FIG. 14.38 Inflamed Fat With Phlegmon. Oblique sagittal ultrasound image of the right lower quadrant shows the thickened terminal ileum with echogenic inflamed fat and hypoechoic perienteric phlegmon formation *(arrow)*.

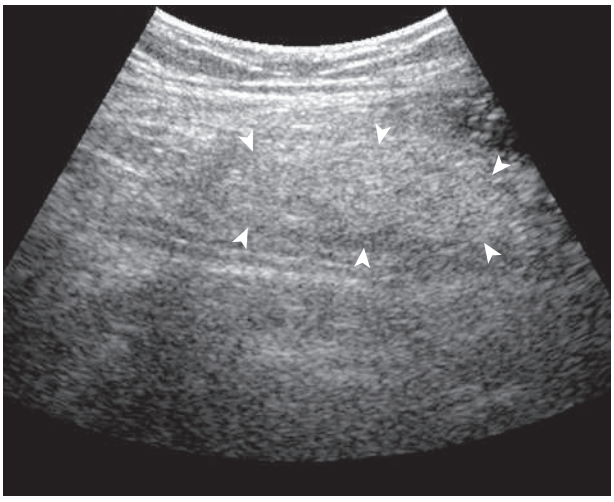

FIG. 14.39 Right-Sided Segmental Omental Infarction. Sagittal image of the right midabdomen shows an ovoid echogenic mass *(arrowheads)*. This was the site of the patient's maximal tenderness.

and occasionally laparoscopic evaluation may be necessary, with biopsy of the peritoneum to rule out tumor.

Another possible sonographic finding in endometriosis is the presence of hypoechoic **endometrial plaques** on the serosal surface of pelvic bowel loops or urinary bladder. These plaques may tether the wall of the affected organ and show flow with color Doppler imaging. They are best demonstrated with the transvaginal probe (Fig. 14.41, Videos 14.9 and 14.10). "The sliding sign" is proving useful at predicting pouch of Douglas obliteration in women caused by endometriosis.[76-78]

LEIOMYOMATOSIS PERITONEALIS DISSEMINATA

Leiomyomatosis peritonealis disseminata is a relatively rare clinical entity characterized by multiple nodules, mainly the result of smooth muscle proliferation over the surface of the peritoneal cavity.[79] Leiomyomatosis peritonealis disseminata often mimics a malignant process, but the diagnosis is easily made with biopsy.

Typically, leiomyomatosis peritonealis disseminata is an incidental finding at imaging or during procedures such as laparoscopy, cesarean section, laparotomy, and postpartum tubal ligation.[29] It occurs mainly in women, primarily during the reproductive period. Exposure to estrogen seems to play an etiologic role. Many patients have uterine leiomyomas as well. Conservative care is generally indicated. When leiomyomatosis peritonealis disseminata occurs during pregnancy or with the oral contraceptive use, it may regress spontaneously after delivery or with oral contraceptive discontinuation. Malignant transformation of leiomyomatosis peritonealis disseminata remains uncertain. In a few isolated cases, malignant leiomyosarcomas have been

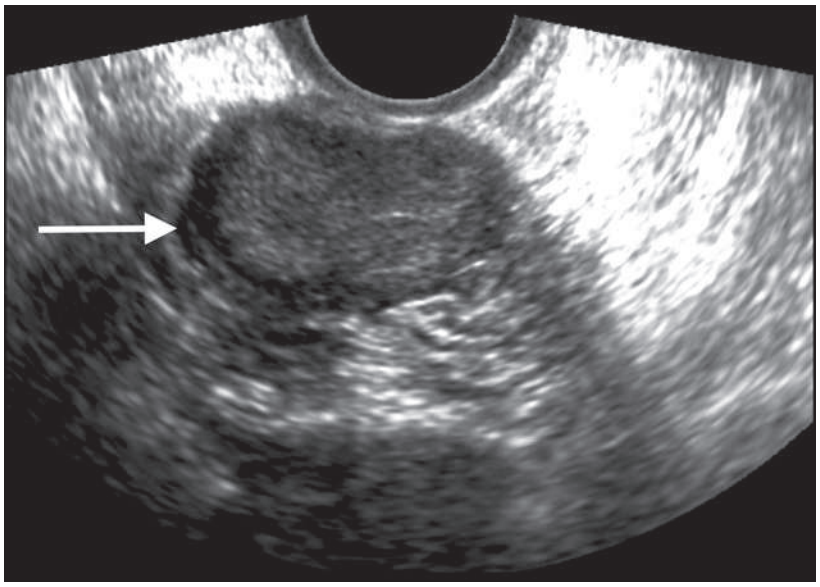

FIG. 14.40 Endometrioma in the Pouch of Douglas. Sagittal TVS shows a hypoechoic nodule deep in the pouch of Douglas *(arrow)* separate from the uterus and ovaries. This nodule could only be visualized by elevating the examining hand holding the probe. See also Video 14.8.

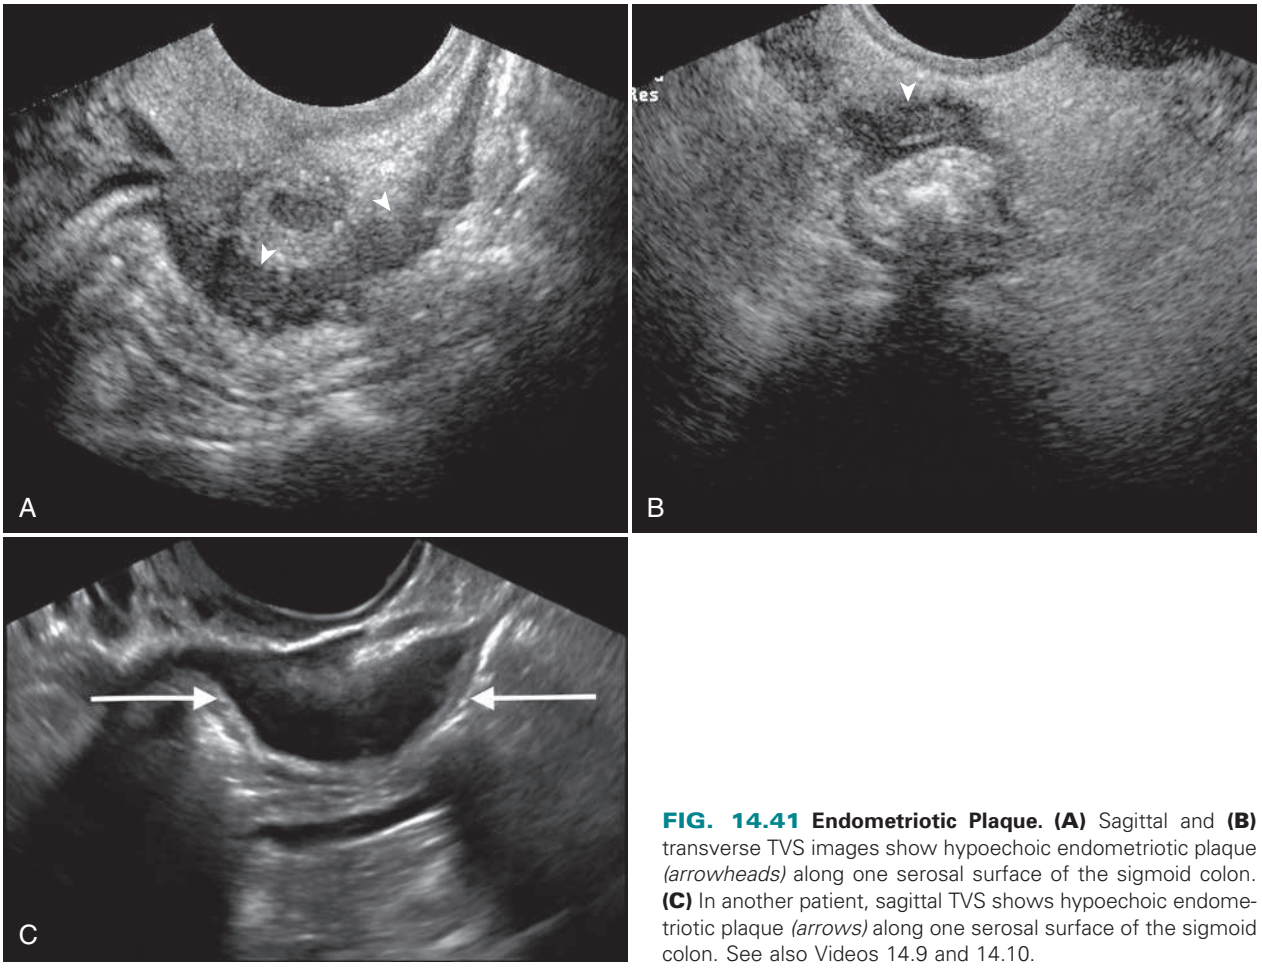

FIG. 14.41 Endometriotic Plaque. (A) Sagittal and **(B)** transverse TVS images show hypoechoic endometriotic plaque *(arrowheads)* along one serosal surface of the sigmoid colon. **(C)** In another patient, sagittal TVS shows hypoechoic endometriotic plaque *(arrows)* along one serosal surface of the sigmoid colon. See also Videos 14.9 and 14.10.

described shortly after making the diagnosis of leiomyomatosis peritonealis disseminata. A clear association, however, has not been established. Sonographic evaluation may show multiple small, hypoechoic nodules throughout the peritoneal cavity (Fig. 14.42).

PNEUMOPERITONEUM

CT is regarded as the standard for detecting, localizing, and quantifying free air.[80] Plain radiographs are also sensitive at detecting free air, with even 1 mL potentially visible on an erect

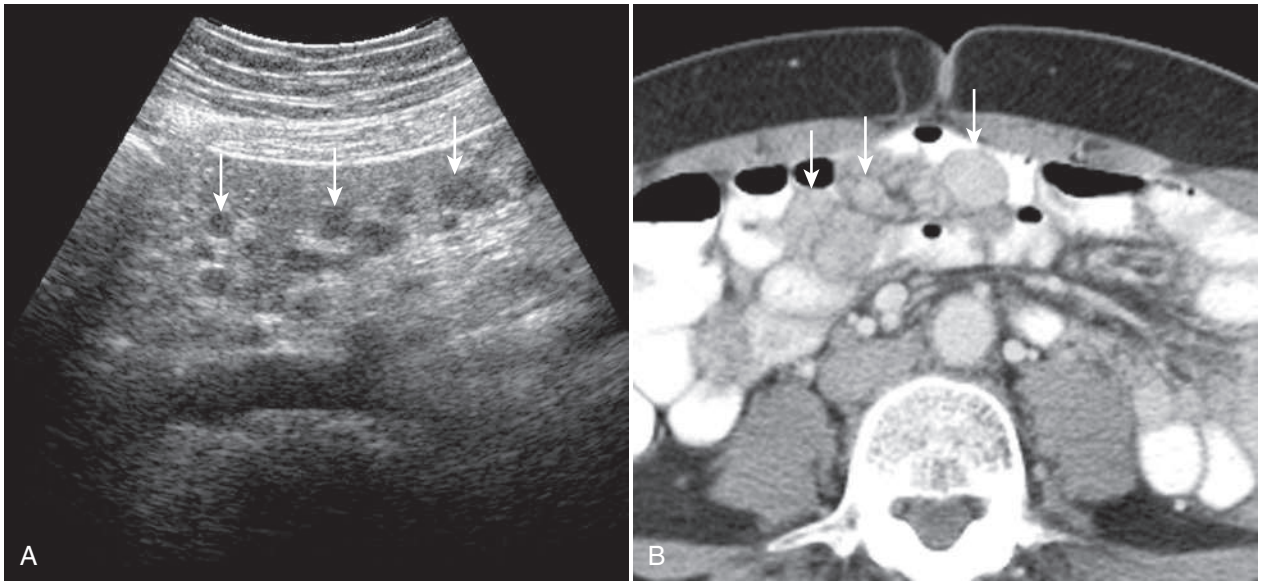

FIG. 14.42 Leiomyomatosis Peritonealis Disseminata. (A) Sagittal ultrasound and **(B)** axial CT, images show multiple small, hypoechoic, enhancing peritoneal nodules *(arrows)*.

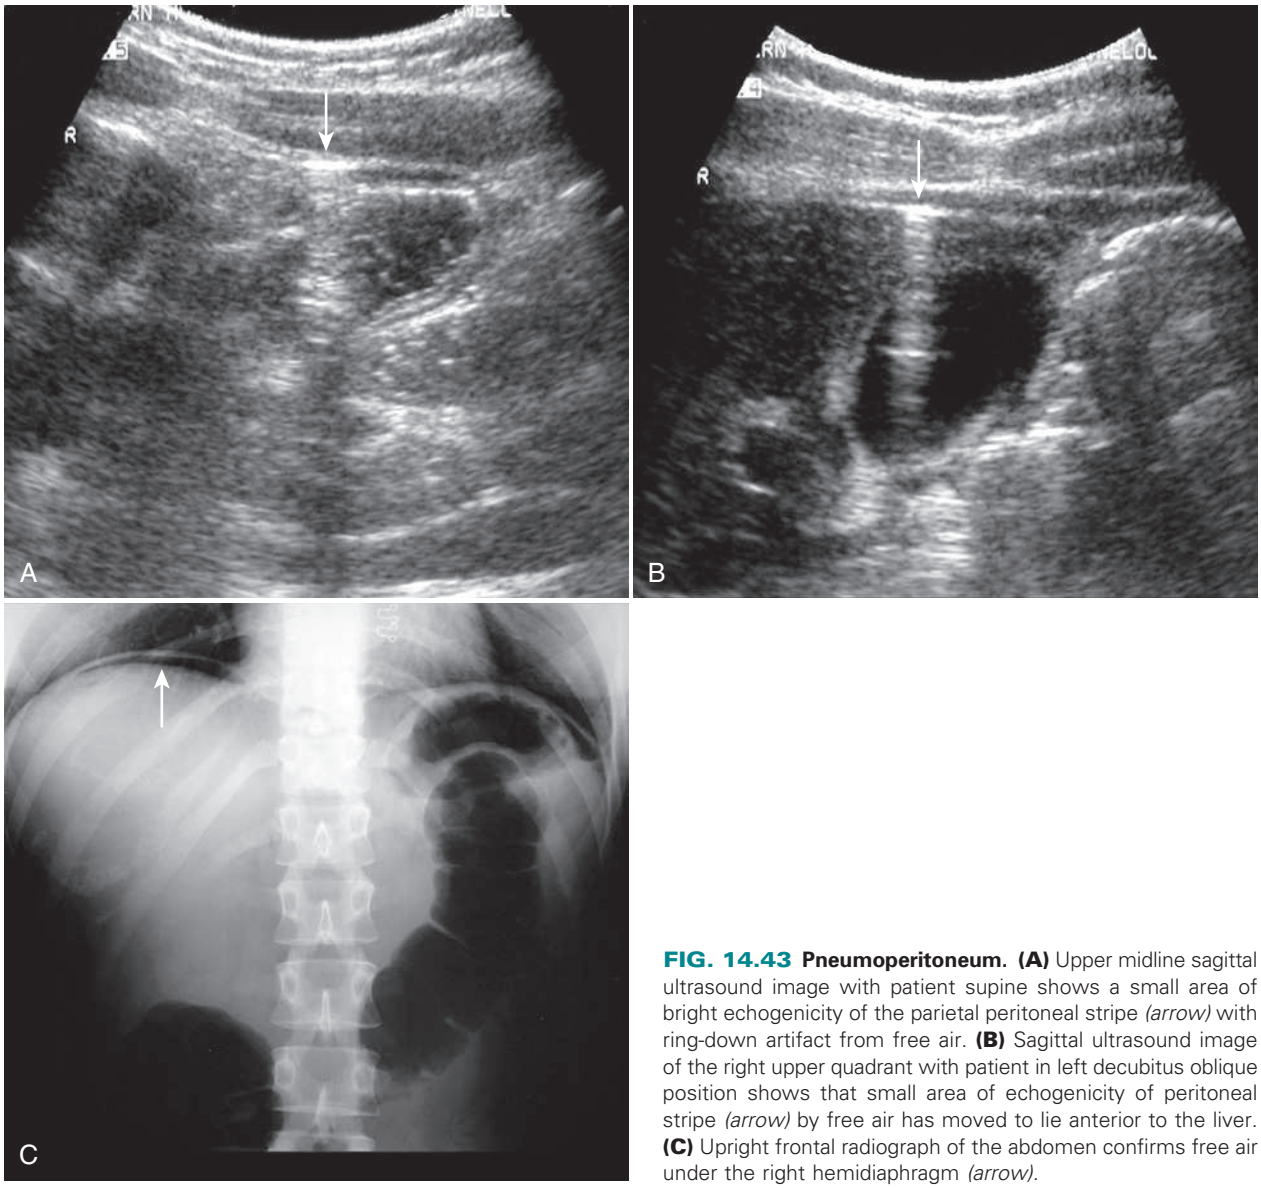

FIG. 14.43 Pneumoperitoneum. (A) Upper midline sagittal ultrasound image with patient supine shows a small area of bright echogenicity of the parietal peritoneal stripe *(arrow)* with ring-down artifact from free air. **(B)** Sagittal ultrasound image of the right upper quadrant with patient in left decubitus oblique position shows that small area of echogenicity of peritoneal stripe *(arrow)* by free air has moved to lie anterior to the liver. **(C)** Upright frontal radiograph of the abdomen confirms free air under the right hemidiaphragm *(arrow)*.

chest radiograph. Ultrasound is often the initial imaging modality requested to assess abdominal pain, however, so the identification of free air is an extremely important finding.

Sonographic technique is critical when assessing for free air. The patient should be scanned in the supine and steep left posterior oblique positions, paying particular attention to the epigastrium and right upper quadrants, respectively.[81,82] **Free air** in the epigastrium, with the patient lying supine, will frequently shift to the right upper quadrant with the patient lying in a left posterior oblique position (Fig. 14.43). Free air is most often seen just deep to the parietal peritoneum, is best appreciated with a linear array transducer, and appears as a region of extreme echogenicity of the parietal peritoneal line, often with posterior ring-down artifact.[83] Another sonographic sign of pneumoperitoneum in patients with ascites is gas bubbles in the ascitic fluid. Gas bubbles may appear as tiny, floating echogenic foci and have a high association with gut perforation and infection of the peritoneal fluid. When free air is detected, ultrasound will frequently reveal the underlying cause, so the remainder of the abdomen and pelvis should be carefully assessed for evidence of inflammation or tumor.[82]

CONCLUSION

Assessment of the peritoneum is easily performed with ultrasound in the majority of patients and should not add significantly to scanning time when the peritoneum is normal. There are limitations in extremely obese and postoperative patients, but in general, most peritoneal diseases can be readily detected and characterized with ultrasound. Many patterns of peritoneal disease are nonspecific, however, and sonographic findings must be interpreted in light of the patient's clinical symptoms, physical findings, and laboratory investigations. When fluid or tissue is required to reach a specific diagnosis, ultrasound is an efficient, cost-effective modality for guidance.[84] It is also a safe, readily available, and relatively inexpensive modality for monitoring disease progression and response to treatment. In patients with ovarian cancer, ultrasound is invariably performed as part of the patient's initial clinical workup. Because peritoneal dissemination is the major determinant of both prognosis and treatment choices, we recommend including the peritoneal cavity in the sonographic assessment of this patient population.

CHAPTER 15

The Uterus

Douglas Brown and Deborah Levine

SUMMARY OF KEY POINTS

- Transvaginal ultrasound is usually needed for optimal assessment of the uterus.
- Uterine enlargement in a nonpregnant patient is most commonly caused by fibroids or adenomyosis.
- Adenomyosis should be considered when there is an enlarged globular shape of the uterus; heterogeneity or asymmetrical thickening of the myometrium; indistinct interface between the endometrium and myometrium; or cysts, echogenic striations, or echogenic nodules in the myometrium.
- Leiomyosarcomas of the uterus overlap in appearance with much more common leiomyomas and are difficult to diagnose by ultrasound.
- If an intrauterine device (IUD) is low in the uterus, one should suspect that one or both arms of the IUD are embedded in the myometrium.
- Assessment of the fundal contour of the myometrium and endometrium in the coronal plane using three-dimensional (3-D) ultrasound is important for diagnosing the most common müllerian duct anomalies.
- Infrequently the endometrium will not be fully seen on ultrasound; when this occurs, one should state that it cannot be reliably measured.

INTRODUCTION AND SCANNING TECHNIQUES

Sonography plays an integral role in evaluation of the uterus. Both transabdominal sonography (TAS) and transvaginal sonography (TVS) are well-established techniques for assessing the enlarged uterus and patients with abnormal vaginal bleeding. The anterior surface of the uterine fundus and body is covered by peritoneum. The peritoneal space anterior to the uterus is the **vesicouterine pouch,** or **anterior cul-de-sac.** This space is usually empty, but it may contain small bowel. Posteriorly, the peritoneal reflection extends to the posterior fornix of the vagina, forming the **rectouterine recess,** or **posterior cul-de-sac.** Laterally, the peritoneal reflection forms the **broad ligaments,** which extend from the lateral aspect of the uterus to the lateral pelvic side walls (Fig. 15.1). The **round ligaments** arise from the uterine cornua anterior to the fallopian tubes in the broad ligaments, extend anterolaterally, and course through the inguinal canals to insert into the fascia of the labia majora.

The **cervix** is located posterior to the bladder and opens into the upper vagina through the external os. The **vagina** is a fibromuscular canal that lies in the midline and runs from the cervix to the vestibule of the external genitalia. The cervix projects into the proximal vagina, creating a space between

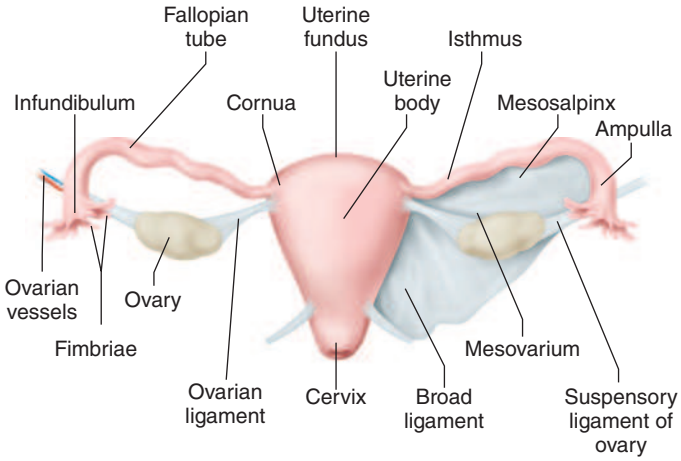

FIG. 15.1 Normal Gynecologic Organs. Diagram of uterus, ovaries, fallopian tubes, and related structures. On left side of the image, the broad ligament has been removed.

the vaginal walls and the surface of the cervix called the **vaginal fornix.**

The arterial blood supply to the uterus comes primarily from the **uterine artery,** a major branch of the anterior trunk of the internal iliac artery. The uterine artery ascends along the lateral margin of the uterus in the broad ligament and, at the level of the uterine cornua, runs laterally to anastomose with the ovarian artery. The uterine arteries anastomose extensively across the midline through the anterior and posterior arcuate arteries, which run within the broad ligament and then enter the myometrium.[1] The uterine plexus of veins accompanies the arteries.

The uterus is usually best imaged with TVS, with as high a frequency as possible that also allows sound to adequately penetrate the uterus. However, scanning with TAS is often helpful when the uterus is enlarged and/or fibroids are located very superiorly or laterally; in such instances TVS alone may miss important findings. Thus it is important to look, albeit sometimes briefly, with TAS regardless of the degree of fullness of the urinary bladder.

Advantages of Transvaginal Sonography

Use of higher-frequency transducers with better resolution
Examination of patients who are unable to fill their bladder
Examination of obese patients
Evaluation of a retroverted or retroflexed uterus
Better characterization of the internal characteristics of a pelvic mass
Better detail of a pelvic lesion
Better detail of the endometrium

Doppler ultrasound evaluation, most often with conventional color Doppler or power Doppler, is helpful in some patients. It can be used to evaluate for the presence of vascular flow and in select cases can provide an assessment of the degree and character of vascularity. As true for any application of color or power Doppler imaging, small pixels of color that are not part of a distinct vessel should have spectral Doppler evaluation to distinguish arterial or venous flow from noise.

Three-dimensional ultrasound (3-D ultrasound), usually performed with a transvaginal transducer, is most useful for evaluating **müllerian** anomalies of the uterus and for assessment of abnormal position of an **intrauterine device** (IUD).[2] 3-D ultrasound may also be helpful in other instances such as defining the relationship of uterine lesions to the endometrial cavity and may be useful to document findings during sonohysterography (SHG).

Sonohysterography can provide assessment of endometrium or submucosal myometrial lesions, by distending the endometrial cavity. Most studies on infusion techniques have used sterile saline.[3-6] However, gel infusion is now also being used at some centers.[7,8] SHG is not routinely needed but may be helpful if the endometrium is not adequately evaluated by TVS or TAS and may also be helpful in women with abnormal bleeding when a focal lesion is not visualized sonographically. Other indications may include evaluation of endometrial or intracavitary abnormalities detected by TVS, infertility,[9] suspected congenital uterine malformations,[10] and evaluation of women taking tamoxifen.[11]

The procedure involves placement of a sterile speculum, cleansing of the external cervical os with an aseptic solution, and placement of a sterile catheter through the cervix into the endometrial cavity. Several catheters are available, including some with a balloon (to help prevent leakage of the saline back out the cervix) and some without a balloon. If a balloon catheter is used, it should also be filled with saline, as using air may obscure part of the endometrium. Once the speculum has been removed and the transvaginal transducer inserted, sterile saline is slowly injected during ultrasound observation while fully scanning the entire endometrial cavity. If a balloon catheter is used, one should be careful that it does not obscure part of the endometrium; this generally requires deflation of the balloon at the end of the procedure. For premenopausal women, SHG should generally be performed at about day 4 to 10 of the menstrual cycle, when the patient is no longer bleeding but is still early in the menstrual cycle when the endometrium tends to be thin, allowing for avoidance of normal changes in the latter part of the menstrual cycle that can simulate pathology.[12] In postmenopausal women receiving sequential **hormone replacement therapy** (HRT), SHG is performed shortly after the monthly bleeding period. In postmenopausal women not receiving HRT, the procedure can be performed at any time. SHG should not be performed in patients who are pregnant or who have acute pelvic inflammatory disease. Prophylactic antibiotics may be considered in some women, such as those with chronic pelvic inflammatory disease,[12,13] including those in whom a hydrosalpinx is discovered at the time of the study.

Other sonographic methods are used infrequently. Transrectal ultrasound may occasionally be useful to evaluate portions of the uterus if TVS is inadequate, if the patient is a virgin, or if additional imaging is needed for better assessment of the endometrium or pelvic floor.[14,15] Translabial or transperineal scanning, although helpful for abnormalities of the pelvic floor,[16] is rarely useful to evaluate the uterus in a nonpregnant patient. Use of

intravenous ultrasound contrast agents to evaluate the uterus is still in its infancy but there are possible applications in such areas as endometrial lesions.[17] Elastography could potentially help in the evaluation of fibroids, adenomyosis, or sarcomas.[18] Both of these techniques need further investigation before routine clinical use.

NORMAL UTERINE FINDINGS

The uterus is typically divided into at least three sections anatomically, although precise boundaries may be difficult to determine with ultrasound. The **fundus** of the uterus is the most superior portion of uterus, often defined as that portion superior to the ostia of the fallopian tubes. The **body of the uterus** is the largest portion and lies between the fundus and the cervix. The term "isthmus" or "lower uterine segment" is sometimes used, usually referring to the region where the body of the uterus becomes slightly thinner just superior to the cervix. The **cervix** is the inferior portion of the uterus between the external cervical os and internal cervical os. The internal cervical os is often difficult to precisely locate in the nonpregnant uterus.

The position of the uterus is variable and can change with the degree of bladder and/or rectal distension (Fig. 15.2). It may also change during the course of the ultrasound examination in response to pressure from the transvaginal transducer or pressure from the examiner's hand on the lower abdominal wall. The term "version" is used to describe the sagittal axis of the cervix with respect to the sagittal axis of the vagina. The term "flexion" is used to describe the sagittal axis of the uterine body with respect to the sagittal axis of the cervix. These are usually subjective determinations; objective criteria have been suggested but are not widely accepted.[19] The direction of flexion and version

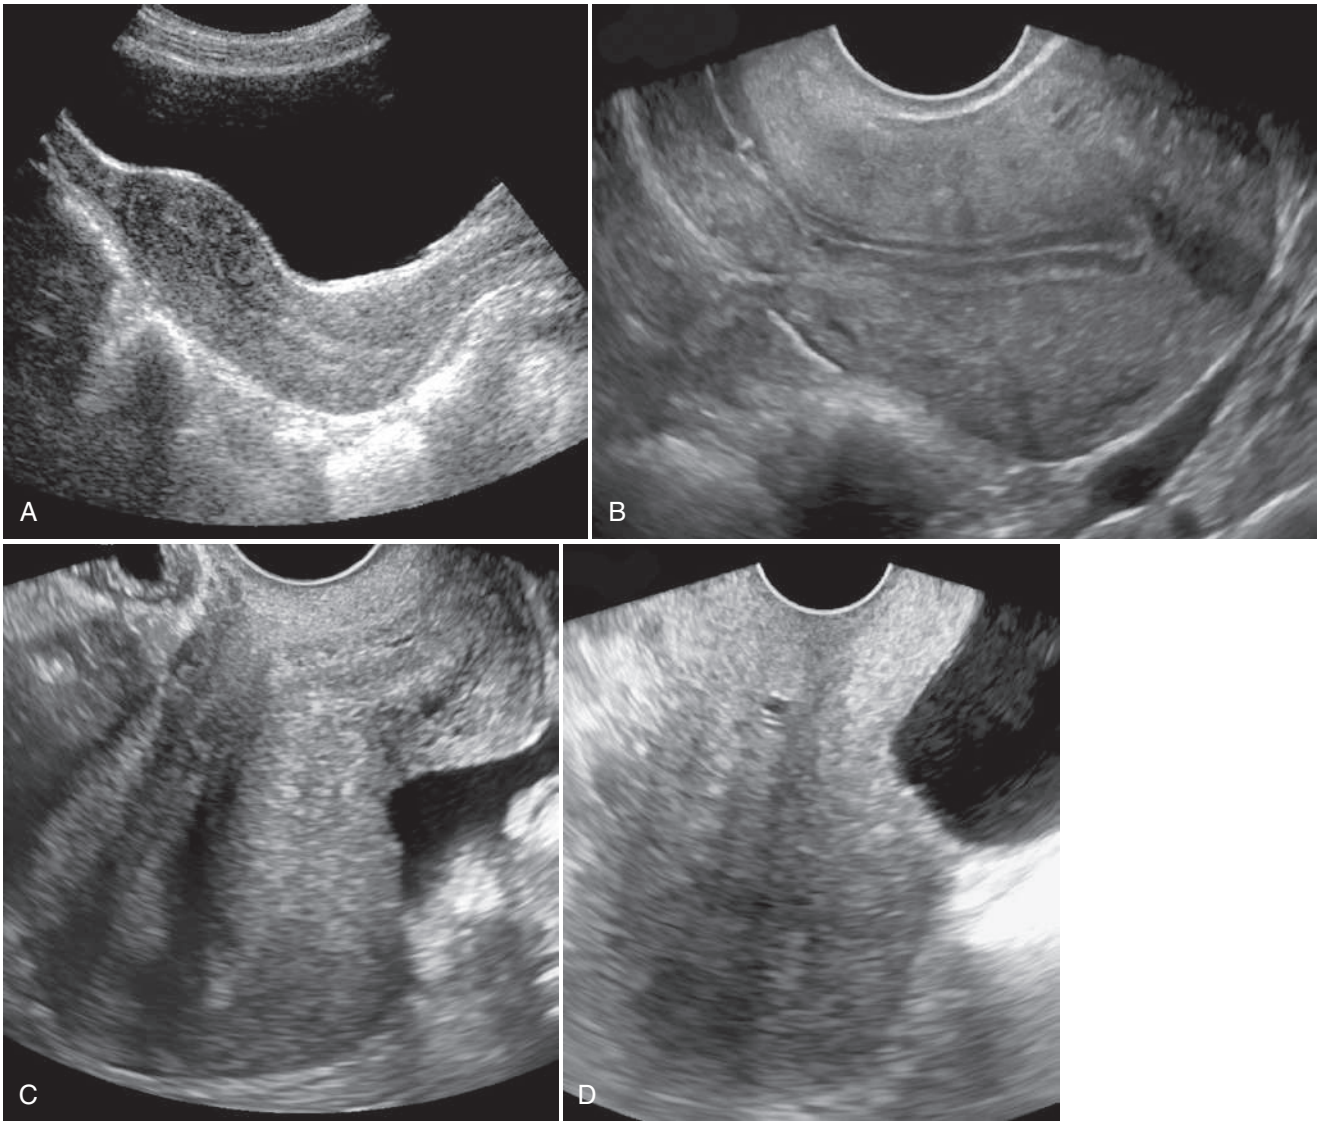

FIG. 15.2 Uterine Positions in the Sagittal Plane. (A) Anteverted, anteflexed position on TAS. **(B)** Retroverted, retroflexed position on TVS. **(C)** Anteverted, retroflexed position on TVS. The uterine body and fundus may be poorly seen with such a uterine position, as in this case. **(D)** Axial uterine position on TVS. The uterus is usually poorly seen when in this position.

are usually the same and the uterus is most frequently anteverted and anteflexed.[19] Anteverted, retroflexed position has been associated with prior cesarean section.[19] Occasionally the sagittal axis of the uterus is the same as the sagittal axis of the vagina. Such a position usually limits TVS evaluation of the uterus. Variable terms have been used to describe this latter position of the uterus, including "axial," "vertical," "midposition," or "partly retroverted."[19-21] One can try to change the uterine position by moving the transducer into the anterior or posterior vaginal fornix and applying gentle pressure with the transducer and/or the nonscanning hand on the lower abdominal wall.

Uterine size varies depending on patient age and gravidity.[13,22-24] In nulliparous adult women, a normal uterus has a pear-shaped appearance, with the diameter and length of the body about double that of the cervix.[25] In general, it measures less than about 8 cm in length, 5 cm in width, and 4 cm in anteroposterior (AP) diameter. **Parity** (pregnancy) can increase the normal size by 1 to 2 cm in each dimension.[23,22,26] After menopause the uterus atrophies, with the most rapid decrease in size occurring in the first 10 years after cessation of menstruation.[23] In patients older than 65 years, the uterus ranges from 3.5 to 6.5 cm in length and 1.2 to 1.8 cm in AP diameter.[26]

In premenopausal patients the endometrium varies in appearance and thickness during the menstrual cycle[27-32] (Fig. 15.3). The endometrium is composed of a **superficial functional layer** and a **deep basal layer.** The functional layer thickens throughout the menstrual cycle and is shed with menses. The basal layer remains intact during the cycle and contains the spiral arteries, which become tortuous and elongated to supply the functional layer as it thickens. The **proliferative phase** of the cycle before ovulation is under the influence of estrogen, whereas progesterone is mainly responsible for maintenance of the endometrium in the **secretory phase** following ovulation.

When obtaining an **endometrial thickness measurement,** one should make the measurement in the sagittal plane of the uterus, perpendicular to the long axis of the endometrium, at the endometrium's thickest point, including both the anterior and posterior layers.[33] If fluid is present in the endometrial cavity, it should be excluded from the measurement. If one cannot see the entire endometrium, which may occur in up to 10% of patients, a thickness measurement should not be reported and instead one should report that it cannot be reliably measured.[33] Such limited assessment of the endometrium may occur for various reasons including fibroids, marked obesity, and uterine position.[34] SHG may be helpful in these patients.

During the **menstrual phase** the endometrium is usually a thin hyperechoic line but may be irregular or contain a small amount of fluid from blood. During the **proliferative phase** the endometrium thickens slightly, and later in the proliferative phase develops a multilayered appearance, also known as trilaminar or triple layer. This appearance is due to the thin echogenic line centrally that represents the opposed endometrial mucosal surfaces, the functional layer of the endometrium that becomes relatively hypoechoic, and a thin echogenic outer line. The thin echogenic outer line may be the basal layer of the endometrium or the interface between the endometrium and the myometrium. One potential pitfall in measuring the endometrium is to mistake the hypoechoic inner myometrium as part of the endometrium. One can usually make the distinction because the multilayered appearance of the proliferative phase has a distinct outer echogenic line, whereas the hypoechoic inner myometrium has no such defining outer echogenic line. After ovulation, in the **secretory phase** the functional layer of the endometrium becomes hyperechoic, usually starting on the outer edge and progressing inward. It generally becomes uniformly hyperechoic by the mid to late secretory phase.[29-32] The endometrium tends to have more distal acoustic enhancement in the secretory phase, which can potentially be mistaken for the endometrium itself when the endometrium is poorly seen. The secretory endometrium may measure up to 16 to 20 mm (though there is no accepted upper limit of normal), and the appearance may be heterogeneous. One may occasionally see endometrial folds that can simulate polyps during the secretory phase.[33,34] One should be cautious before diagnosing polyps or an abnormally thick endometrium during this phase of the menstrual cycle and consider follow-up ultrasound in the proliferative phase.

In postmenopausal women the endometrium is normally homogeneously hyperechoic in appearance. In postmenopausal women without vaginal bleeding, the upper limit of acceptable thickness is 8 to 11 mm.[35-40] It should be noted that these limits are greater than expected for an atrophic endometrium and that polyps or hyperplasia could be present. However, because cancer tends to bleed early, this higher threshold in postmenopausal women who are not bleeding is acceptable in order to limit the number of endometrial biopsies for benign disease. When there is abnormal vaginal bleeding, the upper limit of normal thickness is based on the trade-off between sensitivity and specificity, and thresholds of 3 to 5 mm have been suggested. These are described in more detail in the section on endometrial bleeding.

The myometrium is normally homogeneous in echogenicity. The normal **myometrium** consists of three layers, although they are not distinctly separated from one another. The **intermediate layer** is the thickest and has a uniformly homogeneous texture of low to moderate echogenicity. The **inner layer** of myometrium is thin, compact, and relatively hypovascular.[41,42] This inner layer, which is hypoechoic and surrounds the relatively echogenic endometrium, has also been referred to as the **subendometrial halo.** It should be noted that this is not necessarily the same as the junctional zone on magnetic resonance imaging (MRI).[43] The thin **outer layer** is slightly less echogenic than the intermediate layer and is separated from it by the arcuate vessels.

The **arcuate arteries** lie between the outer and intermediate layers of the myometrium and branch into the **radial arteries,** which run in the intermediate layer to the level of the inner layer. The radial arteries then branch into the **spiral arteries,** which enter the endometrium and supply the functional layer. The **uterine veins** are larger than the accompanying arcuate arteries and are frequently identified as small, focal anechoic or hypoechoic areas on both TAS and TVS.[44] These veins can occasionally be prominent and simulate cystic areas (Fig. 15.4). Although Doppler imaging may be helpful in confirming the vascular nature of these spaces, the flow may be too slow to be detected by color Doppler imaging. Power Doppler imaging may be helpful in this instance; however, observation of these spaces

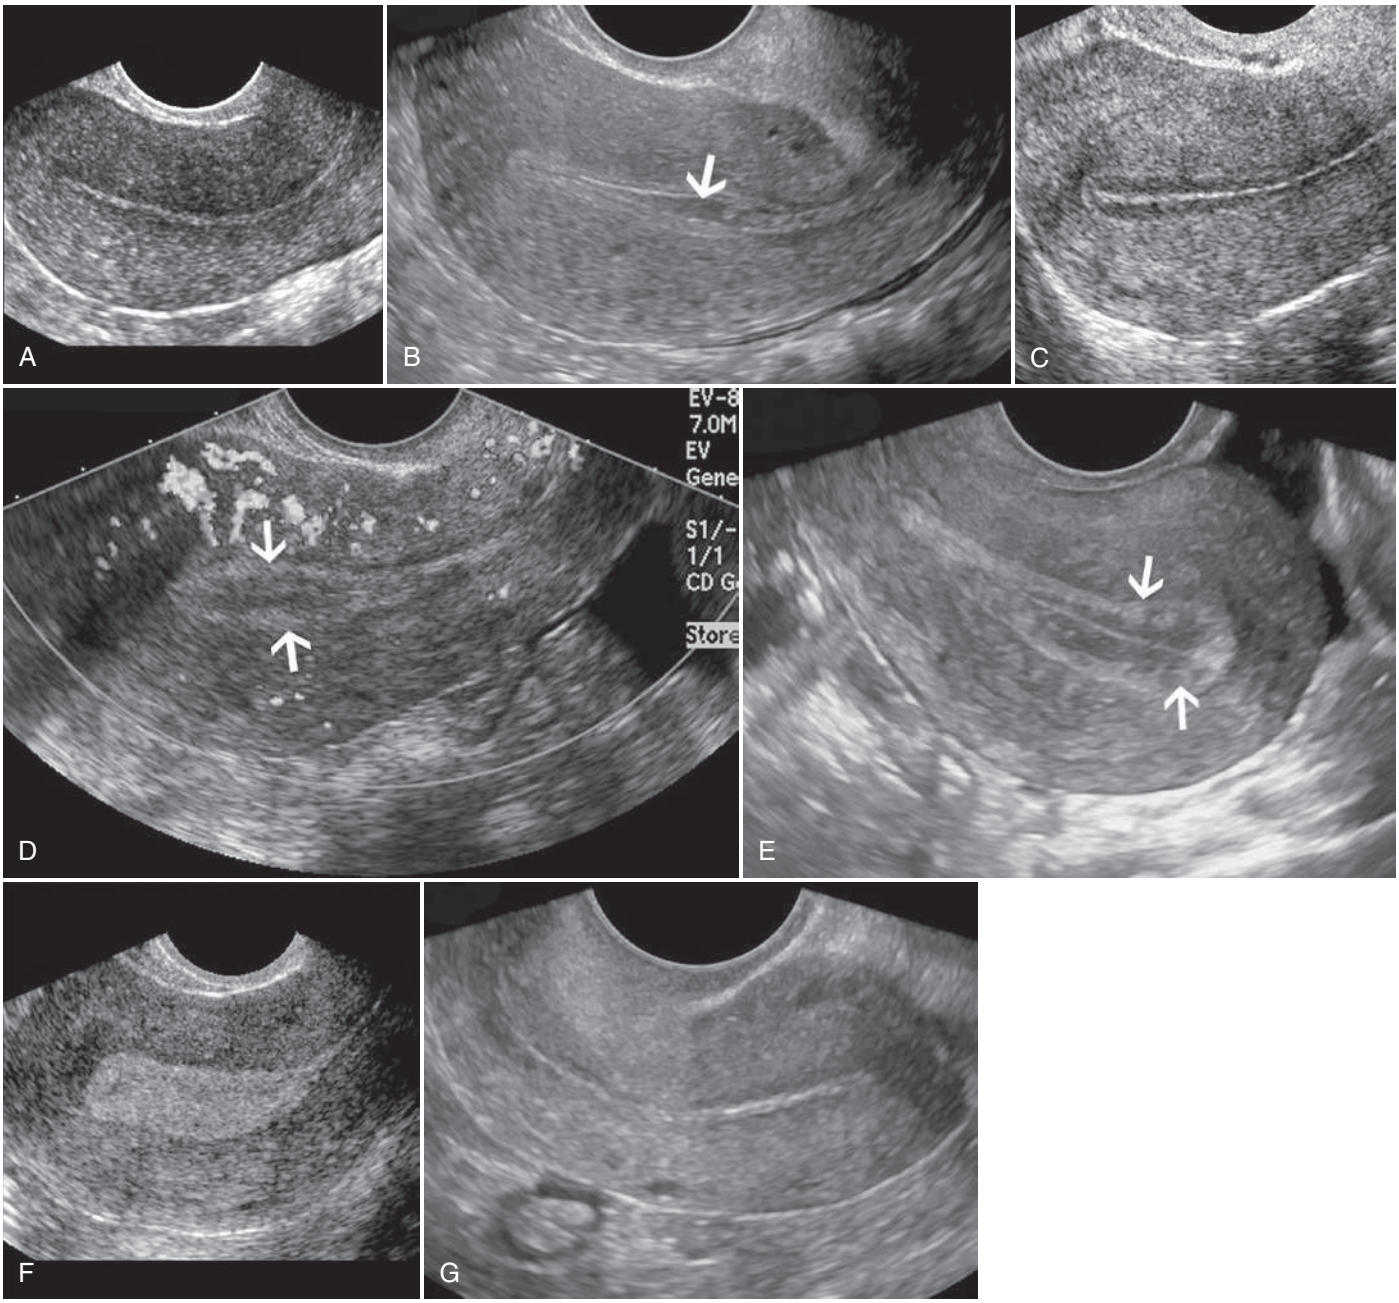

FIG. 15.3 Endometrium—Normal Appearances. All images were obtained with sagittal TVS. **(A)** Normal thin endometrium that may be seen in the menstrual phase or very early proliferative phase. A similar appearance is normal in postmenopausal women. **(B)** Normal thin endometrium with trace fluid *(arrow)* in the endometrial cavity in the menstrual phase. **(C)** Multilayered, also known as "triple-layered" or "trilaminar" (or sandwich sign), appearance typical of the mid to late proliferative phase. **(D)** In the secretory phase, the endometrium begins to become hyperechoic, usually beginning at the outer edge *(arrows)* and progressing inward. **(E)** As the endometrium becomes hyperechoic in the secretory phase, it sometimes does so in an irregular fashion, which can simulate polyps. These have been referred to as **endometrial moguls** or **pseudopolyps** *(arrows)*. Repeat scanning in the proliferative phase of the menstrual cycle can be helpful in such cases. **(F)** Uniformly hyperechoic appearance of the endometrium in the late secretory phase. **(G)** Normal thin postmenopausal endometrium, in this case measuring 2 mm in thickness.

with real-time gray-scale imaging, perhaps with increased gain settings, will usually show the movement of echoes in these veins with slow flow, confirming their vascular nature. Small calcifications may be present in the outer myometrium (Fig. 15.5), thought to be in arcuate arteries, and are most commonly seen in postmenopausal women.[45,46] Although it has been suggested that these calcifications might be more common in women with systemic diseases such as diabetes mellitus and renal failure, the literature thus far describes only a small number of patients.[13,45,46] The peripheral location and diffuse linear nature of these vascular calcifications should help distinguish them from calcified fibroids.

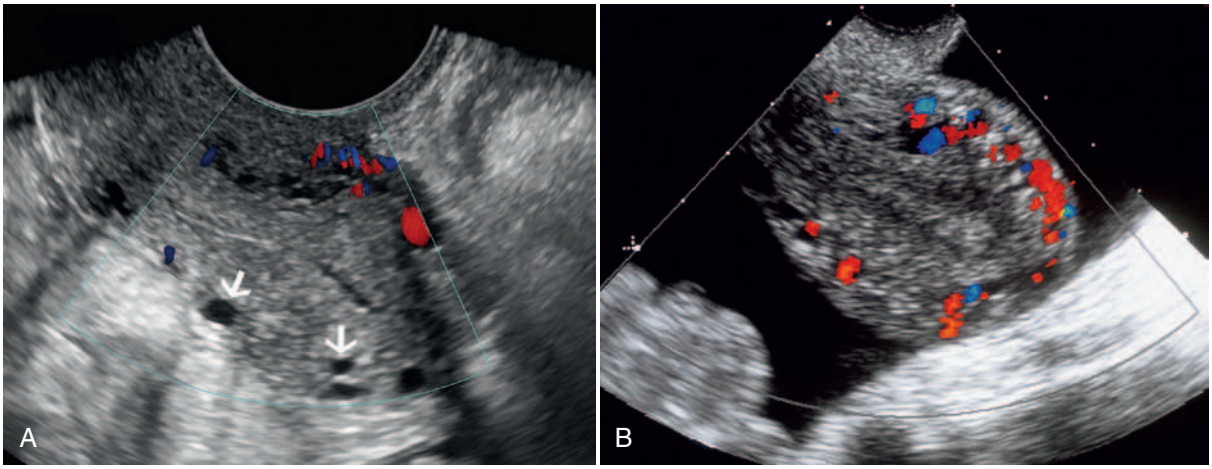

FIG. 15.4 Myometrial Veins. (A) Sagittal TVS shows prominent veins in the outer myometrium. A few had flow demonstrated on Doppler imaging, but many did not have detectable flow on Doppler (two indicated by *arrows*), owing to slow velocity of flow. Real-time imaging showed movement of echoes within these veins. **(B)** Another similar example. There is fluid in the pelvis surrounding the uterus.

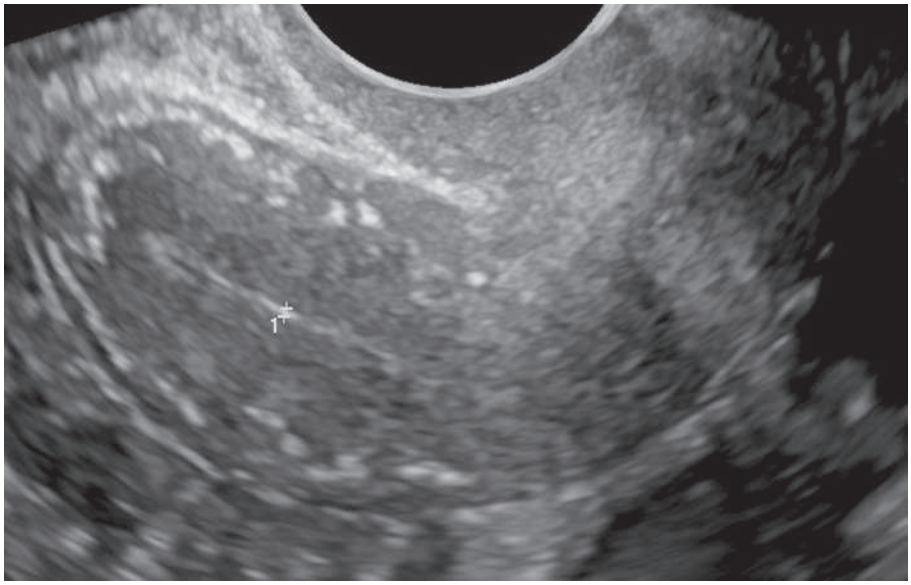

FIG. 15.5 Arcuate Artery Calcifications. Sagittal TVS demonstrates multiple echogenic foci in the outer myometrium due to arcuate artery calcifications. A normal thin endometrium is also noted in this postmenopausal patient (*calipers* centrally).

Myometrial contractions, although more commonly seen during pregnancy, can occasionally be seen in the inner myometrium of nonpregnant women.[47] However, these are subtle contractions and in general not as large or as likely to be mistaken for pathology as may occur during pregnancy.

Tiny echogenic foci, often without acoustic shadowing, may be present in the inner myometrium near the endometrial/myometrial interface (Fig. 15.6). Few data are available for this finding, but it seems to be of no clinical importance and may be due to dystrophic calcification related to prior uterine instrumentation.[48]

The cervix frequently contains cysts, most of which are mucous retention cysts and are commonly termed **nabothian cysts.** They often appear as simple cysts but may occasionally have internal echoes in the cyst fluid (Fig. 15.7). Although variable in size and number, most nabothian cysts are small and of no clinical importance.[49] Mucosal folds in the cervix, termed **plicae palmatae,** are more commonly seen with MRI but may occasionally be seen with TVS (see Fig. 15.7E). Tiny echogenic foci may also be seen in the inner portion of the cervix and are likely due to punctate calcifications (see Fig. 15.7F). These may be related to prior uterine instrumentation and are considered a benign finding.[50] The inner part of the cervix may also appear slightly hypoechoic compared with the outer cervix and possibly simulate a mass (Fig. 15.8). The uniform elongated nature of this finding should help distinguish it from a true mass.

MÜLLERIAN DUCT ANOMALIES

The fused caudal ends of the two müllerian **(paramesonephric)** ducts form the uterus, cervix, and upper two-thirds of the vagina. Fusion typically occurs in the medial portion of the ducts and

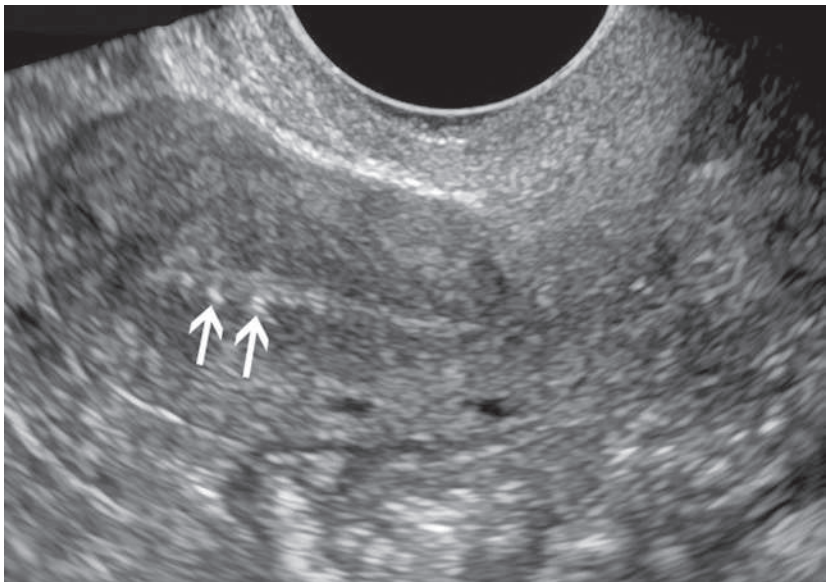

FIG. 15.6 Calcifications at Endometrial/Myometrial Interface. Sagittal TVS shows a few punctate echogenic foci *(arrows),* likely due to calcifications, at the interface of the myometrium and endometrium. This finding is of doubtful importance and may be related to prior uterine instrumentation.

proceeds in either a cephalad or a caudal direction or both.[51,52] The median septum formed by the medial walls of the müllerian ducts then resorbs, leaving a single uterine cavity.

Arrested development of the müllerian ducts, failure of fusion of the müllerian ducts, and/or failure of resorption of the median septum results in variable forms of müllerian duct anomalies (MDAs). MDAs have an estimated prevalence ranging from up to 6% in the general population to up to 15% in populations with recurrent pregnancy losses.[53] Whereas minor anomalies (arcuate uterus with just a mild fundal indentation) probably have no clinical consequence, others are associated with pregnancy loss (septate uterus)[54] and various obstetric complications such as premature delivery (bicornuate uterus).

The anomalies are typically categorized based on their embryology and morphology, and the most commonly used classification is one from 1988 by the American Fertility Society, now known as the American Society for Reproductive Medicine[55] (Fig. 15.9). Failure of fusion of the müllerian ducts results in **uterus didelphys** or **bicornuate uterus,** and failure of resorption of the uterine septum results in a **septate uterus** (the most common MDA).[56] Other anomalies may be seen in patients exposed to **diethylstilbestrol** (DES) *in utero*, although this is seen less frequently now since its use was stopped in the early 1970s. In DES exposure, sonography may demonstrate a diffuse decrease in the size of the uterus and an irregular T-shaped uterine cavity.[57,58]

The aforementioned classification system is problematic, however, because vaginal anomalies are not included, not all anomalies fit the classification, and there are no specific imaging features defined for diagnosis. Various imaging criteria have been proposed. We will focus on the more commonly used criteria, realizing there is no clear agreement on the best criteria. Alternative classification systems of MDAs have been suggested.[59-61] Some patients will have complex anomalies that do not fit neatly into classification systems; accurate description of the various components of the anomaly is important in such cases, with measurements such as fundal indentation, septal thickness, and myometrial thickness, being potentially helpful.

The coronal view of the uterus is important for many of the MDAs (Fig. 15.10, Videos 15.1 and 15.2), particularly when trying to diagnose the more common anomalies such as septate uterus. One cannot usually obtain a view of the uterus in its coronal plane with two-dimensional (2-D) TVS, although occasionally one can obtain a coronal view of the uterus with TAS when there is little fluid in the urinary bladder, and the uterus is sufficiently anteflexed. In general, 3-D ultrasound is needed for determining the type of MDA.[52,62] A recent meta-analysis for accuracy and diagnosis of MDAs (based on studies that predominately used the 1988 classification system[55]) showed that the highest degrees of mean diagnostic accuracy were, in decreasing order, as follows: 3-D ultrasound, 97.6%; SHG, 96.5%; hysterosalpingography (HSG), 86.9%; and 2-D ultrasound, 86.6%.[53]

The most common distinction to be made in clinical practice is when the endometrium appears slightly divided on 2-D ultrasound and one needs to determine whether this is an arcuate, septate, or bicornuate uterus. This is an important distinction to make because (particularly for infertility patients) when the MDA is thought to have reproductive consequences, a **septate uterus** will in general be treated surgically (because the septum may have a poor blood supply and can contain fibrous and/or myometrial tissue[63,64] and is associated with recurrent miscarriage), whereas a bicornuate uterus will in general not be treated surgically. Using the 3-D TVS reconstructed coronal view of the uterus, one should evaluate the contour of the myometrium in the fundus of the uterus. If the fundal myometrium is outwardly convex or has an inwardly concave indentation of less than 1 cm (from a

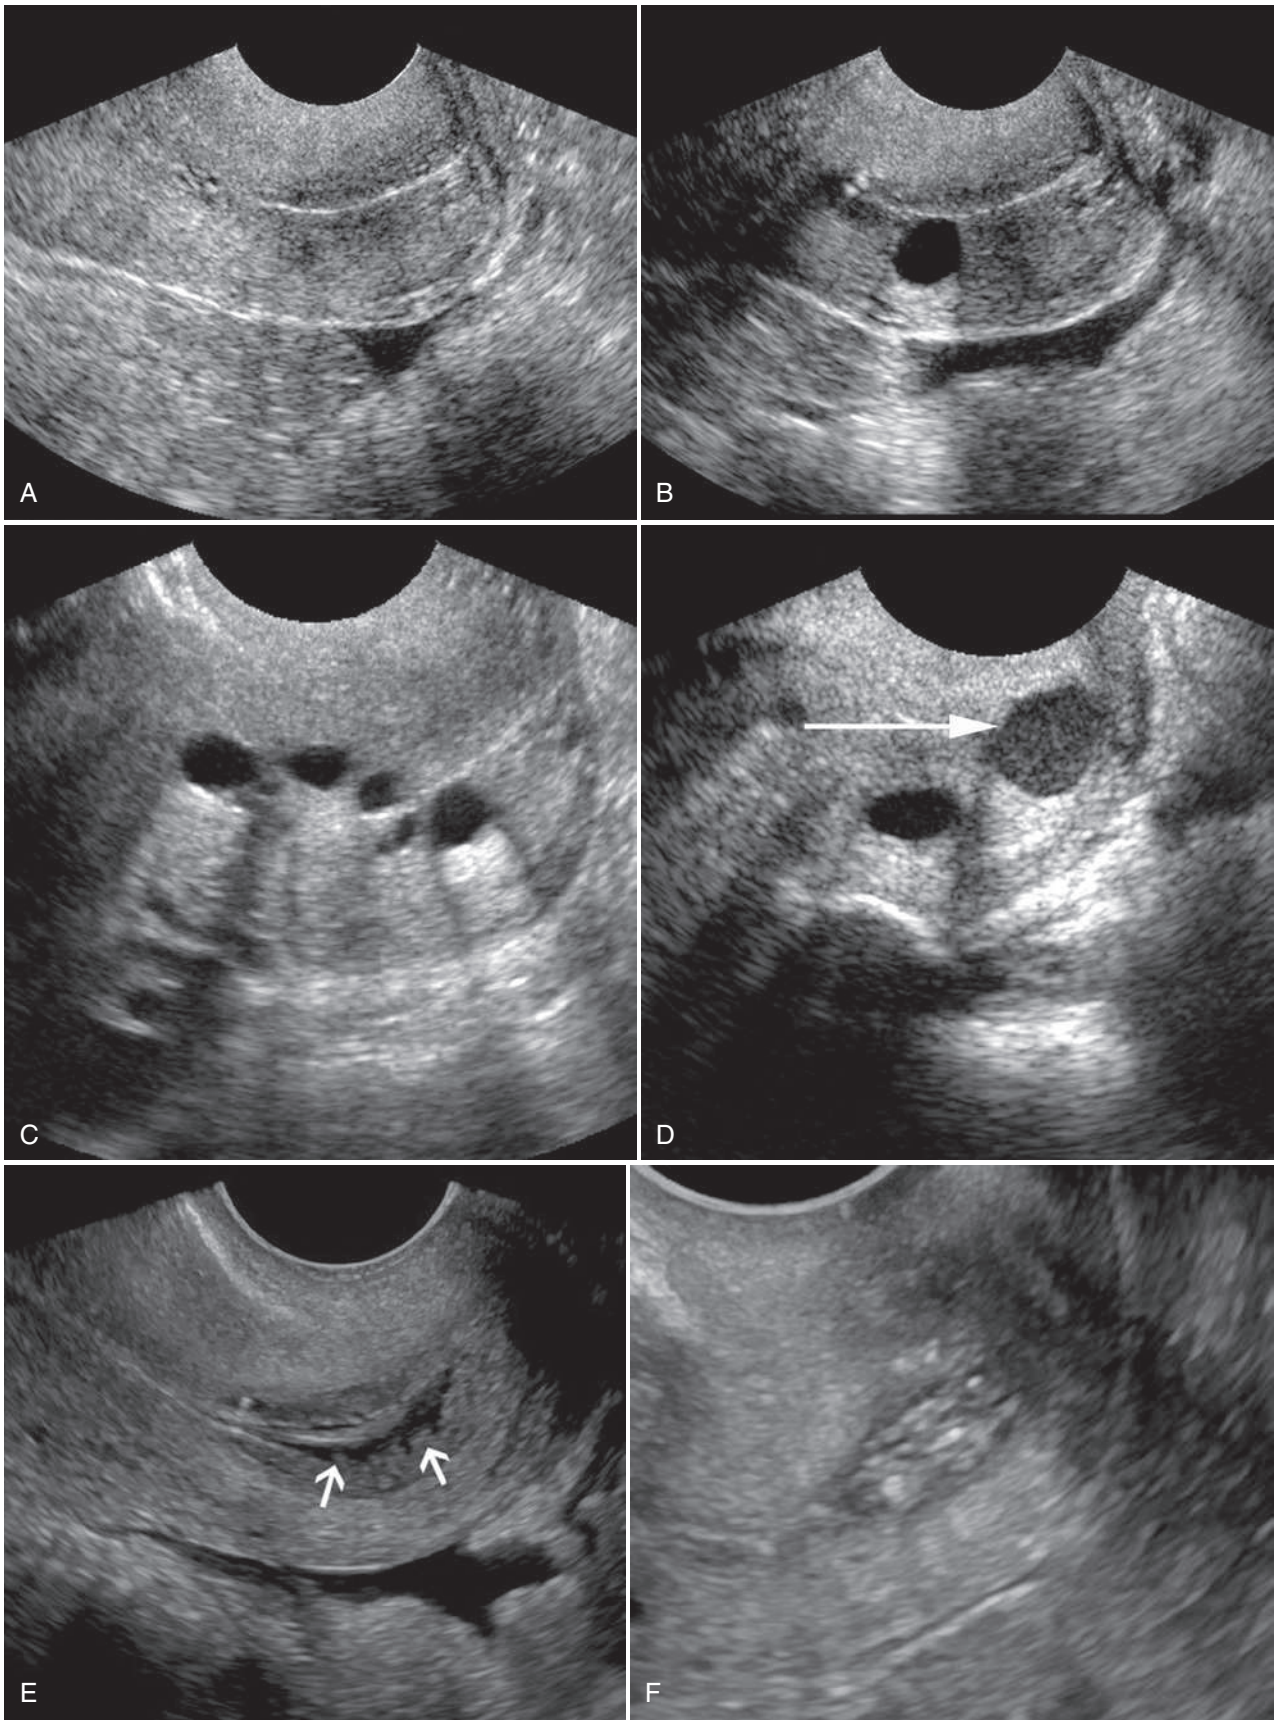

FIG. 15.7 Normal and Insignificant Cervical Findings. All images are sagittal TVS. **(A) Normal cervix. (B)** Single **nabothian cyst. (C)** Multiple nabothian cysts. **(D)** Nabothian cyst with internal echoes *(arrow)* likely due to proteinaceous material or hemorrhage. There is also a simple nabothian cyst. **(E) Cervical folds.** A small amount of fluid in the endocervical canal helps outline a few undulations (two of which are indicated by *arrows*), due to cervical folds, also known as **plicae palmatae.** They may be more easily seen when there is a small amount of fluid in the endocervical canal, as in this case. **(F)** Several tiny echogenic foci in the inner portion of the cervix.

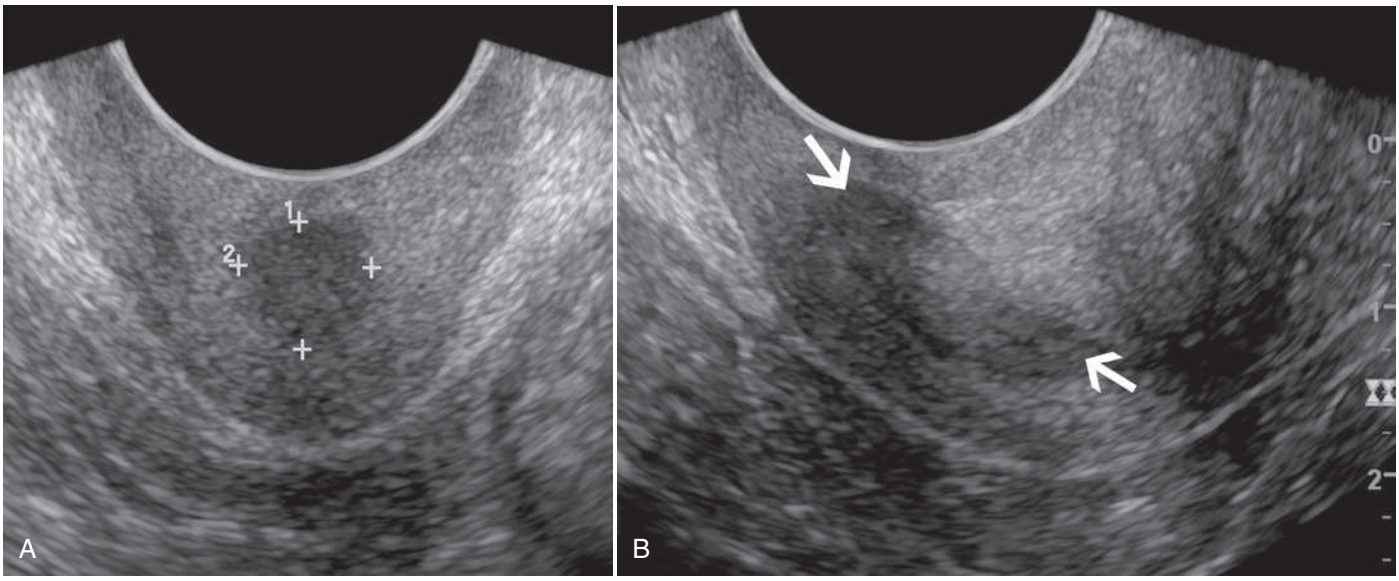

FIG. 15.8 Cervical Pseudomass. (A) Transverse TVS of cervix shows central hypoechoic area simulating a mass *(calipers).* **(B)** Sagittal TVS in same patient shows the smooth elongated nature of the inner portion of the cervix (between *arrows*) in a retroverted uterus. The inner portion of cervix is sometimes relatively hypoechoic to the outer portion and can simulate a mass.

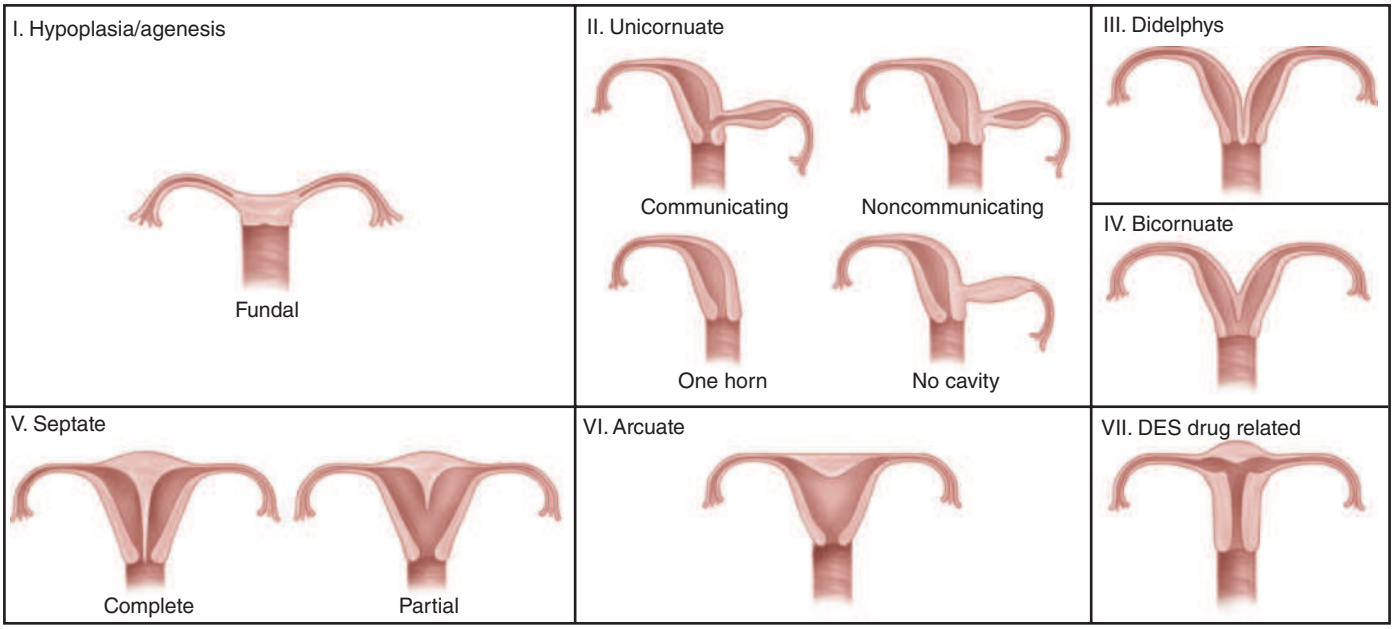

FIG. 15.9 Drawing of Müllerian Abnormalities. *DES,* Diethylstilbestrol. (Reprinted by permission from the American Society for Reproductive Medicine. The American Fertility Society classifications of adnexal adhesions, distal tubal occlusion, tubal occlusion secondary to tubal ligation, tubal pregnancies, mullerian anomalies and intrauterine adhesions. Fertil Steril. 1988;49(6):944-955.[55])

reference line across the superior aspect of the myometrial edge in the two cornual regions), the distinction narrows to a septate (or subseptate) versus arcuate uterus. The term "subseptate" or "partial septate" is sometimes used when the septum does not extend all the way from the fundus to the cervix. The 1-cm fundal cleft criterion to distinguish septate (or arcuate) from bicornuate uterus is a commonly used criterion, although other methods have been suggested.[54,56,65,66]

The significance of and diagnostic criteria for an arcuate uterus are unclear. Arcuate uterus refers to slight indentation of the fundal myometrium into the endometrium. There is debate about whether it is truly an anomaly or just a normal variant, and further debate about whether it has clinical importance.[56,67] Part of the difficulty in sorting out these questions arises from uncertainty in what criteria one uses for the diagnosis. We are also unaware of criteria for distinguishing mild arcuate uterus from a normal uterus. Suggested criteria for diagnosis of an arcuate uterus are an angle greater than 90 degrees at the end point of the fundal indentation[65] or a less than 1-cm indentation of myometrium into the endometrium (from a reference line

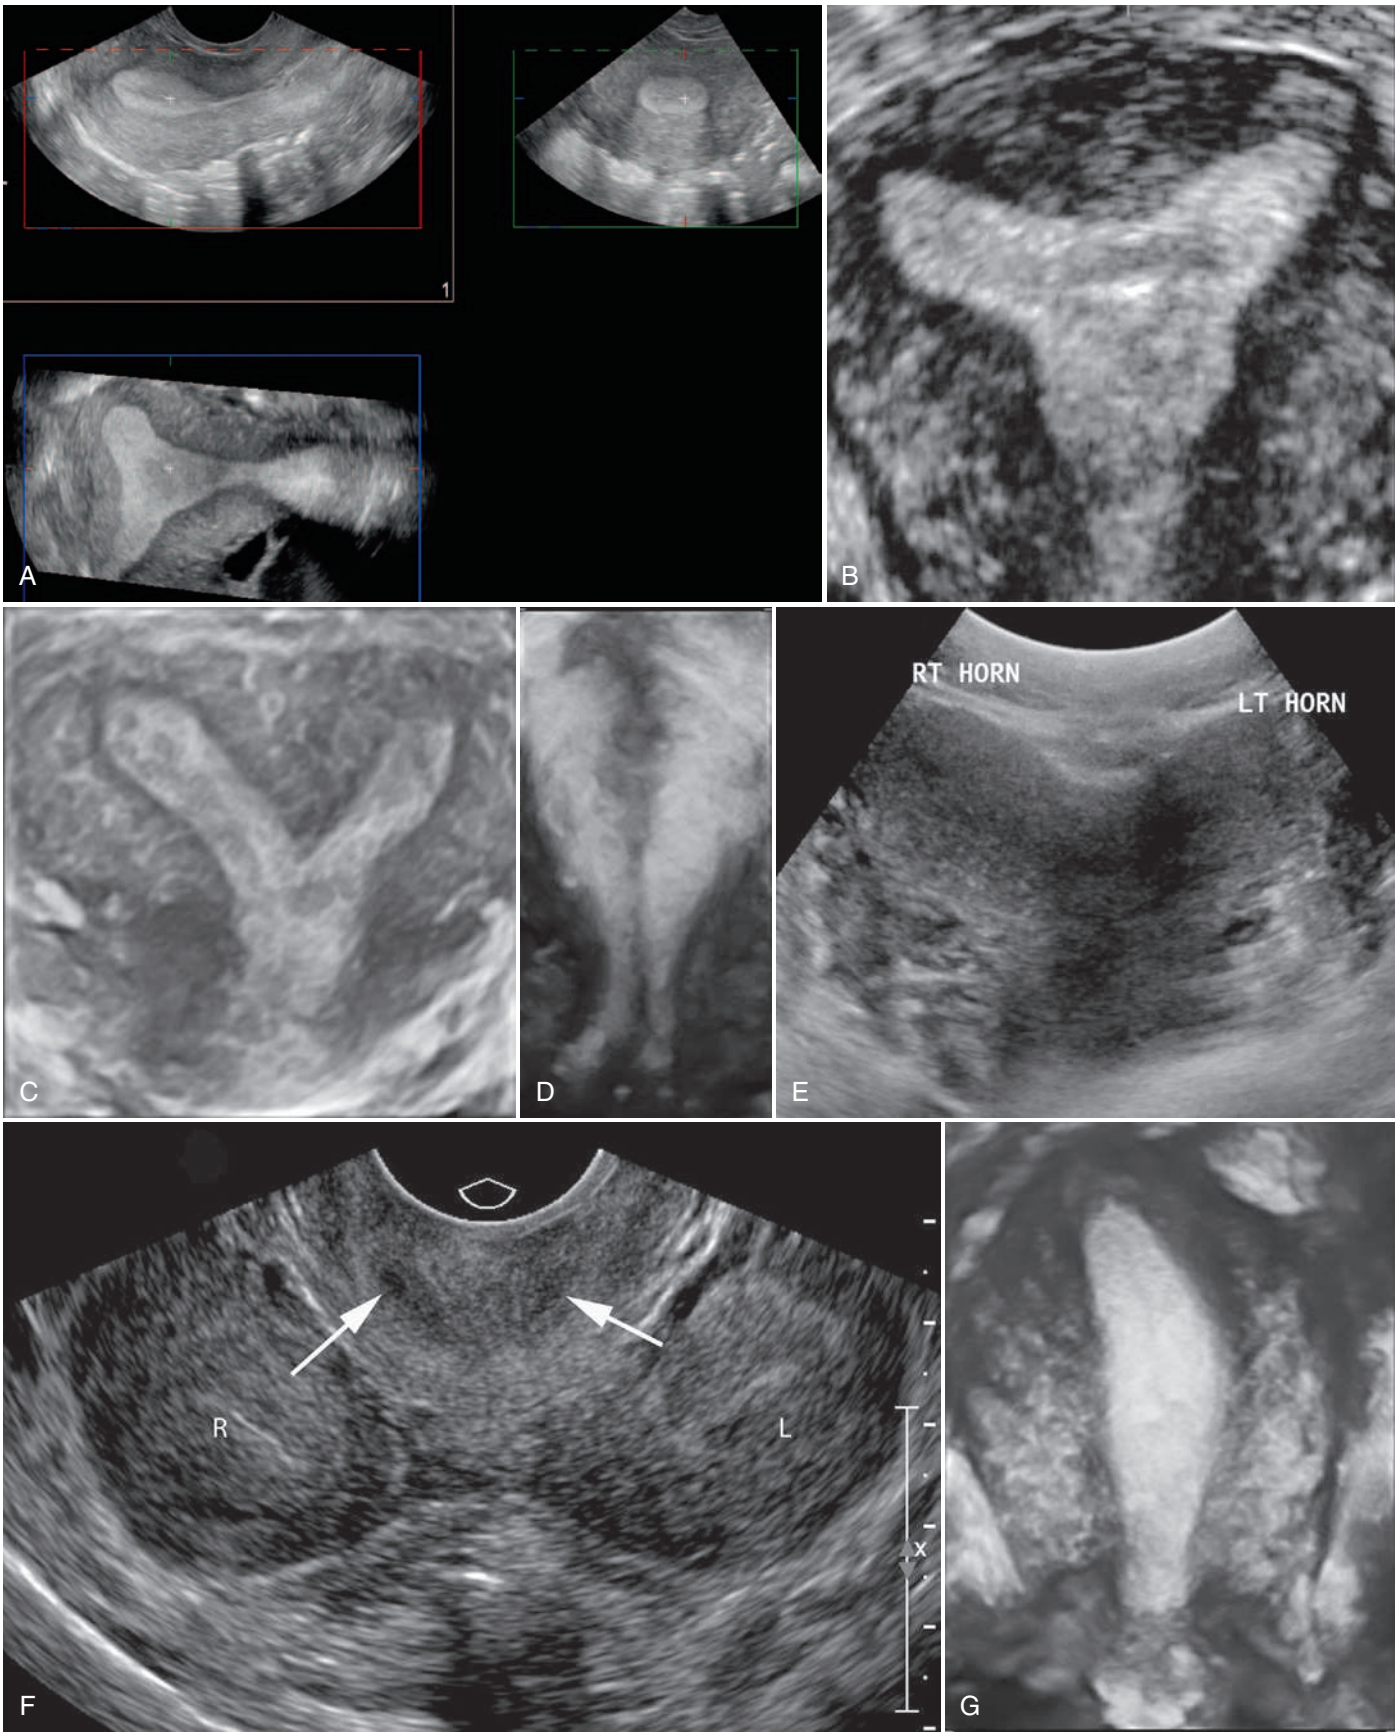

FIG. 15.10 Coronal Images of Normal Uterus and Müllerian Duct Anomalies. (A) Normal uterus with three-dimensional (3-D) views. It is often helpful to reconstruct the coronal plane when assessing for müllerian duct anomalies. **(B), (D),** and **(G)** are reconstructed 3D coronal images. **(E)** and **(F)** are coronal images obtained directly from two-dimensional (2-D) imaging. **(B) Arcuate uterus. (C) Subseptate uterus. (D)** Complete **septate uterus. (E) Bicornuate uterus** (note how the two horns come together). **(F) Uterus didelphys** (note two separate uterine cavities *[R, L]* and two cervices *[arrows]*). The endometrial cavities were always separate. **(G) Unicornuate uterus.** See also Video 15.1 for unicornuate uterus and Video 15.2 for bicornuate uterus.

across the superior aspect of the endometrial edge in the two cornual regions).[68]

In general, if there is an indentation of greater than 1 cm in the fundal myometrium, one then needs to distinguish between a bicornuate uterus and uterus didelphys. In bicornuate uterus, the two endometrial cavities join at some point, usually just above the cervix. There can be either one cervix (bicornis unicollis) or two cervices (bicornis bicollis). In uterus didelphys, there are two separate uterine horns and two cervices. However, the distinction between a bicornuate uterus with two cervices versus uterus didelphys may be difficult, and perhaps not clinically relevant. In a newer classification system the overlap between septate and bicornuate uterus is better described[53]; however, septate uterus is probably overdiagnosed by these definitions.[69]

Arrested development of one müllerian duct results in variable forms of a **unicornuate uterus.** In general, unicornuate uterus is easily recognized on 3-D ultrasound because the single horn configuration, sometimes referred to as "banana-shaped," is usually obvious on the reconstructed coronal plane. The single horn configuration of the endometrium, with absence of one cornual region, is easy to overlook on 2-D ultrasound unless one pays close attention. A unicornuate uterus may be deviated to one side of the pelvis, but this uterine deviation can be overlooked on 2-D ultrasound. When a unicornuate uterus is seen, it is important to determine if there is a rudimentary horn and if that rudimentary horn contains endometrium, as such determination will typically affect management of the patient.[54,70] About a third of patients with unicornuate uterus will not have a rudimentary horn. For the approximate two-thirds of patients with a unicornuate uterus who have a rudimentary horn, about half will have endometrium in the rudimentary horn.[54,70] In most patients with a **rudimentary horn** that has endometrium, the rudimentary horn does not communicate with the other horn. These latter patients are at increased risk for endometriosis and rudimentary horn pregnancy, which has a high likelihood of rupture. Hydrometra in the rudimentary horn may be mistaken for a uterine or adnexal mass. Surgical resection of a rudimentary horn that contains endometrium, especially if noncommunicating, is often recommended.[54] It is not clear how reliably ultrasound, whether 2-D or 3-D, can exclude the presence of a rudimentary horn because they are sometimes small and may be obscured by bowel gas. If a rudimentary horn is not seen on ultrasound, one should consider MRI to be more confident there is truly no rudimentary horn.

There are variable and often complex forms of **uterine hypoplasia** or agenesis. One may not be able to perform TVS in such patients, and MRI may be needed to fully define the anatomy as small uterine remnants may be present and difficult to identify sonographically. The most common form is Mayer-Rokitansy-Kuster-Hauser syndrome, with most patients having uterine and vaginal agenesis.[56]

Vaginal septa may be transverse or longitudinal in orientation and are most commonly seen with uterus didelphys, although they can occur with other MDAs. A transverse septum may cause obstruction and result in **hematocolpos** or **hematometrocolpos.** A duplicated cervix is a component of uterus didelphys but can occur with other anomalies. Other than clearly separated cervices, it can be difficult to distinguish true cervical duplication from a cervix divided by a septum. With this in mind, in women with a double cervix it is important to evaluate the full uterine anatomy because a complete septate uterus is at least as common as uterus didelphys.[71]

The kidneys should be evaluated in patients with MDAs because renal anomalies occur with increased frequency in such patients compared with the general population.[54] The most common renal anomalies are absent or ectopic kidney. The most common types of MDAs to have associated renal anomalies are uterus didelphys (often with renal agenesis ipsilateral to an obstructed horn) and unicornuate uterus (usually renal agenesis ipsilateral to the side of the absent or rudimentary horn).

ABNORMALITIES OF THE MYOMETRIUM

Leiomyoma

Uterine **leiomyomas,** commonly referred to as **fibroids,** are common benign neoplasms of the uterus. They are composed of varying amounts of smooth muscle and fibrous tissue. The lifetime prevalence of uterine leiomyomas is greater than 80% among black women and approaches 70% in white women.[72] Some women with leiomyomas are asymptomatic but leiomyomas can cause abnormal vaginal bleeding, pain, or "bulk" symptoms such as bowel or bladder dysfunction.[72]

Causes of Uterine Enlargement

Normal variant
Fibroids
Adenomyosis
Obstructed uterus
Malignancy
Endometrial cancer
Uterine sarcoma
Cervical cancer

Leiomyomas can be classified by location: submucosal (abutting the endometrium), intramural (within the myometrium) and subserosal (involving the serosal surface of the uterus). Some subserosal leiomyomas are pedunculated, with a common definition having the center of the leiomyoma outside the uterus and attached to the uterus by a stalk narrower than 50% of the diameter of the leiomyoma.[73] Pedunculated subserosal leiomyomas may be difficult to distinguish from a solid ovarian neoplasm if the ipsilateral ovary is not identified. In such cases, it is often helpful to use color or power Doppler imaging to search for vessels connecting the leiomyoma to the uterus (Fig. 15.11). Leiomyomas occasionally occur in the cervix. Submucosal leiomyomas, many of which can be treated hysteroscopically, are often subclassified into type 0 (completely within the endometrial cavity), type I (more than 50% in the endometrial cavity), and type II (less than 50% in the endometrial cavity).[74] This distinction is important

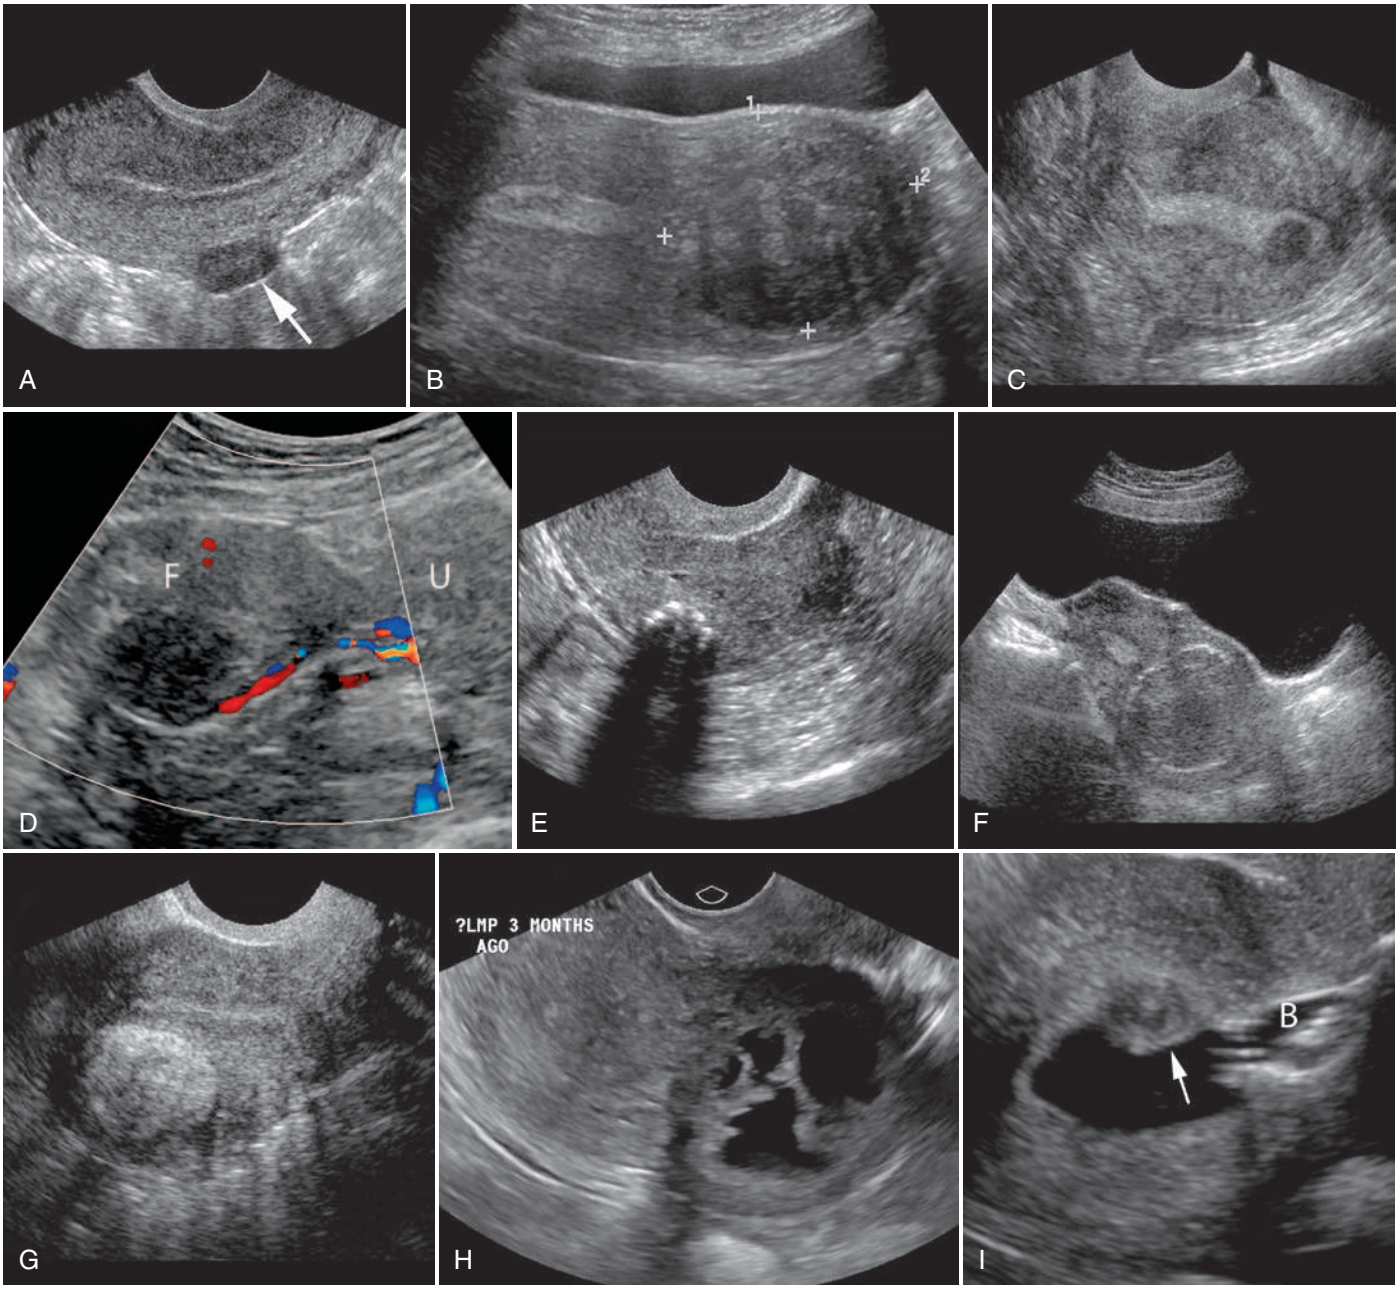

FIG. 15.11 Leiomyomas, Variable Appearances. (A) Sagittal TVS shows a hypoechoic **subserosal leiomyoma** *(arrow).* **(B)** Transverse TAS demonstrates a heterogeneous hypoechoic intramural fibroid *(calipers).* **(C)** Sagittal TVS shows a hypoechoic submucosal leiomyoma, almost entirely within the endometrial cavity. **(D)** TAS with color Doppler imaging shows vessels connecting the fibroid *(F)* to the uterus *(U),* confirming a **pedunculated subserosal leiomyoma. (E)** TVS of a leiomyoma with globular calcification with shadowing. **(F)** Sagittal TAS image of a leiomyoma with peripheral calcification. **(G)** Transverse TVS shows a hyperechoic mass, typical of a **lipoleiomyoma. (H)** Sagittal TVS demonstrates a leiomyoma with cystic degeneration. When pedunculated from the uterus, such a leiomyoma can be mistaken for an ovarian mass. See also Video 15.3. **(I)** Sagittal TVS from a sonohysterogram shows the endometrium *(arrow)* overlying the **submucosal fibroid.** Note the balloon catheter *(B).*

because when fibroids are more than 50% within the endometrial cavity, they can frequently be removed hysteroscopically. The location of some leiomyomas spans several of these more general groups, and a more detailed classification of leiomyoma location has been suggested.[75,76] Thus when fibroids are seen to distort the endometrium, it is frequently helpful to estimate the percentage within the endometrial cavity in addition to using whatever classification system is preferred by the referring clinicians. Although TVS is often adequate when fibroids are small and/or few in number, it is important to also assess the patient with TAS. Large fibroids, fibroids located superiorly in an enlarged uterus, or pedunculated subserosal leiomyomas may be incompletely seen or entirely overlooked if only TVS is performed.

Leiomyomas: Sonographic Features

Hypoechoic or heterogeneous solid mass, occasionally hyperechoic
Round or oval shape
Distortion of external uterine contour or endometrium, depending on size and location
Attenuation or shadowing
Calcification
Cystic areas from degeneration or necrosis

Fibroids may have variable appearances (see Fig. 15.11, Video 15.3) but most often appear as well-defined, spherical to ovoid, solid masses that are hypoechoic compared with normal myometrium. They are frequently heterogeneous and tend to produce mass effect on adjacent structures depending on size and location. Leiomyomas may attenuate sound deep to the entire mass, but also commonly have bandlike areas of shadowing originating from nonhyperechoic areas within the mass, termed "refractory shadowing."[77] Calcification occurs in a minority of leiomyomas. The calcification is usually in one or more focal areas and has associated acoustic shadowing. Less frequently, rim calcification may occur and in general is seen after hemorrhagic degeneration or after **uterine artery embolization** (UAE). Occasionally, leiomyomas are isoechoic or hyperechoic compared with myometrium. When one encounters a hyperechoic leiomyoma, a **lipoleiomyoma** should be considered,[78,79] although it is likely that not all hyperechoic leiomyomas are lipoleiomyomas. The fat in a lipoleiomyoma is probably due to adipocyte differentiation rather than a degenerative change.[80] Lipoleiomyomas are most frequently noted in postmenopausal women[78] and usually have a benign clinical course.[80,81]

Uterine leiomyomas occasionally undergo various forms of benign degeneration. Many types of degeneration are not evident sonographically and may be better detected on MRI.[82] Cystic spaces within a leiomyoma usually indicate **cystic degeneration** but may also be seen with **myxoid degeneration.** Hyaline, hemorrhagic, and hydropic degeneration are usually difficult to diagnose by ultrasound. **Hemorrhagic degeneration** may not produce any change in appearance, although homogeneity, a hyperechoic rim, and lack of detectable flow by Doppler imaging have been described.[76] In a patient with acutely degenerating fibroid (typically during rapid growth in pregnancy or as a result of UAE), pain will usually be localized to the fibroid(s) undergoing degeneration, and thus the diagnosis can be suggested during the sonographic examination, even if the sonographic appearance of degeneration is not yet evident.

Fortunately, the vast majority of myometrial masses are due to leiomyomas. There are other uncommon forms of myometrial neoplasms, such as **cellular leiomyomas** and **smooth muscle tumors of uncertain malignant potential** (STUMPs), but we are not aware of any specific sonographic features to diagnose such entities.[76] Rarely, leiomyomas have unusual growth patterns such as **intravenous leiomyomatosis, disseminated peritoneal leiomyomatosis, benign metastasizing leiomyomas,** and **parasitic leiomyomas;** the leiomyomas in these rare entities have a similar appearance to the more usual leiomyomas but are in vastly different locations.[76,82]

After noninvasive treatment with UAE most fibroids remain hypoechoic, although cystic change or increased echogenicity occasionally occurs; diminished or absent flow on Doppler imaging is expected.[83] Tubular hyperechoic structures thought to be due to thrombosed uterine artery branches have been described after UAE.[84] Echogenic foci due to gas may occur in leiomyomas as a normal finding after UAE, and clinical assessment is needed to help distinguish this from a **pyomyoma.**[82] Submucosal fibroids may prolapse and thus a mass may be seen in the endometrial cavity, cervix, or vagina.[85] Little has been reported about the appearance of leiomyomas after MRI-guided focused ultrasound ablation.

Leiomyosarcoma

Uterine **sarcomas** are uncommon. Although some forms of uterine sarcoma arise in the endometrium, the more common leiomyosarcomas arise in the myometrium. Risk factors for **leiomyosarcoma** include pelvic irradiation, tamoxifen, and rare genetic syndromes.[72] Unfortunately, it is difficult to diagnose leiomyosarcomas by ultrasound or other imaging modalities because their appearance and growth rate overlap with the much more common leiomyomas. Other than evidence of metastasis, no currently known imaging feature is reliably predictive. Leiomyosarcomas tend to be large and heterogeneous and to have cystic change (Fig. 15.12), but such changes are also common in leiomyomas.[82] Doppler imaging has not proven reliable. Rapid growth, particularly in a postmenopausal patient, has been considered a worrisome sign for leiomyosarcomas but "rapid" is not well defined and the usefulness of rapid growth is unclear. Diagnosis of leiomyosarcoma by MRI is also challenging, although diffusion-weighted imaging may be helpful.[86,87] Serum lactate dehydrogenase levels may be helpful for diagnosis of leiomyosarcoma.[87a,87b]

Adenomyosis

Adenomyosis is a benign condition wherein endometrial glands and stroma are present in the myometrium. In general, the histologic diagnosis of adenomyosis requires the presence of endometrial glands or stroma to be located more than 2.5 or 3 mm away from the outer edge of the endometrium.[88,89] It may cause pain, abnormal vaginal bleeding, or infertility, although some patients are asymptomatic. The prevalence of adenomyosis is uncertain; there are widely varying estimates from 5% to 70%.[90] Adenomyosis and

Adenomyosis: Sonographic Features

Diffuse, sometimes globular-shaped, uterine enlargement
Diffusely heterogeneous myometrium
Asymmetrical thickening of myometrium
Indistinct hypoechoic areas
Myometrial cysts
Poor definition of endometrial-myometrial border
Focal tenderness elicited when scanning over the uterus
Subendometrial echogenic linear striations
Subendometrial echogenic nodules

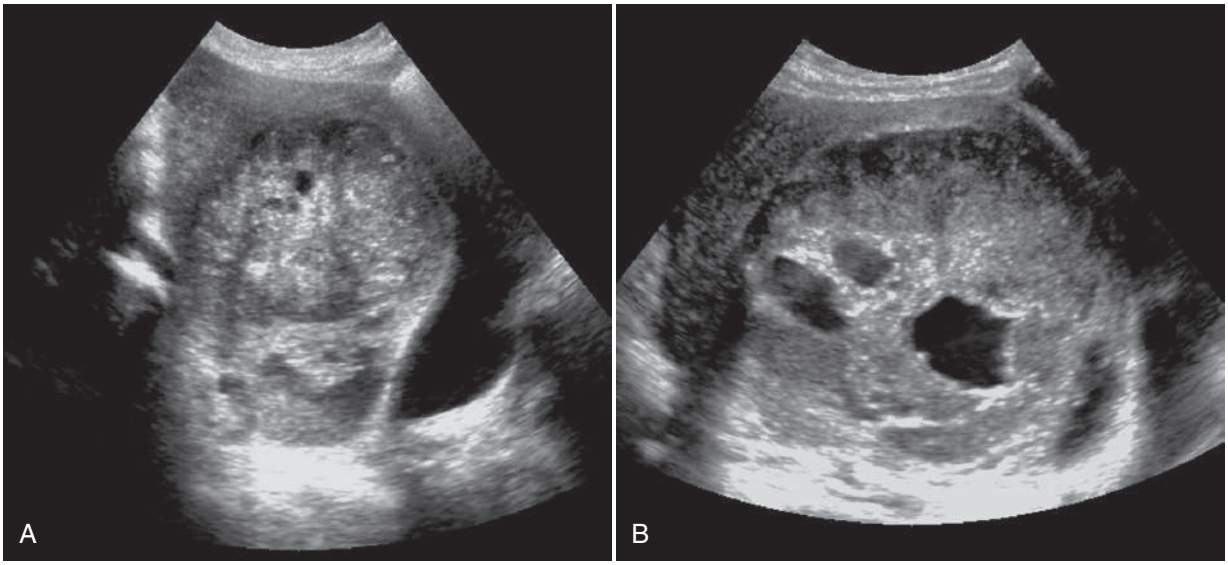

FIG. 15.12 Leiomyosarcoma. (A) Sagittal and **(B)** transverse TAS show a large heterogeneous uterine mass that is mostly solid but contains cystic areas. It is difficult to distinguish this from a benign leiomyoma with cystic degeneration because the appearance of leiomyomas and leiomyosarcomas overlap.

endometriosis may coexist; 22% to 49% of women with endometriosis are reported to also have adenomyosis.[91]

Adenomyosis most often affects the myometrium diffusely. Occasionally it occurs in a focal form (sometimes called "focal adenomyosis" when involving only part of the myometrium or an "adenomyoma" when more distinct)[92] and rarely can take the form of a cyst ("cystic adenomyoma").[76] Ultrasound is an accurate diagnostic test for adenomyosis, although about 9% of affected patients have normal ultrasound findings.[93] Sonographic findings that are suggestive of diffuse adenomyosis include enlarged globular shape of the uterus, heterogeneous myometrium, asymmetrical thickening of the myometrium, indistinct interface between the endometrium and myometrium, myometrial cysts, and echogenic striations or nodules in the myometrium (Fig. 15.13, Video 15.4).[94-97] Heterogeneity of the myometrium has been reported as the most common finding but has poor specificity[96]; this may be related to the subjective nature of determining heterogeneity. Thus it is important to look for other sonographic features when one identifies a heterogeneous myometrium. Echogenic linear striations, myometrial cysts, globular uterine shape, and asymmetrical myometrial thickness have all been reported to have high specificity.[94,96,97] Although not generally performed to diagnose adenomyosis, SHG may show communication between the lesions of adenomyosis and the endometrial cavity.[98] Rarely, adenomyosis can appear as an isolated cystic mass, larger than the small myometrial cysts typically seen in adenomyosis, and has been termed a **juvenile cystic adenomyoma.**[99] However, these isolated larger myometrial cysts may instead represent a rare, recently proposed type of MDA, an **accessory and cavitated uterine mass** (ACUM). Specific criteria to diagnose ACUM have been proposed.[100,101]

Adenomyosis and leiomyomas often coexist; 15% to 57% of women with leiomyomas are reported to also have adenomyosis in surgical series.[102] It can sometimes be difficult to distinguish these two entities, or determine if both are present, by ultrasound. Focal adenomyosis is usually the form most difficult to distinguish from leiomyomas. Distinct borders are typical of leiomyomas, whereas indistinct borders suggest adenomyosis. It has been suggested that color or power Doppler may be helpful in making the distinction, with adenomyosis tending to have more central vascularity and leiomyomas tending to have mostly peripheral vascularity.[92] However, the reliability of Doppler findings to make this distinction has not been adequately evaluated. In patients in whom one is uncertain whether the findings represent adenomyosis or leiomyomas or both (when making this distinction is important for clinical care), MRI is helpful.

Although adenomyosis is usually considered to occur mostly in premenopausal women, it can be seen in postmenopausal women.[103] Women with breast cancer who are treated with tamoxifen have a higher incidence of adenomyosis. It may be that the estrogen agonist effects of tamoxifen on endometrial tissue cause adenomyosis or reactivate preexisting adenomyosis.[90]

Occasionally one may encounter one or a few small cysts at the endometrial/myometrial border, in the absence of other sonographic findings of adenomyosis. The significance of such an isolated finding is not clear. As mentioned previously, the histologic diagnosis of adenomyosis generally requires the presence of endometrial glands or stroma to be located more than 2.5 or 3 mm away from the outer edge of the endometrium.[88,89] Thus we would be reluctant to diagnose adenomyosis based solely on one or a few small cysts at the endometrial/myometrial border, in the absence of other sonographic features of adenomyosis.

ABNORMALITIES OF THE CERVIX

After a supracervical hysterectomy, one expects to see most or all of the cervix remaining, and should not mistake the remaining cervix for a mass (Fig. 15.14A). Occasionally one may observe a cervical polyp on ultrasound (Fig. 15.14B), although many of

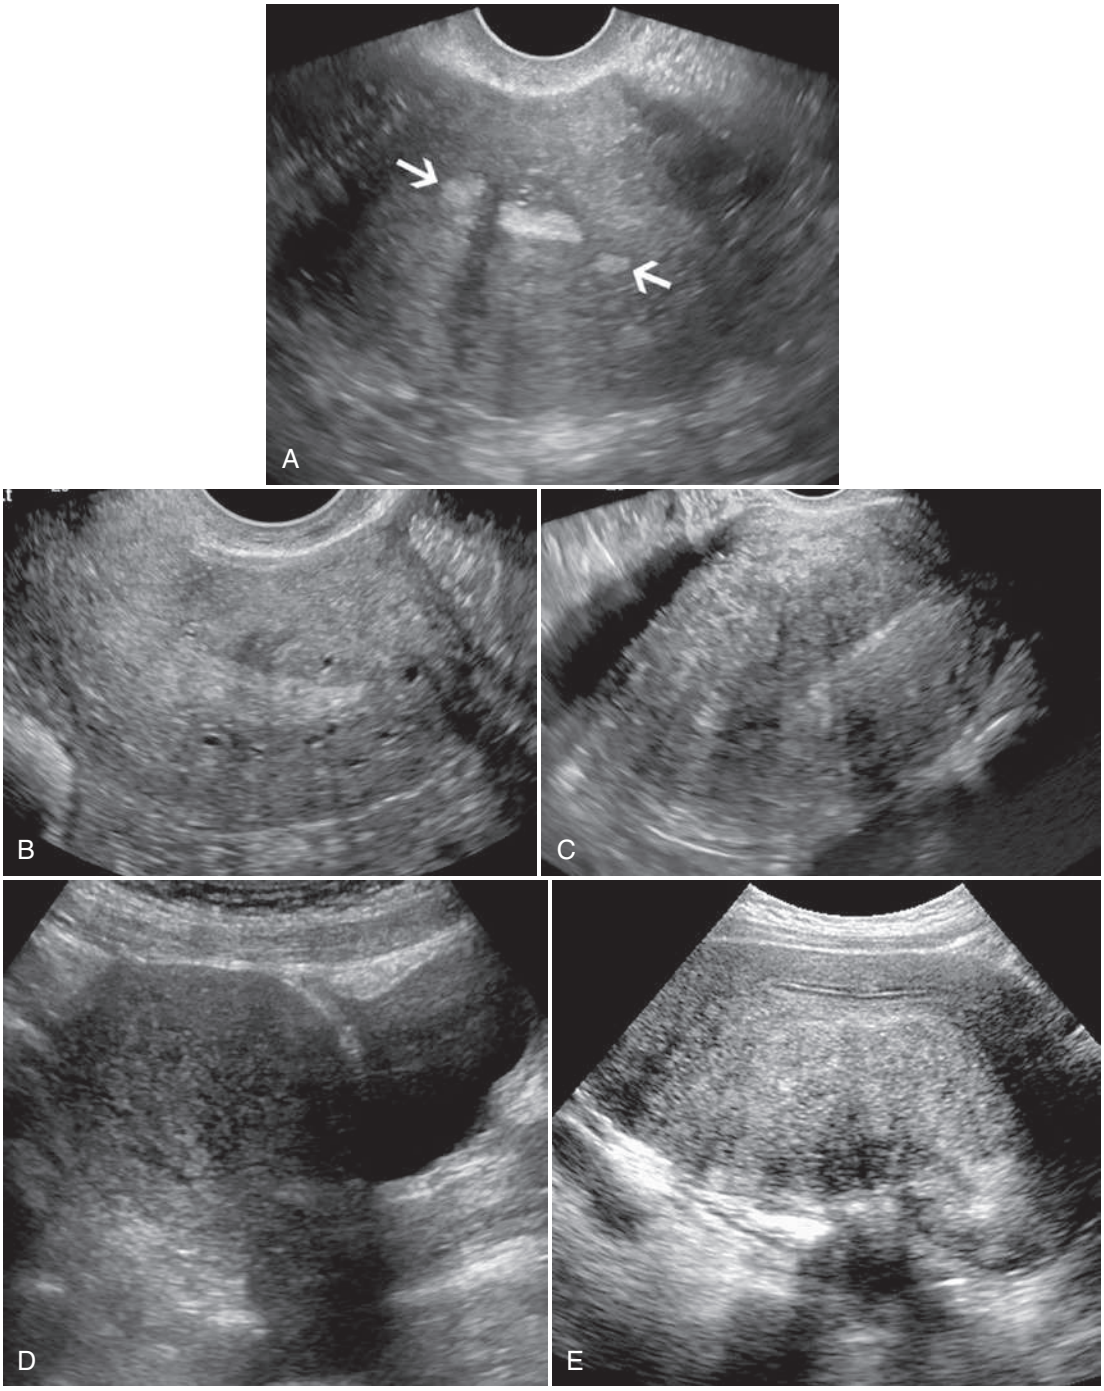

FIG. 15.13 Adenomyosis. (A) Transverse TVS shows echogenic nodules *(arrows).* The central echogenic area in this image is the endometrium. Striations and nodules are likely the same feature, with the term "striations" being used when more elongated in shape and "nodules" when more spherical. **(B)** Sagittal TVS reveals multiple small cysts in the myometrium. **(C)** Sagittal TVS shows diffuse myometrial heterogeneity. In addition, the endometrium is poorly defined. **(D)** Sagittal TAS demonstrates globular shape of the uterus. **(E)** Sagittal TAS shows asymmetrical myometrial thickness, with the posterior myometrium thicker and heterogeneous compared with the anterior myometrium. See also Video 15.4.

these are evident on clinical examination. Small cervical polyps may be difficult to identify sonographically unless there is surrounding fluid. At times, endometrial polyps (or endocavitary leiomyomas) will prolapse into the cervix. The diagnosis can be made based on visualization of the vascular stalk leading to the prolapsed lesion in the endocervical canal (Fig. 15.14C–D, Video 15.5).

Cervical carcinoma is usually diagnosed without imaging, but occasionally one may incidentally encounter a patient with cervical carcinoma. Cervical carcinoma typically appears as a heterogeneously hypoechoic solid mass (Fig. 15.14E). It may be difficult to distinguish from a leiomyoma by ultrasound, although increased vascularity on Doppler imaging has been described.[104]

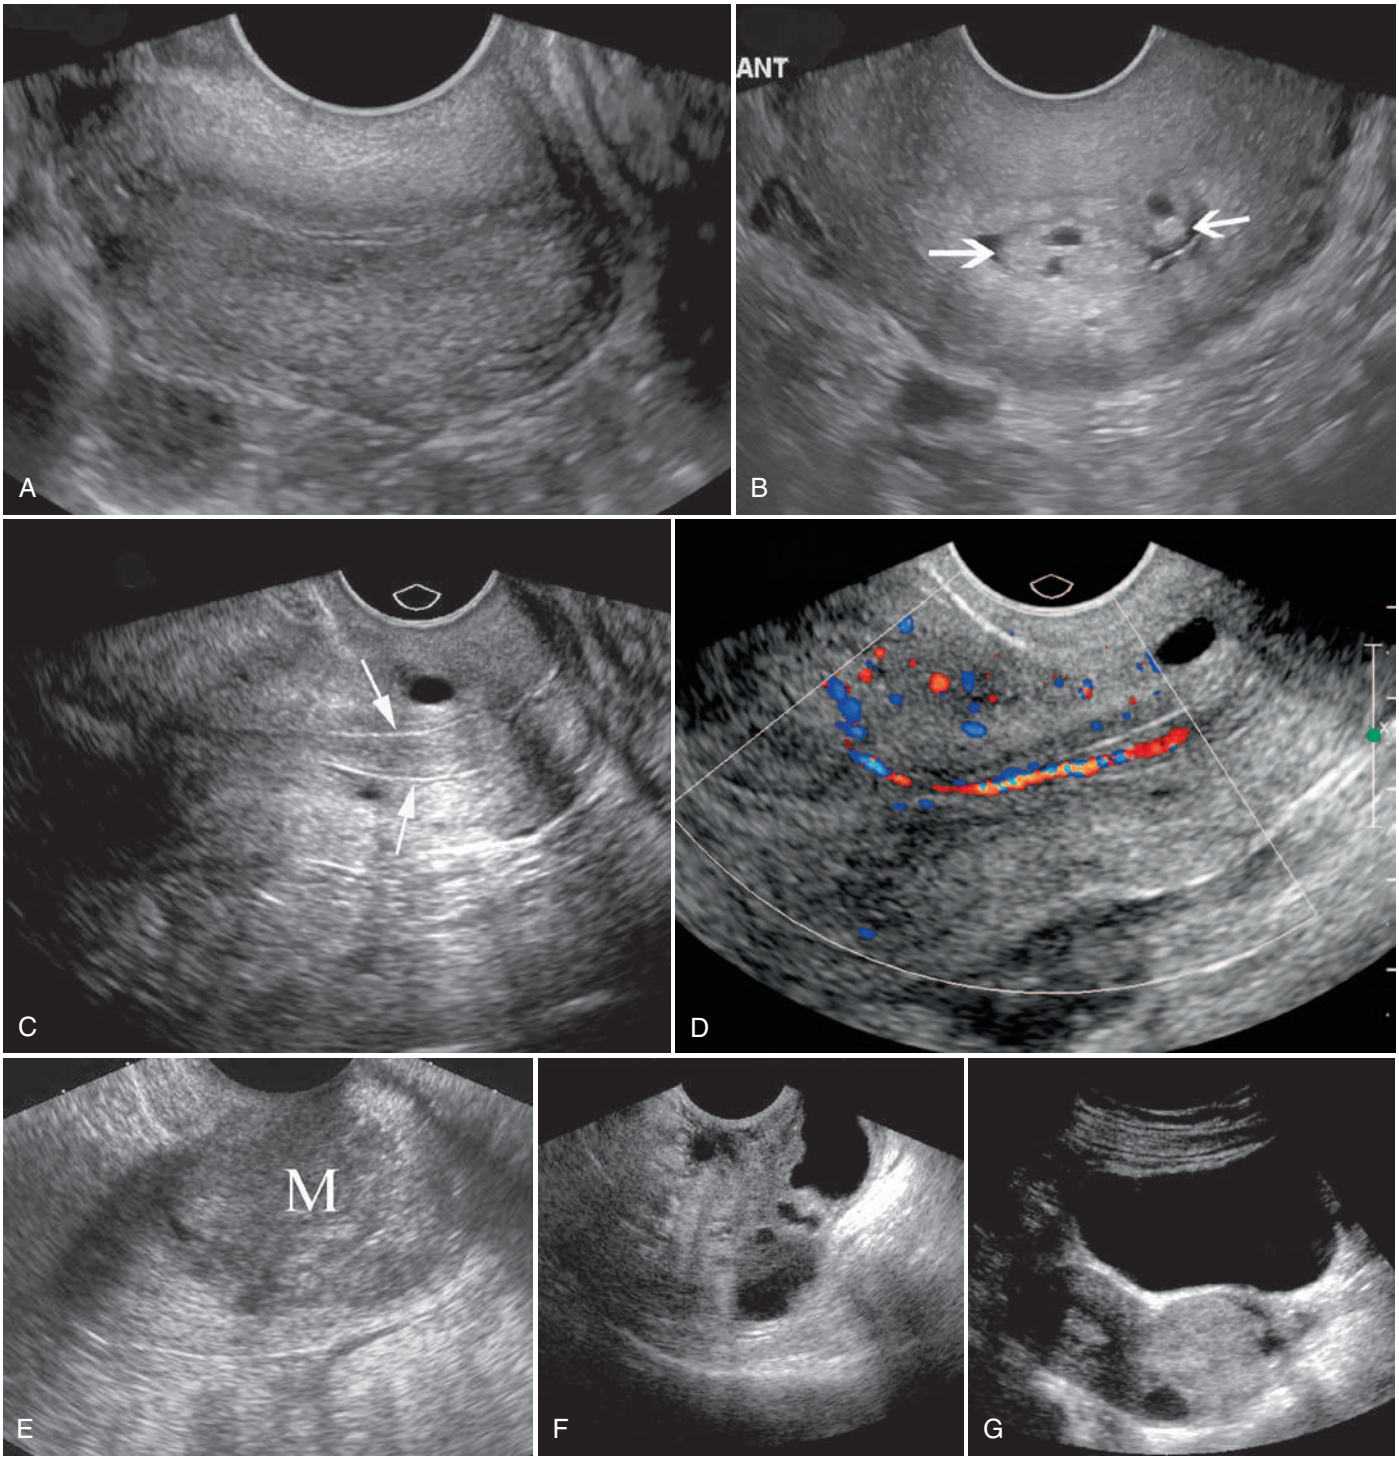

FIG. 15.14 Cervical Lesions. (A) Supracervical hysterectomy. Sagittal TVS shows the remaining normal cervix in a patient after supracervical hysterectomy. **(B) Cervical polyp.** Transverse TVS demonstrates a cervical polyp (between *arrows*). This polyp contains small cystic spaces that might be mistaken for nabothian cysts, but in this instance a small amount of fluid in the endocervical canal helps define borders of the polyp. **(C)** Sagittal gray-scale and **(D)** color Doppler TVS in patient with **endometrial polyp prolapsing into the cervix.** Note the vascular pedicle of the polyp extending from the endometrial cavity into the cervical region. See also Video 15.5. **(E) Cervical carcinoma.** Sagittal TVS shows a hypoechoic solid mass *(M)* due to cervical carcinoma. **(F)** Sagittal TVS and **(G)** sagittal TAS images from a patient with **adenoma malignum** show a mixed cystic and solid mass.

Adenoma malignum, also termed **minimal deviation adenocarcinoma,** is an uncommon type of cervical carcinoma that has been associated with **Peutz-Jeghers syndrome.** Watery vaginal discharge has been described as a common symptom. Sonographically these are most often multiloculated cystic masses with a solid component or completely solid masses (Fig. 15.14F–G).[105] Multiple adjacent nabothian cysts might simulate this lesion, but when a solid component is present, particularly with flow by Doppler imaging, one should consider this uncommon neoplasm.

ABNORMALITIES OF THE ENDOMETRIUM

Because of its improved resolution, TVS is better able to image and depict subtle abnormalities within the endometrium and clearly define the endometrial/myometrial interface than is TAS.[106] Knowledge of the varied normal sonographic appearances of the endometrium that vary with respect to time of the menstrual cycle, patient menopausal status, and hormone use allows for recognition of pathologic conditions manifested by endometrial thickening because the expected upper limits of normal thickness will vary with these factors. Many endometrial pathologies, such as **hyperplasia, polyps,** and **carcinoma,** can cause abnormal bleeding. Abnormal bleeding can be due to abnormally heavy menstrual periods at the expected time of the menstrual cycle (menorrhagia, for example due to fibroids or adenomyosis), abnormal bleeding at an unexpected time of the cycle (metrorrhagia), or both (menometrorrhagia).

Causes of Metrorrhagia

Pregnancy
Systemic disease (liver disease, blood dyscrasias)
Endometrial polyps or hyperplasia
Endometrial cancer
Intrauterine device (IUD) malposition
Cesarean section scar defect

Although heavy vaginal bleeding is typically from a myometrial or endometrial cause, abnormal bleeding can at times arise from other sources such as bleeding from the vulva or vagina (lacerations, infection, or cancer), from the cervix (polyps, fibroids, or cancer), from the fallopian tubes (salpingitis, tumors, or tubal pregnancy), or be secondary to ovarian pathology (estrogen-producing tumor, cancer, functional ovarian cysts).

SHG can be of great value in further evaluating the abnormally thickened endometrium.[5,6,107-110] SHG can distinguish between focal and diffuse endometrial abnormalities and help guide further management. If the abnormality is diffuse, a blind, nondirected biopsy can be done, but a focal process, such as a polyp, typically requires hysteroscopy with directed biopsy or excision.[5,110] SHG may also be able to help distinguish benign from malignant endometrial processes.[111,112] Patients with endometrial cancer may have poorly distensible endometrial cavities.[112]

Causes of Endometrial Thickening

Pregnancy
Retained products of conception
Fibroids (submucosal or intracavitary)
Endometritis
Adhesions
Hyperplasia
Polyps
Cancer

Postmenopausal Endometrium

Hormone Use

When assessing the postmenopausal endometrium, it is important to know if the patient is taking any exogenous hormones **(hormone replacement therapy).** These hormones used to be given long term to prevent osteoporosis and alleviate menopausal symptoms. Because unopposed estrogen replacement is associated with an increased risk of endometrial hyperplasia and carcinoma, estrogen therapy is frequently combined with progesterone in continuous combined or in sequential regimens. However, these hormones are no longer frequently used for long-term therapy owing to the known increased risk of thromboembolism, breast cancer, adverse cardiac events, and stroke (which are not offset by benefits of lower rates of colorectal cancer and hip fractures).[113] They may be given for a short time around the time of menopause to help alleviate menopausal symptoms. Use of continuous combined estrogen should lead to a thin atrophic-appearing endometrium. Use of sequential estrogen and progesterone may lead to a changing appearance of the endometrium similar to that of premenopausal women with increased thickness in the latter half of the hormonal cycle.[114] Women who are taking unopposed estrogen need to be monitored, given the known increased risk of endometrial cancer.

Effects of Hormones on the Postmenopausal Endometrium

Hormone Regimen	Expected Endometrial Appearance
No hormones	Thin, atrophic
Unopposed estrogen	Thick, maybe heterogeneous
Daily estrogen/progesterone	Thin, atrophic
Sequential estrogen/progesterone	Thickness varies with phase of cycle
Tamoxifen	Thick, cystic spaces (some changes are in the myometrium)

Tamoxifen and other hormonal treatments for breast cancer can have estrogenic effects in the uterus. An **increased risk of endometrial carcinoma** has been reported in patients receiving tamoxifen therapy,[115] as well as an increased risk of **endometrial hyperplasia** and **polyps.**[116,117] A correlation exists between increased endometrial thickness and cumulative dose of tamoxifen.[118] On sonography, tamoxifen-related endometrial changes are nonspecific and similar to those described in hyperplasia,

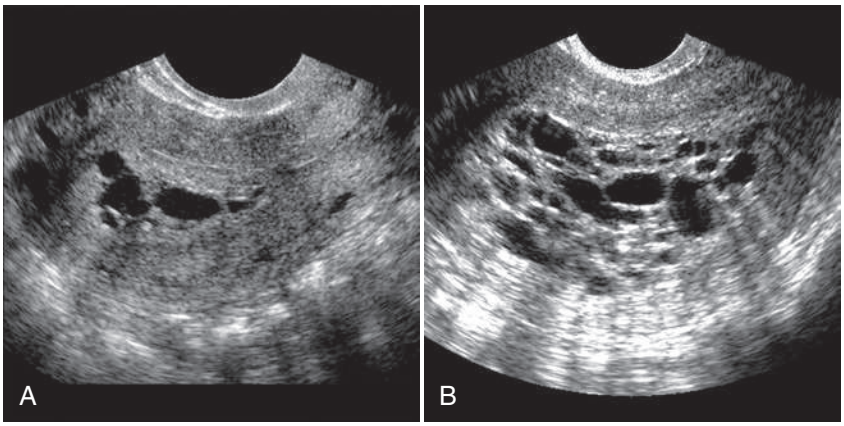

FIG. 15.15 Tamoxifen-Related Changes on TVS. (A) Thick, cystic endometrium caused by **endometrial hyperplasia** in patient taking tamoxifen. **(B)** Thick, cystic endometrium caused by a large **polyp** in patient receiving tamoxifen.

polyps, and carcinoma.[117,119,120] Cystic changes within the thickened endometrium are frequently seen (Fig. 15.15). Polyps are frequently present, have a higher incidence in women receiving tamoxifen than in untreated women, and can be quite large.[118,121] However, because cancer occurs in polyps in a higher percentage of women taking tamoxifen than in the general population, focal lesions in these women should be investigated.[122] As mentioned previously, in some women taking tamoxifen, the cystic changes are subendometrial in location and represent reactivation of adenomyosis in the inner layer of myometrium.[123] Because it is difficult to distinguish the endometrial/myometrial border in many of these patients, SHG may be valuable in determining whether an abnormality is endometrial or subendometrial.[11,124] It is also important to recognize that this adenomyosis-like change is a diagnosis of exclusion. When a cystic endometrial appearance is seen in a woman taking tamoxifen, although the effects of tamoxifen should be mentioned as part of the differential diagnosis, polyps, hyperplasia, and cancer also need to be considered.

Postmenopausal Bleeding

Postmenopausal bleeding is considered to be any vaginal bleeding that occurs in a postmenopausal woman other than the expected cyclic bleeding with sequential HRT. Because the prevalence of endometrial cancer is low and endometrial atrophy accounts for a large proportion of cases of postmenopausal bleeding, the negative predictive value of a thin endometrium is high; therefore a thin endometrium can be reliably used to exclude cancer. Several studies have shown that in patients with postmenopausal bleeding who have had endometrial sampling, an endometrial measurement of up to 3 mm,[125] up to 4 mm,[126-128] or up to 5 mm[129-131] can be considered normal. The bleeding in these patients is often related to an atrophic endometrium.

The majority of women with postmenopausal uterine bleeding have **endometrial atrophy.**[127-132] On TVS, an atrophic endometrium is thin and homogeneous. Histologically, the endometrial glands may be dilated, but the cells are cuboidal or flat and the stroma is fibrotic. A thin endometrium with cystic changes on TVS is consistent with a diagnosis of cystic atrophy, but when the endometrium is thick, the appearance is indistinguishable from that of cystic hyperplasia.[133]

A meta-analysis of 35 published studies that included 5892 women showed that an endometrial thickness of 5 mm or greater detected 96% of endometrial cancer and 92% of any endometrial disease.[134] For a postmenopausal woman with vaginal bleeding with a 10% pretest probability of cancer, her probability of cancer is 1% following a normal TVS result. However, many of the studies used in the meta-analysis were biased by only including those patients who underwent biopsy. In a recent study by Wong and colleagues of 4383 women who all underwent an ultrasound and biopsy after having postmenopausal bleeding, 3 mm was found to be the optimal threshold. The sensitivities for the detection of endometrial cancer at 3-, 4-, and 5-mm cutoffs were 97.0%, 94.1%, and 93.5%, respectively. The corresponding estimates of specificity at these thresholds were 45.3%, 66.8%, and 74.0%.[125] However, it should be noted that the incidence of endometrial cancer was low in this population (3.8%, which is much lower than the expected rate of 10% in postmenopausal women with bleeding), so results might not be reproducible in other populations. Local practice will likely dictate the threshold that is acceptable to patients and their physicians. It may also be that in the future, individualized risk ratios will be used, assessing risk factors such as increasing age, older age at menopause, body mass index, nulliparity, and diabetes.[135] Regardless, if a woman has continued postmenopausal bleeding after a normal sonogram, then biopsy is typically recommended.

Transvaginal assessment of endometrial thickness has been shown to be highly reproducible, with excellent intraobserver and good interobserver agreement.[136] If the endometrium cannot be visualized in its entirety or its margins are indistinct, the examination should be considered "nondiagnostic" and lead to further investigation (e.g., SHG, hysteroscopy).[137] Some recommend that all women with postmenopausal bleeding should undergo SHG, even if the TVS findings are normal[138,139]; however, if the endometrium is well seen on TVS and is thin with no morphologic abnormality, we feel this is usually adequate. Dubinsky and colleagues found that of 81 postmenopausal women with bleeding and thickness greater than 4 mm within 1 month after aspiration biopsy, endoluminal masses were present in 45 (56%) and that 41 of these were false-negative biopsy results.[140] The important question is whether finding and treating these

benign conditions (such as small polyps or fibroids) improves the patient's quality of life, morbidity, and survival; further investigation is warranted.[137]

Other studies have assessed the endometrium in asymptomatic postmenopausal patients and concluded that an endometrium of 8 mm or less can be considered normal.[35-39] Most of these reports have included a mixed group of patients, with some undergoing HRT and some not undergoing HRT. In a theoretical cohort of postmenopausal women aged 50 years or older who were not bleeding or receiving HRT, Smith-Bindman and colleagues[40] recommended that biopsy should be considered if the endometrium measures greater than 11 mm, because the risk of cancer is 6.7% (similar to that of a postmenopausal woman with bleeding and endometrial thickness >5 mm). If the endometrium measures 11 mm or less, biopsy is not needed because the risk of cancer is extremely low.[40] Using this cutoff provides an acceptable trade-off between cancer detection and unnecessary biopsies prompted by an incidental finding. In a recent study by Jokubkiene and colleagues, it was confirmed that even if endometrial focal lesions are present, there is likely no malignancy. In that study of 510 asymptomatic postmenopausal women, 11% had workup for endometrium of 5 mm or greater, and 34 (7%) underwent hysteroscopic surgery or ultrasound surveillance. There were 14.5 surgical procedures per premalignant lesion (endometrial hyperplasia) diagnosed, and two women developed severe complications from hysteroscopy.[141] At our institutions we currently use the more sensitive but less specific threshold of 8 mm.

The Obstructed Uterus: Hydrometrocolpos and Hematometrocolpos

Obstruction of the genital tract results in the accumulation of secretions and blood in the uterus *(metro)* and/or vagina *(colpos)*, with the location depending on the amount and level of obstruction. Before puberty, the accumulation of secretions in the vagina and uterus is referred to as **hydrometrocolpos.** After menstruation, **hematometrocolpos** results from the presence of retained menstrual blood. The obstruction may be congenital and is usually caused by an **imperforate hymen.** Other congenital causes include a **vaginal septum** or **vaginal atresia,** or a **noncommunicating rudimentary uterine horn.**[142] Hydrometra and hematometra may also be acquired as a result of cervical stenosis from endometrial or cervical tumors or from **postradiation fibrosis.**[143,144]

Causes of Endometrial Fluid

Congenital (imperforate hymen, vaginal septum, müllerian anomaly)
Current menstruation
Pregnancy
Recent instrumentation or trauma
Prior radiation
Infection
Cervical stenosis
Obstructing lesion (endometrial or cervical cancer)

Sonographically, if the obstruction is at the vaginal level, there is marked distention of the vagina and endometrial cavity with fluid. If seen before puberty, the accumulation of secretions is often anechoic. After menstruation, the presence of old blood results in echogenic material in the fluid (Fig. 15.16). There may also be layering of the echogenic material, resulting in a fluid-fluid level. Infrequently, blood may distend only the cervix, which has been termed **hematotrachelos.**[145]

Acquired hydrometra or hematometra usually shows a distended, fluid-filled endometrial cavity that may contain echogenic material (Fig. 15.17). Superimposed infection **(pyometra)** is difficult to distinguish from hydrometra on sonography, and this diagnosis is usually made clinically in the presence of hydrometra.[144]

In postmenopausal women endometrial fluid is of particular concern given their increased risk of endometrial cancer owing to age. However, even in this population the accumulation of endometrial fluid is more likely to be from a benign than from a malignant cause. A small amount of fluid within the endometrial canal, detected on TVS, may be a normal finding in asymptomatic

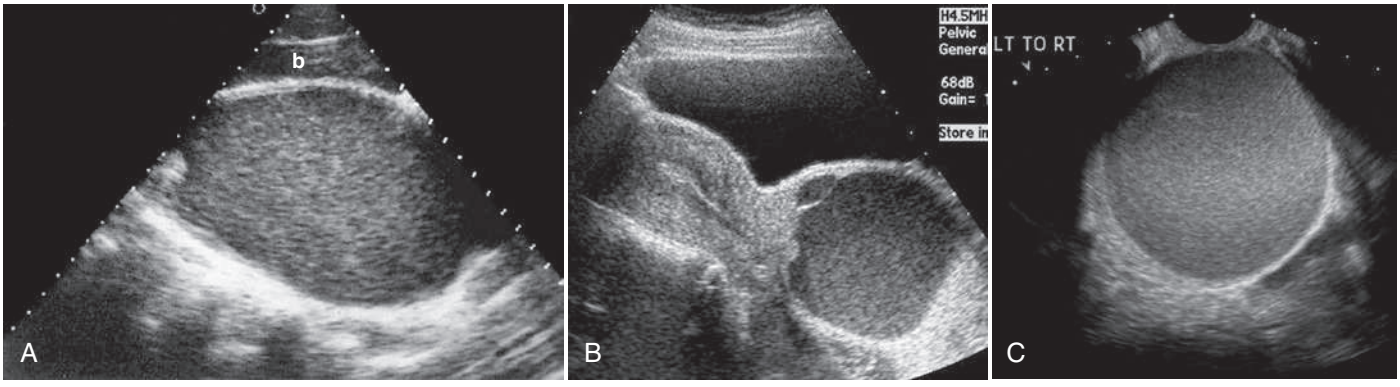

FIG. 15.16 Hematocolpos. (A) Sagittal TAS in a young patient with imperforate hymen shows the vagina distended with moderately echogenic material due to blood, compressing the bladder (b) anteriorly. **(B)** and **(C)** Fluid with internal echoes due to blood distends the vagina in a 26-year-old patient with benign vaginal stenosis. **(B)** is a TAS image and **(C)** is a translabial ultrasound image.

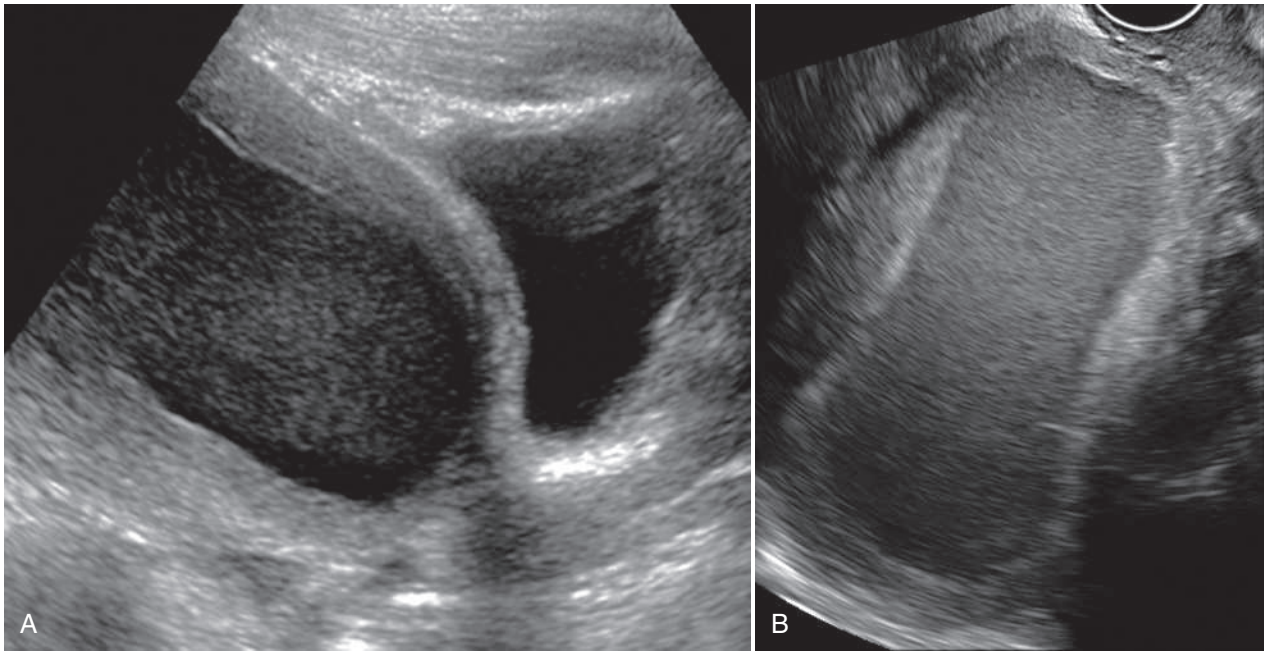

FIG. 15.17 Hematometra in Patient With Cervical Stenosis Due to Cervical Carcinoma. (A) TAS and **(B)** TVS show distended endometrial cavity filled with moderately echogenic material due to blood. The cancer was obstructing at the level of the cervix and is not shown on these images.

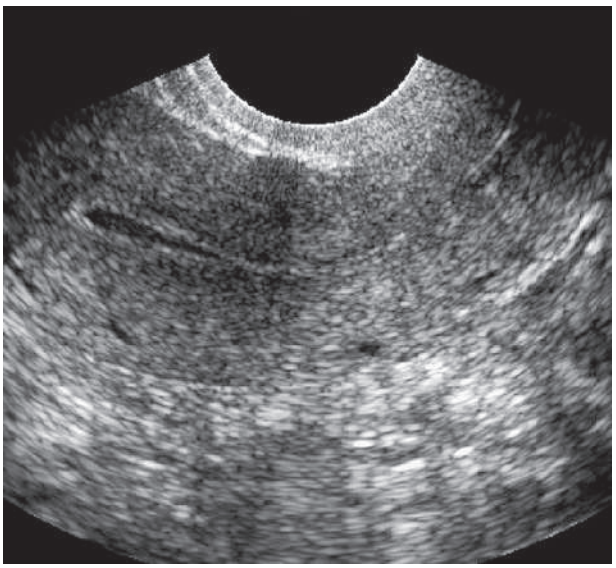

FIG. 15.18 Normal Postmenopausal Endometrium. Sagittal TVS shows a small amount of fluid in the endometrial cavity.

patients[146] (Fig. 15.18). Larger amounts of fluid may be associated with benign conditions, most often related to cervical stenosis.[143,147]

In a study of 1074 asymptomatic postmenopausal women, endometrial fluid was found in 134 (12%).[148] Biopsy was attempted in 131. Cervical stenosis precluded sampling in 12 and an additional 32 women had some degree of cervical stenosis (44/131 = 34%). Pathology included two polyps, and one case each of cystic hyperplasia, adenomatous hyperplasia, and carcinoma. Thus there were only two concerning endometrial lesions in the 131 patients (1.5%) in whom biopsy was attempted.

Endometrial Hyperplasia

Hyperplasia of the endometrium is defined as a proliferation of glands of irregular size and shape, with an increase in the gland-to-stroma ratio compared with the normal proliferative endometrium.[149] The process is typically diffuse but at times may simulate a broad-based polypoid lesion. Histologically, endometrial hyperplasia can be divided into hyperplasia without cellular atypia and hyperplasia with cellular atypia **(atypical hyperplasia).** Long-term follow-up studies have shown that about 25% of atypical hyperplasia will progress to carcinoma, versus less than 2% of hyperplasia without cellular atypia.[149] Each of these types may be further subdivided into **simple** or **complex** hyperplasia, depending on the amount of glandular complexity and crowding. In simple **(cystic)** hyperplasia, the glands are cystically dilated and surrounded by abundant cellular stroma, whereas in complex **(adenomatous)** hyperplasia, the glands are crowded together with little intervening stroma.

Endometrial hyperplasia is a common cause of abnormal uterine bleeding. Hyperplasia develops from unopposed estrogen stimulation which could be due to use of unopposed estrogen HRT, persistent anovulatory cycles (such as with polycystic ovarian syndrome) and in obese women with increased production of endogenous estrogens. Hyperplasia may also be seen in women with estrogen-producing tumors, such as ovarian granulosa cell tumors and thecomas.

Sonographically, the endometrium is usually diffusely thick and echogenic, with well-defined margins (Fig. 15.19). Focal or asymmetrical thickening can also occur. Small cysts may be

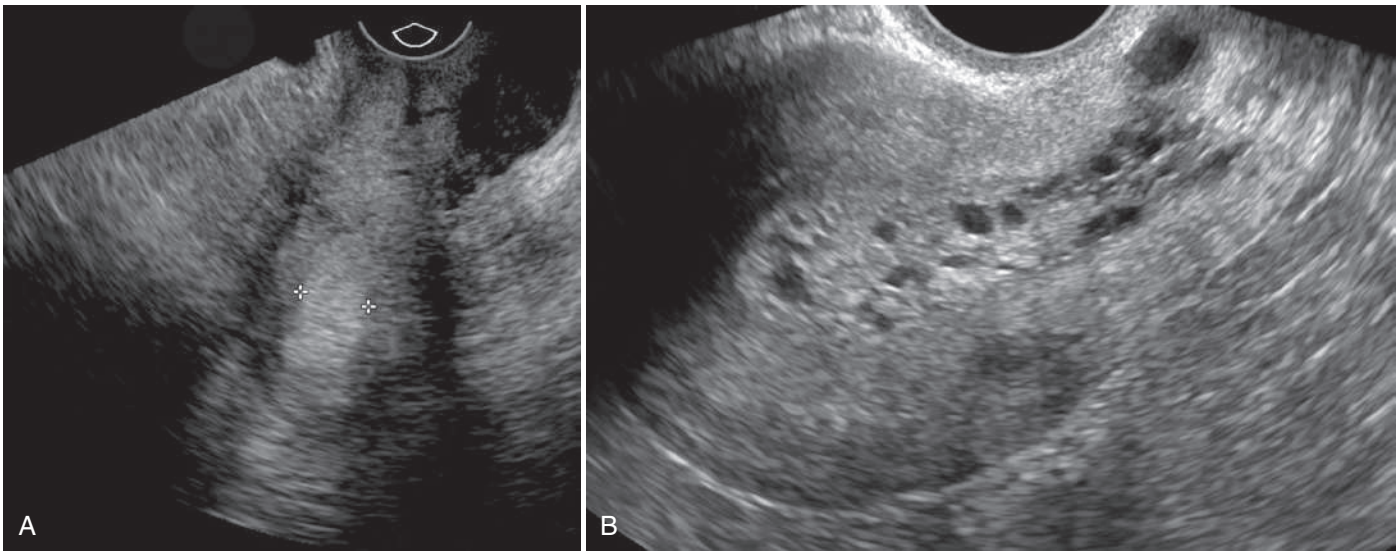

FIG. 15.19 Endometrial Hyperplasia in Two Patients. (A) Endometrial hyperplasia in a 58-year-old woman not taking hormones with abnormal bleeding. Sagittal TVS shows uniform hyperechoic thickening (*calipers*, 14 mm). **(B)** Complex endometrial hyperplasia without atypia in a 52-year-old postmenopausal woman with vaginal bleeding. Sagittal TVS shows numerous small cystic spaces diffusely in an endometrium that measured 16 mm in thickness.

seen within the endometrium in **cystic hyperplasia;** however, a similar appearance may be seen in **cystic atrophy,** and cystic changes can also be seen in endometrial **polyps.** These cystic areas represent the dilated cystic glands seen at histology.[150,151] Although cystic changes within a thickened endometrium are more frequently seen in benign conditions, they can also be seen in endometrial **carcinoma.**[133] Because hyperplasia has a nonspecific sonographic appearance, biopsy is necessary for diagnosis.

Endometrial Polyps

Endometrial polyps are common benign lesions frequently seen in perimenopausal and postmenopausal women. Polyps may cause bleeding at any point in the menstrual cycle, although many are asymptomatic. Histologically, polyps are localized overgrowths of endometrial tissue covered by epithelium and projecting above the adjacent surface epithelium.[149] They may be pedunculated or broad based, or may have a thin stalk. Approximately 20% of endometrial polyps are multiple. Malignant degeneration is uncommon. Occasionally a polyp will have a long stalk, allowing it to protrude into the cervix or even into the vagina.

On sonography, polyps may appear as nonspecific echogenic endometrial thickening, which may be diffuse or focal. However, they may also appear as a focal, round, echogenic mass within the endometrial cavity[152] (Fig. 15.20, Video 15.6). At times they will have a cystic appearance and distend the endometrial cavity (Video 15.7). This specific diagnosis of a polyp is much more easily made when there is fluid within the endometrial cavity outlining the mass and in premenopausal patients is better seen during the proliferative phase when the endometrium is typically less echogenic than the polyp. Because fluid is instilled into the endometrial cavity during SHG, this technique is ideal for demonstrating polyps (Fig. 15.20C–D). SHG is also a valuable technique when TVS is unable to differentiate an **endometrial polyp** from a **submucosal leiomyoma.** A polyp can be seen arising from the endometrium, whereas a normal layer of endometrium may be seen overlying a submucosal fibroid (see Fig. 15.11I). Cystic areas may be seen within a polyp representing the histologically dilated glands.[150,151] A feeding artery in the pedicle can frequently be seen with color Doppler ultrasound (pedicle artery sign).[153] The hyperechoic line sign may also be useful for identifying a polyp, helping one to recognize that there is a focal abnormality of the endometrium.[154]

Endometrial polyps may not be diagnosed on endometrial biopsy because a polyp on a pliable stalk may be missed by the curette. If abnormal bleeding persists after nondiagnostic dilation and curettage (D&C) in a postmenopausal woman with an endometrial thickness greater than 8 mm, hysteroscopy with direct visualization of the endometrial cavity is recommended.[155]

Endometrial Carcinoma

Endometrial carcinoma is the most common gynecologic malignancy in North America. The National Institute of Health estimated that there were 54,870 cases of endometrial cancer in the United States in 2015, with 10,170 deaths. There is an 82% overall 5-year survival rate. For endometrial cancer, 67% are diagnosed at the local stage. The 5-year survival for these localized cancers is 95.3%.[156]

Most endometrial carcinomas (75%-80%) occur in postmenopausal women. The most common clinical presentation is uterine bleeding, although only about 10% of women with postmenopausal bleeding will have endometrial carcinoma. There is a strong association with estrogen replacement therapy in postmenopausal women and anovulatory cycles in premenopausal women. Other risk factors include obesity, diabetes, hypertension, and low parity. Approximately 25% of patients with atypical endometrial hyperplasia will progress to develop well-differentiated endometrial carcinoma.[149]

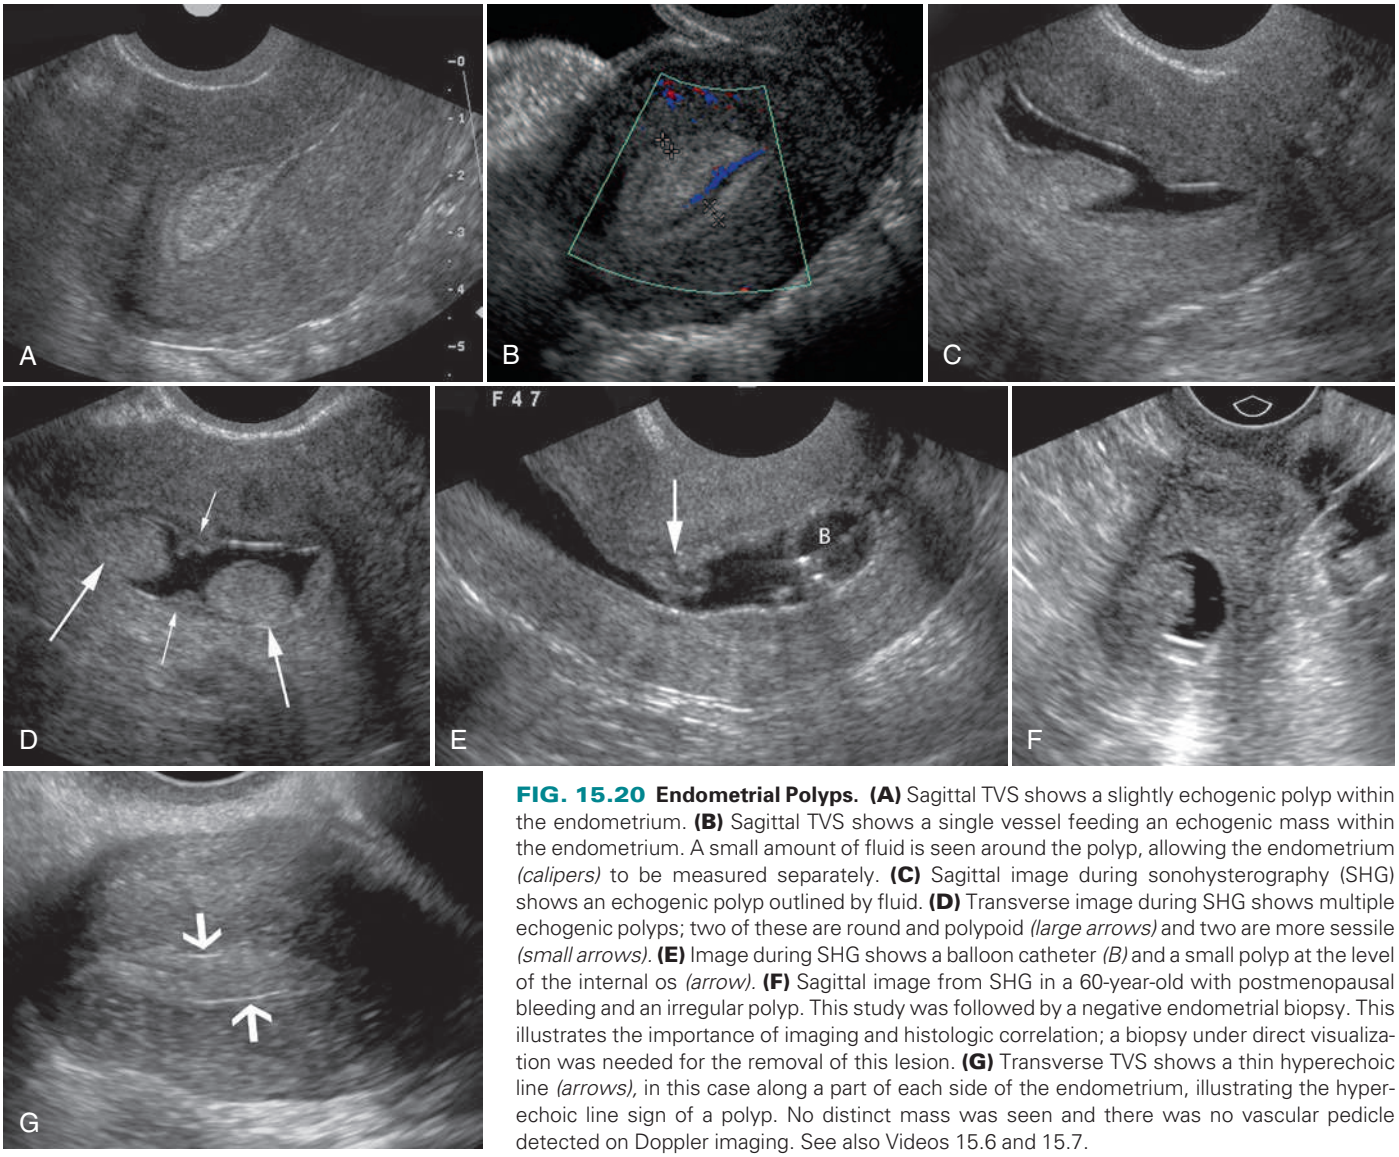

FIG. 15.20 Endometrial Polyps. (A) Sagittal TVS shows a slightly echogenic polyp within the endometrium. **(B)** Sagittal TVS shows a single vessel feeding an echogenic mass within the endometrium. A small amount of fluid is seen around the polyp, allowing the endometrium *(calipers)* to be measured separately. **(C)** Sagittal image during sonohysterography (SHG) shows an echogenic polyp outlined by fluid. **(D)** Transverse image during SHG shows multiple echogenic polyps; two of these are round and polypoid *(large arrows)* and two are more sessile *(small arrows)*. **(E)** Image during SHG shows a balloon catheter *(B)* and a small polyp at the level of the internal os *(arrow)*. **(F)** Sagittal image from SHG in a 60-year-old with postmenopausal bleeding and an irregular polyp. This study was followed by a negative endometrial biopsy. This illustrates the importance of imaging and histologic correlation; a biopsy under direct visualization was needed for the removal of this lesion. **(G)** Transverse TVS shows a thin hyperechoic line *(arrows),* in this case along a part of each side of the endometrium, illustrating the hyperechoic line sign of a polyp. No distinct mass was seen and there was no vascular pedicle detected on Doppler imaging. See also Videos 15.6 and 15.7.

Sonographic findings in endometrial cancer include a thickened endometrium, poor definition of the endometrial/myometrial interface, and an indistinct endometrium in an enlarged uterus. The thickened endometrium may be well defined, uniformly echogenic, and indistinguishable from hyperplasia and polyps. Cancer is more likely when the endometrium has a heterogeneous echotexture with irregular or poorly defined margins (Fig. 15.21, Videos 15.8 and 15.9). When invasion is clearly identified into the myometrium, then malignancy is almost certainly present. Cystic changes within the endometrium are more frequently seen in endometrial atrophy, hyperplasia, and polyps, but can also be seen with carcinoma. Endometrial carcinoma may also obstruct the endometrial canal, resulting in hematometra. Although certain sonographic appearances tend to favor a benign or malignant etiology, there are overlapping features, and endometrial biopsy is usually required for a definitive diagnosis.

The role of color and spectral Doppler ultrasound in the diagnosis of endometrial carcinoma is still controversial. Blood flow may be difficult to detect in the normal endometrium. In endometrial cancer, abnormal-appearing vessels may be seen (Fig. 15.21E). Initial studies using TVS color and spectral Doppler ultrasound suggested that endometrial carcinoma could be differentiated from a normal or benign postmenopausal endometrium by the presence of low-resistance flow in the uterine arteries in women with endometrial cancer, compared with high-resistance flow in women with normal or benign endometria.[157,158] Subsequent reports, however, have shown no significant difference in uterine blood flow between benign and malignant endometrial processes.[159-161] Low-resistance flow in the uterine artery has also been reported in association with uterine fibroids.[158] Some reports have shown low-resistance flow in the subendometrial and endometrial arteries in malignant endometrial lesions,[38,162] whereas others have found no statistically significant difference.[160,161,163] Sladkevicius and colleagues[161] found that endometrial thickness is a better method for discriminating between normal and pathologic or benign and malignant endometrium than Doppler ultrasound of the uterine, subendometrial, or intraendometrial arteries.[161]

Sonography can be used in the preoperative evaluation of a patient with known endometrial carcinoma to determine

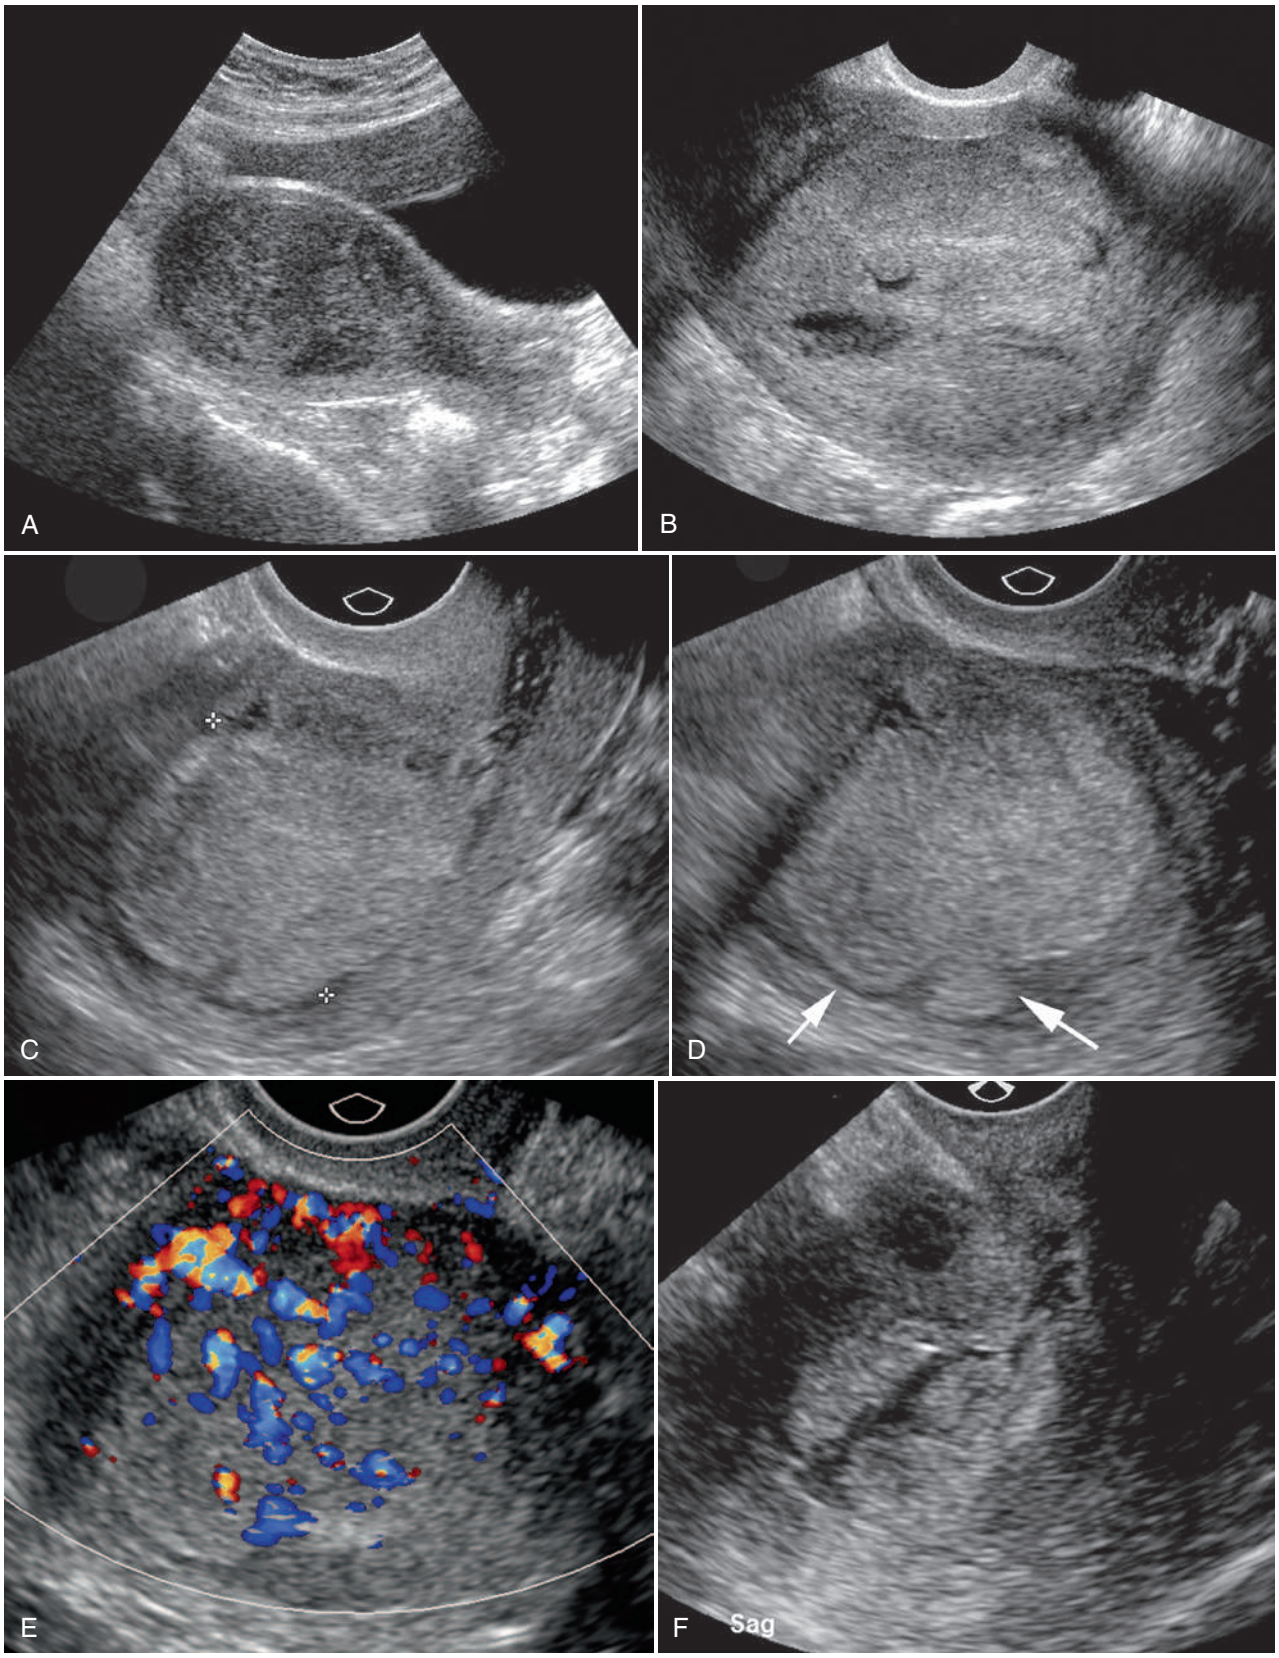

FIG. 15.21 Endometrial Carcinoma. (A) TAS and **(B)** TVS from same patient show a large, heterogeneous endometrial mass compressing the myometrium. Images **(C)-(E)** are from another patient with endometrial cancer. **(C)** The endometrium measures 33 mm *(calipers)*. **(D)** Areas of myometrial invasion are seen posteriorly *(arrows)*. **(E)** Color Doppler imaging shows irregular hypervascular tumor. **(F)** Another patient with multiple irregular polypoid lesions due to endometrial carcinoma. See also Videos 15.8 and 15.9.

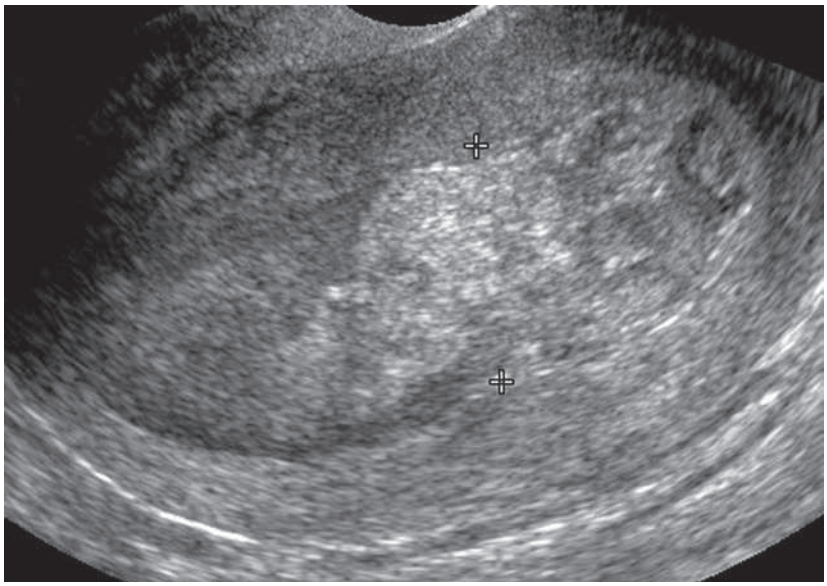

FIG. 15.22 Endometrial Carcinosarcoma. TVS shows a heterogeneous endometrial mass *(calipers)* that measures 27 mm in thickness.

myometrial invasion.[164-166] An intact **subendometrial halo** (inner layer of myometrium) usually indicates no more than superficial invasion, whereas obliteration of the halo indicates deep invasion.[166] Several objective sonographic parameters have been evaluated for staging, but subjective assessment of myometrial or cervical invasion has been shown to be as good or better than objective measurements.[167] TVS and unenhanced T2-weighted MRI have been reported to have similar accuracy,[168] but contrast-enhanced MRI has been shown to be superior to both in demonstrating myometrial invasion.[169-172] In stage IA, cancer is in the endometrium only or less than halfway through the myometrium. In stage IB, the tumor is still localized to the uterus but has spread halfway or more into the myometrium. In stage II, cancer has spread into connective tissue of the cervix, but has not spread outside the uterus. In stage III, the cancer has spread outside of the uterus or into nearby tissues in the pelvic area. In stage IV, the cancer has spread to the inner surface of the urinary bladder or the rectum (lower part of the large intestine), to lymph nodes in the groin, and/or to distant organs, such as the bones, omentum, or lungs.[173] MRI can also assess cervical extension (stage II) and extrauterine extension (stages III and IV).

Endometrial Sarcoma

Uterine sarcomas are a rare and heterogeneous group of malignancies.[174] Leiomyosarcomas have been discussed previously. Other uterine sarcomas may arise from the endometrium and include **carcinosarcomas** (also termed "malignant mixed müllerian tumors," and many now consider this a subtype of carcinoma rather than a sarcoma) (Fig. 15.22), **endometrial stromal sarcoma,** adenosarcomas, and undifferentiated sarcomas.[174,175] There is little information available regarding the sonographic appearance of these rare tumors and no specific appearance is known. Endometrial stromal sarcoma may appear as a diffuse or focal mass; may involve the myometrium, hampering determination of the origin of the lesion; and can be mistaken for a leiomyoma.[174,176]

Endometrial Adhesions

Endometrial adhesions **(synechiae)** are posttraumatic, postinfection, or postsurgical in nature and may be a cause of infertility or recurrent pregnancy loss. **Asherman syndrome** is the combination of synechiae that lead to menstrual dysfunction or infertility. The endometrium usually appears normal on TAS and TVS, although adhesions may be seen transvaginally as irregularities or a hypoechoic bridgelike band within the endometrium.[177] This is best seen during the secretory phase, when the endometrium is hyperechoic. The sonographic diagnosis is difficult unless there is endometrial fluid. SHG is an excellent technique for demonstrating adhesions.[178] Thick, broad-based adhesions may prevent distention of the uterine cavity,[108] and thus the patient may experience pain when fluid is being instilled. Synechiae appear as bridging bands of tissue that distort the cavity (Fig. 15.23, Video 15.10) or as thin, undulating membranes best seen on real-time sonography.[4] The adhesions can be divided under hysteroscopy.

Endometrial Ablation

The endometrium is typically indistinct after global **endometrial ablation** procedures (Fig. 15.24A).[179] Complications may arise when there is residual nonablated endometrium (which is common after endometrial ablation) and adjacent endometrial scarring.[180] This can result in a **cornual hematometra** (localized to the cornual region) or central hematometra (within the uterine cavity), and either may cause pain (Fig. 15.24B). **Postablation tubal sterilization syndrome** is a delayed complication of endometrial ablation that may occur in patients who previously had tubal ligation; these patients usually have pain due to a hematosalpinx of the proximal tubal stump and a cornual hematometra.[180,181] When

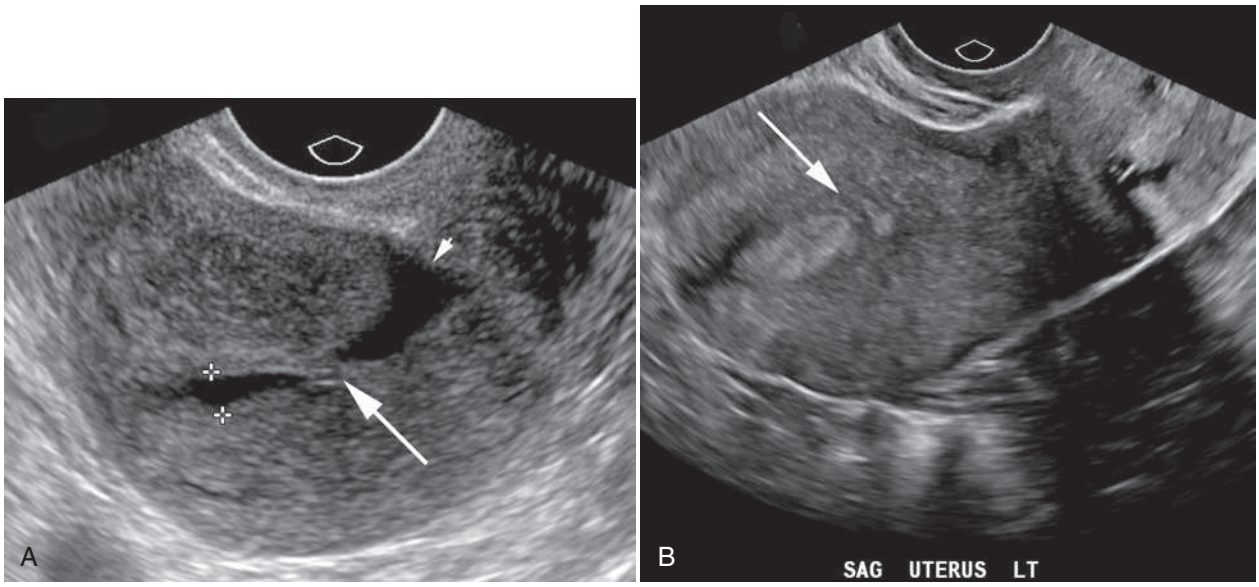

FIG. 15.23 Synechia. (A) During sonohysterography (SHG) a bridging band of tissue *(long arrow)* is seen within the fluid in the endometrial cavity. Fluid also extends into the cesarean section defect *(short arrow)*. Patients often experience pain during SHG owing to nondistensibility of the endometrial cavity when many adhesions are present. *Calipers* show the fluid in the endometrial cavity. **(B)** TVS in secretory phase shows a band of tissue similar in echogenicity to myometrium *(arrow)* spanning anterior to posterior. Note that a uterine septum would be oriented in the vertical plane extending from the fundus downward. A band of tissue in the short axis of the uterus therefore is not due to a müllerian abnormality. See also Video 15.10.

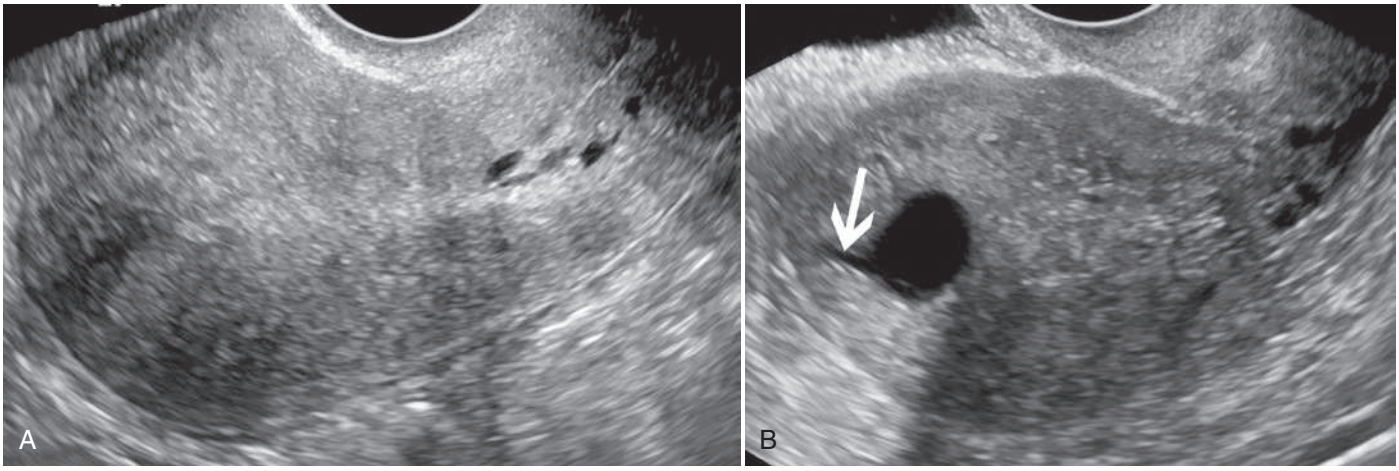

FIG. 15.24 Endometrial Ablation. (A) Sagittal TVS shows no distinct endometrial borders, a common finding after endometrial ablation. **(B)** Sagittal TVS on left side of uterus shows fluid collection due to a cornual hematometra. In this patient, there is also trace fluid extending into the intramural portion of the fallopian tube *(arrow)*.

evaluating for these complications, it may be helpful to perform imaging when the patient is symptomatic, because fluid in the obstructed area may be resorbed during the rest of the menstrual cycle.[180]

SONOGRAPHY OF CONTRACEPTIVE DEVICES

Intrauterine Contraceptive Devices

Intrauterine contraceptive devices (IUCDs or IUDs) are usually easily identified with ultrasound (Fig. 15.25). Most devices encountered in North America are T-shaped, although a circular IUD has been used in China and one may rarely still encounter a patient with a Lippes loop IUD (Ortho Pharmaceutical, Raritan, NJ).[182] The copper IUD (ParaGard, Teva Women's Health, North Wales, PA) can be left in place for up to 10 years. A levonorgestrel-releasing IUD (Mirena, Bayer HealthCare Pharmaceuticals, Pittsburgh, PA) can also be used to treat abnormal uterine bleeding rather than primarily for contraception and can be left in place for up to 5 years. Another levonorgestrel-releasing IUD (Skyla, Bayer HealthCare Pharmaceuticals) is slightly smaller than the Mirena IUD and can be left in place for up to 3 years.

In general, the shaft of an IUD is brightly echogenic and easily identified, although the levonorgestrel-releasing IUDs may

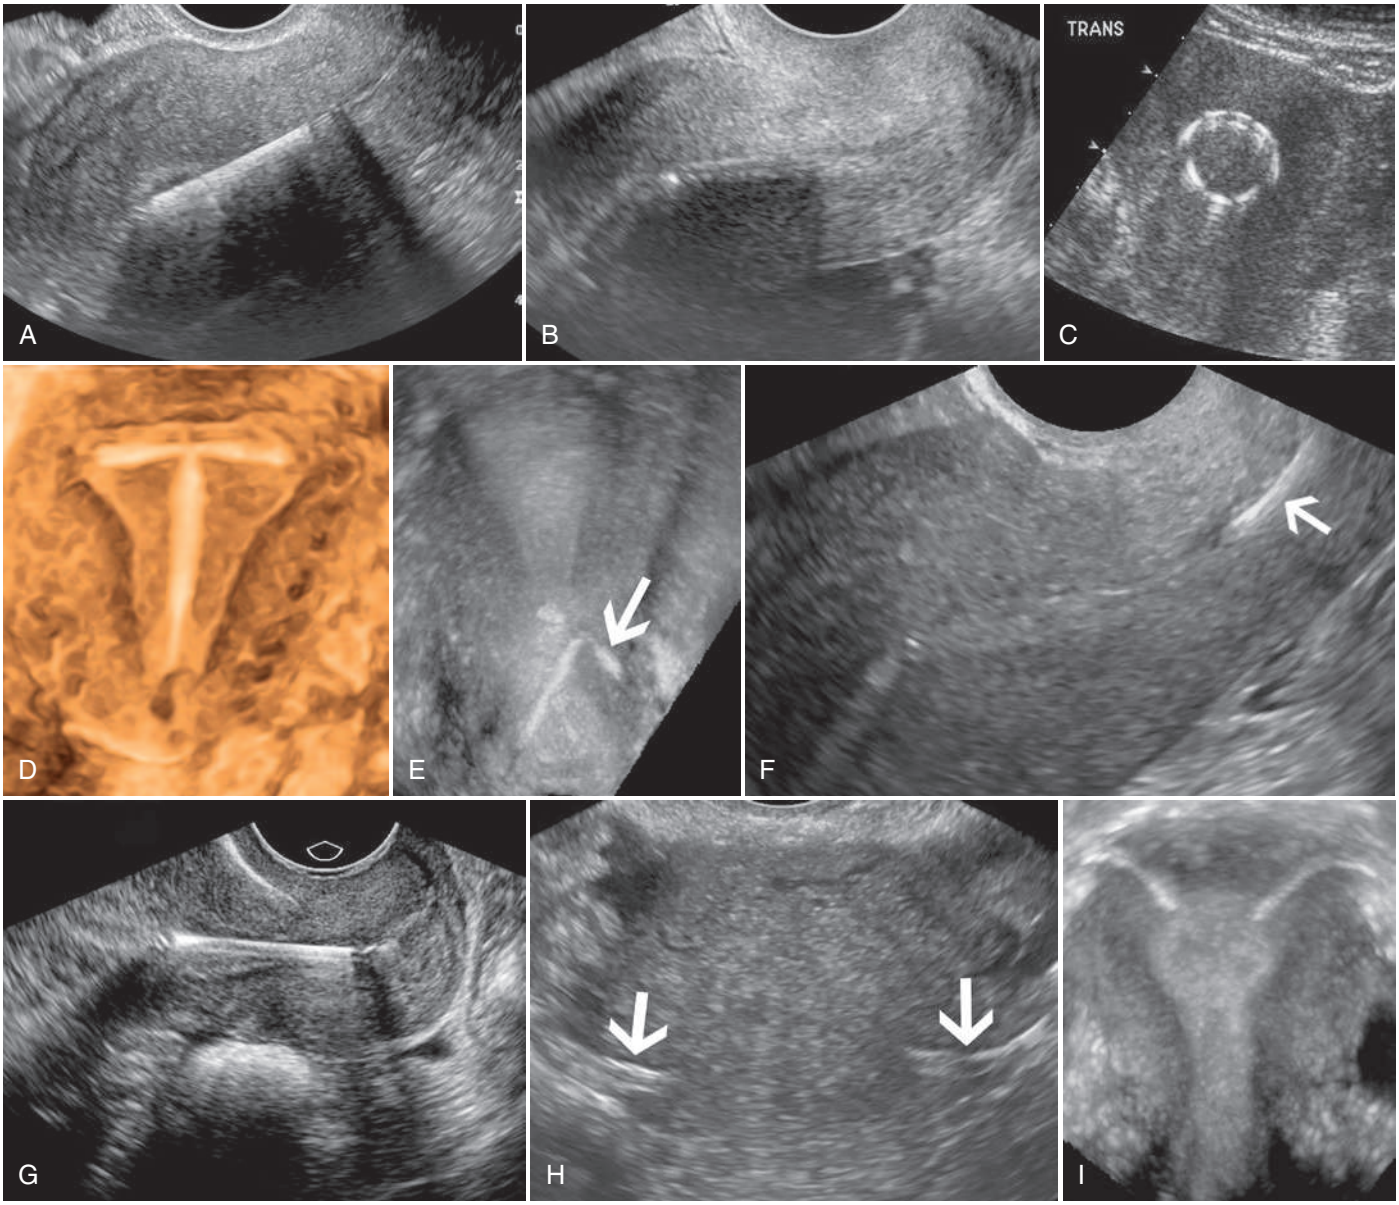

FIG. 15.25 Devices in the Uterus. (A) Sagittal TVS shows copper intrauterine device (IUD), with marked acoustic shadowing, in normal position. **(B)** Sagittal TVS shows a levonorgestrel-releasing IUD in normal position. Compared with copper IUDs, these IUDs are often not as echogenic and may have less intense acoustic shadowing. **(C)** Transverse TAS shows a circular IUD that had been placed in China. **(D)** Coronal reconstructed image from three-dimensional (3-D) ultrasound shows a levonorgestrel-releasing IUD in appropriate position. **(E)** Coronal reconstructed image from 3-D ultrasound shows an IUD that is low, being in the cervix and lower uterine segment, with the left arm *(arrow)* of the IUD embedded in the myometrium and cervical stroma. **(F)** String *(arrow)* of the IUD is seen in the cervix. IUD was normally positioned and is not visible in this image. Care should be taken to not mistake the string for the IUD itself. **(G)** TVS shows an IUD in low position, extending from the midcervix into the lower uterus. See also Video 15.11. **(H)** Transverse TVS shows tubal occlusion device *(arrows)* in their expected location in the cornual region of the uterus bilaterally. **(I)** Coronal reconstructed image from 3-D ultrasound shows tubal occlusion devices in their expected location in the cornual region of the uterus bilaterally.

be more difficult to identify than the copper IUD on 2-D ultrasound.[183] If a brightly echogenic interface of a levonorgestrel-releasing IUD is not seen, one should look carefully for acoustic shadowing originating from the shaft or arms to help in locating the IUD. Occasionally one may encounter endometrial calcifications that simulate an IUD, but the discontinuous nature of the calcifications should help prevent confusion. The upper end of the IUD and the arms of the IUD should normally be in the superior most portion of the endometrium. If the IUD is located lower in the uterus (Video 15.11), one should suspect that one or both arms of the IUD are embedded in the myometrium. 3-D ultrasound may help in identifying abnormal position of IUDs.[184] The most common location of a malpositioned IUD is the lower uterus or cervix.[185] The string of many IUDs is brightly echogenic and should not be confused for the shaft (Fig. 15.25F).

If an IUD is not seen on ultrasound and not known to have been expelled, one should evaluate the adnexa sonographically (Fig. 15.25G). However, if the IUD has perforated and is in the pelvis, it might be difficult to identify sonographically owing to bowel gas. A radiograph of the abdomen and pelvis should then be done to determine if the IUD is present in the peritoneal cavity.

Tubal Occlusion Devices

Tubal occlusion devices may be placed hysteroscopically into the fallopian tube to provide permanent sterilization. The Essure device (Bayer HealthCare Pharmaceuticals) has been most frequently used. These devices normally appear as curvilinear hyperechoic structures in the cornual region bilaterally (Fig. 15.25H–I).[186,187] Ideally the device spans the uterotubal junction, extending slightly into the endometrial cavity and into the fallopian tube.[188]

The Adiana device (Hologic, Bedford, MA) is a nonabsorbable silicone matrix that is inserted into the proximal fallopian tube. The product has been discontinued, although one may still encounter women with this device, which may appear as a small hyperechoic area in the cornual region of the uterus.[189]

POSTPARTUM FINDINGS

Normal Findings

The uterus will be enlarged initially after delivery and usually returns to its nongravid size by about 6 to 8 weeks after delivery. The uterus is often soft and easily compressible by the transducer during the first few days after delivery. TAS alone is often adequate to evaluate the uterus in the first few postpartum weeks, as the enlarged uterus usually provides an adequate sonographic window. TVS is more often needed later in the postpartum period. The inner myometrium may be hyperechoic relative to the outer myometrium in the early postpartum period and can potentially be mistaken for the endometrium (Fig. 15.26A).[190] Echogenic foci due to air are normal and can persist for up to 3 weeks.[191] Small amounts of fluid and heterogeneous tissue due to clot are commonly seen in the early postpartum period (Fig. 15.26B).

Bleeding Postpartum

Some amount of bleeding postpartum is expected and is normal; therefore visualization of blood and debris within the postpartum uterus is a normal finding. When patients have an abnormal amount of bleeding, pain, and/or fever, then sonographic evaluation is typically used to assess for causes such as **retained products of conception** (RPOC) or **endometritis.**

Retained Products of Conception

At times the calcified appearance of the term placenta will be visualized and the diagnosis of RPOC will be obvious. When there is vascularized (based on detectable flow on Doppler imaging) tissue in the endometrial cavity (Fig. 15.27), this is usually indicative of RPOC. If there is tissue that is not vascularized, this could be due to either blood clot or devascularized RPOC. The size of the suspected RPOC is important because that may guide therapy. For example, at one of our institutions, medical management is typically initiated for smaller regions of RPOC (usually 2 cm or less) whereas D&C is typically performed for larger areas which are felt to be unlikely to respond to medical therapy. If RPOC are seen and they extend beyond the expected endometrial cavity into myometrium, this is indicative of an invasive placental condition such as placenta accreta. This is an important diagnosis to suggest because the placenta will not be easily removed at D&C and the patient will be at increased risk

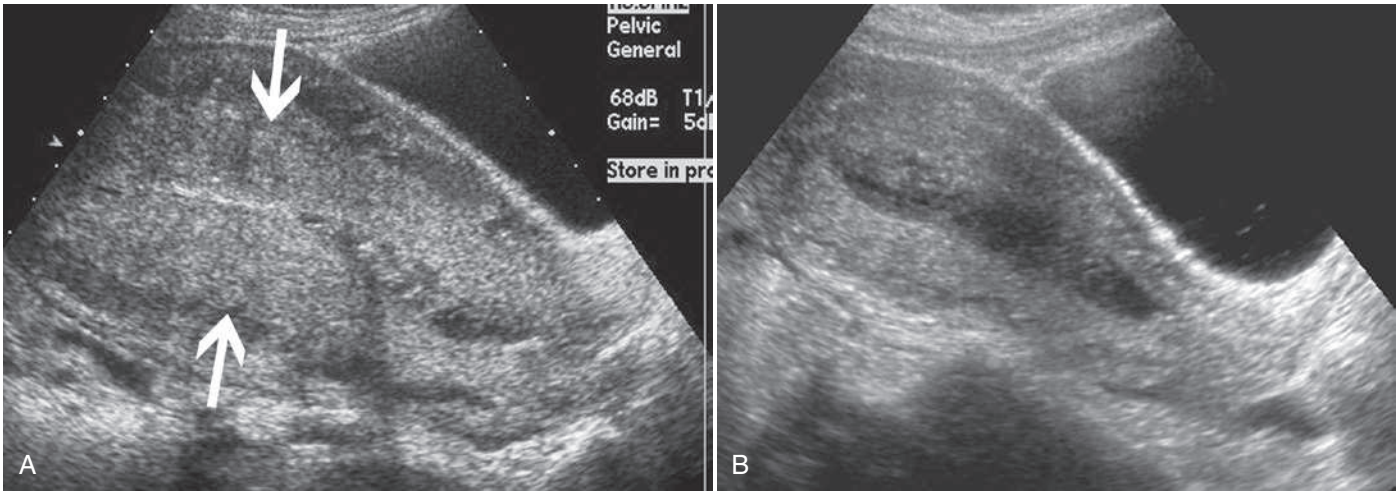

FIG. 15.26 Normal Postpartum Findings. (A) Normal hyperechoic myometrium. Sagittal TAS image from a patient 4 days after vaginal delivery shows hyperechoic appearance of inner portion of myometrium (between *arrows*). One could potentially misinterpret this entire area as endometrium. **(B)** Normal endometrial fluid. Sagittal TAS image from a patient 9 days after vaginal delivery shows a small amount of fluid in the endometrial cavity, a common finding in postpartum women.

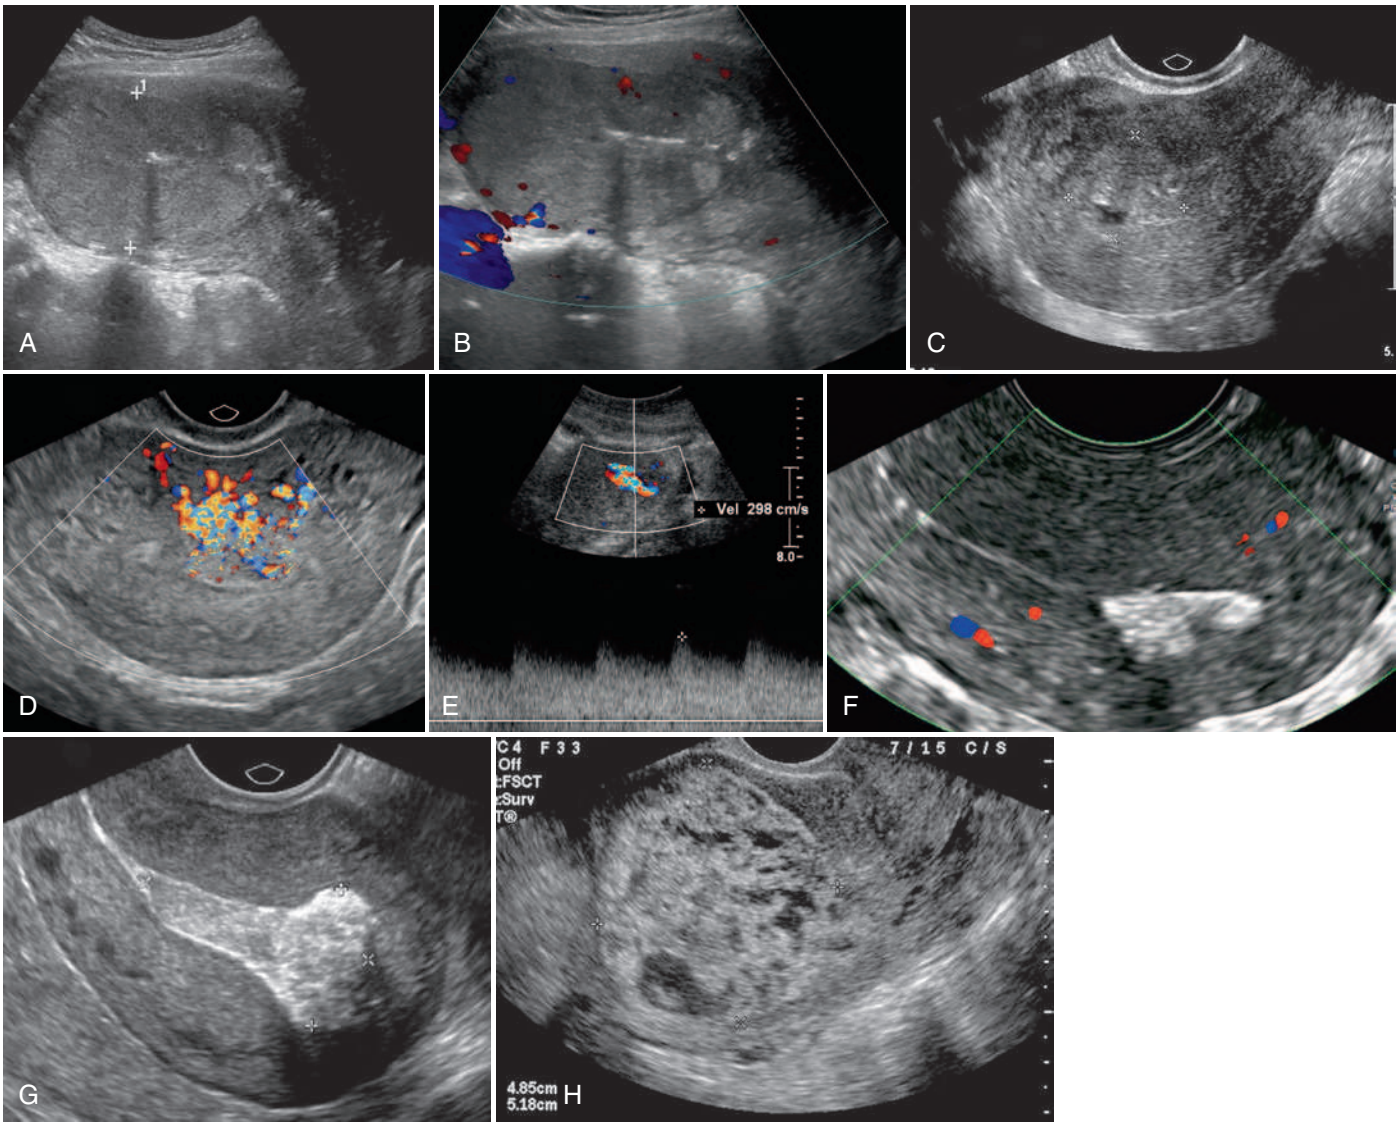

FIG. 15.27 Retained Products of Conception (RPOC). (A) and **(B)** Sagittal TAS scans in a patient 6 days after vaginal delivery. **(A)** There is a hyperechoic mass *(calipers)* in superior region of the uterus. **(B)** Color Doppler image shows a few areas of flow in the periphery of the mass. (**A** and **B** courtesy of Shannon Sheedy, MD.) **(C)-(E)** Retained products of conception 1 month after a miscarriage. **(C)** There is a hyperechoic mass *(calipers)* in the endometrial cavity. **(D)** Color Doppler shows substantial flow from the myometrium extending into the RPOC. **(E)** Angle-corrected spectral Doppler shows peak systolic velocity of 298 cm/sec. See also Video 15.12. **(F)** and **(G)** Sagittal TVS from two different patients, each a few months after delivery with calcified RPOC. **(H)** Sagittal sonogram shows a large area of RPOC after a cesarean section. The thin myometrium suggests placental invasion, in this case due to **placenta accreta.**

for uterine rupture. At times the myometrium and endometrium are heavily vascularized by RPOC (Fig. 15.27C–D, Video 15.12). In these cases, one study suggested that if there is higher-velocity flow (which they defined as >60 cm/sec), surgical removal of the residual tissue may be performed using sonographic guidance.[192] However, these were not angle-corrected velocity measurements, limiting the usefulness of relying on a specific velocity threshold.

Placental site trophoblastic tumor (PSTT) is an uncommon cause of postpartum bleeding but should be considered when there are persistently low serum levels of human chorionic gonadotropin (hCG) and/or elevated levels of human placental lactogen.[193] The hCG levels tend to be low, sometimes only minimally elevated, compared with the more common forms of gestational trophoblastic neoplasia. The sonographic appearance of PSTT is most commonly a heterogeneous predominately solid mass involving the endometrium and/or myometrium; occasionally it can be predominately cystic with marked vascularity simulating an arteriovenous malformation.[194] This is discussed in more depth in Chapter 30.

Endometritis

Endometritis should be considered as a potential diagnosis in the postpartum period when patients have fever and/or pain.

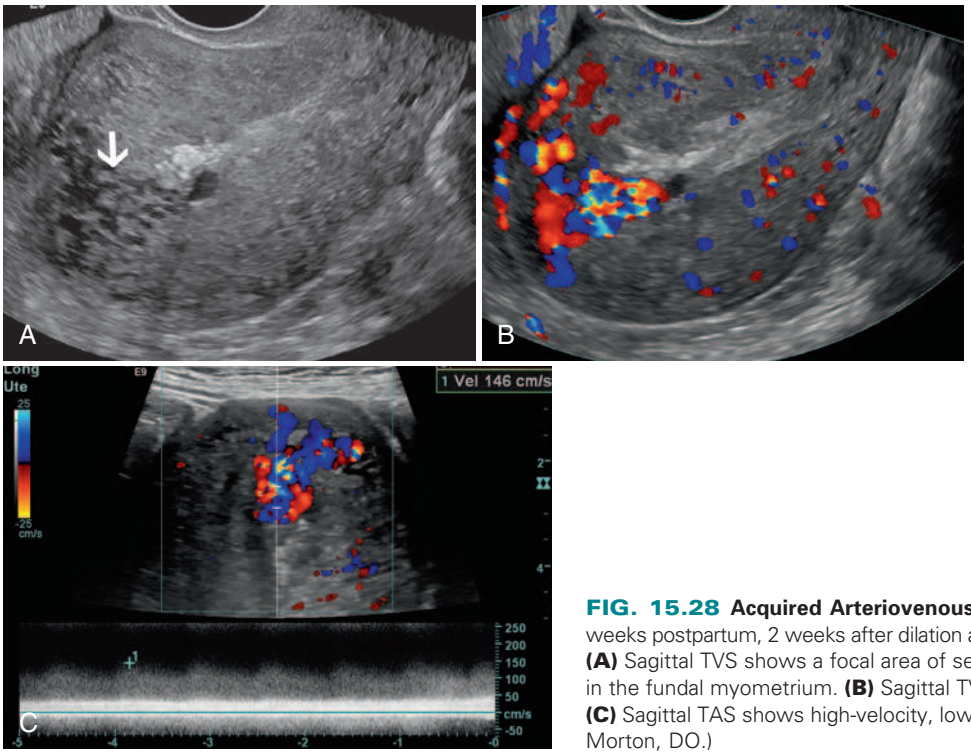

FIG. 15.28 Acquired Arteriovenous Malformation (AVM). AVM in a patient 9 weeks postpartum, 2 weeks after dilation and curettage, with continued vaginal bleeding. **(A)** Sagittal TVS shows a focal area of serpiginous cystic-appearing structures *(arrow)* in the fundal myometrium. **(B)** Sagittal TVS shows flow in the serpiginous structures. **(C)** Sagittal TAS shows high-velocity, low-resistance arterial flow. (Courtesy of Marilyn Morton, DO.)

Endometritis is a clinical diagnosis. The sonographic findings are variable and may be normal.[190] Fluid and/or air may be seen in the endometrial cavity in patients with endometritis, but these are also common normal findings in the first few postpartum weeks, limiting their usefulness.

Arteriovenous Malformation

Arteriovenous malformations (AVMs) are rare. In general, they are acquired lesions resulting from prior uterine instrumentation. Although they can be seen at other times, they are often diagnosed during the postpartum period or after a miscarriage, and patients usually have abnormal vaginal bleeding on presentation. It is important to diagnose AVM so that inappropriate treatment does not worsen the hemorrhage.[13]

Sonographically, AVMs should be considered when there is focal area of serpiginous tubular structures in the myometrium.[195,196] Color or power Doppler imaging will typically show exuberant flow in the AVM (Fig. 15.28), and spectral Doppler imaging will demonstrate low-resistance arterial flow. It has been suggested that the arterial velocities in the AVM may guide treatment, with higher velocities (>83 cm/sec) suggesting the need for embolization and lower velocities allowing for more conservative management.[197] However, in most published studies the reported velocities are not true velocities because angle correction was not used, confounding the usefulness of such measurements.

Uterine AVMs can be easily overdiagnosed in the postpartum and postmiscarriage periods.[198] Findings similar to true AVMs can be due to **subinvolution of the placental bed.**[199] Thus in stable patients one should try for conservative management because many of these seeming AVMs will resolve spontaneously. Focal areas of low-resistance arterial flow may also be seen in the myometrium in patients with RPOC and **gestational trophoblastic disease,** similar to an AVM.[200] A negative serum hCG may be helpful because hCG is typically elevated in patients with gestational trophoblastic disease.[13] Serum hCG level may not be as helpful for RPOC; about half of patients with RPOC are reported to have a negative or only minimally positive hCG level.[201]

Findings After Cesarean Section

Most patients undergoing a cesarean delivery will have a transverse incision in the lower uterine segment. In the initial postpartum period after a cesarean section, one typically will see small echogenic foci, due to sutures and/or gas, in the anterior myometrium of the lower uterine segment (Fig. 15.29A, Video 15.13). It is uncertain how long these can normally be seen but likely for several weeks or months. One may also see heterogeneity in this region of the myometrium, probably due to small areas of hemorrhage. For the minority of cesarean section patients who have a classic hysterotomy with a longitudinal incision higher in the uterus, one may see similar heterogeneity and/or echogenic foci in that region of the myometrium in the postpartum period.

Bladder flap hematomas, due to bleeding at the incision site, may occur in the lower uterine segment of the uterus or between it and the urinary bladder. Sonographically, they appear as a mass of variable echogenicity (see Fig. 15.29B, Video 15.13). Small hematomas are common and may not be clinically

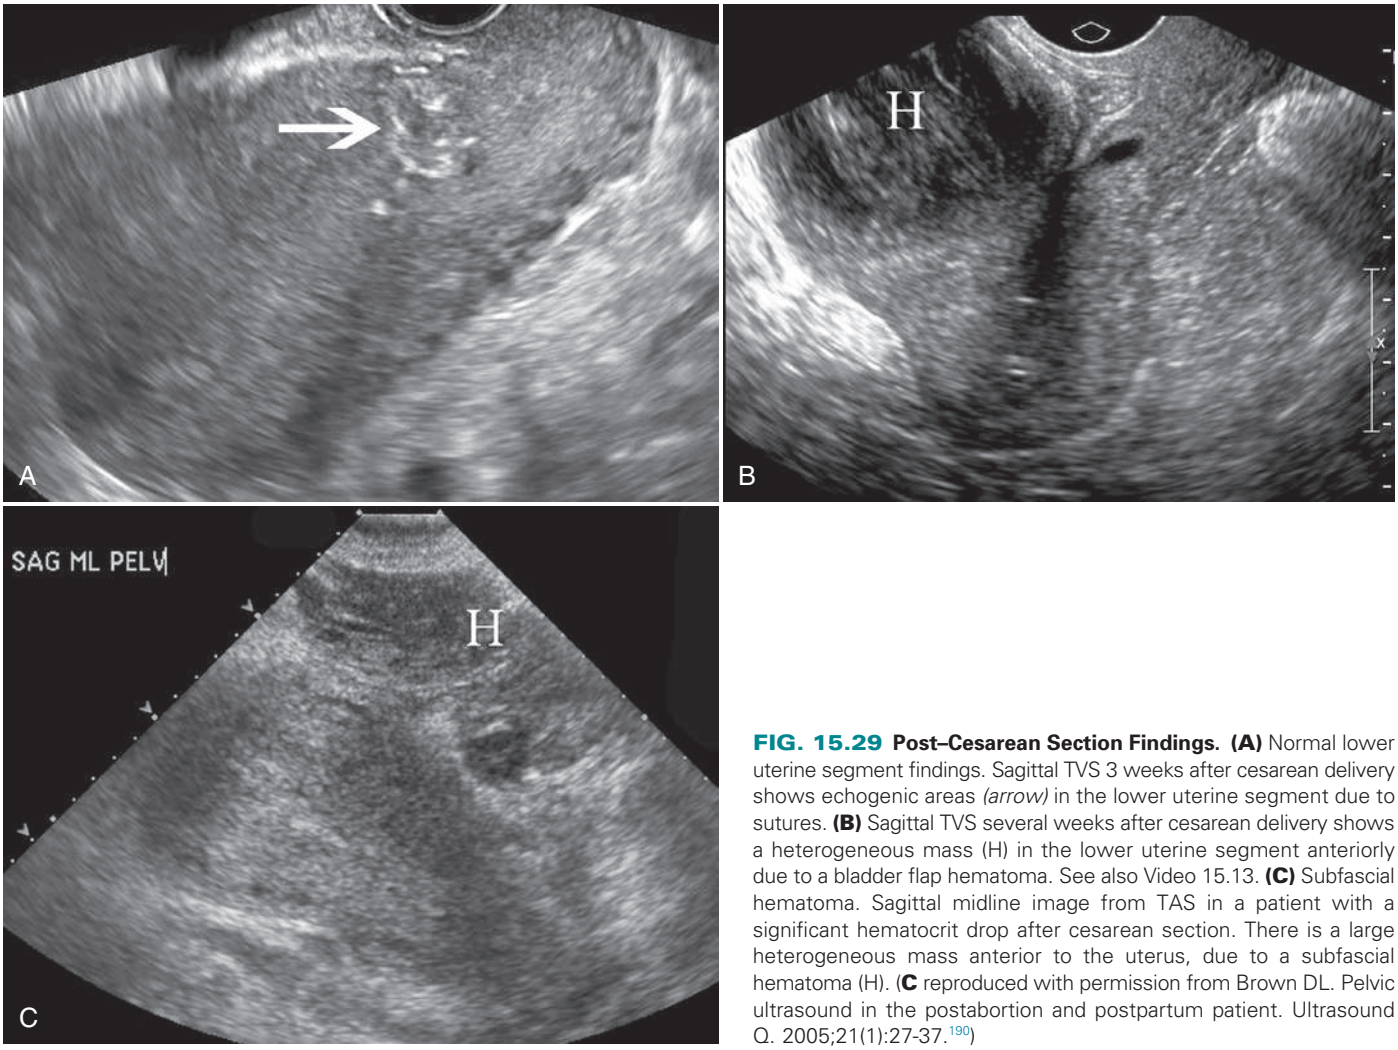

FIG. 15.29 Post–Cesarean Section Findings. (A) Normal lower uterine segment findings. Sagittal TVS 3 weeks after cesarean delivery shows echogenic areas *(arrow)* in the lower uterine segment due to sutures. **(B)** Sagittal TVS several weeks after cesarean delivery shows a heterogeneous mass (H) in the lower uterine segment anteriorly due to a bladder flap hematoma. See also Video 15.13. **(C)** Subfascial hematoma. Sagittal midline image from TAS in a patient with a significant hematocrit drop after cesarean section. There is a large heterogeneous mass anterior to the uterus, due to a subfascial hematoma (H). (**C** reproduced with permission from Brown DL. Pelvic ultrasound in the postabortion and postpartum patient. Ultrasound Q. 2005;21(1):27-37.[190])

significant. The size above which hematomas tend to be clinically important is uncertain, although it has been suggested that hematomas smaller than 4 cm[202] are unlikely to be clinically significant. **Subfascial hematomas** are thought to be due to disruption of inferior epigastric vessels and are located extraperitoneally.[203] They can appear as a mass of variable echogenicity, located posterior to the rectus abdominal muscles of the lower abdominal wall (see Fig. 15.29C). Subfascial and bladder flap hematomas may occur in the same patient, but it is important to distinguish them if surgical treatment is planned, because the approach is different.[203,204]

After several months, when healing is complete, a thin linear echo representing the hysterotomy scar can often be seen in the lower uterine segment[205] and is a normal, expected finding (Fig. 15.30A). More than one scar may be seen in patients with multiple prior cesarean deliveries. The myometrium superior to the scar, or between two adjacent scars, may have a convex outer contour and potentially be mistaken for a leiomyoma[204,206] (Fig. 15.30B–C). Fluid sometimes accumulates in the scar, either spontaneously or during SHG. Variable terminology has been used to describe this collection of fluid in the scar: **cesarean scar diverticuli, cesarean scar pouch, cesarean scar defect, uterine niche, and isthmocele.**[207-211] In general, this entity is considered present when fluid extends into a triangular defect in the anterior lower uterine segment (Fig. 15.30D); however, there is no standard definition.[211] It is also unclear whether such a "defect" is necessarily abnormal because many patients are asymptomatic.[211] However, these may cause intermenstrual bleeding and can be treated surgically.[211] Cesarean scar defects might also be a cause of dysmenorrhea, chronic pelvic pain, or infertility.[211] Larger defects, with thinner myometrium, seem to be associated with a higher likelihood of uterine rupture or dehiscence in a subsequent pregnancy, but it is not yet clear how this should affect clinical practice.[212]

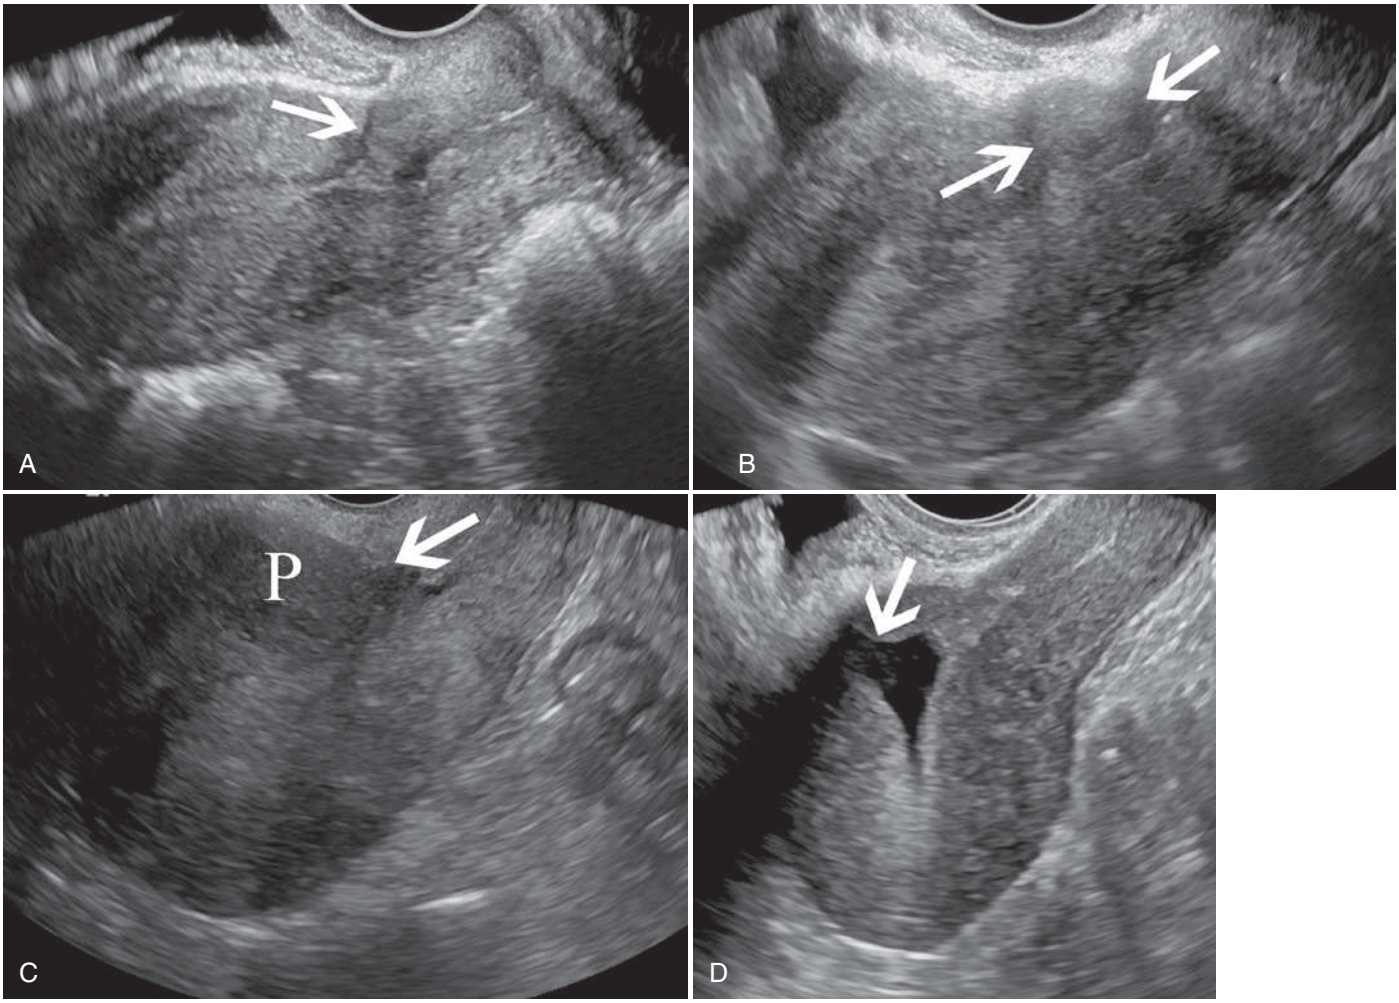

FIG. 15.30 Cesarean Section Scars Remote From Time of Surgery on Transvaginal Sonography (TVS). (A) Normal cesarean section scar *(arrow)* in anterior lower uterine segment. **(B)** Pseudomass due to bulbous area of myometrium, in this instance located between two cesarean sections scars *(arrows)*. This could be mistaken for a leiomyoma. **(C)** Pseudomass *(P)* due to bulbous area of myometrium superior to a cesarean section scar *(arrow)*. **(D)** Fluid *(arrow)* extends into the cesarean section scar in the anterior lower uterine segment. Variable terms, including "isthmocele," have been used to describe this finding.

CHAPTER 16

The Adnexa

Rochelle Filker Andreotti and Lori A. Deitte

SUMMARY OF KEY POINTS

- The normal sonographic appearance of the ovaries changes with the menstrual cycle because of the influence of gonadotropins. These changes cease to occur as late menopause is reached and developing follicles are no longer present.
- Nonneoplastic lesions of the ovary and adnexa are usually simple cysts or cysts that contain blood products and are often physiologic. These include hemorrhagic physiologic cysts and endometriomas that can often be differentiated based on the sonographic appearance of the type of blood products. Other common nonneoplastic cysts include paraovarian cysts, hydrosalpinges, and peritoneal inclusion cysts.
- Ovarian torsion, a condition caused by rotation of the ovarian pedicle on its axis, is a surgical emergency and sonography is valuable in making the diagnosis.
- Morphologic and Doppler sonographic findings in neoplasms can be highly accurate in differentiating benign from malignant masses.

Sonography is the modality of choice for imaging the pelvis, including the adnexa, because it is noninvasive, radiation free, cost effective, and widely available. Sonography allows for accurate delineation of uterine and ovarian architecture and assessment of vascular flow. **Transvaginal sonography** (TVS) is a fundamental part of pelvic ultrasound examinations because of the use of higher frequency transducers (up to 10 MHz) and the vaginal probe's proximity to the uterus and adnexa. However, **transabdominal sonography** (TAS) continues to be the mainstay when structures are high in the pelvis, out of the field of view of the TVS probe; in pediatric patients; and in those who have difficulty tolerating TVS. Color and spectral **Doppler** sonography allow for assessment of normal and pathologic blood flow. Doppler ultrasound can also distinguish vascular structures from non-vascular structures, such as dilated fallopian tubes or fluid-filled bowel loops.

NORMAL ANATOMY

Bilaterally, the broad and round ligaments, fallopian tubes, ovaries and their associated vascularity extend from lateral uterine corpus forming the pelvic adnexa. Laterally, the peritoneal reflection

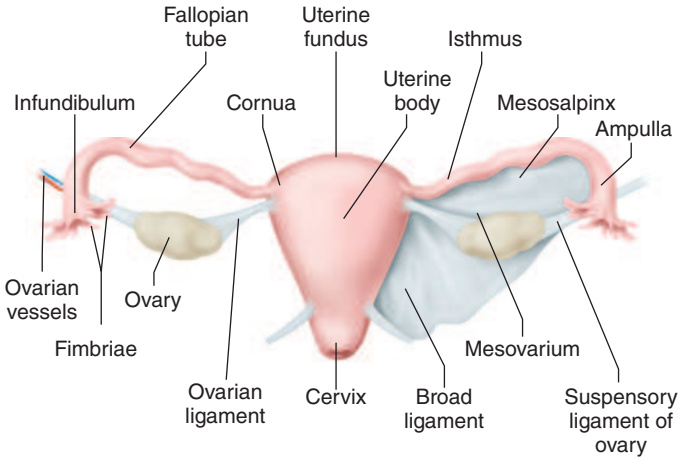

FIG. 16.1 Normal Gynecologic Organs. Diagram of uterus, ovaries, tubes, and related structures. On left side, broad ligament has been removed.

forms the **broad ligaments,** which extend from the lateral aspect of the uterus to the lateral pelvic side walls (Fig. 16.1). Encompassing the superior and lateral margin of the broad ligament is the **suspensory** (infundibulopelvic) **ligament.** The free border of the broad ligament contains the fallopian tube within its superior margin, which is referred to as the **mesosalpinx.** The ovary is attached to the posterior layer of broad ligament by reflections of peritoneum called the **mesovarium.** The **round ligaments** arise from the uterine cornua anterior to the fallopian tubes in the broad ligaments, extend anterolaterally, and course through the inguinal canals to insert into the fascia of the labia majora.[1]

Each **fallopian tube** varies from 7 to 12 cm in length and is divided into intramural, isthmic, ampullary, and infundibular portions. The intramural, or **interstitial,** portion is approximately 1 cm long, is contained within the muscular wall of the uterus, and is the narrowest part of the tube. The **isthmus,** constituting the medial third, is slightly wider, round, cordlike, and continuous with the **ampulla,** which is tortuous and forms approximately one-half the length of the tube. The ampulla terminates in the most distal portion, the **infundibulum,** or fimbriated end, which is funnel shaped and opens into the peritoneal cavity.[2]

The **ovaries** are elliptical in shape, with the long axis usually oriented vertically. The surface of the ovary is not covered by peritoneum but by a single layer of cuboidal or columnar cells called the **germinal epithelium,** which becomes continuous with the peritoneum at the hilum of the ovary. The internal structure of the ovary is divided into an outer **cortex** and inner **medulla.** The cortex consists of an interstitial framework, or stroma, which is composed of reticular fibers and spindle-shaped cells and which contains the ovarian follicles and corpus lutea. Beneath the germinal epithelium, the connective tissue of the cortex is condensed to form a fibrous capsule, the **tunica albuginea.** The medulla, which is smaller in volume than the cortex, is composed of fibrous tissue and blood vessels. In the nulliparous female, the ovary is located in a depression on the lateral pelvic wall called the *ovarian fossa*, which is bounded anteriorly by the obliterated umbilical artery, posteriorly by the ureter and the internal iliac artery, and superiorly by the external iliac vein.[2] The fimbriae of the fallopian tube lie superior and lateral to the

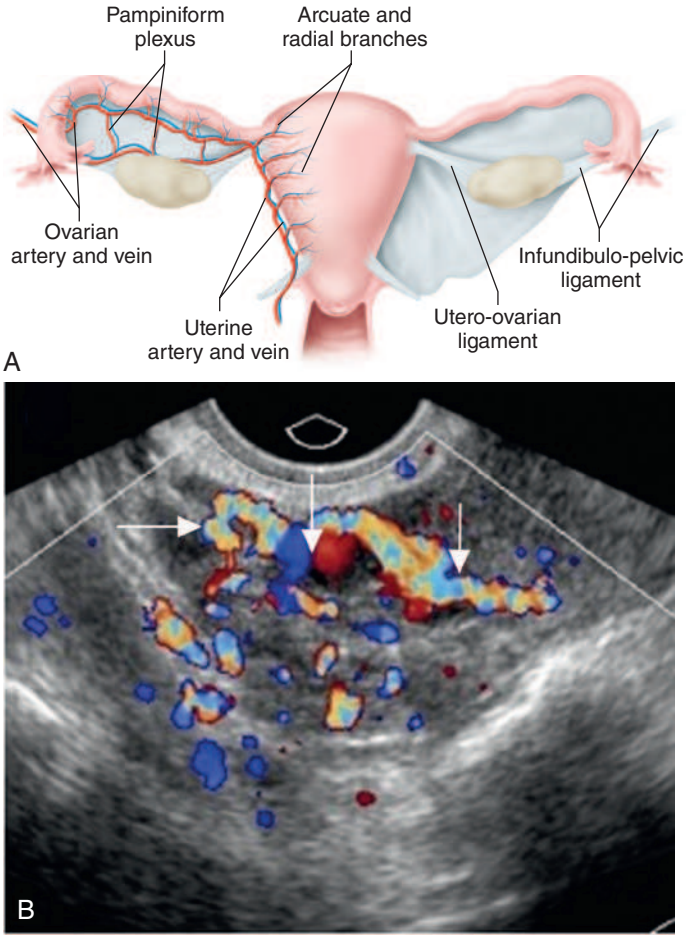

FIG. 16.2 Adnexal Vascularity. (A) Diagram of uterine artery along the lateral margin of the uterus and the ovarian artery seen lateral to the ovary within the right adnexa, both joining to form the pampiniform plexus anterior to the ovary. **(B)** Transverse color Doppler image demonstrating the ovarian artery *(right arrow),* uterine artery *(left arrow),* and pampiniform plexus *(middle arrow)* of the right adnexa.

ovary. The anterior surface of the ovary is attached to the posterior surface of the broad ligament by the short **mesovarium.** The upper pole of the ovary is attached to the lateral wall of the pelvis by the lateral extension of the broad ligament, the **suspensory (infundibulopelvic) ligament** of the ovary. Arising from the uterine cornu posteriorly to the tubes and attaching to the inferior aspect of the ovary is the **utero-ovarian ligament.** These ligaments are not rigid, and therefore the ovary can be quite mobile, especially in women who have had pregnancies and/or who have had a hysterectomy.

The vascularity to the adnexa consists of a dual blood supply. The ovary is chiefly supplied by the **ovarian artery,** a branch of the hypogastric (internal iliac) artery but usually receives additional arterial flow from the ovarian branches of the **uterine artery** (Fig. 16.2). The veins tend to parallel the arteries. From the ovarian **pampiniform plexus,** the right ovarian vein drains directly into the inferior vena cava, while the left ovarian vein empties into the left renal vein. The ovarian ligaments that include the **broad ligament,** the **ovarian ligament,** and the **infundibulopelvic ligament** contain vascular, lymphatic, and nervous supplies to the organs. The ovarian nerves and vessels

course with the suspensory (infundibulopelvic) ligament and the utero-ovarian ligament. The lymph vessels of the ovary accompany the ovarian artery to the lateral aortic and periaortic lymph nodes. Coursing superior and adjacent to the utero-ovarian ligament that arises from the uterine cornu posteriorly to the tubes and attaches to the inferior aspect of the ovary in the utero-ovarian ligament is the ovarian branch of the uterine artery. Derived from the main ovarian artery and the ovarian branch of the uterine artery are numerous arterioles extending to the capsule of the ovary and small penetrating arteries within the ovary itself. The ovarian blood supply may vary from five to six branches that penetrate the capsule to two large branches with multiple twigs.[2]

Although not considered part of the adnexal structures, the rectouterine recess **(posterior cul-de-sac)** is often involved in adnexal processes. It is the most posterior and inferior reflection of the peritoneal cavity and is located between the rectum and vagina and is also known as the **pouch of Douglas.** The posterior fornix of the vagina is closely related to the posterior cul-de-sac and is separated by the thickness of the vaginal wall and the peritoneal membrane. The cul-de-sac is a potential space, and because of its location, it is frequently the initial site for intraperitoneal fluid collection. As little as 5 mL of fluid has been detected by TVS.[3]

Technique

The standard examination of the pelvic adnexa is included in the routine pelvic sonogram and is composed of the traditional TAS combined with the TVS, frequently using color and spectral Doppler. TAS uses a distended bladder as window to pelvic structures for a global view and may be advantageous when ovaries are high in the pelvis, outside of the field of view of the TVS probe. However, using TAS, visualization of pelvic organs may be limited because of attenuation from the body wall and the distance from the area of interest of the transducer. As a result, it is not often possible to use higher frequency transducers and benefit from their inherent higher axial and lateral resolution. **TVS** gives a more detailed evaluation of adnexal architecture using higher frequency transducers at closer proximity to pelvic structures and should be used whenever feasible. Still, TVS should not be performed in premenarchal patients, in the majority of virginal patients, or in any patient who does not willingly consent to vaginal examination. Because TVS is typically performed, routine bladder distention is not required unless there is a reason for additional TAS images, or unless the woman declines vaginal scanning. Initial imaging with TAS is performed using the patient's bladder distention at presentation followed by a full TVS. When TVS is not going to be performed, then we require a full bladder for best visualization of the uterus, endometrium, and adnexa.

TVS with abdominal compression is a valuable technique for improving adnexa visibility. Abdominal pressure with one hand, while holding the transducer with the other hand, is used to displace bowel, bring structures closer to the transducer, and identify focal areas of tenderness. The pressure of the transducer between two adjacent structures in the pelvis can be used to determine if they move together or slide past each other as separate entities. This is often referred to as the **"sliding organ sign."** Examples of the value of this technique include its use to confirm that an adnexal mass is unattached to the ovary or a mass is ovarian and not uterine in origin.

Spectral and color and power Doppler are routinely used to characterize vascularity to the ovaries and fallopian tubes, helping to narrow the differential considerations. This is especially useful when there is suspicion of neoplasia or in patients presenting with pelvic pain with diagnostic considerations that include pelvic inflammatory disease (PID), ovarian torsion, or functional cysts. Because color or power Doppler signal may be produced artifactually, it is important to always confirm flow by demonstrating a spectral waveform.

Normal Sonographic Appearance of the Ovary and Fallopian Tube

The ovary can be quite variable in position and may be located high in the pelvis or in the cul-de-sac because of the laxity of the ligamentous attachments. Uterine location influences the position of the ovaries. The normal ovaries are usually identified laterally or posterolaterally to the anteflexed midline uterus. When the uterus lies to one side of the midline due to exogenous pressure by a mass or a normal variant, the ipsilateral ovary often lies superior to the uterine fundus. In a retroflexed uterus, the ovaries tend to be located laterally and superiorly, near the uterine fundus. When the uterus is enlarged, the ovaries may be displaced more superiorly and laterally. After hysterectomy, the ovaries tend to be located more medially and directly superior to the vaginal cuff. A common location of the ovaries, especially in nulliparous patients, is **Waldeyer fossa.** In this location, the ellipsoid configuration of the ovary has its craniocaudad axis paralleling the internal iliac vessels, which lie posteriorly and serve as a helpful reference (Fig. 16.3). Waldeyer fossa is also bounded by the obliterated umbilical artery anteriorly, the ureter posteriorly, and the external iliac vein superiorly. Superiorly or extremely laterally placed ovaries may not be visualized by the TVS approach because they may be outside of the field of view of the TVS probe.

Because of the variability in shape, **ovarian volume** has been considered the best method for determining ovarian size. The volume measurement is based on the formula for a prolate ellipse ($0.523 \times \text{length} \times \text{width} \times \text{height}$). In women of reproductive age, a normal ovary may have a volume as large as 22 mL. Cohen et al.[4] assessed 866 normal ovaries by TAS and reported a mean ovarian volume of 9.8 ± 5.8 mL, with an upper limit of 21.9 mL.[4] Another study of 406 patients with normal ovaries used TVS and reported a mean ovarian volume of 6.8 mL, with an upper limit of 18.0 mL.[5] There is no significant parity-related change in ovarian volume in premenopausal women.[6]

Punctate echogenic foci are commonly seen in an otherwise normal-appearing ovary (Fig. 16.4). Many are tiny (1-3 mm) nonshadowing foci, usually multiple and peripherally located, although they can be diffuse. Kupfer et al.[7] examined five patients with peripherally distributed echogenic ovarian foci who subsequently underwent bilateral oophorectomy for other clinical indications. All 10 ovarian specimens showed multiple surface epithelial inclusion cysts and associated psammomatous

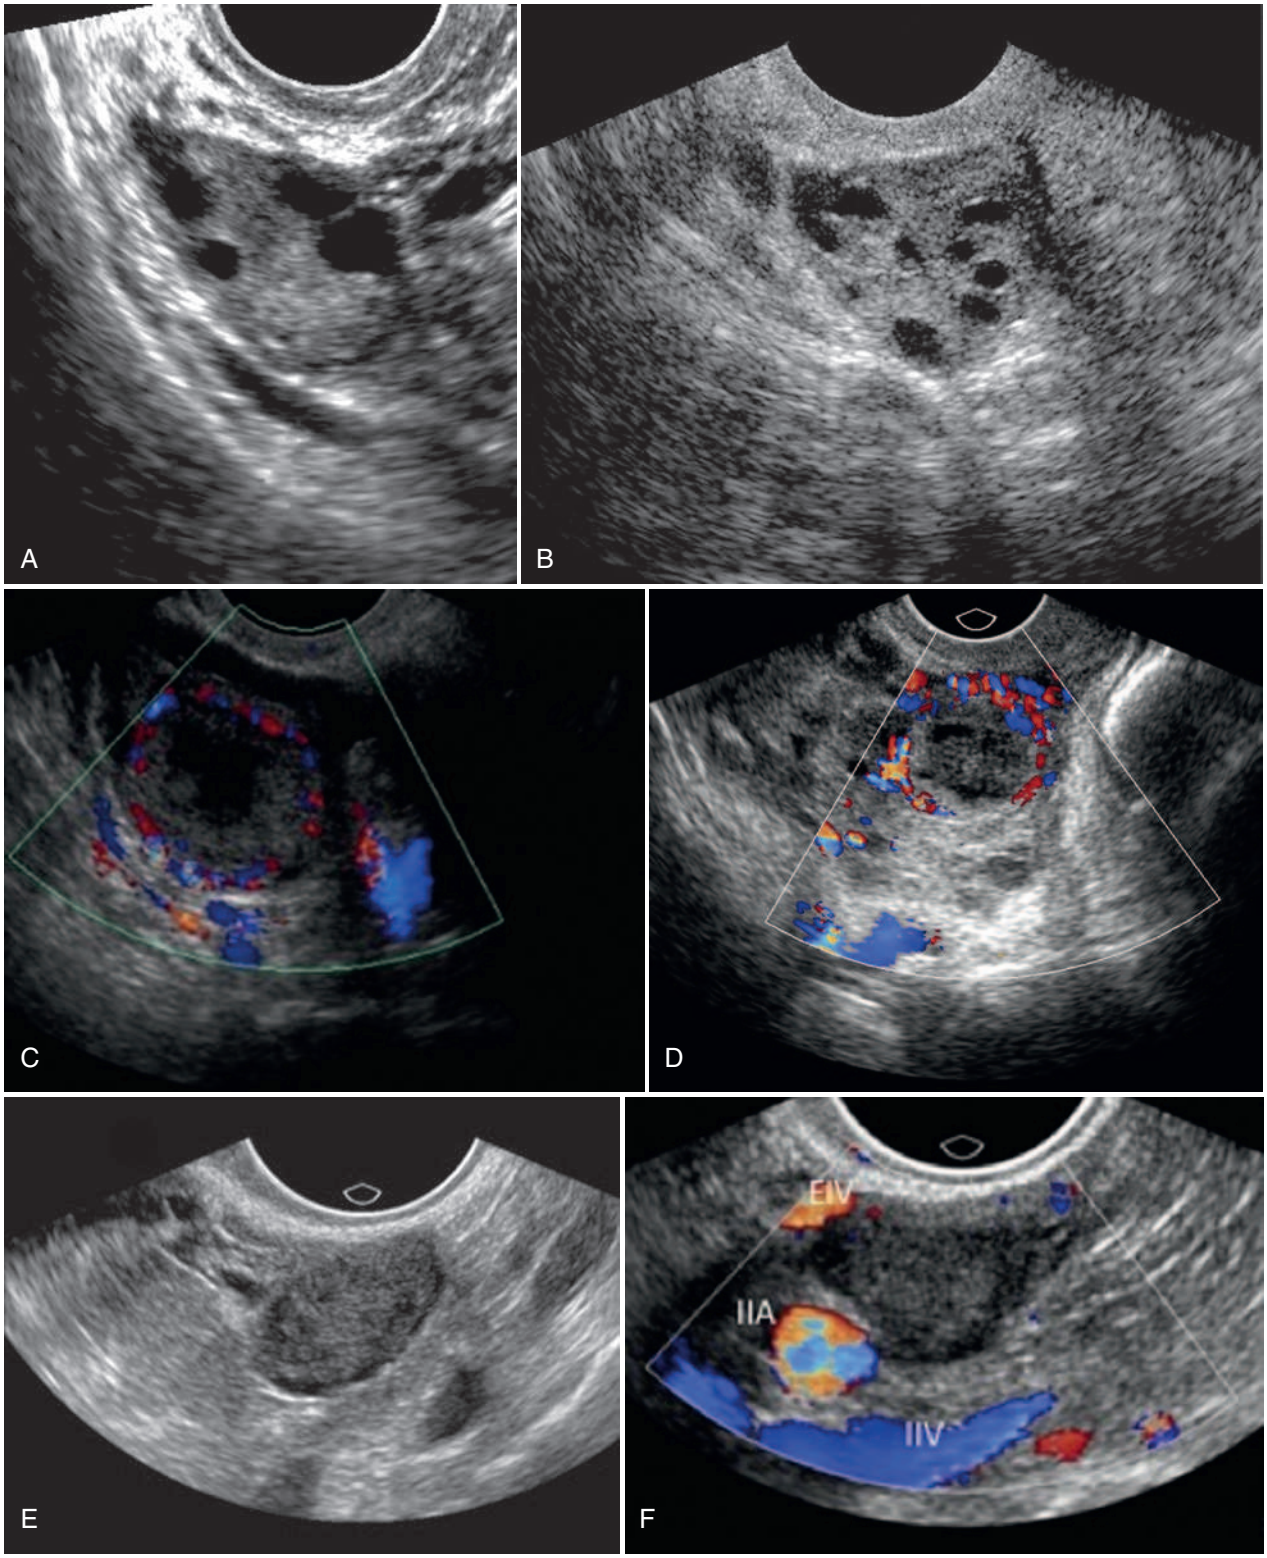

FIG. 16.3 Normal Ovary. (A) and **(B)** TVS images show normal ovaries in the follicular phase containing a few developing follicles in two patients. Internal iliac vein is posterior to ovary. **(C)** and **(D)** TVS color Doppler images of the early and late corpus luteum. Both demonstrate peripheral color Doppler flow. The early corpus luteum contains internal low-level echoes consistent with hemorrhage whereas the late corpus luteum has collapsed. **(E)** Transverse gray-scale and **(F)** sagittal color Doppler TVS images of the same patient show a normal postmenopausal ovary in the left adnexa anterior and medial to the internal iliac artery *(IIA)* and vein *(IIV)* and inferior to the external iliac vein *(EIV)* in the Waldeyer fossa. The ovary is small in size and lacks follicles.

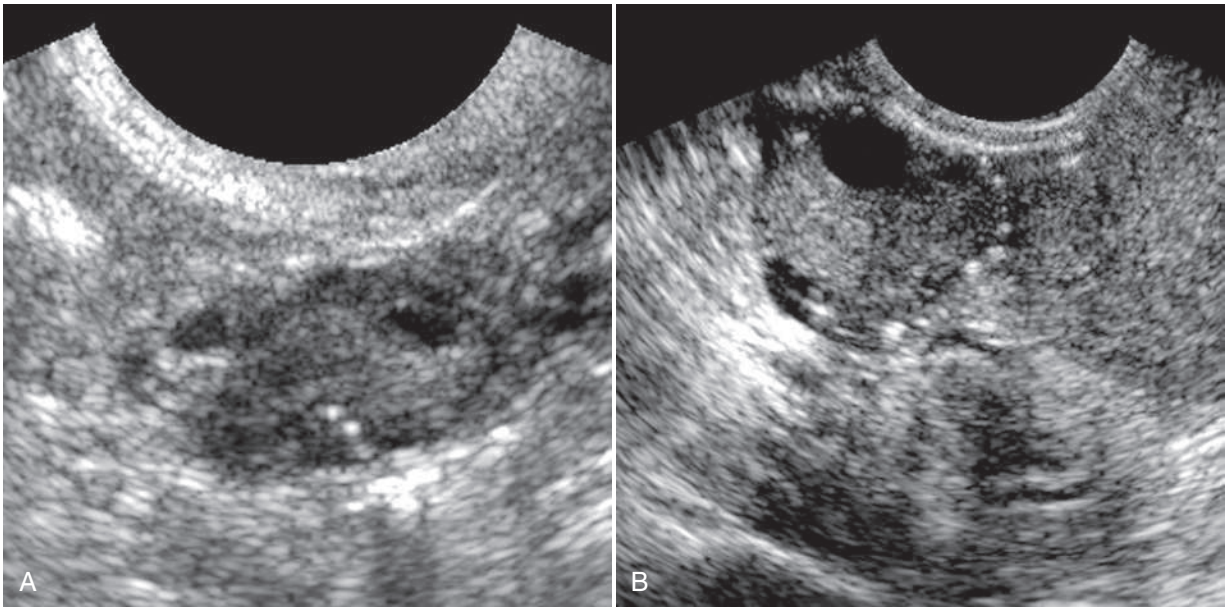

FIG. 16.4 Punctate Echogenic Foci in the Ovary. TVS images of two patients. **(A)** Two tiny echogenic foci in normal-appearing ovary. **(B)** Multiple peripheral tiny echogenic foci (back walls of tiny unresolved cysts).

calcifications. In another study with histopathologic correlation in seven normal ovaries with echogenic foci, Muradali et al.[8] showed that these foci are caused by a specular reflection from the walls of tiny unresolved cysts below the spatial resolution of ultrasound rather than calcification. These echogenic foci do not indicate significant underlying disease, so no further investigation or follow-up is necessary. Brandt et al.[9] reported that echogenic foci with associated shadowing consistent with **focal calcification** may occasionally be seen in an otherwise normal-appearing ovary. At histologic analysis, 4 of 17 ovaries analyzed (24%) were associated with benign neoplasms, whereas the remaining ovaries were unremarkable. It was proposed that these represent stromal reaction to previous hemorrhage or infection. Zeligs et al.[10] recently reported echogenic ovarian foci with atypical morphologic characteristics and distribution in addition to extraovarian echogenic foci. These proved to be calcifications associated with a serous borderline ovarian tumor with extraovarian noninvasive implants. This finding is unusual, however, as the vast majority of punctate ovarian calcifications without associated mass are of benign etiology. When there is an associated mass or morphology or distribution of calcifications is atypical, additional imaging is recommended.

The fallopian tubes are musculomembranous structures measuring up to 12 cm in length and consisting of the intramural, isthmic, and ampullary portions. Although documentation of fallopian tubes is not a routine part of a normal pelvic examination, at least a portion of each tube can be demonstrated in most patients. Sonographically, the length of the fallopian tube can be identified by its tubular structure containing a linear echogenic lumen that can be followed to the uterine cornua.

Changes During the Menstrual Cycle

The appearance of the ovary changes with age and phase of the menstrual cycle. Under the influence of follicle-stimulating hormone (FSH), human follicular development begins with a follicular size of approximately 0.03 mm with potential ovulation after more than 150 days of growth. It is only after follicles reach approximately 4 mm that they are routinely visualized by ultrasound. During the menstrual cycle, multiple immature, less than 1-cm follicles appear in the early follicular phase before day 10. Subsequently, one or more ovulatory follicles become dominant, increasing in size to 18 to 25 mm in average diameter. The average size of the dominant follicle is 20 mm in diameter at ovulation, which usually occurs on day 14 of a normal 28-day menstrual cycle. The other follicles become atretic. The disappearance of the dominant follicle with associated free fluid in the pelvis signifies ovulation. Other, less specific and sensitive findings may include irregularity of the cyst wall with internal echoes.[11] A **follicular cyst** develops if ovulation does not occur and follicular growth continues because of the lack of the luteinizing hormone surge and excessive stimulation by FSH.

Following release of the ovum and collapse of the dominant follicle, the postovulatory **corpus luteum** is formed, a crenulated thick-walled cyst demonstrating peripheral color Doppler signal. The corpus luteum may bleed internally as a result of vascularization of the inner granulosa layer following ovulation forming a **hemorrhagic corpus luteum** (see Fig. 16.3C and D). As the corpus luteum ages, it collapses and progressively transforms into a more solid, fatty structure, a **corpus albicans,** usually not well visualized sonographically. However, if pregnancy ensues, the corpus luteum continues to be maintained for hormonal support until approximately 10 to 13 weeks' gestation when placental hormone production can support the pregnancy.

Fluid in the cul-de-sac (Fig. 16.5) is a normal finding in asymptomatic women and can be seen during all phases of the menstrual cycle. Possible sources include blood or fluid caused by follicular rupture, blood from retrograde menstruation, and increased capillary permeability of the ovarian surface caused

FIG. 16.5 Fluid in Cul-De-Sac. TVS shows echogenic fluid in cul-de-sac caused by blood.

by the influence of estrogen.[12,13] Pathologic fluid collections in the pouch of Douglas may be seen in association with generalized **ascites, blood** resulting from a ruptured ectopic pregnancy or hemorrhagic cyst, or **pus** from infection. Sonography can aid in differentiating the type of fluid, because blood, pus, mucin, and malignant exudates usually contain echoes within the fluid, whereas serous fluid (either physiologic or pathologic) is usually anechoic. Clotted blood may be very echogenic, mimicking a solid mass.[14]

Postmenopausal Ovary

Differentiation of **perimenopause** and early **postmenopause** is often difficult. The postmenopausal period begins when at least 1 year or more has elapsed since the final menstrual period.[15] In early postmenopause (1 to 5 years since final menstrual period) ovulatory cycles may occur infrequently and folliculogenesis may continue. Once late postmenopause is reached (more than 5 years since final menstrual period),[16] folliculogenesis ceases, the ovary atrophies, and the follicles disappear, with the ovary decreasing in size with increasing age.[6,17-19] Because of its smaller size and lack of follicles, the postmenopausal ovary may be difficult to visualize sonographically (see Fig. 16.3E and F). A stationary loop of bowel may be mistaken for a normal ovary; therefore scanning must be done slowly to look for peristalsis (Video 16.1). However, because the colon does not always peristalse during a sonographic exam, lack of peristalsis is not sufficient for differentiation. Sonographic visualization of normal postmenopausal ovaries varies greatly in the literature, from a low of 20% to a high of 99%, using either the TAS or TVS.[5,17-22] The variation is likely caused by differences in technique and length of time since menopause, and the series with very high percentages of visualization likely include some loops of bowel rather than ovaries. The ovary decreases in size with increasing age, and therefore the ability to see the ovaries decreases as the length of time since menopause increases.[23] Also, the absence of the uterus may play a role in the visualization of ovaries that are less likely to be seen following hysterectomy because of the loss of normal anatomic landmarks.[23]

In 290 postmenopausal ovaries known to be present, Wolf et al.[23] visualized only 41% of ovaries through use of TVS, 58% through use of TAS, and 68% using both techniques. Highly placed ovaries may be out of the field of view of TVS transducers, and TAS may not image very small or deeply placed ovaries. Although nonvisualization of an ovary does not exclude an ovarian lesion, it can be a fairly reassuring finding since most ovarian neoplasms are cystic, and an ovarian mass will usually displace adjacent bowel loops and be more easily visible.

Mean postmenopausal ovarian volume ranges are reported from 1.2 to 5.8 mL.[4,5,17-21] The mean values in these studies may be somewhat high because nonvisualized ovaries were not included. One study assessing 563 patients with normal postmenopausal ovaries by TVS reported a mean ovarian volume of 2.0 mL with an upper limit of normal of 8.0 mL.[5] A postmenopausal ovarian volume of more than 8.0 mL should be considered abnormal. Because normal size varies widely, some authors suggest that an ovarian volume more than twice that of the opposite side should also be considered abnormal.[18,20]

Postmenopausal Cysts

As patients progress from early to late menopause, small simple cysts, defined as thin-walled, round or oval anechoic cysts with posterior acoustic enhancement, no internal solid component or septation, and no internal color Doppler flow, become less frequently observed. While follicles may still be present in the early menopause, other cysts may be paraovarian or paratubal in origin or ovarian **surface epithelial inclusion cysts.**

One report suggests that simple cysts of all sizes may be seen in up to 15% of postmenopausal ovaries and are not related to age, length of time since menopause, or hormone use[23] (Fig. 16.6). Smaller cysts are more frequently seen by TVS with its improved resolution, but in some women, especially those with hysterectomy or highly placed ovaries, the cysts may be seen only by TAS. Most of these cysts either disappear or decrease in size over time.[24-26] Other reports suggest that even in late menopause, when folliculogenesis is unlikely, small simple cysts are seen in up to 21% of women.[27,28]

Several studies have shown a very low incidence of malignancy in unilocular postmenopausal cysts less than 5 cm in diameter and without septations or solid components.[25,26,29-32] In surgical lesions that are inclined to be larger cysts and/or those in postmenopausal patients, 84% of simple ovarian cysts have been found to be cystadenomas.[33] Although it has been shown that an ovarian cystadenoma may be a precursor of borderline tumors (those of low malignant potential and low-grade carcinomas), there is an extremely slow rate of transformation so that these lesions can be considered benign and are safe to watch over time rather than remove surgically.[32,34] Ekerhovd et al.[32] found four borderline or malignant tumors in 247 postmenopausal women (1.6%) who underwent surgery for simple ovarian cysts detected by TVS. These four tumors were all greater than 7.5 cm in diameter. It is generally recommended that asymptomatic postmenopausal women with simple ovarian cysts less than 7 cm

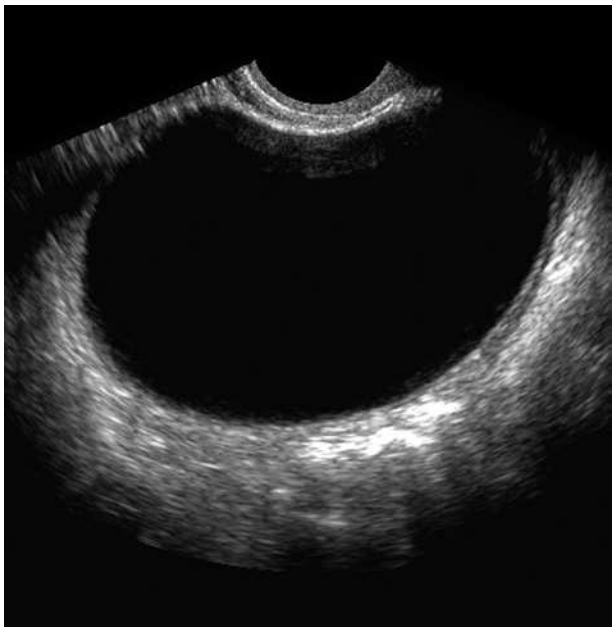

FIG. 16.6 Postmenopausal Large Ovarian Cyst. TVS image of a 7-cm ovarian cyst that contains no internal echoes or septations and had not changed in size over 4 years.

and greater than 1 cm in diameter be followed by serial yearly sonographic examinations without surgical intervention unless there is an increase in size or change in the characteristics of the lesion. Cysts measuring less than 1 cm are felt to be almost certainly benign and follow-up is not necessary. Surgery is usually recommended for postmenopausal simple cysts greater than 7 cm and for those containing multiple internal septations or one or more solid nodules. However, magnetic resonance imaging (MRI) is better able to characterize these larger cysts in which small mural nodules can be missed by ultrasound and thus may be a reasonable alternative to surgery.[28]

NONNEOPLASTIC LESIONS

Functional Cysts

Functional cysts are physiologic and not neoplastic lesions of the ovary whose appearance and disappearance is hormonally driven. These cysts may be simple or hemorrhagic and are commonly divided into three categories: follicular, corpus luteum, and theca lutein cysts. Acute abdominal pain caused by internal hemorrhage, rupture, or leakage is the most common symptom, but pelvic discomfort may simply be the result of the large size, greater than 2.5 to 3.0 cm.

A follicular cyst develops when a mature follicle fails to ovulate or to involute. Because normal follicles can vary from a few millimeters up to 2.5 cm, a follicular cyst cannot be diagnosed with certainty until it is larger than 2.5 cm. Therefore a simple cyst less than 2.5 cm in a premenopausal woman should be referred to as a *follicle* and considered to be normal. Follicles and follicular cysts are usually unilateral, asymptomatic, and frequently detected incidentally on sonographic examination. Follicular cysts usually regress spontaneously.

After ovulation, the corpus luteum develops and may be identified sonographically as a small, hypoechoic or isoechoic structure within the ovary. The corpus luteum usually contains low-level internal echoes, frequently with a thicker wall than a follicle and a crenulated appearance. It typically has a peripheral rim of color around the wall on color Doppler ultrasound (ring of fire; see Fig. 16.3C). The corpus luteum usually involutes before menstruation but may persist because of failure of absorption or internal bleeding. Timor-Tritsch and Goldstein[35] recommend using the term *corpus luteum* rather than *corpus lutein cyst* unless it is greater than 4 cm. Corpus lutein cysts are less common than follicular cysts but tend to be larger and more symptomatic. Pain is the major symptom. These cysts are usually unilateral and are prone to hemorrhage and, less commonly, rupture. If the ovum is fertilized, the corpus luteum continues as the corpus luteum of pregnancy, which may become enlarged with a simpler cystic appearance than the original corpus luteum. Maximum size is reached at 8 to 10 weeks of gestation, and by 16 weeks the cyst has usually resolved.[36]

Theca lutein cysts are associated with high beta–human chorionic gonadotropin (B-hCG) levels and are the largest of the functional ovarian cysts, increasing the risk of ovarian torsion. These cysts typically occur in patients with gestational trophoblastic disease but can also be seen as a complication of drug therapy for infertility causing ovarian hyperstimulation syndrome. Sonographically, theca lutein cysts are usually bilateral, multilocular, and very large. Similar to other functional cysts, they may undergo hemorrhage or rupture.

Although hemorrhage may occur in all types of functional cysts, it is most frequently seen in corpus luteal cysts. Women with hemorrhagic cysts frequently present with acute onset of pelvic pain. Hemorrhagic cysts show a spectrum of findings because of the variable sonographic appearance of blood (Fig. 16.7, Video 16.2). The appearance depends on the amount of hemorrhage and the time of the hemorrhage relative to the time of the sonographic examination.[37-39] The internal architecture is much better appreciated on TVS when compared to TAS because of its superior resolution. An acute hemorrhagic cyst is usually hyperechoic and may mimic a solid mass. However, it usually has a smooth posterior wall and shows posterior acoustic enhancement, indicating the cystic nature of the lesion. Diffuse low-level internal echoes may be appreciated, although this appearance is more frequently seen in endometriomas. As the clot hemolyzes, a reticular-type pattern is demonstrated internally containing intertwining linear internal echoes representing fibrin strands.[40] These should not be confused with septations, which are thicker. As the clot retracts, it will have a concave outer margin with angularity compared with a solid mural nodule, which will have a convex outer margin. Color Doppler ultrasound will show no flow within the clot but will demonstrate peripheral vascularity within the cyst wall. Care should be taken when assessing for flow in hemorrhagic cysts, because a clot can move and show color without true vascularity. Spectral Doppler can be helpful in these cases. Patel et al.[40] found that a specific diagnosis could be made in approximately 90% of hemorrhagic cysts by demonstrating the presence of a reticular pattern or a retractile clot. The presence of echogenic, free intraperitoneal fluid in the

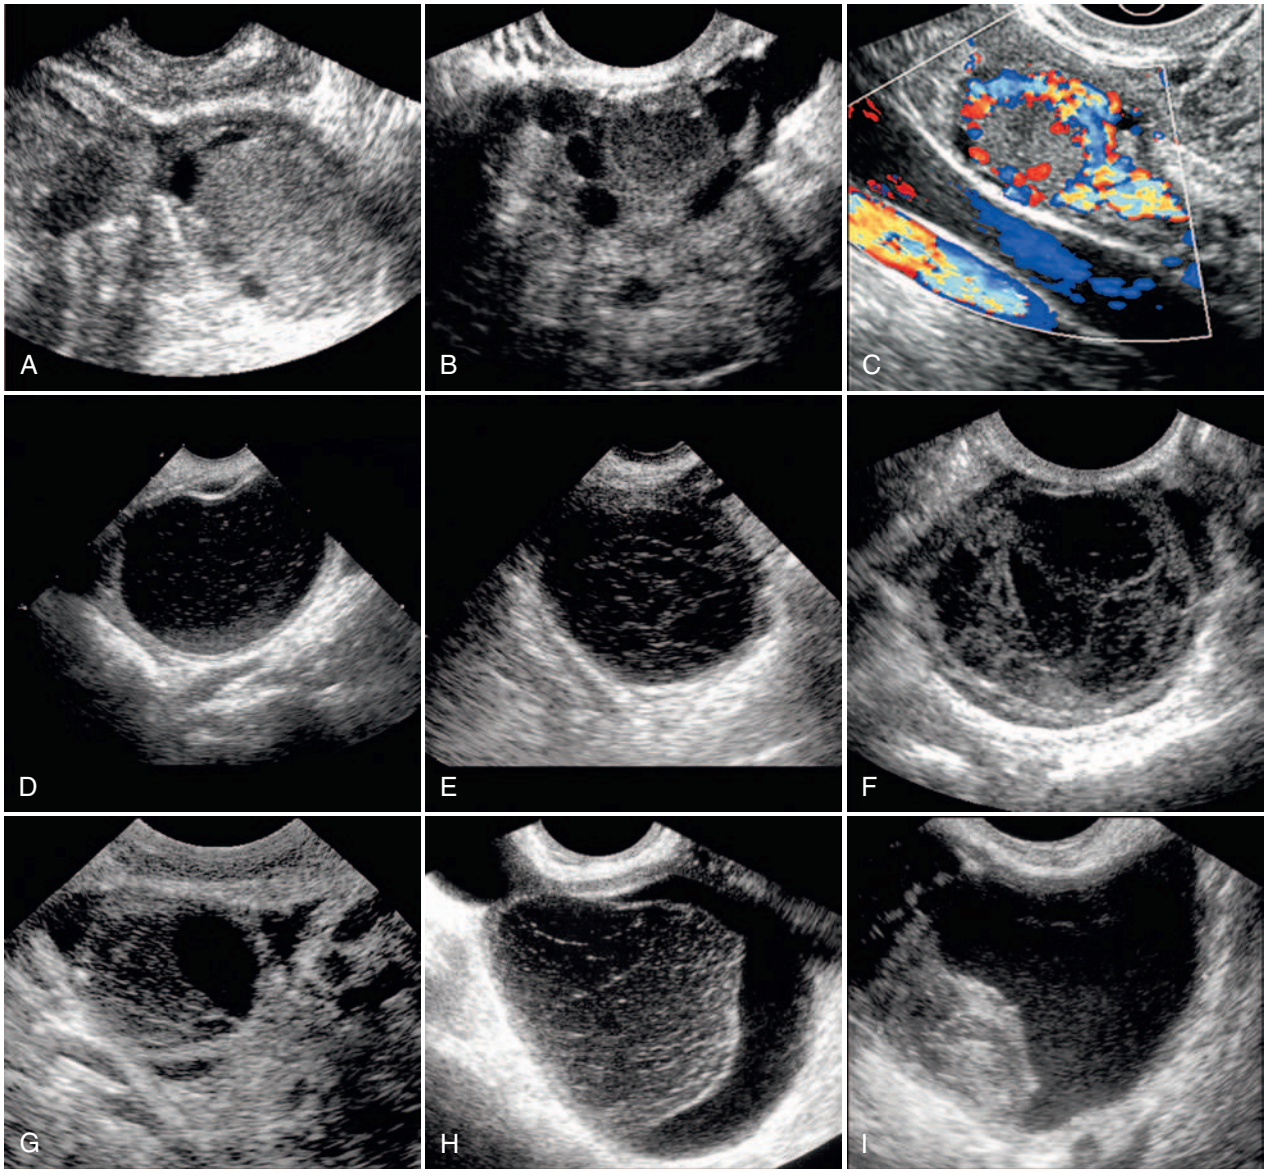

FIG. 16.7 Hemorrhagic Cysts on TVS Scans: Spectrum of Appearances. (A) Acute hyperechoic hemorrhagic cyst. **(B)** Acute hemorrhagic cyst mimicking a solid lesion. **(C)** Color Doppler ultrasound shows peripheral ring of vascularity **(ring of fire),** typical of a corpus luteum, but no vascularity within the cyst. **(D)** Large cyst containing low-level internal echoes. **(E)** Reticular pattern of internal echoes and septations within cyst. **(F)** Reticular pattern. **(G)-(I)** Variations in clot retraction. Concave margins in G are a sign of retracting clot. The blood products in I suggest a solid mass. Lack of color Doppler ultrasound signal supports its benign nature. See also Video 16.2.

cul-de-sac helps confirm the diagnosis of a leaking or ruptured hemorrhagic cyst. Rupture or leakage of a hemorrhagic cyst with associated peritoneal irritation in the setting of a positive serum B-hCG level may mimic a ruptured ectopic pregnancy, both clinically and sonographically.

Functional cysts are the most common cause of ovarian enlargement in young women. Because these cysts typically resolve within one to two menstrual cycles, follow-up is usually not required for small, simple cysts or typical hemorrhagic cysts less than 5 cm in asymptomatic patients. However, follow-up of larger cysts and those in symptomatic patients can be performed following a normal menstrual cycle, usually in 6 weeks. Because ultrasound may be unable to identify small mural nodules within larger cysts, surgical intervention or further characterization using MRI is generally recommended for cysts greater than 7 cm.[28]

Ovarian Remnant Syndrome

Infrequently, a cystic mass may be encountered in a patient who has undergone bilateral oophorectomy due to a small amount of residual ovarian tissue has been unintentionally left behind. The surgery has usually been technically difficult because of adhesions from endometriosis, PID, or tumor.[41] The residual ovarian tissue can develop functional cysts and produce pelvic pain and/or extrinsic compression of the distal ureter. Sonographically, the cysts vary in size and can be both simple and hemorrhagic.[42,43] A thin rim of ovarian tissue is usually present in the wall of the cyst.[43]

Pregnancy-Associated Ovarian Lesions

Ovarian lesions associated with pregnancy include hyperstimulated ovaries, ovarian hyperstimulation syndrome, theca lutein cysts, hyperreactio luteinalis, and the rare luteoma of pregnancy.[36] Most are related to the normal or abnormal response to serum hCG levels. **Hyperstimulated ovaries** are a normal response to elevated circulating levels of hCG. Ovarian hyperstimulation is most common in women undergoing ovulation induction. Sonographically, the ovaries are enlarged with multiple cysts, some of which may be hemorrhagic. The enlarged ovaries may undergo torsion.[44] They usually regress spontaneously during the pregnancy.

The term **ovarian hyperstimulation syndrome** (OHS) is used when the hyperstimulation is accompanied by fluid shifts[45] (Fig. 16.8). Clinically, three degrees of OHS are described: mild, moderate, and severe. The **mild** form is associated with lower abdominal discomfort, but no significant weight gain. The ovaries are enlarged, but less than 5 cm in average diameter. **Moderate** OHS presents with weight gain of 5 to 10 pounds and ovarian enlargement 5 to 12 cm. The patient may have nausea and vomiting. With **severe** OHS, there is weight gain of more than 10 pounds and the patient typically has severe abdominal pain and distention. The ovaries are greatly enlarged (>12 cm in diameter) and contain numerous large, thin-walled cysts, which may replace most of the ovary. The associated ascites and pleural effusions may lead to depletion of intravascular fluids and electrolytes, resulting in hemoconcentration with hypotension, oliguria, and electrolyte imbalance.[46] Severe OHS is usually treated conservatively to correct the depleted intravascular volume and electrolyte imbalance and usually resolves within 2 to 3 weeks.

Theca lutein cysts are the largest of the functional ovarian cysts and are associated with high hCG levels. These cysts typically occur in patients with gestational trophoblastic disease. However, theca lutein cysts are typically not seen in first-trimester diagnosis of gestational trophoblastic disease, because the hCG level will not have been sufficiently high for a long enough time for them to develop.[47] Theca lutein cysts can also be seen in OHS as a complication of drug therapy for infertility. Sonographically, theca lutein cysts are usually bilateral, multilocular, and very large. They may undergo hemorrhage, rupture, and torsion.

Hyperreactio luteinalis is caused by an abnormal response to circulating hCG in the absence of ovulation induction therapy. Approximately 60% of hyperreactio luteinalis cases occur in singleton pregnancies with normal circulating levels of hCG. Hyperreactio luteinalis usually occurs in the third trimester or less often in the puerperium. The majority of patients are asymptomatic, although maternal virilization may be seen in up to 25% of patients. The incidence of hyperreactio luteinalis increases in women with polycystic ovarian disease.[48] In contrast to OHS, body fluid shifts are rare. Sonographically, there are bilaterally enlarged ovaries with multiple cysts similar to OHS, although the ovaries tend not to be as large and the condition occurs later in pregnancy. Hyperreactio luteinalis is a self-limited condition that resolves spontaneously.

Luteoma of pregnancy is the only solid mass in this group of pregnancy-related processes. It is a rare benign process unique to pregnancy that is due to stromal cells that may become hormonally active, producing androgens and replacing the normal ovarian parenchyma. Most patients are asymptomatic, although maternal virilization may occur in up to 30%. These patients have a 50% risk of virilization of the female fetus.[49] Sonographically, luteomas usually present as nonspecific, heterogeneous, predominantly hypoechoic masses that may be highly vascular. An ovarian mass in a pregnant patient with signs of virilization should suggest this diagnosis, because luteoma is the most common cause of maternal virilization during pregnancy. Surgery is not indicated since the condition resolves spontaneously, typically after delivery.

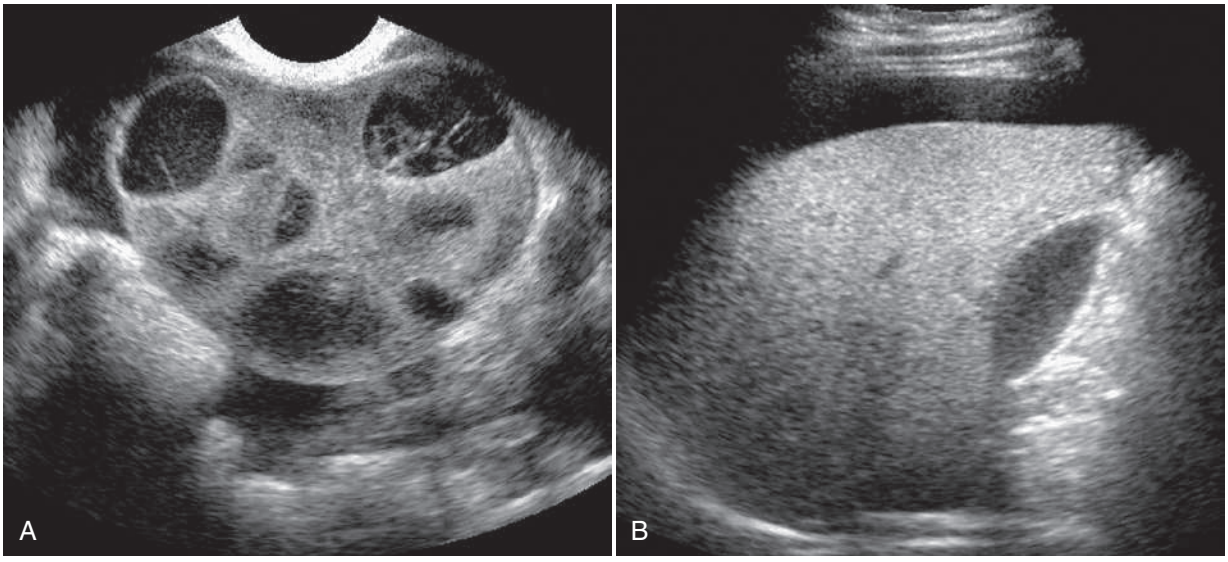

FIG. 16.8 Ovarian Hyperstimulation Syndrome. (A) TVS shows a greatly enlarged ovary with multiple cysts, some hemorrhagic. **(B)** Sagittal sonogram in right upper quadrant shows large volume of free intraperitoneal fluid.

Surface Epithelial Inclusion Cysts

Surface epithelial inclusion cysts are nonfunctional cysts usually seen in postmenopausal women, although they may be seen at any age, and are usually located peripherally in the cortex. They arise from cortical invaginations of the ovarian surface epithelium.[50] When very small, the cysts themselves may not be seen, but rather they may appear as punctate echogenicities in the surface of the ovary. Although usually tiny, unilocular, and thin walled, these cysts can measure up to several centimeters in diameter. Occasionally, surface epithelial inclusion cysts may be hemorrhagic, particularly if torsion has occurred.

Paraovarian and Paratubal Cysts

Paraovarian and **paratubal cysts** are wolffian or müllerian duct remnants in the mesosalpinx, often located superior to the uterine fundus. They are generally epithelium-lined simple cysts, rarely multiloculated or containing small wall nodularities. Echoes may also be occasionally seen with the cyst sonographically because of hemorrhage. They show no cyclic changes. There is an estimated incidence of 3%, accounting for about 10% to 20% of all adnexal masses. Typically, these cysts are small but may range in size up to 8 cm. They may occur at any age but are most commonly visualized in the third and fourth decades. Most are asymptomatic although patients with large cysts may have pelvic pain or the cysts may act as a fulcrum for torsion.[51-53] A specific diagnosis of a paraovarian cyst is possible only by demonstrating a normal ipsilateral ovary adjacent to, but separate from, the cyst.[54,55]

Benign neoplasms such as cystadenomas and cystadenofibromas of paraovarian origin are uncommon. Malignancy has been reported in 2% to 3% of parovarian cystic masses on histopathologic examination,[56,57] although it occurs even less often in masses smaller than 5 cm.[54,58]

Peritoneal Inclusion Cysts

Peritoneal inclusion cysts are seen in patients with peritoneal adhesions, occurring mostly in premenopausal women with a history of previous abdominal surgery, but they may also be seen in patients with a history of trauma, PID, or endometriosis. In patients with peritoneal adhesions, fluid produced by the ovary (which is the main producer of peritoneal fluid in women[13]) may accumulate within the adhesions and entrap the ovaries, resulting in an adnexal mass.[59-62] Peritoneal inclusion cysts are lined with mesothelial cells. Clinically, most patients present with pain and/or a pelvic mass.

On sonography, peritoneal inclusion cysts are multiloculated cystic adnexal masses, often with a bizarre shape frequently described as a spider web pattern[63] (Fig. 16.9). The diagnostic finding is the presence of an intact ovary positioned eccentrically amid septations and fluid.[60-62] The septations represent mesothelial and fibrous strands. The fluid is usually anechoic but may contain echoes in some compartments as a result of hemorrhage or proteinaceous fluid. Doppler evaluation may demonstrate vascularity within septations, at times mimicking a malignancy.

Peritoneal inclusion cysts must be differentiated from other extraovarian conditions such as parovarian cysts and a hydrosalpinx. Paraovarian cysts are separate from the ovary, whereas the ovary lies inside a peritoneal inclusion cyst. **Parovarian cysts** are usually round or ovoid and not associated with a history of pelvic surgery, trauma, or inflammation. A **hydrosalpinx** appears as a tubular or ovoid cystic structure often with visible folds, and the ovary is demonstrated as a separate entity. Accurate diagnosis of peritoneal inclusion cysts is important because the risk of recurrence after surgical resection is 30% to 50%.[64] Conservative therapy, such as ovarian suppression with oral contraceptives or fluid aspiration, is recommended.[62]

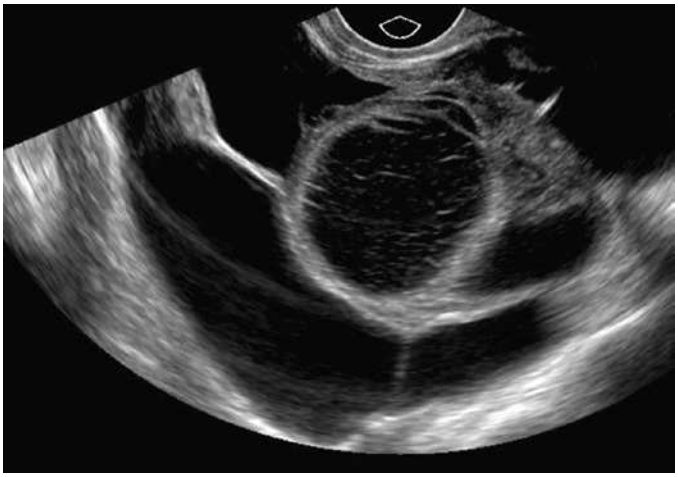

FIG. 16.9 Peritoneal Inclusion Cyst. TVS image shows a multilocular cyst with linear septations attached to the right ovary that projects within the structure and contains a hemorrhagic cyst. This represents adhesions attached to the right ovary.

Polycystic Ovarian Syndrome

Polycystic ovarian syndrome (PCOS) is now known to be a multifaceted endocrinologic disorder of ovarian dysfunction that includes abnormal estrogen and/or androgen production resulting in chronic anovulation and hyperandrogenism. Pathologically, the ovaries contain an increased number of follicles in various stages of maturation and atresia, and increased local concentration of androgens produces stromal abnormality. PCOS is a common cause of infertility and a higher-than-usual rate of early pregnancy loss.[65,66] Clinical manifestations of PCOS range from mild signs of hyperandrogenism in thin, normally menstruating women to the classic **Stein-Leventhal syndrome** (oligomenorrhea or amenorrhea, hirsutism, and obesity).

The typical sonographic findings of PCOS are bilaterally enlarged ovaries containing multiple small, 2- to 9-mm follicles and increased stromal echogenicity (Fig. 16.10). The ovaries have a rounded shape, with the follicles usually located peripherally ("string of pearls"), although they can also occur randomly throughout the ovarian parenchyma. Because of its superior resolution, TVS is more sensitive than TAS in detecting the small follicles. However, many women with PCOS will not have these typical sonographic findings. Ovarian volume may be normal in 30% of patients.[67,68] Using TVS, increased stromal echogenicity has also been reported as a sensitive and specific sign of polycystic ovaries.[69,70] In a small number of patients, the sonographic findings may be unilateral.[66,71]

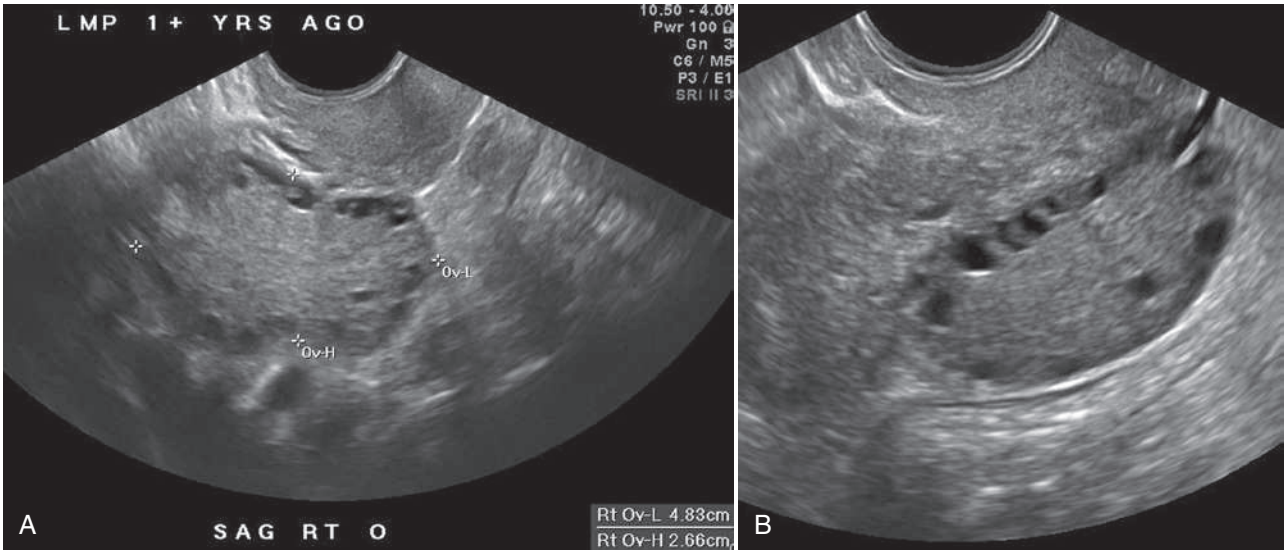

FIG. 16.10 Polycystic Ovaries: Typical Appearance on TVS in Woman With Hirsutism and Oligomenorrhea. (A) and **(B)** Enlarged ovaries *(cursors)* with mildly increased stromal echogenicity and multiple peripheral follicles, "string of pearls" sign.

A 2003 consensus meeting of the American Society for Reproductive Medicine and European Society of Human Reproduction and Embryology defined PCOS as requiring two of three criteria: (1) oligo-ovulation and/or anovulation, (2) hyperandrogenism (clinical and/or biochemical), and (3) polycystic ovaries.[72] An elevated serum luteinizing hormone (LH) level and insulin resistance have also been characteristic features. Historically, an elevated serum LH level and elevated LH/FSH ratio had been used as diagnostic tools. However, based on data that include the variability of LH depending on proximity to ovulation and its questionable importance in management, recommendations no longer support its necessity for clinical diagnosis.[73]

According to decisions made at the 2003 Rotterdam consensus workshop, the sonographic findings of polycystic ovaries should include either 12 or more follicles within the entire ovary measuring 2 to 9 mm in diameter[72] or increased ovarian volume greater than 10 mL. Although increased stromal echogenicity has been considered specific for polycystic ovaries, because of its subjective nature it was not included in the criteria. The consensus makers thought that measurement of ovarian volume worked as well as stromal evaluation in clinical practice. These criteria are not considered valid if the patient is taking oral contraceptives or has a dominant follicle greater than 10 mm. More recently, it has been reported that with the use of newer, higher resolution ultrasound technology and an offline reliable grid system to count follicles, a significantly higher follicle count threshold within the entire ovary is necessary to support the diagnosis of PCOS. Lujan et al.[74] advocated the use of a count of 26 and Christ et al.[75] a count of 28 follicles measuring 2 to 9 mm within the entire ovary as a better predictor of PCOS.

Because anovulation plays a key role in this disorder, the follicles will persist on serial studies. Long-term follow-up is recommended in patients with PCOS because the resulting high-unopposed estrogen levels can be associated with an increased risk of endometrial and breast carcinoma.

Endometriosis

Endometriosis is considered the most common benign gynecologic disorder. It is estimated that endometriosis affects between 5% and 45% of women in the reproductive age group, causes significant morbidity, and represents a major public health concern.[76,77] Clinical symptoms include pelvic pain, dysmenorrhea, dyspareunia, dyschezia, urinary symptoms, and infertility.[78]

The process is defined as the presence of functioning endometrial tissue outside the uterus. Endometriosis may present in different forms that include adnexal cysts (endometriomas), peritoneal plaques and adhesions, and deep infiltrating endometriosis consisting of implants or nodules that contain glands and stroma. Besides the ovary, the most commonly involved areas in the pelvis are the fallopian tube, broad ligament, and posterior cul-de-sac, but endometriosis can occur almost anywhere in the body, including the bladder and bowel.

The correct diagnosis and evaluation of the extent of disease are key in determining the best treatment approach. Ultrasound is well accepted as the initial imaging modality of choice, whereas MRI is considered the problem-solving tool.

The most common manifestation of endometriotic tissue is the **endometrioma,** which is readily diagnosed by its appearance sonographically with diffuse homogenous low level internal echoes. Endometriomas, often referred to as **chocolate cysts,** are frequently multiple, with a variety of appearances, from an anechoic cyst to a solid-appearing mass caused by the degradation of blood products over time.[79] The characteristic sonographic appearance is that of a well-defined, unilocular or multilocular, predominantly cystic mass containing diffuse, homogeneous, low-level internal echoes (Fig. 16.11, Video 16.3).[80] Color Doppler typically shows little if any vascularity within cyst walls (as opposed to the corpus luteum, which typically has pronounced flow). The low-level internal echoes may be seen diffusely throughout the mass or in the dependent portion. Occasionally, a fluid-fluid level may be seen, particularly if the woman has been lying in a similar position for sufficient time for the blood

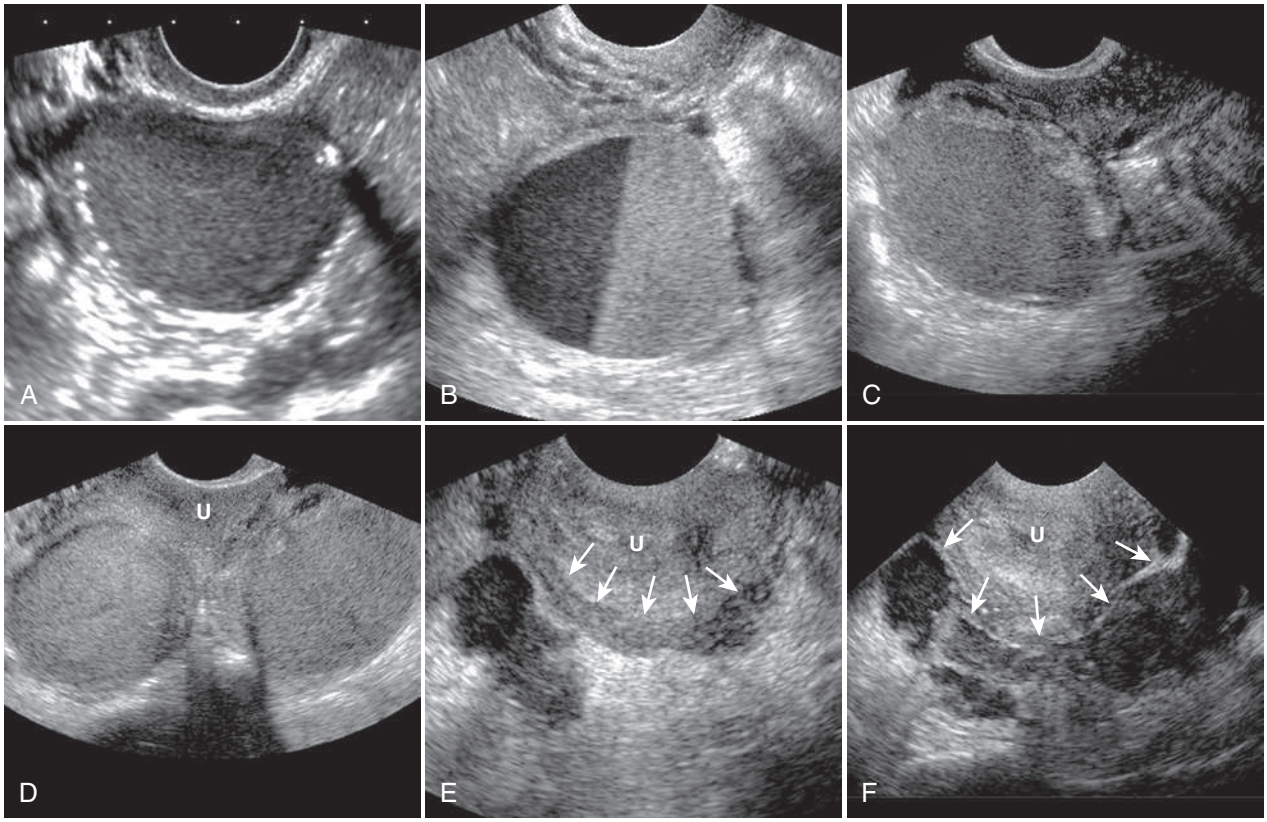

FIG. 16.11 Endometriosis: Spectrum of Appearances. products to settle into layers. In a retrospective study, Patel et al.[81] found diffuse, low-level internal echoes in 95% of endometriomas. They concluded that this finding in the absence of neoplastic features is highly likely to be an endometrioma, especially if multilocularity or hyperechoic wall foci are present, whereas an endometrioma is highly unlikely when no component of the mass contains low-level echoes. A prospective study by Dogan et al.[82] found a positive predictive value of 97% for typically appearing endometriomas with low-level internal echoes, regular margins, round shape, and thick walls.

Differentiation of endometriosis from benign and malignant neoplasms is occasionally required. Papillary wall projections have been frequently described. Patel et al. demonstrated small, linear, hyperechoic foci sometimes present in the wall of the cyst that were thought to represent cholesterol deposits accumulating in the cyst wall.[81] Guerriero et al.[83] described papillations projecting within the cyst with a height of greater than 3 mm and no internal Doppler flow that were felt to represent adjacent fibrin or blood products (Video 16.4). In rare cases in pregnant women, decidualization of the wall of an endometrioma may occur, resulting in a solid vascular mural mass that cannot be differentiated from malignancy[84,85] (Fig. 16.12). Calcification is occasionally present in an endometrioma and can be confused with a dermoid.[86] Endometriomas may serve as precursors of borderline endometrioid and clear cell tumors that may eventually become low-grade invasive carcinoma and therefore, if not surgically removed, these are followed yearly.[50,87]

Endometriomas may be present in postmenopausal women, although their appearance generally differs. Instead of the unilocular cyst containing low-level echoes, the postmenopausal endometrioma more often has the appearance of a multilocular mass. When cyst fluid is present, it is more frequently anechoic or comprised of a more heterogeneous echogenicity.[88]

The appearance of an endometrioma may be similar to a **hemorrhagic ovarian cyst** because both are cystic masses that contain blood products of variable age. However, a hemorrhagic cyst more frequently demonstrates a reticular internal pattern rather than the pattern of homogeneous low-level echoes and is more frequently associated with free fluid in the cul-de-sac. A hemorrhagic cyst will resolve or show a significant decrease in size over the next few menstrual cycles, whereas endometriomas tend to show little change in size and internal echo pattern. Clinically, most women with a symptomatic hemorrhagic cyst present with acute pelvic pain, whereas women with an endometrioma have more chronic discomfort associated with their menses.

Endometriosis is frequently accompanied by the presence of pelvic adhesions. The evaluation of adhesions of the uterus and ovaries as well as obliteration of the pouch of Douglas can be challenging with ultrasound although techniques have been reported that can be performed successfully by experienced operators.[89,90] Movement of the normally mobile uterus and ovaries by abdominal palpation or pressure with the abdominal probe can show adherence of these structures to the adjacent

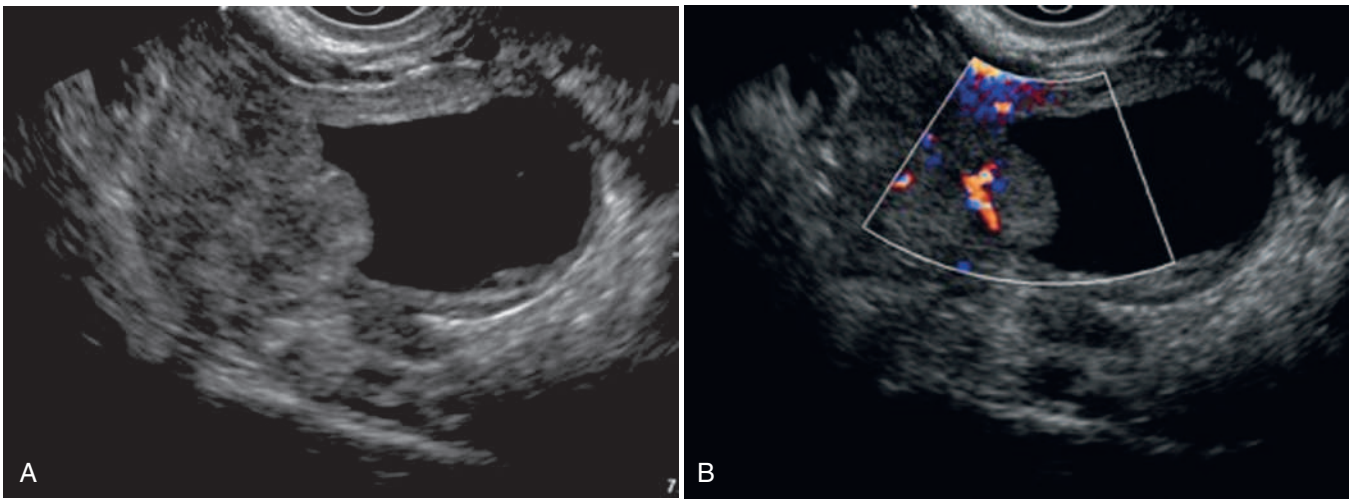

FIG. 16.12 Decidualization of Endometrioma in Pregnancy. (A) and **(B)** Sagittal gray-scale and color Doppler TVS images of a cyst containing low-level echoes and a peripheral echogenic nodule. The nodule demonstrates color Doppler flow, a finding seen in a borderline neoplasm or a decidualized endometrioma in a pregnant patient.

broad ligament, pouch of Douglas, bladder, rectum, or peritoneum. The use of the sliding sign on TVS has been described to diagnose the obliteration of the pouch of Douglas.[91,92] This procedure entails the placement of gentle pressure against the cervix with the TVS probe to determine if the posterior cervix slides easily along the anterior rectal and vaginal wall. Additionally, if fluid is present within the pelvis, fine linear structures representing adhesions may be seen joining the ovary with attached endometrioma, uterus and cul-de-sac peritoneum.

Deep infiltrating endometriosis is the most severe form of the disease although the extent of disease based laparoscopic staging may not correlate with the severity of symptoms.[78] Variable accuracy of TVS in the identification of deep infiltrating endometriosis has been reported. Most implants are found in dependent areas of the pelvis that is divided into the anterior and posterior compartment according to the deep infiltrating endometriosis classification by Chapron et al.[93] The **anterior compartment** is composed of the urinary bladder, and the **posterior compartment** includes the cul-de-sac, the uterosacral ligament, bowel wall, rectum and recto-sigmoid junction, vagina, and rectovaginal septum. Sonographically, implants appear as hypoechoic nodules or as diffuse or nodular retroperitoneal thickening. Within the bowel wall, the lesion often takes on the appearance of a fusiform swelling (Fig. 16.11E and F, Video 16.5). Few, if any, vessels are apparent using color Doppler evaluation.[94-97]

Adnexal Torsion

Adnexal torsion is a relatively infrequent gynecologic emergency requiring prompt surgical intervention with a reported incidence of 3% in some series. The process primarily affects women of reproductive age or younger and is uncommon in the postmenopausal age group.[98,99] Initially, there is twisting of the ovary, the fallopian tube, or both structures, causing venous and lymphatic compromise with resulting ovarian edema and adnexal enlargement. However, until venous and arterial thrombosis has occurred, reperfusion may permit complete recovery. Complete and unalleviated torsion can progress rapidly from interference with venous and lymphatic drainage to arterial occlusion and eventually necrosis. Torsion may be partial or complete, and acute or chronic. Not infrequently, torsion may be intermittent with periods of spontaneous remission of symptoms. The diagnosis of torsion is complicated by its vague clinical presentation. The most consistent presenting symptom is abdominal and pelvic pain, with other nonspecific signs and symptoms such as fever and nausea and vomiting more variably present. Early diagnosis and intervention prior to infarction permit ovarian preservation and prevent peritonitis.

Because the only consistent symptom cited in most studies is abdominal pain, usually intense and progressive, and localized to a lower quadrant, differential considerations include other gynecologic causes such as PID, ovarian cysts, and ectopic pregnancy as well as nongynecologic causes. Although often difficult to palpate, a demonstrable mass may be present. A right-sided predominance also exists that is attributed to the protective presence of the sigmoid colon on the left and the hypermobility of the right-sided cecum. As a result, the presentation of ovarian torsion may mimic that of appendicitis.[100,101]

Most cases of ovarian torsion (50%-80%) are associated with adnexal pathologic conditions such as ovarian tumors or cysts. This usually involves an ipsilateral ovarian mass 5 to 10 cm in diameter that acts as a fulcrum to potentiate torsion due to increased ovarian volume or weight within adnexal structures. Although associated with a neoplasm in as many as 50% of cases, previous studies have indicated that the lesions are usually benign since the inflammatory and invasive changes caused by malignant lesions may be protective against ovarian mobility.[102] It is associated with 1 in 1800 pregnancies, most commonly in the first trimester or immediately postpartum.[103] Women undergoing ovulation induction are at high risk secondary to the development of large theca lutein cysts.[100]

The initial role of sonography in the evaluation of patients at risk for ovarian torsion is to not only diagnose torsion but also exclude other causes of acute abdominal pain such as appendicitis,

PID, ruptured ovarian cyst, and ectopic pregnancy. The most consistent finding of ovarian torsion is an enlarged edematous ovary (Fig. 16.13) or ovarian complex of ovary and adnexal mass. The location of the ovary is frequently medial and superior to its usual location (Fig. 16.14A).[104] If the fallopian tube is involved, a hydrosalpinx will usually be demonstrated.

Peripherally placed follicles and homogeneous echoes seen centrally consistent with areas of edema within enlarged ovaries have also been reported,[105,106] although these descriptors are nonspecific (Video 16.6). Entities such as endometriomas, polycystic ovaries, hemorrhagic cysts, tubo-ovarian complexes, and hyperstimulated ovaries undergoing ovulation induction are often similarly described. The irregular internal texture of the ovary seems to correlate with intraovarian hemorrhage. Free fluid within the cul-de-sac is another nonspecific finding frequently associated with cases of ovarian torsion. The fluid may be a transudate from the ovarian capsule secondary to obstruction of veins and lymphatic vessels.[107]

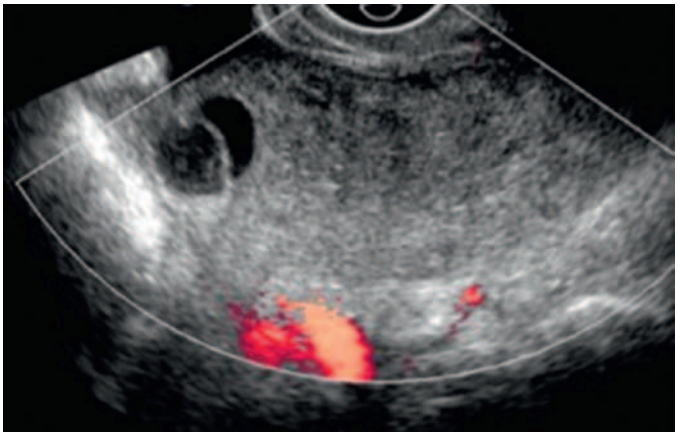

FIG. 16.13 Ovarian Torsion: Doppler Evaluation of Enlarged Ovaries. TVS color Doppler image of a young woman presenting with acute pelvic pain shows no evidence of color Doppler flow within an enlarged ovary containing irregular parenchyma; flow is demonstrated distally within the iliac artery. See also Video 16.6.

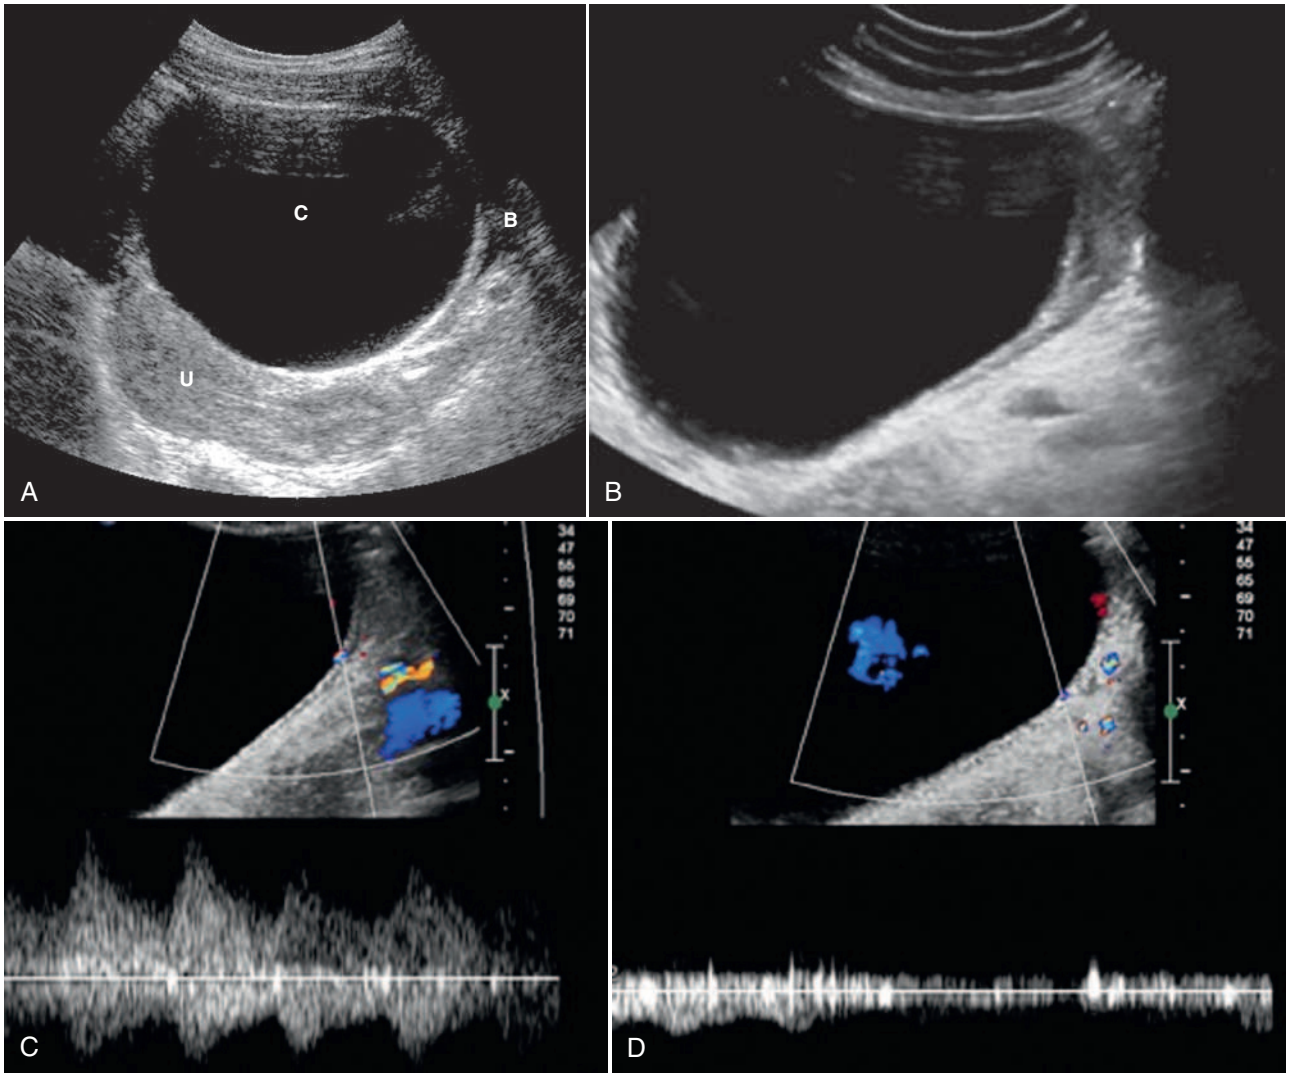

FIG. 16.14 Ovarian Torsion With Cyst as Fulcrum. (A) TAS sagittal image of a young woman with acute pain shows a large, simple cyst *(C)* that lies anterior to the uterus *(U)* and cephalad to the bladder *(B)*. This unusual position should raise the suspicion of torsion. **(B)-(D)** Another young female patient who is postpartum presenting with acute pelvic pain. **(B)** TAS shows a large simple ovarian cyst superior to the uterus. **(C)** and **(D)** TAS spectral Doppler images show normal arterial and venous waveforms within the wall of the cyst.

Doppler findings vary depending on degree of torsion and its chronicity. Lack of arterial and venous Doppler flow should enable confident diagnosis although false positive diagnoses may be obtained as a result of the depth of penetration being greater than the capabilities of the ultrasound beam, improper Doppler or gray-scale priority settings, and too high filter pulse repetition frequency (PRF) settings.[108] Thus it is helpful to scan the asymptomatic ovary first to ensure that Doppler settings are appropriate. Conversely, both arterial and venous ovarian spectral Doppler signal has been frequently reported in cases of surgically proven torsion. Absent venous Doppler flow has a positive predictive value as high as 94% for ovarian torsion despite persistence of arterial signal.[107] Explanations proposed include venous occlusion leading to symptoms before arterial occlusion occurs and that persistent adnexal arterial flow is related to the dual-ovarian arterial blood supply (ovarian artery and ovarian branches of uterine artery).[109] Occasionally, a twisted vascular pedicle (consisting of broad ligament, fallopian tube, and adnexal and ovarian branches of uterine artery and vein) may be demonstrated as a round hyperechoic structure with multiple concentric hypoechoic stripes (target appearance) or as an ellipsoid or tubular structure with internal heterogeneous echoes.[110] Using color or power Doppler ultrasound, the presence of circular or coiled twisted vessels within the vascular pedicle (whirlpool sign) is helpful in diagnosing torsion.[110] Absence of blood flow within the vascular pedicle suggests a nonviable ovary.[110,111] Comparison with the morphologic appearance and flow patterns of the contralateral ovary can also be helpful since decreased or abnormal flow may be present in the torsed ovary.[107,112]

Massive edema of the ovary is a rare condition resulting from partial or intermittent torsion of the ovary, causing venous and lymphatic obstruction but not arterial occlusion, leading to marked stromal edema. The few cases described in the literature show a large, edematous multicystic adnexal mass.[113-115]

The use of duplex and color Doppler imaging is most useful in making the diagnosis in the absence of Doppler flow although the presence of Doppler signal cannot eliminate the diagnosis. In the appropriate clinical setting, an enlarged ovary or ovary and adnexal mass complex should suggest torsion even in the presence of ovarian Doppler flow[112,116] Torsion is extremely unlikely if the ovary is morphologically normal and of normal size regardless of Doppler findings.

NEOPLASMS

Ovarian Cancer

Ovarian cancer is the fifth leading cause of cancer death among US women and causes more deaths than any other cancer of the female reproductive system. The American Cancer Society estimated 21,980 new cases of ovarian cancer in the United States in 2014, with about 14,270 deaths.[117] Between 1987 and 2010, the incidence decreased at a rate of 0.9% a year.[117,118] Ovarian cancer represents approximately 25% of all gynecologic malignancies, with peak incidence in the sixth decade of life. Ovarian cancer has the highest mortality rate of all gynecologic malignancies, mostly a result of late diagnosis. Because there are few clinical symptoms, 60% to 70% of women have advanced disease (stages III or IV) at diagnosis. The overall 5-year survival rate is 20% to 30%, but with early detection in stage I, the rate rises to 80% to 90%. Therefore efforts have been directed at developing methods of early diagnosis of ovarian cancer.

Increasing age, nulliparity, a family history of ovarian cancer, and a patient history of breast, endometrial, or colon cancer are associated with increased risk of ovarian cancer. The lifetime risk of a woman developing ovarian cancer is 1 in 70 (1.4%). However, if a woman has a first-degree relative (mother, daughter, sister) or second-degree relative (aunt or grandmother) who has had ovarian cancer, the risk is 5%. With two or more relatives who have had ovarian cancer, the lifetime risk increases to 7%.[119] About 3% to 5% of women with a family history of ovarian cancer have a hereditary ovarian cancer syndrome. The three main hereditary syndromes associated with ovarian cancer are the **breast-ovarian cancer syndrome,** the most common, caused by mutations in the suppressor genes BRCA1 and BRCA2, with a high frequency of both cancers; the **hereditary nonpolyposis colorectal cancer syndrome (Lynch II),** in which ovarian cancer occurs in association with nonpolyposis colorectal cancer or endometrial cancer, or both; and **site-specific ovarian cancer syndrome,** the least common, without an excess of breast or colorectal cancer.[120] Hereditary ovarian cancer syndromes are thought to have an autosomal dominant inheritance, and the lifetime risk of ovarian cancer in these patients is 40% to 50%. They have an earlier age of onset (10-15 years earlier) than do other ovarian cancers.[120] Therefore oophorectomy is commonly advocated after child-bearing in these women.

A number of clinical screening trials of asymptomatic women have been reported using TVS (either alone or in combination with Doppler sonography) and/or biologic markers such as cancer antigen (CA) 125.[121-126] **CA 125** is a high-molecular-weight glycoprotein recognized by the OC 125 monoclonal antibody. It has proved extremely useful in following the clinical course of patients undergoing chemotherapy and in detecting recurrent subclinical disease.[127,128] Although serum CA 125 is elevated in approximately 80% of women with epithelial ovarian cancer, it detects less than 50% of stage I disease and is insensitive to mucinous and germ cell tumors.[128] Other malignancies, as well as many benign conditions, are associated with elevated serum CA 125. The use of serum CA 125 and/or sonography as a screening test for ovarian cancer is not currently recommended for routine clinical use.[129] Routine screening has resulted in unnecessary surgery with its attendant risks.[129] The largest screening trial to date is the United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS), a randomized study evaluating annual screening using either TVS or serum CA 125 with TVS as a second-line test (multimodal screening). Preliminary results are encouraging, with superior sensitivity and positive predictive value reported with the multimodal screening strategy compared to TVS alone for detecting primary invasive epithelial ovarian and fallopian tube cancers.[130]

Histologically, **epithelial neoplasms** represent 65% to 75% of ovarian tumors and 90% of ovarian malignancies[50] (Table 16.1). The remaining neoplasms consist of **germ cell tumors** (15%-20%), **sex cord–stromal tumors** (5%-10%), and **metastatic**

TABLE 16.1 Ovarian Neoplasms

Tumor	Incidence	Examples
Surface epithelial–stromal tumors	65%-75%	Serous cystadenoma/carcinoma Mucinous cystadenoma/carcinoma Endometrioid carcinoma Clear cell carcinoma Transitional cell tumor
Germ cell tumors	15%-20%	Teratoma Dysgerminoma Yolk sac tumor
Sex cord–stromal tumors	5%-10%	Granulosa cell tumor Sertoli-Leydig cell tumor Thecoma and fibroma
Metastatic tumors	5%-10%	Uterus Stomach, colon, breast Lymphoma

tumors (5%-10%). Sonographically, ovarian cancer usually presents as an adnexal mass. Well-defined anechoic cysts are more likely to be benign, whereas lesions with irregular walls, thick irregular septations, mural nodules, and solid elements with flow are more likely to be malignant.[131,132] Many scoring systems and mathematical models based on the morphologic characteristics have been proposed for distinguishing between benign and malignant masses. However, **subjective evaluation** of the ultrasound morphologic features **(pattern recognition)** by an experienced interpreting physician has been shown to be the superior method.[133,134] Using this method, a physician should be able to distinguish benign from malignant masses in approximately 90% of cases.[135]

Color and pulsed Doppler sonography have been advocated for distinguishing benign from malignant ovarian masses. Support is based on the premise that malignant masses, because of internal neovascularization, will have high diastolic flow. Malignant tumor growth depends on angiogenesis, with the development of abnormal tumor vessels.[136] These abnormal vessels lack smooth muscle within their walls, which, along with arteriovenous shunting, leads to decreased vascular resistance and thus higher diastolic flow velocity. Therefore the pulsatility index (PI) and resistive index (RI) should be lower in malignant lesions. Although many reports have found a tendency for both PI and RI to be lower in malignant lesions, there is too much overlap to differentiate reliably between benign and malignant lesions in individual patients.[137-142] Other parameters such as vessel location have been suggested to improve the specificity of Doppler ultrasound assessment of ovarian masses.[143] Malignant lesions tend to have more central flow, whereas benign lesions tend to have more peripheral flow. However, Stein et al.[138] found considerable overlap, with 21% of malignant lesions having only peripheral flow and 31% of benign lesions having central flow. Guerriero et al.[144] found a higher accuracy in predicting malignancy when color Doppler ultrasound demonstrated arterial flow within the solid portions of the mass.

Studies comparing the morphologic features on sonography with the Doppler findings found that Doppler ultrasound showed no more diagnostic information than morphologic assessment alone.[133,139,140,145] Valentin[133] concluded that, in experienced hands, morphologic assessment is the best method for discriminating between benign and malignant masses. The main advantage of adding Doppler ultrasound would be to increase the confidence with which a correct diagnosis is made. Others have found that Doppler ultrasound, when added to sonographic morphologic assessment, improves specificity and positive predictive value.[142,146-148] Brown et al.[149] found that a nonhyperechoic solid component was the most statistically significant predictor of malignancy. Schelling et al.[150] also found that a solid component in an adnexal mass with central vascularity achieved high accuracy, sensitivity, and specificity in predicting malignancy. A meta-analysis of 46 published studies concluded that ultrasound techniques that combine morphologic assessment with color Doppler flow imaging is significantly better in characterizing ovarian masses than morphologic assessment, color Doppler flow imaging, or Doppler indices alone.[151] Doppler ultrasound is probably not needed if the mass has a characteristic benign morphology, because morphologic assessment is highly accurate in this group of lesions.[138,141] Doppler ultrasound is likely valuable in assessing the mass that is morphologically indeterminate or suggestive of malignancy. Doppler findings should be combined with morphologic assessment, clinical findings, patient age, and phase of menstrual cycle for optimal evaluation of an adnexal mass.[152]

Recently, contrast-enhanced TVS (CE-TVS) has been used to evaluate ovarian tumor neovascularity. With dynamic CE-TVS, malignant tumor neovascularity usually demonstrates more prolonged contrast washout compared with benign tumors. The difference in contrast enhancement patterns between benign and malignant ovarian masses results in potential improvement in differentiating benign from malignant lesions with CE-TVS compared with conventional TVS.[153]

Surface Epithelial–Stromal Tumors

In the past, epithelial-stromal tumors were generally considered to arise from the surface epithelium that covers the ovary and the underlying ovarian stroma. It has since been proposed that epithelial ovarian cancer is a collection of diseases arising from varying cells of origin. Evidence suggests that the majority of primary ovarian cancers (in particular, high-grade serous cancers) are derived from the fallopian tube rather than the ovary. A dualistic model that categorizes ovarian cancer into two groups (type I and type II) has been described. Type I tumors usually present at a low stage and include low-grade serous, low-grade endometrioid, clear cell, and mucinous carcinomas. Type II tumors include high-grade serous carcinomas, high-grade endometrioid carcinomas, carcinosarcomas, and undifferentiated carcinomas. Type I tumors tend to be clinically indolent, whereas type II tumors are typically highly aggressive.[154,155]

Epithelial-stromal tumors can be divided into five broad categories based on epithelial differentiation: **serous, mucinous, endometrioid, clear cell,** and **transitional cell (Brenner).**[50] This group of tumors accounts for 65% to 75% of all ovarian neoplasms and 80% to 90% of all ovarian malignancies. The mode of spread

of the malignant tumors is primarily intraperitoneal, although direct extension to contiguous structures can occur. Lymphatic spread is predominantly to the paraortic nodes. Hematogenous spread usually occurs late in the course of the disease.

Serous Cystadenoma and Cystadenocarcinoma

Serous tumors are the most common surface epithelial–stromal tumors, representing 30% of all ovarian neoplasms. Approximately 50% to 70% of serous tumors are benign. Serous **cystadenomas** account for about 25% of all benign ovarian neoplasms, and serous **cystadenocarcinomas** account for about 50% of all malignant ovarian neoplasms.[50] The peak incidence of serous cystadenomas is in the fourth and fifth decades, whereas serous cystadenocarcinomas most frequently occur in perimenopausal and postmenopausal women. Approximately 20% of benign serous tumors and 50% of malignant serous tumors are bilateral. Their sizes vary greatly, but in general they are smaller than mucinous tumors.

Sonographically, **serous cystadenomas** are usually large, thin-walled cysts. They are typically unilocular, but may contain thin septations (Fig. 16.15A and B). Papillary projections are occasionally seen. **Serous cystadenocarcinomas** may be quite large and usually present as multilocular cystic masses containing multiple papillary projections arising from the cyst walls and septa (Fig. 16.15G-I) The septa and walls may be thick. Echogenic solid material may be seen within the loculations. Papillary

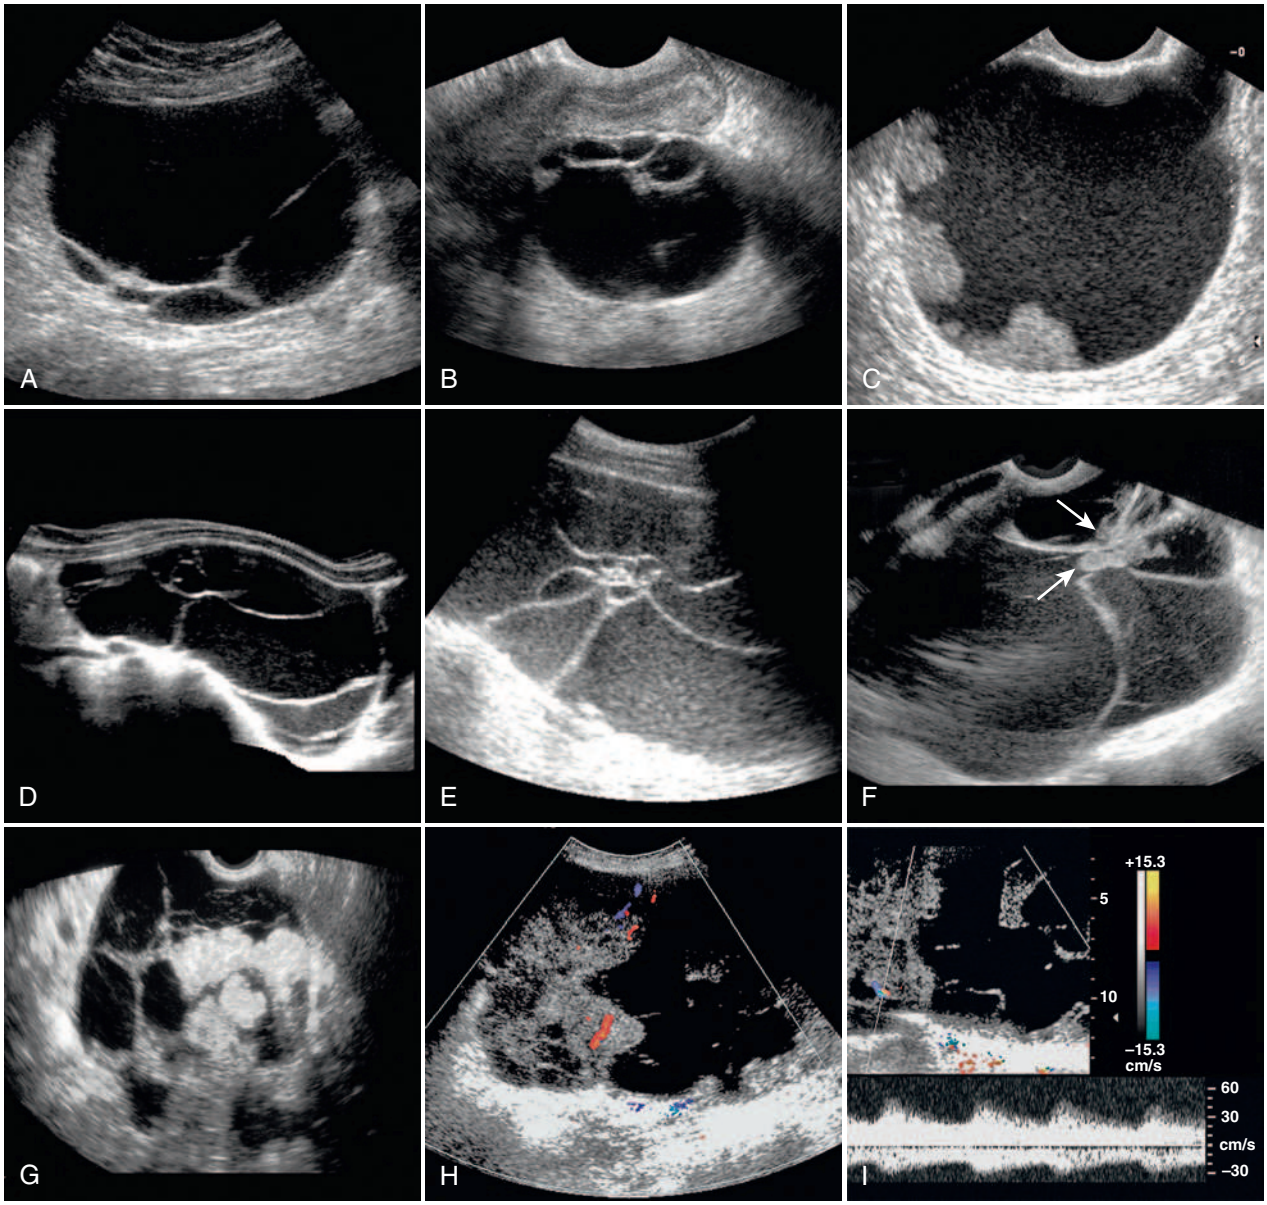

FIG. 16.15 Epithelial Ovarian Neoplasms: Spectrum of Appearances. (A) and **(B) Serous cystadenomas. (A)** Septations within a cystic mass are fairly thin. **(B)** Septations are thicker. **(C) Serous cystadenoma of low malignant potential.** Low-level echogenic particles and mural nodules. **(D)** and **(E) Mucinous cystadenomas. (F) Mucinous cystadenocarcinoma.** Large size and septations are characteristic; septal nodularity is marked *(arrows)*. **(G)-(I)** Patient with **serous cystadenocarcinoma.** Extensive nodularity shows vascularity, confirming the morphologic suspicion of a malignant mass. There is high diastolic flow resulting in a low resistive index.

