D) Coronal view through parietal brain** shows the notch of the cingulate sulcus *(arrow)* above the bodies of the lateral ventricles and cavum septi pellucidi *(csp).* This is an excellent view to confirm normal cavum septi pellucidi. **(E) Lateral view of brain surface at 26 weeks** shows the scan plane used to evaluate the insula *(In)* and superior temporal sulcus *(ST)* behind it. **(F) Angular plateau of the insula** on axial view, and behind it the subtle indentation of the **superior temporal sulcus** *(arrow with ST).* (Anatomic images modified from Dorovini-Zis K, Dolman C. FIG. 34.6 Bilateral Choroid Plexus Cysts *(Arrows).* Note that on the right, an oblique scan plane has been used to view the upper hemisphere through the squamosal suture. See also Video 34.4.

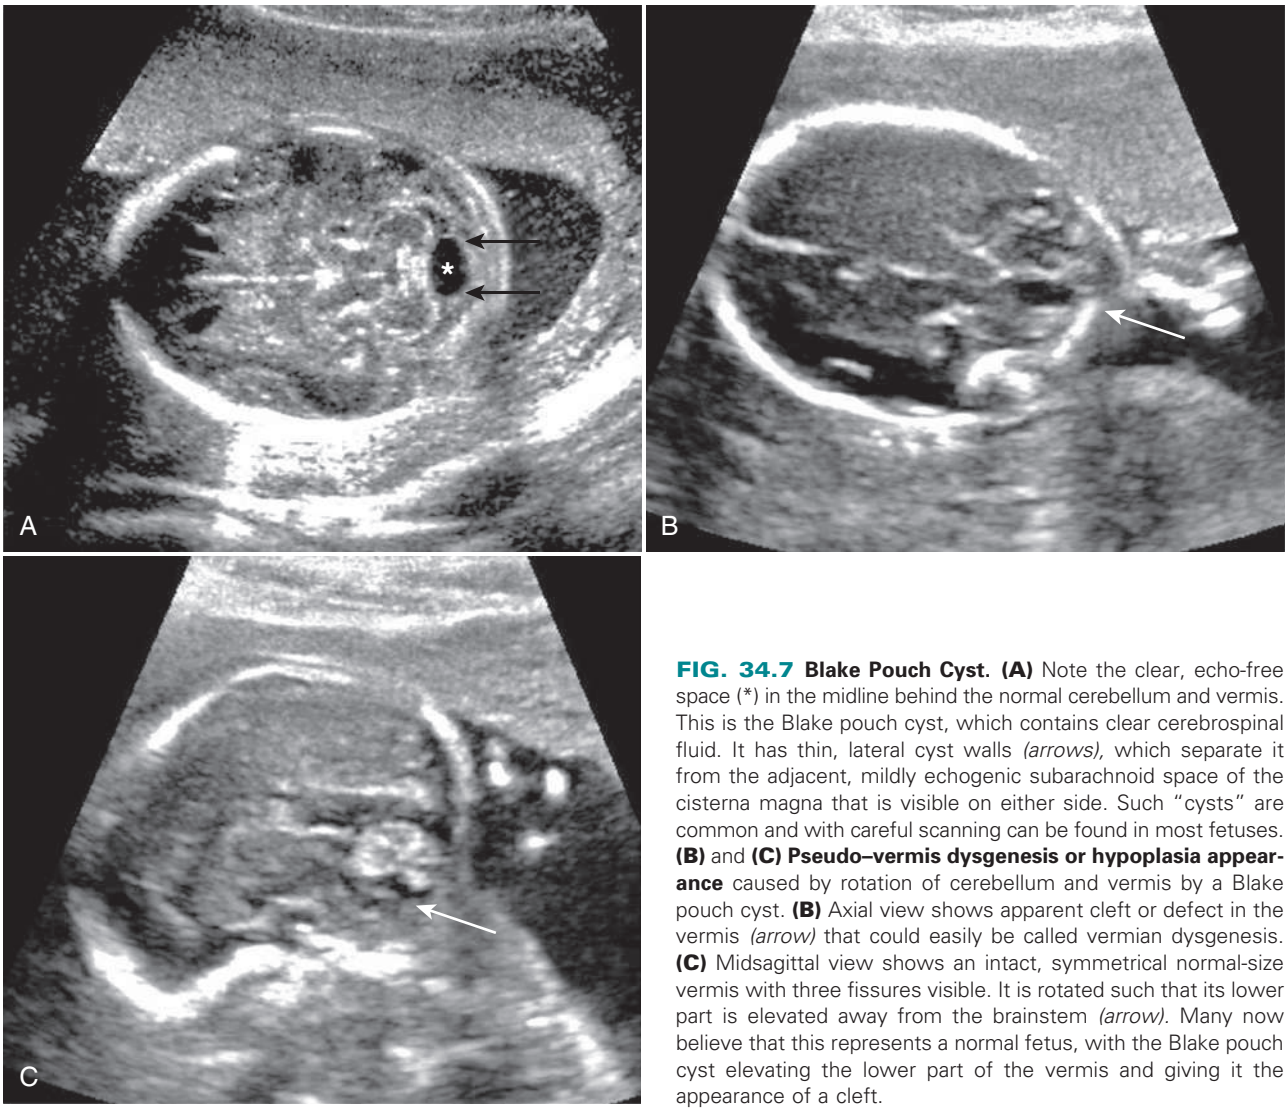

FIG. 34.7 Blake Pouch Cyst. (A) Note the clear, echo-free space (*) in the midline behind the normal cerebellum and vermis. This is the Blake pouch cyst, which contains clear cerebrospinal fluid. It has thin, lateral cyst walls *(arrows),* which separate it from the adjacent, mildly echogenic subarachnoid space of the cisterna magna that is visible on either side. Such "cysts" are common and with careful scanning can be found in most fetuses. **(B)** and **(C) Pseudo–vermis dysgenesis or hypoplasia appearance** caused by rotation of cerebellum and vermis by a Blake pouch cyst. **(B)** Axial view shows apparent cleft or defect in the vermis *(arrow)* that could easily be called vermian dysgenesis. **(C)** Midsagittal view shows an intact, symmetrical normal-size vermis with three fissures visible. It is rotated such that its lower part is elevated away from the brainstem *(arrow).* Many now believe that this represents a normal fetus, with the Blake pouch cyst elevating the lower part of the vermis and giving it the appearance of a cleft.

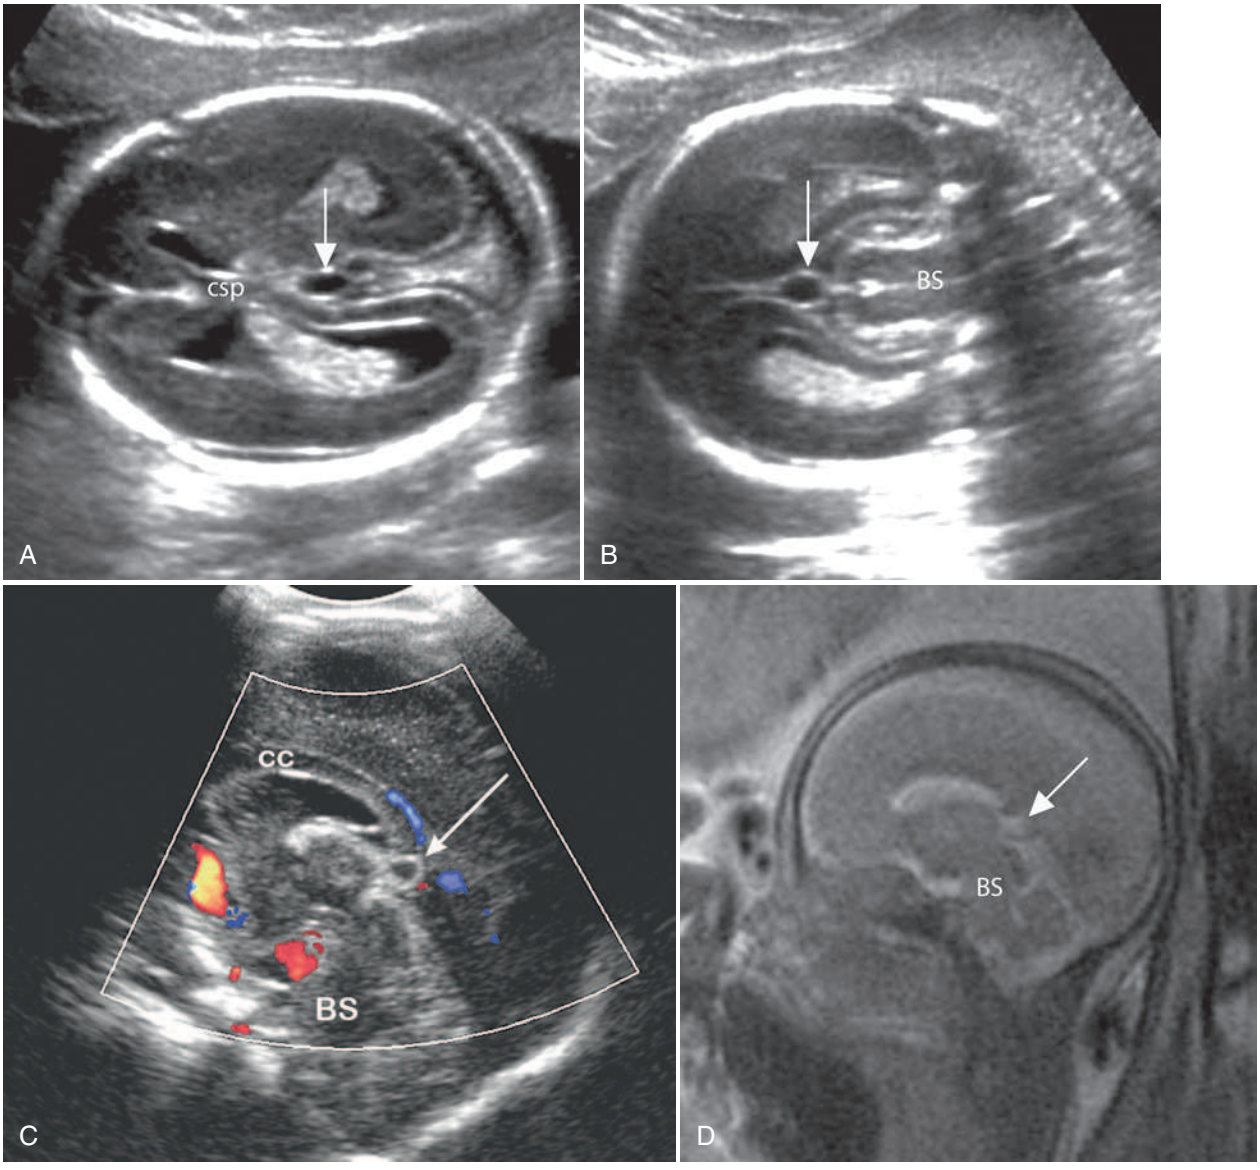

FIG. 34.8 Cavum Veli Interpositi (CVI). (A) CVI on axial view at 19 weeks *(arrow). csp,* Cavum septi pellucidi. CVIs of this size are frequent but are commonly overlooked. **(B)** CVI on coronal view *(arrow). BS,* Brainstem. **(C)** CVI on color Doppler sagittal view *(arrow)* lying just below the splenium of the corpus callosum *(cc). BS,* Brainstem. There is no flow on color Doppler. **(D)** T2-weighted magnetic resonance image of 21-week fetus showing CVI *(arrow).*

Fetuses with suspected CVI cysts should undergo detailed neurosonography and anatomic scan including Doppler to exclude vein of Galen aneurysm. If there are any atypical features or associated findings, then MRI can be helpful in further investigation. We no longer monitor incidentally discovered small (<8 mm) isolated cysts but perform follow-up scans if the cysts are especially conspicuous or if there is parental concern.

VENTRICULOMEGALY AND HYDROCEPHALUS

The term **ventriculomegaly** (VM) describes ventricles 10 mm or larger at the atrium. Care should be taken to measure the ventricles in the appropriate plane; an oblique plane will lead to an apparently enlarged ventricle if the trigone is measured. The head itself may be normal, large, or even smaller than expected for menstrual age. "Hydrocephalus" refers to enlarged ventricles associated with increased intracranial pressure and thus is typically associated with head enlargement.[66] Ventricular abnormality, especially enlargement, is the most commonly encountered cranial abnormality at prenatal ultrasound, with prenatal incidence of 10 to 80 per 10,000 pregnancies. It is often the key finding in the initial detection of CNS abnormalities and is found in about 88% of fetuses with cerebral abnormalities[39,43,67,68] (Fig. 34.9).

Ventricle measurement technique is important and details should be remembered. With the head in a true axial view, measurements are generally taken only of the distal ventricle since the near ventricle is obscured by skull bone artifact and ventricles are presumed to be symmetrical. Calipers are placed

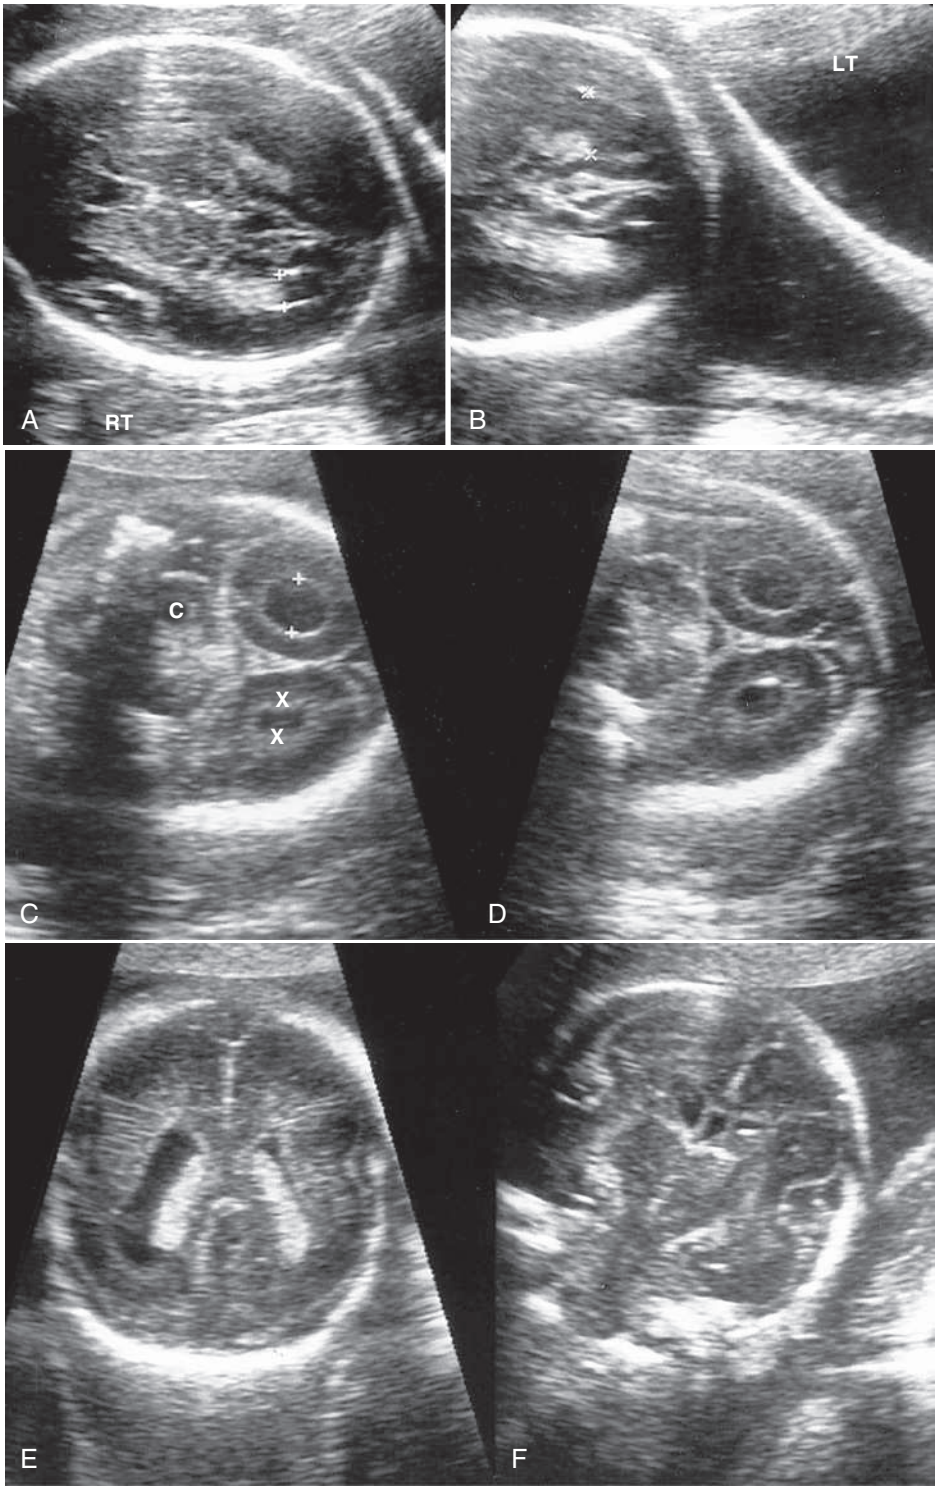

FIG. 34.9 Assessment of Ventricles at 23 Weeks Shows Normal, Mild Asymmetry. (A) Axial view shows the usually measured lower ventricle *(calipers).* **(B)** By viewing through the posterior squamosal suture, one can visualize the upper ventricle in the oblique axial plane *(calipers).* Oblique image planes can increase the ventricular measurement; thus it is important to obtain a true axial view that shows both ventricles for measurement if the upper ventricle appears enlarged. **(C)** and **(D)** Coronal "owl's eye" view through the lambdoid suture shows asymmetry of the occipital horns *(calipers).* Mild asymmetry less than 2 to 3 mm is common and normal. *c,* Cerebellum. **(E)** and **(F)** Views taken through the anterior fontanelle analogous to neonatal head ultrasound are an alternate approach to assessing both ventricles. **(E)** shows the occipital horns and **(F)** shows the anterior horns and confirms slight ventricular asymmetry.

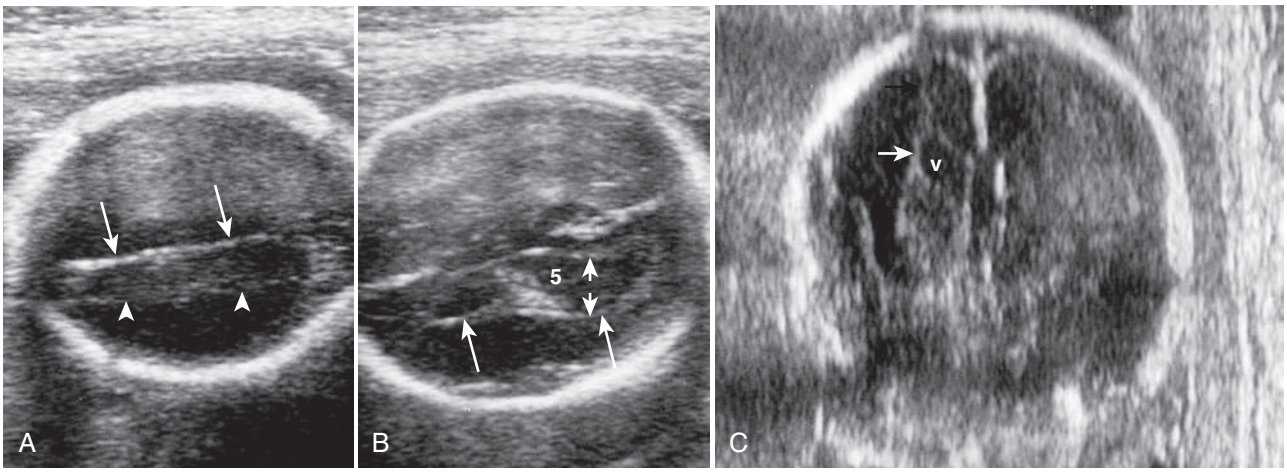

FIG. 34.10 Supraventricular Marginal Venous Echoes at 26 Menstrual Weeks Versus Ventricular Walls. (A) Transverse view above the level of the ventricles shows echoes from the marginal veins, which form a finely dotted line *(arrowheads)* parallel to the interhemispheric fissure *(long arrows)* that should not be mistaken for ventricular margins. **(B)** Transverse view at the ventricular plane shows mild ventricular enlargement, with the occipital horn measuring over 10 mm *(short arrows)* and the choroid separated from the medial wall of the occipital horn by 5 mm *(5)*. The margin of the lateral ventricle *(long arrows)* is curved and diverges from the midline, unlike the venous "line," which is straight and parallels the midline. **(C)** Coronal view through the region of the thalamus. The lateral ventricle wall echo *(arrow)* is lateral to the supraventricular venous echo, which goes from the top of the ventricle *(v)* to the surface of the hemisphere.

at the widest part in the fluid space touching the inner ventricle wall perpendicular to the ventricle axis.[6] For consistency measurements should be taken opposite the parieto-occipital fissure.[69] It is possible, however, to measure the near ventricle directly by waiting for the head to turn or exploiting access provided by the squamosal and lambdoid sutures and the posterolateral (mastoid) fontanelles and on 3-D multiplanar reconstructions and even on coronal views using the "owl's eye" view. But it is important to ensure that all measurements are made in the true axial plane[5,39] (see Figs. 34.3 and 34.9). Visualization of the near ventricle and hemisphere should be performed whenever VM is suspected.

There are pitfalls to ventricular measurement. Errors arise if the plane of view is not axial or if there is an improper choice of ventricle boundary.[70] The insula, the extreme capsule of the basal ganglia, the supraventricular veins, the medial wall of the occipital lobe (see Fig. 34.2A-B and Fig. 34.10), and reverberation echoes of the proximal skull all can appear as lines, which should not be mistaken for ventricular walls.

Between 14 and 38 weeks, the transverse atrial measurement is reported constant at 7.5 mm (standard deviation [SD], 0.7 mm).[2] Measurements of 10 mm or larger suggest VM with a low false-positive rate. A finding of 10 mm is not a clear criterion of abnormality, but rather it is generally accepted that at 10 mm or more the ventricle is sufficiently different to warrant additional attention and investigation.[6,43,71-73] Note that the 10-mm limit was initially proposed by Dr. Filly as the upper limit not because it definitively distinguished normal from abnormal, but rather because it was an easy number to remember at all gestational ages and identified most fetuses with findings that were felt to be different enough to warrant counseling and further investigation. It was understood that some fetuses with ventricles larger than 10 mm may be entirely normal.[43,73]

In general, 10 to 12 mm is termed **mild** or **borderline;** 12 to 15 mm is **moderate** (although some authors consider up to 15 mm in the mild range); and greater than 15 mm is **marked** VM.[66,71] Although 10.0 mm has been considered the upper limit of normal, there are reports of normal outcomes with ventricles larger than 10 mm,[72] and some have suggested raising the upper limit of normal to 11 or 12 mm. Ten millimeters is already about 4 SDs above the mean, and we agree with others that 10 mm should remain the criterion above which counseling and investigation should occur[5,43,72] (Fig. 34.11).

As an alternative approach to detection of mild VM, Mahony and colleagues suggested using choroid separation from the medial ventricle wall and reported that normally this distance is 1 to 2 mm after 15 weeks. Measurements of 3 mm or more were associated with abnormal outcomes when combined with other fetal abnormalities, even if the ventricle measurement was normal.[74] Hertzberg and colleagues found that 20% of such fetuses had abnormal outcomes.[75] However, many believe that this approach is too sensitive and unnecessarily creates anxiety in parents.

Ventricular enlargement is termed **isolated ventriculomegaly** (IVM) if there are no associated cerebral or somatic findings and the karyotype is normal. At time of diagnosis of VM, about 60% will have additional abnormalities, and 40% will not. Unfortunately, at birth, even after detailed ultrasound and prenatal MRI, about 7% to 16% of infants with apparent IVM are found to have additional abnormalities.[71,76,77]

Enlargement of the lateral cerebral ventricles is not the primary problem. Although VM may be an isolated finding, it is often the sonographically conspicuous finding of numerous disorders and syndromes.[43,78,79] It is the underlying changes in the brain that are clinically important, not only the size and appearance of the ventricles. Cerebral functional alterations are only variably

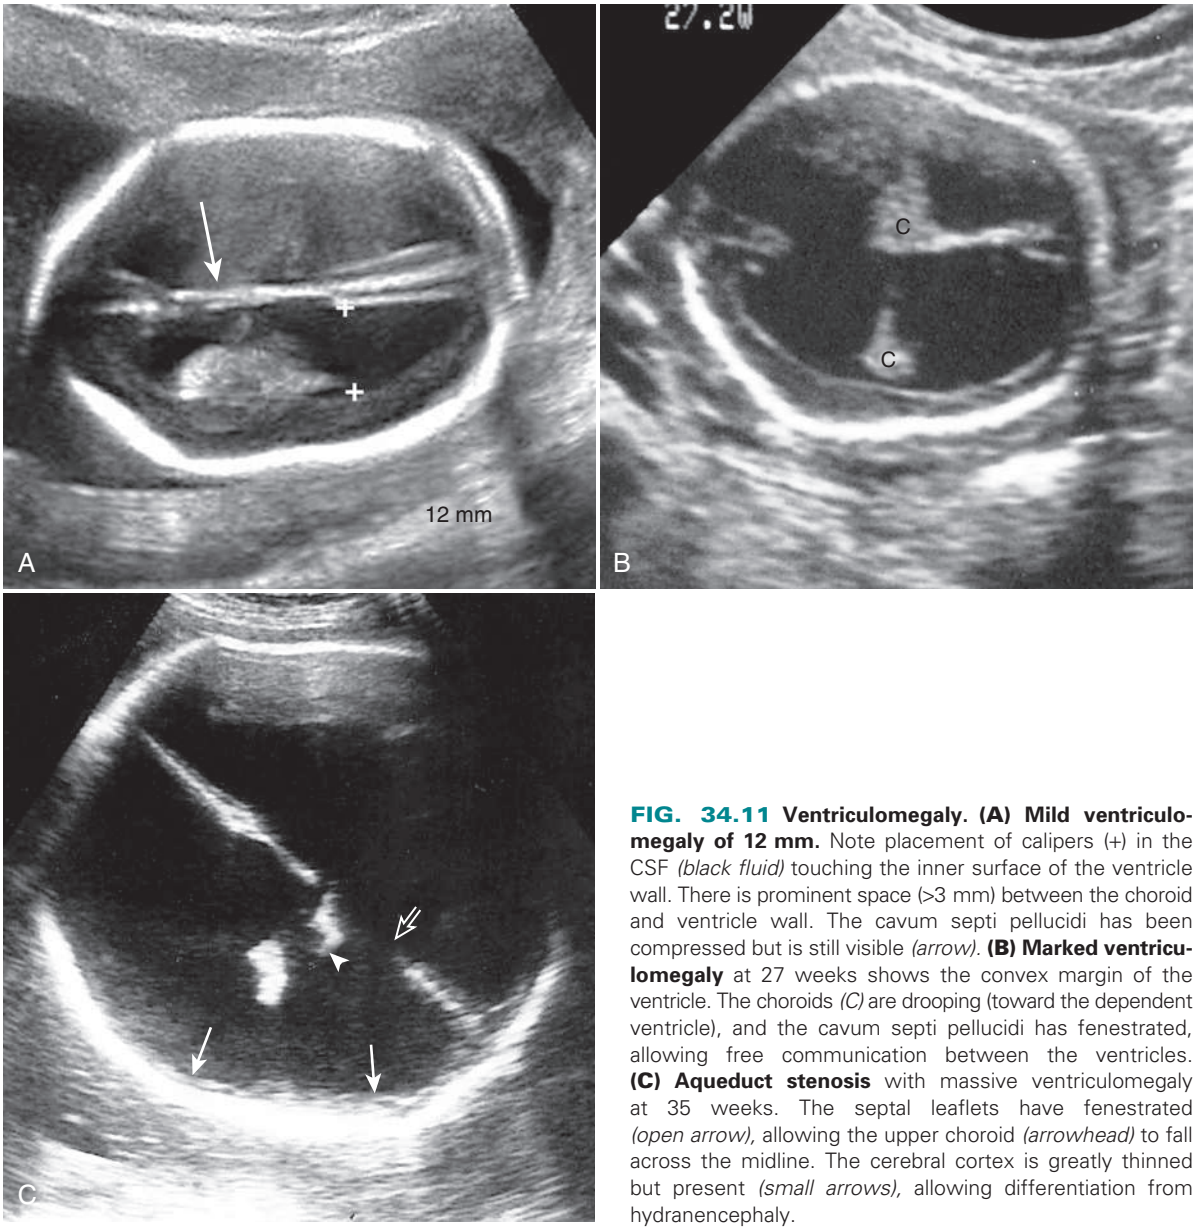

FIG. 34.11 Ventriculomegaly. (A) Mild ventriculomegaly of 12 mm. Note placement of calipers (+) in the CSF *(black fluid)* touching the inner surface of the ventricle wall. There is prominent space (>3 mm) between the choroid and ventricle wall. The cavum septi pellucidi has been compressed but is still visible *(arrow).* **(B) Marked ventriculomegaly** at 27 weeks shows the convex margin of the ventricle. The choroids *(C)* are drooping (toward the dependent ventricle), and the cavum septi pellucidi has fenestrated, allowing free communication between the ventricles. **(C) Aqueduct stenosis** with massive ventriculomegaly at 35 weeks. The septal leaflets have fenestrated *(open arrow),* allowing the upper choroid *(arrowhead)* to fall across the midline. The cerebral cortex is greatly thinned but present *(small arrows),* allowing differentiation from hydranencephaly.

predicted by ventricular size, cortical thinning, and appearance.[66] A single institution study of 29,000 pregnancies found VM in 0.38% of fetuses (1 in 265). Of these, 57% were not isolated and had other abnormalities. In the 43% with IVM, VM was mild in 40% (10-15 mm) and marked in 60% (>15 mm). Abnormal neurodevelopmental outcome was poorest with nonisolated (91%) and marked IVM cases (68%) but was seen in only 19% of mild VM cases.[77]

The approximate frequencies of cerebral abnormalities seen with VM are **aqueduct stenosis,** 30% to 40%; **Chiari II malformation** with spina bifida, 25% to 30%; **Dandy-Walker complex,** 7% to 10%; and less common conditions including **agenesis of the corpus callosum**. In general, associated CNS and somatic malformations are common. Chromosomal and genetic abnormalities are more common with nonisolated (25%-36%) than isolated (3%-6%) VM and include the **trisomies** and **X-linked hydrocephalus** in males and numerous other conditions.[67,71,78,79]

Pathogenesis of Ventriculomegaly

CSF is secreted by the choroid plexus of the lateral, third, and fourth ventricles, as well as by the cerebral capillaries.[80] CSF flows from the lateral ventricles with assistance of ciliary activity of ependymal cells through the foramina of Monro, third ventricle, aqueduct of Sylvius, and fourth ventricle and out the **foramina of Magendie and Luschka** into the subarachnoid space of the posterior fossa, from where it courses over the surface of the brain to be absorbed by the **pacchionian** or **arachnoid granulations** and lymphatics.[66,81]

Ventricular enlargement generally occurs in one of four scenarios. First and most commonly, there is obstruction of CSF flow in the brain, usually at the aqueduct **(intraventricular**

obstructive hydrocephalus). Alternatively, the site of blockage may be outside the ventricular system, or there may be failure of absorption (**extraventricular obstructive hydrocephalus** or **communicating hydrocephalus**). Second and less often, VM results from excess CSF secretion with **choroid plexus papillomas.** Third, VM can follow cerebral destruction and brain shrinkage as a result of abnormal brain development or diverse insults **(hydrocephalus ex vacuo)**. Fourth, it may be a feature of generalized cerebral malformation. Apart from the effects of the basic underlying disorder, the degree of brain injury with HC varies with age of onset and magnitude and duration of the dilation, all of which affect periventricular axons, myelin, and microvasculature, resulting in cerebrovascular injury, gliosis, and inflammation and compensation by neuroplasticity.[66,82]

Examples of Conditions Associated With Ventriculomegaly

Obstructive hydrocephalus
Aqueduct stenosis (idiopathic, infections, bleeding, X-linked, obstructing masses)
Spina bifida with Chiari II malformation
Large choroid plexus cyst
Excess cerebrospinal fluid (CSF) production
Choroid plexus papillomas
Destructive processes (encephaloclasis)
Vascular insult
Infection
Ischemia
Schizencephaly
Hydranencephaly
Cerebral malformations
Aneuploidy (trisomies 21, 18, 13)
Agenesis of corpus callosum
Vermian dysgenesis and Dandy-Walker malformation
Holoprosencephaly
Neuronal migration abnormalities (lissencephaly, schizencephaly)
Microcephaly

Ultrasound Evaluation of Ventriculomegaly

The detection of VM is generally straightforward, but the determination of its etiology can be difficult. Several approaches to measuring ventricular size have been described: atrial width, choroid separation, ventricle-to-hemisphere ratio, combined anterior horn width, and visual anatomic appearance. Of these, the universally accepted method is the **transverse measurement of the atrium of the occipital horn** (see Figs. 34.3, 34.9A, and 34.11A). Methodological scanning can often determine specific causes.[39] The size of the head is not helpful in detecting VM, and frequently the BPD remains normal even with severe ventricular enlargement. Nomograms of other parts of the ventricles are available but not in common use.[83]

In the first trimester the choroid plexus should fill the prominent-appearing lateral ventricle, except for the conspicuous fluid containing anterior frontal horn of the lateral ventricle, which should not be mistaken for abnormality (see Fig. 34.1B). VM manifests as a small-appearing choroid plexus with excess surrounding fluid.[8]

Qualitative appearances suggesting ventricular enlargement include convexity (outward bulge) to the lateral wall of the lateral ventricle and asymmetrical position of the left and right choroids, which fall with gravity when unsupported by ventricular walls because the choroids are denser than CSF ("droopy" or "dangling" choroids) (Fig. 34.11B, Video 34.5). With massive ventricular enlargement, the interhemispheric structures, particularly the septum pellucidum, undulate with maternal pulse and movements and can become disrupted (fenestrate), allowing the left and right lateral ventricles to communicate. The upper choroid can fall across the midline through this hole and into the lower ventricle (Fig. 34.11C).

Once ventricular enlargement is suspected, attention turns to etiology and a detailed search for associated cerebral and somatic abnormalities that may suggest specific causes or syndromes. Both left and right ventricles should be measured, and both hemispheres evaluated.[5,39,67,68] Associated brain abnormalities may be subtle and not readily appreciated on standard axial scanning. Coronal and sagittal views both transabdominally and transvaginally and use of 3-D multiplanar scans can be especially helpful to detect abnormalities of the cerebellar vermis and corpus callosum.[5,79] MRI adds additional information in 5% to 50% of cases, especially with respect to parenchymal injury, migrational disorders, ischemia, hemorrhage, and brainstem abnormalities.[17,71,76,84-86]

Fetuses with suspected VM should be evaluated by a knowledgeable team with experience in the investigation, counseling, management, and follow-up of prenatally discovered abnormalities. Additional testing can be offered including karyotype and molecular analysis, testing for infection (especially CMV, *Toxoplasma,* and rubella), platelet antibodies, and follow-up examinations to follow ventricle growth and to detect additional late-appearing findings that may relate to prognosis (porencephaly, malformation of cortical development, hemorrhage). Postpartum evaluation is important to evaluate for additional prenatally unsuspected abnormalities and to plan treatments.[39,66,68,71,82]

Prognosis relates to the degree of VM, progression of VM, and especially the presence of associated abnormalities. In cases of VM associated with chromosomal or other CNS and somatic abnormalities, the prognosis and recurrence risk relate to underlying conditions.[71,87] When VM is truly isolated, neurodevelopmental outcome relates to the degree of enlargement. Normal functional outcome is reported in about 85% to 96% of mild (10-12 mm), 76% of moderate (12-15 mm), and 28% of severe (>15 mm) cases. Outcome is better if VM is stable or decreases, and worse with enlarging ventricles. Unilateral cases behave similarly.[71,78,88,89]

Counseling of parents remains difficult, and long-term outcome remains guarded. Laskin and colleagues[88] reported that initially 85% of children had a favorable outcome, but this decreased to 79% by 20 months. Remember also that 2% to 3% or more of entirely normal-appearing fetuses and children can also have developmental disability, and it is not clear how this rate compares with those with IVM.[71,76]

SPECIFIC ABNORMALITIES

Congenital CNS abnormalities often reflect the *time* of insult in prenatal life rather than the specific cause. Increasingly, CNS abnormalities are being associated with gene mutations at the molecular level. Genes control cortical development and neuron migration, and the same genes also have roles in somatic development. The understanding of these complex and interrelated molecular mechanisms of disease and maldevelopment is changing rapidly. Increasingly, malformations are starting to be categorized based on their underlying genetic and molecular abnormalities rather than on morphologic appearances.[21,90-92] Even if the genes are normal, their functions can be variably disturbed by external influences, such as anoxia, infections, and teratogens, and the final outcomes will typically reflect the timing and intensity of the insults more than their specific nature.[36]

To reach an accurate diagnosis and help with investigation, counseling, and treatment, evaluation should include not only CNS changes, but also additional, subtle cerebral and somatic findings. Additional clues can be found in pregnancy history, family history, course of current pregnancy (including maternal conditions such as diabetes), medications, illnesses, occupations and exposures, and evaluation of parents and close relatives. If there is a known risk of specific conditions, online resources such as Online Mendelian Inheritance in Man (OMIM, http://www.ncbi.nlm.nih.gov/omim) and consultation with experts in other specialties can be helpful in providing a list of findings to target on ultrasound examination and MRI.

ERRORS OF DORSAL INDUCTION

CNS development begins with development of the notochord, which subsequently induces the dorsal development of the neural plate, which closes to form the neural tube, which becomes the spinal cord and part of the brain. Errors of **dorsal induction** can result from many different genetic and teratogenic factors and affect development of the dorsal neural plate and closure of the neural canal **(neurulation).**[93,94]

Anencephaly and Exencephaly

Anencephaly follows failure of closure of the rostral neuropore leading to failed cranial vault development and unprotected exposed brain tissue **(exencephaly),** the subsequent destruction of which leaves a flattened, amorphous vascular-neural mass (area cerebrovasculosa) characteristic of anencephaly (Fig. 34.12). Facial structures and orbits are present. Associated spinal and non-CNS abnormalities and polyhydramnios are common. On occasion, the dysraphic abnormality involves the head and entire spine **(craniorachischisis).**[95,96] **Acrania** is sometimes defined as a normal brain with absent skull, and therefore this term should not typically be used in cases of anencephaly or exencephaly, even though the cranial vault is absent.

Prevalence of anencephaly is about 1 per 1000 births. Risk is increased in families with neural tube defects (NTDs), young or old mothers, or diabetes and with antiepileptic drugs. Folate appears protective. Chromosomal abnormality is seen in 2%, and additional abnormalities are common including cleft lip, cardiac defects, club feet, and abdominal wall defects.[96,97]

Detection of anencephaly before 14 weeks can be difficult because a relatively normal-appearing brain structure can be present, but the diagnosis has been suggested as early as 10½ weeks.[10,38] The diagnosis can be missed unless the examiner specifically looks for ossified cranial bones. Ultrasonically visible ossification of frontal bones may not be apparent until 10 weeks, and anencephaly should not be diagnosed before this gestational age. Commonly, however, the cerebral mass is deformed, often looking like "Mickey Mouse ears." An additional clue to diagnosis is the identification of amniotic fluid that is more echogenic than the extraamniotic subchorionic fluid owing to intraamniotic debris shed from the uncovered brain.[98] The introduction of the NT scan and increasing familiarity with first-trimester appearances has shown that most anencephalic fetuses can be detected in the late first trimester.[10,99]

Differential diagnosis includes other conditions in which the cranial bones are absent or lack mineralization, such as **amniotic band sequence,** large **encephaloceles, osteogenesis imperfecta,** and **hypophosphatasia.** With amniotic band sequence **(early amnion rupture sequence)** the fetuses typically have an asymmetrical defect accompanied by body wall defects and/or amputation of body parts and occasional oligohydramnios, and membranes may be visible in amniotic fluid, or the fetus may be stuck to the side of the uterus or placenta. Unlike anencephaly and open spina bifida, early amnion rupture sequence is sporadic and without increased recurrence risk. In general, large encephaloceles have more calvarial development than seen with anencephaly, but occasionally the two can appear similar. In either case, the prognosis remains hopeless.[96,100]

The outcome of anencephaly is invariably fatal, and pregnancy termination is offered at any gestational age.

Cephalocele and Encephalocele

A **cephalocele** is a herniation of intracranial structures through a defect in the cranium or skull base. It is termed **cranial meningocele** when it contains only meninges and CSF and **encephalocele** when it contains brain tissue. Among live births the incidence is about 1 to 5 per 10,000, but this underestimates the true incidence because many die at or before birth.[101,102] Most encephaloceles occur in the midline in the occipital (75%), frontal (13%), or parietal (12%) regions (Fig. 34.13). Anteriorly they can extend into the mouth, nasal, and sphenoid areas, where their identification can be difficult.[103-106] Off-midline lesions are commonly associated with amniotic band syndrome.[101] Cephaloceles can occur as isolated lesions, but most (20%-60%) are associated with other anomalies or syndromes involving the head, spine, face, skeleton, or kidneys. Chromosomal abnormality is seen in 14% to 60%, especially trisomies 18 and 13.[97,102] Interestingly, in the Western world the occipital location is more common, whereas in Asia frontonasal location predominates.[102,105,106]

Although at first glance cephaloceles resemble spina bifida, there are some differences. Spina bifida is a failure of primary closure (neurulation), whereas many cephaloceles are skin covered and likely are a secondary abnormality after neurulation, possibly

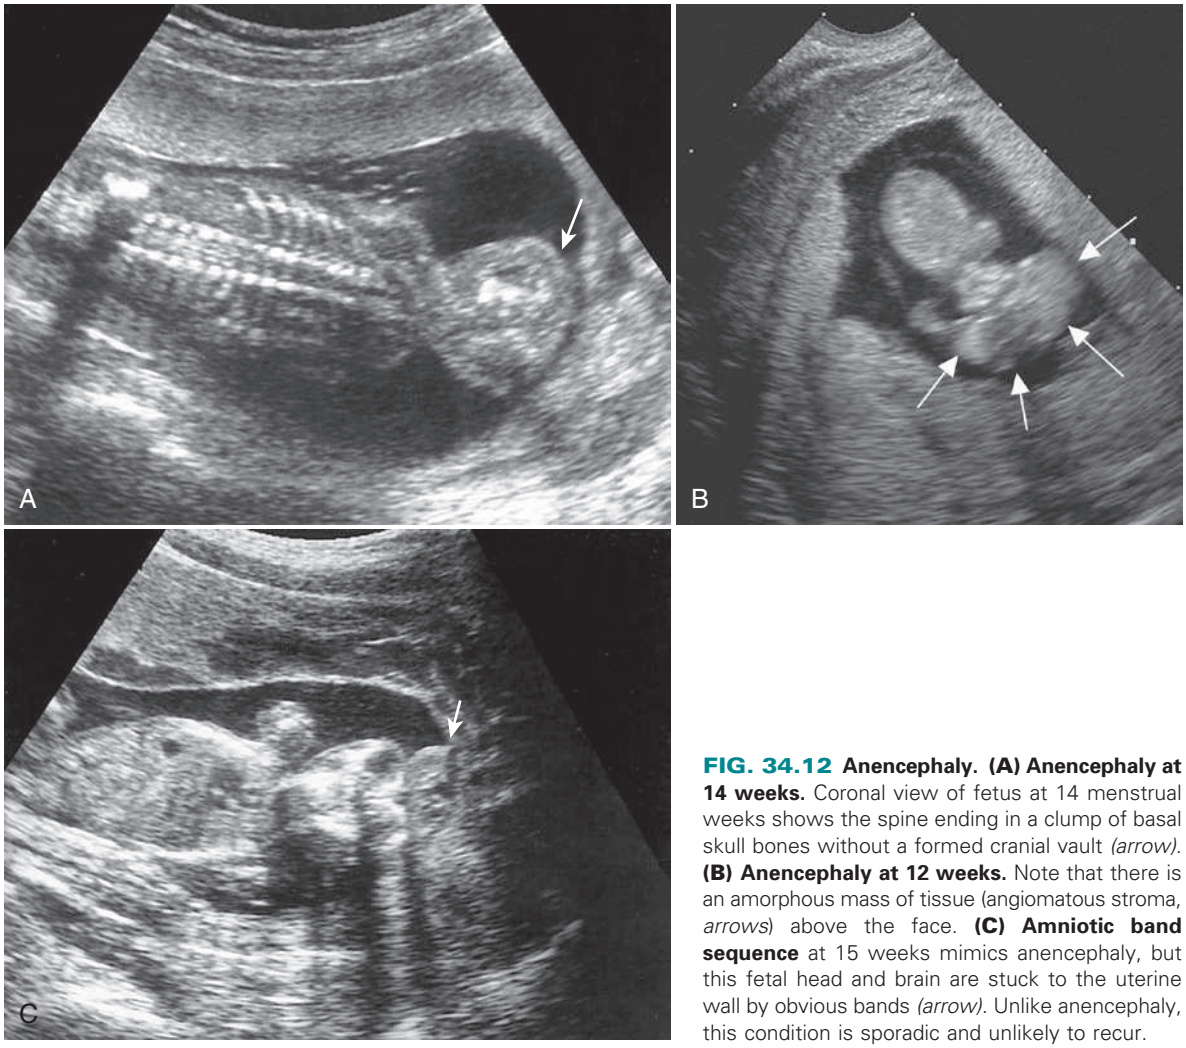

FIG. 34.12 Anencephaly. (A) Anencephaly at 14 weeks. Coronal view of fetus at 14 menstrual weeks shows the spine ending in a clump of basal skull bones without a formed cranial vault *(arrow)*. **(B) Anencephaly at 12 weeks.** Note that there is an amorphous mass of tissue (angiomatous stroma, *arrows*) above the face. **(C) Amniotic band sequence** at 15 weeks mimics anencephaly, but this fetal head and brain are stuck to the uterine wall by obvious bands *(arrow)*. Unlike anencephaly, this condition is sporadic and unlikely to recur.

representing abnormal mesenchymal migration or, in the case of frontonasal cephaloceles, a failure of closure of normal diverticulation. Because many are skin covered, MS-AFP is elevated in only 33% compared with spina bifida (62%) and anencephaly (92%). This makes ultrasound the primary diagnostic tool. Cephaloceles are more likely to be associated with additional cerebral and somatic abnormalities and syndromes. Common associated cerebral abnormalities involve the midline structures such as the corpus callosum, cerebellum, and brainstem and include venous abnormalities, holoprosencephaly (HPE), HC, and facial clefting (Table 34.2). Over 30 syndromes include cephaloceles; many are related to gene dysfunctions that affect both CNS and somatic development. These additional abnormalities strongly affect prognosis, so whenever a cephalocele is found, there should be a detailed search for other anomalies, and MRI and genetic evaluation should be considered.[102-105,107,108]

Ultrasonographically, an encephalocele manifests as a cystic mass at the surface of the skull, typically in the midline (see Fig. 34.13). Contained brain with a visible bony defect confirms the diagnosis, but it may be difficult to see the contained, often abnormal, brain tissue, and the bony defect may also be small and difficult to detect. Encephaloceles can be seen during first-trimester ultrasound and are often preceded by an enlarged rhombencephalic cavity.[99] MRI is helpful to confirm the diagnosis and, more important, to search for additional features that can affect prognosis and counseling.[18,101,102]

Other lesions that should be considered in the differential diagnosis when a scalp lesion is seen include cystic hygroma, hemangioma, scalp edema or cephalohematoma, epidermal scalp cyst, branchial cleft cyst, dermoid cyst, dacryocystocele, epignathus, and cervical teratoma.[104,110,111]

The **atretic cephalocele** is a variant that is infrequently recognized prenatally, manifesting as a small, blisterlike subcutaneous collection in the skin in the midline near the vertex at the surface of a seemingly intact skull (see Fig. 34.13E). Diagnostic clues are abnormalities of the superior sagittal sinus, which may have multiple channels, and the persistence of the prosencephalic **vein of Markowski,** which runs in the falx (falcine sinus) from the region of the start of the vein of Galen to the sagittal sinus underlying the encephalocele. As with other cephaloceles, there may be other cerebral abnormalities, especially involving the midline, which can affect outcomes. However, if the cephalocele is isolated, the children in general do well.[104,110,111]

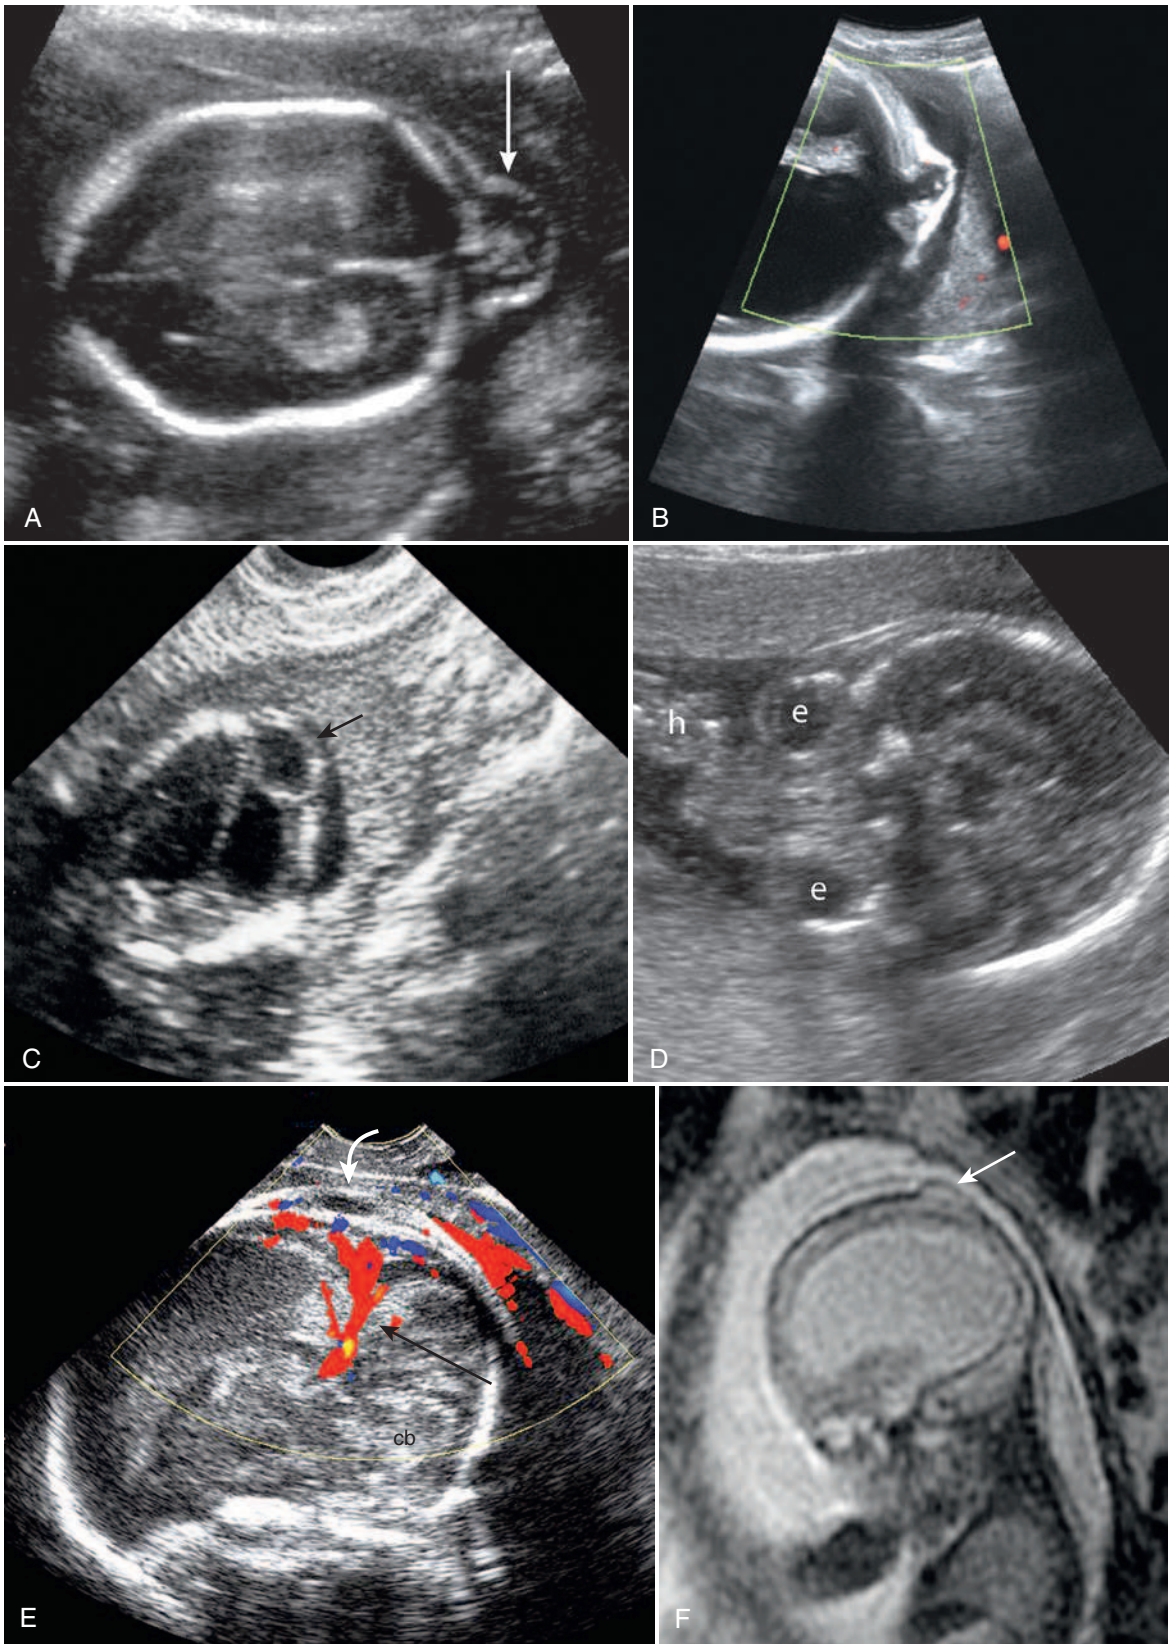

FIG. 34.13 Encephalocele. (A) Occipital encephalocele on axial view at 22 menstrual weeks shows brain tissue *(arrow)* herniating through the occipital bony skull defect. **(B)** In another fetus, a small skull defect is seen with only meninges and no brain tissue in this fetus with ventriculomegaly and **meningocele. (C) Asymmetrical parietal encephalocele** *(arrow).* Coronal view at 21 menstrual weeks shows asymmetrical encephalocele. **(D) Anterior encephalocele** *(arrow)* at 18 weeks containing brain herniated through a defect between the orbits where it appears as a mass in the expected area of the nose. Also, slight hypertelorism is present. *e,* Eyes; *h,* hand. **(E) Atretic encephalocele** seen as a small subtle blister *(curved arrow)* in the scalp on midsagittal color Doppler image. Typically, these do not contain brain tissue but are associated with an abnormal falcine venous sinus of Markowski *(arrow),* which courses from the cerebral vein to the superior sagittal sinus. The vein of Galen can be absent. *cb,* Cerebellum. **(F)** Small encephalocele *(arrow)* associated with severe ventriculomegaly on magnetic resonance image.

TABLE 34.2 Features of Some Autosomal Recessive Syndromes Associated With Encephalocele[a]

Meckel-Gruber	Cystic renal dysplasia, polydactyly, other central nervous system abnormalities, microphthalmia, cleft lip and palate, micrognathia, ciliopathy
Walker-Warburg	Hydrocephalus, agyria (lissencephaly type 2), retinal dysplasia, vermis hypoplasia, kinked brainstem, muscular dystrophy
Joubert and related	Vermian hypoplasia, deep interpeduncular fossa (molar tooth), hydrocephalus, ciliopathy
Hydrolethalus	Hydrocephalus, cerebral abnormality, polyhydramnios, micrognathia, polydactyly, heart defects
Fraser	Cryptophthalmos, syndactyly, genital abnormality, renal abnormality, laryngeal stenosis
Robert	Phocomelia (pseudo-thalidomide), cleft lip and palate, intrauterine growth restriction

[a]Note that all have many other additional findings.[109]

The prognosis of cephaloceles depends on the location of the lesion, the amount of herniated brain, the formation of the underlying brain, associated anomalies, and genetic abnormalities. Prenatal and perinatal mortality rates are high, and intellectual impairment is common. If discovered before viability, pregnancy termination is considered. Later in pregnancy, management depends on the size and location of the encephalocele and associated anomalies.[102,112,113]

Ciliopathies

Ciliopathies are a group of disorders resulting from abnormal structure or function of cell surface cilia due to mutations in ciliary genes. Cilia are found on the surface of almost all cells of vertebrates, and their functions are very much more complex than providing simple transport as seen in bronchi and various anatomic ducts. Normally functioning cilia are required for the normal development and function of seemingly unrelated sites including brain, kidneys, eyes, liver, and skeleton. In the brain, cell surface cilia are involved with brain patterning and neuronal migration and help direct CSF flow. Abnormal ciliary function may result in HC and other cerebral malformations including encephaloceles.[114] Over 40 mutations of ciliary genes have been found, resulting in over 1000 polypeptide abnormalities. As result, the expression of ciliary gene mutation is variable. A single gene mutation may cause different phenotypes, and mutations of different genes may result in the same phenotype. Commonly encountered ciliopathies have overlapping features such as encephaloceles and include **Meckel-Gruber syndrome, Joubert syndrome, orofaciodigital syndrome, Bardet-Biedl syndrome, autosomal recessive polycystic kidneys, autosomal dominant polycystic kidneys, Jeune asphyxiating thoracic dystrophy, Ellis-van Creveld syndrome,** and others.[115]

Joubert Syndrome

Joubert syndrome and related disorders (JSRD) have the key feature of molar tooth sign visible on MRI. The molar tooth appearance results from hypoplasia of the cerebellar vermis, horizontal thick elongated cerebral peduncles, and deep interpeduncular fossa at upper pons; on axial MRI of the brainstem, these features look like a **molar tooth.** This sign is used as the diagnostic test in children. JSRD is clinically characterized by hypotonia, ataxia, psychomotor delay, irregular breathing, and abnormal eye movements and has an incidence of about 1 per 80,000 pregnancies. Different combinations of ciliary gene mutations can result in primary Joubert syndrome, and related disorders have variable abnormalities of the neurons, eye, renal tubules, and bile ducts and polydactyly.[116]

On ultrasound the molar tooth sign findings of vermian hypoplasia, thickened cerebral peduncles, and interpeduncular notch may be visible by 20 weeks and confirmed by MRI if needed.[117] Additional cerebral imaging findings can include abnormalities of the corpus callosum and neuronal migrational abnormalities, Dandy-Walker malformation (DWM), and encephalocele as well as abnormalities in somatic structures. If the mutation is known (about 50%), early diagnosis is possible with chorionic villus sampling (CVS).

Prognosis is generally poor and related to extent of breathing and feeding problems in the short term and renal and hepatic complications in the long term.

Meckel-Gruber Syndrome

Meckel-Gruber syndrome is likely the most common syndromic abnormality of the CNS and is characterized by occipital encephalocele, enlarged dysplastic kidneys, hepatic duct proliferation, polydactyly, posterior fossa abnormalities, and craniofacial and heart defects and has features that overlap with JSRS. Incidence is 1 per 13,000 to 140,000 live births. It is a lethal autosomal recessive disorder associated with mutations in several ciliary genes. The detection of its classic triad of large echogenic kidneys, encephalocele, and postaxial polydactyly can allow diagnosis as early as 14 weeks, but oligohydramnios in later pregnancy may hinder detection of some of these features. Autosomal recessive polycystic disease and trisomy 13 should be considered in the differential diagnosis. Genetic testing may be possible in at-risk families.[118]

Amniotic Band Sequence/Limb–Body Wall Complex

Amniotic band sequence/limb–body wall complex describes a variable collection of disruptive abnormalities and is associated with adherence of the fetus to bands in the amnion.

Cases are sporadic, occurring in about 1 to 10 per 10,000 pregnancies, and typically have normal karyotype. Fetuses with these conditions have a very variable range of complex, generally

asymmetrical abnormalities that range from minor to massively disruptive. Cranial manifestations may initially mimic anencephaly, encephalocele, and other cerebral abnormalities and are often associated with asymmetrical facial disruptions. The literature on the etiology and pathogenesis of these sporadic conditions is confusing and controversial and includes amniotic rupture, vascular disruption, and abnormal development of embryonic body folds. There is a common theme of combinations of amniotic abnormality and asymmetrical fetal disruptions. Bands may be seen attached to abnormal body parts, or the fetus is partly fixed to the uterine wall. **Limb–body wall complex** terminology is often used if there is a more severe malformation consisting of encephalocele with facial clefts, thoracoschisis or abdominoschisis, short umbilical cord, and limb defects. Often there are internal abnormalities that cannot be explained by amniotic bands such as congenital heart disease, renal agenesis, and intestinal atresias. Minor variants may have only **constrictive amniotic bands** resulting in annular constrictions or focal malformations of limb parts.

The findings at ultrasound vary with affected areas. Clues to diagnosis are asymmetrical abnormalities and amniotic bands attaching to the fetus or fetal parts that are stuck to the uterine wall (as with limb–body wall complex). The bands can be hard to see, and technique needs to be optimized and gain increased to demonstrate them. In some cases fetal anatomy is so disrupted that parts become unrecognizable and this massive disruption is the clue to the diagnosis. The condition can mimic anencephaly or encephalocele, and often additional intracranial abnormities are present (see Fig. 34.12C).

The major disruptions are lethal. Three-dimensional ultrasound and MRI can be helpful in clarifying the extent of the lesions. Prognosis, counseling, and management depend on the nature and degree of disruptions. Fortunately, these anomalies are sporadic, with negligible recurrence risk.[96,119-121]

Cranial Changes in Spina Bifida

Spina bifida or **neural tube defect** (NTD) is the second most common birth defect after congenital heart disease. Two general groups are recognized: open (not skin covered) and closed (skin covered). Both result from abnormalities associated with neural tube closure. Open lesions result from failure of closure of the neural tube, leaving a defect that leaks CSF and exposes neural tissue to the damaging effects of amniotic fluid. About 80% to 90% are open, appearing as dorsal cyst (myelocele or meningomyelocele depending on neural content) or rachischisis (uncovered open defect). Open lesions are commonly associated with elevated MS-AFP above 2.50 multiples of the median (MoM). The remaining 10% to 20% are closed (occult) lesions that are skin covered and do not leak AFP and in which MS-AFP levels are normal. Closed defects result from failure of separation of the neural tube from the skin and abnormal adjacent mesenchymal tissue development. These cause variable spinal, vertebral, and cutaneous lesions including lipoma, lipomeningocele, hypertrichosis, tags, dorsal pits, and others.[122]

The incidence is about 0.2 to 10 per 1000 pregnancies and has decreased by about 70% following folate supplementation. The etiology is multifactorial and includes syndromes, genetic abnormalities, and maternal and fetal factors including diabetes and teratogens such as anticonvulsants.[108,123,124]

Open spina bifida is virtually always associated with the **Chiari II** malformation which is a complex deformity involving calvaria, dura, cerebrum, and hindbrain. In Chiari II malformation the striking abnormalities are evident in the small posterior fossa and include herniations of the vermis, pons, and medulla; **brainstem kinking; small fourth ventricle; aqueduct stenosis;** and **tectal beaking.** There are, however, additional pancranial changes that involve the skull bones (beaten silver appearance or **Lükenschädel**), small posterior fossa, falx (interdigitation of sulci, low-lying tentorium and transverse sinuses), large massa intermedia, cerebral hemispheres (hydrocephalus, dysgenesis of corpus callosum, heterotopias, malformations of cortical development, and distortion of the limbic system).[125-127] It is believed that leakage of CSF through the spinal defect leads to a cascade of events resulting in a small underdeveloped posterior fossa followed by hindbrain compression and obstruction to CSF flow, which leads to additional cerebral and calvarial abnormalities.[126] Some believe that failure of neural tube closure is not just a single event, but rather is only part of a spectrum of developmental abnormalities not yet fully defined but that result in multiple additional cerebral and somatic abnormalities.[125]

Of newborns with spinal NTDs, it was found that 80% had isolated NTDs. The remaining 20% had additional anomalies including chromosomal abnormalities or sporadic abnormalities involving virtually all systems.[123,128] An autopsy study found that 68% of cases with spina bifida had non-CNS anomalies, most commonly skeletal (club feet), but also involving kidneys, gastrointestinal tract, abdominal wall, and other structures.[129] A recent multicenter prenatal ultrasound study found chromosome abnormalities in 6.2% of cases (most commonly, trisomy 18 and triploidy) and structural abnormalities in 4.6% (most commonly heart defects).[130]

The actual spinal abnormality of open NTD can be very difficult to see at screening ultrasound, but the defect leaks CSF containing alpha-fetoprotein (AFP), which may become detectable in maternal serum (MS-AFP). This was the basis of earlier serum AFP screening for open defects. Maternal serum levels greater than 2.5 MoM at 16 to 18 weeks detected 88% of anencephalic fetuses and 79% of fetuses with open NTDs but were also found in 3% of normal fetuses. However, all closed, skin-covered NTDs were missed by MS-AFP screening.[131]

In the 1980s it was found that open NTDs are virtually always associated with readily detected ultrasonographic cranial changes of **Chiari II malformation** in the second trimester (Fig. 34.14, Video 34.6). This is unlike closed spina bifida, in which the brain and posterior fossa are normal and the spinal abnormality can be detected only with careful direct examination of the spine (Fig. 34.15).[132] Improvements and standardization and use of these cerebral signs now allow second-trimester detection of open spina bifida in 88% to 96% of cases, and even 100% in some expert hands. Many believe that second-trimester ultrasound has replaced MS-AFP screening for open lesions (anencephaly, encephalocele, open spina bifida).[130]

Many second-trimester cranial signs of spina bifida have been suggested (Table 34.3). The most commonly used are obliteration

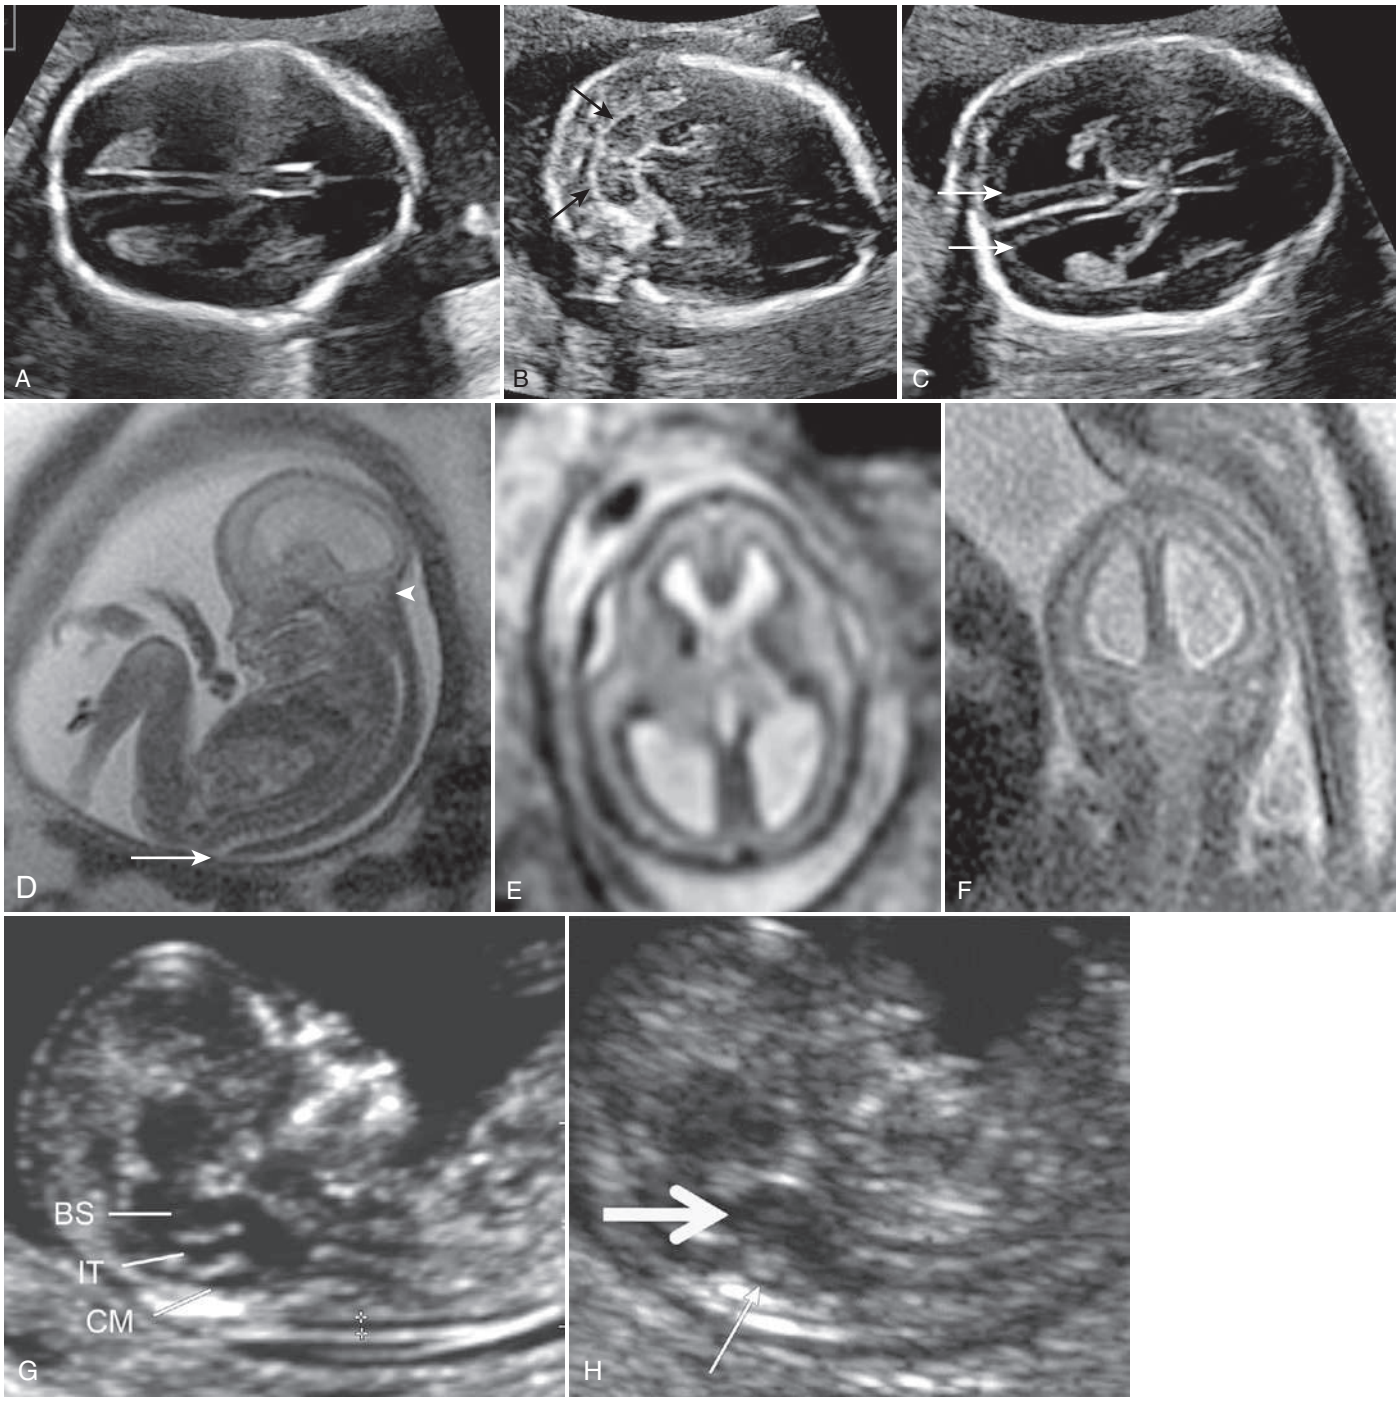

FIG. 34.14 Cranial Findings of Chiari II Malformation With Open Spina Bifida. (A) "Lemon sign" with indentation of frontal bones. **(B) "Banana sign"** of compressed cerebellum *(arrows).* The cerebellum is tightly compressed against the occipital bone and curves around the brainstem, and there is no fluid in the cisterna magna (effacement of cisterna magna). **(C)** Axial ultrasound shows the pointed appearance of the posterior tips of the ventricles *(arrows).* **(D)** Sagittal T2-weighted magnetic resonance image shows inferior displacement of the cerebellum typical of the Chiari II malformation *(arrowhead)* and inferiorly, the spinal defect *(arrow).* **(E)** Axial magnetic resonance image shows the pointed appearance of the ventricles. **(F)** Coronal magnetic resonance image shows ventriculomegaly and obliteration of the cisterna magna. **(G) Normal intracranial translucency** *(IT)* at 12 weeks. Note three dark bands and four white lines. Intracranial translucency is really the forming fourth ventricle. *BS,* Brainstem; *CM,* cisterna magna. **(H) Abnormal IT with spina bifida.** The brainstem *(thick arrow)* is thickened. The IT and CM are absent (do not contain fluid) *(small arrow).* (Courtesy of Dr. K. Fong, Mt. Sinai Hospital, Toronto, Ontario.)

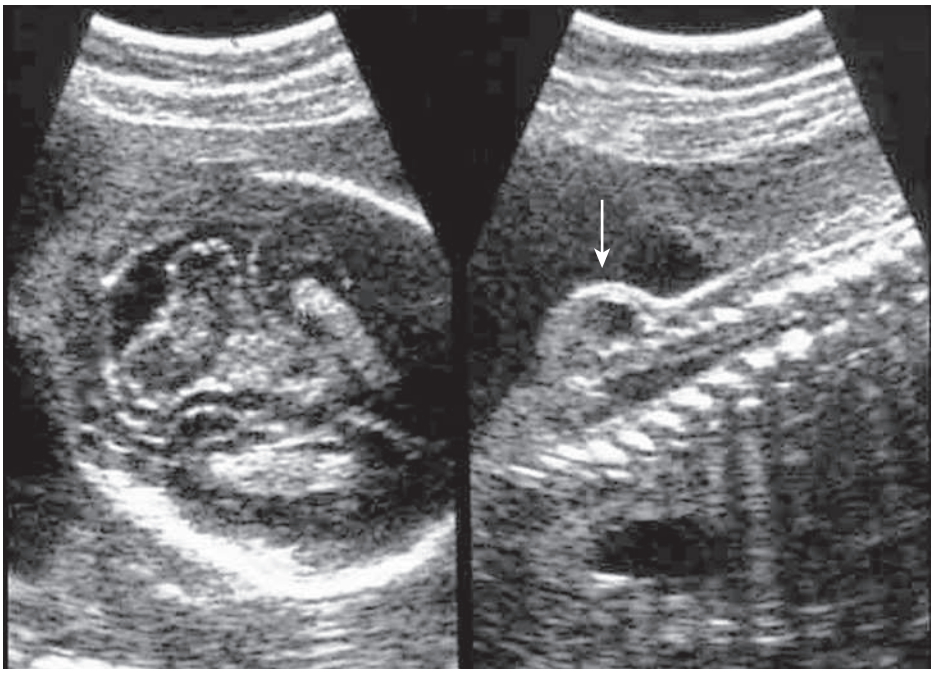

FIG. 34.15 Closed, Skin-Covered Spina Bifida at 21 Weeks. The right image shows an obvious meningomyelocele *(arrow)*. On the left image, note the normal ventricles, cerebellum, and cisterna magna. Fetuses with closed, skin-covered spina bifida do not have a Chiari II malformation and lack the typical intracranial signs. The maternal serum alpha-fetoprotein (MS-AFP) is normal because the skin covers the defect.

TABLE 34.3 Second-Trimester Cranial Signs Associated With Open Spina Bifida[122,130,133,135]

Finding	Frequency	Comments
Effacement of cisterna magna	95%-100%	From about 14 weeks onward
Bifrontal indentation ("lemon sign")	53%-100%	14-24 weeks, disappears later. Also seen in 1% of normal fetuses and in other conditions such as skeletal dysplasia
Cerebellar "banana" sign	62%-97%	Cerebellum wrapped around brainstem
Ventriculomegaly > 10 mm	46%-86%	More common after 24 weeks
Small BPD < 5th percentile	26%-70%	
Small head circumference < 5%	26%-70%	
Small cerebellum < 10%	96%	
Funneling of posterior fossa	96%	Clivus-supraocciput angle < 72 degrees
Pointed dilated occipital horns	70%	Seen on axial view

or effacement of the cisterna magna, the **"lemon sign"** (bifrontal indentation), the **"banana sign"** (cerebellum wrapped around brainstem) and VM exceeding 10 mm. Less frequently used second-trimester signs include small BPD and head circumference (even if VM is present), funneling of the posterior fossa as measured by a small clivus-supraocciput angle, and pointing of the occipital horn. Some caveats to these signs bear attention. The level or extent of the spina bifida does not relate to the cranial signs. The lemon sign is seen more commonly before 24 weeks (5%-100%) but in only 13% after 24 weeks. It is less pronounced in fetuses with abnormal chromosomes and can also be seen in about 1% of normal fetuses.[133-135] The banana sign and VM can worsen over the course of gestation.

There are increasing efforts to screen for spina bifida with ultrasound at time of NT scan.[99,136-145] Interestingly, the spinal defect has been detected as a dorsal abnormality as early as 9 weeks before head changes become apparent.[38,137] After about 12 weeks, cranial changes may begin to be observed (see Fig. 34.14G-H, Table 34.4). These include decrease in head size, altered head shape, and alterations in the posterior fossa including posterior displacement of the midbrain and cerebral peduncles, thickening of the brainstem, and loss of fluid spaces in the cisterna magna and fourth ventricle. A recent prospective study of markers in the first trimester by highly trained operators using IT and cisterna magna appearances found positive or suspicious findings in 11 of 11 cases (100%).[140] Management in first-trimester cases

TABLE 34.4 First-Trimester Signs of Open Spina Bifida

Sign	Sensitivity	Comments
DIRECT SIGN		
Spinal abnormality (meningocele, kyphoscoliosis)[38,140]	50%-60%	9 weeks onward Dorsal mass or irregularity apparent before cranial changes
INDIRECT SIGNS		
BPD plus biomarkers[131,136]	70%	BPD small, AFP elevated
BPD/abdominal diameter ratio ≤1[145]	69%	
BPD below 5th percentile[145]	50%-56%	
Frontomaxillary angle below 5% for CRL[144]	90%	Sloping forehead appearance
"Lemon sign" or "acorn sign"[146]	?	Similar to "lemon sign" in midtrimester
Brainstem/occipital bone ratio[143]	87%-100%	Decreased with spina bifida
Brainstem diameter above 95th percentile[143]	96.7%	Brainstem diameter is increased
Four-line view observed[142]	67	The normal four lines demarcating the anterior and posterior brainstem, fourth ventricle, and occipital bone are not seen
Parallel cerebral peduncles or posterior position of brainstem[137,138]	?	Seen on axial view below BPD level
Absent IT[140]	18%	
Absent cisterna magna[140]	64%	Fluid not seen in cisterna magna
Prospective studies using IT, four-line view, BPD, IT/CM ratio, brainstem diameter, BSOB[140]	50%-100%	

BPD, Biparietal diameter; *BSOB,* brainstem/occipital bone ratio; *CM,* cisterna magna; *CRL,* crown-rump length; *IT,* intracranial translucency.
References 38, 99, 131, 136-138, 140-142, 144-146.

differs from management during the second trimester because the indirect cranial findings are only suggestive, and direct confirmation of the spinal defect in the first trimester is difficult. The sensitivity, specificity, and false-positive rate of these signs have not been established. It is prudent to reassess suspected cases at 15 to 16 weeks when spinal abnormalities and more specific cranial findings become more confidently detectable.[99]

The investigation of fetuses suspected of having spinal abnormalities includes detailed evaluation for associated cranial and somatic abnormalities. Determination of the spinal level of the defect is important for functional prognosis regarding bowel and bladder function and ambulation. MRI may help demonstrate additional brain abnormalities including cerebral hypoplasia and migrational and callosal abnormalities. Karyotype testing should be performed because 7% to 16% have chromosomal abnormality even with apparently isolated NTDs.[97,147]

Prognosis varies and depends on associated abnormalities. Overall survival is about 66% at 20 years. Prenatal surgery in selected cases is associated with additional maternal and prematurity risks related to the procedure. However, fetuses that undergo surgery have reduced hindbrain herniation, reduced need for ventricular shunting (40% vs. 82%), and improvement in neuromotor functions such as walking (42% vs. 21%), but no improvement in urinary function.[148] Prognosis and quality of life in children with open NTDs relates to manifestations of Chiari II malformation including apnea, swallowing, lower cranial nerve function, and foramen magnum impaction. Other issues include spinal deformities, tethered cord, and progressive orthopedic problems. About 70% have an IQ above 80, half can live independently, and 25% to 38% are capable of active employment.[124]

ERRORS OF VENTRAL INDUCTION

Errors of **ventral induction** occur in the rostral end of the embryo and result in brain abnormalities of the prosencephalon, mesencephalon, and rhombencephalon and usually also affect facial development.[93] The prosencephalon is induced to develop through a process of ventral induction consisting of formation, cleavage, and development of midline structures and facial structures. Several developmental abnormalities can occur. Absence of prosencephalic formation is rare and includes **aprosencephaly** (absence of the prosencephalon) and **atelencephaly** (absence of the telencephalon). More common is failure of prosencephalic and adjacent facial patterning and cleavage resulting in incomplete separation of prosencephalon into two distinct hemispheres, associated with abnormalities of midline and facial structures manifesting as the different degrees of HPE.[149,150]

Holoprosencephaly

Holoprosencephaly (HPE) is a complex brain malformation resulting from incomplete separation of the prosencephalic diverticulum into right and left cerebral hemispheres. It is often associated with facial abnormalities. It is the most common abnormality of brain development and is seen in about 1 per 250 conceptuses but only 1 per 16,000 live births because only 3% survive to delivery.[149,151-153]

Cerebral hemisphere development starts at about 5 weeks with prechordal mesoderm migration into the area anterior to the notochord where under genetic control it induces midface and forebrain development. Normally apoptosis of midline areas results in separation of facial and prosencephalic structures into left and right sides by 5 weeks. The failure to separate by apoptosis results in the fused cerebral and facial appearances of HPE. The severity of facial dysmorphism correlates with cerebral abnormalities in about 80% of cases ("the face predicts the brain"). Not surprisingly, additional abnormalities involving any part of the brain and body are found in about 50% to 65% of cases.[149-153]

HPE etiology and phenotype are heterogeneous and result from multiple varied genetic and environmental "hits" to the development process. HPE is part of different syndromes and about 40% have chromosomal abnormalities, but many cases are sporadic and without etiologic explanation.[150-152,154]

Factors Associated With Holoprosencephaly

Environmental teratogens: alcohol, smoking, retinoic acid, salicylates, anticonvulsants
Metabolic: insulin-dependent diabetes (1% risk)
Infections: cytomegalovirus, toxoplasmosis, rubella
Syndromes with normal karyotype (about 25% of holoprosencephaly)
- Smith-Lemli-Opitz
- Pallister-Hall
- Velocardiofacial
- Meckle

Chromosomal abnormalities
- Trisomy 13 (70% have holoprosencephaly)
- Trisomy 18
- Triploidy

Gene mutations
- *SHH* (Sonic Hedgehog; expressed in notochord and floor plate of neural tube)
- *ZIC2* (has role in neurulation in dorsal midline)
- Unexplained/sporadic (50%-65%)

Isolated HPE can have autosomal dominant inheritance with incomplete penetrance and variable expression. Parents of affected children should be examined for mild manifestations such as single central incisor and absent nasal cartilage.[153-155]

HPE is a continuous malformation that is classically divided by DeMyer[156] into three overlapping phenotypic types depending on severity: **alobar** (75% of cases, monoventricular, face typically abnormal), **semilobar** (10% of cases, anterior hemispheres fail to separate but there are two posterior lobes), and **lobar** (10% of cases, two hemispheres form, but the anterior forebrain is incompletely separated). About 5% are atypical forms, including a **midline interhemispheric form (syntelencephaly).** Severe cases often have a dorsal cyst, the dilated suprapineal recess of the third ventricle dilation secondary to obstruction of CSF flow by thalamic fusion[149,151-154] (Fig. 34.16, Video 34.7). The range of abnormalities is much larger than these simple categorizations suggest, involving not only the cerebrum but also basal ganglia and other lower areas. Furthermore, there are **microforms of HPE** with mild manifestations such as single midline incisor tooth, hypotelorism, or absence of olfactory lobes.[149,151-154]

General Anatomic Classification of Holoprosencephaly

ALOBAR
Single forebrain ventricle
No interhemispheric division
Absent olfactory tracts
Absent corpus callosum
Nonseparation (fusion) of deep gray nuclei
Dorsal cyst
Facial abnormality common

SEMILOBAR
Rudimentary cerebral lobes
Incomplete anterior hemisphere division
Absent or small olfactory tracts
Absent anterior corpus callosum (posterior part may develop)
Variable nonseparation of deep gray nuclei

LOBAR
Fully developed cerebral lobes
Distinct interhemispheric division
Midline continuous frontal neocortex
Corpus callosum absent, hypoplastic, or normal
Separation of deep gray nuclei
Fused fornices
Azygous (wandering) anterior cerebral artery

MIDLINE INTERHEMISPHERIC FORM (SYNTELENCEPHALY)
Failed separation of parietal hemispheres
Vertical sylvian fissure appearing to connect across the midline at the vertex
Anterior and posterior corpus callosum formed
Absent or abnormal central corpus callosum
Normal separation of hypothalamus and lentiform nuclei
Gray matter heterotopia

Prenatal diagnosis is based mainly on imaging findings.[149,154] HPE has been diagnosed as early as 9 weeks through demonstration of a single ventricle, single orbit, and proboscis.[152,153] In such early cases, it is important not to mistake the normal rhombencephalic cavity for HPE.

In later pregnancy, typically there is absence of the CSP, variable absence of the falx, and fused appearance of midline structures. **Alobar holoprosencephaly** has three variants—pancake, cup, and ball—depending on the size and configuration of the dorsal cyst. The **pancake** type has a small, flattened plate of cerebrum anteriorly, with a large dorsal cyst posteriorly. The **cup** type has more anterior cerebrum, forming an anterior cuplike mantle and a dorsal cyst. The **ball** type has a single, featureless, monoventricle surrounded by a mantle of ventricle of varying thickness. With **semilobar holoprosencephaly** there is a rudimentary attempt at cleavage of occipital horns (see Fig. 34.16D). Because

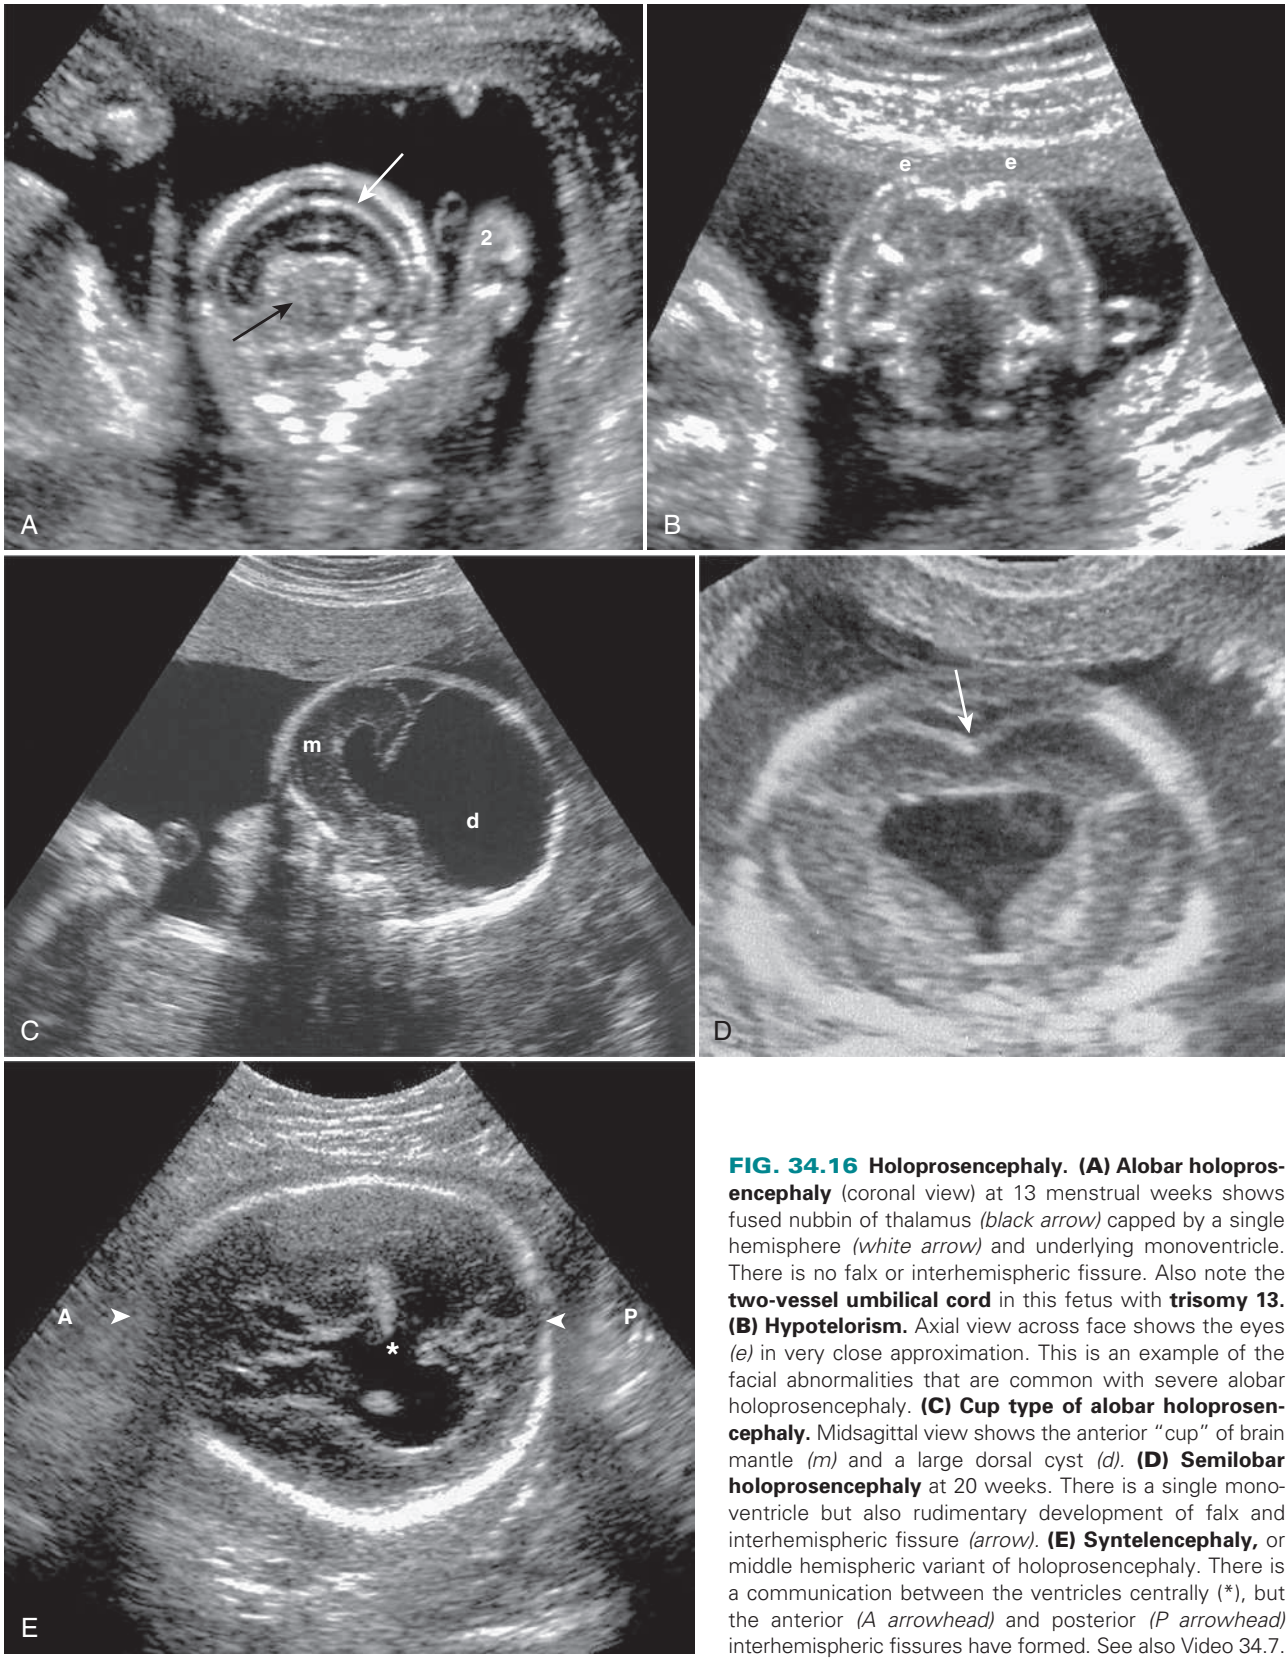

FIG. 34.16 Holoprosencephaly. (A) Alobar holoprosencephaly (coronal view) at 13 menstrual weeks shows fused nubbin of thalamus *(black arrow)* capped by a single hemisphere *(white arrow)* and underlying monoventricle. There is no falx or interhemispheric fissure. Also note the **two-vessel umbilical cord** in this fetus with **trisomy 13. (B) Hypotelorism.** Axial view across face shows the eyes *(e)* in very close approximation. This is an example of the facial abnormalities that are common with severe alobar holoprosencephaly. **(C) Cup type of alobar holoprosencephaly.** Midsagittal view shows the anterior "cup" of brain mantle *(m)* and a large dorsal cyst *(d)*. **(D) Semilobar holoprosencephaly** at 20 weeks. There is a single monoventricle but also rudimentary development of falx and interhemispheric fissure *(arrow)*. **(E) Syntelencephaly,** or middle hemispheric variant of holoprosencephaly. There is a communication between the ventricles centrally (*), but the anterior *(A arrowhead)* and posterior *(P arrowhead)* interhemispheric fissures have formed. See also Video 34.7.

lobar holoprosencephaly forms cerebral hemispheres, it may be difficult if not impossible to diagnose prenatally. Features that suggest lobar HPE include absence of septi pellucidi, fusion and squaring of the frontal horns, and an abnormal appearance of two large nerve trunks, the **fornices,** which are rudimentary and appear fused into a single tract above the third ventricle. With color Doppler sonography, the anterior cerebral artery may have an azygous (wandering) course, "crawling" under the skull. Fusion of the fornices in HPE may help differentiate HPE from **septo-optic dysplasia** (SOD).[157]

Many authors emphasize detection of associated facial abnormalities in diagnosing HPE (see Fig. 34.16B). Facial changes are seen more frequently with more severe HPE and have been categorized into four main groups, with severity approximating degree of brain abnormality.[151-155]

Facial Changes Associated With Holoprosencephaly[151]

Cyclopia with single eye, with or without proboscis
Ethmocephaly (hypotelorism and proboscis between the eyes)
Cebocephaly (hypotelorism, nose with single nostril)
Median cleft lip and palate and hypotelorism
Single central incisor

The differential diagnosis includes severe **hydrocephalus, septo-optic dysplasia** (SOD), **absence of septi pellucidi, schizencephaly, hydranencephaly,** and **porencephaly.**[153,158] Milder forms can be difficult to diagnose even after delivery and may need specialized experienced neuroradiologic consultation.[153] For counseling purposes, it is important to determine the degree of cerebral malformation and whether it is isolated or part of a syndrome or associated with additional abnormalities. MRI and chromosome and genetic analysis can be helpful.[151,154]

Prognosis is variable and depends on severity of HPE, associated abnormalities, and medical and neurologic complications. Severely affected fetuses do poorly or die in utero. Mildly affected children may exhibit few symptoms and may live a normal life. About 75% need shunting.[151] In general, the severity of clinical problems and neurologic dysfunction correlates with the degree of hemispheric and hypothalamic failure of separation and can include endocrinopathy (especially diabetes insipidus), temperature dysregulation, motor and movement abnormalities, and developmental delay.[154,159] Pregnancy termination is generally considered after prenatal diagnosis. Survivors are managed symptomatically.

The fourth variant of HPE, the **middle interhemispheric form** of HPE, also called **syntelencephaly,** has a separation of the anterior and posterior parts of the hemispheres, but fusion is present in the central region of the brain between parietal hemispheres, and the face is typically normal. In general, cases involve mild VM, absence of parts of the septi pellucidi, abnormality of the midpart of the corpus callosum, and dorsal cysts. The condition can resemble mild VM with septal fenestration. Coronal scanning may show fusion of the central parts of the hemisphere. MRI helps confirm this appearance and typically shows sylvian fissures connecting abnormally across the midline[153,154,158,160] (see Fig. 34.16E).

The middle interhemispheric form tends to have better outcomes with functional disabilities similar to those with lobar HPE, but endocrine functions are normal because the hypothalamus tends to be spared.

Posterior Fossa and Cerebellum

Cerebellar development starts at about 6 to 7 weeks' gestation, and the final gross form is achieved by about 18 to 20 weeks. It develops as thickenings of lateral rhombic lips, which enlarge posteriorly and are joined in the midline by the vermis, which develops from the rostral aspect. These thickenings grow into the thin membranous dorsal aspect of the neural tube, the **area membranacea,** which is the rhombencephalic "cyst" that is prominent in early pregnancy and later becomes the fourth ventricle and fenestrates, forming the foramina of Magendie and Luschka.[27,29] There is a rapid acceleration of growth starting about 24 weeks, after which the rule that "cerebellar diameter = weeks gestation" no longer holds. Cerebellar components continue to develop to about 7 months after birth, and final neuronal organization continues to about 20 months after delivery. As the posterior fossa develops, the brainstem initially becomes flexed or kinked (mesencephalic, pontine, and cervical flexures) but again straightens out by about 14 to 16 weeks as the spinal cord expands with developing spinal nerve tracts.[161] There are many genetic and molecular mechanisms involved in cerebellar development, and these have additional roles in CNS and somatic development. Consequently, abnormal cerebellar development is often accompanied by developmental and functional changes in the cerebral cortex and other parts of the body. Specific malformations may suggest genetic syndromes, but any malformation can also result from disruptive processes including infection or teratogenic, metabolic, or traumatic insults.[162,163] Functionally, the cerebellum not only controls voluntary movements but is also involved in nonmotor and cognitive functions. Many children with cerebellar malformations come to medical attention because of developmental and behavioral issues.[162,164-166]

The cerebellum is routinely examined with standard axial views, focusing on transverse diameter, the intactness and size of the vermis, and the depth of the cisterna magna, which should measure less than 10 mm.[5] When an abnormality is suspected, midsagittal views are important to evaluate the integrity, size, rotation, and fissures of the vermis as well as the appearance of the fourth ventricle and brainstem. Transvaginal scanning, 3-D ultrasound, and MRI including sagittal views are especially useful (Fig. 34.17). Care should be taken before 18 weeks to not mistake the incompletely formed vermis for a defect.[30,86,167-171]

With careful technique, as discussed earlier, a small physiologic **Blake pouch** is visible in over 80% of fetuses, as a small cyst in the midline just below the valleculae at the lower border of the cerebellum that does not affect the cerebellum in the midline (see Fig. 34.7A). When this structure enlarges, it can rotate the vermis or it may expand behind the cerebellum as a **mega–cisterna magna.**[29]

Additional anatomic features of the vermis are visible on midsagittal views (see Fig. 34.17). The fourth ventricle is a small

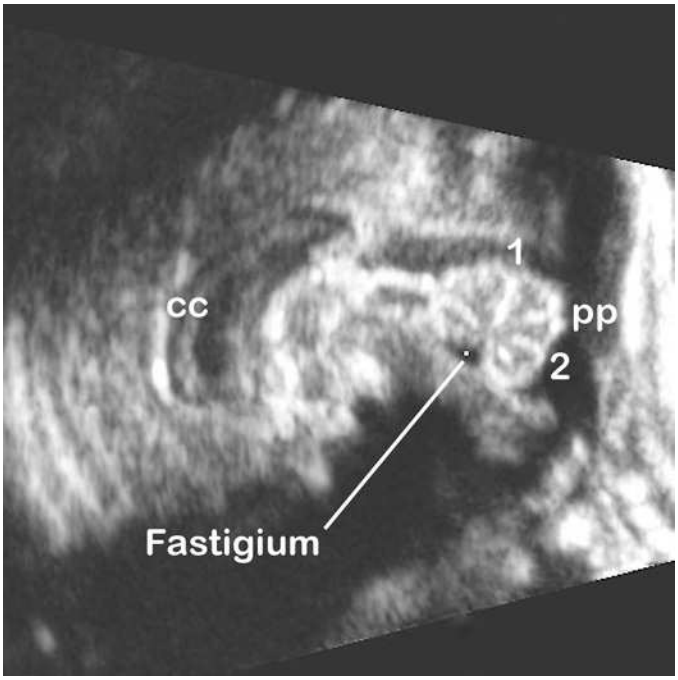

FIG. 34.17 Three-Dimensional (3-D) Midsagittal View of Normal Brain. Three-dimensional midsagittal view of normal brain at 21 weeks using volume contrast imaging (VCI). This is basically a thick-slice scan that increases contrast and decreases noise. Note the triangular shape of the cerebellar vermis behind the brainstem. This is the best view to evaluate the corpus callosum *(cc)* and vermis. Line indicates apex of the fourth ventricle and fastigial point. Normally as here, the upper and lower parts of the cerebellum touch the brainstem. A line connecting the fastigium and declive (the most posterior bulging part of the vermis) normally divides the vermis into approximately equal upper and lower portions. After about 20 weeks, three vermian fissures can usually be identified as white septa invaginating into the darker cerebellum. They are the primary *(1),* the prepyramidal *(pp),* and the secondary *(2)* fissures. More fissures become visible with advancing age as are seen in this fetus.

triangular space that normally has a pointed apex, the **fastigial point.** The upper and lower parts usually touch the brainstem, but the lower part may rotate outward **(tegmento-vermian angle)** to about 10 degrees. A line drawn between the fastigial point and the most posterior bulge of the vermis bisects the vermis into approximately equal halves. Nomograms are available for vermian dimensions. Vermian fissures become visible after about 18 weeks and can be used to help determine normal vermis development. The primary fissure between the culmen and declive is seen at about the 2 o'clock position by 24 weeks, and the secondary between the pyramis and uvula at the 5 o'clock position by 30 weeks. Commonly a third fissure is visible horizontally between these two.

Practically, it is easiest to approach posterior fossa abnormalities anatomically and consider three elements as suggested by Guibaud: fluid space in the posterior fossa, cerebellar size, and cerebellar morphology.[169,170] Suspected abnormalities should be further evaluated with detailed examination of the brain and body including midsagittal views and 3-D ultrasound along with MRI to evaluate the brainstem and cerebellar vermis.[30,59,169-171]

Increased fluid and torcular elevation suggest **Dandy-Walker malformation,** whereas normally sited torcular position and normal cerebellar morphology suggest **mega–cisterna magna, Blake pouch cyst,** or **arachnoid cyst.** If the cerebellum is globally small, then the brainstem should be evaluated. A normal brainstem suggests **cerebellar hypoplasia,** and a small brainstem suggests **pontocerebellar hypoplasia.** Focal reductions suggest ischemia or hemorrhage. Global reductions suggest syndromes, aneuploidy, and infections. If there is anatomic abnormality, then considerations include **vermian agenesis** as with **Joubert syndrome** and spina bifida with **Chiari II.**

Counseling regarding posterior fossa abnormalities is difficult because fetuses with different conditions are variously grouped together.[172,173] Frustratingly, prenatal appearances often do not correlate with findings at pathology.[174] Genetic abnormalities have been described with many posterior fossa disorders, and many have autosomal recessive inheritance.[162,175] If posterior abnormalities are suspected, expert imaging opinion and interdisciplinary consultation should be considered.[30]

Dandy-Walker Malformation

Classic DWM is a triad of partial or complete vermian agenesis, cystic enlargement of the fourth ventricle, and elevated torcular or tentorium (Fig. 34.18). It occurs in about 1 per 30,000 pregnancies and is felt to arise from abnormal development of the membranous roof of the fourth ventricle at about 7 to 10 weeks. Midsagittal imaging is important because prognosis is associated with the degree of vermian abnormality as well as the presence of associated abnormalities. Additional CNS anomalies are common, especially **hydrocephalus** (70%-90%), **dysgenesis of the corpus callosum** (30%), **encephalocele** (16%), **migrational disorders, brainstem dysgenesis,** and **spina bifida.** Somatic abnormalities occur in 20% to 30%, including cystic kidneys, congenital heart disease, and facial clefts. DWM has a multifactorial etiology, and most cases are seen in association with genetic and nongenetic syndromes. At the 11- to 14-week scan, a large posterior fossa may be the first sign of DWM but can also be seen with chromosomal abnormality and other malformations and should be reassessed later in the pregnancy.[99,176]

The differential diagnosis includes **vermian dysplasia, Blake pouch cyst,** and **posterior fossa subarachnoid cysts.** Investigations include fetal MRI, assessment for maternal TORCH infection, chromosome analysis, microarray analysis, and consideration of syndromic forms, including **Walker-Warburg syndrome.**

The prognosis of DWM depends on associated abnormalities. Those with isolated DWM and relatively normal vermis do better, but those with associated CNS or somatic abnormalities do poorly. Neonatal mortality ranges from 12% to 55%. In live-born children, intelligence is normal in about 40%, borderline in 20%, and subnormal in 40%.[170,177]

Vermis Hypoplasia or Dysplasia

Vermis hypoplasia or dysplasia describes a conspicuous cleft between the inferior parts of the cerebellar hemispheres due to deficiency or absence of the lower part of the vermis. Controversy surrounds this appearance, which has been variously termed

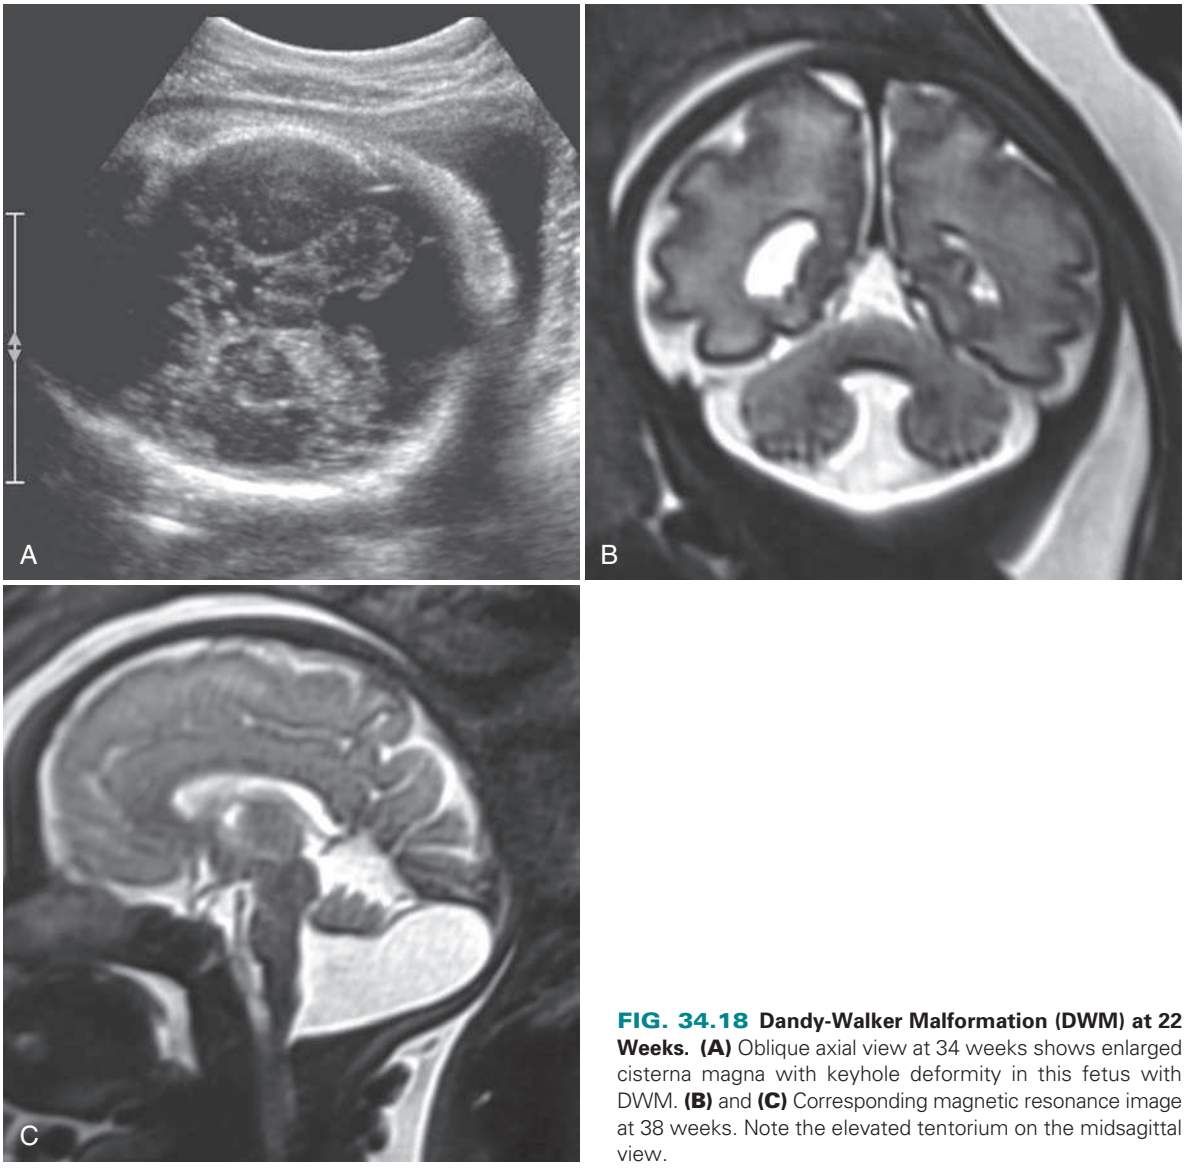

FIG. 34.18 Dandy-Walker Malformation (DWM) at 22 Weeks. (A) Oblique axial view at 34 weeks shows enlarged cisterna magna with keyhole deformity in this fetus with DWM. **(B)** and **(C)** Corresponding magnetic resonance image at 38 weeks. Note the elevated tentorium on the midsagittal view.

Dandy-Walker variant; Dandy-Walker continuum; (inferior) vermian hypoplasia, dysgenesis, or agenesis; and **Blake pouch cyst.**[30] The currently accepted term is **vermian hypoplasia or dysplasia.** Problems have arisen because on standard axial cerebellar views the Blake pouch can mimic this appearance.[28]

The vermis develops superiorly to inferiorly. Hypoplasia or developmental arrest results in varying-size deficits of the inferior portion, leaving a relatively square defect that communicates with the fourth ventricle and separates the lower cerebellar hemispheres. In general, the posterior fossa is not enlarged. Midsagittal scans, 3-D imaging, and MRI are important to evaluate the size and shape of the vermis and the shape of the fourth ventricle and to determine if normal early fissures have developed.[30,59,169,171]

There are diagnostic pitfalls. Hypoplasia or dysplasia should not be diagnosed earlier than 18 weeks, before vermian development is complete. On routine axial scans an excessively steep scanning angle may give the appearance of a prominent cleft between the lower portions of the cerebellar hemispheres that mimics vermian hypoplasia[30,178] (see Fig. 34.7B-C).

True cases of vermian hypoplasia are usually associated with additional abnormalities similar to those seen with DWM, and these help confirm the diagnosis (Fig. 34.19). Vermian hypoplasia can be associated with several syndromes, including **Joubert and related syndromes, Walker-Warburg syndrome, cerebro-oculo-muscular syndrome,** and **pontocerebellar syndrome.**[30,175]

Counseling is difficult. In one series, up to 50% of fetuses with the characteristic ultrasound findings of vermian dysplasia were functionally normal after delivery.[179] Ultrasound findings more likely to predict true abnormality were **trapezoidal vermian defect,** cisterna magna larger than 10 mm, and complete aplasia of the vermis. In contrast, normal cases tended to have a **keyhole-shaped defect.**[174] Prenatal MRI is helpful but also has limitations.

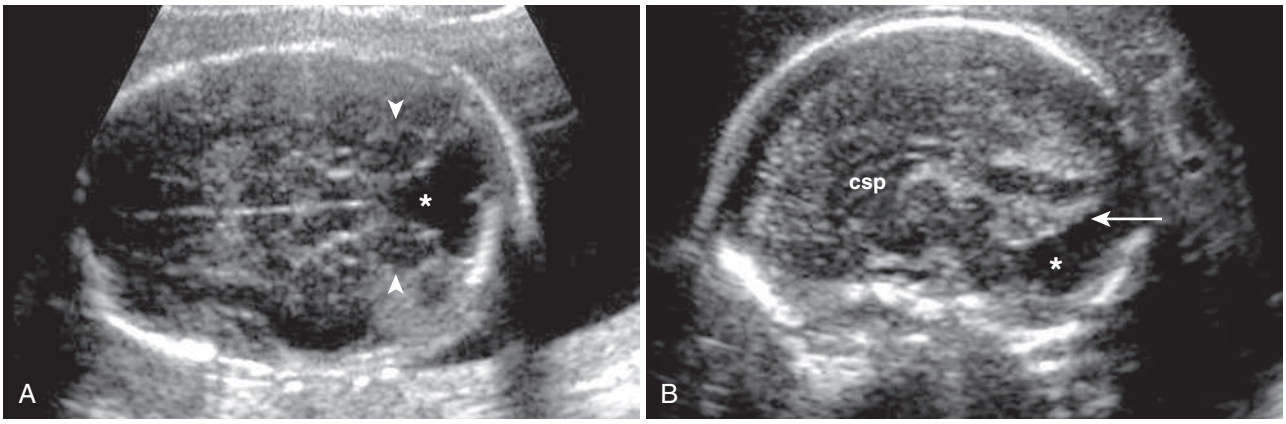

FIG. 34.19 Vermis Dysplasia or Hypoplasia. (A) Axial view shows fetus at 20 weeks with cleft (*) separating the cerebellar hemispheres *(arrowheads).* **(B)** Sagittal view shows the cerebellar vermis to be deficient in its inferior portion *(arrow),* with a fluid space in the expected region of the lower vermis (*). *csp,* Corpus callosum and cavum septi pellucidi.

In studies from Children's Hospital in Boston, postnatal MRI failed to confirm prenatal MRI findings in 6 of 42 cases (5 vermian hypoplasia, 1 mega–cisterna magna) but found additional, mainly cerebral abnormalities in 10 of 42 cases (heterotopias, brainstem hypoplasia, lissencephaly, hemorrhage).[164,180] Because of the diagnostic uncertainties, when vermian abnormality is suspected, additional anomalies should be sought. Additional investigation includes history, assessment for maternal TORCH infection, MRI, chromosome analysis, and molecular DNA analysis if the chromosomes are normal.[30]

Mega–Cisterna Magna

Mega–cisterna magna (MCM) refers to an enlargement of the cisterna magna beyond 10 mm with intact vermis (Fig. 34.20). On careful scanning, it can be noted that the contained fluid is anechoic and cyst walls can be seen in the far periphery, similar to a large Blake cyst. Many believe that MCM is just enlargement of a Blake cyst behind the cerebellum and without vermis rotation. When the condition is isolated, most children are normal. However, if not isolated, only 11% have normal outcome. The majority of nonisolated cases have VM, congenital infection, or karyotype abnormalities, especially trisomy 18. Differential diagnosis includes arachnoid cyst compressing the posterior fossa and DWM. Arachnoid cysts displace an otherwise normally formed cerebellum and frequently lie behind or above the cerebellum, may be asymmetrical, and do not communicate with the fourth ventricle.[46,177]

Rhombencephalosynapsis

Rhombencephalosynapsis is a rare hypoplasia of the cerebellum characterized by complete or partial absence of the vermis and fusion of the cerebellar hemispheres and dentate nuclei. Most cases are sporadic, although familial cases have been described.

Rhombencephalosynapsis may manifest with VM as early as 14 weeks. Cerebellar findings may not be initially conspicuous on the usual axial views. The defining findings at ultrasound are a small, bean-shaped cerebellum that lacks the typical echogenic waistlike narrowing at the vermis and cerebellar hemispheric fissures that are continuous from side to side without midline interruption. Midsagittal views show absence of the typical vermian fissures and may show an abnormally shaped fourth ventricle. These findings are more readily seen on MRI.[181,182]

Additional cerebral and somatic abnormalities are common. Cerebral findings primarily involve midline structures and include aqueduct stenosis, agenesis of the corpus callosum, absent septum pellucidum, and SOD. Somatic abnormalities include segmentation errors of the spine, phalangeal and radial ray defects, and occasional defects of the cardiovascular, respiratory, and urinary tract.

Prognosis is poor and most children die in childhood, but some may survive into adulthood. Most survivors are neurologically delayed and have movement disorders.[182]

Other Posterior Fossa Abnormalities

The vermis receives a disproportionate degree of discussion because vermian abnormalities are relatively conspicuous on routine second-trimester ultrasound. Numerous other, difficult-to-detect or late-appearing abnormalities also involve the posterior fossa. These include hypoplasia, clefts, changes related to ischemia, hemorrhage and infarct, cortical migration disorders (type 2 cobblestone lissencephaly), metabolic disorders, and other neurodegenerative disorders.

When abnormalities of the cerebellum and posterior fossa are suspected, then detailed neurosonography and somatic sonography should be performed and consideration given to further investigations including MRI and karyotype, assessment for infections, and expert counseling.[30,166,172,175,183]

Arachnoid Cysts

Arachnoid cysts are benign, noncommunicating fluid collections within arachnoid membranes. Most appear stable and require no surgical treatment. They can occur intracranially and in the spinal canal and on occasion they can be detected in the first trimester. Locations by order of frequency are the sylvian fissure or temporal fossa, posterior fossa, over the cerebral convexity, and midline supratentorial, including suprasellar (Fig. 34.21). Even if very large, arachnoid cysts rarely cause symptoms. Occasionally they interfere with CSF

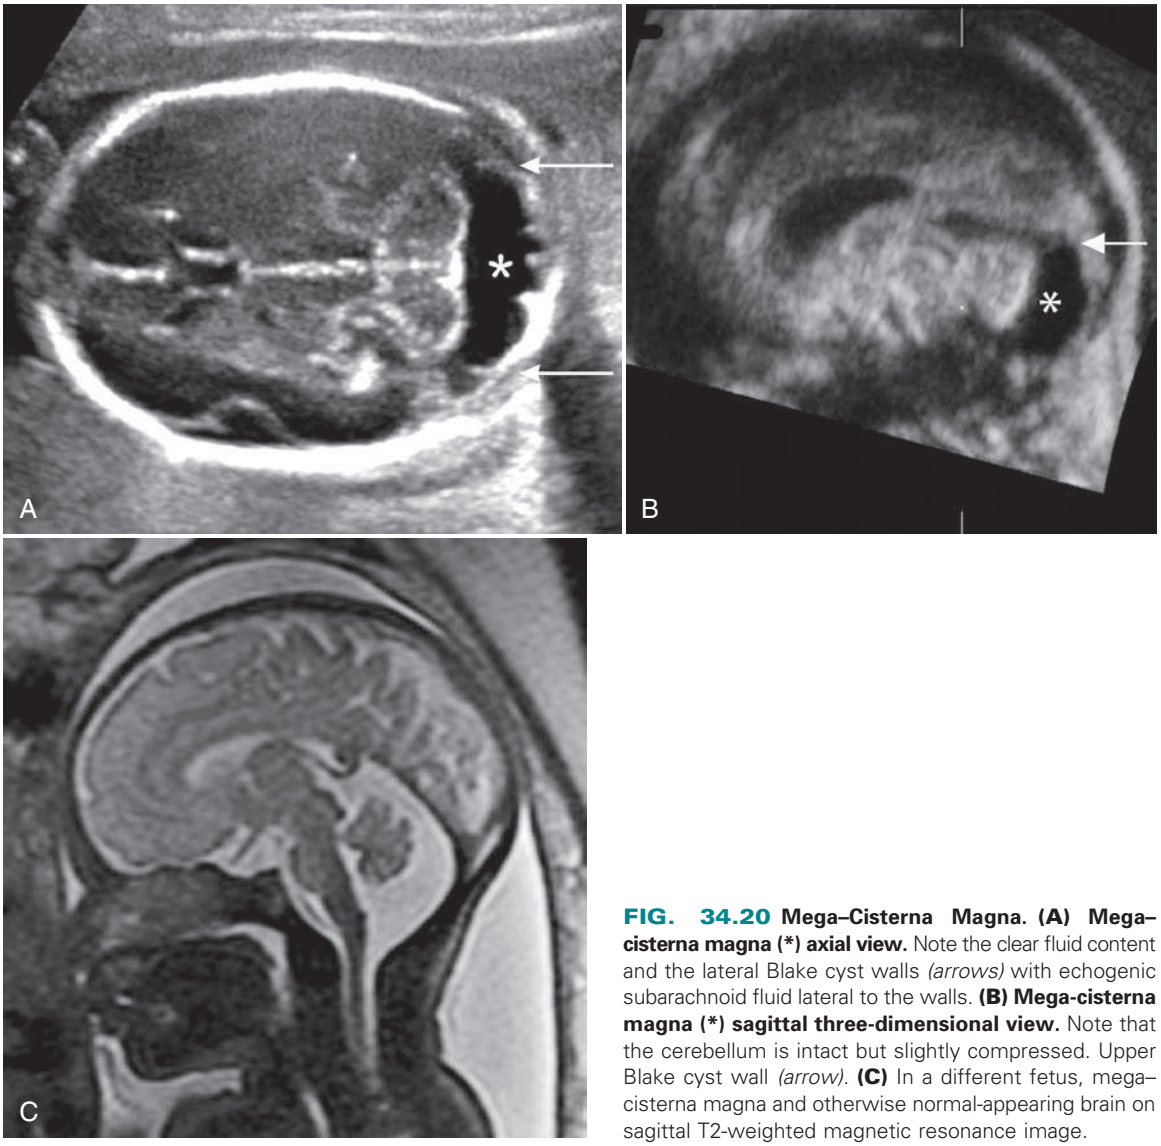

FIG. 34.20 Mega–Cisterna Magna. (A) Mega–cisterna magna (*) axial view. Note the clear fluid content and the lateral Blake cyst walls *(arrows)* with echogenic subarachnoid fluid lateral to the walls. **(B) Mega-cisterna magna (*) sagittal three-dimensional view.** Note that the cerebellum is intact but slightly compressed. Upper Blake cyst wall *(arrow)*. **(C)** In a different fetus, mega–cisterna magna and otherwise normal-appearing brain on sagittal T2-weighted magnetic resonance image.

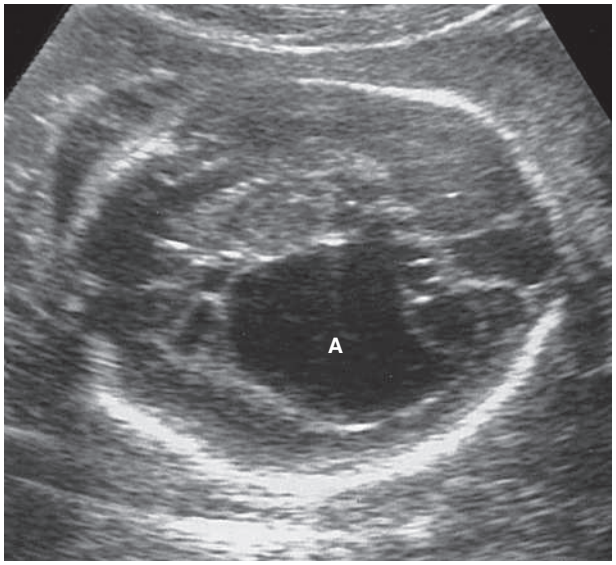

FIG. 34.21 Arachnoid Cyst. Arachnoid cyst *(A)* in the supratentorial, interhemispheric position at 25 weeks.

circulation and require decompression. Midline cysts can accompany dysgenesis of the corpus callosum, so when a supratentorial cyst is seen, it is important to evaluate the entire corpus callosum. In the suprasellar region these cysts may be associated with pituitary dysfunction. The differential diagnosis depends on the location. Arachnoid cysts in the posterior fossa can be confused with **DWM, inferior vermian hypoplasia, mega–cisterna magna,** and **Blake pouch cysts.** The differential diagnosis of supratentorial cysts includes **cavum veli interpositi** (CVI), **aneurysm of vein of Galen, hemorrhage,** and **cystic tumors.** Pediatric neurosurgical opinion is important in evaluating and counseling these patients, many of whom require no treatment.[27,65,184,185]

Malformations of Cortical Development

Malformations of cortical development comprise a broad and heterogeneous collection of conditions resulting from disturbances in the major steps of cortical development including neuronal proliferation in germinal zone and apoptosis, migration, and cortical organization. Cortical changes may be focal or global

and can result from intrinsic factors, as mutations in genes controlling brain development, or extrinsic insults including syndromes, maternal diseases (phenylketonuria), teratogens (anoxia, drugs, x-rays), metabolic abnormalities, and fetal infections, but often a cause cannot be found. Changes often reflect time of insult rather than its specific nature.[91,186-188] The responsible genes often function at many developmental stages and in many different body structures apart from the brain. Different mutations of the same gene may result in different syndromes. Abnormalities may be found in seemingly unrelated organs, as in **thanatophoric skeletal dysplasia,** in which abnormal function of the *FGFR3* gene causes both cortical brain malformations and skeletal abnormalities.[189]

Cerebral changes with malformations of cortical development are heterogeneous. VM is common. They generally share variable degrees of thickened, disorganized cortical neuronal layers and alterations in sulcal, gyral, and white matter patterns and abnormal corpus callosum or posterior fossa. Cortical abnormalities may be difficult to detect until sulcal development becomes visible at about 24 weeks. Some may not be detectable in utero and may become evident only as symptoms (and abnormalities) develop in later life. Detailed classification of these disorders is complex and based variously on genetics, biologic pathways, neuroimaging features, and first-affected developmental stage. The past few years have shown a dramatic increase in the understanding of the genetic and molecular basis of these malformations. The current classification is acknowledged to be neither perfect nor complete and is subject to updating with new genetic discoveries. In practice they are described by the general conspicuous patterns they present, including **microcephaly, macrocephaly, lissencephaly, polymicrogyria** (PMG), **periventricular nodular heterotopia,** and **schizencephaly.**[91,190-192]

For all these conditions, investigation requires detailed examination including MRI, which can help focus further directions for more targeted testing. Multidisciplinary consultation is important for optimal prenatal assessment and counseling. Additional investigations depend on individual situations and can include detailed family and pregnancy history, infection screening, amniocentesis for karyotype and array-comparative genomic hybridization (CGH), commonly called microarray, other testing for specific gene mutations, and other specific testing as suggested by clinical and imaging appearances. Prognosis varies depending on the severity of the condition and associated abnormalities, and epilepsy and developmental delay are common.[193-195]

Classification of Malformations of Cortical Development

ABNORMAL NEURONAL PROLIFERATION OR APOPTOSIS

Abnormal Brain Size
Microcephaly
Megalencephaly (macrocephaly)
Hemimegalencephaly

Abnormal Proliferation
Nonneoplastic or neoplastic

ABNORMAL NEURONAL MIGRATION
Classical lissencephaly and subcortical band heterotopia
Cobblestone lissencephaly and complex or congenital muscular dystrophy
Heterotopia

ABNORMAL CORTICAL ORGANIZATION
Polymicrogyria
Schizencephaly

NOT OTHERWISE CLASSIFIED
Secondary to inborn errors of metabolism (mitochondrial, pyruvate)
Peroxisomal disorders

Modified from Raybaud[191] and Barkovich.[196]

Microcephaly

Microcephaly describes a disproportionately small head for fetal age and body size. Precise diagnostic definition is difficult, but in general, microcephaly is diagnosed if the head circumference less than 3 SDs below the expected mean and intrauterine growth restriction (IUGR) has been excluded. Some suggest using 2 SDs, but this would include many normal individuals. Incidence at birth ranges from 1 per 1360 to 10,000. The diagnosis implies failure of brain development **(micrencephaly).** Etiology is heterogeneous and can be related to a great variety of prenatal causes including genetic factors, environmental issues, asphyxia, infections **(Zika virus),**[197] maternal conditions **(phenylketonuria),** drugs (e.g., **fetal alcohol syndrome**), diverse syndromes (e.g., **Smith-Lemli-Opitz, Cornelia de Lange**), and **irradiation.** On pathologic examination, the brain may be small but normal in appearance, or it may have diverse findings, including simplified gyri, porencephaly, absent corpus callosum, and VM. Associated CNS and non-CNS abnormalities are common.[91,188,198]

Microcephaly should be suspected if the head size is smaller than expected. Measurements alone have only a limited ability to diagnose microcephaly. In one study, only 4 of 24 fetuses with small measurements had the diagnosis confirmed at delivery. Other findings include brain abnormality, abnormal head-to-abdomen circumference ratio, sloping forehead, and small frontal lobe size (Fig. 34.22).

Microcephaly is usually is not evident until late in pregnancy when the head size fails to grow normally, but it has been seen as early as 15 weeks. When a smaller-than-expected fetal head is encountered, there should be a careful search for cerebral and other anomalies that would help to confirm clinical importance. Ultrasonography of the brain can be difficult because the cranial bones become closely approximated and hinder visibility. MRI is helpful in evaluation of the cerebral parenchyma and associated abnormalities.[7,199] Small head size can be associated with subnormal mental ability; the smaller the head circumference, the lower the performance level. Prognosis varies with CNS and associated abnormalities.

Macrocephaly and Megalencephaly

Macrocephaly implies a large head with circumference of 2 SDs or greater or at the 98th percentile for gestational age. It excludes

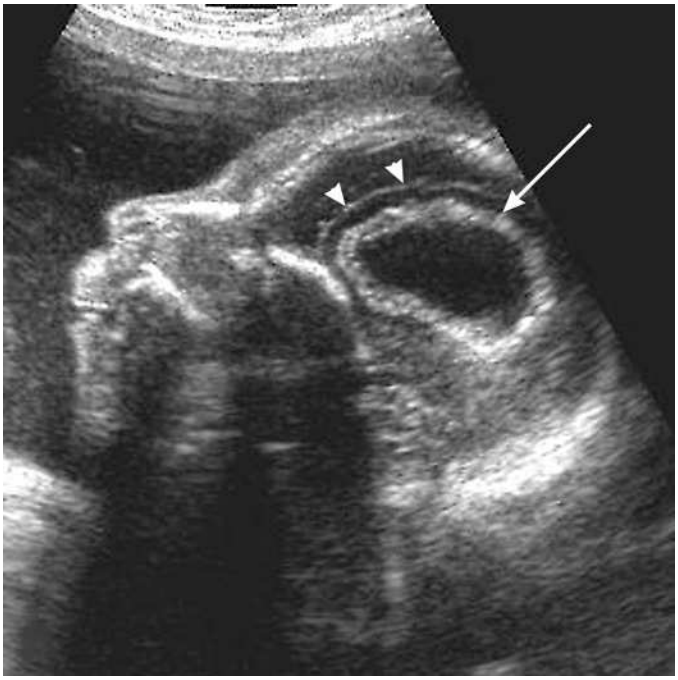

FIG. 34.22 Microcephaly and micrencephaly at 25 weeks with **periventricular calcification** *(arrow)* in fetus with **pseudo-TORCH.** Note the underdeveloped brain parenchyma *(arrowheads).*

conditions with relative head enlargement such as asymmetrical IUGR, HC, tumors, and triploidy. **Megalencephaly** refers to cerebral gigantism (i.e., enlarged brain). It is typically categorized as genetic (nonsyndromic or syndromic) or nongenetic (HC following hemorrhage or infection, posttraumatic, arachnoid cysts). Nonsyndromic implies isolated head or brain enlargement without other significant abnormality. Syndromic implies association with other abnormalities or syndromes such as overgrowth syndromes **(Beckwith-Wiedemann, Sotos, Weaver),** skeletal dysplasias **(thanatophoric dysplasia, achondroplasia),** neurocutaneous syndromes **(neurofibromatosis type 1),** and metabolic conditions such as **leukodystrophy** and organic acidurias. Head enlargement can appear early by 20 weeks but typically does not manifest until the third trimester or in early childhood.[200-203]

Benign familial macrocephaly (external HC) accounts for about 50% of cases of macrocephaly. It is an autosomal dominant condition with increased subarachnoid fluid. It typically manifests late in pregnancy or even after delivery but has been seen as early as 18 weeks when there is a history of other family members who had large heads. Most children are functionally normal.[201,202]

When the head measurements are larger than expected (macrocephaly), there should be a careful search for intracranial abnormalities and non-CNS abnormalities. Family history of large headedness can help. Multidisciplinary counseling and investigation are important. Prognosis can be favorable to poor depending on etiology.

Hemimegalencephaly

Hemimegalencephaly is a malformation of cortical development with hamartomatous enlargement of one hemisphere with defects in all aspects of neuronal migration. Most cases are sporadic and of unknown cause. Typically there is macrocephaly at birth. It may be isolated or associated with neurocutaneous and somatic hemihypertrophy syndromes including **neurofibromatosis, tuberous sclerosis** (TSC), **epidermal nevus syndrome, Proteus syndrome, Klippel-Trénaunay-Weber** syndrome, and others. On the affected side the hemisphere and ventricle are enlarged and the brain has abnormal texture and sulcation. The unaffected hemisphere is generally normal but can be distorted owing to compression and may also show less severe migrational abnormalities. Functional deficiency and seizures are common, the latter on occasion requiring hemispherectomy.[204-207]

Lissencephaly

Lissencephaly describes a brain that has a smooth surface lacking normal gyration. It is due to a global disturbance in neuronal migration. The most severe manifestation is a completely smooth cortex lacking gyri **(agyria),** but some cases show large, malformed gyri **(pachygyria).** There are two general types that have fundamentally different developmental mechanisms. In **type 1 lissencephaly (classical lissencephaly),** neurons fail to migrate to the cortex. In **type 2 lissencephaly (cobblestone lissencephaly),** the neurons migrate but do not stop at the cortical surface and overmigrate into the subarachnoid membranes overgrowing surface vessels, resulting in "cobblestone cortex." Both types are etiologically heterogeneous and related to many gene mutations and are commonly associated with additional CNS and somatic abnormalities.[21,91,192,208] Previously it was thought that lissencephaly could not be diagnosed before 28 weeks, but familiarity with the normal early sulcal development has allowed diagnosis of type 1 **(Miller-Dieker syndrome)** by 23 weeks,[48] and type 2 **(Walker-Warburg syndrome)** at 14 weeks.[209]

Type 1 or **classical lissencephaly** manifests as a smooth cortex and hourglass shape on axial views associated with mild VM, a primitive insula, delayed or absent sulcation, and abnormal cortical vascularity but sparing of the cerebellar vermis (Fig. 34.23). There are several variants. The more common Miller-Dieker syndrome has gene abnormality at 17p13.3 *(LIS1)* and is associated with **congenital heart disease, omphalocele, genitourinary abnormalities, IUGR,** and **dystrophic facies.** Girls with **X-linked** type 1 lissencephaly may function normally despite "double cortex" cerebral changes that can be seen with MRI, but boys do poorly.[48]

Type 2 or **cobblestone lissencephaly** is associated with malfunction of genes that also function in muscle development (e.g., *POMT1/2, FKRP, FKTN*). These conditions are grouped as **congenital muscular dystrophy.** These infants typically have additional CNS and somatic abnormalities and lack muscle tone at birth (floppy baby). The most severe phenotype, **Walker-Warburg syndrome,** is also called **HARD-E** for ***h*ydrocephalus, *a*gyria, *r*etinal *d*ysplasia, and/or *e*ncephalocele** and includes a **kinked brainstem.** Less severe phenotypes include **Fukuyama syndrome** and **muscle-eye-brain disease.** Ultrasound changes may be evident by 20 weeks and include VM and absent, delayed, or abnormal sulcal development; cerebellar vermian dysplasia; eye abnormalities; small encephalocele; and abnormal kinked brainstem (Fig. 34.24).[48,208,209]

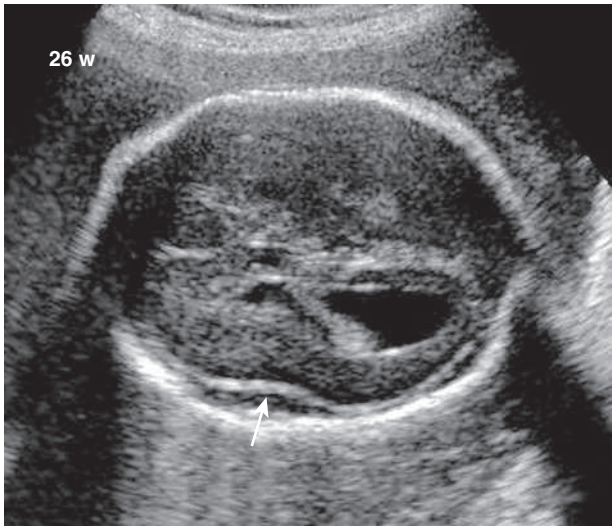

FIG. 34.23 Type 1 Lissencephaly (Miller-Dieker Syndrome) in 26-Week Fetus. Note the mild ventriculomegaly and lack of sulcal formation. The insula is very smooth and shallow *(arrow)* and lacks the angular plateau appearance expected at this age. Brain shows increased echogenicity associated with migrational disturbance.

Fetal MRI and gene mutation analysis can help confirm the diagnosis. Postnatal outcome is poor but varies with the specific condition.[192,208]

Focal Cortical Changes

Polymicrogyria (PMG) is probably the most common malformation of cortical development. It is a heterogeneous malformation characterized by excessive numbers of small shallow, abnormal gyri and irregularity of the cortex/white matter interface. The distribution may be focal or global. PMG may be isolated or associated with many genetic and acquired conditions; however, in most cases the cause cannot be found. Mutations have been found in over 30 genes including the tubulin family and include metabolic conditions such as **peroxisomal disorders** and **DiGeorge syndrome** (22q11.2). Nongenetic conditions include infection with **CMV** and hypoxia and ischemia.

Focal cortical changes typically manifest in mid to late pregnancy and are difficult to detect with ultrasound, where the cortical contour can have a **sawtooth** appearance. They are typically found at MRI in fetuses referred for evaluation of other abnormalities initially detected by ultrasound. PMG is the most common cortical malformation in children with epilepsy and can manifest with developmental delay. The heterogeneity of causes and manifestations makes counseling difficult[192,195,205,210] (Fig. 34.25).

Heterotopia describes localized nodules of disorganized neurons in abnormal locations anywhere in the brain. On MRI three types are described: **periventricular nodular heterotopia, focal subcortical heterotopia,** and **band heterotopia.** Only the periventricular nodules are readily detectable on prenatal ultrasound and visible as irregular lining of the ventricular surface (Fig. 34.26). The nodules are more conspicuous on MRI, which can also depict the intraparenchymal and cortical nodules, which are difficult to recognize by ultrasound. Etiology is heterogeneous. Cases can be isolated but other CNS and somatic abnormalities are common, especially involving the corpus callosum. The differential diagnosis includes ventricular irregularity associated with **CMV, hemorrhage,** and **tuberous sclerosis.** Prognosis varies depending on underlying syndromes and associated abnormalities and ranges from essentially normal to having variable deficits and epilepsy, which are common; in some the disorder is lethal.[192,195,205,211]

Schizencephaly (split brain) is a rare structural malformation of the cerebrum characterized by congenital clefts or defects that extend through the hemisphere from ventricle to outer cortex. The clefts are usually symmetrical and involve the parietal or temporal regions. They are lined by cortical gray matter often with PMG, unlike clastic injury resulting in porencephaly in which white matter lines the clefts. The tracts may be open **(open lip),** allowing CSF communication between the ventricle and subarachnoid space, or solid (**closed lip,** consisting of an abnormal, solid gray matter tract between the ventricle and brain surface). Etiology can be destructive **(encephaloclastic)** or developmental. Destructive etiologies include **vascular injury, ischemia,** teratogen exposure (e.g., **cocaine**), infections (especially **CMV**), and trauma, and appearances can be similar to **porencephaly** or **hydranencephaly.** Developmental cases are considered to be related to PMG arising from disordered neuronal migration and organization. Most cases are found in late pregnancy during investigation of VM, but they have been seen in the middle trimester. The diagnosis rests on detection of the cerebral clefts or abnormal gray matter traversing from ventricle to cortex (Fig. 34.27). There may be associated midline defects including SOD, dysgenesis of the corpus callosum, absence of the septi pellucidi, other malformations of cortical development, and optic nerve abnormalities. Fetal MRI allows superior characterization of cortical and gray matter changes.