FIG. 16.16 Mucinous Cystadenoma. Gross pathologic specimen shows multiple cystic loculations.

projections may form on the surface of the cyst and surrounding organs, resulting in fixation of the mass. Ascites is frequently seen.

Mucinous Cystadenoma and Cystadenocarcinoma

Mucinous tumors are the second most common ovarian epithelial tumor, accounting for 20% to 25% of ovarian neoplasms. Mucinous **cystadenomas** constitute 20% to 25% of all benign ovarian neoplasms, and mucinous **cystadenocarcinomas** make up 5% to 10% of all primary malignant ovarian neoplasms.[50] Mucinous cystadenomas occur most often in the third to sixth decades but may be seen in very young women, whereas mucinous cystadenocarcinomas most frequently occur in the fourth to seventh decades. Mucinous tumors are less frequently bilateral than their serous counterparts, with only 5% of the benign and 15% to 20% of the malignant lesions occurring on both sides. A high percentage, 80% to 85%, of mucinous tumors are benign.[156]

M**ucinous cystadenomas** can be huge cystic masses, measuring up 30 cm and filling the entire pelvis and abdomen (Figs. 16.15D and E and 16.16). Multiple thin septa are present, and low-level echoes caused by the mucoid material may be seen in the loculations. Papillary projections are less frequently seen than in the serous counterpart. **Mucinous cystadenocarcinomas** are usually large, multiloculated cystic masses containing papillary projections and echogenic material; they generally have a sonographic appearance similar to that of serous cystadenocarcinomas (Fig. 16.15F).

Penetration of the tumor capsule or rupture may lead to intraperitoneal spread of mucin-secreting cells that fill the peritoneal cavity with a gelatinous material. This condition, known as **pseudomyxoma peritonei,** may be similar sonographically to ascites or may contain multiple septations or floating debris in the fluid that fills much of the pelvis and abdomen. This condition may occur in mucinous cystadenomas and in mucinous cystadenocarcinomas. A ruptured mucocele of the appendix and mucinous tumors of the appendix and colon can also lead to pseudomyxoma peritonei.

Borderline (Low Malignant Potential) Tumors

There is an intermediate group of epithelial tumors that are histologically categorized as "borderline" or of "low malignant potential." They occur in about 10% to 15% of serous and mucinous tumors. These tumors have cytologic features of malignancy but do not invade the stroma and, although malignant, have a much better prognosis. They present at an earlier age than cystadenocarcinomas and have 5-year and 20-year survival of 95% and 80%, respectively. They may be treated by ovary-sparing surgery to preserve fertility.

Sonographic features suggestive of low malignant potential tumors are a small- to medium-sized cyst containing low-level echoes (similar to an endometrioma) with vascular mural nodules (Figs. 16.15C) or a cystic mass with a well-defined multilocular (honeycomb) nodule.[157,158] Normal ovarian tissue may be seen adjacent to the lesion and may be helpful in excluding invasive ovarian cancer.[157,159] This has been referred to as the **ovarian crescent sign.**[159] Although the presence of this sign decreases the likelihood of invasive adnexal malignancy, it was found to be a poor discriminator between benign and malignant adnexal masses in a prospective study by Van Holsbeke et al.[160]

Endometrioid Tumor

Almost all endometrioid tumors are malignant. They are the second most common epithelial malignancy, representing 20% to 25% of ovarian malignancies; 25% to 30% are bilateral, and they occur most frequently in the fifth and sixth decades. Their histologic characteristics are identical to those of endometrial adenocarcinoma, and approximately 30% of patients have associated endometrial adenocarcinoma, which is thought to represent an independent primary tumor. Approximately 15% to 20% of endometrioid cancer is associated with endometriosis, which may occur within the endometriosis, the ipsilateral or contralateral ovary.[50] The endometrioid tumor has a better prognosis than other epithelial malignancies, probably related to diagnosis at an earlier stage. Sonographically, it usually presents as a cystic mass containing papillary projections, although some endometrioid tumors are predominantly a solid mass that may contain areas of hemorrhage or necrosis.[156]

Clear Cell Tumor

This tumor is considered to be of müllerian duct origin and a variant of endometrioid carcinoma. Clear cell tumor is almost always malignant and constitutes 5% to 10% of primary ovarian carcinomas. It occurs most frequently in the fifth to seventh decades and is bilateral in about 20% of patients. Associated pelvic endometriosis is present in 50% to 70% of clear cell carcinomas, and approximately one-third arise within the lining of endometriomas.[50] Sonographically, it usually presents as a nonspecific, complex, predominantly cystic mass (Fig. 16.17, Video 16.7).[156]

Transitional Cell Tumor

Also known as **Brenner tumor,** transitional cell tumor is derived from the surface epithelium that undergoes metaplasia to form typical uroepithelial-like components.[156] It is uncommon, accounting for 2% to 3% of all ovarian neoplasms, and is almost always benign; 6% to 7% are bilateral. Most patients are asymptomatic, and the tumor is discovered incidentally on sonographic examination or at surgery. About 30% are associated with cystic neoplasms,

FIG. 16.17 Clear Cell Carcinoma in Endometrioma. TVS shows a complex cyst with homogenous low-level internal echoes centrally and solid nodules peripherally. See also Video 16.7

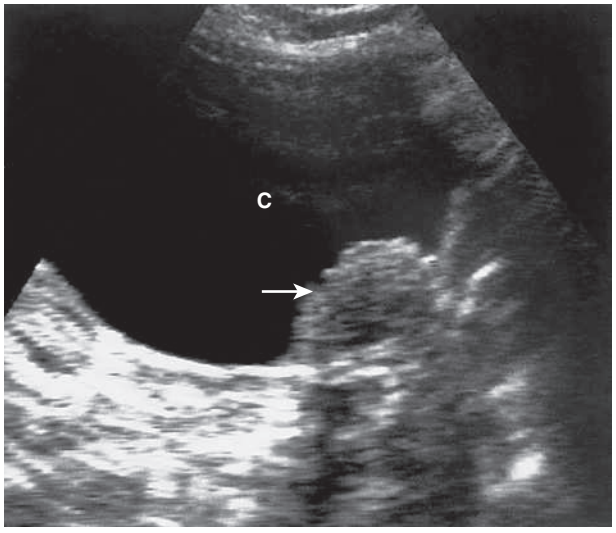

FIG. 16.18 Transitional Cell (Brenner) Tumor in Wall of Mucinous Cystadenoma. TAS shows a large, well-defined cystic mass *(C)* with a solid hypoechoic mural nodule *(arrow)*. Pathologic examination showed a Brenner tumor within the wall of a large, mucinous cystadenoma.

usually serous or mucinous cystadenomas or cystic teratomas, frequently in the ipsilateral ovary[161] (Fig. 16.18). Sonographically, Brenner tumors are hypoechoic solid masses. Calcification may occur in the outer wall. A cystic component is uncommon, but when present, usually results from a coexistent cystadenoma.[156,162] Pathologically, transitional cell masses are solid tumors composed of dense fibrous stroma. They appear similar to ovarian fibromas and thecomas and to uterine leiomyomas, both sonographically and pathologically.

Germ Cell Tumors

Germ cell tumors are derived from the primitive germ cells of the embryonic gonad. They account for 15% to 20% of ovarian neoplasms, with 95% being **benign cystic teratomas (dermoids).** The others, including **dysgerminomas** and **endodermal sinus** (yolk sac) **tumors,** occur mainly in children and young adults and are almost always malignant. Germ cell tumors are the most common ovarian malignancies in children and young adults. When a large, predominantly solid ovarian mass is present in a girl or young woman, the diagnosis of a malignant germ cell tumor should be strongly considered[163] (Video 16.8).

Cystic Teratoma

Cystic teratomas make up approximately 15% to 25% of ovarian neoplasms; 10% to 15% are bilateral. They are composed of well-differentiated derivatives of the **three germ layers:** ectoderm, mesoderm, and endoderm. Because **ectodermal elements** generally predominate, cystic teratomas are virtually always benign. Cystic teratomas are frequently seen in the reproductive years but can occur at any age and can be seen in postmenopausal women. These tumors may present as a palpable mass. Cystic teratomas are usually asymptomatic and often are discovered incidentally during sonography. In approximately 10% of cases, the tumor is diagnosed during pregnancy.[50] Torsion is the most common complication, whereas rupture is uncommon, occurring in 1% of patients and causing a secondary chemical peritonitis. Malignant transformation is also uncommon, occurring in 2% of patients, usually older women,[50] and is almost exclusively due to squamous cell carcinoma.[28]

Sonographically, cystic teratomas have a variable appearance ranging from completely anechoic to completely hyperechoic. However, certain features are considered specific (Fig. 16.19). These include a predominantly cystic mass with a highly echogenic mural nodule, the **dermoid plug.**[164] The dermoid plug usually contains hair, teeth, or fat and frequently casts an acoustic shadow. In many cases the cystic component is pure **sebum** (which is liquid at body temperature) rather than simple fluid.[165]

Cystic Teratomas: Sonographic Features

Dermoid plug
"Tip of the iceberg" sign
Dermoid mesh
Mobile spherules (rare)
Fat-fluid level

A mixture of matted hair and sebum is highly echogenic because of multiple tissue interfaces, and it produces poorly defined acoustic shadowing that obscures the posterior wall of the lesion. This has been termed the **"tip of the iceberg"** sign[166] (Fig. 16.19B). Highly echogenic foci with well-defined acoustic shadowing may arise from other elements, including teeth and bone. Multiple linear hyperechogenic interfaces, often described as lines and dots, may be seen floating within the cyst and have been shown to be hair fibers.[167] This is also considered a specific sign and has been referred to as the **dermoid mesh**[168] (Fig. 16.19G). A **fat-fluid** or **hair-fluid level** may also be seen (Fig. 16.19D and E). In most cases, as in other lesions such as endometriomas and hemorrhagic cysts, the dependent layer will be more echogenic. However, in approximately 30% of dermoids,

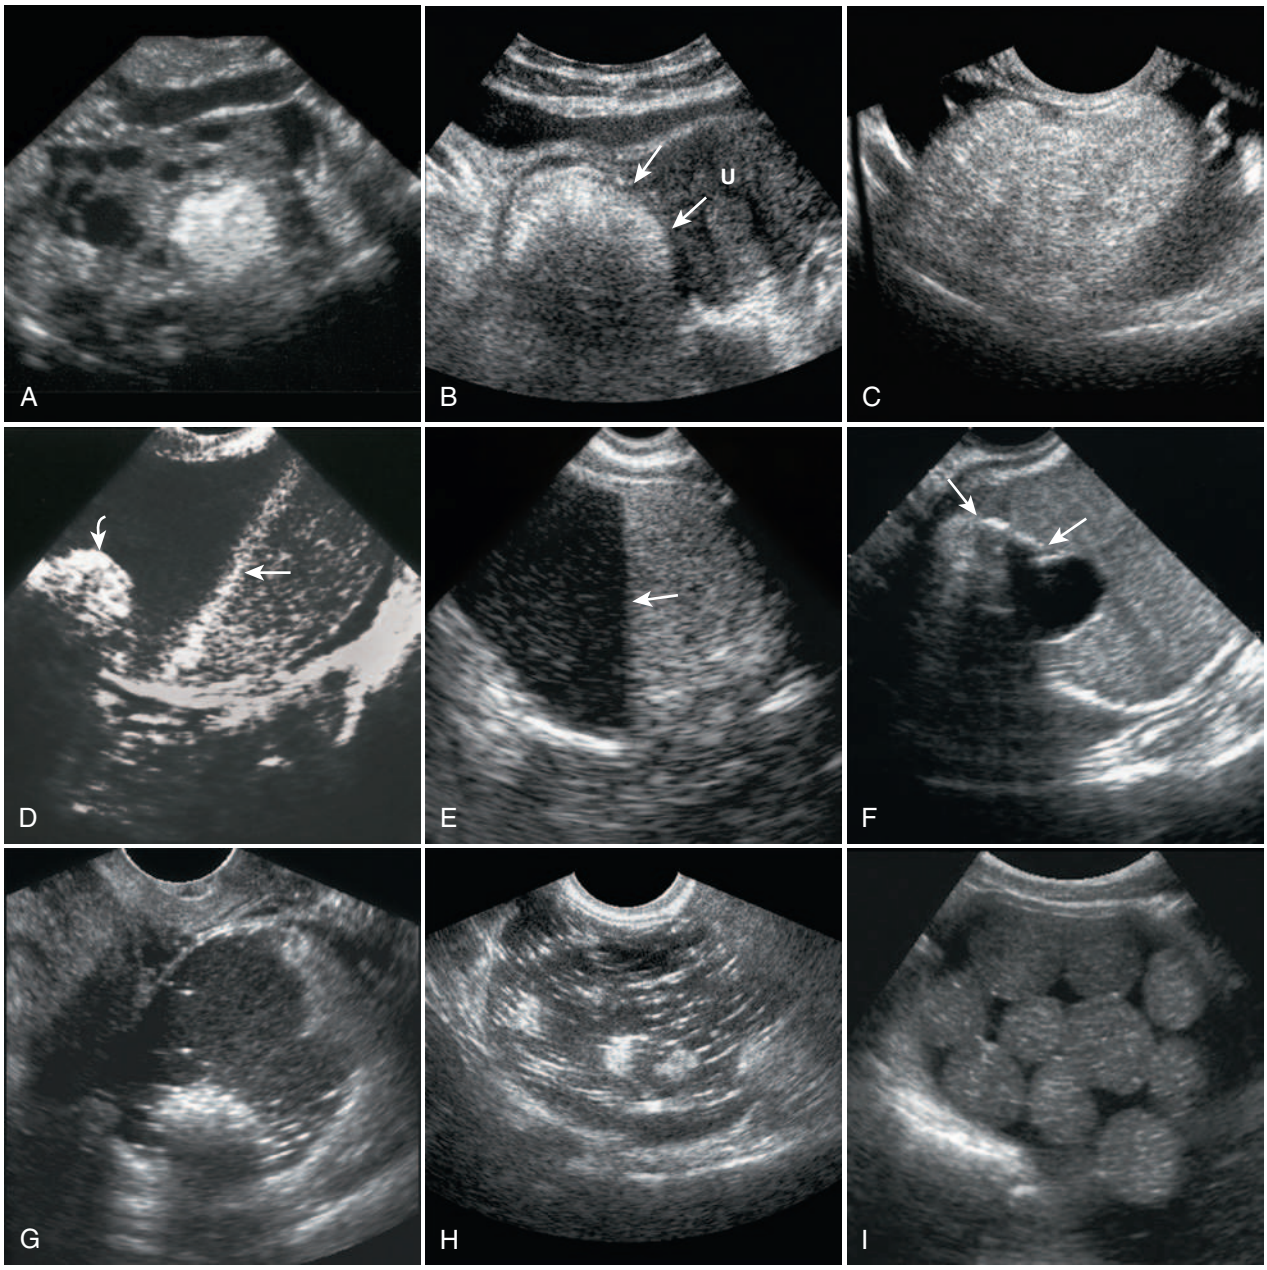

FIG. 16.19 Dermoid Cysts: Spectrum of Appearances. (A) Small, highly echogenic mass in an otherwise normal ovary. **(B)** Transverse TAS shows the uterus *(U)*. In the right adnexal region, there is a highly echogenic and attenuating mass *(arrows)*, the "tip of the iceberg" sign. **(C)** Highly echogenic intraovarian mass with no normal ovarian tissue. **(D)** Mass of varying echogenicity with **hair-fluid level** *(straight arrow)* and highly echogenic, fat-containing **dermoid plug** *(curved arrow)* with shadowing. **(E)** Mass with **fat-fluid level** *(arrow)*, with dependent layer more echogenic. **(F)** Mass containing uniform echoes, small cystic area, and calcification *(arrows)* with shadowing. **(G)** Combination of **dermoid mesh** and **dermoid plug** appearances. **(H) Dermoid mesh**, multiple linear hyperechogenic interfaces (lines and dots) floating within cystic mass. **(I)** Multiple mobile spherical echogenic structures floating in a large, cystic pelvic mass.

the nondependent layer will be more echogenic.[169] Another rare but characteristic feature is multiple mobile spherical echogenic structures floating in a large, cystic pelvic mass[170] (Fig. 16.19I). These spheres are typically composed of desquamative keratin-containing fibrin, hemosiderin, and hair.

Patel et al.[171] found that an adnexal mass showing two or more characteristic sonographic dermoid features had a positive predictive value of 100%. Pitfalls in the diagnosis of cystic teratomas have been described.[172] Acute hemorrhage into an ovarian cyst or an endometrioma may be so echogenic that it resembles a dermoid plug. However, posterior sound enhancement is usually seen with acute hemorrhage, whereas the dermoid plug tends to attenuate sound. Other pitfalls include pedunculated fibroids, especially lipoleiomyomas, and perforated appendicitis with an appendicolith. An echogenic dermoid may appear similar to bowel gas and may be overlooked. If a definite pelvic mass is clinically palpable and the sonogram appears normal, the patient should be reexamined, to carefully assess for a dermoid.

Doppler evaluation of a benign teratoma may show peripheral flow, but malignancy should be considered if flow is seen centrally and/or within solid areas. Additional findings suggesting malignancy include isoechoic branching structures within the lesion and invasion into adjacent organs.[28]

Struma ovarii is a teratoma composed entirely or predominantly of thyroid tissue. It occurs in 2% to 3% of teratomas. Color Doppler sonography detected central blood flow in solid tissue in four reported cases of struma ovarii, compared with absent central blood flow in benign cystic teratomas.[173] This is likely caused by the highly vascularized thyroid tissue in struma ovarii, compared with the avascular fat and hair found in benign cystic teratomas. Although associated hormonal effects are rare, sonography may be valuable in identifying a pelvic lesion in a hyperthyroid patient when there is no evidence of a thyroid lesion in the neck.[174]

Immature teratoma is uncommon, representing less than 1% of all teratomas, and contains immature tissue from all three germ-cell layers. It is a rapidly growing malignant tumor that most often occurs in the first two decades of life. Sonographically, the tumor usually presents as a solid mass, but cystic structures of varying size may also be seen.[163] Calcifications are typically present.

Dysgerminoma

Dysgerminomas are malignant germ cell tumors that constitute 1% to 2% of primary ovarian neoplasms and 3% to 5% of ovarian malignancies.[50] They are composed of undifferentiated germ cells and are morphologically identical to the male testicular **seminoma.** Dysgerminomas are highly radiosensitive and have a 5-year survival of 75% to 90%. This tumor occurs predominantly in women younger than 30 years and is bilateral in approximately 15% of cases.

Sonographically, they are solid masses that are predominantly echogenic but that may contain small anechoic areas caused by hemorrhage or necrosis[163] (Fig. 16.20). CT and MRI have shown these solid masses to be lobulated with fibrovascular septa between the lobules.[175] A report using color Doppler ultrasound in three dysgerminomas showed prominent arterial flow within the fibrovascular septa of a multilobulated, solid, echogenic mass.[176]

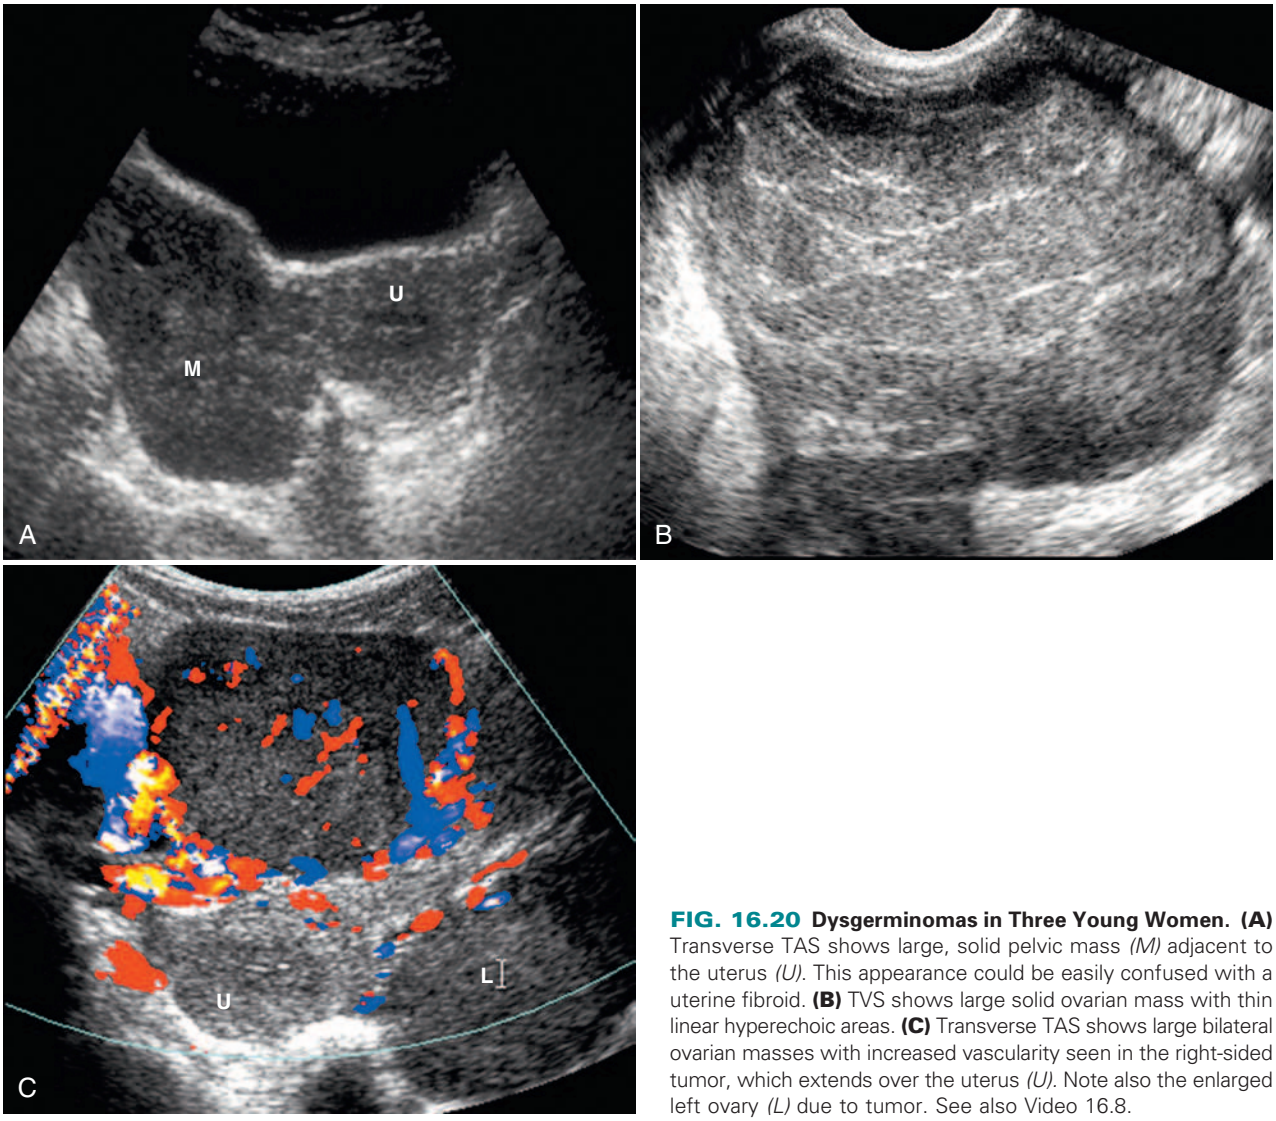

FIG. 16.20 Dysgerminomas in Three Young Women. (A) Transverse TAS shows large, solid pelvic mass *(M)* adjacent to the uterus *(U)*. This appearance could be easily confused with a uterine fibroid. **(B)** TVS shows large solid ovarian mass with thin linear hyperechoic areas. **(C)** Transverse TAS shows large bilateral ovarian masses with increased vascularity seen in the right-sided tumor, which extends over the uterus *(U)*. Note also the enlarged left ovary *(L)* due to tumor. See also Video 16.8.

Yolk Sac Tumor

This rare, rapidly growing tumor, also called **endodermal sinus tumor,** is the second most common malignant ovarian germ cell neoplasm after dysgerminoma. Yolk sac tumor has a poor prognosis. It is thought to arise from the undifferentiated, multipotential embryonal carcinoma by selective differentiation toward yolk sac or vitelline structures.[50] It usually occurs in females under 20 years of age and is almost always unilateral. Increased levels of serum alpha-fetoprotein may be seen in association with endodermal sinus tumor. The sonographic appearance is similar to that of the dysgerminoma[163] (see Video 16.8).

Sex Cord–Stromal Tumors

Sex cord–stromal tumors arise from the sex cords of the embryonic gonad and from the ovarian stroma. The main tumors in this group include **granulosa cell tumor, Sertoli-Leydig cell tumor (androblastoma), thecoma,** and **fibroma.** This group accounts for 5% to 10% of all ovarian neoplasms and 2% of all ovarian malignancies.

Granulosa Cell Tumor

Representing 1% to 2% of ovarian neoplasms, granulosa cell tumor has a low malignant potential. About 95% are of the **adult type** and occur predominantly in postmenopausal women; almost all are unilateral. Granulosa cell tumors are the most common estrogenically active ovarian tumor,[50] and clinical signs of estrogen production can occur, including development of endometrial carcinoma (in 10%-15%). The **juvenile type** makes up 5% of granulosa cell tumors, occurring mainly in patients younger than 30 years. Granulosa cell tumors have a variable appearance, ranging from small solid masses to tumors with variable degrees of hemorrhage or fibrotic changes, to multilocular cystic lesions.[177]

Sertoli-Leydig Cell Tumor

This rare tumor, also called **androblastoma and arrhenoblastoma,** constitutes less than 0.5% of ovarian neoplasms. It generally occurs in women younger than 30 years of age; almost all are unilateral. Malignancy occurs in 10% to 20% of these tumors. The malignant tumors tend to recur relatively soon after initial diagnosis, with few recurrences after 5 years.[178] Clinically, signs and symptoms of virilization occur in about 30% of patients, although about half will have no endocrine manifestations.[50] Occasionally, these tumors may be associated with estrogen production. Sonographically, Sertoli-Leydig cell tumors usually appear as solid hypoechoic masses or may be similar in appearance to granulosa cell tumors.[178]

Thecoma and Fibroma

Thecoma and fibroma arise from the ovarian stroma and may be difficult to distinguish from each other pathologically. Tumors with an abundance of thecal cells are classified as **thecomas,** whereas those with fewer thecal cells and abundant fibrous tissue are classified as **thecofibromas** and **fibromas. Thecomas** constitute approximately 1% of all ovarian neoplasms, and 70% occur in postmenopausal females. They are unilateral, almost always benign, and frequently show clinical signs of estrogen production.

Fibromas represent about 4% of ovarian neoplasms, are benign, usually unilateral, and occur most often in perimenopausal and postmenopausal women. Unlike thecomas, fibromas are rarely associated with estrogen production and therefore are frequently asymptomatic, despite reaching a large size. Ascites is present in up to 50% of patients with fibromas larger than 5 cm in diameter.[179] **Meigs syndrome** (associated ascites and pleural effusion) occurs in 1% to 3% of patients with ovarian fibromas but is not specific, having been reported in association with other ovarian neoplasms as well. Fibromas also occur in approximately 17% of patients with the **basal cell nevus (Gorlin) syndrome.** In this condition the fibromas are usually bilateral, calcified, and occur in younger women (mean age, 30 years).[178]

Sonographically, these tumors have a characteristic appearance of a fibrous lesion (Fig. 16.21). A hypoechoic mass with marked posterior attenuation of the sound beam is seen.[179] The main differential diagnosis is a pedunculated uterine fibroid. Not all fibromas and thecomas show this characteristic appearance, and a variety of sonographic appearances have been noted, probably because edema and cystic degeneration tend to occur within these tumors.[180]

Metastatic Tumors

About 5% to 10% of ovarian neoplasms are metastatic in origin. The most common primary sites of ovarian metastases are tumors of the breast and gastrointestinal tract. The term **Krukenberg tumor** should be reserved for those tumors containing the typical mucin-secreting "signet ring" cells, usually of gastric or colonic origin. Endometrial carcinoma frequently metastasizes to the ovary, but it may be difficult to distinguish from primary endometrioid carcinoma, as discussed earlier. Sonographically, **ovarian metastases** are usually bilateral solid masses (Fig. 16.22A-C), but they may become necrotic and may have a complex, predominantly cystic appearance that simulates primary cystadenocarcinoma[181,182] Testa et al.[183] found that almost all ovarian metastases from primary tumors of the breast, stomach, and uterus were solid, whereas those from the colon and rectum were more heterogeneous, most being multicystic with irregular borders. Ascites may be seen in either primary or metastatic tumors. **Lymphoma** may involve the ovary, usually in a diffuse, disseminated form that is frequently bilateral. The sonographic appearance is that of a solid hypoechoic mass similar to lymphoma elsewhere in the body (Fig. 16.22D-F).

FALLOPIAN TUBE

With careful TVS examination, a normal fallopian tube may be identified as an undulating structure measuring less than 10 mm in thickness that extends from the uterine cornu posterolaterally to the ipsilateral ovary. This assessment is not included as part of a routine pelvic sonogram. Identification becomes easier when the fallopian tube is dilated or surrounded by fluid. The contour of the lumen is not seen unless it is obstructed and fluid-filled[184] (Fig. 16.23). Diagnosis of an asymptomatic hydrosalpinx is important because it allows for what might otherwise be considered to be a concerning adnexal cyst to be ignored rather than followed (Videos 16.9 and 16.10). Developmental

See also Videos 16.9 and 16.10.

abnormalities of the fallopian tube are rare. Abnormalities of the tube include pregnancy, infection, torsion, and neoplasm as well as scarring and obstruction due to other causes.

Pelvic Inflammatory Disease

PID is a common condition that is increasing in frequency. It consists of inflammation of the endometrium, fallopian tubes, pelvic peritoneum, and adjacent structures. Typically, the primary infection is a sexually transmitted disease most often associated with gonorrhea and chlamydia, although with previous disruption of endometrial and tubal tissue due to prior infection, or postsurgical or postpartum changes, the patient can be infected by her own vaginal flora. The infection typically spreads by ascent from the cervix and endometrium. The disease is manifested by tubo-ovarian complexes, peritonitis, and abscess formation and is usually bilateral. Long-term sequelae include chronic pelvic pain, infertility, and increased risk of ectopic pregnancy.

Less common causes include direct extension from appendiceal, diverticular, or postsurgical abscesses that have ruptured into the pelvis, as well as puerperal and postabortion complications. Hematogenous spread is rare but can occur from tuberculosis. When caused by direct extension of an adjacent inflammatory process, it is most often unilateral. The presence of an intrauterine device (IUD) increases the risk of PID, although only during a period of a few weeks following its placement. PID may be unilateral in patients with IUDs.

Patients usually present clinically with pain, fever, cervical motion tenderness, and vaginal discharge. A pelvic mass may be palpated. TVS with color or power Doppler is highly specific in the diagnosis of the disease process.[185] However, because the success of the technique is dependent on the level of operator expertise and also because early changes can be subtle, TVS usually only detects complications of the disease. The sonographic findings may be normal early in the course of PID.[186] Increased echogenicity of peritoneal fat and indistinctness of the uterus may be seen early in the disease process but may be difficult to appreciate. Sonographic findings of the fallopian tubes are the most specific and conspicuous indicators of PID (Table 16.2).

TABLE 16.2 Sonographic Findings of Pelvic Inflammatory Disease

Endometritis	Endometrial thickening Intracavitary fluid
Purulent material in cul-de-sac	Fluid containing low-level echoes
Periovarian inflammation	Enlarged ovaries with multiple cysts and indistinct margins
Salpingitis	Fluid-filled fallopian tube with (pyosalpinx) or without (hydrosalpinx) internal echoes Increased echogenicity of peritoneal fat Indistinctness of the uterus
Tubo-ovarian complex	Fusion of inflamed, fluid-distended tube and ovary
Tubo-ovarian abscess	Multiloculated mass with variable septations, irregular margins, and low-level internal echoes

When imaging a normal appearing fallopian tube, hypervascularity with color Doppler flow within the tubal wall is a valuable early finding. As the disease progresses, a spectrum of findings may occur (Fig. 16.24). With inflammation, the tube swells and endosalpingeal folds thicken. With progressive inflammation and distal occlusion of the lumen, the tube fills with purulent echogenic fluid, becoming a **pyosalpinx.** In the presence of a fluid-distended fallopian tube, common findings include wall thickness greater than 5 mm, incomplete septa seen as the tube folds back on itself, and thickening of endosalpingeal folds **(cogwheel sign).**[187,188] Color or power Doppler allows for detection of hyperemia in the walls and incomplete septi associated with fallopian tube inflammation (Fig. 16.24B).[189] On TAS, dilated tubes appear as complex, predominantly cystic masses that are often indistinguishable from other adnexal masses. However, TVS allows for depiction of the fluid-filled tube with a tubular shape, somewhat

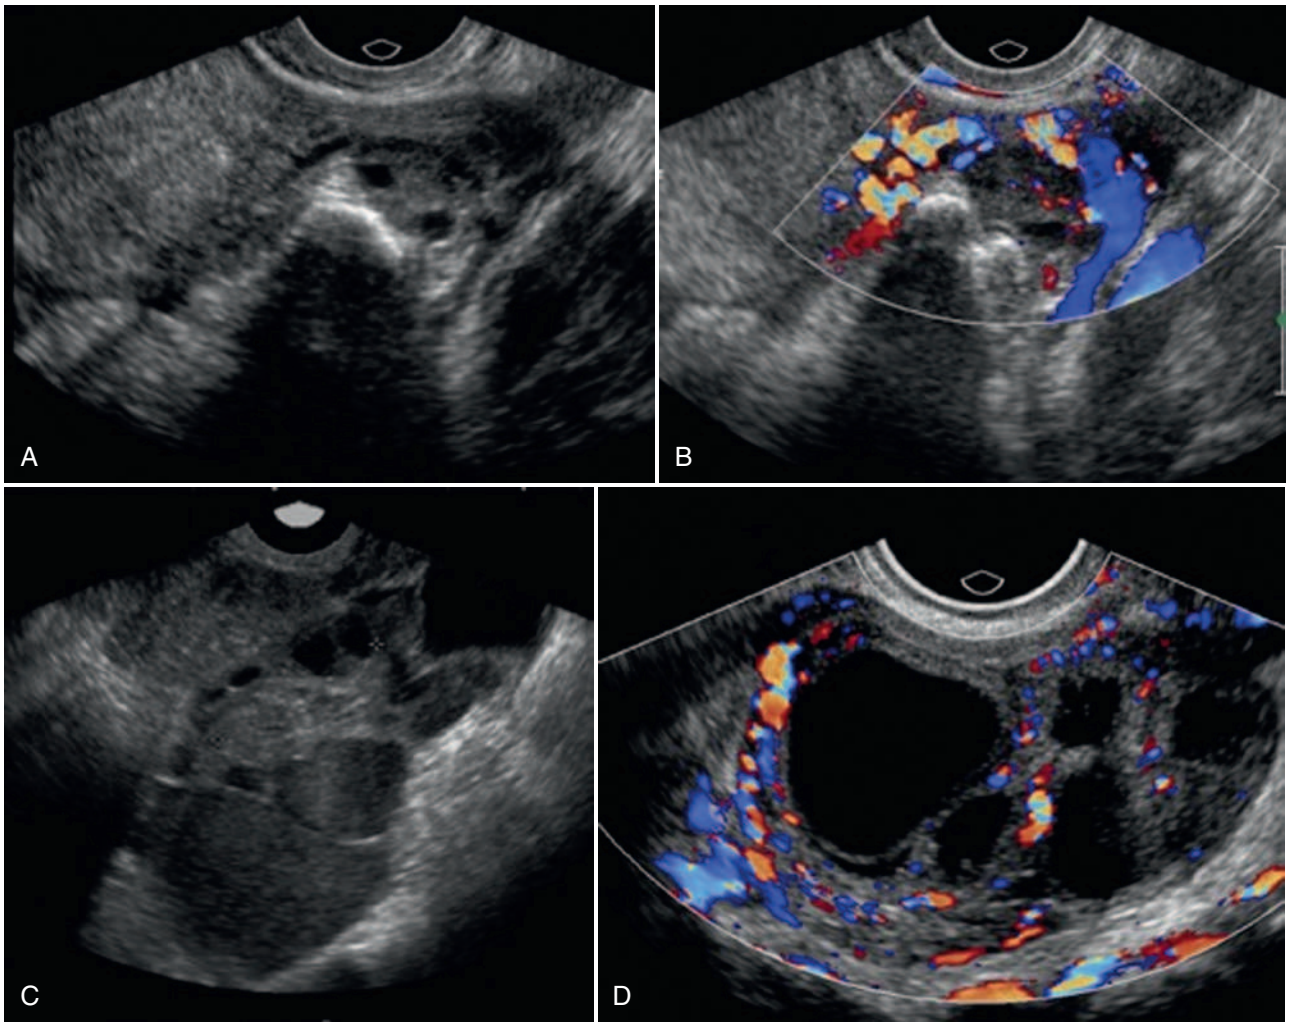

FIG. 16.24 Progression of Pelvic Inflammatory Disease. (A) TVS gray-scale and **(B)** color Doppler images show a normal appearing left fallopian tube by gray-scale imaging but markedly increased associated vascularity using color Doppler, consistent with salpingitis. **(C)** TVS image of a tubo-ovarian complex, a complex mass of fallopian tube and ovary that can still be identified as separate structures. **(D)** TVS color Doppler image of a tubo-ovarian abscess, a cystic, vascular mass containing thick septations in which the fallopian tube and ovary are no longer identifiable. See also Video 16.11.

folded configuration, and well-defined walls.[190] The dilated tube can be distinguished from a fluid-filled bowel loop by the lack of peristalsis. A fluid-pus level may occasionally be seen (Fig. 16.24A). Anechoic fluid within the tube indicates hydrosalpinx. In assessing 14 acute and 60 chronic cases of PID, Timor-Tritsch et al.[188] described three appearances of tubal wall structure: (1) **cogwheel sign,** an anechoic cogwheel-shaped structure visible in the cross section of the tube with thick walls, seen mainly in acute disease; (2) **"beads on a string" sign,** hyperechoic mural nodules measuring 2 to 3 mm on cross section of the fluid-filled distended tube, caused by degenerated and flattened endosalpingeal fold remnants and seen only in chronic disease; and (3) **incomplete septa,** hyperechoic septa that originate as a triangular protrusion from one of the walls, but do not reach the opposite wall, seen frequently in both acute and chronic disease and not discriminatory. Patel et al.[191] found that the presence of a tubular fluid-filled mass with diametrically opposed indentations in the wall **("waist sign")** had the highest likelihood ratio in discriminating hydrosalpinx from other adnexal masses (Fig. 16.23B).[191] Other findings include thick tubal walls and bilateral adnexal masses appearing as small solid masses or thick-walled cystic masses.[192] Nonspecific findings of PID include fluid in the endometrial cavity and/or cul-de-sac, and ill-defined ovarian enlargement often. Endometrial thickening or fluid may indicate endometritis. Fluid containing low-level echoes may be demonstrated in the cul-de-sac consistent with purulent material.

With progression of disease, there is exudation of pus from the distal fallopian tube, periovarian adhesions may form, with fusion of the inflamed dilated tube and ovary, forming an inflammatory **tubo-ovarian complex** (Fig. 16.24C, Video 16.11). The ovary is still recognizable but cannot be separated from the tube by applied pressure using the vaginal transducer.[186] Further progression results in complete breakdown of tubal and ovarian architecture so that separate structures are no longer identified and there is obscuration of the posterior and lateral margins of the uterus resulting in a **tubo-ovarian abscess** (Fig. 16.24D). Sonographically, this appears as a multiloculated mass with incomplete septations, irregular margins, and low-level internal

echoes. There is usually posterior acoustic enhancement, and a fluid-debris level or gas may occasionally be seen within the mass. The sonographic appearance may be indistinguishable from other benign and malignant adnexal masses. Clinical correlation is necessary to suggest the correct diagnosis. Regions of identifiable ovarian tissue may be seen within the inflammatory mass by TVS since the ovaries are relatively resistant to infection.[3]

Both TAS and TVS are useful in making the initial diagnosis in patients with PID and determining management. The TAS approach is helpful in assessing the extent of the disease, whereas the TVS approach is more sensitive in detecting dilated tubes, periovarian inflammatory change, and the internal characteristics of tubo-ovarian abscesses.[186,193] However, because of cervical motion tenderness, it may be quite difficult to perform a good quality TVS examination.

Although the use of outpatient antibiotic therapy has become the standard of care for mild to moderate cases of PID, according to guidelines from the Centers for Disease Control and Prevention,[185] hospitalization for intravenous antibiotic therapy would be prompted by the presence of a tubo-ovarian abscess. By making this diagnosis, TVS is pivotal in determining management.

Sonography is also used to follow the disease process following antibiotic therapy. If antibiotic therapy fails, sonographically guided drainage of tubo-ovarian abscesses in combination with antibiotics has been shown to be highly successful.[194] This initial approach allows for decreased need for surgical intervention.

Tubal Torsion

Tubal torsion is usually seen in conjunction with ovarian torsion, but isolated torsion of the fallopian tube is an infrequent finding. This may be seen in cases of paratubal cysts but also can be seen in association with chronic hydrosalpinx.[195] The patient usually presents with sudden onset of severe pelvic pain. Hydrosalpinx and tubal torsion have also been reported as late complications in patients who have undergone tubal ligation.[196]

Fallopian Tube Carcinoma

The fallopian tube is now thought to be the location for the initial development of high-grade serous cystadenocarcinomas. Thus whereas fallopian tube cancer used to be considered a rare finding, it is now managed similarly to ovarian cancer. Serous tubal intraepithelial carcinoma, a lesion too small to visualize using imaging modalities, represents the acknowledged precursor of these neoplasms.[154]

A minority of patients have a profuse watery discharge, known as **hydrops tubae profluens.** The tumor usually involves the distal end, but it may involve the entire length of the tube. Sonographically, carcinoma of the fallopian tube has been described as a sausage-shaped, solid, or cystic mass with papillary projections.[197-200] Patlas et al.[201] stated that this diagnosis should be considered when a solid vascular mass corresponding to the expected location of the fallopian tube is seen in association with normal ovaries, especially if the mass is mobile.[201]

VASCULAR ABNORMALITIES IN THE ADNEXA

Ovarian Vein Thrombosis or Thrombophlebitis

Ovarian vein thrombosis or thrombophlebitis is an uncommon condition that is usually seen 48 to 96 hours postpartum (Fig. 16.25). Symptoms include fever, lower abdominal pain, and a palpable mass. The underlying cause is venous stasis and spread of bacterial infection from endometritis. The right ovarian vein is involved in 90% of cases. Retrograde venous flow occurs in the left ovarian vein during the puerperium, which protects this side from bacterial spread from the uterus.[50] The condition may be diagnosed by sonography although CT and MRI usually perform better in this diagnosis.[202,203] Sonography may demonstrate an inflammatory mass lateral to the uterus and anterior to the psoas muscle. The ovarian vein may be seen as a tubular structure directed cephalad from the mass and containing echogenic thrombus. The thrombus usually affects the most cephalic portion of the right ovarian vein and can be demonstrated sonographically at the junction of the right ovarian vein with the inferior vena cava, sometimes extending into the inferior vena cava.[204] Doppler ultrasound will demonstrate complete or

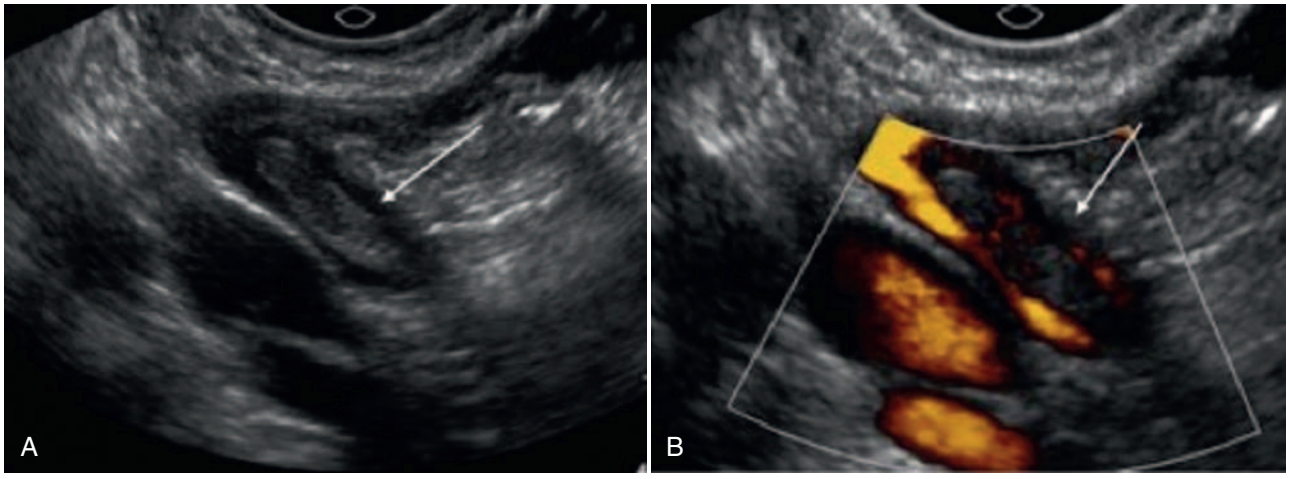

FIG. 16.25 Ovarian Vein Thrombophlebitis. (A) Transverse gray-scale and **(B)** color Doppler images of the right ovarian vein containing echogenic material representing thrombus. Color Doppler image shows Doppler signal surrounding the thrombus.

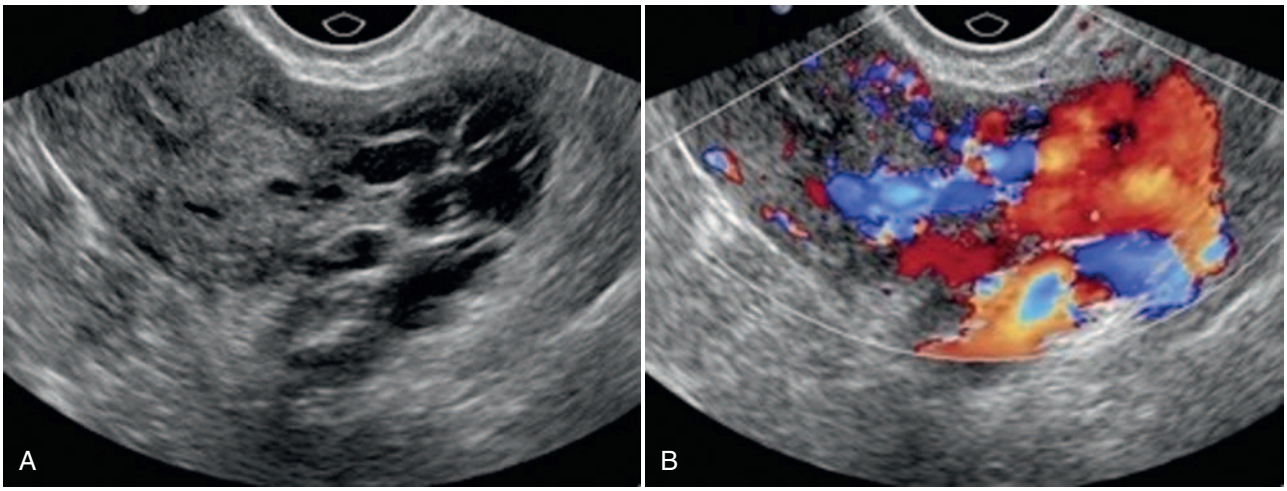

FIG. 16.26 Pelvic Congestion Syndrome. Transverse TVS images, **(A)** without and **(B)** with color Doppler, of the left adnexa demonstrating multiple large vascular structures consistent with varices.

partial absence of flow in these veins.[205] Most patients respond to anticoagulant and antibiotic therapy, and follow-up sonography may show resolution of the thrombus and normal flow by duplex and color Doppler imaging.

Pelvic Congestion Syndrome

Pelvic congestion syndrome is a condition that consists of dilatation of pelvic veins (pelvic varices) and reduced venous return causing dull chronic pain that is exacerbated by prolonged standing and relieved by lying down and elevating the legs. Although venography remains the reference standard for diagnosis, sonography can demonstrate an ovarian vein diameter of greater than 5 to 10 mm with reflux, uterine vein engorgement, congestion of ovarian plexuses (tortuous and dilated pelvic venous plexuses in the adnexa with individual varices measuring greater than 5 mm in diameter, Fig. 16.26), filling of the pelvic veins across the midline, or filling of vulvovaginal and thigh varicosities.[206] Dilated arcuate veins may also be seen crossing the myometrium. Spectral Doppler evaluation of ovarian veins may demonstrate reversed caudal flow.

SONOGRAPHIC EVALUATION OF AN ADNEXAL MASS IN ADULT WOMEN

Sonography in the setting of certain clinical features is often used to evaluate an ovarian/adnexal mass. Clinical features to be considered when evaluating an adnexal mass include symptoms, patient age, menstrual status, and family history. Comparison with previous examinations, if available, is often critical and may save the patient a surgical intervention, since many of these masses are hormonally driven and will resolve. A prior study will also demonstrate if there has been any change in size or internal characteristics.

When a mass is found by sonography, it should be characterized by the following:

- Location (intraovarian or extraovarian)
- Size
- External contour (thin or thick walled and regularity of borders)
- Internal consistency (cystic unilocular or multilocular with or without solid components, predominantly solid, or solid)

Generally, ovarian masses are predominantly cystic, whereas uterine masses are usually solid tumors, benign leiomyomas. Even solid adnexal masses are usually exophytic or interligamentous leiomyomas. Demonstrating a uterine origin by gray-scale and color Doppler is diagnostic and excludes a solid ovarian tumor. Occasionally, it may be difficult to determine the exact origin of the mass by sonography in which case MRI may be a problem-solving tool.

In 2010 the Society of Radiologists in Ultrasound published results of a consensus conference regarding the reporting and follow-up needed for asymptomatic adnexal cysts (Table 16.3). Use of these guidelines allows for decreased need for follow-up of benign adnexal cysts.[207,208] The vast majority of ovarian masses are functional in nature. Ovarian masses that are simple cysts are almost always benign. In premenopausal asymptomatic women, simple cysts or typical hemorrhagic cysts less than 5 cm can be considered functional. The simple adnexal cyst less than or equal to 1 cm in a postmenopausal woman is also very likely benign. These findings should be considered of no clinical significance in asymptomatic women and do not require follow-up. Simple cysts greater than 5 cm in premenopausal women are also likely functional, but resolution should be confirmed with a follow-up examination. In postmenopausal women, simple cysts greater than 1 cm are most often benign cystadenomas or hydrosalpinges or paraovarian/paratubal cysts that demonstrate no significant malignant potential. Cysts that are greater than 7 cm cannot be adequately evaluated sonographically for mural nodules, so MRI or surgical evaluation is recommended.[28]

Larger masses, especially those greater than 10 cm, and those with solid components have a higher incidence of malignancy. Solid ovarian masses that are not classic for fibromas are typically surgically removed because of association with malignancy. Cystic

TABLE 16.3 Society of Radiologists in Ultrasound Recommendations for Follow-Up of Asymptomatic Adnexal Cysts

Patient Population	Description in Report	Recommended Follow-Up
Premenopausal women	Simple or hemorrhagic cysts 3-5 cm	Simple or hemorrhagic cysts > 5 cm, 6 weeks to document resolution
Postmenopausal women	Cysts > 1 cm	Yearly
Any age	Hydrosalpinx	No follow-up needed
Any age	Dermoid, endometrioma	Yearly

With permission from Levine D, Brown DL, Andreotti RF, et al. Management of asymptomatic ovarian and other adnexal cysts imaged at US: Society of Radiologists in Ultrasound Consensus Conference Statement. Radiology. 2010;256(3):943-954.[28]

masses with solid components may be either benign or malignant and should be further assessed for wall contour, septations, and mural nodules. Irregular borders, thick irregular septations, papillary projections, and echogenic solid nodules favor malignancy. Color and spectral Doppler ultrasound may demonstrate vascularity within the septa or nodules. Although ascites may be associated with benign masses such as the mucinous cystadenoma or fibroma, it is more commonly seen with malignant disease. Malignant ascites often contains echogenic particulate matter.

If a pelvic mass is suspected of being malignant, the abdomen should also be evaluated for evidence of ascites and peritoneal implants, obstructive uropathy, lymphadenopathy, and hepatic and splenic metastases. Hepatic and splenic metastases are uncommon in ovarian carcinoma, but when they occur, they are usually peripheral on the surface of the liver or spleen as a result of peritoneal implantation. Hematogenous metastases within the liver or splenic parenchyma may occur late in the course of the disease.

Attempts have been made to standardize reporting of adnexal features and preoperatively classify these masses. The largest study to date analyzing features of ovarian and adnexal masses has been performed by the International Ovarian Tumor Analysis (IOTA) group.[209] Timmerman et al.[210] used these ultrasound-based features to develop simple rules that can correctly classify the majority of masses as benign or malignant (Table 16.4). If one or more of the malignant (M) rules or one or more of the benign (B) rules are present, the mass is classified as benign or malignant. If both M and B rules are present or no rules are present, the mass cannot be classified.

TABLE 16.4 Ten Simple Rules for Identifying a Benign or Malignant Tumor

Rules for Predicting a Malignant Tumor (M-Rules)	Rules for Predicting a Benign Tumor (B-Rules)
M1 Irregular solid tumor	B1 Unilocular
M2 Presence of ascites	B2 Presence of solid components where the largest solid component has a largest diameter <7 mm
M3 At least four papillary structures	B3 Presence of acoustic shadows
M4 Irregular multilocular solid tumor with largest diameter ≥100 mm	B4 Smooth multilocular tumor with largest diameter <100 mm
M5 Very strong blood flow	B5 No blood flow

If one or more M-rules apply in the absence of a B-rule, the mass is classified as malignant. If one or more B-rules apply in the absence of an M-rule, the mass is classified as benign. If both M-rules and B-rules apply, the mass cannot be classified. If no rule applies, the mass cannot be classified.

NONGYNECOLOGIC ADNEXAL MASSES

Pelvic masses and pseudomasses may not be of gynecologic origin. To make this diagnosis, it is important to visualize the uterus and ovaries separately from the mass. This is frequently not possible because of displacement of the normal pelvic structures by the mass. Nongynecologic pelvic masses most frequently originate from the gastrointestinal or urinary tract or may develop after surgery. These include bladder diverticulum, urachal cysts, gut duplication cysts, and Tarlov cysts.

Postoperative Pelvic Masses

Postoperative masses may be **abscesses, hematomas, lymphoceles, urinomas,** or **seromas.** Sonographically, **abscesses** are ovoid-shaped, hypoechoic masses with thick, irregular walls and posterior acoustic enhancement. Variable internal echogenicity may be seen, and high-intensity echoes with shadowing caused by gas may be demonstrated. With optimized settings, color Doppler usually demonstrates vascularity within the wall of the abscess. **Hematomas** show a spectrum of sonographic findings, varying with time.[211] During the initial hyperacute phase, hematomas are anechoic. After organization and clot formation, they become highly echogenic. With lysis of the clot, hematomas develop a reticular pattern and/or concave margins due to retracting clot, until finally, with complete lysis, they are again anechoic. An abscess may be indistinguishable from a hematoma sonographically requiring clinical correlation to make the final diagnosis.

Pelvic **lymphoceles** occur after surgical disruption of lymphatic channels, usually after pelvic lymph node dissection or renal transplantation. Sonographically, lymphoceles are anechoic, having an appearance similar to that of **urinomas,** which are localized collections of urine, or **seromas,** which are collections of serum. Sonography-guided aspiration may be necessary to differentiate these conditions.

Gastrointestinal Tract Masses

The most frequent pelvic pseudomasses are fecal material in the rectum simulating a complex mass in the cul-de-sac and a fluid-filled rectosigmoid colon presenting as a cystic adnexal mass. TVS can usually distinguish the pseudomass from a true mass, but when it cannot, a repeat examination or MRI may be necessary. **Bowel neoplasms,** especially those involving the rectosigmoid, cecum, and ileum, may simulate an adnexal mass. These tumors frequently show the characteristic target sign of a gastrointestinal mass, consisting of a central echogenic focus caused by air within the lumen, surrounded by a thickened hypoechoic wall.[212] **Abscesses** related to inflammatory disease of the gastrointestinal tract may also present as an adnexal mass. On the right side, this is most frequently caused by appendicitis or Crohn disease, whereas abscesses on the left side are usually caused by diverticular disease and are seen in an older age group.

Urinary Tract Masses

Patients with a **pelvic kidney** may present with a clinically palpable mass. This is readily recognized sonographically by the typical reniform appearance and the absence of a kidney in the normal location. Occasionally, a greatly distended bladder may be mistaken for an ovarian cyst. When a cystic pelvic mass is identified, it is imperative that the bladder be seen separately from the mass. If the origin of the cystic mass continues to be in question, having the patient void or draining the bladder with a Foley catheter can ensure a decompressed bladder. **Bladder diverticula** may also simulate a cystic adnexal mass. The diagnosis can be confirmed by demonstrating communication with the bladder and a changing appearance after voiding. **Dilated distal ureters** may simulate adnexal cysts on transverse scans; however, sagittal scans show their tubular appearance and continuity with the bladder.

CHAPTER 17

Ultrasound-Guided Biopsy of Chest, Abdomen, and Pelvis

Theodora A. Potretzke, Thomas D. Atwell, J. William Charboneau, and Carl Reading

SUMMARY OF KEY POINTS

- Ultrasound is a key method of guidance for biopsy and fluid drainage because of its real-time needle visualization and the ability to image and intervene in multiple anatomic locations and planes.
- Effective periprocedural antithrombotic management requires an understanding of specific antithrombotic agents as well as the balance of the potential risk of hemorrhage from a given procedure versus the risk of a thrombotic event if a blood thinner is discontinued.
- Ultrasound typically offers excellent guidance for superficial biopsies, paracentesis, thoracentesis, and most solid organ biopsies in the abdomen including liver, kidney, and spleen. CT guidance is often utilized for adrenal, retroperitoneal, and certain deep pelvic biopsies or deep drain placement.
- Familiarity with both trocar and Seldinger techniques is useful for ultrasound-guided drain placement.

Ovarian Cyst

Percutaneous biopsy and fluid drainage are invaluable diagnostic and therapeutic procedures for the management of patients. Ultrasound is a central method of guidance for these interventional techniques because it allows real-time needle visualization and the ability to image and intervene in multiple anatomic locations and planes. An approach to this topic requires knowledge of the current fundamental methods and applications of these procedures in general and in terms of specific anatomic locations.

PERCUTANEOUS NEEDLE BIOPSY

Because of its relatively low cost and wide availability, ultrasound-guided biopsy has become one of the most important methods of tissue diagnosis in radiology practices worldwide. Ultrasound-guided biopsy is a safe and accurate technique for confirmation of suspected malignant masses and characterization of benign lesions in locations throughout the body.[1,2] In addition, minimally invasive tissue confirmation decreases patient costs by obviating the need for a surgical diagnosis and decreasing duration of hospital stay and number of ancillary diagnostic tests. In addition, lack of ionizing radiation and real-time imaging during the procedure make the procedure safer.

Indications and Contraindications

In most cases a biopsy is performed in the setting of possible malignancy, for either initial diagnosis of cancer, confirmation of metastatic disease, or to obtain tissue for molecular profiling and targeted treatment planning. In other patients, biopsy is performed to gauge the presence of parenchymal disease in a

native organ or rejection in a transplanted organ. Occasionally, biopsy is indicated simply to determine the nature of an incidentally discovered mass.

Relative contraindications to percutaneous needle biopsy include severe uncorrectable coagulopathy, lack of a safe biopsy route, and an uncooperative patient. To assess for inherent **coagulopathy,** the most valuable information comes from the patient history,[3] including bleeding tendency or need for transfusion or a family history of bleeding diathesis. Patient medications should also be reviewed for recent use of antithrombotic agents.

The second relative contraindication is the **lack of a safe biopsy route.** A biopsy path extending through large vessels such as the splenic or extrahepatic portal vein increases the risk of hemorrhage. A biopsy path free of overlying stomach or bowel is also a preferable route, although such biopsies have been safely performed using smaller (21-gauge) needles.[4] Biopsies performed through ascites have also proved to be safe, although drainage of ascites prior to biopsy may increase target accessibility.[5,6]

The third relative contraindication to needle biopsy is an **uncooperative patient** in whom uncontrolled motion during needle placement increases the risk of unanticipated injury and hemorrhage. This is a particularly common problem in pediatric patients, and deeper sedation may be required.

Periprocedural Antithrombotic Management

An effective approach to the management of **periprocedural antithrombotics** depends on an understanding of the balance of hemorrhagic and thrombotic complications. That is, the potential risk of hemorrhage from biopsy or drainage in a patient on an antithrombotic agent versus the risk in that same patient of a thrombotic event if a blood thinner is discontinued. Significant thromboembolic events, including myocardial infarction and ischemic stroke, have been shown to occur in 1% to 4% of select patients in whom aspirin or warfarin is withheld without bridging therapy.[7-11] Although decisions on periprocedural antithrombotic management are best made in collaboration with the referring clinician, the performing radiologist typically makes the ultimate judgment of whether and when to perform a procedure for a patient on an antithrombotic agent. It is therefore important for the radiologist to have a general knowledge of common anticoagulants and antiplatelet agents as well as the bleeding risks associated with certain procedures. However, any withdrawal of a therapeutic agent should be deferred to the ordering clinical provider, often following a discussion with the radiologist regarding procedure-specific bleeding risk.

Although helpful institutional and society guidelines have been put forth on the topic of periprocedural antithrombotic management, true consensus and uniformity in practice remain elusive. This is due to the expanding pharmacy of **antiplatelet agents** and **anticoagulation** as well as to evolving literature showing lower bleeding risks for some procedures than previously thought. In general, our own practice has leaned toward liberalizing guidelines; that is, foregoing preprocedural labs in certain patients for lower-risk procedures (superficial biopsies such as thyroid and superficial lymph nodes as well as thoracentesis, paracentesis, and superficial abscess drainage) and performing certain lower-risk procedures, especially if urgent, without discontinuing antithrombotic agents.

The most commonly encountered antithrombotics in both inpatient and outpatient populations are the antiplatelet agents aspirin and clopidogrel (Plavix), the vitamin K antagonist warfarin, and the clotting factor inhibitor heparin (unfractionated or low-molecular-weight). Anticoagulants using other mechanisms such as direct thrombin inhibitors (e.g., dabigatran), direct factor Xa inhibitors (e.g., fondaparinux), and glycoprotein IIb/IIIa inhibitors (e.g., abciximab) are being increasingly utilized and may also be encountered in practice. General familiarity with mechanisms and metabolism of these agents is important for decision making. For example, the direct thrombin inhibitor dabigatran has a half-life of 12 to 14 hours but is excreted by the kidneys; therefore the period of preprocedural discontinuation, if pursued for a nonurgent deep biopsy, should be extended in a patient with renal impairment (6-7 days vs. 4-5 days if normal renal function in our practice).

For low-risk procedures, such as thoracentesis and paracentesis, we have found little impact on bleeding risk from therapeutic anticoagulation or aspirin use. Bleeding complication rates in coagulopathic and thrombocytopenic patients (international normalized ratio [INR] > 1.6 and/or platelets < 50×10^9/L) after thoracentesis or paracentesis are very low (up to 1%).[12-15] Patients often benefit greatly from these procedures. Accordingly, we have eliminated routine complete blood count prior to these procedures for most patients and request warfarin be held only if patient is at low risk for thromboembolic event. If patients will be taking warfarin at the time of the procedure, an INR should be obtained within 24 hours prior to procedure to ensure they are not supratherapeutic. Additional labs may be requested by the radiologist at their discretion, but we have found this is rarely needed. Aspirin may also be continued in our practice for thoracentesis or paracentesis. A similar approach is used for superficial biopsies and superficial drain placement.

Higher-risk procedures include liver and kidney biopsy as well as mesenteric, retroperitoneal, or deep pelvic lymph node biopsy, and deep abscess drainage. Although called "higher risk" this is relative to other procedures, and the true risk of postprocedural bleeding, even for these procedures, is low.

Native renal parenchymal biopsies have the highest risk of postbiopsy bleeding with reported rates of significant bleeding of 0.3% to 6.6%.[16-23] Liver and renal transplant biopsy bleeding rates are generally lower and at our own institution are 0.5% and 0.2%, respectively.[16] If a higher-risk biopsy is nonurgent or elective, aspirin can be held for 5 days beforehand if the risk of thromboembolic event is acceptably low and then restarted at 24 hours after biopsy. However, our clinical experience has shown little if any association of recent aspirin use on significant postprocedural bleeding. In a study of 15,181 percutaneous core biopsies, the incidence of bleeding in patients taking aspirin within 10 days before biopsy was 0.6% and that of patients not taking aspirin was 0.4% ($p = .34$).[24] This study included 585 liver biopsies performed in patients with recent aspirin use with a 0.3% risk of major hemorrhage (not significantly different to the 0.5% in those not taking aspirin). Consequently, we continue to

perform many solid organ biopsies in patients on aspirin and rarely postpone or cancel a biopsy because of aspirin usage. Exceptions to this practice include elective biopsies, especially in a local patient who will be able to easily reschedule the procedure, and in some cases native kidney biopsies that already confer an increased risk of bleeding. The incidence of major hemorrhage after native or transplant renal biopsy in patients taking aspirin was slightly higher when compared to those not taking aspirin (1.0% vs. 0.6%) although this difference was not statistically significant ($p = .08$).[24] For warfarin and heparin, we recommend holding prior to a higher-risk biopsy if possible—5 days for warfarin (to INR ≤ 1.5), 4 hours for therapeutic dose intravenous (IV) unfractionated heparin, 24 hours for therapeutic dose low-molecular-weight heparin, and 12 to 24 hours for prophylactic dose unfractionated or low-molecular-weight heparin.

If the history suggests a bleeding disorder but the patient is not on an antithrombotic agent, prothrombin time (PT), activated partial thromboplastin time (aPTT), and platelet count should be obtained if a higher-risk procedure is planned.[25] The role of bleeding time measurement is of uncertain value in determining bleeding risk; in most cases, no good evidence supports the value of the bleeding time to predict bleeding.[3,26] For core biopsies or drains, platelets greater than 50×10^9/L and an INR of 1.6 or less are the suggested thresholds but biopsy may be pursued even if patients fall outside these parameters at the discretion of the performing radiologist and the referring clinician after weighing the risks and benefits. Data have shown that a platelet count of 50×10^9/L or less is a statistically significant risk factor for major bleeding after liver biopsy (2.2% vs. 0.5% rate of significant bleeding, $p = .04$).[27] Interestingly, in the same study group, no patients with an INR of 1.6 or greater ($n = 43$, range 1.6-1.9) had a significant postbiopsy hemorrhage.[27]

Some coagulopathies can be corrected with the transfusion of appropriate blood products although there is unpredictable impact of this on postprocedural bleeding rates for certain procedures such as thoracentesis.[12] For higher-risk biopsies, however, we continue to believe that there is benefit to transfusing to reach previously mentioned thresholds of platelets greater than 50×10^9/L and INR of 1.6 or less in thrombocytopenic and coagulopathic patients if possible. Desmopressin (DDAVP) can be given to a uremic patient to improve functioning platelet activity.[28] Postbiopsy embolization of the needle track has been reported to control hemorrhage in patients at high risk for bleeding and in whom the need for biopsy outweighs any risk, but it is not routinely performed in our practice.[29,30]

Imaging Methods

Both ultrasound and computed tomography (CT) can be used to guide percutaneous needle intervention. The choice of method depends on multiple factors, including lesion size and location, relative lesion conspicuity on the two modalities, equipment availability, and personal preference.

Ultrasound

Ultrasound has several strengths as a means of guiding percutaneous intervention. It is readily available, relatively inexpensive, and portable. Ultrasound uses no ionizing radiation and can provide guidance in almost any anatomic plane. The greatest advantage, however, is that sonography allows the real-time visualization of the needle tip as it passes through tissue into the target. This allows precise and confident needle placement and avoidance of important intervening structures. In addition, **color Doppler flow imaging** (CDFI) may help prevent complications of needle placement by identifying the vascular nature of a mass and by allowing the clinician to avoid vascular structures lying within the needle path.

Ultrasound guidance can be used for the biopsy of many organs and regions of the body. The technique is optimal for lesions located superficially or at moderate depth in a thin to average-sized person such as the omentum (Video 17.1), as well as for lesions within organs prone to respiratory motion (e.g., liver, kidney) (Video 17.2). In the latter scenario, the advantage of real-time ultrasound-guidance allows continuous visualization of the target during the biopsy. Lesions located within or behind bone or gas-filled bowel cannot be visualized because of near-complete reflection of sound from the bone or air interface.

Theoretically, any mass that is well visualized with ultrasound is amenable to ultrasound-guided needle biopsy. In our practice, most liver and kidney biopsies are performed with ultrasound guidance, as are biopsies of the thyroid and parathyroid glands. Superficial lymph nodes are also particularly well suited to real-time ultrasound-guided biopsy. Occasionally, the pancreas (particularly pancreas transplants) and other sites in the abdomen and pelvis undergo biopsy with ultrasound guidance if lesion visualization is adequate.

Compared with CT, ultrasound-guided procedures require less time to perform and can be more cost-effective.[31-33] Ultrasound-guided biopsy has been shown to be more accurate than CT, with a lower false-negative rate.[32,34]

Computed Tomography

CT is well established as an accurate guidance method for percutaneous biopsy of most regions in the body. It provides excellent spatial resolution of structures between the skin surface and targeted lesion, and it provides an accurate image of the needle tip. In addition, lesions located deep in the abdomen or within bone are better seen with CT than with ultrasound. In our practice, many pelvic, adrenal, pancreatic, retroperitoneal, and bone biopsies are performed with CT guidance because these structures are often best seen with this imaging method.

Historically, CT was limited by its lack of continuous visualization of the needle during insertion and biopsy. In the past decade, CT **fluoroscopy** has allowed real-time visualization of needle positioning. This has reduced the time required for interventional procedures at the cost of increased radiation dosage.[35]

Needle Selection

A variety of needles with a spectrum of calibers, lengths, and tip designs are commercially available for use in percutaneous biopsy. Needle caliber is based on outer diameter, with larger-caliber needles having a lower gauge number. Conceptually, needles can be grouped into small-caliber (20 gauge or smaller) or large-caliber (19 gauge or larger) sizes. **Small-caliber needles**

are traditionally used to obtain cells for cytologic analysis by using a procedure commonly referred to as **fine-needle aspiration** (FNA). However, small pieces of tissue may be obtained for histologic examination as well. With these small-caliber needles, masses behind loops of bowel can be punctured with minimal likelihood of infection.[4] The smaller samples yielded by small-caliber needles are appropriate to confirm tumor recurrence or metastasis in a patient known to have a previous primary malignancy. Even if the sample is small, the pathologist is usually able to make an accurate diagnosis by comparing the biopsy specimen with the original tissue.

Large-caliber needles can be used to obtain greater amounts of tissue for more thorough histologic and cytologic analysis. Larger needles may be necessary to obtain sufficient tissue to diagnose and subtype some types of malignancies (e.g., lymphoma), many benign lesions, and most chronic diffuse parenchymal diseases (e.g., hepatic cirrhosis, renal glomerulonephritis, renal allograft rejection).[36] The large-caliber tissue sample can also be used to generate an additional "touch prep" specimen, whereby the tissue is manually swiped across a glass pathology slide, leaving a cellular sample on the slide for cytologic analysis.[37]

The preference and level of expertise of the pathologist involved in the interpretation of biopsy specimens are considerations in the selection of needle size and type. **Cytopathologists** specialize in the interpretation of cellular samples, rendering a diagnosis based on the cells provided. Unfortunately, some clinical facilities do not offer cytopathologic interpretation. **Histopathologists,** in contrast, often prefer a large biopsy specimen for interpretation. For example, a large biopsy specimen from a metastatic lesion often allows a more reliable prediction of the primary site of the malignancy than a tiny sample or a cytologic aspirate. Determination of the primary site allows the oncologist to tailor subsequent treatment.

Biopsy Procedure

Before any invasive procedure is performed, the procedure, risks, alternatives, and benefits should be explained in terms that the patient can understand so that informed consent can be obtained. The performing physician must address patient apprehension about potential pain during the procedure and possible complications of the biopsy. After discussing the procedure, any patient questions should be answered fully.

Biopsies are frequently performed on an outpatient basis. Discomfort during the procedure is rarely severe and is usually controlled by appropriate administration of local anesthetic after the skin is cleaned and draped. An IV access may be established before the biopsy in the event that fluid or medications are necessary during the procedure. Premedication is usually not necessary. Sedatives and analgesics such as midazolam or fentanyl can be administered intravenously after consent has been obtained.[38] In patients with an increased risk of bleeding, a larger or second IV access site may be prudent.

There are two options to **sterilize the transducer.** The transducer may be covered with a sterile plastic sheath, although this may degrade image quality and make the transducer more difficult to handle. Alternatively, the transducer itself may be directly sterilized and placed directly on the skin. Sterile gel is used as an acoustic coupling agent. After the biopsy, the transducer is soaked for 10 minutes in a bactericidal dialdehyde solution.

Most ultrasound-guided biopsies are performed under continuous real-time visualization. **Needle guidance systems** designed to facilitate proper needle placement are commercially available. These guides attach to the transducer and direct the needle to various depths from the transducer surface, depending on the preselected angle of the guide relative to the transducer (Fig. 17.1A,B). Many radiologists prefer the **"freehand" technique** in which the needle is inserted through the skin directly into the view of the transducer without the use of a guide (Fig. 17.1C). The needle is then independently directed to the target lesion by the operator under real-time ultrasound visualization (Videos 17.3 and 17.4).

In contrasting these two biopsy techniques, one can appreciate the technical ease provided by the needle guidance method. This can decrease the time to perform a biopsy, particularly in the hands of a novice operator.[39] However, the freehand technique allows greater flexibility to the operator in performing subtle adjustments to the needle path in the event of patient movement, particularly with respiration.

FNA biopsies are performed by placing the tip of the needle into the target lesion and rapidly "bobbing" the needle within the mass, collecting cellular samples within the lumen of the small needle. Some biopsy devices include a syringe on the end to provide negative pressure within the lumen, increasing the cellular yield.

Large-caliber needles are used to obtain cores of tissue. With the typical spring-loaded core biopsy device (biopsy "gun"), the needle tip is advanced to the margin of the target lesion. Careful attention is made to the anticipated excursion of the device to prevent injury to deeper structures. Some biopsy devices allow initial manual advancement of the stylet through the target lesion to the desired depth. When the spring-loaded cutting sheath is activated, the sheath advances over the stylet, but there is no additional forward motion of the needle (Fig. 17.2).

Most biopsies are performed by making one or more passes into a mass with a single needle. Occasionally, two needles are used in a **coaxial** manner, whereby a larger introducer needle is first placed into the mass. The inner stylet of this needle is then removed, and a longer, smaller-caliber needle is placed through its lumen. Multiple samples can then be obtained with the smaller needle without the need to reposition the larger introducer needle. This technique allows a large amount of tissue to be obtained with only one puncture of the organ capsule, although gas introduced during the procedure may interfere with ultrasound imaging. Although intuitively this should decrease bleeding complications, this has not been conclusively demonstrated in real practice.[40] This may be related to the large caliber of the introducer needle or the extended time during which the introducer needle lies within the organ, potentially tearing the capsule.

After the biopsy is performed, the patient is typically observed in the radiology department for a period commensurate with procedure risk. Longer observation may be appropriate if there

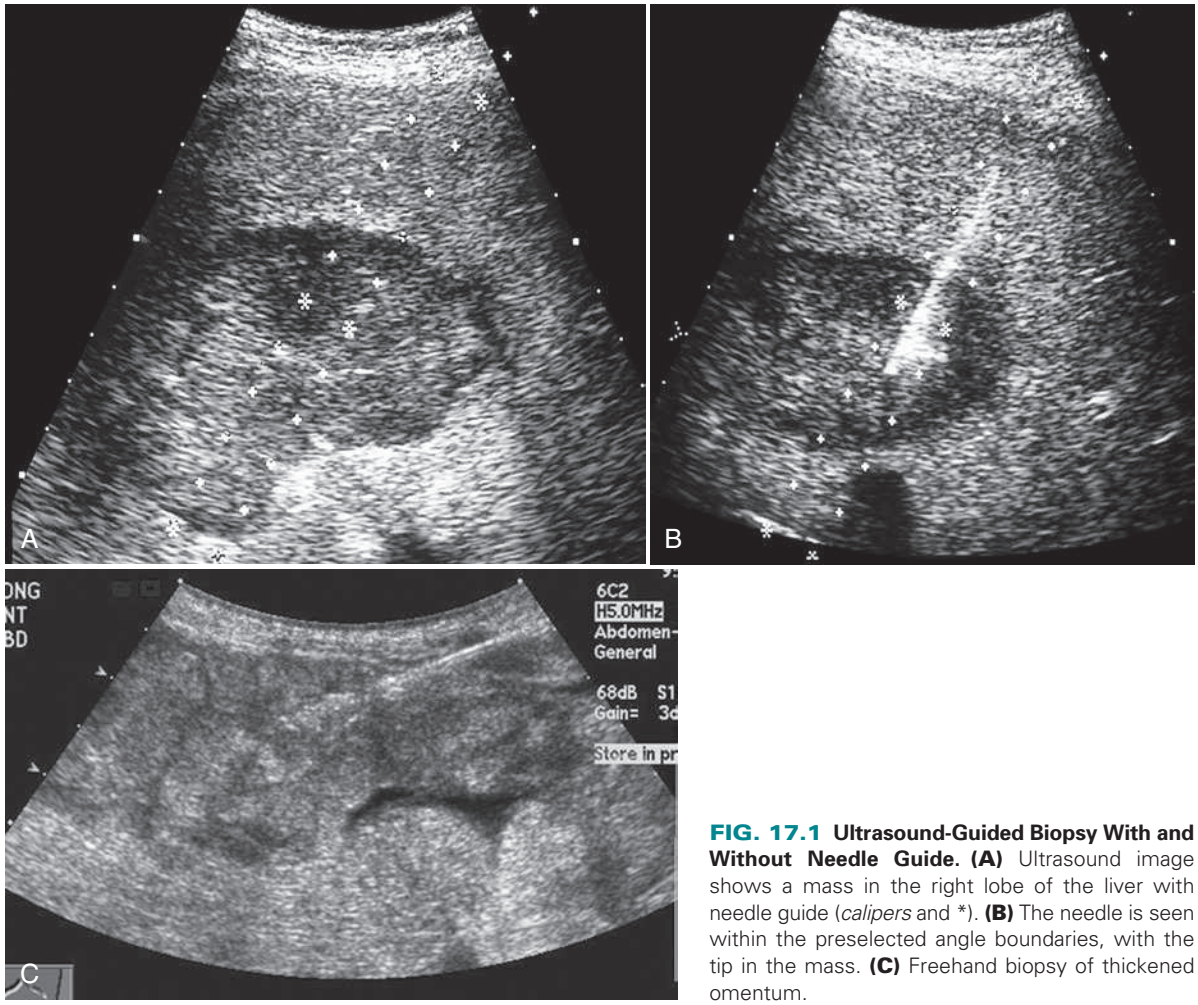

FIG. 17.1 Ultrasound-Guided Biopsy With and Without Needle Guide. FIG. 17.2 Biopsy Needle With Central Stylet. (A) Biopsy needle tip before stylet deployment. **(B)** Stylet is deployed, with the biopsy trough *(arrows)* evident on the exposed stylet. **(C)** Outer cannula is fired over the stylet, allowing tissue to be obtained in the trough.

is clinical concern about a potential complication. In many medical centers, initial cytologic results are available within this time. If the results of the initial cytologic analysis are not conclusive, a **repeat biopsy** may be performed while the patient is in the department. When core biopsy tissue samples are obtained, frozen-section analysis may be performed for diagnosis if the touch-prep cytology specimen is inconclusive. In this case, additional samples may be necessary if permanent fixation or special staining is required.

Needle Visualization

Continuous real-time visualization of needle tip advancement is one of ultrasound's greatest strengths as a biopsy guidance method. Unfortunately, this is frequently the most technically difficult aspect of ultrasound-guided biopsy for many radiologists. Beginners may choose to practice on a homemade ultrasound biopsy phantom to develop the coordination necessary for ultrasound-guided procedures.[41,42]

The most common reason for nonvisualization of the needle tip is **improper alignment** of the needle tip and transducer. To visualize the entire needle, the needle and central ultrasound beam of the transducer must be in the same plane. This allows the entire shaft of the needle to be visualized. Although malalignment rarely occurs with the use of a mechanical needle guide, such parallel placement can be challenging using the freehand technique, particularly when the radiologist is focused on the ultrasound image. In many cases the radiologist can simply look at the alignment of the needle with the transducer to allow gross correction of path deviation (Fig. 17.3), and then fine-tune the needle alignment with ultrasound imaging.

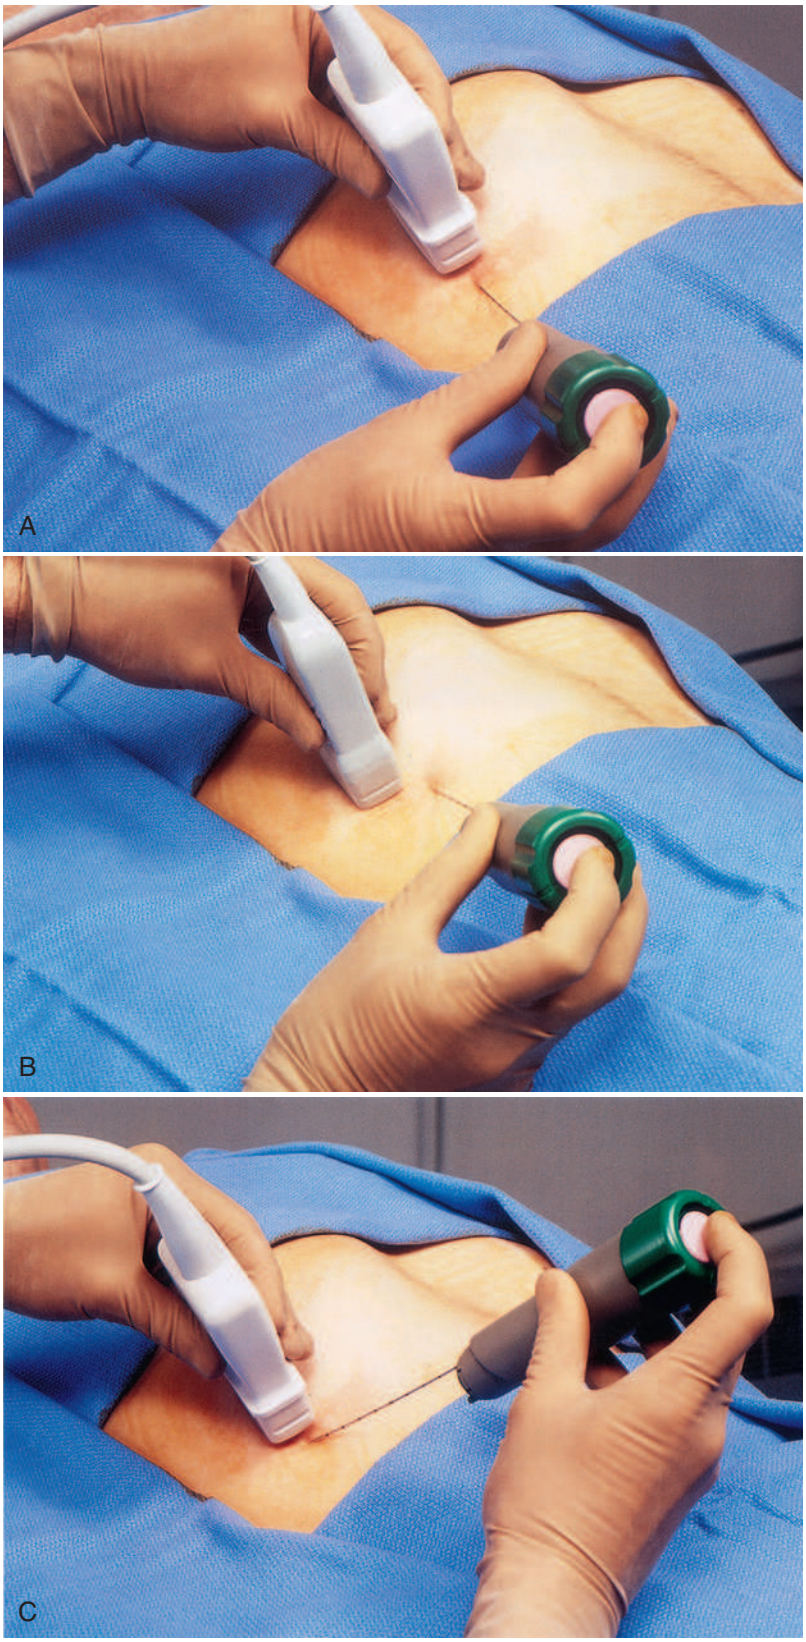

FIG. 17.3 Freehand Alignment of Biopsy Needle With Ultrasound Transducer. (A) Correct alignment for optimal sonographic visualization. Biopsy needle is aligned precisely within the central plane of the transducer. **(B)** Incorrect alignment. Biopsy needle is aligned off-center relative to the transducer. **(C)** Incorrect alignment. Biopsy needle is aligned correctly with the center of the transducer but is angled away from the central plane.

A **bobbing** or in-and-out jiggling movement of the biopsy needle during insertion improves needle visualization. This bobbing motion causes deflection of the soft tissues adjacent to the needle and makes the trajectory of the needle much more discernible within the otherwise stationary field. Alternatively, if using a coaxial system, the inner, smaller needle can be "pumped" or moved in and out within the larger cannula.

Needle visualization can also be improved by **increasing the reflectivity** of the biopsy needle. Large-caliber needles are more readily visualized than small-caliber needles. Keeping the bevel of the needle directed toward the transducer may also increase the conspicuity of the needle tip. Some authors have found CDFI helpful to visualize needle motion,[43] although we have not routinely incorporated Doppler ultrasound into our practice. Modifications in needle tip design to enhance needle visualization include scoring the needle tip and using a screw stylet. Extrareflective needles specifically designed for ultrasound guidance are commercially available. Most needles, however, are sufficiently visible sonographically as long as the needle and transducer are aligned.

The **echogenicity** of the parenchyma of the organ undergoing biopsy also affects the visibility of the biopsy needle. If the parenchyma is relatively hypoechoic, such as liver, kidney, or spleen, the echogenic needle can usually be identified easily. Conversely, if the organ or soft tissues are relatively hyperechoic, it is usually difficult to visualize the echogenic needle tip in this background. This is particularly relevant in the biopsy of masses in obese patients or masses surrounded by complex fat, as in the retroperitoneum.

Linear or curved array transducers are frequently used for guiding procedures because of their good near-field resolution, which allows visualization of the needle after relatively little tissue penetration. The **focal zone of the ultrasound beam should also be placed in the near field** for better needle visualization. Sector transducers are often used if there is a small acoustic window or if there is a deep lesion where a steep needle approach will be needed.

Clear visualization of the biopsy needle is an important element in the success of ultrasound-guided needle biopsies. The various techniques described here can be used to enhance needle visualization. However, considerable real-time scanning **experience** remains the key factor to the successful performance of ultrasound-guided biopsies.

Specific Anatomic Applications

Liver

The liver is the abdominal organ in which percutaneous biopsy is most frequently performed. Common indications for biopsy include nonsurgical confirmation of metastatic disease, characterization of focal liver mass(es) with inconclusive imaging, and diagnosis of parenchymal disease, although random parenchymal biopsies have decreased at our own institution as a result of increasing utilization of elastography for liver fibrosis evaluation. Biopsy of large or superficial lesions is most easily done. With experience, deep lesions and lesions smaller than 1 cm can undergo accurate biopsy[44,45] (Fig. 17.4).

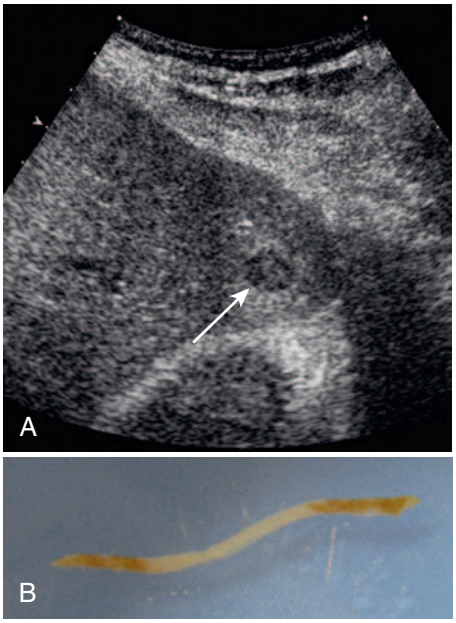

FIG. 17.4 Ultrasound-Guided Biopsy of Small Hepatic Metastasis. (A) Longitudinal ultrasound image of inferior right lobe of the liver shows a 1-cm mass *(arrow)*. **(B)** Gross photograph of the core biopsy sample shows the typical white core of pathologic tissue *(arrows)* bordered by typical-appearing normal liver parenchyma *(arrowheads)*.

In our practice, liver biopsy is almost universally performed under ultrasound guidance because of the real-time visualization of the needle. This advantage becomes particularly obvious when there is significant movement of the liver caused by respiration and diaphragm excursion.

Lesions in the left lobe of the liver and in the inferior portion of the right lobe can usually undergo biopsy through a subcostal approach. Lesions located superiorly in the dome of the liver present a technical challenge for traditional CT-guided biopsy, but real-time, off-axial imaging with ultrasound allows for accurate needle targeting of such tumors, often through an intercostal approach. Although the intercostal approach may violate the pleural space, aerated lung is rarely punctured because it is well visualized sonographically and can be avoided. We usually place the patient in a left posterior oblique rather than supine position when an intercostal approach is used to improve visibility of the liver. If working along the right side of the patient, such a position also prevents the patient from watching needle manipulation. As feasible, **orienting the transducer along the longitudinal axis** of the patient is preferable. Such orientation minimizes the interference of respiration, because the tumor and needle remain in the field of view throughout the procedure.

Benign hepatic lesions such as focal fatty infiltration, focal areas of normal liver within a fatty infiltrated liver, cavernous hemangiomas, focal nodular hyperplasia, and even atypical hemangiomas can usually be confidently characterized as benign by magnetic resonance imaging (MRI) of the liver. However, they occasionally mimic the appearance of malignancy on imaging studies. Biopsy of these processes can be done with ultrasound guidance to exclude malignancy and to confirm their benign nature if MRI findings are equivocal and especially if the

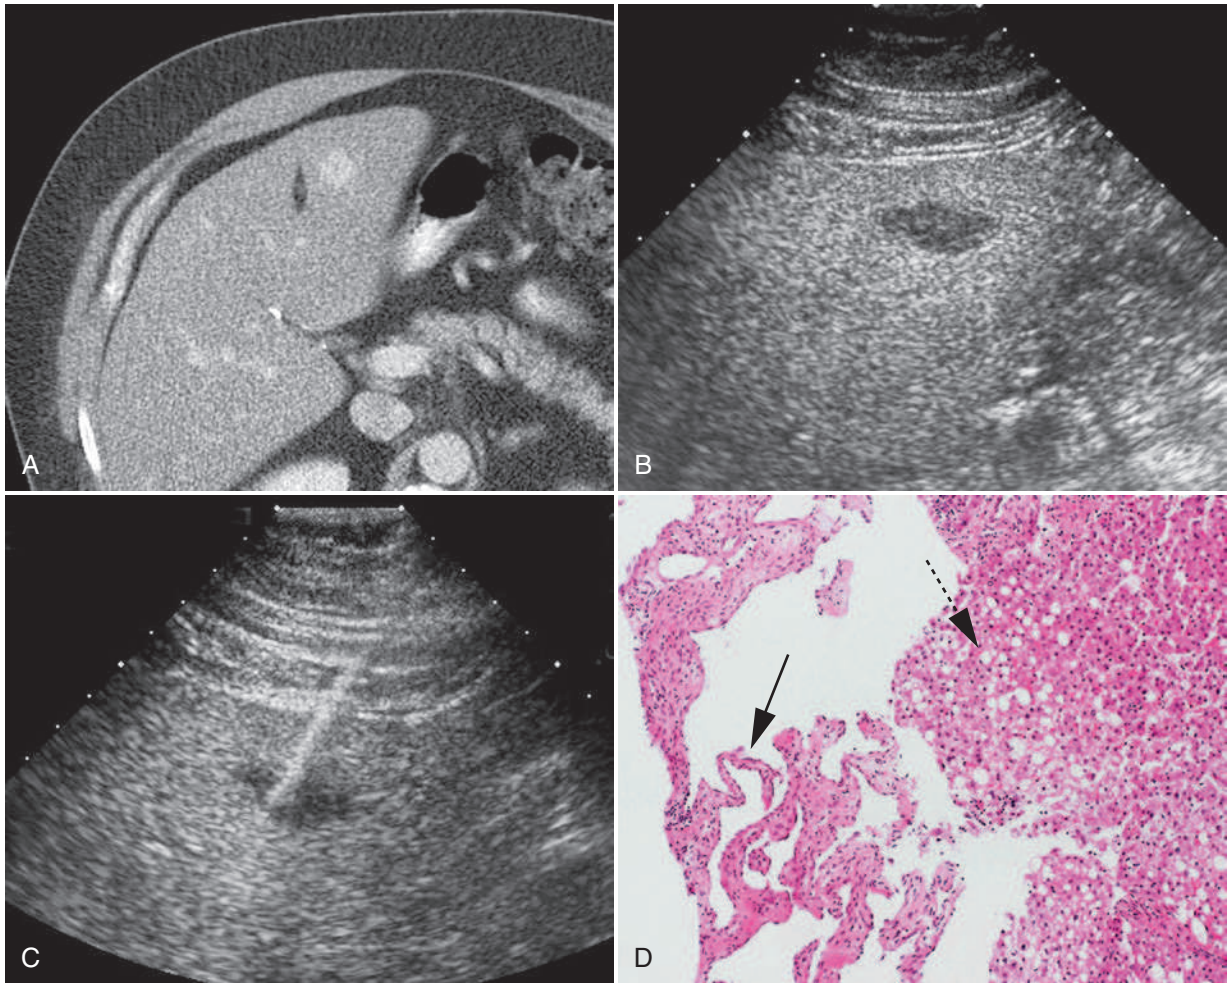

FIG. 17.5 Biopsy of Cavernous Hemangioma. (A) Contrast-enhanced CT scan shows a 1.5-cm vascular mass in left lobe of the liver. **(B)** Transverse ultrasound demonstrates a hypoechoic ellipsoid mass in a fatty infiltrated liver. **(C)** Ultrasound-guided biopsy using an 18-gauge needle. **(D)** Histologic specimen shows endothelial-lined vascular spaces *(arrow)* diagnostic of cavernous hemangioma, as well as small, round, fat globules *(dashed arrow)* within hematoxylin and eosin–stained hepatocytes.

patient has a known primary malignancy (Fig. 17.5). Although **cavernous hemangiomas** are vascular lesions, these masses have undergone successful percutaneous biopsy without significant complications.[46-48] Particular care must be taken to avoid direct puncture of cavernous hemangiomas without intervening liver parenchyma because this may result in significant bleeding.[49] Normal overlying liver may tamponade potential bleeding from the hemangioma in these cases. Significant bleeding after direct puncture of hypovascular liver masses is less of a concern.

There has been increasing interest in biopsy of suspected **hepatic adenomas** as a result of evolving classification schemes and subtyping. Different subtypes carry different potential for bleeding and malignant transformation and this has implications for patient management.[50] Although biopsy of hepatic adenoma is safe, there remains a small risk of discordant pathology results between initial biopsy and either subsequent biopsy or surgical resection specimen based on pitfalls in pathologic interpretation and occasional overlap in histologic features between adenoma, focal nodular hyperplasia, and hepatocellular carcinoma. In a series that included biopsy of 60 suspected hepatic adenomas, 6 (10%) showed discordant at time of follow-up pathology, including 4 later diagnosed as focal nodular hyperplasia and two later diagnosed as hepatocellular carcinoma.[51]

Percutaneous ultrasound-guided biopsy of **portal vein thrombus** has proved to be a safe and accurate diagnostic procedure for staging of hepatocellular carcinoma, although also performed less frequently in the context of advanced MRI techniques.[52]

Liver biopsies are relatively safe, with an overall significant complication rate of less than 1%.[16,24,53-59] Hemorrhage is most common. Such significant bleeding complications are more likely to occur in the biopsy of patients with malignancy and those with acute liver failure, chronic active hepatitis, or cirrhosis.[58,60,61] Most complications occur soon after the biopsy procedure, with about 60% occurring within 2 hours and 80% within 10 hours.[58] Several large series report mortality of percutaneous liver biopsy as 0.1% or less.[27,58-60]

Pancreas

Despite the growing use of **endoscopic ultrasound** (EUS) and EUS-guided FNA, percutaneous biopsy of pancreatic tumors remains necessary in some cases when the tumor is in the tail

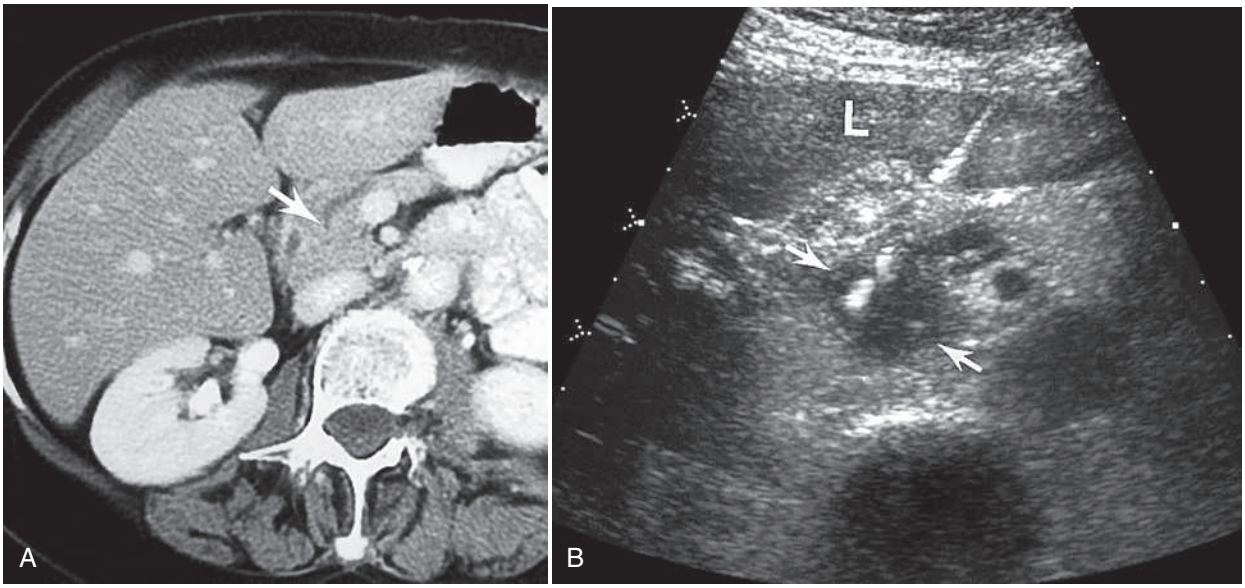

FIG. 17.6 Ultrasound-Guided Pancreatic Biopsy. (A) Contrast-enhanced CT scan shows a mildly dilated pancreatic duct with abrupt termination in the head of the pancreas *(arrow).* No definite mass is identified on CT scan. **(B)** Ultrasound for guided biopsy shows a 19-gauge needle passing through left lobe of the liver *(L),* with needle tip within a 2-cm hypoechoic mass in the head of the pancreas *(arrows).* The biopsy was positive for adenocarcinoma.

of the pancreas or when EUS is unavailable. Biopsy is occasionally required to document malignancy or differentiate malignancy from a benign condition, such as focal pancreatitis.

At our institution, most pancreatic biopsies are done with CT guidance because depth of the pancreas and presence of overlying bowel gas and hyperechoic abdominal fat can make visualization of the needle difficult. Nevertheless, biopsy of pancreatic masses in normal-size and slender patients can be done accurately under ultrasound guidance (Fig. 17.6).

The **gastrointestinal (GI) tract** may be traversed when biopsying the pancreas. With ultrasound, the stomach or bowel is either displaced or compressed. Brandt et al.[4] demonstrated the safety of traversing the GI tract (stomach, small bowel, colon) in performing percutaneous biopsies in 66 procedures. Most of these biopsies were performed using a 21-gauge needle, with no complications related to the biopsy route in these patients.

A particular advantage of ultrasound over CT is the ability to biopsy pancreatic masses in an off-axis plane, which is very useful if overlying vessels are present on CT. Ultrasound-guided biopsy has 93% to 95% accuracy, compared with 86% to 100% accuracy for CT guidance.[4,62,63]

In some series, the biopsy success rate for the diagnosis of pancreatic carcinoma has been lower than the success rate for the diagnosis of malignant lesions in other organs of the abdomen.[4,64,65] This may be related to sampling error, because significant desmoplastic reaction often accompanies pancreatic adenocarcinoma. By targeting the central hypoechoic portion of the pancreatic mass, the clinician can improve the diagnostic yield. In addition, core biopsy, either alone or in addition to FNA, results in improved diagnostic performance compared with FNA alone.[63]

The differentiation between **benign serous** and potentially **malignant mucinous pancreatic tumors** can be difficult with imaging alone. Unfortunately, cystic pancreatic malignancies are difficult to accurately diagnose with percutaneous biopsy; a definitive diagnosis was achieved in only 60% of patients in one study.[66] In biopsy of a cystic pancreatic lesion, it is critical to obtain **epithelial cells,** either in the wall of the lesion or within the cyst fluid. Analysis of **percutaneous fluid aspirates** from a cystic lesion has also been proposed as an aid to distinguish cystic neoplasms from pseudocysts.[66-68] A high amylase level is consistent with a pseudocyst. The presence of tumor markers with the cyst fluid may also be helpful in suggesting a cystic neoplasm.

The safety of percutaneous biopsy of the pancreas has been well established, with a complication rate of 0.8% to 2%.[4,16,24,69] A historic review reported six deaths related to pancreas biopsy.[70] Five of these deaths were attributed to pancreatitis and one to sepsis. No pancreatic cancer was found in either the biopsy specimen or the postmortem examination of these patients, suggesting an increased risk for developing pancreatitis after biopsy of normal pancreas. In this same large review of percutaneous biopsies, 10 of 23 cases of needle track seeding occurred after the biopsy of pancreatic malignancies. For this reason, biopsy may not be indicated in patients who are surgical candidates.

Kidney

Biopsy of the kidney is performed to assess intrinsic parenchymal disease or to characterize a renal mass (Fig. 17.7). Although there has been long-standing acceptance of **renal mass biopsy** for suspected metastasis, lymphoma, abscess, or unresectable suspected renal cell carcinoma, biopsy of potentially resectable suspected renal cell carcinoma has historically been controversial because of concerns regarding accuracy and safety as well as questionable impact on patient management.[71] In recent years, however, incidental detection of potentially benign small renal

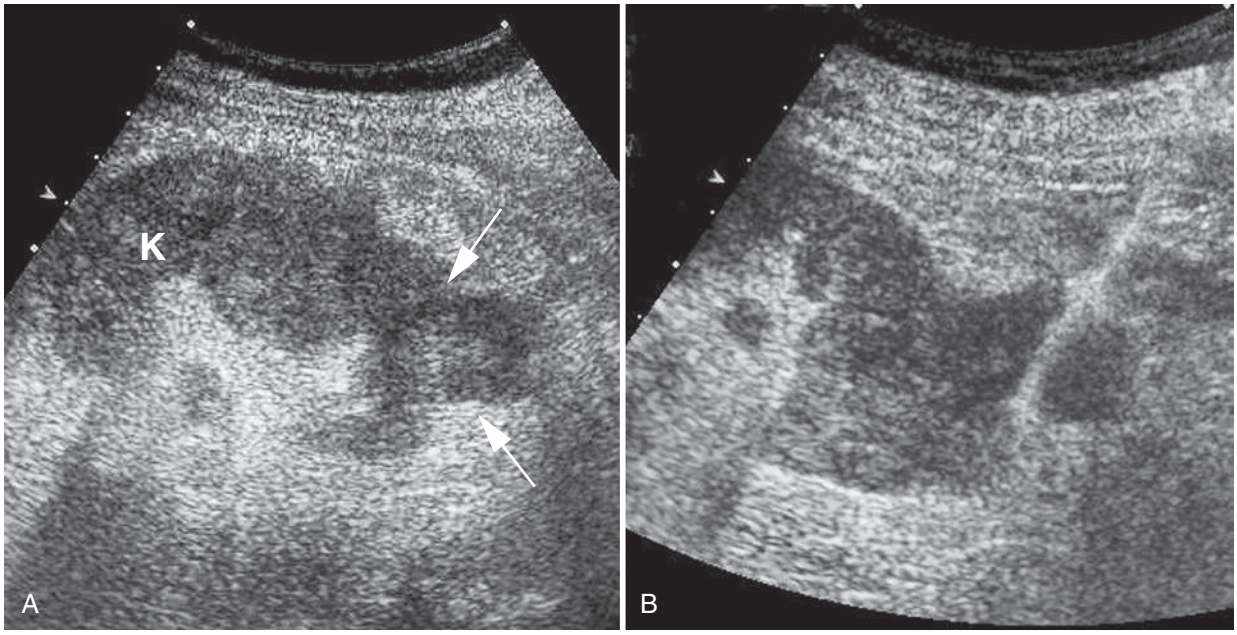

FIG. 17.7 Ultrasound-Guided Biopsy of Renal Mass. (A) Longitudinal image shows a 2-cm solid mass *(arrows)* extending from lower pole of the left kidney *(K)*. **(B)** Mass was biopsied using an 18-gauge biopsy device, confirming renal cell carcinoma.

masses has increased and both biopsy accuracy and safety profiles have improved. Current literature shows diagnostic rates for renal mass biopsy of 85% to 92%.[72,73] Other authors have also shown exceptional results,[74-76] but these studies are in some cases limited by the mode of determining true-negative results, which is based on stability on imaging follow-up. However, we know that the lack of growth in a renal mass does not imply a true-negative result, because 25% of renal tumors will not grow.[77] Nondiagnostic biopsies are more common in cystic or nonenhancing masses especially if small (<4 cm) or deep (>13 cm skin-to-tumor distance).[73]

It is helpful to keep in mind that the smaller the renal mass is, the more likely it is to be benign.[78,79] In one large series, 46% of tumors less than 1 cm were benign.[78] Cross-sectional imaging has allowed accurate characterization of many benign renal masses, notably benign **cysts** and fat-containing **angiomyolipomas.** The problem is with the indeterminate, small, enhancing renal mass, specifically the **oncocytoma, small renal cell carcinoma, and lipid-poor angiomyolipoma,** which cannot be reliably differentiated by imaging.[80] For these reasons and because a wider range of treatment options, including active surveillance and ablation, is available to patients, renal mass biopsy is being increasingly utilized. The current guidelines of the American Urological Association state that renal mass biopsy is appropriate for patients with a clinical stage 1 renal mass (confined to the kidney and ≤7 cm) in whom a wide range of management options are under consideration, ranging from surgery to observation. When performed in the appropriate circumstances, biopsy may affect a change in clinical management in 40% of patients.[74]

Sonographic guidance can be used in the biopsy of kidneys with **diffuse parenchymal disease.** Insertion of the needle into the cortex of the lower-pole renal parenchyma with tip directed away from the central hilum under continuous real-time guidance results in few complications and produces a tissue sample of excellent quality for analysis. An **18-gauge biopsy needle** provides a specimen that is equivalent in diagnostic quality to the biopsy specimen obtained by the traditional 14-gauge cutting needle.[81] In fact, Hergesell et al.[19] found a 99% success rate in obtaining diagnostic tissue using an 18-gauge needle, with only 0.36% of patients experiencing a significant bleeding complication. In this series, postbiopsy ultrasound revealed a clinically occult hematoma greater than 2 cm in 2% of patients. Similarly, asymptomatic hemorrhage may be detected by CT in up to 90% of patients after uncomplicated kidney biopsy.[82] **Arteriovenous (AV) fistulas** may be seen in about 10% of patients immediately after kidney biopsy and usually resolve spontaneously (Fig. 17.8).

Clinically important bleeding is the most serious complication after kidney biopsy, occurring in 0.3% to 6.6% of patients.[16,17,23] Gross hematuria may occur in 5% to 7% and usually stops within 6 to 12 hours.[83] Microscopic hematuria occurs in up to 100% of patients and should not be regarded as a complication.

Adrenal Gland

The most common indication for adrenal biopsy is to **confirm metastatic disease** in a patient with an adrenal mass and a known primary malignancy elsewhere. Currently, CT and MRI characterization of adrenal masses has supplanted biopsy in many cases in establishing benignity of an adrenal mass. Nevertheless, occasional histologic diagnosis is required. In this case, CT guidance is generally the preferred adrenal biopsy technique because of the deep location of the adrenal glands in the retroperitoneum. Percutaneous biopsy can yield a diagnosis in more than 93% of patients.[84,85]

The right adrenal gland is more accessible to ultrasound-guided biopsy than the left adrenal gland because the right lobe of the liver provides a sonographic window to optimize imaging (Fig. 17.9). Bright, echogenic, fat-containing adrenal masses and homogeneous, thin-walled, fluid-filled adrenal masses may not

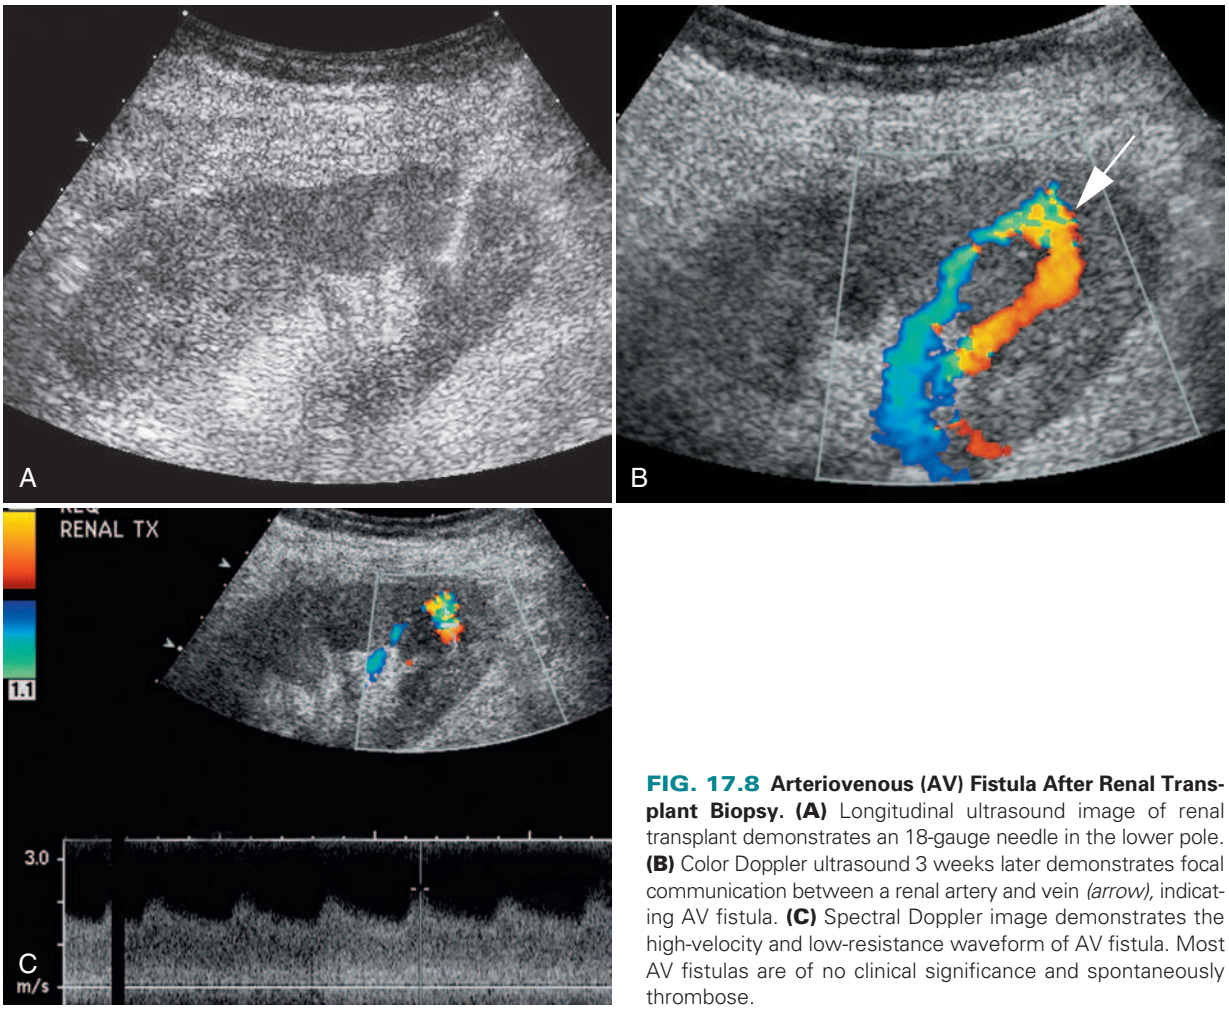

FIG. 17.8 Arteriovenous (AV) Fistula After Renal Transplant Biopsy. (A) Longitudinal ultrasound image of renal transplant demonstrates an 18-gauge needle in the lower pole. **(B)** Color Doppler ultrasound 3 weeks later demonstrates focal communication between a renal artery and vein *(arrow),* indicating AV fistula. **(C)** Spectral Doppler image demonstrates the high-velocity and low-resistance waveform of AV fistula. Most AV fistulas are of no clinical significance and spontaneously thrombose.

require biopsy because these should represent benign adrenal **myelolipomas** and **cysts,** respectively. CT or MRI can be performed to confirm this before considering biopsy.

Although **benign adenomas** can be larger than 3 cm, the likelihood of silent adrenal carcinoma increases significantly if an incidentally discovered adrenal mass is larger than 4 cm.[86] In this setting, surgical excision is recommended because biopsy will yield insufficient tissue to differentiate a benign adenoma from adrenocortical carcinoma.

Radiologists performing adrenal biopsies should be familiar with the management of a hypertensive crisis after inadvertent biopsy of a **pheochromocytoma.**[87] Although adrenal pheochromocytomas have been safely biopsied without premedication,[84] if the clinical history suggests pheochromocytoma, further laboratory tests, not biopsy, should establish the diagnosis. If biopsy is necessary, consultation with an endocrine specialist and pretreatment with alpha-adrenergic blockers and metyrosine should be considered.[88]

Spleen

The spleen is the abdominal organ that undergoes biopsy **least** often. First, isolated metastases to the spleen are exceptionally rare. In most cases, when the splenic tumor is visualized, there is concomitant disease in other abdominal organs, such as the liver or lymph nodes, in which a biopsy can be performed. Second, the spleen is a highly vascular organ, and the risk of needle biopsy would seem to be high. The reported rate of significant hemorrhage from needle biopsy varies from no hemorrhage up to 8%.[89-98] In some cases, splenectomy is required.[91,99] Pneumothorax may also occur as a complication after spleen biopsy.[97]

At this time, the main clinical reason for performing percutaneous biopsy of the spleen is to differentiate recurrent **lymphoma, metastasis,** and **infection** in a patient who has a new splenic lesion but no disease elsewhere in the abdomen (Fig. 17.10). In the immunocompromised patient, differentiation between **malignancy** and **fungal infection** can be critical in patient management. Percutaneous biopsy can yield a specific diagnosis in approximately 90% of patients.[90,91,100]

Lung

Percutaneous biopsy of the lung is typically performed with CT guidance. However, ultrasound has proved to be effective in the biopsy of masses that abut the chest wall, without the imaging interference of aerated lung parenchyma[101,102] (Fig. 17.11). Such lesions include **pulmonary, pleural,** and **mediastinal** masses. Notable advantages of ultrasound in the lung include (1) real-time guidance during patient respiration, (2) ability to biopsy efficiently in the off-axial plane, (3) ability to biopsy lesions in patients

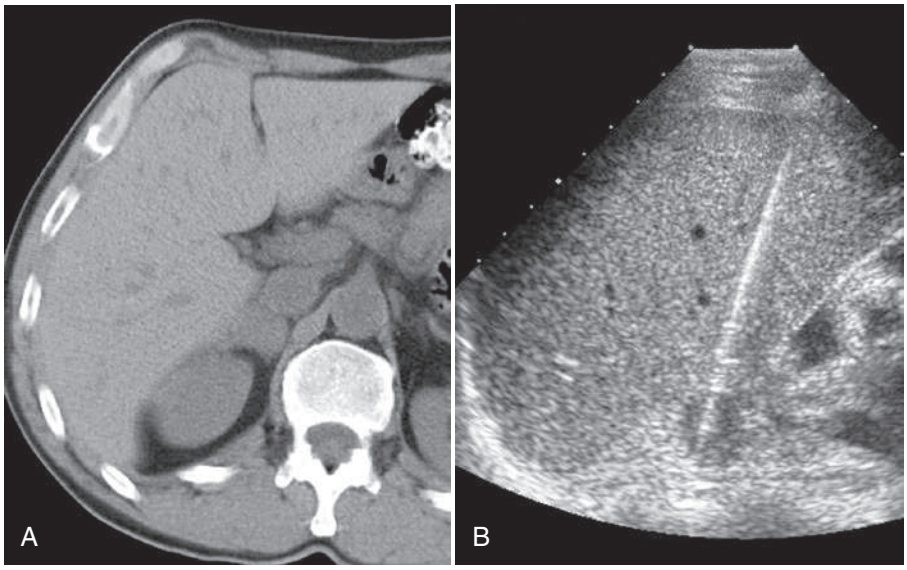

FIG. 17.9 Ultrasound-Guided Biopsy of Adrenal Mass. (A) CT scan without contrast demonstrates a 2-cm mass in the right adrenal gland. **(B)** Longitudinal ultrasound image shows value of the liver as a biopsy path to the right adrenal gland.

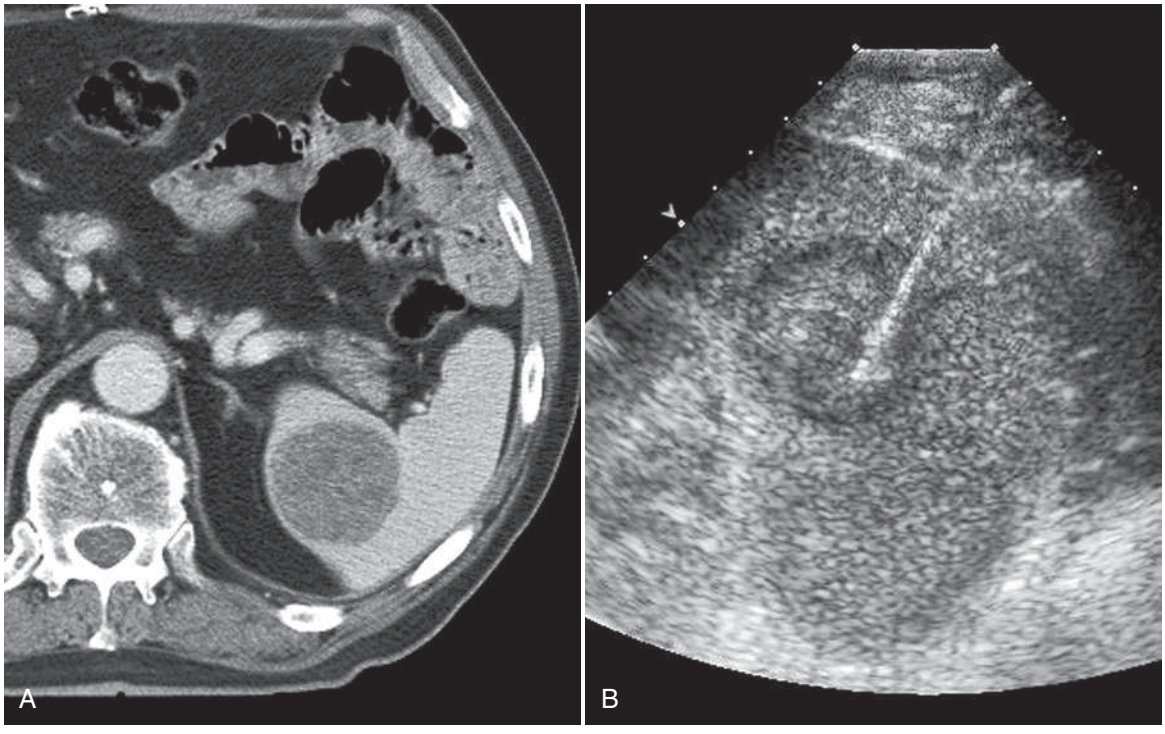

FIG. 17.10 Ultrasound-Guided Biopsy of Melanoma Metastasis to the Spleen. (A) Contrast-enhanced CT shows a 4-cm mass in the spleen. **(B)** Transverse ultrasound demonstrates the 18-gauge biopsy needle within the mass.

who would otherwise have difficulty cooperating, and (4) absence of ionizing radiation.[103] Ultrasound biopsy of mediastinal masses can be performed if the mass is visible. Mediastinal vessels in the path of the needle may be avoided with the use of color Doppler ultrasound before needle placement.

Complications

Image-guided percutaneous needle biopsy is a widely accepted mode of obtaining tissue for diagnosis, in part because of its well-documented safety. Several large reviews using multi-institutional questionnaires have reported major complication rates of 0.05% to 0.5% and mortality rates of 0.008% to 0.038%.[16,24,70,104-106]

Although rare, **hemorrhage** is the most common major complication of solid-organ biopsy and accounts for most biopsy-associated deaths. If hemorrhage is suspected after biopsy and the patient is hemodynamically stable, CT should be obtained. CT is more accurate than ultrasound to evaluate for hemorrhage.[82] On ultrasound, fresh blood has an echogenicity similar to that of surrounding tissues and can be overlooked (Fig. 17.12).

The difference in the complication rates associated with the use of larger-caliber core biopsy needles and small-caliber needles

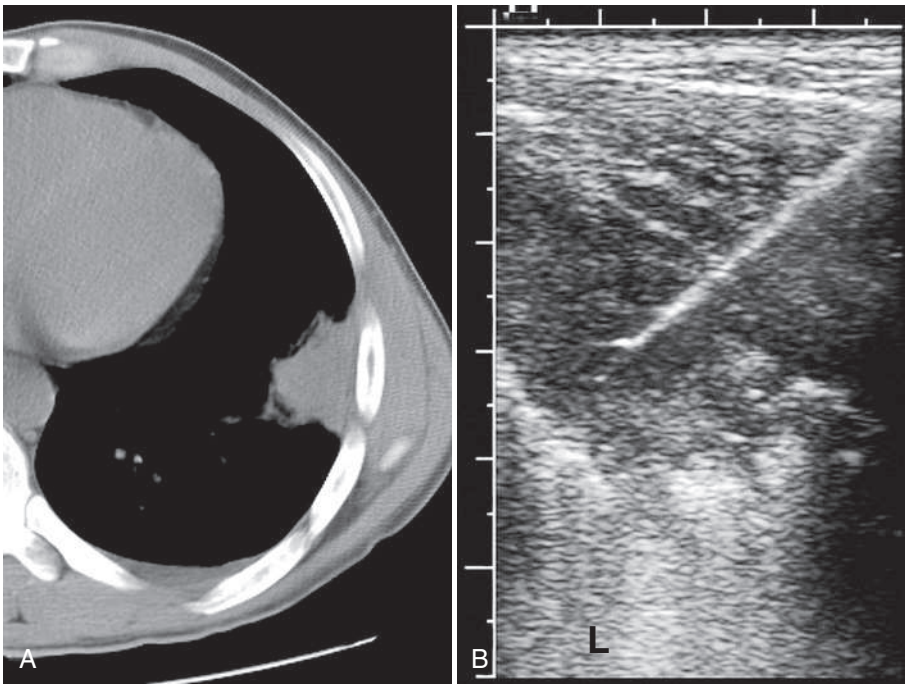

FIG. 17.11 Ultrasound-Guided Biopsy of Peripheral Lung Mass. (A) Noncontrast-enhanced CT demonstrates an indeterminate peripheral left lung mass. **(B)** Oblique ultrasound image shows a 20-gauge biopsy needle isolated within the hypoechoic mass, which is surrounded by aerated lung *(L)*. Biopsy confirmed histoplasmosis.

is not as great as might be expected. An early comparative study found complication rates of 0.8% with fine needles (22 gauge) and 1.4% with large-caliber needles (14 and 18 gauge); this difference was not statistically significant.[107] In addition, the larger needles provided a diagnostic tissue in 90% of biopsies compared with 65% in fine-needle biopsies. Welch et al.[108] found equal rates of complications from the use of 18-gauge and 21-gauge biopsy needles (0.3%).

Other major complications secondary to biopsy include **pneumothorax, pancreatitis, bile leakage, peritonitis,** and **infection** (Fig. 17.13). An exceedingly rare complication (0.003%),[70] **needle track seeding** has been reported after biopsy of various malignancies, including those arising from the pancreas, prostate, liver, kidney, lung, neck, pleura, and retroperitoneum.[70,109-120] Because seeding is so rare, in most cases it should not affect the decision to perform percutaneous biopsy.

Minor complications more often encountered include **vasovagal reactions** and **pain.**

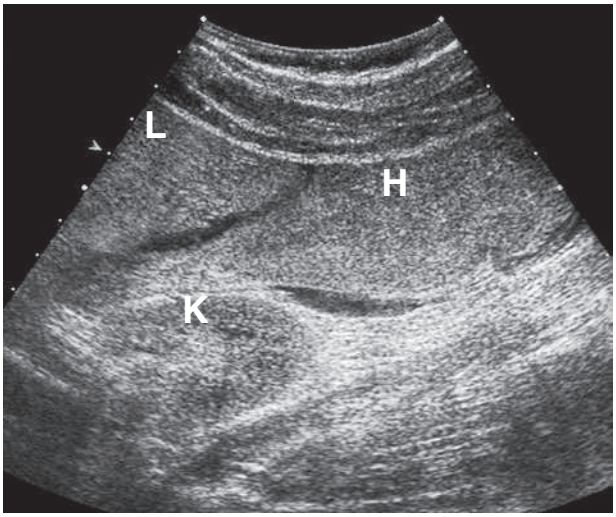

FIG. 17.12 Isoechoic Hematoma After Biopsy of Pancreas Transplant. Large, fresh, postbiopsy intraperitoneal hematoma *(H)* is isoechoic with the adjacent liver *(L)* and right kidney *(K)*. Newly evolving clot (<30 min) can be echogenic and therefore overlooked.

ULTRASOUND-GUIDED DRAINAGE

As with needle biopsy, percutaneous aspiration and drainage procedures have gained wide acceptance in clinical practice because of their safety, simplicity, and effectiveness. Ultrasound provides precise needle guidance to allow for needle aspiration or catheter drainage of superficial and deep fluid collections throughout the body.

Indications and Contraindications

Original criteria for percutaneous drainage specified that the fluid collection be unilocular with no communications, and surgical backup was considered essential.[121,122] Currently, percutaneous abscess drainage is performed safely for solitary, multilocular, and multifocal fluid collections with or without communication to the GI tract.[122,123] Such collections include complex solid-organ **abscesses,** enteric-related abdominal abscesses (e.g., caused by **appendicitis** and **diverticulitis**), **tubo-ovarian abscesses,** and **percutaneous cholecystostomy** for an inflamed gallbladder. Percutaneous drainage is more likely to be successful in abscesses with air-fluid levels or superficial gas collections, whereas abscesses with deep, trapped gas bubbles are less likely to be successfully managed with percutaneous drainage.[124] Poorly defined fluid in the peritoneum with an

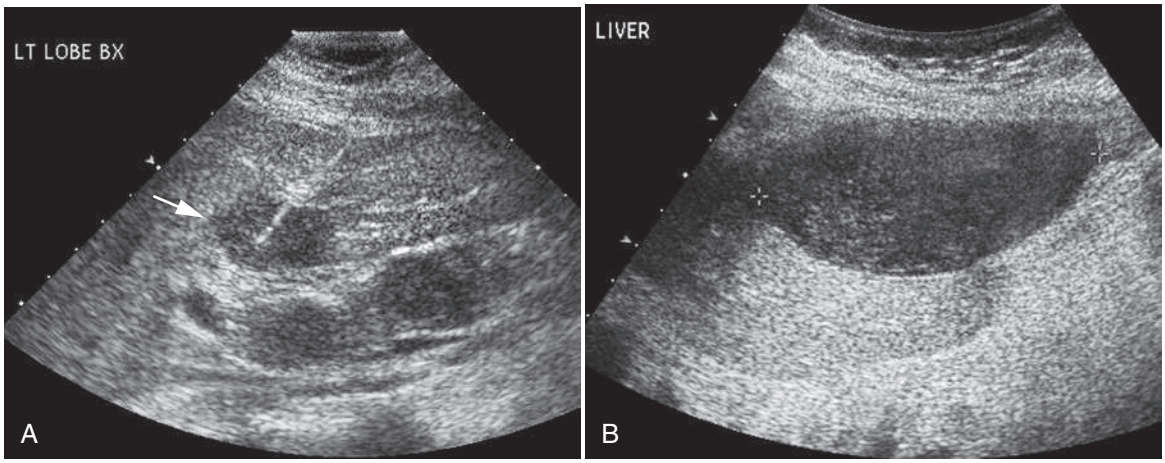

FIG. 17.13 Abscess After Liver Mass Biopsy. (A) Transverse ultrasound image shows an 18-gauge biopsy needle in a 3-cm metastasis *(arrow)*. **(B)** Longitudinal image obtained 2 weeks later demonstrates a 6-cm debris-containing fluid collection, anterior to left lobe of the liver, at biopsy site. Subsequent aspiration and drain placement confirmed abscess.

underlying surgically correctable abnormality (e.g., perforated bowel) is better treated with surgery.

Most percutaneous abscess drainage is performed to achieve a cure without the need for surgery. In other patients, it is a temporizing procedure that either postpones definitive surgery until the patient is stable (e.g., periappendiceal abscess drainage) or permits a single-stage rather than a multistage surgery (e.g., peridiverticular abscess drainage). This is particularly desirable in high-risk, medically complicated patients who present with sepsis.

Contraindications to image-guided percutaneous catheter drainage are all relative and are similar to those for percutaneous biopsy. Although uncommon, lack of a safe route for percutaneous drainage precludes the procedure. Unlike percutaneous biopsy, in which bowel may be traversed without complication, fluid aspiration and percutaneous abscess drainage through bowel should be avoided. Initial advancement of the drain through normally contaminated bowel may seed a sterile fluid collection, resulting in iatrogenic infection. In addition, drain placement through bowel may result in not only significant perforation but also enteric fistula.

Bleeding diathesis should be maximally corrected before drain placement, and appropriate sedation (local and systemic) should be given.

Imaging Methods

Selection of ultrasound or CT for guidance of aspiration and drainage is influenced by several factors, including the location of the fluid collection and the strengths and weaknesses of each imaging modality, as discussed earlier. For example, a **simple paracentesis** is best performed under ultrasound guidance (Fig. 17.14). More complicated drainage procedures in the retroperitoneum or pelvis are best performed with CT guidance. More **superficial abdominal fluid collections** may be aspirated or drained easily with ultrasound guidance. Obtaining a CT scan before the procedure often provides a more detailed view of potentially deeper components to the collection and an anatomic map for planning a safe access route.

FIG. 17.14 Ultrasound-Guided Paracentesis. Longitudinal image shows a 5-French angiocatheter with side holes in the left lower peritoneal cavity during a paracentesis.

In certain anatomic areas, such as the gallbladder, biliary tract, and kidneys, combined ultrasound and **fluoroscopic guidance** of catheter placement may be preferred. The combined use of ultrasound for initial needle placement and fluoroscopy for catheter placement, using the **guidewire exchange technique** (Seldinger), optimizes the strengths of both guidance modalities. Fluoroscopy can then be used to opacify the area drained and confirm final catheter placement and adequacy of drainage.

No single method of guidance for percutaneous drainage is appropriate for all abdominal fluid collections or abscesses. The approach to any fluid collection or potential abscess must be tailored to the patient, procedure, and specific circumstances.

Catheter Selection

Various catheters and introducing systems are available for percutaneous abscess drainage; choice depends mainly on operator preference. As with most interventional procedures, the clinician or radiologist must be familiar and comfortable with the system

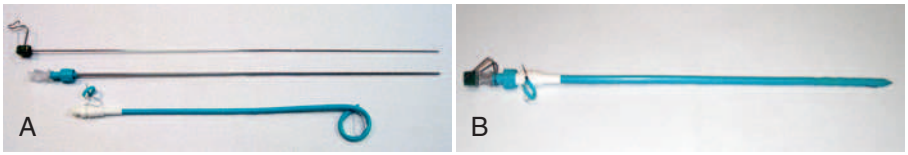

FIG. 17.15 Locking-Loop Drainage Catheter. (A) Three components of the locking-loop catheter are sharpened inner stylet *(top),* stiffener *(middle),* and catheter with distal locking loop *(bottom).* **(B)** Assembled catheter is ready for placement using trocar technique.

chosen. In general, thicker fluid is best drained with larger-caliber catheters. A 10- to 14-French catheter provides adequate drainage for most abscesses. Smaller (6-8 French) catheters are adequate for less viscous collections. Catheters with retention devices, such as a locking loop, are frequently used to prevent catheter dislodgement (Fig. 17.15).

Patient Preparation

The procedure and risks should be explained to the patient and informed consent obtained. The patient's hemostatic status should be assessed through clinical history, and recent coagulation studies should be available. We routinely require platelets and PT for drainage procedures. IV access is obtained in all patients for administration of medications and for emergency access, in the event of a complication, such as hemorrhage, sepsis, or hypotension. Patients often receive broad-spectrum antibiotics intravenously to decrease the risk of sepsis. Satisfactory analgesia is necessary throughout the procedure to provide optimal patient comfort and cooperation. Local anesthesia is usually sufficient for needle aspiration; however, IV sedatives and analgesics such as midazolam (Versed) or fentanyl (Sublimaze) are beneficial for percutaneous catheter insertion; dilation of the drain tract can be extremely painful to the patient.

Diagnostic Aspiration

Because fluid collections often have a nonspecific appearance, diagnostic aspiration is the first step. A fine needle is guided into the fluid collection by the selected imaging modality. This needle insertion defines a precise and safe route to the fluid collection. A small amount of fluid is aspirated and sent for appropriate microbiologic evaluation. The resulting culture and sensitivity data are used to direct the antibiotic therapy. If the fluid does not appear infected (i.e., clear, colorless, and odorless), the radiologist may elect to aspirate the cavity completely and not perform the drainage procedure. This is important, because a catheter placed in a sterile fluid collection will eventually serve as a nidus of infection, with subsequent infection of the collection. If pus is aspirated, care should be taken to aspirate only a small amount of fluid, because any decrease in the cavity size may make subsequent catheter placement more difficult.

Catheter Placement

Catheter insertion can be performed using the trocar or the Seldinger technique; the choice usually depends on operator preference. In the **trocar technique** the catheter fits over a stiffening cannula, and a sharp inner stylet is placed within the cannula for insertion (see Fig. 17.15). The catheter assembly is advanced into the fluid collection. The catheter is then pushed from the cannula, and the distal loop is formed and tightened to secure the catheter within the fluid collection. This method works best for large and superficial fluid collections.

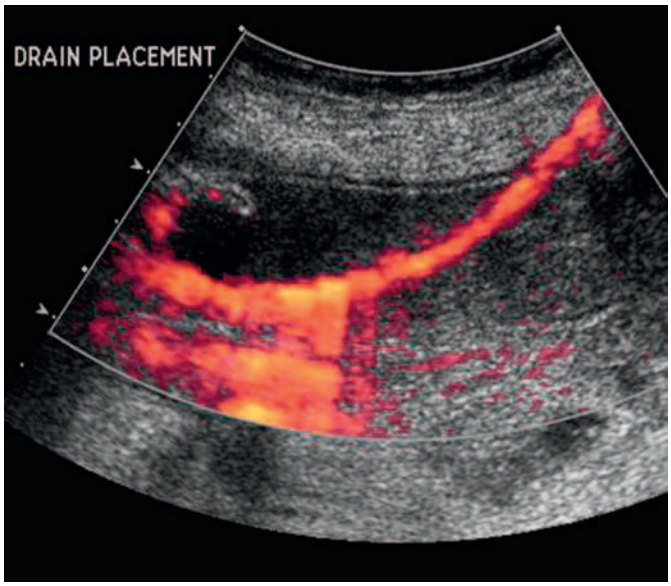

FIG. 17.16 Drain Within Deep Pelvic Abscess. With aspiration of the abscess and subsequent fluid motion within the drain, longitudinal transperineal Doppler ultrasound image shows a color shift, allowing good visualization of the catheter.

With the **Seldinger technique** (guidewire exchange technique), a guidewire is advanced through the aspiration needle and coiled within the fluid collection. The needle is then removed, and the guidewire is used as an anchor for passage of a dilator to widen the catheter track. The catheter-cannula assembly is placed over the guidewire into the fluid collection. The guidewire and inner cannula are removed as the catheter is simultaneously advanced. The distal locking loop of the catheter is re-formed to prevent catheter dislodgement. If the catheter is difficult to see with ultrasound, the use of CDFI may improve conspicuity. During aspiration or irrigation, Doppler shifts improve catheter visualization (Fig. 17.16, Video 17.5).

Final positioning of the catheter is important in maximizing the effectiveness of drainage. For this purpose, ultrasound and CT are complementary and at times should be used together. CT provides an anatomic road map for ideal catheter placement. Because this ideal position seldom lies in the true axial plane, ultrasound can be used to direct the needle, guidewire, and catheter into the ideal position. Final placement can then be verified with CT.

Drainage Procedure

After the drainage catheter is placed, the cavity is completely aspirated and gently irrigated. Care should be taken not to distend the cavity during the irrigation because this may increase the risk of bacteremia. Repeat images are obtained to determine the size of the residual cavity, the position of the drainage tube, and whether the entire abscess communicates with the drainage tube. If the abscess cavity has not completely resolved, the drainage catheter may need to be repositioned, or a second drain may need to be placed. Such manipulations are often performed under fluoroscopy the day after initial drain placement. Correct catheter position and adequate catheter size are the most important factors for successful drainage.

Follow-Up Care

All drains must be **irrigated regularly.** Injection and aspiration of 10 mL of isotonic sterile saline three or four times daily is usually sufficient. If drainage is especially tenacious or the abscess is large, more frequent irrigations with greater volumes of saline may be necessary. The flu id collection can be drained dependently or by low, intermittent suction. The character and volume of the output should be recorded each nursing shift and checked daily on rounds by the radiology service. If the drainage changes significantly in volume or character or if fever recurs, the patient should be reexamined to check for fistulas, catheter blockage, reaccumulation of the abscess, or a previously undiagnosed collection.

From 24 to 48 hours after tube placement, a sinogram may be performed to look at the abscess cavity size, completeness of drainage, and catheter position and to look for fistulas. Simple abscess cavities may drain for 5 to 10 days. Abscesses secondary to fistulas from bowel, biliary, or urinary tracts may drain for 6 weeks or longer. Follow-up sinograms can be performed as clinically indicated based on collection complexity and amount and character of drainage. Many patients can be cared for on an outpatient basis once stable.

Catheter Removal

The three criteria for catheter removal are as follows:

1. Negligible drainage over 24 hours
2. Afebrile patient
3. Minimal residual cavity

Drains in small, superficial abscess cavities can be pulled all at once, whereas drains in large, deeper cavities may be gradually removed over a few days, which promotes healing by secondary intention.

Abdominal and Pelvic Abscesses: General

Most abdominal and pelvic abscesses are secondary to underlying bowel disease or seen after surgery. Percutaneous abscess drainage for postoperative abdominal abscesses has become the accepted primary treatment of choice, with cure being the expected goal. Percutaneous drainage has also played a principal role in the treatment of **diverticular, appendiceal,** and **Crohn disease**–related abscesses.[125-127] Drainage of abscesses in these acutely ill patients can help alleviate sepsis and allow the necessary curative surgery to be performed on an elective basis.

Drainage of **abdominal abscesses** is often best performed with CT guidance, which allows the best visualization and avoids adjacent bowel loops. CT also provides an overview of the entire abdomen, to ensure all collections are drained. Ultrasound can provide excellent guidance for percutaneous abscess drainage; however, careful review of CT imaging assists in planning an optimal approach free of intervening bowel. Unlike CT, ultrasound is especially valuable in the treatment of critically ill patients who cannot be transported to the radiology department.

Pelvic abscesses are of variable origin and have been notoriously difficult to access because of their deep location, overlying bowel, blood vessels, and urinary bladder. Traditional approaches include an **anterior transperitoneal** approach or a **posterior transgluteal** approach. The transgluteal approach is relatively painful, and care must be taken to avoid the sciatic nerve. Small, deep pelvic abscesses may be difficult to access safely using traditional approaches.

Ultrasound-guided **transvaginal drainage** has been established as a viable alternative to these traditional approaches[128,129] (Fig. 17.17). Needle guides are available for endovaginal probes that help guide the needle into the fluid collection (Videos 17.6 and 17.7). This transvaginal approach can be used to drain tuboovarian abscesses unresponsive to medical treatment. The trocar technique may also be used successfully for transvaginal drain placement. **Transrectal** ultrasound-guided drainage has also been described in the drainage of pelvic fluid collections,[130] but such an approach is infrequently used.

For **nonpurulent pelvic collections,** immediate catheter drainage is not necessarily indicated. Many of these patients respond to a one-step aspiration, lavage, and antibiotic therapy based on results of cultures of the aspirates.[131,132]

Enteric abscesses often have communication with the GI tract. For these abscesses to be drained successfully, the GI communication first must be recognized, then allowed to heal and close before removal of the catheter. Fistulas will not close if there is distal obstruction, tumor, or persistent infection. Even with the most aggressive techniques, however, success in treating abscesses with enteric communication is lower than for noncommunicating abscesses.[133,134] A particular challenge exists in the percutaneous treatment of Crohn disease–related abscesses. Obviating surgery in the short term can only be achieved in about 50% of patients, with a much lower success rate in patients with preexisting bowel fistulas.[127,135] **Enterocutaneous fistulas** may develop along the drain tract in these patients.

Specific Anatomic Applications

Liver

In addition to antibiotics, percutaneous aspiration or drainage should be considered as a primary treatment for most **pyogenic liver abscesses** (Fig. 17.18). Pyogenic liver abscesses are most often caused by (1) hematogenous seeding from intestinal sources, such as **appendicitis** or **diverticulitis;** (2) direct extension from **cholecystitis** or **cholangitis** (Fig. 17.19); or (3) surgery or trauma.

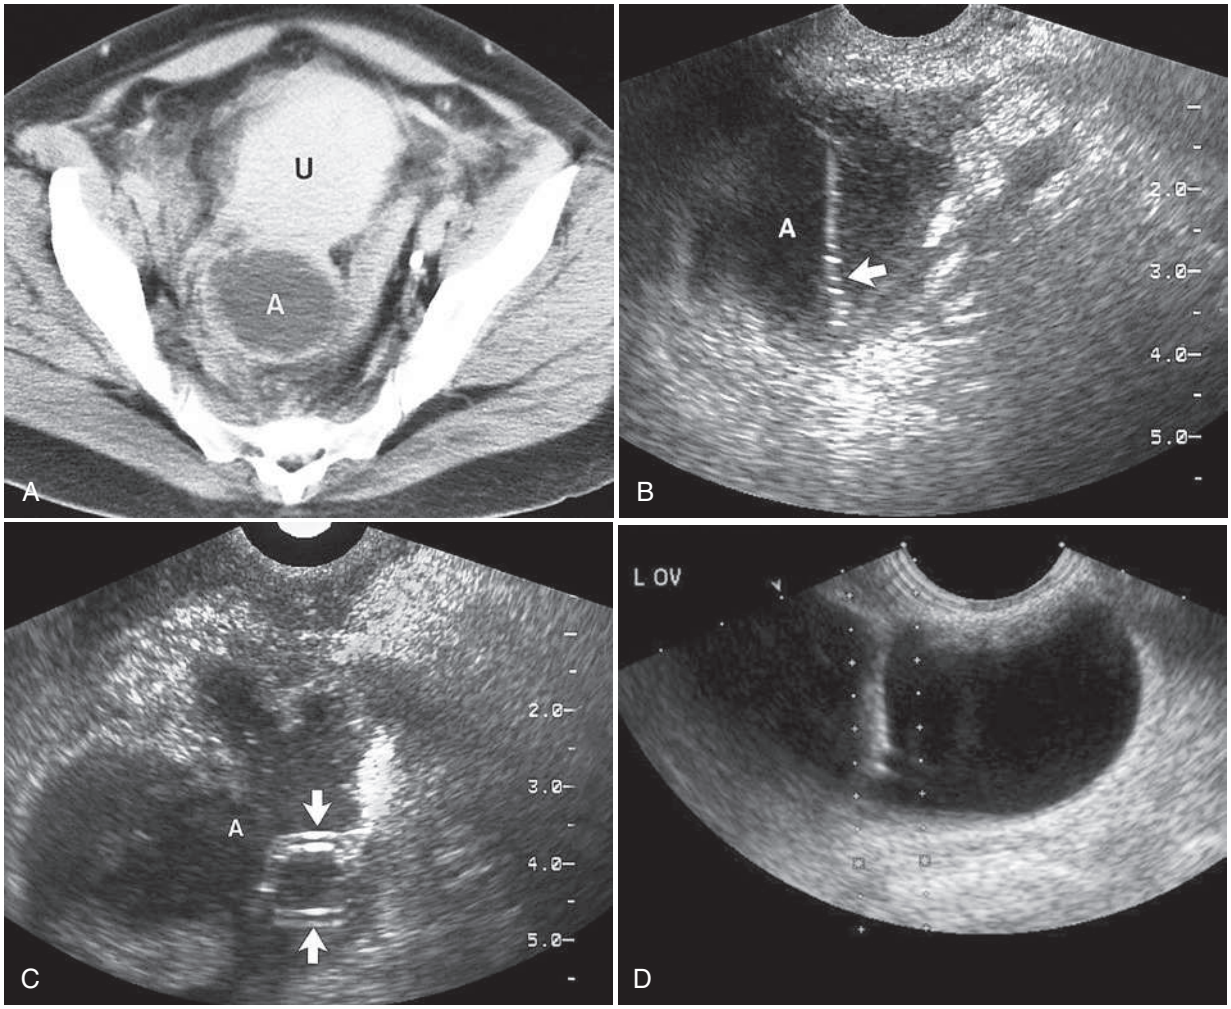

FIG. 17.17 Ultrasound-Guided Transvaginal Drainage of Pelvic Abscess. (A) Contrast-enhanced CT scan shows an abscess *(A)* deep in the pelvis, posterior to the uterus *(U)*. **(B)** TVS shows needle tip *(arrow)* in abscess cavity *(A)*. **(C)** With the catheter exchange technique, a locking-loop catheter *(arrows)* was inserted into the abscess cavity for drainage. **(D)** In a different patient, TVS shows needle within adnexal cyst at time of aspiration centered within needle guide markers.

As with abscesses elsewhere in the body, the sonographic appearance of hepatic abscess is usually a complex fluid collection. Both ultrasound and CT provide excellent guidance for percutaneous aspiration or drainage of hepatic abscesses, with a 67% to 94% cure rate.[133,136-138]

Some suggest treating pyogenic liver abscesses with antibiotics and percutaneous needle aspiration alone, without catheter drainage, although multiple aspiration procedures may be required.[139] Such an approach is particularly reasonable in smaller abscesses, less than 5 cm.[140,141] Multiple small (<1 cm) **microabscesses** are typically treated with antibiotics alone after diagnostic aspiration.[142] Final cure often depends on identification and appropriate treatment of the infectious source.

Amebic liver abscesses are caused by *Entamoeba histolytica*. Most amebic liver abscesses are effectively treated with metronidazole alone with 85% to 95% success.[143,144] However, percutaneous abscess drainage of amebic abscesses is indicated if the diagnosis is uncertain, the cavity is large (>5 cm) or enlarging, pyogenic superinfection is a concern, or there are signs of abscess cavity rupture.[144,145] Catheter drainage in these situations is safe and generally provides a rapid cure.

Historically, liver **hydatid abscesses** caused by *Echinococcus granulosus* were considered a contraindication to percutaneous abscess drainage because of the concern of **anaphylactic reaction** to cyst contents. More recently, these abscesses have been successfully treated with percutaneous aspiration combined with appropriate anthelmintic therapy.[146]

Complications of percutaneous hepatic abscess drainage include sepsis, hemorrhage, and catheter transgression of the pleura. Sepsis may occur in up to 25% of patients, even with antibiotic therapy.[141] Intercostal placement of a drain should be avoided; such a path could introduce bacteria into the pleural space.

Biliary Tract

Gallbladder. Percutaneous **cholecystostomy** has evolved into a favorable alternative to surgery in critically ill patients with **acute calculous** and **acalculous cholecystitis.** In contrast to

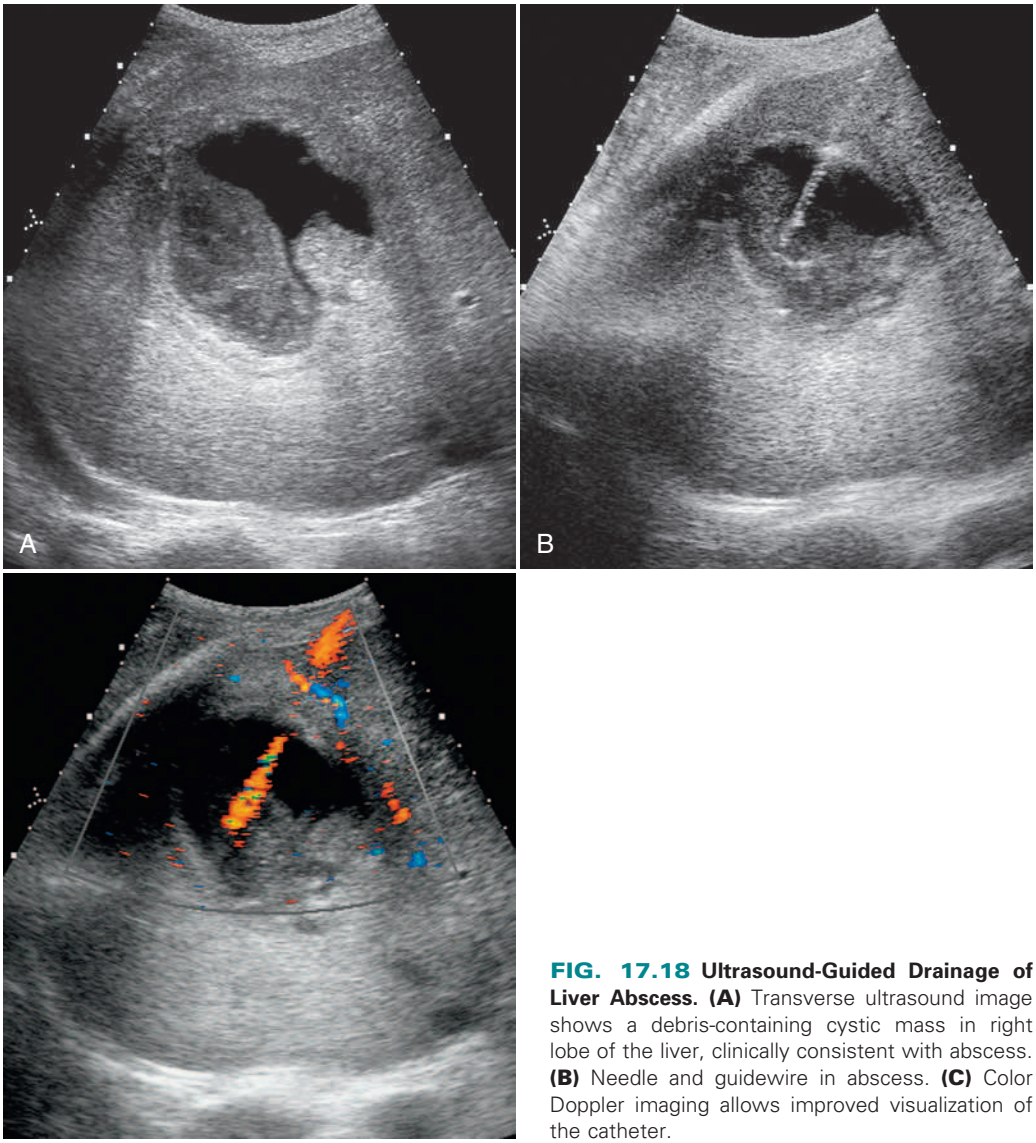

FIG. 17.18 Ultrasound-Guided Drainage of Liver Abscess. (A) Transverse ultrasound image shows a debris-containing cystic mass in right lobe of the liver, clinically consistent with abscess. **(B)** Needle and guidewire in abscess. **(C)** Color Doppler imaging allows improved visualization of the catheter.

surgical cholecystostomy, a major advantage of ultrasound-guided cholecystostomy is that the procedure can be performed at the patient's bedside. Thus critically ill patients need not be moved to the operating room or the radiology department. Similar to other drainage procedures, the cholecystostomy catheter is easily placed with ultrasound guidance using a transhepatic route and either the trocar method or guidewire exchange (Seldinger) technique (Fig. 17.20).

Cholecystostomy can be successfully performed in up to 100% of cases, with rapid clinical improvement in 56% to 95% of patients.[147-149] Because of the severe comorbidities of these patients, mortality rates of 36% to 59% have been reported in hospitalized patients after cholecystostomy tube placement.[147,149]

Gallbladder aspiration alone may also be considered in treating the noncritically ill patient with acute cholecystitis who is a high surgical risk (Fig. 17.21). Given that positive blood cultures are present in less than 50% of patients with acute cholecystitis, continuous drainage may not be as critical in the management of this condition. One study showed a 77% clinical response in high-risk surgical patients using aspiration alone, compared with a 90% response in those treated with percutaneous cholecystostomy.[150] Care must be taken to avoid direct puncture of the gallbladder wall without intervening hepatic parenchyma in patients with biliary obstruction because of the risk of significant bile leakage.[151]

Bile Ducts. Percutaneous **transhepatic cholangiography** and drainage is traditionally performed using "blind" cholangiography with fluoroscopy for initial needle placement. However, the combined use of ultrasound for the initial needle puncture and fluoroscopy for final catheter placement using the guidewire exchange technique optimizes the advantages of both guidance systems for transhepatic cholangiography, biliary drainage, and other invasive procedures. Select ducts may be punctured under ultrasound guidance for transhepatic cholangiography or as the site of definitive catheter placement. In patients with segmental biliary obstruction, a blind technique allows initial opacification

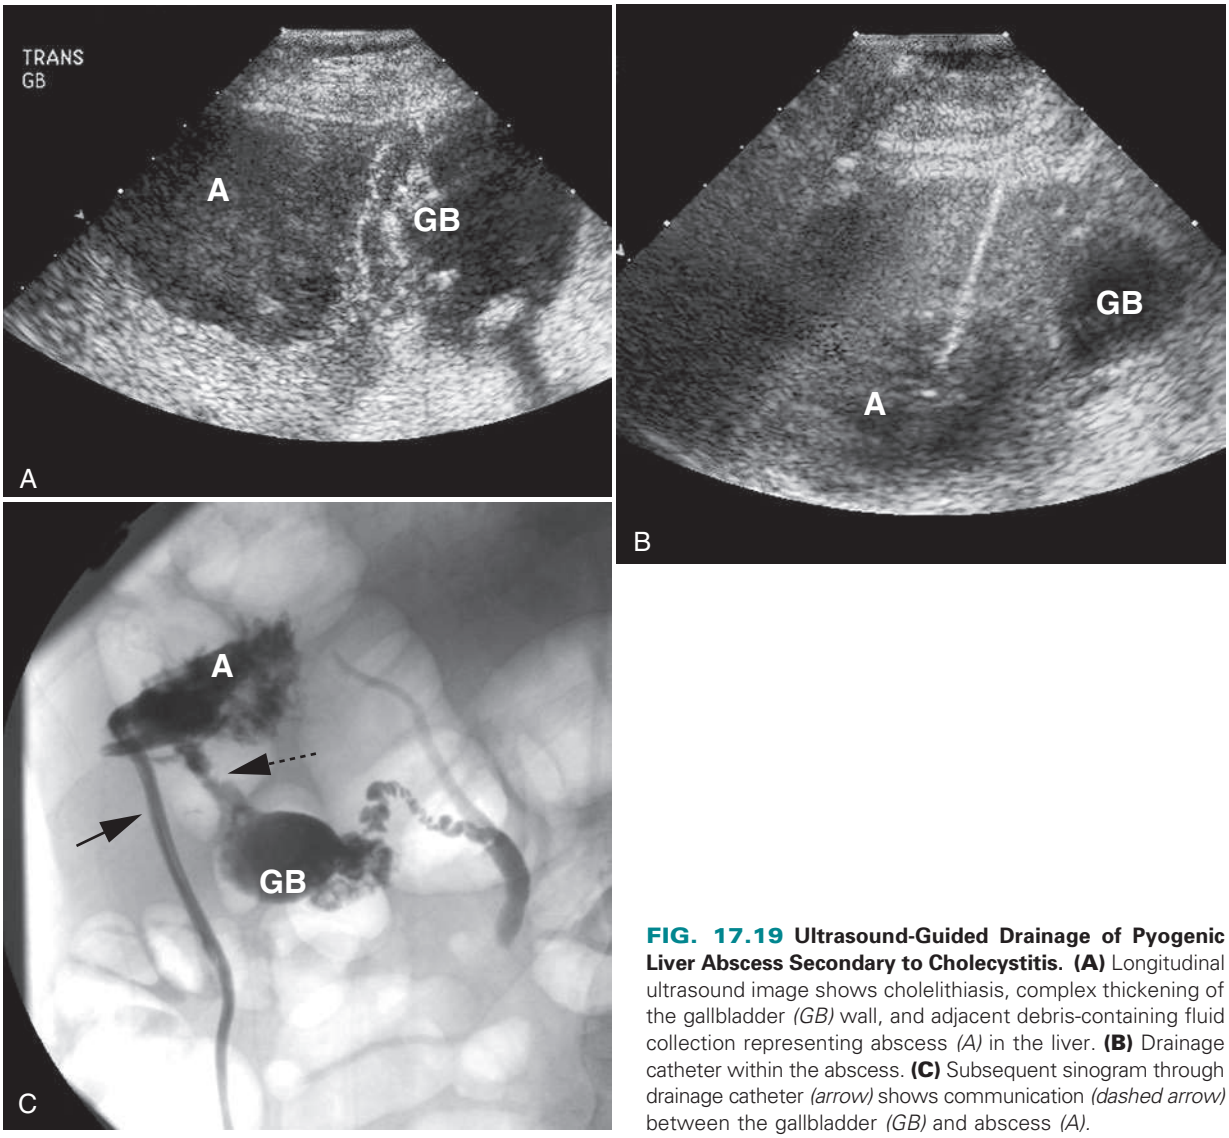

FIG. 17.19 Ultrasound-Guided Drainage of Pyogenic Liver Abscess Secondary to Cholecystitis. (A) Longitudinal ultrasound image shows cholelithiasis, complex thickening of the gallbladder *(GB)* wall, and adjacent debris-containing fluid collection representing abscess *(A)* in the liver. **(B)** Drainage catheter within the abscess. **(C)** Subsequent sinogram through drainage catheter *(arrow)* shows communication *(dashed arrow)* between the gallbladder *(GB)* and abscess *(A)*.

of the biliary system only by "chance," whereas ultrasound allows guided, direct puncture of the appropriate bile duct.

Pancreas

Percutaneous aspiration or drainage of pancreatic fluid collections typically arises in the setting of pancreatitis. In the absence of infection or obstruction of an adjacent hollow viscus, acute pancreatis-related peripancreatic fluid collections require no therapy.[152] Similarly, sterile pancreatic necrosis does not usually require treatment.

Infected **pancreatic necrosis** and some **pseudocysts** eventually require percutaneous intervention. Although CT is superior to ultrasound in evaluation of pancreatitis, ultrasound provides easy guidance for percutaneous interventional procedures (e.g., fluid aspiration) in these patients. Standard management of infected pancreatic necrosis is surgical debridement.[153] However, percutaneous drainage may provide short-term control of sepsis in almost 75% and cure in 50% of patients. Such a procedure typically involves very-large-bore catheters with frequent, vigorous irrigation, essentially resulting in a "percutaneous necrosectomy."[154]

Pancreatic pseudocysts arise in about 6% of patients following an episode of acute pancreatitis.[155] About half of pseudocysts will resolve spontaneously (but only a third of those >6 cm).[156,157] Simple aspiration of pancreatic pseudocysts is associated with a high rate of recurrence; therefore catheter drainage is preferred in select cases[156-159] (Fig. 17.22). Depending on location, endoscopic cystogastrostomy is another commonly used technique. Indications for pancreatic pseudocyst drainage include the following[160]:

- Symptoms related to pseudocyst
- Complication of infection or bleeding
- Increase in size during the observation period
- A diameter of 6 cm or more
- No decrease in size during last 6 weeks of observation

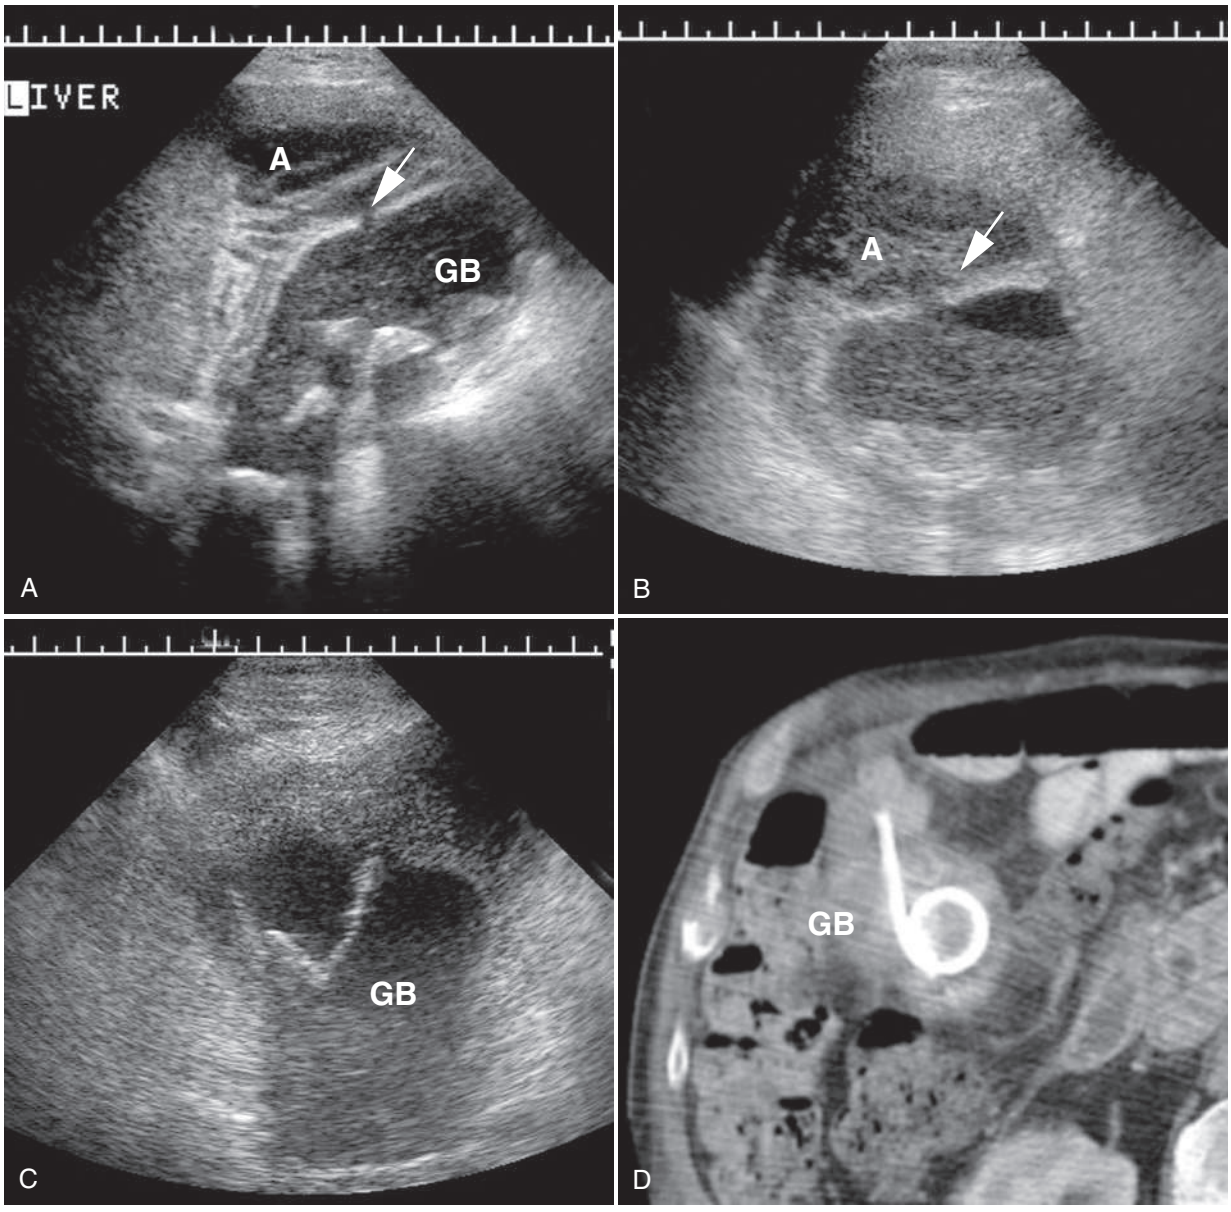

FIG. 17.20 Cholecystostomy Using Ultrasound Guidance. (A) Longitudinal and **(B)** transverse ultrasound images show stones within the gallbladder *(GB)* and adjacent debris-containing fluid collection representing abscess *(A)*. Perforation of gallbladder wall is identified *(arrow)*. **(C)** Drainage catheter was placed using ultrasound guidance. **(D)** Subsequent CT confirms catheter placement within gallbladder lumen.

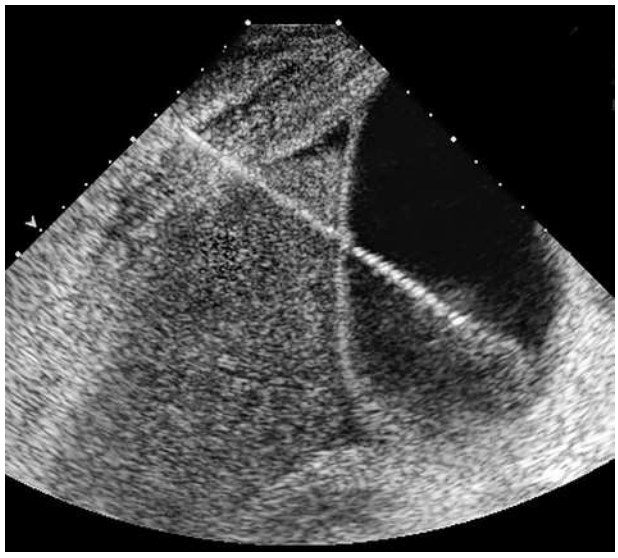

FIG. 17.21 Ultrasound-Guided Gallbladder Aspiration. Using freehand technique, a needle is advanced transhepatically into the lumen of a sludge-filled gallbladder.

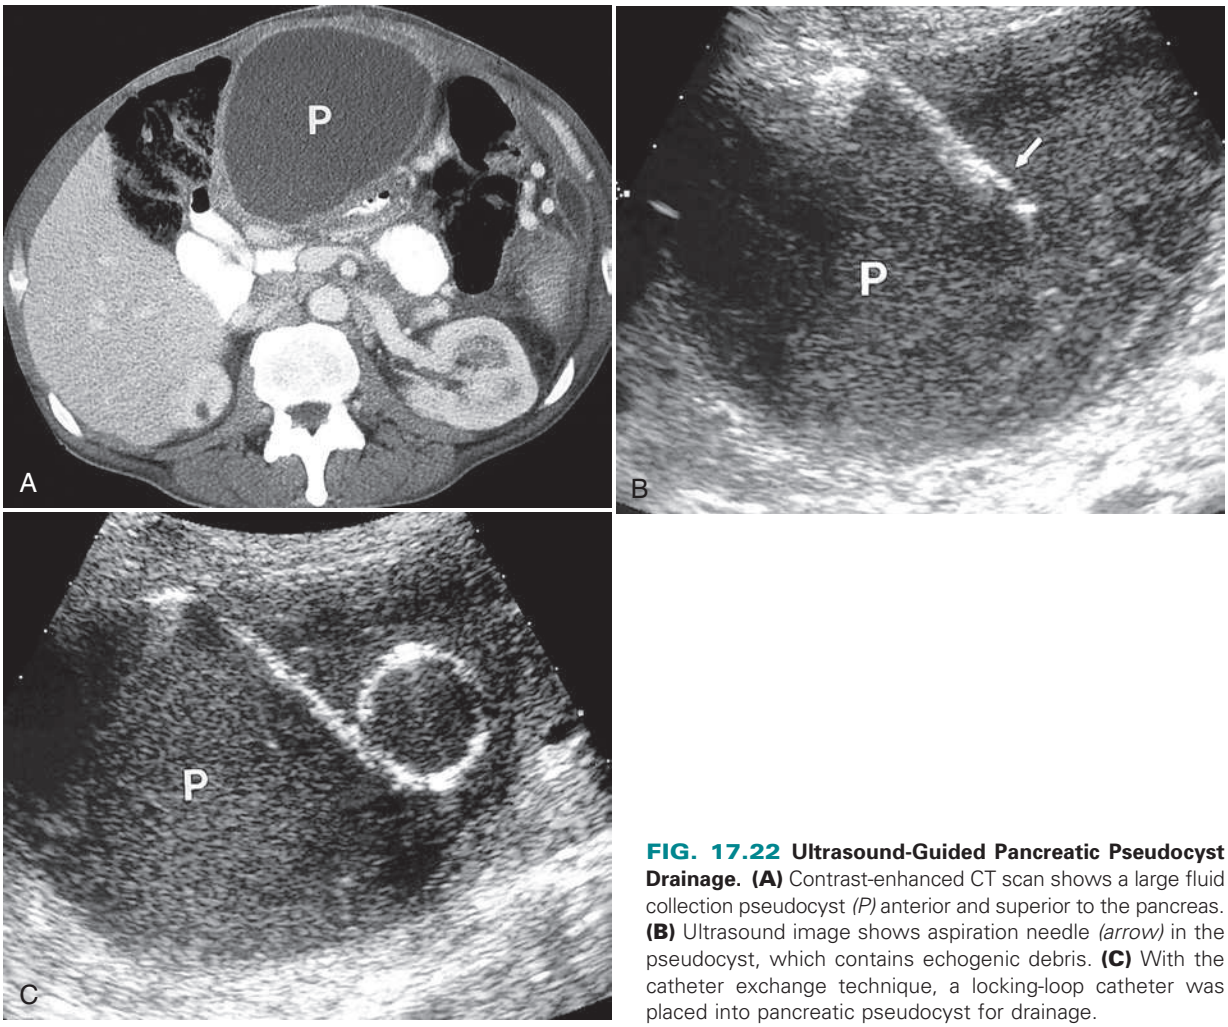

FIG. 17.22 Ultrasound-Guided Pancreatic Pseudocyst Drainage. (A) Contrast-enhanced CT scan shows a large fluid collection pseudocyst *(P)* anterior and superior to the pancreas. **(B)** Ultrasound image shows aspiration needle *(arrow)* in the pseudocyst, which contains echogenic debris. **(C)** With the catheter exchange technique, a locking-loop catheter was placed into pancreatic pseudocyst for drainage.

Success of percutaneous pseudocyst drainage ranges from 70% to 100%.[158] Ultimate success is associated with the integrity of the pancreatic duct.[161]

Spleen

Splenic abscesses are uncommon, and in the past they were often managed surgically. However, with increasing experience in percutaneous abscess management, image-guided drain placement into select splenic abscesses has been successfully performed in up to 100% of patients.[162-164] With smaller (≤3 cm) infected splenic fluid collections, a trial of aspiration may be reasonable, with drain placement if reaccumulation of fluid occurs. More complex, multiloculated abscesses or deep-seated collections should be managed surgically. The primary risk of spleen drainage is bleeding.[99]

Kidney

Most **renal abscesses** can be successfully managed with percutaneous drainage combined with systemic antibiotics (Fig. 17.23). The size of the abscess should be considered when determining the type of treatment. For abscesses smaller than 3 cm, antibiotics alone are typically sufficient for treatment.[165] Success in the percutaneous drainage of larger abscesses ranges from 70% to 90%, with better results in treating smaller abscesses.[165]

PERCUTANEOUS CYST MANAGEMENT

Renal Cyst

Simple aspiration of large, symptomatic or obstructing renal cysts is ineffective in the long-term management of renal cysts because of rapid reaccumulation of cyst fluid within the cavity.[166] This has led to interest in **aspiration combined with sclerosis** to provide more permanent ablation of the cyst (Fig. 17.24).

The procedure involves placing a 6- to 8-French drain into the cyst with aspiration of the cyst fluid. If the cyst's true benign nature is in doubt, the fluid may be sent for cytology and other chemical markers to confirm a serous nature of the fluid. If there is no evidence of malignancy, the cyst is then injected with contrast material under fluoroscopy to exclude a communication with the urinary collecting system; sclerosis should not be performed

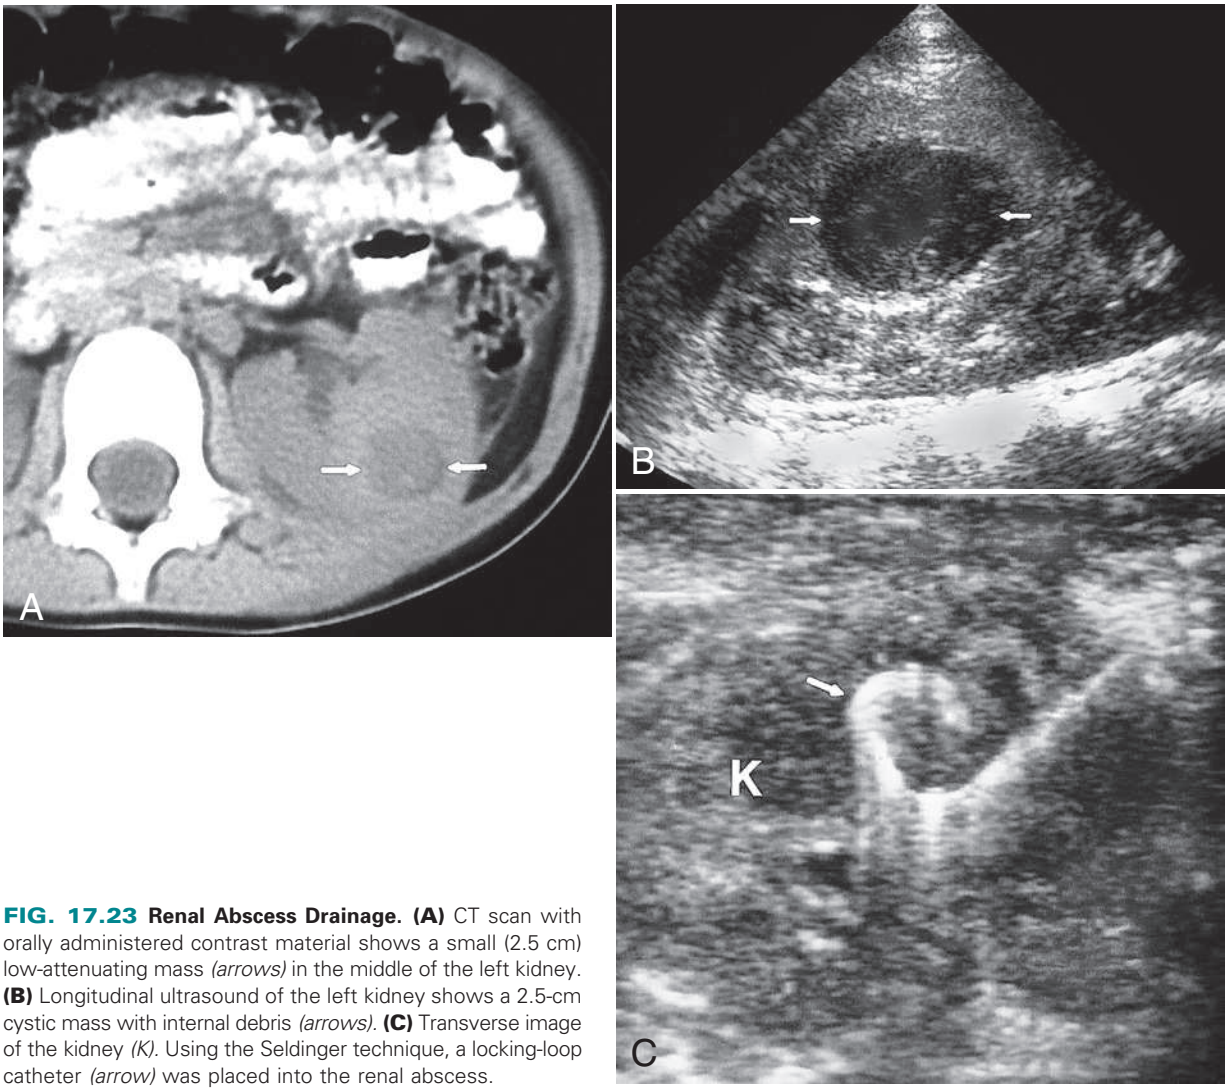

FIG. 17.23 Renal Abscess Drainage. (A) CT scan with orally administered contrast material shows a small (2.5 cm) low-attenuating mass *(arrows)* in the middle of the left kidney. **(B)** Longitudinal ultrasound of the left kidney shows a 2.5-cm cystic mass with internal debris *(arrows)*. **(C)** Transverse image of the kidney *(K)*. Using the Seldinger technique, a locking-loop catheter *(arrow)* was placed into the renal abscess.

if such a communication exists. The cyst is then injected with 95% alcohol at half the cyst volume, not to exceed 100 mL.[167] Injection of lidocaine with the alcohol minimizes the burning pain that often accompanies alcohol i njection. The patient is turned in various positions over a 20-minute period to facilitate exposure of the cyst wall to the sclerosing agent. The alcohol is aspirated and the drain removed or placed to continuous suction. Repeat injections may be performed over the subsequent 2 to 3 days to maximize sclerosis. This technique is successful in more than 95% of patients.[166,168] Although alcohol is the sclerosing agent typically used, other agents include tetracycline, doxycycline, talc, and iodine.

Liver Cyst

Similar to renal cysts, hepatic cysts can be effectively sclerosed to provide long-term relief of symptoms. A communication to the biliary tract is usually excluded by injecting the cyst with contrast under fluoroscopy. A smaller amount of alcohol (25% cyst volume) has been proposed.[169] In one study, investigators used alcohol and/or tetracycline or doxycycline in successfully treating 85% of symptomatic hepatic cysts.[170]

Ovarian Cyst

Historically, surgical extirpation of symptomatic ovarian cysts has been the standard of care. Percutaneous management has been discouraged because of the concern about seeding malignant cells in the inadvertent aspiration of a low-grade neoplasm and the poor sensitivity in characterizing aspirated cyst fluid.[171,172] However, given the well-recognized sonographic criteria of benign ovarian cysts, the confidence level in percutaneous aspiration of such symptomatic simple cysts has improved.

Ultrasound-guided aspiration of symptomatic, benign ovarian cysts is highly effective in alleviating patient symptoms.[173] A thorough ultrasound examination should be performed initially to fully characterize the symptomatic cyst. If the cyst can be confidently characterized as benign with no worrisome features, aspiration can be performed. Some recommend obtaining

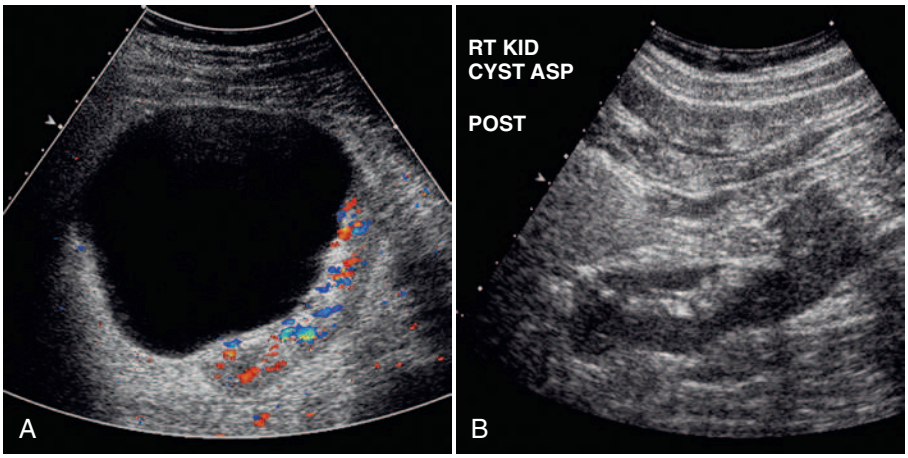

FIG. 17.24 Renal Cyst Sclerosis. (A) Longitudinal image of the right kidney shows a large, benign cyst. **(B)** After aspiration and sclerosis, the cyst is completely decompressed.

preprocedural serum tumor markers to help exclude malignancy.[174] Using either a transabdominal or an endovaginal approach, a 20-gauge or 22-gauge needle can be used to aspirate the cyst completely, with 100% relief in one series.[173] Fluid should be sent for appropriate studies, including cytology. Recurrence of the cyst may be seen in 11% to 26% of patients.[175,176]

CHAPTER 18

Organ Transplantation

Derek Muradali and Tanya Punita Chawla

SUMMARY OF KEY POINTS

- To perform an ultrasound assessment of a transplanted organ, the sonographer should be aware of the surgical technique used including the type and location of vascular and nonvascular anastomoses.
- Gray-scale parenchymal changes often reflect the vascular status of the allograft (e.g., echogenic intraluminal material within a dilated biliary tree of a transplanted liver may result from sloughing of the biliary epithelium as a result of hepatic arterial narrowing or thrombosis).
- Evaluation of the tissues surrounding the allograft is just as important as assessment of the allograft itself.
- Any presumed cyst identified in the parenchyma of the allograft or in the region of the hilum should be assessed with color Doppler to exclude the possibility of a pseudoaneurysm.
- The criteria for arterial stenosis are similar with different allografts in that high-turbulence flow is detected at the region of narrowing with a distal tardus-parvus waveform.
- When assessing transplanted veins (portal vein, renal vein, inferior vena cava), a threefold to fourfold velocity increase at the site of stenosis relative to the prestenotic segment on spectral interrogation represents a hemodynamically significant stenosis.
- Elevated resistive indices may be of limited value depending on the allograft being interrogated—in renal transplants they are a nonspecific marker of renal dysfunction; in liver transplants they are of no clinical relevance; and in pancreatic transplants that are failing, the resistive indices may not be elevated owing to the lack of a pancreatic capsule.

CHAPTER OUTLINE

Treatment Options

Organ transplantation is the preferred treatment for patients with end-stage liver, renal, and pancreatic disease. Patients with fulminant liver failure have no other treatment option apart from orthotopic liver transplantation. Although patients with renal or pancreatic failure may be treated with dialysis or medical therapy, their long-term survival and quality of life are far superior with organ transplantation. Recent improvements in graft survival have been attributed to a combination of better donor-recipient matching,[1] more effective immunosuppressive therapy, improvements in surgical technique, and early recognition

of transplant-related complications. These improvements have resulted in a 1-year patient survival rate of over 80% for each of these organ transplants.[2,3]

Because the clinical presentation of posttransplant complications varies widely and is often nonspecific, imaging studies are essential for monitoring the status of the allograft. If diagnosis is delayed, the function of the allograft may be permanently compromised, and in severe cases with complete loss of function, retransplantation may be warranted. However, the chronic shortage of suitable donor organs may delay or preclude immediate retransplantation, with devastating clinical consequences. Therefore preservation of the allograft function and early detection of complications, with institution of appropriate treatment, are essential in the clinical management of these patients.

Ultrasound has revolutionized the practice of organ transplantation. Liver, renal, and pancreatic transplants should be assessed with gray-scale, color Doppler, and spectral Doppler interrogation. Gray-scale sonography permits optimal assessment of the textural and morphologic changes of the parenchyma, and color and spectral Doppler ultrasound permit evaluation of both parenchymal perfusion and the status of the major transplanted artery and vein. This chapter focuses on the ultrasound appearances of the normal organ transplant, acute and chronic transplant-related complications, and potential errors of interpretation that can lead to misdiagnoses.

LIVER TRANSPLANTATION

From January 1, 1988 to June 30, 2016 in the United States, 143,856 patients underwent liver transplantation.[4] One-year survival in liver transplant patients is approximately 87%, with 1-year graft survival of 80.3%. Patients are selected for transplantation when their life expectancy without transplantation is less than their life expectancy after the procedure. **Hepatitis C** is the most common disease requiring transplantation, followed by **alcoholic liver disease** and **cryptogenic cirrhosis.** Other end-stage liver disorders treated by transplantation include **chronic cholestatic diseases,** such as primary biliary cirrhosis and primary sclerosing cholangitis; **metabolic diseases,** including hemochromatosis and Wilson disease; and **other hepatitides,** such as autoimmune hepatitis, chronic hepatitis B, and acute liver failure. Patients with end-stage hepatitis B cirrhosis were initially regarded as poor transplant candidates because of the high rate of recurrence of infection in the implant, associated with rapid progression to cirrhosis. The use of hyperimmunoglobulins and nucleoside analogues has changed these expectations to a more favorable outcome.[5]

Most centers consider transplantation only in patients with **early-stage hepatocellular carcinoma** (HCC) or rarely **neuroendocrine metastasis.** The generally accepted guidelines for transplantation in patients with HCC are the Milan criteria: (1) no lesion greater than 5 cm in diameter or (2) no more than three lesions greater than 3 cm in diameter.[5,6]

Contraindications for liver transplantation include compensated cirrhosis without complications, extrahepatic malignancy, cholangiocarcinoma, active untreated sepsis, advanced cardiopulmonary disease, active alcoholism or substance abuse, or an anatomic abnormality precluding the surgical procedure. Although portal vein thrombosis is not an absolute contraindication to liver transplantation, its presence makes the surgery more complex, and posttransplantation patients show higher morbidity and mortality rates.[5]

Surgical Technique

Traditionally, most adult liver transplants involve explantation of the recipient liver and replacement with a cadaveric allograft. The surgery requires four **vascular anastomoses** (suprahepatic vena cava, infrahepatic vena cava, hepatic artery, portal vein) as well as a **biliary anastomosis** (Fig. 18.1).

The **hepatic artery** is reconstructed with a "fish-mouth" anastomosis between the donor common hepatic artery and either the bifurcation of the right and left hepatic arteries or the branch point of the common hepatic artery into the gastroduodenal and proper hepatic arteries of the recipient. When the native hepatic artery is small in diameter or shows minimal flow, a donor iliac artery or splenic artery interposition graft may be anastomosed directly to the supraceliac or infrarenal aorta.[7] The end-to-end attachment of these patulous arterial ends leads to a normally expected mild widening at the arterial anastomosis.

The **portal vein anastomosis** is usually end to end between the donor and recipient portal veins. In cases of extensive recipient portal vein thrombosis, a venous jump graft from the donor portal vein or the iliac vein may be used, to the portomesenteric confluence, superior mesenteric vein (SMV), or a collateral vein, or as a last resort, an anastomosis between both the portal vein and the hepatic artery of the donor and the arterial vessels of the recipient.[7,8]

During hepatectomy, the **inferior vena cava** (IVC) of the recipient usually is transected above and below the intrahepatic

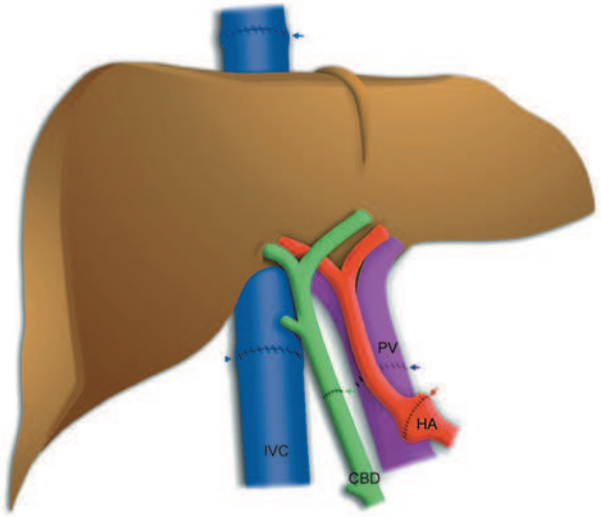

FIG. 18.1 Normal Liver Transplant: Surgical Approach. The transplanted liver shows four vascular anastomoses and a biliary anastomosis. The inferior vena cava *(IVC, blue)* is transplanted with a suprahepatic and infrahepatic anastomosis. An end-to-end anastomosis is often used for the common bile duct *(CBD, green)* and portal vein *(PV, purple),* whereas the hepatic artery *(HA, red)* is reconstructed with a "fish-mouth" anastomosis.

portion. The donor IVC is then anastomosed with two end-to-end suprahepatic and infrahepatic anastomoses. In an attempt to preserve the recipient retrohepatic IVC, some techniques advocate creation of an anastomosis between the donor and recipient IVC in an end-to-side or side-to-side configuration ("piggyback" anastomosis) or an end-to-end anastomosis between the donor IVC and a common stump of the three hepatic veins.[7] This piggyback anastomosis also prevents the need for venovenous bypass and retrocaval dissection, which are required for interposition of the donor IVC.

The donor and recipient **common bile duct** (CBD) are usually anastomosed end to end, after cholecystectomy. With this technique the sphincter of Oddi is preserved and acts as a barrier to the spread of infection. A T tube is typically left in situ for about 3 months and permits access for cholangiography or other biliary procedures. The use of a T tube has, however, decreased owing to an increased risk of bile leak.

When the recipient common hepatic duct is diseased (e.g., **sclerosing cholangitis**), too short, or too narrow in diameter, a **choledochojejunostomy** is performed.[7] This procedure involves an end-to-side anastomosis between the donor bile duct and a 40-cm recipient jejunal loop. It is associated with a higher risk of bile leaks, bleeding, enteric reflux and recurrent cholangitis compared with an end-to-end anastomosis.

The growing discrepancy between the number of patients awaiting transplantation and the number of available cadaveric donor organs has led to a progressive increase in the number of living related donor transplantations as well as split liver grafts from deceased donors. The recipient liver is replaced with the right lobe of a living donor. In the pediatric population, the lateral segment of the left lobe or the entire left lobe has been used successfully; the relatively small size of the left lobe is not sufficient, however, to sustain adequate liver function in an adult. Another advantage of using a right lobe (vs. left lobe) as the donor portion for transplantation is the relative ease of positioning the right lobe in the right subphrenic space, allowing a technically less challenging hepatic venous anastomosis, with a decrease in the incidence of torsion, compared with left lobe grafts.[9]

For **living related transplants,** donor surgery consists of cholecystectomy followed by right hepatectomy, removing segments V, VI, VII, and VIII as well as the right hepatic vein. Occasionally an extended right hepatectomy may be done to include a portion of segment IV and the middle hepatic vein. However, most surgeons prefer not to remove the middle hepatic vein, but to leave it intact in the donor because of the intimate relationship of the middle and left hepatic veins near their drainage into the IVC.[9]

In a **split liver graft from a deceased donor,** an adult recipient typically receives a trisegmental graft including the right lobe and segment IV and a pediatric recipient receives the left lateral segments. This technique is useful in increasing the numbers of transplants available but is more complex than when there is a single recipient.

Regardless of the type of liver transplantation, routine imaging evaluation of each anastomosis must be assessed with gray-scale ultrasound, color Doppler, and spectral Doppler interrogation. To interpret the gray-scale appearance and Doppler features of these anastomotic regions, the sonographer should be aware of the surgical techniques used in liver transplantation.

Normal Liver Transplant Ultrasound

The normal liver transplant has a homogeneous or slightly heterogeneous echotexture on gray-scale ultrasound, appearing identical to a normal, nontransplanted liver. In the early postoperative period, there is usually a small amount of free intraperitoneal fluid or small, perihepatic seromas or hematomas, which tend to resolve within 7 to 10 days.

The **biliary tree** should have a normal appearance, with an anechoic lumen and thin, imperceptible walls. If a T tube is in situ, the adjacent duct wall may appear mildly prominent secondary to irritation and edema. Ideally, the biliary anastomosis (end to end or biliary enteric) should be visualized and inspected for changes in caliber or wall thickness.

Pneumobilia is often observed in patients with choledochojejunostomy and appears as bright, echogenic foci with or without posterior acoustic shadowing in the bile duct lumen. The disappearance of previously documented pneumobilia should alert the sonographer to possible interval development of a biliary stricture at the biliary-enteric anastomosis. In addition, the sonographer should be aware that **intraductal biliary air** may be confused with tiny biliary stones or adjacent hepatic arterial calcifications because these structures can appear identical on gray-scale imaging (Fig. 18.2).

Vascular patency of the transplanted vessels (hepatic artery, portal vein, hepatic veins, IVC) is assessed by (1) direct inspection for narrowing of the diameter, (2) presence of thrombus within the vessel lumen, and (3) documentation of normal spectral waveforms with appropriate directional flow. Particular attention should be paid to the anastomotic regions because these areas have a higher propensity to develop a hemodynamically significant stenosis compared with the remaining vessel. Because intrahepatic segmental stenoses or occlusions can develop, the hepatic artery and main portal vein, as well as their major right and left branches, should be investigated with color and spectral Doppler (Fig. 18.3).

The **normal hepatic artery** shows a rapid systolic upstroke, with an acceleration time (AT; time from end diastole to first systolic peak) of less than 100 cm/sec, and continuous flow throughout diastole, with a resistive index (RI) of 0.5 to 0.7. A **normal portal vein** is typically smooth in contour, has an anechoic lumen, and may show a subtle change in caliber at the surgical anastomosis. The portal veins show continuous, monophasic, hepatopetal flow with mild velocity variations caused by respiration. The Doppler appearance of the **hepatic veins** shows a phasic waveform, reflecting physiologic changes in blood flow during the cardiac cycle.

Biliary Complications

Biliary tract complications are an important cause of morbidity and mortality in 15% to 30% of patients with liver transplantation.[10-12] Complications related to biliary-enteric anastomoses usually manifest within the first month of surgery and include anastomotic breakdown, bleeding, and an increased risk of ascending cholangitis from bacterial overgrowth.

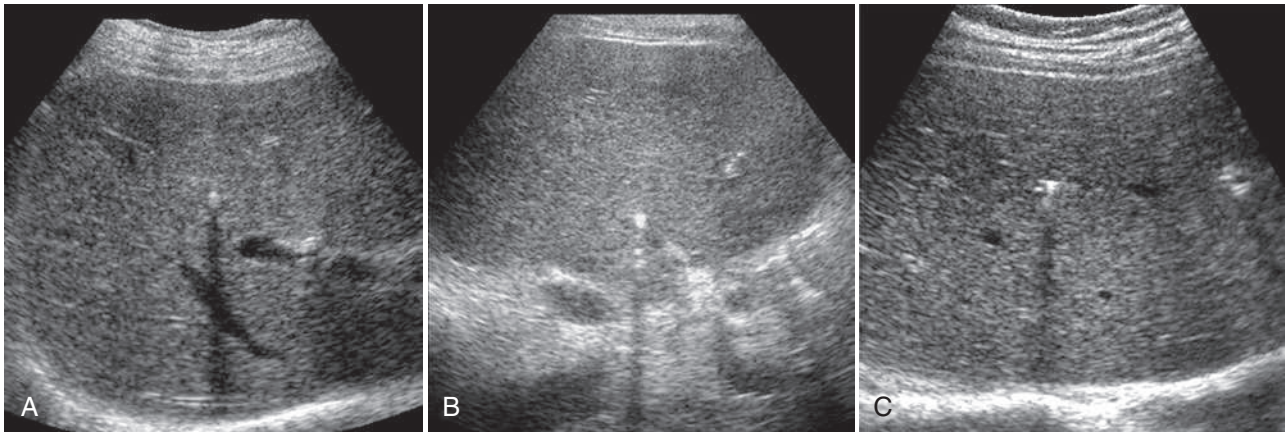

FIG. 18.2 Echogenic Foci in Liver Transplant. Transverse sonograms show similar bright echogenic foci with posterior acoustic shadowing secondary to **(A)** intrahepatic calcification; **(B)** hepatic arterial calcifications; and **(C)** pneumobilia. Note the ring-down artifact associated with the pneumobilia.

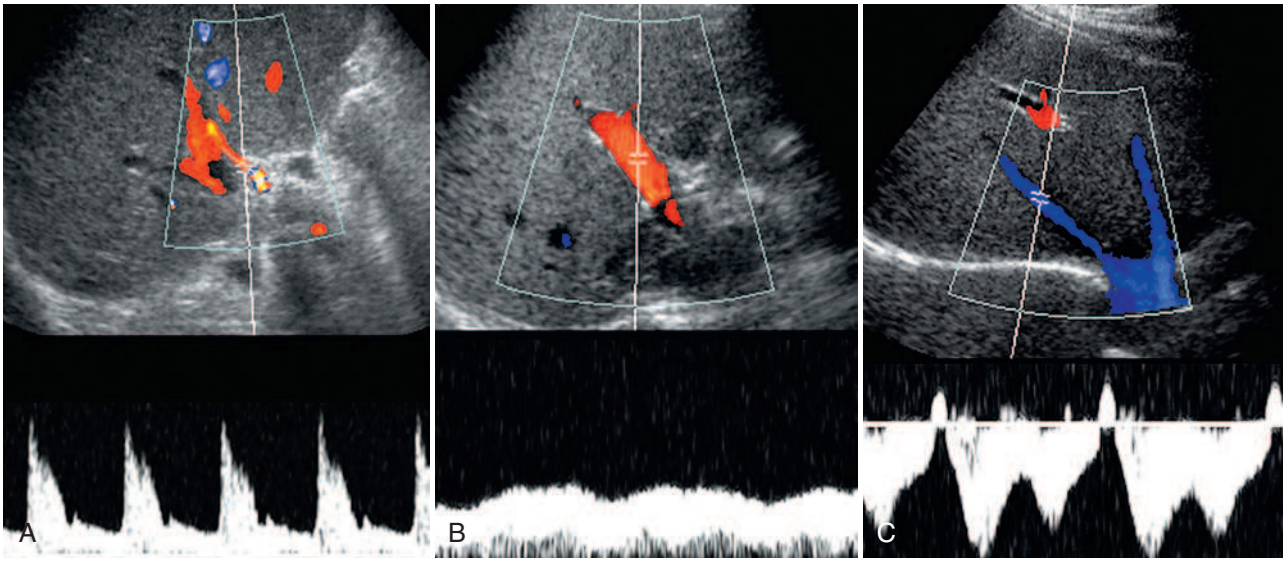

FIG. 18.3 Normal Liver Transplant: Color and Spectral Doppler. Color and spectral Doppler images of normal **(A)** hepatic artery, **(B)** main portal vein, and **(C)** right hepatic vein. (With permission from Crossin JD, Muradali D, Wilson SR. US of liver transplants: normal and abnormal. Radiographics. 2003;23[5]:1093-1114.[5])

Choledochocholedochostomy-related complications most frequently manifest after the first posttransplantation month and are often managed by endoscopic retrograde cholangiopancreatography (ERCP).[11] Regardless of the type of anastomoses used, biliary tract complications can be broadly classified as those related to leaks, strictures, intraluminal sludge or stones, dysfunction of the sphincter of Oddi, and recurrent disease.

Biliary Strictures

Early diagnosis of biliary tree complications may be difficult because transplant recipients do not typically experience colic; the transplanted liver has a poor supply of nerves.[13] Therefore patients with biliary strictures may be asymptomatic or may have painless obstructive jaundice or abnormalities in liver function test (LFT) results.[11] These strictures can be categorized based on location and pathophysiology as anastomotic (extrahepatic) and intrahepatic strictures (Fig. 18.4).

Anastomotic strictures are the most common cause of biliary obstruction after transplantation[14,15] and arise from postsurgical scarring, resulting in retraction of the duct wall and narrowing of the luminal diameter.[16] These strictures are more common in patients with a Roux-en-Y choledochojejunostomy than in patients with an end-to-end biliary anastomosis. On ultrasound, a focal narrowing can sometimes be observed at the anastomoses, associated with dilation of the intrahepatic bile ducts, with a normal-sized or near-normal-sized distal CBD.

Intrahepatic strictures occur proximal to the anastomosis and may be unifocal or multifocal. The arterial supply of the distal CBD (recipient duct) is rich because of prominent collateral flow, whereas the reconstructed hepatic artery is the only blood supply to the proximal CBD and intrahepatic bile ducts (donor ducts).[11,17] Therefore most intrahepatic duct strictures result from ischemia caused by **hepatic artery occlusion** (thrombosis or significant stenosis). In rare cases, biliary ischemia may also be

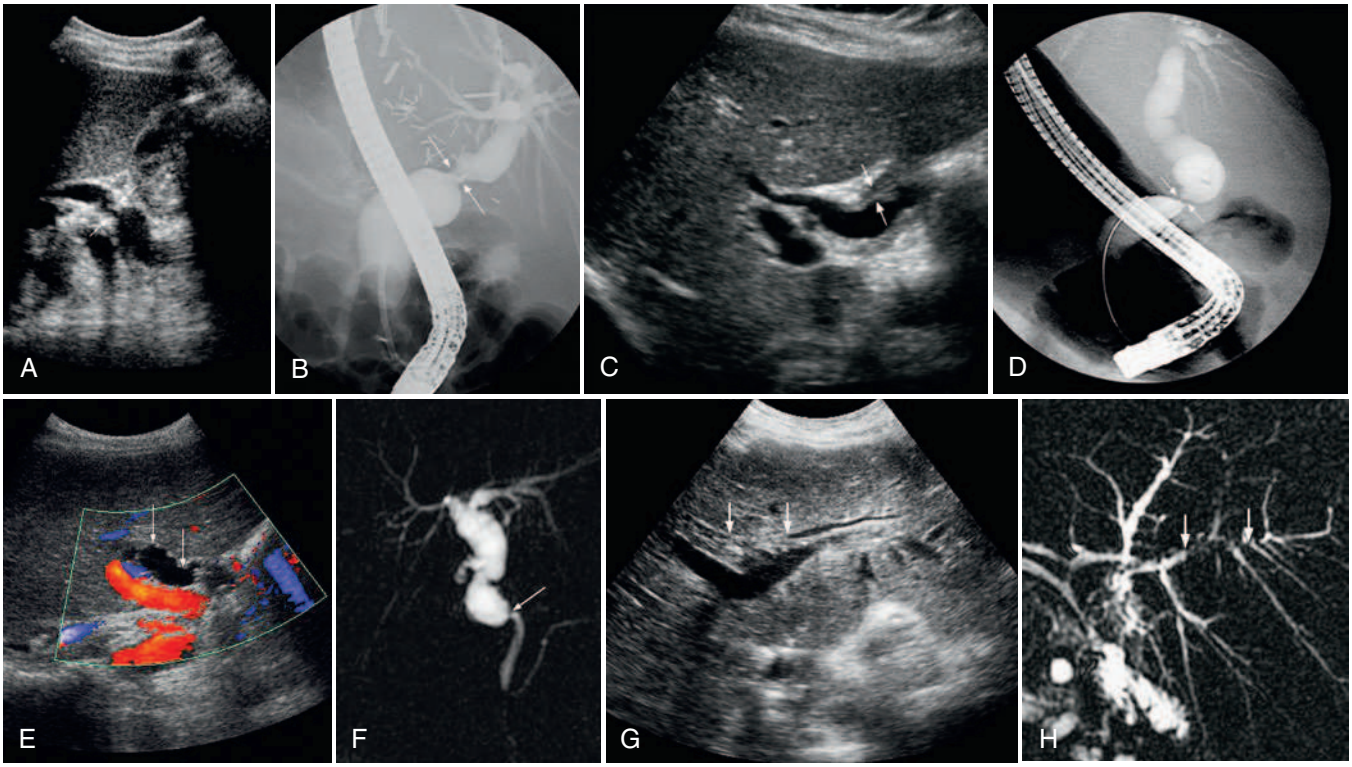

FIG. 18.4 Bile Duct: Strictures in Four Patients. *Patient 1:* **(A)** Gray-scale sonogram and **(B)** endoscopic retrograde cholangiopancreatography (ERCP) of common bile duct (CBD) anastomotic stricture *(arrows). Patient 2:* **(C)** Gray-scale sonogram and **(D)** ERCP show grossly thickened CBD walls *(arrows),* secondary to ascending cholangitis, a consequence of an anastomotic stricture. *Patient 3:* **(E)** Transverse sonogram shows central biliary dilation *(arrows).* **(F)** Magnetic resonance cholangiopancreatography (MRCP) image shows anastomotic stricture *(arrow). Patient 4:* **(G)** Transverse sonogram and **(H)** radial T2-weighted MRCP image show left intrahepatic bile duct stricture *(between arrows),* secondary to ischemia from hepatic artery stenosis. (**A** and **B** with permission from Crossin JD, Muradali D, Wilson SR. US of liver transplants: normal and abnormal. Radiographics. 2003;23[5]:1093-1114.[5])

caused by **prolonged cold preservation time** of the donor organ.[16,18] Other causes of intrahepatic strictures include immunogenic injury produced by chronic rejection, recurrent sclerosing cholangitis, ascending cholangitis, and cytomegalovirus (CMV) infections.

Ultrasound findings include focal areas of narrowing in the intrahepatic or proximal CBD and segmental dilation of the intrahepatic bile ducts, without evidence of an obstructing mass. The presence of echogenic intraluminal material within a dilated biliary tree is an ominous sign, sometimes caused by severe biliary ischemia, resulting in sloughing of the entire biliary epithelium. In this scenario the **intraluminal echogenic material** represents a combination of biliary sludge or stones, sloughed biliary epithelium, and intraluminal hemorrhage[16] (Fig. 18.5).

Bile Leaks

The incidence of bile leaks in patients with cadaveric liver transplants is 5% to 23%. The biliary complication rate is substantially higher in living related transplant recipients, possibly because of (1) leaks caused by division of the liver at retrieval, (2) variant biliary anatomy resulting in more than one bile duct orifice at the resection margin, and (3) ischemia of the right biliary tree.[19] Overall, biliary leaks can be categorized as occurring (1) at the anastomotic site, (2) at the T-tube exit site, (3) as a result of bile duct necrosis, and (4) secondary to percutaneous liver biopsies[20] (Fig. 18.6).

Most anastomotic leaks and T-tube exit site leaks occur within the first postsurgical month. **Anastomotic leaks** may be related to surgical technique or may result from ischemia caused by hepatic artery compromise. Clinically, anastomotic leaks are associated with bile peritonitis or intraabdominal sepsis and may manifest on ultrasound as a large periportal collection, a subhepatic collection, or ascites. **T-tube exit leaks** are related to technical errors when placing the T-tube and are usually detected incidentally at cholangiography. The resulting biloma is usually small, and patients with these types of bile leaks are usually asymptomatic.[20]

Leaks from **bile duct necrosis** usually occur after the first postsurgical month and are a result of severe hepatic artery stenosis or hepatic artery thrombosis. This condition is often associated with progressive hepatic dysfunction and a poor clinical course, eventually necessitating retransplantation. On ultrasound, the biliary tree may be dilated and thick walled and may communicate with multiple surrounding bilomas.[20]

In rare cases, bile leaks can occur as a result of bile duct injury from **percutaneous liver biopsies.** Bile may leak from the needle track into the peritoneal cavity. These leaks can resolve without

treatment or may persist and become clinically noticeable if distal biliary obstruction is present.[20]

Recurrent Sclerosing Cholangitis

Recurrent sclerosing cholangitis occurs in up to 20% of recipients undergoing orthotopic transplantation for sclerosing cholangitis, with a mean interval of 350 days.[5,8,21] Ultrasound findings include diffuse mural thickening of the intrahepatic bile duct and CBD and diverticulum-like outpouchings of the CBD[16,22] (Fig. 18.7). Recurrent disease should be suspected in patients who have undergone transplantation for end-stage primary sclerosing cholangitis and who have biliary dilation and mural thickening in the presence of a normal hepatic arterial waveform.

Occasionally, patients with ascending cholangitis show a similar ultrasound appearance. Infectious causes include both enteric flora and opportunistic infections (e.g., CMV, *Cryptosporidium*).[16]

Biliary Sludge and Stones

Biliary sludge can be detected within the hepatobiliary tree in 10% to 29% of liver transplant patients, as early as 6 days or as late as 8 years after surgery. The pathogenesis of biliary sludge in these patients is uncertain, although it has been related to ischemia, infection, rejection, mechanical obstruction, biliary leaks, and presence of stents or T tubes and is more common in patients with hepaticojejunostomy.[13] Once in the donor or recipient biliary tree, sludge can cause biliary obstruction and life-threatening ascending cholangitis (Fig. 18.8). The detection of biliary sludge is an ominous sign that should prompt meticulous evaluation of the CBD to rule out an obstructing lesion or leak, evaluation of the hepatic artery to ensure an optimal arterial supply, and a detailed clinical assessment to check for infection.

Intraductal stones are rare but may result from cyclosporine-induced changes in bile composition inciting crystal formation in the CBD, with subsequent stone development. Other causes include retained donor stones and stones secondary to biliary stasis from mechanical obstruction (e.g., stricture, dysfunctional T-tubes, mucocele formation in cystic duct remnant, kinking in redundant CBD)[23-25] (Fig. 18.9).

Dysfunction of the Sphincter of Oddi

In a minority of patients who have undergone a biliary end-to-end anastomosis, hepatic dysfunction is observed in the presence of diffuse dilation of the donor and recipient bile ducts in the absence of biliary stenosis. The cause of this is uncertain but may be related to devascularization or denervation of the ampulla of Vater, resulting in dysfunction of the sphincter of Oddi. Patients are usually treated with ERCP-guided sphincterotomy, which has been shown to normalize LFT values and decompress the biliary tree.[11,14]

Arterial Complications

At explantation, extrahepatic arterial vessels that supply the liver, such as the parabiliary arteries, are disrupted.[26] This results in the transplanted hepatic artery becoming the only arterial blood supply to intrahepatic biliary epithelium. Any compromise of the hepatic arterial perfusion can result in biliary ischemia and, potentially, biliary necrosis. Biliary necrosis is incompatible with graft survival and is an absolute indication for retransplantation, but uncomplicated biliary ischemia (i.e., without necrosis) can be reversible if hepatic arterial flow is reinstituted.[27] Thus the detection of hepatic arterial dysfunction before the development of biliary necrosis is paramount in the management of liver transplant patients.

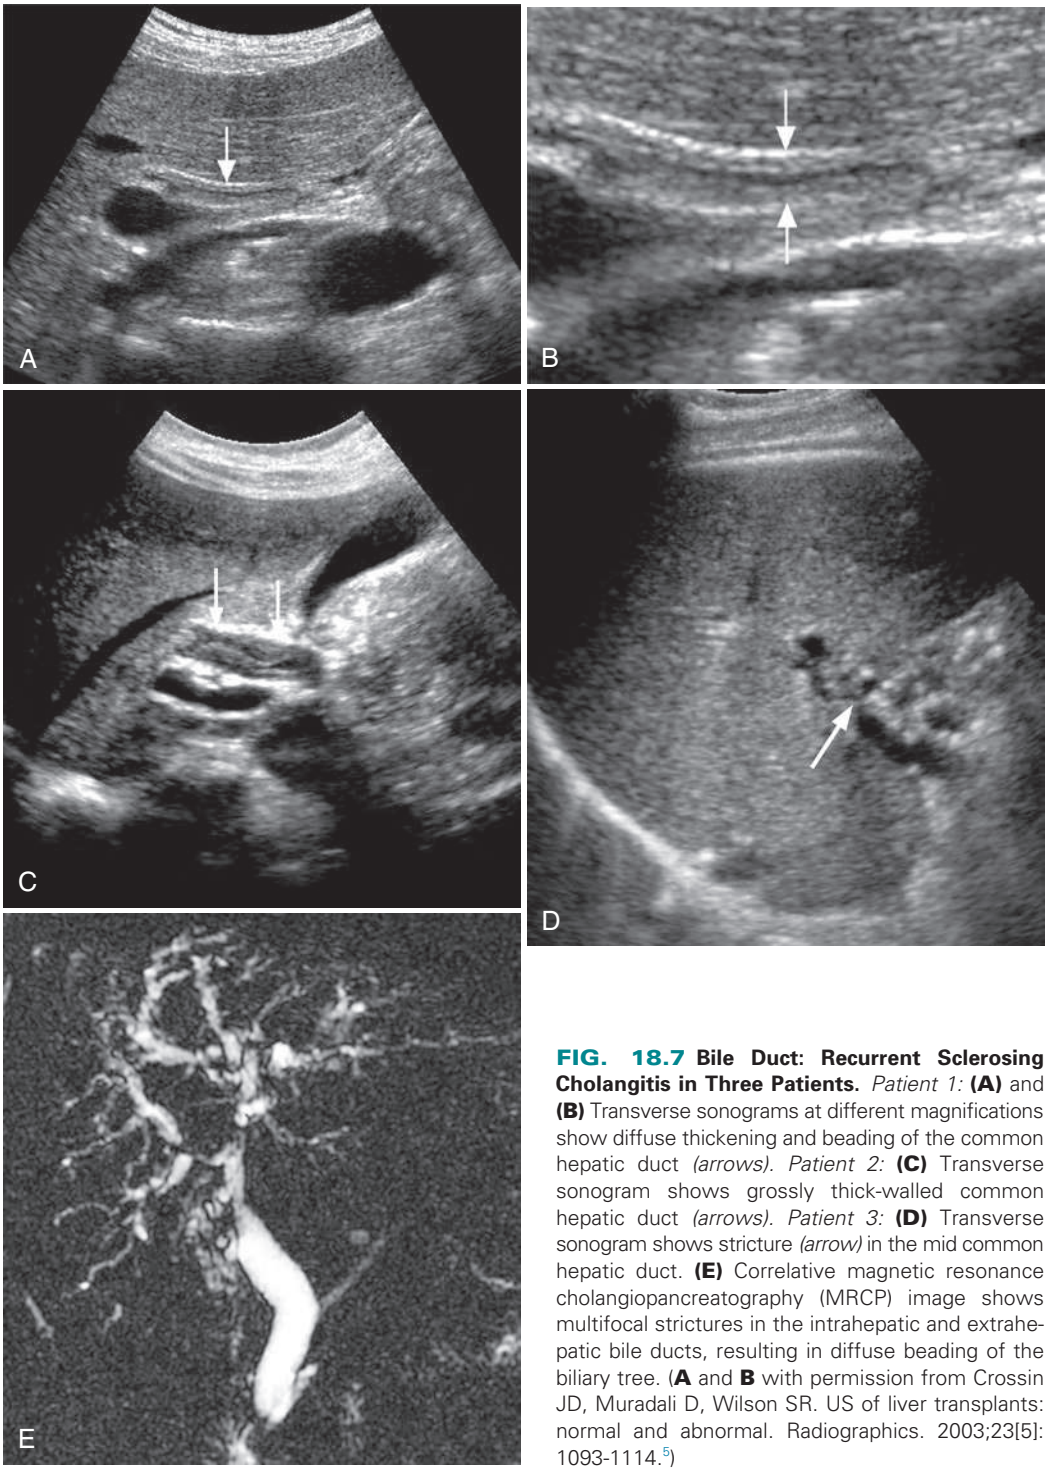

FIG. 18.7 Bile Duct: Recurrent Sclerosing Cholangitis in Three Patients. *Patient 1:* **(A)** and **(B)** Transverse sonograms at different magnifications show diffuse thickening and beading of the common hepatic duct *(arrows). Hepatic Artery Thrombosis

Hepatic artery thrombosis is the most important vascular complication of liver transplantation, with an incidence of 2.5% to 6.8% and mortality as high as 35%.[28] If retransplantation is not performed for these patients, mortality can increase to 73%.[29]

The pathophysiology is often difficult to decipher. Risk factors include patients requiring complex vascular reconstruction (caused by multiple arterial supply to the liver or small donor and recipient vessels), rejection, severe stenosis, increased cold ischemic time of the donor liver, and ABO blood type incompatibility.[8,30]

After transplantation, the donor bile duct is entirely dependent on the transplanted hepatic artery, particularly the right, for its arterial blood supply. Therefore patients with hepatic artery thrombosis can present clinically with delayed biliary leak, fulminant hepatic failure, or intermittent episodes of sepsis thought to be secondary to liver abscess formation within infarcted tissue.[30] However, the clinical presentation, imaging findings, and patient outcomes are related to the **timing of thrombosis** of the hepatic artery. Hepatic artery thrombosis occurring within 1 month of transplantation can be classified as **early** hepatic artery thrombosis. This is often associated with biliary tract necrosis, bacteremia, acute fulminant hepatic failure, and a high patient morbidity rate.[29] Gray-scale sonography may show the hepatic artery at the porta hepatis; however, no flow is detected on color or spectral Doppler in the hilum or parenchyma.

Hepatic artery thrombosis occurring after 1 month of transplantation can be classified as **late** hepatic artery thrombosis. This is usually associated with a milder clinical course, with patients remaining either asymptomatic for months to years or showing an insidious course eventually involving biliary tract complications, relapsing fevers, or bacteremia. It is thought that the development of collateral arterial vessels, as early as 2 weeks after surgery, accounts for the survival of the transplant in these patients. Although resection of all vascular connections in the transplant can hinder development of collateral circulation, arterial collateral vessels could develop from the angiogenic potential of the omentum and mesentery. On ultrasound, a **tardus-parvus arterial waveform** (RI < 0.5; AT > 100 ms) is detected within the hepatic parenchyma (Fig. 18.10). Within the hilum, no arterial flow is demonstrated, or if periportal arterial collaterals are present, a tardus-parvus waveform may be detected. Therefore demonstration of arterial flow in the hepatic parenchyma does not exclude the presence of hepatic arterial thrombosis, and meticulous inspection of the parenchymal waveform is warranted[29,30] (see Fig. 18.10).

Occasionally, a false-positive diagnosis of hepatic artery thrombosis can occur with severe hepatic edema, systemic hypotension, and high-grade hepatic artery stenosis.[8] In situations with poor visibility of the porta hepatis because of abdominal girth or overlying bowel gas, lack of detectable flow within the hepatic artery should be viewed with caution and confirmed on computed tomography angiography (CTA).

Hepatic Artery Stenosis

Hepatic artery stenosis has been reported in up to 11% of transplant recipients and most often occurs at or within a few centimeters of the surgical anastomosis. Risk factors for development of stenosis include faulty surgical technique, clamp injury, rejection, and intimal trauma caused by perfusion catheters.[27] Clinically, patients have biliary ischemia and/or abnormal LFT values.

Doppler ultrasound can provide direct and indirect evidence of hepatic artery stenosis. **Direct** evidence involves identifying and localizing a hemodynamically significant narrowing within the vessel. The porta hepatis should be initially screened with color Doppler ultrasound to detect a focal region of color aliasing within the hepatic artery, which indicates high-velocity turbulent flow produced by the stenotic segment. If the stenosis is hemodynamically significant, spectral tracing will reveal peak systolic velocity (PSV) of greater than 2 to 3 m/sec, with associated turbulent flow distally. **Indirect** evidence of hepatic artery stenosis includes a tardus-parvus waveform anywhere within the hepatic artery (RI < 0.5; AT > 100 ms). This waveform suggests the presence of a more proximally located stenotic region.[27] Indirect evidence of stenosis is much more common in clinical practice than documentation of the stenosis itself (Figs. 18.11 and 18.12).

The presence of an intraparenchymal tardus-parvus waveform indicates alterations in the intrahepatic arterial bed from impaired arterial perfusion of the liver. Although it is detected most often in patients with hepatic artery stenosis, tardus-parvus waveform may also result from collateral vessels arising from hepatic artery thrombosis or, less frequently, from severe aortoiliac atherosclerosis. Therefore an intraparenchymal tardus-parvus waveform cannot distinguish between hepatic artery stenosis and thrombosis if the hepatic arterial trunk is not visualized and meticulously investigated.[31]

Mild degrees of hepatic artery narrowing may also be present without Doppler abnormalities. Therefore if clinical suspicion is high, a normal Doppler study should not preclude further

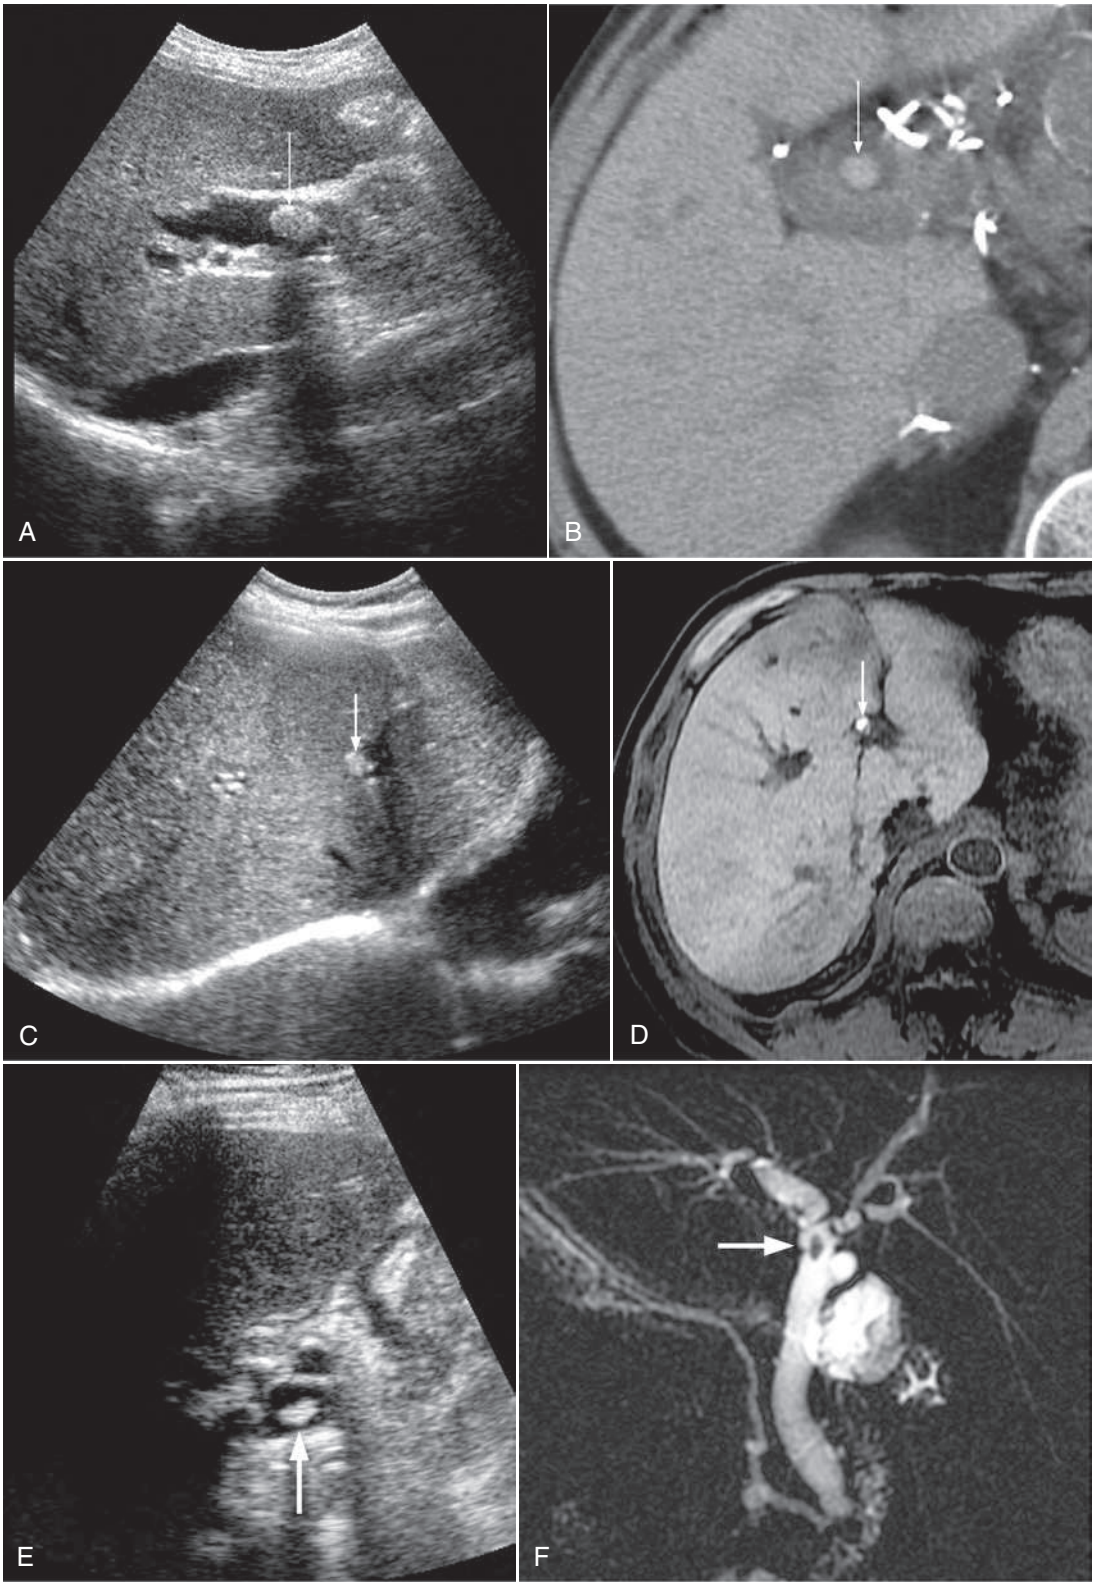

FIG. 18.9 Bile Duct: Stones. (A) Sonogram and **(B)** correlative noncontrast-enhanced CT show the presence of a large obstructing stone *(arrow)* in the common hepatic duct. **(C)** Transverse sonogram shows an echogenic focus *(arrow)* consistent with an intraductal calculus in this patient with recurrent primary sclerosing cholangitis. **(D)** Corresponding axial SPGR (spoiled gradient echo) T1-weighted pregadolinium-enhanced magnetic resonance image shows intraductal high-frequency signal *(arrow)* consistent with a stone. **(E)** Transverse sonogram at level of the common hepatic duct shows a nonshadowing echogenic focus *(arrow)* in the duct, consistent with a soft stone. **(F)** Corresponding T2-weighted magnetic resonance image shows a well-defined filling defect *(arrow),* confirming the presence of a calculus within the proximal common duct.

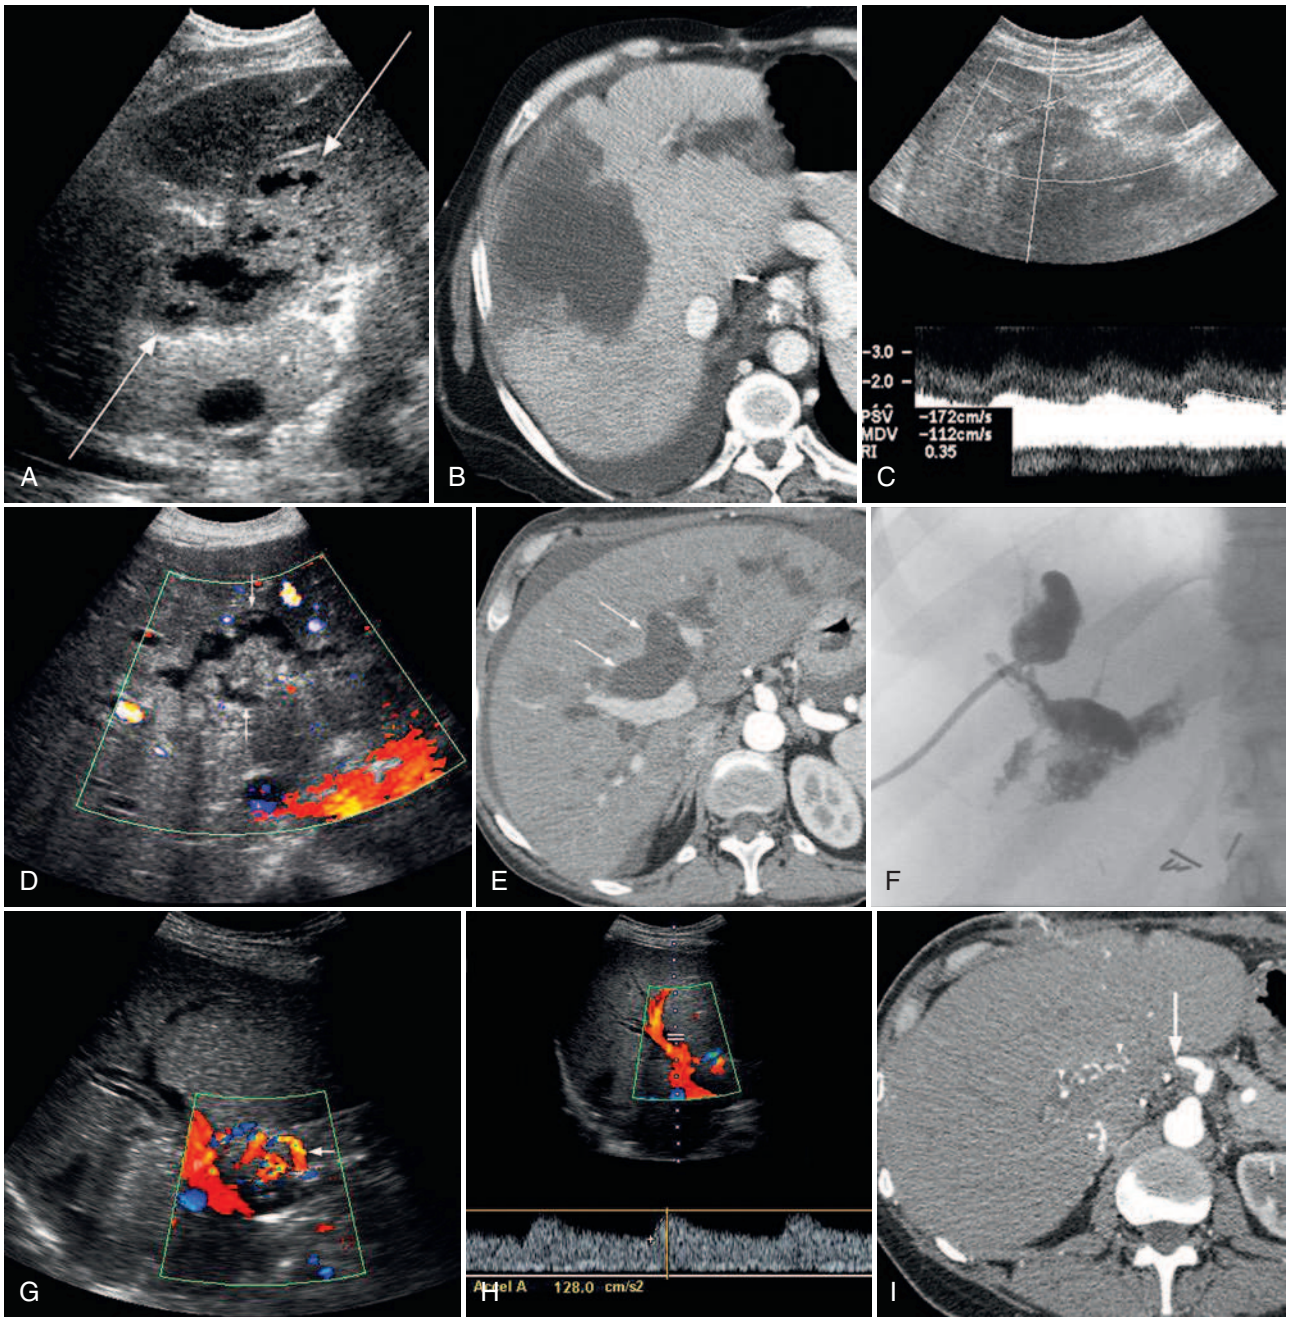

FIG. 18.10 Hepatic Artery: Thrombosis in Three Patients. *Patient 1:* **(A)** Transverse sonogram shows a right lobe infarct appearing as a solid-cystic region *(arrows),* resulting from hepatic arterial thrombosis. **(B)** Corresponding CT scan shows the infarct as a low-attenuating wedge-shaped region. **(C)** On spectral Doppler, no flow could be detected in the main hepatic artery. A tardus-parvus waveform detected within the liver indicates an upstream hepatic arterial problem—in this case, hepatic artery thrombosis with collateral arterial vessels supplying the hepatic tissue. *Patient 2:* **(D)** Transverse sonogram shows a greatly distended bile duct *(arrows)* with echogenic material within the lumen secondary to sloughed mucosa and blood. **(E)** Corresponding CT scan shows dramatically dilated intrahepatic bile ducts *(arrows).* The biliary necrosis is less well appreciated on CT. **(F)** Percutaneous cholangiogram shows contrast filling shaggy, intrahepatic ducts with multiple filling defects. The filling defects correspond to the sloughed biliary mucosa. *Patient 3:* **(G)** Transverse sonogram demonstrates multiple collateral vessels *(arrow)* at the porta hepatis. **(H)** Spectral Doppler sonogram within the liver shows a tardus-parvus waveform. **(I)** CT angiogram shows occlusion of the hepatic artery *(arrow)* caused by acute thrombosis. Multiple arterial collateral vessels *(arrowheads)* are identified, as seen on **(G).**

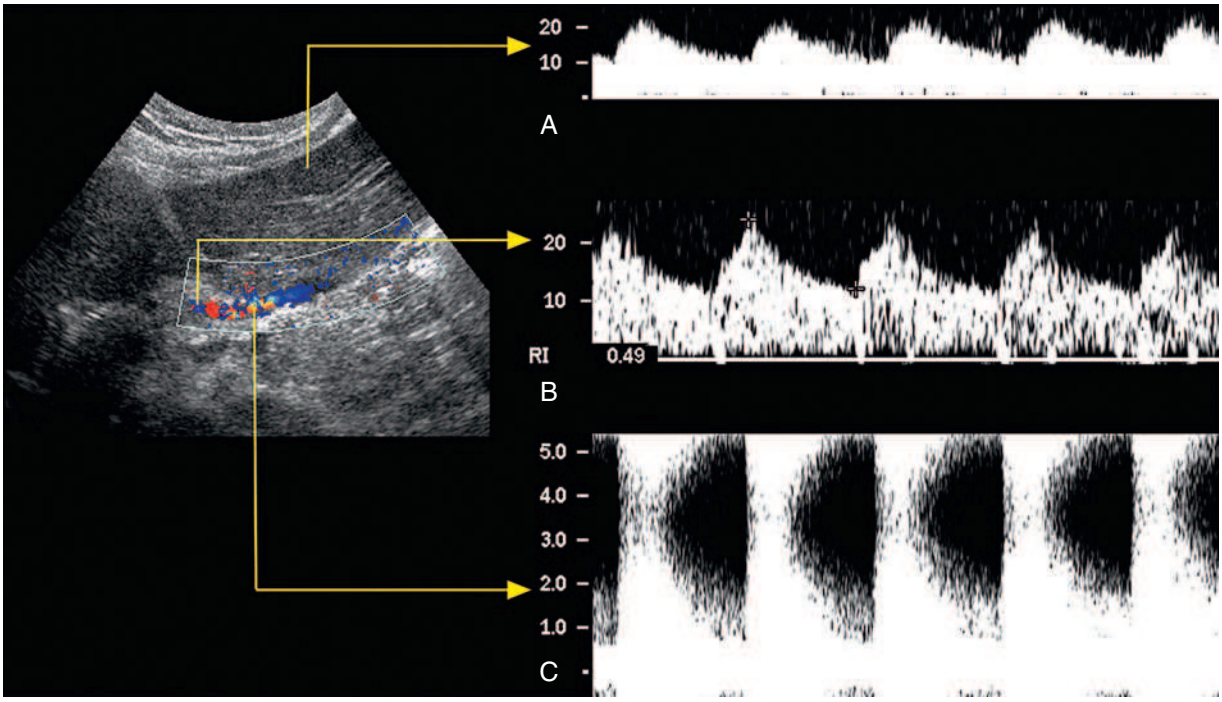

FIG. 18.11 Hepatic Artery Stenosis: Doppler Features. (A) Intrahepatic spectral waveform and **(B)** hepatic artery waveform at porta hepatis show a prolonged acceleration time and low resistance, a tardus-parvus waveform, suggesting an upstream problem. **(C)** Spectral waveform at the anastomosis shows high-velocity flow greater than 400 cm/sec. The corresponding color Doppler sonogram shows aliasing as turquoise and yellow between the red and blue at the stenosis, with turbulence beyond.

investigation with other cross-sectional techniques, although the stenosis, if detected, may be mild in these patients.

Although detection of a tardus-parvus waveform should incite further assessment, false-positive diagnoses can occur, particularly in the early postoperative period (within 48 hour of surgery), possibly because of postoperative edema. In one study, approximately 30% of false-positive tardus-parvus waveforms were idiopathic and not associated with any causative factors.[32]

Elevated Hepatic Arterial Resistive Index

In the early postoperative period, a normal hepatic artery may display a high-resistance arterial flow (RI > 0.8) or a complete lack of flow in diastole (RI = 1.0) on Doppler interrogation. In these patients the flow within the hepatic artery usually returns to normal in a few days. The cause of this waveform is uncertain, although it may be related to older donor age or prolonged cold ischemic time of the graft. RIs may also be higher in normal grafts with an infrarenal aortohepatic anastomosis compared with those grafts with an end-to-end anastomosis. Thus a high RI of the hepatic artery on Doppler assessment frequently has no clinical relevance and should not be misinterpreted as a sign of a hepatic artery abnormality.[33,34]

Hepatic Artery Pseudoaneurysms

Hepatic artery pseudoaneurysms are uncommon complications of transplantation (1%) and occur most frequently at the vascular anastomosis or as a result of prior angioplasty. **Intrahepatic** pseudoaneurysms are rare, usually peripherally located, and associated with percutaneous needle biopsies, infection, or biliary procedures. Intrahepatic aneurysms are often asymptomatic but can cause life-threatening arterial hemorrhage or, in mycotic pseudoaneurysms, produce fistulas between the aneurysm and the biliary tree or portal veins.[8] **Extrahepatic** pseudoaneurysms occur at the donor-recipient arterial anastomosis and may be caused by infection or technical failure.

Gray-scale ultrasound of hepatic artery pseudoaneurysms shows a hypoechoic structure (at times simulating a cyst), typically following the course of the hepatic artery, with intense swirling flow on color Doppler and a disorganized spectral waveform (Fig. 18.13). Management options are dictated by the location of the pseudoaneurysm. Extrahepatic pseudoaneurysms can be treated by surgery, transcatheter embolization, or stent insertion, whereas intrahepatic pseudoaneurysms are often treated with endovascular coil embolization.

Celiac Artery Stenosis

Celiac artery stenosis may be caused by **atheromatous disease** or impingement of the celiac axis by the **median arcuate ligament** of the diaphragm. If severe, celiac stenosis can result in decreased arterial flow to the allograft. Patients are often asymptomatic before transplantation, presumably because of rich collateral networks, usually through the pancreaticoduodenal arcade. After transplantation, patients may become symptomatic, with evidence of biliary ischemia and abnormalities in serum LFT values, a result of the greater flow demand imposed on the celiac artery by the newly transplanted liver.

Doppler ultrasound may be normal or may reveal a low-resistance tardus-parvus waveform in the transplanted hepatic

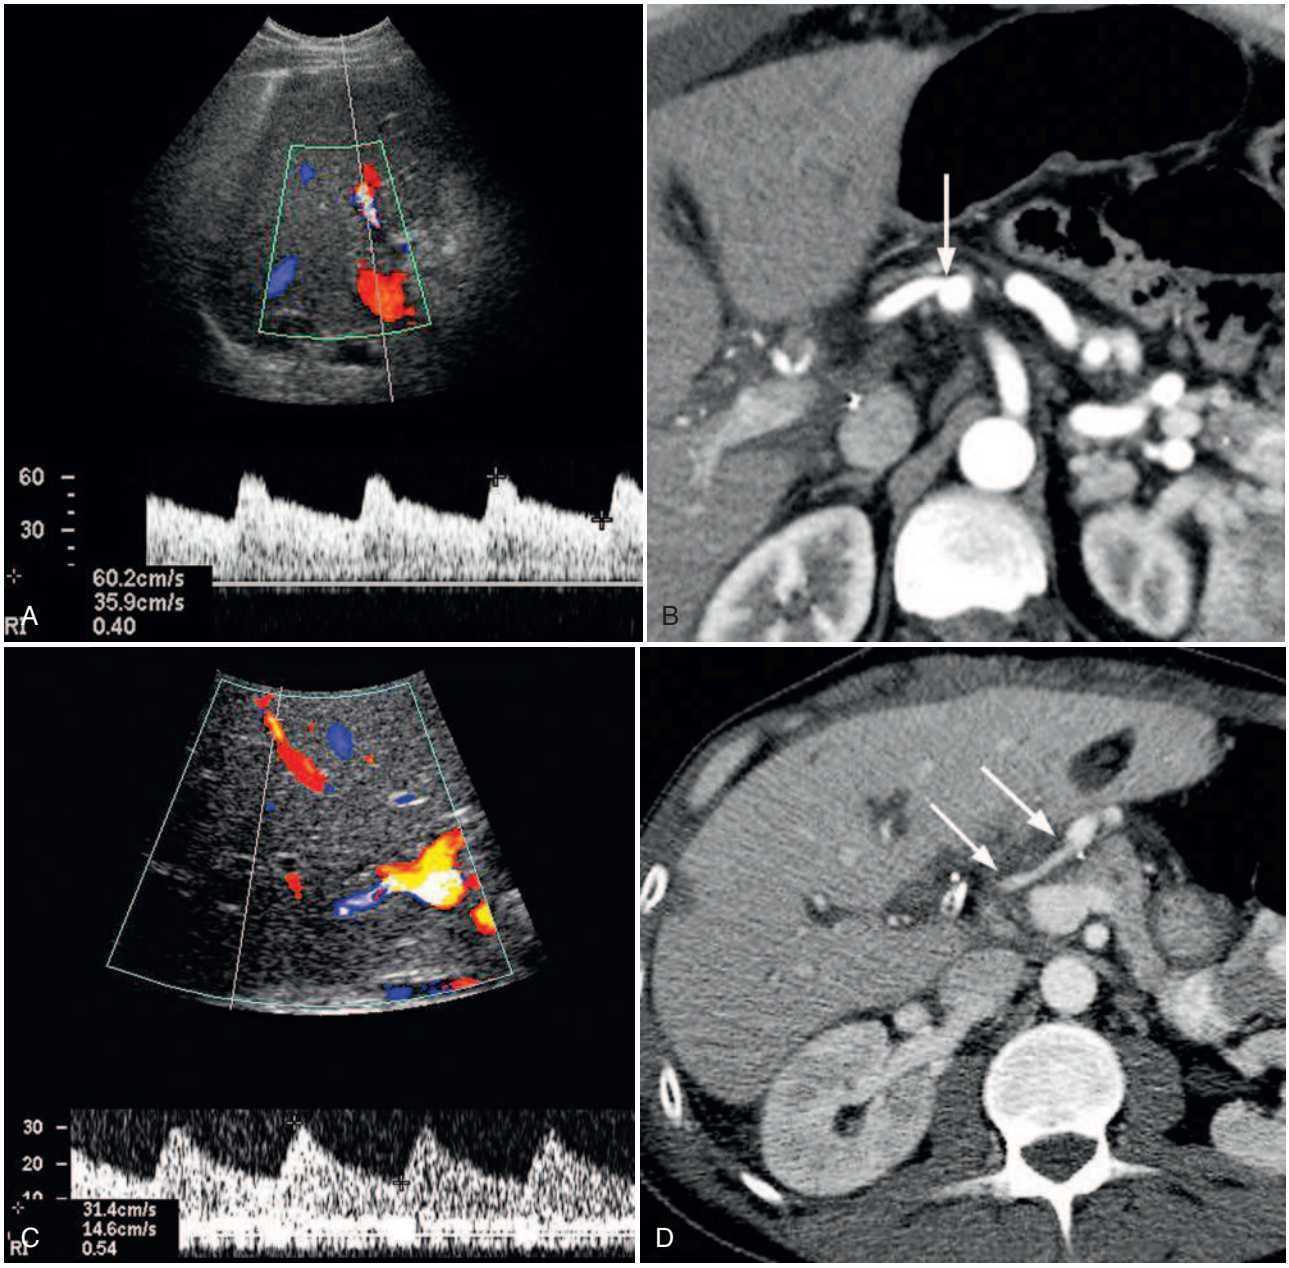

FIG. 18.12 Hepatic Artery Stenosis in Two Patients. *Patient 1:* **(A)** Intraparenchymal spectral Doppler ultrasound shows a low-resistance waveform (resistive index [RI] = 0.4). **(B)** Corresponding contrast-enhanced CT angiogram shows subtle stenosis of the proximal hepatic artery *(arrow). Patient 2:* **(C)** Intraparenchymal spectral Doppler shows a tardus-parvus, low-resistance waveform with a delayed acceleration time of 120 ms. **(D)** Corresponding CT angiogram shows long stenosis of the hepatic artery *(between arrows).*

artery and high-velocity jet across the celiac stenosis. Patients are treated with division of the median arcuate ligament or, in the case of atheromatous disease, an aortohepatic interposition bypass graft[35,36] (Fig. 18.14).

Portal Vein Complications

Portal vein **stenosis** or **thrombosis** is uncommon, with a reported incidence of 1% to 13%.[30,37,38] Risk factors include faulty surgical technique, misalignment of vessels, excessive vessel length, hypercoagulable states, and previous portal vein surgery.[30] Factors extrinsic to the portal vein may also contribute, such as increased downstream resistance caused by a suprahepatic stricture of the IVC or diminished portal venous blood flow. Clinical presentations include hepatic failure and signs of portal hypertension (gastrointestinal hemorrhage from varices or massive ascites).

Gray-scale ultrasound of **portal vein stenosis** may show narrowing of the vessel lumen, usually at the anastomosis. Doppler interrogation shows a focal region of color aliasing, reflecting turbulent, high-velocity flow, with a threefold to fourfold velocity

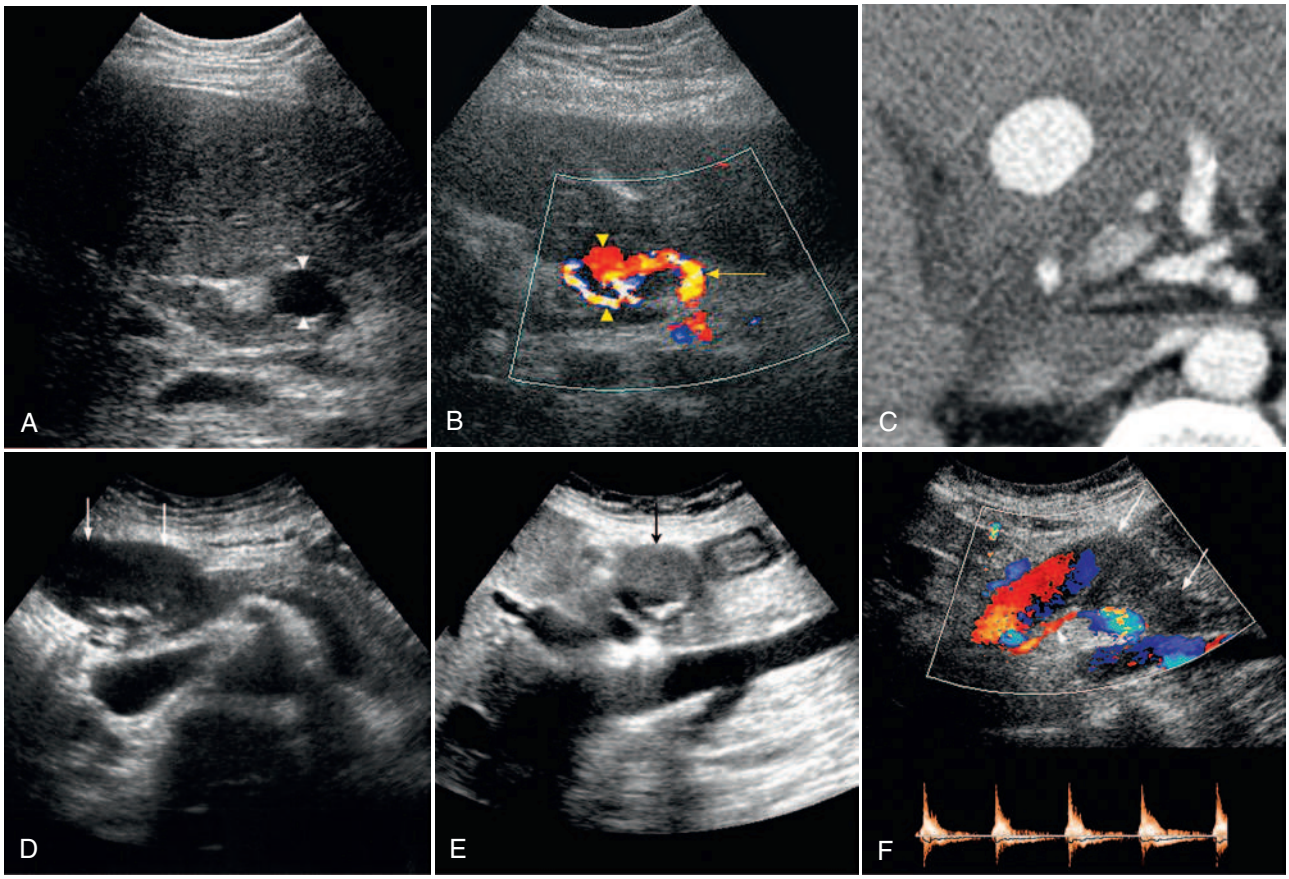

FIG. 18.13 Hepatic Artery Pseudoaneurysms in Two Patients. *Patient 1:* **(A)** Gray-scale sonogram shows a small cystic mass close to the porta hepatis *(arrowheads).* **(B)** Color Doppler ultrasound confirms vascularity within the pseudoaneurysm *(arrowheads)* arising from the hepatic artery *(arrow).* **(C)** Corresponding enhanced CT confirms the pseudoaneurysm arising at the hepatic artery anastomosis. *Patient 2:* **(D)** Transverse and **(E)** sagittal sonograms show a midline oval mass *(arrows).* **(F)** On color and spectral Doppler ultrasound, disorganized flow is identified in a portion of the mass, representing a partially thrombosed pseudoaneurysm. Arrows mark the thrombosed portion of the pseudoaneurysm. (**A-C** with permission from Crossin JD, Muradali D, Wilson SR. US of liver transplants: normal and abnormal. Radiographics. 2003;23[5]:1093-1114.[5])

increase at the site of stenosis relative to the prestenotic segment on spectral interrogation (Fig. 18.15). Chong and colleagues[39] showed that the presence of elevated portal vein anastomotic velocities greater than 125 cm/sec, or a velocity ratio of 3:1 at the anastomosis, was greater than 95% specific for portal vein stenosis.

True portal vein stenosis must be distinguished from a **pseudostenosis** of the portal vein. This entity is seen when the recipient portal vein is larger than the donor portal vein and no associated differential gradient exists across the site of narrowing.

Portal vein thrombosis manifests as echogenic solid material within the portal vein lumen (Figs. 18.16 and 18.17). In the acute state the thrombus may be anechoic, making detection difficult on gray-scale ultrasound and emphasizing the necessity for careful Doppler assessment of the entire portal venous system. As with portal vein thrombosis in the native liver, the thrombus may decrease in size and eventually recanalize, showing multiple venous flow channels within the thrombus. Treatment options for portal vein thrombosis or stenosis include thrombectomy, segmental portal vein resection, percutaneous thrombolysis, stent placement, and balloon angioplasty.

Inferior Vena Cava Complications

Stenosis of the IVC is a rare complication of liver transplantation and may occur at the suprahepatic or infrahepatic anastomosis. IVC stenosis occurs more frequently in pediatric recipients and patients undergoing retransplantation.[40] Causes of IVC stenosis include anastomotic discrepancy, IVC kinking, fibrosis, or neointimal hyperplasia. On gray-scale ultrasound, the IVC may show obvious narrowing at the site of anastomosis, associated with a focal region of aliasing on color Doppler. On spectral interrogation, a threefold to fourfold greater velocity gradient is observed across the stenosis compared with the prestenotic segment. The hepatic veins may show reversal of flow or may lose their normal phasicity, with a monophasic waveform[8] (Figs. 18.18 and 18.19).

Thrombosis of the IVC has been reported in less than 3% of recipients and is caused by technical difficulties at surgery, hypercoagulable states, or compression from adjacent fluid

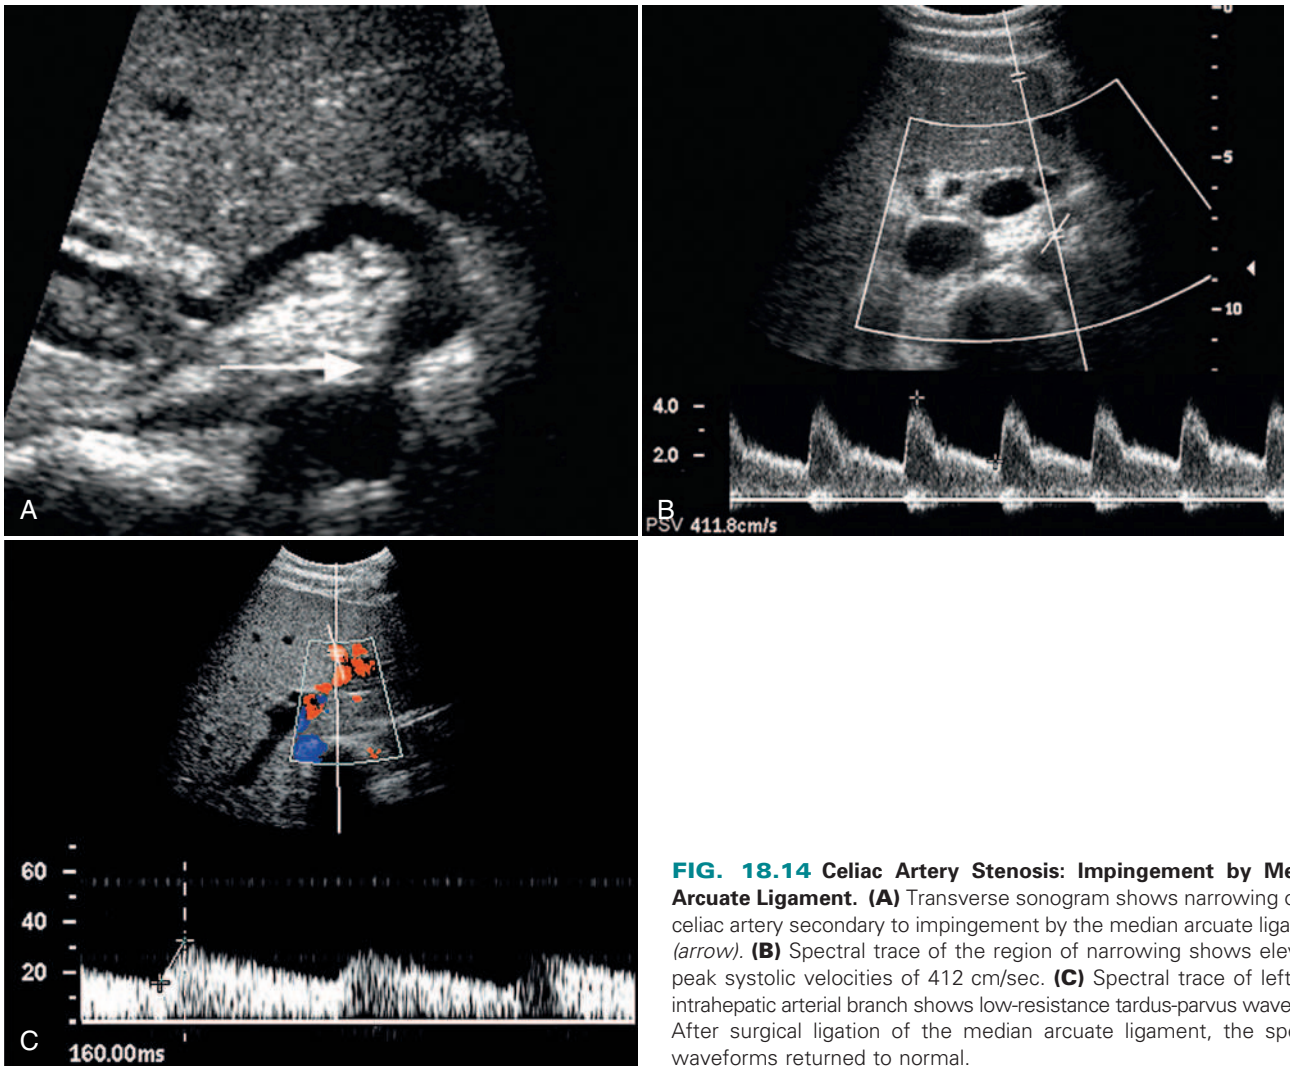

FIG. 18.14 Celiac Artery Stenosis: Impingement by Median Arcuate Ligament. (A) Transverse sonogram shows narrowing of the celiac artery secondary to impingement by the median arcuate ligament *(arrow)*. **(B)** Spectral trace of the region of narrowing shows elevated peak systolic velocities of 412 cm/sec. **(C)** Spectral trace of left lobe intrahepatic arterial branch shows low-resistance tardus-parvus waveform. After surgical ligation of the median arcuate ligament, the spectral waveforms returned to normal.

collections.[26,40] Gray-scale ultrasound shows echogenic thrombus within the IVC that may continue into the hepatic veins. In cases of recurrent HCC, tumor thrombus may extend from the hepatic veins into the IVC (Fig. 18.20).

Hepatic Vein Stenosis

Hepatic vein stenosis occurs with a frequency of 1% in **orthotopic liver transplant** and 2% to 5% in **living donor transplants.** This discrepancy in frequency is primarily related to different surgical techniques. In orthotopic liver transplants, an anastomosis is performed between the donor and recipient IVC without touching the hepatic veins. In living donor transplants, however, the donor hepatic vein is anastomosed to either the hepatic vein stump or the IVC of the recipient. This results in the hepatic veins being rigidly fixed in position, such that any movement of the graft produces a buckling and narrowing of the hepatic veins. In addition, progressive growth of partial liver grafts after surgery may result in stretching or twisting of the hepatic veins, further contributing to narrowing of the venous outlet.[41,42]

Clinically, hepatic vein stenosis manifests with liver congestion, hepatomegaly, ascites, and/or pleural effusions. Hepatic venous obstruction in the **early postoperative state** is a surgical emergency, and reoperation is usually necessary for correction or for retransplantation, if substantial hepatic necrosis has occurred. **Late-onset hepatic venous obstruction** may be associated with a more insidious deterioration in liver function. These patients may benefit from metallic stent insertion or balloon venoplasty, because surgical correction is often difficult as a result of fibrotic changes around the anastomotic sites.[41,42]

Direct signs of hepatic vein stenosis include focal narrowing on gray-scale ultrasound associated with turbulent flow on color and spectral Doppler interrogation (Fig. 18.21). A persistent, monophasic spectral waveform is suggestive of, but not diagnostic of, hepatic vein stenosis; monophasic waveforms may also be present in normal, nonobstructed hepatic veins. However, the presence of a triphasic or biphasic waveform rules out clinically important hepatic vein stenosis.[42]

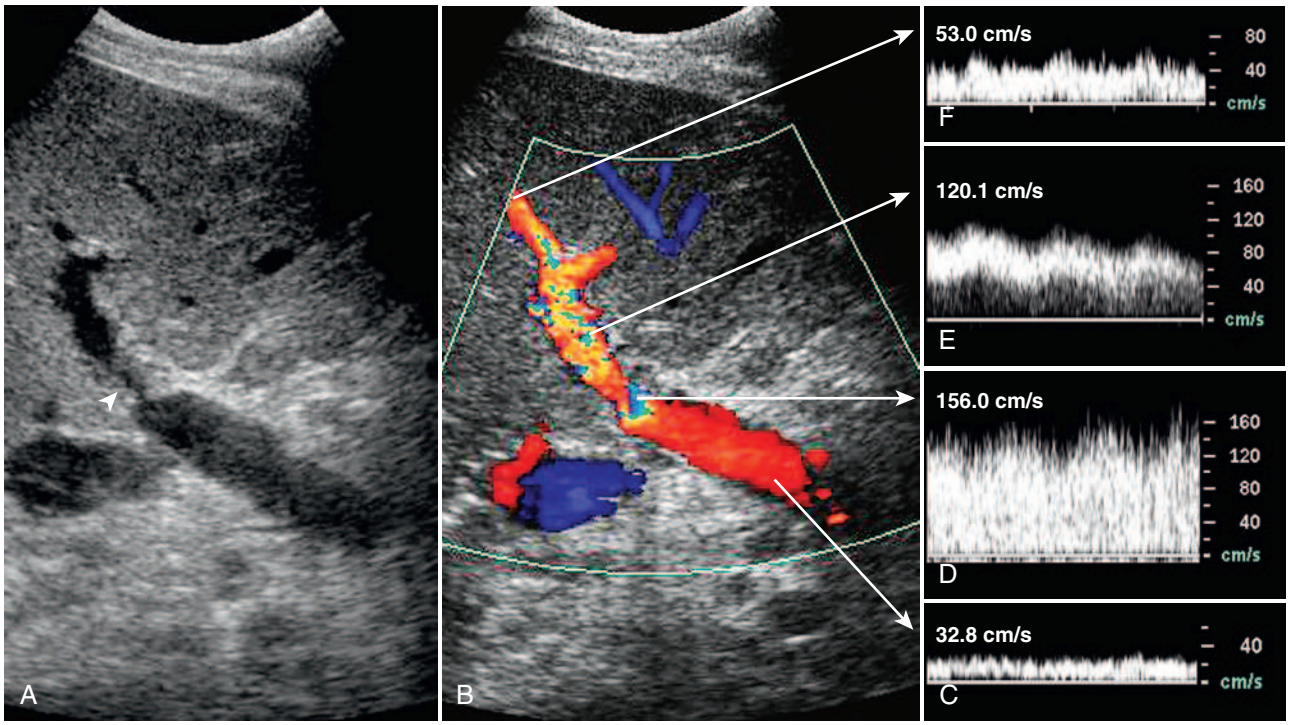

FIG. 18.15 Portal Vein Stenosis: Anastomotic Stricture. (A) Gray-scale sonogram of main portal vein shows narrowing at the anastomosis *(arrowhead).* **(B)** Color Doppler shows aliasing at the region of stenosis caused by high-velocity turbulent flow. **(C)** Spectral Doppler shows velocities of 32.8 cm/sec proximal to the stenosis. **(D)** Velocities at the stenosis are elevated at 156 cm/sec. **(E)** Poststenotic high-velocity turbulent flow is identified, measuring 120.1 cm/sec. **(F)** Beyond the turbulent flow, velocities of 53 cm/sec are obtained. This represents a threefold increased velocity gradient across the anastomosis, indicating that the stenosis is hemodynamically significant.

Extrahepatic Fluid Collections

Perihepatic fluid collections and ascites are frequently observed after transplantation. In the early postoperative period a small amount of free fluid or a right pleural effusion may be observed, but these usually resolve in a few weeks. **Fluid collections** and **hematomas** are common in the areas of vascular anastomosis (hepatic hilum and adjacent to IVC) and biliary anastomosis, in the lesser sac, and in the perihepatic and subhepatic spaces.[7] Because the peritoneal reflections surrounding the liver are ligated at transplantation, fluid collections can occur around the **bare area** of the liver, a location for fluid that is not encountered in the preoperative liver[5] (Fig. 18.22).

Ultrasound is highly sensitive in detecting these fluid collections, although it lacks specificity with regard to etiology because bile, blood, pus, and lymphatic fluid can all have a similar sonographic appearance. The presence of internal echoes in a fluid collection suggests blood or infection. Particulate ascites may also be observed in peritoneal carcinomatosis, although this would seem less likely in the transplant recipient population.[5]

Adrenal Hemorrhage

Right-sided adrenal hemorrhage may be observed in the immediate postoperative period and results from (1) venous engorgement caused by ligation of the right adrenal vein during the removal of a portion of the IVC or (2) a coagulopathy caused by the patient's preexisting liver disease.[26] On ultrasound, adrenal hemorrhage may be seen as a hypoechoic nodular structure or as a fluid collection in the right suprarenal region (Fig. 18.23).

Intrahepatic Fluid Collections

Sterile postoperative fluid collections are often located along the falciform ligament and ligamentum venosum, usually appearing as fluid-filled anechoic collections surrounding the echogenic ligaments (Fig. 18.24). **Bilomas** may manifest as a hypoechoic or complex cyst. **Intraparenchymal hematomas** may result from the transplant surgery or percutaneous biopsy or may be a sequela of donor trauma (e.g., motor vehicle crash).

Abscess Versus Infarct

In the early stages it may be difficult to differentiate a liver abscess from an infarct. Initially, both abscesses and infarcts may appear as a subtle hypoechoic region, associated with a localized coarsening of the parenchymal echotexture. **Infarcts** may subsequently organize into avascular round or wedge-shaped lesions, which can eventually develop central hypoechoic areas reflecting liquefaction and necrosis. A focal liver infarct should be diagnosed with accompanying Doppler evidence of hepatic arterial compromise.

As with infarcts, the ultrasound appearance of a **liver abscess** also varies with its maturation. The classic appearance of a mature transplant liver abscess is a complex, cystic structure with thick,

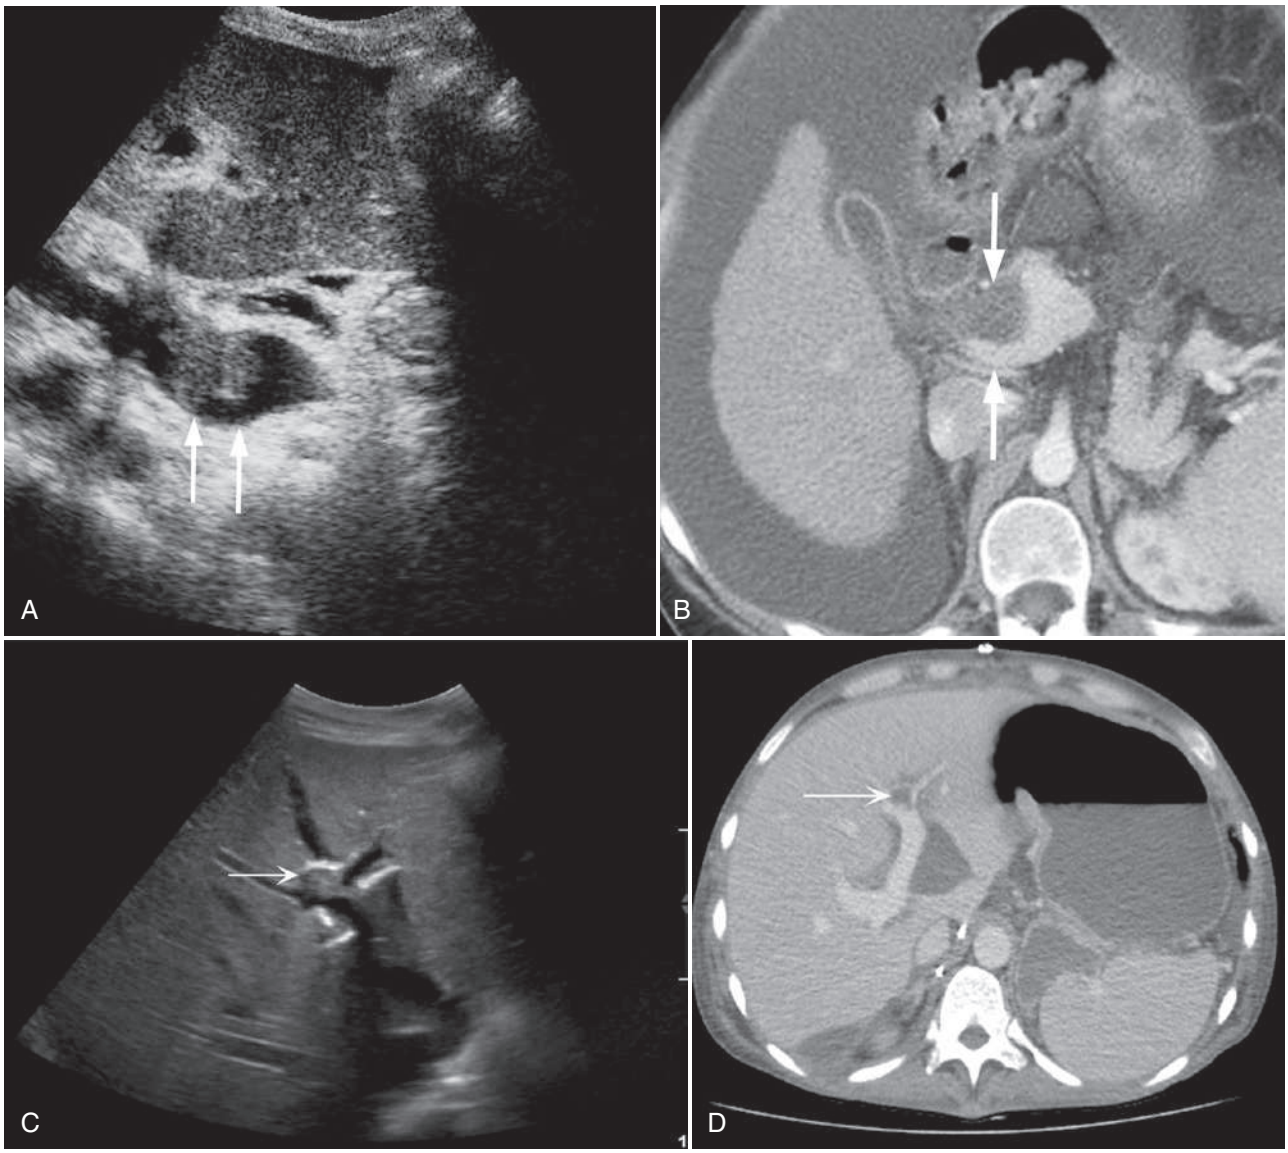

FIG. 18.16 Portal Vein: Bland Thrombus in Two Patients. *Patient 1:* **(A)** Transverse sonogram and **(B)** corresponding contrast-enhanced CT show nonocclusive thrombus in the main portal vein *(arrows). Patient 2:* **(C)** Transverse sonogram and **(D)** corresponding contrast-enhanced CT scan show nonocclusive thrombus in the ascending ramus of the left portal vein *(arrows).*

irregular walls and particulate internal fluid, with or without associated septations.

Both infarcts and abscesses may contain bubbles of air, visualized as bright echogenic foci with or without posterior acoustic shadowing (Fig. 18.25). Occasionally, bubbles of air within the lumen of an intraparenchymal abscess can be confused with benign pneumobilia or may be mistaken for air outside the liver within the gastrointestinal tract. A high index of suspicion is critical in patients at risk for either abscess or infarct to avoid these misinterpretations.

Intrahepatic Solid Masses

The differential diagnosis of a solitary mass in the transplanted liver is similar to that in the native liver. For example, benign lesions, such as hemangiomas and cysts, are relatively common in the transplanted liver, with the same range of appearances as described for the native liver. However, several pathologies unique to the transplanted liver may also appear as a solid or complex mass on gray-scale ultrasound, including infarcts (Fig. 18.26), abscesses, hematomas, recurrent or metastatic HCC, and post-transplant lymphoproliferative disorder (PTLD).

Recurrent hepatocellular carcinoma is a serious complication that can potentially develop after transplantation in patients with a preoperative history of end-stage cirrhosis with known or occult hepatomas. The most common site of recurrent HCC is the lung, presumably caused by embolization with tumor cells through the hepatic veins before or during transplantation. The second most common location of recurrent hepatomas is within the allograft, followed by regional or distant lymph nodes. Early detection of **recurrent hepatomas** in the transplanted liver is

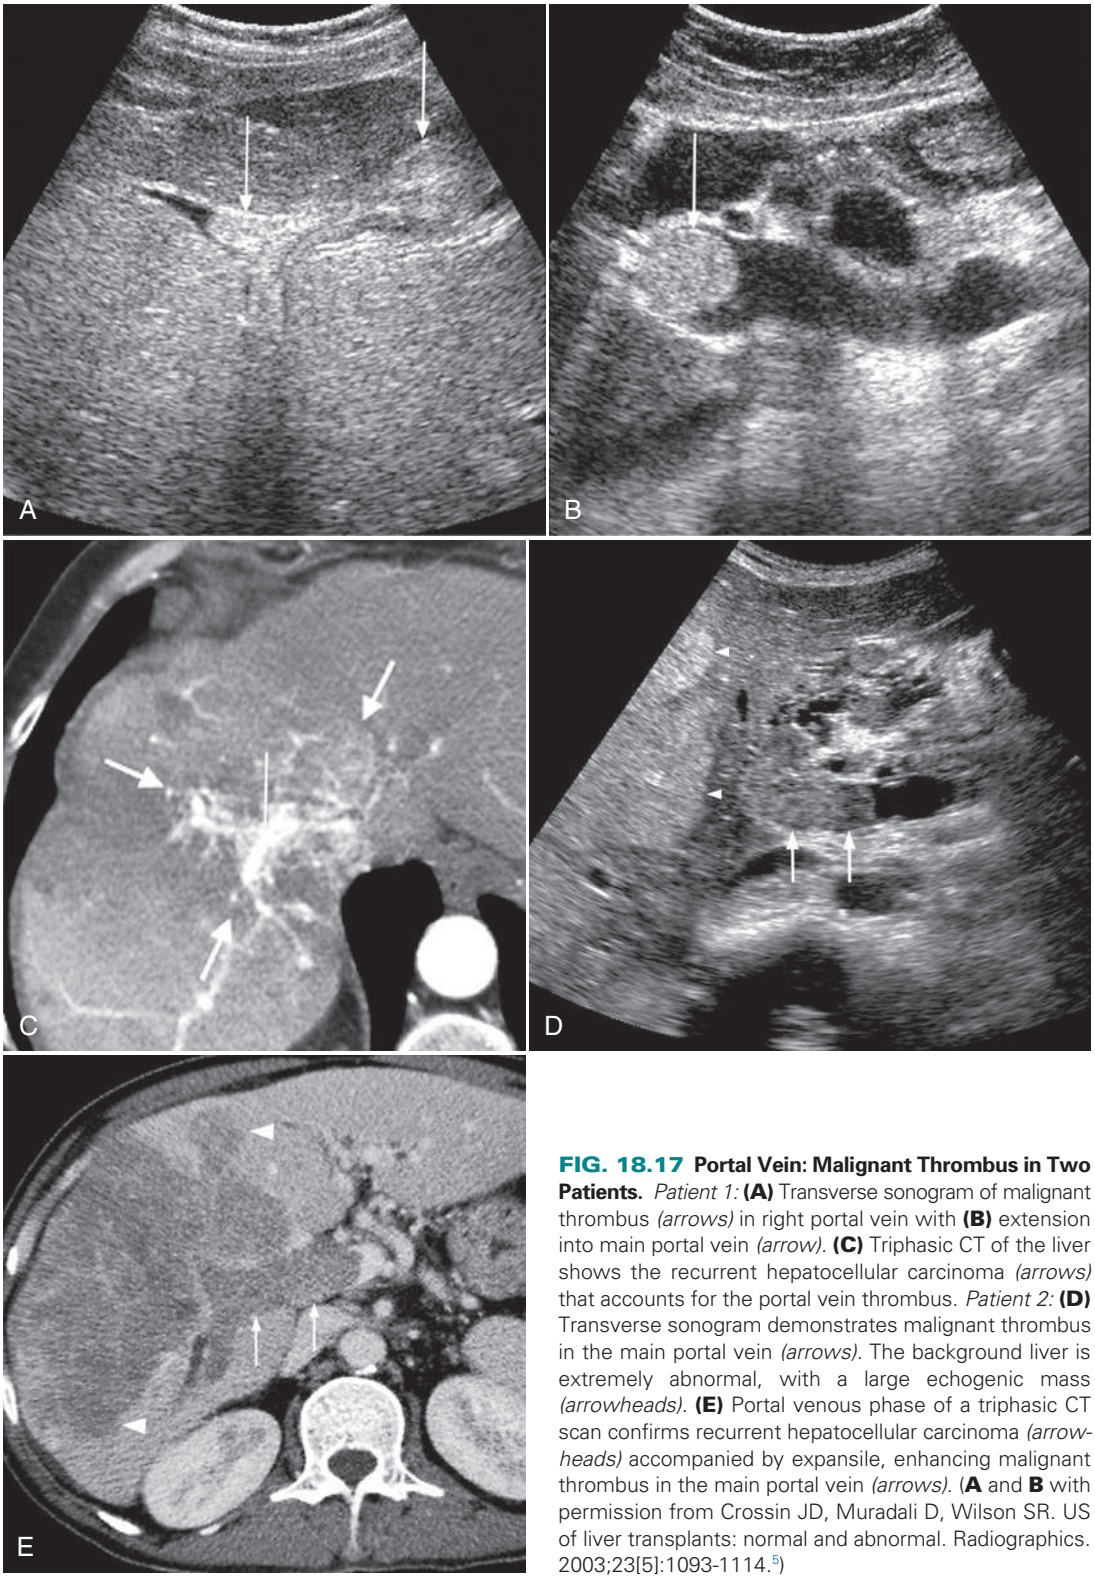

FIG. 18.17 Portal Vein: Malignant Thrombus in Two Patients. *Patient 1:* **(A)** Transverse sonogram of malignant thrombus *(arrows)* in right portal vein with **(B)** extension into main portal vein *(arrow).* **(C)** Triphasic CT of the liver shows the recurrent hepatocellular carcinoma *(arrows)* that accounts for the portal vein thrombus. *Patient 2:* **(D)** Transverse sonogram demonstrates malignant thrombus in the main portal vein *(arrows).* The background liver is extremely abnormal, with a large echogenic mass *(arrowheads).* **(E)** Portal venous phase of a triphasic CT scan confirms recurrent hepatocellular carcinoma *(arrowheads)* accompanied by expansile, enhancing malignant thrombus in the main portal vein *(arrows).* (**A** and **B** with permission from Crossin JD, Muradali D, Wilson SR. US of liver transplants: normal and abnormal. Radiographics. 2003;23[5]:1093-1114.[5])

Spectral tracing shows a greater than threefold velocity increase at the stenotic region *(left arrow)*.

essential to facilitate early resection, ablation, or chemotherapy[26,43] (Fig. 18.27). As in the general population, transplant recipients can develop any type of primary or secondary neoplasm within the liver.

RENAL TRANSPLANTATION

Transplantation is the treatment of choice for many patients with **chronic renal failure** (CRF) severe enough to warrant dialysis. The only contraindications to transplantation are unsuitability for general anesthesia or surgery, preexisting infection or malignancy, and a risk of recurrent renal disease (e.g., active vasculitis or oxalosis). Before transplantation, a suitable donor must be obtained with appropriate human lymphocyte antigen (HLA) matching with the recipient.[44]

As the number of patients with CRF continues to rise, the major limitation for expanding transplant programs is the shortage of suitable donor kidneys. This organ shortage has resulted in an increasing number of renal transplantations from living related donors. These donors may include family members or close friends with a long-standing relationship with the recipient. The average life expectancy for a cadaveric allograft is 7 to 10 years, whereas that for a live donor allograft is 15 to 20 years.[44]

Regardless of whether a cadaveric or live donor allograft is used, the cost-benefit ratio of a functioning successful transplant far outweighs that of a patient with persistent CRF, so multiple health care resources are targeted to ensure high rates of success. Ultrasound is the most valuable noninvasive imaging modality in monitoring the renal transplant.

Surgical Technique

Detailed sonography of the renal transplant requires knowledge of the surgical procedure used in most institutions as well as the postsurgical anatomic relationships. The right or left lower quadrant is selected for the incision, based on the patient's prior surgical history and the surgeon's preference. Usually, the right lower quadrant is selected because the right iliac vein is more superficial and horizontal on this side of the pelvis, facilitating creation of a vascular anastomosis.[45,46]

The type of **arterial anastomosis** used depends on whether the allograft is cadaveric or living related and on the number

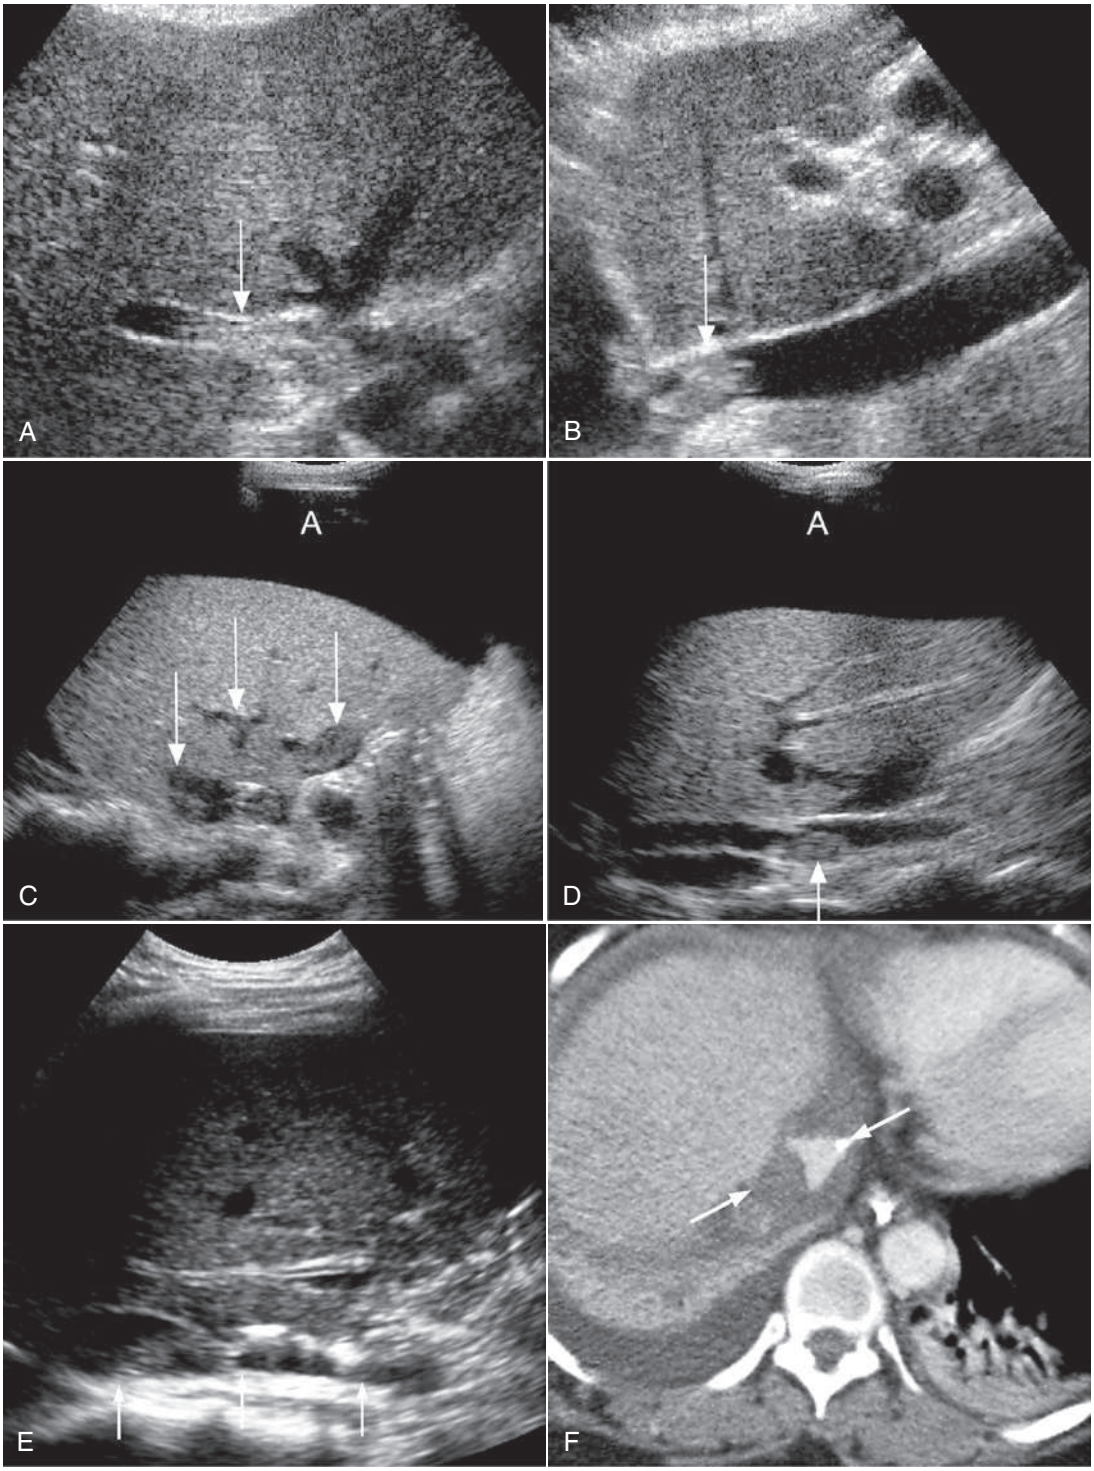

FIG. 18.20 Inferior Vena Cava (IVC) Thrombosis in Three Patients. and size of donor renal arteries. In patients with cadaveric transplants, the donor artery, along with a portion of the aorta (Carrel patch) are anastomosed end to side to the external iliac artery. In patients with living donor transplants, the donor renal artery is anastomosed to either the internal iliac artery (end to end) or the external iliac artery (end to side) of the recipient. Multiple donor arteries of similar size may be joined together with a side-to-side anastomosis to form a common ostium. Alternatively, multiple arteries may be anastomosed as a Carrel patch, or anastomosed separately to the external iliac artery.[45,46]

The **donor renal vein** is almost always anastomosed end to side to the external iliac vein. In the case of multiple renal veins, the smaller veins are usually ligated, resulting in a single donor vein.[46]

The **ureter** is usually anastomosed to the superolateral wall of the urinary bladder through a neocystostomy. Several techniques are used to create a neocystostomy, but the basic procedure involves tunneling the ureter through the bladder wall to prevent reflux to the transplant. For patients undergoing repeat surgery on the collecting system and those with complex surgeries, the recipient's ureter may be used as a conduit to the bladder[45] (Fig. 18.28).

Because of the chronic shortage of donor organs, **paired cadaveric kidneys** from young (<5 years old) donors may be

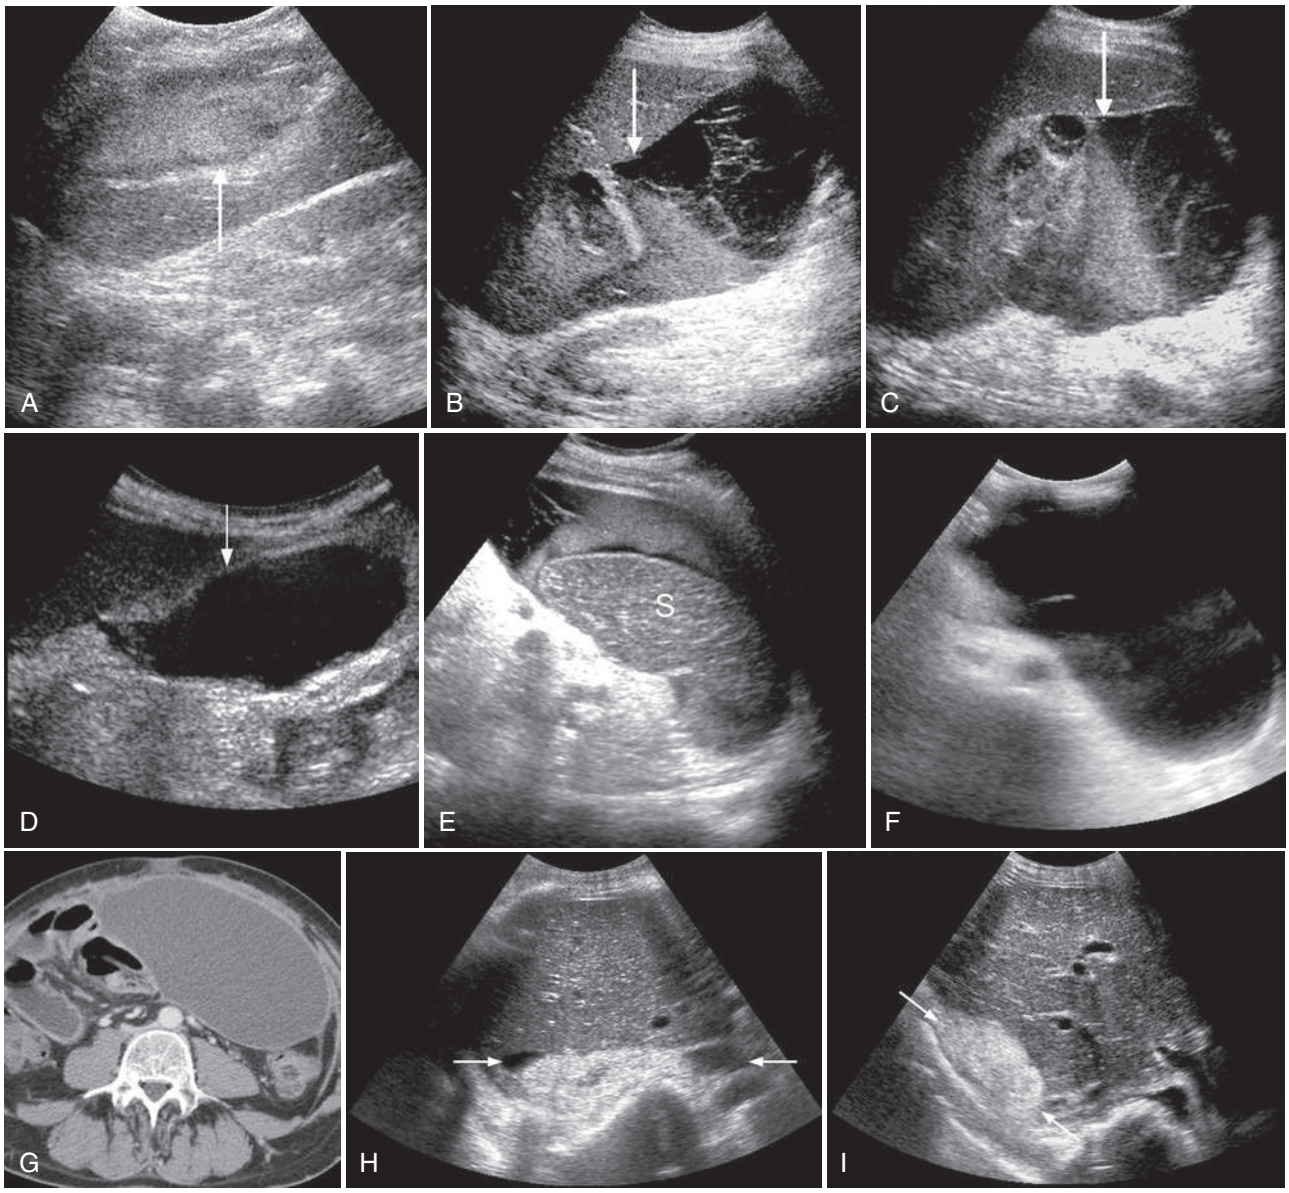

FIG. 18.22 Extrahepatic Fluid Collection. (A)-(D) Hematoma at surgical margin of a right lobe in living related transplant. **(A)** Transverse sonogram shows acute hematoma that appears echogenic, heterogeneous, and solid. **(B)** and **(C)** Hematoma liquefies after 3 weeks, with internal strands and a fluid-debris level. **(D)** After 2 months, further liquefaction of the hematoma appears as a smaller, anechoic collection. *Arrows* mark boundary of hematoma with liver. **(E)** Sagittal sonogram shows **hemoperitoneum** around spleen *(S),* with fluid-fluid level and internal strands. **(F)** and **(G) Anastomotic leak from roux-en-Y.** Transverse sonogram and correlative CT show large fluid collection in the left lower quadrant. **(H)** and **(I) Biloma secondary to anastomotic leak.** Sagittal sonogram and transverse sonogram show complex subphrenic echogenic collection *(arrows).*

transplanted en bloc in an attempt to provide a functional renal mass analogous to the renal mass of a single cadaveric kidney transplanted from an adult. At harvesting, both kidneys are removed en bloc with preservation of the ureters and main renal arteries and veins, as well as segments of the suprarenal and infrarenal abdominal aorta and IVC. The donor aorta and IVC are oversewn just cephalad to the origin of the renal arteries and veins, and the caudal ends anastomosed end to side to the recipient's external iliac artery and vein. The donor ureters are implanted into the urinary bladder through individual or common ureteroneocystostomies.[47] This surgery is more common in the pediatric population than in adults (see Fig. 18.28).

Normal Renal Transplant Ultrasound

Gray-Scale Assessment

Sonography of the renal transplant is usually easily performed because of the superficial location of the kidney in either the right or the left lower quadrant. Because the allograft is held in place by its pedicle, a variety of orientations may be encountered.

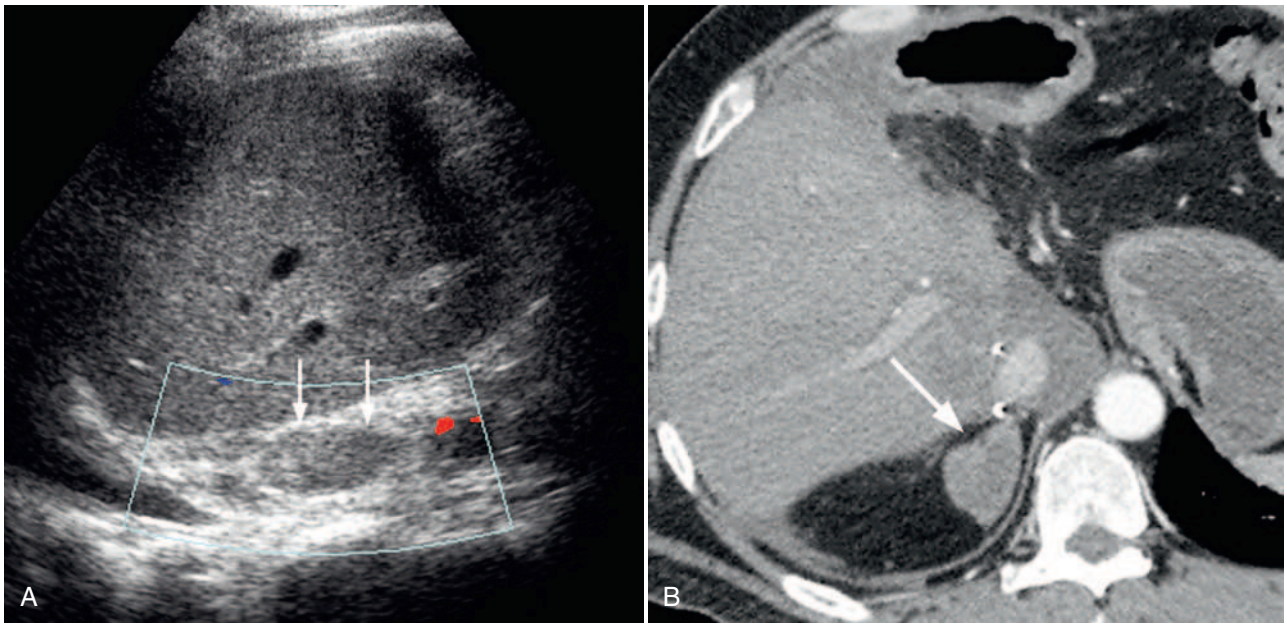

FIG. 18.23 Right Adrenal Hemorrhage. (A) Sagittal sonogram and **(B)** CT show a small right adrenal mass *(arrows).*

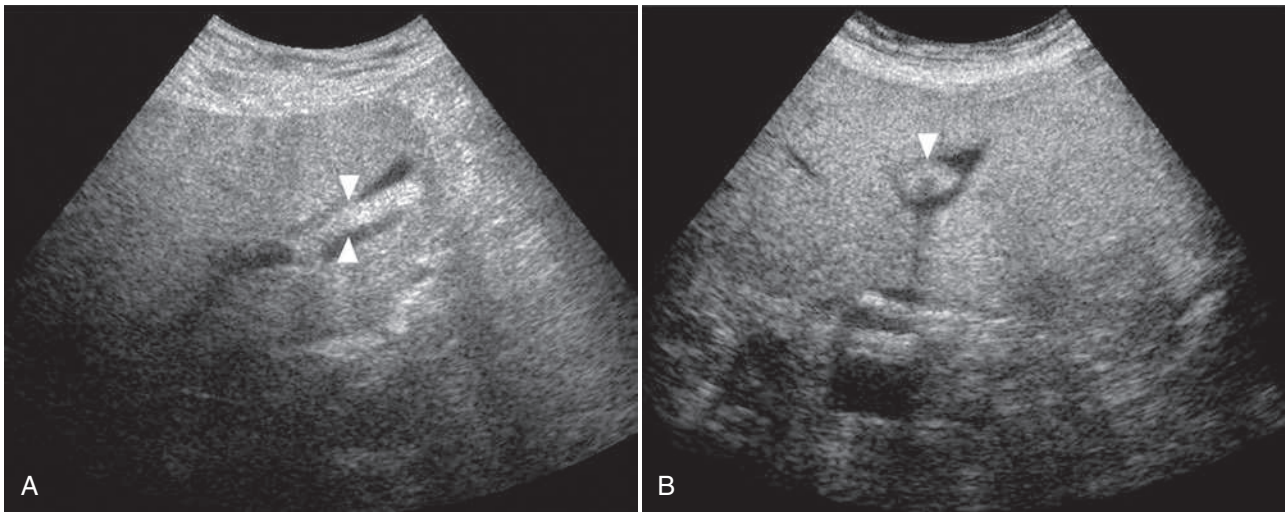

FIG. 18.24 Intrahepatic Fluid Collection. (A) Transverse and **(B)** sagittal sonograms show anechoic fluid surrounding echogenic falciform ligament *(arrowheads).*

Most often, the kidney is aligned with its long axis parallel to the surgical incision, with the hilum oriented inferiorly and posteriorly. Occasionally, in obese patients, the long axis may lie in an anterior-to-posterior plane.[48]

Longitudinal and transverse measurements of the transplant should be obtained with the kidney imaged through the hilum. Although there are no normative data for comparison, these measurements serve as a useful baseline for future reference to assess for interval changes in volume of the allograft. The transplant kidney may hypertrophy by up to 15% within the first 2 weeks after surgery, and eventually may increase in volume by 40%, with the final size attained at about 6 months.[49-51]

The transplanted kidney appears morphologically similar to the native kidney, with many of the subtle differences attributed to the improved resolution from proximity of the allograft to the skin surface (Fig. 18.29, Video 18.1 and Video 18.2). The normal renal cortex is well defined, hypoechoic, and easily differentiated from the highly reflective, central echogenic renal sinus fat. Apart from this improved corticomedullary differentiation, the renal pyramids of the allograft are more easily visualized than in the native kidney, appearing as wedge-shaped structures that are hypoechoic to the surrounding parenchyma.[44]

The collecting system should be assessed for the presence of hydronephrosis. If a stent is present, its proximal and distal

positions should be documented. Transverse and sagittal images of the bladder should also be recorded. The perinephric space and surrounding regions should be assessed for the presence of fluid collections or free fluid.[52]

The sonographer should be aware that the transplanted kidney might show pathology that was likely present at the time of donation, such as benign cysts, angiomyolipomas, and medullary sponge kidney (Figs. 18.30 and 18.31).

Doppler Assessment

Color Doppler gives a global assessment of the intraparenchymal perfusion and is useful in localizing the main renal artery and vein. The renal parenchyma should be screened initially with color Doppler to check for focal regions of hypoperfusion and locate the interlobar arteries for spectral interrogation.[44]

Spectral traces of the interlobar arteries should be obtained from the upper-pole, middle-pole, and lower-pole regions with low filter settings, maximal gain, and the smallest scale demonstrating the PSV. The normal waveform is low impedance with a brisk upstroke and continuous diastolic flow; RI of 0.6 to 0.8 is normal. An intraparenchymal RI between 0.8 and 0.9 is considered equivocal, and greater than 0.9 is classified as abnormal, suggesting increased intraparenchymal resistance. Overall, an **elevated resistive index** is a nonspecific marker of transplant dysfunction but is not helpful in determining the cause of the dysfunction.[53]

The number of main renal arteries should be documented, and if there is more than one arterial anastomosis, then each anastomosis should be interrogated separately. Doppler assessment should also be performed of the external iliac artery and vein cephalad to the surgical anastomosis.[52] Provided that flow in the recipient common iliac artery is normal, the velocity of the transplanted main renal artery should be less than 250 cm/sec[53,54] (Figs. 18.32 and 18.33).

The intraparenchymal and extraparenchymal renal veins show either monophasic continuous flow or phasicity with the cardiac cycle. There are no accepted normal peak velocity values for these vessels. Documentation of the presence or absence of flow within the transplant and main renal vein, with an appropriate velocity gradient across the venous anastomosis, is of prime importance in the management of these patients.