Neurodevelopmental delay and seizures are common. Suspected cases benefit from multidisciplinary consultation and counseling. Prognosis relates to the size of the defect and associated abnormalities.[19,195,205,212,213]

Other Malformations of Cortical Development

Cortical malformations can accompany infections, inborn errors of metabolism (e.g., **peroxisomal disorders**), **mitochondrial disease,** and conditions with unknown etiology.[91,188] **Metabolic** and **neurodegenerative disorders** can be associated with abnormal brain development but are typically not detectable prenatally by ultrasound. However, some are associated with diverse changes such as IUGR, microcephaly or macrocephaly, abnormal corpus callosum, migrational and cerebellar abnormality, cerebral calcifications, cerebral cysts, renal and hepatic changes, congenital heart disease, and hydrops.[214,215] The most common is **Zellweger (cerebrohepatorenal) syndrome,** a lethal peroxisomal disorder. Affected fetuses can have increased NT in the first trimester and later show VM, subependymal germinolytic cysts, migrational abnormality, hepatomegaly, cortical renal cysts, and **chondrodysplasia punctata.** The diagnosis can be confirmed by DNA and biochemical testing of fetal cells obtained by CVS.[214-216]

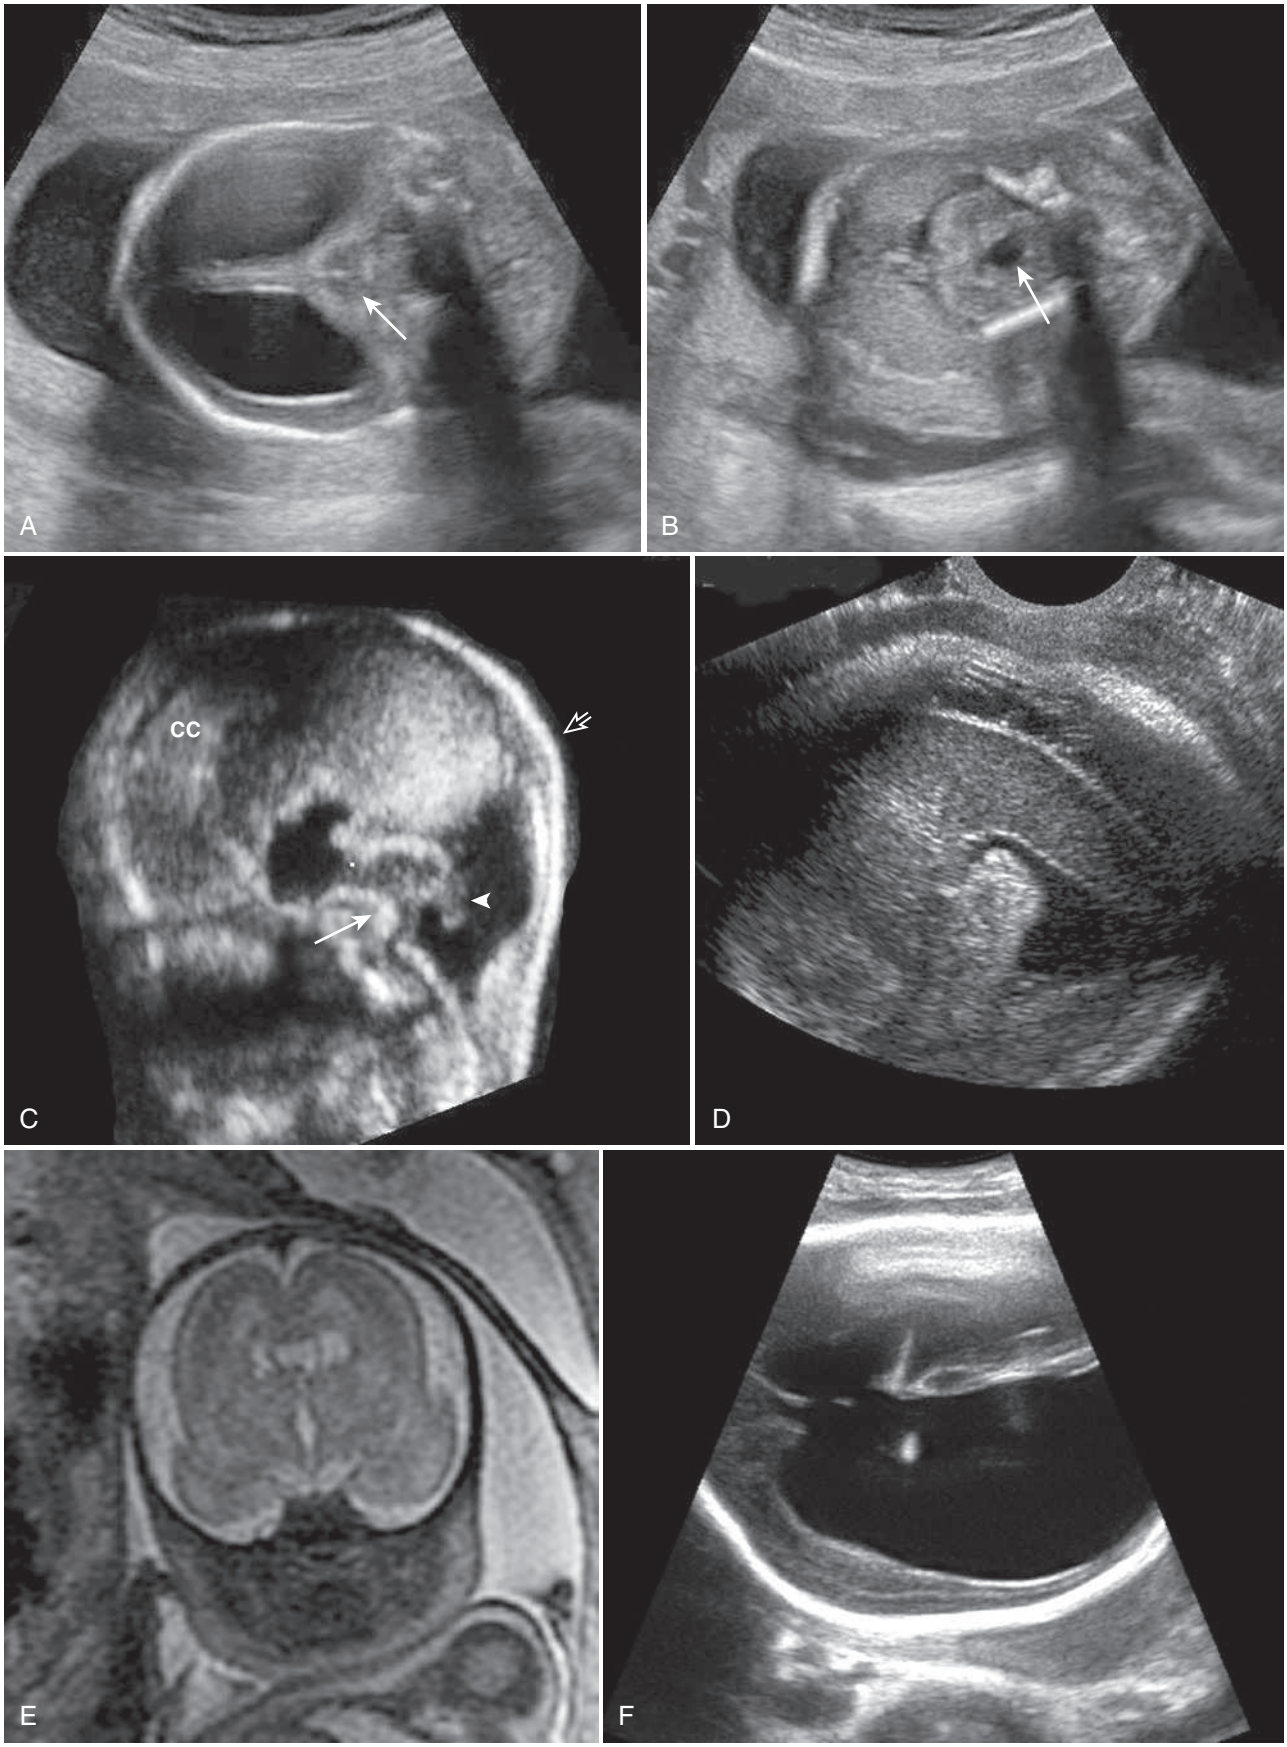

FIG. 34.24 Type 2 Lissencephaly (Cobblestone Cortex, Walker-Warburg Phenotype) at 21 Weeks. (A) Coronal view shows the large, smooth ventricles and the very small brainstem *(arrow).* **(B)** Defect in vermis (vermian hypoplasia; *arrow*). **(C)** Midsagittal view shows the Z-shaped kink in the brainstem *(arrow),* which represents failure of the brainstem to straighten and lose the early embryologic flexures, a process that normally occurs after 12 to 13 weeks. Also, the cerebellar vermis is very small *(arrowhead).* The third ventricle is malformed. The corpus callosum *(cc)* is malformed and extremely elevated. There is a minute occipital encephalocele *(open arrowhead).* This fetus also had eye abnormalities. **(D)** In a different fetus at 36 weeks, transvaginal scan shows smooth cortex (agyria), abnormal for this gestational age. **(E)** Coronal T2-weighted magnetic resonance image shows the smooth cortex and abnormal bands of high signal intensity in the parenchyma. Note the prominent extraaxial CSF spaces. **(F)** Another fetus with severe VM and lissencephaly caused by Walker-Warburg syndrome. Note that this is the same fetus shown in Fig. 34.13B with a small cephalocele.

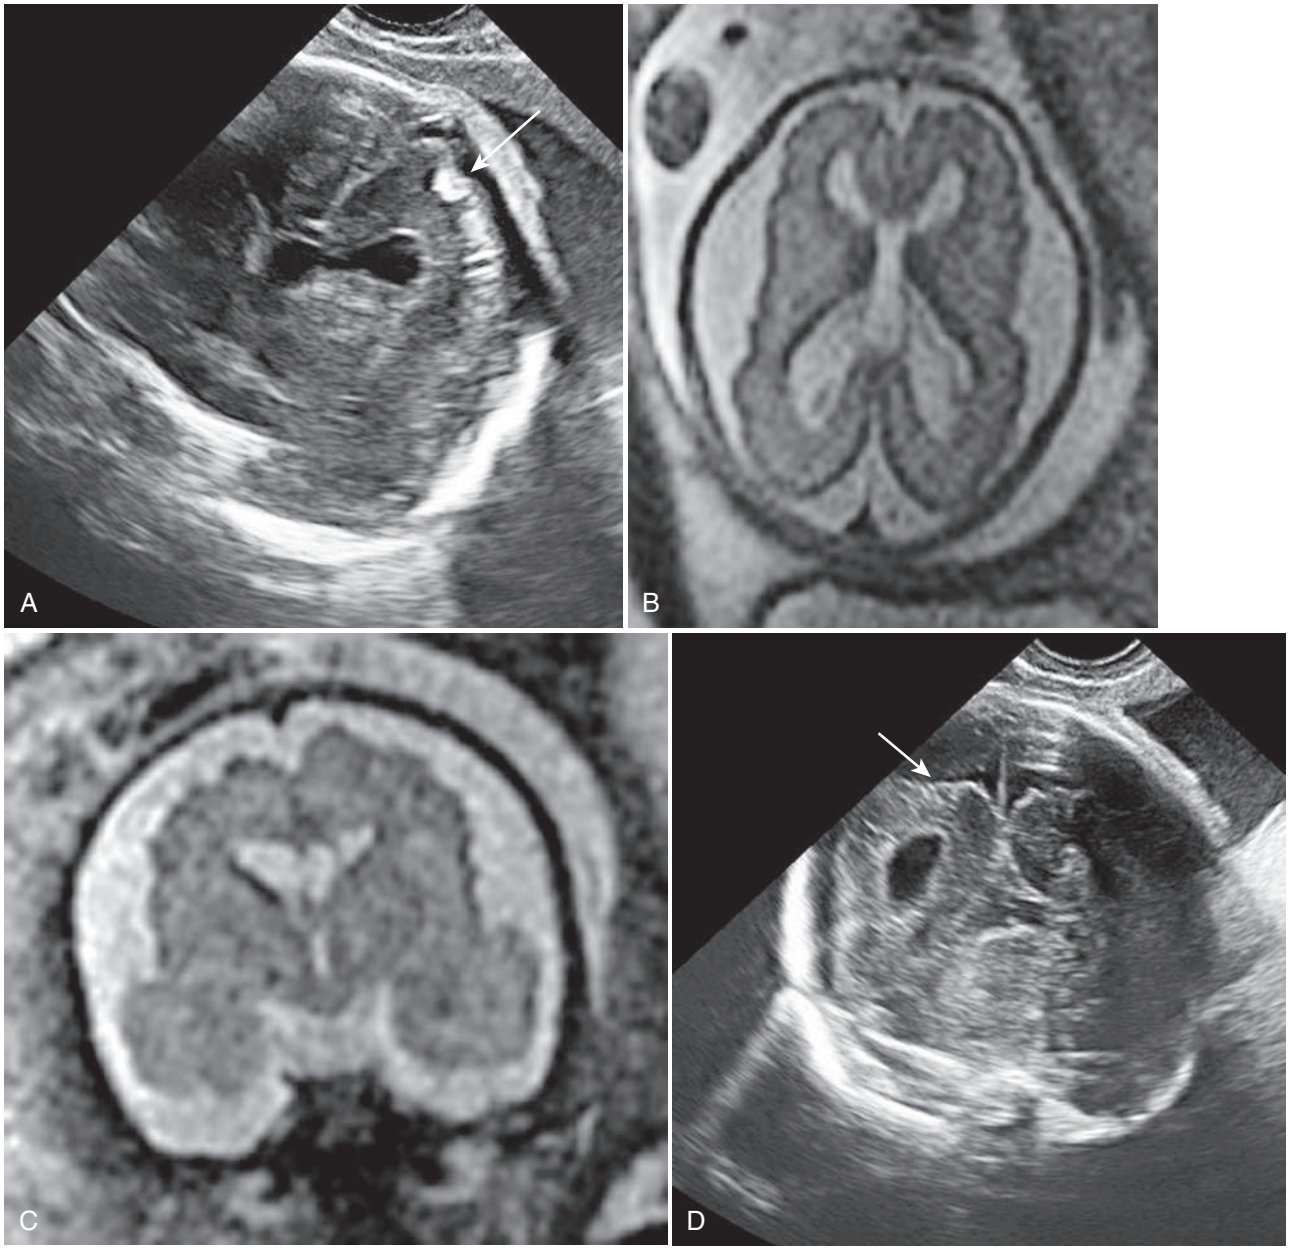

FIG. 34.25 Polymicrogyria. (A) Irregular appearance to the cortex and cortical calcification *(arrow)* on coronal transvaginal sonogram at 25 weeks. **(B)** and **(C)** Axial **(B)** and coronal **(C)** T2-weighted magnetic resonance imaging (MRI) scans show **sawtooth** appearance of the cortex at 25 weeks. Note how the calcifications were better visualized on the sonogram than on MRI. **(D)** Polymicrogyria at 30 weeks' gestational age. Note ventriculomegaly and prominent extraaxial cerebrospinal fluid (CSF). The shrunken brain has fallen away from the skull, leaving a wide, CSF-filled subarachnoid space **(hydrocephalus ex vacuo).** Note also the fine nodularity of the surface of the brain *(arrow).*

Tuberous Sclerosis

Tuberous sclerosis (TSC) is a multisystem, hamartomatous condition involving abnormalities of the brain, skin, heart, eyes, and kidneys. It is autosomal dominant related to abnormal *TSC1* and *TSC2* genes; however, about 70% of cases are a de novo mutation. Clinical diagnosis is made using a combination of major and minor findings including cranial findings of cortical tubers and white matter migration lines, subependymal nodules, subependymal giant cell astrocytomas, cardiac rhabdomyomas, renal angiomyolipomas, and skin lesions.[217,218]

Prenatal diagnosis usually is made in late pregnancy after discovery of echogenic cardiac rhabdomyomas and demonstration of subependymal nodules or cortical tubers on neurosonography or MRI (Fig. 34.28). MRI has shown lesions as early as 21 weeks in fetuses known to be at risk.[219] If the gene abnormality is known, prenatal diagnosis is possible using CVS or amniocentesis as well as neurosonography and fetal MRI. Diagnosis in other suspected cases may be aided by looking for subtle manifestations of TSC in the parents. Epilepsy and neurologic impairment are common. Morbidity and mortality predominantly relate to CNS and renal disease.[218]

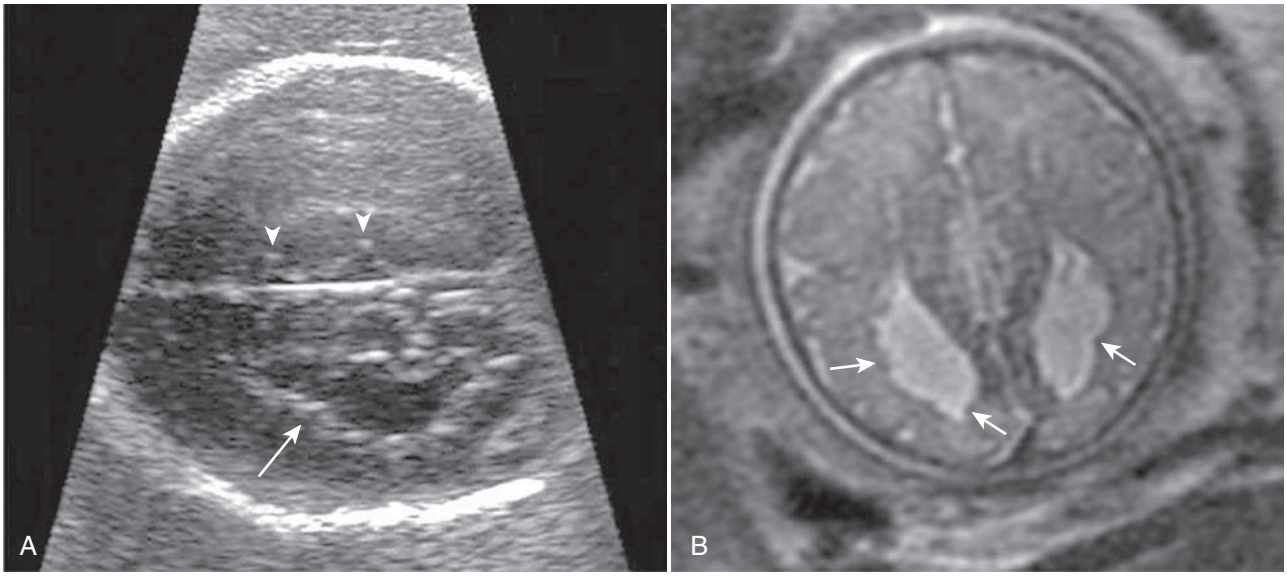

FIG. 34.26 Periventricular Nodular Heterotopia and Agenesis of the Corpus Callosum (ACC). (A) In fetus with ACC at 31 weeks, note the very nodular lining of the ventricle wall *(arrow)*. This represents accumulations of neurons that have failed to migrate to the cortex. Note the separation of the hemispheres and abnormal orientation of interhemispheric sulci (hairy midline; *arrowheads*). **(B)** Transverse T2-weighted magnetic resonance image in a different fetus at 35 weeks shows ACC and nodular heterotopias *(arrows)*.

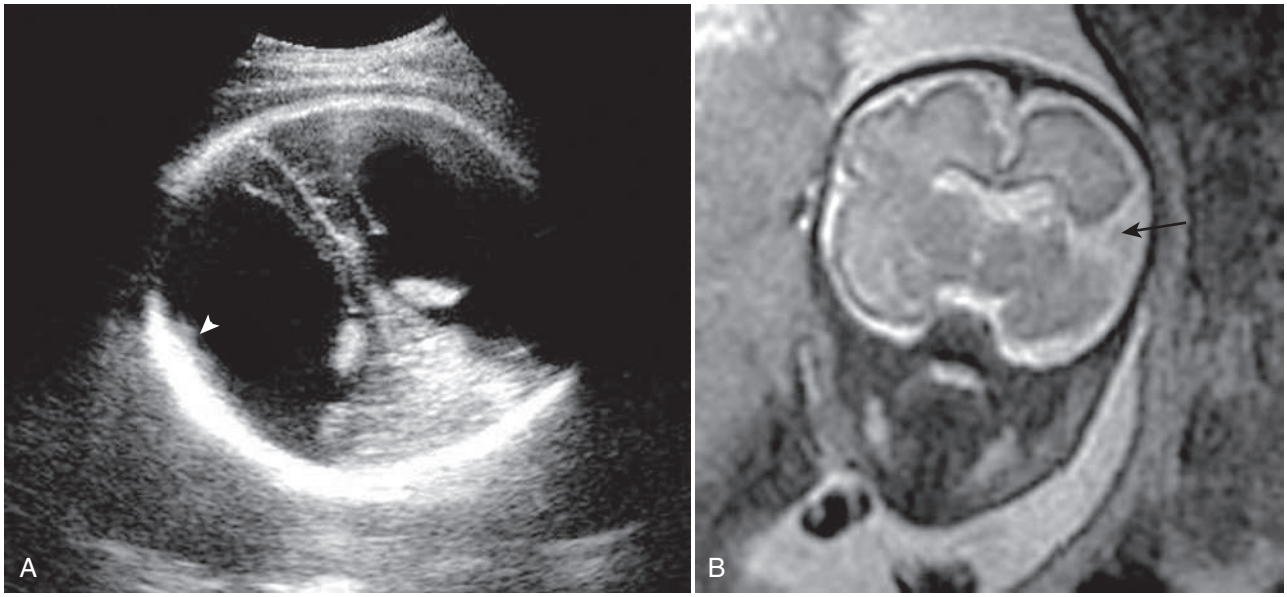

FIG. 34.27 Open-Lip Schizencephaly. (A) There are large gaps in the parietal regions with no brain tissue at the periphery *(arrowhead)*. There is partial sparing of the frontal and occipital regions. **(B)** Coronal T2-weighted magnetic resonance image in a different fetus with absent septal leaflets (absent septum pellucidum) shows region of schizencephaly *(arrow)*.

Agenesis and Dysgenesis of Corpus Callosum

Agenesis of the corpus callosum (ACC) is failure of normal development of the corpus callosum and other commissures that connect the left and right hemisphere. The prevalence of ACC in neonates is about 1.4 per 10,000 live births but is higher in developmentally disabled individuals. This likely is an underestimate of the prenatal incidence because many affected fetuses die in utero, and not all cases are postnatally diagnosed.[154,220]

The corpus callosum is the largest of three commissures that connect and allow communication between the cerebral hemispheres, the other two being the anterior commissure and the posterior hippocampal commissure. Any of these three commissures may be absent singularly or in combination. Development of the corpus callosum starts at about 12 weeks from the lamina terminalis near the anterior end of the third ventricle; it becomes detectable by about 15 weeks and is complete by about

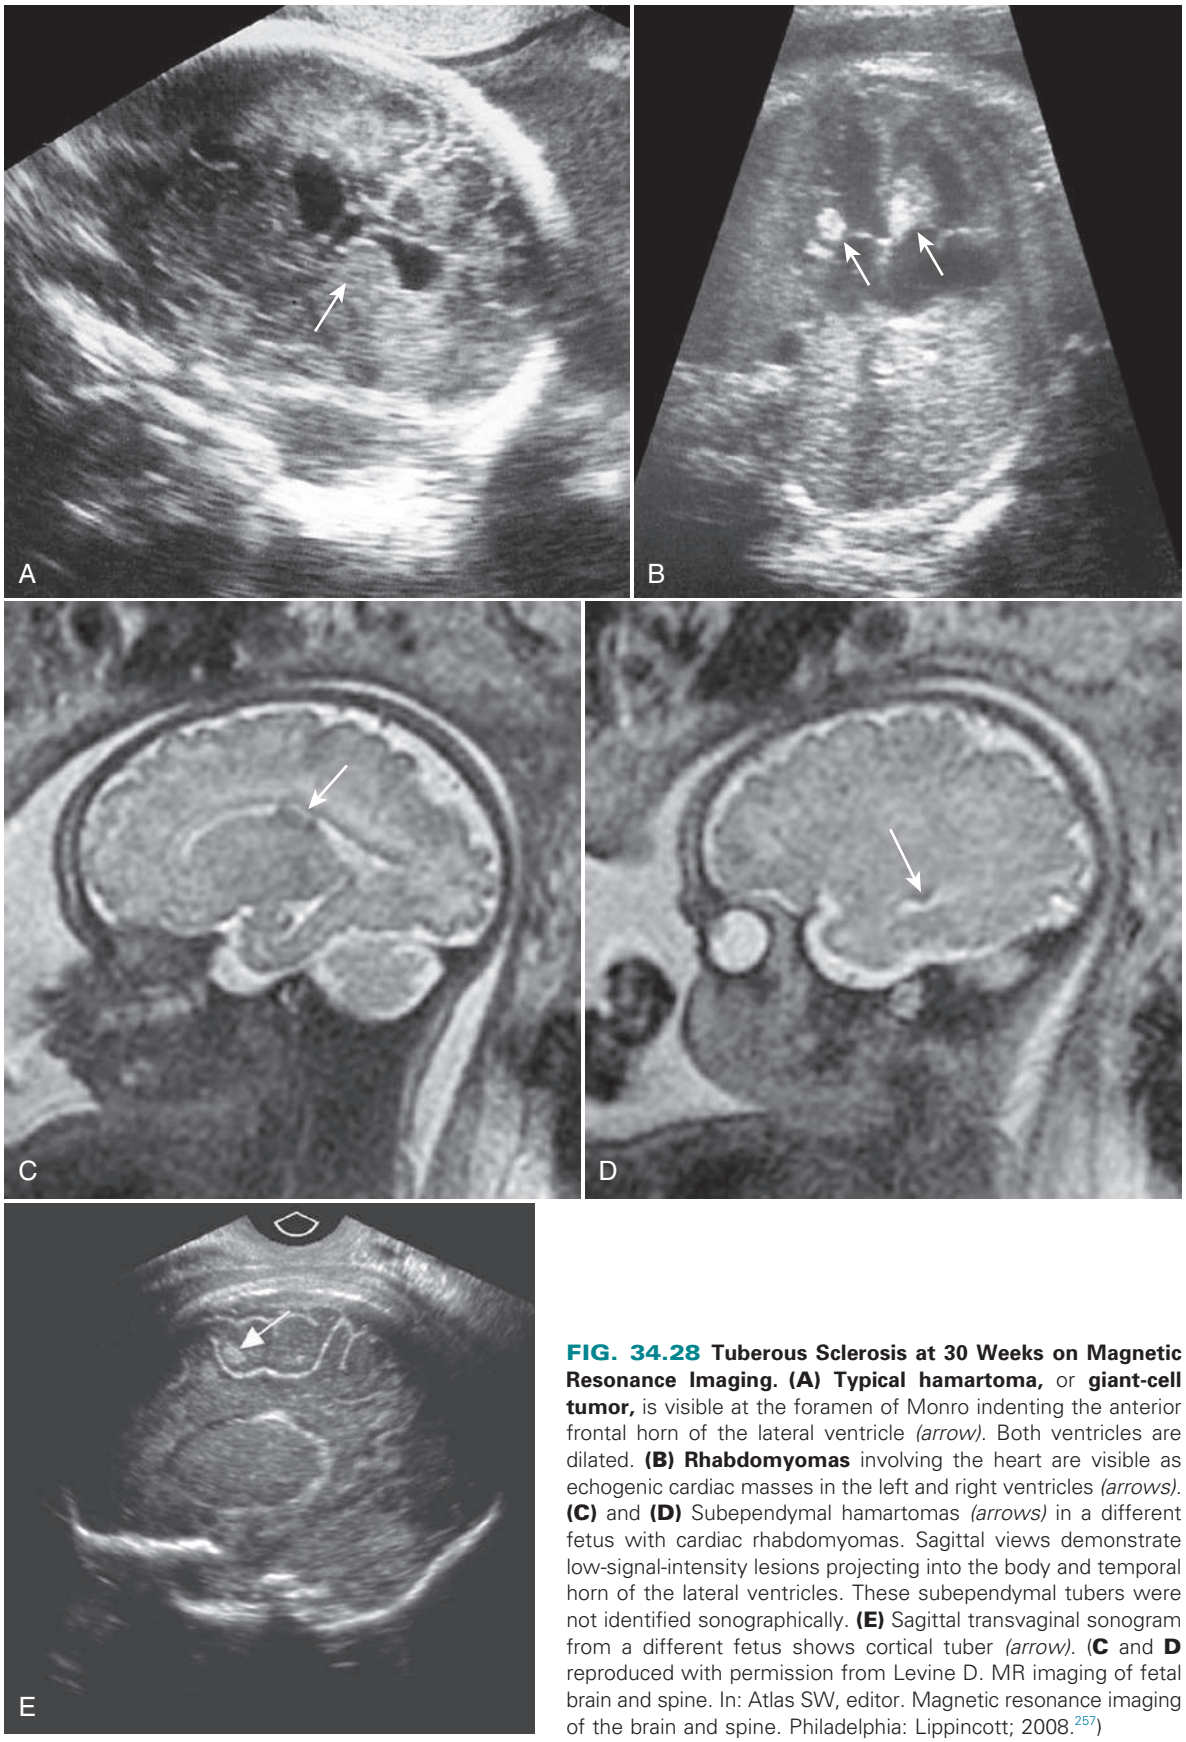

FIG. 34.28 Tuberous Sclerosis at 30 Weeks on Magnetic Resonance Imaging. (A) Typical hamartoma, or **giant-cell tumor,** is visible at the foramen of Monro indenting the anterior frontal horn of the lateral ventricle *(arrow)*. Both ventricles are dilated. **(B) Rhabdomyomas** involving the heart are visible as echogenic cardiac masses in the left and right ventricles *(arrows)*. **(C)** and **(D)** Subependymal hamartomas *(arrows)* in a different fetus with cardiac rhabdomyomas. Sagittal views demonstrate low-signal-intensity lesions projecting into the body and temporal horn of the lateral ventricles. These subependymal tubers were not identified sonographically. **(E)** Sagittal transvaginal sonogram from a different fetus shows cortical tuber *(arrow)*. (**C** and **D** reproduced with permission from Levine D. MR imaging of fetal brain and spine. In: Atlas SW, editor. Magnetic resonance imaging of the brain and spine. Philadelphia: Lippincott; 2008.[257])

20 weeks. Development proceeds in an anteroposterior manner, beginning anteriorly with the genu, then body and splenium posteriorly, and finally the anterior tip, the rostrum.[8,25,154] The corpus callosum measures 4 mm at 16 weeks and grows to 45 mm by term. There is no gender difference in length, but it is thicker in girls.[221] Callosal development is associated with the development of the septal leaflets and the CSP. When septal leaflets are present, at least the anterior portion of the corpus callosum has formed.[25,40]

ACC may be complete or partial, developmental or acquired. ACC has a high incidence of associated malformations, suggesting that it is part of a generalized widespread developmental disturbance. Additional CNS abnormalities are reported in 45% to 80% of fetuses, especially involving the posterior fossa, including **DWM, inferior vermian hypoplasia, Chiari II,** and abnormal neuronal migration. Somatic and metabolic abnormalities are seen in up to 60% and include facial abnormalities, congenital heart disease, and skeletal and genitourinary abnormalities. ACC is part of numerous syndromes including **Aicardi** and **Joubert** syndrome and acquired conditions such as **fetal alcohol syndrome** and infections.[25,154,220]

Developmental disturbances after the corpus callosum has started to form usually interrupt the formation of the more posterior parts of the corpus callosum, but insults after callosal development is complete can cause secondary atrophy of previously developed central portions. Because callosal development is not complete until 20 weeks, early diagnosis of ACC may be difficult.[154,222] Diagnosis of abnormalities of the corpus callosum requires it to be directly imaged in the midsagittal plane; this view is not currently included in the recommended views for the routine anatomy scan (see Figs. 34.2E and 34.17) but should be used with detailed neurosonography whenever a fetal morphologic abnormality is detected.

On routine scans reliance for screening for callosal and other midline abnormalities is placed on indirect findings on the standard views, especially the CSP, which should be sought on all axial scans after about 16 to 17 weeks. These indirect findings include absent or deformed CSP, VM with colpocephaly (teardrop ventricles), ventricles parallel to the midline, interhemispheric widening, and on occasion associated findings such as interhemispheric cysts and lipomas (Fig. 34.29; see also Fig. 34.26; Video 34.8, Video 34.9, Video 34.10, and Video 34.11). If the CSP is not seen with certainty on standard scans, then additional coronal and sagittal views should be taken to evaluate it and, more important, the corpus callosum and to evaluate for other midline conditions such as HPE.[2,25,223,224] Unless care is taken, it is possible to overlook CSP abnormality because with partial ACC a small CSP may be present and with complete ACC there may be a high-riding third ventricle or an interhemispheric cyst that mimics the CSP. Unfortunately, the indirect signs such as VM, colpocephaly, and hemispheric separation are not always present.[222]

Once the diagnosis is suspected, coronal and median views, especially with transvaginal scanning and 3-D ultrasound, help to confirm the diagnosis. The diagnosis is made on midsagittal views that show that the corpus callosum is absent or deficient and can show corroborating findings. On coronal views the third ventricle may be elevated and the crossing corpus callosum tracts are absent. The medial walls of the anterior horns of the lateral ventricles are commonly indented from their superomedial aspect by the **bundles of Probst** (buildup of callosal fibers that fail to cross midline) and change the ventricular configuration from a V to a U (**Viking** or **steer horn** appearance). Color flow Doppler scans can be used to demonstrate an abnormal course of the pericallosal and cingulate arteries, which normally follow the contour of the callosomarginal sulcus, but with ACC they assume a more radial course. This vascular change may already be seen in the first trimester.[99] Occasionally, fetuses with callosal abnormalities develop **interhemispheric cysts** or a **midline lipoma.** The cysts may be herniations from the third ventricle or separated from the ventricles when they are commonly associated with migrational abnormality. In the third trimester the medial hemispheric sulci assume a "sunburst" orientation radiating from the thalamus instead of the normal arc of the cingulate sulcus. On axial views this gives the appearance of a **"hairy midline"** with sulci radiating out from the interhemispheric fissure.[154] MRI is helpful to confirm the diagnosis and especially to search for additional, subtle abnormalities such as migrational disorders.[154,220]

Pitfalls in sonographic interpretation include mistaking the high position of the third ventricle, other fluid spaces, and the fornices for the CSP. On 3-D scans, care must be taken to avoid mistaking the pericallosal sulcus for the corpus callosum.[225,226] Other conditions may also show CSP abnormality including HC with septal fenestrations, SOD, HPE, and schizencephaly. Marked HC may fenestrate the septal leaves, raising the suspicion of ACC, but midsagittal scanning can show the displaced stretched corpus callosum in its expected location.

Investigation of suspected cases includes detailed CNS and somatic ultrasound, karyotype (chromosomal abnormalities occur in about 18%), microarray, screening for TORCH infections, and MRI. If pregnancy continues, follow-up examinations may detect late-appearing abnormalities. Prognosis relates to the associated anomalies, but unfortunately about 15% of associated problems are not evident prenatally. The prognosis for truly isolated ACC can be good in 65% to 75% of cases but guarded, because unfortunately in some cases functional deficits do not become apparent until later life.[220]

Absence of Septi Pellucidi and Septo-Optic Dysplasia

Absence of the septi pellucidi is rare and occurs in about 2 to 3 per 100,000 pregnancies. It can be primary, resulting from developmental disturbances including HPE, SOD, schizencephaly, ACC, and malformations of cortical development, or secondary after disruption as with HC or porencephaly.[25,154] Absence is virtually always associated with other abnormalities, and absence of the CSP warrants detailed neurosonography assessment. Rarely it can be isolated with good outcome.

Septo-optic dysplasia (SOD, **de Morsier syndrome**) manifests as heterogeneous triad of absence of septi pellucidi and CSP, hypoplasia of optic nerves and chiasm, and pituitary dysfunction (Fig. 34.30, Video 34.12). It is heterogeneous in etiology and appearance. Most cases are sporadic, but some are familial. On ultrasound, there is absence of the septi pellucidi. On coronal

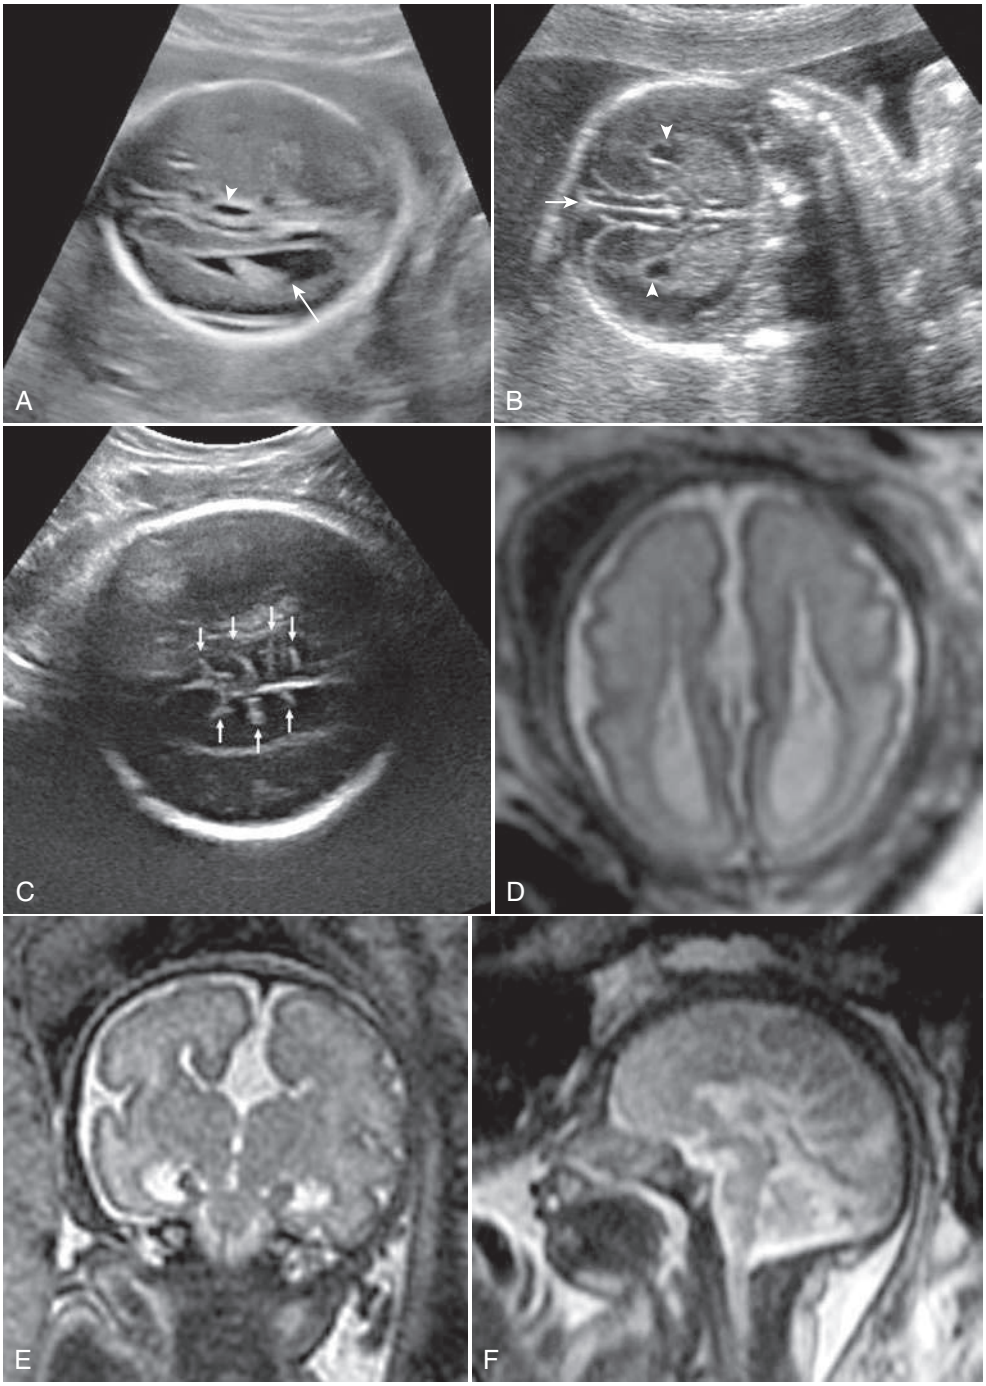

FIG. 34.29 Agenesis of Corpus Callosum (ACC). (A) Ventricular view at 21 menstrual weeks shows characteristic borderline dilation of occipital ventricle *(arrow)* and pointed, slightly spread anterior horns. This "teardrop" ventricle configuration is called **colpocephaly.** The midline fluid space *(arrowhead)* is the elevated dilated third ventricle, which should not be mistaken for the cavum septi pellucidi (CSP), which should be more rectangular and is absent in fetuses with ACC. **(B)** Coronal view through the anterior ventricles *(arrowheads)* shows that the frontal horns have a U or "Viking horn" configuration instead of the normal V orientation. The hemispheres are excessively separated from the falx *(arrow),* and the septal leaflets and CSP are absent. **(C)** Axial supraventricular view at 38 weeks shows the "hairy midline" with many sulci perpendicular to the interhemispheric fissure *(arrows),* the axial correlate of the "sunburst" sign caused by the abnormal radial orientation of interhemispheric sulci. **(D)** Transverse T2-weighted magnetic resonance image at 29 weeks shows colpocephaly with teardrop-shaped ventricles, parallel orientation of the frontal horns, and hemispheric separation. **(E)** Coronal magnetic resonance image in a different fetus at 30 weeks shows the vertical orientation of the frontal horns and lack of crossing fibers of the corpus callosum. **(F)** Sagittal view from fetus at 31 weeks with **partial ACC** shows the sunburst radial orientation of sulci posteriorly, where interhemispheric sulci extend farther inferiorly than normal owing to lack of corpus callosum. See also Videos 34.8, 34.9, and 34.10.

Ultrasound Findings of Agenesis or Dysgenesis of Corpus Callosum

SECOND TRIMESTER

Axial Views

Cavum septi pellucidi (CSP) is absent or appears atypical (consider also holoprosencephaly, septo-optic dysplasia, hydrocephalus, schizencephaly)

Mild ventriculomegaly with pointed anterior horns (teardrop shape = colpocephaly)

Ventricles are parallel

Widening of interhemispheric space (the normal single line becomes 3 lines = falx + medial surface of each hemisphere)

Coronal Views

Anterior horns have a U configuration (Viking helmet or steer horn)

CSP is not visible above the fornices

Possible high-riding third ventricle in 50%-60% (which may mimic CSP)

Midsagittal Views

Corpus callosum absent, short, or deformed

Circular loop of pericallosal artery is not present

THIRD TRIMESTER

On axial view, many sulci perpendicular to the interhemispheric fissure (hairy midline)

Midsagittal view shows radial orientation of sulci from the thalamus (sunburst appearance)

OTHER

Interhemispheric cyst or lipoma

Additional anomalies, especially of midline and posterior fossa structures

FIG. 34.30 Septo-Optic Dysplasia. Coronal image shows absence of the cavum of the septum pellucidum. See also Video 34.11.

views the frontal horns are squared with inferior pointing astride the fornices. The interhemispheric fissure and anterior cerebral arteries are normal. Differentiation from mild degrees of HPE can be difficult, and some believe that SOD is a mild variant of lobar HPE. MRI is helpful to assess the brain for other abnormalities such as migrational disorders and also to assess the optic nerves and chiasm. Tests of maternal urine and blood and fetal blood may be helpful to evaluate for the associated fetal endocrine deficiencies. Counseling is difficult because the prognosis is variable and includes disturbed vision and hypothalamic-pituitary insufficiency, including growth deficit and diabetes insipidus.[154,223]

INTRACRANIAL CALCIFICATIONS

Brain calcifications may be found in any part of the brain including white matter, periventricular regions, brain surface, and vessels. Calcification patterns may suggest underlying etiology. They usually occur in late gestation (see Figs. 34.22, 34.31, and 34.32). There are numerous associated conditions including **microcephaly,** intrauterine infections **(CMV, toxoplasmosis, herpes, parvovirus, HIV, Zika),** hemorrhagic and hypoxic or ischemic conditions including **twin-twin transfusion,** tumors **(teratoma),** neurocutaneous syndromes **(tuberous sclerosis, neurofibromatosis, Sturge-Weber syndrome),** other syndromes **(Aicardi, pseudo-TORCH), aneuploidy** (especially trisomy 13 and 21), and vascular abnormalities **(venous thrombosis, arteriovenous malformations).** When calcifications are found, detailed examination and multidisciplinary consultation are suggested. Prognosis depends on the underlying condition.[227-229]

Lenticulostriate vasculopathy (also called **thalamostriate vasculopathy**) is seen as branching linear densities in the thalami and basal ganglia caused by mineralization around the vessels in the basal ganglia (Fig. 34.31). Lenticulostriate vasculopathy appears because of perivascular deposition of iron rather than calcium. Etiology is undetermined. It may be seen in normal fetuses with good outcome but also occurs in association with many diverse conditions, including infection (CMV, rubella, varicella, syphilis, HIV, Zika), aneuploidy (mainly trisomy 13 and 21), fetal alcohol syndrome, asphyxia, twin-twin transfusion, dysmorphism, and congenital disorders. Parenchymal calcifications are more likely to be associated with infection than isolated lenticulostriate vasculopathy. When associated with other conditions, the prognosis depends on the underlying condition.[230,231]

INFECTIONS

A variety of infections that involve the fetal CNS caused by viruses, bacteria, or parasites are vertically transmitted from mother to fetus or baby during pregnancy or delivery. These are included in the TORCH complex, an acronym that is changing over time. **TORCH infections** include ***t*oxoplasmosis,** *o*ther, ***r*ubella, *C*MV,** and ***h*erpes simplex virus.** The "other" group includes variable pathogens such as **Coxsackie virus, varicella zoster (chickenpox), HIV, human T-lymphotropic virus, parvovirus, hepatitis, syphilis,** and **Zika.** They have differing

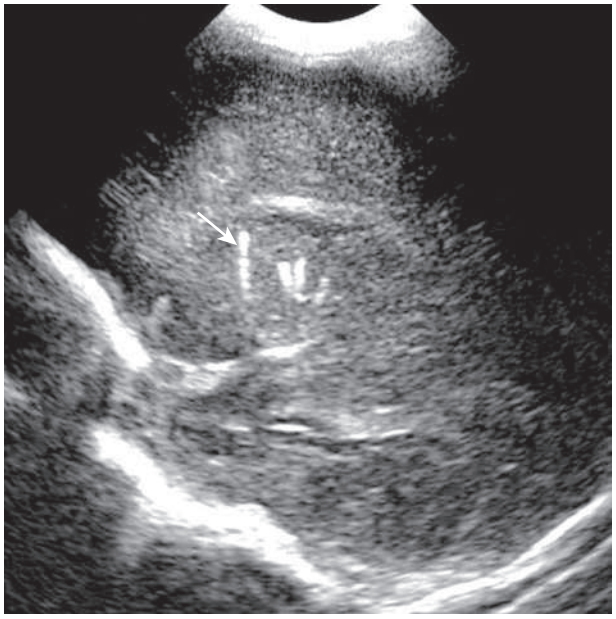

FIG. 34.31 Echogenic Mineralized Thalamostriate Vessels *(Arrow).* These vessels form an echogenic arborizing (branching) pattern in the thalamus, which may be seen in normal fetuses but can be associated with many fetal conditions.

effects depending on the individual pathogens and time of maternal infection. Immunization, prenatal screening, and case management protocols have been proposed.[232] The Zika infection (particularly in the first trimester) tends to be very severe with micrencephaly, microcephaly, cortical abnormalities, dysgenesis of the corpus callosum, and calcifications, which are often at the gray-white junction.[197]

In North America, **CMV** is most common intrauterine infection, affecting about 0.2% to 2.0% of live births, and is a common cause of mental retardation and sensorineural hearing loss. The next most common infections in North America are **toxoplasmosis** and **herpes simplex.** The severity of injury often relates more to the age when infection first occurs and affects brain development than to the specific organism. Cerebral and noncerebral ultrasound findings as noted below for CMV are shared by many of the infections, so detection of any of these findings should include general assessment for infections. Unfortunately, several findings can appear or evolve in late pregnancy, so surveillance with ultrasound should continue throughout pregnancy, with MRI employed as appropriate.[11,233-235]

Most mothers acquire primary CMV infection through contact with infected persons, but reinfection can also occur. CMV affects 1% to 2% of pregnancies, and vertical transmission to the fetus occurs in 30% to 40%. About 10% to 15% of these have symptoms at birth, and of these about 20% to 30% die and 90% of survivors have neurodevelopmental handicap. Of the 85% to 90% of infants who appear normal at birth, 5% to 15% will develop late complications including hearing loss or developmental delays.

Diagnosis of fetal infection can be made via amniocentesis. Ultrasound and MRI are used to help determine prognosis but are imperfect at predicting outcomes. The odds ratio of poor outcome with noncerebral abnormality is 7.2 and with cerebral abnormality is 25.5; although the absence of findings is reassuring, it does not guarantee a good outcome. Cerebral and posterior fossa findings include VM, increased periventricular echogenicity, calcifications, ventricular synechiae, microcephaly, periventricular pseudocysts or other cysts, malformations of cortical development, and cerebellar abnormality (Fig. 34.32). Noncerebral findings include **echogenic bowel, hepatomegaly, IUGR, oligohydramnios** or **polyhydramnios, ascites** or **pleural effusion, liver calcifications,** and **placental enlargement.**[233-237]

Congenital **toxoplasmosis** is caused by the transplacental passage of the parasite *Toxoplasma gondii* from an infected mother who is typically asymptomatic and acquires infection through contact with raw or undercooked meat, cat litter, or exposure to infected water or soil (gardening). In the United States, 15% of childbearing-age women are infected, and incidence of congenital toxoplasmosis is about 400 to 4000 per year. Interestingly, transmission to the fetus increases with gestational age and is estimated at about only 6% to 15% in the first trimester but increases to 60% to 81% in the third trimester. If untreated, about 20% to 50% develop infection. Fetal disease severity, however, decreases with age and is highest in the first trimester. Prenatal cerebral findings may appear late after 24 weeks and suggest a poor prognosis and can include **VM, cerebral calcifications, echogenic parenchymal nodules, diffuse periventricular echogenicity, callosal dysgenesis, microcephaly, IUGR,** and **hydrops.** Most fetuses (70%-90%) are infected in later pregnancy and are asymptomatic at birth, but some manifest the diagnostic triad **(chorioretinitis, hydrocephalus, intracranial calcifications)** and **hepatosplenomegaly.** Asymptomatic infants remain at high risk of developing late chorioretinitis and neurologic deficits. Maternal serum testing and amniocentesis can confirm infection. Prenatal and postnatal therapy can improve outcomes.[232,238-240]

VASCULAR MALFORMATIONS

A variety of vascular malformations are described prenatally, including the **vein of Galen aneurysmal malformation, dural sinus malformation, and pial arteriovenous malformation.**[241] The most common is the vein of Galen aneurysmal malformation, which is a congenital anomaly of midline choroidal and mural vessels that drain into and dilate the embryonic precursor of the vein of Galen, the median prosencephalic **vein of Markowski,** which in turn drains through an aberrant falcine sinus that can be mistaken for the vein of Galen. In general, this anomaly becomes detectable in the third trimester as a cystlike midline space behind the thalamus with turbulent follow on Doppler (Fig. 34.33). In prenatal cases 81% are associated other abnormalities that predict a poor outcome, including heart failure and cerebral abnormalities such as VM, malformations of cortical development, and ischemic and hemorrhagic changes. It is not associated with chromosomal abnormality. Postnatal treatment is with embolization, which is delayed to about 6 months unless there is heart failure. Outcome can be good in the few who have isolated lesions and no heart failure.[11,241-243]

Pial arteriovenous malformations are abnormal, usually supratentorial, superficial arteriovenous communications eventually draining into and dilating the vein of Galen. They may result

FIG. 34.32 Fetal Infection. (**A** and **B** courtesy of Dr. K. Fong, Mt. Sinai Hospital, Toronto, Ontario. **C** and **D** Reproduced with permission from Soares de Oliveira-Szejnfeld P, Levine D, Melo AS et al. Congenital brain abnormalities and Zika virus: what the radiologist can expect to see prenatally and postnally. Radiology. 2016;281[1]:203-218.[197])

in heart failure. Treatment is with embolization early after delivery.[241]

Dural sinus malformations are congenital vascular malformations, characterized by massive dilation of one or more dural sinuses, which usually appear postnatally but can occur prenatally as early as 19 weeks. There may be associated thrombus or arteriovenous fistula. Color Doppler may be helpful, but in some the flow is too slow to create a signal. These malformations can regress prenatally or progress to cause brain damage, hemorrhage, or heart failure. Evaluation includes detailed ultrasound and MRI. Treatment is with embolization, but only 10% have normal outcomes.[241,242,244]

Thrombosis of Dural Sinuses

Dural sinus thrombosis can be idiopathic (40%), but cases can be seen with hypercoagulable states such as trauma, infection, **polycythemia,** and deficiency of physiologic anticoagulants (e.g., **antithrombin protein C, protein S, factor V Leiden**). Ultrasound typically reveals an echogenic mass (the thrombus) surrounded by a hypoechogenic area in the region of the venous sinuses, generally near the torcula and associated with absence of flow (Fig. 34.34). The more proximal sinuses may be dilated and the brain compressed. Many dural thromboses are initially misdiagnosed as tumors or subdural bleed. Most cases are found in

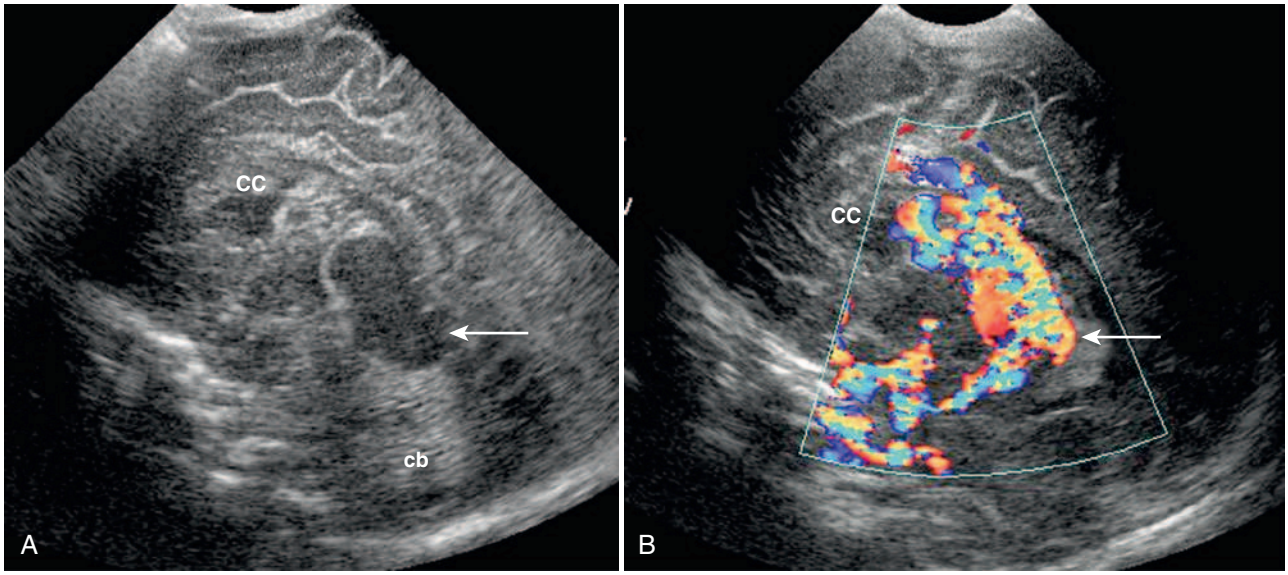

FIG. 34.33 Vein of Galen Aneurysm. (A) Midsagittal view shows a hypoechoic "cyst" *(arrow)* behind the brainstem and under the splenium of the corpus callosum *(cc). cb,* Cerebellum. At first glance it could be mistaken to be a large cavum veli interpositi. **(B)** Color Doppler examination shows the prominent vascularity characteristic of this malformation.

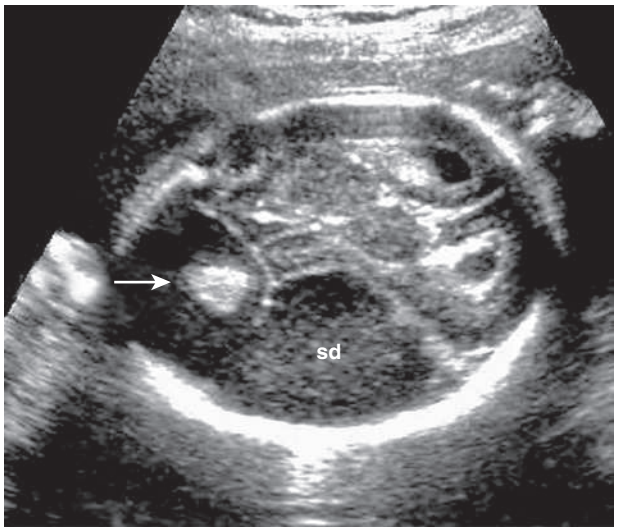

FIG. 34.34 Sagittal Sinus Thrombosis. There is an echogenic mass *(arrow)* in a fluidlike space in the midline anteriorly. This represents thrombus in a dilated sagittal sinus. There is also a subdural collection *(sd).* (Courtesy of Dr. K. Fong, Mt. Sinai Hospital, Toronto, Ontario).

the second and third trimesters and can be confirmed with MRI, which also helps to evaluate the brain for other abnormalities and areas of hemorrhage. Differential diagnosis includes tumors, intracranial bleeding, and dural sinus malformations. A substantial proportion resolve spontaneously over 3 to 11 weeks. The prognosis appears good if no other abnormalities are found and the brain appears normal.[11,245]

Hemorrhagic Lesions

Intracranial hemorrhage describes bleeding in and around the brain. The incidence is about 1 per 10,000 live births.[246] The most common sites are similar to those seen in premature neonates. In a series of 109 antenatal intracranial bleeds, 89 were intracerebral (79 intraventricular, 10 infratentorial), and 20 were subdural.[247] As in neonates, cerebral bleeds are graded from 1 to 4 and may be followed by **chemical ventriculitis** (thick echogenic ventricular lining), **hydrocephalus, porencephalic cysts, white matter injury,** and **periventricular leukomalacia.** About half are idiopathic. Predisposing factors include hypoxia, fetal coagulation disorders (including **alloimmune thrombocytopenia** and maternal anticoagulation), **death of a monochromic co-twin,** seizures, viral or bacterial **infection,** febrile disease, drugs **(cocaine), maternal-fetal hemorrhage,** and trauma.[11,246-248]

On ultrasound, the bleed appears as an echogenic collection in the ventricles and surrounding brain (Fig. 34.35). This hemorrhage later organizes and condenses into clots and may be associated with VM and echogenic thickening of ventricular walls (chemical ventriculitis). The findings may resolve or progress to HC, porencephaly, cerebral clefts, and cortical malformations. Those with ischemia may also develop cystic leukomalacia. Subdural hemorrhages appear as an echogenic collection underlying the skull and compressing the adjacent brain.[246,247]

The prognosis varies greatly and depends largely on fetal age, extent of injury, and underlying factors. About 50% die in utero or shortly after birth, and about half the survivors have deficits. As expected, some with mild changes may resolve completely, and more severe (grade 3-4) changes and cerebral changes predict a poor outcome. Ultrasound can accurately diagnose bleeds, but MRI can more accurately define the extent of the lesion and may demonstrate additional ischemic changes in white matter[246,247] (see Fig. 34.35). Investigation of suspected cases includes trauma and drug history, as well as maternal screening for antiplatelet antibodies and thrombophilia.[246,248]

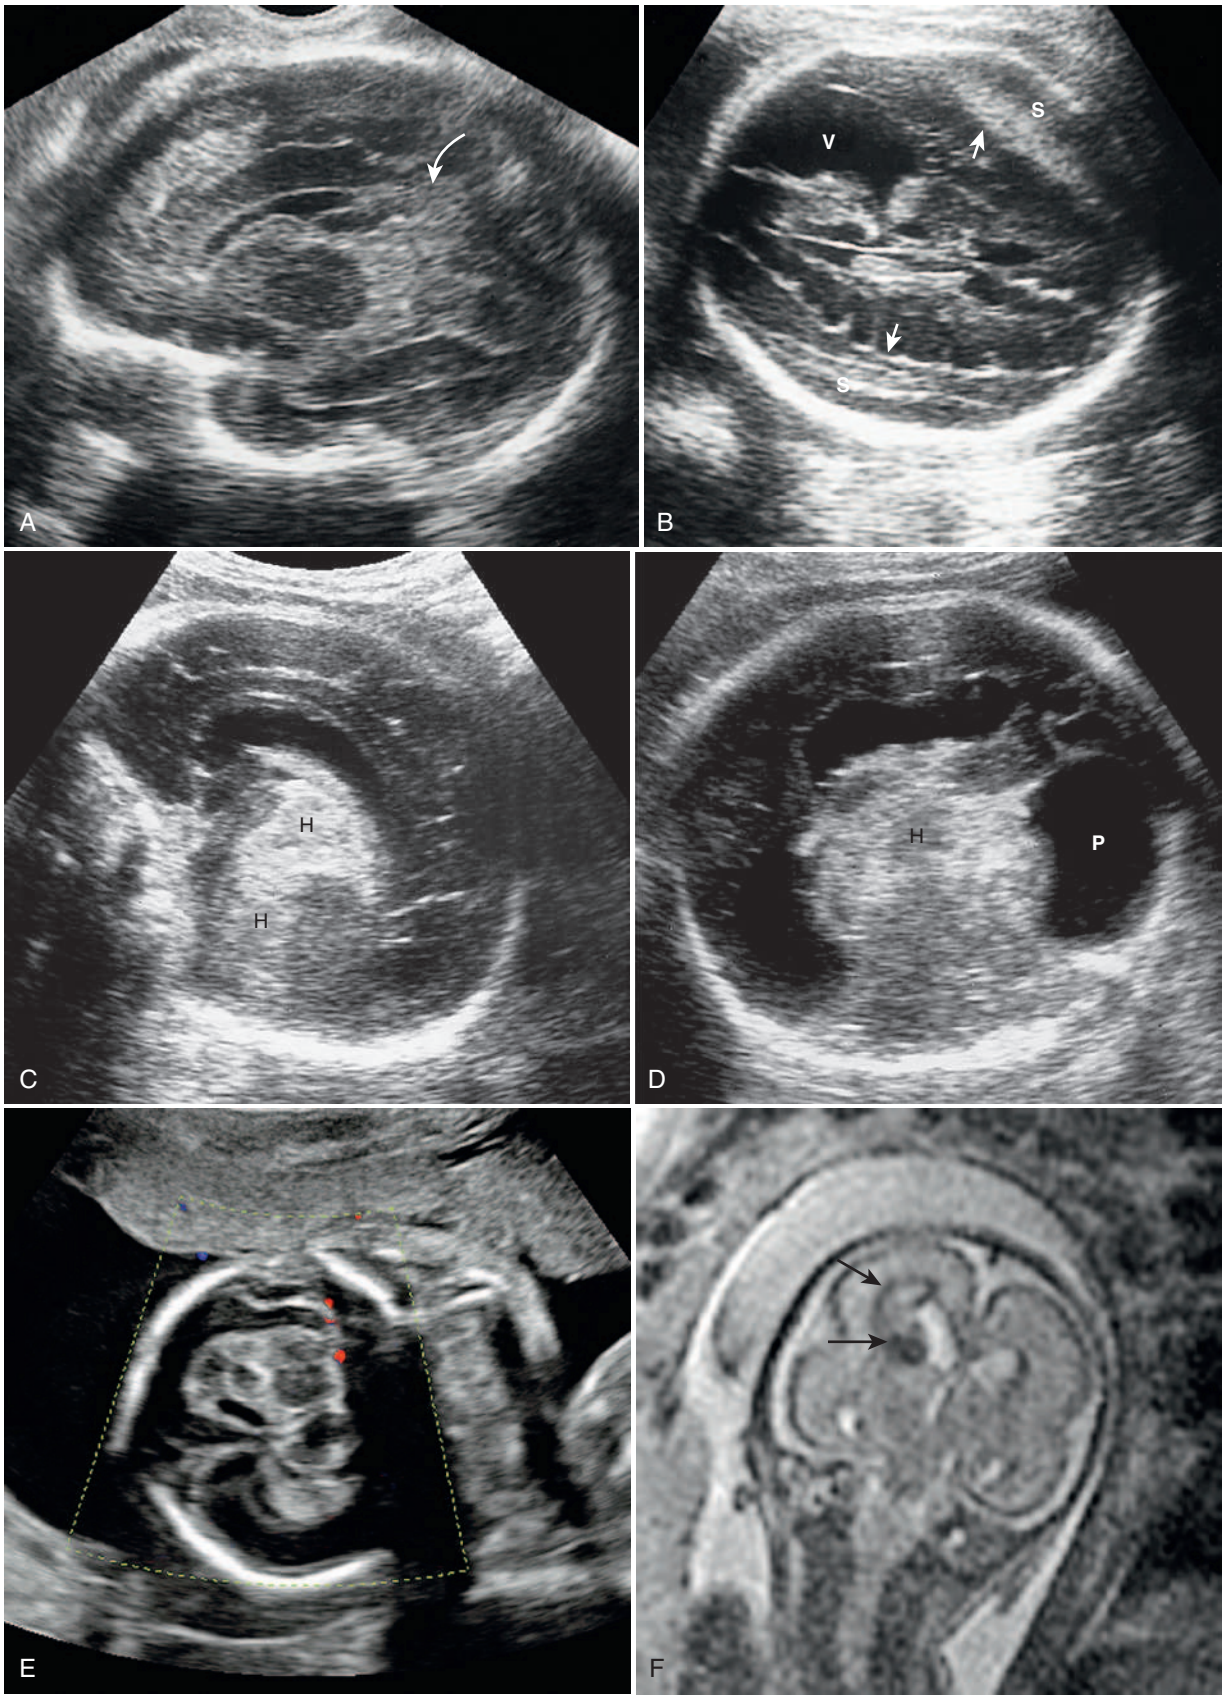

FIG. 34.35 Intracranial Hemorrhage. (A) Grade 4 intracerebral hemorrhage with clot *(arrow)* extending into the occipital cortex on parasagittal view. **(B) Bilateral subdural hemorrhages** *(S)* compressing the brain *(arrows)* and associated with slight asymmetrical ventricular enlargement *(V)*. These hemorrhages resolved spontaneously in this case, and the child did well. No cause was found. Most children with this finding do poorly. **(C)** Parasagittal and **(D)** coronal views of **thalamic and brainstem hemorrhage** *(H)* at 38 weeks. The posthemorrhagic porencephalic cyst *(P)* helps to differentiate this from tumor such as teratoma. Hypoxia was the likely cause. This fetus died shortly after the examination. **(E)** Coronal view at 23 weeks shows a grade 4 hemorrhage with clot extending into the parenchyma. **(F)** T2-weighted magnetic resonance image shows the low signal intensity of blood products in the parenchyma *(arrows)*. The relatively high signal intensity in the surrounding parenchyma suggests edema and venous infarction.

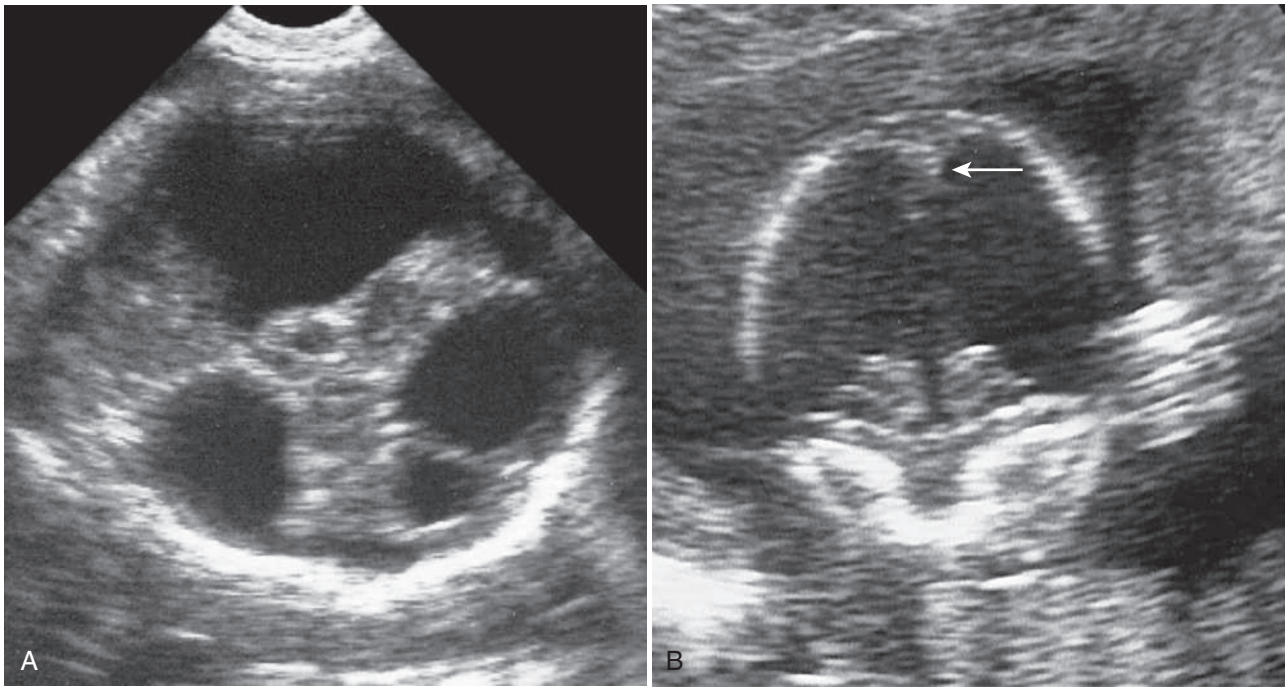

FIG. 34.36 Hydranencephaly. (A) Transverse thalamic view at 38 weeks shows asymmetrical cerebral destruction with preserved interhemispheric fissure. **(B)** Hydranencephaly at 17 weeks shows cranium filled with fluid. At first, the appearance suggests alobar holoprosencephaly, but the presence of the falx *(arrow)* and lack of thalamic fusion as indicated by the large third ventricle help confirm hydranencephaly.

Hydranencephaly

Hydranencephaly is a rare disorder in which almost all the cerebral hemispheres in the approximate distribution of the supraclinoid middle cerebral artery are absent and replaced by CSF and debris covered by a thin, membranous sac. Commonly there is partial sparing in the distribution of the anterior and posterior cerebral arteries, including portions of the frontal, temporal, and occipital lobes. The basal ganglia and thalami are hypoplastic, but the brainstem and cerebellum are intact. Cases are sporadic, with an incidence of about 1 per 5000 pregnancies. Many consider hydranencephaly to be the most severe form of porencephaly following occlusion of the internal carotid artery or middle cerebral artery. It may be associated with infections, toxins, hypoxic conditions, and trauma and may occur as a complication of twin-twin transfusion syndrome.

On ultrasound, the cerebral cortex is absent and the cerebrum is replaced initially by mildly echogenic fluid that becomes clear over time (Fig. 34.36). The falx is present but may be hypoplastic. Posterior fossa structures appear normal. Most cases are found in late pregnancy, but cases have been described as early as 11 weeks. Findings start with cerebral echogenicity, thought to result from ischemia or hemorrhage, followed by characteristic fluid replacement of the cerebrum. The differential diagnosis includes other conditions causing large, fluid-filled cranial spaces, such as severe **hydrocephalus, alobar holoprosencephaly,** bilateral subdural collections, **schizencephaly,** and **atelencephaly.** With **hydrocephalus,** there is generally uniform VM and a peripheral thin cerebral mantle, and color Doppler ultrasound shows flow in the middle cerebral arteries. In **holoprosencephaly** there is thalamic fusion and absence of the falx. **Subdural collections** compress the brain into the midline. Large **schizencephalic clefts** can appear similar to hydranencephaly, but in schizencephaly the lips of the clefts are lined by gray matter, which may be identifiable on MRI.

Most affected fetuses die in utero. At birth, diagnosis can be readily made clinically by cerebral transillumination. Most die in the first year, but survival in a vegetative state to 32 years has been described.[96,249,250]

TUMORS

Prenatal intracranial solid tumors are rare, occurring in about 1.4 to 3.6 per 100,000 pregnancies, and account for about 10% of all perinatal tumors. About 45% are **teratomas,** followed by **neuroepithelial tumors (astrocytomas, medulloblastoma, choroid plexus papilloma, gliomas)** (43%), **craniopharyngioma** (7%), **mesenchymal tumors (meningioma, sarcoma)** (5%), and **hemangioblastoma** (0.4%). Most are sporadic. A few are associated with familial syndromes that have genetic abnormalities, such as **neurofibromatosis, tuberous sclerosis, von Hippel–Lindau,** and **Li-Fraumeni syndrome.** Fetal brain tumors tend to be supratentorial in location, unlike tumors in older children, which are more likely to involve posterior fossa structures.[251-253]

The prenatal sonographic finding is an enlarged head containing a complex intracranial mass, occasionally with calcifications, macrocephaly, and HC (Fig. 34.37). The tumors grow quickly and can erode into the orbit, oral cavity, or neck. Associated

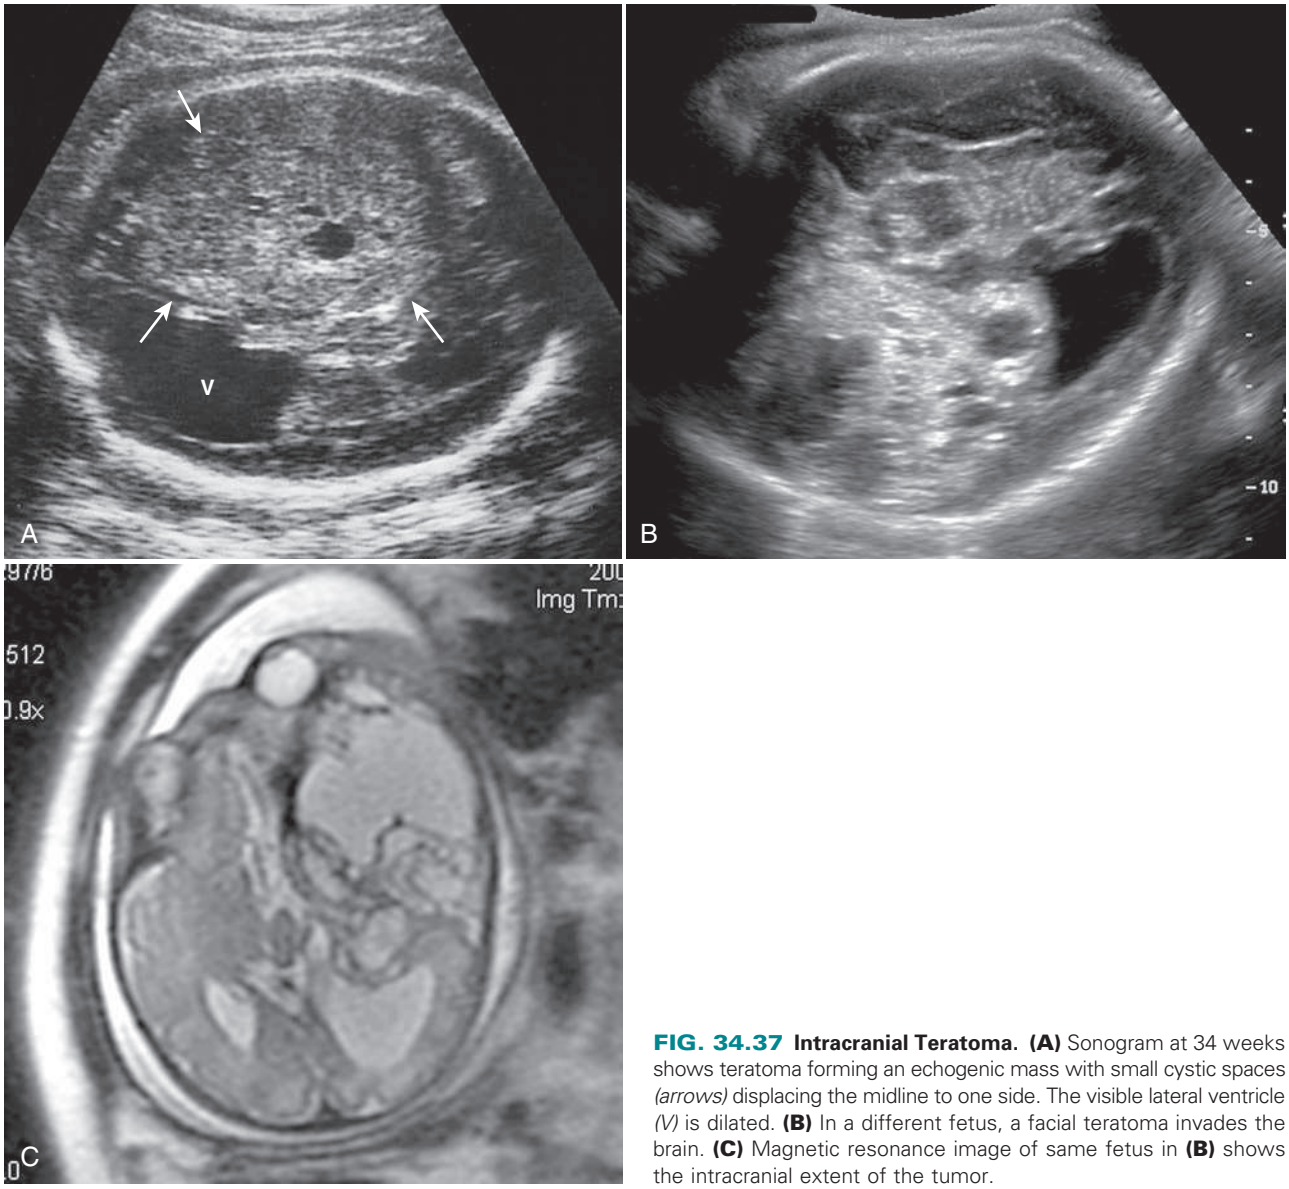

FIG. 34.37 Intracranial Teratoma. (A) Sonogram at 34 weeks shows teratoma forming an echogenic mass with small cystic spaces *(arrows)* displacing the midline to one side. The visible lateral ventricle *(V)* is dilated. **(B)** In a different fetus, a facial teratoma invades the brain. **(C)** Magnetic resonance image of same fetus in **(B)** shows the intracranial extent of the tumor.

findings include polyhydramnios and intracranial hemorrhage. Diagnosis is typically made in the third trimester on ultrasound triggered by excessive uterine growth due to polyhydramnios, although teratomas have been discovered as early as 17 weeks. Fetuses suspected to have brain tumors should undergo detailed ultrasound examination to look for associated abnormalities, which can occur in about 12% of cases, especially involving the face. Most have normal karyotype. MRI is helpful in characterizing the mass, evaluating tumor extension, and differentiating tumors from other conditions such as hemorrhage, sinus thrombosis, and vascular malformations.[251,252]

Outcomes are poor, especially if tumors appear early. Overall survival is about 28% and relates to size and location of tumor, its histology, surgical resectability, response to chemotherapy, and condition of the fetus at diagnosis. The large head size can interfere with delivery and require cephalocentesis to allow vaginal delivery. Of the few survivors, almost all have long-term neurologic deficits. Slightly better survival is seen with choroid plexus papilloma (73%) and meningeal tumors (36%).[251-253]

Choroid plexus papillomas are large, finely nodular masses that grow into the lateral ventricle and produce excessive CSF, resulting in severe dilation of the entire ventricular system and macrocephaly. Most are sporadic, but a few are associated with **Aicardi syndrome** and **giant pigmented nevi.** Surgical resection can be curative but is technically difficult because the vascular nature of choroid plexus papillomas can result in fatal hemorrhage. Overall survival is about 73%.[251]

Intracranial lipomas are not "neoplasms" but rather a malformation of meninx primitiva development. Instead of resorbing at 8 to 10 weeks, the meninx persists and develops into a mass of mature adipose tissue. The incidence is 4 to 40 per 100,000 autopsies. Most are near the corpus callosum, but they can arise in any cistern. They can interfere with callosal development, and associated dysgenesis of the corpus callosum

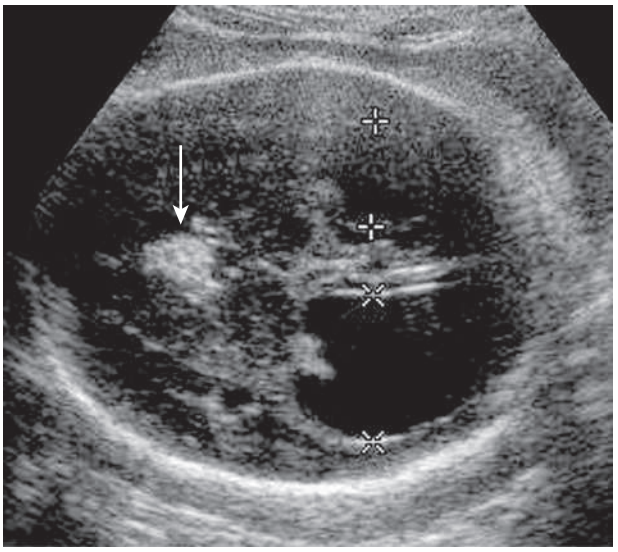

FIG. 34.38 Lipoma. Midline lipoma forming an echogenic mass near the foramina of Monro at the expected anterior end of the corpus callosum *(arrow)*. These are not neoplasms and represent abnormal differentiation of meningeal anlagen (precursors) into fat. Midline lipomas are often associated with dysgenesis of the corpus callosum, as in this fetus, in which the cavum septi pellucidi is absent and the ventricles *(calipers)* are dilated.

is common. Additional associations include aneurysms and other midline brain and facial malformations. At ultrasound, intracranial lipomas appear as early as 23 weeks as an echogenic mass or plaque in the midline in the region of the corpus callosum with occasional calcification and even ossification. (Fig. 34.38). MRI is helpful to confirm the fatty nature of the mass and to further evaluate changes in the corpus callosum and remaining brain. Most do not grow. Many patients are asymptomatic, but the associated abnormalities may cause symptoms including seizures and developmental delays. Surgical treatment of the lipoma is generally not indicated and can be dangerous because of the strong attachment of the lipoma to surrounding structures and the nerves and vessels within the mass.[254,255]

CONCLUSION

Assessment of the fetal CNS, more than any other organ system, is frequently enhanced by the addition of fetal MRI. The combination of ultrasound and MRI allows for many other experts to aid in the investigation, diagnosis, and management of fetal conditions, including pediatric neuroradiologists, neurologists, neurosurgeons, geneticists, pathologists, and other specialists. The understanding of the genetic basis, pathophysiology, natural history, and prognosis of many conditions and syndromes is increasing explosively as a result of this cross-fertilization and collaboration. Those performing ultrasound are discovering the complexities and large spectrum of neonatal diseases. Those providing postnatal care are discovering that prenatal conditions affecting the fetus are often very different from conditions that affect neonates who survive pregnancy. Best results are obtained when there is multidisciplinary consultation and collaboration.

Acknowledgments

The advice and support of our colleagues Drs. Susan Blaser, David Chitayat, Katherine Fong, Charles Raybaud, and Patrick Shannon are acknowledged and appreciated.

CHAPTER 35

The Fetal Spine

Elizabeth Asch and Eric Sauerbrei

SUMMARY OF KEY POINTS

- Neural tube defects (NTDs) are a common congenital anomaly with clinically important associated morbidity and mortality rates.
- Most open NTDs will have associated intracranial abnormalities, most commonly Chiari II malformation, detected by sonography.
- Although much less common, closed NTDs are less likely to have associated intracranial abnormalities and require careful examination of the spine for detection.
- Other spinal abnormalities such as scoliosis, sacral agenesis, caudal regression, sirenomelia, and sacrococcygeal teratoma have distinct sonographic appearances that aid in prenatal diagnosis.

CHAPTER OUTLINE

DEVELOPMENTAL ANATOMY

SCOLIOSIS AND KYPHOSIS
SACRAL AGENESIS
CAUDAL REGRESSION
SIRENOMELIA
SACROCOCCYGEAL TERATOMA
PRESACRAL FETAL MASS

Abnormalities of the spine are some of the most common congenital abnormalities. In the United States, overall incidence of neural tube defects (NTDs) was approximately 1 to 2 in 1000 births[1] before 2000, but by 2007 it was less than 0.5 in 1000 pregnancies primarily as a result of the widespread use of folic acid before conception[2,3] and the addition of folic acid to enriched grain products.[4] Since the institution of folic acid supplementation, an estimated 1300 cases of NTDs each year have been prevented in the United States.[5] At least 42 nations practice mandatory folic acid fortification to combat NTDs.[6-10]

NTDs are associated with substantial morbidity and mortality rates. Many survivors have severe long-term morbidity that has a profound emotional, physical, and financial impact on their families. Fortunately, the birth incidence of spina bifida and anencephaly is decreasing in many areas of the world as a result of maternal screening programs (maternal serum tests and antenatal ultrasound) and, more recently, the administration of folic acid to women of child-bearing age.

In prenatal imaging, **three-dimensional** (3D) **ultrasound** and **fetal magnetic resonance imaging** (MRI) are making a positive impact, especially for precise localization of spina bifida and complete delineation of associated abnormalities. This precise information is useful for prognosis and possibly for prenatal surgery. Prenatal surgery for closure of myelomeningoceles is practiced in only a few centers at this time.

DEVELOPMENTAL ANATOMY

Embryology of the Spine

The precursors of the spinal cord and surrounding spinal column develop in the third and fourth weeks after conception (fifth and sixth menstrual weeks). During the third conceptual week, the bilaminar germ disc evolves into the trilaminar germ disc, which consists of the **ectoderm** layer (part of the amniotic cavity), the middle **mesoderm** layer, and the **endoderm** layer (part of the yolk sac cavity) (Fig. 35.1A). The mesoderm layer develops a midline central tube, the **notochordal process,** which runs along the long axis of the embryonic disc. The mesoderm lateral to the notochordal process has three components: paraxial mesoderm, intermediate mesoderm, and lateral plate mesoderm. By day 21 conceptual age, the hollow-tube notochordal process

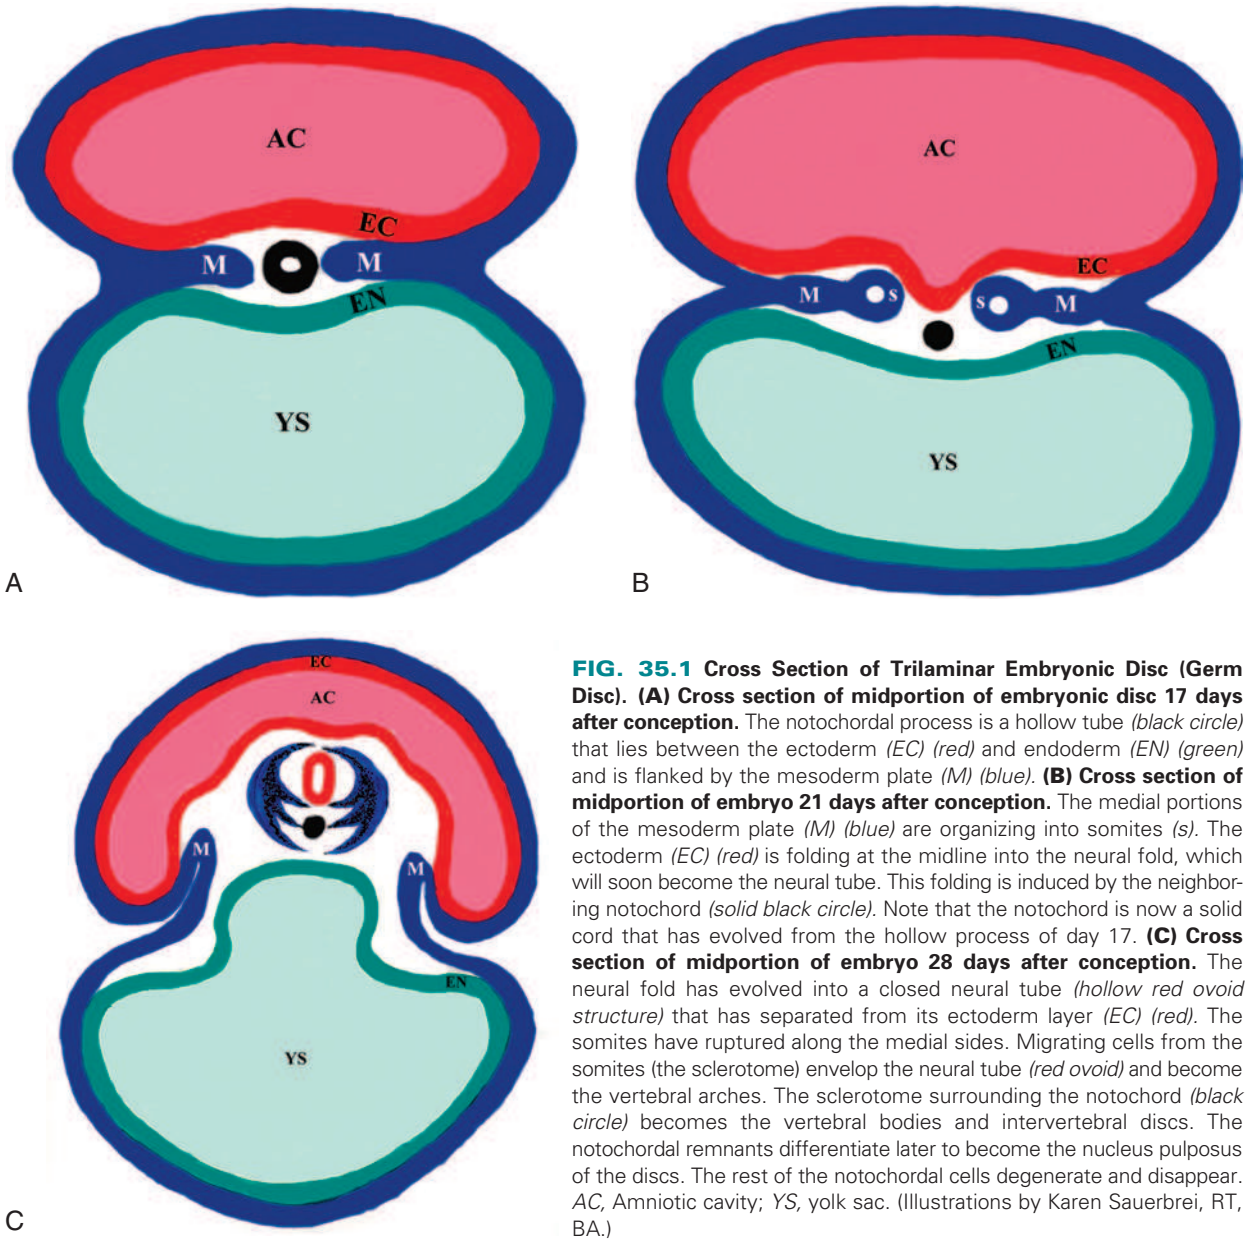

FIG. 35.1 Cross Section of Trilaminar Embryonic Disc (Germ Disc). (A) Cross section of midportion of embryonic disc 17 days after conception. The notochordal process is a hollow tube *(black circle)* that lies between the ectoderm *(EC) (red)* and endoderm *(EN) (green)* and is flanked by the mesoderm plate *(M) (blue).* **(B) Cross section of midportion of embryo 21 days after conception.** The medial portions of the mesoderm plate *(M) (blue)* are organizing into somites *(s).* The ectoderm *(EC) (red)* is folding at the midline into the neural fold, which will soon become the neural tube. This folding is induced by the neighboring notochord *(solid black circle).* Note that the notochord is now a solid cord that has evolved from the hollow process of day 17. **(C) Cross section of midportion of embryo 28 days after conception.** The neural fold has evolved into a closed neural tube *(hollow red ovoid structure)* that has separated from its ectoderm layer *(EC) (red).* The somites have ruptured along the medial sides. Migrating cells from the somites (the sclerotome) envelop the neural tube *(red ovoid)* and become the vertebral arches. The sclerotome surrounding the notochord *(black circle)* becomes the vertebral bodies and intervertebral discs. The notochordal remnants differentiate later to become the nucleus pulposus of the discs. The rest of the notochordal cells degenerate and disappear. *AC,* Amniotic cavity; *YS,* yolk sac. (Illustrations by Karen Sauerbrei, RT, BA.)

has evolved into a solid cord called the **notochord,** and the paraxial mesoderm has developed multiple discrete bumps called **somites,** of which there are 37 pairs when fully developed (Fig. 35.1B).

The notochord and the rest of the intraembryonic mesoderm induce the development of the **neural plate** in the ectoderm layer (amniotic cavity side of the germ disc), starting on conceptual day 18. The neural plate grows in length and breadth until conceptual day 21, when neurulation begins. **Neurulation** is the process of folding of the neural plate into the **neural tube,** probably induced by the adjacent notochord. The lateral edges of the neural folds begin to fuse dorsally into a closed neural tube in the occipitocervical region, leaving an opening at the cranial end **(cranial neuropore)** and the caudal end **(caudal neuropore).** The hollow center of the neural tube is called the **neural canal,** which will become the central canal of the spinal cord and ventricular system of the brain. By day 24 conceptual age, the cranial neuropore closes, and by day 25 the caudal neuropore closes (Table 35.1).

The cranial end of the neural tube becomes the brain, and the caudal end becomes the spinal cord. In week 4 conceptual age, after the neural tube has formed, the adjacent 37 pairs of somites in the intraembryonic mesoderm give rise to the vertebral bodies and vertebral arches that will surround the spinal cord. A group of cells, the **sclerotome,** migrates from the somites and surrounds the adjacent neural tube and notochord. The ventral portion of the sclerotome surrounds the notochord and forms the rudiment of the vertebral body. The dorsal portion of the sclerotome surrounds the neural tube and forms the precursors to the vertebral arch (Fig. 35.1C). In the fetus, the **notochordal**

TABLE 35.1 Spine Embryology During Third and Fourth Weeks After Conception

Menstrual Age (Days)	Conceptual Age (Days)	Embryo Length (mm)	Sac Diameter (mm)	Landmarks
31	17	0.5	2	Trilaminar disc Notochordal process Paraxial mesoderm (Fig. 35.1A)
35	21	2	4	Notochord Neural plate Somites (Fig. 35.1B)
42	28	5	10	Neural tube Notochord Sclerotome (Fig. 35.1C)

remnant corresponds to the nucleus pulposus of the intervertebral discs.[11]

Abnormalities of neural tube closure not only affect the spinal cord and brain but also interfere with normal development of surrounding vertebral arches, which are derived from adjacent mesodermal somites. Disturbances of neural tube closure underlie **spina bifida** and **anencephaly** defects.

Caudal regression defects may be related to defective development of the mesoderm layer in week 3 conceptual age, during transformation of the germ disc from two layers (bilaminar) to three layers (trilaminar). Various degrees of abnormal mesoderm development account for the wide spectrum of abnormalities found in caudal regression.

A failure of part of the neural tube to close, called **spinal dysraphism,** disrupts development of the nervous system and disrupts the induction of the overlying vertebral arches. The resulting open vertebral canal is called **spina bifida.** If dura and arachnoid protrude from the spinal canal, the result is a **meningocele.** If neural tissue and meninges protrude, the result is a **myelomeningocele.** In the most severe NTDs, the neural tube fails to form and fails to separate from the overlying ectoderm. In the spine, this condition is called **rachischisis** or **myeloschisis;** the open spinal cord is exposed along the dorsal surface of the fetus. If the defect involves the cranial neural tube, the brain is represented by an exposed dorsal mass of undifferentiated neural tissue, called **exencephaly, anencephaly,** or **craniorachischisis.** Differentiated brain and meninges may bulge from a nonossified gap in the skull **(meningoencephalocele),** but this is not related to failure of neural tube closure.

In animals, certain teratogens can induce NTDs: **retinoic acid, insulin,** and **high plasma glucose levels.** In humans, implicated factors include **valproic acid** (antiepileptic), **maternal diabetes,** and **hyperthermia.** Valproic acid may interfere with folate metabolism.

Ossification of the Fetal Spine

Prenatal sonography readily portrays the ossified portions of the fetal spine, whereas the nonossified cartilage is more difficult to delineate. It is therefore important for sonographers and sonologists to understand the temporal and spatial ossification patterns during fetal development in order to optimize spinal evaluation.

Each vertebra will develop three ossification centers: the centrum, right neural process, and left neural process.[12] The **centrum** will form the central part of the vertebral body, and the **neural process** will form the posterolateral parts of the vertebral body and pedicles, the transverse processes, the laminae, and the articular processes.

Ossification begins in the lower thoracic fetal spine at approximately 10 weeks' gestation (menstrual age).[13] Ossification of the **centra** progresses in cranial and caudal directions simultaneously. **Neural arch** ossification proceeds caudally from the lower thoracic (T) spine to the lumbar (L) spine. It proceeds sequentially from L1 through L5 and then into the sacral (S) spine. By 13 weeks' menstrual age, there are three ossification centers in vertebrae C1 through L3[14] (Fig. 35.2). Neural arch ossification begins as a small focus at the base of the transverse process and extends simultaneously into the pedicle anteriorly and into the lamina posteriorly (Fig. 35.3).

Ultrasound evaluation for spina bifida usually occurs between 16 and 22 weeks' gestation. By 16 weeks, there is enough ossification in the neural arches to assess for spina bifida to level L5,[15] by 19 weeks to level S1, and by 22 weeks to level S2 (Figs. 35.4 and 35.5). In some fetuses, there may be enough neural arch ossification to assess for spina bifida before these gestational ages. Braithwaite et al.[16] assessed the fetal anatomy at 12 to 13 weeks' gestation by a combination of transabdominal and transvaginal sonography and reported successful examination of the vertebrae and overlying skin in both the transverse and the coronal plane in all cases. Others have reported successful prenatal diagnosis of spina bifida at 12 to 14 weeks' gestation on the basis of abnormal cranial findings.[17-19] They caution that although the characteristic cranial findings may be present at 11 to 14 weeks, the prevalence of these findings in the first trimester remains to be determined (Table 35.2). Furthermore, closed NTDs are less likely to be associated with abnormal cranial findings and therefore are more difficult to detect in the first trimester.

Normal Position of the Spinal Cord

For fetuses at 19 to 33 weeks' gestation, the **conus medullaris** is normally situated at level L2-L3 or higher (Fig. 35.6). Level L3 is taken to be *indeterminate* and L3-L4 or lower as *abnormal.*[20] For those fetuses with tethered cord, the position of the conus

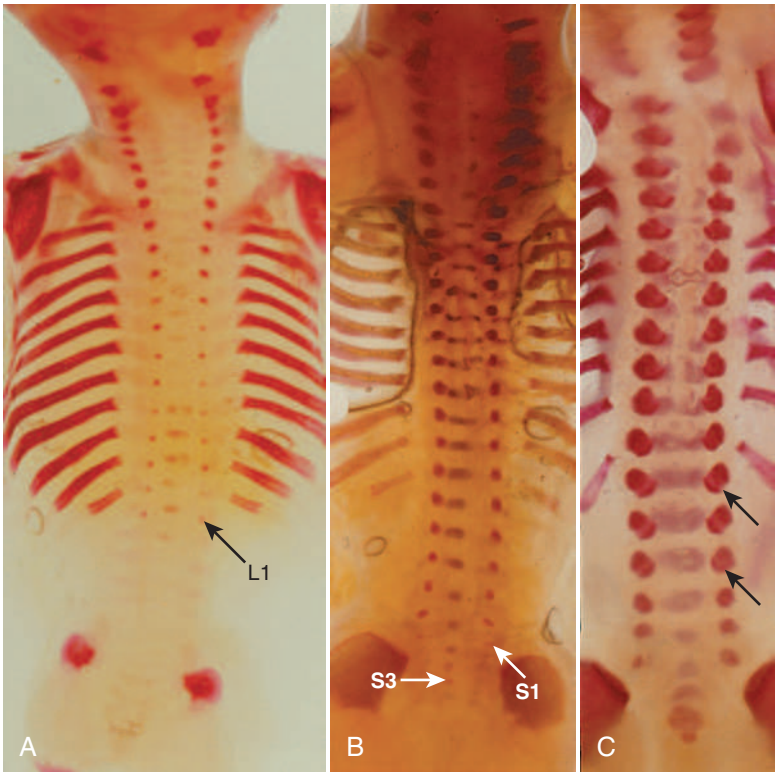

FIG. 35.2 Spine Ossification at 11 Weeks + 4 Days' Menstrual Age. (A) Ossification of neural processes extends from C1 to L1 *(arrow).* The neural process ossification starts at the base of the transverse process, which lies at the junction of the pedicle and the lamina. **(B) Spine ossification at 13 weeks' menstrual age.** Ossification extends to level S1 neural process *(S1 arrow)* and S3 vertebral body *(S3 arrow).* **(C) Spine ossification at 15 weeks + 2 days' menstrual age.** Ossification now extends into the laminae of the vertebral arches in the thoracic and lumbar spine. Arrows demonstrate ossification of the laminae at levels L1 and L3. Ossification of the laminae is minimal at S1.

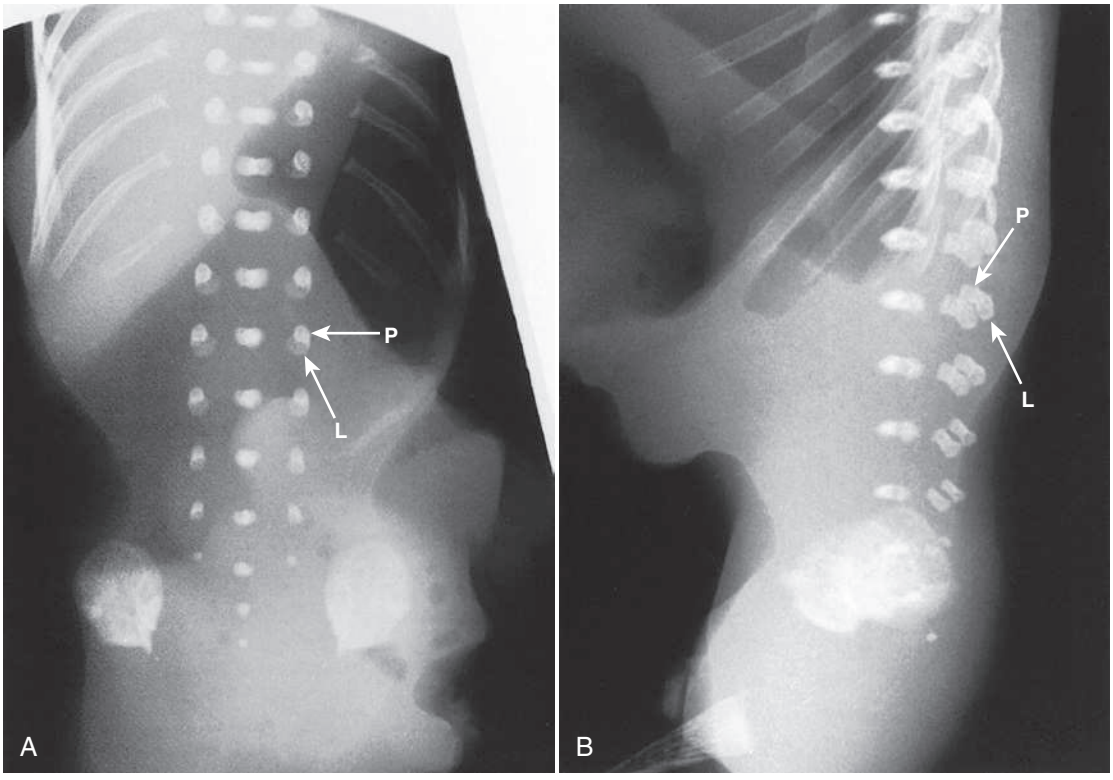

FIG. 35.3 Spine Ossification on Radiographs at 14 Weeks' Gestation. (A) Anteroposterior and **(B)** lateral radiographs. Well-developed ossification in the centra now extends down to level S3. Ossification in the lumbar neural processes extends into the lamina *(L)* and pedicles *(P).* The neural process ossification starts to resemble the shape of the cartilaginous neural process rather than the focal dotlike ossification at 13 weeks' gestation.

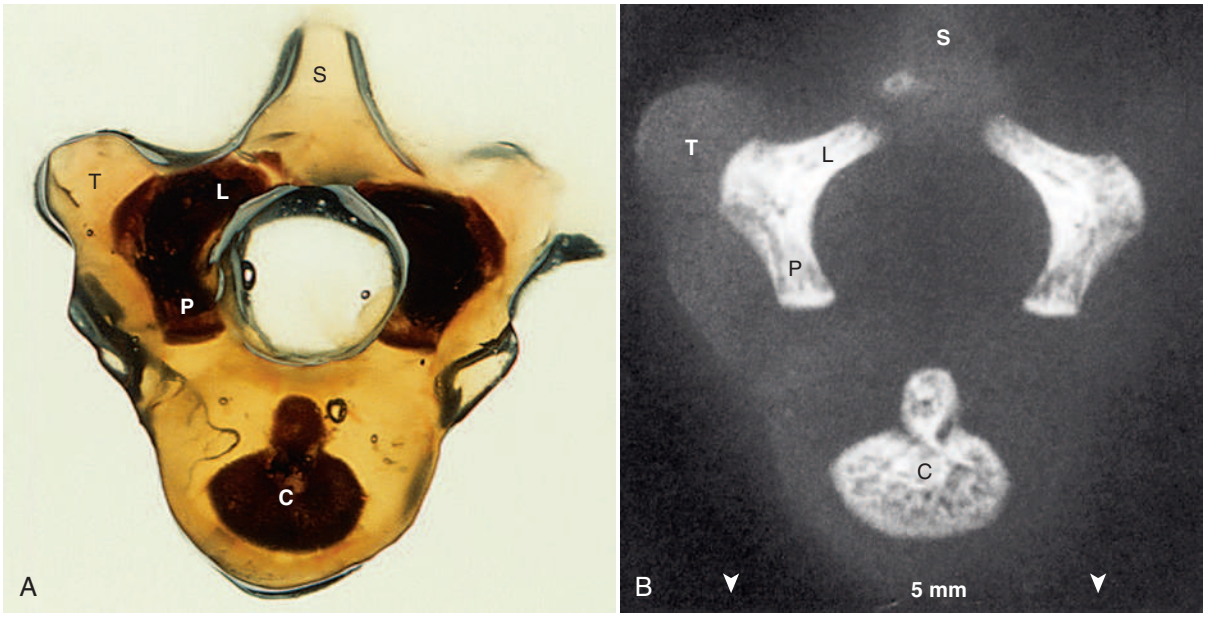

FIG. 35.4 Vertebral Ossification of T9 at 16 Weeks' Gestation. (A) Specimen. **(B)** Radiograph. Ossification extends quite far into the pedicles *(P)* and laminae *(L)*. Note the early ossification in the base of the transverse processes *(T)*. The width of the vertebra is about 5 mm. There is ossification within the centrum *(C)*. *S,* Spinous process (cartilage); *T,* transverse process (cartilage). The distance between the *arrowheads* is 5 mm.

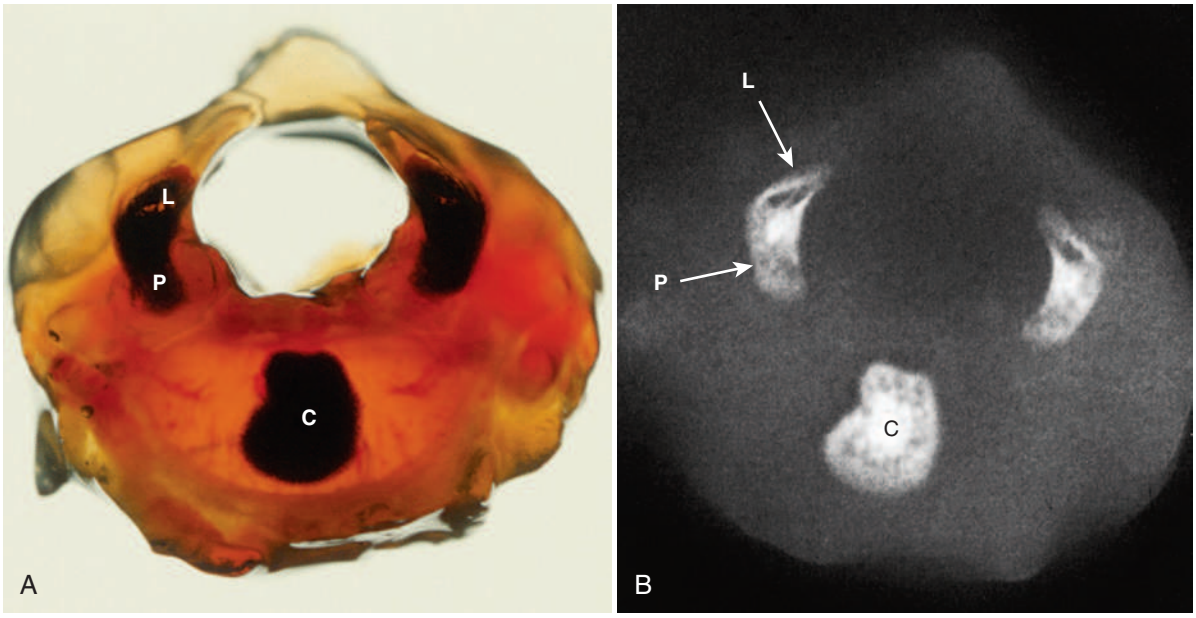

FIG. 35.5 Vertebral Ossification of L5 at 17 Weeks' Gestation. (A) Specimen. **(B)** Radiograph. There is usually enough ossification at this gestation in the pedicles *(P)* and laminae *(L)* to determine the true course of these structures in radiographs and sonograms. The width of the vertebra is about 5 mm. There is ossification within the centrum *(C)*.

TABLE 35.2 Timing and Pattern of Fetal Spine Ossification (10-22 Weeks' Menstrual/Gestational Age)

Age (Wk)	Events
10	Ossification appears in lower thoracic spine vertebral bodies.
13	Some ossification is present from C1 to L5 vertebral bodies and arches.
13-22	Neural arch ossification simultaneously extends anteriorly into the pedicles and posteriorly into the laminae.
16	Enough neural arch ossification appears to assess for spina bifida to level L5.
19	Enough neural arch ossification appears to assess for spina bifida to level S1.
22	Enough neural arch ossification appears to assess for spina bifida to level S2.

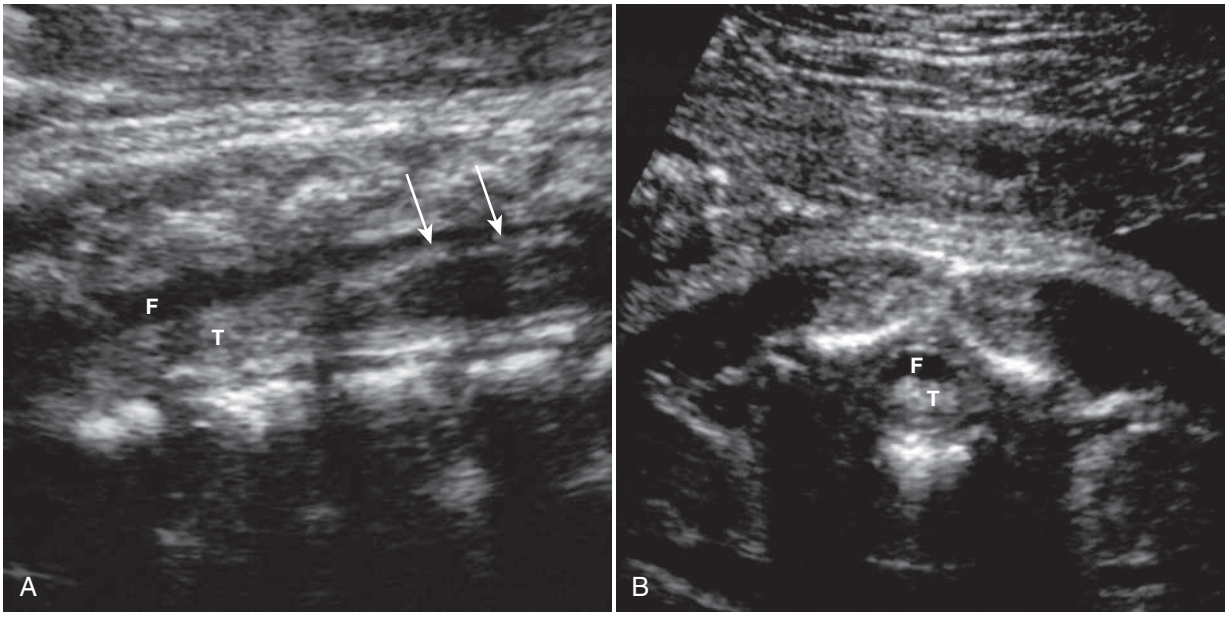

FIG. 35.6 Normal Spinal Cord. (A) Posterior longitudinal and **(B)** posterior transaxial (transverse) sonograms of a normal spinal cord. Note the normal position of the cord *(arrows)* and filum terminale *(T)* in the dependent portion of the spinal canal. Cerebrospinal fluid *(F)* is seen between the anterior aspect of the spinal cord and the anterior wall of the spinal canal.

medullaris is usually lower than normal. For earlier pregnancy (13-18 weeks' gestation), the conus medullaris may be normally as low as L4. At term, the conus is normally at or above L2.[21]

SCANNING TECHNIQUES

In clinical practice, the most useful scan planes to assess the posterior neural arches are posterior transaxial (Fig. 35.7), lateral transaxial (Fig. 35.8), lateral longitudinal (coronal) (Fig. 35.9), posterior longitudinal (sagittal) (Fig. 35.10), and posterior angled transaxial (Fig. 35.11). The posterior angled transaxial scan plane is useful to visualize the pedicles and laminae simultaneously. Because the laminae course caudal to the transaxial plane, which contains the centrum and pedicles, only the angled scan plane can depict the pedicles and laminae simultaneously in their entirety.

The detection rate of spina bifida at 18 to 20 weeks' gestation may be 80% or less during routine screening ultrasound,[22] because the accuracy of ultrasound depends on the skill and experience of the operator. The accuracy of referral centers performing detailed targeted imaging because of a suspected NTD or high **maternal serum alpha-fetoprotein** (MS-AFP) level is close to 100%.

A detailed sonogram of the fetal spine may be requested for several reasons: previous suspicious ultrasound, family history of NTD, or raised serum or amniotic fluid AFP. To enhance detection of spina bifida, a detailed protocol should be consistently followed. The first step in assessing for spina bifida is scanning the head, because most fetuses with open spina bifida have signs of a **Chiari II malformation** in the brain at 16 to 22 weeks' gestation. These signs include obliterated cisterna magna **(banana sign),** concave frontal bones **(lemon sign),** and dilated lateral cerebral ventricles.[23,24] The sensitivity of the banana sign for open spina bifida is close to 99%, and false-positive diagnoses are rare, although the lemon sign may occur in 1% to 2% of normal fetuses.

The next step is to determine the position of the fetal spine. The scan plane is placed perpendicular to the long axis of the fetal spine, either posterior transaxial or lateral transaxial (see Figs. 35.7 and 35.8). The sonographer should scan from one end of the spine to the other while maintaining the scan plane perpendicular to the spine (Video 35.1). This is repeated several times. In the process, the sonographer builds up an impression of the 3D structures of the spine. The scan plane should then be repositioned parallel to the long axis of the fetal spine to obtain posterior longitudinal and lateral longitudinal views. The sonographer then examines all levels of the spine in posterior transaxial, lateral transaxial, lateral longitudinal, and posterior longitudinal scan planes (Video 35.2). This may not be possible in a short time because of fetal position, but this usually changes enough in 30 to 45 minutes at 16 to 22 weeks to obtain all scan planes. If the spine cannot be visualized optimally, a repeat scan can be performed at a later gestational age. In both axial and longitudinal scan plans, it is important to visualize the skin covering the fetal back by ensuring that amniotic fluid is interposed between the fetus and the uterine wall.

Three-Dimensional Ultrasound

Three-dimensional ultrasound imaging has shown promise in evaluating normal fetal structures and in providing additional information in abnormalities of many fetal structures, including the spine, hand, foot, and face.[25-34] Bony structures can be visualized with maximum-intensity projection methods (see Fig. 35.9D). In evaluation of spinal abnormalities, 3D ultrasound is most

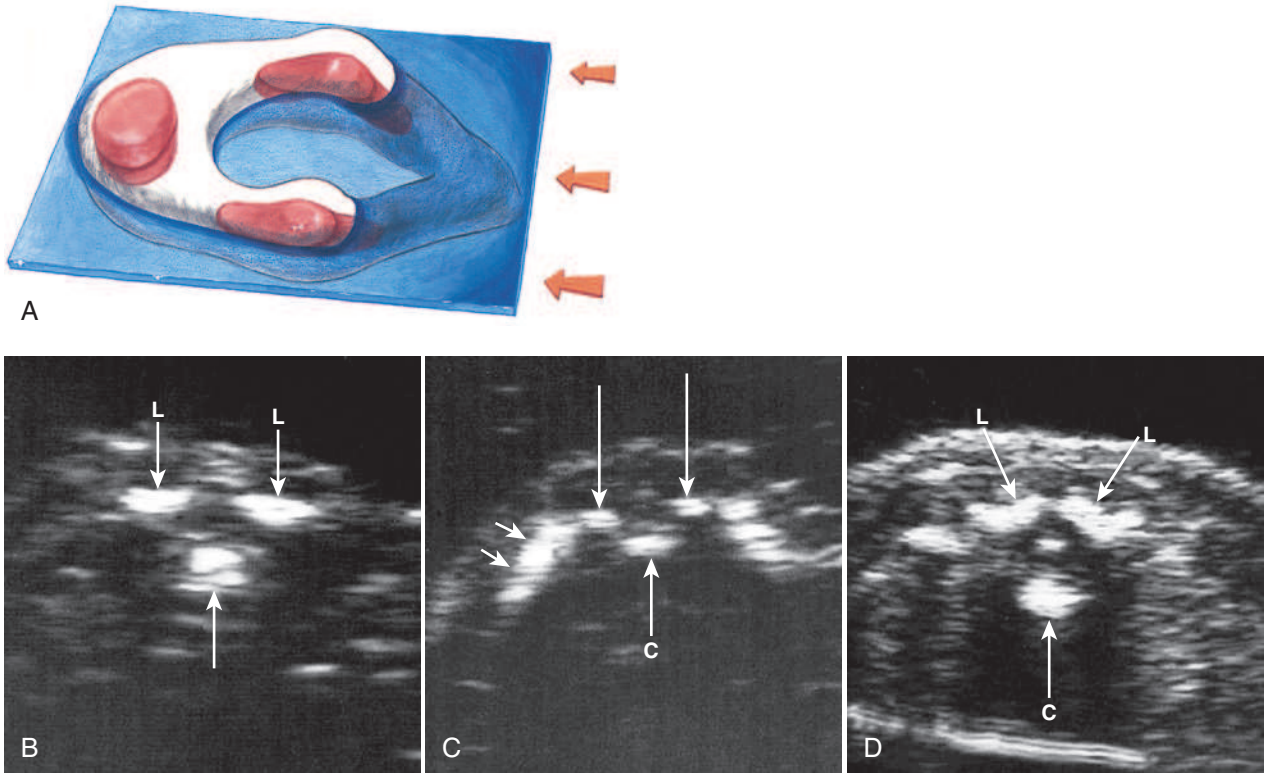

FIG. 35.7 Posterior Transaxial Scan Plane. (A) Diagram shows the incident sound beam *(arrows)* reflecting off the posterior surfaces, clearly demonstrating the **laminae** and **centrum** but not the pedicles. The red structures represent the ossified portions of the vertebra. **(B)** The L3 vertebra at 17 weeks' gestation demonstrates the ossified laminae *(L)* and the ossified centrum *(bottom arrow)* but not the pedicles. **(C)** Scan of S1 vertebra at 17 weeks shows early ossification at the lamina-pedicle junction on each side *(long thin arrows).* With this amount of ossification, determining the course of the laminae is not possible, and thus excluding spina bifida is difficult. *C,* Ossified centrum; *short arrows,* iliac wing. **(D)** Scan of T10 at 24 weeks' gestation shows advanced ossification in the laminae *(L, arrows)* almost reaching midline. Despite their advanced ossification, the pedicles are not visualized in this scan plane. *C,* Ossified centrum.

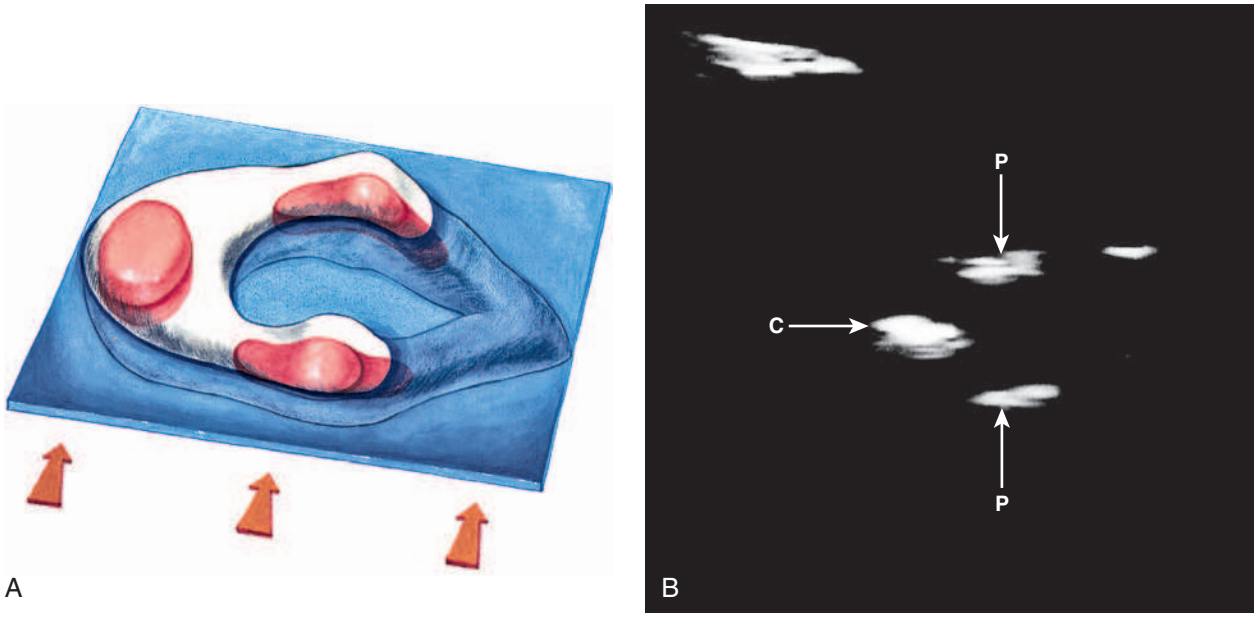

FIG. 35.8 Lateral Transaxial (Transverse) Scan Plane. (A) Diagram shows the incident sound beam *(arrows)* reflecting off the lateral surfaces of the centrum and the near pedicle and off the medial surface of the far pedicle, demonstrating the **centrum** and **pedicles,** but not the laminae. The laminae course toward midline (thus sound beam is not perpendicular to laminar surface) and caudally (thus out of the plane of sound beam). The red structures are ossified portions of the vertebra. **(B)** Scan of vertebra L3 at 17 weeks' gestation shows the ossified pedicles *(P)* and the ossified centrum *(C)* but not the laminae.

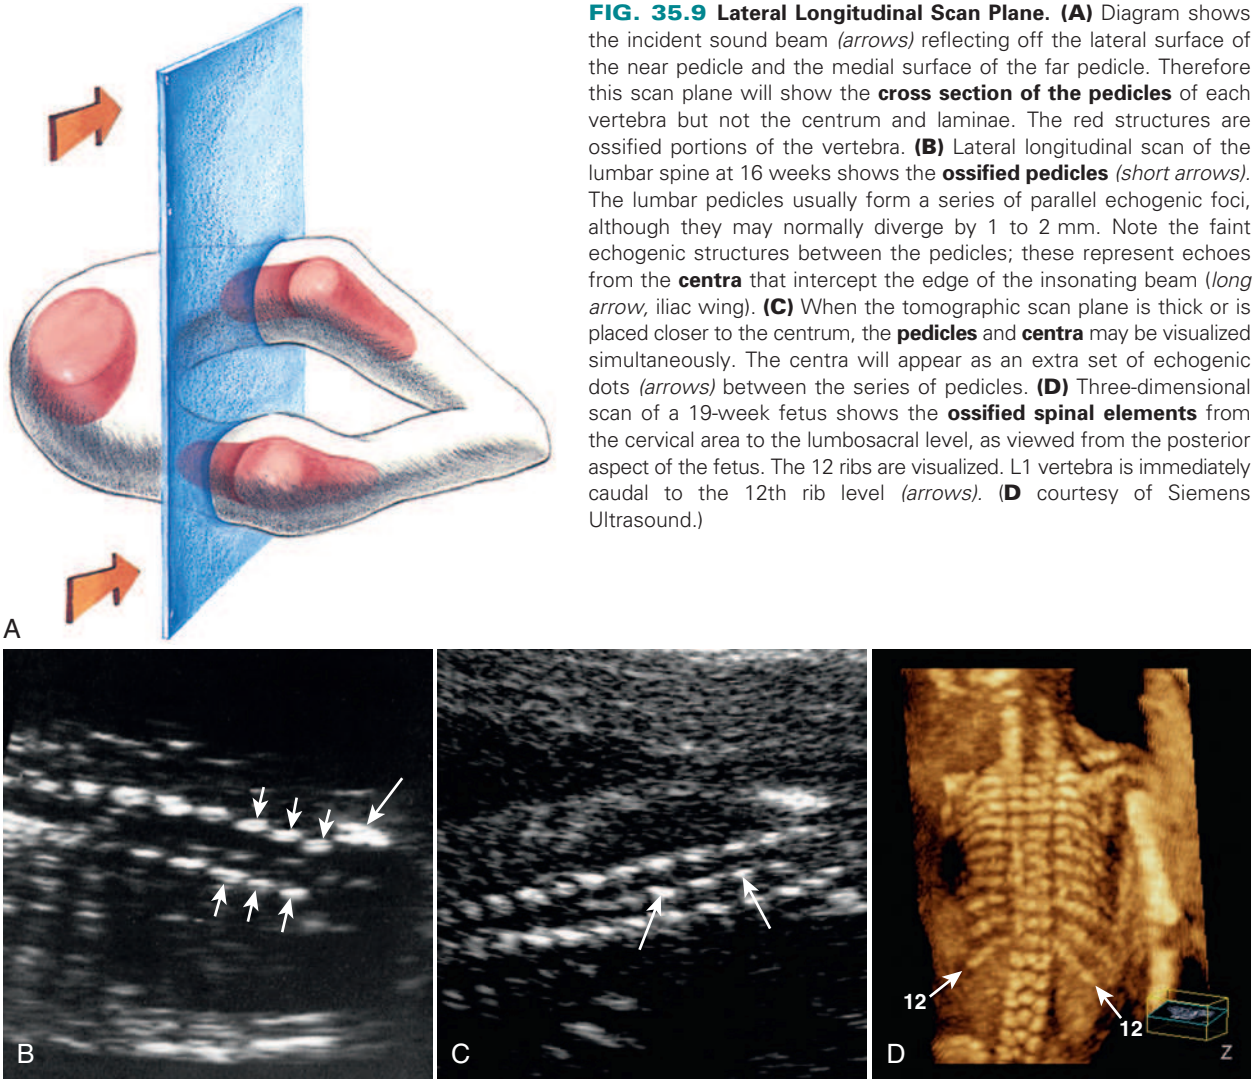

FIG. 35.9 Lateral Longitudinal Scan Plane. (A) Diagram shows the incident sound beam *(arrows)* reflecting off the lateral surface of the near pedicle and the medial surface of the far pedicle. Therefore this scan plane will show the **cross section of the pedicles** of each vertebra but not the centrum and laminae. The red structures are ossified portions of the vertebra. **(B)** Lateral longitudinal scan of the lumbar spine at 16 weeks shows the **ossified pedicles** *(short arrows).* The lumbar pedicles usually form a series of parallel echogenic foci, although they may normally diverge by 1 to 2 mm. Note the faint echogenic structures between the pedicles; these represent echoes from the **centra** that intercept the edge of the insonating beam (*long arrow,* iliac wing). **(C)** When the tomographic scan plane is thick or is placed closer to the centrum, the **pedicles** and **centra** may be visualized simultaneously. The centra will appear as an extra set of echogenic dots *(arrows)* between the series of pedicles. **(D)** Three-dimensional scan of a 19-week fetus shows the **ossified spinal elements** from the cervical area to the lumbosacral level, as viewed from the posterior aspect of the fetus. The 12 ribs are visualized. L1 vertebra is immediately caudal to the 12th rib level *(arrows).* (**D** courtesy of Siemens Ultrasound.)

helpful in localizing spinal defects accurately by using simultaneous multiplanar imaging and referencing to the volume-rendered image.[25,28] For determination of spinal level, T12 is taken to be the most caudal vertebra with a corresponding rib. Three-dimensional ultrasound may also show concomitant rib deformities in the setting of spinal abnormalities and is useful for counseling prospective parents by providing a more understandable visual demonstration of the skeletal abnormality.

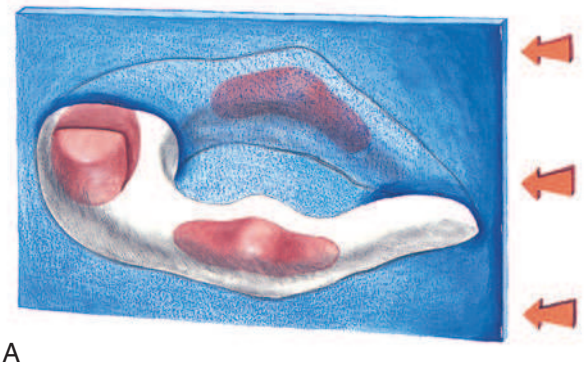
SPINA BIFIDA

Spina bifida implies a physical defect in the structure of the spinal canal that may result in a protrusion of its contents (meninges, cerebrospinal fluid, and neural tissue) (Table 35.3). These defects usually occur along the dorsal midline (most often in the lumbosacral area) but in rare cases may occur anteriorly.

Open NTDs occur in less than 0.5 per 1000 births in North America and with higher frequencies in other geographic areas. Hispanic women in the United States have a higher incidence of births affected by NTDs, possibly because of a higher prevalence of a mutation in the methylenetetrahydrofolate reductase deficiency gene.[35] In one area of China, the overall prevalence of NTDs in 2003 was 13.9 per 1000 live births.[36] In recent years, however, there has been a decline in the incidence of NTDs. Some of this decline may be attributed to screening programs, which include measurement of MS-AFP and performance of second-trimester ultrasound.[37,38]

Protocol to Evaluate Spina Bifida With Three-Dimensional Volume Data

- Volume data are acquired from sagittal and transverse sweeps through the spine.
- Volume data are reformatted to display standardized multiplanar views of the fetal spine.
- Three-dimensional reconstruction of the fetal spine (with maximum-intensity projection filter) visualizes the ossified spinal elements.
- To determine spinal level, the 12th thoracic (T12) is taken to be the most caudal vertebra with a corresponding rib.



A

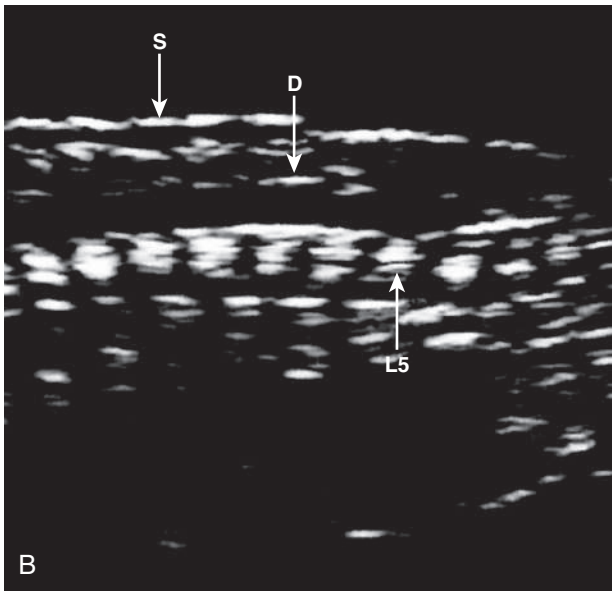


FIG. 35.10 Posterior Longitudinal Scan Plane. (A) Diagram shows the incident sound beam *(arrows)* reflecting off the posterior surface of the **centrum.** If there is no ossification in the laminae near the midline, the laminae will not be visible on the scan; only the centra will be seen. If the laminar ossification is present near the midline, the centra and laminae will be seen as echogenic foci. The red structures are ossified portions of the vertebra. **(B)** Posterior longitudinal scan of the lumbosacral spine at 15 weeks shows **ossification in the centra** of the lower thoracic, lumbar, and sacral spine (*L5,* centrum of vertebra). In this midline scan, no ossification is present posterior to the posterior surface of the dural sac *(D). S,* Skin surface.

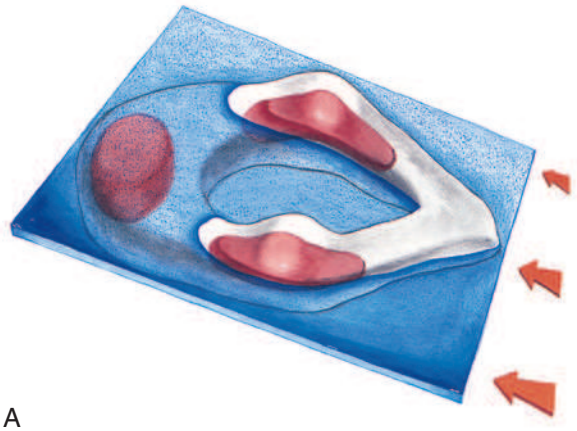

A

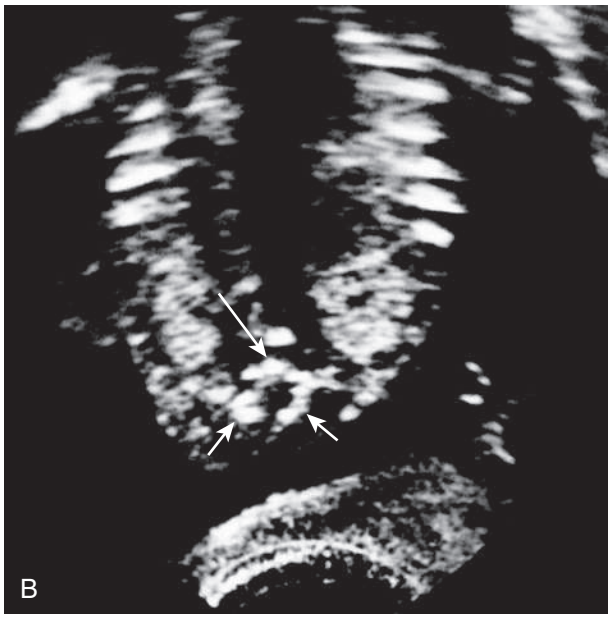

FIG. 35.11 Posterior Angled Transaxial (Transverse) Scan Plane. (A) Diagram shows the incident sound beam *(arrows)* reflecting off the posterior aspects of the **laminae** and portions of the **pedicles.** The beam may also reflect off the ossified centrum. This scan plane can depict the **entire ring of ossification** of the spinal canal. The red structures are ossified portions of the vertebra. **(B)** Endovaginal scan at 18 weeks in the midlumbar spine outlines the curvilinear structure of each neural arch (*short arrows,* lamina plus pedicle) and the ossified centrum *(long arrow).* Together these structures form the **ossified ring of the spinal canal.**

Folic Acid Fortification

Another major factor in the decline of the incidence of NTDs is the use of folic acid to prevent NTDs. Several clinical trials have demonstrated a decreased risk of NTDs by at least 60% with the maternal use of periconceptual folic acid supplements.[39-43] The reduction occurs in mothers with previously affected pregnancies and in mothers without this risk. In 1992 the U.S. Department of Health and Human Services[44] and the Expert Advisory Group in the United Kingdom[45] recommended supplementation of 0.4 mg of folic acid for women in the general population trying to conceive. Women who are at high risk because of a previously affected fetus should take 4 mg of folic acid daily.[1] Routine folic acid supplementation around the time of conception confers a 72% to 87% decrease in probability of NTDs.[3,40] However, this knowledge and these recommendations have not translated into a reduction of the incidence of NTDs in the general population,[46,47] largely because only a minority take folic acid routinely in the reproductive years, and in those who do, supplementation may not be taken at the proper time. Studies in the 1990s demonstrated that less than 45% of pregnant women took folic acid before conception.[48-50] In 2007, 40% of all U.S. women of reproductive age (15-45 years) took daily supplements of folic acid. Daily supplements could be one serving of breakfast cereal fortified with 100% of the recommended daily value of folic acid or a supplement with 0.4 mg of folic acid daily.[4]

Another strategy to increase folic acid levels is the systematic fortification of food stuffs with folic acid. In March 1996 the

TABLE 35.3 Definition of Terms for Spinal Abnormalities

Term	Definition	Comment
Spinal dysraphism (neural tube defect)	Failure of part of neural tube to close.	This disrupts both differentiation of central nervous system and induction of vertebral arches.
Spina bifida	Defect in posterior midline neural arch.	Arches fail to fuse along dorsal midline and fail to enclose vertebral canal.
Spina bifida occulta	Vertebral arches of a single vertebra fail to fuse.	Underlying neural tube differentiates normally; does not protrude from vertebral canal.
Meningocele	Dura and arachnoid protrude from vertebral canal through spina bifida defect in posterior midline neural arches.	
Myelomeningocele	Dura, arachnoid, and neural tissue protrude from vertebral canal through spina bifida defect in posterior midline neural arches.	
Rachischisis (e.g., myeloschisis)	Neural folds corresponding to future spinal cord fail to fuse and fail to differentiate (myeloschisis), invaginate, and separate from surface ectoderm.	The deformed underdeveloped spinal cord is exposed dorsally. This is the most severe form of spinal neural tube defect.
Cranioschisis (e.g., exencephaly, anencephaly)	Neural folds corresponding to future brain fail to fuse and fail to differentiate, invaginate (exencephaly, anencephaly), and separate from surface ectoderm.	The brain is represented by an exposed dorsal mass of undifferentiated neural tissue.
Inionschisis	Failure of neural tube to differentiate properly and close in occipital and upper spinal region.	

U.S. Food and Drug Administration ordered that fortification with folate of all enriched grain products be started no later than January 1, 1998 (0.14 mg per 100 g of grain). Honein et al.[51] demonstrated a 19% reduction in NTDs in the United States as an effect of folic acid fortification of grains. This study did not take into account the large percentage of NTDs that are prenatally diagnosed and electively terminated. A study in Nova Scotia demonstrated a decrease of annual incidence of NTDs by 54% after implementation of folic acid fortification, from 2.58 in 1000 births from 1991 to 1997 to 1.17 in 1000 births from 1998 to 2000.[52] This study included terminated pregnancies, which is important because more than 50% of all pregnancies affected with NTDs in Nova Scotia resulted in elective termination. A failure to include these terminated pregnancies may underestimate the benefit of folic acid–fortified grains. In Canada, folic acid fortification of grain products was legislated to begin in November 1998, at levels similar to U.S. levels. Since then in Canada, the prevalence of NTDs nationally has decreased from 1.58 in 1000 births before fortification to 0.86 in 1000 births during the full-fortification period, a 46% reduction.[7] Geographic differences almost disappeared after fortification began. The observed reduction rate was greater for spina bifida (53%) than for anencephaly and encephalocele (38% and 31%, respectively).

Lipomyelomeningocele (LMMC) is a type of NTD similar to myelomeningocele, with a prevalence of about 0.5 in 10,000 births. Studies in Hawaii and Canada have shown that LMMC rates are not affected by folic acid fortification, unlike the significant rate reduction in myelomeningoceles. LMMC seems to be pathogenetically distinct from myelomengocele.[53,54]

The risk of NTD rises to 20 to 30 per 1000 live births for women with a previous infant with an NTD. This constitutes about a 10-fold increase in risk over the general population.[55] A meta-analysis of randomized trials of folic acid for the prevention of recurrent NTDs demonstrated an 87% reduction in NTDs in women who took supplements before the start of pregnancy.[3] Other factors that increase the risk of NTD include anticonvulsant therapy with valproic acid or carbamazepine (10-20:1000), warfarin and vitamin A use, pregestational diabetes, obesity, parent with spina bifida (11:1000), and sibling of fetus with multiple vertebral defects and scoliosis (15-30:1000).[56] Low maternal vitamin B12 status may also be a risk factor for NTDs. In Ontario, Ray et al.[57] demonstrated a tripling of the risk for NTD in the presence of low maternal B12 status, as measured by serum holotranscobalamin at 15 to 20 weeks' gestation.

Risk Factors for Neural Tube Defect (NTD)

- Folic acid deficiency
- Previous sibling with NTD
- Maternal anticonvulsants
  - Valproic acid
  - Carbamazepine
- Maternal warfarin
- Maternal vitamin A
- Pregestational diabetes
- Obesity
- Parent with spina bifida
- Low maternal vitamin B12

Pathogenesis and Pathology

Most cases of spina bifida result from failure of closure of the embryologic neural tube, although some may be caused by rupture of the neural tube after primary closure. Most NTDs occur as isolated malformations in chromosomally normal individuals, although 9% to 17% of fetuses with spina bifida have chromosomal abnormalities (mostly trisomy 18 and trisomy 13).[58,59] Typically, chromosomally abnormal fetuses have other abnormalities detected by sonography in addition to the spinal abnormality. Some NTDs are part of a genetic condition. Autosomal dominant conditions include **Lehman syndrome.** Autosomal recessive conditions include **Meckel-Gruber syndrome** and **VATER syndrome** (vertebral defect, imperforate anus, tracheoesophageal fistula, radial and renal dysplasia). Two X-linked conditions are the **Mathias laterality sequence** and **X-linked neural tube defects.**[2]

A number of studies have found the incidence of NTD to be about 10 times higher in spontaneously aborted pregnancies than in term births, indicating an in utero selection against embryos with such defects.[60]

In the most severe form of NTD, the embryologic neural tube (the precursor to the spinal cord) remains open in addition to the overlying mesodermal structures, which include the neural arch, muscles, and skin. The resultant pathology is **myeloschisis;** the open, flattened spinal cord is exposed posteriorly through a wide defect in the posterior neural arch and associated musculature and skin.

In less severe cases of NTD, the major anatomic defect is in the structures derived from the mesodermal tissues overlying the embryologic neural tube. Although the spinal cord often is anatomically intact, the embryologic neural tube has failed to induce closure of the overlying neural arches, muscles, and skin. The result is a **myelomeningocele,** a cystic mass protruding from the spinal canal. The cystic mass wall is composed of thin arachnoid membrane without skin covering, and the contents are cerebrospinal fluid and neural elements. Occasionally, a myelomeningocele is covered with skin. A skin-covered myelomeningocele is considered a **closed defect,** and a myelomeningocele without skin covering is considered an **open defect.** An open defect allows AFP to escape into the surrounding amniotic fluid; a closed defect does not. Thus a closed or skin-covered defect is not usually associated with raised levels of AFP in the amniotic fluid or maternal serum. Infrequently, the protruding cystic mass contains only cerebrospinal fluid and no neural elements, a **meningocele.**

Spina bifida occulta is restricted to involvement of the mesoderm of the posterior vertebral arch and rarely exhibits intrinsic maldevelopment of the spinal cord. This may result from an insult occurring at the end of the fourth embryologic week (sixth menstrual week), causing failure of complete formation of the posterior midline structures. The prevalence of spina bifida occulta, excluding cases that later disappear (i.e., delayed ossification of preexisting intact cartilage), is approximately 17%.[61] The lumbosacral spine is most often involved. About 66% of spina bifida occulta cases have skin manifestations: nevi, lumbosacral lipomas, dermal sinus, hypertrichosis (tuft of hair, "horse's tail or fawn's tail"), or scarred area. A sacral pit or dimple is not highly correlated with spina bifida occulta. Although infrequently associated with other abnormalities, spina bifida occulta may be associated with urologic dysfunction and tethered cord syndrome, foot deformity, increased incidence of spondylolisthesis, and intervertebral disc herniation. Spina bifida occulta is difficult to detect with prenatal ultrasound unless it is associated with a **lipoma,** a simple **meningocele,** or **tethered cord.** A history of familial spina bifida occulta is not known to be a risk factor for an open NTD.[2]

Alpha-Fetoprotein and Ultrasound Screening

Because most NTDs occur in families with no history of such abnormalities, prenatal detection relies on routine screening measures, including ultrasound and MS-AFP measurement.

Alpha-fetoprotein is a glycoprotein (molecular weight 70,000) produced by fetal liver. Some of it enters the amniotic fluid through fetal urine, and a small amount crosses the placenta to maternal serum. Normal AFP levels in amniotic fluid and maternal serum vary with gestational age. MS-AFP and amniotic fluid AFP are elevated in NTDs that are not skin covered. If the upper limit of normal MS-AFP is taken to be 2.5 multiples of the median (MOM) for a given gestational age, MS-AFP will be elevated in approximately 90% of open NTDs. About 2% of normal pregnancies have an elevated MS-AFP; that is, of all the elevated test results for MS-AFP, most fetuses will be normal (Fig. 35.12). At this stage, a detailed ultrasound examination is required to determine which fetuses actually have an NTD.

Causes of Elevated Maternal Serum Alpha-Fetoprotein

- Multifetal pregnancy
- Fetal death
- Fetomaternal transfusion
- Omphalocele and gastroschisis
- Congenital nephrosis
- Esophageal or duodenal atresia
- Polycystic kidney disease
- Renal agenesis
- Urinary obstruction
- Epidermolysis bullosa
- Sacrococcygeal teratoma
- Cystic hygroma
- Osteogenesis imperfect
- Cloacal exstrophy
- Cyclopia
- Normal (2% of pregnancies)

Norem at al.[62] found that MS-AFP testing was normal in 25% of NTDs (25 of 102 cases). These included 15 of the 40 (38%) spina bifida cases screened, 6 of the 9 (67%) encephalocele cases screened, and 4 of the 53 (8%) anencephaly cases screened. Of the 186 NTD cases diagnosed prenatally, 115 (62%) were initially

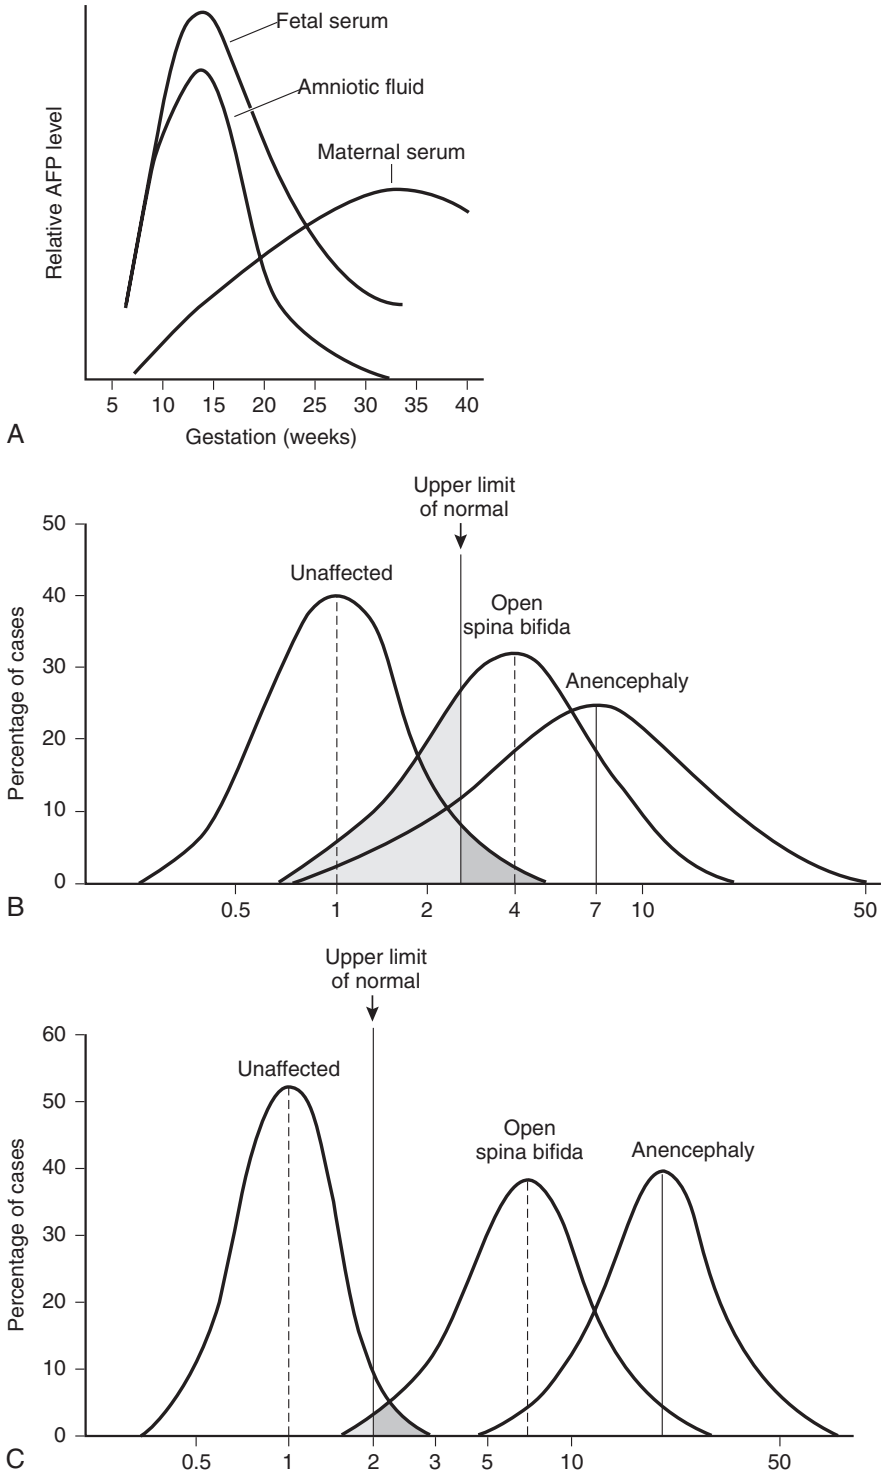

FIG. 35.12 Alpha-Fetoprotein Levels Versus Gestational (Menstrual) Age. (A) Normal alpha-fetoprotein (AFP) levels in fetal serum, amniotic fluid, and maternal serum (MS) vary with gestational age. It is imperative to have accurate dating to evaluate AFP results properly. **(B)** MS-AFP at 16 to 18 weeks' gestation. (Percentage of cases vs. AFP levels, expressed as multiples of the median [MOM] along horizontal axis.) There is considerable overlap in the values of MS-AFP between normal pregnancies and those with fetuses affected with open spina bifida and anencephaly. This illustration demonstrates the overlap (*shaded areas* under the curves) when 2.5 MOM are taken to be upper normal. A cutoff of 2.0 MOM would detect more affected pregnancies but increase the rate of false positives and possible amniocentesis in normal pregnancies. *Lighter-shaded area,* False negatives (i.e., test negative, but NTD present); *darker-shaded area,* false positives (i.e., test positive, but fetus normal). **(C)** Amniotic fluid AFP at 16 to 18 weeks' gestation. (Percentage of cases vs. AFP levels, expressed as MOM along horizontal axis.) There is significantly less overlap between normal pregnancies and pregnancies with open NTDs. The shaded area under the curves to the left of 2 represents the false negatives, and the shaded area to the right of 2 represents the false positives. In practice, the false positives can be largely excluded by normal acetylcholinesterase levels in the amniotic fluid.

detected by routine sonography during the second trimester without knowledge of MS-AFP values. Sixty-nine (37%) were diagnosed by targeted sonography after MS-AFP screening indicated a higher risk for NTD. Two (1%) were diagnosed by pathology examination after miscarriage.

MS-AFP is also elevated in **multifetal pregnancy, fetal death, fetomaternal transfusion,** and in other fetal anomalies associated with a defect in the skin, such as **omphalocele** and **gastroschisis** (50%-60% of cases), **congenital nephrosis** (Finnish type, 100% of cases), and infrequently in esophageal or duodenal atresia, polycystic kidney disease, renal agenesis, urinary obstruction, epidermolysis bullosa, sacrococcygeal teratoma, cystic hygroma, osteogenesis imperfecta, cloacal exstrophy, and cyclopia.

Because of the high sensitivity of the cerebellar signs associated with open spina bifida, some centers rely almost exclusively on ultrasound to diagnose NTDs. For women with elevated MS-AFP and no sonographic explanation for the abnormal test result (e.g., wrong dates, multiple fetuses, dead fetus, anencephaly, spina bifida, abdominal wall defect, other fetal abnormality causing elevated AFP), or when there is poor visualization of the spine, **amniocentesis** may be offered. If the amniotic fluid AFP is normal and there is no **acetylcholinesterase** (AChE) present, the likelihood of an open NTD is very low. If the amniotic fluid AFP is elevated and AChE is present, an open NTD or abdominal wall defect may be present but undetected by sonography.

Between 1989 and 1990, 1.1 million women in California had MS-AFP tests in early pregnancy.[63] From these tests, 1390 fetal abnormalities were found (1.3 fetal anomalies per 1000 pregnancies), consisting of 710 NTDs (417 cases of anencephaly, 247 cases of spina bifida, and 46 cases of encephalocele) and 680 nonneural abnormalities (286 anterior abdominal wall defects, 163 cases of trisomy 21, and 231 other chromosomal abnormalities). With the declining use of MS-AFP testing in favor of genetic screening, sonography is increasingly important in screening for NTDs.

Sonographic Findings in the Spine

Spina bifida may occur anywhere in the fetal spine but is most common in the **lumbosacral** area.[64] Ultrasound findings in the spine consist of abnormalities of the ossified posterior elements and related soft tissues.

In spina bifida the **laminae** fail to converge toward midline, and this is best visualized with the posterior transaxial scan plane (Fig. 35.13A and B, Video 35.3). If the **pedicles** are normally positioned and there is no myelomeningocele, the posterior transaxial scan plane is the only view that will depict the abnormality with reliability. When the pedicles are displaced more laterally than usual, the lateral transaxial and lateral longitudinal scan planes will also demonstrate the bony abnormalities of spina bifida (Fig. 35.13C and D). All these scan planes will usually demonstrate the meningocele or myelomeningocele if it is present (Figs. 35.14, 35.15, and 35.16; Videos 35.4 and 35.5). The posterior longitudinal scan best demonstrates a myelomeningocele and the soft tissue defect when no cystic mass is present.

In most cases of spina bifida, there is abnormal divergence or splaying of the pedicles over several vertebral levels. This is best appreciated in 3D images and in lateral longitudinal views, where multiple interpedicular distances can be evaluated simultaneously (see Fig. 35.13). However, there is normally mild divergence of the pedicles in the cervical spine compared with the thoracic spine, and there may be slight divergence (by 1 to 2 mm) in the lumbar spine compared with the thoracic spine in normal fetuses (see Fig. 35.2).

Sonography can also be used to determine the level and extent of the spinal abnormality. The level of the defect is taken to be the top or most cephalic end of the bone malformation.[65] Fetal MRI and fetal ultrasound are equally effective in determining the lesion level in a fetus with myelomeningocele,[66] although each modality may misdiagnose the upper level by two or more segments in 20% of cases. Fetal MRI is more sensitive in evaluation of the spinal cord itself, yielding additional information in about 10% of cases.[67]

The prognosis is influenced by the defect level, the NTD type, the presence or absence of associated anomalies, the presence or absence of chromosomal abnormalities, and the presence or absence of cranial abnormalities, such as Chiari II malformation and ventriculomegaly. Biggio et al.[68] described the outcome in 33 infants with isolated open spina bifida. Lower lesion levels and smaller ventricular size were associated with ambulatory status. All infants with L4-sacral NTD were ambulatory. Of patients with L1-L3 NTD, 50% were ambulatory. No infant with thoracic NTD was ambulatory. No infant with myeloschisis was ambulatory.

Associated Cranial Abnormalities

The biparietal diameter may be less than expected (even when the lateral ventricles are enlarged).[69,70] Four other cranial findings are particularly useful in raising suspicion of an NTD: nonvisualization of the cisterna magna, deformation of the cerebellar shape (banana sign), concave frontal bones (lemon sign), and dilation of the lateral cerebral ventricles.

Chiari II malformation is highly associated with open spina bifida (>97% of cases). This cranial lesion consists of variable degrees of displacement of the cerebellar vermis, fourth ventricle, and medulla oblongata through the foramen magnum into the upper cervical canal and is usually easier to identify than the spinal lesion between 16 and 24 weeks' gestation. In transaxial scans through the posterior fossa, Chiari II malformation is manifest as a deformation of the cerebellar shape (banana sign) and nonvisualization of the cisterna magna. Cranial malformations may signal the sonographer that a detailed study of the spine is required to search for spina bifida.

Anatomic Landmarks Used to Establish Level of Bony Defect

- T12 corresponds to the medial ends of the most caudal ribs.
- L5-S1 lies at the superior margin of the iliac wing.[28]
- S4 is the most caudal vertebral body ossification center in the second trimester.[65]
- S5 is the most caudal vertebral body ossification center in the third trimester.[65]

Thoracic *(T),* lumbar *(L),* and sacral *(S)* vertebrae.

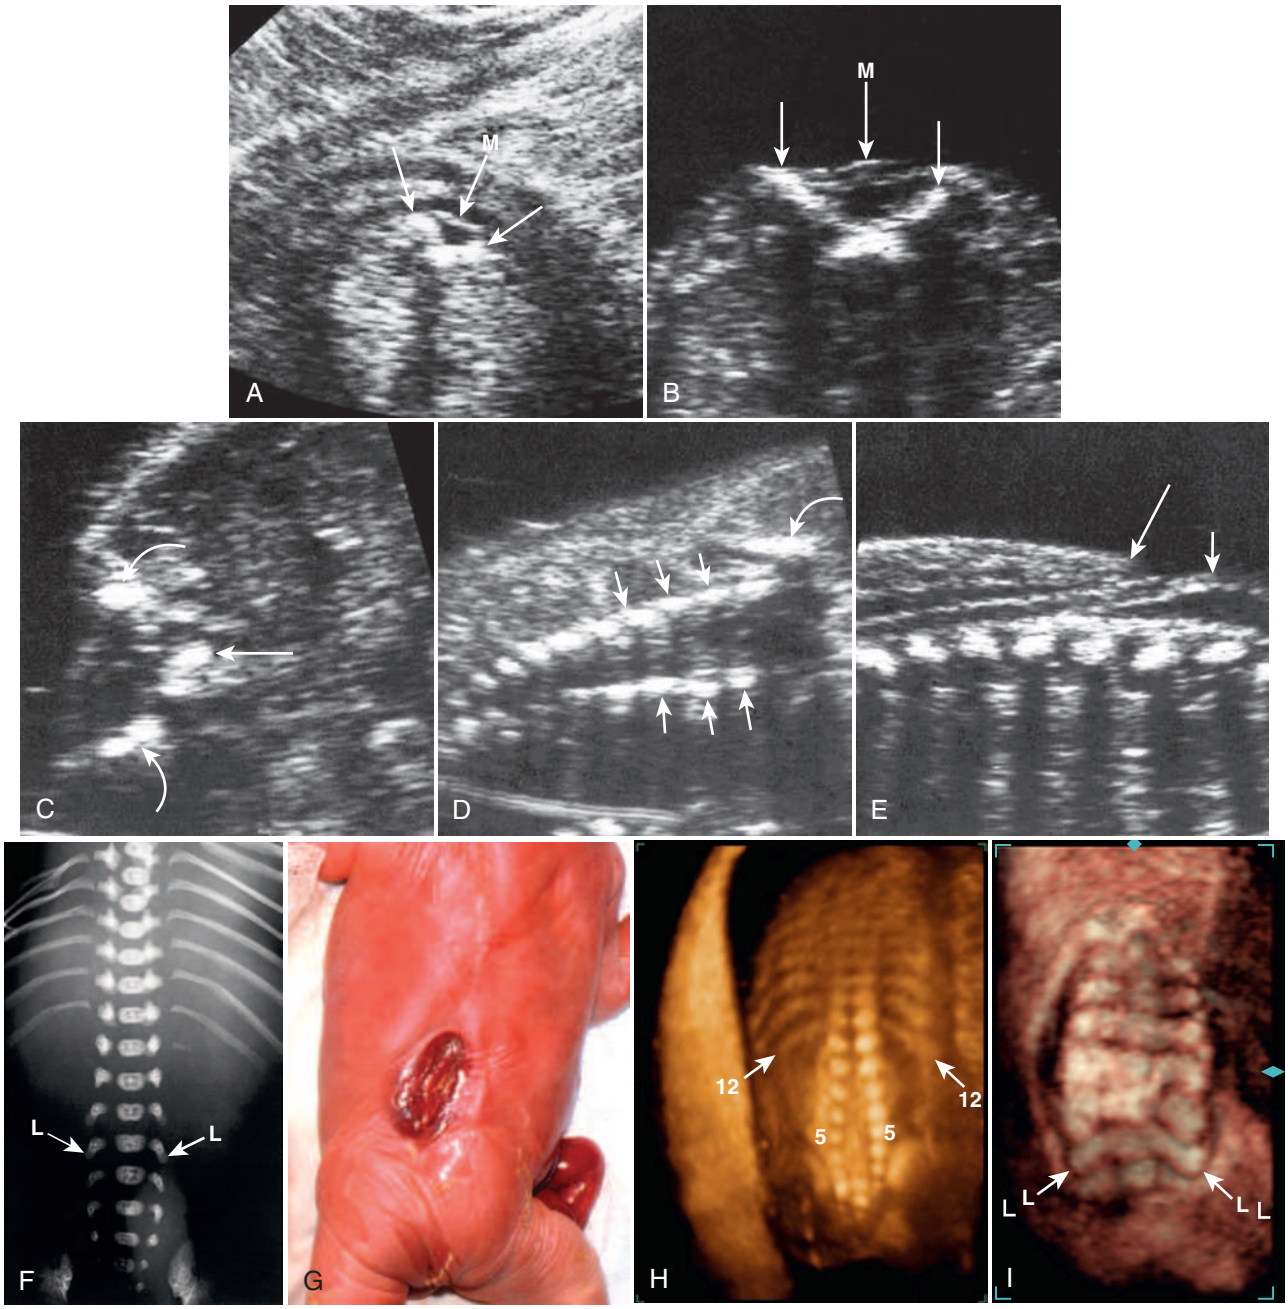

FIG. 35.13 Myeloschisis. (A) Posterior transaxial scan shows splaying of the lumbar laminae *(arrows)* away from midline. Only a thin membrane *(M)* overlies the spinal defect posteriorly. **(B)** Posterior transaxial scan of the specimen after delivery shows in more detail the splaying of the laminae *(arrows)* away from midline and the membrane *(M)* covering the defect. **(C)** Lateral transaxial scan of specimen shows increased distance between the pedicles *(curved arrows)* and mild lateral angulation of the pedicles away from their expected positions (*straight arrow,* ossified centrum). **(D)** Lateral longitudinal scan of specimen shows the progressive enlargement of the interpedicular distances in the lumbar spine, indicative of spina bifida. Ossified pedicles *(straight arrows);* iliac wing *(curved arrow).* **(E)** Posterior longitudinal scan of specimen shows abrupt truncation of the soft tissues of the fetal back *(long arrow)* at the site of the open neural tube defect; *short arrow,* spinal cord. **(F)** Radiograph of specimen shows divergence of the laminae *(L)* away from midline instead of the normal course, which is toward midline. **(G)** Photograph of myeloschisis defect of the thoracolumbar spine shows exposed, disorganized neural tissue within the defect. **(H)** Three-dimensional scan of another fetus at 19 weeks, as viewed from the posterior aspect of the fetus. Note the abnormal divergence of the pedicles in the lumbar spine (*arrows,* 12th rib level; *5,* level L5). **(I)** Three-dimensional scan of a different fetus at 21 weeks, as viewed from the posterior aspect of the fetus. Note the divergence of the lumbar pedicles and the splaying of the laminae *(L)* away from the midline. (**I** courtesy of Siemens Ultrasound.)

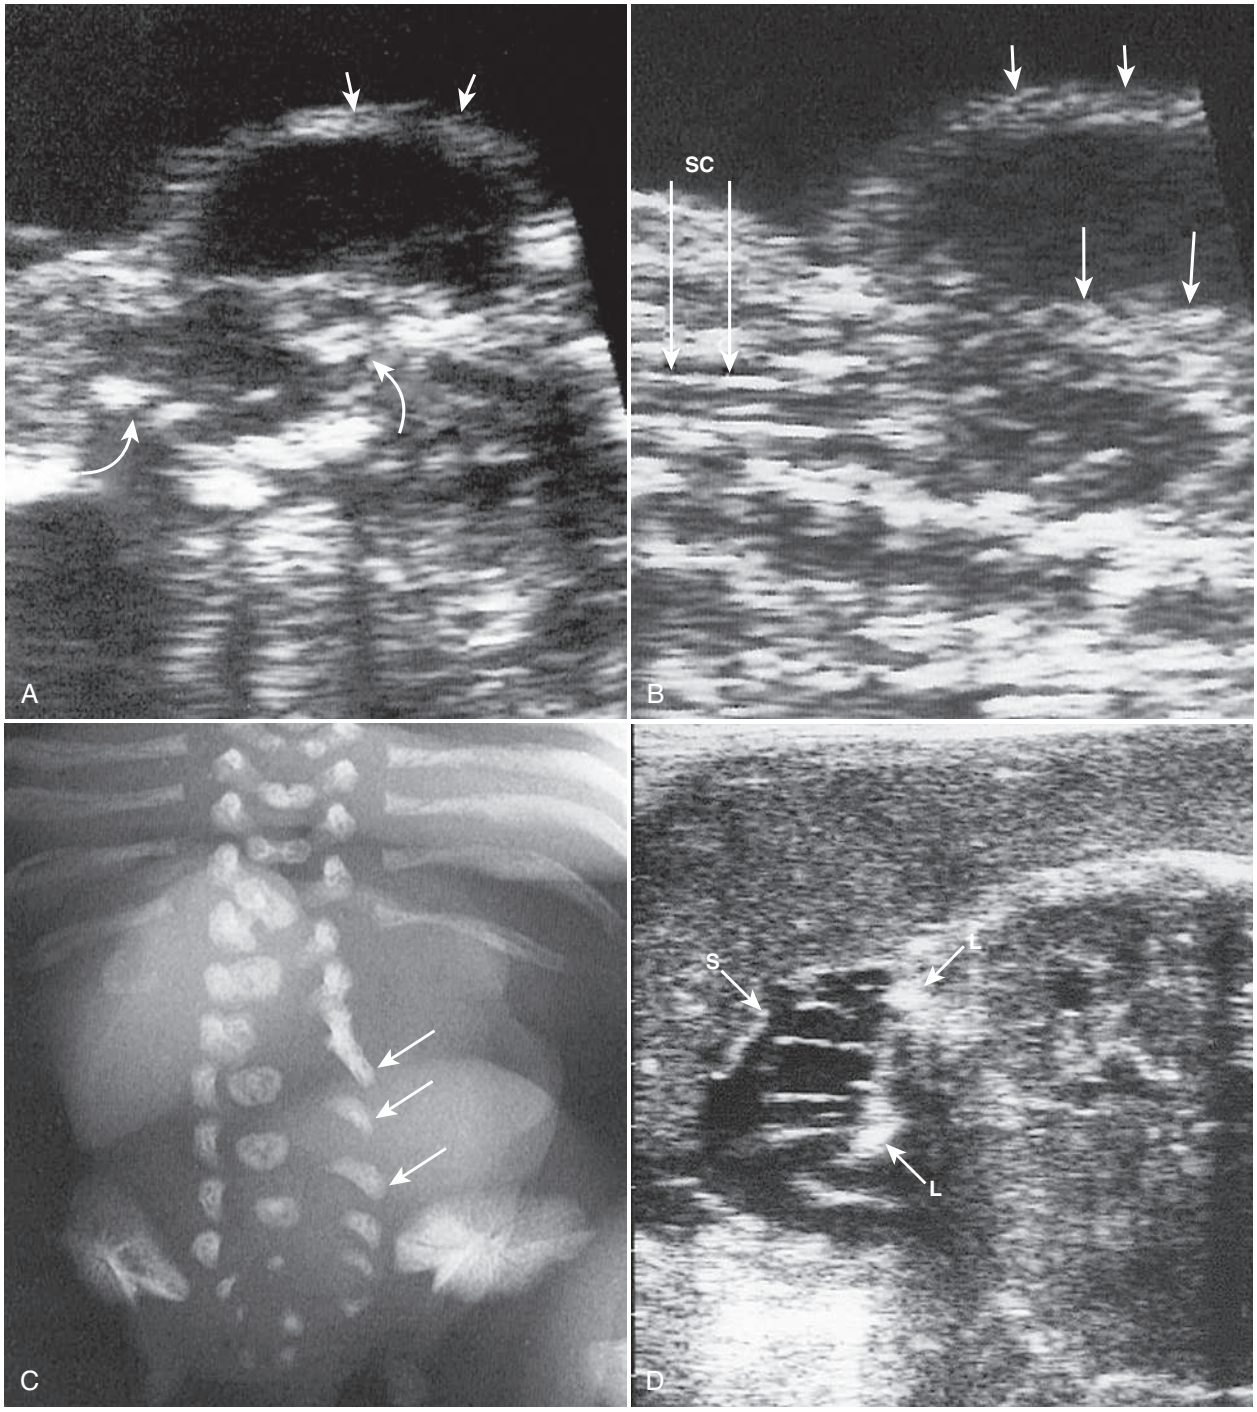

FIG. 35.14 Spina Bifida With Myelomeningocele, 17 Weeks' Gestation Specimen. (A) Posterior transaxial scan of the midlumbar spine shows the splaying of the laminae *(curved arrows)* and the myelomeningocele sac *(short arrows)*. **(B)** Posterior longitudinal scan of the thoracolumbar area shows the myelomeningocele sac *(short arrows)* and disorganized neural tissue *(long arrows)* within it; *SC,* spinal cord. **(C)** Radiograph shows the interpedicular distances in the lumbar spine are widened and the laminae are splayed laterally *(arrows)*. **(D)** Lateral transaxial scan in a different fetus shows the myelomeningocele sac *(S)* containing linear echoes representing neural tissue and the splayed laminae/pedicles complex *(L, arrows)*.

Spinal dysraphism allows a leak of cerebrospinal fluid from the spinal canal into the amniotic fluid, which causes low intracranial pressure early in pregnancy. Low intracranial pressure induces a smaller-than-normal posterior fossa compartment. The cerebellum then grows into this abnormally small space, which leads to obliteration of the cisterna magna, compression of the cerebellar hemispheres, herniation of the cerebellar tonsils into the cervical spinal canal, and related abnormalities such as **ventriculomegaly.** Ventriculomegaly is usually mild in the second trimester and worsens postpartum after repair of the spinal defect. Ventriculomegaly is seen in 44% to 86% of fetuses with spina bifida.[71,72] The most common single cause of ventriculomegaly is

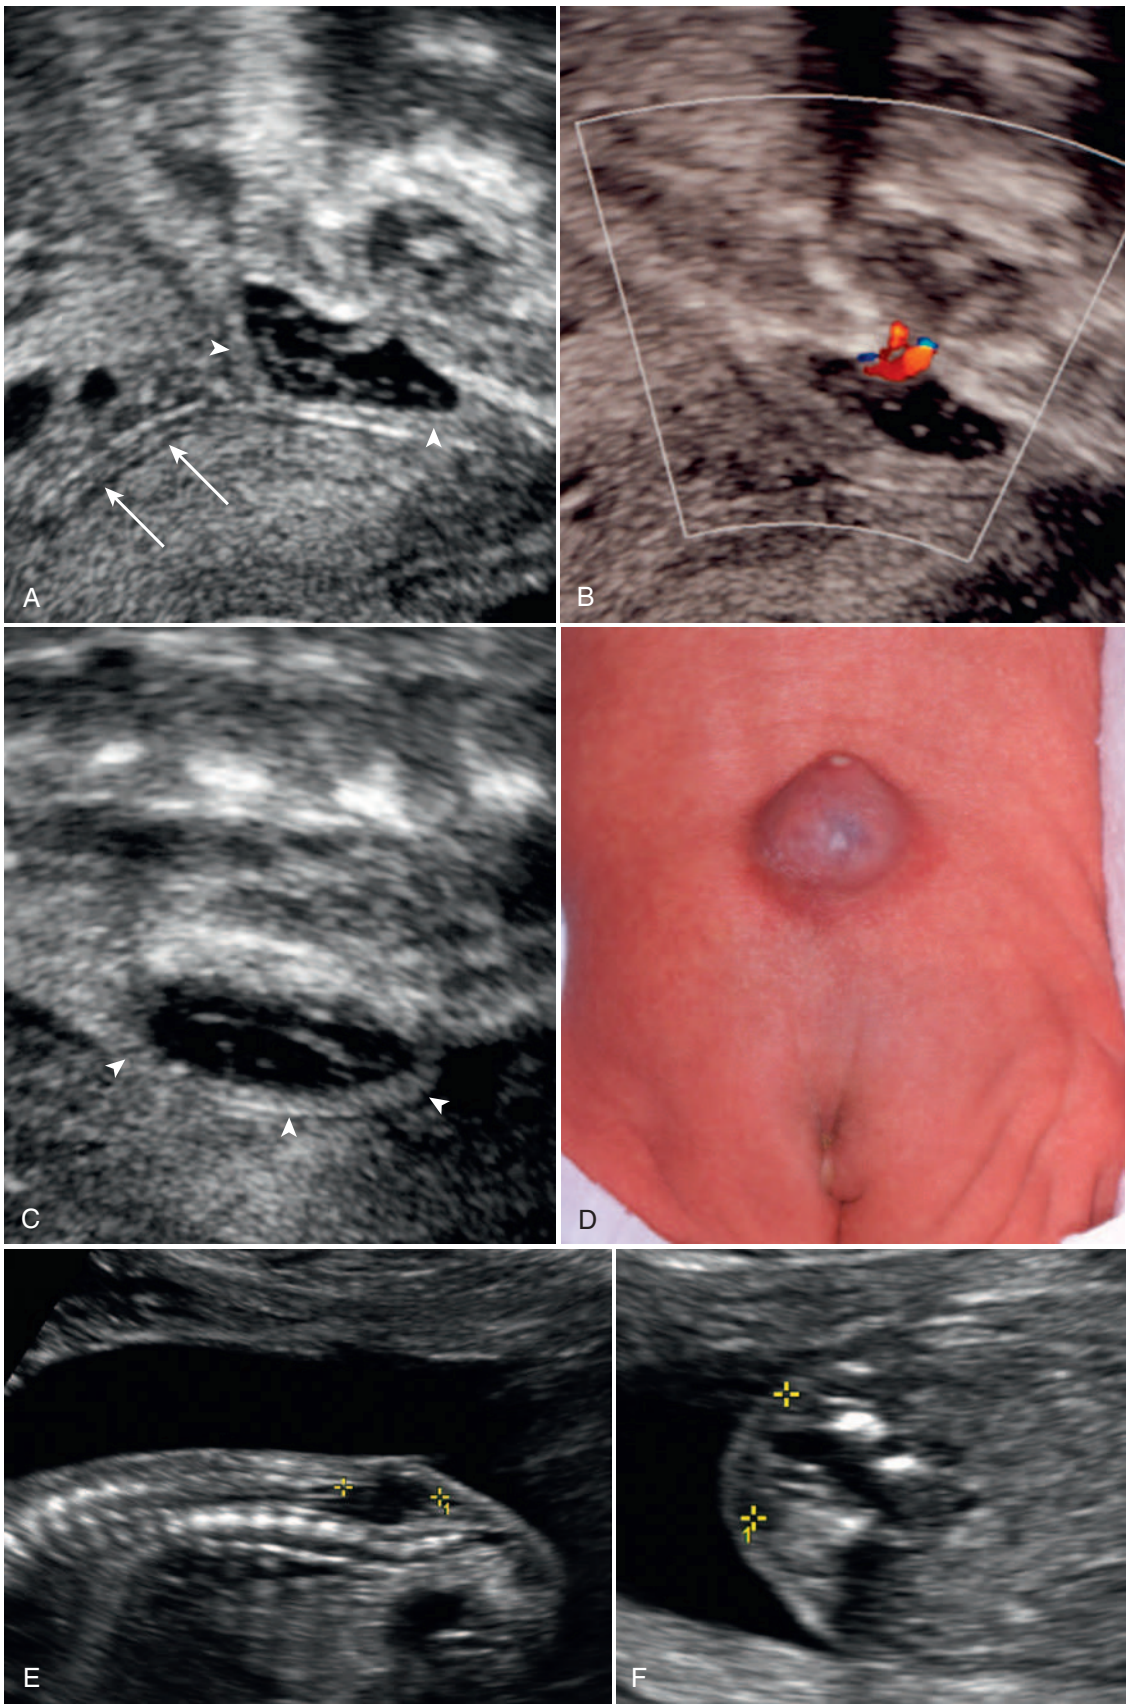

FIG. 35.15 Skin-Covered Myelomeningocele. (A) Endovaginal posterior transaxial scan shows a myelomeningocele sac covered by a thick wall *(arrowheads).* Echogenic material passes through the spina bifida defect into the myelomeningocele sac. Endocervical canal *(arrows).* **(B)** Endovaginal color Doppler posterior transaxial scan demonstrates a blood vessel protruding from the spinal canal into the myelomeningocele sac. **(C)** Endovaginal posterior longitudinal scan shows the myelomeningocele sac covered by a thick wall *(arrowheads).* **(D)** Neonatal picture shows the focal skin-covered lumbar myelomeningocele. The bluish tinge within the sac is a blood vessel detected by endovaginal color Doppler in **B. (E)** and **(F)** Longitudinal and posterior transaxial scans of a different fetus at 19 weeks' gestational age demonstrate a small posterior cyst containing neural elements *(calipers)* covered by skin protruding through the splayed laminae. No intracranial abnormalities were demonstrated.

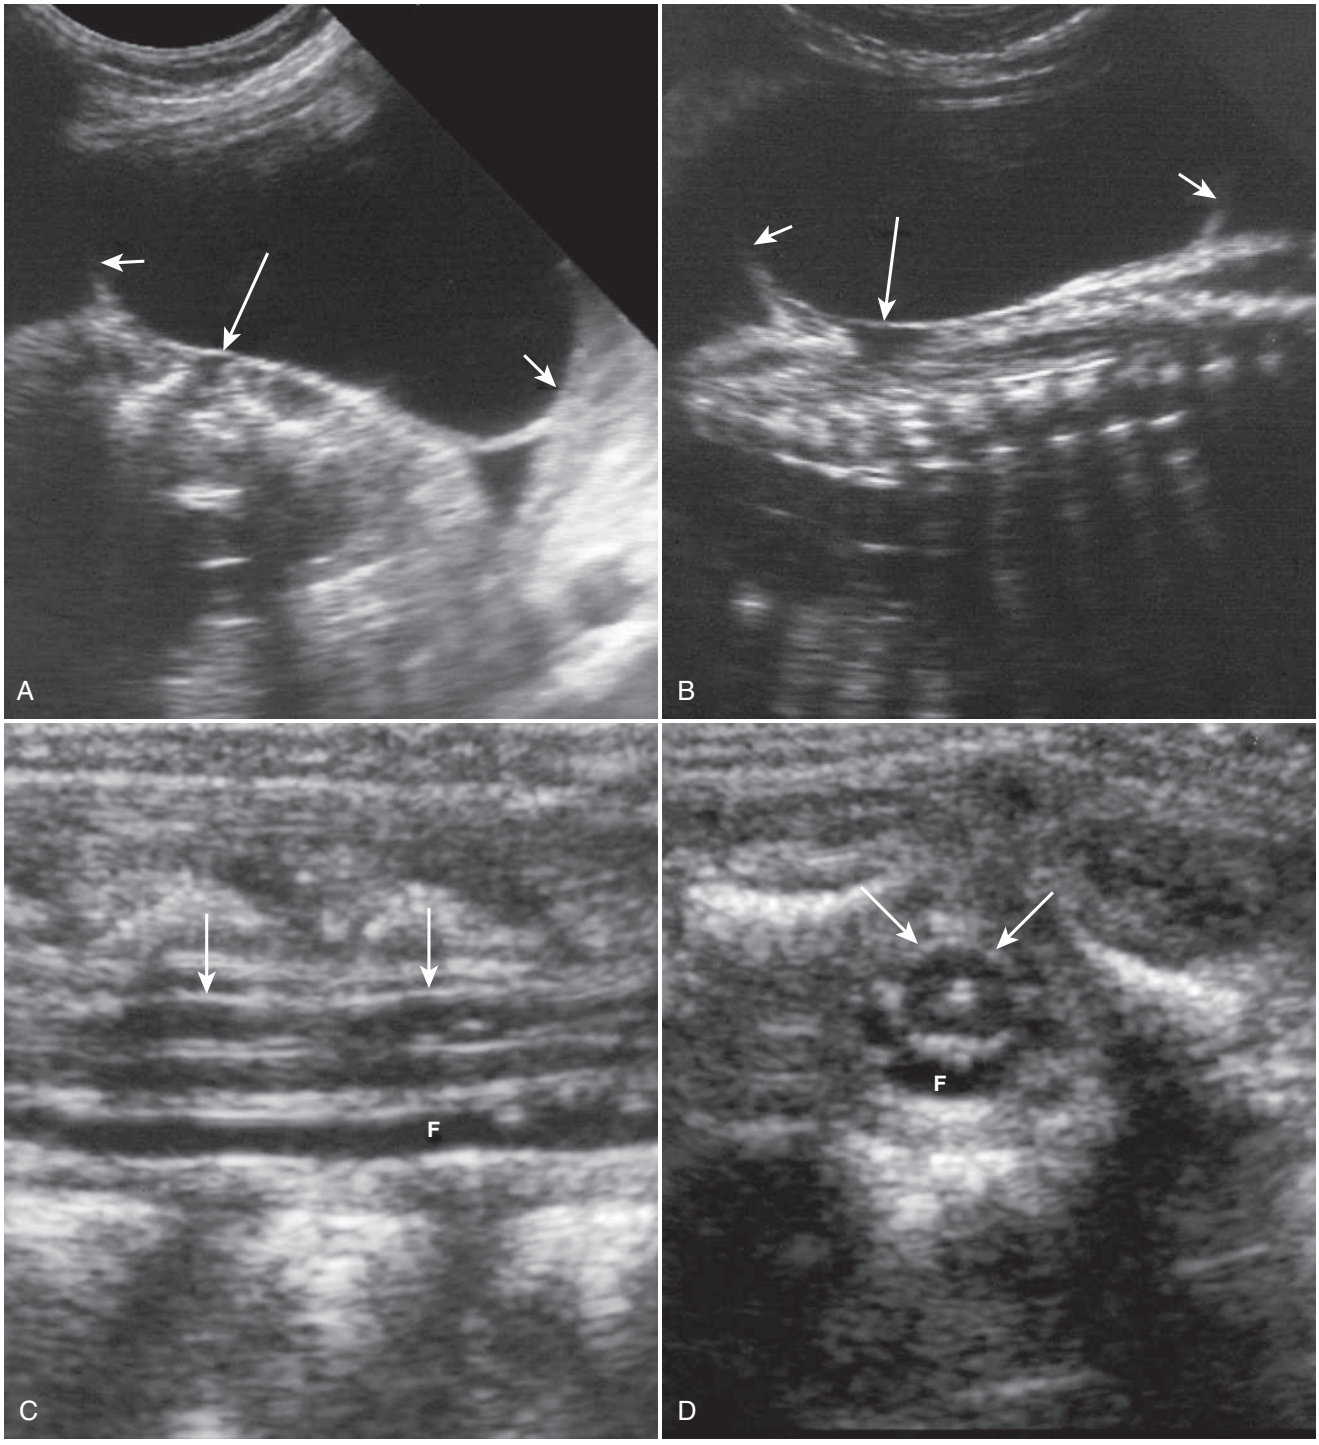

FIG. 35.16 Lumbar Meningocele, 34 Weeks' Gestation. (A) Posterior transaxial sonogram demonstrates a fluid-filled sac *(short arrows)* along the fetal back. There is a small defect in the neural arch *(long arrow)*. **(B)** Posterior longitudinal sonogram shows the wall of the meningocele *(short arrows)* and the focal spina bifida defect in the posterior neural arch *(long arrow)*. **(C)** Posterior longitudinal and **(D)** posterior transaxial sonograms demonstrate abnormally posterior thoracic spinal cord *(arrows)* in the nondependent portion of the spinal canal. Cerebrospinal fluid *(F)* is between the anterior aspect of the spinal cord and the anterior wall of the spinal canal.

spina bifida, although only 30% to 40% of fetuses with enlarged ventricles actually have spina bifida. On ultrasound, the Chiari II malformation manifests as obliteration of the cisterna magna.[73,74] The compression of the cerebellum changes its shape, giving the **banana sign.**[71,75] In two different series, obliteration of the cisterna magna was noted in 22 of 23 cases with spina bifida at 16 to 27 weeks' gestation[74] and in 18 of 20 cases at 24 weeks and earlier.[74]

Concave deformity of the fetal frontal bones in the second trimester is called the **lemon sign.**[76] Various authors have shown that 85% of fetuses with spina bifida before 24 weeks' gestation have the lemon sign.[72,77-79] In practice, the lemon sign can be

difficult to portray unequivocally. The lemon sign spontaneously resolves in the third trimester.[78] In addition, it is seen in 1% of normal fetuses.[77,78] The lemon sign should prompt detailed examination of the posterior fossa, to search for obliteration of the cisterna magna and for the banana sign, and the fetal spine, for direct evidence of spina bifida.

Associated Noncranial Abnormalities

Foot deformities, primarily **clubfoot,** and **dislocation of the hips** are frequently associated with spina bifida.[80] These abnormalities are caused by imbalanced muscular actions resulting from peripheral nerve involvement with the NTD. In fetuses with open spina bifida, 24% demonstrate additional morphologic abnormalities on second-trimester sonography, such as renal abnormalities, **choroid plexus cysts, cardiac ventricular septal defect, omphalocele,** and **intrauterine growth restriction.**[58]

Sonographic Signs of Spina Bifida

Nonvisualization of cisterna magna
Deformation of cerebellum (banana sign)
Concave frontal bones (lemon sign)
Dilation of the lateral ventricles
Chiari II malformation (97%)
Biparietal diameter lower than expected

Prognosis

It is difficult to predict the long-term prognosis in a fetus with an identified myelomeningocele. However, the outcome is better for low lesions (lower lumbar or sacral), closed defects, and those with minimal or no hydrocephalus and no compression of the hindbrain from Chiari II malformation.[55,66,75,81] In more than 880 patients[82] of live deliveries with spina bifida, about 85% survived past age 10, and 2% died in the neonatal period. Of the survivors, about 50% had some type of learning disability. About 25% of survivors had an intelligence quotient (IQ) above 100, with about 75% above 80. About 33% of survivors developed symptoms and signs related to pressure on the hindbrain and brainstem (e.g., pain, weakness, and spasticity in arms), and some required cervical laminectomy to relieve the pressure. Wong and Paulozzi[83] found 5-year survival rates of 82.7% for 1979-1983, 88.5% for 1984-1988, and 91.0% for 1989-1994. Determining prognosis for survival for current newborns is more difficult because of medical and surgical advances since studies describing patients born in the 1960s, 1970s, and 1980s.[2]

Beyond survival, multiple impairments may affect the individual, including **motor dysfunction, bladder and bowel dysfunction,** and **intellectual impairment.**[2] Degree of muscle dysfunction is defined by the highest level of the open NTD, not by the number of involved vertebrae or the size of the overlying sac. When the lesion is thoracic, the **legs** are without muscle function, and when it is upper lumbar (L1-L2), useful leg function is minimal. When the upper level is L3-L5, the prognosis for long-term walking and the need for assistive devices are difficult to predict. Those with sacral defects will usually be able to walk well but with imperfect gait. Almost all people with spina bifida, including those with sacral defects, will have some degree of bowel and bladder dysfunction.

It is very difficult to predict the ultimate level of **intellectual functioning.** In general, those who do not require ventricular shunting have much better outcomes for intellectual functioning. In those requiring shunts, the average IQ is approximately 80, which is low-normal range.[84] The rate of profound intellectual impairment (IQ < 20) in those with shunts is 5%, usually related to medical complications such as shunt infections and Chiari II effects (e.g., apnea, hypoxia).

Fetal Surgery for Myelomeningocele

The first fetal surgery for repair of myelomeningocele was performed in 1997. A formal clinical trial was performed from 2003 to 2010, with early termination of the study due to positive fetal results (decreased hindbrain herniation/need for shunt and improved spinal level of function). However, families and clinicians must evaluate the potential for improved function for the child against the risks of fetal/maternal surgical morbidity, most commonly preterm delivery and uterine dehiscence.[85] Fetal myelomeningocele is a nonlethal entity; in utero surgery for repair of myelomeningocele is potentially lethal.[86]

Although myelomeningocele is a primary embryologic disorder, neurologic damage is also secondary to progressive in utero damage to the exposed spinal cord. The development of techniques to close open NTDs before birth has generated great interest and hope for fetal interventions and outcomes. Prior to the 2003 trial, preliminary observations from two centers suggested that improvements may occur not in spinal cord function as originally postulated[87] but in the extent of the hindbrain herniation and the frequency that shunting is required to control hydrocephalus. In a report of 25 patients who underwent intrauterine myelomeningocele repair at Vanderbilt University, no improvement in leg function resulted from the surgery, but there was a substantially reduced incidence of moderate to severe hindbrain herniation (4% vs. 50%) and a moderate reduction in the incidence of shunt-dependent hydrocephalus (58% vs. 92%).[88] The number of U.S. centers is limited to prevent the uncontrolled proliferation of new centers offering this complex multidisciplinary procedure.[89] Prospective parents electing surgery[90] should weigh the potential benefits against the potential risks.[90-93]

MYELOCYSTOCELE

Myelocystocele is an uncommon form of spinal dysraphism. There is dilation of the central canal of the spinal cord. The central canal herniates posteriorly through the spinal cord and through the posterior neural arch to form an exterior sac. There may be no associated spina bifida lesion.

The sac is composed of three layers, from inner to outer: the **hydromyelia sac,** which is lined by spinal canal ependyma; the **meningeal layer,** which is contiguous with the meninges around the spinal cord; and the **skin.** The fluid within the inner sac is continuous with the fluid of the central canal of the spinal cord; the fluid between the hydromyelia sac and the meningeal layer is continuous with the subarachnoid fluid.

Myelocystocele may occur at any level of the spine and is often associated with Chiari II malformation.[94-96] Prenatal and postnatal sonography demonstrates a "cyst within a cyst" appearance (Fig. 35.17). Splaying of the laminae and pedicles may or may not be present. The prognosis for a myelocystocele is worse than for a simple meningocele; infants with a simple meningocele may remain normal neurologically after surgical repair. The prognosis with myelocystocele is worse because there is usually some degree of associated myelodysplasia (i.e., dysplasia of spinal cord). Although neurologic function is normal in the immediate postoperative period, neurologic deficits often become apparent later in life.

A **terminal myelocystocele** occurs at the spinal cord termination. The central canal of the spinal cord herniates with overlying arachnoid and cerebrospinal fluid through a defect in posterior spinal elements and presents as a skin-covered mass along the posterior aspect of the lumbosacral area. There may be associated maldevelopment of the lower spine, pelvis, genitalia, bowel, bladder, kidneys, and abdominal wall. MRI provides the best imaging evaluation of the morphologic abnormalities after birth.[97-99]

DIASTEMATOMYELIA

Diastematomyelia, also termed **split-cord malformation,** is a partial or complete sagittal cleft in the spinal cord, the distal conus of the cord, or filum terminale. Diastematomyelia is characterized by a sagittal osseous or fibrous septum in the spinal

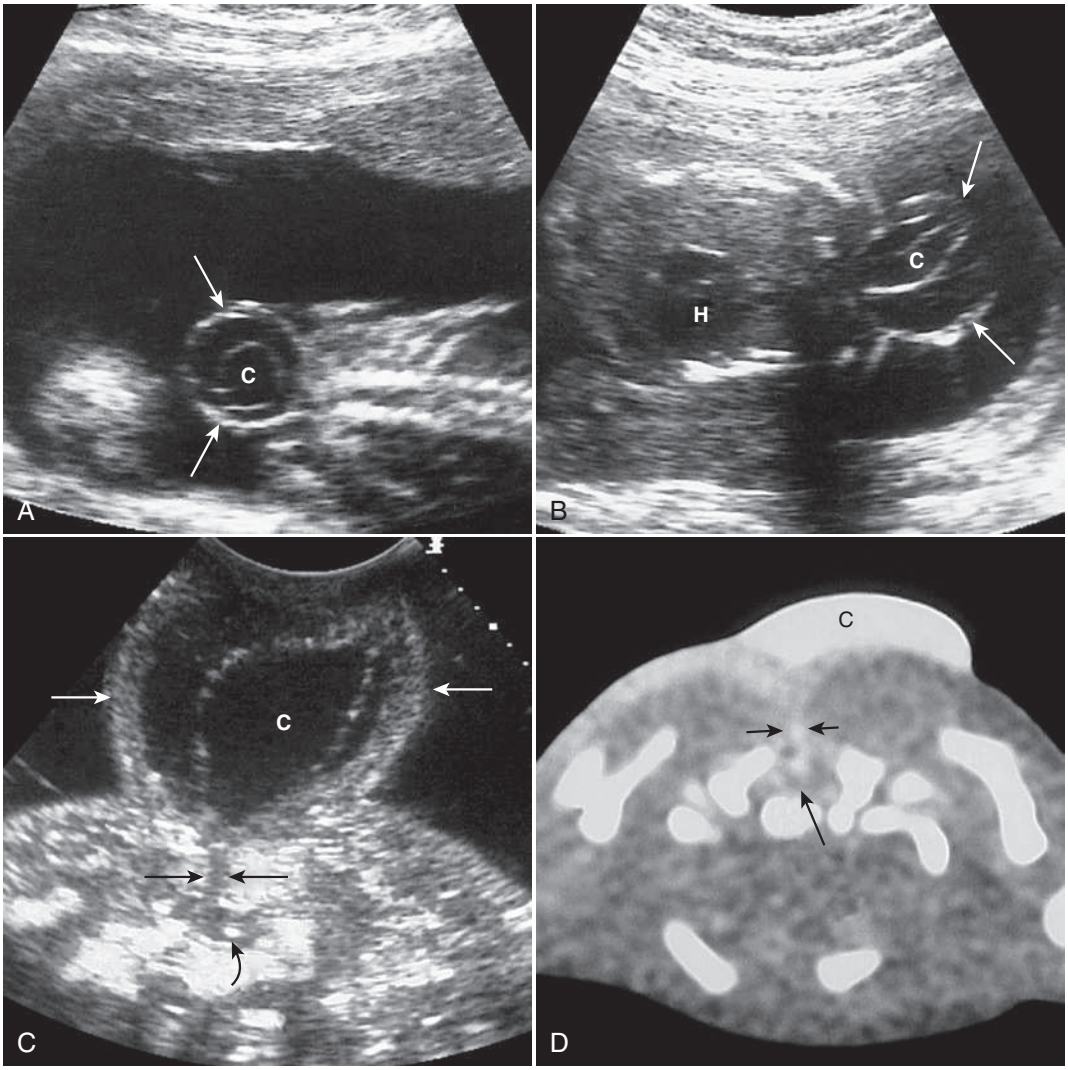

FIG. 35.17 Myelocystocele. (A) Coronal sonogram of thoracic spine at 18 weeks' gestation demonstrates a double-walled cystic mass *(arrows)* with inner cystic component *(C)* arising from the upper thoracic area. **(B)** Axial sonogram of the fetal chest 1 week later demonstrates a double-walled cystic mass *(arrows)* arising along the posterior aspect of the fetal chest; *H,* fetal heart. The inner cystic component *(C)* is slightly smaller and flattened compared to the first scan. No abnormality was noted in the ossified neural arch. **(C)** Sonogram of the specimen demonstrates the double-walled cystic mass *(white arrows)* arising from the posterior thorax with a hypoechoic tract *(black arrows)* extending from the posterior aspect of the spinal cord *(curved arrow)* toward the central cystic component *(C)* of the posterior mass. **(D)** CT scan of the specimen after injection of water-soluble contrast material into the cyst demonstrates contrast within the cyst *(C)* and within a sinus tract *(short arrows),* leading to the spinal cord *(long arrow).*

Continued

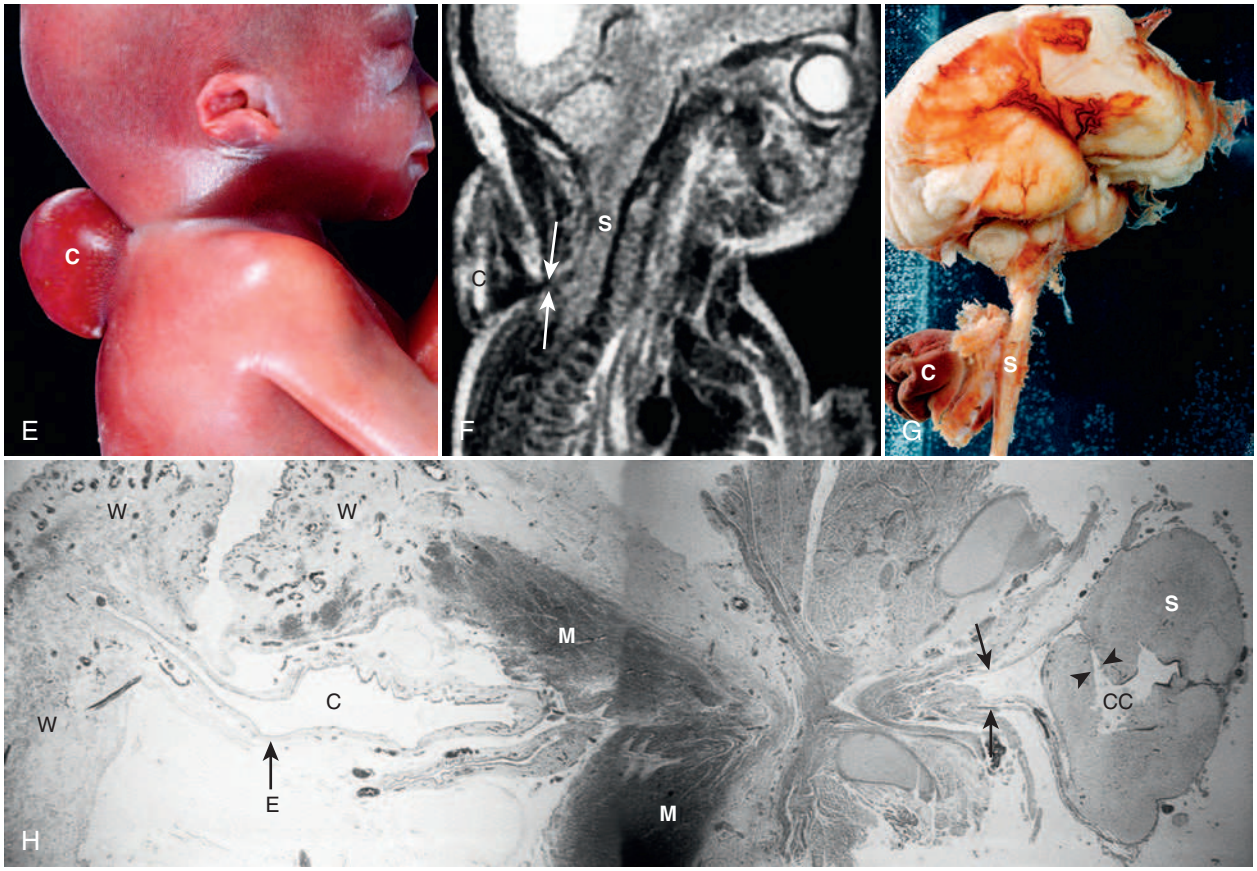

FIG. 35.17, cont'd **(E)** Lateral view of the posterior cystic thoracic mass *(C).* **(F)** Sagittal magnetic resonance scan demonstrates the cystic mass along the upper thoracic area, with the small sinus tract *(arrows)* extending from the posterior aspect of the spinal cord *(S)* toward the cystic mass *(C).* **(G)** Gross pathologic specimen demonstrates the collapsed cyst *(C)* in contiguity with the cervical portion of the spinal cord *(S).* **(H)** Histologic section shows abnormal channel *(arrows)* communicating with the posterior aspect of the spinal cord *(S),* as well as defect in the posterior spinal cord *(arrowheads)* communicating with the central canal *(CC)* of the spinal cord. *C,* Central cystic component of posterior mass *(M); E,* ependymal lining of central cyst, which communicates with central canal of spinal cord; *W,* outer wall of cystic mass.

cord.[100,101] This may be associated with a spina bifida defect and hydromyelia (dilation of central canal of spinal cord) but may occur in the absence of overt spina bifida.[102] Diastematomyelia may also be associated with segmental anomalies of the vertebral bodies or visceral malformations such as horseshoe or ectopic kidney, utero-ovarian malformation, and anorectal malformation. If the spinal canal is traversed by a **bony septum** or **spur,** the septum will appear as an abnormal hyperechoic focus,[103-105] which is best demonstrated in the posterior transaxial and lateral longitudinal scan planes (Fig. 35.18). When diastematomyelia is not associated with other spinal anomalies, the prognosis is favorable. In seven of eight cases reported by Has et al.,[106] the defects had normal amniotic AFP and AChE levels and were considered isolated. Their review of the literature showed 26 cases diagnosed prenatally, 12 of which had no associated abnormality and had a favorable prognosis.

SCOLIOSIS AND KYPHOSIS

Kyphosis is exaggerated curvature of the spine in the sagittal plane. **Scoliosis** is lateral curvature of the spine in the coronal plane. Kyphosis and scoliosis may be positional and nonpathologic or permanent based on an underlying structural abnormality, such as **hemivertebrae, butterfly vertebrae,** and **block vertebrae.** Pathologic kyphosis and scoliosis are often associated with **spina bifida** or **ventral abdominal wall defects.**[107] Less common associations include limb–body wall complex, amniotic band syndrome, arthrogryposis, skeletal dysplasias, VACTERL association (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula, renal agenesis, and limb defects),[108,109] and caudal regression syndrome. Mild scoliosis may be caused by a **hemivertebra** (Fig. 35.19).[106,109]

The posterior longitudinal scan is the best view to assess for kyphosis; the lateral longitudinal plane is the best to assess for scoliosis (Fig. 35.19). Because oligohydramnios can cause positional curvature in the fetal spine, a confident diagnosis of pathologic kyphosis or scoliosis should be made only if the curvature is severe. Possible associated anomalies must then be sought because prognosis depends on the coexistent anomalies.

A **hemivertebra** represents underdevelopment or nondevelopment of one-half of a vertebral body; that is, one of the two early

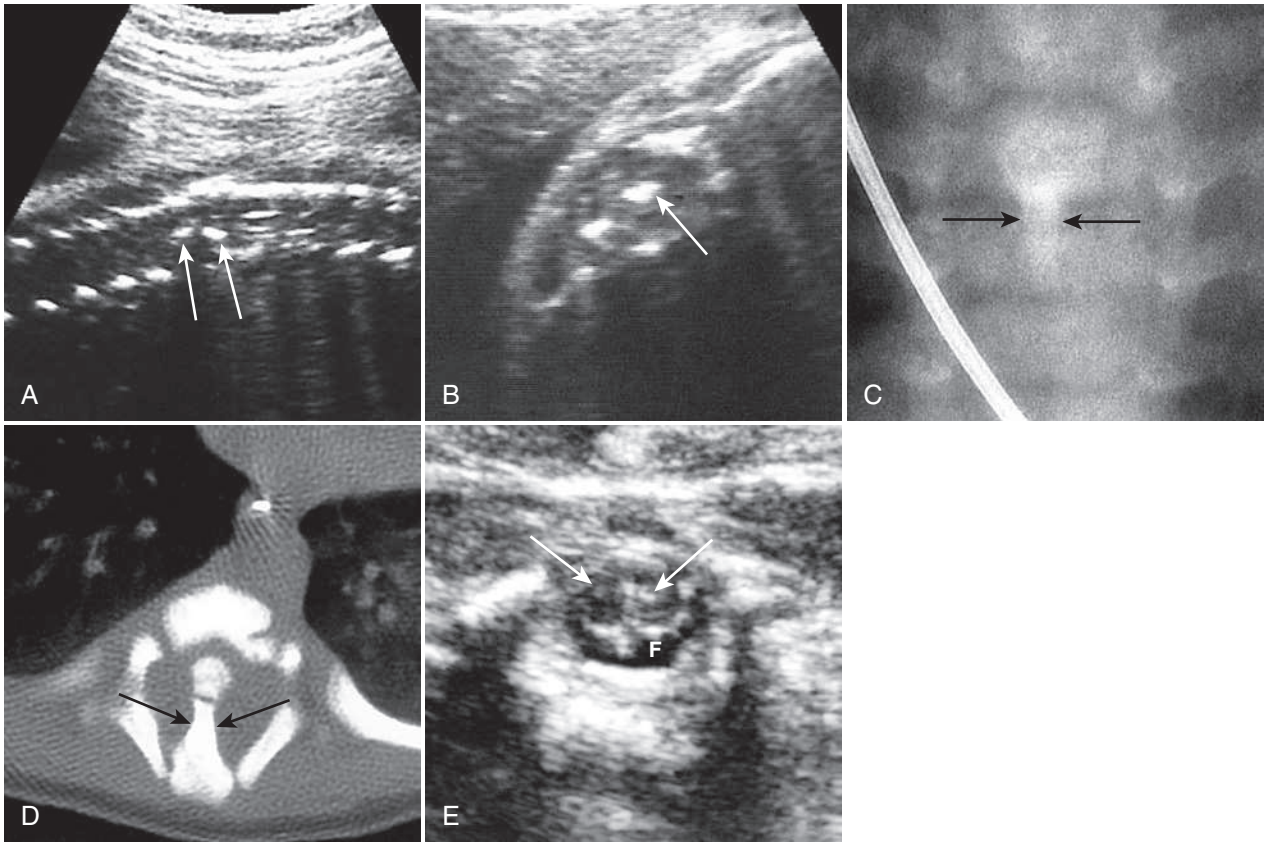

FIG. 35.18 Diastematomyelia. (A) Coronal and **(B)** axial sonograms of the spine demonstrate two hyperechoic foci *(arrows)* caused by the bony septum within the spinal canal with intact skin along the fetal back. **(C)** Anteroposterior radiograph and **(D)** CT scan demonstrate a bony septum *(arrows)* within the central portion of the spinal canal. **(E) Diplomyelia** and **tethered cord.** Posterior transaxial sonogram of another fetus shows cord in the nondependent portion of the spinal canal with fluid *(F)* interposed between the cord and anterior margin of the spinal canal. The anterior aspect of the cord has a bilobed shape instead of a smooth, circular arc with bilateral central canal echoes *(arrows)*.

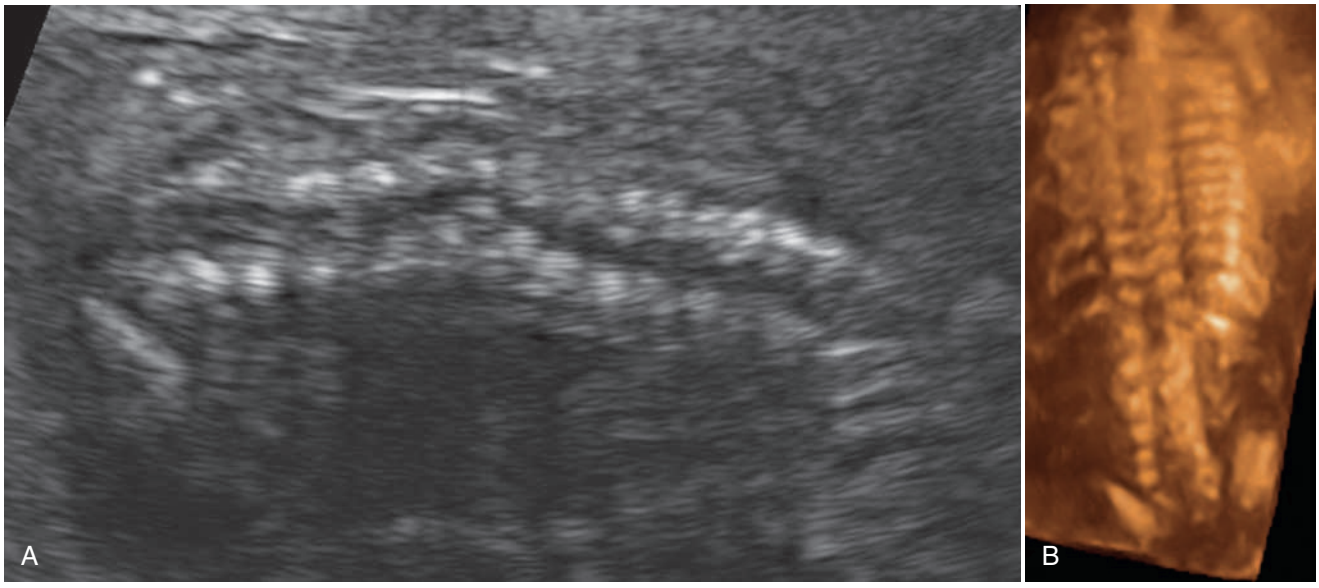

FIG. 35.19 Kyphosis. (A) Sagittal scan of the spine demonstrates a focal kyphosis at the thoracolumbar junction. **(B)** Three-dimensional image of the same patient demonstrates a left upper lumbar hemivertebra as the cause of the kyphosis.

chondrification centers is deficient. The remaining ossification center is displaced laterally with respect to the vertebrae above and below it, leading to a short-segment mild scoliosis. The abnormalities can be detected prenatally and may be best portrayed with 3D ultrasound.[31-34] Fetuses with an isolated hemivertebra have an excellent prognosis, whereas those with other fetal anomalies (e.g., Potter syndrome; cardiac, intestinal, intracranial, and limb anomalies) have a poor prognosis.[110] The presence of associated anomalies reduces the survival rate to approximately 50%. If oligohydramnios is also present, the mortality rate approaches 100%.[111]

Causes of Scoliosis or Kyphosis

Hemivertebrae
Butterfly vertebrae
Block vertebrae
Spina bifida
Ventral abdominal wall defects
Limb–body wall complex
Amniotic band syndrome
Arthrogryposis
Skeletal dysplasias
VACTERL[a] association
Caudal regression syndrome

[a]Vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula, renal agenesis, and limb defects.

SACRAL AGENESIS

Sacral agenesis is an uncommon fetal abnormality that may be present in conditions such as **caudal regression sequence, sirenomelia sequence, cloacal exstrophy sequence,** and the **VACTERL association.** The caudal regression sequence (caudal regression syndrome) and the sirenomelia sequence are thought to be separate pathologic entities.[112,113]

CAUDAL REGRESSION

In caudal regression or dysplasia, abnormalities of the lower spine and limbs occur, including **sacral agenesis, lumbar spine deficiency,** and leg anomalies such as **femoral hypoplasia** (Fig. 35.20). Defects of the neural tube and the genitourinary,

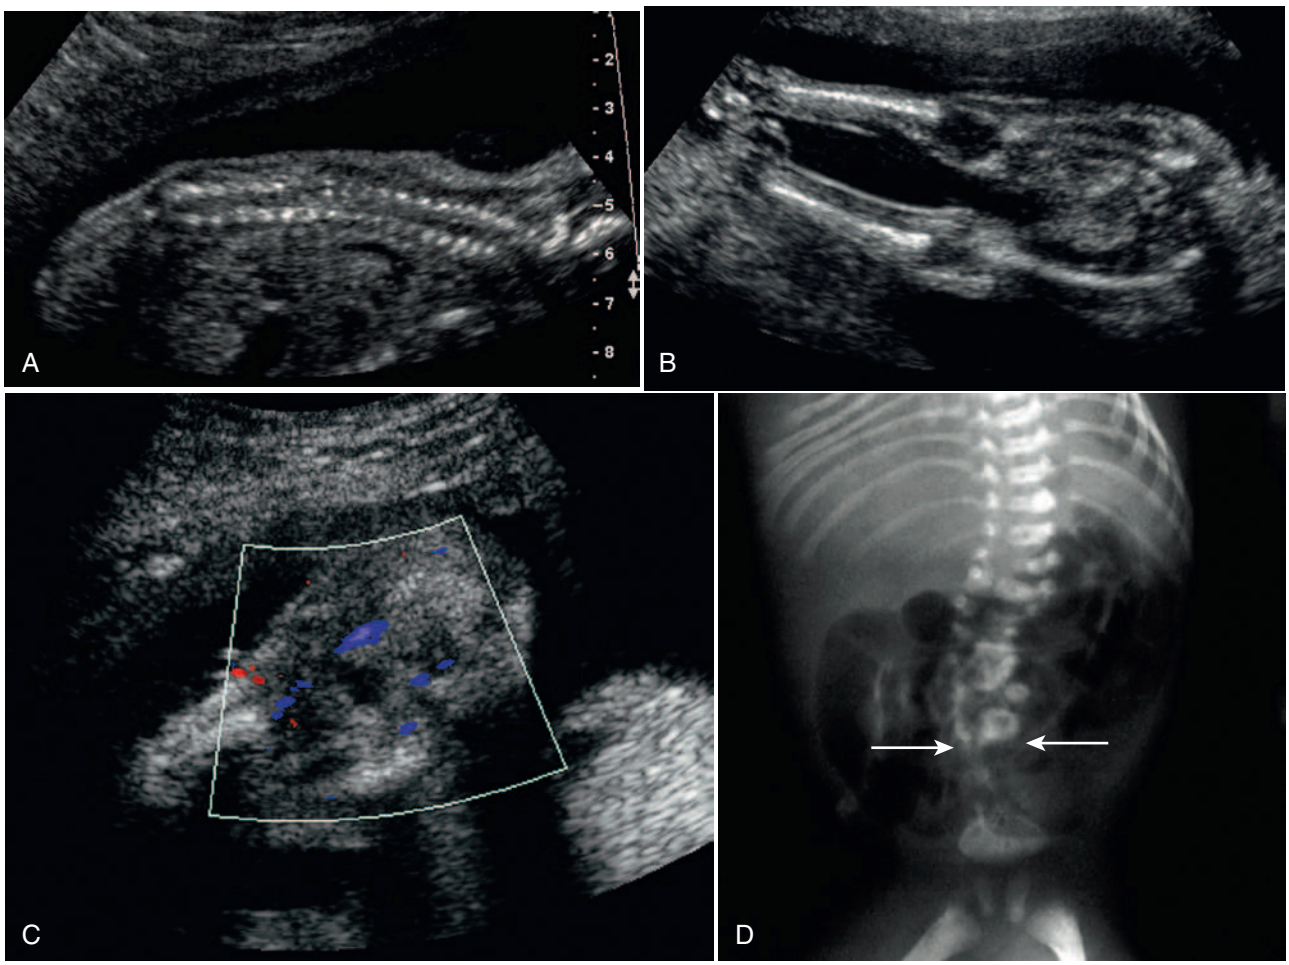

FIG. 35.20 Caudal Regression. (A) Sagittal sonogram of spine at 21 weeks shows abrupt termination of ossified vertebral bodies. **(B)** Transverse view of pelvis with legs in long axis shows lack of ossified pelvic bones and atrophic musculature about the lower extremities. **(C)** Transverse color Doppler image at level of bladder shows lack of ossified pelvic bones. **(D)** In a different fetal specimen, radiograph shows abrupt termination *(arrows)* of the lumbar spine and absence of the sacrum. The pelvic bones are small and deformed.

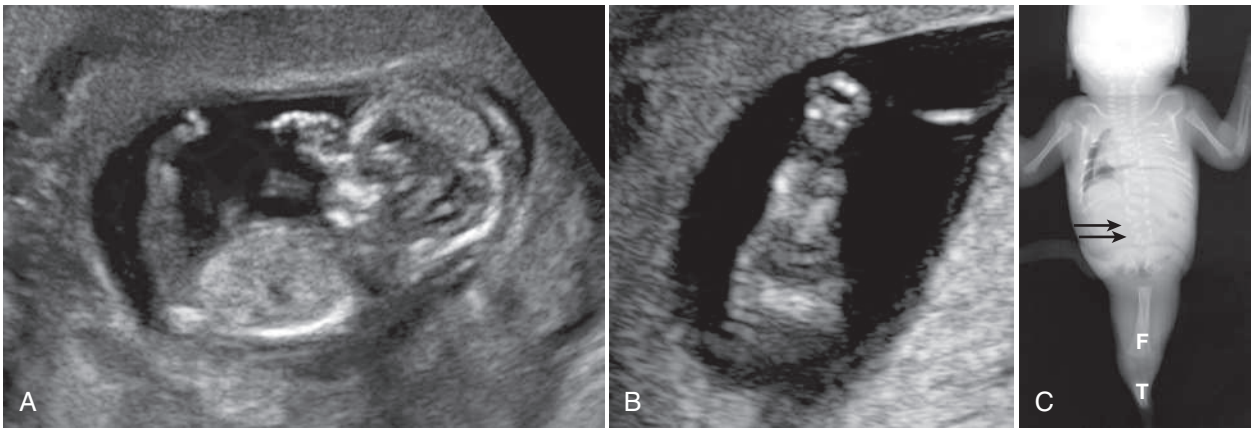

FIG. 35.21 Sirenomelia. (A) Sagittal view of fetus at 12 weeks' gestation shows unusual angulation of lower extremity. **(B)** Long-axis view of a single lower extremity. **(C)** In a different fetus, radiograph shows single femur *(F)* and single tibia *(T)*. Note the segmented defects in the vertebrae of the thoracic and lumbar spine *(arrows)*.

gastrointestinal, and cardiac systems are common. Occurrence is sporadic; caudal regression is more common in infants of mothers with diabetes mellitus. The cause has not been established. Sonography can demonstrate absence of the sacrum and shortened femurs. The legs can be flexed and abducted at the hips, and there may be clubfoot. Sonography may detect associated urinary anomalies (renal agenesis, cystic dysplasia, caliectasis) and gastrointestinal abnormalities (e.g., duodenal atresia).[114] The prognosis depends on the severity and extent of the skeletal abnormalities and associated anomalies. In sacral agenesis with no internal organ involvement, there are usually deficits in the legs and deficient control of bladder and bowel functions. In infants with internal organ involvement, the prognosis is related to these defects.

SIRENOMELIA

Sirenomelia sequence is a rare disorder in which the legs are fused and the feet are deformed or absent[115] (Fig. 35.21). The cause is probably an **aberrant fetal artery** that branches from the upper abdominal aorta and passes into the umbilical cord to the placenta.[116] Arterial blood flow bypasses the lower fetal body. The distal abdominal aorta, the aorta's distal branches, and subtended structures are small and underdeveloped. This leads to malformations of spine, legs, kidneys, gut, and genitalia. Normally the umbilical arteries, which arise from the fetal iliac arteries, carry blood from the fetus into the umbilical cord and then into the placenta.

At sonography, there is advanced **oligohydramnios** because of reduced or absent renal function. The legs are fused, or there is a single leg. The feet are absent, or there may be a single foot. There may be sacral agenesis, deficiency of the lower lumbar spine, and thoracic anomalies. These findings may be difficult to appreciate because of the advanced oligohydramnios or anhydramnios.[112] The prolonged anhydramnios causes pulmonary hypoplasia, which is usually fatal. The risk of recurrence is the same as in the general population.

SACROCOCCYGEAL TERATOMA

Fetal teratomas may arise from the sacrum or coccyx, from other midline structures from the level of the brain to the coccyx, or from the gonads.[117] Sacrococcygeal teratomas arise from the pluripotent cells of Hensen node located anterior to the coccyx. Sacrococcygeal teratomas contain all three germ layers (ectoderm, mesoderm, and endoderm) and thus may contain elements of many tissues, including neural, respiratory, and gastrointestinal. Sacrococcygeal tumor is rare (1:35,000 births)[118] but is the most common tumor among neonates. Females are affected four times more frequently than males. Sacrococcygeal teratomas are classified into four types[118]: **type I,** tumor predominantly external with only minimal presacral involvement; **type II,** tumor presenting externally but with significant intrapelvic extension; **type III,** tumor apparent externally but with predominant pelvic mass and extension into the abdomen; **type IV,** tumor presacral with no external presentation (Fig. 35.22).[117]

Types of Sacrococcygeal Teratomas

Type I (47%): external mass predominant
Type II (34%): external mass with significant internal component
Type III (9%): internal mass predominant, with smaller external component
Type IV (10%): presacral mass only

At birth, 75% of sacrococcygeal teratomas are benign, 12% are immature, and 13% are malignant. Because malignant potential increases with the age of the infant, surgery must be performed shortly after birth.

Sonography usually demonstrates a mass in the rump or buttocks area adjacent to the spine[119] (Video 35.6). Most teratomas (85%) are either solid or mixed (solid and cystic); 15% are mostly cystic, which is a benign sign. Calcifications are frequently present.

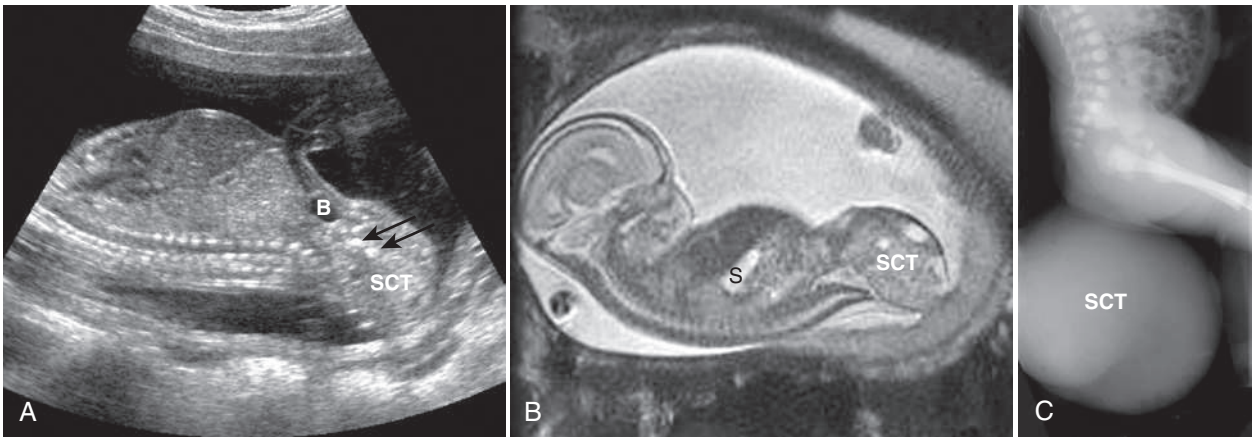

FIG. 35.22 Sacrococcygeal Teratoma. (A) Sagittal sonogram shows type II sacrococcygeal teratoma *(SCT)* that is predominantly external but has a substantial intrapelvic component. The tumor extends up to level L5 and displaces the fetal urinary bladder *(B)* anteriorly. Note the calcifications *(arrows)* within the tumor. **(B)** T2-weighted sagittal magnetic resonance image demonstrates the extent and internal structure of the sacrococcygeal tumor *(SCT); S,* stomach. **(C)** Lateral radiograph in a different neonate. (**A** and **B** courtesy of Drs. Fong, Pantazi, and Toi, Mt. Sinai Hospital, Toronto.)

Large masses may displace and distort neighboring structures, such as the rectum and urinary bladder (see Fig. 35.22). Compression of the distal ureters may cause hydronephrosis. Larger solid tumors may develop substantial **arteriovenous shunting,** causing **fetal cardiac failure** and **hydrops.**[120] The development of hydrops in the presence of a sacrococcygeal teratoma carries a poor prognosis.[120-124]

PRESACRAL FETAL MASS

The differential diagnosis of a presacral fetal mass also includes chordoma, anterior myelomeningocele, neurenteric cyst, neuroblastoma, sarcoma, lipoma, bone tumor, lymphoma, and rectal duplication. Amniotic fluid AFP is often elevated in sacrococcygeal tumor, and AChE is often present in the amniotic fluid. These results exclude most other causes, except a myelomeningocele.

Presacral Masses

Sacrococcygeal teratoma
Chordoma
Anterior myelomeningocele
Neurenteric cyst
Neuroblastoma
Sarcoma
Lipoma
Bone tumor
Lymphoma
Rectal duplication

If a fetal sacrococcygeal teratoma is suspected from prenatal sonograms, serial sonograms should be arranged to monitor the pregnancy to assess for complications, especially signs of fetal cardiac failure. Complete fetal assessment should also include the internal characteristics of the tumor, the size of the tumor, and associated fetal anomalies.

For masses less than 4.5 cm in diameter, without associated abnormalities, vaginal delivery is considered. For masses greater than 4.5 cm diameter, cesarean section may be considered because of the risk of dystocia and hemorrhage during vaginal delivery. In utero surgery for arteriovenous shunting has been described for treatment of fetal hydrops from congestive heart failure in early pregnancy (<30 weeks), but this should be considered only in experienced hands.[120,121]

CHAPTER 36

The Fetal Chest

Dorothy Bulas

SUMMARY OF KEY POINTS

- Normal fetal lungs appear homogeneously echogenic on ultrasound surrounding the heart with a cardiothoracic ratio that remains constant through the second and third trimesters.
- Pulmonary hypoplasia can be primary or secondary and unilateral or bilateral.
- Congenital pulmonary airway malformations (CPAMs) are a spectrum of disorders that include bronchopulmonary malformation, hybrid lesions (CPAM and sequestration), and congenital lobar overinflation/bronchial atresia.
- A large fetal lung mass can compress and shift the heart and vena cava, resulting in fetal hydrops.
- Congenital pulmonary airway malformation volume ratio (CVR) is the CPAM volume divided by the head circumference. A CVR of 1.6 or less without a dominant cyst is considered low risk for the development of hydrops.
- Congenital lobar overinflation (CLO) appears echogenic on ultrasound and can involve a segment or subsegment of lung. CLO accounts for up to 20% of prenatally diagnosed fetal lung malformations.
- Congenital diaphragmatic hernias have a variable outcome dependent on severity of lung hypoplasia, liver herniation, and the presence of additional anomalies.

CONCLUSION

Familiarity with the normal development of the fetal chest is critical both for recognizing chest anomalies and for understanding the consequences of these anomalies. Accurate prenatal diagnosis of thoracic lesions is important in providing appropriate recommendations for counseling, planning potential in utero interventions, and determining the optimal mode of delivery and postnatal care. Prenatal imaging can identify thoracic lesions and assess their impact on mediastinal structures and potential development of hydrops. Although chest abnormalities may be associated with lethal pulmonary hypoplasia, fatal chromosomal abnormalities, and lethal structural anomalies, many chest lesions resolve in utero with minimal sequelae. Fetal magnetic resonance imaging (MRI) can be a useful adjunct in cases with unclear sonographic diagnosis or potential need for in utero interventions.

DEVELOPMENT OF STRUCTURES IN THE CHEST

Pulmonary Development

In the human lung, there are five distinct stages of development, during which the lung matures and the number of alveoli increases.[1,2] At birth, the lungs are functional but structurally immature; the greatest increase in number of alveoli occurs postnatally. During the first 3 years of life, the alveoli are formed through a septation process that increases the gas exchange surface area. It is important to understand that this lung development process is ongoing, and that **space-occupying lesions,** or extrinsic abnormalities that do not allow for normal lung growth, can lead to improper lung development.

Normal Sonographic Features of the Fetal Chest

The fetal lungs are identified by ultrasound as homogeneously echogenic tissue surrounding the heart, separated by the hypoechoic, dome-shaped diaphragm from the abdominal organs (Fig. 36.1A and B). The fetal ribs are highly echogenic, curved bony structures arising near the spine and extending anteriorly to encompass more than half the thoracic circumference. Lung echogenicity varies during gestation, in general increasing in echogenicity as lung development progresses.

Assessment of lung volume is important for evaluation of fetuses at risk for pulmonary hypoplasia, particularly in cases of **congenital diaphragmatic hernia** (CDH), **pleural effusions,** prolonged **oligohydramnios,** and **skeletal deformities.** Methods to assess pulmonary size include measurement of the thoracic circumference,[3] lung area (defined as internal thoracic area minus cardiac area in diastole on a transverse four-chamber view[4]), and three-dimensional lung volumetry with ultrasound or MRI.[5-7]

The fetal lungs, thorax, and heart grow at similar rates, such that the normal cardiothoracic ratio remains constant in the

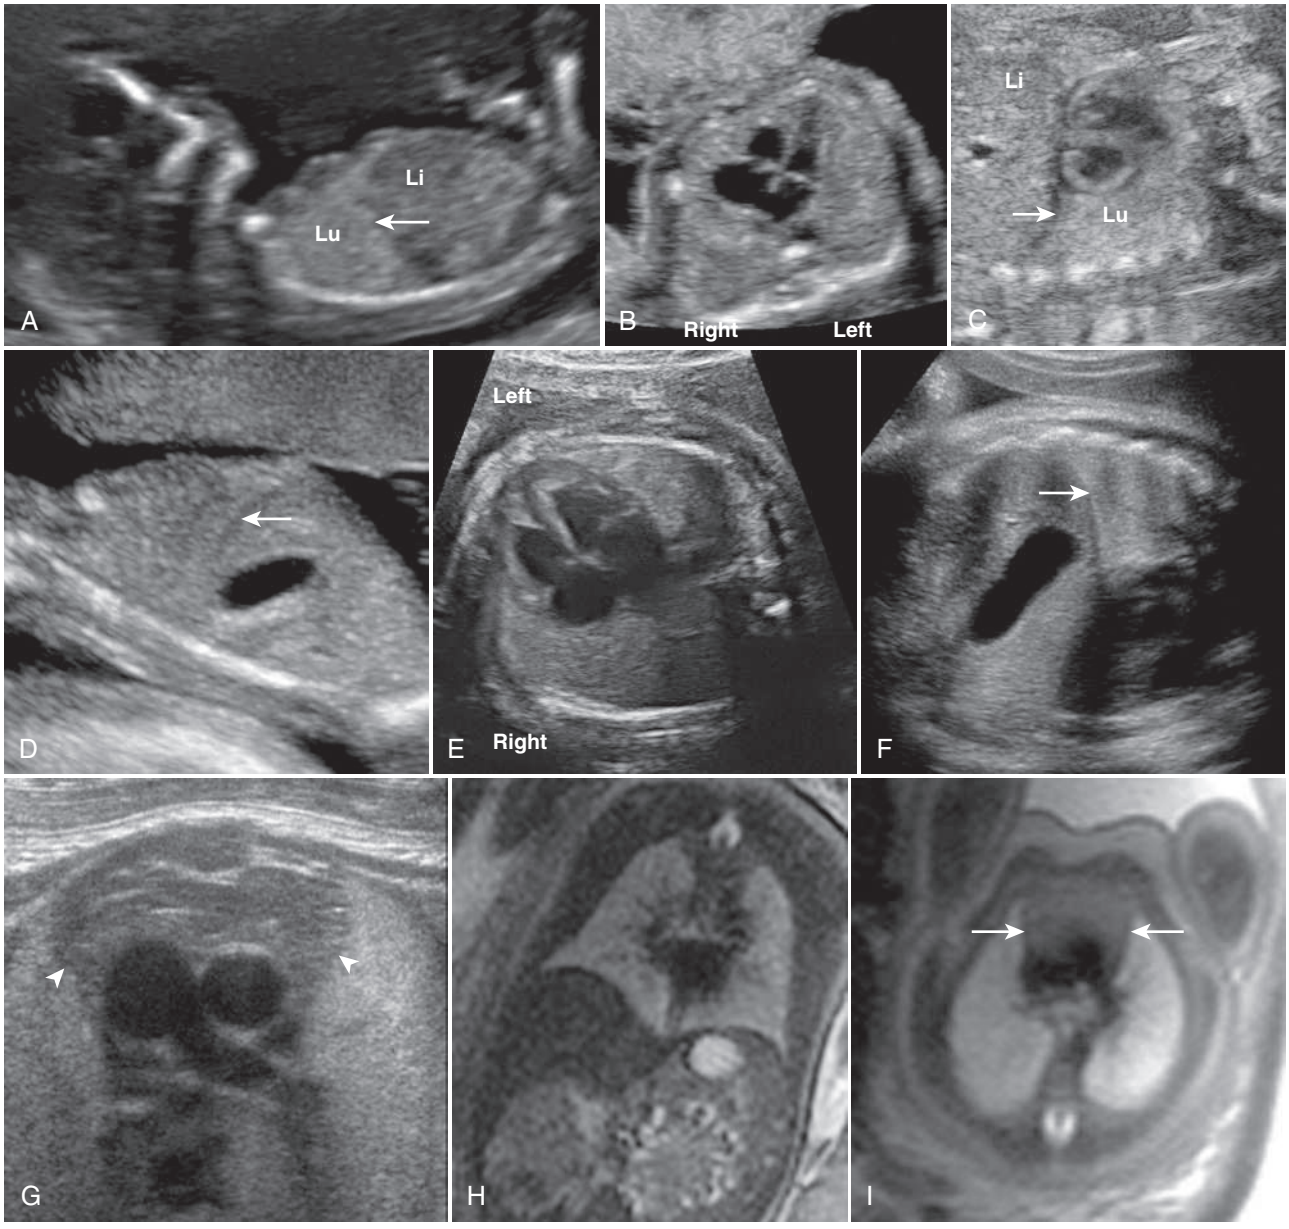

FIG. 36.1 Normal Fetal Chest. (A) Sagittal view of torso at 13 weeks. Note liver *(Li),* lungs *(Lu),* and diaphragm *(arrow).* **(B)** Four-chamber view of the heart surrounded by the homogeneous echogenic lungs at 18 weeks. **(C)** Coronal and **(D)** sagittal views of chest at 18 weeks show the dome-shaped hemidiaphragms *(arrow)* separating the lungs *(Lu)* from intraabdominal organs and the relative hypoechoic appearance of the liver *(Li).* **(E)** and **(F)** Axial and sagittal views of fetal chest *(arrow)* at 37 weeks. **(G)** Normal appearance of fetal **thymus** *(arrowheads)* at 37 weeks' gestation. **(H)** Coronal T2-weighted MRI shows normal lungs and diaphragm at 37 weeks. **(I)** Axial T2-weighted MRI of thymus *(arrows)* anterior to heart. The thymus is relatively hypoechoic to the surrounding lungs on ultrasound and intermediate signal on MRI.

second and third trimesters. On a normal four-chamber transverse view of the heart, the heart should occupy one-third to one-half the sonographic diameter of the thorax.

Stages of Human Lung Development

1. **Embryonic stage.** Extends to about 7 weeks
2. **Pseudoglandular stage.** Extends from 6 to 16 weeks; the lungs resemble tubuloacinar glands, with epithelial tubes sprouting and branching into the surrounding mesenchyme
3. **Canalicular stage.** Extends from 16 to 28 weeks; the cuboid epithelium differentiates into type I and type II cells, with production of surfactant and formation of the first, thin, air-blood barriers
4. **Saccular stage.** Extends from 28 to 36 weeks; the pulmonary parenchyma forms, the surrounding connective tissues thins, and the surfactant system matures
5. **Alveolar stage.** Extends from the 36th week of gestation to the first 3 years of life

The cardiac position and axis are constant in normal fetuses. The apex of the heart points left and touches the anterior chest wall. The posterior aspect of the right atrium lies to the right of midline[8] (Fig. 36.1E).

Familiarity with the normal anatomy and position of the fetal heart is crucial, along with in utero establishment of the right and left sides of the fetus. The reference to cardiac position and **situs** is identified by noting that the left atrium lies posteriorly, closest to the spine, and the right ventricle lies anteriorly, closest to the chest wall. Any deviation in the position of the heart should prompt a search for cardiac or pulmonary abnormalities. Anatomy of the fetal heart, including size and position, can be easily influenced by extracardiac thoracic anomalies.

Normal Diaphragm

Early in embryogenesis, the narrow pleuroperitoneal duct connects the **pleural and peritoneal cavities.** The development of the **diaphragm,** at 9 weeks' gestation, divides the two cavities. The normal diaphragm can be visualized as early as 10 weeks of gestation.[9,10] The diaphragm appears as a thin, hypoechoic, arched line separating the chest from intraabdominal contents (Fig. 36.1C-F). It is best recognized as a dome on each side on sagittal and coronal views, with no difference in the height of the diaphragm on either side.[11] The intact left hemidiaphragm is more easily verified by the presence of the fluid-filled stomach in the abdomen. On the right side, however, meticulous effort is required to identify the hypoechoic linear muscular diaphragm between the liver and lung.

Normal Thymus

The fetal thymus can be identified as early as 14 weeks' gestation in the anterior mediastinum. By the third trimester, the thymus is visualized as an ovoid, relatively hypoechoic structure[12,13] (Fig. 36.1G and I). The thymus contains spindle-shaped echogenicities that differentiate it from the surrounding echogenic lungs.[14] Thymus size varies greatly during gestation. Thymic imaging and measurements are not performed routinely on prenatal scans. However, prenatal identification and measurement of the fetal thymus is important when **DiGeorge syndrome** (with thymic aplasia or hypoplasia) is suspected. At times a large thymus will be confused with a mediastinal mass. Homogeneity and lack of mediastinal deviation can help differentiate normal thymus from a mediastinal teratoma or thymic cyst. The normal thymic average transverse measurement is 12 mm at 19 weeks' gestation and 33 mm at 33 weeks.[14] The normal thymic average perimeter is 128 mm at 38 weeks.[12] Acute fetal thymic involution has been reported in association with chorioamnionitis.[15]

Mediastinal teratomas[16,17] are rare anterior mediastinal complex masses. By ultrasound, the mass is heterogeneous and calcifications may be noted. MRI is a useful adjunct in the assessment of the mass for potential in utero and postnatal surgical treatment. The mass can cause polyhydramnios secondary to esophageal compression, and hydrops due to impaired venous return with resultant fetal demise.[16] Fetal intervention with aspiration of the tumor cyst has been described with a resultant decrease in intrathoracic pressure, which may stop the progression to hydrops and prevent lung hypoplasia. The ex utero intrapartum treatment (EXIT) procedure may be recommended to establish a proper airway at delivery.[16]

PULMONARY HYPOPLASIA, APLASIA, AND AGENESIS

Pulmonary hypoplasia is defined as a reduction in the number of cells, airways, and alveoli that results in an absolute decrease in the size and weight of the fetal lungs relative to gestational age.[18] Aplasia is the presence of rudimentary bronchi with no associated lung parenchyma. Agenesis is the complete absence of bronchi, vessels, and lung parenchyma. The earlier the insult to the fetal lungs occurs, the more severe is the degree of pulmonary hypoplasia, aplasia, or agenesis.[19] Pulmonary hypoplasia can result in postnatal respiratory distress and associated high neonatal mortality.[20] Pulmonary hypoplasia can be primary or secondary and can be unilateral or bilateral depending on the cause and time of insult to the lungs. **Primary** pulmonary hypoplasia is rare and is caused by a primary process in which the lung does not form normally. **Unilateral pulmonary agenesis** has an incidence of 1 in 15,000 births and is associated with other congenital anomalies.[21] **Bilateral pulmonary agenesis** is incompatible with postnatal life.

Secondary causes of pulmonary hypoplasia include masses that compress the lungs (e.g., CDH), skeletal malformations that do not allow the lungs to grow (e.g., thanatophoric dysplasia) (Fig. 36.2), and severe prolonged oligohydramnios (e.g., bilateral renal agenesis). Other factors that contribute to pulmonary hypoplasia include hormonal influences, pulmonary fluid dynamics, and abnormal fetal breathing movements.[22] The majority of cases of pulmonary hypoplasia are associated with major structural or chromosomal abnormalities (Table 36.1).

FIG. 36.2 Secondary Pulmonary Hypoplasia in Fetus With Thanatophoric Dysplasia. Transverse sonogram of the fetal chest at 20 weeks' gestation demonstrates a small chest circumference secondary to abnormally **short ribs** in this fetus with thanatophoric dysplasia.

TABLE 36.1 Causes of Pulmonary Hypoplasia

Main Category	Examples
Primary pulmonary hypoplasia or aplasia	Developmental abnormality
Thoracic space-occupying process	Congenital diaphragmatic hernia Lung masses Mediastinal mass Large pleural effusions
Oligohydramnios	Bilateral renal agenesis Prolonged preterm rupture of membranes
Skeletal anomalies	Skeletal dysplasias Chest wall tumors
Abnormal breathing	Phrenic nerve abnormalities, neuromuscular and central nervous system abnormalities
Chromosomal anomalies and syndromes	Trisomy 13, 18, and 21

Prenatal prediction of pulmonary hypoplasia and the degree of severity are important for parental counseling as well as for postnatal management planning, particularly if intensive respiratory care is required immediately after birth.[23] Proposed methods for prediction of prenatal pulmonary hypoplasia[24] include estimation of lung volumes by three-dimensional ultrasound[25,26] or by MRI,[27] thoracic circumference[28,29] (Table 36.2),[30] lung-to-head ratio,[9,31] lung-to-body weight ratio,[23] and Doppler studies of pulmonary arteries.[32]

Prognosis and management are variable and depend on the severity of the hypoplasia, age at delivery, and nature of the associated conditions. Absence of fetal breathing movements in the setting of oligohydramnios in pregnancies resulting from **premature rupture of membranes** is a predictor for pulmonary hypoplasia.[4] The spectrum of clinical outcomes ranges from mild respiratory insufficiency to neonatal death.

In cases of **unilateral** pulmonary hypoplasia or aplasia, there is mediastinal shift to the side of the hypoplastic lung, with no associated mass in the contralateral lung to explain the degree of mediastinal shift[33] (Fig. 36.3). The contralateral lung may be enlarged and echogenic.[21] Pulmonary hypoplasia can also be secondary to space-occupying lesions, such as congenital pulmonary airway malformations (CPAMs), diaphragmatic hernia (CDH), or pleural effusion.

CONGENITAL PULMONARY AIRWAY MALFORMATION SPECTRUM

An echogenic lesion in the fetal thorax (Table 36.3) or a cystic lesion in the fetal thorax can be part of the **CPAM** spectrum. This spectrum includes lesions that have been historically called **congenital cystic adenomatoid malformation** (CCAM), **bronchopulmonary sequestration** (BPS), and **congenital lobar emphysema.** CPAM is a congenital hamartomatous lung lesion that communicates with the bronchial tree through an abnormal communication and has normal pulmonary blood supply and venous drainage into the pulmonary veins.[34] BPS is normally developed lung tissue with systemic circulation. However, CPAM and BPS lesions often occur together and are then call hybrid lesions or part of the CPAM spectrum.[35-37] For clarity, we will describe these lesions separately, but the reader should be aware that careful histologic inspection will often find regions of CPAM in what appears to be a sequestration, as well as lesions that resemble a CPAM that have both pulmonic and systemic feeding vessels. Both of these types of lesions can have air trapping postnatally and therefore may have elements of congenital lobar overinflation (CLO; previously known as **congenital lobar emphysema**).

Congenital Pulmonary Airway Malformation

CPAM accounts for about 25% of congenital lung masses,[38] with an incidence of 1 in 25,000 live births.[39] It is comprised of pulmonary tissue with abnormal bronchial proliferation that may involve either lung or any lobe. In 85% to 95% of cases, CPAM is limited to one lobe or segment, with 2% to 3% of CPAMs occurring bilaterally and with the right and left lungs equally affected.[40]

CPAM results from a pulmonary insult during embryologic development of the bronchial tree before the seventh week of gestation, resulting in failure of bronchial maturation and lack of normal alveoli. Histologically, CPAM is differentiated from other lung masses by the absence of bronchial cartilage and bronchial tubular glands, with overproduction of terminal

TABLE 36.2 Normal Thoracic Circumference Correlated With Gestational Age

	PREDICTIVE PERCENTILES								
Age (Wk)	**2.5**	**5**	**10**	**25**	**50**	**75**	**90**	**95**	**97.5**

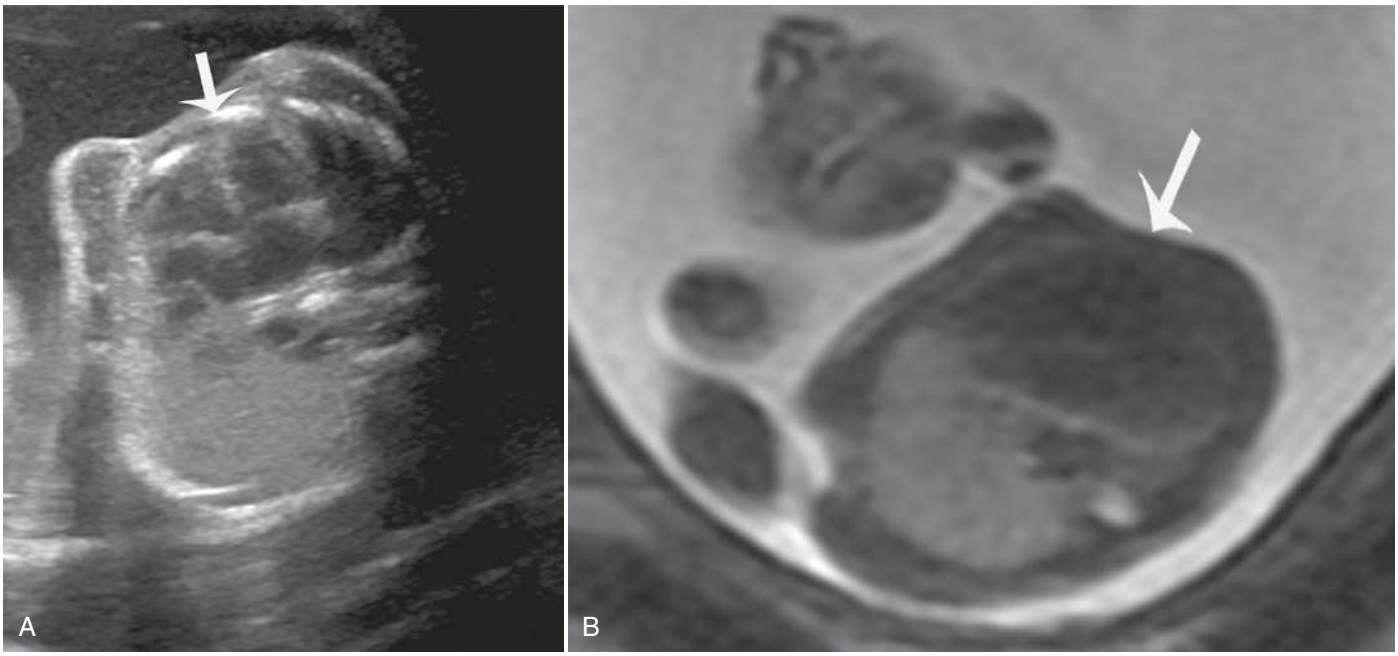

FIG. 36.3 Unilateral Pulmonary Hypoplasia. (A) Axial sonogram of the fetal chest at 33 weeks' gestation demonstrates mediastinal shift to the left *(arrow)*. No lung mass is present. **(B)** Axial MRI of the chest confirms the mediastinal shift and lack of a lung mass.

TABLE 36.3 Differential Diagnosis of Echogenic Lesion in Fetal Thorax

Abnormality	Location	Distinguishing Features
Congenital pulmonary airway malformation (CPAM)	Unilateral (2%-3% bilateral)	Multiple cysts may be seen in association with echogenic lesion
Sequestration	Unilateral; left lower lobe most often	Systemic blood supply
Congenital lobar overinflation	Unilateral; upper lobe most often	Similar to microcystic CPAM; enlarged echogenic lung with mediastinal shift
Congenital diaphragmatic hernia (CDH)	Typically unilateral; left sided most often	Peristalsis of bowel in chest Stomach above diaphragm Absence of part of the diaphragm
Congenital high airway obstruction (CHAOS)	Bilateral	Distended trachea and main central airways Symmetrical bilateral enlarged lungs with eversion of hemidiaphragms

bronchiolar structures without alveolar differentiation, except in the subpleural areas.[41-43] The resulting cystic lesions result in enlargement of the affected lobe (or segment). If sufficiently large, CPAM will result in mediastinal shift and interfere with normal alveolar development in the adjacent lung. Communication with the tracheobronchial tree usually is retained, with vascular supply and venous drainage to the pulmonary circulation, unless CPAM is associated with sequestration. In these cases this is called a "hybrid lesion."

There are different classification schemes for CPAMs depending on histology[44] or on prenatal sonographic appearance.[44,45] The three main types described sonographically are **type I** (large cysts measuring 2-10 cm), **type II** (multiple small cysts), and **type III** (microcystic, appearing as echogenic lesions).

Sonographic diagnosis can be made as early as 16 weeks. CPAM may appear as a solid echogenic lung mass (microcystic) or as a mixed, cystic and solid mass (Fig. 36.4, Video 36.1). Color Doppler ultrasound may demonstrate vascular flow to the lesion from branches of the pulmonary artery. Typically, there is no systemic feeding vessel, although as mentioned, CPAM can occur in concert with sequestration. The lesions with microcysts appear solid and echogenic, whereas the macrocystic CPAMs have demonstrable cysts. Occasionally, only a single large cyst is visualized.

As with any chest mass, it is important to assess for associated mediastinal shift, polyhydramnios, and hydrops because these factors impact prognosis and management.[45,46] It is the size of the CPAM rather than the size of the cysts that determines whether or not the fetus develops **hydrops.** Macrocystic lesions usually have a more favorable prognosis. Large CPAMs can result in cardiac and vena cava compression, leading to altered hemodynamics and hydrops as a result of elevated central venous pressure that may require in utero intervention.[47]

The CPAM volume ratio (CVR), a measurement initially described by ultrasound, should be measured to assess prognosis and risk of hydrops. It is obtained by calculating the volume of the lung mass (height × anteroposterior diameter × transverse diameter × 0.52) and dividing it by the head circumference. A CVR less than 1.6 indicates a 14% risk of developing hydrops for fetuses with macrocystic lesions and 3% for those with microcystic lesions. If the CVR is greater than 1.6, the risk increased to 75%.[48] In the absence of hydrops, the prognosis is good, with reported live birth rates of 95% and higher.[49-51] Untreated hydrops as a result of CPAM, however, has an anticipated mortality rate of up to 100%.[52-61] Hydrops is therefore an indication for in utero fetal therapy, and close follow-up in the second and early third trimesters is important when a high CVR is encountered. However, if there is fluid, such as ascites, in only a single body cavity, spontaneous regression of the lesion and improvement in fluid status is still possible.[62] Steroids have been used in an attempt to prevent the development of hydrops or help speed the regression of the lesion, particularly with microcystic CPAM. In uncontrolled studies, maternal steroid administration appeared to reverse hydrops and improve outcome.[55-59] However, it is possible that fetal thoracic growth and/or CPAM regression rather than steroids account for the resolution of hydrops.

With macrocystic CPAM, steroid therapy appears to be less helpful, with in utero therapy generally consisting of either draining the largest cyst with a single stick procedure[48] (Fig. 36.4G) or, if fluid reaccumulates, placing a shunt.[60,61] Rarely is open fetal surgery indicated. A meta-analysis showed that shunting of CPAMs improved survival in fetuses with hydrops compared with no effect on survival in fetuses with chest masses without hydrops.[63] The success with open fetal surgery in cases of CPAM ranges between 29% and 62% but has the limitation of expected preterm delivery.[64]

Associated anomalies, most often renal, intestinal, and cardiac, are present in up to 26% of cases,[35,44-46,65] more frequently when CPAM is bilateral.[40] Therefore a complete fetal anatomic survey is indicated. The differential diagnosis includes BPS, CLO, bronchogenic cyst, CDH, laryngeal or tracheal occlusion, neurenteric/enteric cysts, and mediastinal teratomas.

MRI has become a useful adjunct in the evaluation and management of CPAM[66] (Fig. 36.4H and I). Macrocysts have a high T2-weighted signal intensity, whereas microcysts have moderately high signal intensity and are relatively homogeneous. As the lesions regress, they develop lower signal intensity on T2-weighted imaging.[67]

Longitudinal studies of CPAM have demonstrated that most CPAMs demonstrate rapid progressive growth from about weeks

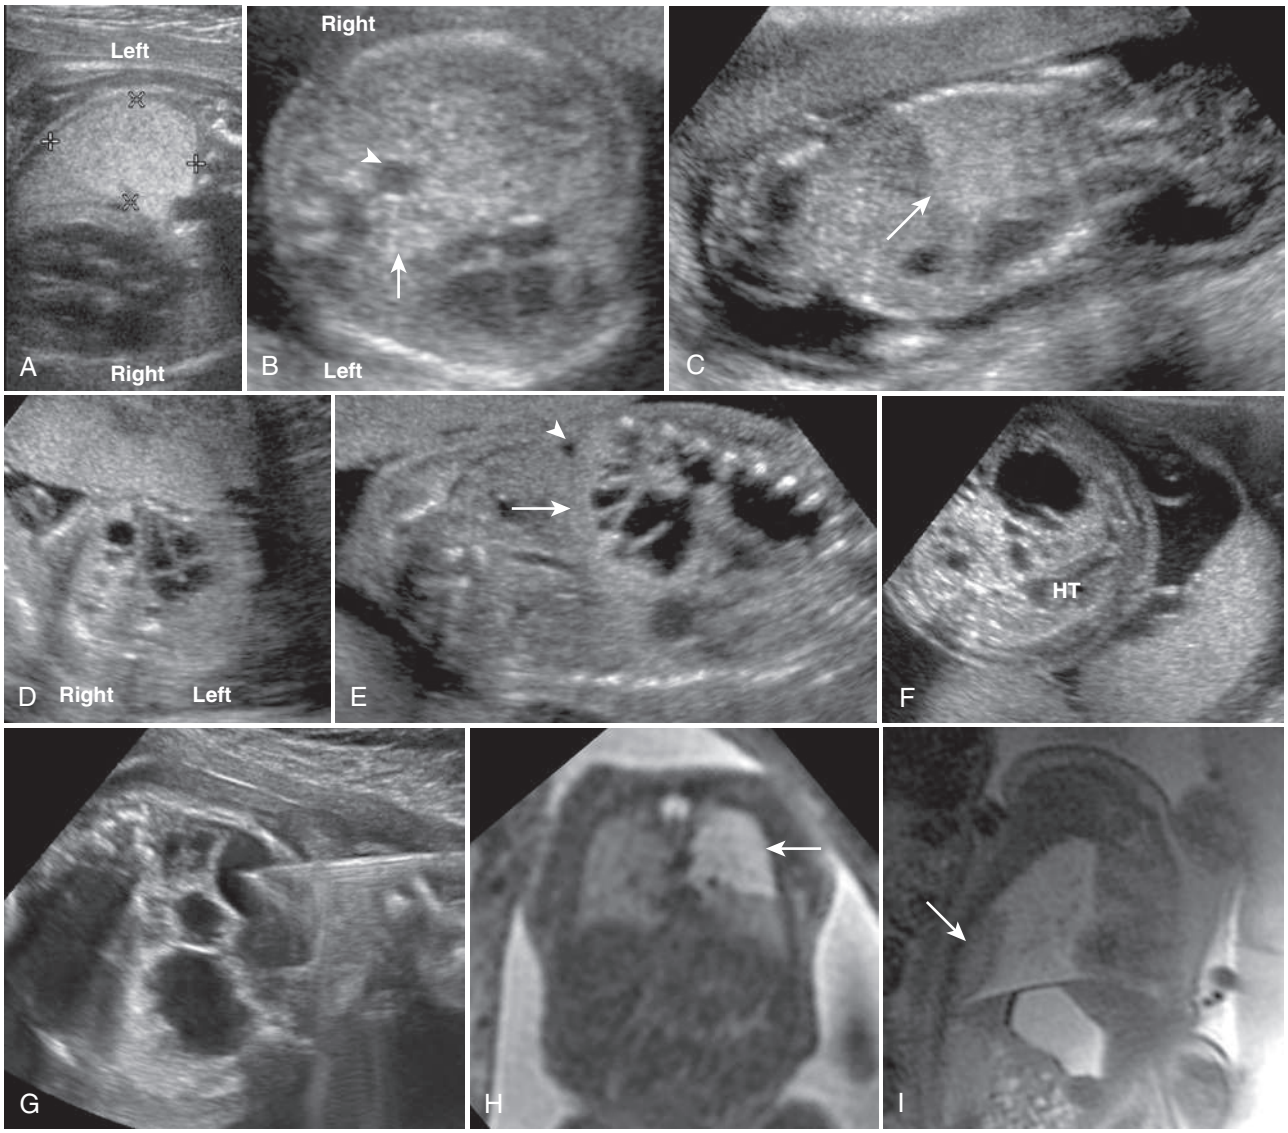

FIG. 36.4 Congenital Pulmonary Airway Malformation (CPAM). (A) Axial sonogram at 28 weeks shows a homogeneously echogenic mass *(calipers)* in the mid–left hemithorax with no large cysts or feeding vessels. There is mild mediastinal shift to the right. **(B)** Axial sonogram of right-sided CPAM *(arrow)* at 20 weeks with small cysts, the largest of which is 8 mm *(arrowhead).* There is moderate mediastinal shift to the left. **(C)** Sagittal oblique sonogram shows CPAM everting the hemidiaphragm *(arrow).* **(D)** Transverse view of chest with CPAM containing small cysts and mild mediastinal shift. **(E)** and **(F)** Axial and oblique coronal images at 25 weeks in a macrocystic CPAM *(arrow)* with eversion of the hemidiaphragm, trace ascites *(arrowhead),* and severe mediastinal shift with compression of the heart *(HT).* **(G)** Ultrasound-guided percutaneous drainage of CPAM. A 20-gauge needle was inserted into the largest cyst with relief of cardiac compression. **(H)** Coronal T2-weighted MRI shows a well-circumscribed area of T2 hyperintensity *(arrow)* in the left upper lobe. **(I)** Oblique coronal T2-weighted MRI shows a well-circumscribed area of low T2 signal *(arrow)* in a fetus with a typical, resolving CPAM. See also Video 36.1.

20 to 26 of gestation, peaking at about 25 weeks,[48,62] and then growth plateaus and often regresses.[68] There are no reliable criteria for determining which lesions will continue to grow versus those that will stabilize or regress. About 50% of masses persist to delivery.[49] Fifteen percent of these masses decrease in size during the late second and the third trimesters; the majority have a relative decrease in size as a result of normal fetal thoracic growth, but a few increase in size.[46,62] As masses decrease in size, their echogenicity can become similar to that of surrounding normal lung because of an increase in normal lung echogenicity and decrease in echogenicity of the CPAM. Thus they may become difficult to visualize late in gestation, with residual mass effect being the main finding on ultrasound.

If the fetus does not develop hydrops before 26 weeks, the prognosis is generally good.[49,69] Close surveillance of the growth of these lesions is recommended throughout the second trimester particularly if the CVR is higher than 1.6. Delivery planning should be made in conjunction with the neonatology and/or pediatric surgery teams. If the lung mass has resolved or is small with no mediastinal shift or hydrops, the presence of a CPAM itself is not an indication for early delivery or cesarean delivery[69] as neonatal respiratory issues are unlikely.

CVR may help predict the risk of neonatal respiratory problems.[49,70] In a retrospective study a final CVR of greater than 1.0 in nonhydropic fetuses was predictive of respiratory symptoms at birth (sensitivity, specificity, positive and negative predictive values: 75%, 98%, 75%, and 98%, respectively) and perinatal resection (sensitivity, specificity, positive and negative predictive values: 100%, 98%, 75%, and 100%, respectively).[49]

For fetuses with large masses that cause mediastinal shift and/or hydrops, delivery should be planned for a tertiary care center with an neonatal intensive care unit (NICU) capable of providing extracorporeal membrane oxygenation (ECMO), and with pediatric surgeons experienced in care of these infants.[50,71] If hydrops develops after 32 weeks of gestation, early delivery is recommended, possibly with the use of the EXIT procedure.[71] In EXIT, the fetus is partially delivered and intubated without clamping the umbilical cord. Uteroplacental blood flow and gas exchange are maintained to provide uterine relaxation, and amnioinfusion is performed to maintain uterine volume. This provides time for resection of the lung mass prior to complete delivery of the infant in rare instances or, more often, cannulation for ECMO, thus creating a controlled situation for delayed removal of the CPAM. Overall neonatal survival of 90% has been reported.[72]

Although regression of CPAM on prenatal ultrasound is common, the lesion does not completely disappear.[73] In asymptomatic neonates, the lesion may not be seen on chest radiography after birth. In these cases, postnatal computed tomography (CT) is recommended. Postnatal removal of asymptomatic masses is recommended because of potential secondary infection, and risk of carcinomas arising in CPAM.[74] The timing of surgical resection of CPAM remains controversial, but most centers favor elective surgical resection in the first year of life.[75]

Bronchopulmonary Sequestration

BPS is an anomaly in which nonfunctioning pulmonary tissue is not in normal continuity with the native tracheobronchial tree[76] and has a blood supply from the systemic circulation. Sequestrations account for up to 6% of congenital lung malformations.[77,78] Concomitant anomalies associated with sequestration include CDH, **diaphragmatic eventration and paralysis, bronchogenic cyst, ectopic pancreas, vertebral anomalies,** and **foregut duplication.** Hybrid combinations of CPAM and BPS are relatively common, having connection with both the pulmonary and the systemic arterial supply.

There are two main types of sequestration: intralobar and extralobar. A third variant is suggested when communicating bronchopulmonary foregut malformation is present.[79]

Extralobar sequestration (also known as **extrapulmonary sequestration**) accounts for 25% of BPS postnatally. This lesion is a supernumerary lung bud invested by its own pleura, typically deriving its blood supply from the splanchnic vessels surrounding the foregut, which results in the systemic blood supply.[80] The venous drainage is usually through a single vessel into the azygous, hemiazygos, and/or the vena cava system. In up to 25% of cases, however, the extralobar sequestration is partially drained through pulmonary veins. Extralobar sequestration is typically found in the left posterior costodiaphragmatic sulcus between the lower lobe and the hemidiaphragm (80%).[81] Extralobar sequestrations occur below the diaphragm in suprarenal locations in 10% to 15% of cases (with a differential diagnosis of **neuroblastoma and adrenal hemorrhage**).[82] In rare cases, sequestration may present as a mediastinal or pericardial mass.[83]

Intralobar sequestration comprises abnormal lung tissue with systemic arterial supply within the normal lung, sharing the visceral pleura and draining to pulmonary veins although connections to the vena cava, azygous vein, or right atrium can also occur.[81] It occurs more often in the lower lobes and slightly more often on the left. Postnatally it accounts for 75% of cases of BPS.[84]

Sequestration can be detected on prenatal sonogram as early as 16 weeks' gestation.[85] Typically, a sequestration appears as a well-defined, homogeneous, echogenic wedge-shaped pulmonary mass in the lower lobe adjacent to the hemidiaphragm (Fig. 36.5). Classically, these lesions do not have cysts. However, cysts can result from dilated bronchioles or hybrid lesions of concomitant CPAM. Sequestration can be distinguished from other congenital lung masses by identifying on Doppler interrogation a systemic artery arising from the thoracic or abdominal aorta feeding the mass. Determination of where the vessel arises is important for counseling parents about the approach that will be needed for postnatal surgical removal of the mass. The differential diagnosis includes CPAM, CLO, CDH, neuroblastoma, and adrenal hemorrhage.

MRI can help confirm the diagnosis and location of the mass (above, within, or below the diaphragm). The mass is high signal on T2-weighted images. A feeding vessel may be noted as a low signal line coursing from the aorta to the mass.[61,86] Small sequestrations with minimal mediastinal shift have a benign clinical course.[37] As with other chest masses, a large sequestration may result in mediastinal shift. However, most prenatally detected sequestrations are of small or medium size. These lesions usually regress in size during gestation.[37,45] Large sequestrations can be complicated by pleural effusions and with hydrops can lead to increased prenatal mortality (Fig. 36.6). Effusions can be secondary to a large mass compressing the heart and vena cava or due to torsion around the vascular pedicle.[89] Hydrops is rare but can occur secondary to shunting of the systemic arterial feeder or mass effect from the sequestration itself with associated mediastinal shift and compression of the heart or inferior vena cava. For such complicated cases, the pleural effusion can be treated with pleuroamniotic shunting and drainage.[87-89] Laser surgery has also been attempted with some success.[90,91]

Prognosis is excellent in the absence of hydrops.[92] Mortality rate is as high as 80% if hydrops is present.[61] Masses that appear to resolve in utero are typically still present on postnatal CT scans.

Apparent resolution of masses can be the result of outgrowth of the systemic circulation or torsion around the vascular pedicle. As they regress, they are more difficult to see on ultrasound and can produce low signal intensity on MRI.[52,93]

Delivery planning should include input from the neonatologist and pediatric surgeon. If the mass is small, there is no indication for early delivery or cesarean section. For fetuses with large masses with hydrops, delivery should be at a tertiary care center. If

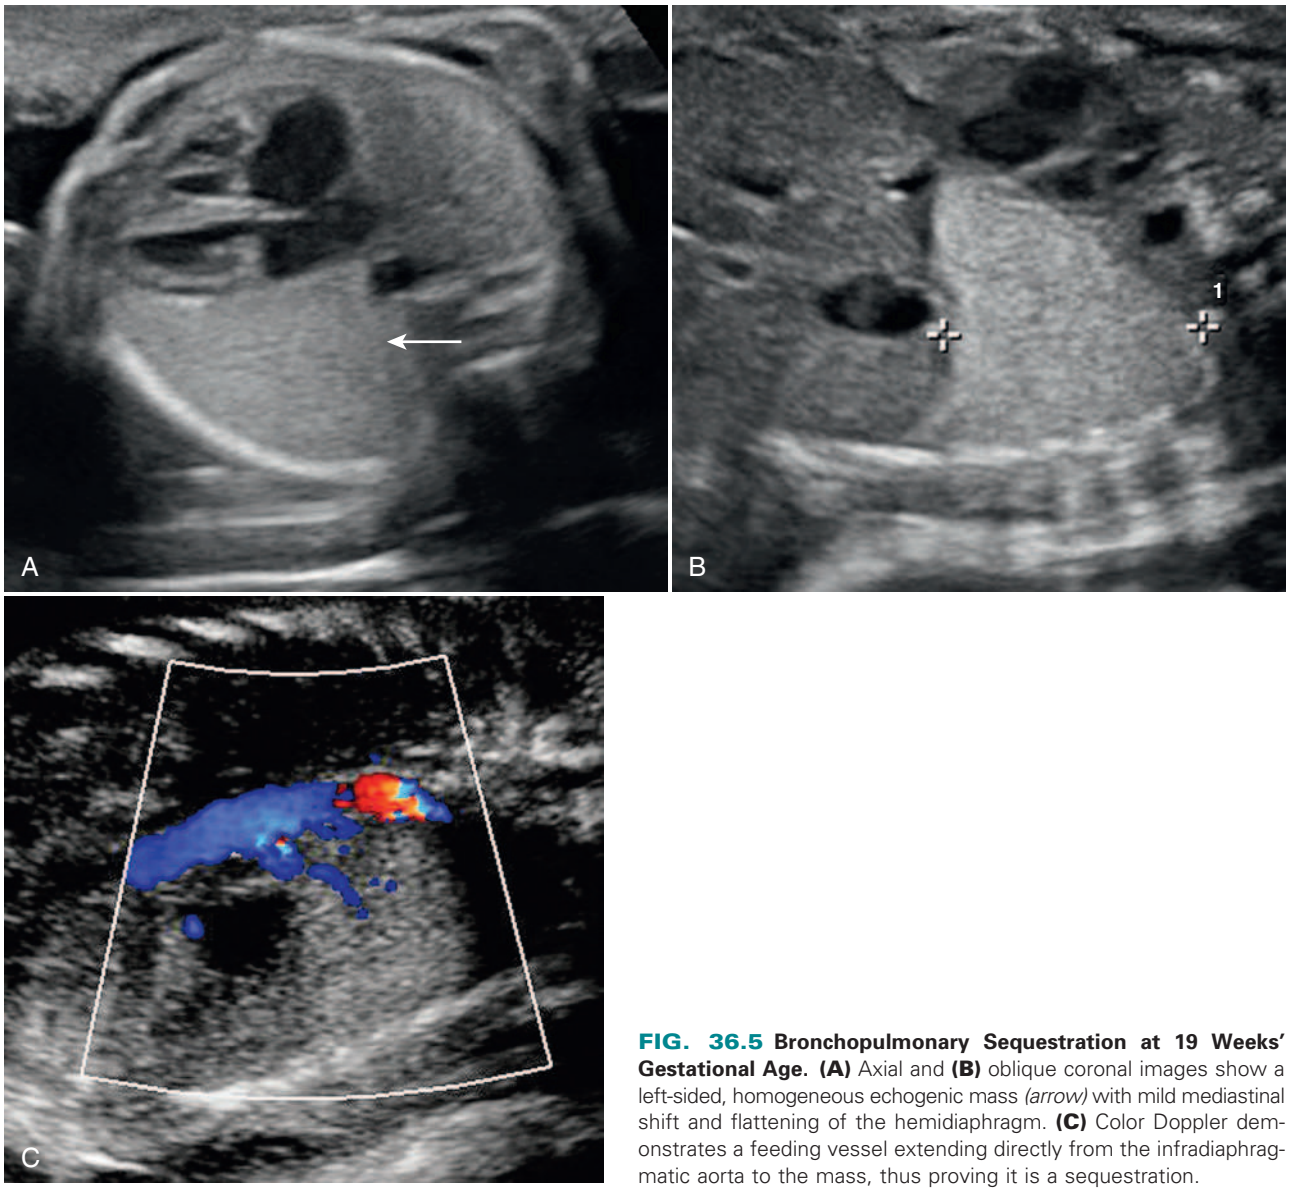

FIG. 36.5 Bronchopulmonary Sequestration at 19 Weeks' Gestational Age. (A) Axial and **(B)** oblique coronal images show a left-sided, homogeneous echogenic mass *(arrow)* with mild mediastinal shift and flattening of the hemidiaphragm. **(C)** Color Doppler demonstrates a feeding vessel extending directly from the infradiaphragmatic aorta to the mass, thus proving it is a sequestration.

hydrops develops after 32 weeks' gestation, early delivery is recommended, possibly with use of the EXIT procedure.

Congenital Lobar Overinflation

CLO is overinflation of a lung lobe without destruction of alveolar septa. Pathologically there are two subgroups. One is associated with an overinflated lung secondary to an intrinsic cartilage abnormality of the airway, absent bronchial cartilage, or extrinsic compression by a dilated pulmonary artery or bronchogenic cyst. The collapsed airway acts as a one-way valve resulting in trapping of fluid prenatally and air postnatally. This form, previously known as **congenital lobar emphysema,** occurs more frequently in the left upper lobe. A second subgroup is characterized by lobar, segmental, or subsegmental overinflation with an association with bronchial atresia. This subgroup can be seen in the lower lobes and has fewer symptoms. In up to 50% of cases CLO is idiopathic.[94,95]

On prenatal ultrasound, CLO is similar in appearance to microcystic CPAM, manifesting as a homogeneous echogenic mass. A central dilated bronchus helps confirm the diagnosis of an associated bronchial anomaly. Mass effect with mediastinal shift may occur with herniation of the overinflated lung to the contralateral side[96-98] (Fig. 36.7).

On color Doppler, CLO has a blood supply from the pulmonary artery and drains to the pulmonary vein.[94] Echocardiogram should be performed to exclude congenital heart disease.[99]

On MRI, CLO is characterized by increased T2-weighted signal intensity with a lobar distribution. It is more homogeneous than CPAM and less high in signal than BPS. The lung anatomy is intact with stretched hilar vessels.[100]

As with CPAM, the lesion can regress in utero.[101] Hydrops has been described; thus follow-up examination should be performed prenatally to document stability.[102,103] Because of the nonspecific appearance, even if the mass regresses in size, postnatal

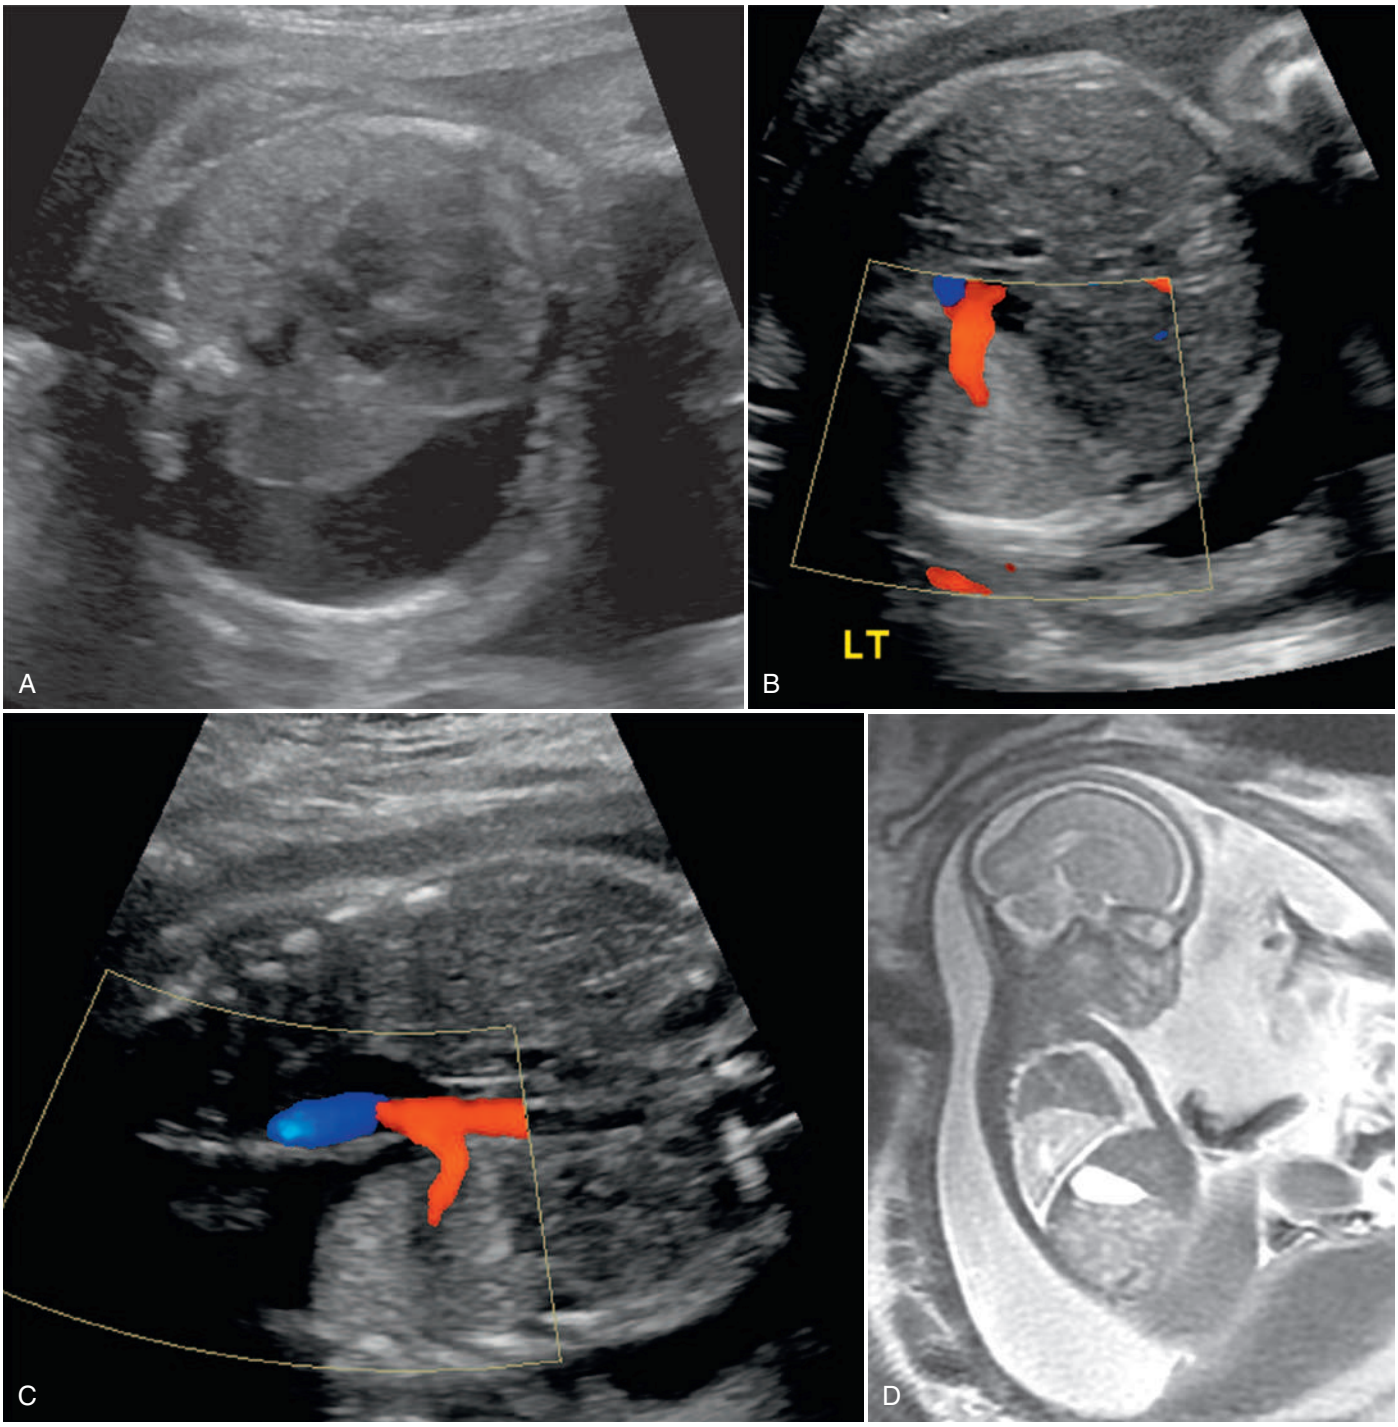

FIG. 36.6 Bronchopulmonary Sequestration With Effusion. (A) Axial image of the fetal chest demonstrates a left pleural effusion with moderate mediastinal shift to the right. **(B)** Axial and **(C)** coronal color Doppler images show a systemic feeding vessel coursing into the echogenic left lower lobe. **(D)** Sagittal T2-weighted MRI shows the high signal intensity left lower lobe mass with a moderate surrounding effusion.

follow-up is required because air trapping and respiratory distress may necessitate lobar resection.[102]

PLEUROPULMONARY BLASTOMA

Pleuropulmonary blastoma is a rare primary neoplasm originating from the pleuropulmonary mesenchyme (previously called **pulmonary blastoma** or **malignant mesenchymoma**).[104] Three pleuropulmonary blastoma types have been described: type I (exclusively cystic), type II (mixed cystic and solid lesion), and type III (predominantly solid mass).[105]

Seen on ultrasound, pleuropulmonary blastoma appears as a complex macrocystic lesion in the chest, indistinguishable from a CPAM. Features that help differentiate pleuropulmonary blastoma from CPAM include a positive family history, presence of multifocal lesions, and association with pleural effusion.[106]

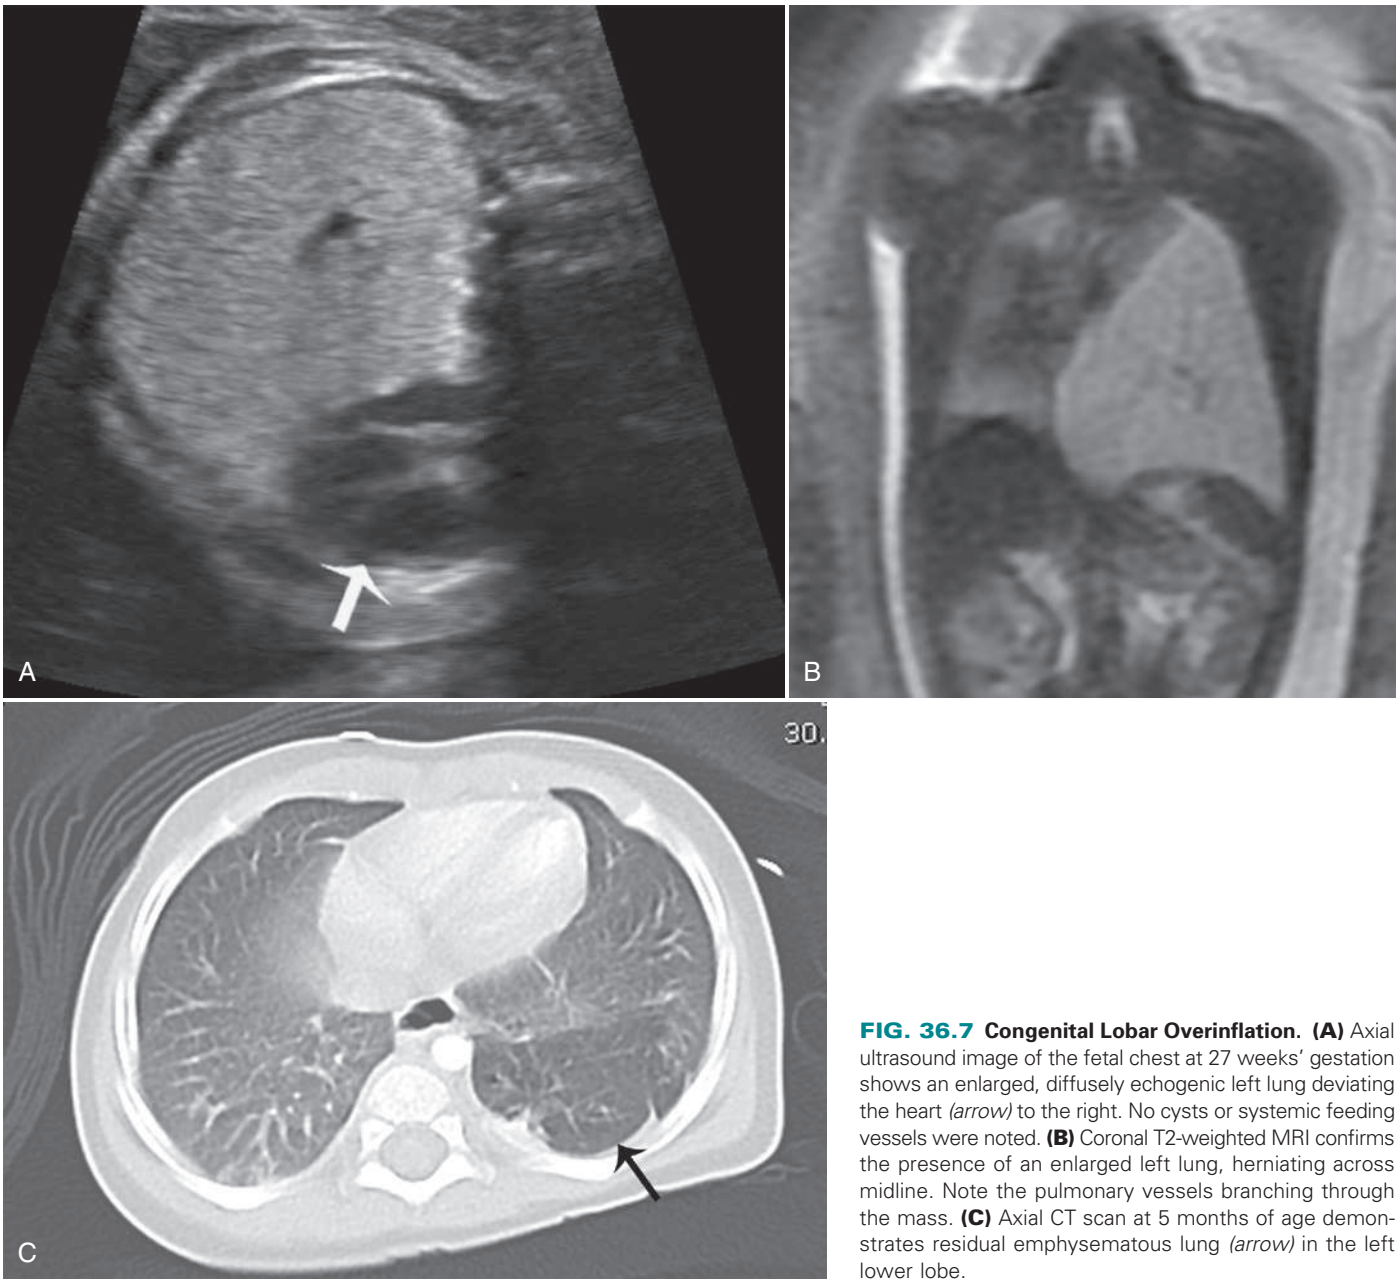

FIG. 36.7 Congenital Lobar Overinflation. (A) Axial ultrasound image of the fetal chest at 27 weeks' gestation shows an enlarged, diffusely echogenic left lung deviating the heart *(arrow)* to the right. No cysts or systemic feeding vessels were noted. **(B)** Coronal T2-weighted MRI confirms the presence of an enlarged left lung, herniating across midline. Note the pulmonary vessels branching through the mass. **(C)** Axial CT scan at 5 months of age demonstrates residual emphysematous lung *(arrow)* in the left lower lobe.