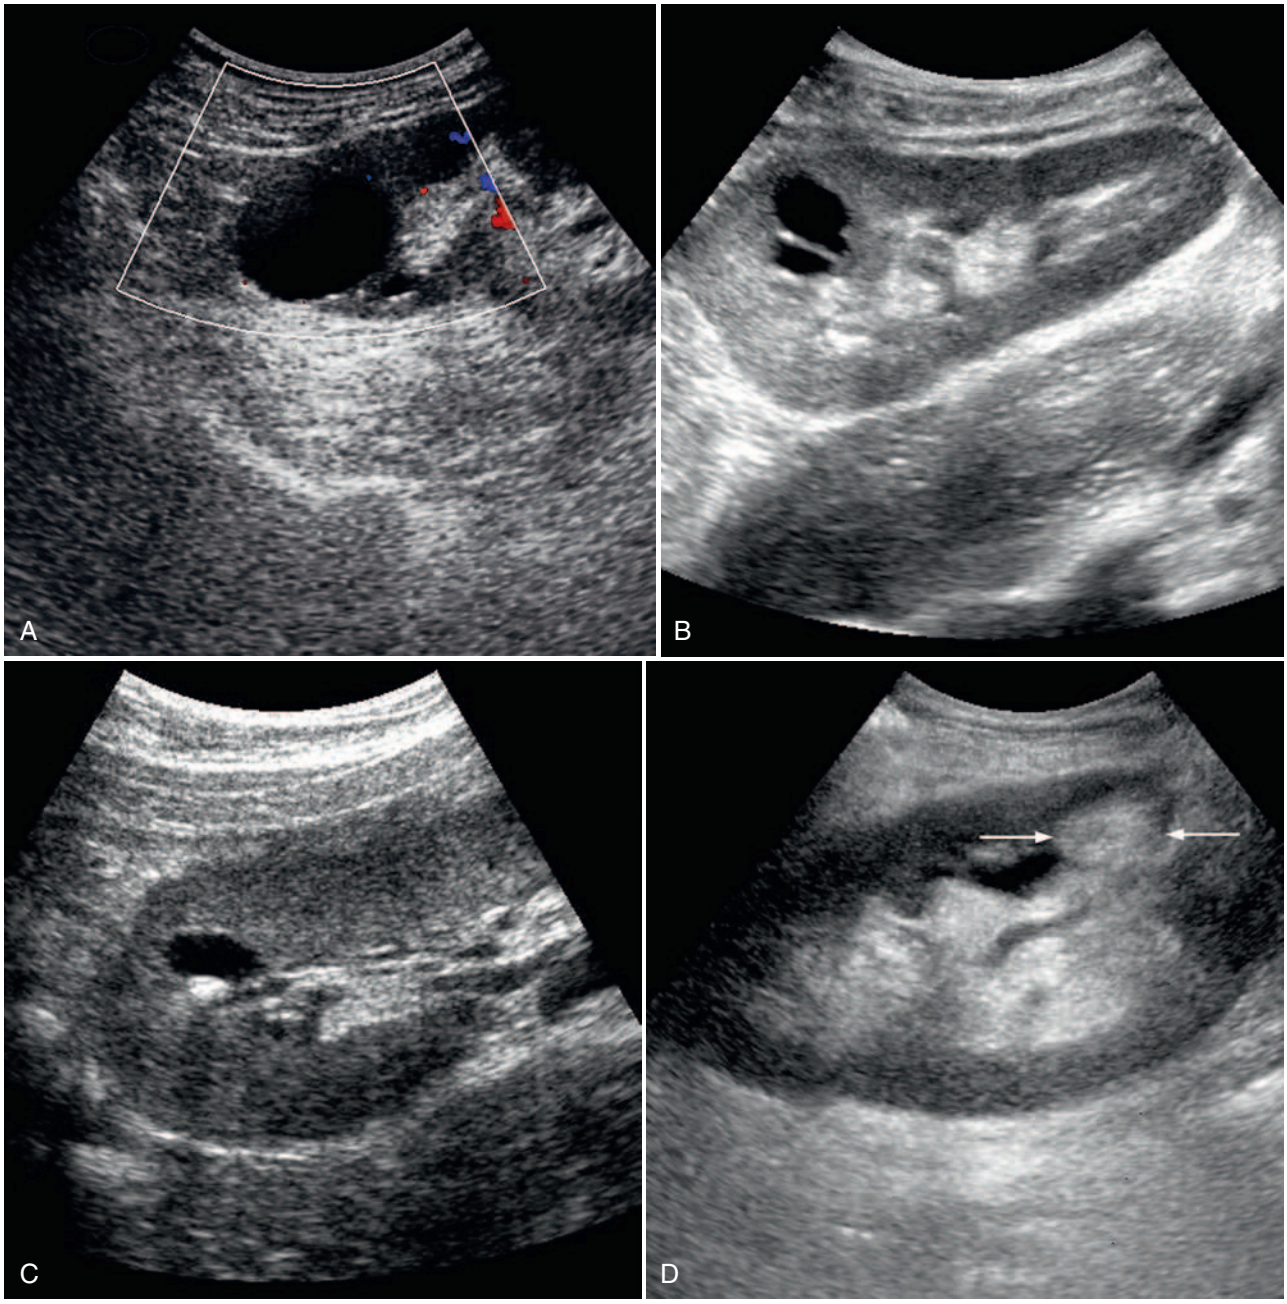

FIG. 18.30 Benign Renal Cysts in Four Patients. Sagittal sonograms of transplant kidneys. **(A)** Simple upper-pole cyst, which is avascular on color Doppler ultrasound. **(B)** Upper-pole cyst with a single thin strand. **(C)** Milk of calcium cyst with dependent calcification. **(D)** Marsupialized renal cyst *(arrows)* appearing as an echogenic mass.

Abnormal Renal Transplant

Renal transplants are routinely evaluated with sonography as either a component of a screening protocol or a workup for renal dysfunction based on a rising serum creatinine level or a decreased urine output. Postoperative complications have been reported in up to 20% of renal transplant recipients.[46] When encountered in a graft with a clinical suspicion of dysfunction, the sonographer should approach the possible causes in terms of (1) parenchymal pathology, (2) prerenal causes, and (3) postrenal complications. Parenchymal transplant pathology includes acute tubular necrosis (ATN), acute and chronic rejection, and infection. Prerenal problems include all factors affecting blood flow to the kidney or venous drainage from the graft. Postrenal complications include intrinsic or extrinsic lesions that can obstruct either a component of the calyceal system or the transplanted ureter.

Parenchymal Pathology

Acute Tubular Necrosis and Acute Rejection

Acute tubular necrosis results from donor organ ischemia either before vascular anastomosis or secondary to perioperative

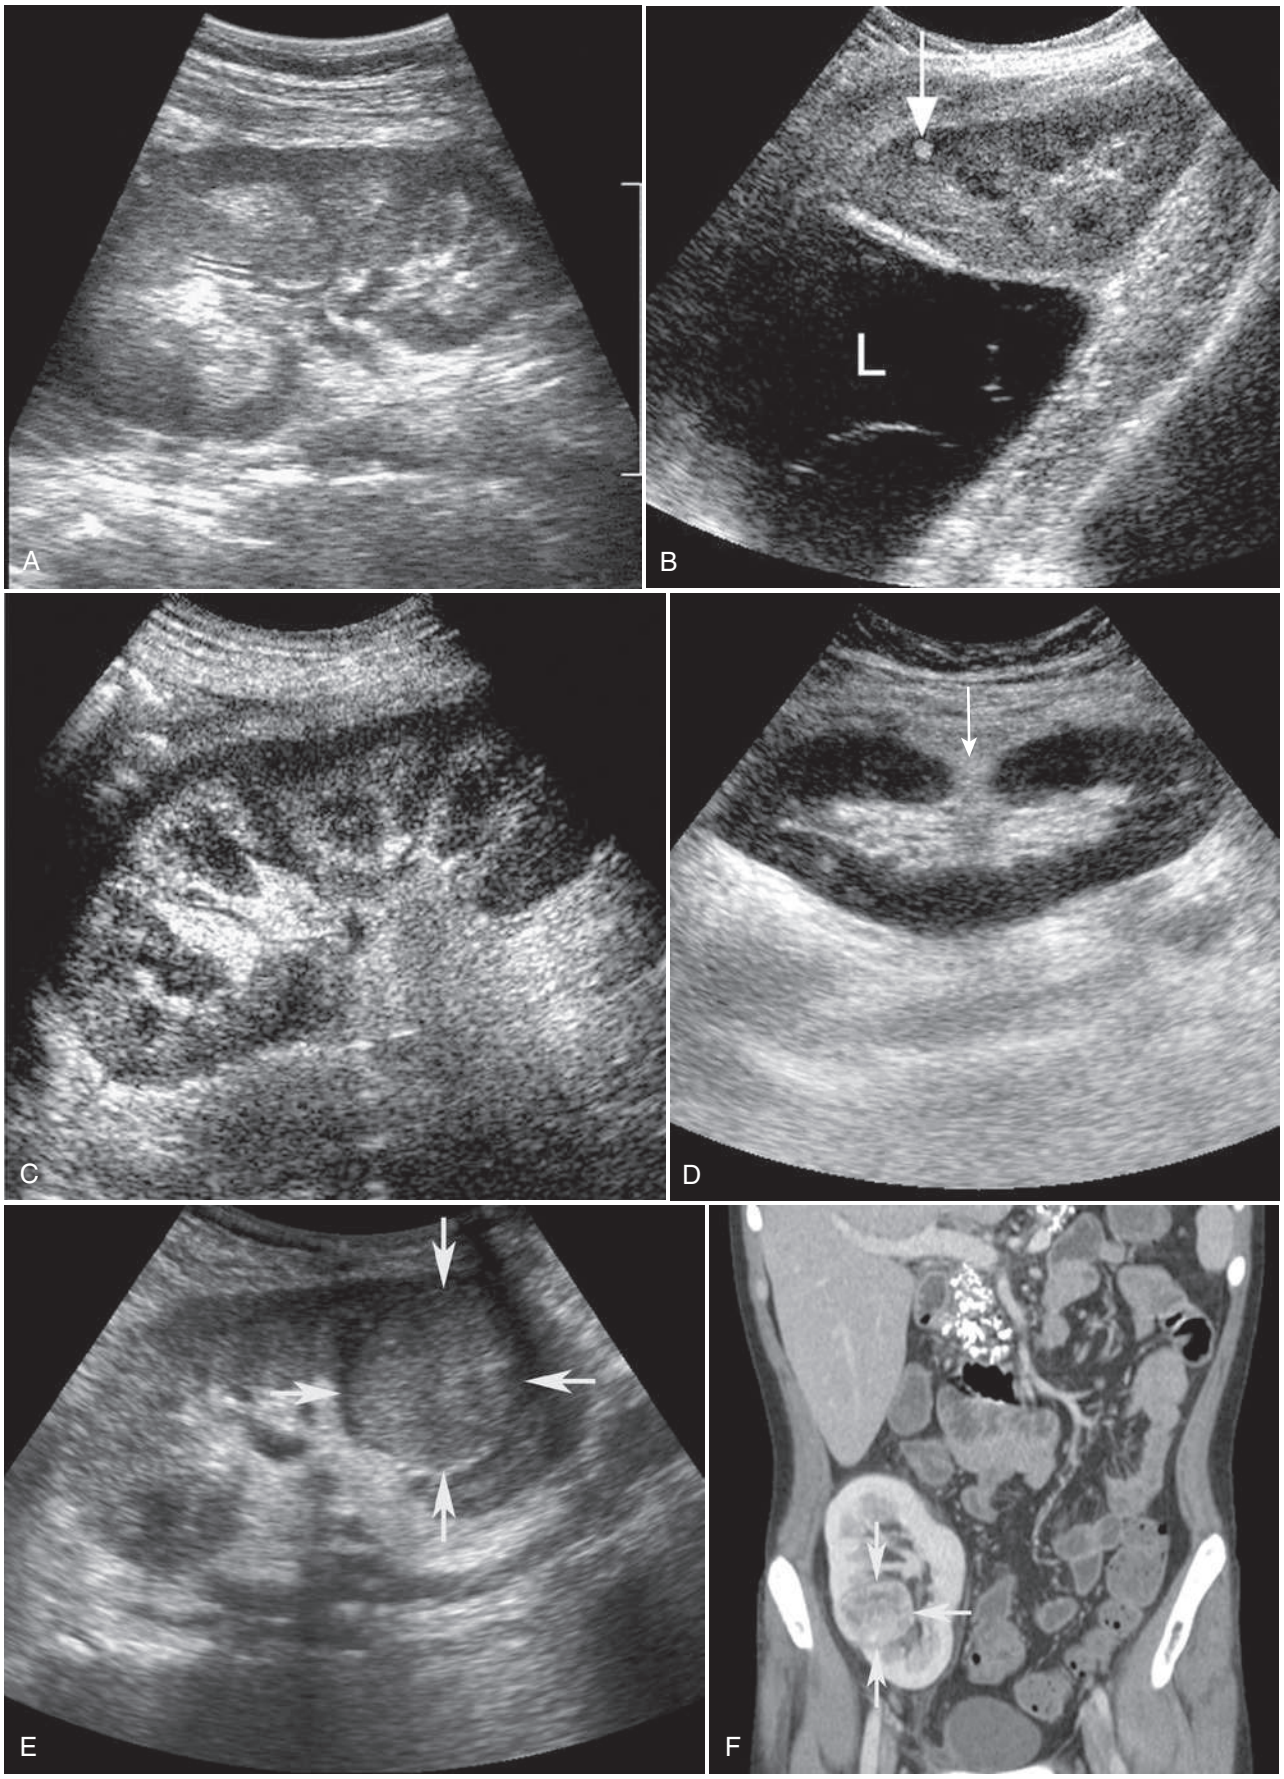

FIG. 18.31 Donor Pathology in Four Patients. Sagittal sonograms of transplant kidneys. **(A)** Nephrocalcinosis with calcifications in the renal medulla. **(B)** Tiny angiomyolipoma *(arrow). FIG. 18.32 Normal Renal Transplant Doppler. Color Doppler shows flow throughout kidney *(top)*. Intrarenal spectral traces of upper, middle, and lower poles show a resistive index of less than 0.8 and continuous flow throughout diastole. The main renal artery shows continuous flow with peak velocities less than 200 cm/sec *(bottom)*.

hypotension. It is most common in the early postoperative period and is the major cause of delayed graft function (defined as the need for dialysis within the first week of transplantation).[45,55] In patients requiring dialysis, recovery is usually in the first 2 weeks of transplantation but may be delayed by up to 3 months. ATN occurs in most cadaveric grafts and is observed infrequently in living related renal transplants because of the relatively short cold ischemic time of the donor kidney.[44]

Transplants affected by **hyperacute rejection** are rarely imaged because graft failure occurs immediately at the vascular anastomosis during surgery.[45] **Acute rejection** occurs in up to 40% of patients in the early transplant period, peaking at 1 to 3 weeks after surgery, and is an adverse long-term prognostic indicator. Most patients with acute rejection are asymptomatic, but a small proportion may have flulike symptoms, malaise, fever, and graft tenderness. Provided that the diagnosis can be rapidly established, acute rejection usually can be promptly reversed with high-dose steroids or antibiotic therapy.[44,56]

The imaging features of ATN and acute rejection are almost identical on gray-scale and Doppler ultrasound. Both conditions can produce increases in renal volume of the allograft. However, precise volumetric comparisons between interval studies can prove difficult; subtle changes in two-dimensional (2-D) measurements have not been adopted as a strong clinical sign of potential dysfunction. Other gray-scale findings include increased cortical thickness, increased or decreased cortical echogenicity, reduction of the corticomedullary differentiation, loss of the renal sinus echoes, and prominence of the pyramids (Fig. 18.34).

Color Doppler assessment may be normal or may occasionally show diffuse decreased blood flow. The RI of the intraparenchymal arteries is also nonspecific in these conditions and may be normal or elevated. In severe cases, there may be a complete lack of flow in diastole or a reversal of diastolic flow[44] (Fig. 18.35). Despite the lack of specificity of gray-scale and Doppler ultrasound in these acute conditions, **serial spectral Doppler** measurements, in combination with clinical assessments and biochemical findings, provide a useful guide to the clinician in terms of monitoring the allograft function and in determining the need for percutaneous biopsy.

Chronic Rejection

Chronic rejection is defined as a reduction in allograft function starting at least 3 months after transplantation in association with fibrous intimal thickening, interstitial fibrosis, and tubular atrophy on histology. It is the most common cause of late graft loss. The most frequent predisposing risk factor for development of chronic rejection is recurrent previous episodes of acute rejection.[44,45] On ultrasound, there is progressive thinning of the renal cortex, prominence of the central renal sinus fat, and a reduction in the overall size of the transplant. **Dystrophic calcifications** may be seen scattered throughout the residual parenchyma. In the end-stage renal transplant, the entire renal cortex can become calcified, appearing as a sharp echogenic interface associated with clean distal shadowing (Fig. 18.36).

Infection

Over 80% of patients with renal allografts will experience an episode of infection within the first year after transplant surgery.[57] Transplant pyelonephritis can result from an ascending infection, hematologic seeding, or contiguous spread from an adjacent infected fluid collection. Ultrasound findings include a focal or diffusely granular, echogenic renal cortex associated with loss of the corticomedullary junction; increased echogenicity and thickening of the perirenal fat secondary to extension of inflammation or infection into the surrounding tissue; and uroepithelial thickening (Fig. 18.37).

Pyonephrosis may occur occasionally in a chronically obstructed transplanted kidney. In the early stages, the lumen of the dilated collecting system appears anechoic. Once the lumen becomes filled with purulent material, low-level echoes develop within the calyceal system and ureter, sometimes associated with fluid-debris levels. Echogenic material within the collecting system may also result from intraluminal blood or other filling defects, or it may be artifactual as a result of scatter or s1ide-lobe artifact (see Fig. 18.37).

Abscesses can arise from infection of a previously sterile collection. On ultrasound, abscesses appear as a complex cystic structure and may be associated with fluid-fluid levels or intraluminal air (Fig. 18.38).

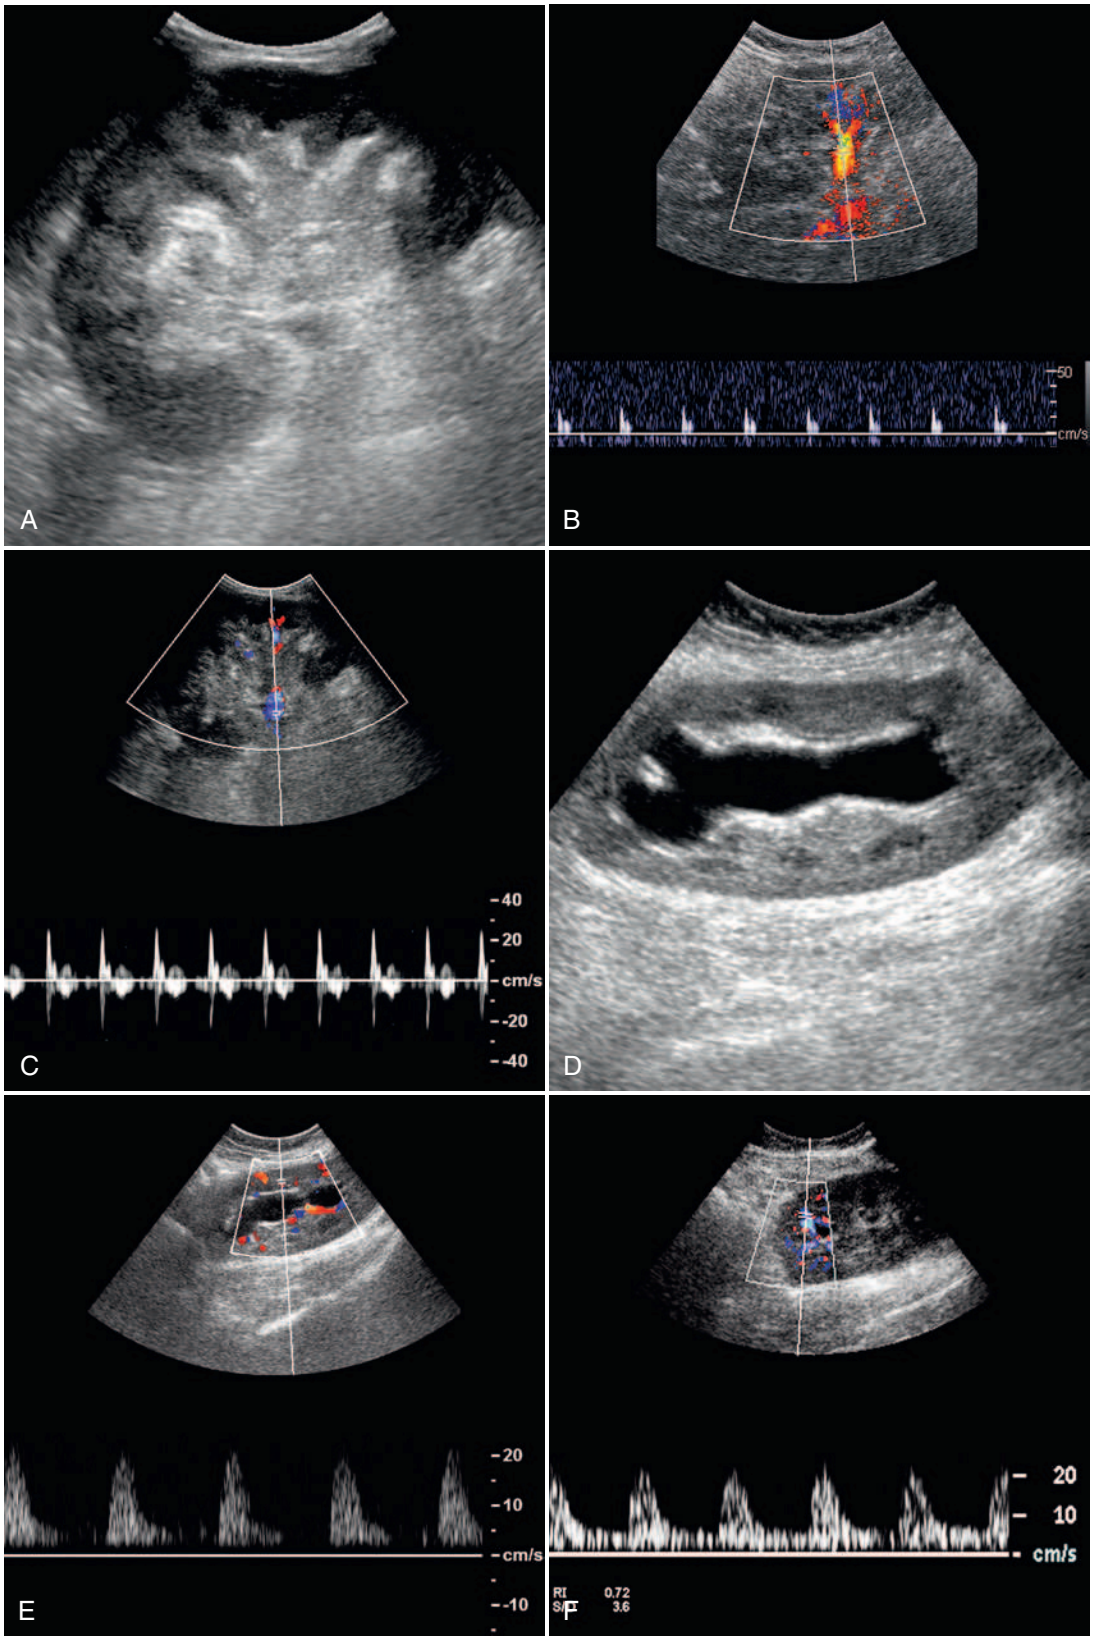

FIG. 18.33 Elevated Resistive Indices (RIs) in Two Patients. (A)-(C) Acute rejection. (A) Sagittal sonogram shows increased cortical echogenicity. **(B)** Spectral Doppler ultrasound done initially shows no flow in diastole and thus an RI of 1.0. **(C)** Follow-up spectral Doppler ultrasound 1 week later shows reversal of flow in diastole, which coincided with the clinical deterioration of the patient. **(D)-(F) Collecting system obstruction. (D)** Sagittal scan shows grade 3 pelvocaliectasis secondary to ureteral stricture (not shown). **(E)** Spectral Doppler shows RI of 1.0. **(F)** Spectral Doppler ultrasound performed after resolution of the pelvocaliectasis shows a normal RI of 0.72.

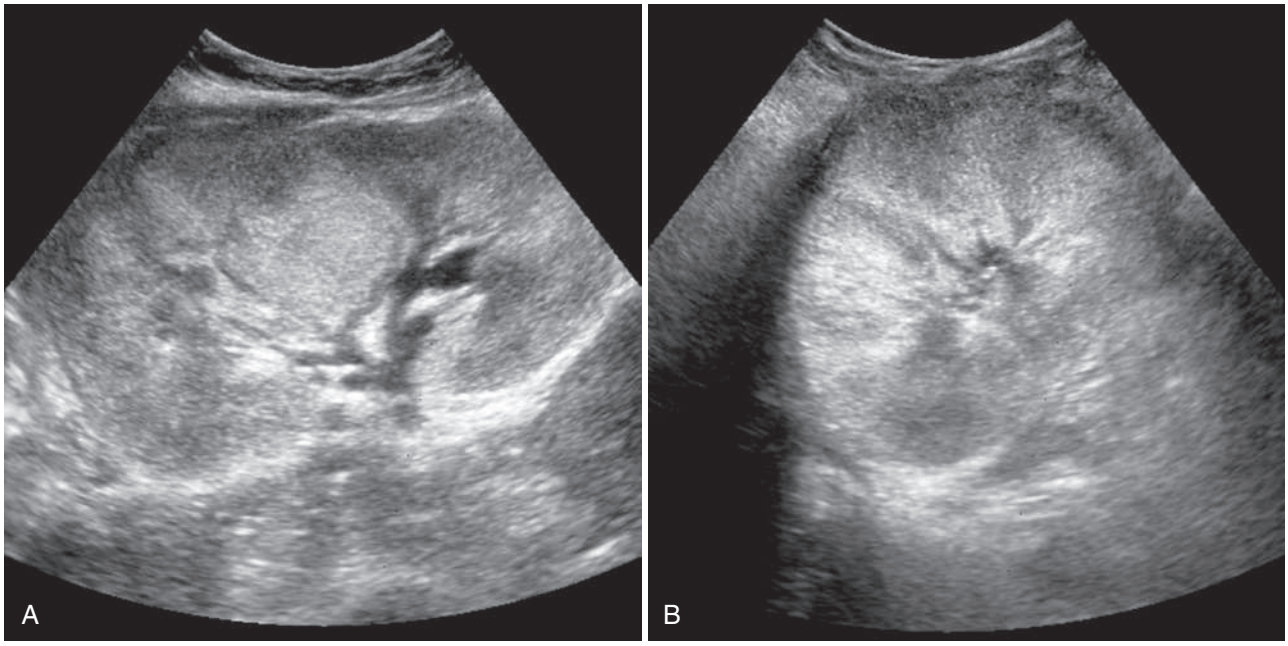

FIG. 18.34 Acute Tubular Necrosis. (A) Sagittal and **(B)** transverse sonograms show increased cortical thickness and echogenicity as well as loss of the normal corticomedullary differentiation.

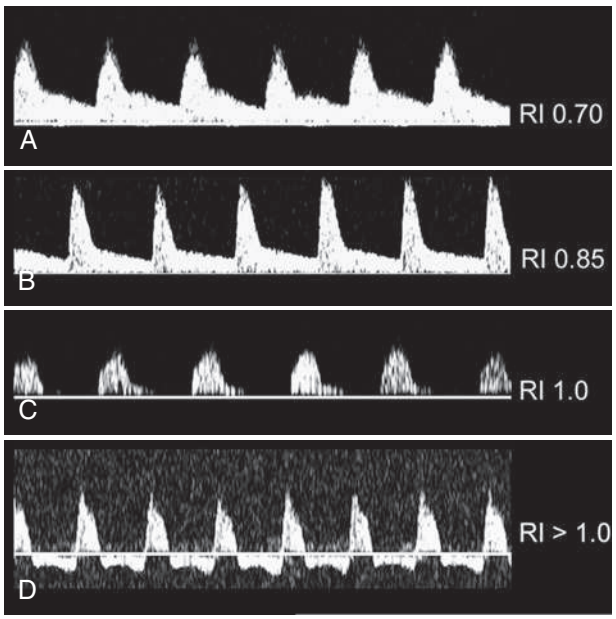

FIG. 18.35 Intrarenal Spectral Waveforms in Four Patients. (A) Normal waveform shows resistive index (RI) of 0.70. **(B)** RI in a gray zone (0.85). **(C)** RI elevated (1.0) with no flow in diastole. **(D)** Elevated RI (>1.0) with reversal of flow in diastole. This is seen with severely increased vascular resistance in the kidney from rejection or renal vein thrombosis.

Gas can be observed within the collecting system in **emphysematous pyelonephritis,** appearing as a bright echogenic focus with distal dirty shadowing. **Milk of calcium cysts** can produce dirty shadowing, mimicking an intrarenal abscess. Scanning the patient in a decubitus position allows for differentiation; gas rises to the nondependent portion of the lumen, whereas milk of calcium does not (Fig. 18.39).

Prerenal Vascular Complications

Arterial Thrombosis

Renal artery thrombosis occurs in less than 1% of transplants, usually within the first month of surgery, and is often initially asymptomatic. The most common cause is hyperacute or acute rejection, which results in occlusion of the intraparenchymal arterioles with retrograde main renal artery thrombosis. Other predisposing factors include a young pediatric donor kidney, atherosclerotic emboli, acquired renal artery stenosis, hypotension, vascular kinking, cyclosporine, hypercoagulable states, intraoperative vascular trauma, and poor intimal anastomosis.[58]

Global infarction of the allograft occurs when there is occlusive thrombosis of the main renal artery, with no perfusion to the renal parenchyma. On gray-scale ultrasound, the kidney may appear diffusely hypoechoic and enlarged. On color and spectral Doppler ultrasound, complete absence of arterial and venous flow distal to the occlusion, within both the hilar and the intraparenchymal vessels, is observed. Although surgical thrombectomy with arterial repair is often attempted, nephrectomy is frequently indicated in these patients.[46]

Segmental infarction of the allograft may occur in transplants with a single main renal artery with thrombosis of a major arterial branch (Fig. 18.40), in transplants with multiple renal arteries where a single artery is thrombosed, and in patients with systemic vasculitis. On gray-scale sonography, a segmental infarct may appear as a poorly defined hypoechoic region, a hypoechoic mass, or a hypoechoic mass with a well-defined echogenic wall.

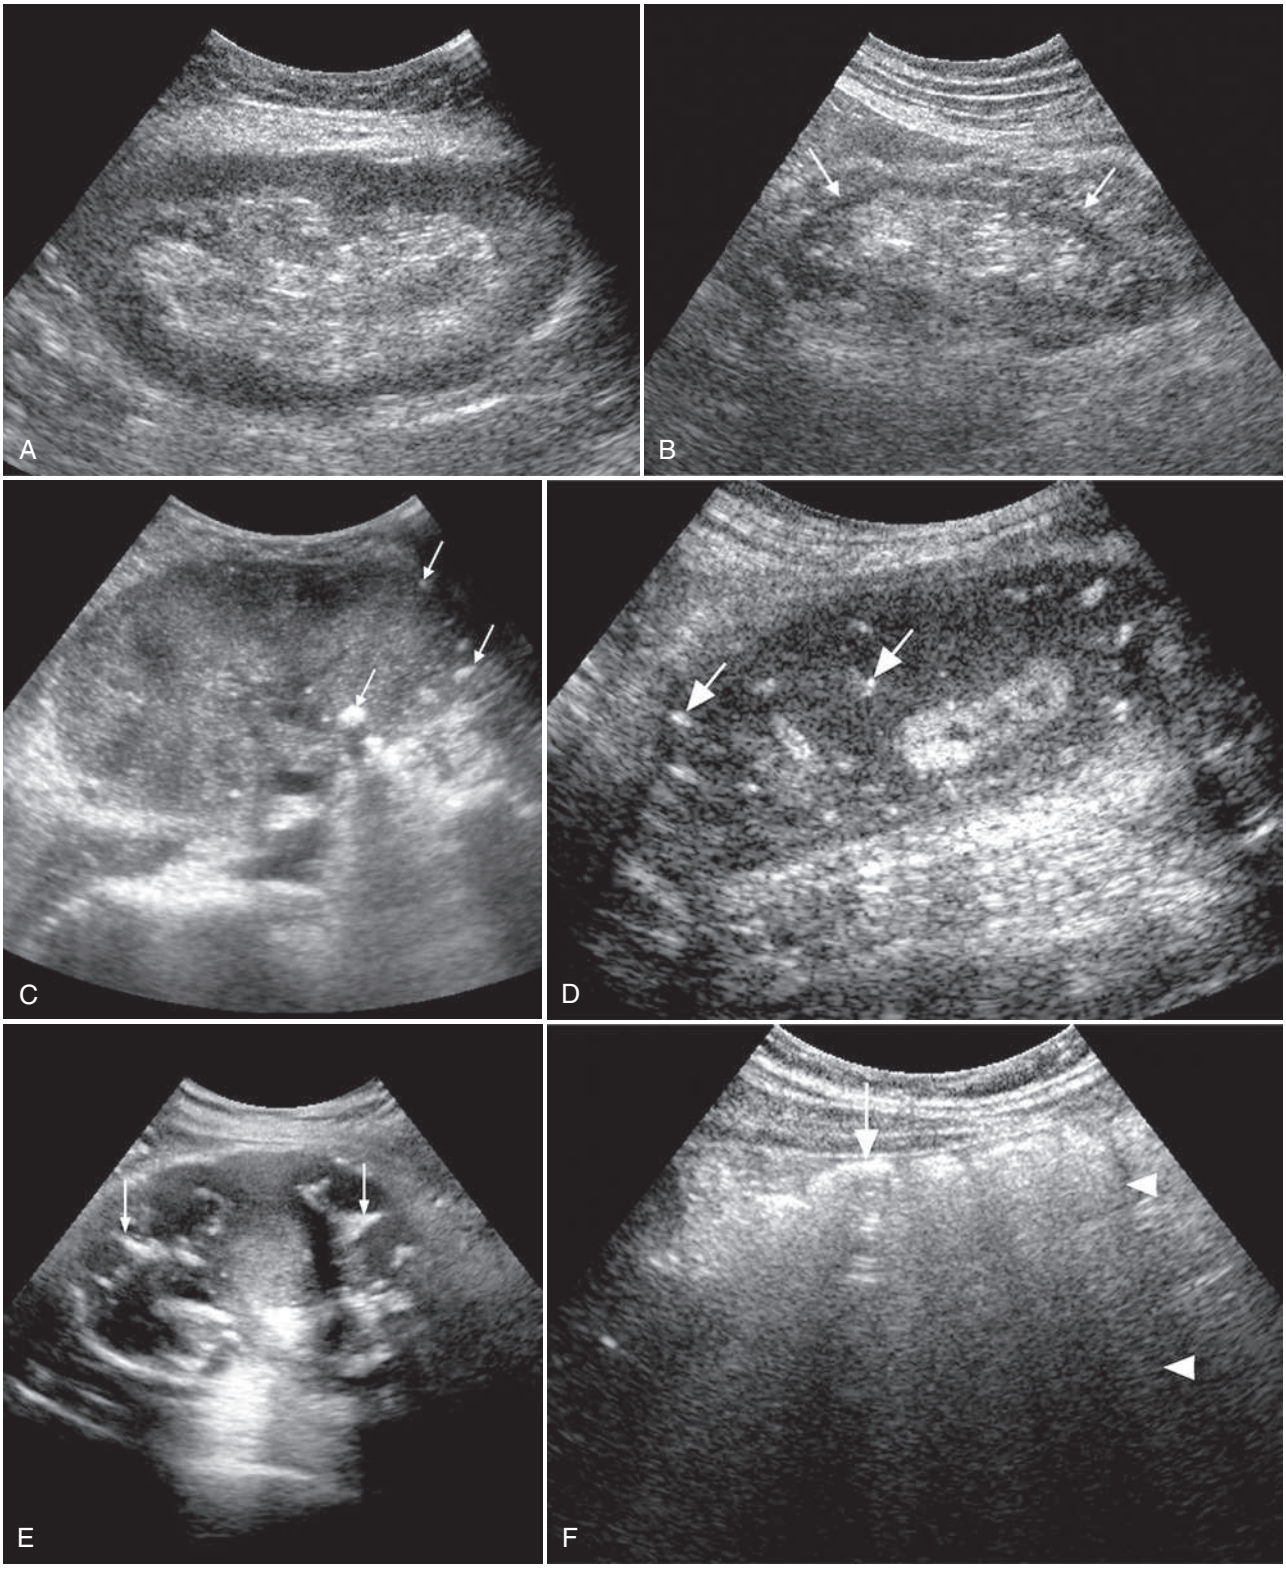

FIG. 18.36 Chronic Renal Failure in Six Patients. (A) and **(B) Cortical thinning. (A)** Sagittal scan shows moderate cortical thinning with abundant renal sinus fat. **(B)** With progression, the kidney *(arrows)* becomes smaller and the cortex thinner. **(C)-(F) Dystrophic calcifications.** Sagittal sonograms show **(C)** a few punctuate peripheral cortical calcifications *(arrows);* **(D)** multiple peripheral and central cortical calcifications *(arrows);* and **(E)** linear calcifications that extend from the peripheral to deep cortex *(arrows).* **(F)** The end-stage kidney becomes calcified, appearing as an echogenic interface *(arrow)* associated with dirty shadowing *(arrowheads).* The kidney is frequently not identified on sonography at this stage.

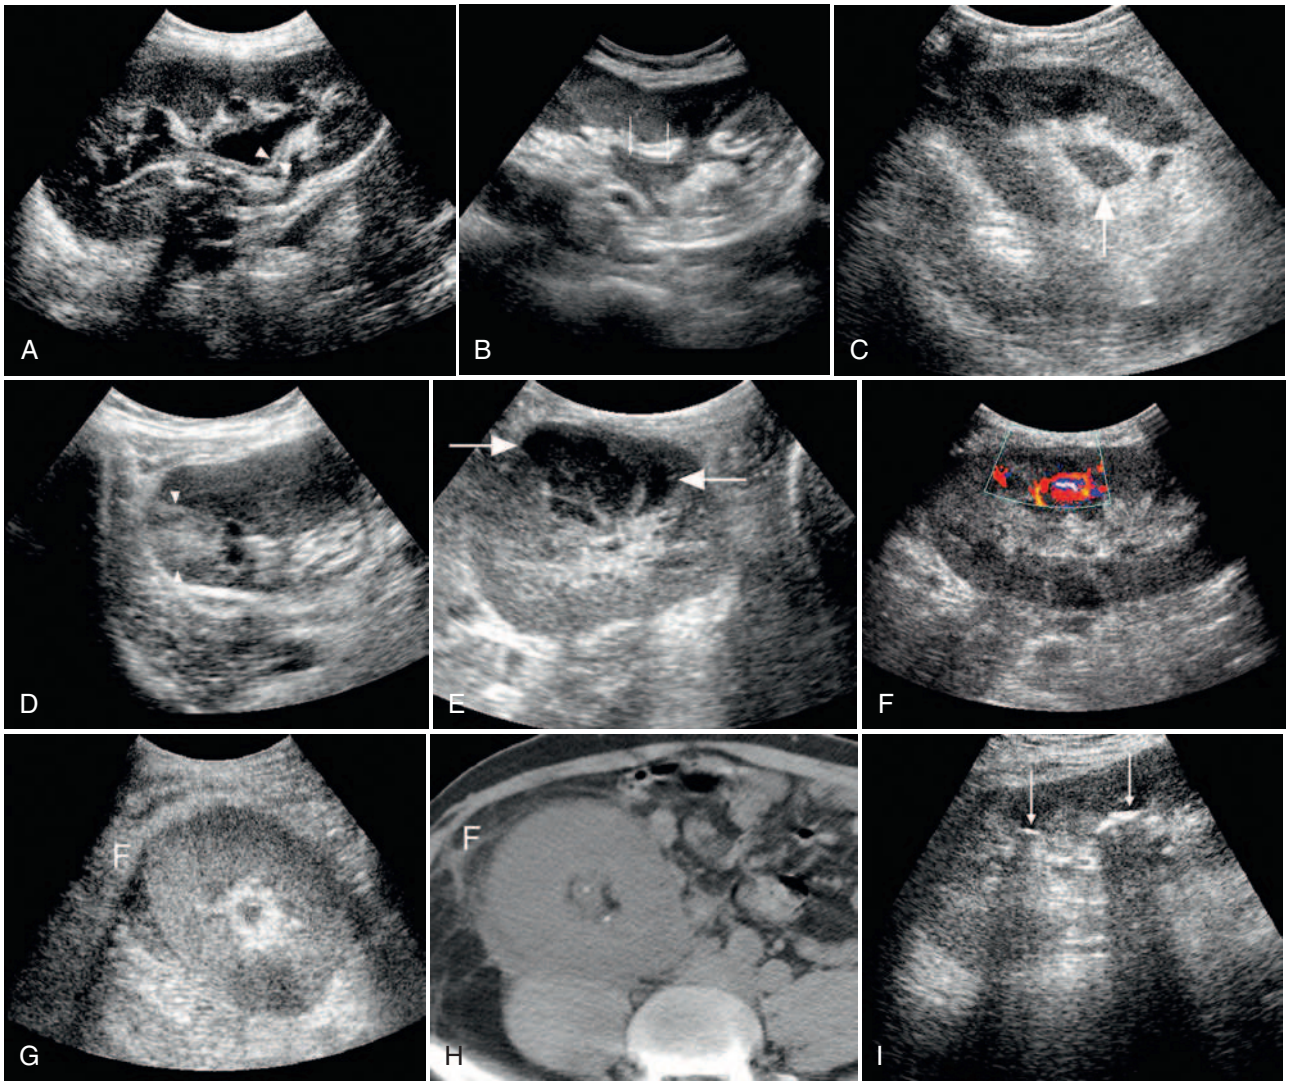

FIG. 18.37 Renal Transplant-Related Infections. (A) Uroepithelial thickening. Sagittal sonogram shows mild uroepithelial thickening *(arrowheads).* **(B)** Sagittal scan shows mild uroepithelial thickening *(arrows)* surrounding a mildly dilated collecting system with internal echoes, secondary to early pyonephrosis. **(C)** Transverse sonogram shows moderate to severe uroepithelial thickening *(arrow),* which can be misinterpreted as a mass in the renal pelvis. **(D)-(F) Focal pyelonephritis. (D)** Sagittal sonogram shows subtle, focal echogenic region in the upper-pole cortex *(arrowheads).* **(E)** Intraparenchymal phlegmon appearing as a hypoechoic mass within the renal cortex *(arrows).* **(F)** On color Doppler, the phlegmon seen in image **(E)** is vascular. **(G)** and **(H) Diffuse pyelonephritis. (G)** Transverse sonogram shows a generous kidney with echogenic granular renal cortex, surrounded by inflamed echogenic perinephric fat *(F).* **(H)** Corresponding CT shows inflamed fat *(F)* as perinephric streaking. **(I) Emphysematous pyelonephritis.** Sagittal sonogram shows air *(arrows)* within collecting system, appearing as bright, echogenic linear foci with distal dirty shadowing.

On Doppler sonography, the infarcted region appears as a wedge-shaped area devoid of flow on color or spectral interrogation.[57] Interpretation of the gray-scale and Doppler findings should not be influenced by urine output of the allograft or laboratory data, because segmental infarction may occur in the presence of preserved renal function.

The absence of blood flow on Doppler interrogation in the kidney parenchyma may be observed in conditions other than arterial thrombosis, including **hyperacute rejection** and **renal vein thrombosis.** In these conditions, however, the main renal artery is patent on spectral Doppler ultrasound and may exhibit reversal of diastolic flow.[44]

Renal Artery Stenosis

Renal artery stenosis, the most common vascular complication of transplantation, occurs in up to 10% of patients within the first year, is more frequent in living donor allografts compared with cadaveric allografts, and should be suspected in cases of severe hypertension refractory to medical therapy. Transplants with multiple renal arteries are now being used more frequently

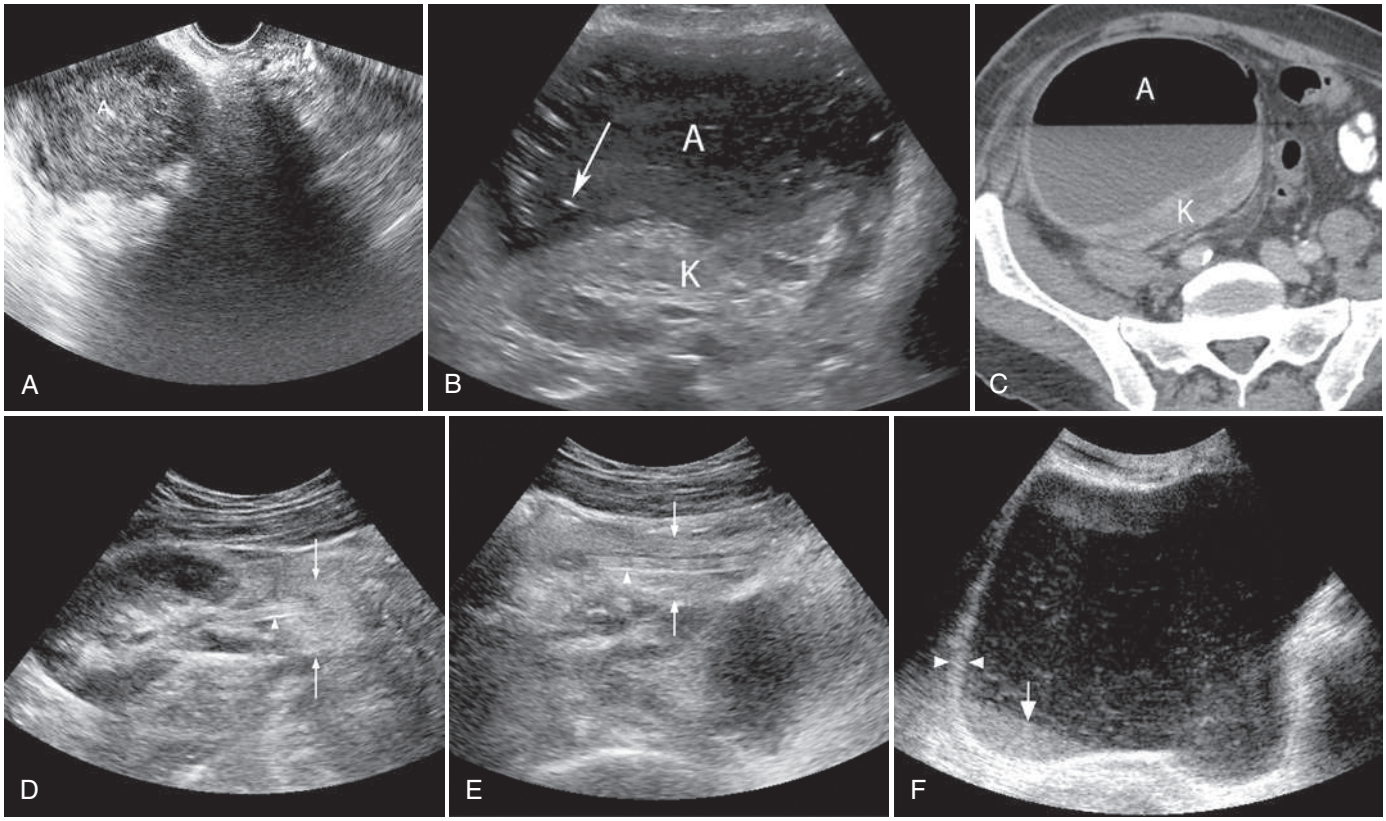

FIG. 18.38 Renal Transplant-Related Infections. (A) Perirenal *Candida* abscess. Transabdominal sagittal scan shows abscess *(A)* abutting the lower pole of the transplant kidney. **(B)** and **(C)** Subcapsular abscess on ultrasound and CT. Note the heterogeneous abscess *(A)* with gas *(arrow)* compressing the kidney *(K)*. **(D)** and **(E) Ureteritis.** Sagittal sonograms of proximal **(D)** and midline **(E)** ureter show inflamed echogenic periureteral fat *(arrows)* secondary to an infected ureteral stent *(arrowhead)*. **(F) Cystitis.** Transverse sonogram shows internal echoes and fluid-debris level *(arrow)* in urinary bladder, secondary to cystitis. *Arrowheads* show thickened bladder wall.

and show a very slightly higher rate of renal artery stenosis compared with those renal allografts with a single artery. Stenosis may occur in one of three regions of the transplanted artery: the **donor** portion (Fig. 18.41), most frequently observed in end-to-side anastomoses and thought to arise from either rejection or difficult surgical technique; the **recipient** portion (Fig. 18.42), which is more uncommon and usually the result of intraoperative clamp injury or intrinsic atherosclerotic disease; and the **anastomosis** (Fig. 18.43), which is more frequent in end-to-end anastomoses and is directly related to surgical technique or may be secondary to rejection.[54,58-60]

Initially, color Doppler ultrasound should be used to determine the location of the anastomosis, as well as to document focal regions of aliasing, which would indicate the presence of high-velocity turbulent flow and serve as a guide for meticulous spectral interrogation. A spectral tracing should then be obtained at the anastomosis and in any area where color aliasing is detected to determine the PSV in that region.

The upper limit of normal for arterial PSV is unclear. Assigning a PSV upper limit of 200 cm/sec for diagnosing renal artery stenosis may result in a relatively high false-positive rate. Thus some authors have suggested using an arterial threshold PSV of 250 cm/sec for the diagnosis of renal artery stenosis.[54,61]

However, high velocities in the renal artery may be secondary to changes in the external iliac artery. Therefore the renal artery–external iliac artery PSV ratio can be calculated to determine if renal artery velocity measurements are a result of narrowing or high flow rates from the external iliac artery. A renal artery–external iliac artery PSV ratio greater than 1.8:1 is suggestive of renal artery stenosis.[54,62] In addition, within the renal parenchyma, a tardus-parvus spectral waveform can be observed in the intraparenchymal arteries in patients with renal artery stenosis.[46,57] If no flow abnormality is detected within the main renal artery after color and spectral Doppler interrogation, significant stenosis can be excluded.[63]

Doppler Criteria for Renal Artery Stenosis

Color aliasing at the stenotic segment
Distal turbulent flow
Peak systolic velocity > 250 cm/sec
Velocity gradient between the renal artery and external iliac artery greater than 1.8:1

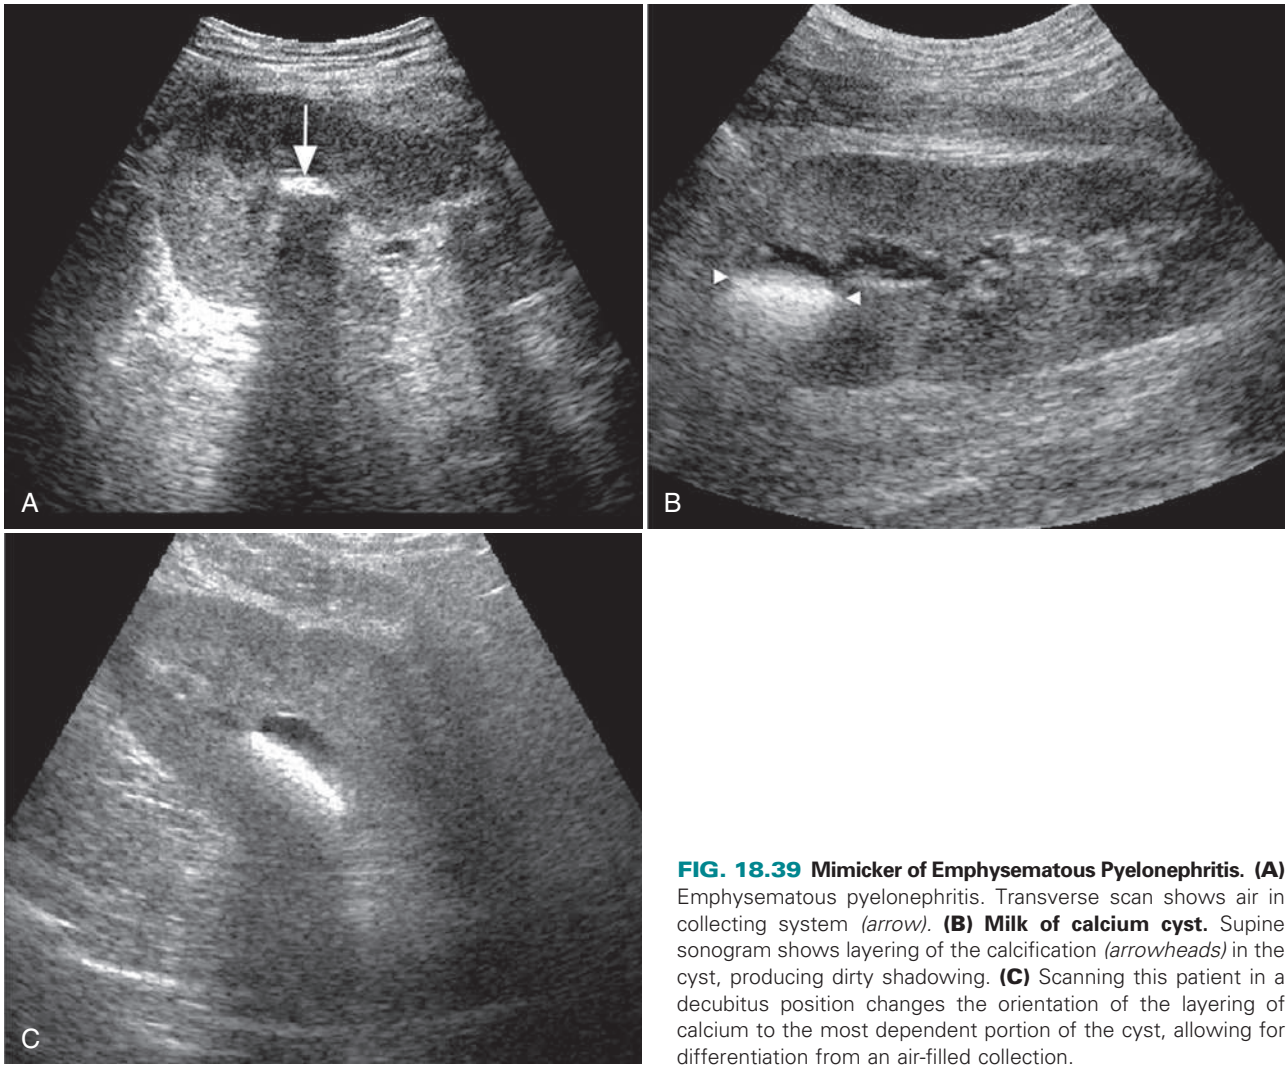

FIG. 18.39 Mimicker of Emphysematous Pyelonephritis. (A) Emphysematous pyelonephritis. Transverse scan shows air in collecting system *(arrow)*. **(B) Milk of calcium cyst.** Supine sonogram shows layering of the calcification *(arrowheads)* in the cyst, producing dirty shadowing. **(C)** Scanning this patient in a decubitus position changes the orientation of the layering of calcium to the most dependent portion of the cyst, allowing for differentiation from an air-filled collection.

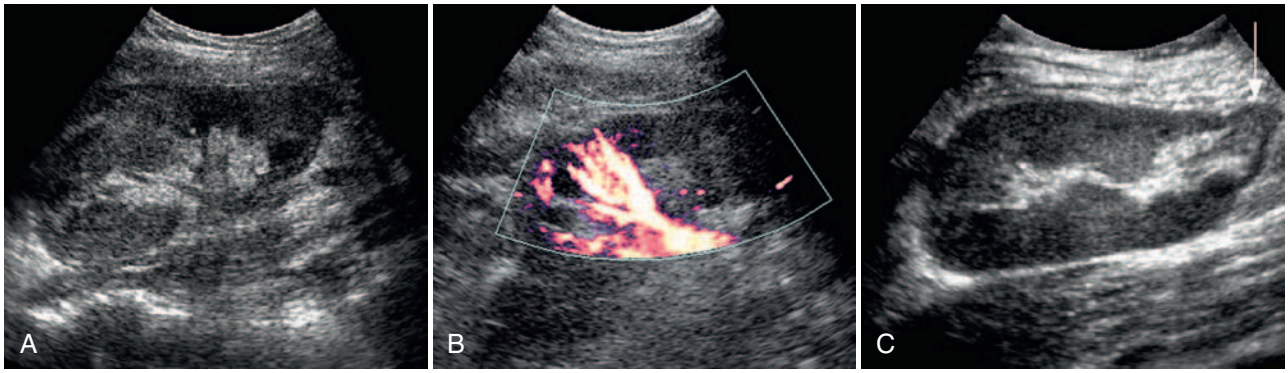

FIG. 18.40 Renal Artery Thrombosis. (A) Sagittal sonogram shows normal gray-scale ultrasound on postoperative day 1. **(B)** However, power Doppler shows no flow in the lower pole because of thrombosis of a segmental artery. **(C)** Three months later, there is secondary scarring of the entire lower pole *(arrow)*.

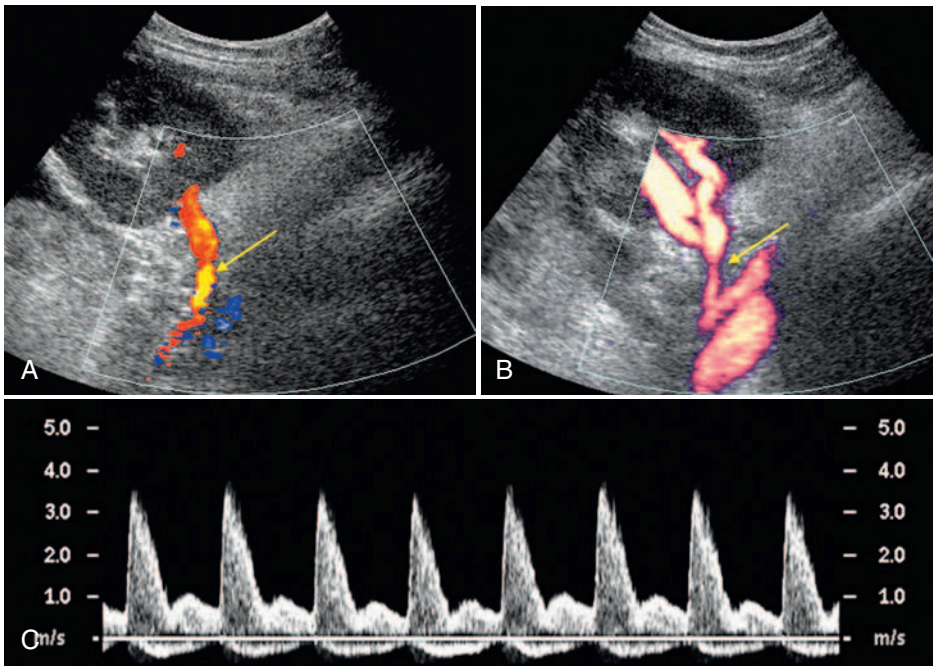

FIG. 18.41 Renal Artery Stenosis: Donor Portion. (A) Color Doppler ultrasound of donor renal artery anastomosis shows focal area of aliasing *(arrow).* **(B)** Power Doppler shows area of narrowing in this region *(arrow).* **(C)** Spectral Doppler shows elevated angle-corrected velocities at the site of the arrow, greater than 400 cm/sec.

Intraparenchymal arterial stenosis may be observed in chronic rejection as a result of scarring in the tissues surrounding the involved vessels. On spectral Doppler ultrasound, a prolonged AT may be observed in the segmental and interlobar arteries, with a normal main renal artery waveform.[45]

Treatment options for renal artery stenosis include percutaneous transluminal angioplasty, endovascular stent placement, and surgery. Surgical management of these transplants involves resection and revision of the stenosis with insertion of a patch graft at the stenotic segment.[46]

A **false-positive Doppler diagnosis** of renal artery stenosis can occur if there is an abrupt turn in the main renal artery, if the artery is severely tortuous, or if there are errors in Doppler technique (Fig. 18.44). Inadvertent compression of the main renal artery by the sonographer while performing spectral interrogation may also produce transient narrowing of the artery and elevated PSV readings. Turning the patient in a decubitus position such that the anterior abdominal or pelvic wall tissues are displaced from lying over the transplant can reduce external pressure on the allograft during scanning.

Venous Thrombosis

Occlusive renal vein thrombosis is slightly more common than arterial thrombosis, occurring in up to 4% of transplants, and is associated with acute pain, swelling of the allograft, and an abrupt cessation of renal function between the third and eighth postoperative day. Risk factors include technical difficulties at surgery, hypovolemia, propagation of femoral or iliac thrombosis, and compression by fluid collections.[58,64]

On gray-scale ultrasound, the allograft may appear enlarged, and in rare cases intraluminal thrombus may be detected in a dilated main renal vein or within the intraparenchymal venous system. Spectral and color Doppler ultrasound will show a lack of venous flow in the renal parenchyma, absence of flow in the main renal vein, and reversal of diastolic flow in the main renal artery, as well as sometimes in the intraparenchymal arteries[65,66] (Fig. 18.45). The sonographer should be aware that **reversal of flow in diastole in the main renal artery** or the intraparenchymal arterial branches is highly suggestive of renal vein thrombosis only in the absence of venous flow in the renal parenchyma and main renal vein.

Reversed diastolic arterial flow, with preservation of venous flow, is a nonspecific finding indicating extremely high vascular resistance in the small intrarenal vessels or main hilar vessels. The outcome for these patients is generally poor, with allograft loss rates of 33% to 55%. Potential causes of reversed diastolic flow include acute rejection, ATN, peritransplant hematomas (compressing renal graft or hilar vessels), and glomerulosclerosis.[67]

Renal Vein Stenosis

Renal vein stenosis most often occurs from perivascular fibrosis or external compression by adjacent fluid collections. The renal cortex appears either normal or hypoechoic, and on color Doppler, aliasing is identified at the stenotic region because of focal, high-velocity turbulent flow. On spectral Doppler sonography, a threefold to fourfold increase in velocity across the region of

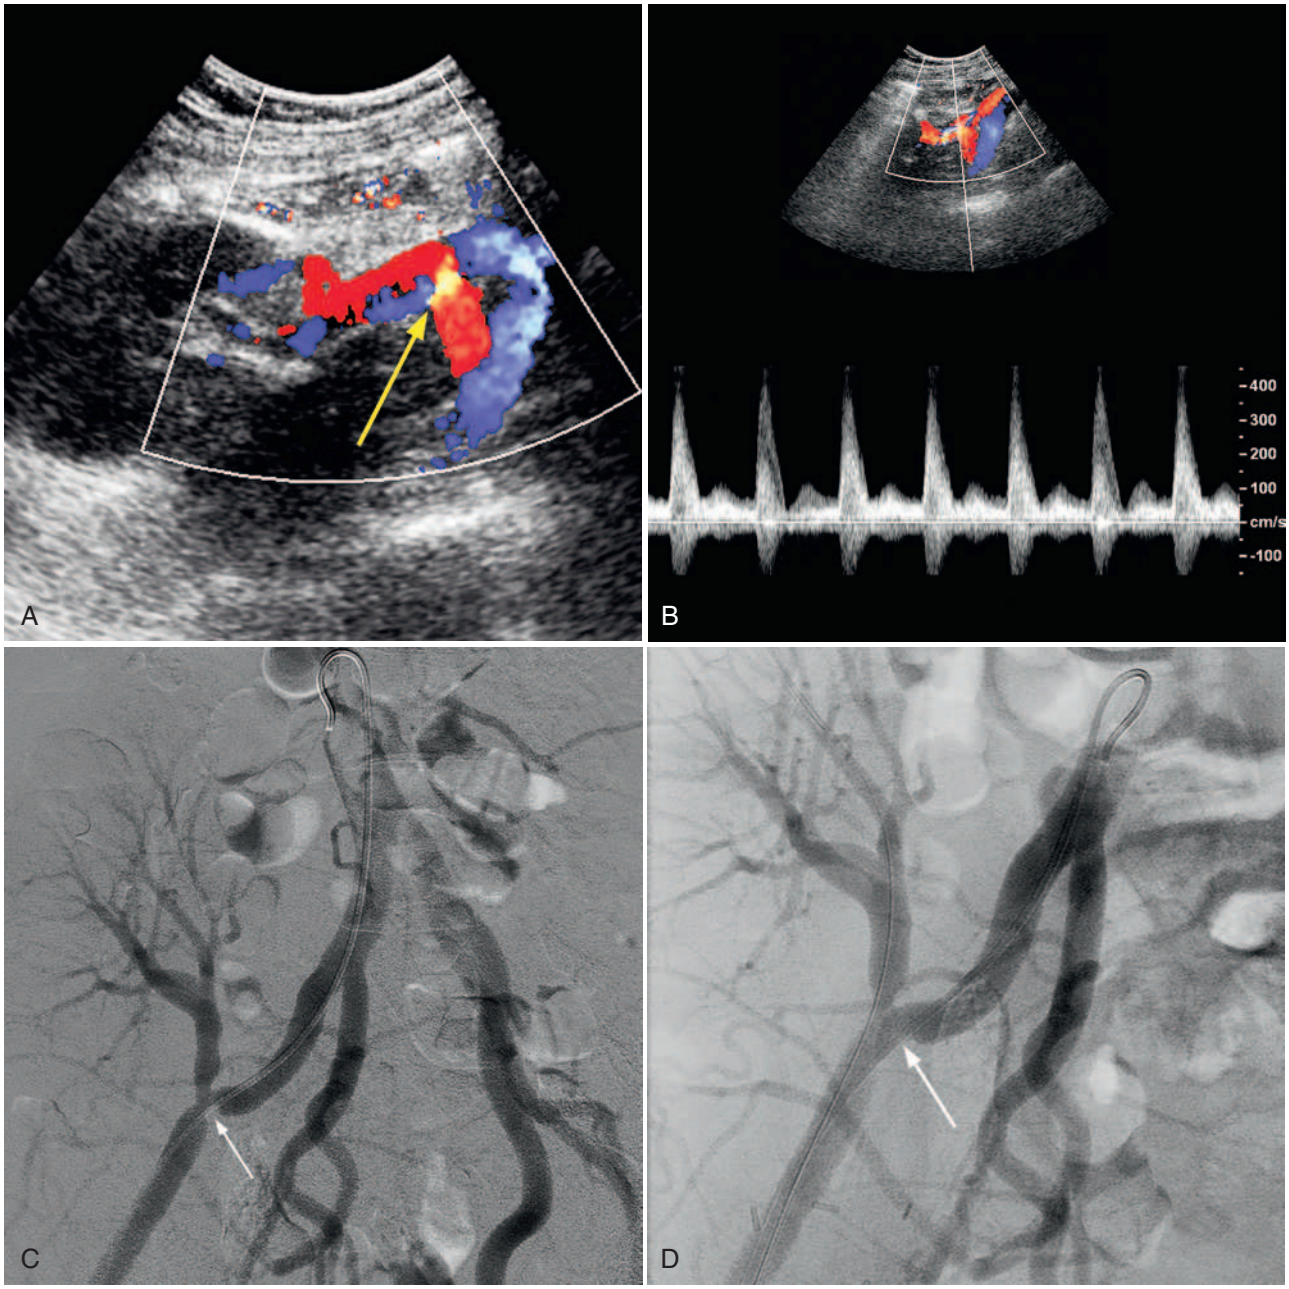

FIG. 18.42 Renal Artery Stenosis: Recipient Portion. (A) Color Doppler ultrasound shows focal area of aliasing *(arrow)* proximal to the renal artery anastomosis. **(B)** Spectral Doppler of the region of aliasing seen in image **(A)** shows angle-corrected peak velocities of 400 cm/sec. **(C)** Angiography shows a focal area of stenosis *(arrow)* arising from the external iliac artery. **(D)** Angiogram performed after angioplasty shows resolution of the stenotic region *(arrow)*.

narrowing indicates a hemodynamically significant stenosis[63] (Fig. 18.46).

Postrenal Collecting System Obstruction

Collecting system obstruction is unusual in renal transplants, occurring in less than 5% of patients.[45,63] Because the allograft is denervated, the collecting system dilates without clinical signs of pain or discomfort. The diagnosis is often made as an incidental finding on routine screening sonography or in the workup of the transplant patient for asymptomatic deterioration of renal function parameters.

The most common cause of **ureteral obstruction** is from ischemic strictures, usually involving the terminal ureter at the ureterovesical junction. The transplanted ureter is particularly susceptible to ischemic events because of its limited vascular supply from the renal artery. The ureterovesical junction is usually the region of most pronounced involvement because it is farthest anatomically from the renal

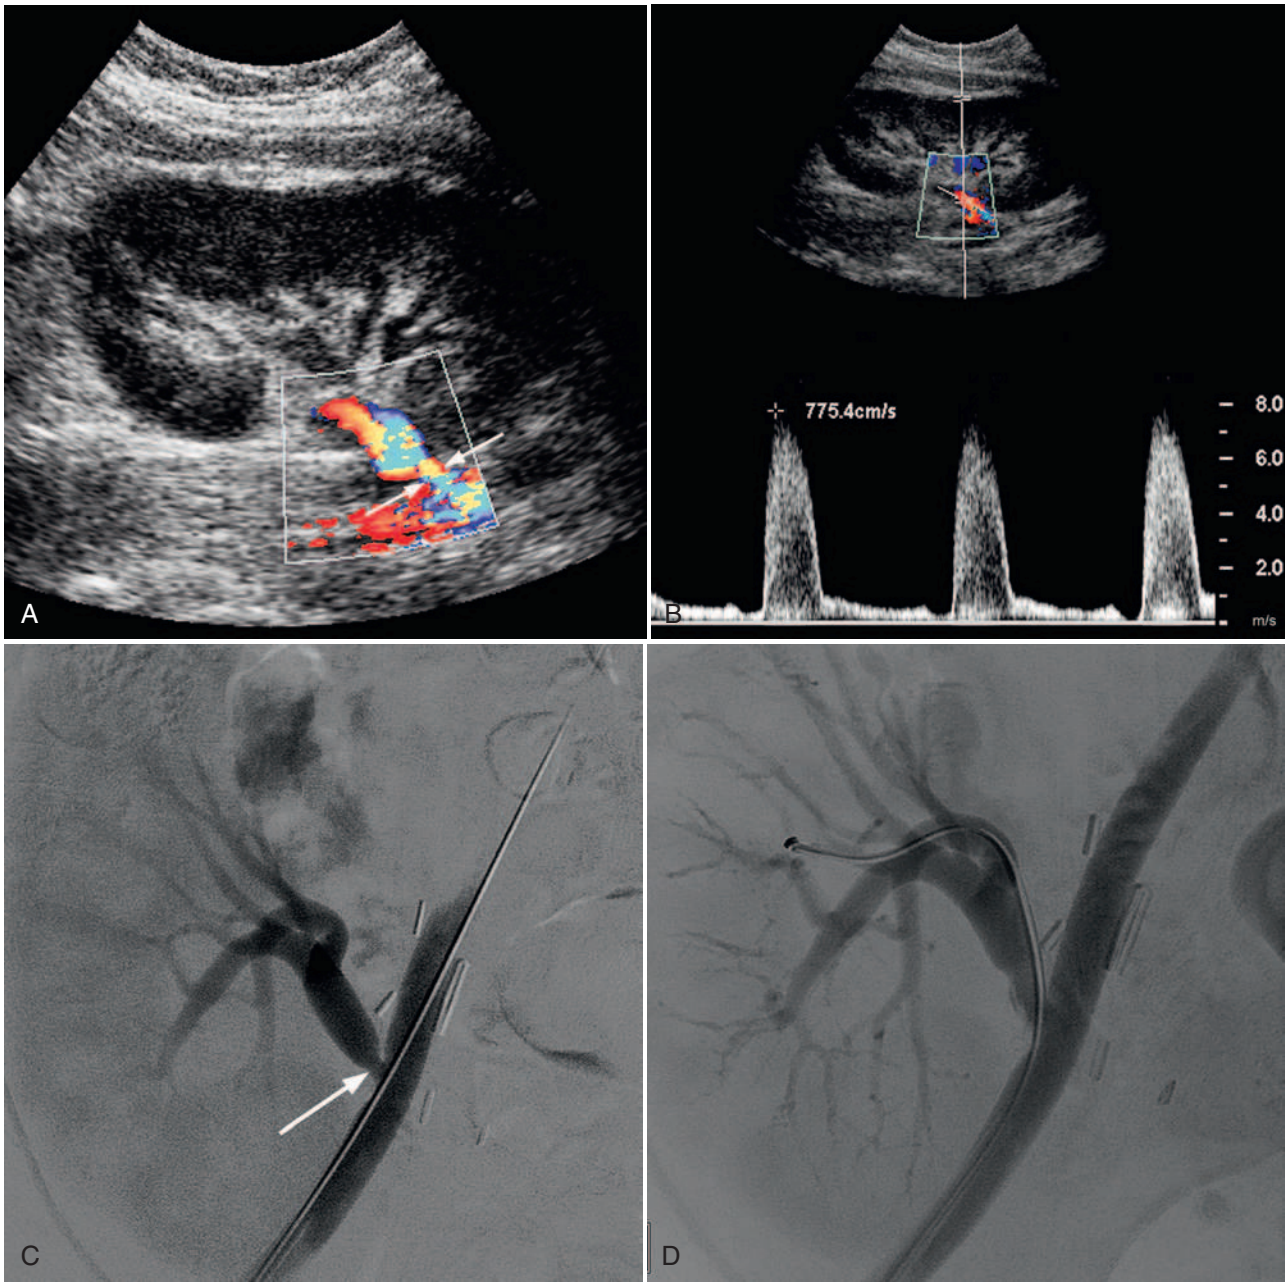

FIG. 18.43 Renal Artery Stenosis: Anastomosis. (A) Color Doppler ultrasound shows focal area of narrowing and aliasing at the anastomosis *(arrows).* **(B)** Spectral Doppler at the anastomosis shows elevated angle-corrected velocity of 775.4 cm/sec. **(C)** Renal arterial angiogram confirms stenosis at the anastomosis *(arrow).* **(D)** Angiogram performed after angioplasty shows resolution of the anastomotic stenosis.

hilum, where the ureteral branch originates.[46] Other causes of ureteral obstruction include strictures from iatrogenic injury, intraluminal lesions (e.g., stones, blood clots, sloughed papillae), perigraft fibrosis, and ureteral kinking (Figs. 18.47 and 18.48). Extrinsic compression of the ureter from peritransplant collections can also result in collecting system obstruction.

Patients with renal transplants are at higher risk for stone development compared with the general population. In approximately 15% of these patients, the stone development is related to hypercalcemia. Because the transplant is denervated, patients with stone-related collecting system obstruction may not have typical symptoms of renal colic.[54]

Evaluation of the collecting system with fundamental gray-scale imaging may be difficult because of side-lobe and scatter artifact, which can potentially obscure optimal evaluation of the calyceal system and ureter. Harmonic imaging, however, uses a narrower ultrasound beam with smaller side lobes and is less susceptible to scatter artifact. These parameters make harmonic imaging ideal for evaluating anechoic structures,

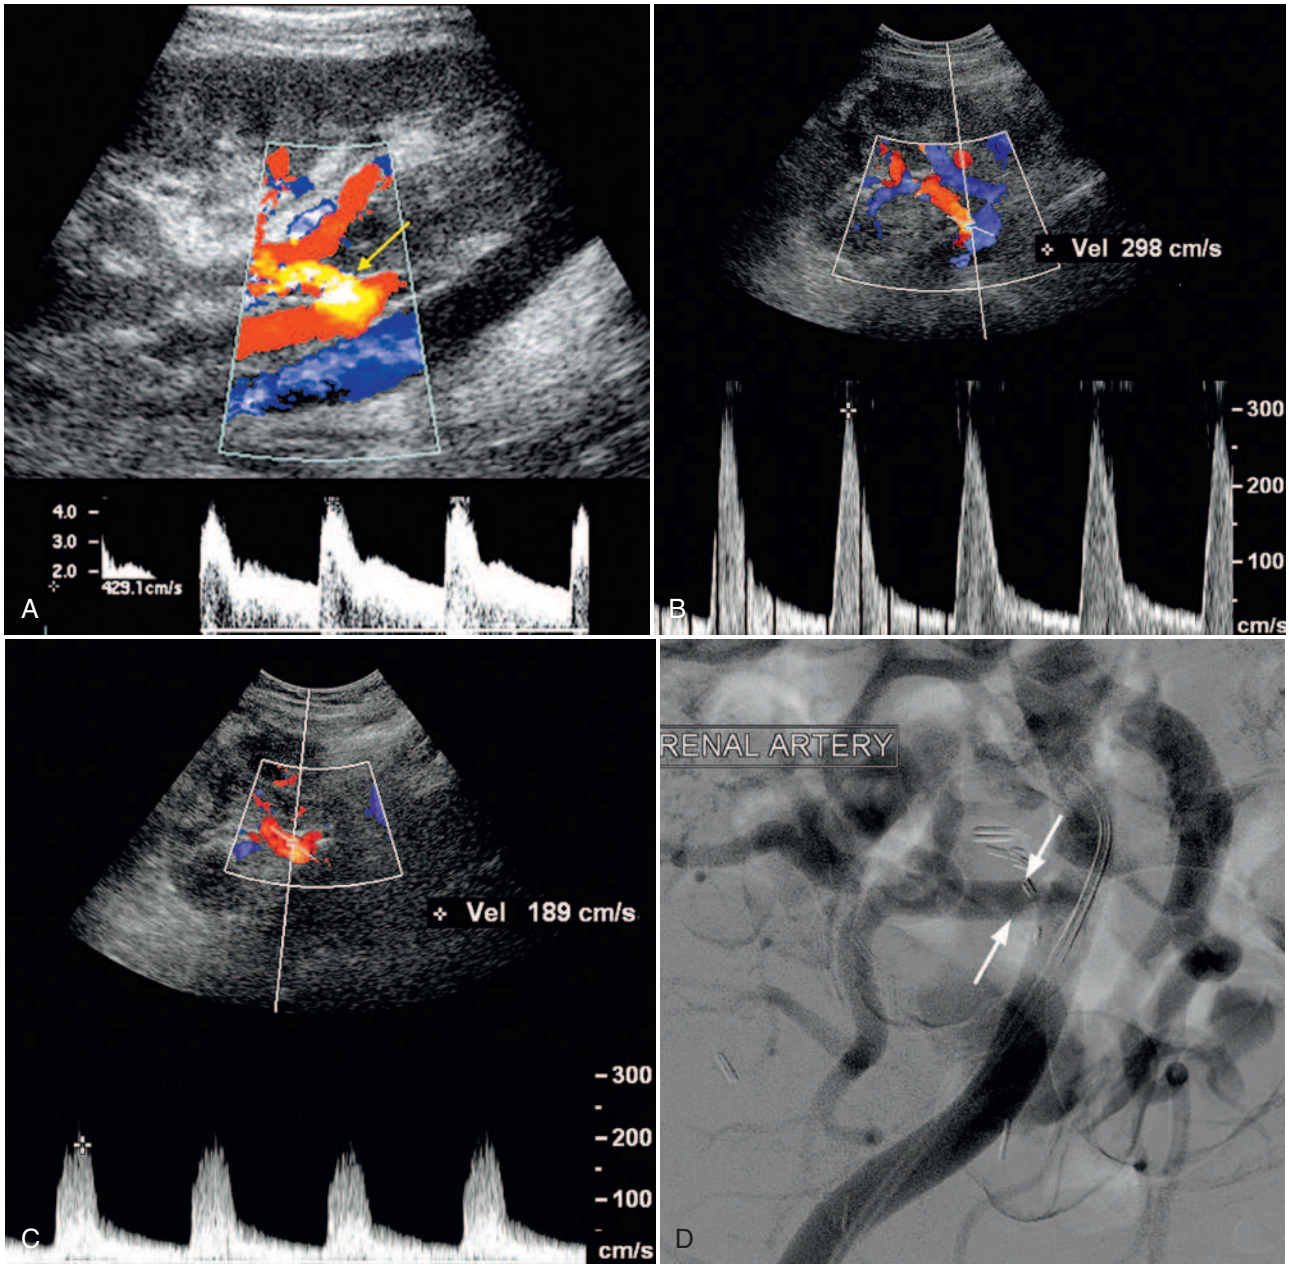

FIG. 18.44 Mimickers of Renal Artery Stenosis. (A) Abrupt turn in renal artery. On color Doppler ultrasound, aliasing is identified in this region *(arrow),* with peak systolic velocities of 429 cm/sec on spectral Doppler. **(B)-(D) Misaligned angle correction. (B)** Initial spectral Doppler shows elevated renal artery anastomotic velocity of 298 cm/sec. This elevated velocity reading is artifactual because the spectral angle correction is not aligned with the direction of the renal artery. **(C)** Follow-up spectral Doppler ultrasound shows a normal renal artery velocity of 189 cm/sec, with appropriate angle correction in the direction of the artery. **(D)** Renal angiogram confirms a normal renal artery *(arrows)* with no evidence of stenosis.

such as the renal collecting system for regions of subtle dilation, and the presence of **small intraluminal stones** (Fig. 18.49).

Mild pelvicaliectasis may be secondary to nonobstructive causes such as overhydration, decreased ureteric tone (from denervation of transplant), and ureteric-vesical reflux or can occur transiently in the immediate postoperative period from perianastomotic edema.[45,68] In addition, multiple parapelvic cysts can mimic a dilated collecting system (Fig. 18.50).

Arteriovenous Malformations and Pseudoaneurysms

Intraparenchymal arteriovenous malformations (AVMs) result from vascular trauma to both artery and vein during percutaneous biopsies and are usually asymptomatic with few clinical sequelae. Because most of these are small and resolve spontaneously, the incidence of posttransplant AVMs is unknown, although rates of 1% to 18% have been reported. In rare cases, large AVMs may manifest with bleeding, high-output cardiac failure, or decreased

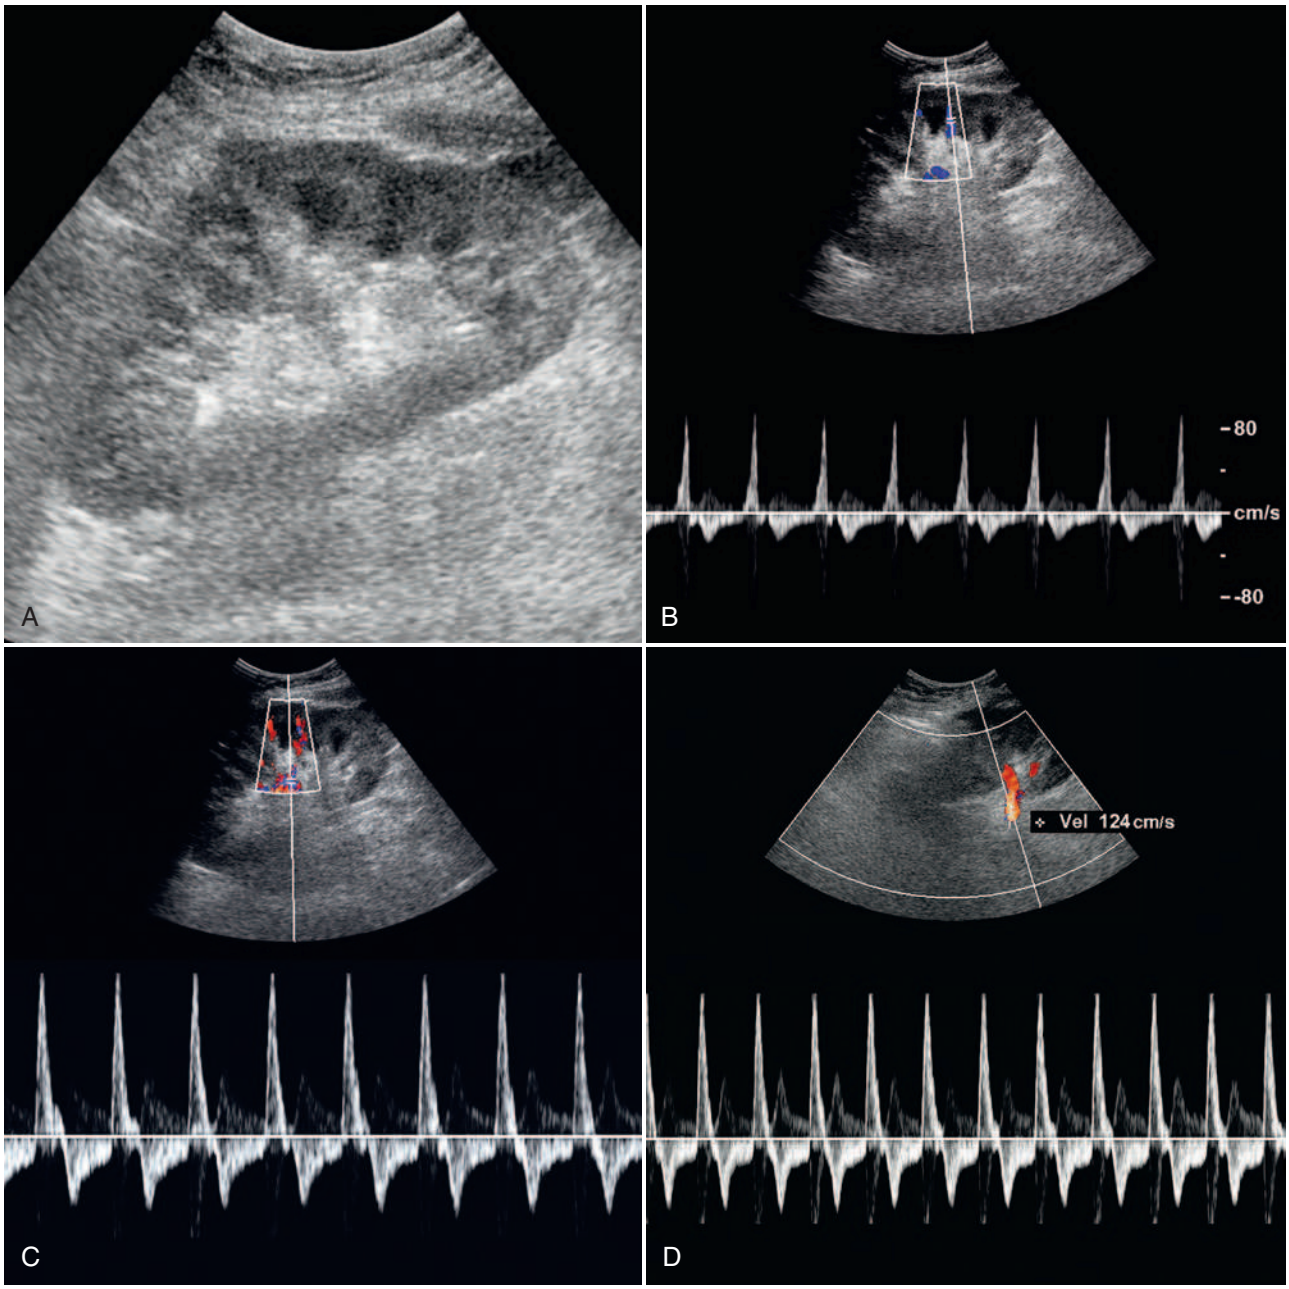

FIG. 18.45 Renal Vein Thrombosis. (A) Sagittal sonogram shows increased cortical echogenicity with a coarse echotexture. **(B)-(D)** Spectral Doppler ultrasound images of **(B)** cortical arteries, **(C)** renal sinus arterial branches, and **(D)** main renal artery show reversal of flow in diastole. No venous flow was detected in the transplant.

renal perfusion caused by the large shunt. In these patients, treatment usually involves percutaneous embolization therapy.[44]

Gray-scale ultrasound may not reveal small AVMs. Color Doppler sonography shows a focal region of aliasing with myriad intense colors, often associated with a prominent feeding artery or draining vein. Turbulent flow within the AVM produces vibration of the perivascular tissues, resulting in these tissues being assigned a color signal outside the borders of the renal vasculature. Spectral Doppler ultrasound is typical of that for all AVMs, with low-resistance, high-velocity flow and difficulty differentiating between artery and vein within the malformation. If a dominant draining vein is detected, the waveform may be pulsatile or arterialized[58,68-70] (Fig. 18.51, Video 18.3).

On color Doppler ultrasound, focal regions of cortical dystrophic calcifications or small stones can mimic an AVM by producing an intense color signal known as a *twinkling artifact*.[71] These artifacts can be differentiated from a true AVM on spectral tracing because both calcifications and stones produce characteristic linear bands on spectral interrogation. In our clinical experience, we have also observed a linear band of color posterior to these regions of calcium that extend to the limits of the color box. We have not observed this phenomenon with AVMs and

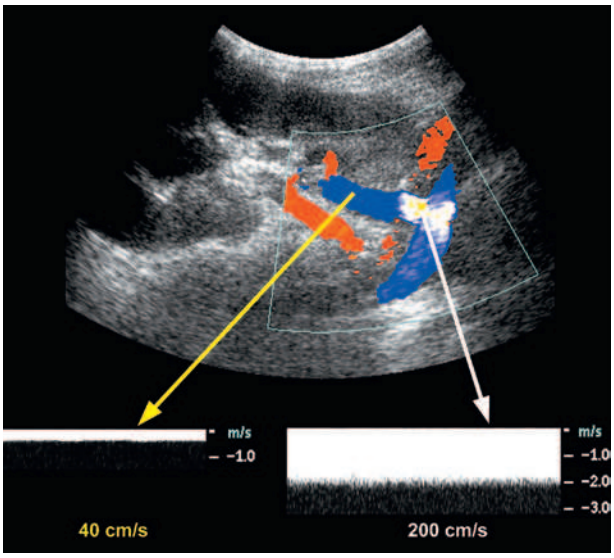

FIG. 18.46 Renal Vein Stenosis. Color Doppler of renal vein anastomosis shows focal area of aliasing *(white arrow)*. Spectral interrogation in region of aliasing shows velocities of 200 cm/sec. Spectral interrogation proximal to aliasing shows velocities of 40 cm/sec *(yellow arrow),* indicating a hemodynamically significant stenosis of the renal vein.

have found it a useful tool in differentiating vascular malformations from focal calcifications (Fig. 18.52).

Pseudoaneurysms result from vascular trauma to the arterial system during percutaneous biopsy or, more frequently, occur at the site of the vascular anastomosis. They may be intrarenal or extrarenal (Figs. 18.53 and 18.54,Video 18.4). Pseudoaneurysms located in the renal hilum are somewhat more concerning than intrarenal pseudoaneurysms owing to their increased risk of rupture. On gray-scale sonography, pseudoaneurysms can mimic a simple or complex cyst. On color Doppler ultrasound, flow can easily be obtained in the lumen of patent pseudoaneurysms, often with a swirling pattern, whereas on spectral Doppler, a central to-and-fro waveform or a disorganized arterial tracing may be obtained.[45,54] Presumed cysts in the renal parenchyma or in the region of the hilum should be assessed with color Doppler to exclude the possibility of a pseudoaneurysm.

Fluid Collections

Perinephric collections are demonstrated in up to 50% of transplant recipients.[72,73] The most common collections include

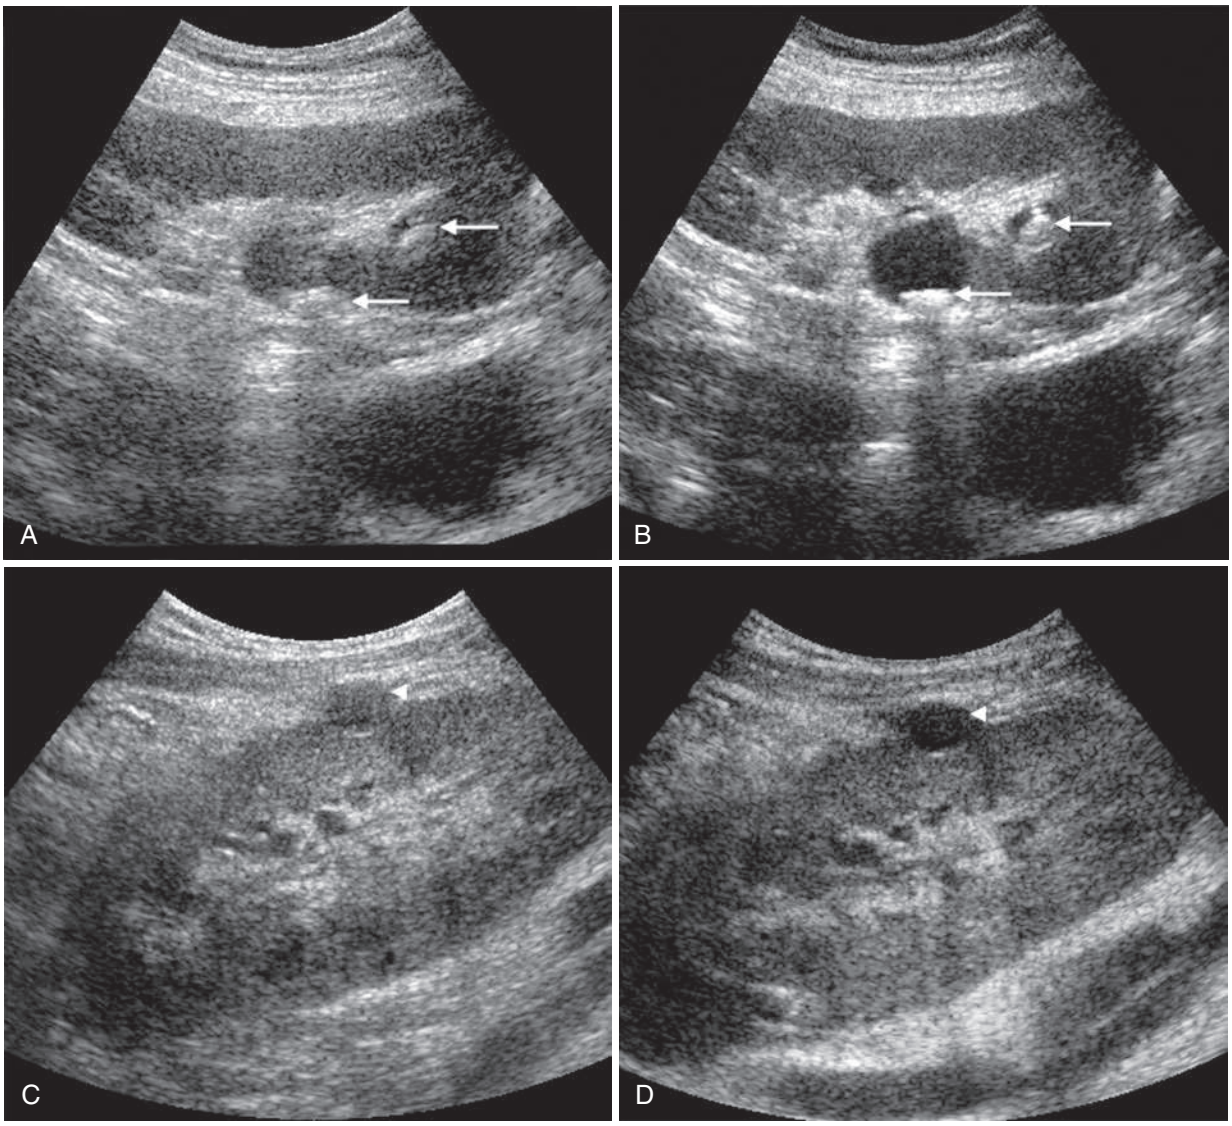

FIG. 18.49 Harmonic Imaging in Two Patients. (A) Sagittal fundamental image shows barely detectable stones *(arrows)* and a dilated collecting system. **(B)** Harmonic image shows improved resolution of stones *(arrows),* now seen associated with distal acoustic shadowing, within anechoic dilated collecting system. **(C)** Fundamental image shows cortical cyst *(arrowhead)* with internal echoes and minimal through transmission. **(D)** Harmonic image shows cyst *(arrowhead)* to be anechoic and simple, now associated with an appropriate amount of through transmission.

hematoma, urinoma, lymphocele, and abscess. The ultrasound appearances of these peritransplant collections are often nonspecific, and clinical findings are warranted to determine their cause. However, the presence of air within a perirenal collection, without a history of recent percutaneous intervention, is highly suggestive of an **abscess.** The size and location of each collection should be documented on baseline scans because an increase in size may indicate the need for surgical intervention.

Postoperative **hematomas** are variable in size but are often small, perirenal in location, and insignificant clinically and often resolve spontaneously.[68] Their ultrasound appearance depends on the age of the collection. An acute hematoma will appear as an echogenic heterogeneous solid mass. With time the hematoma will liquefy, becoming a complex fluid collection with internal echoes, strands, or pseudoseptations. Postbiopsy hematomas have a morphology similar to that of their postoperative counterparts (Figs. 18.55 and 18.56).

Urine leaks, or **urinomas,** have been reported in up to 6% of renal transplants and occur within the first 2 weeks after surgery.[44] They are usually secondary to either anastomotic leaks or ureteric ischemia. Rarely, urinomas can result from high-grade collecting system obstruction (Fig. 18.57). On sonography, urinomas are well defined and anechoic, may be associated with hydronephrosis, and in some cases can increase rapidly in size.[57] Large urine leaks may result in widespread extravasation and gross intraperitoneal urinary ascites.

Lymphoceles result from surgical disruption of the iliac lymphatics and have been reported in up to 20% of patients. They most often occur 4 to 8 weeks after surgery but may develop years after transplantation. Although most are discovered

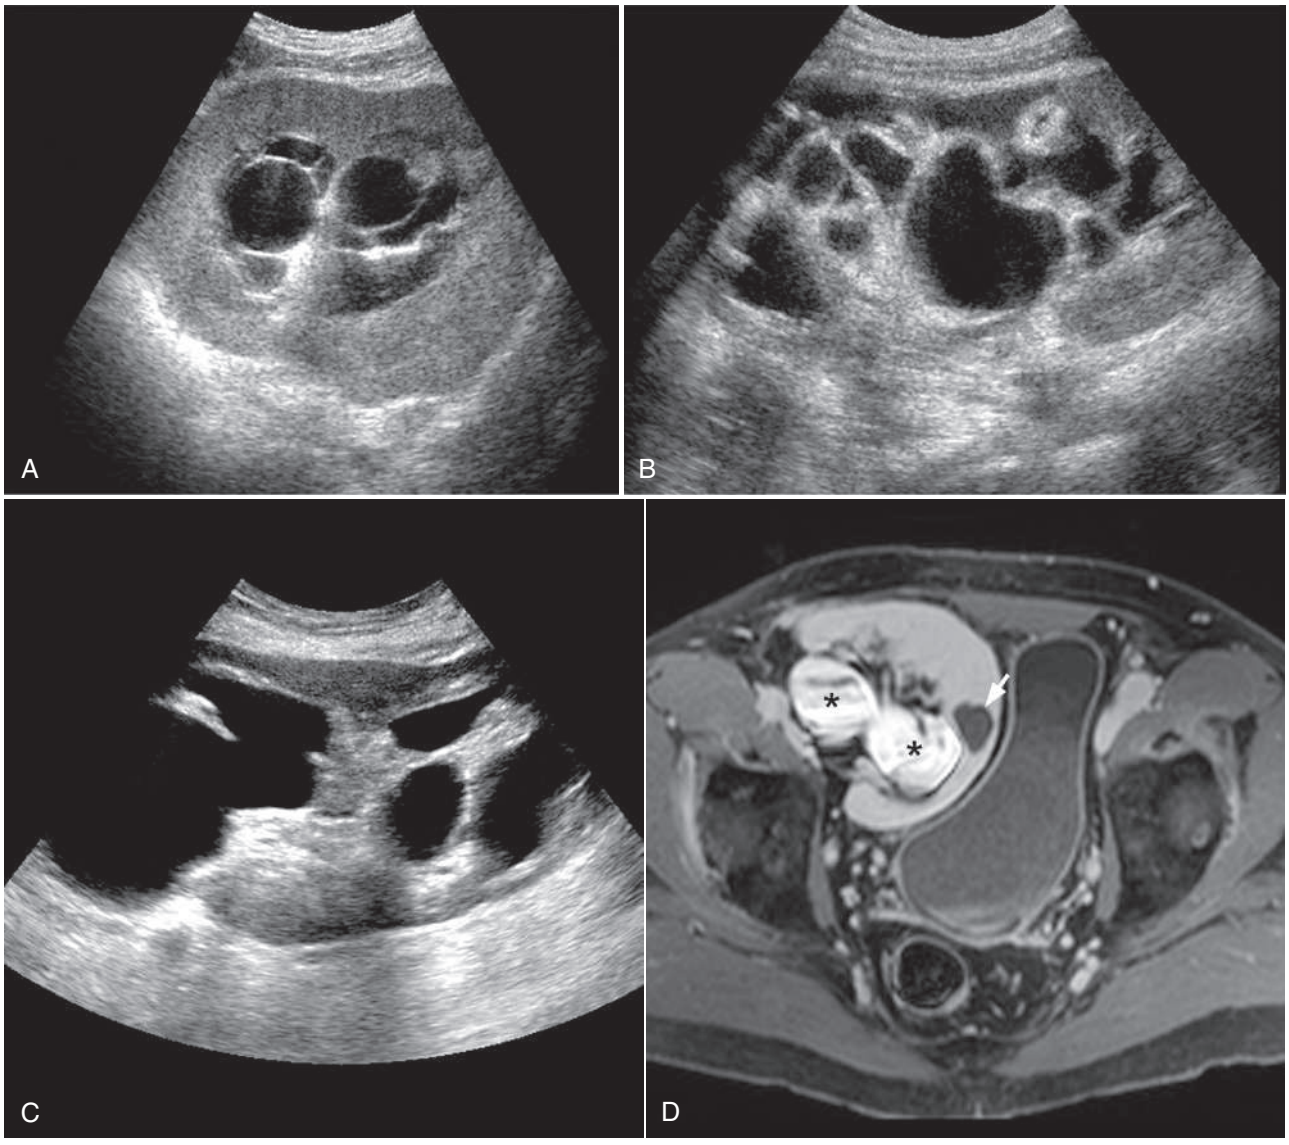

FIG. 18.50 Parapelvic Cysts Versus Pelvocaliectasis in Two Patients. *Patient 1:* **Parapelvic cysts. (A)** Transverse and **(B)** sagittal sonograms show multiple parapelvic cysts mimicking pelvocaliectasis. *Patient 2:* **Grade 3 pelvocaliectasis mimicking parapelvic cysts. (C)** Sagittal sonogram shows multiple anechoic structures in the central aspect of the kidney, initially interpreted as multiple parapelvic cysts. **(D)** Contrast-enhanced magnetic resonance image shows contrast filling grossly dilated calyces (*). A single parapelvic cyst *(arrow)* is present.

incidentally and are asymptomatic, lymphoceles are the most common fluid collection to result in ureteric obstruction. Lymphoceles can become infected or can obstruct venous drainage, resulting in edema of the lower limb, scrotum, or labia.[45] Symptomatic collections are drained (surgically or percutaneously) or undergo marsupialization. On sonography, lymphoceles are well-defined collections that are anechoic or that may contain fine internal strands (Figs. 18.58 and 18.59).

PANCREAS TRANSPLANTATION

Pancreatic transplantation is performed in select patients who have major complications related to type 1 diabetes. Pancreas transplant represents the only form of self-regulating endocrine replacement therapy, with more than 80% of recipients becoming free of exogenous insulin requirements within 1 year of surgery. Since 1988 in the United States, more than 15,000 kidney-pancreas transplants and 6000 pancreas transplants have been performed, with 1-year patient survival greater than 90%.[3,74]

Pancreatic transplantation aims to restore an adequate functioning beta cell mass and therefore to regain physiologic normoglycemic function, typically in the setting of insulin dependent diabetes. Recipients are typically type 1 diabetics in end-stage renal failure with other sequelae of long-term diabetes including neuropathy and atherosclerotic disease. Improvement in glycemic control diminishes the risk of long-term complications in diabetic patients.[75] In particular, simultaneous pancreas

transplant in the setting of kidney transplants has been known to improve long-term patient survival.

Surgical Technique

The simultaneous pancreas-kidney transplant is the most common form of pancreas transplantation in the United States and accounts of 80% of all pancreatic transplant procedures. To achieve optimum functioning beta cell mass, the procedure is a whole-organ pancreas transplant performed in conjunction with a kidney transplant. Best results are achieved if the procedure is performed before the need for dialysis. This approach allows serum creatinine to be used not only as a marker of renal rejection, but also as a surrogate marker of pancreatic graft rejection. This is particularly important because serum amylase and lipase are not sensitive or specific markers of pancreatic rejection. Serum amylase has only 50% sensitivity for detection of rejection, and lipase may be elevated in both rejection and pancreatitis. The ultimate diagnosis of graft dysfunction is often made on biopsy.

There are several further strategies for pancreas transplantation. A pancreas transplant can be performed as a second step following a successful renal transplant. The latter will typically be a living donor kidney and is usually advised for diabetic patients younger than age 5 with ongoing severe complications. The most severe complication is hypoglycemic unawareness wherein a patient may be wholly lacking the normal stigmata or warning signs of a low glucose level (such as trembling, sweating, and tachycardia).[76] This is the second most common mode of pancreatic transplant and contributes about 25% of all transplants in the United States.

Finally, pancreas-only transplantation can be performed in diabetic patients who have no evidence of diabetic nephropathy. Only a minority of diabetic patients are eligible for this approach because it is limited to patients whose hypoglycemic awareness is challenging to manage medically.

There are two well-established techniques for pancreas transplantation. Use of the bladder for exocrine drainage (duodenocystostomy) and use of the iliac vessels for arterial and venous supply were considered safer with regard to postoperative infection. This more traditional surgery, **exocrine bladder drainage,** involved anastomosing the donor duodenum to the urinary bladder and the donor portal vein to the recipient external iliac vein (systemic venous-endocrine drainage)[77] (Fig. 18.60). In this circumstance the pancreas graft is placed in the right hemipelvis and the renal graft on the left. The chronic loss of pancreatic secretions into the bladder can result in problems with dehydration, metabolic acidosis, and allograft pancreatitis.[3] There is also a higher risk of chemical cystitis secondary to the high amylase and lipase levels of pancreatic secretions. This can result in

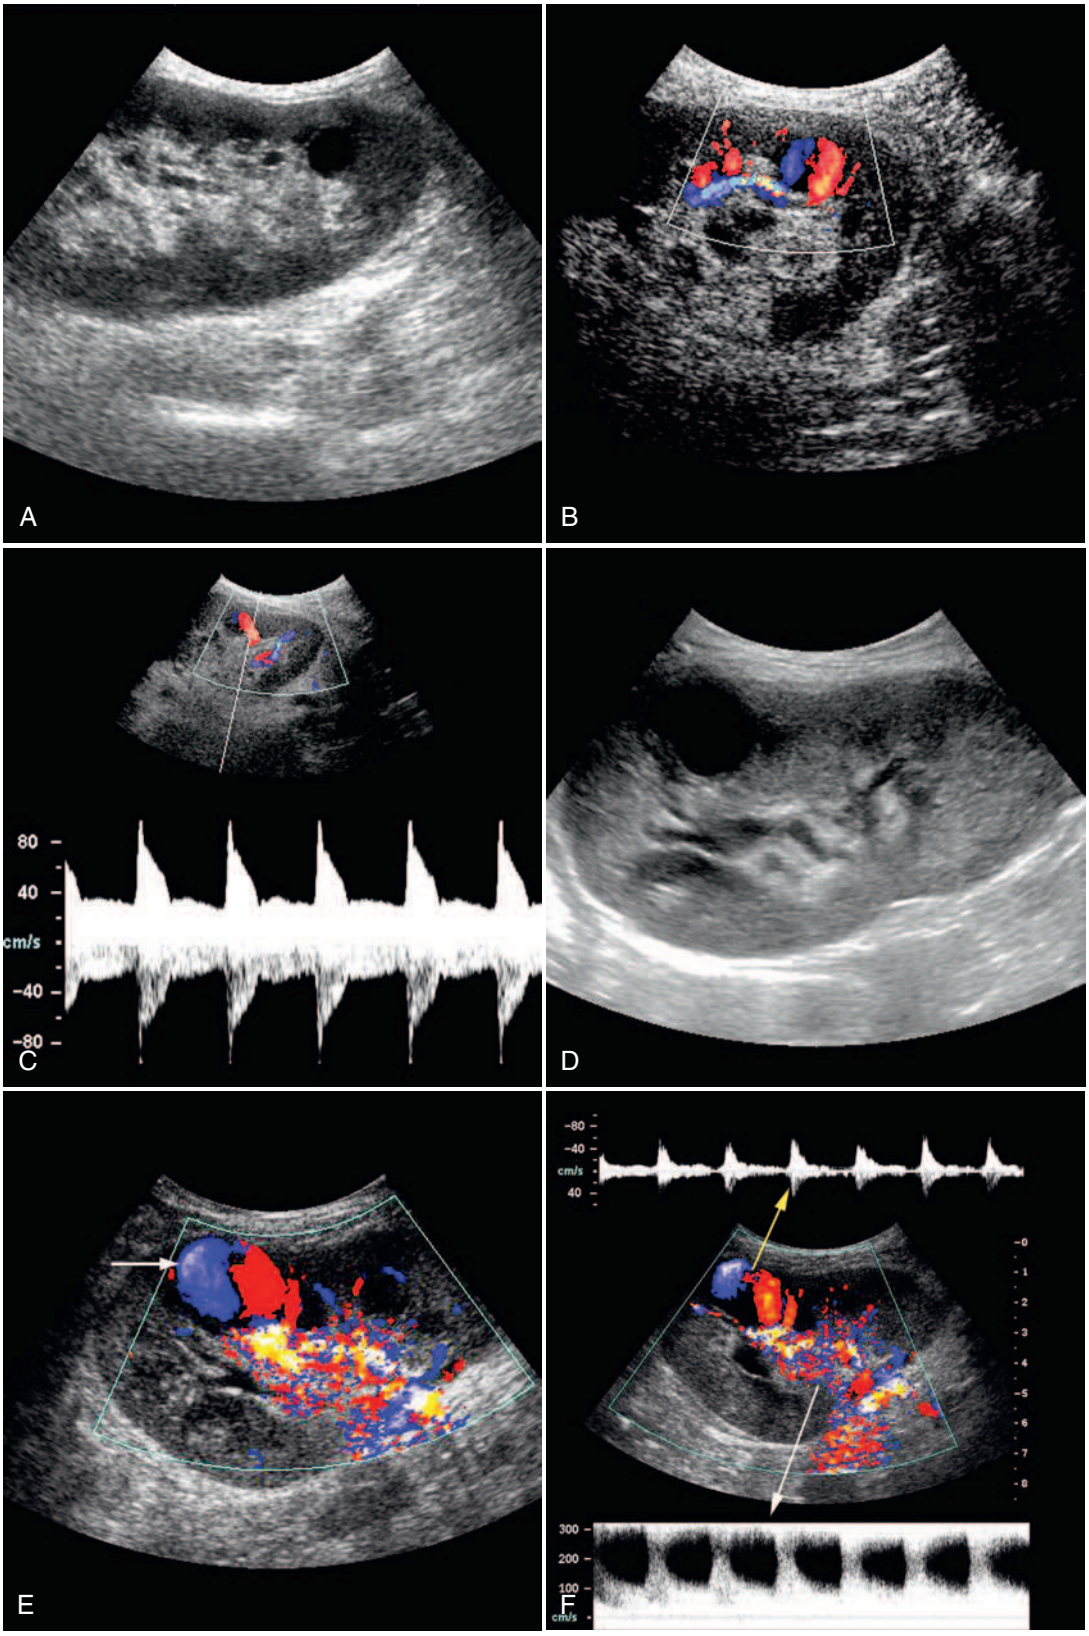

FIG. 18.53 Intrarenal Pseudoaneurysms in Two Patients. *Patient 1:* **(A)** Sagittal sonogram shows lower-pole anechoic structure, mimicking a simple cyst. **(B)** On color Doppler ultrasound, however, swirling flow is identified in this structure, indicating that it represents a pseudoaneurysm. **(C)** Spectral Doppler ultrasound shows disorganized swirling flow within the pseudoaneurysm identified on image **B.** *Patient 2:* **(D)** Sagittal sonogram shows upper-pole anechoic structure. **(E)** On color Doppler ultrasound, swirling flow is identified in the anechoic structure identified on image **(D)** *(arrow).* This is adjacent to a large central arteriovenous malformation (AVM). **(F)** Spectral Doppler ultrasound shows disorganized flow in the pseudoaneurysm *(yellow arrow)* and low-resistance high-velocity flow in the central AVM *(white arrow).*

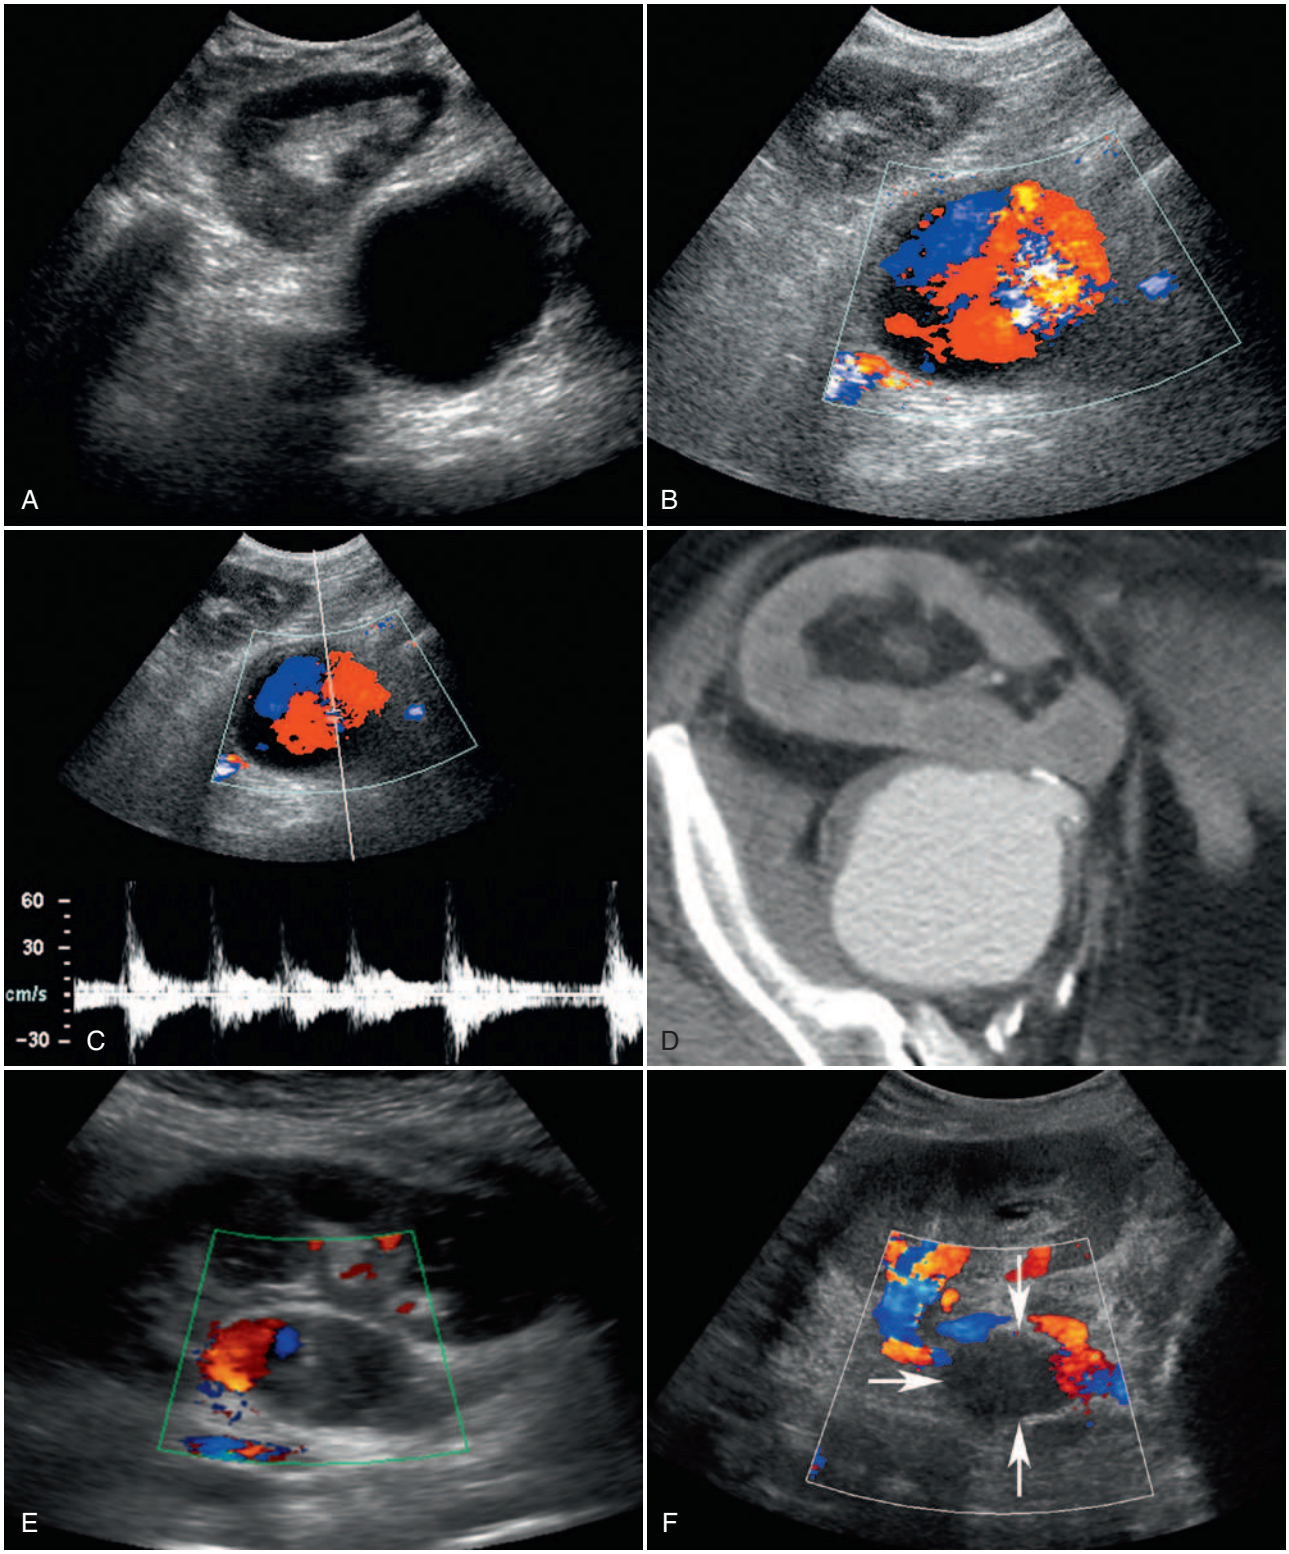

FIG. 18.54 Extrarenal Pseudoaneurysm of Renal Artery. (A) Transverse sonogram shows anechoic structure adjacent to renal hilum. **(B)** Color Doppler ultrasound shows that this structure contains swirling flow and represents a pseudoaneurysm. **(C)** Spectral Doppler ultrasound shows disorganized internal flow within pseudoaneurysm. **(D)** CT shows pseudoaneurysm arising from site of renal artery anastomosis. **(E)** and **(F)** In another patient, color Doppler images show a partially thrombosed pseudoaneurysm *(arrows).* See also Video 18.4.

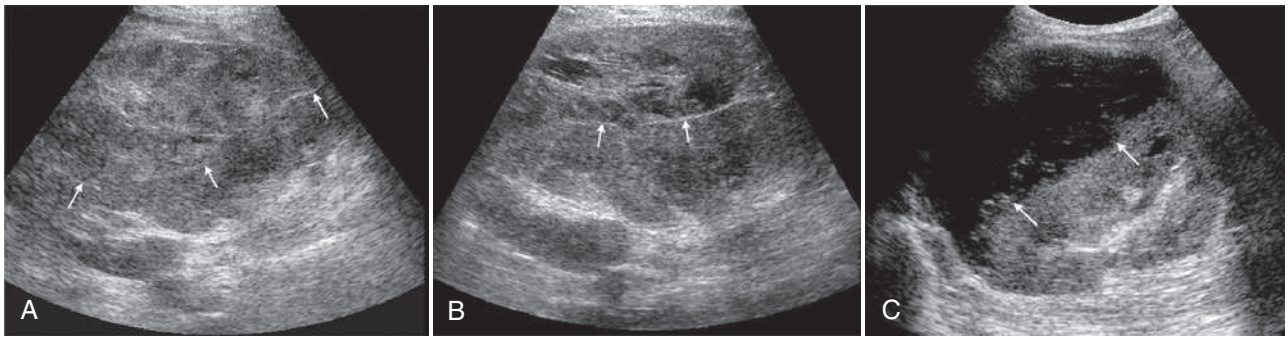

FIG. 18.55 Renal Transplant Subcapsular Hematoma Secondary to Biopsy. (A) Sagittal sonogram shows acute hematoma appearing as solid heterogeneous structure. **(B)** After 1 week, cystic regions have developed within the hematoma. **(C)** After 1 month, hematoma has liquefied and is larger because of a hyperosmolar effect. *Arrows* mark the junction of the renal cortex and hematoma.

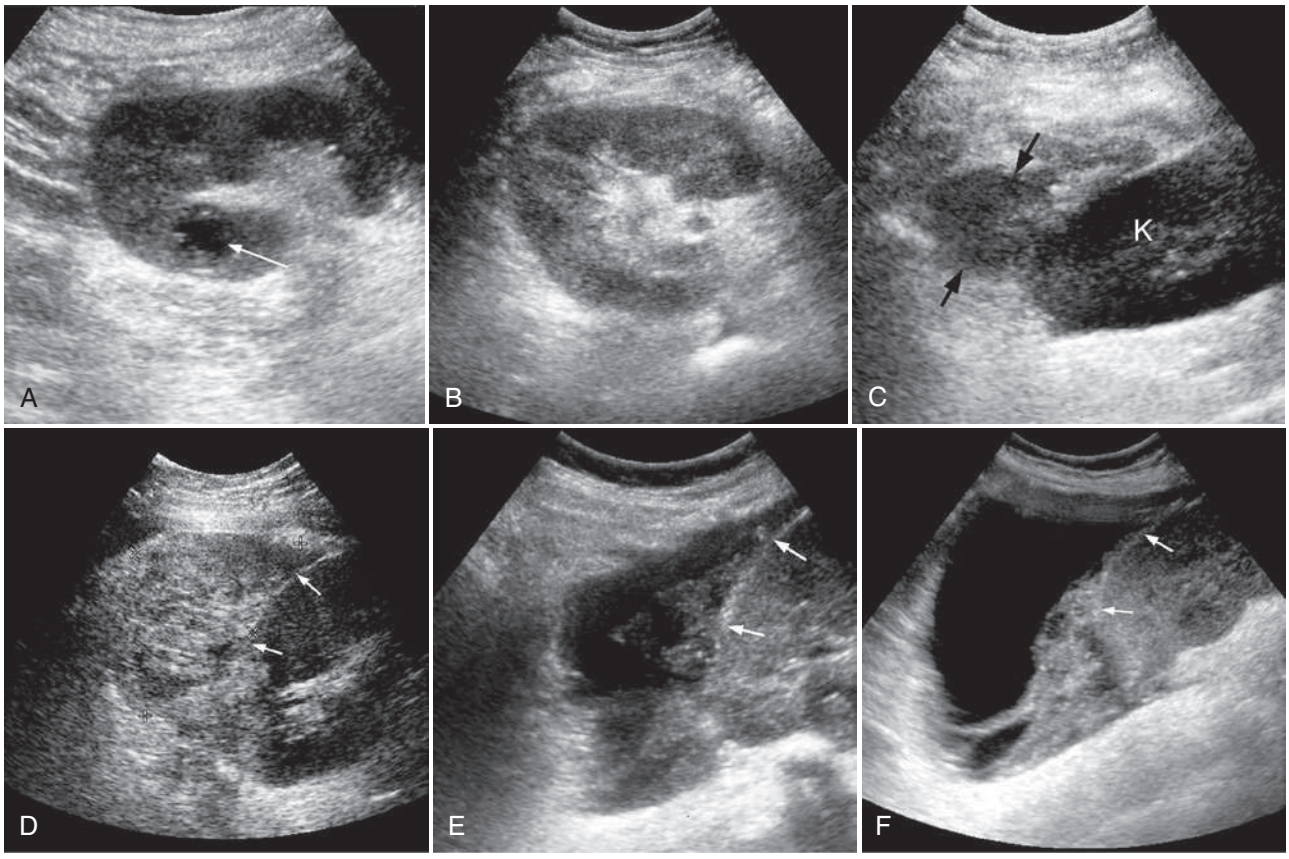

FIG. 18.56 Hematomas in Three Patients. *Patient 1:* **(A)** Transverse sonogram shows an intraparenchymal hematoma appearing as an anechoic cyst with mildly irregular walls *(arrow).* **(B)** Eight months later, the cyst has resolved. *Patient 2:* **(C)** Sagittal sonogram shows a hypoechoic solid-appearing mass *(arrows)* abutting the upper pole of the transplant kidney *(K). Patient 3:* **(D)-(F) Postoperative perirenal hematoma. (D)** Sagittal sonogram shows hematoma 1 day after surgery, appearing as a solid echogenic heterogeneous mass. **(E)** Four weeks later, hematoma has begun to liquefy, with interspersed solid components. **(F)** Six weeks later, hematoma is almost completely liquefied; arrows mark the junction of the hematoma and renal cortex.

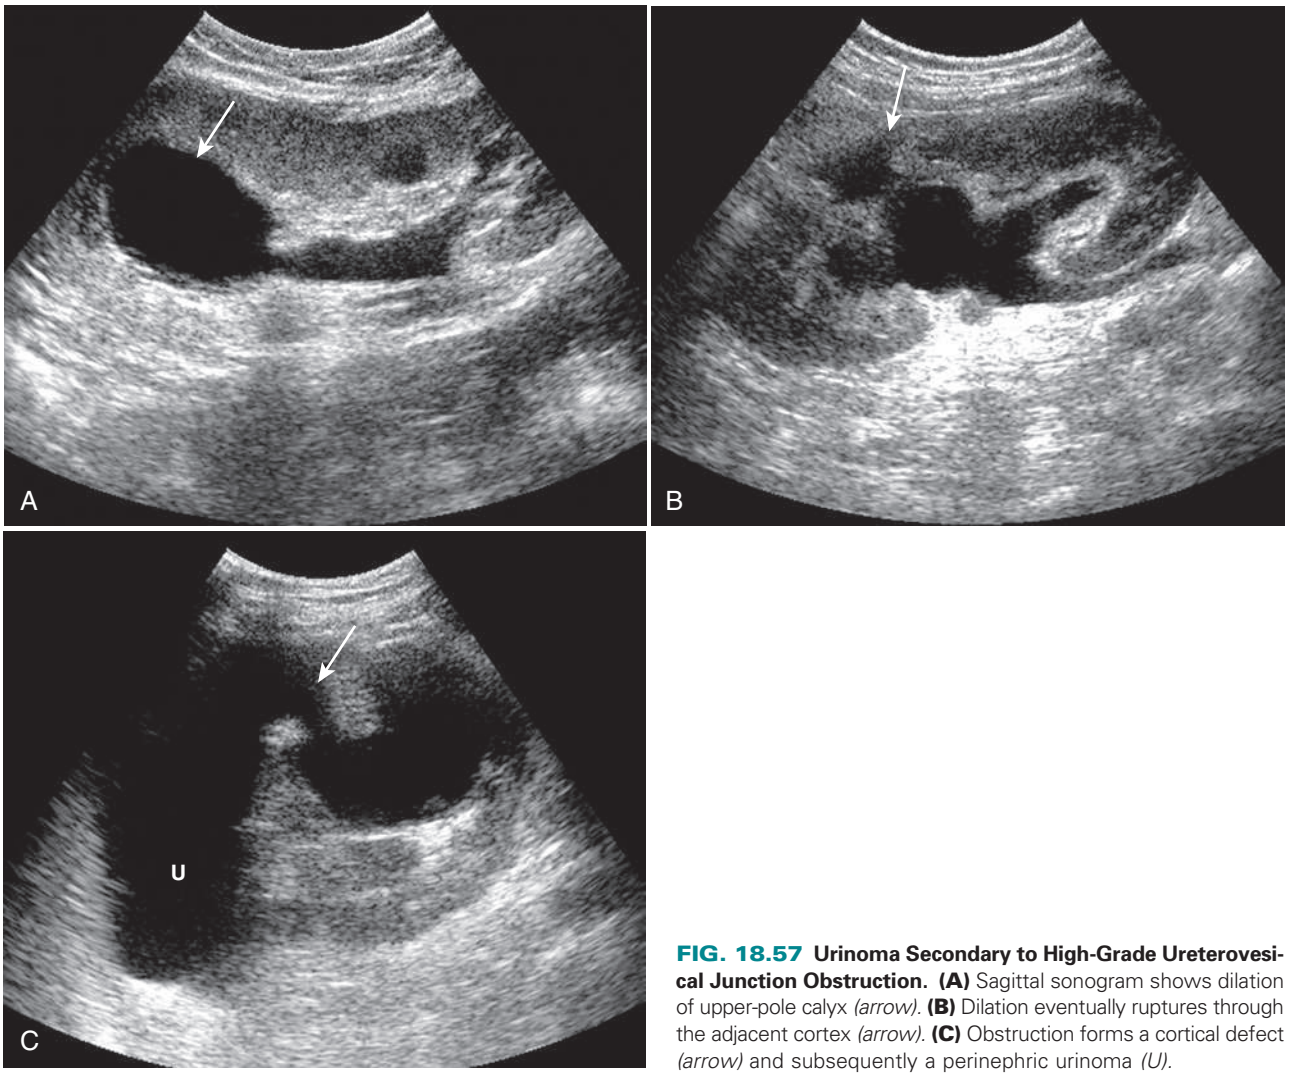

FIG. 18.57 Urinoma Secondary to High-Grade Ureterovesical Junction Obstruction. (A) Sagittal sonogram shows dilation of upper-pole calyx *(arrow)*. **(B)** Dilation eventually ruptures through the adjacent cortex *(arrow)*. **(C)** Obstruction forms a cortical defect *(arrow)* and subsequently a perinephric urinoma *(U)*.

recurrent urinary tract infections and hematuria. In male patients there is a higher risk of urethral infections and **balanitis,** which in turn may lead to urethral strictures.

These complication risks have resulted in a move toward the intestinal or **enteric-based drainage** procedure whereby a duodenojejunostomy is created for **exocrine** drainage of pancreatic secretions. This is performed as either a side-to-side anastomosis or a Roux-en-Y anastomosis.

The **endocrine drainage** is either systemic (anastomosis of donor portal vein to right common iliac vein or distal IVC) or portal venous (anastomosis of donor portal vein to SMV) (Fig. 18.61). This type of surgery provides a more physiologic transplant than the more traditional techniques and is not associated with dehydration or metabolic acidosis. In addition, it provides more appropriate glycemic control, with lower fasting insulin levels, and may be associated with a lower incidence of transplant rejection than the more traditional systemic venous-bladder drainage allografts.[3,78] Table 18.1 shows the major differences between two types of pancreatic transplants (exocrine bladder drainage and exocrine enteric drainage).

Venous Drainage

The two methods for venous drainage can be categorized as **systemic,** wherein the transplanted portal vein is anastomosed to an iliac vein or vena cava, or alternately as using the **portal** technique, whereby it drains into the SMV of the recipient. The latter technique has over time been shown to confer no additional advantage in terms of outcome compared with the systemic technique.

Arterial Supply

In both techniques (systemic and portal venous drainage) the arterial blood supply to the graft is via the donor common iliac artery being attached to the common or external iliac artery of the recipient. Most commonly at our institution, an arterial Y graft of the donor common iliac artery and external and internal iliac artery is anastomosed end to end with two separate anastomoses to the donor superior mesenteric and splenic arteries. There are some alternate methods, however, which include forming a single donor iliac arterial conduit (comprising either the common iliac and either the external or internal iliac artery),

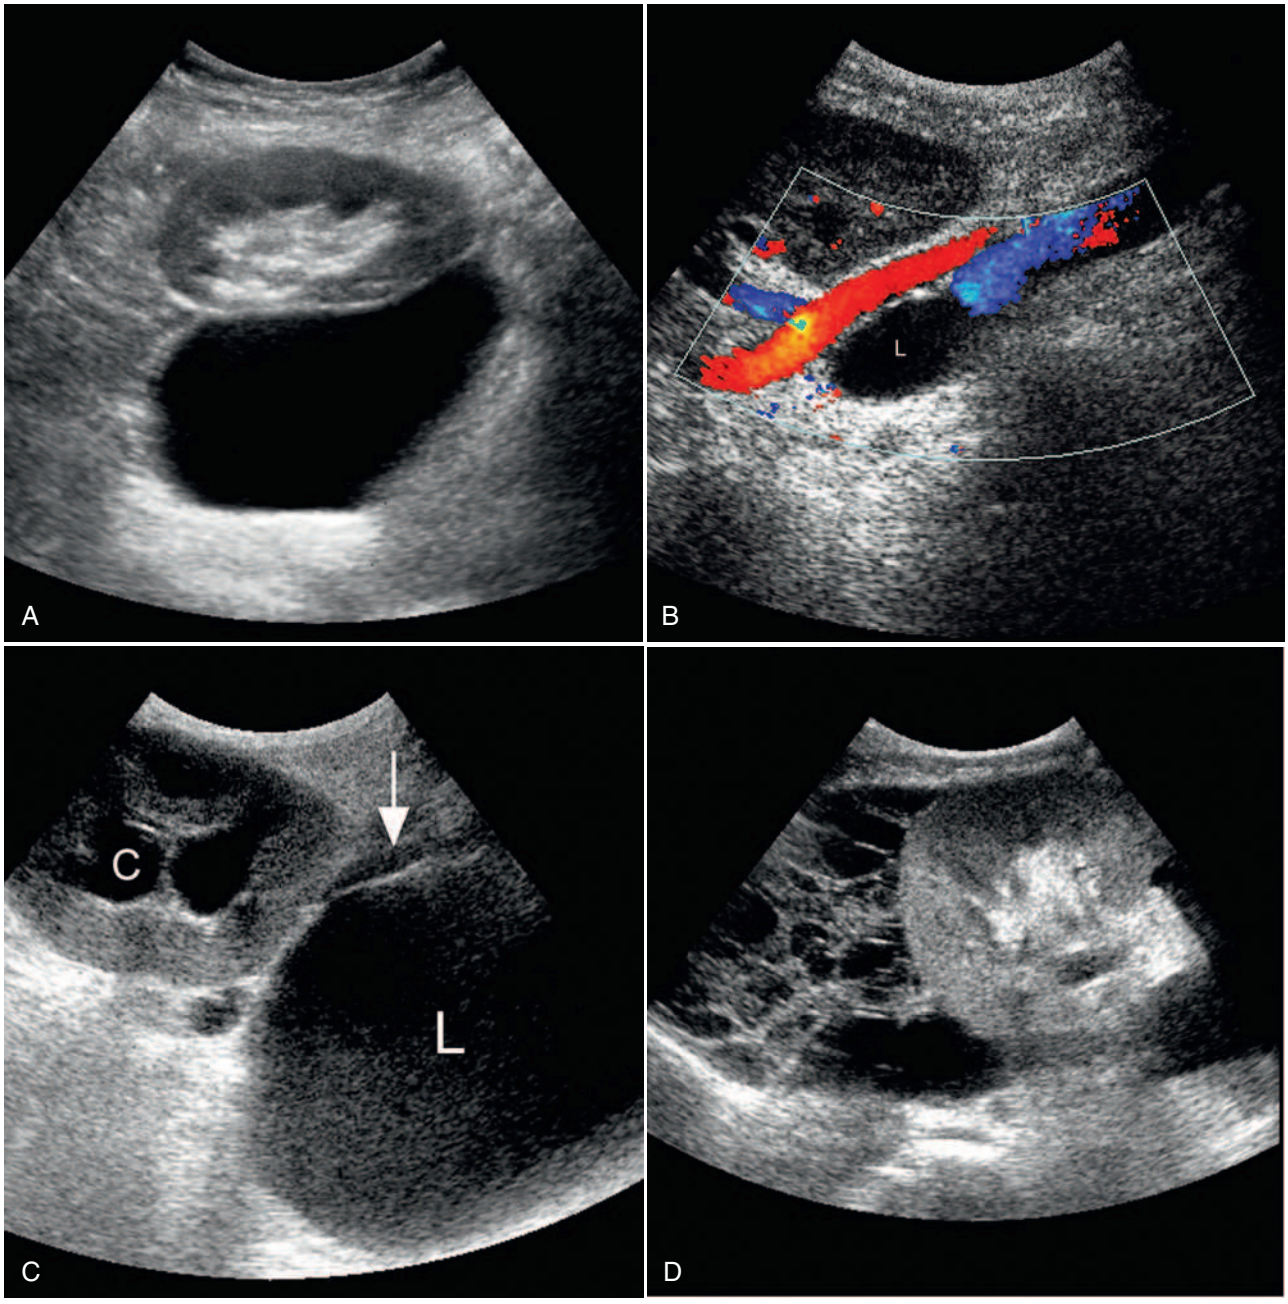

FIG. 18.58 Sterile Lymphoceles in Four Patients. (A) Sagittal sonogram shows large, simple lymphocele abutting the transplant. **(B)** Sagittal scan shows small lymphocele *(L)* adjacent to the external iliac artery and vein. **(C)** Anechoic lymphocele *(L)* causes obstruction of the midureter *(arrow)* and dilation of the calyceal system *(C)*. **(D)** Transverse sonogram shows septated perinephric lymphocele.

TABLE 18.1 Surgical Techniques for Pancreatic Transplantation

	Systemic Venous-Bladder Drainage	Portal Venous-Enteric Drainage
Location	Right lower quadrant	Right upper quadrant
Pancreatic orientation	Head caudad	Tail caudad
Arterial supply	Y-shaped donor arterial graft anastomosed to recipient common iliac artery	Donor splenic artery to recipient common iliac artery
Venous drainage	Donor portal vein is attached to external iliac vein	Donor portal vein anastomosed to superior mesenteric vein
Endocrine drainage	Systemic venous	Portal venous
Exocrine drainage	En bloc donor duodenal stump to recipient bladder	Duodenal segment anastomosed to Roux-en-Y loop of jejunum

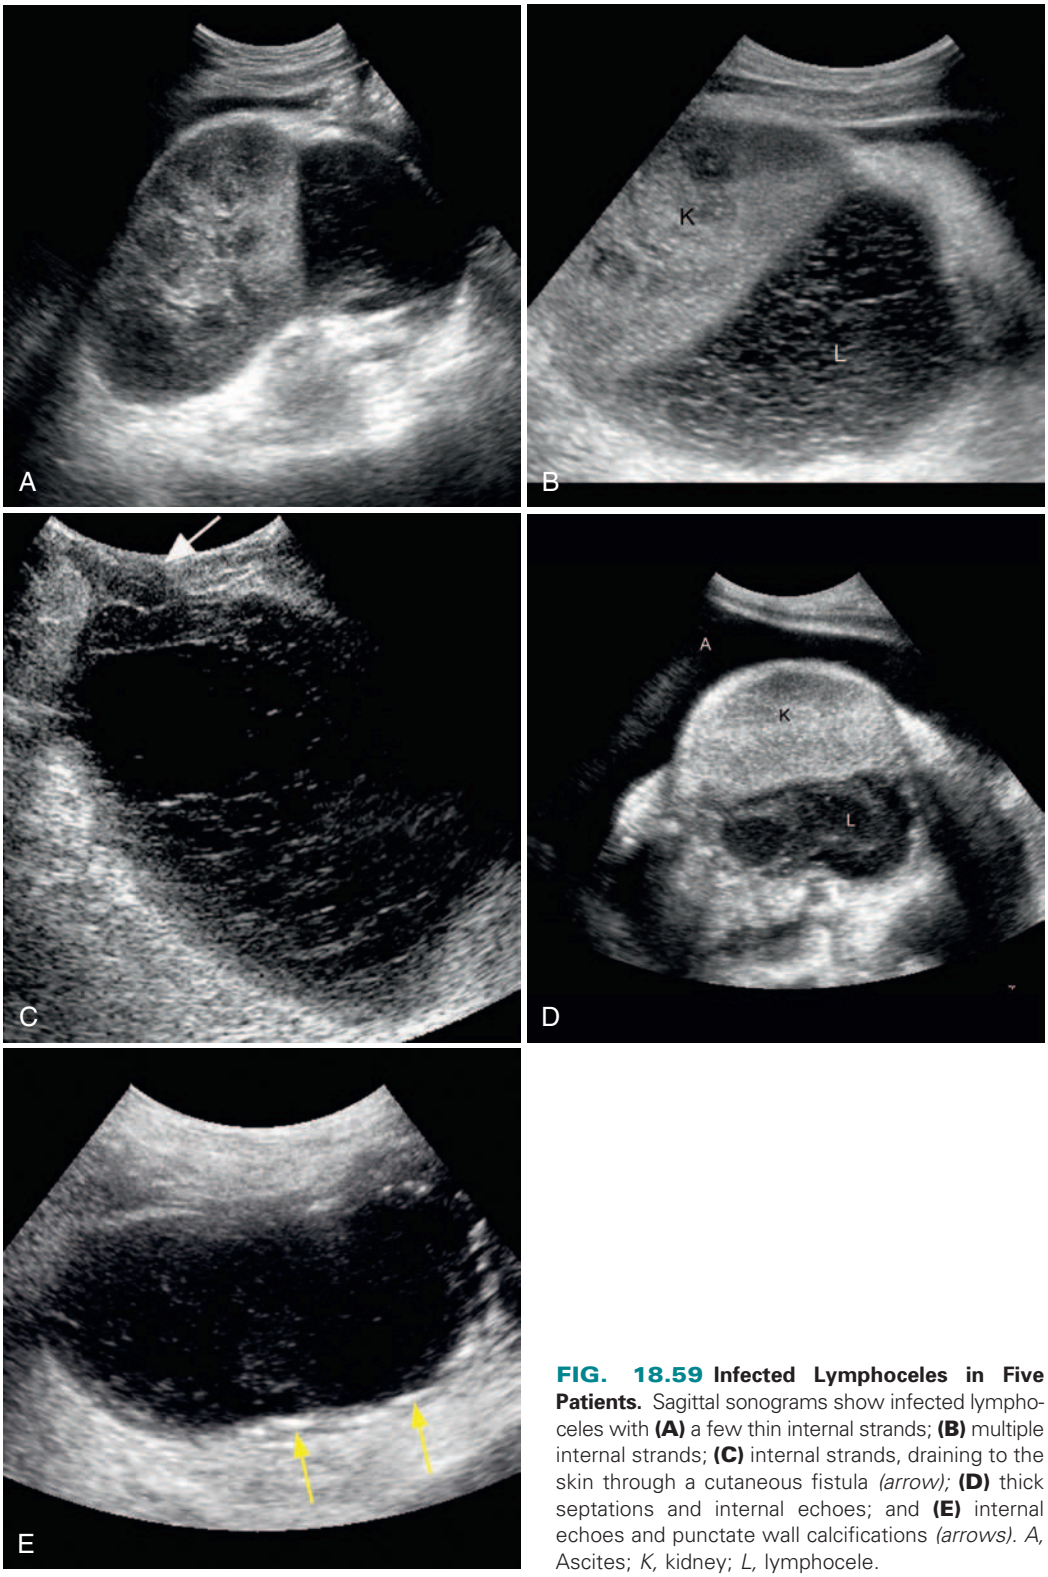

FIG. 18.59 Infected Lymphoceles in Five Patients. Sagittal sonograms show infected lymphoceles with **(A)** a few thin internal strands; **(B)** multiple internal strands; **(C)** internal strands, draining to the skin through a cutaneous fistula *(arrow);* **(D)** thick septations and internal echoes; and **(E)** internal echoes and punctate wall calcifications *(arrows). A,* Ascites; *K,* kidney; *L,* lymphocele.

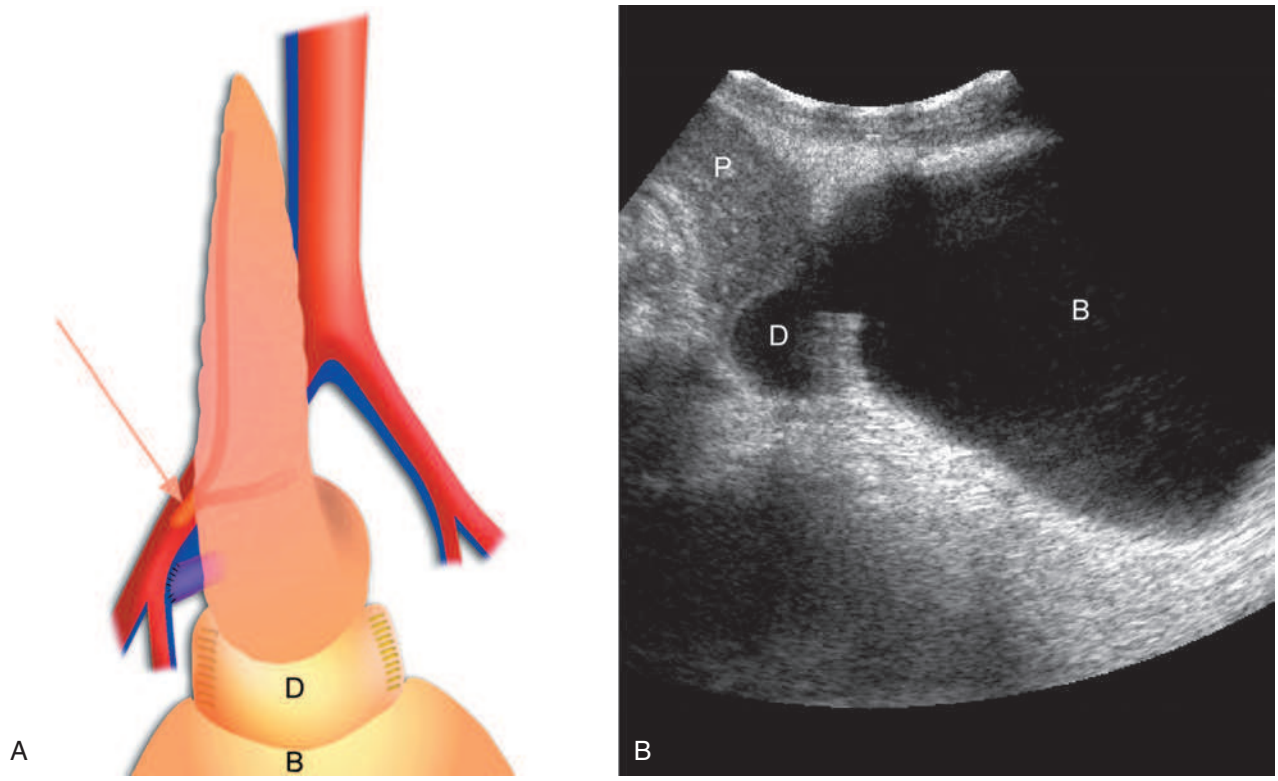

FIG. 18.60 Pancreas Transplant: Systemic Venous-Bladder Drainage (Traditional Surgery). (A) Donor portal vein *(purple)* is anastomosed to the external iliac vein, and donor artery Y graft *(coral arrow)* to the external iliac artery. Duodenal stump *(D)* is anastomosed to the bladder *(B).* **(B)** Sagittal sonogram shows duodenal stump anastomosed to the bladder *(B). P,* Pancreas.

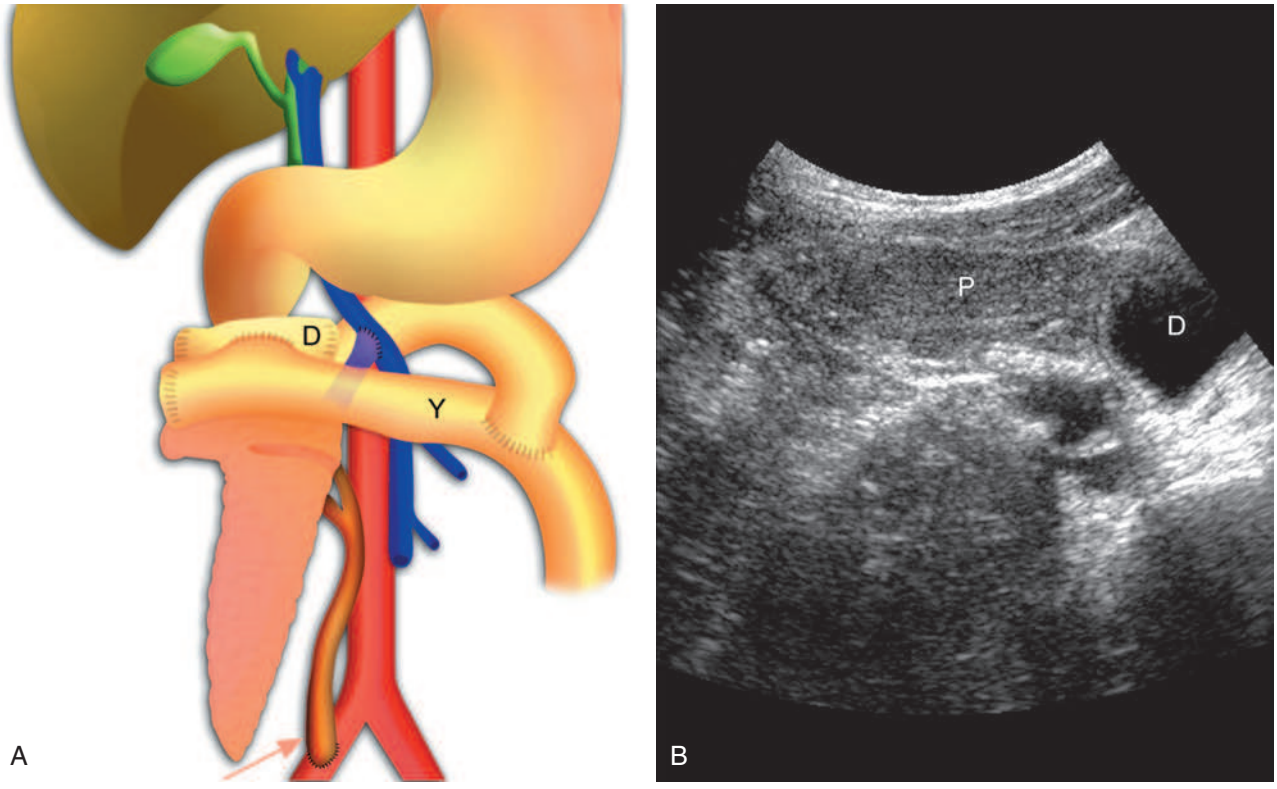

FIG. 18.61 Pancreas Transplant: Portal Venous-Enteric Drainage (New Technique). (A) Donor portal vein *(purple)* is anastomosed to the superior mesenteric vein *(blue),* and donor artery *(arrow)* is anastomosed to the common iliac artery. Duodenal stump *(D)* is anastomosed to a Roux-en-Y *(Y).* **(B)** Transverse sonogram shows pancreas transplant *(P)* with fluid-filled duodenal stump *(D).*

which is then anastomosed in an end-to-end fashion to the donor superior mesenteric artery (SMA) and end donor splenic artery to side donor iliac artery anastomosis. If the graft is portally drained, the arterial conduit is much longer than in a systemically drained graft.

Normal Pancreas Transplant Ultrasound

To perform an ultrasound assessment of a transplanted pancreas, the sonographer should be aware of the surgical technique used, the position of the allograft in the abdomen at surgery, and the sites of vascular anastomosis. This often entails a detailed review of the intraoperative surgical notes or discussion with the surgeon before scanning the patient.

With the **systemic venous** technique, the pancreatic head is placed in the iliac fossa, with the body and tail placed obliquely in the midabdomen. The pancreatic tail is therefore positioned superior to the head.

With the **portal venous** technique, the orientation of the graft is such that the pancreatic head lies superiorly and the body and tail lie inferiorly. The graft is positioned within the right side of the abdomen within the inferior mesocolic space. This allows the recipient's SMV to be anastomosed to the portal vein of the graft. In some instances the graft may be oriented in the transverse midline such that the recipient SMV is sagittally oriented to the transplant portal vein.

The normal allograft retains the normal gray-scale morphology of a native pancreas with well-defined margins; a homogeneous echotexture, isoechoic or minimally echogenic to liver; and a thin, nondilated pancreatic duct (Fig. 18.62, Video 18.5 and Video 18.6). The peripancreatic fat shows a normal echogenicity. Occasionally a trace amount of peripancreatic fluid may be observed and usually resolves without complication. Color Doppler ultrasound is useful for locating the mesenteric vessels, particularly when the graft is poorly visualized because of overlying bowel gas. Spectral Doppler sonography of the normal graft shows continuous monophasic venous flow and low-resistance arterial waveforms.

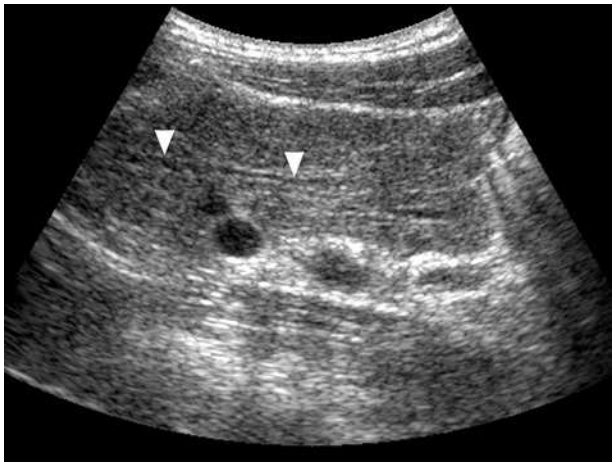

FIG. 18.62 Normal Pancreas Transplant. Gray-scale ultrasound of pancreas transplant shows normal echogenicity and echotexture of allograft, with nondilated pancreatic duct *(arrowheads)*. See also Video 18.5 and Video 18.6.

If patient habitus is slim and the graft lies in a relatively superficial location within the right iliac fossa, a high-frequency linear probe in the range of 5 to 12 MHz can be used for interrogation. Probe compression as well as placement of the patient in a right anterior oblique position will help to displace overlying bowel gas. Color and power Doppler ultrasound are useful for locating the parenchymal and graft vessels, particularly when the graft is poorly visualized because of overlying bowel gas. Spectral Doppler sonography of the normal graft shows continuous monophasic venous flow and low-resistance arterial waveforms, with a rapid systolic upstroke and continuous diastolic flow.

Role of Contrast-Enhanced Ultrasound

CT and MRI are often used for problem solving in the setting of postoperative complications; however, in the setting of associated renal impairment in this vulnerable patient group, the impact of iodinated contrast agents must be considered. Similarly, the potential risk of nephrogenic systemic fibrosis needs to be weighed against any possible diagnostic benefit when performing contrast-enhanced MRI, particularly in patients with elevated creatinine.

Contrast-enhanced ultrasound (CEUS) circumvents any underlying issues with renal impairment and facilitates the conspicuity of the graft relative to the surrounding tissues. It also allows assessment of areas of hypoperfusion. Its other inherent advantages have been well described and include safety, patient tolerance, and lack of ionizing radiation. Because the graft pancreas is highly vascularized, CEUS allows for visualization of areas of reduced or absent microcirculation. The contrast agent remains entirely intravascular, so focal areas of diminished perfusion or necrosis can be seen, and biopsy readily performed under ultrasound guidance. CEUS may also potentially allow an earlier diagnosis of graft rejection.[79]

Abnormal Pancreas Transplant

The graft vasculature consists of the following:

1. The iliac arterial graft is connected to the donor SMA and splenic artery. A Doppler arterial waveform is usually obtained from the SMA, the proximal and distal splenic artery, the intrapancreatic arcade, and the transverse vessels. The waveform is assessed for peak systolic flow velocity as well as being evaluated for vascular resistance within the graft. A normal graft should have arterial flow with a sharp systolic upstroke and continuous antegrade diastolic flow. This is seen in conjunction with an RI of 0.5 to 0.7, which implies a relatively low intragraft vascular resistance. Because there is no capsule enveloping the graft pancreas, normal resistance may be seen in a transplanted pancreas with edema (in the setting of either pancreatitis or rejection). This is in contradistinction to the graft kidney, wherein intrarenal edema results in elevation of vascular resistance.
2. The graft splenic vein and SMV join together to form the donor portal vein. This can be anastomosed to the recipient iliac vein, vena cava (systemic drainage), or SMV (portal drainage). Cardiac phasicity can be seen in the venous waveform when there is systemic venous drainage. Relative flattening of the venous waveform at the site of the donor portal vein

anastomosis to the recipient iliac or SMV is not an uncommon finding and is related to mild narrowing at this site.

The most common complications are venous thrombosis and arterial pseudoaneurysm.

Potential symptoms of graft thrombosis include unexplained hyperglycemia, graft tenderness, and, in the context of systemic-bladder drainage technique, hematuria and diminished urinary amylase levels. Potential complications of graft thrombosis include graft dysfunction and necrosis, pancreatitis, leakage of pancreatic secretions, and sepsis.

Thrombosis

Graft thrombosis, including both venous and arterial thrombosis, occurs in 2% to 19% of patients and is the second leading cause of transplant loss, after rejection. Pancreatic transplants are more vulnerable to graft thrombosis than renal transplants because the rate of blood flow in the transplanted pancreas is slower than that in a transplanted kidney.[80,81] Although the clinical signs and symptoms of graft thrombosis are nonspecific, detection of vascular thrombosis is imperative for both salvaging the transplant and preventing life-threatening sequelae, such as sepsis and cardiovascular collapse. Venous thrombosis, which occurs with an estimated incidence of 5%, is a particular concern because of the increased risk of hemorrhagic pancreatitis, tissue necrosis, infection, thrombus propagation, and pulmonary embolism.[81]

Graft thrombosis can be categorized as early or late, depending on the time of diagnosis after surgery. **Early** graft thrombosis occurs within 1 month of transplantation and is secondary to either microvascular injury during preservation of the graft or technical error during surgery. **Late** graft thrombosis occurs 1 month after transplant surgery and is usually caused by **alloimmune arteritis,** in which gradual occlusion of the small blood vessels eventually culminates in complete proximal vessel occlusion.[80] Other technical factors predisposing to graft thrombosis include coagulopathies, long preservation time, poor donor vessels, left-sided graft placement resulting in a deeper anastomosis, and the use of a venous extension graft.[81]

Prompt surgical intervention may be required depending on the severity of the thrombosis. Thrombosis of the graft splenic artery and vein results in infarction of the graft pancreatic body and tail. If there is thrombosis of the graft SMA and SMV, it may result in infarction of the pancreatic head and transplanted duodenum. In the context of acute thrombosis the graft may appear enlarged, whereas in more chronic thrombosis the graft appears diffusely atrophic.

Venous thrombosis is far more common than arterial thrombosis and is either completely or partially occlusive. It can be localized to the SMV, the splenic vein, or both vessels. A venous thrombosis may form owing to a phlebitis related to an underlying pancreatitis. Alternate mechanisms include stasis caused by a perianastomotic fluid collection or a torque on the venous anastomosis related to a shift in position of the graft resulting in stretching or twisting. Stasis in a stump of the SMV distal to the pancreaticoduodenal vessels may be a nidus for venous thrombosis.

Venous thrombi within the pancreatic graft may remain localized and not propagate into the portal vein, the iliac vein, or the IVC (systemic venous drainage) or the SMV (portal venous drainage). Normal graft function can therefore be maintained.[82] However, the potential for propagation of venous thrombi always exists, and if not well seen on ultrasound may need to be imaged dynamically in the venous phase on multiphase computed tomography (CT) or magnetic resonance imaging (MRI).

Splenic vein thrombosis results in reversal of arterial diastolic flow and absence of splenic venous flow on Doppler ultrasound. Diffuse narrowing of the transplanted portal vein can be visualized with either technique and is typically seen in association with elevation of venous pressure within the graft.

A combination of systemic anticoagulation and/or thrombolytic therapy may be necessary to treat complete splenic vein occlusion.[83] Endovascular thrombectomy may also be performed for partial or occlusive thrombus, provided there is no underlying pancreatitis or extrinsic vascular compression.[84]

Pseudoaneurysms occur at anastomotic sites or elsewhere as a result of pancreatitis or underlying infections or abscess. They can also occur secondary to biopsy or surgical trauma. The iatrogenic pseudoaneurysms may be seen in association with arteriovenous fistulas. Similar to the stump venous thrombi described earlier, stasis in low-flow surgically created vascular stumps can occur in peripheral superior mesenteric and splenic arterial segments and contributes to formation of stump thrombi.

Arterial thrombosis involves the graft SMA, the graft splenic artery, or the donor Y construct. The pancreas has a smaller microcirculatory blood flow in comparison with other graft types, and this increases its risk for thrombosis. It is usually mitigated by the formation of intrapancreatic arterial collaterals, which means that patency of only one allograft artery (SMA or splenic artery) is sufficient for graft survival and function. These collaterals are often better appreciated on a modality such as CT owing to the relatively diminutive caliber of the vessels.

Thrombosis is least common in the simultaneous pancreas-kidney transplant as compared with the other techniques, as well as being less likely when the systemic-bladder drainage technique is used as compared with the portal-enteric drainage technique. However, kinking of the Y graft is more likely in the portal enteric technique and is related to the length of the vessel (the graft is placed higher in the abdomen).

Many of these arterial complications can be managed via endovascular intervention, including coil embolization and covered stents. Surgical resection of aneurysms and grafting are usually reserved for patients who have infected grafts and pseudoaneurysms in the setting of abscesses in the transplant bed.

On ultrasound, occlusive or nonocclusive thrombus may be visualized within the lumen of the transplanted arteries or veins (Fig. 18.63). We have also observed several cases of thrombus occurring at the suture line of blind-ending arteries or veins (Fig. 18.64). On spectral Doppler, no arterial flow is detected in transplants with occlusive arterial thrombus. In grafts with occlusive venous thrombus, a lack of venous flow is detected on spectral tracing, with high-resistance arterial flow showing either no flow in diastole (RI = 1) or reversal of diastolic flow.[81] Surgically ligated arteries containing thrombus may show a cyclic pattern of flow adjacent to the thrombus, which we presume is secondary

to local eddy currents, with a normal arterial waveform more proximally.

Arteriovenous Fistula and Pseudoaneurysms

Arteriovenous fistulas and pseudoaneurysms are rare complications of pancreatic transplants and may be related to the blind ligation of mesenteric vessels along the inferior border of the pancreas during retrieval. In some patients, mycotic pseudoaneurysms may occur in the setting of graft infection.[85]

On gray-scale ultrasound, **arterial malformations** may not be detectable. On color Doppler sonography, however, a mosaic of intense colors may be identified, produced by the tangle of vessels within the malformation and adjacent tissue vibration. Spectral Doppler ultrasound reveals high-velocity, low-resistance flow within the lesion, which is typical of arteriovenous shunting (Fig. 18.65). On gray-scale ultrasound, **pseudoaneurysms** usually appear as anechoic spherical structures, although mural-based intraluminal thrombus may be detected. On spectral Doppler ultrasound, the classic to-and-fro pattern may be observed.

Rejection

Rejection is the most common cause of pancreatic graft loss after transplantation. This condition affects up to 40% of grafts and can be hyperacute, acute, or chronic.[77] Early recognition of transplant rejection remains a challenge because clinical

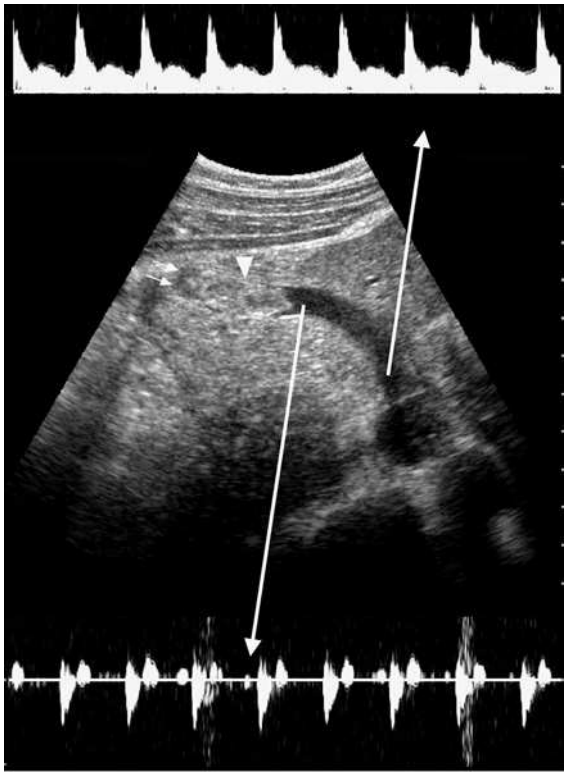

FIG. 18.64 Thrombus Adjacent to Suture Line. Echogenic thrombus *(arrowhead)* at suture line *(small arrows)* of blind-ending ligated artery. Spectral trace adjacent to thrombus shows to-and-fro waveform *(bottom)*, whereas spectral trace *(top)* more distally is normal.

parameters used to evaluate pancreas graft dysfunction have low sensitivity and specificity in detection of rejection. In particular, there is no individual biochemical marker that would permit acute rejection to be distinguished from vascular thrombosis or pancreatitis.

Although current advances in immunosuppressives have had an impact on acute rejection rates, chronic rejection remains one of the major causes of long-term graft failure.

Hyperacute rejection is rare and occurs in the immediate postsurgical period, usually as a result of preformed circulating cytotoxic antibodies in the recipient's blood. Thrombosis and immediate graft loss occur with this condition.

Acute rejection occurs as a result of an autoimmune vasculitis and develops 1 week to 3 months after transplantation. There is small vessel occlusion, which results in diminished perfusion and long-term infarction if not treated early.[86] Recurrent episodes of inadequately treated or unrecognized rejection result in chronic rejection, with progressive endarteritis of small vessels with acinar atrophy, and eventually with fibrosis and parenchymal atrophy. Chronic rejection occurs in 4% to 10% of patients and is seen as gradual decline in exocrine and then endocrine function.

On gray-scale ultrasound, the allograft may appear hypoechoic or may contain multiple anechoic regions, and the parenchymal echotexture may be patchy and heterogeneous[87,88] (Fig. 18.66). In addition, there may be abnormal graft size, typically enlargement in acute rejection and atrophy in chronic rejection. Pancreatic enlargement in acute rejection has a sensitivity of 58% and a specificity of 100%.[89]

The usefulness of arterial RIs as an indicator of rejection is controversial. It has been shown that RIs of the arteries supplying the pancreatic transplant cannot differentiate allografts with mild or moderate rejection from normal transplants without rejection.[90] The reason may be that the pancreatic transplant does not contain a discrete investing capsule, and therefore swelling from transplant rejection may not necessarily result in increased parenchymal pressures or elevated vascular resistance.[91] Grossly elevated RIs greater than 0.8 have been observed in pancreatic allografts with biopsy-proven acute severe rejection. Although these elevated RIs may be sensitive, they are not specific in the detection of severe pancreatic transplant rejection.[90] Similarly, graft enlargement and heterogeneity may be seen in acute pancreatitis and ischemia.

In a small series of patients, CEUS played a useful role in the surveillance of pancreatic grafts and in particular helped in the earlier diagnosis of rejection. Time-intensity curves in patients during rejection showed a significantly slower ascent and diminished maximum intensity. Overall, there was a significantly reduced maximum intensity and time to reach peak intensity. After successful treatment of the episode of rejection, these parameters near normalized to initial values.

Ultimately, image-guided biopsy is the reference standard for confirming and grading the severity of rejection.

Pancreatitis

Almost all patients develop symptoms of pancreatitis immediately after surgery, presumably caused by reperfusion injury and ischemia.[91] This typically involves the entire graft.

A temporary elevation of serum amylase 48 to 96 hours posttransplantation is therefore common and usually of no clinical consequence. There is also a mild transient elevation in amylase.

Focal edema of the donor mesenteric fat attached to the arterial stump of the SMA should not be misdiagnosed as a focal pancreatitis. This finding is related to ligation of the donor's lymphatic vessels. Other causes of pancreatitis include partial or complete occlusion of the pancreatic duct, poor perfusion of the allograft, and, in patients with systemic venous-bladder drainage, reflux-related pancreatitis.[87]

Long term, graft pancreatitis is seen in up to 35% of transplants. Underlying predisposing factors include prolonged warm ischemia time, graft handling, and reperfusion injury. The major differential diagnoses to consider include graft rejection and ischemia.

The ultrasound appearance of pancreatitis in the allograft is similar to that of pancreatitis in the native gland (Fig. 18.67). Gray-scale findings include a normal-sized or bulky edematous pancreas, poorly defined margins, increased echogenicity of the peripancreatic fat secondary to surrounding inflammation, peripancreatic fluid, and thickening of the adjacent gut wall. In cases of pancreatitis resulting from ductal obstruction, a dilated pancreatic duct may be observed.[87,91] In nonacute cases of pancreatitis, pseudocysts adjacent to or distal from the transplant may be identified, usually appearing as a well-circumscribed fluid collection with minimal adjacent inflammatory changes. Needle aspiration of this structure typically demonstrates fluid with high amylase content.

Pancreatitis may be seen in association with vascular sequelae such as a focal arterial aneurysm or venous thrombosis. Similarly,

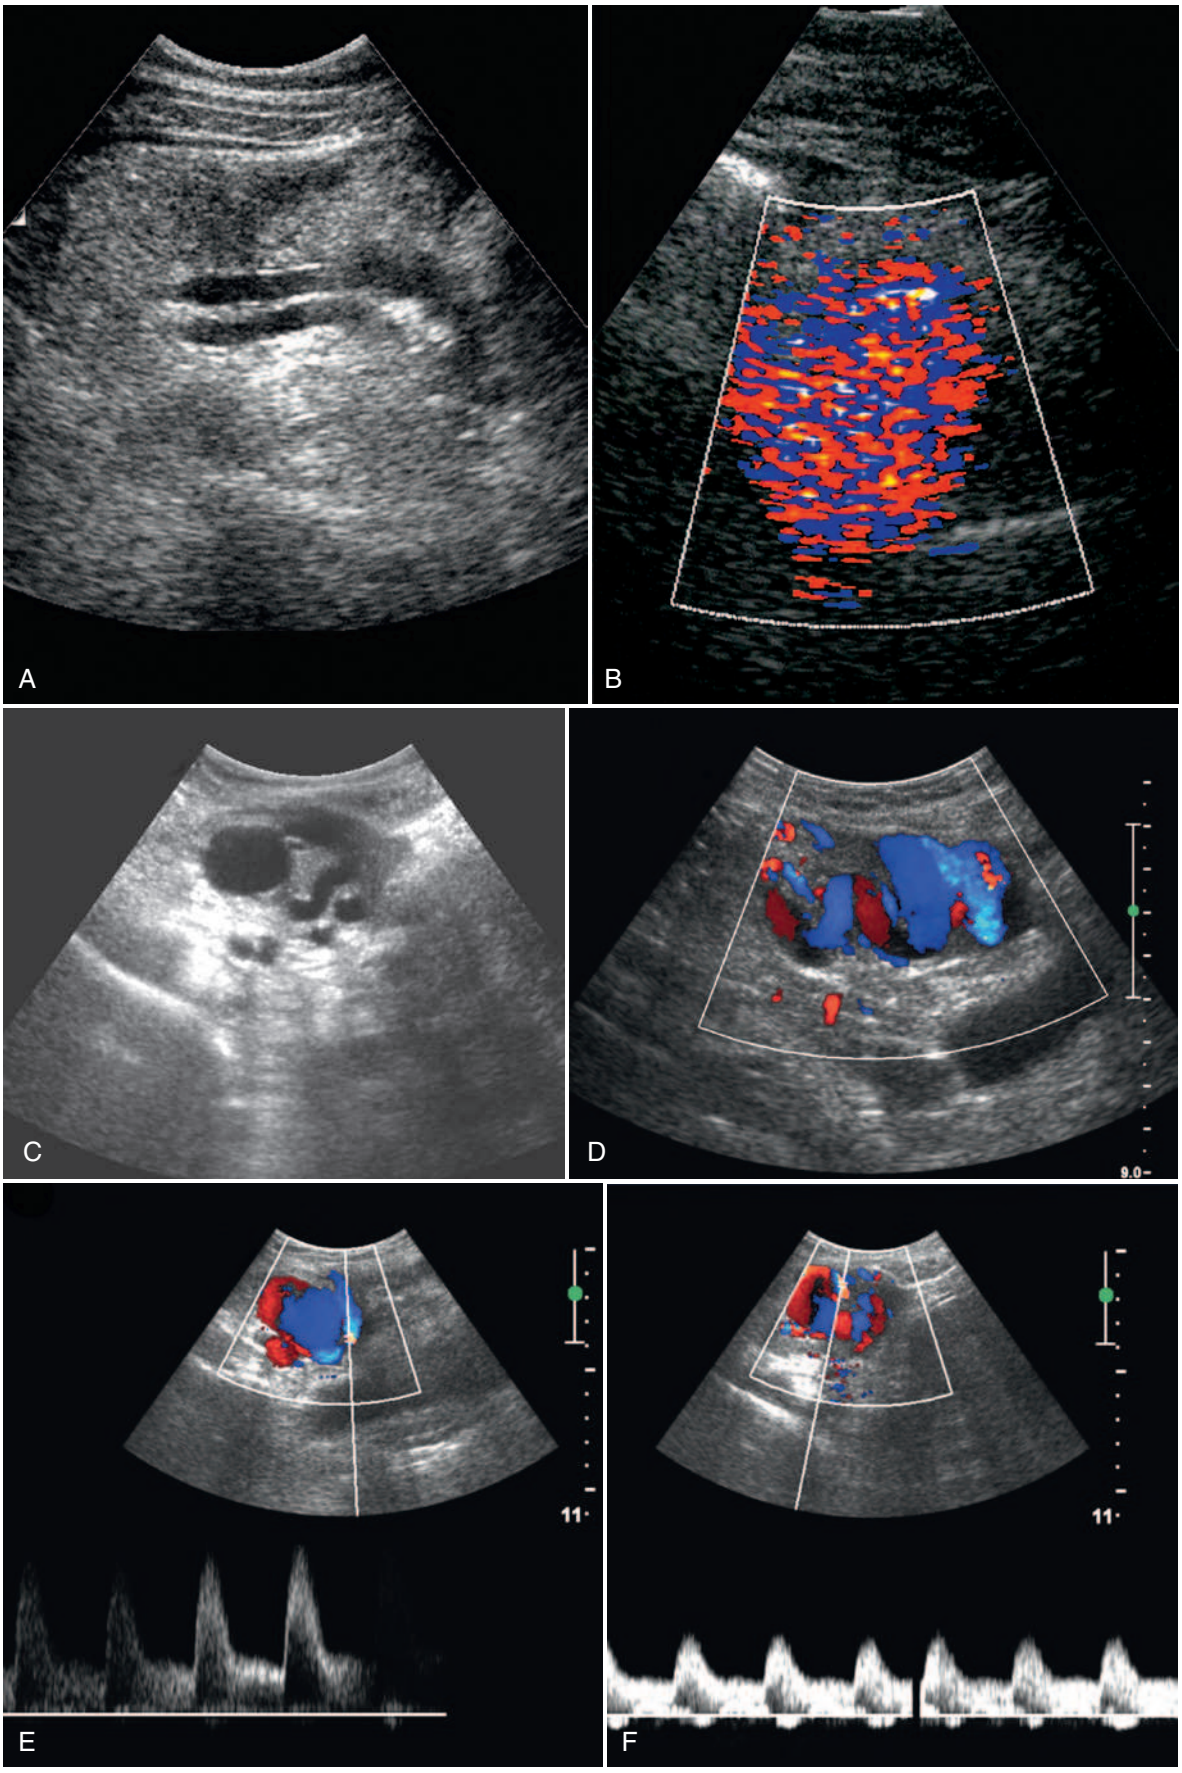

FIG. 18.65 Pancreas Transplant Vascular Malformations. (A) and **(B) Parenchymal arteriovenous malformation** (AVM). Transverse gray-scale ultrasound shows no abnormality. **(B)** Color Doppler ultrasound, however, shows an intense mosaic of color within the pancreas, secondary to a parenchymal AVM. **(C)-(F)** Transplant-related arteriovenous fistula (AVF). Gray-scale **(C)** and color Doppler **(D)** show dilated vessels with arterial **(E)** and mixed atrial and venous **(F)** waveforms.

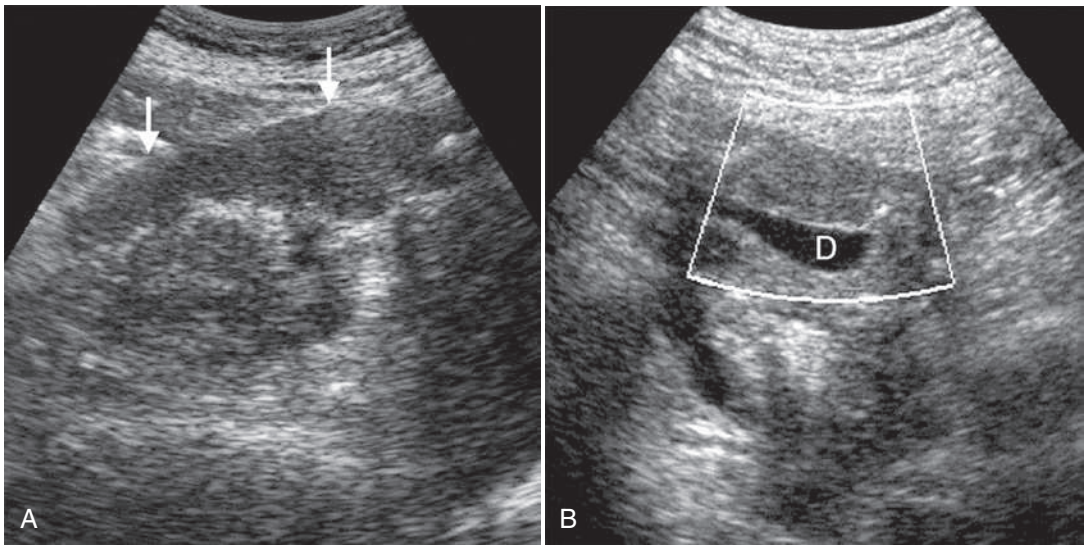

FIG. 18.66 Pancreas Transplant Rejection. (A) Transverse sonogram shows hypoechoic pancreas *(arrows)*. The pancreatic parenchyma is also atrophied. **(B)** Oblique sonogram shows dilated pancreatic duct *(D)* secondary to surrounding parenchymal atrophy.

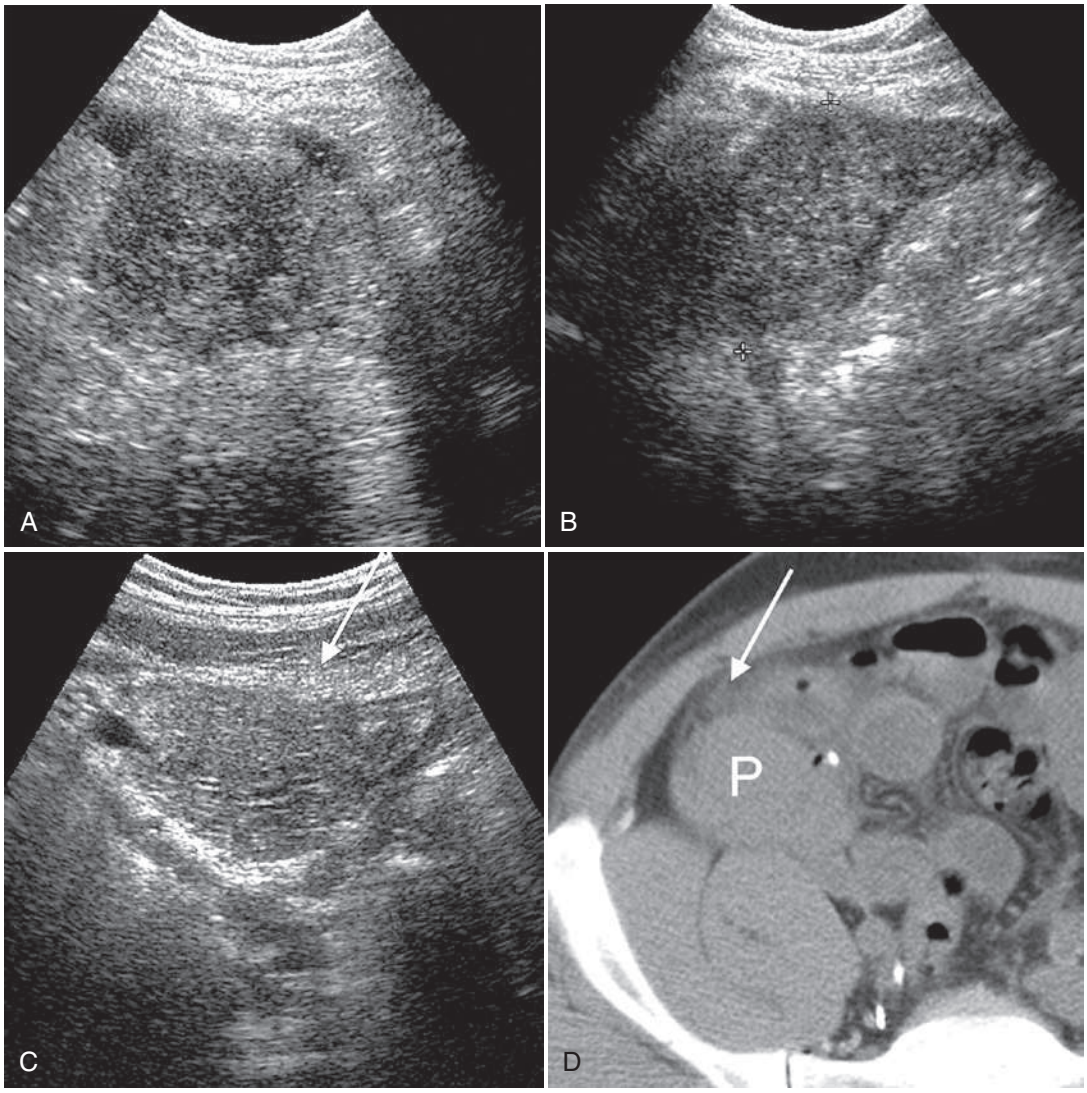

FIG. 18.67 Pancreatitis. (A) Transverse and **(B)** oblique images show bulky, edematous allograft. **(C)** Oblique ultrasound shows echogenic inflamed peripancreatic fat *(arrow)*. **(D)** This appears as "stranding" in the peripancreatic fat on CT *(arrow)*. *P,* Pancreas transplant.

severe graft pancreatitis is associated with a range of complications akin to those seen in a native pancreas such as pancreatic hemorrhage and necrosis, peripancreatic fluid collections, pseudocysts, abscesses, and pseudoaneurysms.

Ultrasound can be used to guide aspiration of potential fluid collections and help discriminate pseudocysts from abscesses or seromas. If infection is demonstrated at the time of ultrasound-guided aspiration, CT is often performed to assess the graft in its entirety and in particular to evaluate for areas of duct disruption as well as to demonstrate the location of fluid collections in relation to the duodenal C loop and duodenojejunostomy. Early fluid collections are often surgically managed.

Fluid Collections

Peripancreatic transplant-related fluid collections are associated with an increased likelihood of loss of allograft function and overall increased mortality and morbidity. Early diagnosis and characterization of these collections are imperative, because treatment in the acute stages is associated with improved graft function and decreased recipient morbidity.[92]

In the immediate postoperative period, peritransplant fluid may be caused by leakage of pancreatic fluid from transected ductules and lymphatics, an inflammatory exudate, blood, or urine (Fig. 18.68). These collections may require either close serial imaging follow-up or drainage, depending on the clinical status of the patient.

Duodenal leaks in **systemic venous-bladder drainage** transplants occur from dehiscence of the duodenal-bladder anastomosis and result in the formation of urinomas, frequently at the medial aspect of the transplant. Urinomas may also result from infection or necrosis of the graft.[92]

Duodenal leaks in **portal venous-enteric drainage** transplants occur at the blind end of the donor duodenum or from the anastomosis with the recipient Roux-en-Y loop. On ultrasound, gross ascites, duodenal wall thickening, or free intraperitoneal air may be observed in patients with breakdown of the duodenal anastomoses. These leaks may result in overwhelming sepsis and can be life-threatening. Furthermore, the presence of digestive enzymes in contact with the graft may lead to substantial tissue necrosis.[91]

Patients with pancreatic transplants are also susceptible to **infection** because of their immunosuppressive therapy, as well as their underlying diabetes mellitus. Abscesses are occasionally identified and are often associated with hematomas, urinary tract infections, and pancreatitis. Although gas within a fluid collection may indicate the presence of a gas-forming organism, bubbles of air within a collection may also result from the presence of a fistula or tissue necrosis in cases of vascular thrombosis.

On sonography these collections may demonstrate a thick irregular wall with peripheral hyperemia on Doppler interrogation. If gas is present, it typically is seen as echogenic foci with posterior reverberation artifact. Adjacent changes in the fat include increased echogenicity and fluid. In the posttransplant period, the development of a new collection or change in the sonographic morphology of the collection may result from a variety of causes, including infection; malfunction of the pancreatic duct, stent, or external drain; hemorrhage; or associated tissue infarction.[92]

Miscellaneous Complications

Other complications of pancreatic transplants include intussusception of the Roux-en-Y loop, small bowel obstruction from adhesions, internal hernias (due to the surgically created mesenteric defect), and volvulus along the long axis of the graft. Because the patient is immunocompromised, there is a higher incidence of entities such as typhlitis or *Clostridium difficile* colitis.

POST TRANSPLANT LYMPHOPROLIFERATIVE DISORDER

The global improvement in survival after transplantation can be attributed to a parallel improvement in immunosuppressant regimens. The depressed immune response to oncoviruses such as the Epstein-Barr virus (EBV) results in increased vulnerability of these patients to malignancies that are mediated by such oncoviruses. This contributes to a threefold to eightfold increased malignancy risk in transplant patients as compared with the baseline population.[93-95]

PTLD is the second most common malignancy in adult transplant patients, following skin malignancy (nonmelanoma).[96] PTLD encompasses myriad disease processes ranging from lymphoid hyperplasia to poorly differentiated lymphoma. Biopsy is required to discriminate among the various subtypes. Many patients are asymptomatic or have vague symptomatology, resulting in a delayed diagnosis. It can be hard to discriminate PTLD from infection or allograft rejection. Imaging is therefore important in establishing the diagnosis, enabling tissue sampling, and monitoring response to treatment.

EBV infection is relatively prevalent, with 90% to 95% of adults being seropositive; however, most immunocompetent hosts can eradicate B cells that display EBV antigens by using T cells. However, in immunocompromised patients as well as a small group of immunocompetent hosts, a small number of EBV-infected B cells escape and survive with resultant latent EBV infection.[97]

After solid organ transplantation, cytotoxic EBV-specific T cells may be completely lost within 6 months of transplantation as a result of immunosuppressive medication.[98] Latently infected B cells have the potential to proliferate, resulting in PTLD.[99]

A variety of genetic mutations (including ***p53, NRAS***) can result in PTLD. These genes are involved in the division, proliferation, and death of cells. Overproduction of cytokines such as interleukin-6 has also been implicated in the genesis of PTLD. Similarly, CMV-seronegative patients have a higher risk of developing PTLD after solid organ transplantation.[100]

The incidence of PTLD is thought to be related to the degree of immunosuppression and the type of allograft. The aggressive immunosuppressive therapy required to prevent heart-lung transplant rejection has resulted in a reported incidence of PTLD as high as 4.6%. However, the milder immunosuppression used in patients with liver transplant or renal transplant has resulted in a lower incidence of PTLD, reported as 2.2% and 1%, respectively.[101,102]

In addition, the numbers of lymphoid aggregates are higher in intestinal and lung transplants, both of which are associated with some of the highest incidences of PTLD.[103] It is therefore

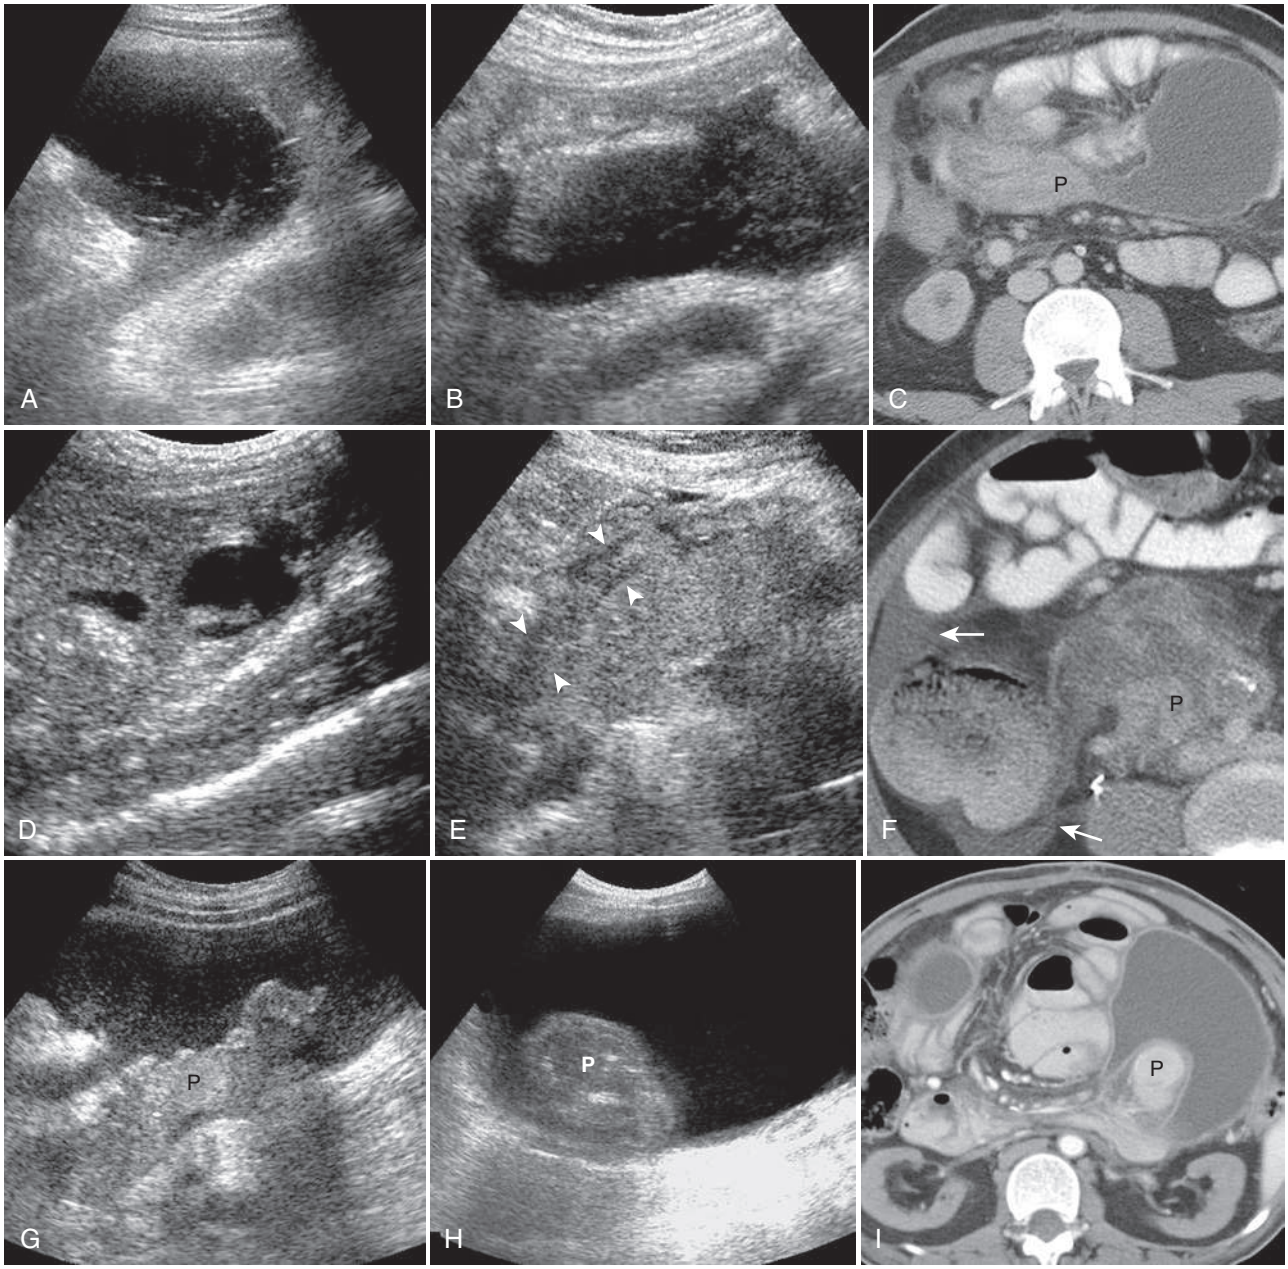

FIG. 18.68 Fluid Collections. (A)-(C) Hematoma. (A) Sagittal and **(B)** transverse sonograms show complex collection with internal echoes and strands. **(C)** Correlative CT shows hematoma in left upper quadrant that extends to pancreas *(P)*. **(D)-(I) Pseudocysts in three patients.** *Patient 1:* **(D)** Sagittal sonogram shows complex epigastric cyst with internal septation. *Patient 2:* **(E)** Sagittal sonogram shows complex collection adjacent to pancreas *(arrowheads)*. **(F)** Correlative CT scan shows collection extending into pancreatic head *(P)* and associated with free fluid *(arrows)*. *Patient 3:* **(G)** Sagittal sonogram shows large pseudocyst with internal echoes surrounding pancreatic tail *(P)*. **(H)** and **(I) Seroma.** Transverse sonogram and correlative CT scan show large, anechoic cystic structure surrounding pancreatic body *(P)*. The wall enhanced on CT scan. The collection was sterile on aspiration.

not surprising that agents that suppress T-cell activity are associated with a higher risk of PTLD. By the same token, a larger total number of immunosuppressant agents used by a patient may result in an increased risk of PTLD.[104]

The incidence of PTLD is bimodal, with the initial peak in the first year after transplantation and the second peak approximately 4 to 5 years after transplantation.[105] Biologically, the two peaks have a very different clinical course. The early-onset disease has a more favorable course, is pleomorphic in subtype, and has a positive response to reducing the level of immunosuppression. Late-onset disease is more commonly seen in conjunction with EBV infection, a monomorphic subtype, and an aggressive disease course. There is a higher mortality, and the disease is often resistant to chemotherapy.[106]

PTLD can be categorized depending on its primary location into either nodal disease (22%) or extranodal disease (81%). Nodal disease is either mediastinal or retroperitoneal in location. The involved lymph nodes have an abnormal appearance, showing a hypoechoic thickened cortex with an absent or flattened fatty hilum (Figs. 18.69 to 18.72). Extranodal disease

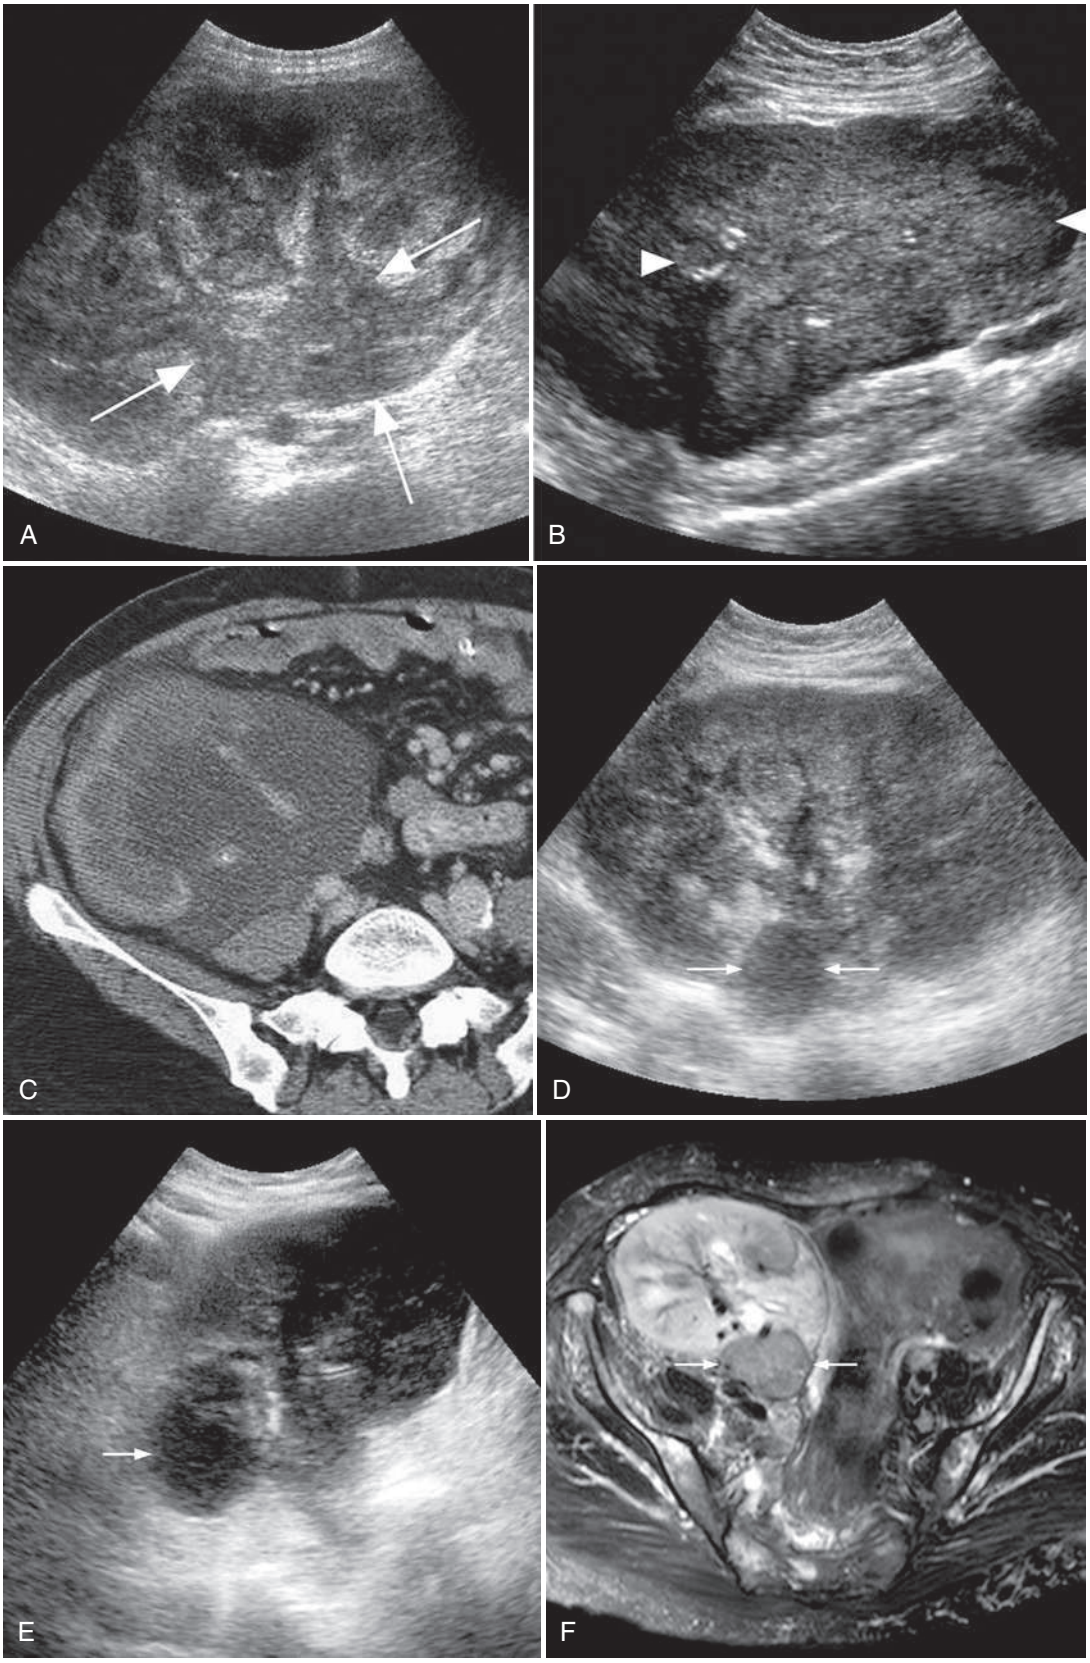

FIG. 18.69 Renal Posttransplant Lymphoproliferative Disorder in Two Patients. *Patient 1:* **(A)** Sagittal sonogram shows infiltrative mass *(arrows)* in renal hilum. **(B)** Six months later, the mass *(arrowheads)* has infiltrated into the renal cortex. **(C)** Correlative CT shows hilar mass infiltrating into renal cortex. *Patient 2:* **(D)** Sagittal and **(E)** transverse sonograms show a hypoechoic to anechoic structure with low-level echoes *(arrows)* in the renal hilum that could be interpreted as a complex cyst. **(F)** Contrast-enhanced MRI shows that this structure represents a solid mass *(arrows)*.

by definition involves three main sites—the central nervous system, solid organs, or the gastrointestinal tract. The liver is the most common site of intraabdominal involvement, occurring in 30% to 45% of patients with PTLD. In rare cases, intraosseous lesions may be present, with imaging features on CT and MRI similar to those of metastatic disease, infection, or primary bone lymphoma. Overall, PTLD should be considered in the differential diagnosis of any transplant patient with lymphadenopathy or a new lesion within a solid viscus or the skeletal system.[107-110]

When the solid organs are involved, there are four main patterns of disease:

1. **Infiltrative pattern:** There is an ill-defined mass or masses that are extrinsic to the hilum and can result in secondary mass effect and/or vascular compromise. For instance, within the liver it may cause biliary obstruction and obstruction of blood flow within the periportal space. In renal involvement the mass typically is located extrinsic to the renal pelvis with resultant mass effect and obstruction of the vessels and the collecting system. In both instances the mass is usually relatively hypoenhancing but fluorodeoxyglucose (FDG) avid on positron emission tomography (PET) imaging.
2. **Parenchymal pattern:** This is characterized by multiple lesions that are disseminated throughout the affected organ. These also tend to be hypoenhancing. In the lung they are typically solid and may rarely cavitate. There may also be ill-defined alveolar infiltrates.
3. **Solitary mass:** A solitary mass in the affected organ is seen on ultrasound as a hypoechoic lesion with no Doppler signal on color Doppler imaging. Calcification is unusual but seen in the context of posttreatment changes or tumor necrosis.
4. **Infiltrative lesion:** This lesion involves the organ in question but also extends to involve regional structures such as the chest, abdominal wall, and adjacent solid organs. As a secondary manifestation, there may be dysfunction of the other organ(s) that are involved. Pancreatic PTLD tends to produce diffuse glandular enlargement, with an appearance that is indistinguishable from pancreatitis or rejection.[111]

Gastrointestinal disease can involve either bowel or the peritoneal cavity. When there is peritoneal disease, it can be nodular or diffusely infiltrating.[112] PTLD involving the gastrointestinal tract is seen in association with mural thickening, aneurysmal dilatation, ulceration, intussusception, and polypoidal lesions. Perforation is a rare manifestation of intestinal PTLD; the decline in perforation rates has been attributed to improved diagnosis and treatment of PTLD. As with any other lymphomatous-type lesions of the gut, obstruction of the bowel segments is rare.

Treatment Options

Stratification and patient management are determined by the subtype of PTLD, the distribution of disease, and the type of allograft. Potential management options include modification of immunosuppression, chemotherapy, radiation, and rituximab therapy as well as surgical resection of isolated lesions. Rituximab is a monoclonal antibody against B cell receptors, has a low toxicity profile, and has a response rate on the order of 60%. Preservation of graft function is an important goal of management while treating the PTLD.[113,114]

PET-CT has a pivotal role to play in monitoring response to therapy, particularly in patients in whom there are persistent focal lesions. In this scenario, FDG uptake allows discrimination between residual tumor and fibrosis.

CHAPTER 19

The Thyroid Gland

Luigi Solbiati, J. William Charboneau, Vito Cantisani, Carl Reading, and Giovanni Mauri

SUMMARY OF KEY POINTS

- Ultrasound is the best imaging modality to study the thyroid gland for both diffuse and nodular disease.
- The overwhelming majority of thyroid nodules are benign. Thyroid cancer is rare and accounts for less than 1% of all malignant neoplasms.
- Approximately 80% of nodular thyroid disease is caused by hyperplasia. When hyperplasia leads to an overall increase in size or volume of the gland, the term "goiter" is used.
- Most hyperplastic or adenomatous nodules are isoechoic compared with normal thyroid tissue, but may become hyperechoic because of the numerous interfaces between cells and colloid substance.
- Hyperfunctioning (autonomous) nodules often exhibit an abundant perinodular and intranodular vascularity.
- Purely anechoic areas are caused by serous or colloid fluid.
- Adenomas represent only 5% to 10% of all nodular disease of the thyroid and are seven times more common in women than men. In general, the cytologic features of follicular adenomas are indistinguishable from those of follicular carcinoma.
- Solid consistency, hypoechogenicity, microcalcifications, taller-than-wide appearance, hypervascularity, irregular margins, invasion of adjacent structures, and presence of cervical lymph node metastases are suspicious signs of thyroid malignancy.
- Ultrasound-guided fine-needle aspiration is the most effective method for diagnosing malignancy in a thyroid nodule.
- After partial or near-total thyroidectomy for carcinoma, sonography is the preferred method for follow-up, by detecting residual, recurrent, or metastatic disease in the neck.
- The Thyroid Imaging Reporting and Data System (TIRADS) can be used to stratify the risk of malignancy of a thyroid nodule according to its ultrasonographic characteristics.
- Ultrasound-guided ablation with chemical agents (ethanol) or thermal energy (radiofrequency and laser ablation) can be used to treat thyroid adenoma, benign cold nodules, and even nodal metastases of thyroid cancers.

Acknowledgment

Because of the superficial location of the thyroid gland, high-resolution real-time gray-scale and color Doppler sonography can demonstrate normal thyroid anatomy and pathologic conditions with remarkable clarity. As a result, ultrasound plays an increasingly important role in the diagnostic evaluation of thyroid disease, although it is only one of several diagnostic methods currently available. To use ultrasound effectively and economically, it is important to understand its current capabilities and limitations.

INSTRUMENTATION AND TECHNIQUE

High-frequency transducers (7.5-15.0 MHz) currently provide both deep ultrasound penetration—up to 5 cm—and high-definition images, with a resolution of 0.5 to 1.0 mm. No other clinically used imaging method can achieve this degree of spatial resolution. Linear array transducers with either rectangular or trapezoidal scan format are preferred to sector transducers because of the wider near field of view and the capability to combine

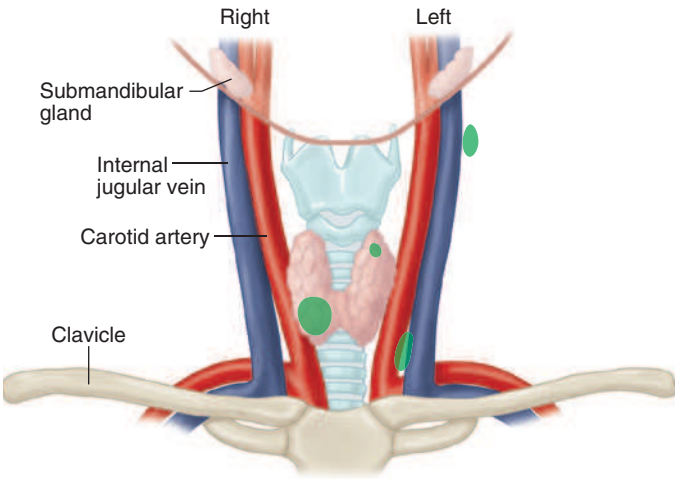

FIG. 19.1 Cervical "Map." Such diagrams help communicate relationships of pathology to clinicians and serve as a reference for follow-up examinations.

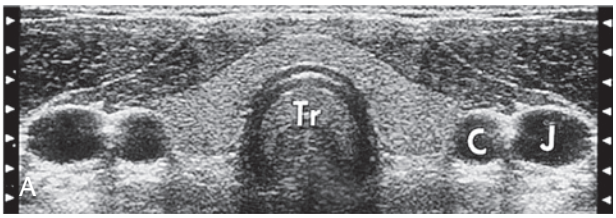

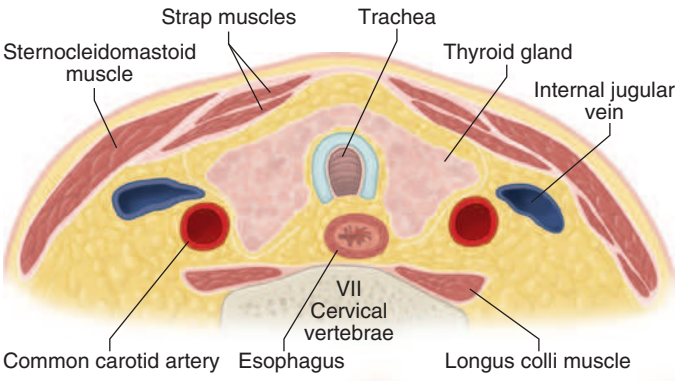

FIG. 19.2 Normal Thyroid Gland. (A) Transverse sonogram made with 7.5-MHz linear array transducer. **(B)** Corresponding anatomic drawing. *C,* Common carotid artery; *J,* jugular vein; *Tr,* tracheal air shadow.

high-frequency gray-scale and color Doppler images. The thyroid gland is one of the most vascular organs of the body. As a result, Doppler examination may provide useful diagnostic information in some thyroid diseases.

Two newer techniques used for the sonographic study of the thyroid gland are contrast-enhanced sonography and elastography. **Contrast-enhanced sonography** using second-generation contrast agents and very low mechanical index can provide useful information for the diagnosis of select cases of nodular disease and for ultrasound-guided therapeutic procedures. **Elastography** is based on the principle that when body tissues are compressed, the softer parts deform more easily than the harder parts. The amount of displacement at various depths is determined by the ultrasound signals reflected by tissues before and after they are compressed, and the corresponding strains are calculated from these displacements and displayed visually.

The patient is typically examined in the supine position, with the neck extended. A small pad may be placed under the shoulders to provide better exposure of the neck, particularly in patients with a short, stocky habitus. The thyroid gland must be examined thoroughly in both transverse and longitudinal planes. Imaging of the lower poles can be enhanced by asking the patient to swallow, which momentarily raises the thyroid gland in the neck. The entire gland, including the isthmus, must be examined. The examination must also be extended laterally to include the region of the carotid artery and jugular vein to identify enlarged jugular chain lymph nodes, superiorly to visualize submandibular adenopathy, and inferiorly to define any pathologic supraclavicular lymph nodes.

In addition to the images recorded during the examination, some operators include in the permanent record a diagrammatic representation of the neck showing the location(s) of any abnormal findings (Fig. 19.1). This cervical "map" helps to communicate the anatomic relationships of the pathology more clearly to the referring clinician and the patient. It also serves as a useful reference for the radiologist and sonographer for follow-up examinations.

ANATOMY

The thyroid gland is located in the anteroinferior part of the neck (infrahyoid compartment) in a space outlined by muscle, trachea, esophagus, carotid arteries, and jugular veins (Fig. 19.2). The thyroid gland is made up of **two lobes** located along either side of the trachea and connected across the midline by the **isthmus,** a thin structure draping over the anterior tracheal wall at the level of the junction of the middle and lower thirds of the thyroid gland. From 10% to 40% of normal patients have a small thyroid **(pyramidal)** lobe arising superiorly from the isthmus and lying in front of the thyroid cartilage.[1] It can be regularly visualized in younger patients, but it undergoes progressive atrophy in adulthood and becomes invisible. The size and shape of the thyroid lobes vary widely in normal patients. In tall individuals the lateral lobes have a longitudinally elongated shape on the sagittal scans, whereas in shorter individuals the gland is more oval. In the newborn the thyroid gland is 18 to 20 mm long, with an anteroposterior (AP) diameter of 8 to 9 mm. By 1 year of age, the mean length is 25 mm and AP diameter is 12 to 15 mm.[2] In adults the mean length is approximately 40 to 60 mm, with mean AP diameter of 13 to 18 mm. The mean thickness of the isthmus is 4 to 6 mm.[3]

Sonography is an accurate method for calculating **thyroid volume.** In about one-third of cases, the sonographic measurement of volume differs from the estimated physical size on examination.[4] Thyroid volume measurements may be useful for goiter size determination to assess the need for surgery, permit calculation of the dose of iodine-131 (^{131}I) needed for treating thyrotoxicosis, and evaluate response to suppression treatments.[5] Thyroid volume can be calculated with linear parameters or more precisely with mathematical formulas. Among the linear

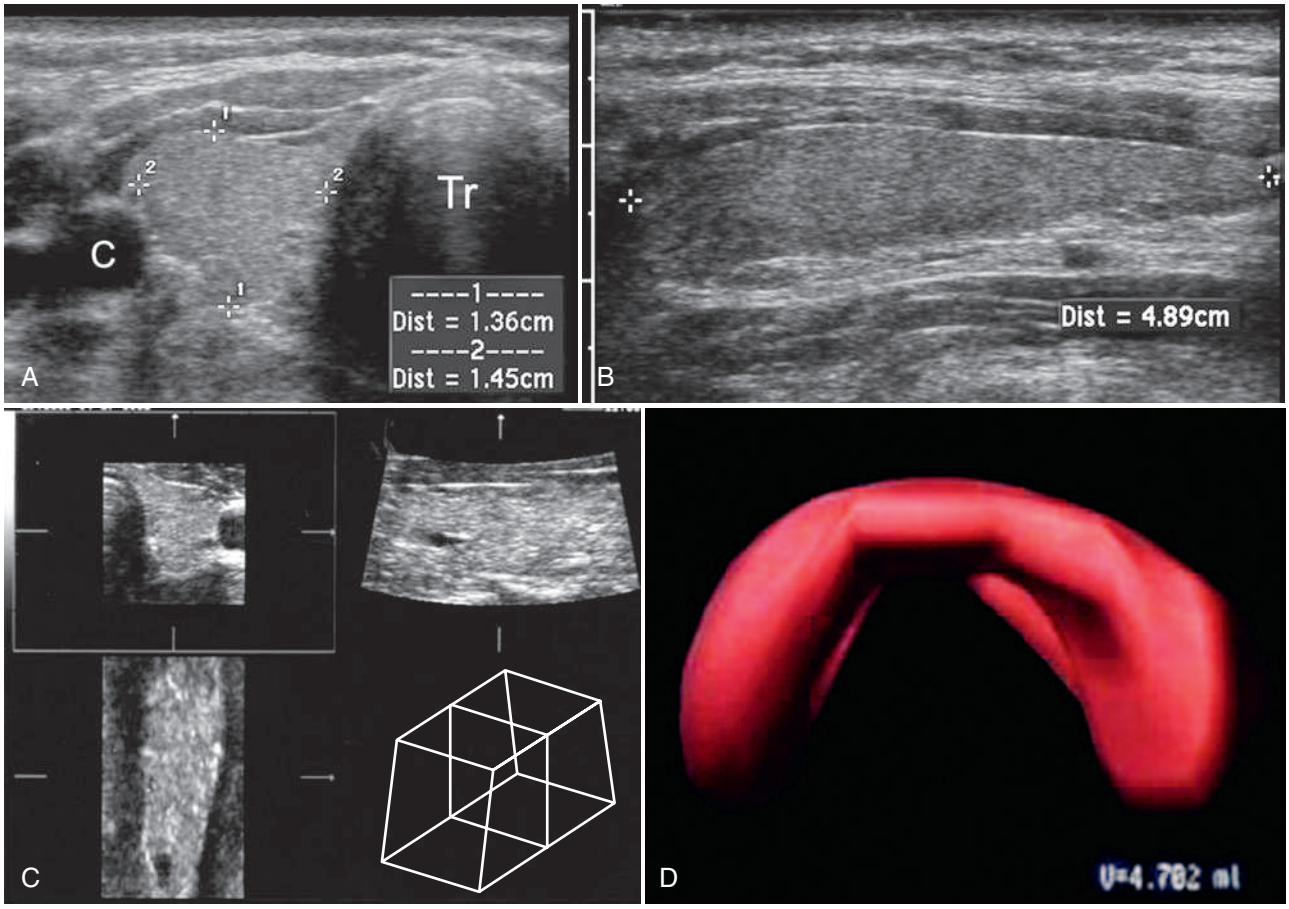

FIG. 19.3 Volume Measurement of Thyroid Gland. (A) Transverse and **(B)** longitudinal images show calipers at the boundaries of thyroid gland. *C,* Carotid artery; *Tr,* trachea air shadow. The calculated thyroid volume is based on the ellipsoid formula with a correction factor (length × width × thickness × 0.52 for each lobe). In this case, the volume is 10 mL (or grams), which is within normal limits for this female patient. **(C)** Images from real-time three-dimensional study of normal thyroid lobe, visualized simultaneously in axial *(top left),* longitudinal *(top right),* and coronal *(bottom left)* planes. **(D)** Volumetric reconstruction of gland.

parameters, the AP diameter is the most precise because it is relatively independent of possible dimensional asymmetry between the two lobes. When the AP diameter is more than 2 cm, the thyroid gland may be considered "enlarged."

The most common mathematical method to calculate thyroid volume is based on the ellipsoid formula with a correction factor (length × width × thickness × 0.529 for each lobe)[6] (Fig. 19.3A-B). With use of this method, the mean estimated error is approximately 15%. The most precise mathematical method is the integration of the cross-sectional areas of the thyroid gland, achieved through evenly spaced sonographic scans.[7] With this method the mean estimated error is 5% to 10%.[8] Modern three-dimensional (3-D) ultrasound technology allows one to simultaneously obtain the three orthogonal planes of thyroid lobes and then to calculate the volume either automatically or manually[9] (Fig. 19.3C-D).

In neonates, thyroid volume ranges from 0.40 to 1.40 mL, increasing by 1.0 to 1.3 mL for each 10 kg of body weight, up to a normal volume in adults of 10 to 11 ± 3 mL.[7] In general, thyroid volume is larger in patients living in regions with iodine deficiency and in patients who have acute hepatitis or chronic renal failure. Volume is smaller in patients who have chronic hepatitis or have been treated with thyroxine or radioactive iodine.[5,7]

Normal thyroid parenchyma has a homogeneous, medium- to high-level echogenicity that makes detection of focal cystic or hypoechoic thyroid lesions relatively easy in most cases. The thin, hyperechoic line around the thyroid lobes is the **capsule,** which is often identifiable on ultrasound. It may become calcified in patients who have uremia or disorders of calcium metabolism. With currently available high-sensitivity Doppler instruments, the rich vascularity of the gland can be seen homogeneously distributed throughout the entire parenchyma (Fig. 19.4). The **superior thyroid artery and vein** are found at the upper pole of each lobe. The **inferior thyroid vein** is found at the lower pole (Fig. 19.5), and the **inferior thyroid artery** is located posterior to the lower third of each lobe. The mean diameter of the arteries is 1 to 2 mm; the lower veins can be up to 8 mm in diameter. Normally, peak systolic velocities reach 20 to 40 cm/sec in the major thyroid arteries and 15 to 30 cm/sec in intraparenchymal arteries. These are the highest velocities found in blood vessels supplying superficial organs.

The **sternohyoid** and **omohyoid muscles** (strap muscles) are seen as thin, hypoechoic bands anterior to the thyroid gland (see Fig. 19.2). The **sternocleidomastoid muscle** is seen as a larger oval band that lies lateral to the thyroid gland. An important anatomic landmark is the **longus colli muscle,** located posterior to each thyroid lobe, in close contact with the prevertebral space.

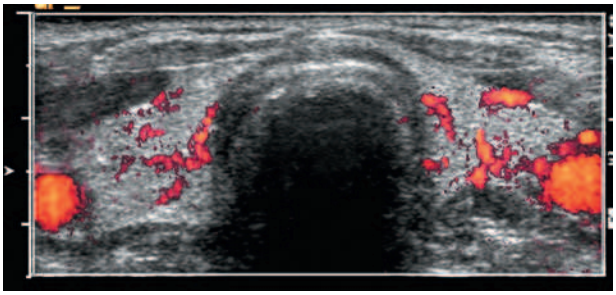

FIG. 19.4 Normal Thyroid Vascularity on Power Doppler Ultrasound.

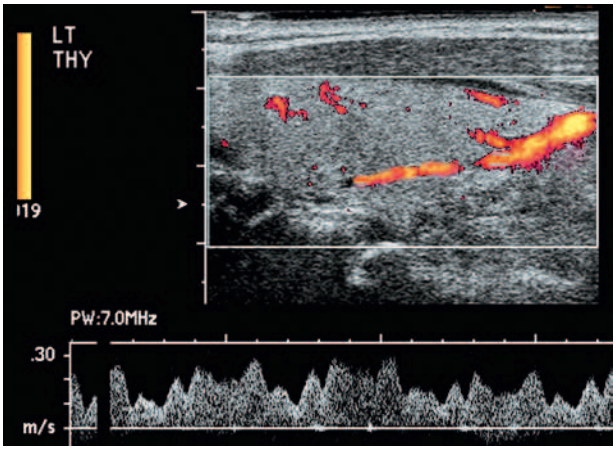

FIG. 19.5 Normal Inferior Thyroid Vein. Longitudinal power Doppler image shows a large inferior thyroid vein with associated normal venous spectral waveform.

The **recurrent laryngeal nerve** and the inferior thyroid artery pass in the angle among the trachea, esophagus, and thyroid lobe. On longitudinal scans, the recurrent laryngeal nerve and inferior thyroid artery may be seen between the thyroid lobe and esophagus on the left and between the thyroid lobe and longus colli muscle on the right. The **esophagus,** primarily a midline structure, may be found laterally and is usually on the left side. It is clearly identified by the target appearance of bowel in the transverse plane and by its peristaltic movements when the patient swallows.

CONGENITAL THYROID ABNORMALITIES

Congenital conditions of the thyroid gland include **aplasia** of one lobe or the whole gland, varying degrees of **hypoplasia,** and **ectopia** (Fig. 19.6). Sonography can be used to help establish the diagnosis of hypoplasia by demonstrating a diminutive gland. High-frequency ultrasound can also be used in the study of **congenital hypothyroidism** (CH), a relatively common disorder occurring in about 1 in 3000 to 4000 live births. Determining the cause of CH (dysgenesis, dyshormonogenesis, or pituitary or hypothalamic hypothyroidism) is clinically important because prognosis and therapy differ. Early initiation of therapy can prevent mental retardation and delayed bone development.[10,11]

Measurement of thyroid lobes can be used to differentiate aplasia (absent gland) from **goitrous hypothyroidism** (gland enlargement). Radionuclide scans are more often used to detect **ectopic thyroid tissue** (e.g., in a lingual or suprahyoid position).

NODULAR THYROID DISEASE

Many thyroid diseases can manifest clinically with one or more thyroid nodules. Such nodules represent common and controversial clinical problems. Epidemiologic studies estimate that

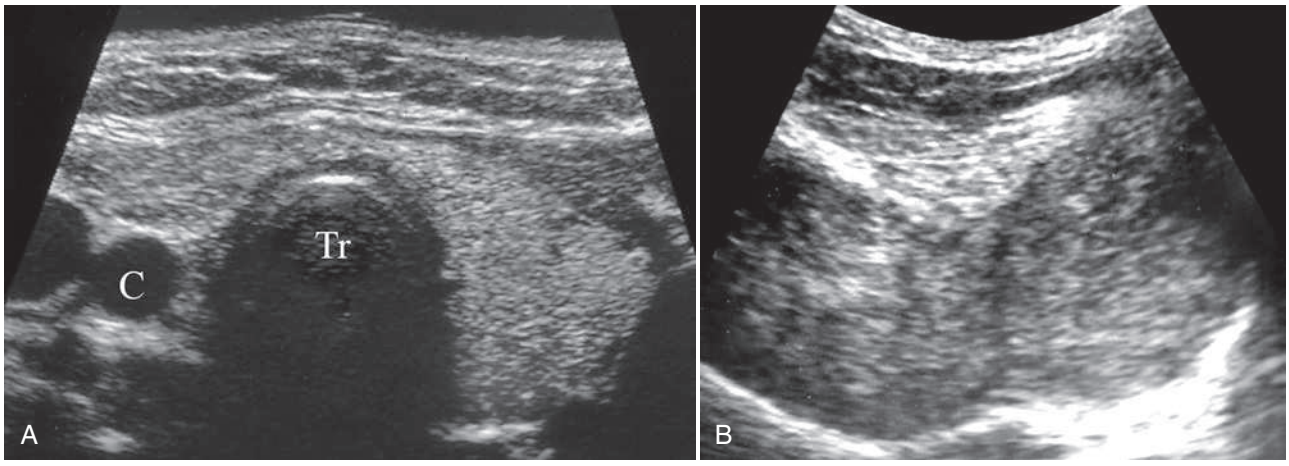

FIG. 19.6 Congenital Thyroid Abnormalities. (A) Hypoplasia of right thyroid lobe. *C,* Carotid artery; *Tr,* tracheal air shadow. **(B) Ectopic (sublingual)** thyroid gland. Transverse ultrasound image inferior to the base of the tongue shows a U-shaped parenchymal structure.

4% to 7% of adults in the United States have palpable thyroid nodules, with women affected more frequently than men.[12,13] Exposure to ionizing radiation increases the incidence of benign and malignant nodules, with 20% to 30% of a radiation-exposed population having palpable thyroid disease.[14,15]

Although nodular thyroid disease is relatively common, **thyroid cancer** is rare and accounts for less than 1% of all malignant neoplasms.[16] The overwhelming majority of thyroid nodules are benign. The clinical challenge is to distinguish the few clinically significant malignant nodules from the many benign nodules and thus identify patients who need surgical excision. This task is complicated because nodular disease of the thyroid gland often is clinically occult (<10-15 mm), although it can be readily detected by high-resolution sonography. The important question of how to manage these small nodules discovered incidentally by sonography is addressed later in this chapter.

Nodular Thyroid Disease: Sonographic Evaluation

- Determine location of palpable neck mass (e.g., thyroid or extrathyroid)
- Characterize benign versus malignant nodule features
- Detect occult nodule in patient with history of head and neck irradiation or multiple endocrine neoplasia (MEN) type II syndrome
- Determine extent of known thyroid malignancy
- Detect residual, recurrent, or metastatic carcinoma
- Guide fine-needle aspiration of thyroid nodule or cervical lymph nodes
- Guide percutaneous-thermal ablation of thyroid nodules, parathyroids, or lymph nodes

Pathologic Features and Sonographic Correlates

Hyperplasia and Goiter

Approximately 80% of nodular thyroid disease is caused by **hyperplasia** of the gland and occurs in up to 5% of any population.[17] Its etiology includes **iodine deficiency** (endemic), **disorders of hormonogenesis** (hereditary familial forms), and **poor utilization of iodine** as a result of medication. When hyperplasia leads to an overall increase in size or volume of the gland, the term **goiter** is used. The peak age of patients with goiter is 35 to 50 years, and women are affected three times more often than men.

Histologically, the initial stage is cellular hyperplasia of the thyroid acini, followed by micronodule and macronodule formation, often indistinguishable from normal thyroid parenchyma, even at histology. Hyperplastic nodules often undergo liquefactive degeneration with the accumulation of blood, serous fluid, and colloid substance (Fig. 19.7, Video 19.1). Pathologically, they are often referred to as **hyperplastic, adenomatous,** or **colloid** nodules. Many (if not all) cystic thyroid lesions are hyperplastic nodules that have undergone extensive liquefactive degeneration. Pathologically, true epithelial-lined cysts of the thyroid gland are rare. In the course of this cystic degenerative process,

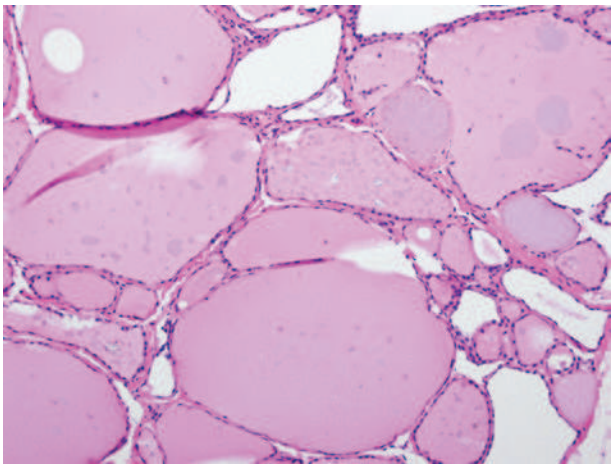

FIG. 19.7 Histology of Hyperplastic (Adenomatous) Change of Thyroid Gland. Histologic specimen shows many large dilated follicles that are filled with colloid material.

calcification, which is often coarse and perinodular, may occur.[3,5] Hyperplastic nodule function may have decreased, may have remained normal, or may have increased (toxic nodules).

Sonographically, most hyperplastic or adenomatous nodules are **isoechoic** compared with normal thyroid tissue (Fig. 19.8A) but may become **hyperechoic** because of the numerous interfaces between cells and colloid substance[5,18] (Fig. 19.8B-C). Less frequently, a hypoechoic spongelike or **honeycomb** pattern is seen (Fig. 19.9, Video 19.2). When the nodule is isoechoic or hyperechoic, a thin peripheral **hypoechoic halo** is typically seen, most likely caused by perinodular blood vessels and mild edema or compression of the adjacent normal parenchyma. Perinodular blood vessels are typically detected with color Doppler sonography; with current high-sensitivity Doppler technology, intranodular vascularity can also be seen.[5,19,20] **Hyperfunctioning** (autonomous) nodules often exhibit an abundant perinodular and intranodular vascularity; however, because of the hypervascular pattern shown in most solid thyroid nodules on high-sensitivity Doppler systems, this feature does not allow detection of hyperfunctioning nodules within multinodular goiters with sonography.[19,20]

The degenerative changes of goitrous nodules correspond to their sonographic appearances (Fig. 19.10). Purely anechoic areas are caused by **serous or colloid fluid.** Echogenic fluid or moving fluid-fluid levels correspond to **hemorrhage.**[21] Bright echogenic foci with **comet-tail artifacts** are likely caused by **microcrystals** or aggregates of colloid substance, which may also move slowly, like snowflakes, within the fluid collection.[22] **Thin, intracystic septations** probably correspond to attenuated strands of thyroid tissue and appear completely avascular on color Doppler ultrasound. These degenerative processes may also lead to the formation of calcifications, which may be either **thin, peripheral shells** ("eggshell") or **coarse, highly reflective foci** with associated acoustic shadows, scattered throughout the gland[8] (Fig. 19.11).

Intracystic solid projections, or papillae, usually containing color Doppler signals, may appear similar to the rare cystic papillary thyroid carcinoma (PTC).[20,21] In some cases, sonography and color Doppler imaging cannot differentiate the septations

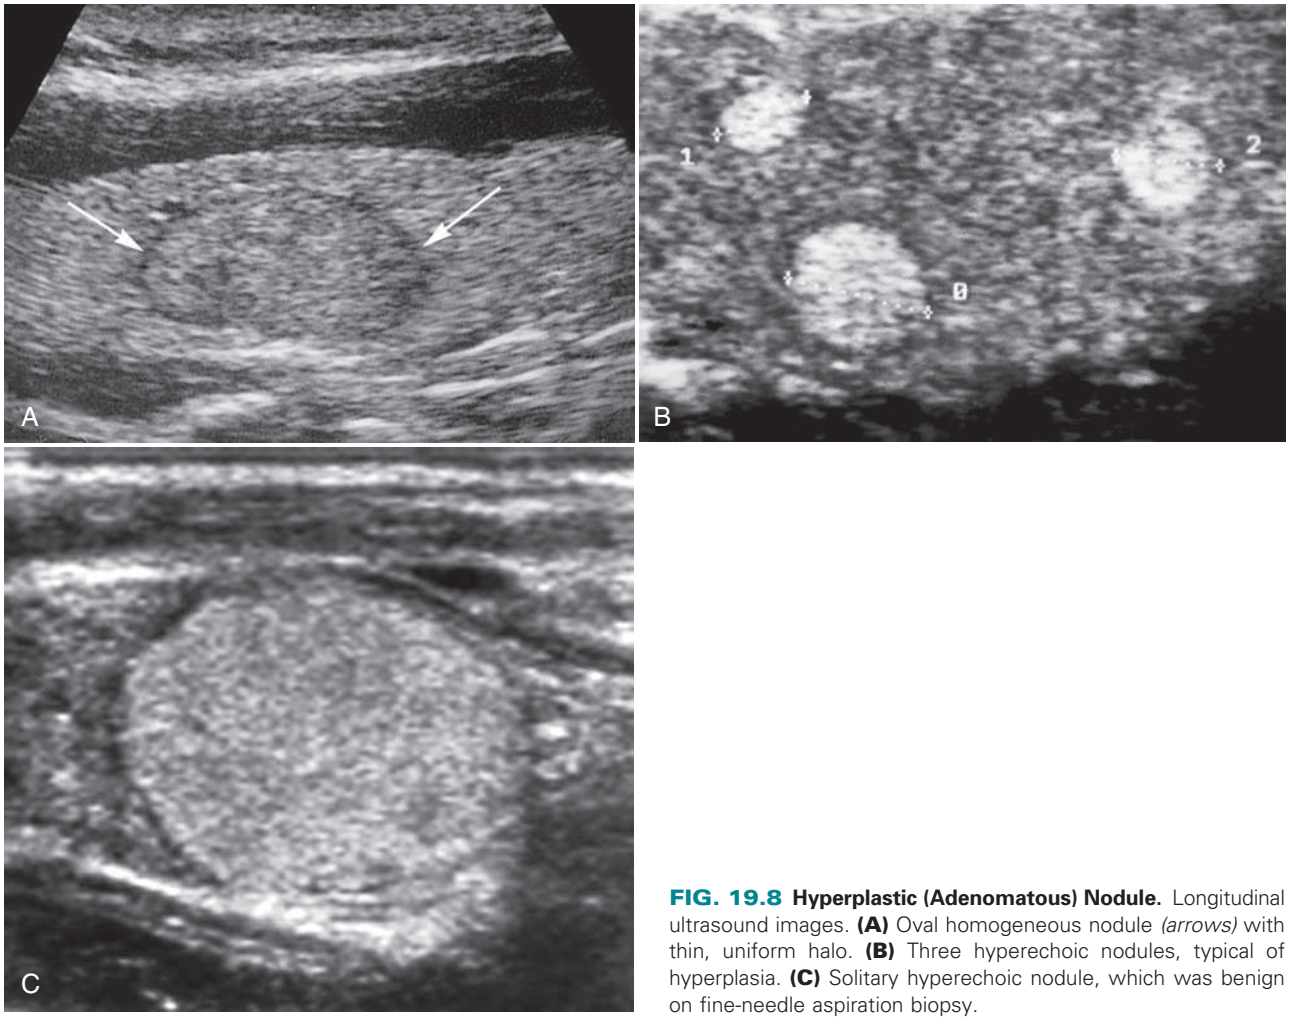

FIG. 19.8 Hyperplastic (Adenomatous) Nodule. Longitudinal ultrasound images. **(A)** Oval homogeneous nodule *(arrows)* with thin, uniform halo. **(B)** Three hyperechoic nodules, typical of hyperplasia. **(C)** Solitary hyperechoic nodule, which was benign on fine-needle aspiration biopsy.

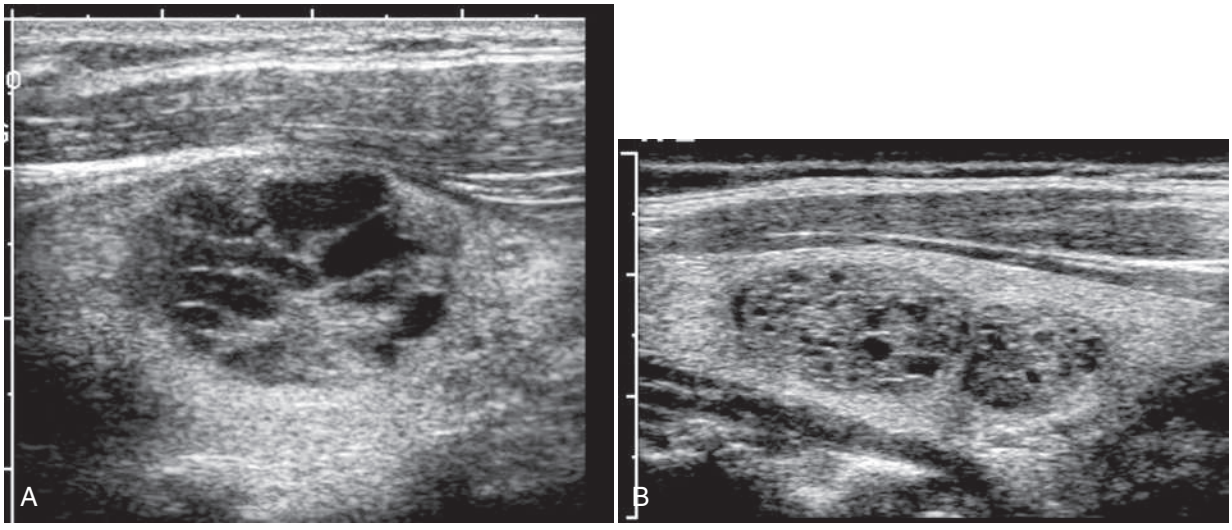

FIG. 19.9 Benign Nodule Feature. Longitudinal images. Extensive honeycomb-like or cystic changes, with nodules showing **(A)** larger cystic spaces and **(B)** smaller cystic spaces. These features indicate a very high probability of a benign process.

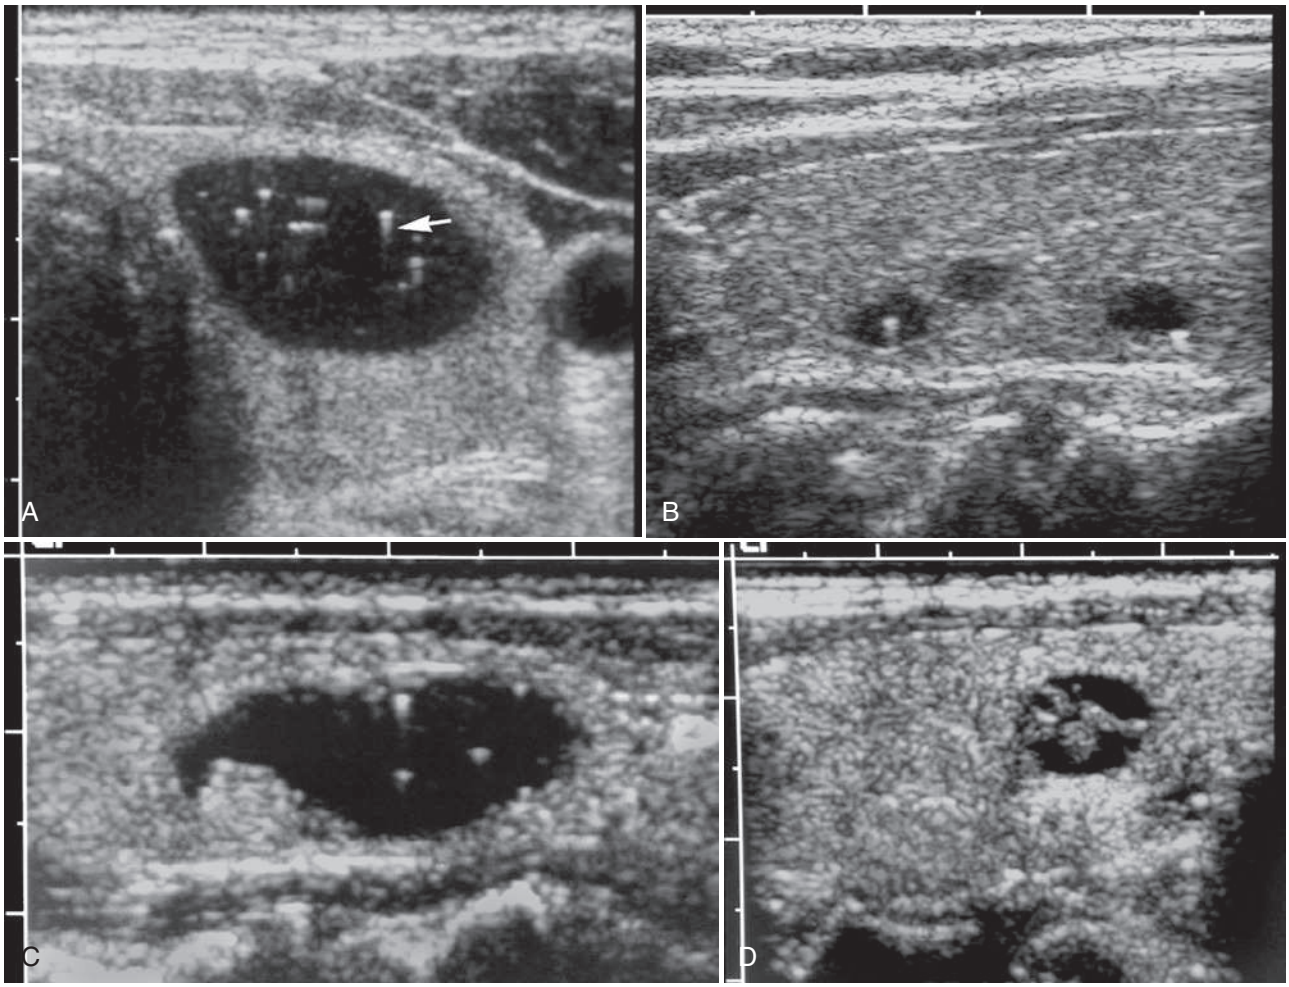

FIG. 19.10 Colloid Cysts. Transverse **(A)** and longitudinal **(B)-(D)** images of four patients show the typical appearance of colloid cysts. Some of the nodules have tiny echogenic foci that are thought to be microcrystals. A few of these foci are associated with comet-tail artifacts (*arrow* in **[A]**) posteriorly. Nodules that are mostly cystic, such as these, are considered benign. Colloid cysts often contain internal echoes.

of colloid hyperplastic nodules from the vegetations seen in papillary carcinomas; before moving to aspiration cytology studies, contrast-enhanced sonography with second-generation microbubbles and nondisruptive imaging can be used. **Benign septa** and **intracystic contents** do not show enhancement (and "disappear" in harmonic mode) (Fig. 19.12), whereas **malignant vegetations** show intense enhancement in arterial phase with relatively fast wash-out.

Adenoma

Adenomas represent only 5% to 10% of all nodular disease of the thyroid and are seven times more common in women than men.[5] Most result in no thyroid dysfunction; a minority (<10%) hyperfunction, develop autonomy, and may cause thyrotoxicosis. Most adenomas are solitary, but they may also develop as part of a multinodular process.

The **benign follicular adenoma** is a true thyroid neoplasm, characterized by compression of adjacent tissues and fibrous encapsulation. Various subtypes of follicular adenoma include the **fetal adenoma, Hürthle cell adenoma,** and **embryonal adenoma,** each distinguished according to the type of cell proliferation. The cytologic features of follicular adenomas are generally indistinguishable from those of follicular carcinoma. Vascular and capsular invasion are the hallmarks of **follicular carcinoma,** identified by histologic rather than cytologic analysis. Needle biopsy is therefore not a reliable method to distinguish between follicular carcinoma and cellular adenoma. Therefore such tumors are usually surgically removed.

Sonographically, adenomas are usually solid masses that may be hyperechoic, isoechoic, or hypoechoic (Fig. 19.13, Video 19.3). They often have a thick, smooth peripheral hypoechoic halo resulting from the fibrous capsule and blood vessels, which can be readily seen by color Doppler imaging. Often, vessels pass from the periphery to the central regions of the nodule, sometimes creating a "spoke and wheel" appearance. This vascular pattern is usually seen in both hyperfunctioning and poorly functioning adenomas and thus does not allow the detection of hyperfunctioning lesions.

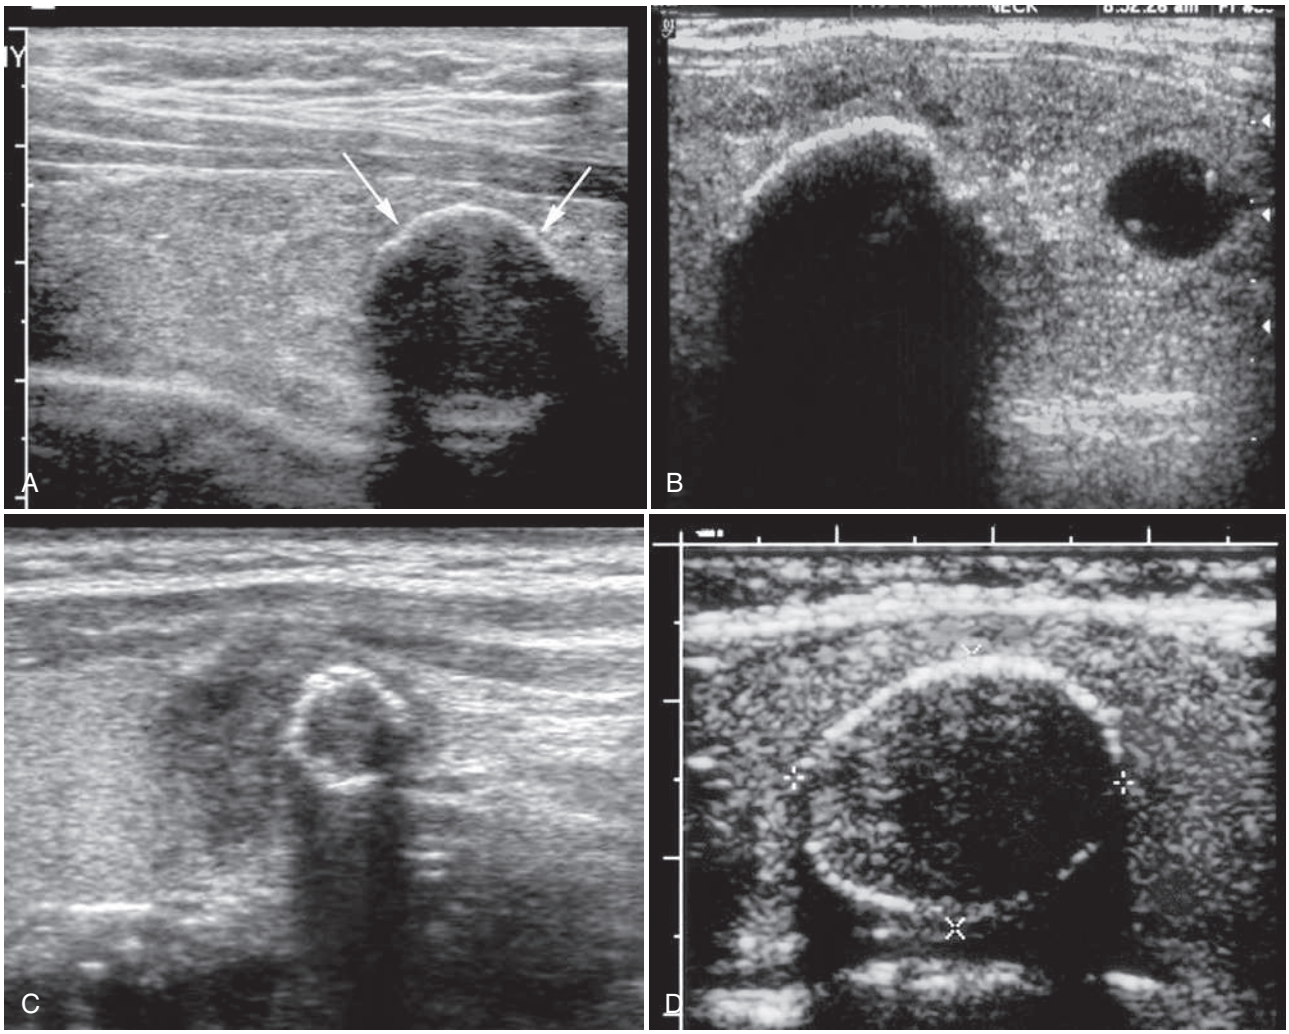

FIG. 19.11 "Eggshell" Calcification. Peripheral (eggshell) calcification was previously thought to indicate a benign nodule, but malignant nodules may have the appearance shown on these longitudinal images. **(A)** Coarse peripheral calcification *(arrows)* casts a large acoustic shadow. **(B)** Eggshell calcification and a typical appearance of colloid cyst on the right side in another patient. **(C)** Hypoechoic solid mass caused by papillary carcinoma surrounds area of eggshell calcification. **(D)** Peripheral shell (eggshell) calcification *(calipers)*.

Carcinoma

Most **primary thyroid cancers** are of epithelial origin and are derived from follicular or parafollicular cells.[16] Malignant thyroid tumors of mesenchymal origin are exceedingly rare, as are metastases to the thyroid. Most thyroid cancers are well differentiated, and papillary carcinoma (including so-called mixed papillary and follicular carcinoma) accounts for 75% to 90% of all cases.[16,23] In contrast, medullary, follicular, and anaplastic carcinomas (combined) represent only 10% to 25% of all thyroid carcinomas currently diagnosed in North America.

Papillary Carcinoma of Thyroid. Although it can occur in patients of any age, prevalence of PTC peaks in both the third and the seventh decades of life.[16] Women are affected more often than men. On microscopic examination, the tumor is multicentric within the thyroid gland in at least 20% of cases.[24] Round, laminated calcifications **(psammoma bodies)** in the cytoplasm of papillary cancer cells are seen in approximately 35% of patients. The major route of spread of papillary carcinoma is through the lymphatics to nearby cervical lymph nodes. In fact, a patient with PTC may have enlarged cervical nodes and a palpably normal thyroid gland.[25,26] Interestingly, the presence of nodal metastasis in the neck generally does not appear to worsen the prognosis for this malignancy. Distant metastases are very rare (2%-3%) and occur mostly in the mediastinum and lung. After 20 years, the cumulative mortality from PTC is typically only 4% to 8%.[25]

Papillary carcinoma has peculiar histologic (fibrous capsule, microcalcifications) and cytologic ("ground glass" nuclei, cytoplasmic inclusions in nucleus, indentations of nuclear membrane) features, which often allow a relatively easy pathologic diagnosis.[27] In particular, microcalcifications, which result from the deposition of calcium salts in the psammoma bodies, are frequently present in both the primary tumor and the cervical

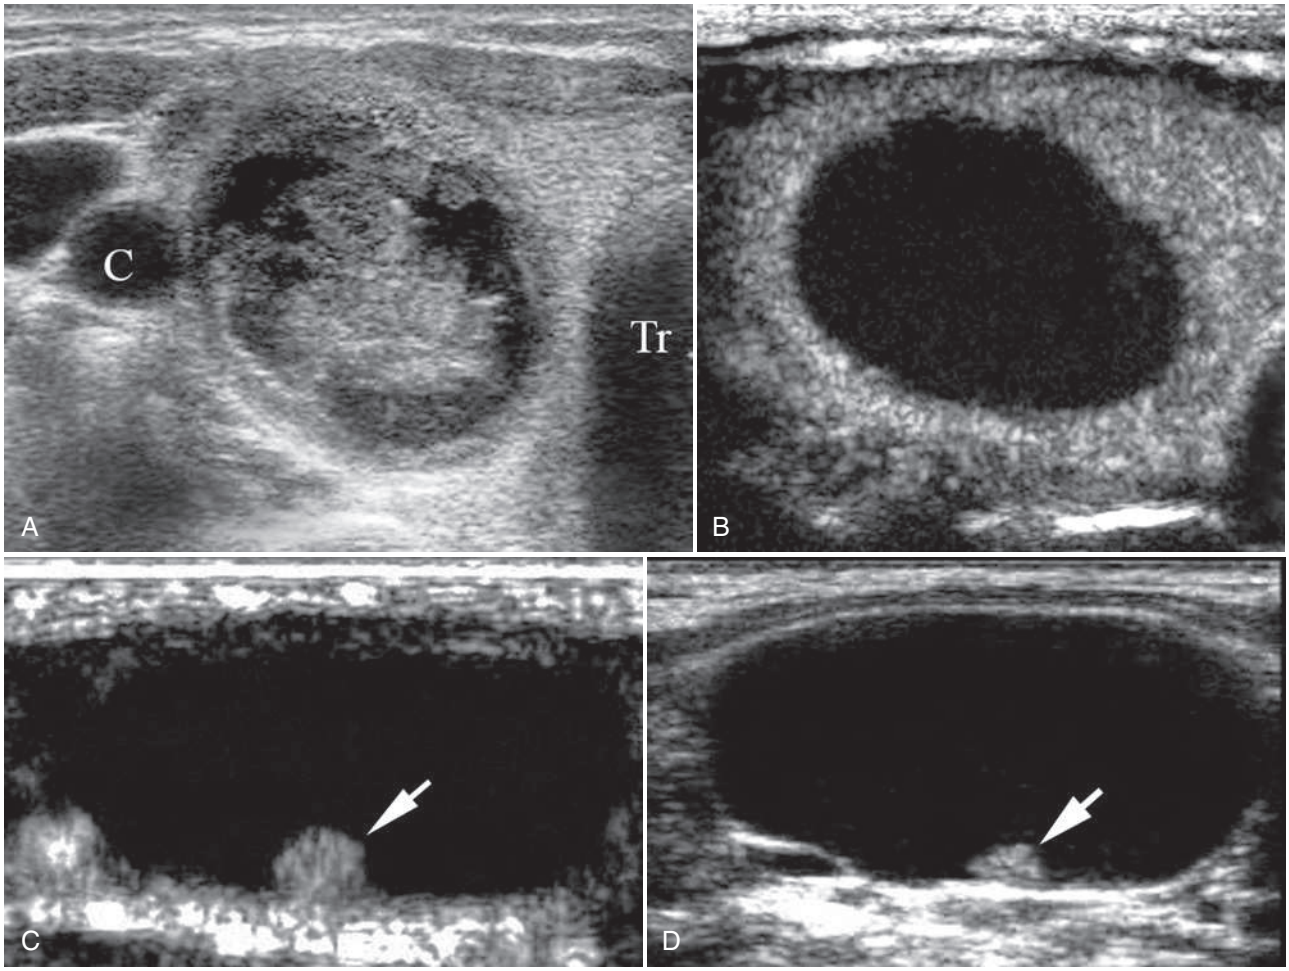

FIG. 19.12 Contrast-Enhanced Sonography to Differentiate Benign From Malignant Fluid-Filled Thyroid Nodules With Internal Septations or Solid Projections. (A) Conventional B-mode sonogram of right thyroid lobe demonstrates large, mixed solid and cystic nodule. *C,* Common carotid artery; *Tr,* tracheal air shadow. **(B)** Contrast-enhanced sonogram. After administration of contrast material, the internal contents are no longer visible because they lack enhancement, indicating that the contents were likely colloid and blood products. **(C)** Conventional B-mode sonogram in longitudinal plane demonstrates a nodule *(arrow)* arising from the posterior wall. **(D)** Contrast-enhanced longitudinal sonogram shows that the nodule remains visible, indicating enhancement after contrast enhancement. The lesion was a cystic papillary carcinoma.

lymph node metastases[26,28] (Fig. 19.14, Video 19.4 and Video 19.5). Similar to the pathologic features, sonographic characteristics of papillary carcinoma usually are relatively distinctive (Figs. 19.15 and 19.16):

- Hypoechogenicity (90% of cases), resulting from closely packed cell content, with minimal colloid substance.
- Microcalcifications, appearing as tiny, punctate hyperechoic foci, either with or without acoustic shadows. In rare but usually aggressive cases of papillary carcinomas of childhood, microcalcifications may be the only sonographic sign of the neoplasm, even without evidence of a nodular lesion[3,20,29,30] (see Fig. 19.15B).
- Hypervascularity (90% of cases), with disorganized vascularity, mostly in well-encapsulated forms[30] (see Fig. 19.16).
- Cervical lymph node metastases, which may contain tiny, punctate echogenic foci caused by microcalcifications (Fig. 19.17). These are mainly located in the caudal half of the deep jugular chain. Occasionally, metastatic nodes may be cystic as a result of extensive degeneration (Fig. 19.17H).

Cystic nodal metastases show a thickened outer wall, internal nodularity, and septations in most cases, although they may appear purely cystic in younger patients.[26] Cystic lymph node metastases in the neck occur almost exclusively in association with PTC, but occasionally with nasopharyngeal carcinomas.[31] On power Doppler sonography, noncystic nodes often show diffuse hypervascularity with tortuous vessels, arteriovenous (AV) shunts, and high vascular resistance (resistive index [RI] > 0.8). In some cases, however, these nodes may show only prominent hilar vascularity, similar to that of reactive nodes, and low RIs.[30]

Papillary carcinoma rarely displays extensive cystic change (Fig. 19.18). In our review of the amount of cystic change found in 360 thyroid carcinomas, a large amount of cystic change occurred in less than 3% of cases.[32] The overwhelming majority

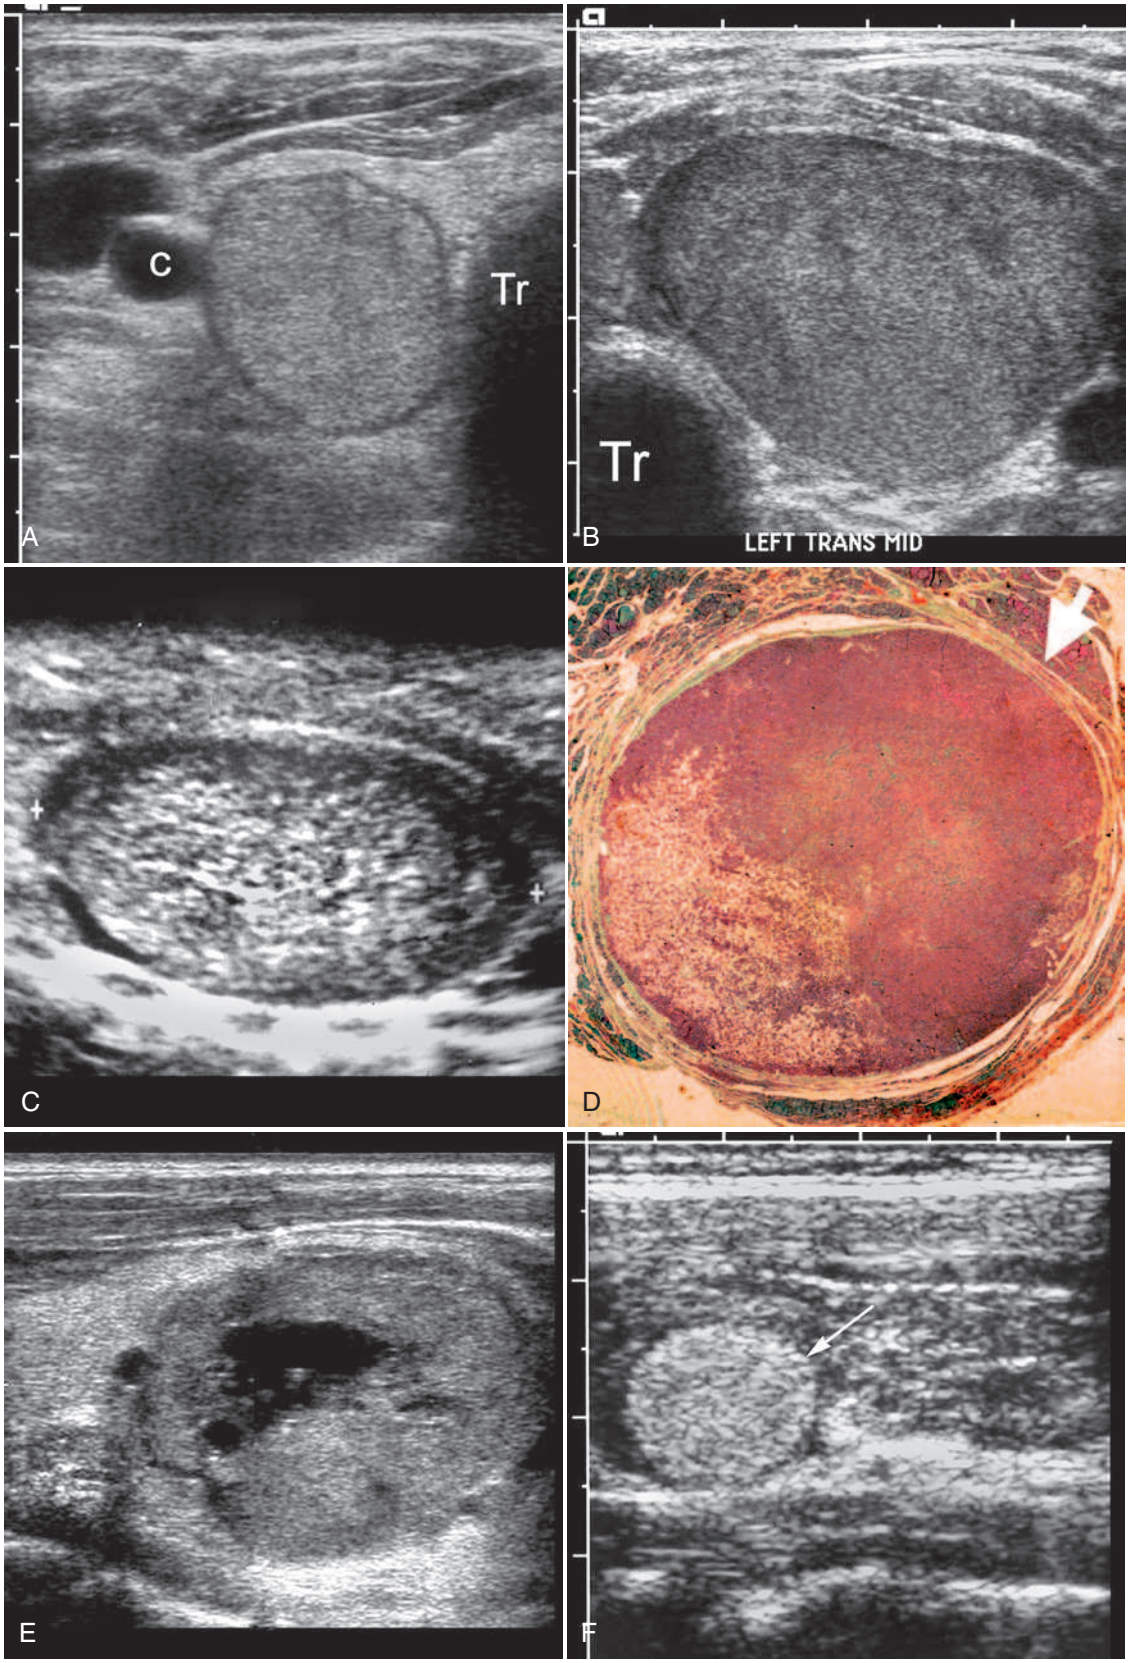

FIG. 19.13 Benign Follicular Adenoma: Spectrum of Appearances. Transverse images of **(A)** right lobe and **(B)** left lobe of thyroid gland in two patients show homogeneous, hypoechoic, round to oval masses with a surrounding thin halo, the capsule of the adenoma. *C,* Carotid artery; *Tr,* tracheal air shadow. **(C)** Longitudinal image shows oval hyperechoic lesion with thick peripheral halo. **(D)** Histology of lesion in **(C).** Note the uniform capsule *(arrow)* of the mass. **(E)** Longitudinal image shows oval mass with internal cystic component. **(F)** Longitudinal image shows round, hyperechoic homogeneous mass *(arrow)* in patient with Hashimoto thyroiditis.

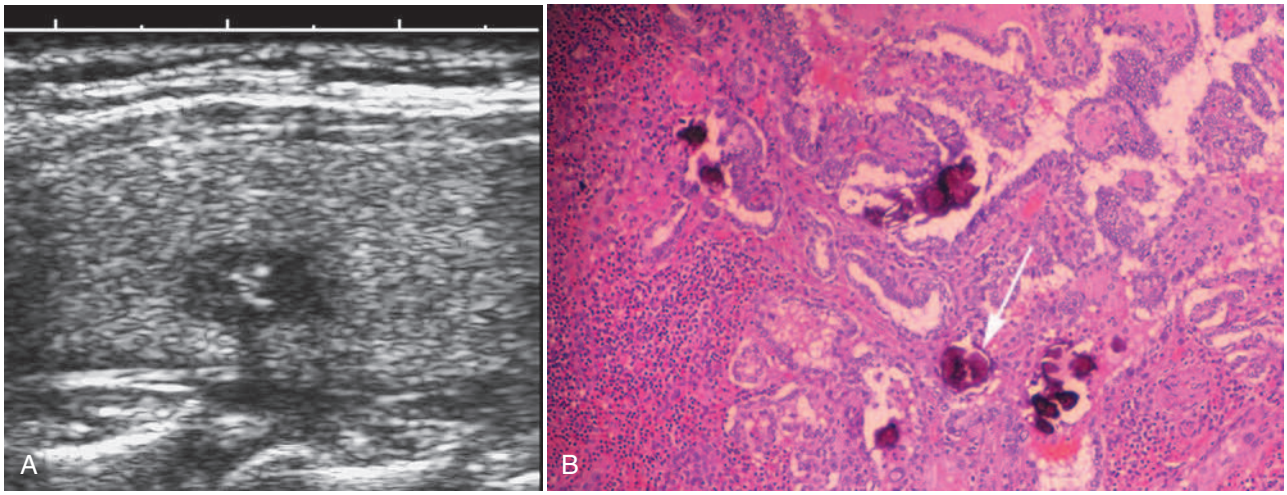

FIG. 19.14 Papillary Carcinoma: Small Cancer With Microscopic Correlation. (A) Longitudinal image shows 7-mm, hypoechoic solid nodule containing microcalcifications. **(B)** Microscopic pathologic image shows microcalcifications, or psammoma bodies *(arrow)*.

of papillary carcinomas appear as a predominantly solid mass. **Invasion of adjacent muscles** is infrequently visualized by ultrasound but indicates that the mass is malignant (Fig. 19.19). A **follicular variant** accounts for 10% of cases of papillary carcinoma and appears similar to a follicular neoplasm on gross pathologic inspection and ultrasound (Fig. 19.20). High-power microscopic studies show that the nuclear features are those of papillary carcinoma, and it is classified as a "follicular variant of papillary carcinoma." The clinical course and treatment are the same as for typical PTC.

Papillary microcarcinoma is a rare, nonencapsulated sclerosing tumor measuring 1 cm or less in diameter (Fig. 19.21). Most patients (80%) have enlarged cervical nodes and a palpably normal thyroid gland.[25,27] Papillary microcarcinoma can be imaged by high-frequency ultrasound in approximately 70% of cases, either as a small, hyperechoic patch (fibrotic-like) under the capsule with thickening and retraction of the capsule, or as a minute hypoechoic nodule with blurred irregular outline with no visible microcalcifications, but often with intense vascular signals within and around the lesion.

Follicular Carcinoma. Follicular carcinoma is the second subtype of well-differentiated thyroid cancer. It accounts for 5% to 15% of all cases of thyroid cancer, affecting women more often than men.[16] The two variants of follicular carcinoma differ greatly in histology and clinical course.[16,23,27] The **minimally invasive** follicular carcinomas are encapsulated, and only the histologic demonstration of focal invasion of capsular blood vessels of the fibrous capsule itself permits differentiation from follicular adenoma. The **widely invasive** follicular carcinomas are not well encapsulated, and invasion of the vessels and the adjacent thyroid is more easily demonstrated. Both variants of follicular carcinoma tend to spread through the bloodstream rather than the lymphatics, and distant metastases to bone, lung, brain, and liver are more likely than metastases to cervical lymph nodes. The widely invasive follicular carcinoma variant metastasizes in about 20% to 40% of cases, and the minimally invasive type metastasizes in only 5% to 10%. Mortality from follicular carcinoma is 20% to 30% at 20 years postoperatively.[16,25]

No unique sonographic features allow differentiation of follicular carcinoma from adenoma, which is not surprising, given the cytologic and histologic similarities of these two tumors (Figs. 19.22 and 19.23). Similarly, fine-needle aspiration (FNA) is not reliable in differentiating benign from malignant follicular neoplasms because the pathologic diagnosis is not based on cellular appearance but rather on capsular and vascular invasion. Therefore most follicular nodules must be surgically removed for accurate pathologic diagnosis. Features that suggest follicular carcinoma are rarely seen but include irregular tumor margins, a thick irregular halo, and a tortuous or chaotic arrangement of internal blood vessels on color Doppler imaging.[19,31]

Medullary Carcinoma. Medullary carcinoma accounts for about 5% of all malignant thyroid diseases. It is derived from the parafollicular cells, or C cells, and typically secretes the hormone **calcitonin,** which can be a useful serum marker. This cancer is frequently familial (20%) and is an essential component of the **multiple endocrine neoplasia (MEN) type II syndromes.**[33] The disease is multicentric and/or bilateral in about 90% of the familial cases[16] (Fig. 19.24). There is a high incidence of metastatic involvement of lymph nodes. The prognosis for patients with medullary cancer is somewhat worse than for follicular cancer.

Follicular Thyroid Carcinoma: Sonographic Features

Irregular tumor margins
Thick, irregular halo
Tortuous or chaotic arrangement of internal blood vessels

Text continued on p. 707.

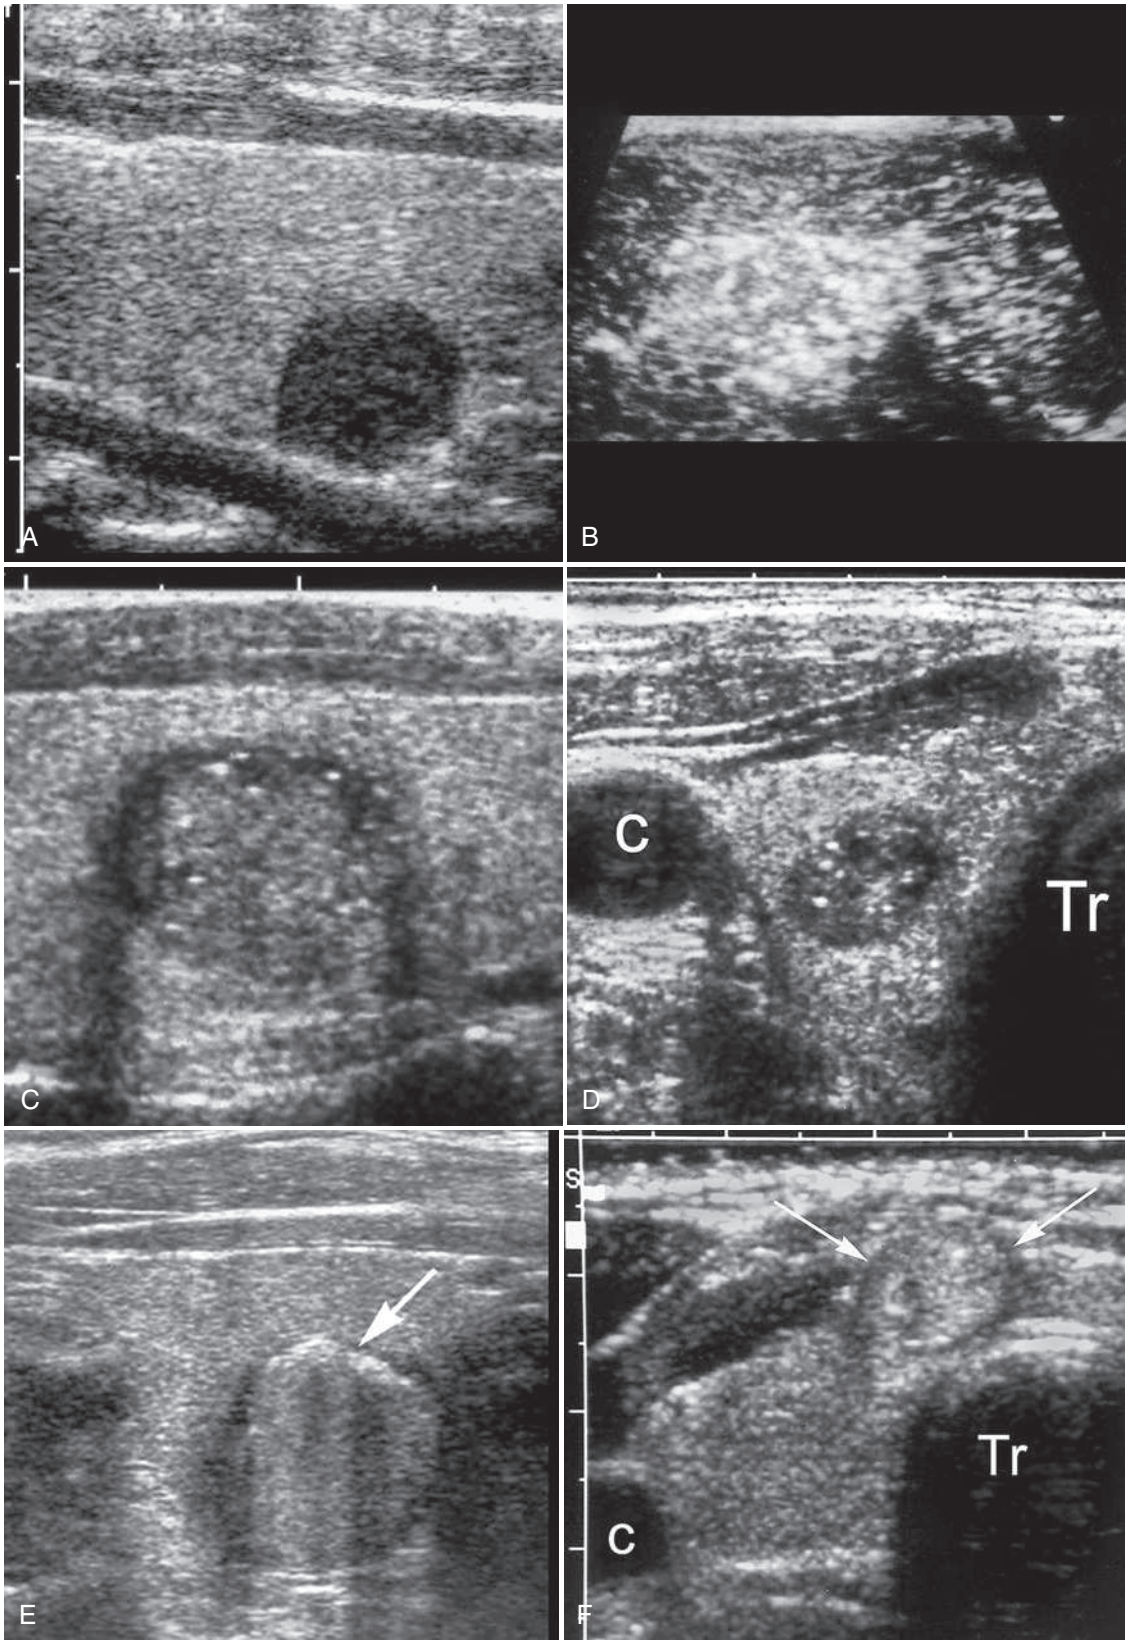

FIG. 19.15 Papillary Thyroid Carcinoma: Spectrum of Appearances. (A) Longitudinal image demonstrates extremely hypoechoic solid nodule without evidence of calcification. **(B)** Longitudinal image of the thyroid of a 6-year-old patient shows extensive diffuse microcalcifications without discrete mass. This is a very rare appearance and is more often encountered in children than adults. **(C)** Longitudinal and **(D)** transverse images show hypoechoic nodules that contain echogenic foci caused by microcalcification. **(E)** Longitudinal image shows hypoechoic solid nodule with thick, irregular halo and linear calcifications at anterior margin *(arrow)*. **(F)** Transverse image shows heterogeneous but isoechoic mass in the isthmus *(arrows)* that contains microcalcifications and has a thick, irregular halo. *C,* Carotid artery; *Tr,* tracheal air shadow.

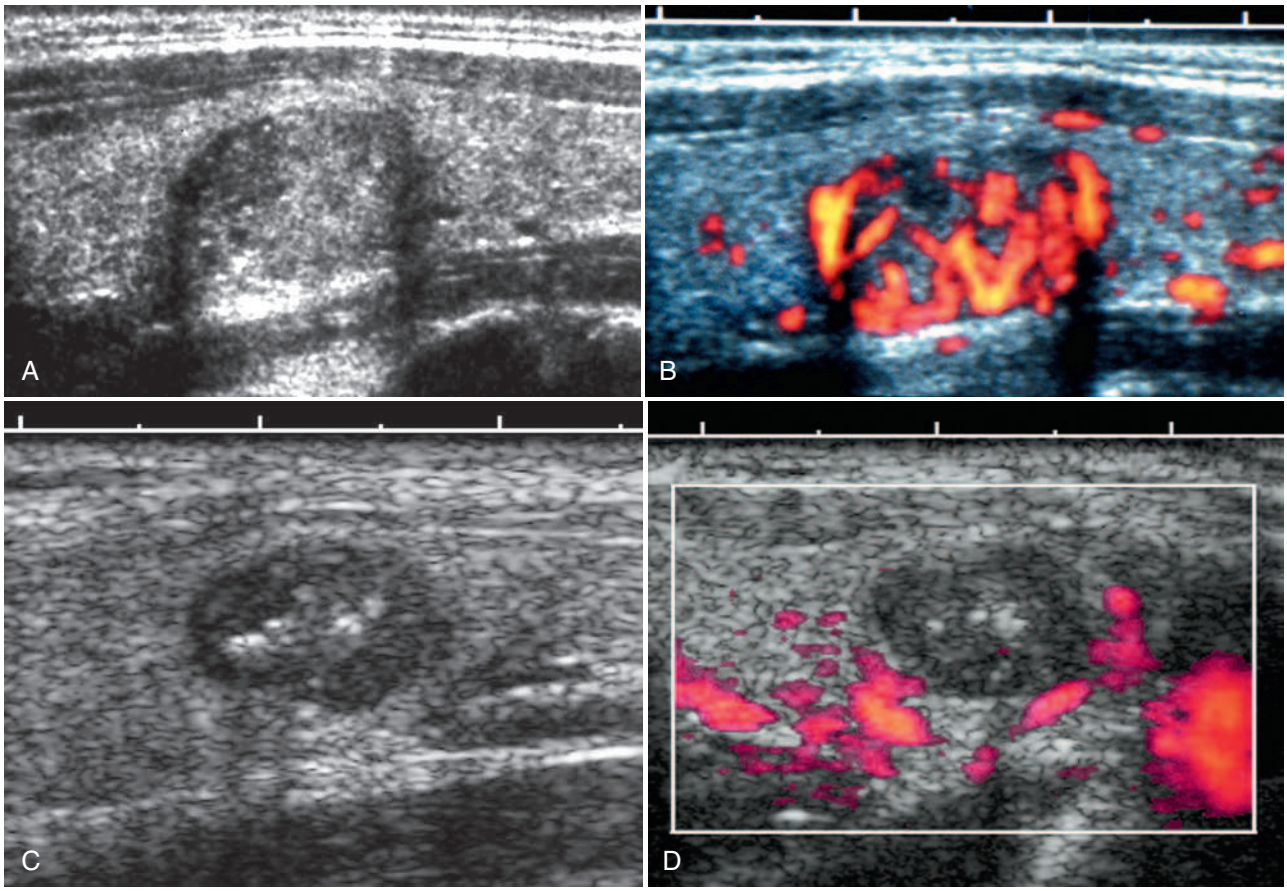

FIG. 19.16 Papillary Carcinoma: Power Doppler Appearances. Blood flow within cancer is often, but not always, increased. **(A)** Longitudinal image shows 1.5-cm nodule with a thick, irregular halo. **(B)** Power Doppler image shows that nodule is hypervascular and has flow in the center and at the periphery. **(C)** Longitudinal image shows hypoechoic nodule with microcalcifications. **(D)** Power Doppler image shows no blood flow within the cancer.

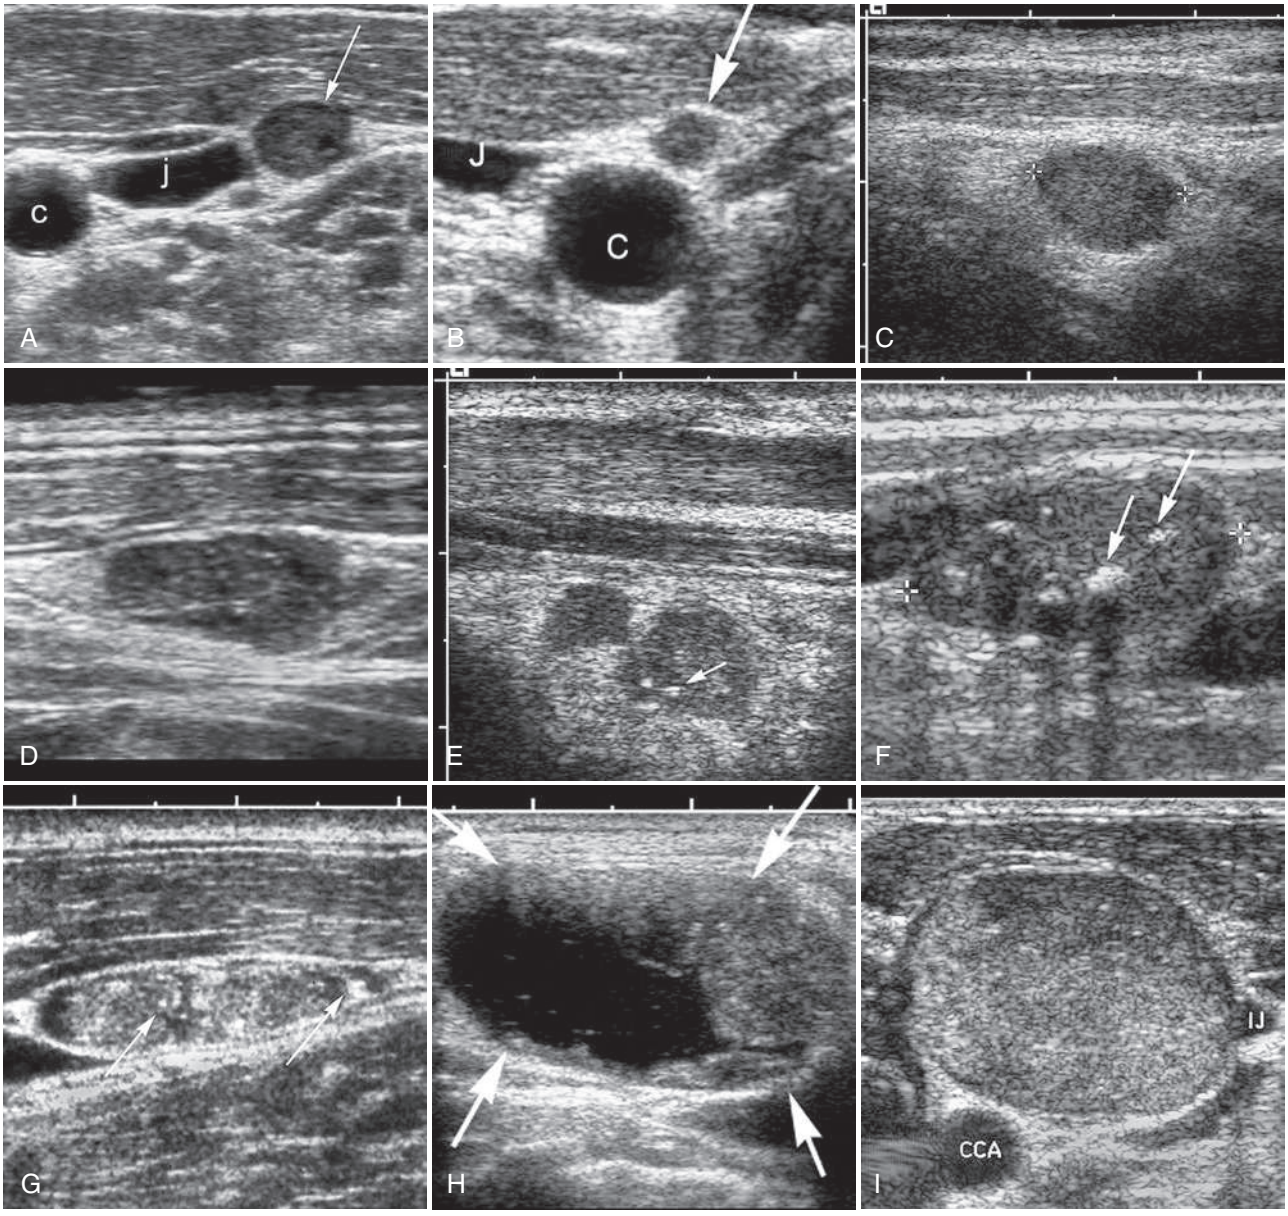

FIG. 19.17 Metastases Involving Cervical Lymph Nodes: Spectrum of Appearances. (A) and **(B)** Transverse images near the carotid artery *(C)* and jugular vein *(J)* show small, round, hypoechoic lymph nodes *(arrows).* Despite their small size (~4 mm), the round shape and the hypoechoic appearance are highly indicative of metastasis. **(C)** and **(D)** Longitudinal images show oval hypoechoic nodes. **(E)** Longitudinal image of thyroid bed after thyroidectomy shows two abnormal lymph nodes, one of which contains microcalcifications *(arrow).* **(F)** and **(G)** Longitudinal images show heterogeneous lymph nodes containing calcification *(arrows).* **(H)** Longitudinal image shows a large lymph node *(arrows)* containing cystic change. Cystic change in a cervical lymph node is almost always caused by metastatic papillary carcinoma. **(I)** Transverse image shows a large, round lymph node between the internal jugular vein *(IJ)* and the common carotid artery *(CCA).*

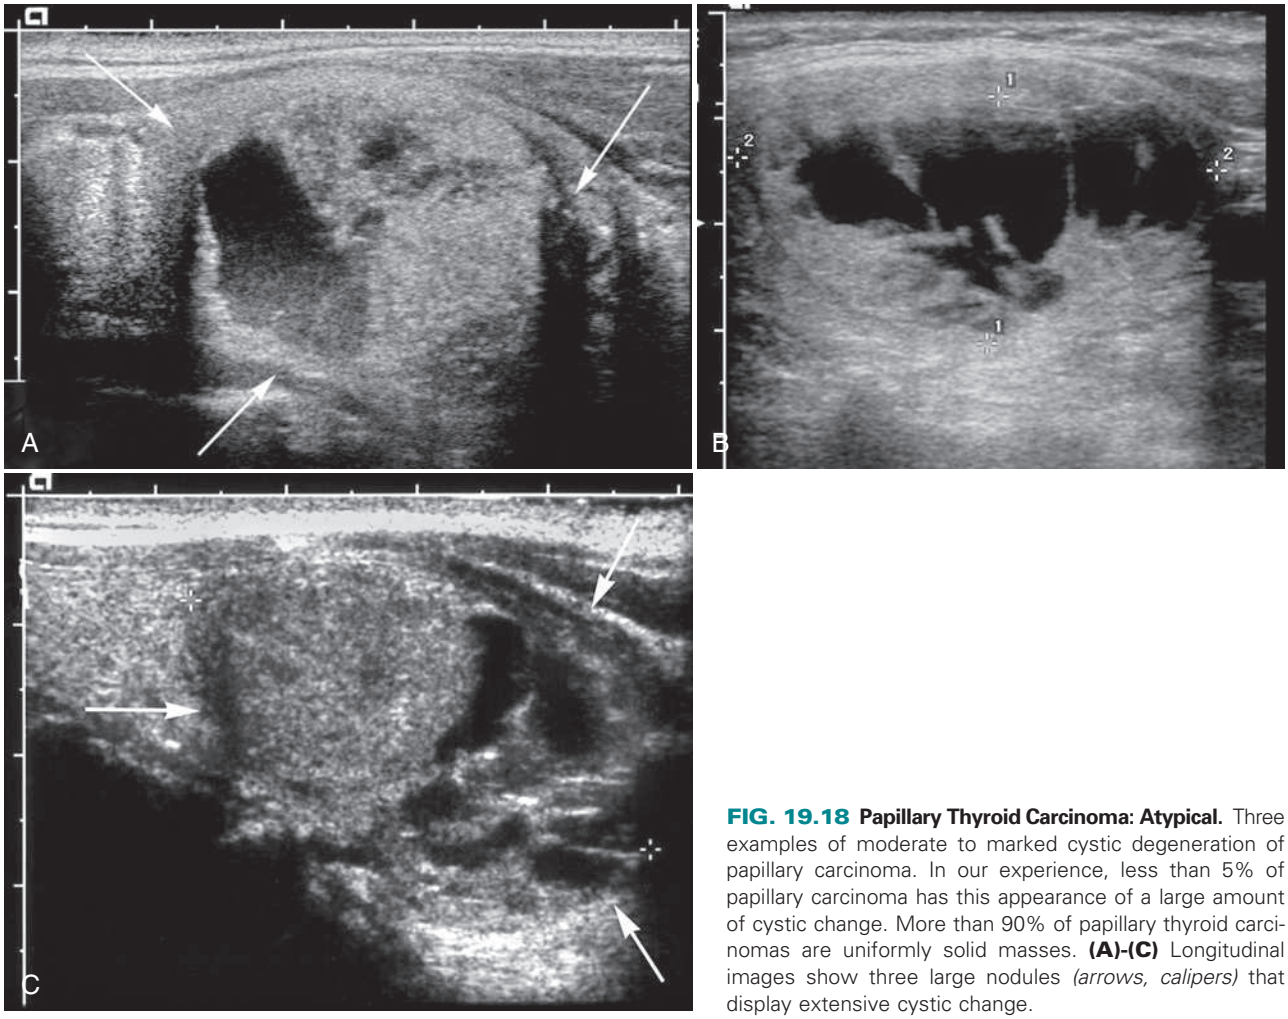

FIG. 19.18 Papillary Thyroid Carcinoma: Atypical. Three examples of moderate to marked cystic degeneration of papillary carcinoma. In our experience, less than 5% of papillary carcinoma has this appearance of a large amount of cystic change. More than 90% of papillary thyroid carcinomas are uniformly solid masses. **(A)-(C)** Longitudinal images show three large nodules *(arrows, calipers)* that display extensive cystic change.

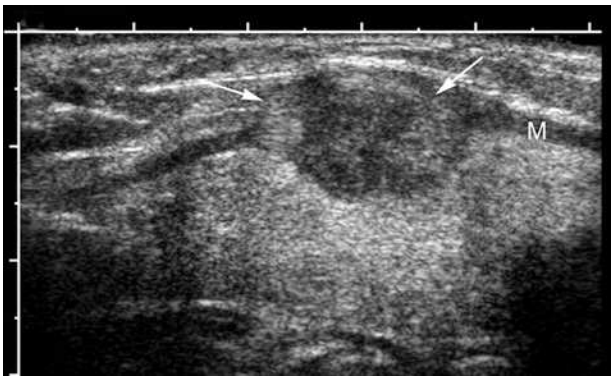

FIG. 19.19 Papillary Carcinoma Invades Muscle. Longitudinal image shows hypoechoic mass arising from anterior surface of the thyroid. This mass invades *(arrows)* adjacent strap muscle *(M)*. Muscular invasion is very rare.

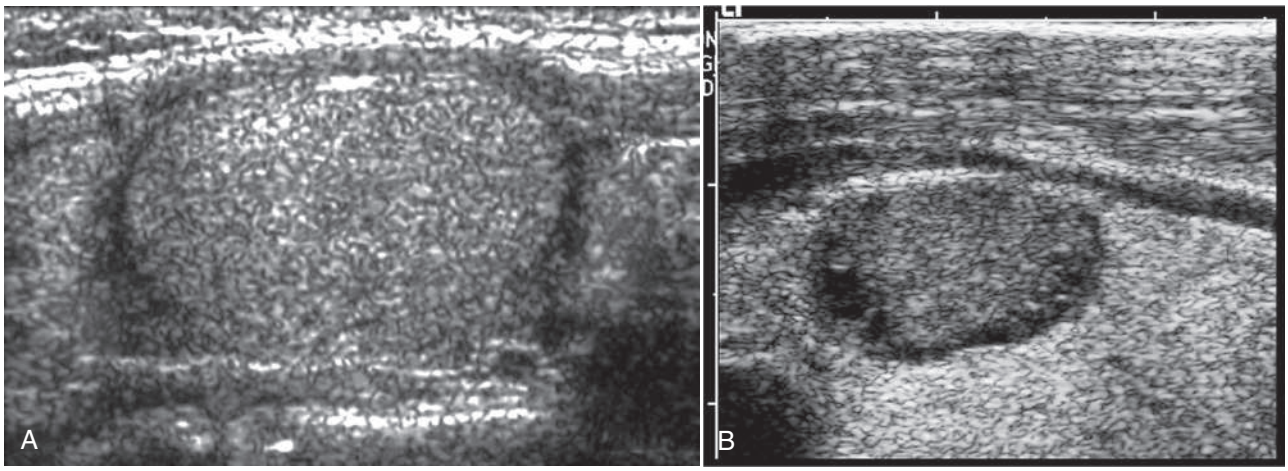

FIG. 19.20 Atypical Papillary Thyroid Carcinoma. Longitudinal images show two examples of the follicular variant of papillary thyroid carcinoma. **(A)** Oval isoechoic and **(B)** hypoechoic masses that look similar to the typical ultrasound appearance of a follicular neoplasm. This follicular variant is uncommon, accounting for 10% of cases of papillary carcinoma. The clinical course and treatment are the same as for typical papillary thyroid carcinoma.

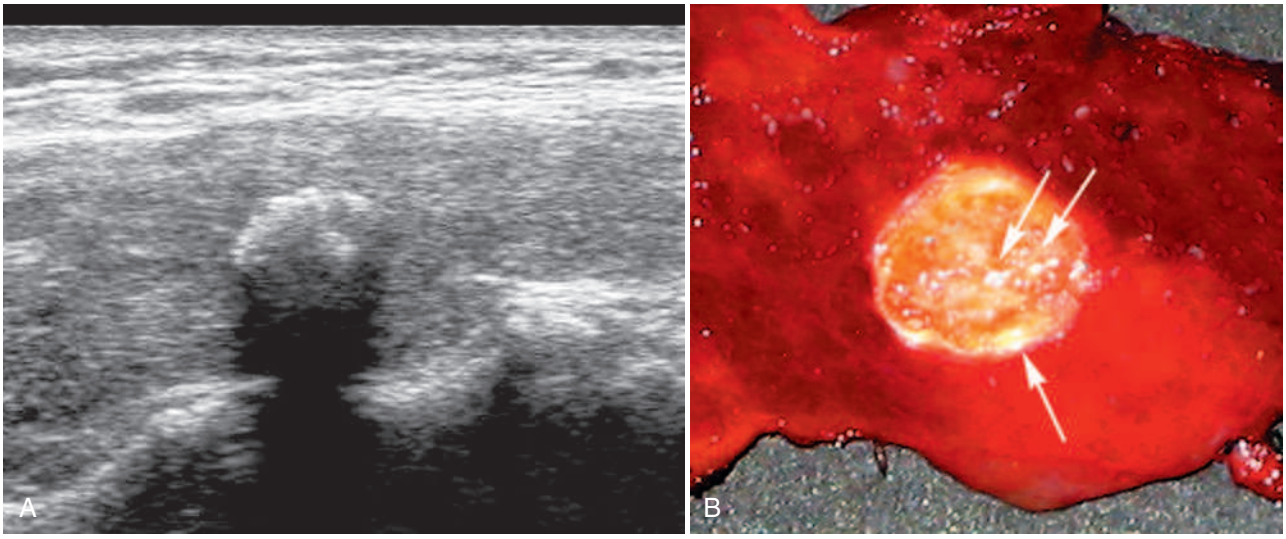

FIG. 19.21 Atypical Papillary Carcinoma. (A) Longitudinal image shows coarse calcification without mass effect, seen at the periphery and internally. **(B)** Gross pathologic specimen of **(A)** shows round nodule that contains multiple areas of grossly visible calcifications *(arrows)*. This is a rare sclerosing form of papillary carcinoma that contains a large amount of fibrosis and calcification.

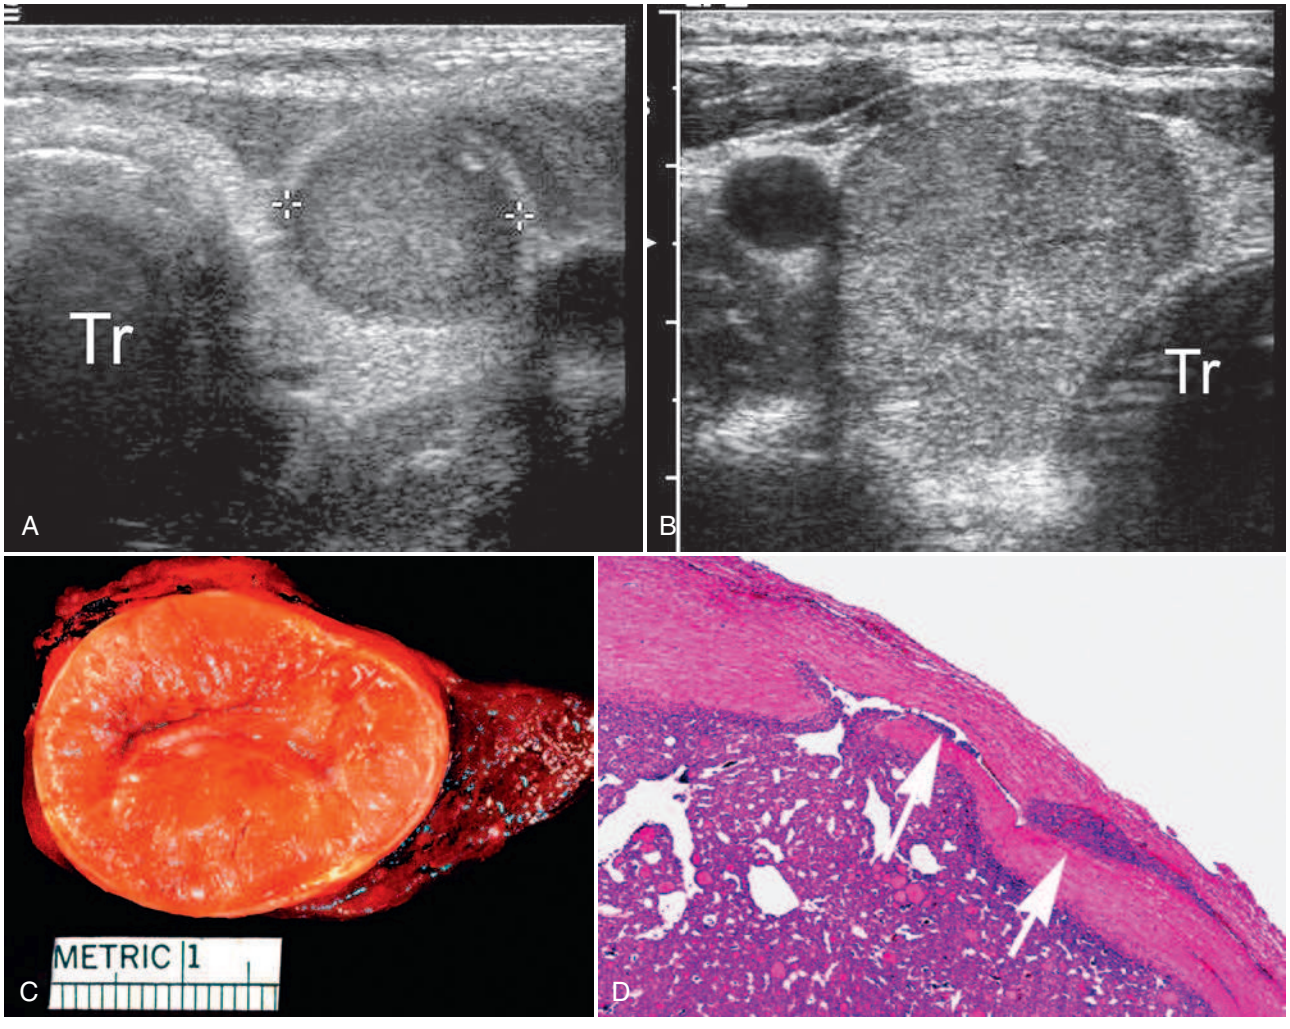

FIG. 19.22 Follicular Neoplasms: Benign and Malignant in Same Patient. (A) Left lobe and **(B)** right lobe of the thyroid show round, homogeneous hypoechoic masses that appear identical except for size differences on transverse images. *Tr,* tracheal air shadow. The smaller mass was malignant and the larger mass benign. **(C)** Gross pathologic specimen of follicular neoplasm shows a homogeneous tumor with a thin capsule. This capsule is present in both benign and malignant follicular neoplasms and is often seen on ultrasound. **(D)** Microscopic appearance of the capsule shows invasion of the follicular cells into the capsule *(arrows)*. This is one of the microscopic features that allows a pathologic diagnosis of malignancy but is not visible by ultrasound.

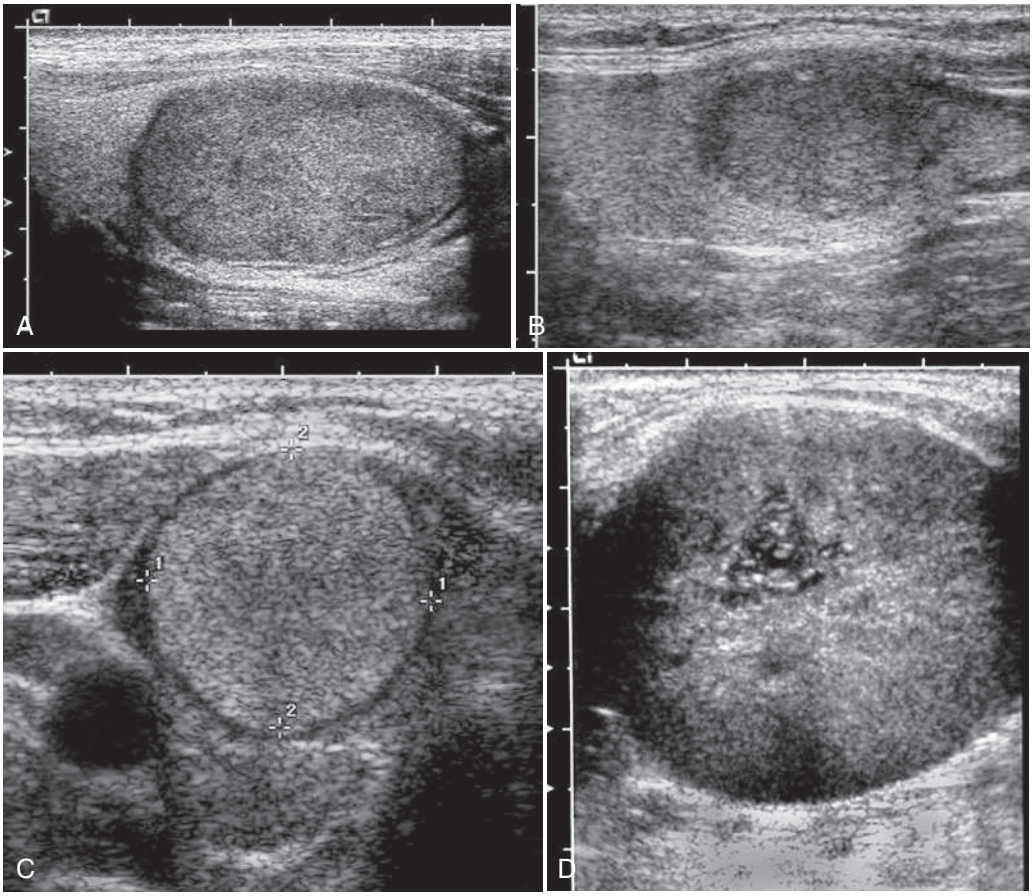

FIG. 19.23 Malignant Follicular Neoplasms. (A) and **(B)** Longitudinal images of two patients with oval homogeneous hypoechoic masses. **(C)** and **(D)** Transverse images of two other patients with round homogeneous masses. These four carcinomas appear identical to the benign follicular neoplasms (see Fig. 19.13), and surgical removal is required to exclude or establish malignancy of most follicular tumors.

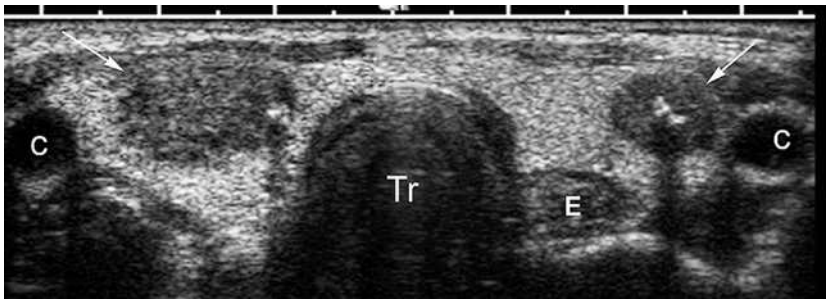

FIG. 19.24 Multicentric Medullary Thyroid Carcinoma. Transverse dual image in patient with multiple endocrine neoplasia type II (MEN II) shows bilateral hypoechoic masses *(arrows)* that contain areas of coarse calcification. *C,* Carotid arteries; *E,* esophagus; *Tr,* trachea.

The sonographic appearance of medullary carcinoma is usually similar to that of papillary carcinoma and is seen most often as a hypoechoic solid mass. Calcifications are often seen (histologically caused by calcified nests of amyloid substance) and tend to be more coarse than the calcifications of typical papillary carcinoma[34] (Fig. 19.25). Calcifications can be seen not only in the primary tumor but also in lymph node metastases and even in hepatic metastases.