There are no definitive imaging findings to distinguish type I pleuropulmonary blastoma from type I CPAM.[107] Progressive enlargement in the third trimester or postnatally is suggestive of a pleuropulmonary blastoma in contradistinction of a CPAM, which should get smaller over time. Early diagnosis and complete resection are key to a good outcome.[106]

CONGENITAL HIGH AIRWAY OBSTRUCTION

Congenital high airway obstruction syndrome (CHAOS) is a spectrum of conditions characterized by incomplete or complete obstruction of the high fetal airway.[108,109] Any fetal abnormality that obstructs the larynx or trachea, causing intrinsic atresia or extrinsic compression can result in CHAOS. **Laryngeal atresia** is the most frequent cause. Other causes include **laryngeal** or **tracheal webs, laryngeal cysts, tracheal atresia, subglottic stenosis** or **atresia,** and **laryngeal *or* tracheal agenesis.**[110] If untreated, CHAOS is almost always lethal.[109]

Although sporadic with unknown incidence, CHAOS can be part of various chromosomal disorders.[111,112] It can be familial with autosomal dominant inheritance and variable expression.[113] Laryngeal atresia can occur as part of **Fraser syndrome** (tracheal or laryngeal atresia, renal agenesis, microphthalmia, and syndactyly or polydactyly) with autosomal recessive inheritance.[112-114]

Prenatal ultrasound findings can be visualized as early as 16 weeks' gestation.[115] Findings include bilateral symmetrically enlarged echogenic lungs, dilated fluid-filled trachea and central bronchi, and flattened or everted diaphragms[116-119] (Fig. 36.8).

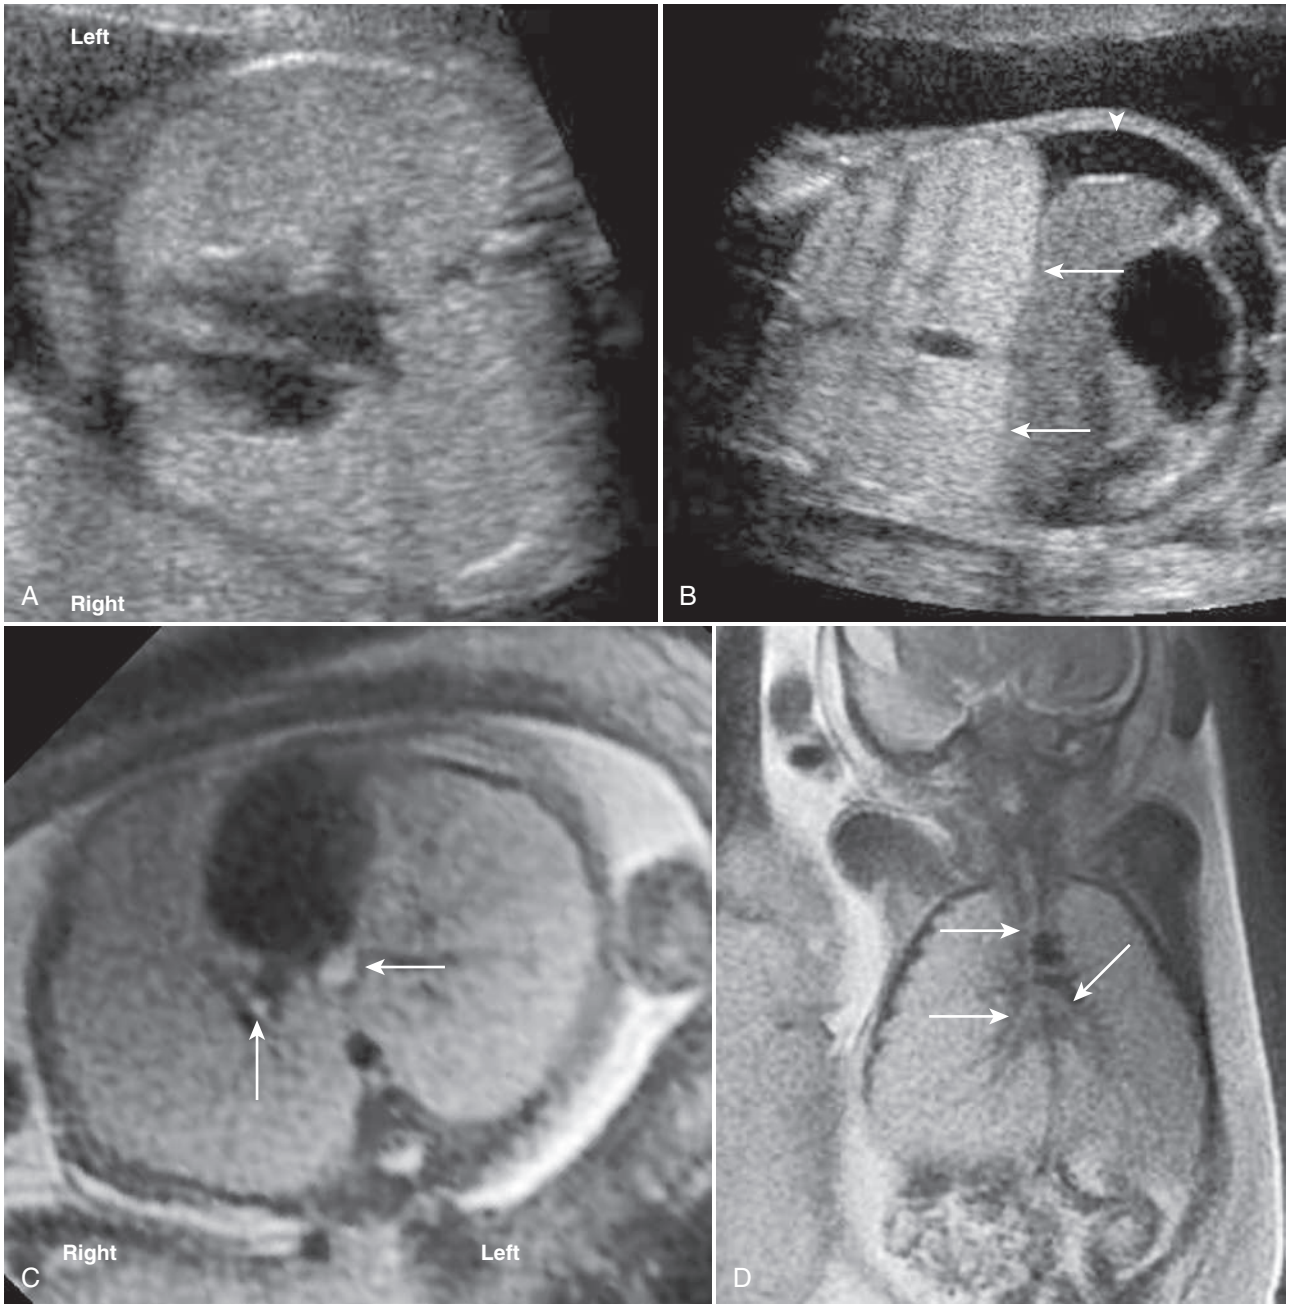

FIG. 36.8 Congenital High Airway Obstruction Syndrome (CHAOS) at 19 Weeks. (A) Axial and **(B)** and coronal views of the chest show diffusely enlarged, echogenic lungs bilaterally with eversion of the hemidiaphragms *(arrows)* and ascites *(arrowhead)*. **(C)** and **(D)** Axial and coronal T2-weighted MR images show increased lung volume and fluid-filled airways *(arrows)*. (Courtesy of Katherine Fong, MD, University of Toronto.)

The heart usually assumes a more central and anterior position than normal and is often compressed as the size of the lungs increases.[110] Frequently, there are associated findings of ascites and other signs of hydrops. The mechanism of ascites may be from compression of the heart and great vessels by the enlarged lungs.[120] Either polyhydramnios or oligohydramnios may be present.

The lungs are distended and appear homogeneously echogenic because of increased fluid and increased lung growth induced by the upper airway obstruction.[110] The increased number of tissue-fluid interfaces produces the hyperechoic appearance of the lungs. Lung volume can increase up to 15 times the expected size. The hyperplastic lungs are edematous but otherwise histologically normal.[110]

MRI can be used to identify the region of obstruction and assist in decisions regarding in utero intervention and intrapartum procedures. Characteristic findings include increased lung volume, diffuse increase in lung intensity on T2-weighted images, and a dilated fluid-filled trachea and bronchi.[116] Extrinsic causes of tracheal compression can be evaluated.[118]

More than 50% of fetuses with laryngeal obstruction have associated abnormalities, most often in the renal system and

central nervous system. At times, CHAOS is in association with a **tracheoesophageal fistula.** This fistula acts as an alternative pathway for the accumulated fluid, leading to a decrease in lung volume, reversal of diaphragmatic eversion, and resolution of ascites and polyhydramnios.[108]

If untreated, laryngeal and tracheal atresia can lead to death either in utero from hydrops or within minutes after birth from respiratory compromise. Neonatal survival is possible if the delivery is performed with the **ex utero intrapartum treatment** (EXIT) procedure.[121-124] The EXIT procedure involves tracheostomy placement below the level of the obstruction while maternal placental circulation is maintained.

BRONCHOGENIC CYST

Bronchogenic cysts (Table 36.4) are rare anomalies that result from abnormal budding or branching of the tracheobronchial tree. They are most often located in the mediastinum in the subcarinal region.[125] However, 15% of bronchogenic cysts occur in the lungs, pleura, and diaphragm. They account for 11% to 18% of mediastinal masses in infants and children.[126,127] The cyst is lined by ciliated mucus-secreting bronchial epithelium and may be mucus-filled. Although the mediastinal cysts do not communicate with the bronchopulmonary tree, intrapulmonary cysts usually do.

Bronchogenic cysts range in size from a few millimeters to more than 5 cm. On prenatal ultrasound, they usually appear as anechoic unilocular intrathoracic cysts (Fig. 36.9), at times with layering echogenic material.[128,129] If the cyst does not cause mass effect, it typically will not cause a problem in utero. However, if the cyst compresses the airway, it can lead to airway obstruction at birth.[130] The main differential diagnosis is CPAM. However, CPAM usually has more than one cyst and an associated echogenic mass with mass effect. If a bronchogenic cyst causes obstruction, it may lead to the distal lung accumulating fluid, masquerading as an echogenic lung lesion such as CPAM or sequestration.

The cyst can be mediastinal or parenchymal. Mediastinal lesions are typically unilocular, located midline in the subcarinal region (75%). Parenchymal lesions are usually simple unilocular cysts located along the tracheobronchial tree. Septations may be seen. At times the cyst can cause bronchial compression and result in distal overinflation.

Fetal MRI can be helpful in cases with an unclear diagnosis. The cyst exhibits high signal intensity on T2-weighted imaging. When the cyst causes obstruction, there will be distal lung overinflation, and the lung will become hyperintense as well.[130] Surgical resection for bronchogenic cysts is performed postnatally

TABLE 36.4 Differential Diagnosis of Fetal Thoracic Cystic Lesion

	Distinguishing Features
Congenital pulmonary airway malformation (CPAM)	Associated with echogenic lung mass, typically multiple cysts
Congenital diaphragmatic hernia (CDH)	Peristalsis of bowel in chest Stomach above diaphragm Absence of part of the diaphragm
Teratoma	Mass does not obey lobar boundaries; may have calcifications
Neurenteric cyst	Adjacent to spine
Bronchogenic cyst	Typically single cyst, may obstruct and have distal hyperinflated lung
Esophageal duplication	Adjacent to esophagus
Lymphangioma	Crosses anatomic boundaries

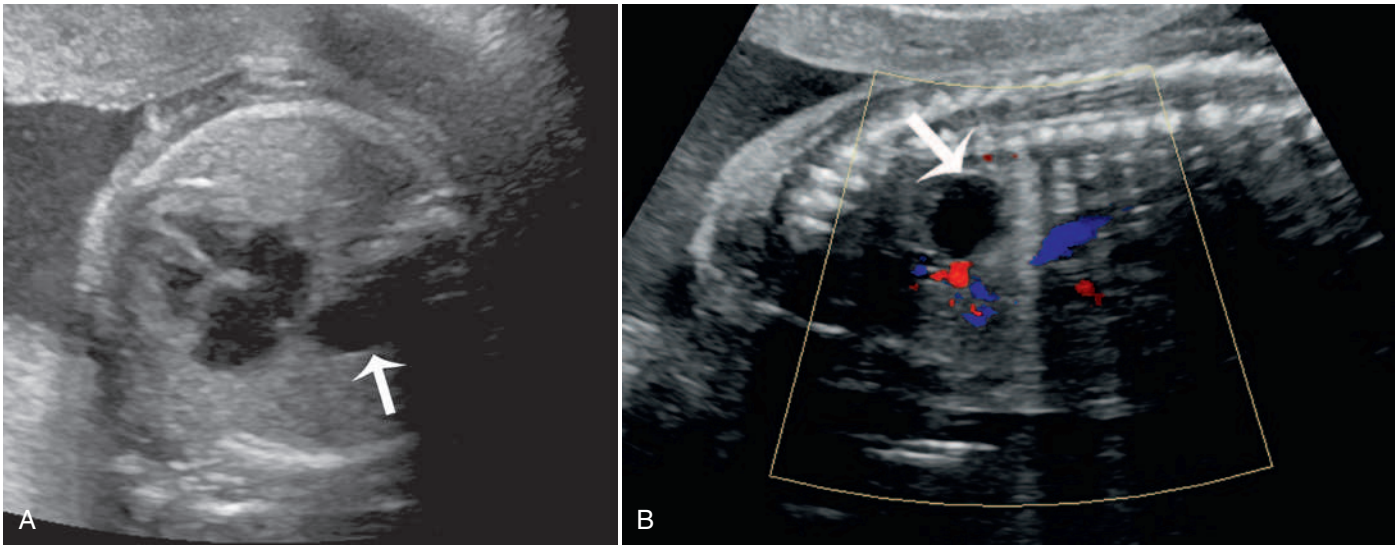

FIG. 36.9 Bronchogenic Cyst at 23 Weeks. (A) Axial gray-scale and **(B)** sagittal color Doppler ultrasound images of the chest demonstrate a simple cyst *(arrow)* posterior to the heart.

because of the associated increased risk for hemorrhage, infection, or malignancy.[131]

NEURENTERIC CYST

Neurenteric cysts represent a posterior enteric remnant caused by incomplete separation of the notochord from the foregut during embryogenesis. They typically occur in the posterior mediastinum or in the spinal canal midline. The cysts can have a septated or bilobed appearance. Associated spinal abnormalities are typically present but difficult to identify prenatally.[132-135] MRI is a useful adjunct in the further evaluation of the spine. **Esophageal duplication cysts** should be considered in the differential of midline chest cysts.

PLEURAL EFFUSION

Any fluid in the pleural space is abnormal. If sufficiently large, pleural effusion may result in mass effect, leading to compression of the heart and hydrops as well as compression of the lungs, resulting in pulmonary hypoplasia.[136]

Primary pleural effusion is rare, with an incidence of up to 1 in 15,000 pregnancies.[137,138] It is most often caused by chylothorax,[139] which results from defective development of the lymphatic system. Any insult to the course of the **thoracic duct** in the posterior mediastinum in the fetal chest can result in chylous fetal pleural effusion.[140] This can be on either the right or the left side, because the thoracic duct in the posterior mediastinum crosses from right to left at the fifth thoracic level. Primary pleural effusion is suspected when the effusion is unilateral or is much larger on one side than the other and when no other signs of hydrops are present. Primary effusions are characterized by having high pressures, resolving rapidly after thoracentesis and developing hydrops restricted to the upper fetal body.[141]

Primary chylothorax is associated with aneuploidy in 2% to 6% of cases.[142,143] By definition, chylothorax in neonates is identified when fluid contains more than 1.1 mmol/L triglycerides with oral fat intake, with lymphocyte proportion exceeding 80%.[144] However, the fetus is fasting in utero, and the mean percentage of lymphocytes in the blood of normal fetuses is normally greater than 80%.[145] Therefore these parameters do not apply in utero.

Secondary pleural effusion occurs in association with aneuploidy **(Turner syndrome or trisomy 21), infection** (**TORCH** [toxoplasmosis, rubella, cytomegalovirus, herpes simplex, HIV]), genetic syndromes, and other structural malformations (**CPAM, BPS, lymphangiectasia,** cardiac anomalies).[142-145] These syndromes typically present with bilateral pleural effusions (particularly in fetuses with hydrops)[140] but occasionally with unilateral effusion.

Pleural effusions appear on prenatal ultrasound as anechoic fluid collections in the pleural space, leading to the appearance of the lung floating in the fluid, surrounded by the chest wall and diaphragm[146] (Fig. 36.10, Video 36.2). Small effusions appear as an anechoic thin rim outlining the lungs and the mediastinum. Larger unilateral effusions result in mass effect, causing mediastinal shift and flattening or eversion of the diaphragm. If isolated and small, pleural effusions have a benign course. If large with mass effect, untreated fetal pleural effusion has a mortality rate of 22% to 53%.[137,140,147-149]

Small pleural effusions do not shift the mediastinum. Pleural effusions associated with hydrops may be unilateral or bilateral, often beginning as unilateral collections that progress bilaterally. Once hydrops develops (cardiac compression from unilateral effusion), distinguishing between primary and secondary effusion can be difficult. If mediastinal shift is visualized in association with a small pleural effusion, a chest mass such as a CDH, CPAM, or BPS should be sought. MRI may help identify associated abnormalities not seen by ultrasound, such as an inconspicuous CPAM or BPS. Depending on the content of the pleural fluid (lipid, protein, or blood products), different signal intensities might be seen with MRI in both T1- and T2-weighted images that may help establish the causal diagnosis.[150]

Prenatal pleural effusion has a variable natural course ranging from spontaneous resolution to progressive development of hydrops and polyhydramnios with high risk for perinatal morbidity and mortality.[140] An effusion ratio can be obtained by ultrasound (area of effusion divided by area of thorax) and followed with serial examinations. If it elevates, it increases the risk of evolution to hydrops,[141] but no cutoff ratio has demonstrated usefulness as a prognostic tool.[151]

A fetal assessment for associated anomalies, including echocardiography, maternal serology for infections, and fetal karyotyping, should be performed.[141,152] Prognosis depends on the presence of associated abnormalities, whether it is unilateral or bilateral, the size of hydrothorax, and severity of mediastinal shift. A small primary hydrothorax can have spontaneous resolution in 22% of cases.[142] Unilateral effusions, spontaneously resolved effusions, and those without mediastinal shift or hydrops have a 73% to 100% survival rate.[140,141]

Progression from unilateral to bilateral effusions is associated with impending hydrops. When large, bilateral, and with mediastinal shift, the mortality rate increases to 52%.[140] With progression to hydrops, the mortality rate increases to 62%.[140] Secondary hydrothorax has a worse outcome. The mortality rate in these cases can be up to 98% depending on size, progression to hydrops, and underlying cause.[140]

Pleural effusions are treated by drainage if the effusion is isolated (or asymmetrical) without additional anomalies, typically in fetuses at risk for developing hydrops (i.e., those with severe mediastinal shift or with other signs of hydrops already present).[63] Typically, a pleural effusion is drained with a single stick procedure.[153] If it recurs, placement of a thoracoamniotic shunt is an option.[154] A series of 65 fetuses showed thoracoamniotic shunts to have a high survival rate in nonhydropic fetuses of 93%, with survival of 86% in the hydropic group.[4] Risks of prenatal thoracoamniotic shunts include fetal hemorrhage, blockage or migration of the shunt, and placental abruption or preterm labor. In cases of large effusions, drainage immediately before delivery can assist in airway management at birth. A 2007 systematic review of prenatal intervention for isolated primary pleural effusion without hydrops suggested that survival rates after prenatal intervention are as high as 60%.[138]

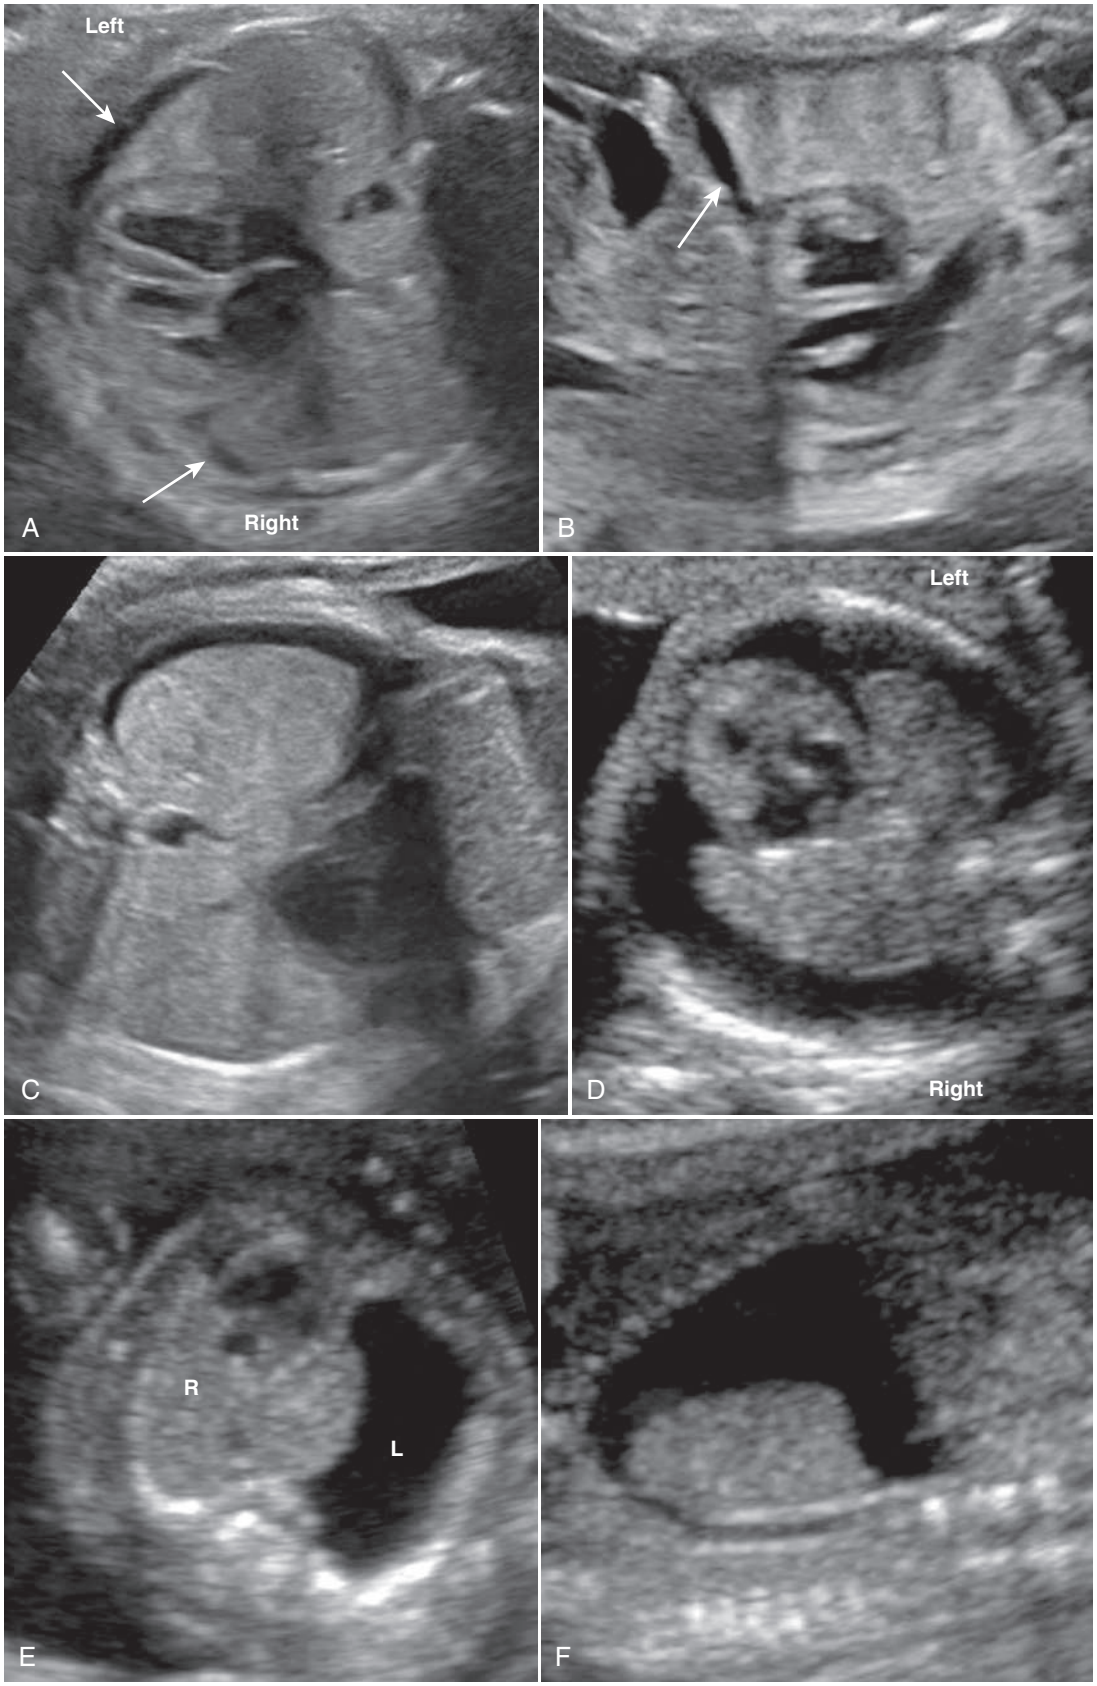

FIG. 36.10 Pleural Effusion. (A) Axial and **(B)** coronal views of small pleural effusions at 25 weeks *(arrows).* **(C)** Axial view of effusion at 28 weeks with mild mediastinal shift. **(D)** Axial view shows moderate bilateral effusions outlining the lungs. The effusions are about the same size, so there is no mediastinal shift. **(E)** Axial and **(F)** oblique sagittal views at 17 weeks show a large left effusion *(L)* with severe mediastinal shift to the right *(R).* See also Video 36.2.

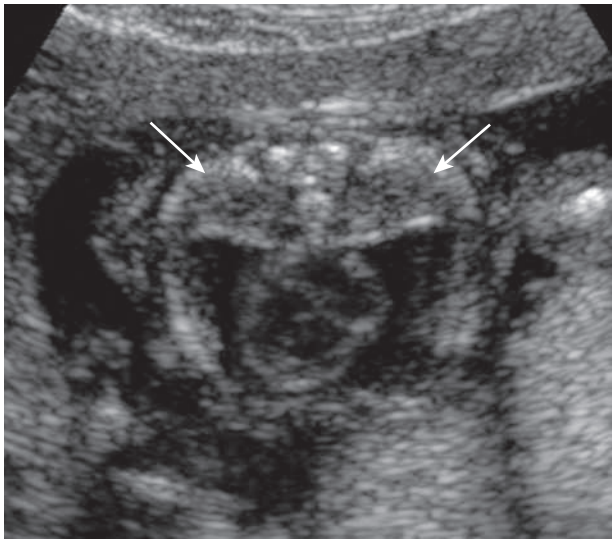

FIG. 36.11 Pericardial Effusion. Note how the lungs *(arrows)* are compressed posteriorly in the fetal chest by the effusion surrounding the heart.

Case reports of other treatment options include pleurodesis and intrapleural injection of autologous blood, which yield a survival rate of 80%.[155,156]

PERICARDIAL EFFUSION

In contrast to pleural effusions that surround the lungs and compress the tissue medially, pericardial effusions are antero-medial fluid collections. Fluid collections of up to 2 mm in thickness are common, and a small amount of pericardial fluid (up to 7 mm, in isolation) can be a normal finding.[157] A large pericardial effusion compresses the lungs against the posterior chest wall (Fig. 36.11). The heart is visualized as "floating" within the anterior thoracic fluid collection.

PULMONARY LYMPHANGIECTASIA

Pulmonary lymphangiectasia is a congenital obstruction and dilation of the pulmonary lymphatic system. The lungs become enlarged and stiff, with development of effusions that can result in respiratory failure. There are primary and secondary forms of pulmonary lymphangiectasia. The secondary form is caused by congenital heart diseases that result in poor venolymphatic return.[158-160] Ultrasound findings can be subtle with pleural effusions and heterogeneous lung parenchyma (Fig. 36.12). The use of echocardiography is important to exclude cardiac anomalies.

Fetal MRI demonstrates pleural effusions and lung heterogeneity. Tubular T2-hyperintense branches may be present radiating from the hila. A heterogeneous pattern referred to as the "nutmeg lung" (Fig. 36.12C) provides a more specific diagnosis.[161]

Postnatal management includes restriction of dietary fats, pleural effusion drainage, pleurodesis, and thoracic duct ligation. Recent experimental treatment using ethiodized oil to embolize the patulous pulmonary lymphatics has shown some success.[162]

CONGENITAL DIAPHRAGMATIC HERNIA

CDH results from failure of the pleuroperitoneal canal to close at the end of organogenesis.[163] A "dual hit" hypothesis suggests that the defect arises in the embryologic period (first hit), and during further gestation, lung development is impaired (second hit).[164] The defect in the diaphragm allows herniation of viscera into the chest. Mass effect from visceral organs in the chest has an adverse impact on the normal development of the fetal cardiac and pulmonary systems. Thus CDH is associated with substantial morbidity and mortality.[165-168] The incidence of CDH is about 1 in 3000 births.

CDHs can be classified based on location; types include posterolateral Bochdalek hernia (70%-75%), anterior Morgagni hernia (23%-28%), and central defects (2%-7%). Most CDHs (85%-90%) are left sided, 10% to 15% are right sided, and only 2% are bilateral.[169-173] Complete **agenesis of the diaphragm,** herniation of the central tendinous part, **pericardial hernia,** membrane-covered hernias, and **eventration of the diaphragm** are rarer manifestations.[173]

Ultrasound findings of CDH include presence of stomach bubble, gallbladder or bowel within the thoracic cavity, deviation of the heart and mediastinum, herniated liver, abnormal position of the umbilical and hepatic veins, pleural effusion, and polyhydramnios.[170,174,175] The abdominal circumference is often small, with a scaphoid shape of the abdomen secondary to displacement of viscera into the chest.[176]

Left-sided CDH is most often diagnosed when the stomach is in the chest near the left atrium, with absence of the normal stomach below the diaphragm (Fig. 36.13, Videos 36.3 and 36.4). Small and large bowel as well as the liver, spleen, and kidney can herniate into the thorax. As the abdominal contents herniate into the chest, mediastinal shift occurs with the heart deviating to the right.[9,172,177] In large hernias, mediastinal shift is severe, leading to vascular compromise. Compression of the heart, impaired swallowing, and partial obstruction of the gastrointestinal tract lead to polyhydramnios, which is present in up to 69% of cases, particularly late in gestation (by the third trimester).[165,178,179]

Prenatal sonographic diagnosis of CDH can be made as early as the first trimester.[180-182] Detection rate sonographically in centers with screening programs is as high as 74%, with an increased detection rate when CDH is associated with other anomalies.[183]

At times, a left-sided hernia will be present with the stomach in the abdomen and only small bowel loops in the chest. Real-time ultrasound can demonstrate peristalsis of the bowel in the chest. Paradoxical movement of abdominal contents during fetal inspiration on real-time sonogram may help to confirm CDH, along with traditional sonographic findings.[166]

In most left-sided hernias the left lobe of the liver herniates into the chest. The diagnosis of liver in the chest is made by direct visualization of the liver (Video 36.5). At times, sonographic detection of intrathoracic liver is difficult because of the liver's isoechoic appearance with the fetal lung. In these cases,

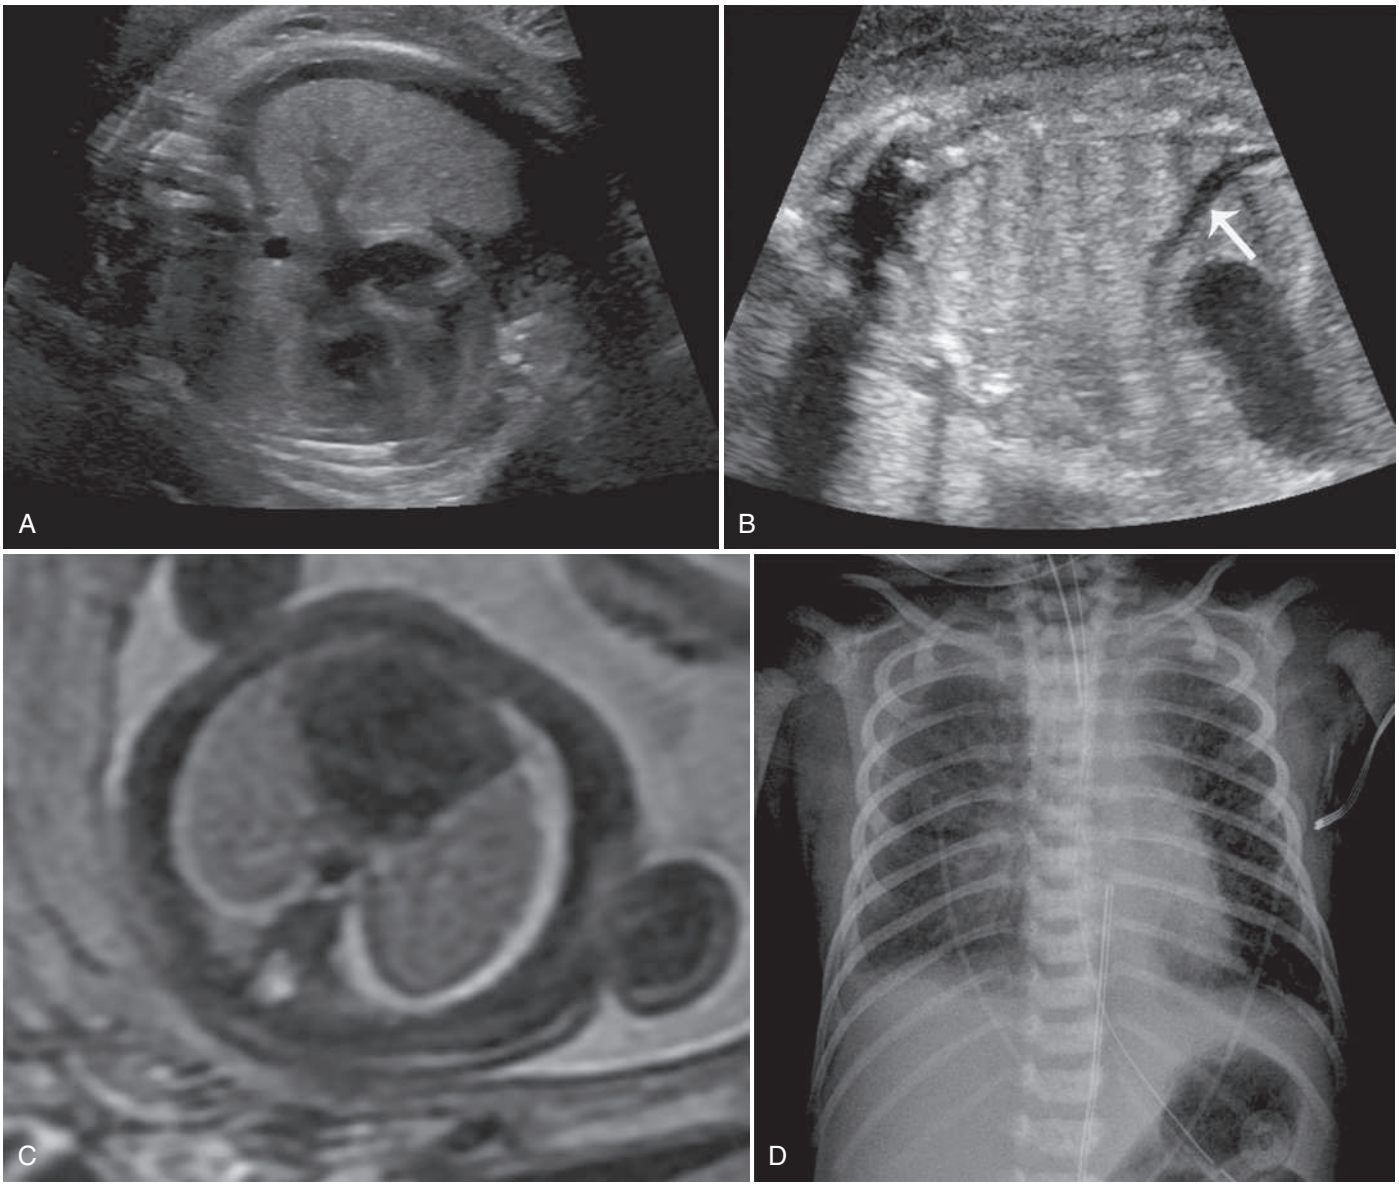

FIG. 36.12 Congenital Primary Pulmonary Lymphangiectasia. (A) Axial and **(B)** sagittal sonograms of the fetal chest at 28 weeks' gestation demonstrate pleural effusions *(arrow)*. The underlying lungs are heterogeneous. **(C)** Axial T2-weighted image confirms the presence of small effusions and heterogenous lung parenchyma "nutmeg" in appearance. **(D)** Chest radiograph at 2 days of age demonstrates course interstitial markings and small effusions, right greater than left.

examination of the course of the portal and hepatic veins is helpful to demonstrate hepatic vessels extending into the chest.[177] The intraabdominal hepatic vein takes a curved course (Fig. 36.13E), and the left portal vein branches will be seen at or above the diaphragm.[174]

In a right-sided hernia, the liver herniates into the chest, and mediastinal shift is to the left (Fig. 36.14, Video 36.6). Liver echogenicity can appear similar to the lung, so visualization of gallbladder and hepatic vessels in the thorax is helpful in confirming the diagnosis. Bowel can also herniate, but the stomach is located below the diaphragm. Because of kinking of the intrahepatic inferior vena cava, ascites (with fluid extending into the chest) and hydrops can develop. Absence of the hypoechoic muscular diaphragm on the right helps in differentiating CDH from other fetal chest masses.

Complete anatomic examination should be performed to assess for presence of associated anomalies (25%-75%). Echocardiography is indicated because congenital cardiac defects occur in 10% to 35% of cases and decrease survival from 73% to 67% if it is a minor defect or to 36% if it is a major complex cardiac defect.[184]

MRI is a useful adjuvant for confirming the diagnosis of a CDH and assessing for additional abnormalities. MRI better demonstrates the position of the liver and the amount of herniation due to differentiation of the hepatic lobe (bright on T1-weighted imaging) from the compressed lung or a solid type

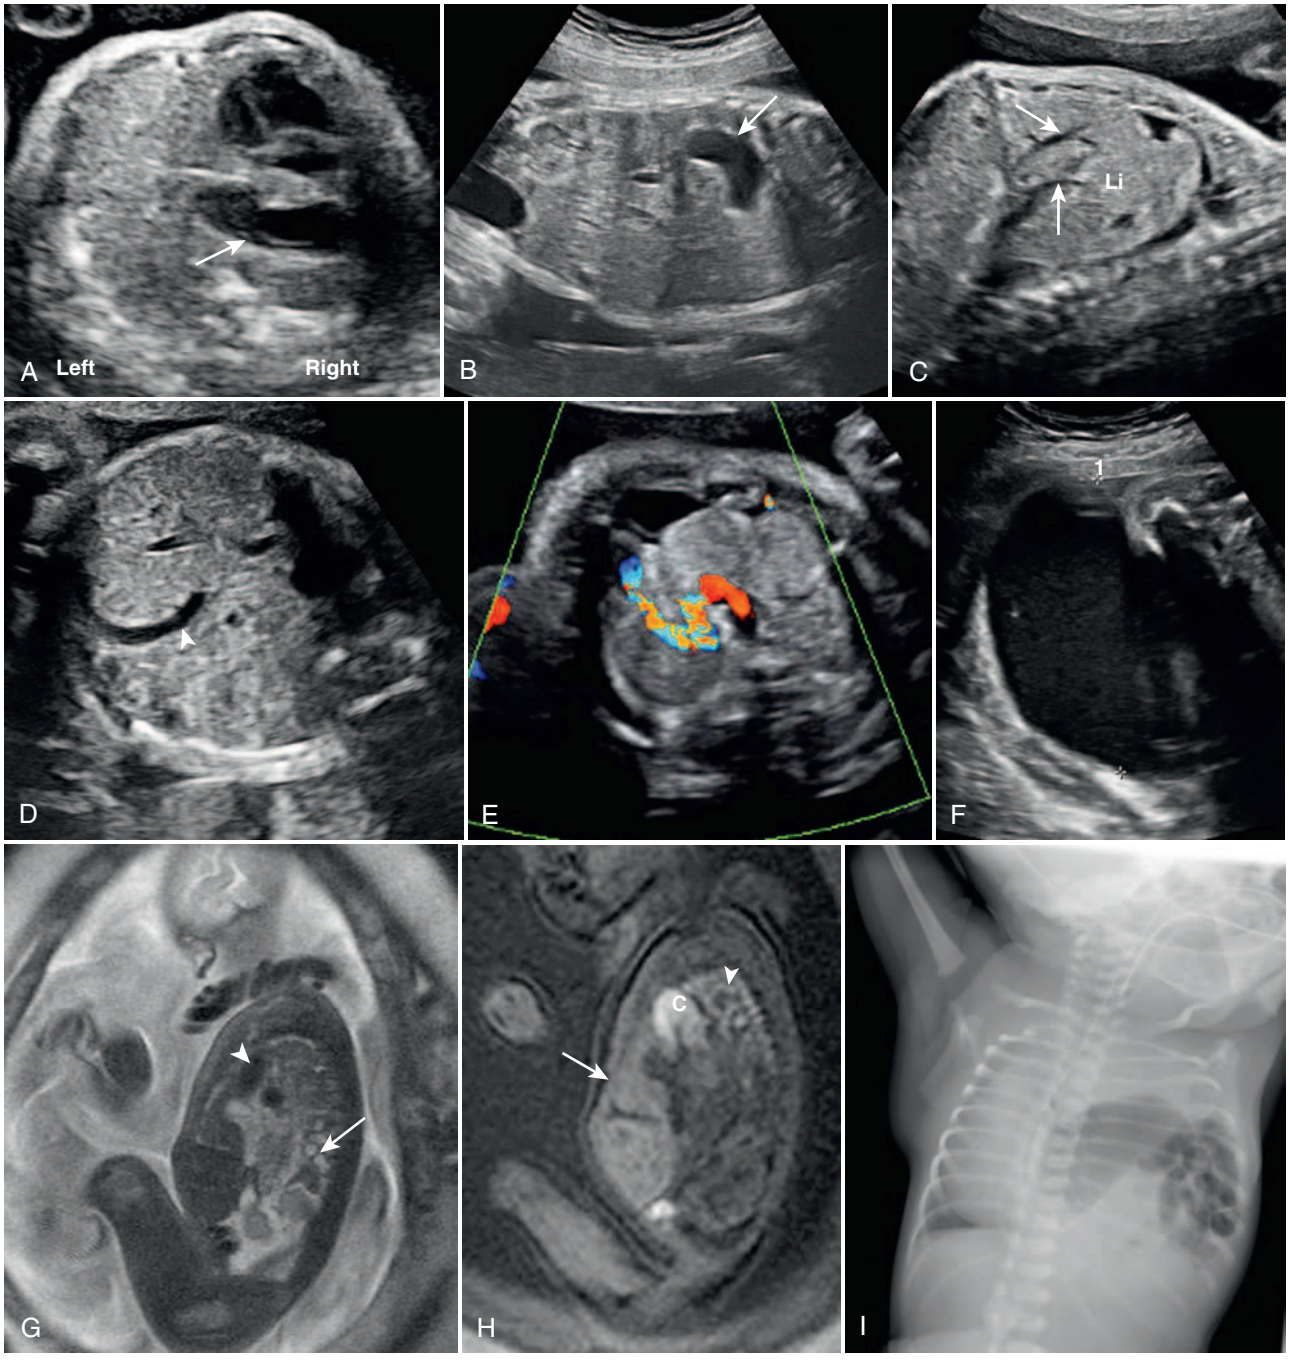

FIG. 36.13 Left-Sided Congenital Diaphragmatic Hernia. (A) Axial view of chest at 28 weeks' gestation shows the stomach *(arrow)* in the chest with mediastinal shift to the right. **(B)** Coronal image in a different fetus at 28 weeks shows a slightly distended stomach *(arrow)* in the chest. **(C)** Oblique sagittal image shows a large amount of liver *(Li)* in the chest. Note the hepatic vessels *(arrows).* **(D)** Axial view of abdomen shows abnormal course of umbilical vein *(arrowhead)* resulting from the liver herniation into the chest. **(E)** Oblique axial view of chest shows kinked hepatic vessels. **(F)** Axial view in the right lower quadrant shows the associated polyhydramnios complicating the pregnancy in the same fetus. **(G)** Sagittal T2-weighted fetal MRI shows the small bowel *(arrow)* and colon *(arrowhead)* in chest with small pleural effusion. **(H)** Sagittal T1-weighted fetal MRI shows liver *(arrow)* in chest. Note bright signal of meconium in colon *(C)* in chest, as well as small bowel loops *(arrowhead)* in chest. **(I)** Postnatal radiograph shows the bowel in the left chest, nasogastric tube in the left chest, and a tiny, hypoplastic right lung. See also Videos 36.3, 36.4, and 36.5.

of CPAM.[185-187] MRI can reveal the location of bowel because of the bright T1 signal of meconium. If the superior aspect of herniated bowel is rounded with trapped fluid below, a hernia sac can be suggested. These membrane-covered hernias are associated with a better prognosis.[185] MRI is also useful for the visualization of the normal ipsilateral and contralateral lung, allowing for the measurement of lung volumes useful for predicting outcome.[188] MRI measurements include total lung volume, observed-to-expected total fetal lung volume (o/e TFLV), percent predicted lung volume (PPLV), fetal

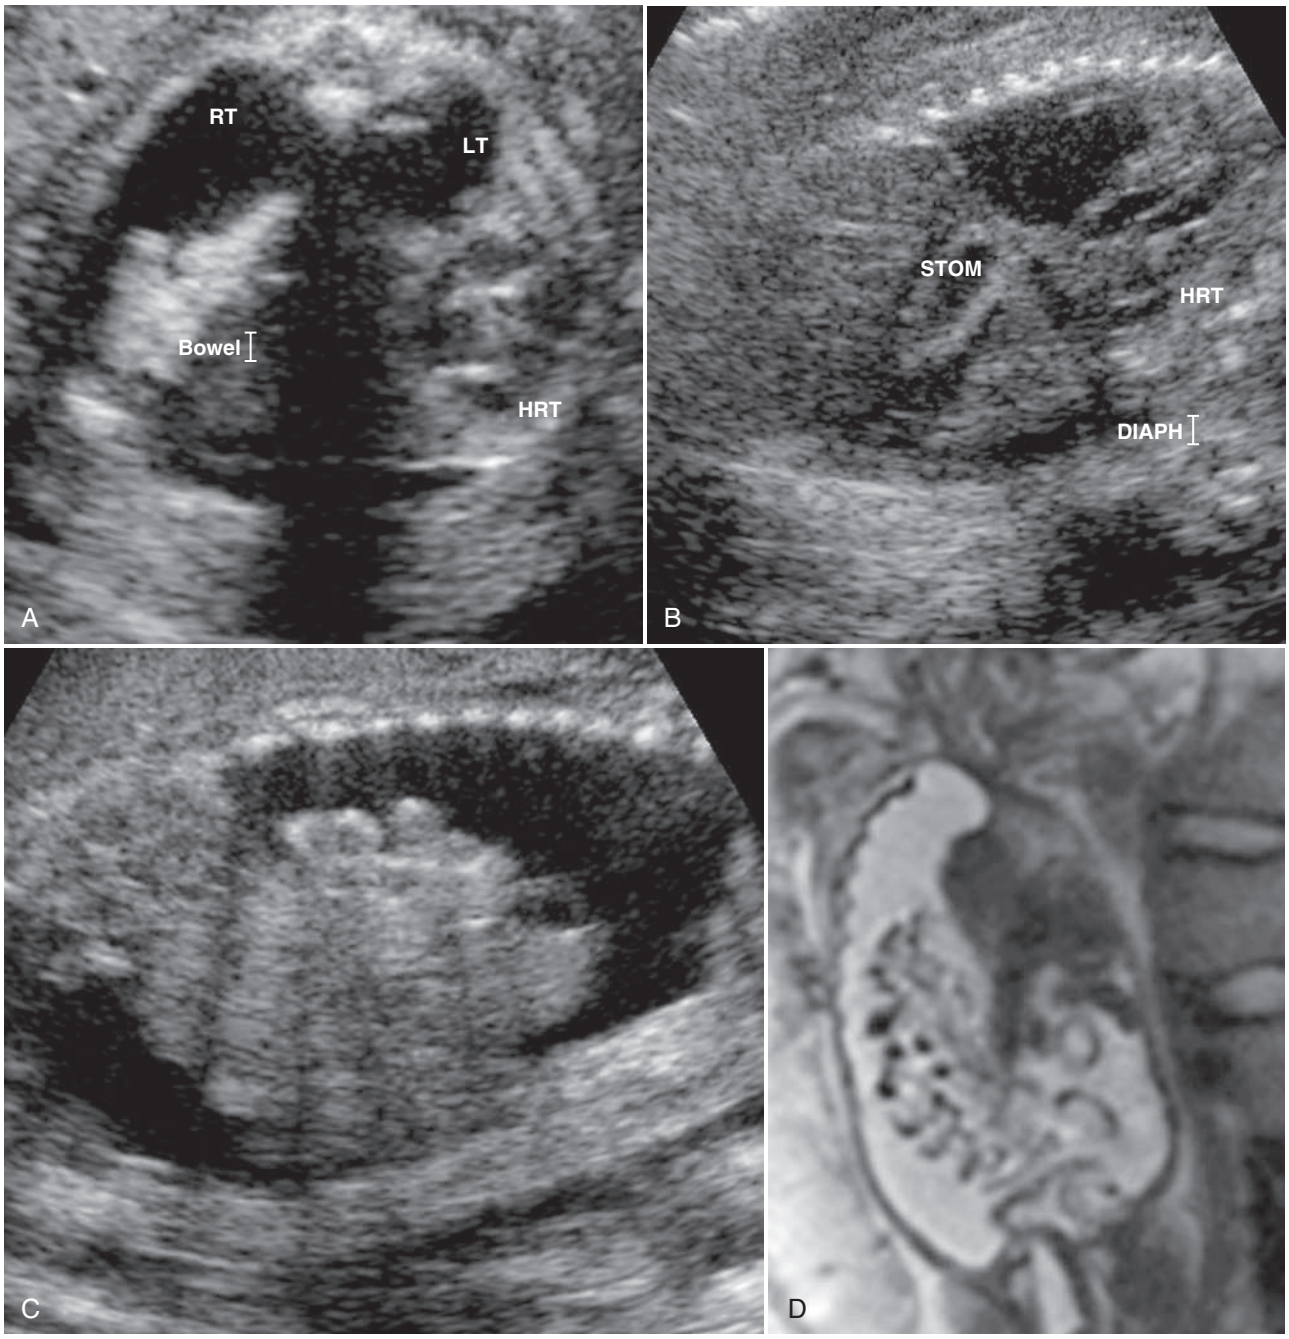

FIG. 36.14 Right-Sided Congenital Diaphragmatic Hernia at 30 Weeks. (A) Axial and **(B)** and **(C)** oblique sagittal images show bilateral pleural effusions *(RT, LT)* and bowel loops in the right hemithorax with mediastinal shift with heart *(HRT)* displaced to the left. The left hemidiaphragm *(DIAPH)* is intact, with the stomach *(STOM)* below the diaphragm. **(D)** Coronal T2-weighted MRI shows fluid extending from the abdomen into the chest with mediastinal shift to left. Note the lack of a right hemidiaphragm, as well as bowel in the right chest. See also Video 36.6.

lung volume to fetal body volume (FLV/FBV) ratio, percent liver herniation (%LH), and herniated liver to fetal thoracic volume ratio (LiTR).[186,188] MRI can also measure the diameter of the aorta and pulmonary arteries used to obtain the modified McGoon index as a prognostic indicator of pulmonary hypertension.[189]

Prognosis varies depending on the side of the herniation, the position of the liver, associated abnormalities, and gestation age at diagnosis.[190-196] The presence of a large amount of herniated liver decreases survival substantially.[197] The severity of lung hypoplasia and lung hypertension are major determinants in mortality and morbidity rates.[31,198,199] A large hernia diagnosed early in gestation results in relatively worse pulmonary hypoplasia with a resulting higher mortality rate than does a small hernia diagnosed late in gestation without associated findings. Bilateral hernias are typically fatal. Familial and syndromic hernias usually have a worse prognosis compared to isolated hernias.[184,191-195]

Poor Prognostic Factors in Congenital Diaphragmatic Hernia

Right-sided or bilateral hernia
Early gestational age at diagnosis
Small lung size (measured by lung-to-head ratio or volumetry)
Associated abnormalities (structural or chromosomal)
Hydrops
Polyhydramnios
Degree of mediastinal shift
Intrauterine growth restriction
Liver in chest

Predictors of Decreased Survival in Congenital Diaphragmatic Hernia

Ultrasound LHR < 1
Ultrasound o/e LHR < 25%
Three-dimensional ultrasound TFLV < 35%
Low o/e pulmonary artery ratios
MRI o/e TFLV < 25%
MRI PPLV < 15%
MRI LiTR > 20%

LHR, Lung-to-head ratio; *LiTR,* liver to fetal thoracic volume ratio; *MRI,* magnetic resonance imaging; *o/e,* observed-to-expected; *PPLV,* percent predicted lung volume; *TFLV,* total fetal lung volume.

With the use of ultrasound and MRI various measurements have been taken to estimate the severity of lung hypoplasia and probable outcome of the fetus. By ultrasound, the **lung-to-head circumference ratio** (LHR) has been used as a predictor of outcome for left-sided CDH. To obtain this ratio the right lung is measured at the level of the four-chamber view and that number is divided by the head circumference to standardize for gestational age. Metkus et al. first described the LHR, noting those with an LHR less than 0.6 did not survive.[31] Laudy et al. found that an LHR less than 1 had 100% mortality whereas an LHR greater than 1.4 predicted a 100% survival.[200] The LHR appears to be most reliable between 24 and 34 weeks' gestation.[201]

Three techniques to calculate the LHR using ultrasound have been described:

1. At the four-chamber heart, the largest transverse dimension of the right lung is drawn parallel to the sternum and the largest anteroposterior measurement is obtained at a perpendicular angle. These are multiplied and then divided by the head circumference in millimeters.
2. At the four-chamber heart, the maximum transverse measurement is multiplied by the longest perpendicular anteroposterior measurement. These are multiplied, and then the total is divided by the head circumference in millimeters.
3. At the four-chamber heart, the outline of the right lung is traced in millimeters and then divided by the head circumference.

The tracing method has been shown to be the most accurate in predicting survival in some centers.[202] Generally an LHR less than 1 suggests a poor outcome, with a survival rate of 45%.[203,204] The variability of LHR's prognostic value is due to differences in methodology and dependence on gestational age resulting in a controversial association with mortality.[204,205]

To improve outcome assessment, another ultrasound measure, **the observed-to-expected lung-to-head ratio (o/e LHR)** has been used. This ratio appears to have a better predictive value compared with LHR.[206-209] A ratio of less than 25% is associated with lower survival rates.[207,210]

Three-dimensional ultrasound has been utilized in patients with CDH to assess lung volume. An o/e TFLV less than 35% shown to predict survival. However, in up to 45% of cases, the measures are suboptimal with sonographic measurements typically 25% lower than MRI values.[206]

Prenatal pulmonary artery measurements at the hila at the level of the four-chamber view have been performed.[211-214] Measuring the main right and left pulmonary artery and comparing with normals via an observed-to-expected ratio shows a reduction in values in fetuses with CDH and pulmonary hypoplasia. Doppler wave forms have been useful in defining the most severe CDH cases. Increased pulmonary artery pulsatility index (>1) and peak early diastolic reversed flow in the main pulmonary artery (>3.5) reflect high resistance in pulmonary vascular bed with preferential flow through the ductus arteriosus and are correlated with poor lung growth.[215,216]

Other tests utilized in CDH include a hyperoxygenation test for pulmonary vascular reactivity at 31 to 36 weeks' gestation, in which reactivity (20% reduction in pulmonary artery pretest pulsatility index) suggests a good outcome,[217,218] and assessment of fractional moving blood volume because a decrease in this fraction is correlated with decreased lung growth and an increased intrapulmonary artery impedance in CDH.[219-223]

Patients with fetuses with CDH generally undergo extensive prenatal imaging and counseling. Follow-up ultrasound examinations should be performed to assess fetal well-being, amniotic fluid levels, lung volume, and changes in mediastinal shift that could result in hemodynamic changes.

Other Hernias and Eventration

In **bilateral hernias** the falciform ligament is drawn into the hernia.[224,225] Mediastinal shift is variable, but typically the heart is displaced anteriorly and superiorly. Features of both right- and left-sided CDH are present.

Pericardial hernias result from failure of the retrosternal portion of the septum transversum to close the communication between the pericardial and peritoneal cavities.[226] The liver may herniate into the pericardial sac.[171,225] Pericardial effusion results from mass effect on the heart and obstruction of venous return or from mechanical irritation of membranes.[227] Because the differential diagnosis of a pericardial mass includes pericardial tumors such as teratoma, it is important to recognize the liver as part of the hernial sac contents by identifying the hepatic vessels in the mass.[219,228]

In **diaphragmatic eventration** the intact diaphragm is displaced cephalad at the weakened muscular portion, without communication between the abdominal and thoracic cavities[229] (Fig. 36.15). Diaphragmatic eventration is associated with a lower

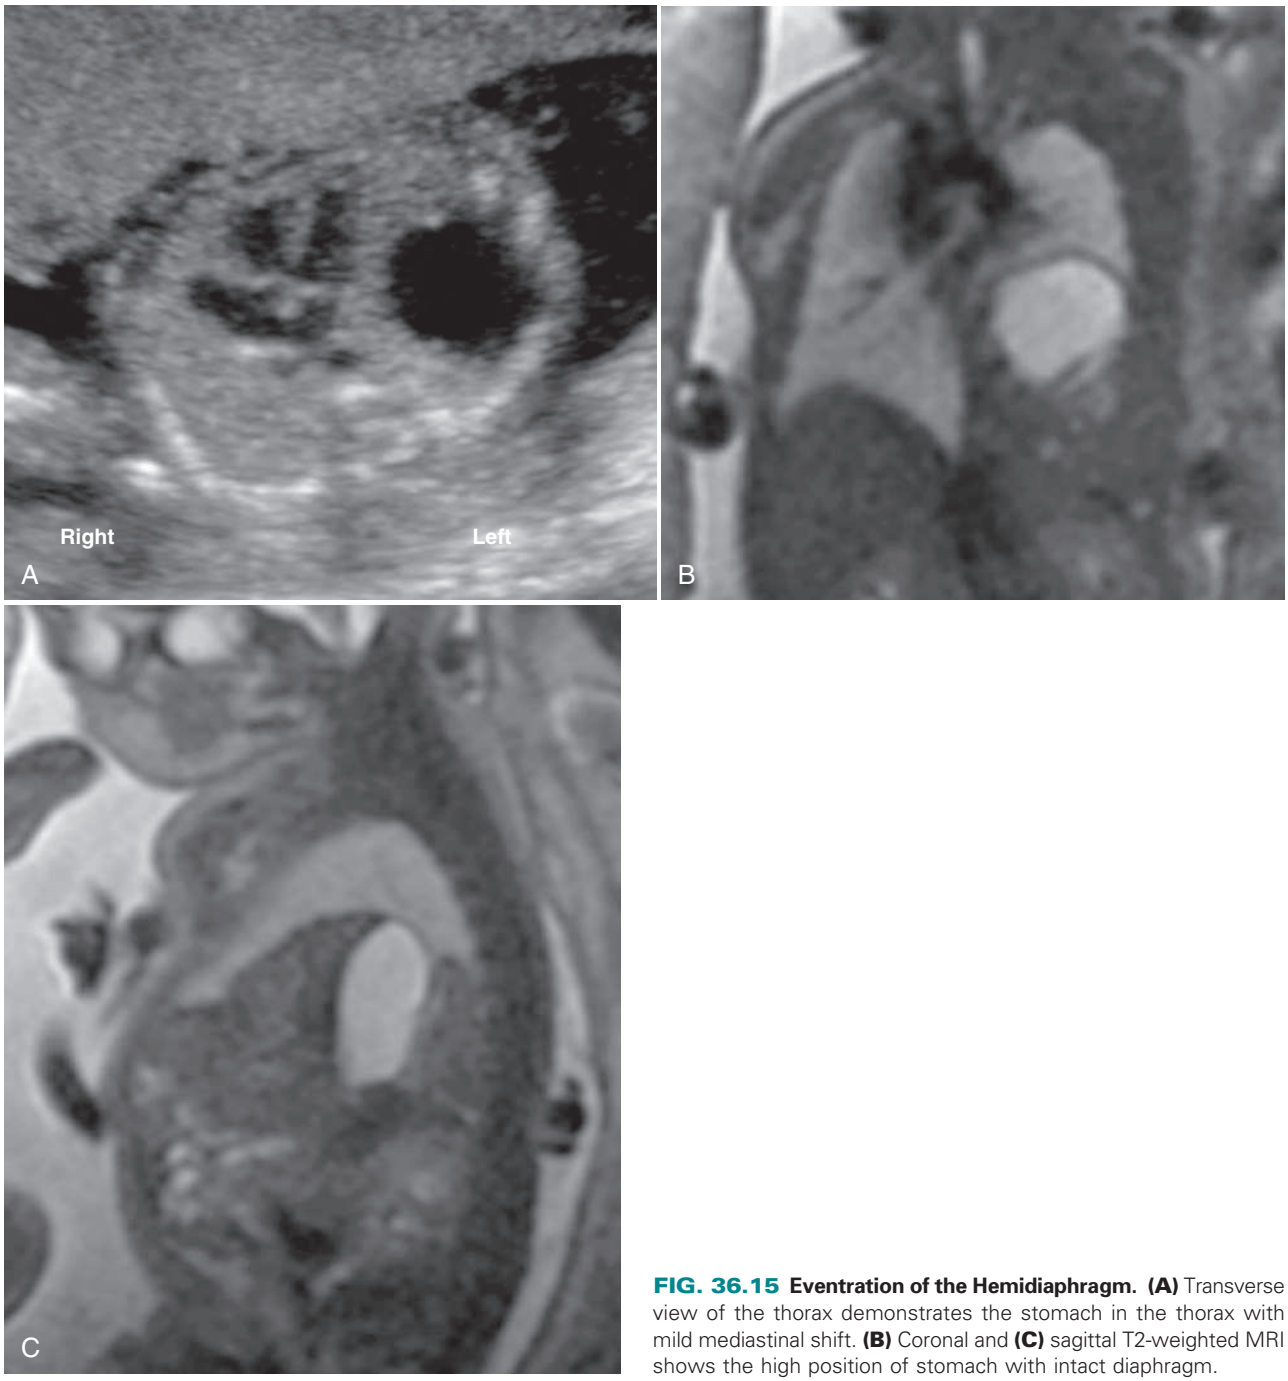

FIG. 36.15 Eventration of the Hemidiaphragm. (A) Transverse view of the thorax demonstrates the stomach in the thorax with mild mediastinal shift. **(B)** Coronal and **(C)** sagittal T2-weighted MRI shows the high position of stomach with intact diaphragm.

perinatal mortality rate compared to CDH and may not require surgical repair. Thus it is crucial to make the distinction between the two diagnoses to provide appropriate counseling.

Associated Anomalies

CDH may be an isolated defect or may be associated with other structural, chromosomal, or syndromal anomalies. Associated anomalies are present in 25% to 55% of cases. **Congenital heart disease** is the most common association (20%), with hemodynamically significant heart disease in 11% of cases.[230-232] Because of the high rate of associated cardiac abnormalities, formal fetal echocardiography is indicated in fetuses with CDH.

Associated central nervous system anomalies are second in frequency of associated structural abnormalities in fetuses with CDH; these anomalies include **anencephaly, ventriculomegaly,** and **neural tube defects.**[191] Chromosomal abnormalities occur in 10% to 20% of antenatally detected CDH, the most common being **trisomy 18.**[192,193] Chromosomal abnormalities are most common when CDH is present in association with other structural abnormalities. Given the high association with aneuploidy, chromosomal assessment is typically performed. Associated syndromes include **Fryn, Beckwith-Wiedemann, Simpson-Golabi-Behmel, Brachmann–de Lange,** and **Perlman.**[195]

TABLE 36.5 Sample Studies of Predictors of Survival in Left-Sided Congenital Diaphragmatic Hernia

Imaging Findings	Sign/ Value	Outcome (% Survival)
Liver position[208]	Liver up	45%
	Liver down	93%
LHR ratio[208]	<1	35%
	>1	75%
o/e LHR[210]	<25%	poor
o/e TLV MRI[184,207]	<25%	poor (13%)

LHR, Lung to head ratio; *o/e*, observed to expected; *TLV*, total lung volume.

Morbidity and Mortality

Mortality varies widely depending on gestational age at diagnosis, side of the hernia (right-sided hernias have poorer survival than left-sided hernias,[195] and bilateral hernias have worse prognosis than do unilateral hernias), associated abnormalities, hernia size, liver position,[183] presence of hydrops, degree of mediastinal shift, polyhydramnios, and size of the residual lung.[31] Table 36.5 provides examples of using imaging findings to predict prognosis (survival predictors).

Mortality from CDH can be high because of termination of pregnancy and in utero demise (secondary to associated abnormalities and hydrops). After birth, CDH results in high rates of morbidity and mortality because of pulmonary hypoplasia, pulmonary hypertension, and iatrogenic trauma to the airways from mechanical ventilation. Pulmonary hypertension in newborns in association with CDH is thought to be caused by the wall thickening of the small pulmonary arteries. Severity of pulmonary hypoplasia and pulmonary hypertension is related to the volume and timing of herniation of abdominal viscera into the hemithorax.[233,234] In a 2000 meta-analysis[234] of studies from 1975 to 1998, of 676 prenatally diagnosed fetuses, 142 (21%) were terminated, 36 (5%) died in utero, 333 (49%) died postnatally, and only 165 (24%) survived. More recent studies show improved survival rates. In a 1999-2001 trial, survival of fetuses (without in utero intervention) with an LHR of less than 1.4 and liver in the chest (i.e., fetuses presumed to have poor survival rates) was 77%.[235] Impro`ved overall survival rates in recent years have been attributed to alterations in clinical care for CDH, including minimization of iatrogenic lung injury by gentle ventilation and nutritional support.[232,236-238] Outcome is improved if delivery is at a center with health care professionals experienced in caring for infants with CDH.

In Utero Therapy

Options for treatment of CDH focus on lung development. Small hernias with a large amount of visualized lung or hernias diagnosed late in pregnancy can be delivered at a tertiary care center where NICU services (including ECMO) are available. EXIT to ECMO has been offered in some centers but has not demonstrated significant survival benefit.[197]

Fetal surgery can be performed at specialized centers for fetuses least likely to survive with conventional postnatal therapies.[180] Surgery is performed to aid in lung growth and typically is not directed at repair of the diaphragmatic defect, because open fetal surgery is associated with premature rupture of membranes and premature labor. In addition, repair of CDH is associated with intraoperative death caused by kinking of the umbilical vein and ductus venosus as the liver is reduced into the abdomen.[239]

Current in utero therapy is aimed at **fetal endoscopic tracheal occlusion** (FETO), by balloon or clips, which stimulates lung growth.[240-242] The procedure is performed under combined spinal and epidural anesthesia and fetal analgesia. A 1.2-mm endoscope within a 3.0-mm sheath is introduced into the trachea to place a detachable balloon between the carina and vocal cords.[243] FETO has improved prognosis of severe CDH, with its effect dependent on the preexisting lung size. Other treatment options, such as combining FETO with other modalities (e.g., surfactant, corticosteroids), are being investigated.[244,245]

New nonsurgical prenatal options are being evaluated, including pharmacologic treatments and stem cell–based strategies, and could be promising in treating pulmonary hypertension and hypoplasia.

CONCLUSION

When an abnormality of the fetal thorax is visualized, it is important to have a thorough approach to the fetal evaluation. The echogenicity of the lesion, whether it is cystic or solid, location and appearance of the heart, size of normal-appearing lung, evidence of hydrops, and associated abnormalities are important at initial diagnosis. Follow-up to assess interval change in appearance and development of hydrops is important for prognosis. The specific diagnosis is important in determining potential in utero therapy, guiding the appropriate mode of delivery, and explaining to the parents the types of postnatal therapy that may be needed.

CHAPTER 37

The Fetal Heart

Elizabeth R. Stamm and Julia A. Drose

SUMMARY OF KEY POINTS

- Moderate to severe congenital heart disease (CHD) occurs in approximately 6 per 1000 live births.
- The incidence of CHD is much higher in the fetal population, estimated to be at least 15 per 1000.
- The incidence of CHD is higher with positive family history, monochorionic twins, and *in vitro* fertilization.
- Most fetuses with CHD have no known risk factors.
- Fetal echocardiography is a safe and effective method of detecting CHD.
- Early detection of CHD may have a substantial impact on care and prognosis, allowing intrauterine therapy, carefully planned delivery, and parental counseling.
- Advancements in surgical techniques and perioperative management have significantly improved prognosis in many cases.

CHAPTER OUTLINE

NORMAL FETAL CARDIAC ANATOMY AND SCANNING TECHNIQUES
STRUCTURAL ANOMALIES
Atrial Septal Defect
Ventricular Septal Defect
Atrioventricular Septal Defect
Ebstein Anomaly
Hypoplastic Right Ventricle
Hypoplastic Left Heart Syndrome
Univentricular Heart
Tetralogy of Fallot
Truncus Arteriosus
Double-Outlet Right Ventricle
Transposition of Great Arteries
Anomalous Pulmonary Venous Return
Coarctation of Aorta
Aortic Stenosis
Pulmonic Stenosis
Cardiosplenic Syndromes
Cardiac Tumors
Cardiomyopathy
Ectopia Cordis
ARRHYTHMIAS
Premature Atrial and Ventricular Contractions
Tachycardia
Bradycardia
Congenital Heart Block

Sonographic evaluation of the fetal heart can identify cardiac abnormalities that affect obstetric care in a variety of ways, including mode of delivery, location of delivery, intrauterine therapy, parental reassurance, and opportunity for termination. **Congenital heart disease** (CHD) is a significant problem, with an incidence of moderate and severe CHD of approximately 6 per 1000 live births. If trivial lesions such as tiny muscular **ventricular septal defects** (VSDs) are included, the incidence is as high as 75 per 1000 live births.[1] It is more difficult to determine the exact incidence of CHD in the fetal population. One large study suggested that CHD occurs in at least 15 per 1000 fetuses.[2] More than 20% of perinatal deaths caused by congenital malformations are the result of a congenital heart defect.[3] In 85% of CHD cases, both environmental and genetic factors are involved (Table 37.1).[4-7] The remaining 15% of cardiac anomalies are associated with a single gene or chromosomal abnormality.[5] The risk of CHD increases to 2% to 3% with an affected sibling and to approximately 10% with two affected siblings or an affected mother—although the incidence is variable depending on the type of CHD in the affected relative.[5,8] The risk to offspring of affected mothers is substantially higher than for those with affected fathers, suggesting that cytoplasmic inheritance may play a role in the genetics of CHD (Tables 37.2 and 37.3). Only 50% of recurrent heart lesions are of the same type as the previously diagnosed defect.[9]

Extracardiac malformations occur in 25%,[10] and **chromosomal anomalies** occur in 13% of live-born neonates with CHD.[11-13] About 50% of fetuses with nonimmune hydrops and cardiac anomalies have a chromosomal anomaly, and 10% will have extracardiac anomalies.[14] **Hydrops** in the setting of CHD is predictive of a very poor prognosis.

Although the most common indications for formal **fetal echocardiography** are family history of CHD and **fetal arrhythmia,** the majority of these fetuses will have normal hearts. The highest incidence of CHD occurs in patients referred because of an abnormal four-chamber view, fetal hydrops, or significant polyhydramnios on a routine obstetric ultrasound.[15,16] A routine ultrasound examination with a suspected fetal cardiac anomaly is associated with a 50% to 69% risk of CHD in live-born infants.[17,18] Monochorionic twins are at a higher risk for CHD,

TABLE 37.1 Congenital Heart Disease and Associated Risk Factors

Factor	Frequency	Most Common Lesions
MATERNAL CONDITIONS		
Diabetes	3%-5%	TGA, VSD, coarctation
Lupus erythematosus	(1%-5%)	Heart block
Phenylketonuria	(12%-14%)	TOF, VSD, ASD, coarctation
Infection		Cardiomyopathy
Rubella	(1%-2%)	TOF, PS, VSD, ASD, PDA, cardiomegaly
DRUGS		
Accutane (retinoic acid)	8%-20%	Truncus, TGA, TOF, DORV, VSD, AO arch interruption, or hypoplasia
Alcohol	25%-30%	VSD, ASD, PDA, DORV, PA, TOF, dextrocardia
Amantadine		Single vent with PA
Amphetamines	5%-10%	VSD, TGA, PDA
Azathioprine		PS
Carbamazepine		ASD, PDA
Chlordiazepoxide		Unspecified CHD
Codeine		Unspecified CHD
Cortisone		VSD, coarctation
Coumadin		Unspecified CHD
Cyclophosphamide		TOF
Cytarabine		TOF
Daunorubicin		TOF
Dextroamphetamine		ASD
Diazepam		Unspecified CHD
Dilantin (hydantoin)		AS, VSD, ASD, coarctation
Lithium	<2%	Ebstein anomaly, TA, ASD, dextrocardia, MA
Methotrexate		Dextrocardia
Oral contraceptives		Unspecified CHD
Paramethadione		TOF
Penicillamine		VSD
Primidone		VSD
Progesterone		TOF, truncus, VSD
Quinine		Unspecified CHD
Thalidomide	5%-10%	TOF, VSD, ASD, truncus
Trifluoperazine		TGA
Trimethadione	15%-30%	ASD, VSD, TGA, TOF, HLHS, AS, PS
Valproic acid		TOF, coarctation, HLHS, AS, ASD, VSD, interrupted AO arch, PA without VSD
Warfarin (Coumadin)		Unspecified CHD
SYNDROMES		
Apert		VSD, coarctation, TOF
Arthrogryposis multiplex congenita		VSD, coarctation, AS, PDA
Atrial myxoma, familial		Myxoma
Beckwith-Wiedemann		Cardiomegaly
C syndrome (Opitz trigonocephaly)		PDA
Carpenter		VSD, PS, TGA, PDA
Cat's eye (22 partial trisomy)	40%	TAPVR, VSD, ASD
CHARGE		VSD, ASD
CHILD		VSD, ASD
Conradi-Hünermann (chondrodysplasia punctata)		VSD, PDA
de Lange	29%	VSD, TOF, DORV, PDA
DiGeorge		VSD, coarctation, truncus
Ellis–van Creveld (chondroectodermal dysplasia)	50%	ASD, single atrium
Fanconi pancytopenia		ASD, PDA
Goldenhar		TOF, VSD, ASD
Holt-Oram		ASD, VSD

Continued

TABLE 37.1 Congenital Heart Disease and Associated Risk Factors—cont'd

Factor	Frequency	Most Common Lesions

with literature suggesting a ninefold increase in the incidence of CHD in **monochorionic-diamniotic twin** gestations.[19] Lastly, there appears to be a slightly increased risk of CHD with ***in vitro* fertilization** (IVF), although at least some of this increased risk appears to be related to the increased incidence of twin pregnancies associated with IVF.[20] Most fetuses with CHD have no known risk factors, which underscores the importance of a meticulous evaluation of the four-chamber heart views and outflow tracts on all routine obstetric ultrasound examinations. When severe structural cardiac anomalies are identified before viability, termination may be offered. Certainly, one of the most important aspects of fetal echocardiography is the psychological relief it affords parents whenever normal cardiac anatomy and function are documented in a fetus at risk.

NORMAL FETAL CARDIAC ANATOMY AND SCANNING TECHNIQUES

The fetal heart is similar to that of the adult, with several anatomic and physiologic differences. The long axis of the fetal heart is perpendicular to the long axis of the body, such that a transverse section through the fetal thorax demonstrates the four cardiac chambers in a single view. The adult heart, in contrast, is obliquely oriented with its long axis along a line between the left hip and the right shoulder. The **four-chamber view** is important because 10% to 96% of structural anomalies are detectable on this view.[21-26]

Common Indications for Fetal Echocardiography

- Abnormal heart on routine ultrasound
- Hydrops
- Polyhydramnios
- Fetal arrhythmia
- Fetal chromosomal anomalies
- Fetal extracardiac anomalies
- Family history (congenital heart disease [CHD], syndromes associated with CHD)
- Maternal disease (diabetes, collagen vascular, phenylketonuria)
- Maternal infection (rubella)
- Teratogen exposure
- Increased nuchal translucency on first-trimester screening
- *In vitro* fertilization
- Monochorionic twins
- Monitoring response to intrauterine therapy
- Monitoring fetus at risk for decompensation (persistent tachyarrhythmia, hydrops)

Cardiac axis and position are normally such that the apex of the heart points to the left and the bulk of the heart is in the left side of the chest (Fig. 37.1A). This is **levocardia.** In **mesocardia** the heart is central with the apex pointing anteriorly. In **dextrocardia** the apex is directed rightward, and the heart is primarily in the right side of the chest. This abnormality must be distinguished from **dextroposition** (Fig. 37.1B), in which the heart maintains a normal axis but is displaced to the right by an external process, such as a left chest mass or pleural effusion. **Abnormal cardiac axis** is associated with a 50% mortality and **abnormal cardiac position** with an 81% mortality.[27]

The fetal cardiovascular system contains several unique shunts: the **ductus venosus, foramen ovale,** and **ductus arteriosus** (Fig. 37.2). Antenatally, the placenta rather than the lungs is the fetus's sole source of oxygen. Oxygenated blood leaves the placenta through the umbilical vein and travels through the hepatic vasculature and ductus venosus to the inferior vena cava (IVC) and then into the fetal right atrium. As a result of increased velocity, blood entering the IVC via the ductus venosus is shunted

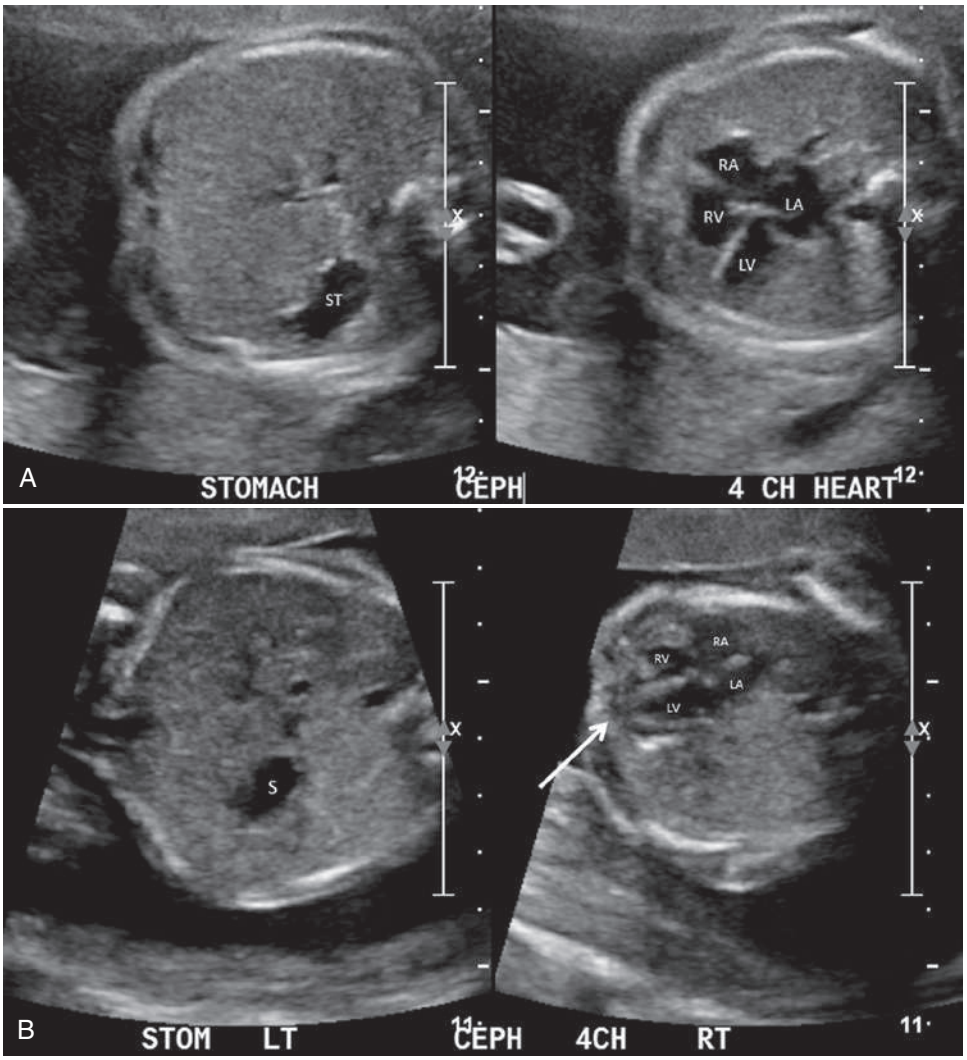

FIG. 37.1 Heart Position and Axis. (A) Normal position and axis of the heart. The heart is predominantly in the left side of the chest, with the apex of the heart pointing leftward. Dual-screen image shows the stomach also on the left side. **(B) Dextroposition** of fetal heart caused by a large, **congenital pulmonary airway malformation.** Transverse image through the fetal chest shows the heart displaced to the right, but the apex *(arrow)* remaining leftward. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle; *S,* stomach. Dual-screen image shows the stomach on the correct left side.

across the foramen ovale to the left atrium and then into the left ventricle, the aorta, and the fetal brain. Poorly oxygenated blood from the superior vena cava (SVC) also enters the right atrium, and mixes with the blood entering from the IVC, but continues to the right ventricle and pulmonary artery. Most of this blood is directed through the ductus arteriosus into the descending aorta. Thus these shunts function so that the majority of output from both ventricles enters the systemic circulation, rather than a substantial portion entering the pulmonary circulation, as in the adult. Blood that enters the pulmonary vasculature via the pulmonary artery is returned to the left atrium by the four pulmonary veins. From the left atrium it enters the left ventricle and ultimately the descending aorta, returning to the placenta via the iliac and umbilical arteries. Normal values for measurements of the fetal heart and great vessels are shown in Figs. 37.3 and 37.4.

Fetal echocardiography is best accomplished at 18 to 22 weeks of gestation.[28] Before 18 weeks, resolution is frequently limited by the small size of the fetal heart. After 22 weeks the examination may be compromised by progressive ossification of the fetal skull, spine, and long bones; the relatively smaller amniotic fluid volume; and unaccommodating fetal position. Importantly, some congenital cardiac abnormalities progress in utero and may be subtle or unrecognizable at or before 22 weeks but more obvious closer to term.[29,30] Tachyarrhythmias may not become apparent until the third trimester.[31] In some cases, first-trimester evaluation of the fetal heart may be accomplished with transvaginal ultrasound as early as 11 to 14 weeks.[32-34] More recently, diagnostic results have been possible with a transabdominal approach at 11 to 13 weeks.[34] However, first-trimester fetal echocardiography is limited and should be considered an adjunct to second-trimester evaluation, not a replacement.

Scanning the fetal heart requires a systematic approach, beginning with determination of the position of the fetus within the uterus and the heart within the fetal chest. A transverse view through the fetal thorax above the level of the diaphragm

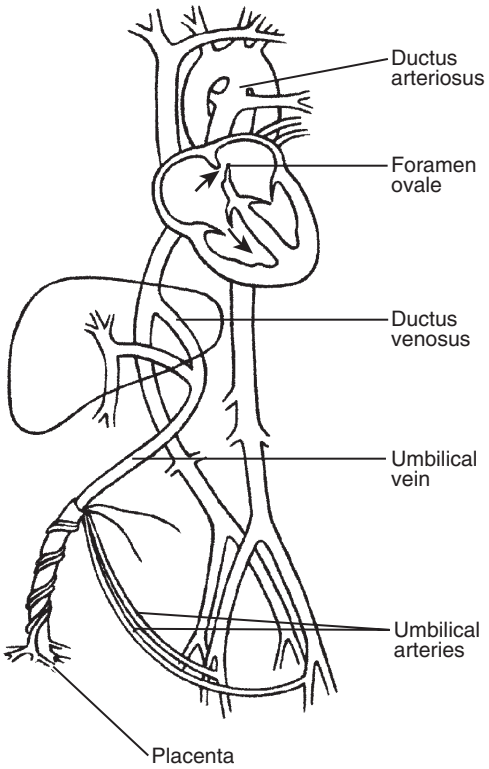

FIG. 37.2 Diagram of Fetal Shunts. Blood from the umbilical vein is shunted through the ductus venosus to the right atrium and then across the foramen ovale to the left atrium. Fetal cardiac output from the right side of the heart is shunted to the descending aorta through the ductus arteriosus.

demonstrates four cardiac chambers. **Four-chamber views** can be obtained with the angle of insonation parallel to the interventricular septum (**apical four-chamber view;** Fig. 37.5A, Video 37.1) or perpendicular to the septum (**subcostal four-chamber view;** Fig. 37.5B, Video 37.2). In a four-chamber view the echogenic foraminal flap of the **foramen ovale** can be observed moving into the left atrium. The two superior pulmonary veins may be seen entering the spherical left atrium. The **atrioventricular valves** are visible in the four-chamber view. The septal leaflet of the tricuspid valve inserts slightly more apically on the interventricular septum than the anterior leaflet of the mitral valve. The left ventricle has a relatively smooth inner wall, and a more elongated shape than the right ventricle. In the normal heart, the left ventricle is the apex forming ventricle. The internal surface of the right ventricle is coarse, particularly near the apex, where the **moderator band** of the **trabecula septomarginalis** is frequently recognized as a small, brightly echogenic focus. This helps identify the morphologic right ventricle.

From the subcostal four-chamber view, angling the transducer toward the fetus's right shoulder permits evaluation of the continuity of the left ventricle with the ascending aorta (Fig. 37.6). Further angulation in the same direction shows the right ventricle in continuity with the pulmonary artery (Fig. 37.7, Videos 37.3 and 37.4). The diameter of the pulmonary artery is approximately 9% larger than that of the aorta between 14 and 42 weeks. The measured differences in these vessels and with M-mode versus two-dimensional (2-D) imaging are negligible (2%-5%) for both the pulmonary artery and the aorta.[35] Further rightward rotation produces a sagittal view of the fetal thorax and a short-axis view of the ventricles (Fig. 37.8, Video 37.5). Angulation toward the left fetal shoulder from this view shows the aorta as a central circle, with the pulmonary artery draping anteriorly and to the left (Fig. 37.9).

The **apical four-chamber view** may also be used as a starting point when evaluating normal cardiac anatomy. Yagel and colleagues[36] described a series of planes arising from the apical four-chamber view, all accomplished by moving the transducer in a cephalad direction. A slight cephalad advancement will show an **apical five-chamber view,** which is useful in assessing continuity of the ascending aorta with the left ventricle (Fig. 37.10). Continued cephalad movement should result in visualization of the bifurcating pulmonary artery and its relationship to the right ventricle. A **three-vessel and trachea view** should be visualized next (Fig. 37.11, Video 37.6). This view allows evaluation of the main pulmonary artery–ductus arteriosus confluence, the transverse aortic arch, and the SVC. Comparison of vessel size, confirmation of vessel presence, and determination of blood flow direction with color Doppler can all be accomplished at this level. In addition, appropriate location of both great vessels to the left of the trachea can be confirmed.[36] Returning to a sagittal plane of the fetus, directing the transducer from the fetal left shoulder to the right hemithorax demonstrates the distinctive candy-cane shape of the **aortic arch** (Fig. 37.12, Videos 37.7 and 37.8). The three major vessels to the head and neck and the **ductus arteriosus** may be seen. The aortic arch should not be confused with the **ductal arch** (Fig. 37.13), which is formed by the right ventricular outflow tract, pulmonary artery, and ductus arteriosus. The ductal arch is broader and flatter than the aortic arch. Lastly, sliding the transducer to the right while maintaining a sagittal plane on the fetus should allow visualization of the IVC and SVC entering the right atrium.

M-mode echocardiography provides a 2-D image of motion over time. It is useful in evaluating heart rate, chamber size, wall thickness, and wall motion (Fig. 37.14). Simultaneous M-mode imaging through an atrium and ventricle is helpful in analyzing arrhythmias (Fig. 37.15). Chamber size and function should be evaluated at the level of the atrioventricular (A-V) valves.[37]

Spectral Doppler ultrasound evaluation of the fetal heart can be used to determine the velocity of flow through the vessels or valves (Fig. 37.16) and to evaluate regurgitant flow through the valves of the heart (Fig. 37.17). Variation in flow velocity may reflect structural or functional cardiac abnormalities. For example, a stenotic A-V valve will be associated with an abnormal flow pattern through the affected valve. Spectral Doppler ultrasound is useful in assessing the functional significance of structural abnormalities and arrhythmias.

Color Doppler ultrasound permits a rapid interrogation of flow patterns within the heart and great vessels (Fig. 37.18), allowing functional and structural abnormalities to be more rapidly characterized. For example, **valvular stenosis** is clearly demonstrated with color Doppler ultrasound, as is reversed flow through insufficient valves or in the great vessels. Color Doppler ultrasound often reduces the amount of time required for spectral

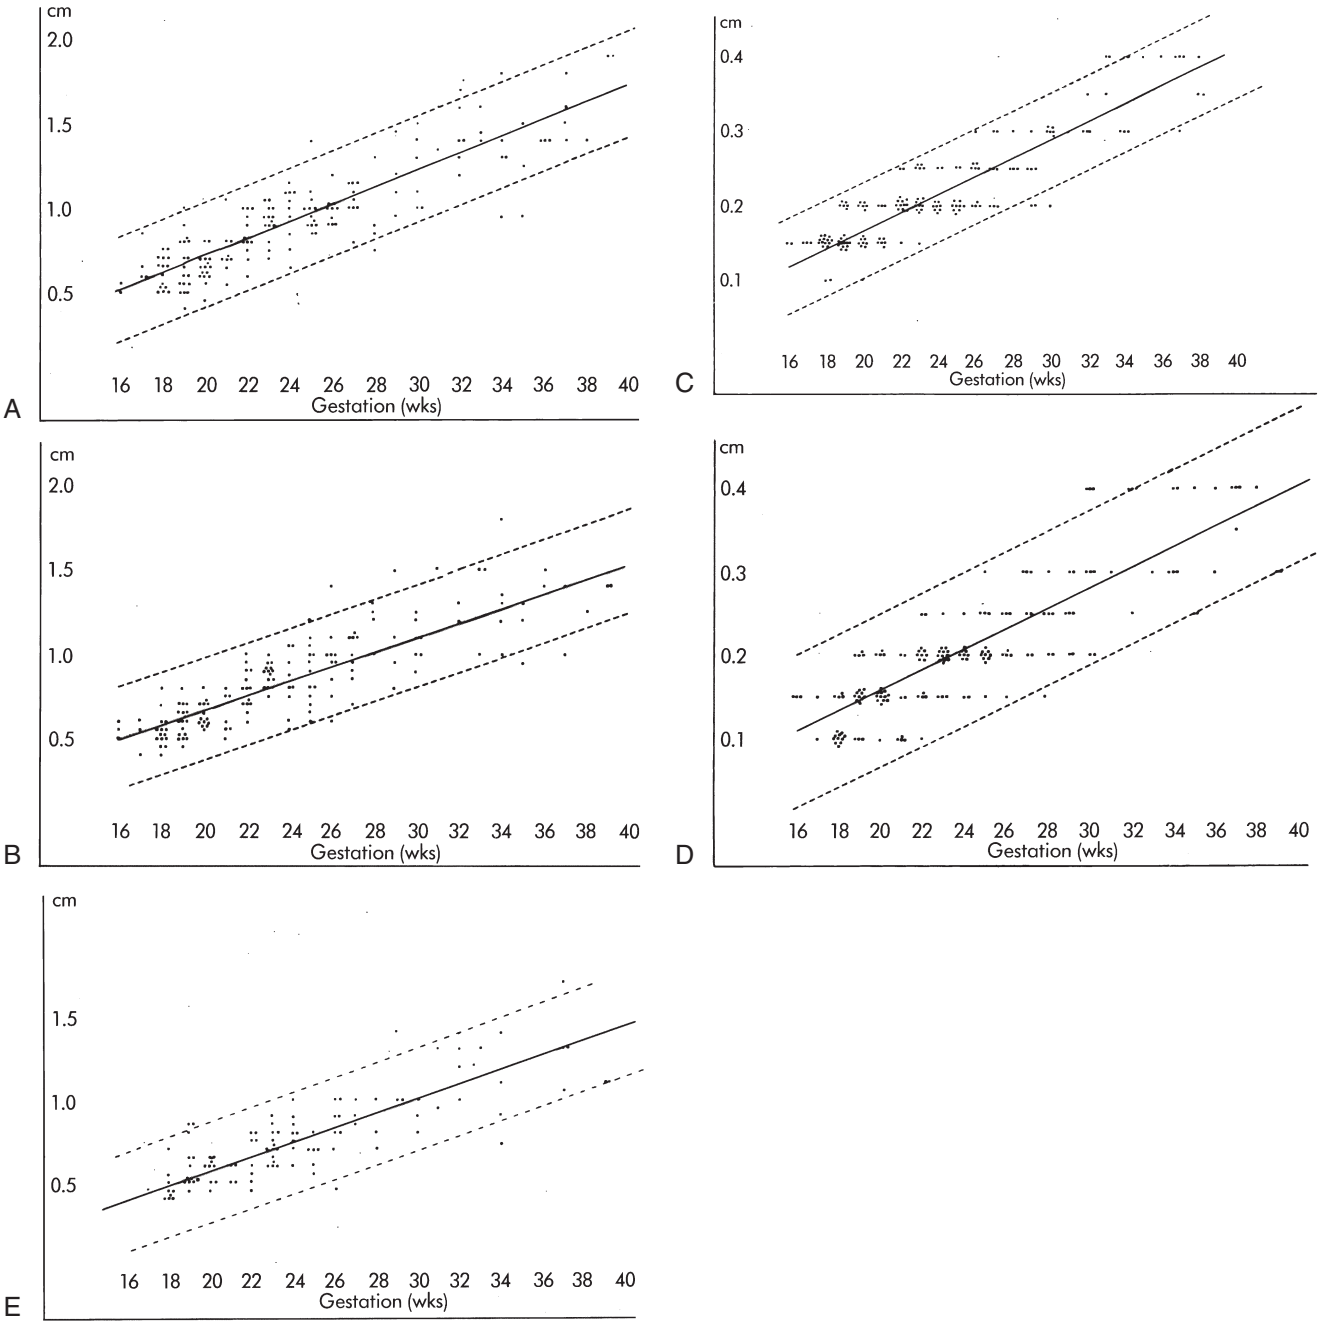

FIG. 37.3 Cardiac Dimensions. (A) Left ventricular internal dimension versus gestational age. $y = 0.049x - 0.262$. **(B)** Right ventricular internal dimension versus gestational age. $y = 0.045x - 0.228$. **(C)** Posterior left ventricular wall thickness versus gestational age. $y = 0.012x - 0.063$. **(D)** Septal thickness versus gestational age. $y = 0.012x - 0.088$. **(E)** Left atrial internal dimension versus gestational age. $y = 0.040x - 0.214$. In each graph, the 95% confidence limits represent twice the standard error of the mean. (With permission from Allan LD, Joseph MC, Boyd EG, Campbell S, Tynan M. Norms and confidence limits for echocardiographic measurements. (With permission from Cartier MS, Davidoff A, Warneke LA, et al. The normal diameter of the fetal aorta and pulmonary artery: echocardiographic evaluation in utero. Am J Roentgenol. 1987;149[5]:1003-1007.[35])

Doppler ultrasound evaluation of the heart, particularly in the setting of complex cardiac anomalies.[38-41] Subtle lesions such as small VSDs may be more reliably and easily identified with the use of color flow Doppler ultrasound.

The utility of several advanced technologies has been reported in the evaluation of the fetal heart, including three-dimensional (3-D) and four-dimensional (4-D) ultrasound, **tissue Doppler imaging, strain** and **strain rate imaging,** as well as **fetal magnetocardiography** and **cardiovascular magnetic resonance imaging** (MRI).[42-44] However, many of these require specialized transducers or other equipment, sophisticated algorithms and specialized technical expertise. Additionally, limited resolution and cardiac motion are still considered major disadvantages in some settings.[45]

STRUCTURAL ANOMALIES

Atrial Septal Defect

An **atrial septal defect** (ASD) results from an error in the amount of tissue resorbed or deposited in the interatrial septum. It is the fifth most common form of CHD and is the most common form in adult patients.[46,47] ASDs occur in 1 per 1500 live births[48,49] and comprise 6.7% of CHD in live-born infants.[46] ASDs occur twice as often in females as males.[50,51] ASDs are associated with a variety of cardiac, extracardiac, and chromosomal abnormalities. ASDs can be classified by embryogenesis, size, or relationship to the fossa ovalis.

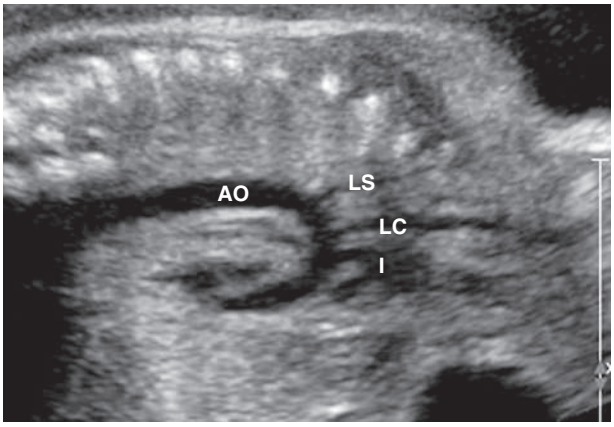

FIG. 37.12 Normal Aortic Arch. Sagittal view shows the rounded, "candy-cane" appearance of aortic arch and the head and neck vessels arising from it. See also Video 37.7 and Video 37.8. *AO,* Descending aorta; *I,* innominate artery; *LC,* left carotid artery; *LS,* left subclavian artery.

FIG. 37.11 Three-vessel and trachea view shows the correct orientation of the main pulmonary artery–ductus arteriosus confluence *(P),* the transverse aortic arch *(A),* and the superior vena cava *(S).* This view also shows the two great vessels correctly positioned on the left side of the trachea *(T).* See also Video 37.6. *SP,* Spine.

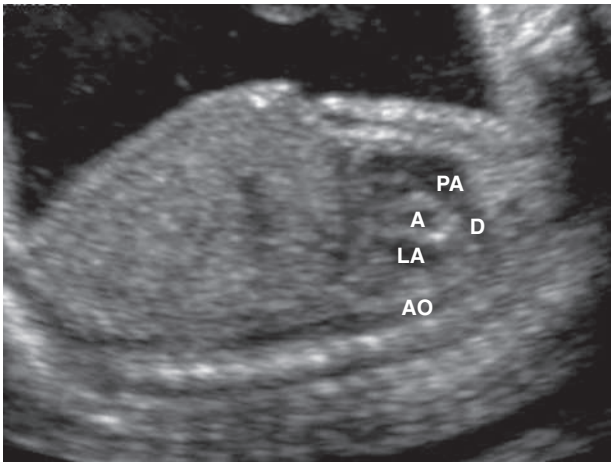

FIG. 37.13 Normal Ductal Arch. Sagittal view shows pulmonary artery *(PA)* draping over the aorta *(A)* and joining the ductus arteriosus *(D),* which then joins the descending aorta *(AO). LA,* Left atrium.

Embryologically, between the fourth and sixth weeks of gestation the primitive atrium is divided into right and left halves. The **septum primum,** a crescent-shaped membrane, develops along the cephalad portion of the atrium and grows caudally toward the **endocardial cushions.** The space between these two structures, termed the **ostium primum,** disappears when the septum primum fuses with the endocardial cushion. Before complete fusion, however, multiple small fenestrations develop in the septum primum, coalescing to form the **ostium secundum.**

A second crescent-shaped membrane subsequently develops just to the right of the septum primum. As this membrane grows toward the endocardial cushion, it partially covers the ostium secundum. Its crescent-shaped lower border never entirely fuses with the endocardial cushion, leaving an opening, the **foramen ovale** (Fig. 37.19).

Ostium secundum ASDs make up more than 80% of all ASDs and generally occur in isolation. This ASD is caused by excessive resorption of the septum primum (foraminal flap) or by inadequate growth of the septum secundum (Fig. 37.20A). The **ostium primum ASD** is the second most common type and is located low in the atrial septum, near the atrioventricular (A-V) valves. Although the ostium primum ASD may occur alone, it is more frequently associated with a more complex congenital cardiac anomaly, the **atrioventricular septal defect** (AVSD) (Fig. 37.20B).

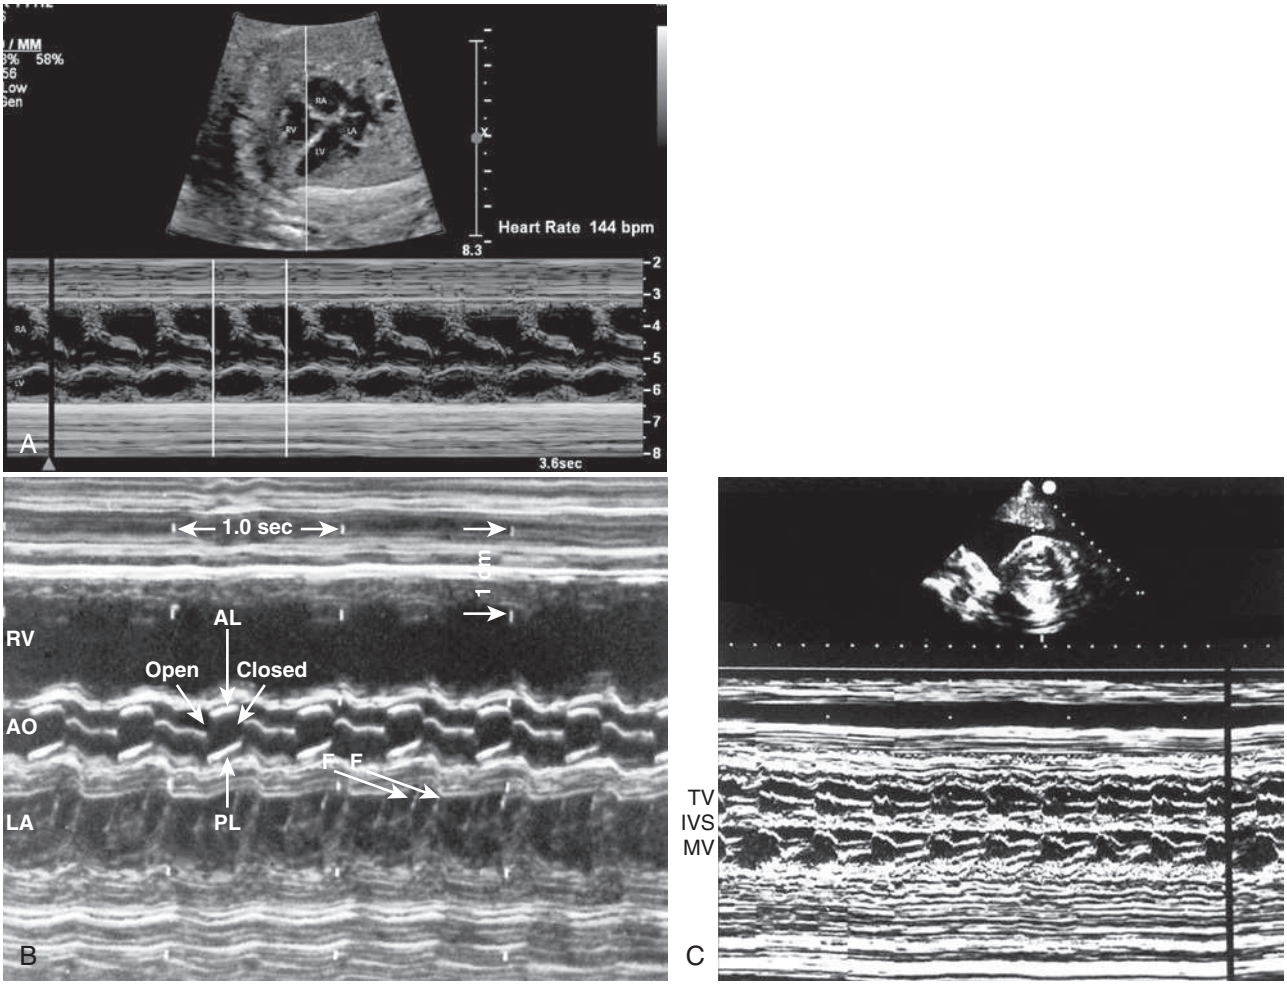

FIG. 37.14 M-Mode Echocardiography. (A) M-mode tracing through the right atrium *(RA)* and the left ventricle *(LV)* showing normal atrial contractions followed by normal ventricular contractions. *LA,* Left atrium; *RV,* right ventricle. **(B)** M-mode tracing through the aortic root shows the aortic valve opening and closing. The foraminal flap *(F)* can be seen opening into the left atrium *(LA). AL,* Anterior leaflet of aortic valve; *AO, aorta; PL,* posterior leaflet of aortic valve; *RV,* right ventricle. **(C)** M-mode tracing shows opening and closing of the mitral valve *(MV)* and tricuspid valve *(TV). IVS,* Interventricular septum.

The **sinus venosus ASD** is a rare defect that can be divided into two types: (1) **sinus venosus ASD of the SVC,** with the defect adjacent to the SVC, and (2) **sinus venosus ASD of the IVC,** with the defect adjacent to the IVC. The first type is often associated with **anomalous pulmonary venous return** (APVR) (Fig. 37.20C). **Coronary sinus ASDs,** located at the ostium of the coronary sinus in the right atrium, may also occur but are exceedingly rare.

The prenatal sonographic diagnosis of ASD is difficult because the normal patent foramen ovale, which allows blood to flow from the right to the left atrium in utero, itself represents an ASD. It can be difficult to distinguish a small, pathologic ASD from the normal patent foramen ovale. The foraminal flap, or septum primum, is clearly visualized on the four-chamber view. It has a "loose pocket" configuration, appearing either circular or linear in shape as it opens into the left atrium[52,53] (Fig. 37.21).

The **septum secundum,** which is thick and relatively stationary, makes up the majority of the atrial septum. The foramen ovale is an opening in the septum secundum. The septum secundum and foramen ovale are well visualized in the four-chamber views. The maximal size of the normal foramen ovale differs by 1 mm or less from the aortic root diameter at all gestational ages.[54] An **ostium secundum ASD** appears as a larger than expected defect in the central portion of the atrial septum near the foramen ovale. Alternatively, it can appear as a deficient foraminal flap.

If the lowest portion of the atrial septum (just adjacent to the A-V valves) is deficient, an **ostium primum** defect should be suspected (Fig. 37.22). Color Doppler ultrasound may be helpful in the diagnosis of larger ASDs. However, small ASDs are commonly obscured by the normal flow through the patent foramen ovale.[55,56]

A large right-to-left shunt is physiologic in utero, and thus an ASD usually does not compromise the fetus hemodynamically. After birth, the shunt may cause right ventricular overload and pulmonary hypertension. Spontaneous closure of an ASD will occur in approximately two-thirds of patients.[57] Patients with small ASDs may remain asymptomatic into their 50s.[58]

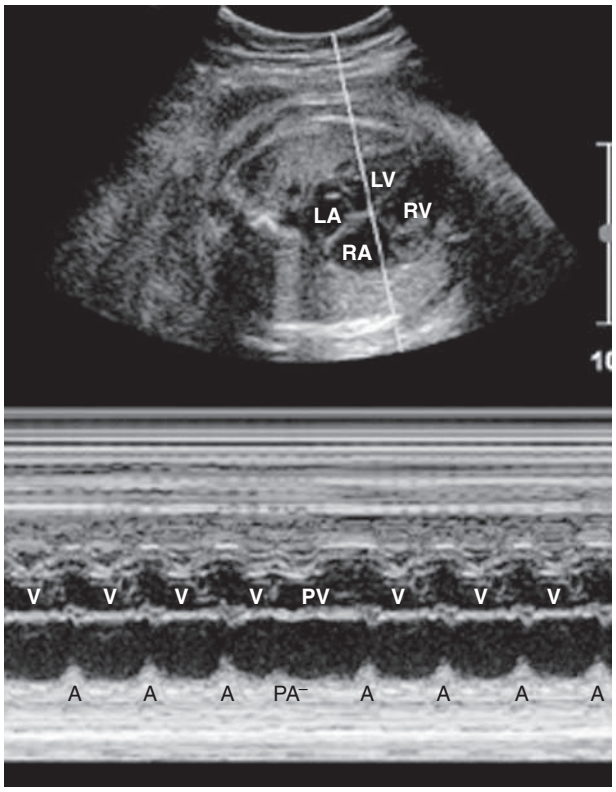

FIG. 37.15 Using M-Mode Echocardiography to Analyze an Arrhythmia: Conducted Premature Atrial Contractions. The cursor is placed simultaneously through the left ventricle *(LV)* and right atrium *(RA)*. The M-mode tracing shows normal atrial beats *(A)* followed by a premature atrial contraction *(PA)*. The ventricles show normal ventricular contraction *(V)* following each atrial beat and a premature beat *(PV)* following the premature atrial contraction. *LA,* Left atrium; *RV,* right ventricle.

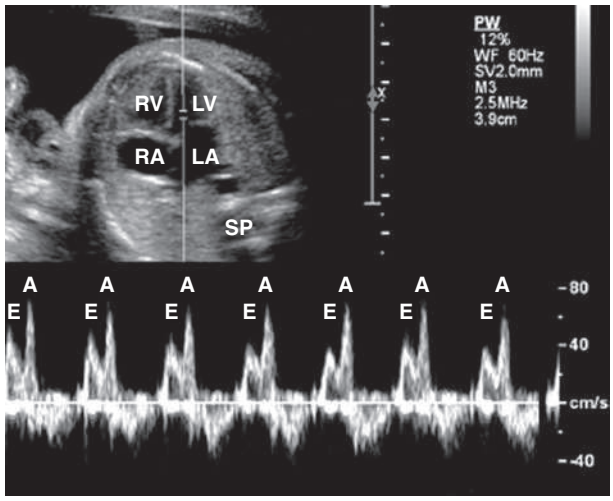

FIG. 37.16 Spectral Doppler Ultrasound Used to Interrogate a Normal Mitral Valve. Spectral Doppler sample volume is placed distal to the mitral valve in the left ventricle *(LV)*. A normal mitral valve waveform is appreciated above the baseline, showing the normal early diastolic *(E)* and atrial contraction *(A)* wave points. *LA,* Left atrium; *RA,* right atrium; *RV,* right ventricle; *SP,* spine.

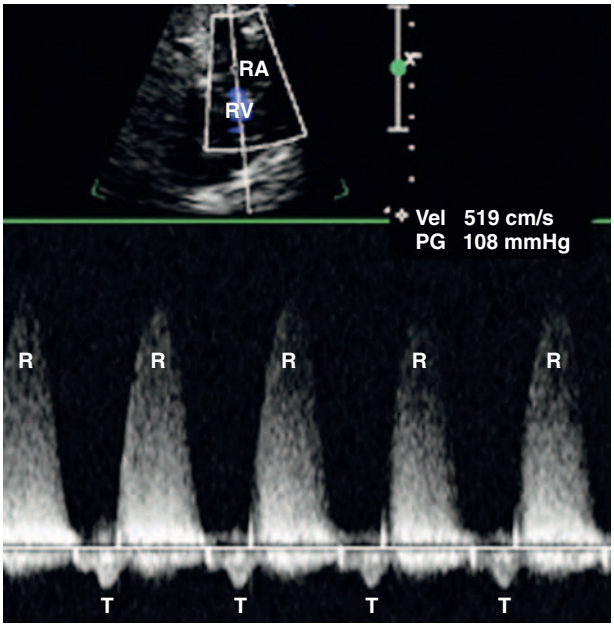

FIG. 37.17 Tricuspid Insufficiency. Spectral Doppler sample volume is placed proximal to the tricuspid valve in the right atrium *(RA)*. The regurgitant flow *(R)* can be seen above the baseline. This implies that the valve has not closed completely during systole, and therefore blood flow is retrograde into the right atrium. *RV,* Right ventricle; *T,* tricuspid valve.

Ventricular Septal Defect

Isolated VSD is the most common cardiac anomaly, accounting for 30% of heart defects diagnosed in live-born infants and 9.7% diagnosed in utero.[46,47,59] VSDs are associated with other cardiac anomalies in 50% of cases.[60] Of the structural cardiac defects, VSDs have the highest recurrence rate and the highest association with teratogen exposure. They are classified according to their position in the interventricular septum (Fig. 37.23) as **membranous** or **muscular VSD** (inlet, trabecular, outlet).[60]

About 80% of VSDs occur in the membranous portion of the septum.[61] However, because most membranous defects also involve a portion of the muscular septum, they are usually referred to as **perimembranous** defects. The subcostal four-chamber view provides optimal evaluation of the interventricular septum. At sonography, a VSD appears as an area of discontinuity in the interventricular septum. When the defect is small, this diagnosis is problematic, and at least one-third of VSDs are missed on the four-chamber view.[21,55,62-66] Color Doppler imaging may improve the diagnostic accuracy for VSD. However, most are missed on fetal echocardiography.[55,66,67] Small VSDs not detectable on gray-scale echocardiography may be documented with color Doppler ultrasound in some cases[39] (Fig. 37.24). In the setting of an isolated VSD, color Doppler ultrasound imaging typically shows bidirectional interventricular shunting, with a systolic right-to-left shunt and a late diastolic left-to-right shunt.

The prognosis for an infant with an isolated VSD is excellent, and many such defects go undetected. The rate of spontaneous closure of isolated muscular VSDs by 5 years of life is much higher (65%) than that for isolated perimembranous VSDs (20%).[68] Overall about 40% of VSDs spontaneously close in the first year

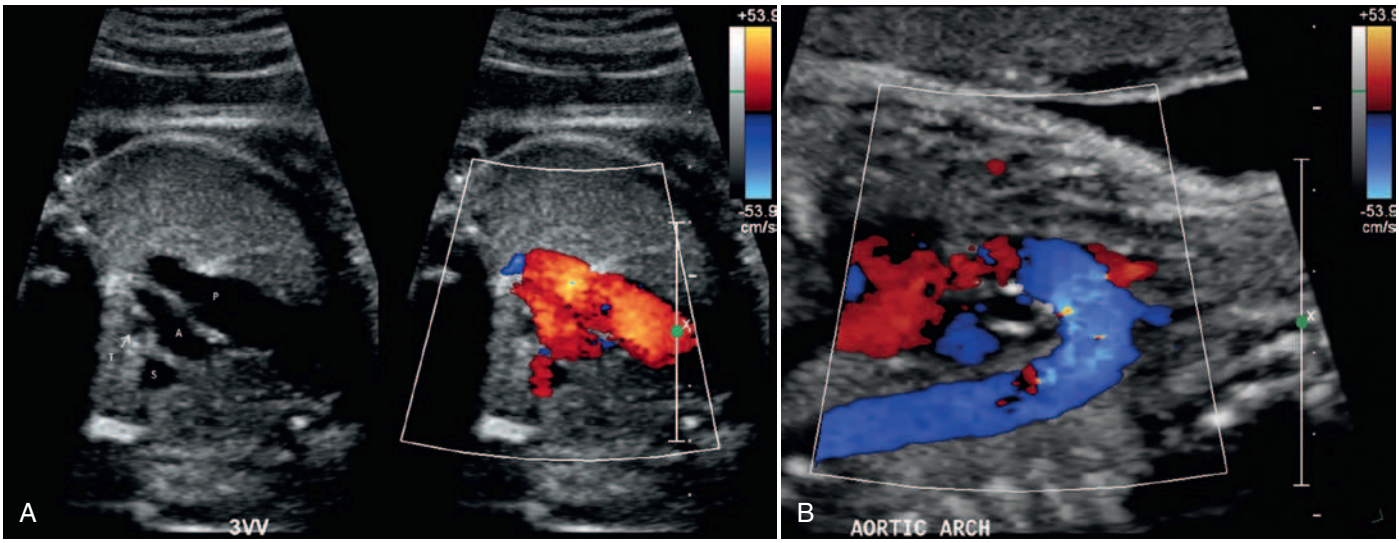

FIG. 37.18 Using Color Doppler Ultrasound to Access Normal Blood Flow. (A) Dual screen three-vessel view (3VV) image with color Doppler ultrasound shows normal flow through the pulmonary artery *(P),* the aorta *(A),* and the superior vena cava *(S).* **(B)** Color Doppler ultrasound shows normal blood flow through the aortic arch.

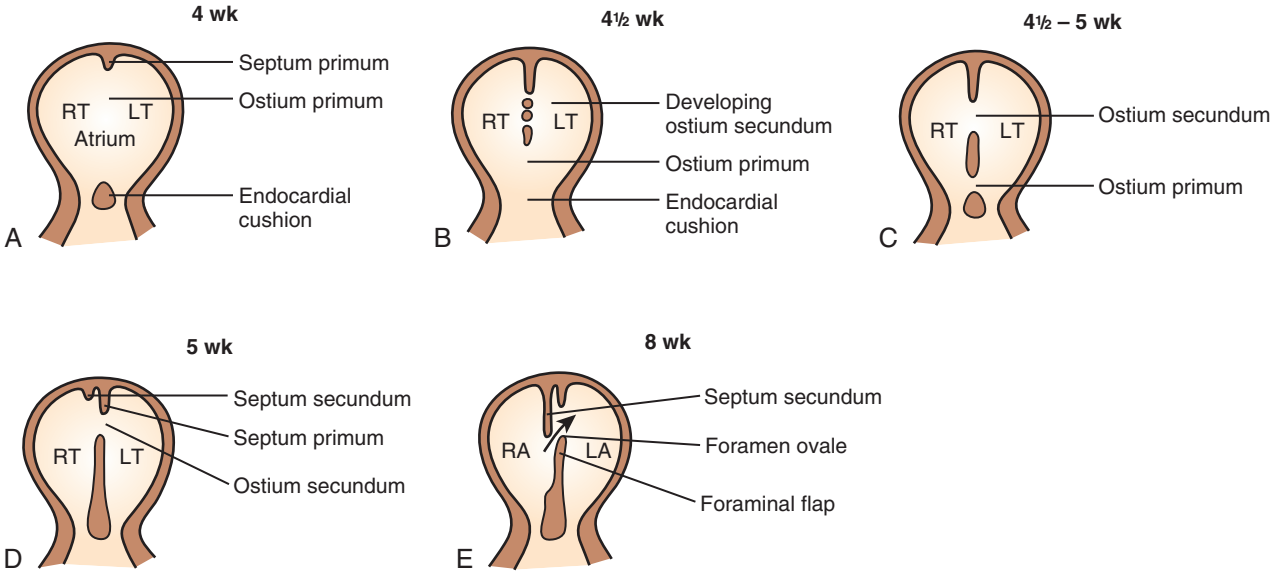

FIG. 37.19 Development of Intraatrial Septum (Viewed Facing Patient). (A) At 4 weeks' gestation the septum primum is small. A large ostium primum is present. **(B)** At 4½ weeks, enlargement of the septum primum results in reduction in size of the ostium primum. Perforations in the septum primum develop. **(C)** Perforations in the septum primum coalesce to form the ostium secundum. **(D)** At 5 weeks the septum primum has fused to the endocardial cushions, and the septum secundum begins to develop to the right of the septum primum. **(E)** At 8 weeks the septum secundum has enlarged, now covering the ostium secundum. Blood flows from the right atrium through the valve mechanism (foraminal flap) of the foramen ovale.

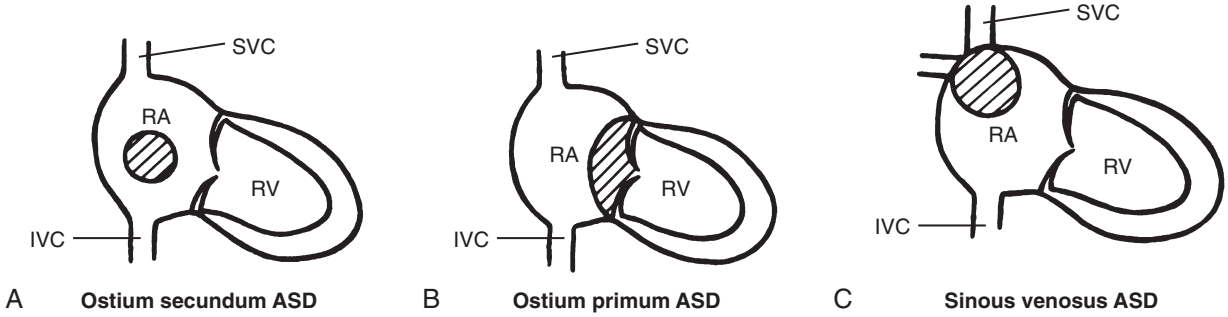

FIG. 37.20 Types of Atrial Septal Defect (ASD). Schema of the atrial septum viewed from the right atrium *(RA).* **(A)** Ostium secundum ASD. **(B)** Ostium primum ASD. **(C)** Sinus venosus ASD. *IVC,* Inferior vena cava; *RV,* right ventricle; *SVC,* superior vena cava.

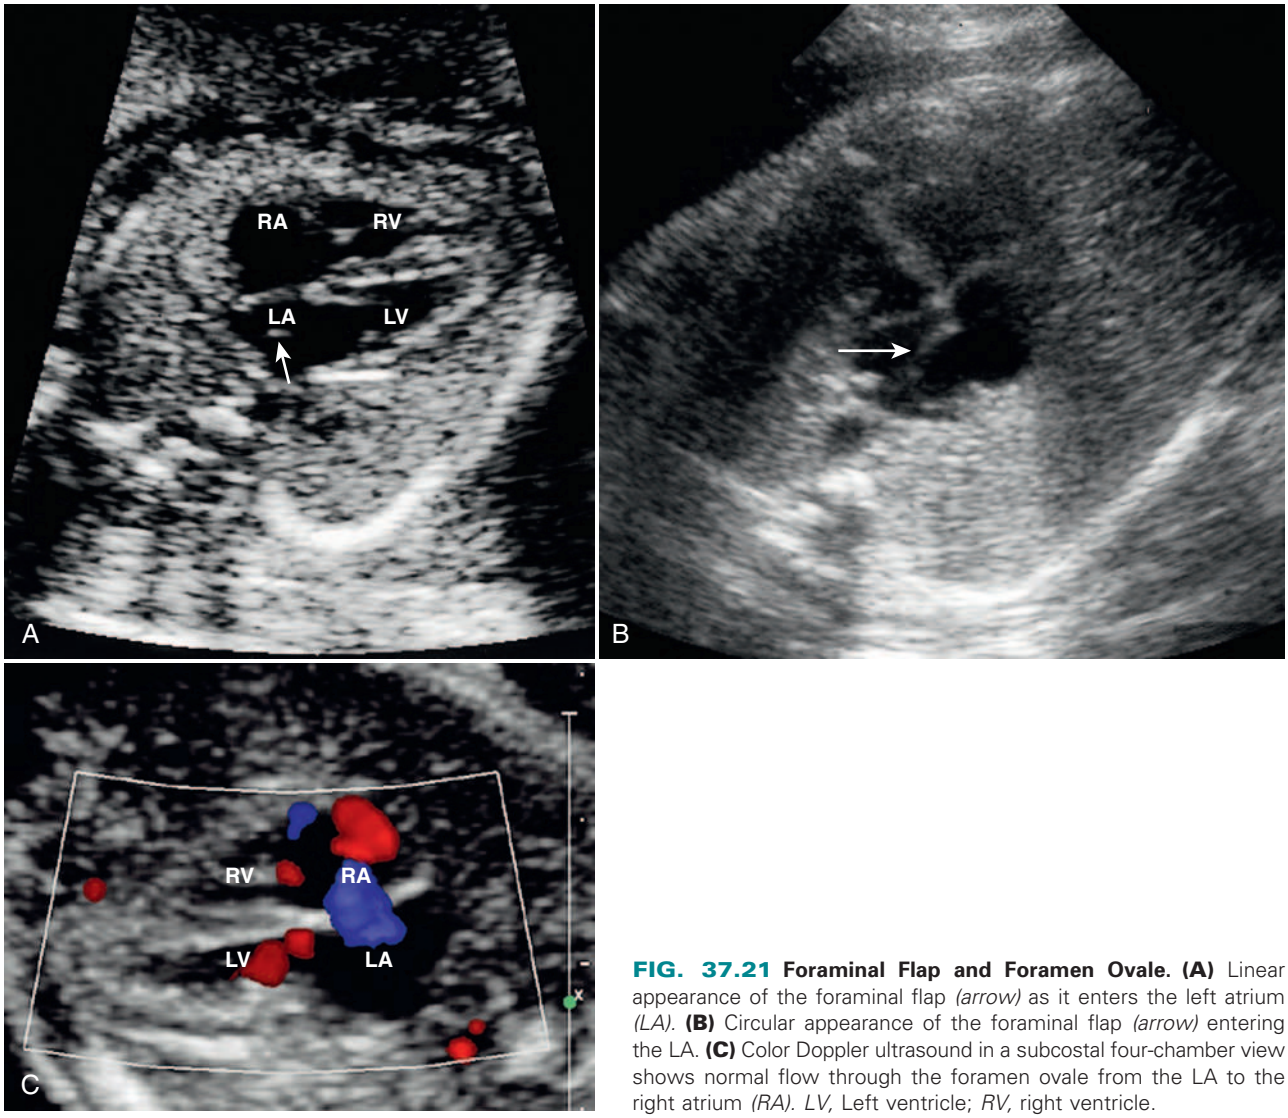

FIG. 37.21 Foraminal Flap and Foramen Ovale. (A) Linear appearance of the foraminal flap *(arrow)* as it enters the left atrium *(LA).* **(B)** Circular appearance of the foraminal flap *(arrow)* entering the LA. **(C)** Color Doppler ultrasound in a subcostal four-chamber view shows normal flow through the foramen ovale from the LA to the right atrium *(RA). FIG. 37.22 Four-chamber view shows an **ostium primum atrial septal defect** *(arrow)* in a fetus with an atrioventricular septal defect. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

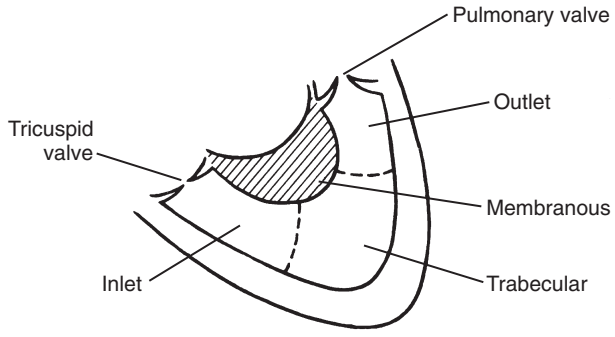

FIG. 37.23 Interventricular Septum Viewed From Right Ventricle. The membranous septum and the three portions of the muscular septum (inlet, outlet, and trabecular) are demonstrated. Ventricular septal defects may occur in any of these locations.

of life, and 60% resolve by 5 years of age.[69-71] However, large defects detected in the fetus are associated with an 84% mortality.[72] Concurrent cardiac, extracardiac, and chromosomal anomalies (trisomy 13, 18, 21, and 22) are associated with a worse prognosis.

VSDs may be extremely difficult to diagnose in utero, particularly when small in size. In addition, many small VSDs will close in utero or shortly after birth. A "pseudo" VSD in the membranous portion of the septum may be appreciated when evaluating the interventricular septum from an apical four-chamber view. This occurs when the angle of insonation is parallel to the septum, causing an artifactual dropout of the thin, membranous septum.

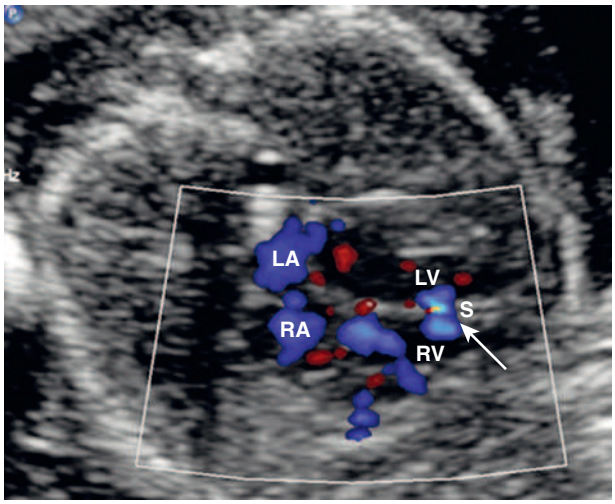

FIG. 37.24 Muscular Ventricular Septal Defect (VSD). Subcostal four-chamber view using color Doppler ultrasound shows a muscular VSD *(arrow)* across the interventricular septum *(S). LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

Atrioventricular Septal Defect

AVSD refers to a spectrum of cardiac abnormalities involving various degrees of deficiency of the interatrial and interventricular septa and of the mitral and tricuspid valves. These defects arise when the endocardial cushions fail to fuse properly and were previously called **endocardial cushion defects** or **A-V canal defects.** Almost two-thirds of fetuses with AVSD have additional cardiac anomalies.[73-75] About one-third are associated with **left atrial isomerism** (both atria anatomically resemble the left), and of these the majority of affected fetuses have **complete heart block.**[72,73] Chromosomal (especially **trisomy 21**) or extracardiac anomalies are associated in 78% of AVSDs.[72]

Embryologically, in the primitive heart, the common atrium and ventricle communicate through the A-V canal. Development of the endocardial cushion results in division of the single, large A-V canal into two separate orifices, separating the atria from the ventricles (Fig. 37.25). The interatrial and interventricular septa develop concurrently, eventually dividing the single atrium and ventricle into right and left portions. When the endocardial cushions fail to fuse properly, normal development of the mitral and tricuspid valves cannot occur, and an AVSD results (Fig. 37.26).

AVSDs are divided into complete and partial or incomplete forms.[76] In both, the A-V valves are abnormal. In **complete AVSD** a single, multileaflet valve is present, whereas in **incomplete AVSD** two of the leaflets (bridging leaflets) are connected by a narrow strip of tissue, resulting in the appearance of two valve

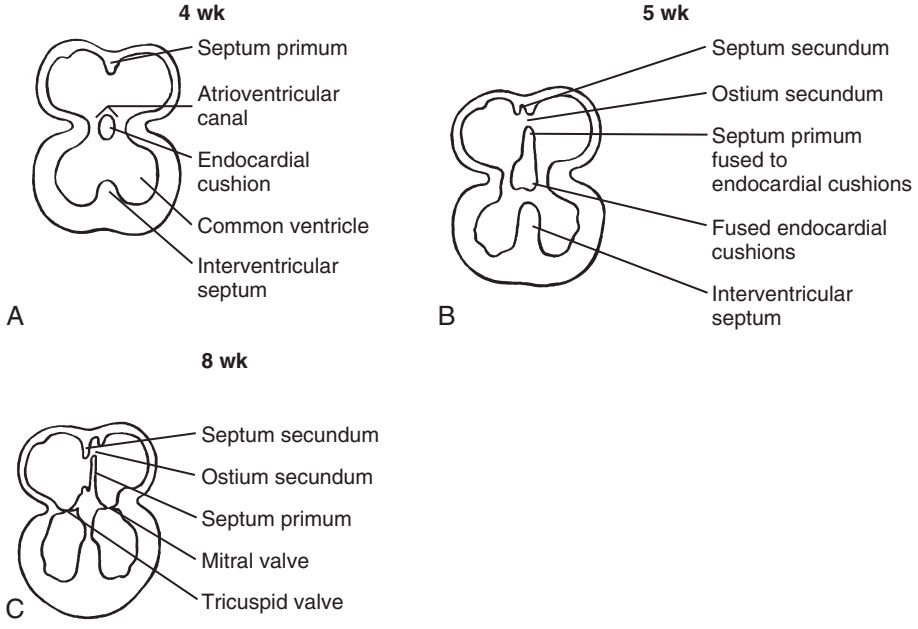

FIG. 37.25 Normal Development of Endocardial Cushions. (A) In the fourth week the endocardial cushions divide the atrioventricular canal into two orifices. **(B)** By the fifth week the communication between the atria, the ostium secundum, is smaller. The ventricular septum has grown, almost obliterating the communication between the ventricles. **(C)** At 8 weeks, complete development of the endocardial cushions and atrioventricular valves results in four distinct cardiac chambers.

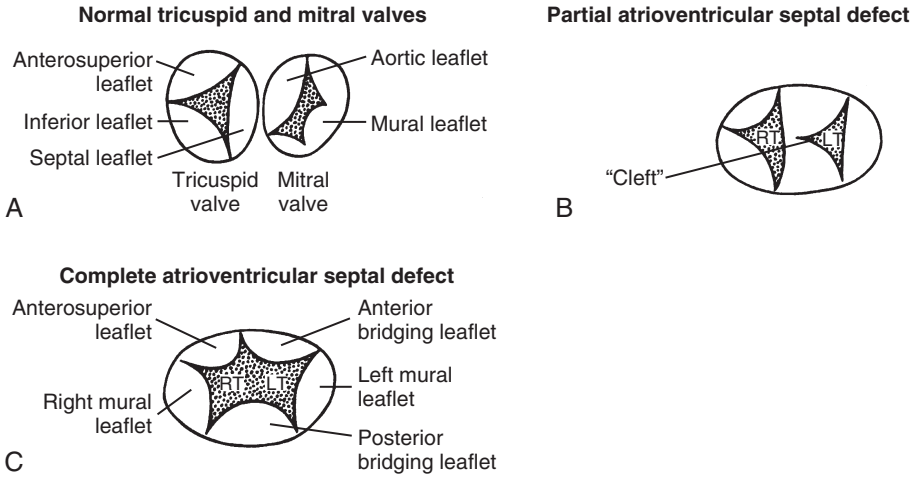

FIG. 37.26 Valve Leaflet Morphology. (A) Normal heart. **(B)** Partial atrioventricular septal defect (AVSD). **(C)** Complete AVSD. *LT,* Left abnormal valve; *RT,* right abnormal valve.