Anaplastic Thyroid Carcinoma. Anaplastic thyroid carcinoma is typically a disease of elderly persons; it represents one of the most lethal of solid tumors. Although it accounts for less than 2% of all thyroid cancers, it carries the worst prognosis, with a 5-year mortality rate of more than 95%.[35] The tumor typically manifests as a rapidly enlarging mass extending beyond the gland and invading adjacent structures. It is often inoperable at presentation. Anaplastic carcinomas are often associated with papillary or follicular carcinomas, presumably representing a dedifferentiation of the neoplasm. They tend not to spread via the lymphatics but instead are prone to aggressive local invasion of muscles and vessels.[27]

Sonographically, anaplastic thyroid carcinomas are usually hypoechoic and often encase or invade blood vessels and neck muscles (Fig. 19.26). Often these tumors cannot be adequately examined by ultrasound because of their large size. Instead,

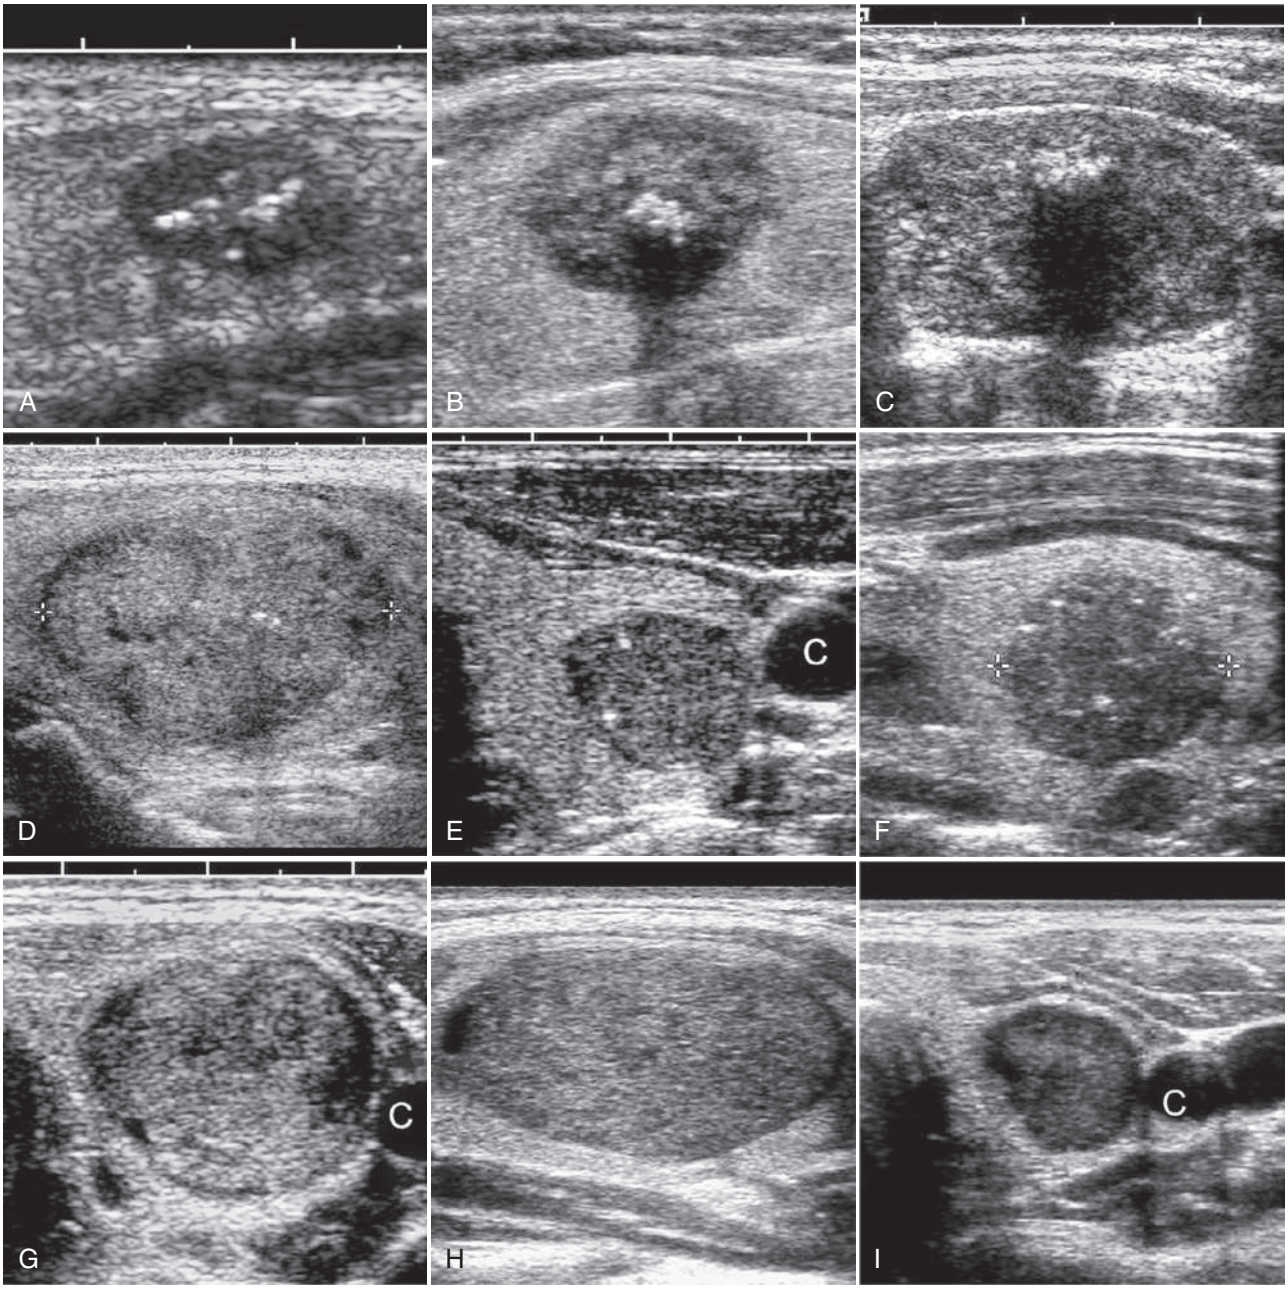

FIG. 19.25 Medullary Thyroid Carcinoma: Spectrum of Appearances. (A)-(C) Hypoechoic solid nodules with coarse internal calcifications. **(D)-(F)** Hypoechoic solid nodules with fine internal calcifications. **(G)-(I)** Hypoechoic solid nodules without calcification and with a similar appearance as follicular neoplasms. *C,* Carotid artery.

computed tomography (CT) or magnetic resonance imaging (MRI) of the neck usually demonstrates the extent of disease more accurately.

Anaplastic Thyroid Carcinoma: Sonographic Features

Large, hypoechoic mass
Encase or invade blood vessels
Invade neck muscles

Lymphoma

Lymphoma accounts for approximately 4% of all thyroid malignancies. It is mostly of the non-Hodgkin type and usually affects older women. The typical clinical sign is a rapidly growing mass that may cause symptoms of obstruction such as dyspnea and dysphagia.[36] In 70% to 80% of patients, lymphoma arises from a preexisting **chronic lymphocytic thyroiditis (Hashimoto thyroiditis)** with subclinical or overt hypothyroidism. The prognosis is highly variable and depends on the stage of the disease. Five-year survival ranges from almost 90% in early-stage cases to less than 5% in advanced, disseminated disease.

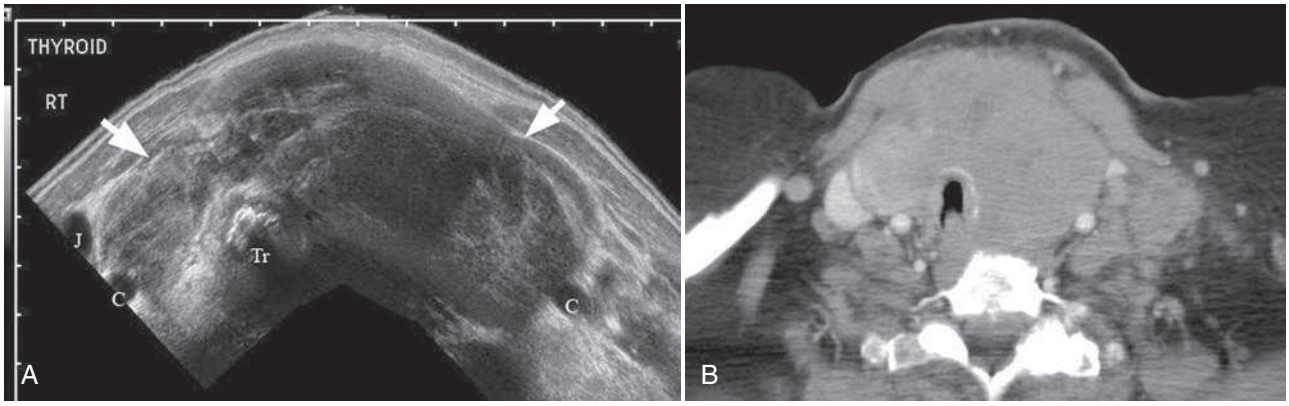

FIG. 19.26 Anaplastic Thyroid Carcinoma. (A) Transverse image shows large hypoechoic mass *(arrows)* involving the entire gland, greater on the left, which causes deviation of the trachea to the right. *C,* Common carotid artery; *J,* jugular vein; *Tr,* tracheal air shadow. **(B)** Contrast-enhanced computed tomography scan of the patient shows the large mass and its relationship to adjacent structures.

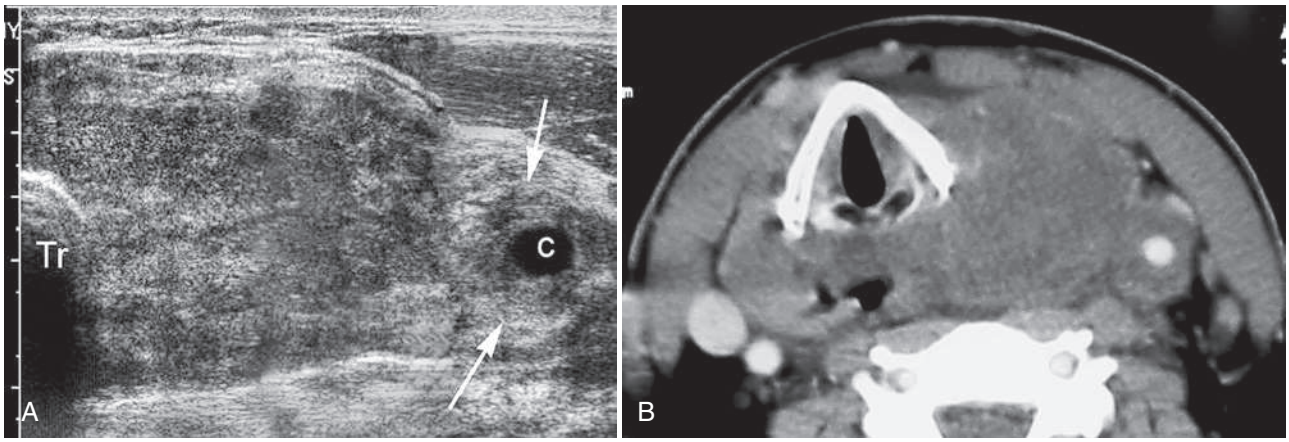

FIG. 19.27 Lymphoma. (A) Transverse image of left lobe of the thyroid shows diffuse mass enlarging the lobe and extending into the soft tissues *(arrows)* surrounding the common carotid artery *(c). Tr,* Tracheal air shadow. **(B)** Contrast-enhanced computed tomography scan shows a hypovascular mass in the left thyroid lobe and soft tissue encasement of the carotid artery.

Sonographically, lymphoma of the thyroid appears as an extremely hypoechoic and lobulated mass. Large areas of cystic necrosis may occur, as well as encasement of adjacent neck vessels[37] (Fig. 19.27). On color Doppler imaging, both nodular and diffuse thyroid lymphomas may appear mostly hypovascular or may show blood vessels with chaotic distribution and AV shunts. The adjacent thyroid parenchyma may be heterogeneous as a result of associated chronic thyroiditis.[38]

Thyroid Metastases

Metastases to the thyroid are infrequent, occurring late in the course of neoplastic diseases as the result of hematogenous spread or less frequently a lymphatic route. Metastases usually are from **melanoma** (39%), **breast** (21%), and **renal cell** (10%) carcinoma. Metastases may appear as solitary, well-circumscribed nodules or as diffuse involvement of the gland. On sonography, thyroid tumors are solid, homogeneously hypoechoic masses, without calcifications[39] (Fig. 19.28).

Fine-Needle Aspiration Biopsy

Once a thyroid nodule has been detected, the fundamental challenge is to determine if it is benign or malignant. Short of surgical excision, several methods for nodule characterization are in common use, including radionuclide imaging, sonography, and FNA biopsy. Each of these techniques has advantages and limitations, and the choice in any specific clinical setting depends largely on available instrumentation and expertise.

It is generally recognized that FNA biopsy is the most effective method for diagnosing malignancy in a thyroid nodule.[40-42] In many clinical practices, FNA under direct palpation is the first diagnostic examination performed on any clinically palpable nodule. Neither isotopic nor sonographic imaging is used routinely, instead reserved for special situations or difficult cases. FNA has had a substantial impact on the management of thyroid nodules because it provides more direct information than any other available diagnostic technique. It is safe and inexpensive and results in better selection of patients for surgery. The successful use of FNA in clinical practice, however, depends heavily on the presence of an experienced aspirationist and an expert cytopathologist.

Fine-needle thyroid aspirates are often classified cytopathologically into the following four categories:

1. Negative (no malignant cells)
2. Positive for malignancy

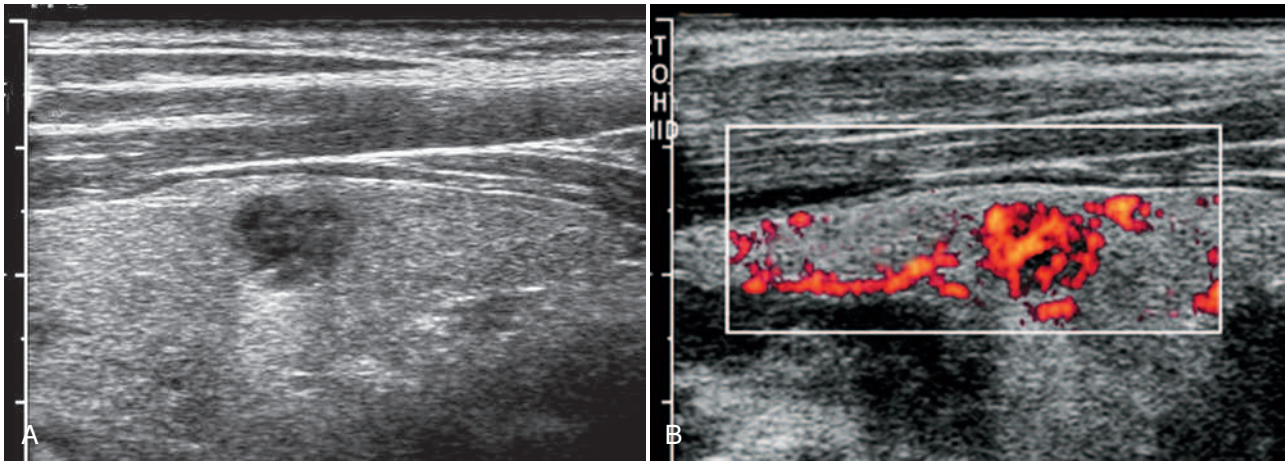

FIG. 19.28 Thyroid Metastasis From Renal Cell Carcinoma. (A) Longitudinal (gray-scale) and **(B)** power Doppler images show a 1-cm solid vascular mass.

TABLE 19.1 Diagnostic Yield of Thyroid Fine-Needle Aspiration (FNA)

Series	No. of Cases	FN rate	FP rate	Sensitivity	Specificity
Hawkins et al.[44]	1399	2.4%	4.6%	86%	95%
Khafagi et al.[45]	618	4.1%	7.7%	87%	72%
Hall et al.[46]	795	1.3%	3.0%	84%	90%
Altavilla et al.[47]	2433	6.0%	0.0%	71%	100%
Gharib and Goellner[43]	10,971	2.0%	0.7%	98%	99%
Ravetto et al.[48]	2014	11.2%	0.7%	89%	99%

FN, False-negative; *FP,* false-positive.
Modified from Gharib H, Goellner JR. Fine-needle aspiration biopsy of the thyroid: an appraisal. Ann Intern Med. 1993;118(4):282-289.[43]

3. Suggestive of malignancy
4. Nondiagnostic

If a nodule is classified in either of the first two categories, the results are highly sensitive and specific.[42] The major limitation of the technique is the lack of specificity in the third group—results are suggestive of malignancy—primarily because of the inability to distinguish follicular or Hürthle cell adenomas from their malignant counterparts. In these cases, surgical excision is required for diagnosis. In addition, up to 20% of aspirates may be nondiagnostic, approximately half of which result from inadequate cell sampling of cystic lesions. In these cases, repeat FNA under sonographic guidance can be performed for **selective sampling** of the solid elements of the mass. In the world literature, FNA of thyroid nodules has a sensitivity range of 65% to 98% and specificity of 72% to 100%, with a false-negative rate of 1% to 11% and a false-positive rate of 1% to 8%[43-49] (Table 19.1). In a study based on more than 5000 cytologic examinations, the most frequent cause of false-negative findings was the failure to recognize the follicular variant of papillary carcinoma.[49] In our practices, the overall accuracy of FNA exceeds 95%, and therefore it is currently the most accurate and cost-effective method for initial evaluation of patients with nodular thyroid disease. Since the introduction of FNA into routine clinical practice, the percentage of patients undergoing thyroidectomy has substantially decreased (to ~25%), and the cost of thyroid nodule care has been reduced by 25%.[43]

The evaluation of thyroid nodules primarily by FNA is common in North America and northern Europe. In other European countries and Japan, where goiter is prevalent, the initial evaluation often relies on radionuclide and sonographic imaging because of the need to select nodules that must undergo FNA.

Sonographic Applications

Although FNA is the most reliable diagnostic method for evaluating clinically palpable thyroid nodules, high-resolution sonography has four primary clinical applications[50-52]:

- Detection of thyroid and other cervical masses before and after thyroidectomy
- Differentiation of benign from malignant masses on the basis of their sonographic appearance
- Guidance for FNA biopsy
- Guidance for the percutaneous treatment of nonfunctional and hyperfunctioning benign thyroid nodules and of lymph node metastases from papillary carcinoma

Detection of Thyroid Masses

A practical use of sonography is to establish the precise anatomic location of a palpable cervical mass. The determination of whether

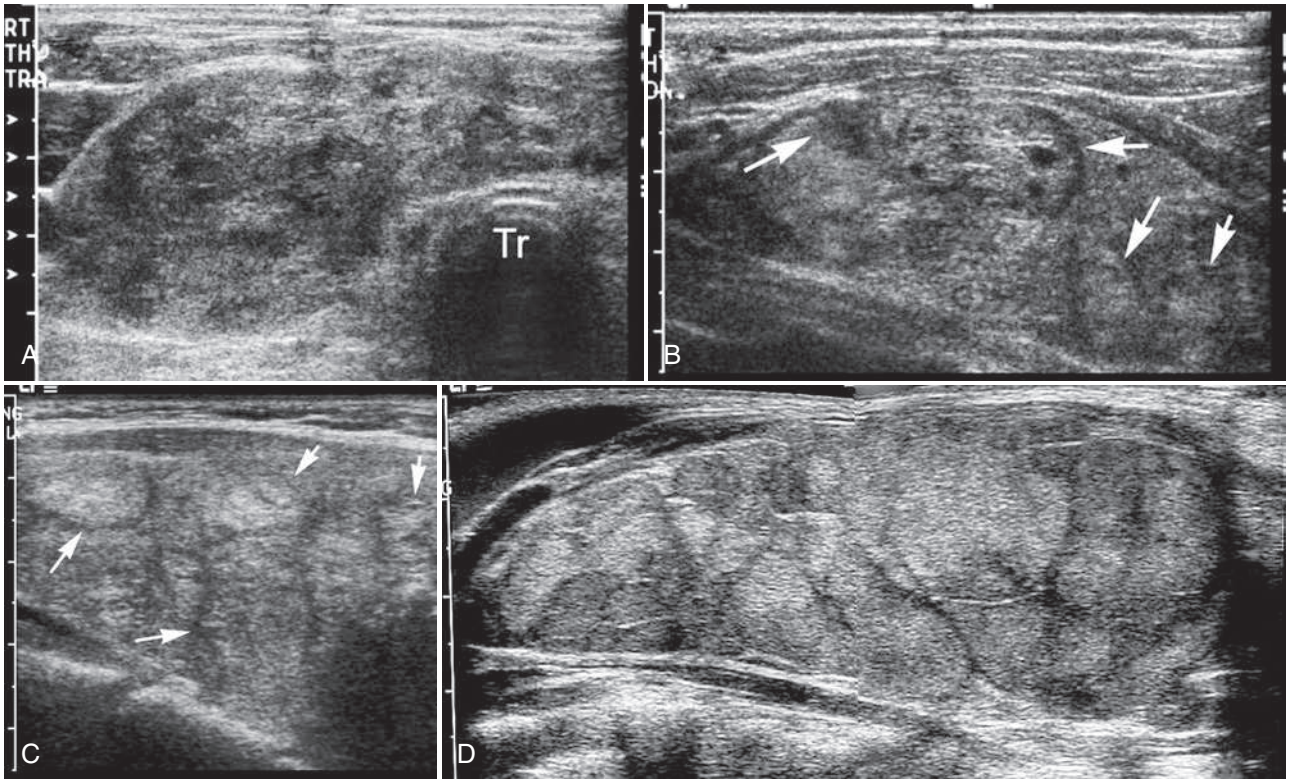

FIG. 19.29 Multinodular Goiter. (A) Transverse image shows enlargement of the right lobe and isthmus by multiple confluent hypoechoic and hyperechoic nodules. *Tr,* Tracheal air shadow. **(B)** and **(C)** Longitudinal images show multiple confluent nodules *(arrows).* **(D)** Longitudinal dual image shows enlargement of a lobe by multiple nodules.

such a mass is within or adjacent to the thyroid cannot always be made on the basis of the physical examination alone. Sonography can readily differentiate thyroid nodules from other cervical masses, such as cystic hygromas, thyroglossal duct cysts, and enlarged lymph nodes. Alternatively, sonography may help to confirm the presence of a thyroid nodule when the findings on physical examination are equivocal.

Sonography may be used to detect occult thyroid nodules in patients who have a **history of head and neck irradiation** during childhood as well as those with a **family history of MEN II syndrome;** both groups have a known increased risk for development of thyroid malignancy. If a nodule is discovered, a biopsy can be performed under sonographic guidance. It is unknown, however, whether the detection of a thyroid cancer before it becomes clinically palpable will change the ultimate clinical outcome for a given patient.

In the past, when thyroid nodules were evaluated primarily with isotope scintigraphy, it was generally accepted that a "solitary cold" nodule carried a probability of malignancy of 15% to 25%, whereas a "cold" nodule in a multinodular gland was malignant in less than 1% of cases.[53] However, benign goiter is multinodular in 70% to 80% of cases, and 70% of nodules considered "solitary" on scintigraphy or physical examination are actually *multiple* when assessed with high-frequency ultrasound[21,54] (Fig. 19.29).

It has been suggested, therefore, that sonography may be used to detect additional occult nodules in patients with clinically solitary lesions, thereby implying that the dominant palpable mass is benign. Such a conclusion is unwarranted, however, because pathologically, benign nodules often coexist with malignant nodules. In a series of 1500 consecutive patients undergoing surgery for papillary carcinoma, 33% had coexistent benign nodules at surgery.[55] In addition, PTC is recognized to be multicentric in at least 20% of cases and occult (<1.5 cm in diameter) in up to 48% of cases.[23,53] In a previous study, almost two-thirds (64%) of patients with thyroid cancer had at least one nodule in addition to the dominant nodule detected sonographically.[56] Pathologically, these extra nodules can be benign or malignant. Therefore in patients with a clinically solitary nodule, the sonographic detection of a few additional nodules is not a reliable sign for excluding malignancy.

An ultrasound-guided FNA biopsy is performed for patients with **multinodular goiter** when there is a dominant nodule. A **dominant nodule** is the largest nodule or has ultrasound features different from the other nodules or features suggestive of carcinoma.

In patients with known thyroid cancer, sonography can be useful to **determine the extent of disease,** both preoperatively and postoperatively. In most patients a sonographic examination is not performed routinely before thyroidectomy, but it can be useful in those with large cervical masses for evaluation of nearby structures, such as the carotid artery and internal jugular vein for evidence of direct invasion or encasement by the tumor. Alternatively, in patients with cervical lymphadenopathy caused by PTC but in whom the thyroid gland is palpably normal, sonography may be used preoperatively to detect an occult, nonpalpable primary focus within the gland.

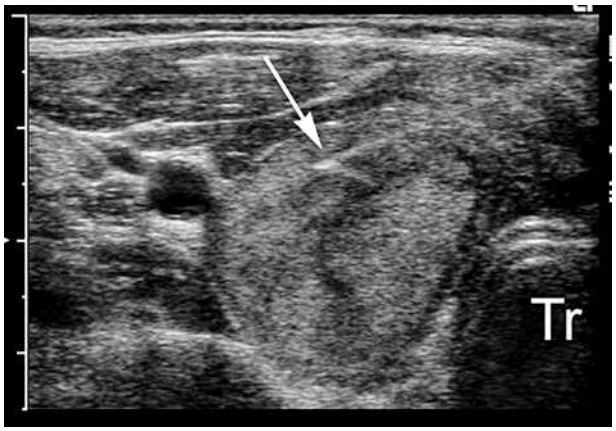

FIG. 19.30 Fine-Needle Aspiration of Thyroid Nodule Caused by Follicular Neoplasm. Transverse image shows a large nodule replacing the right thyroid lobe. *Tr,* Tracheal air shadow. The tip of the 25-gauge needle is highly visible *(arrow),* and the shaft of the needle is faintly visible.

After partial or near-total thyroidectomy for carcinoma, sonography is the preferred method for follow-up, by detecting **residual, recurrent, or metastatic disease** in the neck.[57] In patients who have had subtotal thyroidectomy, the sonographic appearance of the remaining thyroid tissue may serve as an important factor in deciding whether complete thyroidectomy is recommended. If a mass is identified, its nature can be determined by ultrasound-guided FNA (Fig. 19.30). If no masses are seen, the clinician may choose to follow the patient with periodic sonographic studies. For patients who have had total or near-total thyroidectomy, sonography has proved to be more sensitive than physical examination in detecting recurrent disease within the thyroid bed or metastatic disease in cervical lymph nodes.[58] Patients with a history of thyroid cancer often undergo periodic sonographic examinations of the neck to detect nonpalpable recurrent or metastatic disease. When a mass is identified, FNA under sonographic guidance can establish a diagnosis of malignancy and help in surgical planning.

Differentiation of Benign and Malignant Nodules

According to several reports, for the differentiation of benign from malignant thyroid nodules, sonography has sensitivity rates of 63% to 94%, specificity of 61% to 95%, and overall accuracy of 78% to 94%.[4,5,59-65] Currently, no single sonographic criterion distinguishes benign thyroid nodules from malignant nodules with complete reliability.[5,59-61,65] Nevertheless, certain sonographic features are seen more often with one type of histology or another type, thus establishing general diagnostic trends[31] (Table 19.2).

The fundamental anatomic features of a thyroid nodule on high-resolution sonography are as follows:

- Internal consistency (solid, mixed solid and cystic, or purely cystic)
- Echogenicity relative to adjacent thyroid parenchyma
- Margin
- Shape
- Presence and pattern of calcification

TABLE 19.2 Reliability of Sonographic Features in Differentiation of Benign From Malignant Thyroid Nodules

	PATHOLOGIC DIAGNOSIS	
Feature	**Benign**	**Malignant**
SHAPE		
Wider than tall	+++	++
Taller than wide	+	++++

Data from authors' experience and literature reports.

- Peripheral sonolucent halo
- Presence and distribution of blood flow signals

Internal Contents. In our experience, approximately 70% of thyroid nodules are solid, whereas the remaining 30% exhibit various amounts of cystic change. A nodule that has a significant cystic component is usually a **benign adenomatous (colloid) nodule** that has undergone degeneration or hemorrhage. When detected by older, lower-resolution ultrasound machines, these lesions were called "cysts" because the presence of internal debris and a thick wall could not be appreciated. Pathologically, a true

epithelium-lined, simple thyroid cyst is extremely rare. Virtually all cystic thyroid lesions seen with high-resolution ultrasound demonstrate some wall irregularity and internal solid elements or debris caused by nodule degeneration (see Figs. 19.9 and 19.10). When high-frequency gray-scale sonography and color Doppler imaging cannot differentiate debris and septa from neoplastic intracystic vegetations, contrast-enhanced sonography can sometimes resolve the problem by demonstrating the arterial enhancement in tumoral projections and the complete lack of enhancement of benign septa and debris (see Fig. 19.12). **Comet-tail artifacts** are frequently encountered in cystic thyroid nodules and are likely related to the presence of microcrystals (see Fig. 19.10). In a published series of 100 patients with this feature, FNA biopsy was benign in all cases.[22] These comet-tail artifacts can be located in the cyst walls and internal septations or in the cyst fluid. When a more densely echogenic fluid is gravitationally layered in the posterior portion of a cystic cavity, the likelihood of hemorrhagic debris is very high. Frequently, patients with hemorrhagic debris clinically demonstrate a rapidly growing, often tender neck mass. The **spongiform appearance** of thyroid nodules, related to the presence of tiny colloid changes, is an extremely uncommon finding in malignant nodules, particularly when it is associated with other findings such as well-defined margins and isoechogenicity. This pattern is highly predictive of a benign nodule (see Fig. 19.9).

Papillary carcinomas rarely exhibit varying amounts of cystic change, appearing almost indistinguishable from benign cystic nodules.[66-68] In cystic papillary carcinomas, however, the frequent sonographic detection of solid elements or projections (≥1 cm with blood flow signals and/or microcalcifications) into the lumen can lead to suspicion of malignancy (see Fig. 19.18). Cervical metastatic lymph nodes from either a solid or a cystic primary papillary cancer may also demonstrate a cystic pattern; this is likely pathognomonic of malignant adenopathy.

Shape. A taller-than-wide shape, in which the AP diameter is equal to or less than the transverse diameter on a transverse or longitudinal plane, is specific for differentiating malignant nodules from benign nodules, likely because malignant neoplasms (taller than wide) grow across normal tissue planes, whereas benign nodules grow parallel to normal tissue planes.[59,65,66]

Echogenicity. Thyroid cancers are usually hypoechoic relative to the adjacent normal thyroid parenchyma (see Fig. 19.15). Unfortunately, many benign thyroid nodules are also hypoechoic. In fact, most **hypoechoic nodules** are benign because benign nodules are so much more common than malignant nodules. However, marked hypoechogenicity is highly specific for diagnosing malignant nodules, whereas the hypoechogenicity often found in benign lesions is usually less marked.[65] A predominantly **hyperechoic nodule,** although relatively uncommon, is more likely to be benign.[21] The **isoechoic nodule,** visible because of a peripheral sonolucent rim that separates it from the adjacent normal parenchyma, has an intermediate to low risk of malignancy. Isoechogenicity has low sensitivity but high specificity and positive predictive value for the diagnosis of benign nodules.[65]

Halo. A peripheral sonolucent halo that completely or incompletely surrounds a thyroid nodule is present in 60% to 80% of benign nodules and 15% of thyroid cancers.[21,69] Histologically, it is thought to represent the capsule of the nodule, but hyperplastic nodules that have no capsule often have this sonographic feature. The hypothesis that it represents compressed normal thyroid parenchyma seems acceptable, especially for rapidly growing thyroid cancers, which often have thick, irregular, and incomplete halos (see Fig. 19.15C) that are hypovascular or avascular on color Doppler scans. Color and power Doppler imaging demonstrates that the thin, complete peripheral halo, which is strongly suggestive of benign nodules, represents blood vessels coursing around the periphery of the lesion—the "basket pattern."

Margin. Benign thyroid nodules tend to have sharp, well-defined margins, whereas malignant lesions tend to have irregular, spiculated, or poorly defined margins. For any given nodule, however, the appearance of the outer margin cannot reliably predict the histologic features because many exceptions to these general trends have been identified, even if the association of spiculated margins with malignant nodules has been demonstrated as highly specific.[65]

Calcification. Calcification can be detected in about 10% to 15% of thyroid nodules, but the location and pattern of the calcification have a more predictive value in distinguishing benign from malignant lesions.[21] **Peripheral shell (eggshell) calcification,** although rarely present, has traditionally been considered a characteristic of a benign nodule (see Fig. 19.11). As recently reported, however, **thickened and interrupted peripheral calcifications,** particularly if associated with hypoechoic halo, have very high sensitivity for the diagnosis of malignant nature.[70,71] Scattered echogenic foci of calcification with or without associated acoustic shadows are more common. When these calcifications are **large and coarse** (usually related to fibrosis and degeneration), the nodule is more likely to be a benign nodule, with long disease duration. When the calcifications are **fine and punctate,** however, malignancy is more likely. Pathologically, these fine calcifications may be caused by psammoma bodies, typically seen in papillary cancers (see Figs. 19.14 and 19.15).

Medullary thyroid carcinomas often exhibit bright echogenic foci either within the primary tumor or within metastatically involved cervical lymph nodes.[33] The larger echogenic foci are usually associated with acoustic shadowing (see Fig. 19.25). Pathologically, these densities are caused by reactive fibrosis and calcification around amyloid deposits, which are characteristic of medullary carcinoma. In the appropriate clinical setting (e.g., MEN II syndrome, increased serum calcitonin level), the finding of echogenic foci within a hypoechoic thyroid nodule or a cervical node can be highly suggestive of **medullary carcinoma.**

Kakkos and colleagues[72] found a strong association between sonographically detected thyroid calcifications and thyroid malignancy, particularly in young patients or those with a solitary thyroid nodule. Patients younger than 40 with calcified nodules constitute a high-risk group, four times more likely to harbor thyroid malignancies than patients of the same age but without intranodular calcifications. Similarly, the presence of calcifications within a solitary nodule increases the incidence of malignancy. Therefore these patients must be further evaluated or followed.

According to multiple studies of the various sonographic features seen in thyroid nodules, **microcalcifications** show the highest accuracy (76%), specificity (93%), and positive predictive value (70%) for malignancy as a single sign. However, sensitivity is low (36%) and insufficient to be reliable for detection of malignancy.[29,65,72,73]

Doppler Flow Pattern. It is well known from histologic studies that most hyperplastic nodules are hypovascular lesions and are less vascular than normal thyroid parenchyma. On the contrary, most **well-differentiated thyroid carcinomas** are generally hypervascular, with irregular tortuous vessels and AV shunting (see Fig. 19.16). **Poorly differentiated and anaplastic carcinomas** are often hypovascular because of the extensive necrosis associated with their rapid growth (see Fig. 19.26).

Quantitative analysis of flow velocities is not accurate in differentiating benign from malignant nodules, so the only Doppler feature that may be useful is the distribution of vessels. With current technology, no thyroid nodule appears totally avascular or extremely hypovascular on color and power Doppler imaging. The two main categories of vessel distribution are nodules with peripheral vascularity and nodules with internal vascularity (with or without a peripheral component).[19,20,74] Studies have demonstrated that 80% to 95% of hyperplastic, goitrous, and adenomatous nodules display **peripheral vascularity,** whereas 70% to 90% of thyroid malignancies display **internal vascularity,** with or without a peripheral component.[3,5,74-76] In addition, the RI of intranodular vessels was significantly higher in malignant nodules. Consequently, the vascular pattern and RI have been reported to provide high sensitivity (92.3%) and specificity (88%) for the differentiation between benign and malignant tumors.[76] According to other reports, however, color Doppler imaging was not a reliable aid in the sonographic diagnosis of thyroid nodules.[77-79] With the current generation of Doppler instruments, which have extremely high sensitivity to blood flow, the overlapping of the two populations of nodules significantly increased, significantly reducing the diagnostic reliability of Doppler findings.[80]

Findings on gray-scale and color Doppler ultrasound become highly predictive for malignancy only when multiple signs are simultaneously present in a nodule.[59,60,65] In a series the combination of **absent halo sign plus microcalcifications plus intranodular flow pattern** achieved a 97.2% specificity for the diagnosis of thyroid malignancy.[59] In a large study the presence of at least one malignant sonographic finding (taller-than-wide shape, spiculated margin, marked hypoechogenicity, microcalcification and macrocalcification) had sensitivity of 83.3%, specificity of 74.0%, and diagnostic accuracy of 78.0%.[65] The presence of other findings (e.g., rim calcification) showed no statistical significance in the differentiation of a malignant nodule from a benign nodule. In a recent pictorial review based on the ultrasound classification of the British Thyroid Association, benign and malignant features of thyroid nodules have been highlighted and discussed.[81]

Thyroid Imaging Reporting and Data System

To facilitate interpretation and standardization among specialists, recently a standardized system for analyzing and reporting thyroid ultrasound and for risk stratification (Thyroid Imaging Reporting and Data System [TIRADS]) was proposed,[82,83] following the BIRADS system widely used for mammography.

According to this system, thyroid nodules can be categorized in six different risk groups according to their ultrasonographic characteristics:

- TIRADS 1: normal thyroid gland.
- TIRADS 2: benign conditions (0% malignancy), including simple cyst, spongiform nodules, and isolated macrocalcifications.
- TIRADS 3: probably benign nodules (<5% malignancy).
- TIRADS 4: suspicious nodules (5%-80% malignancy rate). Nodules in this group can be further categorized as 4a (malignancy 5%-10%) and 4b (malignancy 10%-80%).
- TIRADS 5: probably malignant nodules (malignancy > 80%).
- TIRADS 6: biopsy-proven malignant nodules.

Contrast-Enhanced Ultrasound and Elastography

Ultrasound elastography and contrast-enhanced ultrasound (CEUS) are advanced techniques for thyroid nodule characterization, with a substantial amount of research in the last decade. CEUS may depict the macrovascularization and microvascularization of thyroid nodules, providing both qualitative and quantitative evaluation. Nodules show heterogeneous enhancement depending on histology. Malignant nodules most frequently have isohypovascular contrast enhancement and slower wash-out than thyroid parenchyma, whereas benign nodules show hypervascular enhancement and a rimlike pattern.[84] A recent meta-analysis based on seven studies regarding CEUS evaluation of thyroid nodules concluded that CEUS, with pooled sensitivity, specificity, and positive and negative likelihood ratio (LR) of 0.853, 0.876, 5.822, and 0.195, respectively, is accurate to differentiate benign from malignant nodules,[85] but studies with larger sample sizes are needed to confirm these preliminary data.

Elastography has also been applied to the study of thyroid nodules. Elastography provides information on tissue elasticity, based on the premise that pathologic processes such as cancer alter the physical characteristics of the involved tissue. The purpose is to acquire two sonographic images (before and after tissue compression) and track tissue displacement by assessing the propagation of the beam, providing accurate measurement of tissue distortion.[86,87]

Elastography applied to the thyroid gland uses principally two different approaches according to the type of compression force (excitation) and elasticity evaluation: (1) freehand ultrasound strain elastography, with its qualitative (based on colorimetric maps and divided into four or five classes)[88] and semiquantitative variants (strain ratio value); and (2) quantitative approach with transducer-induced high acoustic pulse and measures of the speed of the shear wave generated (shear wave elastography [SWE]). SWE can be performed using acoustic radiation force impulse (ARFI) technology either in a small region of interest (ROI) (point–shear wave elastography, p-SWE) or over a larger field of view using color-coding to visually display the stiffness values (two-dimensional shear wave elastography [2D-SWE]). An additional semiquantitative variant of strain elastography uses the internal (physiologic) pulsation of the carotid artery (*in vivo* quasi-static elastography). In this approach, no external

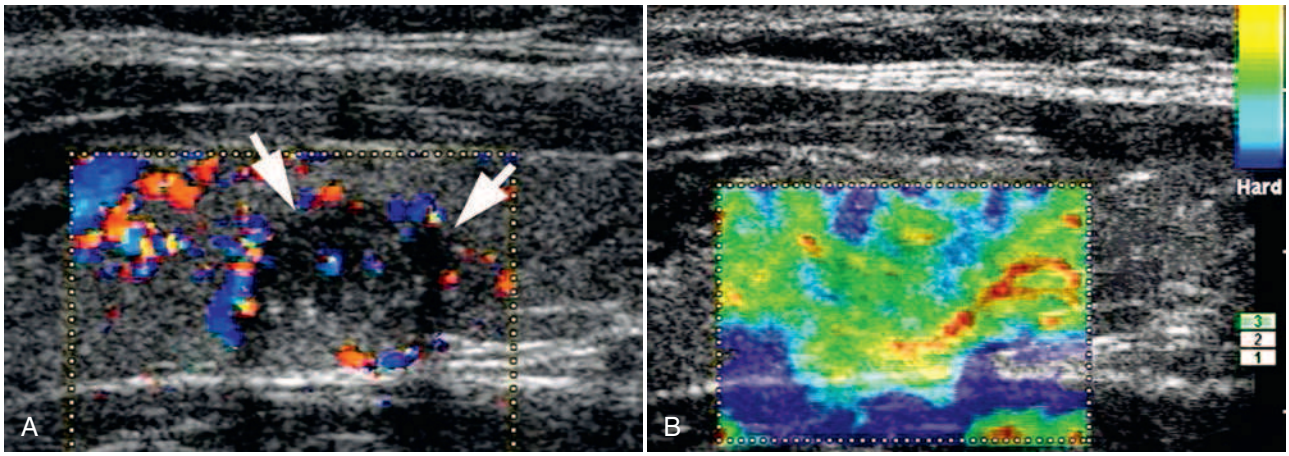

FIG. 19.31 Use of Ultrasound Elastography on Thyroid Nodule: Benign Nodular Hyperplasia (Pattern 1). (A) Conventional longitudinal B-mode sonogram with color Doppler shows a hypoechoic solid nodule *(arrows)* with peripheral halo, internal comet-tail artifacts, and perilesional blood flow pattern. **(B)** Longitudinal ultrasound elastography at same location demonstrates a "soft" color pattern.

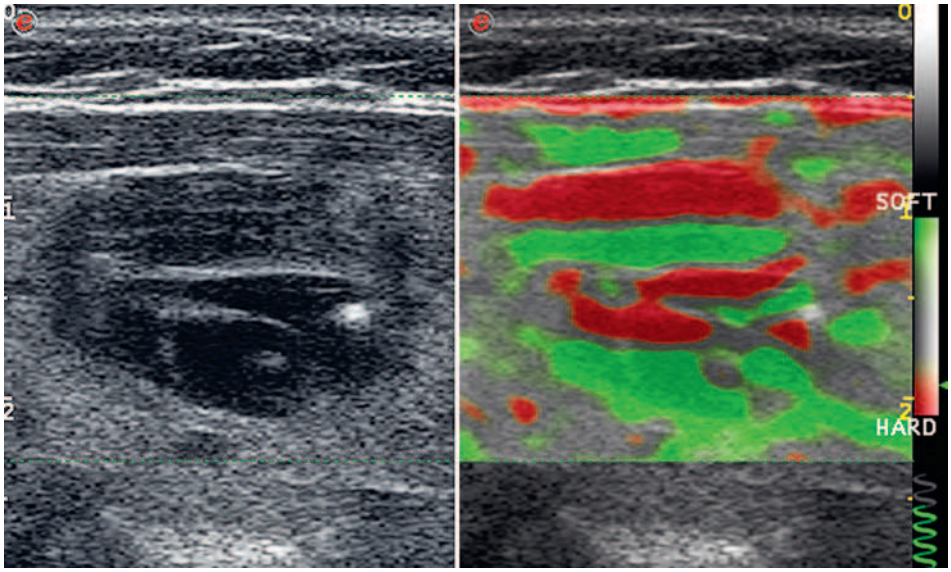

FIG. 19.32 Use of Ultrasound Elastography on Thyroid Nodule: Benign Nodular Hyperplasia With Cystic Changes (Pattern 2). Left half of image shows a cystic, poorly defined nodule on conventional B-mode gray-scale sonogram. Right half of elastogram of the nodule shows a predominantly elastic *(green)* pattern with a few internal anelastic bandlike areas.

pressure is required and pulsations of the carotid artery induce the displacement necessary to assess tissue elasticity.[89] Several papers and recent meta-analyses show very interesting results of qualitative and quantitative elastography.[90-93]

Four elastographic patterns have been classified as follows[86,87,94,95]:

Pattern 1: Elasticity in the whole nodule (Fig. 19.31)

Pattern 2: Elasticity in a large part of the nodule, with inconstant appearance of anelastic areas (Fig. 19.32)

Pattern 3: Constant presence of large unelastic areas at the periphery (Fig. 19.33)

Pattern 4: Uniformly unelastic (Fig. 19.34)

In literature reports, 78% to 100% of benign nodules had a score of 1 to 2, whereas 88% to 96% of malignant nodules had a score of 3 to 4. Sensitivity was 82% to 97%, specificity 78% to 100%, positive predictive value 64% to 81%, and negative predictive value 91% to 98%.[87-98] Specificity and sensitivity are relatively independent of the nodule size. However, the best accuracy is achieved in small nodules and when FNA biopsy is nondiagnostic or suggests a follicular lesion, provided the nodule is solid and devoid of coarse calcifications. Both strain elastography and SWE should be performed as additional tools to conventional ultrasound and to guide follow-up of lesions previously diagnosed as benign at FNA because multiparametric sonographic assessment can increase the accuracy of the ultrasound evaluation (Fig. 19.35), avoiding unnecessary biopsies or surgery.

Guidance for Needle Biopsy

Sonographically guided percutaneous needle biopsy of cervical masses has become an important technique in many clinical situations. Its main advantage is that it affords continuous real-time visualization of the needle, a crucial requirement for the biopsy of small lesions. Most physicians use a 25-gauge needle, employing either capillary action or minimal suction with a

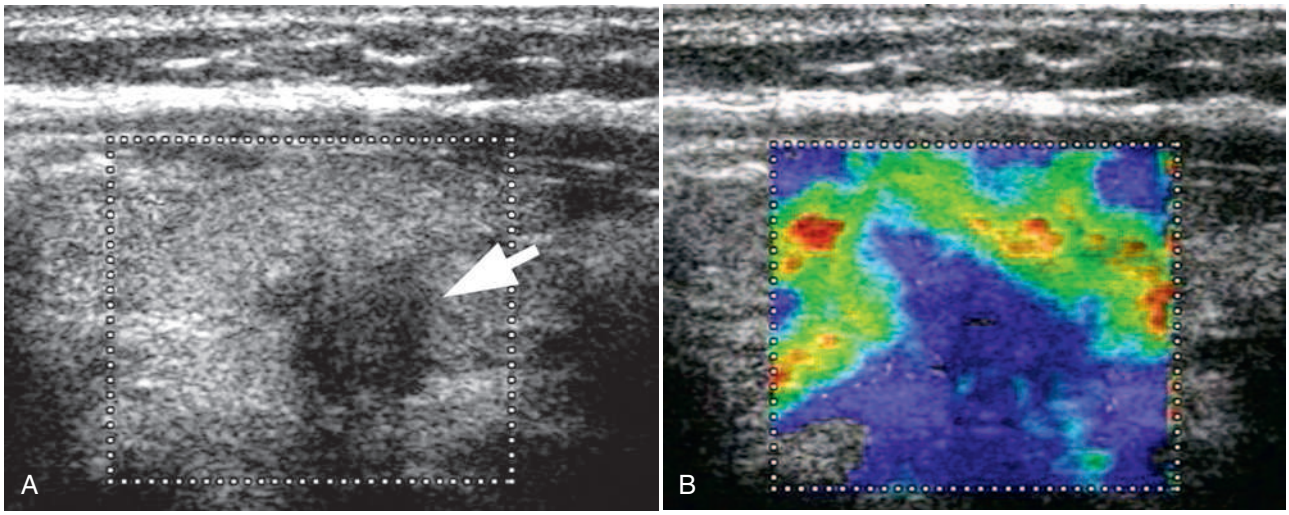

FIG. 19.33 Use of Ultrasound Elastography on Thyroid Nodule: Papillary Thyroid Carcinoma (Pattern 3). (A) Conventional longitudinal B-mode sonogram demonstrates a hypoechoic papillary carcinoma with irregular, poorly defined margins *(arrow)*. **(B)** Ultrasound elastography shows a predominantly inelastic *(blue)* pattern with a few small, elastic *(green)* areas in the posterior portion.

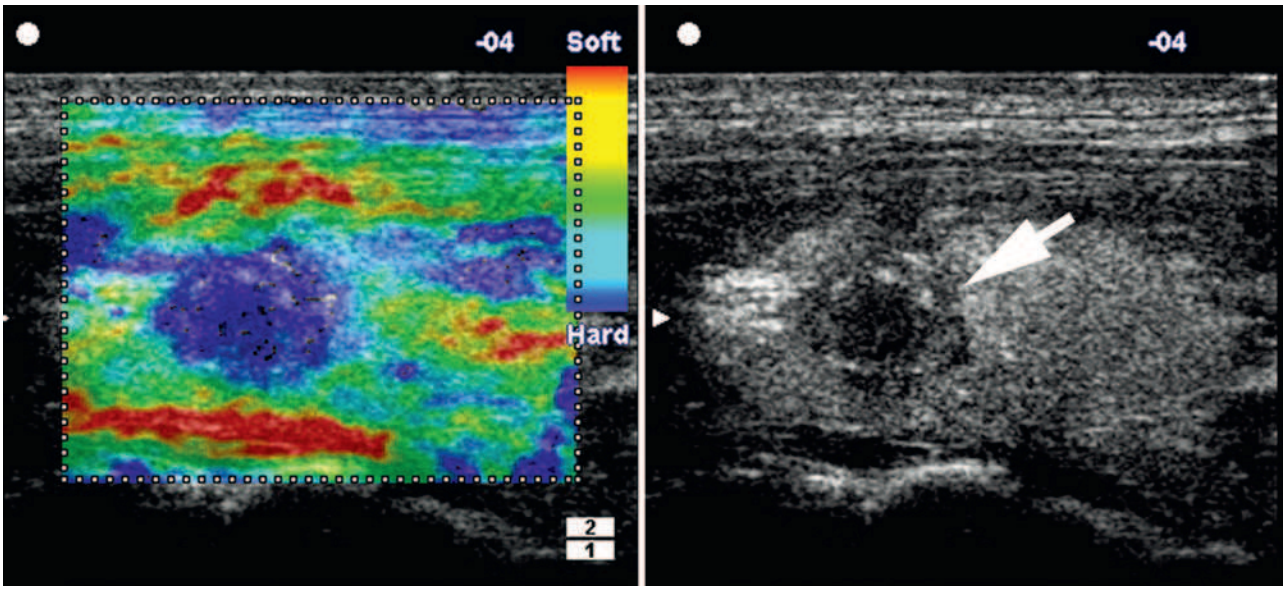

FIG. 19.34 Use of Ultrasound Elastography on Thyroid Nodule: Papillary Thyroid Carcinoma (Pattern 4). Right half of image shows a hypoechoic solid nodule *(arrow)* with microcalcifications, typical of papillary carcinoma. Left half of image shows that on ultrasound elastography, the nodule is almost entirely inelastic *(blue)* pattern 4. The small, elastic areas in the posterior portion of the lesion are artifacts caused by pulsations of the underlying carotid artery.

syringe (Video 19.6). There are reports of the usefulness of large-gauge, automated cutting needles for improved pathologic diagnosis.[99,100] Sonographic guidance is generally suggested for all thyroid aspiration biopsies, but it is strongly recommended in three settings. The first situation is the questionable or inconclusive physical examination in which a nodule is suggested but cannot be palpated with certainty. In these patients, sonography is used to confirm the presence of a nodule and to provide guidance for accurate biopsy. The second setting involves patients at high risk for thyroid cancer with a normal gland on physical examination but a sonographically demonstrated nodule. This group includes patients with a previous history of head and neck irradiation, a positive family history of MEN II syndrome, or a previous subtotal thyroid resection for malignancy. The third situation for ultrasound FNA guidance involves patients who have had a nondiagnostic or inconclusive biopsy performed under direct palpation. Usually about 20% of specimens obtained by palpation guidance are cytologically inconclusive, most often because of the aspiration of nondiagnostic fluid from cystic lesions. Sonography may be used in these cases to guide the needle selectively into a solid portion of the mass. The diagnostic accuracy of FNA is very high, with sensitivity approximately 85% and specificity of 99% in centers with extensive experience performing these procedures.[41-48,101]

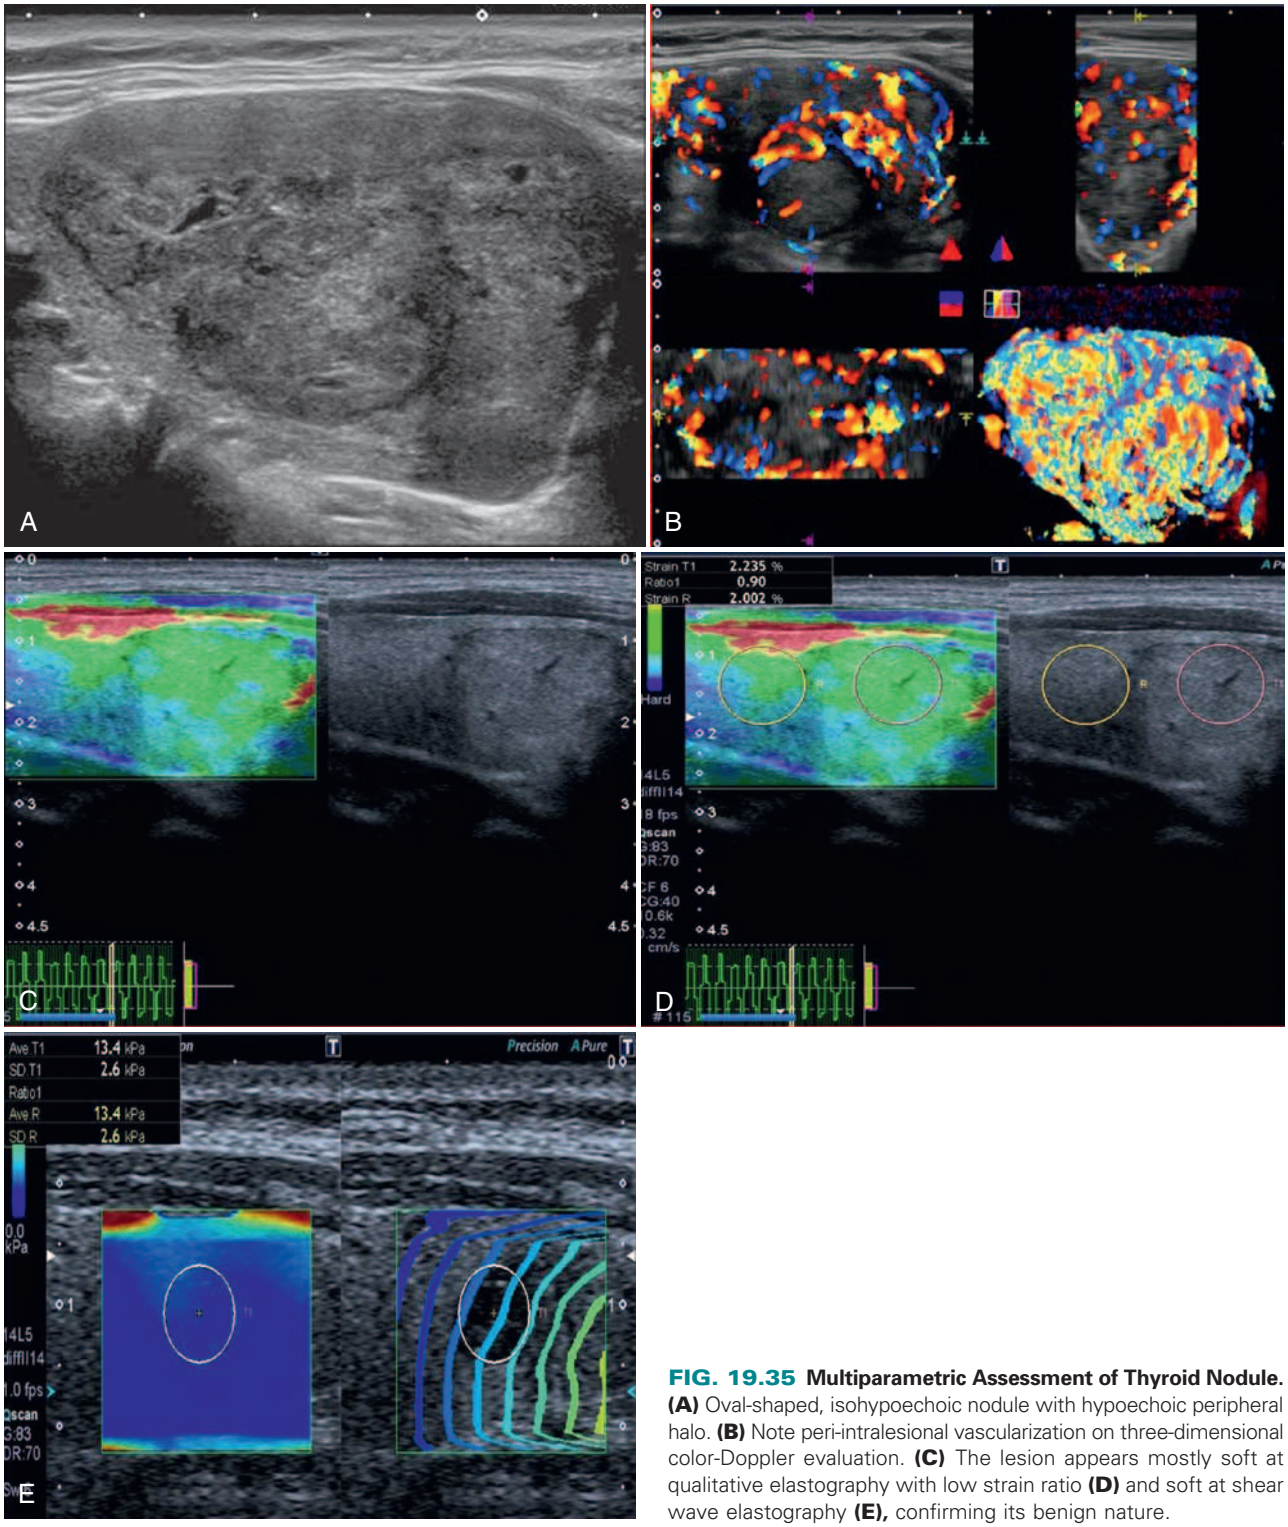

FIG. 19.35 Multiparametric Assessment of Thyroid Nodule. **(A)** Oval-shaped, isohypoechoic nodule with hypoechoic peripheral halo. **(B)** Note peri-intralesional vascularization on three-dimensional color-Doppler evaluation. **(C)** The lesion appears mostly soft at qualitative elastography with low strain ratio **(D)** and soft at shear wave elastography **(E),** confirming its benign nature.

In patients who have undergone a previous thyroid resection for carcinoma, sonographically guided FNA has become an important method in the early diagnosis of recurrent or metastatic disease in the neck (Fig. 19.36). In patients who have undergone hemithyroidectomy for a benign nodule, with the detection of one or more foci of occult malignant tumor in the surgical specimen, ultrasound evaluation of the contralateral lobe is warranted to exclude the existence of a residual nodule.

Cervical lymph nodes, both normal and abnormal, can be readily visualized by high-resolution sonography. They tend to lie along the internal jugular chain, extending from the level of the clavicles to the angle of the mandible, or to be in the region of the thyroid bed. **Benign cervical lymph nodes** usually have

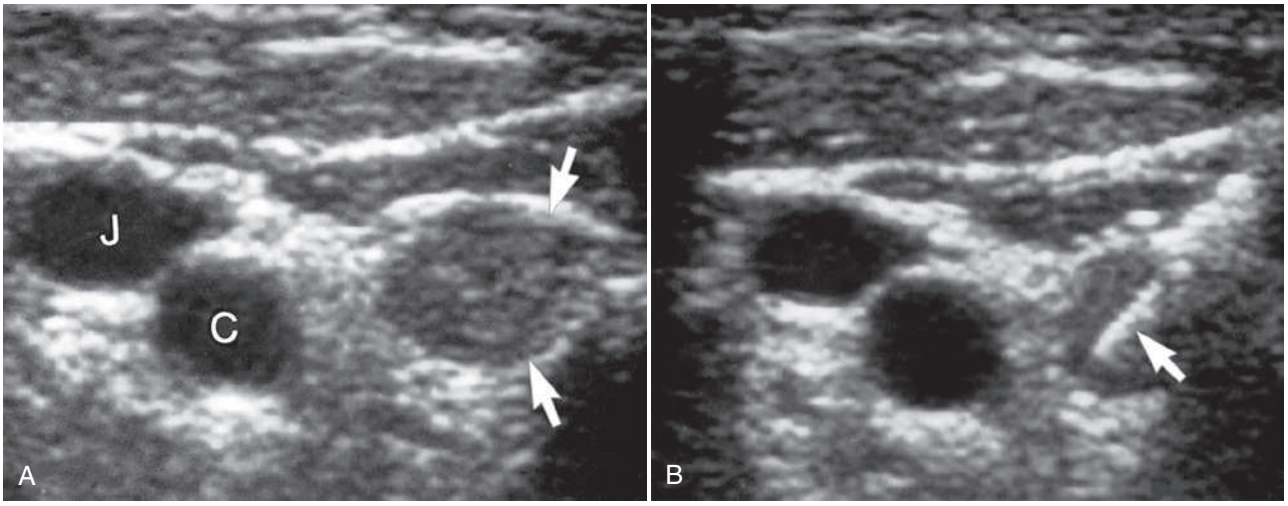

FIG. 19.36 Biopsy of Recurrent Papillary Carcinoma in Thyroid Bed After Thyroidectomy. (A) Transverse scan of right side of the neck shows a 1-cm solid mass *(arrows)* medial to carotid artery *(C)* and jugular vein *(J)*. **(B)** Sonographically guided fine-needle aspiration with needle seen within mass *(arrow)*.

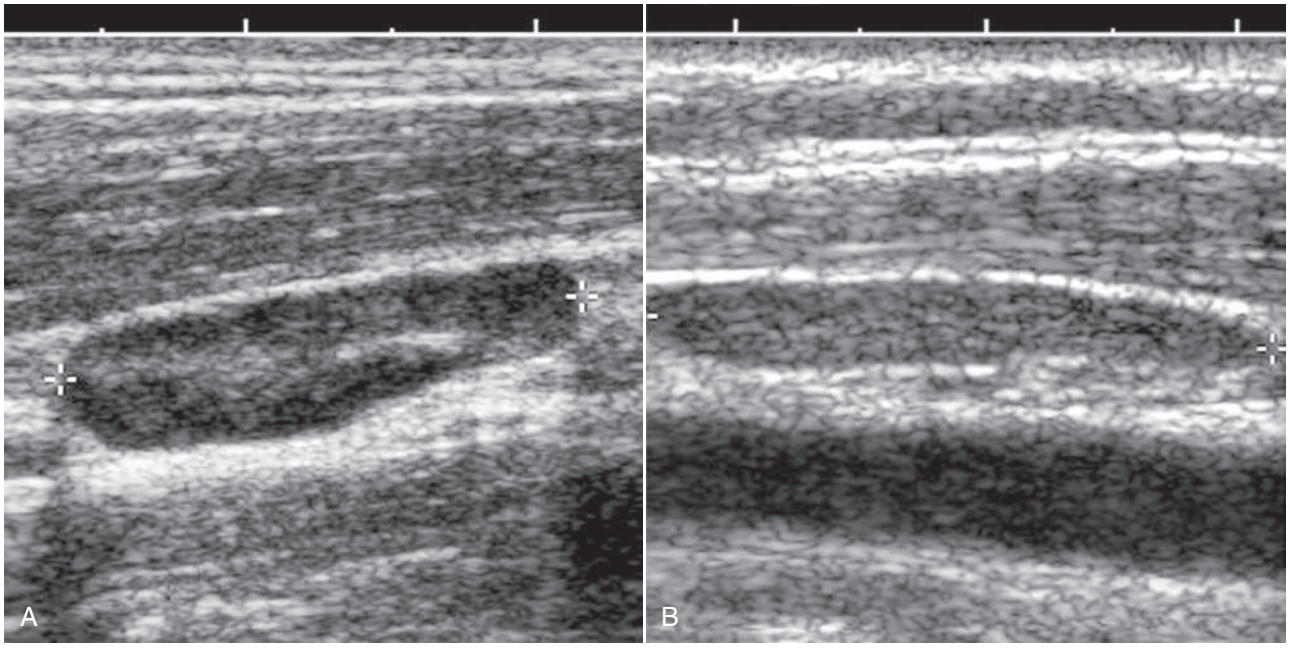

FIG. 19.37 Normal Cervical Lymph Nodes: Elongated Shape Is Typical. Longitudinal images. **(A)** Slender node *(calipers)* is homogeneous except for central echogenic hilum. **(B)** Normal homogeneous slender node *(calipers)* near the jugular vein without a visible hilum.

a slender, oval shape and often exhibit a central echogenic band that represents the fatty hilum (Fig. 19.37). **Malignant lymph nodes,** on the other hand, are more often located in the lower third of the neck and are usually rounder and have no echogenic hilum, presumably because of obliteration by tumor infiltration (see Fig. 19.17). Although often hypoechoic, malignant nodes may be diffusely echogenic, may be heterogeneous, and may contain calcifications and cystic changes. Calcifications can be seen in nodal metastases from papillary and medullary thyroid malignancies, and cystic changes are very characteristic in metastatic papillary carcinoma.[102] In addition, Lyshchik and colleagues[103] reported that with use of elastography, cervical lymph nodes with a strain index greater than 1.5 are usually malignant (85% sensitivity and 98% specificity).

When the differentiation between benign and malignant lymph nodes is not feasible with sonography, FNA under sonographic guidance is often used. In our experience, biopsy can be done with a high degree of accuracy in cervical nodes that are as small as 0.5 cm in diameter.[58] In addition to cytologic analysis, the "wash-out" of the aspirate can be sent for thyroglobulin assay, which is highly accurate for the diagnosis of metastatic papillary and follicular cancer.[104]

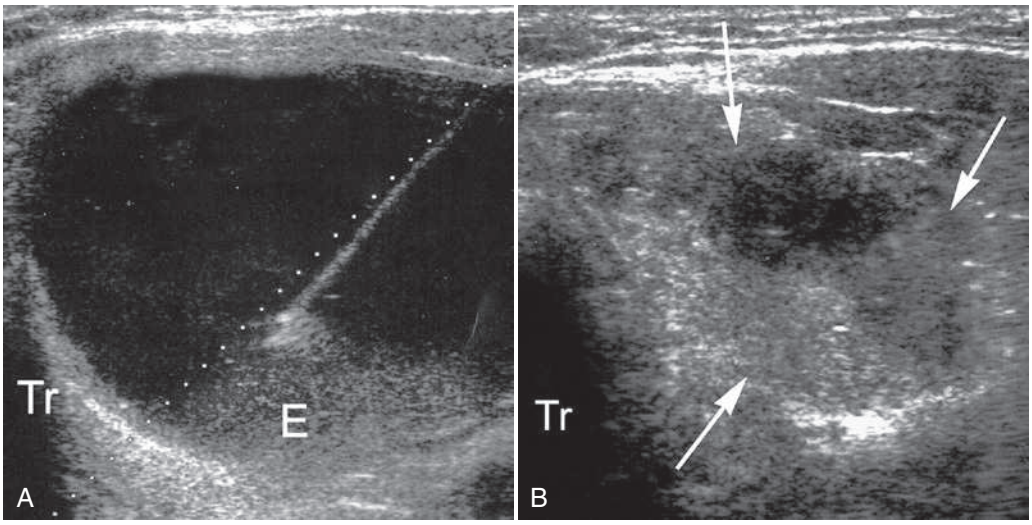

FIG. 19.38 Ethanol Treatment of Large Colloid Cyst. (A) Transverse image shows large colloid cyst with needle. Injected ethanol appears as low-level echoes *(E). Tr,* Tracheal air shadow. **(B)** Follow-up image 1 month later shows that the large cystic component has mostly resolved, leaving a slightly enlarged residual gland *(arrows).*

Guidance for Percutaneous Treatment

Ethanol Injection of Benign Cystic Thyroid Lesions. Lesions containing fluid (usually colloid cysts) account for 31% of thyroid nodules found on sonography, but less than 1% of these are pure epithelial-lined cysts.[5] Management of cystic thyroid nodules relies first on FNA biopsy to rule out malignancy. Simple aspiration may result in permanent shrinkage of the lesion, but the recurrence rate after aspiration is high, 10% to 80%, depending on the number of aspirations and the cyst volume; the greater the volume, the greater the recurrence risk.[105,106]

Prevention of cyst recurrence requires intranodular injection of a sclerosing agent. Ethanol has been used successfully for the past 20 years, with accurate placement using real-time sonographic guidance. Ethanol is distributed within tissues by diffusion and induces cellular dehydration and protein denaturation, followed by coagulation necrosis and reactive fibrosis. The cyst fluid is completely aspirated with a fine needle, and then sterile 95% ethanol is injected under ultrasound guidance, in an amount varying from 30% to 60% of the aspirated fluid[107,108] (Fig. 19.38). Subsequently, ethanol can be either reaspirated in 1 to 2 days or permanently left in place. In large cystic cavities, this procedure can be repeated once or twice after several weeks. The volume reduction of the cyst is more substantial if a larger amount of ethanol is injected; thus a relationship exists between the volume of ethanol instilled and the ablative effect.

Ethanol injection is usually well tolerated by the patient. Transient mild to moderate local pain is the most common complication, a result of ethanol leaking into subcutaneous tissue. Rare complications of **ethanol sclerotherapy** are transient hyperthyroidism, hoarseness, hematoma, and dyspnea.

Reported success rates (total disappearance or volume reduction greater than 70% of initial volume) of this treatment range from 72% to 95% at long-term follow-up,[107-110] achieved without a change in thyroid function. Ethanol injection is considered the percutaneous treatment of choice for cystic lesions of the thyroid gland at some institutions.

Ethanol Injection of Autonomously Functioning Thyroid Nodules. Thyroid nodules with independent secretory and proliferative activity are defined as **autonomous** thyroid nodules. On radionuclide scans, these nodules appear "hot," in contrast to the low or absent extranodular uptake, likely related to the avidity of iodine trapping and the degree of thyroid hyperfunction. The patient's condition may be toxic or nontoxic, depending on the amount of thyroid hormones secreted. The level of hyperthyroidism is usually proportional to the nodule volume. Therefore autonomous thyroid nodules can cause a range of functional abnormalities, from euthyroidism (compensated) to subclinical hyperthyroidism (pretoxic) and clinical hyperthyroidism (toxic).

The currently available treatments of autonomous nodules include surgery and radioactive iodine therapy. Surgery is effective but has the disadvantage of anesthesiology and surgical risks. Radioactive iodine therapy may require repeated sessions before achieving euthyroidism.

Percutaneous ethanol injection under ultrasound guidance, first proposed by Livraghi and colleagues[111] in 1990, is an alternative therapy. The diffusion of ethanol causes direct damage. Cell dehydration is followed by immediate coagulation necrosis and subsequent fibrotic changes. Sterile 95% ethanol is injected through a 21- or 22-gauge spinal needle with closed conical tip and three terminal side holes. This allows the injection of a large amount of ethanol, reduces the total number of sessions, increases the treated volume, and minimizes the risk of laryngeal nerve damage because of the lateral diffusion of ethanol. Several treatment sessions are needed (usually four to eight), typically performed at 2-day to 2-week intervals. The total amount of ethanol delivered is usually 1.5 times the nodular volume.

Color Doppler imaging and, if available, contrast-enhanced sonography are extremely valuable to assess the results of ethanol injection. The reduction (up to complete disappearance) of vascularity and contrast enhancement is directly related to the ethanol-induced necrosis. In addition, residual vascularity after

treatment can be targeted to achieve complete ablation.[112] **Complete cure** is defined as normalization of serum free thyroid hormones and serum thyrotropin and scintigraphic reactivation of extranodular tissue. **Partial cure** occurs when serum free thyroid hormones and thyrotropin levels are normalized, but the nodule is still visible on scintigraphy.[111,113]

Percutaneous ethanol injection is generally well tolerated. The common side effect is a brief burning sensation or moderate pain at the injection site, radiating to the mandibular or retroauricular regions. The slow withdrawal of the needle and use of the multihole needle reduce this side effect. In some patients with larger nodules, when the amount of necrosis is high, fever lasting 2 to 3 days develops after the initial treatments. The only important complication is transient damage of the recurrent laryngeal nerve, reported in 1% to 4% of cases.[80,94] Nerve damage is induced chemically or by compression. Full nerve recovery is likely because, in contrast to surgery, there is no anatomic nerve interruption.

Efficacy of response is inversely proportional to the nodule volume; the smaller the nodule, the more complete the response. Complete cure is achieved in 68% to 100% of pretoxic nodules and 50% to 89% of toxic nodules.[111-116] Ultrasound-guided percutaneous ethanol injection is the treatment of choice in older patients with contraindications to surgery, in pregnant patients, and in patients with large autonomous nodules (>40 mL), in addition to medical treatment to obtain euthyroidism more rapidly.

More recently, the use of **radiofrequency ablation** (RFA) with either internally cooled or multipronged electrodes has been reported in the treatment of autonomously functioning thyroid nodules, mostly for large nodules causing compressive symptoms. A significant decrease in size (≥50%) of the treated lesions was reported in all cases, and complete normalization of thyroid function was achieved in 24% to 44% of patients.[117,118] Also **laser ablation** has been used in the treatment of large toxic nodular goiter and has been proposed as combined treatment with ^{131}I to fasten the volumetric reduction and reduce the radioactive dose administered to the patient.[119]

Percutaneous Treatment of Solitary Solid Benign "Cold" Thyroid Nodules. In patients with solitary solid, biopsy-proven, benign "cold" thyroid nodules, ethanol injection, interstitial laser photocoagulation, and RFA have been proposed as ultrasound-guided percutaneous treatments, to achieve marked shrinkage of the nodule to a small, fibrous-calcified mass. With percutaneous ethanol injection, a mean nodule volume reduction of 84% (range, 73%-98%) has been reported after 3 to 10 treatments.[120] With low-power interstitial laser photocoagulation, mean thyroid nodule volumes decreased by 40% to 50% after 6 months, with improvement of local clinical symptoms in approximately 80% of patients and no side effects.[121-124]

RFA with internally cooled electrodes and low power (20-70 W) has also been employed for the treatment of benign cold thyroid nodules, with only one ablation session for a single nodule. A significant volume reduction of the treated nodules without adverse effects has been reported at follow-up, but studies with longer follow-up are needed to assess efficacy and safety.[125,126]

Treatment of Cervical Nodal Metastases From Papillary Carcinoma. RFA, laser ablation, and ethanol injection have been proposed for the treatment of recurrent disease and metastatic lymph nodes in patients who have previously undergone surgery. Percutaneous ethanol injection is an effective and safe method of treatment for limited lymph node metastasis from thyroid cancer. In a 2002 report from the Mayo Clinic, 14 patients who had undergone thyroidectomy for PTC had 29 metastatic lymph nodes on follow-up sonographic imaging.[127] Each node was treated with direct injection of ethanol using ultrasound guidance. Follow-up examination at 2 years showed a 95% decrease in the size of treated nodes. There were no major complications (e.g., recurrent laryngeal nerve palsy, bleeding) in the Mayo Clinic series or in 187 patients with papillary cancer nodes treated with percutaneous ethanol injection at the Ito Hospital in Japan.[128,129]

The percutaneous ethanol injection technique is similar to the method used for percutaneous ethanol therapy of parathyroid adenomas. A 25-gauge needle is attached to a tuberculin syringe containing up to 1 mL of 95% ethanol. The needle is placed with ultrasound guidance using a freehand technique that allows fine positioning of the needle within the node (Fig. 19.39). Each node is injected in several sites. The portion of the node that is injected becomes hyperechoic owing to the formation of microbubbles of gas. After usually less than 1 minute, the hyperechoic zone decreases. The needle is repositioned in the node, and several injections are made until the node appears adequately treated. Patients may experience mild to moderate pain at injection, but this resolves within minutes. For small nodes about 5 mm in diameter, a single injection may be sufficient. For larger nodes, a reinjection the following day is needed for complete therapy. Follow-up ultrasound at 3 to 6 months will show a reduction in size of the node in most cases. If blood flow was visualized in the node before therapy, it will often be substantially decreased or absent on follow-up. If on follow-up the size of the node has not decreased, or if there is residual blood flow on power Doppler examination, a repeat injection is performed.

Thermal ablation of nodal recurrent thyroid cancer has also been tested, with both RFA and laser ablation. In particular, laser ablation seems to be particularly promising in the treatment of nodal metastases from thyroid carcinoma; it is performed using thin (21-gauge) needles, and the energy can be delivered with great precision, allowing avoidance of damage to critical surrounding structures.[130-132]

The Incidentally Detected Nodule

Although using high-frequency sonography to detect small, nonpalpable thyroid nodules may be beneficial in certain clinical settings, it may actually introduce problems in other situations. What should one do with the many thyroid nodules detected incidentally during carotid, parathyroid, and other sonographic examinations of the neck? The goal should be to avoid extensive and costly evaluations in the majority of patients with benign disease, without missing the minority of patients who have clinically significant thyroid cancer. In our literature review, the incidence of thyroid nodules in patients can be estimated by method of detection: autopsy (49%), sonography (47%), palpation

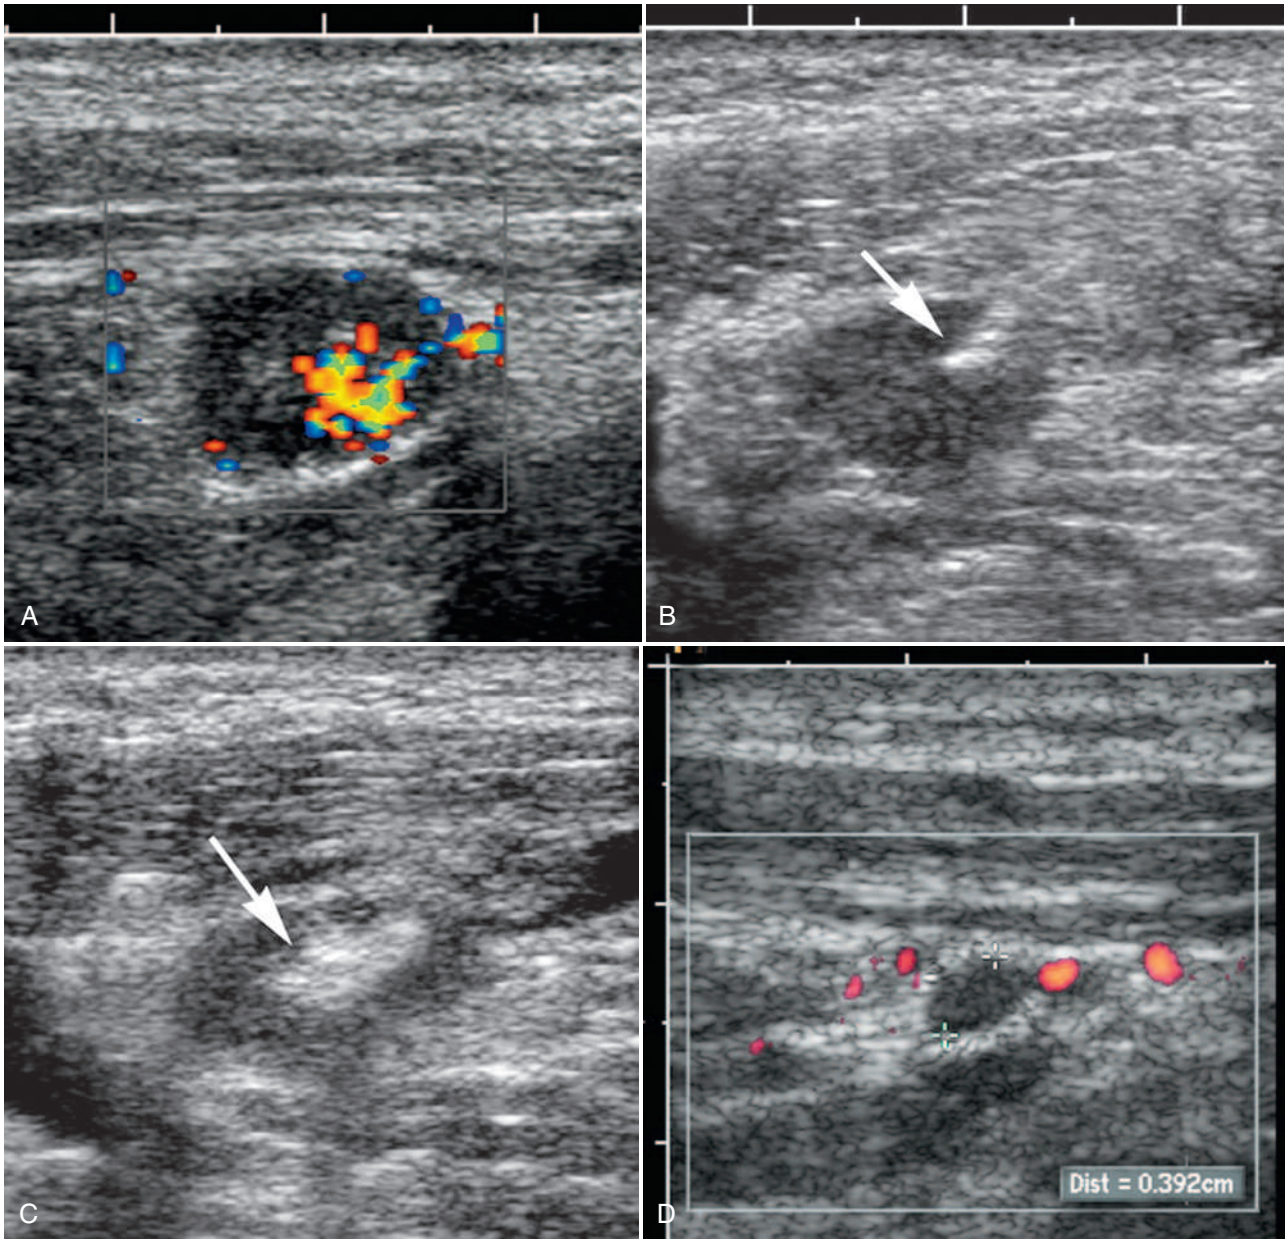

FIG. 19.39 Ethanol Treatment of Thyroid Metastasis in a Cervical Lymph Node. (A) Longitudinal color Doppler image shows a round, 1.6-cm, pathologic-appearing node with moderate vascularity. **(B)** The tip of a 25-gauge needle *(arrow)* is in the lymph node. **(C)** The ethanol effect is visible as a focal hyperechoic area *(arrow)* at injection and is caused by microbubbles that form from the interaction of ethanol with the tissues. This hyperechoic appearance will last from several seconds to several minutes and will be followed by a normal or near-normal appearance. During the injection, the hyperechogenicity is a useful marker to identify the areas treated. **(D)** Follow-up power Doppler image 6 months after ethanol injection shows that the lymph node has dramatically decreased in size (0.4 cm) and is no longer vascular. No further therapy is needed except to follow every 6 to 12 months to confirm lack of change.

(7%), occult cancer at autopsy (2%), and annual cancer incidence (0.005%).

Understanding the challenge of selecting nodules for workup requires background information in the following four areas:

1. The epidemic of thyroid nodules has resulted mostly from ultrasound imaging.

On physical palpation, an estimated 7% of the North American population has at least one thyroid nodule. In contrast, there is an "epidemic" of thyroid nodules detected by ultrasound, with studies showing up to 67% of patients having a nodule.[133] Our study of 1000 consecutive patients imaged with 10-MHz ultrasound transducers showed a prevalence of 41%.[134] This study also showed an increasing prevalence with advancing age, which parallels autopsy rates of prevalence compared with patient age (Fig. 19.40).

From these studies it is reasonable to estimate that more than 100 million Americans have thyroid nodules on ultrasound. The problem of the high rate of incidentally detected thyroid nodules, the so-called "incidentaloma," has led some to ask if it is "time to turn off the ultrasound machines."[135] The morbidity and cost

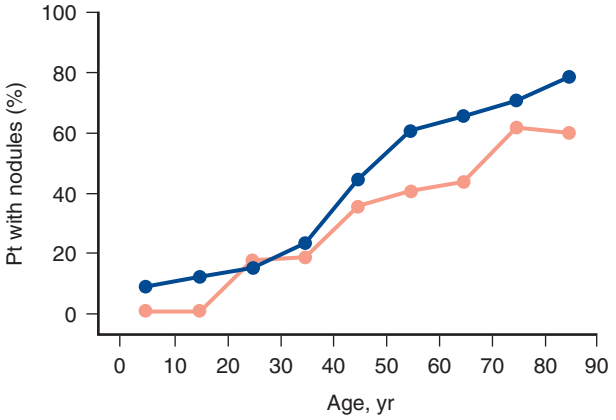

FIG. 19.40 Prevalence of Thyroid Nodules on Autopsy and Sonography. Autopsy *(blue circles)* revealed thyroid nodules on average in 49% of patients in 1955, and sonography *(orange circles)* detected thyroid nodules in 41% in 1985, with both shown here as a function of patient age. (With permission from Horlocker T, Hay I, James E. Prevalence of incidental nodular thyroid disease detected during high-resolution parathyroid ultrasonography. In: Medeiros-Neto G, Gaitan E, editors. Frontiers in thyroidology. New York: Plenum; 1986. p. 1209-1312.[134])

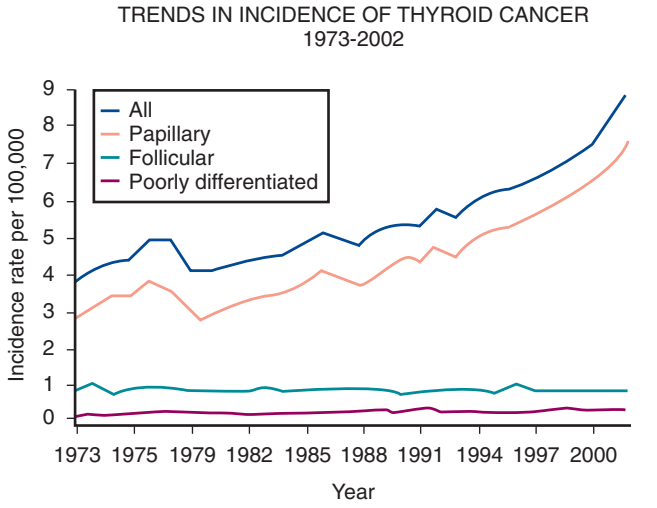

FIG. 19.41 Thyroid Cancer: Incidence. Graph shows the increasing incidence of thyroid cancer in North America during the past three decades. Note that the type of thyroid malignancy is almost entirely papillary carcinoma. The increasing incidence results from the increased rate of detection by diagnostic imaging methods such as ultrasound, rather than from an increase in the true occurrence of thyroid cancer. (Modified from Davies L, Welch HG. Increasing incidence of thyroid cancer in the United States, 1973-2002. JAMA. 2006;295[18]: 2164-2167.[138])

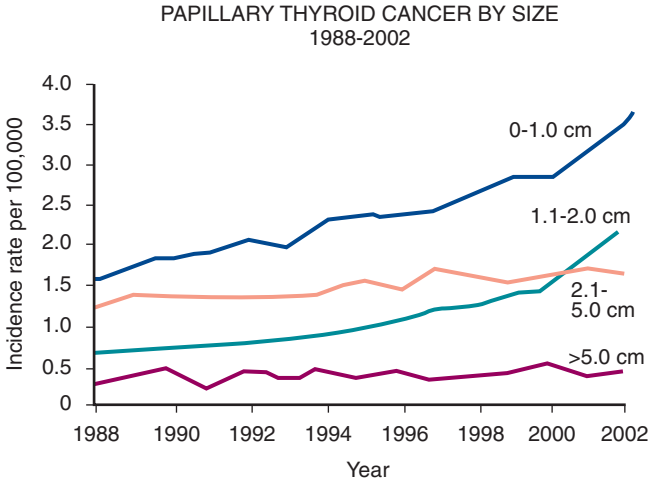

FIG. 19.42 Thyroid Cancer: Incidence by Size of Tumor. Note that the increased incidence of thyroid carcinoma is primarily the result of the detection of smaller tumors. (Adapted from Davies L, Welch HG. Increasing incidence of thyroid cancer in the United States, 1973-2002. JAMA. 2006;295[18]:2164-2167.[138])

to patients and society from workup of these nodules may far outweigh the benefit of detecting an occult thyroid cancer, because the vast majority of thyroid cancers behave in a benign manner. Specifically, patients with PTC have a 99% 10-year survival and approximately a 95% overall 30-year survival.[55,136]

2. The incidence of thyroid cancer is increasing.

Over 50 years ago, pathologists reported that clinically insignificant thyroid cancer was a common finding at autopsy. In the 1980s, Harach and colleagues[137] studied thinly sectioned thyroid glands at autopsy and found that 36% had occult thyroid cancer. They stated that had they sectioned the glands even more finely, almost every person would harbor a thyroid cancer. They concluded that occult PTC was a "normal" finding at autopsy.

Over the last three decades, the reported incidence of thyroid cancer in North America has more than doubled.[138] This raises the question of whether the increase represents a real increased incidence of thyroid cancer or is simply a result of an increased rate of detection by diagnostic imaging methods such as ultrasound. Analyzing the data, Davies and Welch[138] found that the increased incidence resulted from increased detection of subclinical disease rather than from an increase in the true occurrence of thyroid cancer. Their work showed that PTC accounts for virtually the entire increase in incidence (Fig. 19.41). They also showed that the increased rate of detection is caused by small, subclinical thyroid cancer (Fig. 19.42). Furthermore, although the prevalence of thyroid cancer more than doubled over 30 years, the mortality rate remained unchanged (Fig. 19.43). According to Ross,[139] "Considering the anxiety, costs and complications suffered by many of these patients, one can reasonably question the benefits of increased cancer detection."

3. What are the costs of frequent use of FNA biopsy for management of incidentally detected thyroid nodules?

If FNA biopsy were used as the automatic next step after nodule detection, the costs to patients and society would be great. Whereas FNA biopsy is considered the "reference standard" for nodule diagnosis, it is an imperfect technique for many reasons. First, the results are nondiagnostic in 10% to 20% of cases.[101,140] Second, there is a false-negative rate of 3% to 5%.[141] Third, interpretative skills vary widely regarding cytopathology of the thyroid nodule. Unfortunately, in less experienced centers, the report of "follicular cells are present, cannot exclude follicular neoplasm" occurs more frequently than in centers with greater interpretive experience. This report typically leads to the need for surgical excision. Given these considerations, an estimated 18% of all patients who have FNA biopsy ultimately undergo

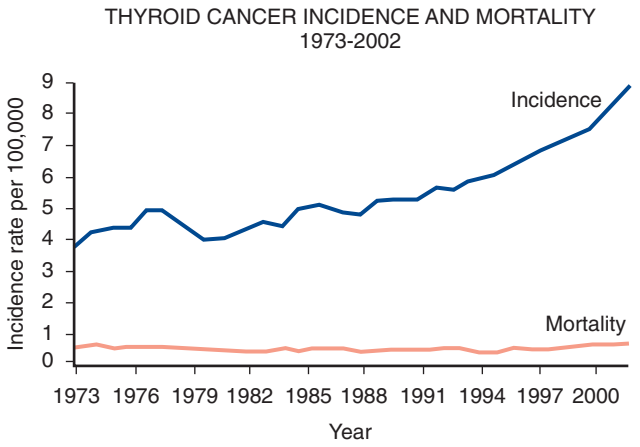

FIG. 19.43 Thyroid Cancer: Incidence Versus Mortality. Although the rate of occurrence of thyroid cancer has more than doubled in the last 30 years, the mortality rate is unchanged over that period. (Adapted from Davies L, Welch HG. Increasing incidence of thyroid cancer in the United States, 1973-2002. JAMA. 2006;295[18]:2164-2167.[138])

surgery for nodule excision based on positive, suspicious, or nondiagnostic results, and most of these nodules are benign.[101,142,143] Of these surgical patients, only 15% to 32% have cancer.[101,142] Therefore the majority of patients who undergo surgery for thyroid nodule excision will have had an operation for clinically insignificant, benign nodular disease.

The potential cost of the FNA biopsy workup of these nodules must be considered. For discussion purposes, assume that 1 million of the estimated 300 million people in the United States undergo a high-frequency ultrasound thyroid examination, and that one or more thyroid nodules are detected in approximately 40%. Therefore 400,000 people will have one or more thyroid nodules detected by ultrasound imaging. Assuming a cost of approximately $1500 for an ultrasound-guided FNA and cytologic analysis, $600 million could theoretically be spent to exclude or detect thyroid cancer in this group. If 18% of these FNA biopsies result in suspicious or nondiagnostic results, 72,000 procedures could occur at a cost of almost $20,000 each, for an additional cost of $1.44 billion. Finally, approximately 5%, or almost 3600 patients, could experience significant postsurgical morbidity, including hoarseness, hypoparathyroidism, and long-lasting pain.[144] Clearly, this type of aggressive management of thyroid nodules would entail massive health care expenditures and could have an extremely negative clinical impact.[145]

4. Which incidentally discovered nodules should be pursued? Because of the many nodules detected on ultrasound, the therapeutic approach should allow most patients with clinically significant cancers to go on to further investigations. More important, it should allow most patients with benign lesions to avoid further costly, potentially harmful workup. With this goal in mind, many practices, including ours, have found that it is both impractical and imprudent to pursue the diagnosis for most of the small nodules detected incidentally on ultrasound. If technically possible, we usually obtain FNA biopsy of lesions that exhibit sonographic features strongly associated with malignancy, such as marked hypoechogenicity, taller-than-wide shape, and thick irregular margins, as well as lesions containing microcalcifications.

Evaluation of Nodules Incidentally Detected by Sonography

Sonographic Findings	Follow-Up
Nodules < 1.5 cm	Followed by palpation at next physical examination
Nodules > 1.5 cm	Evaluation, usually by fine-needle aspiration
Nodules that have malignant features (marked hypoechogenicity, taller-than-wide shape, thick irregular margins, and/or calcifications or microcalcifications)	Evaluation by fine-needle aspiration

DIFFUSE THYROID DISEASE

Several thyroid diseases are characterized by diffuse rather than focal involvement. This usually results in generalized enlargement of the gland **(goiter)** and no palpable nodules. Specific conditions that produce such diffuse enlargement include chronic autoimmune lymphocytic **thyroiditis (Hashimoto thyroiditis), colloid or adenomatous goiter,** and **Graves disease.** These conditions are usually diagnosed on the basis of clinical and laboratory findings and occasionally FNA biopsy. Sonography is seldom indicated. However, high-resolution sonography can be helpful when the underlying diffuse disease causes **asymmetrical thyroid enlargement,** which suggests a mass in the larger lobe. The sonographic finding of generalized parenchymal abnormality may alert the clinician to consider diffuse thyroid disease as the underlying cause. FNA, with sonographic guidance if necessary, can be performed if a nodule is detected. Recognition of diffuse thyroid enlargement on sonography can often be facilitated by noting the thickness of the isthmus, normally a thin bridge of tissue measuring only a few millimeters in AP dimension. With diffuse thyroid enlargement, the isthmus may be up to 1 cm or more in thickness.

Diffuse Thyroid Diseases

Acute suppurative thyroiditis
Subacute granulomatous thyroiditis
Hashimoto thyroiditis (chronic lymphocytic thyroiditis)
Adenomatous or colloid goiter
Painless (silent) thyroiditis

Each type of thyroiditis, including acute suppurative thyroiditis, subacute granulomatous thyroiditis (de Quervain disease), and chronic lymphocytic thyroiditis (Hashimoto disease) has distinctive clinical and laboratory features.[146] **Acute suppurative thyroiditis** is a rare inflammatory disease usually caused by bacterial

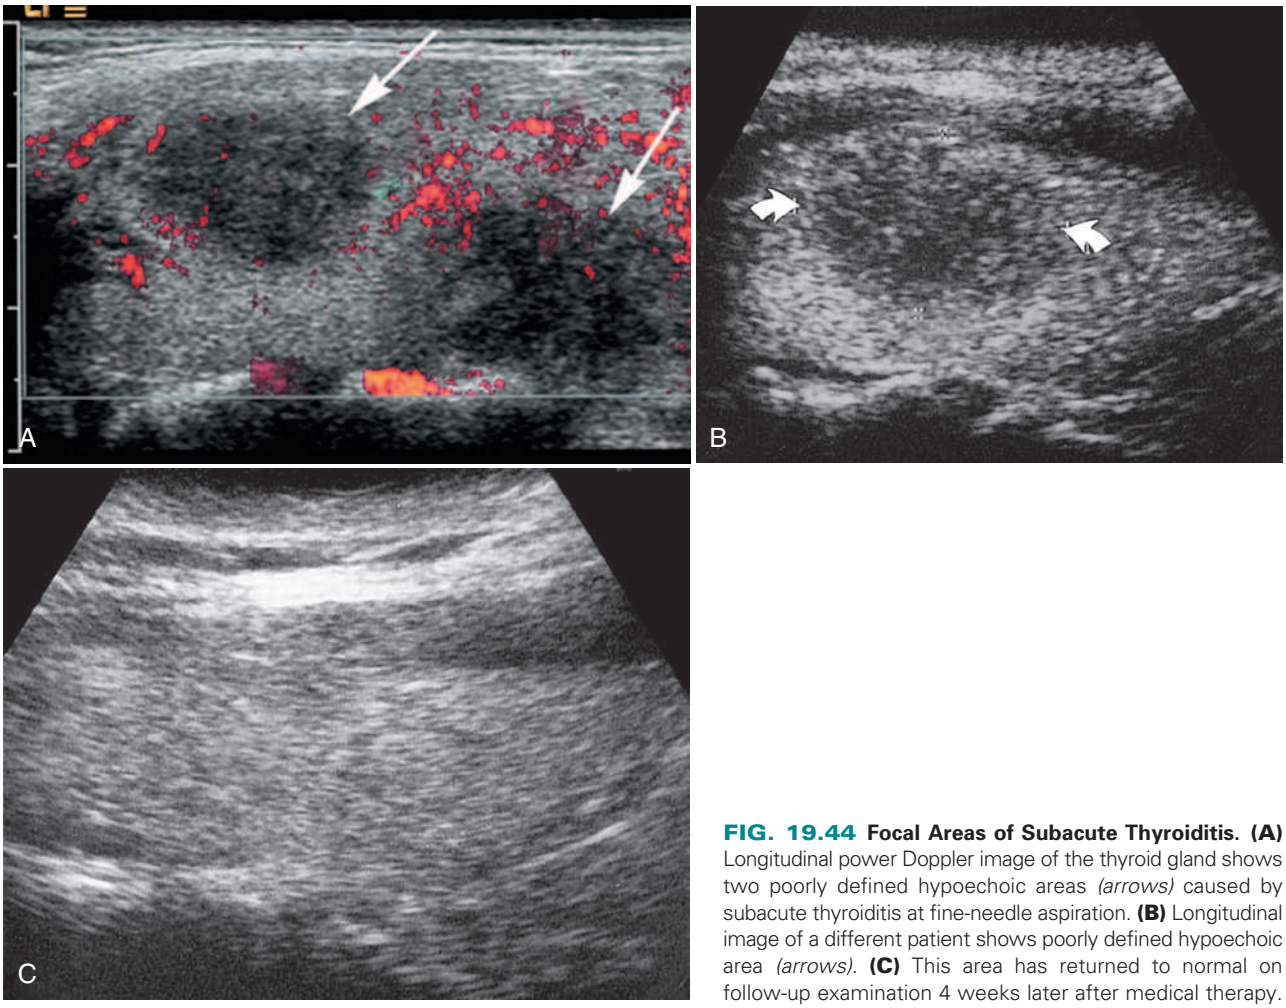

FIG. 19.44 Focal Areas of Subacute Thyroiditis. (A) Longitudinal power Doppler image of the thyroid gland shows two poorly defined hypoechoic areas *(arrows)* caused by subacute thyroiditis at fine-needle aspiration. **(B)** Longitudinal image of a different patient shows poorly defined hypoechoic area *(arrows)*. **(C)** This area has returned to normal on follow-up examination 4 weeks later after medical therapy.

infection and affecting children. Sonography can be useful in select patients to detect the development of a frank thyroid abscess. The infection usually begins in the perithyroidal soft tissues. On ultrasound images, an abscess is seen as a poorly defined, hypoechoic heterogeneous mass with internal debris, with or without septa and gas. Adjacent inflammatory nodes are often present.

Subacute granulomatous thyroiditis or De Quervain disease is a spontaneously remitting inflammatory disease probably caused by viral infection. The clinical findings include fever, enlargement of the gland, and pain on palpation. Sonographically, the gland may appear enlarged and hypoechoic, with normal or decreased vascularity caused by diffuse edema of the gland, or the process may appear as focal hypoechoic regions[147,148] (Fig. 19.44). Although usually not necessary, sonography can be used to assess evolution of de Quervain disease after medical therapy.

The most common type of thyroiditis is **chronic autoimmune lymphocytic thyroiditis, or Hashimoto thyroiditis.** It typically occurs as a painless, diffuse enlargement of the thyroid gland in a young or middle-aged woman, often associated with hypothyroidism. It is the most common cause of hypothyroidism in North America. Patients with this autoimmune disease develop antibodies to their own thyroglobulin as well as to the major enzyme of thyroid hormonogenesis, thyroid peroxidase. The typical sonographic appearance of Hashimoto thyroiditis is diffuse, coarsened, parenchymal echotexture, generally more hypoechoic than a normal thyroid[144] (Fig. 19.45). In most cases the gland is enlarged. Multiple, discrete **hypoechoic micronodules** from 1 to 6 mm in diameter are strongly suggestive of chronic thyroiditis; this appearance has been called **micronodulation** (see Fig. 19.45, Video 19.7). Micronodulation is a highly sensitive sign of chronic thyroiditis, with a positive predictive value of 94.7%.[149] Histologically, micronodules represent lobules of thyroid parenchyma that have been infiltrated by lymphocytes and plasma cells. These lobules are surrounded by multiple linear echogenic fibrous septations (Fig. 19.46). These fibrotic septations may give the parenchyma a "pseudolobulated" appearance. Both benign and malignant thyroid nodules may coexist with chronic lymphocytic thyroiditis, and FNA is often necessary to establish the final diagnosis[150] (Figs. 19.47 to 19.49). As with other autoimmune disorders, there is an increased risk of malignancy, with a B-cell malignant lymphoma most often arising within the gland.

The vascularity on color Doppler imaging is normal or decreased in most patients with the diagnosis of Hashimoto thyroiditis (see Fig. 19.45). Occasionally, hypervascularity similar to the "thyroid inferno" of Graves disease occurs. One study

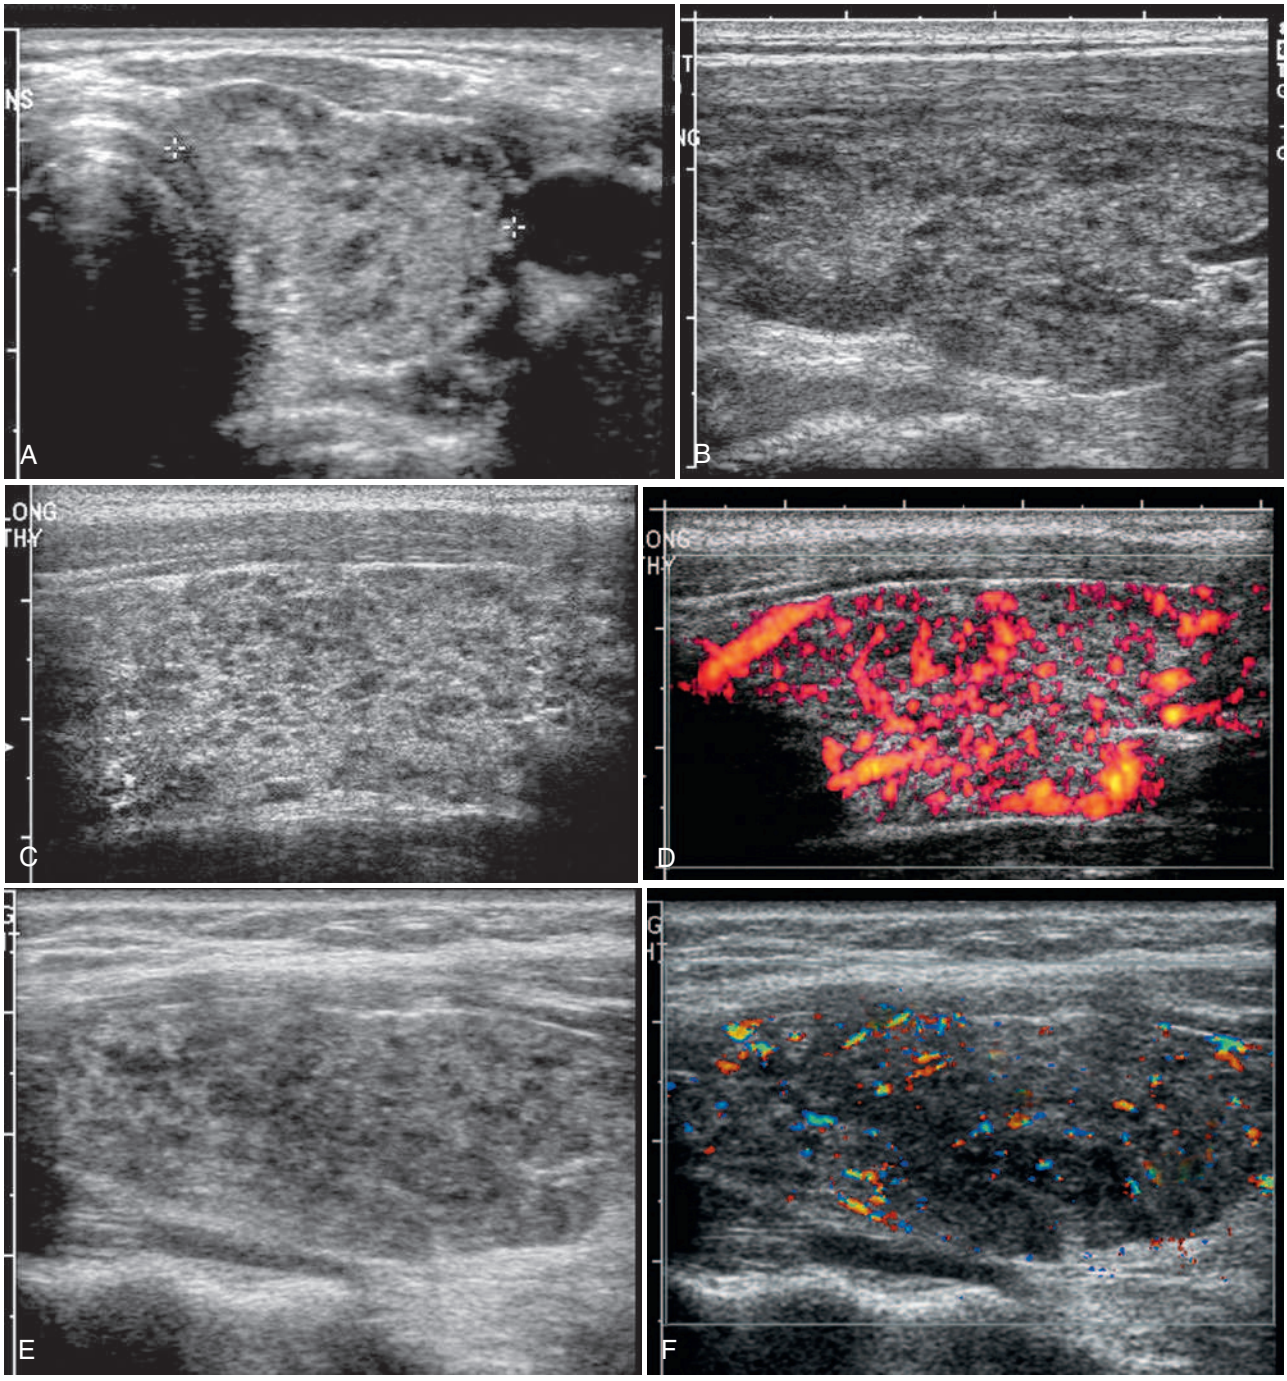

FIG. 19.45 Hashimoto Thyroiditis: Micronodularity. (A) Transverse and **(B)** longitudinal images of the left lobe demonstrate multiple small hypoechoic nodules that are lymphocyte infiltration of the parenchyma. **(C)** and **(D)** Longitudinal images of another patient show multiple tiny hypoechoic nodules and increased flow on power Doppler. This increased flow may indicate an acute phase of the thyroiditis. **(E)** and **(F)** Longitudinal images of a different patient show multiple tiny hypoechoic nodules and decreased flow on color Doppler scan. The blood flow is normal or diminished in most cases of Hashimoto thyroiditis.

suggested that hypervascularity occurs when hypothyroidism develops, perhaps related to stimulation from the associated high serum levels of thyrotropin (TSH).[151] Often, cervical lymphadenopathy is present, most evident near the lower pole of the thyroid gland (Fig. 19.50). The end stage of chronic thyroiditis is atrophy, when the thyroid gland is small, with poorly defined margins and heterogeneous texture caused by progressive fibrosis. Blood flow signals are absent. Occasionally, discrete nodules occur, and FNA biopsy is needed to establish the diagnosis.[150]

Painless (silent) thyroiditis has the typical histologic and sonographic pattern of chronic autoimmune thyroiditis (hypoechogenicity, micronodulation, and fibrosis), but clinical findings resemble classic subacute thyroiditis, with the exception of node tenderness. Moderate hyperthyroidism with thyroid

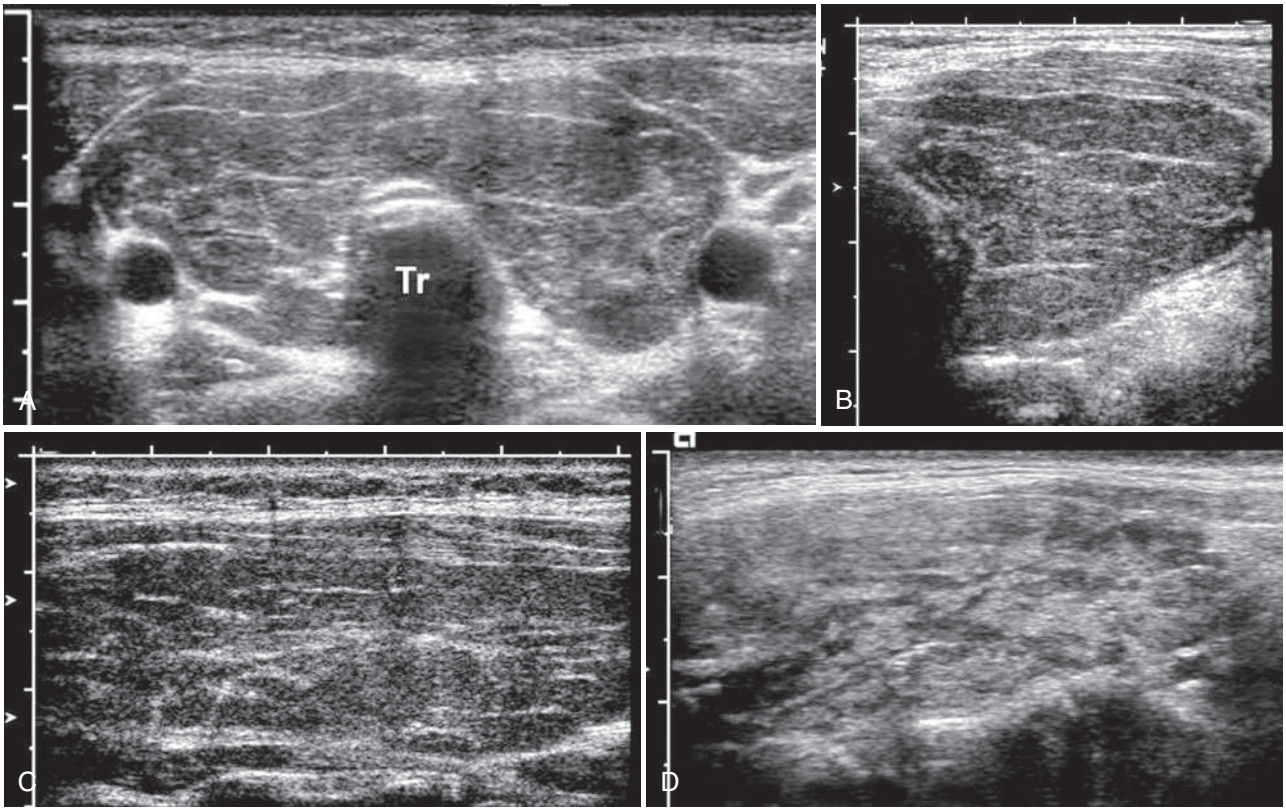

FIG. 19.46 Hashimoto Thyroiditis: Coarse Septations. (A) Transverse dual image of the thyroid shows marked diffuse enlargement of both lobes and the isthmus. Multiple linear bright echoes throughout the hypoechoic parenchyma are caused by lymphocytic infiltration of the gland with coarse septations from fibrous bands. *Tr,* Tracheal air shadow. **(B)** Transverse and **(C)** longitudinal images of another patient demonstrate linear echogenic septations throughout the gland. **(D)** Longitudinal image of another patient shows thicker echogenic linear areas that separate hypoechoic regions.

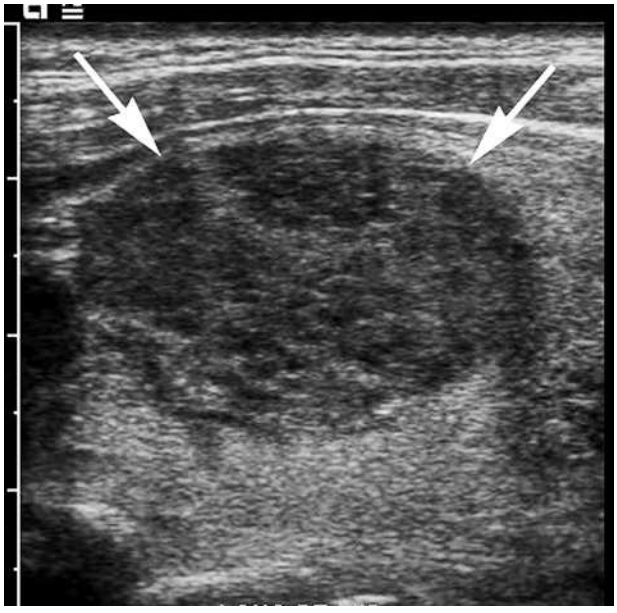

FIG. 19.47 Hashimoto Thyroiditis: Nodule. Longitudinal image shows a discrete hypoechoic nodule *(arrows)* that proved to be Hashimoto thyroiditis at fine-needle aspiration biopsy.

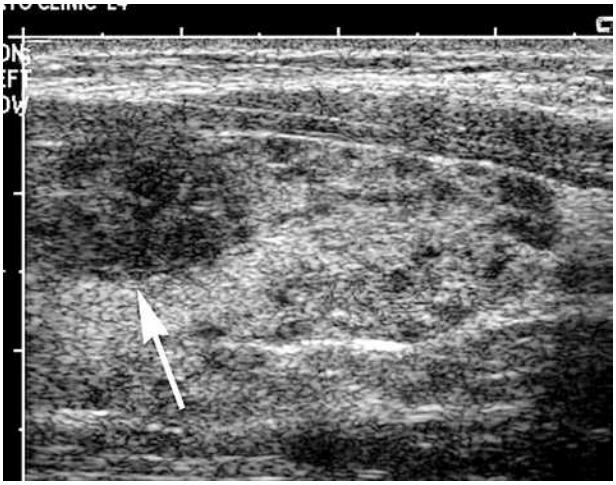

FIG. 19.48 Hashimoto Thyroiditis With Papillary Thyroid Cancer. Longitudinal image shows classic Hashimoto thyroiditis (micronodularity) and a hypoechoic dominant nodule *(arrow)* in the upper pole caused by papillary thyroid carcinoma. A dominant nodule in Hashimoto thyroiditis should be considered "indeterminate" and fine-needle aspiration performed.

FIG. 19.49 Lymphoma in Hashimoto Thyroiditis. Transverse image of the left lobe shows diffuse hypoechoic enlargement caused by lymphoma in a gland with Hashimoto thyroiditis. *Tr,* Tracheal air shadow.

FIG. 19.50 Hashimoto Thyroiditis With Hyperplastic Enlarged Lymph Nodes. Longitudinal image shows micronodularity of Hashimoto thyroiditis and an enlarged lymph node *(arrow)* inferior to the lower pole.

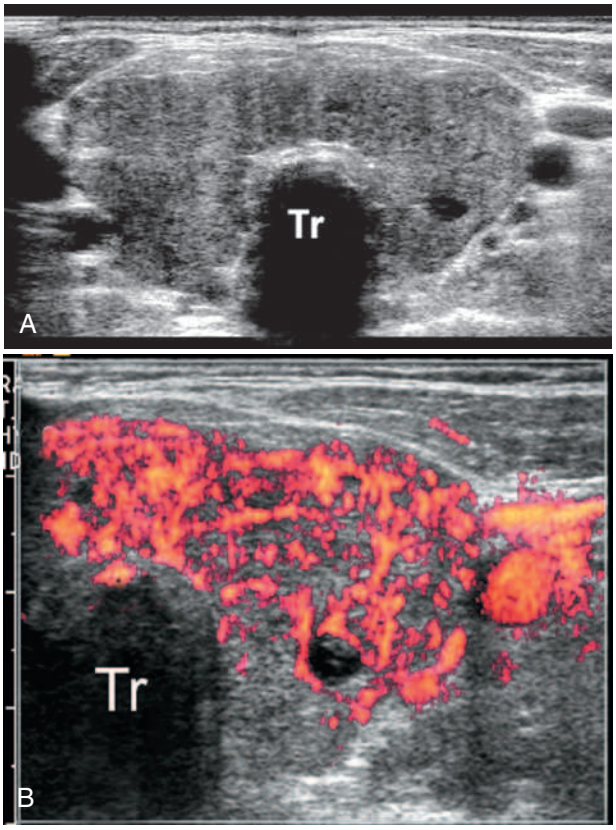

FIG. 19.51 Hyperthyroidism: Graves Disease. (A) Transverse dual image of the thyroid gland shows marked diffuse enlargement of both thyroid lobes and the isthmus. The gland is diffusely hypoechoic. **(B)** Transverse color Doppler image of the left lobe shows increased vascularity, indicating an acute stage of the Graves disease process. *Tr,* Trachea.

enlargement usually occurs in the early phase, in some cases followed by hypothyroidism of variable degree. In **postpartum thyroiditis** the progression to hypothyroidism is more common. In most cases the disease spontaneously remits within 3 to 6 months, and the gland may return to a normal appearance.

Although the appearance of diffuse parenchymal inhomogeneity and micronodularity is typical of Hashimoto thyroiditis, other diffuse thyroid diseases, most frequently **multinodular** or **adenomatous goiter,** may have a similar sonographic appearance. Most patients with adenomatous goiter have multiple discrete nodules separated by otherwise normal-appearing thyroid parenchyma (see Fig. 19.29); others have enlargement with rounding of the poles of the gland, diffuse parenchymal inhomogeneity, and no recognizable normal tissue. Adenomatous goiter affects women three times more often than men.

Graves disease is a common diffuse abnormality of the thyroid gland and is usually biochemically characterized by hyperfunction (thyrotoxicosis). The echotexture may be more inhomogeneous than in diffuse goiter, mainly because of numerous large, intraparenchymal vessels. Furthermore, especially in young patients, the parenchyma may be diffusely hypoechoic because of the extensive lymphocytic infiltration or the predominantly cellular content of the parenchyma, which becomes almost devoid of colloid substance. Color Doppler sonography often demonstrates a hypervascular pattern referred to as the **thyroid inferno** (Fig. 19.51). Spectral Doppler will often demonstrate peak systolic velocities exceeding 70 cm/sec, which is the highest velocity found in thyroid disease. There is no correlation between the degree of thyroid hyperfunction assessed by laboratory studies and the extent of hypervascularity or blood flow velocities. Previous studies have shown that Doppler analysis can be used to monitor therapeutic response in patients with Graves disease.[152] A significant decrease in flow velocities in the superior and inferior thyroid arteries after medical treatment has been reported.

The rarest type of inflammatory thyroid disease is **invasive fibrous thyroiditis,** also called **Riedel struma.**[146] This disease primarily affects women and often progresses to complete destruction of the gland. Some cases may be associated with

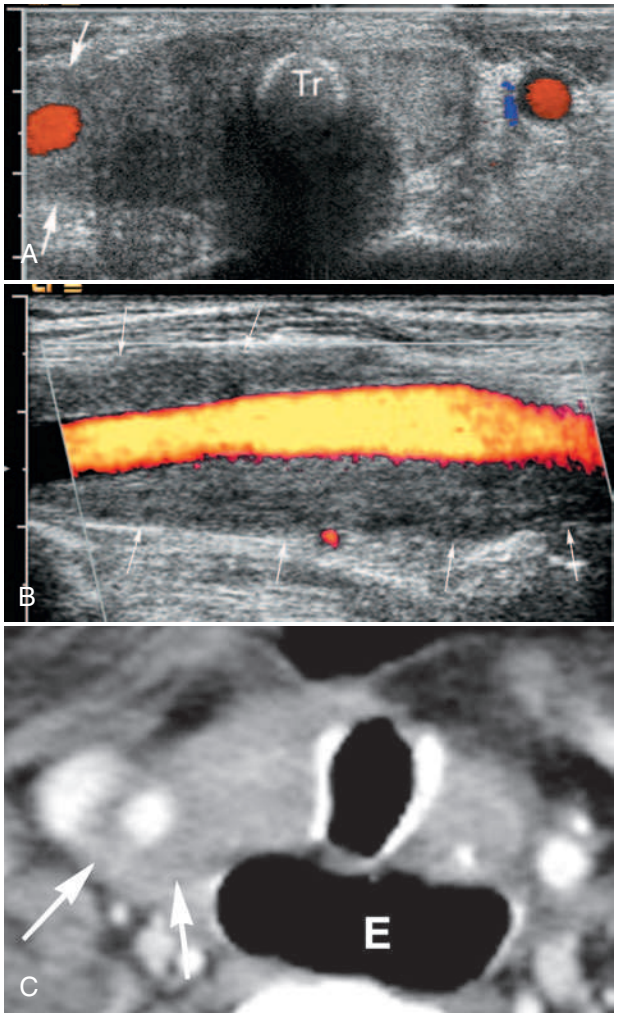

FIG. 19.52 Riedel Struma (Invasive Fibrous Thyroiditis). (A) Transverse dual-color Doppler ultrasound image of the thyroid shows a diffuse hypoechoic process in the right lobe extending around the common carotid artery *(arrows)*. *Tr,* Trachea. **(B)** Longitudinal power Doppler image of the right common carotid artery shows a hypoechoic soft tissue mass *(arrows)* encasing the vessel. **(C)** Contrast-enhanced CT scan shows mild enlargement of the right thyroid lobe and soft tissue thickening *(arrows)* around the right common carotid artery. Incidentally noted is dilation of the air-filled esophagus *(E)*.

mediastinal or retroperitoneal fibrosis or sclerosing cholangitis. In the few cases of invasive fibrous thyroiditis examined sonographically, the gland was diffusely enlarged and had an inhomogeneous parenchymal echotexture. The primary reason for sonography is to check for extrathyroid extension of the inflammatory process, with encasement of the adjacent vessels (Fig. 19.52). Such information can be particularly useful in surgical planning. Open biopsy is generally required to distinguish this condition from anaplastic thyroid carcinoma. The sonographic findings in these two diseases may be identical.

CHAPTER 20

The Parathyroid Glands

Bonnie J. Huppert and Carl Reading

SUMMARY OF KEY POINTS

- In the vast majority of cases, primary hyperparathyroidism is caused by hyperfunction of a single parathyroid gland due to adenoma, much less commonly due to multiple gland involvement.
- Surgical removal of the abnormal gland is the only definitive treatment for primary hyperparathyroidism, and selective, minimally invasive surgical techniques are most commonly used for first-time surgery.
- The role of parathyroid imaging is not in the diagnosis of primary hyperparathyroidism but rather to provide accurate adenoma localization to successfully direct selective surgical parathyroid resection.
- When used by an experienced examiner, parathyroid sonography can provide high-resolution anatomic imaging with good sensitivity and accuracy which is noninvasive, lacks radiation exposure, is relatively low cost, and has the added ability to assess for concomitant thyroid disease prior to surgery.
- In persistent or recurrent hyperparathyroidism, liberal use of multimodality preoperative imaging is particularly beneficial prior to reoperation.
- In selected cases, ultrasound can also be used to guide biopsy of suspected parathyroid adenomas to provide preoperative confirmation and to guide ablation of abnormal parathyroid glands in patients who are not surgical candidates.

INTRAOPERATIVE SONOGRAPHY
PERCUTANEOUS BIOPSY
ETHANOL ABLATION

High-frequency sonography is a well-established, noninvasive imaging method used in the evaluation and treatment of patients with parathyroid disease. Sonography is often used for the preoperative localization of enlarged parathyroid glands or adenomas in patients with hyperparathyroidism. Ultrasound is also used to guide the percutaneous biopsy of suspected parathyroid adenomas or enlarged glands, particularly in patients with persistent or recurrent hyperparathyroidism, as well as in some patients with suspected ectopic glands. In select patients, sonography can be used to guide the percutaneous ethanol ablation of parathyroid adenomas as an alternative to surgical treatment.

EMBRYOLOGY AND ANATOMY

The paired superior and inferior parathyroid glands have different embryologic origins, and knowledge of their development aids in understanding their ultimate anatomic locations.[1-3] The **superior parathyroid glands** arise from the paired fourth branchial pouches (clefts), along with the lateral lobes of the

thyroid gland. Minimal migration occurs during fetal development, and the superior parathyroids usually remain associated with the posterior aspect of the middle to upper portion of the thyroid gland. The majority of superior parathyroid glands (>80%) are found at autopsy within a 2-cm area located just superior to the crossing of the recurrent laryngeal nerve and the inferior thyroid artery.[4]

The **inferior parathyroid glands** arise from the paired third branchial pouches, along with the thymus.[2] During fetal development, these "parathymus glands" migrate caudally along with the thymus in a more anterior plane than their superior counterparts, bypassing the superior glands to become the inferior parathyroid glands.[3] Because of their greater caudal migration, the inferior parathyroid glands are more variable in location than the superior glands and can be found anywhere from the angle of the mandible to the pericardium. The majority of inferior parathyroid glands (>60%) come to rest at or just inferior to the posterior aspect of the lower pole of the thyroid[4] (Fig. 20.1).

A significant percentage of parathyroid glands lie in relatively or frankly **ectopic** locations in the neck or mediastinum. Symmetry to fixed landmarks occurs in 70% to 80%, so side-to-side comparisons can often be made.[3,4] The ectopic superior parathyroid gland usually lies posterior to the esophagus or in the tracheoesophageal groove, in the retropharyngeal space, or has continued its descent from the posterior neck into the posterosuperior mediastinum.[5,6] Superior glands are less often found higher in the neck, near the superior extent of the thyroid, or, in rare cases, surrounded by thyroid tissue within the thyroid capsule.[4] The inferior parathyroid gland is more frequently ectopic than its superior counterpart.[4,6] About 25% of the inferior glands fail to completely dissociate from the thymus and continue to migrate in an anterocaudal direction and are found in the low neck along the thyrothymic ligament or embedded within or adjacent to the thymus in the low neck and anterosuperior mediastinum. Less common ectopic positions of the inferior parathyroid glands include an undescended position high in the neck anterior to the carotid bifurcation associated with a remnant of thymus, and lower in the neck along or within the carotid sheath.[7] In other rare cases, ectopic glands have also been reported in the mediastinum posterior to the esophagus or carina, in the aortopulmonic window, within the pericardium, or even far laterally within the posterior triangle of the neck.

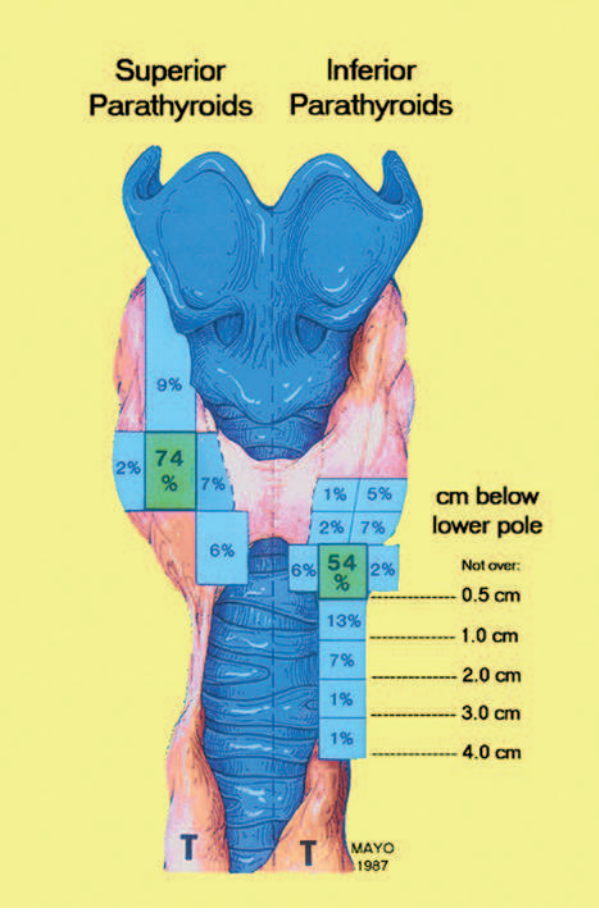

FIG. 20.1 Location of Parathyroid Glands. Frequency of the location of normal superior and inferior parathyroid glands. Anatomic drawing from 527 autopsies. *T,* Thymus. (Modified from Gilmour JR. The gross anatomy of the parathyroid glands. J Pathol 1938;46:133-148.[1])

Most adults have four parathyroid glands, two superior and two inferior, each measuring about 5 × 3 × 1 mm and weighing on average 35 to 40 mg (range, 10-78 mg).[3,8] **Supernumerary glands** (>4) may be present and result from the separation of parathyroid anlage when the glands pull away from the pouch structures during the embryologic branchial complex phase.[9,10] These supernumerary glands are often associated with the thymus in the anterior mediastinum, suggesting a relationship in their development with the inferior parathyroid glands.[11] Supernumerary glands have been reported in 13% of the population at autopsy studies[3,4]; however, many of these are small, rudimentary or split glands. "Proper" supernumerary glands (>5 mg and located well away from the other four glands) are found in 5% of cases. The presence of fewer than four parathyroid glands is rare clinically but has been reported in 3% at autopsy.

Normal parathyroid glands vary from a yellow to a red-brown color, depending on the degree of vascularity and the relative content of yellow parenchymal fat and chief cells.[8] The chief cells are the primary source for the production of **parathyroid hormone (PTH, parathormone).** The percentage of glandular fat typically increases with age or with disuse atrophy. Hyperfunctioning glands resulting from adenomas or hyperplasia contain relatively little fat and are vascular, thus more reddish. The glands are generally oval or bean shaped but may be spherical, lobular, elongated, or flattened. Although normal parathyroid glands are occasionally seen with high-frequency ultrasound,[12,13] typically they are not visualized, likely because of their small size, deep location, and poor conspicuity related to increased glandular fat. **Eutopic** parathyroid glands typically derive their major blood supply from branches of the inferior thyroid artery, with a lesser and variable contribution to the superior glands from the superior thyroid artery.[3,7]

PRIMARY HYPERPARATHYROIDISM

Prevalence

Primary hyperparathyroidism is a common endocrine disease, with prevalence in the United States of 1 to 2 per 1000

population.[14] Women are affected two to three times more frequently than men, particularly after menopause. More than half of patients with primary hyperparathyroidism are older than 50 years, and cases are rare in those younger than age 20.

Diagnosis

Primary hyperparathyroidism is usually suspected because an increased serum calcium level is detected on routine biochemical screening. Elevated ionized serum calcium level, **hypophosphatasia,** and **hypercalciuria** may be further biochemical clues to the disease. A serum PTH level that is "inappropriately high" for the corresponding serum calcium level confirms the diagnosis. Even when the PTH level is within the upper limits of the normal range in a hypercalcemic patient, the diagnosis of primary hyperparathyroidism should still be suspected, since **hypercalcemia** from other nonparathyroid causes (including malignancy) should suppress the glandular function and decrease the serum PTH level. Because of earlier detection by increasingly routine laboratory tests, the later "classic" signs of hyperparathyroidism, such as "painful bones, renal stones, abdominal groans, and psychic moans," are often not present. Many patients are diagnosed before severe manifestations of hyperparathyroidism, such as **nephrolithiasis, osteopenia, subperiosteal resorption,** and **osteitis fibrosis cystica.** In general, patients rarely have obvious symptoms unless their serum calcium level exceeds 12 mg/dL. However, subtle nonspecific symptoms, such as muscle weakness, malaise, constipation, dyspepsia, polydipsia, and polyuria, may be elicited from these otherwise asymptomatic patients by more specific questioning.

Pathology

Primary hyperparathyroidism is caused by a **single adenoma** in 80% to 90% of cases, by **multiple gland enlargement** in 10% to 20%, and by **carcinoma** in less than 1%.[6,15,16] A solitary adenoma may involve any one of the four glands. Multigland enlargement most often results from primary parathyroid hyperplasia and less often from multiple adenomas. Hyperplasia usually involves all four glands asymmetrically, whereas multiple adenomas may involve two or possibly three glands. An adenoma and hyperplasia cannot always be reliably distinguished histologically, and the sample may be referred to as "hypercellular parathyroid" tissue. Because of this inconsistent pattern of gland involvement, and because distinguishing hyperplasia from multiple adenomas is difficult pathologically, these two entities are often histologically considered together as "multiple gland disease."[17]

Causes of Primary Hyperparathyroidism

Type of Disease	Percentage
Single adenoma	80%-90%
Multiple gland disease	10%-20%
Carcinoma	<1%

Most cases of primary hyperparathyroidism are sporadic. However, **prior external neck irradiation** has been associated with the development of hyperparathyroidism in a small percentage of cases. Patients receiving **long-term lithium therapy** may also present with primary hyperparathyroidism. Up to 10% of cases may occur on a hereditary basis, most often caused by **multiple endocrine neoplasia syndrome,** type I **(MEN I).** This condition is an uncommon disorder that most typically follows an autosomal dominant pattern of inheritance and has a high penetrance, resulting in adenomatous parathyroid hyperplasia, as well as pancreatic islet cell tumors and pituitary adenomas. Multiple–parathyroid gland enlargement occurs in more than 90% of patients with MEN I.[18,19] Most MEN I patients present with hypercalcemia before their third or fourth decade of life. Not all the parathyroid glands may be grossly enlarged at these patients' initial operation, but all of them likely will ultimately be involved with hyperplasia. Patients with the **MEN IIA syndrome** less frequently develop parathyroid hyperplasia. Other, rarer familial syndromes may also be associated with primary hyperparathyroidism caused by hyperplasia, adenomas, or carcinoma. An important hereditary hyperparathyroidism that must be distinguished from primary hyperparathyroidism caused by hyperplasia or adenoma is **familial hypocalciuric hypercalcemia** (benign familial hypercalcemia). Most of these patients are asymptomatic, without the complications of primary hyperparathyroidism. Parathyroidectomy does not cure the hypercalcemia, and thus surgery is inappropriate.

Parathyroid carcinoma is a rare cause of primary hyperparathyroidism.[20-23] The histologic distinction from adenoma is difficult to establish with certainty because both carcinomas and atypical adenomas can exhibit increased mitotic activity and cellular atypia. Patients with parathyroid carcinoma usually present with a very high serum calcium level (>14 mg/dL). The diagnosis is often made at operation when the surgeon discovers an enlarged, firm gland that is adherent to the surrounding tissues due to local invasion. A thick, fibrotic capsule is often present. Treatment consists of en bloc resection without entering the capsule, to prevent tumor seeding. In many cases, cure may not be possible because of the invasive and metastatic nature of the disease. Generally, death occurs not from tumor spread but from complications associated with unrelenting hyperparathyroidism.

Treatment

No effective definitive medical therapies are available for the treatment of primary hyperparathyroidism. Medications utilized include short-term hypocalcemic agents such as calcitonin and **calcimimetics** (calcium-sensing receptor agonists) such as cinacalcet. The bisphosphonates aid in preventing bone mass loss. Synthetic vitamin D analogs such as paricalcitol are mainly used in the treatment of secondary hyperparathyroidism.

Surgery is the only definitive treatment for primary hyperparathyroidism. Studies demonstrate that surgical cure rates by an experienced surgeon are greater than 95%, and the morbidity and mortality rates are extremely low.[24,25] Therefore in symptomatic patients with primary hyperparathyroidism, the treatment of choice is surgical excision of the involved parathyroid gland or glands.

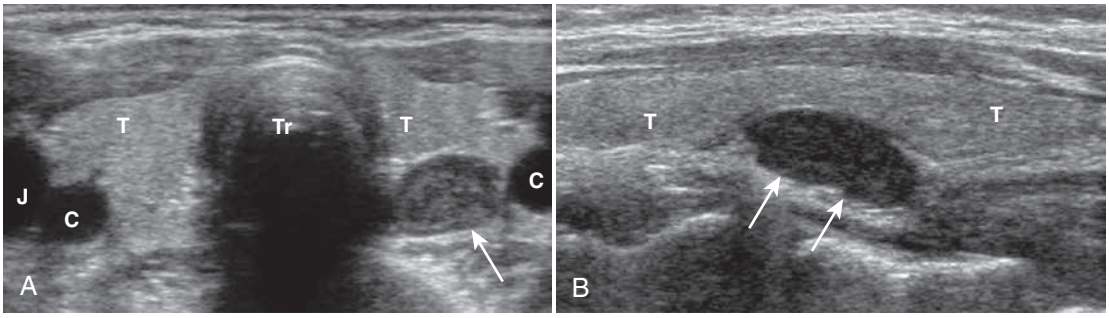

FIG. 20.2 Typical Parathyroid Adenoma. (A) Transverse and **(B)** longitudinal sonograms of a typical adenoma *(arrows)* located adjacent to the posterior aspect of the thyroid *(T). C,* Common carotid artery; *J,* internal jugular vein; *Tr,* trachea.

However, since in current practice, most cases of primary hyperparathyroidism are discovered in the early stages of the disease, some controversy exists as to whether asymptomatic patients with minimal hypercalcemia should be treated surgically, or followed medically with frequent measurements of bone density, serum calcium levels, and urinary calcium excretion and monitoring for nephrolithiasis.[26] Recommendations for the management of asymptomatic primary hyperparathyroidism have been outlined in various articles, many of which are based on International Workshop and National Institutes of Health (NIH) Consensus Conference statements and subsequent updates. This area continues to evolve, and approaches to treatment may differ slightly among clinical practices.[24-31]

SONOGRAPHIC APPEARANCE

Shape

Parathyroid adenomas are typically oval or bean shaped (Fig. 20.2). As parathyroid glands enlarge, they dissect between longitudinally oriented tissue planes in the neck and acquire a characteristic oblong shape. If this process is exaggerated, they can become tubular or flattened. There is often asymmetry in the enlargement, and the cephalic and/or caudal end can be more bulbous, producing a triangular, tapering, teardrop or bilobed shape.[19,32-34]

Echogenicity and Internal Architecture

The echogenicity of most **parathyroid adenomas** is substantially less than that of normal thyroid tissue (Fig. 20.3). The characteristic **hypoechoic** appearance of parathyroid adenomas is caused by the uniform hypercellularity of the gland with little fat content, which leaves few interfaces for reflecting sound. Occasionally, adenomas have a heterogeneous appearance, with areas of increased and decreased echogenicity. The rare, functioning **parathyroid lipoadenomas** are more echogenic than the adjacent thyroid gland because of their high fat content[35] (Fig. 20.3G). A great majority of parathyroid adenomas are **homogeneously solid.** About 2% have internal cystic components resulting from **cystic degeneration** (most often) or true simple cysts (less often)[36-38] (Fig. 20.3E and F, Video 20.1). Adenomas may rarely contain internal calcification (Fig. 20.3H and I).

Vascularity

Color flow, spectral, and power Doppler sonography of an enlarged parathyroid gland may demonstrate a hypervascular pattern with prominent diastolic flow (Fig. 20.4). An enlarged **extrathyroidal artery,** often originating from branches of the **inferior thyroidal artery,** may be visualized supplying the adenoma with its insertion along the long-axis pole.[39-44] A finding described in parathyroid adenomas is a **vascular arc,** which envelops 90 to 270 degrees of the mass. This vascular flow pattern may increase the sensitivity of initial detection of parathyroid adenomas and aid in confirming the diagnosis by allowing for differentiation from lymph nodes, which have a central hilar flow pattern. Asymmetric increased vascular flow may also be present in the thyroid gland adjacent to a parathyroid adenoma.

Size

Most parathyroid adenomas are 0.8 to 1.5 cm long and weigh 500 to 1000 mg. The smallest adenomas can be minimally enlarged glands that appear virtually normal during surgery but are found to be hypercellular on pathologic examination (Fig. 20.5, Video 20.2). Large adenomas can be 5 cm or more in length and weigh more than 10 g. Preoperative serum calcium levels are usually higher in patients with larger adenomas.[32]

Multiple Gland Disease

Multiple gland disease may be caused by diffuse hyperplasia or multiple adenomas. Individually, these enlarged glands may have the same sonographic and gross appearance as other parathyroid adenomas (Fig. 20.6, Videos 20.3 and 20.4). However, the glands may be inconsistently and asymmetrically enlarged, and the diagnosis of multigland disease can be difficult to make sonographically. For example, if one gland is much larger than the others, the appearance may be misinterpreted as solitary adenomatous disease. Alternatively, if multiple glands are only minimally enlarged, the diagnosis may be missed altogether.

Carcinoma

Carcinomas are usually larger than adenomas.[45-47] Carcinomas often measure more than 2 cm compared with about 1 cm for adenomas (Fig. 20.7). On ultrasound, carcinomas also frequently have a lobular contour, heterogeneous internal architecture, and internal cystic components. However, large adenomas may also

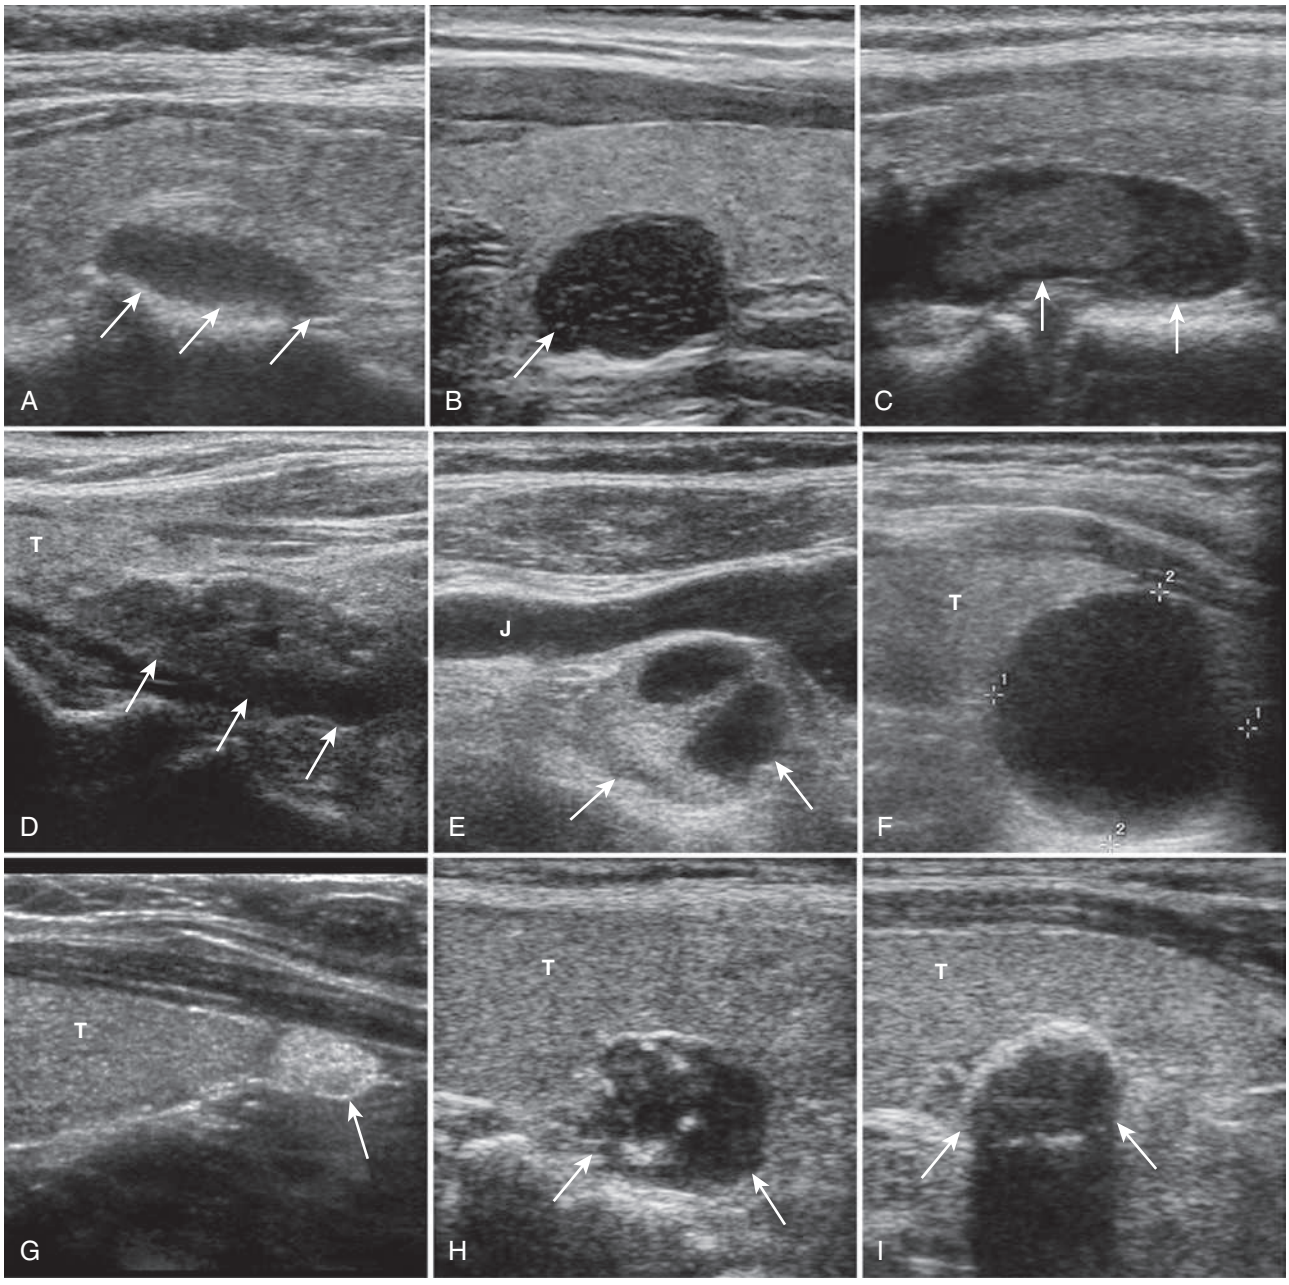

FIG. 20.3 Spectrum of Echogenicity and Internal Architecture of Parathyroid Adenomas and Enlarged Hyperplastic Glands. Longitudinal sonograms. **(A)** Typical homogeneous hypoechoic appearance of a parathyroid adenoma *(arrows)* with respect to the overlying thyroid tissue. **(B)** Highly hypoechoic solid **adenoma. (C)** Mixed-geographic echogenicity. The adenoma is hyperechoic in its cranial portion and hypoechoic in its caudal portion. **(D)** An adenoma with diffusely heterogeneous echogenicity. **(E)** Partial cystic change. An ectopic adenoma posterior to the jugular vein *(J)* has both solid and cystic components. **(F)** Completely cystic 2-cm adenoma *(calipers)* near the lower pole of the thyroid *(T)*. See also Video 20.1. **(G)** A **lipoadenoma** is more echogenic than the adjacent lower pole thyroid tissue. **(H)** Enlarged parathyroid gland with small, nonshadowing calcifications in the setting of **secondary hyperparathyroidism** related to chronic **renal failure**. **(I)** Enlarged parathyroid gland with densely shadowing peripheral calcifications in the setting of secondary hyperparathyroidism.

have these features. In many cases, carcinomas are indistinguishable sonographically from large, benign adenomas.[45] Some authors report that a depth-to-width ratio of 1 or greater is a sonographic feature more associated with carcinoma than with adenoma, with sensitivity and specificity of 94% and 95%, respectively.[47] Gross evidence of invasion of adjacent structures, such as vessels or muscles, is a reliable preoperative sonographic criterion for the diagnosis of malignancy, but this is an uncommon finding.

ADENOMA LOCALIZATION

Sonographic Examination and Typical Locations

The sonographic examination of the neck for parathyroid adenoma localization is performed with the patient supine. The patient's neck is hyperextended by a pad centered under the scapulae, and the examiner usually sits at the patient's head. High-frequency

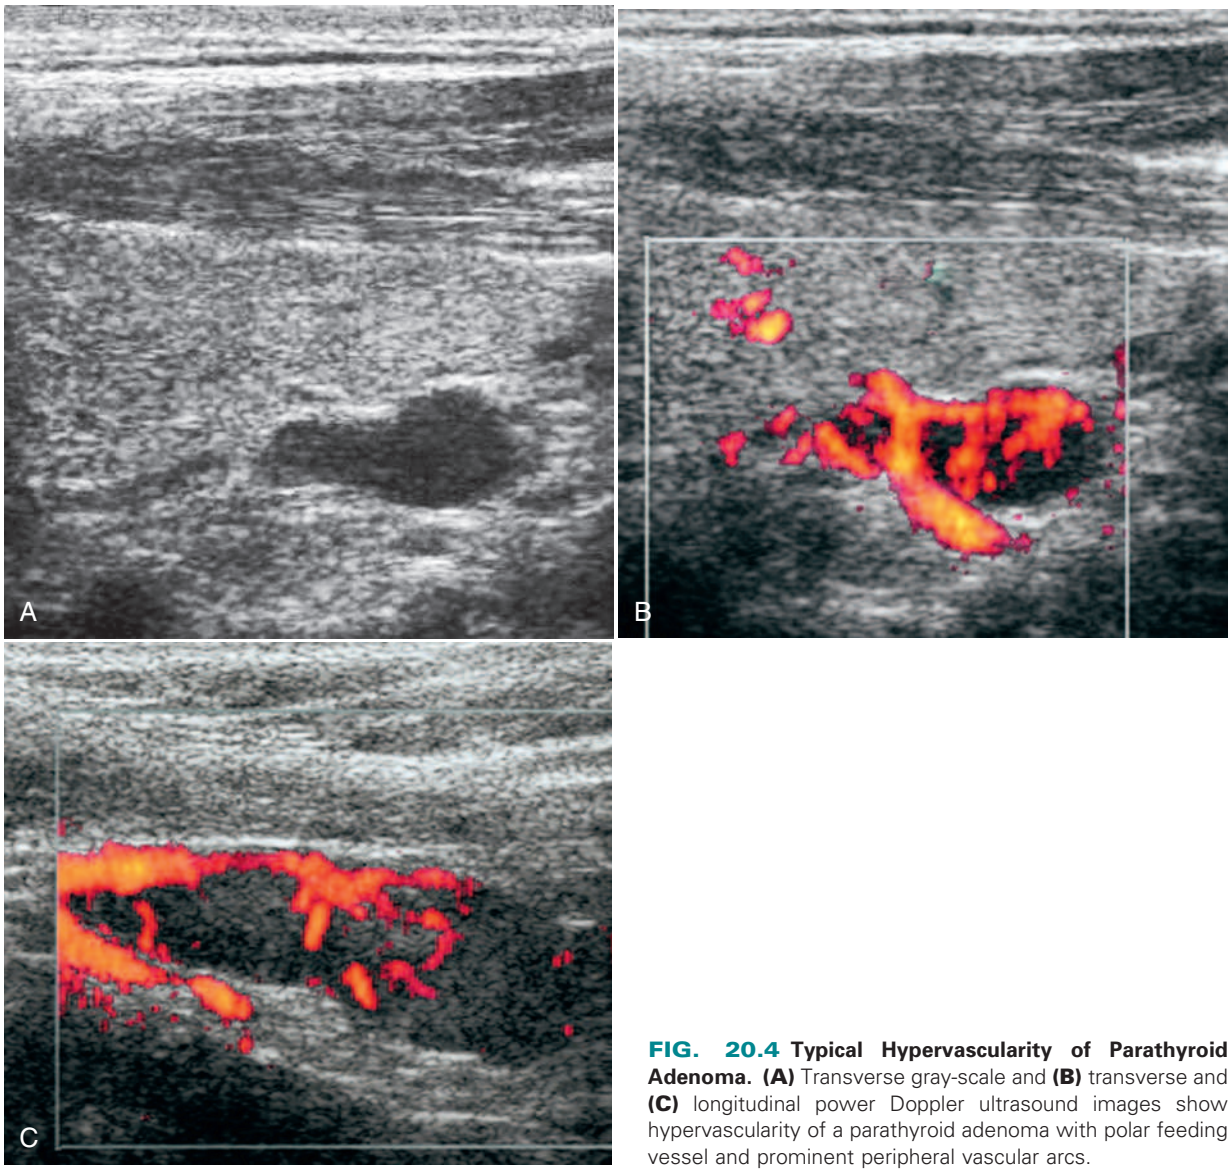

FIG. 20.4 Typical Hypervascularity of Parathyroid Adenoma. (A) Transverse gray-scale and **(B)** transverse and **(C)** longitudinal power Doppler ultrasound images show hypervascularity of a parathyroid adenoma with polar feeding vessel and prominent peripheral vascular arcs.

transducers (6-15 MHz and 8-18 MHz) are used to provide optimal spatial resolution and visualization in most patients; the highest frequency possible should be used that still allows for tissue penetration to visualize the deeper structures, such as the longus colli muscles. In obese patients with thick necks or with large multinodular thyroid glands, use of a 5- to 8-MHz transducer may be necessary to obtain adequate depth of penetration.

The pattern of the sonographic survey of the neck for adenoma localization can be considered in terms of the pattern of dissection and visualization that the surgeon uses in a thorough neck exploration. The typical **superior parathyroid adenoma** is usually adjacent to the posterior aspect of the midportion of the thyroid (Fig. 20.8, Videos 20.5 and 20.6). The location of the typical **inferior parathyroid adenoma** is more variable but usually lies

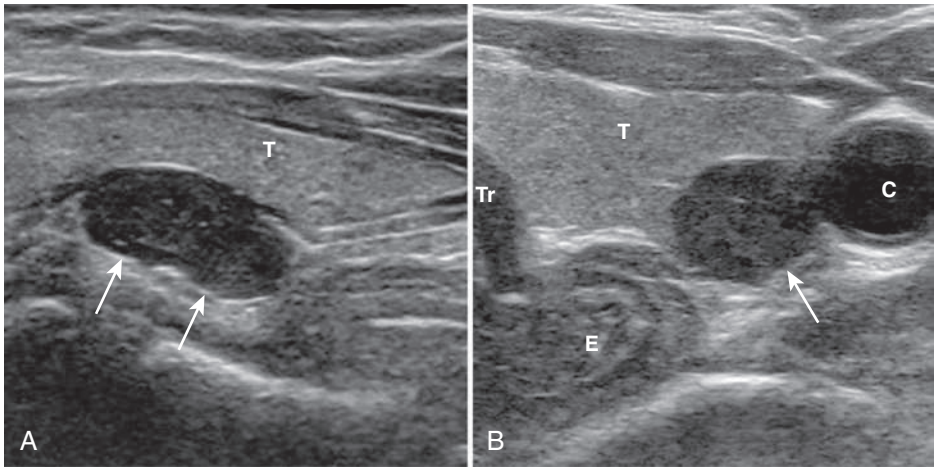

FIG. 20.8 Superior Parathyroid Adenoma. (A) Longitudinal and **(B)** transverse sonograms show an adenoma *(arrows)* adjacent to the posterior aspect of the midportion of the left lobe of the thyroid *(T). C,* Common carotid artery; *E,* esophagus; *Tr,* trachea. See also Videos 20.5 and 20.6.

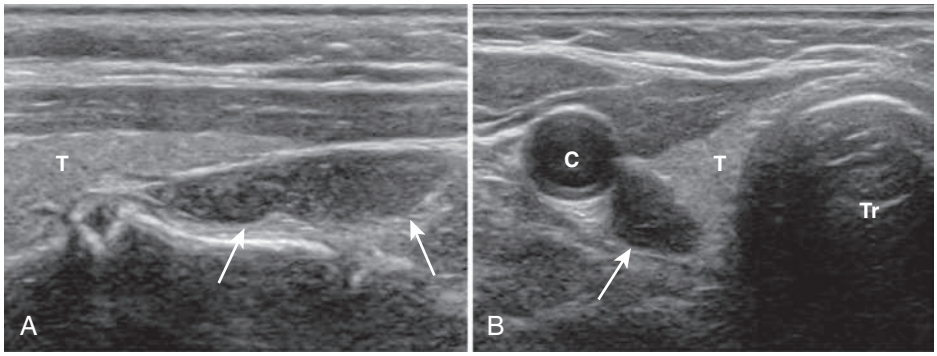

FIG. 20.9 Inferior Parathyroid Adenoma. (A) Longitudinal and **(B)** transverse sonograms show an adenoma *(arrows)* adjacent to lower pole of right lobe of the thyroid *(T). C,* Common carotid artery; *Tr,* trachea. See also Videos 20.7 and 20.8.

close to the lower pole of the thyroid (Fig. 20.9, Videos 20.7 and 20.8). Most of these inferior adenomas are adjacent to the posterior aspect of the lower pole of the thyroid, and the rest are in the soft tissues 1 to 2 cm inferior to the thyroid. Therefore the examination is initiated on one side of the neck, centered in the region of the thyroid gland, with the focal zone placed deep to the thyroid. High-resolution gray-scale images are obtained in the transverse (axial) and longitudinal (sagittal) planes. Any potential parathyroid adenomas detected in the transverse scan plane must be confirmed by longitudinal imaging to prevent mistaking other structures for an adenoma.

Some authors recommend the use of **compression** of the superficial soft tissues to aid in adenoma detection.[12,43,48] This has been described as "graded" compression with the transducer to effect minimal deformity of the overlying subcutaneous tissues and strap muscles and increase the conspicuity of deeper, smaller adenomas (<1 cm). Color flow and/or power Doppler sonography are also used to assess the vascularity of any potential adenoma, aid in detection, and support differentiation from other structures.[40-44,48] Hypervascularity may be evident with a polar insertion of a prominent extrathyroidal feeding artery, also with peripheral arcs of blood flow. After one side of the neck has been examined, a similar survey is conducted of the opposite side. However, 1% to 3% of parathyroid adenomas are frankly ectopic and not found in typical locations adjacent to the thyroid. Therefore the sonographic examination must be extended laterally along the carotid sheaths, superiorly from the level of the mandible, and inferiorly to the level of the sternal notch and clavicles. The four most common ectopic locations are considered separately next.

Ectopic Locations

Retrotracheal/Retroesophageal Adenoma

Superior adenomas tend to enlarge between tissue planes that extend toward the posterior mediastinum; the most common location of an ectopic superior adenoma is deep in the neck, posterior or posterolateral to the trachea or esophagus (Fig. 20.10, Video 20.9). Acoustic shadowing from air in the trachea can make evaluation of this area difficult. The transducer should be angled medially to visualize the tissues posterior to the trachea. Often the adenoma protrudes slightly from behind the trachea,

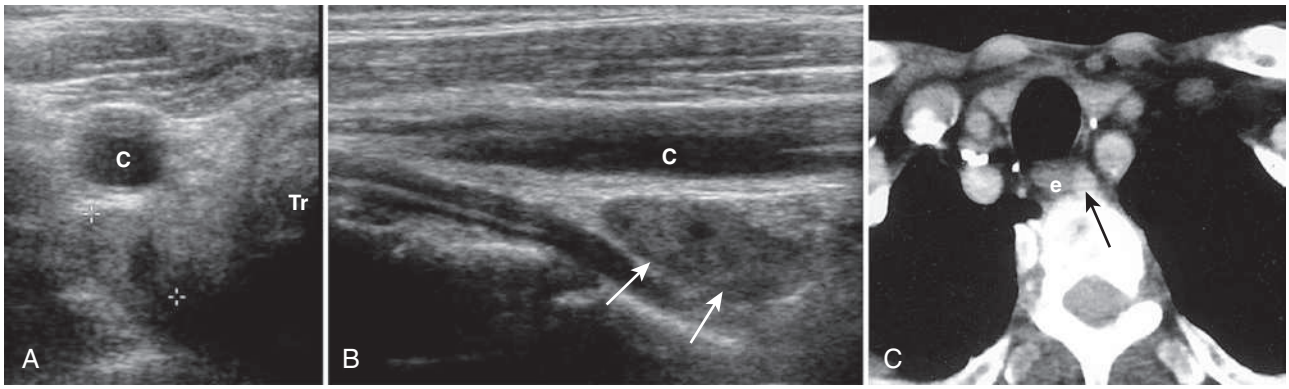

FIG. 20.10 Ectopic Superior Parathyroid Adenoma: Tracheoesophageal Groove. (A) Transverse sonogram reveals an adenoma *(calipers)* arising from the right tracheoesophageal groove located posteriorly in the neck. The patient's head is turned to the left, which deviates the adenoma laterally and aids in visualization. *C,* Common carotid artery; *Tr,* trachea. **(B)** Corresponding longitudinal sonogram shows the ectopic superior parathyroid adenoma *(arrows)* posterior in the low neck adjacent to the cervical spine. **(C)** CT scan of the low neck/upper mediastinum in another patient shows an ectopic adenoma *(arrow)* in the left tracheoesophageal groove adjacent to the esophagus *(e).* See also Video 20.9.

and only a portion of the mass will be visible. Turning the patient's head to the opposite side will accentuate the protrusion and provide better accessibility to the retrotracheal area. This process is then repeated on the other side of the neck to visualize the contralateral aspect of the retrotracheal area. This process is analogous to the maneuver that a surgeon uses to run a fingertip behind the trachea in an attempt to palpate a retrotracheal adenoma. Maximal turning of the head also often causes the esophagus to move to the opposite side of the trachea as it becomes compressed between the trachea and the cervical spine. If the examiner sees the esophagus move completely from one side of the trachea to the opposite side during maximal head turning, the esophagus has effectively "swept" the retrotracheal space and will have pushed any parathyroid adenoma in this location out from behind the trachea.

Mediastinal Adenoma

The most common location for ectopic inferior parathyroid adenomas is low within the neck or in the anterosuperior mediastinum[4,6,49,50] (Fig. 20.11). Parathyroid adenomas are sufficiently hypoechoic that they may be visualized as discrete structures separate from the thymus and surrounding tissues. To visualize this area optimally, the patient's neck is maximally hyperextended. With this technique and the transducer angled posterior and caudal to the clavicular heads, sonographic visualization is often possible to the level of the brachiocephalic veins. If the adenoma lies caudal to this level or far anterior, just deep to the sternum, it cannot be visualized sonographically.

Ectopic superior adenomas located in the mediastinum tend to stay in a more posterior plane than their ectopic inferior counterparts and are often not visible with traditional sonography. They usually lie deep in the low neck or posterior superior mediastinum, requiring use of a 5-MHz transducer for maximal penetration. Ectopic superior adenomas may be intimately associated with the posterior aspect of the trachea, and the head-turning maneuver described for retrotracheal adenomas in the neck can be applied here as well. With the patient's neck hyperextended and the transducer angled caudally, the posterior mediastinum may sometimes be visualized to the level of the apex of the aortic arch; adenomas lying caudal to this level cannot be visualized.

Intrathyroid Adenoma

Intrathyroid parathyroid adenomas are uncommon and have been described as either superior or inferior gland adenomas.[4,6,8] Most intrathyroid adenomas are in the posterior half of the middle to lower thyroid, are completely surrounded by thyroid tissue, and are oriented with their greatest dimension in the cephalocaudal direction (Fig. 20.12, Videos 20.10 and 20.11). Intrathyroid adenomas may be overlooked at surgery because they are soft and are similar to the surrounding thyroid tissue on palpation. A thyroidotomy or subtotal lobectomy may be needed to find an intrathyroid adenoma. Sonographically, however, parathyroid adenomas usually are well visualized because they are hypoechoic, in contrast to the echogenic thyroid parenchyma, and a polar feeding vessel is often present on color flow or power Doppler imaging.[51] The internal architecture and appearance of these adenomas are the same as for adenomas elsewhere in the neck. However, because intrathyroid parathyroid adenomas can be similar to thyroid nodules in appearance, percutaneous biopsy is often necessary to distinguish between these entities.

Some parathyroid adenomas lie under the pseudocapsule or sheath that covers the thyroid gland or within a sulcus of the thyroid, but these are not usually considered to be true intrathyroid adenomas. These adenomas may be difficult for the surgeon to visualize at surgery unless this sheath is opened.[4,8] Sonographically, these may appear the same as other parathyroid adenomas that lie immediately adjacent to the thyroid, although the typical thin, echogenic capsular interface often seen between the thyroid and a parathyroid adenoma may be absent.

Carotid Sheath/Undescended Adenoma

Rare ectopic adenomas can lie in a high position superior and lateral in the neck, near the **carotid bifurcation** at the level of

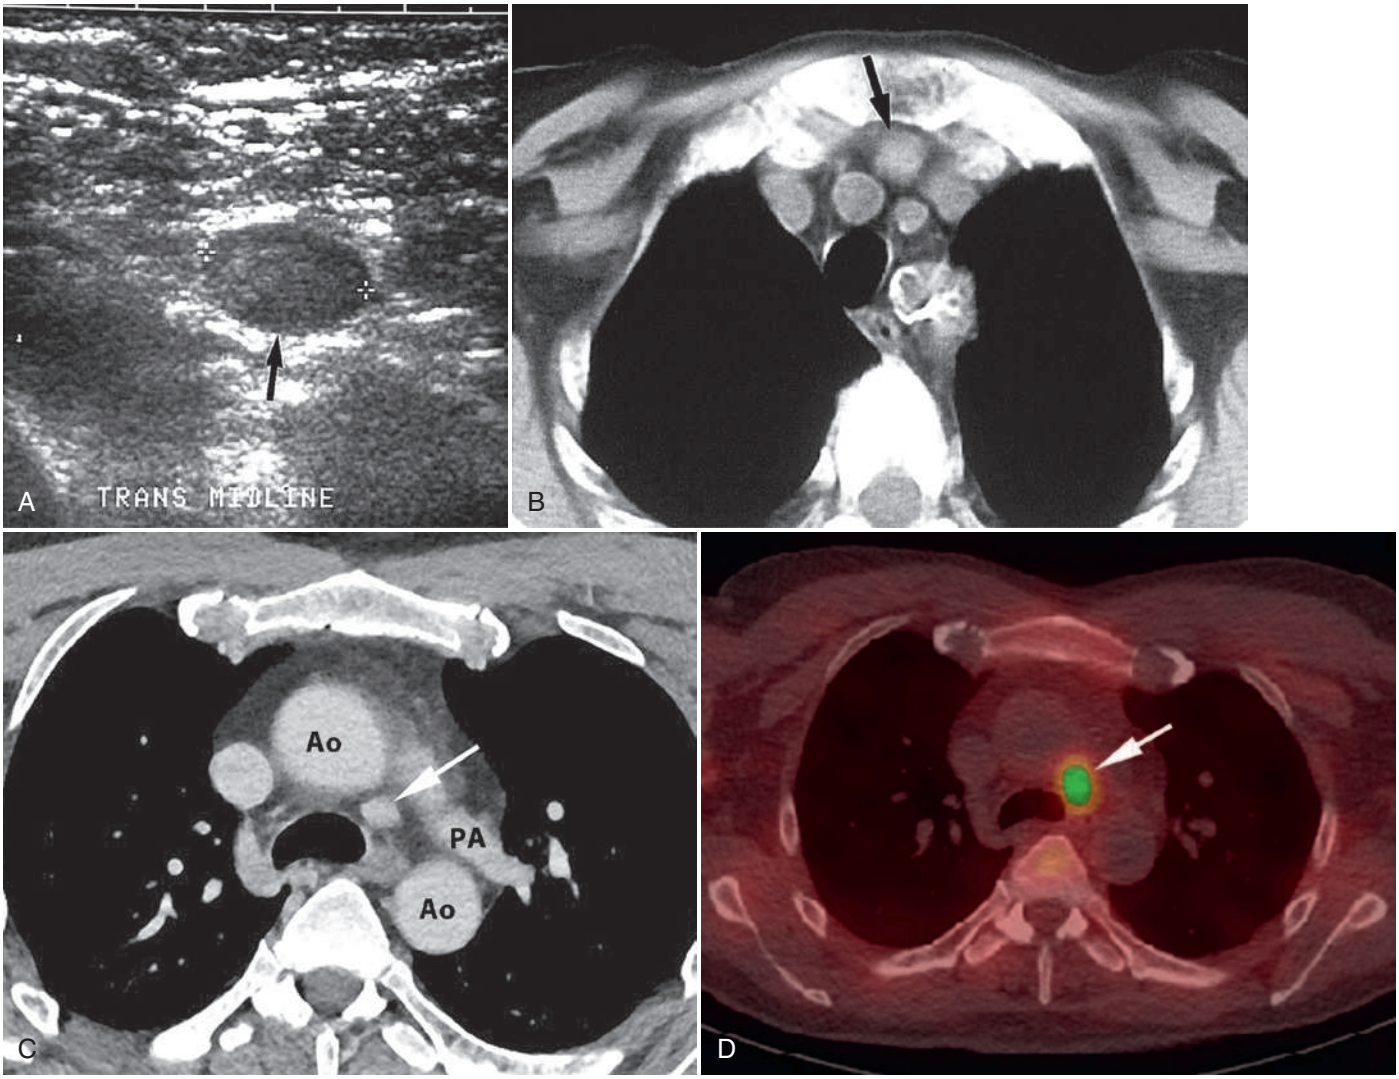

FIG. 20.11 Ectopic Parathyroid Adenoma: Mediastinum. (A) Transverse sonogram angled caudal to the clavicles shows an oval, 1-cm ectopic inferior parathyroid adenoma *(arrow)* in the soft tissues of the anterosuperior mediastinum. **(B)** CT scan of the upper mediastinum shows the ectopic adenoma in the anterosuperior mediastinum, deep to the manubrium and adjacent to the great vessels. **(C)** Enhanced axial CT performed in another patient shows an enhancing ectopic middle mediastinal parathyroid adenoma. *Ao,* Aorta; *PA,* left pulmonary artery. **(D)** Technetium-99m (^{99m}Tc) sestamibi axial single-photon emission computed tomography (SPECT)/CT scintigraphy shows the same ectopic adenoma in the middle mediastinum.

the hyoid bone and adjacent to the submandibular gland, or elsewhere within or along the carotid sheath[4,7,19,52-54] (Fig. 20.13, Video 20.12). These adenomas likely arise from inferior glands that are embryologically undescended, or partially descended, having come to reside within or adjacent to the carotid sheath that surrounds the carotid artery, jugular vein, and **vagus nerve.** They may be associated with a small amount of **ectopic thymic tissue.** These adenomas are frequently overlooked during surgery unless the surgeon specifically opens the carotid sheath and dissects within it.[6,7] Sonographically, these masses can appear similar to mildly enlarged lymph nodes in the jugular chain; correlative imaging and percutaneous biopsy are often necessary for confirmation before surgery. Ectopic undescended superior gland adenomas may be present high in the neck in a parapharyngeal location but frequently are not seen with traditional sonography.

PERSISTENT OR RECURRENT HYPERPARATHYROIDISM

Persistent hyperparathyroidism is the persistence of hypercalcemia after previous failed parathyroid surgery. This is frequently caused by an undiscovered ectopic parathyroid adenoma or unrecognized multiple gland disease, with failure to resect all the hyperfunctioning tissue during surgery.[55-57] **Recurrent hyperparathyroidism** is defined as hypercalcemia occurring after a 6-month interval of normocalcemia, resulting from the new development of hyperfunctioning parathyroid tissue from previously normal glands.[58] Recurrent hyperparathyroidism is often seen in patients with unrecognized MEN syndromes.

Because of scarring and fibrosis from previous surgery, the curative rate for repeat surgery is lower than for initial surgery; the risk of recurrent laryngeal nerve damage and postoperative

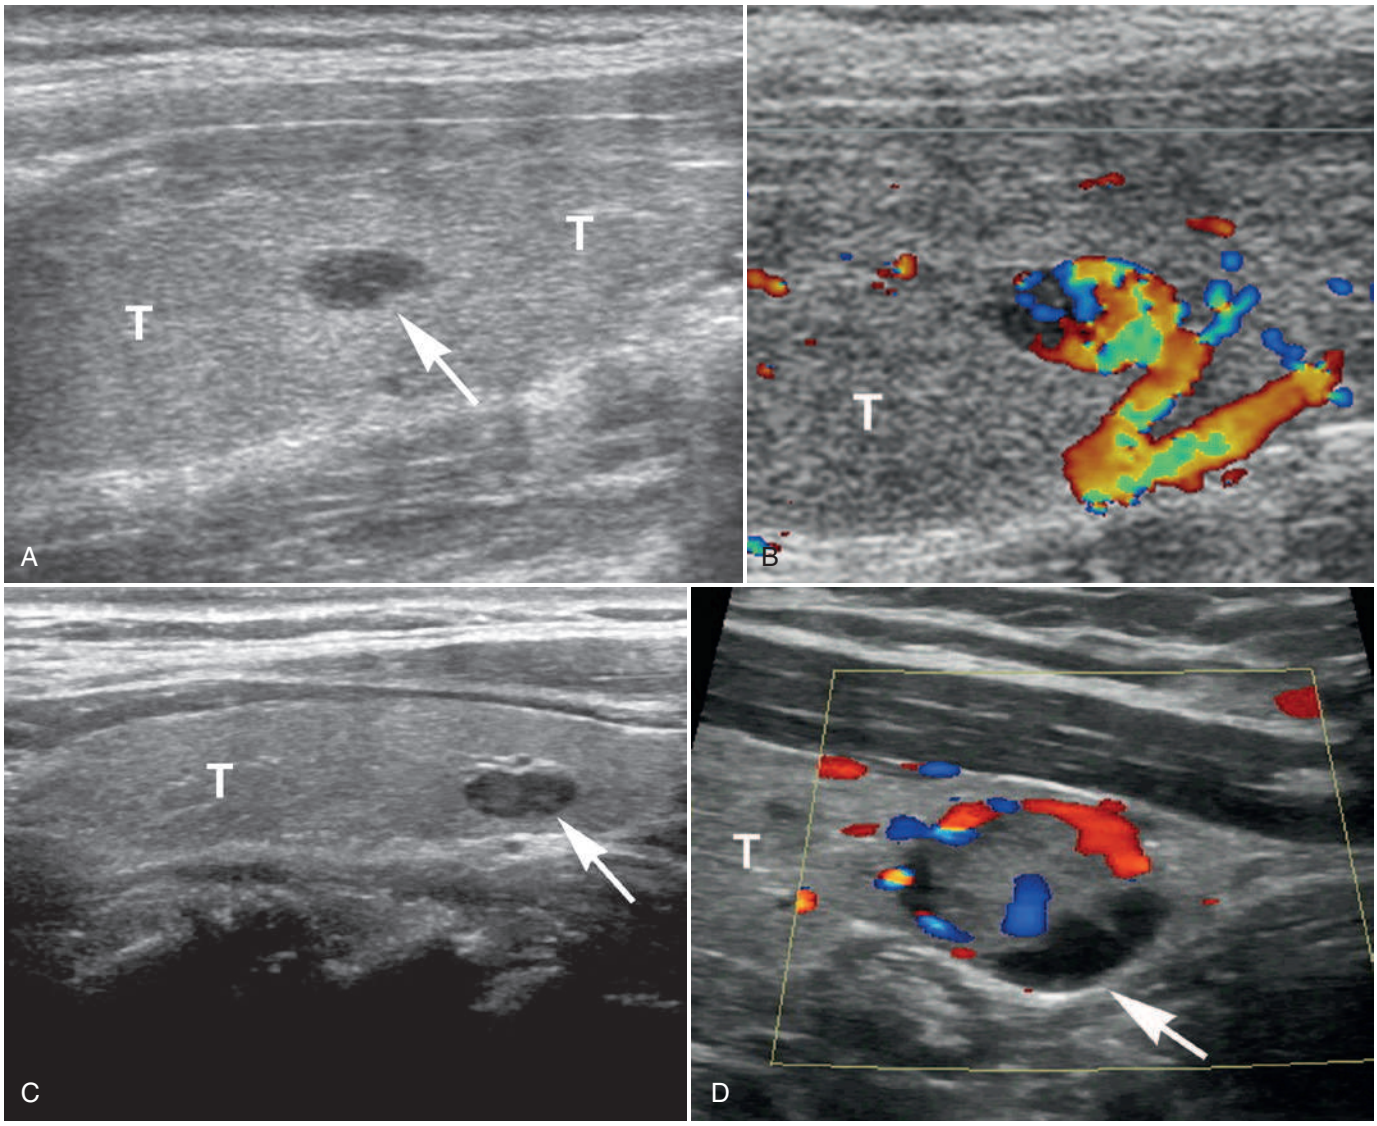

FIG. 20.12 Ectopic Parathyroid Adenoma: Intrathyroidal. (A) Longitudinal sonogram shows a subcentimeter hypoechoic intrathyroid parathyroid adenoma *(arrow)* in the midlobe completely surrounded by thyroid tissue. *T,* Thyroid. **(B)** Corresponding color Doppler flow imaging demonstrates typical hypervascularity with polar insertion of feeding vessel. **(C)** Longitudinal sonogram in another patient shows a subcentimeter hypoechoic intrathyroid parathyroid adenoma in the lower portion of the thyroid. **(D)** Longitudinal color Doppler flow sonogram in another patient shows a partially cystic intrathyroid parathyroid adenoma with prominent peripheral vascularity. See also Video 20.10.

hypocalcemia from hypoparathyroidism is also greater.[59,60] Imaging before reoperation is particularly beneficial.[57,60-64] Ultrasound is an effective first-line imaging modality in the preoperative and reoperative assessment of parathyroid disease, providing anatomic localization with a relatively inexpensive, noninvasive method that avoids the use of ionizing radiation.[43,44,63,64] During sonographic evaluation of reoperative patients, specific attention is paid to the most likely ectopic parathyroid locations—those associated with a gland that was not discovered at the initial neck dissection.

A small subgroup of patients who develop recurrent hyperparathyroidism underwent previous **autotransplantation** of parathyroid tissue in conjunction with previous total parathyroidectomy, typically for complications of chronic renal failure. Hyperparathyroidism in the setting of parathyroid autotransplantation is referred to as **graft-dependent hyperparathyroidism.** In parathyroid autotransplantation, a gland is sliced into fragments that are inserted into surgically prepared intramuscular pockets in the forearm or sternocleidomastoid muscle. Normal-functioning autotransplanted parathyroid grafts are typically too small and similar in echotexture to the surrounding muscle to be adequately visualized sonographically. However, graft-dependent recurrent hyperparathyroidism can be imaged sonographically, appearing as oval, sharply marginated, hypoechoic hypervascular nodules measuring 5 to 11 mm and similar in appearance to hyperfunctioning parathyroid glands or adenomas arising in the neck[65] (Fig. 20.14). The hyperfunctioning autotransplanted fragments usually can be found by the surgeon while the patient is under local anesthesia, and a portion of the grafted tissue can be excised to cure the hypercalcemia.

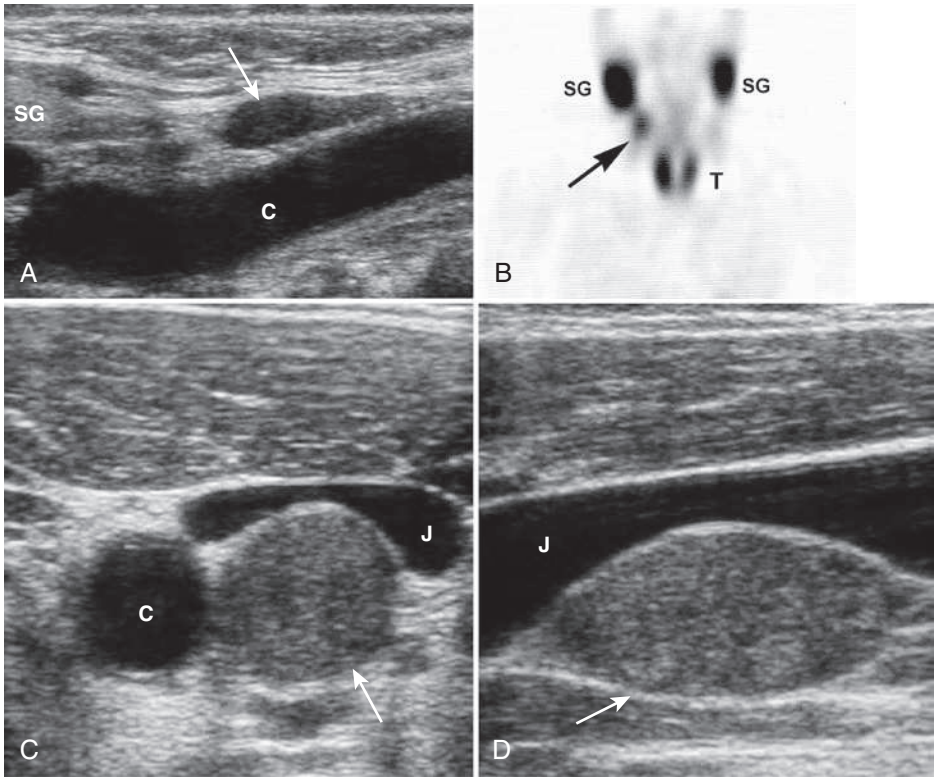

FIG. 20.13 Ectopic Parathyroid Adenoma: Near Carotid Sheath. (A) Longitudinal sonogram of the right side of the neck shows an ectopic undescended parathyroid adenoma *(arrow)* external to the carotid sheath, anterior to the common carotid artery *(C).* Ultrasound-guided biopsy confirmed parathyroid tissue before surgical exploration. *SG,* Submandibular gland. **(B)** ^{99m}Tc sestamibi coronal SPECT imaging shows a focal area of increased activity in right superior lateral neck, which corresponds to the ectopic adenoma. *SG,* Salivary glands; *T,* thyroid. **(C)** Transverse and **(D)** longitudinal sonograms in another patient show an ectopic left inferior adenoma located within the carotid sheath, posterior to the internal jugular vein *(J).* Ultrasound-guided biopsy confirmed parathyroid tissue before surgical exploration. At surgery, the adenoma was adherent to the vagus nerve. See also Video 20.12.

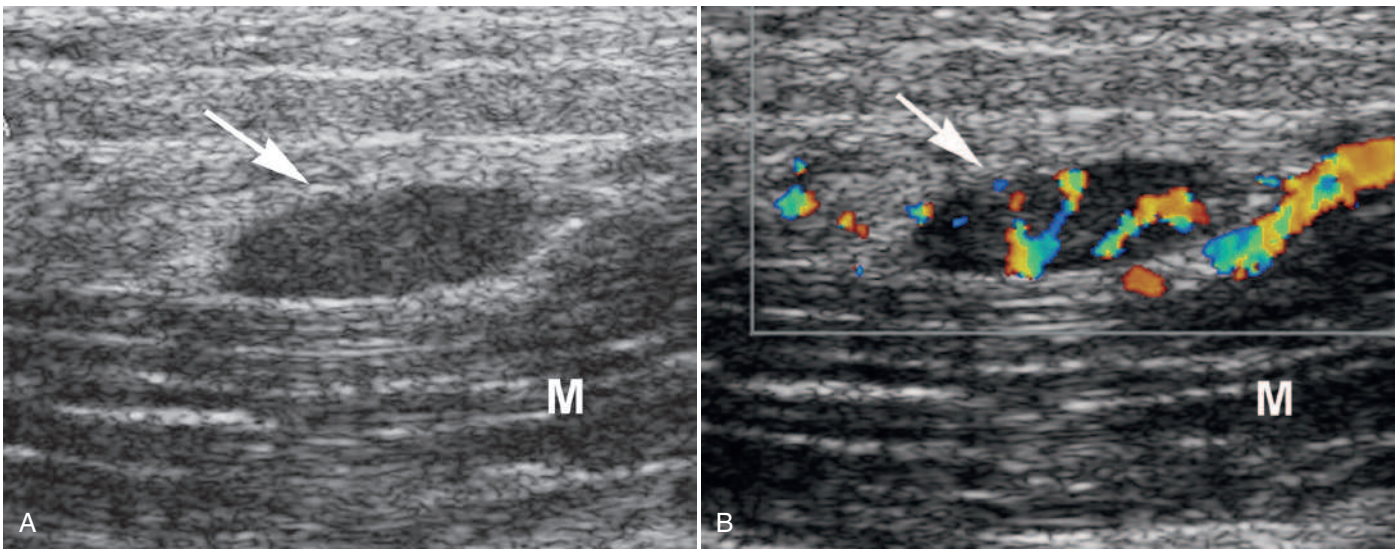

FIG. 20.14 Graft-Dependent Hyperparathyroidism. (A) Longitudinal sonogram of left forearm shows an oval, 2-cm hypoechoic nodule *(arrow)* resulting from hyperplasia of autotransplanted parathyroid tissue. *M,* Muscle. **(B)** Corresponding color Doppler flow sonogram shows hypervascularity of the hyperfunctioning parathyroid tissue in this patient with recurrent graft-dependent hyperparathyroidism.

Occasionally, for patients who are not candidates for repeat surgery, ultrasound-guided percutaneous ethanol injection may be used for ablation of recurrent hyperparathyroid disease in the neck or at a graft site (see "Ethanol Ablation").

A rare cause of persistent or recurrent hyperparathyroidism is **parathyromatosis,** a condition in which multiple foci of benign hyperfunctioning parathyroid tissue are present in the neck and/or mediastinum.[66,67] The theory of most common pathogenesis is inadvertent spillage and seeding of parathyroid cells during parathyroid excision. However, rare cases of hyperplasia of preexisting embryologic rests under the influence of physiologic stimuli have also been described.[66-70] The condition is most commonly seen in patients with a history of previous parathyroid surgery and those with secondary hyperparathyroidism resulting from chronic renal disease.[71] Sonographic imaging in the setting of recurrent hyperparathyroidism after previous parathyroid resection may demonstrate multiple hypoechoic to isoechoic neck nodules of varying size in locations atypical for missed parathyroid disease. Larger nodules may display hypervascularity, parasitized from local vessels[72] (Fig. 20.15, Video 20.13).

SECONDARY HYPERPARATHYROIDISM

Secondary hyperparathyroidism is characterized by pronounced parathyroid gland hyperfunction resulting from end-organ resistance to PTH and is most often found in patients with chronic

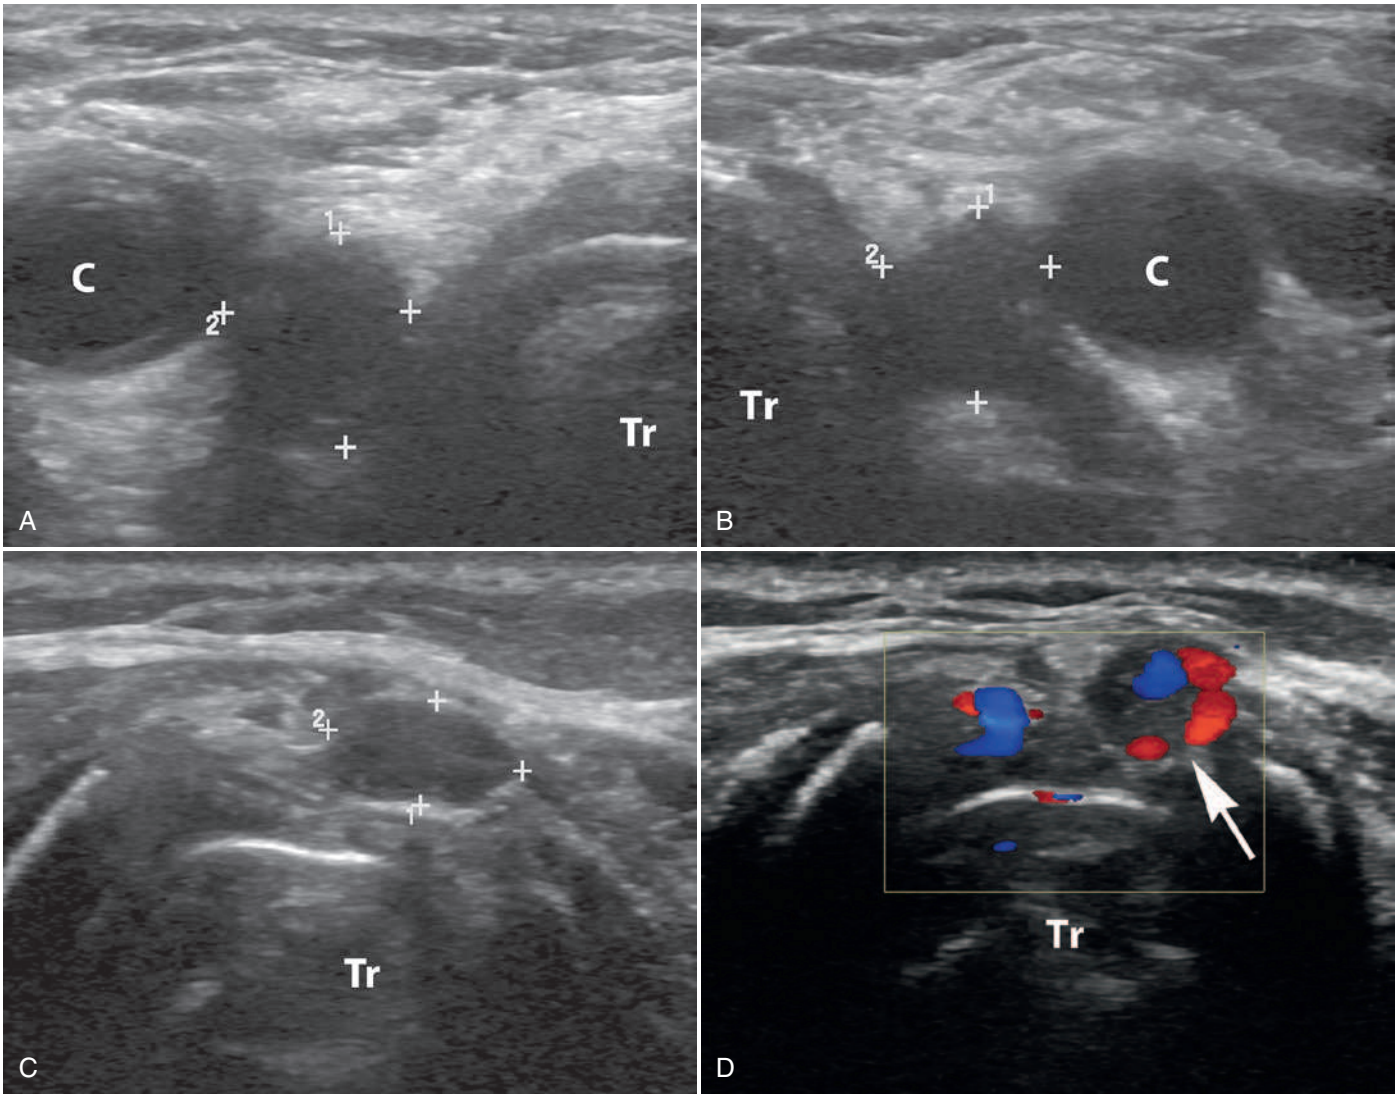

FIG. 20.15 Parathyromatosis in Persistent Primary Hyperparathyroidism. (A) Transverse sonogram of the right side of the neck in a patient with persistent primary hyperparathyroidism despite multiple surgeries for parathyroid and thyroid resection shows a 7-mm hypoechoic nodule *(calipers)* representing hyperfunctioning benign parathyroid tissue between the trachea *(Tr)* and common carotid artery *(C)*. **(B)** Transverse sonogram of the left side of the neck shows a similar-appearing 7-mm hypoechoic nodule *(cursors)* representing hyperfunctioning benign parathyroid tissue between the trachea and common carotid artery. **(C)** Transverse sonogram of the midline upper neck shows a 3 × 6–mm hypoechoic nodule representing hyperfunctioning benign parathyroid tissue. *T,* Trachea. **(D)** Corresponding color Doppler flow sonogram demonstrates peripheral parasitized hypervascularity *(arrow)*. See also Video 20.13.

renal failure. In these patients, chronic relative hypocalcemia is the result of multiple complex factors, including decreased synthesis of the active form of vitamin D, poor calcium and vitamin D absorption, persistent hyperphosphatemia, and skeletal resistance to the actions of PTH. These factors contribute to parathyroid hyperplasia. If untreated, secondary hyperparathyroidism can result in bone demineralization, soft tissue calcification, and acceleration of vascular calcification. Surgical treatment for secondary hyperparathyroidism is less common because of the success of renal transplantation, dialysis, and medical therapy, including the newer calcimimetics. However, in symptomatic patients who are refractory to these therapies, subtotal parathyroidectomy or total parathyroidectomy with autotransplantation are surgical options.[25,73-75]

Patients with secondary hyperparathyroidism have multiple enlarged glands. Individually, these glands may have the same sonographic appearance as other parathyroid adenomas (see Fig. 20.6, Videos 20.3 and 20.4). However, the glands may be asymmetrically enlarged and more lobular. Although imaging is not usually necessary, sonography can be used to evaluate the severity of parathyroid hyperplasia by assessing gland enlargement.[76,77] Patients with sonographically enlarged glands tend to have significantly worse symptoms, laboratory values, and radiographic signs of secondary hyperparathyroidism than patients without gland enlargement. Sonography can also be used to aid in localization of the enlarged parathyroid glands before surgical resection for secondary hyperparathyroidism. Ultrasound-guided percutaneous ethanol injection is also a treatment option for ablation of hyperplastic parathyroid glands in patients with refractory secondary hyperparathyroidism who are not surgical candidates (see "Ethanol Ablation").

PITFALLS IN INTERPRETATION

False-Positive Examination

Normal and pathologic cervical structures, such as lymph nodes, small veins adjacent to the thyroid gland, the esophagus, the longus colli muscles, and thyroid nodules, can simulate parathyroid adenomas, producing false-positive results during neck sonography.

Parathyroid Adenoma: Causes of Examination Errors

FALSE-POSITIVE RESULTS
Cervical lymph node
Prominent blood vessel
Esophagus
Longus colli muscle
Thyroid nodule

FALSE-NEGATIVE RESULTS
Minimally enlarged adenoma/gland
Multinodular thyroid goiter
Ectopic parathyroid adenoma

One source for a false-positive ultrasound study is confusion of **cervical lymph nodes** for a parathyroid adenoma.[32] Cervical lymph nodes are usually visualized sonographically in the lateral neck adjacent to the jugular vein and away from the thyroid. However, lymph nodes found adjacent to the carotid artery may occasionally simulate an ectopic adenoma. Lymph nodes may also be visualized within the central compartment near the inferior pole of the thyroid, simulating an inferior gland adenoma. Enlarged cervical lymph nodes may have an oval, hypoechoic appearance similar to parathyroid adenomas, but they often also have a central echogenic band or hilum composed of fat, vessels, and fibrous tissue, which differentiates them from parathyroid adenomas.[78] Nonetheless, ultrasound-guided biopsy may be necessary to distinguish a potential parathyroid adenoma from an atypical lymph node, particularly in the postoperative setting.

Many **small veins** lie immediately adjacent to the posterior and lateral aspects of both lobes of the thyroid, and a tortuous or segmentally dilated vein can simulate a small parathyroid adenoma. Scanning maneuvers to help establish the structure as a vein, not an adenoma, include (1) real-time imaging in multiple planes to show the tubular nature of the vein; (2) a Valsalva maneuver by the patient, which may cause transient engorgement of the vein; and (3) spectral or color Doppler sonography to show flow within the vein.

The **esophagus** may partially protrude from behind the posterolateral aspect of the trachea and simulate a mass or parathyroid adenoma (see Fig. 20.8B). Turning the patient's head to the opposite side will accentuate the protrusion. Careful inspection of this structure in the transverse plane shows that it has the typical concentric ring appearance of bowel, with a peripheral hypoechoic muscular layer and the central echogenic appearance of the mucosa and intraluminal contents. Using a longitudinal scan plane helps to demonstrate the tubular nature of this structure. Real-time imaging while the patient swallows will cause a stream of brightly echogenic mucus and microbubbles to flow through the lumen, which confirms that the structure is the esophagus.

The **longus colli muscle** lies adjacent to the anterolateral aspect of the cervical spine. When viewed in the transverse plane, it appears as a hypoechoic triangular mass that can simulate a large parathyroid adenoma located posterior to the thyroid gland. However, scanning in the longitudinal plane will show that this structure is long and flat and contains longitudinal echogenic striations typical of skeletal muscle. Real-time imaging while the patient swallows can be useful because swallowing will cause movement of the thyroid gland and adjacent thyroid structures, such as a parathyroid adenoma, but the longus colli muscle, which is attached to the spine, will remain stationary. Finally, comparison with the opposite side of the neck will demonstrate similar symmetric findings because the longus colli muscles are paired structures located on both sides of the cervical spine.

Thyroid nodules are also potential causes of false-positive ultrasound and scintigraphic imaging.[32,79] If a thyroid nodule protrudes from the posterior aspect of the thyroid, it can simulate a mass in the location of a parathyroid adenoma (Fig. 20.16). A

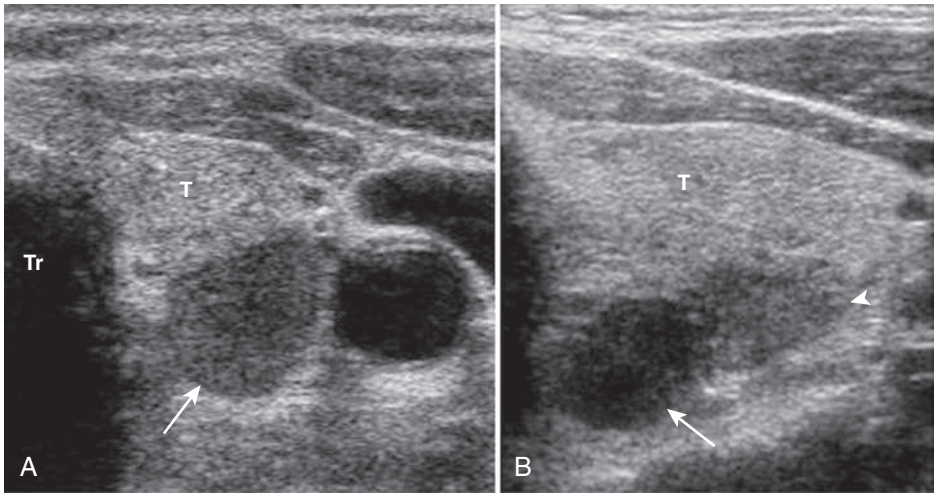

FIG. 20.16 Thyroid Nodules May Simulate Parathyroid Adenoma. (A) Transverse sonogram shows hypoechoic thyroid nodule *(arrow)* arising within the posterior aspect, left lobe of the thyroid *(T),* which could simulate a parathyroid adenoma. *Tr,* Trachea. **(B)** Transverse sonogram in another patient shows highly hypoechoic parathyroid adenoma *(arrow)* posterior to left lobe of the thyroid. An adjacent, slightly hypoechoic thyroid *(T)* nodule *(arrowhead)* is also present and might simulate a parathyroid adenoma.

useful sign in this situation is the thin, echogenic line of the capsular interface that separates the parathyroid adenoma (which usually arises outside the thyroid) from the thyroid gland itself (Video 20.14). Thyroid nodules, which arise within the thyroid gland, typically do not show this tissue plane of separation.[80] Morphologically, thyroid nodules, unlike parathyroid adenomas, are often partially cystic, and some are calcified. Also, thyroid nodules often are of a heterogeneous, mixed echogenicity, whereas parathyroid adenomas are typically of a homogeneous, hypoechoic echogenicity. When a parathyroid adenoma cannot be distinguished from a thyroid nodule by imaging criteria, ultrasound-guided percutaneous biopsy may be necessary.

False-Negative Examination

Minimally enlarged adenomas, adenomas displaced posteriorly and obscured by a greatly enlarged nodular thyroid, and ectopic adenomas may cause false-negative imaging results.

Minimally enlarged adenomas or **hyperplastic glands** are a common cause of error because they can be difficult to distinguish from the thyroid and adjacent soft tissues[32,81] (see Fig. 20.5A, Video 20.2). The abnormal but minimally enlarged gland can be encountered with single adenomas or with multigland disease caused by hyperplasia. **Multinodular thyroid goiters** interfere with parathyroid adenoma detection in two ways.[32,79,81] First, the thyroid gland enlargement displaces structures located adjacent to the posterior thyroid, away from the transducer. This can necessitate the use of 5-MHz transducers rather than higher-frequency transducers to obtain the necessary penetration, which decreases spatial resolution. Second, thyroid goiters may have a multinodular contour and irregular echotexture, which can cast refractive shadows, decrease the conspicuity and thereby hinder the detection of adjacent parathyroid gland enlargement (Videos 20.15 and 20.16). Some **ectopic adenomas,** such as retrotracheal adenomas or adenomas located deep in the mediastinum, will not be visible because of acoustic shadowing from overlying air and bone.

ACCURACY IN IMAGING

Ultrasound

Sonographic imaging provides a noninvasive and economical method to localize parathyroid adenomas in the preoperative setting of primary hyperparathyroidism, without the need for patient radiation exposure.[43,44,63,64,82-91] However, the success of parathyroid ultrasound depends on the use of high-frequency, higher-resolution technology and improves with operator experience and diligence. The sensitivity of sonographic parathyroid adenoma localization in primary hyperparathyroidism varies from 74% to 89% and improves with the use of higher-resolution sonography and in the hands of an experienced examiner.[42,43,63,85-88,92,93] The reported accuracy for ultrasound in detecting adenomatous disease is 74% to 94%, the specificity 96%, and the positive predictive value 93% to 98%.[42,43,82,86,87,92,93] However, the sensitivity of ultrasound to detect ectopic mediastinal adenomas is predictably much lower, and the accuracy, sensitivity, and specificity decrease in the setting of multigland disease.[42-44,82,84,88,92] Therefore the success of sonographic parathyroid adenoma localization also depends on the specific characteristics of the patient population imaged, including the prevalence of multigland and ectopic mediastinal parathyroid disease. However, overall successful localization of solitary or multiglandular parathyroid disease in the neck by an experienced examiner has been reported as 78%.[92]

As described later, ultrasound-guided **fine-needle aspiration (FNA) biopsy** is a valuable adjunct to the ultrasound examination and can be used to improve its accuracy. For any suspected adenoma mass, aspirates should be sent for PTH assay, in addition to cytologic analysis.[19,60,92,94-99] Another advantage of ultrasound is its ability to assess for concomitant thyroid disease during the evaluation for parathyroid disease, which may further impact surgical planning.

In persistent or recurrent hyperparathyroidism, sensitivity of sonography in adenoma localization varies widely. However,

sonography has demonstrated some of the highest sensitivities and accuracies of all modalities for adenoma detection in the reoperative setting, especially when combined with ultrasound-guided FNA biopsy of a suspected parathyroid adenoma.[57,59,60,62,64,100-103] Ultrasound augmented by FNA biopsy and PTH assay can lead to a specificity approaching 100%, a sensitivity of 84% to 90%, and an accuracy 82% to 84%.[60,103] It is important to understand that in most large clinical series of patients undergoing reoperation for hyperparathyroidism, the great majority of parathyroid adenomas are still found in the neck or are accessible through a neck incision.[59-61,64] Therefore a thorough ultrasound examination of the neck is important in these reoperative patients. If the adenoma is not visible sonographically, an ectopic mediastinal location must be considered. There should be a low threshold to utilize multiple imaging modalities, especially when initial imaging findings are ambiguous or the surgical risk is high.[57,60,61,64] This approach significantly improves the success rate and decreases the procedural time and cost in the reoperated patient.[57,59,60]

Other Modalities

Another widely used imaging modality for parathyroid localization is **scintigraphy** with technetium-99m (^{99m}Tc) labeled agents, providing combined functional and anatomic imaging in the primary preoperative imaging of patients with parathyroid disease.[44,81,85,88,104-111] ^{99m}Tc sestamibi scintigraphy, using single-isotope, dual-phase ("washout") imaging, or dual-isotope, single-phase ("subtraction") imaging, particularly when combined with single-photon emission computed tomography (SPECT) or SPECT/CT, has sensitivity similar to or better than ultrasound[44,62,81,85,104-109,111-116] (Fig. 20.17). Scintigraphy can demonstrate adenomas in areas that are missed by ultrasound, including the mediastinum and retrotracheal space. However, scintigraphy is more expensive than ultrasound and requires the use of ionizing radiation. As with ultrasound, parathyroid scintigraphy also appears to be less sensitive and accurate in multiglandular parathyroid disease, for smaller adenomas, and in the presence of multinodular thyroid disease.[92,93,111]

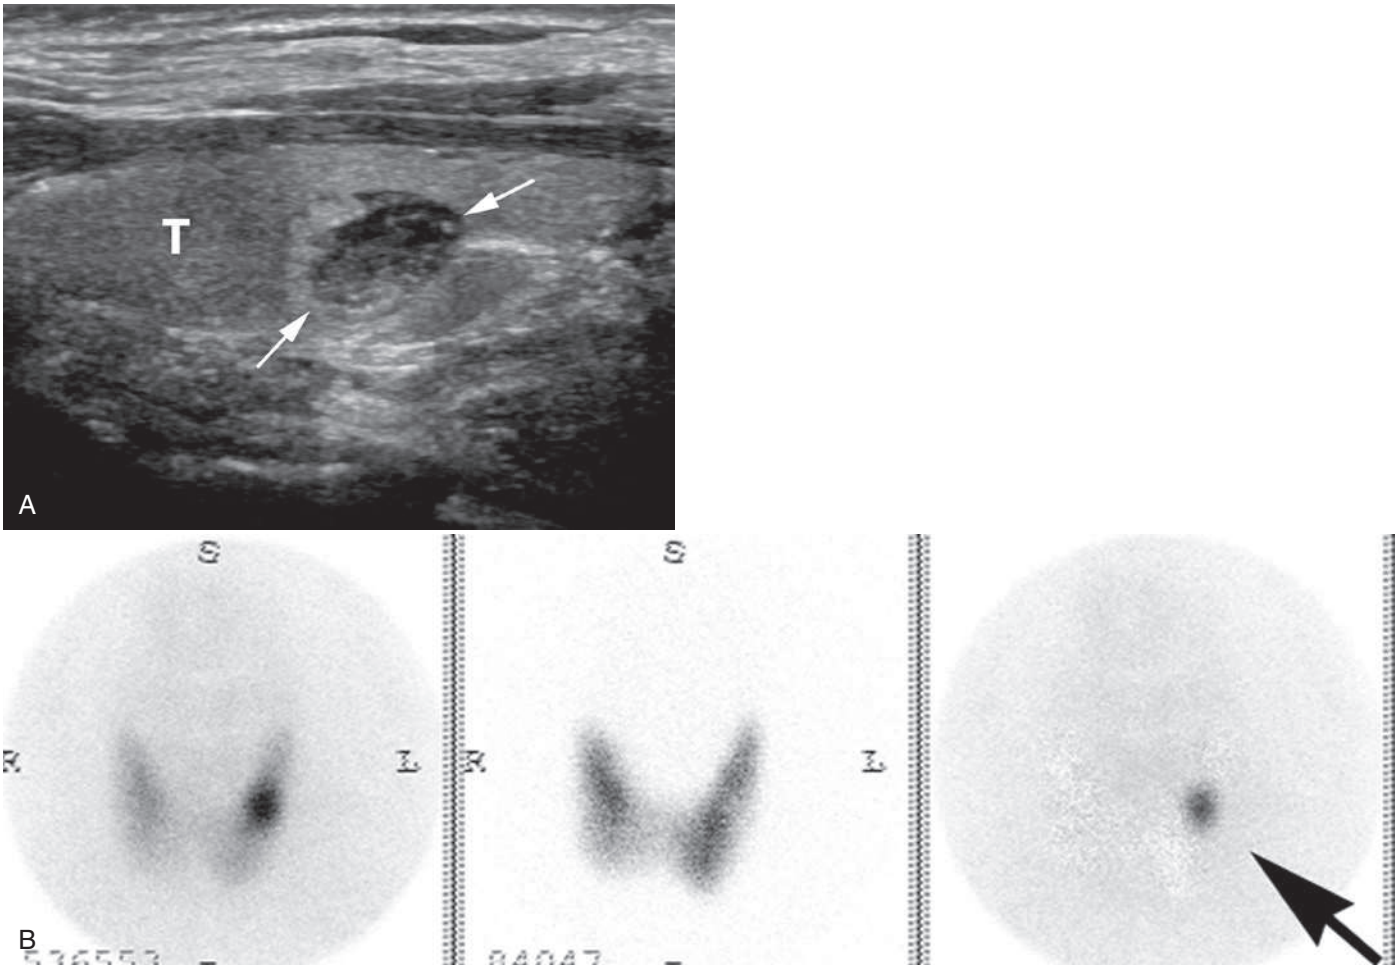

FIG. 20.17 Ectopic Intrathyroid Parathyroid Adenoma. Correlation of ultrasound and scintigraphy. **(A)** Longitudinal sonogram of the left neck in a patient with persistent hyperparathyroidism shows a heterogeneous ectopic intrathyroid parathyroid adenoma *(arrows). T,* Thyroid. **(B)** Corresponding anterior projection using ^{99m}Tc sestamibi *(left image)* and iodine-123 *(middle image)* dual-agent subtraction *(right image)* coronal SPECT imaging shows a concordant focal area of increased activity *(arrows)* in the left thyroid lobe, which corresponds to the ectopic intrathyroid parathyroid adenoma.

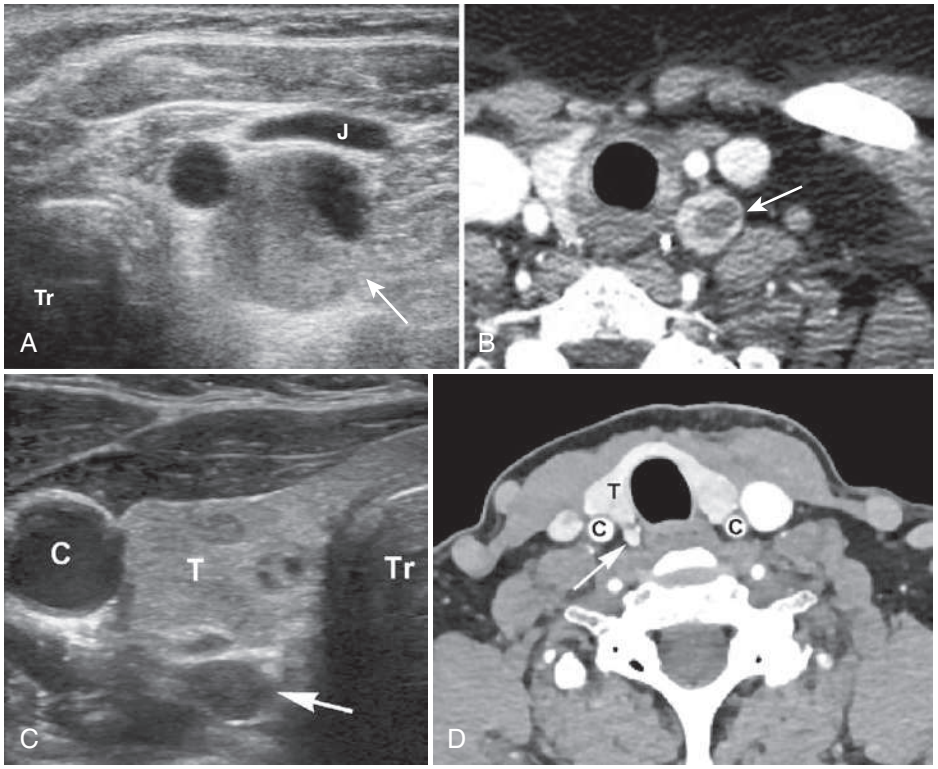

FIG. 20.18 Parathyroid Adenoma: Correlation of Ultrasound and CT. (A) Transverse sonogram shows a partially cystic ectopic supernumerary parathyroid adenoma *(arrow)* posterior to the left internal jugular vein *(J)* but external to the carotid sheath. Left superior and inferior parathyroid glands and the left thyroid lobe had previously been resected. *Tr,* Trachea. **(B)** Enhanced conventional axial CT image of the neck shows the same partially cystic parathyroid adenoma. **(C)** Transverse sonogram in another patient shows a subcentimeter parathyroid adenoma posterior to the right thyroid lobe *(T). C,* Common carotid artery. **(D)** Contrast enhanced axial CT of the neck shows the enhancing adenoma posterior to the right thyroid lobe.

Computed tomography (CT) is also used in the evaluation of parathyroid disease. More recently, thin-acquisition thickness, multidetector CT (MDCT) with reconstruction has been utilized with multiphase technique ("four-dimensional" ["4D"]), and provides high-resolution, multiplane diagnostic information based on the temporal perfusion characteristics of parathyroid tissue[117-122] (Fig. 20.18). Successful imaging requires experience in interpretation with close attention to exam technique; in such studies, preoperative lateralization of single gland parathyroid disease accuracies of 92% to 94%, sensitivities of 88% to 92%, and specificity of 93% have been reported, with sensitivity decreasing to 43% in the setting of multigland disease.[117-122] However, these examinations typically utilize multiphase, thin-acquisition thickness techniques, which lead to concerns of increased radiation exposure to the patient, despite dose reduction with protocol modifications. In addition, potential drawbacks of the technique include exam costs and the need to administer iodinated IV contrast material. Therefore it has not been widely supported in the literature as initial first-line preoperative imaging method to detect parathyroid disease.

Magnetic resonance imaging (MRI) is also a useful noninvasive modality in the evaluation of parathyroid disease but is not widely performed nor widely supported by the literature for first-line parathyroid imaging[44,111,123-127] (Fig. 20.19). As with ultrasound, MRI is performed without the need for patient radiation exposure; however, it is more expensive than ultrasound. MRI has demonstrated particular utility in localizing **mediastinal adenomas** and in the evaluation of the reoperative patient, especially in cases when other functional and cross-sectional imaging has been inconclusive.

The previously described modalities have largely replaced angiography and venous sampling in the imaging of parathyroid disease.[44,86,128] Selective **venous sampling** is more invasive, expensive, and technically demanding than other imaging modalities. However, it can be an occasional useful technique to lateralize parathyroid disease, particularly in a high-risk reoperative setting or when previous noninvasive imaging is inconclusive.[128]

The combination of multiple preoperative imaging studies demonstrates improved sensitivity compared with single-modality evaluation. Combined imaging with ultrasound and ^{99m}Tc sestamibi scintigraphy increases the sensitivity for the preoperative diagnosis of parathyroid disease.[44,85,90,104,110-112] When multiple studies are used, ultrasound is a good choice for initial preoperative imaging because of its noninvasiveness, lack of radiation exposure, relative low cost, high-resolution anatomic detail, ability to assess for concomitant thyroid disease, and competitive sensitivity and accuracy when used by an experienced examiner.[92,103,110,111,113,115,116,129]

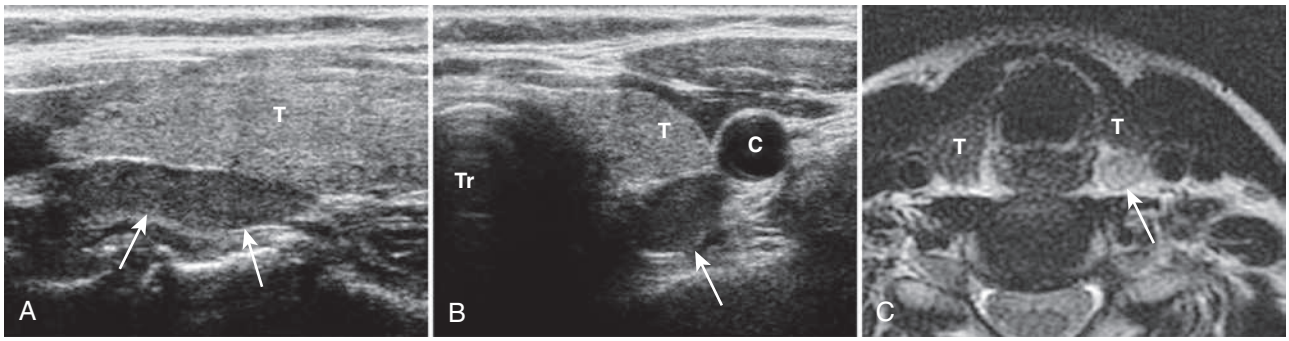

FIG. 20.19 Parathyroid Adenoma: Correlation of Ultrasound and MRI. (A) Longitudinal and **(B)** transverse sonograms show superior parathyroid adenoma *(arrows)* posterior to upper-middle portion of left lobe of the thyroid *(T). C,* Common carotid artery; *Tr,* trachea. **(C)** T2-weighted fast spin-echo axial MRI of the neck shows the same left superior parathyroid adenoma *(arrow),* which appears hyperintense compared with the thyroid gland.

Importance of Imaging in Primary Hyperparathyroidism

Primary hyperparathyroidism is commonly clinically recognized, and both clinicians and patients desire definitive treatment for it. Definitive cure of primary hyperparathyroidism requires surgical parathyroidectomy, which can be accomplished with a very high degree of success and minimal morbidity when performed by an experienced surgeon.[24,25,27] Historically, the standard surgical procedure involved open bilateral neck dissection with inspection of each parathyroid gland, and routine preoperative imaging was not considered necessary.

Minimally invasive surgical techniques, termed **minimal-access parathyroidectomy (MAP),** now predominate as standard surgical technique for first-time surgery in primary hyperparathyroidism.[24,27,130-133] In MAP the abnormal gland or adenoma is selectively removed through a small unilateral incision in the neck, thereby potentially improving cosmesis, reducing complication risks, and decreasing operative time, hospital stay, and overall cost, often without sacrificing significant operative efficacy when performed by an experienced surgeon (Fig. 20.20). Moreover, postsurgical fibrosis is limited to a smaller area, thus facilitating any necessary repeat surgery in the future. The successful institution of these minimally invasive techniques is predicated on the availability of (1) accurate preoperative imaging techniques to direct a focused surgical approach and (2) reliable, rapid (10-15 minutes) **intraoperative parathyroid hormone monitoring,** which facilitates the surgical determination of the need for further exploration. With intraoperative PTH monitoring the surgeon can quickly assess the success of a focused unilateral approach. If intraoperative PTH levels fail to normalize or decrease by at least 50%, multigland disease should be suspected, and the procedure may be converted to a bilateral dissection.

Many investigators promote the use of both anatomic and functional imaging, such as ultrasound and ^{99m}Tc sestamibi scintigraphy, to increase the preoperative certainty of unilateral disease and aid in excluding patients with multigland disease who are not candidates for MAP.[19,62,82,84-86,103,104,110,112,113,116,129] Proponents of preoperative imaging in primary hyperparathyroidism also note that some adenomas are found lower in the neck or mediastinum and that the initial operative approach may be changed or optimized if imaging shows parathyroid disease near the thymus.[24,60,87,91]

In patients with persistent or recurrent hyperparathyroidism, localization studies are liberally used because of the lower surgical success rate and the higher morbidity rate of reoperation. Preoperative localization studies in recurrent hyperparathyroidism contribute to both the success and the speed of the repeat surgery. In patients who had reexploration for persistent or recurrent hyperparathyroidism, the surgical cure rate was 88% to 89%, and it was thought that prospective localization studies contributed to this high rate of success and decreased surgical time.[57,59,60] Because most persistent and recurrent parathyroid adenomas are accessible in the neck or the upper mediastinum through a cervical incision, sonography and ^{99m}Tc sestamibi scintigraphy, particularly with SPECT or SPECT/CT, may be the initial localizing procedures of choice and, in select patients, can aid in directing a focused, minimal-access surgical approach[44,59,60,62,64,92,100,103,110,111,113,115,116,129] (Fig. 20.21). However, low threshold for additional diagnostic confirmation with ultrasound-guided biopsy, 4D MDCT, and/or MRI is supported.[103,110,111,118,120] (Fig. 20.22).

INTRAOPERATIVE SONOGRAPHY

Intraoperative sonography is occasionally a useful adjunct in the surgical detection of parathyroid adenomas, particularly in the reoperative setting.[19,134,135] Intraoperative scanning can be performed with a small, conventional, high-frequency (8-18 MHz) transducer draped with a sterile plastic sheath or with a dedicated sterilized intraoperative transducer. Intraoperative ultrasound appears to be most useful for localizing abnormal inferior and intrathyroid parathyroid glands.[135] Correlated with preoperative imaging, intraoperative sonography can also help guide a focused surgical resection to limit tissue damage associated with exploration in the reoperated patient; it also allows directed resection of ectopic adenomas in the mediastinum, thyroid, and carotid sheath. If an abnormal parathyroid gland is detected, surgical time can be shortened.

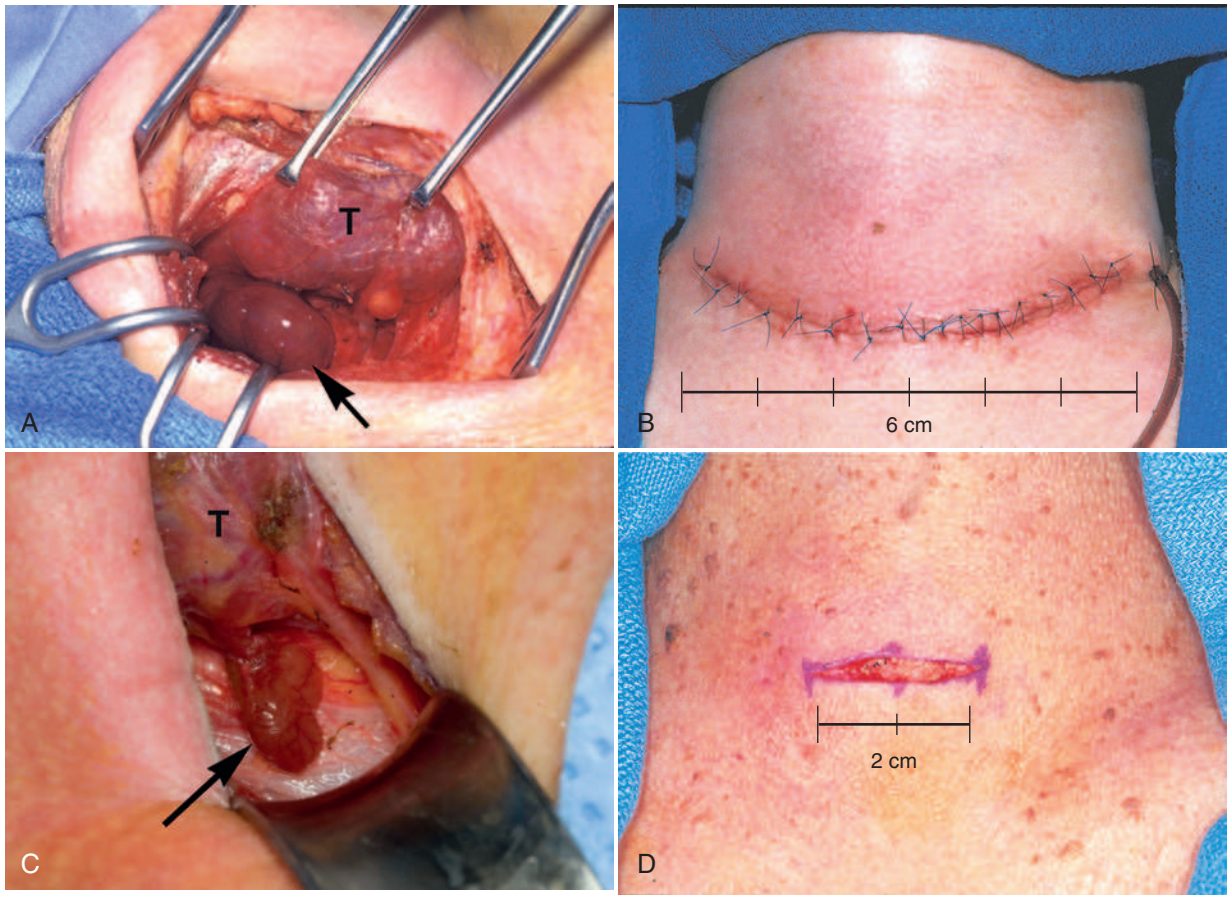

FIG. 20.20 Comparison of Surgical Procedures for Removal of Parathyroid Adenoma. (A) Intraoperative photograph during bilateral neck dissection for parathyroidectomy. The thyroid gland *(T)* is retracted back and a parathyroid adenoma *(arrow)* exposed. **(B)** Corresponding 6-cm "collar" incision with a surgical drain. **(C)** Intraoperative photograph during minimally invasive surgery uses a much smaller incision. Parathyroid adenoma is exposed adjacent to the thyroid *(T)*. **(D)** Minimally invasive surgical incision, approximately 2 cm. (Courtesy of Geoffrey B. Thompson, MD, Mayo Clinic, Rochester, Minn.)

PERCUTANEOUS BIOPSY

Sonographically guided percutaneous FNA biopsy can be used for preoperative confirmation of suspected abnormal parathyroid glands in selected cases, particularly in the candidate for reoperation.[59,60,94,96-102,136] This technique can decrease the false-positive rate and increase the specificity of sonography by permitting the reliable differentiation of parathyroid adenomas from other pathologic structures, such as thyroid nodules and cervical lymph nodes. In addition to its value to the surgeon, a positive biopsy may reassure the reluctant reoperative patient. FNA biopsy is also generally obtained for diagnostic confirmation before percutaneously injected ethanol ablation of a suspected abnormal gland.

If the suspected parathyroid adenoma is in a location remote from the thyroid gland, the main differential diagnostic consideration is a lymph node. Percutaneous biopsy is performed by using a standard noncutting 25- or 27-gauge needle to obtain aspirates that contain either parathyroid cells or lymphocytes (Fig. 20.23, Videos 20.17 and 20.18). The aspirate must also be analyzed for PTH because elevated levels indicate the presence of parathyroid tissue, even if the cytologic results are inconclusive.[19,96-99] After the aspirated material is expelled onto a slide for cytologic review, the residual sample in the needle hub is rinsed with a tiny amount of sterile saline, emptied into a tube, and placed on ice. This is repeated for each aspirate, diluting the sample for PTH assay into a total volume of 1 to 1.5 mL. Alternatively, three to four aspirates may be expelled and rinsed directly into a tube containing 1 to 1.5 mL of sterile saline, then placed on ice. When performed in this manner, positive aspirate assays yield PTH levels markedly higher than that of normal serum levels, and typically much higher than the patient's own inappropriately elevated serum PTH levels. If the suspected parathyroid adenoma lies adjacent to the thyroid, FNA biopsy may be necessary to differentiate parathyroid and thyroid tissue. These aspirates should also be analyzed for PTH because parathyroid and thyroid tissue can be very difficult to differentiate by cytology.[19,96-99] In addition, thyroid tissue sometimes must be traversed to access a parathyroid adenoma, causing possible sample contamination with thyroid cells.[19] A histologic specimen obtained with a small-caliber (20- to 22-gauge) cutting needle may provide more cellular material for analysis but usually is unnecessary if PTH assay is performed. In addition, the possibility of **postbiopsy periglandular fibrosis** complicating subsequent

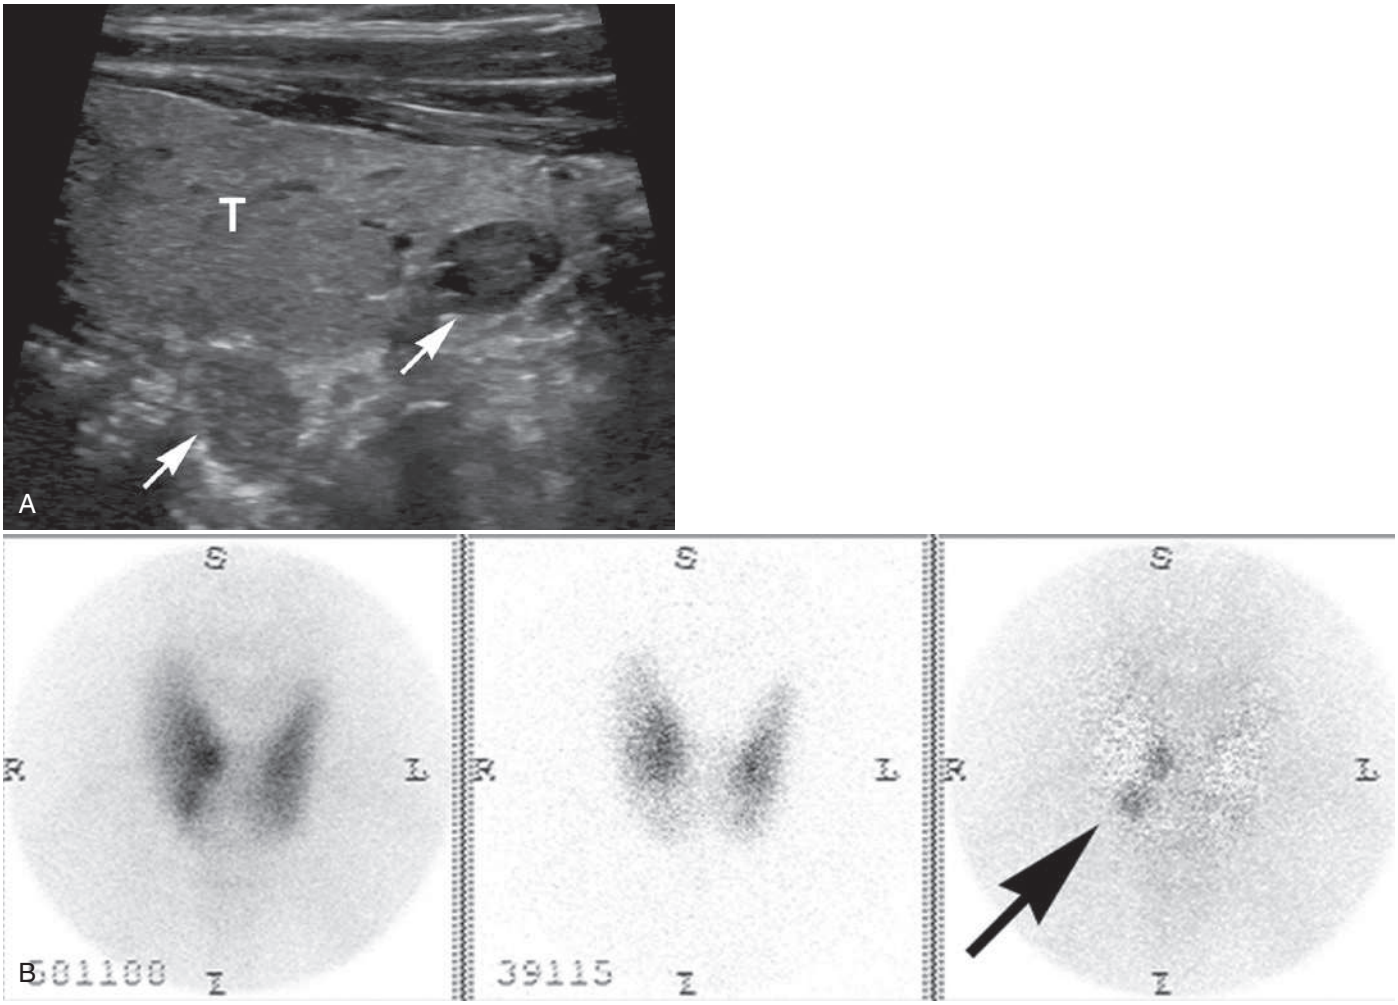

FIG. 20.21 Multimodality Imaging in Recurrent Hyperparathyroidism. (A) Longitudinal sonogram of the right neck in a patient with recurrent hyperparathyroidism shows two subcentimeter nodules *(arrows)* along the posterior surface of the thyroid *(T),* consistent with hyperplastic parathyroid tissue at the site of previous remote parathyroid resection for multiple gland disease. **(B)** Corresponding anterior projection from ^{99m}Tc sestamibi *(left image)* and iodine-123 *(middle image)* dual-agent subtraction *(right image)* coronal SPECT imaging shows two concordant focal areas of increased activity *(arrow).*

surgery may be greater with cutting-needle biopsy. FNA biopsy of suspected parathyroid adenomas is well tolerated, with few reported complications.[103] Although a theoretic consideration, parathyromatosis does not appear to be a complication of FNA biopsy.[137]

ETHANOL ABLATION

Sonography can be used to guide percutaneous injection of ethanol into abnormally enlarged parathyroid glands for chemical ablation.[138-151] Ethanol ablation is most often used in postoperative patients with recurrent or persistent hyperparathyroidism who have sonographically visible, biopsy-proven hyperfunctioning parathyroid tissue but who are poor surgical candidates.[141,144,146] Some dialysis patients with secondary hyperparathyroidism and patients with a history of multigland disease with recalcitrant recurrent hyperparathyroidism after previous subtotal surgery have also received this treatment.[141,146-151] Ethanol ablation has been shown to be very useful in patients with MEN I who have had previous subtotal parathyroidectomy and recurrent disease in their remaining residual half-gland in the neck.[141,152] A portion of the remaining gland can be ablated with ethanol to control hypercalcemia and avoid repeat surgery, which has a very high complication rate of postoperative hypoparathyroidism in these patients. Autografts in patients with recurrent graft-dependent hyperparathyroidism can be similarly treated[153] (Fig. 20.24, Video 20.19). Adenomatous hyperplasia with autonomously functioning glands **(tertiary hyperparathyroidism)** has also been treated with ultrasound-guided ethanol injection to reduce gland mass, but with unpredictable results.[154,155]

Ethanol ablation is generally performed under local anesthesia, typically after confirmation of parathyroid tissue with FNA biopsy. Under real-time ultrasound guidance, a standard 25-gauge needle attached to a 1-mL tuberculin syringe is inserted into the mass. With the tip in constant visualization, sterile 95% ethanol is injected into multiple regions of the mass, with a volume about

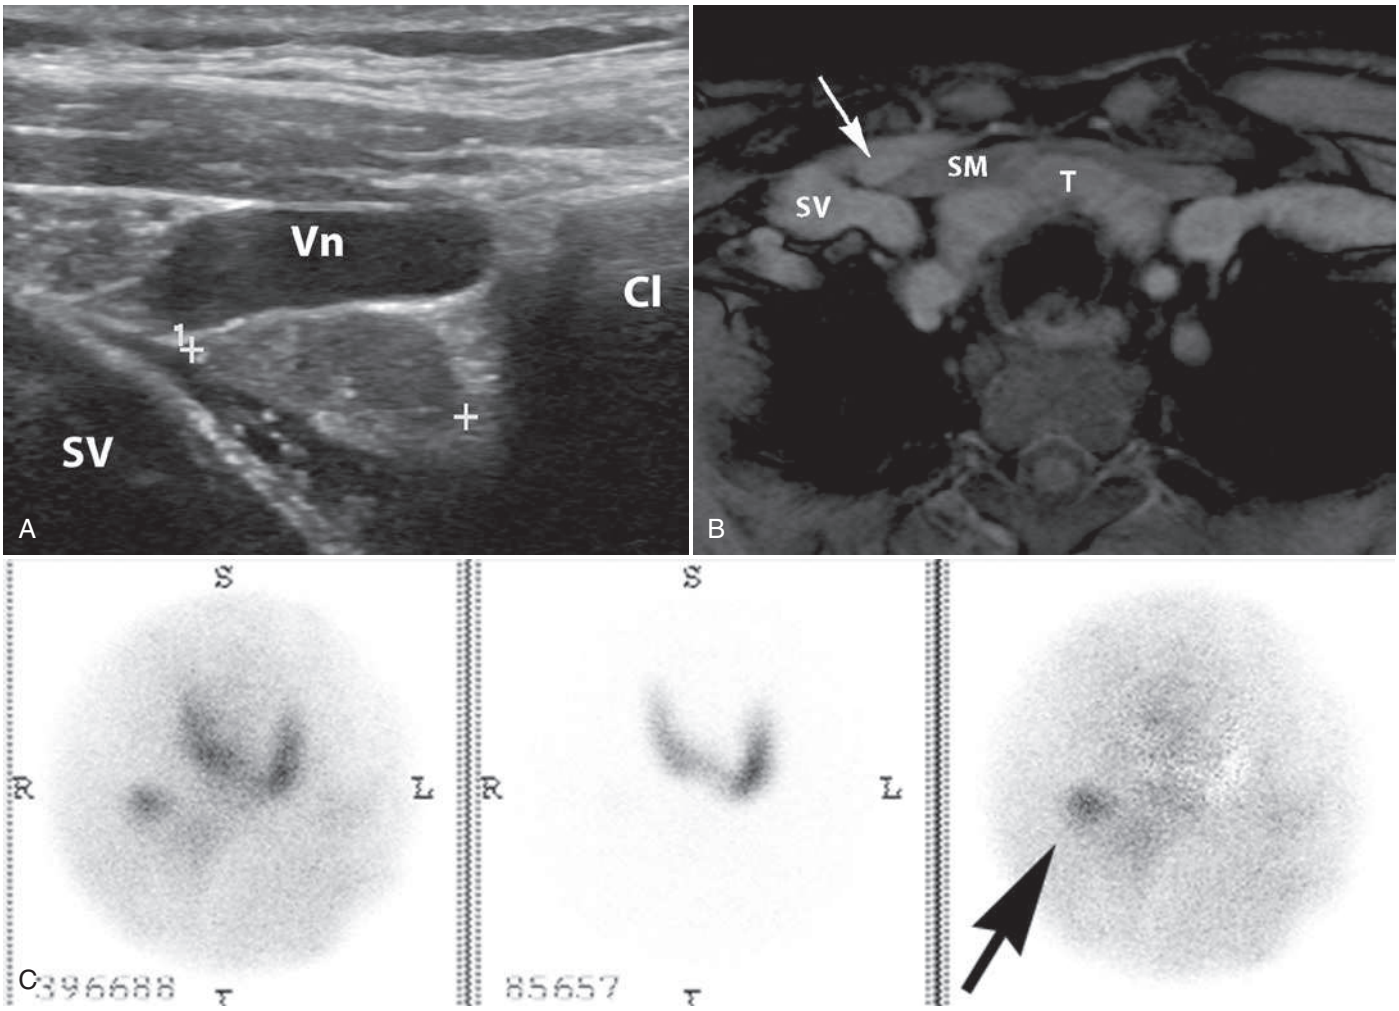

FIG. 20.22 Ectopic Parathyroid Adenoma: Multimodality Imaging in Persistent Hyperparathyroidism. (A) Longitudinal, sonogram demonstrates an ectopic parathyroid adenoma *(calipers)* adjacent to the right clavicle *(Cl),* overlying the subclavian vein *(SV)* and deep to a prominent collateral vein *(Vn).* **(B)** Artifact from the adjacent clavicle and IV contrast bolus limited CT evaluation (not shown), however, enhanced axial MRI demonstrates the enhancing ectopic parathyroid adenoma *(arrow)* overlying the strap musculature *(SM)* and the subclavian vein. *T,* Thyroid. **(C)** Corresponding right anterior oblique projection from ^{99m}Tc sestamibi *(left image)* and iodine-123 *(middle image)* dual-agent subtraction *(right image)* coronal SPECT imaging shows a concordant focal area of increased right periclavicular activity *(arrows)* which corresponds to the ectopic parathyroid adenoma.

half that of the mass, typically 0.1 to 1.0 mL. The tissue becomes highly echogenic at the moment of injection; the echogenicity slowly disappears over 1 minute. There is also a marked decrease in vascularity of the parathyroid adenoma after alcohol injection, presumably secondary to thrombosis and occlusion of parathyroid vessels (Fig. 20.24D). The injections are repeated every day or every other day until the serum calcium level reaches the normal range. In most patients, three or fewer injections are necessary. All patients undergoing parathyroid ethanol ablation require long-term close follow-up of serum calcium levels to detect subsequent hypoparathyroidism or, more often, recurrent hyperparathyroidism.

The reported adverse effects from ethanol ablation of parathyroid adenomas have been limited to temporary jaw pain during the procedure and dysphonia from vocal cord paralysis. Dysphonia is caused by recurrent laryngeal nerve palsy, which is typically a transient effect. Patients who have had prior subtotal parathyroid surgery are also theoretically at increased risk for postablation hypoparathyroidism, and conservative ablation of only a portion of the remaining gland is prudent.

The long-term efficacy of ethanol ablation as a treatment of hyperparathyroidism in patients with primary disease does not approach that of surgery.[139-142,144,146,152] In addition, postablation periglandular fibrosis may make future surgical procedures more difficult. Therefore ethanol ablation as a treatment of primary hyperparathyroidism is reserved for patients who cannot or will not undergo surgery. Studies on the outcomes of ethanol ablation in primary hyperparathyroidism report that most patients had either partial or complete biochemical improvement, although many of these patients will have recurrent disease.[141,142,146] Thus close clinical and biochemical follow-up is necessary, and repeat treatments may be required. Reasons for failure include (1) incomplete ablation of hyperfunctioning tissue within the treated adenoma and (2) residual

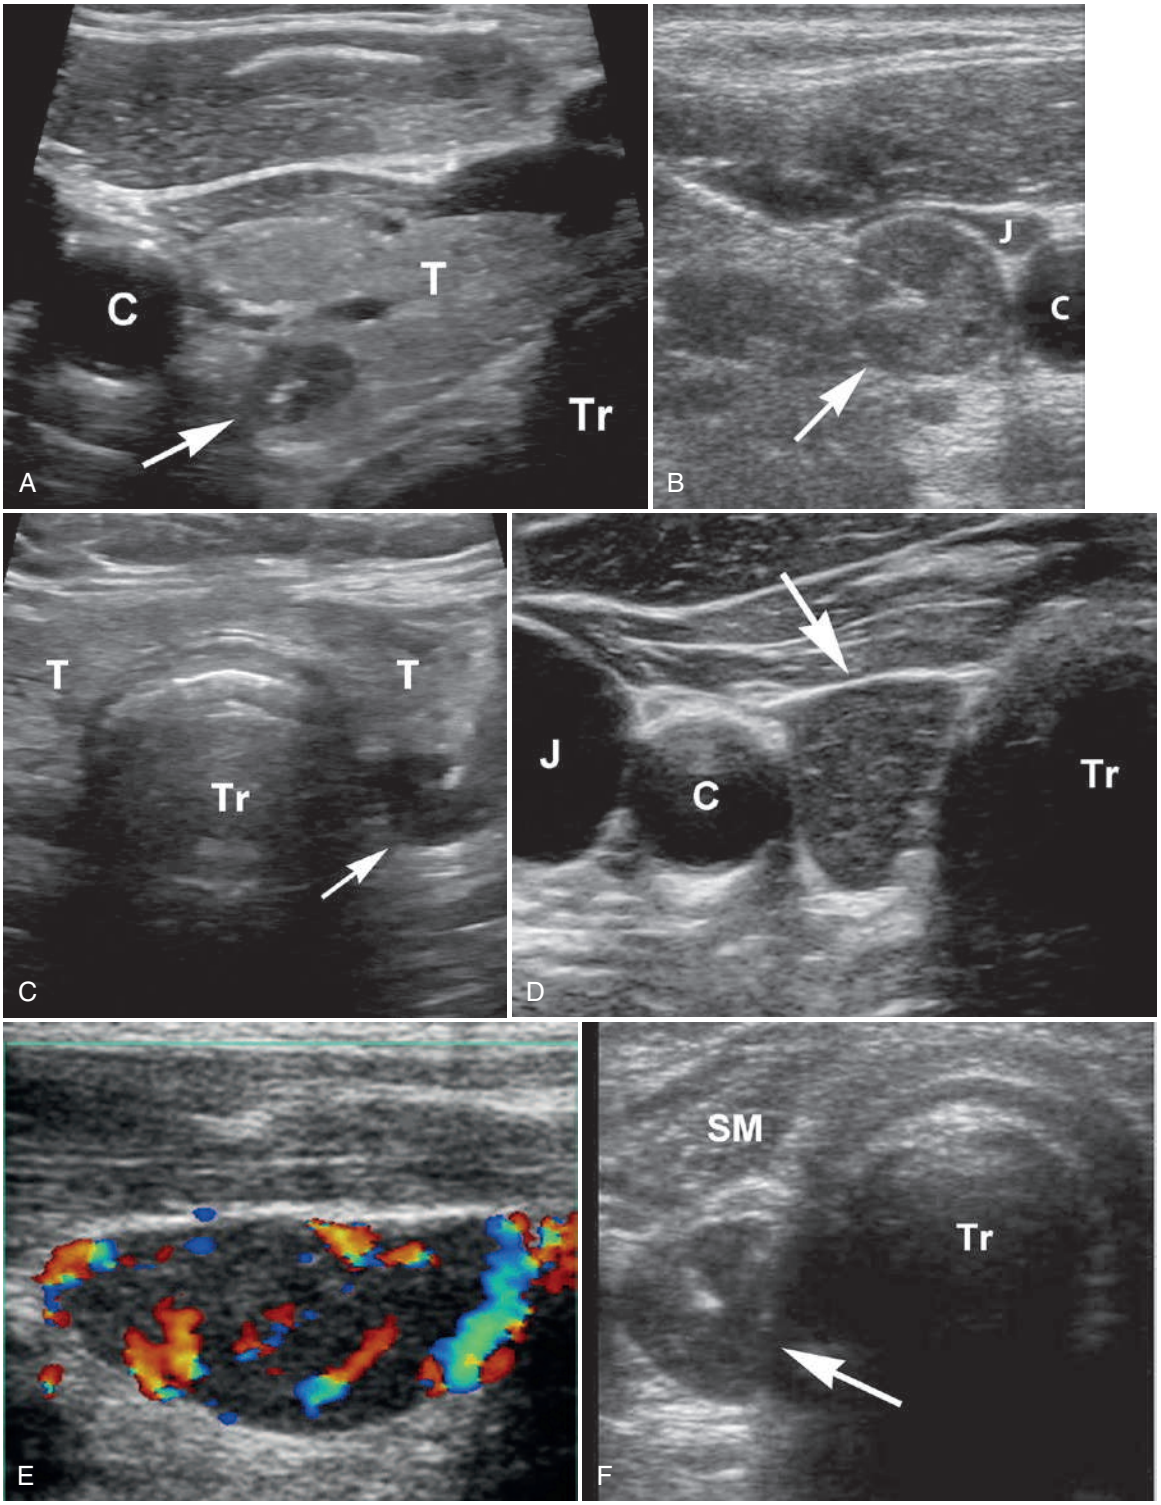

FIG. 20.23 Percutaneous Needle Biopsy of Parathyroid Adenoma Prior to Reoperation. (A) Transverse sonogram shows needle tip within a subcentimeter hypoechoic ectopic intrathyroid parathyroid adenoma *(arrow)* in a patient with persistent hyperparathyroidism. *C,* Common carotid artery; *T,* thyroid. *Tr,* trachea. **(B)** Transverse sonogram in another patient with persistent hyperparathyroidism shows needle biopsy of an ectopic inferior adenoma *(arrow)* located within the carotid sheath, posterior to the internal jugular vein *(J).* **(C)** Transverse sonogram in a patient with recurrent hyperparathyroidism shows biopsy of recurrent hyperplastic parathyroid tissue *(arrow)* at the site of previous remote parathyroid resection for multiple gland disease. **(D)** Transverse sonogram of a patient with hyperparathyroidism and prior subtotal thyroidectomy demonstrates hypoechoic tissue in the right thyroid bed *(arrow)* between the trachea *(Tr)* and common carotid artery *(C)* indeterminate for residual thyroid versus parathyroid tissue. **(E)** Longitudinal color Doppler flow sonogram in the same patient demonstrates indeterminate hypervascular tissue in the right thyroid bed. **(F)** Transverse sonogram in the same patient shows needle biopsy of the indeterminate tissue in the right thyroid bed *(arrow)* which confirmed parathyroid adenoma when multimodality imaging was equivocal for thyroid versus parathyroid tissue. *SM,* Strap muscle. See also Video 20.18.

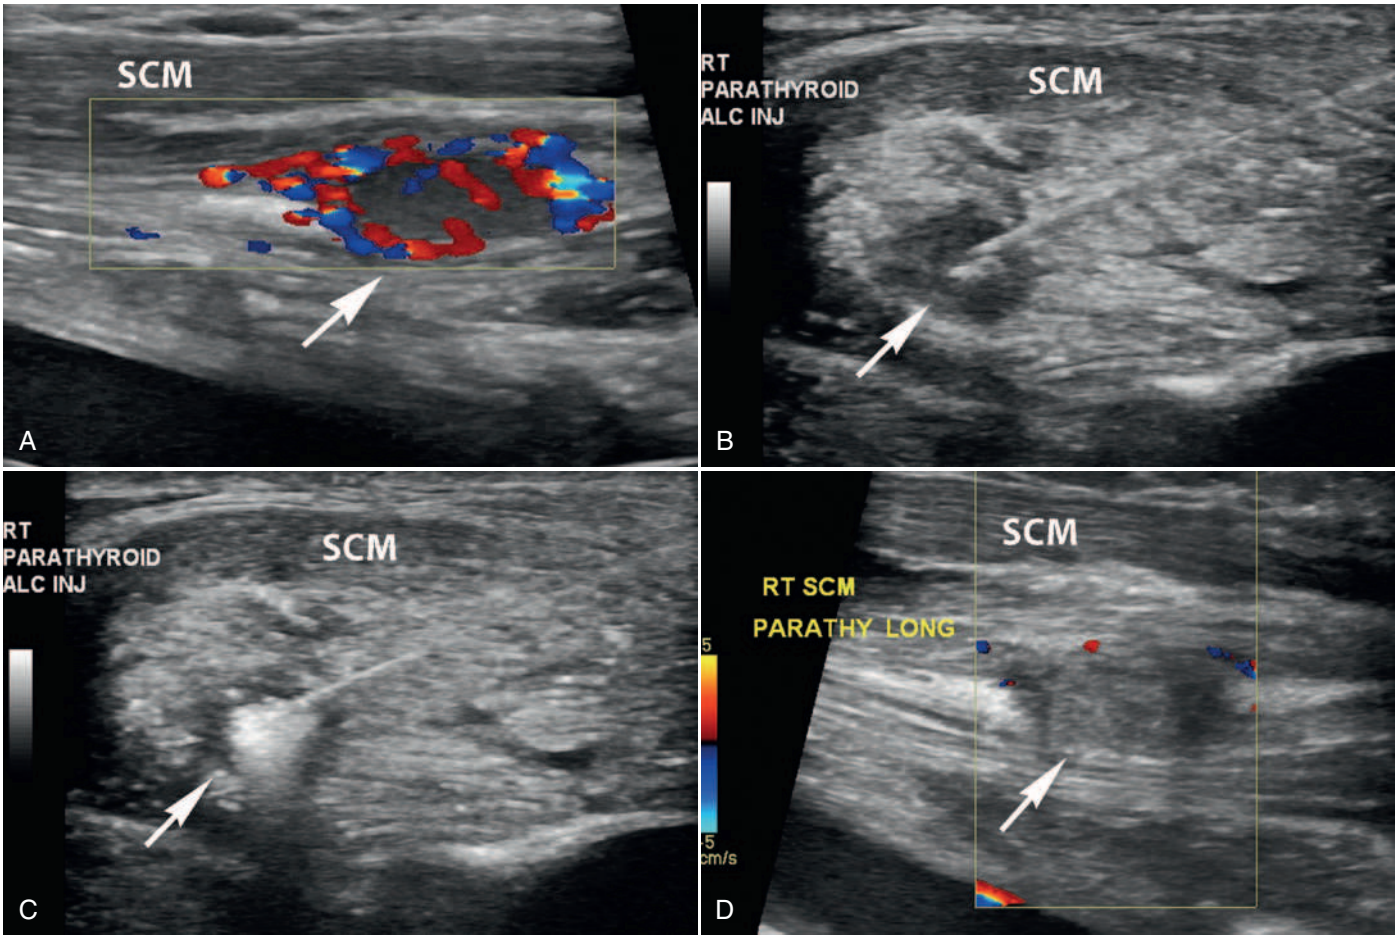

FIG. 20.24 Ethanol Ablation of Hyperplastic Autotransplanted Parathyroid Tissue. (A) Longitudinal color Doppler flow sonogram of the right neck shows a dominant vascular nodule that represents hyperfunctioning parathyroid tissue *(arrow)* in a patient with **recurrent graft-dependent hyperparathyroidism.** *SCM,* Sternocleidomastoid muscle. **(B)** Transverse sonogram shows a needle tip *(arrow)* is placed within the nodule. **(C)** Transverse sonogram shows ethanol is injected into portions of the nodule, which causes the tissues adjacent to the needle tip to become transiently, brightly echogenic *(arrow).* **(D)** Subsequent to ethanol ablation, longitudinal color Doppler flow sonogram shows decreased vascularity in the injected nodule *(arrow).* See also Video 20.19.

hyperfunctioning of other untreated glands in the patient with unrecognized multigland disease.

In theory, methods of thermal tissue ablation such as radiotherapy, cryotherapy, and laser therapy, which have been used to treat tumors elsewhere in the body, could also be applied to treat parathyroid disease in the neck. These methods are limited at present by the lack of ablation devices that can precisely treat very small amounts of tissue. In patients not considered surgical candidates, there have been reports of successful treatment of parathyroid adenomas using ultrasound-guided percutaneous laser ablation.[156-158] However, as with ethanol ablation, the clinical efficacy is transient and these methods of ablation are not definitive treatment of parathyroid disease.

CHAPTER 21

The Breast

Jordana Phillips, Rashmi J. Mehta, and A. Thomas Stavros

SUMMARY OF KEY POINTS

- Breast ultrasound plays a key role in supplemental breast cancer screening, diagnostic imaging, and interventional breast procedures.
- All images should be annotated with the following: the side (left or right), clock face position, distance from the nipple in centimeters, and transducer orientation. All lesions should be scanned and measured in two orthogonal planes to assess the size, surface, internal characteristics, and shape.
- A negative whole-breast screening ultrasound examination should include a minimum of five images of each breast, including one image in one plane of each quadrant of the breast, typically at the same distance from the nipple, and one image of the retroareolar breast.
- For diagnostic ultrasound examinations, it is necessary to document that the area in question was imaged, even if no abnormality is seen. If the area is palpable, make sure to palpate the area and place the probe immediately over this location.
- The Breast Imaging Reporting and Data System (BI-RADS) is a required standardized lexicon for describing and classifying findings and their probability of malignancy.
- Suspicious findings include irregular shape; indistinct, speculated, angular, or microlobulated margins; orientation that is not parallel; acoustic shadowing; hypoechoic echotexture; and calcifications.
- For mammographic-sonographic correlation, it is important to confirm that the size, shape, location, and surrounding tissue density of the mammographic and sonographic findings are the same.
- Tools that can aid diagnosis include Doppler imaging and elastography. Three-dimensional imaging and contrast-enhanced ultrasound are currently being studied.

APPLICATIONS OF BREAST ULTRASOUND

There are four main roles for sonography in breast imaging: (1) primary screening; (2) supplemental screening (after mammography); (3) diagnosis—for example, evaluation of palpable mass or other breast-related symptoms; and (4) interventional breast procedures. Other uses include evaluation of problems associated with breast implants and treatment planning for radiation therapy.[1]

Sonography currently does not have a proven role in primary breast cancer screening, but the use of sonography in **supplemental screening** (after mammography, as an ancillary study), especially in women with dense breast tissue on mammography, has expanded in recent years and its use continues to grow. Multiple studies[2-5] have shown promising results for sonography as an adjunct to mammography for screening women with dense breast tissue. Early studies evaluating bilateral handheld sonography performed by either radiologist or technologist detected approximately three carcinomas that were missed by primary screening mammography per 1000 patients. These cancers were often less than 1 cm in size and had not yet involved the axillary lymph nodes (termed "node negative"). In addition, supplemental screening with whole-breast ultrasound significantly increased mammography's sensitivity by approximately 20% to 30%.

The American College of Radiology Imaging Network whole-breast ultrasound screening trial (ACRIN 6666) was designed to assess the role of bilateral whole-breast screening ultrasound in a group of patients at increased risk for breast cancer and with dense breast tissue on mammography using a standardized technique. Each patient had three scans over 3 years in addition to mammography. The results of the first prevalence scan showed that ultrasound detected 4.2 cancers per 1000, more than were detected by mammography, but at a high cost in benign biopsies compared with mammography.[6] Subsequent evaluation at years 2 and 3 demonstrated that an additional 3.7 cancers were detected with screening whole-breast ultrasound per 1000 patients screened.[7] Unfortunately, the identification of additional breast cancers is associated with an increase in the false-positive rate, with lower true-positive biopsy rates. This likely will decrease over time as technologists and radiologists become more accustomed to performing and interpreting whole-breast ultrasound screening examinations. Given that the probability of malignancy is much lower in a screening population compared with a diagnostic population, some findings that might be viewed with suspicion in a patient with a palpable lump or suspicious mammographic abnormality in the diagnostic setting can potentially be ignored in a screening setting. As radiologists learn this over time, the false-positive rate of screening ultrasound should improve.

The encouraging data regarding whole-breast ultrasound coincided with 2009 Connecticut legislation mandating radiologists to inform patients of their tissue density and the potential benefit of adjunct screening, possibly with ultrasound or breast magnetic resonance imaging (MRI). As a result, whole-breast screening ultrasound began to be implemented into clinical practice. Although an additional three cancers were found per 1000 women screened,[8,9] the challenges of screening ultrasound in the clinical setting began to surface. These included low compliance rates and the increased length of time necessary to perform the examination. Of those for whom supplemental whole-breast screening was offered, only 28% initially accepted.[8] The expectation is that this rate will improve as the workflow and culture for screening ultrasound improve.

To shorten the length of time for the examination and the radiologist time commitment during image acquisition, **automated whole-breast ultrasound** (ABUS) was introduced. **ABUS** is a system by which an ultrasound probe moves across a women's breast and ensures that all areas of the breast are imaged. The technologist helps direct the probe, but probe movement is largely automatic. The images then are stored for later interpretation. Unlike handheld ultrasound, in which the technologist takes representative images of each breast for radiologist review, ABUS allows the radiologist to review all imaging through each breast. Although the ultrasound examination is still lengthy, taking approximately 15 minutes per breast, the main benefit is that the radiologist does not need to be present at the time of image acquisition, similar to screening mammography. This provides more options for how to integrate ABUS into a screening setting.

Several dedicated automated breast ultrasound machines are being developed, the first of which was approved by the U.S. Food and Drug Administration (FDA) in 2012. Performance data have been very promising. Similar to handheld screening ultrasound, studies have shown that ABUS detects an additional 2 to 3 cancers per 1000 women screened. It has improved sensitivity as compared with mammography alone by 30% to 40%, and the identified cancers are often invasive and node negative.[10-13] As with earlier studies of handheld ultrasound, both call-back rates and false positives are higher than with mammography alone. Again, it is the expectation that these rates will decrease with experience.

The most widespread role for breast ultrasound is **diagnosis.** This is usually performed in a targeted fashion after mammography and clinical examination, to provide a more specific diagnosis than can be obtained from mammography or clinical examination alone. Palpable masses and mammographic abnormalities constitute the most common indications for targeted diagnostic breast ultrasound. Specific goals of targeted diagnostic sonography are to prevent biopsies and short-interval follow-up mammography of benign lesions, to guide interventions of all types, to give feedback that improves clinical and mammographic skills, and to find malignancies missed on mammography.

Ultrasound also plays a large role in **interventional breast procedures.** In general, procedures performed with ultrasound are relatively quicker, more comfortable for the patient, and less expensive than procedures performed with stereotaxis or MRI guidance.

BREAST ANATOMY AND PHYSIOLOGY

The breast is a modified sweat gland that is composed of varying number of lobes ranging from 4 to 20[14] that are not well delineated from one another; they overlap and vary greatly in size and distribution. Each lobe consists of parenchymal elements (lobar

duct, smaller branch ducts, and lobules) and supporting stromal tissues (compact interlobular stromal fibrous tissue, loose periductal and intralobular stromal fibrous tissue, and fat). Historically, it was believed that the lobar ducts converge in the subareolar region to form lactiferous sinuses that serve as reservoirs for milk storage during lactation. However, more recent data suggest that lactiferous sinuses do not exist.[14] As the lobar ducts extend deep into the breast, they divide into segmental and subsegmental ducts that lead to the terminal ducts and acini of the lobules. Each lobule consists of the intralobular segment of the terminal duct, ductules, acini, and loose intralobular stromal fibrous tissue. Acini are saclike structures that produce milk during lactation. The functional unit of the breast is the **terminal ductolobular unit** (TDLU), which consists of a lobule and its extralobular terminal duct.

TDLUs are important because they are the site of origin of most breast pathology and of **aberrations of normal development and involution** (ANDIs). Most breast carcinomas are thought to arise in the terminal duct near the junction of the intralobular and extralobular segments. Most **invasive ductal carcinomas** have **ductal carcinoma in situ** (DCIS) components that can use the ductal system as conduits for growth into other parts of the breast. Unlike TDLUs, lobar ducts give rise to few pathologic processes. They are the primary site of origin for large **duct papillomas** and the **duct ectasia–periductal mastitis complex.**

Each lobar duct has several rows of TDLUs arising from it. Anterior TDLUs tend to have long extralobular terminal ducts, whereas posterior TDLUs tend to have shorter extralobular terminal ducts. Some TDLUs lie at the distal end of the ductal system and are horizontally oriented. Anterior TDLUs are more numerous than posterior and terminal TDLUs, and over time the posterior TDLUs tend to regress, leaving a progressively larger percentage of anterior TDLUs. Because anterior TDLUs greatly outnumber posterior TDLUs, most breast pathology that arises from TDLUs occurs in the superficial half of the mammary zone, just deep to the anterior mammary fascia.

The breast can be divided into three zones (Fig. 21.1). The most superficial zone is the **premammary zone,** or **subcutaneous zone,** which lies between the skin and the anterior mammary fascia. The premammary zone is part of the integument, and processes that arise primarily within the premammary zone are usually not true breast lesions. Rather, these are lesions of the skin and/or subcutaneous tissues that are identical to those arising from skin and subcutaneous tissues covering any other part of the body (e.g., **lipomas, sebaceous cysts**). The **mammary zone** is the middle zone and lies between the anterior mammary fascia and the posterior mammary fascia. It contains the lobar ducts, their branches, most of the TDLUs, and most of the fibrous stromal elements of the breast. The deepest of the zones is the **retromammary zone.** It mainly contains fat, blood vessels, and lymphatics and is usually much less apparent on sonograms than on mammograms because sonographic compression flattens the retromammary zone against the chest wall. This differs greatly from mammography, in which mammographic compression pulls the retromammary fat away from the chest wall and expands it in the anteroposterior (AP) direction. Because most breast pathology arises from TDLUs and, to a lesser extent, from the mammary ducts, and because most of the ducts and lobules lie within the mammary zone, most true breast pathology arises from the mammary zone. Although lesions that arise within the premammary or retromammary zone are usually skin lesions, true breast lesions that arise within the mammary zone can secondarily involve the premammary and retromammary tissues.

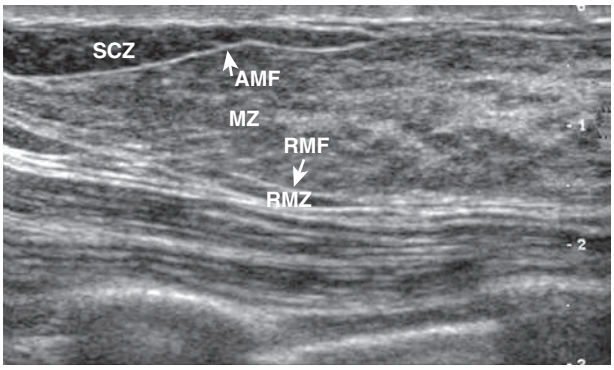

FIG. 21.1 Three Zones of the Breast. The premammary or **subcutaneous zone** *(SCZ),* **mammary zone** *(MZ),* and **retromammary zone** *(RMZ).* The mammary zone is where most of the ducts and lobules of the breast that give rise to breast pathology lie. The mammary zone is enveloped in thick, tough fascia. Anteriorly it is delineated from the subcutaneous fat by the premammary or anterior mammary fascia *(AMF)* and posteriorly from the retromammary fat by the posterior or retromammary fascia *(RMF).* The anterior mammary fascia is continuous with the **Cooper ligaments,** with each ligament being formed by two apposed layers of anterior mammary fascia. The retromammary zone is compressed during real-time sonography in the recumbent position and is relatively small and unapparent in comparison to its appearance on mammography.

The **mammary fascia** that envelops the mammary zone is tough and is relatively more resistant to invasive malignancy than are loose, stromal fibrous tissues. The anterior mammary fascia is continuous with the **Cooper ligaments.** At the point where it is continuous with a ligament, the anterior mammary fascia continues superficially obliquely through the subcutaneous fat, attaches to superficial fascia, and then courses back down through the subcutaneous fat, where it continues as the anterior mammary fascia. Each Cooper ligament is composed of two closely applied layers of anterior mammary fascia with a potential space inferiorly, where the two layers separate and course away from each other as anterior mammary fasciae (Fig. 21.2). This affects the sonographic appearance of invasive malignancies, as discussed later.

The normal anatomic structures of the breast span a spectrum of echogenicities, from midlevel gray to intensely hyperechoic. **Hyperechoic** normal structures include compact interlobular stromal fibrous tissue, anterior and posterior mammary fasciae, Cooper ligaments, and skin. Duct walls, when visible, also appear hyperechoic. **Isoechoic** normal structures that have midlevel echogenicity include fat, epithelial tissues in ducts and lobules, and loose, intralobular and periductal, stromal fibrous tissue.

Water density tissue on mammography corresponds to a variety of different normal tissues that can be shown sonographically. Consequently, although dense interlobular stromal fibrous tissue, loose periductal or intralobular stromal fibrous tissue,

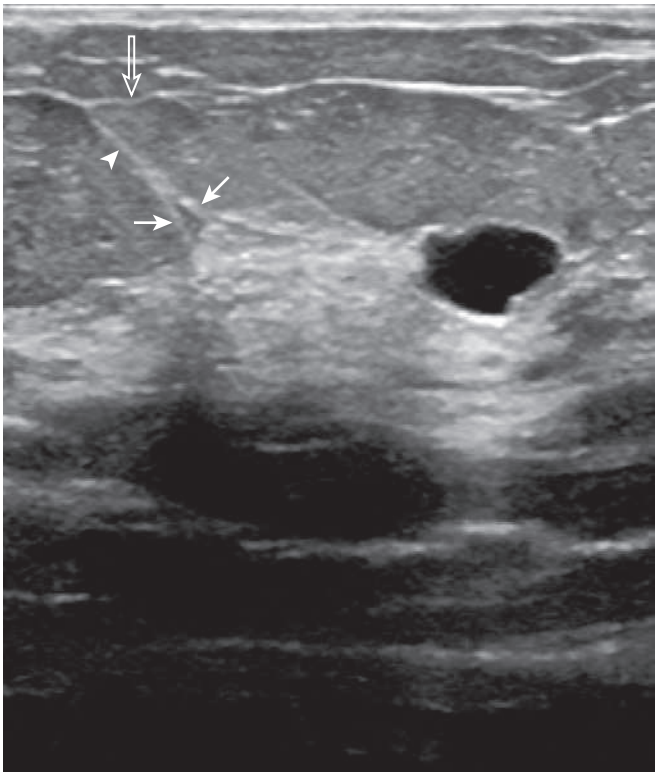

FIG. 21.2 Mammary Fasciae and Cooper Ligaments. Two layers of anterior mammary fascia *(arrows)* form the bases of a Cooper ligament *(white arrowhead),* which inserts into superficial fascia *(open arrow).* Invasive malignancies often develop angles as they invade the base of Cooper ligaments.

and epithelial elements in ducts and lobules all have different sonographic appearances, they all appear to be water density on mammography. **Mammographically dense tissue** can correspond to purely hyperechoic, purely isoechoic, or mixed hyperechoic and isoechoic tissues on sonography (Fig. 21.3). Most contain mixtures of fibrous and glandular elements interspersed with variable amounts of fat (Fig. 21.4). Over time, atrophy tends to occur more rapidly in the areas of the mammary zone that lie between Cooper ligaments, leaving progressively more of the residual fibroglandular elements within these ligaments (Fig. 21.5).

Normal mammary ducts that are not ectatic can appear in two ways sonographically. A mammary duct can appear purely isoechoic when the centrally located hyperechoic duct wall cannot be visualized because of poor angle of incidence or suboptimal transducer resolution and only the loose periductal stromal fibrous tissue is visible. A mammary duct can also be shown as a central, bright echo surrounded by isoechoic loose stromal fibrous tissue when the apposed walls of the central duct can be optimally demonstrated (Fig. 21.6A). It is common for a single duct to have both sonographic appearances, depending on the angle of incidence with the duct walls. Variable degrees of **ductal ectasia** become increasingly common with age, particularly in the subareolar region. In **ectatic ducts,** anechoic or hypoechoic fluid separates the two duct walls and compresses the loose periductal stromal tissues to variable degrees (Fig. 21.6B-C). Duct ectasia occurs commonly in women over age 50 and usually is asymptomatic.[15] In certain patients, however, ductal ectasia may be associated with nipple discharge or may lead to periductal mastitis and its acute and chronic complications.

The ducts within the nipple and immediate subareolar regions are poorly seen when scanned from straight anteriorly because they course almost parallel to the beam in those locations. However, special maneuvers designed to improve the angle of incidence enable adequate demonstration of the entire mammary duct throughout the subareolar region, even within the nipple when necessary. These maneuvers include the **peripheral compression technique, two-handed compression technique,** and **rolled nipple technique.** These maneuvers are most useful when evaluating patients with nipple discharge (Fig. 21.7) and in assessing malignant nodules for extensive intraductal involvement growing within the duct toward the nipple. The two-handed compression technique is also useful in assessing gynecomastia.

Individual TDLUs may be sonographically visible—under ideal conditions—as small isoechoic structures (Fig. 21.8). In patients who are pregnant or lactating and in patients with adenosis, not only are TDLUs enlarged, but they are also increased in number. In certain cases, TDLUs become large and numerous enough to form continuous sheets of isoechoic tissue. The variable prominence of TDLUs creates a continuous spectrum in the appearance of breast tissue from TDLUs that are not visible to breasts that appear to be totally isoechoic (Fig. 21.9). This most often occurs anteriorly, where lobules are most numerous, but in certain cases can fill and distend the entire mammary zone.

Lymphatic drainage from most of the breast is from deep to superficial, toward the subdermal lymphatic network, then to the periareolar plexus **(Sappey plexus),** and finally on to the axilla. Most drainage of the breast is to the axillary lymph nodes; however, some of the deep portions of the breast, particularly medially, preferentially drain along the chest wall to the **internal mammary lymph nodes.** As a result, most lymphatic metastases from the breast are to the axilla, with a minority occurring in the internal mammary lymph nodes. The three levels of axillary lymph nodes are determined by their location relative to the pectoralis minor muscle. Lymph nodes that lie peripheral to the inferolateral edge of the pectoralis minor are **level 1** lymph nodes; nodes that lie deep to the pectoralis minor muscle are **level 2** lymph nodes; and nodes that lie medial to the superomedial border of the pectoralis minor muscle are **level 3** lymph nodes or **infraclavicular nodes.** Lymphatic drainage to the axilla usually passes through level 1, then level 2, and finally to level 3 lymph nodes (Fig. 21.10). From level 3 nodes, metastases may progress to internal jugular or supraclavicular lymph nodes. **Rotter nodes** lie between the pectoralis major and pectoralis minor muscles. It is important to identify level 2 and 3 lymph nodes and Rotter lymph node metastases, because unrecognized and untreated metastases to these lymph nodes can be a source of recurrence.

Internal mammary nodes lie in a chain parallel to the internal mammary artery and veins along the deep side of the chest wall, just lateral to the edges of the sternum. Metastases most often

Text continued on p. 767.

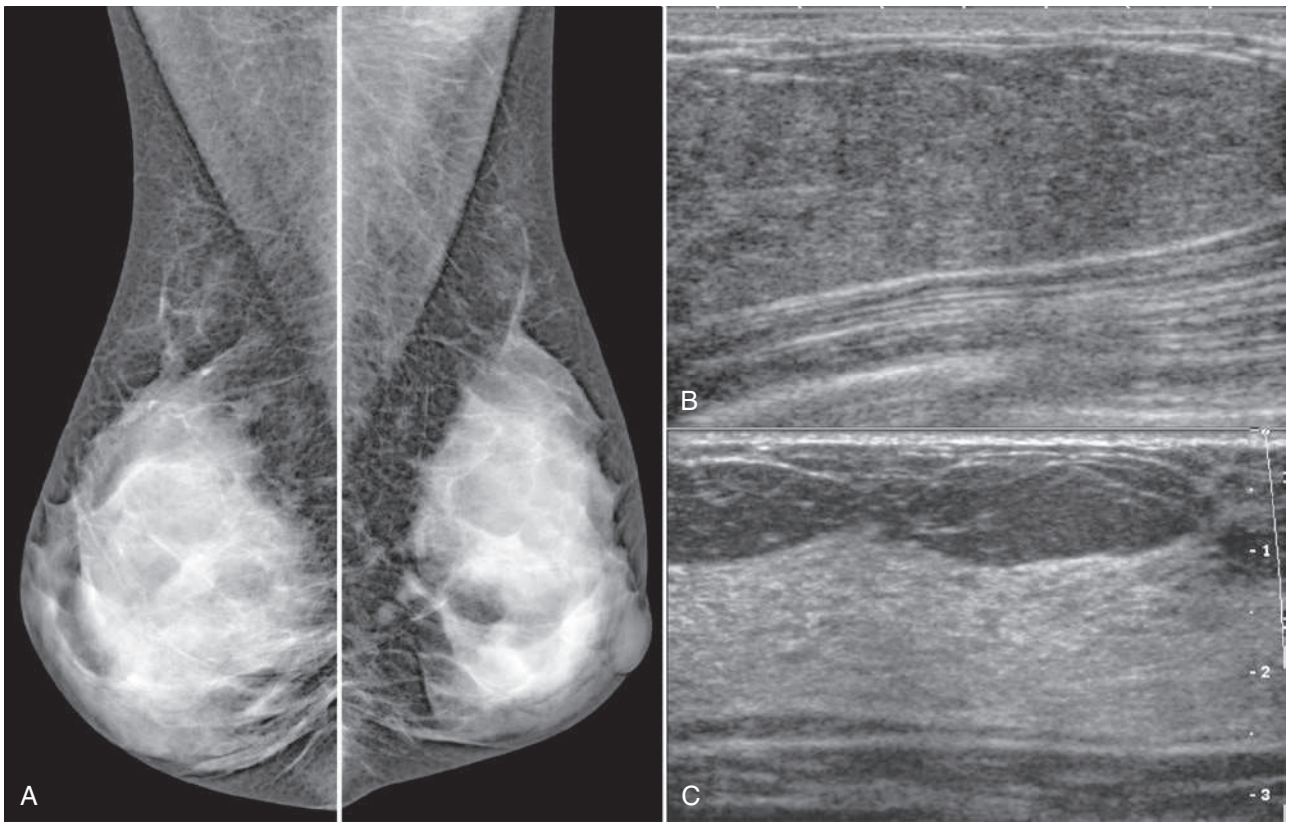

FIG. 21.3 Dense Breast Tissue: Radiographic-Sonographic Correlation. Radiographically dense (water density) tissue on mammograms **(A)** can correspond to two different types of tissue on sonography: **(B)** almost-isoechoic glandular tissue, and **(C)** intensely hyperechoic interlobular stromal fibrous tissue.

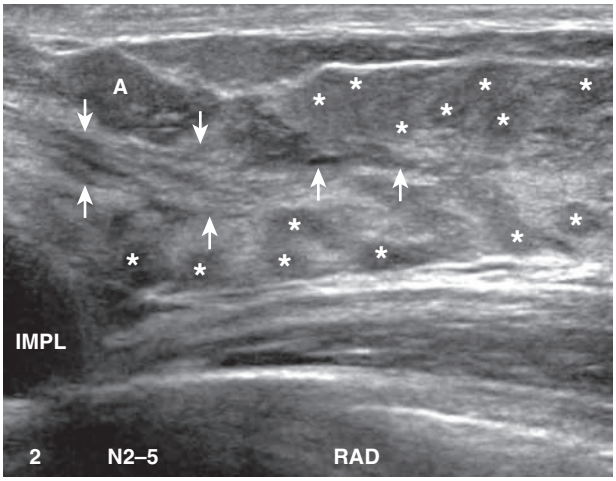

FIG. 21.4 Water Density Breast Tissue. Most water density tissue on mammography is not pure fibrous or glandular tissue, but a mixture of hyperechoic interlobular stromal fibrous tissue and isoechoic glandular or loose periductal and intralobular stromal tissue. Note that the lobar duct is mildly ectatic *(arrows)*. The round or taller-than-wide isoechoic elements (*) within the peripheral segments of the mammary zone represent epithelial and loose stromal tissues within terminal ductolobular units (TDLUs). Note that TDLUs are more numerous and prominent anteriorly than they are posteriorly.

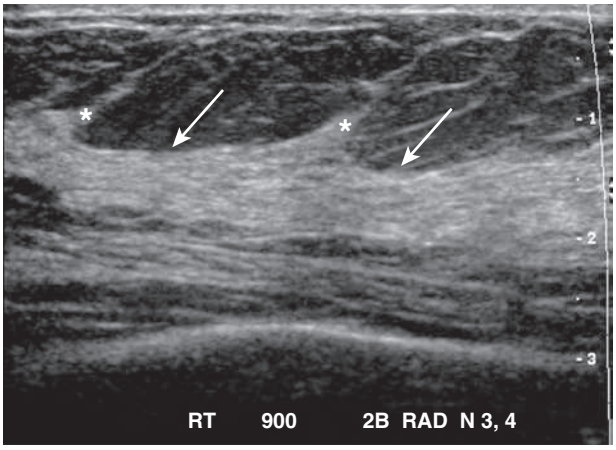

FIG. 21.5 Breast Atrophy. With advancing age, and particularly after full-term pregnancy and breastfeeding, the fibroglandular elements of the breast regress more rapidly in the areas of the mammary zone *(arrows)* that lie between Cooper ligaments than in the area within the ligaments. This eventually can leave much or all of the residual breast tissue entrapped within Cooper ligaments (*).

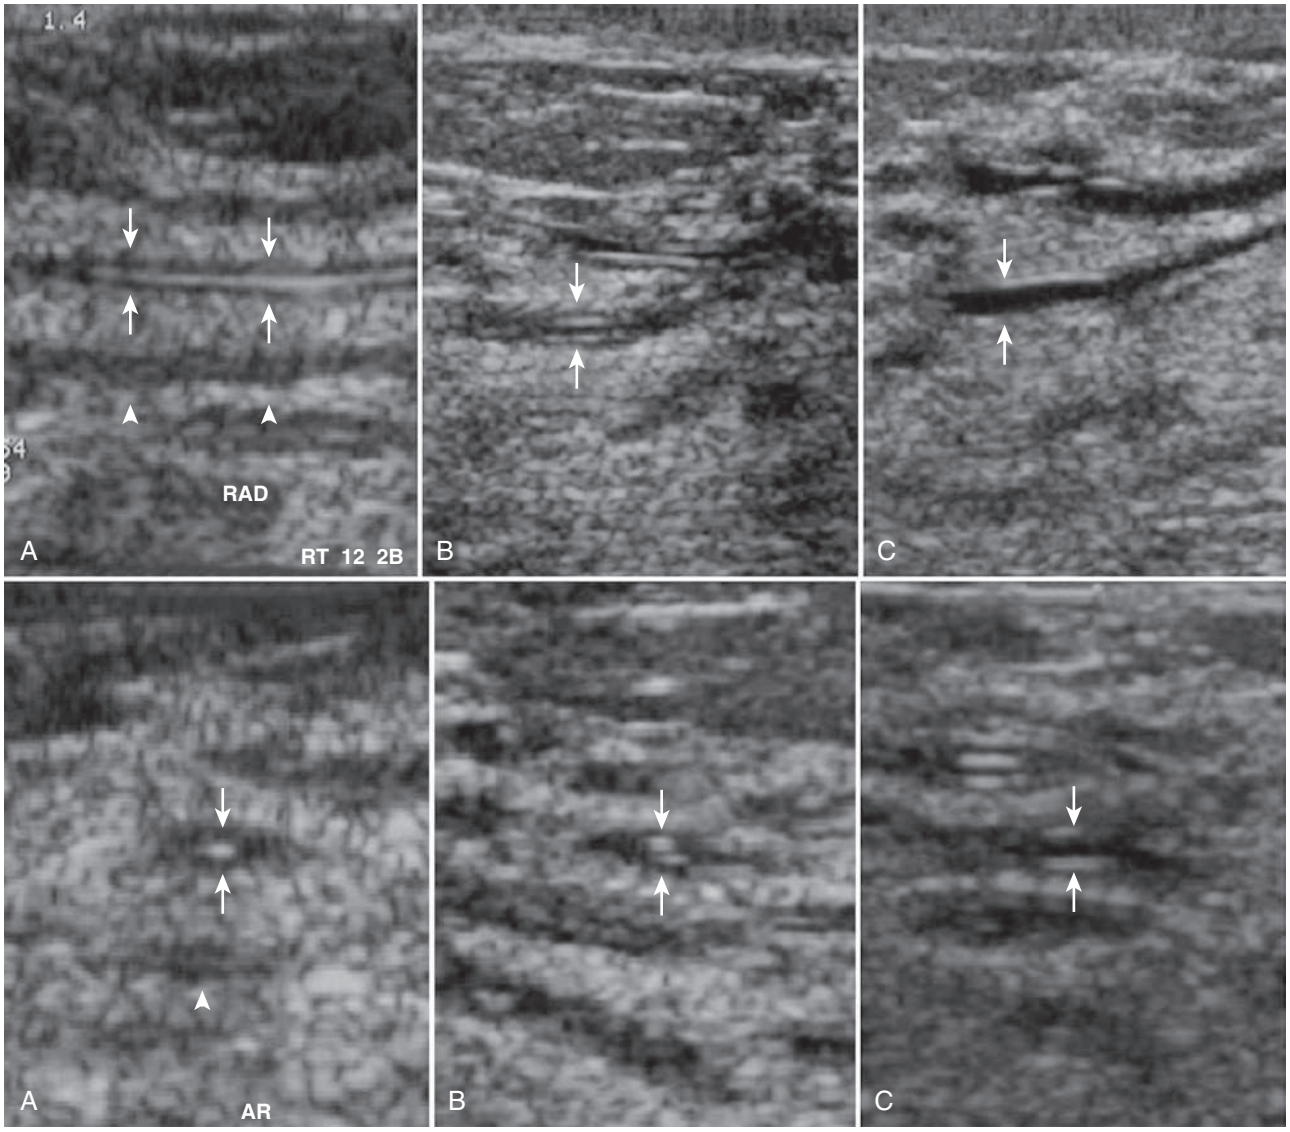

FIG. 21.6 Mammary Duct: Spectrum of Normal Appearances. (A) With high spatial resolution, 90-degree angle of incidence, and perfect centering, the duct appears to be composed of a central echogenic line *(arrows)* that represents the apposed walls of the collapsed mammary duct. The surrounding isoechoic tissue represents loose periductal stromal tissue. Unfortunately, only a minority of the ducts seen have this trilaminar appearance in the long axis and targetoid appearance in the short axis. Ducts that are slightly out of focus, coursing at an angle, or not perfectly centered within the beam have a different appearance. The deeper duct *(arrowheads)* is too deep for the short-axis focal length of the transducer. The central echo that represents the apposed walls of the collapsed duct is not seen. Only the isoechoic loose periductal stromal tissue can be identified. **(B)** This mildly ectatic duct *(arrows)* is shown in long axis *(upper image)* and short axis *(lower image)*. The duct is now represented by two hyperechoic lines that represent the anterior and posterior walls of the duct separated by secretions within the duct lumen. **(C)** This severely ectatic duct *(arrows)* is shown in long axis *(upper image)* and short axis *(lower image)*. As the degree of ductal ectasia increases, the walls of the duct become more separated, and the loose periductal stromal tissue becomes more compressed and less apparent. In severe ductal ectasia the periductal loose stromal tissue may no longer be visible.

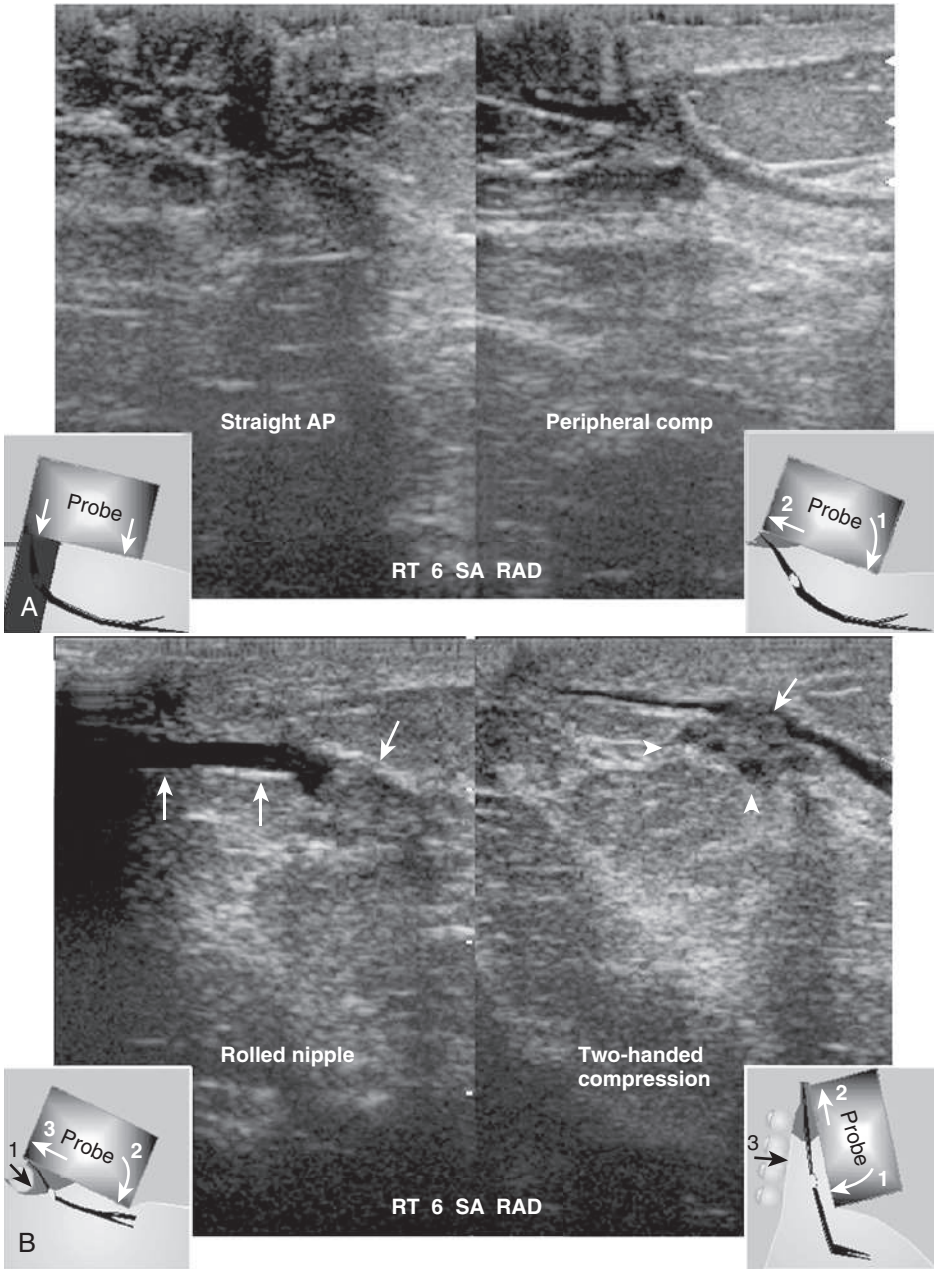

FIG. 21.7 Maneuvers for Demonstrating Subareolar and Intranipple Mammary Ducts. (A) *Left image,* The subareolar ducts are difficult to assess from a straight anterior approach because shadowing arises from the nipple and areola and the tissue planes of the nipple are parallel to the ultrasound beam. *Right image,* Peripheral compression technique. With vigorous compression on the peripheral end of the transducer and by sliding it over the nipple to push the nipple to the side, shadowing can be minimized, and the angle of incidence of the beam with the subareolar ducts can be improved. Lesions that lie in the immediate subareolar region can often be demonstrated. **(B)** *Left image,* Rolled nipple technique is the best way to demonstrate the ducts within the nipple and whether a lesion extends into the nipple from the subareolar ducts. *Right image,* Two-handed compression technique further improves the angle of incidence with the subareolar ducts and helps assess the compressibility of the ducts. This can help to distinguish echogenic, inspissated secretions from intraductal papillary lesions and determine whether the lesion *(arrows)* has penetrated through the duct wall *(arrowheads).* The rolled nipple technique shows that this **malignant intraductal papillary lesion** does not extend into the intranipple segment of the duct, but the two-handed compression maneuver shows that it has invaded through the posterior duct wall and is forming angles within the periductal tissues.

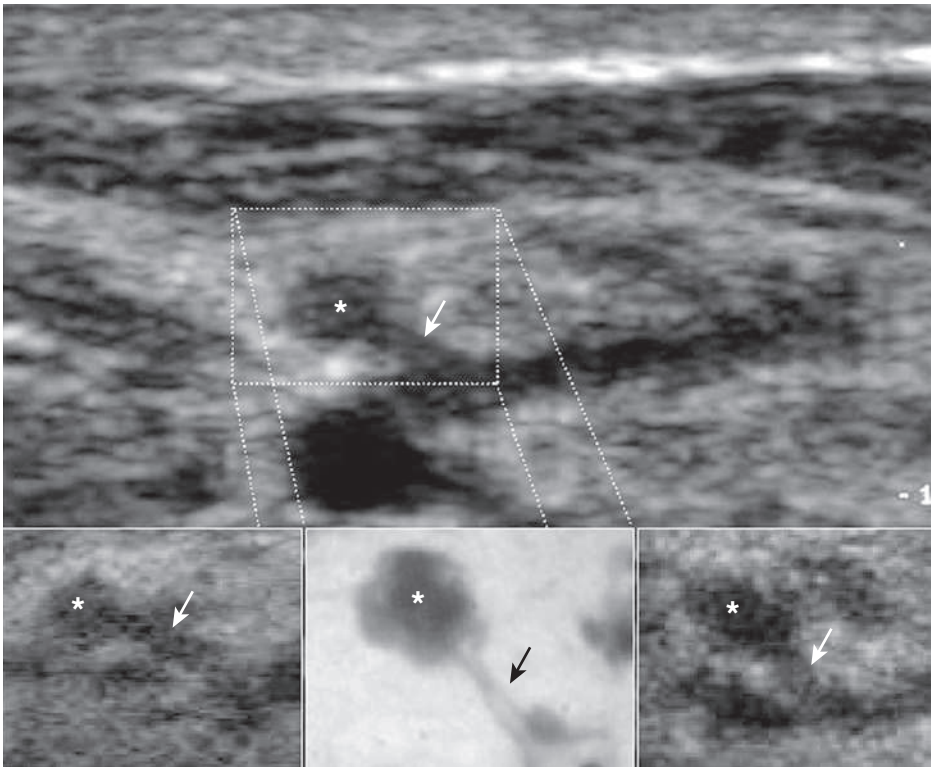

FIG. 21.8 Terminal Ductolobular Units (TDLUs). The TDLU includes the extralobular terminal duct and the lobule, which contains the intralobular terminal duct, ductules, and intralobular isoechoic loose stromal tissue. TDLUs appear as an isoechoic structure similar to a tennis racket; the head of the racket (*) represents the lobule, and the handle and neck of the racket *(arrows)* represent the extralobular terminal duct. Bottom center image is three-dimensional histology. (Courtesy of Hanne M. Jensen, MD.)

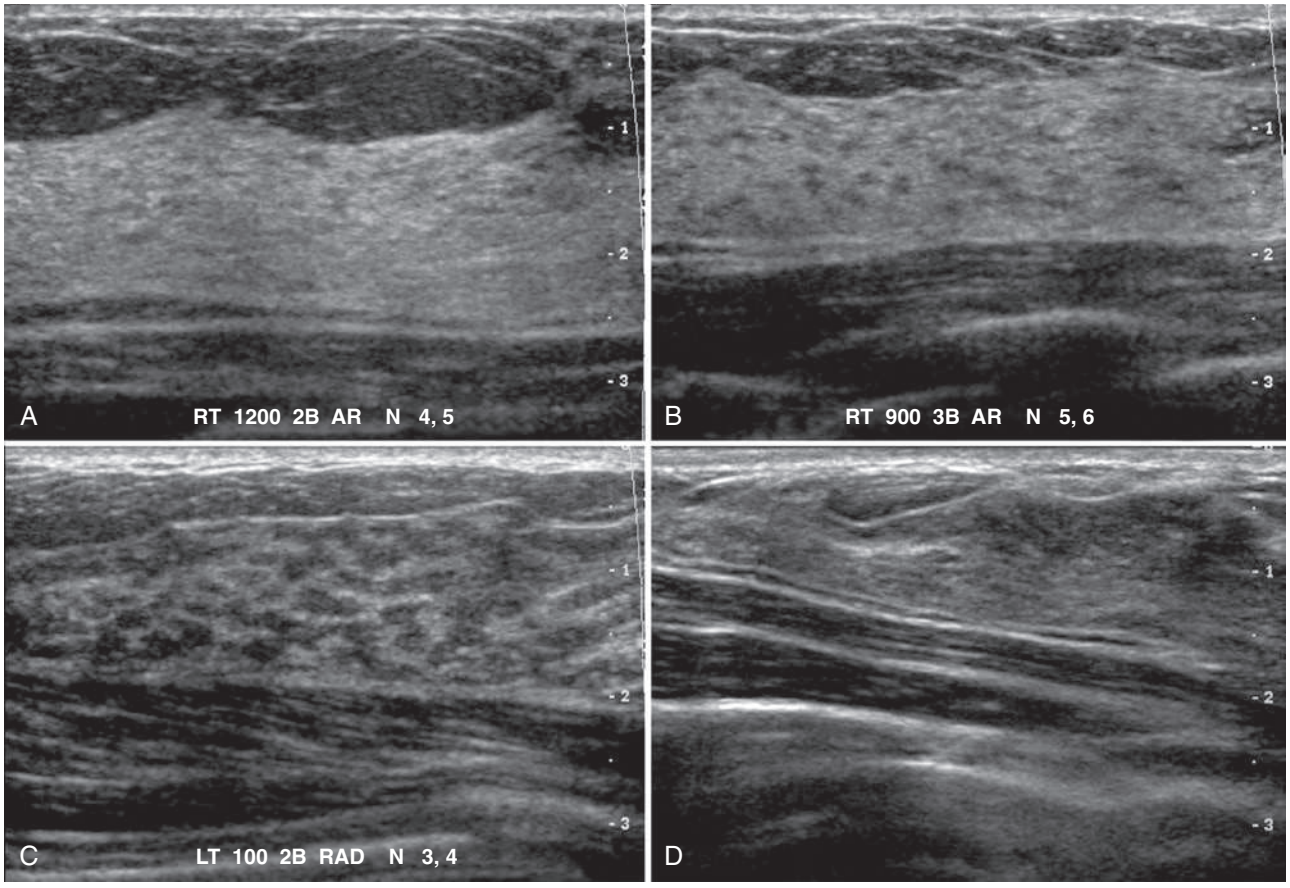

FIG. 21.9 Variable Prominence of Terminal Ductolobular Units (TDLUs). (A) Only a few scattered TDLUs may be visible. **(B)** As TDLUs become larger and more numerous in adenosis and adenosis of pregnancy, they may almost touch each other. Because anterior TDLUs are more numerous than posterior TDLUs, these changes tend to affect the superficial aspect of the mammary zone earlier and to a greater extent than they affect its deep aspect. **(C)** When lobular enlargement is pronounced, the entire superficial aspect of the mammary zone may appear isoechoic, with the deep half still being hyperechoic. **(D)** When lobular prominence is most pronounced, both superficial and deep aspects of the mammary zone may appear almost homogeneously isoechoic.

involve internal mammary lymph nodes in the second and third interspaces. Using color Doppler sonography to identify the internal mammary vessels can be helpful in finding abnormal internal mammary lymph nodes. Normal internal mammary lymph nodes can be identified under ideal circumstances, but not in all patients.

A significant percentage of patients have lymph nodes that lie within the breast and are called **intramammary lymph nodes.** These can lie anywhere within the breast but are most common in the axillary segment just below the axilla. They usually lie within a centimeter of the posterior mammary artery, a branch of the axillary artery that extends from the axilla toward the nipple. Intramammary lymph nodes can also be found occasionally in the medial edge of the breast superficial to the internal mammary lymph nodes. These medial lymph nodes are seen much less frequently on mammography than on sonography because mammographic compression can seldom pull them far enough away from the chest wall to be mammographically visible. Medial intramammary lymph nodes can be difficult to demonstrate sonographically without the use of an acoustic standoff because of their superficial location just beneath the skin.

Breast cancer metastases can involve the **supraclavicular lymph nodes,** but these nodes are positive only when lymph node metastases are extensive. Metastases often involve levels 1, 2, and 3 axillary lymph nodes or internal mammary and internal jugular lymph nodes before reaching the supraclavicular nodes.

The first lymph node to which lymphatic drainage flows and the first node involved by metastases has been termed the **sentinel lymph node.** The location of the sentinel node varies, depending on the location of the primary tumor within the breast. The sentinel lymph node is usually a level 1 axillary lymph node, but in certain cases it may be an intramammary node or even a level 2 node. Occasionally the sentinel node may be an internal mammary node.

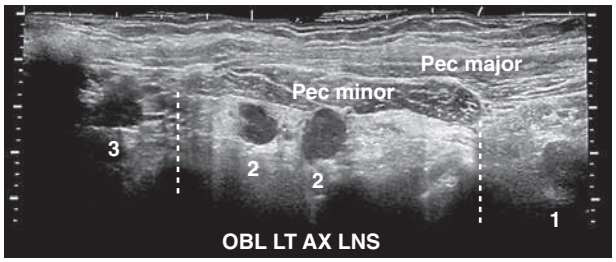

FIG. 21.10 Pectoralis Minor Muscle and Levels of Axillary Lymph Nodes. Extended–field-of-view (FOV) sonogram shows metastases to all three axillary lymph node levels on the left. The level of axillary lymph nodes is determined by the pectoralis minor muscle. Lymph nodes that lie inferior and lateral to the inferolateral edge of the pectoralis minor muscle are level 1 nodes; those that lie deep to the pectoralis minor muscle are level 2 lymph nodes; and those that lie superior and medial to the superomedial edge of the pectoralis minor muscles are level 3 (infraclavicular) lymph nodes.

SONOGRAPHIC EQUIPMENT

Breast ultrasound requires high-frequency transducers that are optimized for near-field imaging. Transducers used for breast sonography should be high-resolution, real-time, linear-array, broad-bandwidth transducers operating at a center frequency of at least 12 MHz and preferably higher. Other transducers may be used in special circumstances. Focal zones should be electronically adjustable. In general, the highest frequency capable of adequate penetration to the depth of interest should be used.[1] When evaluating more superficial lesions, such as those within the skin or those that are palpable and "pea-sized" or smaller, an acoustic standoff should be used (Fig. 21.11). This is either an acoustic standoff pad or a thick layer of acoustic gel that allows better characterization of these areas. In some patients, simply scanning with lighter compression can obviate the need for a standoff.

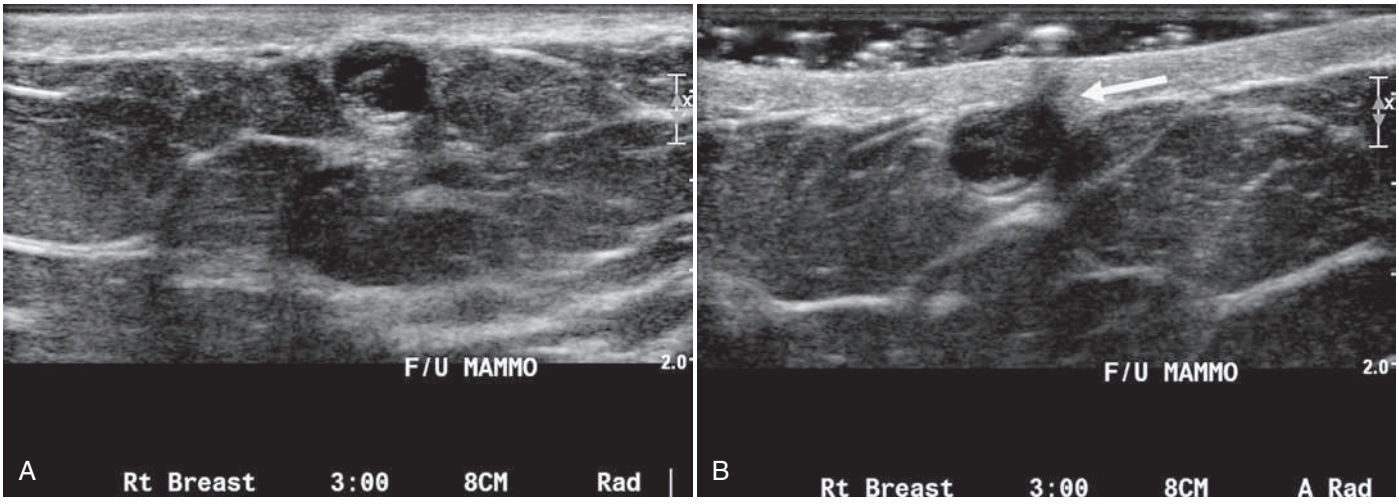

FIG. 21.11 Value of Standoff Pad. (A) Ultrasound evaluation of an **epidermal inclusion cyst** in the skin without a standoff pad did not delineate the obstructed gland neck. **(B)** A thick layer of acoustic gel was then used and clearly shows the obstructed gland neck extending to the skin surface *(arrow)*.

SONOGRAPHIC TECHNIQUE

For optimal scanning of the breast, the patient should be positioned supine with the arm on the side of interest relaxed up by the side of the head. Images should be acquired using the highest frequency probe that allows penetration of the targeted area. Initial images should include the pectoralis muscle to ensure that the entire depth of the breast has been imaged. The gain should be set such that the fat is a midlevel gray.

Patient Position

Breast sonographic evaluation depends heavily on special **dynamic** and **positional** maneuvers performed during the examination. Dynamic maneuvers include **varying compression** to assess compressibility and mobility. Lesions that are compressible are benign with a high degree of certainty and may represent either a normal fat lobule or a benign lipoma. Superficial venous thrombosis **(Mondor disease)** has a lack of flow on Doppler ultrasound and may be incompressible.[16] **Ballottement** (alternating compression and compression release) can be helpful to demonstrate mobility of echoes with ectatic ducts or complex cysts. Varying compression can also eradicate artifactual shadowing from critical angle shadowing off steeply oblique tissue planes. **Heeling and toeing of the transducer** can minimize critical angle shadowing arising from Cooper ligaments and better demonstrate the thin, echogenic capsule on the ends of solid nodules, an important sign of a noninvasive lesion margin. Heeling and toeing can also improve the angle of incidence with duct walls, allowing better demonstration of ductal anatomy and pathology, especially in the subareolar portions of the ducts. **Doppler ultrasound assessment** of the breast depends greatly on using as little compression pressure as possible (Video 21.1 and Video 21.2). Blood flow in a breast lesion can easily be decreased or even completely ablated if compression is too vigorous.

Positional changes are important in assessment of complex cysts. **Fluid-debris levels, milk of calcium,** and **fat-fluid levels** can all be shown to change sonographically between supine and upright or lateral decubitus positions. Some palpable abnormalities are clinically evident only in the upright position and therefore require that the scan be performed in the upright position. Even routine whole-breast scanning may require changing the position of the patient during the examination. Contralateral posterior oblique positions are better for evaluating the lateral half of the breast, whereas supine positioning is better for the medial half of the breast.

Annotation

The location of a scan plane in the breast or the location of a lesion in the breast should be annotated in compliance with American College of Radiology (ACR) ultrasound Breast Imaging Reporting and Data System (BI-RADS) lexicon.[17,18] The side (left and right), clock face position, distance from the nipple in centimeters, and transducer orientation must be recorded. Distance from the nipple should be measured from the nipple itself because the areolar width is variable among patients. Painting centimeter markers on the transducer can facilitate recording the distance from the nipple in centimeters, but the distance is usually estimated from the known lengths of linear high-frequency transducers, either 38 mm or 50 mm. The transducer orientation can be longitudinal, transverse, **radial,** or **antiradial,** which is orthogonal to the radial plane. The advantage of radial imaging is that the central ducts are radially oriented with respect to the nipple. Scanning in a plane that lies radial to the duct enables visualization of **DCIS** components of lesions growing within the ductal system of the breast. Identifying intraductal components of tumor can reduce the chances of mischaracterizing a malignant solid nodule as benign or "probably benign" and also facilitates demonstrating the true extent of DCIS components of mixed invasive and intraductal malignant lesions.

Thus a lesion at the 12 o'clock position of the right breast that lies 2 cm from the nipple when scanned radially could be annotated as "Right breast 12:00 2 cm Rad." This method of annotation allows reproducibility within and across practice sites. An icon of the right or left breast with a linear marker that demonstrates the position and orientation of the transducer is an acceptable alternative for annotation of scan location, and most ultrasound equipment manufacturers provide breast icons for this.

The farther from the nipple a lesion lies, the less likely the duct will course in a plane that is truly radial with respect to the nipple because of tortuosity of the duct, or because the duct of interest is a branch duct that is not oriented perfectly radially. In this scenario, the sonographer should think of *internal* radial planes versus the *external* true radial plane with respect to the nipple. The internal radial plane is parallel to the long axis of the ducts in the region of interest. If the internal plane of the duct of interest does not fall into a standard category of longitudinal, transverse, radial, or antiradial, one can opt to annotate this as an oblique view.

In addition to the ACR BI-RADS lexicon mandates,[17,18] some elect to record the depth of a lesion in addition to the parameters previously discussed. One option is to use three zones: **A** for the superficial third, **B** for the middle third, and **C** for the deep third of the breast.

Documentation of Lesions

All lesions should be scanned in their entirety in two orthogonal planes to assess the surface and internal characteristics as well as shape. These orthogonal planes could be longitudinal and transverse, but many practitioners prefer radial and antiradial planes. Each image plane should be recorded with and without calipers. It is important to document the maximum dimensions of the lesion in both planes because this is an important prognostic indicator. If the maximum diameter does not lie in one of the standard longitudinal, transverse, radial, or antiradial planes, an additional oblique view parallel to the long axis of the lesion should be obtained with and without calipers. Films without calipers are especially important in small lesions, where the calipers may interfere with assessment of surface characteristics. It is also recommended to document lesion vascularity using color or power Doppler imaging.

When performing a whole-breast screening ultrasound examination and when no abnormal imaging finding has been

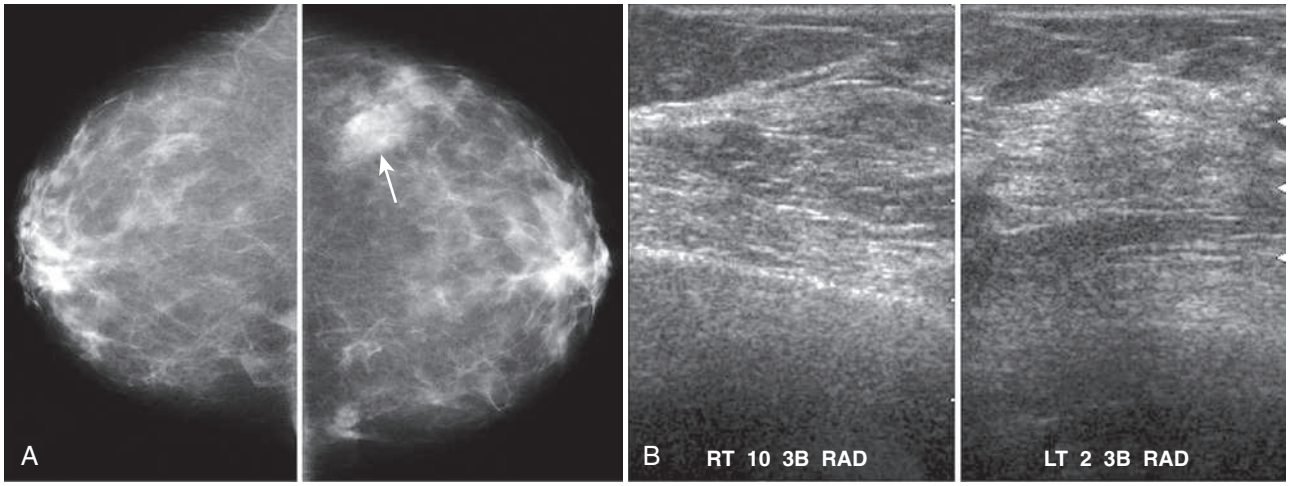

FIG. 21.12 Value of Split-Screen Mirror Ultrasound Image. (A) Mammography of both breasts showed a focal asymmetrical density in the left breast, upper outer quadrant on the craniocaudal (CC) view *(arrow).* **(B)** Split-screen mirror-image ultrasound images show focal fibrous tissue in the upper outer quadrant of the left breast that is markedly asymmetrical with the thickness of tissue in the mirror-image upper outer quadrant location of the right breast. This collection of **asymmetrical fibrous tissue** is the cause of the mammographic asymmetry.

identified, five images of each breast should be acquired.[18] These include one image in one plane of each quadrant of the breast, typically at the same distance from the nipple, and one image of the retroareolar breast. The axilla can be scanned, but this is not required.

When performing a targeted diagnostic ultrasound examination, it is necessary to document that the area in question was imaged. If the area is palpable, make sure to first evaluate for the palpable finding and place the probe immediately over this location. If a finding is seen, then documentation as described earlier is necessary. If no abnormal finding is seen—for example, in the case of a mammographic asymmetry corresponding to normal breast tissue—then documentation of that area showing normal breast tissue is still necessary.

Split-Screen Imaging

Split-screen imaging capability is invaluable in breast imaging. Split-screen images are most frequently used to compare mirror-image locations in the right and left breasts to document that **asymmetrical fibroglandular tissue** causes either a mammographic asymmetry or a palpable lump (Fig. 21.12). Split-screen imaging can also be used to document dynamic events, such as compressibility and mobility, on a single freeze-frame image and in simultaneous mode, to show both the gray-scale image on one side and the color or power Doppler image on the other. It may also be used to document a finding in both orthogonal views on the same screen.

Multiple lesions and lesions larger than the width of the transducer require special techniques for demonstration. Of several methods for demonstrating larger fields of view (FOVs), one can use combined split-screen images or extended-FOV imaging. Extended-FOV images can be helpful in demonstrating very large lesions, multifocal and multicentric malignant lesions, lymph node levels, implant integrity, or, as in Fig. 21.13, extensive fibrocystic change (FCC) with numerous cysts of variable size within the breast.

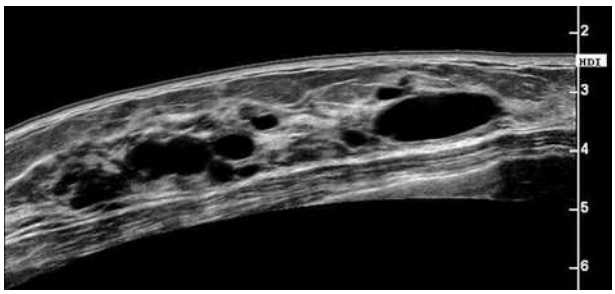

FIG. 21.13 Extended–field-of-view (FOV) images shows extensive **fibrocystic change** with numerous cysts of variable size within the breast.

Special Breast Techniques

Doppler Sonography

One of the main purposes of Doppler ultrasound is to help classify masses seen on ultrasound as benign or malignant. Once a breast malignancy exceeds about 3 mm in size, it must stimulate neovascularity to continue to grow. To accomplish this, tumors elaborate a variety of angiogenesis factors. A net of peripheral neovessels forms to nourish the rapidly proliferating periphery of the tumor. Studies have been performed evaluating the presence or absence of flow, the distribution and pattern of vessels, vessel density, peak systolic velocity (PSV), pulsatility index, and resistive index (RI) and have found conflicting results, some demonstrating that these measures could predict malignancy, but others showing substantial overlap of findings.[19-23] As a result, Doppler cannot be used independently to classify solid masses as benign or malignant but rather should be used to supplement the routine ultrasound evaluation.

That being said, Doppler ultrasound can be used to differentiate solid masses from those that are cystic. Some markedly hypoechoic solid nodules can have a pseudocystic appearance. Demonstrating

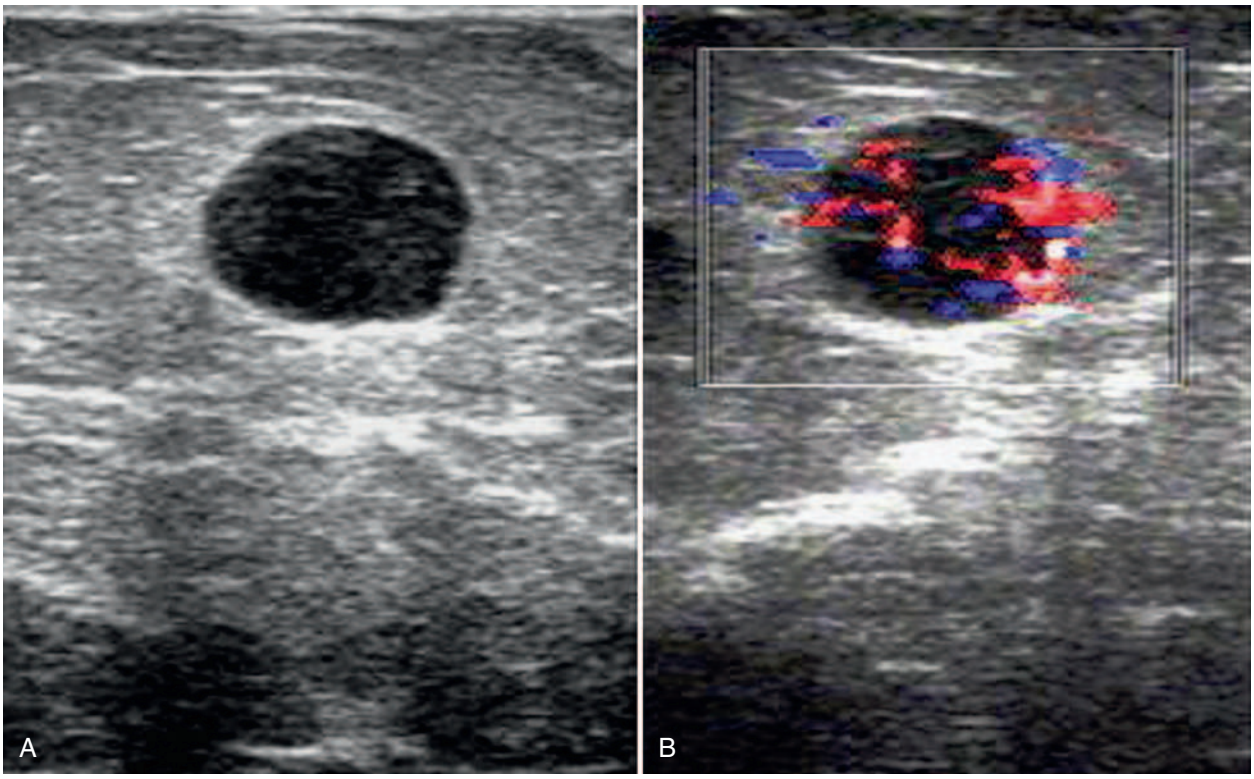

FIG. 21.14 Pseudocystic Solid Nodule Versus Complicated Cyst. Color Doppler ultrasound can be helpful in distinguishing between complex cysts and solid nodules when the distinction is uncertain based on the image alone. **(A) Metastatic leiomyosarcoma of the breast** shows a pseudocystic appearance on the sonogram. **(B)** Color Doppler sonography shows abundant internal flow, indicating that the lesion is solid.

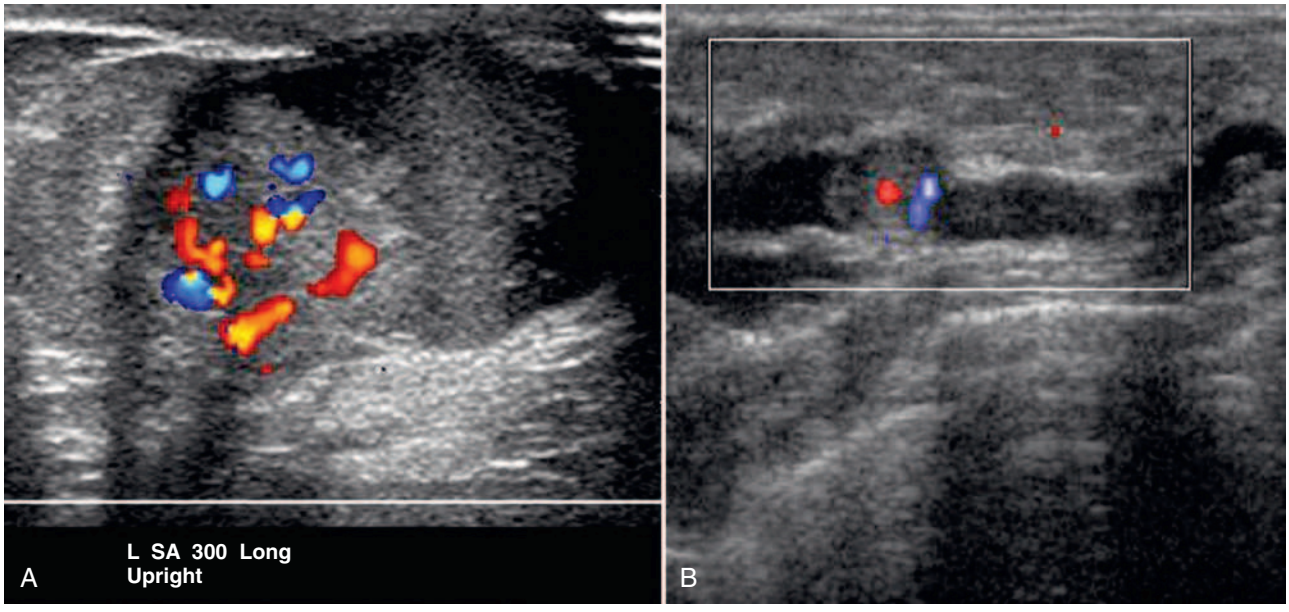

FIG. 21.15 Intracystic Papillary Lesions and Intraductal Papillomas. (A) Malignant lesion fed by multiple vessels. **(B)** Benign intraductal papillomas with a small vascular stalk demonstrable on color Doppler ultrasound.

an internal vessel on color Doppler ultrasound indicates that the lesion is either solid or a cyst completely filled by a papillary lesion (Fig. 21.14). Similarly, Doppler sonography can be useful in distinguishing between an echogenic lipid layer or tumefactive sludge within a cyst and a true intracystic papillary lesion. Intracystic papillary lesions, whether benign or malignant, are among the most vascular lesions of the breast and usually have a prominent vascular stalk that is demonstrable with color or power Doppler sonography (Fig. 21.15A). Benign intracystic papillomas tend to have a single, large feeding vessel within the vascular stalk, whereas malignant intracystic papillary lesions tend to be fed by multiple feeding vessels.

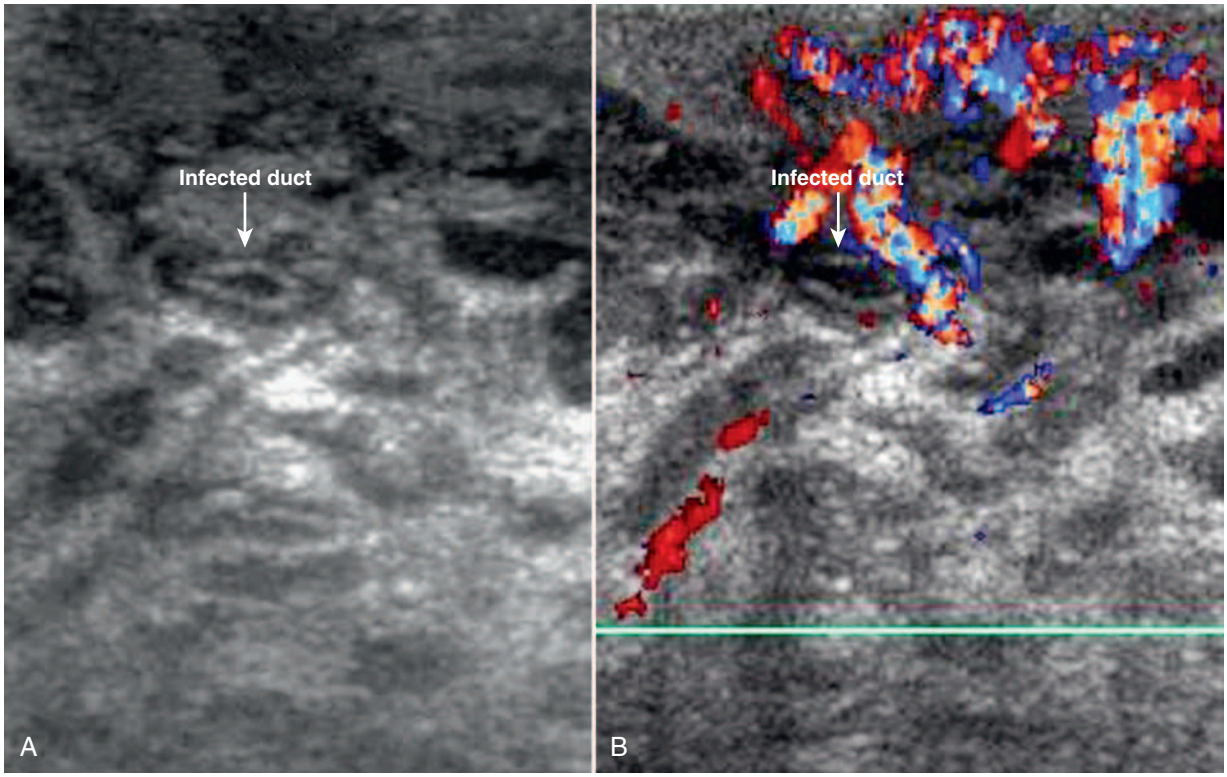

FIG. 21.16 Duct Wall Hyperemia in Acute Periductal Mastitis. (A) Gray-scale image shows uniform isoechoic wall thickening in the inflamed or infected duct *(arrow)*. The noninflamed ectatic duct just to the right has a normal, thin, echogenic wall. **(B)** Color Doppler sonogram shows marked hyperemia of the wall and tissues around the inflamed duct. The vessel is oriented parallel to the wall.

Ectatic ducts, like cysts, often contain echogenic secretions or blood that can be difficult to distinguish from intraductal papillomas or DCIS by gray-scale imaging alone. Ballottement of ectatic ducts that contain diffuse low-level echoes can cause the echoes to slosh back and forth within the duct. This can be appreciated on real-time gray-scale imaging or cine clips and can be documented on color Doppler sonography as well. The secretions tend to move posteriorly during compression and anteriorly during compression release, creating color signals of opposite color. Demonstrating such a "color swoosh" documents that the internal echoes are caused by inspissated secretions or blood rather than tumor. It is important that the color signal fills the duct because echogenic blood from an intraductal papillary lesion can lead to a color swoosh, but the underlying papillary lesion will cause a defect in the color signal. As with intracystic papillary lesions, intraductal papillary lesions are often vascular enough to have a demonstrable vascular stalk on color Doppler sonography (Fig. 21.15B). This helps to identify intraductal papillary lesions and to distinguish them from echogenic lipid or debris layers within the duct.

Doppler may also be useful to evaluate acute breast pain by helping to reveal an acute inflammatory etiology. Acutely **inflamed cysts** and acute **periductal mastitis** are the most common causes for this pain. The normally thin, echogenic wall of an acutely inflamed cyst or duct becomes thick, isoechoic, and hyperemic, which can be easily demonstrated by color or power Doppler ultrasound (Fig. 21.16). In comparison, the walls of noninflamed cysts and ducts have no demonstrable flow on color Doppler sonography. The direction in which the vessels course within the walls of inflamed cysts and ducts differs from the orientation of vessels that feed intracystic or intraductal papillary lesions. Vessels that lie within the walls of inflamed ducts or within the periductal tissues course *parallel* to the duct wall because they are feeding and draining the duct wall and periductal tissues. Vessels that feed intraductal papillary lesions are oriented *perpendicular* to the axis of the duct wall because the vessels are merely passing through the wall to feed a lesion inside the duct. Doppler ultrasound and other imaging findings in acutely inflamed or infected peri-implant capsules are similar to those in acutely inflamed cysts or ducts.

Doppler sonography can be helpful in assessing **lymph nodes** that are not normal but have nonspecific imaging findings that prevent determination of whether the node is merely inflamed or contains metastasis. The histologic and biologic behavior of lymph node metastases is usually identical to that of the primary lesion. A vascular primary tumor will tend to have a vascular lymph node metastasis. If the spectral waveforms obtained from the center of the primary are high impedance and have high and sharp systolic peaks, the waveforms obtained from lymph node metastases from that primary will have similar waveforms. Conversely, inflamed or reactive lymph nodes will usually have low-impedance waveforms with low, rounded systolic peaks. The

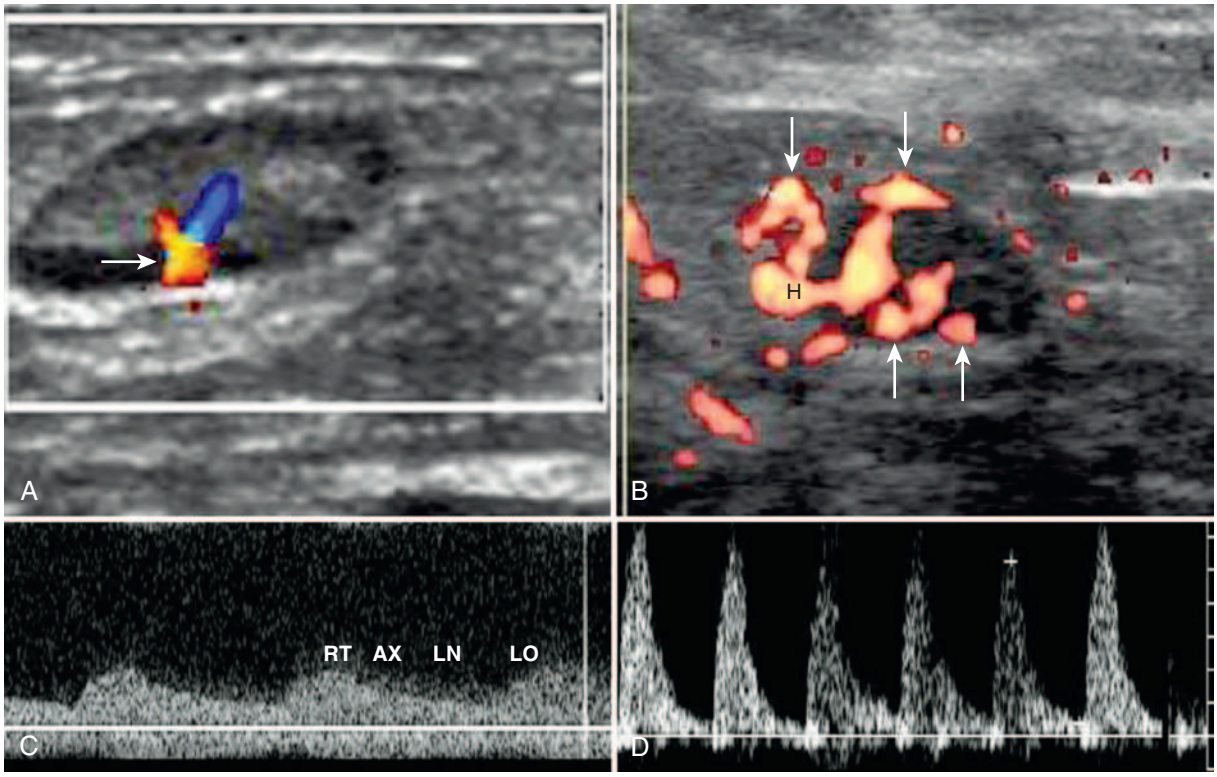

FIG. 21.17 Color Doppler Flow Patterns and Special Waveforms Help Distinguish Between Metastatic and Inflammatory Etiologies of Mild Lymphadenopathy. (A) Benign reactive lymph node is usually fed by a single hilar artery *(arrow).* **(B)** Lymph nodes that bear metastasis often develop transcapsular feeding vessels *(arrows)* in addition to having a normal hilar artery *(H).* **(C)** Pulsed Doppler spectral waveforms obtained from benign reactive nodes tend to have low resistive index (RI) and low peak systolic velocity (PSV) with rounded systolic peaks. **(D)** Waveforms obtained from metastasis-bearing lymph nodes tend to have high RI, high PSV, and sharp systolic peaks.

pattern of blood vessels within lymph nodes can also be helpful. Inflamed or reactive lymph nodes tend to be fed by a single hilar artery that arborizes to various degrees within the mediastinum of the lymph nodes (Fig. 21.17A). Well-differentiated and low-grade lymphomas can have a similar pattern. Metastases to lymph nodes can stimulate development of transcapsular tumor neovascularity (Fig. 21.17B).

Doppler sonography can also be useful for diagnosing vascular conditions such as **arteriovenous malformations, arteriovenous fistulas, venous malformations,** and **superficial venous thrombosis (Mondor disease).** Along these lines, Doppler can help identify blood vessels that should be avoided during interventional procedures.

When assessing blood flow in the breast, it is critical to use exceedingly light compression. Tumor vessels have no muscle or elastic to prop them open and are very soft. The transducer is hard, the chest wall is firm, and even the weight of the sonographer's arm on the transducer can compress a lesion between the probe and chest wall enough to decrease or even completely ablate flow within breast lesions (Fig. 21.18; see Videos 21.1 and 21.2). As a result, Doppler sonography must be performed with such light scan pressure that the transducer barely contacts the skin. In some cases, using a standoff of acoustic gel may be necessary so that Doppler ultrasound–detectable blood flow will not be affected.

Elastography

Elastography is a technique that uses the lesion's stiffness to inform the likelihood of malignancy. This phenomenon is captured quantitatively by Young's modulus, which measures stiffness, wherein E (elasticity) = stress/strain. Stress is the force that is applied to the mass during the imaging evaluation and strain is the amount of tissue displacement that occurs in response to this force. A less compressible mass has a higher Young's modulus and a greater likelihood of malignancy. There are two methods of performing elastography: strain and shear wave. **Strain elastography** requires the operator to provide gentle repetitive compression to the breast tissue either via repetitive motion or using the patient's own breathing or heartbeat. The strain of the tissue is measured through longitudinal displacement of the tissue before and after compression. Because the delivered force is variable, Young's modulus cannot be calculated. The result is predominantly qualitative information. The strain of the mass and surrounding normal tissue can be compared to create a strain ratio (Fig. 21.19). **Shear wave elastography** employs a force automatically applied by the transducer to the targeted mass, making it less operator dependent. Horizontal shear waves are then produced at variable speeds based on the mass's hardness, and the elasticity of the mass can be calculated.[24,25]

Stiffness measures for both strain and shear wave elastography are typically color-coded for quick interpretation. Although red

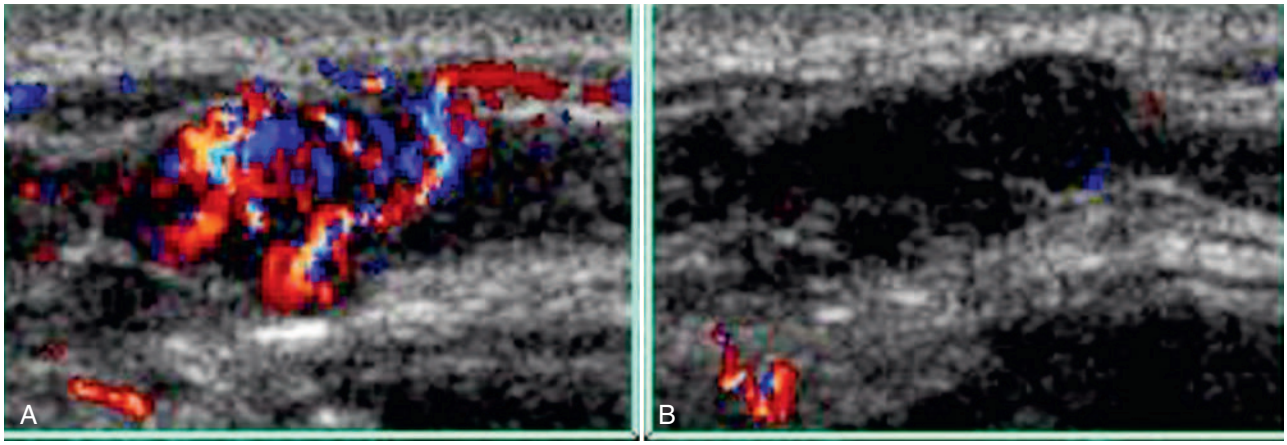

FIG. 21.18 Importance of Light Pressure for Color Doppler Examination. (A) Micropapillary ductal carcinoma in situ lesion appears exceedingly hypervascular when scanned with light pressure. **(B)** Lesion appears avascular when just the weight of the scanning arm is allowed to rest on the transducer during scanning.

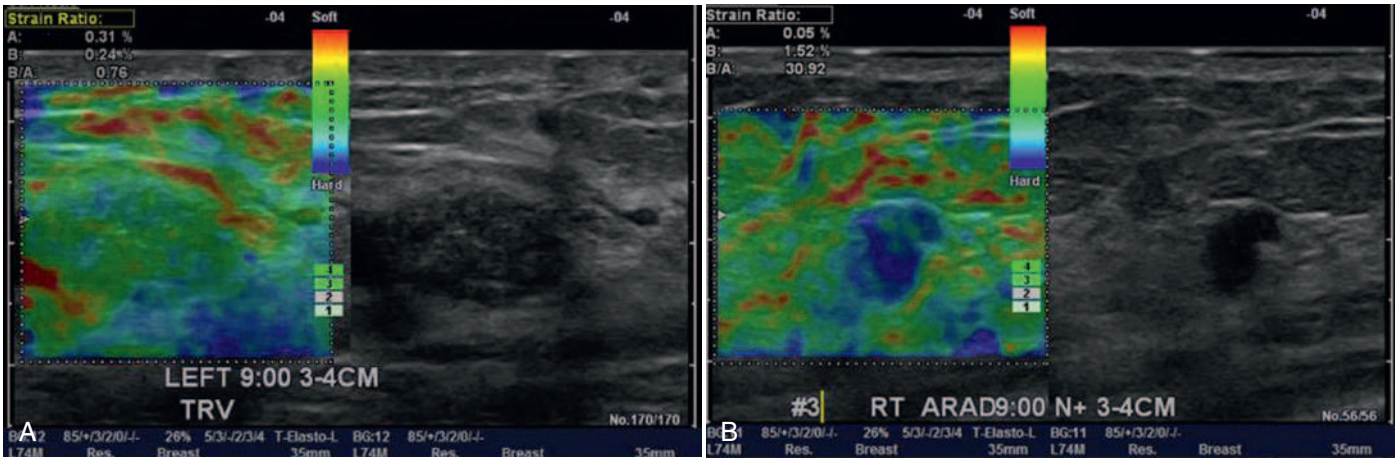

FIG. 21.19 Elastography Depicts Benign and Malignant Masses. (A) A benign-appearing hypoechoic macrolobulated mass has a strain value, which is similar to the strain value of the surrounding tissue. The ratio is therefore close to 1. **(B)** An irregular, spiculated, not parallel mass has a lower strain value as compared with surrounding tissue, consistent with malignancy. (Courtesy of Sughra Raza, MD.)

typically indicates increased stiffness and increased likelihood of malignancy and blue indicates less stiffness and increased likelihood of benignity, these color conventions have not been standardized. Elastography features including shape, size, heterogeneity, and stiffness all complement the features obtained during routine diagnostic ultrasound imaging. Quantitative values have also been advocated for improved standardization. Studies have shown that elastography can be helpful to improve specificity of diagnostic imaging and to identify more advanced malignancies.[26-29]

Limitations of elastography primarily relate to the lack of standardization of technique and implementation across vendors. Grading schemes,[30,31] quantification of signal,[28] and color-coding of lesions vary.[24,27] In addition, these techniques are based on compression, which can vary by user and, in turn, can affect elasticity measures.

Three-Dimensional Ultrasound

Three-dimensional (3-D) ultrasound captures volumetric information about breast lesions so they can be viewed in sagittal, coronal, and transverse planes. This is being studied with both hand-held and automated breast ultrasound methods to determine its added value above conventional ultrasound. Initially, 3-D ultrasound was not shown to be superior to conventional ultrasound[32,33]; however, more recent studies suggest that 3-D ultrasound may help with identifying cancer.[34]

Contrast-Enhanced Ultrasound

New vascular networks are created as malignant tumors grow. Doppler ultrasound is currently used to capture these areas of neovascularity. However, Doppler has not been shown to be sufficiently accurate in its ability to differentiate malignant from benign masses. As a result, contrast-enhanced ultrasound has

TABLE 21.1 Breast Imaging Reporting and Data System (BI-RADS) Categories[43]

BI-RADS Category	Description and Examples	Risk of Malignancy	Recommended Follow-Up
0	Incomplete examination; additional imaging is necessary to evaluate the finding or area of clinical concern		
1	Sonographically normal tissues that cause mammographic or clinical abnormalities	0%	Routine screening[a]
2	Benign entities: includes intramammary lymph nodes, ectatic ducts, all simple and some complicated cysts (milk of calcium), and definitively benign solid nodules, such as lipomas and hamartomas	0%	Routine screening[a]
3	"Probably benign" complicated and complex cystic and solid masses, some small intraductal masses possibly representing debris or papilloma, and a subset of fibroadenomas	≤2%	Short-interval follow-up recommendation with either mammography or ultrasound, typically 6 months[a]
4a	Mildly suspicious	>2-10%	Histologic sampling either with percutaneous biopsy or surgical excision
4b	Moderately suspicious	>10%-≤50%	
4c	Highly suspicious	>50%-<95%	
5	Very highly suspicious	≥95%	
6	Known malignancy		

[a]In the above BI-RADS description, should the patient have a palpable abnormality or other clinical finding and be rated as BI-RADS 1 or 2, the patient should also have a clinical follow-up in 6 weeks to 3 months to ensure that the clinical finding has not changed. If BI-RADS 3 characterization is associated with a stable lesion at first follow-up, then an additional 6-month follow-up is recommended. After 1 year of stability, an additional 1 year, and possibly 2 years, of imaging follow-up may be performed.

been increasingly used to better identify masses associated with neovascularity that more likely represent malignancy.[35-40] Additional studies have evaluated whether contrast-enhanced ultrasound can identify sentinel lymph nodes during the preoperative evaluation[41] and tumor response to chemotherapy.[42]

REPORTING

The ACR **Breast Imaging Reporting and Data System (BI-RADS)** was initially developed for mammography but has similar categories and descriptors for ultrasound[18] to standardize reporting and data. BI-RADS has developed a standardized lexicon for describing findings seen on ultrasound in addition to a system for classifying these findings and their probability of malignancy.[17] The BI-RADS assessment categories for classification of findings range from BI-RADS 0 through BI-RADS 6 (Table 21.1).

SONOGRAPHIC FINDINGS

When evaluating the breast by ultrasound, it is important to adhere to the BI-RADS descriptors of sonographic findings because they provide a standard lexicon for communicating results. In this section, we review common imaging findings and how to describe them according to the most recent edition of the ACR BI-RADS Atlas.[18]

The sonographic findings that correlate with mammographic abnormalities or areas of clinical concern can fall into several different categories: (1) ANDIs, (2) cysts, (3) solid masses, and (4) indeterminate (cystic vs. solid) lesions.

Normal Tissues and Variations

Normal breast tissues and variations of normal tissues, including duct ectasia, FCC, and benign proliferative disorders, can cause both mammographic and sonographic abnormalities. These changes have been termed "ANDIs" (aberrations of normal development and involution). ANDIs can appear sonographically not only as normal tissues but as cysts and solid nodules, accounting for some false-positive results at biopsy. Most sonographically normal tissues can be characterized as BI-RADS 1. That being said, ANDIs can cause a spectrum of abnormalities that can be characterized as BI-RADS 2, 3, or 4.[44]

Cysts and Cystic Masses

Simple Cysts

Simple cysts are anechoic, round or oval, and surrounded completely by a thin, echogenic wall or capsule with enhanced sound transmission and thin-edge shadows (Fig. 21.20, Video 21.3). They form from dilation of the acini in the TDLU. When multiple acini dilate, they can form a group of small microcysts. They can then coalesce together to form a solitary cyst. Cysts that meet strict criteria for being simple are "definitively benign" and do not require further follow-up. Aspiration of simple cysts is generally reserved for relief of pain and tenderness in very tense simple cysts.

Demonstrating that a benign simple cyst causes a palpable lump or mammographic nodule is by far the most valuable finding demonstrable on sonography because the negative predictive value is 100%.[45]

FIG. 21.20 Simple Cysts. Simple cysts are anechoic and have enhanced sound transmission, well-circumscribed borders, thin-edge shadows, and thin, echogenic walls. They are benign (Breast Imaging Reporting and Data System [BI-RADS] 2) and require no aspiration or follow-up. See also Video 21.3.

Complicated Cysts

Complicated cysts are cysts that contain debris. This manifests as echogenic fluid, fluid-debris levels, or fat-fluid levels without a solid vascular component. Cellular debris, epithelial cells, blood, proteinaceous material, and pus can all contribute to the appearance of low-level echoes within a complicated cyst. Complicated cysts are generally benign as part of the broad spectrum of benign **fibrocystic change,** but have a low risk of containing papillomas or carcinomas[46] and are therefore often classified as BI-RADS 3, for which follow-up is recommended.

There are some instances in which complicated cysts can be characterized as BI-RADS 2. This is the case when the complicated cyst can confidently be characterized as a specific benign lesion such as a galactocele (which is a cyst that contains milk and often demonstrates a fat-fluid level on ultrasound) or a cyst of skin origin such as an epidermal inclusion cyst.

Cysts can contain particles suspended in fluid that are so light that they can be moved by the energy of the B-mode imaging or color or power Doppler ultrasound beam. Such particles are subcellular in size and are often seen with uncomplicated FCC. In general, high-transmit power settings are necessary to cause such particles to move during real-time B-mode imaging. However, the energy of the color or power Doppler ultrasound beam is high enough to cause these particles to move at even default low-power settings, creating what has been termed **"color streaking."** Particles are forced posteriorly by the energy of the Doppler ultrasound beam, creating vertically oriented color streaks within the cyst as they move (Fig. 21.21). The particles that cause color streaking have been shown to be cholesterol crystals, which can be seen on cytologic evaluation as birefractive crystals when viewed with polarized light.

Milk of calcium is a BI-RADS 2 mammographic finding that has been directly applied to sonography. Milk of calcium is a collection of tiny calculi within the lumen of a cyst. Such calculi are very common in benign FCC and can be demonstrated definitively on horizontal beam mammographic films. Sonography can prove the presence of milk of calcium by demonstrating that the calcifications move within the cyst to new dependent positions created by lateral decubitus or upright positioning of the patient (Fig. 21.22). Although mammography can generally show smaller and more numerous calcifications, sonography has one advantage over mammography in demonstrating milk of calcium. Mammography requires dozens of small calcifications before the classic "teacup" appearance can be shown on horizontal beam films, whereas sonography can definitively demonstrate a single mobile calculus in a cyst (Fig. 21.23). Thus, although less sensitive than mammography for calcifications, sonography can be more specific than mammography for milk of calcium. This is particularly true when mammography shows a nonspecific cluster of punctate microcalcifications that might require biopsy, but sonography shows benign clustered microcysts, each containing one or more tiny calculi (Fig. 21.24).

Fat-fluid levels within cysts are definitively benign mammographic findings that have been directly applied to ultrasound. Fat-fluid levels are rarely demonstrated on mammography, and usually only within classic **galactoceles,** but are much more frequently demonstrated by sonography. The lipid layer appears echogenic compared with cyst fluid and floats on the fluid in the nondependent portion of the cyst. The lipid layer moves within the cyst to a new nondependent position with change in the patient's position from supine to lateral decubitus or upright (Fig. 21.25). As with tumefactive sludge, lipid layers tend to shift very slowly within a cyst when the patient's position is changed, requiring up to 5 minutes to document the shift of a fat-fluid level. During the shift in position, the shape of the interface between the lipid and fluid layers changes and is usually obliquely oriented with respect to the tabletop and has a sigmoid shape. The oblique orientation of the interface in combination with the sigmoid shape is characteristic of a fat-fluid level in the process of equilibrating to a new position and may represent a shortcut to waiting 5 minutes for the fat-fluid level to shift. Power Doppler ultrasound **fremitus** can also be used to distinguish a mural nodule from a fat-fluid level.[47] The lipid layer is not attached to the cyst wall, so the fremitus artifact will not pass through it. On the other hand, true papillary lesions that are attached to the cyst wall will vibrate and transmit the fremitus artifact on power Doppler; having the patient hum in a deep voice creates an orange artifact on power Doppler ultrasound (Fig. 21.26).

Lipid cysts or oil cysts are definitively benign mammographic findings. Unfortunately, lipid cysts usually appear more definitively benign on mammography than sonography. Most lipid cysts lack enhanced sound transmission and may actually have posterior shadowing due to calcified walls. Most have some additional suspicious features on sonography, such as (1) mural nodules; (2) thick septations; (3) thick walls; and (4) fluid debris levels (Fig. 21.27). This should not be surprising because most lipid

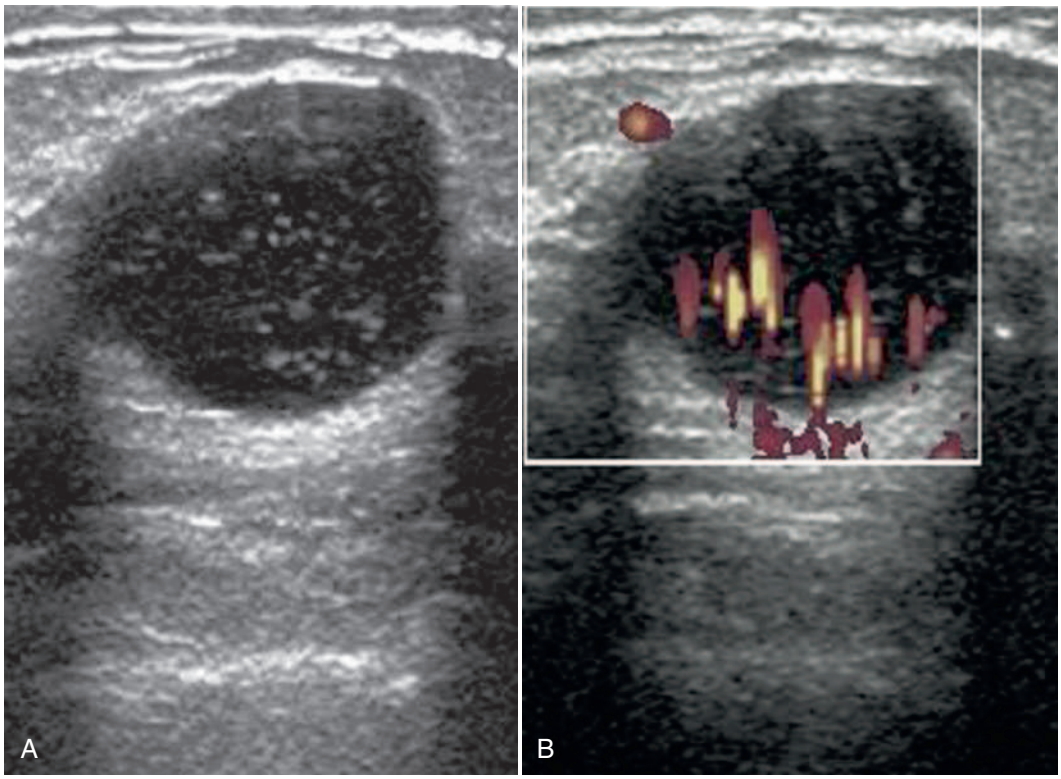

FIG. 21.21 Cyst With Scintillating Echoes and Color Streaking. (A) This complicated cyst contains floating punctate echoes that move posteriorly while being scanned, creating a scintillating appearance on gray-scale sonography. **(B)** Power Doppler ultrasound pushes the echoes posteriorly faster and with more energy than does the gray-scale beam. The echoes move fast enough that color persistence creates the appearance of "color streaking," an artifact that should not be confused with blood flow.

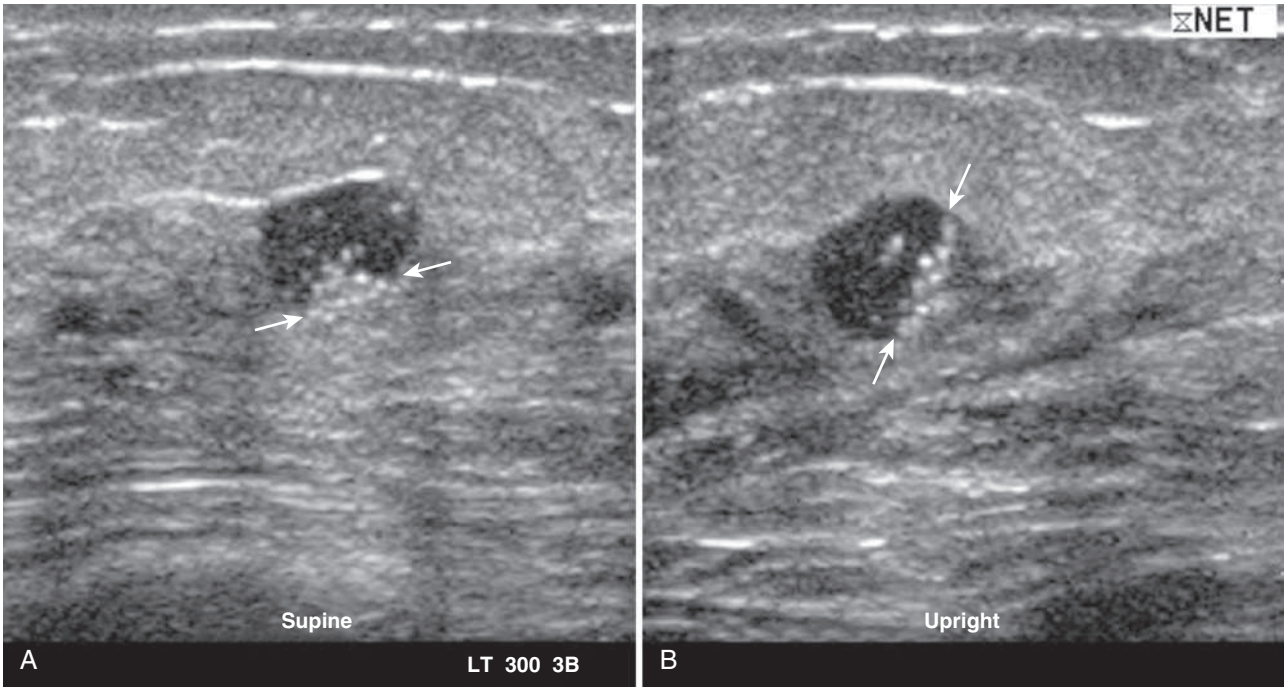

FIG. 21.22 Milk of Calcium. Milk of calcium is actually a dependent layer of tiny calculi *(between arrows)* within a breast cyst that moves when the patient changes position. **(A)** The calculi lie along the dependent posterior wall in the supine position. **(B)** The calculi fall to the dependent inferior position when the patient is in the upright position and scanned in the longitudinal plane.

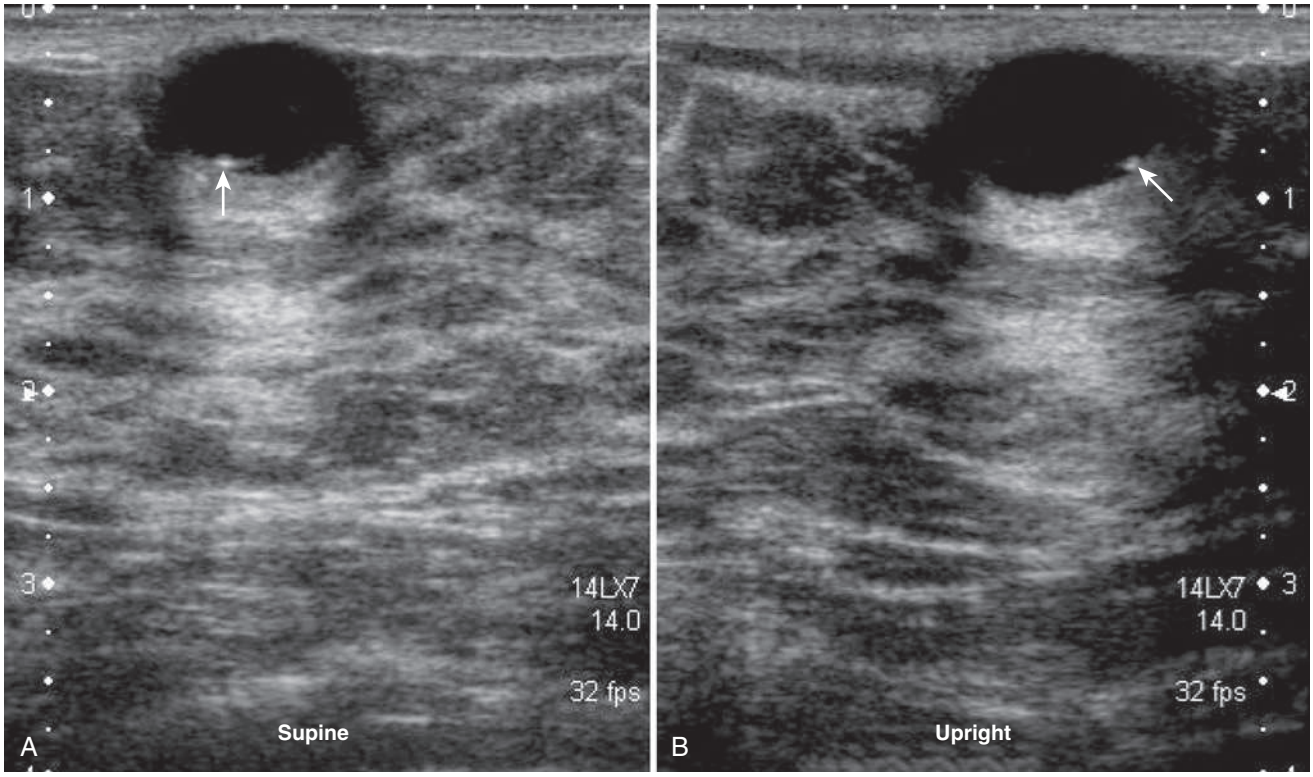

FIG. 21.23 Milk of Calcium Appearing as Single Calculus Within Cyst. (A) Sonogram shows a single stone *(arrow)* lying on the posterior wall of cyst in the supine position. **(B)** Stone falls to the dependent inferior wall of the cyst *(arrow)* when the patient is upright and the cyst is scanned in the longitudinal plane.

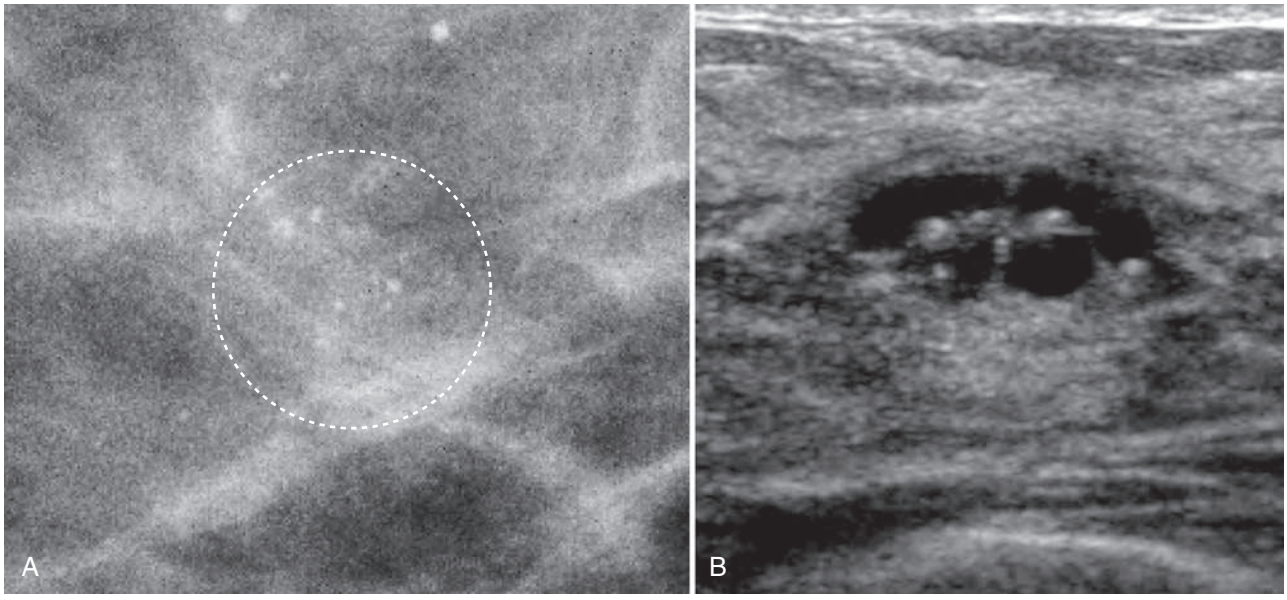

FIG. 21.24 Milk of Calcium Within Clustered Microcysts. (A) Mammogram shows a nonspecific cluster of punctate and granular calcifications indicated by *dashed circle*. **(B)** Sonography shows a cluster of microcysts (avascular on color Doppler), many of which contain single dependent calculi, that is definitively benign.

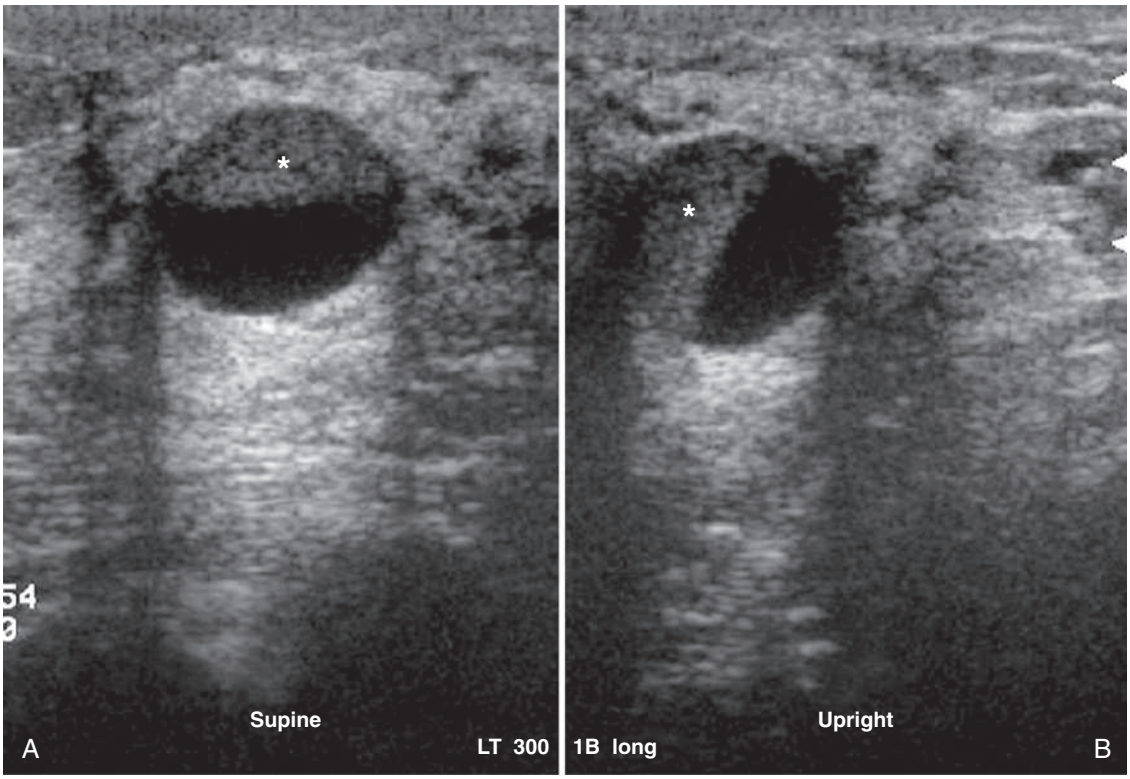

FIG. 21.25 Fat-Fluid Level. The lipid layer is echogenic compared with cyst fluid and moves within the cyst to its nondependent part when the patient changes position. **(A)** The echogenic lipid layer (*) floats to the nondependent anterior wall of the cyst, and the interface is oriented horizontally when the patient is scanned in the supine position. **(B)** The echogenic lipid layer has floated to the new nondependent superior wall, and the interface is oriented vertically when the patient is in the upright position and the cyst is scanned longitudinally.

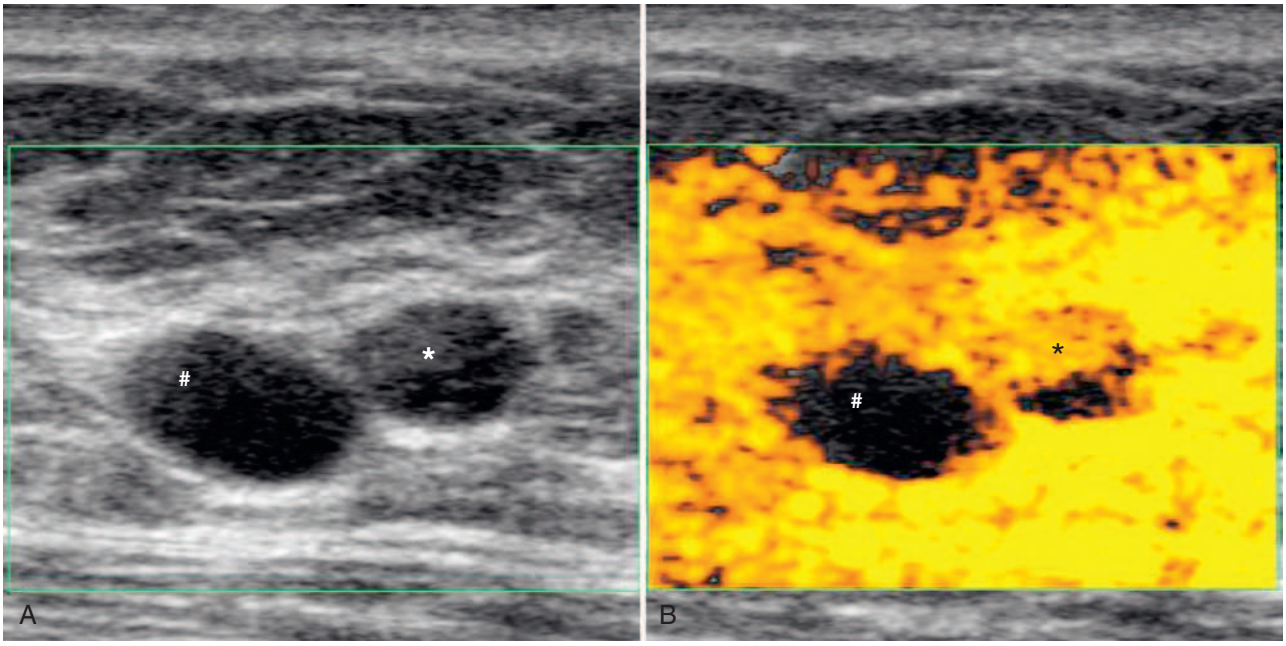

FIG. 21.26 Acorn Cysts of Two Different Types. (A) Sonogram shows two cysts that have crescentic echogenic thickening along the anterior wall, resembling the caps on acorns. The echogenic material in the left acorn cyst (#) is floating lipid debris, whereas the echogenic material along the anterior wall of the right acorn cyst (*) is **papillary apocrine metaplasia** (PAM). Unfortunately, the distinction cannot be made from a single image obtained in the supine position. Changing position can help but often takes 5 minutes; with power Doppler vocal fremitus, the distinction can be made virtually instantly. Having the patient hum in a deep voice creates an orange artifact on power Doppler in normal breast tissues and within any mural nodules or thick septations that are attached to the wall of the cyst, but not within unattached debris. **(B)** Power Doppler ultrasound image shows that the vocal fremitus artifact does not fill the echoes caused by the unattached debris level in the left acorn cyst (#) but does fill the attached echogenic PAM (*) within the right acorn cyst.

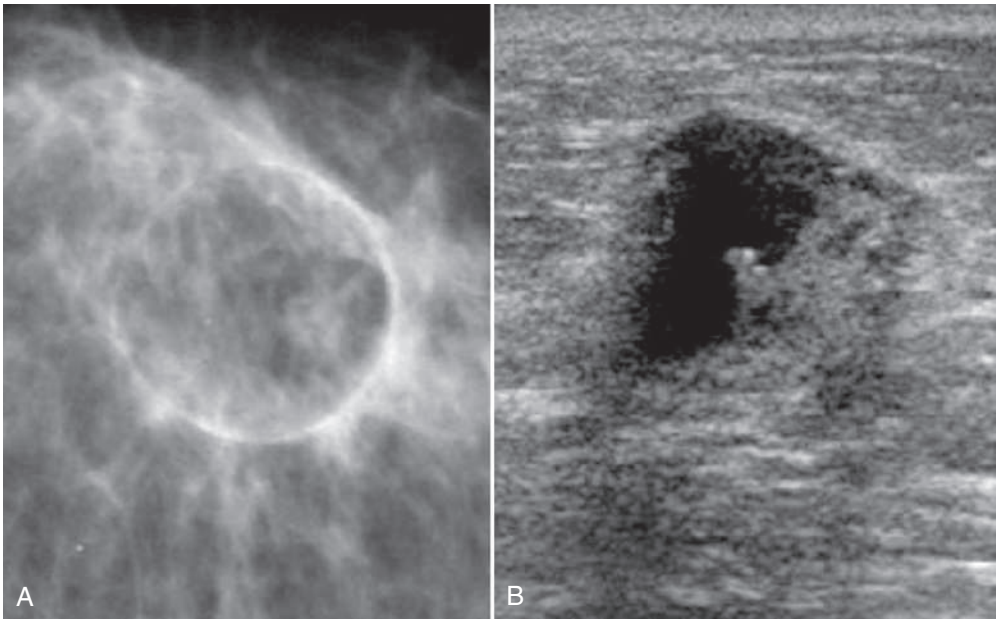

FIG. 21.27 Lipid Cyst. Mammographic spot compression views can more accurately characterize lipid cysts than sonography. On ultrasound images, **(A)** lesions that appear to be classic benign lipid cysts on mammography often have suspicious features, such as **(B)** thick irregular wall, thick isoechoic septations, and mural nodules. These sonographically suspicious features are typical of chronic hematomas, from which most lipid cysts arise.

cysts originate in chronic seromas or hematomas, which often manifest such findings. However, the suspicious sonographic findings in lipid cysts are avascular, unlike those in cysts containing true papillary lesions. Nevertheless, lipid cysts frequently appear more worrisome sonographically than on spot compression mammograms. Thus, when sonographic and mammographic findings are discordant, we rely more on the mammographic findings in this subset of patients, unless color Doppler ultrasound shows internal vascularity.

Eggshell calcifications are benign mammographic findings that have been applied directly to sonography. In general, eggshell calcifications are so definitively benign on mammography that they do not require sonographic assessment (Fig. 21.28A-B). Occasionally they will be seen on sonography in a patient who has not had mammography or for whom the mammograms are not available. Punctate calcifications that occur within the normal thin, echogenic cyst wall represent incomplete eggshell calcifications and therefore can be considered BI-RADS 2 sonographic findings (Fig. 21.28C). In such cases the sonographic findings are more definitively benign than the mammographic findings. Calcifications that are suspended within the lumen of a cyst cannot be characterized as BI-RADS 2. In most cases they occur with **papillary apocrine metaplasia** (PAM), but they can also occur in DCIS (Fig. 21.28D).

Clustered macrocysts are identical to thinly septated cysts (Fig. 21.29). The septations represent the residual walls of individual, cystically dilated ductules within an individual TDLU. Each cystically dilated ductule can be thought of as a simple cyst; a thinly septated cyst is typically a cluster of simple cysts, each having BI-RADS 2 characteristics.

Cysts of skin origin are benign and usually represent **sebaceous cysts** or **epidermal inclusion cysts.** Sebaceous cysts have three typical appearances: (1) a complex or solid-appearing lesion that lies entirely within the skin (Fig. 21.30); (2) a complicated cyst that lies mainly within the subcutaneous tissues but has clawlike hyperechoic skin wrapped around it (Fig. 21.30B); and (3) a lesion that lies entirely within the subcutaneous fat but has an associated, abnormally hypoechoic, thickened inflamed gland neck that courses through the skin (Fig. 21.30C). The gland neck is obliquely oriented and is often better demonstrated by heeling or toeing the transducer to change the angle of incidence. Because cysts of skin origin are so superficial in location, optimal demonstration of one of these three patterns usually requires that an acoustic standoff be used.

Foam cysts are cysts whose lumens are completely filled with low-level echoes (Fig. 21.31A). Other names include **gel cysts** and **inspissated cysts.** The foam cyst appearance can actually represent a spectrum of lesions, from those completely filled with PAM to those that contain only echogenic proteinaceous debris or lipid material.[48] Others may contain mixtures of PAM and proteinaceous or fatty debris. These lesions have sonographic features that overlap with those of fibroadenomas, and in about 3% of cases it is not possible to determine with certainty whether the lesion is cystic or solid. In this scenario, the clinician should characterize the mass using BI-RADS descriptors and make a recommendation based on the most suspicious finding. If the sonographic features suggest a low probability for malignancy, this mass—whether cystic with low-level echoes or solid—can be followed and classified as BI-RADS 3. Otherwise, sampling should be performed. Aspiration may be attempted first, followed by core biopsy if unsuccessful. When the internal echoes are all caused by PAM, the lesion cannot be aspirated. When the lesion is filled with proteinaceous or fatty debris, it can be completely aspirated. If partially filled with PAM, the lesion will be only partially aspirated. In this case, core biopsy of the residual material or additional short-term follow-up is recommended.

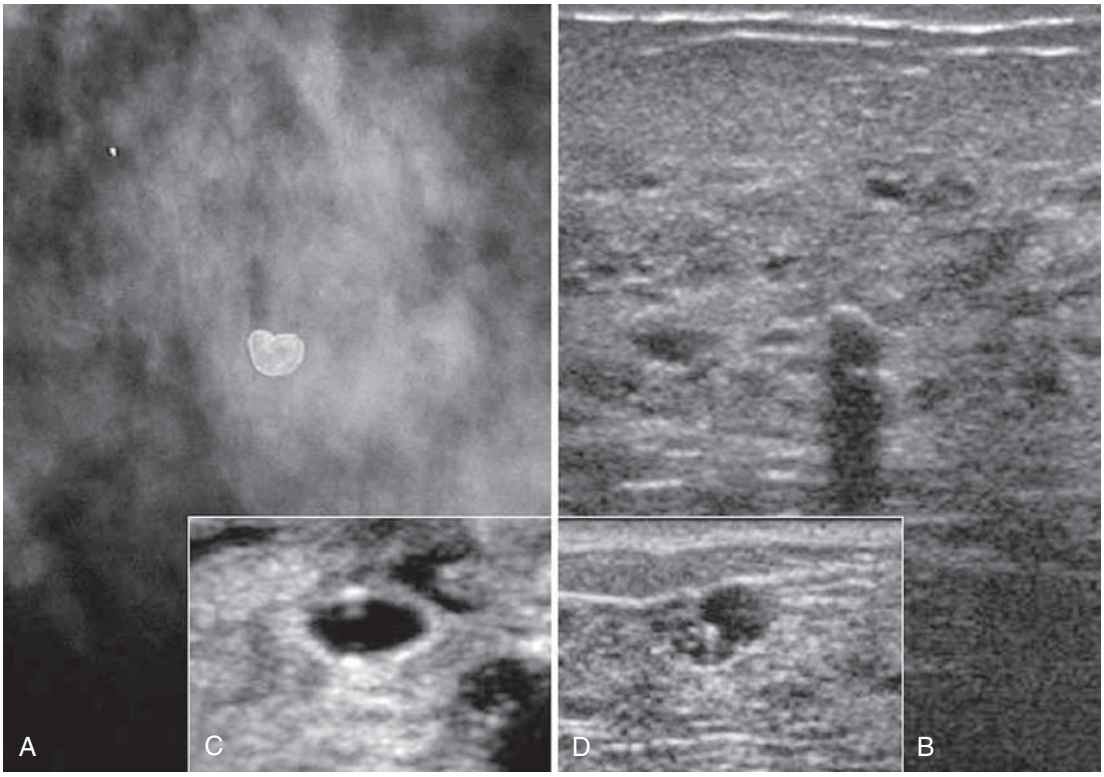

FIG. 21.28 Eggshell Calcification. (A) Eggshell calcifications are mammographic findings that are definitively benign. **(B)** Dense eggshell calcifications cause acoustic shadowing on ultrasound. **(C)** Punctate calcifications confined to the thin echogenic cysts walls can be thought of as incomplete eggshell calcifications and therefore are benign. **(D)** Nondependent and nonmobile punctate calcifications within the interior of the cyst are nonspecific and can be associated with papillary apocrine metaplasia (PAM) or ductal carcinoma in situ (DCIS).

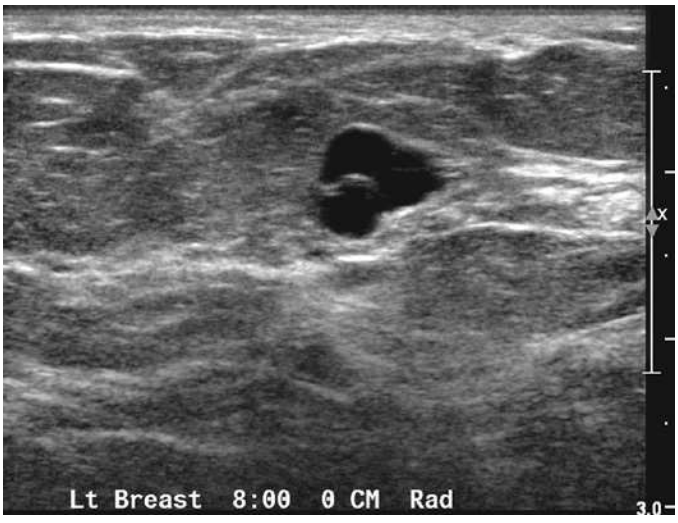

FIG. 21.29 Clustered Macrocysts. Thin, echogenic septations within cysts are not suspicious. Such septations represent residual walls of cystically dilated acini within a single terminal ductolobular unit (TDLU) and can be thought of as clusters of simple cysts.

Acorn cysts have a crescentic, eccentrically thickened wall caused by PAM that does not completely fill the cyst (see Fig. 21.31B). Unlike the echogenic crescent within cysts that contain fat-fluid levels, the echogenic crescent caused by PAM does not shift within the cyst when the patient changes position, regardless of duration (see Fig. 21.31C and D). In these cases the normal, thin, echogenic outer cyst wall is preserved along the entire thickened wall, and there is no vascular stalk (see Fig. 21.31E). It is important to confirm that none of the internal components is vascular or solid because this may be suggestive of a complex cystic and solid mass rather than an acorn cyst (see next section). If there is any question as to whether this represents a true mural nodule, biopsy should be performed. If no suspicious features are identified, then this can be followed and classified as BI-RADS 3.

The algorithm used for evaluation of nonsimple cysts has been derived from the mammographic and solid nodule algorithms. The BI-RADS lexicon should be used to characterize the mass. The presence of even a single suspicious finding requires exclusion from the BI-RADS 2 category, and possibly the BI-RADS 3 category. Although every effort should be made to characterize as many nonsimple cysts as BI-RADS 2 as possible, they must meet strict criteria before they can be characterized as such.

Complex Cystic and Solid Masses

Complex cystic and solid masses contain both solid and cystic components. They may have thick and irregular walls, mural nodules, thick septations, and internal blood flow (Fig. 21.32). These complex masses are at increased risk of containing papillomas or carcinomas such as DCIS, papillary carcinoma, or infiltrating ductal carcinoma, with or without necrosis. Since it is not always easy to determine whether the internal material is

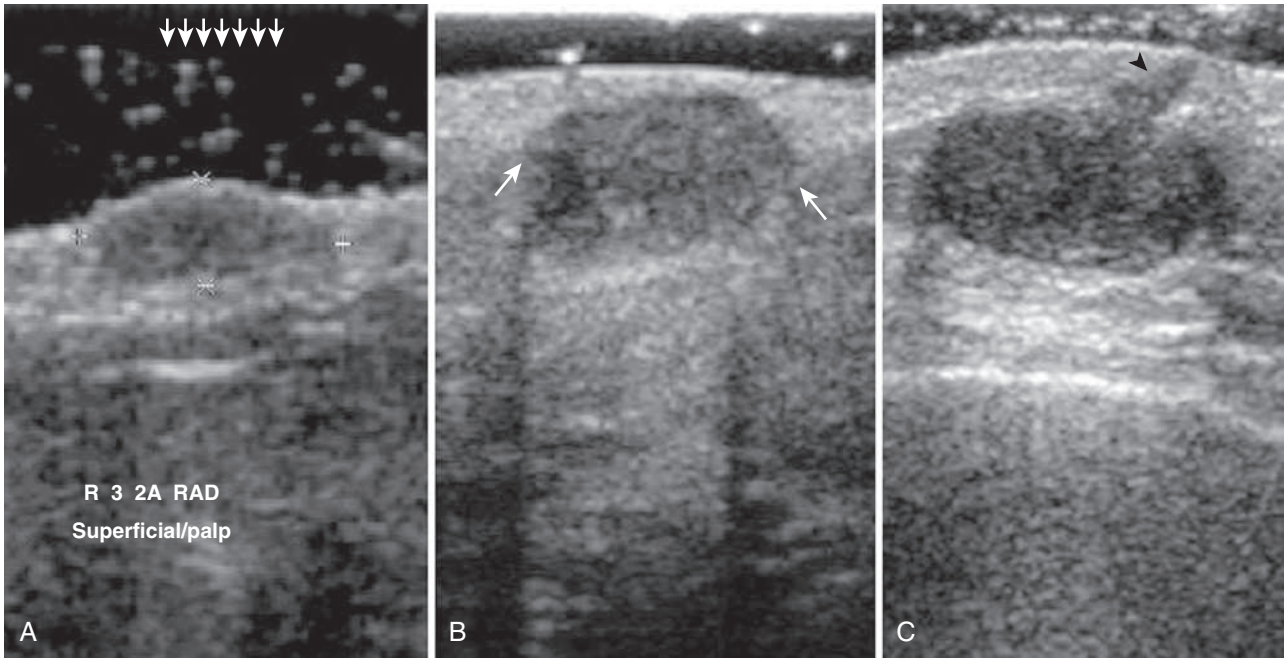

FIG. 21.30 Benign Sebaceous Skin Cysts. (A) Sebaceous cyst is entirely within the skin *(calipers)*. Extra gel has been used as a stand off pad for scanning *(arrows)*. **(B)** Cyst is primarily within the subcutaneous fat, but a thin "claw sign" of echogenic skin *(arrows)* can be shown to wrap around the cyst, confirming that it originates within the skin. **(C)** Cyst is entirely within the subcutaneous fat, but a dilated and obstructed gland neck can be seen coursing obliquely through the skin *(arrowhead)*. A standoff of acoustic gel is necessary to see these lesions. To show the obliquely oriented hair follicle, heeling or toeing of the transducer may be necessary.

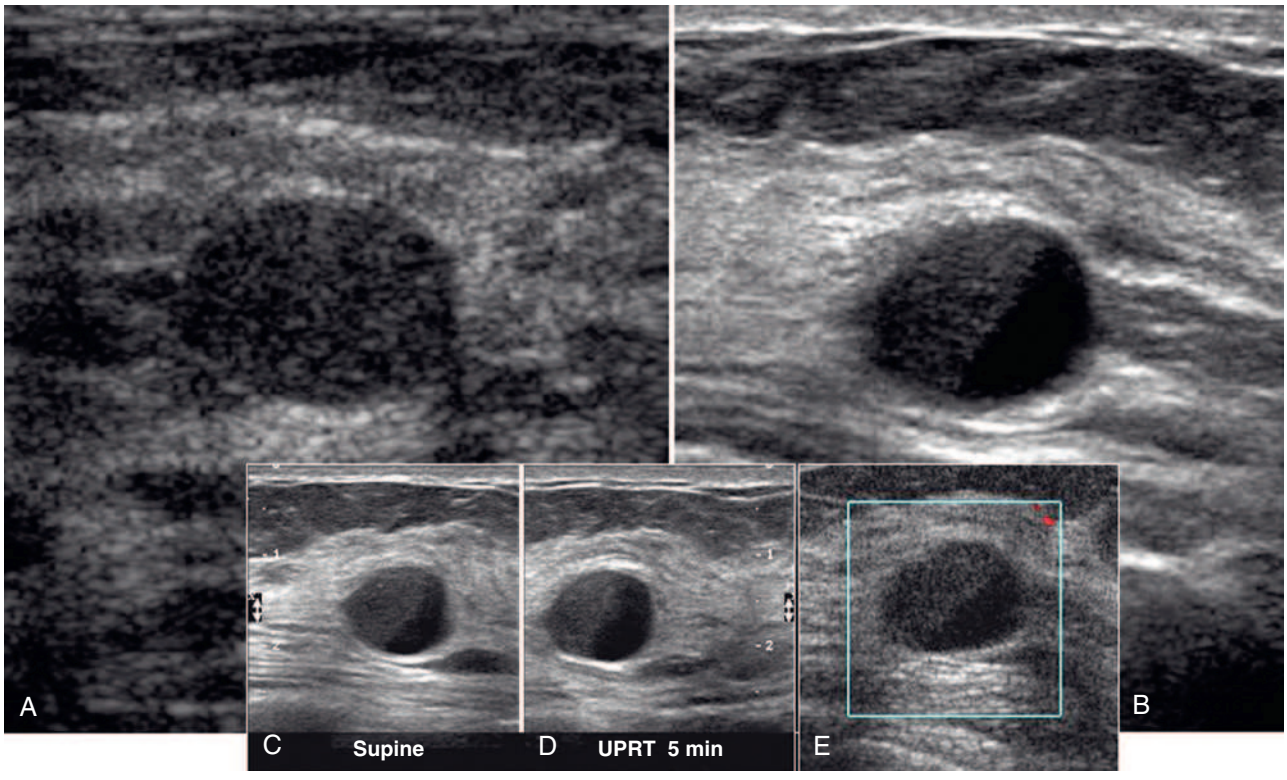

FIG. 21.31 Foam and Acorn Cysts. (A) Foam cysts are filled with diffuse low-level echoes and can be difficult to distinguish from solid nodules. Foam cysts have also been called **inspissated cysts, gel cysts,** and **mucoceles. (B)** Acorn cysts have an echogenic concave rim of **papillary apocrine metaplasia** (PAM) that appears similar to the cap on an acorn. Unlike similar-appearing lipid layers within cysts that have fat-fluid levels, the position of the PAM does not change from the supine **(C)** to the upright **(D)** or left lateral decubitus position. **(E)** Color Doppler ultrasound image shows that, unlike intracystic papillomas or carcinomas, PAM rarely has a demonstrable vascularity.

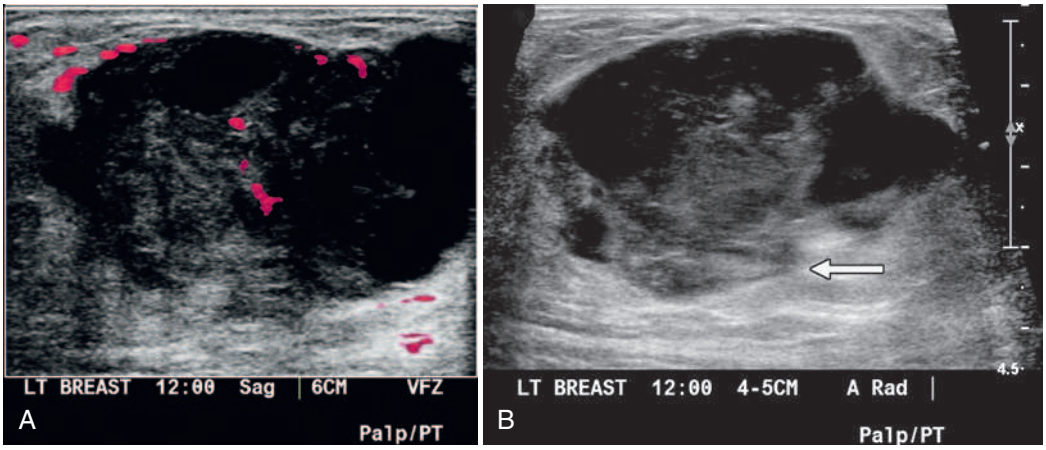

FIG. 21.32 Complex Cystic and Solid Mass. (A) This mass has both solid and cystic components. Color Doppler demonstrates that the thick internal septations are highly vascular, suggesting they represent solid material rather than internal debris, increasing the probability of malignancy. **(B)** Also note the extension of the solid component beyond the margin of the mass *(arrow),* most consistent with a malignant process.

solid or thick fluid, additional nonmalignant differential considerations for a cystic and solid appearing mass include hematoma, fat necrosis, abscess, or galactocele. Given the increased probability for malignancy for complex cystic and solid masses, they should be classified as BI-RADS 4 or BI-RADS 5 lesions and biopsy should be performed. When the mass is sampled, special attention should be paid to the solid component.

Papillary Lesions. Complex cystic and solid masses may involve intracystic or intraductal papillary lesions. Sonography does not distinguish benign from malignant intraductal or intracystic masses as effectively as it does for purely solid nodules because of the direction of invasion. Invasion arising from solid nodules is *outwardly* directed, greatly affecting the shape and the surface characteristics of the lesion. However, invasion arising from intracystic or intraductal lesions is *inwardly* directed, into the fibrovascular stalk of the lesion. As a result, the surface characteristics and shape are not distorted, making it more challenging to use sonographic descriptors to identify an abnormality. Any intracystic or intraductal papillary lesion with solid components should be characterized as BI-RADS 4a or higher and undergo histologic evaluation.

Findings that are suspicious for true intracystic or intraductal papillary lesions include thick isoechoic septations, mural nodules, a Doppler-demonstrable vascular stalk within a thick septation, and clustered complex microcysts. Thick, isoechoic septations are suspicious for **intracystic papilloma** or **intracystic carcinoma** (Fig. 21.33A), whereas thin echogenic septations merely represent **fibrocystic change** and the intact walls between multiple ductules with severe cystic dilation within an individual TDLU (Fig. 21.33B). Most **mural nodules** are caused by PAM, which is part of the benign FCC spectrum, or are pseudonodules caused by tumefactive sludge or lipid layers rather than papillomas or intracystic papillary carcinomas. Suspicious mural nodules demonstrate loss of the thin echogenic outer cyst wall along their points of attachment, extension beyond the circular or oval shape of the cyst into surrounding ducts (Fig. 21.34A), or angular margins at the point of attachment. Mural nodules that are caused by PAM remain confined within the circular or round shape of the cyst in which they lie and do not disrupt the thin, echogenic outer cyst wall (Fig. 21.34B). Regardless, biopsy of all these masses should be performed to ensure there is no malignancy present.

Papillomas and intracystic carcinomas are generally vascular and tend to develop easily demonstrable and prominent vascular stalks (Fig. 21.35A, Video 21.4), whereas mural nodules and thick internal septations caused by florid PAM rarely develop vascular stalks (Fig. 21.35B). Papillomas and intracystic carcinomas frequently undergo hemorrhagic infarction that can obscure vascularity. Most benign papillomas have a single feeding vessel, whereas malignant intracystic papillary lesions tend to incite the formation of multiple feeding vessels.[49] **Clustered microcysts** most frequently merely represent FCC and **apocrine metaplasia**[50] (Fig. 21.36A), but high–nuclear-grade micropapillary DCIS can also appear as clustered microcysts (Fig. 21.36B). The gray-scale appearances of microcysts caused by apocrine metaplasia and micropapillary DCIS can be virtually indistinguishable. However, clustered microcysts caused by micropapillary DCIS are usually vascular on color Doppler sonography, whereas microcysts caused by apocrine metaplasia, like mural nodules caused by apocrine metaplasia, are usually avascular on color Doppler ultrasound assessment (Fig. 21.36C). If even one suspicious finding is present, the cystic lesion should be characterized as BI-RADS 4a or higher and should be evaluated histologically.[45]

Inflammation and Infection. Nonsimple cysts may be caused by inflammation and/or infection. The findings that are suspicious for acute inflammation or infection are (1) uniform isoechoic thickening of the cyst wall, (2) fluid-debris levels (tumefactive sludge or layered pus), and (3) inflammatory hyperemia of cyst wall and surrounding tissues. Usually, all three findings coexist (Fig. 21.37A). Uniform isoechoic thickening is typical of inflammation, not tumor, so this finding does not raise much concern about malignancy. Debris levels can be shown to shift to the dependent portion of complex cysts when the patient is placed

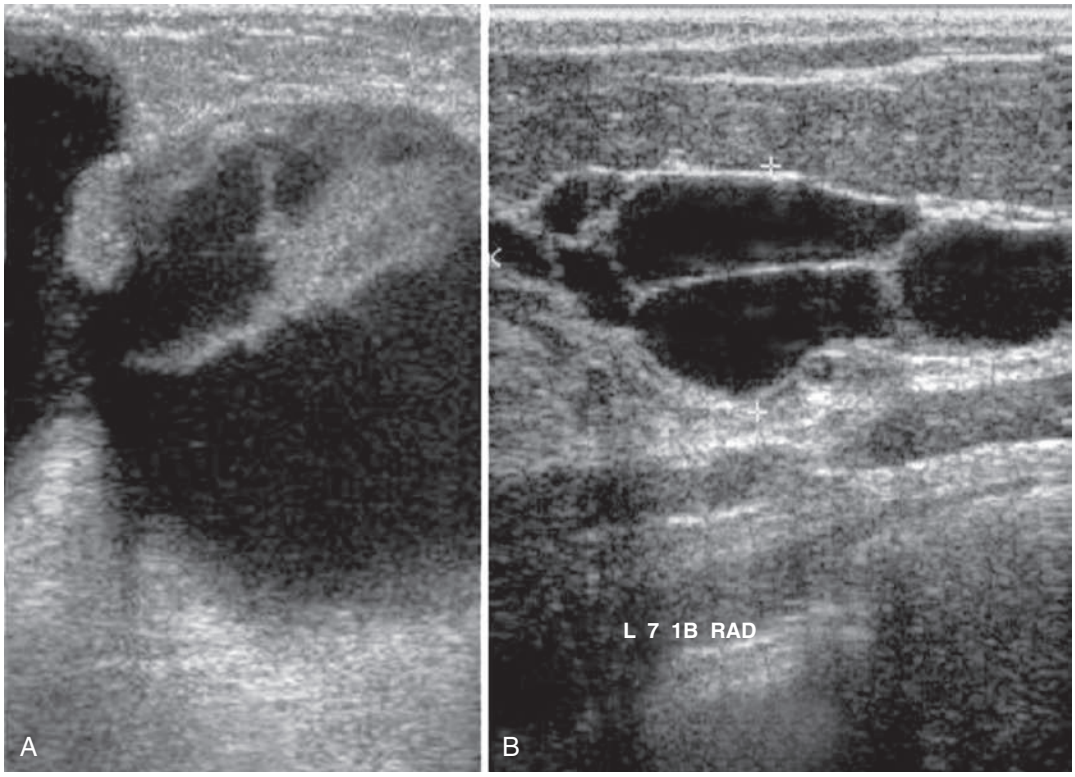

FIG. 21.33 Septations Within Cystic Masses. (A) Thick, isoechoic septations within complex cystic and solid masses are suspicious for intracystic papilloma or intracystic papillary carcinoma. **(B)** Thin, echogenic septations are not suspicious. Such septations represent residual walls of cystically dilated acini within a single terminal ductolobular unit (TDLU) and can be thought of as clusters of simple cysts.

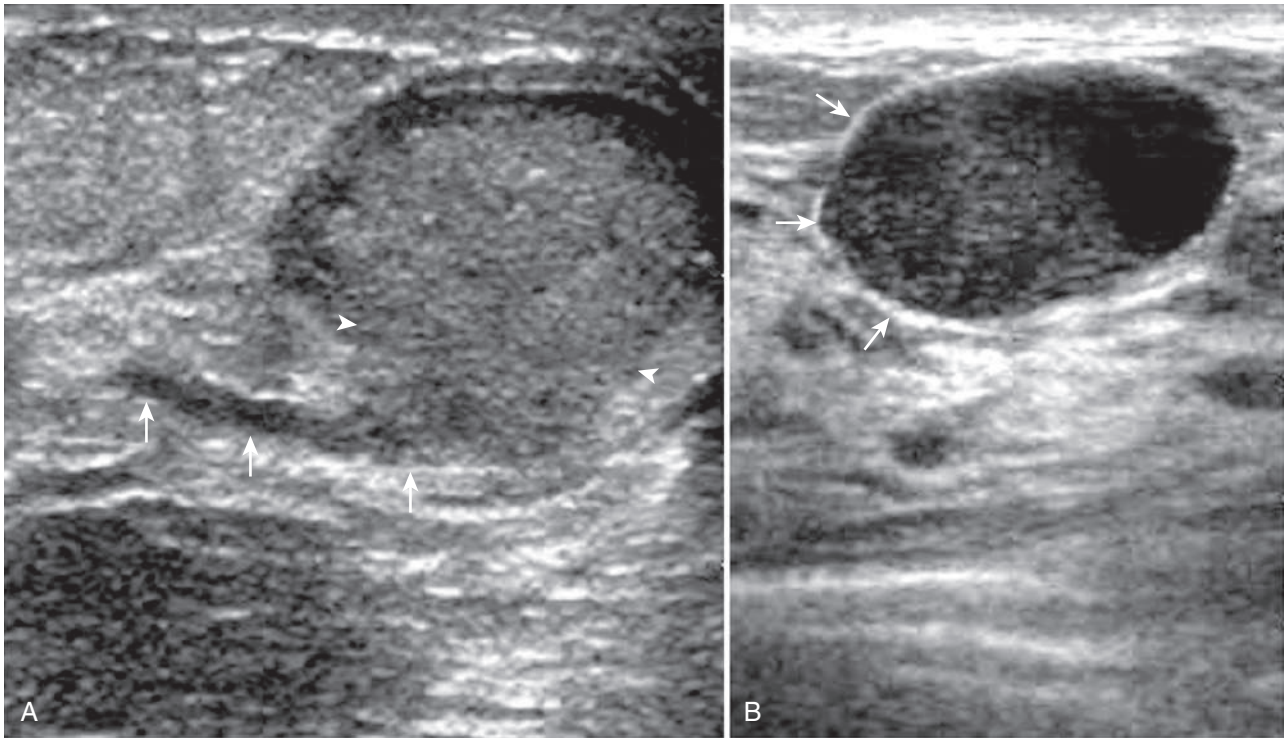

FIG. 21.34 Cysts With Mural Nodules. (A) Mural nodules that protrude beyond a circular or elliptical shape *(arrowheads),* lack a thin echogenic capsule at the point of attachment to the cyst wall, are angular at the point of attachment, or extend into surrounding ducts *(arrows)* are suspicious for intracystic papilloma or intracystic papillary carcinoma. **(B)** Mural nodules that are caused by papillary apocrine metaplasia remain confined within the circular or elliptical shape of the cyst. The thin, echogenic outer wall of the cyst is intact all along the attached surface of the mural nodule *(arrows).*

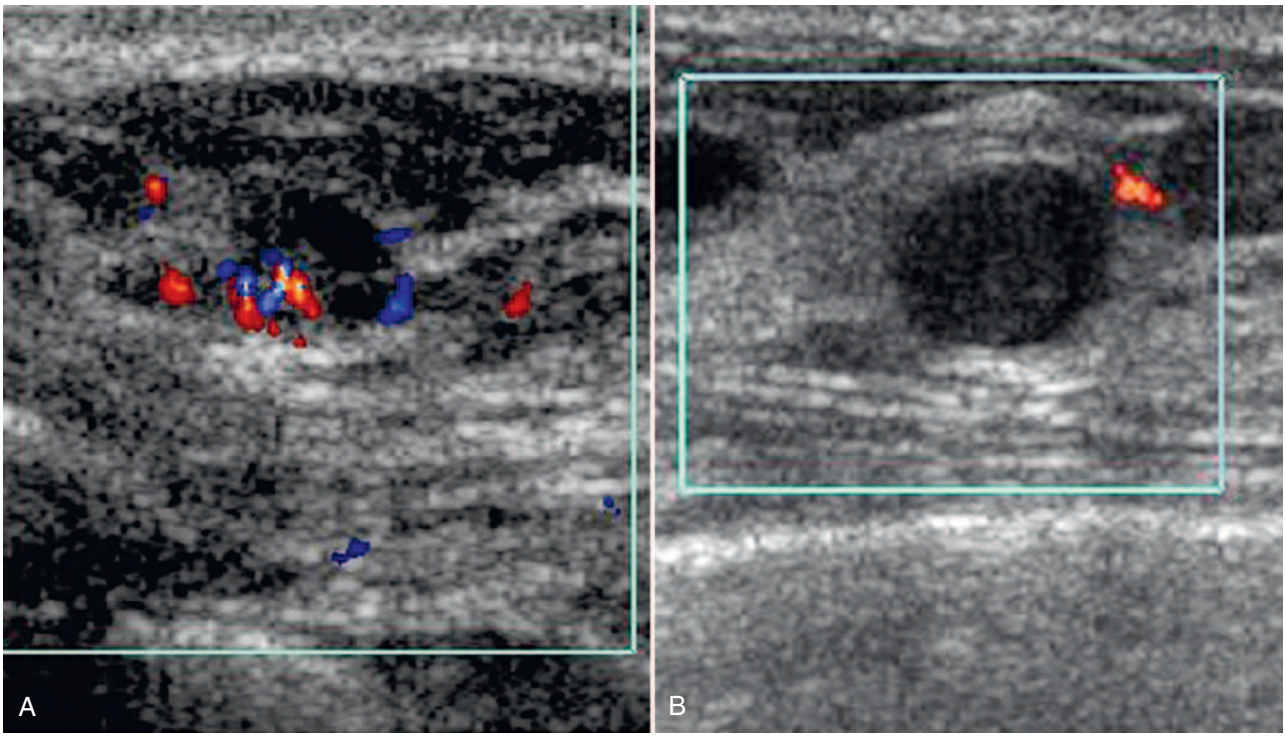

FIG. 21.35 Use of Color Doppler Ultrasound for Mural Nodules. (A) Mural nodules caused by intracystic carcinoma, as in this case, tend to be fed by multiple vessels. **(B)** Mural nodules caused by papillary apocrine metaplasia (PAM) rarely develop a fibrovascular stalk with demonstrable flow on color Doppler ultrasound.

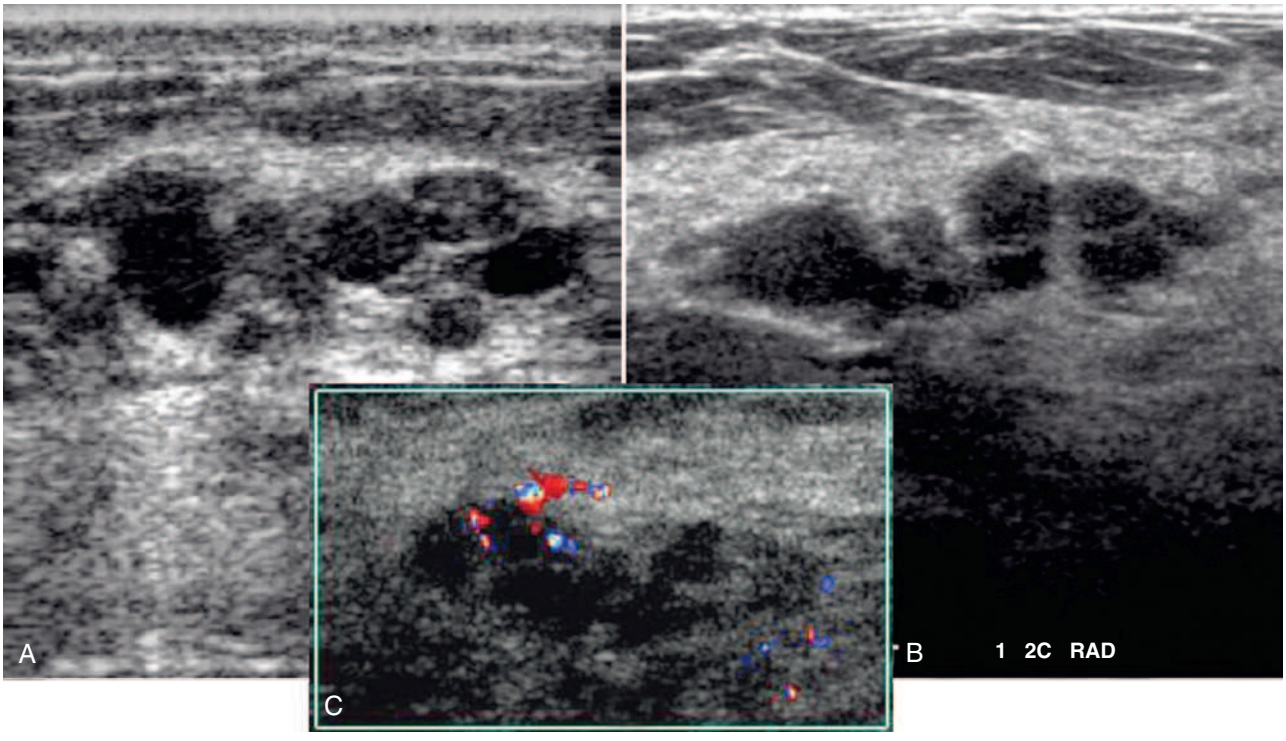

FIG. 21.36 Microcysts. Clustered microcysts can represent **(A)** fibrocystic change, in which the microcysts are caused by papillary apocrine metaplasia (PAM), or **(B)** neoplasm, in which the microcysts represent ducts distended with secretions and micropapillary ductal carcinoma in situ (DCIS). Unfortunately, the gray-scale appearances of fibrocystic change and DCIS may be indistinguishable. **(C)** However, clustered microcysts caused by micropapillary DCIS frequently show internal blood flow on color or power Doppler ultrasound, whereas clustered microcysts caused by PAM, as with mural nodules caused by PAM, rarely have demonstrable internal flow.

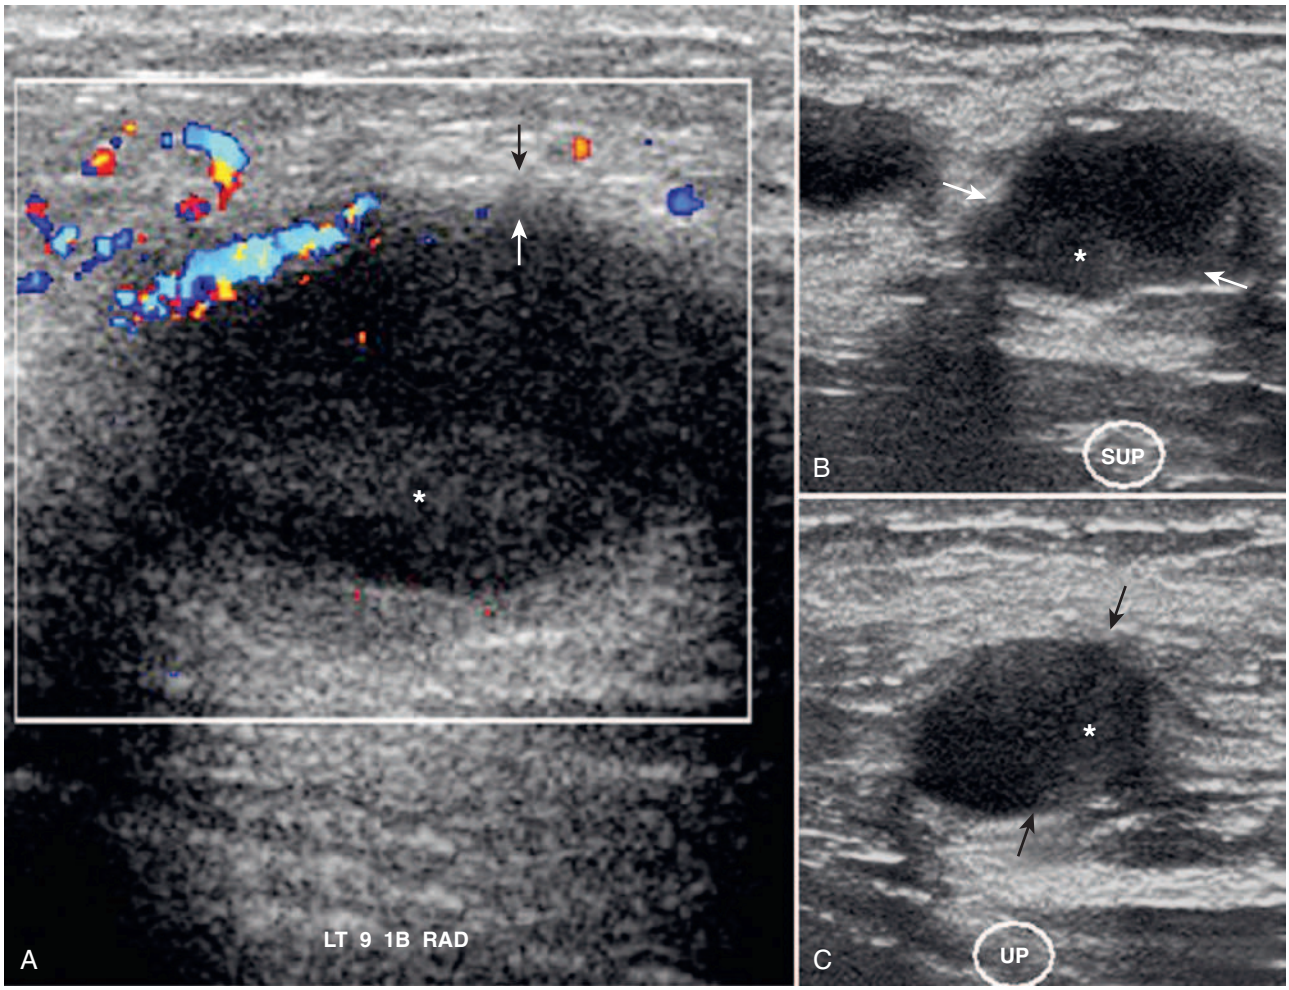

FIG. 21.37 Inflamed or Infected Cyst. (A) Acutely inflamed or infected cysts demonstrate three findings: (1) abnormal uniform isoechoic wall thickening *(between arrows),* (2) dependent debris (*), and (3) hyperemia of the thickened wall. **(B)** Supine and **(C)** upright images show the debris (*), resembling sludge within a gallbladder, shifting to the dependent part of the cyst when the position of the patient is changed from supine to upright or lateral decubitus position. Note the change in the position of the interface between the nondependent fluid and the dependent debris or pus *(arrows).*

in lateral decubitus or upright positions (Fig. 21.37B-C). However, tumefactive sludge may be so viscous that it requires 5 minutes or more to shift to the new dependent position. The hyperemic vessels in the wall of inflamed cysts course in a direction parallel to the cyst wall, in contrast to vessels that feed intracystic malignancies, which tend to course perpendicular to the cyst wall. These findings indicate acute inflammation, which is common in FCC, but do not necessarily indicate infection. Even after aspirating pus under ultrasound guidance, the clinician cannot determine whether the cyst is infected or merely inflamed. This requires Gram stain and culture. Many times, however, the key to differentiating inflammation from infection lies with the clinical examination. Often patients with infection will have tenderness, erythema, and warmth overlying the area of clinical concern.

Uniform wall thickening may also be seen in cysts with fibrotic walls, but in such cases, there is no hyperemia or tenderness of the thickened wall because cysts with fibrotic walls represent the healed phase of acute inflammation. The fluid and debris within acutely inflamed cysts usually can be completely aspirated, but the residually thickened cyst wall will persist. If the cyst was not infected, usually the fluid and debris do not reaccumulate, and the residually thickened wall gradually resolves over a few days. Because the sonographic appearances of acute inflammation are so characteristic and do not raise questions about neoplasm, we usually do not perform cytologic evaluation of the aspirated cyst fluid. Rather, if there is concern for infection, Gram stain and culture are recommended. Often patients will be provided with empiric antibiotic therapy while awaiting culture results.

Solid Masses

Initially, sonographic studies reported substantial overlap between the features of benign and malignant solid nodules that prevented a clear distinction to be made. These studies were performed with older, lower-frequency, lower-resolution equipment and generally assessed only single sonographic findings. Since then, the approach to characterizing solid nodules has substantially improved.

The key to developing a successful algorithm for characterizing solid nodules is having realistic goals. Distinguishing all benign from all malignant solid nodules is challenging, and therefore a more realistic goal is to identify a subpopulation of all solid

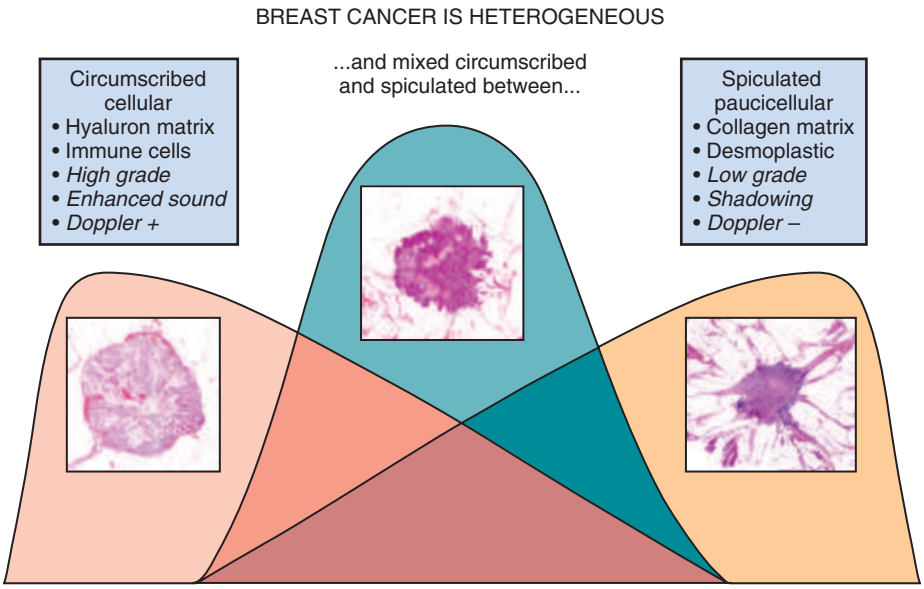

FIG. 21.38 Malignant Masses: Spectrum of Appearances. The appearance of breast cancer spans a spectrum from classic spiculated lesions to circumscribed carcinomas. There are also mixed spiculated and circumscribed lesions in the middle of the spectrum. Sonographic findings for circumscribed and spiculated lesions can be opposite from each other. Only by using multiple findings capable of identifying lesions at both ends of the spectrum can carcinomas be identified with the desired 98% or greater sensitivity.

nodules that is so likely to be benign that the patient can be offered the option of follow-up in addition to the option of biopsy. BI-RADS 3 lesions must have a 2% or lower risk of being malignant.

Before delving into the sonographic appearance of various solid nodules it is important to gain an understanding of what pathologic features contribute to the findings we see on ultrasound. Fig. 21.38 illustrates the **heterogeneity** of breast cancer, which can be thought of as spanning a spectrum from spiculated to circumscribed lesions. Not only is breast cancer heterogeneous from one mass to another, but it also can be heterogeneous within an individual mass, and thus there is a peak of mixed circumscribed-spiculated lesions in the center of the spectrum. These features should be considered when classifying a mass as probably benign (BI-RADS 3) or classifying a mass as suspicious and recommending a biopsy.

Spiculated and circumscribed cancers differ greatly. The histologic and gross morphologic features of the spiculated and circumscribed ends of the malignant spectrum differ in cellularity, constituents of the extracellular matrix, host reaction to the tumor, and water content. Spiculated or stellate malignant lesions tend to be low to intermediate in histologic grade, whereas circumscribed lesions tend to be either special-type tumors (e.g., colloid or medullary carcinoma) or high-grade invasive ductal carcinoma. The classic **spiculated breast carcinoma** is composed of tumor cells, collagenous extracellular matrix, and desmoplastic host response to the lesion. The usually low-grade spiculated carcinomas are paucicellular—a small percentage of the total volume of the lesion is composed of tumor cells. The paucicellular nature, collagenous matrix, and desmoplastic host response of spiculated malignant lesions makes them relatively water poor, so they often cause acoustic shadowing. **Circumscribed carcinomas,** usually high-grade invasive ductal carcinomas, on the other hand, are highly cellular. They have more hyaluronic acid in the matrix and manifest a primarily lymphoplasmacytic immune response. The high cellularity, hydrophilic hyaluronic acid matrix, and lymphoplasmacytic response in circumscribed lesions makes them water rich.[45] Thus circumscribed lesions usually manifest increased sound transmission.

Because breast tumors have varying histology, specific sonographic features do not universally apply to all malignancies. For example, **acoustic shadowing** can help clinicians detect lesions at the spiculated end of the spectrum and some of the mixed lesions in the middle of the spectrum, but it is much less effective at the circumscribed end of the spectrum. On the other hand, **Doppler** ultrasound is very helpful for circumscribed carcinomas because of their high tumor cellularity and associated abundant angiogenesis factors. In addition, the **lymphoplasmacytic immune-inflammatory response of circumscribed carcinomas** causes vasodilation of surrounding vessels. Doppler is not as helpful for spiculated lesions that have relatively few tumor cells that elaborate angiogenesis factors. These masses also have a collagen matrix and desmoplasia that require little blood flow. As a result, spiculated lesions often do not have perceptibly increased flow compared with benign lesions or normal tissue. The heterogeneity of breast cancer therefore requires that multiple different sonographic features be used to characterize masses to detect cancer with adequate sensitivity.

The algorithm that we use to evaluate lesions must account for internal heterogeneity by assessing the shape, orientation, margin, echo pattern and posterior features of the lesion for suspicious findings completely in two orthogonal planes (preferably radial and antiradial). In lesions that have a mixture of suspicious and nonsuspicious findings, it is important to focus on the most suspicious findings.

TABLE 21.2 Comparison of Morphologic and Histopathologic Features of Suspicious Sonographic Findings

Morphologic Features	Histopathologic Features
SURFACE CHARACTERISTICS AND MARGINS	**"HARD" FINDINGS**
Spiculation	Spiculation
Angular margins	Echogenic rim
Indistinct margin	Angular margins
Microlobulation	Acoustic shadowing
SHAPES	**MIXED FINDINGS**
Irregular	Hypoechogenicity
Not parallel	Not parallel
Duct extension	
INTERNAL CHARACTERISTICS	**"SOFT" FINDINGS**
Calcifications	Microlobulation
Acoustic shadowing	Duct extension
Hypoechogenicity	Microcalcifications

FIG. 21.39 Indistinct Margins in Invasive Ductal Carcinoma, Grade 3. An indistinct margin refers to the inability to delineate the margin of the breast mass. This feature, in combination with other suspicious features including hypoechoic and not parallel appearance, make this mass highly suspicious for malignancy.

Suspicious Findings

The suspicious sonographic features can be classified into subgroups by morphologic features or by histopathologic features (Table 21.2).

Table 21.2 shows the suspicious findings listed by their morphologic features: **shape** (irregular), **margins** (indistinct, spiculation, angular margins, and microlobulations); **orientation** (termed "not parallel" in ACR BI-RADS ultrasound lexicon[17]); duct changes; and **internal characteristics** (acoustic shadowing, hypoechoic echotexture, and calcifications). Histopathologic categories include **"hard" findings** that indicate the presence of invasion of surrounding tissues (angular margins, spiculation, thick echogenic rim, and acoustic shadowing); **"soft" findings** that indicate the presence of DCIS components of tumor (microlobulations, calcifications, and duct changes); and **mixed findings** that can be seen in association with either invasive or DCIS components of tumor (hypoechoic echotexture and not parallel orientation).

Soft suspicious findings help in three ways. First, soft findings can help clinicians detect pure DCIS, which rarely develops hard suspicious findings, and the most common breast carcinoma usually contains DCIS components. Second, including soft findings can help to detect and characterize the circumscribed invasive duct carcinomas that contain both invasive and DCIS components. In such cases, the new periphery of the lesion is where the DCIS components are located. Thus the surface characteristics and shapes of the lesion are created by the DCIS elements of the lesion, not by the centrally located invasive components. Finally, the use of soft findings can aid in accurately staging malignant breast lesions on sonography, because the DCIS components of the lesion that extend into the surrounding tissues for variable distances can be identified only by soft findings. Although soft findings do increase the sensitivity of the sonographic algorithm for detecting malignant disease, they also increase the false-positive rate, especially for lesions that contain only soft findings. Lesions that demonstrate only soft findings are most likely to be benign and include papillomas, fibroadenomas, and FCC. However, given that the risk of malignancy for solid masses that demonstrate only soft suspicious findings is greater than 2%, it is still important that such lesions be characterized as mildly suspicious (BI-RADS 4a) and that biopsy be performed.

Indistinct Margins

"Indistinct margins" refers to the inability to distinguish any portion of the margin of the mass from the surrounding tissue (Fig. 21.39). This also includes masses that have an echogenic rim, because the surrounding echogenic area prevents clear demarcation of the mass' margins.

Spiculation or Thick Echogenic Rim

Spiculation is a hard sonographic finding that corresponds to invasion of surrounding tissues and a desmoplastic host response to the lesion. Spiculation is a subcategory of the ACR BI-RADS category "Margin–Not Circumscribed"[17] and is a mammographic finding that can be directly applied to sonography (Fig. 21.40A). When the spiculations are coarse, they manifest as alternating hypoechoic and hyperechoic lines that radiate perpendicular to the surface of the nodule; the **hypoechoic** components represent either fingers of invasive tumor or DCIS components of tumor extending into the surrounding tissues, and the **hyperechoic** elements represent the interfaces between the spicules and surrounding breast tissues (Fig. 21.40B). In most cases, however, spicules are fine and manifest with only a single echogenicity.

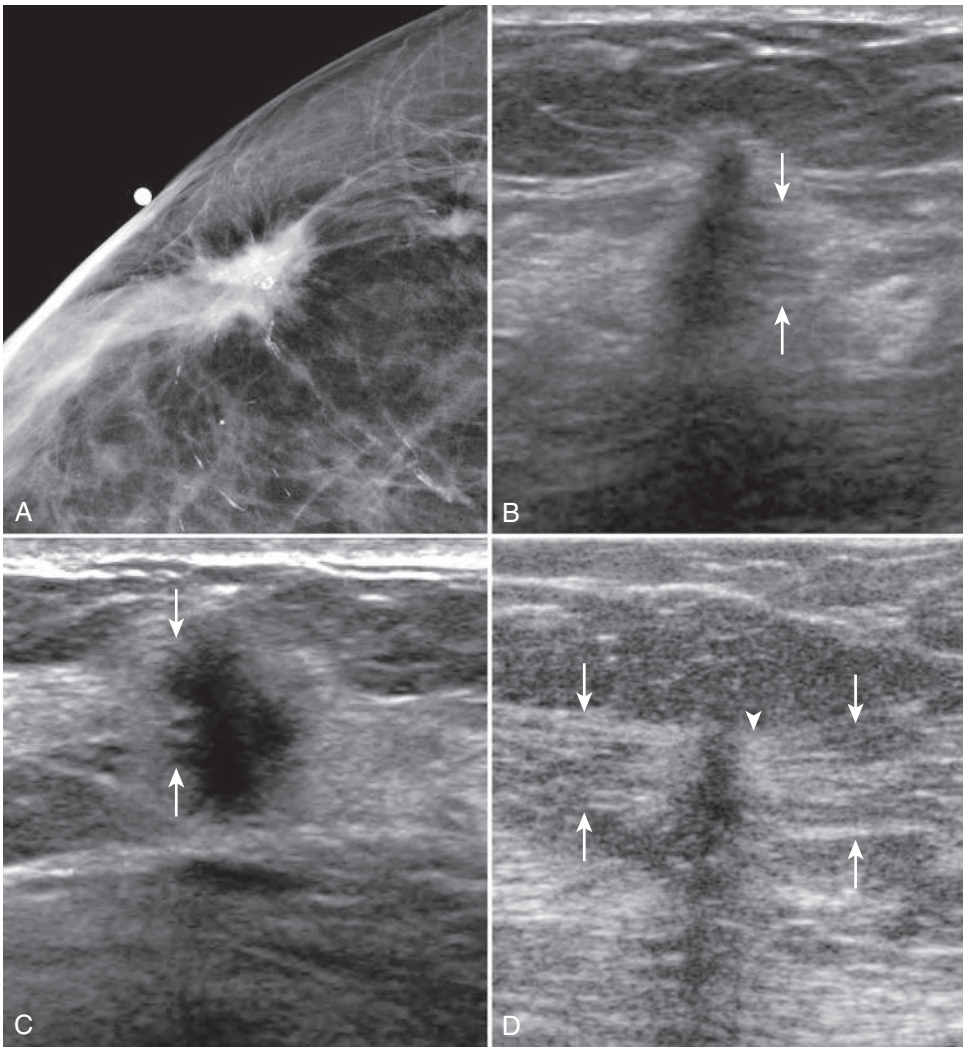

FIG. 21.40 Spiculation. (A) Spiculation is a "hard" mammographic finding that indicates invasion. **(B)** Coarse spiculations *(arrows)* appear as alternating hypoechoic and hyperechoic lines radiating from the nodule on ultrasound. The hypoechoic parts represent fingers of invasive tumor or ductal carcinoma in situ, and the hyperechoic lines represent the interface between the tumor and surrounding tissue. Most spicules are fine rather than coarse and appear with only a single echogenicity opposite that from the background tissues. **(C)** The spiculations extending from lesions surrounded by hyperechoic fibrous tissues are hypoechoic *(arrows).* **(D)** Fine spicules in lesions surrounded by fat appear hyperechoic *(arrows).* Note that spiculations are most prominent within the coronal plane along the sides of the nodule.

They appear to be either hyperechoic or hypoechoic depending on echogenicity of the tissue within which the lesion lies. The spicules in malignant nodules that are surrounded by hyperechoic fibrous tissues appear hypoechoic (Fig. 21.40C), whereas spicules in malignant nodules that are surrounded by fat appear hyperechoic (Fig. 21.40D).

The thick, echogenic rim that surrounds some malignant solid nodules represents spiculations that are too small to demonstrate sonographically. For this reason, either frank spiculations or the presence of a thick, echogenic rim should be considered as spiculations, which approximately doubles the sensitivity of spiculation for malignant nodules, from 36% to 70%. The classic thick echogenic rim often appears thicker along the edges of the nodule than on its anterior and posterior surfaces (Fig. 21.41). The presence of an echogenic rim can be used in conjunction with the BI-RADS descriptor "indistinct" when referring to margins.

Sonographic imaging in three dimensions is very helpful at demonstrating spiculations. Most spiculations are oriented in the coronal plane, so the reconstructed coronal plane is especially helpful. Thick, echogenic rims in standard planes can often be resolved as frank spiculations in the coronal plane. This is true for hand-held and automated breast scanners (Figs. 21.42 and 21.43).

Angular Margins

Angular margins are a subcategory of the ACR BI-RADS category "Margin–Not Circumscribed."[17] Angular margin represents a hard sonographic finding indicative of invasion. The angles of the lesion margins can be acute, right angle, or obtuse. Angles on the surface of the mass occur in regions of low resistance to invasion. In lesions surrounded by fat, angulations can occur on any surface of the nodule (Fig. 21.44A). In fibrous-surrounded lesions, angular margins tend to occur on the edges of the lesion,

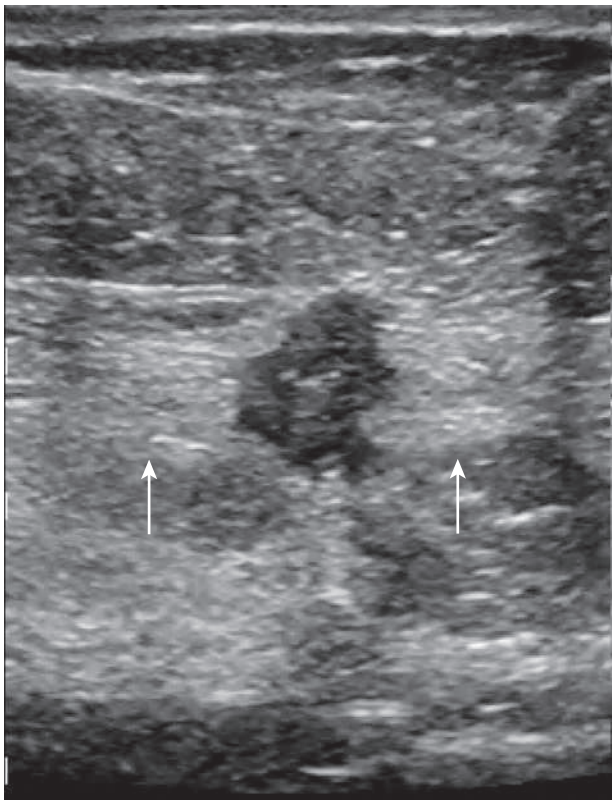

FIG. 21.41 Echogenic Rim With Hyperechoic Spicules. The thick, poorly defined echogenic rim that can be seen around some invasive malignant lesions surrounded by fat represents hyperechoic spicules too small to be resolved individually. The rim is more often seen and is thicker along the sides of the nodule within the coronal plane *(arrows)* because spicules are more common in the coronal plane and because the spicules that lie within the coronal plane are perpendicular to the ultrasound beam, where they make strong specular reflectors.

within loose periductal stromal tissues, and between tissue planes within the fibrous tissue (Fig. 21.44B-C). A single angle of any type on the surface of the lesion should be considered suspicious. **The presence of angular margins has the greatest individual sensitivity and overall accuracy of any of the features.**[45]

Microlobulations

Microlobulations are 1-mm to 2-mm lobulations that vary in number and distribution along the surface and within the substance of a mass. Microlobulations are a subcategory of the ACR BI-RADS category "Margin–Not Circumscribed."[17] They may occur over only a small percentage of the surface of a nodule. Microlobulation is a mixed finding that can be seen with both invasive and DCIS components of tumor, but more often represents *in situ* components of tumor. When microlobulations are angular and are associated with a thick echogenic rim, they usually represent fingers of invasive carcinoma[45] (Fig. 21.45A). When the microlobulations are rounded and associated with a thin echogenic capsule, they usually represent DCIS components of tumors. DCIS components can create microlobulations in two ways: involved lobules (Fig. 21.45B), or ductules or ducts that are distended with tumor and necrosis (Fig. 21.45C-D).

Not Parallel (Not Taller-Than-Wide) Orientation

Lesions that are larger in the AP dimension than in any horizontal dimension are considered not parallel and are suspicious for malignancy. Round masses are also viewed as not parallel in their orientation. Not parallel orientation is unique to sonography and is not seen on mammography. It is a subcategory of the ACR BI-RADS category "Orientation."[17] This is a mixed finding that can be seen with both invasive and DCIS lesions (Fig. 21.46). This orientation is primarily a feature of small, solid malignant

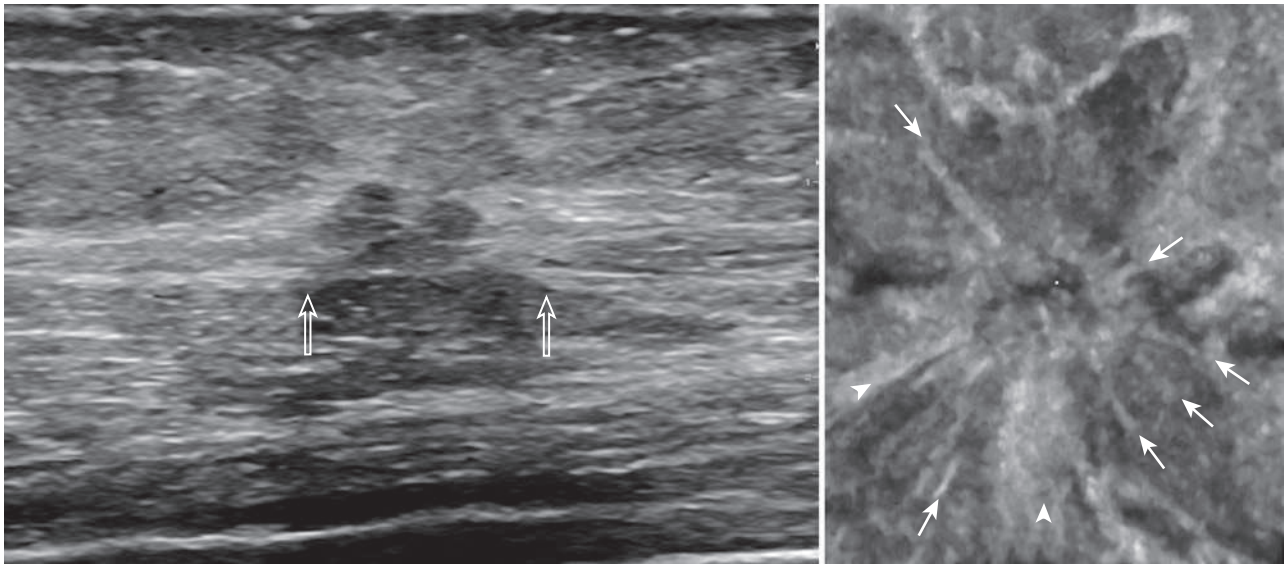

FIG. 21.42 Three-Dimensional or Volume Imaging With a Hand-Held Transducer. The coronal reconstructed plane can be especially useful in assessing for spiculations. What appears to be a poorly defined, thick, echogenic rim in radial or antiradial planes *(left, arrows),* can often be resolved as individual hyperechoic spicules in the reconstructed coronal plane *(right, arrows).* The coronal plane can also better demonstrate other architectural distortions, such as **thickened Cooper ligaments** *(right, arrowheads).*

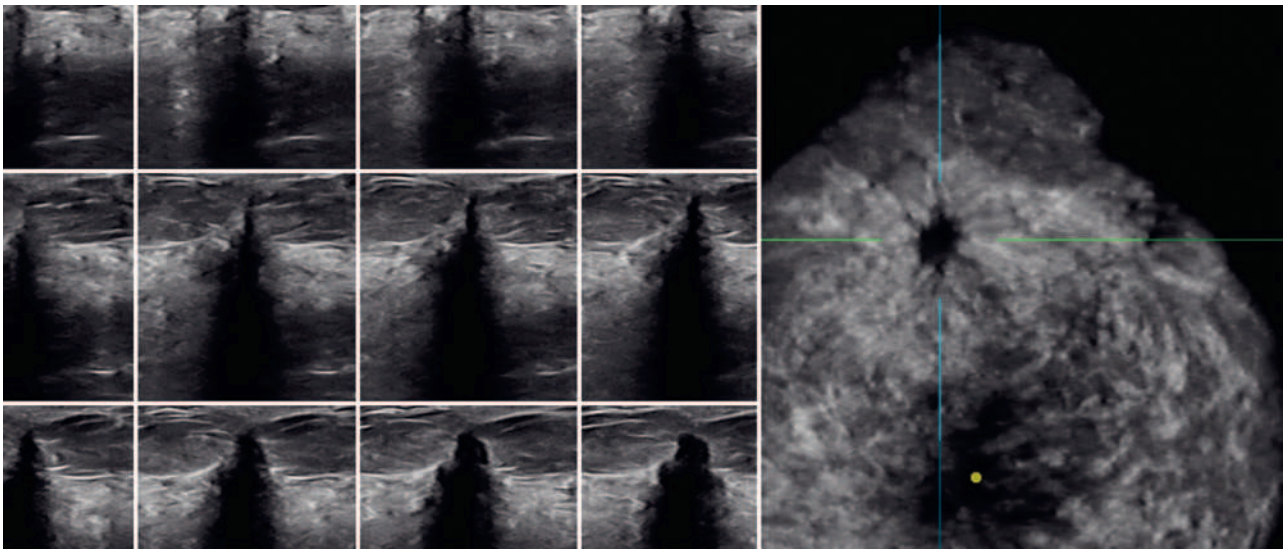

FIG. 21.43 Three-Dimensional or Volume Imaging With Automated Breast Scanner. Spiculations are better demonstrated on the reconstructed coronal plane *(right)* than on the serial native (original) plane images.

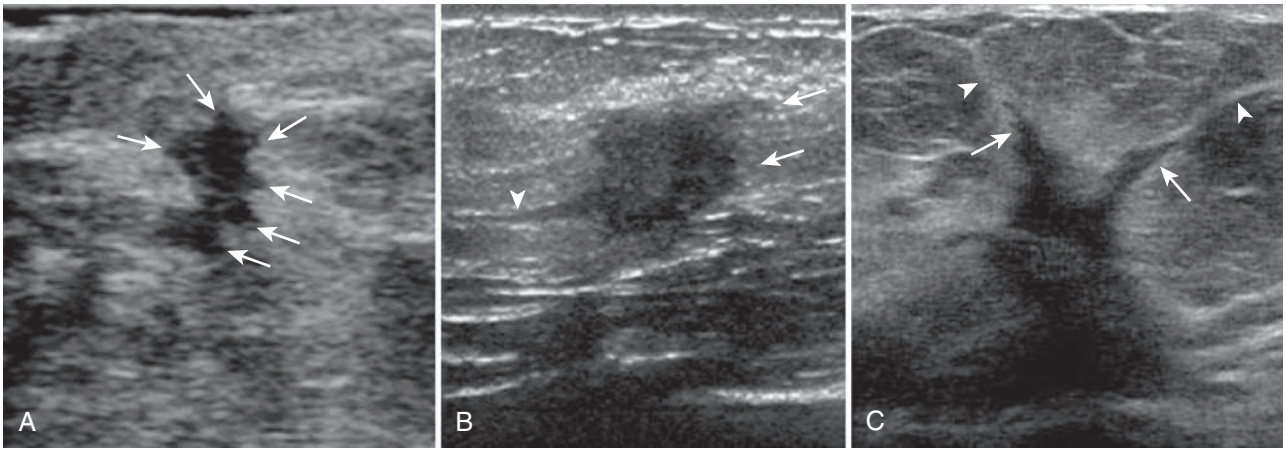

FIG. 21.44 Angular Margins Represent Invasion of Carcinoma Into Low-Resistance Pathways. (A) Fat offers little resistance to invasion, so malignant nodules surrounded by fat can develop angles along any surface *(arrows)*. **(B)** In lesions surrounded by hyperechoic fibrous tissues, paths of low resistance are along the periductal tissues *(arrowhead)* and horizontally along the tissue planes within the fibrous tissue *(arrows)*. **(C)** Following Cooper ligaments *(arrowheads)* down to their base, where they intersect the surface of the nodule, is the best way to detect angles *(arrows)* on the surface of malignant solid nodules.

nodules that have a volume of 1 cc or less. As lesions enlarge, they tend to become parallel (previously termed "wider-than-tall"). The best of several explanations for this finding is that the orientation of small carcinomas reflects the shape of the TDLUs within which the carcinoma arose. Most TDLUs lie anteriorly and are oriented in a not parallel axis. As malignant lesions expand into the lobar ductal system, which is oriented horizontally within the breast, they tend rapidly to become parallel (Fig. 21.47). Given that some carcinomas can have parallel orientation, orientation alone should not be the distinguishing feature between benign and malignant.

Duct Extension

Duct extension is a "soft" shape finding that correlates with the presence of DCIS components of tumor. Duct extension is a part of the ACR BI-RADS subcategory "Associated Features–Duct Changes."[17] Other changes that are part of this subcategory include ductal dilation, irregularities in caliber and/or arborizaton, and the presence of an intraductal mass, thrombus, or detritus. Duct extension correlates with mammographic calcification patterns that have been applied to components of solid nodules. Duct extension can best be demonstrated when the scan plane is oriented parallel to the long axis of the mammary ducts in the region of the mass. Duct extension usually manifests as a single projection of solid growth toward the nipple from the main mass (Fig. 21.48). Additional projections of the solid mass into multiple small ducts peripherally can also occur. Solid masses that have long duct extensions tend to have extensive intraductal DCIS components that increase the likelihood of local recurrence.

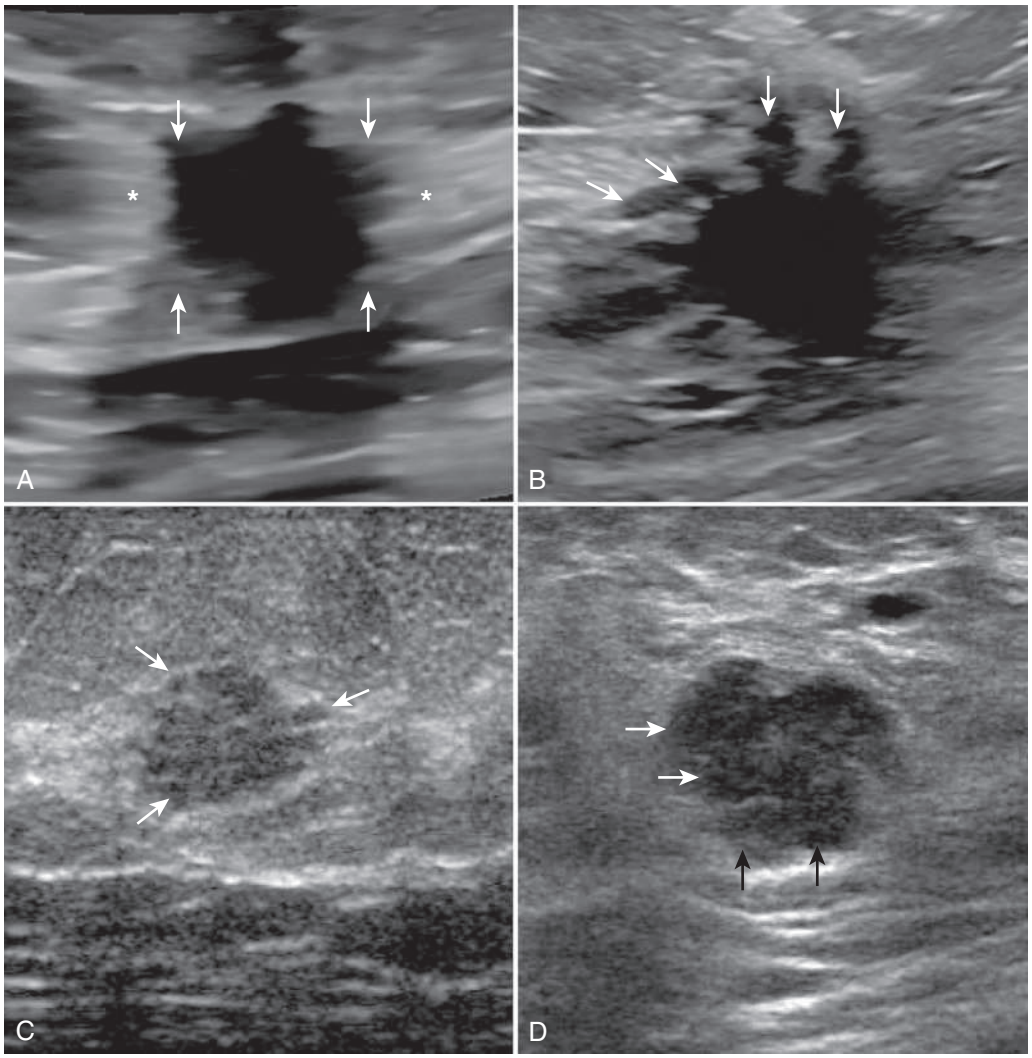

FIG. 21.45 Microlobulations. These can represent either angles of invasive tumor or ductal carcinoma in situ (DCIS) components of the lesion. **(A)** When microlobulations are pointed or angular *(arrows)* and associated with spiculations or thick, echogenic rim (*), they represent fingers of invasive tumor. **(B)** When microlobulations appear as small "tennis rackets" *(arrows)* projecting from the surface of the nodule, they represent surrounding lobules distended with DCIS or cancerous lobules. Microlobulations that are round or oval with thin, echogenic capsules represent tumor-distended ducts. The thin capsule represents the intact duct wall. **(C)** Small microlobulations *(arrows)* correspond to minimally distended ducts that are filled with low–nuclear-grade DCIS. **(D)** Large microlobulations *(arrows)* correspond to grossly distended ducts that contain high–nuclear-grade DCIS.

The presence of duct extension is not a specific sign of malignancy, but rather suggests an intraductal growth pattern. Benign intraductal lesions such as papillomas and chronic periductal mastitis and fibrosis can also demonstrate duct extension. Overall, it is important to recognize duct extension for two reasons: (1) to minimize false-negative characterization of pure DCIS and (2) to identify extensive intraductal components of tumor.

Acoustic Shadowing

Acoustic shadowing is a subcategory of the ACR BI-RADS category "Posterior Features."[17] Acoustic shadowing is a hard suspicious internal characteristic finding that suggests the presence of invasive malignancy. Acoustic shadowing tends to occur in solid nodules that lie on the spiculated end of the malignant spectrum and represent about one-third of all solid malignant nodules. The desmoplastic components of the tumor substance and spiculations cause the shadowing (Fig. 21.49). Because breast carcinomas can be internally heterogeneous, only part of a solid malignant nodule might give rise to acoustic shadowing. Other parts of the lesion might be associated with **normal** or **enhanced sound transmission.** High-grade invasive ductal carcinomas, the most common circumscribed malignant nodules, do not usually cause shadowing. In fact, they most often have associated enhanced sound transmission (Fig. 21.50A). Even pure DCIS that is high nuclear grade may be associated with enhanced through transmission. Many intermediate-grade lesions demonstrate normal sound transmission (Fig. 21.50B). Special-type tumors

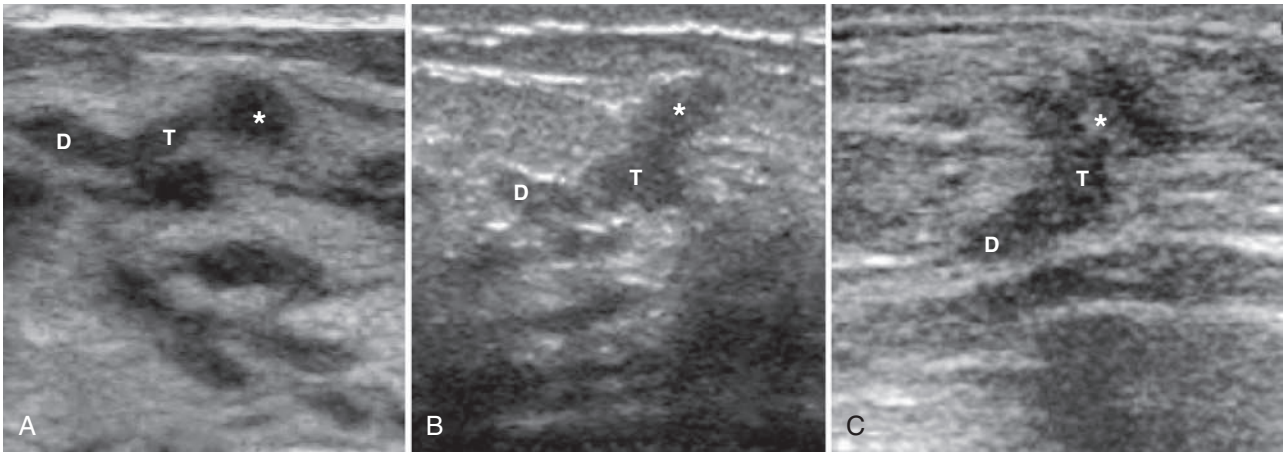

FIG. 21.46 Terminal Ductolobular Unit (TDLU) Carcinoma. Taller-than-wide orientation corresponds to a small, in situ or invasive carcinoma involving a single TDLU. **(A)** Normal lobule (*), its extralobular terminal duct *(T),* and part of the segmental duct *(D).* The TDLU orientation is taller than wide. **(B)** Small, intermediate–nuclear-grade ductal carcinoma in situ (DCIS) grossly distends the lobule and its extralobular terminal duct, remaining oriented in the taller-than-wide axis of the lobule from which it arose. **(C)** Small, low–nuclear-grade invasive ductal carcinoma more grossly distends and distorts the lobule and extralobular terminal duct from which it arose, but remains oriented taller than wide. Note the angles that indicate invasion into the surrounding tissues.

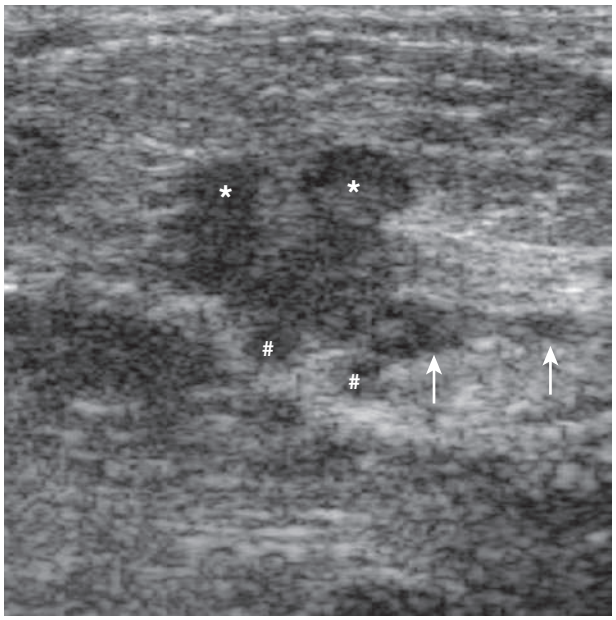

FIG. 21.47 Ductal Carcinoma in Situ (DCIS). Growth of DCIS changes shape to parallel. As malignant solid nodules enlarge, DCIS components grow down the lobar duct toward the nipple and develop cancerized adjacent lobules, changing from not parallel to parallel shape. Tumor-distended anterior lobules (*); tumor-distended but smaller posterior lobules (#); and tumor-distended lobar duct *(arrows)* are shown.

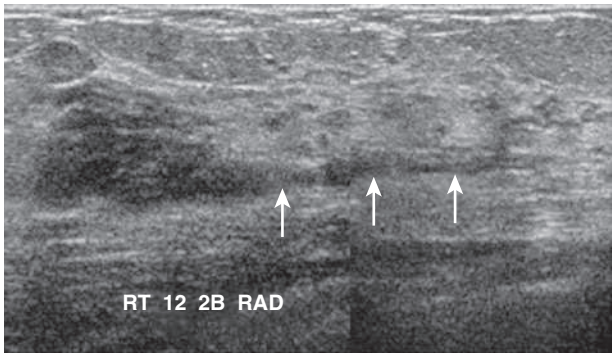

FIG. 21.48 Duct Extension of Ductal Carcinoma in Situ (DCIS). DCIS growing within the lobar duct toward nipple. Most invasive duct carcinomas contain DCIS components. In some cases the DCIS growing away from the tumor toward the nipple within the lobar duct may grossly distend the duct enough to allow recognition of duct extension sonographically *(arrows).* If such duct extensions are not recognized on ultrasound, they might be transected at surgery, leading to positive margins, local recurrence, and the need for reresection.

and invasive lobular carcinomas also tend to cause either acoustic shadowing or enhanced sound transmission.

The differential diagnosis for malignant masses that cause acoustic shadowing, in order of frequency, consists of (1) low-grade to intermediate-grade invasive ductal carcinoma, (2) invasive lobular carcinoma, (3) tubulolobular carcinoma, and (4) tubular carcinoma. The differential diagnosis for malignant masses associated with enhanced sound transmission includes high-grade malignancies, colloid carcinoma, medullary carcinoma, and invasive papillary carcinoma.[51-55]

Hypoechogenicity

Hypoechogenicity is a subcategory of the ACR BI-RADS category "Echo Pattern."[17] Marked hypoechogenicity of the substance of a solid mass (compared with fat) is a mixed suspicious internal characteristic sonographic feature of malignancy. It can be the result of several different tumor characteristics. High-grade invasive ductal carcinomas that are highly cellular and contain abundant hyaluronic acid in the extracellular matrix may appear hypoechoic because of the high water content. Pure DCIS may appear hypoechoic because of either necrosis or secretions within the lumina of tumor-distended ducts. Low-grade invasive ductal carcinomas can appear "markedly hypoechoic" because of acoustic

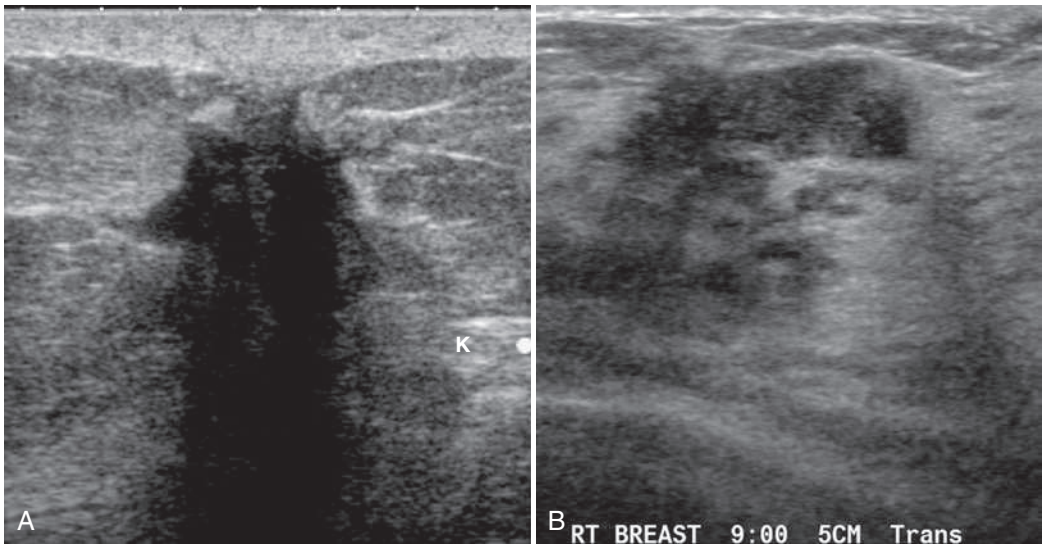

FIG. 21.49 Cancer Causing Acoustic Shadowing. Acoustic shadowing is a "hard" finding that suggests the presence of desmoplastic invasive tumor. Any acoustic shadowing should be considered suspicious—whether **(A)** complete, or **(B)** partial. Tumors that are becoming progressively more dedifferentiated and that are polyclonal or that contain mixtures of low-grade and intermediate-grade or high-grade components tend to create partial shadows.

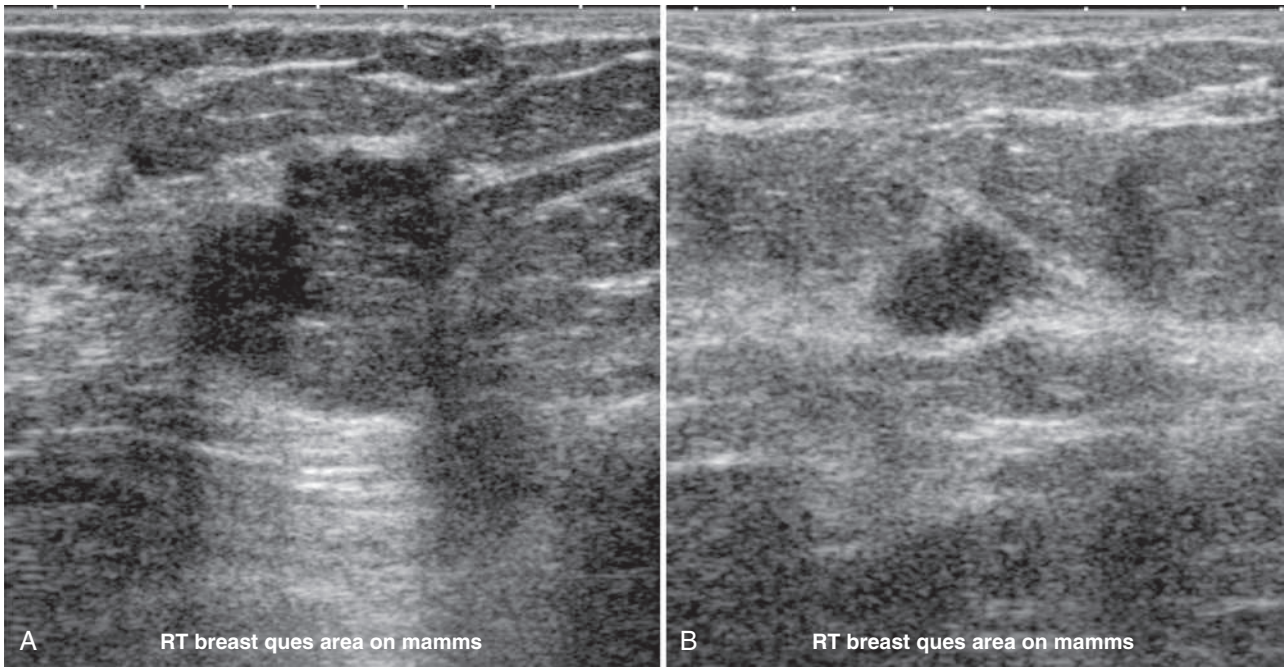

FIG. 21.50 Variable Sound Transmission Deep to Carcinomas. (A) High-grade invasive ductal carcinomas tend to be associated with enhanced sound transmission. **(B)** Intermediate-grade invasive duct carcinomas tend to be associated with normal or mixed sound transmission.

shadowing (Fig. 21.51). Digitally encoded harmonic ultrasound can make solid masses appear markedly hypoechoic compared with the surrounding fat (Fig. 21.52).

Calcifications

Calcifications within solid nodules are soft suspicious sonographic findings that suggest the presence of DCIS components. In the ACR BI-RADS ultrasound lexicon, calcifications are classified according to their location as either within a mass, outside a mass, or intraductal.[17] Calcifications can develop within necrotic debris within the center of the lumen of DCIS-distended ductules or ducts. Because microlobulations and duct extension represent DCIS components of the tumor distending ducts, malignant calcifications can often be found within the other soft findings that represent DCIS. Thus many malignant calcifications can be found within the center of microlobulations or duct extensions (Fig. 21.53).

The calcifications that are shown on sonography are smaller than the beam width and therefore are subject to volume averaging. They are usually in the 200- to 500-micron size range.

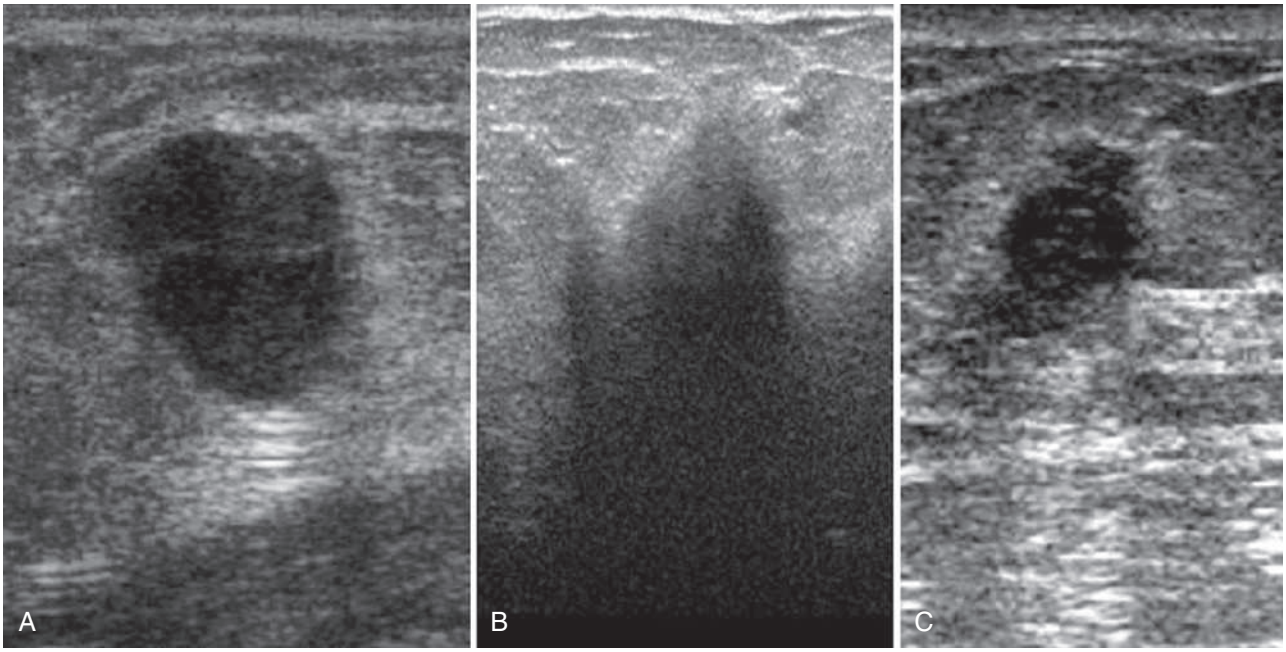

FIG. 21.51 Hypoechoic Carcinomas. Malignant nodules are often markedly hypoechoic in comparison to fat. Hypoechogenicity can be the result of **(A)** high cellularity and high content of hyaluronic acid within the extracellular matrix, or **(B)** intense acoustic shadowing associated with invasive carcinomas. **(C)** Necrosis within the lumen of tumor-containing ductules can cause marked hypoechogenicity in lesions composed of pure ductal carcinoma in situ (DCIS).

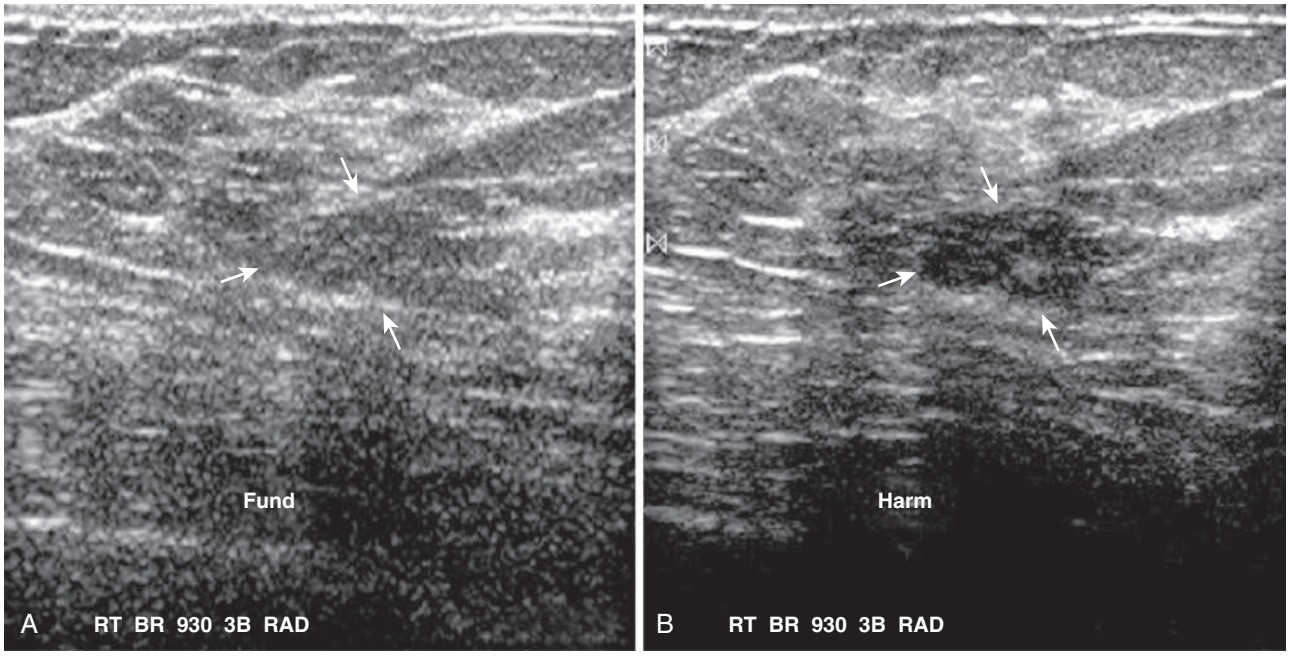

FIG. 21.52 Harmonic Imaging Improves Mass Visibility. (A) Nodules that are isoechoic with surrounding tissues and difficult to identify with fundamental imaging *(arrows)* often appear **(B)** markedly hypoechoic and more conspicuous *(arrows)* when viewed with harmonics.

Calcifications that are narrower than the beam width do not cast acoustic shadows, appear larger than their true size, and appear less echogenic than their true echogenicity. Most **benign calcifications** lie within a fairly echogenic background, so that when volume is averaged with the surrounding echogenic tissues, they are no longer bright enough to be identified sonographically. **Malignant calcifications** lie within rather homogeneously hypoechoic tumor substance and remain visible even though they are subject to volume averaging with surrounding tissues. Thus sonography can generally demonstrate a higher percentage of malignant than benign microcalcifications.

Associated Features

Other findings that can be associated with malignancy but are less specific than the suspicious features listed earlier include architectural distortion, skin changes, edema, and elasticity. These

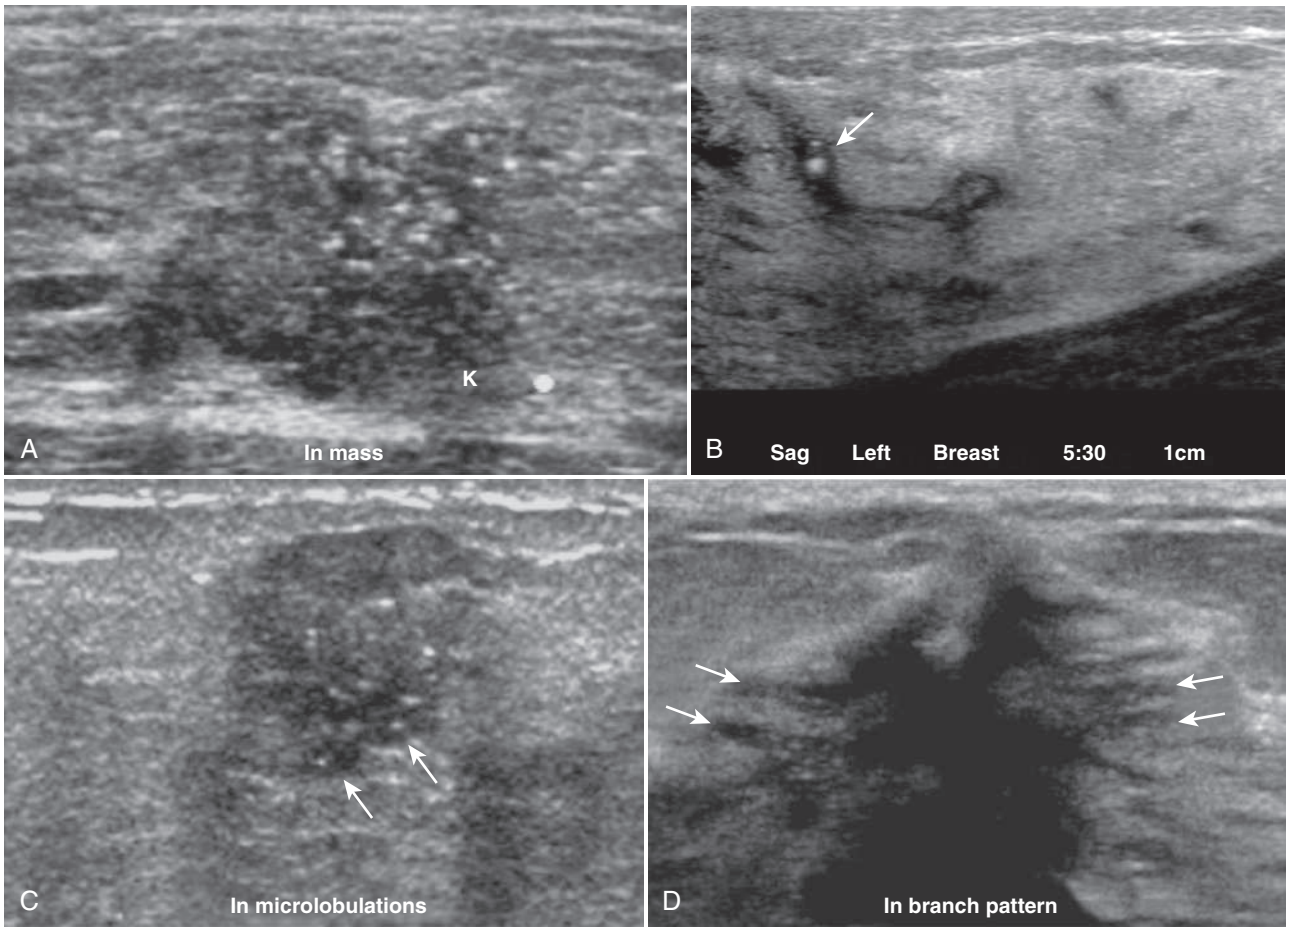

FIG. 21.53 Microcalcifications. These appear as bright echoes too small to create acoustic shadows. Microcalcifications are "soft" findings that suggest the presence of ductal carcinoma in situ (DCIS) elements. **(A)** Microcalcifications can occur amorphously within a mass. **(B)** However, most malignant breast calcifications occur within the necrotic debris in the center of the lumen of tumor-distended ducts. **(C)** Calcifications can also be found within microlobulations *(arrows)* or **(D)** within branch patterns *(arrows)*.

terms are found under the category "Associated Features" in the ACR BI-RADS lexicon.[17]

Architectural distortion associated with malignancy is caused by the effect of a mass on the surrounding tissues. These can manifest as compression of the surrounding tissues by the mass, obliteration of the tissue planes, changes to Cooper ligaments including thickening or straightening, and aberrations in the ductal pattern. Architectural distortion can also be present from benign causes such as radial scars or complex sclerosing lesions. Postsurgical change is an important iatrogenic cause of architectural distortion.

Skin changes include skin thickening and skin retraction. Skin thickening as defined by the ACR BI-RADS system is greater than 2 mm and can be focal or diffuse.[18] An important note is that skin in the periareolar area and inframammary folds can be up to 4 mm. Skin retraction is defined as a concave skin surface or a skin surface that appears ill defined and pulled in. Although skin changes can be present in benign processes such as infection or inflammation, prior surgery or biopsy, or radiation, skin changes can also be a sign of malignancy. Inflammatory breast cancer is an aggressive form of breast cancer that involves the skin through dermal lymphatic vessels and can result in skin thickening. Ductal carcinomas can also result in skin involvement. For example, some ductal carcinomas develop superficially in the peripheral zone and can extend into the skin.

Edema is suggested with increased echogenicity of breast tissue and interdigitating hypoechoic lines that may represent interstitial fluid or dilated lymphatics. Edema can be associated with inflammatory breast cancer but also with benign causes such as mastitis and congestive heart failure.

Elasticity assessment evaluates the stiffness of masses. Malignant masses are typically stiff or hard, whereas benign masses are more compressible. Descriptors for masses include soft, intermediate, and hard. This feature is far less important than the morphologic descriptors because there is significant overlap in appearance for benign and malignant masses.

Benign Findings

Benign findings should be sought only if no suspicious findings are present. The benign findings are (1) **pure and total hyperechogenicity,** which represents interlobular stromal fibrous tissue or fat; (2) an **oval circumscribed mass with parallel orientation,** completely encompassed by a thin, echogenic capsule; and (3) **an oval mass with gently lobulated margins** (three or fewer

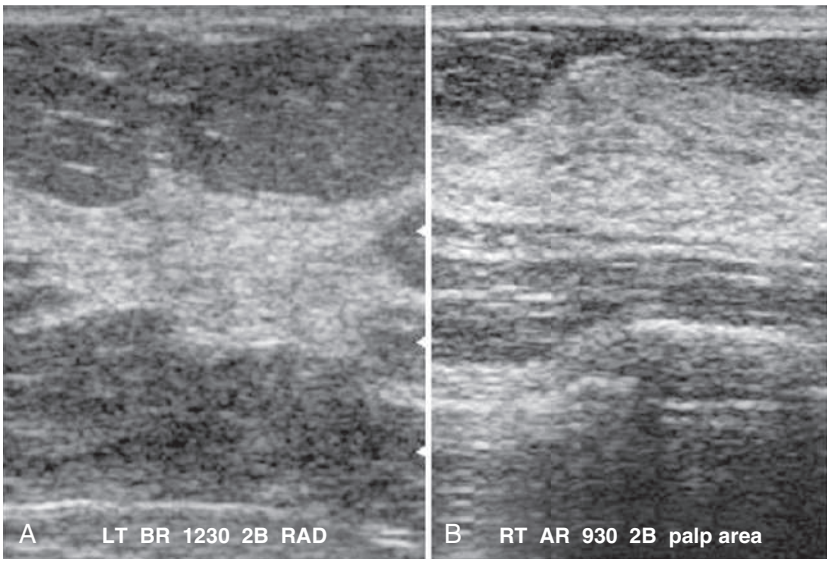

FIG. 21.54 Hyperechoic Fibrous Tissue Collections. Normal isolated collections of hyperechoic interlobular stromal fibrous tissue can cause **(A)** mammographic nodules and masses, or **(B)** palpable ridges.

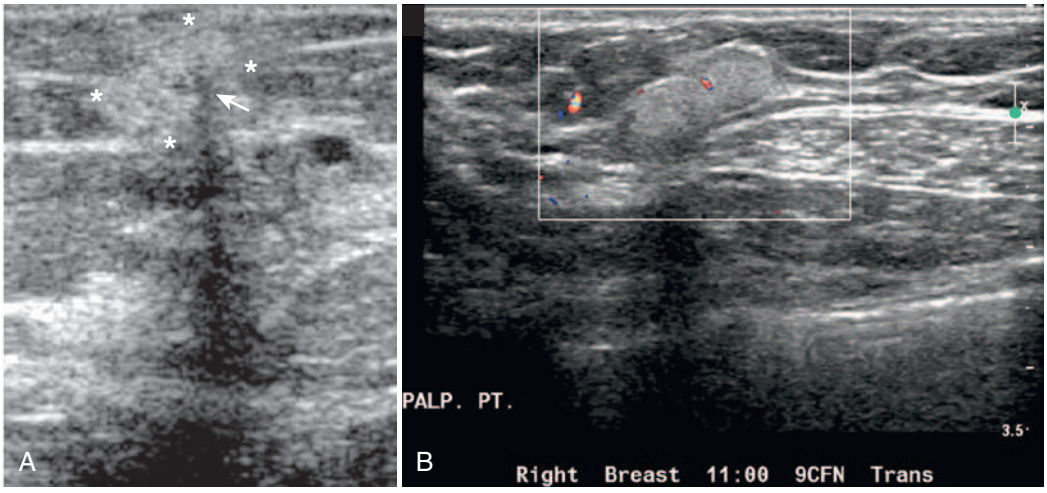

FIG. 21.55 Hyperechoic Malignancies. The negative predictive value of purely and intensely hyperechoic tissue is essentially 100%. However, collections of hyperechoic tissue should not contain any hypoechoic or isoechoic areas that are larger than normal ducts or terminal ductolobular units (TDLUs). **(A)** Certain small, invasive carcinomas can appear with tiny hypoechoic central foci *(arrow)* surrounded by a very thick, echogenic rim (*). Near-field volume averaging or tangential imaging through the thick, echogenic rim of such lesions can make them falsely appear to be purely hyperechoic. **(B)** In addition, hyperechoic masses with internal vascularity may also represent malignancy and should be sampled.

lobulations) and **parallel orientation** that is completely encompassed by a thin, echogenic capsule. If a nodule fits into one of these three categories, it can be characterized as BI-RADS 3, "probably benign."

Hyperechoic Tissue

Purely hyperechoic tissue is often normal interlobular stromal fibrous tissue or fat, which can cause either palpable or mammographic abnormalities (Fig. 21.54). To be considered benign, the hyperechoic tissue should contain normal-sized ducts or TDLUs without any isoechoic or hypoechoic structures larger than normal ducts or lobules. Purely hyperechoic carcinomas are exceedingly rare, but occasionally a carcinoma may have a very small, hypoechoic central nidus and a very thick, echogenic rim, and technical errors such as volume averaging or tangential imaging through the rim can make the lesion falsely appear to be purely hyperechoic (Fig. 21.55A).

It is important to correlate all hyperechoic masses with the mammographic findings. Hyperechoic masses that appear radiolucent on mammography are benign fat-containing masses, such as lipoma, oil cysts, or fat necrosis. Hyperechoic masses seen with a water density mass on mammography in the setting of trauma could represent fat necrosis or hematoma, and follow-up is warranted to ensure resolution. Biopsy of any hyperechoic mass that has any suspicious mammographic or sonographic feature should be performed. Similarly, although benign hyperechoic masses such as angiolipoma or pseudoangiomatous stromal hyperplasia can be vascular, any hyperechoic mass with increased

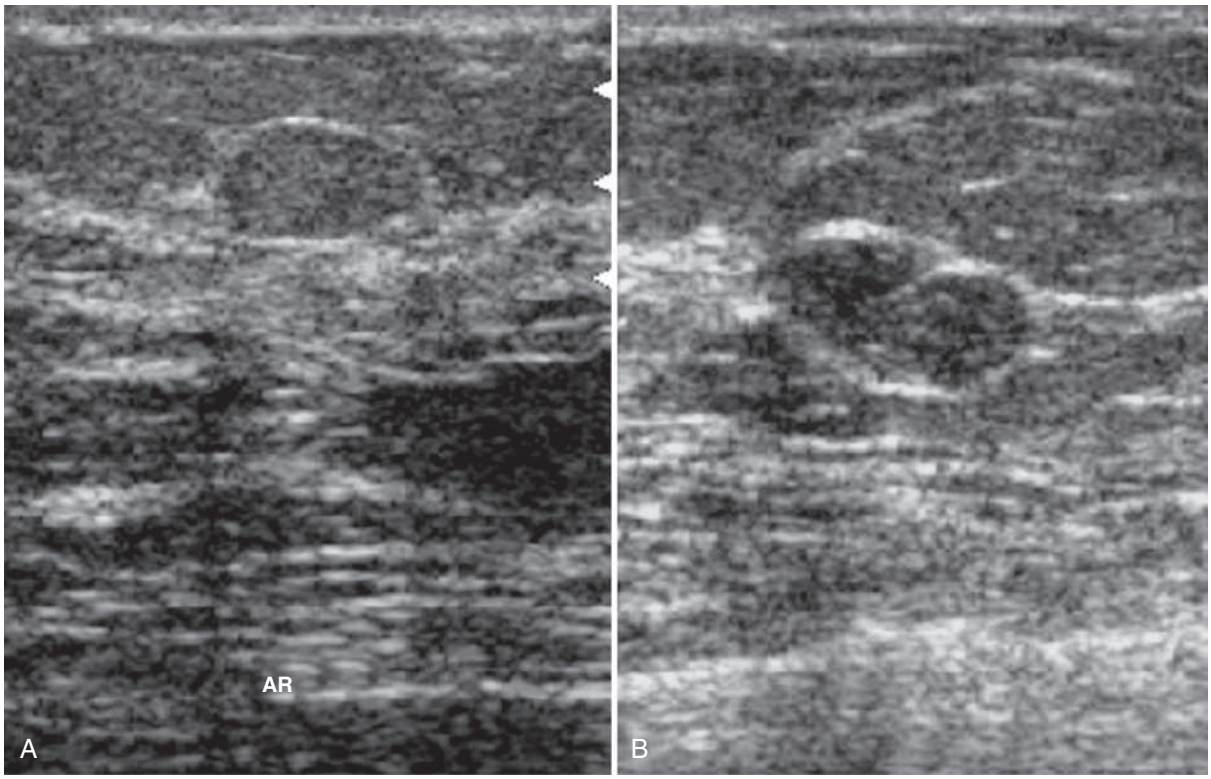

FIG. 21.56 Fibroadenoma. (A) Classic shape of benign fibroadenomas is elliptical. Such lesions are wider than tall and completely encompassed by a thin, echogenic capsule. **(B)** Second most common shape of benign fibroadenomas is gently lobulated. Classic lobulated fibroadenomas have three or fewer lobulations, are wider than tall, and are completely encompassed by a thin, echogenic capsule.

blood flow should be sampled to exclude malignancies such as invasive ductal carcinoma, lymphoma, or angiosarcoma[56] (Fig. 21.55B).

Parallel (Wider-Than-Tall) Orientation

An oval shape with parallel orientation is the classic appearance of a fibroadenoma (Fig. 21.56A). An oval mass with gently lobulated margins containing three or fewer lobulations and parallel orientation is the second most common shape of fibroadenomas (Fig. 21.56B). Masses that appear to be circumscribed in one view and gently lobulated in the orthogonal view are common. The negative predictive value of the oval shape is 97%, and the negative predictive value of the gently lobulated shape is 99%, in a population of masses with 33% malignancy.[45] Despite the high likelihood of benignity, these masses should always be followed or biopsy performed to ensure no malignancy is present.

Thin Echogenic Capsule

It is important to combine the circumscribed or gently lobulated margins with the presence of a complete, thin, echogenic capsule to minimize false-negative results in circumscribed carcinomas and in pure DCIS. Although carcinoma has an echogenic pseudocapsule and DCIS can have an echogenic surrounding duct wall, they almost never have an elliptical or gently lobulated shape. In addition, the thin echogenic pseudocapsule that can be seen around circumscribed carcinomas is often absent along part of the surface of the nodule. Carcinoma and DCIS are also usually associated with other suspicious findings, such as angular margins, not parallel orientation, microlobulations, or duct extension. By combining the presence of a **complete, thin, echogenic capsule with the oval circumscribed mass or oval gently lobulated mass** we can achieve a negative predictive value of greater than 99%.[45]

Rocking the transducer in its short axis and heeling and toeing the transducer along its long axis are often necessary to demonstrate the presence of a thin, echogenic capsule along the edges of the masses. Using less compression often helps to demonstrate the thin echogenic capsule in benign masses that are surrounded by hyperechoic fibrous tissue.

DIAGNOSTIC ULTRASOUND INDICATIONS

Most diagnostic breast ultrasound is performed in a targeted fashion to evaluate a particular symptom or mammographic abnormality.

Symptomatic Breast

Breast Pain

The evaluation of breast pain is based on whether the patient has focal pain or nonfocal pain. Although focal pain alone indicates a low likelihood of malignancy,[57] ultrasound is often performed to provide reassurance to the patient or to identify a benign cause that may be treatable. Ultrasound is not

recommended for diffuse unilateral or bilateral breast pain that may or may not be cyclic in nature.

Palpable Abnormality

The specific goal of targeted sonographic evaluation of palpable lumps is either (1) to find a malignant lesion that has been obscured by surrounding dense tissues on the mammogram or (2) to find normal or definitively benign causes of the lump that do not require biopsy or short-interval follow-up.

Ultrasound is most useful when there is dense tissue in the area of the palpable lump on mammography. Lesions that do not contain calcifications may be obscured by surrounding dense tissues on mammography. Sonography has much less to contribute to cases with a background of predominantly fat and only fatty density in the area of the palpable lump on mammography. It is unlikely that the mammogram missed anything significant, and the palpable lump is most likely to be either a fat lobule or a benign lipoma in such cases. The rare exception to this general rule occurs in cases of pea-sized or smaller palpable lumps when the skin line is overpenetrated on the mammogram and thus cannot be appreciated. These patients may have a tiny, superficial lesion just under the skin that is not adequately shown on the mammogram. This situation is much less common on digital mammograms with current tissue equalization techniques. Should the palpable lump be an asymmetric mixture of fat and water density in a predominantly fatty breast, sonographic evaluation should be aggressively performed, because this could represent a malignancy. When a palpable area correlates with a suspicious mass on ultrasound, the ultrasound evaluation can be used to help target the area for subsequent biopsy.

When used to confirm that a palpable abnormality is benign, ultrasound can help avoid biopsy or additional imaging follow-up. Should the mammogram reveal a finding in the area of clinical concern, ultrasound can be used to demonstrate whether the finding is benign such as a simple or complicated cyst. Should the mammogram be normal in the area of clinical concern, targeted ultrasound to that location should be performed as well. If only normal breast tissue is seen, then there is a high probability that the area is not malignant. Several studies have now shown an extremely high (≥99%) negative predictive value for the combination of normal mammography and normal or benign ultrasound findings.[58,59] That being said, should a patient have a new or increasing palpable area that is clinically suspicious, the clinicians can perform a blind biopsy of the area to confirm that it is not malignant. Accordingly, a notation for clinical follow-up is important as part of the management recommendations.

If sonography is to be effective at evaluating a palpable abnormality, it is essential that the abnormality be simultaneously palpated while being scanned. The image should be annotated with the word "palpable." An image could be acquired during the act of palpation wherein the finger is documented in the image (Fig. 21.57). Simply showing that normal tissue or a benign cyst exists in the same quadrant is insufficient proof that it is the cause of the palpable lump. For large lesions in compressible breasts, the operator can usually slide the nonscanning index finger under the transducer while scanning. For smaller lesions and firmer breasts, the index finger may lift the ends of the transducer so far off the skin that the lesion cannot be scanned with the finger between the transducer and skin. In such cases, trapping the lesion between the index and middle fingers and scanning the lesion while it is trapped may be useful (Fig. 21.58). For very small and superficial lesions, an opened paper clip can be used to palpate the lesion during scanning without lifting the ends of the transducer off the skin.

Nipple Discharge

Evaluation of nipple discharge begins with a review of the symptoms. Bilateral nonspontaneous milky nipple discharge is more often associated with hormonal changes that are either physiologic or are associated with prolactin-producing tumor, and imaging evaluation of the breast is not needed.

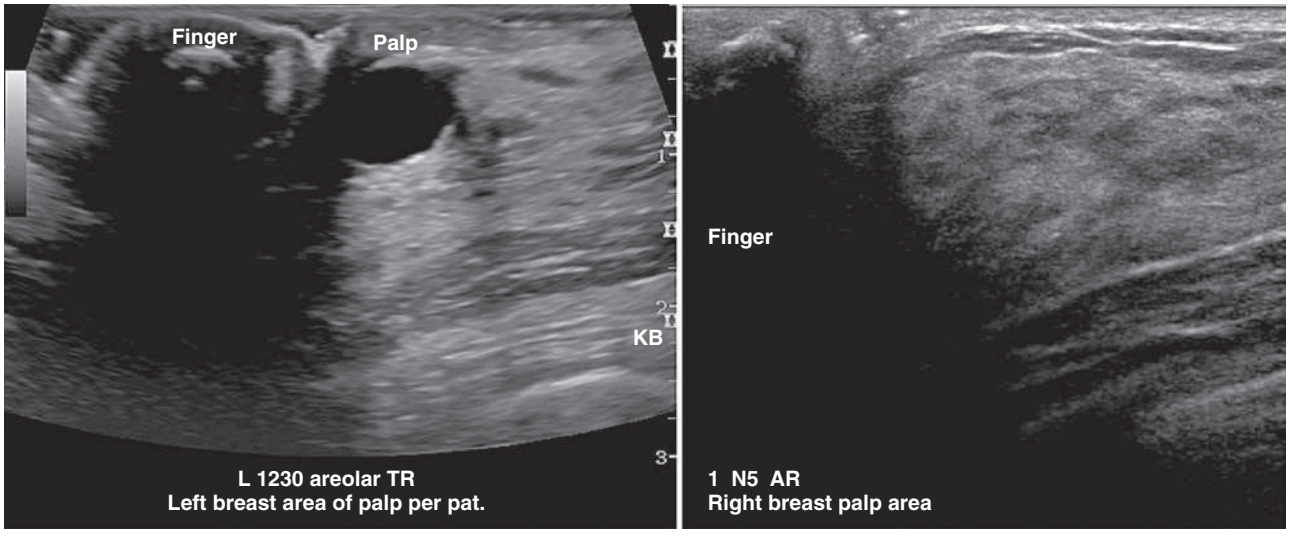

FIG. 21.57 Marking Palpable Lesions During Targeted Diagnostic Sonography Is Critical. *Left,* Small, simple cyst is palpated with the nonscanning index finger during imaging. *Right,* Fibroductal ridge is palpated during scanning.

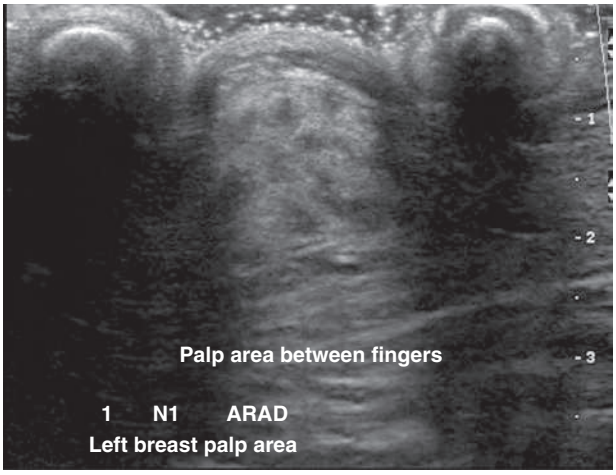

FIG. 21.58 Finger Trapping to Document Breast Lesion. Trapping the palpable abnormality between the index and middle fingers can be helpful in documenting the cause of the "lump."

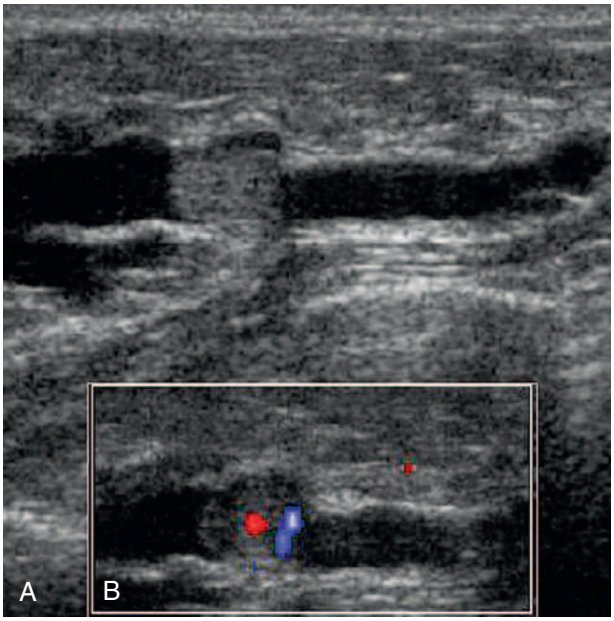

FIG. 21.59 Intraductal Papillary Lesion. (A) Small, ovoid intraductal papillary lesions that do not expand the duct represent benign large duct papillomas in more than 98% of cases. **(B)** Even small intraductal papillomas typically have a readily demonstrable vascular stalk.

Discharge that is more concerning for breast malignancy is unilateral and spontaneous. The discharge may be bloody, serosanguinous, or clear, although color alone should not lead one to dismiss the sign. Unilateral nipple discharge is most often caused by papillomas; however, carcinoma must be excluded. Other causes include duct ectasia, benign FCC with communicating cysts, or an idiopathic cause. Historically, imaging evaluation of unilateral nipple discharge was primarily with **galactography;** however, other tools including ultrasound are now more commonly used. Ultrasound can be performed during the initial diagnostic workup or can be used during a second-look evaluation after MRI or galactography.[60-62] As a first-line evaluation, retroareolar ultrasound is performed to identify an intraductal mass that may be causing the discharge. Because **intraductal papillary lesions** that cause nipple discharge often lie within the large mammary ducts under or near the areola, this is the area that should be targeted for the ultrasound evaluation.[49] Warm room temperature, warm acoustic gel, and special maneuvers, such as the two-handed compression maneuver and the rolled nipple technique, help minimize shadowing that can arise in the nipple and areola.

Papillomas appear to be isoechoic nodules (less echogenic than the duct wall) within ectatic fluid-filled ducts (Fig. 21.59). The appearance of papillomas varies with the degree and distribution of duct dilation, with the diameter and length of the lesion, and with involvement of branch ducts and TDLUs. In addition, papillary lesions that affect TDLUs are, by definition, **peripheral papillomas,** regardless of their distance from the nipple. Peripheral papillomas are at much higher risk for being malignant than large duct papillomas (Fig. 21.60). However, because ultrasound characteristics of malignant versus benign papilloma have not been well established, biopsy is performed on most intraductal masses and likely papilloma.

Sonography can show causes of nipple discharge other than large duct papilloma, such as **carcinoma, duct ectasia, communicating cysts,** and **hyperprolactinemia** (Fig. 21.61).

Mammographic Findings

Sonography is the best diagnostic tool for assessing mammographic abnormalities that do not contain suspicious calcifications. These mammographic abnormalities range from discrete masses to one-view asymmetries. It is important to complete the mammographic workup of these findings and determine the level of suspicion before beginning the ultrasound evaluation. This essentially becomes the pretest probability for identifying a malignancy and will help drive one's recommendations. Only in a small percentage of patients will sonography show findings that are more suspicious than those suggested by mammography. Completing the mammographic workup initially is most important for the scenario in which no ultrasound correlate is found and management must depend solely on the mammographic evaluation.

When completing the ultrasound evaluation, it is important to be sure that the sonographic finding explains the mammographic abnormality, and that there are not two completely disparate findings—a mammographic finding and a separate and incidental sonographic finding. To ensure that there is only a *single* finding and that the sonographic finding and mammographic finding are the same, the clinician must rigorously ensure that the size, shape, location, and surrounding tissue density of the mammographic and sonographic findings are the same. **Mammographic-sonographic correlation** of size, shape, location, and surrounding tissue density is best made between the craniocaudal (CC) mammographic view and the transverse sonographic view because there is little rotation and no obliquity of the x-ray beam on the mammographic CC view. If a mammographic lesion can be seen only on the mediolateral oblique (MLO) view, it is usually best to obtain a true mediolateral (ML)

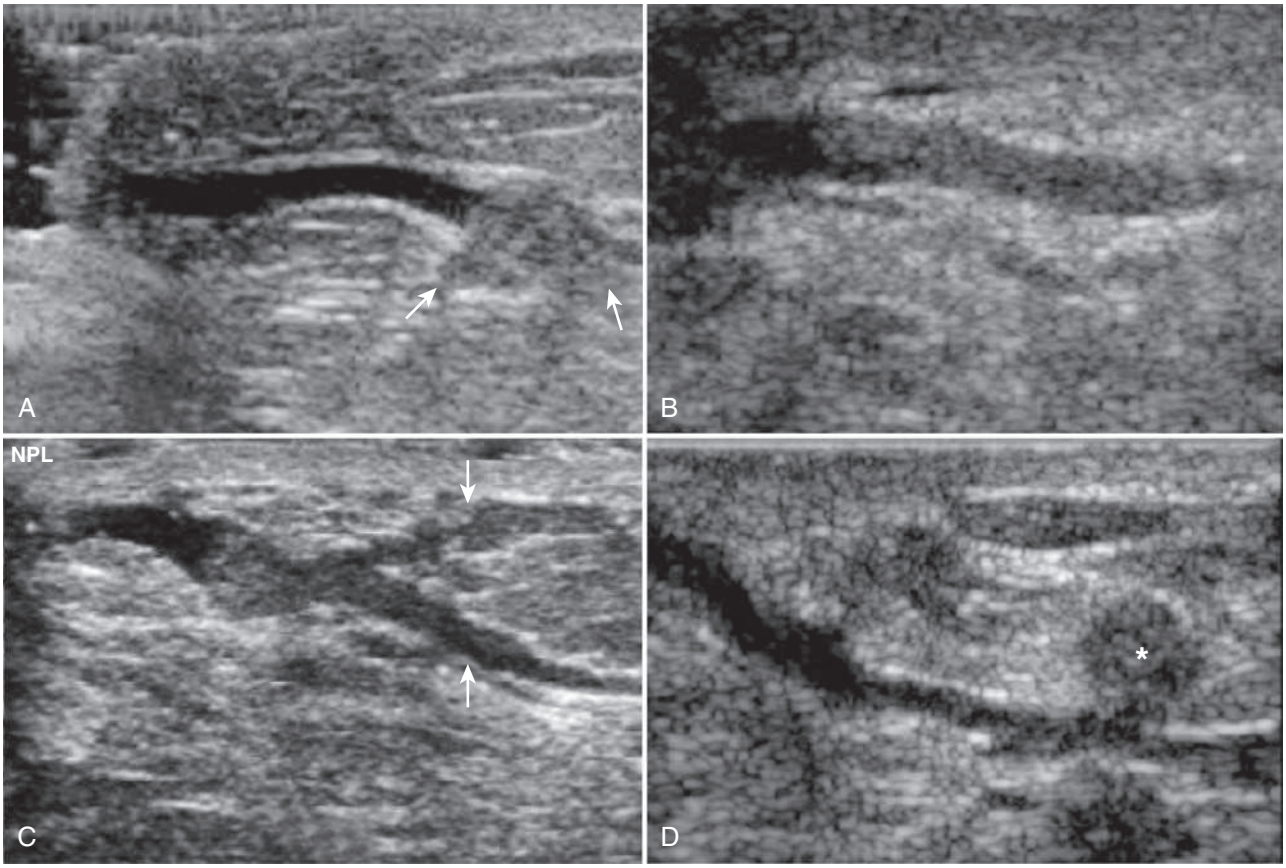

FIG. 21.60 Suspicious Intraductal Papillary Lesions. Intraductal papillary lesions that have greater than a 2% risk of being malignant and that should be characterized as Breast Imaging Reporting and Data System (BI-RADS) 4 and undergo biopsy include **(A)** lesions that expand the duct or breach *(arrows)* its wall, **(B)** lesions that are longer than 1.5 cm, **(C)** lesions that involve multiple peripheral branch ducts *(arrows),* and **(D)** lesions that involve terminal ductolobular units (TDLUs; *) **(peripheral papillomas).**

view, taking care not to rotate the breast during compression, and then obtain a true longitudinal ultrasound view to correlate with the mammographic ML view.

Size Correlation

Mammographic-sonographic correlation of size should take into account everything that is water density on the mammogram. Therefore an oval, 3-cm, circumscribed mass on mammography could correlate with multiple different types of masses on ultrasound that all measure 3 cm, such as (1) a cyst, (2) a solid nodule with a thin echogenic capsule, (3) a cyst that contains a mural nodule, (4) a 3-cm collection of fibroglandular tissue, (5) a smaller cyst, or (6) a solid nodule surrounded by fibroglandular tissue (Fig. 21.62). All six sonographic structures would constitute a perfect mammographic-sonographic size match. Measurements on ultrasound should be made outside-to-outside to include the capsule that surrounds the cyst or solid nodules, because the capsule is water density and will be included in the measurement of the lesion on the mammogram. Ideally, the lesion will be measured identically on both modalities to maximize sonographic-mammographic correlation.

Maximum diameter is used for sonographic-mammographic correlation rather than mean diameter, because many mammographic lesions are partially compressible. Lesions that appear to be spherical on mammography are often oval on ultrasound (Fig. 21.63). The mean diameter of partially compressible lesions will appear larger on mammography than on sonography.

Shape Correlation

Sonographic-mammographic correlation of shape must consider two phenomena: **partial compressibility** and **rotary forces** applied during compression. This can be demonstrated when a partially compressible spherical mass on mammography appears oval on ultrasound (see Fig. 21.63). When the mammographic lesion is spherical and *not* compressible, the shape will be spherical on sonography as well.

Mammographic compression and sonographic compression apply different rotatory forces on lesions that are not spherical. Mammographic compression not only pulls lesions away from the chest wall, but also tends to rotate the lesion so that its long axis lies perpendicular to the chest wall. Sonographic compression will push lesions closer to the chest wall and tends to rotate the lesion's long axis parallel to the chest wall. There is typically a 90-degree difference in the orientation of the long axis of lesions between the mammogram and the sonogram (Fig. 21.64). If this rotation is not considered, the breast sonographer may falsely conclude that the shape of the lesion is different on the mammographic and sonographic images.

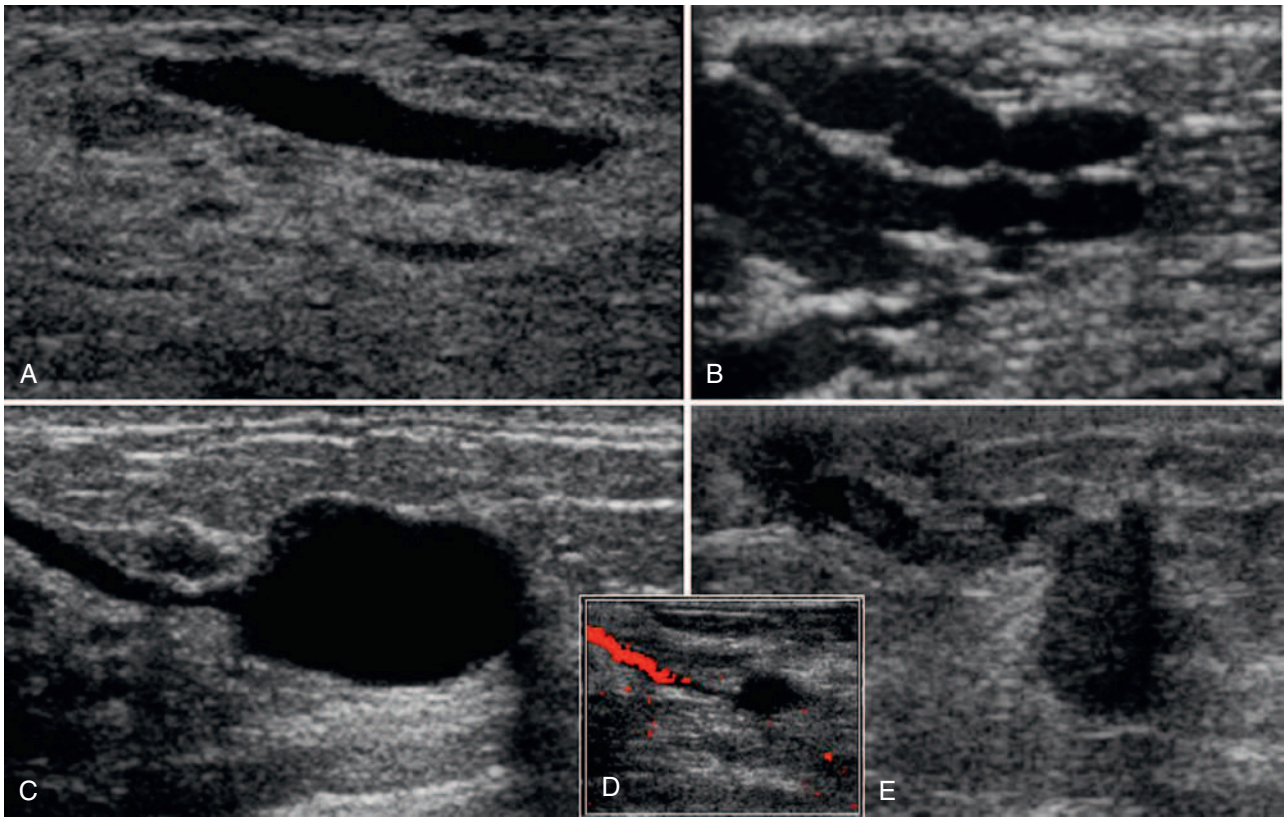

FIG. 21.61 Lesions Other Than Papillomas That Cause Nipple Discharge. Duct ectasia usually involves one lobar ductal system at a time. **(A)** Early in its course, only a single duct might be involved. **(B)** Over time, additional lobar ducts can become involved, leading to multiple dilated ducts. When all the ducts are severely involved, one must consider **hyperprolactinemia** as an underlying factor. **(C) Communicating cysts. (D)** Confirmation that the cyst truly communicates with the ductal system can be made by showing a "color-swoosh" with the communicating duct when the cyst undergoes ballottement with the transducer. **(E)** Pure ductal carcinoma in situ (DCIS) and invasive duct carcinomas that have DCIS components can also give rise to nipple discharge.

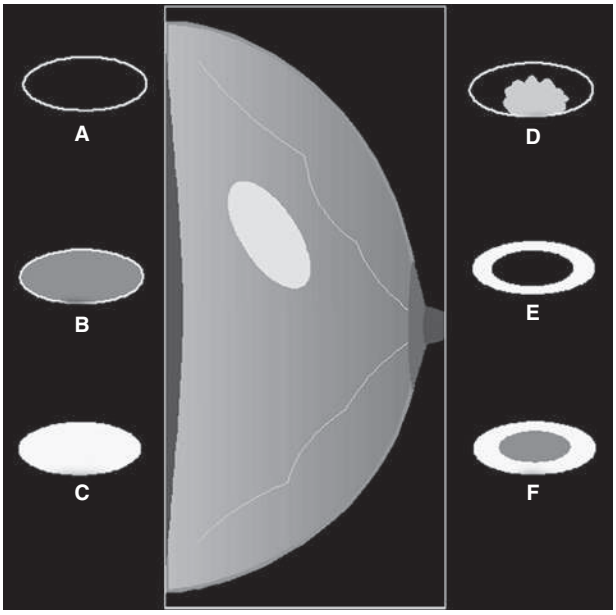

FIG. 21.62 Importance of Mammographic-Sonographic Correlation. Everything that is water density could contribute to the size of the mammographic lesion. Thus a 3-cm, ovoid, circumscribed mammographic mass could represent **(A)** a cyst, or **(B)** a solid nodule, surrounded by a thin echogenic capsule; **(C)** 3-cm collection of interlobular stromal fibrous tissue; **(D)** 3-cm cyst containing a mural nodule; or **(E)** smaller cyst, or **(F)** solid nodule, surrounded by fibrous or glandular tissue.

Location or Position Correlation

Because mammographic compression pulls a lesion away from the chest wall and sonographic compression pushes the lesion closer to the chest wall, lesions usually appear much closer to the chest wall on sonography than on mammography. Lesions that appear to lie several centimeters from the chest wall on mammography may appear to lie very close to the chest wall, even indenting the chest wall musculature, on sonography. If this routine apparent difference in depth of lesions on mammography and sonography is not understood, the clinician might falsely conclude that the sonographic lesion lies too deep to correspond to the mammographic lesion.

Surrounding Tissue Density Correlation

The final step in correlating the sonographic and mammographic findings is assessment of the density of surrounding tissues. A lesion that protrudes into the subcutaneous fat from the mammary zone, and that is surrounded by fat superficially and water density tissue along its deep margins on the mammogram, should lie at the junction of the subcutaneous fat and mammary zone on the sonogram. It should be surrounded by subcutaneous fat along its superficial margin and by either hyperechoic fibrous tissue or isoechoic glandular tissue along its deep border on the sonogram (Fig. 21.65).

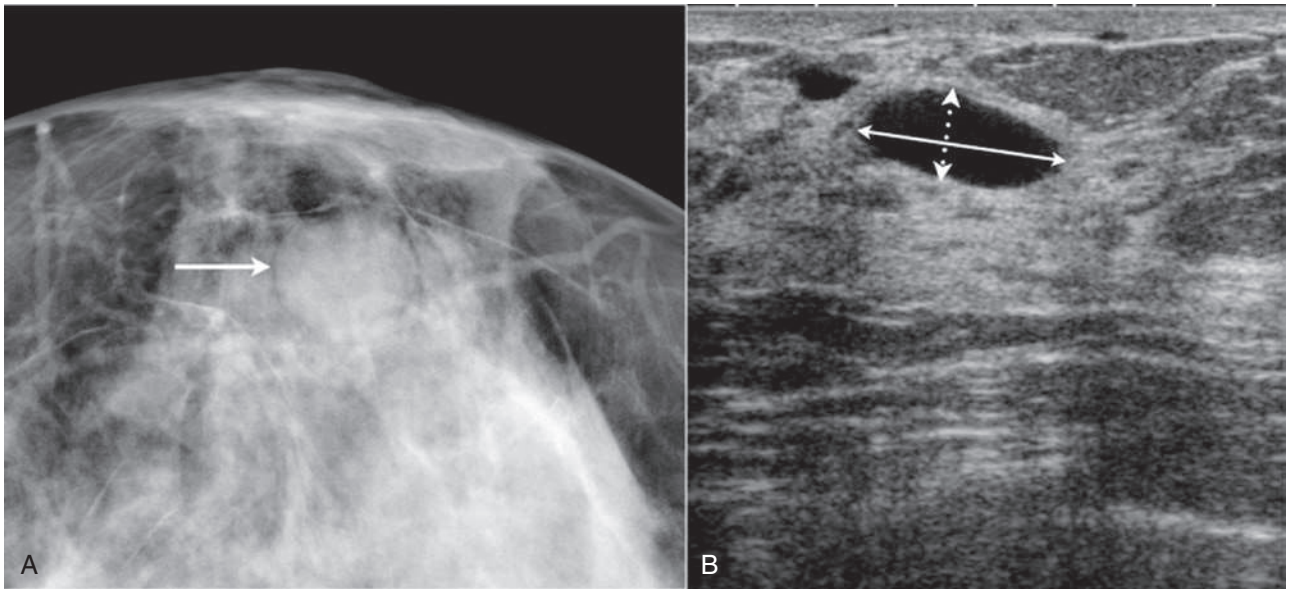

FIG. 21.63 Lesions That Appear Spherical on Mammography Often Appear Elliptical on Sonography. (A) Circumscribed isodense mammographic nodules appeared circular in both views (spherical) because the mammogram demonstrates only the axes of the cyst that lie perpendicular to the axis of compression and not the compressed axis. Sonography, however, does show the compressed axis. The mean diameter calculated from mammograms includes three large diameters that all lie in axes perpendicular to the axis of compression. **(B)** The mean diameter calculated from the sonographic views includes two large diameters that lie perpendicular to the axis of compression *(solid arrow)* and one smaller diameter that lies parallel to the axis of compression *(dotted arrow)*. For compressible lesions, the mean diameter obtained from sonograms is often smaller than the mean diameter obtained from mammography, but the maximum diameters from mammography and sonography will be similar.

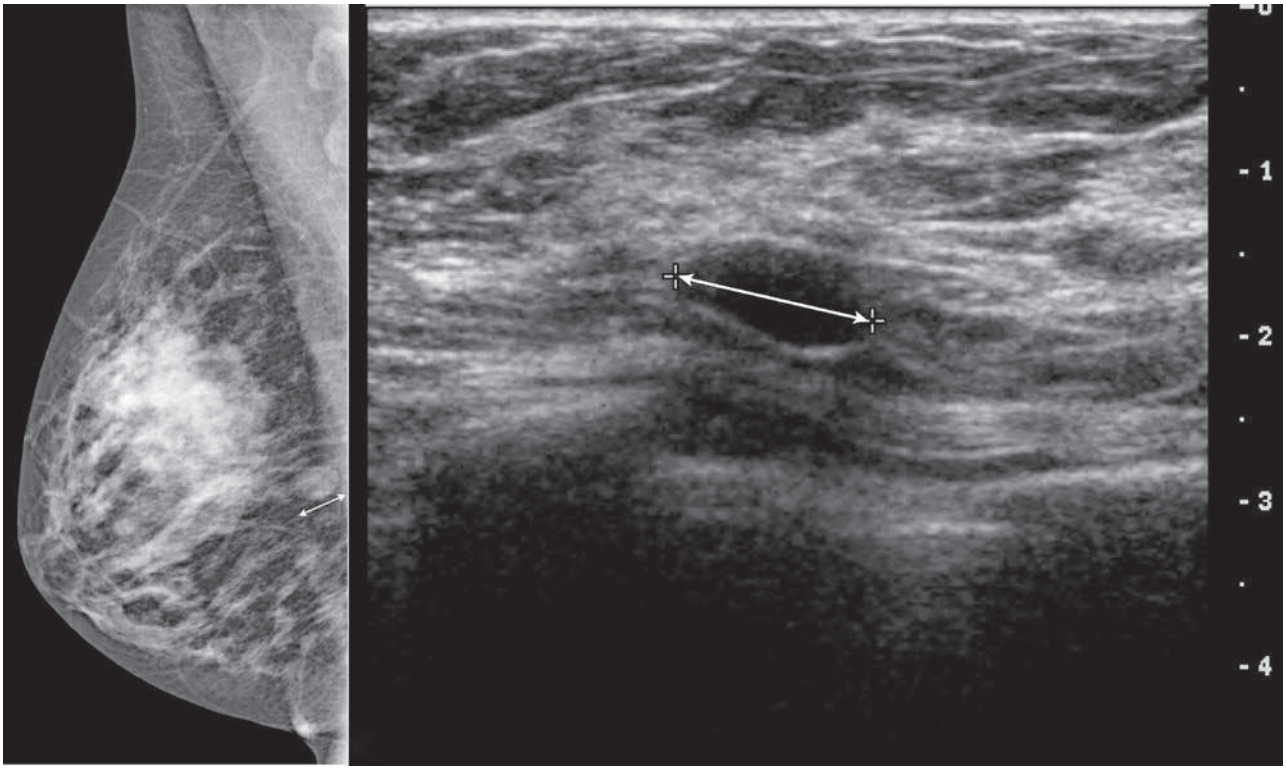

FIG. 21.64 Mammographic-Sonographic Compression and Lesion Orientation. Mammographic compression *(left)* tends to rotate the long axis of the lesion perpendicular to the chest wall, whereas sonographic compression *(right)* tends to rotate the long axis parallel to the chest wall. The long axes of lesions on mammography and sonography often differ by almost 90 degrees. The double-headed arrows show the long axis of the lesions.

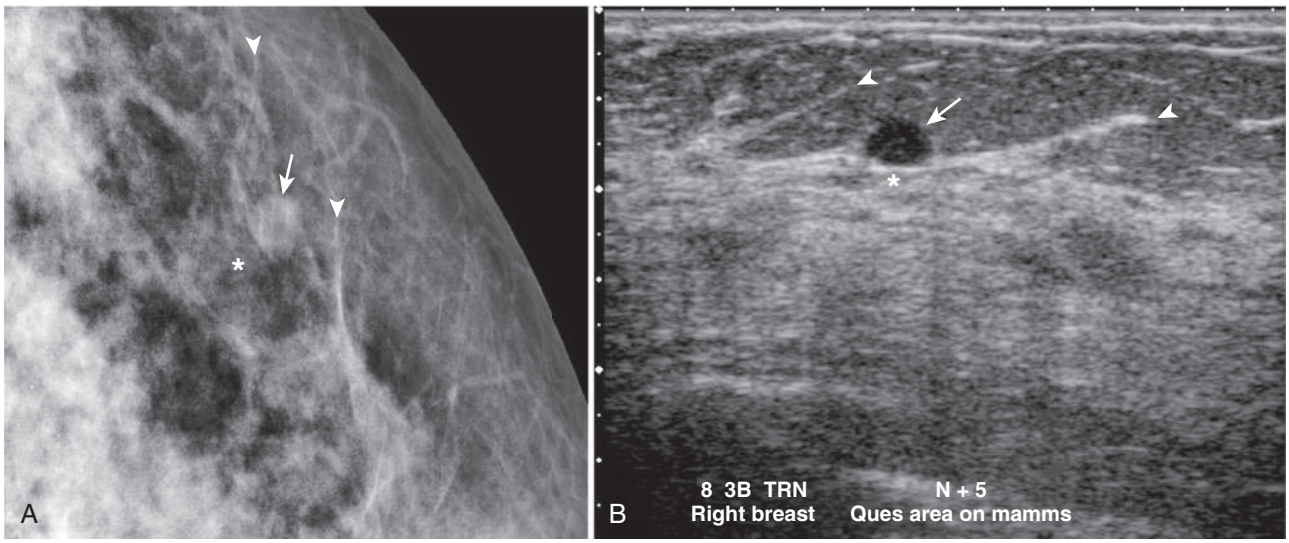

FIG. 21.65 Mammographic-Sonographic Correlation of Surrounding Tissue Density. (A) Mammogram shows a nodule projecting between two Cooper ligaments *(arrowheads)* and bulging anteriorly into the subcutaneous fat *(arrow)* from the mammary zone (*). **(B)** Sonogram shows that the mammographic nodule is a small cyst that protrudes out of fibrous tissue in the mammary zone (*) and into the subcutaneous fat *(arrow).* It lies between two Cooper ligaments *(arrowheads).*

Sonographic-Mammographic Confirmation

Correlating size, shape, location, and surrounding tissue density will allow the mammographic and sonographic findings to be definitively correlated in most cases, but in some cases may fail. If it cannot be determined with absolute certainty that the mammographic and sonographic lesions are indeed the same, minimally invasive sonographic procedures can be performed to confirm the correlation. If sonography shows the suspect mammographic lesion to be cystic, ultrasound-guided cyst aspiration can be performed and the mammogram repeated to see if the mammographic lesion has disappeared. If sonography shows the suspect lesion to be solid, ultrasound-guided placement of a small-gauge needle (e.g., 25 gauge) or removable wire can be performed and the mammogram repeated with the needle or wire in place, to document that the sonographic lesion and mammographic lesion are indeed in the same lesion. Alternatively, an ultrasound-guided core biopsy can be performed with placement of a radiopaque biopsy marker in the sampled area. Subsequent postprocedural mammography can confirm whether the lesion that underwent biopsy and the initially seen finding are the same.

NICHE APPLICATIONS FOR BREAST ULTRASOUND

Infection

The main uses of sonography in patients with **mastitis** is to determine whether there is an abscess, to determine its maturity, to determine if it is multiloculated, and to guide aspiration of, or drain placement into, the abscess in appropriate cases. The appearance of abscesses varies depending on whether the mastitis is puerperal or nonpuerperal and whether it is centrally or peripherally located.[49,63-65] **Peripheral abscesses** in **puerperal mastitis** usually arise in preexisting galactoceles (Fig. 21.66) and may contain milk by-products, whereas peripheral abscesses in **nonpuerperal mastitis often** arise within inflamed cysts. **Central abscesses,** whether arising from puerperal or nonpuerperal mastitis (Fig. 21.67), usually result from rupture of an inflamed or infected duct and tend to be elongated in a plane that is parallel to the inflamed duct. Initially, unilocular abscesses can be treated with sequential ultrasound-guided aspirations. If they continue to re-collect, infectious abscesses may require placement of a percutaneous drain or surgical drainage. However, some noninfectious collections such as those seen with **granulomatous mastitis** may not benefit from continued aspirations because this can result in fistula formation. Biopsy may be necessary to confirm this alternate diagnosis. In these scenarios, treatment may involve antibiotic or steroid therapy or surgical excision. In some cases,

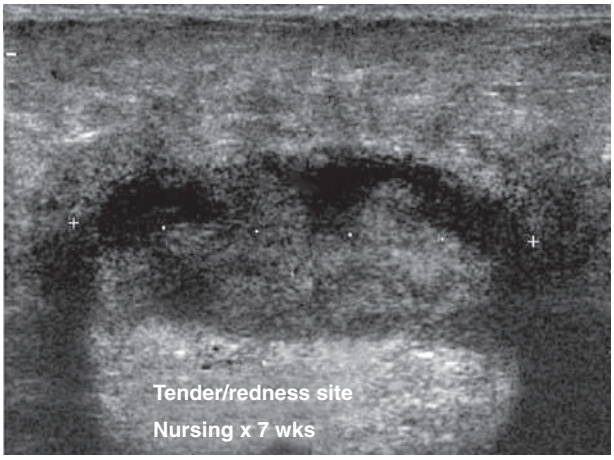

FIG. 21.66 Peripheral Puerperal Abscess. Often arising within preexisting galactoceles, peripheral puerperal abscesses *(calipers)* have very irregular walls and mixtures of fluid and echogenic debris.

sonography may be used to determine if there is an underlying inflammatory carcinoma.

Implants

In general, MRI is considered the modality of choice for evaluating breast implants.[66] However, most patients with implants at risk for **rupture** are within the mammographic screening cohort. Patients with implants may have palpable lumps and mammographic densities that require sonographic evaluation much more often than they require MRI evaluation of their implants. Thus sonographers must understand the wide variations of normal appearances in implants and must be able to identify intracapsular and extracapsular rupture, silicone granulomas, herniation, and capsular infection.

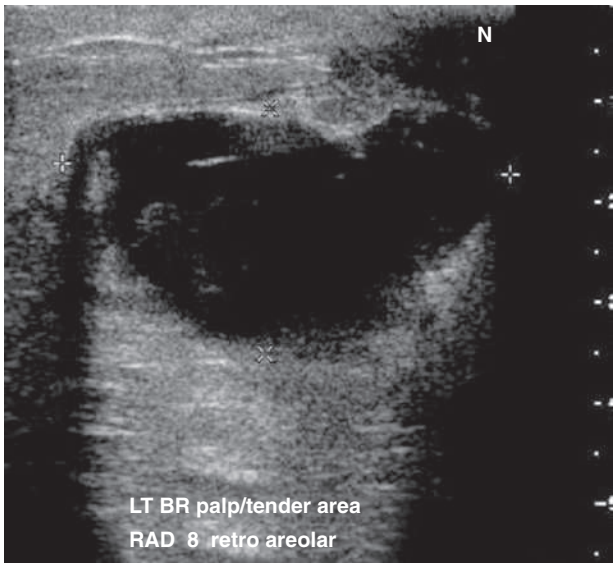

FIG. 21.67 Central Periareolar Abscess. Whether puerperal or nonpuerperal, central periareolar abscesses *(calipers)* usually arise when an inflamed or infected duct ruptures, spilling its contents into the periductal tissues. *N,* nipple.

Sonography allows identification of the type of implant, its implantation site, and many associated complications.[67-70] The **capsule** that surrounds the implant is fibrous and is a normal foreign body reaction to the implant. The capsule is abnormal only when (1) it becomes too thick and causes capsular contracture, (2) it develops a tear through which the implant can herniate, (3) it becomes inflamed or infected or (4) it develops an associated mass that could be either benign or malignant. The implant is filled with saline or silicone gel and is surrounded by a silicone elastomer shell. The **shell,** a part of the implant, must be distinguished from the capsule, which is living tissue formed by the patient in response to the implant.

Normal implants can give rise to palpable abnormalities in certain cases. **Radial folds** may be palpable when the patient is in certain positions. It is important to scan the patient when she is in the position where she feels the lump, because radial folds are dynamic and frequently occur only in certain positions, usually upright. Only anteriorly located radial folds will be palpable (Fig. 21.68A). Radial folds on the posterior surface of the implant are almost never palpable. In patients with saline implants, the **fill valve** can cause palpable abnormalities. In general, fill valves are placed behind the nipple. In certain cases, however, the valve may not be placed directly behind the nipple, or the implant may have rotated after placement. In such cases the valve may be palpable if overlying breast tissue is minimal. In other cases, valves become palpable years after the implant is placed because of eversion of the valve (Fig. 21.68B). **Eversion** is most likely to occur in implants that are under chronic pressure resulting from capsular contracture.

In **intracapsular rupture** the shell develops a tear through which silicone gel extravasates into the space between the shell and the capsule; the capsule remains intact. The classic findings of intracapsular rupture are the **stepladder sign** ("linguini" sign in MRI literature) and abnormally increased echogenicity in the extravasated gel that lies within the intracapsular extrashell space[67,71] (Fig. 21.69). Unfortunately, these signs have low sensitivity for intracapsular rupture because they are present only when

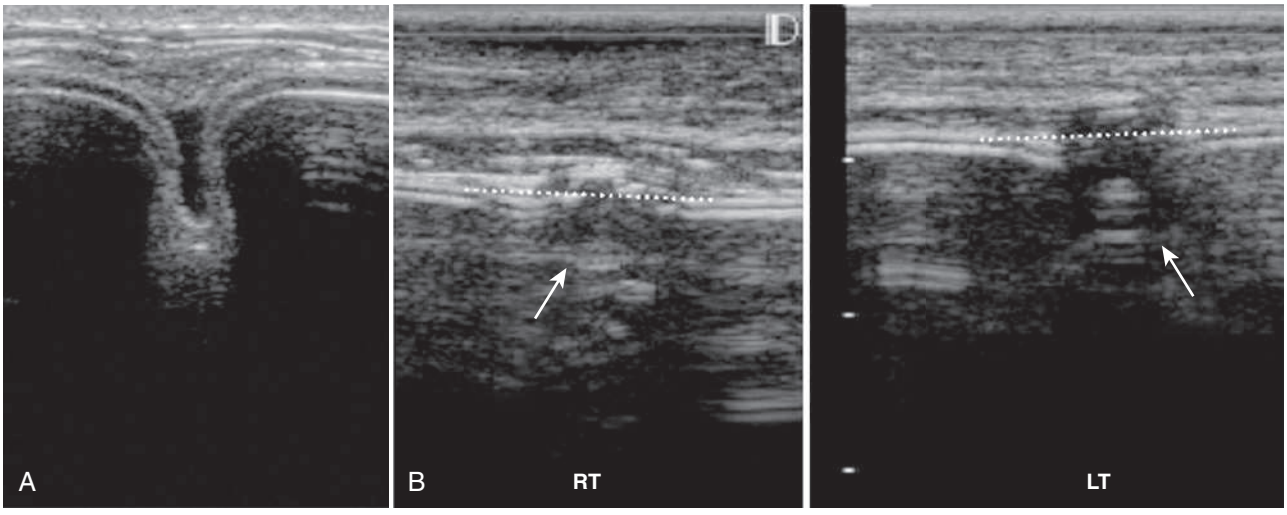

FIG. 21.68 Palpable Implant Components. (A) Anterior radial folds can cause palpable abnormalities; these folds often feel "crinkly." **(B)** Single-lumen saline implants have fill valves. In some cases, particularly with capsular contracture, increased pressure within the implant may cause the valve, which is normally flush with the outer surface of the implant shell *(RT, dotted line),* to evert and become palpable *(LT).*

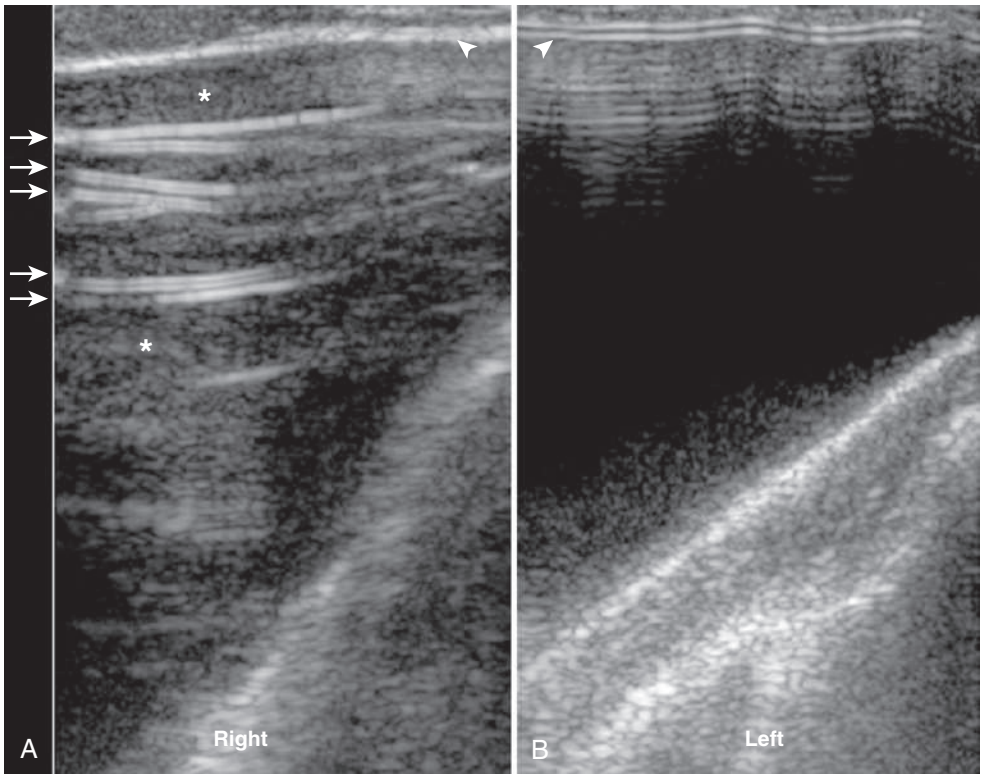

FIG. 21.69 Breast Implant Rupture. (A) Classic findings of intracapsular rupture of a single-lumen silicone gel implant are the "stepladder sign" *(arrows)*. Several linear, horizontally oriented echoes represent folds in a collapsed shell. Several of these are double echogenic lines that represent the inner and outer surfaces of each fold of the shell *(arrows)*. *Asterisk* (*) denotes silicone extravasated outside the implant shell but still within the capsule. **(B)** Normal left breast implant. Note that the superficial aspect of the unruptured left implant shows the double echogenic line *(white arrowhead)* of the shell at the anterior aspect of the silicone gel.

nearly all the silicone gel has extravasated from the shell and the shell is completely collapsed. Lesser degrees of collapse merely lead to abnormal, sheetlike separation of the shell inwardly away from the capsule. In general, there is a continuous spectrum of intracapsular collapse from involvement of a single radial fold to complete collapse. Radial folds are quite dynamic, forming when the patient is in one position, then disappearing when the patient assumes another position; the apex of radial folds therefore is prone to fatigue fractures. Because radial folds normally contain anechoic peri-implant effusion that is identical to silicone gel in echogenicity, for any individual radial fold, it is impossible to know whether the fluid within the fold is normal effusion or extravasated silicone gel from a fatigue fracture at the apex of the fold, unless the extravasated gel within the fold becomes hyperechoic. Radial folds should be considered normal unless they contain hyperechoic contents ("snowstorm" appearance).

In **extracapsular rupture** there is a tear in the capsule as well as in the shell, and silicone gel extravasates into the breast tissues outside the capsule. By definition, all cases of extracapsular rupture must be preceded by intracapsular rupture, although in many cases the intracapsular component is difficult to demonstrate sonographically. The classic finding is the **silicone granuloma** with a snowstorm appearance. Such granulomas are markedly hyperechoic and well circumscribed anteriorly but have an incoherent, "dirty" shadow posteriorly. Silicone granulomas can occur superficial to implants (Fig. 21.70A), but they most often occur at the edges of the implant, where the shell is thinnest and where fatigue fractures are more likely to occur (Fig. 21.70B). In certain cases, extravasated silicone gel forms a thin sheet over the outer surface of the implant rather than a discrete mass (Fig. 21.70C). In other cases, extravasated silicone gel can migrate away from the edge of the implant to the axilla, chest wall, back, or abdominal wall (Fig. 21.70D). Extravasated silicone gel can be picked up and carried by lymphatic vessels into the axillary lymph nodes, where it accumulates from the medullary sinuses within the mediastinum of the lymph node outwardly. Early **accumulation of silicone gel within lymph nodes** can be difficult to detect, although gel in the lymph node hilum will cause a subtle, dirty-appearing shadow.[72] As more silicone gel accumulates, the diagnosis of silicone gel accumulation within the lymph node becomes more obvious, and dirty shadowing arises from the entire lymph node (Fig. 21.70E).

Silicone granulomas have a spectrum of appearances. Not all have the classic snowstorm appearance. Large, acute accumulations of extracapsular silicone gel can appear complex and cystic (Fig. 21.71A). Over time, these may become solid appearing and isoechoic (Fig. 21.71B). The classic snowstorm appearance develops late, after the solid, isoechoic phase. Very late in the history of a silicone granuloma, so much foreign body granuloma may develop that the lesion can become hypoechoic, causing architectural distortion and more intense acoustic shadowing—findings that simulate those of stellate breast malignant lesions

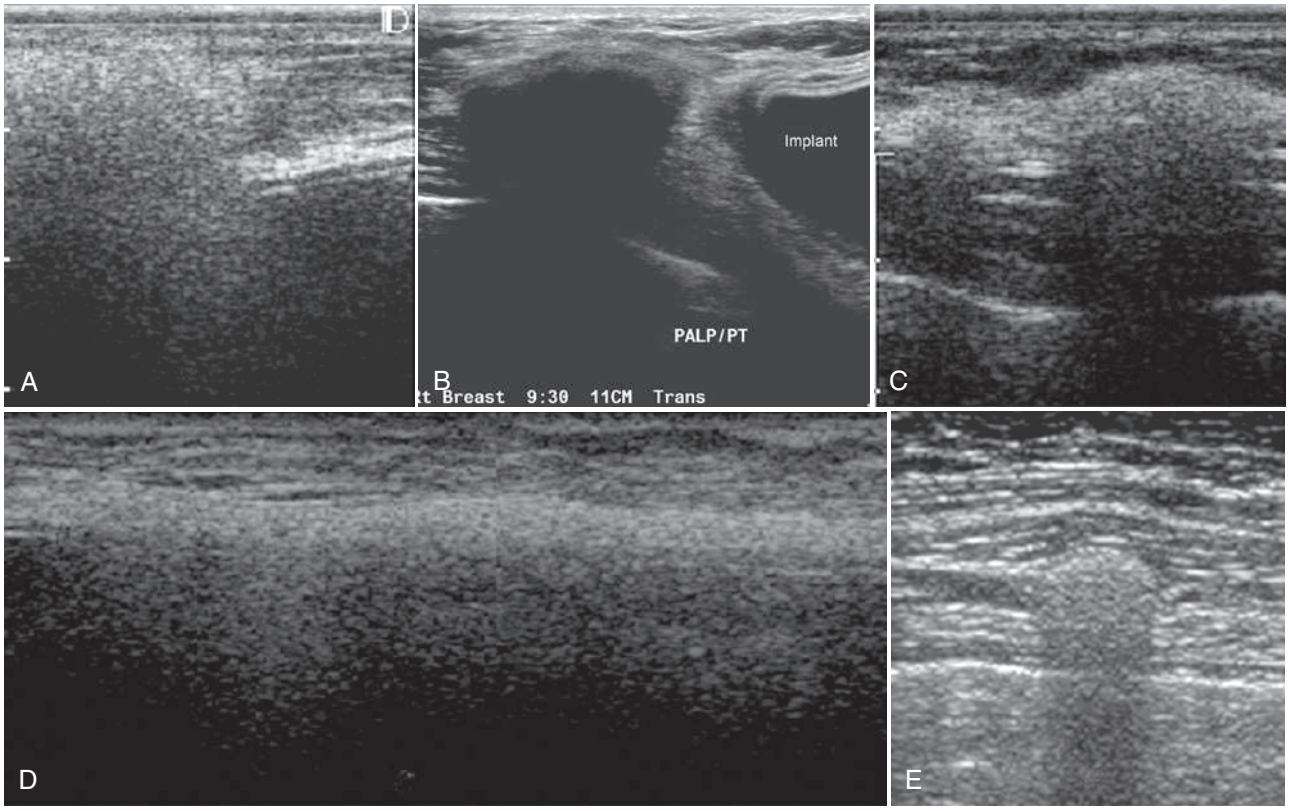

FIG. 21.70 Silicone Granulomas: Typical "Snowstorm" Appearance of Extracapsular Rupture. Silicone granulomas that manifest the snowstorm sign are hyperechoic and have a well-circumscribed superficial border and a posterior border obscured by "dirty" incoherent shadowing. **(A)** Silicone granulomas can occur anterior to the implant. **(B)** However, most occur along the edges of the implant, where the shell is thinner. **(C)** Silicone granulomas can spread over the surface of the implant in a thin sheet rather than forming a discrete mass. **(D)** Silicone granulomas can migrate away from the edge of the implant to lie on the chest or abdominal wall or in the axilla. **(E)** Extravasated silicone can be carried by lymphatics to regional lymph nodes, where it fills the lymph nodes with hyperechoic gel, giving a snowstorm appearance, from the medulla outward, as with this Rotter node that lies between the pectoralis major and pectoralis minor muscles.

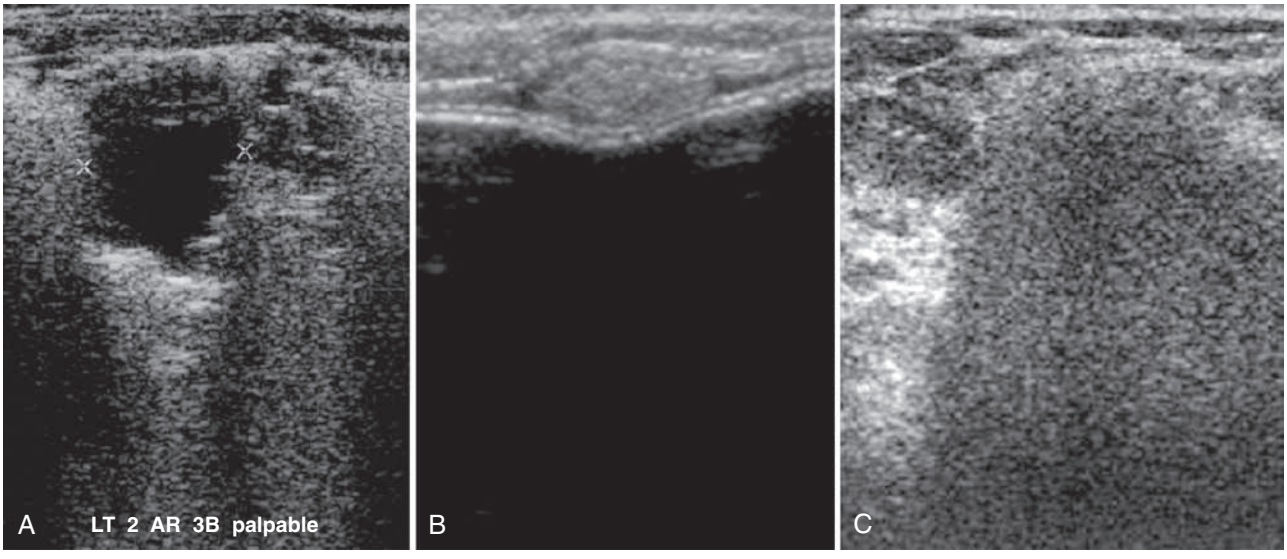

FIG. 21.71 Silicone Granulomas: Less Common Appearances of Extracapsular Rupture. (A) Large collections of acutely extravasated silicone gel can have a complex cystic appearance *(calipers)*. **(B)** Silicone granulomas of a few weeks to a few months' duration can appear to be isoechoic solid nodules. These usually progress to the snowstorm appearance within months. **(C)** Silicone granulomas that are many years old can develop so much foreign body reaction that they become intensely shadowing masses that simulate malignancy. Note also that, although most silicone granulomas result from extracapsular rupture, they can form between the capsule and the shell in certain patients, as in image **(B)**.

(Fig. 21.71C). The sensitivity of ultrasound for extracapsular rupture will be enhanced if the sonographer can recognize the entire spectrum of its sonographic appearances.

The presence of implants should not discourage necessary ultrasound-guided procedures. With ultrasound guidance, an angle of approach that is almost parallel to the surface of the implant can be used. A large amount of local anesthetic can be injected between the lesion and the implant to "hydrodissect" the lesion away from the implant and create a safe working space.

It is important to remember that patients with implants are subject to the same disease processes as patients without implants. Most patients are satisfied with their implants and experience no implant-related problems. The major problem for the sonographer is that the implants are distracting and a breast malignancy can be missed. Consequently, it is important to evaluate breast tissues *overlying* the implant before turning attention to the implants.

Breast Cancer Staging

When a patient is diagnosed with breast cancer, additional imaging may be performed to determine disease extent within the involved breast, disease involvement in the contralateral breast, and ipsilateral lymph node status. The most sensitive imaging study available is breast MRI, which identifies additional sites of malignancy in the ipsilateral breast in approximately 16% of patients and in the contralateral breast in 3% to 4% of patients[73] that would not have been seen on routine mammography. Ultrasound has been studied for evaluation of disease extent and has been shown to identify many of these additional sites, although not as many as breast MRI.[74-76] That being said, some institutions prefer ultrasound for breast cancer staging because histologic sampling of additional abnormalities can occur near simultaneously with the diagnostic evaluation.[77]

However, ultrasound *is* commonly used for evaluating lymph node status. Until recently, if invasive breast cancer was diagnosed, the patient would proceed with a sentinel lymph node biopsy of the ipsilateral axilla at the time of surgical excision to determine lymph node involvement. If positive lymph nodes were discovered, the patient would return for axillary dissection. To bypass this two-step process, preoperative ultrasound of the axilla was commonly performed to identify potentially involved lymph nodes. Should abnormal nodes be identified, histologic sampling could be performed before surgery. If the nodes were positive, then the patient could go straight to axillary dissection and avoid first having a sentinel node biopsy. If negative, the patient would still proceed with sentinel node sampling because the false-negative rate of axillary lymph node sampling is approximately 42%.[78]

A recent clinical trial has changed this routine. The American College of Surgeons Oncology Group Z0011 trial was a randomized, prospective study that compared survival and locoregional recurrence rates after sentinel node biopsy versus complete axillary dissection in women with clinical stage T1 or T2, N0, M0 breast cancer who were found to have one or two positive sentinel nodes at the time of lumpectomy.[79,80] The study revealed no significant difference between the two groups. Because of these findings, the role of preoperative ultrasound evaluation of the axilla is changing. Identifying lymph node metastasis preoperatively in patients who would otherwise meet the Z0011 criteria may no longer be necessary, because these patients may no longer proceed with axillary dissection. Consequently, some institutions no longer image the axilla at all, unless clinically relevant. Other institutions still image the axilla preoperatively but reserve histologic sampling for those patients in whom preoperative identification would change surgical management. Some studies suggest that preoperative lymph node sampling revealing malignant involvement is strongly correlated with tumor burden and the number of involved nodes.[81,82] Therefore some institutions are continuing to perform preoperative lymph node sampling and opting to proceed directly to axillary dissection in patients with positive results, even if they would otherwise quality for Z0011.

It is important to note, however, that the Z0011 results do not pertain to patients with stage 3 tumors, more than two positive sentinel nodes, or clinically positive axillary nodes or patients undergoing mastectomy, neoadjuvant chemotherapy, or partial-breast irradiation.[83] Ultrasound still plays a pivotal role in evaluating the axilla in these patients.

Ultrasound can easily evaluate the lymph node basins involved in breast cancer metastasis including axillary, internal mammary, and supraclavicular. Normal lymph nodes have a sonographic appearance similar to miniature kidneys. They are oval in the long axis, C-shaped in the short axis, and flat in the AP dimension (Fig. 21.72A). The **cortex** of the lymph node includes the marginal sinus, lymphoid follicles, and paracortex and is hypoechoic on ultrasound, whereas the **hilum** of the lymph node includes multiple blood vessels, fat, and the central sinus, which is hyperechoic on ultrasound.[84] As patients age, fatty infiltration of the lymph node may make the hypoechoic cortex very thin or barely visible (Fig. 21.72B). The flow of lymph passes through afferent lymphatic channels, which enter the lymph node from the periphery. The lymph then passes, in order, through the subcapsular sinusoids, cortical sinusoids, medullary sinusoids, and then out the efferent lymphatics, which exit through the hilum.

Many gray-scale criteria have evolved for evaluating lymph nodes, including size, shape, and echogenicity. Minimum diameters greater than 1 cm are considered abnormal. However, we have often seen morphologically abnormal metastatic lymph nodes with diameters less than 1 cm and normal atrophic lymph nodes with diameters well over 1 cm. Thus **size** is a poor criterion for metastasis. Metastatic lymph nodes tend to become **abnormally round,** but unfortunately this is a late finding. The cortex in some (not all) metastatic lymph nodes becomes **abnormally hypoechoic.** This finding may not be detected when using harmonics because harmonics routinely make the cortex appear more hypoechoic.

Morphologic assessment of the lymph node is more effective than evaluating its size, shape, and echogenicity. Lymph nodes that demonstrate **eccentric cortical thickening** should be considered suspicious for metastasis. Given that the lymphatics enter the node from the periphery, metastases initially implant within the subcapsular or cortical sinusoids, causing focal cortical thickening. The pattern of thickening depends on where

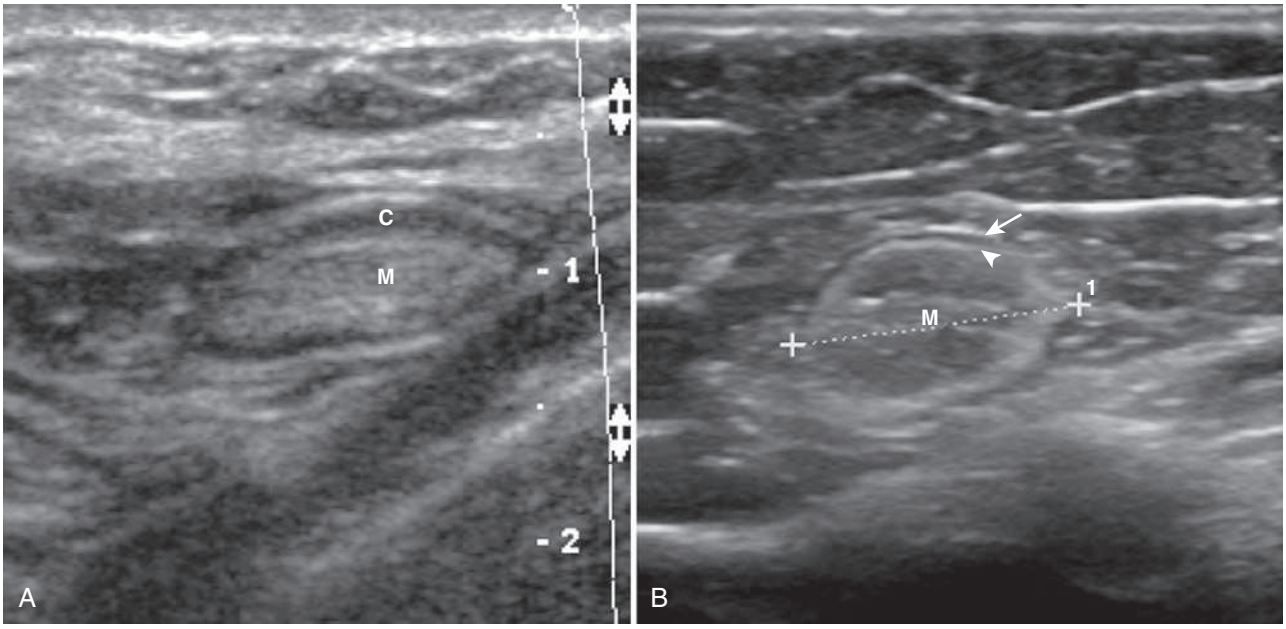

FIG. 21.72 Lymph Node: Spectrum of Normal Appearances. (A) In young patients the mediastinum of the lymph node tends to be uniformly hyperechoic because the medullary cords and sinuses fill the entire mediastinum *(M)*. *C* represents the lymph node cortex. **(B)** In older patients fatty infiltration of the lymph node may make the hypoechoic cortex very thin or barely visible (between the *arrowhead* and *arrow*).

specifically the metastases first implant within the cortex. Metastases that implant near the center of the cortical sinusoids tend to widen the cortex focally and equally in inward and outward directions (Fig. 21.73A). Metastases that implant in the subcapsular sinusoids tend to bulge outwardly, creating a "mouse ear" configuration (Fig. 21.73B). Metastases that implant toward the inner side of the cortical sinusoids tend to bulge into the lymph node hilum, creating "rat bite" defects in the hilum (Fig. 21.73C). When metastasis fills cortical sinusoids throughout the entire lymph node, the cortical thickening becomes uniform, an appearance that can be simulated by benign reactive lymph nodes (Fig. 21.73D). Metastases cause severe enough cortical thickening to obliterate the hilum, which occurs more frequently than inflammation (Fig. 21.73E). Lymph nodes that contain microcalcifications are metastatic until proven otherwise, especially when the primary breast lesion manifests with microcalcifications (Fig. 21.73F). Histologic sampling of the node should specifically target the area of the cortex that is focally thickened.

Lymph nodes that demonstrate mild to moderate, symmetrical cortical thickening of 3 mm or greater have a lower positive predictive value for metastasis than those with clear-cut eccentric cortical thickening, because they can be reactive or metastatic. Comparison versus adjacent lymph nodes is the best way to determine whether a lymph node with symmetrical cortical thickening is a benign reactive node or a metastatic node. Unless there is obvious evidence of inflammation in the ipsilateral breast or upper extremity, reactive lymph nodes are usually reacting to a systemic stimulus; thus all the lymph nodes will be reactive (Fig. 21.74A). However, if the adjacent node is sonographically normal, the node with symmetrical cortical thickening is more likely to be metastatic (Fig. 21.74B). Assessment of adjacent lymph nodes is not necessary when cortical thickening is so severe that the hilum is completely obliterated, because this occurs much more frequently in metastatic than reactive nodes (Fig. 21.74C). Although Doppler sonography can also be used to help determine whether a node with symmetrical cortical thickening is reactive or metastatic, gray-scale imaging of adjacent lymph nodes usually makes this unnecessary.

Although differences in morphology help determine whether lymph nodes are abnormal, clear criteria for classifying these changes have not been well established. Cortical thickness of 2.5 mm to 4 mm is used by some to differentiate normal from abnormal. Others use a cortex-to-hilum ratio; an increased probability for malignancy is associated with a maximum cortical thickness that is greater than the hilar thickness.[85-88]

Abnormal axillary lymph nodes are located most commonly within level 1 of the axilla, located lateral and inferior to the lateral edge of the pectoralis minor muscle. These are the first nodes involved by metastases, except in rare cases in which the sentinel lymph node is a level 2 node. Lymph nodes deep to the pectoralis minor muscle are level 2, and those that lie superior and medial to the medial edge of the pectoralis minor muscle are level 3, or infraclavicular, lymph nodes (Fig. 21.75). Rotter lymph nodes lie between the pectoralis major and minor muscles and lie anterior to and at the same level as level 2 lymph nodes (Fig. 21.76). If undetected and untreated, they can give rise to chest wall invasion. If level 3 nodes are positive, supraclavicular and jugular lymph nodes should be assessed. Internal mammary lymph nodes should be evaluated in all cases, but especially when the primary lesion is medial and deep, and when bulky axillary adenopathy may cause **tumor damming** and collateral flow medially (Fig. 21.77). Presence of metastasis to internal mammary lymph nodes is especially important to radiation oncologists. There is controversy regarding whether to prophylactically irradiate internal mammary lymph nodes when axillary nodes are positive for malignancy. However, if there are known

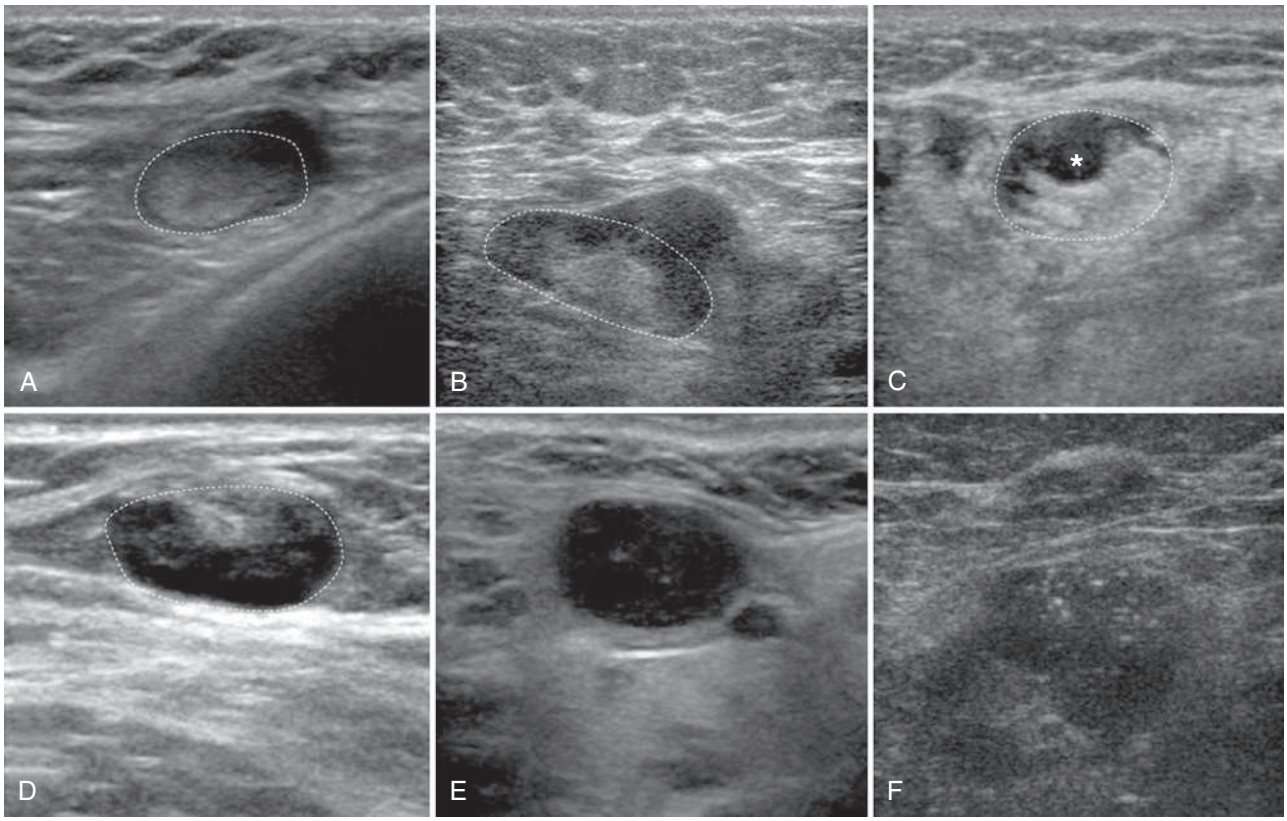

FIG. 21.73 Hallmark of Lymph Node Metastasis: Spectrum of Cortical Thickening. In **A–D,** the anticipated outline of a normal node is shown in dotted line. **(A)** Metastases that implant near the midcortical sinusoids tend to thicken the cortex focally and equally in inward and outward directions. **(B)** Metastases that implant within the subcapsular sinusoids tend to cause focal, outwardly bulging cortical thickening ("mouse ear"). **(C)** Metastases that implant toward the inner part of the cortical sinusoids cause focal cortical thickenings that bulge inwardly into the lymph node mediastinum ("rat bite" defect, *). **(D)** Metastases that implant extensively throughout the cortical sinusoids can cause symmetrical cortical thickening indistinguishable from the cortical thickening caused by inflammation. **(E)** Cortical thickening so severe that the hilum is obliterated is usually caused by metastasis and is strongly against the node being benign and reactive. **(F)** Microcalcifications within a lymph node indicate metastasis until proved otherwise, especially if the primary breast lesion has microcalcifications.

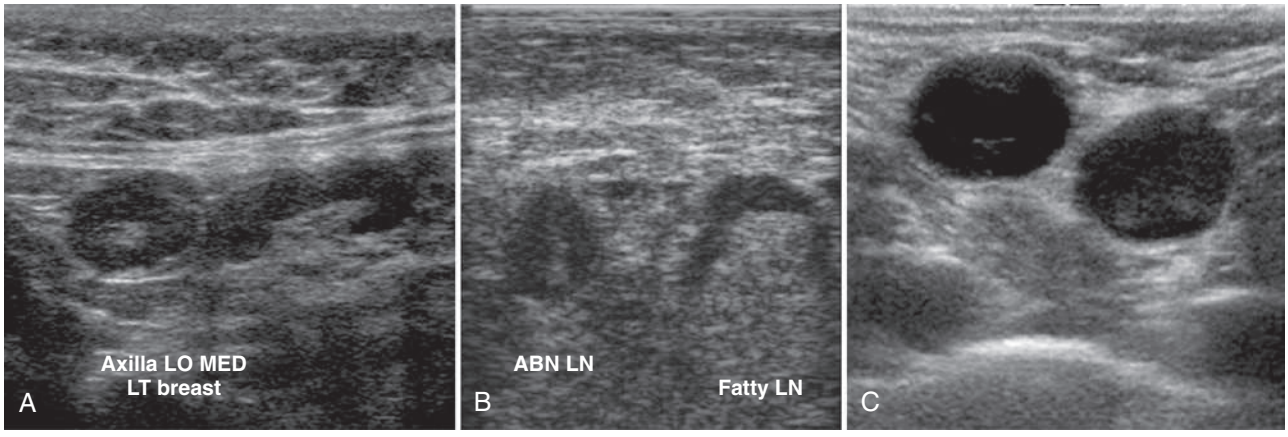

FIG. 21.74 Comparison With Adjacent Lymph Nodes to Assess Significance of Symmetrical Cortical Thickening. (A) When adjacent lymph nodes within the axilla show similar degrees of symmetrical cortical thickening, the lymph nodes are more likely reactive than metastatic. If contralateral axillary lymph nodes show similar degrees of thickening, the risk of metastasis is reduced even further. **(B)** If the adjacent lymph node shows normal cortical thickness, the risk of metastasis in the node with symmetrical cortical thickening is increased. **(C)** When the cortical thickening is so severe that the mediastinum of the lymph node is obliterated, the cause should be assumed to be metastatic, even when adjacent lymph nodes are involved to a similar degree.

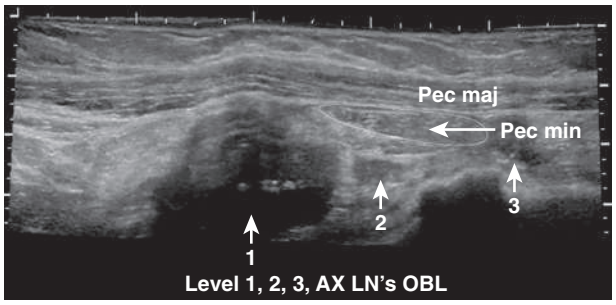

FIG. 21.75 Metastases to Three Lymph Node Levels. Extended–field-of-view (FOV), obliquely oriented sonogram shows metastasis to all three levels of axillary lymph nodes. Massive adenopathy and microcalcifications are seen in a level 1 lymph node that lies lateral and inferior to the pectoralis minor muscle *(dotted oval)*. A mildly enlarged level 2 lymph node lies posterior to the pectoralis muscle. A moderately enlarged level 3 lymph node with a microcalcification lies superior and medial to the pectoralis muscle.

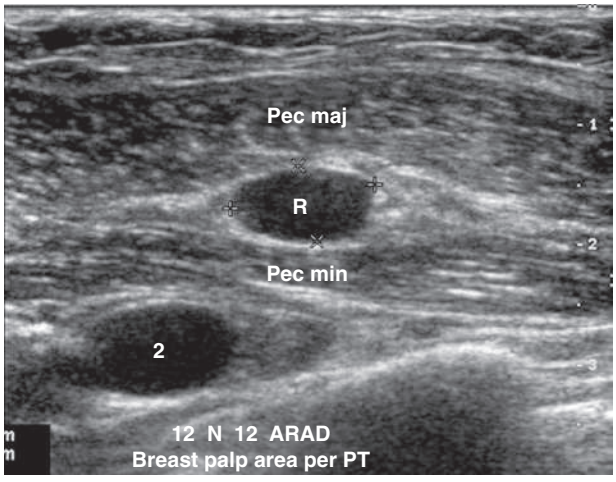

FIG. 21.76 Metastasis to Level 2 and Rotter Lymph Nodes. Rotter lymph nodes *(R)* lie between the pectoralis minor and major muscles at the same level as level 2 lymph nodes *(2)* and, if unrecognized, can be a source for chest wall invasion. This patient has gross metastasis that obliterates the mediastinum of level 2 and Rotter lymph nodes.

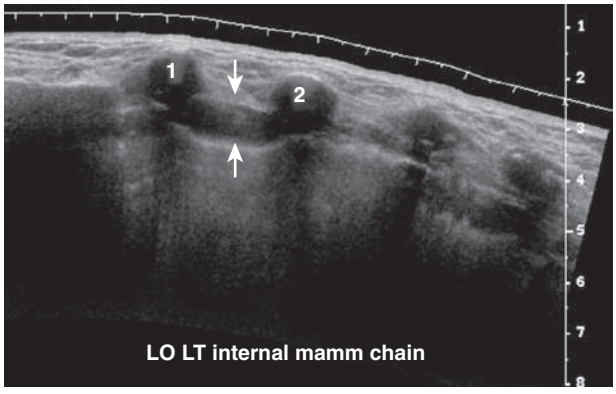

FIG. 21.77 Metastasis to Internal Mammary Lymph Nodes. Long-axis extended–field-of-view (FOV) image shows a gross internal mammary lymph node metastasis *(between arrows)* lying between the first *(1)* and second *(2)* costal cartilages.

internal mammary nodal metastases, the radiation oncologist will add an internal mammary field to the treatment. Internal mammary lymph node metastasis is most common in the first three interspaces just lateral to the sternum.

Sonographic–Magnetic Resonance Imaging Correlation

The role of contrast-enhanced MRI for breast cancer screening as well as diagnostic evaluation has expanded greatly in recent years, along with the role of ultrasound correlation after MRI. Because of the high rate of false-positive results with contrast-enhanced breast MRI, treatment decisions require histologic confirmation of the cause of abnormal enhancement. Thus image-guided biopsy of abnormal areas of enhancement is necessary. However, MRI-guided biopsies can be costly, time-consuming, less readily accessible, and uncomfortable for the patient. Therefore patients are often taken for second-look ultrasound of the targeted area to see if the biopsy can be performed with ultrasound instead. Second-look breast ultrasound can be very effective at confirming the presence of additional ipsilateral or contralateral foci of invasive breast cancer identified on MRI and targeting the finding for biopsy (Fig. 21.78). Similarly, if a probably benign lesion seen on MRI has an ultrasound correlate, this lesion can be followed with ultrasound instead of MRI.

The challenge of second-look ultrasound examinations is confirming that the finding seen on MRI truly correlates with the ultrasound finding. Approximately 50% to 70% of lesions seen on MRI can be found on second-look ultrasound.[89,90] Masses are more easily identified than nonmass enhancement.[89,90] Although it seems intuitive that larger masses would be more easily visualized than smaller masses, this has not been consistently shown in these studies. As a result, it is quite possible to perform a second-look ultrasound and not find an ultrasound correlate. Alternatively, it is also possible to mistakenly correlate an incidental ultrasound finding with the MRI target. If biopsy of this area is then performed with ultrasound, there is the chance of leaving the MRI target unsampled. Therefore it is worthwhile to pause before recommending a second-look ultrasound for smaller, subtle areas of nonmass enhancement seen on MRI, especially if one is sufficiently concerned regarding malignancy and believes that biopsy is warranted. It may be that MRI-guided breast biopsy is the preferred approach for these patients.

If a second-look ultrasound examination is performed for a suspicious MRI finding and identifies a correlate, there is a greater chance that this MRI finding is malignant.[91] Therefore it is worth sampling. This raises the issue of pretest probability for different types of ultrasound examinations. Breast ultrasound involves three different patient groups, each with a different prevalence of breast cancer (pretest probability): the screening group, the diagnostic group, and the MRI correlation group. Different sets of rules are needed for interpreting studies in these patients. In the screening group the risk of cancer will be about 3 to 6 per 1000 patients (0.3%-0.6%). In the diagnostic group the risk will be about 3% to 8%, and in the MRI correlation group the risk is 30% to 60%.[89,90,92] In the screening group, we must deemphasize

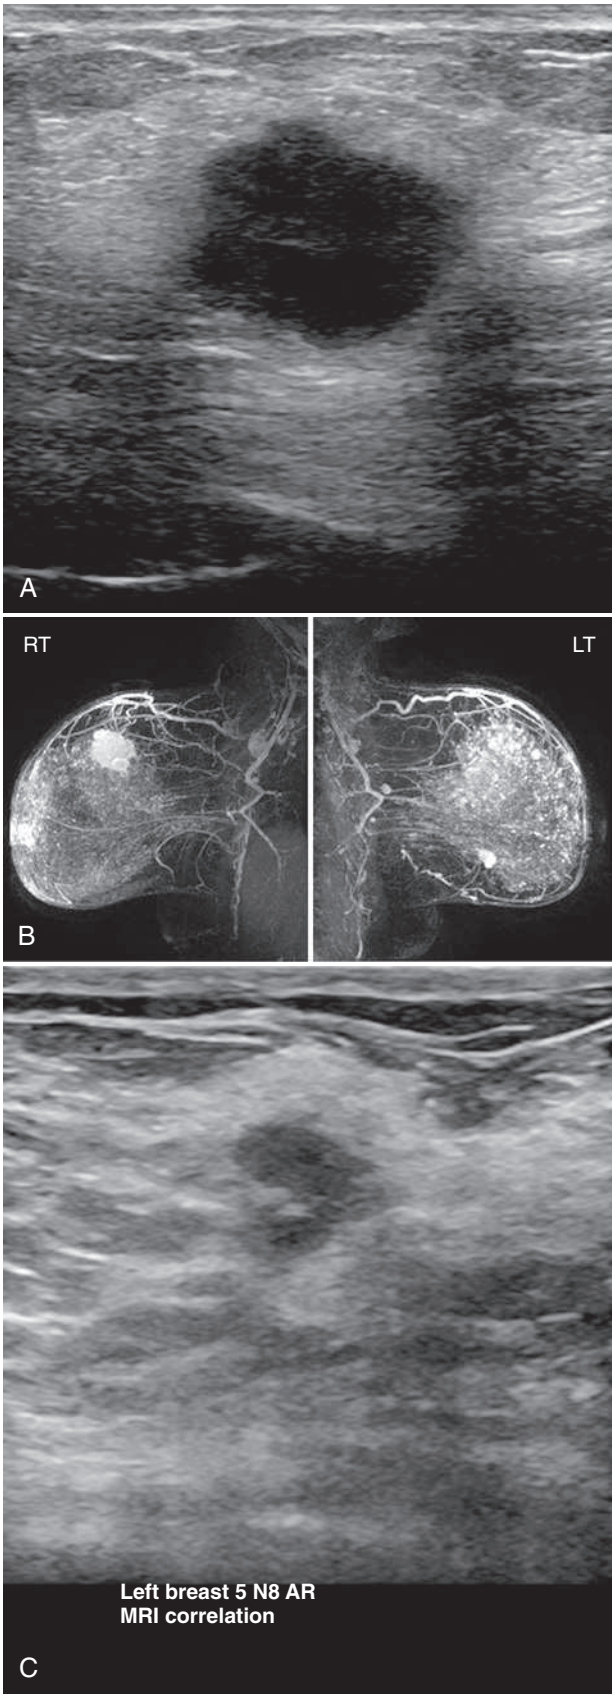

FIG. 21.78 Contralateral Invasive Carcinoma Detected on Magnetic Resonance Imaging (MRI) and Verified on "Second-Look" Ultrasound. (A) Targeted diagnostic sonogram of a high-grade invasive carcinoma in upper right breast that manifested as a palpable lump. Ultrasound-guided biopsy showed high-grade invasive carcinoma. **(B)** Staging MRI showed right breast carcinoma and an enhancing mass inferiorly in the contralateral left breast. **(C)** Second-look ultrasound showed irregular mass corresponding to the left breast lesion on MRI. Ultrasound-guided biopsy showed synchronous high-grade invasive duct carcinoma.

soft, subtle findings. In the diagnostic group, we weight soft and hard findings almost equally, and in the MRI correlation group, we weight soft findings heavily (Fig. 21.79).

ULTRASOUND-GUIDED INTERVENTION

The use of sonography for guiding interventional procedures is almost unlimited. Any type of interventional procedure for a lesion that is visible with sonography can be guided by sonography. Ultrasound can be used to guide cyst aspiration (Fig. 21.80), needle localization for surgical biopsy with specimen sonography (Fig. 21.81), sentinel node injection, sentinel node localization, abscess drainage, percutaneous ductography, foreign body removal (broken localization wires), percutaneous removal, and biopsy using fine needles, spring-loaded needles (Fig. 21.82), and vacuum assistance (Fig. 21.83). Sonography can be used to locate and orient the lumpectomy cavity for booster doses of external radiation, to guide placement of brachytherapy needles, and to place partial-breast irradiation balloons. It can also be used to guide lesion ablation using laser, radiofrequency, and cryotherapy. Sonographic guidance is usually quicker, more precise, and less expensive than mammographic, stereotaxic, or MRI guidance. Ultrasound guidance is truly a real-time procedure, whereas stereotaxic and MRI guidance are not.

When targeting a mass for histologic sampling, biopsy is the most preferred approach, and a 14-gauge biopsy device is sufficient. Different types of biopsy devices exist that have different mechanisms of action. Some function by having the biopsy device sample the breast tissue when it is fired in the breast (see Fig. 21.82; Video 21.5). These biopsy devices are associated with a throw of approximately 2 cm when fired. Others allow the 2-cm throw to occur outside of the patient's breast, and perform the actual sampling only while in the breast tissue. This is helpful for areas that are deep within the breast and there is concern for injuring the chest wall while firing the biopsy device. This also can be helpful if choosing to sample an axillary lymph node using a biopsy device because there is increased probability of injuring adjacent blood vessels and causing hematoma with a device that fires within the breast. Another form of biopsy device uses vacuum assistance wherein no firing is involved. The biopsy device is placed beneath the target. The vacuum then sucks the targeted area into the aperture and removes it (Fig. 21.83). This type of biopsy device does not need to be removed from the breast after each sample, and therefore there is less risk of losing

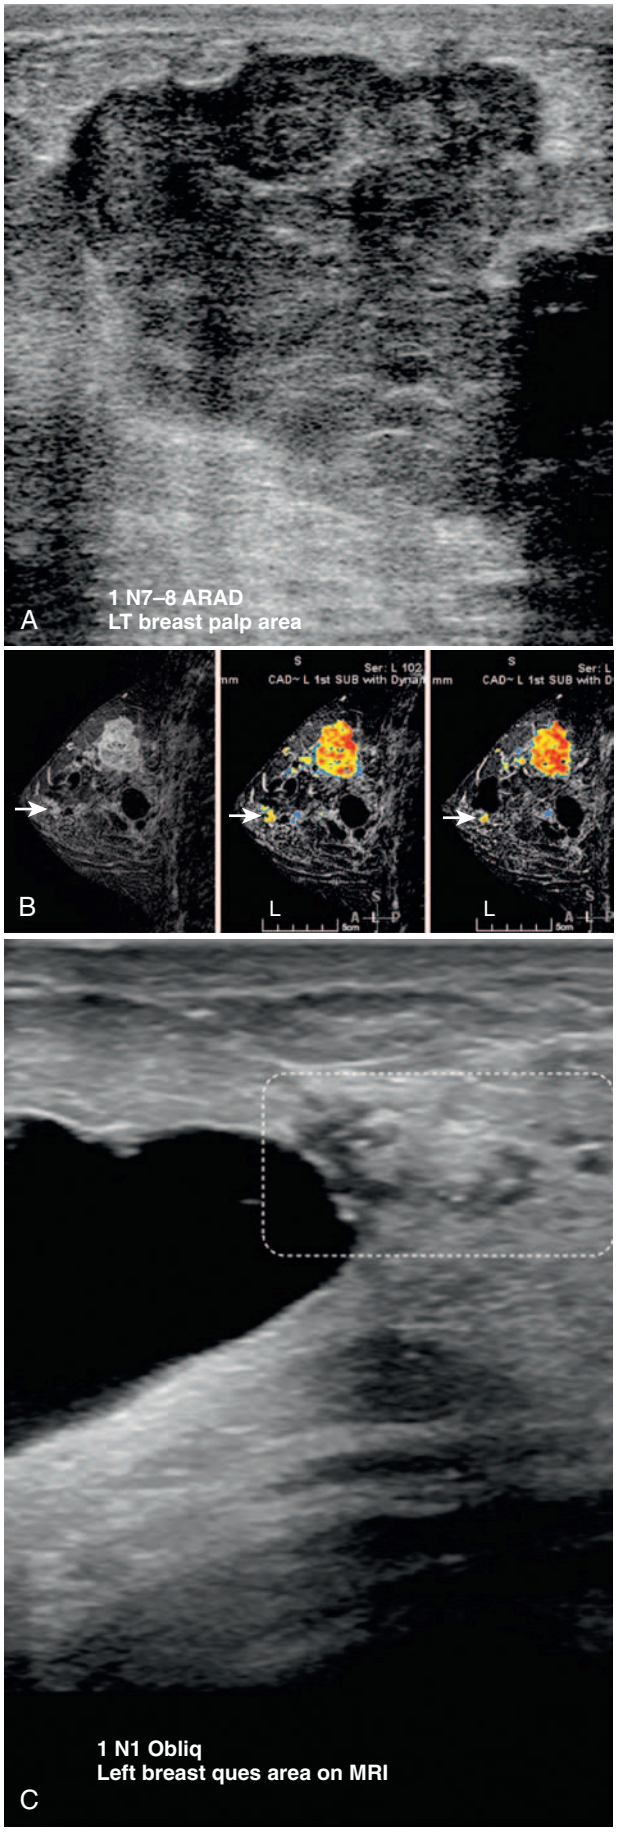

FIG. 21.79 High-Grade Invasive Duct Carcinoma With Second in Situ Lesion With Only "Soft" Finding at Presentation. (A) Targeted diagnostic ultrasound shows an irregularly shaped mass that appeared as a palpable lump. Ultrasound-guided biopsy showed high-grade invasive ductal carcinoma. **(B)** Magnetic resonance imaging (MRI) shows an ipsilateral nonmasslike area *(arrow)* of clumped enhancement farther inferiorly that lies just inferior to a large cyst. **(C)** Second-look ultrasound shows no mass. Only the soft findings of branching ducts and microcalcifications *(within dotted box)* next to a large, simple cyst correspond to clumped enhancement on MRI. Ultrasound-guided vacuum biopsy showed intermediate–nuclear-grade in situ carcinoma.

the target. This is most helpful for intraductal masses or complex cystic masses, in which the cystic component is likely to disappear after initial sampling, making the target less visible with each subsequent pass. Vacuum assistance can also be helpful for masses containing calcifications.

A marker should be placed after every ultrasound-guided biopsy. The reason is that if the biopsy reveals malignant or atypical histology, a needle localization excisional biopsy will frequently be necessary. This marker can be targeted by needle localization when the area is ultimately surgical excised. In addition, if the lesion is malignant, the patient may receive chemotherapy before surgery. After chemotherapy, all imaging evidence of the lesion may disappear, but the marker will continue to denote the area of prior cancer. Finally, the presence of markers placed in a benign lesion helps immensely in interpreting follow-up mammograms. Future imagers will know that the area has undergone biopsy and is benign.

Axillary lymph nodes can be sampled using fine-needle aspiration with smaller-gauge needles, often ranging from 22 to 25 gauge, or with core biopsy. The method of sampling is typically chosen based on radiologist and pathologist preference. Therapeutic and diagnostic aspiration of cysts can be performed with fine-needle aspiration, typically with a larger-gauge needle of 16 to 18 gauge. If the fluid is thick, even larger-gauge needles may be used, including the coaxial introducers from the biopsy device. If the aspirate is benign appearing with colors including black, green, yellow, and clear, then the fluid can be discarded. If the aspirate is bloody, then it should be sent to the cytology department for analysis and a marker should be placed in the breast. Should the aspirate be found to be atypical or malignant, the marker is then present to guide future surgery.

The recommended technique for most procedures, but most importantly for biopsies with devices that have a throw, is to place the **needle along the long axis of the transducer,** enabling the needle to be visualized along its entire course in real time throughout the entire procedure. This is most important to ensure that the biopsy device does not extend into the chest wall musculature during sampling. The main difficulty encountered during a long-axis approach is in keeping the needle and the long axis of the transducer exactly parallel to each other. Watching the ultrasound monitor before the needle has passed far enough into the breast to be within the ultrasound beam is the main cause of misalignment. It is best to watch one's hands until the needle is deep enough within the breast to be within the

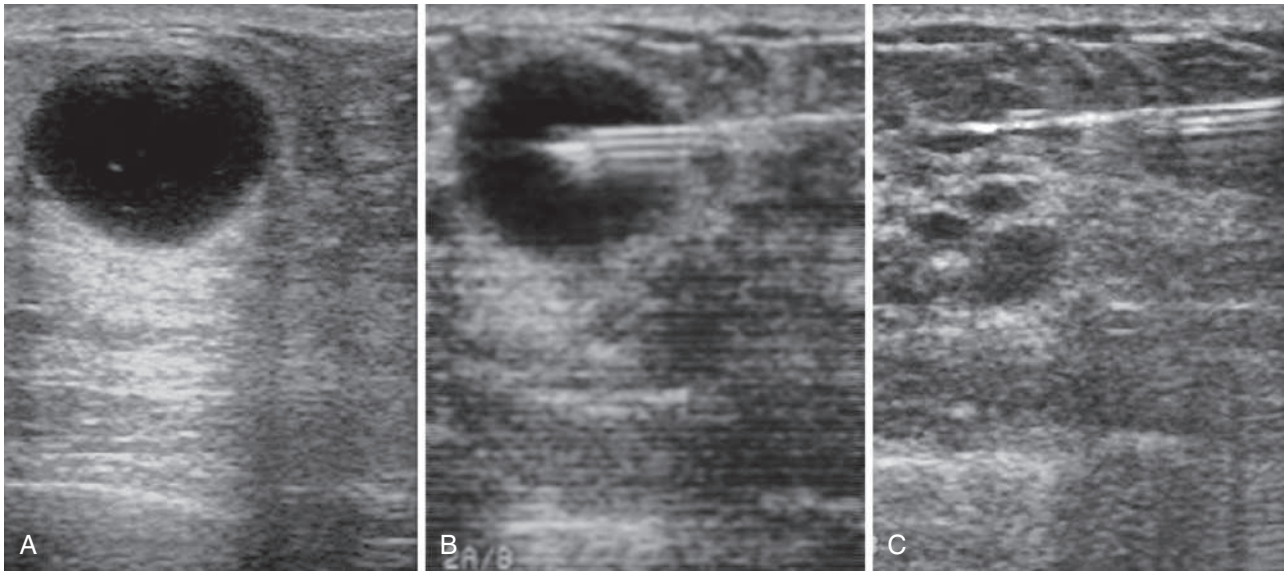

FIG. 21.80 Technique of Needle Aspiration and Biopsy. Ultrasound images show tender, simple tension cyst **(A)** before aspiration; **(B)** during aspiration; and **(C)** after aspiration. Ultrasound-guided interventional procedures of the breast are performed with the needle oriented along the long axis of the transducer, with angulation of the needle and appropriate heeling or toeing of the transducer to place the needle almost parallel to the transducer face and perpendicular to the ultrasound beam. A steeper angle can be used for aspirations because there is no throw associated with the procedure that might injure underlying chest wall structures.

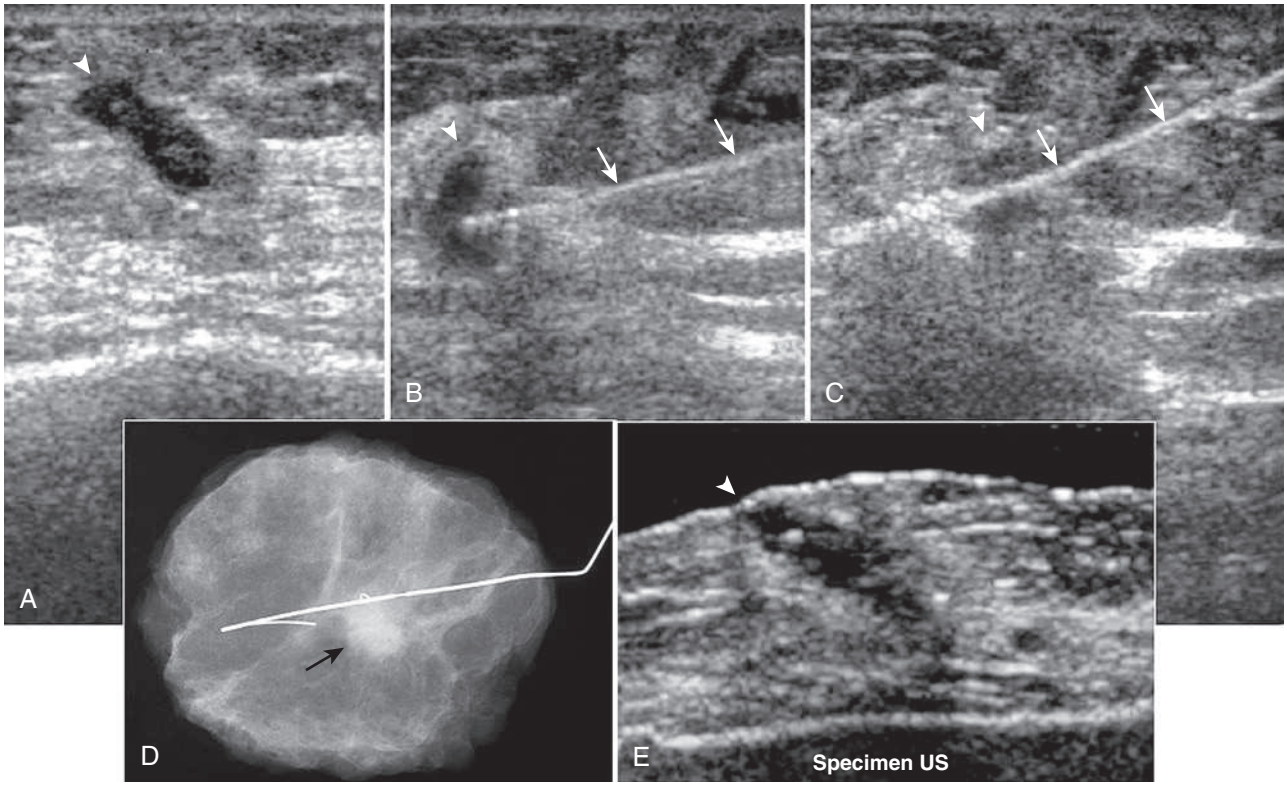

FIG. 21.81 Ultrasound-Guided Wire Localization for Excisional Biopsy. (A) Nodule *(arrowhead)* before the procedure. **(B)** Nodule *(arrowhead)* with the localization needle *(arrows)* in place. **(C)** Localization wire *(arrows)* in place after the needle is removed (*arrowhead,* nodule). **(D)** Specimen radiograph shows the nodule *(arrow)* in center of specimen. **(E)** Specimen sonogram, however, shows the nodule extending to superficial margin of specimen *(arrowhead).*

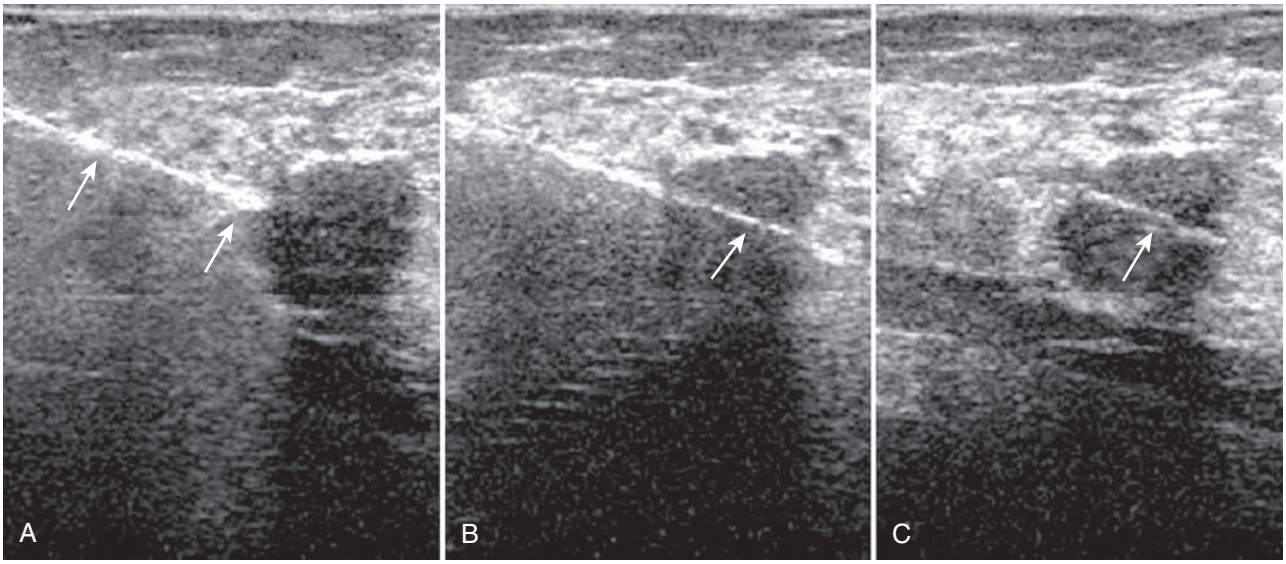

FIG. 21.82 Ultrasound-Guided Needle Biopsy With a 14-Gauge Needle. (A) Needle *(arrows)* has been advanced to the edge of the nodule in the prefire position. **(B)** Needle *(arrow)* has been fired through the nodule and now is in the postfire position. **(C)** Needle has been withdrawn, but a vapor trail of microbubbles *(arrow)* can still be seen within the needle tract, which documents that the needle did pass through the target nodule.

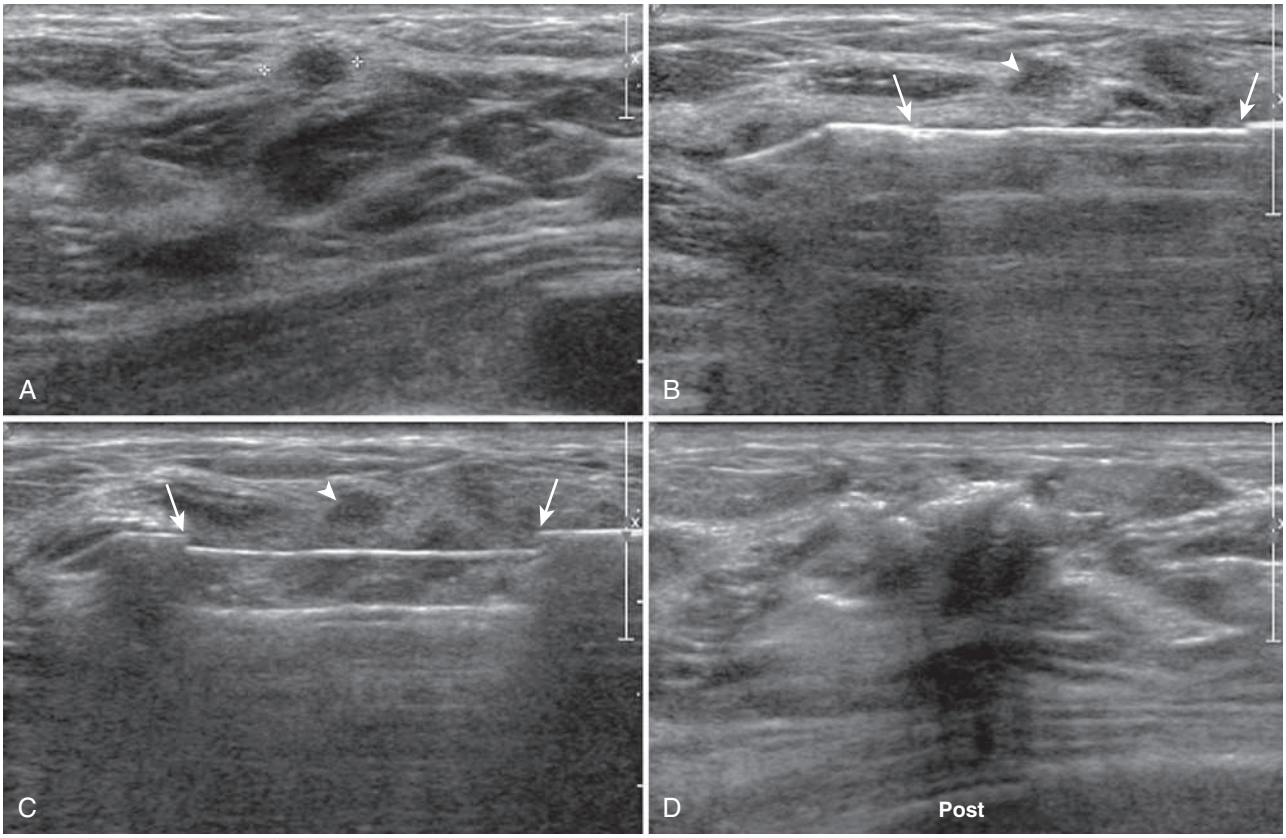

FIG. 21.83 Ultrasound-Guided Directional Vacuum-Assisted Biopsy With 10-Gauge Needle. (A) High-grade 5-mm invasive ductal carcinoma *(calipers)*. **(B)** Vacuum probe has been placed just deep to the lesion, with the closed aperture *(arrows)* just deep to the nodule *(arrowhead)*. **(C)** Aperture has been opened *(arrows)* and is beneath the mass *(arrowhead)*. There is ring-down artifact deep to the aperture created by the vacuum holes. **(D)** Lesion has been removed and a marker placed, consisting of air-impregnated pellets, one of which contains a metallic clip.

ultrasound beam before moving the eyes to the ultrasound monitor. Once the needle is within the beam, it is relatively easy to keep it precisely parallel to the beam. When performing cyst aspirations and fine-needle aspirations of lymph nodes, the needle can be placed at a steeper angle, because there is no firing involved and the needle does not advance past the target. As a result, there is less risk of injuring underlying chest wall structures. That being said, an angle that is too steep will make needle visualization more challenging.

CHAPTER 22

The Scrotum

Daniel Sommers and Thomas Winter

SUMMARY OF KEY POINTS

- Diagnostic ultrasound is an accurate means of evaluating most scrotal processes and can supplement the physical examination.
- Solid intratesticular lesions have a high likelihood of malignancy, whereas cystic extratesticular intrascrotal lesions are almost certainly benign.
- Doppler sonography is the most useful and most rapid technique to assess the patient with acute scrotal pain. Ultrasound can establish the diagnosis of testicular ischemia and help distinguish torsion from other causes of acute pain such as epididymitis and epididymo-orchitis.
- In the setting of acute scrotal trauma, sonography has a primary role to evaluate the continuity of the tunica albuginea and assess for testicular rupture, which requires early surgical intervention.
- Varicocele is the most common correctable cause of male infertility and is diagnosed by ultrasound by visualization of dilatation of the veins (>2-3 mm and increasing in size with Valsalva maneuver or standing) of the pampiniform plexus located posterior to the testis.

CHAPTER OUTLINE

SONOGRAPHIC TECHNIQUE
NORMAL ANATOMY
INTRATESTICULAR SCROTAL MASSES
Malignant Tumors
Germ Cell Tumors
Non–Germ Cell Tumors

Postvasectomy Changes in the Epididymis
Chronic Epididymitis
Sarcoidosis
ACUTE SCROTAL PAIN
Torsion
Epididymitis and Epididymo-orchitis
Fournier Gangrene
TRAUMA
CRYPTORCHIDISM

Diagnostic ultrasound is the most common imaging technique used to supplement the physical examination of the scrotum and is an accurate means of evaluating many scrotal processes. Technical advancements in high-resolution real-time sonography and the ability of color and power Doppler sonography to evaluate testicular perfusion have improved and expanded the clinical applications of scrotal sonography to include (among other indications) assessment of scrotal masses, evaluation of acute scrotal pain, evaluation of scrotal trauma, assessment of varicoceles in the infertility workup, assessment for tumors and metastatic disease, and evaluation of an undescended testis.

SONOGRAPHIC TECHNIQUE

Scrotal ultrasound examination is performed with the patient in the supine position. The scrotum is elevated on top of a towel draped over the thighs, and the penis is placed on the patient's abdomen and covered with a towel. Optimal results are typically obtained with a high-frequency (14-18 MHz) linear array transducer. If greater penetration is needed because of scrotal swelling, a lower-frequency transducer may be used. A direct-contact scan is performed using acoustic coupling gel. Images of both testes are obtained in transverse and sagittal planes. The

Scrotal Sonography: Current Uses

Evaluation of location and characteristics of scrotal masses
Evaluation of acute scrotal pain
Evaluation of scrotal trauma, including surgical or iatrogenic injury
Evaluation for varicoceles in infertile men
Evaluation of testicular ischemia with color and power Doppler sonography
Follow-up of patients with previous testicular neoplasms, lymphoma, or leukemia
Detection of occult primary tumor in patients with known metastatic disease
Localization of the undescended testis

size and appearance of each testis and epididymis should be noted and compared to the contralateral structures. Color and pulsed Doppler parameters should be optimized to evaluate for low flow velocities and to demonstrate blood flow in the testes and surrounding structures. Transverse images including portions of both testes should be acquired in gray-scale and color Doppler modes to demonstrate symmetry. Scrotal structures should be examined thoroughly to evaluate for extratesticular masses or processes. Additional techniques, such as upright positioning of the patient or performing the Valsalva maneuver, may be used to evaluate venous vascularity for varicocele or for inguinal hernia assessment.

NORMAL ANATOMY

The normal scrotal wall consists of the epidermis, superficial dartos muscle, dartos fascia, external spermatic fascia, cremasteric muscle and fascia, and internal spermatic fascia. The scrotum is a fibromuscular sac that is divided by the midline raphe, forming a right and left hemiscrotum. Each hemiscrotum contains a testis, epididymis, spermatic cord, and vascular and lymphatic networks (Fig. 22.1).

The two layers of the **tunica vaginalis** separate the testis from much of the scrotal wall and form an isolated mesothelial lined sac.[1,2] During embryologic development, the tunica vaginalis arises from the **processus vaginalis,** an outpouching of fetal peritoneum that accompanies the testis in its descent into the scrotum. The upper portion of the processus vaginalis, extending from the internal inguinal ring to the upper pole of the testis, is normally obliterated. The lower portion, the tunica vaginalis, remains as a closed pouch within each hemiscrotum, partially folded around the testis. Only the posterior aspect of the testis, the site of attachment of the testis and epididymis, is not in continuity with the tunica vaginalis.

The inner or visceral layer of the tunica vaginalis covers the testis, epididymis, and lower portion of the spermatic cord. The outer or parietal layer of the tunica vaginalis lines the walls of the scrotal pouch and is attached to the fascial coverings of the testis. A small amount of fluid is normally present between these two layers.[3]

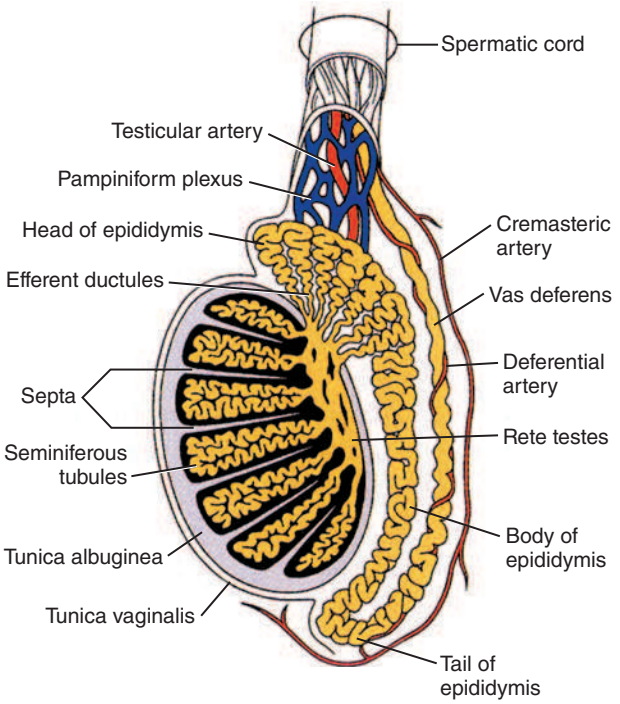

FIG. 22.1 Normal Intrascrotal Anatomy. (With permission from Sudakoff GS, Quiroz F, Karcaaltincaba M, Foley WD. Scrotal ultrasonography with emphasis on the extratesticular space: anatomy, embryology, and pathology. Ultrasound Q. 2002;18[4]:255-273.[78])

The fibrous **tunica albuginea** covers and protects the testis. Posteromedially, the tunica albuginea projects inward into the testis to form the mediastinum. Numerous fibrous septations project inward from the mediastinum, dividing the testis into 250 to 400 lobules. Each lobule consists of one to three seminiferous tubules supporting the Sertoli cells and spermatocytes. The Leydig cells are adjacent to the tubules, within the loose interstitial tissue, and are responsible for **testosterone** secretion.

The adult testes are ovoid glands measuring 3 to 5 cm in length, 2 to 4 cm in width, and 3 cm in anteroposterior dimension. Testicular size and weight decrease with age.[3,4] Sonographically, the **normal testis** has relatively homogeneous, medium-level, granular echotexture (Fig. 22.2A). Prepubertal testes are typically less echogenic than postpubertal testes secondary to incomplete maturation of the germ cell elements and tubules.[5] The tunica (**tunica vaginalis** and **tunica albuginea**) can often be seen as an echogenic outline of the testes. Where the tunica invaginates to form the mediastinum testis, the **mediastinum testis** is sometimes seen as a linear echogenic band extending craniocaudally within the testis (Fig. 22.2C). Its appearance varies according to the amount of fibrous and fatty tissue present. The fibrous septum, or **septula testis,** may be seen as a linear echogenic or hypoechoic structure (Fig. 22.2B).

The **seminiferous tubules** converge to form larger **tubuli recti,** which open into the dilated spaces of the rete testis. The normal **rete testis** can be identified in 20% of patients as a hypoechoic region near the mediastinum.[6] The rete testis drains into the epididymal head via 15 to 20 efferent ductules.

The **epididymis** is a curved structure measuring 6 to 7 cm in length and lying posterolateral to the testis. It is composed

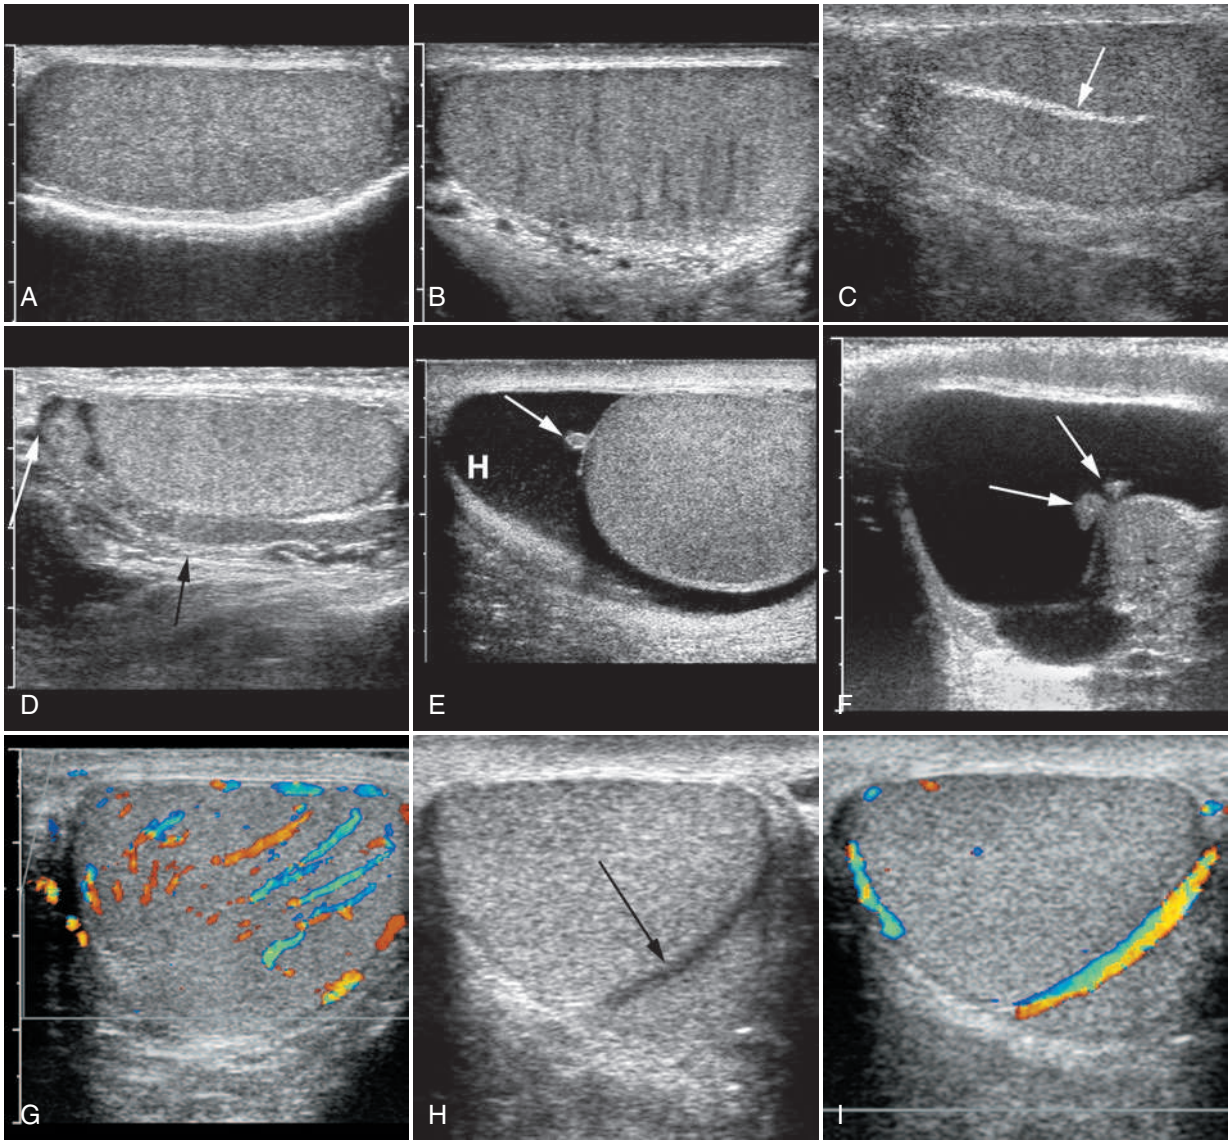

FIG. 22.2 Normal Intrascrotal Anatomy. Longitudinal scans show **(A)** normal homogeneous echotexture of the testis; **(B)** striated appearance of the **septula testis; (C) mediastinum testis** *(arrow)* as a linear echogenic band of fibrofatty tissue; **(D)** head *(white arrow)* and body *(black arrow)* of epididymis; **(E) hydrocele** *(H)* and **appendix testis** *(arrow);* and **(F) appendages of epididymis** *(arrows).* **(G)** Color Doppler scan shows normal testicular arteries. **(H)** Transverse scan shows hypoechoic band of **transmediastinal artery** *(arrow).* **(I)** Color Doppler scan shows transmediastinal artery.

of a head, a body, and a tail. The pyramid-shaped **epididymal head,** or **globus major,** is located at the superoposterior aspect of the testis, measuring 5 to 12 mm in diameter (Fig. 22.2D). It is formed by the efferent ductules from the rete testis, which join together to form a single convoluted duct, the **ductus epididymis.** This duct forms the body and the majority of the tail of the epididymis, measures approximately 6 m in length and follows a convoluted course from the head to the tail of the epididymis. The **body (corpus)** of the epididymis lies adjacent to the posterolateral margin of the testis. The **tail (globus minor)** is loosely attached to the lower pole of the testis by areolar tissue. The ductus epididymis forms an acute angle at the inferior aspect of the globus minor and courses cephalad as the **vas deferens** to the spermatic cord. Sonographically, the epididymal head is normally isoechogenic or slightly more echogenic than the testis, and its echotexture may be coarser. The body tends to be isoechoic or slightly less echogenic than the globus major and testis. The normal body measures less than 4 mm in diameter, averaging 1 to 2 mm.

The **appendix testis,** a remnant of the upper end of the paramesonephric (Müllerian) duct, is a small ovoid structure usually located on the superior pole of the testis or in the groove between the testis and the head of the epididymis. The appendix testis is identified sonographically in 80% of testes and is more readily visible when a hydrocele is present[7] (Fig. 22.2E). The appendix testis may appear stalklike and pedunculated, cystic, or even calcified.[8] The **appendices of the epididymis** are blind-ending tubules **(vasa aberrantia)** derived from the **mesonephric (Wolffian) duct;** they form small stalks, which may be duplicated, and project from the epididymis[9] (Fig. 22.2F). In rare cases,

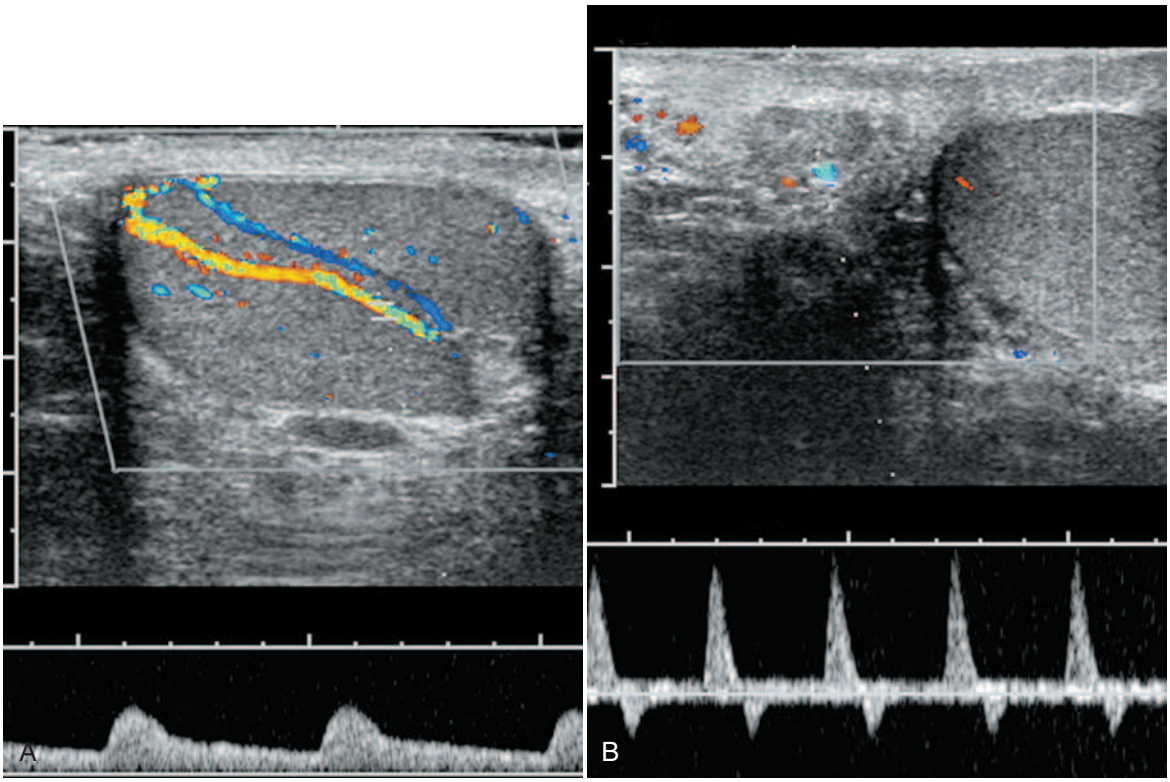

FIG. 22.3 Spectral Doppler of Normal Intratesticular and Extratesticular Arterial Flow. (A) Intratesticular artery has a low-impedance waveform with large amount of end diastolic flow. **(B)** Extratesticular scrotal arterial supply (cremasteric and deferential arteries) has high-impedance waveform with reversed flow in diastole.

other appendages, such as the **paradidymis (organ of Giraldés)** and the superior and **inferior vas aberrans of Haller,** may be seen.[10] The appendages of the epididymis are most often identified sonographically as separate structures when a hydrocele is present.

Knowledge of the arterial supply of the testis is important for interpretation of color flow Doppler sonography of the testis. Testicular blood flow is supplied primarily by the **testicular, deferential,** and **cremasteric (external spermatic) arteries.** The **testicular arteries** arise from the anterior aspect of the aorta immediately below the origin of the renal arteries. They course through the inguinal canal with the spermatic cord to the posterosuperior aspect of the testis. On reaching the testis, the testicular artery divides into branches that pierce the tunica albuginea where the **capsular arteries** form and arborize over the surface of the testis in a layer known as the **tunica vasculosa,** deep to the tunica albuginea. Centripetal branches arise from these capsular arteries; these branches course along the septa to converge on the mediastinum. From the mediastinum, these branches form recurrent rami that course into the testicular parenchyma, where they branch into arterioles and capillaries[11] (Fig. 22.2G). In about 50% of normal testes a **transmediastinal artery** supplies the testis, entering through the mediastinum and coursing toward the periphery of the gland to supply the capsular arteries, and is accompanied by a large vein, frequently seen as a hypoechoic band in the midtestis[11,12] (Fig. 22.2H and I). The transmediastinal artery may be associated with acoustic shadowing obscuring the distal aspect of the testis and giving rise to the "two-tone" testis appearance.[13] The **deferential artery** originates from the superior vesical artery and courses to the tail of the epididymis, where it divides and forms a capillary network. The **cremasteric artery** arises from the inferior epigastric artery. It courses with the remainder of the structures of the spermatic cord through the inguinal ring, continuing to the surface of the tunica vaginalis, where it anastomoses with capillaries of the testicular and deferential arteries.

The velocity waveforms of the **normal capsular** and **intratesticular arteries** show high levels of antegrade diastolic flow throughout the cardiac cycle, reflecting the low vascular resistance of the testis (Fig. 22.3A). Supratesticular arterial waveforms vary in appearance. Two main types of waveforms exist: a low-resistance waveform similar to that seen in the capsular and intratesticular arteries, reflecting the testicular artery; and a high-resistance waveform with sharp, narrow systolic peaks and little or no diastolic flow[14] (Fig. 22.3B). This high-resistance waveform is believed to reflect the high vascular resistance of the extratesticular tissues. The deferential and cremasteric arteries within the **spermatic cord** primarily supply the epididymis and extratesticular tissues, but they also supply the testis through anastomoses with the testicular artery.

The spermatic cord consists of the vas deferens; the testicular, cremasteric, and deferential arteries; a pampiniform plexus of veins; the lymphatics; and the nerves of the testis. It courses superiorly toward the superficial and deep (also called "internal") inguinal rings. Sonographically, the normal spermatic cord lies just beneath the skin and may be difficult to distinguish from

the adjacent soft tissues of the inguinal canal.[15] Distally, it may be visualized within the scrotum when a hydrocele is present or with the use of color flow Doppler sonography.

INTRATESTICULAR SCROTAL MASSES

When a scrotal mass is palpated, the concern is for the presence of a testicular neoplasm. With sonographic examination, intrascrotal masses can be detected with a sensitivity of nearly 100%.[16] Delineation between intratesticular and extratesticular processes is 98% to 100% accurate.[16-19] In general, intratesticular masses should be considered malignant.[19,20] If the mass is extratesticular and cystic, then this process is almost certainly benign, with the general accepted prevalence of malignancy of extratesticular lesions being 3% to 6%.[19,21-24]

Testicular neoplasms account for 1% to 2% of all malignant neoplasms in men and represent the most common nonhematologic malignancy in men in the 15- to 49-year-old age group.[25-27] Most (65%-94%) patients with testicular neoplasms present with painless unilateral testicular masses or diffuse testicular enlargement, and 4% to 14% present with symptoms of metastatic disease.[3,28,29] Approximately 10% to 15% of patients will present with pain and initially may be misdiagnosed as having epididymo-orchitis.[30]

Testicular tumors are subdivided into two major categories: germ cell and stromal tumors, with germ cell tumors accounting for 90% to 95% of all testicular tumors. **Germ cell tumors** arise from primitive germ cells and are further divided into **seminoma** and **nonseminomatous germ cell tumors** (NSGCTs). These tumors are uniformly malignant. Non–germ cell **(sex cord–stromal)** primary tumors of the testis derive from the sex cords **(Sertoli cells)** and the stroma **(Leydig cells)** and are malignant in approximately 10% of cases.[3,29] Nonprimary tumors include lymphoma, leukemia, and metastases and can present as intratesticular masses. Color Doppler imaging has limited ability to distinguish between malignant and benign solid intratesticular masses.[31]

Pathologic Classification of Testicular Tumors

GERM CELL TUMORS
- Seminoma
  - Classic
  - Spermatocytic
- Nonseminomatous germ cell tumors
  - Mixed malignant germ cell
  - Embryonal cell carcinoma
  - Yolk sac tumor (endodermal sinus tumor)
  - Teratoma
  - Choriocarcinoma
  - Placental site trophoblastic tumor
  - Trophoblastic tumor, unspecified
- Regressed tumor

STROMAL TUMORS
- Leydig cell (interstitial)
- Sertoli cell
- Granulosa cell
- Mixed undifferentiated sex cord

MIXED GERM CELL–STROMAL TUMORS
- Gonadoblastoma
- Germ cell–stromal–sex cord, unclassified

METASTATIC NEOPLASMS
- Lymphoma
- Leukemia
- Myeloma
- Carcinoma

OTHER[a]
- Adrenal rests
- Epidermoid cyst
- Malacoplakia
- Carcinoid tumor
- Mesenchymal tumor
- Granulomatous disease

[a]Rare tumors and nonneoplastic tumorous conditions.
Modified from Moch H, Cubilla AL, Humphrey PA, et al. The 2016 WHO classification of tumours of the urinary system and male genital organs-Part A: renal, penile, and testicular tumors. Eur Urol. 2016:70(10):93-105.[32]

Malignant Tumors

Germ Cell Tumors

Intratubular germ cell neoplasia is believed to be the precursor of most germ cell tumors and is the equivalent of carcinoma in situ. It is thought that these abnormal cells develop along a unipotential line and form seminoma, or develop along a totipotential line and form nonseminomatous tumors.[33,34] Seminomas are radiosensitive tumors, whereas NSGCTs respond better to surgery and chemotherapy.[27]

Approximately 95% of primary testicular neoplasms larger than 1.6 cm in diameter show increased vascularity on color flow Doppler examination. However, color Doppler findings do not appear to be important in the evaluation of adult testicular tumors.[35] Color flow may help to identify tumors that are relatively isoechoic with testicular parenchyma,[36] but focal or diffuse inflammatory lesions cannot be distinguished from neoplasms on the basis of color flow Doppler or spectral Doppler findings. Nonpalpable testicular tumors have also been detected with sonography in patients presenting for scrotal discomfort or infertility.[37-40] Incidentally discovered nonpalpable lesions are often benign, but 20% to 30% are malignant.[38,39,41]

Tumor markers have a role in diagnosis, staging, prognosis, and follow-up of a number of germ cell tumors, with three markers having clinical use: **α-fetoprotein, human chorionic gonadotropin,** and, less so, **lactate dehydrogenase.** α-Fetoprotein is produced by the fetal liver, gastrointestinal tract, and yolk sac and is elevated in yolk sac tumors or mixed germ cell tumors containing yolk sac elements. Human chorionic gonadotropin is a glycoprotein produced by syncytiotrophoblasts of the developing placenta. It is elevated in tumors containing syncytiotrophoblasts, including choriocarcinoma and seminoma. Lactate dehydrogenase, although not specific, correlates with bulk of disease and is used in staging.[20]

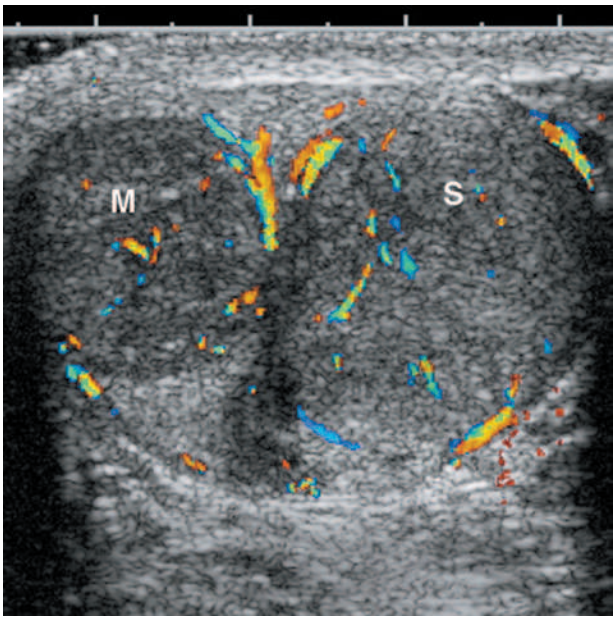

FIG. 22.4 Mixed Tumor. Transverse scan of coexistent solid masses—a mixed germ cell tumor *(M)* and a seminoma *(S)*.

Seminoma. Seminoma is the most common pure, or single cell–type, germ cell tumor in adults, accounting for 35% to 50% of all germ cell neoplasms.[20,30] It is also a common component of mixed germ cell tumors, occurring in 30% of these tumors. Seminomas tend to occur in slightly older patients than do other testicular neoplasms, with a peak incidence in the fourth and fifth decades, and they rarely occur before puberty.[3,42,43] They are typically confined within the tunica albuginea at presentation, with approximately 25% of patients having metastases at diagnosis. As a result of the radiosensitivity and chemosensitivity of the primary tumor and its metastases, seminomas have the most favorable prognosis of the malignant testicular tumors. A **second primary synchronous or metachronous germ cell tumor** occurs in 1% to 2.5% of patients with seminomas (Fig. 22.4).

Seminoma is the most common tumor type in **cryptorchid testes.** Between 8% and 30% of patients with seminoma have a history of undescended testes.[29,43] The risk of a seminoma developing is substantially increased in an undescended testis, even after orchiopexy. Patients with a normally located but atrophic testis have an increased risk of seminoma (Video 22.1). There is also an increased risk of malignancy developing in the contralateral, normally located testis. Therefore sonography is often used to screen for an occult tumor in both testes after orchiopexy.

Seminomas range from a small, well-circumscribed lesion to large masses replacing the testis. Macroscopically, cellular morphology resembles that of primitive germ cells, which are relatively uniform.[25] The sonographic features of pure seminoma parallel this homogeneous macroscopic appearance. Pure seminomas usually have predominantly uniform, low-level echoes without calcification, and they appear hypoechoic compared with normally echogenic testicular parenchyma (Fig. 22.5).[44] Larger tumors may have a more heterogeneous appearance. In rare cases, seminomas become necrotic and appear partly cystic on sonography (Fig. 22.5I).