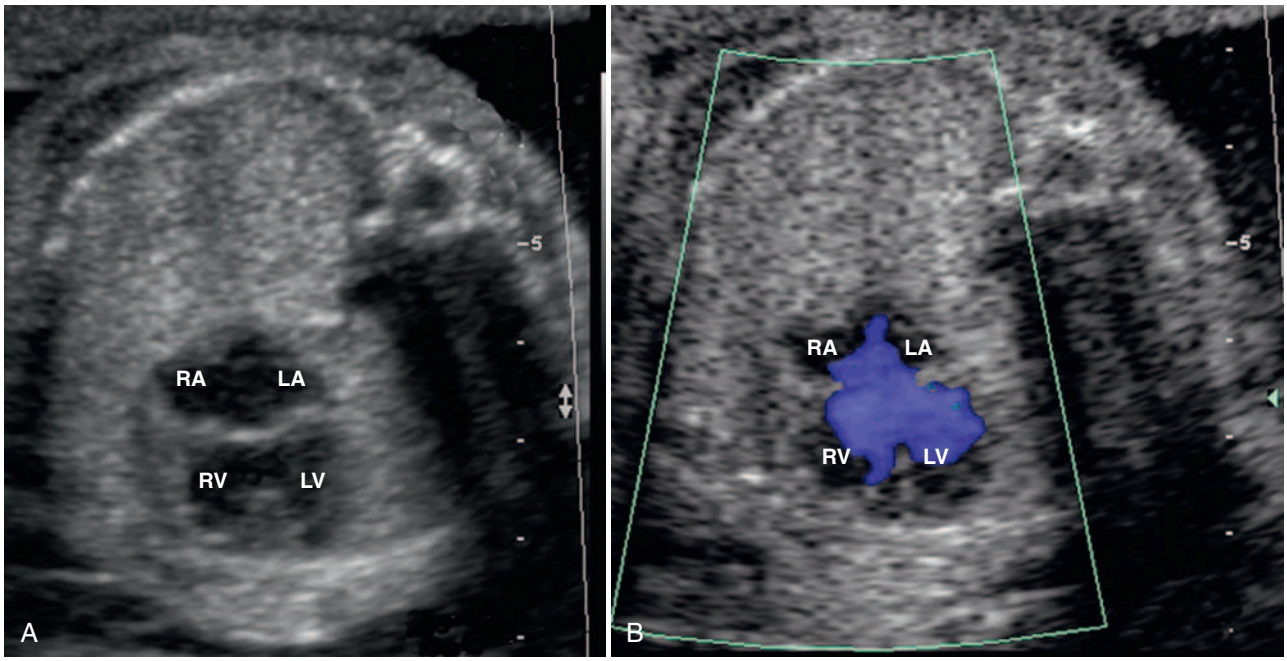

FIG. 37.27 Atrioventricular Septal Defect (AVSD). (A) Apical four-chamber view shows absent atrial septum, resulting in a single large atrium (RA-LA). A ventricular septal defect is visible between the left ventricle *(LV)* and right ventricle *(RV).* A single, multileaflet atrioventricular valve is also appreciated. **(B)** Apical four-chamber view shows color Doppler ultrasound filling the **atrioventricular septal defect.** See also Video 37.9. *LA,* Left atrium; *RA,* right atrium.

orifices. Complete AVSD has variable amounts of deficient tissue in the atrial and ventricular septa. The incomplete form is associated with an ostium primum ASD. At fetal echocardiography, 97% of AVSDs are complete, although after birth only 69% are complete.[67,72] The fetal incidence of AVSD is four times greater than that in the live-born population, indicating a high incidence of in utero demise.[46,47,77]

AVSDs are considered **balanced** when the A-V junction is connected to both the right and the left ventricle, such that blood flow is relatively evenly distributed. If this connection exists with primarily one ventricle, such as in the setting of a hypoplastic left ventricle, it is termed an **unbalanced AVSD.**

Sonographically, a defect in the atrial or ventricular septum with an associated single abnormal A-V valve is visible in a four-chamber view (Fig. 37.27, Video 37.9). The abnormal valve should be suspected when the normal offset of the A-V valves is not visualized or when only a single A-V valve is appreciated in a short-axis view. Demonstration of two A-V valve orifices allows for differentiation between complete and incomplete forms of AVSD.[62]

Color Doppler ultrasound demonstrates an open area of flow across the AVSD and the abnormal A-V valve. Color Doppler ultrasound imaging is particularly useful in the detection of valvular insufficiency.[78] **Holosystolic valvular insufficiency** is

FIG. 37.28 Ebstein Anomaly. See also Video 37.12. *LA,* Left atrium; *LV,* left ventricle.

closely associated with **fetal hydrops** and a worsening prognosis.[79] Frequently, a left ventricular–to–right atrial jet can be identified across the ostium primum defect before the onset of holosystolic valvular insufficiency.[38] **Cardiac malformations** associated with AVSD include septum secundum ASD, hypoplastic left heart syndrome (HLHS), valvular pulmonary stenosis, coarctation of the aorta, and tetralogy of Fallot (TOF). A meta-analysis of published cases of AVSD diagnosed prenatally confirmed that chromosomal anomalies are common, occurring in 25% to 58% of affected fetuses.[80] Therefore karyotyping is indicated. Associated **extracardiac anomalies** are common, including **omphalocele, duodenal atresia, tracheoesophageal atresia, facial clefts, cystic hygroma, neural tube defects,** and **multicystic kidneys.**[80]

The fetus with an AVSD and associated defects has a poor prognosis. When hydrops is present, few survive the neonatal period.[81] Despite advances in pediatric cardiothoracic surgery, the overall outcome for antenatally diagnosed AVSD remains variable, with many studies reporting 5-year to 15-year survival rates below 50%.[80,82] Others have reported excellent long-term results with newer surgical techniques such as the two-patch technique with early complete cleft closure for complete AVSD repair.[83]

Ebstein Anomaly

Ebstein anomaly is characterized by inferior displacement of the tricuspid valve, frequently with **tethered attachments** of the leaflets, **tricuspid dysplasia,** and right ventricular dysplasia[84-88] (Fig. 37.28, Video 37.12). Ebstein anomaly makes up approximately 7% of cardiac anomalies in the fetal population and has an incidence of 0.5% to 1% in high-risk populations.[64,89,90] It occurs in approximately 1 per 20,000 live births.[91]

Early data from biased retrospective studies suggested that **lithium** use during pregnancy was associated with an estimated 500-fold increase in the incidence of Ebstein anomaly in exposed fetuses.[91-96] It is now clear that the increased risk is less than 2%.[45,97] Ebstein anomaly may be associated with a variety of structural cardiovascular defects, particularly **pulmonary atresia or stenosis,**[98] **arrhythmias,** and **chromosomal anomalies.**[86,99-102]

Ebstein anomaly is readily detected in utero.[99,103] The sonographic diagnosis rests on recognition of apical displacement of the tricuspid valve into the right ventricle, an enlarged right atrium containing a portion of the **"atrialized" right ventricle,** and a reduction in size of the functional right ventricle. Differential diagnosis includes tricuspid valvular dysplasia, **Uhl anomaly,** and idiopathic right atrial enlargement, but none of these has an inferiorly displaced tricuspid valve, the most reliable sign of Ebstein anomaly. Ebstein anomaly is one of the few structural defects that may cause substantial **cardiac dysfunction** in utero, frequently with cardiomegaly, hydrops, and tachyarrhythmias.[86] Examination with spectral and color Doppler ultrasound is helpful in demonstrating **tricuspid valve regurgitation,** which causes further enlargement of the right atrium and ventricle.[104] Tethered distal attachments of the tricuspid valve, marked right atrial enlargement, and left ventricular compression with narrowing of the pulmonary outflow tract are all associated with a poor prognosis.[86] Fetuses diagnosed with Ebstein anomaly and tricuspid dysplasia have a poor prognosis, with an overall perinatal mortality (fetal demise or death before neonatal discharge) of 45%.[105]

Arrhythmias, particularly **supraventricular tachycardias** (SVTs), are common with Ebstein anomaly and can further compromise the fetus. Overall, the 3-month mortality rate for patients diagnosed in utero is 80%.[86,103] Surgical correction of Ebstein anomaly in young children is associated with a low mortality rate and an excellent quality of life.[106-108] Because clinical

presentation, treatment options, and prognosis are inconsistent, case-by-case management is variable.[109]

Hypoplastic Right Ventricle

In general, hypoplastic right ventricle occurs secondary to **pulmonary atresia with intact interventricular septum.** It has an incidence of 1.1% among stillbirths.[46] **Tricuspid atresia** may be associated with a hypoplastic right ventricle, but this is not as common.[110] Pathophysiologically, hypoplasia of the right ventricle develops because of a reduction in blood flow secondary to inflow impedance from tricuspid atresia or outflow impedance from pulmonary arterial atresia. Typical sonographic findings include a small, hypertrophic right ventricle and a small or absent pulmonary artery[110] (Fig. 37.29, Video 37.11). Spectral Doppler ultrasound may be helpful in demonstrating decreased flow through the tricuspid valve or pulmonary artery. Congestive heart failure and hydrops may develop from tricuspid regurgitation. After birth, closure of the ductus arteriosus frequently results in neonatal death. Prognosis improves with preoperative prostaglandin infusion to maintain the patency of the ductus.[111]

Hypoplastic Left Heart Syndrome

In **hypoplastic left heart syndrome,** the left ventricular cavity is pathologically reduced in size. HLHS constitutes approximately 7% to 9% of all congenital cardiac lesions.[112] It has a 2:1 male predominance and a recurrence risk of 0.5%.[112,113] The small left ventricle results from decreased blood flow into or out of the left ventricle. The primary abnormalities include **aortic atresia, aortic stenosis,** and **mitral valve atresia.** It is associated with **coarctation of the aorta** in 80% of cases.[114] The primary sonographic feature of HLHS is a small left ventricle (Fig. 37.30, Video 37.10). The mitral valve is typically hypoplastic or atretic, as is the aorta.[115] Color Doppler ultrasound is extremely helpful in the setting of HLHS, usually demonstrating the absence of flow through the mitral and aortic valves.[39]

Three decades ago this syndrome had an extremely poor prognosis, with 25% mortality in the first week of life and most untreated infants dying within 6 weeks.[116] Comfort care was provided, but little could be done to prolong survival. Currently it is expected that up to 70% of newborns with HLHS may reach adulthood owing to advancements in surgical techniques, perioperative management, and postoperative care.[117] Prenatal diagnosis of HLHS is beneficial for preventing ductal shock and keeping affected infants stable in the preoperative stage.[118-120] Monophasic blood flow across the mitral valve, restricted or absent flow through the foramen ovale, and retrograde flow through the aorta are all considered poor prognostic signs in utero. Despite significant advancements in medical and surgical management over the past 30 years, follow-up studies indicate that children with HLHS often experience major developmental delays[121] and decreased exercise performance, even after heart transplantation.[122] A recent meta-analysis found that although deficits remain, substantial improvement in neurodevelopment has occurred over the past 20 years in patients with surgically corrected HLHS.[123]

Univentricular Heart

In univentricular heart, two atria empty into a single ventricle, via two A-V valves or a common A-V valve. Univentricular heart is rare, accounting for approximately 2% of CHD.[47] It results from a failure of the interventricular septum to develop. The single chamber has a left ventricular morphology in 85% of cases.[124] Associated cardiac anomalies are common,[125] with **asplenia** or **polysplenia** occurring in 13%.[126] Sonographically,

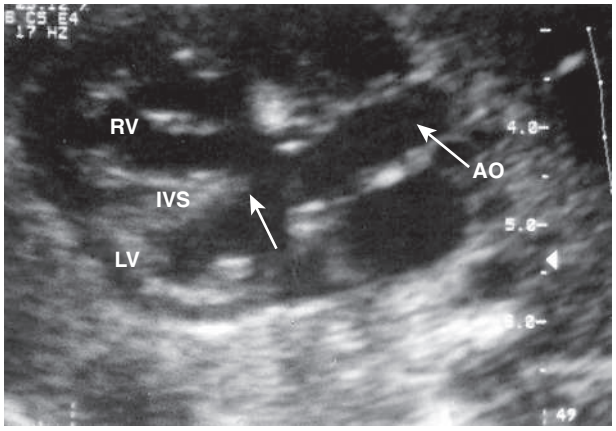

FIG. 37.31 Tetralogy of Fallot. The aorta *(AO)* overrides both the right ventricle *(RV)* and the left ventricle *(LV)*. A ventricular septal defect *(arrows)* is also appreciated. See also Video 37.13. *IVS,* Interventricular septum.

a single ventricle with absence of the interventricular septum is seen. Doppler ultrasound examination is helpful in determining if a normal outflow tract is present. A nonfunctioning, rudimentary accessory ventricle may be present in some cases. Differential diagnosis includes a large VSD and hypoplastic right or left ventricle.

Patients with outflow tract stenosis have a poor prognosis.[127] Death is typically caused by congestive heart failure or arrhythmia.[77] Pulmonary artery banding and shunts yield a 70% 5-year survival rate. Ventricular septation has a postoperative survival rate of approximately 56%.[125,128] More recent literature indicates that there continues to be a high mortality rate for univentricular heart after surgical correction, with an 8-year survival after **modified Blalock-Taussig shunt** of only 68%.[129] After a **Glenn bidirectional cavopulmonary connection,** 8-year survival is slightly higher at 74%.[130]

Tetralogy of Fallot

Tetralogy of Fallot consists of (1) VSD, (2) overriding aorta, (3) hypertrophy of the right ventricle, and (4) stenosis of the right ventricular outflow tract (Fig. 37.31, Video 37.13). It accounts for 5% to 10% of CHD in live births[46] and is associated with a variety of cardiac, extracardiac, and chromosomal anomalies.[72] A study of 129 fetuses diagnosed in utero with TOF reported additional cardiac anomalies in 57%, extracardiac anomalies in 50%, and chromosomal anomalies in 49%. The first trimester nuchal translucency was above the 95th percentile in 47% of fetuses.[131]

TOF occurs when the **conus septum** is located too far anteriorly, thus dividing the conus into a smaller, anterior right ventricular portion and a larger posterior part. Closure of the interventricular septum is incomplete, causing the aorta to override both ventricles.[132] The VSD typically occurs in the perimembranous portion of the septum. Right ventricular hypertrophy rarely occurs in utero, but the overriding aorta is reliably seen.[133,134] **Pulmonary atresia or stenosis,** or a **dilated pulmonary artery** secondary to absence of the valve, may be appreciated. The diagnosis of TOF has been made before 15 weeks' gestation using transvaginal ultrasound.[33] Color Doppler imaging is helpful in making the diagnosis of TOF.[135]

The newborn with the classic form of TOF who has pulmonary stenosis rather than pulmonary atresia is typically asymptomatic at birth but develops cyanosis and a murmur in the first weeks of life. Early primary repair of TOF is routinely performed with a low surgical mortality and postoperative morbidity.[136] Typical cases of TOF are repaired at 4 to 6 months of age, with close to 90% survival at 1 year.[137] Patients surviving early surgery (before 5 years old) have a 32-year survival of 90%.[138] The presence of congestive heart failure in the fetus or newborn with TOF is associated with 17% to 41% mortality.[139,140]

Truncus Arteriosus

Truncus arteriosus accounts for 1.3% of fetal cardiac anomalies and is characterized by a single large vessel arising from the base of the heart. This vessel supplies the coronary arteries and the pulmonary and systemic circulations. Aortic anomalies occur in 20% and noncardiac anomalies in 48% of patients with truncus arteriosus.[141] In almost all patients a VSD is present. The **truncal valve** may have two to six cusps and in general overrides the ventricular septum. Four types of truncus arteriosus have been identified by **Collett and Edwards,**[142] as follows:

- **Type I** has a pulmonary artery that bifurcates into right and left branches after it arises from the ascending portion of the truncal vessel.
- **Type II** has right and left pulmonary arteries arising separately from the posterior truncus.
- **Type III** has pulmonary arteries that arise from the sides of the proximal truncus.
- **Type IV** has systemic collateral vessels from the descending aorta as the source of flow.

The single, large **truncal artery** with overriding ventricular septum and an associated VSD is identified on four-chamber and outflow tract views (Fig. 37.32). This anomaly has been diagnosed as early as 13 weeks.[34] Color Doppler imaging is particularly helpful in the setting of truncus arteriosus because it facilitates accurate localization of the pulmonary arteries and rapidly detects truncal valvular insufficiency. In the 1980s, prognosis was poor, with an overall mortality of 70%.[141] More recent studies have indicated that 10-year to 20-year survival is excellent for infants undergoing complete repair of truncus arteriosus.[143] However, these patients continue to experience significant comorbidities throughout childhood, with significant deficits in exercise tolerance and overall functional status.[144]

Double-Outlet Right Ventricle

Double-outlet right ventricle (DORV) represents less than 1% of all CHD and occurs when more than 50% of both the aorta and the pulmonary artery arise from the right ventricle.[145,146] DORV is classified into the following three types:

- Aorta posterior and to the right of the pulmonary artery
- Aorta and pulmonary artery parallel, with the aorta to the right **(Taussig-Bing type)**
- Aorta and pulmonary artery parallel, with the aorta anterior and to the left

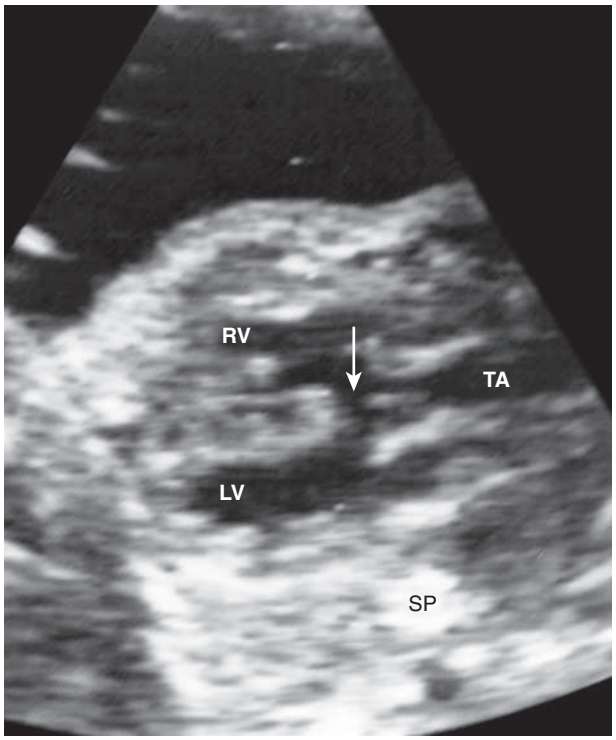

FIG. 37.32 Truncus Arteriosus. The single truncal artery *(TA)* overrides both the right ventricle *(RV)* and left ventricle *(LV)*. A ventricular septal defect *(arrow)* is present. No pulmonary artery was seen, helping to differentiate from tetralogy of Fallot. *SP,* Spine.

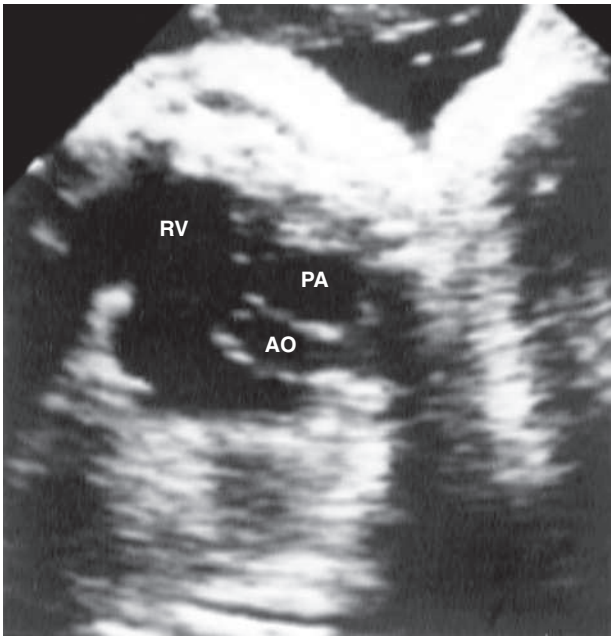

FIG. 37.33 Double-Outlet Right Ventricle. The aorta *(AO)* and pulmonary artery *(PA)* both arise from the right ventricle *(RV)* in a parallel fashion.

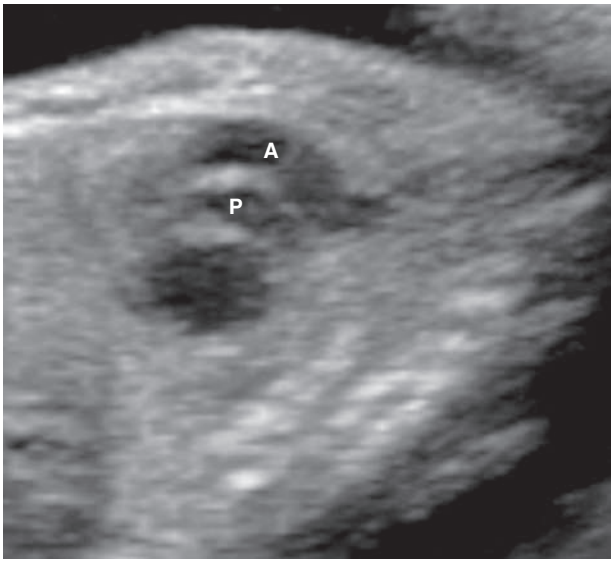

FIG. 37.34 Complete Transposition of Great Arteries. The aorta *(A)* is anterior to the pulmonary artery *(P)*. This abnormal arrangement results in both vessels running parallel to each other in this short-axis view.

DORV is associated with other cardiac defects (particularly VSD), various extracardiac defects, fetal chromosomal anomalies, maternal diabetes, and maternal alcohol consumption.[5,146,147] With surgical intervention, 10-year survival as high as 97% has been reported.[145] A more recent study reported near 94% overall 5-year survival after surgical correction.[148] When extracardiac or chromosomal anomalies are present, prognosis is poor, with 69% mortality when the diagnosis of DORV is made in utero.[147] Sonographically, the aorta and pulmonary artery arise predominantly from the right ventricle (Fig. 37.33). Differential diagnosis includes transposition of the great vessels and TOF.

Transposition of Great Arteries

Transposition of the great arteries (TGA) is subdivided into two types: (1) complete or **dextrotransposition** (D-TGA) in 80% and (2) congenitally corrected or **levotransposition** (L-TGA) in 20% of fetuses with transposition. In both types, **ventriculoarterial discordance** is present. (The aorta arises from the right ventricle, and the pulmonary artery arises from the left ventricle.) **Complete transposition** (D-TGA) is defined as **atrioventricular concordance** (atria and ventricles are correctly paired) with ventriculoarterial (V-A) discordance (Fig. 37.34). It comprises 5.5% of heart disease in the fetal population.[47] D-TGA is also classified into two types, depending on the absence (70%) or presence of a VSD. A variety of cardiac anomalies are associated with D-TGA, including **pulmonic stenosis,** which rarely occurs in the absence of a VSD. In 8% of cases, other organ systems are involved. Chromosomal anomalies are not commonly associated with TGA.

In D-TGA, the aorta arises from the right ventricle, receives systemic blood, and returns it to the systemic circulation. The pulmonary artery arises from the left ventricle, receives pulmonary venous blood, and returns it to the lungs. In general, the aortic root lies anterior and slightly to the right of the pulmonary outflow tract. With closure of the ductus arteriosus and foramen ovale after birth, this condition is incompatible with life unless an associated shunt allows mixing of the separate right and left circulations.

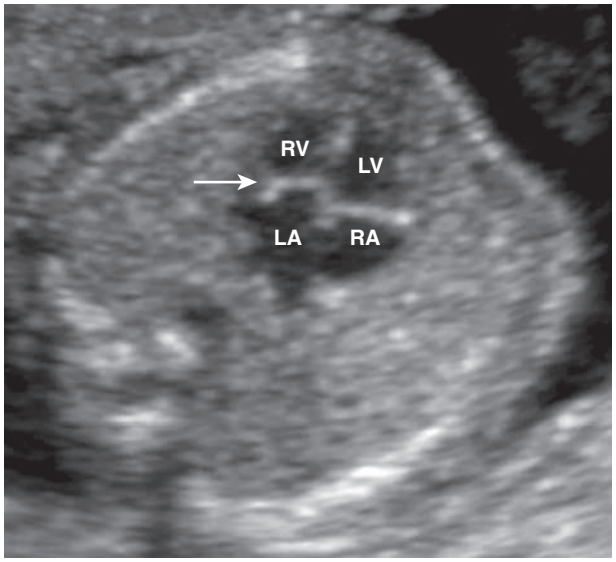

FIG. 37.35 Congenitally Corrected Transposition of Great Arteries. An apical four-chamber view shows the morphologic right ventricle *(RV)* and morphologic left ventricle *(LV)* located on the incorrect sides of the heart. This is evidenced by identifying the atrioventricular valve leaflets inserting *(arrow)* on the left side of the heart in a more apical location than the right-sided atrioventricular valve leaflet insertion. *LA,* Left atrium; *RA,* right atrium.

Sonographic diagnosis depends on demonstrating that the great vessels exit the heart in parallel, rather than crossing in the normal fashion. This is optimally seen in a long-axis or short-axis view of the great vessels. A three-vessel view is also useful because only one great vessel (aorta) is usually visualized at this level, in this setting.

Most neonates with D-TGA require immediate treatment. Initially, a temporizing shunt may be created before definitive treatment, frequently with the arterial switch procedure. With surgical intervention, 12-month survival can be expected in 80%.[149] Early intervention (within 3 days of life) when using the **arterial switch operation** is optimal and is associated with an operative mortality below 2%. Major morbidity and cost increase daily thereafter.[150]

Corrected transposition (L-TGA) is characterized by A-V discordance with V-A discordance (Fig. 37.35). It comprises 1% of CHD and 20% of cases of fetal TGA.[47] The aorta, which arises from the left-sided, morphologic right ventricle, is anterior and to the left of the pulmonary artery. The pulmonary artery arises from the right-sided, morphologic left ventricle. VSD and pulmonic stenosis occur in approximately half the cases.[124,151] Malformation and inferior displacement of the morphologic tricuspid valve may be present. Pathophysiologically, the flow of blood through the heart to the pulmonic and systemic circulations is normal, even though the morphologic right ventricle is on the left and the morphologic left ventricle is on the right.

The antenatal sonographic diagnosis rests on demonstrating a parallel arrangement to the great vessels, similar to D-TGA. Differentiating D-TGA from L-TGA entails identification of the morphologic right and left ventricles. The **moderator band** will be seen on the anatomic left side. In addition, the tricuspid valve will be situated on the anatomic left side, so its more apical septal leaflet should be identified. Associated cardiac defects are common and diverse, including VSD, pulmonary stenosis or atresia, ASD, DORV, tricuspid valve anomalies, dextrocardia, mesocardia, and situs inversus. Fetal **A-V block** is common with TGA.[152]

In the absence of associated cardiac anomalies, patients with corrected TGA may remain asymptomatic throughout their lives.

Anomalous Pulmonary Venous Return

APVR can be divided into two subgroups: **total anomalous pulmonary venous return** (TAPVR), in which none of the pulmonary veins drains into the left atrium, and **partial anomalous pulmonary venous return** (PAPVR), in which at least one of the pulmonary veins has an anomalous connection. TAPVR constitutes 2.3% of cases of CHD.[153,154] The four types of anomalous pathways are as follows:

1. The pulmonary veins drain into a vertical vein that empties into the innominate vein and then into the SVC.
2. The pulmonary veins drain into the coronary sinus and then into the right atrium.
3. The pulmonary veins drain directly into the right atrium.
4. The pulmonary vein drains into the portal vein and into the IVC via the ductus venosus.

Embryologically, TAPVR is thought to result from failure of obliteration of the normal connections between the primitive pulmonary vein and the splanchnic, umbilical, vitelline, and cardinal veins. TAPVR is associated with AVSDs and **polysplenia** and **asplenia** syndromes.

The antenatal sonographic diagnosis of TAPVR is difficult because the anomalous veins are generally extremely small and variable in their course. Often the first sign of APVR is mild right ventricular and pulmonary artery prominence, in which case a careful search for the four normal pulmonary veins should be undertaken.[155] This can be difficult because the two inferior pulmonary veins are usually more difficult to visualize than the two superior veins, even in a normal fetal heart. Color and spectral Doppler ultrasound are helpful in documenting the normal pulmonary venous anatomy and in detecting and following the anomalous connections (Fig. 37.36).

The diagnosis of TAPVR is suspected when no pulmonary veins are seen entering the left atrium (Fig. 37.37). A small left atrium resulting from decreased blood return and lack of normal incorporation of the common pulmonary vein into the left atrium is also suggestive of TAPVR. Approximately one-third of patients with TAPVR have associated cardiac anomalies.[156] **Right atrial isomerism** is common. Associated extracardiac anomalies include gut malrotation and midline liver and stomach.[157,158] TAPVR causes minimal hemodynamic disturbance in utero, although hydrops occasionally results. Left untreated, the majority of infants die before 1 year of age.[133] Although PAPVR has also been diagnosed in utero, the diagnosis is more difficult and can be made only when pulmonary veins are seen entering the left atrium as well as the right atrium or an accessory pathway to the right atrium.[159] APVR is associated with high morbidity and mortality, largely because of the high incidence of additional cardiac anomalies.[157,159] Surgical correction of TAPVR is associated with an operative mortality of nearly 20%.[160]

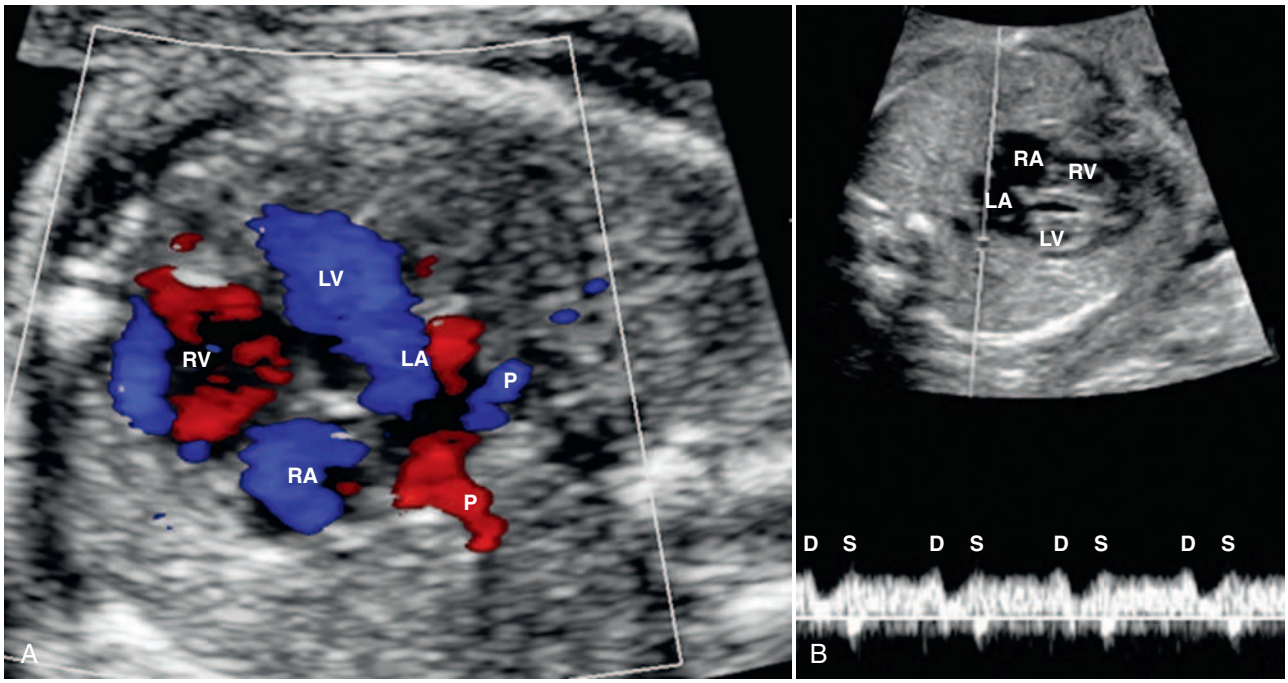

FIG. 37.36 Normal Pulmonary Venous Anatomy. (A) Four-chamber view using color Doppler ultrasound shows two superior pulmonary veins *(P)* entering the left atrium *(LA)*. **(B)** Subcostal four-chamber view using pulsed Doppler ultrasound shows normal waveform and direction of pulmonary venous flow into the LA. *D,* Diastolic peak; *LV,* left ventricle; *RA,* right ventricle; *RV,* right ventricle; *S,* systolic peak.

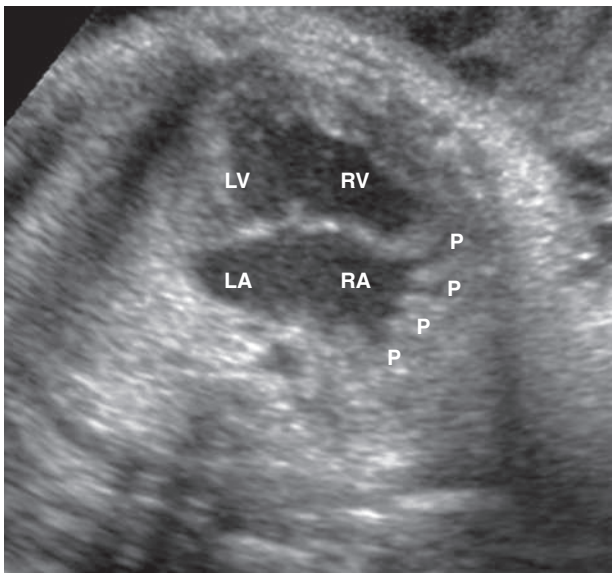

FIG. 37.37 Total Anomalous Pulmonary Venous Return. Apical four-chamber view shows anomalous insertion of all four pulmonary veins *(P)* into the right atrium *(RA). LA,* Left atrium; *LV,* left ventricle; *RV,* right ventricle.

Coarctation of Aorta

Aortic coarctation is a narrowing of the aortic lumen, usually occurring between the insertion of the ductus arteriosus and the left subclavian artery. Its severity ranges from a slight narrowing at the distal end of the arch to severe hypoplasia of the entire arch. Of fetuses with CHD, coarctation has an incidence of 6.8%.[47] Almost 80% of the cases are associated with other cardiac anomalies, including abnormal aortic valve (bicuspid or stenotic), VSD, DORV, and AVSD. Chromosomal abnormalities occur in 5%, and almost 5% of coarctations are associated with maternal diabetes.[59,161] Coarctations are present in approximately 20% of individuals with Turner syndrome (45X).[5]

Three embryologic theories have been proposed to explain the origin of coarctation of the aorta: (1) a primary developmental defect with failure of connection of the fourth and sixth aortic arches with the descending aorta[162]; (2) aberrant ductal tissue at the level of the aortic arch[163,164]; and (3) decreased blood flow through the aortic isthmus.[165]

Sonographic detection of coarctation is difficult.[25] Ventricular size discrepancy with a prominent right ventricle and relatively small left ventricle,[55,165] with a right-to-left ventricle diameter ratio greater than 2 standard deviations (SDs) above the norm,[166,167] suggests coarctation of the aorta. Likewise, a discrepancy in pulmonary artery–to–ascending aorta diameter that falls greater than 2 SDs above the normal ratio of 1.18 to 0.06[167] is suggestive of coarctation.[166] Color Doppler ultrasound is useful in identifying the area of narrowing. Spectral Doppler ultrasound may detect increased velocity distal to the narrowed segment (Fig. 37.38). Many coarctations do not become evident until closure of the ductus arteriosus at birth. In addition, infants with coarctation of the aorta may not develop clinical or echocardiographic signs of coarctation until 6 to 12 weeks after closure of the ductus arteriosus. If coarctation of the aorta is suspected on fetal echocardiogram, the infant should be followed to at least 1 year of age.[168] Although isolated coarctation has a good prognosis, 39% mortality is reported when associated anomalies are present.[169] Treatment is usually accomplished with angioplasty or stenting with good results.[170]

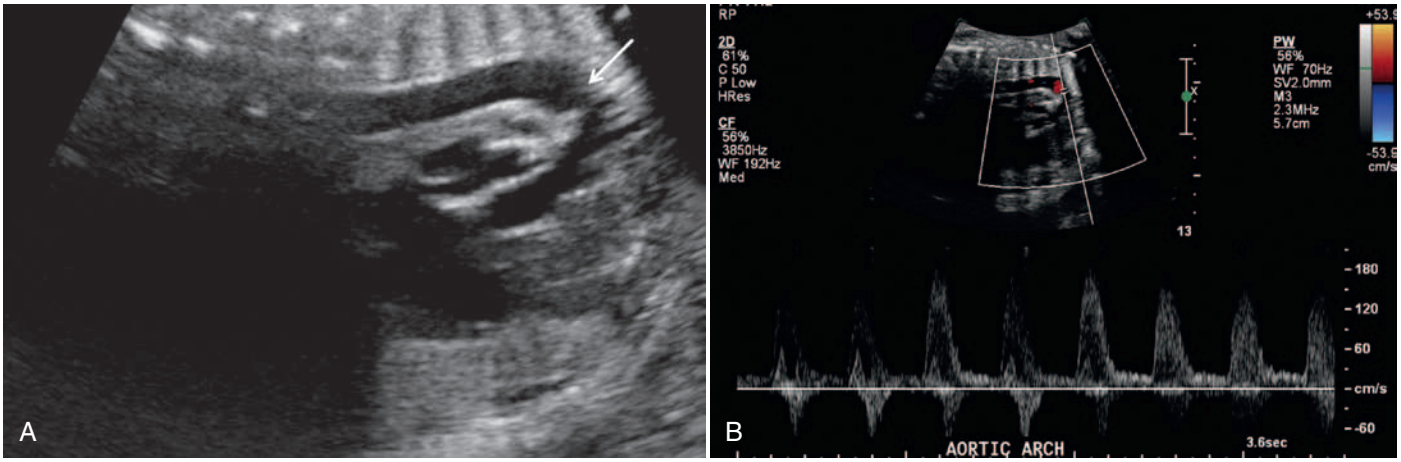

FIG. 37.38 Coarctation of Aorta. (A) Gray-scale image showing narrowing of the aortic arch *(arrow)* at the level of the isthmus. **(B)** Spectral Doppler tracing shows increased velocity and bidirectional blood flow through the aortic arch.

Aortic Stenosis

Aortic stenosis is a stricture or obstruction of the ventricular outflow tract occurring in 5.2% of newborns.[46] Aortic stenosis is divided into supravalvular, valvular, and subvalvular types. The supravalvular type of aortic stenosis has not been reported in utero. **Valvular** aortic stenosis is more frequent in males and is associated with a bicuspid aortic valve and chromosomal abnormalities.[171] **Subvalvular** aortic stenosis is associated with inherited disorders, **asymmetrical septal hypertrophy** (ASH), and **hypertrophic obstructive cardiomyopathy.** Infants of diabetic mothers may have a transient form of left ventricular outflow tract obstruction secondary to ASH.

Thickening of the aortic valve, poststenotic dilation of the aorta, and ventricular enlargement are clues to valvular aortic stenosis. In addition, real-time evaluation of the aortic valve may show it persisting, as opposed to moving normally in and out of the field of view. Thickening of the interventricular septum may be seen in subvalvular aortic stenosis. In all cases, increased velocity through the aortic valve will be identified on pulsed Doppler ultrasound. Early-onset aortic stenosis results in **endocardial fibroelastosis** (EF) and **hypoplastic left ventricle.**[172]

Aortic stenosis progresses in utero and may not be apparent on early (<16 weeks) fetal echocardiograms. In some cases these defects may not be apparent until after birth.[29] A mortality rate of 23% in the first year of life is reported with aortic stenosis.[173] Prognosis has improved with appropriate surgery, with mortality of 1.9% to 9%.[174,175] In some cases, severe aortic stenosis in midgestation may progress in utero to **hypoplastic left heart syndrome.** In cases of critical aortic valvular stenosis, in utero balloon valvuloplasty has been performed with good results.[176]

Pulmonic Stenosis

Pulmonic stenosis may occur at the valve level or at the infundibulum. It occurs in 7.4% of live-born infants with CHD.[46] Dysplastic and stenotic pulmonic valves are seen in **Noonan syndrome** and with **maternal rubella.** Pulmonic stenosis is associated with TAPVR, ASD, supravalvular aortic stenosis, and TOF. The incidence of pulmonic stenosis is higher in monochorionic pregnancies and is 10 times more frequent in the recipient twin of a pregnancy affected with **twin-twin transfusion syndrome.**[177] In this setting the recipient's heart becomes hypertrophic secondary to increased preload. This is similar to the ASH present in fetuses of diabetic mothers and results in anatomic obstruction of the outflow tract.[172]

Increased velocity through the pulmonic valve and hypertrophy of the right ventricle suggest pulmonic stenosis. Similar to aortic stenosis, a real-time image of the stenotic pulmonic valve will show it persisting in the field of view. As with aortic stenosis, pulmonic stenosis tends to progress in utero. Pulmonic stenosis has a variable outcome and can be managed with closed **transventricular valvotomy** or percutaneous balloon valvuloplasty.[178,179] In utero pulmonary balloon valvuloplasty has also been successful but is still in its early phase.[180]

Cardiosplenic Syndromes

Cardiosplenic syndromes are syndromes associated with **asplenia (right isomerism)** and **polysplenia (left isomerism).** Both are defects of lateralization in which symmetrical development of normally asymmetrical organs or organ systems occurs.[180] Asplenia **(Ivemark syndrome)** and polysplenia syndromes are usually considered separate clinical entities. However, they have many characteristics in common, including **situs inversus** or **situs ambiguus** of various visceral organs, complex congenital heart defects,[181] and increased incidence of chronic arrhythmias.[182]

Pathologically, in asplenia or bilateral right-sidedness, left-sided organs are a mirror image of normally right-sided organs. This results in right atrial isomerism, bilateral trilobed lungs, bilateral right bronchi and pulmonary arteries, ipsilateral location of the aorta and IVC (either left or right side), absence of the spleen, a midline horizontal liver, and bilateral SVC.[183] In polysplenia or bilateral left-sidedness, the right lung and bronchial tree morphologically mirror those of the left. In many cases, intrahepatic interruption of the IVC with azygous continuation is present, as are multiple spleens and left atrial isomerism.[184]

Cardiac anomalies associated with these syndromes include TAPVR or PAPVR, ASD, VSD, univentricular heart, TGA, DORV, and pulmonic/aortic stenosis or atresia. Coarctation, hypoplastic

Asplenia and Polysplenia: Associated Findings

ASPLENIA
Absence of spleen
Bilateral right-sidedness
Right atrial isomerism
Bilateral trilobed lungs
Bilateral right bronchi and pulmonary arteries
Ipsilateral location of the aorta and IVC
Bilateral SVC
Situs ambiguous
Midline horizontal liver

POLYSPLENIA
Multiple spleens
Bilateral left-sidedness
Left atrial isomerism
Bilateral bilobed lungs
Bilateral left bronchi and pulmonary arteries
Interruption of IVC
Azygous continuation of IVC
Situs ambiguous
Midline horizontal liver
Congenital heart disease
Complete atrioventricular block

IVC, Inferior vena cava; *SVC,* superior vena cava.

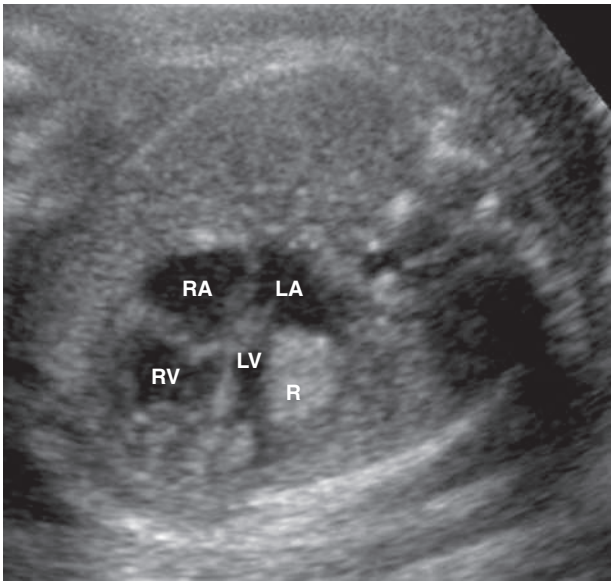

FIG. 37.39 Rhabdomyoma. Apical four-chamber view shows an echogenic mass in the left ventricle *(LV),* consistent with a rhabdomyoma *(R). LA,* Left atrium; *RA,* right atrium; *RV,* right ventricle.

left ventricle, mitral stenosis, cor triatriatum, dextrocardia, right atrial hypoplasia, AVSD, truncus arteriosus, and TOF have also been observed.[184-188] Complete A-V block with an AVSD is associated with polysplenia. Polysplenia syndrome is the second most common disease associated with fetal heart block (after L-TGA).[186]

Cardiosplenic syndromes should be considered when CHD occurs with an arrhythmia. If these syndromes are suspected, a careful search is made for the fetal spleen, which has been visualized at 20 weeks' gestation, with careful consideration of the location of the fetal stomach.[186,189] Other abnormal relationships, such as ipsilateral aorta and IVC (associated with asplenia) or interruption of the IVC with continuation of the azygous vein (associated with polysplenia), may be documented prenatally.

The mortality rate with cardiosplenic syndromes is extremely high. Treatment depends largely on the type and number of associated anomalies. Because cardiac malformations associated with polysplenia are often less severe, they are more amenable to surgical correction than lesions associated with asplenia.[189,190] Neonates with asplenia have a higher mortality and postoperative morbidity because of the high frequency of associated complex cardiac malformations. In polysplenia the greatest attrition occurs in the prenatal period and is often related to heart block with resultant hydrops.[188]

Cardiac Tumors

Fetal cardiac tumors are rare. Approximately 10% are malignant.[191,192] Until the infant is 1 year of age, the majority of cardiac and pericardial masses are **rhabdomyomas** (58%) and **teratomas** (19%). Cardiac **fibromas** account for approximately 12% of the tumors in this age group. Other, less frequent tumors include **mesothelioma** of the A-V node and cardiac **hemangioma** (approximately 2% each).

Sonographically, fetal cardiac **rhabdomyomas** appear as solid, echogenic masses. Rhabdomyomas **(cardiac hamartomas)** are usually multiple, typically arising from the interventricular septum[193-199] (Fig. 37.39). Rhabdomyomas may develop in utero after an initially normal fetal echocardiogram and may increase in size and number over time.[29,196,200-202] This finding underscores the importance of serial fetal echocardiograms in fetuses at risk for rhabdomyomas.

Of patients with cardiac rhabdomyomas, 30% to 78% have **tuberous sclerosis.**[193-195] Other signs of tuberous sclerosis are rarely found in fetal life, with the exception of subependymal tubers in the brain, which can be detected with fetal MRI or by mass effect leading to hydrocephalus.[193] Unfortunately, the absence of cardiac neoplasms in a fetus at risk for tuberous sclerosis does not exclude this diagnosis.[196]

Cardiac tumors become hemodynamically significant by causing obstruction to the outflow tracts or A-V valves, resulting in congestive heart failure, hydrops, pericardial effusion, and arrhythmias.[193] Prognosis depends on the size, number, and location of the tumor as well as associated arrhythmias and anomalies. A meta-analysis of 138 published cases of fetal cardiac rhabdomyomas found that size greater than 20 mm, presence of arrhythmia, and hydrops were significantly associated with increased morbidity.[200] Infants with cardiac rhabdomyomas have a guarded prognosis. Rhabdomyomas are hormone-sensitive neoplasms, which explains their tendency to spontaneously regress.[203] Clinical manifestations associated with fetal cardiac rhabdomyomas are diverse, ranging from spontaneous regression of the tumor to sudden death.[192] After birth, the cells lose the

ability to divide, rhabdomyomas can be expected to shrink or completely resolve, and patients can often be treated conservatively.[204] However, because of the association of rhabdomyomas with tuberous sclerosis and arrhythmias, prognosis remains guarded.[205]

Teratomas may appear as cystic, complex, or solid masses. These are intrapericardial in origin, with attachment to the aortic root or pulmonary artery, and are virtually always associated with a large pericardial effusion. Although teratomas are generally considered to be benign, they can recur after surgical excision and may undergo malignant degeneration.[204] Fetal teratomas are weakly associated with tuberous sclerosis.[196]

Rare cardiac tumors include fibromas and hemangiomas. **Fibromas** are almost always single and typically have central necrosis and calcification.[201] Fibromas are usually located in the ventricular septum, making resection problematic. **Hemangiomas** are even rarer and are usually associated with the right atrium or interventricular septum, often with an intracavitary component. Cardiac hemangiomas are heterogeneous with cystic and solid components, often with calcifications. They are frequently associated with a pericardial effusion.[201]

Echogenic foci within a ventricle should not be mistaken for a cardiac tumor. These are thought to represent areas of mineralization of papillary muscle or chordae tendineae. These usually occur in the left ventricle (93%) but may occur in the right ventricle (5%) or both ventricles (2%) and are generally clinically insignificant[206-208] (Fig. 37.40). Echogenic foci have been associated with chromosomal anomalies such as trisomy 21 and 13. However, more recent literature suggests that in isolation, in an otherwise low-risk pregnancy, an increased risk of aneuploidy does not exist.[208]

Congenital ventricular aneurysms or **diverticula** may be appreciated in utero. Both are usually isolated findings. Ventricular aneurysms appear sonographically as an outpouching of the ventricular myocardium that usually does not contract with the ventricle. A diverticulum of the ventricle appears as a cystic structure connected to the ventricle by a narrow channel. These often do contract with the associated ventricle during systole.[209]

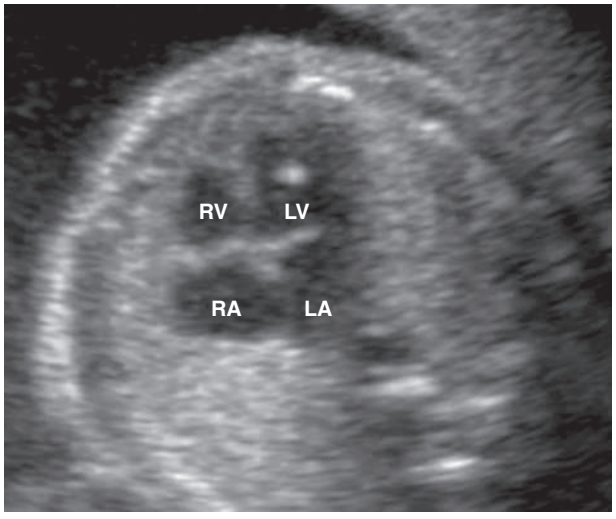

FIG. 37.40 Echogenic Intracardiac Focus. Apical four-chamber view of a fetal heart with an echogenic focus in the left ventricle *(LV). LA,* Left atrium; *RA,* right atrium; *RV,* right ventricle.

Cardiomyopathy

Cardiomyopathy encompasses a diverse group of cardiac disorders with variable etiologies and anatomic and functional characteristics, and all result in an alteration in cardiac function. Cardiomyopathies account for 8% to 11% of fetal cardiovascular disease,[210] but only 1.8% of CHD in live-born infants.[154] Approximately one-third of fetuses with cardiomyopathy die in utero, which accounts for the difference in these numbers.[211]

A variety of conditions can cause fetal cardiomyopathy (Fig. 37.41), including viral and bacterial infections, inborn errors of metabolism, **endocardial fibroelastosis, familial cardiomyopathy,** and **maternal diabetes.** Infectious agents act by damaging the myocardium and producing a myocarditis with resultant cardiomyopathy.[212] In the setting of storage diseases, the myocardium becomes hypertrophic secondary to the accumulation of various products within the myocardial cells. Many cases are idiopathic.[213]

Endocardial fibroelastosis (EF) is a poorly understood process in which diffuse endocardial thickening develops in one or more cardiac chambers. EF is divided into two broad categories, primary and secondary. Primary or isolated EF occurs in the absence of other structural cardiac anomalies. In primary EF the affected ventricle may be dilated or constricted.[214] Viral myocarditis is thought to be the cause of primary fetal EF, with **mumps** and **coxsackievirus B** the most common infections.[213,214] Secondary EF occurs in the setting of a structural cardiac anomaly and usually results in dilation of the affected chambers. The dilated form occurs with **coarctation of the aorta, aortic valvular disease, mitral valvular disease,** and other lesions. The less common constricted form is associated with aortic stenosis or atresia. In both types of EF the mural endocardium is largely replaced by collagen and elastic tissue, giving it a glistening-white appearance grossly[213] and a striking echogenic appearance at echocardiography (Fig. 37.42).

An increased incidence of **asymmetrical septal hypertrophy** (ASH) or **concentric hypertrophy** has long been recognized in **infants of diabetic mothers.**[215] The characteristics of these types of cardiomyopathy have been well documented echocardiographically.[215-218] Overall cardiac size in fetuses of diabetic mothers can be increased as a result of the hypertrophy.[219] Fetal **hypertrophic cardiomyopathy** can be expected in about 20% of pregnancies with pregestational diabetes and appears to be associated with an elevated third-trimester maternal hemoglobin A_{1c} and with an elevated neonatal insulinlike growth factor-1 (IGF-1) level.[220] Regardless of the cause, severe cardiomyopathy results in decreased cardiac function and a tendency to develop congestive heart failure. This may be secondary to obstruction of ventricular emptying in obstructive forms of cardiomyopathy or to pump failure in nonobstructive forms. The sonographic diagnosis of obstructive cardiomyopathy depends on the demonstration of hypertrophy of the ventricular wall or septum. **Nonobstructive cardiomyopathy** can be diagnosed by demonstrating dilation of one or more cardiac chambers along with poor ventricular contractility. About 37% of live-born infants with cardiomyopathy

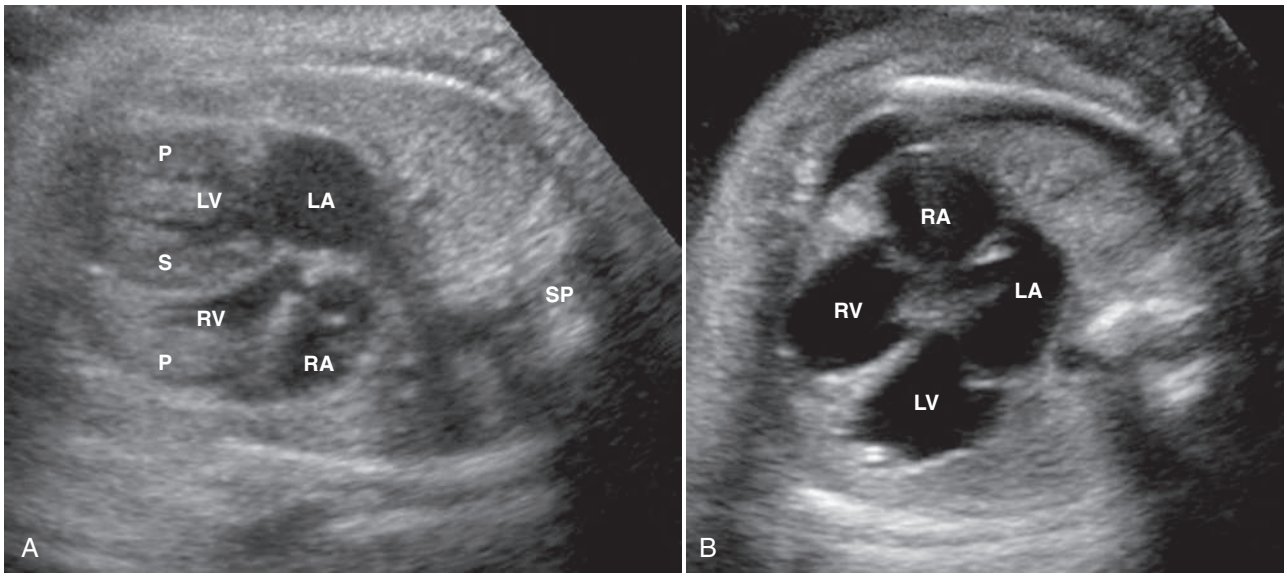

FIG. 37.41 Cardiomyopathy. (A) Concentric hypertrophy of the ventricular heart walls *(P)* and the interventricular septum *(S)* in fetus with **hypertrophic cardiomyopathy. (B)** All four cardiac chambers are enlarged, occupying more than half the fetal chest in this fetus with **dilated cardiomyopathy.** A pleural effusion is also seen. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle; *SP,* spine.

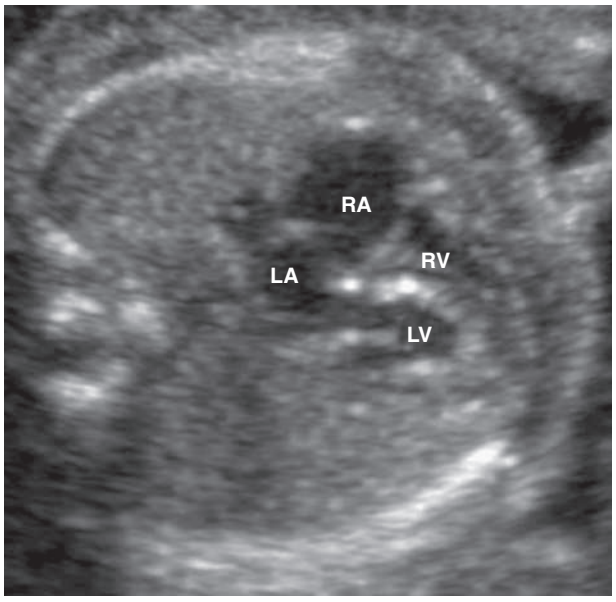

FIG. 37.42 Endocardial Fibroelastosis. Subcostal four-chamber view shows echogenic walls of the left ventricle *(LV). LA,* Left atrium; *RA,* right atrium; *RV,* right ventricle.

have associated anomalies.[154] The prognosis for fetal cardiomyopathy is variable, depending on the severity of the cardiac lesion, the underlying cause, and associated anomalies. When hydrops accompanies cardiomyopathy, the prognosis is poor.

Ectopia Cordis

Ectopia cordis is a rare malformation in which the heart is located outside the thoracic cavity. It results from failure of fusion of the lateral body fold in the thoracic region. Ectopia cordis is classified by the following four types[221]:

1. **Thoracic** (60%). The heart is displaced from the thoracic cavity through a sternal defect.
2. **Abdominal** (30%). The heart is displaced into the abdomen through a diaphragmatic defect.
3. **Thoracoabdominal** (7%). The heart is displaced from the chest through a defect in the lower sternum, with an associated diaphragmatic or ventral abdominal wall defect (pentalogy of Cantrell).
4. **Cervical** (3%). The heart is displaced into the neck area.

Although most cases are isolated, ectopia cordis may be associated with **pentalogy of Cantrell,** a condition characterized by a sternal cleft, ventral diaphragmatic hernia, omphalocele, intracardiac anomalies, and ectopia cordis.[222] A variety of cardiac and chromosomal anomalies are associated with ectopia cordis. The sonographic diagnosis is generally not difficult and has been made as early as 9 weeks' gestation,[223] although the abdominal and cervical types have not been reported in utero (Fig. 37.43). The prognosis is poor, with most infants dying within a few days of birth.[224]

ARRHYTHMIAS

Premature Atrial and Ventricular Contractions

Premature atrial contractions (PACs) and **premature ventricular contractions** (PVCs) are abnormal atrial or ventricular contractions originating from locations other than the sinus node. PACs account for almost 75% and PVCs for 8% of fetal arrhythmias.[40,225] PACs are associated with redundancy of the foraminal flap **(atrial septal aneurysm),** maternal caffeine ingestion, and smoking.[226,227] In 1% to 2% of PACs, a structural cardiac anomaly is present.[37]

PACs may be **conducted** or **nonconducted.** In either case, the **atrial pacemaker** is "reset" so that the next normal atrial

beat is also early. PVCs have an early ventricular contraction that is not preceded by an atrial contraction. The atrial pacemaker is not reset, and the next normal beat occurs when expected, as if the rhythm were regular. Thus PVCs are **compensatory,** allowing the preexisting rhythm to continue, whereas PACs are generally **less than compensatory.** PACs and PVCs may be distinguished by M-mode or spectral Doppler sonography (see Fig. 37.15) by placing the M-mode cursor or spectral Doppler sample volume simultaneously through an atrial and ventricular structure. PACs followed by ventricular contraction are described as **"conducted,"** whereas a PAC that is not followed by a ventricular contraction is **"nonconducted"** or "blocked." These must be differentiated from A-V block, in which a PAC does not occur. Conducted PACs can be distinguished from PVCs by noting that a PAC precedes the early ventricular beat and that, in the majority of cases, PACs are less than compensatory whereas PVCs are generally compensatory.

Premature contractions are benign arrhythmias in most cases. Most disappear in utero or in the early neonatal period. From 1% to 2% of PACs may evolve into sustained tachyarrhythmia.[228]

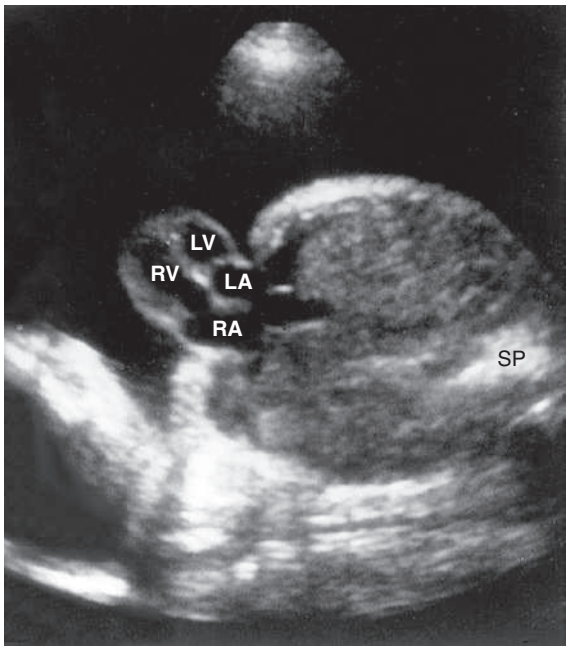

FIG. 37.43 Thoracic Ectopia Cordis. The heart is located outside the thorax. *LA,* Left atrium; *LV,* left ventricle; *RA,* right ventricle; *RV,* right ventricle; *SP,* spine.

Tachycardia

Fetal tachycardia is a heart rate greater than 180 beats/min. **Supraventricular tachycardias** (SVTs) are more common in the fetus than ventricular tachycardias. Of cases of SVT, 5% to 10% are associated with CHD.[229]

SVTs are classified as follows:

- **Paroxysmal supraventricular tachycardia:** atrial rate of 180 to 300 beats/min and a conduction rate of 1:1 (Fig. 37.44).
- **Atrial flutter:** atrial rate of 300 to 400 beats/min, frequently associated with heart block, and a conduction rate of 2:1 to 4:1, yielding a ventricular rate of 60 to 200 beats/min.
- **Atrial fibrillation:** atrial rate of greater than 400 beats/min and an irregular ventricular response at a rate of 120 to 160 beats/min.

Ventricular tachycardia is defined as a rapid heart rate associated with three or more consecutive premature ventricular systoles.

Fetal cardiac rhythm disturbances are usually first suspected on the basis of auscultatory findings. M-mode and pulsed Doppler echocardiography are useful in identifying and characterizing tachycardias by observing the atrial and ventricular rates. The M-mode tracing is obtained through the heart to allow independent assessment of atrial and ventricular wall motion. Further information is obtained from simultaneous recordings of the atrial and ventricular walls or A-V and semilunar valve motion. Spectral Doppler ultrasound evaluation can demonstrate

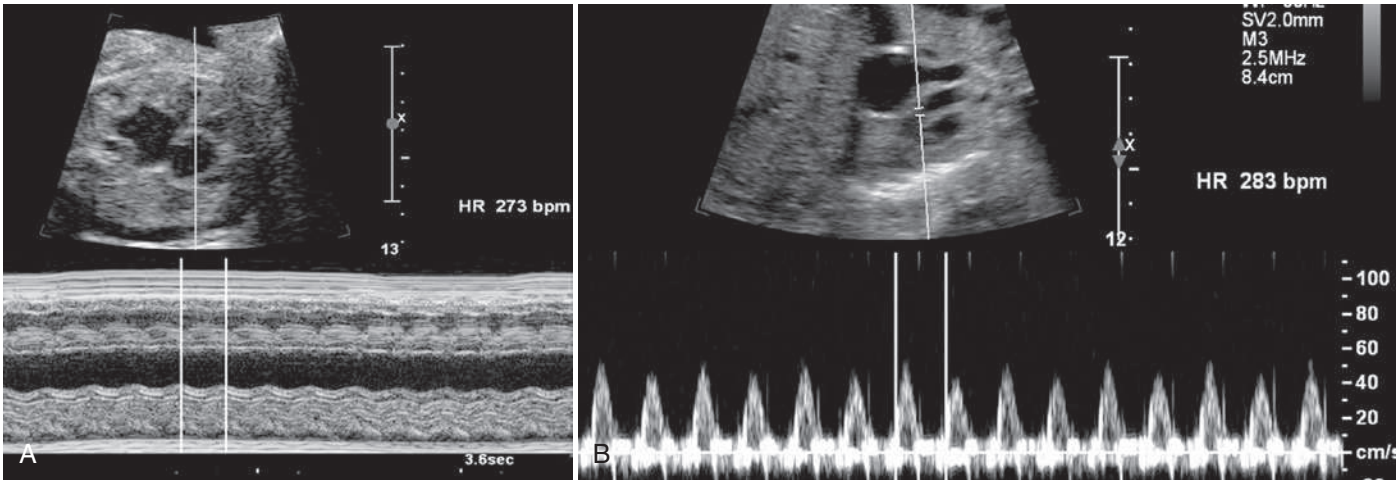

FIG. 37.44 Supraventricular Tachycardia. (A) M-mode tracing through the left ventricle and the right atrium shows a fetal heart rate of 273 beats/min and a 1:1 conduction. **(B)** Spectral Doppler ultrasound through the aortic valve in the same fetus shows a heart rate of 283 beats/min.

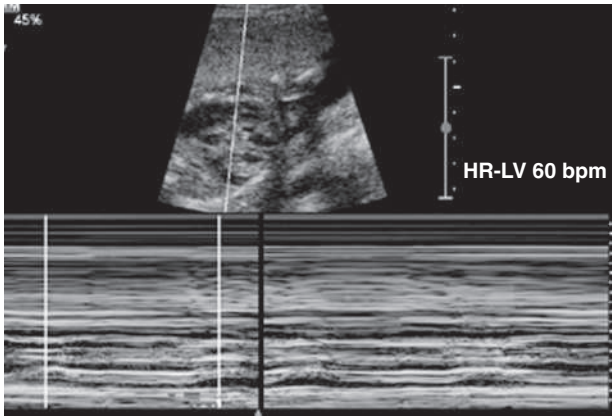

FIG. 37.45 Fetal Bradycardia. M-mode tracing shows ventricular rate of 60 beats/min.

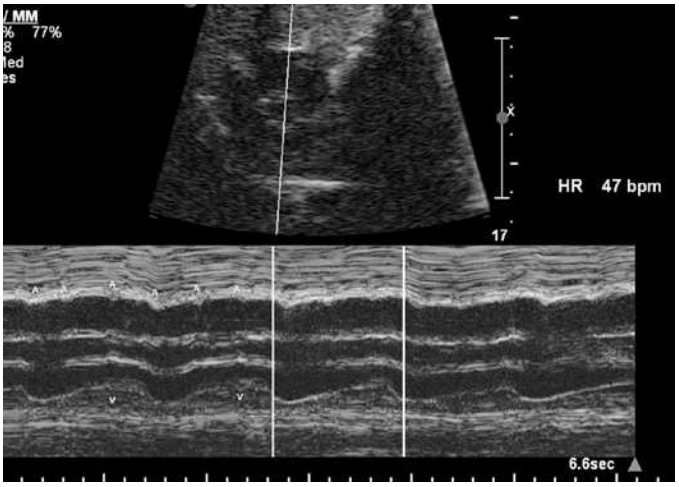

FIG. 37.46 Complete Heart Block. M-mode tracing shows a slow ventricular rate *(V)* of 47 beats/min, with an irregular disassociated atrial rate *(A)*.

decreased flow velocities and cardiac output during SVT.[230] Fetal SVT can lead to fetal cardiovascular compromise, hydrops, and death.

Most fetal tachycardias have a relatively good prognosis and can be treated in utero with various pharmacologic agents. Careful interrogation of the tricuspid valve with color and spectral Doppler ultrasound imaging is warranted in the setting of fetal tachycardia because tricuspid valvular dysfunction with tricuspid regurgitation can be the first indication of imminent congestive failure and hydrops.[231,232] In the presence of hydrops, immediate and aggressive therapy is warranted.[225,228,233-238] Several antiarrhythmic drugs are available to attempt to cardiovert SVTs in utero. Prognosis in the setting of fetal tachyarrhythmia depends on a number of factors, including type and duration of arrhythmia, presence of structural cardiac anomalies, gestational age, and response to intrauterine therapy.[231]

Bradycardia

Fetal bradycardia is a "prolonged" heart rate of 100 beats/min or less (Fig. 37.45). Approximately 5% of fetal arrhythmias are classified as bradycardia.[37] Transient bradycardia can be related to an increase in intrauterine pressure, occasionally secondary to the pressure of an ultrasound transducer or fetal compression of the umbilical cord.[239,240] This is often seen during fetal sonograms and is of no clinical consequence, unless the bradyarrhythmia is sustained.

Sinus bradycardia without fetal hypoxia is rare.[240] If less than 80 beats/min, sinus bradycardia may be associated with fetal asphyxia. A fetal heart rate below 80 beats/min lasting longer than 13 minutes is associated with acidemia-induced cerebral palsy.[241] Heart rates lower than 100 beats/min during the first trimester are associated with an increased risk of fetal demise.[242] When bradycardia is associated with an increased nuchal translucency, risk for CHD is increased, and early transvaginal fetal echocardiography should be considered. Complex CHD has been detected in the first trimester in this clinical setting.[242] The fetus with sustained bradycardia should have careful follow-up and monitoring for signs of cardiac failure. Persistent bradycardia may warrant early delivery. In utero treatment has had limited success.[243]

Congenital Heart Block

Failure of transmission of impulses from the atrium to the ventricles results in **atrioventricular block** (AVB). AVB is classified into the following three types:

- **First-degree block:** a prolonged PR interval results in a conduction delay, but without markedly abnormal rate or rhythm. This may only be appreciated in utero by measuring the PR interval on spectral Doppler tracing.
- **Second-degree block:** with blockage of a single atrial beat **(Mobitz type I)** or with intermittent conduction abnormalities, such that the ventricular rate is a fraction of the atrial rate **(Mobitz type II).**
- **Third-degree** or **complete heart block:** the ventricular and atrial rates are entirely dissociated (Fig. 37.46).

In the normal heart, an electrical impulse originates from the sinoatrial (SA) node and travels to the A-V node and through the **Purkinje system** to the ventricles. AVB results from immaturity or complete absence of the conducting system or from abnormalities at the level of the A-V node. This rare disorder is associated with **maternal collagen vascular disease (systemic lupus erythematosus).**[244] After one affected child, further pregnancies carry a 17% to 30% risk for AVB.[245,246] Serial fetal echocardiograms are useful in the fetus at risk for congenital complete heart block related to maternal lupus. This monitoring allows early detection and treatment of the immune-mediated fetal myocarditis and congenital complete heart block.[247-249]

In the absence of associated structural abnormalities, the prognosis for a fetus with congenital heart block is good. However, at least 40% of fetuses with complete heart block have structural cardiac abnormalities.[37] When associated cardiac anomalies exist, the prognosis is poor. Fetuses with AVB are at risk for heart failure and should be monitored closely. Overall, the vast majority of fetuses with arrhythmias have a good outcome. The incidence of associated structural cardiac disease is as low as 0.3%, similar to that in the general population, and the incidence of significant arrhythmia is only 1.6%.[249]

CHAPTER 38

The Fetal Gastrointestinal Tract and Abdominal Wall

Nir Melamed, Anne Kennedy, and Phyllis Glanc

SUMMARY OF KEY POINTS

- The gastrointestinal (GI) tract and abdominal wall anomalies are diverse. Although they may occur in isolation, many are associated with syndromic or karyotype abnormalities; thus it is important to search for associated anomalies.
- Familiarity with normal development is needed to recognize the varying appearances during gestation of structures such as the abdominal wall with physiologic midgut herniation, the identification of the gallbladder in the latter half of pregnancy, or the appearance of meconium at different stages of gestation.
- The prognosis and presentation of a GI tract or abdominal wall anomaly may vary with the stage of gestation.
- Anomalies of the GI tract may be diagnosed as part of the evaluation of indirect clues such as polyhydramnios.
- Early prenatal diagnosis, in particular of abdominal wall anomalies, may be performed by late first trimester, in conjunction with a nuchal translucency evaluation.
- Abnormalities of the GI tract may not be clinically apparent in the newborn; thus prenatal diagnosis facilitates appropriate triage to a center that can provide treatment.

CHAPTER OUTLINE

THE GASTROINTESTINAL TRACT
Embryology of the Digestive Tube
Esophagus
Esophageal Atresia
Stomach
Small or Absent Fetal Stomach
Dilated Fetal Stomach
Midline or Right-Sided Stomach
Intraluminal Gastric Masses

Cloacal Exstrophy
Ectopia Cordis
Other Complex Body Wall Defects
Pentalogy of Cantrell
Body Stalk Anomaly
Amniotic Band Syndrome

Systematic and thorough evaluation of the fetal gastrointestinal (GI) tract and abdominal wall is critical to ascertain the risk of isolated and multiple fetal abnormalities. Anomalies of the fetal abdomen may be the only sonographic evidence of multisystem organ derangement secondary to conditions such as genetic disorders or fetal infection. Furthermore, detection of fetal intraabdominal masses or abnormalities is important because these conditions may not be detected on the routine newborn examination. In some cases, anomalies of the GI tract may be diagnosed as part of the evaluation of indirect clues such as polyhydramnios.

THE GASTROINTESTINAL TRACT

Embryology of the Digestive Tube

The GI tract begins to develop in the third and fourth weeks of life. The primitive gut tube is formed by incorporation of the

dorsal part of the yolk sac into the embryo following the longitudinal and lateral folding of the embryonic disc. The gut tube is lined by the embryonic endoderm and is closed at its cranial and caudal ends by the oropharyngeal membrane and the cloacal membrane, respectively.[1] Subsequently, the gut tube undergoes regionalization into three portions. The **foregut,** the most cranial portion, gives rise to the esophagus, stomach, duodenum, liver and bile ducts, and pancreas. The **hindgut,** the most caudal portion, differentiates into the distal part of the colon (beyond the splenic flexure), which is partially supplied by the inferior mesenteric artery. In between, the **midgut** gives rise to the largest part of the intestine, which is supplied by the superior mesenteric artery, and includes the second half of the duodenum (distal to the ampulla of Vater), jejunum, ileum, ascending colon, and the proximal two-thirds of the transverse colon. The midgut remains in connection with the yolk sac via the yolk stalk (omphalomesenteric duct or vitelline duct).[2-6]

Esophagus

Esophageal Atresia

The normal fetal esophagus, extending from the pharynx to the stomach, is collapsed and may therefore be difficult to visualize, or it may be demonstrated as two or four echogenic lines representing the esophageal walls.

Developmentally, the trachea and esophagus differentiate inferiorly from the posterior pharynx. Incomplete differentiation of the respiratory and GI tracts can lead to **esophageal atresia** with or without **tracheoesophageal fistulas.** The incidence of all types of tracheoesophageal fistulas is 2.8 per 10,000 pregnancies.[7,8] There are five types of esophageal atresia,[9] with the most common having a fistula to the distal esophagus. Because most types of esophageal atresia (90%)[10] are associated with tracheoesophageal fistulas, in many cases the stomach (although often small) will be visualized on ultrasound, and polyhydramnios may be absent or mild or present only later in gestation (Table 38.1).

The main sonographic signs of esophageal atresia include **absent or small stomach** (Fig. 38.1), **polyhydramnios,** and the **esophageal pouch sign** (fluid collection in the blind end of the esophagus)[11] (Fig. 38.2A). At times a distended oropharynx will be seen (Fig. 38.2B, Video 38.1). However, the demonstration of esophageal pouch can be difficult because of variation in the location and periodic emptying of the pouch. The antenatal diagnosis of esophageal atresia is challenging, and in many cases the diagnosis is only made during the neonatal period. One

TABLE 38.1 Types of Esophageal Atresia

Type	Description	Proportion of Esophageal Atresia (EA) Cases
A	EA without tracheoesophageal (TE) fistula	10%
B	EA with TE fistula to the proximal esophageal segment	<1%
C	EA with TE fistula to the distal esophageal segment	85%
D	EA with TE fistula to both proximal and distal esophageal segments	<1%
E	TE fistula without esophageal atresia	5%

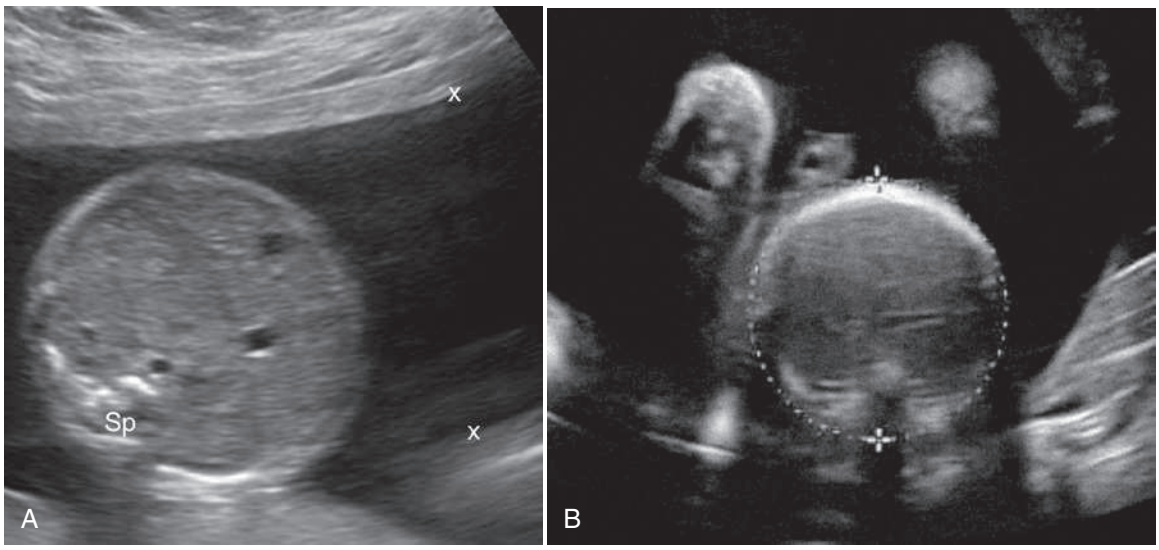

FIG. 38.1 Esophageal Atresia and Absent Stomach. (A) Transverse ultrasound through the abdomen in a 25-week fetus shows no visible stomach. Polyhydramnios is present; vertical pocket of amniotic fluid *(X marks)* measured >8 cm. *Sp,* Spine. **(B)** Third-trimester fetus with absent stomach and polyhydramnios.

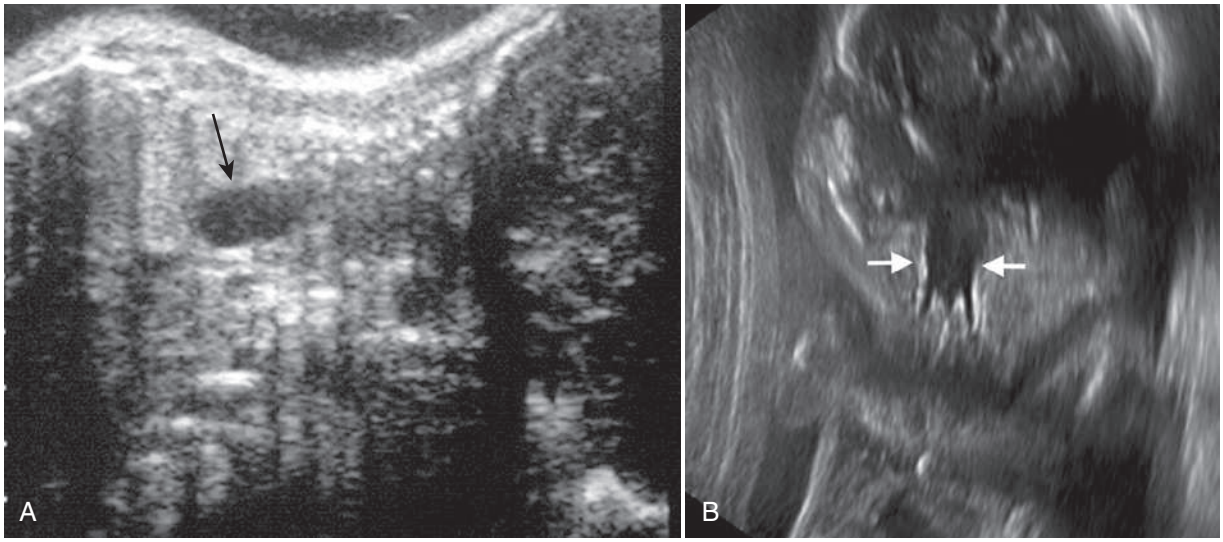

FIG. 38.2 Esophageal Atresia. (A) Coronal view of upper thorax shows a distended **esophageal pouch** *(arrow).* **(B)** Coronal image through the neck in a 25-week fetus shows distended oropharynx *(arrows)* secondary to esophageal atresia. See also Video 38.1.

study reported the antenatal detection rate of esophageal atresia to be 42%.[12] The combination of inability to see the stomach on ultrasound and the presence of polyhydramnios is more suggestive of esophageal atresia than absent stomach alone, but the positive predictive value of this combination is still relatively modest (56%).[12]

Esophageal atresia is associated with additional anomalies in more than 50% of cases,[8,13] and a detailed anatomic evaluation, including echocardiography, should be performed in a fetus with this suspected diagnosis. It has been reported that as many as half of tracheoesophageal fistulas are part of the **VACTERL sequence,**[7] a sporadic nonrandom group of coexisting defects (*v*ertebral defects, *a*nal atresia, *c*ardiac anomalies, *t*racheoesophageal fistula with *e*sophageal atresia, *r*enal and *l*imb defects such as radial dysplasia). Amniocentesis should be considered because the risk of aneuploidy ranges from 5% to 10%.[7] Corrective surgery for esophageal atresia has a success rate of 90% and is influenced by the presence of associated anomalies.[10]

Stomach

The fetal stomach can be seen as early as 7 weeks and should be noted routinely by 13 to 14 weeks' gestation[14] (Fig. 38.3). The stomach should be seen as a cystic structure in the left upper abdomen. It is important to confirm the location of the stomach because a midline or right-sided stomach is associated with heterotaxy syndrome.

Small or Absent Fetal Stomach

Fluid in the stomach should be reliably visualized on first-trimester screening or fetal anatomic survey and all subsequent fetal evaluations. Nonvisualization of the stomach on an anatomic survey (see Fig. 38.1), although potentially a normal finding following recent emptying of the stomach, is associated with an increased risk of fetal abnormalities and may be the result of esophageal obstruction or atresia, disorders affecting the mechanism of swallowing, severe oligohydramnios (which limits the amount of amniotic fluid swallowed by the fetus), or abnormal location of the stomach.

Absent Stomach

ESOPHAGEAL OBSTRUCTION
Esophageal atresia
Esophageal compression (e.g., goiter, tumor or masses in the pharynx, lungs, or mediastinum)

DISORDERS AFFECTING SWALLOWING
Anatomic factors (e.g., cleft palate)
Neurologic disorders

SEVERE OLIGOHYDRAMNIOS OR ANHYDRAMNIOS
DISPLACEMENT OF THE STOMACH
Congenital diaphragmatic hernia
Abdominal wall defects
Heterotaxy syndromes

When the stomach appears small or absent, it is important to allow sufficient time for it to fill, in case it has recently emptied. Generally, the stomach will fill during a 30-minute examination.[15] Careful attention must be paid to the amniotic fluid volume (oligohydramnios or polyhydramnios), general tone and presence of swallowing movements, the appearance of the thorax and diaphragm (masses, diaphragmatic hernia), and abdominal situs.

In one retrospective study, an abnormal outcome (structural abnormalities, antenatal or postnatal death) occurred in 23 (85%) of 27 fetuses with an absent stomach and 27 (52%) of 52 fetuses with a small stomach (combined, 63%). Karyotype was abnormal in 8 (38%) of 21 fetuses with an absent stomach and 2 (4%) of 46 fetuses with a small stomach.[16] For these reasons, the finding of a persistently absent stomach on serial ultrasound scans should trigger a detailed anatomic assessment, genetic counseling, and consideration of chromosomal testing.

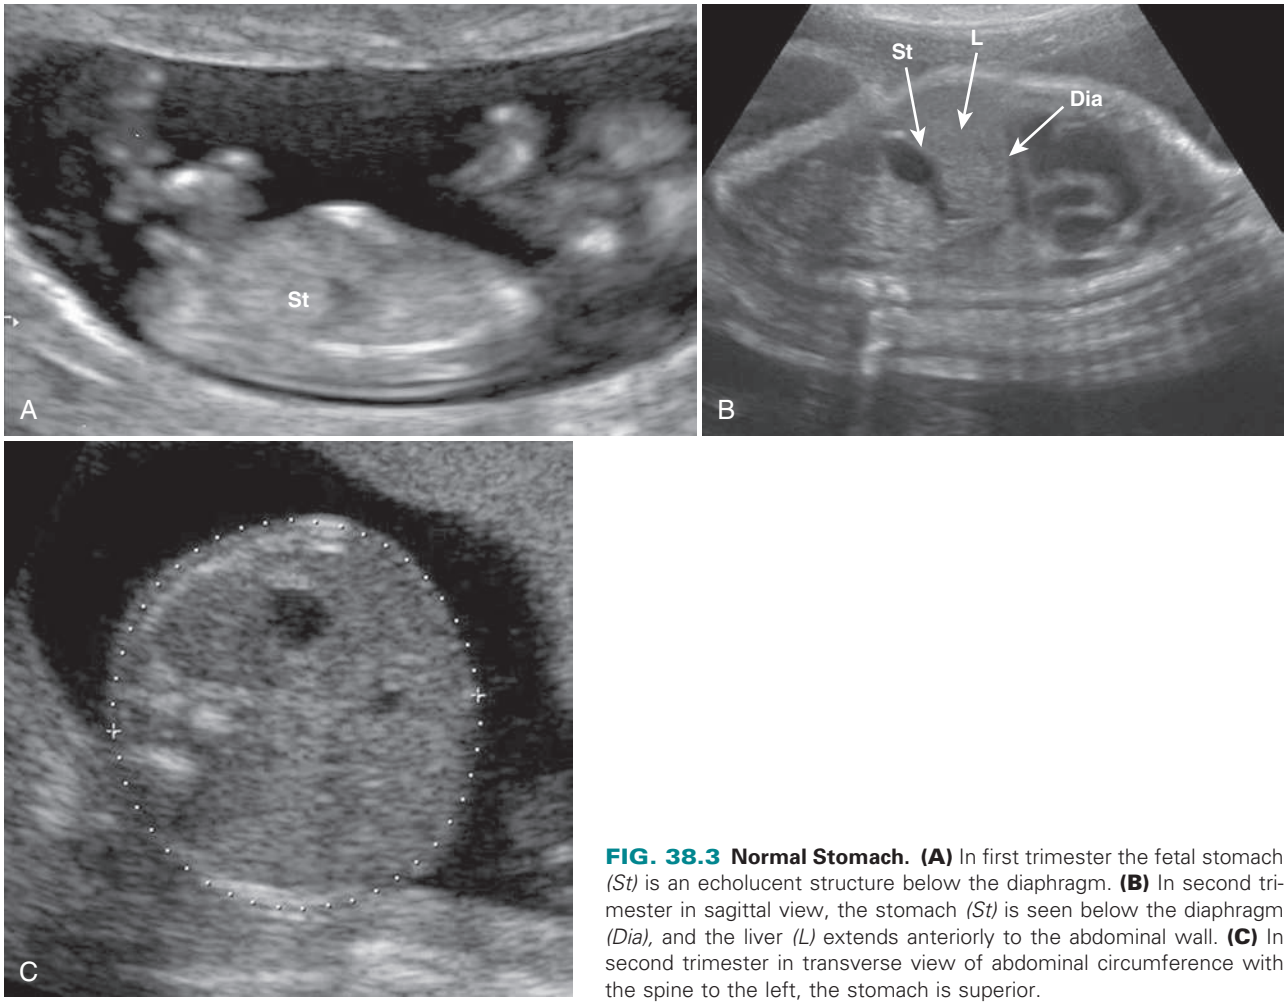

FIG. 38.3 Normal Stomach. (A) In first trimester the fetal stomach *(St)* is an echolucent structure below the diaphragm. **(B)** In second trimester in sagittal view, the stomach *(St)* is seen below the diaphragm *(Dia),* and the liver *(L)* extends anteriorly to the abdominal wall. **(C)** In second trimester in transverse view of abdominal circumference with the spine to the left, the stomach is superior.

Dilated Fetal Stomach

In the second or third trimester a prominent or transiently dilated fetal stomach may be seen on ultrasound. Use of a nomogram can aid in identifying true outliers.[17] However, there is a considerable variation in the normal size of the stomach, and given the asymmetrical shape of the stomach, standardization of the measurement of the stomach dimensions is difficult.[15] In addition, because of the considerable normal fluctuations in stomach size, the diagnosis of a dilated fetal stomach requires that the stomach be persistently dilated throughout a 30-minute assessment as well as on successive examinations. The differential diagnosis of a dilated fetal stomach includes normal variation in stomach size and GI atresia (e.g., **duodenal atresia, pyloric atresia**) as well as pyloric stenosis (Fig. 38.4).

Pyloric atresia is a rare form of intestinal atresia.[18-20] The underlying cause is thought to be different than that of atresia of other parts of the GI tract, and a familial form with an autosomal recessive transmission is well documented.[21] A unique aspect of pyloric atresia is the association with **epidermolysis bullosa,** an often fatal skin disorder characterized by blisters in the skin and mucosal membranes which is inherited in an autosomal recessive pattern. The main sonographic findings in cases of pyloric atresia include gastric dilatation (which can be massive), esophageal dilatation caused by gastroesophageal reflux, and severe polyhydramnios. The co-presence of epidermolysis bullosa may be suggested by elevated levels of maternal serum alpha-fetoprotein and snowflake appearance of the amniotic fluid[22] and can be confirmed by molecular analysis of fetal skin biopsy.[21,23]

Midline or Right-Sided Stomach

An abnormal position of the stomach is an important clue for the presence of a severe abnormality and therefore requires detailed anatomic assessment. A right-sided stomach (Fig. 38.5B) should raise the possibility of **heterotaxy syndrome,** which is characterized by an abnormal symmetry of the viscera and veins and is associated with complex cardiac anomalies, intestinal malrotation, and splenic (asplenia or polysplenia) (Fig. 38.6) and hepatic abnormalities.[24,25] The incidence of heterotaxy syndrome with asplenia or polysplenia is 0.45 per 10,000 pregnancies.[26] Because of the combined cardiovascular and GI abnormalities, infant mortality is high, with the 1-year mortality rate reaching 32%.[27] A midline stomach can represent i**ntestinal malrotation.**[28]

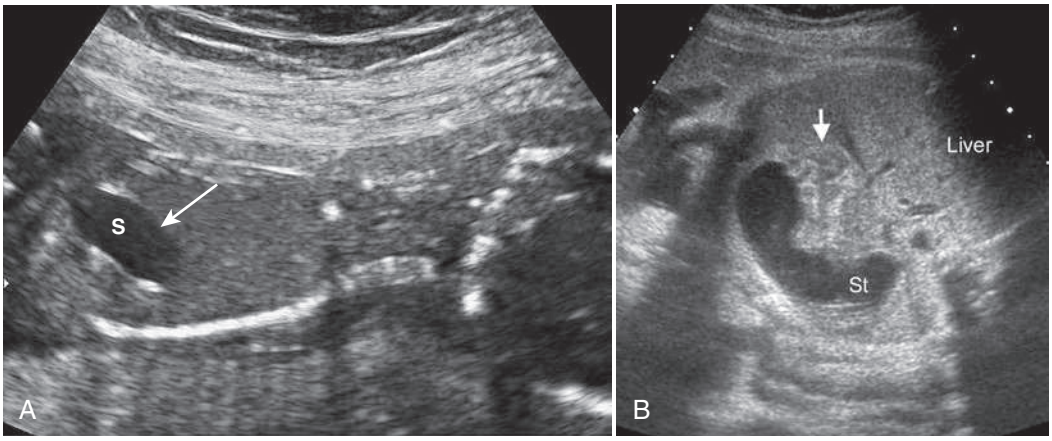

FIG. 38.4 Dilated Stomach. (A) Dilated fetal stomach *(S)* in the second trimester. In sagittal view the stomach is visible extending inferiorly into the pelvis. Although this fetus had a persistently dilated stomach during an anatomic survey, it resolved by the next ultrasound, and the fetus had a normal outcome. **(B) Pyloric stenosis.** Transverse ultrasound in 32-week fetus shows a dilated stomach *(St)* with prominent sustained contraction of the pylorus *(arrow).*

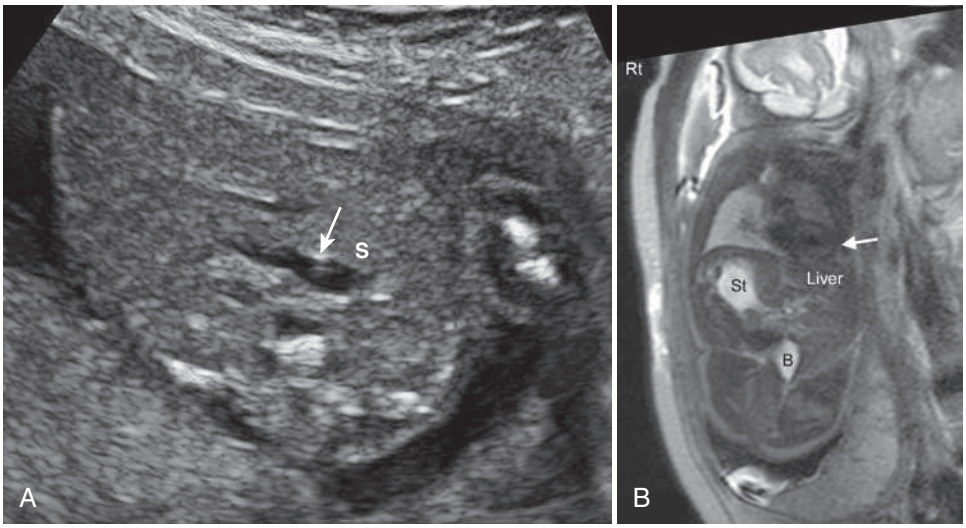

FIG. 38.5 Stomach in Abnormal Location. (A) Midline stomach in fetus with **heterotaxy.** Transverse view of the abdomen shows a midline stomach *(arrow).* This was the only abnormality seen at time of fetal survey; fetal echocardiogram revealed anomalous pulmonary venous return, and the diagnosis of heterotaxy was confirmed postnatally. **(B)** Heterotaxy syndrome with **right-sided stomach.** Coronal T2-weighted fetal magnetic resonance image (MRI) at 34 weeks shows left-sided liver and right-sided stomach *(St).* The cardiac apex *(arrow)* is directed left. *B,* Bladder.

Intraluminal Gastric Masses

The presence of irregular **echogenic content** or **debris** within the fetal stomach can often be seen on routine ultrasound exams (Fig. 38.7, Videos 38.2 and 38.3). This finding is nonspecific and when found in isolation it is most likely to be a normal finding. Such debris most often represents blood, skin cells, or meconium swallowed by the fetus.[29-32]

Small Bowel and Colon

In the first trimester and early in the second trimester, the small and large bowel appear somewhat heterogeneous, with an echogenicity similar to that of the liver. Later in pregnancy, fluid can be seen in the small bowel loops, and meconium can be seen in the colon. Most cases of GI atresia are thought to represent a failure of recanalization of the bowel lumen, which is a solid tube early in fetal life.

Bowel Obstruction

Duodenal Obstruction. Dilatation of the duodenum resulting from **duodenal stenosis** or **duodenal atresia** is the most common type of bowel obstruction in the fetus, occurring in 1 or 2 per 10,000 live births.[33-35] Duodenal atresia may result from failure of recanalization of the duodenal lumen, periampullary obstruction, complete absence of a duodenal segment, or vascular ischemia.[36-39] Less commonly, duodenal obstruction may be secondary to mechanical factors such as **annular pancreas, superior mesenteric artery syndrome,** or **volvulus.**[40,41]

Associated anomalies are common and are present in more than half of cases[42]; most notably, 30% to 44% of cases of duodenal atresia are associated with trisomy 21.[33,43] Familial cases of duodenal atresia have also been reported.[44] Duodenal atresia is also associated with anomalies of the **VACTERL** spectrum.[45,46]

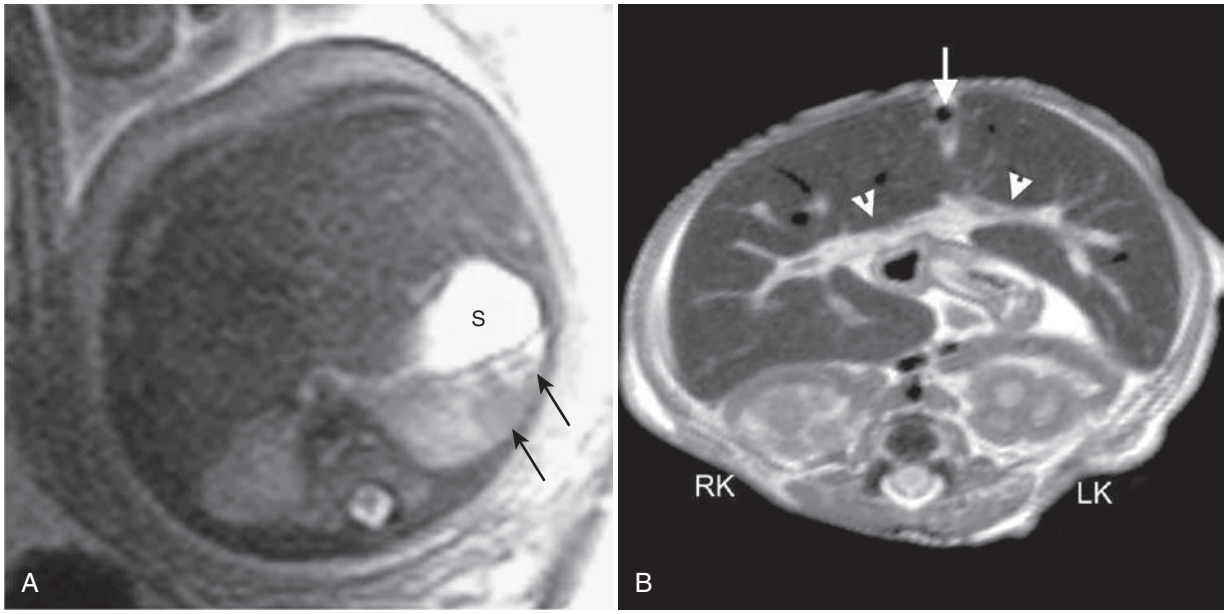

FIG. 38.6 Heterotaxy With Asplenia or Polysplenia. (A) Polysplenia. Transverse MRI of fetus with complex congenital heart disease (not shown) with multiple splenules *(arrows)* in the left upper quadrant. *S,* Stomach. **(B) Asplenia** in a transverse image from an autopsy MRI in a term infant with nonreparable, complex congenital heart disease as part of a heterotaxy syndrome shows asplenia with central liver placement. The portal vein *(arrowheads)* bifurcates centrally. The arrow denotes the umbilical vein. *LK,* Left kidney; *RK,* right kidney.

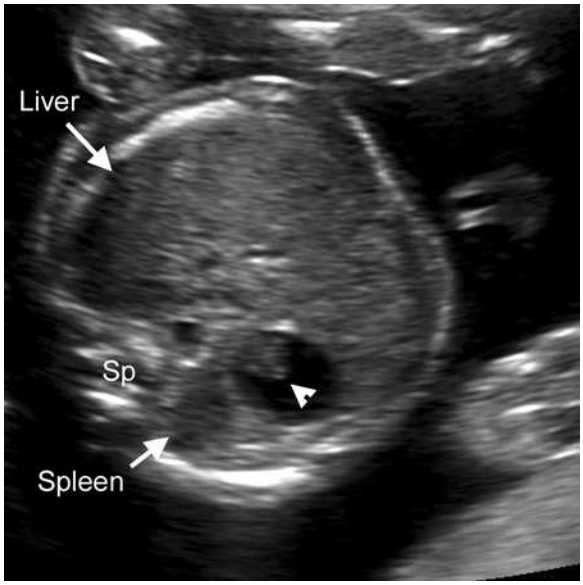

FIG. 38.7 Gastric Debris. Transverse image through the abdomen in a 25-week fetus shows a masslike structure in the stomach *(arrowhead).* This is a benign finding thought to represent swallowed debris or vernix. *Sp,* Spine. See also Videos 38.2 and 38.3.

The sonographic hallmarks in cases of duodenal atresia are the presence of severe polyhydramnios (which may not be present until the late second or third trimester) and the **"double-bubble" sign,** in which a second echolucent mass is seen medial to the stomach bubble in a transverse view of fetal abdomen (Fig. 38.8, Video 38.4). This sign is the result of the dilated segment of the duodenum proximal to the atretic area and is highly suggestive of duodenal obstruction. It is important to demonstrate continuity between the fluid-filled structures to prove that the diagnosis is duodenal stenosis/atresia.

A prominent incisura angularis of the stomach may be mistaken for a "double bubble" if these are in different planes, but a careful real-time longitudinal examination of the stomach can eliminate this possibility. Other, less common reasons for an apparent double-bubble sign include **choledochal cyst** and **duodenal duplication cyst.**[43,47] In addition, several cases of **transient double-bubble sign** during the second trimester have been reported, with normal outcomes.[48,49]

As in all cases of proximal bowel obstruction, polyhydramnios is frequently present by the late second trimester[50-52] but is often absent in the early second trimester at the time of routine fetal survey. This is in part related to the relative difference in the amount of amniotic fluid swallowed per day at different times of gestation. The fetus swallows a relatively small amount of amniotic fluid (2-7 mL of fluid per day) during early second trimester, compared to 450 mL at term.[53] In a European study of 138 cases of postnatally confirmed duodenal atresia, polyhydramnios was present in only 33% of cases.[54] For these reasons, duodenal atresia is commonly diagnosed during the third trimester, whereas in the early second trimester both false-negative and false-positive diagnoses have been reported.[48,49] Thus the proportion of cases diagnosed prenatally ranges widely between 34% and 87%.[43,50,55-57]

It has been suggested that prenatal diagnosis of duodenal atresia has the potential to decrease neonatal morbidity.[50] Finding the double-bubble sign should trigger detailed anatomic survey, fetal echocardiography, as well as genetic counseling and consideration of amniocentesis given the high association with trisomy 21.

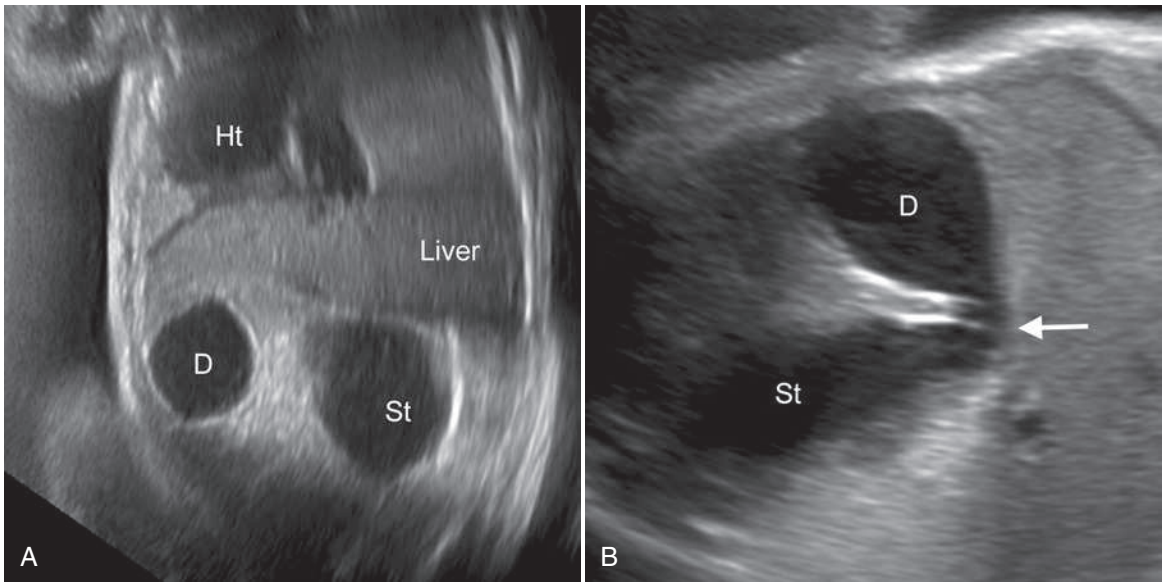

FIG. 38.8 Duodenal Atresia. (A) Oblique sagittal view through the fetal abdomen at 33 weeks shows the "double-bubble" sign of duodenal atresia with the fluid-filled stomach *(St)* and duodenum *(D). Ht,* Heart. **(B)** Oblique coronal view shows continuity *(arrow)* between the stomach and duodenum. See also Video 38.4.

Jejunal and Ileal Obstruction. The prevalence of **jejunoileal atresia** ranges from 0.5 to 1.1 cases per 10,000 live births.[58,59] Jejunal atresias are slightly more common (51%) than ileal.[60] The most common hypothesis with respect to the etiology for jejunoileal atresia is early vascular compromise of the developing midgut.[57] In animals, induced vascular compromise leads to isolated bowel atresias.[61] This hypothesis is also supported by the association of intestinal atresia with placental complications and other abnormalities of vascular origin such as gastroschisis.[62] **"Apple peel" jejunal atresia** is a subtype that involves agenesis of the mesentery, is more often familial,[54,63,64] and is likely of a different etiology. **Cystic fibrosis** is a common underlying cause of ileal obstruction; the thick meconium associated with cystic fibrosis can lead to ileal obstruction **(meconium ileus)** with or without echogenic bowel.[65,66]

Although jejunal and ileal atresia are often discussed as a single entity, there are major differences between these two conditions. Jejunal atresia is more likely to involve multiple sites and is less often associated with in utero perforation than is ileal atresia, likely because of the lower compliance of the ileum. In addition, the risk of associated anomalies depends on the site of obstruction. Whereas jejunal atresias have been associated with extra-GI anomalies and chromosomal disorders in up to 42% of cases, the rate of associated anomalies in cases of ileal atresia is only about 2%.[54,67] Both conditions are associated with other GI abnormalities, including malrotation, meconium peritonitis, and duplication cysts.[68]

The prenatal diagnosis of jejunoileal obstruction is based on **dilated loops of bowel** (Fig. 38.9, Video 38.5), most frequently without a dilated stomach and sometimes with hyperperistalsis. If peristalsis is not observed, dilated small bowel can be difficult to distinguish from dilated colon. The cutoff used to define dilated small bowel is greater than 7 mm for loop diameter or greater than 13 mm for loop length.[65] The diagnosis of jejunoileal atresia is typically not made until late in the second trimester, as dilatation of the bowel is often not seen before that stage. The rate of **polyhydramnios** decreases as the site of bowel obstruction becomes more distal. Thus polyhydramnios in cases of jejunoileal atresia is less common than in cases of duodenal or esophageal atresia; it has been reported in about one-third of cases of jejunal atresia and is even less common in cases of ileal atresia.[69] It is often not possible to confidently differentiate between jejunal and ileal atresia in utero; the more dilated loops visible, the more likely it is to be a distal or ileal obstruction. Another sonographic sign associated with jejunoileal obstruction is **echogenic bowel,** reflecting thickened meconium due to the intestinal stasis. **Ascites** and **abdominal calcifications** can be seen in cases of obstruction complicated by perforation, a complication seen more commonly in cases of ileal obstruction. In a recent systematic review on the accuracy of sonographic diagnosis of small bowel obstruction, a large variation in the detection rate of small bowel obstruction was noted (10%-100%), with the detection rate being considerably higher for jejunal atresia (66%) than for ileal atresia (26%).[70]

Meconium Ileus

Meconium ileus relates to obstruction of the ileum by thickened meconium. Some cases are associated with **cystic fibrosis,** but only a minority (up to 20%) of cases of cystic fibrosis will present with meconium ileus during pregnancy.[71,72] The presence of **echogenic bowel** in addition to the general sonographic signs of bowel obstruction increases the likelihood of meconium ileus. The differential diagnosis and diagnostic approach in cases of echogenic bowel and meconium peritonitis are discussed later in this chapter.

Anorectal Malformations

The incidence of **anorectal malformation** is in the range of 0.8 to 4 per 10,000 live births.[73] The spectrum of anorectal

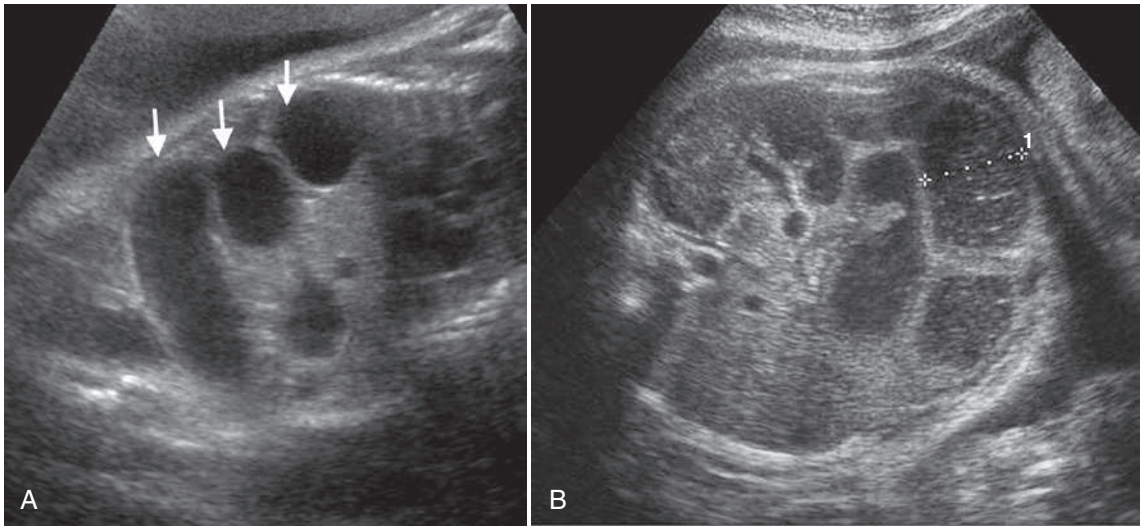

FIG. 38.9 Jejunal and Ileal Atresia. (A) Jejunal atresia. Coronal image through the abdomen of a 30-week fetus shows several dilated loops of small bowel *(arrows).* **(B)** Ileal atresia. Transverse fetal abdomen with multiple dilated loops of bowel. The bowel lumen is measured in the largest transverse diameter *(calipers).* See also Video 38.5.

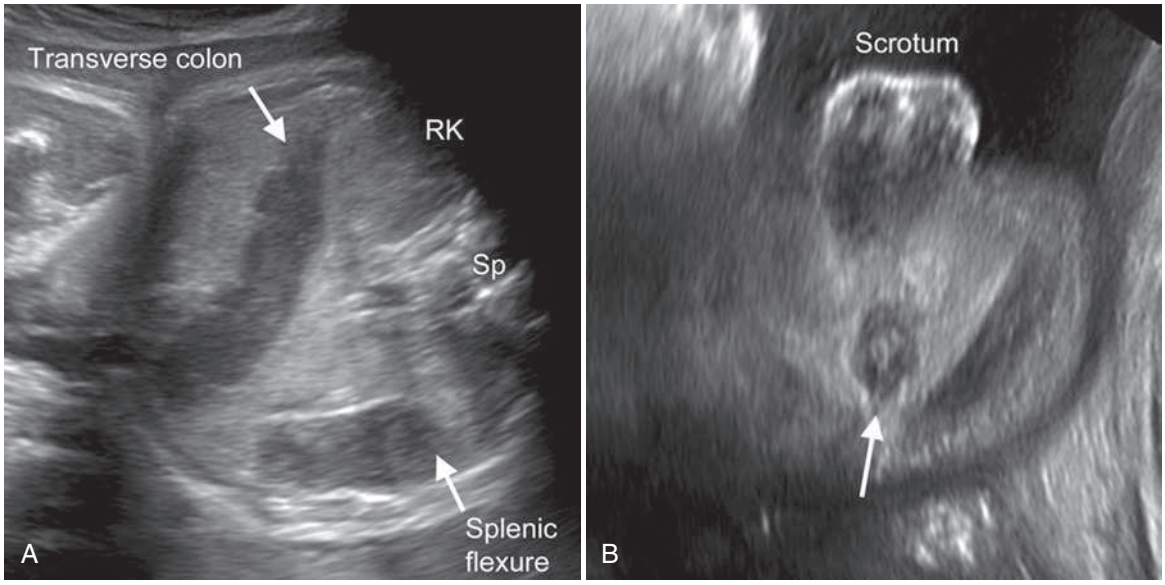

FIG. 38.10 Normal Colon and Anal Dimple. (A) Normal third-trimester large bowel. Transverse image through the abdomen at 37 weeks shows prominent meconium-filled loops of colon. This is normal in the third trimester and should not be taken to indicate bowel obstruction. *RK,* Right kidney; *Sp,* spine. **(B)** Although not part of standard scan guidelines, the anal dimple *(arrow)* can easily be demonstrated on a transverse plan through the perineum. Visualization of the dimple excludes anal atresia.

malformations ranges from isolated **imperforate anus** to more complex **cloacal malformations.** They are classified as **low, intermediate,** and **high** based on whether the bowel ends below, at the same level, or above the level of the levator ani muscle, respectively. The majority of cases (>90%) are **low malformations.**[74] **High malformations** are less common and are often associated with vesicocolic **fistulas.**

Anorectal malformations are frequently associated with chromosomal and structural anomalies, in 48% to 98% of cases.[75-77] **Anal atresia** is also part of the **VACTERL sequence**[76-78] and is associated with a large number of genetic syndromes. Given the high rate of associated abnormalities, a detailed fetal survey, fetal echocardiogram, genetic counseling, and discussion of aneuploidy risk should be included in the management of cases with suspected anorectal malformations.

The prenatal detection rate of anorectal malformations is lower than that of more proximal types of bowel obstruction and ranges from 7% to 24%.[55,79,80] The main sonographic sign is **dilated loops of small or large bowel,** although this should be distinguished from normal prominent colon loops during the third trimester (Fig. 38.10A). **Polyhydramnios** is absent in the majority of cases.[81,82] Sonographic assessment would commonly reveal signs of associated anomalies such as in the case of VACTERL association and associated chromosomal abnormalities.[83] In cases

complicated by **vesicocolic fistula,** intraluminal calcifications may be seen and have been attributed to mixing of meconium with urine.[84] More recently, inability to visualize the anal mucosa on transverse transperineal view (known as the **anal dimple,** which is the result of the echogenic mucosa surrounded by the hypoechoic muscle of the anal sphincter) has been suggested as an important sonographic marker in cases of imperforated anus (Fig. 38.10B).[85]

Hirschsprung Disease

Hirschsprung disease is a congenital disorder of the colon caused by absence of ganglia in the distal colon, thereby leading to functional colonic obstruction. It affects about 1 of 5000 live births.[86] The diseased segment usually involves the most distal part of the colon, including the internal anal sphincter, and extends proximally to involve variable portions of the colon, with the most severe forms involving the whole colon. Hirschsprung disease is associated with chromosomal and structural abnormalities in about 10% to 20% of cases, and up to 10% of cases are associated with trisomy 21.[87]

Prenatal diagnosis of Hirschsprung disease is uncommon and is usually made in severe forms involving the entire length of colon. The sonographic signs in these cases are nonspecific and include bowel dilatation, polyhydramnios, and echogenic bowel (Fig. 38.11).[87] Thus the majority of cases are diagnosed within the early neonatal period, with the most common sign being failure to pass meconium.[88-90]

Enteric Duplication Cysts

Enteric duplication cysts are classified by the anatomic region involved rather than by the histology of the mucosal lining.[91] The incidence is estimated at 1 per 10,000 infants.[92,93] They result from abnormal recanalization of the GI tract and may or may not communicate with the lumen of the GI tract. Enteric duplication cysts can be associated with any area of the GI tract, but they are most common in the terminal ileum.[94] They may present

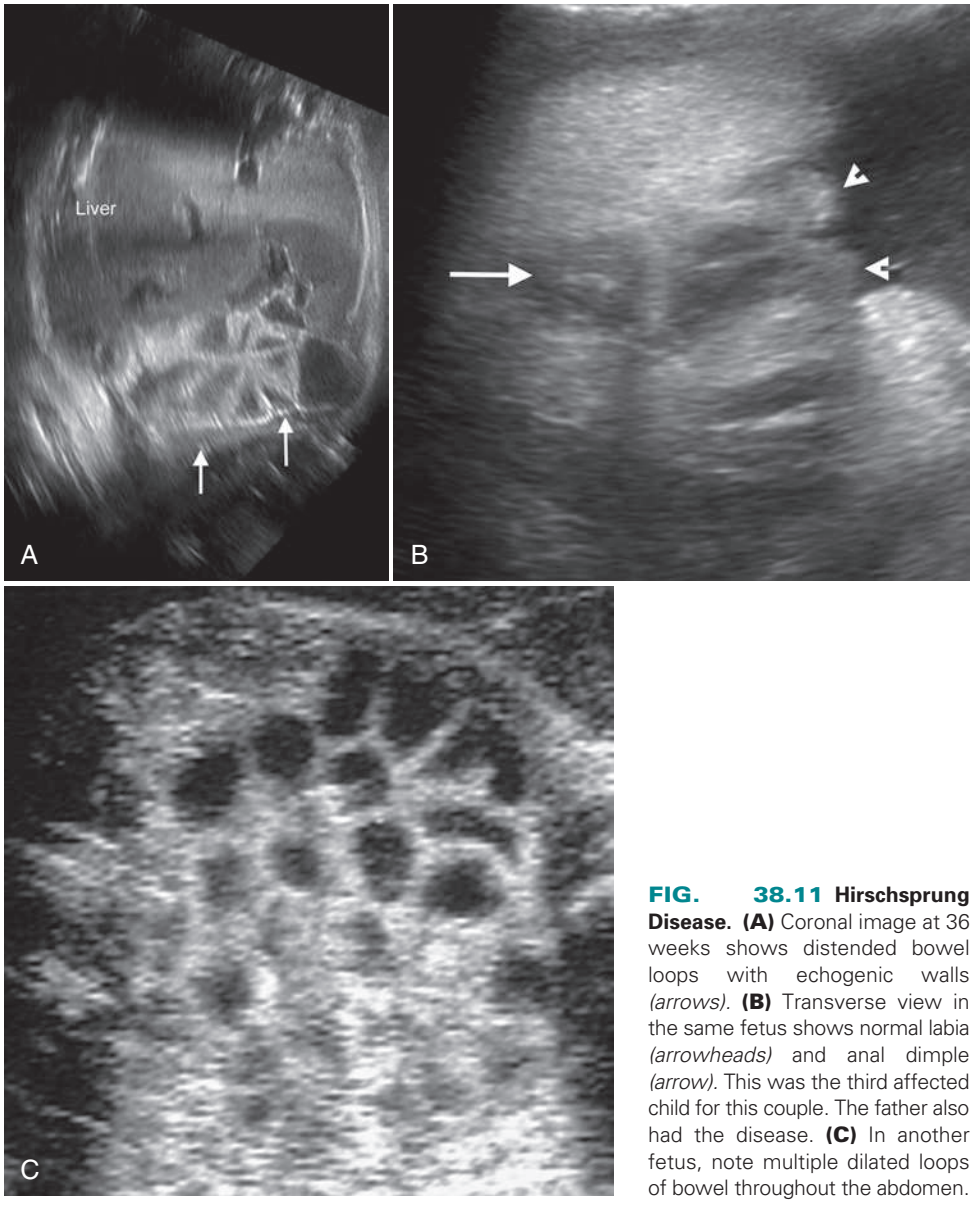

FIG. 38.11 Hirschsprung Disease. (A) Coronal image at 36 weeks shows distended bowel loops with echogenic walls *(arrows).* **(B)** Transverse view in the same fetus shows normal labia *(arrowheads)* and anal dimple *(arrow).* This was the third affected child for this couple. The father also had the disease. **(C)** In another fetus, note multiple dilated loops of bowel throughout the abdomen.

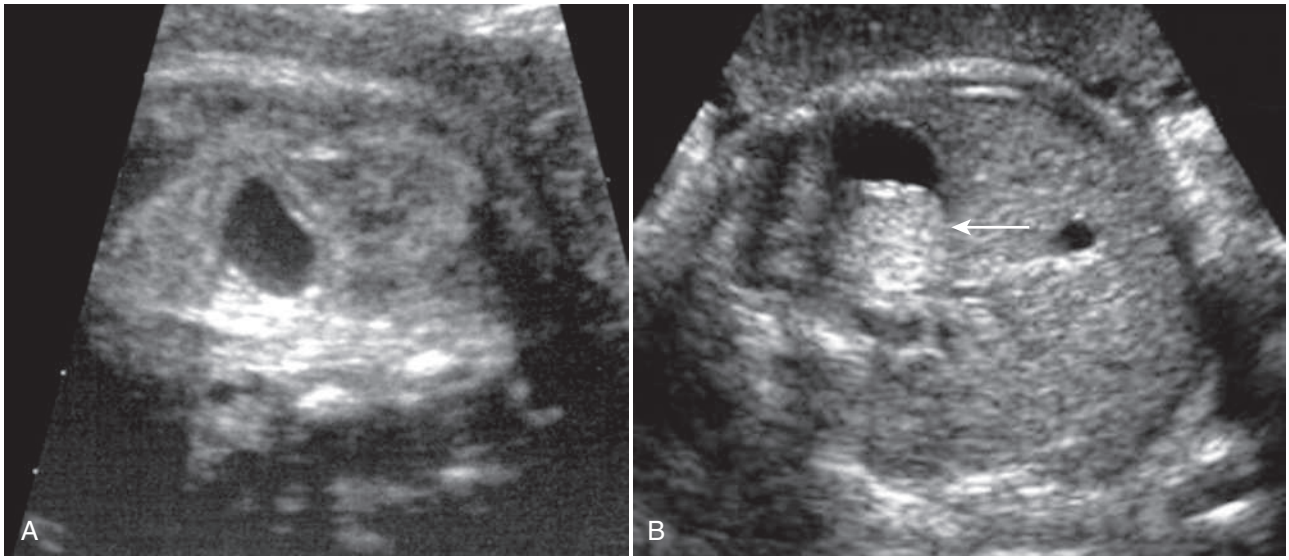

FIG. 38.12 Enteric Duplication Cyst. (A) Note the characteristic double line around the wall, which distinguishes a gut duplication from other abdominal cysts. **(B)** Atypical appearance of gastric duplication cyst with echogenic material *(arrow)*. Note how cyst impinges on stomach. See also Video 38.6. (With permission from McNamara A, Levine D. Intraabdominal fetal echogenic masses: a practical guide to diagnosis and management. Radiographics. 2005;25[3]:633-645.[32])

in utero or postnatally either as an incidental finding or in association with bowel obstruction.[92,94] Associated anomalies occur in up to 30% of cases, most often of the GI tract.[94]

Enteric duplication cysts present at ultrasound as **cystic or echogenic tubular structures** with well-defined borders.[95] They are classically anechoic and cystic but at times are filled with echogenic material. The borders typically have a **double layer ("gut signature"),** although this may be hard to demonstrate and may require high-resolution linear transducers[94,96] (Fig. 38.12, Video 38.6). Depending on the site of presentation, the differential diagnosis includes **hepatic cysts, choledochal cysts, bowel atresias,** and **ovarian cysts.** Peristalsis of the cysts can help differentiate these masses from those of non-GI origin.[97] Postnatally, the standard treatment is surgical because of the associated risk of bowel obstruction.[92]

Meconium Peritonitis and Pseudocyst

Meconium peritonitis is the result of in utero bowel perforation that is followed by leakage of meconium into the peritoneal cavity, which subsequently leads to chemical irritation and inflammatory response. The sonographic hallmark of meconium peritonitis is the finding of **abdominal calcifications** representing calcification of the peritoneum outlining bowel or liver (Figs. 38.13 and 38.14A). Additional findings may include **ascites** (Video 38.7), **echogenic bowel, dilated bowel,** and **polyhydramnios.**[98,99] In some cases, the extruded meconium becomes walled off in the peritoneum and develops a heterogeneous cystic appearance, a finding known as **meconium pseudocyst** (Fig. 38.14). Meconium pseudocyst is characterized by a cyst encircled by an echogenic rim.

Both meconium ileus and meconium peritonitis are associated with cystic fibrosis in 8% to 40% of cases.[98,100] The need for postnatal surgery in cases of meconium peritonitis can be predicted based on the combination of findings observed (Table 38.2).[101] Once meconium peritonitis or meconium ileus has been diagnosed, serial fetal sonography is recommended. Because of the association with additional fetal anomalies, delivery at a center with a neonatal intensive care unit and pediatric surgery is recommended.

TABLE 38.2 Meconium Peritonitis Findings and Likelihood of Need for Surgery

Findings	Likelihood of Need for Postnatal Surgery (%)[101]
Isolated calcifications	0%
Calcifications and pseudocyst, ascites, or bowel dilatation	52%
Calcifications and two of the following: pseudocyst, ascites, or bowel dilatation	80%
Calcifications, pseudocyst, ascites, and bowel dilatation	100%
Polyhydramnios and any of above findings	69%

Modified from Zangheri G, Andreani M, Ciriello E, et al. Fetal intra-abdominal calcifications from meconium peritonitis: sonographic predictors of postnatal surgery. Prenat Diagn. 2007;27(10):960-963.[101]

Echogenic Bowel

Echogenic bowel, which refers to increased brightness of the fetal bowel at the time of ultrasound examination, is a marker for several fetal disorders.[102-105] The most commonly used criterion for the diagnosis of echogenic bowel is echogenicity that is similar

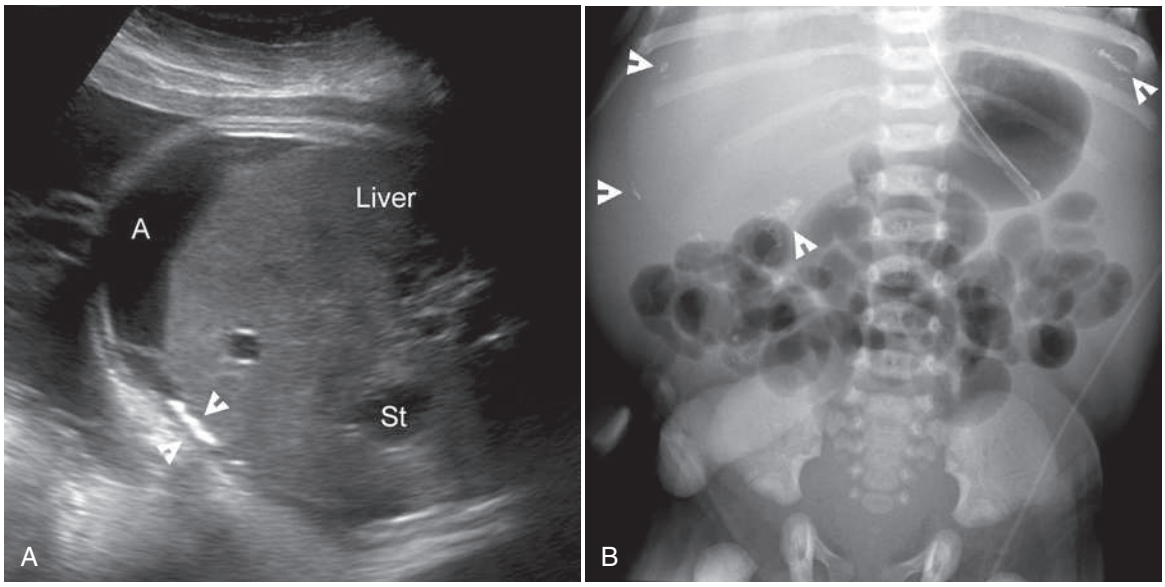

FIG. 38.13 Meconium Peritonitis. (A) Transverse image at 34 weeks shows ascites *(A)* surrounding the liver with associated calcifications *(arrowheads)* on the liver surface; a finding typical of meconium peritonitis. *St,* Stomach. **(B)** Abdominal radiograph in the neonate confirms peritoneal calcifications *(arrowheads).* See also Video 38.7.

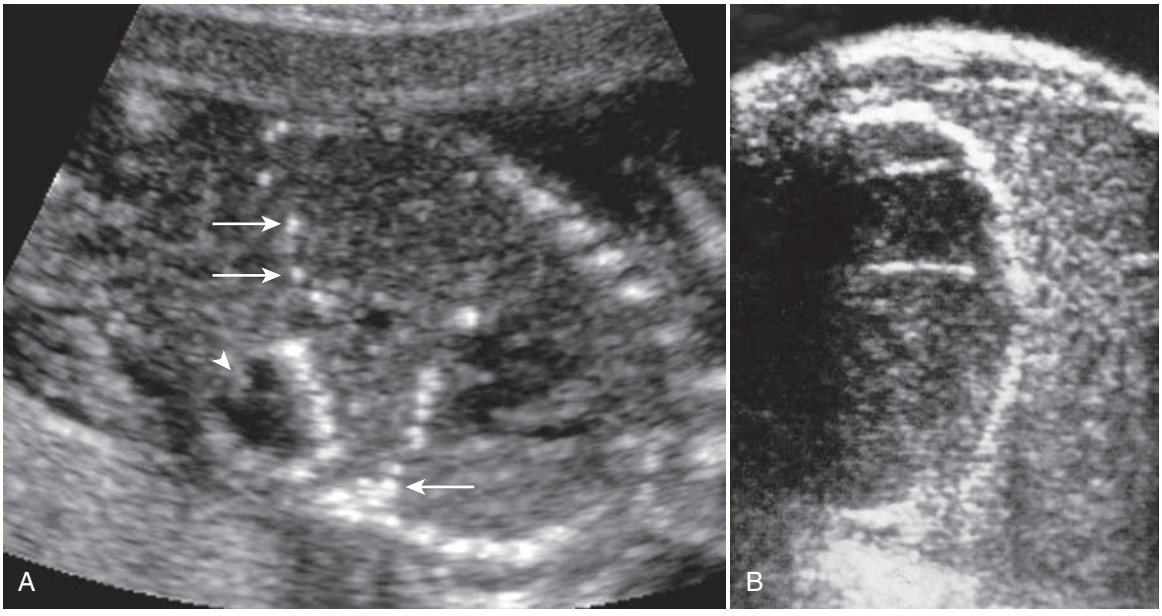

FIG. 38.14 Meconium Pseudocyst. (A) Oblique sagittal view of the torso shows multiple calcifications on the peritoneal surface of the liver in a fetus with a meconium pseudocyst *(arrowhead),* with an irregularly calcified wall. **(B)** Meconium pseudocyst in another fetus. Note cyst with debris with calcified rim *(arrows).* (With permission from McNamara A, Levine D. Intraabdominal fetal echogenic masses: a practical guide to diagnosis and management. Radiographics. 2005;25[3]:633-645.[32])

or greater than that of adjacent bone, such as the iliac bone.[106] To avoid a false-positive diagnosis due to artifacts and image processing, the diagnosis of echogenic bowel requires that the lowest level of ultrasound gain at which bones still appear white be used and that all image enhancement algorithms be disabled (Fig. 38.15, Video 38.8). The use of a high-frequency probe (8 MHz) can lead to overdiagnosis of echogenic bowel[107]; therefore the diagnosis of echogenic bowel should always be confirmed using a low-frequency (≤5 MHz) probe. Despite these attempts to standardize the diagnosis of echogenic bowel, it should be recognized that there is a significant subjective component in the diagnosis of echogenic bowel, which can lead to significant interobserver variability.[108]

When strict diagnostic criteria are used, the incidence of echogenic bowel in the general obstetric population is 0.2% to 0.7%.[79,106] Because the echogenicity of normal bowel increases throughout pregnancy, the finding of echogenic bowel becomes normal in the third trimester. In particular, meconium in the colon can be seen normally as echogenic material in the third trimester.

Aneuploidy. The confirmation of hyperechogenic bowel on second-trimester ultrasound requires careful evaluation of the fetus because of the association with chromosomal abnormalities (Fig. 38.16A). In most series, fetuses with chromosomal abnormalities are likely to have other abnormal sonographic findings.[109]

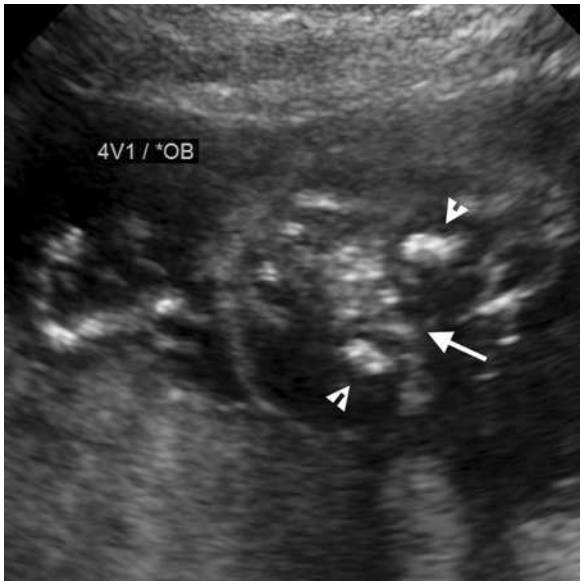

FIG. 38.15 Echogenic Bowel. Transverse image through fetal pelvis shows bowel loops *(arrow)* that are as echogenic as bone (*arrowheads* on ischial tuberosities). The image was obtained with the 4-MHz vector transducer and harmonics turned off. See also Video 38.8.

The risk of aneuploidy in fetuses with echogenic bowel as an isolated finding is 1.4% to 6.7%.[109-111] In a study of 281 fetuses with echogenic bowel, the rate of chromosomal abnormalities was 6.7% in cases of isolated echogenic bowel compared with 17.4% in cases of echogenic bowel accompanied by major anomalies.

The most common chromosomal disorder associated with echogenic bowel is trisomy 21[110,111]; in a recent meta-analysis of second-trimester markers for trisomy 21, echogenic bowel was associated with a positive likelihood ratio of 11.4 for trisomy 21.[112] The reason for the association between trisomy 21 and

Conditions Associated With Echogenic Bowel

Aneuploidy—mainly trisomy 21; less commonly trisomies 13 and 18, 45,X0, triploidy
Cystic fibrosis
Intraamniotic bleeding—swallowed blood (placental hemorrhage, postprocedural)
Fetal infection—CMV, parvovirus B19, varicella, herpes simplex, toxoplasmosis
Gastrointestinal tract atresias, obstructions, dysmotility or stasis
Fetal growth restriction
Fetal anemia
Fetal demise

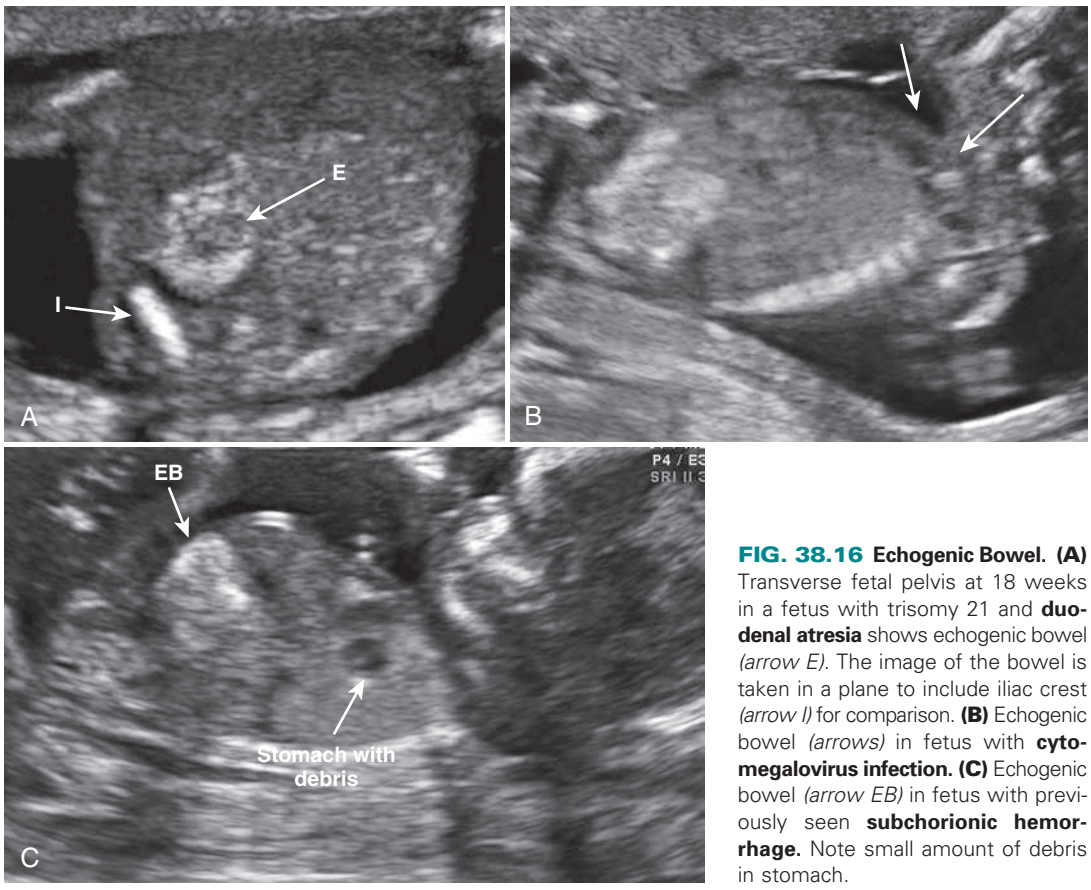

FIG. 38.16 Echogenic Bowel. (A) Transverse fetal pelvis at 18 weeks in a fetus with trisomy 21 and **duodenal atresia** shows echogenic bowel *(arrow E)*. The image of the bowel is taken in a plane to include iliac crest *(arrow I)* for comparison. **(B)** Echogenic bowel *(arrows)* in fetus with **cytomegalovirus infection. (C)** Echogenic bowel *(arrow EB)* in fetus with previously seen **subchorionic hemorrhage.** Note small amount of debris in stomach.

echogenic bowel is unclear, but it has been attributed to the presence of GI dysfunction and dysmotility.[113] Intestinal stasis, for any reason, can lead to increased absorption of fluid from the bowel lumen, which can result in thick meconium and therefore increased echogenicity of the bowel content.[114] Other chromosomal abnormalities that have been associated with echogenic bowel include trisomies 13 and 18, 45,X0, and triploidies.[110,111,115]

Cystic Fibrosis. Echogenic bowel, meconium ileus, and **meconium peritonitis** are possible sonographic findings in fetuses with cystic fibrosis.[116] The echogenic appearance of the bowel in fetuses with cystic fibrosis is the result of the biochemical alterations in the secretory-digestive-absorptive function of the small intestinal mucosa, which can result in the meconium being more viscous than normal and therefore more echogenic.[117] The incidence of cystic fibrosis in fetuses with isolated echogenic bowel varies from 1.3% to 5%.[106,118,119]

Intraamniotic Bleeding. Echogenic bowel has been noted in pregnancies complicated by vaginal bleeding, in those with asymptomatic subchorionic hemorrhage, and following invasive procedures such as chorionic villous sampling and amniocentesis. Each of these conditions may result in intraamniotic bleeding, and the blood-containing amniotic fluid swallowed by the fetus can be visible as echogenic debris in the fetal stomach or as increased echogenicity of the bowel content (Fig. 38.16C).[114,120] In a case series of pregnant women undergoing amniocentesis, there was evidence of blood in the amniotic fluid on spectrophotometry of 8 in 40 (20%) of those with echogenic bowel compared to 3 in 64 (5%) of those without.[121] In one series, 19% of fetuses with isolated echogenic bowel had sonographic evidence of intrauterine bleeding, of which 70% were confirmed to have intraamniotic bleeding on amniocentesis.[122] History of bleeding during pregnancy, history of invasive procedure earlier in pregnancy, sonographic evidence of retroplacental or subchorionic hemorrhage, or evidence of debris in the fetal stomach provides support for intraamniotic bleeding as the cause of echogenic bowel.

Fetal Infection. Echogenic bowel is one of the manifestations of fetal infection, including cytomegalovirus (CMV), parvovirus B19, varicella, herpes simplex, and toxoplasmosis (Fig. 38.16B).[123] The incidence of infection in fetuses with echogenic bowel is in the range of 0.5% to 6.3%.[122,124,125] The cause of the echogenic bowel in fetuses with infection is not known but may be related to inflammation and edema of the bowel wall as well as the associated decreased peristalsis of the infected bowel.

Bowel Obstruction. As previously noted, bowel of obstruction or stasis for any reason, including GI atresia or Hirschsprung disease,[89] can result in thickening of the meconium and therefore increase in the echogenicity of bowel content.

Fetal Growth Restriction and Fetal Demise. The risk of both **fetal growth restriction** and **fetal demise** increases in the second and third trimesters in fetuses with echogenic bowel. The reported incidence is 10% to 20% for fetal growth restriction[102,118] and 6% to 15% for fetal demise.[73,118,126] In a recent study of 188 fetuses with isolated echogenic bowel (i.e., after the exclusion of chromosomal abnormalities, major malformation, and fetal infection), the rate of fetal growth restriction and fetal demise were 19.5% and 7.3%, respectively (compared with 12.9% and 0.9% in the control group, respectively). Possible explanation for these findings is the association between subchorionic bleeding (which can result in echogenic bowel) with fetal growth restriction and fetal demise.[127] In addition, in cases of severe fetal growth restriction, it is believed that redistribution of cardiac output in the compromised fetus to vital organs (i.e., brain, heart, and adrenal gland) results in decreased splanchnic blood flow, including perfusion to the bowel, which can result in impaired peristalsis.[128] The association of echogenic bowel with fetal anemia, which can also result in bowel hypoxia, provides support to this hypothesis.[129]

Summary. Given the associations described previously, the finding of echogenic bowel requires careful investigation and appropriate monitoring. The evaluation of pregnancies with echogenic bowel typically includes (1) genetic counseling and consideration of amniocentesis or cell-free fetal DNA testing; (2) parental screening for cystic fibrosis; (3) maternal serology for viral infections, including CMV and parvovirus B19; (4) detailed sonographic assessment for associated structural anomalies or soft markers, signs of bowel obstruction, assessment of fetal biometry, placental morphology, and amniotic fluid; and (5) follow-up for growth. Information regarding episodes of vaginal bleeding or invasive testing earlier in pregnancy should be recorded. In cases where the investigation is negative, the finding of "isolated" echogenic bowel may represent a normal variant or a false-positive finding, and fetal outcome may be normal.

Liver

The fetal liver is clearly visualized in the upper abdomen in the second half of gestation, although earlier in gestation it has an echogenicity similar to renal echoes.

Hepatomegaly

Given the asymmetrical shape of the liver, accurate determination of its size is difficult and is associated with high interobserver variability. Therefore in many cases the diagnosis of **hepatomegaly** is made subjectively. Hepatomegaly is associated with a variety of conditions including **fetal hemolytic anemia** which results in a compensatory increase in hematopoiesis within the liver,[130] **metabolic and storage diseases, fetal infections**[131] (Fig. 38.17), **liver masses, hepatic congestion secondary to cardiac failure,** and overgrowth syndromes such as **Beckwith-Wiedemann syndrome.**[132,133] Hepatomegaly has also been associated with **trisomy 21,** possibly because of the abnormal myelopoiesis in these fetuses.[134]

Hepatic Calcifications

Hepatic calcifications can be single or multiple (Fig. 38.18). In one series, hepatic calcifications were identified in 14 of 24,600 consecutive pregnancies scanned between 15 and 26 weeks, representing an incidence of 1 in 1750 pregnancies.[135] The pathophysiology of hepatic calcifications in otherwise normal fetuses is unknown, and in the **majority of cases, such calcifications represent an isolated finding** and have no clinical consequence.[136] However, hepatic calcifications are associated with

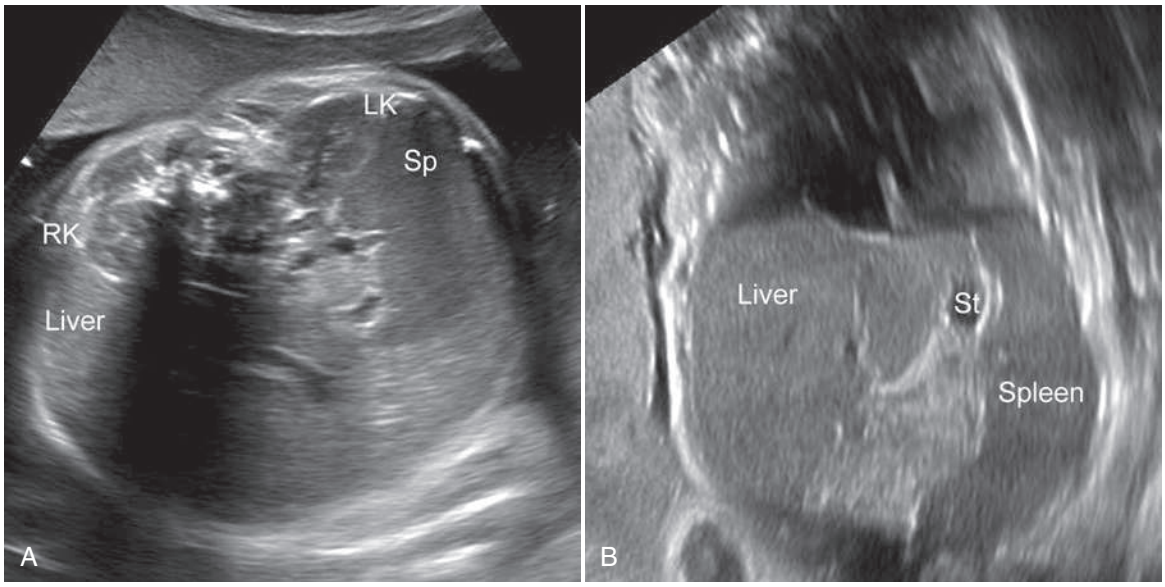

FIG. 38.17 Hepatosplenomegaly. (A) Transverse and **(B)** reconstructed coronal images at 33 weeks show marked hepatosplenomegaly in a fetus with congenital **cytomegalovirus infection.** *LK,* Left kidney; *RK,* right kidney; *Sp,* spleen; *St,* stomach.

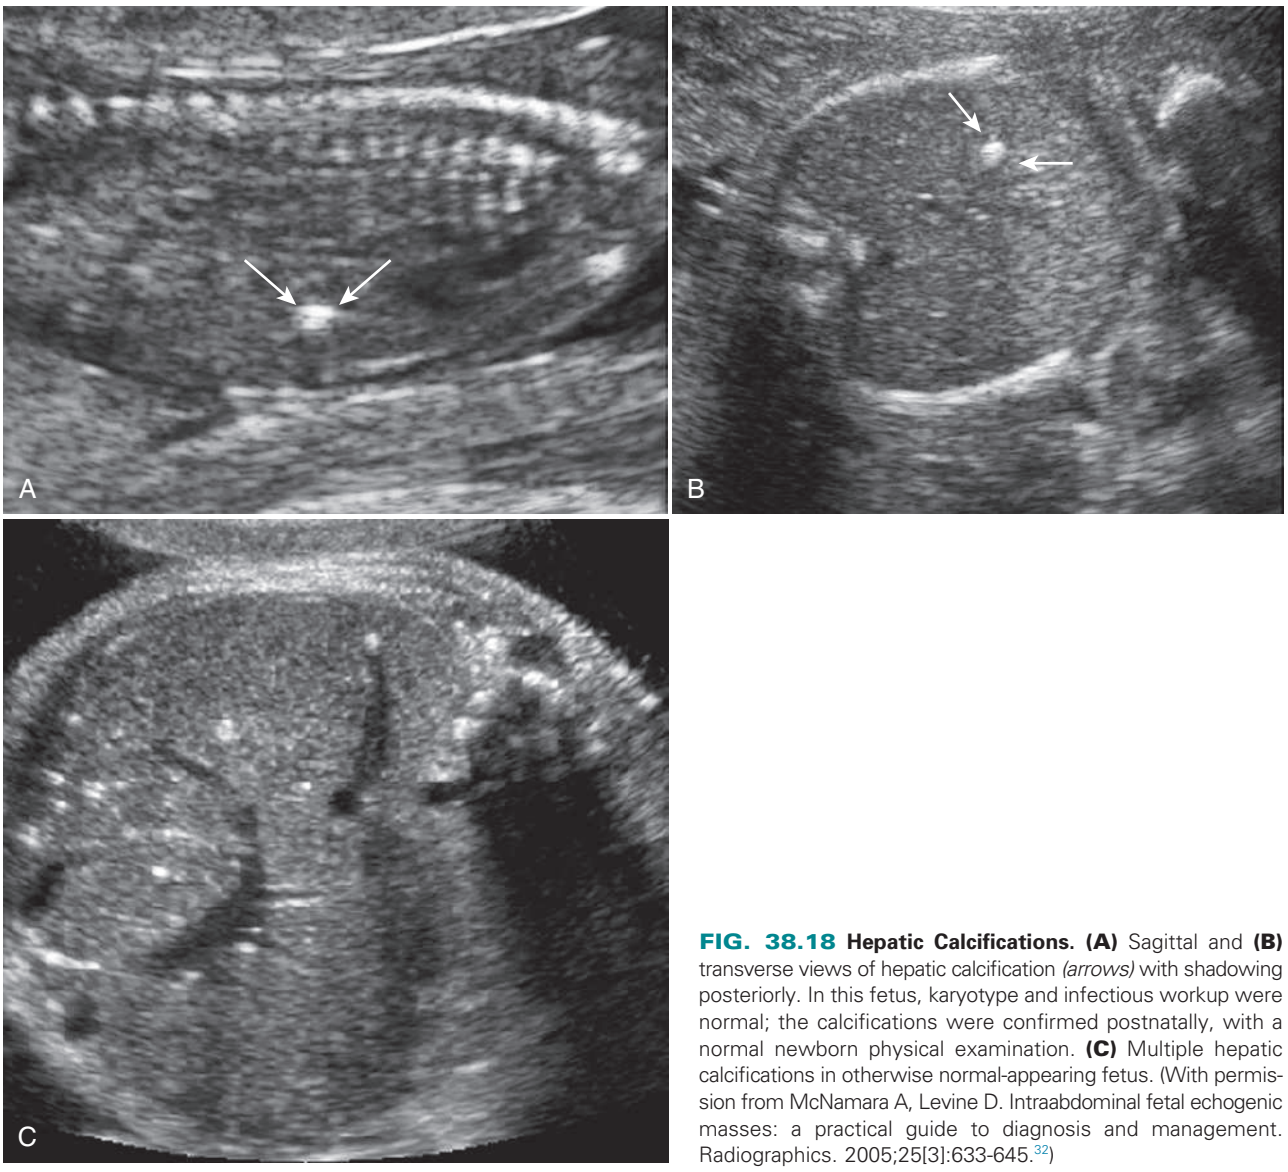

FIG. 38.18 Hepatic Calcifications. (A) Sagittal and **(B)** transverse views of hepatic calcification *(arrows)* with shadowing posteriorly. In this fetus, karyotype and infectious workup were normal; the calcifications were confirmed postnatally, with a normal newborn physical examination. **(C)** Multiple hepatic calcifications in otherwise normal-appearing fetus. (With permission from McNamara A, Levine D. Intraabdominal fetal echogenic masses: a practical guide to diagnosis and management. Radiographics. 2005;25[3]:633-645.[32])

aneuploidy and **fetal infections** (e.g., CMV,[137] parvovirus B19,[138] and varicella[139]). Calcifications of the liver parenchyma should be distinguished from peritoneal calcifications that outline the liver surface and peritoneal cavity, which can be secondary to **meconium peritonitis** and may therefore be associated with **cystic fibrosis.** Calcifications associated with **vascular insult** have also been reported, including **thromboembolism of the hepatic and portal veins.**[140] Hepatic calcifications may occur with **hepatic masses** (discussed later). In a series of 21 pregnancies with isolated hepatic calcifications, there was one case of trisomy 21 and one case of parvovirus B19 infection; the rest of the fetuses had normal outcomes.[138]

Conditions Associated With Hepatic Calcifications

Normal variant—majority of cases when isolated or few
Aneuploidy
Fetal infection—CMV, parvovirus B19, varicella, herpes simplex, toxoplasmosis
Hepatic vascular insult/ischemia
Hepatic mass

When hepatic calcifications are visualized, it is important to assess the number, size, and distribution of the calcifications; determine whether associated hepatic masses are present; document normal flow in the liver to rule out thrombosis; search for other signs of fetal infection; and assess for any structural or growth abnormalities. Genetic counseling and screening for cystic fibrosis and fetal infections should be included in the investigation of these cases.

Hepatic Cysts and Masses

The majority of hepatic masses are hypoechoic or cystic and may include **hepatic cysts** (Fig. 38.19), **hemangiomas** (Fig. 38.20), and **abnormal myelopoiesis** in fetuses with trisomy 21.[134] Less commonly, **solid echogenic masses** may be identified, which may represent benign lesions such as **hamartoma** (which may have a cystic or mixed cystic-solid appearance) and **adenoma,** as well as malignant lesions as **hepatoblastoma.** Color flow Doppler ultrasound should be used to determine the vascularity of the lesions. Vascular hepatic lesions include **congenital hemangiomas** and **hepatoblastomas,** although it should be emphasized that most hemangiomas are small and appear avascular on color Doppler ultrasound. Such vascular lesions, especially when of large size, may lead to **high-output cardiac failure and hydrops,** and **fetal anemia and thrombocytopenia (Kasabach-Merritt sequence).**[141-143] Therefore these fetuses should be followed for signs of hydrops and fetal anemia using middle cerebral artery Doppler.[144-147]

Gallbladder and Biliary System

The normal fetal gallbladder is an oblong, echolucent structure in the anterior liver (Fig. 38.21, Video 38.9), generally located 45 degrees to the right of midline and inferior to the umbilical vein. The gallbladder increases in size with gestation.[148] In multiple series, visualization of the gallbladder was most common from

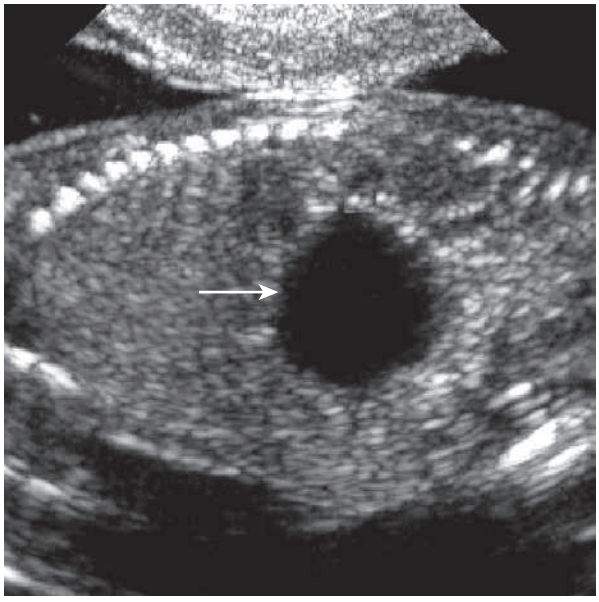

FIG. 38.19 Hepatic Cyst. Hepatic cyst *(arrow)* in sagittal view of the abdomen.

20 to 32 weeks.[149,150] **Enlarged gallbladder** is associated with fetal aneuploidy, but all reported fetuses also had other prenatally visualized anomalies.[114]

Nonvisualization of the Gallbladder

Nonvisualization of the gallbladder is associated with gallbladder agenesis/atresia, cystic fibrosis,[151,152] aneuploidy,[151] and biliary atresia.[149,153,154] Extrahepatic biliary atresia is a rare congenital disorder, with an incidence of 0.6 in 10,000 live births according to a population-based study.[155] It is the single leading cause for liver transplantation during childhood and is commonly associated with additional anomalies.[155,156] The diagnosis of extrahepatic biliary atresia should be considered whenever the gallbladder cannot be visualized. Additional findings may include a cyst in the region of the hepatic hilum.[153] Bardin et al., in a study of 32 fetuses in which the gallbladder could not be visualized, reported that amniotic levels of gamma-glutamyl transpeptidase (GGTP) can assist in the prediction of pregnancy outcome. Of the 27 (84%) fetuses with normal GGTP levels, only 1 had an abnormal karyotype, whereas 3 of the 5 fetuses with low GGTP were diagnosed with extrahepatic biliary atresia.[154]

In a series of 578 fetuses, Hertzberg et al.[149] demonstrated the gallbladder between 12 and 40 weeks in 82.5% of cases, but none of the fetuses with isolated nonvisualization of the gallbladder had any adverse neonatal outcome. Blazer et al.[150] reported on 29,749 consecutive women whose fetuses were imaged by both transabdominal and transvaginal sonography at 14 to 16 weeks. The gallbladder could not be visualized in 34 (0.1%) fetuses, and investigation that included amniocentesis and screening for cystic fibrosis was offered in all of these cases. Additional abnormalities were identified in 14 (41%) of these fetuses. All 20 fetuses in which nonvisualization of the gallbladder was an isolated finding had a normal karyotype and appeared normal after birth. In another series of 37 fetuses with nonvisualization of the gallbladder, 5 (13.5%) were found to have

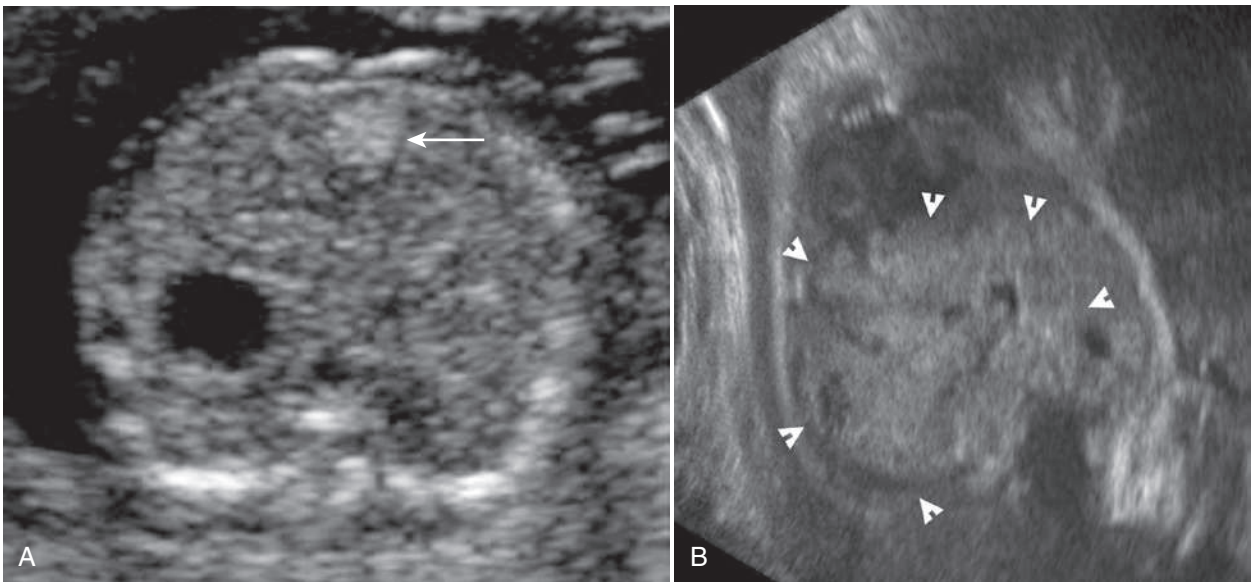

FIG. 38.20 Hepatic Mass. (A) Hepatic hemangioma *(arrow)* in 18-week fetus. **(B)** Coronal ultrasound at 34 weeks shows a large, heterogenous echogenic mass *(arrowheads)* replacing the entire right lobe of the liver, thought to be an **infantile hemangioendothelioma.** The infant was delivered at 38 weeks because of signs of cardiac decompensation but did well with spontaneous tumor involution over several months. (**A** with permission from McNamara A, Levine D. Intraabdominal fetal echogenic masses: a practical guide to diagnosis and management. Radiographics. 2005;25[3]:633-645.[32])

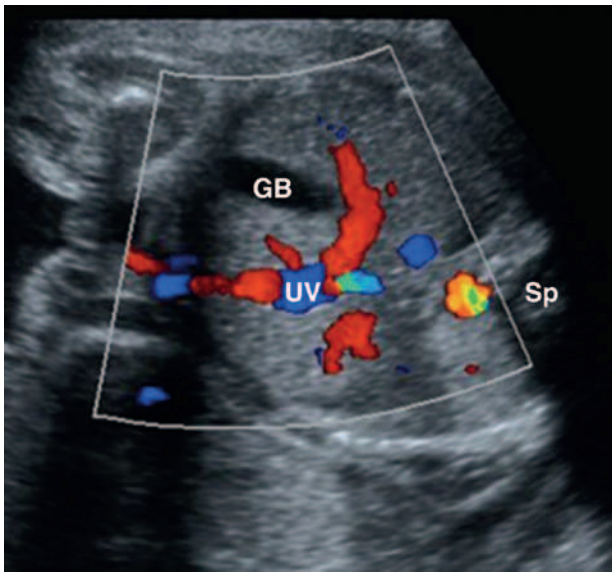

FIG. 38.21 Normal Gallbladder. Transverse color Doppler image at 35 weeks shows the normal gallbladder *(GB)* as an oval, anechoic structure in the right upper quadrant. The umbilical vein *(UV)* enters the portal venous system anterior to the aorta and inferior vena cava, which are seen anterior to the spine *(Sp)*. See also Video 38.9.

cystic fibrosis, but in all of these cases echogenic bowel was present as well.[152]

Thus nonvisualization of the gallbladder should be followed by a detailed scan for additional structural abnormalities, soft markers for aneuploidy, and other markers of cystic fibrosis such as echogenic bowel. Screening for cystic fibrosis and amniocentesis for karyotype and assessment of the level of liver enzymes in the amniotic fluid may be offered as well. When these investigations are negative, fetal outcome is expected to be normal in the majority of cases. In many of these cases, the gallbladder will become apparent later in pregnancy or after delivery.[154] In the remainder of cases, the underlying cause may be agenesis of the gallbladder, which may be considered as an anatomic variant.

Fetal Gallstones

Echodensities in the fetal gallbladder can represent either **sludge** or **gallstones** and are most commonly seen in the third trimester.[157-159] **Gallstones** may produce acoustic shadowing (Fig. 38.22). In most cases, postnatal resolution occurs, and children are asymptomatic.

Choledochal Cyst

Choledochal cysts are rare congenital cystic dilatations of the biliary tree and are associated with biliary atresia and hepatic fibrosis[160] (Fig. 38.23). The most common form involves a segment or all of the extrahepatic common bile duct; however, they may also present as diverticular outpouching of the extrahepatic duct or involve the intrahepatic ducts (Caroli disease). Cystic lesions of the biliary tree in utero may be anechoic or may contain echogenic debris. Although these lesions can be due to choledochal cyst, a cyst in the right upper quadrant can also be due to a rare bilobed gallbladder. The main differential diagnosis is **extrahepatic biliary atresia.** In most cases choledochal cysts are resected after birth, given the risk of cholangitis, fibrosis, and potential malignancy.

Pancreas

Visualization of the pancreas is often not possible at the time of the second-trimester anatomy scan. The pancreas may be seen

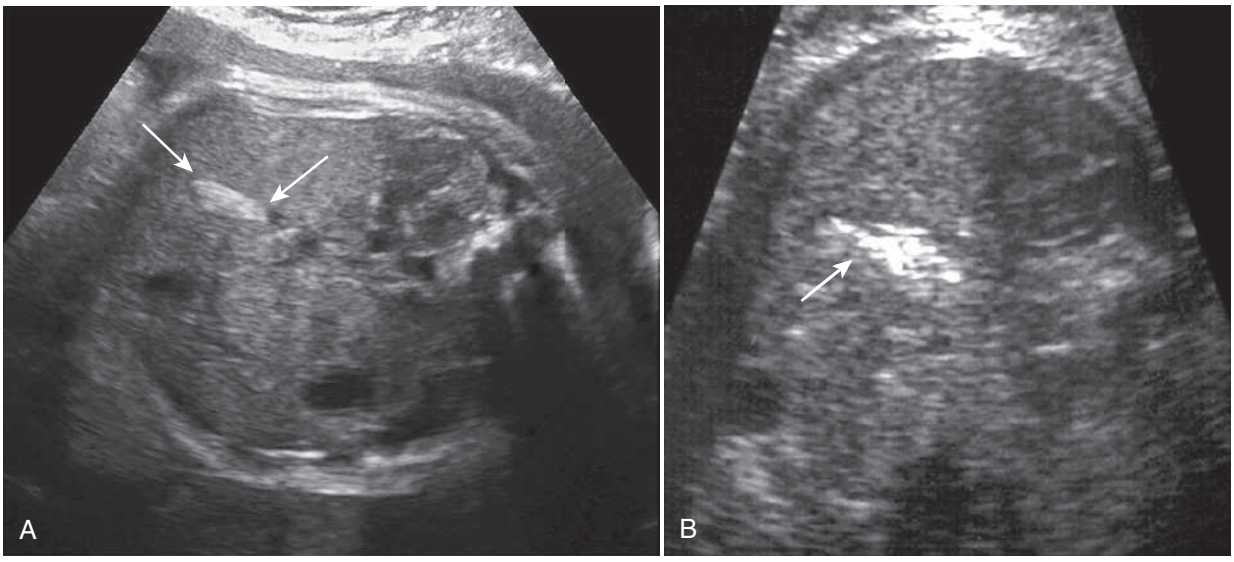

FIG. 38.22 Gallbladder Sludge and Stones. (A) Transverse third-trimester abdomen shows the lumen of the gallbladder surrounding echogenic material *(arrows)* consistent with sludge. This fetus had a normal newborn course. **(B)** Fetus with gallstones *(arrow)*.

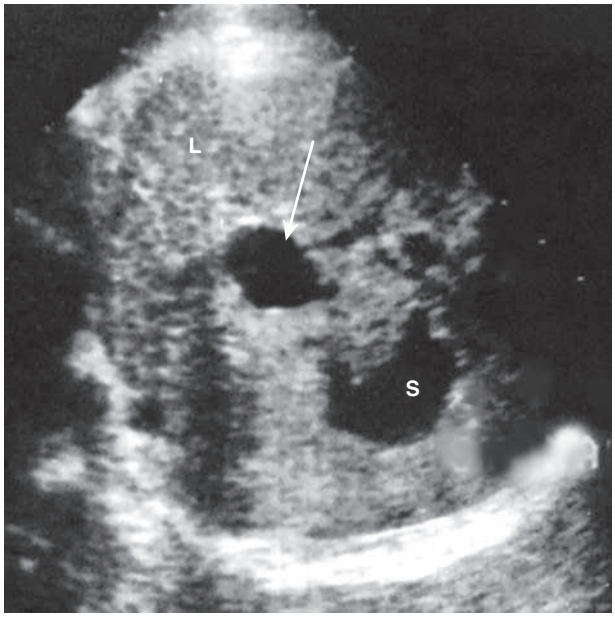

FIG. 38.23 Choledochal Cyst. Transverse view of abdomen shows a cyst *(arrow)* with stomach *(S)* on the left and liver *(L)* on the right.

as elongated structure in a transverse plane at the level of the kidneys and behind the stomach.

Annular Pancreas

Annular pancreas is a rare developmental anomaly that accounts for 1% of neonatal intestinal obstructions.[161,162] The annular tissue in these cases has been suggested to originate from the ventral pancreatic bud.[163] Annular pancreas is considered in the differential diagnosis of a dilated duodenum or the double-bubble sign[54,164] (Fig. 38.24, Video 38.10). A case report demonstrated an echogenic mass surrounding the distal part of the dilated duodenum. Three-dimensional ultrasound was suggested to be helpful in making this diagnosis.[162] Annular pancreas has been associated with trisomy 21 and malrotation.

Pancreatic Cysts

Pancreatic cyst is a rare congenital abnormality of the pancreas that originates from the pancreatic duct and may appear as a single cystic or multicystic mass.[165-168] Pancreatic cysts may be idiopathic but also have been associated with **Beckwith-Wiedemann syndrome,**[169] **polycystic kidney disease,** and **von Hippel–Lindau disease.** In many cases, the pancreatic origin of the cysts cannot be determined prenatally.

Spleen

The fetal spleen is visualized in the left upper abdomen, lateral to the spine and superior to the left kidney. The relationship to the fetal stomach can vary (Fig. 38.25). Nomograms are available for splenic size from 18 weeks until term.[170,171] **Asplenia** or **polysplenia** (see Fig. 38.5) are associated with heterotaxy syndromes and warrant a detailed fetal cardiac examination.

Splenomegaly

Splenomegaly is associated with conditions similar to those associated with **hepatomegaly** (see Fig. 38.17), **hemolytic fetal anemia** when it correlates with the severity of fetal anemia,[172,173] **fetal infections,**[174] **metabolic and storage disorders, trisomy 21,**[175] and overgrowth syndromes such as **Beckwith-Wiedemann syndrome.**

Splenic Cysts

Fetal **splenic cysts** are rare, usually benign, and are associated with overall good prognosis[176,177] (Fig. 38.26, Video 38.11). The natural history of splenic cysts is variable. Although these cysts may regress spontaneously,[178] in some cases they are complicated by infection, rapid growth, rupture, and/or bleeding.[179] Therefore

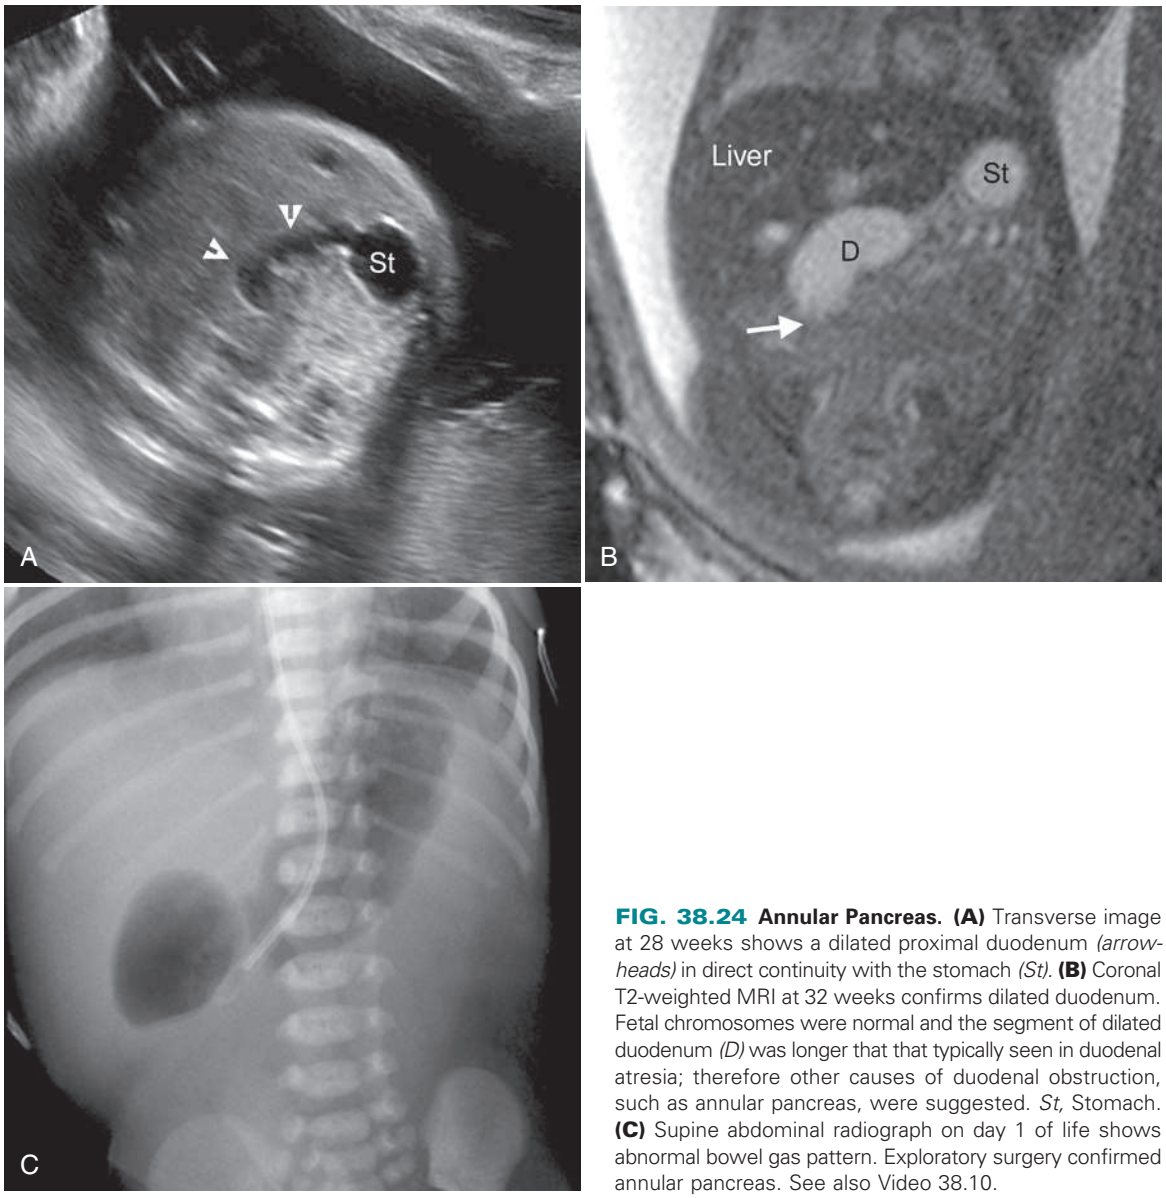

FIG. 38.24 Annular Pancreas. (A) Transverse image at 28 weeks shows a dilated proximal duodenum *(arrowheads)* in direct continuity with the stomach *(St)*. **(B)** Coronal T2-weighted MRI at 32 weeks confirms dilated duodenum. Fetal chromosomes were normal and the segment of dilated duodenum *(D)* was longer that that typically seen in duodenal atresia; therefore other causes of duodenal obstruction, such as annular pancreas, were suggested. *St,* Stomach. **(C)** Supine abdominal radiograph on day 1 of life shows abnormal bowel gas pattern. Exploratory surgery confirmed annular pancreas. See also Video 38.10.

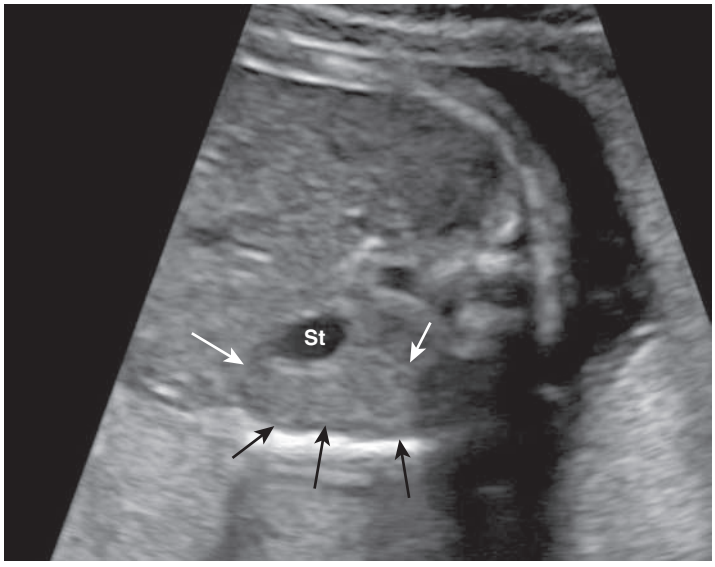

FIG. 38.25 Normal Spleen. Normal spleen *(arrows)* in the transverse view of second-trimester abdomen. *St,* Stomach.

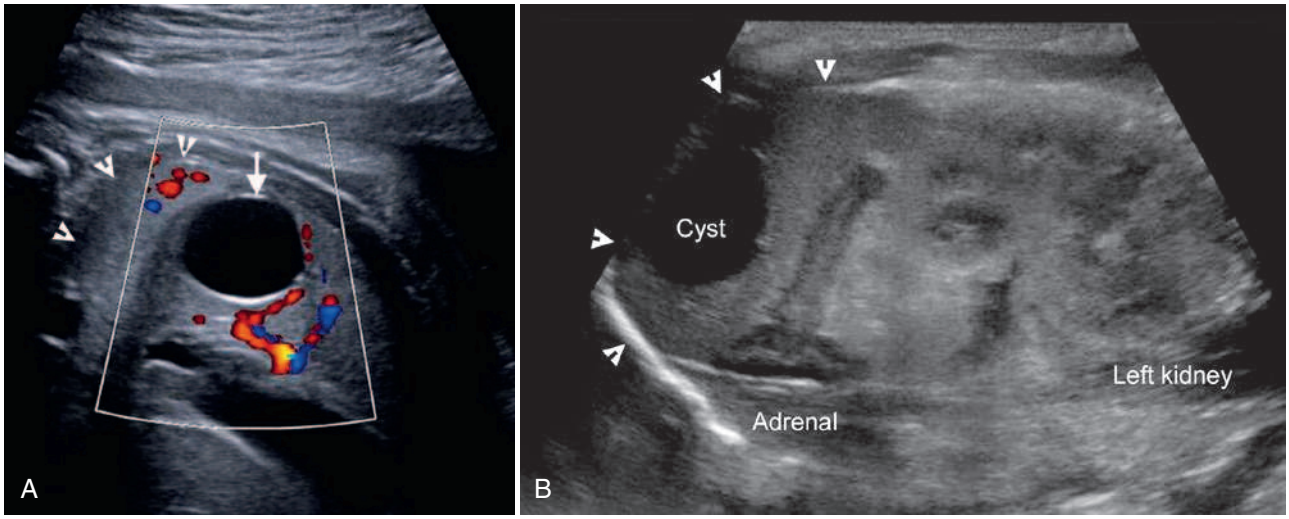

FIG. 38.26 Splenic Cyst. (A) Oblique transverse color Doppler image through the fetal abdomen at 34 weeks shows a simple cyst *(arrow)* in the left upper quadrant. The arrowheads outline the diaphragmatic surface of the spleen. The kidney was clearly separate from the mass. **(B)** Coronal image of the neonatal abdomen confirms that the cyst is in the spleen *(arrowheads)* and separate from the left adrenal and left kidney. See also Video 38.11.

these cysts, when detected antenatally, should be followed by serial ultrasound. Detailed anatomic assessment is indicated for the presence of associated anomalies or cysts involving other organs such as kidneys and liver.

ABDOMINAL WALL

The most common types of abdominal wall defects are **gastroschisis** and **omphalocele.** Other, less common types include **bladder exstrophy, cloacal exstrophy, ectopia cordis,** and more severe ventral body wall defects including **pentalogy of Cantrell, body stalk anomaly,** and **abdominoschisis in amniotic band syndrome.** The overall incidence of abdominal wall defects is 6.3 per 10,000 pregnancies.[180] Because of the loss of integrity in the epidermal covering, abdominal wall defects are associated with elevated levels of **maternal serum alpha-fetoprotein (MS-AFP).** In the past 3 decades, with both maternal serum screening and fetal anatomic surveys becoming routine, the majority of abdominal wall defects are diagnosed by the second trimester. Centers that practice universal first-trimester screening have documented confirmation of diagnoses earlier than 14 weeks.[14,181] With increased access to early scanning, earlier diagnosis is expected to become more common.

Embryology

The embryonic abdominal wall develops from the lateral plate mesoderm and ectoderm between day 16 and day 26 of embryonic life. Each lateral plate of mesoderm splits into parietal and visceral layers, the space between which becomes the body cavity (**coelom** or **celum**), which later differentiates into the peritoneal, pericardial, and pleural cavities.[182-184] The lateral folds (consisting of the parietal layer of the lateral plate mesoderm and the overlying ectoderm) then fold around the coelom caudally, cephalad, and laterally. In the normal enfolding process, the lateral folds come together and fuse to form the ventral body wall. Failure of this process to be completed because of teratogenic or vascular factors lead to a defect in the ventral body wall. Depending on the location of the defect in the ventral abdominal wall, the result can be **gastroschisis** (abdominal region), **ectopia cordis** (thoracic region), or **bladder exstrophy** (pelvic region).

In parallel to the development of the ventral body wall, rapid growth and elongation of the bowel takes place, and the abdominal cavity is temporarily too small to accommodate all of its contents. This results in transient protrusion of the intestine into the extraembryonic coelom at the base of the umbilical cord, a process termed **physiologic midgut herniation**[185] (Figs. 38.27 and 38.28). This herniation is usually visible on ultrasound from 9 to 11 weeks and resolves (or undergoes reduction) by 12 weeks of gestation.[181,186] Therefore if prominent material is seen at the cord insertion site, and it is unclear whether this finding represents an abdominal wall defect or physiologic bowel herniation, a follow-up scan in 1 to 2 weeks will resolve the issue. Failure of the gut loops to return to the body cavity beyond that point has been suggested as the underlying cause in cases of omphalocele.[184] Thus persistence of the midgut herniation beyond 12 weeks or the presence of content other than intestine (e.g., liver) in the herniation should be considered as evidence of true abdominal wall defect (i.e., **omphalocele**).

Gastroschisis

Gastroschisis is a relatively small (<4 cm in most cases), full-thickness paraumbilical defect of the abdominal wall, most often located to the right of the umbilicus. Free-floating loops of bowel in the amniotic fluid are the key finding on ultrasound.

Epidemiology

In population-based studies in Europe, Australia, and Japan, the incidence of gastroschisis has increased from 0.4 to 1.6

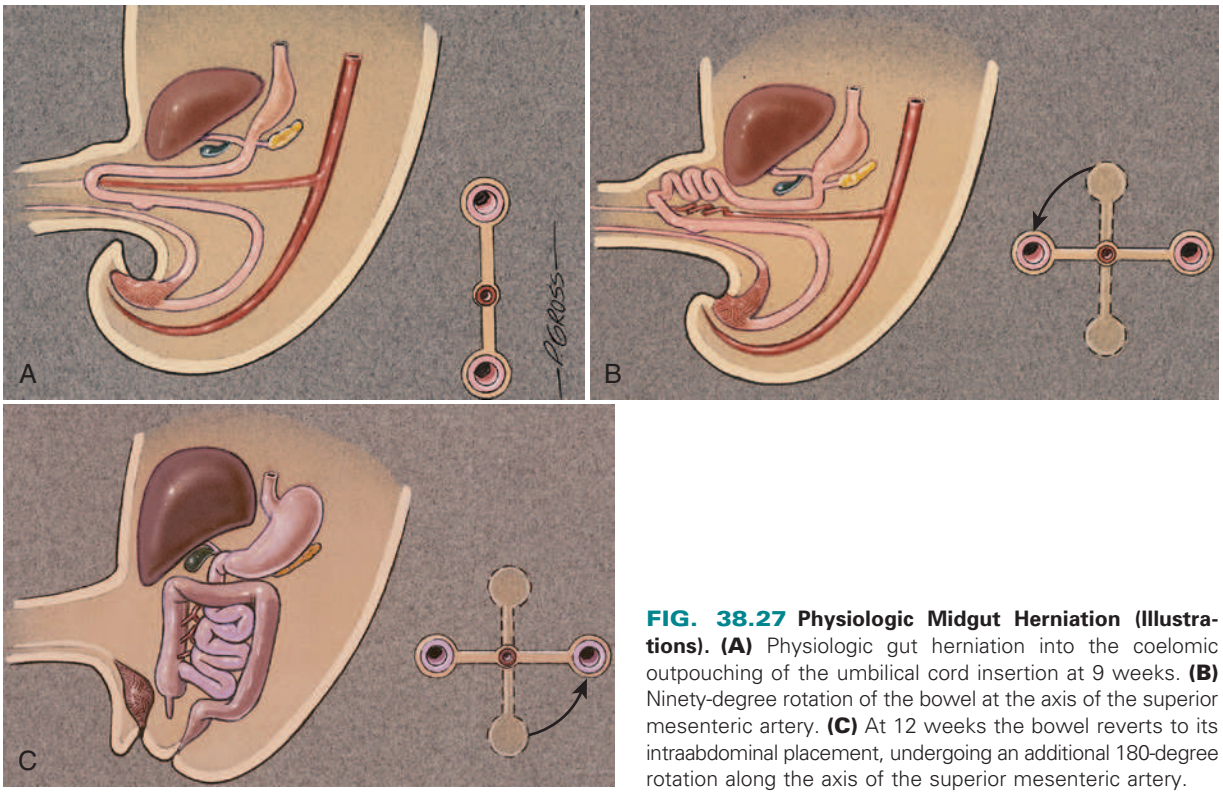

FIG. 38.27 Physiologic Midgut Herniation (Illustrations). (A) Physiologic gut herniation into the coelomic outpouching of the umbilical cord insertion at 9 weeks. **(B)** Ninety-degree rotation of the bowel at the axis of the superior mesenteric artery. **(C)** At 12 weeks the bowel reverts to its intraabdominal placement, undergoing an additional 180-degree rotation along the axis of the superior mesenteric artery.

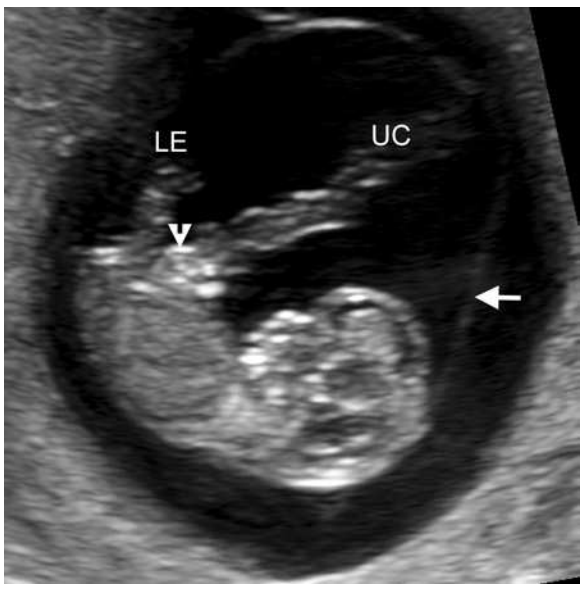

FIG. 38.28 Physiologic Midgut Herniation. Sagittal image at 10 weeks shows echogenic loops of bowel *(arrowhead)* in the base of the normal umbilical cord *(UC)*. The lower extremities *(LE)* are visible and the amnion *(arrow)* has not yet expanded sufficiently to fill the chorionic cavity. These are all normal observations at this gestational age.

per 10,000 up to 1.4 to 4 per 10,000 live births during the past 35 years.[187-191] There is no gender predilection in the affected fetuses. The incidence is higher in **teenage mothers,** with the largest population-based study showing a 10-fold higher incidence in 15- to 19-year-old women compared with 20- to 25-year-old women.[188] Other factors associated with gastroschisis include use of **tobacco, illicit drugs,** and **pseudoephedrine.**[187,188,191-196] More recently, a possible association of gastroschisis with agricultural chemicals such as **atrazine** has been suggested.[197-199]

Pathogenesis

The pathogenesis of gastroschisis is unclear. One hypothesis is that the abdominal wall defect is the result of an isolated vascular compromise of the abdominal wall in the first trimester. This hypothesis is supported by the risk factors for gastroschisis listed in the previous paragraph, as well as by the association of gastroschisis with other fetal abnormalities that are thought to have an underlying vascular cause. Other proposed causes include failed development of the mesoderm and the lateral mesodermal enfolding,[200] rupture of the amniotic membrane at the base of the umbilical cord, disruption of the right vitelline artery with subsequent body wall damage, and abnormal extension of apoptosis patterns during regression of the right umbilical vein.[184]

Prenatal Diagnosis

The diagnosis of gastroschisis is relatively straightforward when the defect is limited, and free-floating loops of bowel are identified intraamniotically; in these cases the diagnosis can already be made as early as the first trimester.[188,201] Most often the defect is located at the right paraumbilical region (Fig. 38.29, Video 38.12). The free-floating bowel has a characteristic **cauliflower-like appearance.** The bowel may appear echogenic due to edema and inflammation of the wall secondary to long-standing exposure

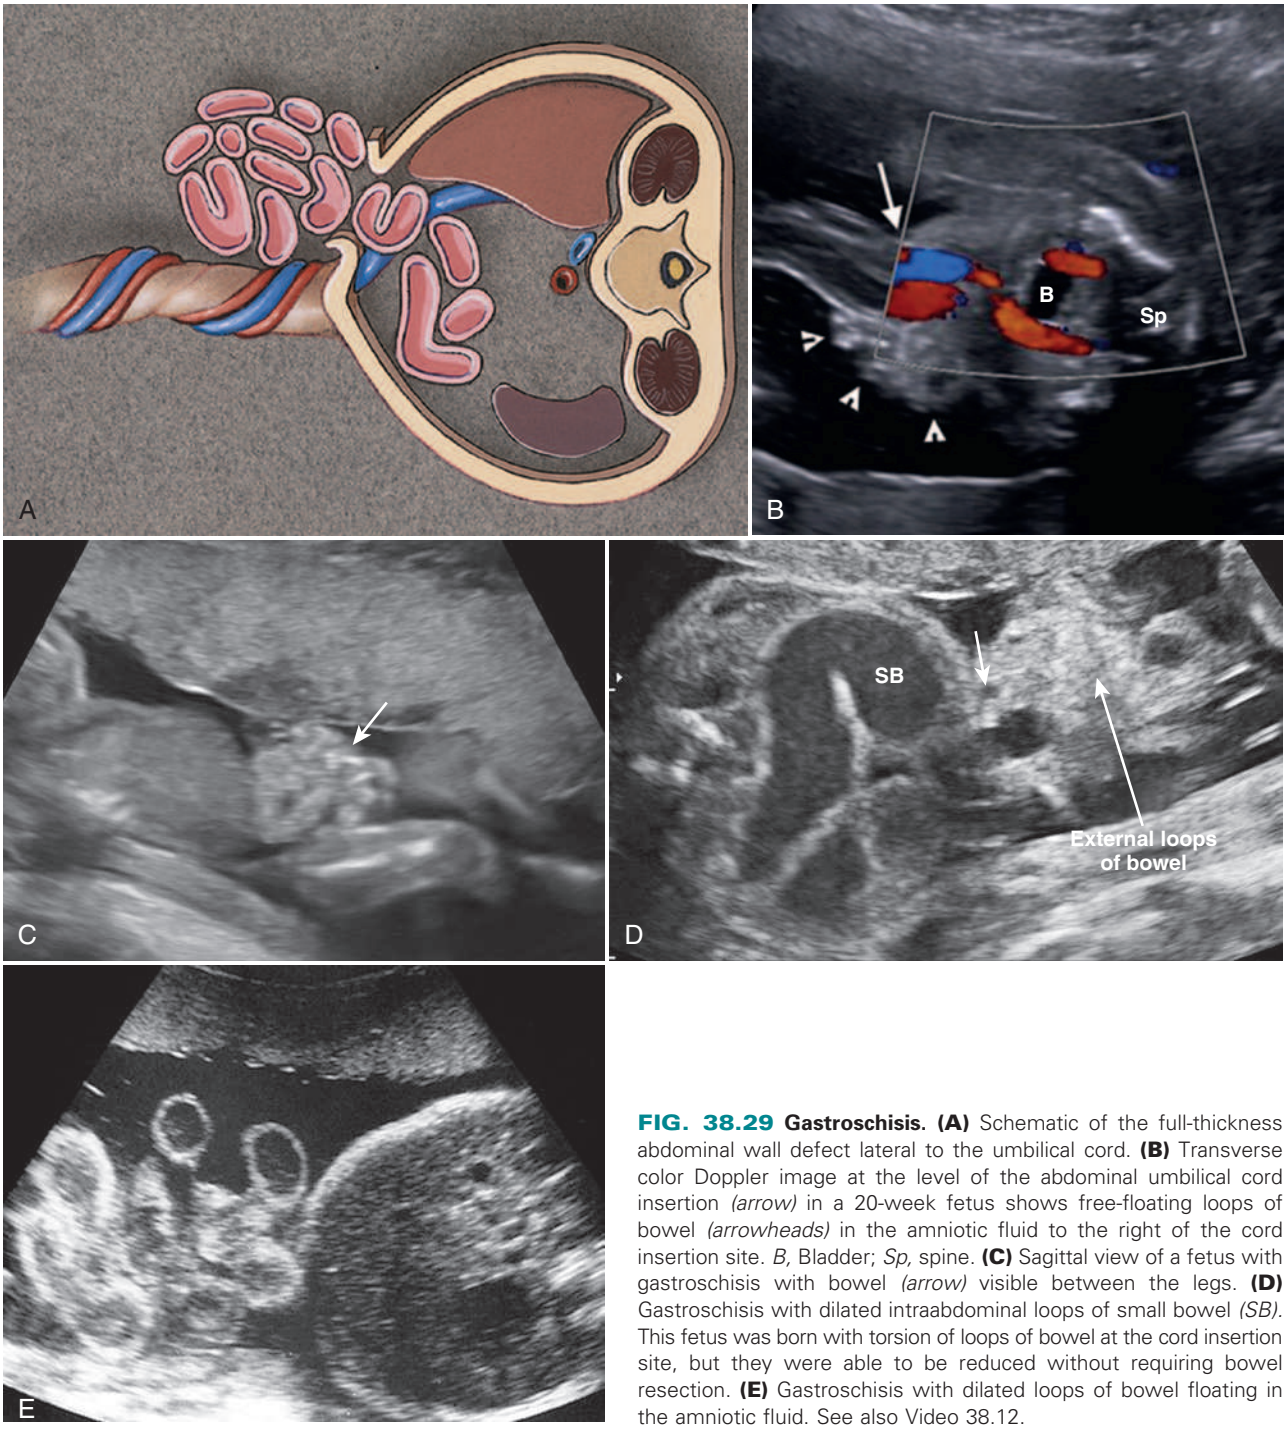

FIG. 38.29 Gastroschisis. (A) Schematic of the full-thickness abdominal wall defect lateral to the umbilical cord. **(B)** Transverse color Doppler image at the level of the abdominal umbilical cord insertion *(arrow)* in a 20-week fetus shows free-floating loops of bowel *(arrowheads)* in the amniotic fluid to the right of the cord insertion site. *B,* Bladder; *Sp,* spine. **(C)** Sagittal view of a fetus with gastroschisis with bowel *(arrow)* visible between the legs. **(D)** Gastroschisis with dilated intraabdominal loops of small bowel *(SB).* This fetus was born with torsion of loops of bowel at the cord insertion site, but they were able to be reduced without requiring bowel resection. **(E)** Gastroschisis with dilated loops of bowel floating in the amniotic fluid. See also Video 38.12.

to amniotic fluid. **Dilated loops of bowel** may be seen either within or outside the abdomen due to associated bowel obstruction secondary to the small abdominal opening or associated volvulus. The stomach is often displaced downward within the abdominal cavity. The umbilical cord inserts normally into the abdomen, adjacent to but separate from the defect. Less often the defect extends upward or laterally and may include structures other than the intestine, such as liver and stomach.

Associated Conditions

Associated GI abnormalities such as atresias, stenosis, perforations, or volvulus are reported in 11% to 31% of cases.[180,202,203] Many of these associated GI conditions are believed to be the result of gastroschisis.[204,205] Additional non-GI anomalies are less common.[202-204,206-208] The risk of **aneuploidy** in cases of isolated gastroschisis is similar to that of the general population.[191,202,206,207] An increased risk of preterm birth, fetal growth restriction (up

to 60% of cases) and stillbirth (4.5%-12%) have been reported in fetuses with gastroschisis. In a recent meta-analysis, the incidence of stillbirth after 36 weeks was only 1.3%.[209] The mechanism responsible for the increased risk of fetal growth restriction and stillbirth remains unclear.[190,206,210]

Management

Initial management of gastroschisis involves detailed sonographic assessment to confirm the diagnosis and assess the extent of the abdominal wall defect and involved organs. The presence of associated anomalies on ultrasound should be documented. Close monitoring with ultrasound and nonstress test are indicated during the third trimester given the increased risk of fetal growth restriction, fetal demise, and GI complications (e.g., obstruction and perforation), although clear guidelines regarding the onset and frequency of monitoring are lacking. The presence of dilated stomach and/or dilated loops of bowel, either within the fetal abdomen or within the amniotic cavity, should be documented. Fetal weight estimation should be done using formulas that are based on indices of fetal head and femur length but not abdominal circumference to avoid underestimation of fetal weight.[211]

The optimal timing of delivery is debated. Given the increased risk of stillbirth and the concern that prolonged in utero exposure of the bowel to amniotic fluid may worsen outcomes, two trials compared the outcome of fetuses that were born preterm (average, 35 weeks) versus those delivered at term or for abnormal fetal testing.[212,213] Neither trial showed an improved outcome in the preterm group. Thus delivery prior to 37 weeks should be considered only in cases of fetal growth restriction or abnormal fetal testing. There is no evidence supporting early delivery in cases of bowel dilatation. In a recent study of 296 pregnancies complicated by gastroschisis, it was found that induction of labor at 37 weeks of gestation was associated with reduced risks of sepsis, bowel damage, and neonatal death compared with pregnancies managed expectantly beyond 37 weeks of gestation.[214] These data may support a practice of routine delivery in the early term period (37-38 weeks). With respect to mode of delivery, there is no evidence that cesarean delivery improves neonatal outcome, and therefore cesarean delivery should be reserved for the usual obstetric indications.[215] Neonatal outcome in cases of gastroschisis is associated with an overall survival rate of over 90%, although outcome is less favorable in cases of complex gastroschisis.[216,217]

Omphalocele

Omphalocele refers to herniation of the intestine and other abdominal organs into the base of the umbilical cord through an enlarged umbilical ring, with the umbilical cord inserting at the apex of the herniated sac. The herniated content is covered by amnion and peritoneum (Fig. 38.30, Video 38.13).

Epidemiology

The incidence of omphalocele varies geographically, from 0.6 per 10,000 births in Japan[191] to 6 per 10,000 births in the British Isles.[202,206] In a registry-based study from the United States, the incidence of omphalocele was 1.92 per 10,000 live births.[218] Omphalocele has been reported to be more common in women 35 to 40 years old[191] and also among women younger than 20 years.[218] Other associations include male sex and multiple gestations.[218]

Prenatal Diagnosis

In the first trimester, **physiologic midgut herniation** can be mistaken for an omphalocele. This normal finding is limited to herniation of bowel loops and should resolve by 12 weeks. It should never include the liver, and the herniation should not be more than 1 cm into the cord. The presence of even small herniation into the base of the umbilical cord beyond 12 weeks is therefore diagnostic of omphalocele (Fig. 38.30B).

Most cases of omphalocele are readily detected at the time of the second-trimester scan as a protrusion of abdominal content, mainly small bowel loops, into the base of the umbilical cord, contained within a sac consisting of peritoneum and amniotic membrane. In cases of large defects, the omphalocele may contain other organs such as liver and stomach (Fig. 38.31). The umbilical cord can be seen inserted on the herniated sac rather than directly to the abdominal wall.

Associated Conditions

In contrast to gastroschisis, omphalocele is commonly associated with chromosomal abnormalities (10%-30%)[191,202] and additional structural abnormalities (55%-58%).[202,208,219] The most common aneuploidies are **trisomies 13 and 18.**[220,221] The risk of genetic abnormalities is higher in the presence of additional structural abnormalities as well as in cases with a small defect when the herniated content is limited to small bowel (see Fig. 38.30B). Thus cases where the liver is found in the omphalocele are less likely to be associated with chromosomal abnormalities. Omphalocele is associated with several single gene mutation syndromes (including autosomal dominant, autosomal recessive, and X-linked recessive disorders),[222] and Beckwith-Weidemann syndrome. **Beckwith-Weidemann syndrome** involves a mutation or deletion of imprinted genes within the chromosome 11p15.5 region and is associated with omphalocele, macroglossia, and overgrowth (Fig. 38.32).

Associated structural abnormalities are common and include midline defects (cardiac, cleft lip and palate, and spinal/vertebral anomalies), clubfoot, and central nervous system anomalies.[219] Because of the common association with aneuploidies and multisystem anomalies, many of these pregnancies are terminated, potentially biasing outcome data.

Management

The finding of fetal omphalocele should trigger a detailed evaluation for the presence of associated structural anomalies, including fetal echocardiography.[223] Genetic counseling is recommended and amniocentesis should be offered to assess for karyotype or microarray, as well as for screening for specific genetic syndromes, including Beckwith-Wiedemann syndrome.

Fetal monitoring with serial ultrasound examinations is recommended given an increased risk for polyhydramnios, ascites, fetal growth restriction, and stillbirth. As in the case of

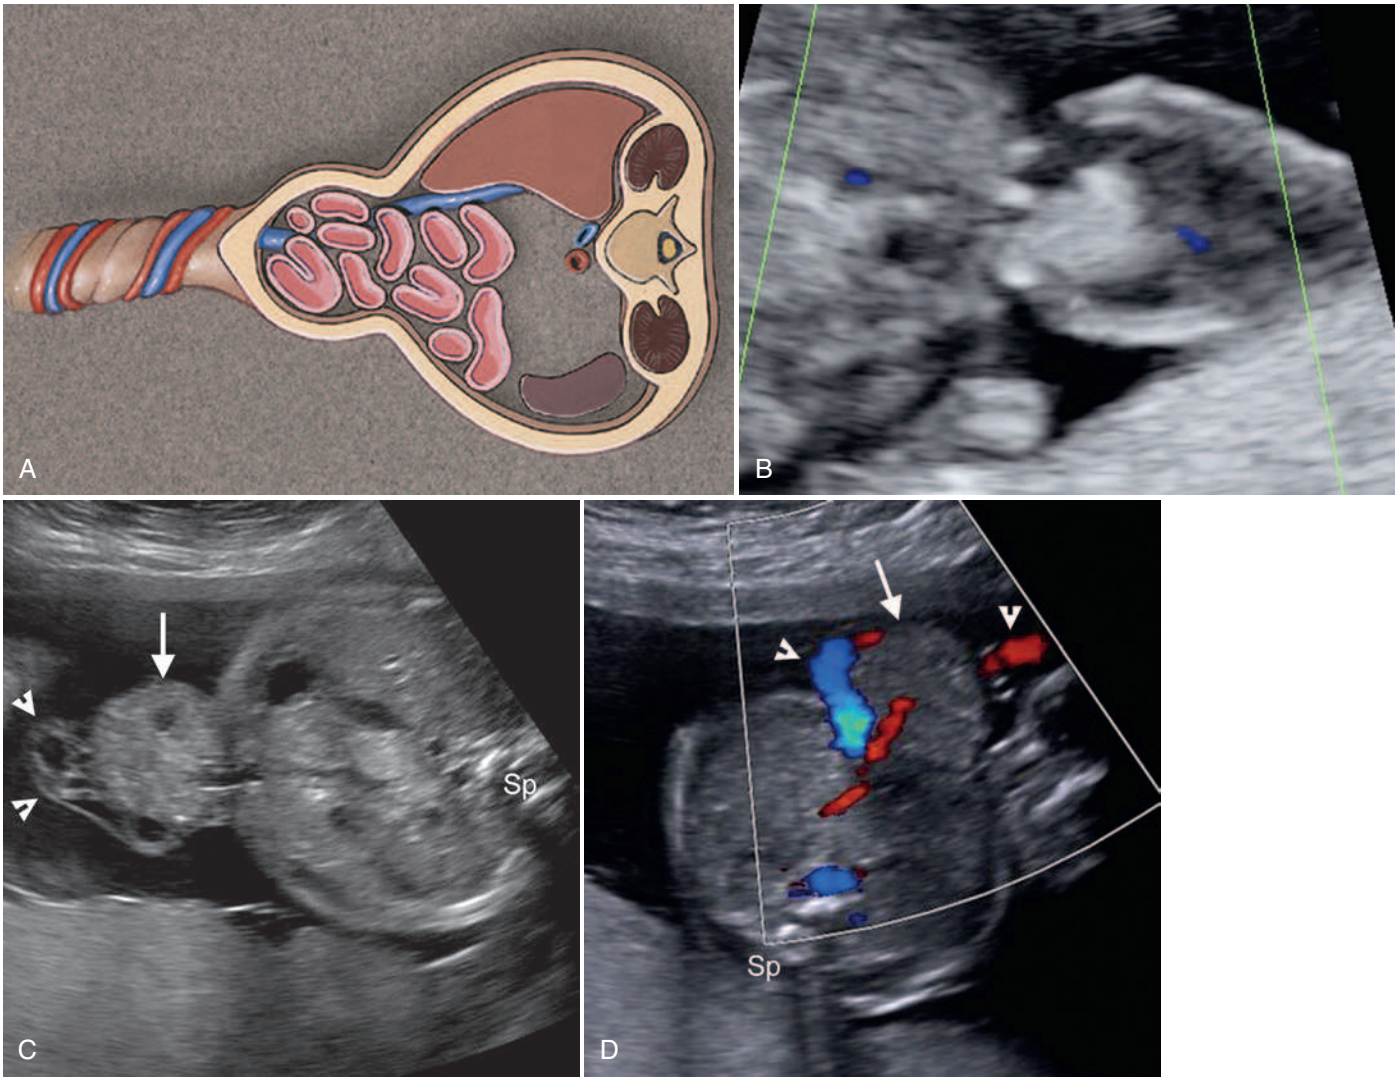

FIG. 38.30 Small Omphalocele. (A) Schematic of membrane covered omphalocele containing only bowel. **(B)** Transverse image of abdomen with loop of bowel herniated into base of umbilical cord. The fetus had trisomy 18. **(C)** Transverse image of abdomen at 26 weeks shows a bowel-only omphalocele *(arrow).* The umbilical cord *(arrowheads)* inserts onto the membrane, which covers the defect. *Sp,* Spine. **(D)** Transverse color Doppler image at 26 weeks shows a bowel-only omphalocele *(arrow).* The umbilical vessels *(arrowheads)* course around the bowel, in the membrane that covers the defect. *Sp,* Spine. See also Video 38.13.

gastroschisis, fetal weight estimation should be done using formulas that are based on indices of fetal head and femur length but not abdominal circumference to avoid underestimation of fetal weight.[224]

There is no evidence that early delivery or cesarean delivery are associated with improved outcomes.[225] Therefore vaginal delivery following spontaneous onset of labor should be preferred unless other indications are present for induction of labor or cesarean delivery. Neonatal outcome is mainly determined by the presence of associated genetic and/or structural anomalies.[191,218]

Bladder Exstrophy

Bladder exstrophy refers to infraumbilical abdominal wall defect that results from incomplete closure of the lower abdominal wall and the anterior wall of the bladder.[226] It is a rare abdominal wall defect with an incidence of about 1 of 30,000 births.[227]

The prenatal diagnosis of bladder exstrophy is mainly based on the inability to visualize the bladder. The exposed bladder mucosa may become inflamed and thickened and may therefore appear as an irregular contour of the lower anterior abdominal wall (Video 38.14).[228] Another clue for the diagnosis is caudal displacement of the umbilical cord insertion site (Fig. 38.33). Associated anomalies include genital abnormalities such as **epispadias,** a combination known as **bladder exstrophy–epispadias complex.**[226]

Neonatal survival is overall good, although the repair of these defects is complex, often requiring staged procedures, to maintain continence and functional genital tissue.[229,230]

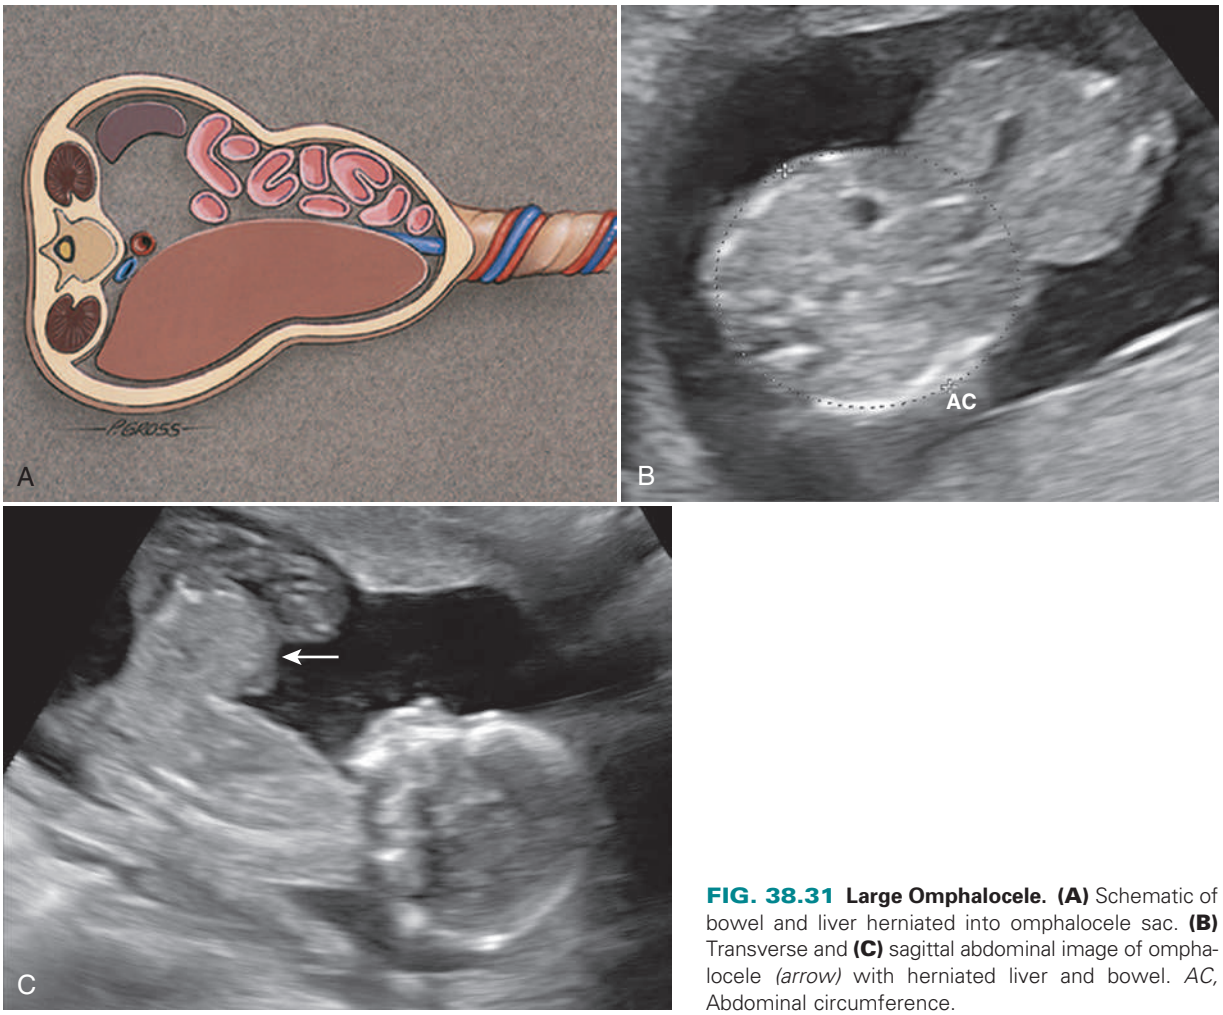

FIG. 38.31 Large Omphalocele. (A) Schematic of bowel and liver herniated into omphalocele sac. **(B)** Transverse and **(C)** sagittal abdominal image of omphalocele *(arrow)* with herniated liver and bowel. *AC,* Abdominal circumference.

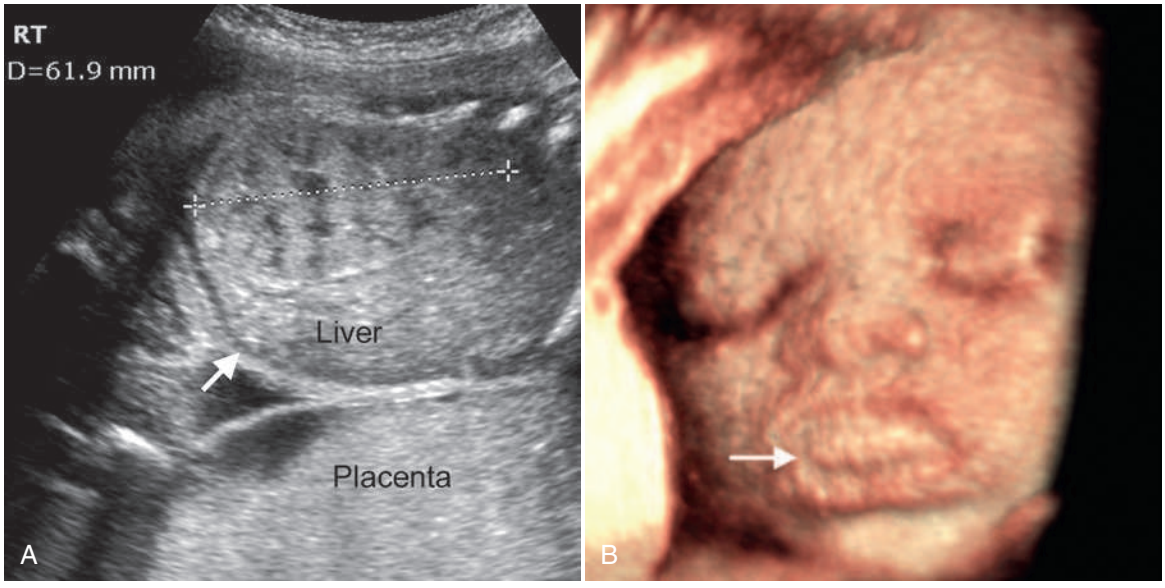

FIG. 38.32 Beckwith-Wiedemann Syndrome. (A) Coronal oblique ultrasound at 28 weeks shows the right kidney measuring 6.9 cm, well above the 95th percentile. The adjacent liver *(arrows)* extends beyond the renal margins indicating that it is enlarged as well. Visceromegaly is part of Beckwith-Wiedemann syndrome. **(B)** Three-dimensional surface rendered view of the fetal face in the same case shows macroglossia *(arrow).*

FIG. 38.33 Bladder Exstrophy. (A) Transvaginal sonogram at 16 weeks shows an abdominal wall defect *(arrows),* located low in the abdomen. The bladder was not visualized. *Sp,* Spine. **(B)** Postmortem photograph shows bladder exstrophy. *UC,* Umbilical cord. **(C)** Bladder exstrophy *(arrow)* in a different fetus. See also Video 38.14.

Cloacal Exstrophy

Cloacal exstrophy is a more complex multisystem abdominal wall defect that affects all the components of the **cloaca** (bladder and urethra, genitalia and rectum), as well as **lower spine.** Cloacal exstrophy is often termed **OEIS complex** (*o*mphalocele-*e*xstrophy–*i*mperforate anus–*s*pinal dysraphism) (Fig. 38.34, Video 38.15). **Genital abnormalities** are also common.[231] The pathogenesis of cloacal exstrophy is unclear but has been attributed to premature rupture of the cloacal membrane or to very early defect in the closure of the ventral body wall.[228] It occurs at a higher rate in monozygous than in dizygous twins,[129] suggesting a vascular component.

The prenatal diagnosis is based on the combination of **omphalocele, inability to visualize the bladder** and **anal dimple,** and the presence of spine anomalies such as **meningomyelocele** or **tethered cord.** Additional findings may include genital abnormalities (e.g., **epispadias**), **single umbilical artery, renal abnormalities** and **ascites.**[232,233] A unique sonographic sign is the **"elephant trunk,"** which is the result of a prolapsed loop of bowel between the two halves of the open bladder.[234]

Diagnosis of OEIS has been reported as early as 13 weeks.[69] Diagnostic difficulties can occur in differentiating this disorder from other complex abdominal wall defects including **limb–body wall complex** and **pentalogy of Cantrell.**[129,231,235] Although the features of OEIS (when seen) are specific, the detection rate is

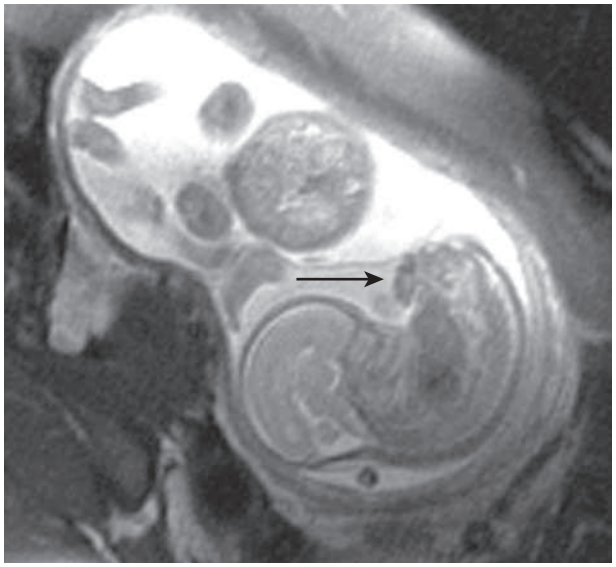

FIG. 38.34 Omphalocele-Exstrophy–Imperforate Anus–Spinal Defects (Cloacal Exstrophy). T2-weighted MRI of twins. The upper twin was normal with normal amniotic fluid. The lower twin had oligohydramnios with a lower anterior abdominal wall defect *(arrow)*. See also Video 38.15.

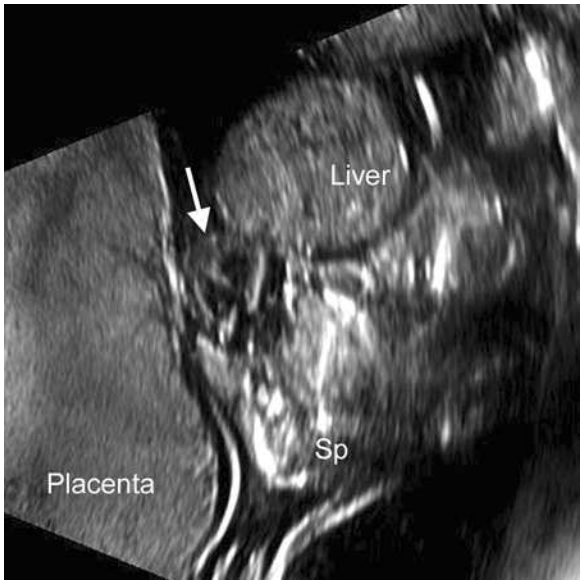

FIG. 38.35 Ectopia Cordis. Transverse image through the chest on one of a dichorionic twin pair shows that the liver and heart *(arrow)* are external to the thorax. *Sp,* Spine. This is a lethal malformation, in this case, caused by amniotic bands, which were visible in real time. The co-twin was normal and was delivered at term.

probably low and it is likely that many cases of OEIS are misdiagnosed. Once this diagnosis has been made, genetic counseling is recommended, and amniocentesis may be considered to identify gender prior to birth.

Ectopia Cordis

Ectopia cordis is a midline defect of the upper fetal ventral body wall through which all or part of the heart extrudes, with or without a membrane (Fig. 38.35). Most commonly the heart protrudes at the level of the chest through a defect involving the sternum, but the heart can be located at the cervical or abdominal region. Association with **structural cardiac anomalies** or other **abdominal wall defects** is common.[236] Prognosis is poor, although survivors have been reported.[237] **Trisomy 18** has been associated with this diagnosis, especially in the presence of additional abnormalities.[238,239]

Other Complex Body Wall Defects

In cases when the insult during the formation of the ventral abdominal wall is severe and takes place at an early embryonic developmental stage, the result is large and/or multiple defects of the ventral body wall, with evisceration of multiple organs of the abdomen, chest, and pelvis. These disorders are often associated with other anomalies involving the limbs, urinary system, external genitalia, and spine. Several syndromes and associations have been suggested to describe these conditions, each including different combinations of the previously listed defects. However, given the considerable overlap between these syndromes, it remains unclear whether they represent distinct pathogenetic entities or different manifestations of a single basic disorder. This overlap often results in a significant confusion in the terminology used to describe these conditions.

Pentalogy of Cantrell

Pentalogy of Cantrell is a rare complex disorder of the ventral body wall that refers to a combination of **defect of the sternum, ectopia cordis, cardiac anomalies** (e.g., septal defects, tetralogy of Fallot, transposition of great arteries), **defect of the anterior diaphragm and diaphragmatic pericardium,** and **supraumbilical abdominal wall defect** (most commonly **omphalocele**).[240,241] Other associated anomalies include midline abnormalities such as **facial cleft** and **encephalocele.** Given the association with **trisomies 18 and 13,** genetic consultation is recommended. Most of these cases are sporadic, and the risk of recurrence is low. The prognosis of this disorder is poor.[242]

Body Stalk Anomaly

Body stalk anomaly (also known as **limb–body wall complex**) is a rare and lethal disorder of the anterior abdominal wall. There are three hallmarks of this disorder: (1) There is a severe disruption of the abdominal and thoracic walls. (2) The abdominal and thoracic organs (e.g., heart, lungs, liver, bowel, bladder) are located outside the body cavity and are contained within a sac that is closely attached to the placenta, leading to a relatively fixed position of the fetus. (3) The umbilical cord is very short or absent, possibly because of a failure of the body stalk to develop properly. Associated musculoskeletal abnormalities are common and include severe **kyphoscoliosis** and **limb defects** such as **club foot** and absent or malformed limbs.[243-245]

The pathogenesis of this disorder is unclear, and several hypotheses have been suggested, including early vascular disruption, disruption due to amniotic bands following early amniotic rupture, or complete failure of the folding process of the embryonic disc.[246] This disorder is always lethal.

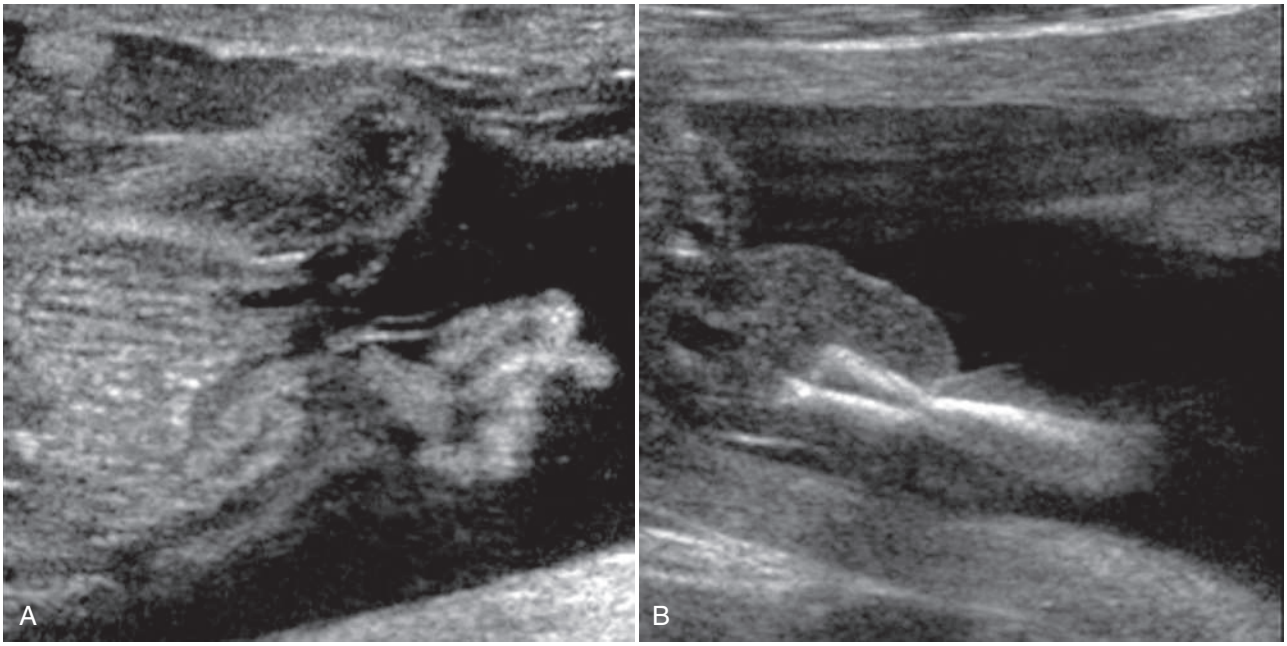

FIG. 38.36 Amniotic Band Syndrome. (A) Transverse view of abdomen shows anterior abdominal wall defect. **(B)** View of lower extremity shows constriction ring caused by amniotic bands. The constellation of findings is consistent with amniotic band syndrome.

Amniotic Band Syndrome

Amniotic band syndrome can affect any part of the fetus, and in a small proportion of cases it can affect the fetal abdominal or thoracic walls.[247] In these cases, the defect can appear similar to that of gastroschisis, with the **abdominal and/or thoracic organs floating freely within the amniotic cavity** with no sac around them (Fig. 38.36). The diagnosis of amniotic band syndrome is suggested by the demonstration of the **amniotic bands** and the presence of additional findings that are associated with disruption due to amniotic bands including **limb defects** (constriction or amputation of a limb), **encephalocele,** and **facial clefts.**[248] Unlike body stalk anomaly, the **umbilical cord can be demonstrated** in these cases.

CHAPTER 39

The Fetal Urogenital Tract

Katherine W. Fong, Julia Eva Kfouri, and Kirsten L. Weind Matthews

SUMMARY OF KEY POINTS

- Evaluation of amniotic fluid volume (subjective assessment combined with semiquantitative methods such as maximum vertical pocket or amniotic fluid index) provides important information about some maternal and fetal conditions, as well as placental function.
- Sonographic findings suspicious of renal cystic disease include cysts, renal hyperechogenicity, and/or large kidneys. Whenever renal cystic disease is suspected, it is useful to perform a renal ultrasound of the parents to check for unknown familial disease.
- Evaluation of urinary tract dilation should include measurement of the anteroposterior renal pelvic diameter; identification of calyceal dilation and renal parenchymal, ureteral, or bladder abnormalities; and assessment of amniotic fluid volume.
- In fetuses with lower urinary tract obstruction, a fetal urinary function profile (combining sonographic and biochemical predictors) is most useful clinically in selecting the fetus that will benefit from in utero intervention.
- Examination of fetal genitalia plays a key role in the diagnostic workup of many structural abnormalities and genetic disorders, as well as in the assessment of multiple pregnancies.

CONCLUSION
Acknowledgments

Evaluation of the fetal urogenital tract is an integral part of the obstetric ultrasound examination. Sonography depicts normal developmental anatomy and allows detection and characterization of many genitourinary abnormalities. In addition, assessment of the amniotic fluid volume (AFV) often provides important prognostic information regarding fetal renal function. Accurate and early prenatal diagnosis is important because this may influence obstetric and neonatal management.

Congenital anomalies of the kidney and urinary tract (CAKUT) account for approximately 30% of all malformations detected on routine prenatal sonography.[1,2] A systematic sonographic approach is proposed, which includes a search for associated anomalies and detailed evaluation of renal structure and function.

THE NORMAL URINARY TRACT

Embryology

The **permanent kidney (metanephros)** is the third in a series of excretory organs in the human embryo, forming after the **pronephros** and **mesonephros.**[3] In the seventh menstrual week, the metanephros begins to develop from two sources: the metanephric diverticulum (ureteric bud) and the metanephric mass of intermediate mesoderm (Fig. 39.1). The **ureteric bud** is an outgrowth from the mesonephric duct, near its entrance into the cloaca. It elongates and branches in a dichotomous pattern, giving rise to the ureter, renal pelvis, calyces, and

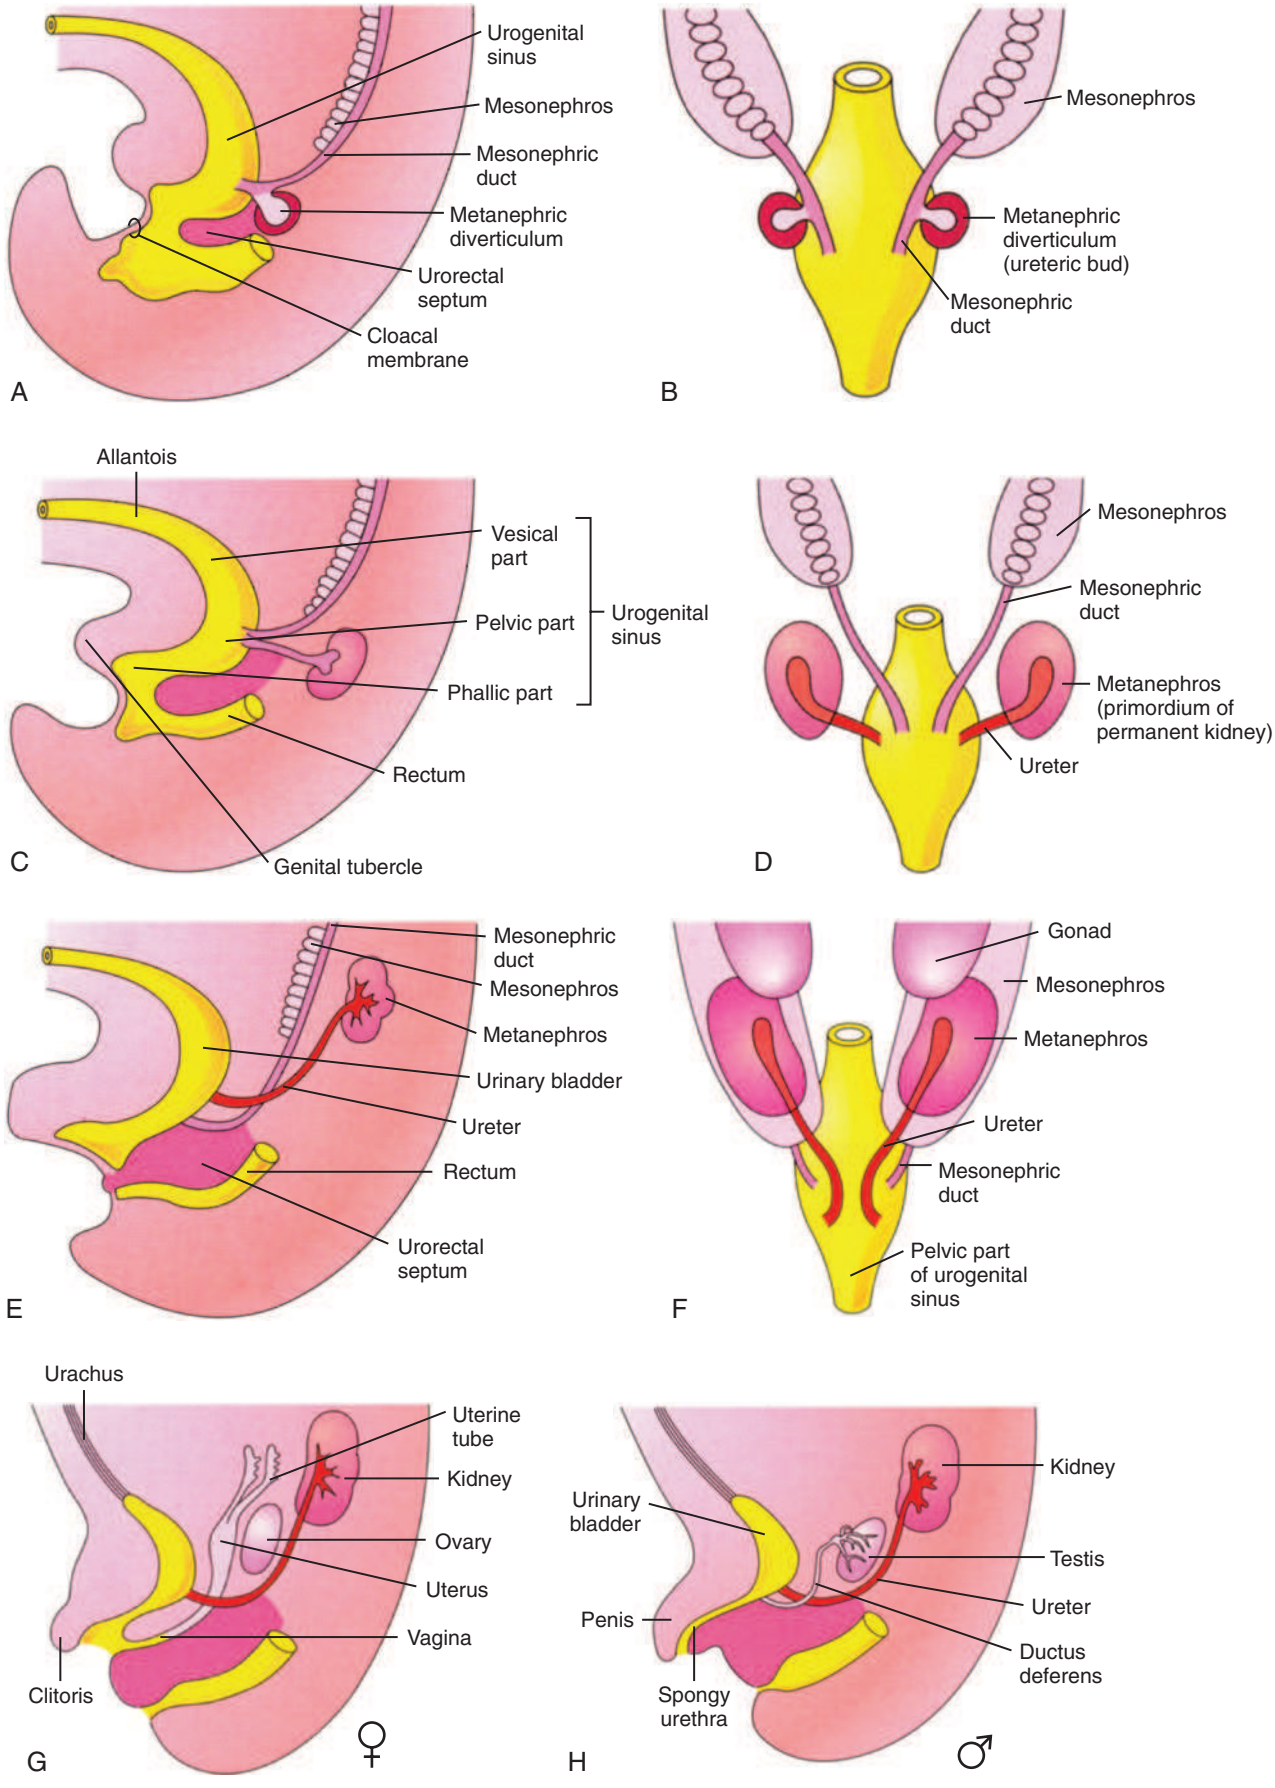

FIG. 39.1 Embryology of the Urinary Tract. Diagrams show division of the cloaca into the urogenital sinus and rectum; absorption of the mesonephric ducts; development of the permanent kidneys (metanephroi), urinary bladder, urethra, and urachus; and changes in the location of the ureters. **(A)** Lateral view of the caudal half of a 5-week-old embryo. **(B), (D),** and **(F)** Dorsal views. **(C), (E), (G),** and **(H)** Lateral views. The stages shown in **(G)** and **(H)** are reached by the 12th week. (With permission from Moore KL, Persaud TVN, editors. The developing human: clinically oriented embryology. 7th ed. Philadelphia: Saunders; 2003.[3])

collecting tubules. Through interaction with the metanephric mesoderm, the ureteric bud induces the formation of nephrons. In early embryonic life, the kidneys are located in the pelvis, but they "ascend" to their adult position by the 11th menstrual week. At this gestation, the kidneys start to produce urine.

By the ninth menstrual week, the **cloaca** (caudal part of hindgut) is divided by the urorectal septum into the rectum posteriorly and the urogenital sinus anteriorly (see Fig. 39.1). The urinary bladder, the female urethra, and most of the male urethra develop from the urogenital sinus and the surrounding splanchnic mesenchyme. Initially, the bladder is continuous with the allantois, but this structure soon constricts and becomes a fibrous cord, the urachus, which extends from the apex of the bladder to the umbilicus.

Sonographic Appearance

In the **first trimester** the fetal kidneys are best examined by transvaginal sonography. The kidneys are seen as oval, hyperechoic structures in the paravertebral regions, with a small, central sonolucent area caused by fluid in the renal pelvis[4] (Fig. 39.2A). By 12 to 13 weeks of gestation, the kidneys can be visualized in 99% of cases with combined transabdominal and transvaginal sonography.[5] In the **second trimester** the kidneys often appear as isoechoic structures adjacent to the fetal spine on transabdominal sonography (Fig. 39.2B). As the fetus matures, corticomedullary differentiation becomes more obvious, especially in the third trimester (Figs. 39.2C-D). The renal pyramids orient in anterior and posterior rows and are hypoechoic relative to the renal cortex. In the **third trimester** the renal cortex is isoechoic or slightly hyperechoic to liver and spleen. With fat deposition in the perinephric region, an echogenic border develops, and the kidney becomes better delineated. Normal fetal lobations are often visible and give the kidneys an undulating contour.

The kidneys grow throughout pregnancy. Table 39.1 provides a **nomogram of renal lengths** at 14 to 42 weeks of gestation.[6] The often-quoted rule of thumb that "renal length in millimeters approximates gestational age in weeks" applies only to a narrow gestational age range of 18 to 21 weeks. There are also published

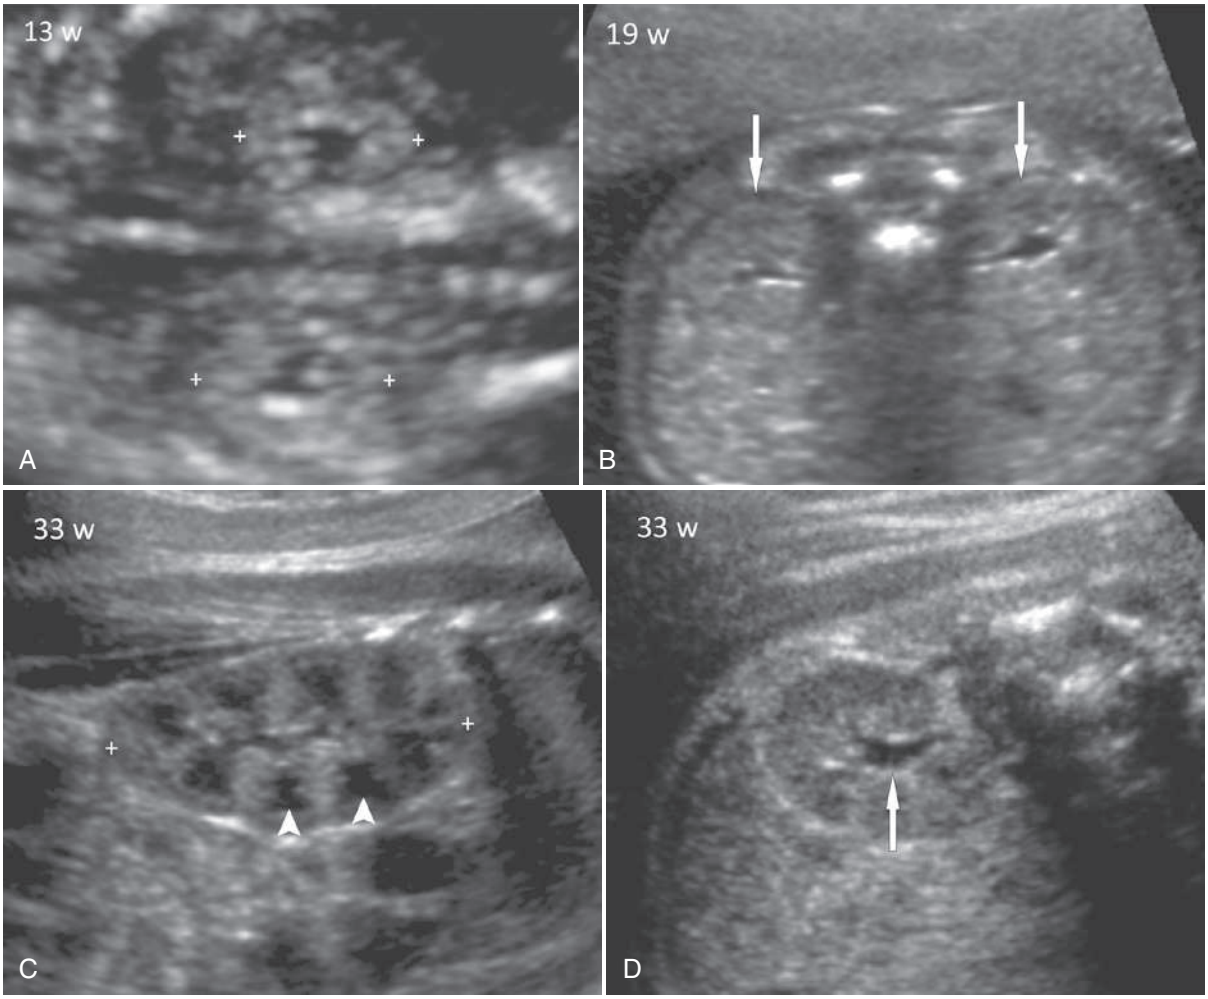

FIG. 39.2 Normal Sonographic Appearance of Kidneys at Different Gestational Ages. (A) Transvaginal scan at **13 weeks** of gestation in the coronal plane shows normal kidneys *(calipers),* which appear hyperechoic, with small central sonolucent area caused by fluid in the renal pelvis. **(B)** Transabdominal scan at **19 weeks** in the transverse plane shows the kidneys *(arrows)* as paired isoechoic structures adjacent to the fetal spine, with a small amount of fluid in the renal pelvis. **(C)** and **(D)** Longitudinal and transverse scans at **33 weeks** show the kidney well outlined by perinephric fat, with normal corticomedullary differentiation. The pyramids *(arrowheads)* are hypoechoic. There is a small amount of fluid in the renal pelvis *(arrow).*

N, Number of fetuses for each week of gestation.
With permission from Chitty LS, Altman DG. Charts of fetal size: kidney and renal pelvis measurements. Prenat Diagn. 2003;23(11): 891-897.[6]

charts of renal anteroposterior diameter, transverse diameter, and volume.[6] Sometimes, it is difficult to define the exact renal borders, especially at the upper pole, because of shadowing from ribs or poor distinction from the adrenal gland. Fetal breathing can aid in renal visualization. It is also important to avoid using an oblique section through the kidney for measurement. The **renal/abdominal circumference** ratio remains constant at 0.27 to 0.30 throughout pregnancy.[7]

The calyces are not normally visualized, but some fluid is typically seen in the renal pelvis. The highly characteristic **renal pelvic echo** is often the key to finding the kidneys in the second trimester. Measurements of the renal pelvis are discussed in the section on upper urinary tract (UT) dilation. The normal ureter is 1 to 2 mm in diameter and is not normally visible.

By using transvaginal sonography, the **bladder** can be seen as early as 11 weeks of gestation.[4] By 12 to 13 weeks, the bladder is visualized in 98% of cases using both transabdominal and transvaginal sonography.[5] The bladder is thin walled and situated anteriorly in the pelvis. The **umbilical** (superior vesical) **arteries** run lateral to the bladder as they course toward the umbilicus (Fig. 39.3). The hourly fetal urine production increases with advancing gestation, from a mean value of 4 to 5 mL/hr at 20 weeks to 52 to 56 mL/hr at 40 weeks.[8,9] Three-dimensional (3-D) ultrasound measurements demonstrate reproducible urine production rates based on bladder volumes, but tend to estimate higher rates in the third trimester compared with the standard two-dimensional (2-D) technique.[10] The **maximum bladder volume** increases from a mean value of 1 mL at 20 weeks to 36 mL at 41 weeks.[8] The normal bladder fills and empties (either partially or completely) approximately every 25 minutes (range, 7-43 min). Therefore changes in bladder volume should be observed during the course of the obstetric sonogram.

Amniotic Fluid Volume

Evaluation of amniotic fluid volume (AFV) provides important information about some maternal and fetal conditions, as well as placental function. Evaluation of AFV is a key component of fetal biophysical assessment. After 16 weeks, fetal urine production becomes the major source of amniotic fluid.[11] Fetal lung secretions, fetal swallowing, and intramembranous resorption of water into the fetal circulation via fetal vessels on the placental surface also contribute to AFV homeostasis.[12]

Several methods are used to assess AFV. Subjective assessment can be combined with semiquantitative techniques, such as measurement of the **maximum vertical pocket** (or **single deepest vertical pocket**) and **amniotic fluid index** (AFI). Significant oligohydramnios results in compression of the fetus, marked crowding of fetal parts, and poor visualization of fetal anatomy. With polyhydramnios, one gets the impression of a "swimming" fetus. The subjective assessment of AFV by experienced sonographers has been shown to be reliable.[13] However, there are conflicting data regarding the reliability of both the maximum vertical pocket technique and the AFI.[13-15] The technique for measuring the deepest amniotic fluid pockets should follow these guidelines:

- The maximum depth of the fluid pocket should be measured in a perpendicular direction.
- The pocket should have a width of at least 1 cm (avoid measuring narrow, slitlike pockets).
- The pocket should be free of fetal small parts and umbilical cord.

The following classification has been proposed for the maximum vertical pocket method: vertical depth of the pocket less than 2 cm indicates moderate to severe oligohydramnios, 2 to 8 cm is normal, and greater than 8 cm indicates polyhydramnios.[16]

Amniotic Fluid Assessment

Vertical Depth	
<2 cm	Oligohydramnios
2-8 cm	Normal
>8 cm	Polyhydramnios

[a]Maximum vertical pocket method.

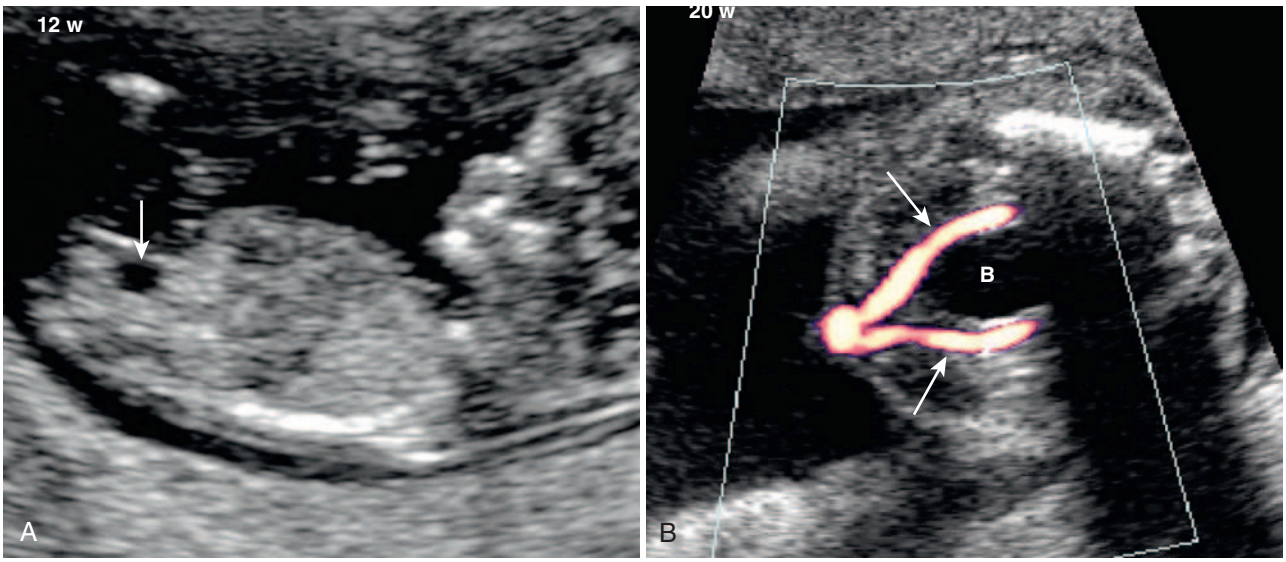

FIG. 39.3 Normal Urinary Bladder. (A) Sagittal image of a 12-week fetus. Note normal urinary bladder *(arrow)*. **(B)** Power Doppler image of the umbilical arteries *(arrows)* at 20 weeks' gestation helps in the identification of any questionable fluid-filled structure in the pelvis as the urinary bladder *(B)*.

The AFI is obtained by measuring the deepest amniotic fluid pocket in each of the four quadrants of the uterus, and the sum of the four measurements is the index.[14,17] AFI varies with gestational age (Table 39.2).[18] In the late second trimester and in the third trimester, an AFI of 5 cm to 24 cm has been considered as normal.[19] It is recommended that when AFI is less than 10 cm, three measurements should be averaged.[14] The semiquantitative methods are useful for following AFV on serial examinations, particularly by multiple examiners of varying experience.

Oligohydramnios is typically defined as either a single maximum vertical pocket of amniotic fluid of less than 2 cm or alternatively, an AFI of less than 5 cm.[20] Recently, a meta-analysis of four randomized controlled trials comparing the use of AFI (<5 cm) versus the single deepest vertical pocket (<2 cm) during antepartum fetal surveillance did not show any evidence that one method is superior to the other in predicting poor perinatal outcomes.[21] However, the use of AFI increased the rate of diagnosis of oligohydramnios and subsequent induction of labor. It was concluded that the single deepest vertical pocket measurement is the method of choice for amniotic fluid assessment during fetal surveillance.[21] This approach is supported by the American College of Obstetricians and Gynecologists (ACOG), as well as the findings of the recently completed SAFE trial.[20,22]

In multiple pregnancies, the maximum vertical pocket technique is commonly used for assessment of amniotic fluid, with similar cutoffs for abnormal as for singletons.[12,19,23] A systematic review of studies on amniotic fluid assessment and adverse outcomes in twin pregnancies has cautioned that sonographic evaluation of AFV has high specificity but poor sensitivity for the detection of abnormal AFV, and more rigorous studies in this area are required.[24]

URINARY TRACT ABNORMALITIES

The prevalence of UT malformations varies among studies, likely because of differences in study population and methods of surveillance. In a recent analysis of 709,030 births in 12 European countries, the prevalence of congenital malformations of the UT was 1.6 per 1000 births.[25] The overall prenatal detection rate was high: 82% and 88.5% in two studies.[1,25] However, it varied from 36% to 100% in different centers.[25] Many factors could account for the variation of prenatal detection rates, including the study population (high risk vs. unselected), timing of the ultrasound scan, expertise of the operator, quality of the ultrasound equipment, extent of follow-up, and ascertainment of congenital anomalies. For major UT anomalies, 57% were detected before 24 weeks.[1] Lethal UT anomalies account for 10% of pregnancy terminations.[26]

Prenatal Diagnosis of Urinary Tract Abnormalities

Assessment of amniotic fluid volume
Localization and characterization of urinary tract abnormalities
Search for associated abnormalities

A systematic approach to the prenatal diagnosis of UT abnormalities includes assessment of AFV, localization and characterization of UT abnormalities, assessment of fetal gender, and search for associated abnormalities.

Normal AFV in the second half of pregnancy implies at least one functioning kidney and a patent urinary conduit to the amniotic cavity. If **oligohydramnios** is present without a history

With permission from Magann EF, Sanderson M, Martin JN, Chauhan S. The amniotic fluid index, single deepest pocket, and two-diameter pocket in normal human pregnancy. Am J Obstet Gynecol. 2000;182(6):1581-1588.[18]

of ruptured membranes, maternal drug intake (e.g., angiotensin-converting enzyme [ACE] inhibitors,[27] angiotensin II receptor antagonists,[28] cyclooxygenase-2 [COX-2] selective and nonselective inhibitors,[29] nonsteroidal antiinflammatory drugs,[30] cocaine[31]), or evidence of intrauterine growth restriction (IUGR), UT anomalies must be strongly suspected. In the setting of a UT abnormality, normal AFV indicates a good prognosis. Oligohydramnios in the early second trimester carries a very poor prognosis because of the associated pulmonary hypoplasia. Occasionally and paradoxically, **polyhydramnios** may occur, especially with unilateral obstructive uropathy, with **mesoblastic nephroma,** or when there are concomitant abnormalities of the central nervous system (CNS) or gastrointestinal (GI) tract.

The following questions are helpful in defining and characterizing the UT abnormality:

- Is the bladder identified and normal in appearance?
- Are kidneys present? Are they normal in position, size, and echogenicity? Are renal cysts identified?
- Is the UT dilated? If so, to what degree, at which level, and what is the cause?
- Is the involvement unilateral or bilateral, symmetrical or asymmetrical?
- What is the fetal gender?

It is important to perform a detailed anatomic scan to search for associated abnormalities, which may indicate the presence of a syndrome or chromosomal abnormality. Renal anomalies may be part of the **VATER association** (vertebral defects, anal atresia, tracheoesophageal fistula, radial defects, and renal anomalies). An expansion of this syndrome, **VACTERL,** includes cardiac and nonradial limb defects. Associated nonurinary anomalies have been reported in 34% of infants with CAKUT, most common in the musculoskeletal, digestive, cardiovascular, and central nervous systems.[32] When there are additional malformations, the risk for fetal chromosomal abnormalities is substantially increased compared with the maternal age–related risk: 30 times higher for multiple defects versus 3 times higher for isolated renal defect.[33]

In addition, **renal ultrasound** is recommended for **parents** (and siblings) of fetuses suspected to have certain renal

abnormalities (polycystic kidney disease, renal agenesis or adysplasia), because it may help to diagnose the type of polycystic kidney disease in the fetus, detect asymptomatic renal pathology in parents (and siblings), and counsel parents regarding the recurrence risk.[34-36]

Fetal magnetic resonance imaging (MRI) may be used as an adjunctive imaging modality for improving diagnostic accuracy of UT abnormalities.[37,38] It may help to identify the kidneys when sonographic visualization is limited by anhydramnios (or severe oligohydramnios) and large maternal body habitus (Fig. 39.4).[39,40] Finally, with the advent of diffusion-weighted imaging, the measurement of water apparent diffusion coefficient has shown promise in differentiating between normal and abnormal renal parenchyma, which could serve as a noninvasive method of assessing fetal renal function.[41,42]

FETAL GENDER

Bilateral Renal Agenesis

Bilateral renal agenesis is a lethal congenital anomaly with an incidence of approximately 1 in 4000 births and a 2.5:1 male preponderance.[43,44] The ureteric buds fail to develop; thus the kidneys are absent. Because no urine is produced, severe oligohydramnios or anhydramnios results. Pulmonary hypoplasia is the major cause of neonatal death. Other features of "Potter's sequence" include typical facies (beaked nose, low-set ears, prominent epicanthic folds, hypertelorism), limb deformities, and IUGR.

The ultrasound findings include severe oligohydramnios or anhydramnios and nonvisualization of the kidneys and bladder. Before 16 weeks' gestation, AFV is not dependent on urine production and may be normal despite absent renal function. The absence of fetal kidneys should be the most specific finding, but this may be difficult to document because of poor image quality associated with oligohydramnios. In addition, bowel or adrenal glands in the renal fossae may be mistaken for kidneys.[45] However, recognition of the distinctive, flattened appearance of the adrenal gland on longitudinal sonogram **("lying down" adrenal sign)** helps to confirm that the kidney did not develop in the flank[46] (Fig. 39.5, Video 39.1).

Repeated and consistent nonvisualization of the urinary bladder (over 1 hour) is a secondary sign of bilateral renal agenesis (Fig. 39.6). Conversely, identification of a normal bladder excludes this diagnosis. A small **urachal diverticulum** may mimic the bladder, but its lack of filling and emptying distinguishes it from the bladder. A major challenge is to reliably distinguish between fetuses with bilateral renal agenesis and those with impaired renal function from severe uteroplacental insufficiency or IUGR.

Several techniques have been proposed to improve visualization of fetal structures: intraamniotic and intraperitoneal infusion of isotonic saline,[47] transvaginal ultrasound,[48] and color Doppler ultrasound imaging.[49,50] The transvaginal probe is particularly useful in the second trimester and with breech presentation (Fig. 39.6, Video 39.2). Color Doppler imaging can be used to diagnose

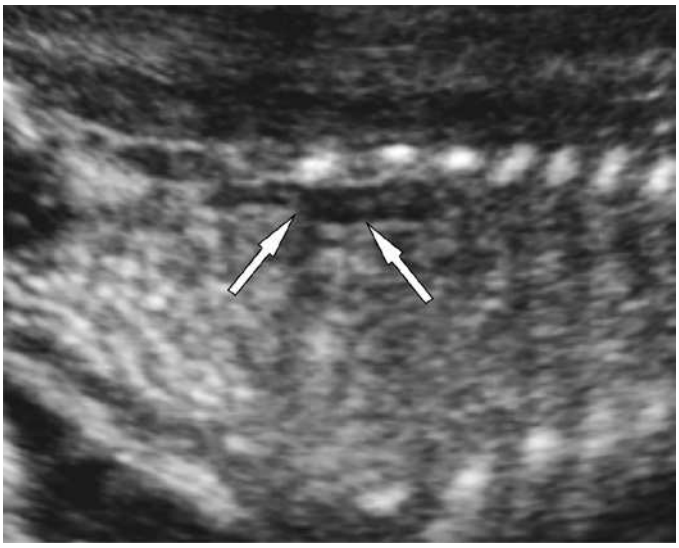

FIG. 39.5 "Lying Down" Adrenal Sign. Longitudinal scan through the renal fossa shows absence of the kidney and the flattened adrenal gland *(arrows)*. The lying-down adrenal sign is an indication of renal agenesis or ectopia. See also Video 39.1.

absent renal arteries, providing further evidence for the diagnosis of bilateral renal agenesis (Fig. 39.7). More important, it helps to map out the renal arteries in difficult cases of oligohydramnios, thereby confirming the presence of kidneys and avoiding confusion (Fig. 39.8).

Fetal MRI may help to identify the kidneys when sonographic visualization is limited. However, the kidneys can be difficult to visualize early in gestation. Therefore it may be difficult for MRI to exclude renal agenesis before 24 weeks' gestation, if the kidneys are not seen.

Bilateral renal agenesis is usually an isolated and sporadic abnormality. However, in a small percentage of cases it may be secondary to a chromosomal abnormality or part of a genetic syndrome (such as Fraser syndrome), or a developmental defect (such as VACTERL association).[51,52] There is conflicting evidence with regard to associations between bilateral renal agenesis and maternal factors such as prepregnancy obesity, periconception smoking, and alcohol consumption.[53] In nonsyndromic cases, the recurrence risk of having another child with bilateral renal agenesis is approximately 4%.[34,54] However, up to 15% of the

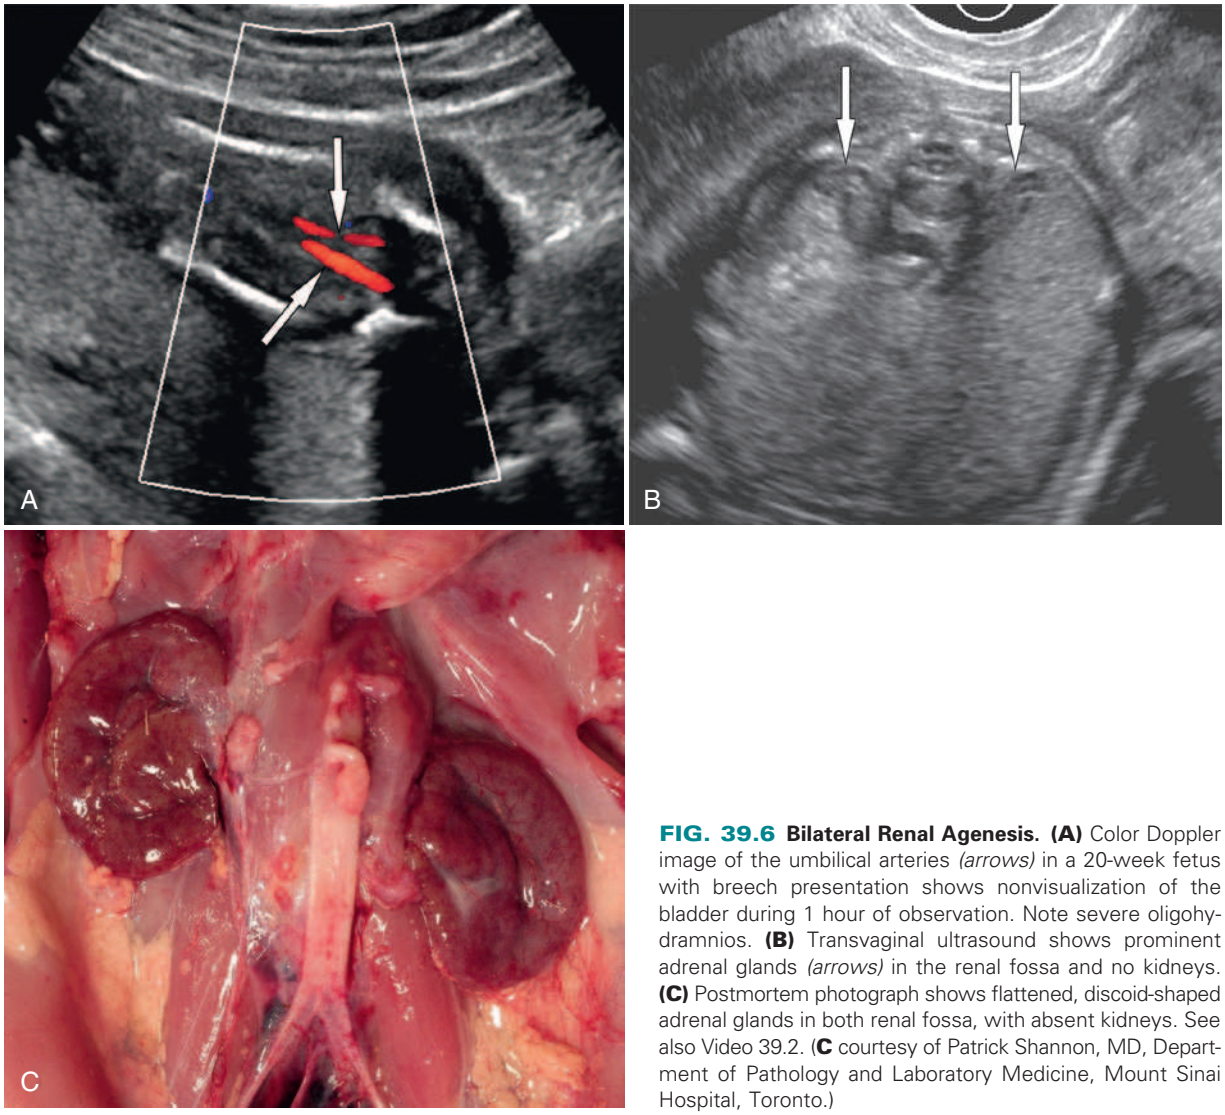

FIG. 39.6 Bilateral Renal Agenesis. (A) Color Doppler image of the umbilical arteries *(arrows)* in a 20-week fetus with breech presentation shows nonvisualization of the bladder during 1 hour of observation. Note severe oligohydramnios. **(B)** Transvaginal ultrasound shows prominent adrenal glands *(arrows)* in the renal fossa and no kidneys. **(C)** Postmortem photograph shows flattened, discoid-shaped adrenal glands in both renal fossa, with absent kidneys. FIG. 39.7 Absent Renal Arteries. Color Doppler ultrasound shows no renal artery arising from the aorta *(Ao)* in a fetus with bilateral renal agenesis.

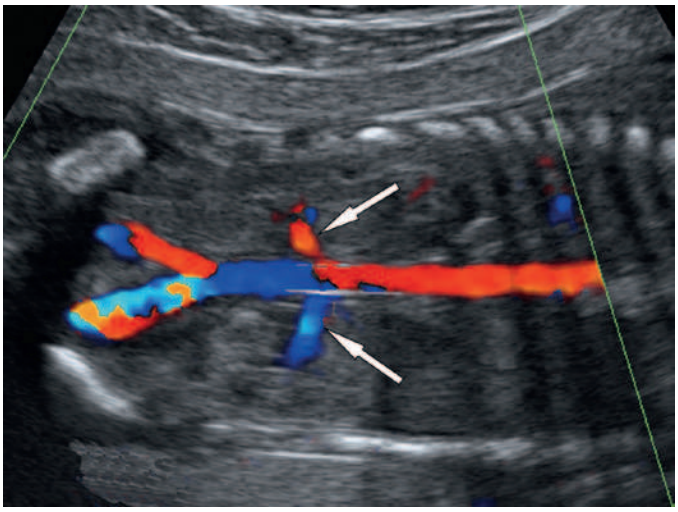

FIG. 39.8 Normal Renal Arteries. Color Doppler ultrasound maps out the renal arteries bilaterally *(arrows)* in a 19-week fetus, confirming the presence of kidneys.

Bilateral Renal Agenesis

SONOGRAPHIC FINDINGS
Severe oligohydramnios
Absent kidneys
"Lying down" adrenal sign
Absent renal arteries on color Doppler imaging
Nonvisualization of bladder (over 1 hour)

TECHNICAL LIMITATIONS
Poor image quality caused by oligohydramnios
Fetal position (breech presentation)

PITFALLS IN INTERPRETATION
Amniotic fluid volume may be normal before 16 weeks' gestation
Bowel or adrenal glands can be mistaken for kidneys
Urachal diverticulum may mimic the bladder
Empty bladder may be caused by impaired renal function from other causes (e.g., intrauterine growth restriction)

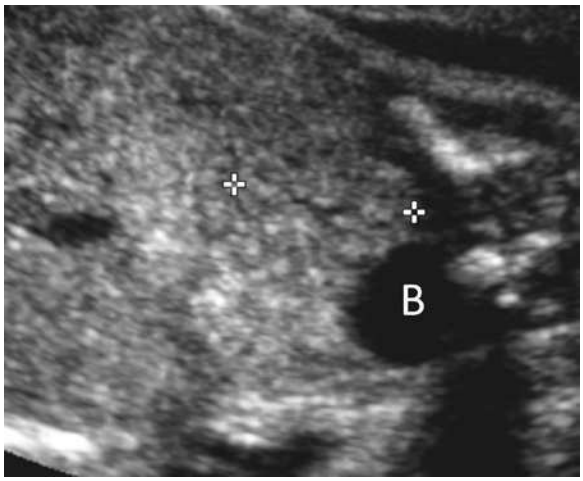

FIG. 39.9 Pelvic Kidney. Coronal image in a 23-week fetus shows the ectopic kidney *(calipers)* adjacent to the iliac wing and bladder *(B)*. See also Video 39.3.

first- and second-degree relatives of affected fetuses have been found to have congenital renal anomalies, most often unilateral renal agenesis; and in these families the recurrence risk may be higher.[34,36] Screening parents and siblings with renal ultrasound is recommended.[34]

Unilateral Renal Agenesis

Unilateral renal agenesis is three to four times more common than bilateral renal agenesis, occurring 1 in 1000 births.[3] It can be difficult to diagnose prenatally because AFV is normal and the bladder appears normal. A common pitfall is failure to image the renal fossa in the far field because of acoustic shadowing from the spine, especially in the transverse plane. Meticulous attention to technique is necessary (rotating the transducer, changing the maternal position, or repeated observations). If a kidney is not found in the renal fossa, most are either congenitally absent or ectopic.[55,56] The contralateral kidney may be enlarged because of compensatory hypertrophy.[57] There is a high incidence of contralateral renal abnormalities, the most common being **vesicoureteral reflux** (VUR).[58] Unilateral renal agenesis is associated with genital, cardiac, skeletal, and GI abnormalities, as well as with multiorgan syndromes.[59] Isolated unilateral renal agenesis has a good prognosis. Neonatal urologic workup is necessary, including a voiding cystourethrogram (VCUG).

The recurrence risk to parents of a baby with isolated unilateral renal agenesis is about 1% if the parents have normal renal ultrasound. However, if one parent has a congenital solitary kidney, the risks to offspring are 7% for congenital solitary kidney and 1% for bilateral renal agenesis.[60]

Renal Ectopia

One or both kidneys may be in an abnormal position. The incidence of renal ectopia varies between 1:500 and 1:1200 births, with **pelvic kidney** being the most common form.[61] When the renal fossa is empty, careful scanning may demonstrate the ectopic kidney adjacent to the bladder or iliac wing (Fig. 39.9, Video 39.3). However, prenatal detection is often difficult because

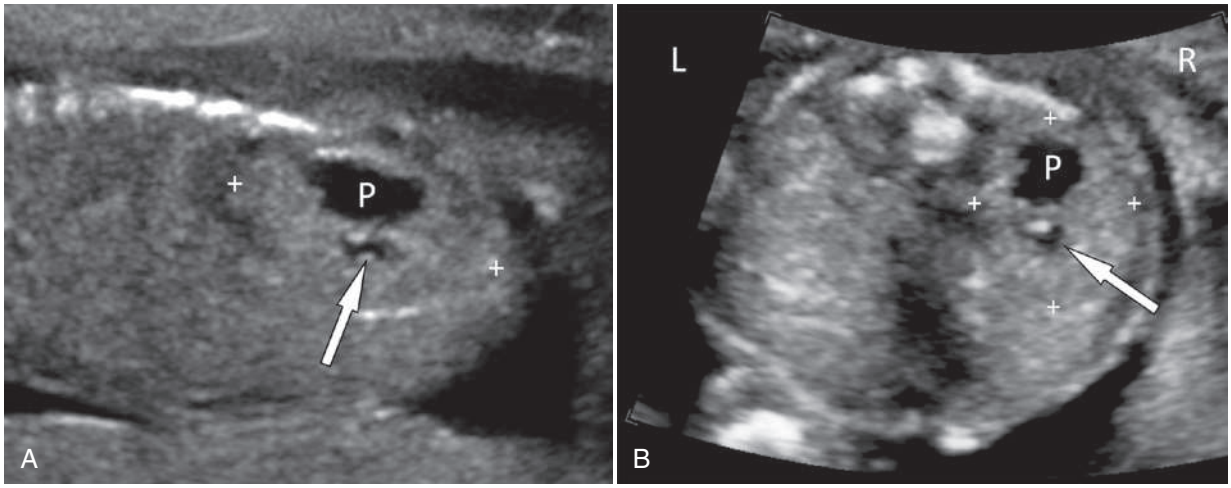

FIG. 39.10 Cross-Fused Renal Ectopia. Sagittal **(A)** and axial **(B)** images show an enlarged bilobed kidney in the right renal fossa *(calipers).* No kidney was seen in the left renal fossa. The normally located right (posterior) kidney has a dilated renal pelvis *(P).* It is fused with the left (anterior) kidney with a normal renal pelvis *(arrow)* to form a "lump kidney." See also Video 39.4.

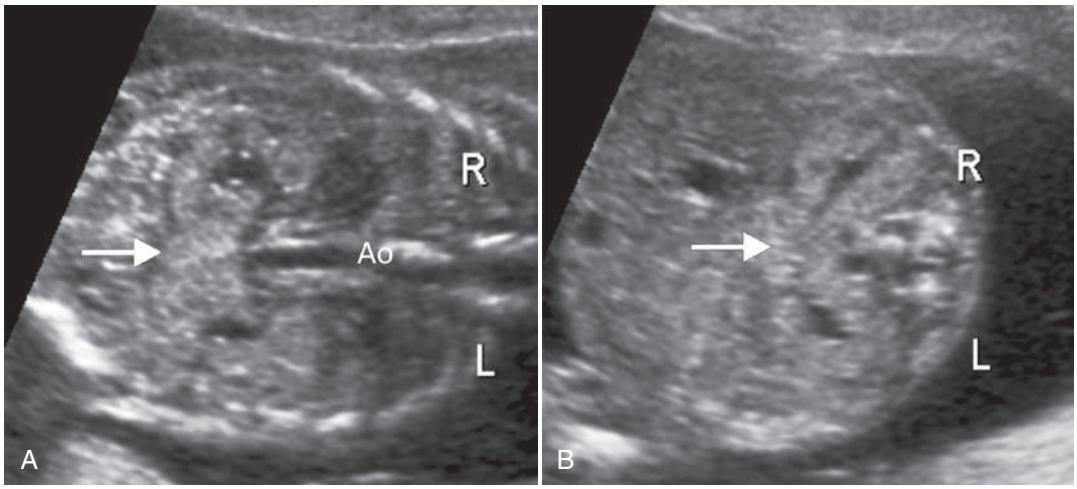

FIG. 39.11 Horseshoe Kidney. (A) Coronal image in a 19-week fetus shows the bridge of renal parenchyma *(arrow)* connecting the lower poles of the kidneys, anterior to the aorta *(Ao).* **(B)** Axial image shows, in addition to the fused isthmus *(arrow),* the abnormal anterior orientation of the renal pelvis bilaterally.

pelvic kidneys may be indistinguishable from bowel loops and are frequently smaller than normally positioned kidneys. Pelvic kidneys may be hypoplastic or dysplastic. Postnatally impaired renal function has been found in 33% of pelvic kidneys, although the overall renal function remained normal at a median follow-up of 8 years.[62]

When the ectopic kidney is located on the opposite side of the abdomen relative to its ureteral insertion into the bladder, it is defined as **crossed renal ectopia.** In most cases, the crossed ectopic kidney fuses with the normally located kidney **(crossed fused renal ectopia),** and an enlarged bilobed kidney is seen (Fig. 39.10, Video 39.4). Crossed renal ectopia is divided into six subgroups based on the degree of fusion and location and rotation of the fused renal mass.[63] Most commonly, the crossed ectopic kidney is inferior to the normally positioned kidney, and the upper pole of the ectopic kidney is fused to the lower pole of the normal kidney.

Renal ectopia is associated with a high incidence of urologic abnormalities (most often VUR), as well as nonurinary malformations.[64] Neonatal renal ultrasound is necessary. A VCUG is indicated if there is hydronephrosis in the ectopic or contralateral kidney.

Horseshoe Kidney

Horseshoe kidney is the most common fusion anomaly of the kidney, occurring in 1:400 to 1:500 births.[3,61] Prenatal sonographic findings include abnormal longitudinal axis of both kidneys and a bridge of renal tissue connecting the lower poles (Fig. 39.11, Video 39.5). Despite its relative frequency, this disorder is seldom diagnosed prenatally because the findings are subtle, and surrounding bowel can obscure the fused isthmus. The majority of horseshoe kidneys have an abnormal anterior orientation of the renal pelvis bilaterally. Measurement of the renal pelvic angle on a true axial image of both kidneys is useful for

diagnosis, and angles less than 140 degrees are highly suggestive of horseshoe kidney.[65] A horseshoe kidney is frequently associated with other anomalies (e.g., urogenital, cardiac, skeletal, CNS) and chromosomal abnormalities such as **Turner syndrome, trisomy 18,** and **trisomy 9.** Isolated horseshoe kidney is a relatively benign disorder that requires postnatal urologic follow-up because of higher prevalence of VUR, renal calculi, UT infections, and hydronephrosis.

Renal Cystic Disease

Renal cystic disease consists of a heterogeneous group of disorders with inherited and acquired causes. Because of their diverse etiology, histology, and clinical presentation, a widely accepted classification does not exist. The Potter classification is based on histology and does not take into account recent advances in molecular genetics.[66] A more recent classification based on the genetic or nongenetic origin of fetal renal cystic diseases has been proposed.[67] Among the **nongenetic cystic diseases,** multicystic dysplastic kidney (MCDK) and obstructive dysplasia are the most common. **Genetic diseases** include **autosomal recessive** and **autosomal dominant polycystic kidney disease** (ADPKD), and a growing number of cilia-related disorders **(ciliopathies)** associated with cystic kidneys as well as other abnormalities.[68,69] Many of these diseases have been associated with one or several genetic mutations, and an accurate genetic diagnosis is crucial for genetic counseling, prenatal diagnosis, and clinical management.

Multicystic Dysplastic Kidney

MCDK is the most common form of renal cystic disease in childhood and represents one of the most common abdominal masses in the neonate. The majority of cases are associated with an **atretic ureter** and **pelvoinfundibular atresia.** The kidney is replaced by multiple cysts of varying sizes. Between the cysts is a dense stroma, and there is usually no normal renal parenchyma. Kidneys affected with multicystic dysplasia are almost always nonfunctional. Thus the prognosis depends entirely on the function of the contralateral kidney. Multicystic renal dysplasia usually affects the whole kidney. However, it can be segmental and can occur in the portion of the duplex kidney supplied by the atretic ureter.

The sonographic findings correlate with the gross pathologic appearance. The malformed kidney is usually enlarged but may be normal in size or small. There are multiple cysts of varying sizes that do not communicate with one another and are randomly distributed (Fig. 39.12). Large peripheral cysts distort the reniform contour. The renal pelvis and ureter are usually atretic and not visible. On color Doppler evaluation, the renal artery is either absent or very small. Occasionally an MCDK with a large central cyst and small peripheral cysts can mimic hydronephrosis from ureteropelvic junction (UPJ) obstruction (see later discussion). In hydronephrosis, however, the dilated calyces are of uniform size and anatomically aligned and communicate with the dilated renal pelvis. The kidney usually maintains the reniform contour, with renal parenchyma present peripherally.

The appearance and size of the MCDK may change markedly during gestation and after birth (see Fig. 39.12). On serial examinations, the kidney and its cysts may increase or decrease in size or may initially enlarge and later involute.[70] This variable appearance may result from residual renal function and/or progressive fibrosis.

Assessment of the contralateral kidney is very important. In 19% to 24% of cases, multicystic renal dysplasia is bilateral[71,72] (Fig. 39.13). In unilateral multicystic renal dysplasia, contralateral renal abnormalities are present in 13% to 26%, including renal agenesis and UPJ obstruction.[71,73] In fetuses with MCDK, severe oligohydramnios and nonvisualization of the urinary bladder imply lethal renal disease, either bilateral MCDK or contralateral severe renal dysfunction or agenesis. Normal AFV is reassuring. If there is contralateral hydronephrosis, follow-up ultrasound is necessary to monitor any progressive dilation or oligohydramnios that may affect obstetric management. Unilateral MCDK, without associated renal or nonrenal abnormalities, is associated with a favorable outcome.[74] A postnatal ultrasound is performed after 48 hours of age. Prophylactic antibiotic therapy is usually initiated soon after birth, pending the results of postnatal ultrasound and

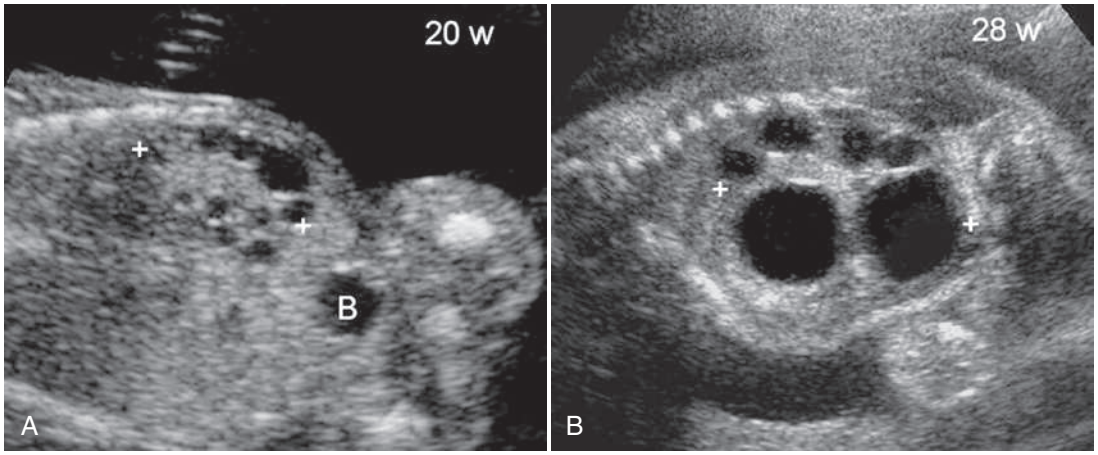

FIG. 39.12 Unilateral Multicystic Dysplastic Kidney. (A) Image of the fetus at 20 weeks' gestation demonstrates multiple small cysts in a slightly enlarged kidney *(calipers); B,* bladder. **(B)** Follow-up image at 28 weeks' gestation demonstrates a greatly enlarged kidney *(calipers).* Cysts have increased in size, do not communicate, and are randomly distributed.

nephrology consultation. A VCUG is indicated if there is contralateral hydronephrosis or a history of UT infection.[75]

The natural history of MCDK is toward spontaneous **involution.** This has been well documented both before and after birth.[70,72] The longer the duration of follow-up, the higher is the likelihood that the dysplastic kidney will become so small as to not be evident sonographically. The risk of hypertension associated with MCDKs does not appear to be greater than that of the general population,[76] and the rates of malignant transformation of MCDK are small.[77] Although there are some proponents for routine laparoscopic nephrectomy, conservative management (with clinical and ultrasound surveillance) is favored in most centers.[78] Most cases of MCDK are sporadic, with a low recurrence risk. However, some cases have been associated with mutations in hepatocyte nuclear factor 1β (HNF1β), which carries an autosomal dominant mode of inheritance with both interfamilial and intrafamilial variability in the clinical manifestations.[79]

FIG. 39.13 Bilateral Multicystic Dysplastic Kidneys. Transvaginal image in a 16-week fetus demonstrates numerous small bilateral cysts *(arrows)* and no normal renal parenchyma. Note anhydramnios due to nonfunctioning kidneys.