Nonseminomatous Germ Cell Tumors. NSGCTs include **embryonal carcinomas, teratomas, yolk sac (endodermal sinus) tumors, choriocarcinomas,** and **mixed germ cell tumors.** These tumors occur more often in younger patients than do seminomas, with a peak incidence during the latter part of the second decade and the third decade. They are uncommon before puberty and after age 50. Approximately 70% of NSGCTs produce hormonal markers.[45] Up to 60% of germ cell tumors are mixed germ cell tumors, composed of at least two different cell types.[20,46] Pure NSGCTs are rare and occur more often in the pediatric population.[20] The sonographic appearance of NSGCTs reflects the histologic features and relative proportions of each component, although as a group these tumors are more heterogeneous than seminoma, demonstrating irregular margins, echogenic foci, and solid and cystic components (Fig. 22.6). These malignancies are more aggressive than seminomas, frequently invading the tunica albuginea and resulting in distortion of the testicular contour (see Fig. 22.6). Approximately 60% of NSGCTs have metastatic involvement at presentation.[46]

Mixed germ cell tumors are the most common germ cell tumors, constituting up to 60% of all germ cell tumors. They contain nonseminomatous germ cell elements in various combinations. Seminomatous elements may also be present but do not influence prognosis or treatment.[47] Embryonal carcinoma is the most common component, although any combination of cell types may occur. Imaging features are variable, reflecting the diversity of this group of tumors. Nonseminomatous tumors are not as radiosensitive as seminomas. **Embryonal carcinoma** is composed of primitive anaplastic cells that resemble early embryonic cells. It is present in 87% of mixed germ cell tumors, but in its pure form it is rare, accounting for only 2% to 3% of testicular germ cell neoplasms (Fig. 22.6C).[48] As with other NSGCTs, embryonal cell tumors occur in younger patients than seminomas do, with a peak incidence during the latter part of the second and third decades. The sonographic features of pure embryonal cell carcinoma are nonspecific, especially in children, in whom the only finding may be testicular enlargement without a defined mass.[36,49]

Totipotent germ cells that differentiate toward extraembryonic fetal membranes give rise to **yolk sac tumors,** or **endodermal sinus tumors.** Yolk sac tumors are the most common germ cell tumor in infants younger than 2 years, accounting for 80% of childhood testicular neoplasms.[49] Yolk sac tumor is rare in its pure form in adults, although it is present in 44% of adult cases of mixed germ cell tumor (Fig. 22.6D).[20] Yolk sac tumor is associated with elevated levels of α-fetoprotein in greater than 90% of infants. **Teratomas** constitute 5% to 10% of primary testicular neoplasms. They are defined according to the World Health Organization (WHO) classification on the basis of the presence of derivatives of the different germinal layers (endoderm, mesoderm, and ectoderm). Histologically, teratomas can be divided into mature and immature. The peak incidence is in infancy and early childhood, with another peak in the third decade of life. In infants and young children, teratomas are the second most common testicular tumor after yolk sac tumor and are considered benign, even when they are histologically immature.[43,50,51] Postpubertal testicular teratomas are malignant and

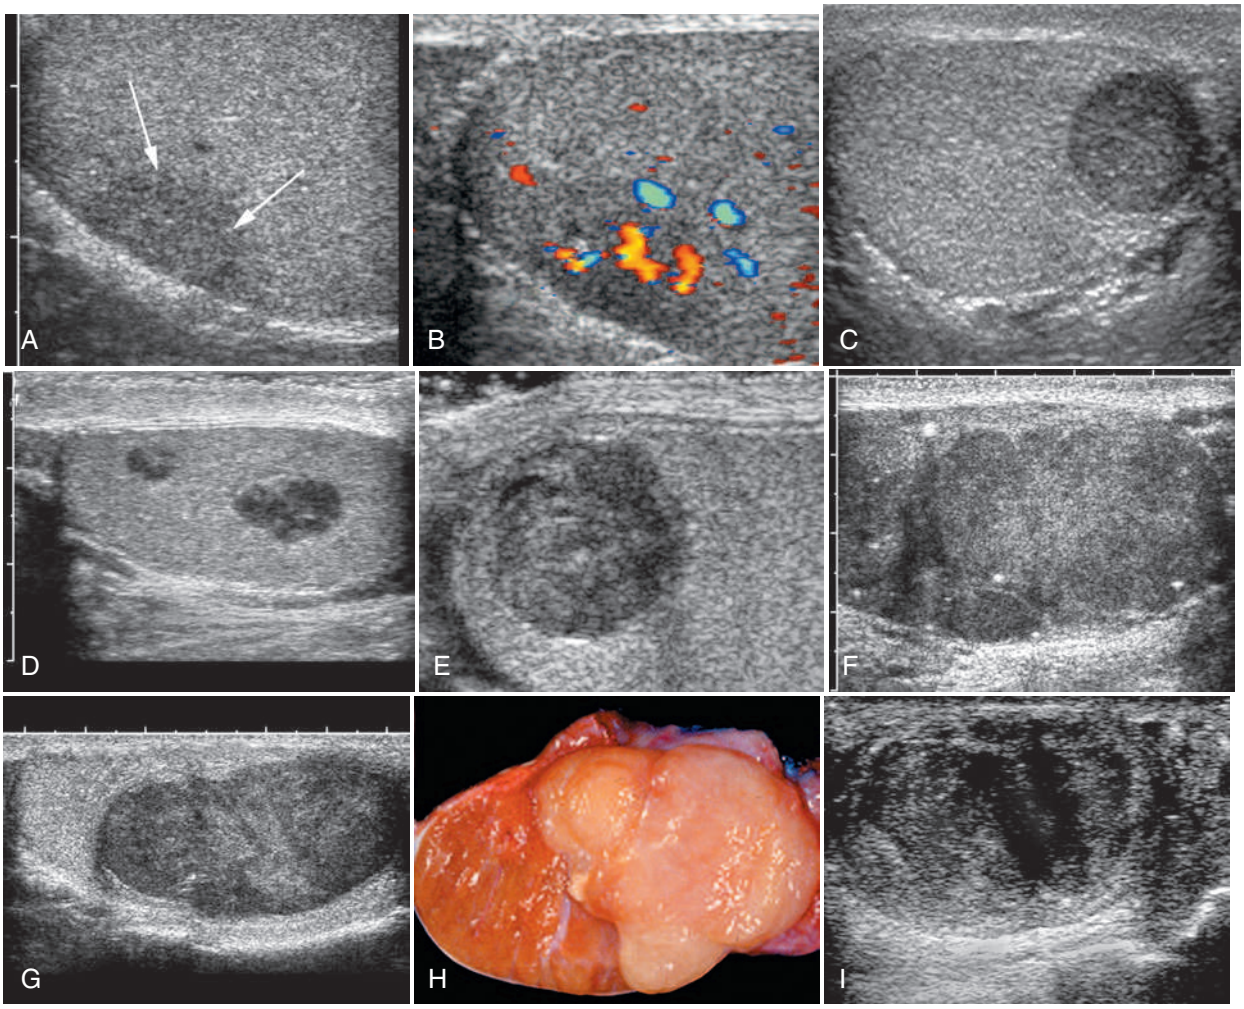

FIG. 22.5 Seminoma: Spectrum of Appearances. have a higher metastatic rate, approximately 20%, than their ovarian counterpart.[52] Teratomas in their pure form are rare in adults, although teratomatous elements occur in approximately half of all adult cases of mixed germ cell tumor (Fig. 22.6B). Both mature and immature teratomas are generally associated with normal tumor markers, although elevated levels of α-fetoprotein or human chorionic gonadotropin may be found.[47] Sonographically, the teratoma is usually a well-defined, markedly heterogeneous mass containing cystic and solid areas of various sizes and appears similar to other NSGCTs. Dense echogenic foci causing acoustic shadowing are common, resulting from focal calcification, cartilage, immature bone, fibrosis, and non-calcific scarring (Fig. 22.6E).[44]

Choriocarcinoma accounts for less than 1% of malignant primary testicular tumors in its pure form but occurs in 8% of mixed germ cell tumors.[20,43,48,50] The peak incidence is in the second and third decades. These tumors are highly malignant and metastasize early by hematogenous and lymphatic routes. The primary tumor and metastases are often hemorrhagic, and patients may have symptoms resulting from hemorrhagic metastases, including hemoptysis, hematemesis, and central nervous system–related symptoms. Focal necrosis of the primary tumor secondary to hemorrhage is an almost invariable feature, and calcification may be present, giving a sonographic appearance similar to the other NSGCTs (Fig. 22.6F). The levels of human chorionic gonadotropin are elevated and cause gynecomastia in 10% of cases.[20,53] Choriocarcinoma has the worst prognosis of any of the germ cell tumors.[50]

Regressed Germ Cell Tumor. Sonography is an important diagnostic tool for patients who present with widespread metastatic testicular carcinoma (Fig. 22.7) even though the primary tumor has involuted (Fig. 22.8); ultrasound is an important component in the search for a primary testicular neoplasm. Mediastinal and central nervous system extragonadal tumors can often present as primary lesions, although retroperitoneal germ cell tumors are more likely to have a testicular origin.[54,55] The primary testicular tumor may regress, despite widespread advancing metastatic disease, resulting in an echogenic fibrous and possibly calcific scar. Regression may be caused by the high metabolic rate of the tumor and vascular compromise from the

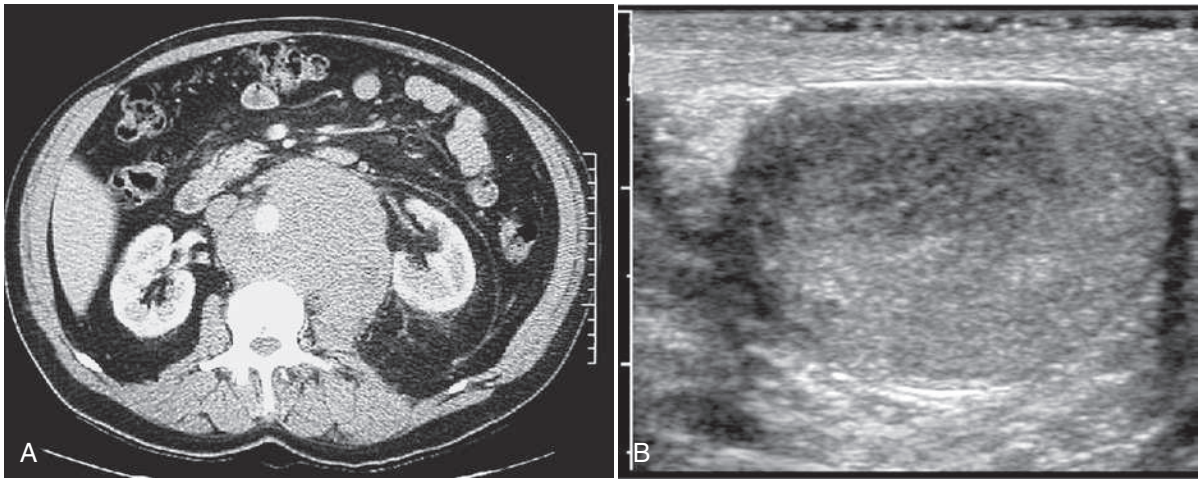

FIG. 22.7 Occult Testicular Seminoma With Retroperitoneal Metastases. (A) Contrast-enhanced CT scan shows extensive retroperitoneal adenopathy from seminoma. **(B)** Longitudinal sonographic scan shows occult homogeneous hypoechoic seminoma. The physical examination of the testis was negative.

tumor outgrowing its blood supply. Tumors are typically clinically occult with the affected testis normal or small on palpation. Histologic analysis may reveal no residual tumor, although intratubular malignant germ cells may be present.[25,28,54] These lesions, also known as **"Azzopardi tumors,"** have a variable sonographic appearance; they can be hypoechoic or hyperechoic or seen as focal calcifications. Although sonographic appearance is not specific for a "burned-out" or regressed tumor, findings are suggestive in the context of histologically proven testicular metastases.[56]

Non–Germ Cell Tumors

Sex Cord–Stromal Tumors. Sex cord–stromal tumors account for 3% to 6% of all testicular neoplasms. The prevalence is greater in the pediatric population where non–germ cell tumors account for 10% to 30% of all testicular neoplasms. The term

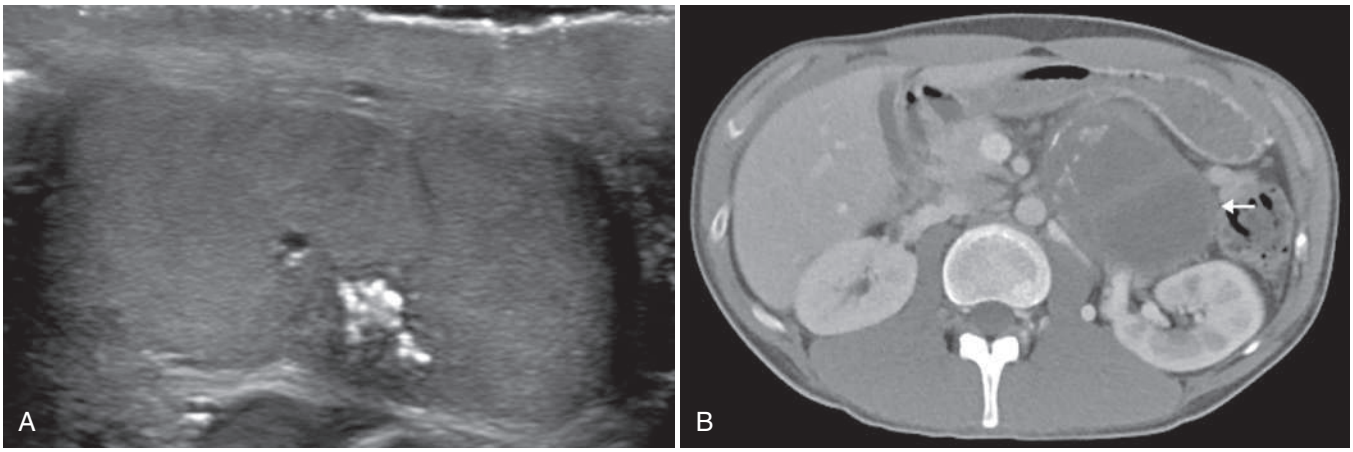

FIG. 22.8 Regressed, or "Burned-Out," Germ Cell Tumor. (A) Longitudinal scan shows a partly calcified nonviable germ cell tumor in a patient with retroperitoneal metastases. Notice the hypoechoic mass around the focus of calcification. **(B)** Contrast-enhanced CT scan in the same patient shows heterogeneous left retroperitoneal adenopathy *(arrow)* from regressed primary testicular teratoma.

sex cord–stromal tumor refers to a neoplasm containing Leydig, Sertoli, thecal, granulosa, or lutein cells and fibroblasts in various degrees of differentiation. These tumors may contain single or multiple cell types because of the totipotentiality of the gonadal stroma.[29]

The most common type of sex cord–stromal tumor is a **Leydig cell tumor,** accounting for 1% to 3% of all testicular neoplasms; these can occur in any age group, although predominantly in patients aged 20 to 50 years.[42,43,53] Patients most often present with painless testicular enlargement or a palpable mass. Approximately 30% of patients present with an endocrinopathy secondary to secretions of androgens or estrogens by the tumor, which may manifest as precocious virilization, impotence, or loss of libido. The tumor is bilateral in 3% of cases. From 10% to 15% of the tumors are malignant, having invaded the tunica at diagnosis. These gonadal tumors are usually small, solid, homogeneous hypoechoic masses on sonography and may show mainly peripheral flow on color Doppler imaging (Fig. 22.9A and B).[57] Foci of hemorrhage and necrosis are present in 25% of tumors,[42,53] and thus cystic spaces due to hemorrhage and/or necrosis are occasionally seen in larger lesions.

Sertoli cell tumors are rare and account for less than 1% of all testicular tumors; they occur with equal frequency in all age groups.[58] They can be of one of three histologic types: **Sertoli cell tumor not otherwise specified, sclerosing Sertoli cell tumor,** or **large cell calcifying Sertoli cell tumor.** The most common presentation is with a painless intratesticular mass. These tumors are less likely than Leydig cell tumors to be hormonally active, although gynecomastia may occur. Sertoli cell tumors may occur in **undescended testes,** in patients with **testicular feminization, Klinefelter syndrome,** and **Peutz-Jeghers syndrome.**[59] Sertoli cell tumors are typically well-circumscribed, unilateral, rounded to lobulated masses. Occasionally, hemorrhage or necrosis may occur, giving a more heterogeneous appearance on sonography. The large-cell calcifying Sertoli cell tumor is a subtype with distinctive clinical, histologic, and sonographic features.[59] These tumors are often bilateral and multifocal and may be almost completely calcified. **Carney complex,** a very rare autosomal dominant multiple endocrine neoplasia syndrome, is often associated with Sertoli cell tumors (Fig. 22.9C).

Additional, less common tumors in this category include **granulosa cell tumors, fibroma-thecomas, and mixed sex cord–stromal tumors** (Fig. 22.9D). Gonadal stromal tumors in conjunction with germ cell tumors are called **gonadoblastomas.** The majority of gonadoblastomas occur in the setting of **gonadal dysgenesis** and **intersex syndromes.**[43,60]

Testicular Metastases

Lymphoma and Leukemia

Lymphoma accounts for 5% of all testicular tumors and is the most common testicular tumor in men older than 60 years, where it can account for up to 50% of intratesticular masses. However, testicular involvement occurs in only 1% to 3% of patients with lymphoma.[29,61] The peak age at diagnosis of lymphoma is 60 to 70 years; 80% of the patients are older than 50 years at diagnosis. Malignant lymphoma is the most common bilateral testicular tumor, occurring bilaterally either in a synchronous or, more often, in a metachronous manner in up to 38% of cases.[60] One-half of bilateral testicular neoplasms are lymphoma.[29,42] Most lymphomas of the testis are B-cell lymphomas, with diffuse large cell lymphoma being the most common. Hodgkin lymphoma of the testis is extremely rare.

Testicular Metastases

LYMPHOMA
Mostly non-Hodgkin lymphoma

LEUKEMIA
Second most common
Acute leukemia: 40%-65%
"Sanctuary" site

NONLYMPHOMA METASTASES

(D) Stromal tumor.** Transverse scan demonstrates a large, heterogeneous tumor (which was a stromal tumor, not otherwise specified) replacing the testis. (**C** courtesy of Theodora Potretzke, MD, Mayo Clinic.)

Testicular lymphoma most frequently occurs in association with disseminated disease, as the initial manifestation of occult nodal disease, or as a site of recurrent disease.[29] True primary lymphoma of the testis has not been conclusively documented.[47] Although most patients with lymphoma of the testis present with a painless intratesticular mass or diffuse testicular enlargement, approximately 25% of the patients have constitutional symptoms, such as fever, weakness, anorexia, or weight loss.

Lymphoma of the testis is often large at diagnosis. The tunica vaginalis is usually intact, but unlike germ cell tumors, extension into the epididymis and spermatic cord is common, occurring in up to 50% of cases.[62] The scrotal skin is rarely involved. Grossly, the tumor is not encapsulated but compresses the parenchyma to the periphery. The sonographic appearance of lymphoma is nonspecific, although generally appears as homogeneous, hypoechoic lesions which may diffusely infiltrate the testis[29]; however, focal hypoechoic lesions can occur (Fig. 22.10). Hemorrhage and necrosis are rare.

Color flow Doppler imaging shows increased vascularity in testicular lymphoma, regardless of lesion size, and the appearance may resemble diffuse inflammation[63] (Fig. 22.10C). Unlike inflammation, lymphoma is usually painless, and the testes are not tender to palpation.

Leukemia is the second most common metastatic testicular neoplasm. Primary testicular leukemia is rare, but leukemic infiltration of the testis during bone marrow remission is common in children.[29,64] The testis appears to act as a "sanctuary" site for leukemic cells during chemotherapy because of the **blood-testis barrier,** which inhibits concentration of chemotherapeutic agents.[64] The highest frequency of testicular involvement is found at autopsy in patients with acute leukemia (40%-65%). Approximately 20% to 35% of patients with chronic leukemia have testicular involvement.[65] Most cases of testicular involvement occur within 1 year of the discontinuation of long-term remission maintenance chemotherapy.

The sonographic appearance of leukemia is nonspecific and similar to lymphoma. Patients most frequently present with diffuse infiltration, which produces diffusely enlarged, hypoechoic testes (Fig. 22.10E).[63] The differential diagnosis includes inflammation.

Extramedullary Myeloma

Involvement of the testis is usually a manifestation of diffuse myeloma, although rarely the testis may be the site of primary **focal myeloma (plasmacytoma).**[66] The testis may have single or multiple nodules that appear hypoechoic and homogeneous

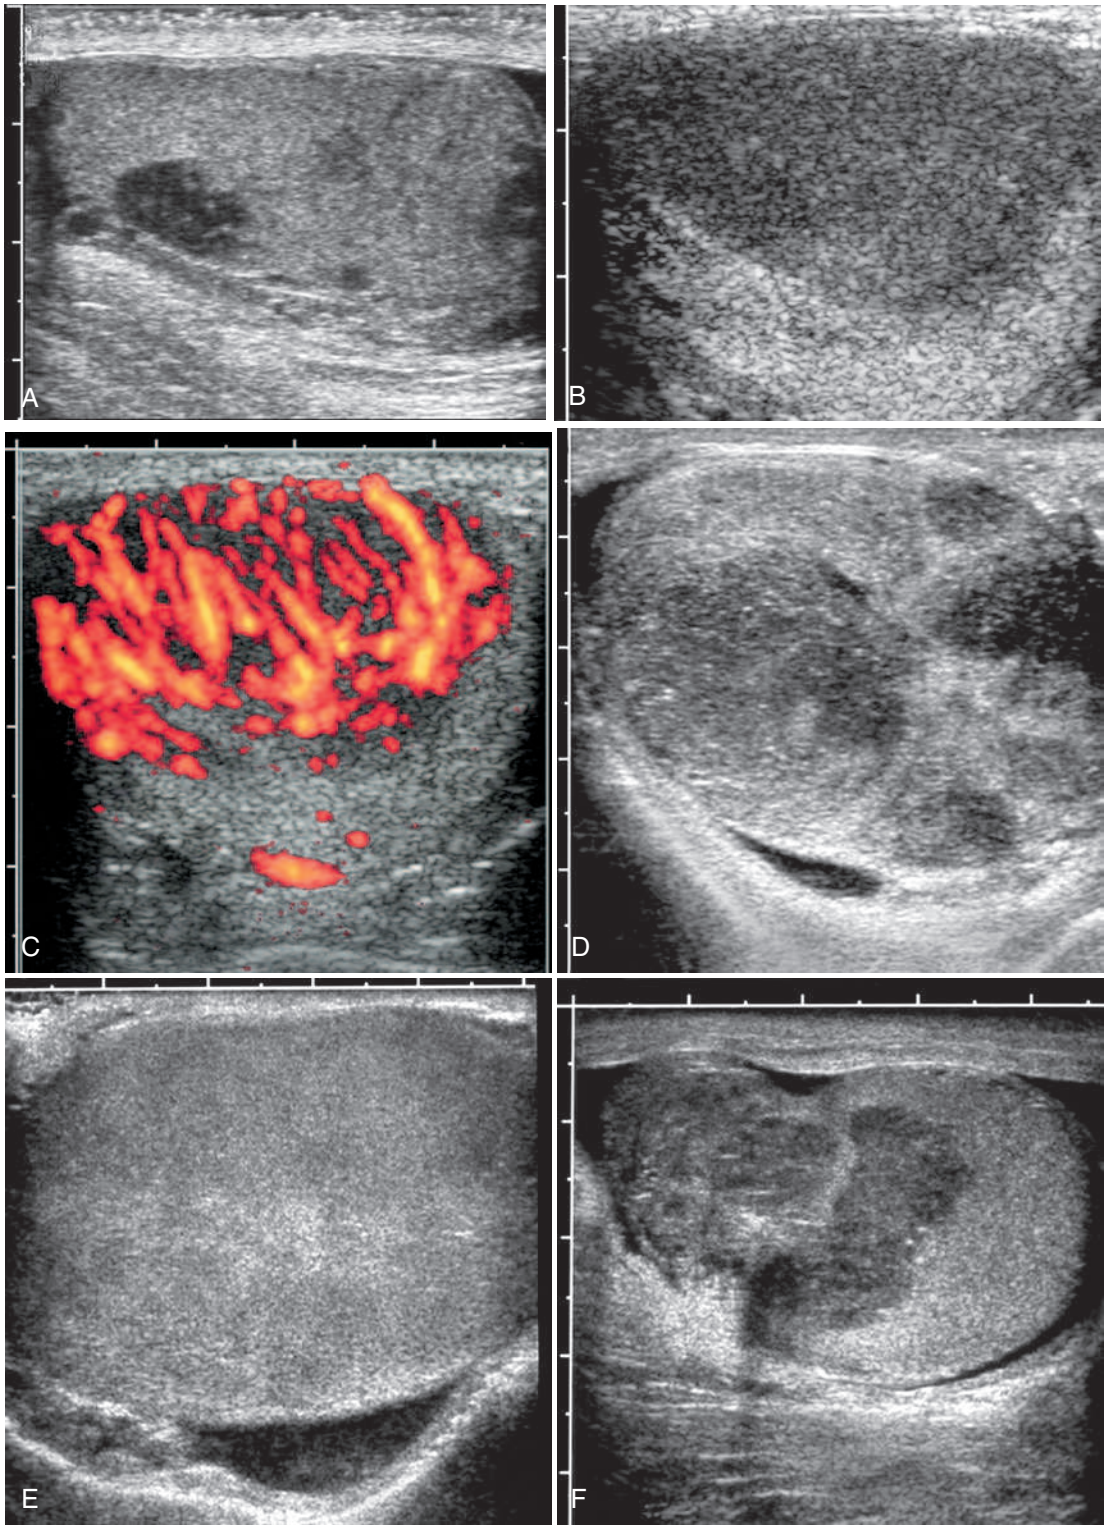

FIG. 22.10 Lymphoma, Leukemia, and Metastases. (A)-(D) Lymphoma. (A) Longitudinal scan shows two subtle hypoechoic foci of lymphoma. In another patient, sagittal gray-scale **(B)** and power Doppler **(C)** images show diffuse, homogeneous hypoechoic hypervascular mass. **(D)** Heterogeneous involvement of the testes in patient with lymphoma. **(E) Leukemia.** Longitudinal scan shows diffuse hypoechoic involvement. **(F) Melanoma metastasis.** Longitudinal scan shows a hypoechoic lobulated mass in the upper pole of the testis and epididymis.

on sonographic examination with marked hypervascularity.[67,68] Bilateral involvement occurs in approximately 20% of cases.[47]

Metastatic Disease

Nonlymphomatous metastases to the testes are uncommon, representing 0.02% to 5% of all testicular neoplasms.[69] The most frequent primary sites are the **lung** and **prostate gland.**[42] Other frequent primary sites for metastatic neoplasms include melanoma, kidney, colon, stomach, and pancreas.[70] Most metastases are clinically silent, being discovered incidentally at autopsy. Testicular metastases are most common in patients during the sixth and seventh decades.[3] They are usually multiple and are bilateral in 15% of cases.[42] Because primary germ cell tumors may also be multicentric and bilateral, these features are not helpful in distinguishing primary from metastatic testicular neoplasms. Widespread systemic metastases are usually present in patients with testicular metastases. Possible routes of metastases to the testis include retrograde venous, hematogenous, retrograde lymphatic, and direct tumor invasion. Metastases from sites remote from the testis, such as the lung and skin, most likely spread hematogenously. Retrograde venous extension through the testicular vein occurs in renal cell carcinoma and may also occur in urinary bladder and prostate tumors.[71] Neoplasms with metastases to the periaortic lymph nodes may involve the testis through retrograde lymphatic extension. Sonographic features of nonlymphomatous testicular metastases vary. The appearance is often hypoechoic but may be echogenic or complex[3] (Fig. 22.10F).

Other rare tumors of the testis include hamartoma (Fig. 22.11), dermoid tumor, hemangioma, intratesticular adenomatoid tumor, carcinoid tumor, carcinoma of the mediastinum testis, neuroectodermal tumor, leiomyoma, Brenner tumor, fibroma, fibrosarcoma, osteosarcoma, chondrosarcoma, and undifferentiated sarcoma, among others.

Benign Intratesticular Lesions

Cysts

Intratesticular cystic lesions are discovered incidentally on sonography in 8% to 10% of men.[72] Benign testicular cysts may be associated with the tunica albuginea, tunica vaginalis, or located within the parenchyma. Cystic testicular lesions are not always benign; testicular tumors (especially NSGCTs) can undergo cystic degeneration from hemorrhage or necrosis. The distinction between a benign cyst and a cystic neoplasm is of utmost clinical importance (Fig. 22.12). Simple intratesticular cysts can be managed conservatively without the need for surgical intervention.[73] Of the 34 cystic testicular masses discovered with sonography by Hamm et al.,[72] 16 were neoplastic, and all of these had sonographic features of complicated cysts. NCGCTs, especially those with teratoma elements, are the most common tumors to contain both cystic and solid components.

Testicular Cystic Lesions

BENIGN
Tunica albuginea cysts
Tunica vaginalis cysts
Intratesticular cysts
Tubular ectasia of rete testis
Cystic dysplasia
Epidermoid cysts
Abscess

MALIGNANT
Nonseminomatous germ cell tumor
Necrosis or hemorrhage in tumor
Tubular obstruction by tumor

Cysts of the tunica albuginea are located within the tunica, which surrounds the testis. They vary in size from 2 to 30 mm and are well defined. They are usually solitary and unilocular but may be multiple or multilocular[72,74] (Fig. 22.12A). The mean age at presentation is 40 years, but cysts also occur in the fifth and sixth decades.[75] The cysts may be asymptomatic, but patients frequently present with cysts that are clinically palpable, firm scrotal nodules. Histologically, they are simple cysts lined with cuboid or low columnar cells and filled with serous fluid.[76] Careful scanning in multiple planes allows delineation of the cyst as arising from the tunica albuginea and clarifies its benign nature. Complex tunica albuginea cysts may simulate a testicular neoplasm.[77]

Cysts of the tunica vaginalis are rare and arise from the visceral or parietal layer of the tunica vaginalis. They may be single or multiple. Sonographically, they usually appear anechoic but may have septations or may contain echoes caused by hemorrhage.[78]

Intratesticular cysts are simple cysts filled with clear serous fluid; they vary in size from 2 to 18 mm.[79] Sonographically, they are well-defined, anechoic cysts with thin, smooth walls and posterior acoustic enhancement. Hamm et al.[72] reported that in all 13 of their cases, the cysts were located near the mediastinum testis, supporting the theory that they originate from the rete testis, possibly secondary to posttraumatic or postinflammatory stricture formation (Fig. 22.12B).

Tubular Ectasia of Rete Testis

Tubular ectasia of the rete testis is a benign, normal variant that may be mistaken for a testicular neoplasm.[80-83] Dilatation of the

(**G** and **H** courtesy of Shane Macauley, MD.)

rete testis is thought to result from obstruction in the efferent tubules or epididymis, with epididymal obstruction caused by inflammation, trauma, or surgery. Sonographic appearance is of multiple fluid-filled tubular structures in or adjacent to the mediastinum testis with no associated soft tissue abnormality and no flow on color flow Doppler imaging (Fig. 22.12C). Rete testis dilatation is often bilateral, asymmetric, and is frequently associated with a spermatocele. The characteristic sonographic appearance and location should allow recognition as a benign condition, thus preventing an orchiectomy. Characteristic findings of the dilated rete testis on magnetic resonance imaging (MRI) include intratesticular signal intensity similar to that of fluid in the region of the mediastinum testis.[80] This appearance is in contrast to the MRI appearance of testicular tumors, which typically have low signal intensity on T2-weighted imaging.

Cystic Dysplasia

Cystic dysplasia is a rare congenital malformation, usually occurring in infants and young children, although one case was reported in a 30-year-old man.[84,85] This lesion is thought to result from an embryologic defect that prevents connection of the tubules of the rete testis and the efferent ductules. Pathologically, the lesion consists of multiple, interconnecting cysts of various sizes and shapes, separated by fibrous septa. This lesion originates in the rete testis and extends into the adjacent parenchyma, resulting in pressure atrophy of the adjacent testicular parenchyma. The cysts are lined by a single layer of flat or cuboidal epithelium. Sonographically, the appearance is similar to acquired cystic dilatation of the rete testis. Renal agenesis or dysplasia frequently coexists with testicular cystic dysplasia.[85]

Epidermoid Cysts

An epidermoid cyst is an uncommon, benign, generally well-circumscribed tumor of germ cell origin, representing approximately 1% of all testicular tumors. These tumors occur at any age but are most common during the second to fourth decades.[42] Usually, patients present with a painless testicular nodule; one-third of the tumors are discovered incidentally on physical examination. Diffuse, painless testicular enlargement occurs in 10% of patients. Pathologically, epidermoid cysts are composed of keratinizing, stratified, squamous epithelium with a well-defined, fibrotic wall. Although the histogenesis of epidermoid cysts is controversial, the current prevailing theory is that these entities represent teratomas that have undergone monodermal differentiation. However, a complete absence of mesodermal or ectodermal components and absence of intraepithelial neoplasia, a histologic precursor of germ cell tumors, brings this theory into question. Additionally, unlike germ cell tumors, epidermoid cysts have an invariably benign course without recurrence or metastatic disease following resection.[86] Squamous metaplasia of seminiferous epithelium or rete testis is an alternative diagnosis.[87] These benign lesions can be differentiated from premalignant teratomas only through histologic examination.

Sonographically, epidermoid cysts are generally well-defined, round to ovoid, avascular masses and may be multiple or bilateral.[86] A characteristic whorled or laminated appearance, like the layers of an onion skin, corresponds to the alternating layers of compacted keratin and desquamated squamous cells seen histologically[88-90] (Fig. 22.12D, Video 22.2). This appearance, however, may not be pathognomonic because it is rarely seen with teratoma.[91] Another typical appearance of an epidermoid cyst is a well-defined hypoechoic mass with an echogenic capsule that may be calcified (Fig. 22.12F). There may be central calcification, giving a "bull's eye" or target appearance.[86] Epidermoid cysts may also have the nonspecific appearance of a hypoechoic mass with or without calcifications and may resemble germ cell tumors (Fig. 22.12E). Avascularity is a clue to the diagnosis.[89] Although the sonographic appearance is characteristic, it is not pathognomonic, and histologic confirmation should be obtained by a conservative testis-sparing approach with local excision (enucleation).[92] MRI has been used to support the sonographic diagnosis of epidermoid cysts as they have a target appearance with low signal capsule. The layers of keratinizing material are rich in water and lipid and can appear as areas of high signal intensity on both T1- and T2-weighted imaging.[93,94]

Abscess

Testicular abscesses are usually a complication of **epididymo-orchitis,** although they may also result from an undiagnosed **testicular torsion, testicular infarct, trauma,** a **gangrenous or infected tumor,** or a primary **pyogenic orchitis.** Infectious causes of abscess formation are **mumps, smallpox, scarlet fever, influenza, typhoid, sinusitis, osteomyelitis,** and **appendicitis.**[95] A testicular abscess may cross the mesothelial lining of the tunica vaginalis, resulting in formation of a **pyocele** or a fistula to the scrotal skin.

Most often, sonography demonstrates an irregularly marginated, hypoechoic or mixed echogenic intratesticular mass (Fig. 22.13). Testicular abscesses have no diagnostic sonographic features but can often be distinguished from tumors on the basis of clinical symptoms and short-term interval change.

In patients with **acquired immunodeficiency syndrome** (AIDS), distinguishing an abscess from a neoplastic process may be difficult on sonographic examination. Clinical findings may

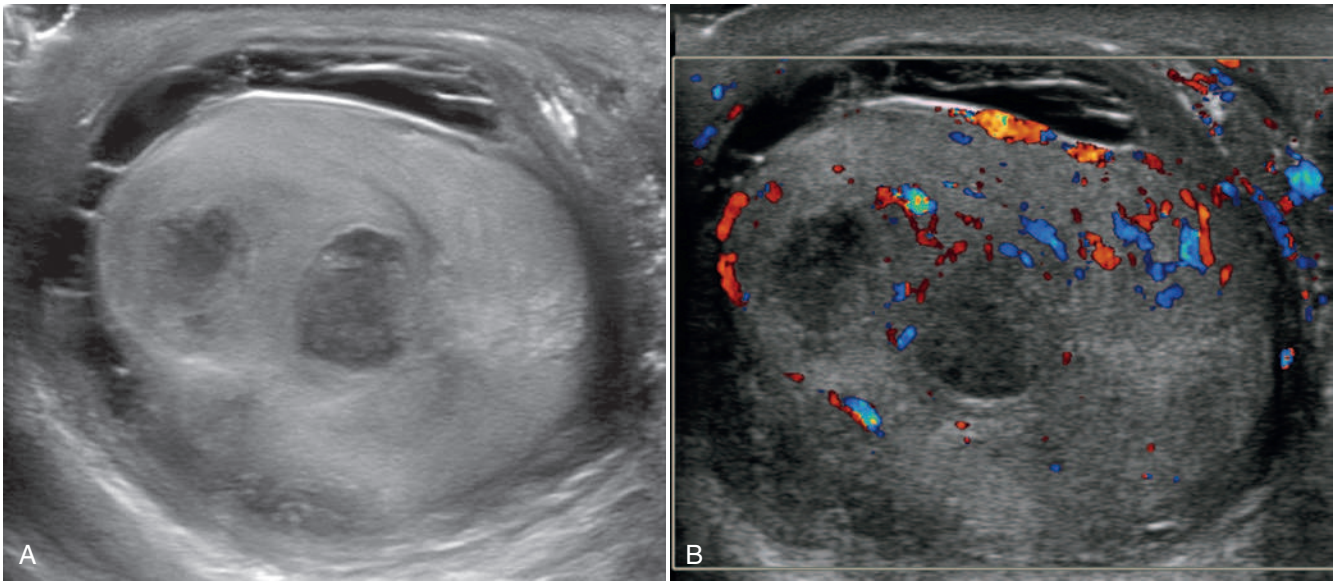

FIG. 22.13 Testicular Abscesses. (A) Transverse gray-scale image shows typical hypoechoic intratesticular abscesses, which may be indistinguishable from a tumor. However, heterogeneity of the parenchyma, skin thickening, and developing pyocele suggest that these masses represent abscesses. **(B)** Transverse color Doppler image shows echogenic and hypoechoic areas in the intratesticular abscesses with increased vascularity around the abscesses.

be helpful; however, orchiectomy is frequently necessary to obtain a histologic diagnosis.[96,97]

Segmental Infarction

Segmental testicular infarction may occur after **torsion, trauma, surgery, bacterial endocarditis, vasculitis, leukemia,** or **hypercoagulable states.**[98] Spontaneous infarction of the testis is rare. The sonographic appearance depends on the age of the infarction. Initially, a typical segmental infarct is seen as a focal, wedge-shaped or round hypoechoic mass, with approximately 80% occurring in the upper pole, likely secondary to vascular supply between the upper and lower poles.[99] The focal hypoechoic mass may not be distinguishable from a neoplasm on the basis of its gray-scale sonographic appearance.[100,101] These lesions should have reduced or absent blood flow, depending on the age of the infarction.[99] If a well-circumscribed, nonpalpable, relatively peripheral, hypoechoic mass shows a complete lack of vascularity on power Doppler imaging or after the administration of sonographic contrast agent, it may be possible to distinguish such benign infarctions from neoplasm[102,103] (Fig. 22.14). With time, the hypoechoic mass or the entire testis often decreases in size and develops areas of increased echogenicity because of fibrosis or dystrophic calcification.[104] The early sonographic appearance may be difficult to distinguish from a testicular neoplasm, but infarcts decrease substantially in size, whereas tumors characteristically enlarge with time.[3,101,105]

Adrenal Rests

Adrenal rests are a rare cause of intertesticular masses and can be seen in the setting of **congenital adrenal hyperplasia** (CAH), and rarely in the setting of **Cushing syndrome.** CAH is an autosomal recessive disease involving an adrenocortical enzyme defect. This disease typically becomes clinically obvious early in life or in early adulthood. Patients often present with a testicular mass or enlargement, **precocious puberty,** and with or without salt-depletion syndrome. Adrenal rests arise from aberrant adrenocortical cells that migrate with gonadal tissues in the fetus. They can form tumorlike masses in response to elevated levels

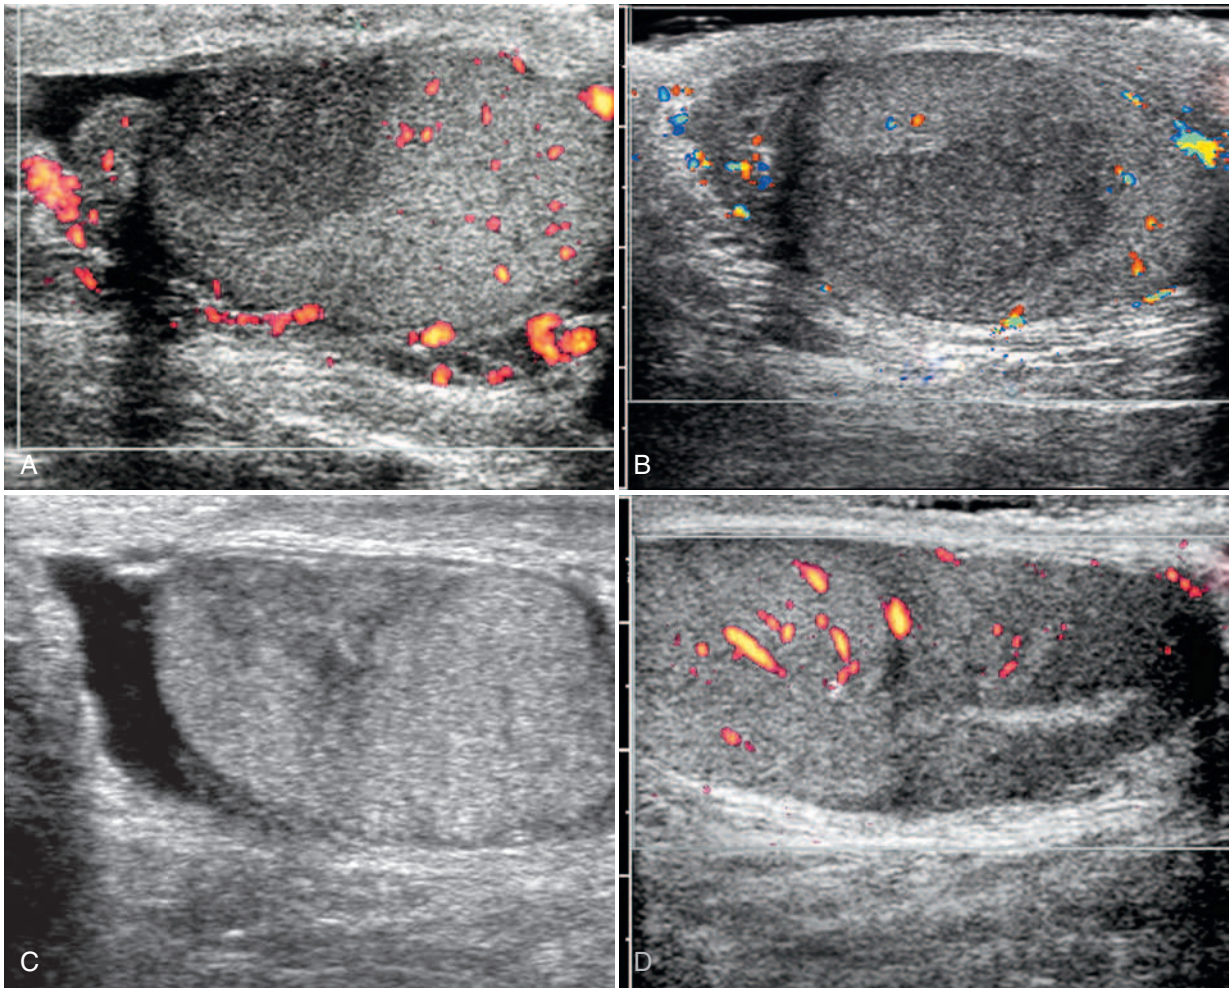

FIG. 22.14 Testicular Infarcts: Spectrum of Appearances. (A) and **(B) Acute infarct. (A)** Longitudinal power Doppler scan shows an avascular area at the upper pole from **partial torsion. (B)** Longitudinal color Doppler scan shows an avascular area in the midtestis caused by **vasculitis. (C)** and **(D) Chronic infarct. (C)** Longitudinal scan shows a peripheral wedge-shaped hypoechoic area caused by prior **mumps orchitis. (D)** Longitudinal power Doppler scan shows lack of vascularity in the lower pole.

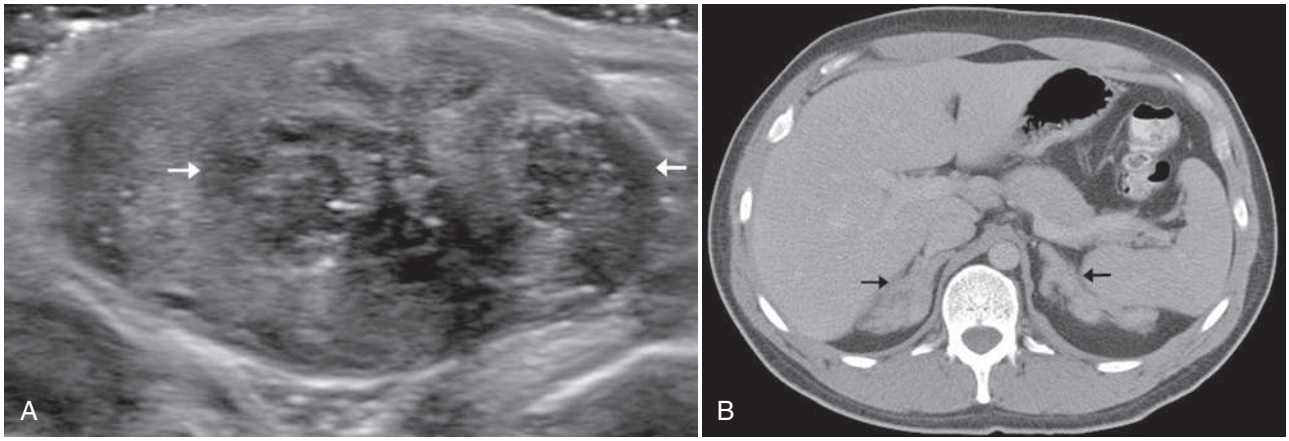

FIG. 22.15 Adrenal Rests in Patient With Congenital Adrenal Hyperplasia. (A) Longitudinal scan shows multifocal hypoechoic masses *(arrows)* within the testis that cannot be distinguished from tumor. **(B)** CT in same patient shows bilateral adrenal hyperplasia *(arrows)*.

of circulating adrenocorticotropic hormone in CAH and Cushing syndrome. These lesions are typically multifocal, bilateral, and eccentrically located. Sonographically, they are variable in appearance, typically presenting as hypoechoic masses, although they may be heterogeneous, hyperechoic masses with posterior acoustic shadowing (Fig. 22.15). Adrenal rests can demonstrate spokelike vascularity with multiple peripheral vessels radiating toward a central point within the mass. Usually, if the patient has the appropriate hormonal abnormalities associated with CAH and if sonography shows the appropriate findings, no further workup is necessary.[106,107] If confirmation of the diagnosis is required, a biopsy under ultrasound guidance may be obtained intraoperatively when the testis is exposed. Additionally, testicular vein sampling will show elevated cortisol levels compared with peripheral blood levels.[108] Treatment with glucocorticoid replacement therapy results in stabilization or regression of the masses.[109]

Splenogonadal Fusion

Splenogonadal fusion is a rare congenital anomaly in which there is fusion of the spleen and gonad. It typically occurs on the left side and is most often associated with cryptorchidism.[110] There are two types of splenogonadal fusion: continuous and discontinuous. In the more common **continuous** form, the gonad is linked to the spleen by a fibrous cord of splenic tissue. In the **discontinuous** form, ectopic splenic tissue is attached to the testis. Rarely, ectopic splenic tissue may occur on the epididymis or spermatic cord. Splenogonadal fusion may mimic testicular malignancy. The diagnosis may be established by documenting uptake on a technetium-99m sulfur colloid scan.

Calcifications

Scrotal calcifications may be seen within the parenchyma of the testis or epididymis, attached to the tunica, or freely located in the fluid between the layers of the tunica vaginalis. Large, smooth, curvilinear intratesticular calcifications without an associated soft tissue mass are characteristic of a large-cell calcifying **Sertoli cell tumor**[111] (see Fig. 22.9C). Scattered calcifications may be found in **tuberculosis, filariasis,** and **scarring** from **regressed germ cell tumor** or trauma.

Scrotal Calcifications

TESTICULAR
Solitary, postinflammatory granulomatous, vascular
Microlithiasis
Regressed, or "burned-out," germ cell tumor
Large-cell calcifying Sertoli cell tumor
Teratoma
Mixed germ cell tumor
Sarcoid
Tuberculosis
Chronic infarct
Posttraumatic

EXTRATESTICULAR
Tunica vaginalis, "scrotal pearls"
Torsed appendages
Chronic epididymitis
Schistosomiasis

Testicular microlithiasis is a condition in which calcifications are present within the seminiferous tubules of the testis either unilaterally or bilaterally. It is postulated that microlithiasis is caused by defective Sertoli cell phagocytosis of degenerating tubular cells, which then calcify within the seminiferous tubules.[112,113] Microlithiasis has been classified as diffuse and limited.[114] In the **diffuse** form, innumerable small, hyperechoic foci are diffusely scattered throughout the testicular parenchyma. These tiny (1-3 mm) foci rarely shadow and occasionally demonstrate a comet-tail appearance (Fig. 22.16). In the **limited** form, less than five hyperechoic foci are seen per image of the testis (Fig. 22.16B).

Microlithiasis is seen in 1% to 2% of patients referred for testicular sonography and has a reported prevalence in the general population of 0.6% to 0.9%.[115] Microlithiasis has been associated with **cryptorchidism, Klinefelter syndrome, Down syndrome, pulmonary alveolar microlithiasis, AIDS, neurofibromatosis, previous radiotherapy,** and **subfertility.**[112,115-117] Microlithiasis is typically an incidental finding on scrotal ultrasound, and if

(F)** Limited microlithiasis with **seminoma.** Longitudinal scan shows a few tiny calcifications and a homogeneous hypoechoic mass. **(G)** Longitudinal scan shows microlithiasis and two hypoechoic homogeneous masses *(arrows)* due to seminoma. **(H)** Longitudinal scan shows large hypoechoic mass with multiple small and coarser calcifications. **(I)** Dual transverse image shows large hypoechoic left testicular mass and microcalcifications in the right testis.

associated with a mass, management is dictated by the intratesticular mass itself. It has been correlated with testicular carcinoma, although the extent of the risk for subsequent development of neoplasm and the recommended surveillance in the setting of microlithiasis remain controversial.[114,115,118] Annual physical examination and periodic self-examination have been suggested for those who have no additional risk factors.[114,115,119,120] Recent literature suggests that there is no causal link and that sonographic follow-up of microlithiasis should be determined by any additional risk factors and not the microlithiasis itself.[121]

EXTRATESTICULAR PATHOLOGIC LESIONS

Tunica Vaginalis

Hydrocele, Hematocele, and Pyocele

The normal scrotum contains a few milliliters of serous fluid between the layers of the tunica vaginalis, and this is usually visible on sonographic examination. Larger volumes of serous fluid, and blood, pus, or urine may also accumulate in the space between the parietal and visceral layers of the tunica vaginalis lining the scrotum. These fluid collections should be confined to the anterolateral portions of the scrotum because of the attachment of the testis to the epididymis and scrotal wall posteriorly (the **bare area**)[9] (Fig. 22.17).

Hydrocele is an abnormal accumulation of serous fluid between the layers of the tunica vaginalis. Hydrocele is the most common cause of painless scrotal swelling[14] and may be congenital or acquired. The **congenital type** results from incomplete closure of **the processus vaginalis,** with persistent open communication between the scrotal sac and the peritoneum, usually resolving by 18 months of age (Fig. 22.17D). **Acquired hydroceles** may be idiopathic or caused by **epididymitis, epididymo-orchitis, torsion,** or, in rare cases, tumors. Hydroceles associated with testicular tumors are usually small.[3,122,123] Sonography is useful in detecting a potential cause of the hydrocele by allowing evaluation of the testis when a

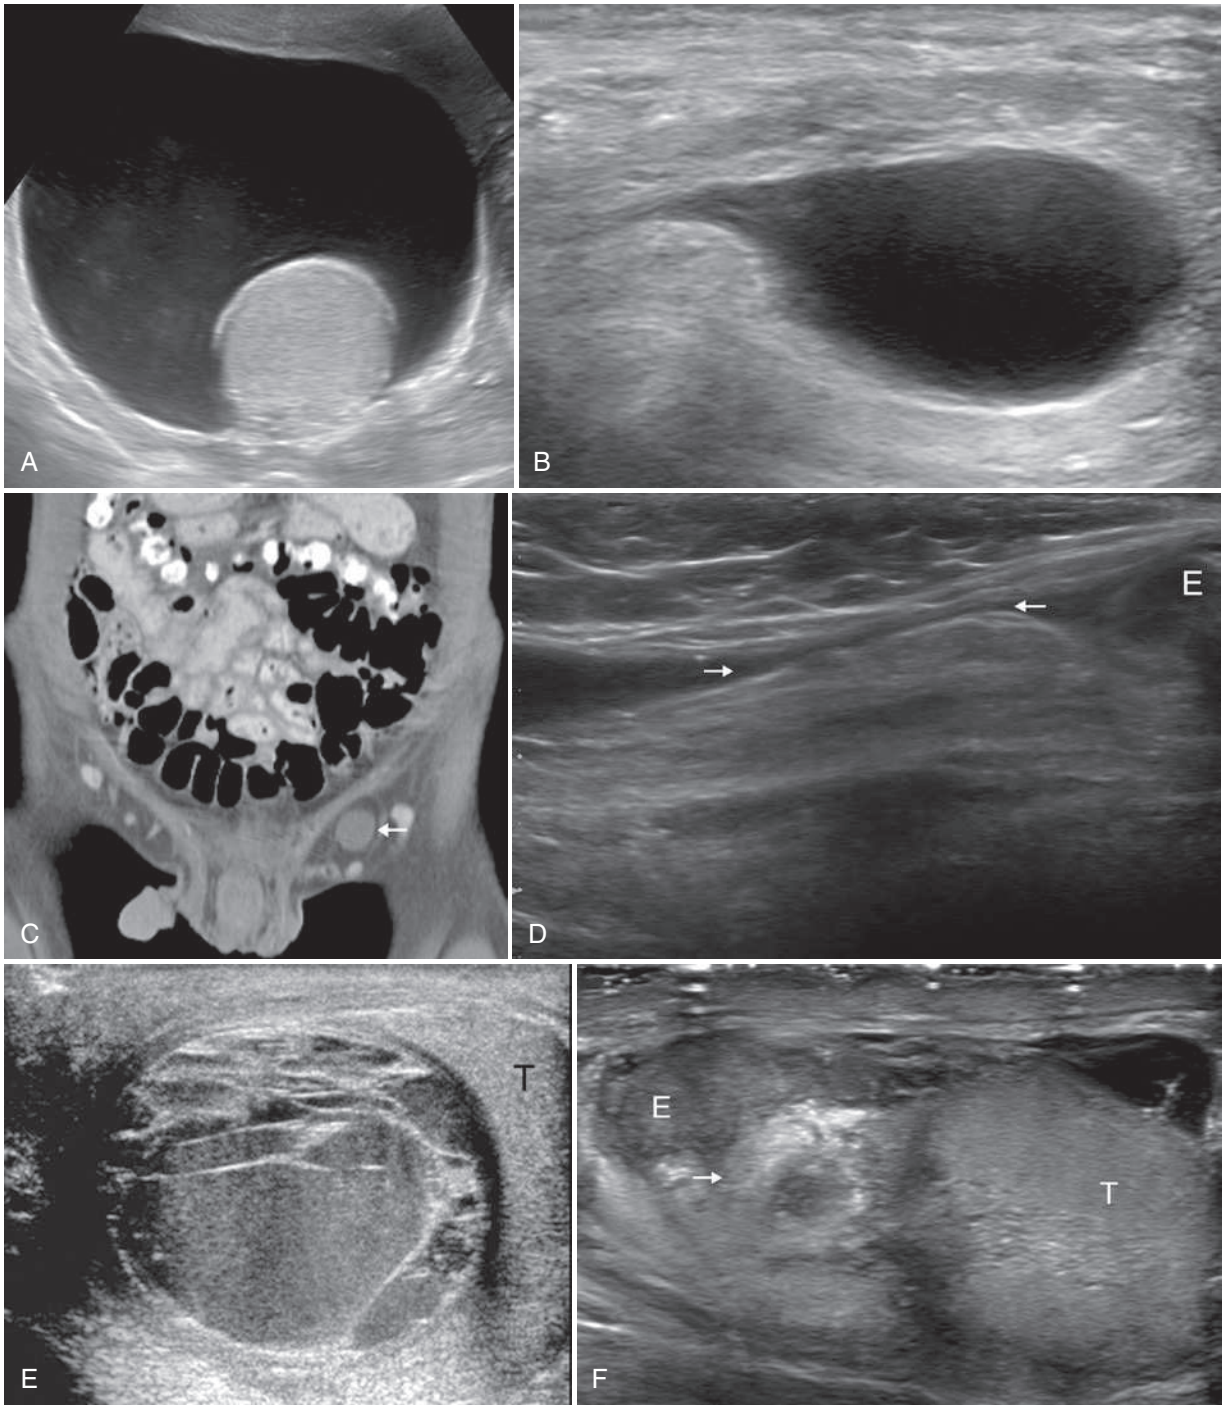

FIG. 22.17 Scrotal Fluid Collections: Spectrum of Appearances. (A) Hydrocele. Transverse scan shows a large hydrocele anterolaterally with testis partially enveloped by tunica vaginalis posteriorly. **(B) Encysted hydrocele.** Longitudinal scan along the spermatic cord shows a fluid collection present in the inguinal canal. **(C) Encysted hydrocele.** Coronal CT image of patient in **B** demonstrates a well circumscribed fluid collection *(arrow)* corresponding to sonographic examination. **(D) Patent processus vaginalis.** Longitudinal scan of inguinal region shows an elongated fluid collection *(arrows)* above the level of the testis and epididymis *(E)* in patient with chronic hydrocele. **(E) Hematocele.** Transverse scan shows loculated fluid with internal echoes and mass affect on the testis *(T)*. **(F) Pyocele.** Longitudinal scan shows an irregular, centrally hypodense, extratesticular (*T,* testis) collection *(arrow)* adjacent to the epididymis *(E)* in the setting of **epididymo-orchitis.**

large hydrocele hampers palpation. Hydroceles are characteristically anechoic collections with good sound transmission surrounding the anterolateral aspects of the testis. Low-level to medium-level echoes from fibrin bodies or cholesterol crystals may occasionally be visualized moving freely within a hydrocele.[124] Rarely, a large hydrocele may impede testicular venous drainage and cause absence of antegrade arterial diastolic flow.[122] Uncommonly, a hydrocele may be loculated around the spermatic cord above the testis and epididymis, representing a noncommunicating, encysted hydrocele; or the

collection communicates with the peritoneum but not the scrotum, a **funicular hydrocele**[125] (Fig. 22.17B and C).

Hematoceles and **pyoceles** are less common than simple hydroceles. Hematoceles (accumulation of blood within the tunica vaginalis) result from trauma, surgery, neoplasms, or torsion.[126] Pyoceles result from untreated epididymo-orchitis or rupture of an intratesticular abscess into the space between the layers of the tunica vaginalis. Both hematoceles and pyoceles appear as complex fluid collections with internal septations and loculations (Fig. 22.17). Thickening of the scrotal skin and calcifications may be seen in chronic cases.

Paratesticular Masses

Most extratesticular neoplasms in adults are benign, but extratesticular neoplasms in children are frequently malignant.[127]

Extratesticular Tumors/Masses

BENIGN
Hernia
Adenomatoid tumor
Fibroma/fibrous pseudotumor
Lipoma
Hemangioma

Liposarcoma
Rhabdosarcoma
Histiocytoma
Lymphoma
Metastases

Hernia

An inguinal hernia is a common paratesticular mass.[128] Although scrotal hernias are usually diagnosed on the basis of clinical history and physical examination, sonography is useful in the evaluation of atypical cases. Hernias are classified as either direct or indirect. An indirect hernia exits the abdominal cavity through the internal inguinal ring, can traverse the inguinal canal, and extend into the scrotum. Indirect hernias are associated with a patent processus vaginalis. A direct hernia represents a protrusion through the abdominal wall at Hesselbach triangle, an area of weakness bordered by the lateral border of the rectus sheath medially, the inferior epigastric artery laterally, and the inguinal ligament inferiorly.

Sonographic appearance of an inguinal hernia depends on its contents. Bowel will often be fluid filled with multiple internal bright echoes. Bowel gas may cause shadowing, a finding also seen with abscesses and thus potentially confusing. The presence of bowel loops within the hernia may be confirmed by the visualization of valvulae conniventes or haustrations and detection of peristalsis on real-time examination (Fig. 22.18A). The presence of highly echogenic material within the scrotum may result from a hernia containing omentum or other fatty masses such as lipomas, although lipomas are typically well defined and herniated omentum can typically be traced back to the inguinal canal (Fig. 22.18B). Sonographic examination of the inguinal canal into the scrotum is necessary to make the diagnosis.[129] Additional discussion of hernias can be found in Chapter 13.

Calculi

Extratesticular scrotal calculi are calcifications within the tunica vaginalis (Fig. 22.19). These fibrinoid loose bodies have been called **scrotoliths,** or **"scrotal pearls"** because of their macroscopic appearance, which is usually rounded, pearly white, and rubbery. Histologically, they consist of fibrinoid material deposited around a central nucleus of hydroxyapatite.[130] They may result from inflammatory deposits that form and then ultimately separate

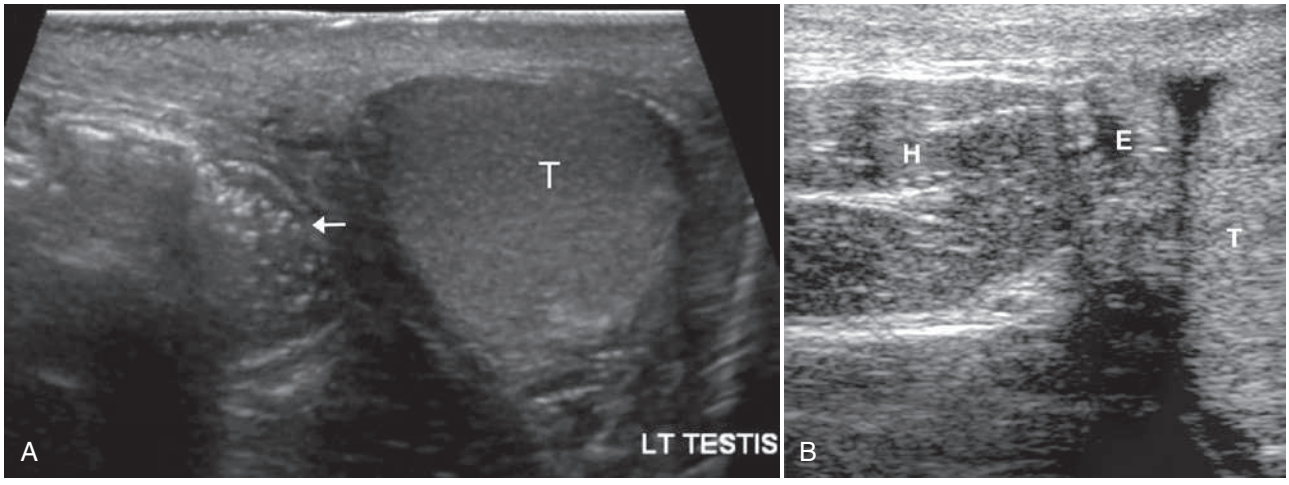

FIG. 22.18 Indirect Inguinal Hernias: Spectrum of Appearances. (A) Herniated small bowel. Oblique scan shows herniated small bowel *(arrow)* superior to and abutting the testis *(T).* **(B) Herniated mesenteric fat.** Longitudinal scan shows herniated fat *(H)* above testis *(T)* and epididymis *(E).*

from the tunica vaginalis, or from torsion of the appendix testis or appendix epididymis. Sonographically, they appear as free floating, echogenic calculi with posterior acoustic shadowing; can be multiple; and range in size from a few millimeters to larger than a centimeter. Hydroceles facilitate the sonographic diagnosis of scrotal calculi.

Varicocele

A varicocele is an abnormal dilatation of the veins of the pampiniform plexus located posterior to the testis, adjacent to the epididymis, and accompanying the vas deferens within the spermatic cord[14] (Fig. 22.20). A varicocele is the most frequently encountered mass of the spermatic cord. The veins of the pampiniform plexus normally range from 0.5 to 1.5 mm in diameter, with a main draining vein up to 2 mm in diameter. The size for normal varies, with some diagnosticians using greater than 2 mm as a guideline for the diagnosis of a varicocele and others using 3 mm.[131]

There are two types of varicoceles: primary (idiopathic) and secondary. The **idiopathic varicocele** is caused by incompetent valves in the internal spermatic vein, which results in impaired drainage of blood from the spermatic vein and pampiniform plexus with the patient in an upright position. Varicoceles affect approximately 15% of men but occur in up to 40% of men attending infertility clinics.[132,133] Varicocele is the most common correctable cause of male infertility.[134] Idiopathic varicoceles occur much more commonly on the left side and are most common in men aged 15 to 25 years. The left-sided predominance probably occurs because the left testicular vein is longer, with venous drainage into the left renal vein entering the renal vein

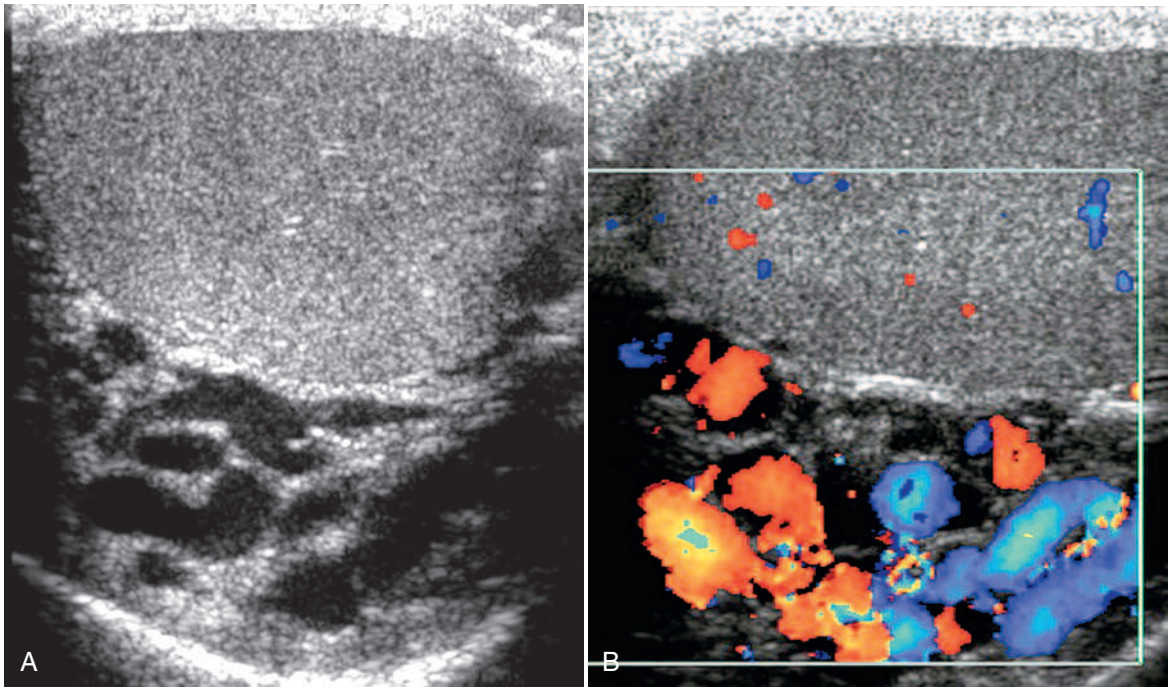

FIG. 22.20 Varicocele. (A) Longitudinal and **(B)** color Doppler images show serpentine, hypoechoic, dilated veins posterior to the testis. The blood flow in a varicocele is slow and may be detected only with low-flow Doppler settings or the Valsalva maneuver. See also Video 22.3.

at a right angle, as opposed to the right spermatic vein, which drains directly into the vena cava. Idiopathic varices normally distend when the patient is upright or performs the Valsalva maneuver and decompress when the patient is supine. Primary varicoceles are bilateral in up to 50% of cases.[135]

Secondary varicoceles result from increased pressure on the spermatic vein or its tributaries by marked hydronephrosis, an enlarged liver, abdominal neoplasms, or venous compression by a retroperitoneal mass.[43] Secondary varicoceles may also occur in **nutcracker syndrome (nutcracker phenomenon),** in which the superior mesenteric artery compresses the left renal vein.[136] A search for neoplastic obstruction of gonadal venous return must be undertaken in cases of a right-sided, nondecompressible, or newly discovered varicocele in a patient older than 40 years[14] (Fig. 22.21). The appearance of secondary varicoceles is not affected by patient position.

In infertile men, sonography aids in the diagnosis of clinically palpable and subclinical varicoceles. Sonography is also of value in assessing testicular size before and after treatment, because varicocele may be associated with a decreased testicular volume.[133] There is poor correlation between the size of the varicocele and the degree of testicular tissue damage leading to infertility, and surgical repair of subclinical varicoceles for infertility has been controversial.[137]

Sonographically, a varicocele consists of multiple, serpentine, anechoic structures more than 2 mm in diameter, creating a tortuous, multicystic collection located adjacent or proximal to the upper pole of the testis and head of the epididymis. A high-frequency transducer in conjunction with low-flow Doppler settings should be used to optimize slow-flow detection within varices. Slowly moving red blood cells may be visualized with high-frequency transducers, even when flow is too slow to be detected by Doppler imaging. Venous flow can be augmented with the patient in the upright position or during Valsalva maneuver (Video 22.3). Varicoceles follow the course of the spermatic cord into the inguinal canal and are easily compressed by the transducer.[3] Rarely, varicoceles may be intratesticular, either in a subcapsular location or around the mediastinum testis[138,139] (Fig. 22.22).

Fibrous Pseudotumor

Fibrous pseudotumor is a rare, nonneoplastic mass of reactive fibrous tissue that most commonly involves the tunica vaginalis. These masses are known by a number of names, including **fibroma, paratesticular fibrosis,** or **inflammatory pseudotumor,** and can become quite large and mimic neoplasms. Most patients present with a painless scrotal mass, possibly with a prior history of infection or trauma. Histologically, masses are composed of hyalinized collagen and granulation tissue and may be partially calcified. On sonography, fibrous pseudotumors may appear as one or more solid masses attached to or closely associated with the capsule of the testis. There may be an associated hydrocele. Echogenicity is variable and they may be seen as a hypoechoic, hyperechoic, or heterogeneous paratesticular mass with posterior acoustic shadowing depending on extent of calicfications[140-142] (Fig. 22.23A and B).

Polyorchidism

Polyorchidism, or **supernumerary testes,** is a rare entity thought to result from abnormal division of the genital ridge embryologically. The supernumery testes are intrascrotal in location in approximately 75% of cases and present as a painless scrotal

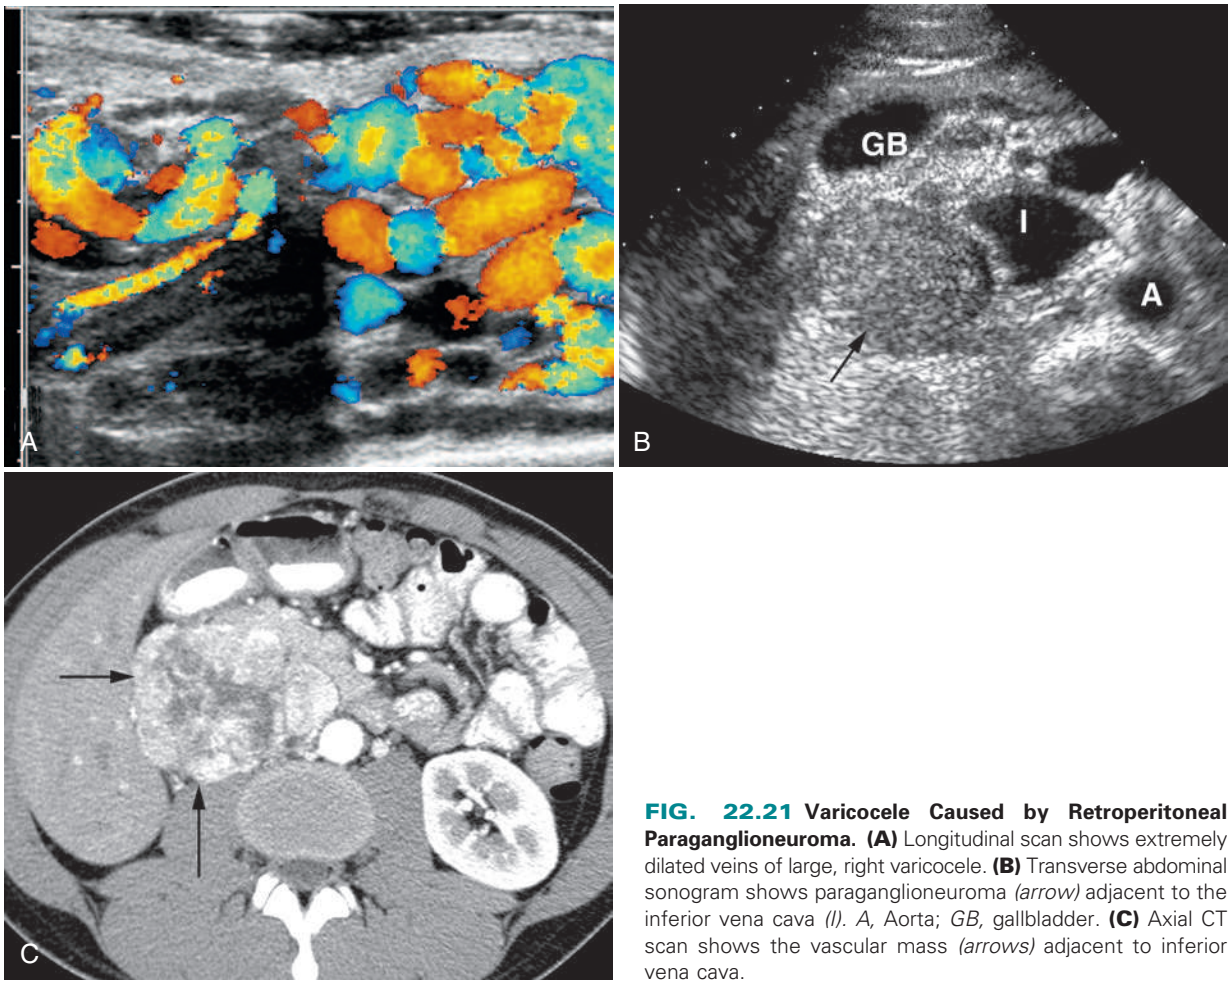

FIG. 22.21 Varicocele Caused by Retroperitoneal Paraganglioneuroma. FIG. 22.22 Intratesticular Varicocele. Longitudinal scan shows the dilated intratesticular veins.

mass (Fig. 22.24). Twenty percent of supernumery testes are inguinal with the remaining retroperitoneal in location.[60] These supernumery testes have similar imaging characteristics to normal testes, but they are more mobile and therefore at increased risk of torsion. There has also been an increased risk of carcinoma reported.[131,135,137,143]

Epididymal Lesions

Cystic Lesions

The most common epididymal mass is a cyst, which includes **epididymal cysts** and **spermatoceles.** Both were seen in 20% to 40% of all asymptomatic patients studied by Leung et al.,[144] and were multiple in 30% of cases. Both epididymal cysts and spermatoceles are thought to result from dilatation of the epididymal ductules, but the contents of these masses differ.[14] Epididymal cysts contain clear serous fluid, whereas spermatoceles are filled with spermatozoa and sediment containing lymphocytes, fat globules, and cellular debris, giving the fluid a thick, milky appearance.[3] Both lesions may result from prior episodes of epididymitis or trauma. Spermatoceles and epididymal cysts appear identical on sonography: anechoic, circumscribed masses with no or few internal echoes. Loculations and septations are often seen (Fig. 22.25). In rare cases, a spermatocele may be hyperechoic.[9] Differentiation between a spermatocele and an epididymal cyst is rarely important clinically. Spermatoceles almost always occur in the head of the epididymis and represent cystic dilatation of efferent ductules, whereas epididymal cysts arise throughout the length of the epididymis.

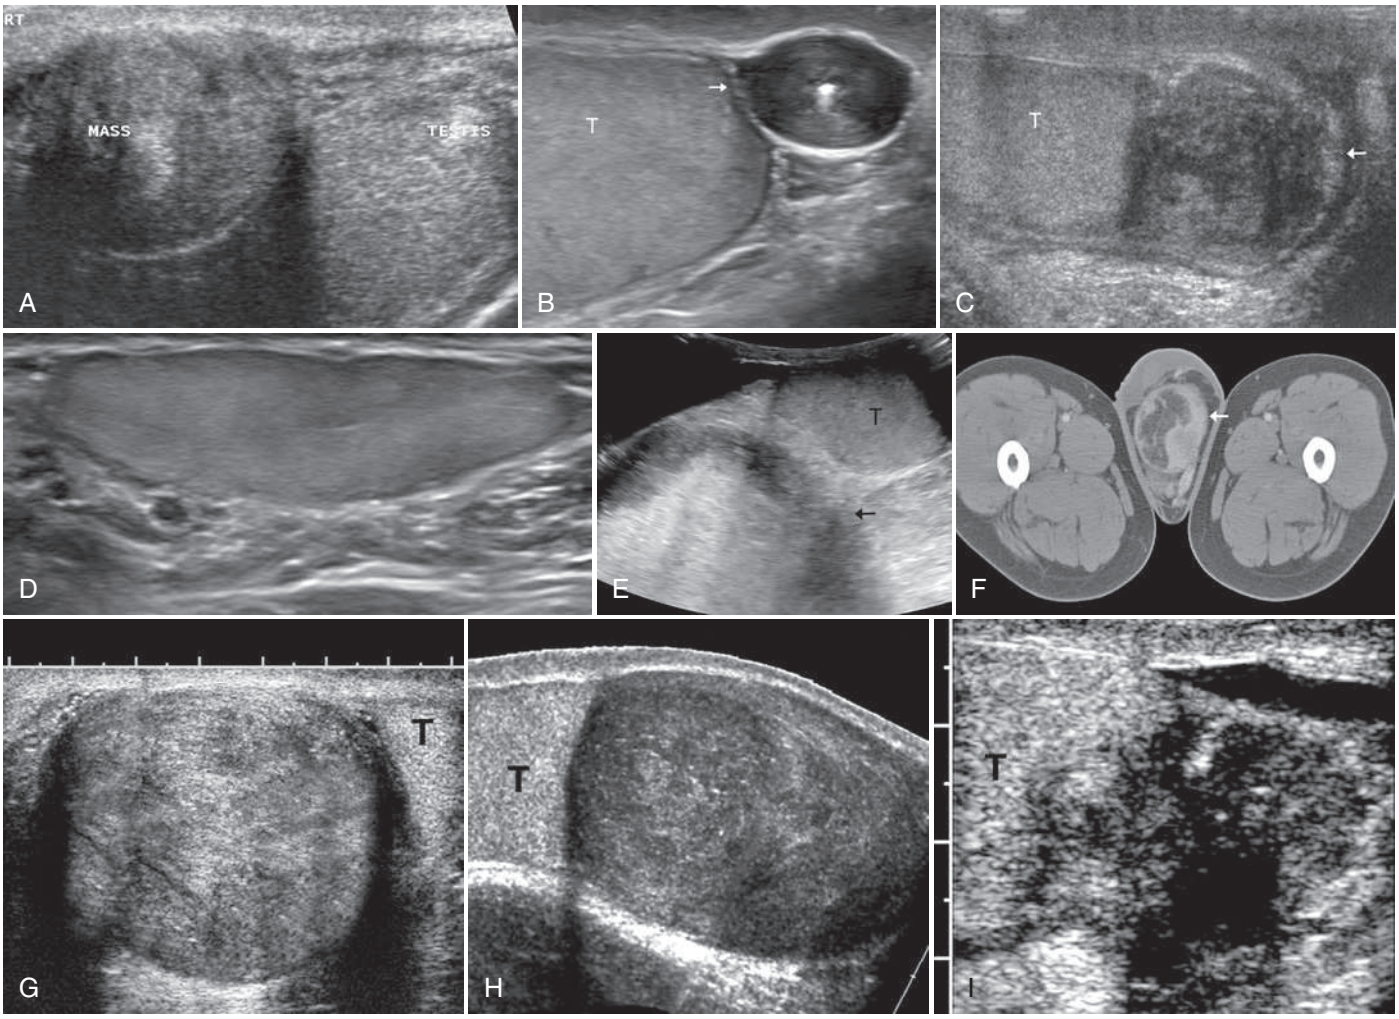

FIG. 22.23 Extratesticular Scrotal Solid Masses: Spectrum of Appearances. (A) Fibrous pseudotumor. Transverse scan shows a mass of mixed echogenicity lateral to and separate from the testis. **(B) Fibrous pseudotumor.** Longitudinal scan shows a lamellated extratesticular mass *(arrow)* with a central echogenic focus adjacent to the tunica of the testis *(T)*. **(C) Benign adenomatoid tumor of epididymis.** Longitudinal scan shows a hypoechoic mass *(arrow)* in the epididymal tail separate from the testis *(T)*. **(D) Spermatic cord lipoma.** Longitudinal scan shows an echogenic mass superior to the epididymis and testis, along the spermatic cord. **(E) Liposarcoma.** Transverse scan shows a large heterogeneous mass *(arrow)* deep to the testis *(T)* in the scrotal wall or spermatic cord. **(F) Liposarcoma.** Contrast-enhanced axial CT image shows a heterogeneous mass containing fat and solid components *(arrow)* associated with the spermatic cord in patient **E,** consistent with a liposarcoma. **(G) Leiomyoma of cord.** Longitudinal scan shows a solid mass superior to the testis. **(H) Rhabdomyosarcoma.** Longitudinal extended–field of view scan in a 12-year-old shows a large, paratesticular mass inferior to the testis. **(I) Metastasis from lung carcinoma.** Longitudinal scan shows a heterogenous mass with calcifications in the tail of the epididymis.

Tumors

The most common epididymal neoplasm is the **benign adenomatoid tumor,** which accounts for approximately 30% of all paratesticular neoplasms, second only to lipoma.[28] Although most frequently located in the tail (see Fig. 22.23C), adenomatoid tumors may occur anywhere in the epididymis and have also been reported in the spermatic cord, as well as the tunica albuginea, where they may grow intratesticularly. Adenomatoid tumor may occur at any age but most often affects patients aged 20 to 50 years.[3,145] Adenomatoid tumors are generally unilateral, solitary, well defined, and round or oval, rarely measuring more than 5 cm in diameter. Occasionally, they may appear plaquelike and poorly defined. Sonography usually shows a solid, well-circumscribed mass with echogenicity that is at least as great as the testis,[3] although they may also be hypoechoic.

Other benign extratesticular tumors are rare and include **lipomas** (see Fig. 22.23D), **leiomyomas** (see Fig. 22.23G), **fibromas, hemangiomas, neurofibromas,** and **cholesterol granulomas.** Adrenal rests may also be encountered in the spermatic cord, testis, epididymis, rete testis, and tunica albuginea, typically in the setting of CAH.

Papillary cystadenoma of the epididymis is a rare tumor with a strong association with **von Hippel–Lindau disease.** Up to 40% of cystadenomas are bilateral, a finding that is virtually pathognomic for von Hippel–Lindau disease. These tumors are benign epithelial tumors of the epididymis, occurring in the

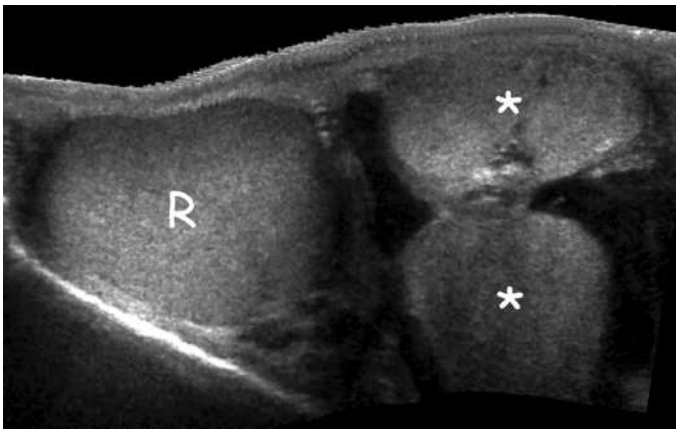

FIG. 22.24 Polyorchidism. Transverse extended field of view image of the right hemiscrotum shows a right testis *(R)* and two additional intrascrotal masses with similar imaging characteristics to the right testis (*) consistent with supernumery testes in an asymptomatic patient with a palpable mass.

efferent ductules of the epididymal head. They generally present as a hard, palpable mass, and at ultrasound appear as an echogenic, solid mass with distinct, small cystic spaces.

The majority of solid epididymal masses are benign. However, primary extratesticular scrotal malignant neoplasms do occur, including adenocarcinoma, **fibrosarcoma, liposarcoma** (see Fig. 22.23E and F), **histiocytoma,** and **lymphoma** in adults and **rhabdomyosarcoma** in children (see Fig. 22.23H). Metastatic tumors to the epididymis are also rare. The most common primary sites include the testis, stomach, kidney, prostate, colon, and, less often, the pancreas[146,147] (see Fig. 22.23I). Size of the lesion and the presence of color flow may be helpful in the diagnosis of extratesticular scrotal masses.[23,148] Larger masses (>1.5 cm) with prominent color flow that present without cl inical symptoms of inflammation are more likely to be malignant.[23,148]

Sperm Granuloma

Sperm granulomas are thought to arise from extravasation of spermatozoa into the soft tissues surrounding the epididymis, producing a necrotizing granulomatous response.[3] These lesions may be painful or asymptomatic, and they are most often found in patients after vasectomy. It is assumed that vasectomy produces increased pressure in the epididymal ductules, causing rupture with subsequent formation of sperm granulomas. Sperm granulomas may also be associated with prior epididymal infection or trauma. The typical sonographic appearance is that of a solid, hypoechoic or heterogeneous mass, usually located in or adjacent to the epididymis, although it may simulate an intratesticular lesion (Fig. 22.26A). Chronic sperm granulomas may contain calcification.[149]

Postvasectomy Changes in the Epididymis

Sonographic changes in the epididymis are very common in patients after vasectomy.[150,151] In addition to the formation of sperm granulomas, these findings include epididymal enlargement with ductular ectasia involving the epididymis (Fig. 22.26B) and rete testis, as well as the development of cysts (Video 22.4). A dilated vas deferens may be seen in addition to the enlarged epididymis. An unusual appearance described as **"dancing megasperm"** is occasionally seen in patients with vasectomy (Video 22.5). High reflective echoes within the dilated epididymis appear to move independently, shown histologically to be aggregations of spermatozoa and macrophages.[152]

Chronic Epididymitis

Chronic epididymitis is more commonly seen with conditions associated with **granulomatous reactions,** including **tuberculosis, brucellosis, syphilis,** and **parasitic** and **fungal infections.**[60] Tuberculosis epididymal infections are the most common of these and are believed to result from renal disease seeding the lower genitourinary tract, with 25% of patients having bilateral involvement.[153] Patients with chronic granulomatous epididymitis caused by spread of tuberculosis from the genitourinary tract complain of a hard, nontender scrotal mass.[14] Sonography most often shows a thickened tunica albuginea and a thickened, irregular epididymis with variable appearance (Fig. 22.27). Calcification may be identified within the tunica albuginea or epididymis.[3] Associated findings include hydroceles, scrotal wall thickening, and fistulas.[153] Untreated granulomatous epididymitis can spread to the testes, causing an epididymo-orchitis, although this is less common than isolated epididymal disease. Focal testicular involvement may demonstrate a variable sonographic appearance and may simulate the appearance of a testicular neoplasm on sonography. Patients may also develop chronic epididymitis after episodes of acute bacterial epididymitis that do not subside.

Sarcoidosis

Sarcoidosis is a noninfectious, chronic, granulomatous disease that may involve the genital tract.[154-156] In an autopsy series, approximately 5% of cases had genital tract involvement, with the epididymis most frequently involved.[60] The clinical presentation is acute or recurrent epididymitis or painless enlargement of the testis or epididymis. Sonographically, sarcoid lesions are irregular, hypoechoic solid masses in the testis or epididymis (Fig. 22.28). Occasionally, hyperechoic, calcific foci with acoustic shadowing may be seen. Distinguishing sarcoidosis from an inflammatory process or a neoplasm is difficult on sonography alone. Resection or orchiectomy may be necessary for definitive diagnosis. As noted previously, tuberculosis can also cause a chronic granulomatous reaction of the genital tract, typically a granulomatous epididymitis.

ACUTE SCROTAL PAIN

Acute scrotal pain may have numerous causes. More common causes include **torsion of the spermatic cord and testis, epididymitis or orchitis, torsion of a testicular appendage, acute hydrocele, strangulated hernia, idiopathic scrotal edema, Henoch-Schönlein purpura, abscess, traumatic hemorrhage, hemorrhage into a testicular neoplasm,** and **scrotal fat necrosis. Torsion of the spermatic cord** and **acute epididymitis** or **epididymo-orchitis** are the most common causes of acute scrotal pain. These entities cannot be distinguished by

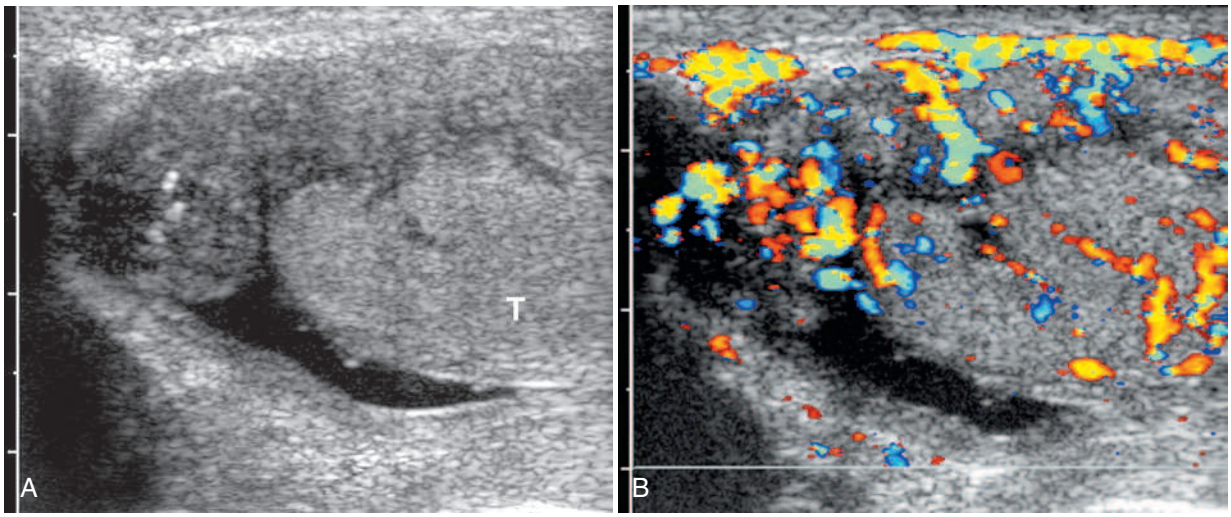

FIG. 22.27 Tuberculous Epididymo-orchitis. (A) Longitudinal scan shows a heterogeneous mass with calcification involving the head and body of the epididymis and the adjacent testis *(T)*. **(B)** Longitudinal color Doppler image shows increased vascularity in the epididymis and adjacent testis.

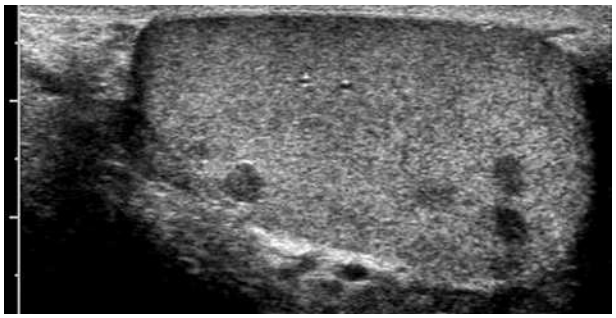

FIG. 22.28 Testicular Sarcoid. Longitudinal scan of the testis shows multiple, small, hypoechoic, solid masses resulting from sarcoid.

routine physical examination or laboratory tests in up to 50% of patients.[157] In the past, immediate surgical exploration was been advised in boys and young men with acute scrotal pain, unless a definitive diagnosis of epididymitis or orchitis was made. This aggressive approach resulted in an increased testicular salvage rate from torsion but also an increase in unnecessary surgical procedures. Real-time sonography, Doppler sonography, testicular radionuclide scintigraphy, and MRI have been used to increase the accuracy of distinguishing between infection and torsion.[158] Currently, sonography using color flow or power Doppler is the imaging study of choice to diagnose the cause of acute scrotal pain.

Causes of Acute Scrotal Pain

Torsion of the testis
Epididymo-orchitis
Testicular or epididymal appendage torsion
Strangulated hernia
Trauma
Idiopathic scrotal edema
Henoch-Schönlein purpura

Torsion

Torsion is more common in adolescent boys and represents approximately 20% of the acute scrotal pathologic phenomena in postpubertal males.[3] Prompt diagnosis is necessary because torsion requires immediate surgery to preserve the testis. The testicular salvage rate is over 80% if surgery is performed within 5 or 6 hours of the onset of pain, 70% if surgery is performed within 6 to 12 hours, and only 20% if surgery is delayed for more than 12 hours.[159]

Two types of testicular torsion have been described: intravaginal and extravaginal. **Extravaginal torsion** occurs prenatally and in newborns up to 30 days after delivery. Torsion occurs outside of the tunica vaginalis when the testis, **gubernaculum,** and tunica vaginalis are not fixed to the scrotal wall, allowing rotation of these structures as a unit and causing torsion of the cord at the level of the external ring. If this occurs prenatally, the affected neonate presents with a firm, painless mass in the scrotum, and swelling and discoloration of the affected side. The testis is typically infarcted and necrotic at birth. Postnatal testicular torsion is detected as a change in the testicular examination.[160,161] **Intravaginal torsion** is the more common type, arising within the tunica vaginalis and occurring most frequently at puberty. It results from anomalous suspension of the testis by a long stalk of spermatic cord mesentery, resulting in complete investment of the distal cord, testis, and epididymis by the tunica vaginalis. This allows the testis to swing and rotate within the tunica vaginalis like a clapper inside a bell, the so-called **bell-clapper deformity** (Fig. 22.29). Anomalous testicular suspension is bilateral in 50% to 80% of patients; hence the contralateral testis is usually fixed at the time of surgery as well. Sonography is considered the first step in evaluation of the acute scrotum, and its role is well established.[162-164] Sonographic findings vary with duration and degree of rotation. Gray-scale sonographic changes are nonspecific in the acute phase of torsion.[157,161,165] A torsed testis with normal, homogeneous echogenicity on gray-scale imaging has a high chance of successful salvage at surgery.[166] Testicular enlargement and decreased echogenicity are the most common findings 4 to 6 hours after the onset of torsion. With continued torsion, at 24 hours the testis can develop heterogeneous echotexture secondary to vascular congestion, hemorrhage, and infarction[167-169] (Fig. 22.30). A hypoechoic or heterogeneous echogenicity may indicate nonviability, although this is not specific.[166]

Torsion may change the position of the long axis of the testis. Extratesticular sonographic findings typically occur in torsion and are important to recognize. The spermatic cord immediately cranial to the testis and epididymis is twisted, causing a characteristic **torsion knot** or "whirlpool pattern" of concentric layers seen on sonography or MRI[161,170,171] (Fig. 22.30G and H). The epididymis may be enlarged and heterogeneous because of hemorrhage or ischemia, and may be difficult to separate from the torsion knot of the spermatic cord. This spherical epididymis-cord complex can be mistaken for epididymitis.[161] A reactive hydrocele and scrotal skin thickening are often seen with torsion. Large, echogenic, or complex extratesticular masses caused by hemorrhage in the tunica vaginalis or epididymis may be seen in patients with undiagnosed torsion.[172] The gray-scale findings of acute and subacute torsion are not specific and may be seen in testicular infarction caused by epididymitis, epididymo-orchitis, and traumatic testicular rupture or infarction.

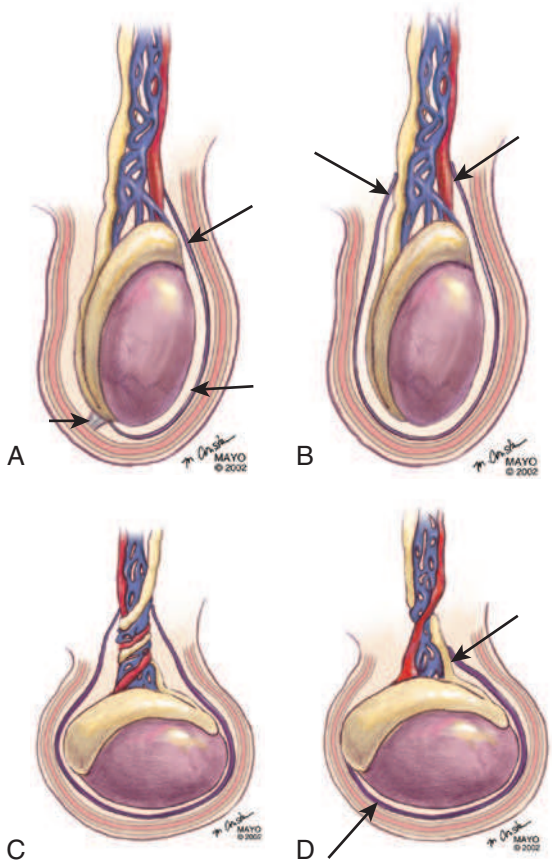

FIG. 22.29 "Bell-Clapper" Anomaly, Intravaginal Torsion, and Extravaginal Torsion. (A) Normal anatomy. The tunica vaginalis *(arrows)* does not completely surround the testis and epididymis, which are attached to the posterior scrotal wall *(short arrow).* **(B) Bell-clapper anomaly.** The tunica vaginalis *(arrows)* completely surrounds the testis, epididymis, and part of the spermatic cord, predisposing to torsion. **(C) Intravaginal torsion.** Bell-clapper anomaly with complete torsion of the spermatic cord, compromising the blood supply to the testis. **(D) Extravaginal torsion in a neonate.** Tunica vaginalis *(arrows)* is in normal position, but abnormal motility allows rotation of the testis, epididymis, and spermatic cord.

Doppler sonography is the most useful and most rapid technique to establish the diagnosis of testicular ischemia and to help distinguish torsion from epididymo-orchitis.[157,162,167] The absence of intratesticular blood flow at color and power Doppler ultrasound is considered diagnostic of ischemia (color and power techniques appear to have equivalent sensitivity in the diagnosis of torsion).[173-178] Meticulous scanning of the testicular parenchyma with the use of low-flow detection Doppler settings (low pulse repetition frequency, low wall filter, high Doppler gain, small color sampling box, lowest possible threshold setting) is important because intratesticular vessels are small and have low flow velocities, especially in prepubertal boys. Color flow Doppler sonography is more sensitive for showing decreased testicular flow in incomplete torsion than is nuclear scintigraphy, which is rarely

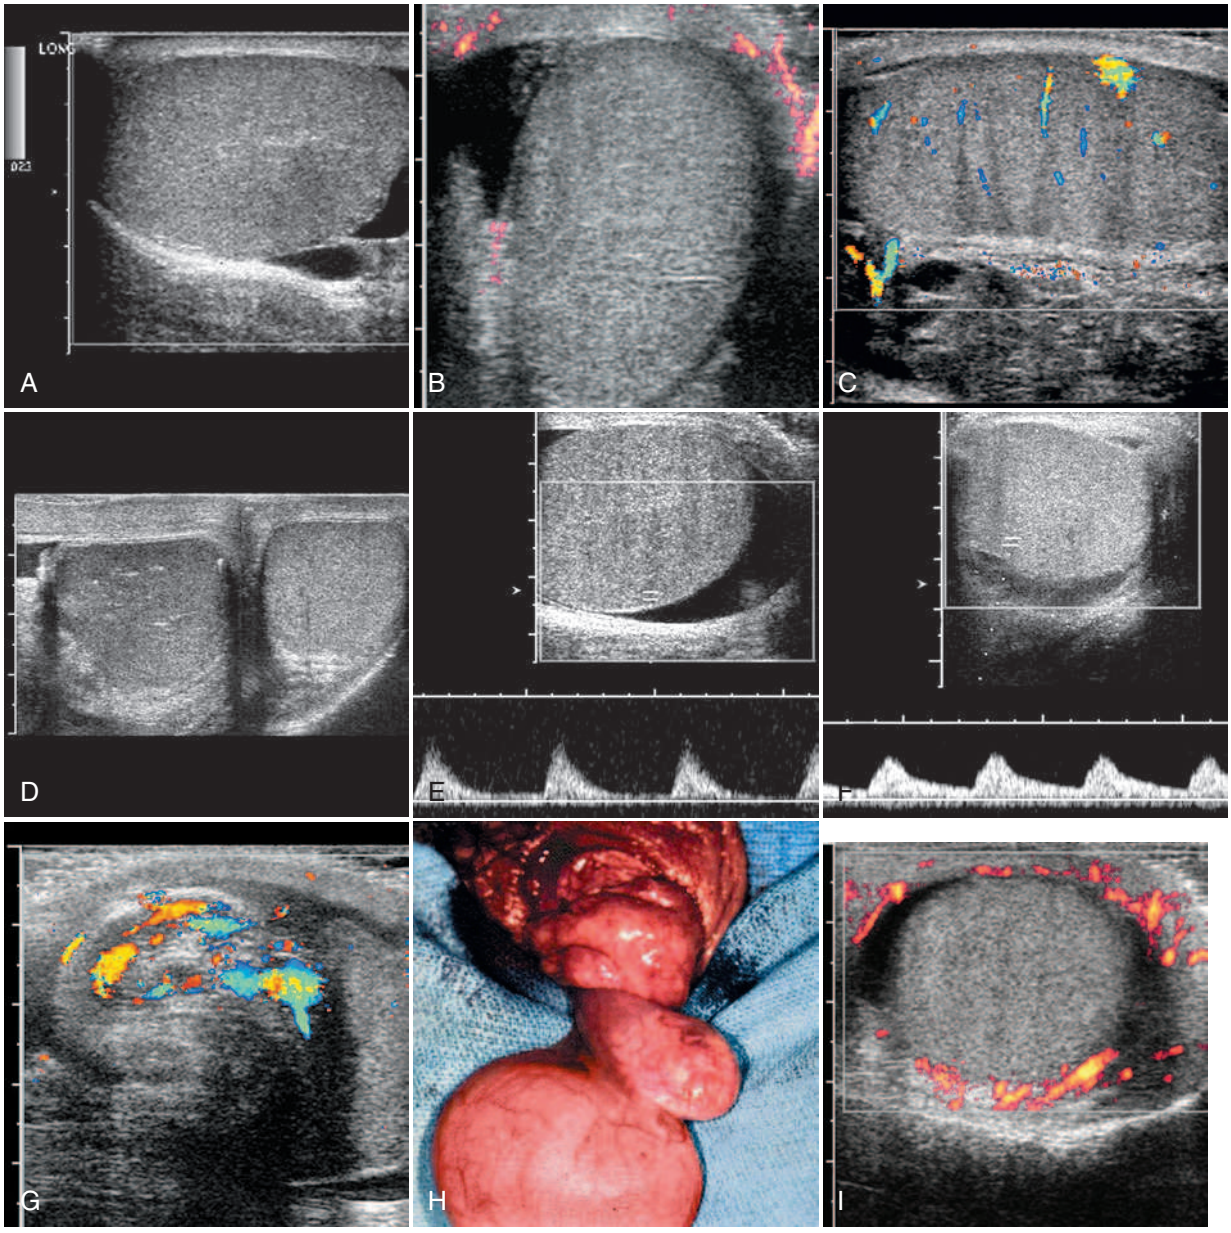

FIG. 22.30 Torsion of Spermatic Cord and Testis: Spectrum of Appearances. (A)-(D) Acute torsion. Longitudinal power Doppler scans show **(A)** no flow in the testis and **(B)** abnormal, transverse, and vertical orientation of the testis with no flow. **(C)** After manual detorsion of case in **B,** longitudinal color Doppler scan shows the normal orientation of the testis with blood flow present. The testis has a striated appearance caused by the previous ischemia. **(D)** Dual transverse gray-scale scan shows enlarged hypoechoic right testis resulting from torsion and skin thickening in the right hemiscrotum. **(E) Partial torsion.** Longitudinal scan with spectral Doppler shows a high-resistance testicular arterial waveform with little diastolic flow because of venous occlusion; a small, reactive hydrocele was found. **(F)** After spontaneous detorsion of case in **E,** longitudinal scan with spectral Doppler shows return of diastolic flow. **(G) Torsion knot.** Longitudinal scan with acute spermatic cord torsion shows the "torsion knot" complex of epididymis and spermatic cord. **(H) Acute torsion.** Intraoperative photograph shows the twisted spermatic cord that gives the torsion knot appearance on sonograph. **(I) Subacute torsion** (3 days of pain). Transverse power Doppler scan shows absent flow within the testis with surrounding hyperemia. (**H** with permission from Winter TC. Ultrasonography of the scrotum. Appl Radiol 2002;31[3]:9-18.[169])

used anymore to diagnose torsion.[179] In testicular torsion, color Doppler sonography has a sensitivity of 80% to 98%, specificity of 97% to 100%, and accuracy of 97%.[161,162,180] The use of intravascular contrast agents in sonography can improve the sensitivity and specificity of detecting blood flow in the scrotum.[175,181] In pediatric patients, it may be difficult to document flow in a normal testis.[182] In practice, many surgeons elect to explore the testis surgically if clinical symptoms and signs are suggestive and results of the sonographic examination are equivocal.

Torsion is not an all or none phenomenon. Potential pitfalls in using sonography in the diagnosis of torsion are **partial torsion, torsion/detorsion,** and **ischemia from orchitis.** Torsion of at least 540 degrees is necessary for complete arterial occlusion.[162,183] With partial torsion of 360 degrees or less, arterial flow may still

occur, but venous outflow is often obstructed, causing diminished diastolic arterial flow on spectral Doppler examination[184,185] (Fig. 22.30E). If spontaneous detorsion occurs, flow within the affected testis may be normal, or it may be increased and mimic orchitis.[186] Spontaneous detorsion can occur with sequelae including a segmental testicular infarction.[102,103] Segmental testicular infarction may also occur with **Henoch-Schönlein purpura** or with **orchitis** (see Fig. 22.14). Orchitis may also cause global ischemia of the testis and mimic torsion.[186]

In subacute or chronic torsion, Doppler sonography demonstrates no flow in the testis and increased flow in the paratesticular tissues, including the epididymis-cord complex and **dartos fascia** (Fig. 22.30I).

Torsion of the appendix testis or appendix epididymis can present with acute scrotal pain, potentially mimicking testicular torsion clinically, although there are no other clinical symptoms and the **cremasteric reflex** can still be elicited. Patients are rarely referred for imaging because the pain is usually not severe, and the twisted appendage may be evident on physical examination as a small firm nodule palpable at the superior aspect of the testis, with a bluish discoloration, or the **"blue dot" sign.**[187] Up to 95% of twisted appendages involve the appendix testis and occur most often in boys aged 7 to 14 years.[65] The sonographic appearance of the twisted testicular appendage has been described as an avascular hyperechoic mass with a central hypoechoic focus adjacent to the head of a normally perfused testis and surrounded by an area of increased color Doppler perfusion.[162,188] These cases are managed conservatively with pain typically resolving in 2 to 3 days with interval atrophy of the torsed appendage. The role of sonography is to exclude testicular torsion or epididymo-orchitis. **Idiopathic scrotal edema** typically affects prepubertal boys, with acute onset of relatively painless scrotal erythema and subcutaneous edema. Idiopathic scrotal edema typically resolves spontaneously in 1 to 3 days without sequelae.

Epididymitis and Epididymo-orchitis

Epididymitis is the most common cause of acute scrotal pain in postpubertal men. It may be acute or chronic, depending on the inciting organism and the duration of the process. Acute epididymitis usually results from a lower urinary tract infection and is less often hematogenous or traumatic in origin. The common causative organisms are ***Escherichia coli, Pseudomonas,*** and ***Klebsiella.*** Sexually transmitted organisms causing urethritis, such as ***Neisseria gonorrhoeae*** and ***Chlamydia trachomatis,*** are common causes of epididymitis in younger men. Less frequently, epididymitis may be caused by **tuberculosis, mumps,** or **syphilitic orchitis.**[153,189] The age of peak incidence is 40 to 50 years. Typically, patients present with the insidious onset of pain which increases over 1 or 2 days. Fever, dysuria, and urethral discharge may also be present.

In **acute epididymitis,** sonography characteristically shows enlargement of the epididymis, involving the tail initially and frequently spreading to the entire epididymis[190] (Fig. 22.31A and B). The echogenicity of the epididymis is usually decreased and its echotexture is often coarse and heterogeneous, likely secondary to edema, hemorrhage, or both. Color flow Doppler sonography usually shows increased blood flow in the epididymis or testis, or both, compared with the asymptomatic side.[191] Reactive hydrocele formation is common, and associated scrotal wall thickening may be seen.

Direct extension of epididymal inflammation to the testis, called **epididymo-orchitis,** occurs in up to 20% of patients with acute epididymitis. Isolated orchitis may also occur. In such cases, increased blood flow is localized to the testis (Fig. 22.31D and E, Video 22.6). Testicular involvement may be focal or diffuse. Characteristically, **focal orchitis** produces a hypoechoic area adjacent to an enlarged portion of the epididymis. Color Doppler shows increased flow in the hypoechoic area of the testis; increased flow in the tunica vasculosa may also be visible as lines of color signal radiating from the mediastinum testis.[192] These lines of color correspond to septal accentuation visible as hypoechoic bands on gray-scale sonography (Fig. 22.31H and I). Spectral Doppler shows increased diastolic flow in uncomplicated orchitis (Fig. 22.32A). If left untreated, the entire testis may become involved, appearing hypoechoic and enlarged. As pressure in the testis increases from edema, venous infarction with hemorrhage may occur, appearing hyperechoic initially and hypoechoic later.[192] Ischemia and subsequent infarction may also occur when the vascularity of the testis is compromised by venous occlusion or venous thrombosis.[193] When vascular disruption is severe, resulting in complete testicular infarction, the changes are indistinguishable from those seen in testicular torsion. Color Doppler sonography may show focal areas of reactive hyperemia and increased blood flow associated with relatively avascular areas of infarction in both the testis and the epididymis in patients with severe epididymo-orchitis. Diastolic flow reversal in the arterial waveforms of the testis is an ominous finding, associated with testicular infarction in severe epididymo-orchitis[194] (Fig. 22.32B).

In addition to infarction, other complications of acute epididymo-orchitis include intratesticular abscess formation and development of a pyocele (see Figs. 22.13 and 22.17F). Chronic changes may be seen in the epididymis or testis from clinically resolved epididymo-orchitis. Swelling of the epididymis may persist and appear as a heterogeneous mass on sonography. The testis may have a persistent, striated appearance of septal accentuation from fibrosis (Figs. 22.33 and 22.34). This striated appearance of the testis is nonspecific and may also be seen after ischemia from torsion or during a hernia repair.[192,195] A similar heterogeneous appearance in the testis may be seen in older patients because of **seminiferous tubule atrophy and sclerosis.**[196] Focal areas of infarction in the testis may persist as wedge-shaped or cone-shaped hypoechoic areas or may appear as hyperechoic scars.[192] If complete infarction of the testis has occurred because of epididymo-orchitis, the testis may become small, with a hypoechoic or heterogeneous echotexture.

Fournier Gangrene

Fournier gangrene is a **necrotizing fasciitis of the perineum,** external genitalia, and perianal area occurring most frequently in men aged 50 to 70 years. The origin is usually a disease process from the overlying skin, urinary tract, or colorectal area, frequently due to a synergistic polymicrobial infection.[197] Predisposing factors include systemic immunosuppression, diabetes mellitus,

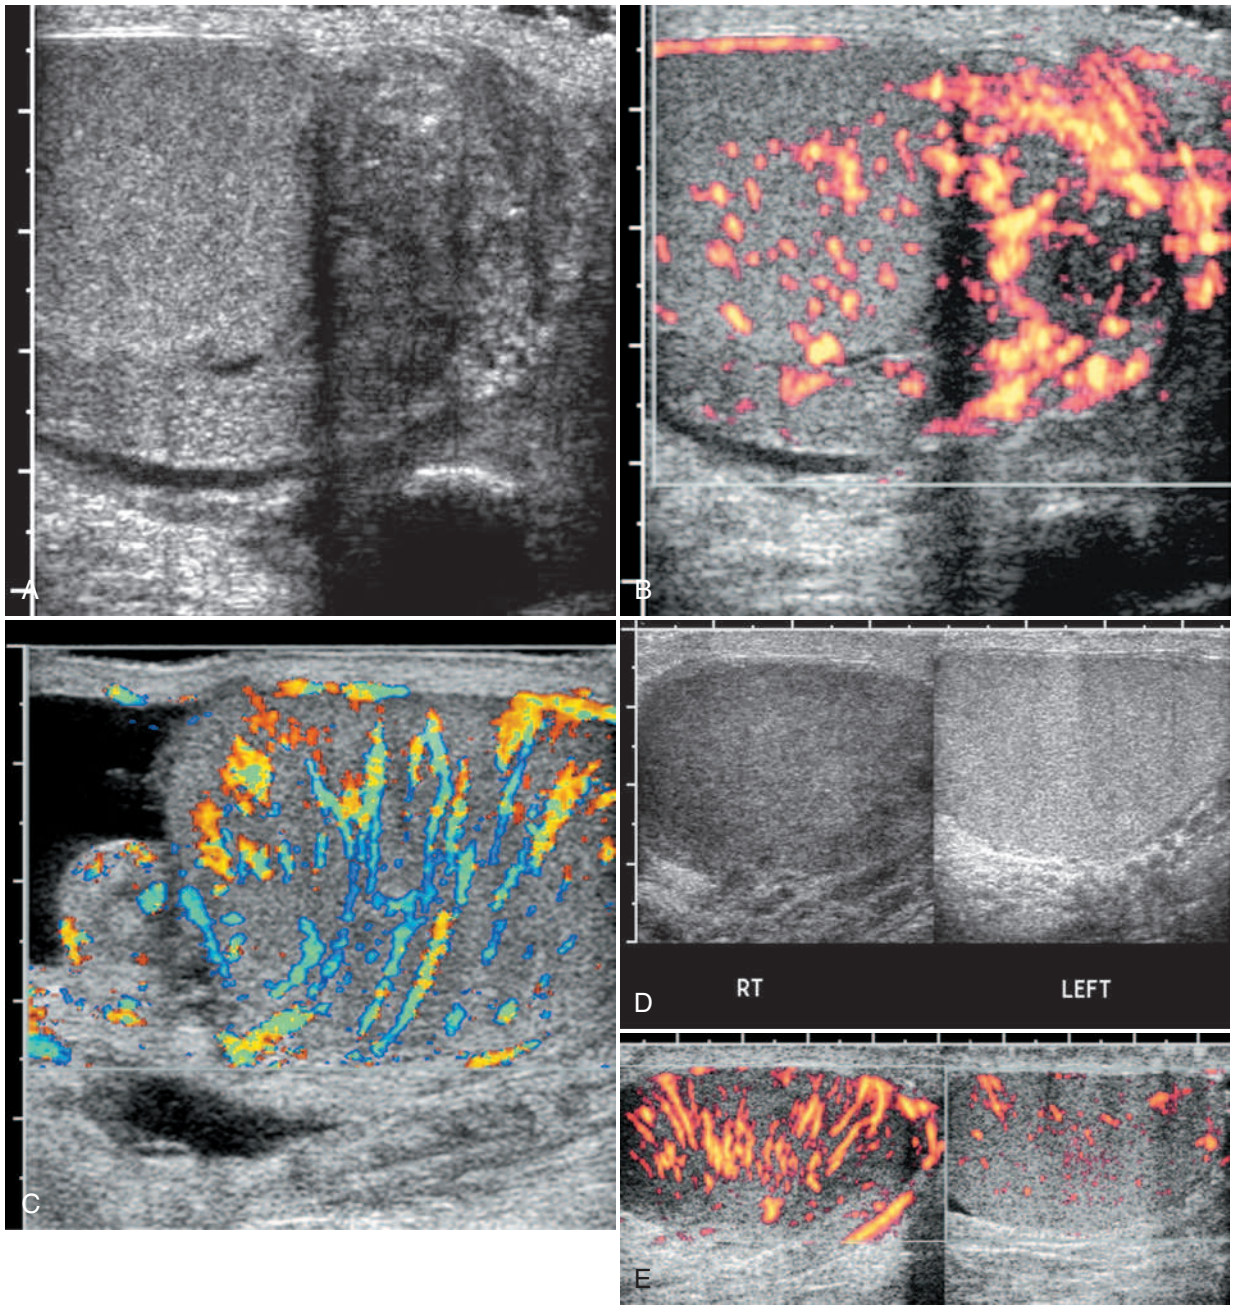

FIG. 22.31 Epididymo-orchitis, Epididymitis, and Orchitis: Spectrum of Appearances. (A) and **(B) Acute epididymitis.** Longitudinal gray-scale and color Doppler images show enlargement and a heterogeneous echotexture of tail of the epididymis, with greatly increased flow in tail of the epididymis and minimally increased flow in the adjacent testis. **(C) Acute epididymo-orchitis.** Longitudinal color Doppler scan shows increased flow in the epididymis and testis. **(D)** and **(E) Acute orchitis.** Longitudinal dual-image gray-scale and color Doppler images show that right testis is hypoechoic and has greatly increased flow.

chronic alcoholism, and steroid therapy.[152] Multiple organisms are usually involved, including *Klebsiella, Streptococcus, Proteus,* and *Staphylococcus.* Surgical debridement of devitalized tissue is usually required, and morbidity and mortality are high without prompt treatment. Ultrasound is helpful in diagnosis by demonstrating scrotal wall thickening containing gas with accompanying shadowing.

TRAUMA

When evaluating testicular integrity in the setting of acute trauma, the primary role of sonography is to assess for the continuity of the tunica albuginea: this determines clinical management. Disruption of the tunica albuginea indicates testicular rupture. Prompt diagnosis of a ruptured testis is crucial because of the

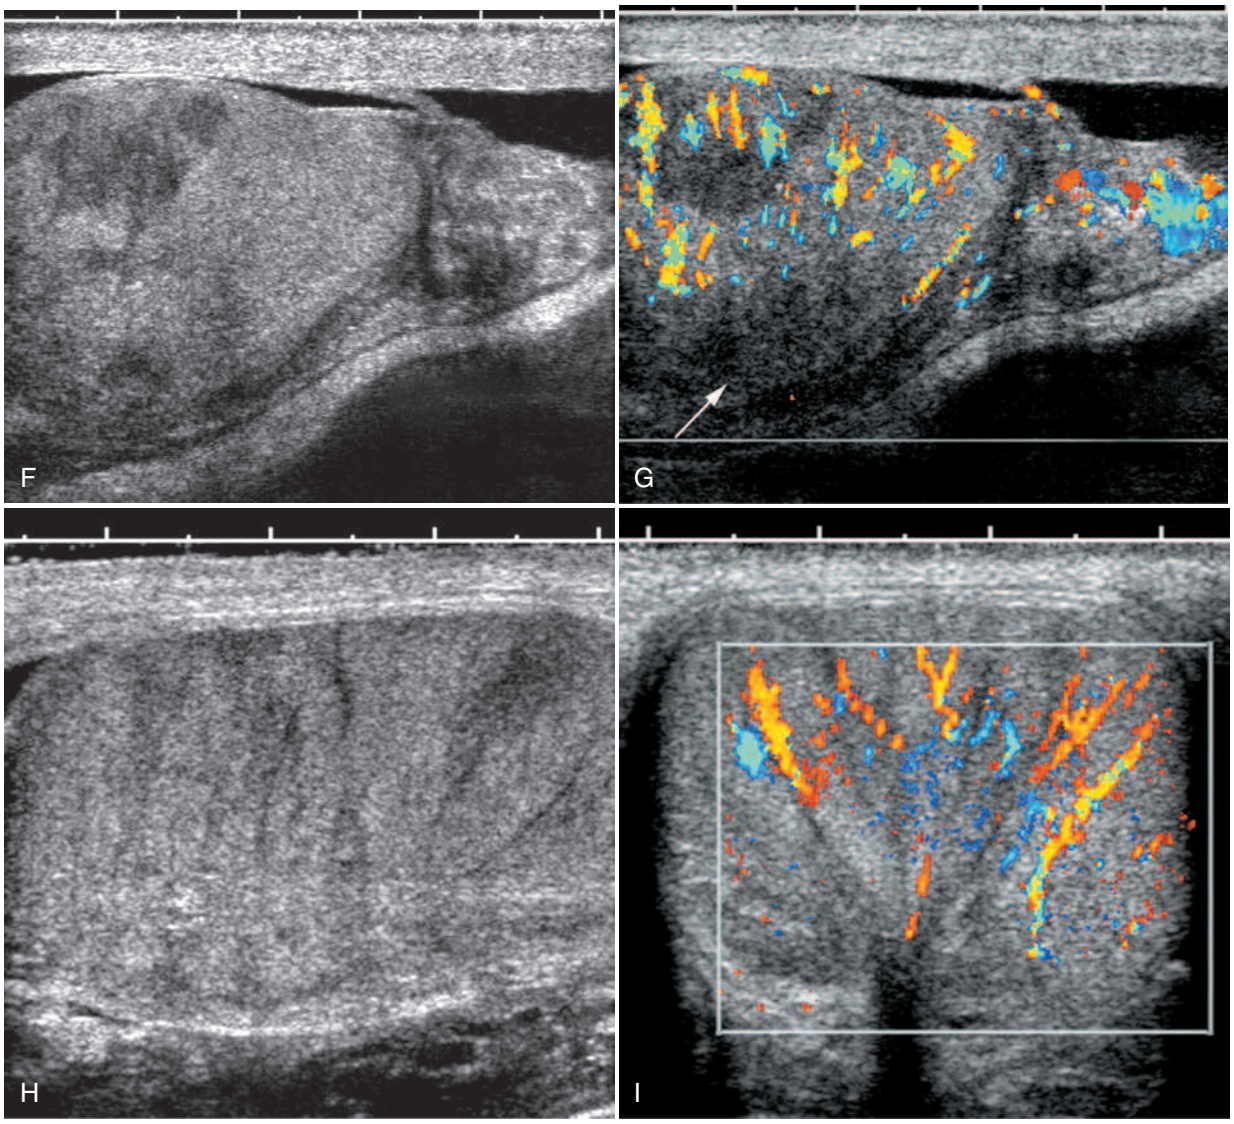

FIG. 22.31, cont'd. **(F)** Longitudinal gray-scale scan with 3 weeks of epididymo-orchitis unresolved with antibiotic therapy shows hypoechoic areas in the testis and an enlarged heterogeneous tail of the epididymis. **(G)** Color Doppler image shows increased flow in the testis and epididymis with an area of decreased flow due to ischemia *(arrow)*. **(H)** and **(I)** **Acute orchitis.** Longitudinal gray-scale and color Doppler images show hypoechoic bands caused by septal accentuation from edema and increased vascularity of the testis. See also Video 22.6.

direct relationship between early surgical intervention and testicular salvageability. Approximately 90% of ruptured testes can be saved if surgery is performed within the first 72 hours, whereas only 45% may be salvaged after 72 hours.[198]

Sonographic features of testicular rupture include focal areas of altered testicular echogenicity, corresponding to areas of hemorrhage or infarction, and hematocele formation in 33% of patients. A discrete fracture plane may not be identified. Tunical disruption associated with extrusion of the seminiferous tubules is specific for rupture (Fig. 22.35E, Video 22.7). However, the sensitivity of the diagnosis of rupture based on tunical disruption alone is only 50%. Heterogeneity of the testis with associated testicular contour irregularity may be helpful in making the diagnosis of rupture.[110,199,200] Color Doppler imaging can be helpful because rupture of the tunica albuginea is almost always associated with disruption of the tunica vasculosa and loss of blood supply to part or all of the testis.[110] Although not specific for a ruptured testicle, these features may suggest the diagnosis in the appropriate clinical setting, prompting immediate surgical exploration.

Clinical diagnosis is often impossible because of marked scrotal pain and swelling; thus sonography can be invaluable in the assessment of tunica albuginea integrity and the extent of testicular hematoma.[110,198-200] A visibly intact tunica albuginea should exclude rupture, but a complex intrascrotal hematoma may be difficult to distinguish from testicular rupture and may obscure the tunica[110,201] (Fig. 22.35A). Patients with large intrascrotal hematomas or hematoceles will often undergo surgical exploration because it is difficult to exclude rupture sonographically in the presence of surrounding complex fluid.[110] If a patient with a presumed intratesticular hematoma is not surgically explored,

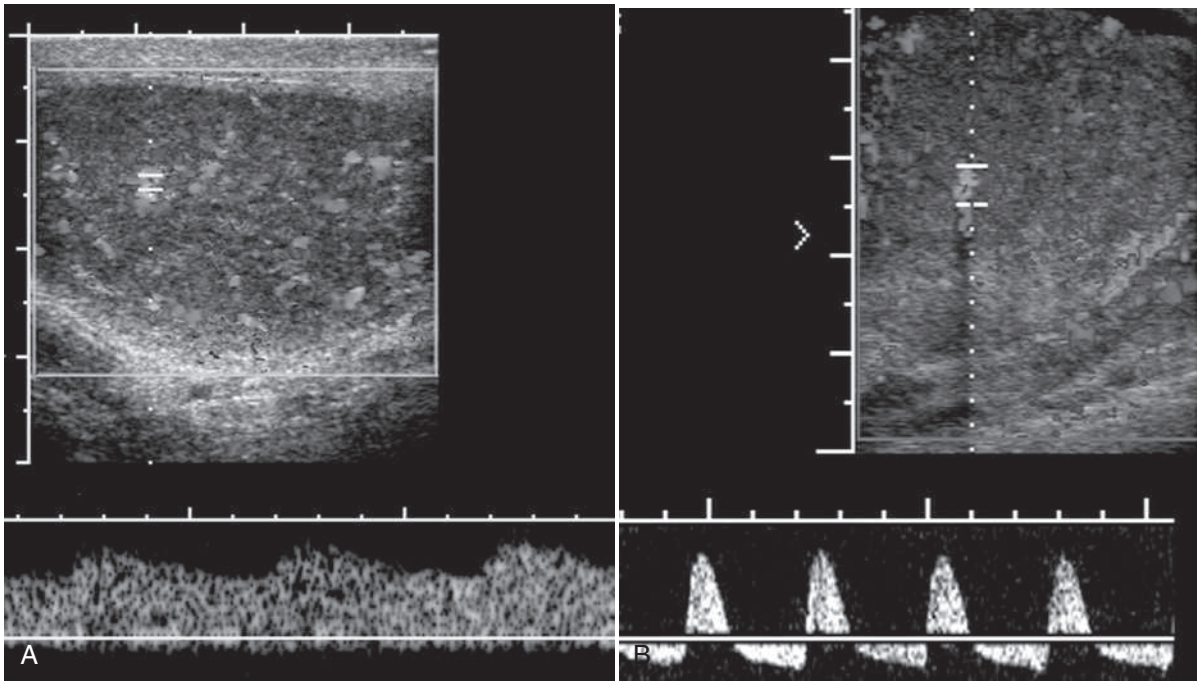

FIG. 22.32 Spectral Doppler Changes in Orchitis. (A) Uncomplicated orchitis. Longitudinal scan with spectral Doppler tracing shows increased diastolic flow in the testis. **(B) Orchitis with venous compromise.** Longitudinal scan with spectral Doppler tracing in more severe orchitis shows reversal of flow in diastole caused by edema impeding venous flow.

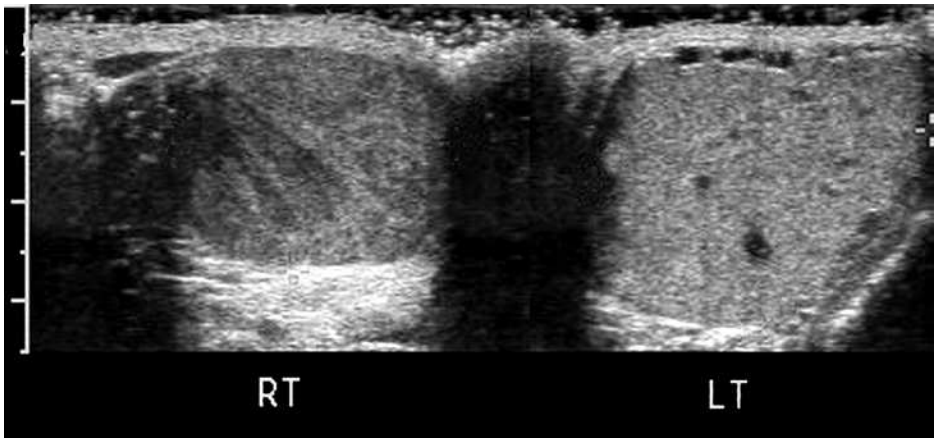

FIG. 22.33 Heterogeneous "Striped" Testis. Transverse dual image shows heterogeneity in the right testis with marked septal accentuation from previous orchitis. This appearance may also be seen after ischemia.

FIG. 22.34 Fibrosis of Testis After Orchitis. Pathologic specimen of testis shows linear bands of fibrosis *(white areas)* caused by previous severe orchitis. A similar "end-stage" testis could have this appearance due to ischemia.

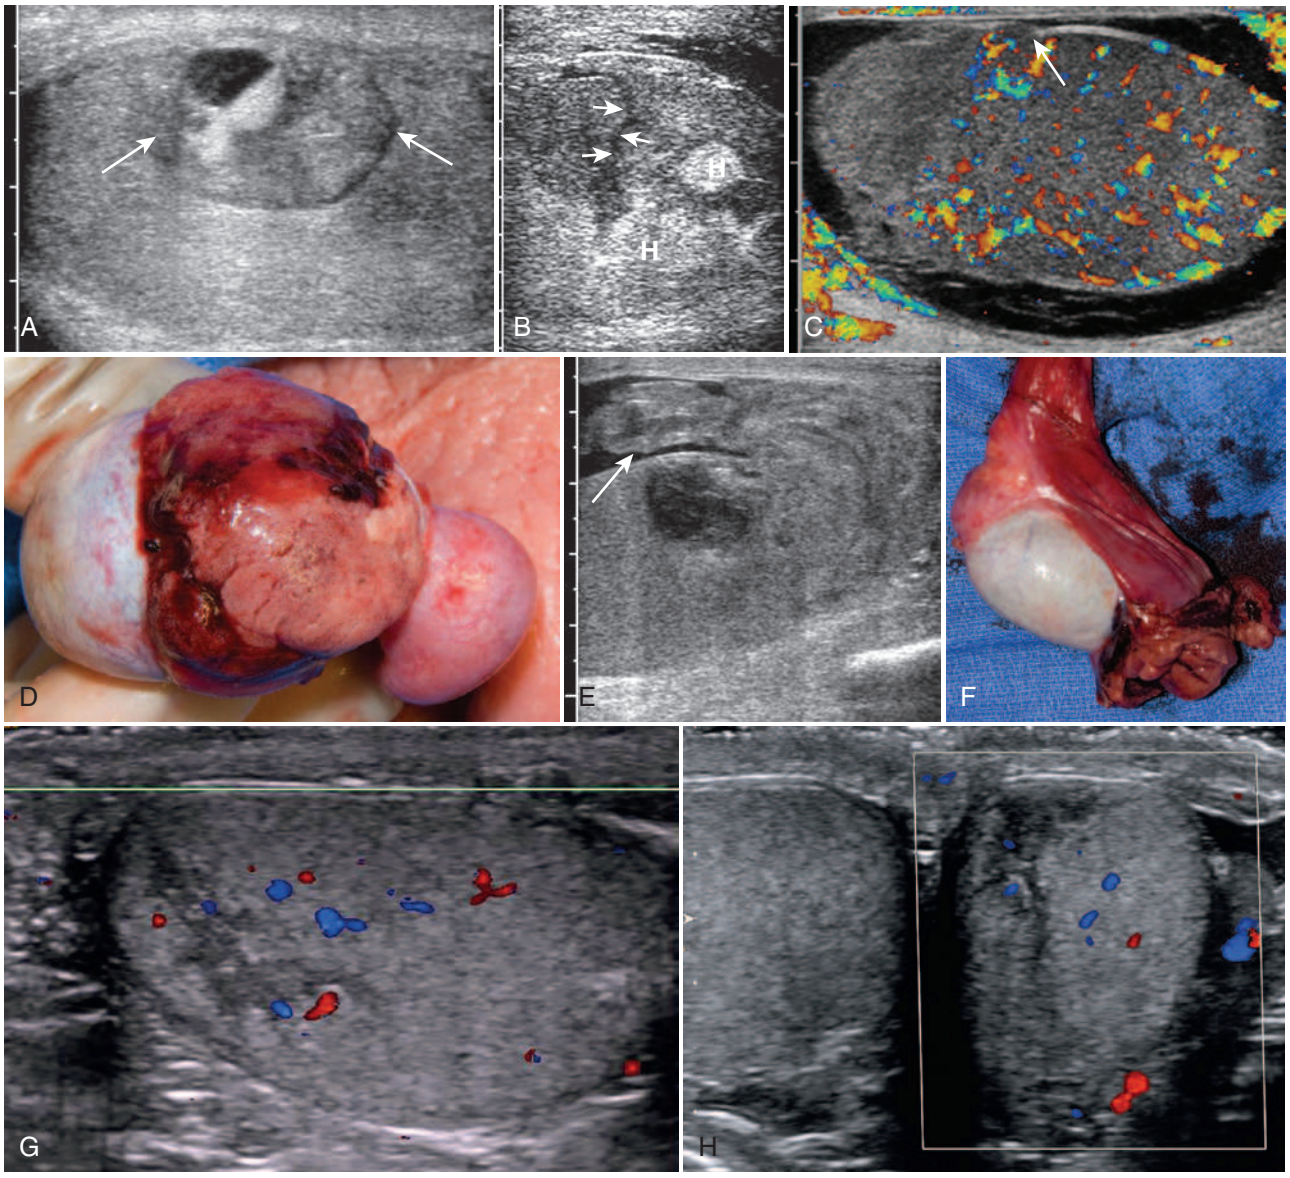

FIG. 22.35 Testicular Trauma: Spectrum of Appearances. (A) Hematoma. Longitudinal image shows hematoma *(arrows)* on the anterior surface of the testis. Tunica intact at surgery. **(B) Fracture of testis.** Transverse scan shows a heterogeneous testicle with a linear band *(arrows)* indicating a fracture. *H,* Testicular hematoma. **(C) Tunical tear.** Longitudinal color Doppler image shows contour irregularity of the testis with disruption of the tunica *(arrow).* Extruded testis parenchyma shows no color flow. **(D)** Same case as **C.** Photograph during surgery shows tunical tear in the exposed right testis. **(E) Rupture of testis.** Longitudinal image shows rupture of the testis with extrusion of seminiferous tubules *(arrow).* **(F)** In same case as **E,** photograph during surgery shows a tear in the tunica inferiorly with extrusion of seminiferous tubules. **(G)** and **(H) Fracture of testis.** Longitudinal and transverse color Doppler images of the left testis show an irregular linear, hypoechoic, avascular band representing a testicular fracture following acute blunt trauma. The tunica albuginea was intact. See also Video 22.7.

it is incumbent upon the clinician to follow the intratesticular abnormality to resolution because a testicular tumor can mimic an intratesticular hematoma and also predispose to rupture following relatively minor trauma.

Testicular fracture refers to discontinuity of normal testicular parenchyma, which may be present in the absence of disruption of the tunica albuginea. An associated intratesticular hematoma or hematocele may be present. Sonographically, the fracture appears as a linear, hypoechoic, avascular band extending across the testicular parenchyma (Fig. 22.35).

Sonography can also be used to discern the severity of scrotal trauma resulting from penetrating scrotal injury. Gunshot injury is the most common cause; other causes include stabbing, self mutilation, human and animal bites, and projectile injuries. Bilateral injuries are more common in the setting of penetrating trauma.[202] Penetrating trauma can disrupt the tunica albuginea, as well as penetrate the parenchyma, causing a fracturelike injury. Ultrasound can assess the degree of injury and evaluate for the presence of foreign bodies and for the presence of air, which may denote the path of the penetrating injury.[203] Doppler

sonography can assess for viability of the testis in the setting of penetrating trauma. A careful gray-scale and color flow Doppler evaluation of the epididymis should be performed in all examinations of blunt trauma. Traumatic epididymitis may be an isolated finding that should not be confused with an infectious process.[204]

CRYPTORCHIDISM

The testes remain near the deep inguinal ring until the seventh month of gestation when they normally begin their descent through the inguinal canal into the twin scrotal sacs.[1,2] The **gubernaculum testis** is a fibromuscular structure that extends from the inferior pole of the testis to the scrotum and guides the testis in its descent, a process normally completed before birth. **Undescended testis** is one of the most common genitourinary anomalies in male infants. At birth, 3.5% of male infants weighing more than 2500 g have an undescended testis; 10% to 25% of these cases are bilateral. This figure decreases to 0.8% by age 1 year because the testes descend spontaneously in most infants. The incidence of undescended testes increases to 30% in premature infants, approaching 100% in neonates who weigh less than 1000 g at birth. Complete descent is necessary for full testicular maturation.[205,206]

Malpositioned testes may be located anywhere along the pathway of descent from the retroperitoneum to the scrotum. Most (80%) undescended testes are palpable, lying distal to the external inguinal ring. **Anorchia** occurs in 4% of the remaining patients with impalpable testes.[206]

Localization of the undescended testis is important for the prevention of two potential complications of cryptorchidism: **infertility** and **cancer.** The undescended testis is more likely to undergo malignant change than is the normally descended testis.[3] The most common malignancy is **seminoma.** The risk of malignancy is increased in both the undescended testis after orchiopexy and the normally descended testis. Therefore careful serial examinations of both testes are essential.

Sonographically, the **undescended testis** is often smaller and slightly less echogenic than the contralateral, normally descended testis (Fig. 22.36). The pars infravaginalis gubernaculi, which is the distal bulbous segment of the gubernaculum testis, can be mistaken for the testis. After completion of testicular descent, the pars infravaginalis gubernaculi and the gubernaculum normally atrophy. If the testis remains undescended, both structures persist. The pars infravaginalis gubernaculi is located distal to the undescended testis, usually in the scrotum, but it may be found in the inguinal canal. Sonographically, the pars infravaginalis gubernaculi is a hypoechoic, cordlike structure of echogenicity similar to the testis, with the gubernaculum leading to it.[207]

Sonography is often used in the initial evaluation of cryptorchidism, although the value of this has been questioned because it is insensitive in detecting high intraabdominal testes.[208] MRI has also been used in cryptorchidism because it is more sensitive than ultrasound in detecting undescended testes in the retroperitoneum.[209,210] Nonvisualization of an undescended testis on sonography or MRI does not exclude its presence, and therefore laparoscopy or surgical exploration should be performed if clinically indicated.

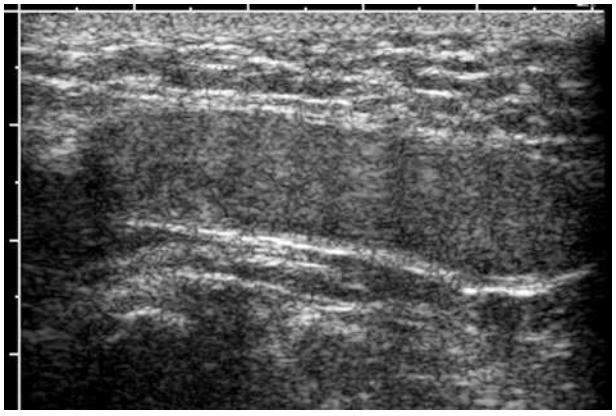

FIG. 22.36 Testis in Inguinal Canal. Longitudinal scan shows an elongated, ovoid, undescended testis.

CHAPTER 23

Overview of Musculoskeletal Ultrasound Techniques and Applications

Colm McMahon and Corrie Yablon

SUMMARY OF KEY POINTS

- A wide variety of inflammatory, degenerative, traumatic, and neoplastic conditions can be imaged accurately and cost-effectively with ultrasound.
- Understanding optimal imaging techniques and recognizing and avoiding common artifacts is essential to musculoskeletal ultrasound.
- Ultrasound can provide higher-resolution imaging of nerves and tendons compared with standard clinical magnetic resonance imaging examinations.
- Dynamic imaging may be performed with ultrasound, which can assist in the diagnosis of tendon and ligamentous injury.

CHAPTER OUTLINE

GENERAL CONSIDERATIONS
Doppler Imaging
Elastography
Extended Field of View Imaging
MUSCLES
TENDONS
LIGAMENTS
NERVES
JOINT ASSESSMENT
SOFT TISSUE MASSES
FOREIGN BODIES
SOFT TISSUE INFECTION
CONCLUSION

GENERAL CONSIDERATIONS

Ultrasound is becoming a central part of the diagnostic pathway for patients with musculoskeletal complaints. In many cases, ultrasound is performed as an alternative or complement to magnetic resonance imaging (MRI). Ultrasound has several advantages over MRI that have been described in the literature, succinctly by Nazarian in a 2008 perspective article.[1] Ultrasound is well tolerated by patients and can be performed in those with contraindications to MRI, such as implanted cardiac devices or other MRI-incompatible implants, large size, or claustrophobia. Ultrasound examinations often take less time to perform than the corresponding MRI examinations. Ultrasound provides higher-resolution imaging of tendons and ligaments than routine musculoskeletal MRI. Ultrasound also provides the ability to image dynamically, which can be important in the diagnosis of disorders of impingement and subluxation of nerves or tendons. It is excellent at determining the fundamental tissue characterization of solid versus cystic in the setting of a mass lesion—this type of characterization may otherwise require the administration of intravenous contrast when MRI is used to distinguish a T2-hyperintense solid mass from a simple cyst. In many cases, patients can be given results at the time of their examination.

As a general rule, a systematic approach to musculoskeletal ultrasound examination of the joints using defined protocols is preferred to a focal examination when time permits. Focused imaging of symptomatic areas of concern adds additional diagnostic information to the routine protocol.[2] When evaluating a foreign body or palpable soft tissue mass, focal assessment can be performed, with attention to the relationship to nearby anatomic structures, critical to treatment planning. As with MRI interpretation, it is imperative that the radiologist have a clear understanding of musculoskeletal anatomy before performing or interpreting a sonographic examination, especially when previous studies are not available for comparison.

High-frequency linear ultrasound probes (12-15 MHz) are recommended for musculoskeletal imaging. Higher-frequency probes (15-17 MHz) can be helpful for evaluating superficial anatomy, for example, ligaments and tendons in the fingers. Hockey stick–style high-frequency probes can be very useful for evaluation of fine structures, providing focused small field of view images and permitting good skin contact in the peripheral extremities. Lower-frequency (3-9 MHz) linear probes may be

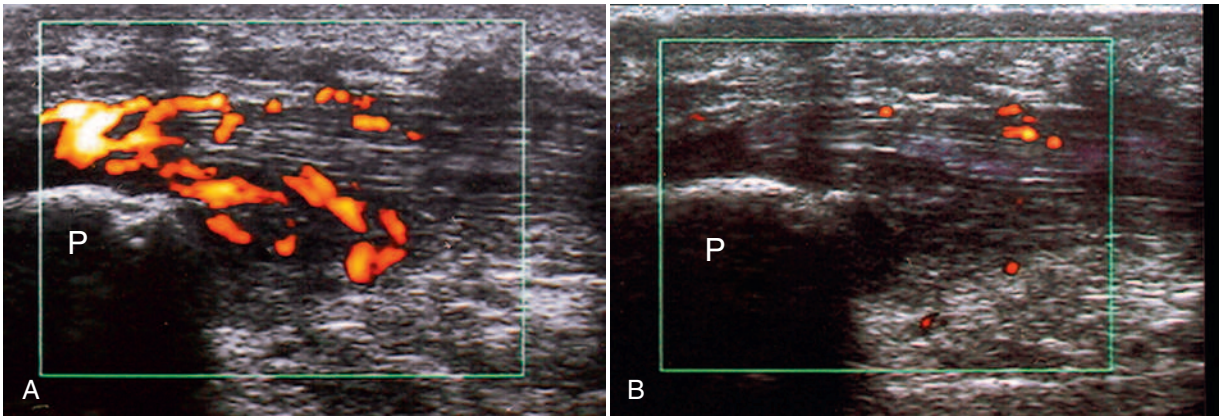

FIG. 23.1 Effect of Examination Technique on Power Doppler Findings. (A) Longitudinal sonogram obtained without pressure exerted on the tendon shows hypervascularity. **(B)** Longitudinal sonogram obtained with the usual pressure on the transducer shows the near complete disappearance of hypervascularity. *P,* Patella.

needed for greater tissue penetration in deeper structure evaluation or when attempting to determine the relationships of a deep pathologic process to the underlying bone and muscle. Although lower-frequency probes provide deeper penetration of soft tissues, there is a corresponding trade-off of lower resolution. In some cases, a low-frequency curvilinear probe may be necessary (2-5 MHz), for example, in the evaluation of the thigh and hip region or the examination of deep thigh or gluteal masses. By using more than one probe, the user may obtain complementary information about a single disease process. As is the case for all ultrasound imaging, careful attention to image optimization, such as positioning the focal zone at the appropriate depth, is important. Adequate ultrasound wave transduction is facilitated by good skin contact with the transducer and the use of ultrasound gel. A standoff pad can help for imaging very superficial structures.

Doppler Imaging

The role of Doppler imaging in musculoskeletal ultrasound includes characterization of neoplastic, inflammatory, and degenerative conditions.[3] Doppler ultrasound is helpful in confirming vascularization of solid masses in distinction from avascular cystic lesions. It is also helpful in characterization of inflammatory conditions, including synovitis, tenosynovitis, myositis, and soft tissue infection. Finally, tendon neovascularization is a sign occasionally seen with the development of degenerative tendinosis. As in other areas of the body, setting the appropriate Doppler gain is important, and imaging with a small sample volume will minimize motion artifacts. Because many structures of interest in musculoskeletal imaging are superficial, care should be taken to avoid excessive probe pressure during imaging, because this can limit flow detection in areas of vascularization (Fig. 23.1).

Elastography

An exciting recent development is imaging and quantification of tissue elasticity. This is defined by the tissue deformability and can be measured as a Young modulus for a given tissue expressed in kilopascals (kPa).[4] The range of Young modulus for musculoskeletal tissue ranges from 1 to 10 kPa. Depending on available hardware, ultrasound elastography may be performed using strain elastography or shear-wave elastography. In the musculoskeletal system, early application of elastography has shown substantial promise in the evaluation of tendinosis. In tendinosis, collagen disorganization and mucoid and lipoid degeneration result in tendon softening, which can be visualized and quantified with sonoelastography.[5] Other emerging applications include diagnosis of muscle disorders such as myositis[6] and characterization of soft tissue masses.[7]

Extended Field of View Imaging

Although high-resolution linear array probes are optimal for imaging relatively superficial musculoskeletal structures with fine anatomic detail, the overall field of view during imaging is limited. This may cause difficulty when viewing the images after acquisition, because the scale and anatomic position and orientation, which are intuitive when scanning real time, may be difficult to convey in the retained static images. This can be overcome by use of cine-clips and also with use of extended field of view (panorama) imaging. With this technique, an image is acquired while the probe is moved in the direction of the probe footprint long axis. The image acquired is a composite panoramic image of the anatomy scanned during the motion path of the probe. The scanners equipped with this technology recognize the degree of probe motion by the degree of frame shift during the movement of the probe. By utilizing knowledge of this motion vector, a blended image of successively acquired image frames during the probe sweep can be formed.[8] This technique can be extremely helpful in putting a specific finding in overall anatomic context, measuring a lesion that is larger than the probe field of view, and can also provide some diagnostic benefit—for example, in comparing the echogenicity and bulk of muscles of the rotator cuff.[9]

MUSCLES

Normal muscle is composed of multiple fascicles each embedded in perimysium, a thin layer of connective tissue and fat.[10] The

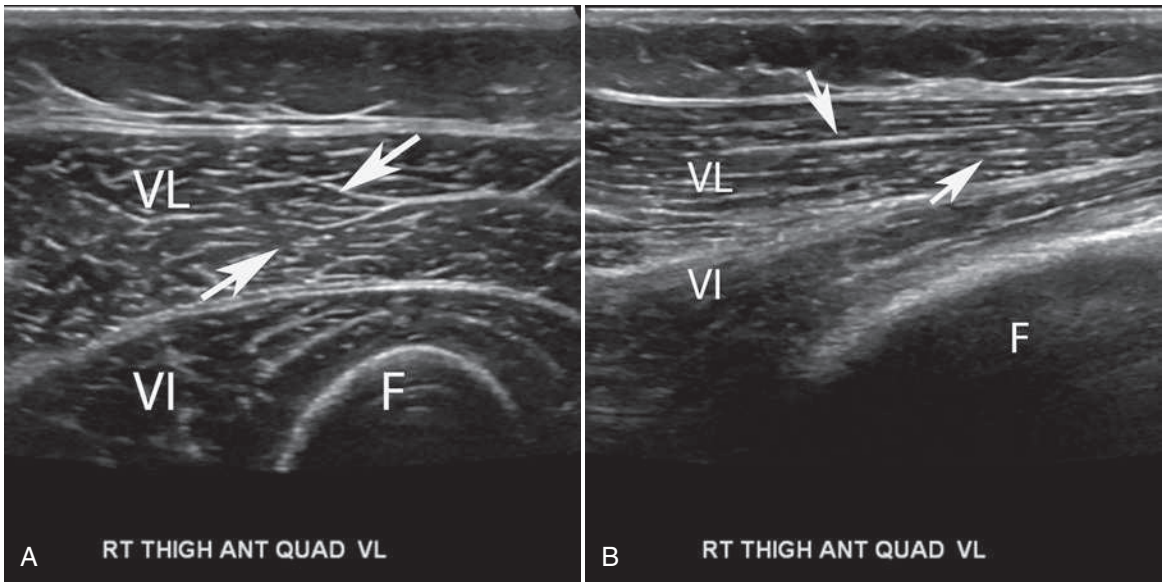

FIG. 23.2 Normal Muscle. (A) In short-axis view a normal vastus lateralis *(VL)* muscle demonstrates a speckled or "starry sky" appearance *(arrows).* **(B)** In long-axis view the normal muscle demonstrates a pennate appearance *(arrows). F,* Femur; *VI,* vastus intermedius.

ultrasound pattern of muscle is typically feathery, or pennate, with fiber orientation usually directed along the long axis of the muscle. In the short-axis view, the muscle fibers demonstrate a speckled appearance (Fig. 23.2). Fibers typically converge to the myotendinous junction and the muscle tapers in diameter at this point (Videos 23.1 and 23.2). A thin layer of fascia surrounds the muscle unit, separating it from adjacent muscles and subcutaneous fat. Muscle is usually overall hypoechoic, with more echogenic internal linear interfaces generated by the perimysium.

Muscle injuries of different grades can be identified with ultrasound.[11] A grade I injury is a minor strain and is depicted on ultrasound as just minimal fiber elongation and hypoechogenicity, but without detectible discontinuity. Ultrasound is less sensitive than MRI to these minor grades of injury, which are usually treated conservatively.[12] A grade II injury is a partial tear. Fiber discontinuity is seen, with a focal anechoic or hypoechoic gap, usually filled by more echogenic hematoma. Gentle probe pressure can demonstrate muscle fibers floating freely within fluid and hematoma, referred to as the "bell-clapper" sign. At the most severe end of the spectrum of muscle injury is a grade III injury, or complete tear (Fig. 23.3). In the case of a grade III injury, the muscle is completely interrupted with retraction of the muscle ends and an interposed gap, which should be measured. A large hematoma is expected in association with a complete tear.

A distinct form of muscle injury that deserves special mention is the avulsion of a muscle from its aponeurosis, a pattern of injury particularly common in the calf in the clinical spectrum of "tennis leg" (Fig. 23.4). In this injury the **medial gastrocnemius muscle** tears away from the aponeurosis with the underlying soleus muscle. Fluid and hematoma may dissect along the aponeurotic plane and there may be some retraction of the medial gastrocnemius. This usually occurs during forceful plantar flexion

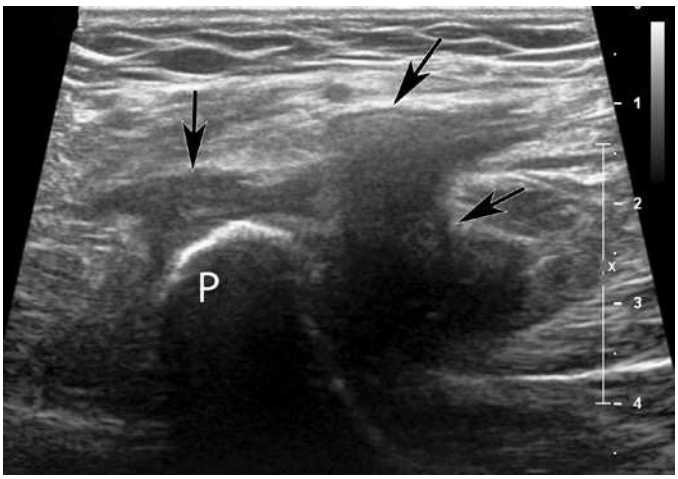

FIG. 23.3 Muscle Tear. Long-axis image of the medial groin region demonstrates hypoechoic fluid *(arrows)* at the pubic symphysis *(P)* origin of the adductor muscles, consistent with a grade III muscle tear.

during sports, for example, in a forceful lunge in tennis. This injury may be accompanied by a plantaris tendon tear.

Symptomatic **myofascial defects** lend themselves well to ultrasound evaluation. In this injury a defect in the muscular fascia allows herniation of muscle fibers, leading to a palpable and often painful mass (Fig. 23.5). In some cases, the patient may have associated neuropathy resulting from compression of adjacent nerves.[13] The mass may be more apparent to the patient during certain movements and activities that lead to muscle contraction, and these can be reproduced during scanning to assist in diagnosis. On ultrasound imaging, focused evaluation of the region of concern reveals focal bulging of muscle fibers through the otherwise smooth fascia. If this is equivocal or the patient reports symptoms only in certain positions such as

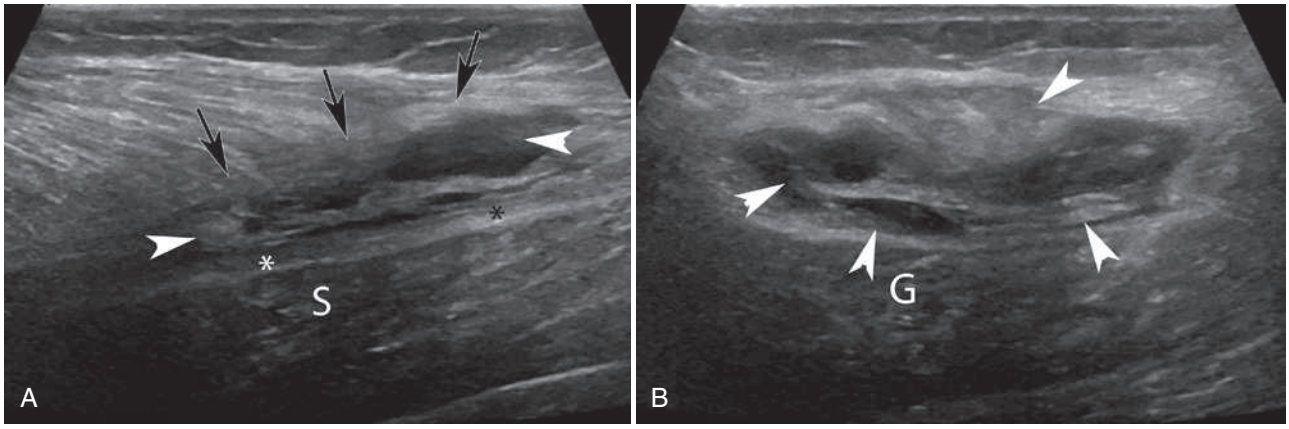

FIG. 23.4 Medial Head Gastrocnemius Tear From the Aponeurosis. (A) Long-axis image shows blunting and retraction of the medial head gastrocnemius fibers *(arrows)* from the aponeurosis (*) with an associated hematoma *(arrowheads)*. **(B)** Short-axis image shows effacement of the normal gastrocnemius muscle *(G)* architecture and a hematoma of mixed echogenicity at the site of the tear from the aponeurosis *(arrowheads)*. *S,* Soleus muscle.

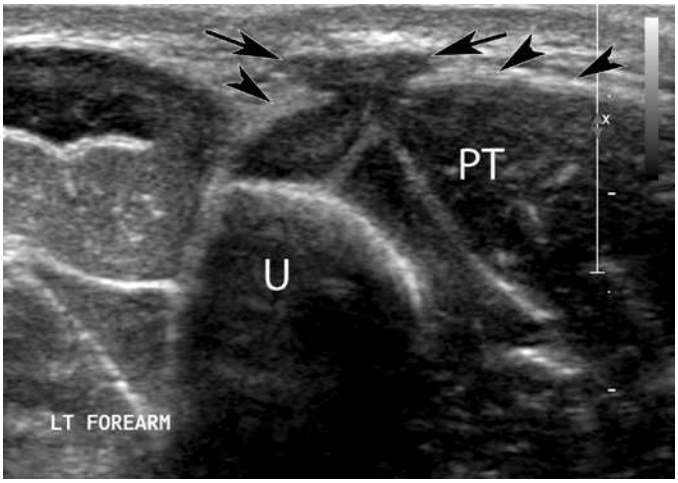

FIG. 23.5 Forearm Muscle Herniation. At the site of the palpable abnormality, there is focal herniation of a portion of the **pronator teres** muscle *(PT) (arrows)* through the muscle fascia *(arrowheads)*. This patient noticed a forearm bulge while weightlifting. *U,* Ulna.

standing, the area should be scanned with the patient reproducing the relevant position where possible.

Muscle atrophy can occur in response to denervation or chronic injury, for example, in the setting of a chronic complete rotator cuff tear. Muscle atrophy is characterized on ultrasound as a decrease in muscle bulk and a relative increase in echogenicity, reflecting replacement of muscle fibers with fatty tissue (Fig. 23.6). Comparison with adjacent muscles or the contralateral side can assist in subtle cases. As a result of increased echogenicity, the visibility of the central tendon at the myotendinous junction is diminished, and there is a loss of normal pennate pattern.[14]

TENDONS

Imaging the musculoskeletal system with ultrasound has built on early success in evaluation of tendons, with initial reports of Achilles tendon assessment.[15] Many tendons are ideally suited to ultrasound evaluation, as they are superficial and require the high-resolution imaging that ultrasound affords. Normal tendons are composed of longitudinally oriented bundles of collagen fibers, which give a highly organized echogenic linear fibrillar or striated pattern on ultrasound when viewed in long axis (Fig. 23.7). In short-axis view, normal tendons are usually smooth and ovoid in outline, with a homogenous stippled appearance, representing the tendon fibers viewed en face. Some tendons, such as the flexor and extensor tendons of the hand and wrist, are invested in a synovial lined sheath, whereas others, such as the Achilles tendon, are enveloped in a layer of loose areolar tissue called a **paratenon.**

It is critically important to understand the concept of **anisotropy** when performing the sonographic evaluation of tendons (Fig. 23.8). **Collagen bundles,** because of their smooth parallel organization within tendons, act as specular reflectors, such that sound waves are reflected in a single direction. When these specular reflectors are imaged with ultrasound, if the angle of insonation is not perpendicular to the tendon fibers, sound waves will be reflected away from the transducer, leading to the generation of an image with artifactual hypoechogenicity within the tendon.[16] This can be resolved by correcting the angle of insonation to 90 degrees when an area of hypoechogenicity is observed. The finding of focal persistent abnormal hypoechogenicity in a second plane with optimized imaging adds further corroboration to the observation of an apparent pathologic hypoechoic region.

Tendon injuries are usually caused by overuse and range from tendinosis to complete tear. The term **tendinosis** refers to intratendinous degeneration without tearing. Histologically, tendinosis consists of tendon expansion and loss of clear demarcation of collagen bundles, with increased mucoid ground substance among collagen bundles.[17] There is noninflammatory fibroblastic and myofibroblastic cellular proliferation. On ultrasound, tendinosis appears as an area of hypoechogenicity, without discontinuity, frequently associated with varying degrees of tendon thickening (Fig. 23.9). **Dystrophic calcification,** and even ossification, can be seen within affected tendons. An additional characteristic feature is the development of neovascularization,

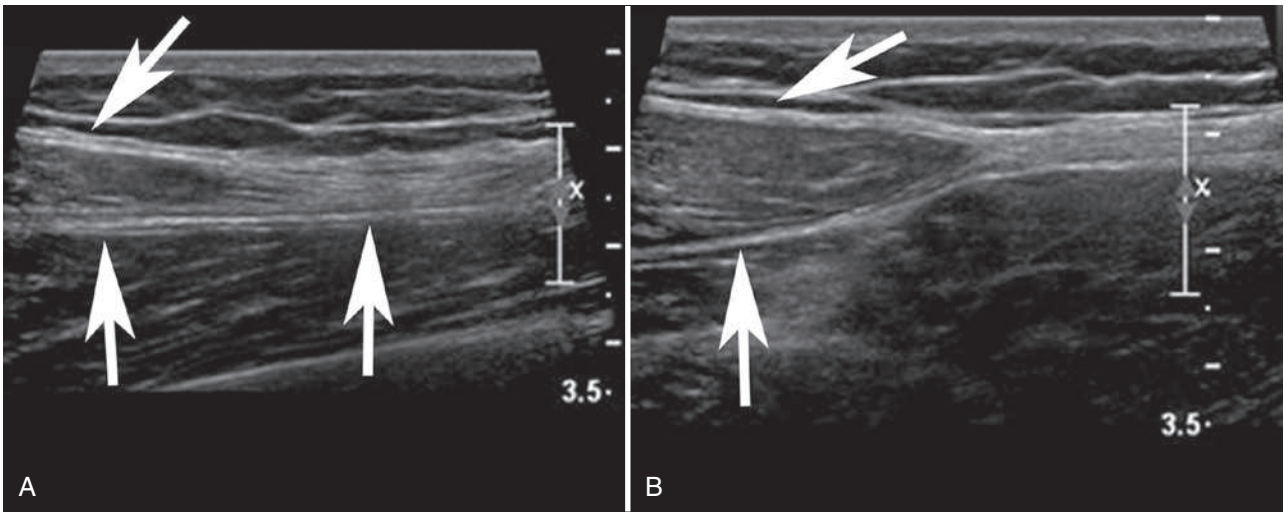

FIG. 23.6 Muscle Atrophy. Patient with a remote history of quadriceps injury presented with noticeable volume loss in his right anterior thigh. **(A)** Ultrasound of the abnormal right side shows marked volume loss in the rectus femoris muscle *(arrows)* with echogenic fatty infiltration of the remaining muscle. **(B)** The normal left side demonstrates normal muscle bulk and echotexture *(arrows).*

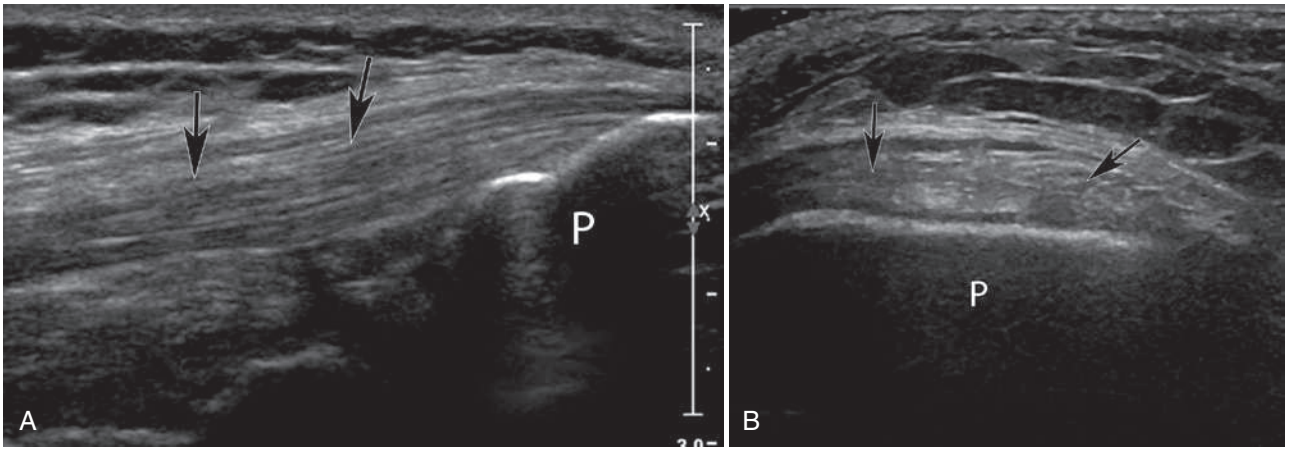

FIG. 23.7 Normal Quadriceps Tendon. (A) In long-axis view, the normal tendon demonstrates a fibrillar appearance *(arrows).* **(B)** In short-axis view, the tendon is ovoid and echogenic with a speckled appearance *(arrows). P,* Patella.

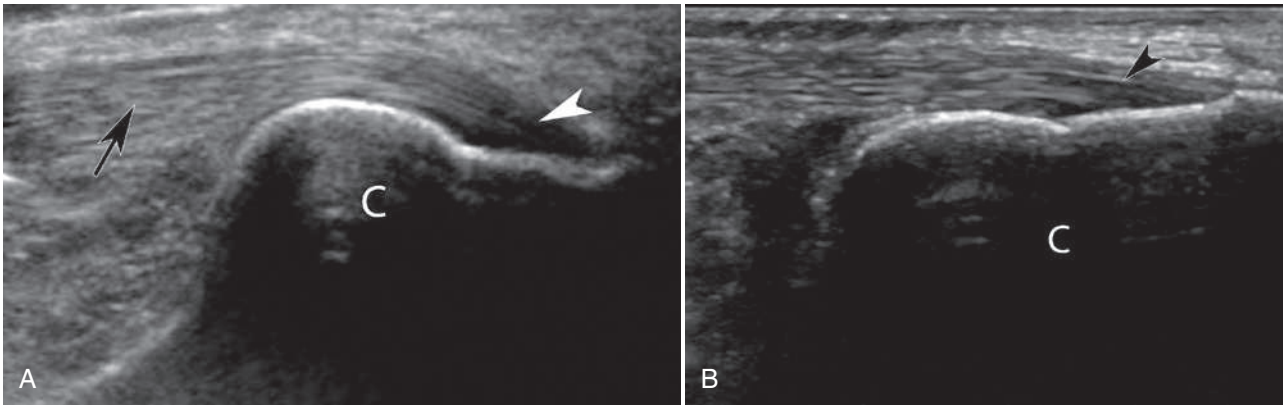

FIG. 23.8 Anisotropy. (A) In this long-axis scan of the Achilles insertion on the calcaneus, the proximal portion of the imaged tendon demonstrates a normal fibrillar appearance *(arrow),* whereas the distal tendon insertion is hypoechoic *(arrowhead).* **(B)** When the transducer is angled 90 degrees to the distal tendon insertion, the tendon then becomes fibrillar and is normal in appearance *(arrowhead). C,* Calcaneus.

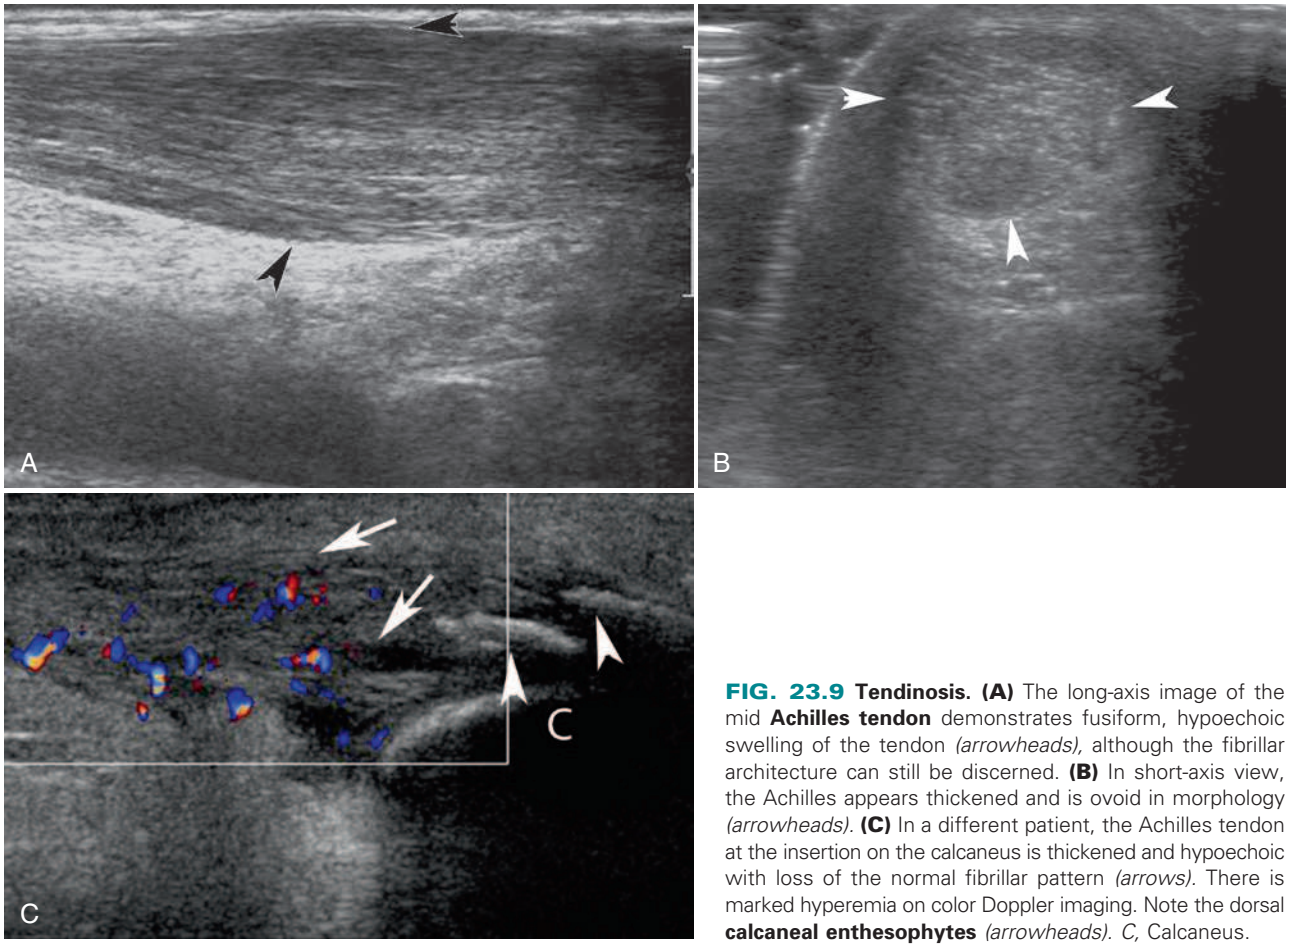

FIG. 23.9 Tendinosis. (A) The long-axis image of the mid **Achilles tendon** demonstrates fusiform, hypoechoic swelling of the tendon *(arrowheads),* although the fibrillar architecture can still be discerned. **(B)** In short-axis view, the Achilles appears thickened and is ovoid in morphology *(arrowheads).* **(C)** In a different patient, the Achilles tendon at the insertion on the calcaneus is thickened and hypoechoic with loss of the normal fibrillar pattern *(arrows).* There is marked hyperemia on color Doppler imaging. Note the dorsal **calcaneal enthesophytes** *(arrowheads). C,* Calcaneus.

which can be visualized on Doppler ultrasound in tendinosis but not in normal tendons.[18]

Tendinosis is common in the **Achilles tendon,** where it most commonly affects the midportion of the tendon, or "watershed," where there is overlapping blood supply. Tendon degeneration can also occur at the bone-tendon interface or enthesis, seen in the Achilles as insertional tendinosis at the calcaneus. Tendinosis at the tendon-bone interface is the most common pattern of degeneration seen in the common flexor and extensor origins at the medial and lateral humeral epicondyles at the elbow, forming part of the clinical spectrum of **epicondylitis.** Similar to tendinosis elsewhere, insertional tendinosis or enthesopathy is characterized by tendon expansion and hypoechogenicity.[19,20] Enthesitis, or inflammation at the enthesis, can occur in patients with rheumatoid arthritis, psoriatic arthritis, or spondyloarthropathy. The imaging features of enthesitis can overlap with tendinosis, with tendon expansion and hypoechogenicity, but neovascularization may be a more prominent feature and bony erosion may also be present.[21,22]

Patients with tendinosis are more prone to **tendon tears.** Tendon tears may be partial or complete. Partial tears may be transversely oriented (parallel to the short axis of the tendon) or longitudinally oriented (parallel to the long axis of the tendon, also referred to as a "longitudinal split tear"). Tears are manifested by anechoic or hypoechoic clefts, with focal tendon fiber discontinuity[23] (Fig. 23.10). When a complete rupture occurs, the tendon fibers are entirely discontinuous and some degree of tendon retraction may occur because of now-unopposed muscle contraction (Fig. 23.11). The extent of retraction is of importance for surgical planning and thus should be measured. In an acute tear, there may be complex fluid and hematoma within and about the tear site. When evaluating flexor and extensor tendons at the hand and wrist, passive and active motion can facilitate accurate identification of the tendon of interest and can provide mechanical correlation for the integrity of a tendon (Video 23.3).

Sonographic Signs of Tendon Tears

Discontinuity of fibers (partial or complete) with hypoechoic or anechoic gap
Focal thinning of the tendon
Hematoma (usually small)
Bone fragment (in cases of avulsion)
Nonvisualization of retracted tendon (in complete tear)

In tendons with surrounding tendon sheaths, inflammation of the tendon sheath **(tenosynovitis)** may occur as an overuse phenomenon or as a result of an inflammatory condition, such as rheumatoid arthritis. Tenosynovitis is manifest on ultrasound

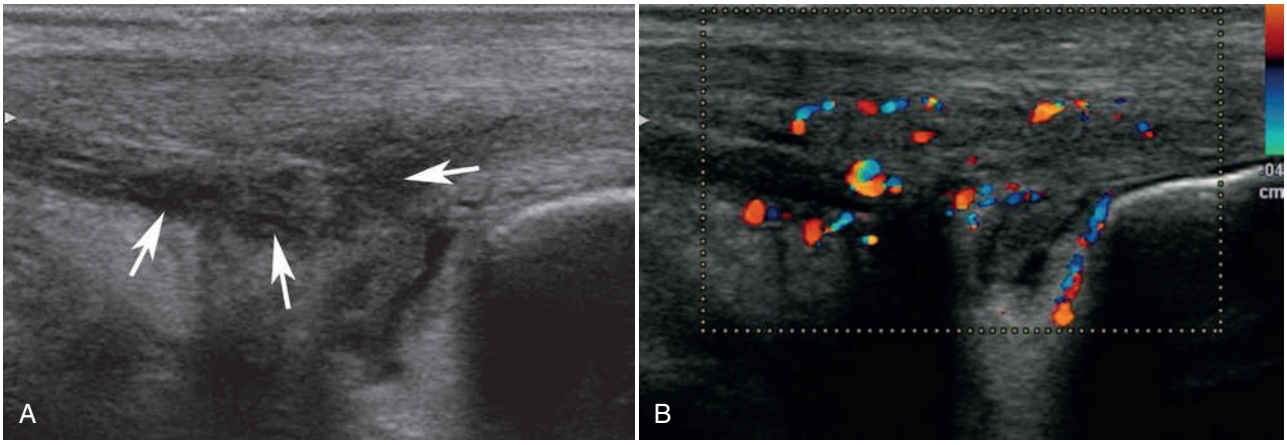

FIG. 23.10 Partial Tear of the Distal Achilles Tendon. (A) There is focal anechoic clefting of the anterior fibers of the Achilles distal insertion *(arrows)* although the posterior fibers remain intact. **(B)** Color Doppler imaging in the same patient demonstrates marked hyperemia in the injured tendon.

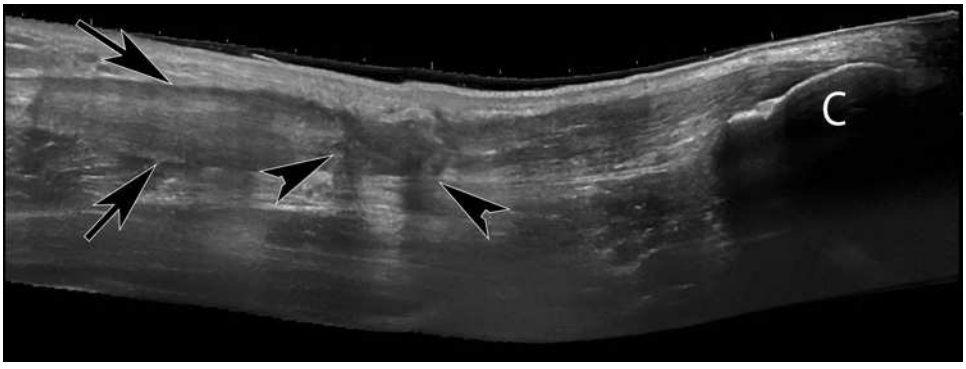

FIG. 23.11 Achilles Tendon Rupture. A panoramic view of the Achilles tendon demonstrates a rupture within the midportion of the tendon. The proximal aspect of the tendon is chronically thickened and hypoechoic *(arrows)*. Refraction artifact *(arrowheads)* is caused by the interfaces between the ruptured tendon edges and hemorrhage. *C,* Calcaneus.

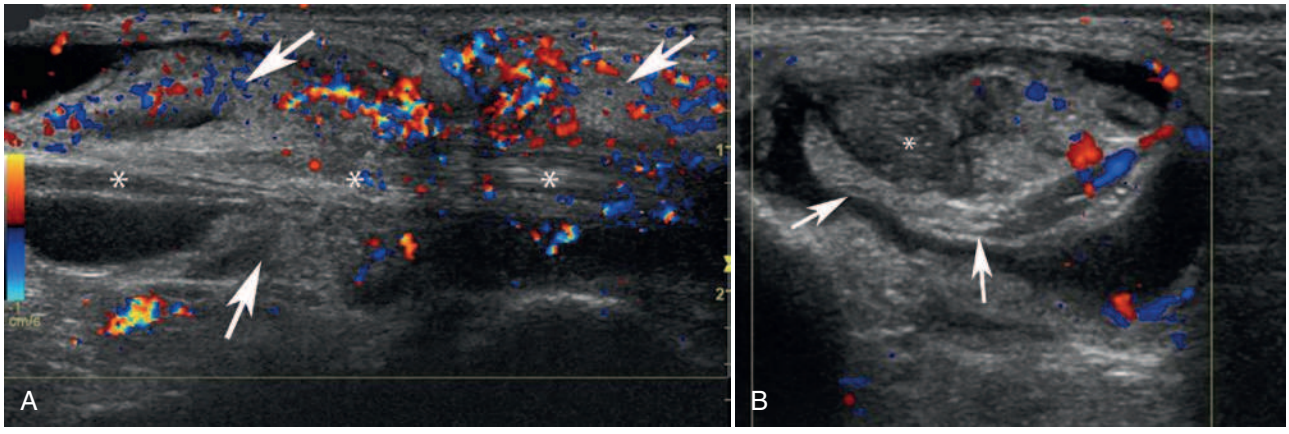

FIG. 23.12 Tenosynovitis. In this patient with rheumatoid arthritis and ankle pain, the peroneus brevis tendon (*) in long-axis **(A)** and short-axis **(B)** views is thickened and heterogeneous. The tendon sheath contains a large amount of echogenic synovium *(arrows),* hypoechoic fluid, and hyperemia on color Doppler imaging.

as an increase of fluid volume around a tendon within its sheath (Fig. 23.12). The tendon sheath itself can thicken and demonstrate hypervascularity on Doppler evaluation.[24] In patients with imaging findings of tenosynovitis and a history of penetrating injury or foreign body, septic tenosynovitis should be considered.[25]

LIGAMENTS

Ultrasound is an excellent technique for the evaluation of **ligamentous injuries,** with some advantages over MRI in this regard. Ultrasound permits high-resolution imaging of small ligaments

in planes that can be individualized to the structure of interest in any given patient, overcoming some intrinsic difficulties that can be encountered with scan plane prescription for MRI. In addition to static imaging, dynamic assessment may provide additional diagnostic information. Normal ligaments consist of interweaved bundles of collagen, extending between bones, usually restricting joint movements to prevent pathologic motion.[26] Ligament injury leads to pain and instability. Normal ligaments are linear bandlike structures and appear hyperechoic and fibrillar[27] (Fig. 23.13). Low-grade injuries consist of mild sprains, which typically have a good prognosis with conservative care. Mild sprains are characterized on ultrasound by swelling, hypoechogenicity, and some loss of fibrillar pattern (Fig. 23.14). Tears can be partial or complete. In the case of complete tears, there may be retraction of the torn ligament components from each other, a finding that can be exaggerated by dynamic imaging with stress maneuvers (Figs. 23.15 and 23.16). The use of stress maneuvers is somewhat controversial, however, because of concerns that a partial tear may be exacerbated or even converted to a complete tear by additional stress.[28,29]

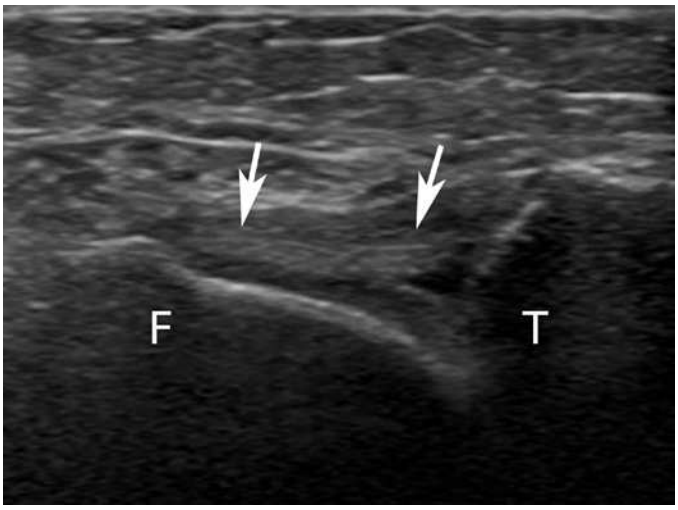

FIG. 23.13 Normal Anterior Talofibular Ligament. Note that the ligament *(arrows)* demonstrates a fibrillar appearance and that the fibers are more densely packed than those seen in a normal tendon. *F,* Fibula, *T,* talus.

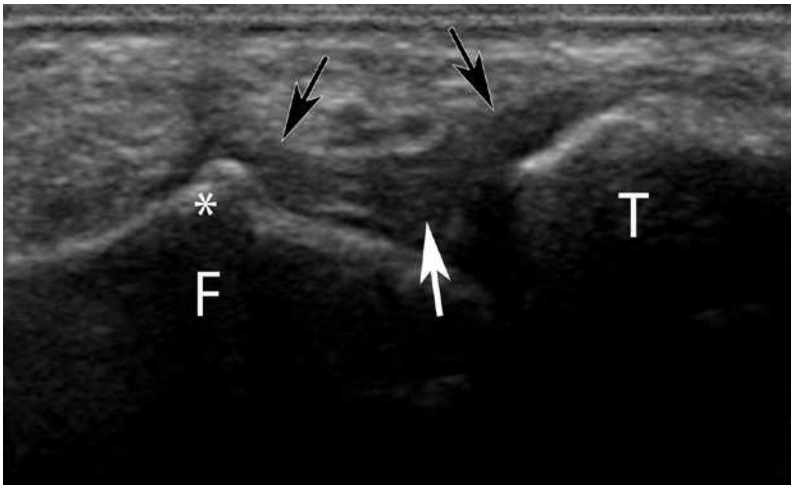

FIG. 23.14 Ligament Sprain. The anterior talofibular ligament *(arrows)* is diffusely thickened and hypoechoic, with intact fibers, consistent with sprain. Note the cortical irregularity at the lateral fibula (*) consistent with prior avulsion. *F,* Fibula, *T,* talus.

FIG. 23.15 Chronic Ligament Rupture. In this patient with a history of multiple ankle sprains, the anterior talofibular ligament is absent and the joint is widened on dynamic stress maneuver. Hypoechoic fluid (*) appears in the lateral recess. *F,* Fibula, *T,* talus.

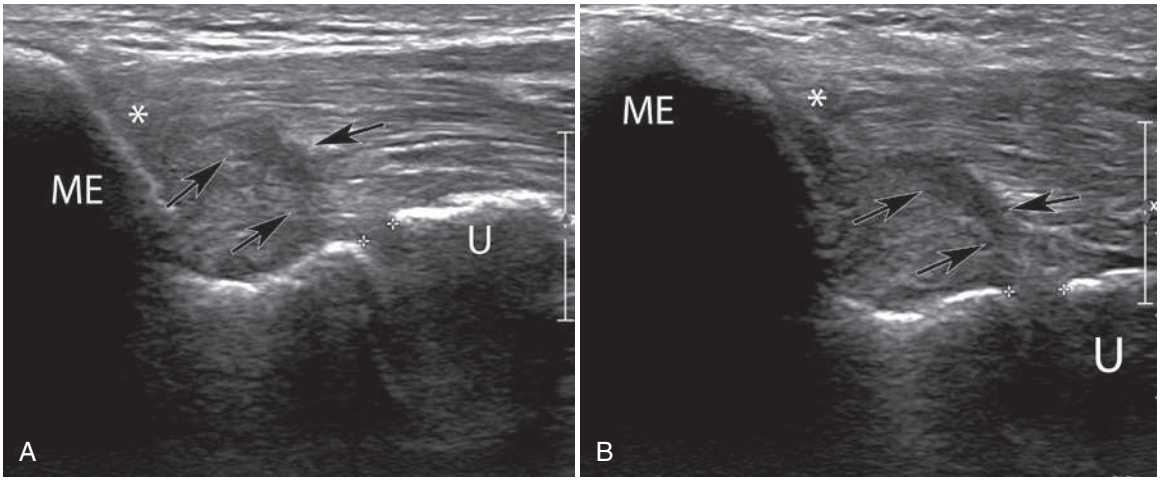

FIG. 23.16 Elbow Joint Widening on Dynamic Valgus Stress. (A) The medial joint is 2 mm *(calipers)* wide at rest in this patient with an ulnar collateral ligament (UCL) tear. Note the UCL is markedly thickened at the proximal humeral attachment and a hypoechoic cleft is present within the ligament consistent with a tear *(arrows)*. **(B)** With valgus stress, the medial joint space widens to 4 mm, confirming the presence of a UCL tear. The overlying common extensor tendon (*) is intact. *ME,* Medial epicondyle of the humerus; *U,* ulna.

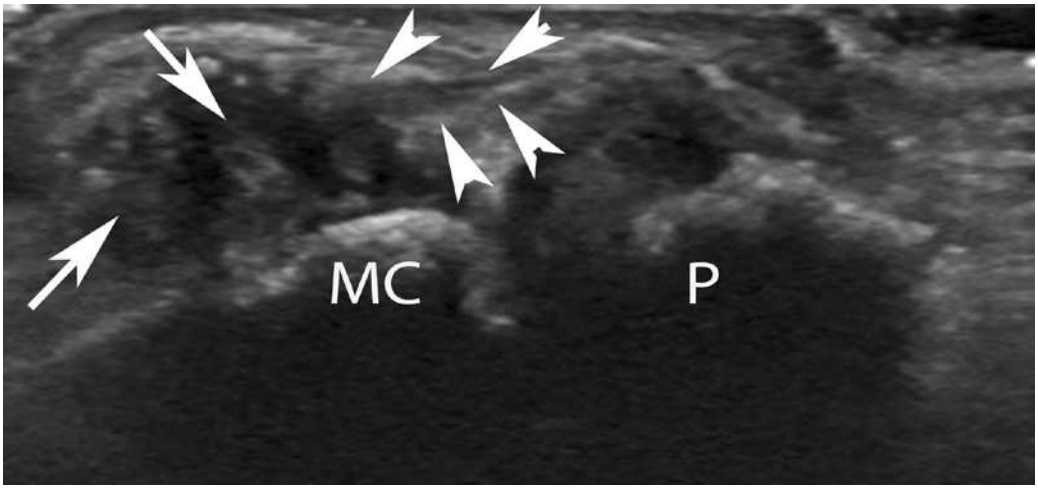

FIG. 23.17 Stener Lesion. The ulnar collateral ligament *(arrows)* of the thumb is torn and the stump is retracted proximal to the metacarpophalangeal joint and to the adductor aponeurosis *(arrowheads),* which is thickened and hypoechoic. *MC,* Metacarpal; *P,* proximal phalanx.

Ultrasound has been effectively utilized to diagnose injury of ligaments at the hand and wrist, notably the ulnar collateral ligament of the thumb metacarpophalangeal joint[28-30] in addition to the scapholunate ligament.[31] Other ligaments, such as the anterior oblique ligament of the thumb, have been identified with ultrasound, but the role of ultrasound in diagnosis has yet to be defined.[32,33] Ultrasound may also be used to evaluate the collateral ligaments of the elbow,[34-39] ankle ligaments,[40] and collateral ligaments of the knee.[41]

When evaluating ligamentous injury, it is important to assess nearby structures such as tendons, which may also have been injured (e.g., common flexor tendon origin injury in the setting of ulnar collateral ligament injury at the elbow) or which may be relevant to the ligamentous injury, as in the case of a **Stener lesion.** A Stener lesion occurs when a thumb metacarpal phalangeal ulnar collateral ligament tear entraps the adductor aponeurosis such that the ligament lies superficial to the aponeurosis (Fig. 23.17). This injury is important to recognize, as the treatment is surgical. The appearance of a Stener lesion on ultrasound is of retracted hypoechoic ligament fibers displaced over the linear aponeurosis, giving rise to the **"yo-yo on a string"** appearance.[28]

NERVES

Normal **peripheral nerves** are well visualized with high-resolution ultrasound. Nerves have a characteristic honeycomb morphology on ultrasound when imaged in short axis[42] (Fig. 23.18). Nerves are tubular structures, and on longitudinal axis, they demonstrate an internal striated pattern, somewhat similar to tendons but with a coarser pattern referred to as a "fascicular pattern."[43,44] This pattern consists of alternating internal hypoechoic and hyperechoic linear components. The hypoechoic components represent **fascicles** or groups of fascicles, whereas the hyperechoic parts correspond with the **epineurium.**[44] The epineurium consists of connective tissue that surrounds nerve fascicles, composed

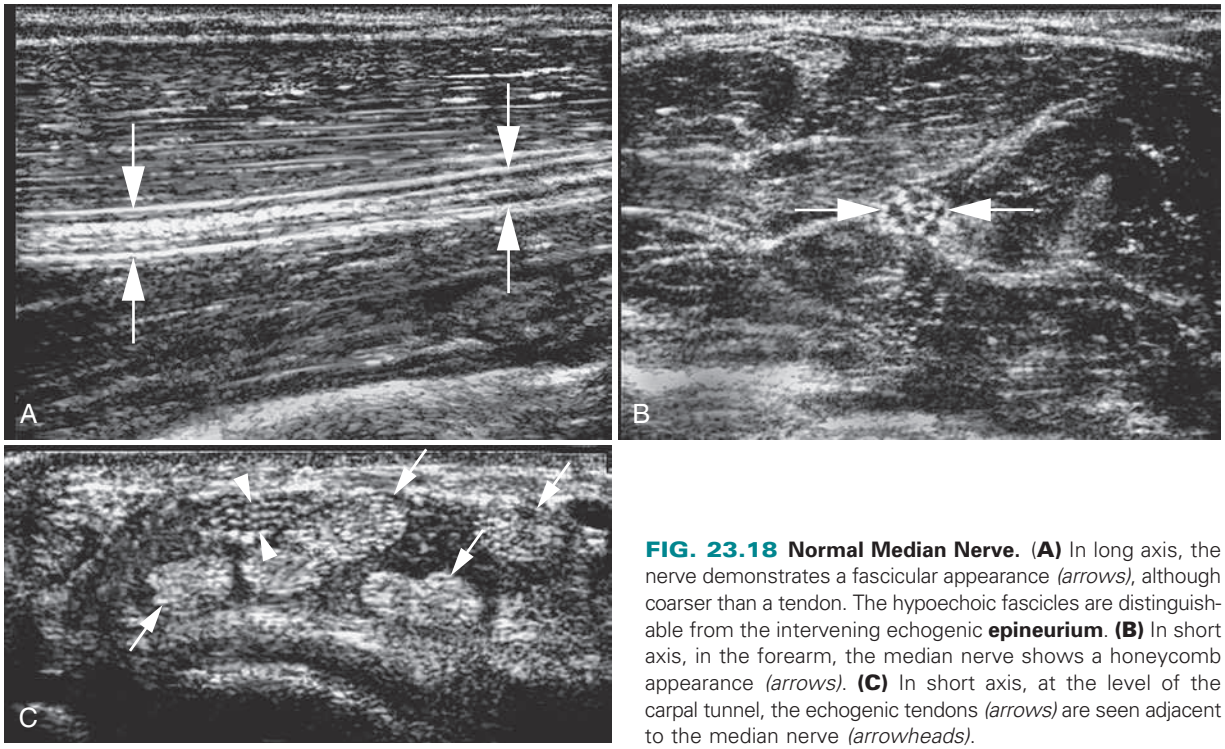

FIG. 23.18 Normal Median Nerve. (**A**) In long axis, the nerve demonstrates a fascicular appearance *(arrows)*, although coarser than a tendon. The hypoechoic fascicles are distinguishable from the intervening echogenic **epineurium**. **(B)** In short axis, in the forearm, the median nerve shows a honeycomb appearance *(arrows)*. **(C)** In short axis, at the level of the carpal tunnel, the echogenic tendons *(arrows)* are seen adjacent to the median nerve *(arrowheads)*.

of collagenous and adipose components, with small blood vessels and lymphatics. On short-axis view, peripheral nerves appear ovoid or round and have punctate internal hypoechoic fat representing nerve fascicles within the echogenic epineurium. Dynamic maneuvers including flexion and extension of the imaged region should show no substantial motion of a peripheral nerve, as distinct from tendons.

Assessment of peripheral nerves using ultrasound is performed primarily in the short-axis plane. The nerve is evaluated at a known anatomic location and followed proximally and distally as needed. Anisotropy is less problematic for peripheral nerves than for tendons.[23] Longitudinal scanning is helpful for providing an overview and illustrating relative caliber changes of peripheral nerves detected on transverse imaging. Caution should be exercised in primary interpretation of longitudinal sonographic images of peripheral nerves because of the potential to scan in a plane, which is not parallel to the nerve with potential artifactual changes in caliber and echogenicity.

Nerve dysfunction can result from compression by masses arising from or adjacent to the nerve, entrapment within fibro-osseous tunnels (such as the **carpal tunnel** in the case of median nerve compression at the wrist), or subluxation from fibro-osseous tunnels. Masses include neurogenic tumors, **neurofibromas** and **schwannomas,** considered more fully later. **Soft tissue ganglia,** usually appearing anechoic on ultrasound, may also cause nerve compression.[45-47] In the setting of nerve compression by any cause, the findings detectible on ultrasound relate to echotextural and caliber changes. Local compression causes venous congestion, which can lead to intraneural edema. Chronic compression can ultimately lead to intraneural fibrosis. These alterations in intraneural composition lead to loss of normal hyperechogenicity of the interfascicular epineural tissue, causing an overall hypoechoic appearance of the nerve in addition to poor definition or disappearance of the normal fascicular pattern.[43]

One of the most common clinical forms of entrapment neuropathy is **carpal tunnel syndrome.** In this condition, compression and flattening of the nerve occurs within the carpal tunnel, at the palmar aspect of the wrist, and the nerve is typically swollen and expanded just proximal to the carpal tunnel. The sonographic diagnosis of carpal tunnel syndrome is made by measuring the cross-sectional area of the median nerve at the level of the pronator quadratus and comparing this to the cross-sectional area of the median nerve in the carpal tunnel at the level of the pisiform. A difference of more than 2 mm^2 between the two measurements is highly associated with carpal tunnel syndrome[48] (Fig. 23.19). Variable cut-off values for the diagnosis of carpal tunnel syndrome based on single cross-sectional measurements of the median nerve in the carpal tunnel have been reported in the literature, in the 9- to 11-mm^2 range.[49-51] Bowing and thickening of the overlying **flexor retinaculum** can also be observed.[51]

Symptoms may also arise from dynamic **nerve subluxation** from fibro-osseous tunnels. One example of this is at the **cubital tunnel,** at the medial posterior aspect of the elbow. The **ulnar nerve** normally passes through this fibro-osseous tunnel at the posterior aspect of the humerus and is stabilized by an overlying retinaculum. This retinaculum normally passes between the olecranon and the medial epicondyle of the humerus. Developmental or posttraumatic deficiency of this retinaculum can allow the ulnar nerve to dynamically subluxate out of the cubital tunnel

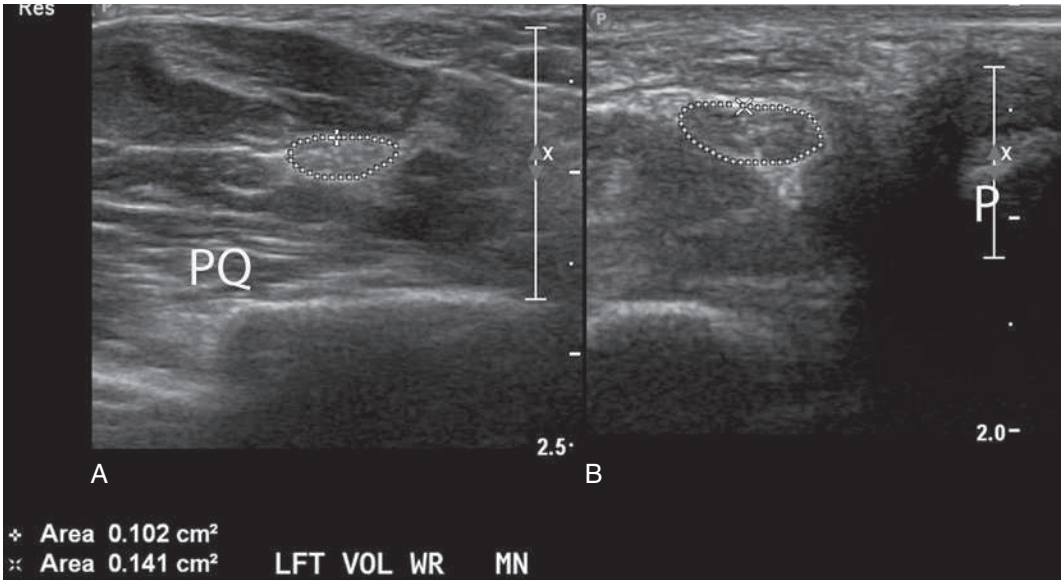

FIG. 23.19 Carpal Tunnel Entrapment of the Median Nerve. (A) Short-axis cross-sectional area of the median nerve obtained at the level of the pronator quadratus *(PQ)* at the distal forearm. **(B)** Cross-sectional area obtained in the carpal tunnel at the level of the pisiform *(P)*. The 4-mm² difference in area between the two images is consistent with **carpal tunnel syndrome.**

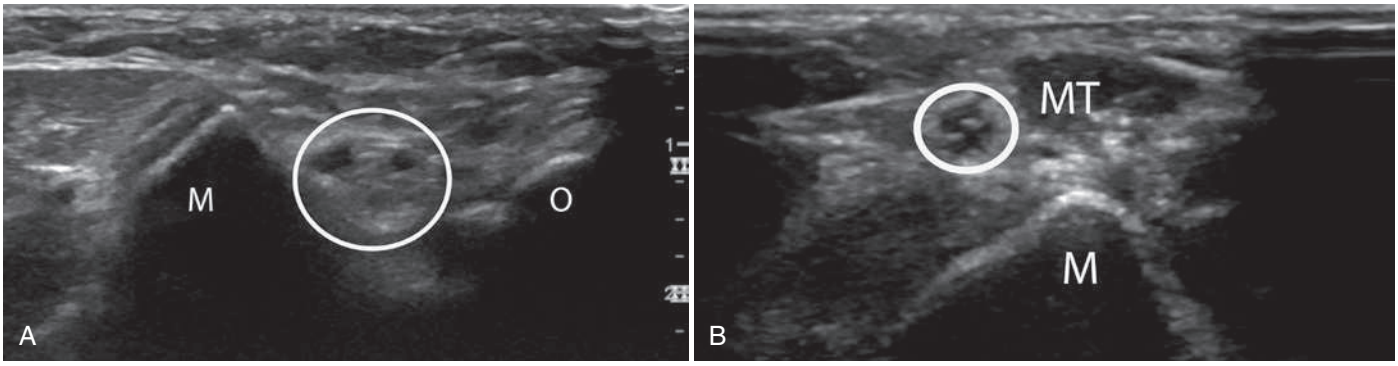

FIG. 23.20 Ulnar Nerve Dislocation at the Elbow. (A) At rest, with the elbow extended and the probe positioned between the medial epicondyle *(M)* and the ulnar olecranon *(O)*, the ulnar nerve *(circled)* is positioned posterior to the epicondyle. Note the ulnar nerve is enlarged at this location. **(B)** On flexion the ulnar nerve *(circled)* dislocates anterior to the medial epicondyle along with the medial head *(MT)* of the triceps muscle (known as **"snapping triceps"** syndrome). Most patients with ulnar dislocation do not exhibit medial head triceps dislocation. See also Video 23.4.

during elbow flexion, and this subluxation can be captured on dynamic imaging (Video 23.4). Scan technique is important in this diagnosis. The probe should be positioned in a transverse plane with respect to the medial posterior elbow. The nerve should normally be visible within the cubital tunnel with the elbow in an extended position. The osseous landmark of the medial epicondyle should be maintained in the visualized field as the patient slowly flexes the elbow. Excessive probe pressure should be avoided because this can limit dynamic motion of the nerve. The nerve should normally remain lateral to the medial epicondyle. Subluxation, where the nerve moves medially and anteriorly along the epicondyle, or dislocation, where the nerve snaps anteromedial to the medial epicondyle, may occur on flexion[52,53] (Fig. 23.20). Patients with ulnar nerve subluxation or dislocation may experience pain or transient numbness, but this dynamic instability can also be seen in asymptomatic in healthy controls, and the association with neuropathy is debated.[54,55]

JOINT ASSESSMENT

Ultrasound can play a helpful role in the diagnosis and follow-up of both inflammatory and noninflammatory arthropathy and may guide diagnostic and therapeutic procedures in patients with these disorders. Patients with **inflammatory arthropathy** such as **rheumatoid arthritis** present with joint pain, swelling, and stiffness. Ultrasound plays a complementary role to clinical history, physical examination, radiographs, and serology tests such as acute phase reactants (e.g., C-reactive protein, erythrocyte sedimentation rate, rheumatoid factor, and antinuclear antibody). In this role, when used systematically, ultrasound can substantially increase diagnostic certainty in patients with suspected inflammatory arthropathy.[56] Ultrasound also represents a great tool in the follow-up of these patients, allowing detection of subclinical relapse in patients with clinical remission and predicting relapse and joint deterioration.[57]

Joint effusions are frequently present in patients with **inflammatory arthritis** but are nonspecific as they may also occur in patients with osteoarthritis, with infection, and in the setting of trauma or internal derangement (Fig. 23.21). The diagnosis of an effusion rests on the visualization of increased volume of joint fluid. Joint fluid is typically anechoic but can contain some mobile low-level echoes. In addition, **joint fluid** is mobile and compressible.[58] Normal joints contain just a trace of fluid, so an increase in this fluid volume constitutes a **joint effusion.**

Synovitis is determined by the presence of intraarticular nondisplaceable hypoechoic to hyperechoic soft tissue, which usually demonstrates hyperemia on color Doppler assessment (Fig. 23.22). On Doppler assessment, the velocity filter should be set to detect low amounts of flow, and the gain settings should be adjusted to just below a level where noise is visualized.[59] Either color Doppler or power Doppler may be more sensitive to flow in the evaluation of synovitis, depending on individual machine, so familiarity with the hardware being used is important.[60] The quantity of synovial hyperemia can be graded as described by Szkudlarek et al.[61]: Grade I (low) hyperemia consists of the visualization of several single vessel dots. Grade II (moderate) hyperemia is shown when there are confluent vessel signals occupying less than half of the visualized synovial tissue. Grade III (high) represents confluent vessel signals in more than half of the synovium. Doppler ultrasound has shown high degrees of sensitivity and specificity in the diagnosis of synovitis at the metacarpophalangeal joints in patients with rheumatoid arthritis when compared with dynamic contrast-enhanced MRI.[61] Ultrasound has also been shown to have high interobserver and intraobserver reliability in detection of synovitis.[62]

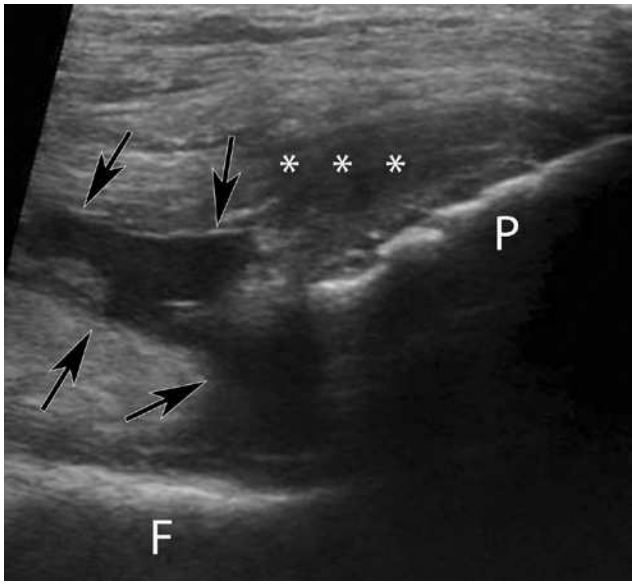

FIG. 23.21 Simple Knee Joint Effusion. Anechoic fluid is present within the suprapatellar recess of the knee *(arrows)*. There is concomitant quadriceps tendinosis (*). *F,* Distal femur; *P,* patella.

Bone erosion in **erosive inflammatory arthritis** such as rheumatoid arthritis can be depicted on ultrasound as a cortical defect visible in two perpendicular planes[63] (Fig. 23.23). Erosions may be graded as small (<2 mm), moderate (2-4 mm), or large (>4 mm).[64] Ultrasound is more sensitive than plain radiographs in the detection of bone erosion and thus may aid in diagnosis of early disease.[65] In addition to cortical discontinuity, there may be acoustic enhancement of marrow subjacent to the inflammatory bony erosion.[65] Patients with inflammatory arthropathy may also have associated **tenosynovitis, enthesitis,** and, in the case of rheumatoid arthritis, **inflammatory periarticular nodules (rheumatoid nodules)**[66] (Fig. 23.24).

Gout is a common inflammatory arthritis with a predilection for first metatarsophalangeal joint involvement, caused by precipitation of uric acid crystals within joints. In patients with gout, there may be **joint effusion, synovial hypertrophy** and hyperemia, soft tissue swelling, and juxtaarticular **erosions** that can be large.[67] Intraarticular crystals may be evidenced by the presence of a characteristic irregular hyperechoic line along the surface of the normally hypoechoic cartilage, termed the **"double contour sign"**[68] (Fig. 23.25). This is distinct from

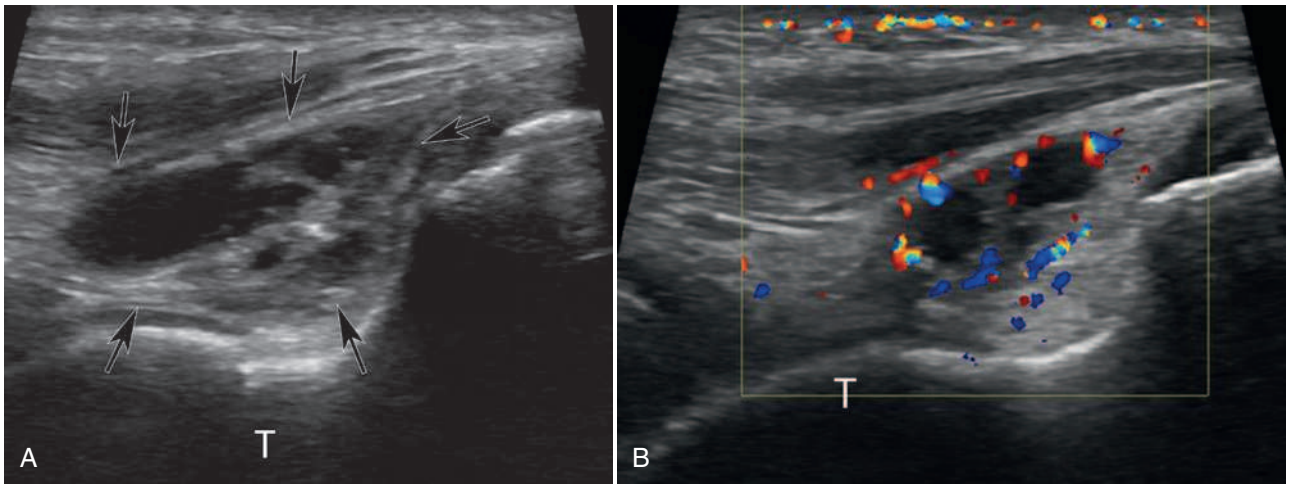

FIG. 23.22 Complex Ankle Joint Effusion in Rheumatoid Arthritis. (A) A long-axis image of the tibiotalar joint demonstrates a complex joint effusion *(arrows)* with both anechoic fluid and echogenic, thickened synovium consistent with synovitis. **(B)** Color Doppler imaging of the tibiotalar joint demonstrates marked hyperemia within the echogenic synovium. *T,* Talus.

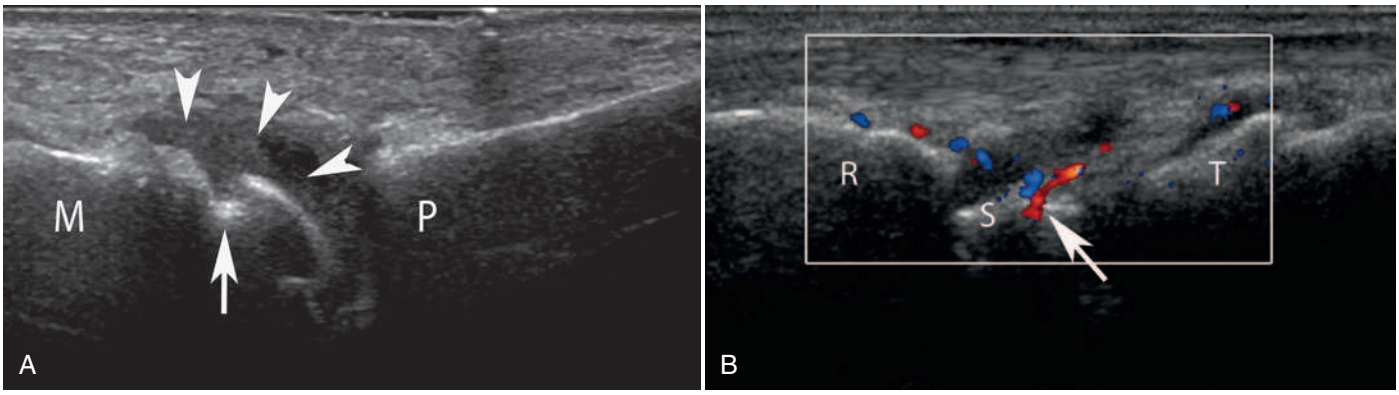

FIG. 23.23 Bone Erosions in Two Different Patients Rheumatoid Arthritis. (A) Long-axis gray-scale image at the fifth metatarsophalangeal joint demonstrates bone erosion in the fifth metatarsal head *(arrow)* with associated cortical irregularity and synovial hypertrophy *(arrowheads). M,* Metatarsal, *P,* proximal phalanx. **(B)** Color Doppler imaging of the dorsal wrist in long-axis view demonstrates hyperemia within the synovium and erosion *(arrow)* of the scaphoid *(S). R,* Distal radius, *T,* trapezium.

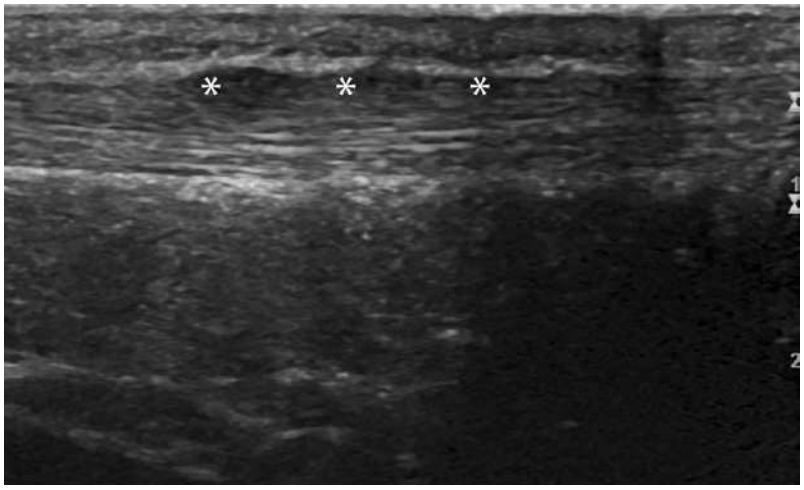

FIG. 23.24 Achilles Tendon With Rheumatoid Nodules. Long-axis image of the Achilles tendon demonstrates hypoechoic nodular thickening (*) of the posterior tendon surface, consistent with rheumatoid nodules. No hyperemia was seen on color Doppler imaging (not shown).

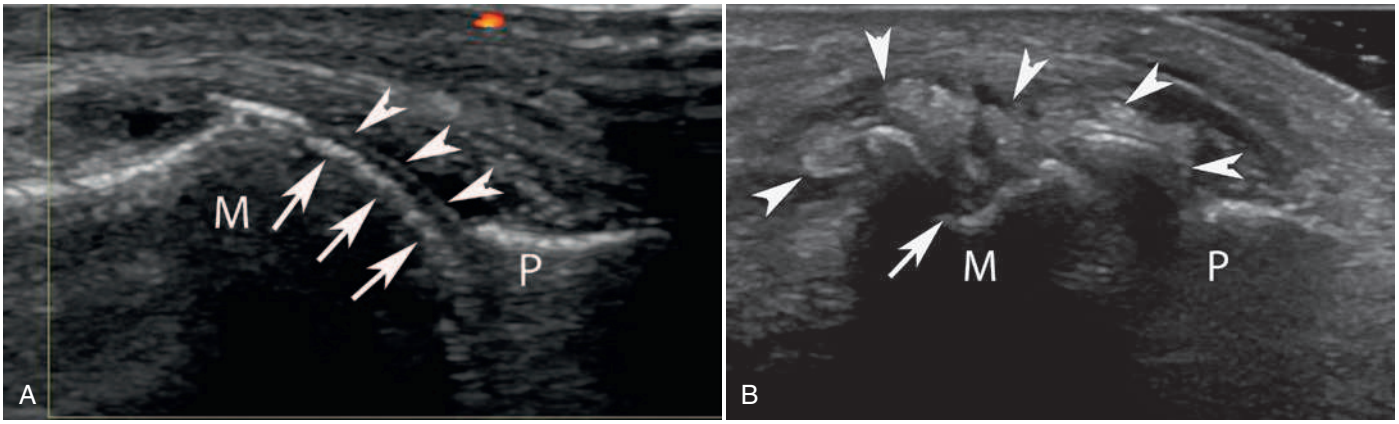

FIG. 23.25 Gout in Two Different Patients. (A) Long-axis gray-scale image of the first metatarsal phalangeal joint demonstrates the **"sugar icing"** appearance where echogenic urate crystals are deposited along the synovial lining of the joint *(arrowheads).* The **"double contour sign"** is formed by the echogenic urate crystals ("sugar icing") layering on the anechoic hyaline cartilage with the underlying echogenic cortex *(arrows).* **(B)** Long-axis gray-scale image of the fifth metatarsal phalangeal joint shows a large erosion *(arrow)* with a large amorphous **tophus** *(arrowheads),* part of which extends into the erosion. *M,* First metatarsal, *P,* first proximal phalanx.

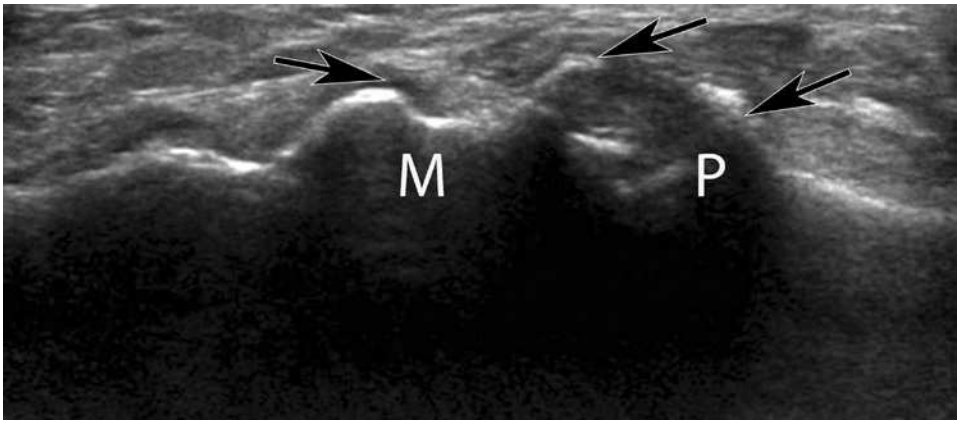

FIG. 23.26 Osteoarthritis. Long-axis gray-scale image of the fifth metatarsophalangeal joint demonstrates osteophyte formation *(arrows)* at both sides of the joint. *M,* Metatarsal, *P,* proximal phalanx.

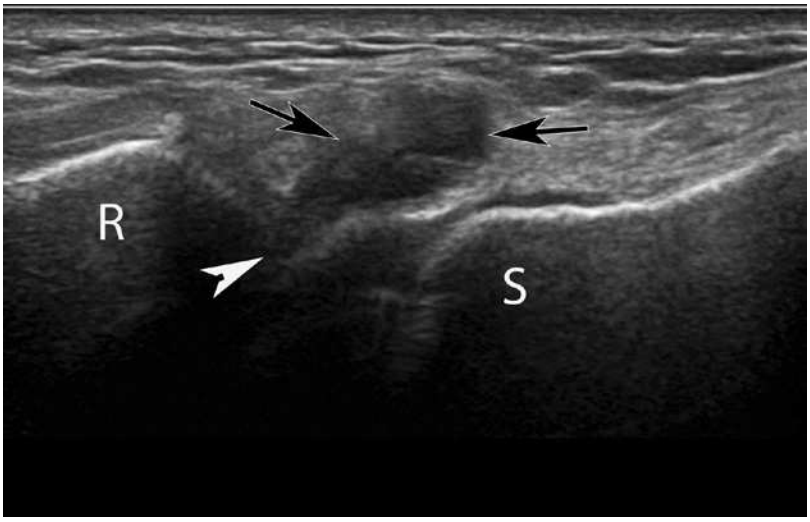

FIG. 23.27 Ganglion Cyst. Long-axis image of the radiocarpal joint at the radioscaphoid articulation demonstrates a lobulated, hypoechoic ganglion cyst *(arrows)* arising from the region of the scapholunate ligament. Note the neck *(arrowhead)* arising from the joint. *R,* Radius, *S,* scaphoid.

chondrocalcinosis in which cartilage calcification may be seen with an intracartilaginous echogenic line. Tophi are focal crystal accumulations, which occur around joints in some patients with gout, appearing as clumps of hyperechoic material, which may have a surrounding hypoechoic rim, an appearance has been referred to as "wet sugar clumps."[68] Bony erosions may be seen adjacent to these tophi.

In **osteoarthritis** (nonerosive), cartilage thinning and irregularity may be seen in addition to osteophytes and typically mild synovitis (Fig. 23.26). Osteophytes appear as cortical protrusions at the margin of the articular surface, with posterior acoustic shadowing.[69] **Synovitis** may be nodular or diffuse. **Joint effusions** may also be demonstrated in osteoarthritis, and although they may occur in the absence of synovitis, the presence and size of effusion correlate with the presence of synovitis and the extent of synovial thickening. Joint effusion and synovitis also correlate with clinical and radiographic disease severity.[70]

SOFT TISSUE MASSES

Palpable soft tissue masses are very common and represent a diagnostic dilemma for physicians. Although the vast majority of these masses are benign, discrimination between benign and malignant masses is not clinically possible. Ultrasound is a complementary modality to MRI in the workup of soft tissue masses. Although MRI has overall higher specificity, several soft tissue masses can be characterized as benign with ultrasound.[71,72] In indeterminate cases, contrast-enhanced MRI can be performed, and this two-tiered strategy may provide an overall cost savings to the health care system if appropriately implemented.

Ganglion cysts are mucin-filled lesions most often found at the wrist; they are usually closely related to a joint or tendon sheath. Approximately 10% of ganglion cysts occur secondary to trauma.[73] The most common location is adjacent to the scapholunate articulation (Fig. 23.27). A neck extending from the lesion to an underlying joint or tendon sheath should be

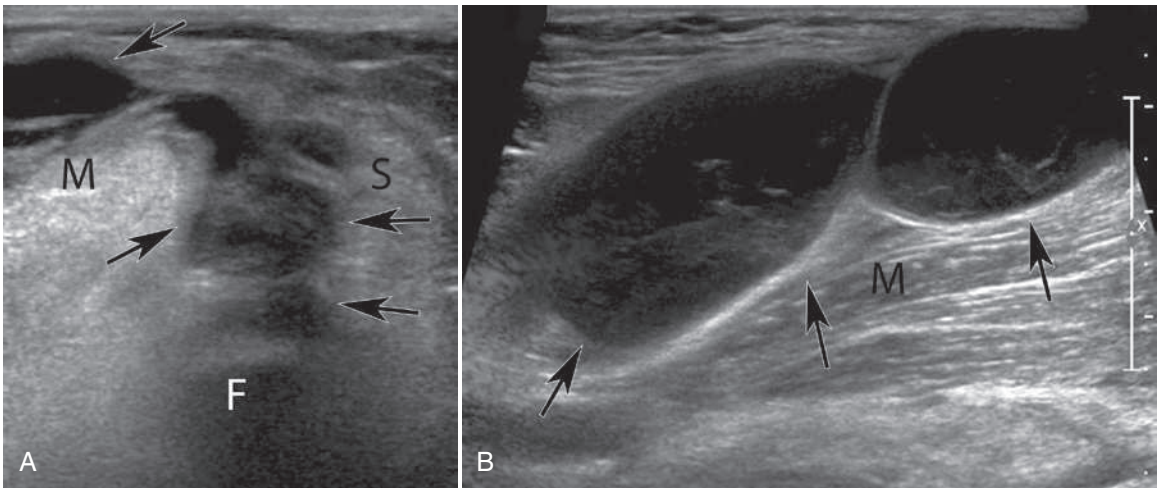

FIG. 23.28 Baker Cyst. (A) Short-axis image from the medial posterior knee shows a lobulated, septated, hypoechoic Baker cyst *(arrows)* communicating with the joint between the medial gastrocnemius muscle *(M)* and the semimembranosus tendon *(S). F,* Posterior medial femoral condyle. **(B)** In a different patient, long-axis image from the posterior medial knee demonstrates an ovoid, septated complex Baker cyst *(arrows)* with internal debris, lined with echogenic synovium. See also Video 23.5.

FIG. 23.29 Ruptured Baker Cyst. Longitudinal sonogram of the calf with extended field of view shows a complex mass *(arrows)* that is connected to a small amount of fluid in the popliteal fossa *(arrowheads),* representing the ruptured Baker cyst.

sought but is often not definable.[74] These lesions typically appear as well-circumscribed, oval or lobulated anechoic cystic masses, with accompanying through transmission.[75] Ganglion cysts may demonstrate low-level internal echoes and may be septated.[74] Ganglion cysts are typically noncompressible (as opposed to **bursae,** which are compressible). Ganglion cysts do not usually demonstrate internal flow on color Doppler evaluation.[76]

Baker cysts, occurring in the medial aspect of the popliteal fossa, deserve special mention, as they are extremely common. A Baker cyst is caused by fluid distention of the **semimembranosus-gastrocnemius bursa,** occurring between the distal semimembranosus tendon and the medial head of the gastrocnemius muscle with a narrow neck arising from the underlying knee joint (Fig. 23.28, Video 23.5). This usually occurs in the setting of an underlying cause of joint effusion, including osteoarthritis, but also in the setting of posterior horn **medial meniscal tear, inflammatory arthritis,** and internal derangement. Although common, they are not reliably diagnosed clinically.[77] Baker cysts are typically anechoic when uncomplicated, yet may have a variable appearance, with complex fluid and hemorrhage, internal septations and debris, and thick, echogenic, hyperemic synovium lining the cyst. The narrow neck can act as a valve, and fluid accumulation within the cyst can lead to rupture, resulting in acute pain, swelling, and erythema behind the knee and in the proximal calf.[78] When this occurs, the margin of the cyst is often irregular caudally and there may be associated medial calf subcutaneous edema, with fluid tracking distally about the medial head of the gastrocnemius (Fig. 23.29). The clinical presentation of this may mimic deep venous thrombosis or developing cellulitis.[79]

Lipomas are the most common palpable soft tissue masses (Table 23.1). These may occur within the subcutaneous tissues, muscle, or deep soft tissues. Simple lipomas are usually homogeneously isoechoic, or slightly hyperechoic to fat, with well-defined margins and internal wavy septations mimicking the surrounding fat[80] (Fig. 23.30). They should be painless, mobile, and compressible with transducer pressure.[81] Simple lipomas should not demonstrate internal complexity or hypervascularity; however, vessels may be seen passing through the lipoma. MRI with contrast should be performed to exclude underlying liposarcoma in the evaluation of any suspected lipoma with the following atypical features: deep acoustic shadowing, internal complexity or hypervascularity, size greater than 5 cm, deep or intramuscular location, pain, or history of enlargement.

TABLE 23.1 Fat-Containing Soft Tissue Lesions

Diagnosis	Sonographic Findings	Follow-Up
Simple lipoma	Similar echogenicity to subcutaneous fat Mobile Soft, compressible Painless Few, small vessels	Clinical follow-up sufficient if classic sonographic appearance
Indeterminate lipomatous lesion	Complex echogenicity Deep acoustic shadowing Hypervascularity Size > 5 cm Deep or intramuscular location Pain History of enlargement	MRI with contrast for further evaluation, with biopsy if needed
Fat-containing hernia	Change in appearance over time or with Valsalva maneuver	

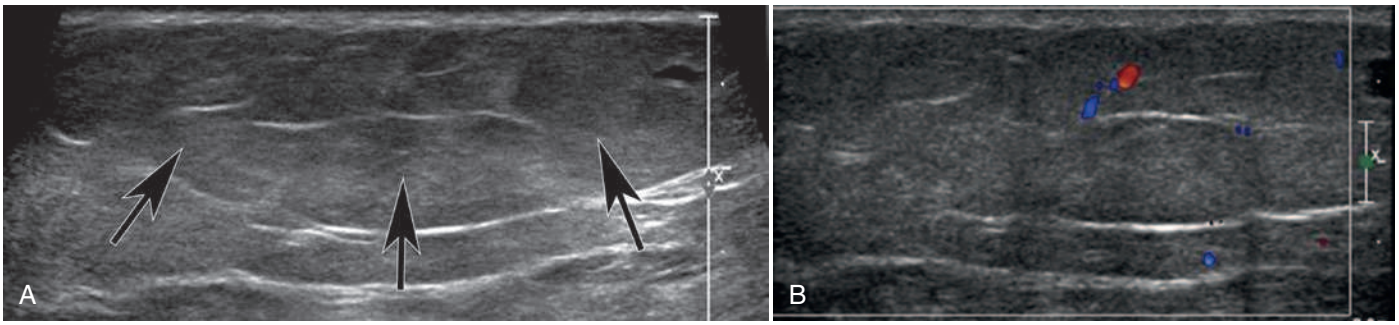

FIG. 23.30 Lipoma. (A) A simple lipoma *(arrows)* is isoechoic to the adjacent subcutaneous fat and contains thin echogenic septations that parallel the skin surface. **(B)** Color Doppler imaging demonstrates two small vessels traversing the lipoma. There is no hyperemia.

A pitfall in the diagnosis of lipoma is that a fat-containing hernia can have some overlapping ultrasound appearances, including similar echogenicity to subcutaneous fat and internal wavy septations.[80] Anatomic location, dynamic change in appearance, and movement with Valsalva maneuver can assist in the diagnosis of hernia. When appearances are typical for benign lipoma, periodic clinical follow-up can be performed rather than additional imaging or biopsy.

Nerve sheath tumors are common, usually benign masses, although malignant nerve sheath tumors may uncommonly occur. Nerve sheath tumors are usually well-circumscribed solid hypoechoic masses, ovoid or fusiform in shape, and have faint deep acoustic enhancement.[82] A contiguous nerve of origin of the lesion may be identified, either centrally within the lesion in the case of neurofibroma or peripherally related to the lesion in a schwannoma (however, these findings are not absolute) (Fig. 23.31). An echogenic capsule may be seen, and occasionally cystic spaces can occur in a degenerated schwannoma. A split-fat sign, although not entirely specific, is often seen in association with benign peripheral nerve sheath tumors. This sign comprises the presence of a rim of fat about the end of the lesion, representing fat normally present about the neurovascular bundle from which the lesion arises.[83] The imaging appearances of benign and malignant peripheral nerve sheath tumors overlap, but malignant lesions should be considered when a lesion is more poorly defined (reflecting its infiltrative nature), is increasing in size, or is internally heterogeneous in appearance as a result of internal necrosis and/or hemorrhage.[84] If lesions typical for benign nerve sheath tumors on imaging are not biopsied or resected, then imaging and clinical follow-up are warranted.

Various benign and malignant soft tissue lesions cannot be definitively discriminated by ultrasound alone. Lesions that remain indeterminate by ultrasound may then be evaluated with contrast-enhanced MRI. Lesions that remain worrisome for malignant neoplasm will typically undergo image-guided biopsy (most often with ultrasound guidance). Primary **soft tissue sarcomas** typically appear solid, with irregular borders, variable internal necrosis, and hemorrhage (Fig. 23.32). They may be partly calcified (especially synovial sarcomas).[85] The lesions usually demonstrate internal vascularization and may show local invasion of adjacent tissues. Secondary lesions (metastases) should be considered when a solid vascularized soft tissue lesion is found in a patient with known underlying malignancy. An important pitfall in the diagnosis of sarcoma is the clinical presentation with a hemorrhagic tumor, which can be incorrectly diagnosed as a bland hematoma, potentially leading to delay in correct diagnosis.[86] To further complicate the diagnosis, patients may report a history of trauma. A spontaneous hematoma in the absence of anticoagulant medication should be regarded with suspicion, as should an apparent hematoma disproportionate to the patient-reported trauma.[73] Such lesions should be evaluated carefully for vascularized components, which should be targeted for biopsy. If none are found, then repeat imaging should be performed in 6 weeks to document resolution of the hematoma. Following surgical

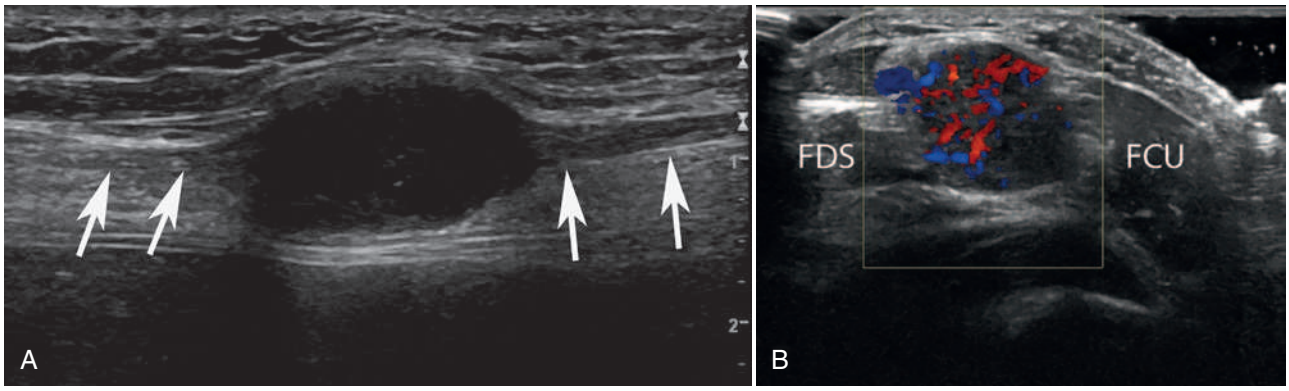

FIG. 23.31 Peripheral Nerve Sheath Tumor. (A) Long-axis image obtained at the site of a palpable mass shows an ovoid, hypoechoic mass with smooth borders, arising from the ulnar nerve. Note the ulnar nerve enters and exits the mass *(arrows).* **(B)** A short-axis image of the forearm demonstrates the mass in the expected location of the ulnar nerve. Color Doppler shows marked hyperemia within the mass. *FCU,* Flexor carpi ulnaris; *FDS,* flexor digitorum superficialis and profunda.

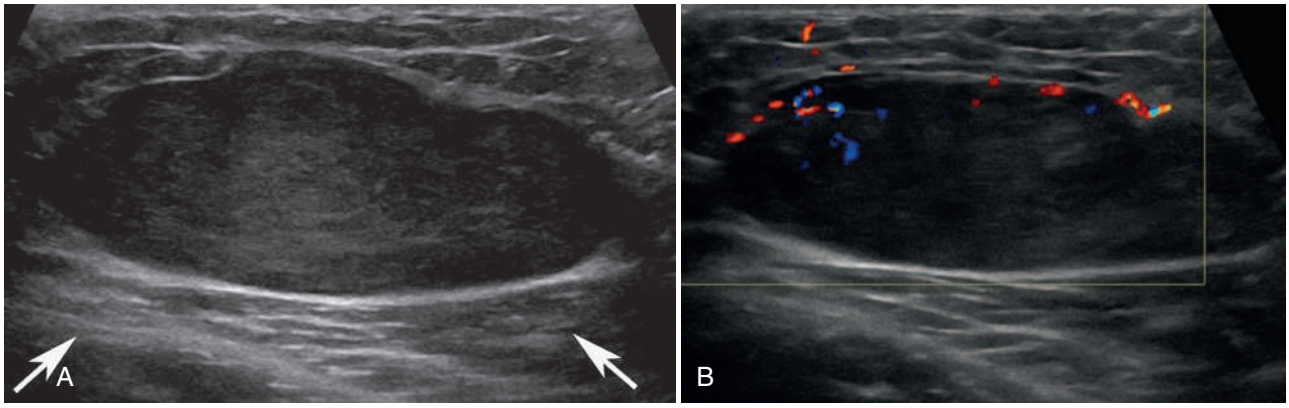

FIG. 23.32 Sarcoma. (A) A myxoid liposarcoma demonstrates mildly increased through transmission *(arrows)* due to the myxoid content. However, the mass is solid, with internal echoes. The superficial border is microlobulated. **(B)** Color Doppler imaging demonstrates increased blood flow within the mass.

resection of soft tissue sarcoma, ultrasound has been shown to have acceptable diagnostic accuracy but may miss a small number of recurrences. Ultrasound could play a complementary role to MRI in follow-up of these cases.[87,88]

FOREIGN BODIES

Embedded **soft tissue foreign bodies** are a common problem in both adult and pediatric populations. Whereas some materials, such as metal and glass, are radiopaque and can be seen on plain radiographs, other materials such as wood are not detected radiographically. In these cases, ultrasound is an effective means for diagnosis. Foreign bodies are typically highly echogenic and may have posterior acoustic shadowing (Fig. 23. 33). They may be surrounded by a hypoechoic halo, representing an inflammatory reaction[89] or hyperemia on color Doppler imaging. A large amount of associated fluid should prompt consideration of a secondary abscess.

From a practical standpoint, the patient can usually accurately direct the sonographer to the area of greatest concern, and observation of skin entry and/or exit sites is helpful to focus evaluation. Knowledge of the trajectory of foreign body entry is particularly helpful in assessment of thin linear objects such as wooden splinters, because they are often seen in nonanatomic oblique planes. Meticulous scanning is needed because small foreign bodies may be occult to cursory scanning in the hands and feet, where they may be obscured by adjacent ligaments, tendons, nerves, and vessels.[90] It is also important to determine the relationship of the object to these anatomic structures and to determine if there is associated injury to them. In addition to the visualization of nonradiopaque foreign bodies, ultrasound may help guide surgical planning by providing accurate three-dimensional localization of both radiopaque and nonradiopaque objects, and the overlying skin can be marked preprocedurally as an aid. Ultrasound can also be used to directly guide foreign body retrieval with real-time imaging.[91,92]

SOFT TISSUE INFECTION

Infection of the skin and subcutaneous soft tissue, **cellulitis,** is a common clinical problem, which can be effectively treated with antibiotics. On ultrasound, the skin and subcutaneous tissues are thickened and hyperechoic early in the process. Later, there may be interdigitating reticular strands of hypoechogenicity representing interstitial inflammatory exudate,[93] also known as the "cobblestone" appearance (Fig. 23.34).

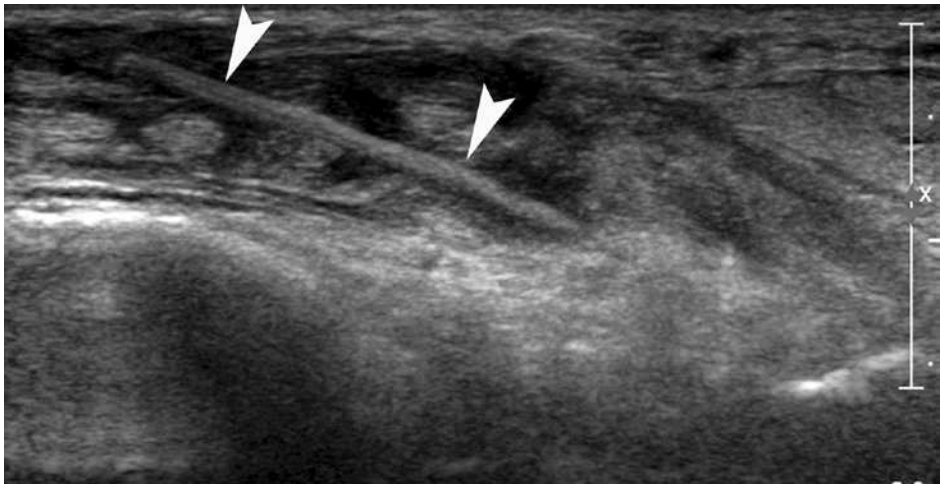

FIG. 23.33 Wood Foreign Body. A wood splinter is embedded within the dorsal soft tissues of the hand. The splinter *(arrowheads)* appears as a linear, echogenic structure.

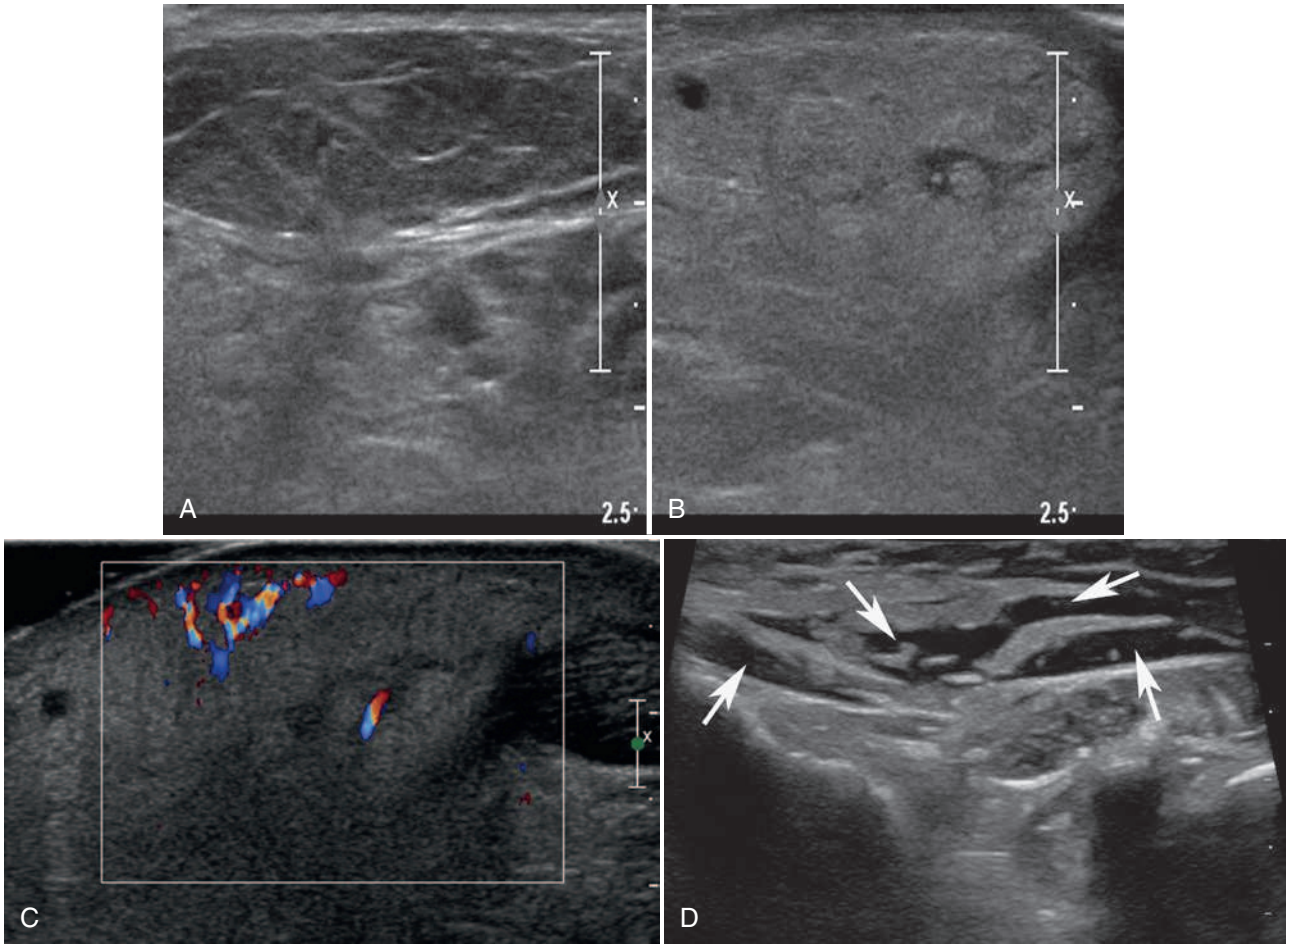

FIG. 23.34 Cellulitis. (A) Normal subcutaneous fat in the lateral nonaffected ankle is juxtaposed with the **(B)** abnormal contralateral ankle in the same patient with cellulitis. Note the hypoechoic echotexture of the normal fat *(left side of image)* versus the echogenic, swollen subcutaneous fat with obscuration of the normal internal septations *(right side of image).* **(C)** Color Doppler imaging demonstrates increased blood flow within the echogenic, swollen subcutaneous fat. **(D)** Gray-scale imaging in a different patient with cellulitis demonstrates anechoic fluid *(arrows)* within the echogenic cellulitic tissue.

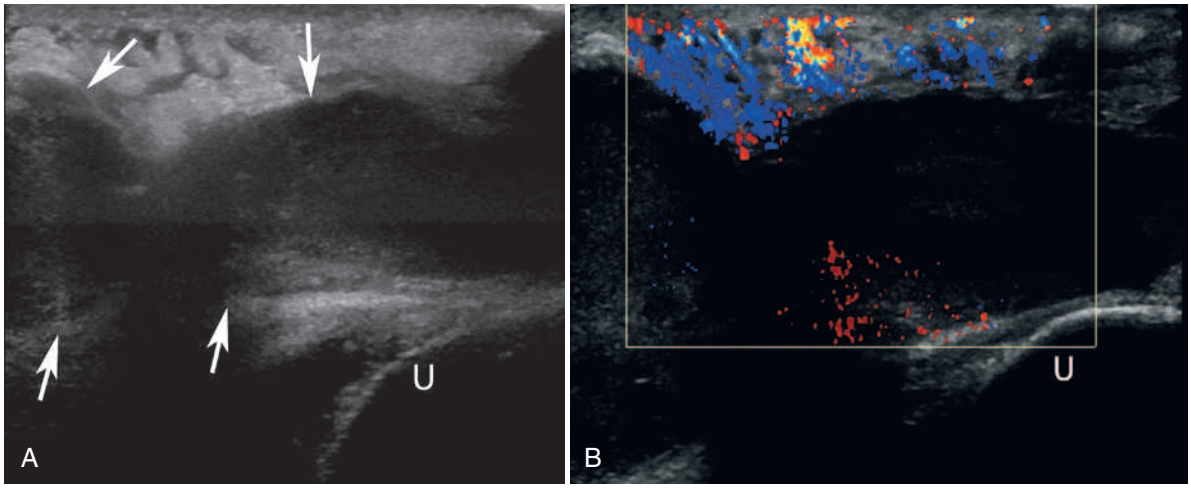

FIG. 23.35 Forearm Abscess. (A) Short-axis image of a complex fluid hypoechoic collection *(arrows)* with echogenic peripheral soft tissue rind and increased through transmission, consistent with an abscess. **(B)** Color Doppler image demonstrates hyperemia within the surrounding soft tissues. *U,* Ulna.

Cellulitis may progress to **abscess** formation. The development of an associated **abscess** is an important finding to diagnose, as this will typically not respond to antibiotics, instead requiring drainage, either surgical or image guided. Abscesses can have a variable appearance on ultrasound evaluation.[94] An abscess border may be well defined or poorly defined and infiltrative (Fig. 23.35). There may be a surrounding rim of hyperemic, thickened soft tissue. The internal liquefied material may demonstrate an anechoic, hypoechoic, or complex echogenic appearance, with internal septations and low-level echoes. Foci of echogenic gas, with associated ill-defined shadowing, may be present within the abscess. With dynamic compression, swirling of the echogenic debris within the abscess can be seen.

In cases of fluid collection, several other entities may be considered and differentiated from an abscess. A seroma can be distinguished from an abscess in that a seroma appears as a simple anechoic to hypoechoic fluid collection without peripheral hyperemia, and there may be increased through transmission. A hematoma may appear as a mixed echogenicity fluid collection, yet will have no internal color Doppler flow and will have scant peripheral hyperemia. A soft tissue sarcoma will demonstrate solid, hyperemic internal components, as well as posterior acoustic shadowing. If the sonographic diagnosis of the fluid collection is indeterminate, confirmation can be obtained with aspiration (sonographically guided, if needed) and microbiologic and histologic assessment of the aspirate.

CONCLUSION

Ultrasound is a cost-effective means by which to provide an accurate diagnosis in many scenarios of musculoskeletal pathology, including tendon and ligament injury, arthritis, and characterization of infection and some soft tissue masses. In addition to ongoing technical developments, critical to the use of this technology in the future will be technologist and physician education and appropriate and consistent incorporation of new technology into patient care pathways.

CHAPTER 24

The Shoulder

Colm McMahon and Corrie Yablon

SUMMARY OF KEY POINTS

- In the diagnosis of full-thickness rotator cuff tears, ultrasound is of comparable accuracy to magnetic resonance imaging, although it may be less accurate in the diagnosis of partial-thickness tears.
- The key to scanning the shoulder is meticulous technique using a protocol that systematically evaluates the entirety of the shoulder.
- Understanding of optimal patient positioning, probe orientation, and shoulder anatomy is critical to effective diagnostic shoulder ultrasound.
- Ultrasound allows dynamic assessment of subacromial and subcoracoid impingement, biceps subluxation, and rotator cuff integrity.

CONCLUSION

CLINICAL PERSPECTIVE

The human **shoulder** represents an intricate balanced anatomic system capable of exerting force in multiple directions, in multiple different positions, all possible because of a number of static and dynamic structures, which when functioning well provide for the competing needs of movement and stability. Proper function of the shoulder is critical for activities ranging from the most basic of daily life to many sporting pursuits including those of the throwing athlete. The shoulder is, however, prone to injury, related to anatomic factors such as **subacromial impingement.**[1,2] Shoulder pain and limitation of motion are very common causes for quality-of-life impairment, medical resource use, and loss of workplace productivity.[3-7] In fact, about 50% of adults have at least one episode of shoulder pain yearly.[8] Clinical presentation varies from acute injury[9,10] to more chronic dysfunction, which is more common with advancing age.[11]

Although shoulder pain and dysfunction are common clinical complaints, the underlying etiology is variable, with causes including **rotator cuff pathology (degeneration, tears, calcific tendinosis),** long head biceps pathology, subacromial subdeltoid bursa pathology, arthropathy of the glenohumeral or acromioclavicular joint (which may be of inflammatory or degenerative cause), or osseous disease. Of these, **subacromial subdeltoid bursitis** and rotator cuff pathology are the most common causes of symptomatic shoulder disease.[12] Correct diagnosis is crucial for treatment decision making, allowing appropriate management with surgical or nonsurgical treatment, which may diminish the personal and societal effect of shoulder problems.[13,14] Of course, clinical history taking and examination are intrinsic parts of patient assessment, but the accuracy of clinical examination in diagnosis of the cause of shoulder pain is both modest and variable.[15-20]

In this clinical and socioeconomic setting, the advantages of ultrasound as a diagnostic test are myriad, as this technique is accurate, cost-effective, and well tolerated by patients. In the diagnosis of full-thickness rotator cuff tears, ultrasound is of comparable accuracy to magnetic resonance imaging (MRI), although it may be less accurate in the diagnosis of partial-thickness tears.[21-30] Ultrasound can also determine **muscle atrophy,** an important parameter in predicting successful surgical outcome of rotator cuff repair.[31] Ultrasound is a good alternative to MRI in patients who are claustrophobic, are of large size, or have

incompatible implanted metallic and electronic devices. Patients with shoulder pain tolerate ultrasound better than MRI owing to relatively increased patient comfort and diminished examination time.[32]

Ultrasound provides several benefits that MRI cannot. Ultrasound offers the possibility of dynamic assessment of the rotator cuff, allowing the patient to be imaged while engaging in the motion that causes pain or clicking. Ultrasound can assess **subacromial impingement, subcoracoid impingement,** and **biceps tendon subluxation** dynamically, in real time, and cine clips can be obtained. If there is a question as to pathology versus a normal variant, comparison to the contralateral side can be easily made. Dynamic compression of rotator cuff tears can aid in the assessment of cuff integrity. Ultrasound is also more sensitive than MRI to the detection of calcium deposits within the tendon. Finally, patients can receive the results of their examination instantaneously, and this adds tremendously to patients' satisfaction with the modality.[33]

It should be noted that ultrasound is not without limitations. In the clinical setting of instability, ligamentous injury, or suspected glenoid labral injury, MRI or MRI arthrography are preferred. Ultrasound is also of limited value in the evaluation of bony disorders, and plain radiography should be considered complementary in the assessment of patients with shoulder pain to further diagnosis of fracture, bone lesions, subacromial spurs, acromioclavicular osteophytes, acromiohumeral interval narrowing, glenohumeral and acromioclavicular alignment and joint space abnormality, and soft tissue calcification.

In view of these considerations, ultrasound should be considered a first-line investigation in patients with acute or chronic shoulder pain in whom rotator cuff tear is suspected. Imaging algorithms detailing the role of shoulder ultrasound in specific common scenarios have been published in a consensus statement by the Society of Radiologists in Ultrasound, a highly useful resource.[34]

SHOULDER ANATOMY

The shoulder consists of the osseous shoulder girdle with associated muscles and ligamentous structures.[35] Central to understanding the anatomy of the shoulder and scan technique is the anatomy of the **scapula** (Fig. 24.1). The scapula consists of a flat triangular bone with anterior and posterior surfaces in addition to the **glenoid fossa** laterally. The glenoid fossa is deepened by a fibrocartilaginous labrum, and lined with hyaline cartilage for articulation with the humerus at the synovial **glenohumeral joint.** The glenoid neck tapers to the flatter triangular body of the scapula. At the anterior aspect of the scapular body is the **subscapular fossa,** a concavity with oblique ridges that gives origin to the **subscapularis muscle.** The posterior surface of the scapula is convex posteriorly and divided into superior and inferior portions by the scapular spine. Above the spine is the **supraspinatus fossa,** which provides origin to the **supraspinatus muscle.** Below the spine is the **infraspinatus fossa,** with the **infraspinatus muscle** originating from the medial two-thirds, and the **teres minor** originating along the medial border. Extending superolaterally from the scapular spine is the **acromion,** a flattened hooklike structure that curves from posterior to anterior where it articulates with the **clavicle** at the **acromioclavicular joint.** The acromion and scapular spine give origin to the **deltoid muscle.** The acromion is important functionally and for the purpose of ultrasound technique as it overlies the supraspinatus and infraspinatus in the neutral position, prohibiting accurate visualization unless specific positioning maneuvers are undertaken. Also, osseous spurs **(subacromial spurs)** along the undersurface of the acromion may be a cause for **subacromial**

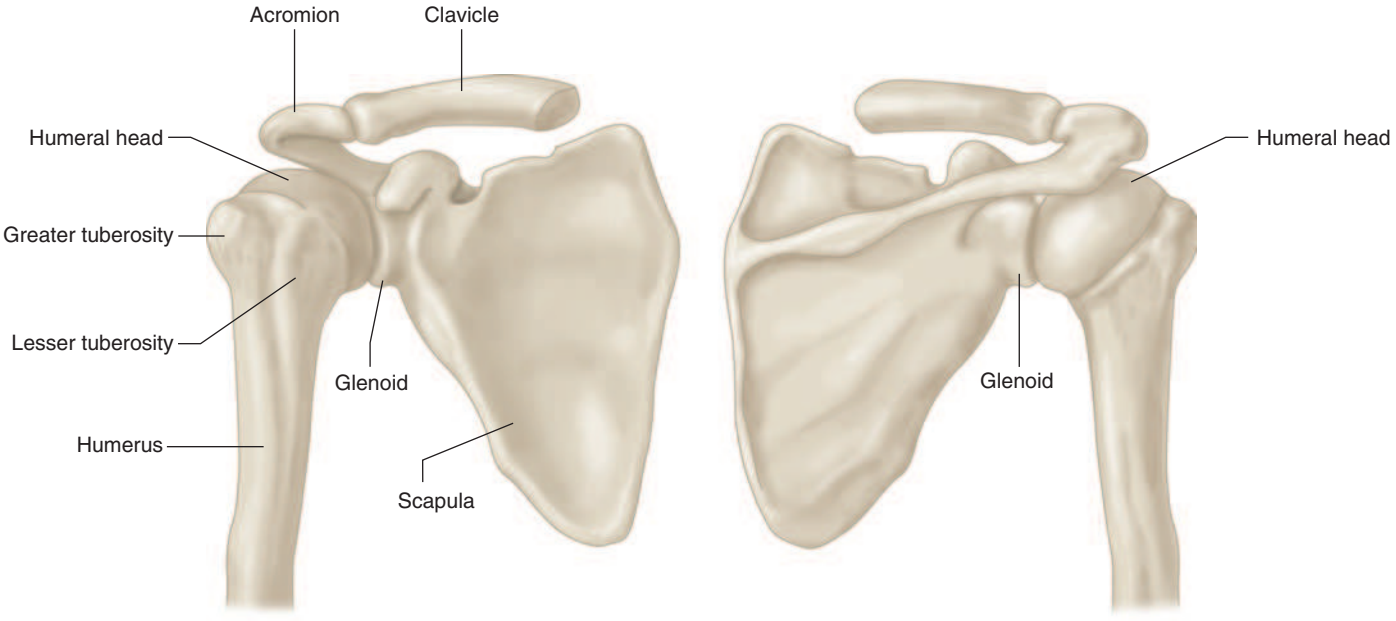

FIG. 24.1 **Illustration of the Scapula and Osseous Landmarks.**

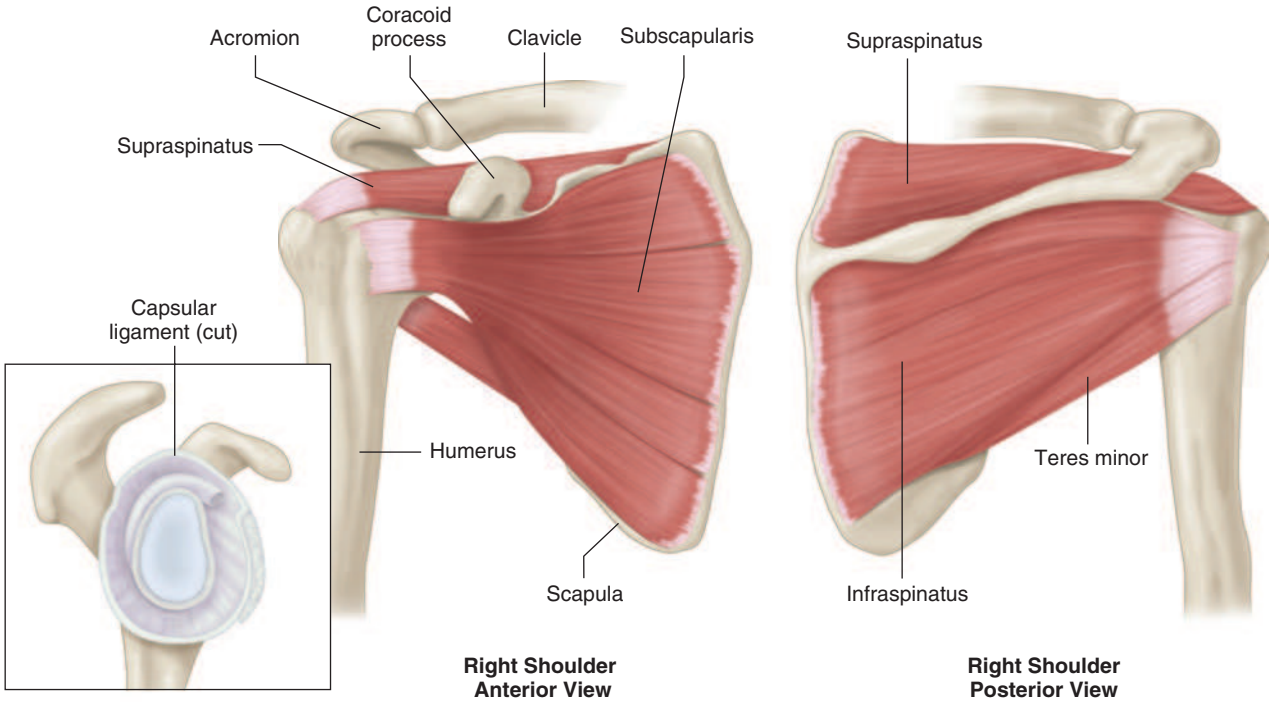

FIG. 24.2 Illustration of Rotator Cuff Anatomy.

impingement. These typically form at the attachment of the **coracoacromial ligament.** Furthermore, **osteoarthritis** at the acromioclavicular joint may result in osteophyte formation, which, when present inferiorly, may cause rotator cuff tendon impingement. The **coracoid process** is a fingerlike curved process extending anteriorly from the scapular neck, giving attachment to the short head of **biceps, coracobrachialis,** and **pectoralis minor muscles** in addition to the **coracohumeral ligament,** and also the **coracoclavicular ligaments,** which help stabilize the **acromioclavicular joint.**

The **rotator cuff** consists of four muscles: the subscapularis, supraspinatus, infraspinatus, and teres minor muscles (Fig. 24.2). These originate from the scapula and insert on the proximal humerus. Normal rotator cuff tendons are about 4 to 6 mm in thickness,[36] tapering out smoothly from medial to lateral along the insertional footprint at the greater tuberosity. The **subscapularis** muscle is a multipennate structure that originates from the anterior surface of the scapula, which converges to a flat tendon laterally to insert on the lesser tuberosity. Of note, the inferior one-third of the subscapularis remains muscular to the level of the lesser tuberosity.[37] The supraspinatus muscle originates from and occupies the supraspinatus fossa, with its tendon extending laterally to insert on the greater tuberosity of the humerus at its anterior aspect. The tendon has a more cordlike component anteriorly and is flatter and more quadrilateral in short axis at its mid and posterior fibers. The **infraspinatus** muscle originates at the infraspinatus fossa and passes laterally to insert on the posterosuperior aspect of the greater tuberosity. The fibers of the supraspinatus and infraspinatus tendons merge at their posterior and anterior borders, respectively, forming a conjoint insertion. The teres minor originates along the lateral border of the scapular body and inserts along the posterior aspect of the greater tuberosity, inferior to the infraspinatus.

The **long head of biceps tendon** originates from a bony tubercle at the superior glenoid, the supraglenoid tubercle, and from the superior labrum. It passes inferolaterally between the subscapularis and supraspinatus tendons, which form the inferior and superior borders of the **rotator interval** (Fig. 24.3). Within the rotator interval, the tendon is stabilized by a ligamentous sling formed by the coracohumeral and superior glenohumeral ligaments. Passing inferolaterally out of the rotator interval, the long head of biceps tendon becomes extraarticular and extends inferiorly in the bicipital or intertubercular groove, which lies between the greater and lesser tuberosities. The biceps tendon is stabilized in the groove by the transverse ligament, formed by tendinous fibers at the subscapularis insertion.[38]

The **subacromial-subdeltoid bursa** is a synovium-lined flat, thin structure that lies between the rotator cuff tendons and the overlying deltoid muscle and acromion.[39] It serves to reduce friction between the rotator cuff and the overlying structures, permitting smooth movement.

SCAN TECHNIQUE

For consistent and accurate shoulder ultrasound performance, a standard protocol is suggested with comprehensive evaluation in every case, rather than targeted scanning (Table 24.1).[40-44] The patient should be sitting upright if possible, either on a rotating stool or at the edge of a bed. A chair with a backrest should not be used, because this would interfere with patient positioning. Likewise, the sonographer should also sit on a rotating stool, with the seat position somewhat higher than the patient's, so

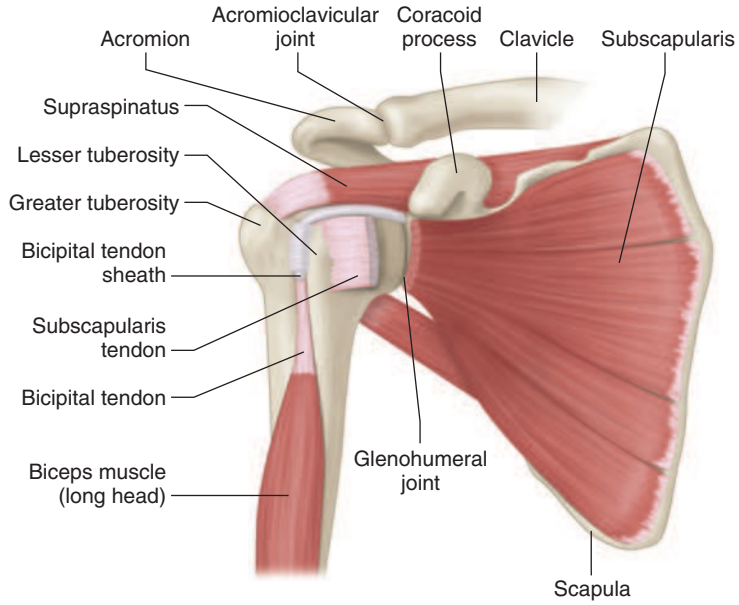

FIG. 24.3 **Illustration of the Long Head Biceps Tendon in the Rotator Interval and in the Bicipital Groove.**

TABLE 24.1 Routine Shoulder Ultrasound Protocol

Posterior shoulder	Axial plane image
Acromioclavicular joint	Coronal plane image

that the sonographer's arm can be held in a natural, ergonomic position. If a patient is wheelchair-bound, it is helpful if possible to temporarily remove the backrest. If the patient cannot sit upright, more limited scanning is possible with the patient lying supine, with the affected shoulder at the edge of the bed. A high-frequency 12- to 15-MHz linear array transducer is used to permit high-resolution scanning. Occasionally, in larger patients, a lower-frequency probe (9 MHz) may be needed to achieve tissue penetration to the required depth, but this incurs a reduction in resolution.

When scanning any tendon, care should be taken to maintain an angle of close to 90 degrees between the probe and the tendon of interest to avoid artifactual hypoechogenicity due to **anisotropy.** This is discussed in more detail later in the chapter.

Biceps Tendon Evaluation

Biceps tendon evaluation is best performed with the arm in a neutral position, resting the forearm on the patient's ipsilateral thigh, with elbow flexed and the palm up (Fig. 24.4). In this position, the biceps tendon is seen anteriorly.[45] The tendon can be imaged in its short axis within the bicipital groove by holding the probe transversely with respect to the upper arm and following the course of the tendon inferiorly where it passes deep to the pectoralis major tendon insertion on the humerus. In short axis, the tendon appears as a homogeneous, echogenic, round or ovoid structure that may be accompanied by a trace of fluid within its tendon sheath. The normal biceps tendon is 2 to 4 mm thick.[36] The tendon can be followed superiorly and medially into the rotator interval, by angling the probe more obliquely to remain orthogonal to its short axis. Finally, the probe can be rotated 90 degrees to view the tendon in its long axis where it should appear smooth and fibrillar.

Subscapularis Tendon Evaluation

The subscapularis is scanned with the patient's arm at the side, in external rotation with the palm facing up[44] (Fig. 24.5). The tendon should be evaluated in long axis, with the probe aligned with the subscapularis tendon, and in short axis, with the probe held perpendicular to the subscapularis tendon. The coracoid process of the scapula, medial to the subscapularis and palpable in many patients, is a useful anatomic landmark when locating the subscapularis tendon. The tendon fibers can be seen emanating from the broad multipennate muscle belly. The normal hypoechoic muscle should not be mistaken for fluid. In this position the patient's arm can be rotated from external rotation to neutral position, while observing the passage of the tendon fibers deep to the coracoid process to assess for subcoracoid impingement (Video 24.1). This dynamic maneuver is also useful to assess for long head biceps tendon subluxation from the bicipital groove.

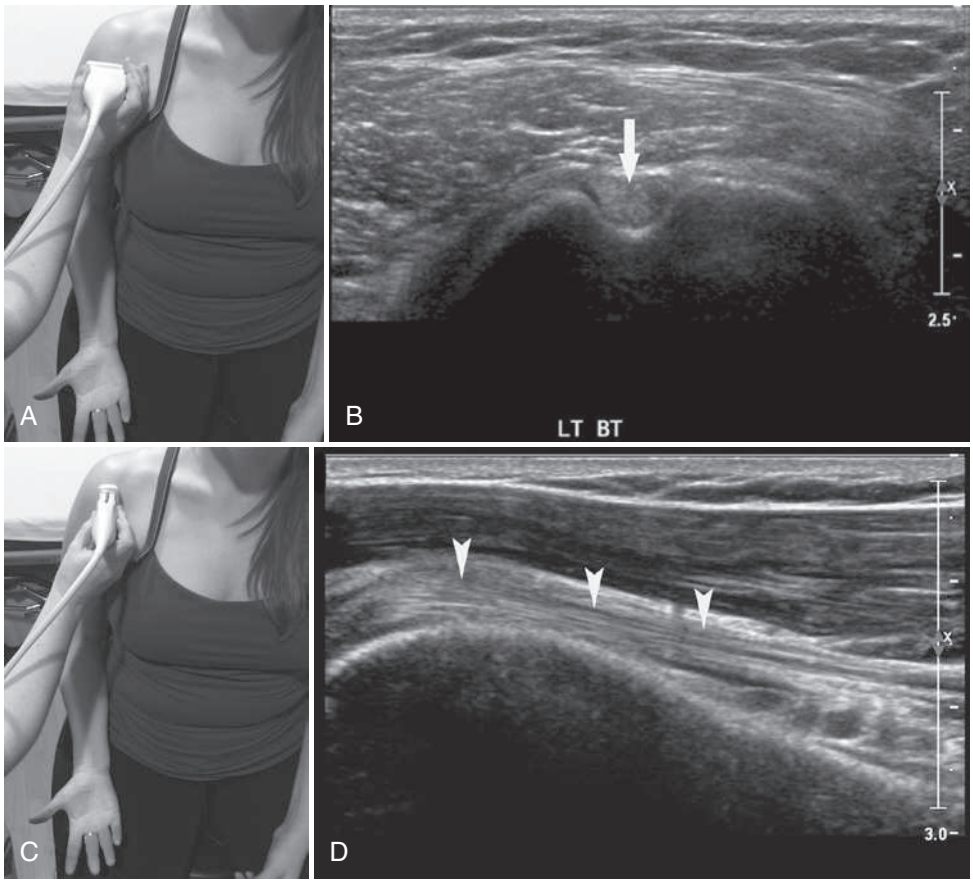

FIG. 24.4 Long Head Biceps Tendon (LHBT). (A) Photograph of the probe position for imaging the LHBT in short axis. The patient's shoulder is externally rotated, with the elbow flexed and held tight to the body, with the forearm palm up, resting on the patient's lap. This position rotates the LHBT anteriorly. **(B)** Short-axis image of LHBT *(arrow)*. **(C)** Photograph of probe position for imaging the LHBT in long axis. The probe is rotated 90 degrees to the short-axis starting position. Patient position remains the same as for the short-axis image. **(D)** Long-axis image of LHBT *(arrowheads)*.

Supraspinatus Evaluation

In neutral position the supraspinatus tendon is largely obscured from view by the overlying acromion. To draw the tendon out from under the acromion, specific maneuvers are needed. The position, originally described by Crass[46] (Fig. 24.6), consists of asking the patient to place his or her hand behind the back, reaching toward the opposite back pocket with the back of the hand. This results in flexion, internal rotation, and adduction of the shoulder. In this position, the greater tuberosity is located anteriorly, so the supraspinatus tendon courses anterolaterally to its insertion and is drawn out from under the acromion, allowing visualization. Patients with shoulder pain often find this position difficult to achieve and maintain, so an alternative position is the **"modified Crass position"** (Fig. 24.7) in which the patient puts the palm of the hand on the ipsilateral hip or buttock, with elbow flexed and directed posteriorly. In this position, the greater tuberosity is similarly positioned as in the original **Crass position,** but the maneuver is usually well tolerated by patients. The supraspinatus tendon will again course anterolaterally to the greater tuberosity.

To visualize the supraspinatus in long axis, the probe should parallel the long-axis orientation of the tendon, resulting in an oblique sagittal probe position relative to the patient, with the probe directed toward the patient's ear (see Fig. 24.7A). The long head biceps tendon in long axis with the patient in the **modified Crass position** is a useful landmark for locating the most anterior portion of the supraspinatus tendon (Fig. 24.8). If the probe in long axis is then moved posteriorly in the same plane, the entire supraspinatus will be assessed. Correctly imaged, the normal supraspinatus should appear smooth, echogenic, and fibrillar, tapering at its insertion or "footprint" with a so called "bird's beak appearance." Normal rotator cuff tendons possess a fibrocartilaginous interface at their bony attachment that may manifest as a thin hypoechoic band paralleling the insertional cortex, similar in echogenicity to hyaline cartilage.[37] This should not be mistaken for a tear.

The probe is then rotated 90 degrees to image the tendon in short axis. In this position, the more cordlike anterior fibers of the supraspinatus tendon are seen merging with the flatter quadrilateral mid and posterior fibers. While visualizing the supraspinatus tendon in short axis, it is important to move the probe anteriorly so that the long head biceps tendon is imaged in short axis. This ensures that the entire anterior leading edge of the supraspinatus has been evaluated. In short axis, the **rotator interval** is well seen

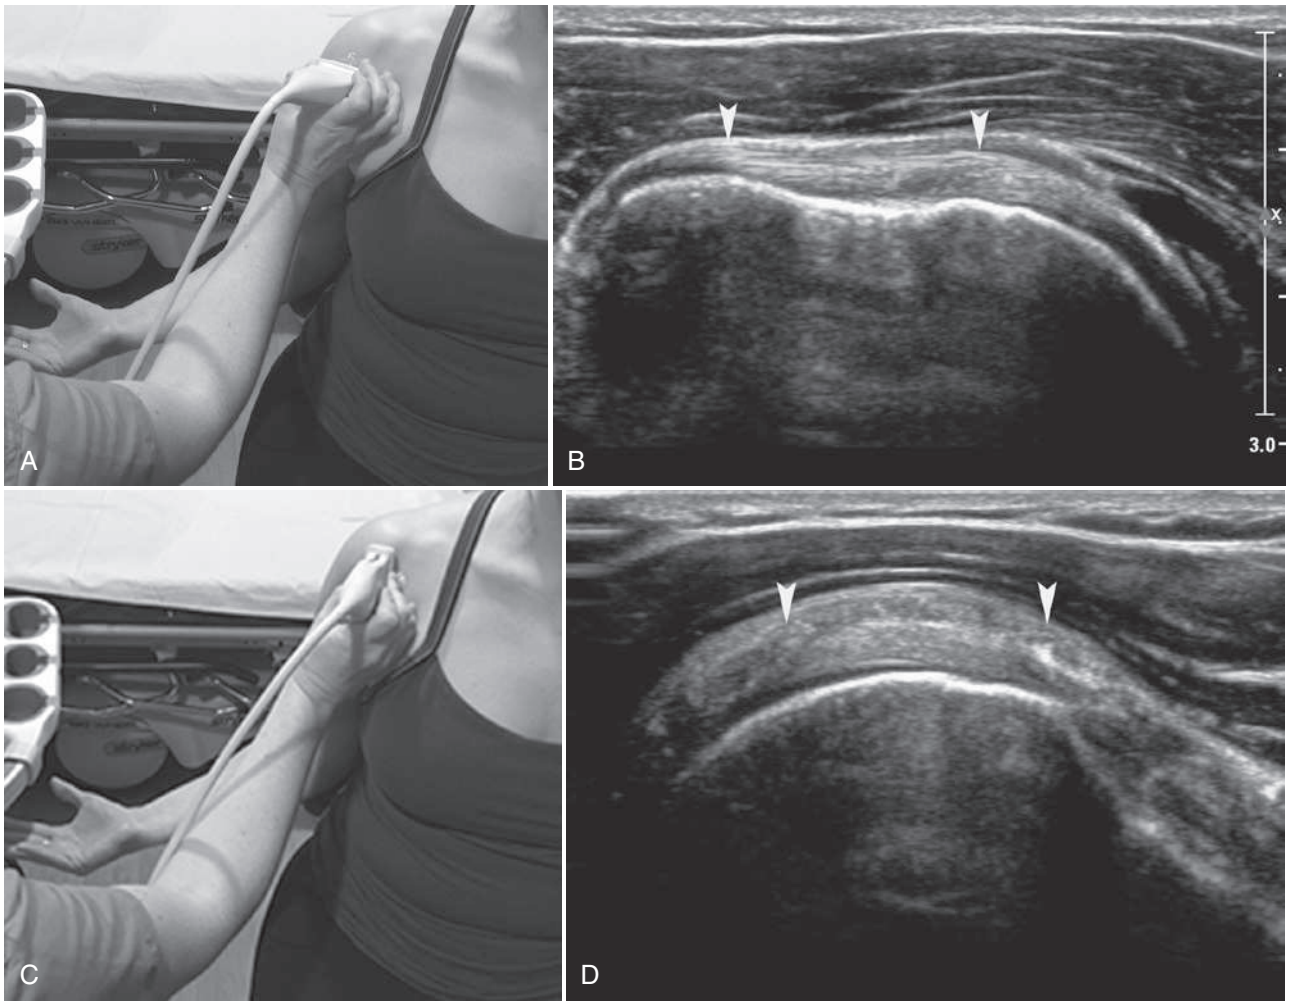

FIG. 24.5 Subscapularis Tendon. (A) Long-axis probe position. From the long head biceps tendon (LHBT) starting position, the patient now externally rotates the elbow, keeping the elbow tight to the body with the palm up. This position elongates the subscapularis tendon and rotates the tendon out from under the coracoid process, allowing visualization. The probe is placed across from the coracoid process. Note that the probe position is similar for imaging the LHBT in short axis, but the patient's position is different. **(B)** Long-axis image of subscapularis tendon *(arrowheads).* **(C)** Short-axis probe position. From the long-axis starting position, the probe is simply turned 90 degrees to image the subscapularis in short axis, with the patient remaining in the same position. Note that the probe position is similar to the LHBT long-axis probe position, but the patient's position is different. **(D)** Short-axis image of subscapularis tendon *(arrowheads).* See also Video 24.1.

anterior to the tendon, with the biceps tendon coursing through the interval, also in short axis, stabilized by the **coracohumeral ligament** and **superior glenohumeral ligament.**

As with all tendons, the supraspinatus should be scanned through its entirety from anterior to posterior in long axis and medial to lateral in short axis. When the posterior fibers of the supraspinatus tendon are reached, the more posteriorly oriented fibers of the infraspinatus tendon are routinely encountered; this is a helpful landmark to ensure the entire supraspinatus tendon has been studied. It is important to note that as the transducer is moved posteriorly, the greater tuberosity changes shape, from ledgelike to flat. This area of transition is where the anterior infraspinatus fibers overlap the posterior supraspinatus fibers. A discrete overlap of fibers can be visualized at this juncture (Fig. 24.9, Video 24.2). Continuing posteriorly from this overlap, the infraspinatus fibers can be evaluated in their entirety, looking for the similar normal fibrillar pattern in the long axis, and the echogenic appearance in the short axis.

The **rotator cable** is a thin fibrous band contiguous with the coracohumeral ligament that passes along the deep surface of the supraspinatus and infraspinatus tendons.[47] This bandlike structure is oriented perpendicular to the long axis of the rotator cuff, running in an anterior to posterior direction, and is felt to have a biomechanical role in stress distribution, likened to the cable of a suspension bridge.[48] It can be visualized consistently with ultrasound, seen in its short axis where it appears elliptical, when scanning the long axis of the supraspinatus and infraspinatus (Fig. 24.10). It is located about 1 cm (average 9 mm, range 4-15 mm[47]) medial to the rotator cuff insertion at the greater tuberosity.

Dynamic assessment for **subacromial impingement** of the supraspinatus can now be performed. The patient's arm rests in a neutral position at his or her side, and the probe is positioned in a coronal plane, with the acromion at the medial aspect of the field of view, and the greater tuberosity laterally. The patient then abducts the arm slowly, and the motion of the supraspinatus

FIG. 24.6 Crass Position. The patient places her arm behind her back with the dorsum of the hand resting on the contralateral back pocket. This position rotates the supraspinatus tendon from underneath the acromion.

tendon under the acromion is observed. The motion should be smooth and uninterrupted, without deformation of the tendon under the acromion, deformation of the bursa, or pooling of bursal fluid (Video 24.3).

A useful alternative technique to assess the supraspinatus has been described by Turrin and Cappello.[49] In this technique, the patient lies supine with the affected shoulder at the edge of the bed, but allows the arm to drop over the side of the bed, with the elbow extended and the forearm pronated. This can be particularly helpful in patients who are unable to sit—for example following cerebrovascular accident with hemiplegia, when associated shoulder pain is not uncommon, though of varied etiology (related to **subluxation, spasticity, adhesive capsulitis,** or **rotator cuff tears**), and standard positioning in the seated position may be difficult.[50]

Infraspinatus, Teres Minor, and Posterior Shoulder Evaluation

Several methods of evaluation of the infraspinatus have been described. The patient can remain in the modified Crass position, or with the arm hanging at the side, and scanning can simply

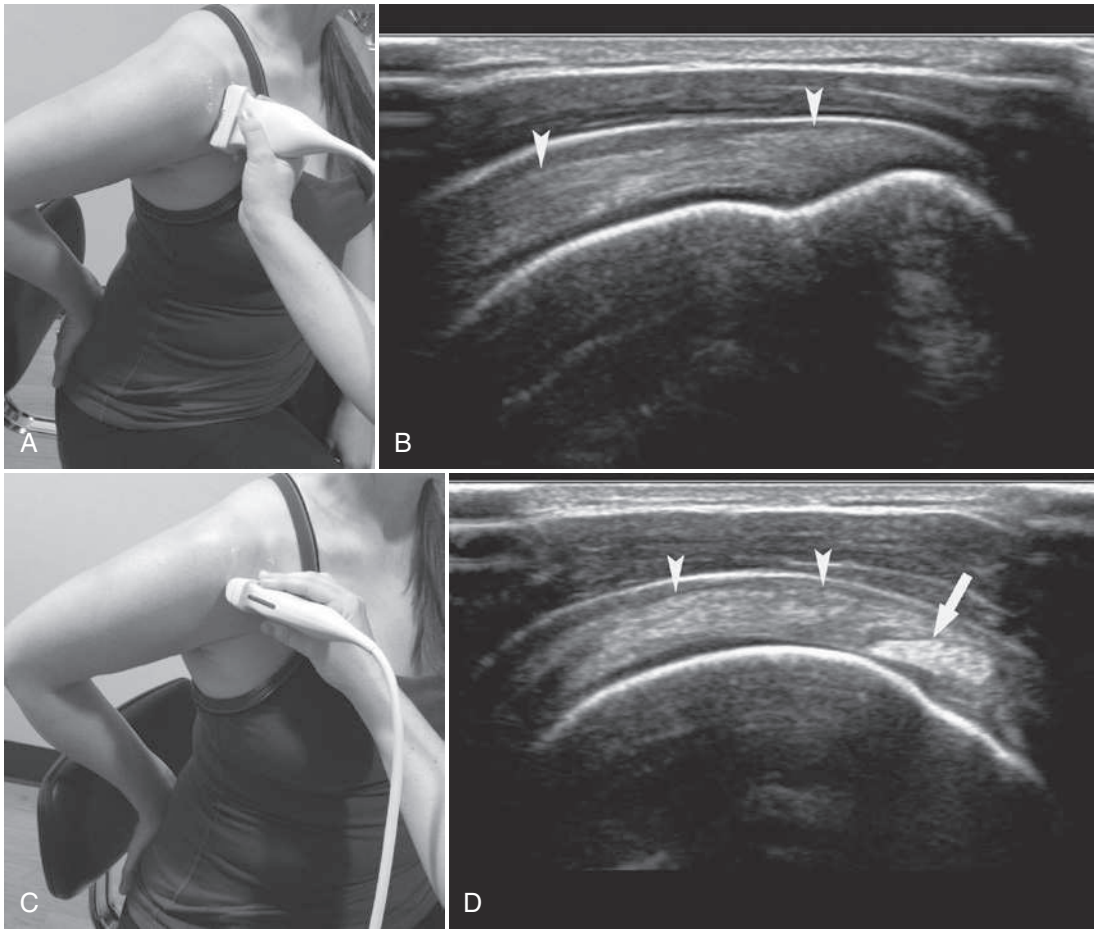

FIG. 24.7 Supraspinatus Tendon and Modified Crass Position. Probe position for supraspinatus in long axis, with the patient in the modified Crass position. The patient places her arm behind her back, palm on the ipsilateral back pocket, with the elbow straight back, as tight to the body as possible. This position rotates the supraspinatus from underneath the acromion. This position is usually better tolerated by patients who have a rotator cuff tear. **(A)** The probe is placed somewhat obliquely, directed toward the patient's ear. **(B)** Long-axis image of the supraspinatus tendon *(arrowheads).* **(C)** Short-axis probe position. The patient remains in the modified Crass position and the probe is rotated 90 degrees from the long-axis starting position. **(D)** Short-axis image of the supraspinatus tendon *(arrowheads).* Note that the long head of biceps tendon is visualized anterior to the supraspinatus tendon *(arrow).*

be continued posteriorly from the supraspinatus both in long and short axis.

An alternate position of scanning the infraspinatus has been described, in which the patient is asked to bring the arm forward across the chest, resting the hand on the contralateral shoulder.[44,51] These positions allow imaging of the infraspinatus tendon and muscle. The probe is held in an oblique transverse orientation, placed on the posterior shoulder to parallel the long axis of the infraspinatus tendon, using the inferior border of the scapular spine as a visual landmark (Fig. 24.11). In long axis the tendon appears similar to the supraspinatus in morphology, although having a more elongated tapered appearance at its insertion, lacking the bird's beak appearance seen at the supraspinatus footprint. The probe is then rotated 90 degrees, to the short axis of the infraspinatus, and the tendon and muscle are evaluated. The normal muscle is hypoechoic and positioned below the scapular spine in the infraspinatus fossa.

The teres minor tendon is also evaluated in this position and is seen inserting at the posterior aspect of the greater tuberosity, inferior to the infraspinatus insertion. The teres minor muscle can be seen arising from the posterolateral scapula, inferior to the infraspinatus muscle.

Also in this position, the posterior shoulder is seen, with visualization of glenohumeral joint fluid and limited views of the posterior labrum and spinoglenoid notch. Scanning the posterior shoulder with external rotation may aid visualization of a glenohumeral effusion.[52]

Rotator Cuff Musculature Evaluation

Using the scapular spine as a visual landmark, the supraspinatus muscle in the supraspinatus fossa can be imaged by placing the probe perpendicular to the scapular spine (Fig. 24.12). This demonstrates the muscle in its short axis. The normal muscle should be hypoechoic and convex in contour, and should fill the

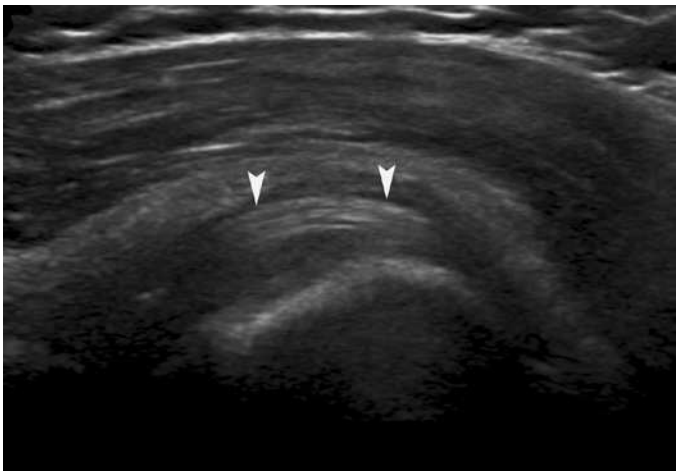

FIG. 24.8 Long-Axis Biceps Tendon Image, With Shoulder in the Modified Crass Position. This is a good starting point for imaging the supraspinatus tendon in long axis. Once the long head biceps tendon is seen well in long axis *(arrowheads),* the probe can simply be moved posteriorly to image the supraspinatus tendon.

FIG. 24.9 Overlap of Posterior Supraspinatus *(Arrow)* and Anterior Infraspinatus Fibers *(Arrowheads)* Seen in Long Axis. See also Video 24.2.

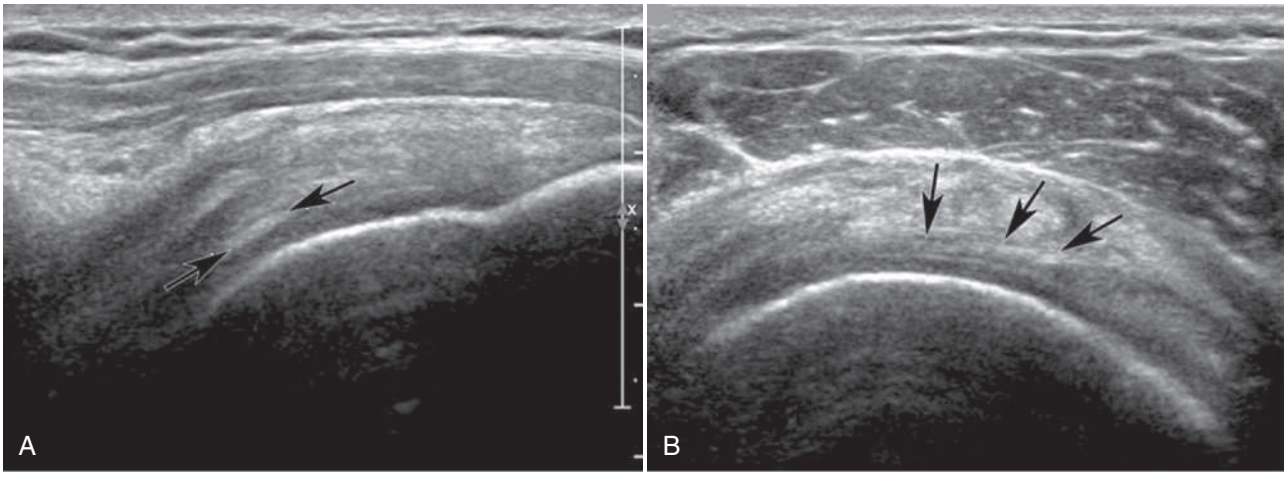

FIG. 24.10 Rotator Cable. (A) The rotator cable *(arrows)* is visualized in short axis along the articular surface of the supraspinatus tendon, when this tendon is imaged in long axis. **(B)** The rotator cable *(arrows)* is visualized as a linear structure in its long axis *(arrows)* along the articular surface of the supraspinatus tendon, when this tendon is imaged in short axis. (Courtesy of Dr. Yoav Morag, Ann Arbor, MI.)

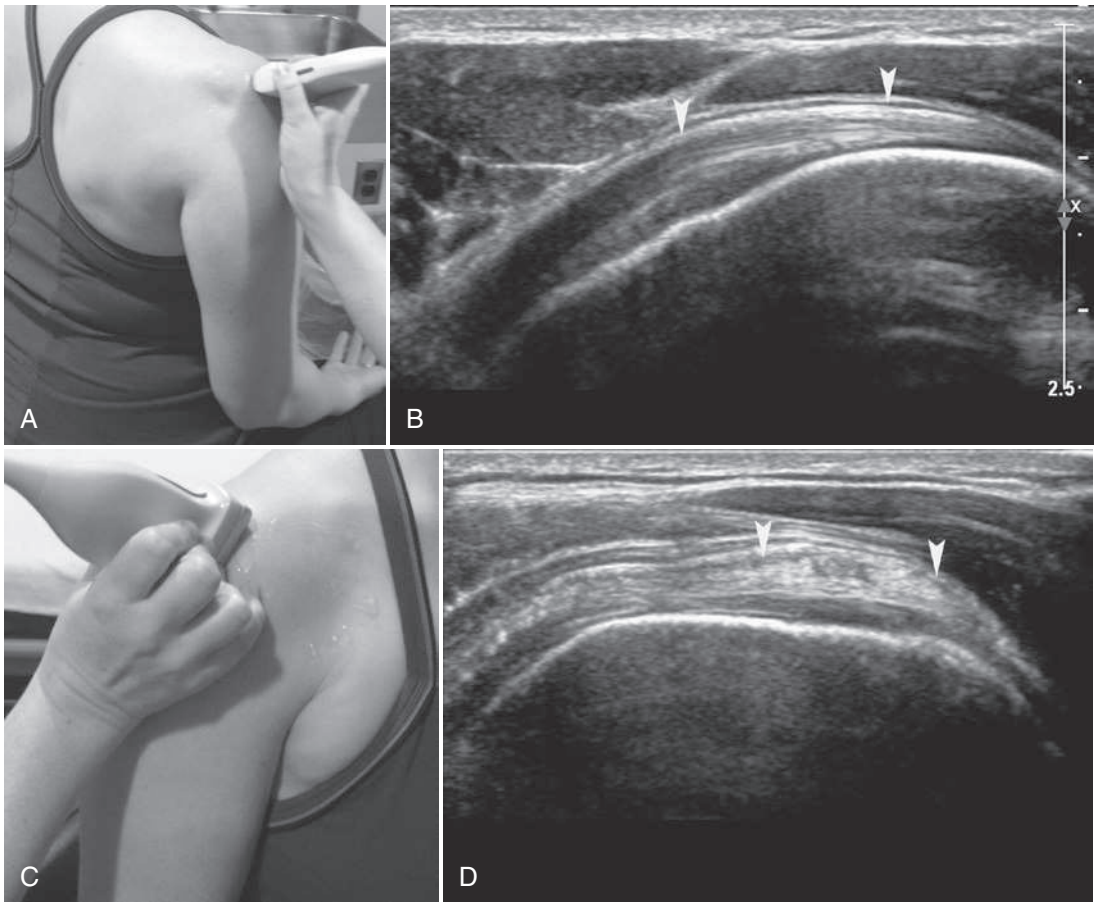

FIG. 24.11 Infraspinatus Tendon. (A) Long-axis probe position. The patient can simply rest the arm at the side, with the forearm palm up in the lap. The probe is placed under the scapular spine and moved laterally to see the distal insertion on the greater tuberosity. **(B)** Long-axis image of infraspinatus tendon *(arrowheads).* **(C)** Short-axis probe position. The probe is rotated 90 degrees to the infraspinatus long-axis starting position. **(D)** Short-axis image of infraspinatus tendon *(arrowheads).*

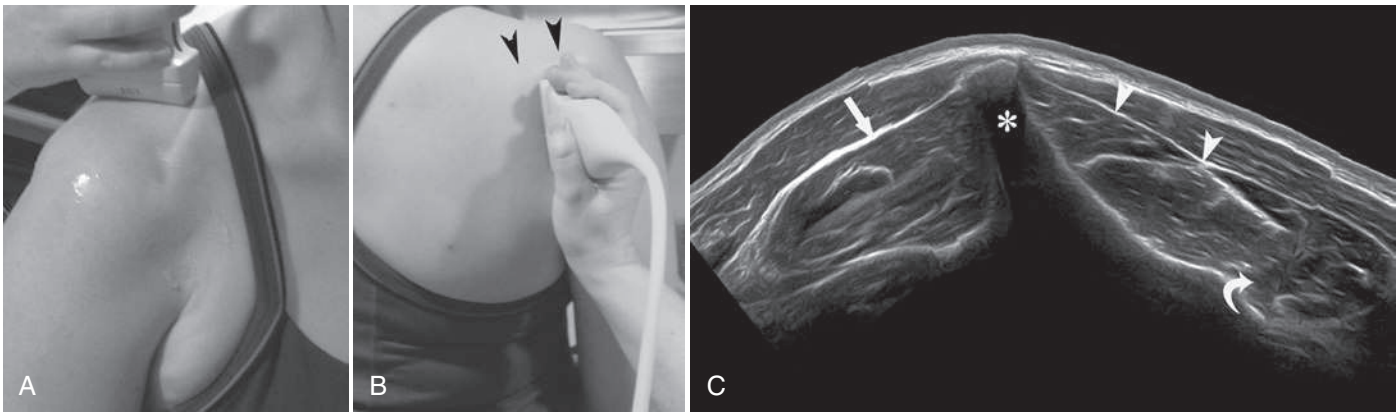

FIG. 24.12 Rotator Cuff Musculature. (A) Probe position for supraspinatus muscle. The probe is placed at the top of the shoulder, medial to the acromioclavicular joint, and posterior to the clavicle. **(B)** Probe position for infraspinatus and teres minor muscles. The probe is placed 90 degrees to the scapular spine, just inferior to the scapular spine *(arrowheads).* **(C)** Extended field-of-view image of supraspinatus *(straight arrow),* infraspinatus *(arrowheads),* and teres minor *(curved arrow).* Note the spine of the scapula (*) separating the supraspinatus and infraspinatus muscles.

supraspinatus fossa. The central tendon should be visible within the muscle.

To image the infraspinatus and teres minor muscles, the transducer is moved distal to the scapular spine, remaining perpendicular to the spine. A relative comparison and assessment of muscle volume and echogenicity can easily be made by using an extended field-of-view scan technique.

ROTATOR CUFF DEGENERATION AND TEARS

Background

Rotator cuff dysfunction, either due to tear or to tendon degeneration, is the most common cause of referral for evaluation of the shoulder.[53] Likewise, rotator cuff disease is the most frequent cause for referral for shoulder ultrasound. The supraspinatus tendon is the most commonly injured tendon in the rotator cuff.[54] The incidence of rotator cuff tears rises as patients age. Up to 22% of patients age 65 and older have rotator cuff tears.[55] It is interesting to note that 70% of imaged patients age 65 and older have asymptomatic rotator cuff defects.[56] Rotator cuff tears in patients younger than 40 are uncommon, but they do occur in the setting of acute trauma or sports-related injuries. Rotator cuff tears in patients older than 40 are usually secondary to tendon degeneration.

Tendinosis

Tendinosis of the rotator cuff is a degenerative process that may be associated with shoulder pain. Histologically, there is no inflammatory component (hence the term **"tendinitis"** is not appropriate for this condition), but rather **mucoid degeneration** and frequently **chondroid metaplasia** are present. On ultrasound, tendinosis appears heterogeneous or hypoechoic, with tendon thickening, and loss of the normal fibrillar pattern[57] (Fig. 24.13). Although discrete defects or tears are not encompassed by this diagnosis, they may coexist.

Full-Thickness Rotator Cuff Tears

Ultrasound is a reliable method for diagnosis of rotator cuff tears, with sensitivity and specificity over 90%[21,26,28,29,58,59] for full-thickness tears, and low interobserver variability.[60,61] Full-thickness tears are visualized as a hypoechoic or anechoic gap within the rotator cuff (Fig. 24.14), which may also have a concave contour at its bursal border.[30,62] Alternatively, a greatly retracted tear can result in nonvisualization of the rotator cuff tendon[62] (Fig. 24.15). This occurs because the tendon may retract deep to the acromion, and is likely in cases in which the degree of retraction exceeds 3 cm.[63] When a full-thickness tear is present, the gap between the retracted tendon end and the greater tuberosity or distal tendon stump may be filled with hypoechoic fluid or echogenic debris (Fig. 24.16) and granulation tissue. Alternatively, the subacromial-subdeltoid bursa (frequently thickened) and the deep surface of the deltoid muscle may occupy the defect created by the tear.[29]

Small foci of debris within the tear gap may give the appearance of mobile or "floating" bright spots.[59] Fluid within the tear gap my accentuate visualization of the underlying humeral head articular cartilage owing to enhanced through transmission of the ultrasound beam, referred to as the **"cartilage interface sign"**[64] (Fig. 24.17). Occasionally one may be uncertain as to whether abnormal echotexture in the location of the rotator cuff represents a partial tear or a full-thickness tear with intervening granulation tissue and debris. Dynamic compression of the abnormal area may clarify this confusion by causing complex fluid and debris to swirl within the rotator cuff tear.

It may be helpful to ascertain if a tear is more likely to be acute or chronic because acute tears are felt to have a greater chance of successful surgical outcome. In this regard, the findings of glenohumeral and bursal effusions are more common in acute tears. In addition, midsubstance tears, medial to the bone-tendon junction, are more likely to be acute. On the other hand, severely retracted tears are more likely to be chronic.[65] In chronic full-thickness tears, the tendon gap may be filled with

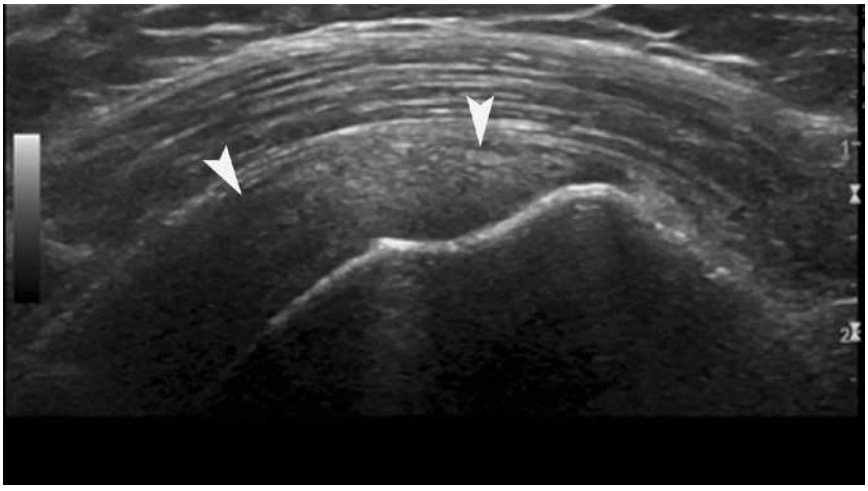

FIG. 24.13 Tendinosis of the Supraspinatus. Long-axis image of the supraspinatus tendon *(arrowheads)* demonstrates hypoechogenicity and diffuse loss of normal fibrillar echotexture.

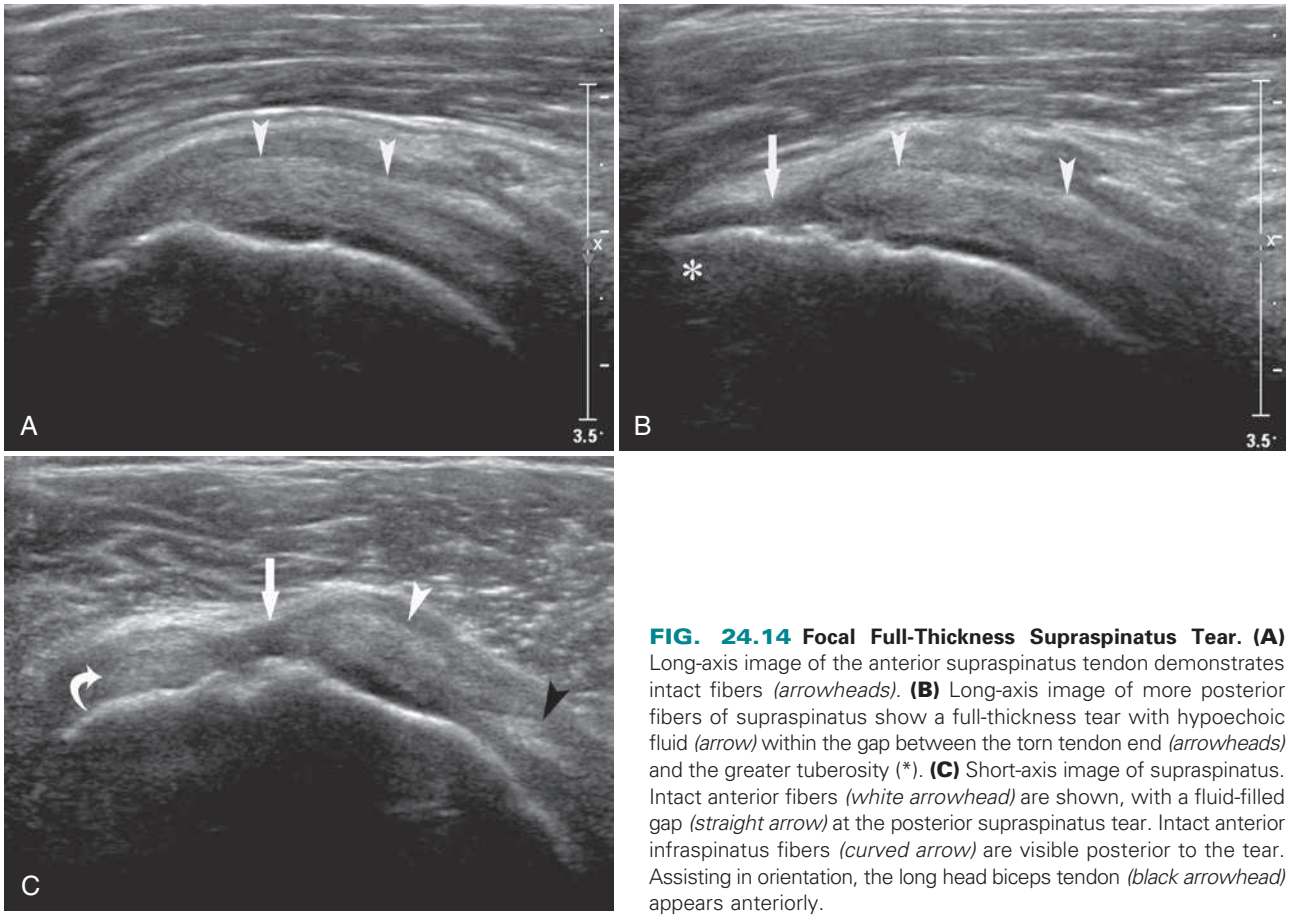

FIG. 24.14 Focal Full-Thickness Supraspinatus Tear. (A) Long-axis image of the anterior supraspinatus tendon demonstrates intact fibers *(arrowheads)*. **(B)** Long-axis image of more posterior fibers of supraspinatus show a full-thickness tear with hypoechoic fluid *(arrow)* within the gap between the torn tendon end *(arrowheads)* and the greater tuberosity (*). **(C)** Short-axis image of supraspinatus. Intact anterior fibers *(white arrowhead)* are shown, with a fluid-filled gap *(straight arrow)* at the posterior supraspinatus tear. Intact anterior infraspinatus fibers *(curved arrow)* are visible posterior to the tear. Assisting in orientation, the long head biceps tendon *(black arrowhead)* appears anteriorly.

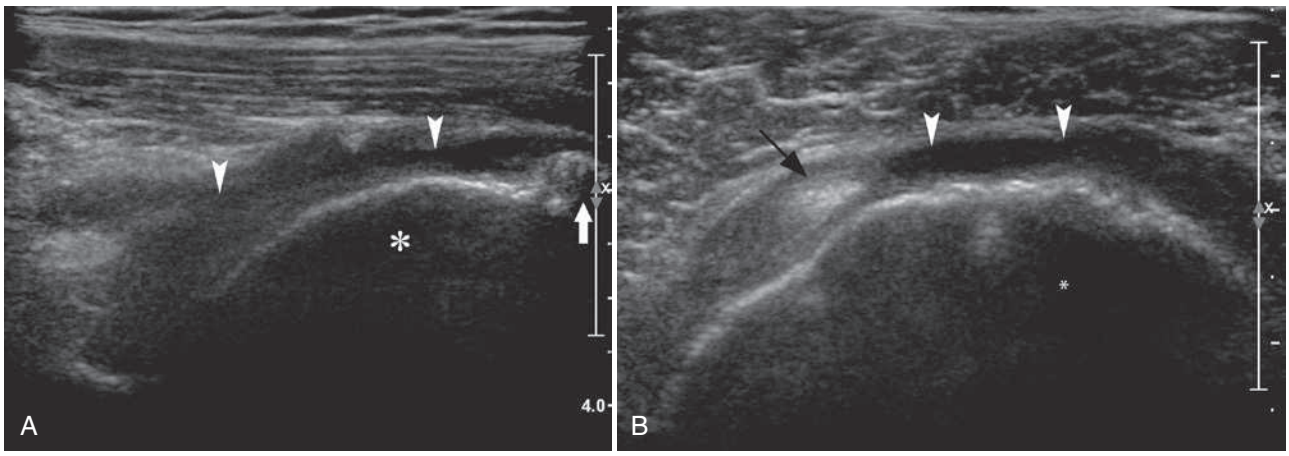

FIG. 24.15 Full-Thickness Supraspinatus Tear With Retraction of the Tendon Beneath the Acromion. Image in the expected location of the supraspinatus tendon in long **(A)** and short **(B)** axis demonstrates absence of the tendon above the humeral head (*) and greater tuberosity *(white arrow)*. Fluid and debris are seen in place of the normal tendon *(arrowheads)*. Note the intact long head biceps tendon anteriorly *(black arrow)*.

noncompressible, complex echogenic debris and granulation tissue that are contiguous with the subacromial subdeltoid bursa, and this may give the false impression of rotator cuff volume to the novice practitioner.

Partial-Thickness Rotator Cuff Tears

As with full-thickness rotator cuff tears, partial-thickness tears occur in both younger and older patients. Partial tears occur more commonly than full-thickness tears in younger patients, and most commonly occur in young athletes. Partial articular-sided supraspinatus tears are the most common subtype in the young athlete.[66] In the older patient population, partial-thickness tears also most commonly occur in the supraspinatus tendon, but the most common cause is tendon degeneration, with increased incidence as patients age.

FIG. 24.16 Focal Full-Thickness Tear of Supraspinatus Tendon. In this long-axis image of the supraspinatus tendon, there is a focal full-thickness tear, and the gap between the tendon retracted end and the greater tuberosity is filled with echogenic debris *(arrow)* and fluid.

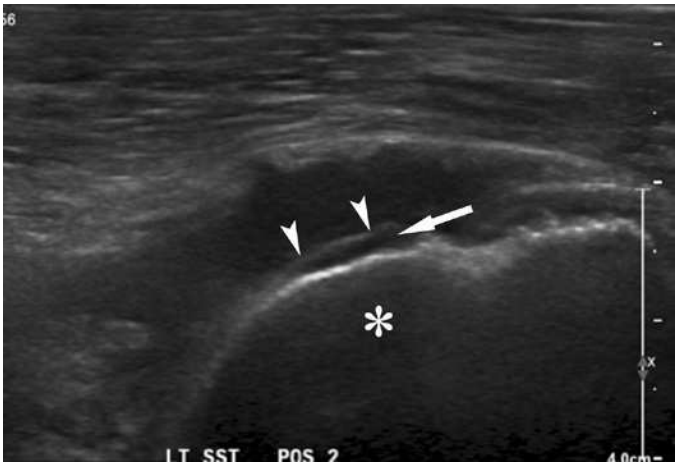

FIG. 24.17 Full-Thickness Supraspinatus Tear With Associated Cartilage Interface Sign. A hyperechoic line *(arrowheads)* is seen along the surface of the normal hypoechoic cartilage *(arrow),* along the superior aspect of the humeral head (*).

Partial-thickness tears are characterized by a focal area of hypoechogenicity or mixed echogenicity involving one side of the tendon, but not extending through the entire thickness.[58] There are several subtypes of partial-thickness tears of the rotator cuff (Figs. 24.18 and 24.19). **Bursal-sided partial-thickness tears** (Fig. 24.19A and B) occur superficially, just deep to the **subacromial subdeltoid bursa. Articular-sided tears** (see Fig. 24.19C and D) occur at the undersurface of the tendon in contiguity with the joint space. **Intrasubstance tears** (Fig. 24.19E) can occur either within the substance of the tendon footprint at the enthesis or longitudinally within the tendon fibers. These tendons may not be identified at arthroscopy because they do not communicate with either the bursal or the articular surfaces of the tendon.

A specific partial-thickness tear type is the **"rim-rent" tear** (see Fig. 24.19F), occurring at the articular side of the supraspinatus tendon, extending into the tendon footprint on the greater tuberosity.[67,68] This type of tear is most commonly seen in athletes who engage in overhead-throwing activities.

Partial-thickness tears vary from small, 1- to 2-mm tears to those involving more than 50% of tendon thickness. Although tears of 50% or greater have typically been referred for repair, patients with tears involving as little as 25% of the tendon may benefit from arthroscopic debridement.[69,70] Surgical decisions, however, are made in the context of the individual patient performance status, limitation by the injury, comorbidities, and patient preference. Partial tears occur most commonly along the articular side of the tendon in younger patients.[70] Care must be taken to adequately assess the anterior leading edge fibers of the supraspinatus tendon, where these tears can often occur.[71] Bursal-sided partial-thickness tears may manifest as flattening of the bursal contour of the tendon of varying severity.[29] This may lead to an hourglass-like diameter shift between areas of normal and attenuated tendon.[28]

An associated sign frequently observed in the setting of both partial- and full-thickness rotator cuff tears is the finding of cortical irregularity of the greater tuberosity, a finding with a 75% positive predictive value for the presence of an associated rotator cuff tear.[72] This is more severe in full-thickness tears and represents bony remodeling with irregularity, pitting, and erosion.[73] A second sign that can be seen in both partial articular-sided and full-thickness tears is the **"cartilage interface" sign,** mentioned earlier.

In analysis of partial- and full-thickness tears, it is important to quantify the extent of the tear in both its long and short axis (tear length and width); for example, in the case of a supraspinatus tendon tear, a measurement of the medial to lateral tear length should be made in long axis, and a measurement of the anterior to posterior tear width should be made on short-axis imaging.

Postsurgical Rotator Cuff

After surgical rotator cuff repair, the appearance of the rotator cuff and surrounding soft tissues is abnormal, as can be expected, with loss of normal soft tissue planes and abnormal echotexture of the rotator cuff tendon. Because of loss of normal interface with the overlying subacromial bursa, dynamic assessment may aid in identification and visualization of the supraspinatus tendon.[74] Bony irregularity at the site of anchor placement is expected, and echogenic suture material within the tendon may contribute to the heterogeneous appearance of the postoperative rotator cuff tendon (Fig. 24.20, Video 24.4). A gap within the tendon and nonvisualization of the tendon owing to retraction are the most reliable signs for a recurrent tear.[75,76] A thinned tendon or one with subtle contour abnormality is considered intact.

Muscle Atrophy

Ultrasound may also be used to assess for rotator cuff muscle atrophy, which may occur in the setting of a subacute or chronic rotator cuff tear. This is characterized by decreased muscle bulk and increased muscle echogenicity (related to increased fat interposed among muscle fibers[77] (Fig. 24.21). Ultrasound appearances also include lack of clarity of the muscle contour, and loss of visibility of the central tendon within the myotendinous

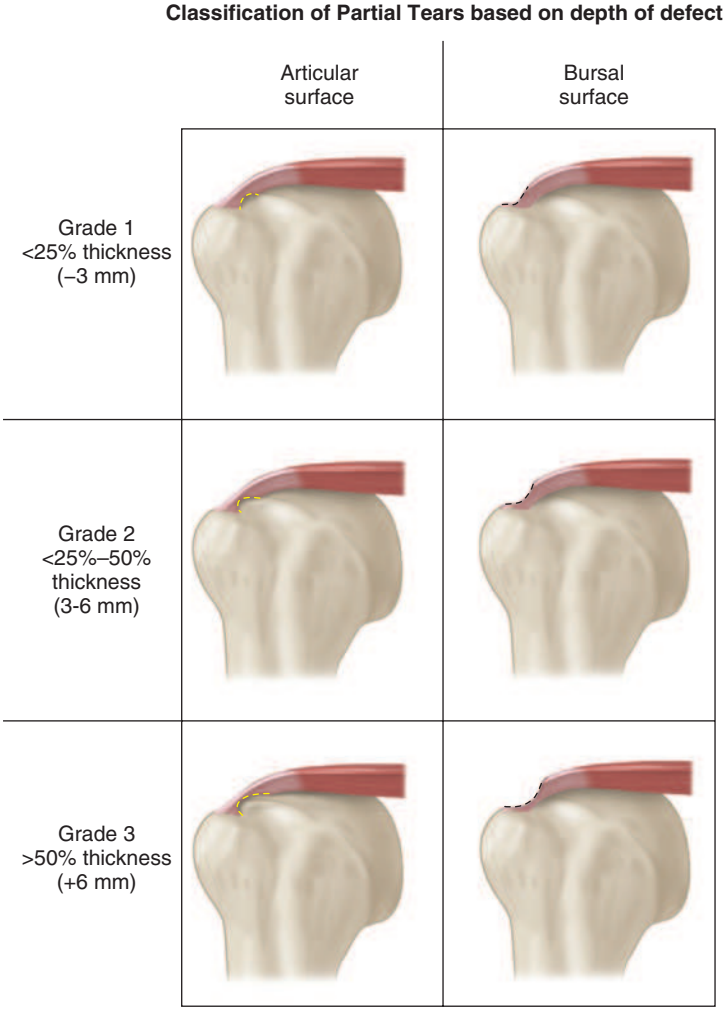

FIG. 24.18 Illustration of Partial Tear Subtypes.

junction.[78] Extended field-of-view imaging, whereby the rotator cuff muscles are imaged in short axis side by side, may assist in reducing interobserver variability in the ultrasound diagnosis of muscle atrophy, presumably by providing an internal control between muscles. Diagnosis of muscle atrophy is of importance in clinical management because the presence of muscle atrophy is considered a negative prognostic indicator with regard to the likelihood of successful surgical repair. It is worth remembering that atrophy may also occur because of denervation.

Muscle atrophy can be qualitatively graded from 0 to 4 as described by Goutallier and colleagues[79]: 0 = normal muscle, 1 = minimal fatty streaks, 2 = more muscle than fat, 3 = equal amounts of muscle and fat, 4 = more fat is present than muscle. This grading system was designed for MRI interpretation; therefore Strobel and colleagues described a modified grading system for ultrasound assessment of muscle atrophy whereby morphology and echogenicity are evaluated.[78] In this system, morphologic changes of atrophy are graded 0 to 2: grade 0 = normal, with clearly visible muscle contours, muscle fibers, and central tendon; grade 1 = only partially visible normal muscle features; grade 2 = normal structures no longer visible. Meanwhile, the echogenicity of muscle is graded in comparison with the deltoid from 0 to 2: grade 0 = isoechoic to deltoid; grade 1 = slightly hyperechoic to the deltoid muscle; grade 2 = markedly hyperechoic to deltoid muscle. Ultrasound grading of fatty atrophy has been shown to correlate well with MRI assessment.[31,80]

Subacromial-Subdeltoid Bursa

The subacromial-subdeltoid bursa is visualized superficial to the rotator cuff tendons, deep to the deltoid muscle and acromion.[39] At its inferolateral aspect, it extends beyond the lateral margin of the rotator cuff, lying superficial to the humeral shaft. This can be a helpful observation in distinguishing this structure from the superficial fibers of the rotator cuff. On ultrasound, the subacromial-subdeltoid bursa normally consists of a thin hypoechoic band measuring less than 2 mm where synovial fluid resides within the bursa, and a thin hyperechoic line superficial and deep to this, representing the wall of the bursa and peribursal fat (Fig. 24.22).

Abnormalities of the subacromial-subdeltoid bursa manifest with increased fluid within and distention of the bursa, and/or by bursal wall thickening (Fig. 24.23). Bursal abnormality detected

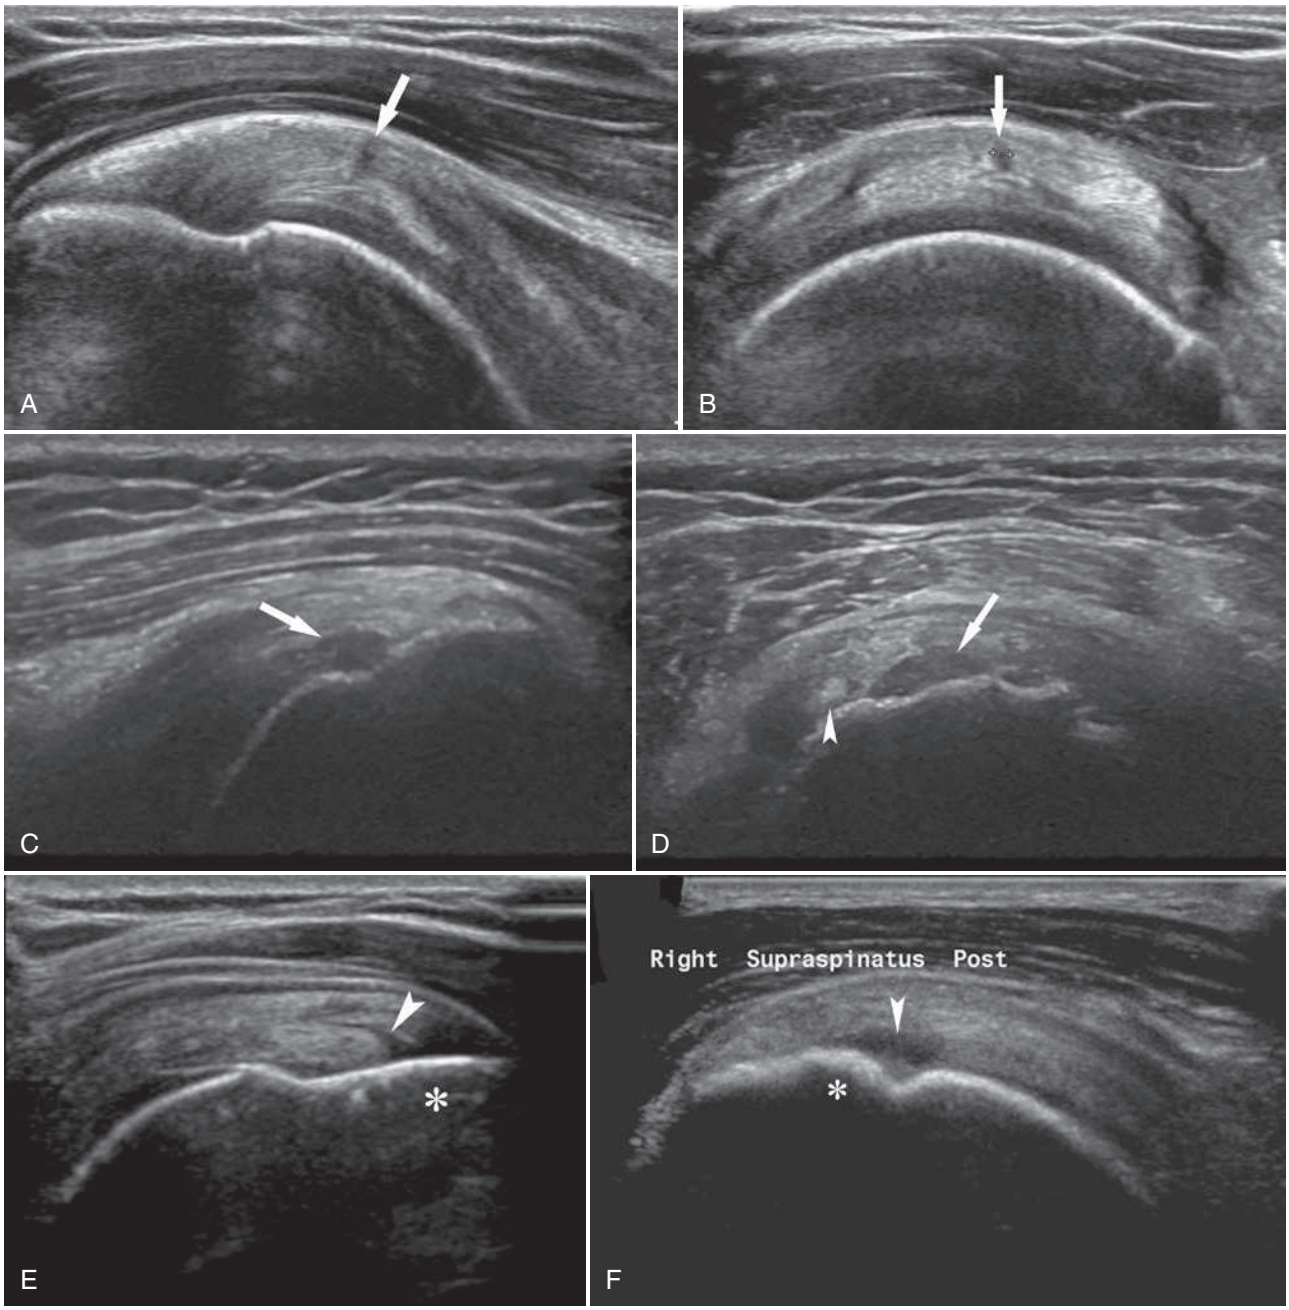

FIG. 24.19 Partial-Thickness Tears of the Rotator Cuff. (A) Bursal-sided tear—long-axis image. A focal hypoechoic area *(arrow)* is shown extending from the bursal surface of the supraspinatus tendon. **(B) Bursal-sided tear—**short-axis image. A focal hypoechoic area *(arrow)* is shown extending from the bursal surface of the supraspinatus tendon. **(C) Articular-sided tear—**a focal hypoechoic tear *(arrow)* is present along the articular side of the supraspinatus, shown here in long axis. **(D) Articular-sided tear—**a focal hypoechoic tear *(arrow)* is present along the articular side of the supraspinatus, seen here in short axis. Note the long head biceps tendon (LHBT) *(arrowhead)* anteriorly. **(E) Intrasubstance tear—**long-axis image of supraspinatus tendon demonstrates linear hypoechoic cleft *(arrowhead)* within the tendon, extending to the greater tuberosity (*) but not extending to either the bursal or articular surface of the tendon. **(F) Rim-rent tear—**long-axis image of the supraspinatus tendon demonstrates a hypoechoic tear *(arrowhead)* along the articular side of the tendon, at the insertional footplate on the greater tuberosity (*).

on ultrasound is highly associated with shoulder pain.[81] The most common cause for fluid distention of the bursa is an underlying rotator cuff tear, which may cause communication with the normally separate glenohumeral joint space. Uncommonly, fluid can also track through the adjacent acromioclavicular joint in this setting and into the soft tissues superficial to the acromioclavicular joint to form a **ganglion ("geyser sign")** (Fig. 24.24). In this case, patients will have a lump over the acromioclavicular joint, and they often do not relate it to background shoulder pain or immobility. Complete examination of the shoulder is indicated in such cases to evaluate for underlying communicating full-thickness rotator cuff tear. This is important

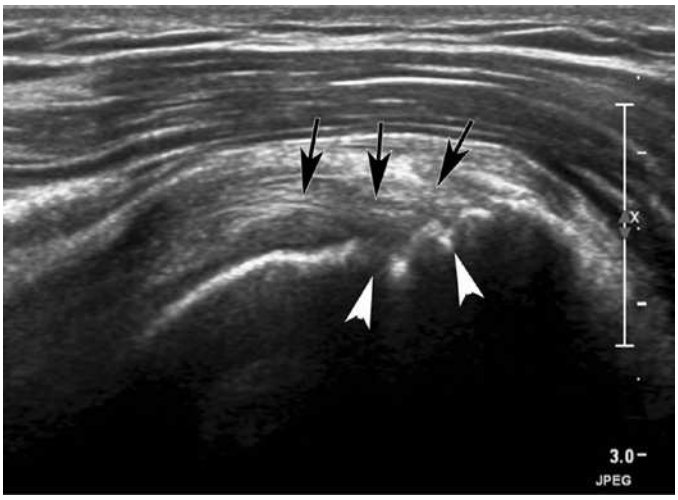

FIG. 24.20 Postoperative Supraspinatus Tendon. Long-axis image of supraspinatus shows a heterogeneous *(arrows)* but intact supraspinatus tendon, and irregularity of the greater tuberosity *(arrowheads)*. See also Video 24.4.

because the natural history of untreated asymptomatic rotator cuff tears is frequently the development of symptoms in addition to tear progression.[82]

Direct trauma to the shoulder can also cause thickening and distention of the subacromial-subdeltoid bursa, sometimes with more echogenic fluid representing blood. The bursa may be chronically irritated by friction related to subacromial impingement, and may worsen this clinical syndrome. Additional inflammatory causes of subacromial subdeltoid bursa thickening and distention include rheumatoid arthritis, polymyalgia rheumatica, and hydroxyapatite deposition **(calcific bursitis).** Infection of the bursa can also occur either through direct inoculation or via communication with underlying septic arthritis in the setting of concomitant full-thickness rotator cuff tear.

Calcific Tendinitis

Hydroxyapatite crystal deposition within rotator cuff tendons can be a cause of severe atraumatic pain. These deposits occur most frequently in the supraspinatus tendon, slightly more

FIG. 24.21 Fatty Atrophy of the Infraspinatus Muscle. Image obtained of the short axis of the infraspinatus tendon shows low-volume, hyperechoic infraspinatus muscle *(arrowheads),* compared with the normal echogenicity of the teres minor (*).

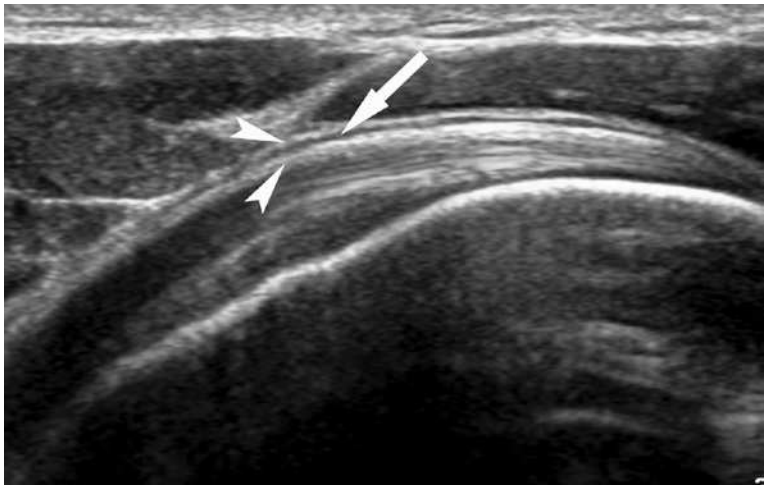

FIG. 24.22 Normal Subacromial-Subdeltoid Bursa. Overlying the infraspinatus tendon, in long axis, the subacromial subdeltoid bursa is visualized as a thin hypoechoic line *(arrow),* with thin hyperechoic borders superficial and deep to the bursa *(arrowheads).*

commonly than the infraspinatus tendon, and more uncommonly in the teres minor and subscapularis tendons.[83] Calcium deposits may undergo resorption, and it is during this resorptive phase that patients are most likely to be symptomatic. The hallmarks of this phase on ultrasound evaluation are fragmented, nodular or cystic echogenic deposits (Fig. 24.25), usually without shadowing, and there may be associated neovascularity on color Doppler assessment.[84] Associated bony osteolysis at the greater tuberosity may be present and denotes a more clinically severe syndrome, with more protracted pain and functional limitation.[85] More dense arclike echogenic calcific deposits with clear posterior acoustic shadowing are more likely to be asymptomatic or less symptomatic. Ultrasound-guided treatment with direct needling and barbotage leads to short- and long-term clinical improvement in this condition.[86,87]

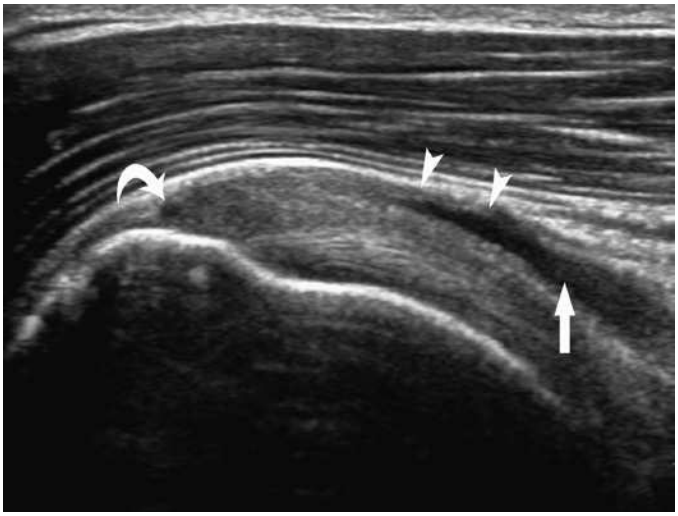

FIG. 24.23 Subacromial-Subdeltoid Bursal Thickening. Image shows increased fluid in the subacromial bursa *(straight arrow),* and thickening of the wall of the subacromial bursa *(arrowheads).* Note also a small bursal-sided tear of the supraspinatus at its insertion *(curved arrow).*

LONG HEAD BICEPS TENDON PATHOLOGY

The long head biceps tendon can be injured in the setting of concomitant rotator cuff tear, shoulder dislocation, or overhead sports. It has been noted by several authors that there is an association between pathologies of the long head biceps tendon and supraspinatus tendon, with coexistent injuries of these structures in 22% to 79% of cases of injury to either structure.[88]

The long head biceps tendon is partly intraarticular and is extrasynovial, with a tendon sheath at the intertubercular groove that communicates with the glenohumeral joint. Because of this, fluid in the tendon sheath may relate to intraarticular processes, particularly if associated with glenohumeral effusion. Inflammation of the tendon sheath **(tenosynovitis)** should be considered, however, if the tendon appears abnormal, if there is hyperemia on color Doppler imaging, if there is no sign of alternative

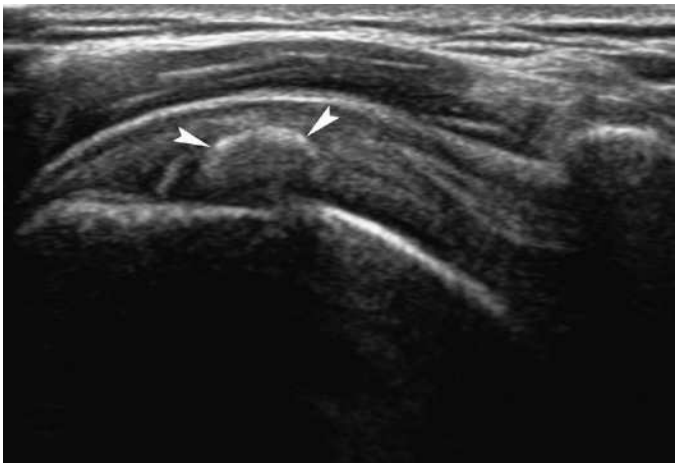

FIG. 24.25 Calcific Tendinitis of the Supraspinatus Tendon. Long-axis image of the supraspinatus image demonstrates a hyperechoic focus of calcification *(arrowheads)* within the supraspinatus tendon.

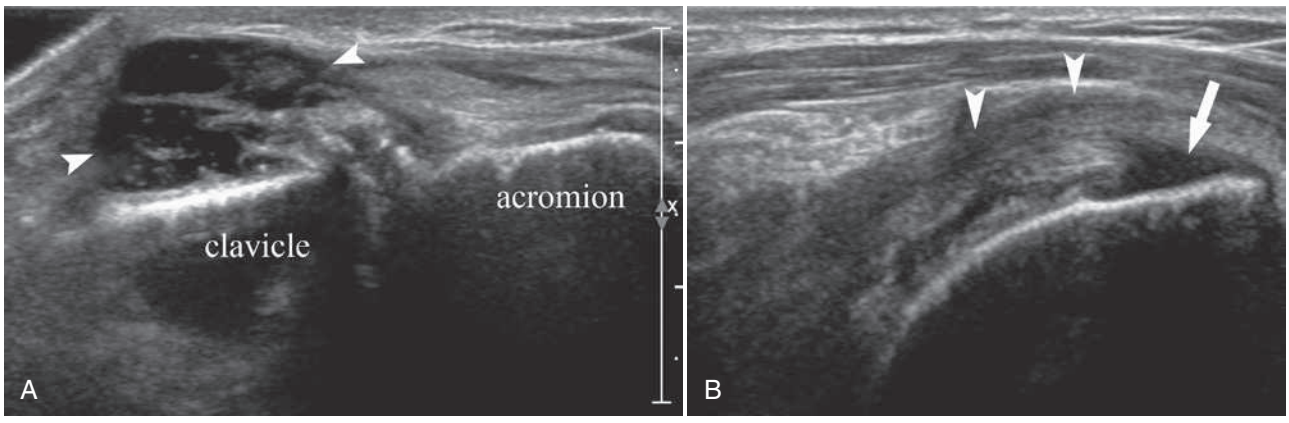

FIG. 24.24 Full-Thickness Supraspinatus Tendon Tear With Geyser Sign. (A) Image obtained at the acromioclavicular joint where the patient felt a mass. The mass corresponds with a heterogeneous hypoechoic lesion *(arrowheads)* with internal debris and septation compatible with a complex **ganglion. (B)** Long-axis image of the supraspinatus tendon in the same patient shows a full-thickness supraspinatus tendon tear *(arrow)* in addition to thickening of the subacromial bursa.

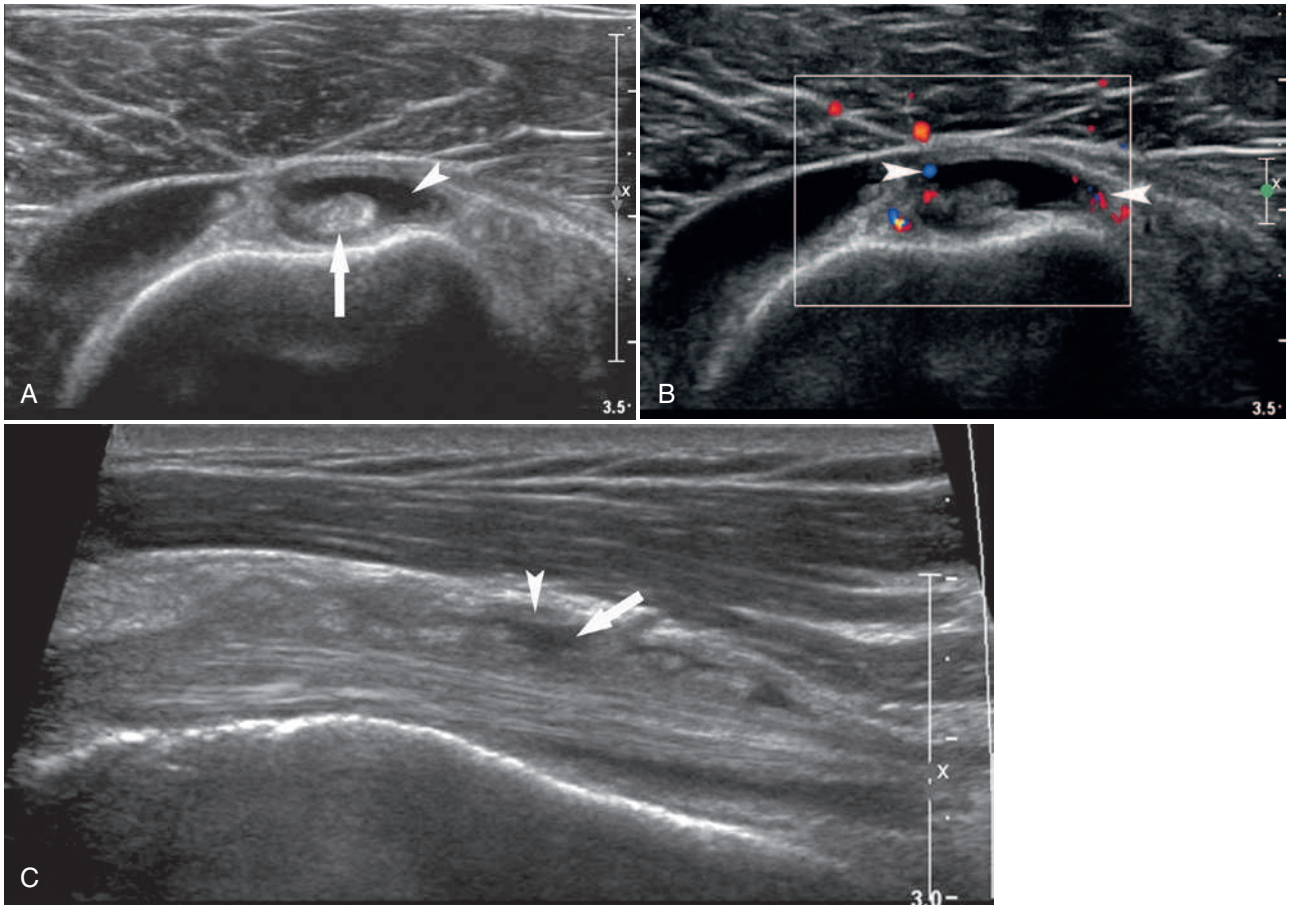

FIG. 24.26 Long Head of Biceps Tenosynovitis. (A) Short-axis image shows increased fluid within the long head biceps tendon sheath *(arrowhead),* surrounding the tendon *(arrow).* **(B)** Short-axis image shows hyperemia *(arrowheads)* in the long head of biceps tendon sheath. **(C)** In a different patient, long-axis image of the long head of biceps tendon shows thickening of the wall *(arrowhead)* of the tendon sheath and increased fluid *(arrow)* within the sheath.

glenohumeral pathology or effusion, or if there is localizing tenderness[89] (Fig. 24.26).

Long head biceps tendinosis is characterized by loss of normal tendon fibrillar pattern, abnormal hypoechogenicity, and often thickening.[90] Ultrasound is an accurate means for diagnosis of full-thickness biceps tendon tears, with more modest accuracy in the diagnosis of partial tears.[90,91] Partial-thickness tears are characterized by anechoic clefts within the tendon, without complete discontinuity. These tears are often longitudinally orientated, paralleling the tendon long axis, and may result in splitting the tendon into two distinct parallel components, termed a **longitudinal split tear** (Fig. 24.27). Long head biceps complete tears typically occur close to the tendon origin and may manifest with acute onset of contour deformity of the biceps muscle. The tendon will usually retract distally, often distal to the insertion of the pectoralis major, which usually inserts on the humerus just anterior to the long head biceps tendon course in the upper arm. A complete tear with retraction is typically diagnosed by nonvisualization of the tendon within the intertubercular groove,[45] but care should be taken to assess for medial dislocation of the tendon as an alternative cause if the tendon is not seen within the bicipital groove. The biceps tendon is normally stabilized within the tendon groove by the thin transverse ligament. Medially, displacement is resisted by the subscapularis tendon. If the subscapularis tendon is torn at its insertion, this may allow medial displacement of the biceps tendon, deep to the subscapularis tendon.[92] Alternatively, if the transverse ligament is torn, this may permit medial **dislocation of the biceps tendon,** which then lies superficial to the otherwise intact subscapularis tendon.

ARTHROPATHY

Degenerative

Osteoarthritis is common and characterized by the formation of marginal bone spurs—osteophytes—at the margin of articular surface. This is particularly common at the acromioclavicular joint (Fig. 24.28). There may be small associated joint effusions, and echogenic intraarticular bodies, which may be calcified, can be observed.

Inflammatory

The shoulder can be involved in **inflammatory arthropathies, including rheumatoid arthritis** and **ankylosing spondylitis.**[93,94] The shoulder involvement in rheumatoid arthritis occurs later than peripheral arthritis. Patients with inflammatory arthropathy

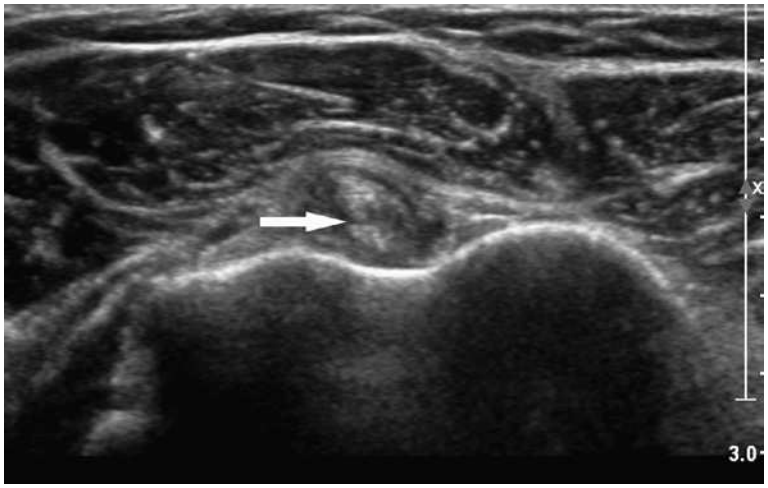

FIG. 24.27 Longitudinal Split Tear of the Long Head of Biceps Tendon. Short-axis image demonstrates a hypoechoic cleft *(arrow)* through the long head of biceps tendon, dividing it into two components.

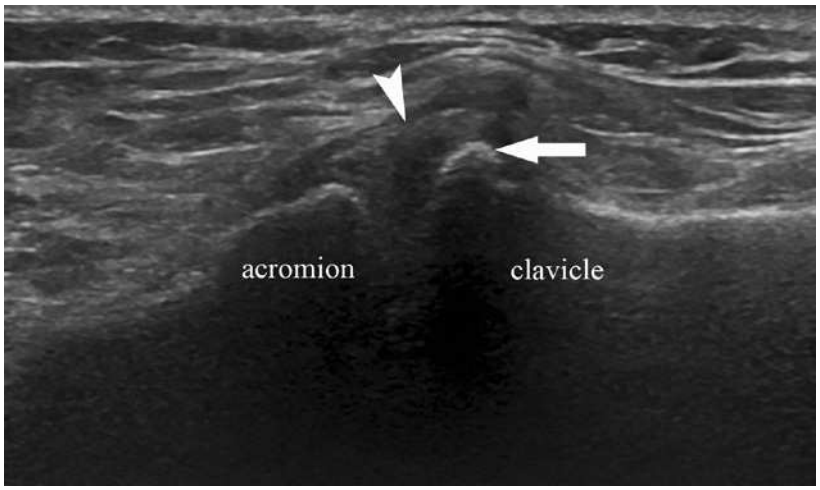

FIG. 24.28 Acromioclavicular Joint Osteoarthritis. Image of the acromioclavicular joint demonstrates osteophyte formation at the distal clavicle *(arrow)* and capsular thickening and hypertrophy *(arrowhead)*.

may have **glenohumeral effusion.** This is best assessed posteriorly, and a thickness of 3 mm or more from the humeral head to the capsule may represent effusion and/or synovial thickening[95] (Fig. 24.29). Ultrasound is particularly sensitive to detection of fluid in the posterior glenohumeral recess when patients are scanned with the arm in external rotation[52] (see Video 24.4). Use of color Doppler, particularly power Doppler,[96] is helpful to elucidate synovial hyperemia and can help separate thickened synovium from complex intraarticular fluid. Bone erosions may also be present, characterized by bony cortical surface rounded or steplike deformations, often at the humeral head margins.[97,98] Ultrasound may be used as a complementary technique to radiographs in assessment for erosions, because it may detect radiographically occult erosions,[94] although overall, MRI has greater sensitivity and can be used for problem solving.[99] In ankylosing spondylitis, acromioclavicular synovitis is common. Patients with inflammatory arthritis may also be affected by subacromial-subdeltoid bursitis, in addition to rotator cuff and biceps tendon tears.

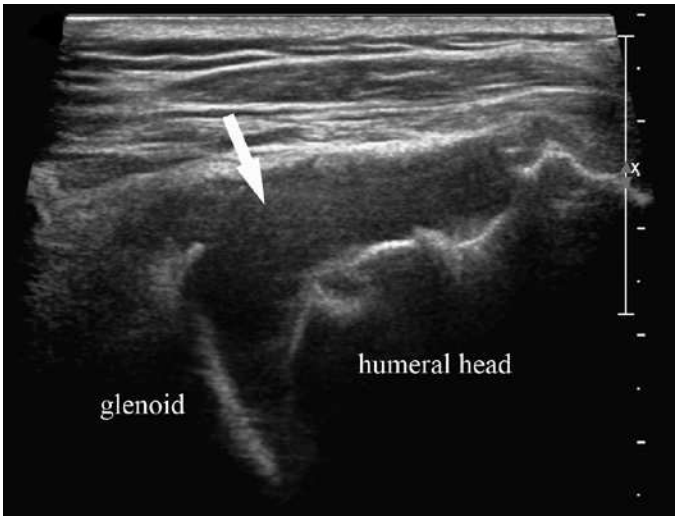

FIG. 24.29 Glenohumeral Joint Effusion. Image of the posterior shoulder shows increased fluid within the joint *(arrow)* in this patient with osteoarthritis.

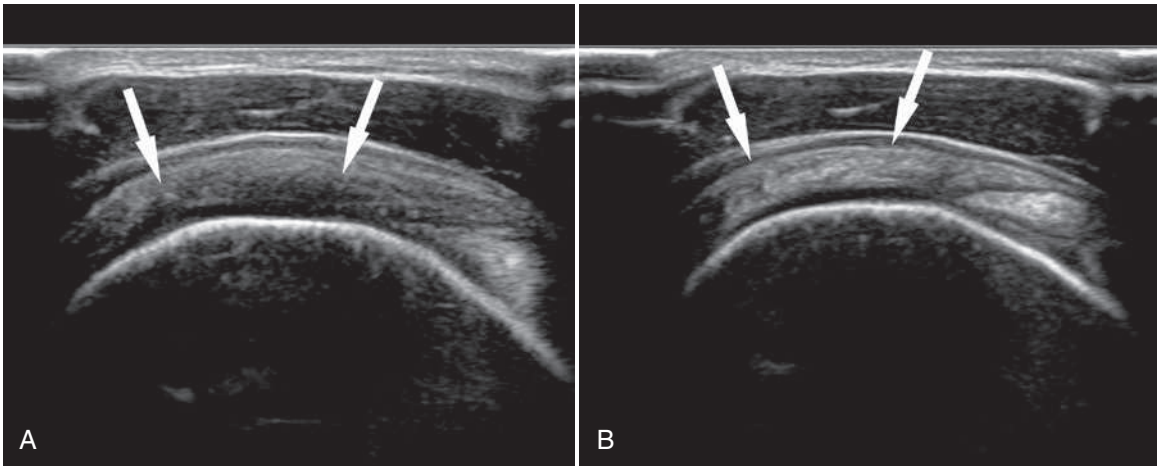

FIG. 24.30 Short-Axis Images of the Supraspinatus Tendon. (A) Artifactual hypoechogenicity of the supraspinatus tendon *(arrows)* may simulate tendinosis or tear. **(B)** Correction of angle of insonation to be perpendicular to the tendon permits visualization of the normal intact supraspinatus tendon *(arrows)*.

PITFALLS IN SHOULDER ULTRASOUND

Anisotropy is a common problem in diagnostic shoulder ultrasound, but thankfully one that can be easily rectified. It consists of artifactual hypoechogenicity within a tendon caused by scanning with the probe in a suboptimal angle with respect to the tendon. As a highly organized linear structure, a tendon reflects ultrasound waves, effectively giving a normal echogenic appearance when the angle of insonation is close to 90 degrees. However, deviation from this angle can result in reflection of sound waves away from the transducer, leading to apparent hypoechogenicity, which can be erroneously interpreted as tendinosis or tearing.[37] This can be corrected by attention to the angle of insonation of the tendon in question and by attempting to visualize any pathologic finding in more than one plane (Fig. 24.30, Video 24.5).

There are several additional scanning pitfalls frequently encountered by the inexperienced sonographer. Tears of the anterior-most fibers of the supraspinatus are easily missed if scanning does not extend anteriorly enough. One way to solve this problem is to use the anatomic landmark of the long head bicipital tendon as the starting point for scanning the supraspinatus tendon, both in short and long axis.

In the hands of novice operators, chronic full-thickness rotator cuff tears with echogenic granulation tissue may be confused for intact, abnormal tendon. Careful evaluation with dynamic compression, and differentiation of bursal tissue from rotator cuff tissue should be performed. In addition, inexperienced operators may mistake the junction of the posterior supraspinatus and anterior infraspinatus, where the tendon fibers overlap, as pathology. Careful angling of the probe with respect to the long axis of the fibers, and direct correlation to short-axis images should ameliorate this misperception.

If the long head biceps tendon is not seen in the bicipital groove, one should not automatically assume that the tendon is torn. It is important to ensure that the transducer is perpendicular to the tendon, as otherwise the tendon may appear artifactually hypoechoic owing to anisotropy. The transducer should then be moved medially to visualize the coracoid process, to look for a medially dislocated tendon. Lastly, one should scan distally to the pectoralis junction to see if the tendon has torn and retracted distally.

Soft tissue distortion by bony abnormality can cause confusion during imaging and can be rectified by referring to a concurrent radiograph.[100] This is particularly the case in the setting of recent trauma wherein an underlying fracture can cause considerable distortion, especially if the greater tuberosity is involved.

As is the case for learning any skill, there is a learning curve involved when performing diagnostic shoulder ultrasound. Accuracy is lower when operators are unfamiliar with the technique, but the learning curve plateaus between 50 and 100 cases,[101] which should be considered when undertaking this examination for the first time and when training and mentoring other sonographers.

CONCLUSION

In conclusion, ultrasound is an accurate and cost-effective technique for diagnosing soft tissue pathology at the shoulder and is well tolerated by patients. Ultrasound confers many advantages over MRI in the evaluation of the rotator cuff. Adequate experience in this technique is important, in addition to correlation with other imaging modalities when available.

CHAPTER 25

Musculoskeletal Interventions

Ronald S. Adler

SUMMARY OF KEY POINTS

- Choose transducer geometry and entry site to visualize the needle as a specular reflector.
- Orient transducer to maximize tendon echogenicity (anisotropy).
- Injected corticosteroid/anesthetic suspension often displays a contrast effect, which can help localize injected mixture.
- Patients with diabetes should be cautioned that they may develop a transient hyperglycemia that may last up to 5 days following therapeutic injection.
- Most small joints and superficial tendon sheaths of hand and foot can be injected using a short-axis approach.
- Shoulder and hip joints can be injected using long-axis approach.
- Ganglion and paralabral cyst fluid can be very viscous or gelatinous and may require a large-bore needle.
- Choose needle trajectory to avoid neurovascular structures.
- Intratendinous injections of platelet-rich plasma (PRP) should be performed in combination with intratendinous fenestration to promote bleeding and initiate an inflammatory response. The patient should avoid nonsteroidal antiinflammatory drugs (NSAIDs) for 1 week before and 2 weeks after the procedure.
- Use of coaxial technique can be of value in performing ablative therapy and core biopsies to minimize extralesional soft tissue damage.

CHAPTER OUTLINE

TECHNICAL CONSIDERATIONS
INJECTION TECHNIQUE
INJECTION MATERIALS
INJECTION OF JOINTS
SUPERFICIAL PERITENDINOUS AND PERIARTICULAR INJECTIONS
Foot and Ankle
Hand and Wrist
INJECTION OF DEEP TENDONS
Biceps Tendon
Iliopsoas Tendon
Abductor and Hamstring Tendons
BURSAL, GANGLION CYST, AND PARALABRAL INJECTIONS
Calcific Tendinitis
INTRATENDINOUS INJECTIONS: PERCUTANEOUS TENOTOMY
PERINEURAL INJECTIONS
CONCLUSION

The real-time nature of ultrasound makes it ideally suited to provide guidance for a variety of musculoskeletal interventional procedures.[1-10] Continuous observation of needle position ensures proper placement and allows continuous monitoring of the distribution of injected and aspirated material. The adverse effects of improper needle placement during corticosteroid administration are well documented.[11-16] Likewise, decompression of fluid-filled lesions and fragmentation of calcific deposits may be performed.

The current generation of high-frequency transducers for sonography of small parts allows excellent depiction of soft tissue detail and articular surfaces, particularly in the hand, wrist, foot, and ankle.[17] This allows needle placement in nonfluid-distended structures, such as a nondistended joint, tendon sheath, or bursa. The injected agent also produces a **contrast** effect, which can improve delineation of surrounding structures (e.g., labral morphology) and provide additional information regarding the agent's distribution.[18,19] Ultrasound guidance has broad appeal because it does not involve ionizing radiation; this feature is particularly advantageous in the pediatric population and during pregnancy.

Ultrasound-guided injections in the musculoskeletal system include injection of joints, tendon sheaths, bursae, and ganglion cysts. The chapter emphasizes the most common injections performed at my institution, an orthopedic and rheumatology specialty hospital. The most common clinical indication for ultrasound-guided injections generally relates to pain that does not respond to other conservative measures, regardless of the anatomic site. The pain may result from a chronic repetitive injury in the work environment, a sports-related injury, or an underlying inflammatory disorder, such as rheumatoid arthritis.

TECHNICAL CONSIDERATIONS

Diagnostic and subsequent interventional examinations are often performed using either linear or curved, phased array transducers,

based on depth and local geometry. Needle selection is based on specific anatomic conditions (i.e., depth and size of region of interest). We use a freehand technique in which the basic principle is to ensure needle visualization as a specular reflector.[7] This relies on orienting the needle so that it is perpendicular (or nearly so) to the insonating beam (Fig. 25.1). The needle then becomes a specular reflector, often having a strong ring-down artifact. Although needle guides are available and may be of value, a freehand technique allows greater flexibility in adjusting needle position during a procedure. Furthermore, needle visualization can be enhanced by injecting a small amount of anesthetic and observing the corresponding moving echoes in either gray-scale or color flow sonographic imaging.[1]

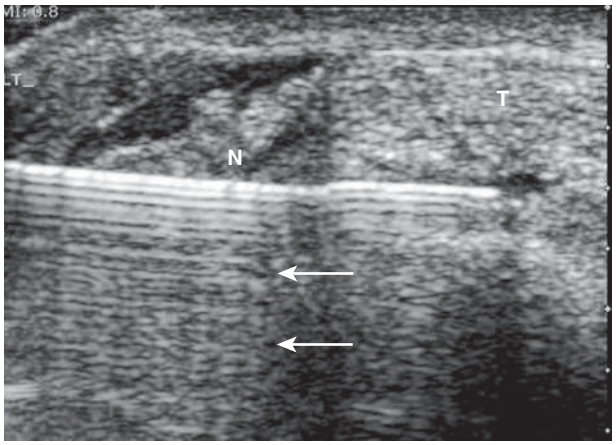

FIG. 25.1 Needle as Specular Reflector With Reverberation Artifact. A 25-gauge needle *(N)* has been positioned into the retrocalcaneal bursa deep to the Achilles tendon *(T)*. Note that the needle is a specular reflector with a characteristic reverberation artifact *(arrows)*.

Patient positioning should be assessed first to ensure comfort and optimal visualization of the anatomy. It is important to keep in mind that tendons display inherent **anisotropy;** they will look hypoechoic if the transducer footprint is not parallel to the tendon.[17] Therefore the transducer must be oriented to maximize tendon echogenicity to avoid false interpretation of the tendon as being complex fluid or synovium. An offset may be required at the skin entry point of the needle relative to the transducer to allow for the appropriate needle orientation. Deep structures, such as tendons about the hip, are often better imaged using a curved linear or sector transducer, operating at center frequencies of about 3.5 to 7.5 MHz. Superficial, linearly oriented structures, such as in the wrist or ankle, are best approached using a linear array transducer with higher center frequencies (>10 MHz). Transducers with a small footprint ("hockey stick") are particularly well suited to superficial injections. These factors should be assessed before skin preparation.

The immiscible nature of the steroid anesthetic mixture may likewise produce temporary contrast effect (Fig. 25.2, Video 25.1). *In vitro* experiments suggest that this property is caused by alterations in acoustic impedance by the scattering material, formed by the suspension of steroid in an aqueous background; this results in an increase in echo intensity of about 20 dB.[19] This contrast effect has the advantage of increasing the conspicuity of the delivered agent during real time, enabling the operator to better define the distribution of delivered agent during ultrasound-guided therapy.

INJECTION TECHNIQUE

We use a sterile technique; the area in question is cleaned with iodine-based solution and draped with a sterile drape. The transducer is cleaned with iodine-based or alcohol-based solutions

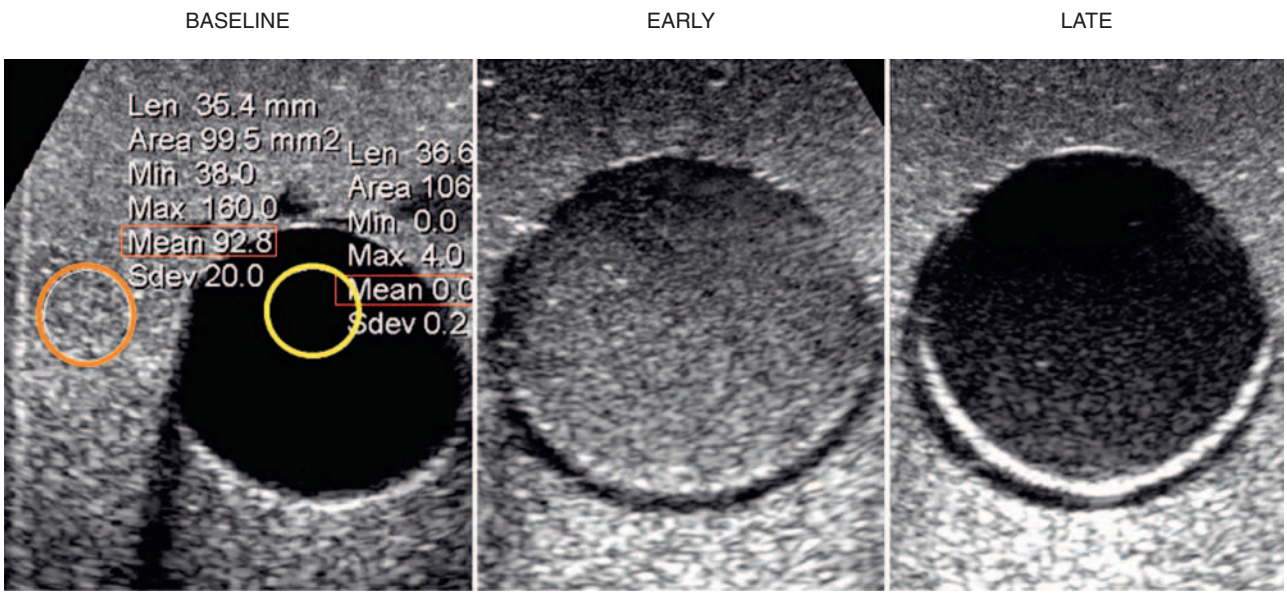

FIG. 25.2 Contrast Effect. A suspension of anesthetic and triamcinolone has been injected into a cyst phantom. *Baseline:* Before injection, anechoic "cyst" is shown in a scattering medium, with baseline pixel intensities listed. *Early:* The early mixing phase is obtained immediately after injection. A contrast effect is evident, in which the cyst becomes almost isoechoic to the background. *Late:* 20 minutes after injection. In the late phase, apparent gravitational effect results in settling of the suspension toward the dependent portions of the cyst phantom and development of a contrast gradient.

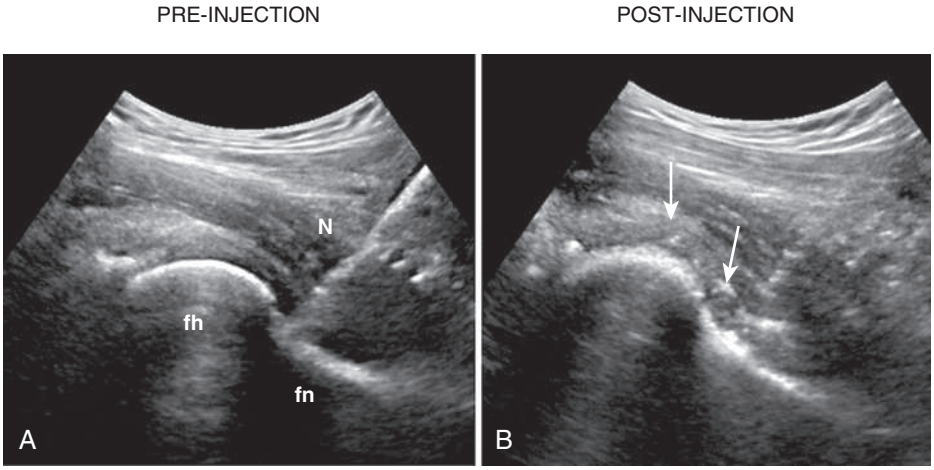

FIG. 25.3 Long-Axis Approach: Injection of Left Hip. The long-axis approach is suitable for deep joint injections, such as the hip or shoulder. **(A)** Before injection, 22-gauge spinal needle *(N)* has been positioned at the femoral head-neck junction in a 50-year-old woman with a labral tear demonstrated on magnetic resonance imaging *(not shown),* to assess relief after therapeutic injection. **(B)** After injection, confirmation of intraarticular deposition of injected material is obtained by the presence of microbubbles *(arrows)* deep to the joint capsule. *fh,* Femoral head; *fn,* femoral neck. See also Video 25.1.

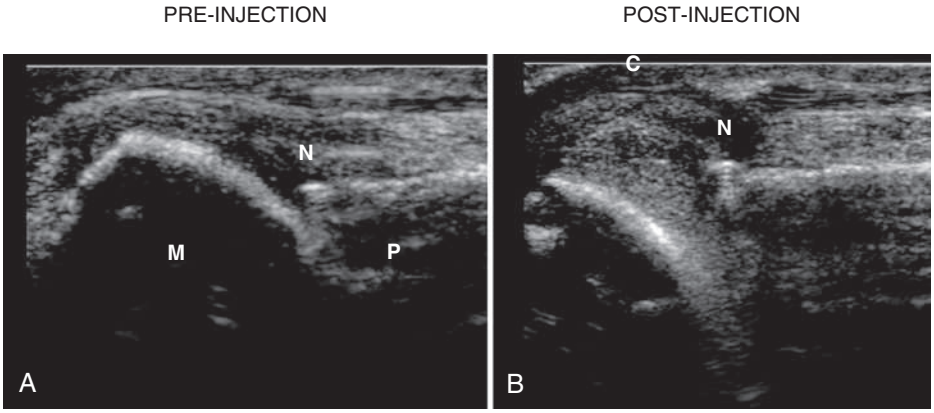

FIG. 25.4 Short-Axis Approach for Injection of First Metatarsophalangeal (MTP) Joint. (A) Long-axis view shows 25-gauge needle positioned in MTP joint of 53-year-old woman with plantar plate injury; needle *(N)* is seen in cross section. *M,* Metatarsal head; *P,* proximal phalanx. **(B)** While monitoring the injection in real time, the joint capsule distends and fills with echogenic material. *C,* Capsule.

and surrounded by a sterile drape. A drape is also placed over portions of the ultrasound unit. A sonographer or radiologist positions the transducer; a radiologist positions the needle and performs the procedure. We use 1% lidocaine and bupivacaine (0.25%-0.75%) for local anesthesia. Once the needle is in position, the procedure is undertaken while imaging in real time. Depending on anatomic location, a 1.5-inch or spinal needle with stylet is used to administer the anesthetic-corticosteroid mixture, generally consisting of local long-acting anesthetic and one of the standard injectable corticosteroid derivatives (e.g., triamcinolone).

Two approaches to performing injections are long axis and short axis, which relate needle orientation to the structure being injected.[9] The **long-axis approach** refers to needle placement in the plane parallel to the structure of interest (Fig. 25.3). For example, longitudinal imaging of the hip to display a hip effusion might be used as the plane to direct the needle for ultrasound-guided aspiration. Alternatively, the **short-axis approach** refers to needle entry in the plane perpendicular to the long axis of a structure (Fig. 25.4). For example, injection of the retrocalcaneal bursa or metatarsophalangeal (MTP) joint might use a lateral approach. In my experience, the short-axis approach works well when performing injections or aspirations in small joints and tendon sheaths of the hand and foot. The long-axis approach appears better suited for deep joint injections, such as in the hip or shoulder. It is important to recognize, however, that such approaches serve merely as guidelines and that no single method necessarily applies to any specific injection.

INJECTION MATERIALS

Most injections involve use of a long-acting corticosteroid in combination with a local anesthetic in relatively small volumes. **Injectable steroids** usually come in either a **crystalline** form, associated with a slower rate of absorption, or a **soluble** form, characterized by rapid absorption.[20-22] Crystalline agents include triamcinolone and methylprednisolone acetate (Depo-Medrol). A common soluble agent is Celestone, which includes a rapidly absorbed betamethasone salt. A reactive inflammatory response or flushing response may occur with crystalline steroids, but typically not with soluble agents.[13]

The most significant complications associated with injectable steroid use in the musculoskeletal system relate to **chondrolysis** (when used in weight-bearing joints), **depigmentation, fat necrosis,** and **impaired healing response** (when used in soft tissues).[11-14] Impaired healing has been associated with tendon, ligament, and plantar fascia rupture. The most frequently used mixtures contain insoluble particles, so a systemic injection could theoretically result in an "embolic phenomenon," which has been implicated as a mechanism for neurologic complications associated with transforaminal epidural injections. We have not encountered this as a complication when performing injections in the appendicular skeletal system.

The most common **anesthetics** are lidocaine (Xylocaine) and bupivacaine (Marcaine).[22,23] Both are characterized as "local injectable anesthetics" but differ in the onset of effect and duration. Lidocaine is characterized by early onset (seconds) and short duration (1-2 hours). Bupivacaine becomes effective in 5 to 10 minutes, and its effects generally last 4 to 6 hours. In addition to allergic reactions, potential adverse effects include neurotoxicity and cardiotoxicity; these are generally rare when small doses are used under image guidance, taking care to avoid an intravascular injection. Bupivacaine has also been associated with chondrolysis when used for intraarticular applications, but only with constant infusions during arthroscopy and *in vitro*.[24] Chondrolysis is probably not an issue with the small, fixed volumes of bupivacaine typically used during injections in the musculoskeletal system.

INJECTION OF JOINTS

A high-frequency linear transducer is used for hand, wrist, elbow, foot, and ankle injections. A short-axis approach is often technically easier for small joint injections. The needle should enter the skin parallel to the plane of the joint space. Superficial joints usually appear as separations between the normally continuous specular echoes produced by cortical surfaces. As in other fluid-containing structures, the presence of an effusion is a helpful feature in visualizing the needle as it enters the joint, because it provides a fluid standoff.

The short-axis approach entails scanning across the joint and looking for the transition from one cortical surface to the next, marking the skin (with a surgical marker), and then placing a needle into the joint using ultrasound guidance. When imaging the joint in long axis, the needle will be seen in cross section (Fig. 25.5). Needle placement is confirmed by injecting a small amount of 1% lidocaine, which should display distention of the joint, as well as echoes filling the joint. Small joint injections generally require 0.5 to 1 mL of the therapeutic mixture. In my experience, this approach works well in the **metatarsophalangeal** (MTP) or **metacarpophalangeal** (MCP) and **interphalangeal** (IP) joints, midfoot, ankle, and elbow. Occasionally a long-axis approach may be efficacious, as in the radiocarpal joint or lateral gutter of the ankle. Ultrasound guidance allows the clinician to negotiate osteophytes and joint bodies. It allows identification of capsular outpouching, thereby affording a more convenient, indirect approach into a joint than slipping a needle into a small joint space.

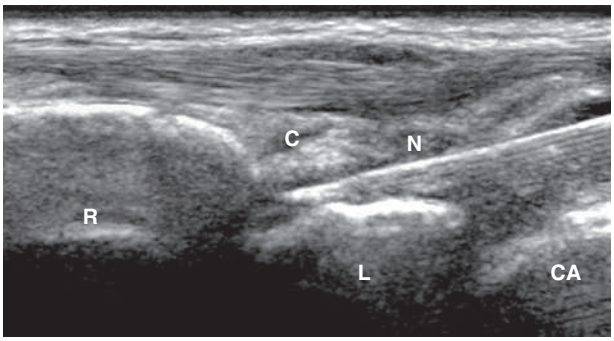

FIG. 25.5 Long-Axis Approach for Therapeutic Radiocarpal Joint Injection. A 25-gauge needle *(N)* has been positioned deep to the dorsal capsule *(C)* and above the lunate bone *(L)* of a 19-year-old female patient with chronic wrist pain, to assess relief. *CA,* Capitate; *R,* radius.

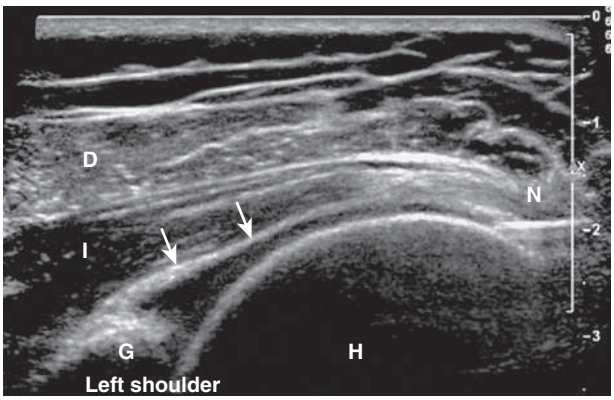

FIG. 25.6 Long-Axis Approach for Glenohumeral Joint Injection. A 22-gauge needle *(N)* has been positioned deep to the posterior capsule *(arrows)* during a glenohumeral joint injection in 42-year-old woman with adhesive capsulitis. Mild fluid distention of the posterior recess of the joint is evident. *D,* Deltoid muscle; *G,* glenoid; *H,* humeral head; *I,* infraspinatus muscle.

A long-axis approach and a spinal needle are used when performing injections of large joints such as the hip or shoulder (Fig. 25.6). A greater volume is usually injected, typically 5 mL of the steroid-anesthetic mixture. In the case of adhesive capsulitis, significantly larger volumes of local anesthetic (5-10 mL) may be added to provide additional joint distention. We generally approach the glenohumeral joint using a posterior approach, with the patient in a decubitus position and the arm placed in cross-adduction. An intermediate-frequency, linear or curvilinear transducer will suffice in most cases. A linear transducer often results in better anatomic detail than curved arrays. The interface of the glenohumeral joint is usually seen with the patient in the decubitus position, as well as the hypoechoic articular cartilage overlying the humeral head. We perform this injection using a long-axis approach, with the needle directed toward the joint along the articular cartilage and deep to the posterior capsule. A test injection with 1% lidocaine should show bright echoes filling the posterior recess or distributed along the articular cartilage.

The hip is approached similarly in long axis, with the transducer placed over the proximal anterior thigh at the level of the joint[25] (see Fig. 25.3, Video 25.1). The approach is similar to that

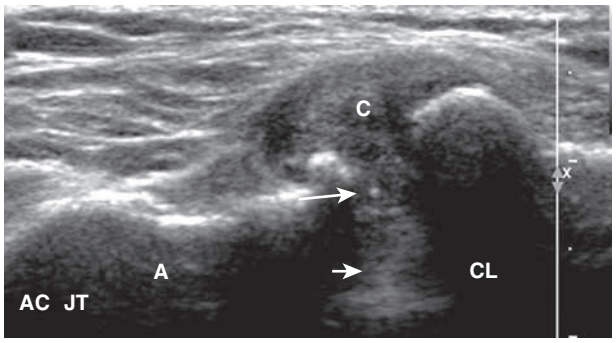

FIG. 25.7 Short-Axis Approach to Injection of Acromioclavicular (AC) Joint. A 25-gauge needle *(long thin arrow)* is seen in cross section in a distended hypertrophic AC joint during therapeutic injection in 73-year-old woman with pain centered over AC joint. The joint appears widened, containing echogenic material caused by the contrast effect *(short thick arrow)* of the therapeutic agent. *A,* Acromion; *C,* distended capsule; *CL,* clavicle.

used in evaluating the joint for an effusion. Ideally, the anterior capsule is imaged at the head-neck junction of the femur. In this approach the scan plane is lateral to the neurovascular bundle. The needle may be directed into the joint while maintaining its position in the scan plane of the transducer. A test injection of 1% lidocaine confirms the intraarticular needle position, and the therapeutic injection follows.

Fibrous joints, such as the **acromioclavicular** (AC) joint, can likewise be injected using ultrasound guidance (Fig. 25.7). A short-axis technique is employed similar to that used in the foot. The majority of these injections can be performed using a 1.5-inch needle with a small volume (0.5-1.0 mL) of therapeutic mixture. In addition to the AC joint, this approach is useful in the sternoclavicular joint and pubic symphysis.

SUPERFICIAL PERITENDINOUS AND PERIARTICULAR INJECTIONS

Peritendinous injection of anesthetic and long-acting corticosteroid is an effective means to treat tenosynovitis, bursitis, and ganglion cysts in the hand, foot, and ankle. These structures are superficially located and well delineated on sonography. Ultrasound-guided injections are an effective means to ensure correct localization of therapeutic agents.

Foot and Ankle

In my experience, peritendinous injections in the foot and ankle are most often requested for patients with chronic **achillodynia** or those with medial or lateral ankle pain caused by posterior tibial or peroneal **tendinosis** or **tenosynovitis.** Less often, patients are referred to help differentiate pain from posterior impingement and stenosing tenosynovitis of the flexor hallucis longus (FHL) tendon.[26] This distinction can be difficult, sometimes requiring diagnostic and therapeutic injection of the corresponding tendon sheath. Patients with plantar foot pain caused by **plantar fasciitis** and forefoot pain resulting from painful neuromas are also frequently referred for ultrasound-guided injections.[27,28]

The large majority of patients with achillodynia have pain referable to the enthesis, with associated retrocalcaneal bursitis and Achilles tendinosis. **Enthesis** is the site of attachment of a muscle or ligament to bone where the collagen fibers are mineralized and integrated into bone. A **retrocalcaneal bursal injection** may help alleviate local pain and inflammation (Fig. 25.8). I scan the patient in a prone position with the ankle in mild dorsiflexion, using a linear transducer of 10 MHz or higher frequency. A 1.5-inch needle usually suffices in these patients, with placement using a short-axis approach. The deep retrocalcaneal bursa is usually well seen. A small amount of anesthetic will help confirm position by active distention of the bursa in real time.

We similarly approach posterior **tibial** or **peroneal** tendons in short axis (Fig. 25.9). Patients with pain in this distribution have been shown to benefit from local tendon sheath injections. The presence of preexisting tendon sheath fluid can facilitate needle visualization. However, careful scanning should be done before the procedure to assess the needle trajectory relative to adjacent neurovascular structures. Use of color or power Doppler imaging can facilitate visualization of the neurovascular bundle. The posterior tibial nerve is closely related to adjacent vascular structures and is usually well seen before bifurcating into medial and lateral plantar branches. Fluid frequently is seen in relation to the posterior tibial tendon, in the submalleolar region. The location of the peroneal tendon is less predictable. Use of power Doppler sonography in conjunction with real-time guidance can help localize areas of inflammation for guided injection. In **stenosing tenosynovitis** the tendons may be surrounded only by a thickened retinaculum, proliferative synovium, or scar tissue. In this case, use of a test injection of local anesthesia can be invaluable to confirm the distribution of the therapeutic agent within the tendon sheath in real time.

The **flexor hallucis longus** (FHL) tendon poses a more challenging problem because of its close relation to the neurovascular bundle of the posterior medial ankle. One helpful feature in performing FHL tendon sheath injections is that tendon sheath effusions tend to localize at the posterior recess of the tibiotalar joint. The neurovascular bundle is easily circumvented by placing the needle lateral to the Achilles tendon while scanning medially (Fig. 25.10). This approach allows flexibility in needle placement while maintaining the needle perpendicular to the insonating beam.

Ultrasound diagnosis of **plantar fasciitis** includes thickening of the medial band of the plantar fascia and fat pad edema. One treatment option for severe plantar fasciitis is regional corticosteroid injection, typically performed using anatomic landmarks. However, "blind" injections into the heel have been associated with rupture of the plantar fascia and failure of the longitudinal arch.[13] Ultrasound can be used to guide a needle along the plantar margin of the fascia, thus avoiding direct intrafascial injection.[26] The plantar fascia is imaged with the patient prone and the foot mildly dorsiflexed, using a long-axis approach. The transducer is centered over the medial band, which is most often implicated in these patients. A mark is placed over the posterior aspect of the heel and the needle advanced superficial to the plantar fascia, approximately to the margin of the medial tubercle (Fig. 25.11). I perform a perifascial injection using this approach, monitoring the distribution of injected material in real time.

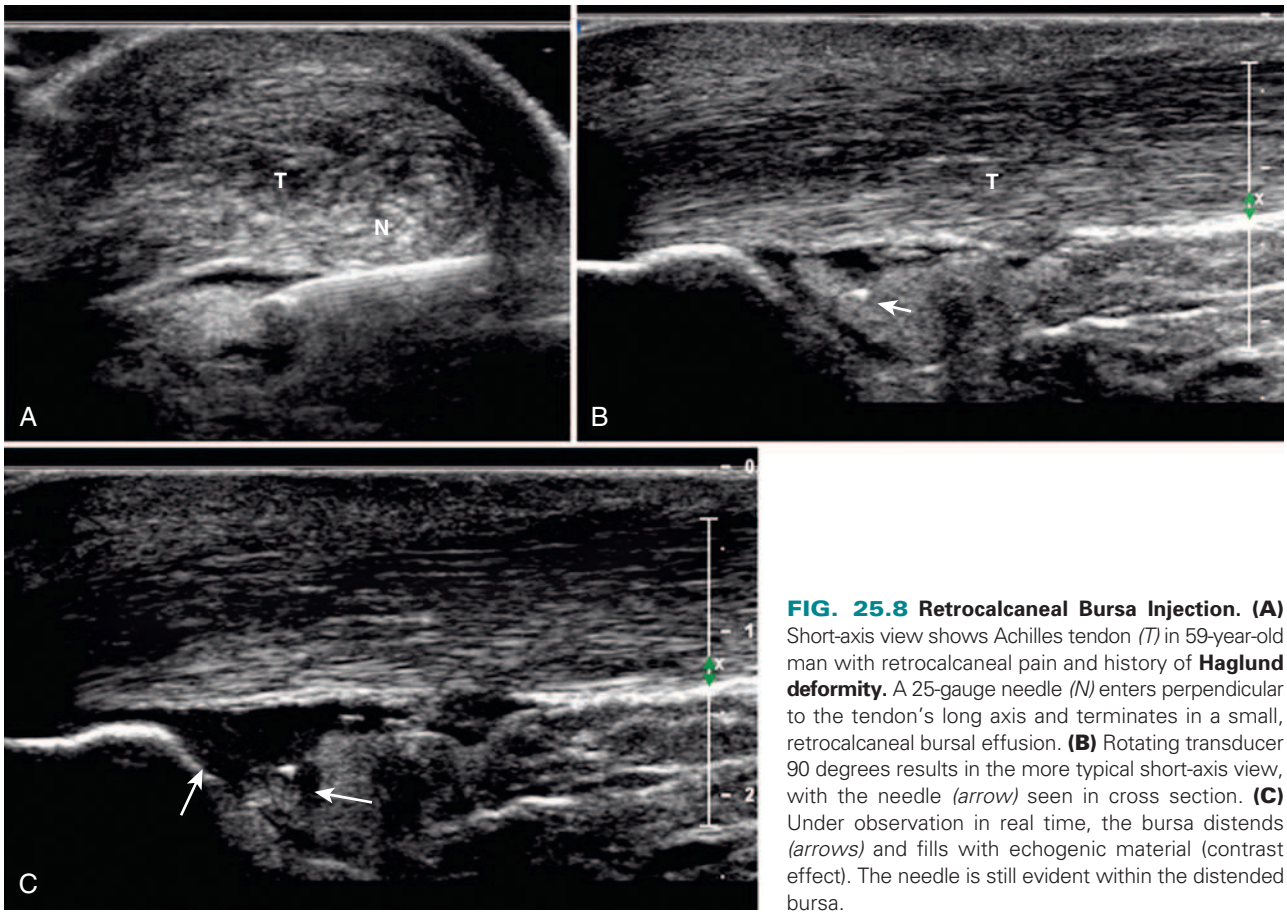

FIG. 25.8 Retrocalcaneal Bursa Injection. (A) Short-axis view shows Achilles tendon *(T)* in 59-year-old man with retrocalcaneal pain and history of **Haglund deformity.** A 25-gauge needle *(N)* enters perpendicular to the tendon's long axis and terminates in a small, retrocalcaneal bursal effusion. **(B)** Rotating transducer 90 degrees results in the more typical short-axis view, with the needle *(arrow)* seen in cross section. **(C)** Under observation in real time, the bursa distends *(arrows)* and fills with echogenic material (contrast effect). The needle is still evident within the distended bursa.

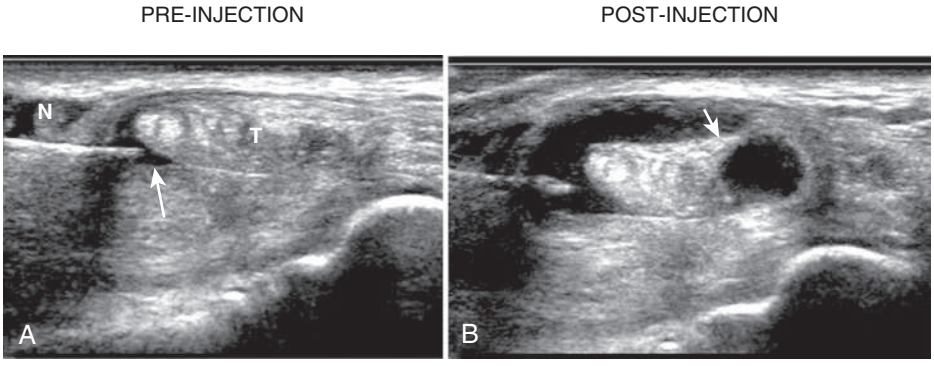

FIG. 25.9 Tendon Sheath Injection Using Short-Axis Approach. A 17-year-old female patient with medial ankle pain was referred for ultrasound-guided injection of posterior tibial tendon sheath. **(A)** Preinjection view shows 25-gauge needle *(N)* within a small tendon sheath effusion *(long arrow)* in the inframalleolar portion of the tendon *(T)*. The tendon, which is inhomogeneous, is seen in cross section. **(B)** Postinjection view shows that the tendon sheath is distended, confirming appropriate deposition of the injected material. Note that the tendon margins are better delineated because of a tenosonographic effect of the injected fluid. The vascular pedicle *(short arrow)* of the tendon is evident.

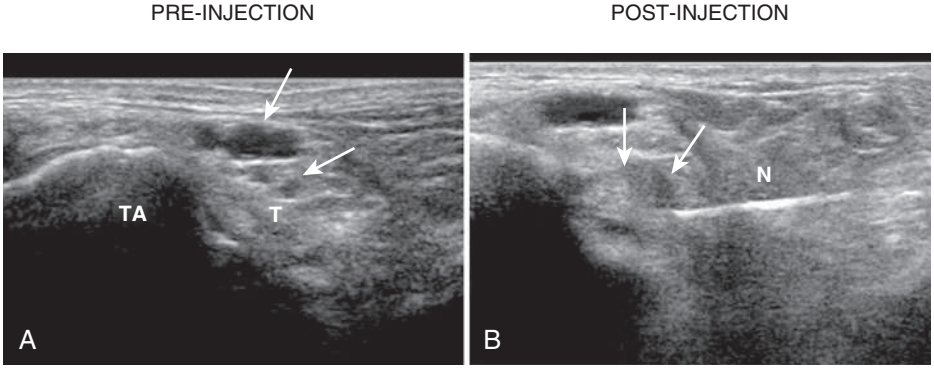

FIG. 25.10 Flexor Hallucis Longus (FHL) Tendon Sheath Injection. Short-axis approach with ultrasound guidance in 31-year-old professional dancer with posteromedial ankle pain during plantar flexion. **(A)** Preinjection image depicts the tendon *(T)* at the level of the posterior sulcus of the talus *(TA)*. The arrows show relationship of the tendon to the neurovascular structures. **(B)** Postinjection image depicts 25-gauge needle *(N)* situated within the distended tendon sheath *(arrows)* below the neurovascular structures.

Interdigital (Morton) neuromas, a common cause of forefoot pain especially in women, have been described at sonography as hypoechoic masses replacing the normal hyperechoic fat in the interdigital web spaces. Occasionally a dilated hypoechoic tubular structure can be seen associated with the neuroma, reflecting the enlarged feeding interdigital nerve. The second and third web spaces are most often involved. I generally inject Morton neuromas using a dorsal approach while imaging the neuroma in long axis[28] (Fig. 25.12). This approach is well tolerated by the majority of patients. In certain patients, however, a plantar approach to injecting the nodule is preferred, such as those with severe subluxation at the MTP joint. In either case, the needle is positioned directly within the neuroma and/or adjacent intermetatarsal bursa (if present) and a small volume of therapeutic mixture injected, similar to that used for a small joint injection (0.5-0.75 mL).

Hand and Wrist

In the hand and wrist, **de Quervain tendinosis** is a frequently encountered tendinopathy involving the abductor pollicis longus and extensor pollicis brevis tendons that respond to local administration of antiinflammatory agents (Fig. 25.13). Injections are also frequently requested for patients with **rheumatoid arthritis** or **psoriatic arthritis.** These patients typically experience severe tenosynovitis, which can lead to secondary tendon rupture and deformity. The approach is similar to that used for superficial structures in the foot and ankle. A short-axis approach avoids the surrounding neurovascular structures, and the corresponding tendon sheaths are injected.

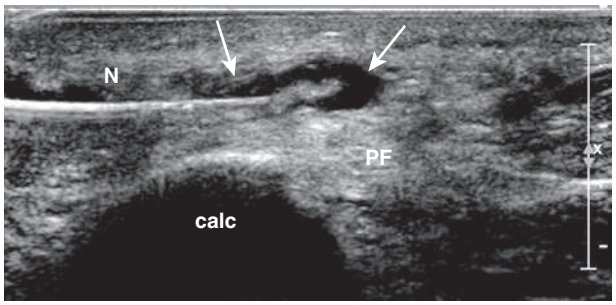

FIG. 25.11 Plantar Fascia Injection. The proximal medial band of the plantar fascia *(PF)* is thickened and inhomogeneous in a 36-year-old man with hindfoot pain. *calc,* Calcaneus. A 25-gauge needle *(N)* has been positioned superficial to this plantar fascia and a perifascial injection performed. The injected material *(arrows)* loculates along the superficial margin of the medial band.

INJECTION OF DEEP TENDONS

Frequently requested deep tendon injections include those for the **bicipital tendon sheath, iliopsoas tendon, gluteal tendon insertion onto the greater trochanter,** and **hamstring tendon** origin.

Biceps Tendon

Anterior shoulder pain with radiation into the arm may be secondary to bicipital tendinitis or tenosynovitis.[29] The biceps tendon can be palpated, but if nondistended, the sheath may offer less than 2 mm of clearance to place a needle. This is complicated by the caudal extension of the subacromial subdeltoid bursa, which may overlie the bicipital tendon sheath. A nonimage-guided injection could therefore result in delivery into an extratendinous synovial space, or possibly result in an intratendinous injection. Ultrasound guidance enables localization of therapeutic agent to the biceps tendon sheath.[10]

The patient is placed recumbent with the forearm supinated and the shoulder mildly elevated. The bicipital groove is oriented anteriorly. A linear transducer, typically 7.5 MHz, is used with a lateral approach and 25- or 22-gauge needle (Fig. 25.14). The long head of the biceps tendon is scanned in short axis. When fluid distends the bicipital tendon sheath, the tip is directed into the fluid. Otherwise, the needle is directed along the superficial margin of the tendon, and a test injection of local anesthetic is used to confirm local distention of the sheath, which is then followed by administration of the long-acting corticosteroid. The

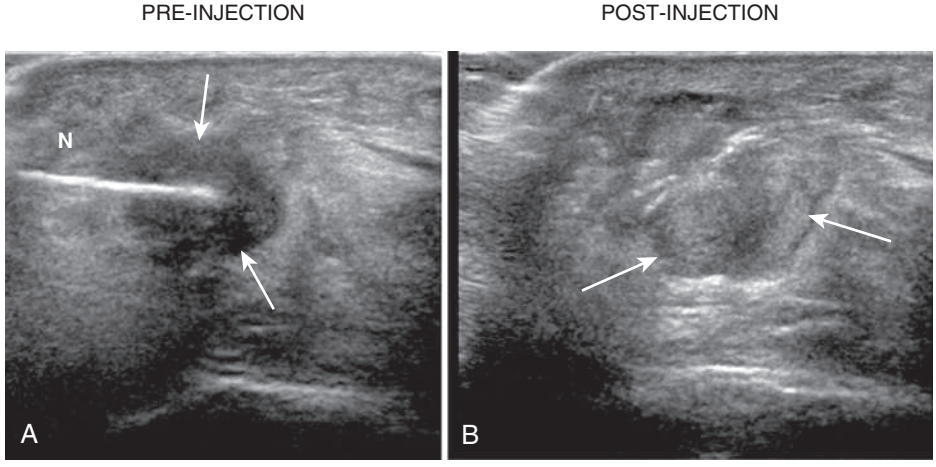

FIG. 25.12 Morton Neuroma Injection. (A) Preinjection image shows 25-gauge needle *(N)* positioned in a third web space neuroma using a dorsal approach in 45-year-old woman with forefoot pain. Neuroma appears as a heterogeneous hypoechoic nodule *(arrows)* within the normal echogenic fat. **(B)** After injection and needle removal, the nodule appears expanded and echogenic *(arrows).* The injected material often decompresses into an adjacent adventitial bursa, which frequently accompanies these nodules.

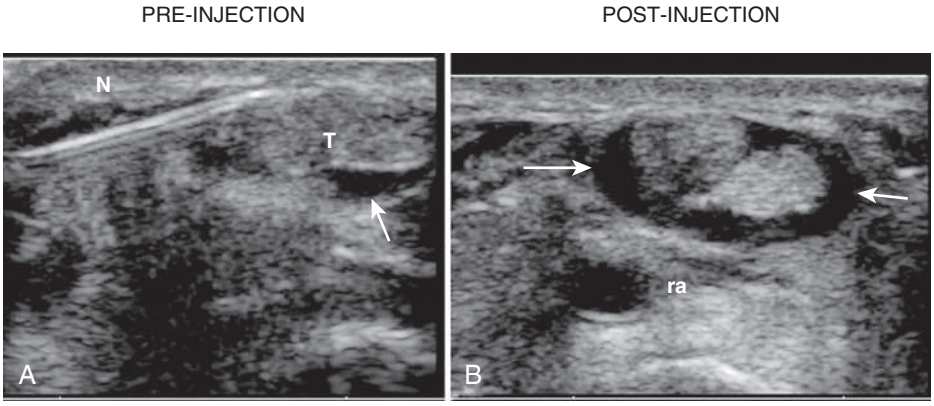

FIG. 25.13 Injection of First Dorsal Compartment of Wrist. This 70-year-old woman with **de Quervain tendinosis** had clinical symptoms of wrist pain radiating along the extensor surface of the forearm. **(A)** Preinjection image shows 25-gauge needle *(N)* positioned in the first dorsal compartment tendon sheath under ultrasound guidance. The tendons *(T)* are inhomogeneous, with a small effusion evident *(arrows)* in the dependent part of the tendon sheath. **(B)** After injection and needle removal, the injected material distends the sheath *(arrows),* producing a tenosonographic effect; the intrinsic tendon abnormalities become more conspicuous. *ra,* Radial artery.

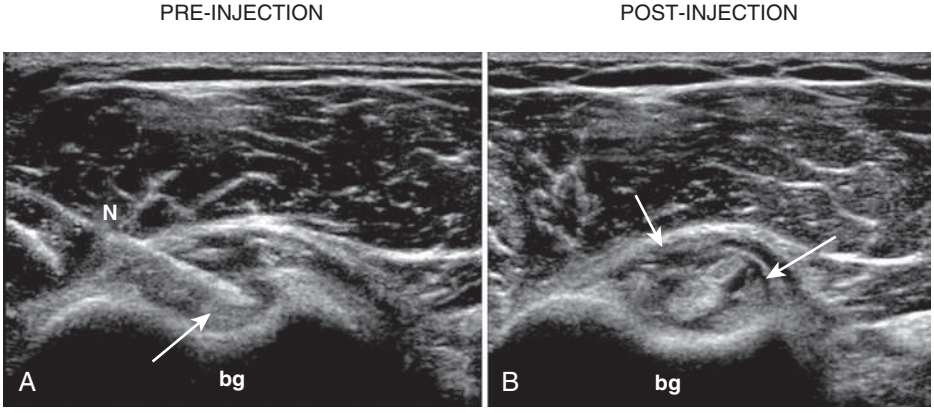

FIG. 25.14 Biceps Tendon Sheath Injection. Biceps tendinosis was clinically suspected and a biceps tendon sheath injection requested for this 41-year-old man with development of anterior shoulder pain after arthroscopic surgery for labral tear. **(A)** Preinjection image shows 25-gauge needle *(N)* placed superficial to the long head of the biceps tendon *(arrow).* **(B)** After injection and needle removal, there is distention of the tendon sheath by fluid *(arrows)* containing low-level echoes caused by contrast effect. *bg,* Bicipital groove.

presence of fluid distention of the sheath with superficially located microbubbles helps to confirm a successful injection. A technique to obviate the need to directly approach the tendon sheath, which can sometimes be challenging in the absence of an effusion, entails direct positioning of the needle within the rotator interval adjacent to the intraarticular portion of the biceps tendon and deep to the biceps pulley mechanism.[30] Stone and Adler reported 100% success in distending the sheath in their series.[30] Therapeutic mixture was also noted to distribute within the rotator interval (Fig. 25.15, Video 25.2).

Iliopsoas Tendon

The iliopsoas tendon lies superficial to and along the medial margin of the anterior capsule of the hip. The tendon inserts onto the lesser trochanter. A bursa that frequently communicates with the hip is present in this location and may be distended because of underling joint pathology or a primary iliopsoas bursitis. Alternatively, iliopsoas tendinosis may occur in the absence of a preexisting bursitis for which a peritendinous injection is requested.[31] A lateral approach to the tendon often requires use of a lower-frequency transducer and curved linear or sector geometry. The neurovascular bundle lies medial and superficial to the tendon, so it is advantageous to approach from the lateral margin of the tendon and perform a small test injection to confirm needle position. A successful injection will show the appearance of fluid or microbubbles distending a bursa that follows the course of the long axis of the tendon (Fig. 25.16).

Abductor and Hamstring Tendons

The most commonly requested peritendinous injections in my experience are about the abductor tendon insertion and hamstring tendon origin. In the first two of these injections, the needle is directed to the greater trochanteric bursa. These injections can be fairly straightforward when the bursa is distended. They become more challenging when there is no preexisting bursal distention. One must then employ anatomic landmarks and test injections with anesthetic for localization (Figs. 25.17 and 25.18). Injections at the hamstring origin are generally peritendinous because no true anatomic bursa exists. An adventitial bursa may be present over the ischium. A lateral approach while scanning the tendons in short axis is preferred for each of these injections, directing

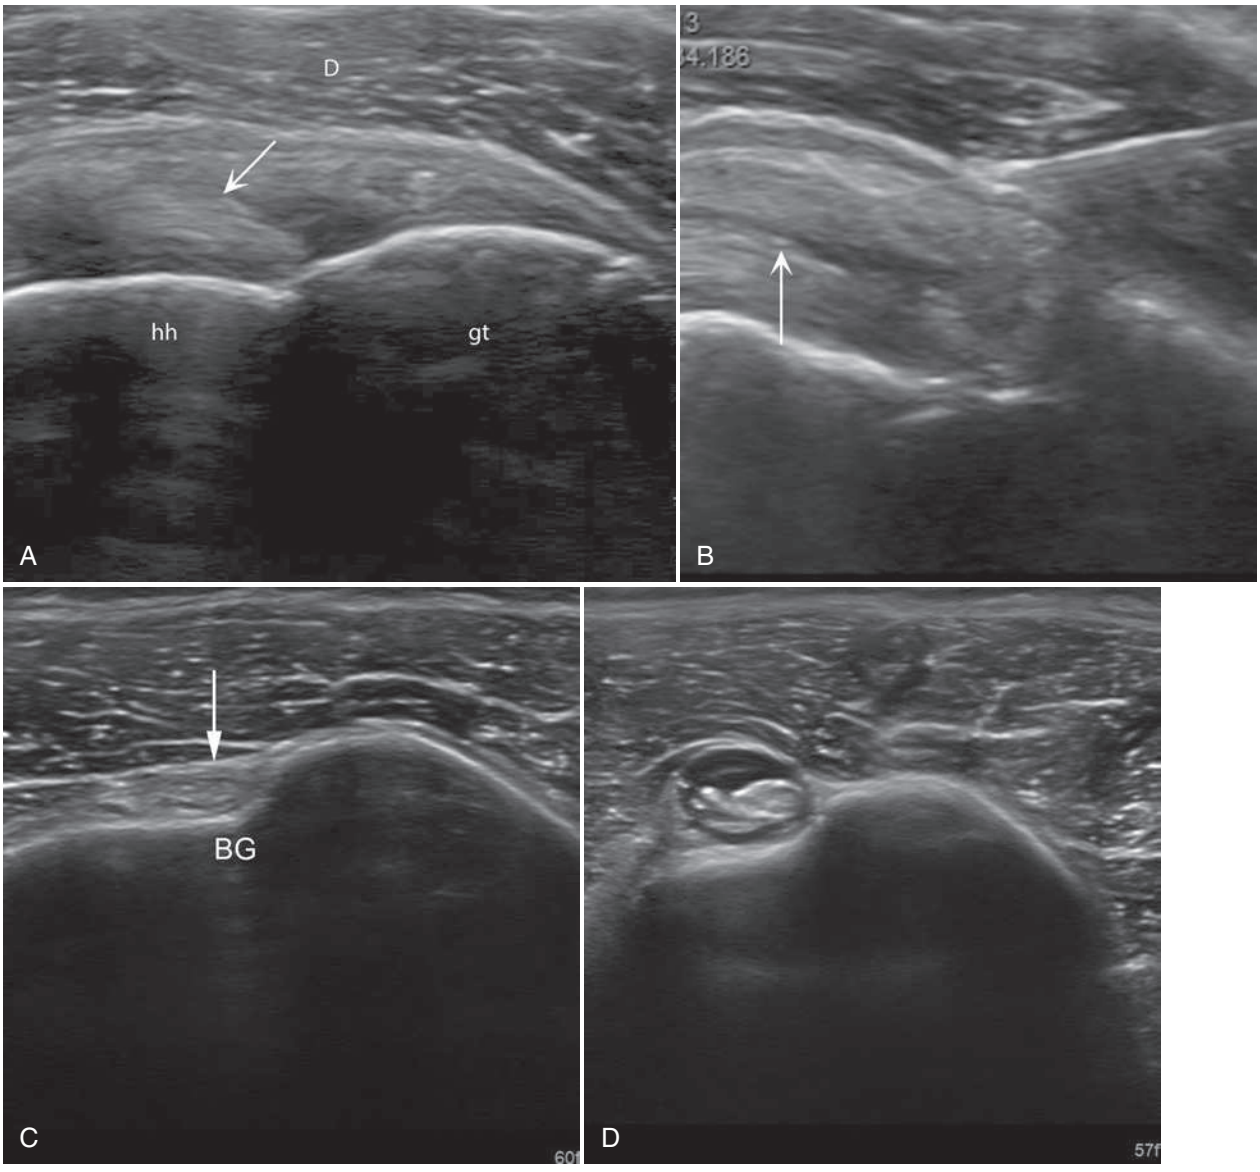

FIG. 25.15 Biceps Tendon Sheath Injection: Rotator Interval Approach. A 44-year-old woman with anterior shoulder pain. **(A)** Gray-scale ultrasound image obtained slightly oblique to the intraarticular biceps tendon *(arrow).* The greater tuberosity *(gt),* humeral head *(hh),* and deltoid *(D)* are labeled. **(B)** A 25-gauge needle is positioned using a short-axis lateral approach adjacent to the margin of the biceps tendon within the rotator interval. The tip of the needle is indicated *(arrow).* A test injection with anesthetic is performed to ensure appropriate needle position. Fluid should not accumulate by the needle tip and the needle position should be adjusted accordingly. **(C)** Short-axis view of the biceps tendon within the sheath before needle placement and injection. The tendon *(arrow)* and bicipital groove *(BG)* are labeled. **(D)** Postinjection image at approximately the same anatomic level as **(C)** depicting the distended biceps tendon sheath. See also Video 25.2.

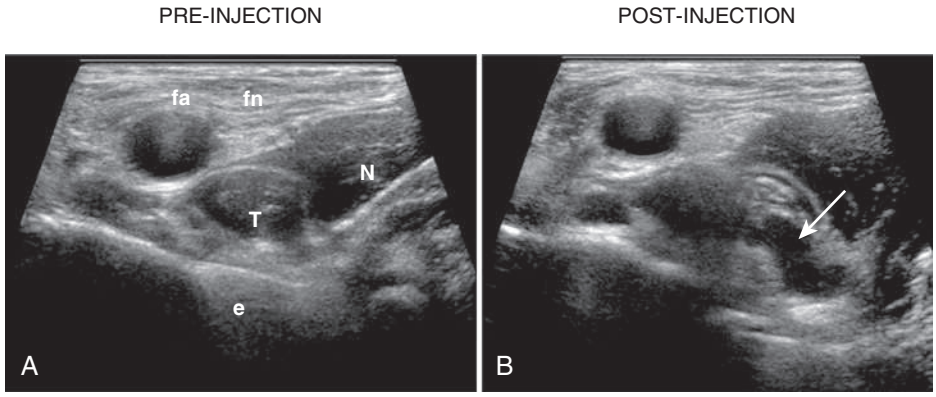

FIG. 25.16 Ultrasound-Guided Iliopsoas Bursa Injection for Pain Relief. This 66-year-old woman with a total hip arthroplasty had developed pain with hip flexion. **(A)** Preinjection image shows 22-gauge spinal needle *(N)* positioned deep to the tendon *(T)* at the level of the iliopectineal eminence *(e),* using a short-axis approach. *fa,* Femoral artery; *fn,* femoral nerve. **(B)** After injection and needle removal, fluid surrounds the tendon within the distended iliopsoas bursa *(arrow).*

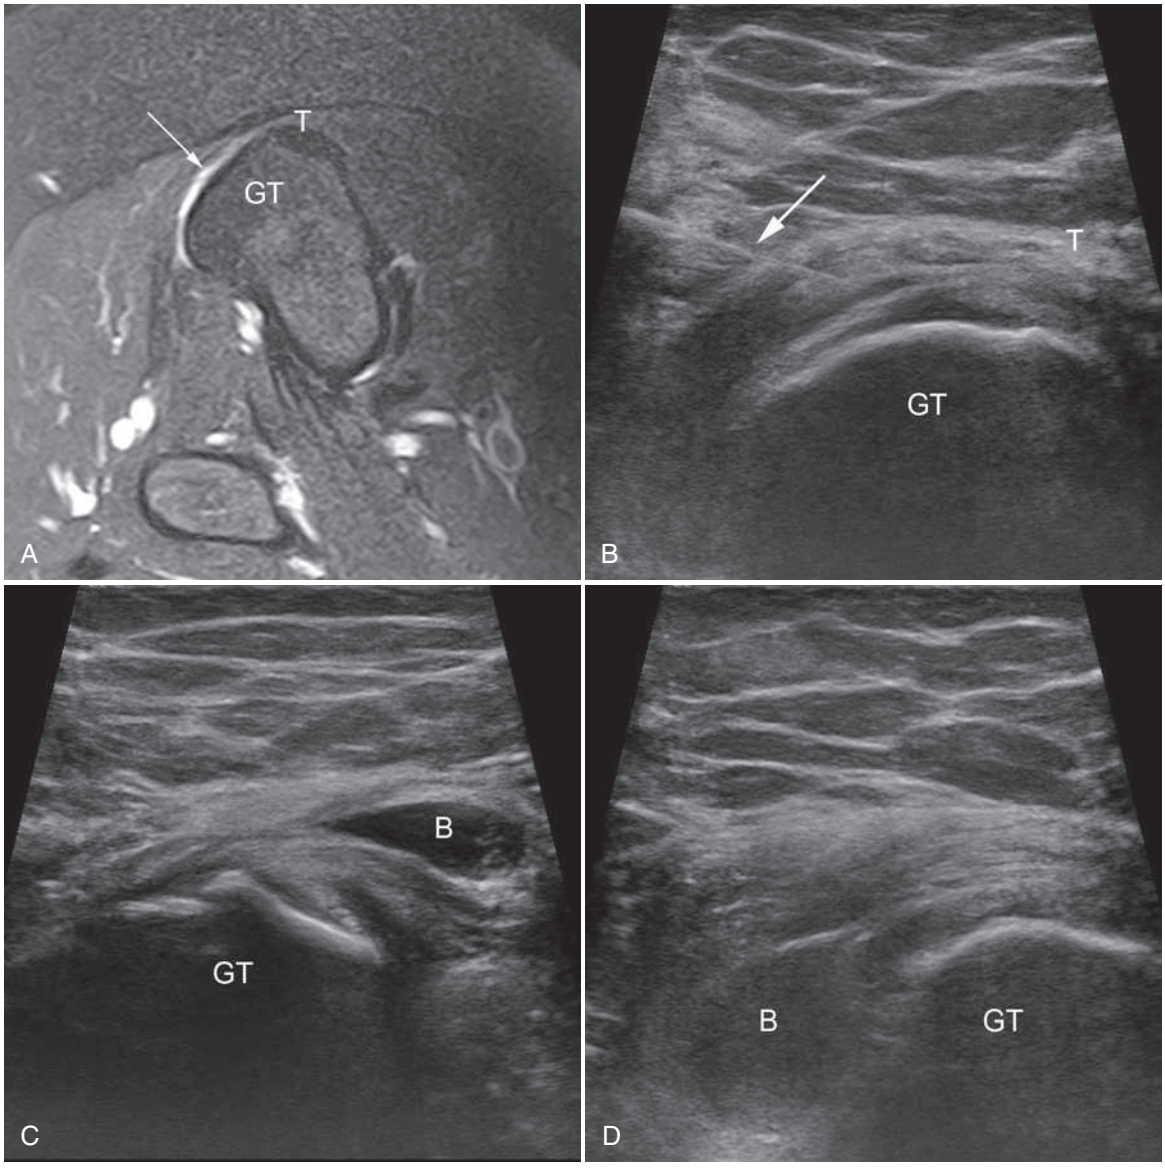

FIG. 25.17 Ultrasound-Guided Greater Trochanteric Bursal Injection. A 53-year-old woman with right lateral hip pain. **(A)** Axial T2-weighted fat-suppressed image depicts the greater trochanter *(GT)* and abductor tendon complex *(T)*. The image is oriented similar to the manner in which it would be viewed during an injection with the patient in a lateral decubitus position. A trace amount of T2-bright fluid *(arrow)* is present in the bursa. **(B)** A 22-gauge spinal needle *(arrow)* is positioned near the posterior margin of the greater trochanter, superficial to the gluteus medius tendon and deep to the gluteus maximus. A test injection with local anesthetic helps ensure appropriate needle placement, which is followed by injection of the therapeutic mixture. **(C)** Short-axis postinjection image at the greater trochanter shows anterior extension of the greater trochanteric bursa *(B)* at the level of the anterior facet. **(D)** Postinjection short-axis image centered more posteriorly over the lateral and posterior facets depicts the posterior extension of the bursa *(B)* abutting the posterior facet of the greater trochanter, also referred to as the "bare area" of the greater trochanter. I usually inject a large volume (10 mL).

the needle toward the posterior facet of the greater trochanter in the case of a trochanteric bursal injection, or adjacent to the margin of the hamstring origin if a peritendinous injection is requested.

BURSAL, GANGLION CYST, AND PARALABRAL INJECTIONS

Distended bursae around tendinous insertions provide anatomic localization for therapeutic agents. Injection of these areas is often requested for the patient with localized **bursitis** and abnormality of the adjacent tendon. Examples include the retrocalcaneal, iliopsoas, greater trochanteric, and ischial bursae (Fig. 25.19). Alternatively, the presence of a bursitis, distended synovial cyst, or ganglion cyst may cause mechanical impingement of adjacent tendons. The decompression of these cysts with subsequent administration of a therapeutic agent may alleviate these symptoms[32] (Fig. 25.20). **Ganglion cysts** typically contain clear gelatinous material, most often occurring in the hand, wrist, foot, and ankle. Not infrequently they may come in close proximity to neurovascular structures and may extend along nerves as perineural ganglia. This occurs most often in the knee, at the

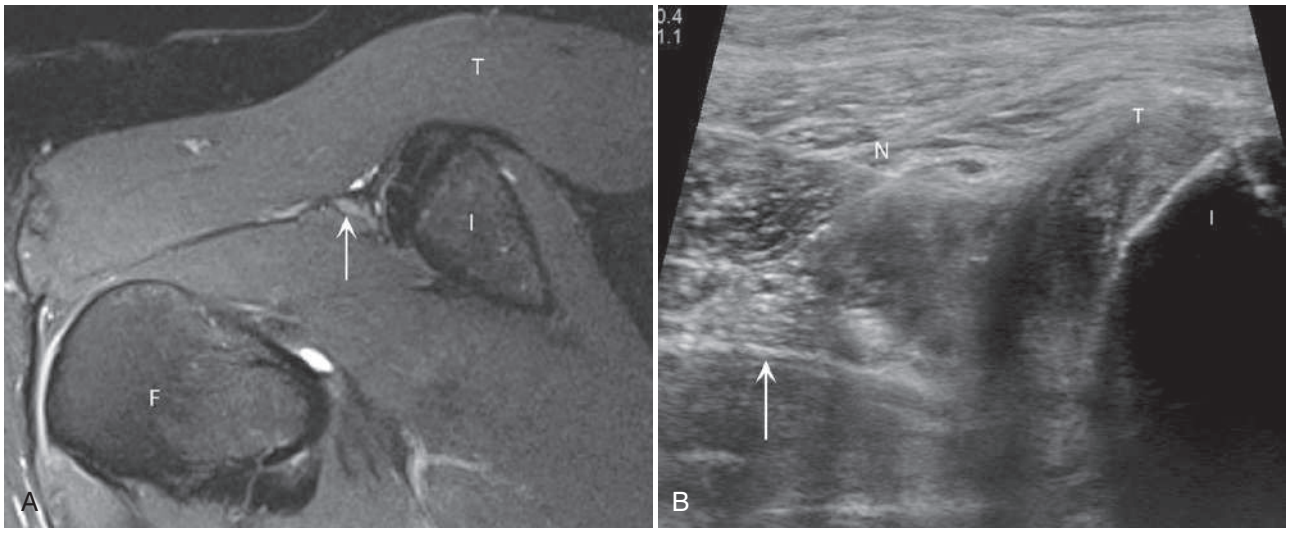

FIG. 25.18 Ultrasound-Guided Hamstring Peritendinous Injection. A 50-year-old female runner with left buttock pain. **(A)** Axial fat-suppressed T2-weighted sequence positioned in a manner similar to that viewed by a sonographer. The hamstring origin *(T)* and ischium *(I)* are labeled. The sciatic nerve *(arrow)* appears as a mildly hyperintense ellipse lateral to the ischium and superficial to the quadratus femoris. *F,* Femur. **(B)** A 22-gauge spinal needle *(N)* is positioned in short axis, using a lateral approach, adjacent to the margin of the hamstring tendon origin *(T).* The sciatic nerve *(arrow)* and ischium *(I)* are labeled.

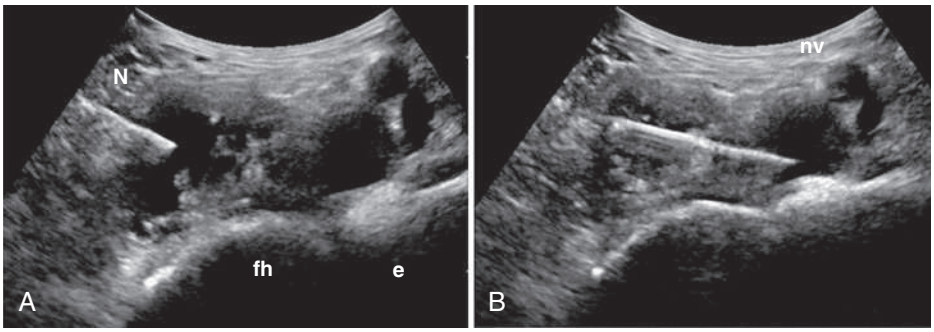

FIG. 25.19 Ultrasound-Guided Aspiration and Injection of Multiloculated Iliopsoas Bursa. (A) Image shows 22-gauge spinal needle *(N)* positioned into the lateral component of the bursa in a 65-year-old woman with groin pain. *e,* Iliopectineal eminence; *fh,* femoral head. **(B)** After aspiration of the lateral component, the needle has been advanced into the medial component for aspiration and subsequent injection with therapeutic mixture. *nv,* Neurovascular structures.

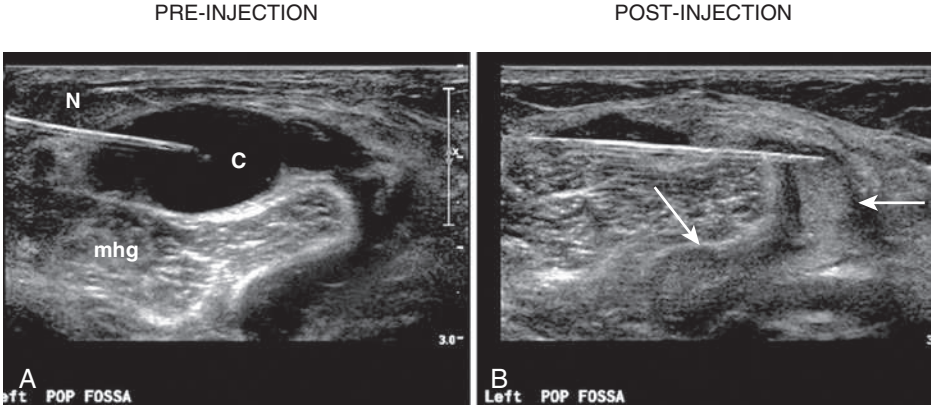

FIG. 25.20 Ultrasound-Guided Aspiration and Injection of Clinically Suspected Baker Cyst. (A) Preinjection image shows 22-gauge needle *(N)* positioned in the cyst *(C)* under ultrasound guidance in 59-year-old woman with posterior knee pain and swelling. *mhg,* Medial head of gastrocnemius muscle. **(B)** After cyst aspiration and injection of the therapeutic mixture, the anechoic fluid is replaced by echogenic fluid resulting from contrast effect *(arrows).*

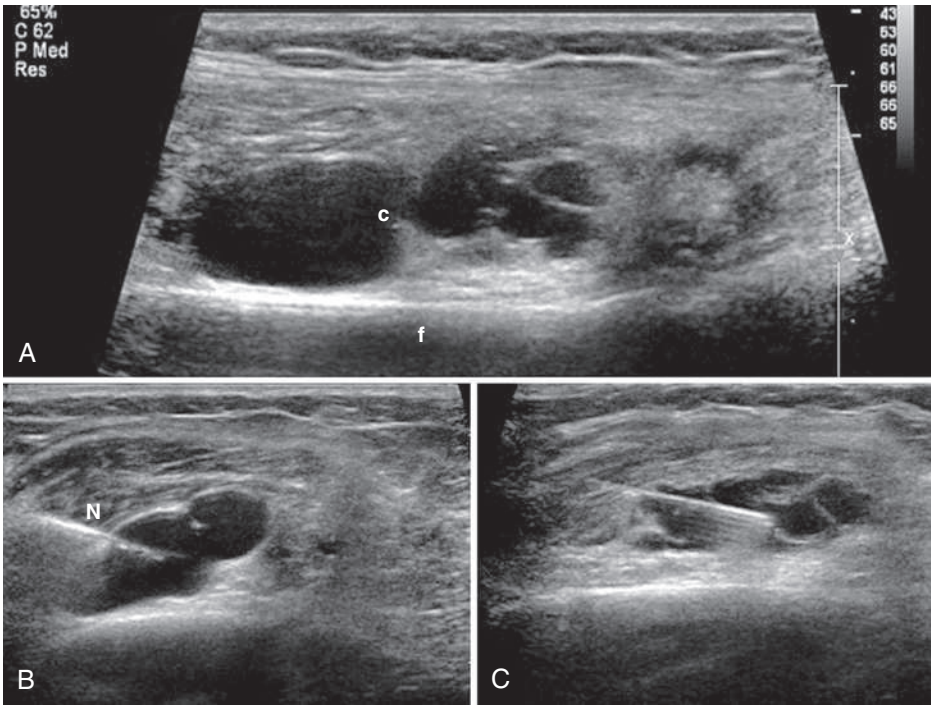

FIG. 25.21 Ultrasound-Guided Aspiration and Injection of Multiloculated Ganglion Cyst. (A) Baseline sonogram shows a multiloculated cyst *(c)* within the vastus lateralis muscle of the left knee and superficial to the lateral margin of the femur *(f)* in a 41-year-old woman. **(B)** A 20-gauge spinal needle *(N)* was initially positioned into the proximal component of the cyst. **(C)** Subsequently the needle was redirected into the distal component. Multiple lavages and aspiration enabled complete decompression of the cyst *(not shown)*.

tibiofibular joint.[33,34] Ultrasound guidance allows the clinician to avoid intratendinous injections as well as adjacent neurovascular structures. Furthermore, the needle may be redirected as necessary in the presence of a multiloculated cyst (Fig. 25.21). We find that performing a lavage technique similar to that employed in treating calcific tendinosis results in progressive dilution of the cyst contents, thereby permitting complete aspiration. In the upper extremity, where cosmesis may also be an issue, use of a rapidly absorbed corticosteroid may reduce potential complications, such as depigmentation and local atrophy. Similar considerations apply when aspirating and injecting **parameniscal and paralabral cysts.** These cysts occur at sites of torn and/or degenerated fibrocartilage and are most often present in the knee, hip, and shoulder. These cysts are similar to ganglion cysts in consistency but often contain additional echogenic debris. In the shoulder, paralabral cysts have been associated with development of a compressive neuropathy, because they can occur in close proximity to the suprascapular nerve.[35] The approach used in aspirating these cysts is variable, depending on location and orientation, as well as location of adjacent neurovascular structures (Figs. 25.22 and 25.23, Video 25.3).

Calcific Tendinitis

The presence of symptomatic intratendinous calcification involves the deposition of **calcium hydroxyapatite.** This often appears as a nodular echogenic mass within the tendon, which may or may not display posterior acoustic shadowing.[36] Although most often affecting the shoulder, this may occur elsewhere in the musculoskeletal system. Ultrasound-guided fragmentation and lavage, also known as **barbotage,** has been described as an excellent method to fenestrate the calcification and reduce the level of calcification and to deposit therapeutic agents.[37-40] Single- and dual-needle techniques have been described and appear to be comparably effective. I currently use a single-needle technique, with the needle acting as inflow for anesthetic and sterile saline and as an outflow for the calcium solution (Fig. 25.24). The elasticity of the pseudocapsule encasing the calcification is sufficient to decompress the calcific mass in the majority of cases (Video 25.4). After multiple lavages, the needle is used to inject the anesthetic and antiinflammatory mixture. The injected mixture is distributed within the adjacent subdeltoid bursa in most cases. If the calcification is too small or fragmented, precluding lavage and decompression, the single needle is used to fenestrate the calcium deposit, and a peritendinous therapeutic injection has been shown to be effective.

INTRATENDINOUS INJECTIONS: PERCUTANEOUS TENOTOMY

Image guidance can be useful for performing percutaneous tenotomy and intratendinous injections with either autologous blood or platelet-rich plasma (PRP).[41-45] These methods are associated with secondary release of local growth factors, such as platelet-derived growth factor, which in turn may produce a direct healing response.[44] Preliminary data show significant promise in promoting ultrasound-guided tendon repair. "Dry needling" techniques have been employed successfully in patients with lateral epicondylitis refractory to other conservative

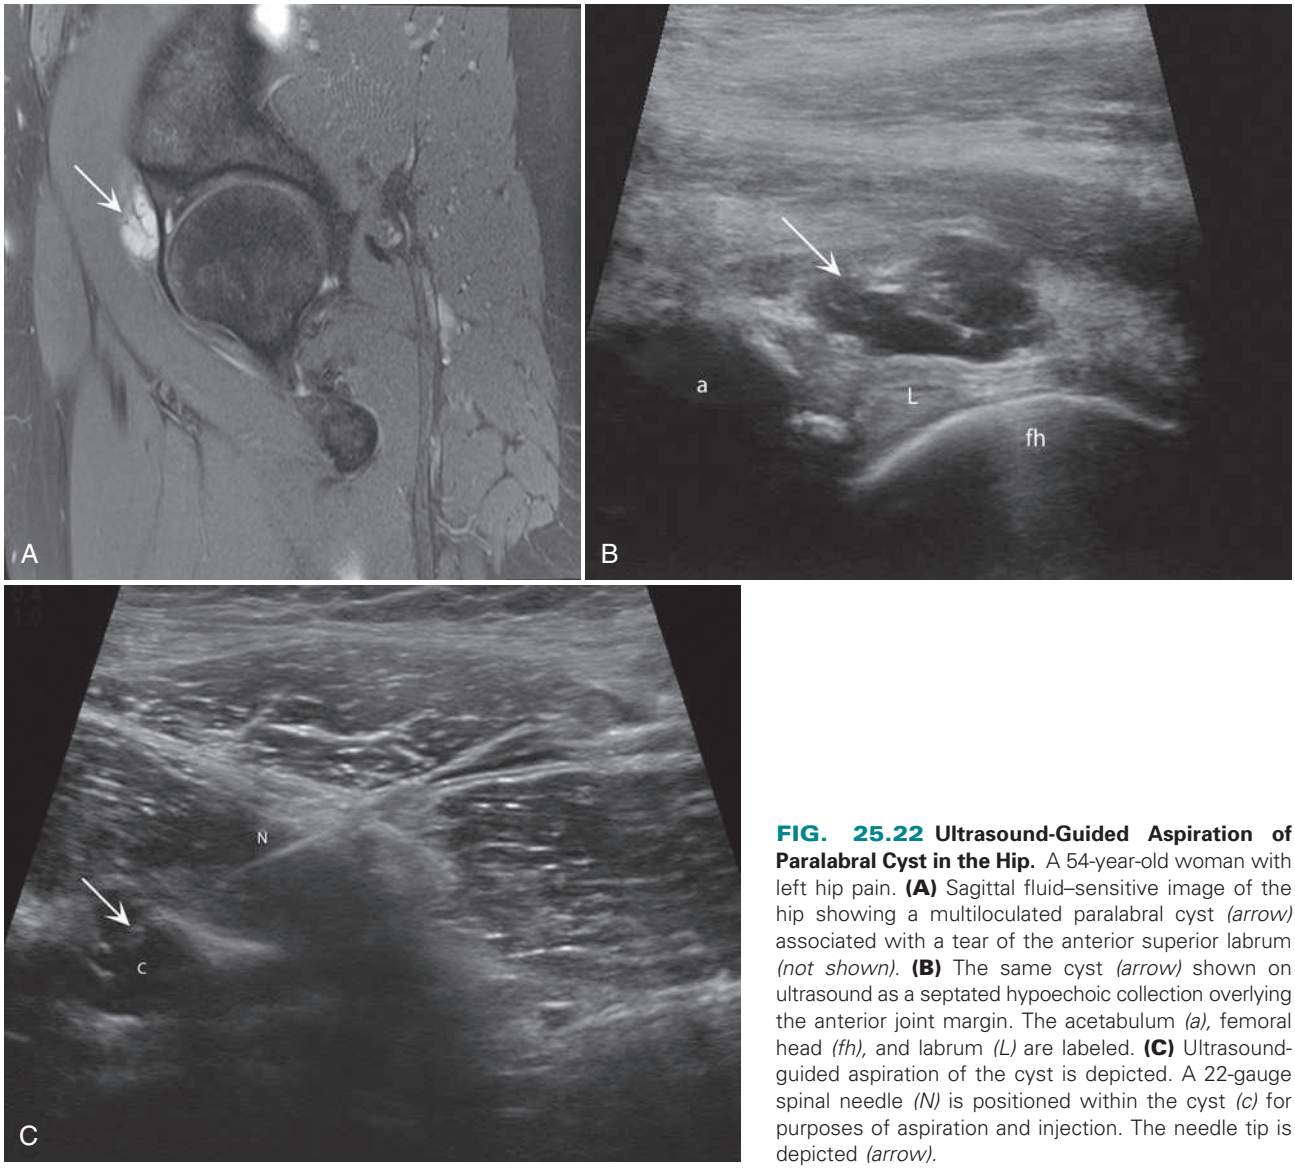

FIG. 25.22 Ultrasound-Guided Aspiration of Paralabral Cyst in the Hip. A 54-year-old woman with left hip pain. **(A)** Sagittal fluid–sensitive image of the hip showing a multiloculated paralabral cyst *(arrow)* associated with a tear of the anterior superior labrum *(not shown)*. **(B)** The same cyst *(arrow)* shown on ultrasound as a septated hypoechoic collection overlying the anterior joint margin. The acetabulum *(a)*, femoral head *(fh)*, and labrum *(L)* are labeled. **(C)** Ultrasound-guided aspiration of the cyst is depicted. A 22-gauge spinal needle *(N)* is positioned within the cyst *(c)* for purposes of aspiration and injection. The needle tip is depicted *(arrow)*.

measures.[41] Likewise, autologous blood injections and PRP injections have been successfully used in both the elbow and the knee[42-44] (Figs. 25.25 and 25.26, Video 25.5). The advantage of performing these injections under ultrasound guidance becomes evident when the clinician wants to generalize such techniques to include tendons close to neurovascular structures, such as the hamstring tendon origin. Newer technology is now available that allows sonographically directed emulsification of focal tendinosis, calcifications, and enthesopathic spurs followed by removal during the course of the procedure.[46] The technique employs a coaxial system with a mechanically active hollow tip that disrupts the tissue and is connected to vacuum suction, while the outer tube supplies sterile water to cool the tip and remove debris as part of the suctioned material (Fig. 25.27, Video 25.6). This technique is relatively new, and no definitive long-term trials are available to assess efficacy, but preliminary results appear promising.

PERINEURAL INJECTIONS

Ultrasound has shown promise in evaluating and treating patients with painful lesions of peripheral nerves due to compressive neuropathies, such as in carpal or cubital tunnel syndromes, or in cases of posttraumatic or postsurgical neuromas.[35] These injections can include nerve blocks with long-acting anesthetic, therapeutic injections using an injectable steroid, or neurolytic therapy with an agent that promotes cellular death such as absolute ethanol.[47,48] A rapidly absorbed injectable steroid, such as dexamethasone, may be preferable for superficial lesion to minimize potential complications, such as depigmentation or atrophy of the subcutaneous fat.

A thorough knowledge of the normal sonographic appearances of nerves and their anatomic course is a prerequisite.[35,36] In the case of small sensory nerves, which can be difficult to visualize, knowledge of the anatomic relationships of the nerves to adjacent

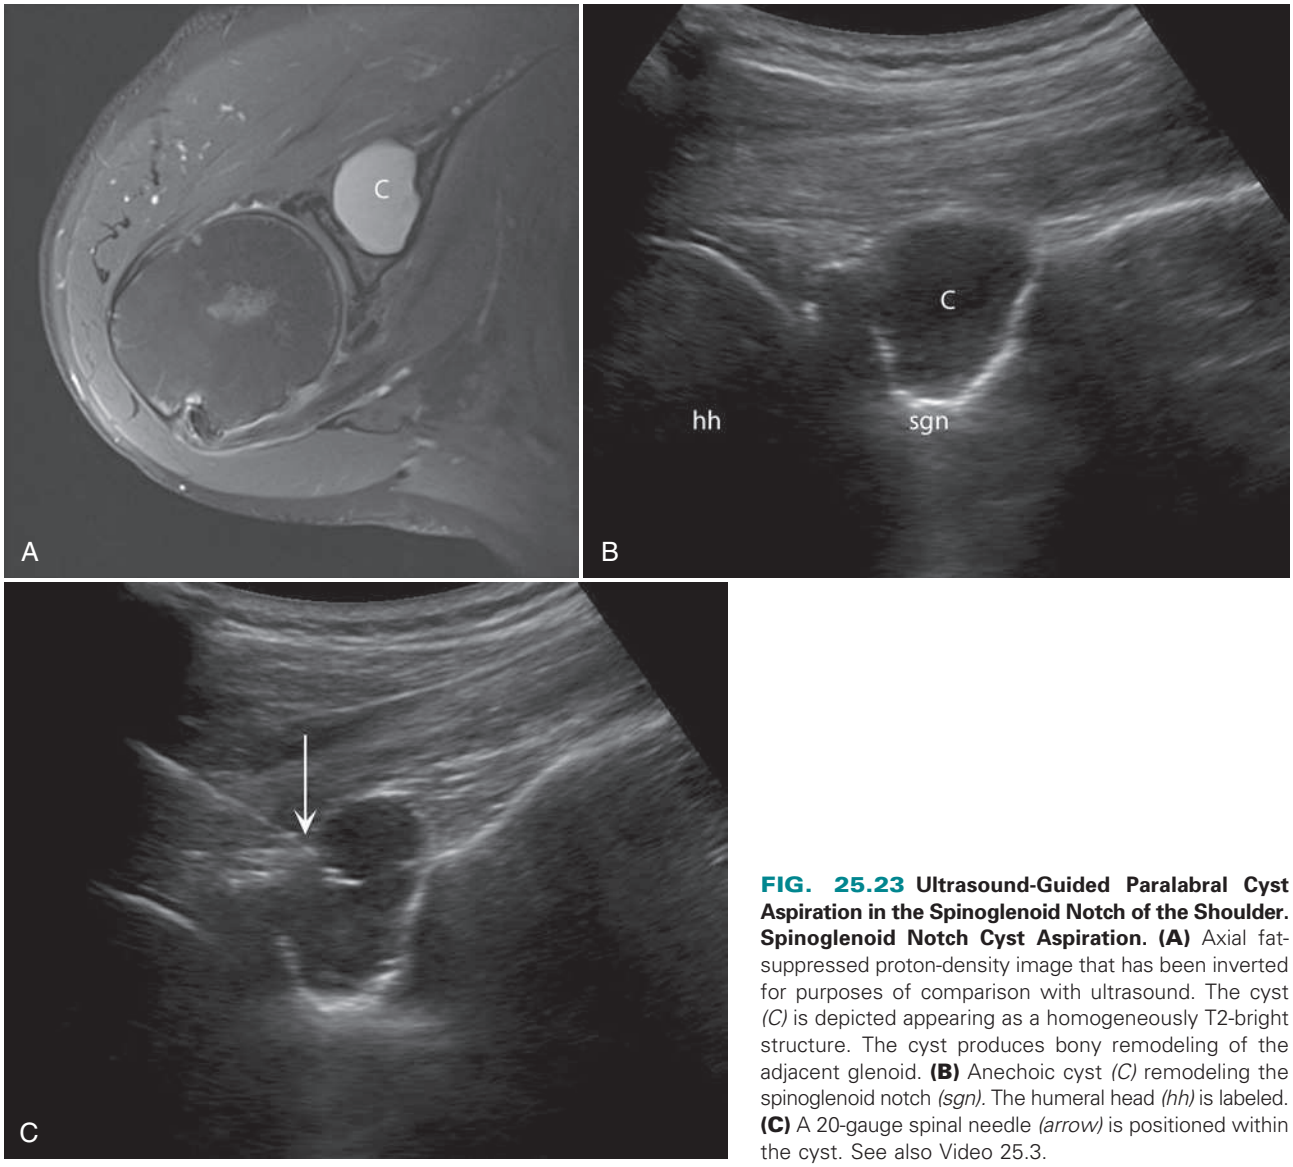

FIG. 25.23 Ultrasound-Guided Paralabral Cyst Aspiration in the Spinoglenoid Notch of the Shoulder. Spinoglenoid Notch Cyst Aspiration. (A) Axial fat-suppressed proton-density image that has been inverted for purposes of comparison with ultrasound. The cyst *(C)* is depicted appearing as a homogeneously T2-bright structure. The cyst produces bony remodeling of the adjacent glenoid. **(B)** Anechoic cyst *(C)* remodeling the spinoglenoid notch *(sgn)*. The humeral head *(hh)* is labeled. **(C)** A 20-gauge spinal needle *(arrow)* is positioned within the cyst. See also Video 25.3.

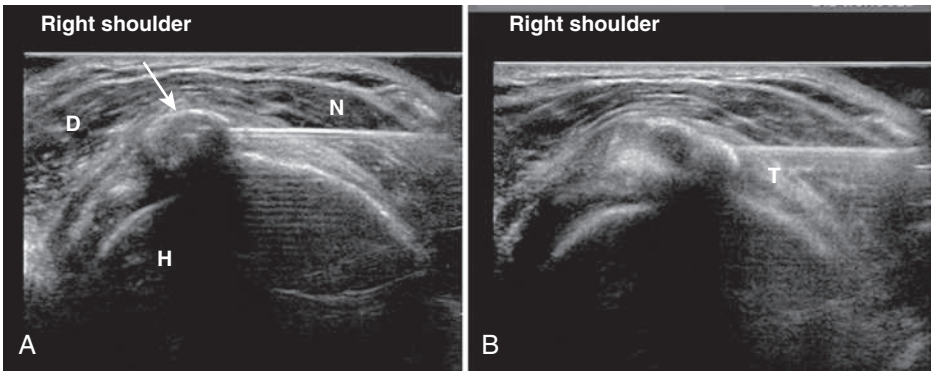

FIG. 25.24 Ultrasound-Guided Aspiration and Injection for Calcific Tendinosis. (A) Image shows 20-gauge spinal needle *(N)* positioned into the calcification *(arrow)* under ultrasound guidance in 42-year-old man with shoulder pain. *D,* Deltoid; *H,* humeral head. **(B)** Series of repeat lavage and aspirations of the calcification are performed, with the calcification eventually largely replaced by fluid contents within the surrounding pseudocapsule of the calcific mass. *T,* Rotator cuff tendons. Note that the degree of posterior acoustic shadowing has diminished and that the center of the calcification (*arrow* on **A**) is partially replaced by fluid. After numerous lavages, the calcification is typically fenestrated, and a therapeutic mixture is injected and often decompresses into the subdeltoid bursa *(not shown)*.

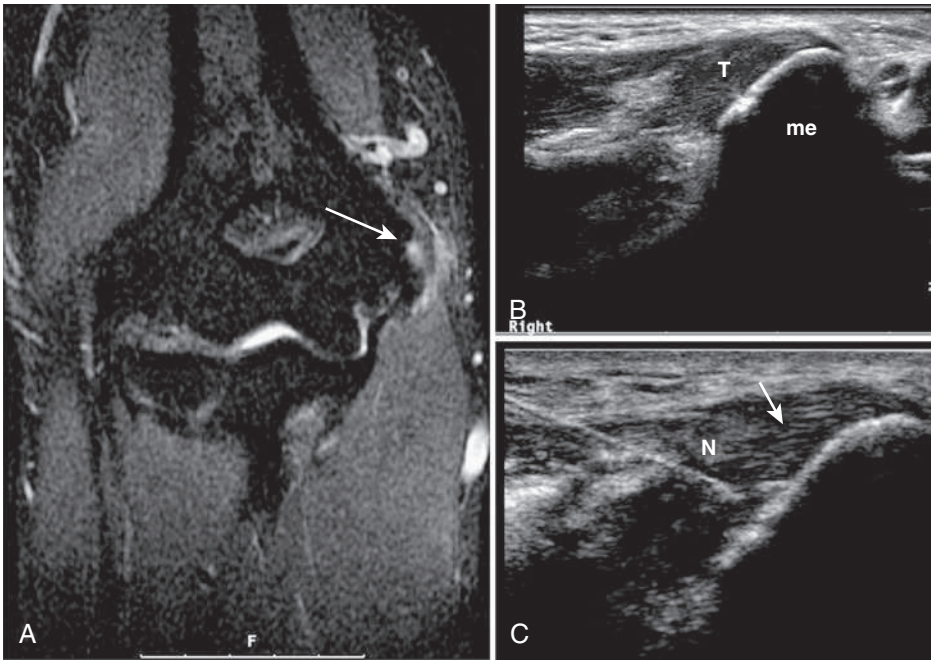

FIG. 25.25 Ultrasound-Guided Injection of Autologous Blood to Induce Healing Response. (A) Coronal inversion-recovery magnetic resonance imaging scan of the affected elbow in a 43-year-old man with medial epicondylitis shows increased signal intensity *(arrow)* of the common flexor tendon mass and adjacent collateral ligament. **(B)** Long-axis ultrasound image of the tendon *(T)* and adjacent medial epicondyle *(me)* shows that tendon is predominantly hypoechoic, reflecting underlying tendinosis. **(C)** Image shows 22-gauge needle *(N)* placed within the common flexor tendon mass, for purposes of mechanical fenestration, and injection of 5 mL of autologous blood, obtained from an antecubital vein. Tendon echogenicity *(small arrow)* is increased by microbubbles within the injected blood.

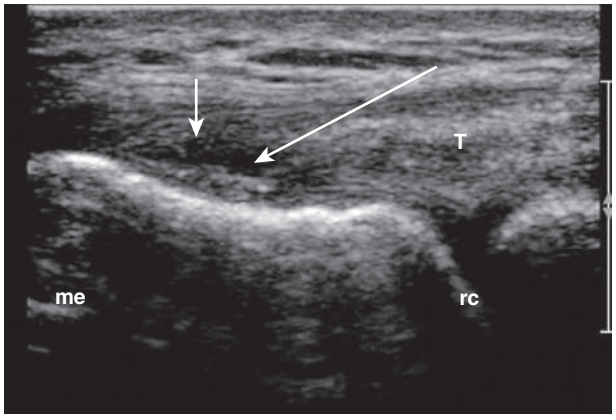

FIG. 25.26 Baseline Image Before Autologous Blood Injection. Common extensor tendon mass *(T)* in 50-year-old woman with partial tear of the deep portion of the tendon (*short arrow,* extensor carpi radialis brevis) as it inserts on the medial epicondyle *(me); rc,* radiocapitellar joint; *long arrow,* plane of needle entry for percutaneous tenotomy and autologous blood injection. See also Video 25.5.

anatomic compartments is of value. Nerves are best visualized in short axis as clusters of hypoechoic fascicles with echogenic septations (internal epineurium), which have a surrounding echogenic epineurial sleeve (external epineurium). An enlarged hypoechoic nerve may indicate neuritis, whereas a focal hypoechoic nodule seen in relationship to the nerve may represent a neuroma in the appropriate clinical setting.

Ultrasound allows direct targeting of the perineural soft tissue or a neuroma for injection (Fig. 25.28, Video 25.7). The nerve is best approached in short axis, usually with a 1.5-inch 25-gauge needle or occasionally a spinal needle. In the case of a perineural injection, it is helpful to position the needle in close proximity to the nerve, injecting small amounts of anesthetic until a clear-cut fluid plane outlining the epineurium is evident. When this is achieved, the therapeutic mixture can be instilled. The same procedure is used when performing ultrasound-guided neurolytic therapy. I typically inject a mixture of long-acting anesthetic (0.75% bupivacaine) with a total of 0.5 to 1 mL of absolute ethanol for peripheral nerve lesions. In my experience, absolute ethanol may require multiple injections and can produce a marked postinjection inflammatory response that can last for several days. The volume injected can be variable and in general does not exceed 1 mL. Multiple small injections have been advocated to be efficacious for Morton neuromas (0.25-0.5 mL).

CONCLUSION

Ultrasound offers distinct advantages in providing guidance for delivery of therapeutic injections. Most important, ultrasound allows the operator to visualize the needle and make adjustments in real time, to ensure that medication is delivered to the appropriate location. Current ultrasound technology provides excellent depiction of relevant musculoskeletal anatomy. The needle has a unique sonographic appearance and can be monitored with

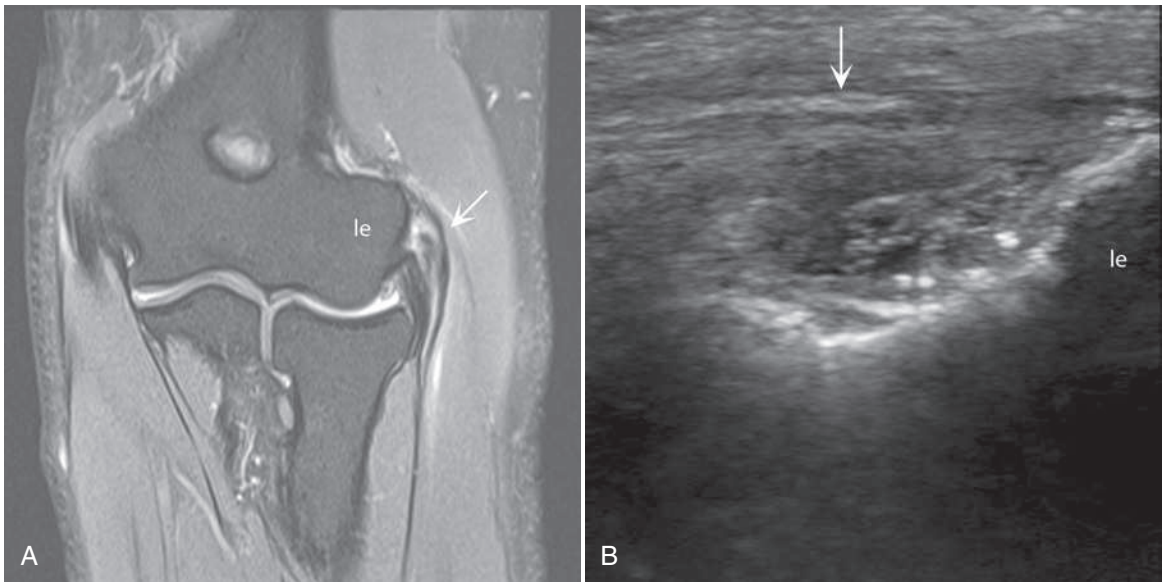

FIG. 25.27 Percutaneous Tenotomy Using Tenex Device. Ideally, fluid hydrodissection of the epineurial fat from the adjacent perineural soft tissues is achieved. See also Video 25.7.

real-time imaging, as can the steroid-anesthetic mixture. Given these advantages, ultrasound guidance should become the method of choice to perform a large variety of guided musculoskeletal interventions.

CHAPTER 26

The Extracranial Cerebral Vessels

Edward I. Bluth, Stephen I. Johnson, and Laurie Troxclair

SUMMARY OF KEY POINTS

- The combination of gray-scale, color-flow Doppler, and Doppler spectral analysis is highly accurate in determining plaque characterization and degree of carotid stenosis.
- Accurate diagnosis of carotid stenosis is critical for patients who would benefit from surgical and interventional treatment.
- Clinicians can accurately follow changes in noncritical carotid stenosis or plaque using ultrasound.
- The assessment of the vertebral arteries is an integral component of the carotid ultrasound examination. However, the degree of stenosis of the vertebral arteries cannot be accurately assessed.
- Carotid atherosclerotic plaque with resultant stenosis usually involves the internal carotid artery within 2 cm of the carotid bifurcation.
- Homogenous plaque, which is stable, has uniform echo pattern with a smooth surface. The amount of sonolucency is less than 50%.
- Heterogeneous plaque, which can be unstable, has a more complex echo pattern with sonolucent areas of more than 50%.
- Either the consensus table by the Society of Radiologists in Ultrasound or other standard reporting tables and criteria can be used to grade carotid stenosis as long as there is appropriate quality outcome feedback for accuracy.

INTRODUCTION: INDICATIONS FOR CAROTID ULTRASOUND EXAMINATION

Stroke secondary to atherosclerotic disease is the third leading cause of death in the United States. Many stroke victims survive the catastrophic event with some degree of neurologic impairment depending on collateral flow.[1,2] Annually, stroke kills more than 130,000 people in the United States with an incidence of more than 795,000 cases of cerebrovascular accident (CVA).[3,4] Ischemia from severe, flow-limiting stenosis caused by atherosclerotic disease involving the extracranial carotid arteries is implicated in 20% to 30% of strokes with a decreasing incidence due to improved control of hypertension and hyperlipidemia with medications.[3,5] An estimated 80% of CVAs are thromboembolic in origin, often with carotid plaque as the embolic source.[6] **Cardioembolic stroke** carries a higher risk of death, recurrent

stroke, hospital readmission, and severe disability than other types of stroke.[6]

Carotid atherosclerotic plaque with resultant stenosis usually involves the **internal carotid artery** (ICA) within 2 cm of the carotid bifurcation. This location is readily amenable to examination by sonography as well as surgical intervention. **Carotid endarterectomy** (CEA) initially proved to be more beneficial than medical therapy in symptomatic patients with carotid stenoses of more than 70%, as reported in the **North American Symptomatic Carotid Endarterectomy Trial** (NASCET) and the **European Carotid Surgery Trial** (ECST).[7,8]

Subsequent NASCET results for moderate stenoses have shown a net benefit for surgical intervention with carotid narrowing between 50% and 69% of vessel diameter. A 15.7% reduction in the 5-year ipsilateral stroke rate was seen in patients treated surgically versus 22.2% stroke reduction in those treated medically. These results are not as compelling as those for the higher degree of stenosis seen in the earlier NASCET trial. The benefit from surgery was greatest in men, patients with recent stroke, and those with hemispheric symptoms. In addition, the NASCET trials dealing with moderate carotid stenoses required rigorous surgical expertise, such that the risks for disabling stroke or death should not exceed 2% to achieve the statistical surgical benefit.[9] The **Asymptomatic Carotid Atherosclerosis Study** (ACAS) trials published in 1995 reported a reduction in ipsilateral stroke in asymptomatic patients with greater than 60% ICA stenoses who undergo CEA.[3] However, these results were less clear-cut than the NASCET trials. According to the Carotid Revascularization Endarterectomy Versus Stenting Trial (CREST), carotid artery stenting has been shown to be comparable to CEA with respect to rates of ipsilateral stroke and death. However, there are increased adverse effects in women and elevated stroke rates and deaths in older patients.[10] With implementation of new medical management regimens—including aspirin, clopidogrel, statins, antihypertensive medications, diabetic management, smoking cessation, and lifestyle changes—future trials may change how carotid disease is treated.[10]

Accurate diagnosis of carotid stenosis clearly is critical to identify patients who would benefit from surgical treatment. In addition, ultrasound can assess plaque morphology, such as determining heterogeneous or homogeneous plaque, known to be an independent risk factor for stroke and **transient ischemic attack** (TIA).

Carotid sonography is the principal screening method for suspected extracranial carotid atherosclerotic disease. Gray-scale examination, color Doppler, power Doppler, and pulsed Doppler imaging techniques are routinely employed in the evaluation of patients with neurologic symptoms and suspected extracranial cerebral disease.[11,12] Ultrasound is an inexpensive, noninvasive, and highly accurate method of diagnosing carotid stenosis. **Magnetic resonance angiography** (MRA) and computed tomography angiography (CTA) are additional noninvasive screening tools for the identification of carotid bifurcation disease as well as for clarification of ultrasound findings. **Angiography** is often now reserved for those patients for whom the ultrasound or MRA was equivocal or inadequate.

Other carotid ultrasound applications include the evaluation of carotid bruits, monitoring the progression of known atherosclerotic disease,[11,13,14] assessment during or after CEA or stent placement,[15] screening before major vascular surgery, and evaluation after the detection of retinal cholesterol emboli.[11] Also, **nonatherosclerotic carotid diseases** can be evaluated, including follow-up of carotid dissection,[16-21] examination of fibromuscular dysplasia or Takayasu arteritis,[22-24] assessment of malignant carotid artery invasion,[25,26] and workup of pulsatile neck masses and carotid body tumors.[27-29]

Indications for Carotid Ultrasound

- Evaluation of patients with hemispheric neurologic symptoms, including stroke, transient ischemic attack, and amaurosis fugax
- Evaluation of patients with a carotid bruit
- Evaluation of pulsatile neck masses
- Evaluation of patients scheduled for major cardiovascular surgical procedures
- Evaluation of nonhemispheric or unexplained neurologic symptoms
- Follow-up of patients with proven carotid disease
- Evaluation of patients after carotid revascularization, including stenting
- Intraoperative monitoring of vascular surgery
- Evaluation of suspected subclavian steal syndrome
- Evaluation of a potential source of retinal emboli
- Follow-up of carotid dissection
- Follow-up of radiation therapy to the neck in select patients

CAROTID ARTERY ANATOMY

The first major branch of the aortic arch is the innominate or brachiocephalic artery, which divides into the right subclavian artery and right **common carotid artery** (CCA). The second major branch is the left CCA, which is generally separate from the third major branch, the left subclavian artery (Fig. 26.1).

The right and left CCAs ascend into the neck posterolateral to the thyroid gland and lie deep to the jugular vein and sternocleidomastoid muscle. The CCAs have different proximal configurations, with the right originating at the bifurcation of the innominate (brachiocephalic) artery into the common carotid and subclavian arteries. The left CCA usually originates directly from the aortic arch but often arises with the brachiocephalic trunk. This is known as a **"bovine arch"** configuration. The CCA usually has no branches in its cervical region. Occasionally, however, it may give off the superior thyroid artery, vertebral artery, ascending pharyngeal artery, and occipital or inferior thyroid artery. At the carotid bifurcation, the CCA divides into the **external carotid artery** (ECA) and the **internal carotid artery** (ICA). The ICA usually has no branching vessels in the neck. The ECA, which supplies the facial musculature, has multiple branches in the neck. The ICA may demonstrate an ampullary region of mild dilation just beyond its origin.

CAROTID ULTRASOUND EXAMINATION

Carotid artery ultrasound examinations are performed with the patient supine, the neck slightly extended, and the head turned away from the side being examined. Some operators prefer to perform the examination at the patient's side, whereas others prefer to sit at the patient's head. The examination sequence also varies with operator preference. This sequence includes the gray-scale examination, Doppler spectral analysis, and color Doppler blood flow interrogations. Power Doppler sonography may or may not be employed. A 5- to 12-MHz transducer is used for gray-scale imaging and a 3- to 7-MHz transducer for Doppler sonography; the choice depends on the patient's body habitus and technical characteristics of the ultrasound machine. Color Doppler flow imaging and power Doppler imaging may be performed with 5- to 10-MHz transducers. In cases of critical stenosis, the Doppler parameters should be optimized to detect extremely slow flow.

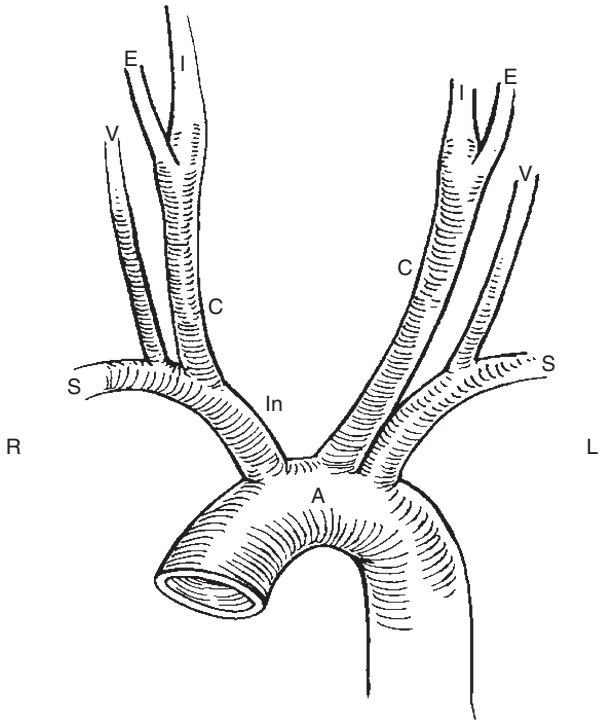

FIG. 26.1 Branches of Aortic Arch and Extracranial Cerebral Arteries. *A,* Aortic arch; *C,* common carotid artery; *E,* external carotid artery; *I,* internal carotid artery; *In,* innominate artery; *L,* left side; *R,* right side; *S,* subclavian artery; *V,* vertebral artery.

Gray-scale sonographic examination begins in the transverse projection. Scans are obtained along the entire course of the cervical carotid artery, from the supraclavicular notch cephalad to the angle of the mandible (Fig. 26.2). Inferior angulation of the transducer in the supraclavicular area images the CCA origin. The left CCA origin is deeper and more difficult to image consistently than the right. The **carotid bulb** is identified as a mild widening of the CCA near the bifurcation. Transverse views of the **carotid bifurcation** establish the orientation of the external and internal carotid arteries and help define the optimal longitudinal plane in which to perform Doppler spectral analysis (Video 26.1). When the transverse ultrasound images demonstrate occlusive atherosclerotic disease, the percentage of "diameter stenosis" or "area stenosis" can be calculated directly using electronic calipers and software analytic algorithms available on most duplex equipment.

After transverse imaging, longitudinal scans of the carotid artery are obtained. The examination plane necessary for optimal longitudinal scans is determined by the course of the vessels demonstrated on the transverse study. In some patients, the optimal longitudinal orientation will be nearly coronal, whereas in others it will be almost sagittal. In most cases, the optimal longitudinal scan plane will be oblique, between sagittal and coronal. In approximately 60% of patients, both vessels above the carotid bifurcation and the CCA can be imaged in the same plane (Fig. 26.3); in the remainder, only a single vessel will be imaged in the same plane as the CCA. Images are obtained to display the relationship of both branches of the carotid bifurcation to the visualized plaque disease, and the cephalocaudal extent

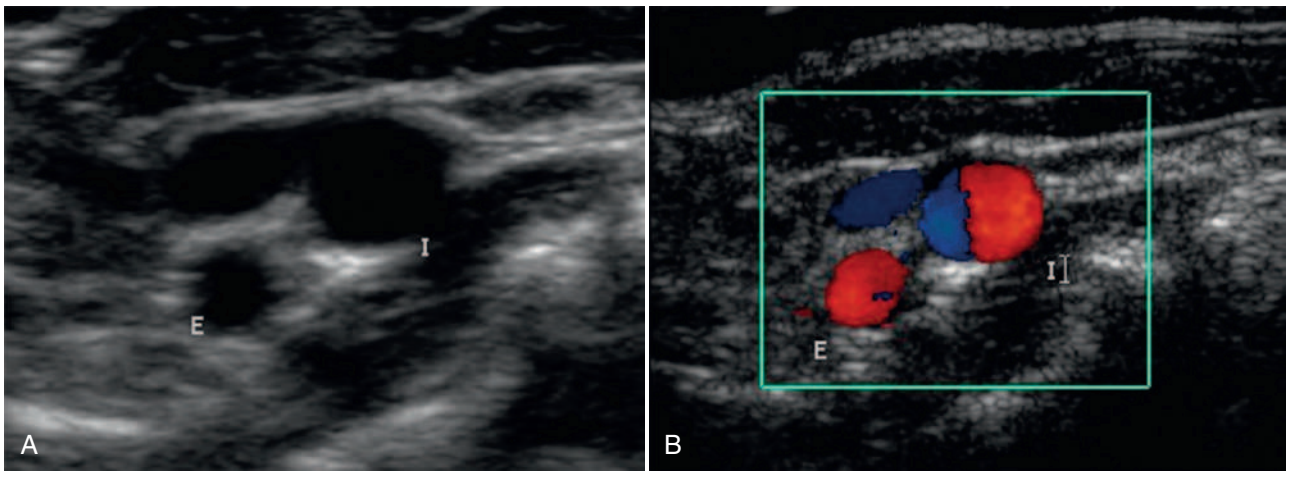

FIG. 26.2 Carotid Sonographic Anatomy. (A) Transverse image of the left internal carotid artery *(I)* and external carotid artery *(E).* The internal carotid artery is lateral and larger in relation to the external carotid artery. **(B)** Color Doppler image of the left internal carotid artery *(I)* and the external carotid artery *(E).* Note normal color-flow separation in the internal carotid artery.

of the plaque is measured. Several anatomic features differentiate the ICA from the ECA. In about 95% of patients, the ICA is posterior and lateral to the ECA. This may vary considerably, and the ICA may be medial to the ECA in 3% to 9% of people.[15] The ICA frequently has an ampullary region of dilation just beyond its origin and is usually larger than the ECA.

One reliable distinguishing feature of the ECA is that it has **branching vessels** (Fig. 26.4A). A useful method to identify the ECA is the tapping of the ipsilateral superficial temporal artery in the preauricular area, the **temporal tap.** The pulsations are transmitted back to the ECA where they cause a **sawtooth** appearance on the spectral waveform (Fig. 26.4B). Although the tap helps identify the ECA, this tap deflection may be transmitted into the CCA and even the ICA in certain rare situations.

The **superior thyroid artery** is often seen as the first branch of the ECA after the bifurcation of the CCA. Occasionally, an aberrant superior thyroid artery branch will arise from the distal CCA. The ICA usually has no branches in the neck, although in rare cases the ICA gives rise to the ascending pharyngeal, occipital, facial, laryngeal, or meningeal arteries. In some patients, a considerable amount of the ICA will be visible, but in others, only the immediate origin of the vessel will be accessible. Very rarely, the bifurcation may not be visible at all.[28] Rarely, the ICA may be hypoplastic or congenitally absent.[30,31]

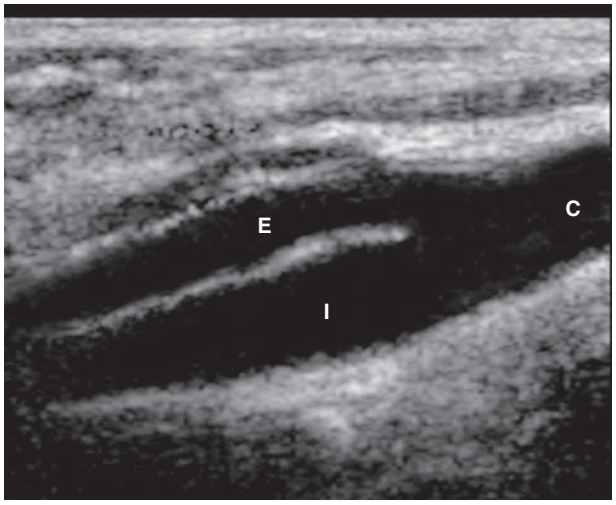

FIG. 26.3 Carotid Bifurcation. Longitudinal image demonstrates common carotid artery *(C);* external carotid artery *(E);* and large, posterior internal carotid artery *(I).*

CAROTID ULTRASOUND INTERPRETATION

Each facet of the carotid sonographic examination is valuable in the final determination of the presence and extent of disease. In most cases, the gray-scale, color Doppler, and power Doppler sonographic images and assessments will agree. However, when there are discrepancies between Doppler ultrasound imaging findings and measured velocities, every attempt should be made to discover the source of the disagreement. The more closely the image and spectral Doppler findings correlate, the higher the degree of confidence in the diagnosis. Generally, gray-scale and color or power Doppler images better demonstrate and quantify low-grade stenoses, whereas high-grade occlusive disease is more accurately defined by Doppler spectral analysis. For **plaque** characterization, assessment must be made in gray-scale only, without color or power Doppler ultrasound.

Visual Inspection of Gray-Scale Images

Vessel Wall Thickness and Intima-Media Thickening

Longitudinal views of the layers of the normal carotid wall demonstrate **two nearly parallel echogenic lines,** separated by a hypoechoic to anechoic region (Fig. 26.5). The first echo, bordering the vessel lumen, represents the lumen-intima interface; the second echo is caused by the media-adventitia interface. The media is the anechoic/hypoechoic zone between the echogenic lines. The distance between these lines represents the combined thickness of the **intima and media (I-M complex).** The far wall of the CCA is measured. Many consider measurement of

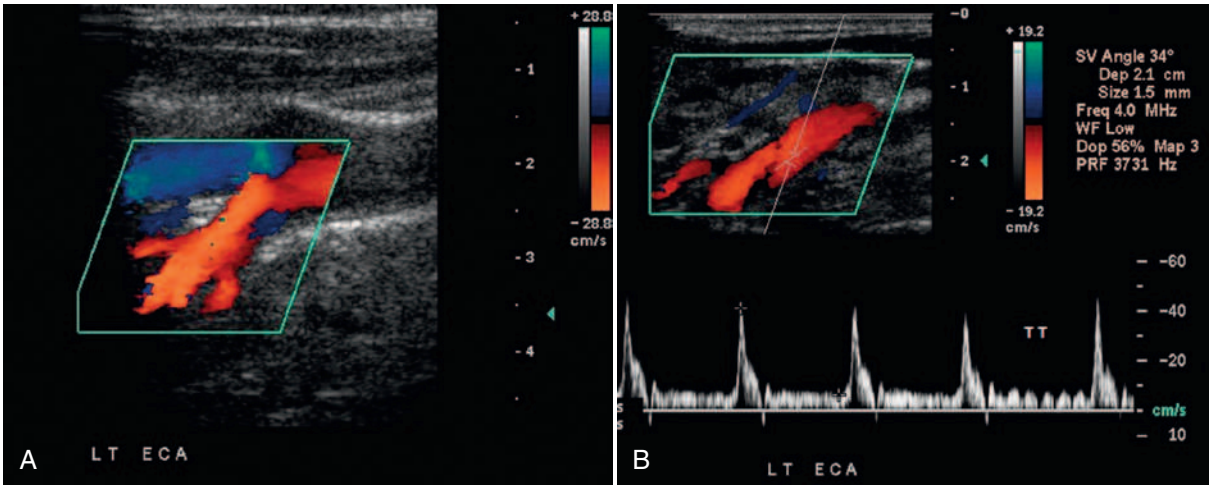

FIG. 26.4 Normal External Carotid Artery (ECA). (A) Color Doppler ultrasound of bifurcation demonstrates two small arteries originating from the ECA. **(B)** ECA spectral Doppler shows the reflected temporal tap *(TT)* as a serrated (sawtooth) flow disturbance.

intima-media thickness (IMT) to be a surrogate marker for atherosclerotic disease in the *whole* arterial system, not only the cerebrovascular system.[32,33] Some believe that thickening of the I-M complex greater than 0.8 mm is abnormal and may represent the earliest changes of atherosclerotic disease. However, because thickness of the I-M increases with age, absolute measurements of IMT for any given person may not be a reliable indicator of atherosclerotic risk factors[34] (Fig. 26.6).

Carotid artery IMT is an independent predictor of new cardiovascular events in persons without a history of cardiovascular disease.[35] Numerous studies support the relationship between IMT and increased risk for myocardial infarction or stroke in asymptomatic patient populations.[19,36-43] Assessment of IMT has been advocated as a means of assessing effectiveness of medical interventions to reduce the progression of I-M thickening or even reverse carotid wall thickening. However, because of concerns regarding minimal impact on prediction models and difficulty in standardizing measurement technique, the 2013 American College of Cardiology/American Heart Association (ACC/AHA) Guideline on the Assessment of Cardiovascular Risk does not recommend the carotid IMT test.[44]

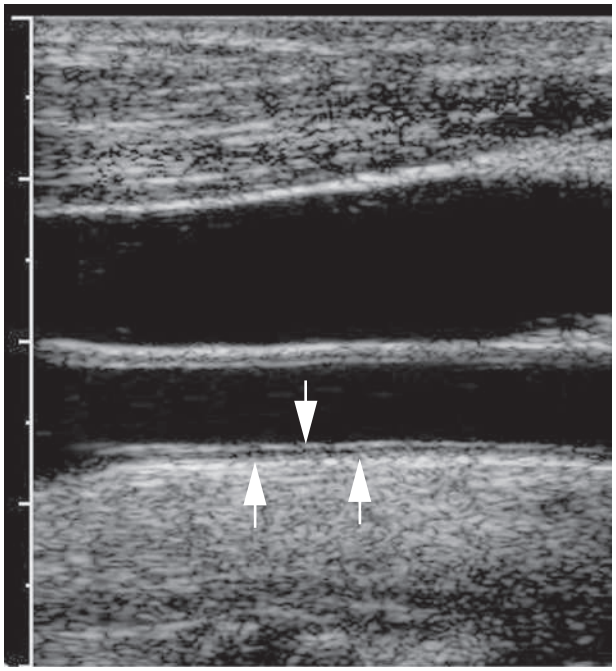

FIG. 26.5 Normal Intima-Media (I-M) Complex of Common Carotid Artery. The I-M complex *(arrows)* is seen in a left common carotid artery.

Plaque Characterization

Atheromatous carotid plaques should be carefully evaluated to determine plaque extent, location, surface contour, and texture, as well as to assess luminal stenosis.[45] The plaque should be scanned and evaluated in both the sagittal and the transverse projections.[46] The most common cause of TIAs is **embolism,** not flow-limiting stenosis; less than half of patients with documented TIA have hemodynamically significant stenosis. It is important to identify low-grade atherosclerotic lesions that may contain hemorrhage or ulceration, which can serve as a nidus for emboli that cause both TIAs and stroke.[1] Polak et al.[47] showed that plaque is an independent risk factor for developing a stroke. Of patients with hemispheric stroke symptoms, 50% to 70% demonstrate hemorrhagic or ulcerated plaque. Plaque analysis of CEA specimens has implicated intraplaque hemorrhage as an important factor in the development of neurologic symptoms.[48-55] However, the relationship between sonographic plaque morphology and the onset of symptoms is controversial.

Currently, substantial gaps in knowledge of the mechanisms involved in **atherosclerotic plaque rupture** exist and this is a critical barrier to developing methodologies for the prevention of myocardial infarction and stroke. Myocardial infarction and stroke, complications of atherosclerosis, are the most common causes of death in developed countries and are caused by inflammation-driven rupture of atherosclerotic plaques. Stable plaques are characterized by a necrotic core with an overlying fibrous cap composed of vascular smooth muscle cells in a

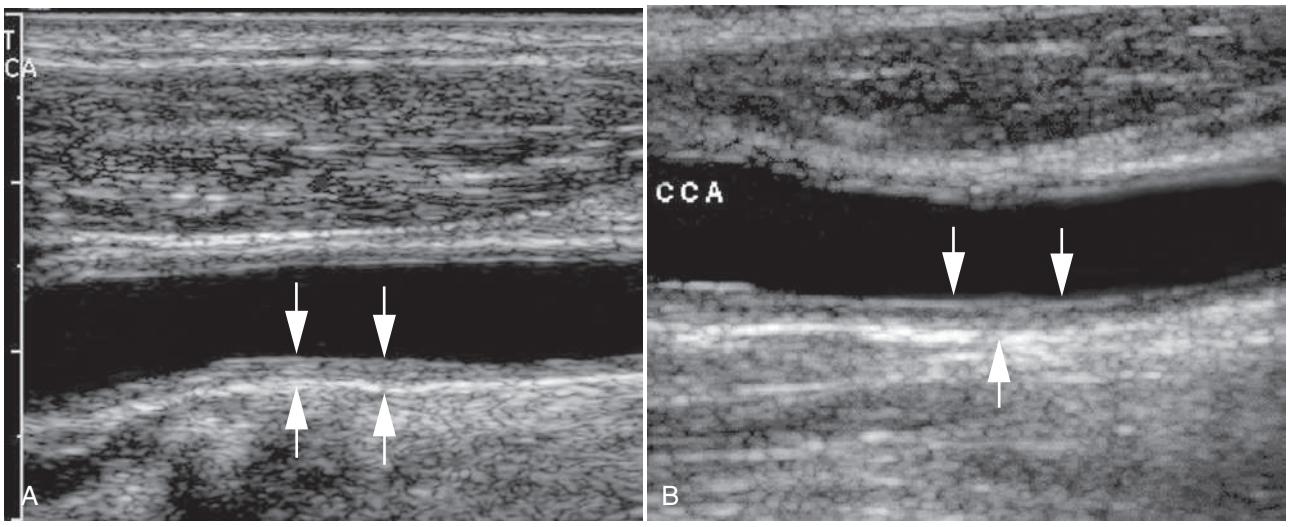

FIG. 26.6 Abnormal Intima-Media (I-M) Complex of Common Carotid Artery (CCA). (A) Early I-M hyperplasia with loss of the hypoechoic component of the I-M complex and thickening *(arrows).* **(B)** Thickening of the I-M complex with hyperplasia *(arrows).*

collagen-rich matrix.[56,57] In **vulnerable/ruptured plaques,** the fibrous cap has thinned, exhibiting fewer vascular smooth muscle cells, decreased collagen, and increased inflammatory cells.

Heterogeneous plaque has been suggested as unstable and vulnerable, in contrast to homogeneous plaque. Some have suggested that environmental factors and toxins cause abnormal flow patterns, damaging the internal structure of the vessels.[58] This can lead to intimal proliferation and potential wall ischemia and the degradation of the vasa vasorum.[58] Because the vasa vasorum do not have a muscular media, these vessels are subsequently at risk to rupture, perhaps leading, in part, to intraplaque hemorrhage.[58] Others have suggested that a bacterial infection etiology may play a role in inflammatory angiogenesis.[58]

Recently, several groups have demonstrated that microRNAs play a key role in the development and thinning of the **fibrous cap.**[59-69] **MicroRNAs** are a class of noncoding RNAs (ncRNAs) that are approximately 21 nucleotides in length and are potent effectors of gene expression, doing so by binding to messenger RNA and inhibiting protein translation. A role for ncRNA in cardiovascular diseases is emerging, including microRNAs (miRNAs) and their inhibition by circular RNA (circRNAs). MicroRNA-221 and microRNA-222 (miR-221/miR-222) are short ncRNAs that inhibit the expression of the cyclin-dependent kinase inhibitor $p27^{Kip1}$, promoting vascular smooth muscle cell proliferation and intimal thickening. Bazan et al. recently demonstrated an important role for the downregulation of miR-221/222 in the shoulder region of carotid plaques shortly after rupture[70] through increased $p27^{Kip1}$ and propose that vascular smooth muscle cell volume is lost, leading to intimal thinning.

Ultrasound Plaque Classification System

Plaque texture is generally classified as homogeneous or heterogeneous.[14,38,41,45,46,48-50,71-75] The accurate evaluation of plaque can only be made with gray-scale ultrasound, without the use of

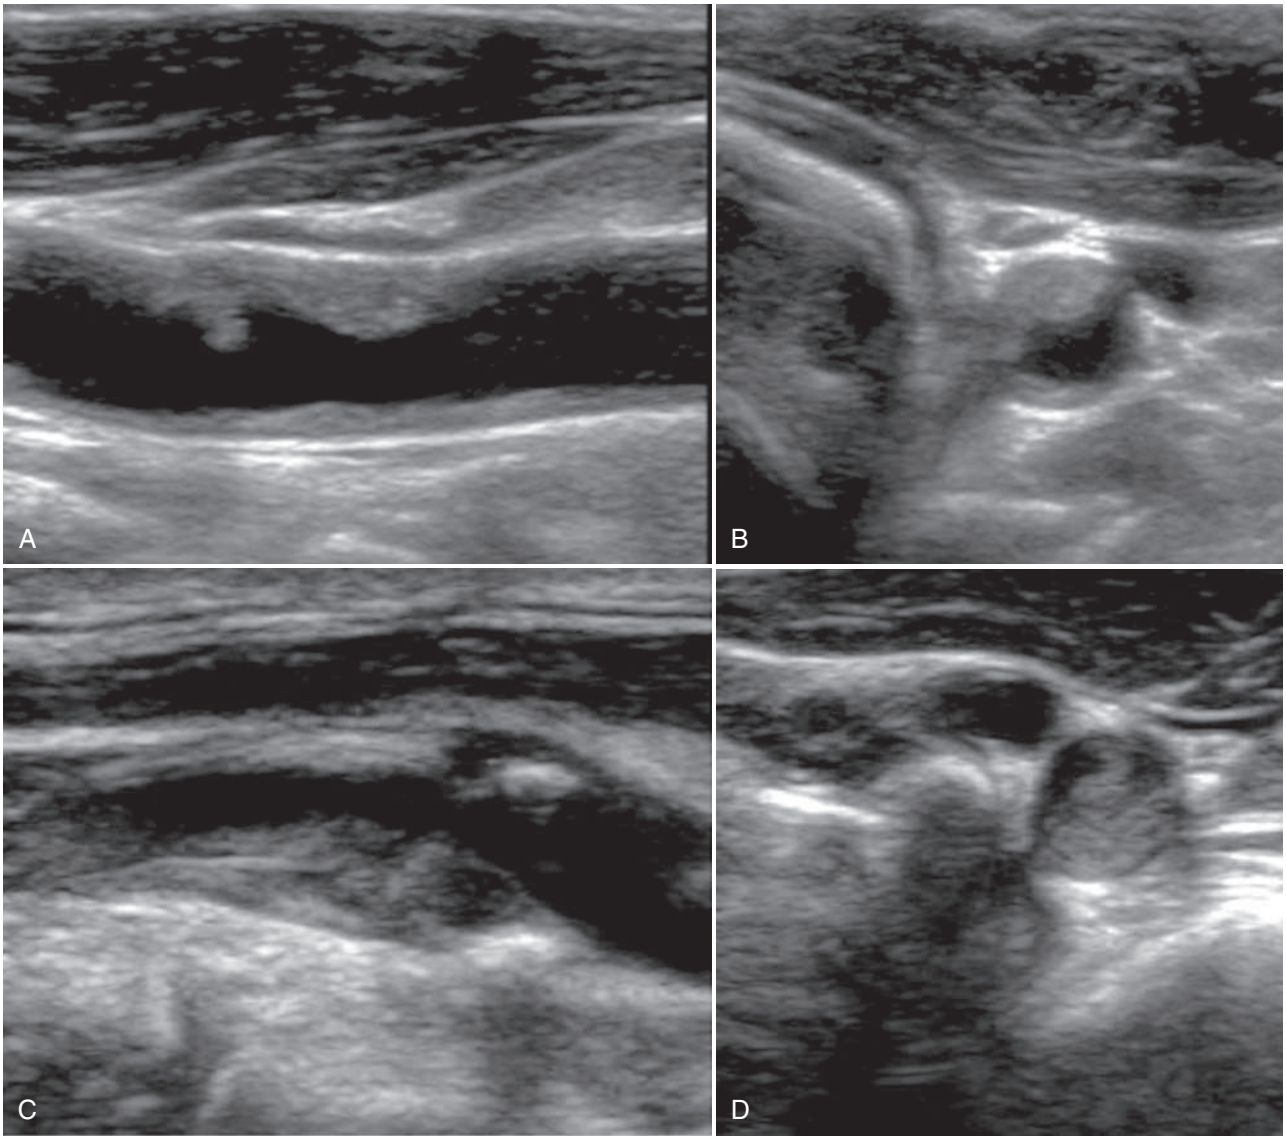

FIG. 26.7 Spectrum of Patterns of Homogeneous Plaque. (A) Sagittal and **(B)** transverse images show homogeneous plaque in left common carotid artery (type 4). Note the uniform echo texture. **(C)** Sagittal and **(D)** transverse images show homogeneous plaque in proximal left internal carotid artery (type 3). Note the focal hypoechoic area within the plaque, estimated at less than 50% of plaque volume.

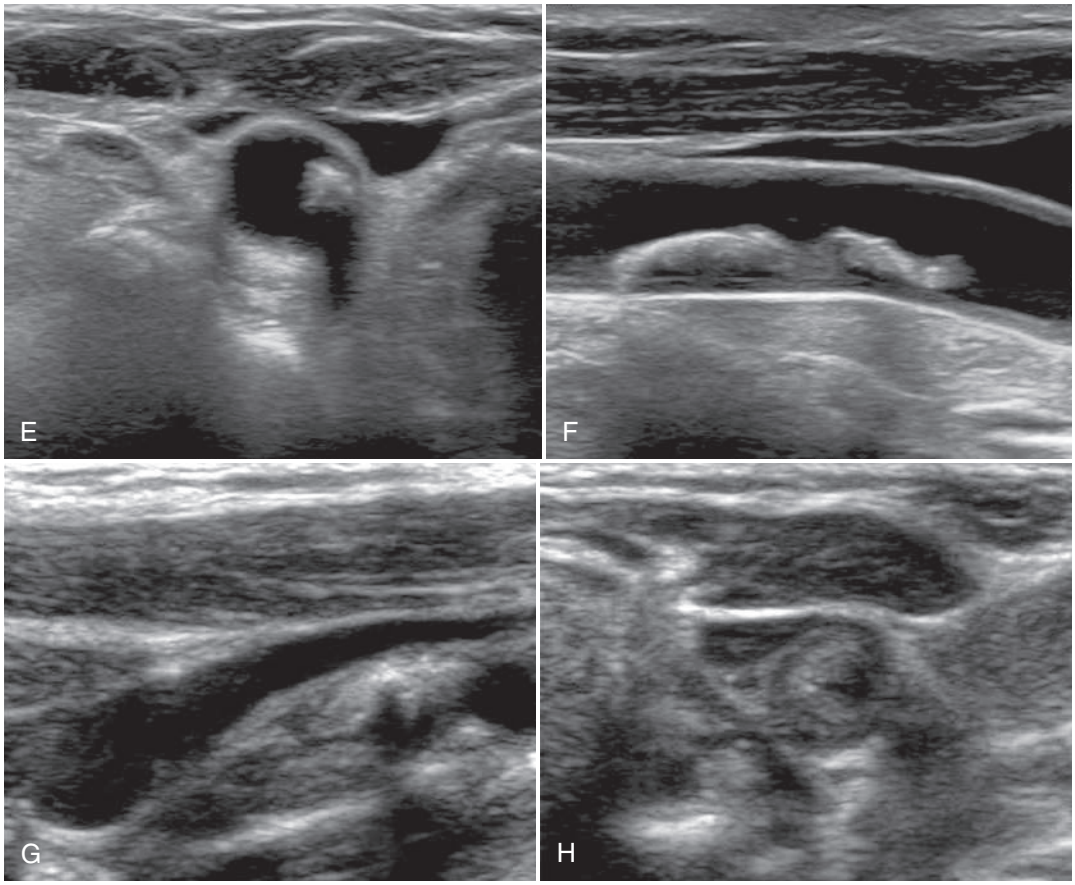

FIG. 26.7, cont'd **(E)** Sagittal and **(F)** transverse images demonstrate homogeneous plaque (type 3). Associated calcifications best seen on image E obscure uniformity of plaque. **(G)** Sagittal and **(H)** transverse images demonstrate homogeneous plaque (type 3) in the carotid bifurcation. The sonolucent areas are less than 50% of the volume of the plaque.

color or power Doppler. The plaque must be evaluated in both sagittal and transverse planes.[46] **Homogeneous plaque** has a generally uniform echo pattern and a smooth surface (Fig. 26.7). Sonolucent areas may be seen, but the amount of sonolucency is less than 50% of the plaque volume. The uniform acoustic texture corresponds pathologically to **dense fibrous connective tissue** (Videos 26.2 through 26.4). **Calcified plaque** produces posterior acoustic shadowing and is common in asymptomatic individuals (Fig. 26.8, Video 26.5). **Heterogeneous** plaque has a more complex echo pattern and contains one or more focal sonolucent areas corresponding to more than 50% of the plaque volume (Fig. 26.9, Videos 26.6 through 26.11). Heterogeneous plaque is characterized pathologically by containing **intraplaque hemorrhage** and deposits of lipid, cholesterol, and proteinaceous material.[15,73] Homogeneous plaque is identified much more often than heterogeneous plaque, occurring in 80% to 85% of patients examined.[47] Sonography accurately determines the presence or absence of intraplaque hemorrhage (sensitivity, 90%-94%; specificity, 75%-88%).[48,54,73,76-80]

Some sources suggest classifying plaque according to four types. Plaque **types 1 and 2,** similar to heterogeneous plaque and much more likely to be associated with intraplaque hemorrhage and ulceration, are considered unstable and subject to abrupt increases in plaque size after hemorrhage or embolization.[14,46,74,81-84] Types 1 and 2 plaque are typically found in symptomatic patients with stenoses greater than 70% of diameter. Plaque **types 3 and 4** are generally composed of fibrous tissue and calcification. These plaque types are similar to homogeneous plaque. These are generally more benign, stable plaques typically seen in asymptomatic individuals (see Fig. 26.8).

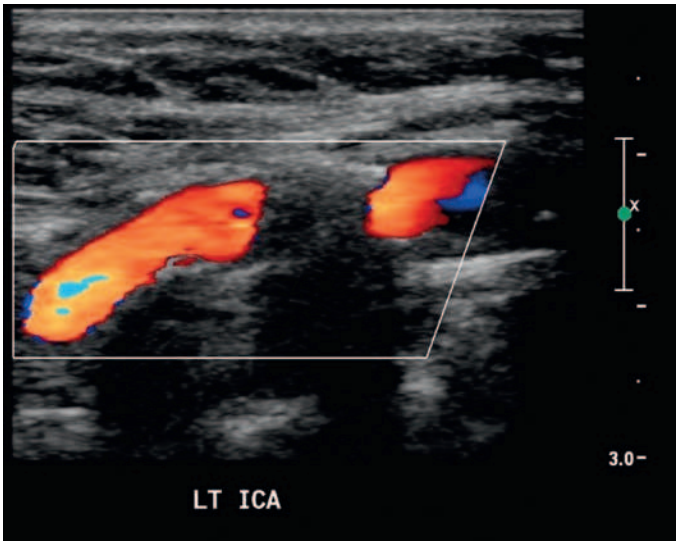

FIG. 26.8 Calcified Plaque. The calcified plaque creates a shadow that obscures characterization of plaque in the left internal carotid artery.

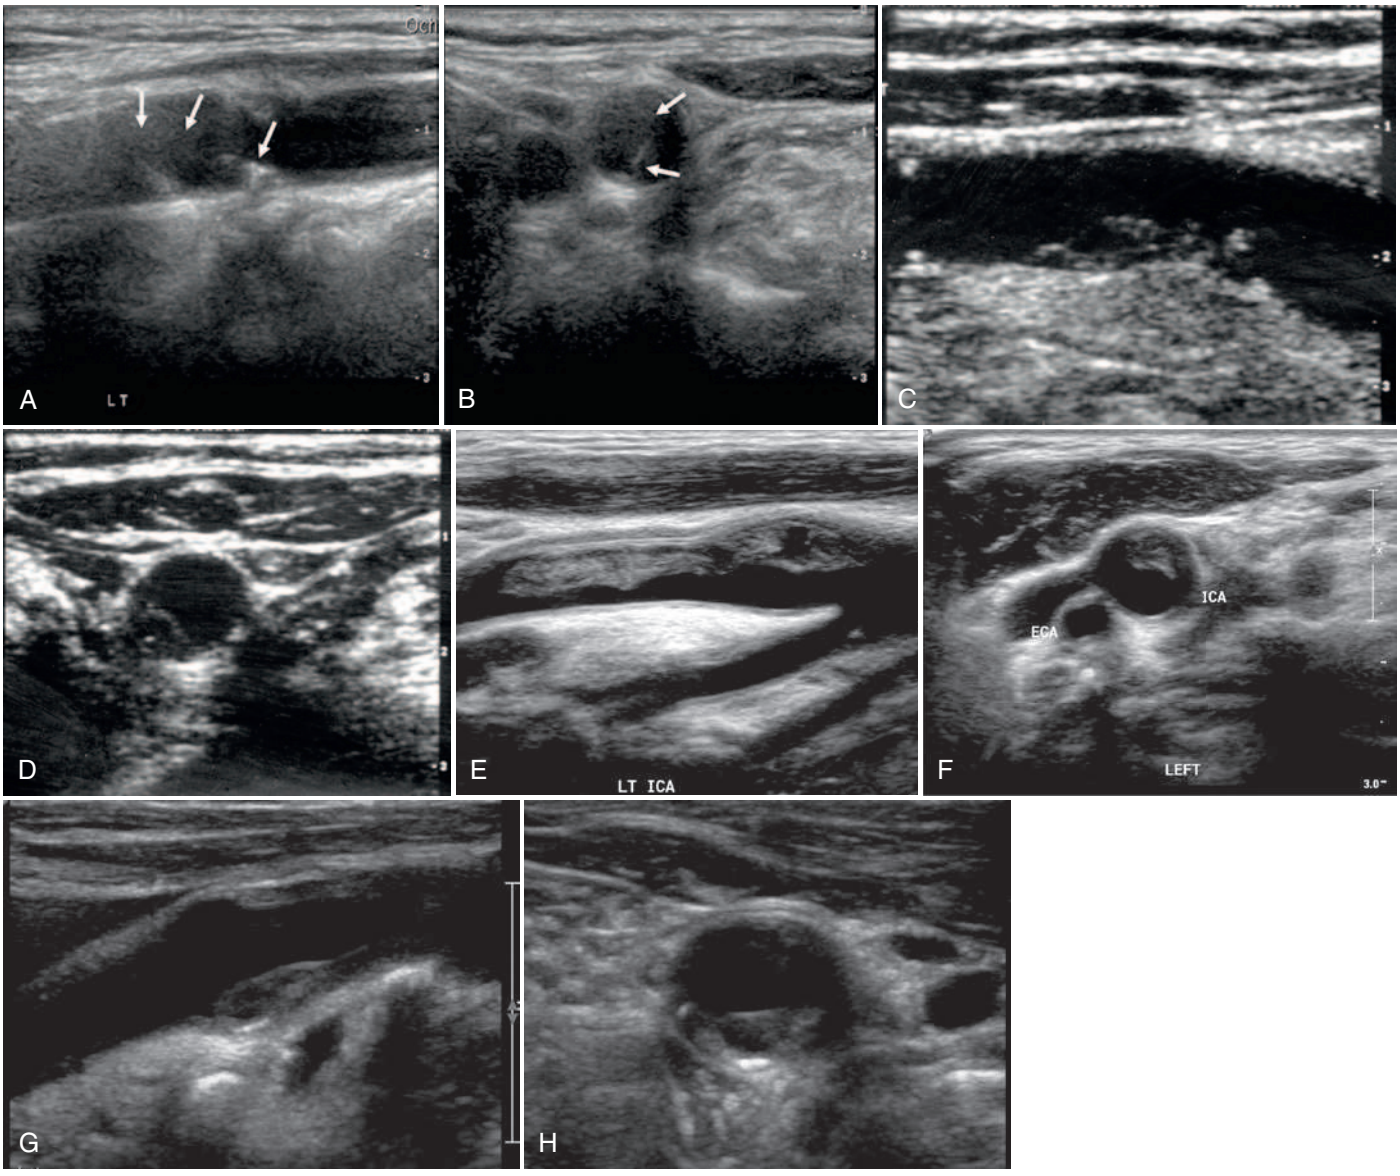

FIG. 26.9 Spectrum of Patterns of Heterogeneous Plaque in the Internal Carotid Artery (ICA). (A) Sagittal and **(B)** transverse images show plaque *(arrows)* virtually completely sonolucent, consistent with heterogeneous plaque (type 1). Note smooth plaque surface. **(C)** Sagittal and **(D)** transverse images show focal sonolucent areas within the plaque greater than 50% of plaque volume, corresponding to heterogeneous plaque (type 2). Note the irregular surface of the plaque. **(E)** Sagittal image demonstrates heterogeneous plaque in the carotid bulb and homogeneous plaque in the internal carotid artery (type 2). **(F)** Transverse image demonstrates heterogeneous plaque (type 2). **(G)** and **(H)** Sagittal and transverse images demonstrate subtle heterogeneous plaque (type 2).

Ultrasound Types of Plaque Morphology

Type 1: Predominantly echolucent, with a thin echogenic cap
Type 2: Substantially echolucent with small areas of echogenicity (>50% sonolucent)
Type 3: Predominantly echogenic with small areas of echolucency (<50% sonolucent)
Type 4: Uniformly echogenic

Other methods are being introduced to characterize plaque in a more automated and reproducible manner. Reiter et al.[85] developed a **gray-scale median level** for echolucency of plaque after standardizing and adjusting the B-mode images. They obtained standardized gray-scale median levels for asymptomatic patients with greater than 30% stenosis and found that decreasing echolucency of carotid plaques over 6 to 9 months is predictive of major cardiovascular events affecting coronary, peripheral, and cerebrovascular circulation. However, absolute gray-scale median levels were not associated with a specific risk.[85]

Plaque Ulceration

Sonography has a low sensitivity (38%) and high specificity (92%) for plaque ulceration.[86] However, when identified, all ulcerated plaques fit into the heterogeneous plaque pattern.[46,81,87,88] Sonographic findings that suggest **plaque ulceration** include a focal depression or break in the plaque surface, causing an irregular surface or an anechoic area within the plaque that extends to the plaque surface without an intervening echo between the vessel lumen and the anechoic plaque region. Color and power Doppler ultrasound may improve sonographic identification of plaque ulceration.[88] Color or power Doppler ultrasound or B-flow imaging (a proprietary non-Doppler imaging technique) may demonstrate slow-moving eddies of color within an anechoic region in plaque, which would suggest ulceration[78,88] (Fig. 26.10). The demonstration of these flow vortices was 94% accurate in predicting ulcerative plaque at surgery in one study.[89] Contrast-enhanced ultrasound represents a promising tool in the characterization of vulnerable carotid plaque with improved detection of intraplaque vascularization and ulceration.[90-92]

Ultrasound Features Suggestive of Plaque Ulceration

Focal depression or break in plaque surface
Anechoic region within plaque extending to vessel lumen
Eddies of color within plaque

A potential pitfall in the diagnosis of plaque ulceration results from a mirror-image artifact producing **pseudoulceration** of the carotid artery. Highly reflective plaque can produce a color Doppler ghost artifact simulating ulceration. However, the region of color within the plaque can be recognized as artifactual because the spectral waveform and color shading within the pseudoulceration are of lower amplitude, but otherwise identical to those within the true carotid lumen.[93] Conversely, pulsed Doppler traces from within **ulcer craters** show low-velocity dampened waveforms (Fig. 26.11).

Although the diagnosis of ulceration varies, the ability to predict intraplaque hemorrhage reliably, with its associated clinical implications, underscores the importance of ultrasound plaque characterization. The presence of heterogeneous, irregular plaque should be noted because of the association of heterogeneous plaque, and intraplaque hemorrhage even in a stenosis of less than 50% may warrant medical therapy. Many now consider heterogeneous plaque to be the "vulnerable," unstable form of plaque that should be treated differently than the more stable homogeneous form of plaque.[94] Plaque characterization should be considered when determining the type of therapy to use in carotid intervention. Angioplasty and subsequent stenting of carotid vessels might be safer if performed in patients with homogeneous plaque than those with heterogeneous plaque.[94]

Gray-Scale Evaluation of Stenosis

Measurements of carotid diameter and area stenosis should be made in the transverse plane, perpendicular to the long axis of the vessel, using gray-scale, B-flow, or power Doppler sonographic imaging[45] (Fig. 26.12, Videos 26.12 and 26.13). Measurements made on longitudinal scans may overestimate or underestimate the severity of stenosis by partial "voluming" through an eccentric plaque. The percentage of diameter stenosis and the percentage of area stenosis are not always linearly related. Clinical records should state the type of stenosis measured. Asymmetrical stenoses are most appropriately assessed with "percentage of area stenosis" measurements,[45] although these are often time consuming and technically difficult. The cephalocaudal extent and length of plaques should be noted, along with the presence of **tandem plaques.** Recently, three-dimensional ultrasound has been used

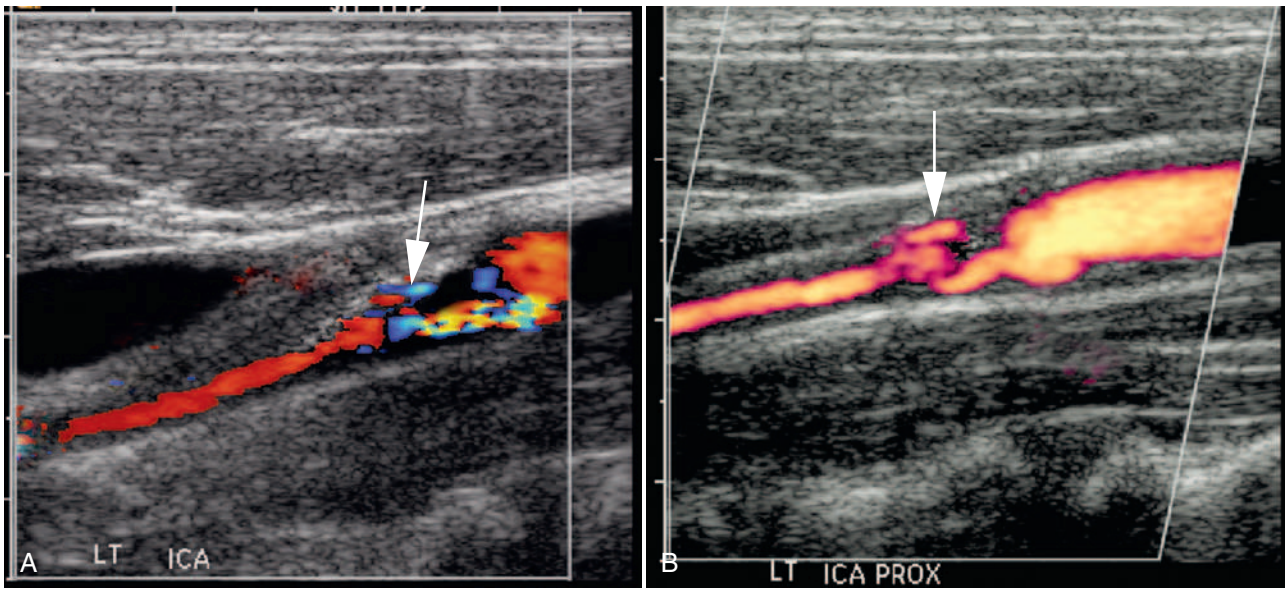

FIG. 26.10 Plaque Ulceration. (A) Color Doppler and **(B)** power Doppler longitudinal images show blood flow *(arrow)* into hypoechoic ulcerated plaque.

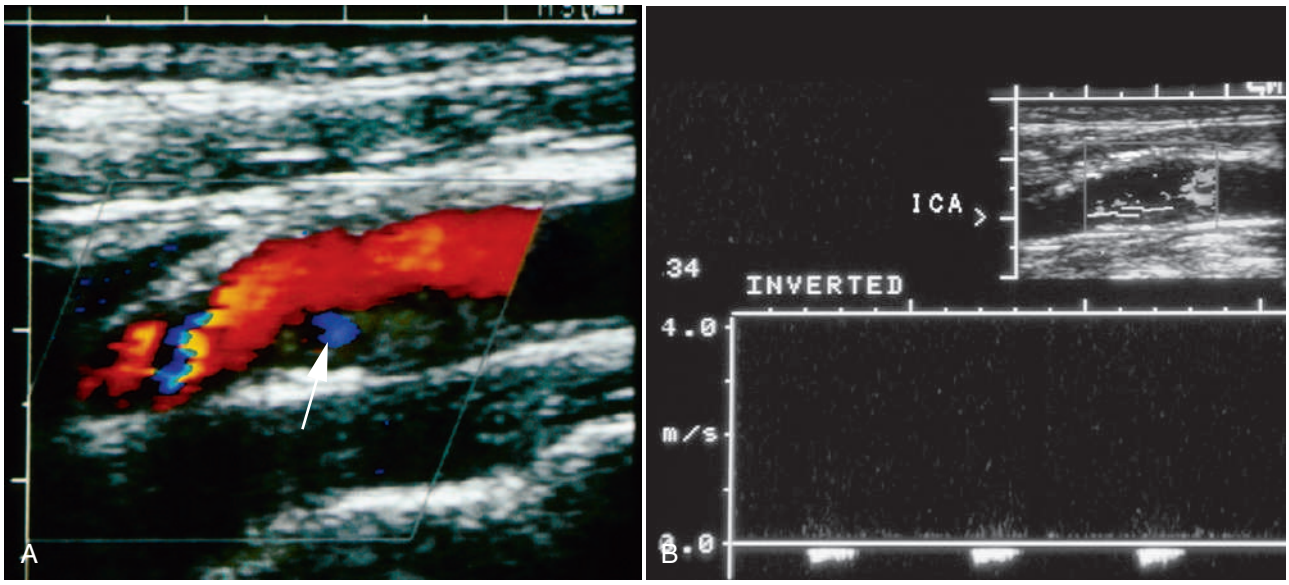

FIG. 26.11 Plaque Ulceration and Abnormal Flow. (A) Longitudinal image of the proximal right internal carotid artery (ICA) demonstrates heterogeneous plaque with an associated area of reversed low-velocity eddy flow within an ulcer *(arrow)*. **(B)** Pulsed Doppler waveforms in this ulcer crater demonstrate the extremely dampened low-velocity reversed flow, not characteristic of that seen within the main vessel lumen of the ICA.

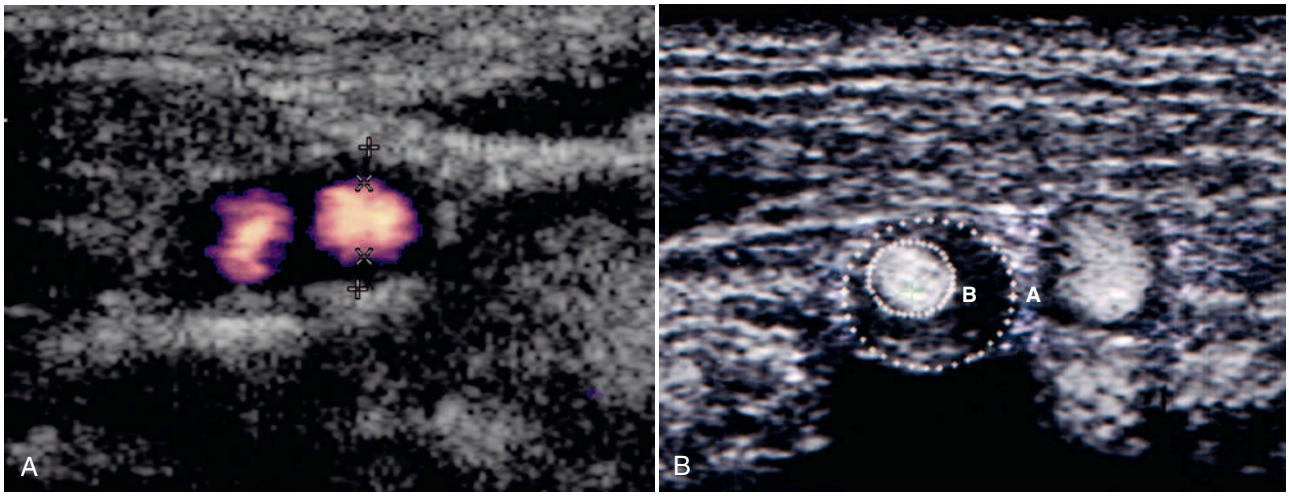

FIG. 26.12 Measurement of Carotid Artery Diameter. (A) Power Doppler transverse image shows a less than 50% diameter stenosis *(cursors)*. **(B)** Transverse B-mode flow image of the right carotid bifurcation shows measurement of stenosis *(B)* in area of internal carotid artery (ICA). *A,* Outer ICA area.

to measure plaque volume with good intraobserver and interobserver variability as well as plaque characterization.[95,96]

As the severity of a stenosis increases, the quality of the real-time image deteriorates.[93,97] Several factors work against successful image assessment of high-grade stenosis. Plaque calcification and irregularity produce shadowing, which obscures the vessel lumen. Heterogeneous plaque often has acoustic properties similar to flowing blood, producing anechoic plaques or thrombi that are difficult to visualize on gray-scale images. In the most extreme cases, vessels can show little visible plaque yet be totally occluded (see Fig. 26.9E and F). Color Doppler sonography readily identifies such phenomena. For these reasons, real-time gray-scale ultrasound is best suited for the evaluation of nonrate-limiting lesions and not for quantifying high-grade stenoses, which are more accurately determined by spectral analysis.[98,99] The gray-scale findings and Doppler spectral analysis values must be integrated and correlated for a complete ultrasound assessment of the carotid vessels (Video 26.14).

It is probably unnecessary to make a quantitative assessment of the amount of plaque. Rather, a **qualitative** assessment of the amount of plaque should be made and compared to the Doppler spectral findings to ensure accuracy in grading stenoses. A mismatch between the qualitative assessment of the amount of plaque and the Doppler findings should alert the examiner to a possible technical error. If these cannot be resolved, further assessment with CTA or MRA should be considered.

Doppler Spectral Analysis

The **Doppler spectrum** is a quantitative graphic display of the velocities and directions of moving red blood cells (RBCs) present in the Doppler sample volume. The Doppler spectral display represents velocities on the *y* axis and time on the *x* axis. By convention, flow toward the transducer is displayed above the zero-velocity baseline, and flow away from the transducer is below. For ease of analysis, spectra that project below the baseline are often inverted and placed above the baseline, always keeping in mind the true direction of flow within the vessel. The amplitude of each velocity component (number of RBCs with each velocity component) is used to modulate the brightness of the traces. This is also known as a **gray-scale velocity plot.** In the normal carotid artery, the frequency spectrum is narrow in systole and somewhat wider in early and late diastole (Videos 26.15 through 26.18). There is usually a black zone between the spectral line and the zero-velocity baseline called the **spectral window**[100,101] (Fig. 26.13).

The ICA and ECA branches of the CCA have distinctive spectral waveforms (Fig. 26.14). The **external carotid artery** supplies the high-resistance vascular bed of the facial musculature, so its flow resembles that of other peripheral arterial vessels. Flow velocity rises sharply during systole and falls rapidly during diastole, approaching zero or transiently reversing direction. The **internal carotid artery** supplies the low-resistance circulation of the brain and demonstrates flow similar to that in vessels supplying other blood-hungry organs, such as the liver, kidneys, and placenta. The common feature in all low-resistance arterial waveforms is that a large quantity of forward flow continues

FIG. 26.13 Normal Internal Carotid Artery (ICA) Waveform. Normal low resistive ICA waveform with clear spectral window indicating the absence of spectral broadening.

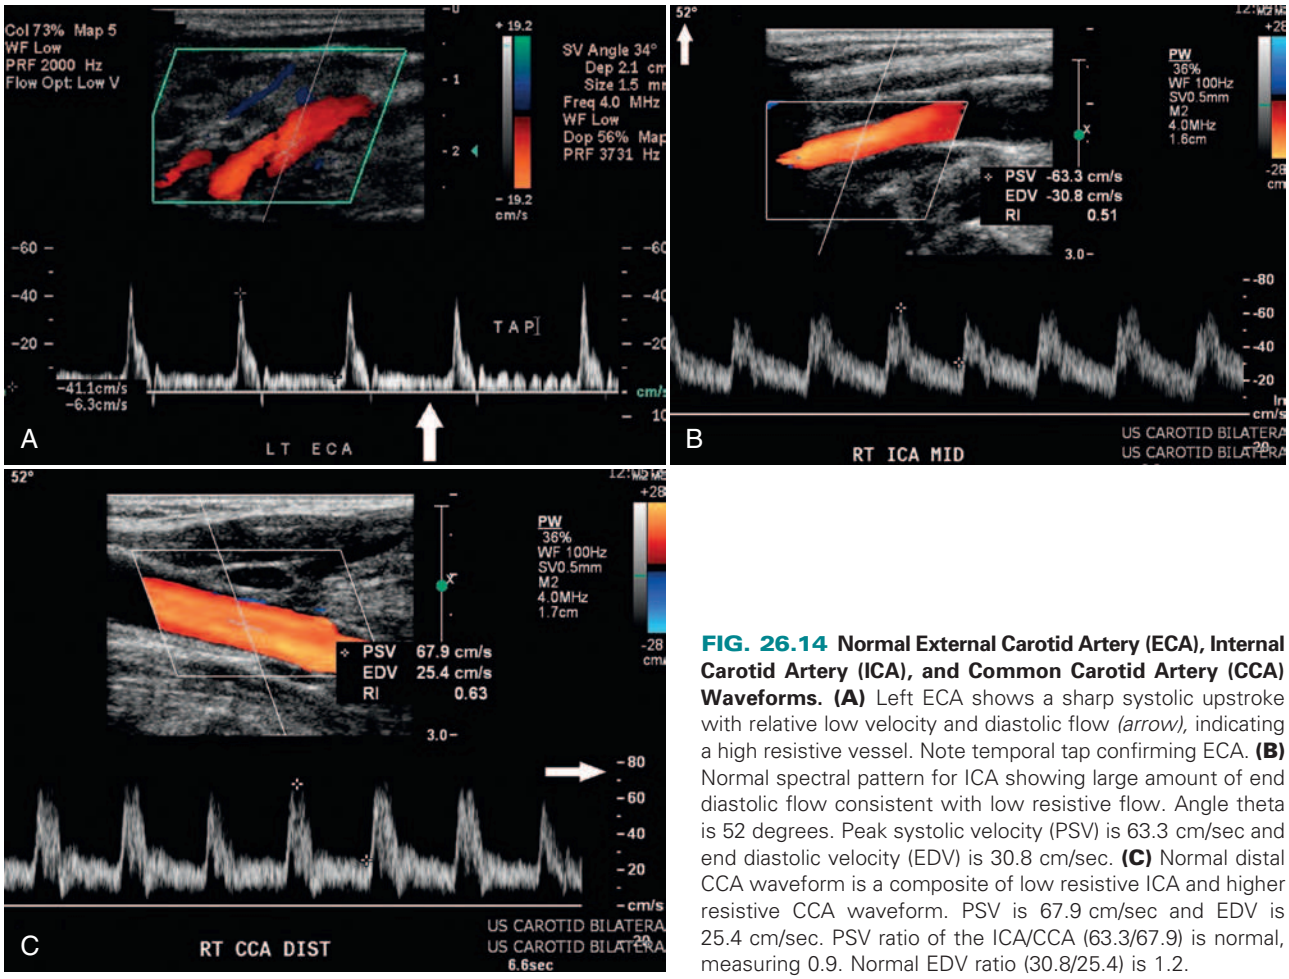

FIG. 26.14 Normal External Carotid Artery (ECA), Internal Carotid Artery (ICA), and Common Carotid Artery (CCA) Waveforms. (A) Left ECA shows a sharp systolic upstroke with relative low velocity and diastolic flow *(arrow),* indicating a high resistive vessel. Note temporal tap confirming ECA. **(B)** Normal spectral pattern for ICA showing large amount of end diastolic flow consistent with low resistive flow. Angle theta is 52 degrees. Peak systolic velocity (PSV) is 63.3 cm/sec and end diastolic velocity (EDV) is 30.8 cm/sec. **(C)** Normal distal CCA waveform is a composite of low resistive ICA and higher resistive CCA waveform. PSV is 67.9 cm/sec and EDV is 25.4 cm/sec. PSV ratio of the ICA/CCA (63.3/67.9) is normal, measuring 0.9. Normal EDV ratio (30.8/25.4) is 1.2.

throughout diastole (see Videos 26. through 26.17). The CCA waveform is a composite of the internal and external waveforms, but most often the CCA flow pattern more closely resembles that of the ICA, and diastolic flow is generally above the baseline (see Video 26.18). Approximately 80% of the blood flowing from the CCA goes through the ICA into the brain, whereas 20% goes through the ECA into the head musculature. The relative decrease in blood flow through the ECA will cause it to have a generally lower amplitude gray-scale waveform than in either the ICA or the CCA.[15]

Standard Examination

Virtually all state-of-the-art ultrasound equipment offers color and power Doppler, as well as gray-scale capabilities and pulsed Doppler, for the carotid examination (Video 26.19). A rapid color Doppler screen allows the detection of abnormal flow patterns, which allows the pulsed Doppler signal volume to be placed in areas that are abnormal, especially those with **high-velocity jets** (Video 26.20). These high-velocity jets are located in the region of and immediately distal to a high-grade stenosis (Figs. 26.15 and 26.16). In cases where both gray-scale and color and power Doppler images of an entire carotid artery are normal, only representative spectral tracings from the CCA, ICA, and ECA are necessary to complete the examination.

The standard Doppler spectral examination consists of traces obtained from the proximal and distal CCA, carotid bulb, and proximal ECA; samples in the proximal, middle, and distal ICA; and a representative trace from the vertebral artery. Normal velocities are higher in the proximal CCA and lower in the distal vessel; normal ICA velocities tend to increase from proximal to distal. In addition, blood flow velocities are obtained immediately proximal to, at, and just beyond regions of maximal visible stenosis and at 1-cm intervals distal to the visualized plaque as far cephalad as possible. Positioning the Doppler angle cursor parallel to the vessel walls determines angle theta, used to convert frequency information into velocity values (see Fig. 26.14B). **Doppler angle theta** is defined as the angle between the Doppler transducer line of sight and the direction of blood flow. The ideal angle theta is 0 degrees, as the cosine of this angle is 1, thus resulting in the greatest possible detectable frequency shift. Because this angle is rarely achievable in the clinical setting, angles from 30 to 60 degrees are considered acceptable for carotid spectral analysis.

Certain schools of ultrasound use a technique in which the Doppler angle is set at 60% and the transducer is "heel and toed" to parallel the carotid artery for Doppler spectral analysis. In our experience, it is frequently not possible to optimize cursor placement in the midportion of the vessel using this technique in tortuous vessels. Therefore our technique involves selecting the site of spectral analysis and paralleling the wall of the vessel at that point, making certain that the Doppler angle does not exceed 60 degrees. Although either technique can be used, results obtained using these different methodologies can result in different velocities. Thus if the first technique is used, a different set of velocity criteria should be expected than if the second is used. This is one of the factors responsible for the differences in velocity spectral criteria used in different laboratories (Fig. 26.16). When angle theta exceeds 60 to 70 degrees, the accuracy of velocity measurement declines precipitously (Fig. 26.17), to the point that virtually no velocity change is detected at angle theta of 90 degrees. The entire course of the CCA and ICA should be

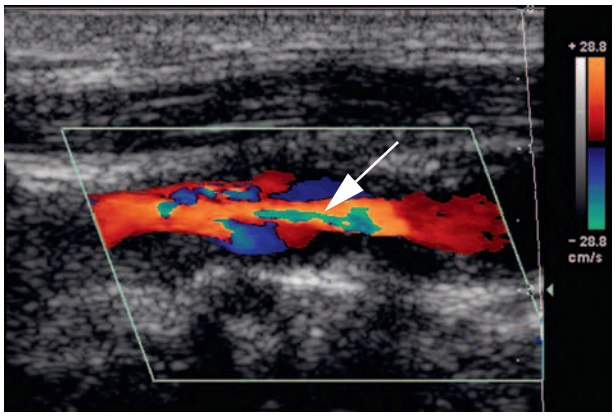

FIG. 26.15 Color Doppler Jet. High-velocity jet *(arrow)* or aliasing color demonstrates the area of highest velocity in the area of stenosis.

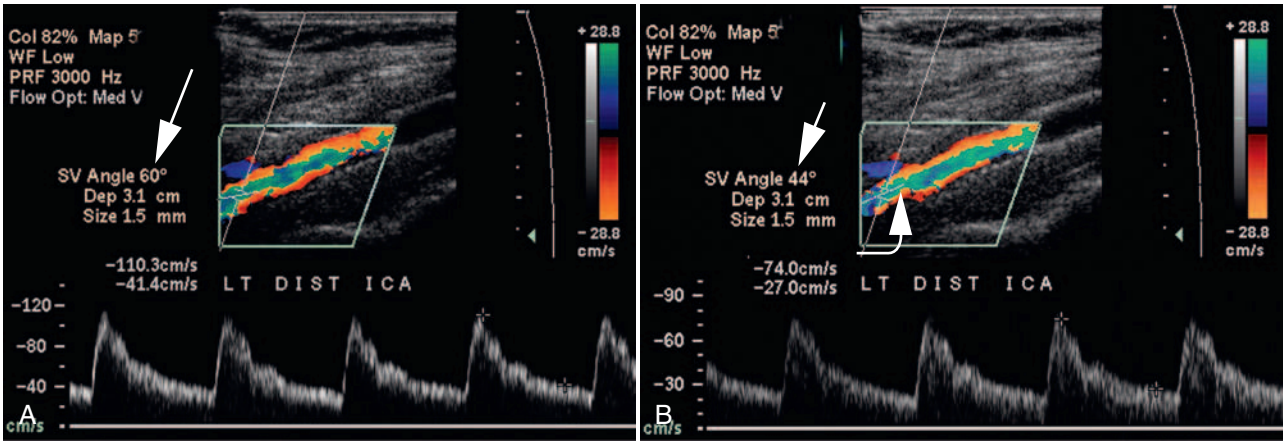

FIG. 26.16 Doppler Angle Theta Measurement. (A) Velocity obtained in the distal internal carotid artery with angle theta of 60 degrees is higher than that obtained at 44 degrees *(arrow)*. **(B)** However, the sample angle does not parallel the vessel wall at 60 degrees. Note central color aliasing in the region of highest velocity *(curved arrow)*.

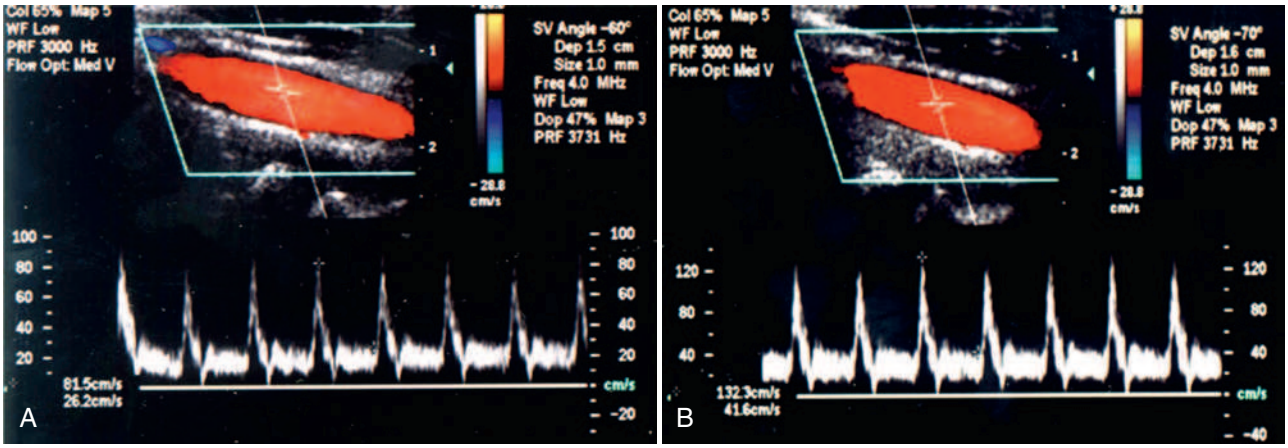

FIG. 26.17 Incorrect Doppler Angle Theta. Velocity obtained in the internal carotid artery (ICA) with angle theta of 60 degrees **(A)** is less accurate than the velocity obtained from the same area of the same ICA with an angle theta of 70 degrees **(B)**.

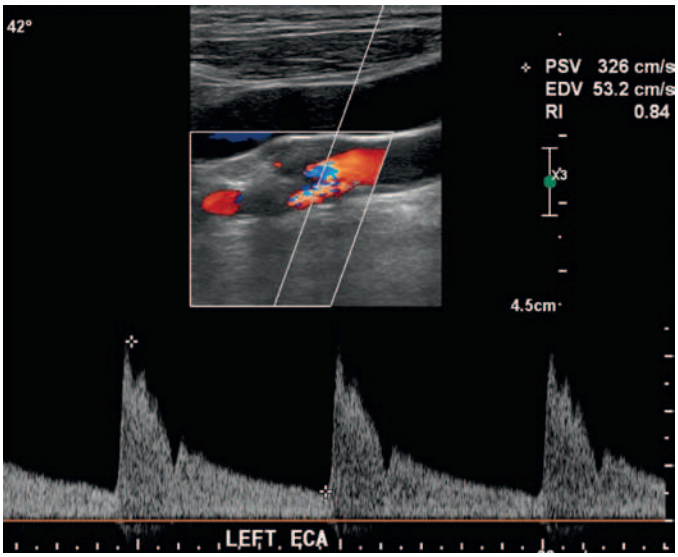

FIG. 26.18 High-Grade External Carotid Artery (ECA) Stenosis. Elevated velocities and visible narrowing. Spectral broadening is present. Color Doppler spectral broadening is also seen.

interrogated with a **consistent angle theta** between the transducer and the vessel maintained throughout the examination, when possible. Generally, only the origin of the ECA is evaluated because occlusive plaque is less common here than in the ICA and is rarely clinically important. A stenosis of the ECA should be noted because it may account for a worrisome cervical bruit when the ICA is normal.[30]

Spectral Broadening

Atheromatous plaque projecting into the arterial lumen disturbs the normal, smooth laminar flow of erythrocytes. The RBCs move with a wider range of velocities, so the spectral line becomes wider, filling in the normally black spectral window. This phenomenon, termed *spectral broadening,* increases in proportion to the severity of carotid artery stenosis[102-104] (Fig. 26.18, Video 26.21). Some duplex machines allow the operator to measure the spectral spread between the maximal and minimal velocities (bandwidth) and thus quantitate spectral broadening. The validity of these measurements remains unproved, however, and further correlative studies are needed to document the relationship of quantitative spectral broadening parameters to specific degrees of stenosis.[104] Most tables no longer include a measurement for spectral broadening when grading carotid stenosis. Nevertheless, a visible gestalt of the amount of spectral window obliteration, as well as color Doppler heterogeneity, provides a useful, if not quantitative, predictor of the severity of flow disturbance.

Pitfalls in Interpretation

Pseudospectral broadening can be caused by technical factors, such as too high a gain setting. In such cases the background around the spectral waveform often contains noise. Whenever spectral broadening is suspected, the gain should be lowered to see if the spectral window clears. Similarly, spectral broadening caused by vessel wall motion can occur when the Doppler sample volume is too large or positioned too near the vessel wall. Decreasing the size of the sample volume and placing it midstream should eliminate this potential pitfall.

Altered flow patterns can normally be found at certain sites in the carotid system. For example, it is normal to find flow separation at the site of branching vessels, such as where the CCA branches into the ECA and ICA.[105] Flow disturbances also occur at sites where there is an abrupt change in the vessel diameter. For example, flow disturbances and bizarre waveforms caused by **flow separation** may be encountered in a normal carotid bulb where the CCA terminates in a localized area of dilation as it divides into the ECA and ICA[15] (Fig. 26.19).

The tendency for spectral broadening increases in direct proportion to the velocity of blood flow. For example, spectral broadening can be observed in a normal ECA, vertebral arteries, and CCA supplying circulation contralateral to an occluded contralateral ICA. Increased velocity may also account for the disturbed flow that is sometimes observed in the normal extracranial carotid arteries of young athletes with normal cardiac outputs or in patients in pathologically high cardiac output states. It is also seen in arteries supplying **arteriovenous fistulas and malformations.**[15,106,107] Postoperative spectral broadening

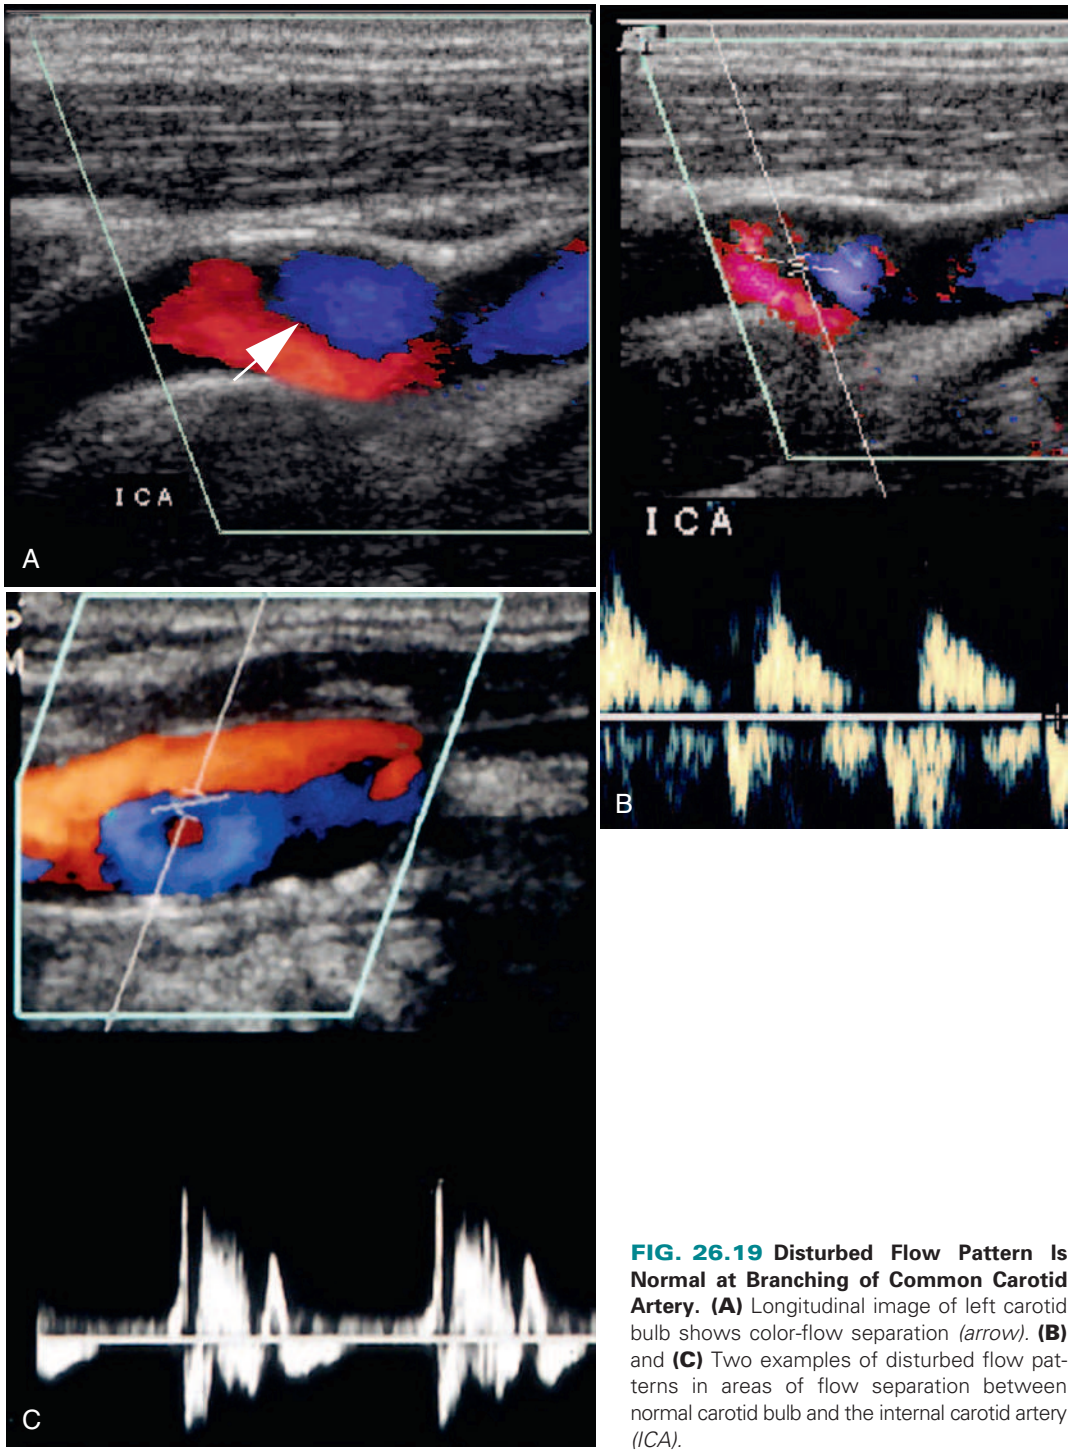

FIG. 26.19 Disturbed Flow Pattern Is Normal at Branching of Common Carotid Artery. (A) Longitudinal image of left carotid bulb shows color-flow separation *(arrow)*. **(B)** and **(C)** Two examples of disturbed flow patterns in areas of flow separation between normal carotid bulb and the internal carotid artery *(ICA)*.

may persist for months after CEA in the absence of significant residual or recurrent disease, possibly from changes in wall compliance.

Tortuous carotid vessels can demonstrate spectral broadening and asymmetrical high-velocity flow jets in the absence of plaque disease. Other nonatheromatous causes of disturbed blood flow in the extracranial carotid arteries include **aneurysms, arterial wall dissections,** and **fibromuscular dysplasia.**

High-Velocity Blood Flow Patterns

Carotid stenoses usually begin to cause velocity changes when they exceed 50% diameter (70% cross-sectional area)[1] (Fig. 26.20). Velocity elevations generally increase as the severity of the stenosis increases. At **critical stenoses** (>95%), the velocity measurements may actually decrease, and the waveform becomes dampened.[99,108]

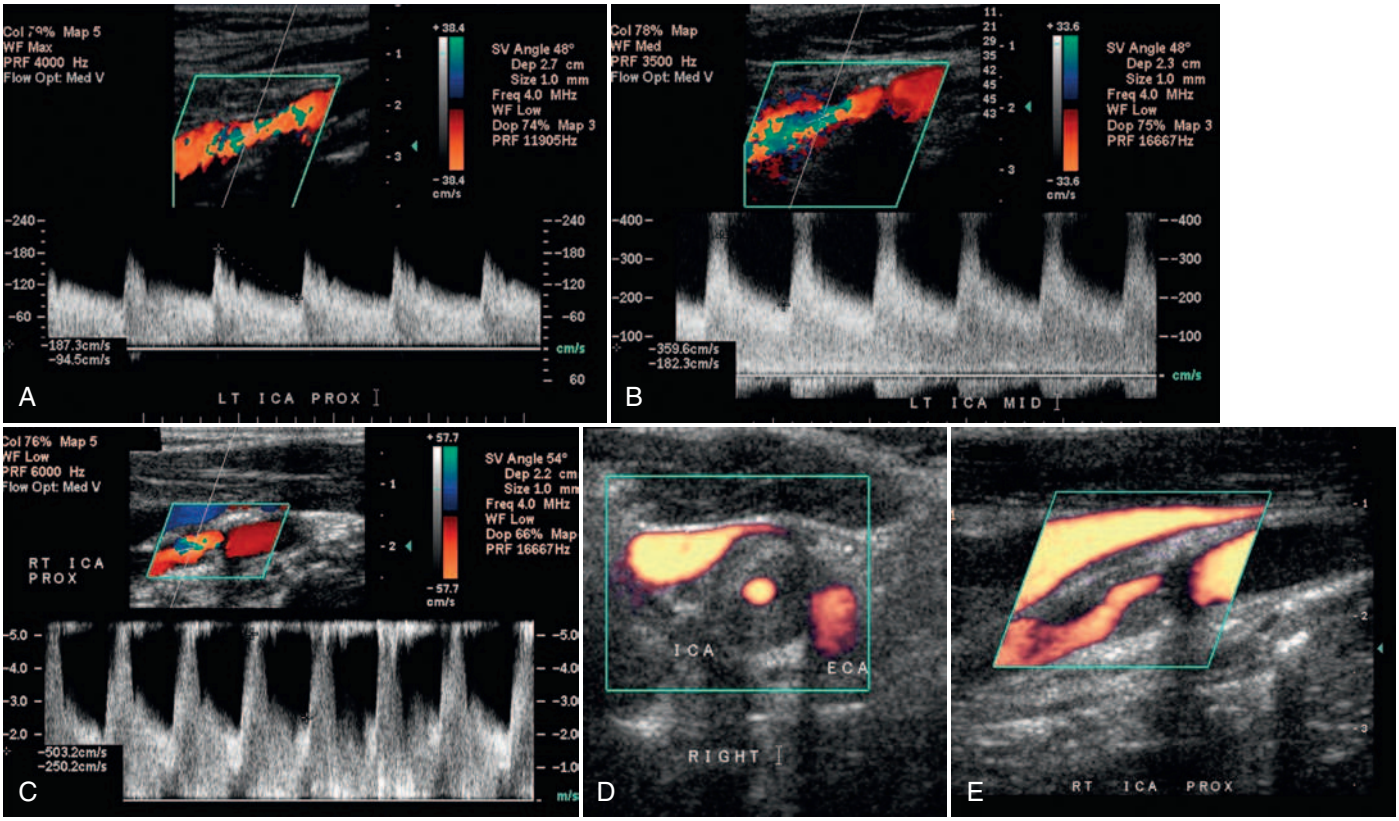

FIG. 26.20 Internal Carotid Artery (ICA) Stenosis. (A) ICA stenosis of 50% to 69% diameter shows a peak systolic velocity (PSV) of 187 cm/sec. **(B)** Left ICA demonstrates a visible high-grade stenosis on color Doppler with end diastolic velocities (EDVs) of greater than 180 cm/sec and PSVs that alias at greater than 350 cm/sec. This is consistent with a very high-grade stenosis. **(C)** Right carotid bulb seen in longitudinal projection with color Doppler demonstrates a high-grade narrowing and spectral broadening with an approximately 500 cm/sec velocity in peak systole and 250 cm/sec in end diastole, consistent with an 80% to 95% stenosis. **(D)** and **(E)** Power transverse and long images demonstrate high-grade stenosis of the ICA.

In these cases, correlation with color or power Doppler imaging is essential to diagnose correctly the severity of the stenoses. Velocity increases are focal and most pronounced in and immediately distal to a stenosis, emphasizing the importance of sampling directly in these regions. Moving further distal from a stenosis, flow begins to reconstitute and assume a more normal pattern, provided a tandem lesion does not exist distal to the initial site of stenosis. Spectral broadening results in the jets of high-velocity flow associated with carotid stenosis; however, correlation with gray-scale and color Doppler images can define other causes of spectral broadening. An awareness of normal flow spectra combined with appropriate Doppler techniques can obviate many potential diagnostic pitfalls.

The degree of **carotid stenosis** that is considered **clinically significant** in the symptomatic or asymptomatic patient is in evolution. Initially, it was thought that lesions causing 50% diameter stenosis were significant; this perception changed as more information was gathered from two large clinical trials. As noted earlier, NASCET demonstrated that CEA was more beneficial than medical therapy in symptomatic patients with 70% to 99% ICA stenosis.[7] ECST demonstrated a CEA benefit when the degree of stenosis was greater than 60%.[8] Interestingly, the method used to grade stenoses in the ECST study was substantially different than that used in the NASCET trials. The NASCET trials compared the severity of the ICA stenosis on arteriogram with the residual lumen of a presumably more normal distal ICA. The ECST methodology entailed assessment of the severity of stenosis with a "guesstimation" of the lumen of the carotid artery at the level of the stenosis. The ECST assessment is more comparable to ultrasound's visible assessment of the degree of narrowing, whereas velocity tables currently in use have been derived to correspond to the NASCET angiographic determinations for stenosis. The ECST method for grading carotid artery stenosis tends to give a more severe assessment of narrowing than the NASCET technique (Fig. 26.21).

The initial NASCET trials retrospectively compared velocity data obtained on the Doppler examination with angiographic measurements of stenosis. No standardized ultrasound protocol was employed by the numerous centers involved in the trials. Despite the lack of uniformity, moderate sensitivity and specificity ranging from 65% to 77% were obtained for grading ICA stenoses using Doppler velocities. If ultrasound technique is standardized and criteria are validated in a given laboratory, **peak systolic velocity** (PSV) and peak systolic ratios have proved to be an accurate method for determining carotid stenosis.[109] The ECST group compared three different angiographic measurement

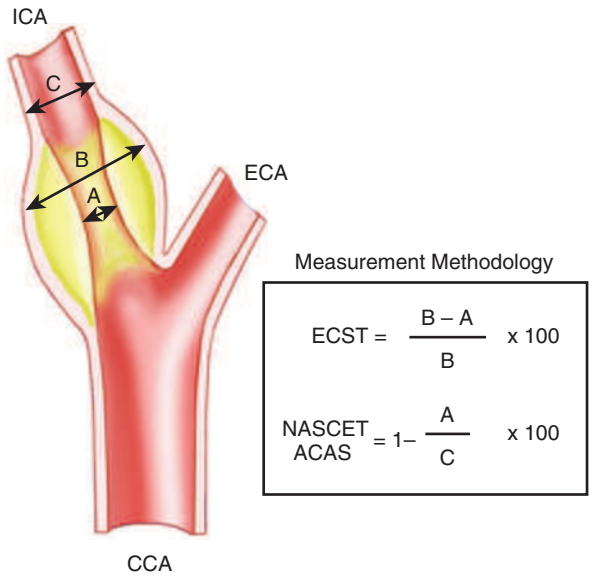

FIG. 26.21 Comparative Measurement Methodology. Different methodologies for grading internal carotid artery stenoses, from the North American Symptomatic Carotid Endarterectomy Trial *(NASCET),* Asymptomatic Carotid Atherosclerosis Study *(ACAS),* and European Carotid Surgery Trial *(ECST). CCA,* Common carotid artery; *ECA,* external carotid artery; *ICA,* internal carotid artery.

techniques: the NASCET, the ECST, and a technique comparing distal CCA measurements with those of ICA stenosis. Researchers concluded that the ECST and NASCET techniques were similar in their prognostic value, whereas the CCA/stenosis measurement was the most reproducible of the three techniques. They also concluded that the CCA method, although reproducible, would be invalidated by the presence of CCA disease.[110] Virtually all investigators advocate using the NASCET angiographic measurement technique.

The results of these trials, as well as the more recent ACAS and moderate NASCET studies, have generated reappraisals of the Doppler velocity criteria that most accurately define 70% or greater stenosis and, more recently, greater than 50% diameter stenoses.[111] Attempts have been made to determine the Doppler parameters or combination of parameters that most reliably identify a certain-diameter stenosis. Most sources agree that the best parameter is the PSV of the ICA in the region of a stenosis.[108] Using multiple parameters can improve diagnostic confidence, particularly when combined with color and power Doppler imaging (see Video 26.19).

The degree of stenosis is best assessed using the gray-scale and pulsed Doppler parameters, including ICA PSV, ICA **end diastolic velocity** (EDV), CCA PSV, CCA EDV, **peak systolic ICA/CCA ratio,** and **peak end diastolic ICA/CCA ratio** (EDR)[108,109,112] (Videos 26.21 and 26.22).[108,109,112] PSV has proved accurate for quantifying high-grade stenoses.[98,109] The relationship of PSV to the degree of luminal narrowing is well defined and easily measured.[113,114] Although Doppler velocities have proved reliable for defining 70% or greater stenosis, Grant et al.[109] showed less favorable results for substenosis classification between 50% to 69% using PSV and ICA/CCA PSV ratios. In our experience, however, using all four parameters and determining a correct category for the degree of stenosis is the most efficacious way to ensure accuracy. Agreement for all four parameters for a clinical situation is most common. When there is an outlying parameter, further assessment and careful attention to technique and detail are required. EDV and EDR are particularly useful in distinguishing between high grades of stenosis. Additionally, correlating the visual estimation of the degree of stenosis and the velocity numbers will help in correctly grading stenosis, particularly when the degree of stenosis is "near occlusion" (Figs. 26.22 and 26.23; see also Fig. 26.20D and E). On rare occasions, alternate imaging methodologies (e.g., MRA, CTA) may need to be recommended.

No criteria for grading **external carotid artery stenoses** have been established. A good general rule is that if the ECA velocities do not exceed 200 cm/sec, no significant stenosis is present. However, we usually rely on a visible assessment of the degree of narrowing associated with velocity changes. Occlusive plaque involving the ECA is less common than in the ICA and is rarely clinically significant.

Similarly, velocity criteria used to grade **common carotid artery stenoses** have not been well established.[115,116] However, if one is able to visualize 2 cm proximal and 2 cm distal to a visible CCA stenosis, a PSV ratio obtained 2 cm proximal to the stenosis (vs. in region of greatest visible stenosis) can be used to grade the "percent diameter stenosis" in a manner similar to that used in peripheral artery studies. A doubling of the PSV across a lesion would correspond to at least a 50% diameter stenosis, and a velocity ratio in excess of 3.5 corresponds to a greater than 75% stenosis.

One persistent problem with duplex Doppler with gray-scale ultrasound evaluation of the carotid arteries is that different institutions use PSVs ranging from 130 cm/sec[117] to 325 cm/sec[111] to diagnose greater than 70% ICA stenosis.[118,119] Factors adding to these discrepancies include technique and equipment.[120] While there is a strong level of correlation between techniques and criteria, the choice of criteria has a significant impact on which patients go to surgery.[119] This wide range of PSVs reinforces the need for individual ultrasound laboratories to determine which Doppler parameters are most reliable in their own institution.[120] Correlation of the velocity ranges obtained by ultrasound with angiographic and surgical results is necessary to achieve accurate, reproducible examinations in a particular ultrasound laboratory.[121]

The Society of Radiologists in Ultrasound, representing multiple medical and surgical specialties, held a consensus conference in 2002 to consider carotid Doppler ultrasound.[122] In addition to guidelines for performing and interpreting carotid ultrasound examinations, panelists devised a set of criteria widely applicable among vascular laboratories (Table 26.1).[122] Although the conference did not recommend all established laboratories with internally validated velocity charts alter their practices, they suggested physicians establishing new laboratories consider using the consensus criteria; those with preexisting charts might consider comparing in-house criteria with those provided by the consensus conference. Velocity criteria corresponding to specific degrees of vascular stenosis are listed in the tables. Our

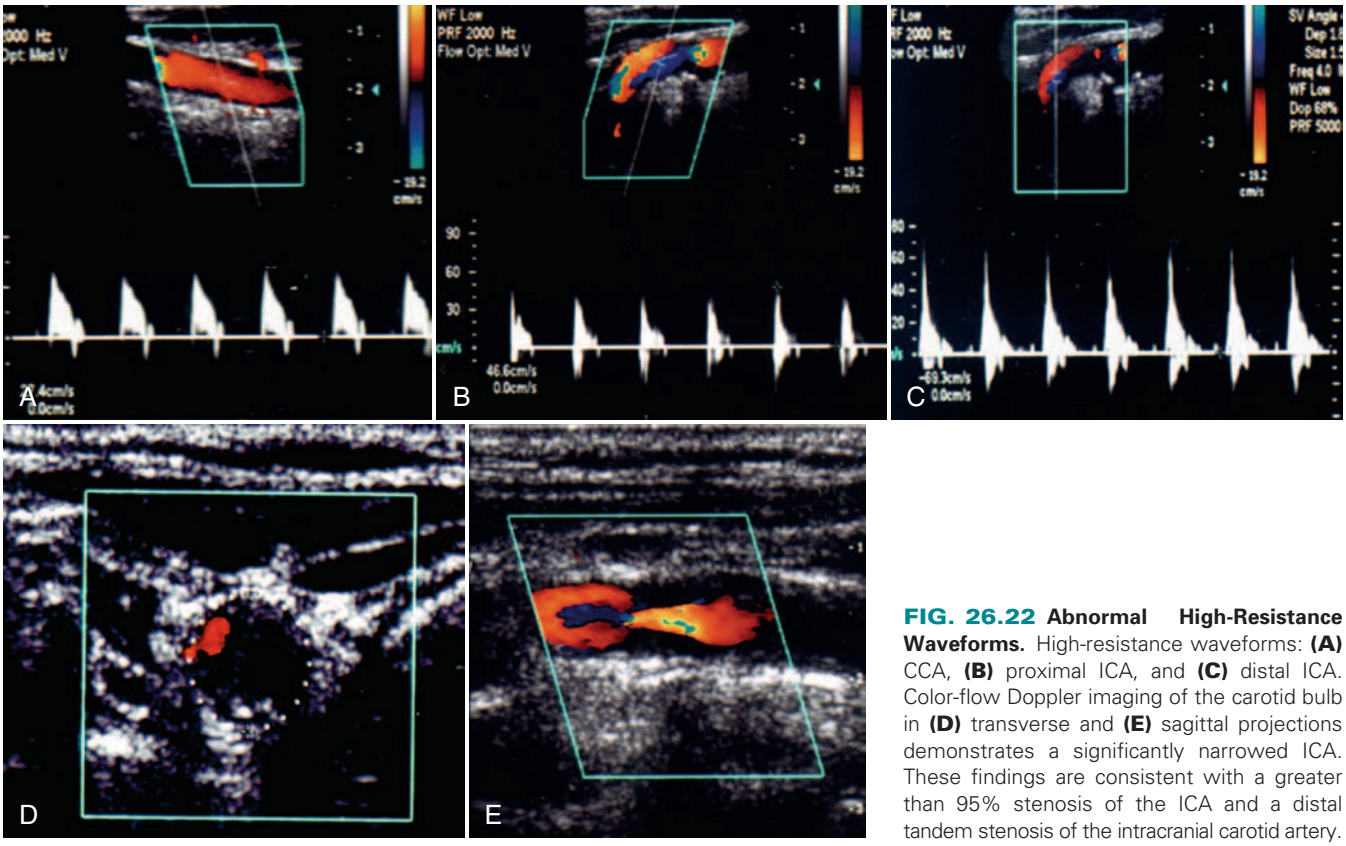

FIG. 26.22 Abnormal High-Resistance Waveforms. High-resistance waveforms: **(A)** CCA, **(B)** proximal ICA, and **(C)** distal ICA. Color-flow Doppler imaging of the carotid bulb in **(D)** transverse and **(E)** sagittal projections demonstrates a significantly narrowed ICA. These findings are consistent with a greater than 95% stenosis of the ICA and a distal tandem stenosis of the intracranial carotid artery.

TABLE 26.1 Diagnostic Criteria for Carotid Ultrasound Examinations

	ICA PSV	Plaque	ICA/CCA PSV Ratio	ICA EDV
Normal	<125 cm/sec	None	<2.0	<40 cm/sec
<50%	<125 cm/sec	<50% diameter reduction	<2.0	<40 cm/sec
50%-69%	125-230 cm/sec	≥50% diameter reduction	2.0-4.0	40-100 cm/sec
≥70% to near occlusion	>230 cm/sec	≥50% diameter reduction	>4.0	>100 cm/sec
Near occlusion	May be low or undetectable	Visible	Variable	Variable
Total occlusion	Undetectable	Visible, no detectable lumen	Not applicable	Not applicable

Determination of sixty percent or greater carotid artery stenosis by duplex Doppler ultrasonography. J Vasc Surg. 1995;22(6):697-703.[123]

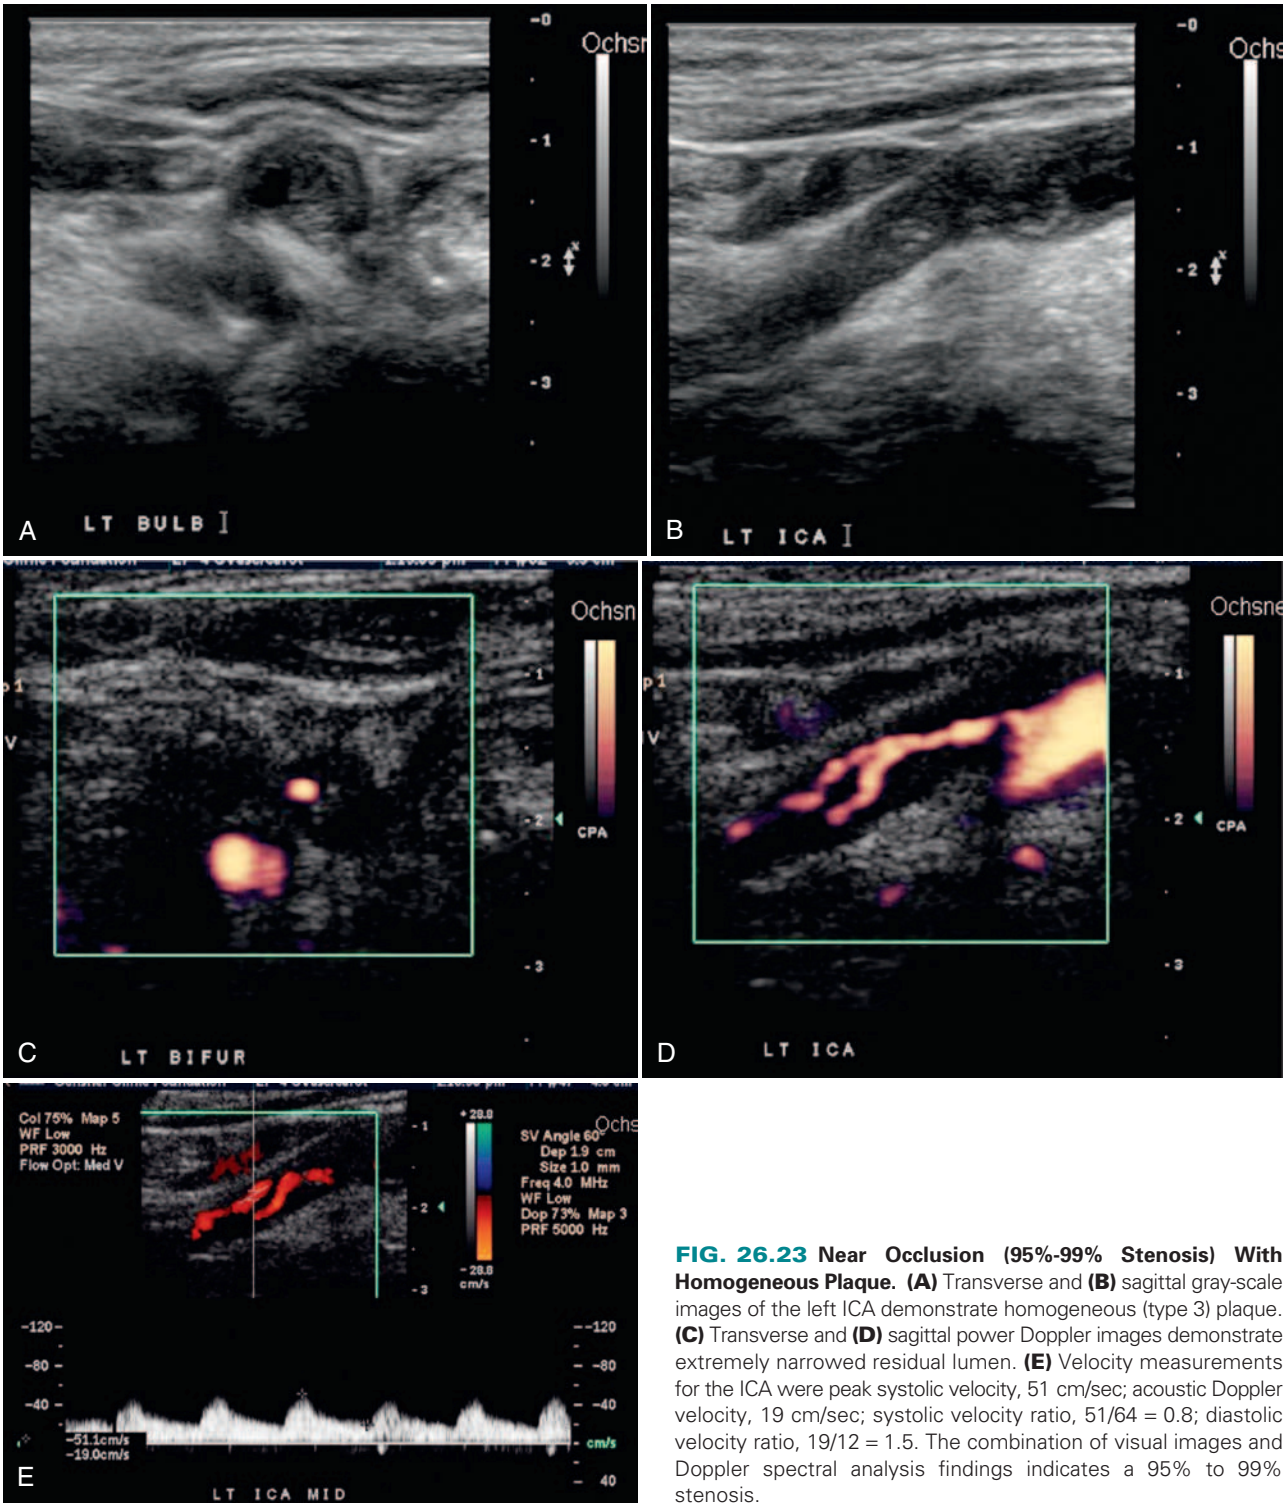

FIG. 26.23 Near Occlusion (95%-99% Stenosis) With Homogeneous Plaque. (A) Transverse and **(B)** sagittal gray-scale images of the left ICA demonstrate homogeneous (type 3) plaque. **(C)** Transverse and **(D)** sagittal power Doppler images demonstrate extremely narrowed residual lumen. **(E)** Velocity measurements for the ICA were peak systolic velocity, 51 cm/sec; acoustic Doppler velocity, 19 cm/sec; systolic velocity ratio, 51/64 = 0.8; diastolic velocity ratio, 19/12 = 1.5. The combination of visual images and Doppler spectral analysis findings indicates a 95% to 99% stenosis.

institution uses Table 26.2, which has a category for 80% to 95% stenoses; our surgeons are more inclined to consider surgery for patients with asymptomatic stenoses greater than 80% than for those with less severe stenoses.[45,123]

The ICA values should be obtained at or just distal to the point of maximum visible stenosis and at the point of greatest color Doppler spectral abnormality. Values from the CCA should be obtained 2 cm proximal to the widening in the region of the carotid bulb. Because velocities normally decrease from proximal to distal in the CCA and increase from proximal to distal in the ICA, it is important that standardized levels be used routinely for obtaining the ICA/CCA velocity ratio.

Color Doppler Ultrasound

Color Doppler ultrasound displays blood flow information in real time over the entire image or a selected area. Stationary soft

tissue structures, which lack a detectable phase or frequency shift, are assigned an amplitude value and displayed in a gray-scale format with flowing blood in vessels superimposed in color. Color assignments depend on the direction of blood flow relative to the Doppler transducer. Blood flow toward the transducer appears in one color and blood flow away from the transducer is in another. These color assignments are arbitrary. Color saturation displays indicate the variable velocity of blood flow. Deeper shades usually indicate low velocities centered around the zero-velocity color-flow baseline. As velocity increases, the shades become lighter or are assigned a different color hue. Some systems allow selected frequency shifts to be displayed in a contrasting color, such as green. This **green-tag feature** provides a real-time estimation of the presence of high-velocity flow.

Setting the color Doppler scale can also be used to create an aliasing artifact corresponding to the highest-velocity flow within a vessel (see Figs. 26.16B, 26.18, and 26.21). These **high-velocity jets** pinpoint areas for spectral analysis. Color assignments are a function of both the mean frequency shift produced by moving RBC ensembles and the Doppler angle theta. If the vessel is tortuous or diving, angle theta between the transducer and vessel will change along the course of the vessel, resulting in **changing color assignments** that are unrelated to the change in RBC velocity. The color assignments will reverse in tortuous vessels as their course changes relative to the Doppler transducer, even though the absolute direction of flow is unchanged. Portions of a vessel that **parallel the Doppler beam** when angle theta is 90 degrees will have little or no frequency shift detected, and no color will be seen.

Optimal Settings for Low-Flow Vessel Evaluation

Color Doppler flow studies should be performed with optimal flow sensitivity and gain settings. Color flow should fill the entire vessel lumen but not spill over into adjacent soft tissues. The **pulse repetition frequency** (PRF) and frame rates should be set to allow visualization of flow phenomena anticipated in a vessel. Frame rates will vary as a function of the width of the area chosen for color Doppler display and for depth of the region of interest. The greater the color image area is, the slower the frame rate will be. The deeper the posterior boundary of the color image is, the slower the PRF will be. Color Doppler sensitivity should be adjusted to detect anticipated velocities, such that if slow flow in a preocclusive carotid lesion is sought, low-flow settings with decreased sampling rates are employed. However, the system will then alias at lower velocities because of the decrease in PRF. In addition to changes in the PRF, optimization of the Doppler angle, increases in gain and power settings, decrease in the wall filter, increase in persistence, and increase in ensemble or dwell time can be used to optimize low-flow detection.

Optimization of Color Doppler Low-Flow Vessel Evaluation

Use low pulse repetition frequency
Use Doppler angle of less than 60 degrees
Increase gain setting
Increase power setting
Decrease wall filter
Increase persistence
Increase dwell time

Flowing blood becomes, in effect, its own contrast medium, with color or power Doppler outlining the patent vessel lumen. This allows determination of the true course of the vessel, facilitating positioning of the Doppler cursor and thus providing more reliable velocity determinations. Furthermore, color Doppler facilitates Doppler spectral analysis by rapidly identifying areas of flow abnormalities. The highest velocities in the region of and immediately distal to a stenosis are seen as **aliasing** high-velocity jets of color. Color Doppler ultrasound facilitates placing the pulsed Doppler range gate in the region of these most striking color abnormalities for pulsed Doppler spectral analysis. The presence of a stenosis can be determined by color Doppler changes in the vessel lumen as well as by visible luminal narrowing. Although color Doppler can be used to determine the presence of hypoechoic plaque, it cannot be used optimally to determine the area of patent lumen in transverse projection because the optimal angle for measuring the area or diameter of narrowing is at 90 degrees to the long axis of the vessel, which is the worst angle for color Doppler imaging. Gray-scale assessment, power Doppler, or B-flow imaging should be used to assess the diameter/area of the patent carotid lumen (see Fig. 26.12). If a stenosis produces a **bruit** or **thrill,** the resultant perivascular tissue vibrations may be seen as transient speckles of color in the adjacent soft tissues, more prominent during systole[124] (Fig. 26.24).

Comparisons of color Doppler ultrasound with conventional duplex Doppler sampling techniques and angiography have shown relatively similar accuracy, sensitivity, and specificity.[125,126] However, color Doppler offers many benefits, including a reduction in examination time by pinpointing areas of color Doppler abnormality for pulsed Doppler spectral analysis.[126] Branches of the ECA are readily detected, facilitating differentiation from the ICA. The real-time flow information over a large cross-sectional area provides a global overview of flow abnormalities and allows ready determination of the course of a vessel. Furthermore, color Doppler improves diagnostic confidence and reproducibility of ultrasound studies, thereby avoiding many potential diagnostic pitfalls.

The laminar blood flow is disrupted in the region of the carotid bifurcation where there is a **normal transient flow reversal** opposite the origin of the ECA (see Fig. 26.19). Color Doppler displays this normal flow separation as an area of flow reversal located along the outer wall of the carotid bulb, which appears either at early systole or in peak systole and persists for a variable period into the diastolic part of the cardiac cycle.[127,128] This flow reversal can produce some strikingly bizarre pulsed Doppler waveforms; however, the color Doppler appearance readily discerns the nature of these waveform changes. Furthermore, the absence of this flow reversal may be abnormal and may

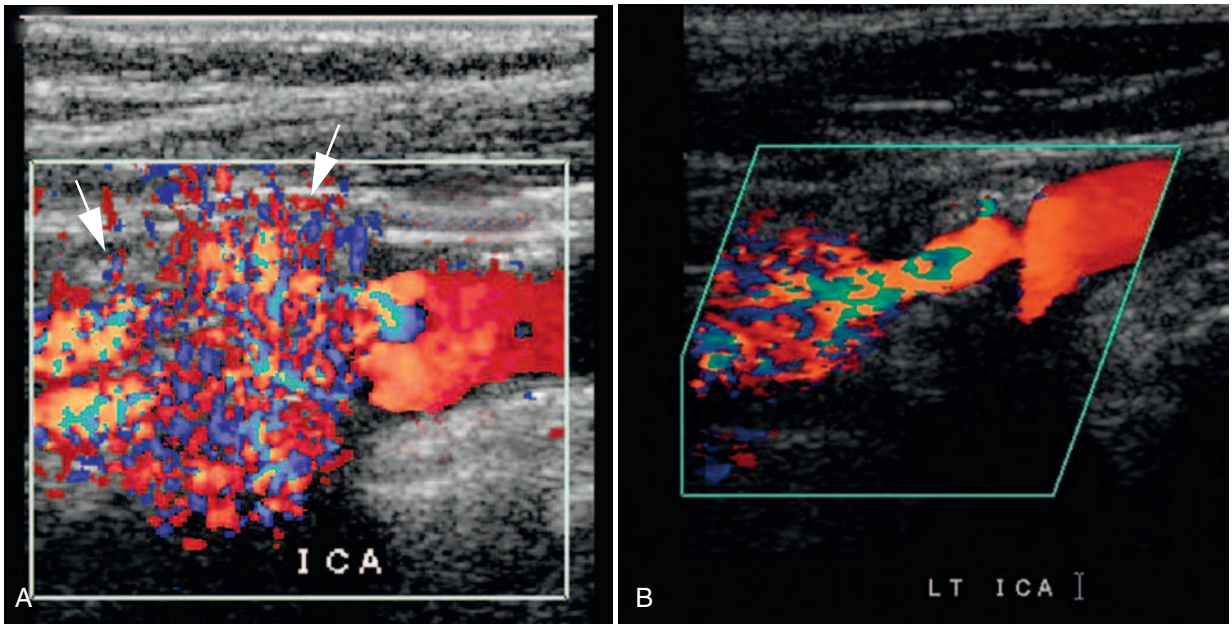

FIG. 26.24 Color Doppler Bruit. (A) Extensive soft tissue color Doppler bruit *(arrows)* surrounds the carotid bifurcation with a 90% internal carotid artery *(ICA)* stenosis. **(B)** ICA demonstrates a small bruit, not as significant as in view A, but nevertheless a bruit showing the appropriate area to place the cursor for Doppler flow evaluation of the significant stenosis.

represent one of the earliest changes of atherosclerotic disease.[127] The flow reversal seen in the region of the carotid bifurcation is clearly different than that seen with color Doppler aliasing. Contiguous saturated areas of red and blue are seen in this low-velocity flow separation versus the very different contiguous color hues representing the highest color assignments for forward and reversed flow.

Helical flow in the CCA may be an indirect indication of proximal arterial stenosis but can occur as a normal variant. Color Doppler sonography graphically displays the eccentric spiraling of flow up the CCA.

Advantages and Pitfalls

Color Doppler ultrasound may help avoid potential diagnostic pitfalls. Alterations in cardiovascular physiology, tandem lesions, contralateral carotid disease, arrhythmias, postoperative changes, and tortuous vessels can lead to underestimation or overestimation of the degree of stenosis. In such cases, color Doppler ultrasound can provide direct visualization of the patent lumen in a fashion analogous to angiography.[129] In fact, because angiography images only the vessel lumen and not the vessel wall, color Doppler and power Doppler ultrasound imaging have the potential to evaluate stenoses even more completely than angiography. Because flow patterns are displayed with color Doppler imaging, the local hemodynamic consequences of the lesion are readily discerned. Color and power Doppler ultrasound have particular value in detecting small residual channels of flow in areas of high-grade carotid stenoses[124,125,129-134] (Fig. 26.25). Power Doppler ultrasound offers a comparable advantage and has the theoretical potential to be more sensitive for detecting extremely low-amplitude, low-velocity flow. Finally, color Doppler and power Doppler ultrasound have the potential to clarify image Doppler mismatches, further improving diagnostic accuracy and confidence.

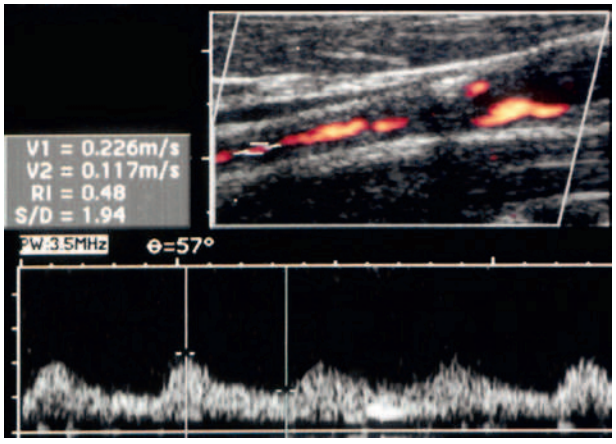

FIG. 26.25 High-Grade "String Sign" Stenosis of Internal Carotid Artery. Tardus-parvus waveform with low velocity in a long segment.

Color Doppler Evolution of Carotid Stenosis

ADVANTAGES

Reduction in examination time
Quick identification of areas of stenosis/high velocity, which facilitates spectral analysis to artifacts
Improved diagnostic reproducibility and confidence
Distinguishes occlusion from "string sign"
Simultaneous hemodynamic and anatomic information, velocity, and directional blood flow information
Improved accuracy in quantitating stenoses
Clarifies pulsed Doppler/image mismatch

DISADVANTAGES

Prone to angle dependence
Resolution less than with gray-scale
Slower frame rates information
Cannot characterize plaque

Although color Doppler ultrasound offers many advantages, it is angle dependent and prone to artifacts, such as aliasing. The spatial resolution of color Doppler ultrasound is less than that of gray-scale imaging, and the Doppler resolution is inferior to pulsed Doppler spectral analysis. Color saturation cannot be equated with velocity.[120] The color image is corrected for only one angle, so changes in color saturation may simply reflect changes in the vessel course and the relative Doppler angle. Color systems generally compute the mean velocity to produce the color pixel in the image. However, the examiner is usually interested in determining the maximum velocity; therefore pulsed Doppler spectral analysis remains necessary for precise quantification of a hemodynamically significant stenosis.

Power Doppler Ultrasound

The color signal in power Doppler ultrasound is generated from the integrated power Doppler spectrum. The amplitude of the reflected echoes determines the brightness and color tone of the color signal. This amplitude depends on the density of RBCs flowing within the sample volume. Power Doppler ultrasound uses a larger dynamic range with a better signal-to-noise ratio than color Doppler ultrasound. Because power Doppler ultrasound does not evaluate frequencies but rather amplitude (or power), artifacts such as aliasing do not occur. Power Doppler sonography, unlike color Doppler ultrasound, is largely angle independent. These features combine to make power Doppler ultrasound exquisitely sensitive to detecting a **residual string of flow** in the region of a suspected carotid occlusion.[130,135]

It is also hypothesized that power Doppler ultrasound has better edge definition than color Doppler ultrasound. The combination of improved edge definition and relative angle-independent flow imaging offers the potential for better visual assessment of the degree of stenosis using power Doppler.[136] Better edge definition may also allow power Doppler ultrasound to define plaque surface characteristics more clearly[137] (see Fig. 26.10B).

Despite the many potential benefits of power Doppler ultrasound, it does not provide velocity or directional flow information.[138] Also, power Doppler is very motion sensitive, which may result in a **pseudostring** of flow. If the vibrations of soft tissue at an echogenic interface exceed the clutter filter level, color information may be displayed in areas where there is no blood flow. Pulsed Doppler evaluation of a color or power string should always be performed to confirm the presence of real flow.

Power Doppler screening may produce an accurate and cost-effective method for patients at risk for carotid disease.[139-141] In one study, power Doppler imaging used independent of spectral analysis was effectively performed in 89 of 100 patients.[139] The sensitivity for the detection of 40% or greater stenoses using power Doppler was 91%, with 79% specificity. This would be reasonable for a screening test, allowing patients with greater than 40% stenosis to undergo more expensive spectral analysis. Some believe that using this less expensive power Doppler screening could result in a more cost-effective approach to carotid Doppler screening. In addition, carotid power Doppler imaging, as well as carotid B-flow imaging, is ideally suited to combined use with vascular contrast agents that may be widely available in the future. However, after evaluating the literature, the US Preventative Task Force has given this a Grade D recommendation and recommends not screening for asymptomatic carotid artery stenosis in the general adult population.[142]

Power Doppler Evaluation of Carotid Stenosis

ADVANTAGES

Produces no aliasing
Potentially increases accuracy of grading stenoses
Aids in distinguishing preocclusive from occlusive lesions
Potentially provides superior depiction of plaque surface morphology
Yields increased sensitivity to detecting low-velocity, low-amplitude blood flow
Is angle independent

DISADVANTAGES

Does not provide direction or velocity flow information
Is very motion sensitive (poor temporal resolution)

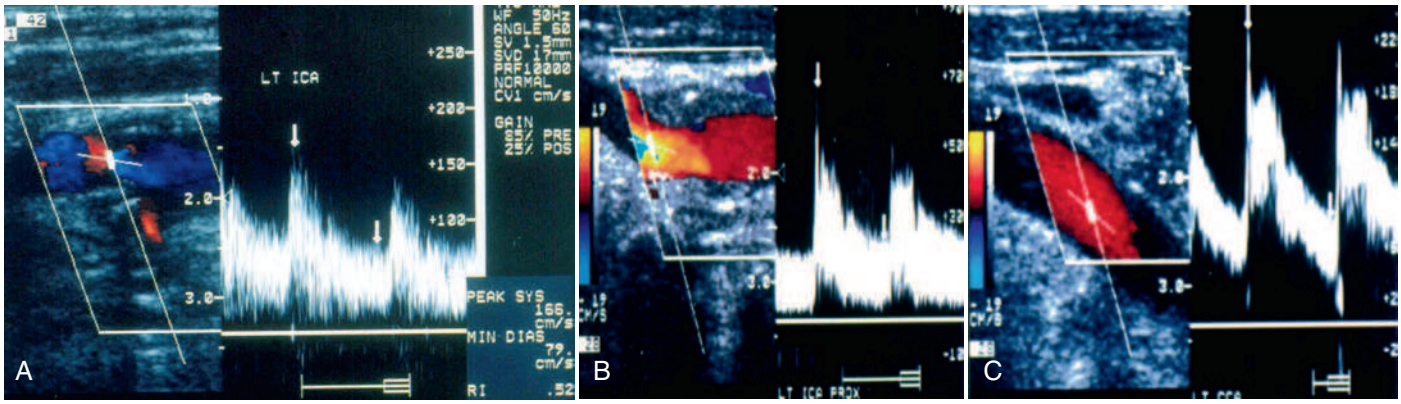

FIG. 26.26 Value of ICA/CCA Ratio. (A) Increased velocity ICA and CCA in a patient with hypertension. ICA PSV is 166 cm/sec; EDV is 79 cm/sec. CCA velocities: PSV = 96 cm/sec, EDV = 36 cm/sec. ICA/CCA systolic velocity ratio is 1.7, and diastolic velocity ratio is 2.2, corresponding to a degree of stenosis less than 50%. **(B)** Low velocities in left ICA: PSV = 67 cm/sec, EDV = 23 cm/sec. **(C)** In left CCA, PSV = 23 cm/sec, EDV = 8 cm/sec. ICA/CCA systolic velocity ratio is 2.9, and diastolic velocity ratio is 2.9, corresponding to a 50% to 69% stenosis in patient with cardiomyopathy.

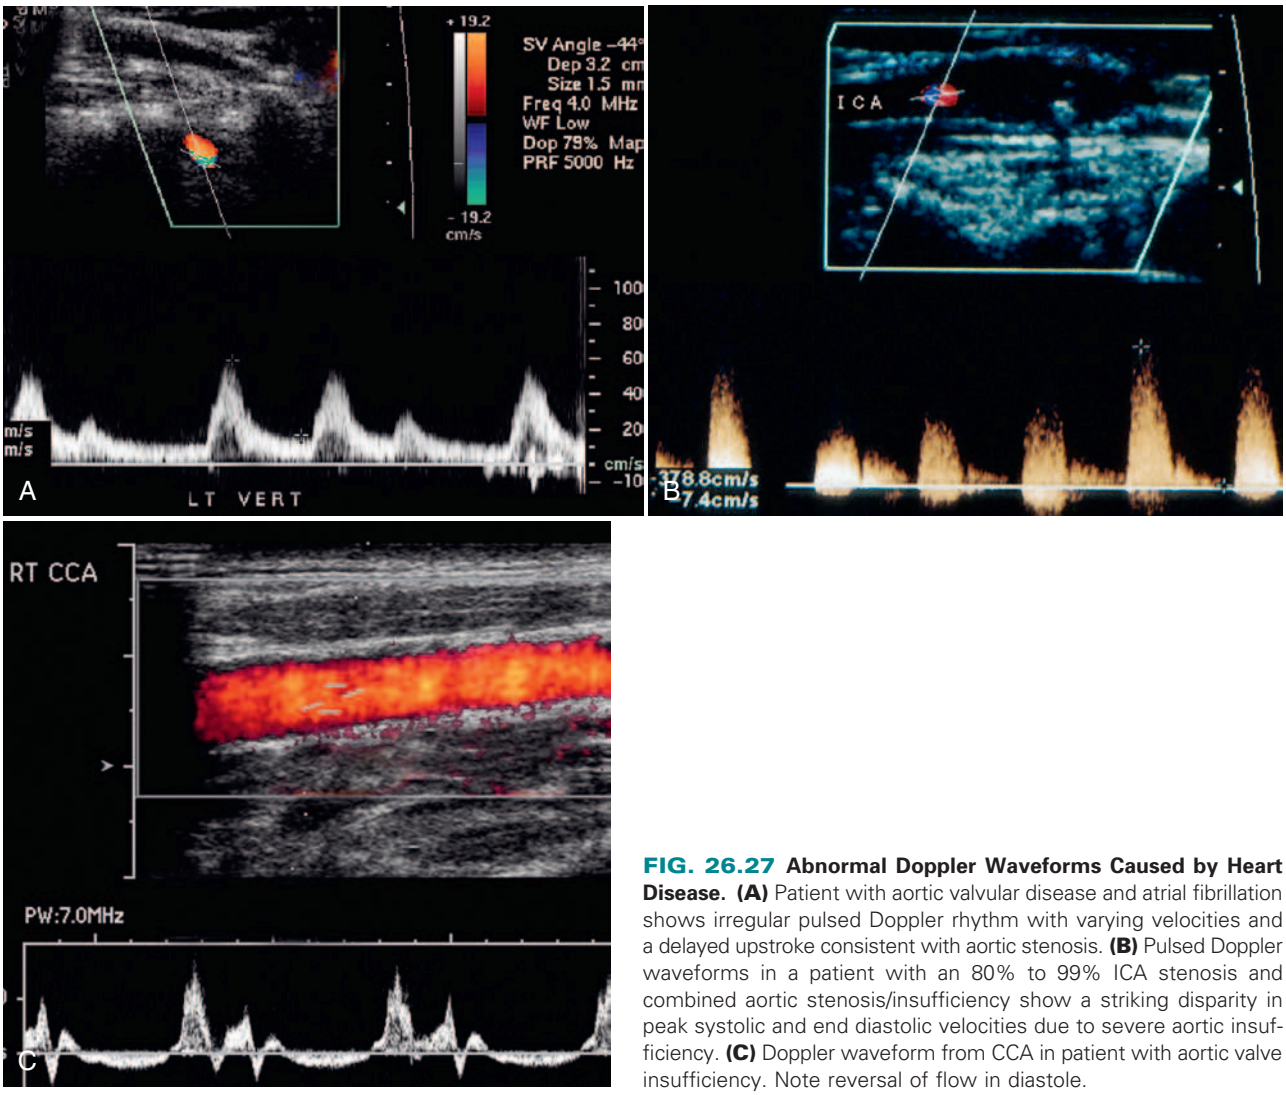

FIG. 26.27 Abnormal Doppler Waveforms Caused by Heart Disease. (A) Patient with aortic valvular disease and atrial fibrillation shows irregular pulsed Doppler rhythm with varying velocities and a delayed upstroke consistent with aortic stenosis. **(B)** Pulsed Doppler waveforms in a patient with an 80% to 99% ICA stenosis and combined aortic stenosis/insufficiency show a striking disparity in peak systolic and end diastolic velocities due to severe aortic insufficiency. **(C)** Doppler waveform from CCA in patient with aortic valve insufficiency. Note reversal of flow in diastole.

Pitfalls and Adjustments

Although absolute velocity determinations are valuable in assessing the degree of vascular stenosis, these measurements are less reliable in certain patients.[1] Variations in cardiovascular physiology may affect carotid velocity measurements.[143,144] For example, velocities produced by a stenosis in a **hypertensive patient** may be higher than those in a normotensive individual with comparable narrowing, especially in the setting of a wide-pulsed pressure.[145] On the other hand, a **reduction in cardiac output** will diminish both systolic and diastolic velocities (Fig. 26.26). **Cardiac arrhythmias, aortic valvular lesions,** and **severe cardiomyopathies** can cause significant aberrations in the shape of carotid flow waveforms and alter systolic and diastolic velocity readings[146] (Fig. 26.27). Use of an **aortic balloon pump** can also distort the Doppler velocity spectrum[147] (Fig. 26.28). These alterations can invalidate the use of standard Doppler parameters to quantify stenoses. **Bradycardia,** for example, produces increased stroke volume, causing systolic velocities to increase, whereas **prolonged diastolic runoff** causes spuriously decreased end diastolic values resulting in underestimation of carotid stenosis.[148]

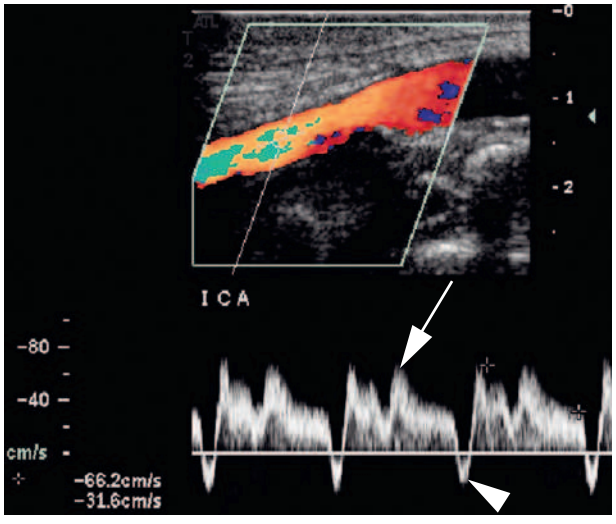

FIG. 26.28 Abnormal Doppler Waveform Caused by Aortic Balloon Pump. ICA pulsed Doppler trace shows the effect of an aortic balloon pump on carotid waveforms. Inflation of the device in systole *(arrow)* produces a second systolic peak, whereas deflation produces flow reversal *(arrowhead)* in end diastole.

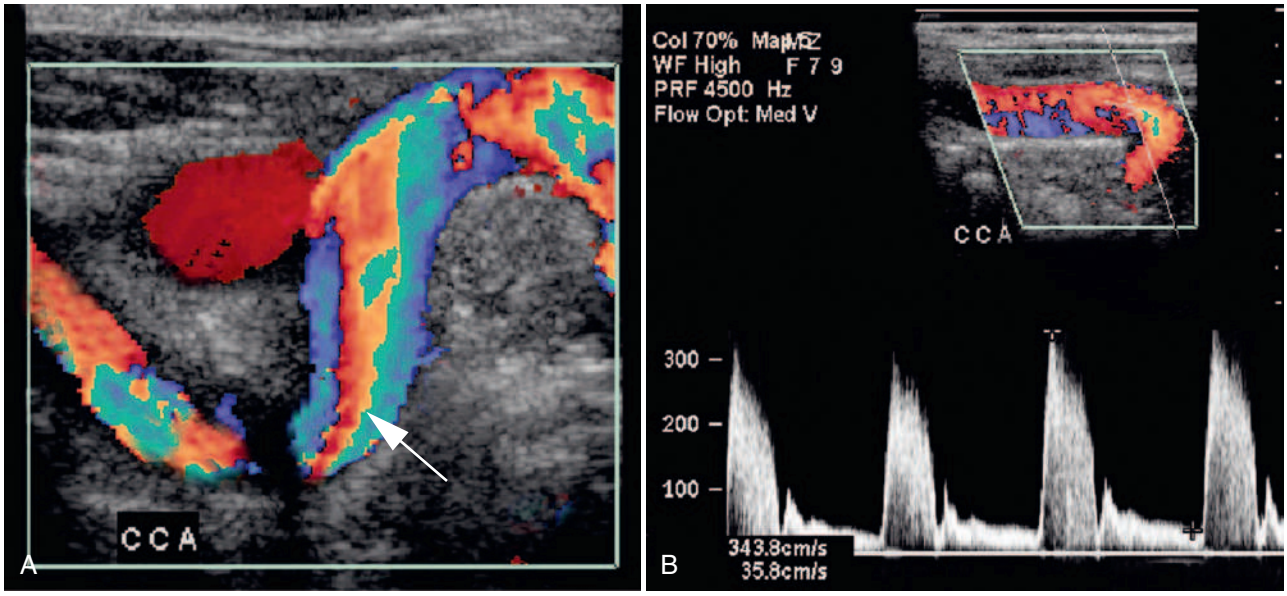

FIG. 26.29 Abnormal Doppler Flow Caused by Tortuous Vessel. (A) Tortuous common carotid artery *(CCA)* displays color Doppler eccentric jets of flow *(arrow).* **(B)** Spuriously elevated velocity is caused by an eccentric jet in a tortuous proximal left CCA without any visible stenosis.

Patients with isolated **severe or critical aortic stenosis** may demonstrate duplex waveform abnormalities, including prolonged acceleration time, decreased peak velocity, delayed upstroke, and rounded waveforms.[149] However, **mild or moderate aortic stenosis** usually results in little or no sonographic abnormality. **Tortuous or kinked carotid arteries** represent either congenital or acquired changes in the carotid artery. The clinical significance of these is debatable; however, the **vascular tortuosity** frequently results in eccentric jets of high-velocity flow, which may show elevated velocities in the absence of significant stenosis[150-152] (Fig. 26.29). Conversely, if the carotid bulb is capacious, a large plaque burden may still fail to produce anticipated velocity increases. The relative difference in area between the distal CCA and the residual patent lumen of the large bulb is not sufficient to produce a greater than 50% velocity change. Some refer to this as **nonstenotic (homogeneous) plaque** (Fig. 26.30). Frequently, an **image/Doppler mismatch** alerts the examiner to potential pitfalls.

Causes of Image/Doppler Mismatch

Cardiac arrhythmia
Cardiac valvular disease, cardiomyopathy
Severe aortic stenosis
Hypotension or hypertension
Tandem lesions
Contralateral carotid stenosis
Nonstenotic plaque
Long-segment, concentric high-grade stenosis
Carotid dissection
Preocclusive lesion
Tortuous vessels
Calcified plaque, hypoechoic or anechoic plaque
Anatomic variants

Color Doppler can be used to overcome diagnostic dilemmas in these situations, particularly when "cine loop" playback capabilities are present. Cine loop allows the computer to store portions of the previous color Doppler flow recording for playback at the real-time rate or frame by frame. This allows the clinician to assess the filling of all parts of the vessel lumen. **Obstructive lesions in one carotid can affect velocities in the contralateral vessel.** For example, severe unilateral ICA stenosis or occlusion may cause shunting of increased flow through the contralateral carotid system. This increased flow artificially increases velocity measurements in the contralateral vessel, particularly in areas of stenosis.[150,153-156] Conversely, a proximal common carotid or innominate artery stenosis may reduce flow, with consequent reduction of velocity measurements in a stenosis that is distal to the point of obstruction **(tandem lesion)** (see Fig. 26.22).

Velocity ratios that compare velocity values in the ICA to those in the ipsilateral CCA can help avoid some pitfalls.[99] Of particular value are the **peak systolic ratio** (PSV in ICA vs. PSV in CCA)[104,157] and the **end diastolic ratio** (ICA/CCA EDV).[112] Grant et al. have shown that PSV ICA/CCA ratios are comparable in accuracy to PSV values for determining the degree of ICA stenosis.[109] Although the PSV and peak systolic ICA/CCA velocity ratio have shown relative comparable sensitivities and specificities, at times the velocity ratio will more correctly identify the degree of stenosis and the absolute velocity. Velocity ratios should always be employed when unusually high or low CCA velocities or significant asymmetry of CCA velocities is detected. Long-segment, high-grade stenoses frequently will not demonstrate the anticipated degree of ICA velocity elevation. In such situations, the velocity ratio coupled with the gray-scale/color/power Doppler appearance may provide insight into the actual degree of narrowing. As discussed for spectral broadening, color and power Doppler sonography are invaluable in the avoidance of pitfalls related to spurious Doppler spectral traces.

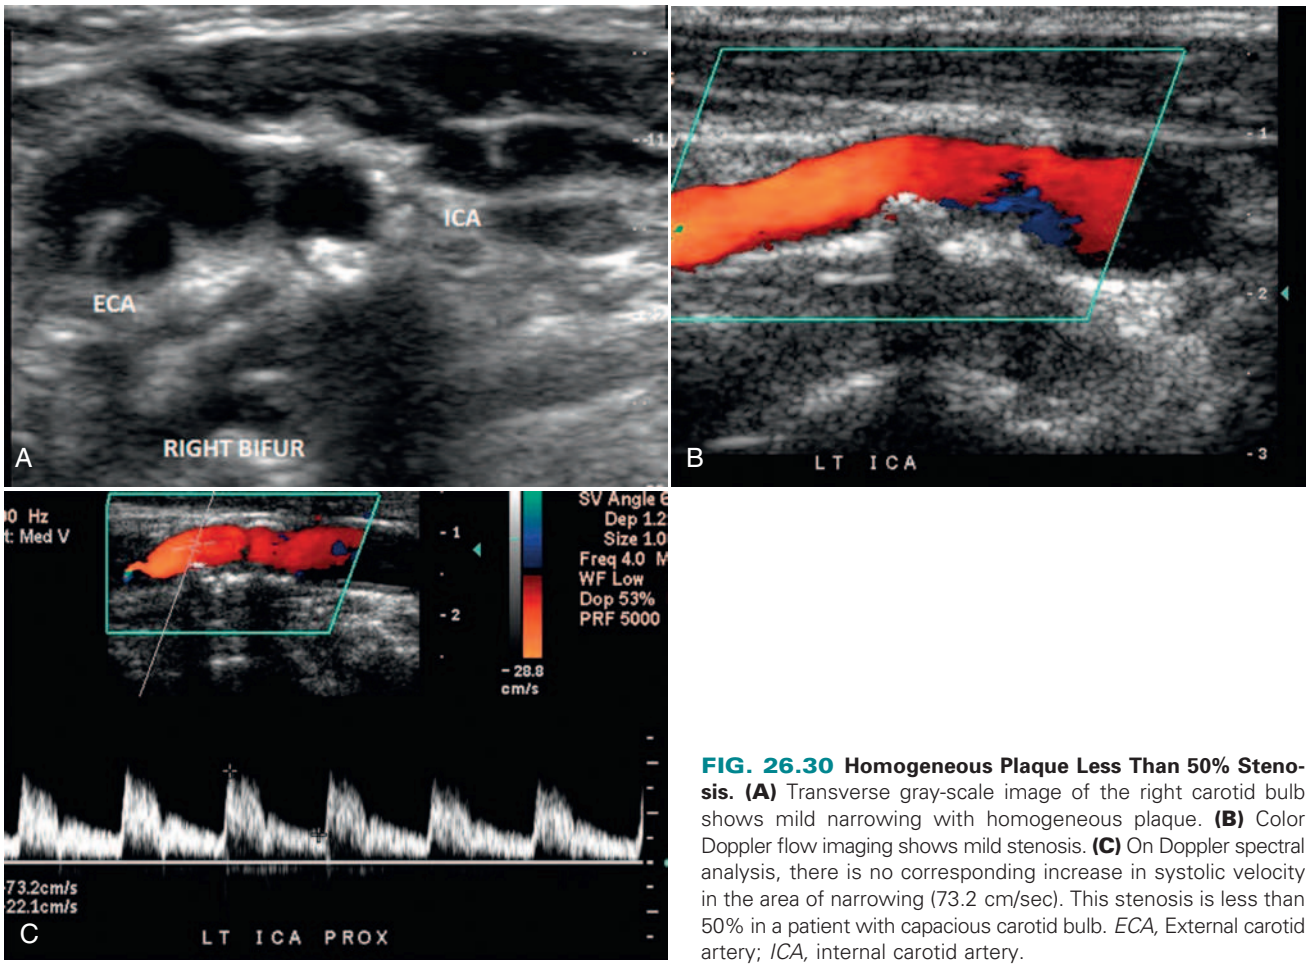

FIG. 26.30 Homogeneous Plaque Less Than 50% Stenosis. (A) Transverse gray-scale image of the right carotid bulb shows mild narrowing with homogeneous plaque. **(B)** Color Doppler flow imaging shows mild stenosis. **(C)** On Doppler spectral analysis, there is no corresponding increase in systolic velocity in the area of narrowing (73.2 cm/sec). This stenosis is less than 50% in a patient with capacious carotid bulb. *ECA,* External carotid artery; *ICA,* internal carotid artery.

Although high-grade stenoses usually produce increased velocity in the region of a plaque and distal to it, high-grade intracranial or extracranial occlusive **lesions in tandem may reduce anticipated velocity shifts** and produce an atypical high-resistance ICA waveform (see Fig. 26.22). Vessels should be examined as far cephalad as possible to avoid missing a distal tandem lesion. Flow immediately distal to stenosis of greater than 95% frequently demonstrates very-low-velocity **tardus-parvus waveforms** versus the anticipated high velocities seen in a high-grade stenosis (see Fig. 26.25). **High-grade vascular narrowings,** particularly those of a circumferential nature that occur over a long segment of a vessel, may also produce dampened waveforms without a high-velocity frequency shift. Although no definite velocity elevations are present in such a long, circumferential narrowing, spectral broadening and disturbed flow distal to such a narrowing are usually apparent. In addition, the fusiform narrowings are usually detected with the real-time color Doppler image. **Innominate artery occlusions** may result in tardus-parvus waveforms, asymmetric, elevated left common carotid to right common carotid ratios, and even carotid steal patterns similar to those noted in the vertebral artery[134] (Fig. 26.31).

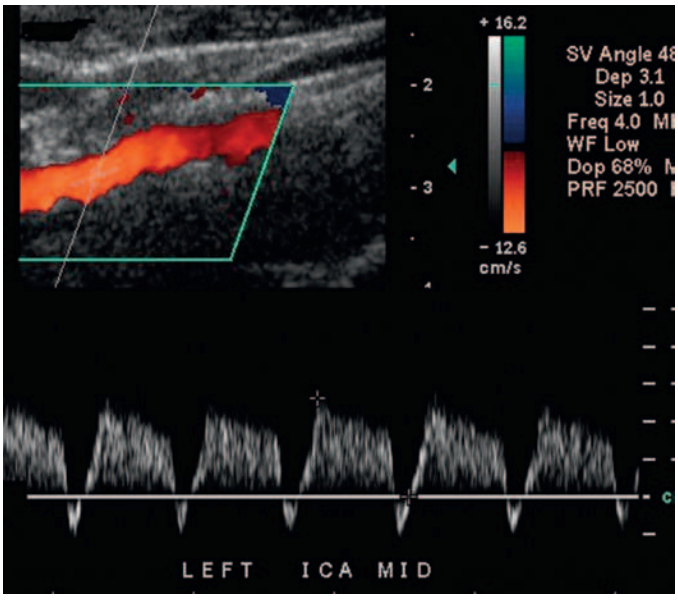

FIG. 26.31 Abnormal CCA Velocity Caused by Innominate Artery Stenosis. Low left ICA velocities with presteal waveform distal to the severe innominate artery stenosis.

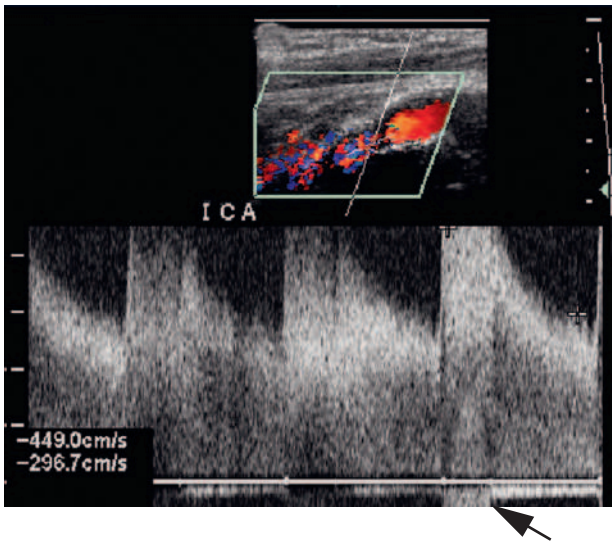

FIG. 26.32 Aliasing of Doppler Waveform in the Region of a High-Grade (80%-95%) Stenosis. Highest velocities are wrapped around *(arrow)* and displayed below the zero-velocity baseline. *ICA,* Internal carotid artery.

Another source of error in pulsed Doppler ultrasound analysis is **aliasing,** which is caused by the inability to detect the true PSV because the Doppler sampling rate, the PRF, is too low. The maximal detectable frequency shift can be no greater than half the PRF. With aliasing, the tips of the time velocity spectrum (representing high velocities) are cut off and wrap around to appear below the baseline (Fig. 26.32). If aliasing occurs, **continuous wave probes** used in conjunction with duplex pulsed Doppler can readily demonstrate the true peak velocity shift. Aliasing can also be overcome or decreased by **increasing the angle theta** (the angle of Doppler insonation), thereby reducing the detected Doppler shift, or by decreasing the insonating sound beam frequency. **Increasing the PRF** increases the detectable frequency shift, but the PRF increase is limited by the depth of the vessel as well as the center frequency of the transducer.[45,101,158] One can also **shift the zero baseline** and reassign a larger range of velocities to forward flow to overcome aliasing. It is also valid to **add velocity values above and below the baseline** to obtain an accurate velocity value, provided that multiple wraparounds do not occur, as seen in extremely high velocities. Aliasing may sometimes be useful in color Doppler image interpretation, where color-flow Doppler aliasing can accent the severity of flow disturbances as well as define the patent lumen.

Internal Carotid Artery Occlusion

Distinguishing between a **string sign** and a **totally occluded carotid artery** has major clinical consequences.[88] Grubb et al.[159] showed that untreated preocclusive lesions carry about a 5% per year risk for stroke. Thus intervention in this patient population is particularly important.

Carotid occlusion is diagnosed when no flow is detected in a vessel. Occasionally, transmitted pulsations into an occluded ICA may mimic abnormal flow in a patent vessel. The pulsed Doppler cursor should be clearly located in the ICA lumen, and arterial pulsatile flow should be identified. Close attention should be paid to the direction of flow and the nature of pulsations. **True center-stream sampling** should be documented by transverse scanning, and the sample volume reduced in size as much as possible. Extraneous pulsations are seldom transmitted to the center of the thrombus.[102]

As a high-grade stenosis approaches occlusion, the high-velocity jet is reduced to a mere trickle. It may be difficult to locate the small residual string of flow within a largely occluded lumen using gray-scale imaging alone, particularly if the adjacent plaque or thrombus is anechoic, making the residual lumen difficult to visualize during real-time examination, or if calcified plaque obscures visualization. In critical high-grade stenoses (>95%), standard-sensitivity color Doppler settings may fail to demonstrate a string of residual flow. Thus it is always prudent to employ the **slow-flow sensitivity settings** on color Doppler to discriminate between critical stenoses and occlusions.[86,125,129] Alternatively, power Doppler ultrasound (with its increased sensitivity to detecting low-amplitude, slow-velocity signals) may be used to visualize a **residual string of blood flow** (Fig. 26.33). Color Doppler is 95% to 98% accurate in distinguishing high-grade stenosis from complete occlusion on angiography when appropriate technical parameters are employed.[160-162]

The presence of a high-grade ICA stenosis or occlusion can often be inferred from inspection of the ipsilateral CCA on a pulsed Doppler waveform or color/power Doppler image (see Fig. 26.31). The pulsed Doppler waveforms in the ipsilateral CCA and ICA proximal to a lesion frequently demonstrate an asymmetrical, high-resistance signal with decreased, absent, or reversed diastolic flow, except when there are **ECA collaterals to the intracranial circulation** (Fig. 26.34). The main intracranial/extracranial collateral pathway exists between the orbital and ophthalmic arteries. Other collateral pathways include the occipital branch of the ECA to the vertebral artery and cervical branches off the arch with the vertebral artery. Similarly, color or power Doppler images may show a flash of color flow in systole but a conspicuous decrease or absence of color flow in diastole, which is asymmetrical compared to the contralateral side. The diagnosis of carotid occlusion versus a string sign is made more accurately with color and power Doppler than with gray-scale duplex scanning and may obviate the need for angiography to confirm a sonographically diagnosed ICA occlusion; however, if ambiguity persists, CTA, MRA, or angiography can be helpful.[88,160,161]

Internal Carotid Artery Occlusion

Internalization of ipsilateral ECA waveform
Absence of flow in ICA by color Doppler, power Doppler, or pulsed Doppler ultrasound
Reversal of flow in segment of ICA or CCA proximal to occluded segment
Thrombus or plaque completely filling lumen of ICA on gray-scale, color Doppler, or power Doppler images
Dampened high-resistance waveform in ipsilateral CCA or proximal ICA
Possibly significantly higher velocities in contralateral CCA than in ipsilateral CCA

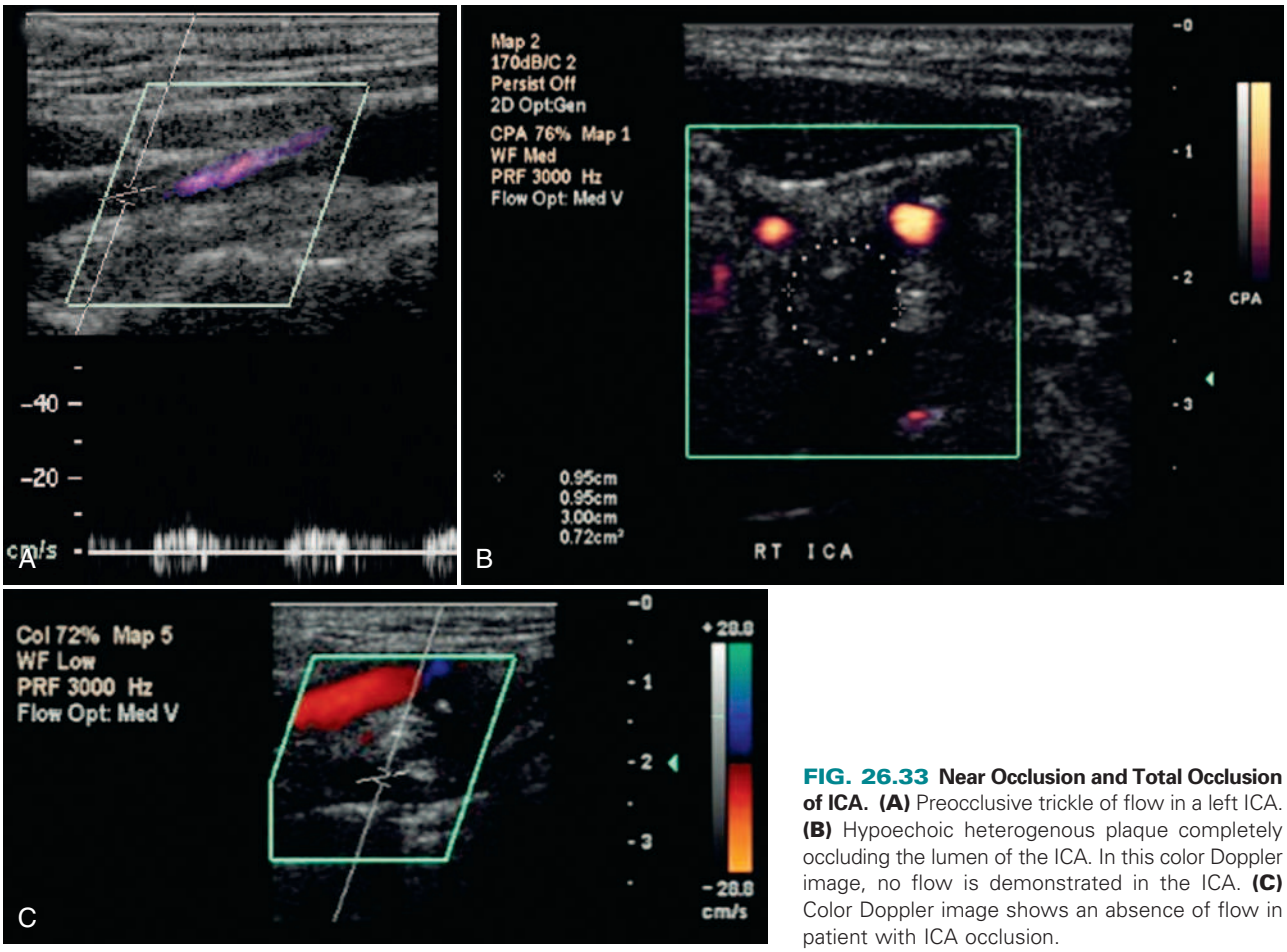

FIG. 26.33 Near Occlusion and Total Occlusion of ICA. (A) Preocclusive trickle of flow in a left ICA. **(B)** Hypoechoic heterogenous plaque completely occluding the lumen of the ICA. In this color Doppler image, no flow is demonstrated in the ICA. **(C)** Color Doppler image shows an absence of flow in patient with ICA occlusion.

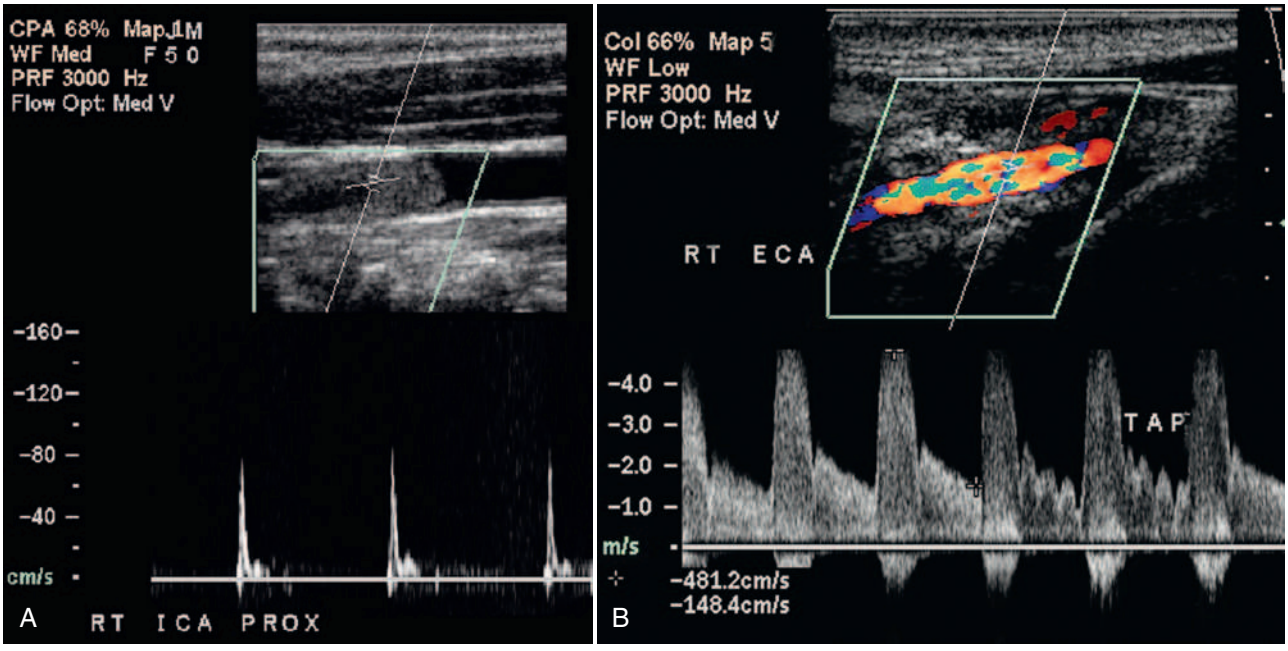

FIG. 26.34 ICA Occlusion. (A) Complete right ICA occlusion shows a spiked waveform consistent with an occlusion. **(B)** Proximal right ECA tracing shows a low-resistance waveform consistent with collaterals to intracranial circulation, as well as increased velocity caused by a stenosis. *TAP,* Temporal artery tap.

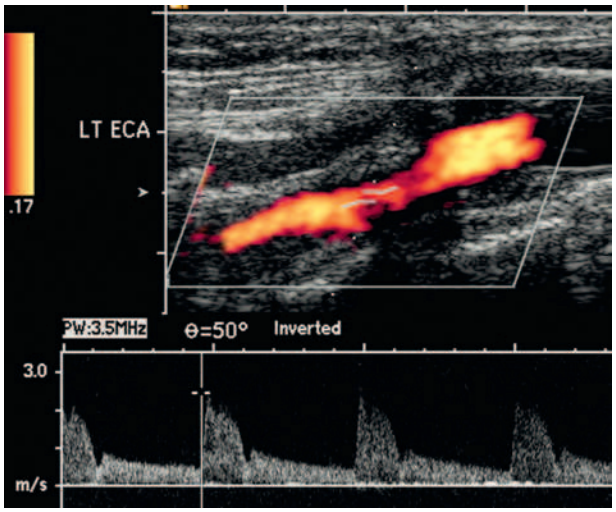

FIG. 26.35 Internalization of ECA Waveform in Association With ICA Occlusion. Long-standing ICA occlusion results in low-resistance waveform in the ECA.

Another pitfall in the diagnosis of a totally occluded ICA is **mistaking a patent ECA** (or one of its branches) **for the ICA.** The situation is especially confusing when the ECA/ICA collaterals open in response to long-standing ICA disease, and the ECA acquires a low-resistance waveform (internalization) (Fig. 26.35). One technique that can aid in identifying the ECA is scanning at the origin of the vessel while simultaneously tapping the temporal artery. Percussion of the superficial temporal artery often results in a serrated distortion of the Doppler waveform in the ECA (80% of ECAs percussed in one study[162]) (see Fig. 26.4B). However, this maneuver should be interpreted with caution because the temporal tap can also be seen in the CCA and ICA, although less frequently (54% and 33%, respectively) than in the ECA.[163] Branching vessels are a unique feature of the ECA, which can also be used to differentiate this vessel from the ICA. Color Doppler sonography can facilitate the identification of such branching vessels (see Fig. 26.4A). Usually, the combination of vessel size, position, waveform shape, presence of branches, and the temporal tap response can correctly identify the ECA.

Although distal propagation of the thrombus almost invariably occurs after an ICA occlusion, CCA occlusions are often localized. Flow may be maintained in the ECA and ICA but must be reversed in one of the two vessels. Sonography is the preferred method for evaluating the maintenance of flow around the carotid bifurcation after proximal CCA occlusion. Most often, retrograde flow in the ECA will supply antegrade flow in the ipsilateral ICA. Occasionally, the opposite flow pattern will be encountered[102,164,165] (Fig. 26.36).

Follow-Up of Stenosis

Although there is a considerable amount of published literature regarding cutoff criteria for determining the degree of stenosis as well as recommendations for interventions, little has been written regarding the appropriate follow-up for stenosis not requiring intervention. There is no accepted national or international consensus regarding surveillance intervals for monitoring stenosis less than 60%.[58] As a result of this lack of national and international consensus, we at Ochsner Clinic Foundation, following discussions with the Cardiology and Vascular Surgery Departments, have come up with our own internal consensus for the follow-up of patients with different degrees of stenosis, differences regarding symptomatology, and different types of plaque (Table 26.3). Patients with heterogeneous plaque and those who are symptomatic are recommended to have shorter interval follow-up studies to watch for more rapid progression compared to others with the same degree of stenosis.

Preoperative Strategies for Patients With Carotid Artery Disease

The preoperative workup of carotid disease is evolving in response to NASCET, ECST, and ACAS results.[7,8,166] The issue of numbers to be used for a carotid ultrasound examination depends on the intent of the examination. Why are we doing the study? How will we use the results? If the examination is a screening test, are we evaluating all patients or only symptomatic patients? If we intend to select patients for surgery on the basis of the ultrasound alone, then a different set of variables is likely to produce the desired outcome. The purpose of a carotid examination and the patient population being screened will impact the selection of velocity thresholds. For example, screening of high-risk, asymptomatic patients might best be performed with high-velocity thresholds with increased specificity, whereas symptomatic patients more likely to undergo surgery for optimal treatment would dictate lower thresholds with increased sensitivity.

Although many still consider angiography as the standard, its critics cite significant intraobserver variability and frequent underestimation of the degree of stenosis.[167,168] Comparisons of angiographic and sonographic estimations of carotid stenosis reveal a closer surgical correlation with the ultrasound measurements.[1] Carotid ultrasound has proved highly accurate in detecting high-grade stenoses, as well as differentiating critical stenoses from occlusion.

MRA is currently demonstrating comparable accuracy as ultrasound and angiography for the detection and quantification of carotid stenosis. During the past 15 years, magnetic resonance imaging (MRI) has also been shown to be useful in the characterization and risk stratification of carotid disease. MRI can accurately identify intraplaque hemorrhage, lipid-rich necrotic core, and thinning and rupture of the fibrous cap, which are associated with increased risk of future stroke and TIA.[169-172] MRA can also evaluate intracranial circulation; however, cost, time, and availability limit MRA as a first-line choice of evaluation of carotid disease.[173] MRA may be helpful in situations where calcified plaque obscures the underlying carotid lumen from insonation. CTA is a fast, widespread modality that can accurately detect ulceration and calcification but cannot differentiate intraplaque hemorrhage and lipid-rich necrotic core.[173] The overall concordance rate between Doppler ultrasound, contrast-enhanced MRA, and CTA is very similar for evaluating carotid stenosis.[174,175]

Many investigators now suggest replacing preoperative angiography with a combination of carotid sonography and MRA. They advocate utilizing angiography only in cases where MRA

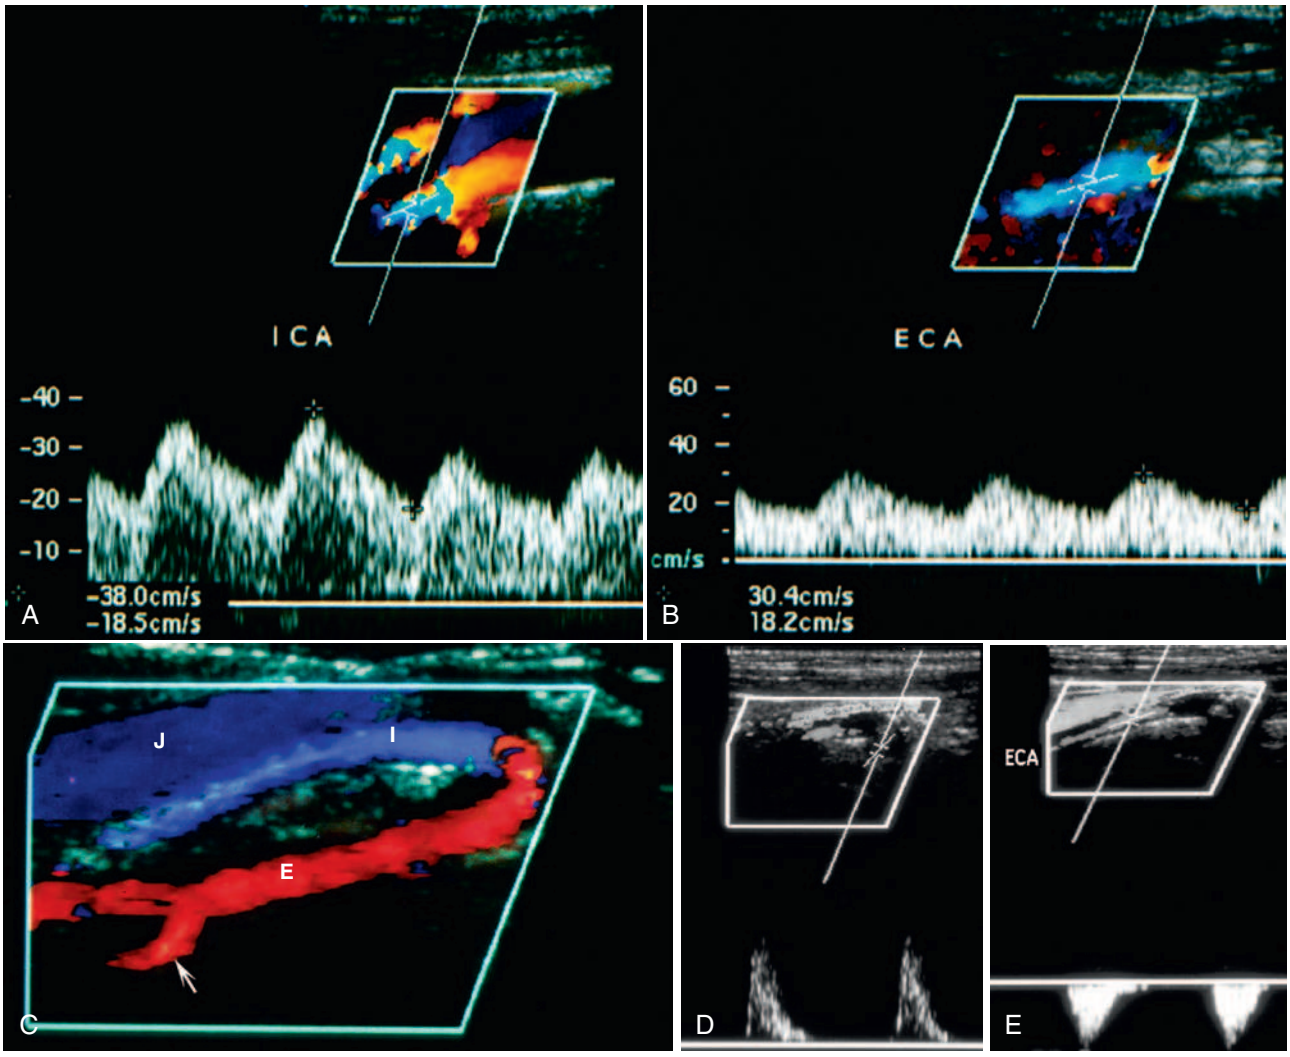

FIG. 26.36 CCA Occlusion Causes Abnormal ICA Waveform. (A) Antegrade tardus-parvus waveform is seen in an ICA distal to a CCA occlusion. **(B)** Retrograde ECA flow with a tardus-parvus waveform caused by collateral flow from the contralateral ECA to supply the ipsilateral ICA distal to a CCA occlusion. **(C)** Color Doppler image shows antegrade ECA flow *(E)* with an ECA branch *(arrow)* and retrograde ICA flow *(I)*. *J,* Internal jugular vein. **(D)** Spectral Doppler image shows high-resistance retrograde right ICA flow. **(E)** High-resistance antegrade flow in the right ECA distal to a CCA occlusion.

and carotid ultrasound have discordant results or they are inadequate.[176-180] Other studies support the use of carotid ultrasound alone before endarterectomy.[177,178,181-185] Numerous studies show that more than 90% of surgical candidates can be adequately screened using clinical assessment and ultrasound alone. However, in suspected aortic arch proximal vessel disease or in cases of suspected complete occlusion, some practitioners still advocate preoperative angiography.