Obstructive Cystic Renal Dysplasia

The effect of urinary obstruction on subsequent renal development depends on the time of onset and severity of the obstruction. Experimental work in lambs has shown that urinary obstruction starting in the last half of gestation causes simple hydronephrosis and, when severe, parenchymal atrophy.[80] However, if the urinary obstruction starts during the first half of gestation, **renal dysplasia** and sometimes cyst formation will occur[80-82] (Fig. 39.14). The fetal UT responds differently to chronic obstruction than the adult UT. In adults with chronic urethral obstruction, the pelvicalyceal system is usually greatly dilated; in the fetus there may be a relative lack of pelvicalyceal dilation and possible development of macroscopic renal cysts.

Unilateral renal dysplasia can be caused by UPJ obstruction or ureterovesical junction (UVJ) obstruction. Bilateral disease is caused by severe **bladder outlet obstruction,** usually due to urethral atresia or posterior urethral valves. The severity of renal dysplasia is related to the timing and severity of obstruction to

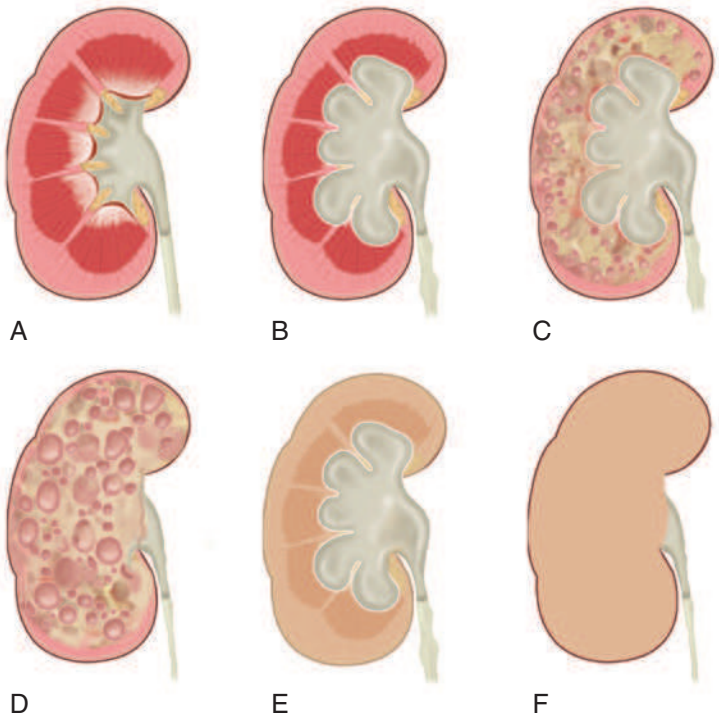

FIG. 39.14 Urinary Tract Obstruction Produces a Varied Response From the Kidneys. (A) Normal kidney. **(B) Pelvicaliectasis,** with or without parenchymal atrophy. **(C) Renal cystic dysplasia,** with parenchymal cysts. **(D)** The dysplastic kidney may cease to function (lack of pelvicaliectasis). **(E)** and **(F)** Alternatively, the kidney may show increased echogenicity, with no visible cysts but with pelvicaliectasis **(E)** or without pelvicaliectasis **(F).** In these cases, dysplasia is probably, but not invariably, present.

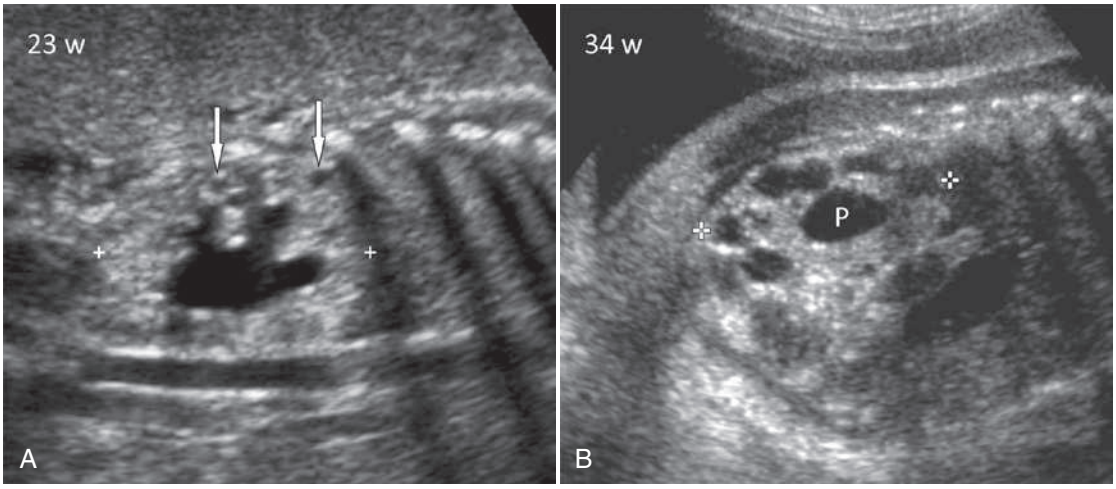

FIG. 39.15 Obstructive Cystic Dysplasia. (A) Coronal image of fetus at 23 weeks with ureteropelvic junction obstruction shows increased echogenicity of the kidney *(calipers)* with small cortical cysts *(arrows),* indicative of irreversible renal damage. **(B)** Sagittal image at 34 weeks shows the cysts have increased in size and the kidney is large. There is some functioning renal tissue, as fluid is seen in the slightly dilated renal pelvis *(P).*

urine flow.[83] The size of the kidneys varies from small to normal to markedly enlarged. In some cases the enlargement is caused partly by the presence of cysts and partly by hydronephrosis. Cysts are usually present in the subcapsular area of the cortex. In a fetus with obstructive uropathy, the sonographic identification of **cortical cysts** is indicative of renal dysplasia (i.e., irreversible renal damage)[84] (Fig. 39.15). Dysplastic kidneys may also demonstrate cortical thinning and increased echogenicity relative to the surrounding fetal structures, with loss of corticomedullary differentiation. However, **increased cortical echogenicity is not a specific finding,**[85] and a diagnosis of renal dysplasia cannot be made on the basis of increased parenchymal echogenicity alone. Furthermore, it is important to recognize that not all dysplastic kidneys have sonographically visible cysts or increased cortical echogenicity, so one cannot accurately predict the absence of renal dysplasia. Renal function relates directly to the degree of dysplasia, which determines the prognosis of patients surviving the perinatal period.

In general, if the obstruction is early and complete, the renal parenchymal findings will be predominantly macroscopic cysts and will simulate multicystic renal dysplasia. Sonographic distinction between MCDK and obstructive cystic renal dysplasia may be difficult, especially in the absence of hydronephrosis. In obstructive cystic renal dysplasia, recognizable parenchyma surrounds the relatively small cysts, whereas in MCDK, no normal renal parenchyma can be identified between cysts, and the cysts can be of varying size and can be quite large. Obstructive cystic renal dysplasia most often occurs with urethral obstruction. Therefore sonographic evidence of urethral obstruction is helpful in suggesting the diagnosis. In addition, renal dysplasia from lower UT obstruction frequently involves both kidneys, whereas bilateral MCDK occurs in only 19% to 24% of cases.[71,72]

Autosomal Recessive Polycystic Kidney Disease

The incidence of autosomal recessive polycystic kidney disease (ARPKD) is 1 in 20,000 live births. In the past this was termed "infantile polycystic kidney disease," but the presentation can be after the neonatal period; thus the preferred term is "autosomal recessive polycystic kidney disease." It primarily involves the kidneys and biliary tract. The clinical spectrum is wide and varies from the **perinatal form,** with severe renal disease, minimal hepatic fibrosis, and early death from pulmonary hypoplasia, to the **juvenile form,** with minimal renal disease, marked hepatic fibrosis, and longer survival. Diffuse dilation of the renal collecting tubules produces numerous cysts smaller than 2 mm, predominantly in the medulla. Both kidneys are enlarged, but a smooth contour is maintained. The cut surface has a spongelike appearance, with small cysts that tend to be arranged perpendicular to the renal capsule (Fig. 39.16).

Sonography reveals **bilateral reniform enlargement** of the kidneys (see Fig. 39.16). There is poor delineation of the intrarenal structures. The numerous tiny cysts are usually smaller than the limit of sonographic resolution, but they create multiple acoustic interfaces, accounting for the characteristic increased renal echogenicity.[86] In a fetus, the finding of bilateral, very large (>4 standard deviations), diffusely hyperechoic kidneys with poor corticomedullary differentiation, with or without visible cysts, is most likely due to ARPKD.[67,87] Another typical pattern is very large kidneys with a peripheral hypoechoic rim surrounding the centrally increased echogenicity or **hyperechoic pyramids (reversed corticomedullary differentiation)** (Fig. 39.17, Video 39.6).[67] When renal function is abnormal, there is oligohydramnios, and the bladder is small or absent.

Usually, but not always, ultrasound shows evidence of ARPKD by 24 to 26 weeks' gestation.[88,89] Autosomal recessive PKD may be diagnosed by ultrasound in the second trimester based on the characteristic renal abnormalities, especially if the fetus is at risk.[88] However, because of the variability in phenotypic expression and gestational age at onset, the kidneys may appear normal initially, only becoming abnormal later.[88] Thus a normal sonogram in a fetus at risk for ARPKD does not exclude this disease, and prenatal diagnosis using sonography can be unreliable, especially in early pregnancy. ARPKD is inherited in an autosomal recessive manner, and thus the recurrence risk is 25%.

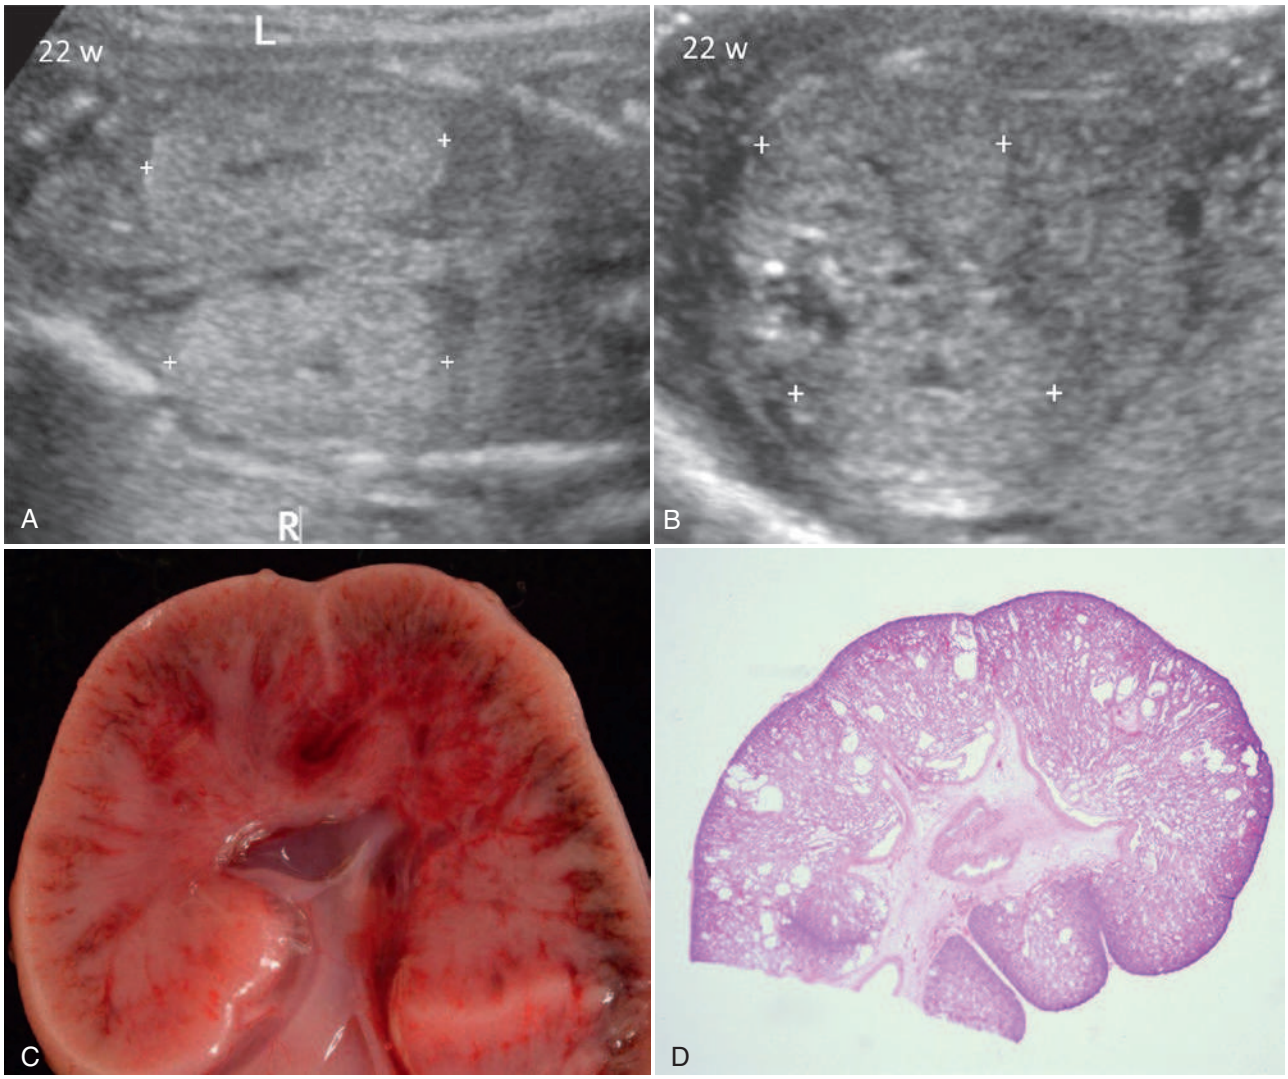

FIG. 39.16 Autosomal Recessive Polycystic Kidney Disease (Early Presentation). (A) and **(B)** Coronal and transverse scans of a 22-week fetus show bilateral large, diffusely hyperechoic kidneys *(calipers)* with loss of corticomedullary differentiation. **(C)** Photograph of cut surface of kidney shows a spongelike appearance. The small cysts are difficult to see. **(D)** Photograph of whole-mount section shows small cysts that tend to be arranged perpendicular to the renal capsule (hematoxylin-eosin stain). FIG. 39.17 Autosomal Recessive Polycystic Kidney Disease (Third-Trimester Presentation). (A) Coronal scan of a 30-week fetus shows markedly enlarged kidneys *(calipers),* with a hypoechoic peripheral rim surrounding the centrally increased echogenicity. Right kidney measures 7.5 cm in length and left kidney 8 cm. **(B)** Coronal scan of a different fetus at 31 weeks' gestation shows markedly enlarged kidneys *(calipers),* with hyperechoic pyramids *(arrowheads),* resulting in "reversed corticomedullary differentiation."

ARPKD is caused by mutation in the ***PKHD1* gene,** which has been mapped to chromosome 6p12, allowing prenatal genetic diagnosis in at-risk families.[90,91]

Autosomal Dominant Polycystic Kidney Disease

ADPKD is the most common of the hereditary renal cystic diseases, with an incidence of 1 : 1000 in the general population. Although this was previously termed "adult polycystic kidney disease," the presentation can be in the prenatal period or in childhood; thus the preferred term is "autosomal dominant polycystic kidney disease." It is characterized by cyst formation in the kidneys and liver. Cysts may also be present in the pancreas and spleen, and the disorder is associated with CNS aneurysms. In the early stage of the disease, only a small percentage of nephrons show cystic dilation. In the established adult disease, the kidneys are enlarged and contain multiple cysts of varying sizes.

ADPKD is usually not detected prenatally because the fetal kidneys typically appear normal. In **rare** cases, ADPKD can manifest during the **fetal or neonatal** period with symmetrical moderately enlarged hyperechoic kidneys, within which small cysts (<7 mm) may be identified (Fig. 39.18).[92,93] The bladder is usually present, and AFV is often normal. In contrast to ARPKD, in which corticomedullary differentiation is absent,[86] increased corticomedullary differentiation has been reported in ADPKD. In a series of 27 cases of abnormal-appearing kidneys on prenatal ultrasound and final diagnosis of ADPKD (note that this is a biased population because the kidneys appeared abnormal prenatally), 20 had increased corticomedullary differentiation, six had absent or decreased corticomedullary differentiation; and 1 had normal corticomedullary differentiation.[93] Because the kidneys may appear normal in the second trimester, follow-up scans are necessary in fetuses at risk for ADPKD.

A **family history** of ADPKD is critical in making the diagnosis of ADPKD in the fetus. Because the disease is autosomal dominant, the recurrence risk is 50%. However, it has been reported that over 50% of the affected parents were not aware of their disease at the time of obstetric ultrasound.[92,93] Therefore ultrasound of the parents' kidneys is helpful in establishing the cause. Two ADPKD causative genes have been identified: ***PKD1*** (located on chromosome 16p13) and ***PKD2*** (located on chromosome 4q21).[94] Hence, prenatal genetic diagnosis is possible. Affected families with early-onset disease in their offspring have a high recurrence risk for fetal presentation in subsequent affected pregnancies.[69]

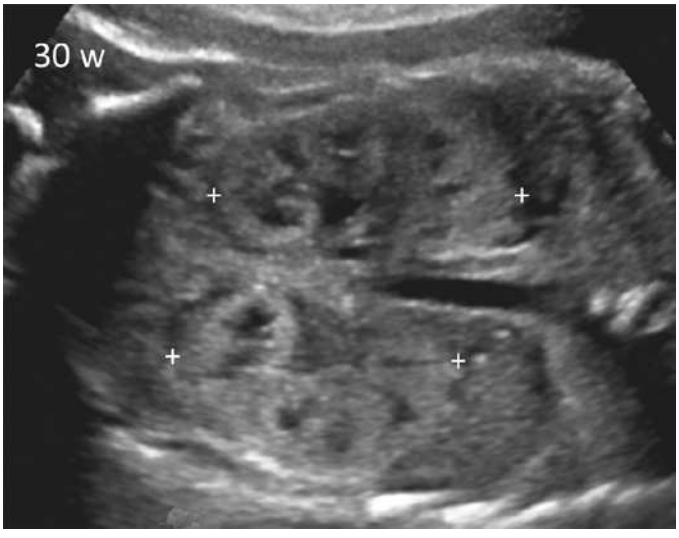

FIG. 39.18 Autosomal Dominant Polycystic Kidney Disease. Coronal scan of 30-week fetus shows enlarged kidneys *(calipers),* measuring 5 cm in length (>3 SD), with increased corticomedullary differentiation due to increased echogenicity of the cortex.

The long-term prognosis for the fetus with ADPKD diagnosed by ultrasound is still not well known because of limited data on postnatal renal evolution and short duration of follow-up. Initial reports suggested that although the majority of ADPKD infants survive, they tend to have earlier onset and more significant hypertension and a more rapid decline in renal function than their affected adult relatives.[90,95,96] More recent studies reported a favorable prognosis in most children with prenatally diagnosed ADPKD.[97,98] In a study of 26 consecutive children with prenatal ADPKD (excluding three terminations of pregnancy with very large kidneys and anhydramnios), Boyer and colleagues reported favorable prognosis in infancy and childhood, with 19 (73%) children asymptomatic, 5 (19%) with hypertension, and 2 (8%) with chronic renal insufficiency (mean duration of follow-up, 76 months; range, 0.5-262 months).[97] In another study of 42 patients with prenatal ADPKD, there were four terminations of pregnancy, and among 35 patients with known serum creatinine (age of patients at last follow-up ranged from 1 month to 20 years), renal function was abnormal in only 2.[98]

Syndromes Associated With Renal Cystic Disease

Approximately 30% of fetuses with trisomy 13 have echogenic/cystic kidneys. Other genetic conditions associated with renal cystic disease include single-gene disorders categorized as **ciliopathies** (disorders caused by mutations in genes with products that localize to the cilium-centrosome complex). These include **Bardet-Biedl syndrome, hepatocyte nuclear factor 1β–related disease, Joubert syndrome,** and **Meckel syndrome.** The phenotypes due to the altered proteins vary from cystic kidney disease and blindness to neurologic phenotypes, obesity, and diabetes.

HNF1β is a transcription factor that is critical for the development of kidney and pancreas. Mutations in the *HNF1β/TCF2* gene result in various phenotypes that include renal cysts and diabetes. *HNF1β* mutations are often found in fetuses with severe renal anomalies.[79,99,100] In a retrospective study of 377 patients with various congenital renal anomalies, the prevalence of *HNF1β* mutation was (20%).[79] Among 56 patients who carried *HNF1β* mutation and who had prenatal sonography, various renal phenotypes were observed. The most common (seen in 34 of 56 fetuses) was isolated bilateral hyperechogenic kidneys, normal in size or slightly enlarged (size ≤ +3 SD).[79] Other, less frequent renal abnormalities were bilateral MCDK (in 2), unilateral MCDK (in 8), and unilateral renal agenesis or hypoplasia (in 5).

HNF1β mutations follow an autosomal dominant mode of inheritance. However, when the family history is evaluated, one has to keep in mind incomplete penetrance and considerable interfamilial and intrafamilial phenotypic variability, as well as

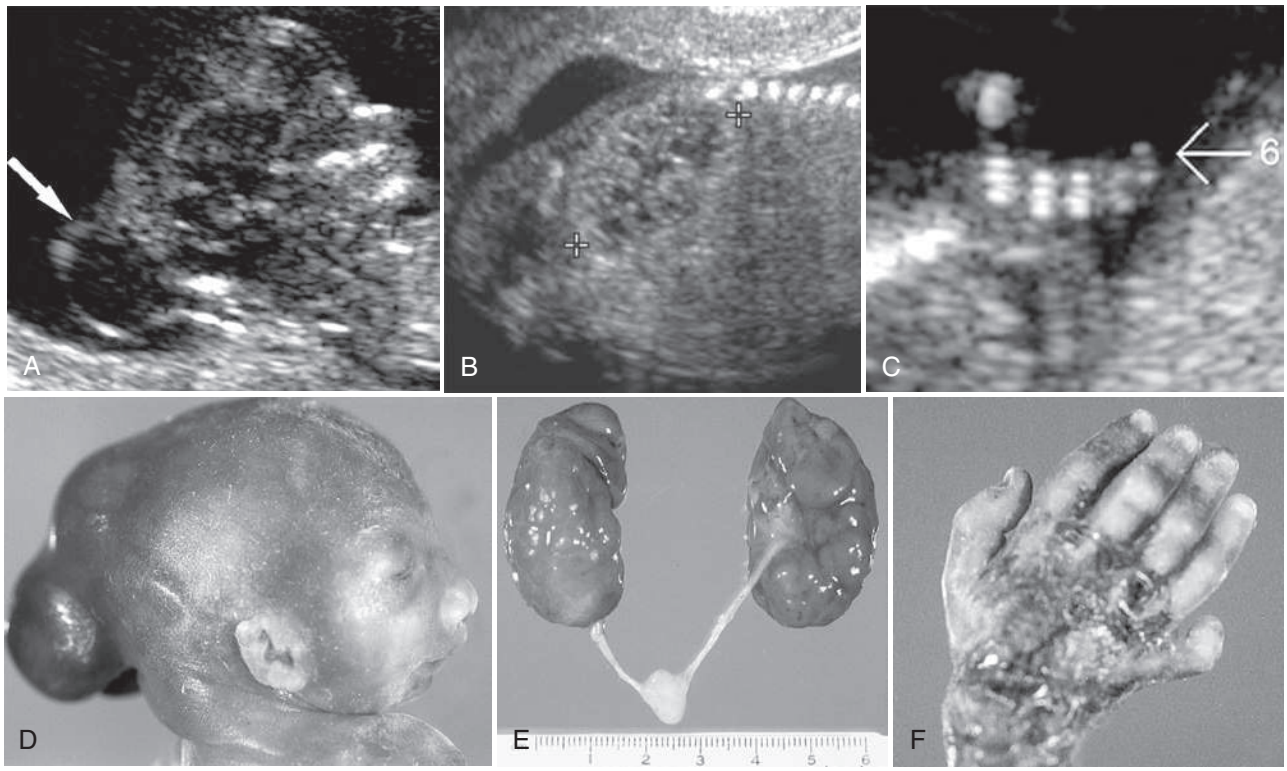

FIG. 39.19 Meckel-Gruber Syndrome. (A)-(C) Ultrasound images of a 14-week fetus show classic features of Meckel-Gruber syndrome: an occipital encephalocele *(thick arrow),* large kidneys (only one shown *[calipers]*) with a mottled cystic appearance, and postaxial polydactyly *(thin arrow).* **(D)-(F)** Postmortem photographs of the fetus (at 18 weeks' gestation) demonstrate occipital encephalocele, large kidneys, and postaxial polydactyly.

new dominant mutation and gene deletion. The severity of the renal disease can be extremely variable (from prenatal oligohydramnios or anhydramnios to normal renal function in adulthood) and is not correlated with the genotype.[79]

Meckel syndrome, also known as **Meckel-Gruber syndrome,** is a lethal autosomal recessive ciliopathy that carries a 25% risk of recurrence. It can be detected by sonography at 11 to 14 weeks' gestation, particularly in families with prior affected pregnancies.[101] Sonographic diagnosis requires identification of at least two features of the classic triad: **enlarged echogenic, cystic kidneys** (present in almost 100% of cases); **occipital encephalocele** (60%-85%); and **postaxial polydactyly** (55%)[102] (Fig. 39.19). During second-trimester sonography, it can be difficult to detect the encephalocele and polydactyly because of oligohydramnios. Microcephaly can be a useful clue to the presence of an encephalocele. The kidneys are markedly enlarged (+4 SD), with a mottled cystic appearance of the medulla surrounded by the hyperechoic cortex.[103] Numerous small cysts are present, most smaller than 5 mm. The diagnosis of Meckel syndrome is particularly important for counseling regarding the recurrence risk and possible prenatal and preimplantation genetic diagnosis in future pregnancies. Meckel syndrome can be caused by mutations in 1 of at least 13 genes. The proteins coded by these genes are known to have a major role in cilia formation.

Hyperechogenic Kidneys

Fetal kidneys are considered hyperechogenic or "bright" when they appear more echogenic than expected, compared with the adjacent liver or spleen (Fig. 39.20).[67] Hyperechogenic kidneys seen on prenatal ultrasound represent a diagnostic and prognostic dilemma, particularly in the presence of normal AFV. There is a wide differential diagnosis, including genetically inherited renal diseases **(ARPKD, ADPKD, HNF1β mutations, Bardet-Biedl syndrome, Perlman syndrome, Simpson-Golabi-Behmel), obstructive dysplasia, aneuploidy,** infections (especially **cytomegalovirus**), **nephroblastomatosis, renal vein thrombosis,** toxic injury, ischemia, and in some cases normal variant.[104]

The proposed algorithm is useful for the evaluation of hyperechogenic kidneys (Fig. 39.21). If there is sonographic evidence of UT obstruction, renal dysplasia is a possibility, especially when the kidneys are small or normal in size and there are peripheral cortical cysts.[85] When extrarenal malformations are detected, assessment of karyotype is indicated to exclude aneuploidy (especially **trisomy 13**). If the kidneys and the biometric measurements are above the 95th percentile, an overgrowth syndrome (Perlman syndrome, Simpson-Golabi-Behmel syndrome) should be considered. In both conditions, there is generalized organomegaly and the AFV may be increased. In **Perlman syndrome** there may be micrognathia and depressed nasal bridge. In **Simpson-Golabi-Behmel syndrome,** there may be congenital diaphragmatic hernia, cleft lip or palate, and polydactyly. In **Bardet-Biedl syndrome,** in addition to enlarged hyperechogenic kidneys, postaxial polydactyly can be detected.

In several prospective and retrospective series of prenatally diagnosed, isolated, bilaterally enlarged hyperechogenic kidneys, the most common underlying diagnosis was ARPKD, followed

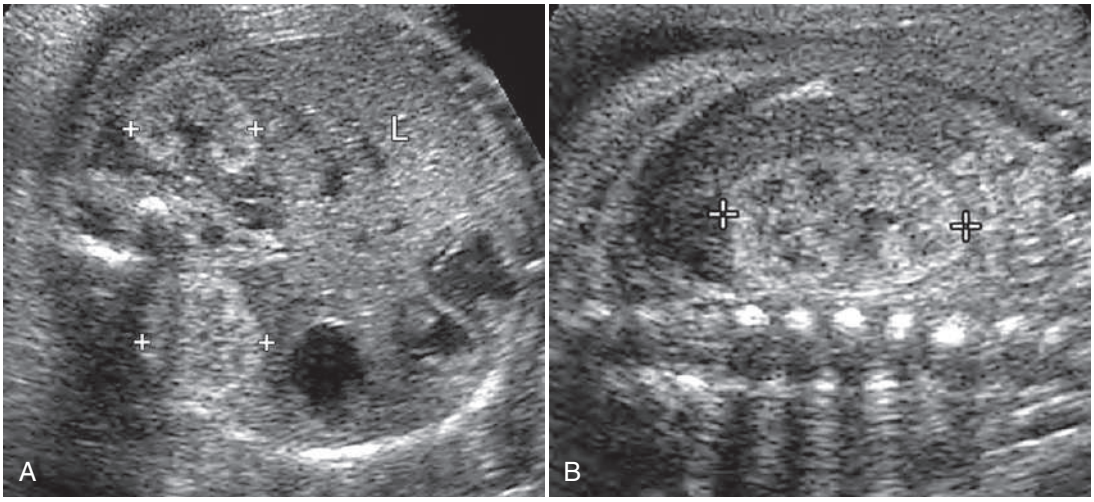

FIG. 39.20 Hyperechogenic Kidneys. Transverse **(A)** and longitudinal **(B)** scans of a 24-week fetus show increased cortical echogenicity of both kidneys *(calipers),* more than expected when compared with liver *(L)* and increased corticomedullary differentiation. The kidneys were normal in size, and AFV was normal. Ultrasound at 32 weeks *(not shown)* showed similar findings. Postnatal ultrasound *(not shown)* on day 8 confirmed normal-sized kidneys with increased cortical echogenicity, and there were several tiny cortical cysts. Parents had normal kidneys. Genetic testing for autosomal recessive polycystic kidney disease (ARPKD) and hepatocyte nuclear factor 1β (HNF1β) was negative. The child, at age 9 years, has normal renal function. Ultrasound *(not shown)* showed multiple 1- to 3-mm cysts in the medulla and cortex bilaterally. No definitive cause for the bilateral cystic kidneys has been identified.

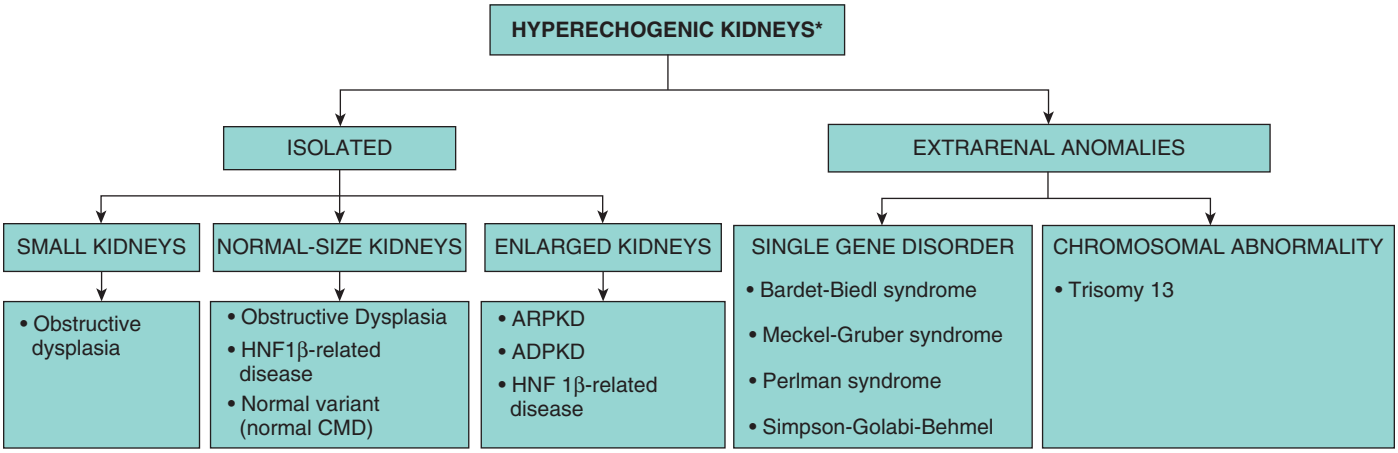

FIG. 39.21 Algorithm for Sonographic Evaluation of Hyperechogenic Kidneys. *No family history. Otherwise, a positive family history suggests recurrence of the known disorder. *ADPKD,* Autosomal dominant polycystic kidney disease; *ARPKD,* autosomal recessive polycystic kidney disease; *CMD,* corticomedullary differentiation; *HNF1β,* hepatocyte nuclear factor 1β–related disease.

by ADPKD.[87,105,106] A detailed family history and an ultrasound examination of the parents' kidneys are important. In ADPKD, usually one parent has the disease, and sonography usually establishes the diagnosis. However, new mutations associated with ADPKD can occur. Normal AFV favors ADPKD. In ARPKD there is usually oligohydramnios, and there may be a previously affected sibling.

Only some of the underlying causes of hyperechogenic kidneys can be diagnosed during the prenatal period on the basis of family history, AFV, associated abnormalities, and genetic analysis.[107] In many cases a definitive diagnosis will require postnatal investigations, including histology and DNA analysis. The kidney size and AFV are the best predictors of perinatal outcome.[105,106] Bilateral hyperechogenic kidneys that are normal in size with preservation of medullary pyramids, and that are associated with normal AFV, have a favorable outcome and may represent a normal variant.[85,108] Although further studies are necessary to determine specific prognostic factors, in cases of prenatal hyperechogenic kidneys, the parents should be counselled that parenchymal renal disease cannot be ruled out and there is a possibility of renal failure after birth or in early childhood.[109]

Renal Neoplasm

Congenital mesoblastic nephroma is the most common renal neoplasm in the fetus and newborn.[110] It is a benign hamartoma composed of mesenchymal tissue (spindle cells), as opposed to the epithelial tissue of **Wilms tumor.** Wilms tumor is a malignant lesion that is extremely rare in the fetus. Sonographically, mesoblastic nephroma is indistinguishable from Wilms tumor.

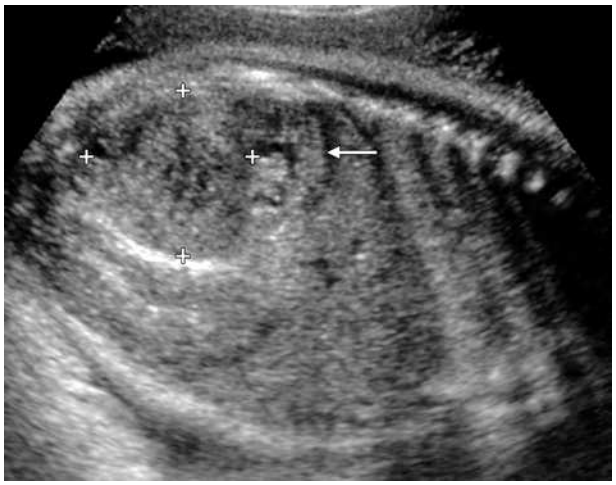

FIG. 39.22 Congenital Mesoblastic Nephroma. Longitudinal scan of a 35-week fetus shows a large, heterogeneous solid mass *(calipers)* replacing most of the right kidney, except for the upper pole *(arrow)*.

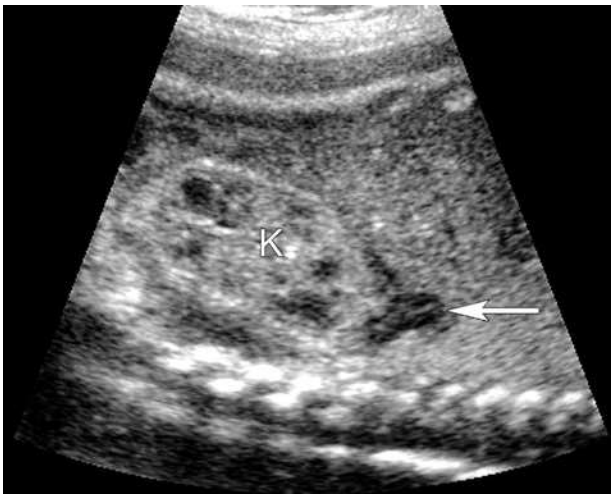

FIG. 39.23 Normal Adrenal Gland. Longitudinal scan of a 31-week fetus demonstrates the Y- or V-shaped adrenal gland *(arrow)* at the superior border of the kidney *(K)*.

Mesoblastic nephroma is usually seen as a moderately echogenic, solid mass completely replacing the kidney or localized to part of the kidney[111] (Fig. 39.22). The mass may demonstrate increased vascularity and cystic components. **Polyhydramnios** is a frequent association[110,112] and may lead to preterm labor and preterm birth. Perinatal complications are likely, including acute fetal distress, neonatal hypertension, and hypercalcemia.[110] Other reported fetal renal tumors include an intrarenal **neuroblastoma,** a tumor much more frequently associated with the adrenal gland.[113]

Adrenal Mass

At the end of the first trimester, the normal adrenal glands appear as pyramid-shaped hypoechoic structures at the superior aspect of the kidneys. They are quite prominent, approximately half the size of the kidney. The size of the adrenal gland increases with gestation, but relatively less than the kidney. During the second and third trimesters, corticomedullary differentiation is apparent, with a hyperechoic medulla and a hypoechoic cortex. On longitudinal sonogram, the adrenals are seen as V- or Y-shaped structures superior to the kidneys (Fig. 39.23).

Abnormalities of the adrenal gland include hemorrhage, cyst, hypertrophy, and tumor. The differential diagnosis for fetal suprarenal masses includes those of adrenal origin (including adrenal **neuroblastoma, adrenal hemorrhage, adrenal cyst,** and **rarely adrenal cortical adenoma or carcinoma**) and those of extraadrenal origin (including those of renal origin [such as **mesoblastic nephroma, duplication anomaly with hydronephrosis, upper-pole cystic dysplasia, urinoma**], intraabdominal **pulmonary sequestration, enteric duplication cysts, splenic cysts,** and **lymphangioma**) (Table 39.3).[114-116]

Neuroblastoma may occur anywhere along the sympathetic chain, but 90% are located in the adrenal gland. The prenatal sonographic appearance is variable and ranges from a complex cystic mass with thick septations (the most common presentation), to a uniformly echogenic solid mass (Fig. 39.24), to rarely calcified.[116-118] Importantly, a complex cystic neuroblastoma is

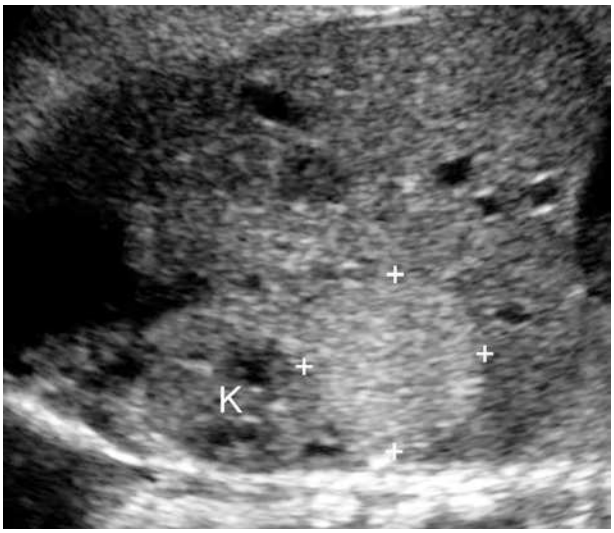

FIG. 39.24 Adrenal Neuroblastoma. Longitudinal scan shows a large echogenic solid mass *(calipers)* adjacent to the upper pole of the left kidney *(K)*. (Courtesy of John R Mernagh, MD, McMaster University Medical Center, Hamilton, Ontario.)

TABLE 39.3 Suprarenal Masses

Adrenal Origin	Nonadrenal Origin
Neuroblastoma	Renal origin: tumor (e.g., mesoblastic nephroma), duplication anomaly, upper-pole cystic dysplasia, urinoma
Hemorrhage	Intraabdominal pulmonary sequestration
Cyst	Enteric duplication cyst
Adenoma or carcinoma	Splenic cyst
	Lymphangioma

more likely to regress, whereas those with an echogenic appearance are more likely to grow.[116] The adrenal gland is not identified on the ipsilateral side. Most reported cases of neuroblastoma have been identified in the third trimester. Metastases (liver, placenta) and **hydrops** are rare but have been reported.[119,120] **Fetal hypertension** with secondary **cardiomyopathy** diagnosed on fetal echocardiography has also been reported, due to either elevation in circulating catecholamines produced by the tumor versus compression of the renal artery by the bulk of the tumor causing renovascular hypertension.[121] MRI may be useful for detailed anatomic characterization of the tumor and extent of disease.[116] Associated fetal anomalies have been reported, particularly cardiac defects, in addition to certain syndromes.[120] There may be maternal symptoms of hypertension, tachycardia, or preeclampsia, which result from elevated catecholamines and correlate with a more advanced stage of disease.[122]

Prenatally detected neuroblastomas generally have a favorable outcome, and surgical resection is usually curative.[120,123] A recent prospective study evaluating expectant observation versus surgical management confirmed the safety and effectiveness of expectant observation as a primary management strategy in infants younger than 6 months with small adrenal masses (solid tumors < 3.1 cm or cystic tumors < 5 cm with at least 25% cystic component) that were shown to be stage 1 according to the International Neuroblastoma Staging System.[124] This approach allows for avoidance of surgery in a large majority of infants whose tumors regress spontaneously.[124]

Adrenal hemorrhage, which is much more common in the neonate than in the fetus, can have a prenatal sonographic appearance similar to that of an adrenal or renal neoplasm. Color Doppler shows no flow within the mass and may be helpful in differentiation.[125] The key to the diagnosis of adrenal hemorrhage is evolution of the lesion over time; serial sonograms demonstrate a change in echogenicity (from solid appearing to cystic) and a decrease in size of the mass.[126,127] However, because neuroblastomas may also regress, it is important to obtain postnatal follow-up in fetuses with presumed adrenal hemorrhage.

Upper Urinary Tract Dilation

Dilation of the upper UT accounts for approximately 50% of all prenatally detected renal abnormalities.[128] It may be unilateral or bilateral and is more common in males than females.[129] Prospective studies in unselected populations have reported a prevalence of 0.7% to 3.9% in the second trimester.[129-131] In the majority of cases (50%-70%), the UT dilation is **transient or physiologic** and has no clinical significance.[132,133] In other cases, the dilation is due to an obstructive or nonobstructive etiology, including **ureteropelvic junction obstruction** (10%-30%), **vesicoureteral reflux** (10%-40%), **ureterovesical junction obstruction/megureter** (5%-15%), **posterior urethral valves** (1%-5%), and uncommon causes (duplex system, ectopic ureter, ureterocele, urethral atresia).[133]

"Hydronephrosis" refers to abnormal dilation of the renal pelvis and calyces. The term "pyelectasis" implies a milder form of hydronephrosis, with dilation of the renal pelvis only. Measurement of the anteroposterior **renal pelvic diameter** (RPD) is the simplest and the most common technique used to evaluate renal pelvic dilation. For optimal technique, a transverse image of the kidneys is obtained with the spine at the 12 or 6 o'clock position, and the measurement should be taken at the maximal diameter of the **intrarenal** pelvis (Fig. 39.25). The size of the renal pelvis increases throughout gestation, and there are published nomograms for RPD.[6,134,135] Controversy surrounds the definition and clinical importance of mild renal pelvic dilation, and different threshold values of RPD have been used for the antenatal diagnosis of renal pelvic dilation. In general, the cutoff values for RPD vary between 4 mm and 5 mm in the second trimester and between 7 and 10 mm in the third trimester.[130,131,136-142] Although using a cutoff value of 4 mm in midgestation can increase the sensitivity for the detection of renal pathology, it is important to realize that it can lead to a high false-positive rate, perhaps generating unnecessary parental anxiety.[143] Factors such as maternal hydration status, maternal pyelectasis, and size of the fetal bladder may affect the RPD measurement.[144-147] These findings suggest caution when considering the implications of renal pelvic dilation based on a single RPD measurement. **Calyceal dilation** is an important finding and is always pathologic, independent of the pelvic size.[131,143] The **Society for Fetal Urology** (SFU) proposed a classification system in 1993, based on the degree of renal pelvic dilation (mild, moderate, marked), while also including parameters of calyceal dilation and the appearance of the renal parenchyma.[132,148] The classification system consists of five grades: grade 0 representing no dilation, and grades 1 to 4 representing dilation of increasing severity (Fig. 39.26).

A consensus conference in March 2014 proposed a standardized classification system for UT dilation based on seven ultrasound parameters: (1) anteroposterior RPD; (2) calyceal dilation—central (major calyces) or peripheral (minor calyces); (3) renal parenchymal thickness (subjective assessment); (4) renal parenchymal appearance (echogenicity, corticomedullary

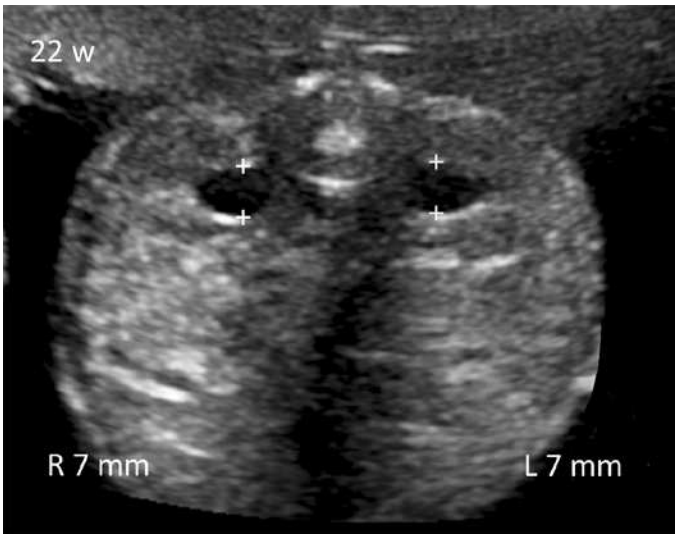

FIG. 39.25 Measurement of Anterior-Posterior Renal Pelvic Diameter (RPD). Transverse scan of the abdomen in a 22-week fetus, obtained with the fetus in a prone position, shows dilated renal pelvis bilaterally. The calipers are placed at the widest part of the intrarenal fluid.

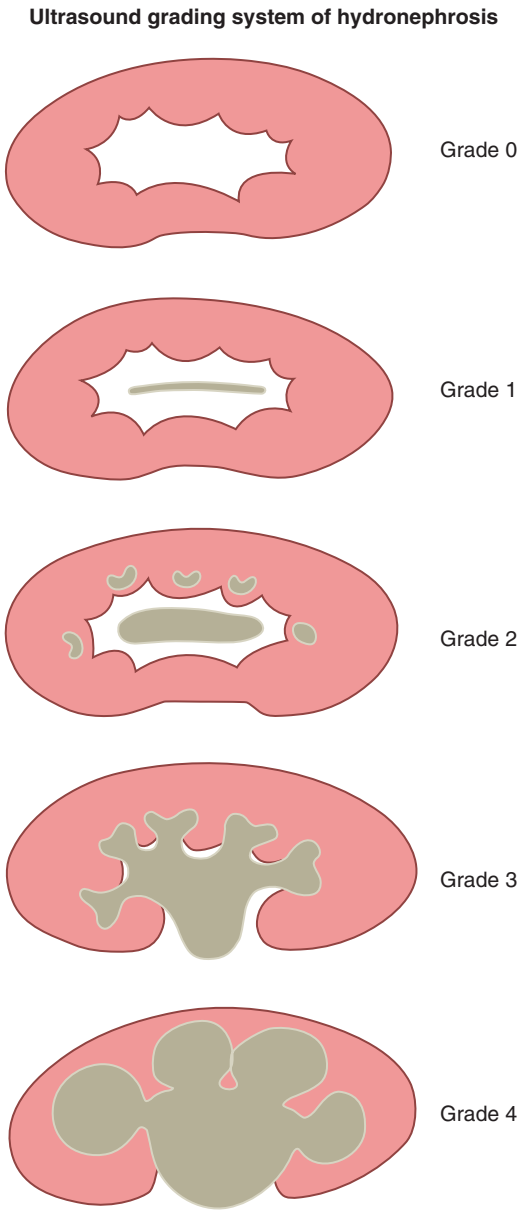

FIG. 39.26 Society for Fetal Urology Grading System. This classification is based on the appearance of the renal pelvis, calyces, and renal parenchyma. **Grade 0:** no hydronephrosis; intact central renal complex. **Grade 1:** only dilated renal pelvis; there is some fluid in the renal pelvis. **Grade 2:** dilated renal pelvis and a few calyces are visible. **Grade 3:** all the calyces are dilated. **Grade 4:** further dilation of renal pelvis and calyces, with thin renal parenchyma. (Modified from Baskin LS. Prenatal hydronephrosis. In: Baskin LS, Kogan B, Duckett J, editors. Handbook of pediatric urology. Philadelphia: Lippincott-Raven; 1997. p. 15.[281])

differentiation, cortical cysts); (5) ureteral abnormalities; (6) bladder abnormalities; and (7) oligohydramnios.[133]

The classification is based on the presence of the most concerning feature. The proposed thresholds for **normal RPD are less than 4 mm at 16 to 27 weeks and less than 7 mm at 28 weeks or more** (Table 39.4).

The detection of UT dilation (pyelectasis) is important for two reasons: **aneuploidy** and **postnatal uropathy.** The significance of UT dilation as a marker for aneuploidy is discussed in Chapter 31. UT dilation is usually an isolated finding, but a detailed ultrasound examination should be performed to detect other UT pathologic processes and nonrenal anomalies. UT dilation may be the first manifestation of obstructive uropathy. Studies that have correlated outcome with UT dilation varied widely in methodology, using different RPD cut-offs and different outcome measures. In a meta-analysis of 17 studies (104,572 patients screened), Lee and colleagues examined antenatal hydronephrosis (1308 subjects) as a predictor of postnatal outcome.[149] The risk of any postnatal pathology was 12% for mild, 45% for moderate, and 88% for severe hydronephrosis (Table 39.5). There was a significant increase in the risk of postnatal pathology with increasing degree of hydronephrosis. A prospective study by Sairam and colleagues[131] reported on the natural history of hydronephrosis diagnosed in 227 fetuses on midtrimester ultrasound in an unselected population. They demonstrated that 96% of the fetuses with mild hydronephrosis (RPD > 4 mm and < 7 mm at 18-23 weeks) experienced resolution in either the third trimester or the early neonatal period; none required postnatal surgery. However, approximately one in three fetuses with moderate to severe hydronephrosis (RPD > 7 mm or presence of caliectasis at 18-23 weeks) required postnatal surgery. A meta-analysis by Sidhu and colleagues combined data from seven studies and reported on the findings of serial postnatal renal sonography in children with isolated antenatal hydronephrosis.[150] There was resolution, improvement, or stabilization of hydronephrosis in 98% of patients with SFU grades 1 and 2 and stabilization of hydronephrosis in 51% of those with SFU grades 3 and 4. These results suggest that mild hydronephrosis is a relatively benign condition.

In utero progression also increases the likelihood of postnatal uropathy and urologic surgery.[141,151-153] An abnormal RPD in the third trimester is the best ultrasound criterion to predict postnatal uropathy.[128,141] In cases of mild isolated UT dilation, serial follow-up scans every 3 to 4 weeks are not necessary, but a repeat ultrasound in the third trimester is recommended. As prenatal resolution has been shown to be frequent,[131,142] this will also identify a group in which postnatal follow-up may not even be necessary.[133] In general, the larger the RPD, the lower the spontaneous resolution rate, the more likely it is associated with postnatal pathology, and the greater the need for postnatal surgery.[131,150,154-156]

A risk stratification of prenatal UT dilation into a low-risk group and an increased-risk group has been proposed.[133] Fetuses with isolated mild UT dilation are classified in the low-risk group (Fig. 39.27) if the RPD is 4 to less than 7 mm at less than 28 weeks, and 7 to less than 10 mm at 28 weeks or more. Fetuses with greater degrees of UT dilation (RPD ≥ 7 mm at <28 weeks and ≥ 10 mm at ≥28 weeks) or any one of several findings—peripheral calyceal dilation, abnormal renal parenchymal thickness or appearance, dilated ureter, abnormal bladder, or oligohydramnios—are considered at increased risk for postnatal uropathy (Fig. 39.28).

The majority of infants identified prenatally as having UT dilation are asymptomatic at birth. Pediatric nephrologists and urologists vary greatly in their management of antenatally diagnosed UT dilation, because an evidence-based protocol

TABLE 39.4 Urinary Tract Classification System and Follow-Up

	Low Risk	Increased Risk
DIAGNOSIS		
Renal pelvic diameter 16-27 weeks	4-<7 mm	≥7 mm

Amniotic fluid[a]	Normal or increased	Oligohydramnios
FOLLOW-UP		
During pregnancy	One additional ultrasound ≥32 weeks	Initial follow-up ultrasound in 4-6 weeks[b]
Postnatal to 1 month of age	Two additional ultrasounds at >48 hours 1-6 months later	Consider antibiotic prophylaxis Ultrasound at >48 hours to 1 month[b]
Other	Aneuploidy risk modification if indicated	Aneuploidy risk modification if indicated Specialist consultation (e.g., nephrology, urology)

[a]Amniotic fluid can be abnormal in low-risk fetuses if due to a nonrenal cause (such as intrauterine growth restriction or premature rupture of membranes).
[b]Certain situations (severe abnormalities such as posterior urethral valves or bilateral severe hydronphrosis) may require more expedient follow-up.
Modified from Nguyen HT, Benson CB, Bromley B, et al. Multidisciplinary consensus on the classification of prenatal and postnatal urinary tract dilation (UTD classification system). J Pediatr Urol. 2014;10(6):982-998.[133]

TABLE 39.5 Risk of Postnatal Pathology by Degree of Antenatal Hydronephrosis

	DEGREE OF ANTENATAL HYDRONEPHROSIS, % (95% CONFIDENCE INTERVAL)			
Pathology	**Mild**	**Moderate**	**Severe**	***P* Value**
Any pathology	11.9 (4.5-28.0)	45.1 (25.3-66.6)	88.3 (53.7-98.0)	<.001
Ureteropelvic junction	4.9 (2.0-11.9)	17.0 (7.6-33.9)	54.3 (21.7-83.6)	<.001
Vesicoureteral reflux	4.4 (1.5-12.1)	14.0 (7.1-25.9)	8.5 (4.7-15.0)	.10
Posterior urethral valves	0.2 (0.0-1.4)	0.9 (0.2-2.9)	5.3 (1.2-21.0)	<.001
Ureteral obstruction	1.2 (0.2-8.0)	9.8 (6.3-14.9)	5.3 (1.4-18.2)	.025
Other[a]	1.2 (0.3-4.0)	3.4 (0.5-19.4)	14.9 (3.6-44.9)	.002

[a]Includes prune belly syndrome, VATER syndrome, and unclassified.
Hydronephrosis was classified based on anteroposterior diameter of renal pelvis:
Second trimester: mild 4-<7 mm, moderate 7-10 mm, severe >10 mm.
Third trimester: mild 7-<9 mm, moderate 9-15 mm, severe >15 mm.
Modified from Lee RS, Cendron M, Kinnamon DD, Nguyen HT. Antenatal hydronephrosis as a predictor of postnatal outcome: a meta-analysis. Pediatrics. 2006;118(2):586-593.[149]

is lacking.[132,157,158] There are no uniformly accepted guidelines regarding antibiotic prophylaxis, postnatal workup, and surgery. However, a **postnatal renal ultrasound** is the first examination of choice. In the neonate, the relative state of dehydration and physiologic oliguria in the first 24 to 48 hours of life can result in underestimation of the degree of dilation and a false-negative renal ultrasound.[159] Therefore ultrasound should not be performed before 48 hours after birth, except for cases of oligohydramnios, urethral obstruction, and bilateral high-grade dilation. It is important to recognize that hydration status can cause a transient increase in renal pelvic size and also has an effect on the bladder volume. In the presence of UT dilation, ultrasound should be repeated after bladder emptying in order to assess accurately the severity of UT dilation. Many authors would perform voiding cystourethrography only when postnatal renal ultrasound findings are abnormal.[160,161] The indication for functional renal imaging by renal scintigraphy depends on the particular clinical situation. Recently, magnetic resonance urography has shown promise as a method to assess renal function without the use of radiation.[162,163]

In summary, we propose the following management protocol for UT dilation detected in the second trimester with regard to

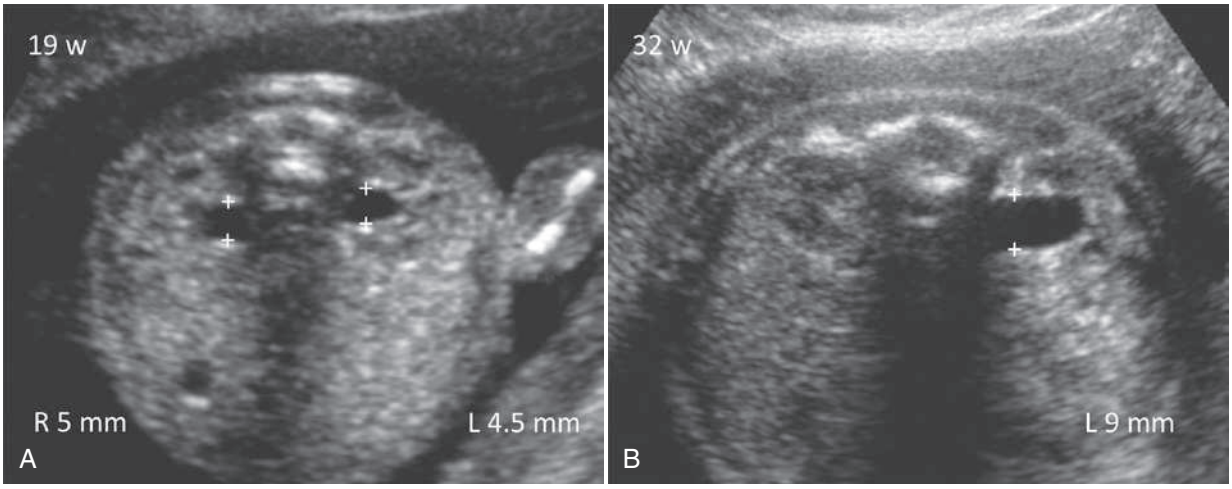

FIG. 39.27 Urinary Tract Dilation—Low Risk. (A) Fetal kidneys at 19 weeks gestation. Transverse image demonstrates an anteroposterior renal pelvic diameter (RPD) measuring 5 mm bilaterally. **(B)** Fetal kidneys at 32 weeks' gestation (different case). Transverse image demonstrates an anteroposterior RPD measuring 9 mm in the left kidney.

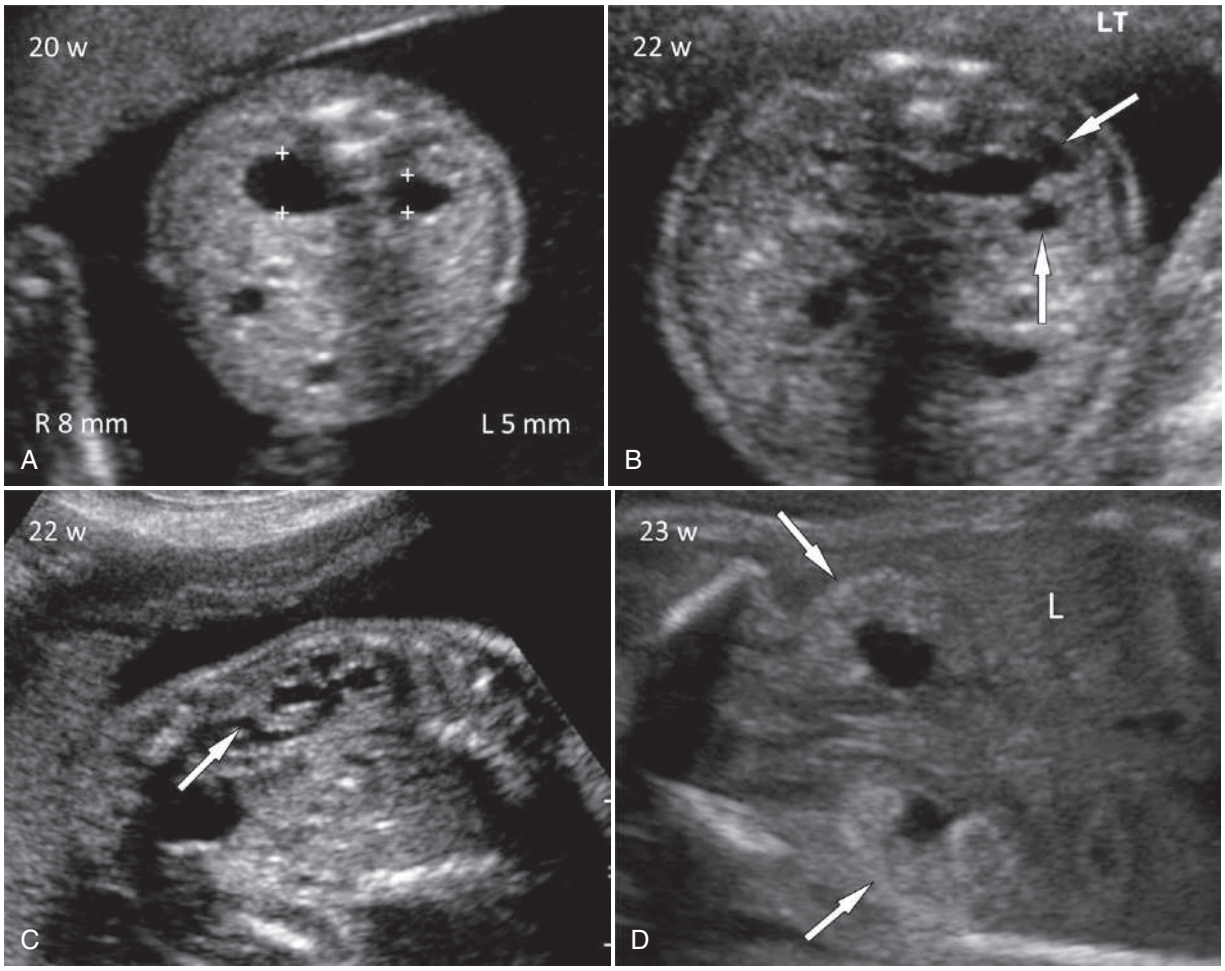

FIG. 39.28 Urinary Tract Dilation—Increased Risk. (A) Fetal kidneys at 20 weeks' gestation. Transverse image demonstrates an anteroposterior renal pelvic diameter (RPD) measuring 8 mm *(calipers)* in the right kidney. **(B)** Transverse image in a different fetus at 22 weeks demonstrates an anteroposterior RPD measuring 6 mm in the left kidney, but there is peripheral calyceal dilation *(arrows)*. **(C)** In the same fetus as **(B),** sagittal view demonstrates peripheral calyceal dilation and a dilated ureter *(arrow)*. The bladder is not dilated. **(D)** In a different fetus at 23 weeks' gestation, coronal image shows abnormal renal parenchyma bilaterally *(arrows),* which is more echogenic than the liver *(L)*. The RPD (measured on transverse view, *not shown*) was 6 mm.

repeating antenatal ultrasound, postnatal ultrasound, and antibiotic prophylaxis after delivery based on the recently published consensus guidelines[133]:

1. **Low-risk group:** If isolated mild UT dilation is detected at 16 to 27 weeks' gestational age, a repeat ultrasound is recommended at 32 weeks or later to reassess the RPD, kidneys, bladder, and AFV. Parents are counseled that it is a common finding and may be physiologic or transient, and that the risk of postnatal uropathy is small. If the ultrasound at 32 weeks' gestational age or later shows resolution (RPD < 7 mm) and no other findings, no further prenatal or postnatal follow-up is necessary. If UT dilation persists (RPD 7 to <10 mm), two postnatal renal ultrasound scans should be performed: the first at more than 48 hours but less than 1 month after birth, and the second exam 1 to 6 months later.
2. **Increased-risk group:** For fetuses in this category, a repeat ultrasound in 4 to 6 weeks is recommended, but the frequency of sonographic monitoring is at the discretion of the health care provider, depending on the findings. Prenatal consultation with pediatric specialists (nephrology, urology) is also recommended, especially in situations that may result in marked renal dysfunction or possible surgical intervention. For fetuses with RPD of 10 mm or greater at the third-trimester ultrasound, our approach is to initiate antibiotic prophylaxis after delivery, pending the results of the postnatal renal ultrasound.

Ureteropelvic Junction Obstruction

Obstruction at the UPJ is the most common cause of nonphysiologic neonatal hydronephrosis,[164-166] with an incidence of 1 in 2000 live births.[167] It is also one of the most common reasons for postnatal surgery of the UT.[128,164] Most cases of UPJ obstruction are functional (caused by a muscular abnormality) rather than the result of fixed anatomic lesions such as fibrous adhesions, kinks, valves, or aberrant vessels.[168] However, the etiology of functional obstruction is multifactorial and likely polygenic, with no known cause in most cases.[165] UPJ obstruction is more common in males, more frequently unilateral, and more often on the left side.[169]

On sonography, a dilated renal pelvis with or without caliectasis is identified. The ureter and the bladder are not dilated. Severe chronic obstruction leads to effacement of the calyces and thinning of the renal cortex (SFU grade 4) (Fig. 39.29). Rarely, the renal pelvis may be extremely dilated, appearing as a large, unilocular cystic mass. Rupture of the collecting system results in the development of a perirenal urinoma (Fig. 39.30, Video 39.7). This "pop-off" mechanism may protect the obstructed kidney from further prenatal damage and may diminish the degree of hydronephrosis. The affected kidney should be carefully assessed for renal dysplasia, however, because the probability of a nonfunctional dysplastic ipsilateral kidney is about 80%.[170]

The AFV is usually normal. When unilateral hydronephrosis is accompanied by oligohydramnios, a search for contralateral renal pathology is warranted (e.g., renal agenesis, multicystic renal dysplasia). UPJ obstruction may be associated with VUR and extrarenal abnormalities. When the contralateral kidney is normal, the prenatal detection of unilateral UPJ obstruction should not alter obstetric management. In cases of unilateral UPJ obstruction diagnosed before 24 weeks, severe dilation (RPD > 15 mm) is predictive of impaired postnatal renal function in the affected kidney.[171] When there is bilateral UPJ obstruction, the prognosis depends on the severity and duration of obstruction and on the AFV. Serial ultrasound evaluations are necessary to assess the AFV, progression of hydronephrosis, and development of renal dysplasia. Early delivery is rarely indicated, except when there is progressive bilateral obstruction with severe oligohydramnios. Treatment algorithms for hydronephrosis due to UPJ obstruction include both conservative and surgical approaches depending on the severity of the hydronephrosis.

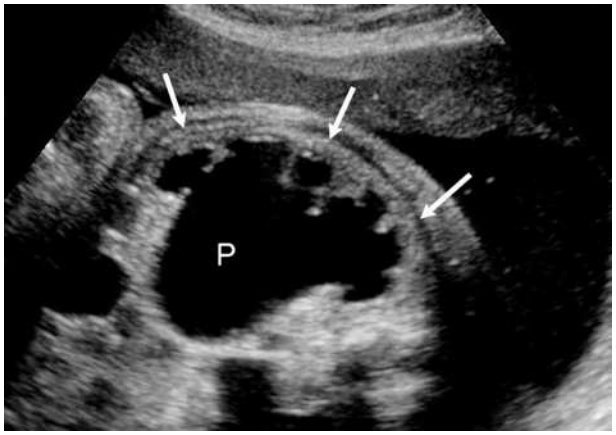

FIG. 39.29 Ureteropelvic Junction Obstruction. Longitudinal scan shows moderate caliectasis and extremely dilated renal pelvis *(P)*, with thinning of the cortex *(arrows)*.

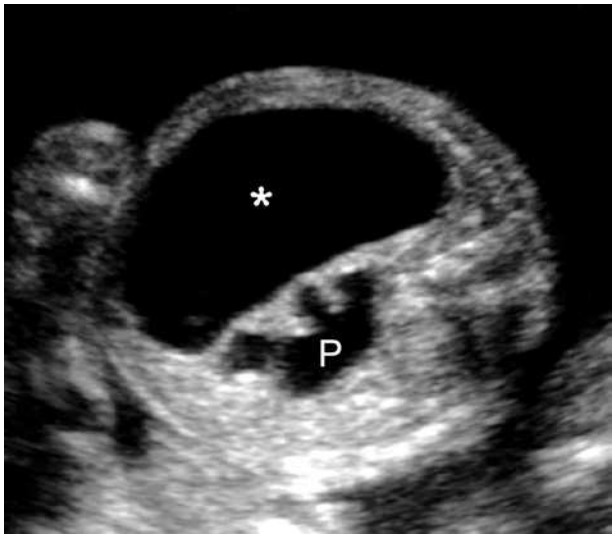

FIG. 39.30 Perirenal Urinoma. Transverse scan of fetal abdomen at 22 weeks' gestation shows a large perirenal urinoma (*) displacing and compressing the kidney, which demonstrates dilated calyces and pelvis *(P)* caused by ureteropelvic junction obstruction. See also Video 39.7.

Vesicoureteral Junction Obstruction and Primary Megaureter

Vesicoureteral junction obstruction is more common in males and is bilateral in up to 25% of cases.[172] Coexisting anomalies

of the UT (VUR, UPJ obstruction, multicystic dysplasia) are frequently present. Primary **megaureters** are classified into three types. In type I or primary obstructed megaureter, there is proximal dilation due to relative obstruction by a short aperisaltic segment of the ureter near the vesicoureteral junction. The transvesical course and insertion of the ureter are normal. It is thought to be due to muscular derangement with increased connective tissue in the affected segment of the ureter. Type II or refluxing primary megaureter is usually the result of an abnormality involving or closely associated with the vesicoureteral junction including a short or absent intravesical ureter, a congenital paraureteric diverticulum, or another abnormality of the vesicoureteral junction. Type III, or nonrefluxing, nonobstructed primary megaureter, is the most common of the three types. As the name suggests, neither reflux nor apparent obstruction of the distal ureter is found. The dilation starts just above the bladder, and the cause is unknown.[173]

On sonography, the affected kidney demonstrates dilation of the ureter with or without dilation of the renal pelvis (Video 39.8). A slightly dilated ureter may be difficult to recognize or may be mistaken for bowel, although bowel contents are usually more echogenic than urine. Identification of peristalsis in a fluid-filled tubular structure does not confirm bowel because it can occur with hydroureter as well. To be certain, the serpiginous cystic segments must be traced to either the renal pelvis or bladder. In addition, the ureter generally comes into close contact with the spine, but the small bowel does not. The ureteral dilation can be severe, so size alone does not preclude megaureter as a possible diagnosis.

In cases diagnosed prenatally as megaureter, prophylactic antibiotic therapy is commenced soon after birth because of the high risk of UT infections. Postnatal investigations including ultrasound and voiding cystourethrography are necessary to exclude VUR and bladder outlet obstruction. In the absence of urethral obstruction or VUR, a diuretic renogram is performed to evaluate for vesicoureteral junction obstruction. Most cases of primary megaureter either resolve spontaneously or improve when managed conservatively.[174,175] The degree of UT dilation and megaureter type are significant predictors of the spontaneous resolution rate.[174,176]

Duplication Anomalies

Embryologically, the duplex kidney results from two ureteral buds arising from the mesonephric duct to grow into the metanephric blastema. Duplication of the collecting system may be partial or complete. Many cases are found incidentally in the general population with no clinical significance.[177] In **complete duplication,** two pelvicalyceal systems and two separate ureters drain the kidney. The lower-pole ureter usually inserts into the bladder at the normal site, although the intramural portion may be shorter than usual. The upper-pole ureter often inserts ectopically, inferior and medial to the orifice of the lower-pole ureter **(Weigert-Meyer rule).**[173,177] Its orifice may be stenotic and obstructed, and there is often a ureterocele. The upper-pole ureter may have an insertion entirely outside the bladder (e.g., into the urethra or vagina). Classically, the upper-pole moiety obstructs, whereas the lower-pole moiety refluxes. Sonographic findings useful for prenatal diagnosis include unilateral renal enlargement, identification of two separate noncommunicating renal pelves, hydronephrosis in the upper and/or lower pole, ipsilateral dilated ureter(s), and ureterocele.[178-181] The finding of dilation of the upper-pole collecting system and ureterocele is the best diagnostic clue[178,179] (Fig. 39.31). The lower-pole moiety may also appear hydronephrotic because of VUR. In some instances, identification of two separate collecting systems, or the nondilated lower pole of a duplex kidney, may be difficult because of its small size and displacement by the dilated upper renal pelvis and ureter. Renal pelvic dilation has been shown to progress with increasing gestational age, and in many cases the diagnosis of a duplex kidney becomes apparent only in the third trimester.[180,181]

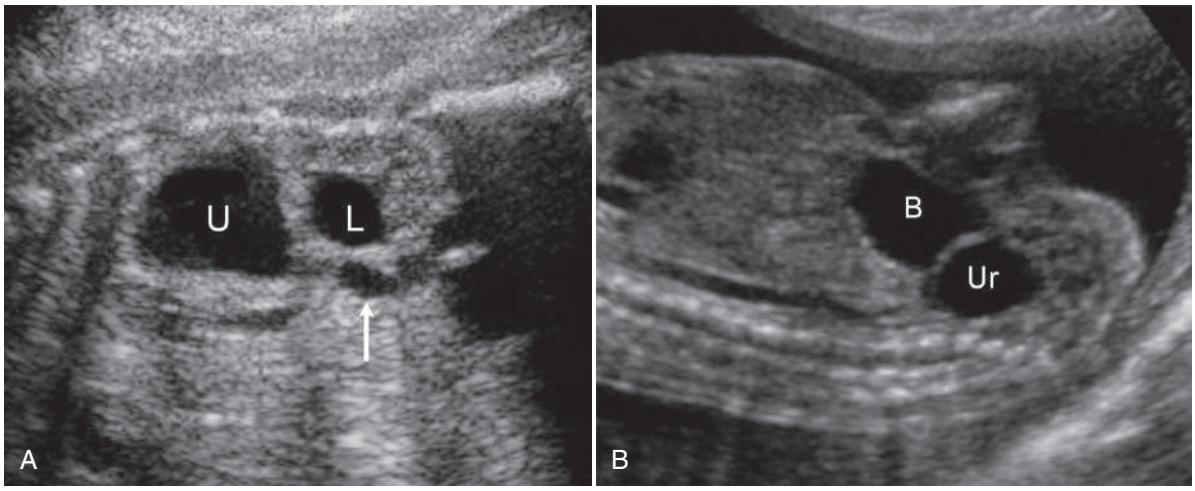

FIG. 39.31 Duplication Anomalies. (A) Longitudinal scan shows two separate collecting systems. The hydronephrotic, upper-pole renal pelvis *(U)* is continuous with the dilated ureter *(arrow)*. The lower-pole collecting system *(L)* is dilated because of reflux. **(B)** Longitudinal scan of the pelvis shows the ureterocele *(Ur)* separated from the lumen of the bladder *(B)* by a thin, curvilinear wall of the ureterocele.

Duplex Kidney Findings

Unilateral renal enlargement
Two separate noncommunicating renal pelves
Hydronephrosis of the upper and/or lower pole
Ipsilateral dilated ureter(s)
Ureterocele

Ureteroceles are cystic dilations of the intravesical submucosal ureter. A careful evaluation of the urinary bladder is necessary to detect the **ureterocele,** which is seen as a well-defined, thin-walled cyst within the bladder (see Fig. 39.31B). The diagnosis is easy when the bladder is partially full but can be overlooked if the bladder is empty or only minimally distended. A full bladder can compress the ureterocele, resulting in nonvisualization. A small nonobstructive ureterocele may be an incidental finding. However, most ureteroceles are detected prenatally during the evaluation of hydronephrosis.[182] A large ureterocele may cross the midline and obstruct the contralateral ureter or the bladder outlet and cause bilateral hydronephrosis. Ureteroceles that are large or prolapsed into the urethra may cause bladder outlet obstruction. Fetal therapy, such as fetoscopic laser surgery to decompress the distal urethral obstruction, can be helpful in cases with progressive bladder outlet obstruction, oligohydramnios, or concerns for permanent damage to the renal parenchyma.[183]

Complicated duplex collecting systems are associated with substantial morbidity. The prognosis depends on the degree of renal damage from reflux and obstruction. The outcome is improved with prenatal diagnosis, because it allows planning of postnatal care, including the administration of prophylactic antibiotics from birth, reducing the incidence of UT infections and renal function impairment.[181,184]

Vesicoureteral Reflux

VUR can be **primary** (incompetent valve mechanism at the UVJ) or **secondary** (due to an obstruction in the UT and high detrusor pressures). The main prenatal sonographic finding is hydronephrosis, which may be unilateral or bilateral. The ureter may be dilated. Intermittent dilation of the collecting system favors VUR. Fluctuation or variation in the RPD (changing by more than 3 mm) during the course of an obstetric sonogram is strongly associated with high-grade VUR (grade IV or V).[185] VUR may be associated with other renal abnormalities, including **UPJ obstruction, duplex kidney, MCDK,** and **unilateral renal agenesis.**[177,186]

The reported prevalence of VUR in children with prenatally detected hydronephrosis varies widely because different RPD cutoff values are used for inclusion and different protocols for postnatal investigations (voiding cystourethrography either in all cases or only after an abnormal postnatal renal ultrasound examination). A systematic review of 18 studies showed a mean prevalence of 15% for postnatal primary VUR after prenatally detected hydronephrosis.[187]

A normal postnatal ultrasound study does not exclude VUR. However, if two successive renal ultrasound examinations (at day 5 and at 1 month) were normal, voiding cystourethrography showed abnormalities in only 6.7% of patients.[188] Neonatal reflux is more common in male infants. It is often of low grade, with a high rate of spontaneous resolution by 2 years of age.[189] However, in those children with high-grade VUR, spontaneous resolution is rare. There is a significant correlation between high-grade VUR and findings of either renal dysplasia on ultrasound or renal damage scars on DMSA renal scan.[189,190] Most neonates with VUR are managed conservatively with antibiotic prophylaxis.

Lower Urinary Tract Obstruction

Fetal **megacystis** has been reported as early as 10 to 14 weeks' gestation when the longitudinal bladder diameter is 7 mm or more[191] (Fig. 39.32). In the second or third trimester, the definition of megacystis is more subjective but includes an enlarged bladder that fails to empty over 45 minutes of observation.[192,193] At 10 to 14 weeks' gestation, the incidence is 1:1600.[191] In a series of 145 fetuses with early megacystis, when the bladder diameter measured 7 to 15 mm, chromosomal abnormalities were detected in approximately 25% of cases.[194] In those with normal karyotype, there was spontaneous resolution of the megacystis by 20 weeks' gestation in 90% of cases. In contrast, with severe megacystis, defined as bladder length greater than 15 mm, the risk of chromosomal defects was 11%; and in the chromosomally normal group, it was invariably associated with progressive, obstructive uropathy.[194] Therefore follow-up ultrasound and assessment of karyotype in cases of identified first-trimester megacystis are necessary to provide prognostic information and identify the role, if any, of a diagnostic or therapeutic fetal procedure.

Causes of Fetal Megacystis

Posterior urethral valves
Urethral atresia or stricture
Ureterocele
Prune belly syndrome
Megalourethra
Cloacal malformation
Megacystis-microcolon–intestinal hypoperistalsis syndrome

FIG. 39.32 Megacystis in First Trimester. Transabdominal sagittal image of a 12-week fetus shows a distended thick-walled bladder *(arrow),* measuring 13 mm in length. There is no hydronephrosis.

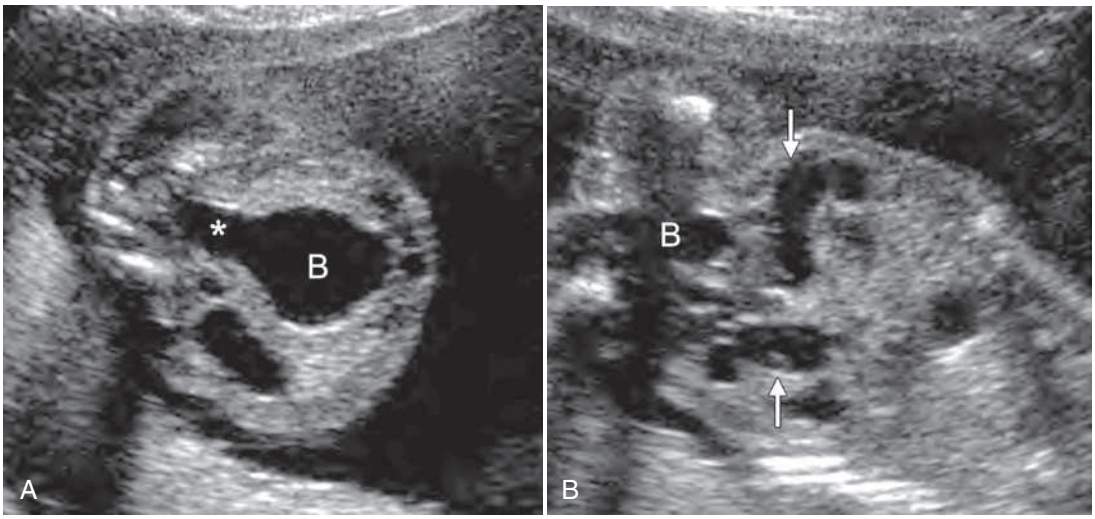

FIG. 39.33 Posterior Urethral Valves Causing Urethral Level Obstruction. (A) Dilated urinary bladder *(B)* and proximal urethra (*) give the appearance of a keyhole, characteristic of urethral obstruction in a 21-week fetus. **(B)** Coronal scan shows dilated tortuous ureters *(arrows)*.

Posterior urethral valves are the most common cause of lower urinary tract obstruction (LUTO), followed by urethral atresia or stricture. Posterior urethral valves are seen exclusively in males and may cause total, intermittent, or partial obstruction, with variable prognosis. Most cases are sporadic, occurring in 1:5000 male births; and the recurrence risk is small.[195] Intravesical pressure generated secondary to the obstruction results in a persistently dilated urinary bladder, with a dilated proximal urethra **(keyhole sign)** (Fig. 39.33). However, the keyhole sign is not a reliable indicator of posterior urethral valves because it can also be seen in fetuses with other pathologies, including VUR and primary megaureter.[196] There may be **thickening of the bladder wall** (>3 mm), bilateral tortuous hydroureters, and hydronephrosis. If the obstruction is severe and long-standing, progressive renal parenchymal fibrosis and dysplasia develop, resulting in severe oligohydramnios, pulmonary hypoplasia, and compression deformities (Potter syndrome). There may be spontaneous bladder rupture with urinary ascites (Fig. 39.34) or a calyceal rupture with perirenal urinoma.[197] If spontaneous decompression occurs, this "safety valve" may protect the kidneys from further prenatal damage and may diminish the degree of hydronephrosis.

Urethral atresia causes the most severe, and earliest detected, form of obstructive uropathy. The sonographic features include a greatly distended bladder that may fill the whole abdomen, and anhydramnios after the first trimester (Fig. 39.35). Urethral atresia is almost always fatal, because of associated renal dysplasia and pulmonary hypoplasia, and only case reports of survivors following antenatal treatment have been described.[195,198]

Prune belly syndrome is a rare congenital disorder characterized by megacystis, deficiency of abdominal musculature, and cryptorchidism. It is rarely reported in females. Several mechanisms for the pathogenesis of prune belly syndrome have been suggested. Some authors believe that it results from a primary mesodermal defect, but the more prevailing theory is that in utero urethral obstruction leads to a distended urinary system with secondary defective abdominal musculature.[199] The abdominal wall has a flaccid, wrinkled appearance; hence the name

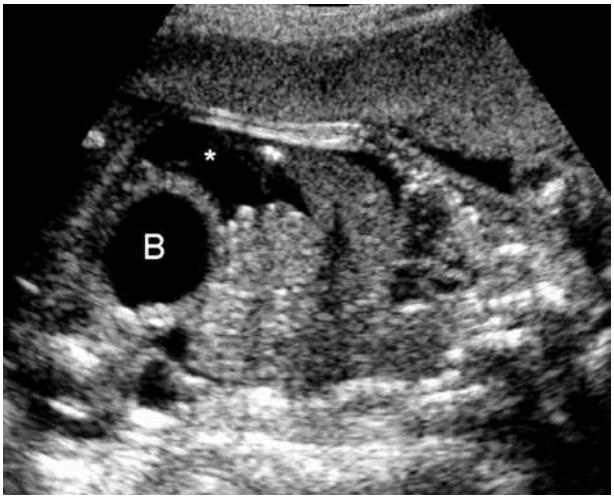

FIG. 39.34 Urinary Ascites. Longitudinal scan of a 22-week fetus shows a thick-walled bladder *(B)* and urinary ascites (*) caused by spontaneous rupture of severe megacystis.

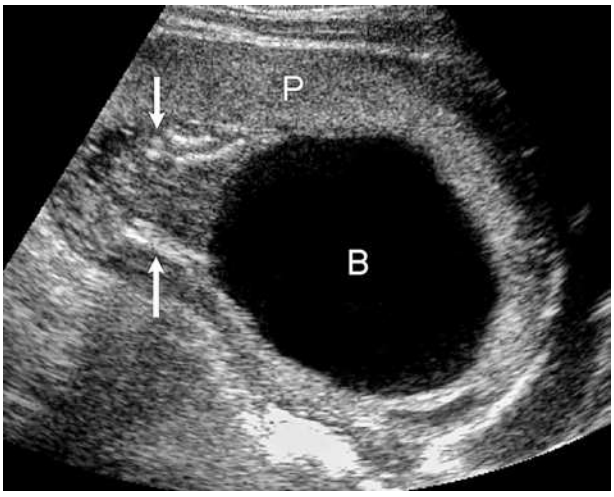

FIG. 39.35 Urethral Atresia. Coronal scan of a 17-week fetus shows a greatly distended bladder *(B)* that occupies the entire abdomen. The thorax *(arrows)* is compressed and bell shaped because of **pulmonary hypoplasia.** There is **anhydramnios.** *P,* Placenta.

"prune belly" syndrome. Typically, the **bladder** is **very large and thin walled.** The posterior urethra is usually not dilated, and there is no keyhole sign.[200] It is very difficult to differentiate this condition from posterior urethral valves, although the appearance of the bladder and urethra may be helpful. The ureters are tortuous and dilated, with bilateral hydronephrosis. If oligohydramnios is present, it is difficult to demonstrate undescended testes. Other abnormalities may be present, including congenital heart disease, intestinal malrotation, and musculoskeletal deformities.

Megalourethra is characterized by a congenital deficiency of the mesodermal tissues of the phallus, with **dilation of the penile urethra and enlargement of the penis.** This condition has been classified into two types, fusiform and scaphoid urethra, but it is preferable to consider it as a spectrum. Urinary stasis in the dilated penile urethra results in functional obstruction of the UT. The prenatal sonographic findings include those of LUTO, with dilation and elongation of the penile urethra[201,202] (Fig. 39.36, Video 39.9). Associated malformations of the UT include urethral atresia, posterior urethral valves, prune belly syndrome, and horseshoe kidney. Abnormalities involving the GI tract and spine and VACTERL association have been reported. The prognosis depends on the degree of renal dysfunction and the severity of associated anomalies. Survivors are at risk of renal insufficiency, impotence, and infertility.

Megacystis-microcolon–intestinal hypoperistalsis syndrome (MMIHS) is a rare, nonobstructive cause of megacystis with a 4:1 female predominance. The syndrome is characterized by the presence of **nonobstructive bladder distention,** intestinal

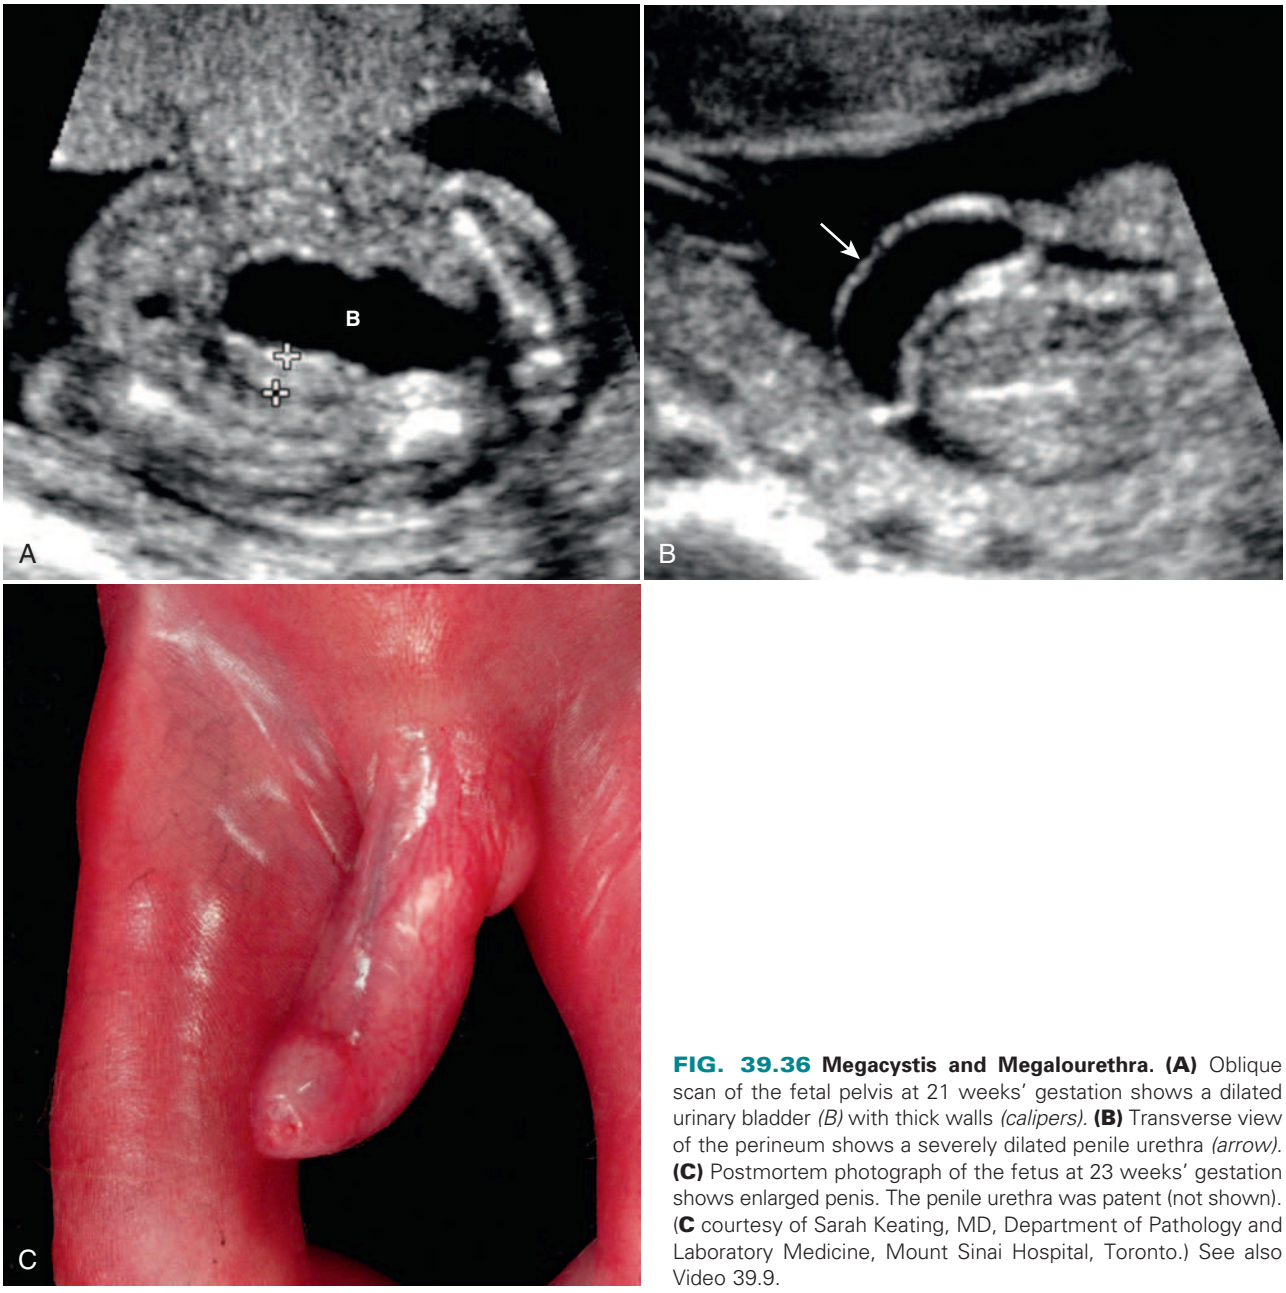

FIG. 39.36 Megacystis and Megalourethra. (A) Oblique scan of the fetal pelvis at 21 weeks' gestation shows a dilated urinary bladder *(B)* with thick walls *(calipers).* **(B)** Transverse view of the perineum shows a severely dilated penile urethra *(arrow).* **(C)** Postmortem photograph of the fetus at 23 weeks' gestation shows enlarged penis. The penile urethra was patent (not shown). (**C** courtesy of Sarah Keating, MD, Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto.) See also Video 39.9.

hypoperistalsis, and **microcolon.** Differentiating this condition from the more common posterior urethral valves is important because MMIHS carries a dismal prognosis and fetal bladder shunting is not indicated. The key distinguishing features are (1) the amniotic fluid is normal or increased; (2) the fetus is usually female; and (3) very rarely, a dilated small bowel may be present.[203] MRI is a useful adjunct for diagnosis; it can confirm the presence of microcolon when an enlarged bladder is visualized on ultrasound.[204] In fetuses with LUTO, an abnormal amniotic fluid digestive enzyme profile has shown a sensitivity of 80% and a specificity of 89% for MMIHS.[205] The precise genetic etiology of this syndrome remains unclear. Most occurrences are sporadic, and case reports of familial consanguineous cases have been described, suggesting an autosomal recessive inheritance model.[206,207] Recently, genetic advances in whole-exome sequencing have allowed the identification of mutations, such as *ACTG2,* encoding smooth-muscle actin, which may be implicated in the etiology of the disease.[208,209]

Cloacal malformation is very rare, with an incidence of 1:50,000 births. It results from failure of migration and/or fusion of the urorectal septum with the cloacal membrane.[210] This in turn causes persistence of the cloaca and cloacal membrane and failure of normal differentiation of external genitalia. There is a wide spectrum of abnormalities, with the most severe being cloacal dysgenesis (in which there is no perineal opening). In some cases, there is a single perineal opening that serves as the outlet for urine, genital secretions, and meconium. Lower UT abnormalities (reflux, ureteral ectopia, duplication of bladder) and genital abnormalities (duplication or atresia of uterus and vagina) are common, as are abnormalities of the kidneys and spine. Additional complications are related to **obstruction of the urinary, genital, and gastrointestinal tracts.** The usual sonographic presentation is that of LUTO in a female fetus (Fig. 39.37, Video 39.10). One or more cystic structures are seen arising from the pelvis, and their appearance depends on the anatomy involved. There may be a dilated bladder, with associated bilateral hydroureter and hydronephrosis. A septate cystic mass may be seen due to hydrocolpos and associated müllerian duct anomalies. The distal bowel may be dilated. If there is a communication between the distal bowel and the urinary system, a cystic mass containing calcifications (meconium mixed with urine) may be seen[211] (see Fig. 39.37B). Oligohydramnios, and in some cases, anhydramnios, may be present. Other sonographic findings include ascites, ambiguous genitalia, and vertebral anomalies.[212] Prenatal sonographic diagnosis of cloacal malformation is challenging. Fetal MRI is useful for assessment of the anorectal and pelvic anatomy. It can clarify cloacal malformations with high position of the distal bowel and a long common cloacal channel.[213]

In Utero Intervention: Fetal Vesicoamniotic Shunting and Cystoscopy

For a carefully selected group of fetuses with severe LUTO, permanent in utero bladder drainage may be a therapeutic option. The objective of vesicoamniotic shunting is to allow free drainage of urine from the bladder into the amniotic cavity. This decompresses the UT and should correct oligohydramnios, may theoretically prevent or stabilize renal dysplastic change, and allows unimpeded lung development. This approach assumes that renal function has not already been destroyed. Careful selection of suitable cases is critical, and the goal is often the identification and rigorous evaluation of reliable predictors of postnatal renal function.[33,214-221]

A detailed sonographic evaluation of the fetus is a prerequisite, to define the probable cause and evaluate prognosis. Intervention is not indicated if the ultrasound examination suggests either MMIHS or cloacal dysgenesis or if the fetus is female, because of their uniformly dismal prognosis.

Fine-needle aspiration under ultrasound guidance **(vesicocentesis)** allows for fetal renal function, karyotype, and microarray to be evaluated.[33,216-218] If the urine reaccumulates rapidly (which itself may indicate function) and the other prognostic factors

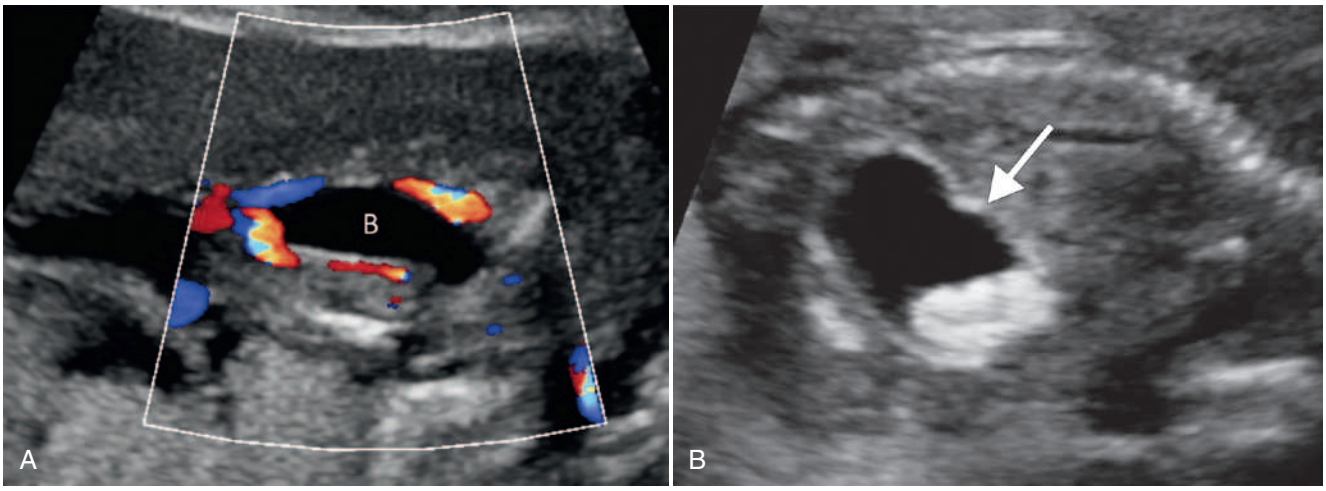

FIG. 39.37 Cloacal Dysgenesis. (A) Transverse view of the pelvis in a 17-week fetus shows a large bladder *(B)* and **(B)** sagittal view of the left side of the abdomen shows a cystic mass *(arrow)* superior to the bladder, representing a dilated bowel loop with intraluminal calcifications (meconium mixed with urine), indicating a urinary-bowel fistula. See also Video 39.10.

are favorable, placement of a permanent vesicoamniotic shunt may be considered. Fetal urinary sodium (Na^+), calcium (Ca^{++}), and β_2-microglobulin (in combination) are the best predictors of postnatal renal function.[215-220,222]

Antenatal Predictors of Poor Postnatal Renal Function

ULTRASOUND
Severe oligohydramnios, especially if early onset
Increased renal echogenicity
Renal cortical cysts
Slow bladder refilling after vesicocentesis

FETAL URINE
↑ Sodium level (Na^+)
↑ Calcium level (Ca^{++})
↑ β_2-Microglobulin level

FETAL BLOOD
↑ β_2-Microglobulin level

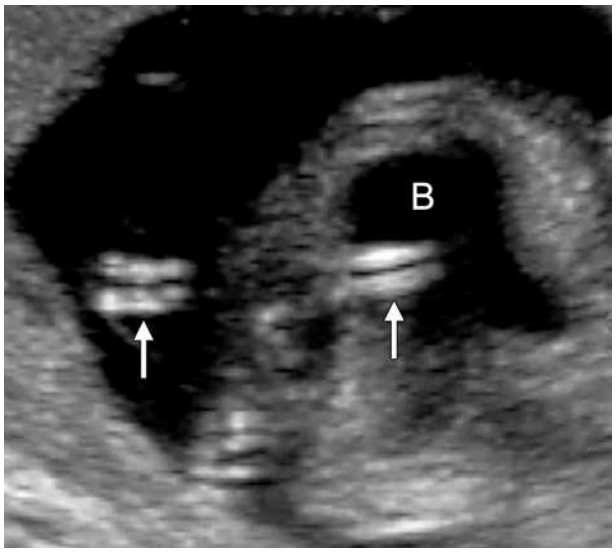

FIG. 39.38 Vesicoamniotic Shunt. Arrows indicate catheter in the decompressed bladder *(B)* and amniotic fluid. Note normal amniotic fluid volume.

Initially, fixed cutoff values were suggested for each variable as prognostic predictors.[82] However, the normal levels of most parameters vary with gestational age and must be interpreted accordingly. Specifically, sodium and β_2-microglobulin levels decrease throughout gestation, whereas calcium and creatinine values rise.[215,216,221] In general, more hypotonic fetal urine correlates with a more favorable outcome. Some groups advocate that sequential urine sampling over 48 to 72 hours is most reflective of true renal function because an initial bladder tap will obtain urine that has been present for an extended period of time.[215,223,224] A systematic review of 23 papers and 572 pregnancies reported that the two most accurate tests of fetal renal function were calcium and sodium above the 95th percentile for gestation, while β_2-microglobulin was slightly less accurate.[225] A recent retrospective study of fetal urine biochemistry in 72 cases of megacystis diagnosed before 23 weeks gestation supported the usefulness of β_2-microglobulin, sodium, chloride, and calcium in defining a poor renal prognosis.[226]

It has been suggested that fetal blood levels of β_2-microglobulin may better assess glomerular filtration rate than urinary markers, which generally reflect tubular function.[227] Blood sampling for electrolytes and β_2-microglobulin may also be useful when no urine can be collected by vesicocentesis.[224] Recently, advances in proteomics have allowed the identification of 26 fetal urinary peptides that show promise in predicting renal function after birth, although they are not yet integrated into clinical practice.[228] To date, a **urinary function profile,** which combines a number of biochemical and sonographic predictors, appears to be of greatest clinical value. We use the reference values published by Muller and colleagues for fetal urinary sodium, calcium, and β_2-microglobulin.[221] Only carefully selected fetuses with "favorable" fetal urinary analysis, despite significant oligohydramnios, are likely to benefit from in utero intervention; and in our center, only a handful of the fetuses who are referred with LUTO go on to such treatment.

Our approach is to counsel the parents extensively beforehand, with input from a multidisciplinary team of fetal medicine, pediatrics, urology, nephrology, and social work specialists. Parents are also given the opportunity to speak to others who have faced similar dilemmas. Before any decision is made, we try to ensure that they have an unbiased and complete account of the situation and are fully aware that, despite successful shunt placement, renal failure or pulmonary hypoplasia may still ensue.[227,229-231]

Vesicoamniotic shunting is performed by the percutaneous insertion of a small, plastic, double-coiled Silastic pigtail catheter into the bladder under continuous ultrasound guidance. To facilitate insertion, amnioinfusion is undertaken beforehand. Antibiotic prophylaxis and tocolysis (rectal indomethacin and oral calcium channel blockers) are used. We strive to place the shunt anteriorly in the midline, ideally below the umbilical cord insertion[224] (Fig. 39.38). Color Doppler is used to help avoid maternal and fetal blood vessels. **Early intervention** is probably necessary for this procedure to successfully prevent pulmonary hypoplasia and preserve renal function.[195] Typically AFV is low before intervention. Occasionally, intervention may be considered in light of documented worsening of renal function on urinalysis or progressively abnormal renal appearance on ultrasound, despite a normal AFV. Rarely, it may be warranted to place the shunt directly into a dilated renal pelvis rather than the bladder. Shunts may become blocked or dislodged and will require replacement in some cases.

Recently, fetal cystoscopy and laser ablation of the posterior urethral valves have been introduced as an alternative diagnostic and therapeutic approach to the management of obstructive uropathy.[232,233] Theoretical advantages include more physiologic drainage by allowing "cyclic voiding," determining the cause of LUTO by differentiating posterior urethral valves (PUV) from urethral atresia, avoiding the need for amnioinfusion, and avoiding shunt complications, such as migration and blockage.

Antenatal management of LUTO is challenging because the natural history of the condition is highly variable and depends on the cause, severity, duration, and gestational age of onset of the obstruction. Studies that have reported on the long-term outcomes in children with in utero vesicoamniotic shunting are observational in nature and based on small and heterogeneous populations.[227,230,231,234,235] As seen in Table 39.6, these retrospective series report 57% to 91% survival in those treated, with normal postnatal renal function in 0% to 50% of survivors. In two of the series, one-third of patients were lost to follow-up. A systematic review of 20 observational studies involving 369 fetuses in which a bladder drainage procedure was attempted concluded that prenatal bladder drainage improved perinatal survival, especially in fetuses with poor predicted prognosis based on fetal urinalysis, but the effects on long-term renal function were uncertain.[236] Recently, a multicenter randomized controlled trial, PLUTO (Percutaneous vesicoamniotic shunting for fetal LUTO), comparing fetal shunting versus conservative management, was stopped early because of poor recruitment (only 31 of the planned 150 pregnancies were randomly assigned during a 4-year period), and its results should be interpreted with caution.[237] The as-treated analysis showed that fetuses that underwent bladder shunting had a three-times-higher chance of postnatal survival (to 28 days) than nonshunted fetuses. However, only two of the seven shunted survivors had normal renal function at age 2 years. The PLUTO results emphasize the need for further research, given that the goal is to improve not only survival, but also long-term renal function. However, the inability to complete the trial does not bode well for future trials of fetal intervention for LUTO. Strategies to assess fetal renal function more reliably and to offer timely therapeutic interventions in appropriate cases are lacking. Furthermore, long-term follow-up data about neurodevelopment, morbidity, and quality of life are necessary to inform parents about the risks and benefits of intervention.

Nonvisualized Bladder

Visualization of the bladder is part of the routine anatomic survey. Visualization of the umbilical arteries on either side of the bladder can aid in detection of a bladder that is difficult to visualize. Because bladder emptying leads to a small or nonvisualized bladder, if the bladder is not initially visualized then additional images should be taken later in the examination. Absent bladder may be due to failure of urine production (e.g., as a result of some combination of severe bilateral abnormalities such as agenesis, dysplasia, or obstruction, severe IUGR or placental insufficiency); failure to store urine (e.g., as a result of cloacal exstrophy, cloacal malformation, or bladder exstrophy or ureters that insert ectopically below the bladder).

Nonvisualization of Fetal Bladder: Etiology

FAILURE OF URINE PRODUCTION
Bilateral severe renal abnormality (renal agenesis, MCDK, ARPKD, UPJ obstruction, renal dysplasia)
Severe intrauterine growth restriction or placental insufficiency

FAILURE TO STORE URINE
Bladder exstrophy
Cloacal exstrophy
Cloacal malformation
Bilateral ectopic ureter with drainage outside of bladder

ARPKD, Autosomal recessive polycystic kidney disease; *MCDK,* multicystic dysplastic kidney; *UPJ,* ureteropelvic junction.

Bladder Exstrophy

Bladder exstrophy occurs once in 10,000 to 40,000 births, more often in males.[3] It is caused by incomplete median closure of the inferior part of the anterior abdominal wall and anterior wall of the urinary bladder. There is exposure and protrusion of the posterior wall of the bladder. Sonographically, AFV and kidneys are normal, but a fluid-filled bladder is not identified.[238,239] An irregular mass may be seen arising from the anterior abdominal wall, inferior to the umbilicus, formed by the exstrophied bladder with heaped-up mucosa (Fig. 39.39). Other findings include a low umbilical cord insertion site into the abdomen, widening of the pubic bones, and abnormal genitalia, such as a small penis.[238,240] Prenatal sonographic diagnosis is challenging because all the findings may not be present, and a urachal cyst may be confused for a bladder.[239] Fetal MRI may be considered to clarify the anatomic defect and confirm the diagnosis.[241] Bladder exstrophy is usually a sporadic and isolated defect. Rarely, it has been reported with the **OEIS complex: omphalocele, exstrophy**

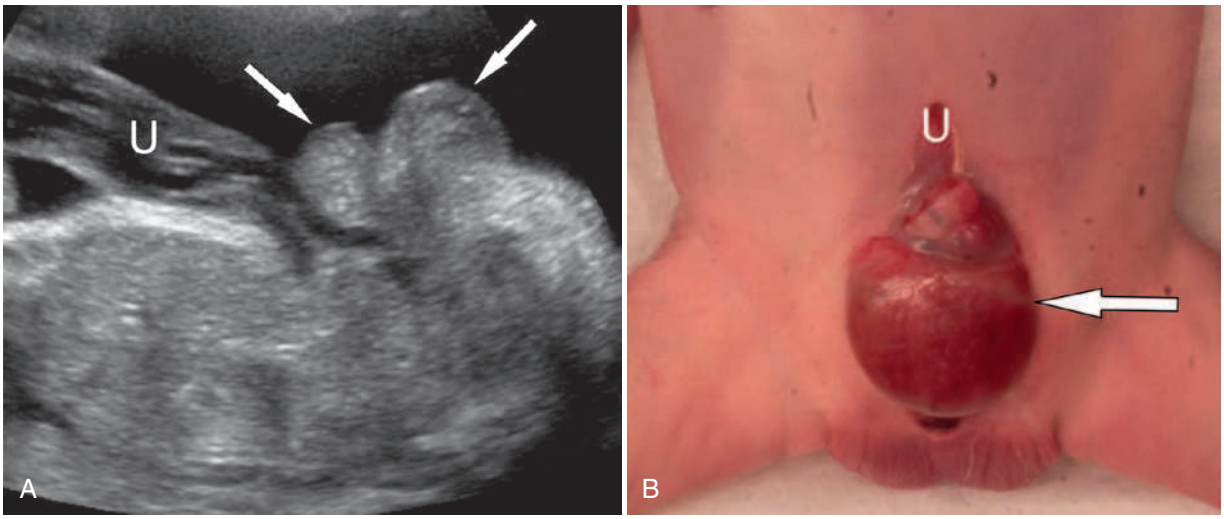

FIG. 39.39 Bladder Exstrophy. (A) Longitudinal scan of the lower fetal abdomen in a 29-week fetus shows an irregular mass on the anterior abdominal wall *(arrows),* below the umbilical cord insertion *(U).* A fluid-filled bladder was not identified. Note normal amniotic fluid volume. **(B)** Corresponding photograph shows the exposed bladder *(arrows)* below the umbilical cord *(U).*

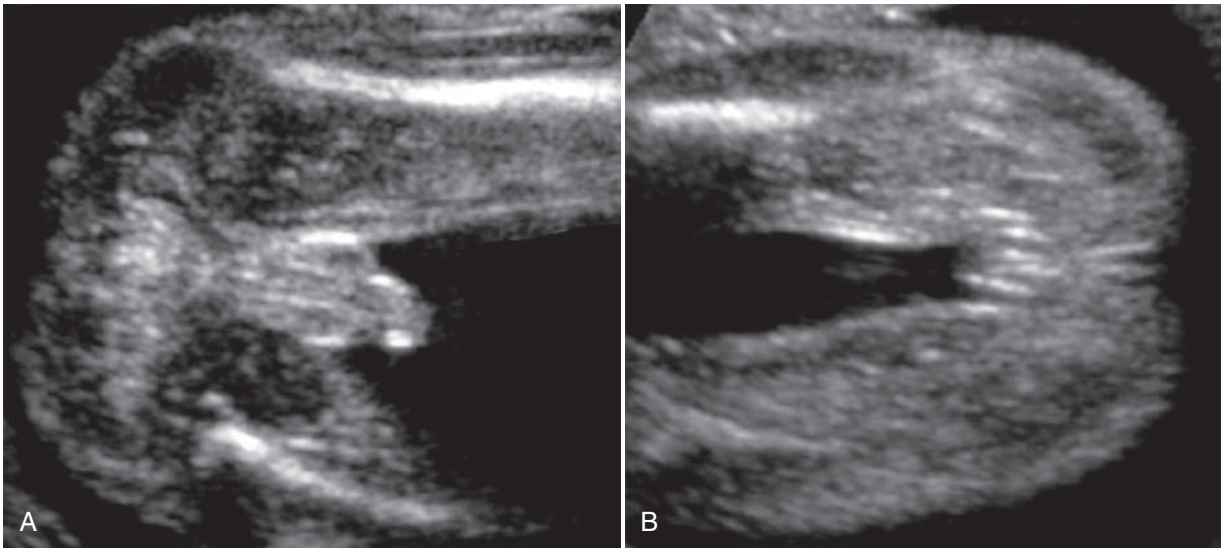

FIG. 39.40 Normal Genitalia. (A) Normal 19-week male fetus. Transverse scan of the perineum shows the penis and scrotum. **(B)** Normal 19-week female fetus. Transverse scan of the perineum shows the labial folds.

of bladder, imperforate anus, and spinal defects. Renal anomalies and abnormalities of the lower limbs are often present.[242,243]

THE GENITAL TRACT

Normal Genitalia

Fetal sex determination has medical as well as social implications. These include (1) history of X-linked disorders, (2) assignment of dizygosity in twin pregnancies, (3) exclusion of maternal cell contamination during amniocentesis or chorionic villous sampling, (4) need to confirm fetal gender to diagnose certain structural abnormalities (e.g., posterior urethral valves, ovarian cysts), and (5) familial syndromes in which genital abnormalities are common.

In the second trimester, fetal sex determination is based on direct visualization of the **external genitalia:** the penis and scrotum in males, and the labia majora and minora, represented by two or four parallel lines, respectively, in females (Fig. 39.40). Inopportune fetal position, oligohydramnios, maternal obesity, and operator inexperience represent the major limitations in fetal gender assessment. Errors may occur when the rounded, apposed labia are mistaken for a small, empty scrotum or when the umbilical cord is mistaken for the penis. The accuracy of fetal sex determination ranges from 92% to 100%.[244] When conventional methods fail or in the setting of ambiguous genitalia, fetal sex can be assigned by sonographic evaluation of the pelvic organs in the second and third trimesters of pregnancy.[245] It has been reported that measurement of the distance between the posterior wall of the fetal bladder and the anterior wall of the

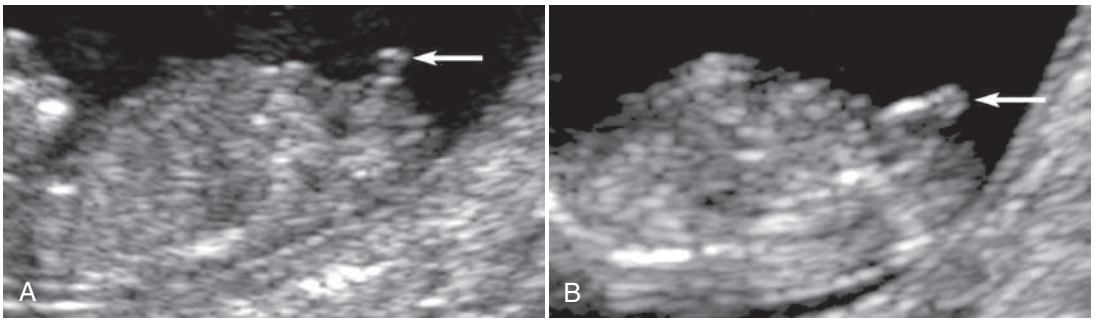

FIG. 39.41 First-Trimester Gender Identification. (A) Sagittal scan of a 12-week male fetus shows the vertical and relatively cranially directed phallus *(arrow).* **(B)** Sagittal scan of a 12-week female fetus shows the horizontal/caudally directed phallus *(arrow).*

rectum, when performed on an axial image of the pelvis, can be used to distinguish between male and female internal genitalia.[245] However, further studies are required to refine the discriminatory values.

In the late first trimester, fetal sex determination is possible, based on the direction of the genital tubercle in the midsagittal plane. In males the genital tubercle (penis) points cranially or vertically; in females the genital tubercle (clitoris) points caudally or horizontally (Fig. 39.41). By measuring the angle of the genital tubercle to a horizontal line through the lumbosacral skin surface (genital angle), gender assignment was possible in 93% of fetuses at 12 to 14 weeks of gestation (male when the angle was greater than 30 degrees and female when the angle was less than 10 degrees).[246] At all ages, male gender was correctly assigned in 99% to 100%. However, the accuracy of female gender assignment improved with gestational age, from 91.5% at 12 to 12 + 3 weeks, to 100% at 13 to 13 + 6 weeks. The use of 3-D multiplanar ultrasound allows the midsagittal plane to be obtained and the genitalia to be visualized more easily.[247] As a result the genital angle can be measured accurately, and this technique has been found to be accurate and reproducible for fetal gender assignment before 14 weeks of gestation.[248]

Testicular descent into the scrotum occurs after 25 weeks' gestation.[249] After 32 weeks, both testes have descended in 97% of the fetuses. Small hydroceles are common in third-trimester male fetuses (15%) and are usually of no clinical importance (Fig. 39.42).[250] However, large hydroceles, especially if they increase in size over time, suggest an open communication between the processus vaginalis and peritoneal cavity. In such cases, postnatal evaluation for inguinal hernia should be performed.[251]

FIG. 39.42 Hydroceles. Scan of the scrotal sac in a 38-week male fetus demonstrates testes and bilateral hydroceles.

Abnormal Genitalia

An abnormality of the genitalia may be an isolated finding or associated with other major malformations. In a male fetus, abnormal ultrasound findings include **micropenis, penile chordee** (abnormal curvature of penis), a shawl or **bifid scrotum,** and **undescended testes** (in third trimester).[252-254] Confirmation of **hypospadias** can be achieved by demonstrating the origin of the urine jet from either the midshaft or the base of the penis. In the female an enlarged clitoris is the most common finding. It can be difficult to define **ambiguous genitalia** accurately (Fig. 39.43). A male fetus with micropenis, bifid scrotum, and undescended testes may not be distinguished from the virilized female with clitoral enlargement (and labial fusion). If ambiguous genitalia are suspected, a karyotype is obtained to determine the genetic makeup of the fetus. Ambiguous genitalia, syndactyly, and multiple other anomalies raise suspicion for **Smith-Lemli-Opitz syndrome,** an autosomal recessive disorder due to mutations in the gene encoding 7-dehydrocholesterol reductase *(DHCR7);* thus elevation of 7-dehydrocholesterol in amniotic fluid is a reliable marker for prenatal diagnosis of Smith-Lemli-Opitz syndrome.[255] This condition is also suggested by low maternal serum estriol (uE3) in the second trimester.[256] DNA analysis can also be performed.[257]

When ultrasound suggests male genitalia and the fetus is genetically female, **congenital adrenal hyperplasia** (CAH) is the most common cause. The condition is autosomal recessive, so there may be a previously affected sibling. More than 90% of cases result from mutations of the *CYP21A2* gene, leading to 21-hydroxylase deficiency. When a proband exists, prenatal diagnosis is possible with chorionic villous sampling.[258] Recent advances in the use of cell-free fetal DNA have shown potential for the noninvasive prenatal diagnosis of CAH as well.[259] In the

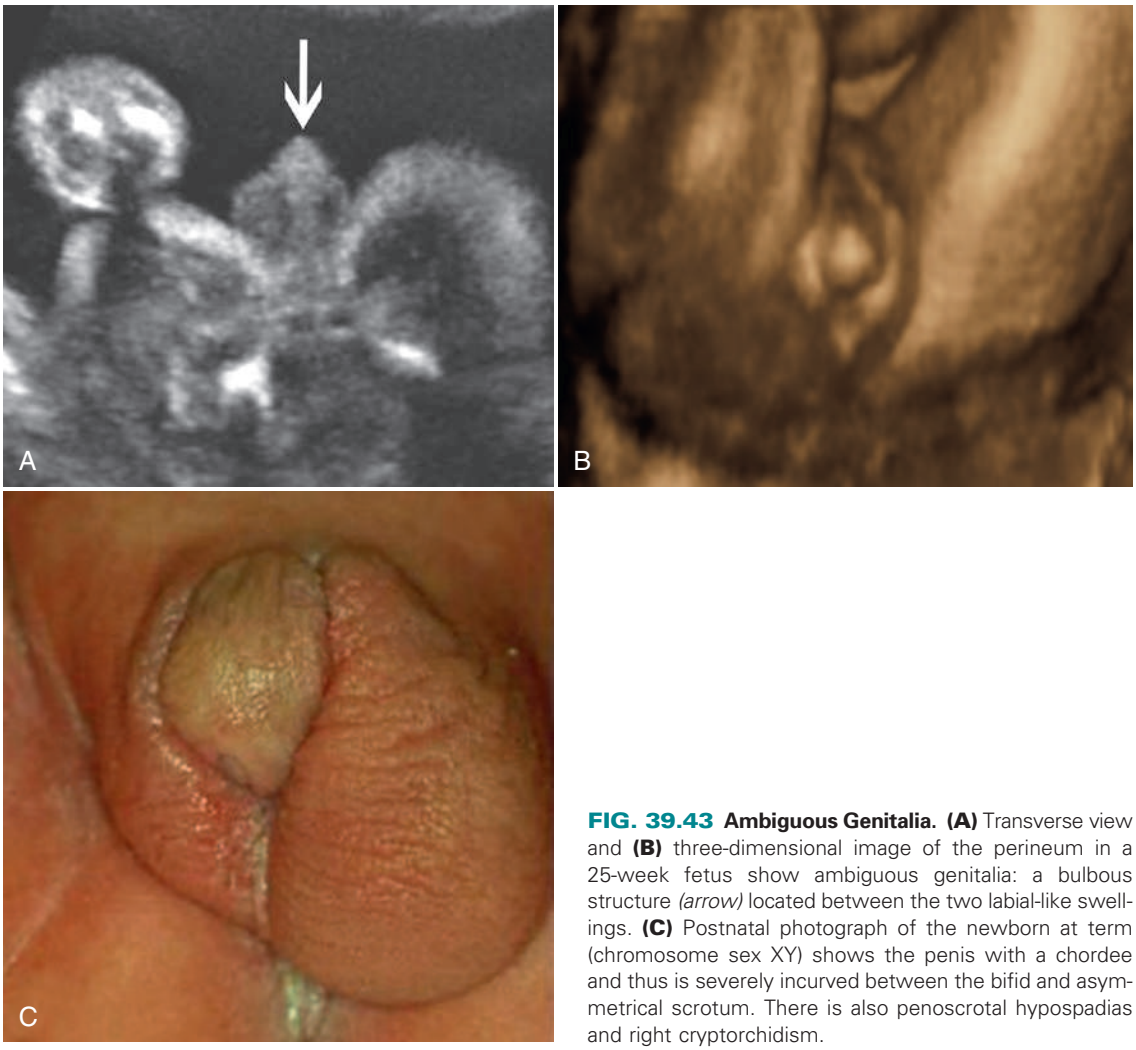

FIG. 39.43 Ambiguous Genitalia. (A) Transverse view and **(B)** three-dimensional image of the perineum in a 25-week fetus show ambiguous genitalia: a bulbous structure *(arrow)* located between the two labial-like swellings. **(C)** Postnatal photograph of the newborn at term (chromosome sex XY) shows the penis with a chordee and thus is severely incurved between the bifid and asymmetrical scrotum. There is also penoscrotal hypospadias and right cryptorchidism.

absence of a family history, the ultrasound findings of enlarged fetal adrenal glands and ambiguous genitalia are suggestive of CAH.[260,261] Prenatal maternal administration of dexamethasone can prevent or reduce virilization in affected female fetuses, but it must be initiated on or before the ninth week of pregnancy (before prenatal diagnosis of CAH can be made currently).[259] Because the offspring of carrier parents have a 1 in 4 chance of having CAH, and therefore only 1 in 8 will be a CAH-affected female, mothers who want to undergo prenatal dexamethasone treatment will be unnecessarily treating seven of eight fetuses, who would be exposed to the risks of several weeks of steroid therapy. A systematic review of the safety of prenatal steroid therapy in CAH concluded that the available literature is uncertain and inconclusive regarding the benefits or harms of dexamethasone use in this setting, and this medication should be prescribed only after the parents have received detailed and informed counseling.[262-264]

Prenatal diagnosis of female **pseudohermaphroditism** with bilateral luteoma of pregnancy has been reported.[265] In a genetic male with female external genitalia, **testicular feminization** is likely. Intersex states may be divided into hormonally and nonhormonally mediated abnormalities. The latter often have associated cloacal anomalies or chromosomal aberrations or may conform to one of numerous multimalformation syndromes. In many cases, an accurate diagnosis and final gender assignment can be made only postnatally.

Hydrocolpos

Hydrocolpos is dilation of the vagina caused by fluid accumulation. It is associated with uterine dilation in hydrometrocolpos. It occurs as a result of vaginal hypoplasia or agenesis, transverse septum, or imperforate hymen. Hydrocolpos appears as a **midline pelvic mass, posterior to the bladder.** It is generally anechoic but may contain echogenic fluid with a fluid-debris level. When associated with müllerian duct anomalies, it may appear as a septate mass.[266] The enlarged vagina and uterus may compress the UT and cause hydronephrosis or hydroureter. Hydrocolpos may be associated with a wide spectrum of urorectal septum malformations. Therefore a detailed sonographic examination including identification of a normal anal canal and rectum provides important information for prenatal counseling.[267] MRI may be useful as an adjunct to ultrasound when pelvic anatomy is not well identified or to aid in diagnosis of cloacal malformation or other associated GI abnormalities.[213,267,268]

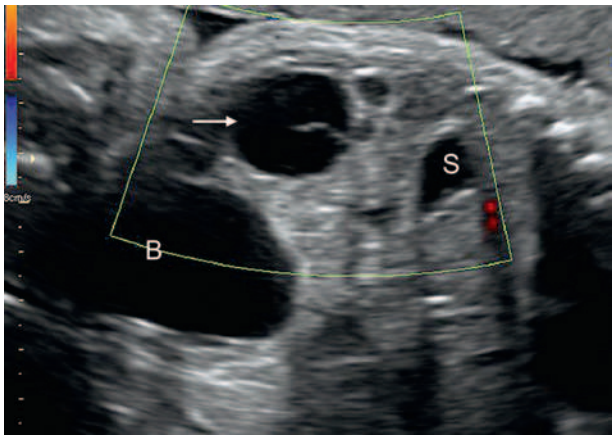

FIG. 39.44 Ovarian Cyst. Coronal scan demonstrates a cyst *(arrow)* in the lower abdomen of a 35-week female fetus, separate from the kidneys *(not shown),* bladder *(B),* and stomach *(S).* (Courtesy of John R. Mernagh, MD, McMaster University Medical Center, Hamilton, Ontario.)

Ovarian Cysts

The vast majority of fetal ovarian cysts are benign functional cysts.[269] They result from excessive stimulation of the fetal ovary by placental and maternal hormones. They are usually diagnosed in the third trimester. The main criteria for diagnosis are the presence of a cystic mass, usually located in one side of the pelvis or lower abdomen; normal urinary and GI tracts; and female gender. The diagnosis is presumptive because other lesions, such as **enteric duplication cysts, mesenteric cysts, meconium pseudocysts,** or **urachal cysts,** cannot be ruled out with certainty. Most ovarian cysts are small and hypoechoic (Fig. 39.44). The "daughter cyst" sign (describing a smaller cyst within a larger ovarian cyst) is considered pathognomonic.[270] When complicated by torsion or hemorrhage, ovarian cysts may appear complex (Video 39.11). A fluid-debris level, a retracting clot, or internal septa may be demonstrated.[271] The wall may be echogenic from dystrophic calcification.

The outcome depends on the cyst size and complications such as torsion. The natural course for most ovarian cysts (>50%) is spontaneous resolution, either prenatally or postnatally (usually within 6 months of birth).[272-274] With simple cysts larger than 4 to 5 cm, there is an increased risk of complications, such as torsion, hemorrhage, and rupture.[275] Because torsion could result in necrosis, adhesion formation, and potential loss of the ovary with impaired fertility, some authors advocate prenatal aspiration of large simple cysts to prevent torsion.[276,277] However, the value of fetal cyst aspiration is controversial.[278,279] Cyst recurrence is common[277] and there are procedure-related complications (infection, premature labor, rupture of membranes).[278] In most cases, identification of an ovarian cyst does not alter obstetric care. Our approach is conservative; we do not aspirate cysts. Serial ultrasound is performed to monitor for change in size or internal echogenicity. Extremely large cysts may cause intestinal obstruction, polyhydramnios, and dystocia.

Postnatal management options include observation, percutaneous cyst aspiration, and surgery. Asymptomatic infants are managed conservatively with serial ultrasound until the cyst resolves.[273,280] Symptomatic cysts and cysts that persist or increase in size are indications for surgery.

CONCLUSION

UT anomalies are among the most common antenatally detected fetal anomalies. A thorough sonographic evaluation of renal structure, function, and associated anomalies will improve the accuracy of antenatal diagnosis, thus enabling optimal obstetric and neonatal management.

Acknowledgments

Special thanks to Dr. David Chitayat for reviewing the section on renal cystic disease; Dr. Greg Ryan for reviewing the sections on lower urinary tract obstruction and in utero intervention; and Dr. Ants Toi and the sonographers of the Joint Department of Medical Imaging at Mount Sinai Hospital and Women's College Hospital in Toronto for providing many wonderful images.

CHAPTER 40

The Fetal Musculoskeletal System

Phyllis Glanc, David Chitayat, and Sheila Unger

SUMMARY OF KEY POINTS

- Two-dimensional ultrasound is the primary imaging modality for the majority of musculoskeletal disorders.
- When a fetal musculoskeletal dysplasia is suspected on ultrasound, referral to a center with expertise may be helpful.
- A main role of ultrasound is to determine if the condition is likely lethal; it is important to use multiple parameters to make this determination.
- After delivery or pregnancy termination, a diagnosis should be established by a combination of clinical examination, imaging, and molecular studies. Cell culture and DNA banking are essential for molecular investigations. The results should be reviewed with the parents to help in their future reproductive plans.

SKELETAL FINDINGS ASSOCIATED WITH ANEUPLOIDY
SUMMARY
Acknowledgments

Congenital bone disorders of the skeleton comprise a large and heterogeneous group of disorders primarily affecting the growth and development of the musculoskeletal system. The prevalence of skeletal dysplasias, also called "osteochondrodysplasias," diagnosed prenatally or during the neonatal period, excluding limb amputations, is 2.4 to 4.5 per 10,000 births.[1]

There are three major categories: skeletal dysplasias, dysostoses, and disruptions (Table 40.1). The number of recognized genetic disorders with a substantial skeletal component is increasing, and the distinction among dysplasias, metabolic bone disorders, dysostoses, and malformation syndromes is constantly evolving. The Nosology and Classification of Genetic Skeletal Disorders 2015 revision recognizes 436 genetic bone disorders with a substantial skeletal component[3-6] (Table 40.2).

Despite increased knowledge about the genetic origins of many of these conditions and the improved ability to diagnose and categorize these disorders correctly, the clinical and imaging features remain a fundamental tool for diagnosing and directing the molecular investigation.[3,7] Although many fetal skeletal dysplasias can be accurately identified by prenatal ultrasound, this remains a challenging task because of the low incidence, phenotypic variability, and wide range of appearances.[8] The majority of cases have no family history of a similar condition. Nonetheless, the majority of **lethal skeletal dysplasias,** and in particular the most common—**thanatophoric dysplasia, achondrogenesis,** and **osteogenesis imperfecta** type II—can be diagnosed solely on the basis of prenatal ultrasound.[9] Tretter et al.[10] determined that 26 of 27 lethal skeletal dysplasias were

TABLE 40.1 Major Categories of Skeletal Dysplasias[2]

Skeletal dysplasias	Developmental disorders of chondro-osseous tissue caused by single-gene disorders with prenatal and postnatal manifestations
Dysostoses	Single-gene disorders resulting in malformations of individual bones caused by transient abnormalities of signaling factors
Disruptions	Morphologic defects of an organ or of larger region resulting from extrinsic breakdown or interference with an originally normal developmental process

Modified from Spranger JW, Brill PW, Poznanski AK. Bone dysplasias: an atlas of genetic disorders of skeletal development. 2nd ed. New York: Oxford University Press; 2002.[2]

TABLE 40.2 Birth Prevalence of Skeletal Dysplasias

Skeletal Dysplasia	Prevalence per 100,000 Births
LETHAL DYSPLASIAS	
Thanatophoric dysplasia	2.4 to 6.9
Achondrogenesis	0.9 to 2.3
Osteogenesis imperfecta type IIA	1.8
Hypophosphatasia congenita	1.0
VARIABLE-PROGNOSIS DYSPLASIAS	
Rhizomelic chondrodysplasia punctata	0.5 to 0.9
Campomelic dysplasia	1.0 to 1.5
Asphyxiating thoracic dystrophy	0.8 to 1.4
Ellis–van Creveld syndrome	0.7
Osteogenesis imperfecta (other types)	1.8
NONLETHAL DYSPLASIAS	
Heterozygous achondroplasia	3.3 to 3.8
OVERALL	24.4 to 75.0

identified correctly by prenatal ultrasound; however, only 13 of 27 (48%) received an accurate specific antenatal diagnosis.[10] Eight of 14 (57%) underwent a substantial change in genetic counseling when cytogenetic (including microarray), molecular, pathologic, and imaging findings were combined. Thus although the ultrasound diagnosis of a lethal skeletal dysplasia is highly accurate (85%-95%), a correct specific diagnosis is obtained in only 40% to 55% of cases.[8-10] The addition of correlative radiographs, cytogenetic analysis (including microarray and whole genome sequencing techniques), and pathologic examination can provide a correct specific diagnosis in up 86%.[11]

Nonetheless, an accurate prenatal determination of the lethality of a given skeletal dysplasia is crucial in helping couples with decision making. Typically, a combination of ultrasound, radiologic, and genetic investigation is required to classify a specific congenital musculoskeletal disorder.[11] A prenatal diagnosis of a musculoskeletal anomaly will provide an opportunity for genetic counseling, resulting in pregnancy termination or tertiary-level care depending on the parental decision. A multidisciplinary approach involving the medical imaging team, obstetrician, medical geneticist, and perinatologist is important in optimizing the accuracy of prognosis and determining recurrence risk.[11] If local expertise is unavailable and/or the diagnosis is unknown, consultation with experts in the field should be considered. Detailed and up-to-date information regarding the molecular tests available for the diagnosis of skeletal dysplasias is available at various organizations.

Resources for Molecular Tests for Diagnosis of Skeletal Dysplasias

European Skeletal Dysplasia Network (http://www.esdn.org)
Gene test (https://www.genetest.org)
International Skeletal Dysplasia Society (www.isds.ch)

This information is crucial to the family and to medical personnel involved in planning the management of both current and future pregnancies. This chapter uses a "key features" approach to the sonographic diagnosis of the common skeletal dysplasias to aid in the classification and differential diagnosis.

NORMAL FETAL SKELETON

Development

The high level of intrinsic contrast of the fetal extremities places them among the earliest structures that can be evaluated by ultrasound. By the end of the embryonic period, the differentiation of bones, joints, and musculature is similar to that of an adult and is associated with increased fetal movements.[12,13] Transvaginal ultrasound can demonstrate the limb buds by 7 weeks' gestation, and the foot and hand plates are visible by 8 weeks.[14] Osteogenesis begins in the clavicle and mandible by 8 weeks as well. By 11 or 12 weeks, the **primary ossification centers** of the long bones (e.g., scapula, ileum), as well as the limb articulations and phalanges, can be identified. The ischium, metacarpals, and metatarsals ossify during the fourth month of gestation. The pubis, calcaneus, and talus ossify during the fifth and sixth months. Ossification of the other tarsal and carpal bones occurs postnatally.[15] The direction of growth in the long bones is from proximal to distal, and the lower extremities lag slightly behind the upper extremities.[13]

Of the **secondary ossification centers** in the long bones, only the distal femoral epiphysis, the proximal tibial epiphysis, and occasionally the proximal humeral epiphysis ossify prenatally (Fig. 40.1). The unossified epiphysis appears hypoechoic, with a variably, mildly echogenic center. Ossification begins centrally. The distal femoral epiphysis can ossify as early as 29 weeks' menstrual age and as late as 34 weeks. When it measures greater than 7 mm, the menstrual age is generally later than 37 weeks.[16,17] The proximal tibial epiphysis begins to ossify by 35 menstrual

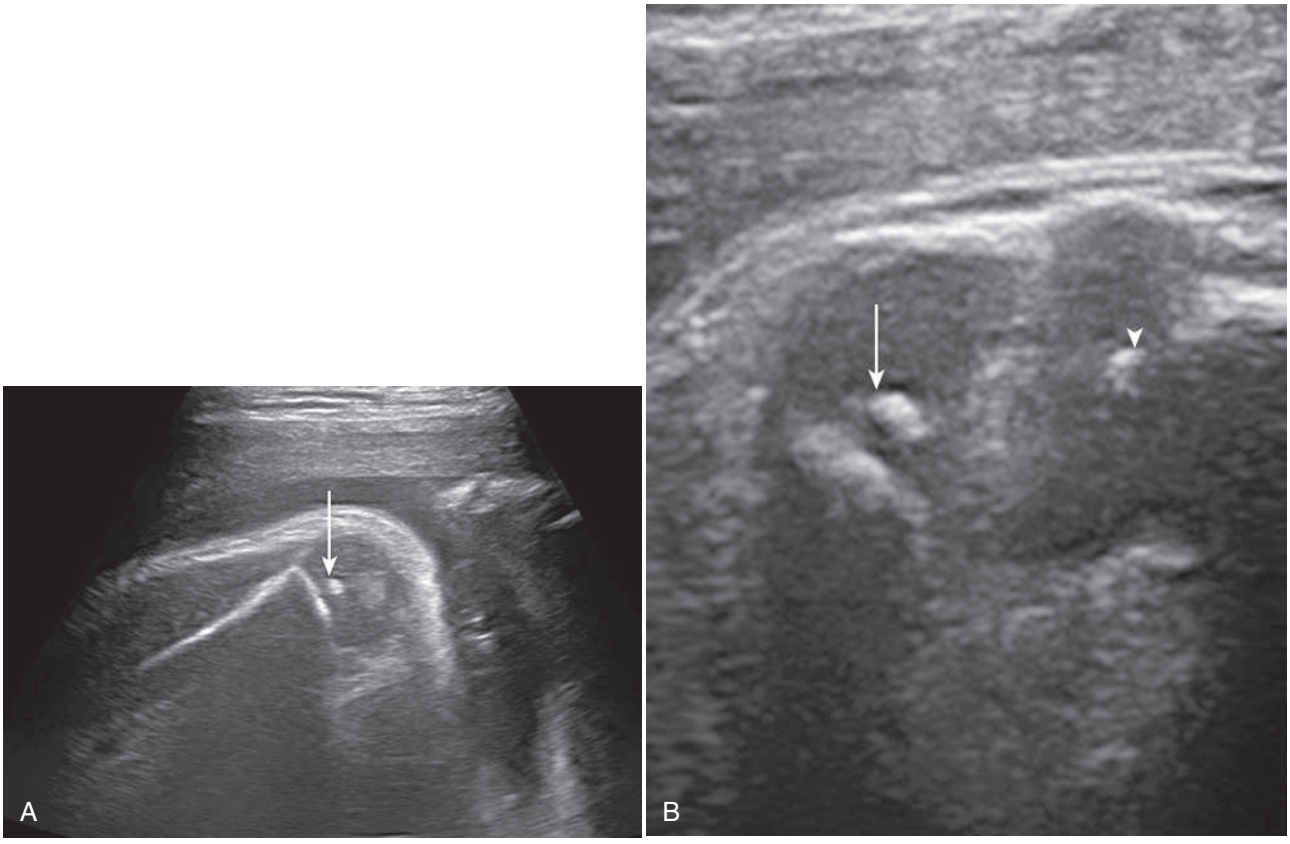

FIG. 40.1 Secondary Ossification Centers in Fetus at 38 Weeks' Gestational Age. (A) View of the femur and distal femoral ossification center *(arrow).* **(B)** View of distal femur and proximal tibia with distal femoral ossification center *(arrow)* and proximal tibial ossification center *(arrowhead).*

weeks.[17] In uncomplicated pregnancies the combination of a distal femoral epiphysis of 3 mm or greater and the presence of a proximal tibial epiphysis is considered a reliable marker of pulmonary maturity.[18] **Intrauterine growth restriction** (IUGR) is associated with a delay in ossification of the distal femoral epiphysis and proximal tibial epiphysis. The earliest secondary epiphysis to ossify is the **calcaneus,** at approximately 20 weeks' gestation, thus marking the earliest point that assessment of delayed ossification of the secondary epiphyseal centers can be attempted.

The fascia within the muscle is highly echogenic compared with the relatively hypoechoic cartilage. The fetal musculature is slightly more echogenic than the relatively hypoechoic cartilage. The fetal joint spaces, in particular the knee, appear echogenic because of the combination of synovium, fat, and microvasculature.[13] The normal development and ultimate function of the fetal musculoskeletal system depend on **fetal movements,** which start by the second half of the first trimester. In the absence of normal fetal motion, the bones and muscles will be underdeveloped, the chest will be narrow, and joint contractures and postural deformities can occur.

Extremity Measurements

It is a standard practice to assess **femur length** (FL) as part of the evaluation of fetal size and morphology. Although measurement of all the long bones is not required in a routine obstetric ultrasound, an overall evaluation of the fetal skeleton should be performed to ensure the presence and bilateral symmetry of the tubular bones. Available charts provide guidance for correlating the length of the extremities with the gestational age (Table 40.3).

The longest femur measurement, excluding both proximal and distal epiphyses, is usually chosen. The inclusion of the **distal femur point,** or the specular reflection of the lateral aspect of the distal femoral epiphysis cartilage, is the most common reason for overestimating FL[19] (Fig. 40.2A). An oblique FL measurement will result in underestimate of length. The lateral border of the femur in the near field of the transducer appears straight, whereas the medial border of the femur in the far field has a curved appearance[20] (Fig. 40.2B).

In the **lower extremity** the lateral bone is the fibula and the medial bone is the tibia. The tibia and fibula end at the same level distally. In the **upper extremity,** pronation may cause the radius and ulna to cross, so it can be difficult to distinguish the ulna from the radius using lateral and medial positions. The ulna is distinguished from the radius by its longer proximal extent and its relationship to the fifth digit distally. The radius and ulna end at the same level distally. Demonstration of this relationship will effectively exclude the majority of radial ray defects.

The **clavicles** grow in a linear fashion, approximately 1 mm per week, and the gestational age in weeks is approximately the length of the clavicle in millimeters from 14 weeks to term. By 40 weeks' gestation, the clavicles measure approximately 40 mm.[21]

TABLE 40.3 Normal Extremity Long-Bone Lengths and Biparietal Diameters at Different Menstrual Ages[a]

Menstrual Age (Weeks)	Biparietal Diameter	BONE					
		Femur	Tibia	Fibula	Humerus	Radius	Ulna

Foot length is measured from the skin edge overlying the calcaneus to the distal end of the longest toe (the first or second toe) on either the plantar or the sagittal view[22-24] (Fig. 40.3). The ossified FL is almost equivalent to the foot length, resulting in a normal **femur-to-foot length ratio** of approximately 1.0. This ratio remains relatively constant from the 14th week of gestation onward. If the fetus is constitutionally small or there is symmetrical IUGR, the ratio is generally 0.9 or greater. In most skeletal **dysplasias** characterized by short limbs, the ratio is generally less than 0.9 because of the relative sparing of the hands and feet. The greater the deviation is from the lower limits of the norm, the greater is the disproportion and usually also the severity.

SONOGRAPHIC EVALUATION OF FETUS WITH SKELETAL DYSPLASIA

A prenatal evaluation of a skeletal dysplasia is indicated if there is a positive family history or an abnormal length or appearance of the bones at ultrasound.

Assessment of Skeletal Dysplasias: Key Features

Family history
Serial measurements
Degree of limb shortening
Pattern of limb shortening
Presence of bowing, fractures, and angulations
Spine
Thoracic measurements
Hands and feet
Calvarium and facial features

Positive Family History

A positive family history of a sibling or parents affected by a skeletal dysplasia or consanguineous parents should prompt an intensive ultrasound investigation with a focus on targeted

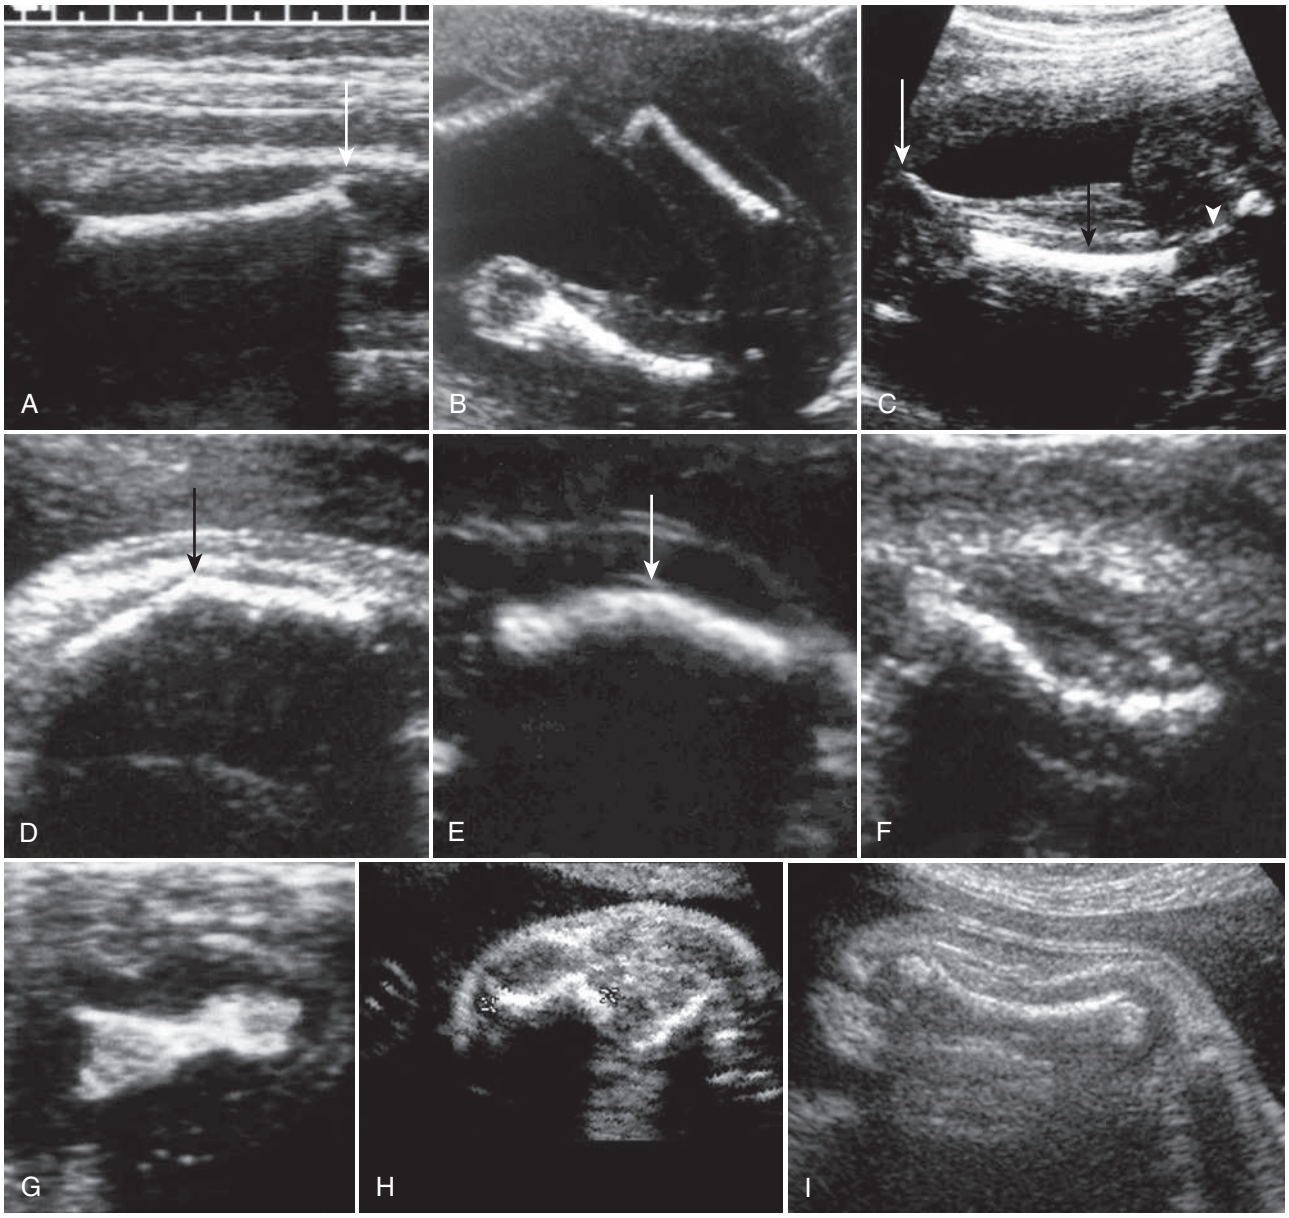

FIG. 40.2 Normal Femur and Spectrum of Abnormal Appearances. (A) Normal femur: measure the longest length, excluding the proximal and distal epiphyses and the specular reflection of the lateral aspect of the distal femoral epiphysis *(arrow).* **(B)** Normal femur in the near field, with straight lateral border versus the curved medial border in the far field of the transducer. **(C)** Isolated **hypoplastic left femur** *(arrowhead),* with normal tibia *(black arrow)* and foot *(white arrow).* **(D) Osteogenesis imperfecta type I.** Isolated femoral fracture with acute angulation *(arrow).* **(E) Campomelic dysplasia.** Mild shortening and a gently curved ventral femoral bowing *(arrow).* **(F) Osteogenesis imperfecta type IIA.** Bowed femur with multiple discontinuities representing fractures. **(G) Hypophosphatasia.** Severe micromelia (relatively broad metaphysis, short diaphysis). **(H) Thanatophoric dysplasia.** Curved, **"telephone receiver"** femur. **(I) Chondrodysplasia punctata.** Third-trimester appearance of a **stippled epiphysis.** (**C** courtesy of Ants Toi, MD, University of Toronto; **D** and **E** courtesy of Shia Salem, MD, University of Toronto.)

abnormalities and serial measurements. A history of consanguinity is important because many of the skeletal dysplasias have an autosomal recessive mode of inheritance. **Heterozygous achondroplasia,** the most common nonlethal skeletal dysplasia, has an autosomal dominant pattern of inheritance. Family history may not be helpful because 80% of cases are caused by a new mutation.

Abnormal Bone Length or Appearance

The fetal femur is often the only long bone routinely measured at the second-trimester ultrasound evaluation. An abnormal FL is traditionally defined as below 2 standard deviations (SD) for gestational age.[25,26] Using this cutoff, 2.5% of all fetuses would be classified as having short limbs. This exceeds the expected frequency of skeletal dysplasias, and thus additional investigations are needed to separate fetuses with a skeletal dysplasia from those with no underlying pathology and those with other diagnoses associated with growth restriction.

When one or all of the long bones measure less than 2 SD for gestational age, a follow-up ultrasound should be done in 3 or 4 weeks to evaluate the interval growth. If the interval femur growth is normal, there is a high likelihood that the fetus does

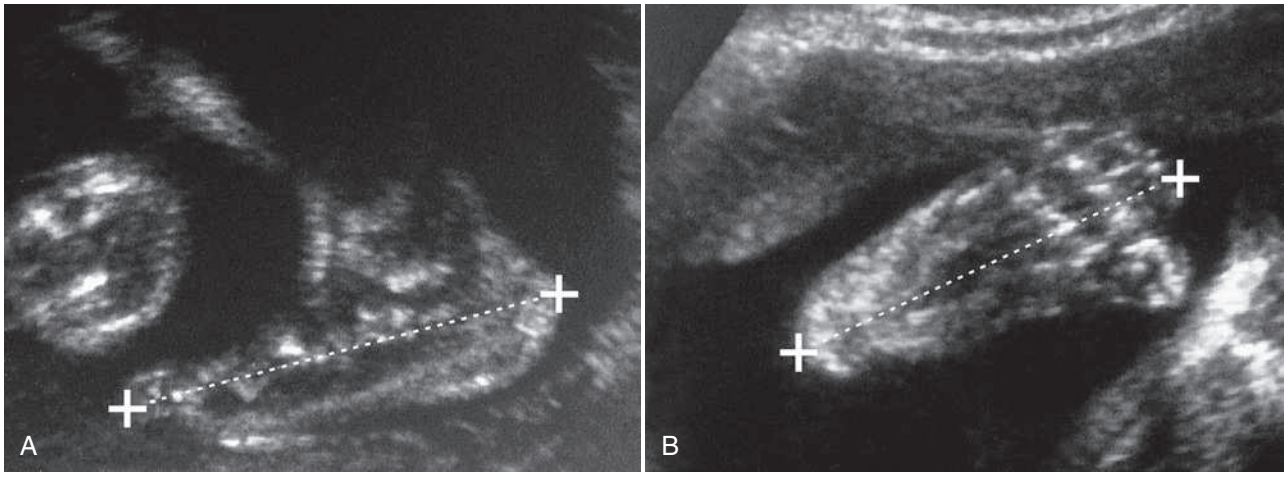

FIG. 40.3 Foot Length Measurement. From the skin edge overlying the calcaneus to the distal end of the longest toe. **(A)** Sagittal measurement; note the normal squared appearance of the heel. **(B)** Plantar measurement.

not have skeletal dysplasia. However, further deviation from the mean by at least 1 SD suggests the presence of a skeletal dysplasia or severe IUGR. When FL measures below 4 SD for gestational age, there is a high likelihood of a skeletal dysplasia. Kurtz et al.[25] have shown that the number of millimeters below the −2 SD line is a simple screening tool to evaluate femoral shortening with the following guidelines:

- If FL is 1 to 4 mm below the −2 SD point, further serial measurements are required to determine if a skeletal dysplasia is present.
- If FL is more than 5 mm below the −2 SD point, there is a high likelihood of a skeletal dysplasia.

The most common cause of a so-called **short femur** is either inaccurate dating or a normal variant in a constitutionally small fetus, which may be associated with a parental or family history of less-than-average stature. In about 13% of cases, a remeasurement will bring the FL into a normal range, likely representing a false-positive diagnosis rather than a growth spurt.[27] Isolated, symmetrical short femurs identified at the second midtrimester ultrasound evaluation are helpful in identifying a group of fetuses at increased risk for low birth weight, small for gestational age, or severe IUGR.[27-29] Typically, these fetuses will also have small abdominal circumference measurements.

Occasionally, fetuses with severe IUGR will have greatly shortened long bones.[30] Associated findings of normal or decreased skin fold measurements, oligohydramnios, abnormal placental morphology, and abnormal Doppler waveforms suggest the diagnosis of IUGR,[31] whereas redundant, thickened skin folds and polyhydramnios typically accompany short-limb dysplasias.

Nonlethal skeletal dysplasias such as **heterozygous achondroplasia** are often not evident before 20 weeks' gestation. The findings of short long bones before 20 weeks indicate a more serious and usually fatal skeletal dysplasia. As a rule, the earlier the detection of limb shortening, the worse is the prognosis. Virtually all cases diagnosed in first trimester are considered severe skeletal dysplasias, with the large majority representing lethal conditions.[32] First-trimester skeletal biometry tables are available.[33] Although mild, isolated shortening of the femur indicates increased risk for **trisomy 21** by 1.5-fold, other factors are more important for assessing this risk.[34]

The **pattern of limb shortening** should be assessed to determine which long-bone segments are most severely affected[9,35] (Fig. 40.4). Rather than millimeters, we find it useful to standardize measurements to "weeks of size" to determine disproportion. There are four main patterns of shortening of the long bones: **rhizomelia,** shortening of the proximal segment; **mesomelia,** shortening of the middle segment; **acromelia,** shortening of the distal segment; and **micromelia,** shortening of the entire limb (mild, mild/bowed, or severe).

Patterns of Limb Shortening

Rhizomelia: shortening of proximal segment (femur, humerus)
Mesomelia: shortening of middle segment (radius, ulna/tibia, fibula)
Acromelia: shortening of distal segment (hands, feet)
Micromelia: shortening of entire limb (mild, mild/bowed, or severe)

The shape, contour, and density of the bones should be assessed for the presence of bowing, angulation, fracture, or thickening. **Bowing** is a nonspecific finding, typically caused by underlying osseous fragility. Although more than 40 distinct disorders are associated with bowed, bent, or angulated femurs, most cases can be accounted for by three relatively frequent disorders: **campomelic dysplasia, thanatophoric dysplasia,** and **osteogenesis imperfecta** (OI).[36] Patients with OI types I and IV can present with apparently isolated in utero bowing of the long bones (especially the femur) without frank fractures (see Fig. 40.2D). Anterior bowing of the tibia, femur, and humerus may suggest the diagnosis of campomelic dysplasia; other more specific findings such as **hypoplastic scapulae** and **cervical kyphosis** are typically present and help distinguish campomelic dysplasia

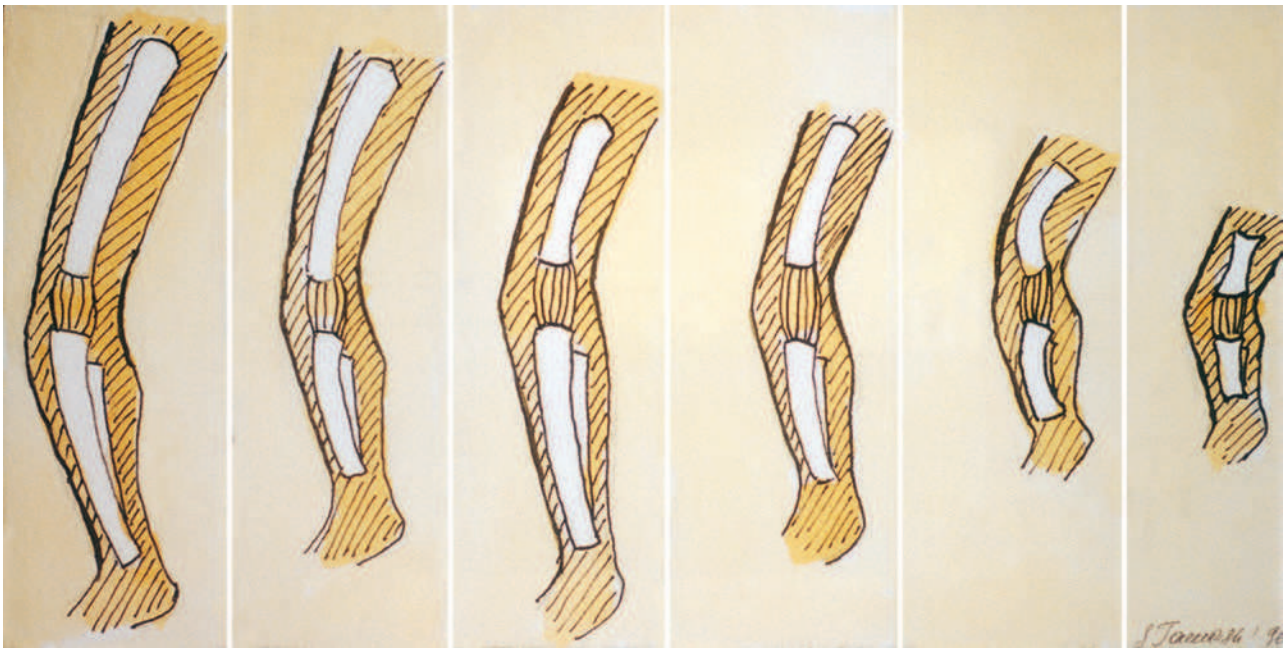

FIG. 40.4 Patterns of Limb Shortening. *Left to right,* Normal, mesomelia, rhizomelia, mild micromelia, mild and curved micromelia, and severe micromelia. (Courtesy of J. Tomash, MD, University of Toronto.)

from OI and thanatophoric dysplasia, which are both more common. Bone **fractures** may appear as angulations or interruptions in the bone contour or as thick, wrinkled contours corresponding to repetitive cycles of fracture and callus formation (see Fig. 40.2F). **Decreased or absent acoustic shadowing** is a marker for decreased mineralization of the long bones. When evident, this is helpful in narrowing the differential diagnosis, but in its absence the bone mineralization may still be abnormal.

The **spine** is assessed for **segmentation anomalies, kyphoscoliosis, platyspondyly** (flattened vertebral bodies), **demineralization, myelodysplasia,** and **caudal regression syndromes.** Although platyspondyly is the most common spine abnormality, it is a challenging prenatal diagnosis.[37] Demineralization of the spine can result in the appearance of ghost vertebrae or nonvisualization of one or all of the three ossification centers (Fig. 40.5). A progressively narrowed lumbar interpedicular distance is associated with homozygous **achondroplasia;** a widened interpedicular distance is associated with **myelodysplasia.** Three-dimensional imaging may provide a large field of view and additional details that may be helpful in achieving a diagnosis (Fig. 40.6).

The most reliable prognostic indicator of the lethality of a given skeletal dysplasia is **pulmonary hypoplasia.** Ultrasound is 85% to 95% accurate in the diagnosis of a lethal skeletal dysplasia on the basis of pulmonary hypoplasia.[8,9] The **thoracic circumference** is measured at the level of the four-chamber heart and compared to nomograms (see Chapter 36, Table 36.2). A thoracic-to-abdominal circumference ratio of less than 0.8 is considered abnormal. The **thoracic length** (from the neck to the diaphragm) is also measured, and the ribs are assessed to determine if they are short. At the level of the four-chamber cardiac view, the ribs should normally encircle at least 70% of the thoracic circumference.[38] The ribs remain in a relatively horizontal plane, as does the cardiac axis, facilitating this evaluation. In a sagittal view, a markedly narrowed anteroposterior diameter of the thorax is associated with pulmonary hypoplasia. In the coronal view, a concave or bell-shaped contour is associated with pulmonary hypoplasia (Fig. 40.7).

The **hands and feet** are examined for deformities such as **clubfoot** or **clubhand.** A **hitchhiker thumb,** or abducted thumb, is associated with **diastrophic dwarfism.** Fixed postural deformities may suggest the diagnosis of **arthrogryposis multiplex congenita. Polydactyly** is associated with **short-rib polydactyly syndromes, Ellis–van Creveld syndrome, asphyxiating thoracic dystrophy,** and some chromosomal abnormalities.

The fetal **cranium** is assessed for the presence of **macrocranium, frontal bossing, cloverleaf skull deformity,** underlying brain abnormalities, and facial abnormalities, such as **saddle nose, hypertelorism,** and **cleft lip and palate.** An abnormal cranial contour may indicate **craniosynostosis** or premature fusion of the sutures. The most reliable sonographic sign of demineralization is increased compressibility of the calvarium. This finding is typically present in fetuses with **osteogenesis imperfecta type II** and **hypophosphatasia.** The falx may appear abnormally bright or echogenic compared to the demineralized calvarium.

The **ribs** are assessed to ensure an adequate length, thus minimizing the risk of pulmonary hypoplasia, and are examined for abnormal number or appearance.[39] The finding of an abnormal number of fetal ribs is an isolated finding of no clinical importance in the majority of cases,[39] associated with minor anomalies in a smaller group (29%) and only occasionally associated with severe malformations. Associated syndromes include **Poland syndrome, VACTERL** association (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula, renal agenesis

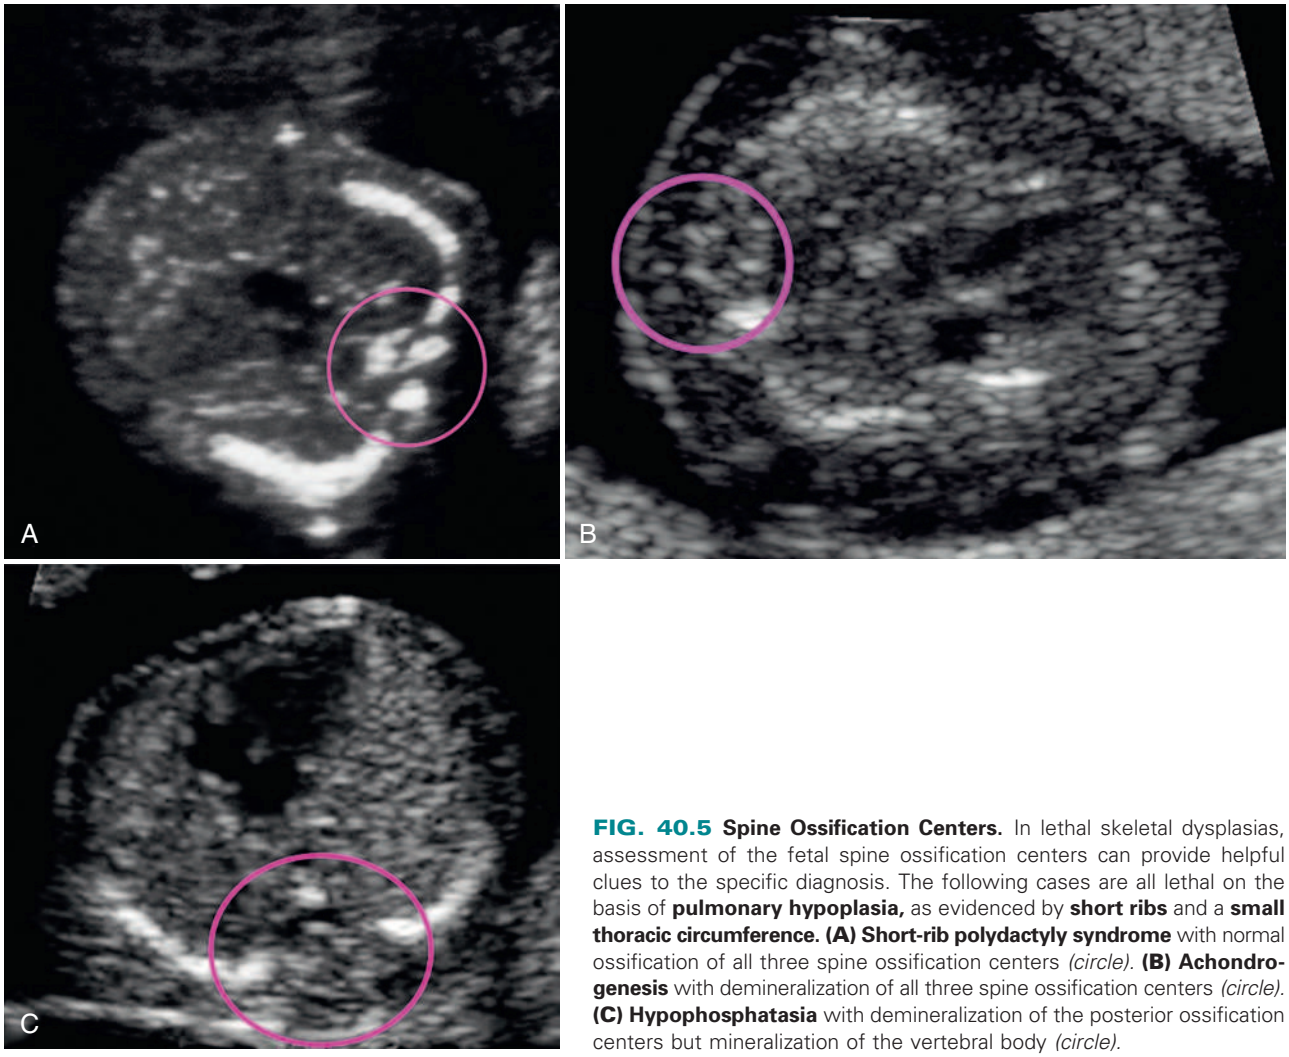

FIG. 40.5 Spine Ossification Centers. In lethal skeletal dysplasias, assessment of the fetal spine ossification centers can provide helpful clues to the specific diagnosis. The following cases are all lethal on the basis of **pulmonary hypoplasia,** as evidenced by **short ribs** and a **small thoracic circumference. (A) Short-rib polydactyly syndrome** with normal ossification of all three spine ossification centers *(circle).* **(B) Achondrogenesis** with demineralization of all three spine ossification centers *(circle).* **(C) Hypophosphatasia** with demineralization of the posterior ossification centers but mineralization of the vertebral body *(circle).*

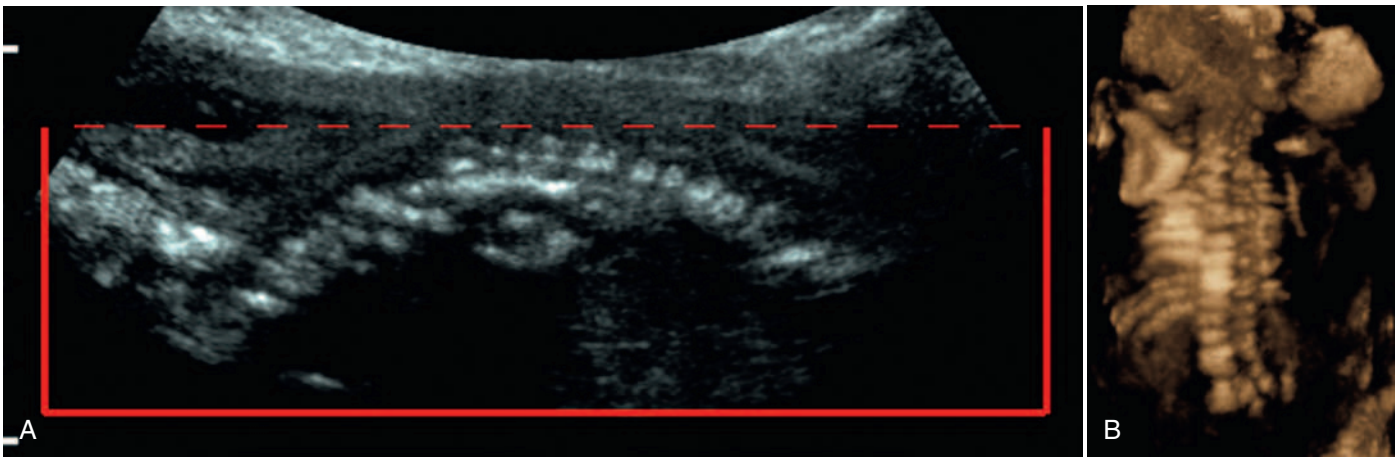

FIG. 40.6 Spondylocostal Dysostosis at 22 Weeks. (A) Sagittal image demonstrates abnormal spine segmentation. **(B)** Three-dimensional rendering of the spine further clarifies the abnormal development of the spine and ribs with abnormal misshapen and abnormally fused vertebrae leading to scoliosis, short trunk length, and widely variant rib spacing.

Calipers measure the scapula. **(B)** Triplet B shows a **bell-shaped thorax. (C)** Radiograph of triplet B confirms a bell-shaped thorax consistent with pulmonary hypoplasia.

FIG. 40.8 Normal Ribs: Three-Dimensional Ultrasound.

and dysplasia, limb defects), **campomelic dysplasia,** and chromosome abnormalities. Three-dimensional ultrasound volume images aid in accurately counting the number of ribs (Fig. 40.8).

Ultimately, a detailed examination of each bone may be required to determine the fetal condition. Specific dysmorphic features of bones (e.g., clavicular or scapular hypoplasia; aplasia of fibula, tibia, or radius; platyspondyly) can be helpful to further define a specific skeletal dysplasia. A detailed evaluation of the cardiovascular, genitourinary, gastrointestinal, and central nervous system should be done concurrently with the musculoskeletal evaluation.

Dizygotic **twin pregnancies** are at similar risk for skeletal abnormalities as singleton pregnancies, and the frequency is increased two to three times in monozygotic twins. Both monozygotic and dizygotic twins can be discordant for genetic and nongenetic skeletal abnormalities. Twin pregnancies are generally discordant and overall, about 15% of twins are concordant for the same anomaly.[40,41]

Additional Diagnostic Techniques

Three-Dimensional Ultrasound

Three-dimensional ultrasound is becoming an increasingly useful complement to two-dimensional ultrasound in diagnosis of skeletal dysplasia and pulmonary hypoplasia. High-contrast structures such as the fetal skeleton are especially amenable to three-dimensional ultrasound-rendering software and post-processing techniques.[42] Surface-rendering capabilities are particularly useful for visualizing subtle facial dysmorphism (such as low-set or deformed ears, micrognathia, or flattening of the facial profile associated with midface hypoplasia), evaluating cranial distortion due to craniosynostosis, or assessing hand and foot abnormalities.[43] However, there are insufficient published data to gauge the diagnostic performance of this modality[44-46] (Fig. 40.9).

Radiography

The role of **prenatal radiography** is limited. Typically, two films might be performed: an anteroposterior view, placing the fetus over the hollow of the pelvis, and an angulated view, with the fetus projected down, away from the maternal sacrum. The appearance of short limbs of normal shape and the presence of growth recovery lines can be useful in distinguishing severe IUGR from a skeletal dysplasia.[31] In contrast, **postnatal radiography** plays an extremely important role in defining the characteristic radiologic features found in many skeletal anomalies.

Three-Dimensional Computed Tomography

Three-dimensional low-dose **computed tomography** (CT) may have a better diagnostic yield than two-dimensional ultrasound

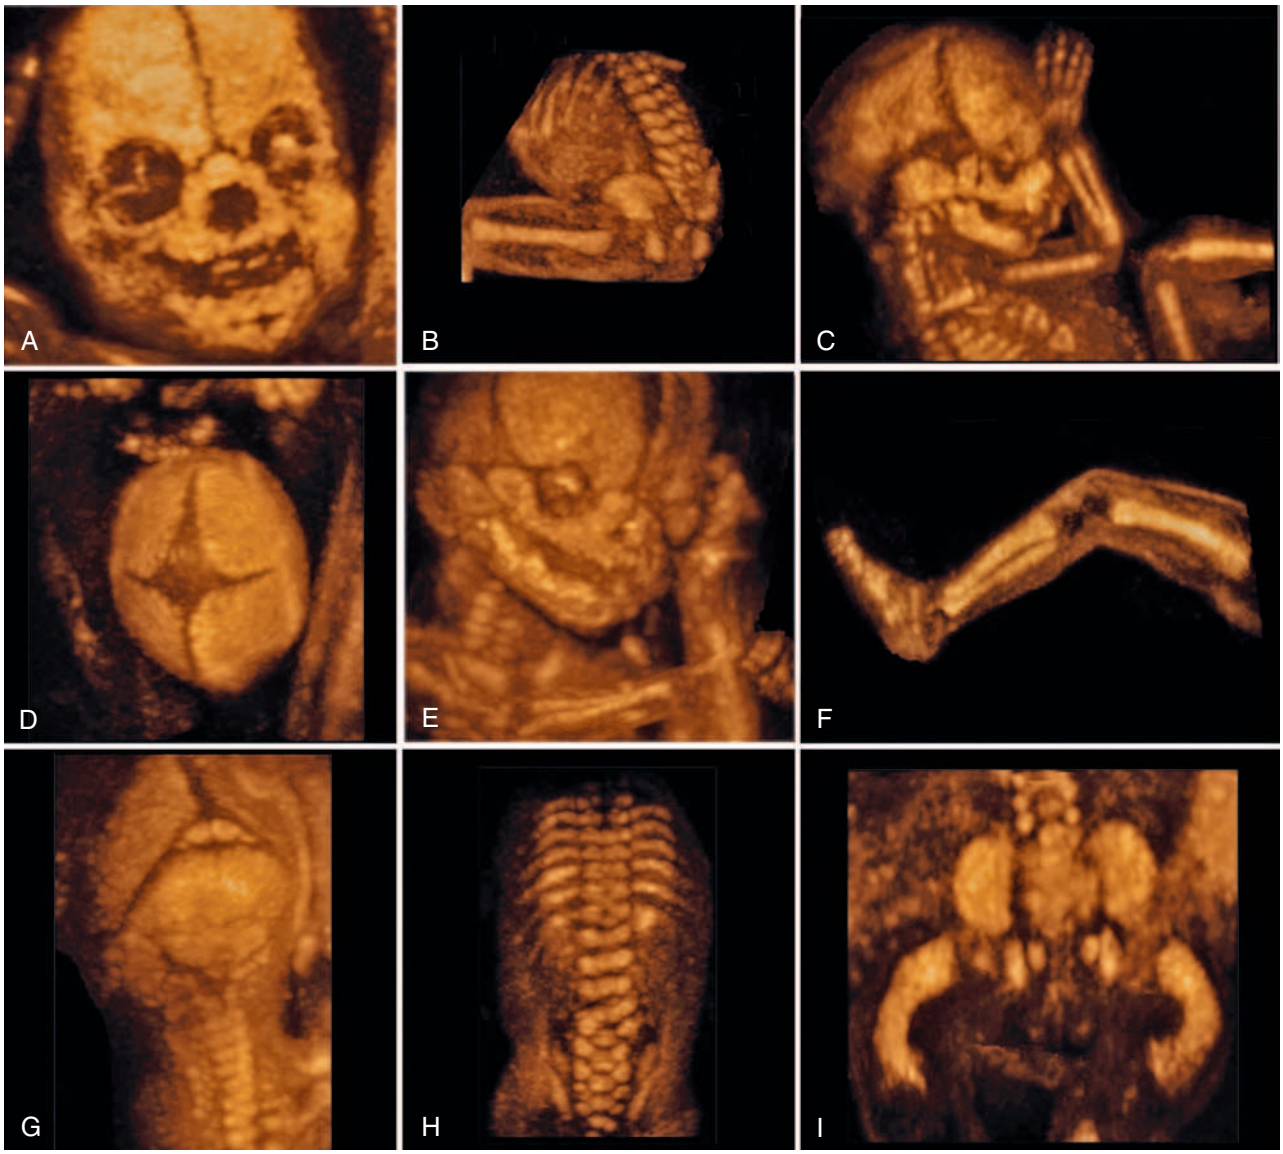

FIG. 40.9 Collage of Three-Dimensional Images. (A) Normal skull at 22 weeks, frontal aspect. **(B)** Femur and iliac bone at 22 weeks. **(C)** Upper extremity at 22 weeks. **(D)** Normal skull at 22 weeks, superior aspect. **(E)** Face and skull at 22 weeks. **(F)** Normal lower limb at 22 weeks, profile. **(G) Wormian bones,** posterior fontanelle. **(H) Hemivertebrae** at 23 weeks. **(I) Osteogenesis imperfecta;** note abnormally shortened, curved, and thickened femurs. (Courtesy of Dr. Bernard Benoit.)

and may provide a valuable complementary diagnostic tool in the appropriate clinical situation.[43,47] It is important to take into consideration the fetal radiation dose, which has been estimated to be in the 3-mGy range. However, new dose reduction techniques such as iterative reconstruction are estimated to reduce the dose by as much as 80%. Postmortem three-dimensional CT scan[48] may provide a "virtual autopsy," particularly when autopsy has been declined.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) plays a relatively limited role in the assessment of the fetal skeletal dysplasia. However, in cases with inconclusive ultrasound findings and for cases in which MRI is expected to provide important additional information, MRI may be useful.[49] MRI can also be helpful in the context of "virtual autopsy" for families who have declined autopsy.[50]

Molecular Diagnosis

Molecular confirmation of suspected skeletal dysplasia during pregnancy has traditionally been of limited usefulness because of the length of time needed to obtain a result, especially if the differential diagnosis required sequencing of several genes. The advent of next-generation sequencing technologies is now enabling the simultaneous examination of multiple genes in a reasonable time frame. It should be noted, however, that negative molecular testing does not exclude the diagnosis of a skeletal dysplasia and the prognosis must be based on the imaging findings.

Prenatal diagnosis of monogenic disorders presenting with ultrasound abnormalities traditionally required invasive procedures such as chorionic villus sampling or amniocentesis for obtaining fetal cells and DNA. More recently the noninvasive approach of genetic analysis using circulating cell-free fetal DNA has been utilized as an aid to sonographic prenatal diagnosis of fetal skeletal dysplasia, thus eliminating the risk of fetal loss associated with invasive testing.

Genetic defects have been identified in approximately 70% of the more than 436 skeletal dysplasias.[6] Cell-free fetal DNA testing allows for testing an early point in the pregnancy, prior to ultrasound diagnosis, and thus may be appropriate for a fetus known to be at risk for having skeletal dysplasia because of an affected parent (for autosomal dominant conditions), a carrier mother (for an X-linked condition), or parents identified as being carriers of an autosomal recessive skeletal dysplasia (due to a personal or family history of an affected child or fetus). Finding the diagnosis is important not only for providing early prenatal diagnosis (before diagnostic findings are seen on ultrasound) but also for preimplantation diagnosis in at-risk families.

If both parents are affected (either with the same or a differing autosomal dominant skeletal disorder), the fetus is at 25% risk of inheriting both conditions and this generally causes a more severe skeletal dysplasia and is frequently lethal. In cases where the mutation status of the parents is known, a molecular diagnosis can distinguish between a fetus that has inherited neither dysplasia, one dysplasia, or both.

If the risk of an affected fetus is relatively low, as when only one parent has an autosomal recessive skeletal dysplasia or each of the parents is affected with a different type of autosomal recessive skeletal dysplasia, the appropriateness of molecular diagnosis is less clear. For couples with a previously affected fetus with a de novo dominant disorder, the recurrence risk is probably less than 1% (due to gonadal mosaicism). Nevertheless, prenatal diagnosis should be discussed and performed if the woman or couple requests it.

When the diagnosis remains unknown, the involvement of specialists in skeletal dysplasias may be helpful in determining the diagnosis. It is crucial to obtain postnatal radiographs, fetal or newborn DNA, and fibroblast culture to try and delineate the diagnosis, the causative gene, and gene mutation. This may help in preimplantation or prenatal diagnosis in future pregnancies.

LETHAL SKELETAL DYSPLASIAS

The lethal skeletal dysplasias are characterized by severe **micromelia** and small thoracic circumference with **pulmonary hypoplasia.**[51] The most important determinant of lethality is the presence and degree of pulmonary hypoplasia.[11] In a prospective series by Krakow et al., lethality was accurately predicted in 96.8% of cases.[8] It is important to use multiple parameters to obtain the most accurate prediction of lethality, typically related to the pulmonary hypoplasia associated with a small chest. This extremely high accuracy of the designation of a lethal skeletal dysplasia is important for the management of the pregnancy, delivery, and the newborn, if alive.

Features Suggestive of Pulmonary Hypoplasia

- Thoracic circumference < fifth percentile, measured at the level of the four-chamber view (axial view)
- Thoracic-to-abdominal circumference ratio < 0.6
- Short thoracic length (measured from the neck to the diaphragm) as compared to nomograms
- Markedly narrowed anteroposterior diameter (sagittal view)
- Concave or bell-shaped contour of the thorax (coronal view)
- Femur length–to-abdominal circumference < 0.16

J Ultrasound Med. 2014;33(6):1085-1090.[53]

A comparative study of eight methods for the prediction of fetal lung hypoplasia determined that the lung volumes and the thoracic circumference to abdominal circumference ratios performed best. However, the majority of these studies were performed in fetuses with congenital diaphragmatic hernia and may not be generalizable to the skeletal dysplasia population.[6,54] Other studies showed that the femur-to-abdomen ratio (<0.16) is more accurate in establishing lethality.[53]

Is There a Lethal Skeletal Dysplasia?

CHARACTERISTIC FEATURES
Severe micromelia
Pulmonary hypoplasia

KEY DISTINGUISHING FEATURES
Abnormal mineralization
Fractures
Presence or absence of macrocranium
Thoracic length

In many fetal skeletal dysplasias, the skin and subcutaneous layers continue to grow at a rate proportionately greater than the long bones, resulting in **relatively thickened skin folds,** on occasion mistaken for hydrops fetalis. **Polyhydramnios** is common and may be related to a variable combination of esophageal compression by the small chest, gastrointestinal abnormalities, micrognathia, and/or hypotonia.

The more common lethal skeletal dysplasias occur in less than 1 in 10,000 births and the rare types occur in less than 1 in 100,000 births. The three most common lethal skeletal dysplasias are thanatophoric dysplasia, achondrogenesis, and OI type II, overall accounting for 40% to 60% of all lethal skeletal dysplasias.[5,8,55] There may be variations depending on location and referral patterns; for example, in our tertiary referral care center, the two most common groups were the OI and the fibroblast growth factor receptor type 3 (FGFR3) chondrodysplasia group, which includes thanatophoric dysplasia.[11]

TABLE 40.4 Severe Micromelia With Decreased Thoracic Circumference

	Mineralization	Fractures	Macrocrania	Short Trunk
Thanatophoric dysplasia[ab]	Normal	No	Yes	No
Achondrogenesis	Patchy demineralization	Occasional	Yes	Yes
Osteogenesis imperfecta type II	Generalized demineralization	Innumerable	No	Yes
Hypophosphatasia congenita	Patchy or generalized demineralization	No	No	No

[a]Homozygous achondroplasia is similar to thanatophoric dysplasia but distinguishable because both parents are affected with the heterozygous form of achondroplasia.
[b]Short-rib polydactyly dysplasias are similar to thanatophoric dysplasia, but no macrocrania or polydactyly is present.

FIG. 40.10 Thanatophoric Dysplasia at 33 Weeks. (A) Anteroposterior (AP) radiograph shows normal mineralization, short curved extremity bones, severe platyspondyly with U-shaped vertebral bodies, and narrow thorax with short ribs. **(B)** AP specimen photograph shows severe micromelia with relative sparing of the feet, telescoping of the redundant skin folds, and small, bell-shaped thorax. **(C)** Profile specimen photograph shows macrocranium, frontal bossing, and flattened nasal bridge.

We recommend using a "key features" approach in assessing degree of micromelia, mineralization, presence of macrocranium, and evaluation of thoracic length and circumference to improve the specificity and ease of diagnosis of lethal skeletal dysplasias (Table 40.4).

Thanatophoric Dysplasia

Thanatophoric dysplasia is the most common lethal skeletal dysplasia, with a prevalence of between 0.24 and 0.69 per 10,000 births. The key ultrasound features are early severe micromelia with rhizomelic predominance and **macrocrania** (disproportionately large head) in association with decreased thoracic circumference but a normal trunk length. Mineralization is normal, without bony fractures. In late gestation (third trimester) the extremities are so foreshortened that they protrude at right angles to the body. The skin folds are thickened and redundant secondary to a relatively greater rate of growth of the skin and subcutaneous layers than the bones (Figs. 40.10 and 40.11, Video 40.1).

Midface hypoplasia/flat nasal bridge

Langer et al.[56] distinguished two types of thanatophoric dysplasia. The more common **type 1** (TD1), usually caused by the R248C and Y373C mutations in the *FGFR3* gene, displays the typical "telephone receiver" shape of the femurs[57,58] (see Fig. 40.2H). This bowed or curved appearance is secondary to the broadened metaphyses at the ends of the severely shortened tubular bones. TD1 is associated with **frontal bossing** and a flattened nasal bridge with **midface hypoplasia.** Occasionally, **craniosynostosis** results in a mild variant of **cloverleaf skull** deformity. **Platyspondyly** is present. In **type 2** (TD2), usually caused by the K650E mutation in the *FGFR3* gene, the femurs are typically straight with flared metaphyses and the skull has a **cloverleaf** or trilobed appearance in the coronal plane that results from premature craniosynostosis of the lambdoid and coronal sutures (Fig. 40.12). Other conditions that may be associated with this unusual skull deformity are **homozygous achondroplasia, campomelic dysplasia,** and **trisomy 13.** Both TD1 and TD2 are autosomal dominant conditions, with all cases caused by new mutations in the *FGFR3* gene. *FGFR* gene mutations are

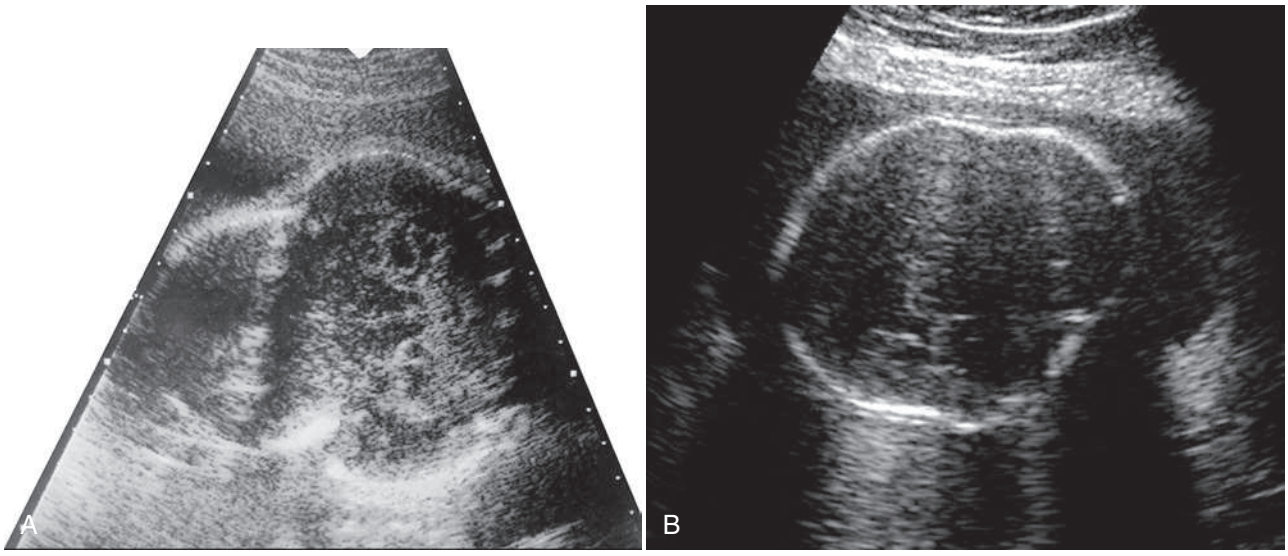

FIG. 40.12 Cloverleaf Deformity of Thanatophoric Dysplasia. (A) Severe variant. **(B)** Mild variant. (Courtesy of Greg Ryan, MD, University of Toronto.)

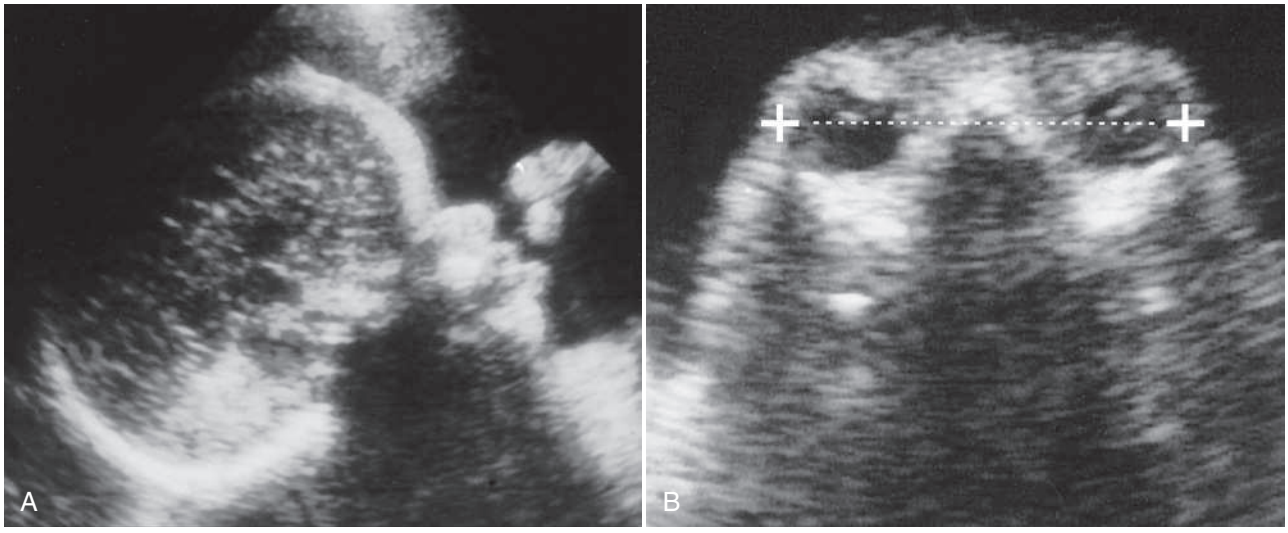

FIG. 40.13 Homozygous Achondroplasia at 34 Weeks. (A) Lateral profile with **macrocranium, frontal bossing,** and **flat nasal bridge. (B)** Axial image through the orbits (*calipers* denote outer orbital diameter) and nasal bones confirms a flat nasal bridge.

also associated with **hypochondroplasia, achondroplasia,** and **acanthosis nigricans (SADDAN syndrome),**[59] as well as a variety of craniosynostoses, including **Crouzon, Apert, and Pfeiffer syndromes.**[58,60]

Thanatophoric dysplasia has many phenotypic similarities to **homozygous achondroplasia.** Both conditions may appear identical from ultrasound and radiographic perspectives. They can be distinguished by the positive family history,[51] in which both parents are affected with the heterozygous form of achondroplasia (Fig. 40.13). Another condition presenting with bowed tubular bones is **campomelic dysplasia,** which can be distinguished from thanatophoric dysplasia by presence or combination of other more specific anomalies such as **hypoplasia of the scapulae** and **micrognathia.**

Platyspondyly, or flattened vertebral bodies, is one of the most characteristic features on anteroposterior radiographs of a thanatophoric dwarf (see Fig. 40.10A). There is a U or H configuration of the vertebral bodies and a relatively increased height of the disc spaces. Platyspondyly appears on ultrasound as a thin vertebral body with a relatively larger, hypoechoic disc space on either side of the vertebral body (Fig. 40.14). The ratio of vertebral body height to vertebral interspace (disc and body) in thanatophoric dysplasia is lower than in normal fetuses. Platyspondyly may also occur in cases of **achondrogenesis** and **OI type II.**[31,51]

Associated central nervous system findings include **holoprosencephaly, agenesis of the corpus callosum, polymicrogyria, heterotopia,** and **ventriculomegaly.** The abnormal deep transverse sulci in the inferior temporal lobes can be visualized on fetal ultrasound routinely at 20 weeks of gestation, thus helping in confirming a specific diagnosis (Fig. 40.15).[61,62] These distinctive features have been identified as early as late first trimester. Prenatal

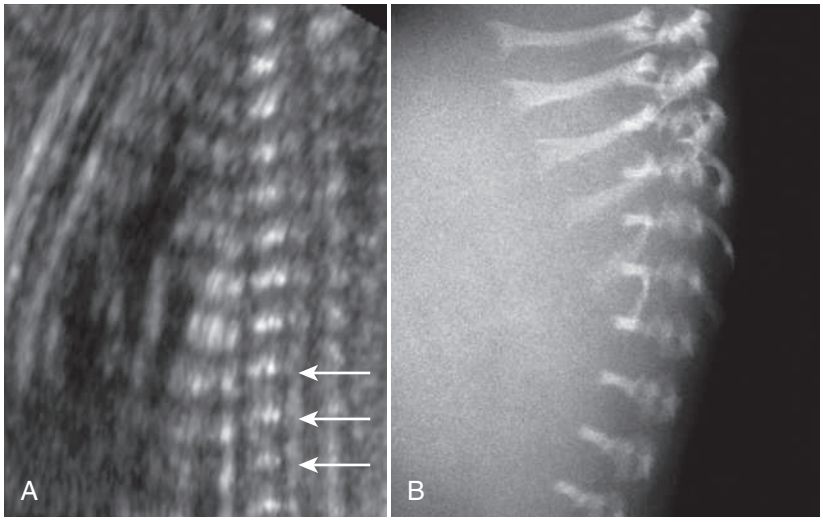

FIG. 40.14 Thanatophoric Dysplasia at 33 Weeks. (A) Platyspondyly appears on ultrasound as a thin vertebral body *(arrows)* with relatively larger hypoechoic intervertebral disc space on either side of the vertebral body. **(B)** Correlative lateral spine radiograph. Note the short ribs with wide-cupped metaphyseal ends.

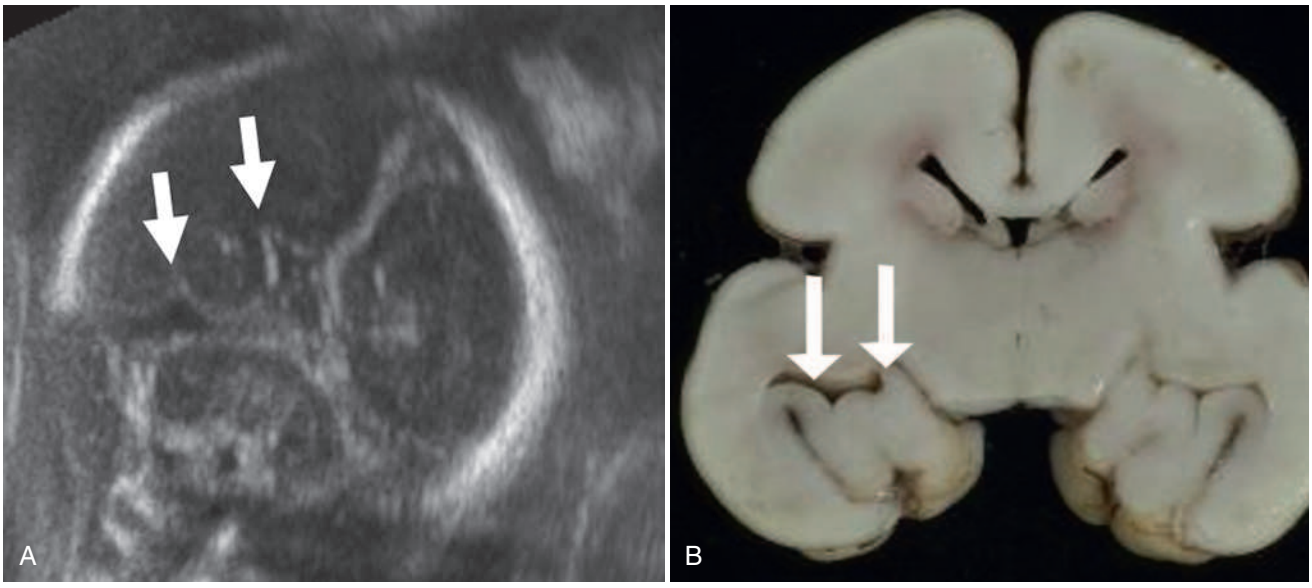

FIG. 40.15 Temporal Lobe Dysplasia in Thanatophoric Dysplasia at 19 Weeks. (A) Modified coronal oblique image demonstrates abnormal temporal lobe gyration with multiple deep sulcation *(arrows).* **(B)** Photograph demonstrates correlation with evidence of deep temporal lobe sulcation *(arrows).*

demonstration of **temporal lobe dysplasia** is variable, likely due to a combination of factors including other striking findings that distract from the diagnosis, lack of dedicated views, and lack of awareness of this feature. Wang et al. demonstrated that 79% of the cases (11/14) had temporal lobe dysplasia detected antenatally even without routine dedicated views.[61] We suggest that in fetuses with severe skeletal dysplasia, specific search for temporal lobe dysplasia using a low axial plane below the level of the biparietal diameter (BPD) image and a coronal oblique plane that includes the cerebellum of midline be added to the institutional protocol to better visualize the temporal lobe in order to improve specificity of diagnosis. Three-dimensional imaging with multiplanar reformats may also demonstrate these findings.

Thanatophoric dysplasia, achondroplasia, and **hypochondroplasia** are all related to the *FGFR3* gene mutation.[51] Temporal lobe dysplasia has been described in children with the latter two conditions; however, the site differs with thanatophoric dysplasia typically showing the abnormal sulcation in the inferior aspect of the temporal lobes versus primarily the medial aspect of the temporal lobes in hypochondroplasia. There is one report of prenatal identification of medial temporal lobe dysplasia on MRI in a case of hypochondroplasia.[63]

Other anomalies may include **horseshoe kidneys, hydronephrosis, congenital heart disease (atrial septal defect and tricuspid insufficiency), radioulnar synostosis,** and **imperforate anus.**[64]

Achondrogenesis

Achondrogenesis is the second most common lethal skeletal dysplasia, with a prevalence of 0.09 to 0.23 per 10,000 births. It is a phenotypically and genetically diverse group of chondrodysplasias characterized by severe **micromelia, macrocranium, decreased thoracic circumference and trunk length,** and **decreased mineralization.**[64,65] The pattern of abnormal mineralization is most marked in the vertebral bodies, ischium, and pubic bones, leading to a greatly shortened trunk length, decreased thoracic circumference, and occasional fractures.[66] Classically, because of abnormal skeletogenesis of the vertebral body, only the two echogenic posterior elements or neural arches appear in a transverse image of the spine. This is in contrast to **hypophosphatasia,** which predominantly involves the posterior elements in the spine with only patchy involvement of the vertebral bodies. Polyhydramnios and thick, redundant skin folds are a common accompaniment of achondrogenesis.[67]

Type 1 achondrogenesis accounts for about 20% of cases and is divided into A and B subtypes (ACG1A and ACG1B).[7,65] ACG1A includes rib fractures, which are not present in ACG1B. Both have autosomal recessive mode of inheritance and thus have a 25% recurrence risk. ACG1A is caused by mutations in *TRIP11,* while ACG1B is caused by mutations in the diastrophic dysplasia sulfate transporter gene. Both ACG1A and ACG1B have a severe form of **micromelia,** evidenced by short, cuboid bones and metaphyseal scalloping with bone spurs at the periphery. Other findings include partial or complete lack of ossification of the calvarium, vertebral bodies, and sacral and pubic bones. Because of the extremely limited skeletal frame, the subcutaneous tissues can appear grotesquely redundant, with multiple telescoped skin folds that may be mistaken prenatally for hydrops fetalis.

Type 2 (AGH2), or the **Langer-Saldino** form, accounts for 80% of achondrogenesis cases. It is caused by a new dominant mutation in the *COL2A1* gene that encodes type II collagen and carries a low recurrence risk. It is characterized by normal calvarial ossification and by absent ossification in the vertebral column and sacral and pubic bones (Fig. 40.16). ACG2 has the least ossification of the vertebral column of all the skeletal dysplasias. The type 2 collagen disorders represent a continuous spectrum from lethal to mild. It may be difficult to come to a firm conclusion about lethality. In general, relatively longer tubular bones and body length are associated with increased survival. **Hypochondrogenesis** is phenotypically similar to ACGE and usually lethal but radiologically less severe with better ossification of the spine, pelvis, and long bones. Another condition to differentiate is **Kniest dysplasia,** characterized by vertebral coronal clefts and metaphyseal expansion (most prominent in the proximal femurs).[2]

These two key features of achondrogenesis—abnormal mineralization and shortened trunk length—distinguish it from thanatophoric dysplasia, which has normal mineralization and a normal trunk length. Both display macrocrania and severe micromelia.

Osteogenesis Imperfecta

OI is a clinically and genetically heterogeneous group of collagen disorders characterized by brittle bones resulting in fractures (Figs. 40.17 and 40.18). The incidence is 1 in 60,000 births. Until recently there were four clinical types of OI, all with an autosomal dominant mode of inheritance and associated with mutations in the *COL1A1* or *COL1A2* genes. Type II OI is lethal, whereas the other types are milder. In the past several years, many new causative genes have been identified.[68,69] Most are involved in the complicated process of maturation, processing, and transport

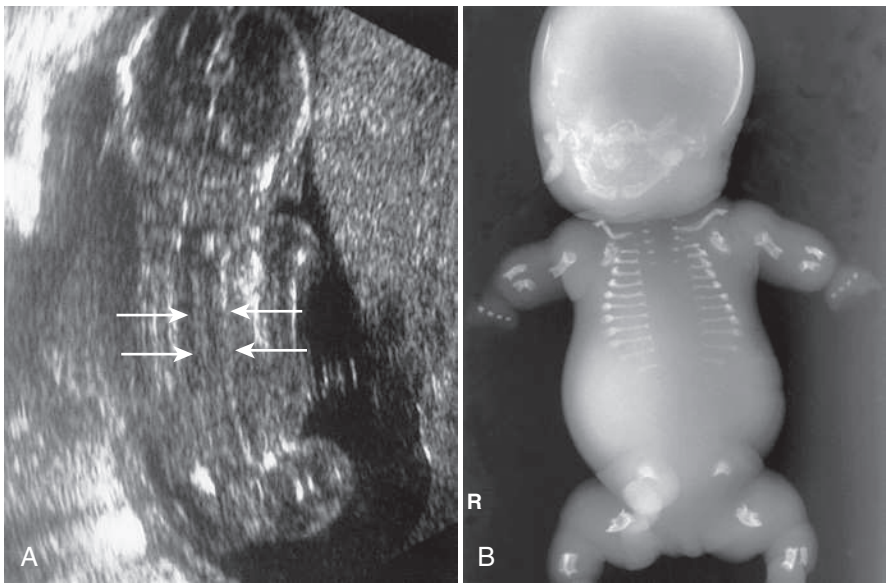

FIG. 40.16 Achondrogenesis at 18 Weeks. (A) Coronal sonogram shows small thorax, redundant subcutaneous tissues, absent spine ossification *(arrows),* and decreased calvarial ossification. **(B)** Postmortem radiograph demonstrates macrocranium, decreased calvarial ossification, virtually absent spine ossification (only some posterior elements are ossified in the cervical region). There is severe **micromelia** with strikingly short wide bones with **metaphyseal spurs.** The ribs are short and horizontal with splayed ends. (Courtesy of Shia Salem, MD, University of Toronto.)

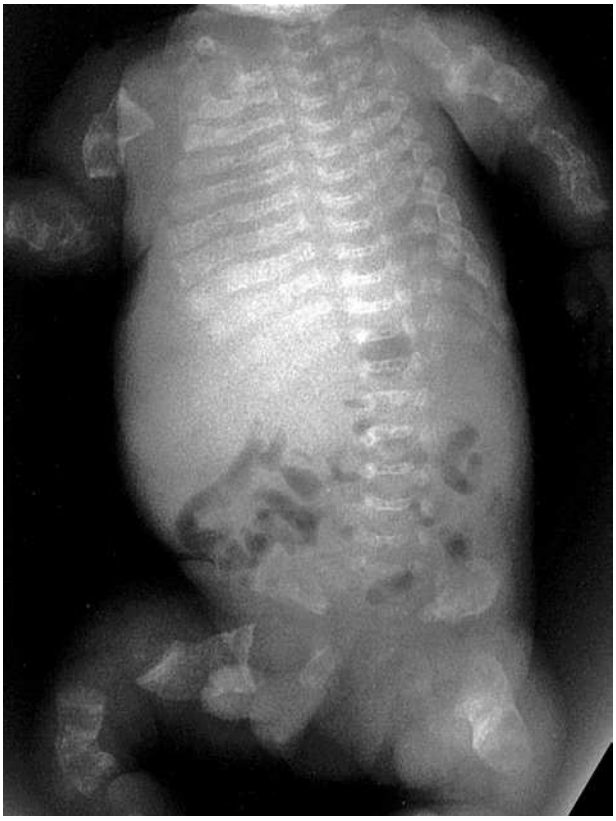

FIG. 40.17 Osteogenesis Imperfecta Type IIA at 32 Weeks. Postmortem radiograph shows severe **micromelia,** thickened bones with wavy contours caused by innumerable fractures and exuberant callus formation, **shortened ribs** with multiple fractures, and **platyspondyly.**

of type 1 collagen (Table 40.5). Most of these forms fit within the Sillence OI phenotypic classification and can still be categorized as OI type I, II, III, or IV despite several having a recessive mode of inheritance. Type V OI is phenotypically distinguishable with hyperplastic callus formation dense metaphyseal bands and ossification of the interosseous membranes of the forearm, and has an autosomal dominant form of inheritance.[70,71] A modification of the Sillence classification, based on skeletal radiographic findings, is still used most often to distinguish the subtypes of OI.[71,72]

Prenatal diagnosis is possible based on DNA obtained from chorionic villus sampling[70] or amniocentesis. Osteogenesis types I, III, and IV are further described in the section on nonlethal skeletal dysplasias.

OI type II is the classic neonatal lethal form and usually results from a new, dominant null mutation in the *COL1A1* gene.[72] The empiric recurrence risk is 6%, most of which are caused by parental germline and somatic mosaicism but can also be the result of one of the autosomal recessive forms of OI. Multiple repetitive in utero fractures occur secondary to defective collagen formation, which results in osseous fragility. Prevalence of OI type II is 0.18 in 10,000 births. The key ultrasound features are severe micromelia, decreased thoracic circumference and trunk length, decreased mineralization, and multiple bone fractures. The cranial vault remains normal in size, but as a result of decreased mineralization there is increased visibility of the intracranial contents and the skull is compressible by the ultrasound transducer (Fig. 40.19). The falx may appear bright or more echogenic than the demineralized cranial vault, with unusual clarity of detail in the near field cerebral hemisphere. Large fontanelles and wormian bones may be noted. Micrognathia is commonly present (Fig. 40.20).

The generalized demineralization results in innumerable fractures. The tubular bones exhibit a classic "accordion" or wrinkled contour caused by multiple in utero fractures with repetitive callus formation. Angulation and bowing are common in association with severe micromelia. On ultrasound, the bones may appear thickened because demineralized bone reflects sound waves less than a normally ossified bone. Acoustic shadowing may be present, absent, or diminished and thus is an unreliable sign. Multiple rib fractures cause the lateral chest contour to be concave rather than convex. The concavity is often most evident at the lateral thorax, and it is speculated that the elbows "bash" in the fragile rib cage. The ribs are hypoplastic, thus appearing shortened. The ribs may have a continuous, beaded, or wavy appearance secondary to repetitive fractures and callus formation. Platyspondyly secondary to multiple compression fractures may be present.

The three criteria for a specific diagnosis of OI type II are (1) FL greater than 3 SD below the mean, (2) demineralization of the calvarium, and (3) multiple fractures within a single bone.[72] The diagnosis may be made as early as 13 to 15 weeks' gestational age. A normal ultrasound examination after 17 weeks excludes this diagnosis.

Hypophosphatasia

Hypophosphatasia congenita, the lethal neonatal form of hypophosphatasia, is an autosomal recessive skeletal dysplasia caused by a deficiency of tissue-nonspecific alkaline phosphatase.[73] Frequency of hypophosphatasia congenita is 1 in 100,000 births. The key features are **severe micromelia, decreased thoracic circumference** with normal trunk length, and **decreased mineralization** with occasional fractures. Cranial vault size remains normal.

The demineralized long bones may be bowed with occasional angulations caused by fractures. The bones appear thin and delicate and may be difficult to visualize. The cranial vault fails to mineralize and may be compressible under locally applied transducer pressure. In contrast to OI, the demineralization in hypophosphatasia congenita varies from a patchy distribution to a diffuse form with severe involvement of the spine and calvarium. The ribs are short, resulting in a decreased thoracic circumference, but the trunk length is normal. Polyhydramnios is a common finding.

The main differential diagnosis is OI type II. Both hypophosphatasia and OI type II display a severe form of micromelia, demineralization, decreased thoracic circumference, and a normal-sized cranial vault that is compressible due to demineralization. In OI type II, the greater degree of osseous fragility results in innumerable fractures and a thickened, wavy appearance of the bones, in contrast to the thin, delicate appearance of the

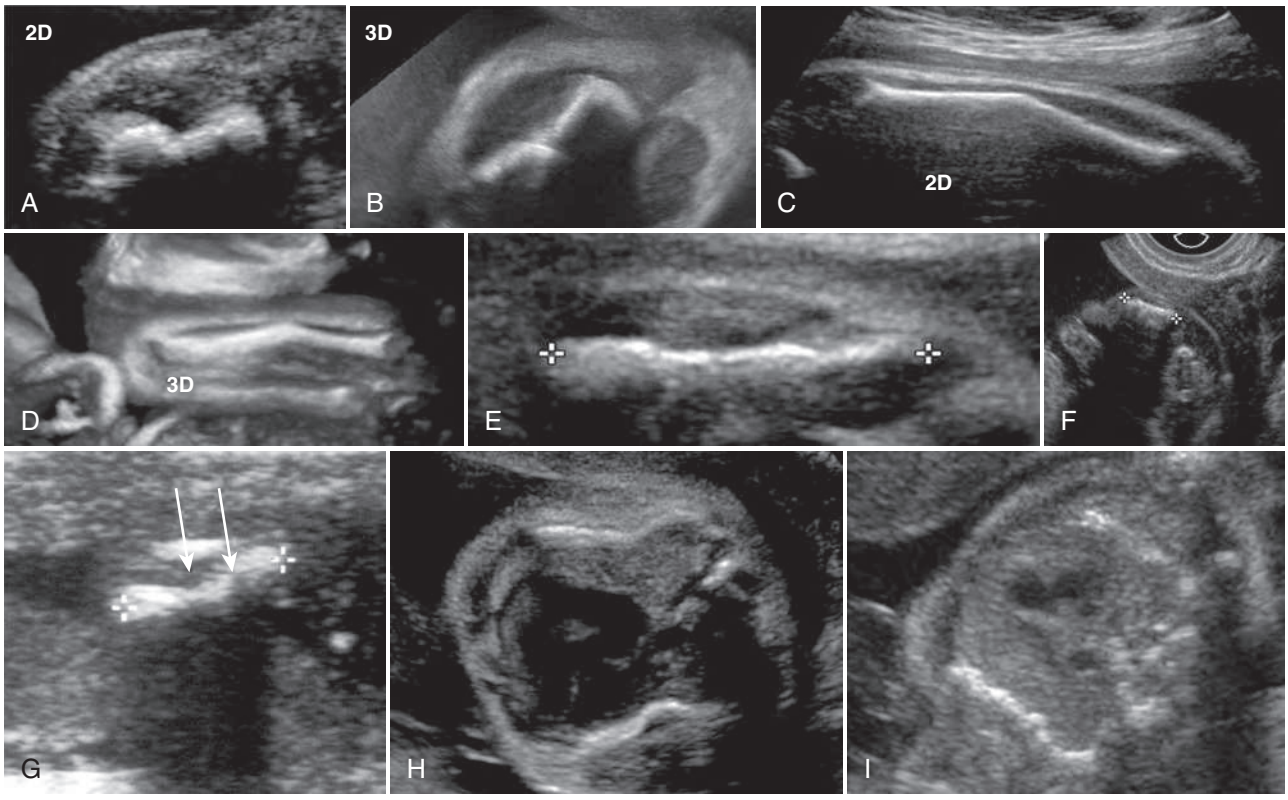

FIG. 40.18 Osteogenesis Imperfecta (OI): Spectrum of Appearances of Fractures. (A) Type IIA. Two-dimensional ultrasound image of extremely shortened femur with at least two bone deformities, consistent with fractures. Note redundant overlying soft tissues. **(B)** Correlative three-dimensional ultrasound image demonstrates a midshaft fracture with callus formation. **(C) Type I.** Nonlethal variant of OI with a mildly angulated femur of normal length. **(D)** Correlative three-dimensional ultrasound image demonstrates the angulated healed fracture. **(E) Type III.** Multiple fractures in the mildly to moderately shortened femur are evidenced by multiple discontinuities in the cortex. The demineralized shaft permits visualization of the thickened cortex. Femur bone length is measured between the *calipers*. **(F) Type II.** Extremely short and thickened femur resulting from repetitive callus formation. Acoustic shadowing is still present in this demineralized fragile bone, and thus its presence is not a reliable sign of normal mineralization. Femur length is measured between the *calipers*. **(G) Type II.** At least two discontinuities are present in the shortened tibia *(arrows),* consistent with fractures. Note acoustic shadowing present despite generalized demineralization. Femur length is measured between the *calipers*. **(H) Type II.** Cross section of the thorax demonstrates a typical concavity noted at the lateral aspect of the thorax. This may be caused by repetitive in utero fractures as the elbows "hit" the fragile rib cage. **(I) Type II.** Cross section of the thorax demonstrates normal-length ribs with multiple fractures within each rib, resulting in a wavy contour.

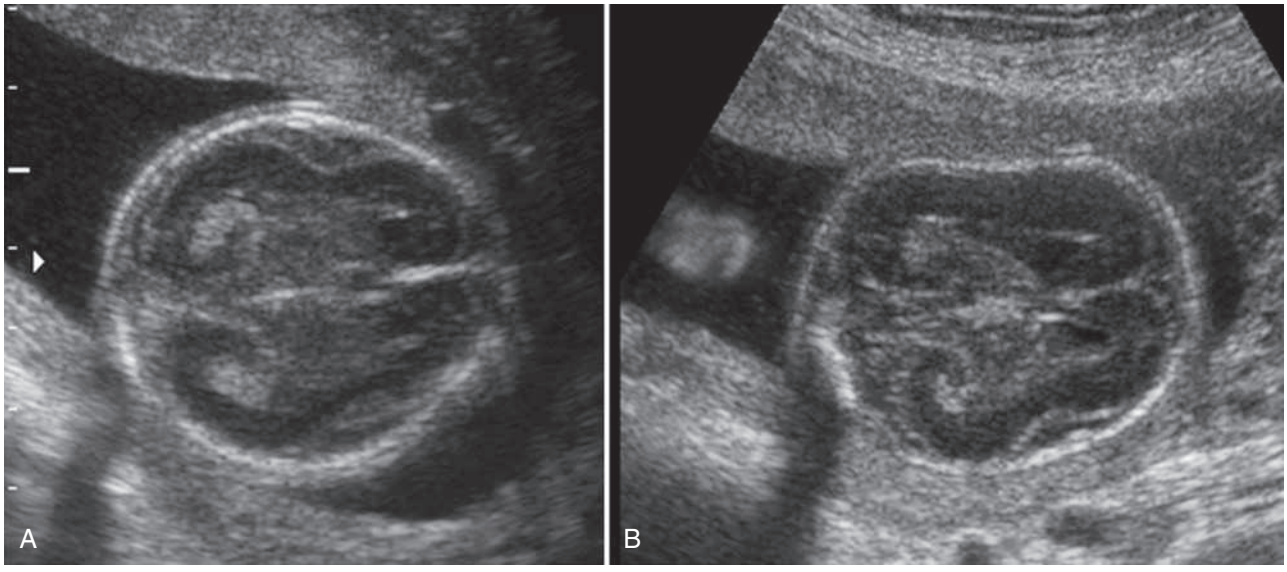

FIG. 40.19 Osteogenesis Imperfecta Type IIA at 17 Weeks. (A) Rounded head contour. **(B)** Gentle transducer compression on the demineralized calvarium results in flattening of the cranial contour. Note widened fontanelles and sutures, as well as ease of visualization of intracranial contents in the near field (which would usually have artifacts caused by shadowing from the ossified skull).

TABLE 40.5 Classification of Osteogenesis Imperfecta by Type

Type	Clinical Features	Prenatal Findings	Prognosis	Inheritance	Molecular Abnormalities
I	Normal stature, little or no deformity, blue sclera, hearing loss in 50% of cases Type IA: normal teeth Type IB: opalescent teeth	Occasionally, short and bowed long bones and fractures	Fair	Autosomal dominant	Nonsense or frameshift mutations in *COL1A1* gene
II	Lethal; hypomineralization of the skull, beaded ribs, compressed femurs, marked long-bone deformity, blue sclera, triangular face, platyspondyly	Severe micromelia Rib and long-bone fractures Hypomineralization of skull	Lethal	Autosomal dominant (new mutations) Parental gonadal mosaicism responsible for recurrence	Glycine missense mutation in *COL1A1* or *COL1A2* genes
III	Usually with long-bone fractures; moderate deformity at birth but progressively deforming bones; triangular face, blue sclera, opalescent teeth, hearing loss, short stature	Occasionally, short and bowed long bones and fractures	Wheelchair bound, nonambulatory	Autosomal dominant Parental gonadal mosaicism responsible for recurrence Autosomal recessive (rare)	Glycine missense mutation in *COL1A1* or *COL1A2* genes
IV	Mild to moderate bone deformity and variable short stature; opalescent teeth in type IVB; hearing loss occurs in some families; white sclera	Occasionally, short and bowed long bones and fractures	Fair	Autosomal dominant Parental gonadal mosaicism responsible for recurrence	Glycine missense mutation in *COL1A1* or *COL1A2* genes

Modified from Sillence DO, Senn A, Danks DM. Genetic heterogeneity in osteogenesis imperfecta. J Med Genet. 1979;16:101-116.[70]

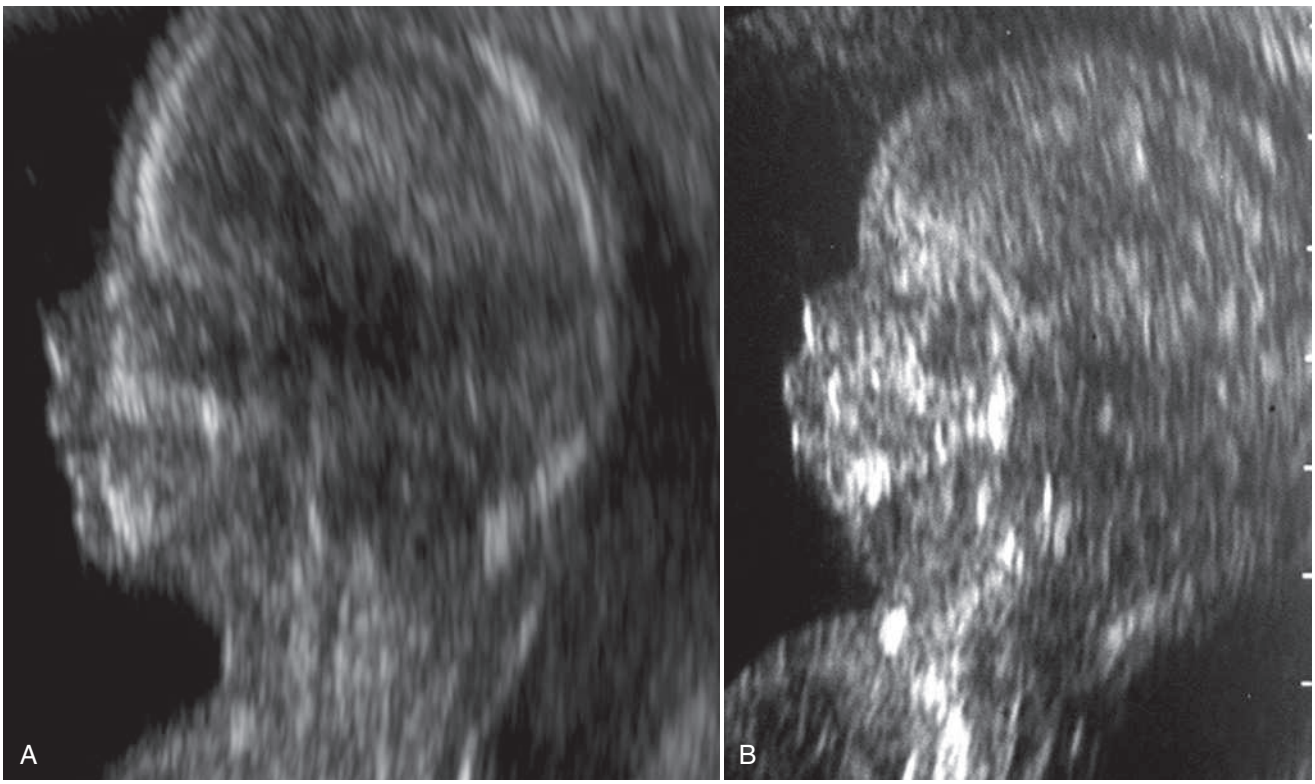

FIG. 40.20 Facial Profile: Normal Versus Osteogenesis Imperfecta (OI). (A) Normal profile of a 14-week fetus. **(B)** Facial profile of a 14-week fetus affected by OI. Note the **absent calvarial and nasal ossification** and **micrognathia.**

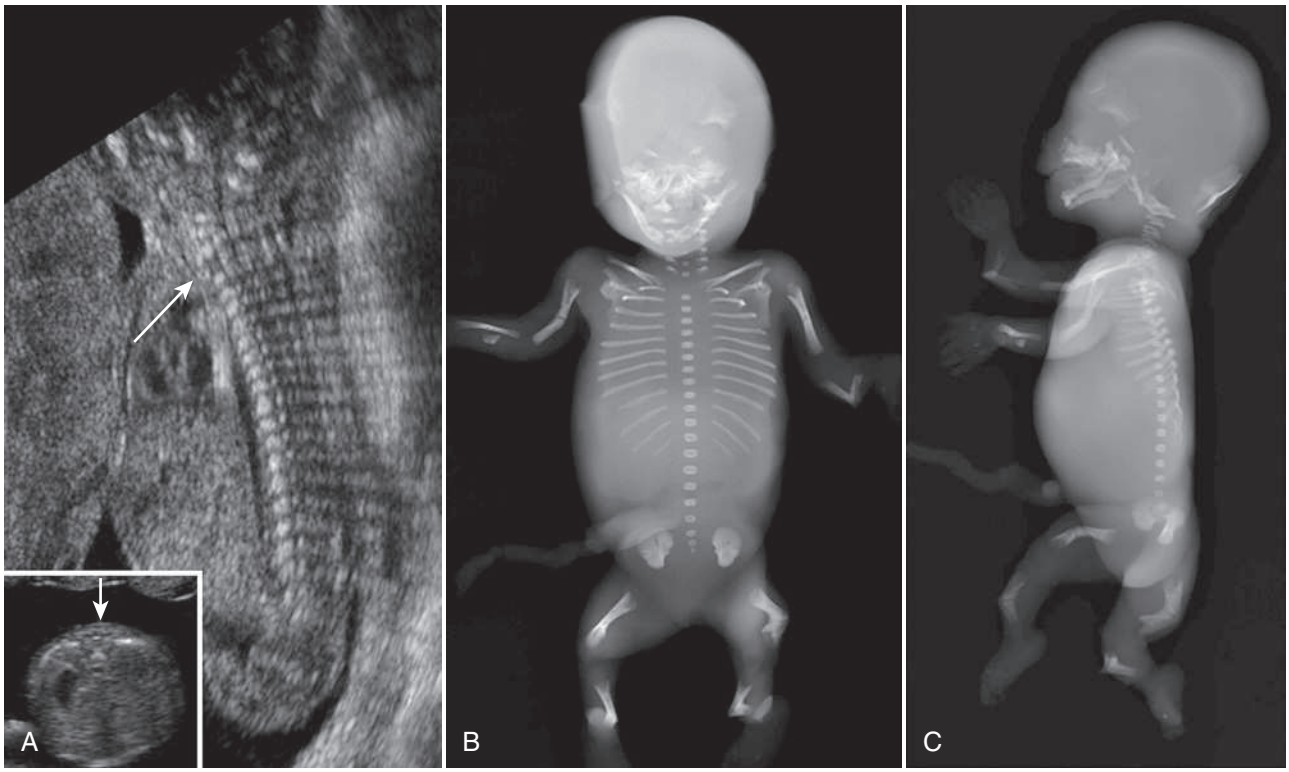

FIG. 40.21 Hypophosphatasia at 18 Weeks. (A) Sagittal image of the spine demonstrates absent ossification of posterior elements of the vertebrae. Patchy form of spine demineralization with absent ossification of a cervical vertebral body *(arrow)*. Note narrow anteroposterior (AP) diameter of thorax. *Inset,* Cross-sectional image of the upper abdomen with absent ossification of posterior elements of the spine *(arrow)* and vertebral body maintaining ossification. **(B)** AP radiograph confirms absent mineralization of a cervical vertebral body, with absent ossification of posterior elements of the vertebrae. Additional findings include **hypoplastic ribs,** occasional fractures, **micromelia,** and decreased cranial vault mineralization. **(C)** Lateral radiograph confirms absent mineralization of posterior elements of the spine.

bones in hypophosphatasia congenita. The normal trunk length and cranial vault size can aid in distinguishing hypophosphatasia from achondrogenesis. Typically, in hypophosphatasia congenita, the posterior elements are poorly ossified, whereas in achondrogenesis, the vertebral bodies are maximally affected by demineralization with relative sparing of the posterior elements[74] (Fig. 40.21). The cartilage is normally formed in hypophosphatasia; thus the fetus has a more normal gross appearance, despite severe bony abnormalities helping to distinguish it from the other lethal skeletal dysplasias.

Campomelic Dysplasia

Campomelic dysplasia, or **bent-limb dysplasia,** is a rare autosomal dominant condition that usually results from a new dominant mutation in *SOX9* (sex-determining region Y-Box 9). The incidence is 0.5 to 1.0 per 100,000 births. Most cases are lethal because of respiratory insufficiency from **laryngotracheomalacia** in combination with a mildly narrowed thorax.

The characteristic skeletal features of campomelic dysplasia are a short and ventrally bowed tibia and femur, a hypoplastic or absent fibula, **talipes equinovarus (clubfoot),** and **hypoplastic scapulae** (Fig. 40.22). Bowing may also occur in the upper extremities. Additional skeletal features may include **scoliosis; hypoplastic or poorly ossified cervicothoracic vertebrae; dislocated hips;** 11 rib pairs; and facial abnormalities, including **micrognathia** and **cleft palate (Pierre Robin sequence).** Approximately 33% of fetuses have congenital heart disease (CHD) and brain (e.g., ventriculomegaly) and renal (e.g., pyelectasis) abnormalities.

Sex reversal is found in about 75% of the affected 46,XY cases, with a gradation of defects ranging from ambiguous genitalia to normal female genitalia phenotype. The gene responsible for campomelic dysplasia is expressed in the fetal brain, the testes, and the perichondrium and chondrocytes of the long bones and ribs.[75]

Short-Rib Polydactyly Syndromes

Short-rib polydactyly dysplasias are a heterogeneous group of rare and lethal skeletal dysplasias with an autosomal recessive mode of inheritance which belongs to a group of conditions called "ciliary chondrodysplasias." Other conditions included in this entity are **Jeune asphyxiating thoracic dystrophy (Jeune syndrome), Mainzer-Saldino syndrome, Sensenbrenner syndrome, cranioectodermal dysplasia, oral-facial-digital syndrome 4 (OFD4, Mohr-Majewski)** and **Ellis–van Creveld syndrome** (EVC). The only exception from this mode of inheritance is **Weyers acrodental dysostosis,** which is caused by heterozygous mutations in the *EVC* genes. All forms are characterized by severe micromelia and decreased thoracic circumference. The cranial vault measurements and bone mineralization are normal. Polydactyly, cardiac, and genitourinary abnormalities are found in most cases.

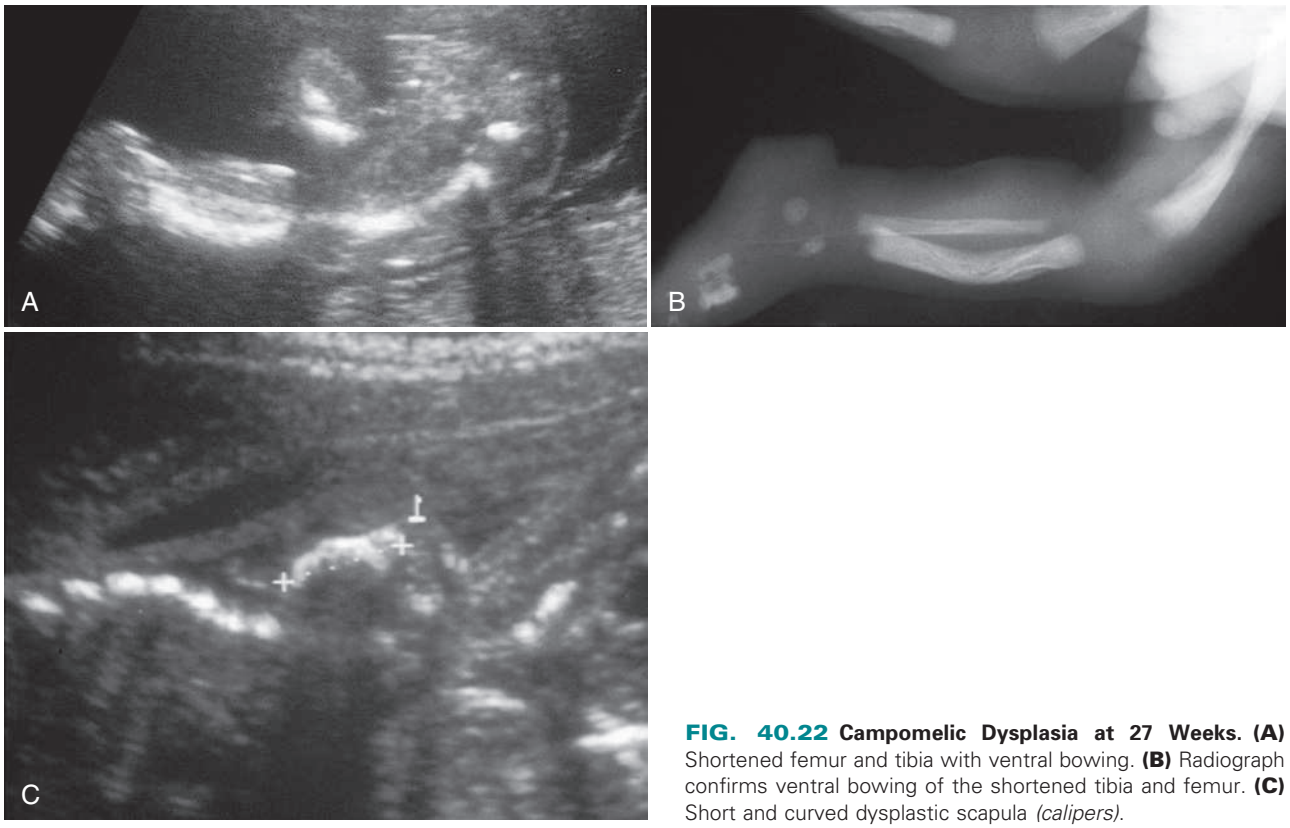

FIG. 40.22 Campomelic Dysplasia at 27 Weeks. (A) Shortened femur and tibia with ventral bowing. **(B)** Radiograph confirms ventral bowing of the shortened tibia and femur. **(C)** Short and curved dysplastic scapula *(calipers)*.

Ellis–van Creveld syndrome (Fig. 40.23A, B, and E) and **asphyxiating thoracic dystrophy** have similar features, but the shortening of the limbs and the narrowing of the thorax are less severe.

The short-rib polydactyly syndromes or short-rib thoracic dysplasia with or without polydactyly consists of multiple types:

Type 1 **(Saldino-Noonan)** and type 3 **(Verma-Naumoff)** syndromes are caused by mutations in the *DYNC2H1* gene (dynein, cytoplasmic 2, heavy chain 1) and *IFT80* gene (intraflagellar transport 80). Type 2 (**Majewski** or **SRTD6**) is caused by mutation in the *DYNC2H1* and *NEK1* genes. Type 4 **(Beemer-Langer)** can occur without polydactyly.[73,76] Type 5 is caused by homozygous or compound heterozygous mutations in the *WDR35* gene. Radiographic and clinical features can distinguish them.[73,76]

Fibrochondrogenesis is a rare, usually fatal condition and survivors suffer from severe physical and neurologic impairment. It is autosomal recessive rhizomelic chondrodysplasia caused by a homozygous mutation or compound heterozygous mutations in the *COL11A1* and *COL11A2* genes. The typical features include narrow chest (short ribs with cupping), short long bones with irregular metaphyses with peripheral spurs, and extraarticular calcifications giving the appearance of stippling, platyspondyly with decreased ossification (particularly cervical vertebrae), and vertebral midline clefts. Other features include flat facies and cleft palate.[77,78]

Other Dysplasias

Other lethal skeletal dysplasias include **atelosteogenesis, boomerang dysplasia, de la Chapelle dysplasia,** and **Schneckenbecken dysplasia.** These dysplasias are rare and difficult to diagnose prenatally.

NONLETHAL OR VARIABLE-PROGNOSIS SKELETAL DYSPLASIAS

The nonlethal or variable-prognosis skeletal dysplasias form a larger group typically presenting with milder and later onset of skeletal abnormalities. Select nonlethal or variable-prognosis skeletal dysplasias with characteristic ultrasound findings are described in Tables 40.6, 40.7, and 40.8.

Heterozygous Achondroplasia

Heterozygous achondroplasia is known to be associated with the c.1138G>A (p.Gly380Arg) gene in about 98% of the cases and the c.1138G>C (p.Gly380Arg) mutation in about 1% of the cases. The *FGFR3* gene is also associated with isolated **craniosynostosis, thanatophoric dysplasia,** and some cases of **hypochondroplasia.**[58,60] The identification of the gene and gene mutations associated with achondroplasia has allowed preimplantation genetic diagnosis as well as prenatal diagnosis, using DNA analysis, when the parents are heterozygous for achondroplasia.[60]

Heterozygous achondroplasia is the most common nonlethal skeletal dysplasia.[5] About 80% of cases are the result of a spontaneous autosomal dominant mutation associated with advanced paternal age, and the remainder are inherited from parental heterozygous achondroplasia. The incidence is 1 in 26,000 births.

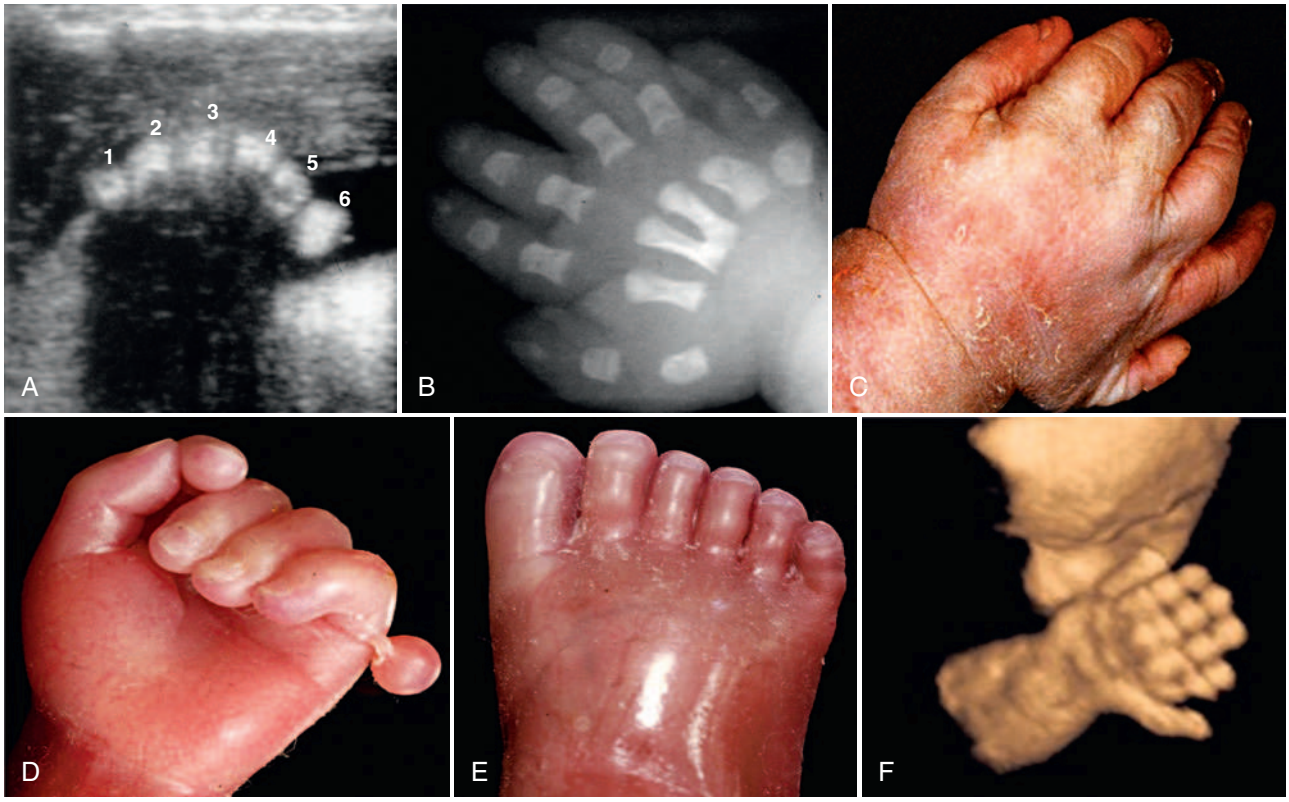

FIG. 40.23 Polydactyly. (A) Ellis–van Creveld syndrome. Postaxial polydactyly on cross section through six digits. **(B)** Corresponding radiograph shows postaxial polydactyly. Note **hypoplastic distal phalanges** and fusion of the third and fourth metacarpals. **(C)** Corresponding pathology specimen. **(D)** Polydactyly may present as a soft tissue nubbin with no bony elements. **(E)** Ellis–van Creveld with toe polydactyly. **(F)** Three-dimensional ultrasound image shows **isolated familial polydactyly.**

TABLE 40.6 Rhizomelic Dysplasia: Key Features

Dysplasia	Prognosis	Degree of Limb Shortening	Key Sonographic Features
Heterozygous achondroplasia	Nonlethal	Mild	Progressive discrepancy in femur length and biparietal diameter
Chondrodysplasia punctata, rhizomelic form	Lethal	Moderate-severe	Stippled epiphysis in third trimester
Diastrophic dysplasia	Variably lethal	Mild-moderate	Hitchhiker thumb, postural deformities, dislocations, joint contractures, clubfoot

TABLE 40.7 Micromelic Dysplasia, Mild: Key Features

Dysplasia	Prognosis	Key Sonographic Features
Asphyxiating thoracic dystrophy	May be lethal	Long narrow thorax, renal anomalies (cystic dysplasia), polydactyly (14%)
Ellis–van Creveld syndrome	May be lethal	Long narrow thorax, congenital heart disease (50% atrial septal defect), polydactyly (100%)

TABLE 40.8 Micromelic Dysplasia, Mild and Bowed: Key Features

Dysplasia	Prognosis	Key Sonographic Features
Osteogenesis imperfecta type III	Nonlethal, progressively deforming	Lower extremities demonstrate greater degree of shortening and fractures/bowing
Campomelic dysplasia	Variably lethal	Ventral-bowing femur and tibia, hypoplastic or absent fibula, hypoplastic scapulas

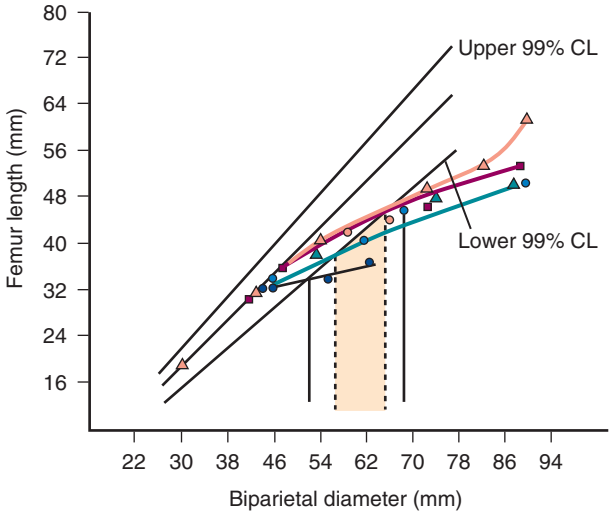

FIG. 40.24 Femur Length (FL) Versus Biparietal Diameter (BPD). Seven cases of recurrent **heterozygous achondroplasia.** The FL falls below the 99% confidence limit (CL) by the time the BPD corresponds to 27 weeks' gestational age (≈69 mm). (With permission from Kurtz AB, Filly RA, Wapner RJ, et al. In utero analysis of heterozygous achondroplasia: variable time of onset as detected by femur length measurements. J Ultrasound Med. 1986;5[3]:137-140.[79])

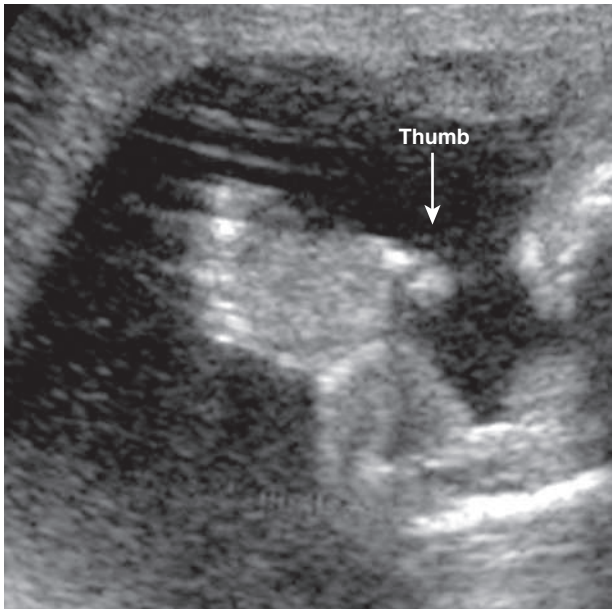

FIG. 40.25 Diastrophic Dysplasia With "Hitchhiker Thumb." (Courtesy of Fetal Assessment Unit, University Health Network.)

The key features are mild to moderate forms of rhizomelic limb shortening (more prominent in upper limbs), **macrocranium, frontal bossing, depressed nasal bridge, midface hypoplasia,** and **brachydactyly,** with a **trident** configuration of the hand. The BPD typically is above the 97th percentile at term. The interpedicular distances progressively narrow from the upper to the lower lumbar spine. There is a progressive discrepancy between FL and BPD during the third trimester, with FL falling below the first percentile compared to BPD[79] (Fig. 40.24). This may occur as early as 21 weeks or as late as 27 weeks' gestational age. Previously considered a diagnosis of the third trimester, recent studies have shown that a second-trimester diagnosis is possible.[79,80]

It is important to recognize that the pattern of BPD greater than expected with FL less than expected for gestational age, in combination with average abdominal circumference measurements, suggests heterozygous achondroplasia. A reliance on the mean of the three values for assessment of gestational age may result in an average value for gestational age, thus masking the BPD/FL discrepancy.

In cases where both parents are heterozygous achondroplasia, fetal ultrasound can differentiate among normal, heterozygous, and homozygous achondroplasia. Patel and Filly[80] report that fetuses with heterozygous achondroplasia have FL that exceeds 34 mm at 26 weeks' BPD age, whereas those with homozygous achondroplasia do not. Fetuses with FL below the third percentile compared with the BPD at 17 weeks' BPD age, with progressive shortening over the following 6 weeks, have homozygous achondroplasia, whereas those with decreasing FL between 17 and 23 weeks' BPD age have heterozygous achondroplasia.[80]

Diastrophic Dysplasia

Diastrophic dysplasia is an autosomal recessive disorder with variable expression and a predominantly rhizomelic form of micromelia. The term *diastrophic* implies "twisted," which reflects the multiple **postural deformities, dislocations, joint contractures,** and **kyphoscoliosis** present.[2] The most characteristic feature is the **"hitchhiker thumb,"** caused by a lateral positioning of the thumb in association with a hypoplastic first metacarpal (Fig. 40.25). The first toe may have similar positioning. There is a severe **talipes equinovarus (clubfoot),** which may be refractory to surgical treatment. Other features include **micrognathia, cleft palate** (50%), and **laryngotracheomalacia.** The life span may be normal if the progressive kyphoscoliosis does not compromise cardiopulmonary function. The diastrophic dysplasia gene was mapped to the long arm of chromosome 5 and found to encode a novel sulfate transporter. Mutations in the same gene are reported in **achondroplasia** type 1B and **atelosteogenesis** type II.[81,82]

Asphyxiating Thoracic Dysplasia

Asphyxiating thoracic dysplasia, or **Jeune syndrome,** is an autosomal recessive disorder with variable expressivity. The incidence is about 1 in 100,000 births. The perinatal mortality rate is high as a result of pulmonary hypoplasia. Those who survive may develop **renal** and **hepatic fibrosis**[2,81] (see Table 40.8). Key features are a mild to moderate form of **micromelia** (60%) with rhizomelic predominance, a long narrow thorax with short **horizontal ribs, inverted "handlebar" appearance of the clavicles, renal dysplasia and cysts,** and **postaxial polydactyly** in 14%.

Ellis–van Creveld Syndrome

Ellis–van Creveld syndrome, or **chondroectodermal dysplasia,** is an autosomal recessive disorder with an incidence of 1 in

150,000 births. The condition has a high prevalence among inbred populations, such as the Amish and the Arabs of the Gaza Strip.[73] It is generally a nonlethal disorder, but death can result from pulmonary hypoplasia.[35,73] The condition is caused by homozygous or compound heterozygous mutation in the *EVC* gene on chromosome 4p16. Ellis–van Creveld syndrome can also be caused by mutation in a nonhomologous gene, *EVC2,* located close to the *EVC* gene. Mutations in the *EVC* and *EVC2* genes also cause **Weyers acrofacial dysostosis,** an allelic disorder showing autosomal dominant mode of inheritance.

Key features include mild to moderate form of **micromelia** with a mesomelic predominance, **short horizontal ribs, postaxial or ulnar polydactyly**[2] (see Fig. 40.23A, B, and E) that is almost 100% in the hands and 25% in the feet,[64] and CHD (50%), most often **atrial septal defect.** Additional findings include a progressive distalward shortening of the extremities with **hypoplastic distal phalanges.** Fusion of the metacarpals and phalanges is common. The presence of polydactyly, CHD, and the absence of renal cysts help to distinguish this condition from **asphyxiating thoracic dystrophy.**

Chondrodysplasia Punctata

Chondrodysplasia punctata, or **stippled epiphyses,** is a heterogeneous group of disorders with many small calcifications **(ossification centers)** in the cartilage, in the ends of bones, and around the spine. Known associated conditions include single-gene disorders such as rhizomelic chondrodysplasia punctata, **Conradi-Hünermann syndrome,** and **Zellweger syndrome (cerebrohepatorenal syndrome);** chromosomal abnormalities such as trisomy 21 and 18; maternal autoimmune diseases; and teratogen exposure (e.g., warfarin, alcohol).[83,84]

Rhizomelic chondrodysplasia punctata is an autosomal recessive condition caused by a peroxisomal disorder that appears as severe, symmetrical, predominantly rhizomelic limb shortening.[73,85] The incidence is 1 in 110,000 births, and it is generally lethal before the second year of life. The condition is the result of peroxisomal dysfunction caused by homozygous or compound heterozygous mutations in the *PEX7* gene. It can be associated with low unconjugated estriol concentration on second-trimester screening for Down syndrome.

The humeri tend to be relatively shorter than the femurs and have **metaphyseal cupping.** The enlarged epiphyses with characteristic stippling may be identified on ultrasound in the third trimester (see Fig. 40.2I). Other abnormalities include dysmorphic facial features, **joint contractures, coronal clefting of the vertebral bodies,** brain abnormalities, and severe mental retardation.

Conradi-Hünermann syndrome, or **the nonrhizomelic** form of chondrodysplasia punctata (CDPX2), is an X-linked dominant condition with extreme phenotypic variations, rendering the antenatal diagnosis difficult in the absence of known family history. The widely variable phenotypic presentation may be related to random X inactivation.[86,87] CDPX2 is uncommon, with X-linked dominant inheritance and possible lethality in the hemizygous male (Xp11).[86] The characteristic skeletal abnormalities are asymmetrical shortening of the extremities with punctate calcifications primarily affecting the ends of long bones, the carpal and tarsal regions, paravertebral region, and pelvic bones. Stature is usually reduced; kyphoscoliosis with shortening of the long bones (particularly femur and humerus) and dysmorphic facial features are common.[84]

Dyssegmental Dysplasia

Dyssegmental dysplasia is a rare autosomal recessive skeletal dysplasia characterized by gross vertebral disorganization. The findings typically include micromelia, short narrow thorax, joint rigidity, **anisospondyly** (gross irregularity of the size and shape of the vertebral bodies) which may include malsegmentation, clefting or "oversize" bodies, kyphoscoliosis, and multiple ossification centers. The gross spine disorganization may be recognized as early as the first trimester. The more severe form is referred to as **Silverman-Handmaker** and the milder form as **Rolland-Desbuquois,** although some think that dyssegmental dysplasia may represent a spectrum of findings caused by different mutations in the heparin sulphate perlecan gene 2 *(HSPG2).*[88]

Osteogenesis Imperfecta Types I, III, IV—Nonlethal Types

OI type I is a mild, "tarda" variant inherited in an autosomal dominant manner as a result of mutation in the *COL1A1* (on chromosome 17) or *COL1A2* (on chromosome 7) and possibly in other collagen genes. OI **type I** is a generalized connective tissue disorder characterized by bone fragility and blue sclerae. The bones are of normal length, and only 5% have fractures at birth. Most fractures occur from childhood to puberty. There is progressive hearing loss in approximately 50% of type I cases. OI **type III** has a heterogeneous mode of inheritance. This is a nonlethal, progressively deforming variety of OI that often spares the humeri, vertebrae, and pelvis. Rib involvement is variable. The blue sclerae will normalize, and there is no associated hearing impairment. **Type IV** is an autosomal dominant form of OI. It is the mildest form, involving isolated fractures. The sclerae are blue at birth but normalize over time. There is no associated hearing impairment.

LIMB REDUCTION DEFECTS AND ASSOCIATED CONDITIONS

These heterogeneous disorders are associated with a spectrum of limb defects caused by chromosomal abnormalities, single-gene disorders, and maternal exposures and diseases. There are three major categories of limb reduction defects. A **malformation** is a defect resulting from an abnormal developmental process. A **deformation** is an abnormality of form, shape, or position caused by mechanical forces. A **disruption** is a defect caused by the extrinsic breakdown or interference with an originally normal developmental process. The defect can consist of the absence of an entire limb **(amelia),** of part of a limb **(phocomelia),** or of digits **(oligodactyly),** or it can involve an increased number of digits **(polydactyly).**[89] It can also affect only the **radial ray** or **ulnar ray,** with or without involvement of the corresponding fingers (Table 40.9).

The overall incidence of congenital limb reduction deformities is estimated at 4 in 100,000 births. An isolated amputation may be caused by **amniotic band sequence, teratogen exposure,** or a vascular accident. The prenatal detection rate of isolated limb reduction defect is estimated at 14.6%, compared to 49.1% when associated anomalies are detected.[90] **Terminal transverse limb defects** are associated with amniotic bands only in some cases, and thus other causes (e.g., vascular disruption, fetal hypoxemia, errors in embryologic development) are suspected in other cases.

TABLE 40.9 Nomenclature of Limb Anomalies

Anomaly	Description
LIMB REDUCTION ANOMALIES	
Amelia	Absent limb
Adactyly	Absent digits
Acheiria	Absent hand
Apodia	Absent foot
Hemimelia	Absent extremity distal to knee or elbow
Phocomelia	Absent middle segment of limb
Ectrodactyly	Split hand
Ulnar or radial hemimelia	Absent ulnar and ulnar digits paraxial or radius and thumb
HAND AND FOOT ANOMALIES	
Clinodactyly	Incurvature of a digit
Camptodactyly	Flexion of a digit
Syndactyly	Fusion of digits
Polydactyly	Extra digits
Oligodactyly	Decreased number of digits

Proximal Focal Femoral Deficiency

Proximal focal femoral deficiency is a rare, sporadic condition, and 35% of those affected are infants of diabetic mothers[64] (see Figs. 40.2C and 40.26). There is an asymmetrical degree of absence of the **subtrochanteric femur,** which may extend to the femoral head and acetabulum.[73] The femoral hypoplasia is often associated with ipsilateral fibular hemimelia, which may result in a bowed appearance of the tibia, similar to that of campomelic dysplasia; however, proximal focal femoral deficiency is generally unilateral. Hypoplasia or aplasia of other long bones, vertebral anomalies, microcephaly, and facial dysmorphism can also occur. If the defect is unilateral, it may represent the **femur-fibula-ulnar complex,** which is nonfamilial, versus the **femur-tibia-radius complex,** which has a strong genetic association.[91] When associated with the unusual facies syndrome, the femoral hypoplasia is usually bilateral.

Radial Ray Defects

Radial ray defects are associated with a wide variety of syndromes. The diagnosis is based on the absence of a visualized distal radius at the same level as the ulna, in association with a radial deviation or clubhand (Fig. 40.27). There may be bowing or hypoplasia of the ulna and a hypoplastic or absent thumb. Ulnar ray defects are rare.

Fanconi pancytopenia (syndrome) is an autosomal recessive blood dyscrasia in which 50% of cases have an associated unilateral or bilateral aplastic or hypoplastic thumb and radius. Identification of the **thumb hypoplasia or aplasia** in association with a **radial ray defect** suggests this diagnosis, initiating discussion of prenatal diagnosis and potential cesarean section to avoid excessive bleeding (Fig. 40.28). Prenatal diagnosis is based on increased chromosome breakage and sister chromatid exchange in cultured amniotic fluid cells, both before and after exposure to diepoxybutane.[92]

FIG. 40.26 Isolated Femoral Hypoplasia at 20 Weeks. Note the downside left femur is short and curved.

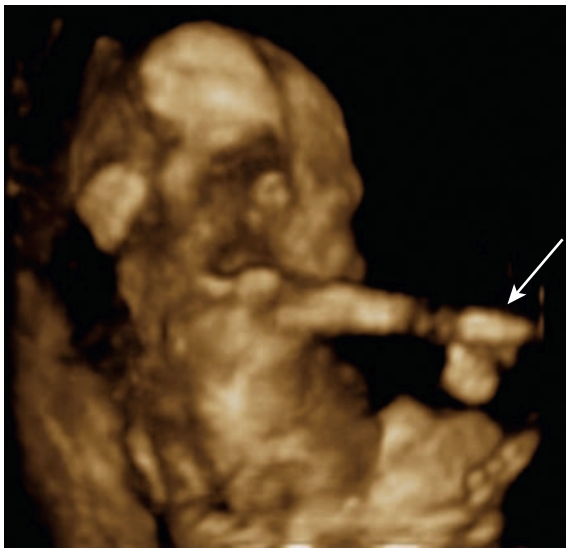

FIG. 40.27 Radial Ray Anomaly Diagnosed at 13 Weeks' Gestation. Three-dimensional ultrasound surface display demonstrates the **hypoplastic radius and ulna** in association with **talipomanus (clubhand)** *(arrow).*

Diamond-Blackfan (Aase syndrome) is genetically a heterogeneous condition with an autosomal dominant mode of inheritance. It is associated with hypoplastic anemia, a hypoplastic distal radius with radial **clubhand,** and a **triphalangeal thumb.** Associated cardiac defects (ventricular septal defect, coarctation of aorta) may be present. Triphalangeal thumb may also be found in **Holt-Oram syndrome,** chromosomal abnormalities, and fetal **hydantoin exposure.**

Thrombocytopenia–absent radius syndrome is an autosomal recessive blood dyscrasia characterized by hypomegakaryocytic thrombocytopenia and bilateral absence of the radii.[93] The thumb is present. The humerus and lower extremities are variably involved. One-third of such patients have CHD, typically tetralogy of Fallot or septal defects. Fetuses are at risk of intracranial hemorrhage, so delivery by cesarean section is recommended (Fig. 40.29). The causative gene is *TBX5.*

Holt-Oram syndrome is an autosomal dominant disorder consisting of a congenital heart defect (atrial or ventricular septal defect) in combination with a variety of upper limb anomalies. The limbs are asymmetrically affected, with the left limb usually showing more effects than the right. The lower extremities are not involved. The causative gene is *TBX5.*

Roberts syndrome, or **pseudothalidomide syndrome,** is an autosomal recessive disorder characterized by **tetraphocomelia** and **bilateral cleft lip and/or palate.** The limb reductions are most prominent in the upper extremities. Typically it is associated with premature separation of the centromere and homozygous or compound heterozygous mutation in the *ESCO2* gene.

Other conditions associated with radial ray abnormalities include **trisomies 18 and 13, the VACTERL association, acrorenal syndrome, Cornelia de Lange syndrome, Goldenhar syndrome, Nager acrofacial dysostosis,** and **Klippel-Feil syndrome.**

Amniotic Band Sequence

Amniotic band sequence is suspected to be secondary to first-trimester rupture of the amnion, resulting in **amniotic bands** that extend from the chorionic surface of the amnion to the fetal tissue.[94,95] The incidence is approximately 1 in 1200 live births but is much higher in spontaneous abortions. Depending on the timing and orientation of the bands, the resultant disruption of fetal organs includes **amputations** of limbs or digits (Figs. 40.30 and 40.31), bizarre facial or cranial clefting, and **thoracoabdominal schisis.** The distribution is asymmetrical. Constriction ring defects are the most common finding. Fibrous bands of tissue with a constricting ring and distal elephantiasis or protrusion of uncovered bone distally are pathognomonic for this anomaly (Fig. 40.32). Antenatally, an aberrant band attached to the fetus, with characteristic deformities and restriction of motion, permits the diagnosis. An amniotic sheet is a **synechia,** or scar in the uterus, and is distinguished from an amniotic band by a thickened base and a free edge.[96] Synechiae are not associated with amniotic band sequence.

The **limb–body wall complex** is a sporadic disorder that occurs in approximately 1 in 4000 births with a similar, but more severe and lethal, complex of fetal malformations.[97] Additional findings include evisceration of internal organs, **myelomeningocele,** marked **scoliosis,** and **short straight umbilical cord.**

Caudal Regression Syndrome and Sirenomelia

Caudal regression syndrome consists of partial to complete **sacral agenesis** and abnormalities of the lumbar spine, pelvis, and lower limbs.[98-100] The majority of cases are associated with maternal **diabetes,** but familial cases have been reported. **Sirenomelia** is characterized by an absent sacrum, fusion of the lower extremities, anorectal atresia, and renal dysgenesis or agenesis (Fig. 40.33). Severe oligohydramnios and single umbilical artery are typically present. Prevalence is approximately 1 in 60,000 births.

Arthrogryposis Multiplex Congenita

Arthrogryposis multiplex congenita is etiologically a heterogeneous group of disorders with **multiple joint contractures** of prenatal onset[101] (Fig. 40.34). Normal fetal motion by approximately 7 or 8 weeks onward is required for development of the musculoskeletal system, and the lack of movement results in joint contractures. Some cases result from extrinsic causes, such as oligohydramnios, twinning, or uterine masses, and most of these have a good prognosis. Intrinsic causes include neuromuscular disorders (most cases) and skeletal and connective tissue disorders. Typically, the severity of the deformity increases distally, with maximal deformity in the hands and feet. This may result in the **"Buddha position"** of the fetus, with arms and legs crossed and ending in clubhand or clubfoot (Fig. 40.34D). The **fetal akinesia sequence** refers to the combination of decreased or no fetal movements, multiple joint contractures, in most cases IUGR, underdevelopment of the bones, pulmonary hypoplasia, typical craniofacial abnormalities, and a short umbilical cord.

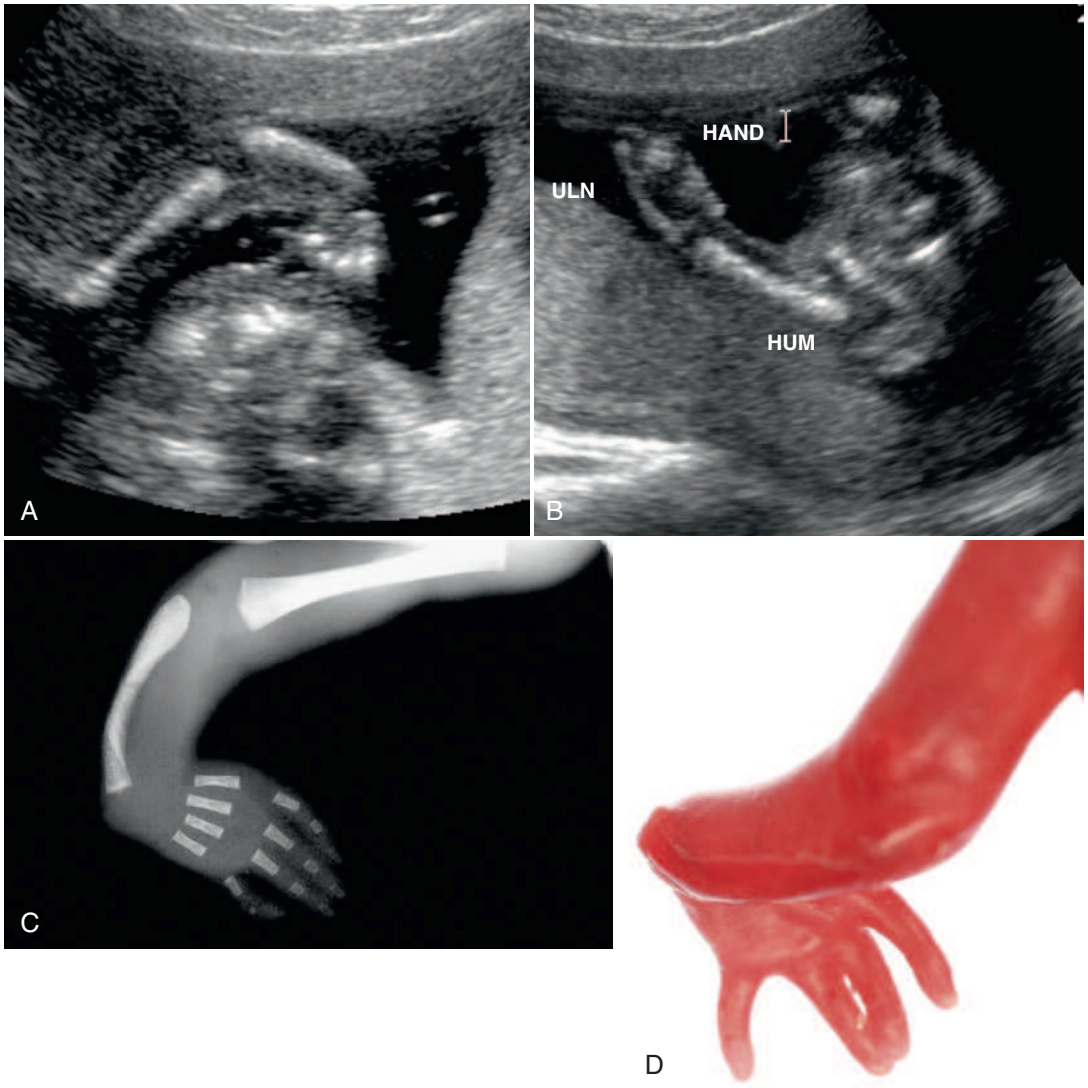

FIG. 40.28 Fanconi Pancytopenia. Radial ray aplasia with talipomanus and bilateral absence of thumbs. (A) Radial deviation left hand, or clubhand, secondary to radial ray aplasia and ulnar hypoplasia. Note absent thumb. **(B)** More extreme example of radial deviation hand or clubhand secondary to radial ray aplasia and ulnar hypoplasia. *HUM,* Humerus; *ULN,* ulna. **(C)** Correlative radiograph (of **A**) of left arm. Note absent thumb. **(D)** Correlative specimen photograph of **A.** Note absent thumb. (Courtesy of Shia Salem, MD, University of Toronto.)

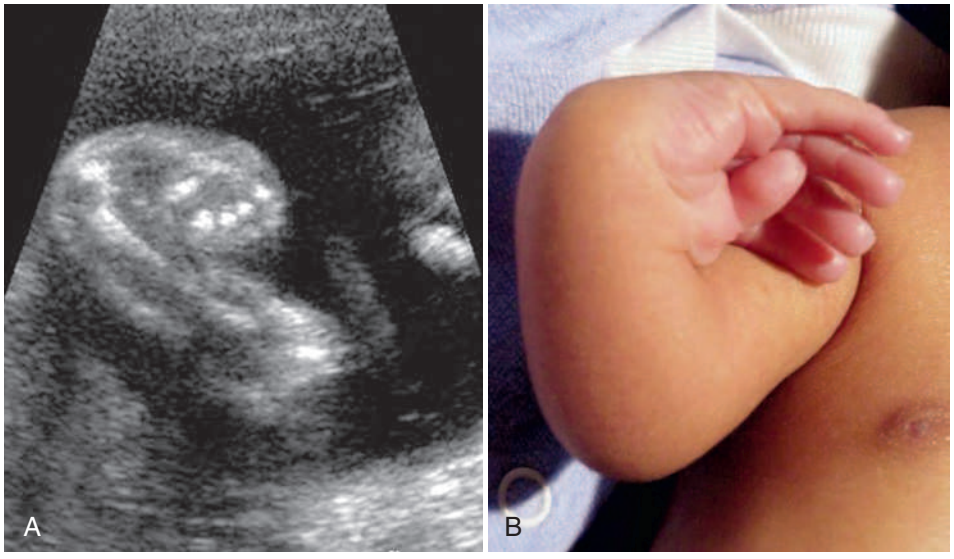

FIG. 40.29 Thrombocytopenia–Absent Radius Syndrome. (A) Absent radius in association with hypoplastic ulna results in talipomanus. Note that thumb is present. **(B)** Correlative specimen photograph.

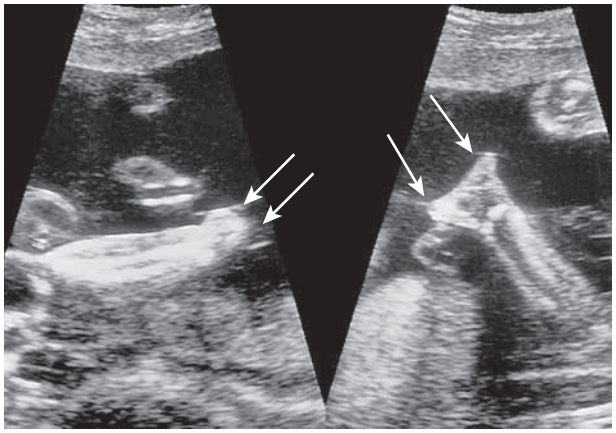

FIG. 40.30 Amputation of the Hand. Upper extremity ends abruptly distal to the wrist, in the midcarpal region *(arrows)*. (Courtesy of Ants Toi, MD, University of Toronto.)

Limb pterygium, or webbing of the skin across a joint, can involve a single joint or several joints[102] and etiologically is a heterogeneous disorder. Popliteal pterygium is the most common dominantly inherited pterygium syndrome and is associated with mutations in the *IRF6* gene.[103]

Asymmetrical **limb enlargement** may be caused by **hemihypertrophy, cutaneous hemangioma** or **lymphangioma, elephantiasis** secondary to a constricting band, **arteriovenous malformations, neurofibromatosis,** or **Beckwith-Wiedemann syndrome.**

Hereditary lymphedema type 1 (Nonne-Milroy lymphedema) is a rare autosomal dominant condition secondary to deficient lymphatic drainage, typically affecting the lower extremities. The subcutaneous tissues of the affected extremity appear diffusely thickened. Associated ascites and pleural effusions may be seen. There is variable expressivity and age of onset[104] (Fig. 40.35).

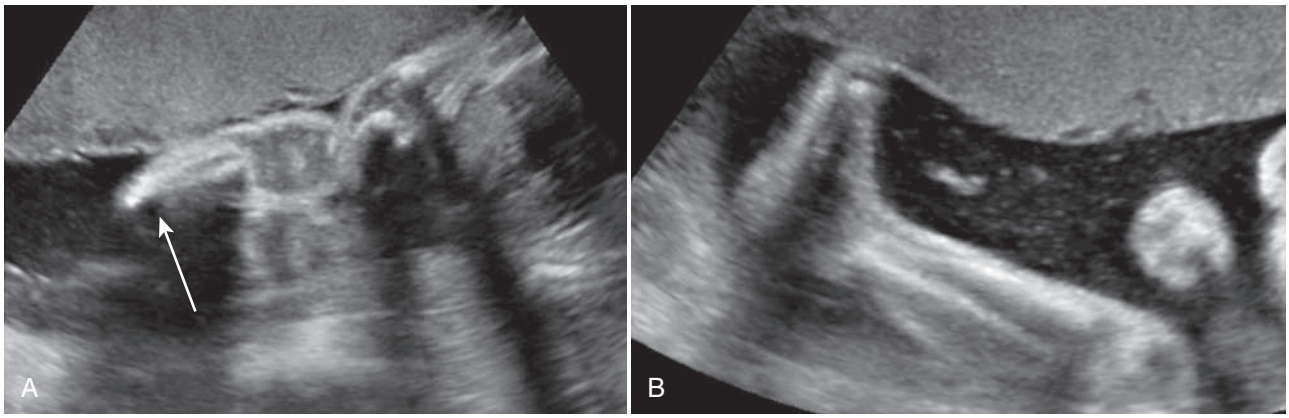

FIG. 40.31 Amputation of Right Lower Extremity. (A) Ultrasound image demonstrates abrupt ending of the right lower limb *(arrow)*. **(B)** Comparison ultrasound image shows normal left lower limb.

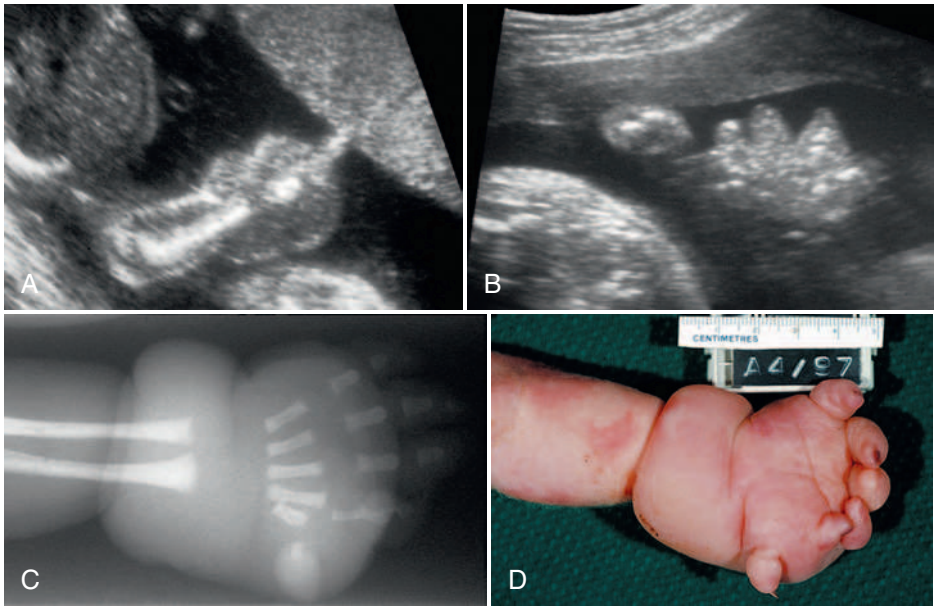

FIG. 40.32 Amniotic Band Sequence. Constriction rings with distal elephantiasis. **(A)** Ultrasound lateral image of the distal forearm and hand demonstrates the two constriction rings with elephantiasis. **(B)** Ultrasound of the digits demonstrates the distal tapering of the digits. **(C)** Radiograph demonstrates the two constriction rings in the distal forearm and hand. **(D)** Correlative specimen photograph.

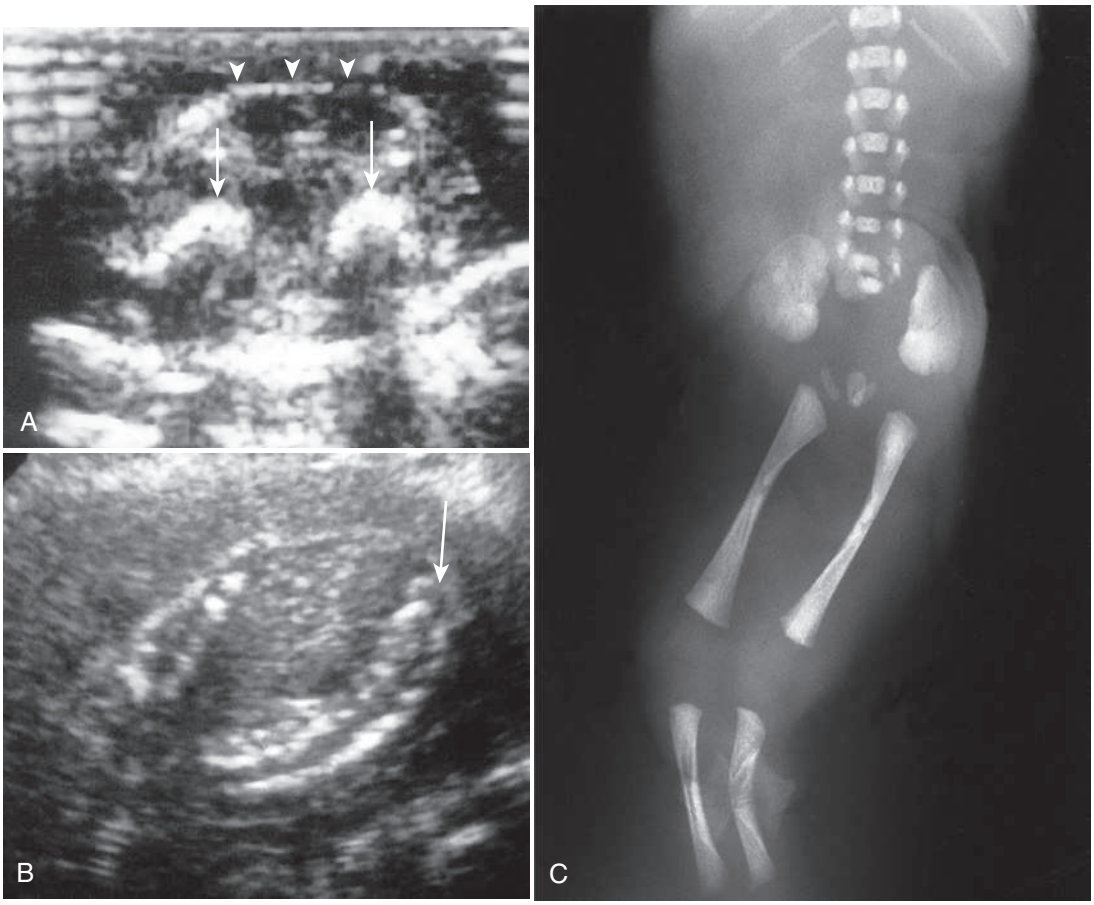

FIG. 40.33 Sirenomelia. (A) Cross section of lower extremities. Femurs *(arrows)* are closer than expected because of fusion of the overlying soft tissues with a continuous layer of overlying skin *(arrowheads).* **(B) Sacral agenesis** with abrupt termination of the lower spine *(arrow).* **(C)** Single, fused lower extremity and sacral agenesis.

Extremity enlargement may also be related to thickened subcutaneous tissues, as in hydrops or large-for-gestational-age infants.