Postoperative Ultrasound

The carotid artery after endarterectomy **(post-CEA)** demonstrates many characteristic features[186,187] (Fig. 26.37). A discrete wedge between the normal I-M complex and the endarterectomized surface is frequently seen, as are periodically spaced echogenic sutures. The absent I-M complex has also been shown to regrow. One study showed that 6% of CEA patients had carotid flaps, residual moderate to moderately severe stenoses, or occluded ECAs.[188] Two of these patients with postoperative abnormalities on ultrasound sustained perioperative stroke. Patients without defects on the postoperative ultrasound had no perioperative sequelae or need for a repeat of procedures. Patients with preoperative stenoses greater than 75% have a greater risk for residual stenoses. Ultrasound appears useful in the symptomatic postoperative population, but its role in the asymptomatic patient population is debatable.[189] Routine follow-up with ultrasound every 6 months after CEA for 2 years and then annually or possibly just once 12 months after CEA has been recommended; however, more research needs to be done.[190,191]

Carotid Artery Stents and Revascularization

Percutaneous transluminal **carotid artery stenting** (CAS) in association with carotid angioplasty is becoming an increasing popular and common means of carotid revascularization. Between 1998 and 2004, the incidence of CEA decreased 17%, whereas

TABLE 26.3 Recommendations for Follow-Up Based on Ultrasound Assessment

Treatment recommended by these specialists could be endovascular stent, endarterectomy, or intensive medical Rx.

incidence of CAS increased 149%.[192] While CAS has emerged as a less-invasive treatment than CEA, several randomized clinical trials and the Society of Vascular Surgery have shown CAS to be associated with lower perioperative morbidity, particularly myocardial infarction, but with an increased incidence of stroke.[193-195] Careful patient selection is critical if the potential benefits of carotid revascularization are to be realized.[193,194] Ultrasound may be helpful in (1) assessing the presence and severity of stenosis; (2) characterizing the carotid bifurcation; and (3) assessing anatomic variants, vessel tortuosity, and plaque calcification before stent placement (Fig. 26.38).

The role of ultrasound in determining patient selection also remains controversial. Certainly, the accuracy of duplex ultrasound in grading flow-limiting stenosis is well established, with a sensitivity of 94% and a specificity of 92%, and is universally accepted as an important criterion in patient selection.[193,194,196] However, although the role of plaque characterization in patient selection remains controversial, it is becoming more important as **vulnerable plaque,** as a cause of stroke, becomes more appreciated. Vulnerable plaque appears to correlate with heterogeneous or echolucent type 1 or 2 plaque. This type of plaque is associated with intraplaque hemorrhage and is thought to have strong embolic potential. Using **intravascular ultrasound,** Diethrich et al.[197] showed a strong correlation between intravascular ultrasound plaque characterization and histologic examination of the plaque after endarterectomy. Considering the accuracy of ultrasound characterization, when intraplaque hemorrhage or vulnerable plaque is identified, CEA rather than CAS might be the preferred method of revascularization to reduce the risk of embolic complications. However, Reiter et al.[85] were unable to use plaque echolucency as a criterion for those at increased risk for post-CAS neurologic events and therefore did not recommend this type of risk stratification. The use of plaque characterization to determine the type of therapeutic intervention needs further assessment.

Grading Carotid Intrastent Restenosis

Sonography allows accurate evaluation of stent placement within the carotid vessels.[198] Carotid **stents** are readily visualized with ultrasound, allowing sonographers to assess disease before, along,

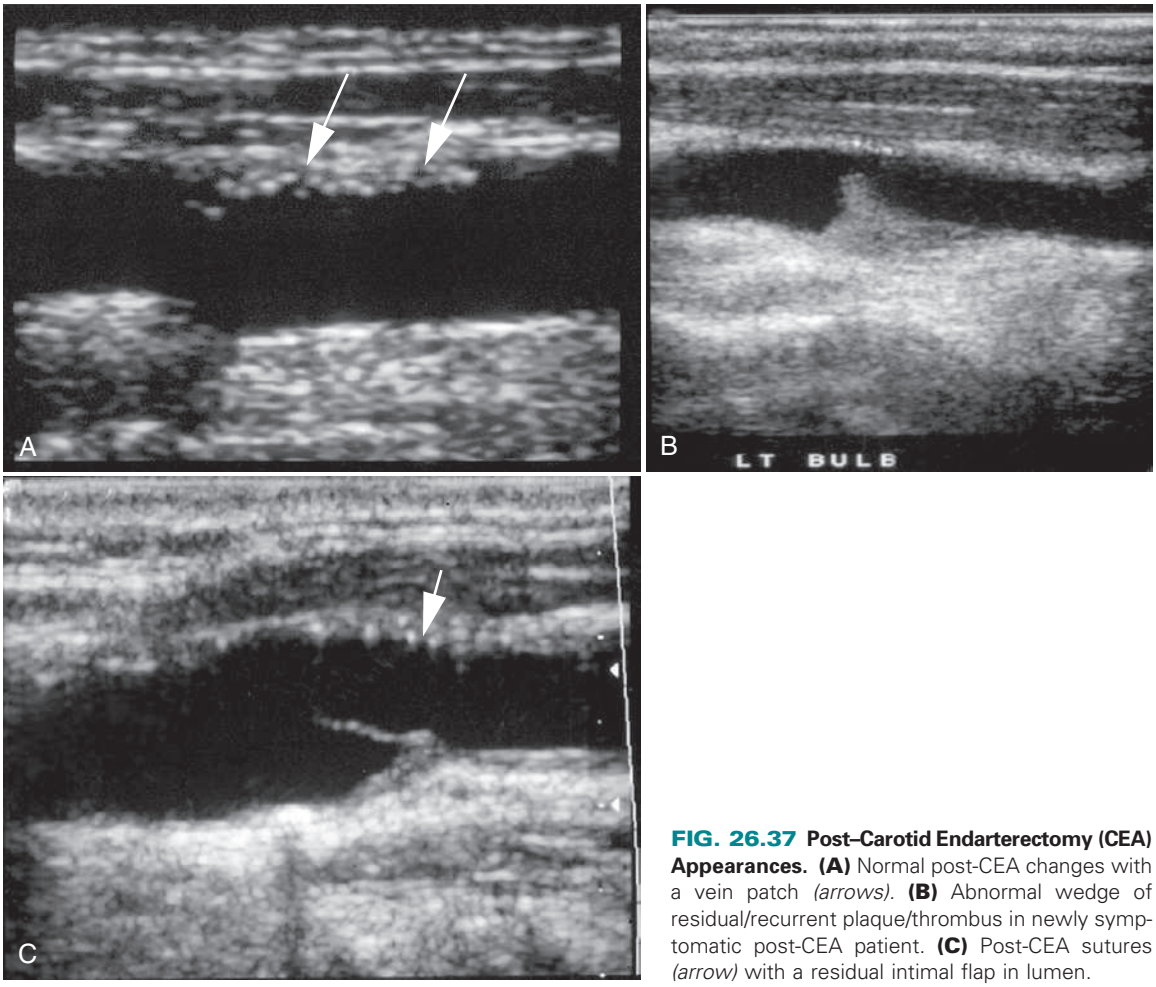

FIG. 26.37 Post–Carotid Endarterectomy (CEA) Appearances. (A) Normal post-CEA changes with a vein patch *(arrows)*. **(B)** Abnormal wedge of residual/recurrent plaque/thrombus in newly symptomatic post-CEA patient. **(C)** Post-CEA sutures *(arrow)* with a residual intimal flap in lumen.

and distal to the stent. The rate of post-CAS restenosis has been reported as between 1.9% and 16%.[198-203] Velocity criteria for grading stenoses in a stent may not be the same as for those in the native carotid artery.[204,205] Some investigators have shown that velocities along the stent are routinely higher than those in a nonstented vessel. Velocity elevations in the range of 125 to 140 cm/sec are fairly common in widely patent stents. In addition, sonographers normally see an increase in velocity in the distal ICA beyond the deployed stent. At present, slight increases in velocity in a stent that appears widely patent on power or color Doppler are unlikely to indicate significant narrowing or warrant further assessment or intervention.

Fleming et al.[198] and Chahwan et al.[206] showed that normal Doppler ultrasound reliably identifies arteriographically normal carotid arteries after CAS. They also reported that post-CAS carotid velocities did not always correlate with the prestent flow-limiting stenosis assessments and that the velocities are disproportionately elevated in mild and moderately restenotic vessels. The disproportionate velocity elevations along the stent may be caused by several factors, including changes in vessel wall compliance and shunting of blood flow away from the ECA. Also, the technique used in many stent trials, which require strict adherence to the 60-degree angle theta technique for Doppler interrogation, may result in systematic velocity increases. As such, it was realized that new tables must be established and validated for the follow-up of patients after CAS. Multiple proposals for grading post-CAS parameters have been suggested[207-211] (Table 26.4).

NONATHEROSCLEROTIC CAROTID DISEASE

Nonatherosclerotic carotid disease is much less common than plaque disease. **Fibromuscular dysplasia,** a noninflammatory process with hypertrophy of muscular and fibrous arterial walls separated by abnormal zones of fragmentation, involves the middle and distal ICA more frequently than other carotid segments. A characteristic "string of beads" appearance has been described on angiography. Only a few reports describe sonographic features of fibromuscular dysplasia.[212-214] Many patients with fibromuscular dysplasia demonstrate nonspecific or no obvious abnormalities on ultrasound; however, some patients may demonstrate redundancy of the mid to distal ICA causing an S-shaped curve.[215] Fibromuscular dysplasia may be asymptomatic or can result in

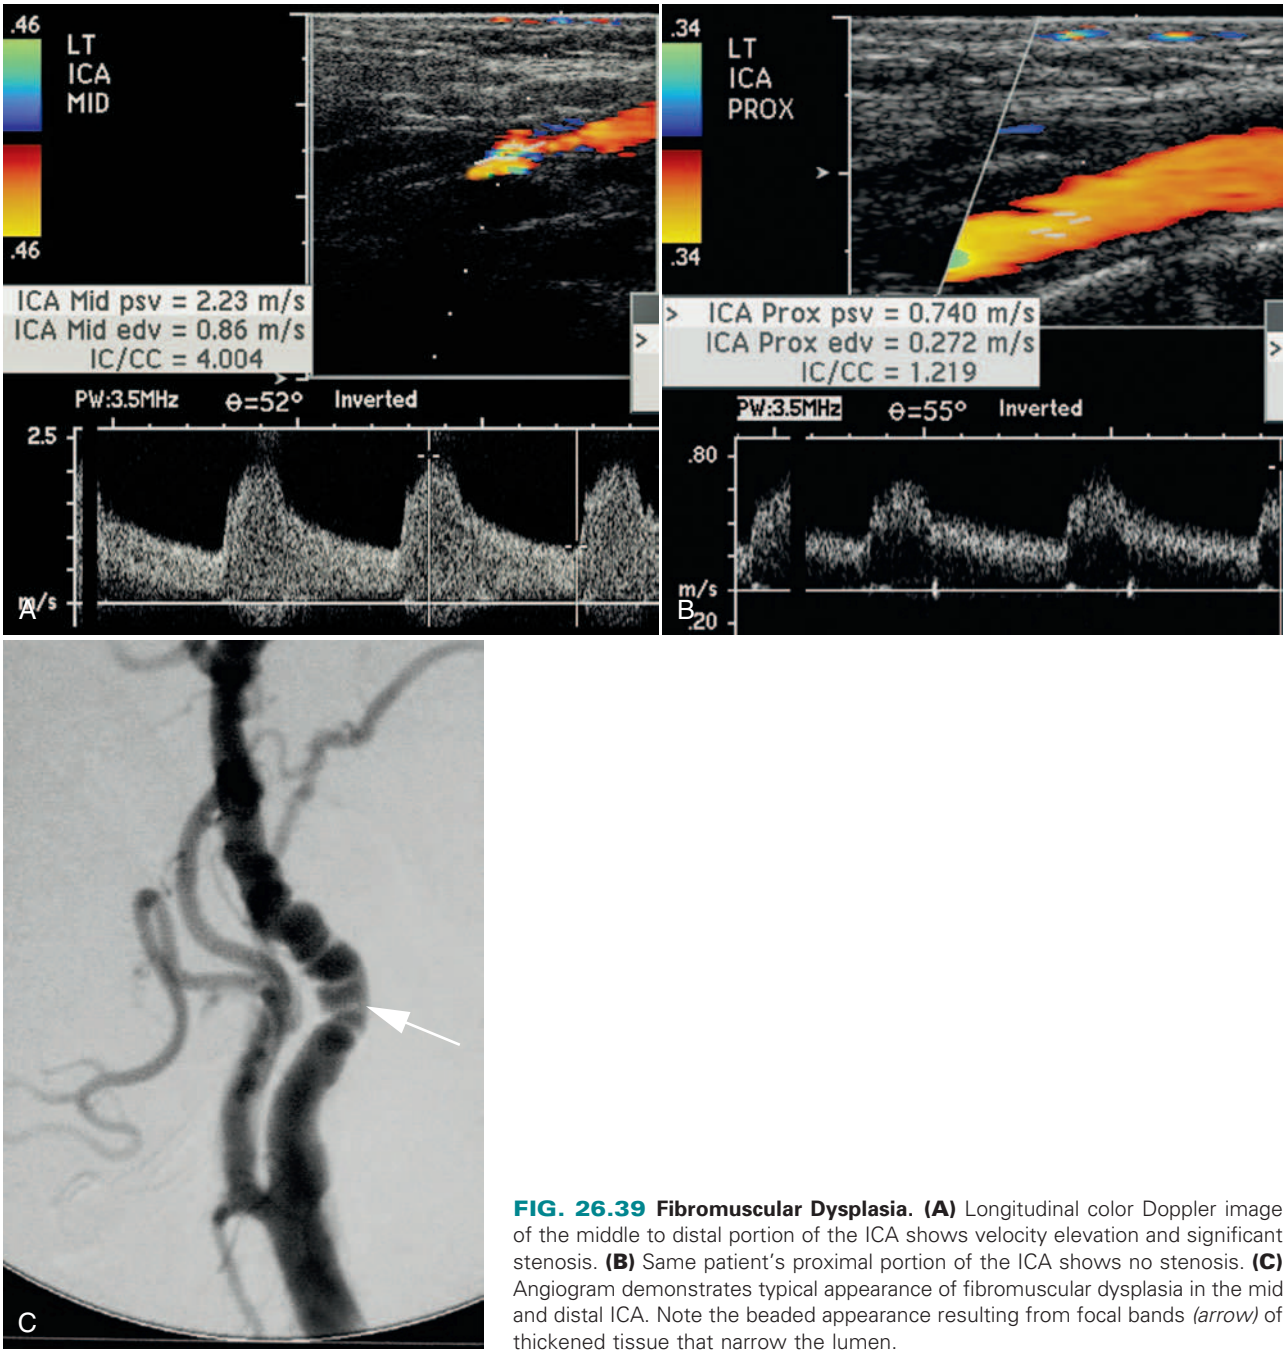

FIG. 26.39 Fibromuscular Dysplasia. (A) Longitudinal color Doppler image of the middle to distal portion of the ICA shows velocity elevation and significant stenosis. **(B)** Same patient's proximal portion of the ICA shows no stenosis. **(C)** Angiogram demonstrates typical appearance of fibromuscular dysplasia in the mid and distal ICA. Note the beaded appearance resulting from focal bands *(arrow)* of thickened tissue that narrow the lumen.

carotid dissection or subsequent thromboembolic events (Fig. 26.39). **Arteritis** resulting from autoimmune processes (e.g., Takayasu arteritis, temporal arteritis) or radiation changes can produce diffuse concentric thickening of carotid walls, which most frequently involves the CCA[23,216,217] (Fig. 26.40).

Cervical trauma can produce carotid dissections or aneurysms. **Carotid artery dissection** results from a tear in the intima, allowing blood to dissect into the wall of the artery, which produces a false lumen. The false lumen may be blind ended or may reenter the true lumen. The false lumen may occlude or narrow the true lumen, producing symptoms similar to carotid plaque disease. Dissections may arise spontaneously or secondary to trauma or to intrinsic disease with elastic tissue degeneration (e.g., **Marfan syndrome**) or may be related to atherosclerotic plaque disease.[20] The ultrasound examination of a carotid dissection may reveal a mobile or fixed **echogenic intimal flap,** with or without thrombus formation.[218] Frequently, there is a striking image/Doppler mismatch with a paucity of gray-scale abnormalities seen in association with marked flow abnormalities (Fig. 26.41).

Color or power Doppler ultrasound can readily clarify the source of this mismatch by demonstrating abrupt tapering of the patent, filled lumen to the point of an ICA occlusion. When the ICA is occluded, the proximal ipsilateral CCA will demonstrate

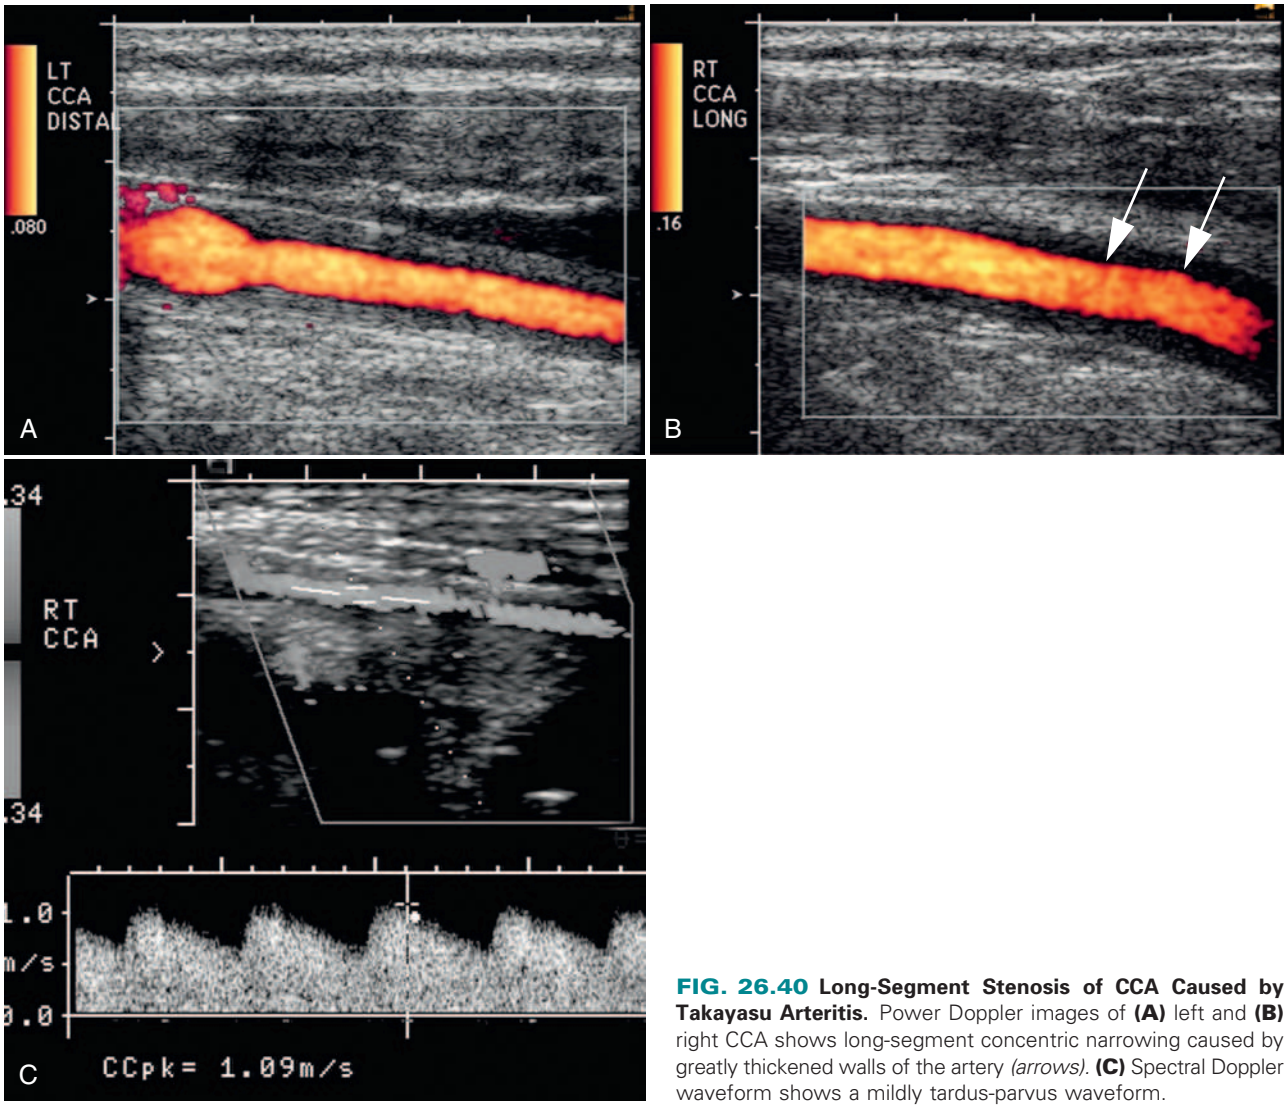

FIG. 26.40 Long-Segment Stenosis of CCA Caused by Takayasu Arteritis. Power Doppler images of **(A)** left and **(B)** right CCA shows long-segment concentric narrowing caused by greatly thickened walls of the artery *(arrows)*. **(C)** Spectral Doppler waveform shows a mildly tardus-parvus waveform.

Normal appearance

a high-resistance waveform. When the ICA is severely narrowed (secondary to hemorrhage and a thrombus in the area of the false lumen), flow in the ICA may demonstrate high velocities. In these nonoccluded ICA cases, flow velocity waveforms in the CCA may be normal. Although conventional angiography, MRA, or CTA can be used initially to diagnose a dissection, ultrasound can be used to follow patients to assess the therapeutic response to anticoagulation. Repeat sonographic evaluation of patients with ICA dissection after anticoagulation therapy reveals recanalization of the artery in as many as 70% of cases.[219-221] It is important to consider the diagnosis of dissection as a cause of neurologic symptoms, particularly when the clinical presentation, age, and patient history are atypical for that of atherosclerotic disease or hemorrhagic stroke.

Pulsatile Neck Masses in the Carotid Region

The most common **CCA aneurysm** occurs in the region of the carotid bifurcation. These aneurysms may result from atherosclerosis, infection, trauma, surgery, or contagious disease, such as **syphilis.** The normal CCA usually measures no more than 1 cm in diameter. **Carotid body tumors,** one of several **paragangliomas** that involve the head and neck, are usually benign,

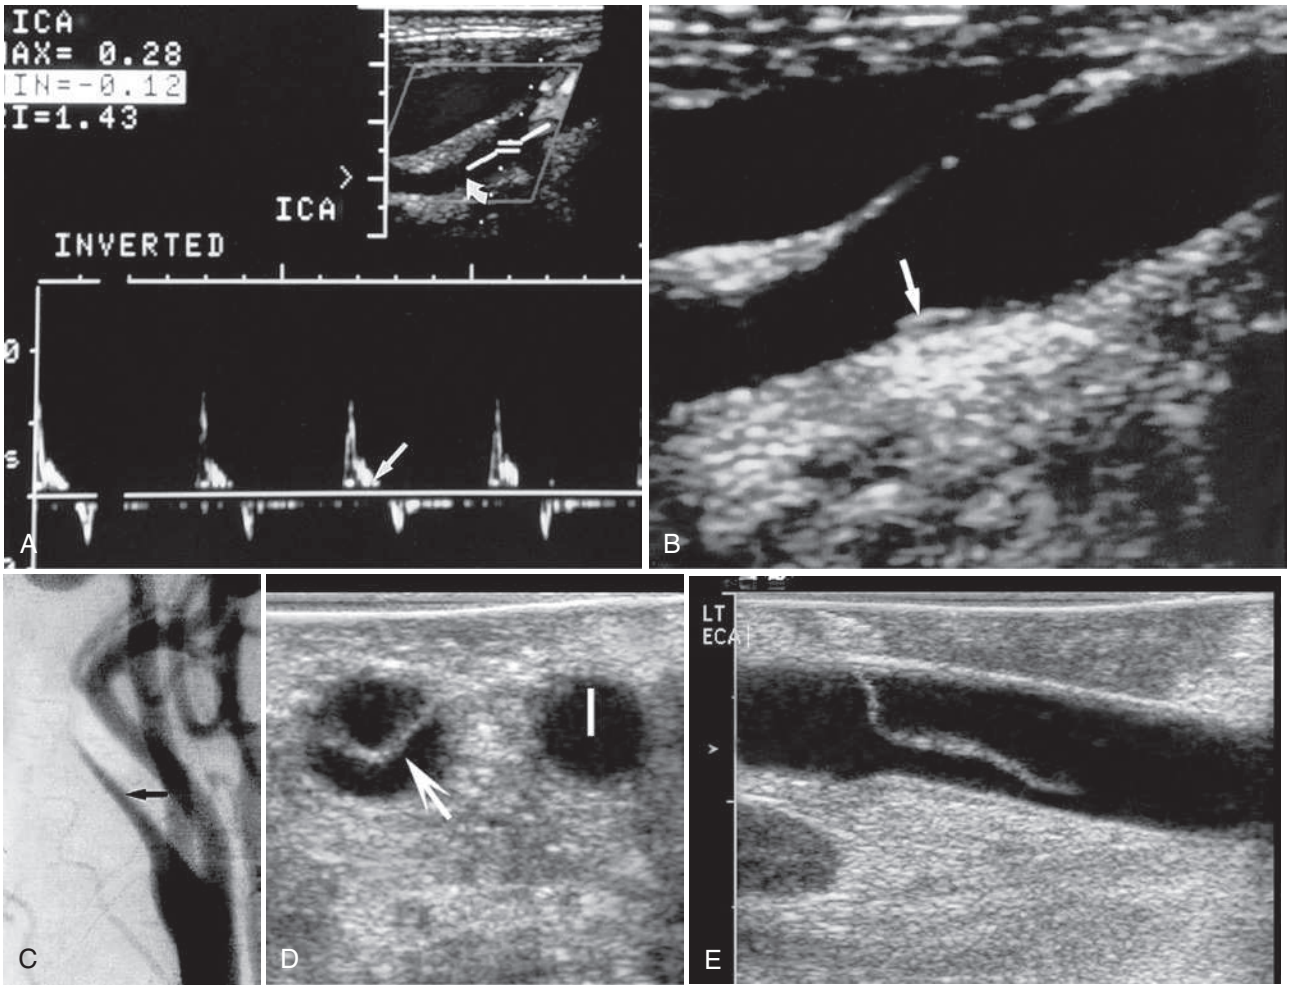

FIG. 26.41 Carotid Artery Dissection. (A) Abnormal high-resistance waveforms *(arrow)* at the origin of the right ICA with no evidence of flow distal to this point *(curved arrow)*. **(B)** Gray-scale evaluation of the vessel in the area of the occlusion demonstrates only a small, linear echogenic structure *(arrow)* without evidence of significant atherosclerotic narrowing. **(C)** Subsequent angiogram demonstrates the characteristic tapering to the point of occlusion *(arrow)* associated with carotid artery dissection and thrombotic occlusion. **(D)** Transverse and **(E)** longitudinal images of another patient show an intimal flap *(arrow)* in an ECA. *I,* Internal carotid artery.

well-encapsulated masses located at the carotid bifurcation.[29] These tumors may be bilateral, particularly in the familial variant, and are very vascular, often producing an audible bruit.[29] Some of these tumors produce catecholamines, leading to sudden changes in blood pressure during or after surgery. Color Doppler ultrasound demonstrates an extremely vascular soft tissue mass at the carotid bifurcation[29] (Fig. 26.42). Color Doppler ultrasound can also be used to monitor embolization or surgical resection of carotid body tumors. A classic nonmass is the **ectatic innominate/proximal CCA,** frequently occurring as a pulsatile supraclavicular mass in older women. The request to rule out a carotid aneurysm almost invariably shows the classic normal features of these tortuous vessels (Fig. 26.43).

Extravascular masses (e.g., lymph node masses [Fig. 26.44], hematomas, abscesses) that compress or displace the carotid arteries can be readily distinguished from primary vascular masses, such as aneurysms or pseudoaneurysms. **Posttraumatic pseudoaneurysms** can usually be distinguished from true carotid aneurysms by the characteristic to-and-fro waveforms in the neck of the pseudoaneurysm, as well as the internal variability (yin-yang) characteristic of a pseudoaneurysm (Fig. 26.45).

TRANSCRANIAL DOPPLER SONOGRAPHY

In transcranial Doppler (TCD) ultrasound, a low-frequency 2-MHz transducer is used to evaluate blood flow within the intracranial carotid and vertebrobasilar system and the circle of Willis. Access is achieved through the orbits, foramen magnum, or, most often, the region of temporal calvarial thinning **(transtemporal window).**[222,223] However, many patients (up to 55% in one series[224]) may not have access to an interpretable TCD examination. Women, particularly African American women, have a thick temporal bone through which it is difficult to insonate the basal cerebral arteries.[224,225] This difficulty limits the feasibility of TCD imaging as a routine part of the noninvasive cerebrovascular workup.[223,224]

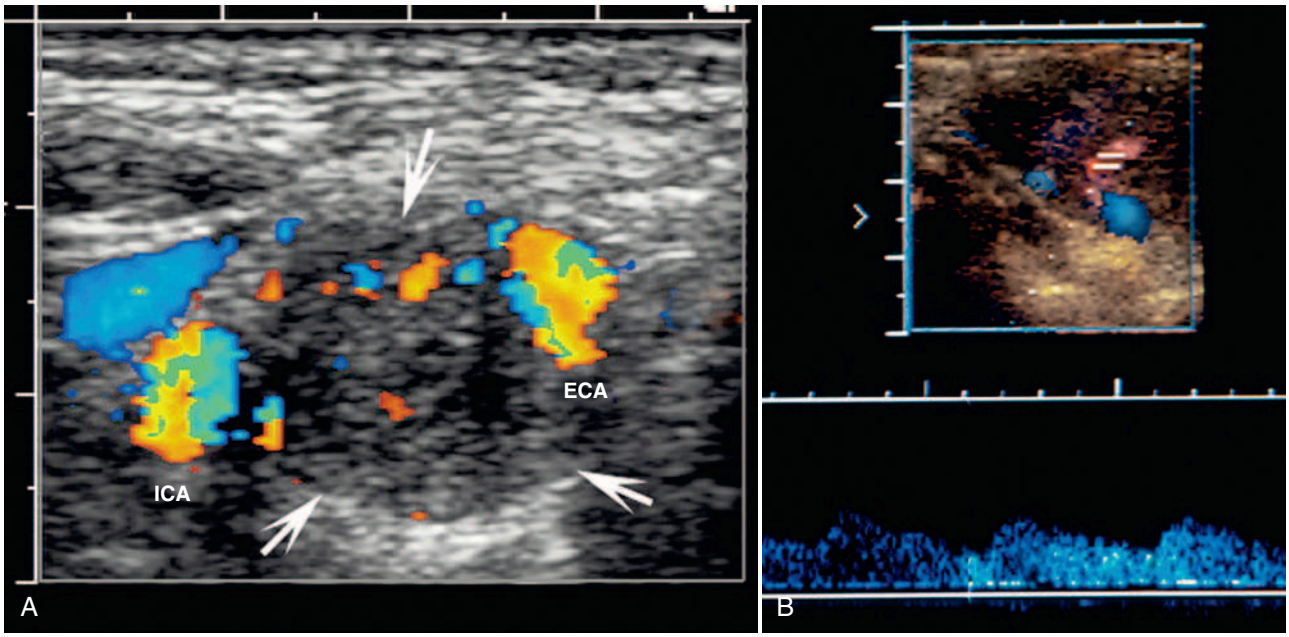

FIG. 26.42 Carotid Body Tumor. (A) Transverse image of the carotid bifurcation shows a mass *(arrows)* splaying the internal carotid artery *(ICA)* and external carotid artery *(ECA)*. **(B)** Pulsed Doppler traces of the carotid body tumor show typical arteriovenous shunt (low-resistance) waveform.

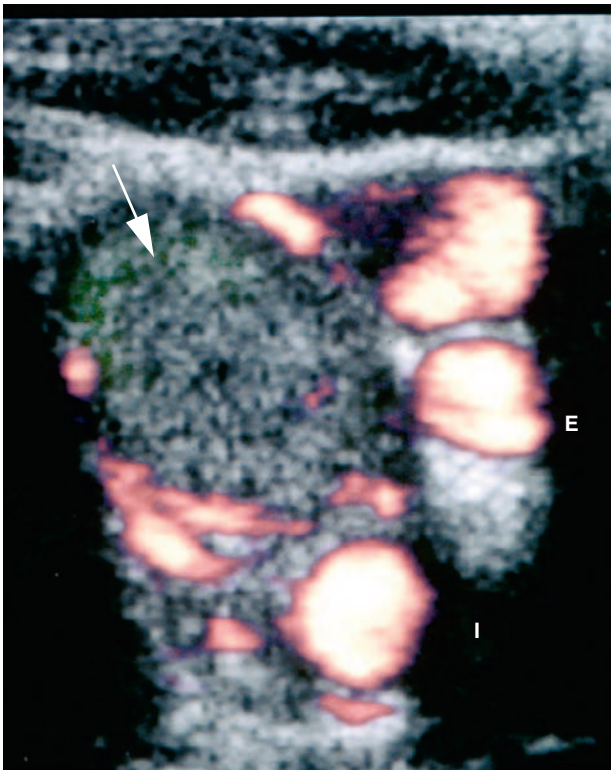

FIG. 26.44 Pathologic Lymph Node Near Carotid Bifurcation. Power Doppler image shows a malignant lymph node *(arrow)* lateral to the carotid bifurcation. *E,* External carotid artery; *I,* internal carotid artery.

By using spectral analysis, various parameters are determined, including mean velocity, PSV, EDV, and the pulsatility and resistive indices of the blood vessels. Color or power Doppler ultrasound can improve velocity determination by providing better angle theta determination and localizing the course of vessels.[222] TCD applications include (1) evaluation of intracranial stenoses and collateral circulation, (2) detection and follow-up of vasoconstriction from subarachnoid hemorrhage, (3) determination of brain death, (4) evaluation of patients with sickle cell disease, and (5) identification of arteriovenous malformation.[219-223,226,227] TCD is most reliable in diagnosing stenoses of the middle cerebral artery, with sensitivities as high as 91% reported. TCD is less reliable for detecting stenoses of the intracranial vertebrobasilar system, anterior and posterior cerebral arteries, and terminal ICA. However, TCD is helpful in assessing vertebral artery patency and flow direction when no flow is detected in the extracranial vertebral artery (Fig. 26.46). Diagnosis of an intracranial stenosis is based on an increase in the mean velocity of blood flow in the affected vessel compared to that of the contralateral vessel at the same location.[223-225]

Advantages of TCD ultrasound also include its availability for monitoring patients in the operating room or angiographic suite for potential cerebrovascular complications.[225] Intraoperative TCD monitoring can be performed with the transducer strapped over the transtemporal window, allowing evaluation of blood flow in the middle cerebral artery during CEA. The adequacy of cerebral perfusion can be assessed while the carotid artery is clamped.[225,228] TCD is also capable of detecting **intraoperative microembolization,** which produces high-amplitude spikes (high-intensity transient signals ["HITS"]) on the Doppler spectrum.[223,224,227,229-231] The technique can be used for the serial evaluation of **vasospasms.** This diagnosis is usually based on serial examinations of the relative increase in blood flow velocity and resistive index changes resulting from a decrease in the lumen of the vessel caused by vasospasms.[225] More description of transcranial Doppler is in Chapter 47.

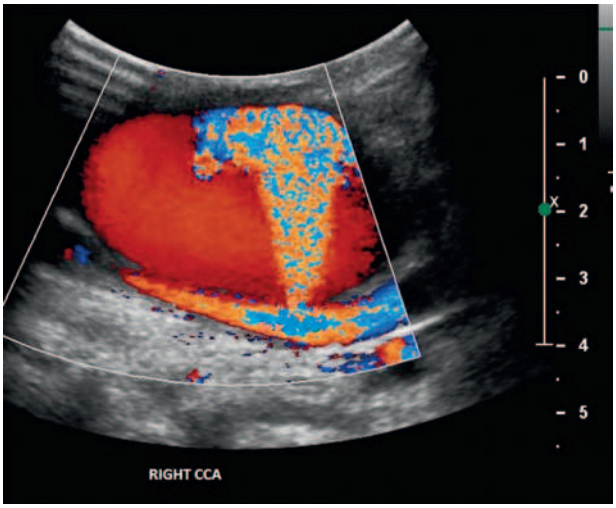

FIG. 26.45 Pseudoaneurysm of the Common Carotid Artery (CCA). Transverse image of the right CCA demonstrates a jet of flow into a pseudoaneurysm, which resulted from an attempted central venous line placement.

VERTEBRAL ARTERY

The vertebral arteries supply the majority of the posterior brain circulation. Through the circle of Willis, the vertebral arteries also provide collateral circulation to other portions of the brain

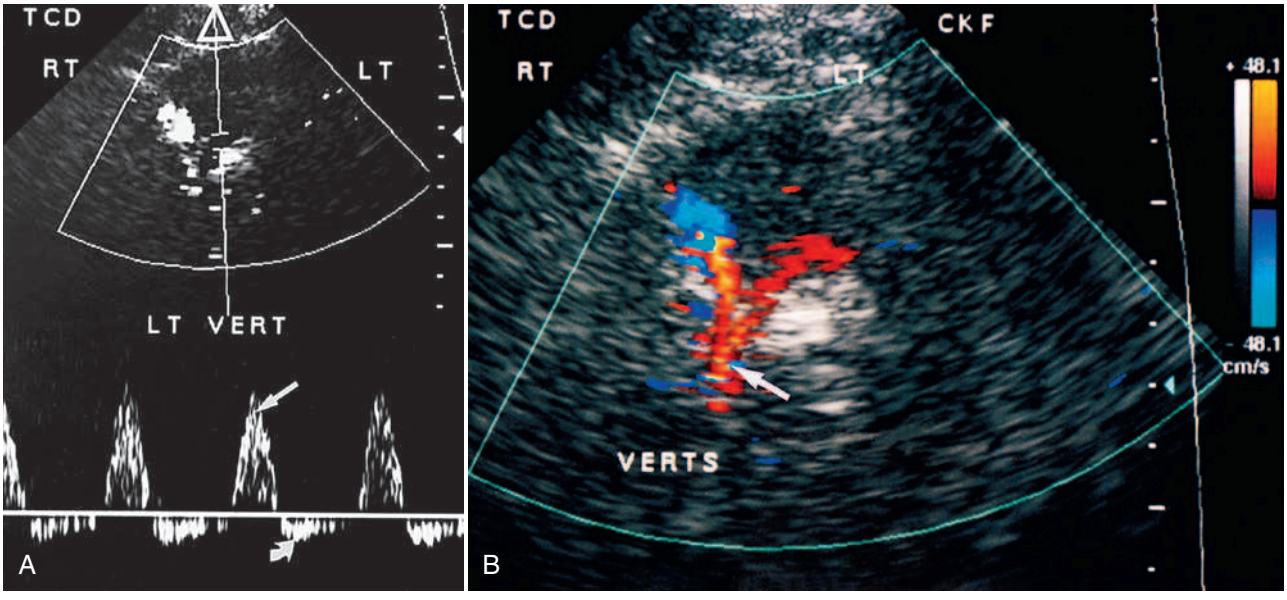

FIG. 26.46 Transcranial Doppler Imaging. (A) Transcranial duplex scan of the posterior fossa in a patient with an incomplete left subclavian steal syndrome demonstrates retrograde systolic flow *(arrow)* and antegrade diastolic flow *(curved arrow).* The scan is obtained in a transverse projection from the region of the foramen magnum *(open arrowhead).* **(B)** Color Doppler image obtained in the same patient demonstrates that there is retrograde flow not only within the left vertebral artery but also within the basilar artery *(arrow).*

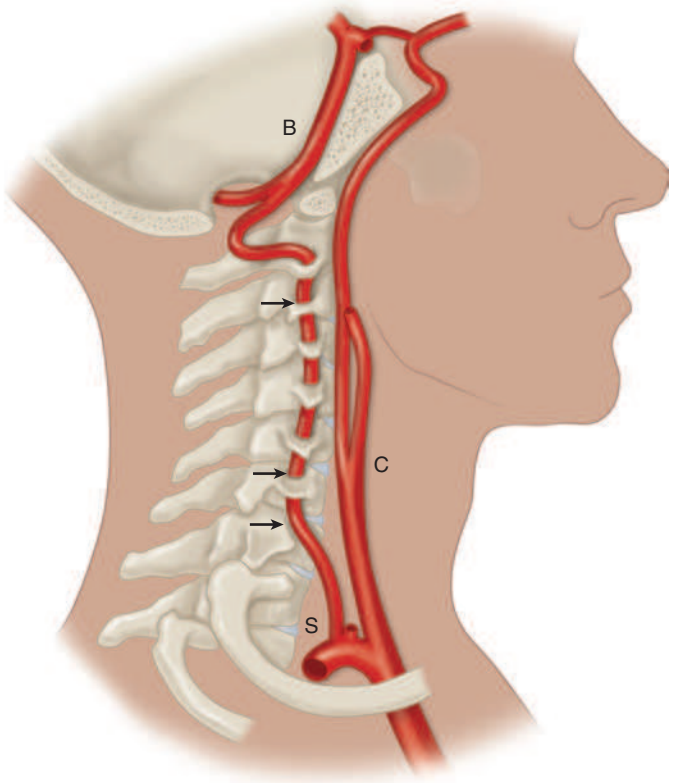

FIG. 26.47 Vertebral Artery Course. Lateral diagram of vertebral artery *(arrows)* shows its course through the cervical spine transverse foramina en route to joining the contralateral vertebral artery to form the basilar artery *(B). C,* Carotid artery; *S,* subclavian artery.

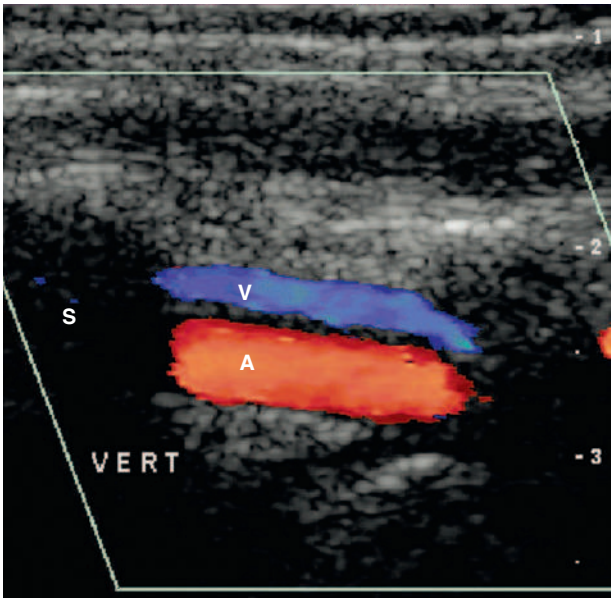

FIG. 26.48 Normal Vertebral Artery and Vein. Longitudinal color Doppler image shows a normal vertebral artery *(A)* and vein *(V)* running between the transverse processes of the second to sixth cervical vertebrae (C2-C6), which are identified by their periodic acoustic shadowing *(S).*

in patients with carotid occlusive disease. Evaluation of the extracranial vertebral artery seems a natural extension of carotid duplex and color Doppler imaging.[232,233] Historically, however, these arteries have not been studied as intensively as the carotids. Symptoms of **vertebrobasilar insufficiency** also tend to be rather vague and poorly defined compared with symptoms referable to the carotid circulation. It is often difficult to make an association confidently between a lesion and symptoms. Furthermore, interest in surgical correction of vertebral lesions has been limited. The anatomic variability, small size, deep course, and limited visualization resulting from overlying transverse processes make the vertebral artery more difficult to examine accurately with ultrasound.[232,234-236] The clinical utility of vertebral artery duplex scanning in diagnosing subclavian steal and presteal phenomena is well established.[237-239] Less clear-cut is the use of vertebral duplex scanning in evaluating vertebral artery stenosis, dissection, or aneurysm.[240]

Anatomy

The vertebral artery is usually the first branch off the subclavian artery (Fig. 26.47). However, variation in the origin of the vertebral arteries is common. In 6% to 8% of people, the left vertebral artery arises directly from the aortic arch proximal to the left subclavian artery.[234,241] In 90%, the proximal vertebral artery ascends superomedially, passing anterior to the transverse process of the seventh cervical vertebra (C7), and enters the transverse foramen at the C6 level. The rest of the vertebral arteries enter into the transverse foramen at the C5 or C7 level and, rarely, at the C4 level. The size of vertebral arteries is variable, with the left larger than the right in 42%, the two vertebral arteries equal in size in 26%, and the right larger than the left in 32% of cases.[242] One vertebral artery may even be congenitally absent. Usually, the vertebral arteries join at their confluence to form the **basilar artery.** Rarely, the vertebral artery may terminate in a posterior inferior cerebellar artery.

Sonographic Technique and Normal Examination

Vertebral artery visualization with Doppler flow analysis can be obtained in 92% to 98% of vessels[232,243] (Fig. 26.48). Vertebral artery duplex examinations are performed by first locating the CCA in the longitudinal plane. The direction of flow in the CCA and jugular vein is determined. A gradual sweep of the transducer laterally demonstrates the vertebral artery and vein running between the transverse processes of C2 to C6, which are identified by their periodic acoustic shadowing. Angling the transducer caudad allows visualization of the vertebral artery origin in 60% to 70% of the arteries, in 80% on the right side, and in 50% on the left. This discrepancy may relate to the left vertebral artery origin being deeper and arising directly from the aortic arch in 6% to 8% of cases.[234,241]

The presence and direction of flow should be established. Visible plaque should be assessed. The vertebral artery usually has a low-resistance flow pattern similar to that of the CCA, with continuous flow in systole and diastole; however, wide variability in waveform shape has been noted in angiographically

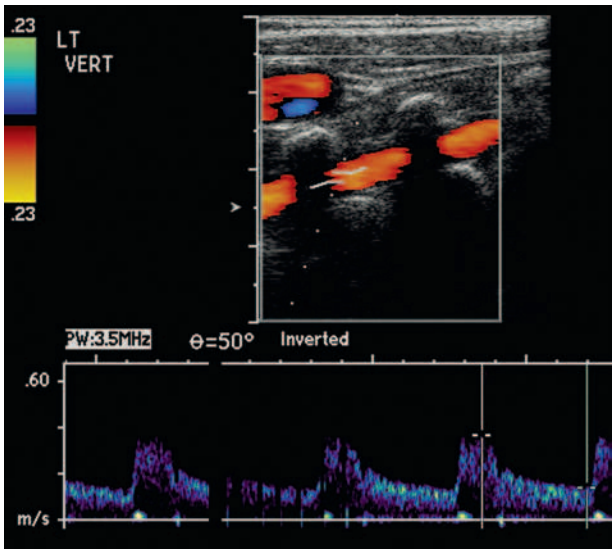

FIG. 26.49 Normal Vertebral Artery Waveform. Normal low-resistance waveform of the vertebral artery with filling of the spectral window.

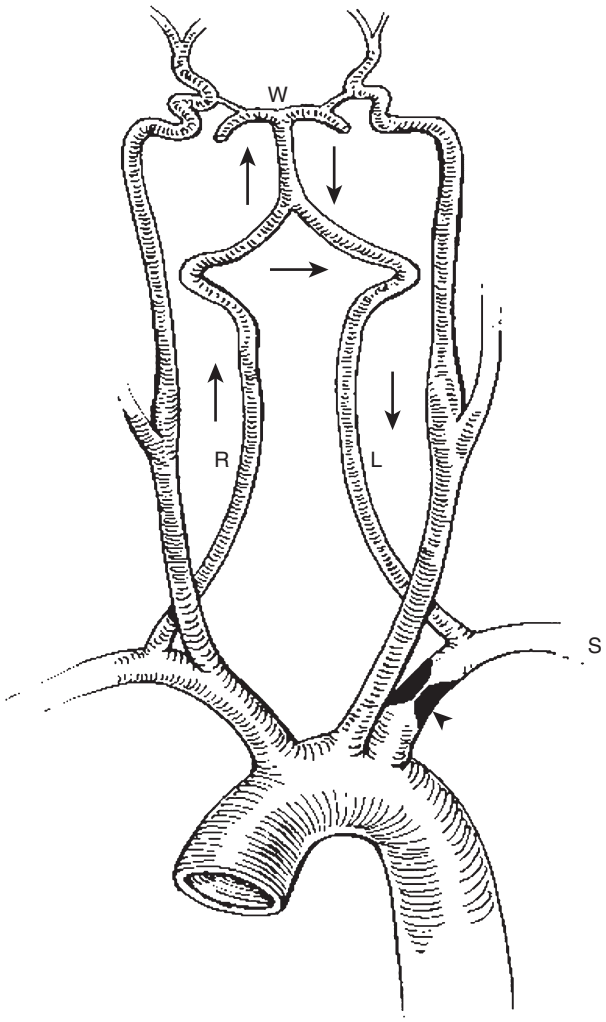

FIG. 26.50 Hemodynamic Pattern in Subclavian Steal Syndrome. Proximal left subclavian artery occlusive lesion *(arrowhead)* decreases flow to the distal subclavian artery *(S)*. This produces retrograde flow *(large arrows)* down the left vertebral artery *(L)* and stealing from the right vertebral artery *(R)* and other intracranial vessels through the circle of Willis *(W)*.

normal vessels.[244] Because the vessel is small, flow tends to demonstrate a broader spectrum. The clear spectral window seen in the normal carotid system is often filled in the vertebral artery[102] (Fig. 26.49).

The **vertebral vein** (often a plexus of veins) runs parallel and adjacent to the vertebral artery. Care must be taken not to mistake its flow for that of the adjacent artery, particularly if the venous flow is pulsatile. Comparison with jugular venous flow during respiration should readily distinguish between vertebral artery and vein. At times, the ascending cervical branch of the thyrocervical trunk can be mistaken for the vertebral artery. This can be avoided by looking for landmark transverse processes that accompany the vertebral artery and by paying careful attention to the waveform of the visualized vessel. The ascending cervical branch has a high-impedance waveform pattern similar to that of the ECA.[237]

TCD sonographic examination of the vertebrobasilar artery system can be performed as an adjunct to the extracranial evaluation. The examination is conducted with a 2-MHz transducer with the patient sitting, using a suboccipital midline nuchal approach, or with the patient supine, using a retromastoidal approach. Color or power Doppler facilitates TCD imaging of the vertebrobasilar system.[245]

Subclavian Steal

The **subclavian steal phenomenon** occurs when there is high-grade stenosis or occlusion of the proximal subclavian or innominate arteries with patent vertebral arteries bilaterally. The artery of the ischemic limb "steals" blood from the vertebrobasilar circulation through retrograde vertebral artery flow, which may result in symptoms of vertebrobasilar insufficiency (Fig. 26.50). Symptoms are usually most pronounced during exercise of the upper extremity but can be produced by changes in head position. However, there is often poor correlation between vertebrobasilar symptoms and the subclavian steal phenomenon. In most cases, flow within the basilar artery is unaffected unless severe stenosis of the vertebral artery supplying the steal exists.[245] Also, surgical or angioplastic restoration of blood flow may not result in relief of symptoms.[246] The subclavian steal phenomenon is most often caused by atherosclerotic disease, although traumatic, embolic, surgical, congenital, and neoplastic factors have also been implicated. Although the proximal subclavian stenosis or occlusion may be difficult to image, particularly on the left, the vertebral artery waveform abnormalities correlate with the severity of the subclavian disease.

Doppler evaluation of the vertebral artery reveals four distinct abnormal waveforms that correlate with subclavian or vertebral

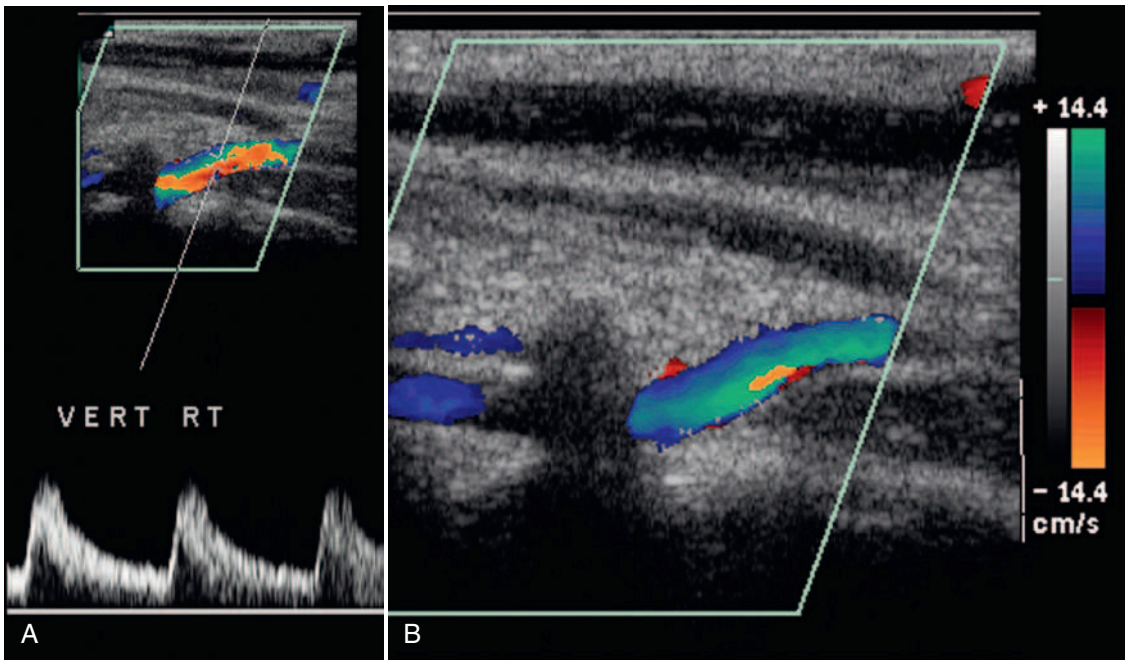

FIG. 26.51 Reversal of Vertebral Artery Flow in Subclavian Steal. Subclavian steal causes reversed flow in vertebral artery. Spectral Doppler **(A)** demonstrates complete vertebral artery flow reversal due to right subclavian artery occlusion. Color-flow Doppler **(B)** demonstrates flow toward the transducer.

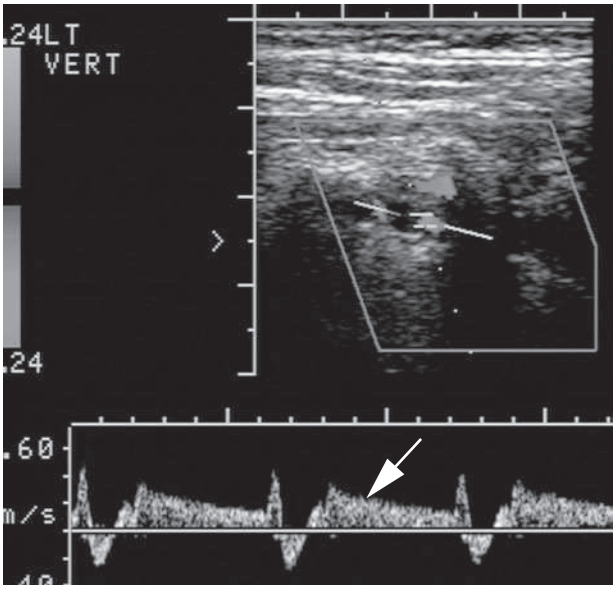

FIG. 26.52 Incomplete Subclavian Steal. Flow in early systole is antegrade, flow in peak systole is retrograde, and flow in late systole and diastole *(arrow)* is again antegrade.

Abnormal Vertebral Artery Waveforms

COMPLETE SUBCLAVIAN STEAL
Reversal of flow within vertebral artery ipsilateral to stenotic or occluded subclavian or innominate artery

INCOMPLETE OR PARTIAL SUBCLAVIAN STEAL
Transient reversal of vertebral artery flow during systole
May be converted into a complete steal using provocative maneuvers
Suggests stenotic, not occlusive, lesion

PRESTEAL PHENOMENON
"Bunny" waveform: systolic deceleration less than diastolic flow
May be converted into partial steal by provocative maneuvers
Seen with proximal subclavian stenosis

TARDUS-PARVUS (DAMPENED) WAVEFORM
Seen with vertebral artery stenosis

artery pathology on angiography. These include the complete subclavian steal, partial or incomplete steal, presteal phenomenon, and tardus-parvus vertebral artery waveforms.[239,244] In a **complete subclavian steal,** flow within the vertebral artery is completely reversed (Fig. 26.51). **Incomplete steal** or **partial steal** demonstrate transient reversal of vertebral flow during systole[239,245] (Fig. 26.52). Incomplete steal suggests high-grade stenosis of the subclavian or innominate artery rather than occlusion. Provocative maneuvers, such as exercising the arm for 5 minutes or 5-minute inflation of a sphygmomanometer on the arm to induce rebound hyperemia on the side of the subclavian or innominate lesion, can enhance the sonographic findings and convert an incomplete steal to a complete steal.[155,185]

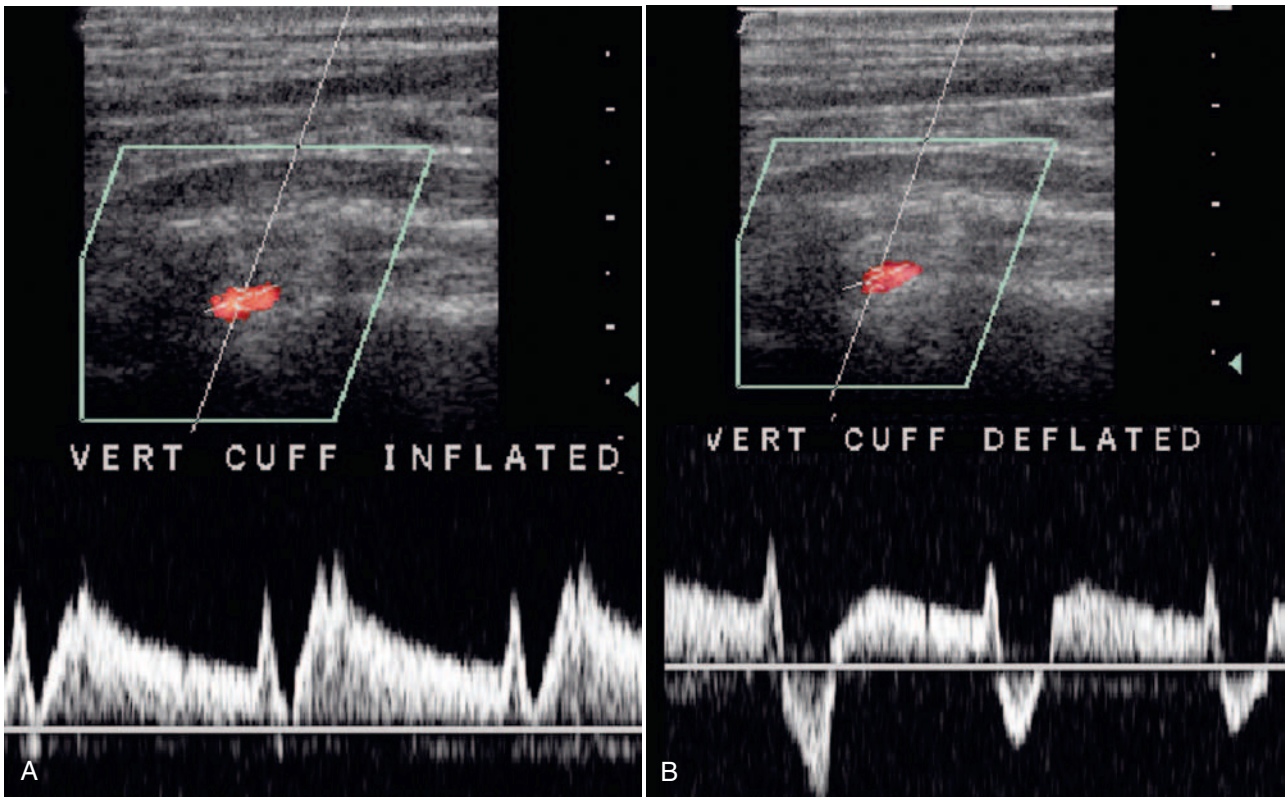

FIG. 26.53 Incomplete Subclavian Steal and Provocative Maneuver. (A) Presteal left vertebral artery waveform. Flow decelerates in peak systole but does not reverse. **(B)** After provocative maneuver, there is reversal of flow in peak systole in response to a decrease in peripheral arterial pressure.

The **presteal** ("bunny") **waveform** shows antegrade flow but with a striking deceleration of velocity in peak systole to a level less than EDV. This is seen in patients with proximal subclavian stenosis, which is usually less severe than in those with partial steal waveform.[239] The bunny waveform can be converted into a partial steal or complete steal waveform by provocative maneuvers (Fig. 26.53). A **tardus-parvus waveform** (also called a dampened waveform) can be seen in patients with high-grade proximal vertebral stenosis.[238,239]

With a subclavian steal, color Doppler may show two similarly color-encoded vessels between the transverse processes, representing the vertebral artery and vein.[129] Transverse images of the vertebral artery with color Doppler show reversed flow compared with those of the CCA. A Doppler spectral waveform must be produced in all such cases to avoid mistaking flow reversal within an artery for flow in a pulsatile vertebral vein.[129,237]

Stenosis and Occlusion

Diagnosis of **vertebral artery stenosis** is more difficult than diagnosis of flow reversal. Most hemodynamically significant stenoses occur at the vertebral artery origin, situated deep in the upper thorax and seen in only 60% to 70% of patients.[234,243,241] Even if the vertebral artery origin is visualized, optimal adjustments of the Doppler angle for accurate velocity measurements may be difficult because of the deep location and vessel tortuosity. No accurate reproducible criteria for evaluating vertebral artery stenosis exist. Because flow is normally turbulent within the vertebral artery, spectral broadening cannot be used as an indicator of stenosis. Velocity measurements are not reliable as criteria for stenosis because of the wide normal variation in vertebral artery diameter. Although velocities greater than 100 cm/sec often indicate stenosis, they can occur in angiographically normal vessels. For example, high-flow velocity may be present in a vertebral artery that is serving as a major collateral pathway for cerebral circulation in cases of carotid occlusion[34,188,247] (Fig. 26.54). Thus only a **focal increase in velocity of at least 50%, visible stenosis on gray-scale or color Doppler, or a striking tardus-parvus vertebral artery waveform** is likely to indicate significant vertebral stenosis. The variability of resistive indices in normal and abnormal vertebral arteries precludes the use of this parameter as an indicator of vertebral disease.[244]

Diagnosis of **vertebral artery occlusion** is also difficult. Often, the inability to detect arterial flow results from a small or congenitally absent vertebral artery or a technically difficult examination. The differentiation of severe stenosis from occlusion is difficult for the same reasons. Extremely dampened blood flow velocity in high-grade stenoses may result in a Doppler

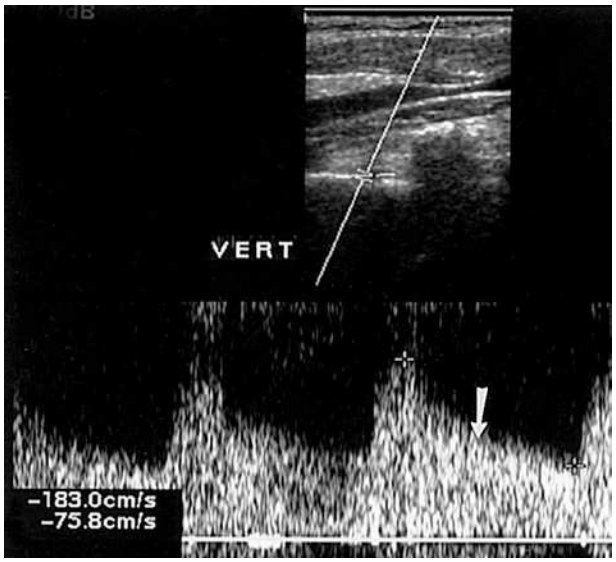

FIG. 26.54 Increased Flow Velocity in Vertebral Artery. Pulsed Doppler spectral trace from a left vertebral artery demonstrates strikingly high velocities and disturbed flow *(arrow)*. Although this degree of velocity elevation and flow disturbance could be associated with a focal stenosis, in this case there was increased velocity throughout the vertebral artery from bilateral internal carotid artery occlusion and increased collateral flow into the vertebral artery.

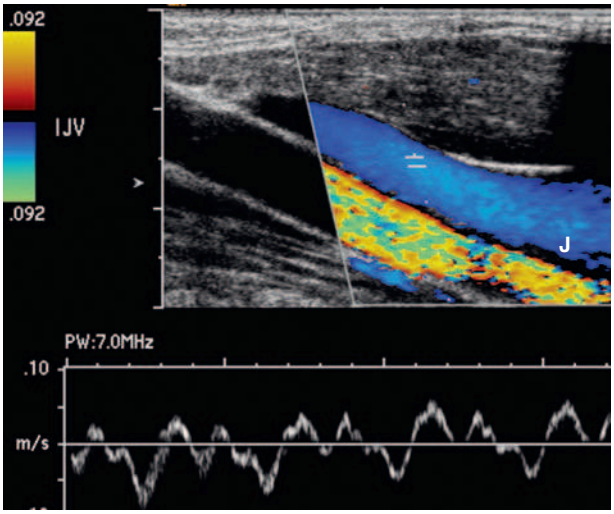

FIG. 26.55 Normal Jugular Vein. Complex venous pulsations in a normal jugular vein *(J)* reflect the cycle of events in the right atrium.

signal with amplitude too low to be detected.[235] Power Doppler imaging may prove useful in this situation. Visualization of only a vertebral vein may indicate vertebral artery occlusion or congenital absence.

INTERNAL JUGULAR VEINS

The internal jugular veins are the major vessels responsible for the return of venous blood from the brain. The most common clinical indication for duplex and color Doppler flow ultrasound of the internal jugular vein is the evaluation of suspected **jugular venous thrombosis.**[248-256] Thrombus formation may be related to central venous catheter placement. Other indications include a diagnosis of jugular venous ectasia[254,255,257,258] and guidance for internal jugular or subclavian vein cannulation,[259-265] particularly in difficult situations where vascular anatomy is distorted.

Sonographic Technique

The normal internal jugular vein is easily visualized. The vein is scanned with the neck extended and the head turned to the contralateral side. Longitudinal and transverse scans are obtained with light transducer pressure on the neck to avoid collapsing the vein. A coronal view from the supraclavicular fossa is used to image the lower segment of the internal jugular vein and the medial segment of the subclavian vein as they join to form the brachiocephalic vein.

The jugular vein lies lateral and anterior to the CCA, lateral to the thyroid gland, and deep to the sternocleidomastoid muscle. The vessel has sharply echogenic walls and a hypoechoic or anechoic lumen. Normally, a valve can be visualized in its distal portion.[251,260,266] The right internal jugular vein is usually larger than the left.[259]

Real-time ultrasound demonstrates **venous pulsations related to right heart contractions,** as well as changes in venous diameter that vary with changes in intrathoracic pressure. Doppler examination graphically depicts these flow patterns (Fig. 26.55). On inspiration, negative intrathoracic pressure causes flow toward the heart and the jugular veins to decrease in diameter. During expiration and during Valsalva maneuver, increased intrathoracic pressure causes a decrease in the blood return, and the veins enlarge, with minimal or no flow noted. The walls of the normal jugular vein collapse completely when moderate transducer pressure is applied. Sudden patient sniffing reduces intrathoracic pressure, causing momentary collapse of the vein on real-time ultrasound, accompanied by a brief increase in venous flow toward the heart as shown by Doppler.[250,252,254]

Thrombosis

Clinical features of jugular venous thrombosis include a tender, poorly defined, nonspecific neck mass or swelling. The correct diagnosis may not be immediately obvious.[251] Thrombosis of the internal jugular vein can be completely asymptomatic because of the deep position of the vein and the presence of abundant collateral circulation.[254] Internal jugular thrombosis most often results from complications of **central venous catheterization.**[249,253,254] Other causes include intravenous drug abuse, mediastinal tumor, hypercoagulable states, neck surgery, and local inflammation or adenopathy.[251] Some cases are idiopathic or spontaneous.[251] Possible complications of jugular venous thrombosis include suppurative thrombophlebitis, clot propagation, and pulmonary embolism.[251,255]

Real-time examination reveals an enlarged, noncompressible vein, which may contain a visible echogenic intraluminal thrombus. An **acute thrombus** may be anechoic and

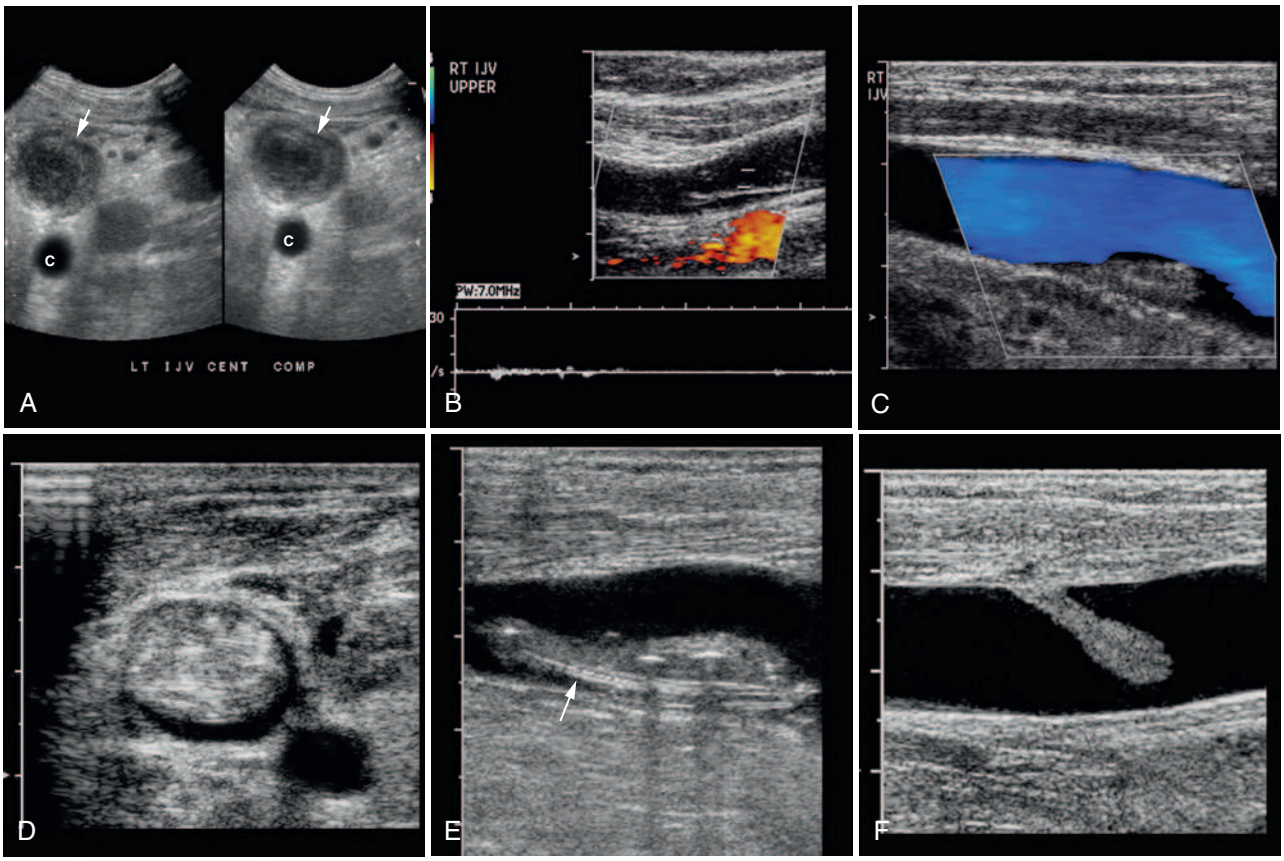

FIG. 26.56 Internal Jugular Vein (IJV) Thrombosis: Spectrum of Appearances. (A) Transverse image of an acute left internal jugular vein thrombus *(arrow).* The vein is distended and noncompressible. *C,* Common carotid artery. **(B)** Longitudinal image of a different patient demonstrates a hypoechoic thrombus and no Doppler signal. **(C)** Longitudinal color Doppler image shows a small amount of thrombus arising from the posterior wall of the IJV. **(D)** Transverse image shows an echogenic thrombus, indicating chronic thrombus in IJV. **(E)** Longitudinal image demonstrates a thrombus *(arrow)* around jugular vein catheter. **(F)** Longitudinal images show a thrombus arising from anterior wall. This thrombus probably results from previous catheter placement in this region.

indistinguishable from flowing blood; however, the characteristic lack of compressibility and absent Doppler or color Doppler flow in the region of a thrombus quickly lead to the correct diagnosis. In addition, there is visible loss of vein response to respiratory maneuvers and venous pulsation. Spectral and color Doppler interrogations reveal absent flow (Fig. 26.56). Collateral veins may be identified, particularly in cases of chronic internal jugular vein thrombosis. Central liquefaction or other heterogeneity of the thrombus also suggests chronicity. **Chronic thrombi** may be difficult to visualize because they tend to organize and are difficult to separate from echogenic perivascular fatty tissue.[260] The absence of cardiorespiratory plasticity in a patent jugular or subclavian vein can indicate a more central, nonocclusive thrombus (Fig. 26.57). The confirmation of bilateral loss of venous pulsations strongly supports a more central thrombus, which can be documented by angiographic or magnetic resonance venography.

A thrombus that is related to catheter insertion is often demonstrated at the tip of the catheter, although it may be seen anywhere along the course of the vein. The catheter can be visualized as two parallel echogenic lines separated by an anechoic region. Flow is not usually demonstrated in the catheter, even if the catheter itself is patent.

Sonography is a reliable means of diagnosing jugular and subclavian vein thrombosis. Sonography has limited access and cannot image all portions of the jugular and subclavian veins, especially those located behind the mandible or below the clavicle, although knowledge of the full extent of a thrombus is not typically a critical factor in treatment planning.[251,255] Serial sonographic examination to evaluate response to therapy after the initial assessment can be performed safely and inexpensively. Sonography can also document venous patency before vascular line placement, facilitating safer and more successful catheter insertion.

Acknowledgment

Thanks to Kathleen McFadden and Barbara Siede for their assistance with manuscript preparation.

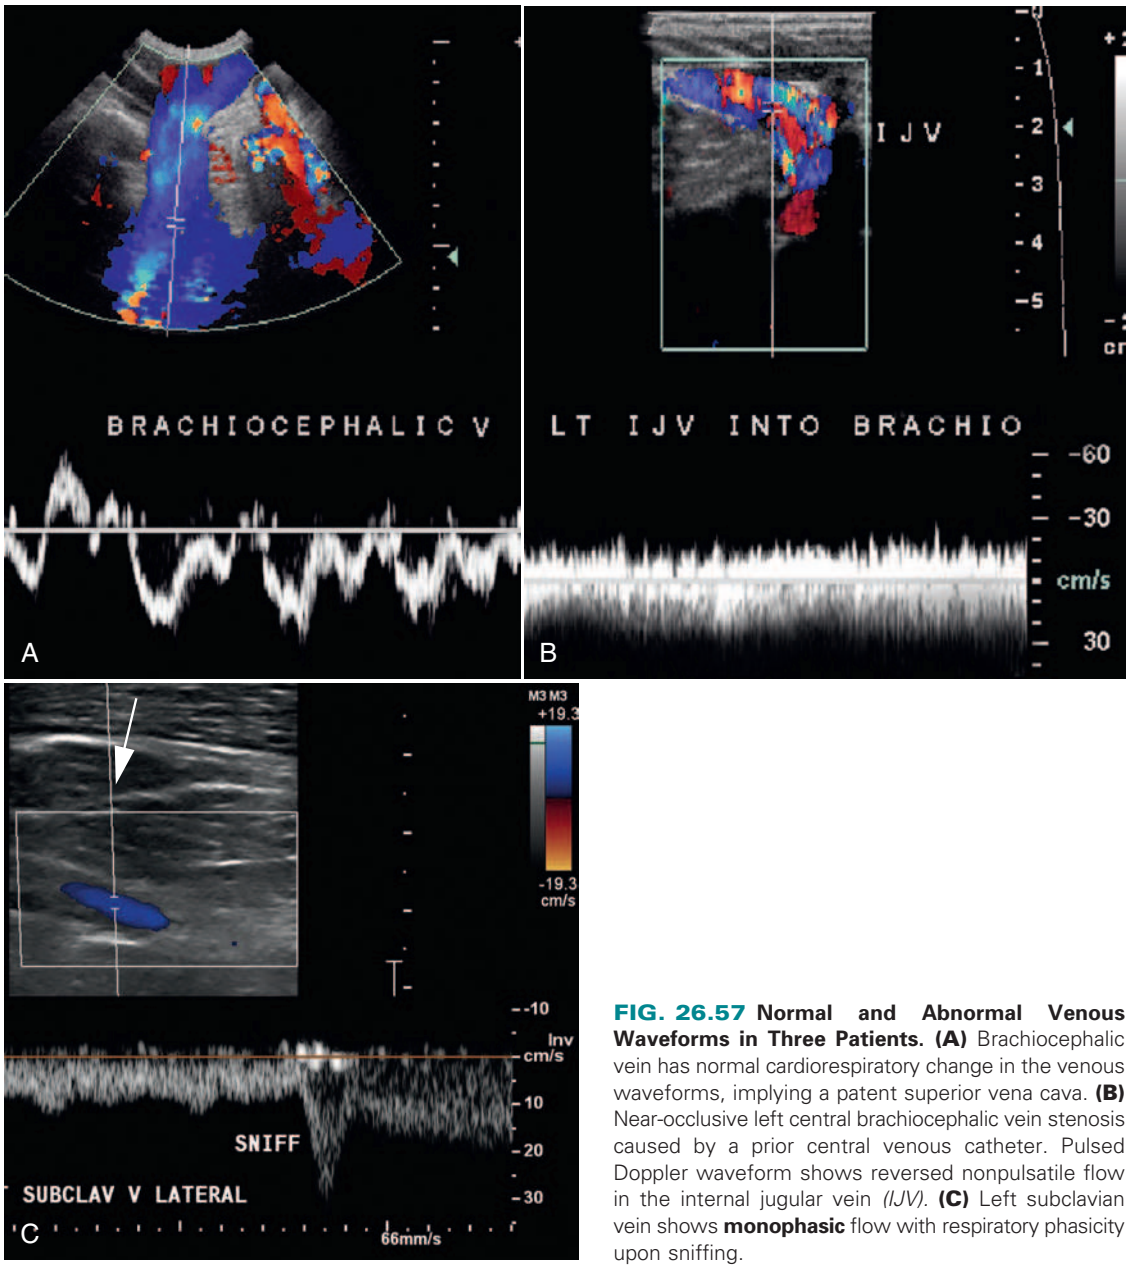

FIG. 26.57 Normal and Abnormal Venous Waveforms in Three Patients. (A) Brachiocephalic vein has normal cardiorespiratory change in the venous waveforms, implying a patent superior vena cava. **(B)** Near-occlusive left central brachiocephalic vein stenosis caused by a prior central venous catheter. Pulsed Doppler waveform shows reversed nonpulsatile flow in the internal jugular vein *(IJV)*. **(C)** Left subclavian vein shows **monophasic** flow with respiratory phasicity upon sniffing.

CHAPTER 27

Peripheral Vessels

Mark E. Lockhart, Heidi R. Umphrey, Therese M. Weber, and Michelle L. Robbin

SUMMARY OF KEY POINTS

- Key aspects of vascular Doppler imaging include knowledge of anatomy and waveform morphology, scanning technique, and attention to detail.
- Spectral Doppler velocity criteria can characterize stenosis detected by gray-scale and color Doppler.
- Doppler evaluation of peripheral artery disease can provide diagnostic information and enable surgical planning and evaluation of bypass grafts.
- Extremity aneurysm and pseudoaneurysm have typical Doppler findings similar to other areas of the arterial system.
- Evaluation of the upper and lower extremity venous system is primarily performed with sonography.
- Differentiation of acute from residual or chronic deep venous thrombosis (DVT) with imaging and clinical parameters is often difficult.
- Controversial venous issues include clinical criteria for treatment of DVT, when to recommend a follow-up examination, calf vein evaluation, and two-point or focused examination approach.
- Preoperative sonographic mapping of upper extremity and thigh vessels assists surgical planning for placement of hemodialysis arteriovenous fistula (AVF) and grafts.
- Postoperative evaluation of hemodialysis AVF and grafts with ultrasound aids the assessment of AVF maturation, as well as evaluation for access stenosis, steal, thrombus, and focal complications.

CONCLUSION

Prior chapters have described details of physics of Doppler analysis and use of ultrasound in the assessment of the vasculature supplying the head and neck. In this chapter we describe assessment of the peripheral arteries and veins, as well as arteriovenous fistula (AVF) and grafts. In general, these areas are readily evaluated by Doppler ultrasound. Because they are usually located at depths of 6 cm or less, the extremity vessels are more consistently imaged than those in the abdomen or thorax. Availability of sufficient imaging windows allows the transducer to be placed over the vascular area of interest with overlying tissue containing bone or gas. Transducers with frequencies greater than 5 MHz can typically be used.

Gray-scale sonography is useful for evaluating the presence of atherosclerotic plaque or confirming extravascular masses. Color flow Doppler imaging allows for a rapid survey of the area of interest, and then spectral Doppler can be used to characterize blood flow patterns.

Standardized protocols, such as those provided by the American College of Radiology (ACR), American Institute of Ultrasound in Medicine, and Society of Radiologists in Ultrasound should be followed.[1,2] It is recommended that examinations be performed in an accredited laboratory with participation in one of the vascular accreditation programs, such as the ACR or the Intersocietal Commission for the Accreditation of Vascular Laboratories, in order to achieve a national standard of excellence and to improve the chance of success of peripheral arterial and venous ultrasound examinations.[3] In the setting of a dedicated staff and with physician support, ultrasound can be used to diagnose many peripheral vascular abnormalities definitively and avoid the need for ionizing radiation or intravenous contrasted cross-sectional studies.

PERIPHERAL ARTERIES

A variety of symptoms and signs can be evaluated by arterial ultrasound. Sonographic examination is relatively rapid and has benefits over other modalities, such as real-time technique, lack of ionizing radiation, and relatively low expense. In the last two decades, the number of indications for peripheral artery ultrasound has expanded. The most recent ACR practice parameter on the topic lists indications for the examination, which include claudication and/or rest pain in the lower extremities to evaluate for arterial stenosis or occlusion.[2] Patients with pain, discoloration, or ulcer formation in the extremities (most commonly lower) may have tissue ischemia or necrosis from arterial stenosis or occlusion. Additional symptoms of numbness or cold extremity may be noted. However, symptomatology may vary depending on the rapidity of onset and whether collaterals have developed to decrease the effects of stenosis on the tissues. In some patients, vascular abnormalities may be subclinical and found incidentally on imaging for other indications. Once an abnormality has been identified, ultrasound can monitor progression of disease, determine success or failure after intervention, and identify acceptable vessels for bypass graft creation.

Other extremity abnormalities can be evaluated sonographically. Focal masses can be assessed to exclude vascular causes such as aneurysm or fistula with venous enlargement. When chronic positional upper extremity symptoms are present, ultrasound can evaluate for thoracic outlet syndrome. More peripherally, Doppler can document patency of the palmar arch in surgical planning for bypass graft harvesting, and it can assess the radial artery before and after vascular access.

In the acute setting, traumatic injuries can be evaluated to determine adjacent arterial patency. Pseudoaneurysms and dissections are visible by ultrasound in these patients. Specific levels of embolic disease can also be depicted.

Sonographic Examination Technique

Gray-scale evaluation of the peripheral arteries is important to determine the amount of atherosclerotic disease or thrombus present. The highest frequency transducer that allows good penetration and visualization should be applied, typically a 5- to 12-MHz linear array transducer, with a higher frequency transducer used in areas where the arteries are more superficial. Occasionally, a 3- to 5-MHz sector or curved array probe may be necessary in large patients or those with large amounts of edema.

Occasionally, atherosclerotic plaque or thrombus is hypoechoic, and color Doppler is extremely useful to evaluate residual lumen, with the gain adjusted so color does not overlap into adjacent tissues. The spectral Doppler gate is adjusted within the lumen of the artery to allow adequate signal. The scale and gain should be optimized to show strong flow signals that use most of the scale to display the waveform. Normally, a medium or high wall filter is used in arterial evaluation. If there is slow flow, a low wall filter may be used to improve detection. In general, for detection of small channels of slow flow in areas of near-occlusion, power Doppler may be more sensitive than color Doppler.[4] However, the advances in color Doppler may have reduced this difference in recent years.

The components of the sonographic evaluation differ based on the indication. For example, imaging for suspected arterial stenosis or occlusion is very different from evaluation of a focal mass or aneurysm. The technical components of the examination have been recently described in the ACR practice parameters.[2]

Stenosis Evaluation

Color and spectral Doppler imaging are key to **stenosis** evaluation, using a combination of waveform morphology and velocity characteristics. On gray-scale imaging, a focal stenosis or occlusion may be visible, but this should be confirmed by Doppler. Collaterals should also prompt additional attention with Doppler. Any areas of visible narrowing or turbulent color Doppler signal should be further characterized with spectral Doppler. A change in spectral waveform morphology from one arterial segment to the next should also be further evaluated with color and spectral Doppler to locate a point of transition (Fig. 27.1). Spectral Doppler should be performed in the longitudinal plane and should be angle corrected 60% or less from the center beam. If a jet at or downstream from a stenosis is seen, angle correction parallel to the orientation of the jet should be performed to more accurately measure peak systolic velocity (PSV). Using this technique, waveform morphology and peak velocity should be evaluated at any suspected area of stenosis, as well as the feeding vessel

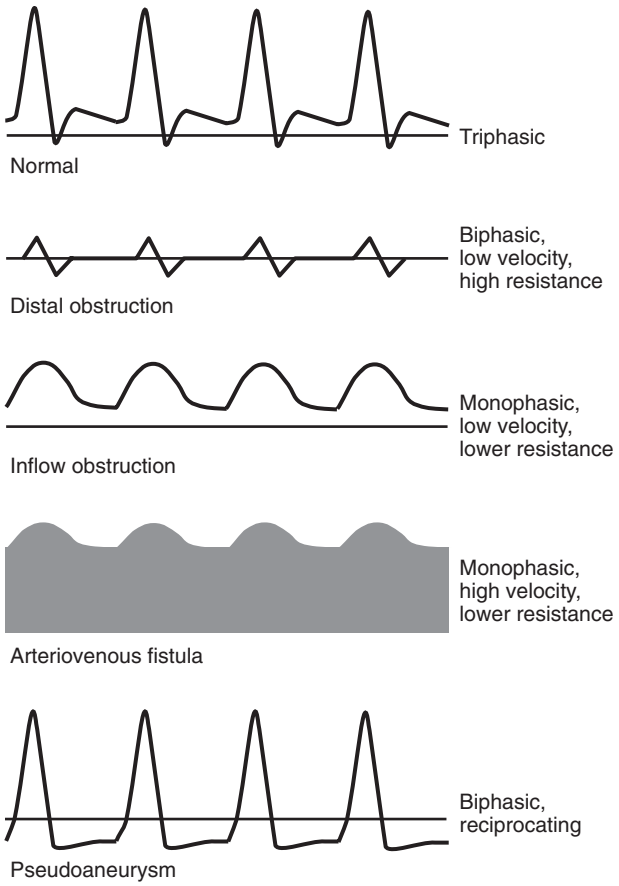

FIG. 27.1 Diagrams of Doppler Flow Patterns in Normal and Abnormal Scenarios. The normal **Doppler spectrum** of flowing blood **in the lower extremity** arteries typically has a **triphasic pattern:** (1) forward flow during systole, (2) a short period of flow reversal in early diastole, and (3) low-velocity flow during the remainder of diastole. Arterial Doppler signals are altered depending on the pathologic change. The four other patterns are examples of common arterial pathologies: distal obstruction, inflow obstruction, arteriovenous fistula, and pseudoaneurysm.

within 4 cm upstream, and the draining artery within 4 cm downstream. The inflow velocity is used as a reference to assess for increased peak velocity at the stenosis, and the downstream location is evaluated for peak velocity drop, decreased resistance, and **tardus parvus** morphology. The same concepts apply to bypass grafts, when looking for stenosis and occlusion, with additional evaluation at the anastomoses, which are common sites of abnormality. Ultrasound is the primary screening for bypass abnormalities but can be a time-consuming study if used to cover all areas of concern in a patient with diffuse atherosclerotic disease. If diffuse atherosclerotic disease is suspected, other imaging techniques such as computed tomography (CT) or magnetic resonance angiography may be able to survey large areas more effectively.

Lower Extremity Arteries

Normal Anatomy

Each lower extremity arterial system is primarily supplied from the **common femoral artery,** which originates from the **external iliac artery** at the level of the inguinal ligament and extends caudally a few centimeters until it divides into the **superficial femoral artery** (SFA) and **profunda femoris artery.** The profunda femoris artery supplies the femoral head and the deep muscles of the thigh through perforators, as well as the medial circumflex artery and the lateral circumflex artery. The **SFA** continues along the medial thigh to the adductor canal in parallel with the femoral vein (FV). Below the adductor canal, it becomes the **popliteal artery,** coursing posterior to the knee and supplying branches of the calf.

The popliteal artery branches into the **anterior tibial artery** and the **tibioperoneal trunk.** The anterior tibial artery courses laterally, perforating through the interosseous membrane between the tibia and fibula into the anterior compartment of the lower leg. The anterior tibial artery becomes the **dorsalis pedis artery** in the dorsum of the ankle and along the first intertarsal space of the foot. The tibioperoneal trunk divides after approximately 3 to 4 cm into the **posterior tibial artery** and the **peroneal artery.** The posterior tibial artery courses posterior to the medial malleolus of the ankle. The peroneal artery courses through the interosseous membrane above the ankle, and then supplies branches of the lateral ankle and foot.

Ultrasound Examination and Imaging Protocol

Lower extremity arterial inflow from the external iliac artery is assessed by groin insonation in supine position, and then each major vessel in the leg is directly evaluated throughout its entire course. **Normal arteries** have thin smooth walls with anechoic lumens and lack of atherosclerotic plaques or stenosis on gray-scale imaging (Fig. 27.2). After gray-scale evaluation, long arterial segments can be screened rapidly with color Doppler to find areas of suspected stenosis. Color Doppler is set to barely fill the lumen in a normal area of the artery. Color aliasing can alert the sonographer to areas of luminal narrowing that need to be evaluated further with spectral Doppler to determine significance. For evaluation of focal abnormalities other than stenosis, the examination may be limited to the general region of concern.

The ACR-AIUM-SRU practice parameter for the performance of peripheral arterial ultrasound suggests that lower extremity ultrasound should examine the common femoral artery; the proximal, mid, and distal SFA; and the popliteal artery above and below the knee.[2] Other arteries are examined as deemed clinically appropriate. The practice parameter states that these may include "iliac, deep femoral, tibioperoneal trunk, anterior tibial, posterior tibial, peroneal, and dorsalis pedis arteries." The guideline further suggests that angle-corrected longitudinal Doppler and/or gray-scale imaging should be documented in each normal and at any abnormal segment. Angle-corrected spectral Doppler is recommended proximal to, at, and beyond any suspected stenosis.[2] Supine position of the patient is acceptable for the thigh vessels, but a decubitus position may aid evaluation of the popliteal artery. Depending on the symptoms and findings of these arteries, imaging of the iliac arterial system may look for inflow disease, or imaging of the calf arteries may be indicated.

Normal outer diameters of the common femoral artery, SFA, popliteal artery, posterior tibial artery, and anterior tibial artery

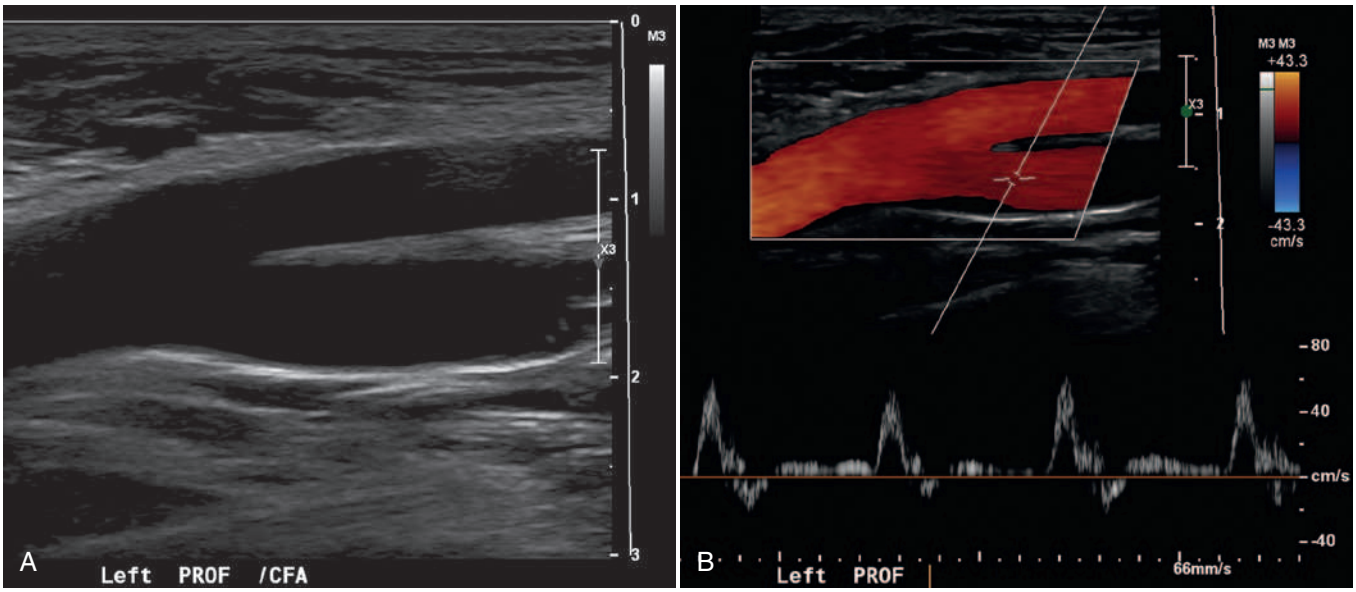

FIG. 27.2 Normal Common Femoral Artery Bifurcation. (A) Gray-scale imaging shows the normal appearance of arterial wall with lack of plaque. **(B)** Color and spectral Doppler normal triphasic spectral waveform in the profunda femoris artery.

are 8.1 mm, 6.1 mm, 6.0 mm, 2.1 mm, and 2.0 mm, respectively, and these vessels are slightly larger in males.[5] The common femoral artery, SFA, and popliteal artery become slightly larger with age, whereas the calf arteries become smaller.[5] **Laminar flow** is present without turbulence or aliasing on color Doppler. A high-resistance **triphasic waveform** with sharp upstroke and transient flow reversal is typically present in the normal lower extremity arteries on spectral Doppler. A monophasic waveform morphology that does not return to baseline can occur after exercise in normal patients, but can be also seen in lower extremity atherosclerotic disease. For differentiation, the PSV will decrease in the ischemic limb of a patient with peripheral artery disease after exercise, whereas it will increase in a patient with a healthy arterial system.

For calf assessment, a posterior medial approach is used for the posterior tibial artery in the midcalf with longitudinal Doppler, and then the artery can be followed proximally and distally. Alternatively, it can be found at the medial malleolus at the ankle and followed cranially. An anterior transducer placement is applied for the anterior tibial artery with the patient lying supine. The anterior tibial artery is well seen along the interosseous membrane near the fibula. The peroneal artery can also be seen from this anterior probe placement; it is more deeply located posterior to the interosseous membrane. A posterior lateral approach may also be used to locate the peroneal artery.

Peripheral Arterial Occlusion

Acute **arterial occlusion** is an emergent situation that can generate severe symptomatology and requires immediate attention. It is usually present in the setting of atherosclerotic disease, although traumatic dissection or embolic disease can occur (Fig. 27.3, Video 27.1). Use of Doppler allows for sensitive and specific demonstration of absent flow, and can differentiate occlusion from stenosis in the lower extremity with 98% accuracy.[6] In another study, sensitivities for occlusion of the SFA and popliteal artery were 97% and 83%, respectively.[7] In the lower leg, Doppler performs better in the anterior and posterior tibial arteries than in the peroneal. Doppler sensitivity for patency of the tibial artery was 93% in a recent study, but with many false positives related to angiography.[8]

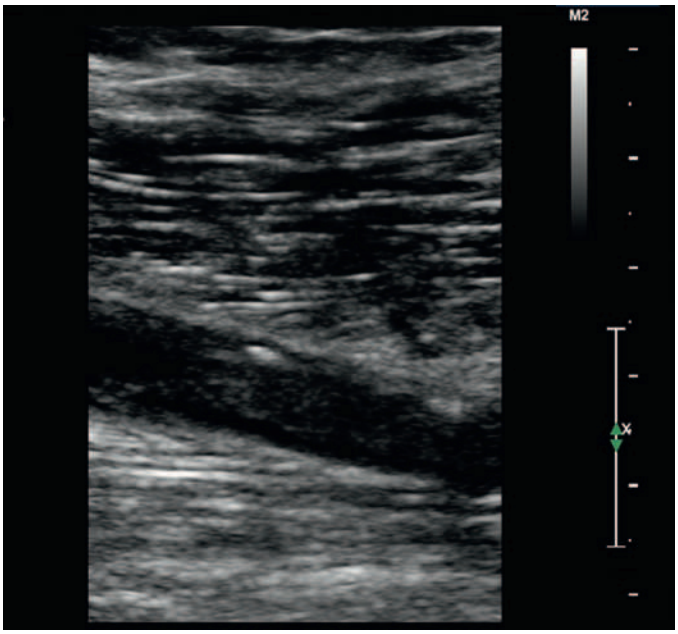

FIG. 27.3 Acute Thrombus in the Superficial Femoral Artery. Note the echogenic material within the arterial lumen. See also Video 27.1, which shows the thrombus to be slightly mobile.

On gray-scale imaging, the anechoic lumen is typically filled with medium-echogenicity thrombus. Using a similar technique as generally performed for detection of deep venous thrombus, the artery can be externally compressed by the transducer to show focal thrombus that is noncompressible. However, if the artery walls completely coapt, then the findings are likely artifactual. On color and spectral Doppler of an occluded artery,

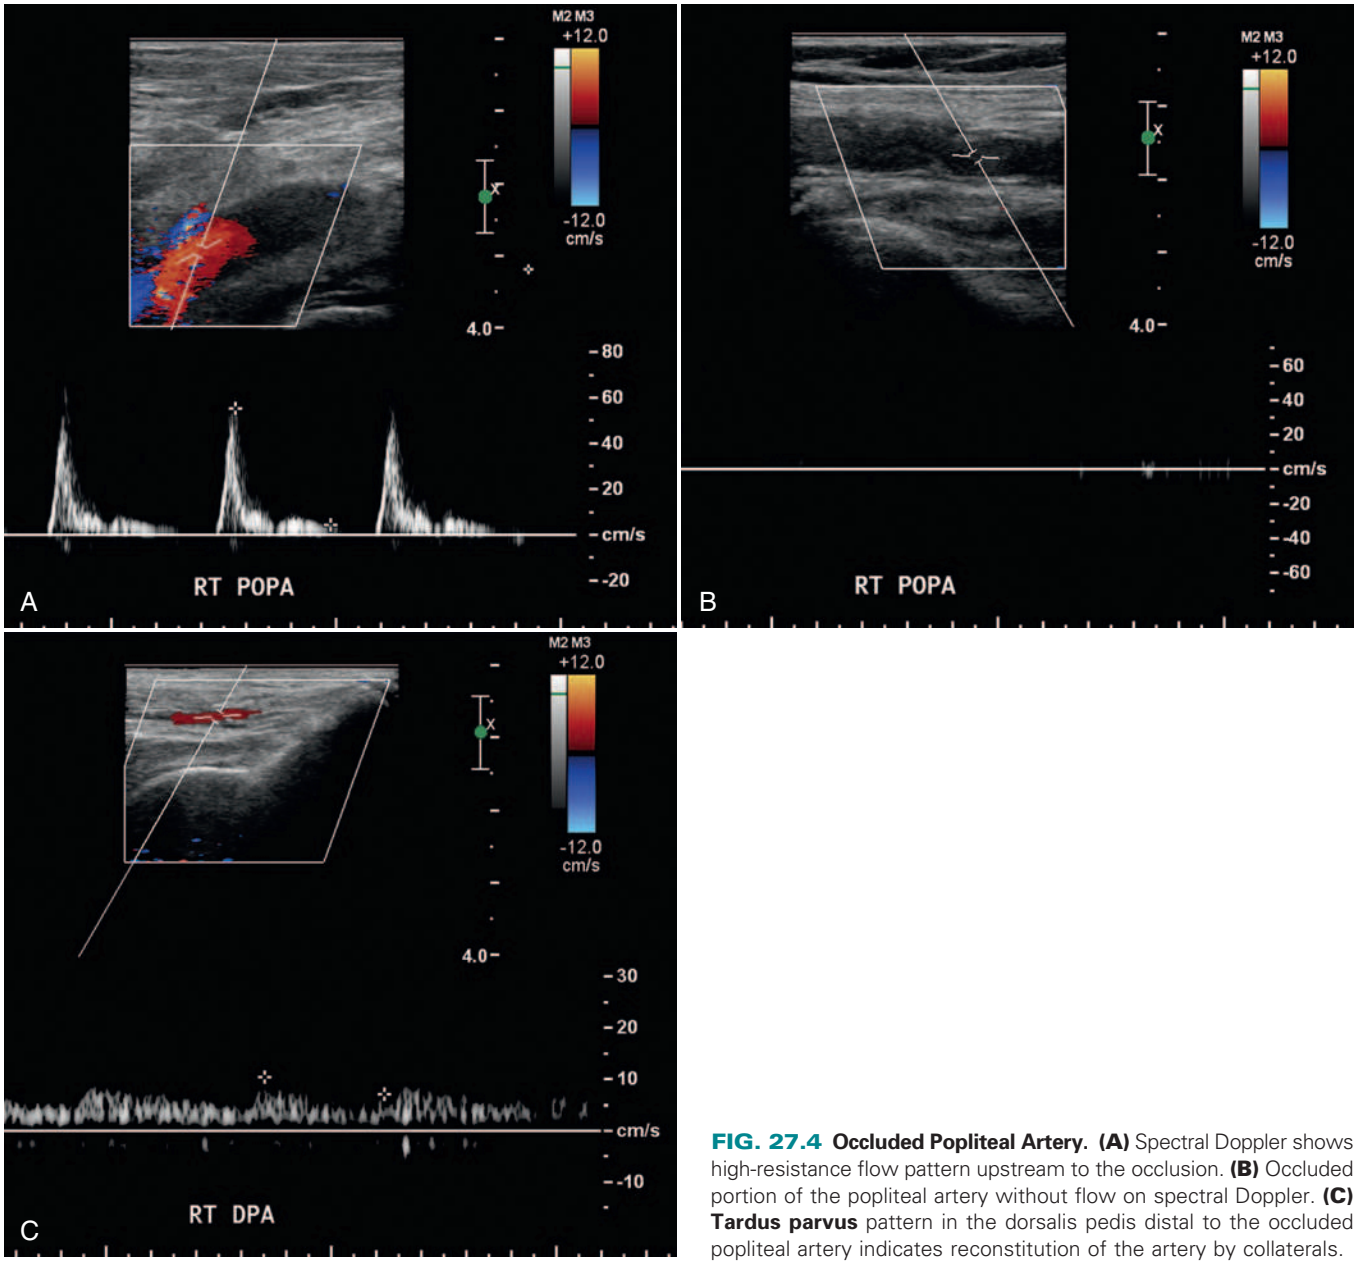

FIG. 27.4 Occluded Popliteal Artery. (A) Spectral Doppler shows high-resistance flow pattern upstream to the occlusion. **(B)** Occluded portion of the popliteal artery without flow on spectral Doppler. **(C) Tardus parvus** pattern in the dorsalis pedis distal to the occluded popliteal artery indicates reconstitution of the artery by collaterals.

no flow signal should be detectable (Fig. 27.4). Collaterals suggest chronic occlusion, but there may be a superimposed acute-on-chronic thrombotic component (Fig. 27.5, Video 27.2).

Peripheral Arterial Stenosis

Detection of **stenosis** in the setting of **atherosclerotic disease** is important owing to its role as a precursor to occlusion. Ultrasound is the primary screening tool for detection of stenosis, using a combination of gray-scale, color, and spectral Doppler. Duplex Doppler should be performed in these patients because of its superior performance relative to segmental Doppler pressures.[9] In a study of 151 lower extremities, duplex Doppler demonstrated 78% to 95% sensitivity and 97% to 100% specificity for high-grade lower extremity arterial stenosis. Spectral broadening can be seen in nonflow-limiting stenoses less than 50%, with an otherwise normal waveform (Fig. 27.6). As regional measurements are made in the arteries of the lower extremity, there may be a change noted from normal triphasic arterial morphology to a pulsatile but monophasic waveform that does not return to baseline or demonstrate transient reversal (Fig. 27.7). When this transition is encountered, the artery between these two measurements should be more closely evaluated by color and spectral Doppler to locate a focal velocity elevation associated with visible narrowing of the artery. Gray-scale can characterize overall plaque burden, but calcifications may limit sonographic penetration into the artery lumen (Fig. 27.8, Video 27.3).

In a patient with diffuse atherosclerotic disease and generalized calcifications, there may be numerous mild stenoses that have a combined effect to reduce flow pressures to the lower leg without a dominant stenosis. Gray-scale imaging is limited in its ability

to measure narrowing of the vessel, and velocity and waveform criteria are more widely applied. Color Doppler improves the examination by rapidly depicting areas of turbulent or high-velocity flow that can be further sampled by spectral Doppler for velocity characterization.

The main criteria for characterizing arterial stenosis involve waveform morphology, PSV, and end-diastolic velocity (EDV). For velocity criteria, the absolute values and the peak velocity ratio (defined as peak velocity at or in the downstream jet divided by peak velocity of the artery 2 cm upstream) have both been applied effectively. In a study of 338 arterial segments, focal increase in the PSV ratio at the stenosis relative to the adjacent nonstenotic artery exceeding 2.0 is consistent with at least 50% diameter stenosis when combined with spectral broadening and loss of transient flow reversal in the artery[10] (Fig. 27.9). The distal artery waveform will be abnormal with tardus parvus waveforms in the setting of stenosis greater than 50% (Fig. 27.10) but is typically normal if a lesser degree of stenosis is present.[10] Direct measurement of PSVs can also be performed. For the femoral-popliteal region of native vessels, a combination of thresholds of PSV greater than 200 cm/sec and ratio above 2:1 have been suggested as criteria for greater than 70% stenosis with sensitivity of 79% and specificity of 99%[11] (Fig. 27.11).

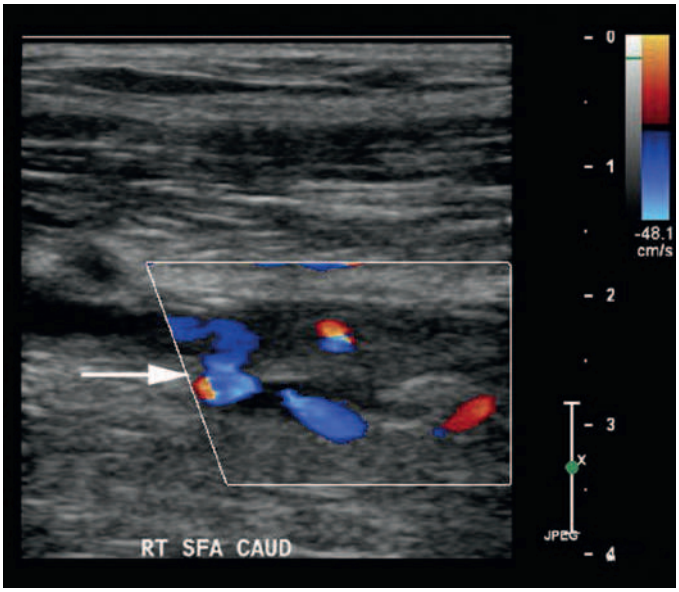

FIG. 27.5 Occlusion of the Superficial Femoral Artery With a Large Collateral Exiting Proximal to the Occlusion *(Arrow).* The presence of a collateral suggests chronic occlusion. See also Video 27.2.

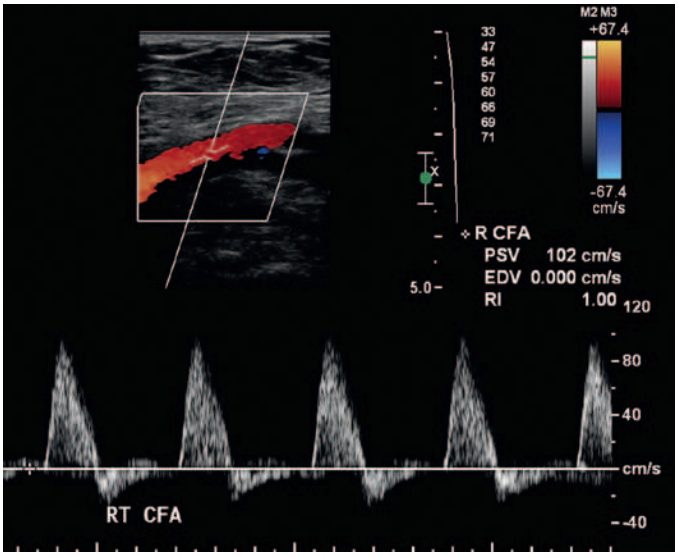

FIG. 27.6 Common Femoral Artery Stenosis. Color and spectral Doppler shows normal biphasic waveform, with fill-in of the waveform spectral envelope, indicating some degree of stenosis but less than 50%.

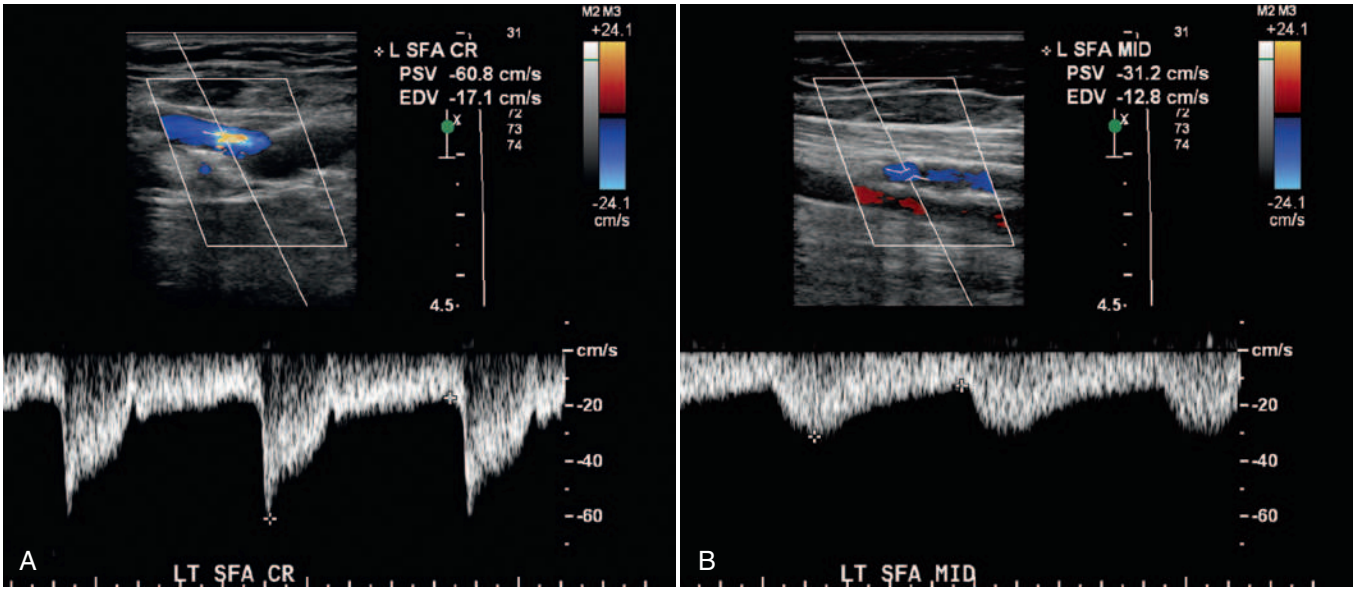

FIG. 27.7 Focal High-Grade Stenosis in the Proximal Superficial Femoral Artery (SFA). (A) Elevated peak systolic velocity at a focal high-grade stenosis in the proximal SFA. **(B)** Tardus parvus pattern downstream.

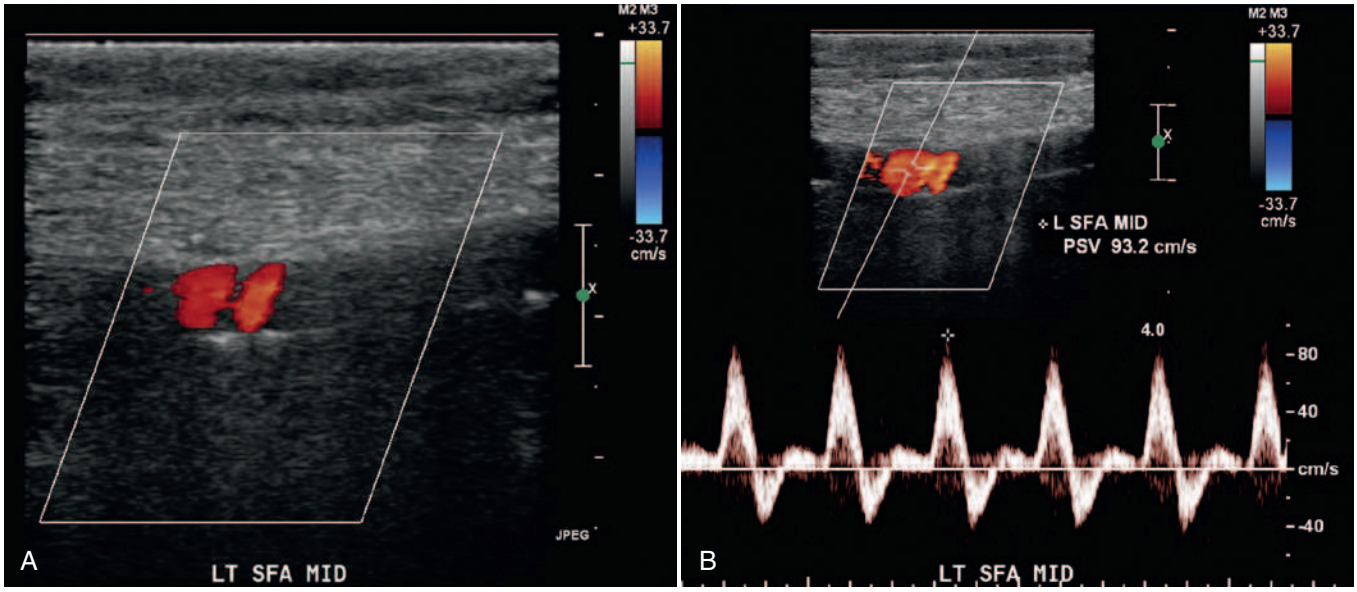

FIG. 27.8 Calcification of the Superficial Femoral Artery (SFA). (A) Severe calcification of the SFA limits ability to see within the artery lumen with gray-scale imaging. Color Doppler is useful to locate a place where spectral Doppler can be sampled. **(B)** Spectral Doppler of the artery has mild spectral broadening but otherwise normal triphasic waveform, without significant stenosis in this location. See also Video 27.3.

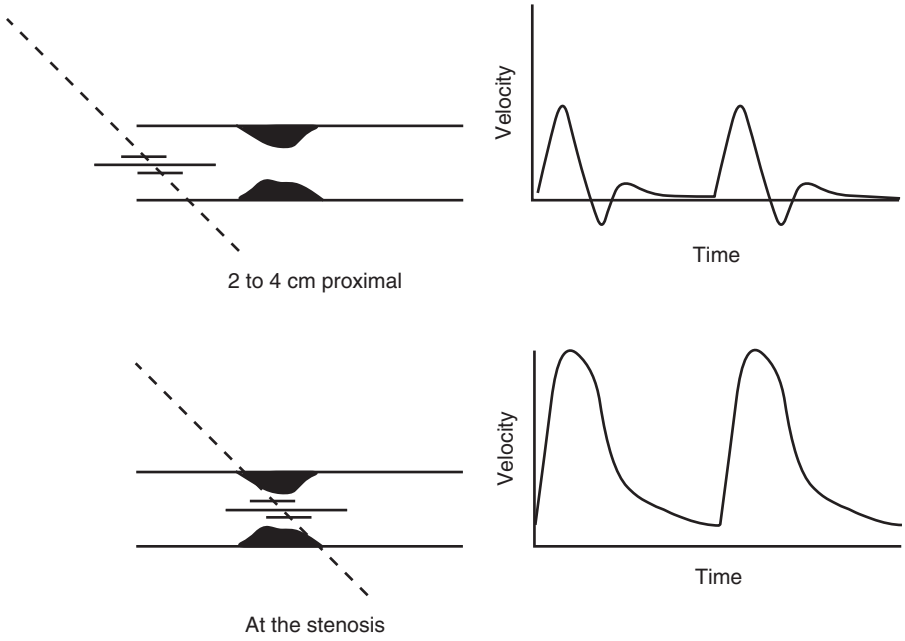

FIG. 27.9 Blood Flow Velocity Alterations Occur With Stenosis of at Least 50%. Proximal to the lesion, the flow pattern is normal. At the stenosis, the peak systolic velocity increases in proportion to the degree of stenosis. Alterations in the diastolic portion of the Doppler waveform sampled at the lesion depend on the state of the distal arteries and the severity and geometry of the lesion; diastolic flow may increase dramatically or may be almost absent.

Ultrasound can direct intervention in these patients. Patients with nonacute conditions can benefit from ultrasound to characterize subacute occlusion or embolic disease versus chronic ischemic disease to help the surgeon decide among therapies such as thrombectomy or bypass procedure.[12,13] Mapping with Doppler before bypass is very useful. Lesions are characterized by severity using the Trans-Atlantic Inter-Society Consensus (TASC) guidelines.[14] Isolated and short category A and B lesions typically are directed to endovascular repair, whereas more complex or longer lesions, C and D, in general require bypass. In one study of 622 TASC C or D lesions, Doppler mapping successfully identified lesions for intervention with sensitivity of 97% and specificity of 99%.[15] Similar high accuracy has been shown in other studies as well.[16,17]

Doppler can also predict which lesions are suitable for percutaneous transluminal angioplasty with good success.[18,19] However, duplex assessment may underestimate the length of **stenosis.** The lesions treated by angioplasty are generally short

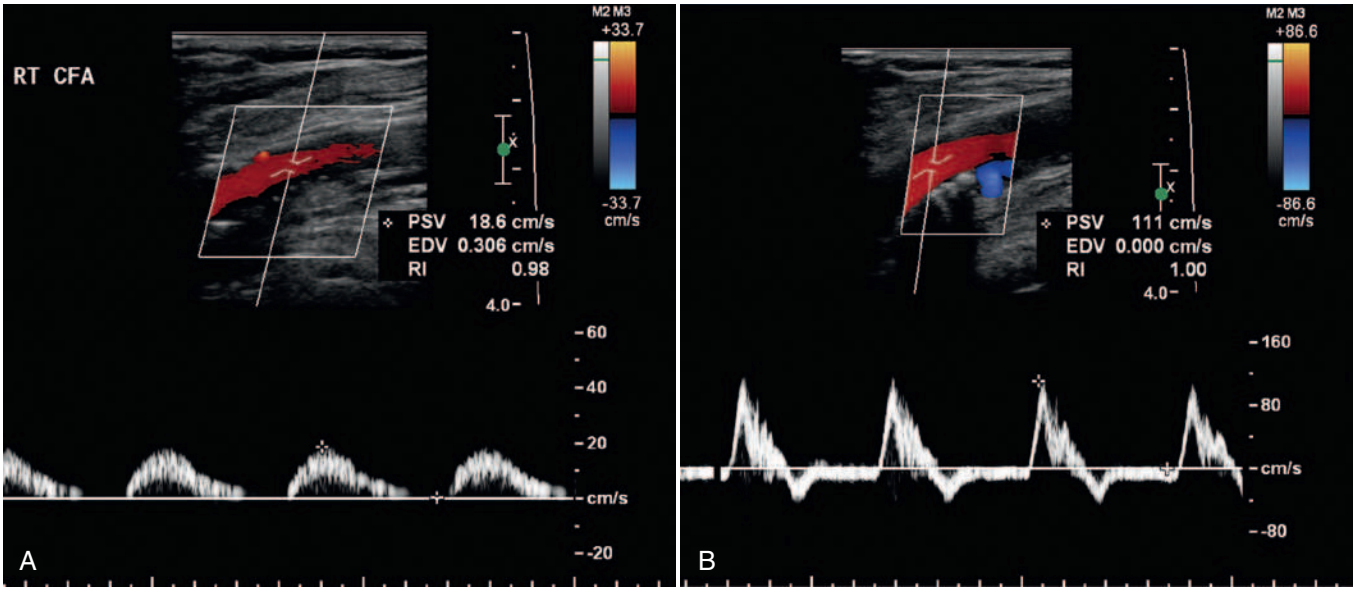

FIG. 27.10 Iliac Artery Stenosis With Tardus Parvus Waveform. (A) Tardus parvus waveform in the right common femoral artery indicates severe upstream stenosis or occlusion. **(B)** Normal velocity biphasic waveform of the contralateral left common femoral artery indicates atherosclerotic disease is in right common or external iliac artery, and not in the aorta (unilateral abnormal waveform).

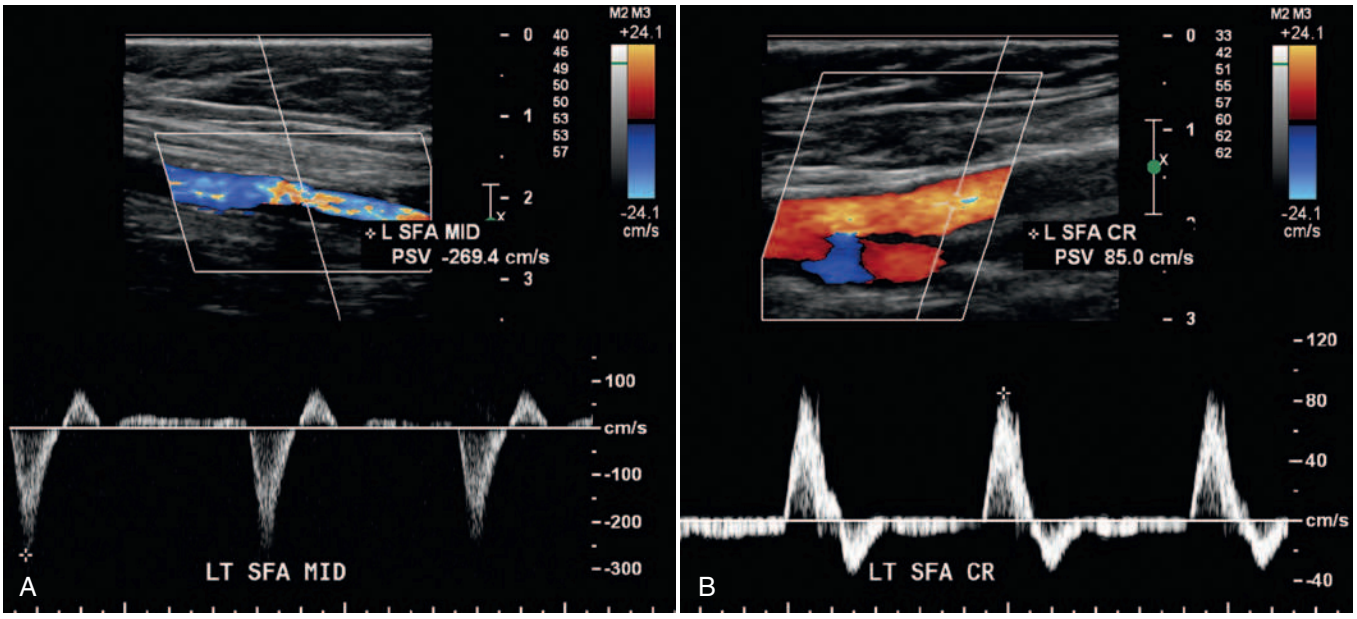

FIG. 27.11 Superficial Femoral Artery (SFA) With >70% Stenosis. (A) Moderately severe stenosis in the SFA with a peak systolic velocity (PSV) of 269 cm/sec. **(B)** At 4 cm upstream from the stenosis the PSV is 85.0 cm/sec, for a ratio exceeding 3:1, indicative of greater than 70% stenosis.

and isolated and have a diameter reduction of greater than 50%. In patients with endovascular intervention and stenting, Doppler can monitor success of the procedure and survey for recurrent stenosis at follow-up. In patients treated for critical limb ischemia, Doppler follow-up should occur every 3 months for the first year.[20] Normal triphasic waveforms at the ankle help exclude stenosis, but spectral Doppler is still performed even in the absence of symptoms. For evaluation of stenosis within a stented artery, the best Doppler criteria to characterize SFA in-stent stenosis of 80% or greater include a combination of PSV above 275 cm/sec and PSV ratio (the ratio of the highest PSV within the stent to the PSV in a disease-free arterial segment 3 cm above the stented area) above 3.5.[21] In patients with stent repair of SFA stenosis, Doppler and CT angiography have strong agreement.[22]

Aneurysm

An **aneurysm** occurs when weakness of the arterial layers allows expansion of the arterial caliber beyond normal limits. Aneurysms of the peripheral arteries are uncommon, but most are found in

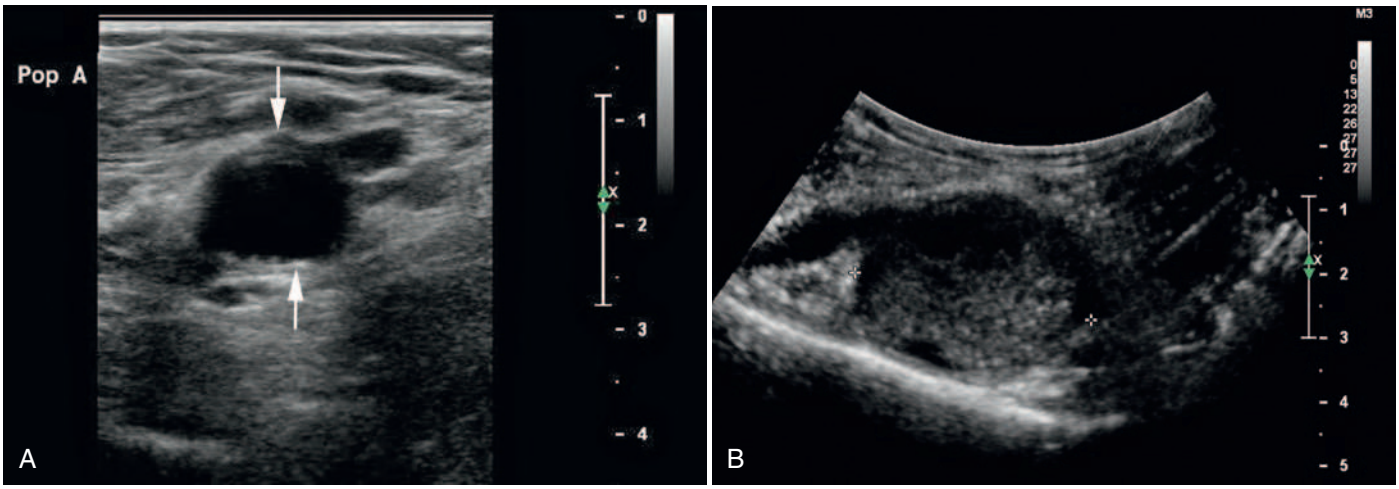

FIG. 27.12 Popliteal Artery Aneurysms. (A) Popliteal artery aneurysm measures 1.2 cm diameter *(arrows)*. **(B)** In a different patient, a 3.7-cm popliteal artery aneurysm contains low-level echoes and is partially thrombosed *(cursors)*.

the popliteal regions.[23] Less commonly, aneurysms are present in the SFA. In more than half of patients with popliteal artery aneurysm, they are bilateral. An association exists between popliteal artery aneurysms and abdominal aortic aneurysm, and thus if a popliteal artery aneurysm is found, the abdominal aorta should be evaluated. There is also an association among peripheral artery aneurysm, tobacco use, and hypertension. Peripheral artery aneurysms may contain clot, which may result in distal emboli with or without soft tissue ischemia and infarction. In these cases, intervention is necessary regardless of aneurysm size. The walls of an aneurysm may calcify, and the presence of calcifications may have some protective effects against rupture.

On gray-scale ultrasound, an aneurysm may appear as a fusiform anechoic or hypoechoic mass along the course of an artery. The Doppler signal depends on the amount of thrombus, the size of the neck of the aneurysm, and presence of calcification. Aneurysms may be saccular and commonly occur at branch points. The normal popliteal artery measures 4 to 6 mm in diameter.[24] A bulge or focal enlargement of 20% of the vessel diameter constitutes a simple functional definition of an aneurysm (Fig. 27.12). Empirically, a 2-cm cutoff has been used to determine need for intervention.[25] For popliteal artery aneurysm, surgical exclusion (ligation of the aneurysm) is the traditional treatment and has high rates of success.[26] However, a recent meta-analysis showed that endovascular repair has similar success.[27] Doppler ultrasound can be used to monitor the success of the intervention.[28] Aneurysm exclusion with covered stents is an increasingly used therapy in place of surgical intervention. Doppler ultrasound can be used to monitor the patency of the stent and confirm the exclusion of the aneurysm from the circulation.[29,30]

Pseudoaneurysm

Pseudoaneurysm describes disruption of an artery with flow in a space beyond the vessel wall. It may arise from any arterial structure and may occur with direct trauma or tumor or inflammatory erosion. Pseudoaneurysms are found in less than 1% of diagnostic angiography examinations and more commonly in coronary angiography.[31] Pathologically, the arterial wall has been at least partially breached. Outer arterial layers, perivascular tissues, clot, or reactive fibrosis contain the pseudoaneurysm sac.[32] The mechanism of pseudoaneurysm formation has been well characterized. A hematoma forms adjacent to the artery at the point of injury. Eventual lysis of the clot results in pseudoaneurysm.

A pseudoaneurysm is different from an aneurysm in that at least one layer of wall is disrupted. It differs from active extravasation in that blood within the pseudoaneurysm flows back into the feeding artery through a narrowed opening rather than into adjacent tissues. Arteriovenous communication, when present, is used to guide appropriate therapy. In patients with arteriovenous communication, thrombin repair is contraindicated owing to the potential for embolization of the thrombin into the venous system with resultant unintended regions of thrombosis.

Gray-scale ultrasound is typically performed first to identify the abnormality. The pseudoaneurysm can appear as a round or oval anechoic structure with or without associated thrombus. When present, thrombus appears isoechoic or hypoechoic; it may be located along the edge of the pseudoaneurysm lumen. Attention should be directed to these areas of extraluminal hematoma or any anechoic collections to determine if there are areas of flow with color Doppler. If flow is detected, spectral Doppler is next performed to characterize arterial versus venous flow and to exclude a superimposed AVF. In the patent portion of a pseudoaneurysm, there may be turbulent or disorganized intraaneurysmal flow with a "yin-yang" appearance. Communication of the sac with the adjacent artery occurs through a neck with a typical "to-and-fro" biphasic flow on spectral Doppler[33] (Fig. 27.13, Video 27.4). Measurement of the neck length and diameter of the neck off the artery is performed as part of the assessment before thrombin injection. A neck with larger diameter has clinical implications because these are less successfully treated by thrombin injection. If the sac is thrombosed, the neck may represent the only patent portion of the pseudoaneurysm. At least one-third of pseudoaneurysm require repair, but spontaneous closure is common for pseudoaneurysm smaller than 1.8 cm in diameter.[34] If the sac is patent, ultrasound-guided thrombin

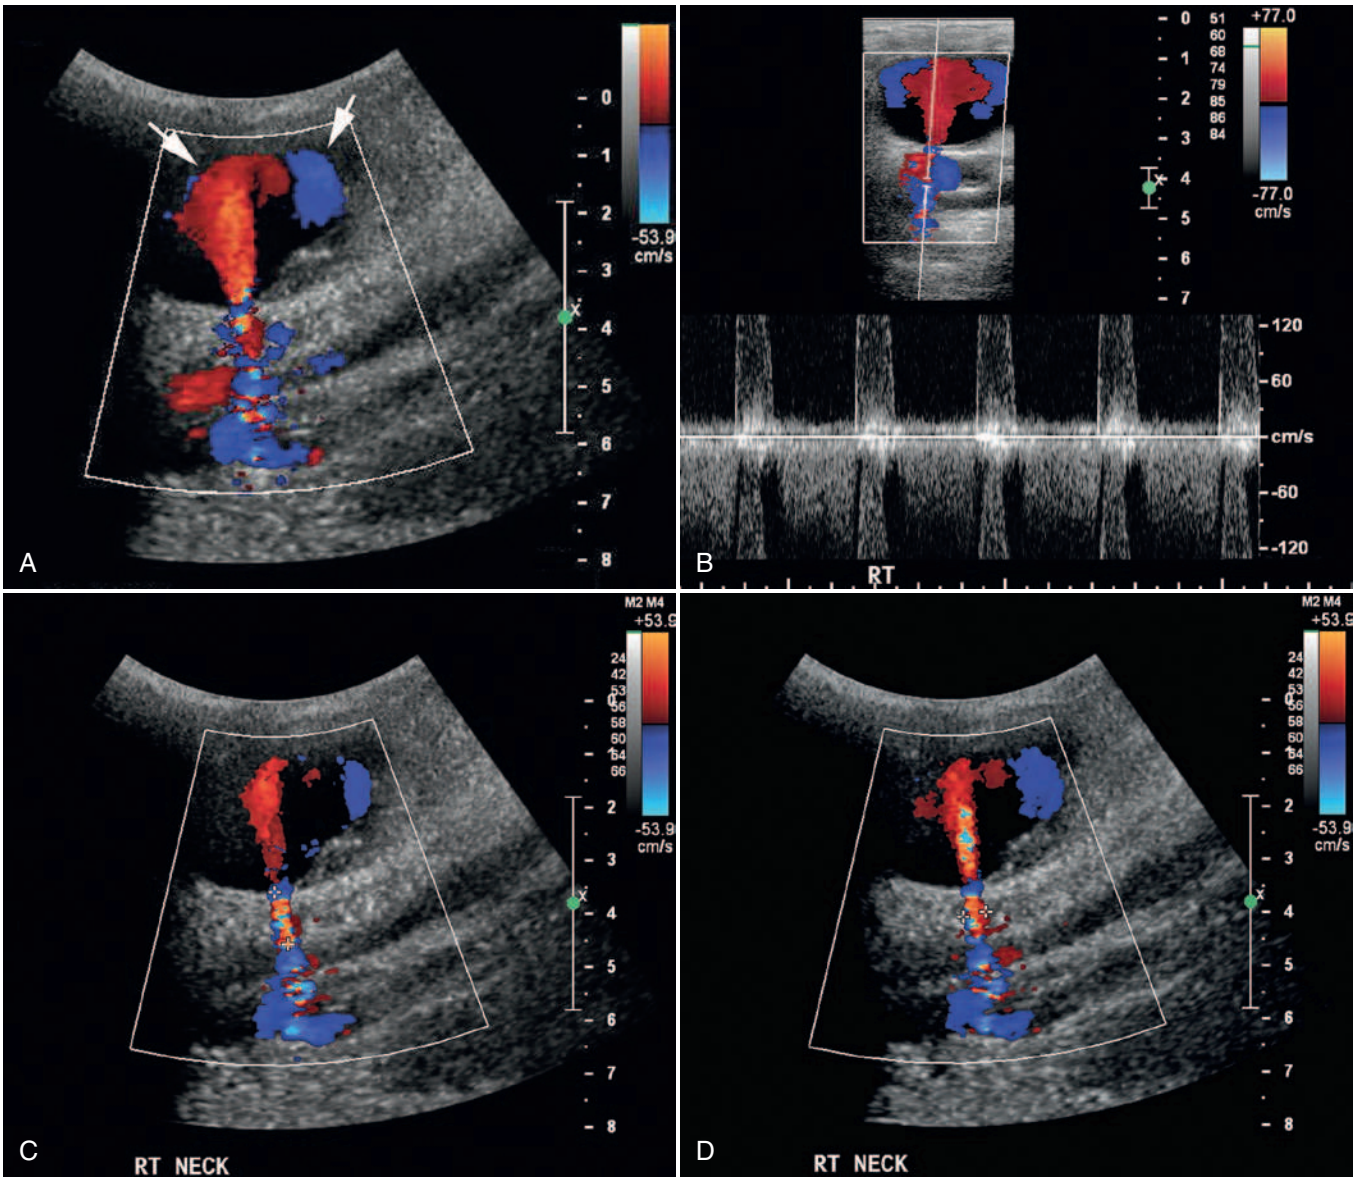

FIG. 27.13 Common Femoral Artery Pseudoaneurysm. (A) Common femoral artery pseudoaneurysm with "yin-yang" color flow pattern in the pseudoaneurysm *(arrows)*. **(B)** Spectral Doppler of the pseudoaneurysm neck shows a high-velocity "to-and-fro" pattern. **(C)** Measurement of the length of the neck from the common femoral artery to the pseudoaneurysm *(calipers)*. **(D)** Measurement of the diameter of the neck *(calipers)* off of the common femoral artery indicates size of hole in artery; a "rent" in the artery is less amenable to thrombin injection. It is preferable to measure the diameter in gray-scale because color may overestimate the diameter, but sometimes the neck cannot be seen without color (as in this case). See also Video 27.4.

injection into the pseudoaneurysm to thrombose is commonly performed, with a success rate of 94% to 97% without surgical intervention.[35-37] Treatment with sonographically guided direct compression has been used in the past but is less successful (up to 85% pseudoaneurysm thrombosis).[38]

Arteriovenous Fistula

The term **"fistula"** describes an abnormal communication between the arterial and venous circulations. There is disruption through all layers of the arterial wall as well as a focal disruption of a nearby venous structure, allowing communication from high–arterial pressure to low-pressure veins. This communication bypasses the capillary bed. It can be congenital, acquired, or rarely spontaneous in nature. Fistulas may be seen after autologous vein bypass grafting[39] and do not appear to affect patency of the graft.[40] In the absence of bypass graft, most are acquired and usually associated with a history of trauma.[41] A **traumatic arteriovenous fistula** may course from normal artery to normal vein in the setting of trauma, but congenital **arteriovenous malformations** (AVMs) may occur with associated abnormal vascular structures. Many are asymptomatic. However, symptomatic AVFs do not typically spontaneously resolve and often require surgery.[42]

Gray-scale imaging may show very little arterial abnormality in a traumatic fistula, but the cluster of dilated structures of an AVM can be identified. In either abnormality, there may be venous

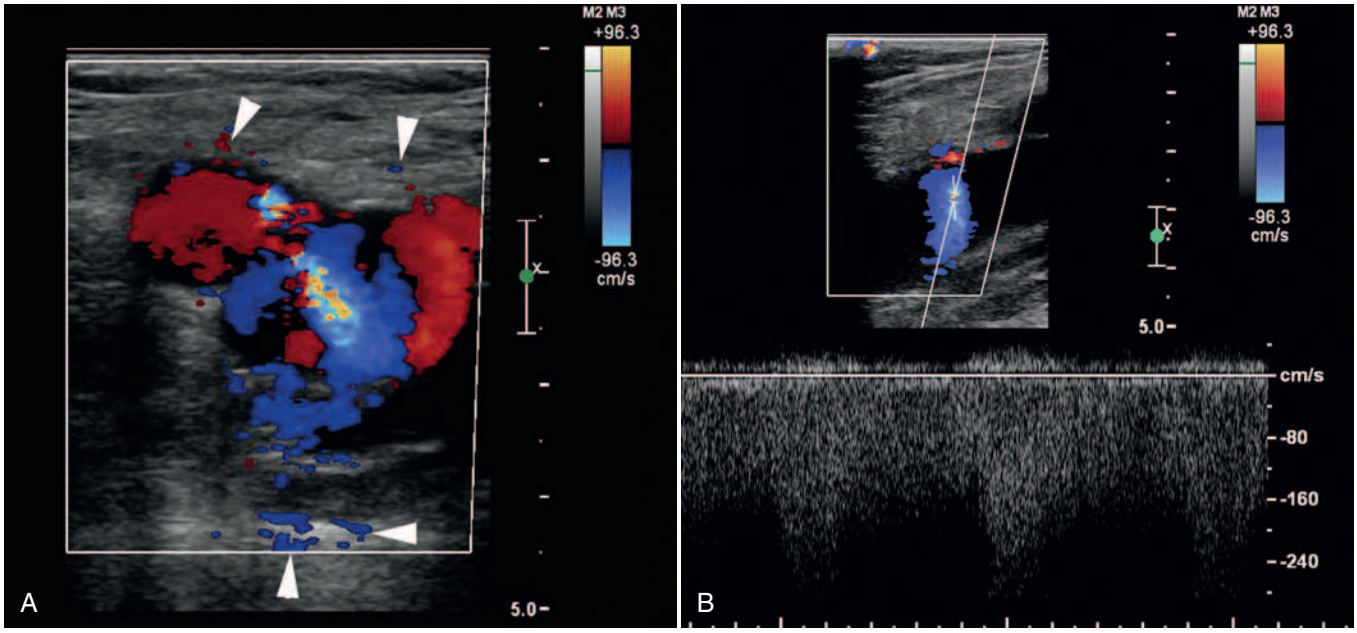

FIG. 27.14 Common Femoral Artery to Common Femoral Vein Arteriovenous Fistula (AVF). (A) Color Doppler shows common femoral artery to common femoral vein AVF. Note the adjacent tissue vibration artifact *(arrowheads)*. **(B)** Arterialized turbulent flow is seen within the vein just downstream to the AVF. See also Video 27.5.

dilation. Color Doppler ultrasound is the best noninvasive imaging modality to evaluate AVF or AVM and may show a large cluster of tortuous vessels with abnormal hyperemic flow. Spectral Doppler waveforms of the inflow arteries feeding the AVF may show low-resistance flow because they bypass the capillary bed. Doppler can show arterialized waveforms in the venous structures near the AVF. **Tissue vibration artifact** is commonly seen with AVFs, consisting of color pixels erroneously placed in the adjacent soft tissue by the ultrasound scanner because of the marked turbulence of the AVF. If the tissue vibration artifact is seen, a search should be made for an AVF. The arterialized waveform may be better seen during the Valsalva maneuver because with the increased thoracic pressure it causes, normal antegrade venous flow is decreased (Fig. 27.14, Video 27.5).

Lower Extremity Vein Bypass Grafts

Bypass grafts may use arterial segments or veins for arterial revascularization. Like bypass conduits in other portions of the body, these have potential complications that can limit their functionality. Failures soon after surgery may result from poor bypass conduit selection or surgical technical factors such as poor selection of the sites for anastomosis. In addition, the valves of an autologous vein may not be fully lysed during surgical preparation. Although completion imaging is commonly performed at the time of surgery, a recent study showed no improvement in graft survival in patients with intraoperative completion angiography or ultrasound.[43,44] In the longer term, fibrosis may occur at the site of a vein valve, or there may be intimal hyperplasia at an anastomotic region. If the bypass survives long enough, the underlying atherosclerotic disease may affect the bypass and inflow vessels to limit function. For synthetic grafts, the characterization of occlusion is similar to the native vessels, with absence of flow on color or spectral Doppler. Echogenic thrombus may be identified within the graft on gray-scale technique.

Ultrasound is a good technique to identify lesions that are likely to result in native vein bypass graft failure. Once the arterial bypass graft has been created, ultrasound is the primary screening modality; Doppler surveillance with revisions when needed is cost-effective.[45] The diagnosis depends on visible identification of **stenosis** on gray-scale imaging in combination with characterization by color and spectral Doppler. Normal triphasic or biphasic waveforms in the ankle arteries distal to the bypass suggest patency of the bypass. Generalized reduced or monophasic flow velocities in a graft are concerning for disease, and further search for a focal abnormality should be performed. Color Doppler sonography can be used to search for areas of aliasing, and subsequent spectral Doppler evaluation for velocity changes is then performed. When a stenosis is detected in a nonbranching vessel, a velocity ratio can be applied to evaluate significance. The PSV ratio is calculated by dividing the PSV at the stenotic site by peak velocity in the graft 2 cm upstream. A PSV ratio of at least 2.0 corresponds to at least 50% diameter stenosis.[46,47] Likewise, a PSV above 180 cm/sec has been associated with stenosis of greater than 50% diameter[47] in lower extremity bypass vein grafts (Fig. 27.15, Video 27.6).

Several ultrasound parameters, including PSV ratio, are associated with future bypass **graft dysfunction.** Once the PSV ratio measures at least 3.5 to 4.0, showing severe stenosis, treatment should be considered if it has not been performed at less severe degrees of stenosis, even in less symptomatic patients.[46,47] A recent study of Doppler and CT showed that patients with PSV ratio above 3.5 were at high risk for graft failure, whereas high-grade stenosis on CT did not correlate as well with graft failure.[48] Velocity criteria for severe stenosis used by Wixon and

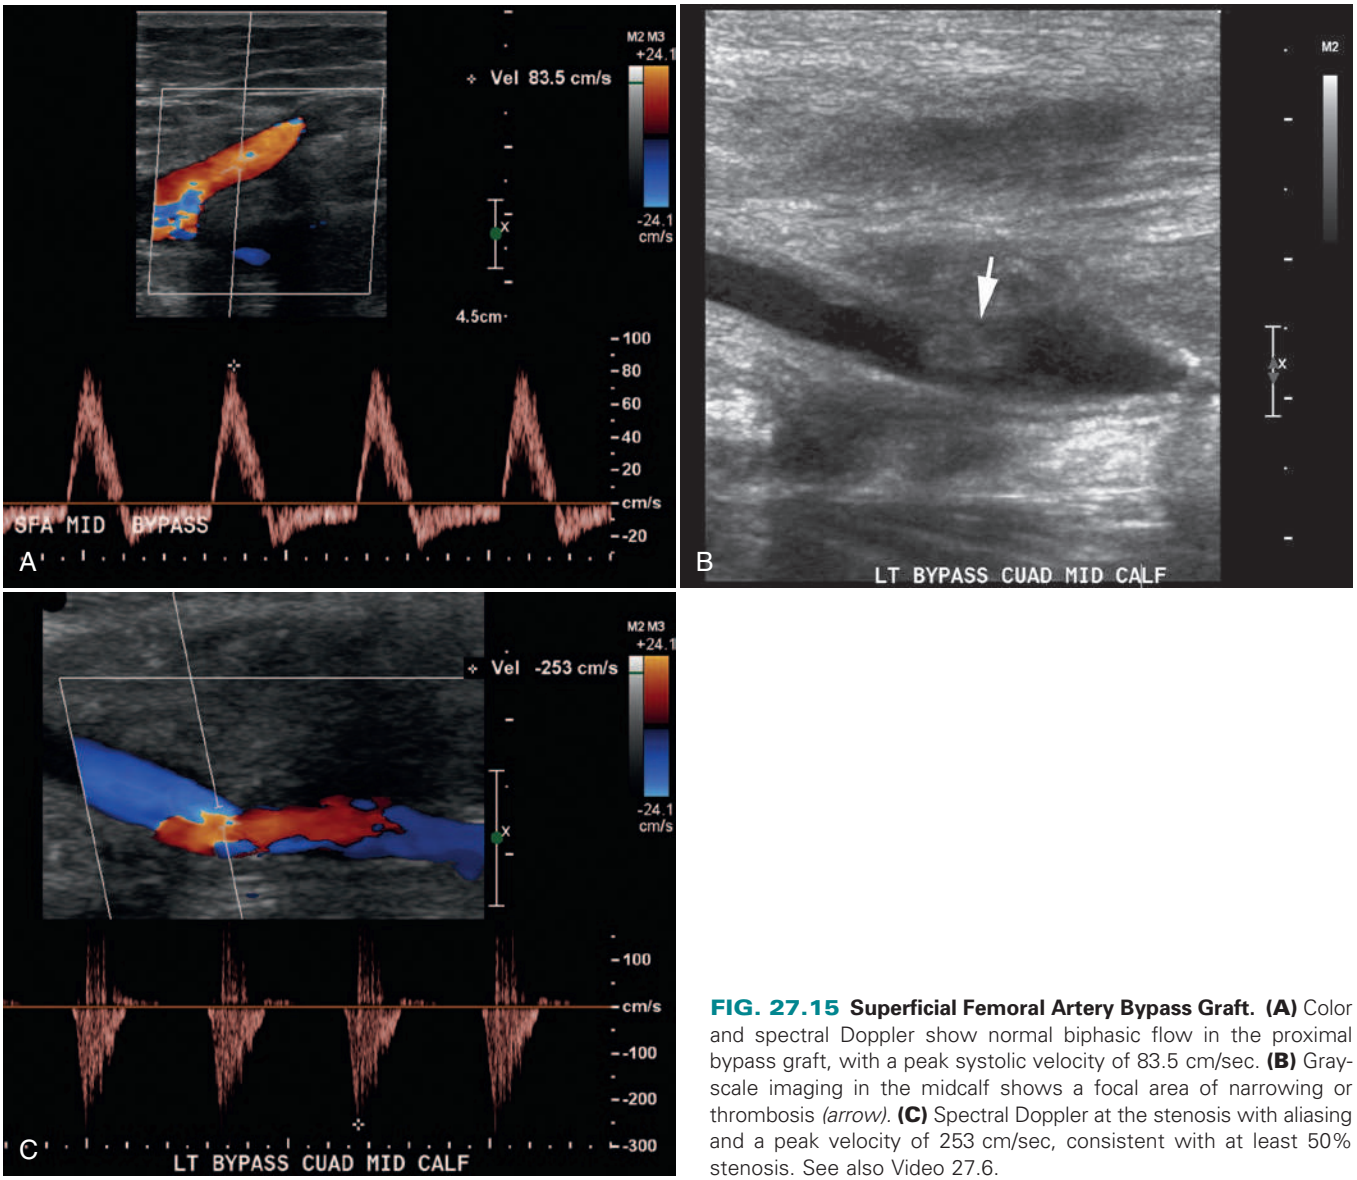

FIG. 27.15 Superficial Femoral Artery Bypass Graft. (A) Color and spectral Doppler show normal biphasic flow in the proximal bypass graft, with a peak systolic velocity of 83.5 cm/sec. **(B)** Gray-scale imaging in the midcalf shows a focal area of narrowing or thrombosis *(arrow)*. **(C)** Spectral Doppler at the stenosis with aliasing and a peak velocity of 253 cm/sec, consistent with at least 50% stenosis. See also Video 27.6.

colleagues suggest that PSV above 300 cm/sec and PSV ratio above 3.5 should direct the patient to intervention of a vein graft stenosis. In patients who meet these criteria, the intervention should be immediate if flow velocity within the graft falls below 45 cm/sec.[45] Decreased flow relative to a prior study is also a worrisome finding on spectral Doppler. In surveillance of vein grafts by Doppler with intervention on stenotic lesions, there is increased survival of the surveillance group. In patients with greater than 70% stenosis, 100% of grafts failed without revision, but only 10% failed with ultrasound detection and a subsequent revision pathway.[49]

Patients with venous bypass graft may form pseudoaneurysms or true aneurysms, but these are rare. When present, they occur most frequently in the anastomotic regions. In a study of saphenous vein grafts, only 10 of 260 (4%) developed true arterial aneurysm,[50] with higher incidence in patients with preexisting aneurysm and in males. The average time to diagnosis was 7 years after graft placement.[51]

Upper Extremity Arteries

Normal Anatomy

Each **upper extremity arterial system** is supplied from either the **brachiocephalic artery** (right) or the **subclavian artery** (left) in patients without normal anatomic variations. The artery is anterior to the vein when insonated from the supraclavicular fossa. The subclavian artery courses laterally and becomes the **axillary artery** once it is beyond the lateral margin of the first rib. The axillary artery courses medially over the proximal humeral head to the inferior margin of the pectoralis muscle, where it becomes the **brachial artery.** The brachial artery typically courses along the medial upper arm to the antecubital fossa and divides into the radial, ulnar, and smaller interosseous arteries.

Occasionally, there is high brachial artery bifurcation above the antecubital fossa[52] (Fig. 27.16). Regardless of the level of origin, the radial and ulnar branches extend to the wrist. On gray-scale imaging, normal upper extremity arteries have smooth

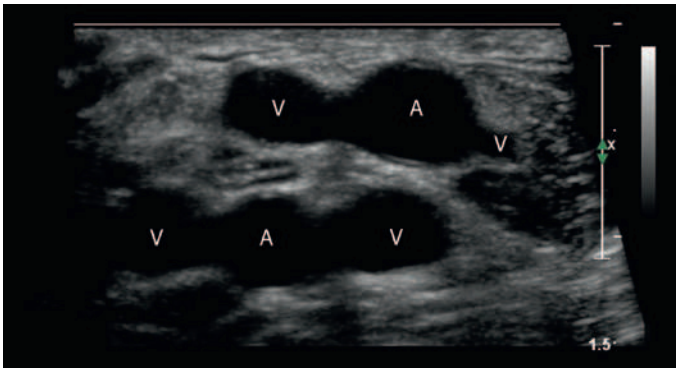

FIG. 27.16 High Brachial Artery Bifurcation. High brachial artery bifurcation, with two arteries *(A)* (radial and ulnar) and their paired accompanying veins *(V)*, above the antecubital fossa.

walls with anechoic lumens and lack of atherosclerotic plaques or stenosis, similar to lower extremity arteries. Laminar flow is present without turbulence or aliasing on color Doppler. A similar high-resistance triphasic waveform with sharp upstroke and transient flow reversal is typically present in the upper extremity arteries on spectral Doppler.

Ultrasound Examination and Imaging Protocol

Higher frequency imaging is usually possible owing to decreased size of the arm with respect to the leg. The subclavian artery, axillary artery, and brachial artery are evaluated to the level of the elbow. Both upper extremities should usually be insonated so that the symptomatic side can be compared with the asymptomatic. The ipsilateral innominate artery should be evaluated to determine an abnormal inflow etiology of the problem when the subclavian artery waveform is abnormal. In the forearm, imaging of the radial and ulnar arteries is the key to most diagnoses.

The ACR-AIUM-SRU practice parameter for the performance of peripheral arterial ultrasound suggests that upper extremity ultrasound should examine the subclavian artery, axillary artery, and brachial artery.[2] Other arteries are examined as deemed clinically appropriate. It states that these may include "innominate, radial, and ulnar arteries, and the palmar arch." The guideline further suggests that angle-corrected longitudinal Doppler and/or gray-scale imaging should be documented in each normal and at any abnormal segment. Angle-corrected spectral Doppler is recommended proximal to, at, and beyond any suspected stenosis.[2]

Arterial Occlusion, Aneurysm, and Pseudoaneurysm

Upper arm arterial **occlusion** is usually the result of trauma, often iatrogenic. The rate of radial artery occlusion after artery access for coronary angiography may be as high as 30.5%, although lower rates are also reported in the literature.[53] For surgical bypass harvest planning, documentation of patency of the **palmar arch** is an additional component. For detection and characterization of arterial aneurysm, the maximal outer diameters of the aneurysm should be measured in transverse (short axis) with gray-scale technique. Doppler can differentiate the patent component from mural thrombus. In **pseudoaneurysm** characterization, the size and Doppler components are also measured, but the pseudoaneurysm neck is also evaluated with spectral Doppler as detailed earlier in the section on lower extremity arteries (Fig. 27.17, Video 27.7 and Video 27.8). If there is concern for AVF, both the arterial inflow portion and venous outflow should be characterized by duplex Doppler within several centimeters of the pseudoaneurysm, because the characteristic arterialization of the downstream venous waveform may be dampened farther away from the fistula. Turbulent flow through the fistula may affect surrounding tissues causing a tissue reverberation artifact, which may be the first clue that an AVF is present.

Arterial Stenosis

Atherosclerotic disease can cause upper extremity **stenosis** but is a less common problem in the arm than encountered in the lower extremities. Gray-scale findings are similar to the lower extremities and include intimal plaques and/or visible irregularity of the vessel lumen. Color Doppler may show aliasing with turbulent flow similar to those findings seen in lower extremity arterial stenosis. On spectral Doppler, velocity criteria are not well defined for the upper extremity arteries. However, for a stenosis in most nonbranching arteries, a greater than 2:1 PSV ratio of the stenosis relative to the upstream artery within 2 to 4 cm is consistent with at least 50% diameter stenosis. Depending on the timing and whether collaterals have formed, this degree of stenosis may or may not be symptomatic or clinically significant (Fig. 27.18).

Subclavian Stenosis

Subclavian stenosis most commonly occurs proximal to the origin of the left vertebral artery. In a subset of patients, flow to the arm is provided by filling through the vertebral artery via retrograde flow. If this reversed flow is significant, there can be a steal phenomenon **("subclavian steal")** from the brain, leading to dizziness with certain arm movements as additional flow is diverted to the arm. In these patients, the vertebral artery waveform should be insonated (Fig. 27.19, Video 27.9). Transient early systolic deceleration with resultant transient cessation of antegrade flow or transient reversal of flow (Fig. 27.20) correlated with subclavian artery mean diameter stenosis of 72% and 78%, respectively.[54] Similar stenosis can occur in the right subclavian artery, but less frequently. If these abnormal vertebral artery waveforms are seen, an attempt should be made to directly visualize a stenosis by gray-scale and duplex Doppler in the subclavian artery itself.

Thoracic Outlet Syndrome

In distal upper extremity ischemic symptoms, embolic or traumatic injury (commonly iatrogenic) to the artery should also be considered. If embolic phenomena are seen, evaluation for **thoracic outlet syndrome** should be considered. In patients with symptoms elicited by specific positioning of the arm, thoracic outlet syndrome is a form of arterial stenosis that should be considered. It occurs by external compression of the artery by adjacent muscles during abduction of the arm, and this narrowing

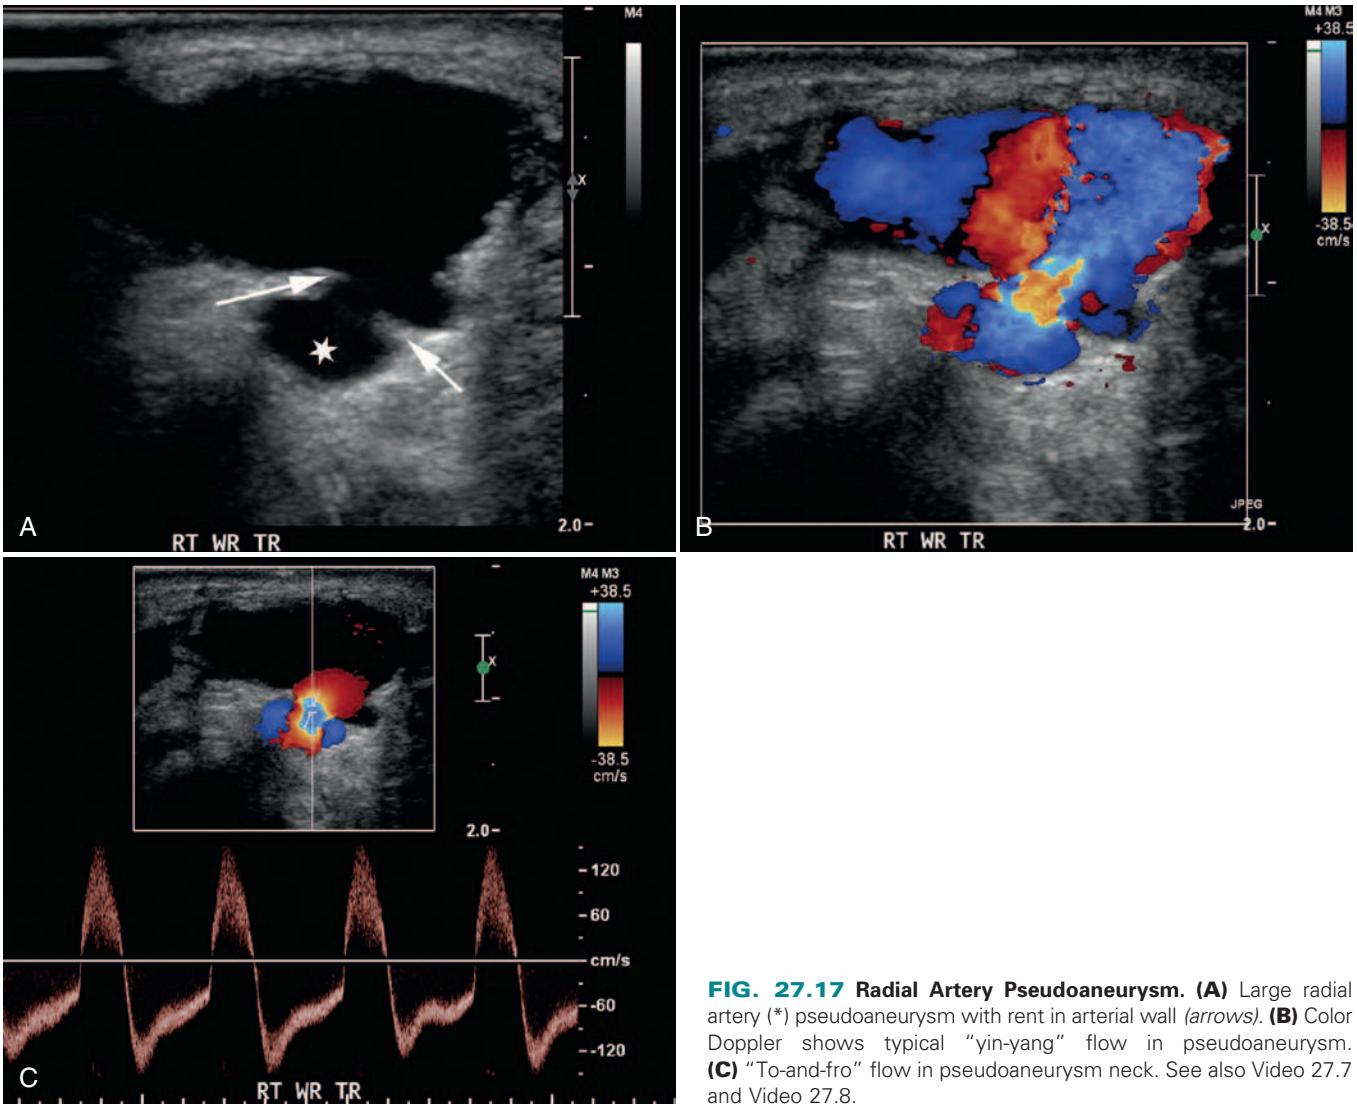

FIG. 27.17 Radial Artery Pseudoaneurysm. (A) Large radial artery (*) pseudoaneurysm with rent in arterial wall *(arrows)*. **(B)** Color Doppler shows typical "yin-yang" flow in pseudoaneurysm. **(C)** "To-and-fro" flow in pseudoaneurysm neck. See also Video 27.7 and Video 27.8.

can affect the waveform morphology of the downstream arteries.[55] Bone and rib anomalies frequently contribute to the pathology.[56] The velocities in the artery should be evaluated during adduction or neutral position then compared with velocities and waveforms in abduction. Over time, the artery may become injured, and this can lead to occlusion and formation of emboli, which may also be visible sonographically. These emboli can then migrate distally within the upper extremity to cause pain in regions such as the hand. For sonographic evaluation of thoracic outlet syndrome in the proper clinical presentation, it is important to begin by insonating the arteries with the arm in neutral position for baseline waveform characterization. Waveforms are acquired from the forearm arteries with the patient sitting comfortably in an upright, seated position. Once the baseline morphology is clearly defined, the arm is moved into the inciting position, usually with abduction and elevation of the arm with external rotation. A combination of inspiration, breath holding, neck extension, and neck turn to the affected side, known as the **Adson maneuver,** may elicit a positive finding on Doppler.[57] The waveform is monitored as the arm is moved into a variety of positions to elicit symptoms. If abnormal waveforms are not readily apparent, a variety of positions should be tested (Fig. 27.21). If positive, a diminished waveform should be apparent in the arteries of the forearm. Once this has been identified, it may be helpful to repeat the baseline and positive results to show reproducibility of the findings. Further support of the diagnosis includes visible narrowing identified in the subclavian artery, or the presence of an aneurysm in this region, if found.[58] Pseudoaneurysms are frequently present in the setting of thoracic outlet syndrome and can lead to embolic events. Care must be taken in the diagnosis because hyperextension can produce arterial flow abnormality in up to 20% of normal volunteers.[59]

Radial Artery Evaluation for Coronary Bypass Graft

Another use of Doppler in bypass patients is to determine suitability of the **radial artery** for **coronary artery grafting.** The ulnar artery typically provides the dominant source of blood

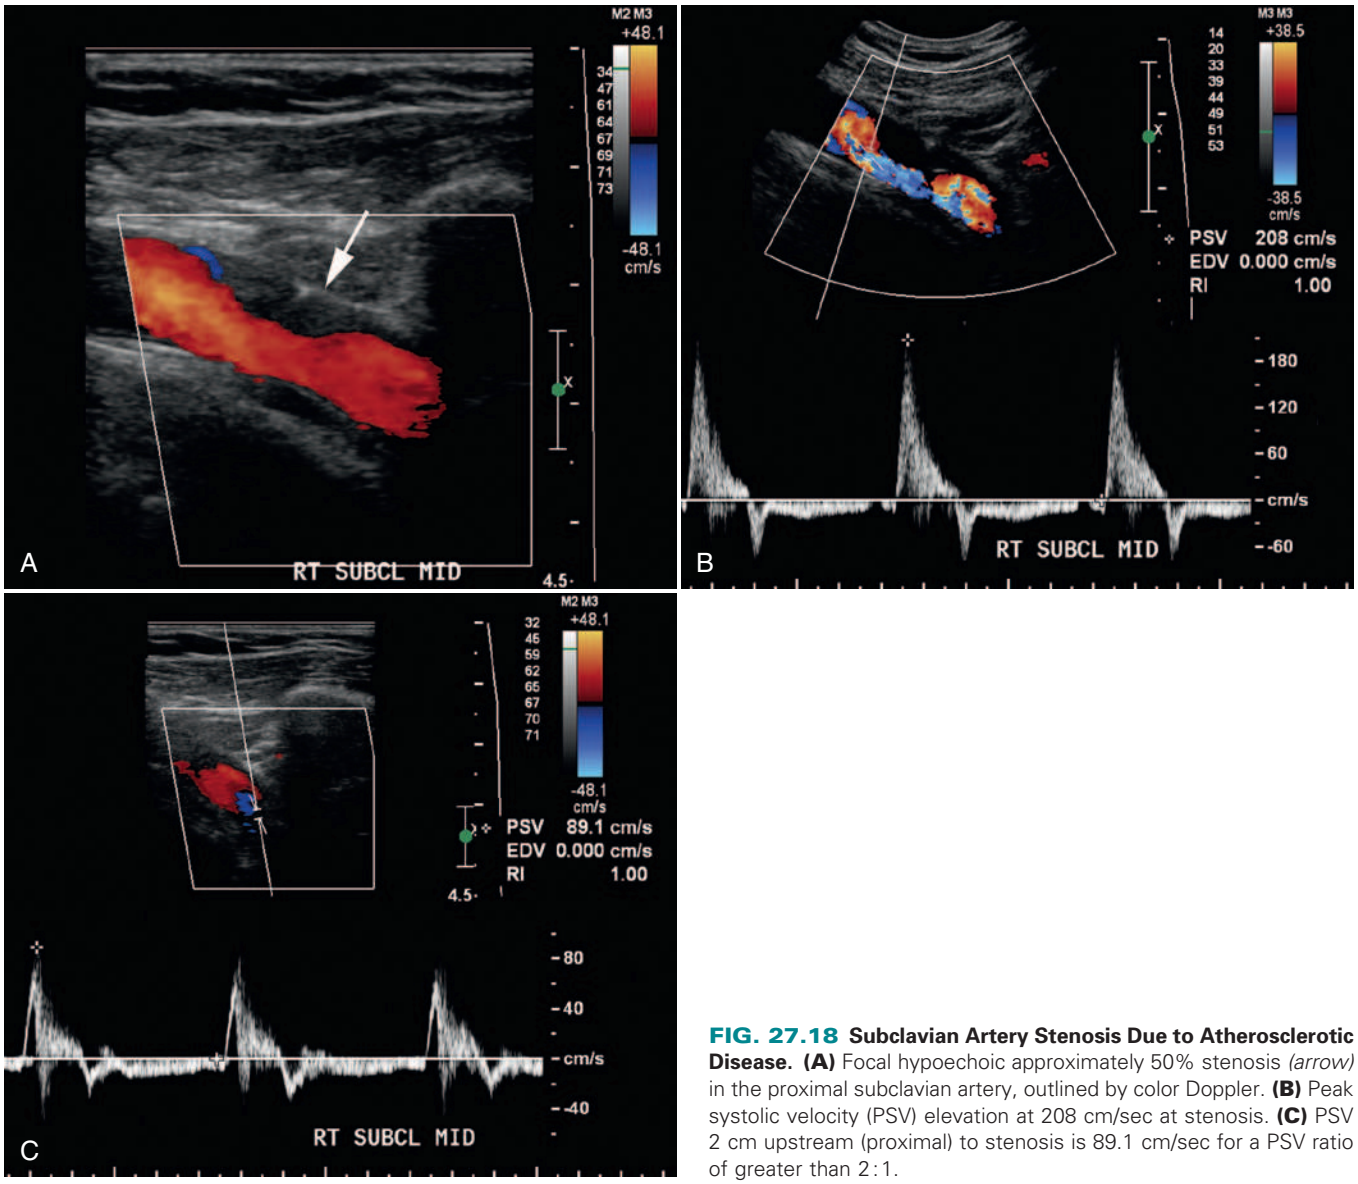

FIG. 27.18 Subclavian Artery Stenosis Due to Atherosclerotic Disease. (A) Focal hypoechoic approximately 50% stenosis *(arrow)* in the proximal subclavian artery, outlined by color Doppler. **(B)** Peak systolic velocity (PSV) elevation at 208 cm/sec at stenosis. **(C)** PSV 2 cm upstream (proximal) to stenosis is 89.1 cm/sec for a PSV ratio of greater than 2:1.

flow to the hand. The ulnar artery supplies the superficial **palmar arch,** which is often incomplete. The radial artery supplies the deep palmar arch, which is more commonly complete, in communication with the ulnar artery. If the superficial palmar arch in the hand is patent, thus allowing flow to the entire hand through the ulnar artery, then the radial artery is harvested. Thus evaluation of palmar arch patency is necessary before harvest. Doppler evaluation of patency is more accurate than the modified Allen test on physical examination, because only about 5 of 43 (12%) patients with an abnormal modified Allen test result will have abnormal Doppler findings.[60]

A small linear array 12- to 15-MHz "hockey stick" transducer initially is used to determine antegrade flow of the ulnar artery and radial artery at the wrist. With duplex Doppler, arterial flow to the hand in the superficial palmar arch at the thenar eminence near the crease of the base of the thumb is characterized first with normal distal radial artery inflow. Subsequently, the radial artery is transiently occluded by direct compression of the radial artery at the wrist, and the resultant spectral Doppler waveform is evaluated. Care should be taken during examination not to hyperextend the hand with regard to the wrist, because a false-negative examination finding may incorrectly suggest lack of patency of the arch. In patients with a patent superficial palmar arch, there should be reversed flow of the radial artery in the hand, measured at the thenar eminence or in the region of the snuff box between the first metacarpal and second carpal bone.[61,62] If there is no flow or absent reversed flow, then the radial artery of that upper extremity is not suitable for harvest owing to an incomplete arch (Fig. 27.22). Increased flow in the ulnar artery may also occur during radial artery compression if the arch is patent.[63]

PERIPHERAL VEINS

Evaluation of the upper and lower extremity venous system is primarily performed with sonography. Useful applications

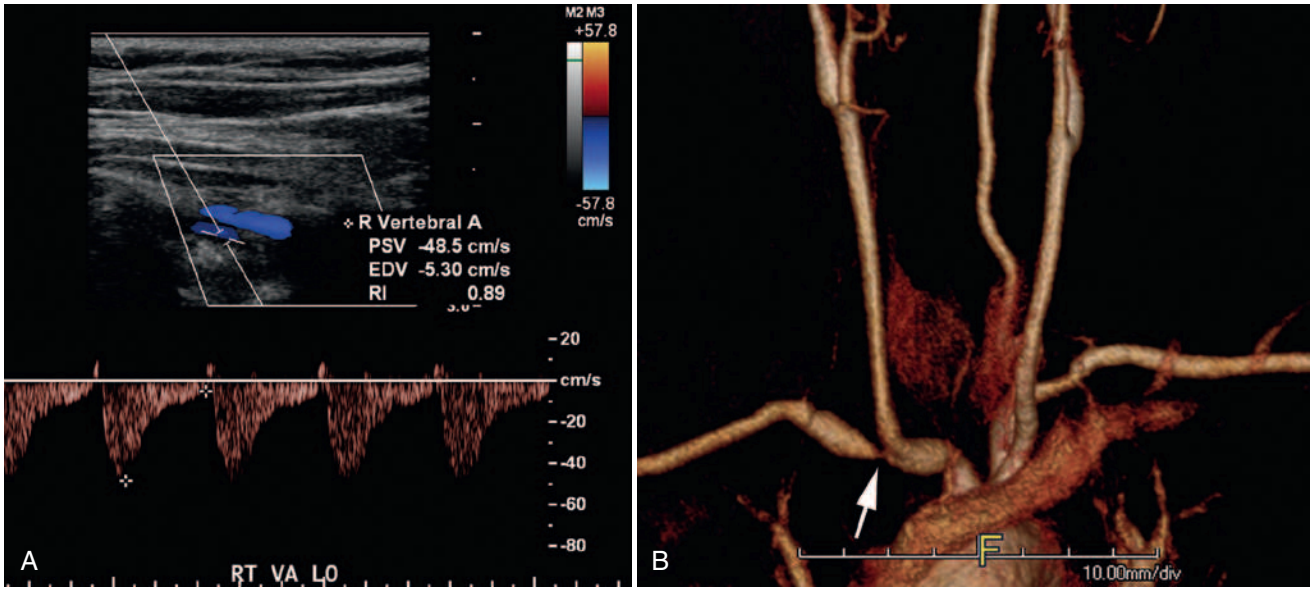

FIG. 27.19 Subclavian Steal Phenomenon. (A) Reversed flow in the right vertebral artery. Note that artery and vein are the same color, indicating abnormal flow direction in one of the vessels. **(B)** Magnetic resonance imaging confirms significant stenosis in the subclavian artery just distal to the vertebral artery *(arrow)*. See also Video 27.9.

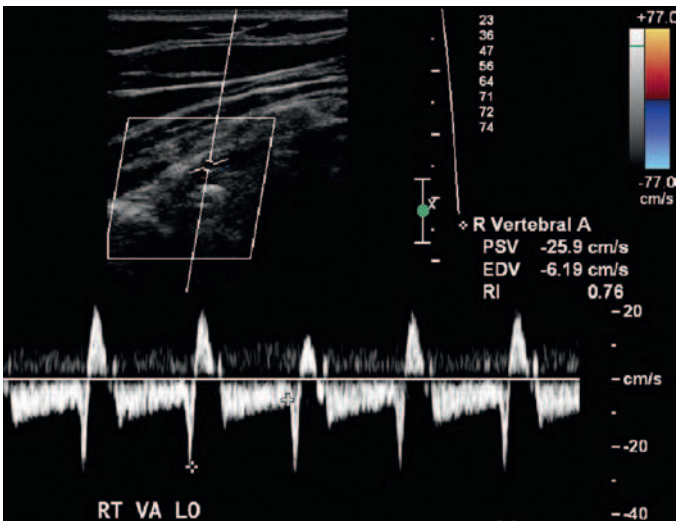

FIG. 27.20 Subclavian Steal With Transient Flow Reversal in the Vertebral Artery.

include evaluation for thrombus, localization for venous access procedures, preoperative venous mapping for hemodialysis AVF and graft placement, and postoperative hemodialysis AVF and graft assessment. Key aspects of venous Doppler imaging include knowledge of anatomy, scanning technique, and attention to detail.

The most common indication for venous Doppler ultrasound is to identify deep venous thrombosis (DVT). Undiagnosed and untreated DVT can result in fatal pulmonary embolism (PE). Sudden death is the first symptom in about 25% of people who have PE[64] (Fig. 27.23). Clinical evaluation of the peripheral venous system is frequently difficult, nonspecific, and often inaccurate. Clinical decision rules to improve pretest probability are recommended by the American College of Physicians and the American Academy of Family Physicians.[65-67] The Wells criteria generate a score for certain physical examination findings and pertinent clinical history.[68] Clinical factors associated with increased probability of DVT include active cancer, immobilization, localized tenderness along the distribution of the deep venous system, swollen extremity, pitting edema localized to the symptomatic extremity, collateral superficial veins, and previously documented DVT.

A modification of the **Wells score** creates two groups: DVT unlikely or DVT likely.[69] Current guidelines recommend a D-dimer test for those with low risk.[70,71] The D-dimer test measures a degradation product of fibrin and has a high negative predictive value that is sensitive, but not specific for DVT.[72] If the D-dimer test result is positive, the patient should be evaluated with venous Doppler. As with patients without cancer, the combination of low probability and negative D-dimer result can exclude DVT in cancer patients.[73,74] In practice, many patients do not undergo this workup.[75] Going directly to sonography is frequently faster than waiting for workup results and may offer an alternative musculoskeletal diagnosis such as popliteal fossa cyst. Also, in cases of technically limited sonographic evaluation of the more central deep venous system (iliac veins and inferior vena cava [IVC]), magnetic resonance venography or CT venography may be more sensitive.[76]

Sonographic Examination Technique

The superficial location of the upper and lower venous system allows the use of linear, higher frequency transducers. The highest frequency linear transducer that still gives adequate penetration should be used to optimize spatial resolution. Typically the examination is best performed using a 5- to 10-MHz linear array transducer, with application of the higher frequency range in upper arm, forearm, calf, and more superficial veins. A curved array or sector probe in the 3- to 5-MHz range may be necessary

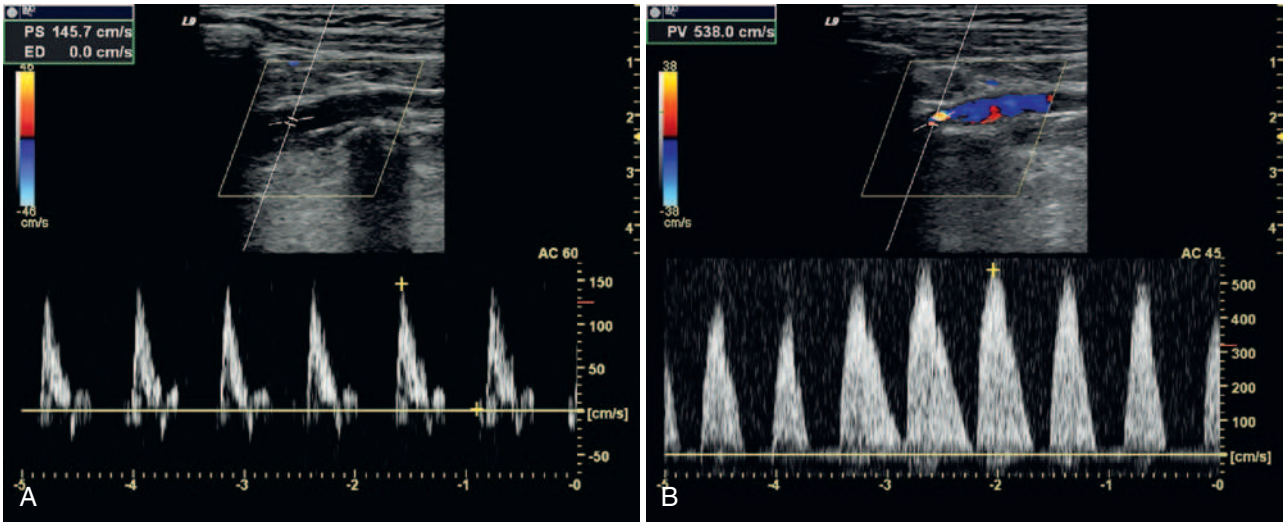

FIG. 27.21 Thoracic Outlet Syndrome. (A) Normal baseline subclavian artery waveform. **(B)** Altered waveform during hyperextension, with compression against the clavicle causing stenosis.

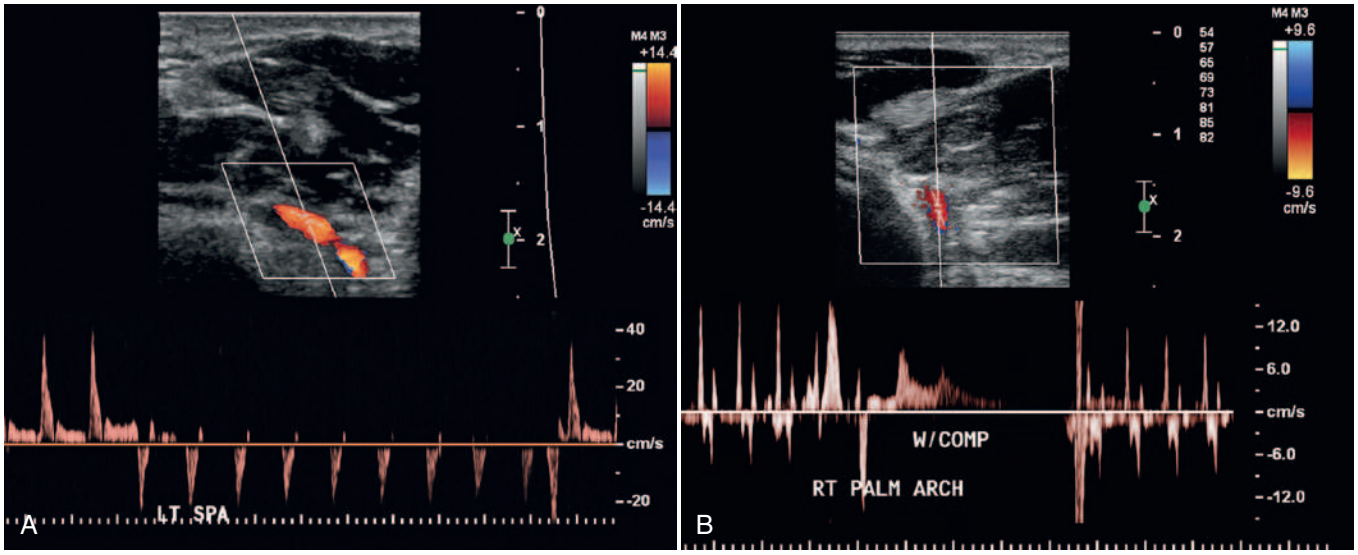

FIG. 27.22 Radial Artery Evaluation for Coronary Bypass Graft. (A) Patent palmar arch, with reversal of flow in the superficial palmar arch on radial artery compression at the wrist. **(B) Incomplete palmar arch,** with lack of flow in the superficial palmar arch on radial artery compression at the wrist.

in very large patients or those with substantial extremity edema. Gray-scale imaging should include compression and should be performed in the transverse plane.

Color flow and spectral analysis are the most common applications of Doppler sonography, with occasional use of power Doppler. Both techniques evaluate the disease process in the peripheral veins and give additional information regarding altered venous hemodynamics. Anatomic and functional detail makes sonography a valuable tool. Color Doppler sonography can be used to evaluate venous segments that cannot be directly assessed by compression, such as the subclavian veins. Power Doppler provides improved detection of very slow flow, especially in small veins. All spectral Doppler waveforms should be obtained in the longitudinal plane.

Lower Extremity Veins

Normal Anatomy

Deep Venous System. The venous anatomy of the leg is illustrated in Fig. 27.24. The **common femoral vein** (CFV) begins at the level of the inguinal ligament as the continuation of the external iliac vein and extends caudally to the bifurcation into the **femoral vein** (FV) and the **profunda femoris vein,** which lie medial to the adjacent artery. The FV courses medially to the adjacent artery through the adductor canal in the caudal thigh. The term "femoral vein," previously called the "superficial femoral vein," should be used to avoid clinical confusion regarding the deep versus superficial venous system.[77] The **popliteal vein** (PV) represents the continuation of the FV after its exit from the adductor canal in the posterior caudal thigh. The PV is located superficial

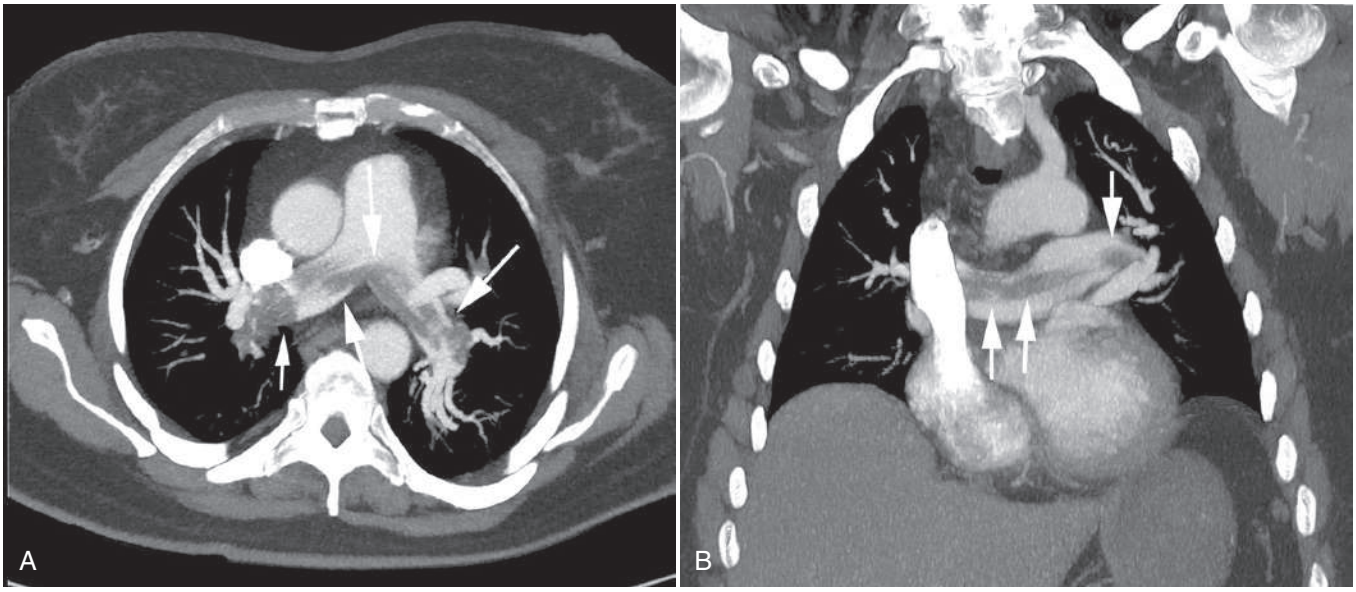

FIG. 27.23 Pulmonary Emboli. (A) Axial CT with contrast shows a large saddle pulmonary embolus extending into the left and right pulmonary arteries *(arrows)*. **(B)** Maximum-intensity projection coronal CT with contrast in the same patient shows extent of bilateral pulmonary emboli *(arrows)*.

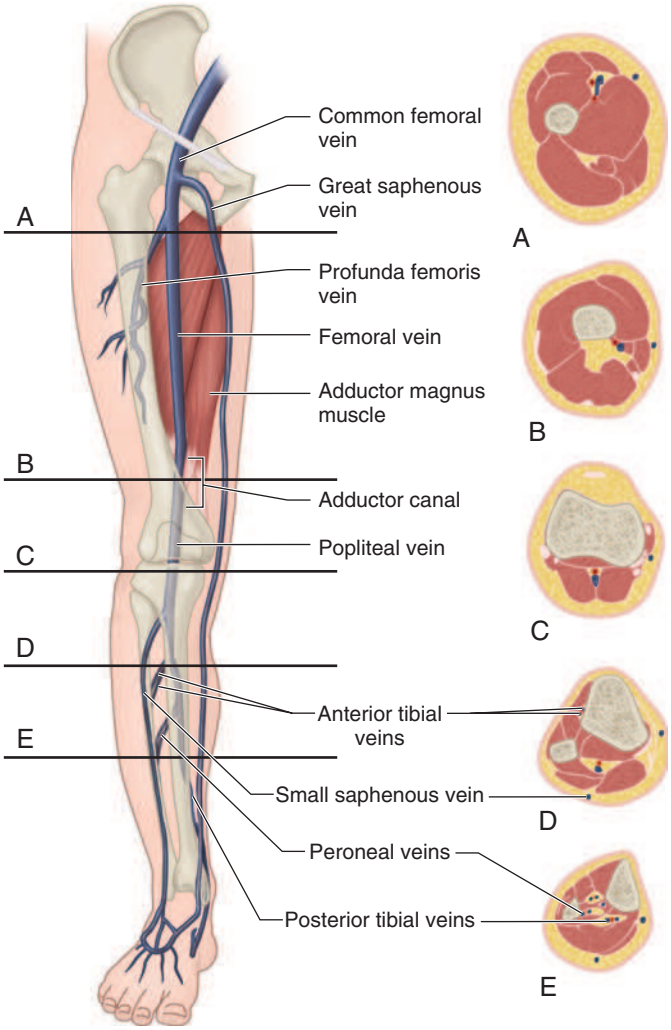

FIG. 27.24 Venous Anatomy of the Lower Extremity.

to the artery and courses through the popliteal space into the proximal calf. Duplication of the FV can be seen in about 30% of patients.[78] Duplication of the FV can also be segmental. It has been shown that these anatomic variants are associated with increased incidence of DVT.[79,80] About 40% of patients with multiple vessels within the popliteal fossa arise from a high confluence of the posterior tibial and peroneal veins, rather than true PV duplication.[78] Description of these anatomic variants assists in avoiding a missed diagnosis on follow-up examinations.

The paired **anterior tibial veins** arise from the PV and course laterally along the anterior calf to the dorsum of the foot. The **tibioperoneal trunk** originates from the PV slightly caudal to the anterior tibial veins and bifurcates into the paired **posterior tibial veins** and **peroneal veins.** The peroneal veins course medial to the posterior aspect of the fibula, whereas the posterior tibial veins course through the posterior calf muscles posterior to the tibia and along the medial malleolus. Deep veins in the gastrocnemius and soleus calf muscles do not have an adjacent artery and are a common site of acute calf vein thrombus in postoperative or high-risk patients.[81]

Superficial Venous System. Anatomic terminology for the lower extremity superficial venous system was standardized in 2002. The great and small saphenous veins and their branches comprise the superficial venous system of the lower extremities.[82] The **great saphenous vein** (GSV) empties into the medial aspect of the CFV in the proximal thigh superior to the bifurcation of the CFV. The GSV courses along the medial thigh and calf. The normal GSV typically is 1 to 3 mm in diameter at the level of the ankle and 3 to 5 mm in diameter at the saphenofemoral junction. These measurements are important when performing saphenous vein mapping for harvesting an autologous vein graft. The **small saphenous vein** has a variable insertion into the posterior aspect of the PV and courses along the dorsal calf to the ankle. Measurements for the small saphenous vein are typically

1 to 2 mm in diameter inferiorly and 2 to 4 mm at the saphenopopliteal junction. In cases of **superficial venous insufficiency,** both the GSV and small saphenous vein can become abnormally enlarged and tortuous.

Ultrasound Examination and Imaging Protocol

The choice of transducer depends on the patient's body habitus and depth of the vessel to be studied. Typically a high-resolution 5- to 7.5-MHz linear array transducer will be used. For larger patients a lower-frequency (2.5- or 3.5-MHz) curvilinear transducer may be needed. Appropriate gain settings are needed to ensure that the vessels show no artifactual internal echoes and that thrombus is not mistaken for echoes caused by slow-flowing blood. Color Doppler imaging settings must be optimized for sensitivity to slow, low-volume flow.

The lower extremity deep venous system should be evaluated from just above the inguinal ligament to the bifurcation of the PV in the upper calf, including compression, color, and spectral Doppler sonography with assessment of respiratory phasicity. The cranial profunda femoris vein and cranial GSV should also be examined. Ultrasound evaluation of the **external iliac veins and IVC** is helpful to determine extent of documented CFV when the top of the thrombus is not seen in the CFV.

The patient is examined in the supine position with the leg abducted and externally rotated with slight flexion of the knee. The most important portion of the examination is venous gray-scale compression. The veins of the deep system are compressed in the transverse plane and evaluated in a stepwise fashion every 1 to 2 cm through the level of the adductor canal (Fig. 27.25, Video 27.10). Pressure on the skin with the transducer should be applied to collapse the vein. If the adjacent artery is deforming, pressure application is adequate. Color Doppler is then performed in selected segments to evaluate for patency and any nonocclusive or hypoechoic thrombus not seen on the gray-scale images. The spectral Doppler waveform obtained is assessed for respiratory phasicity and cardiac pulsatility. The PV is best evaluated with the patient's leg bent in a frog leg position. Applying hand pressure to the posterior surface of the leg when imaging the adductor canal or creating simulated augmentation by asking the patient to "step on the gas" may aid in visualizing the vein if the veins are difficult to see because of slow flow, increased depth, or significant edema.[83]

Ultrasound evaluation of the **calf veins** remains controversial owing to uncertain clinical value and cost-effectiveness. The ACR practice guidelines do not require evaluation of the calf veins. At a minimum, all symptomatic areas should be evaluated, including the calf, to determine the source of symptoms such as superficial varicosities, and thrombophlebitis. Some institutions that routinely evaluate the calf veins start at the PV and track the paired anterior tibial veins, posterior tibial veins, and peroneal veins to the ankle. Calf imaging has become more common and is required for accreditation by the Intersocietal Accreditation Commission,[84] but there is not a standard study protocol.[85] The American College of Chest Physicians guideline for antithrombotic therapy does not favor routine venous Doppler of the calf veins.[65] The more benign natural history of calf venous thrombosis favors management with serial sonographic examination with treatment only if proximal DVT is demonstrated. If calf venous thrombosis is detected, the interpreting physician may not know whether a patient with calf venous thrombosis will be treated. A suggested general statement may include, "If this calf venous thrombosis is not treated, a follow-up in 1 week is recommended to evaluate for progression."[85]

Imaging Protocol. The lower extremity venous imaging protocol includes the following images for each deep venous segment:

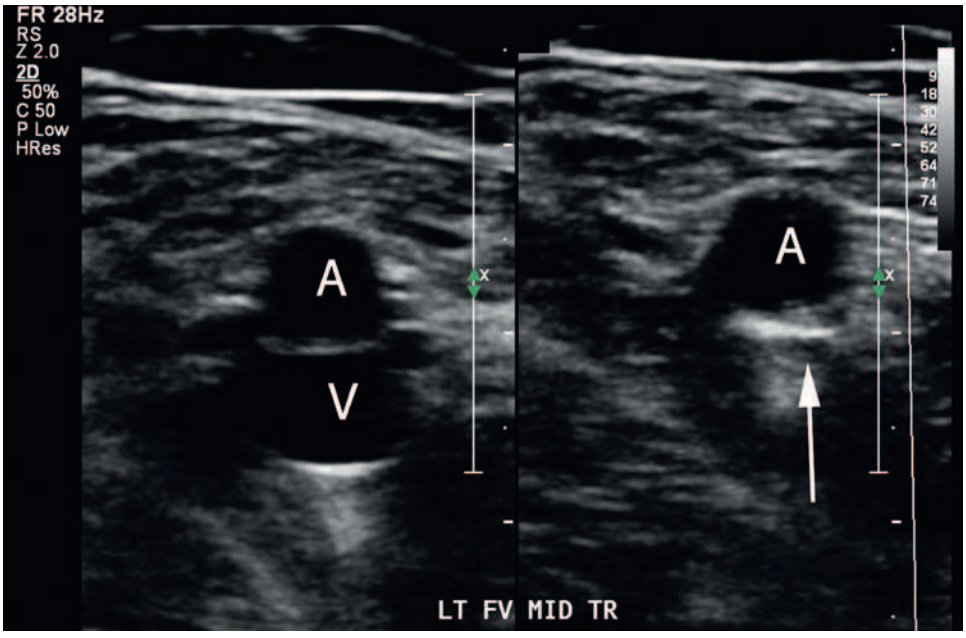

FIG. 27.25 Normal Femoral Vein (FV) Compression. Dual transverse image showing noncompressed *(left)* and compressed FV. (FV is completely compressed in right panel and thus not seen; location marked by arrow.) Accompanying Video 27.10 shows the compression maneuver. *A,* Superficial femoral artery; *V,* femoral vein.

1. Transverse gray-scale image at rest and with compression, or a cine clip of the compression maneuver, of the saphenofemoral junction, CFV, FV (at minimum proximal and distal), and PV.
2. Longitudinal color Doppler with spectral waveform analysis.
   a. CFV at the level of the saphenofemoral junction and distal portions. If only a unilateral examination is requested, the contralateral CFV is also evaluated.
   b. PV at a minimum. Consider recording FV as well.
   c. A separate compression image of the profunda femoris vein at the bifurcation with the FV is not typically obtained, but patency is evaluated on the longitudinal color and spectral Doppler waveform of the CFV bifurcation into the proximal FV and profunda femoris vein.
   d. If a thrombus is seen in the CFV, the most proximal extent of thrombus should be demonstrated with inclusion of the external iliac veins and IVC in the evaluation.
   e. Document additional musculoskeletal findings (such as popliteal cyst, knee joint effusion, or hematoma if present in the region being evaluated).

Acute Deep Venous Thrombosis

There are four findings of acute venous thrombosis: (1) intraluminal material that is deformable during compression, (2) dilation of the vein, (3) smooth intraluminal material, and (4) free tail floating proximally from the attachment of the clot on the vein wall.[85] The classic gray-scale findings of acute DVT are noncompressibility of the vessel with direct visualization of the thrombus. With complete acute vein thrombosis, the vein will typically enlarge. Thrombi may completely or partially occlude the lumen, may be adherent to the wall, or may be free floating (Fig. 27.26, Video 27.11). Compression ultrasound for DVT has been shown to have 95% accuracy with 98% specificity.[86]

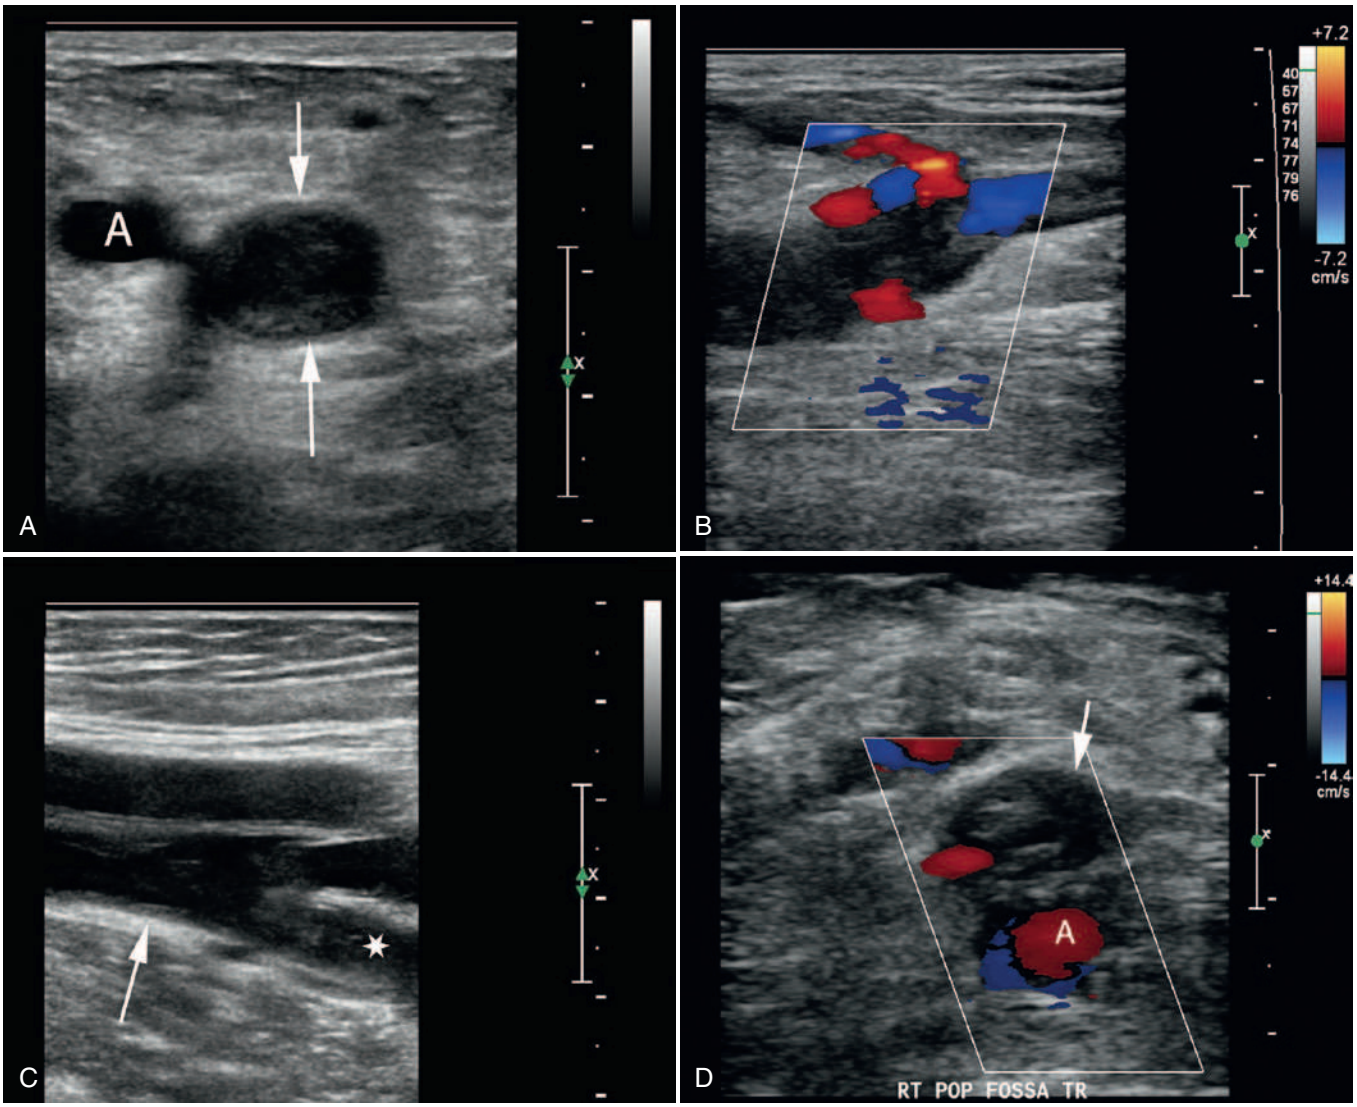

FIG. 27.26 Acute Deep Venous Thrombosis (DVT). (A) Acute common femoral vein (CFV) thrombus: Compression image in the transverse plane shows acute CFV thrombus. Note that the vein *(arrows)* is larger than the adjacent artery *(A)*. **(B)** Longitudinal color Doppler image in the same patient shows acute nearly occlusive common femoral vein thrombus with little flow. See also Video 27.11. **(C)** Longitudinal image of acute DVT in the profunda femoris vein (*), with nonocclusive extension into the CFV *(arrow),* and a small amount of thrombus in the femoral vein as well. **(D)** Transverse color image of acute popliteal vein DVT, with expansion of the vein *(arrow)* relative to the popliteal artery *(A)*.

Thrombus within the proximal GSV may be treated as a DVT if within several centimeters of the insertion of the GSV, or more than 5 cm long, according to physician preference.[65] If the thrombus within the GSV extends into the CFV, it should be treated as a DVT (Fig. 27.27, Video 27.12). If the top of the thrombus is not seen in the CFV or external iliac vein, an IVC and iliac vein examination should be considered to assess for more central thrombus (Fig. 27.28, Video 27.13).

Residual (Chronic) Deep Venous Thrombosis

Differentiation of acute from residual or chronic DVT with imaging and clinical parameters is often difficult. With compression ultrasound, both acute and chronic DVT may show noncompressibility of the vessel. Wall thickening and smaller caliber vein suggest residual or chronic DVT (Fig. 27.29). Because vein noncompressibility can be seen in both acute and chronic DVT, an attempt to differentiate the two is important for the appropriate therapeutic decision. As the thrombus evolves, it loses bulk and the vein may return to normal size or may become smaller in caliber owing to scarring (Fig. 27.30, Video 27.14). Residual thrombus will become broadly adherent to the vein wall. Additional chronic findings that may assist in differentiating chronic from acute DVT are echogenic weblike filling defects within the vein (Fig. 27.31), collateral vessels (Fig. 27.32, Video 27.15), and valvular damage with reflux and subsequent chronic deep venous insufficiency.[23] Differentiation of acute versus residual or chronic thrombus cannot be performed on thrombus echogenicity alone, although if calcifications are present, there is at least an element of chronic thrombus present[87] (Fig. 27.33). If the thrombus is small (several centimeters or less), measurement may be helpful to aid the clinician in determining clinical importance, especially after catheter removal.

Potential Pitfalls

Lower extremity **potential pitfalls** to avoid include the following:

1. Very slowly flowing blood may mimic the appearance of clot (Fig. 27.34, Video 27.16 and Video 27.17); however, compression will be normal.

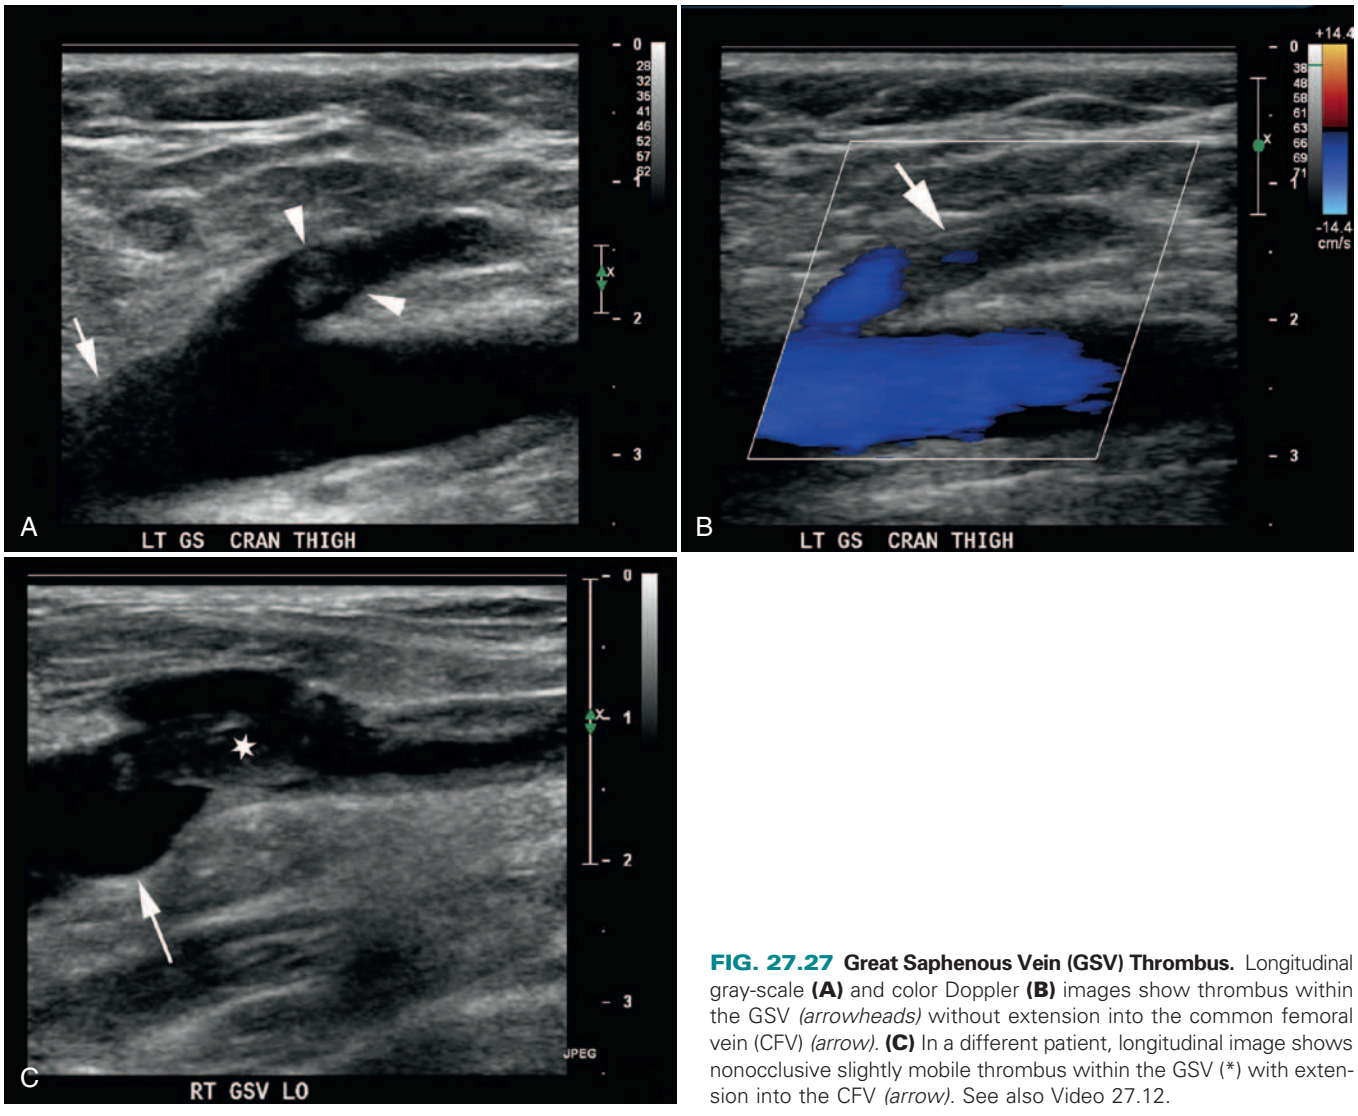

FIG. 27.27 Great Saphenous Vein (GSV) Thrombus. Longitudinal gray-scale **(A)** and color Doppler **(B)** images show thrombus within the GSV *(arrowheads)* without extension into the common femoral vein (CFV) *(arrow)*. **(C)** In a different patient, longitudinal image shows nonocclusive slightly mobile thrombus within the GSV (*) with extension into the CFV *(arrow)*. See also Video 27.12.

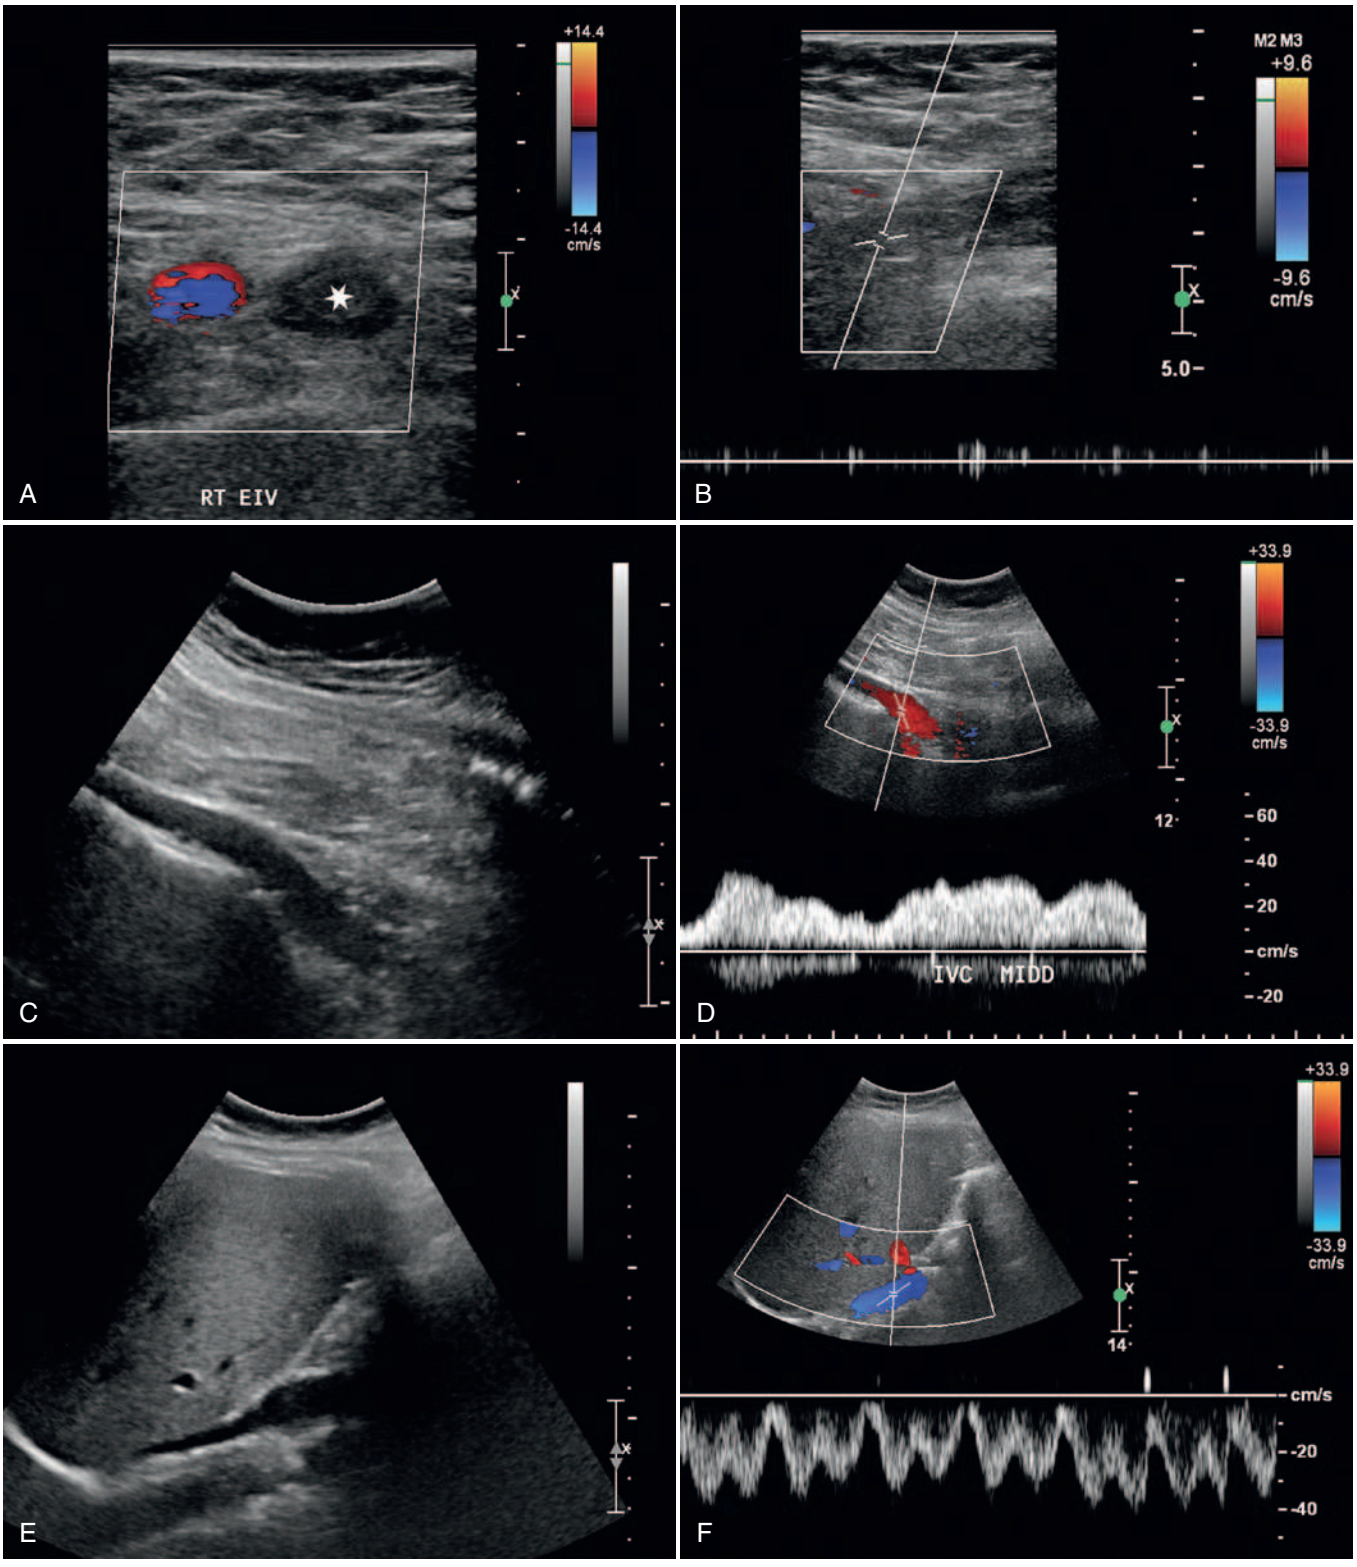

FIG. 27.28 Acute Deep Venous Thrombosis (DVT). (A) Transverse duplex Doppler image shows external iliac vein without demonstrable venous flow (*). The top of the thrombus is not seen, so sonographic evaluation continues to the common iliac vein and inferior vena cava (IVC). **(B)** Longitudinal image of occluded external iliac vein shows large amount of low-level echoes within the vein, without flow on spectral or color Doppler imaging. **(C)** Longitudinal image of caudal IVC shows no definite echoes on gray-scale imaging, confirmed with duplex Doppler imaging *(not shown).* **(D)** Duplex Doppler longitudinal image of the mid IVC shows no thrombus. **(E)** Longitudinal gray-scale image of the intrahepatic IVC shows no thrombus. **(F)** Duplex Doppler longitudinal image of the intrahepatic IVC without thrombus, with normal spectral Doppler waveform. Because the spectral waveform in the left common femoral vein was normal *(not shown),* thrombus in this patient extended into either the right external or common iliac vein, but not into the IVC. See also Video 27.13.

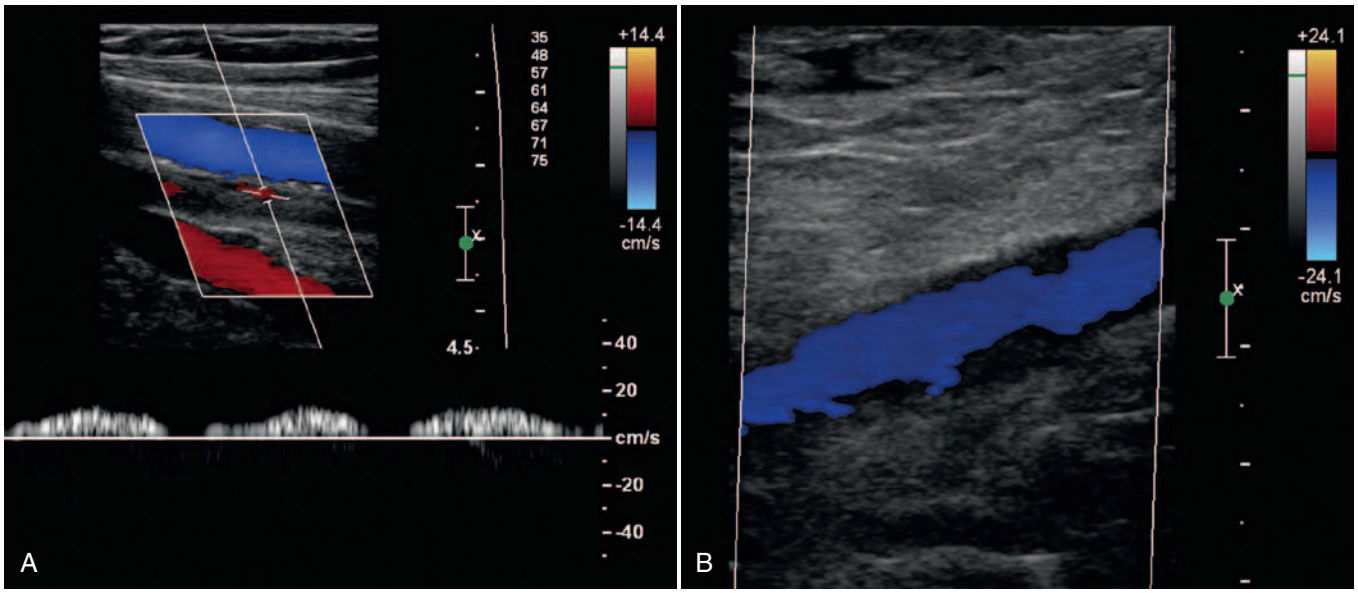

FIG. 27.29 Chronic Deep Venous Thrombosis (DVT). (A) Duplex Doppler longitudinal image of chronic femoral vein DVT, with small vein and peripheral nonocclusive flow. **(B)** Duplex Doppler longitudinal image of chronic DVT and scarring in a patent popliteal vein, with peripheral irregular residual thrombus.

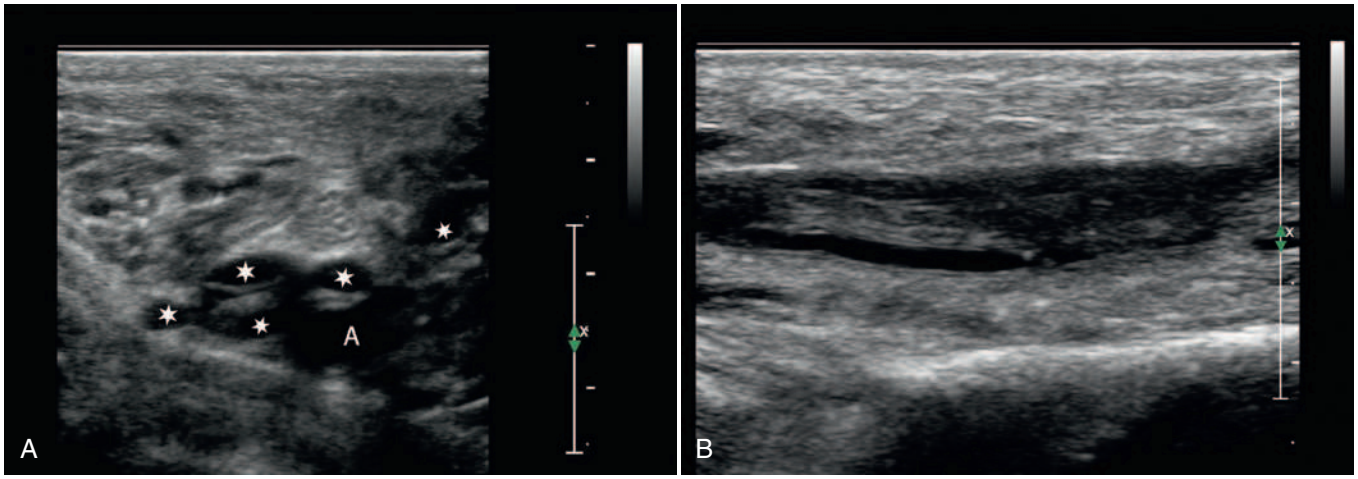

FIG. 27.30 Chronic Vein Occlusion With Collaterals. (A) Transverse image of the popliteal fossa shows multiple small collateral veins (*) in the region of the popliteal vein, adjacent to the popliteal artery *(A)* in the setting of chronic popliteal vein deep venous thrombosis (DVT) and scarring. **(B)** Longitudinal image of chronic DVT and scarring in the popliteal vein shows mildly compressible nonocclusive thrombus with some portions adhering to the wall, in a small vein. See also Video 27.14.

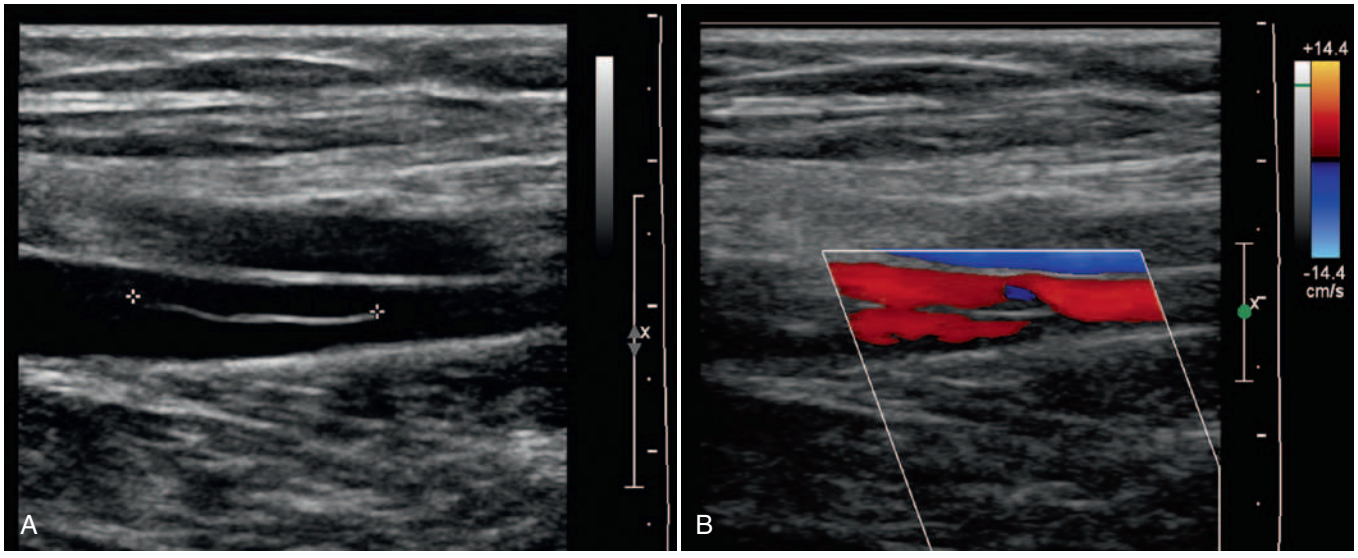

FIG. 27.31 Chronic Deep Venous Thrombosis (DVT) With Vein Web. Longitudinal gray-scale **(A)** and color Doppler **(B)** images show linear weblike chronic DVT *(cursors)* with patent channels around the web.

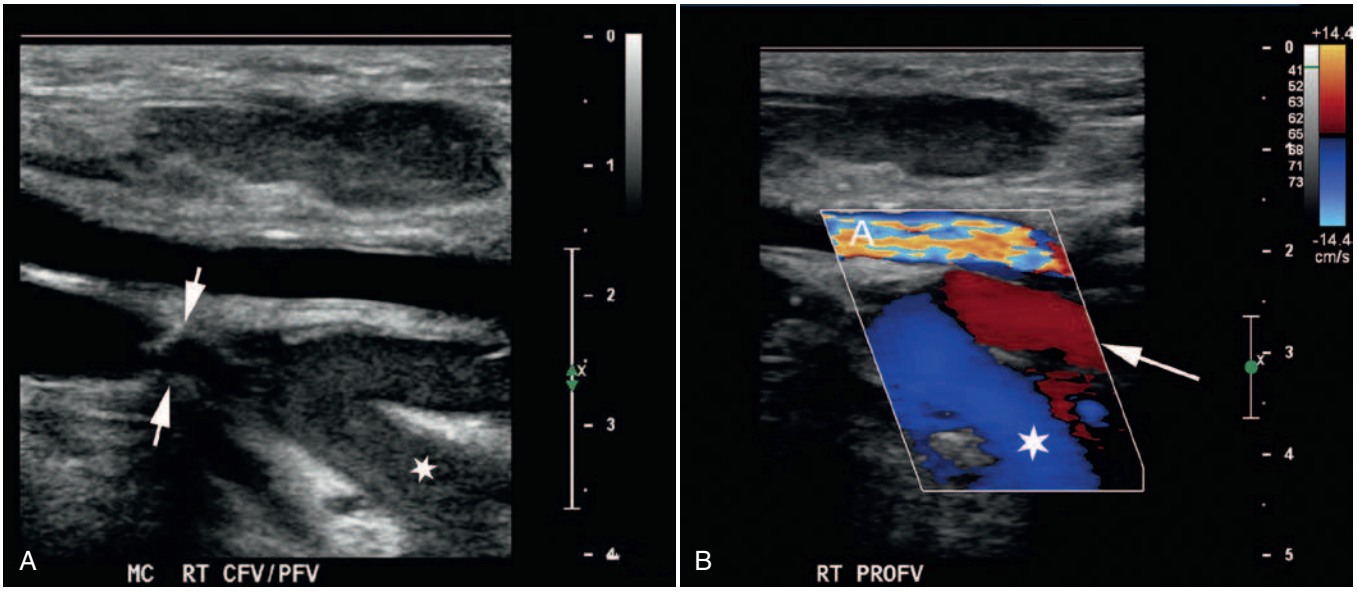

FIG. 27.32 Chronic Common Femoral Vein (CFV) Occlusion With Flow Reversal in the Profunda Femoris Vein (PFV). Longitudinal gray-scale **(A)** and color Doppler **(B)** images show chronic CFV occlusion *(arrows)* and flow reversal in the PFV (*). The artery *(A)* is located anteriorly. See also Video 27.15.

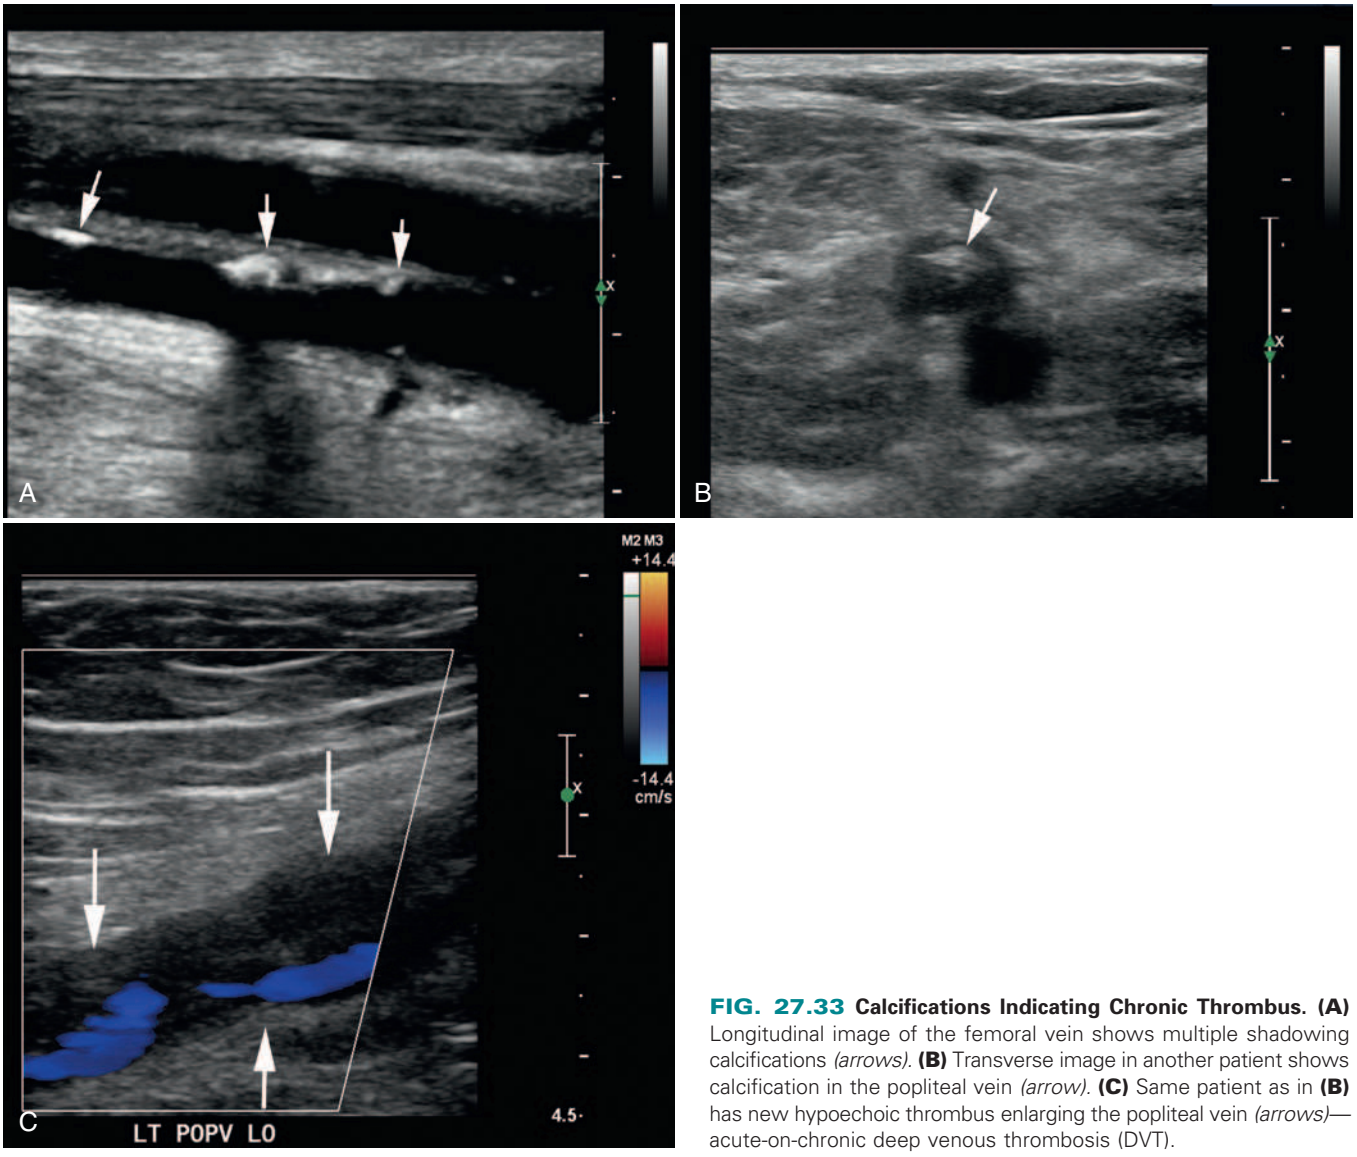

FIG. 27.33 Calcifications Indicating Chronic Thrombus. (A) Longitudinal image of the femoral vein shows multiple shadowing calcifications *(arrows)*. **(B)** Transverse image in another patient shows calcification in the popliteal vein *(arrow)*. **(C)** Same patient as in **(B)** has new hypoechoic thrombus enlarging the popliteal vein *(arrows)*—acute-on-chronic deep venous thrombosis (DVT).

2. Small nonocclusive thrombi in the profunda femoris vein may be missed if not carefully assessed. It is important to remember that DVT may initially be demonstrated in the profunda femoris vein only.
3. Thrombosis of a duplicated FV may be challenging to detect. It is useful to record the presence of this common anatomic variant in the report for comparison in a subsequent study, when only one of several FVs may be thrombosed (Fig. 27.35, Video 27.18).
4. Proximal iliac vein thrombosis may be difficult to demonstrate because of overlying bowel gas. Loss of respiratory phasicity should be recognized as a secondary sign suggesting more proximal thrombosis or obstructive compression by masses or fluid collections (Fig. 27.36). False-negative examination results may occur when the Valsalva maneuver is used while the pelvic veins are evaluated in patients with nonocclusive thrombus in the iliac veins who have well-developed pelvic venous collaterals.

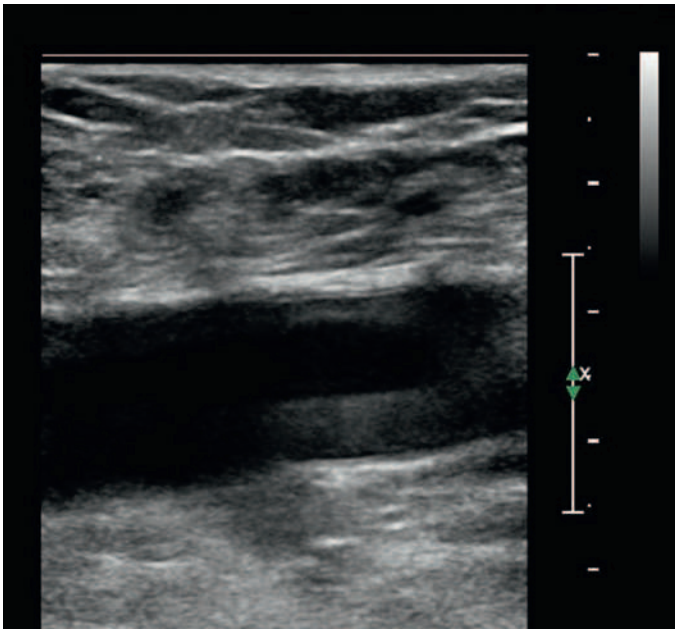

FIG. 27.34 Slow Flow in Patent, Compressible Vein Without Deep Venous Thrombosis (DVT). Accompanying Videos 27.16 and 27.17 show slow flow in longitudinal plane, and no DVT with compression.

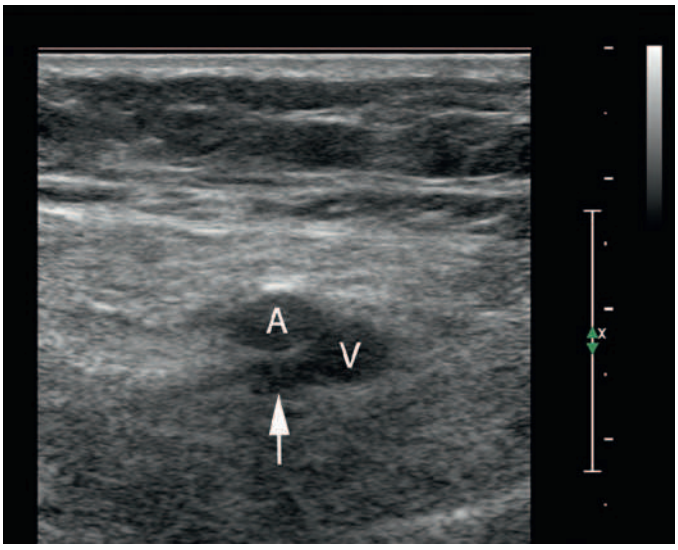

FIG. 27.35 Thrombus in One of Paired Femoral Veins. Transverse image of compressed paired femoral veins shows that one of the veins does not compress because of deep venous thrombosis (DVT). Arrow shows position of one femoral vein, which is completely compressed and thus not seen. See also Video 27.18. *A,* Superficial femoral artery; *V,* thrombus in other (paired) femoral vein.

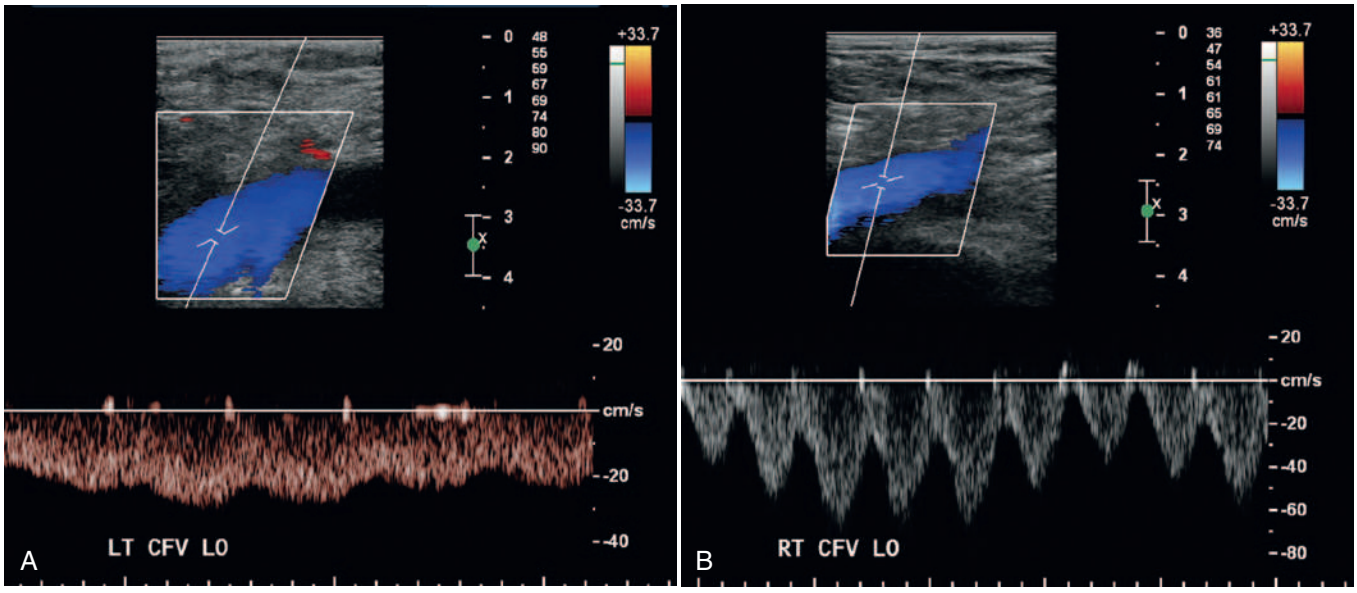

FIG. 27.36 (A) Patient with large pelvic mass compressing the left external iliac vein *(not shown).* Monophasic flow in left common femoral vein (CFV). **(B)** Normal phasic flow in right CFV.

5. Occasionally only the actual coapting of the vein walls is seen during compression, the so-called vessel "wink." The FV can sometimes be difficult to visualize throughout its entire extent. However, isolated FV thrombus is relatively uncommon, reported to occur in fewer than 1% to 4% of patients.[83]

Complete Venous Doppler Versus More Limited Examinations

Complete compression venous Doppler from the inguinal area to the popliteal area is accurate, with less than 1% venous thromboembolic disease at 3-month follow-up in recent analyses.[88,89] Limited, less detailed examinations have recently been proposed. A variety of specialties are performing this type of examination in office settings, intensive care units, and emergency departments. The two-point ultrasonography examination of the CFV and the PV using the compression technique has shown that most, but not all, proximal DVTs are detected.[90,91] However, this approach requires a serial examination 1 week later to detect propagation of calf thrombus into proximal DVT. Two negative study results, 1 week apart, have shown a low likelihood of DVT in the months following the tests.[89] The two-point technique has a 2% to 5.7% chance of detecting DVT on a repeat examination at 2 weeks.[89,90] A carefully performed complete thigh venous ultrasound as detailed earlier remains the standard of care.

Recommendations for Deep Venous Thrombosis Follow-Up

If the patient's clinical condition worsens, follow-up venous Doppler is warranted. In patients with documented DVT on therapy, a repeat venous Doppler during treatment is rarely warranted. Repeat Doppler should not be requested unless there is a clinical change.[85,92] DVT typically lyses or fibroses over 6 to 18 months. Reevaluation near the anticipated end of anticoagulation should be encouraged to establish a new baseline for patients who return with new symptoms suggesting recurrent thrombus, especially those at high risk for recurrent DVT.[85]

In patients with isolated calf DVT, a follow-up Doppler examination at 1 week is warranted if the patient is not treated. In patients with scarring, pregnant women, patients with technically limited examinations, or patients with calf pain wherein DVT is not identified, it may be prudent to suggest follow-up in 1 week. It has been established that use of two limited examinations, 1 week apart, is a safe strategy.[90] In an otherwise normal report, it may be prudent, as a helpful reminder, to state, "If there remains suspicion for DVT or the clinical condition worsens, a follow-up should be considered."[85]

Venous Insufficiency

The cause of deep venous insufficiency in many patients is venous valvular damage after DVT, which occurs in about 50% of patients with acute DVT.[93] The physiology of venous insufficiency entails direct transmission of the hydrostatic pressure of the standing column of fluid in the venous system to the caudal lower extremity. Clinical manifestations include lower extremity swelling, chronic skin and pigmentation changes, woody induration, and eventually nonhealing venous stasis ulcers.

Superficial venous insufficiency has a much better prognosis than deep venous insufficiency and is associated with extensive varicosities. Perforating veins communicate between the superficial and deep system and may also become incompetent owing to chronic deep venous insufficiency.

For assessment of venous insufficiency, the patient is placed in an upright or semi-upright position, with the body's weight supported by the contralateral lower extremity. This positioning produces the hydrostatic pressure needed to reproduce venous insufficiency. Spectral analysis is obtained at several levels of the deep and superficial venous system during Valsalva and other provocative maneuvers in the CFV, proximal aspect of the GSV, PV, and saphenopopliteal junction. Distal augmentation is more reproducible and easier when performed by a single examiner.[94]

Normal veins after brisk distal augmentation will show antegrade flow, with a very short period of flow reversal as returning blood closes the first competent venous valve (Fig. 27.37, Video 27.19). Distal augmentation can be performed manually and more reproducibly with automated devices that inflate every 5 to 10 seconds. Insufficient veins show greater degree of reversed flow for a longer duration (Fig. 27.38). It is important that each vascular laboratory validate its protocol and quantification schemes.

Venous Mapping

Vein mapping of superficial leg or arm veins is performed to determine patency, size, condition, and course of superficial veins to be used for vein grafts. Ultrasound mapping is also helpful when a vein is harvested as autologous graft material for a peripheral arterial bypass graft. Any superficial vein can be used, but the GSV is most often suitable for graft purposes. The examination is performed with the patient in the supine or reverse Trendelenburg position. The GSV is identified from the level of

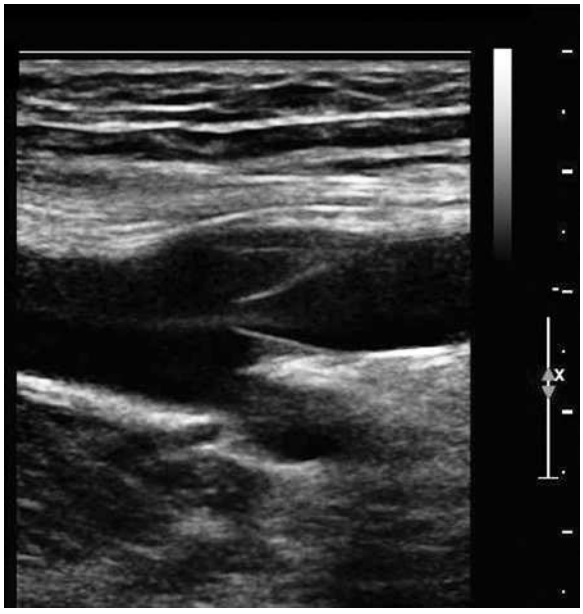

FIG. 27.37 Normal Femoral Vein Valve. Accompanying Video 27.19 shows normal coapting of valve, which prevents retrograde flow.

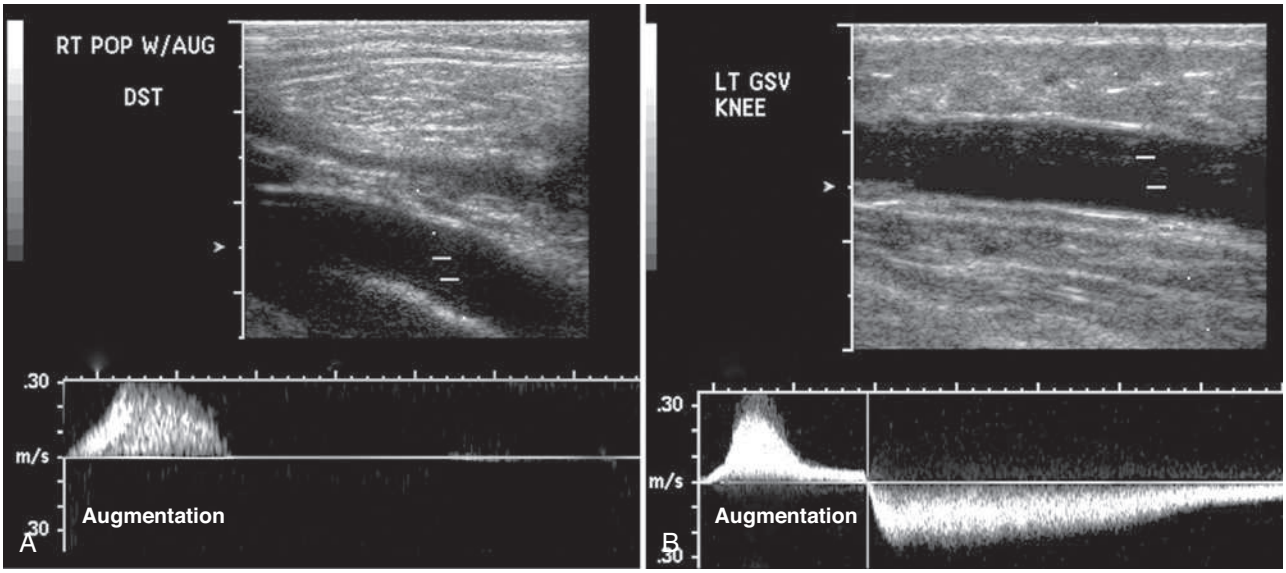

FIG. 27.38 Venous Insufficiency. (A) Duplex spectral analysis of the popliteal vein shows a normal waveform with distal augmentation. Note no reversal of flow following distal augmentation. **(B)** Duplex spectral analysis of the great saphenous vein shows **prolonged reflux** after distal augmentation, consistent with severe superficial venous insufficiency.

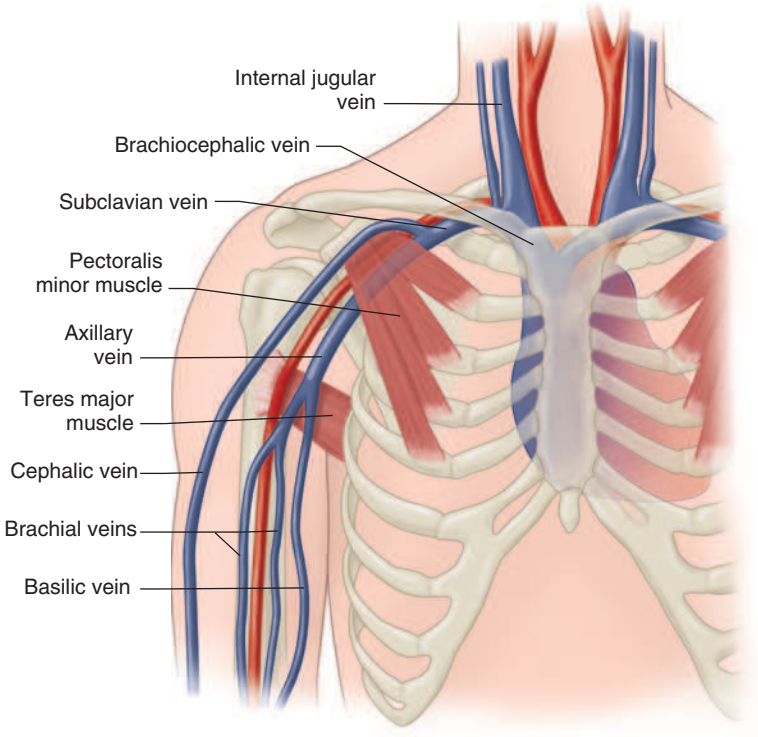

FIG. 27.39 Venous Anatomy of the Upper Extremity Veins.

the saphenofemoral junction to as far inferiorly as possible. A superficial vein typically needs to be larger than 3 mm in diameter, but not varicose, to be suitable graft material.[95] The small saphenous vein and cephalic and basilic veins are secondary choices and can be used if the GSV has already been harvested or is inadequate.

Upper Extremity Veins

Normal Anatomy

The venous anatomy of the neck and arm is illustrated in (Fig. 27.39). The deep venous system includes the paired **radial and ulnar veins** in the forearm, which unite distal to the level of the

elbow to form the **brachial veins.** The brachial veins in the upper arm join with the **basilic vein** at a variable location, typically at the level of the teres major muscle. The confluence of the brachial and basilic veins continues as the **axillary vein,** which passes through the axilla from the teres major muscle to the first rib. As the axillary vein crosses the first rib, it becomes the lateral portion of the **subclavian vein.** The medial portion of the subclavian vein receives the smaller external jugular vein and the larger **internal jugular vein** (IJV) to form the **brachiocephalic (innominate) vein.**

Most ultrasound laboratories define the central veins as the brachiocephalic veins and superior vena cava, which often are difficult to visualize sonographically. Because some angiographers include the subclavian vein when they describe the central veins, it is important to be very specific about the vein segment examined when describing sonographic findings. The presence or absence of clinically important central stenosis or thrombosis may be inferred by evaluating the transmitted cardiac pulsatility and respiratory phasicity in the medial subclavian vein and distal IJV.[96]

The cephalic and basilic veins comprise the most important superficial named veins of the upper extremity. The more laterally located cephalic vein traverses in the superficial soft tissues of the shoulder to drain into the axillary vein in the lateral chest. The basilic vein is located more medially, and typically joins the brachial veins to form the axillary vein.

Ultrasound Examination and Imaging Protocol

Upper extremity Duplex evaluation consists of gray-scale compression and color and spectral Doppler assessment of all the visualized portions of the IJV and subclavian, axillary, and innominate veins, as well as compression gray-scale ultrasound of the brachial, basilic, and cephalic veins in the upper arm to the elbow. A high-frequency, small-footprint transducer can be applied to the suprasternal notch to better demonstrate the brachiocephalic junction and IVC, often difficult to see because of overlying sternum and lung. Venous compression is applied to accessible veins in the transverse plane with adequate pressure on the skin to completely obliterate the normal vein lumen.

The patient is scanned in a supine position with the examined arm abducted from the chest, with the patient's head turned slightly away from the examined arm. Typically a 5- to 10-MHz linear array transducer will be used, with a higher frequency transducer chosen for more superficial veins. A curved array transducer or sector transducer may be more effective in larger patients, especially in the axillary area, because of its increased depth of penetration and larger field of view. All veins are examined with compression every 1 to 2 cm in the transverse plane. Gray-scale transverse images with and without compression or cine clips during compression are obtained from the cranial aspect of the IJV in the neck to the thoracic inlet caudally (Fig. 27.40, Video 27.20). Longitudinal color and spectral images are obtained.

The subclavian vein is evaluated from its medial to lateral aspect with longitudinal color and spectral images, assessing for transmitted respiratory variability, cardiac pulsatility, and color fill-in. To demonstrate the superior brachiocephalic vein and the medial portion of the subclavian vein, an inferiorly angled, supraclavicular approach with color Doppler is necessary. A small-footprint sector probe in or near the suprasternal notch may improve visualization of the brachiocephalic veins and the cranial aspect of the superior vena cava (Fig. 27.41). The midportion of the subclavian vein, located deep to the clavicle, frequently is incompletely imaged. An infraclavicular, superiorly angled approach can be used to demonstrate the lateral aspect of the

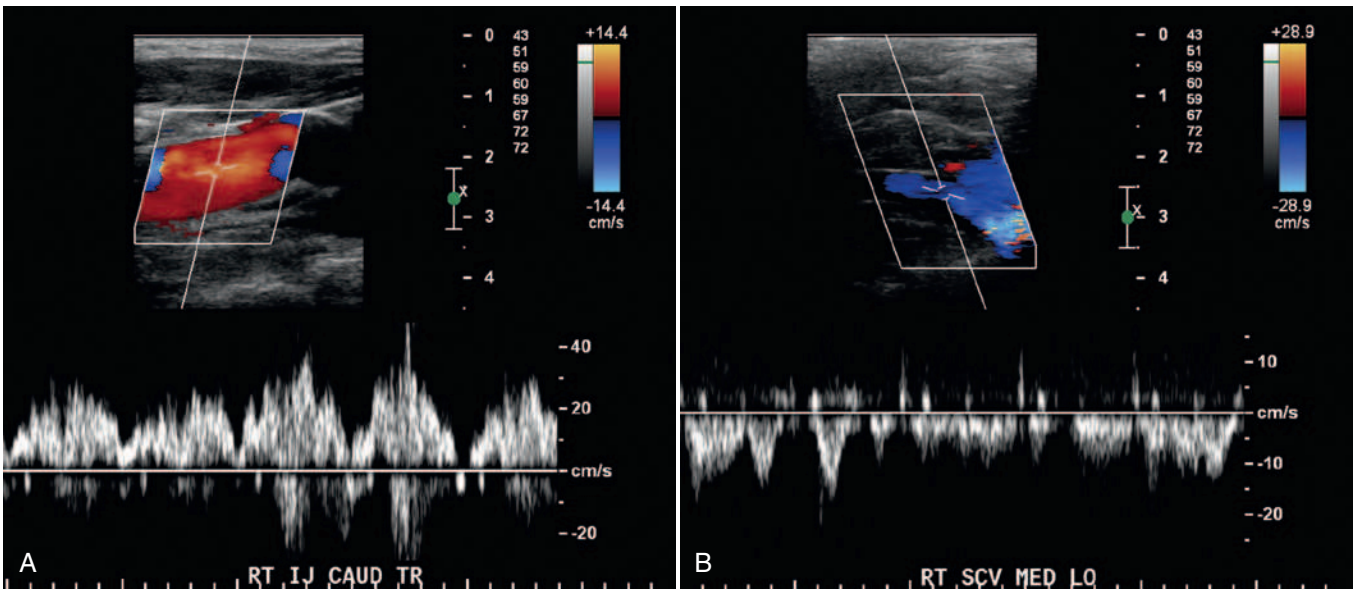

FIG. 27.40 Normal Internal Jugular Vein (IJV) and Subclavian Vein (SCV) Spectral Doppler Waveforms. (A) Normal IJV spectral Doppler waveform, with transmitted cardiac pulsatility and respiratory phasicity, with spectral waveform going to the baseline. Accompanying Video 27.20 shows normal IJV compression. **(B)** Normal medial SCV spectral Doppler, with transmitted cardiac pulsatility and respiratory phasicity, and spectral waveform going to the baseline.

subclavian vein. In many cases the subclavian vein can be compressed.

Accurate spectral waveform evaluation is critical to this examination. Documentation of normal flow in the medial subclavian vein confirms patency of the brachiocephalic vein and superior vena cava, which cannot be examined directly. Each spectral image obtained in the longitudinal plane of the vessel with angle of insonation maintained at less than 60 degrees is evaluated for spontaneous, phasic, and pulsatile flow. Demonstration of transmitted cardiac pulsatility and respiratory phasicity is necessary in the spectral analysis of the caudal IJV and medial subclavian vein. A normal spectral tracing should return to baseline. Absence of pulsatility may be caused by a more central venous stenosis or obstruction (Fig. 27.42).[97]

Spectral tracings from the medial subclavian vein should be compared with tracings from the lateral subclavian vein. A change between these two tracings suggests midsubclavian vein stenosis. Response to a brisk inspiratory sniff or Valsalva maneuver may assist evaluation of venous patency. During a sniff, the normal IJV or subclavian vein normally decreases in diameter or collapses completely. The Valsalva maneuver will increase the vein diameter, demonstrating response to the increased thoracic pressure and documenting communication with the central vasculature. Patients with significant stenosis or obstruction of the central brachiocephalic vein of the superior vena cava will lose this response.[97]

The upper extremity venous **imaging protocol** includes the following images for each deep venous segment:

1. Transverse gray-scale image at rest and with compression, or a cine clip of the compression maneuver of the proximal and distal IJV, subclavian, axillary, and brachial veins. The basilic and cephalic veins are evaluated in the upper arm to the elbow.
2. Longitudinal color Doppler with spectral waveform analysis is performed of the IJV, both proximal and distal portions, as well as the subclavian vein, both medially and laterally, and the axillary vein. If only a unilateral examination is requested, the contralateral subclavian vein is also evaluated.
3. Evaluation of focal symptomatic areas if present, including the forearm.

Upper Extremity Acute Deep Venous Thrombosis

Current literature shows the sensitivity and specificity of venous Doppler ultrasound for upper extremity DVT to range from 78% to 100% and 82% to 100%, respectively.[96,98-102] The classic ultrasound finding in acute upper extremity DVT is an enlarged, tubular structure filled with thrombus showing variable echogenicity and absence of color Doppler flow (Fig. 27.43, Video 27.21). Nonocclusive thrombus may show flow outlining the thrombus, with a variable appearance depending on whether the nonocclusive thrombus is acute or chronic. Nonocclusive thrombus usually does not result in enlargement of the vein (Fig. 27.44). When the obstruction is incomplete, nonphasic flow is demonstrated when the luminal narrowing is significant enough to affect the transmitted cardiac pulsatility and respiratory phasicity from the thorax. Attention to detail is important in the normally paired brachial veins to avoid overlooking thrombus in one of the veins (Fig. 27.45, Video 27.22).

Evaluation of central thrombus relies on spectral analysis. The presence of a nonpulsatile waveform (similar to portal venous flow) that does not cross the baseline strongly suggests central venous thrombosis, stenosis, or extrinsic compression from an adjacent mass.[96] A suspicious waveform should always be compared with the contralateral side to assess a unilateral versus bilateral process. Patel and colleagues[103] found that absent or reduced cardiac pulsatility was a more sensitive parameter in patients who had unilateral venous thrombosis, even though respiratory phasicity often was asymmetric. In cases of bilateral subclavian vein or superior vena cava occlusion, a high level of suspicion must be maintained to detect central thrombus or stenosis. Of importance, because of high-volume flow, there may

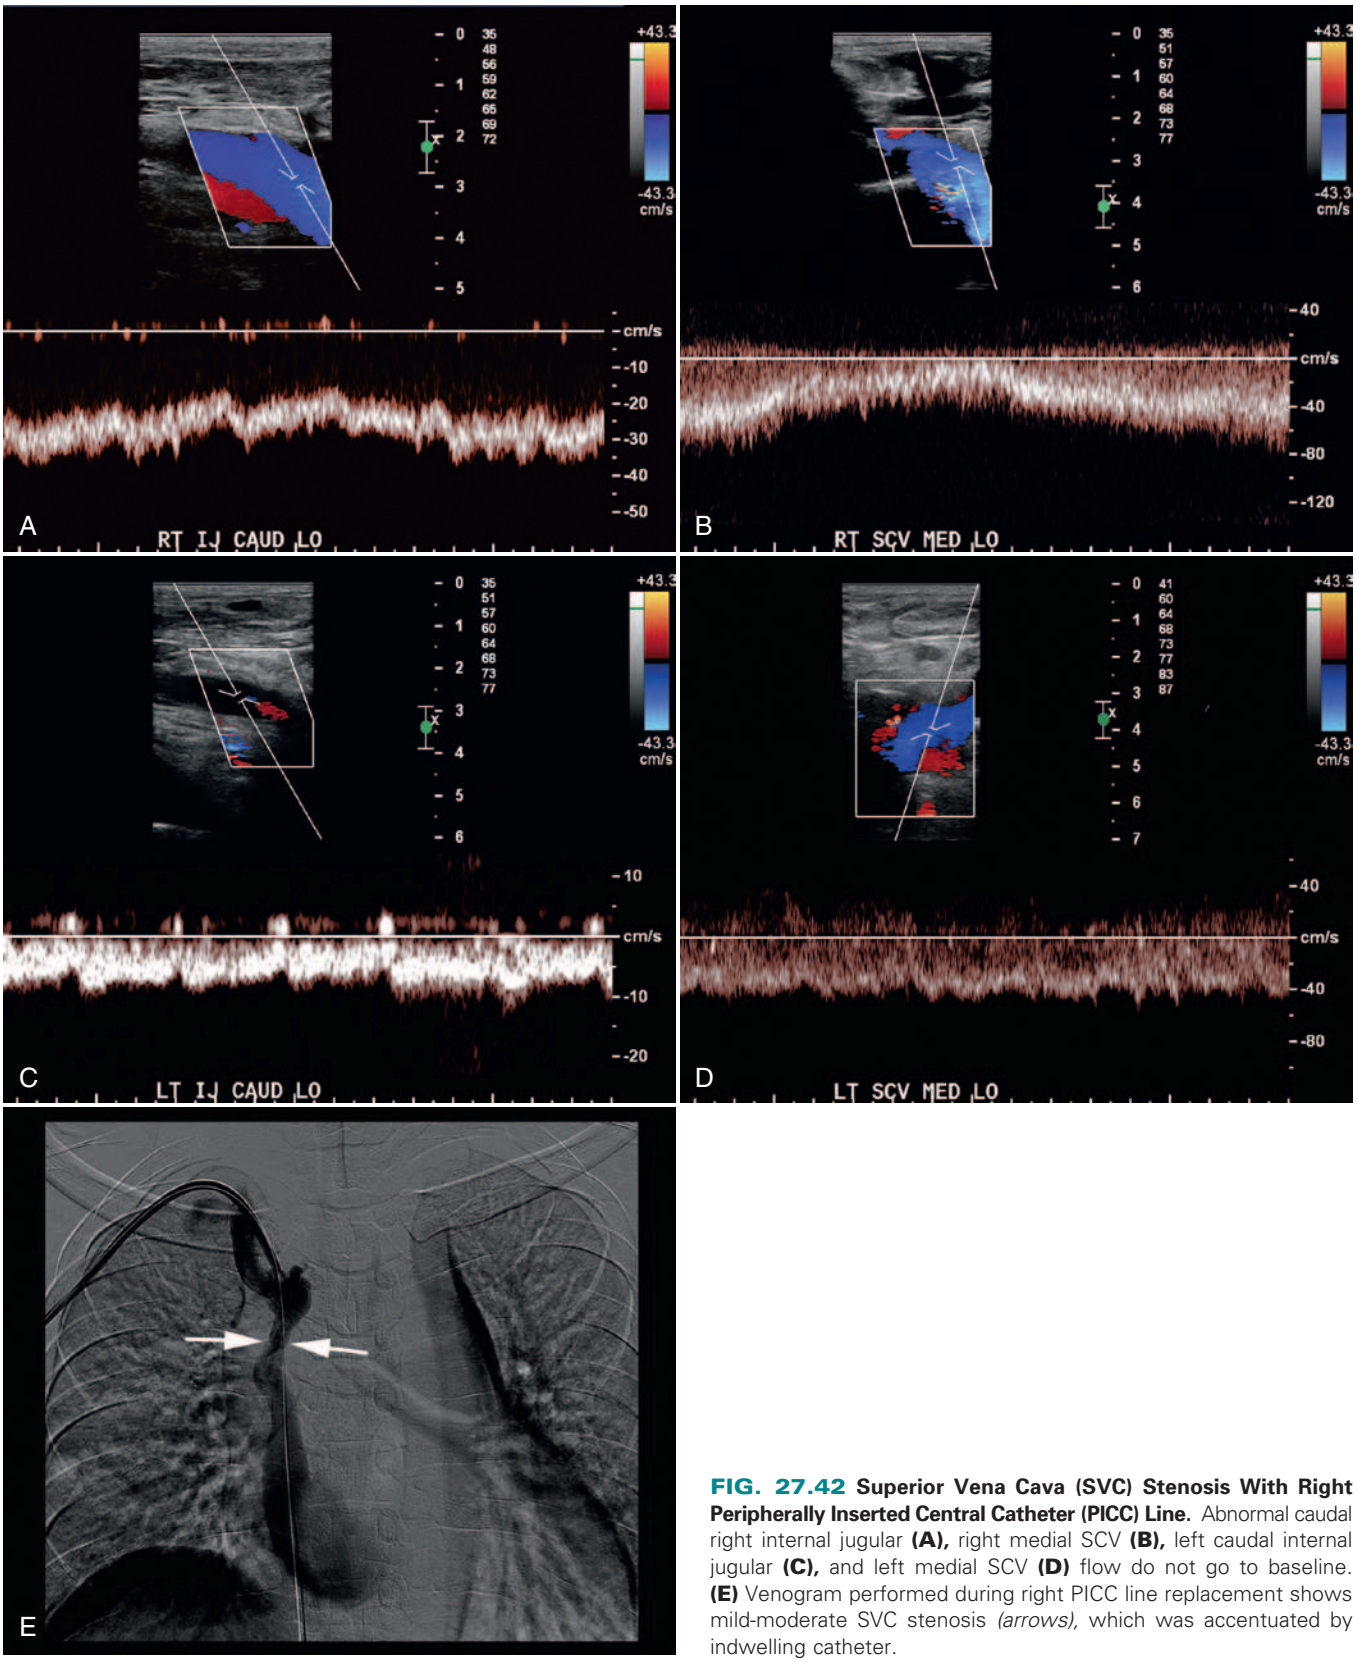

FIG. 27.42 Superior Vena Cava (SVC) Stenosis With Right Peripherally Inserted Central Catheter (PICC) Line. Abnormal caudal right internal jugular **(A),** right medial SCV **(B),** left caudal internal jugular **(C),** and left medial SCV **(D)** flow do not go to baseline. **(E)** Venogram performed during right PICC line replacement shows mild-moderate SVC stenosis *(arrows),* which was accentuated by indwelling catheter.

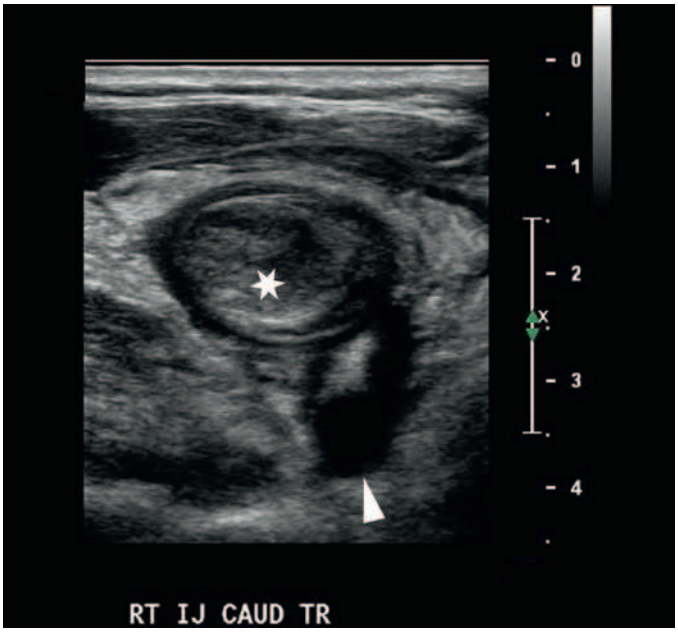

FIG. 27.43 Acute Internal Jugular Thrombus. Transverse image of a noncompressible internal jugular vein filled with thrombus (*). *Arrowhead* shows carotid artery. See also Video 27.21.

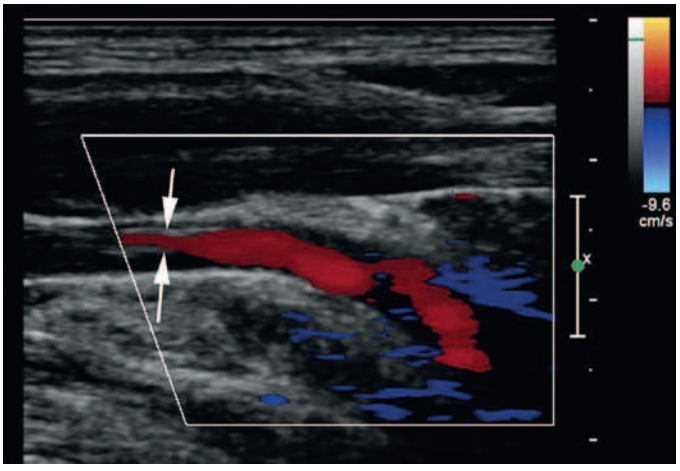

FIG. 27.44 Nonocclusive Chronic Internal Jugular Thrombus. Longitudinal color Doppler image of the small-caliber proximal internal jugular vein with irregular thrombus adjacent to wall, with thickened valves *(arrows)*.

be absence of phasicity without stenosis in the central veins if a hemodialysis graft or AVF is present in the upper arm.

Unlike the lower extremity, most cases of upper extremity DVT are related to the presence of a central venous catheter or electrode leads from an implanted cardiac device. Approximately 35% to 75% of patients who have upper extremity venous catheters develop thrombosis, and approximately 75% are asymptomatic[104-106] (Fig. 27.46, Video 27.23 and Video 27.24).

Frequently a fibrin sheath is found adjacent to the catheter and may be seen after catheter removal. It is important to look carefully at the valves for adherent thrombus. Whether the catheter access site is the subclavian vein or the IJV affects the complication rate. Trerotola and colleagues[107] examined only patients who had symptomatic upper extremity DVT and found a greater incidence of DVT in patients who had subclavian venous access than in those who had internal jugular access. The placement of large-bore catheters into the subclavian vein should be avoided, especially in patients who have end-stage renal disease (ESRD) for whom dialysis access is being considered. Subsequent development of subclavian vein stenosis or thrombosis would limit dialysis access possibilities for that upper extremity.

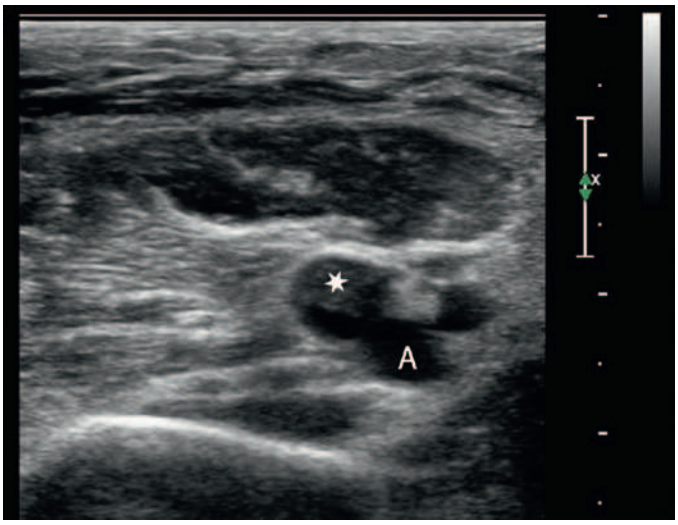

FIG. 27.45 Nonocclusive Thrombus in Brachial Vein. Transverse noncompressed image of nonocclusive thrombus (*) in one brachial vein in the paired brachial veins. *A,* Brachial artery. See also Video 27.22.

Only 12% to 16% of patients who have upper extremity DVT develop PE.[108,109] In comparison, 44% of patients who developed proximal lower extremity DVT detected by sonography had a subsequent PE diagnosed clinically.[110] Acute pulmonary emboli in patients who have upper extremity DVT tend to occur in untreated patients.[111,112] As expected, there is greater risk of PE in catheter-related upper extremity DVT than in upper extremity DVT from other causes.[113] Venous stasis and insufficiency caused by venous thrombosis, more commonly seen with LE DVT, are less common and less severe in the upper extremity. The deep venous system in the arm has less exposure to the physiologic hydrostatic high-pressure pump mechanism that is seen in the lower extremity.[114,115] Development of extensive collateral venous pathways in the arm and chest after venous thrombosis or obstruction contributes to these differences and may cause greater technical challenge in performing the upper extremity venous Doppler examination, as compared with the lower extremity.

Differentiation of Acute From Residual or Chronic Venous Thrombosis

Findings suggesting residual or chronic DVT in the upper extremity include fixed valve leaflets, synechiae, fibrin sheaths, small-caliber veins with noncompressible, thickened walls, and multiple serpiginous veins not paralleling the artery (Fig. 27.47). In some cases of residual or chronic thrombosis, the vein may not be seen in the expected location owing to fibrosis or scarring.

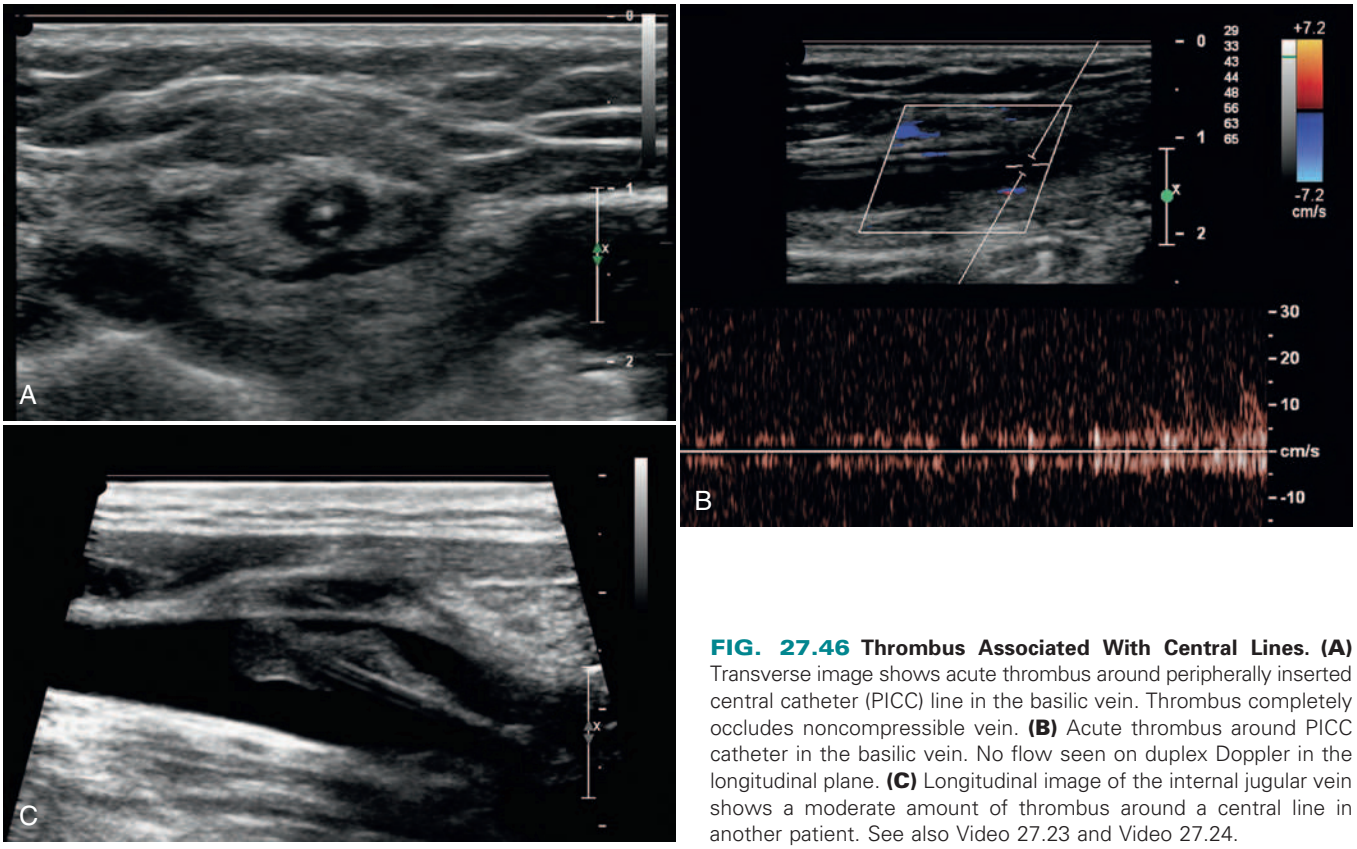

FIG. 27.46 Thrombus Associated With Central Lines. (A) Transverse image shows acute thrombus around peripherally inserted central catheter (PICC) line in the basilic vein. Thrombus completely occludes noncompressible vein. **(B)** Acute thrombus around PICC catheter in the basilic vein. No flow seen on duplex Doppler in the longitudinal plane. **(C)** Longitudinal image of the internal jugular vein shows a moderate amount of thrombus around a central line in another patient. See also Video 27.23 and Video 27.24.

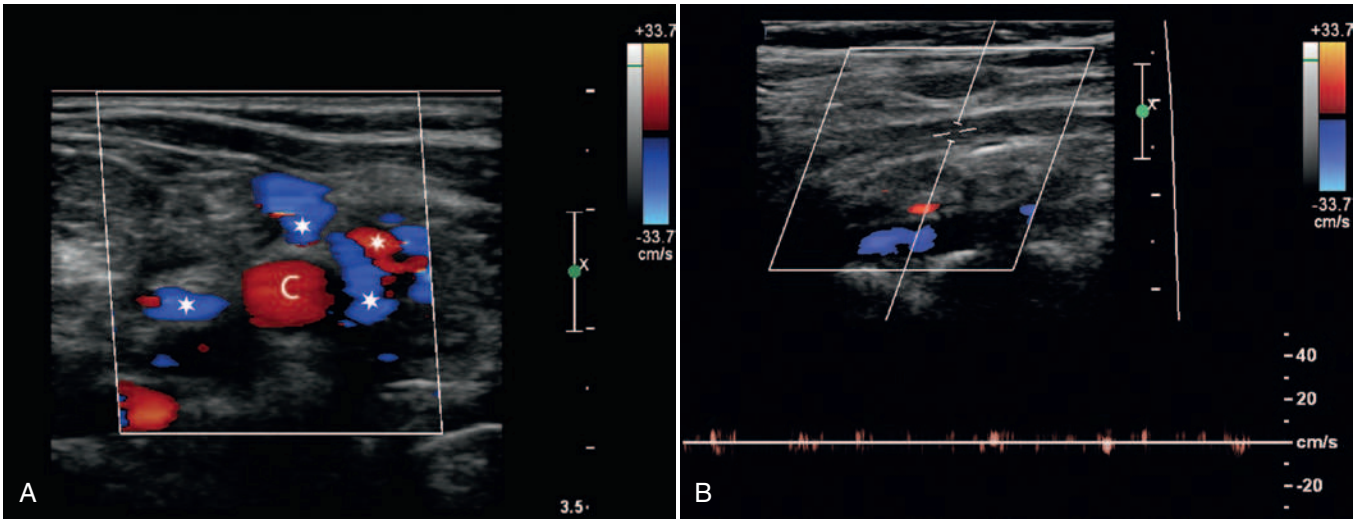

FIG. 27.47 Collateral Formation in the Upper Extremity After Deep Venous Thrombosis (DVT). (A) Transverse images of many serpiginous veins (*) in the region of the chronically occluded proximal internal jugular vein near the base of the neck. *C,* Carotid. **(B)** Longitudinal duplex Doppler image shows no spectral flow in the small, occluded distal internal jugular vein.

An excellent example is demonstration of only one brachial vein because of chronic scarring from prior DVT of the paired brachial veins[116] (Fig. 27.48).

Potential Pitfalls

Upper extremity pitfalls to avoid include the following[117-119]:

1. Axillary versus cephalic vein: The axillary vein of the deep venous system empties into the subclavian vein. The cephalic vein of the superficial venous system empties into the axillary vein and will not have an adjacent artery along its course. Access to the axilla is generally improved by bending the patient's elbow and placing the hand near the patient's head, with an outstretched arm. Excessive abduction may alter the venous waveform, falsely suggesting a more central venous stenosis or obstruction; however, this will resolve with change in position.

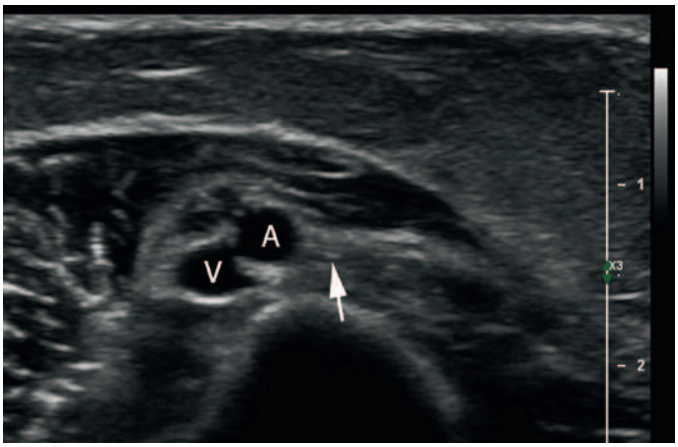

FIG. 27.48 Chronic Clot in Brachial Vein. One of the paired brachial veins is small and chronically occluded *(arrow). A,* Brachial artery; *V,* other, normal brachial vein.

2. Distal occlusion of IJV: The distal aspect of the IJV must be demonstrated flowing into the junction with the medial subclavian vein in the area of the brachiocephalic vein. If the vein being traced is located more than a few millimeters away from the carotid artery, it probably represents a collateral vessel, rather than the IJV. Well-developed collaterals may demonstrate normal respiratory phasicity, an additional pitfall. Collateral vessels tend to be multiple and serpiginous and to follow the occluded vein.

HEMODIALYSIS

There were 661,648 patients being treated for ESRD by the end of 2013 in the United States, with 117,162 new cases that year.[1] Approximately 64% of these patients were undergoing hemodialysis.[120] A major cause of morbidity among ESRD patients is related to vascular access procedures and associated complications that increase health care costs in patients undergoing hemodialysis.[121] There are two options for permanent access placement for ESRD patients requiring hemodialysis—an **arteriovenous fistula** (AVF) or a **synthetic arteriovenous graft.** Mature AVFs are the preferred access when appropriate, because of the lower rates of infection and thrombosis than with graft or catheter access.[122-124]

Several studies have shown that **preoperative ultrasound** evaluation of the upper extremity veins and arteries may increase the number of successful AVF placements through optimization of surgical planning[125-127] as well as before graft placement in the thigh.[128] Although sonographic postoperative hemodialysis access evaluation may be beneficial in assessing AVF maturation,[129-131] the role of **postoperative ultrasound** evaluation for the detection of access pathology and early intervention to improve the longevity of a particular access is still being studied.[132-139]

Ultrasound is useful in evaluation of palpable masses adjacent to the vascular access to differentiate hematoma from pseudoaneurysm. It is also used in the evaluation of the swollen upper extremity in a patient with an AVF or graft, or a swollen lower extremity in a patient with a thigh graft, assessing for outflow vein stenosis and DVT. Ultrasound is also used in the evaluation of patients with arm and hand pain after access placement to evaluate for symptomatic steal.

The surgical creation of an AVF is preferred over a graft when surgically and clinically feasible. Placement of access in the nondominant upper extremity is preferred to allow continuance of daily activities of life while the access site heals; however, a dominant arm AVF is preferred to a graft in most patients. Possible sites of hemodialysis access in order of preference are as follows: (1) forearm AVF (radiocephalic AVF or transposed forearm basilic vein to radial artery AVF); (2) upper arm brachiocephalic AVF; (3) transposed brachiobasilic AVF; (4) forearm loop graft; (5) upper arm straight graft (brachial artery to upper basilic or axillary vein); (6) upper arm axillary artery to axillary vein loop graft; and (7) thigh graft (Fig. 27.49). The cephalic vein is preferred over a basilic vein transposition for fistula formation because the cephalic vein procedure involves less dissection and venous manipulation. Additional, less common access configurations may also be placed based on surgical experience.[140]

Sonographic Examination Technique

Both gray-scale and color Doppler ultrasound techniques should be optimized for venous and arterial imaging as previously discussed in this chapter. A high-frequency linear array 12- to 15-MHz transducer provides optimal spatial resolution and adequate depth penetration to successfully evaluate superficial vascular structures. A lighter-weight transducer with a smaller footprint, such as a hockey stick configuration, can increase the speed and ease of the examination. A lower-frequency linear array 9- to 12-MHz transducer may be needed for adequate penetration in larger patients. A small-footprint curved array transducer may be useful for evaluation of the brachiocephalic vein and distal SVC.

It is important to apply light pressure and use plenty of gel so as not to deform the circular shape of the vessels during the mapping examination for accurate vessel diameters. All diameter measurements are of the inner lumen measured in the anteroposterior dimension in the transverse plane. Color and spectral Doppler evaluation are performed in the longitudinal plane with angle correction of 60 degrees or less. Blood flow rate measurements are performed in the longitudinal plane in a straight area that is not curvy. In blood flow rate measurement, the Doppler gate is increased in size to encompass the entire vessel diameter, and is angle corrected to 60 degrees or less, parallel to the posterior vessel wall. Three to five spectral Doppler waveforms are analyzed, using the automatic blood flow rate calculation in most ultrasound scanners, using the formula of time-averaged mean velocity multiplied by the inner vessel diameter. Three measurements at the same location are performed and averaged, to ensure measurement reliability.

Vascular Mapping Before Hemodialysis Access

Upper Extremity

Attention to technical detail is necessary for optimum ultrasound evaluation for hemodialysis access planning.[126,130,141-143] In general,

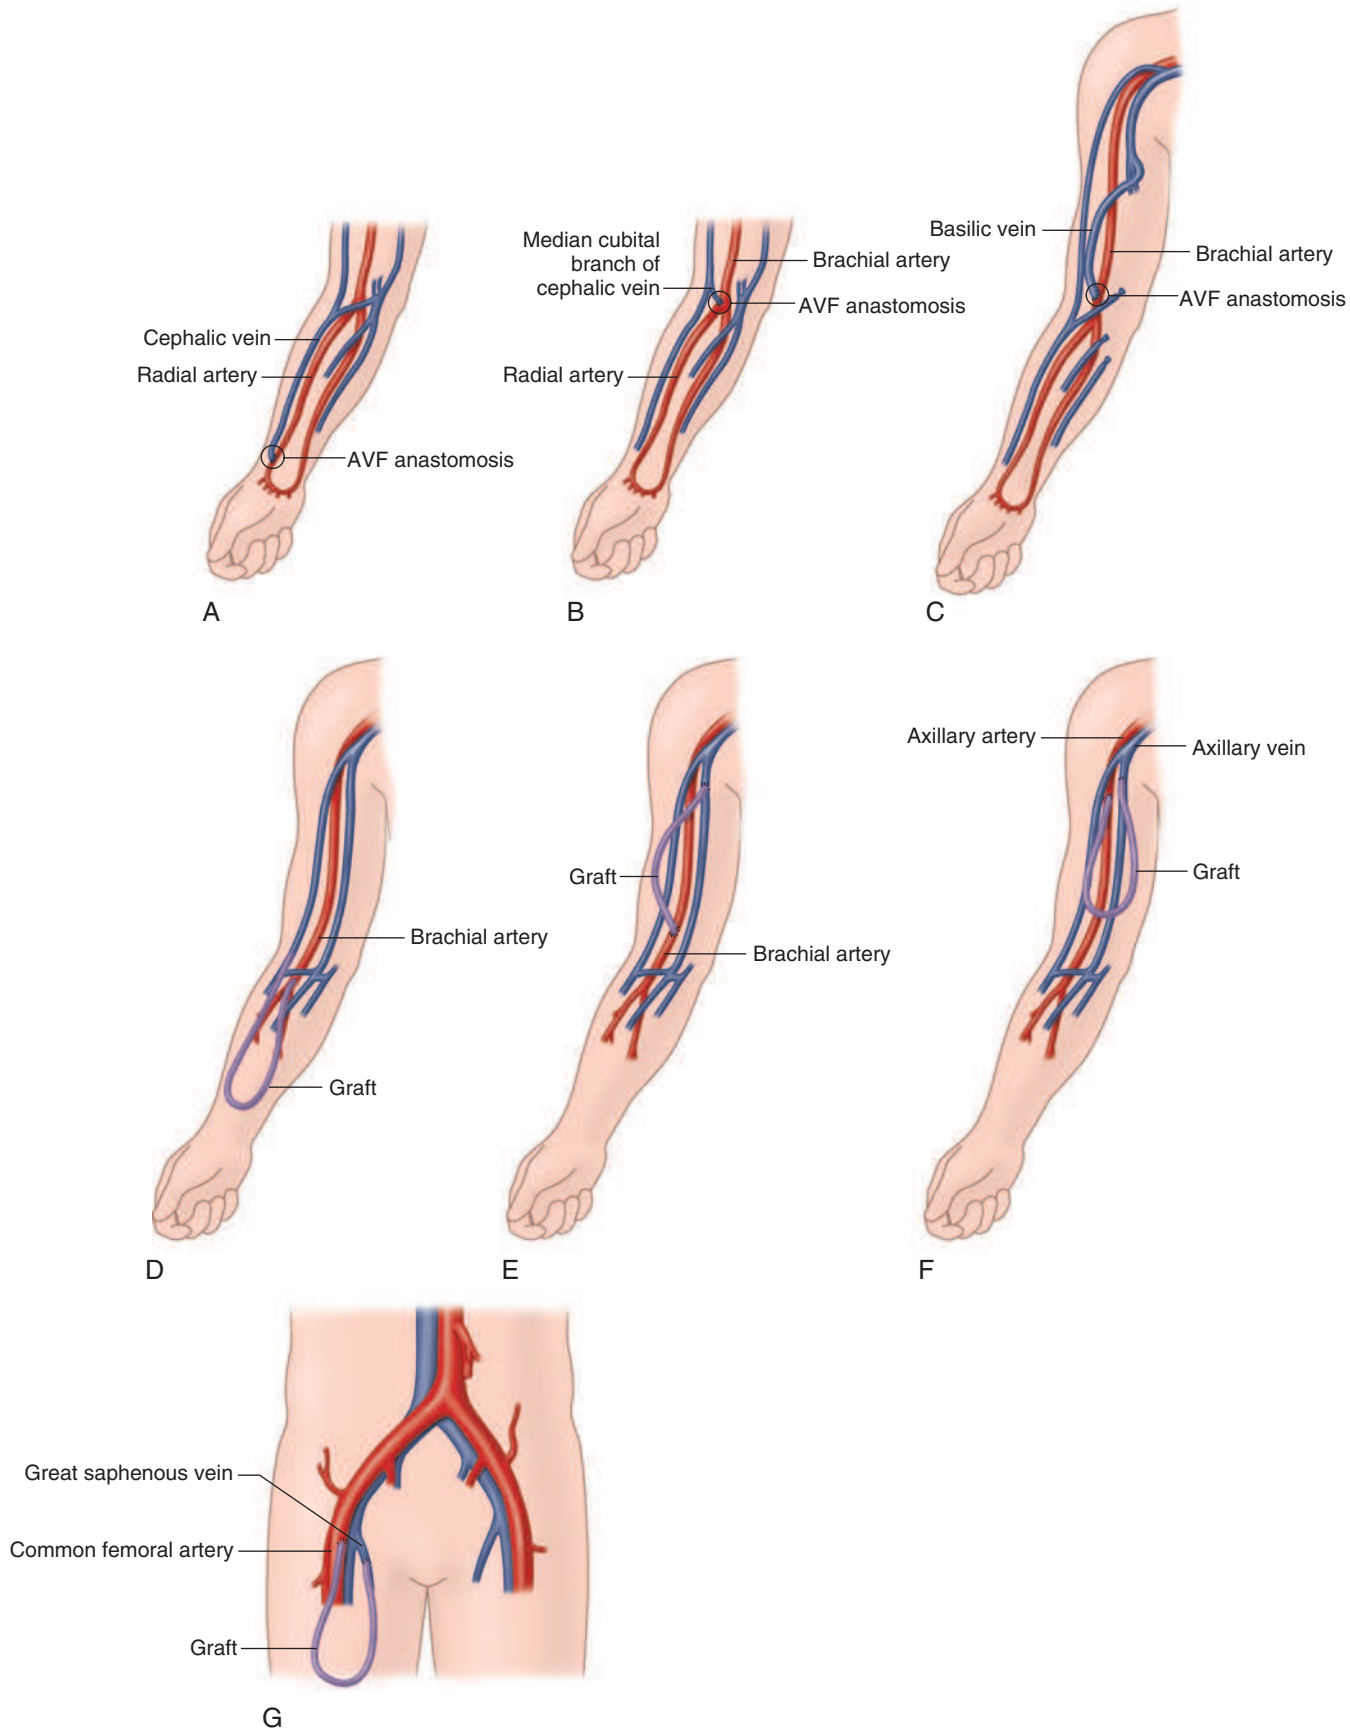

FIG. 27.49 Most Common Arteriovenous Fistula *(AVF)* and Graft Placements. (A) Forearm cephalic vein–radial artery AVF. **(B)** Upper arm cephalic vein–brachial artery AVF, using the median cubital branch of the cephalic vein for the anastomosis. **(C)** Upper arm basilic vein–brachial artery AVF. **(D)** Forearm loop graft. **(E)** Upper arm straight graft. **(F)** Upper arm loop graft. **(G)** Thigh loop graft. Introduction to vascular ultrasonography. 5th ed. Philadelphia: Elsevier; 2005. p. 325-340.[158])

FIG. 27.50 Sonographic Evaluation of the Forearm Veins With Patient's Arm Comfortably Resting on a Surgical Stand.

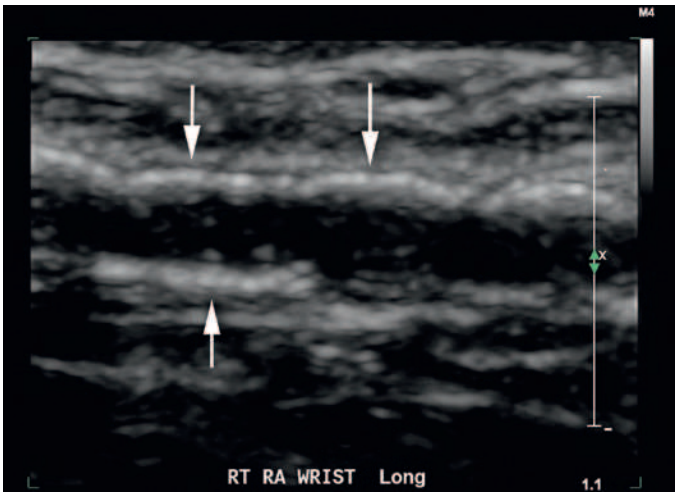

FIG. 27.51 Heavily Calcified Radial Artery at the Wrist. Longitudinal image shows heavy arterial wall calcification *(arrows)*.

it is easier to map all the upper extremity arteries and veins on the same side at one sitting so the surgeon has adequate information if vessel character at surgery is suboptimal and another access site needs to be chosen. If a suitable site for AVF creation is not found on the arm evaluated, the other arm is evaluated. The patient should be sitting upright for optimal evaluation of the upper extremity arteries and veins, with the forearm resting comfortably on a table or armrest. A tourniquet should be placed after arterial assessment, to assess vein caliber and distention[144] (Fig. 27.50). Central venous evaluation to include the IJV and subclavian vein should then be performed with the patient supine, for easier and potentially more accurate waveform assessment.

Sonographic assessment of the arterial wall should evaluate the amount of calcification and degree of stenosis or occlusion, if present. Vein walls should be described with as much detail as possible to assess for wall thickening and thrombus, which may limit future venous distention. The literature suggests that preoperative criteria include a minimum intraluminal arterial diameter of 2.0 mm and a minimal intraluminal venous diameter of 2.5 mm to allow successful AVF creation, and a minimum intraluminal venous diameter of 4.0 mm and a minimum arterial diameter threshold of 2.0 mm for grafts.[145,146]

At least the caudal third of the brachial artery and the entire radial artery are evaluated for intimal thickening, calcification, stenosis, or occlusion, with more extensive evaluation of the brachial and ulnar arteries as warranted, as well as the axillary artery. The severity of arterial calcification may be categorized, depending on surgeon preference, because it may be difficult to suture into a heavily calcified artery, and the risk of emboli at surgery may be higher[123] (Fig. 27.51). The arterial waveform is evaluated for a normal triphasic or biphasic high-resistance flow pattern, and PSV is measured in these regions (Fig. 27.52). A high brachial artery bifurcation is a common anatomic variant and should be suspected when two arteries with accompanying paired veins are seen in the upper arm[52] (Fig. 27.53). The two arteries should be followed into the forearm to the wrist to confirm the presence of a high brachial artery bifurcation and to exclude a prominent arterial branch supplying the elbow, less commonly seen.

For assessment of veins, the upright-seated position ensures venous distention owing to hydrostatic pressure. For optimal venous distention, the tourniquet should be placed on the arm cranial to the area of interrogation so that the veins are distended. Each vein should be inspected, with compression performed along the entire venous length to exclude thrombus (Fig. 27.54). The tourniquet is first placed in the midforearm. The region of the cephalic vein at the wrist is percussed for about 2 minutes for maximal venous distention, and the cephalic vein inner diameter is measured at multiple points in the forearm (Fig. 27.55, Video 27.25). Thereafter, the tourniquet is placed at the antecubital fossa, and then the proximal upper arm, after segmental vein diameter measurement. Cephalic vein anterior wall distance from the skin can be measured because if the cephalic vein is too deep for easy cannulation, it may need to be superficialized in a subsequent surgery (Fig. 27.56). It is not necessary to measure the distance of the basilic vein from the skin; the vein needs to be transposed for easier access. The median antecubital vein typically connects the cephalic vein to the basilic vein and is often part of the AVF draining vein. The median antecubital vein also can be used in creating an upper arm basilic or cephalic vein AVF and so is commonly evaluated at the mapping ultrasound procedure. The axillary vein, subclavian vein, and IJV should be assessed for compressibility (when possible) and normal waveforms (see Fig. 27.40).

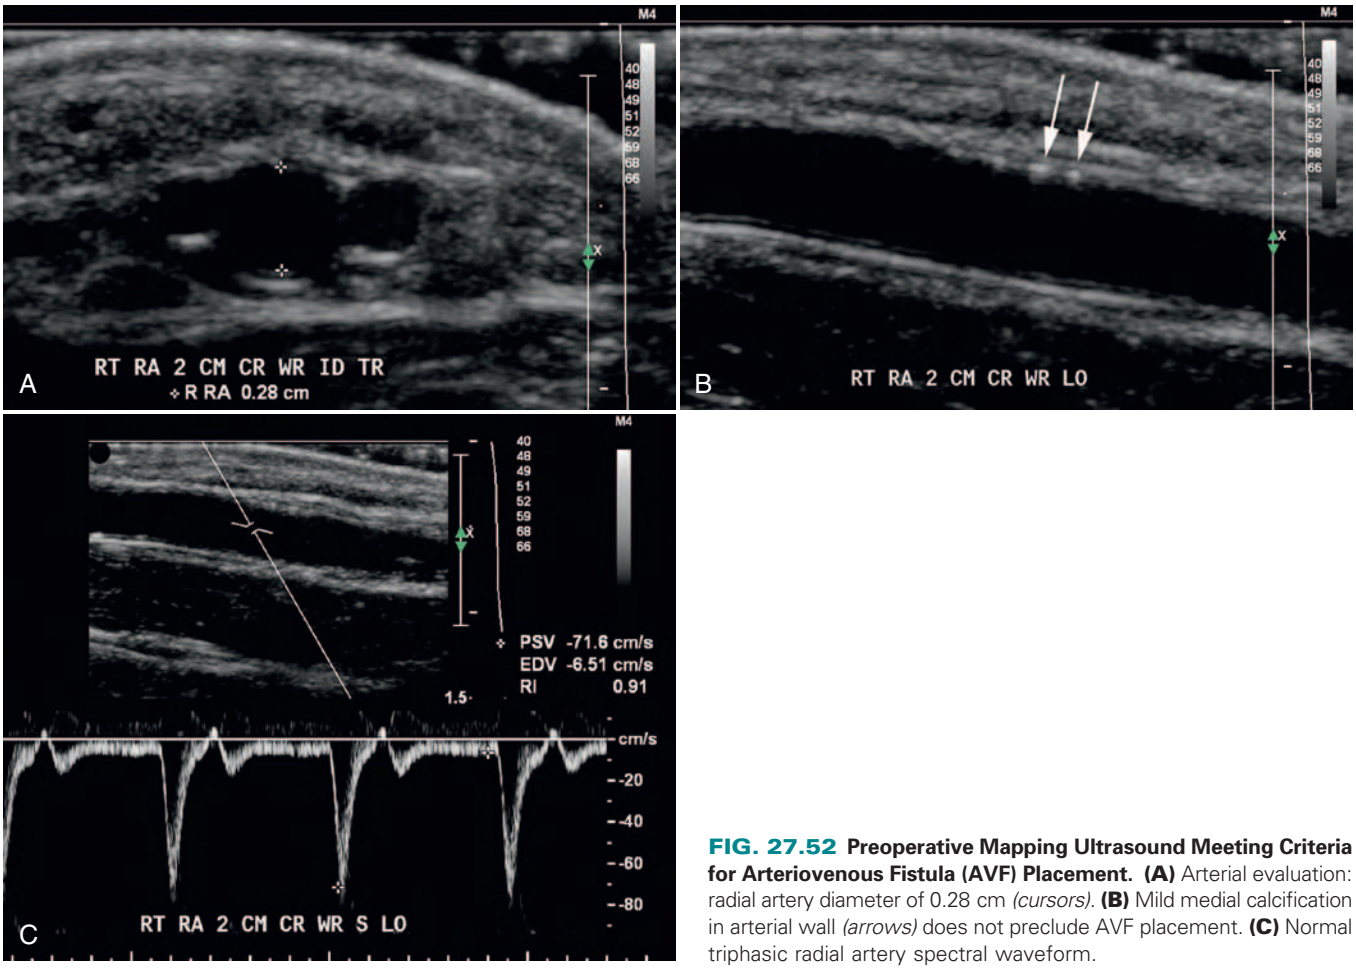

FIG. 27.52 Preoperative Mapping Ultrasound Meeting Criteria for Arteriovenous Fistula (AVF) Placement. (A) Arterial evaluation: radial artery diameter of 0.28 cm *(cursors)*. **(B)** Mild medial calcification in arterial wall *(arrows)* does not preclude AVF placement. **(C)** Normal triphasic radial artery spectral waveform.

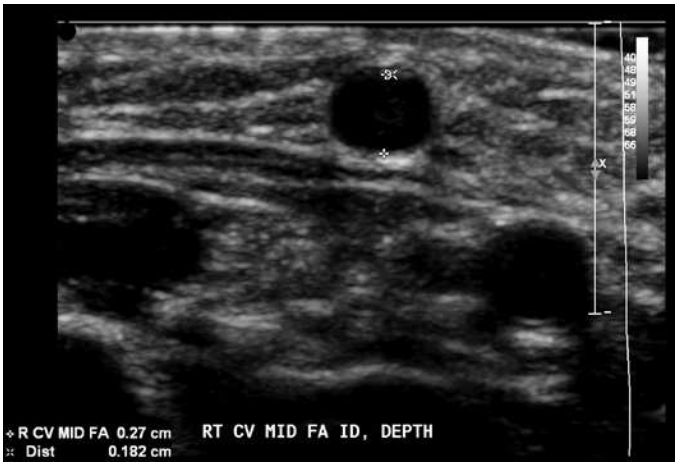

FIG. 27.54 Preoperative Mapping Ultrasound Meeting Criteria for Arteriovenous Fistula (AVF) Placement. Venous evaluation: cephalic vein in the midforearm is 0.27 cm *(+ cursors)*. Anterior vein wall depth is 0.18 cm from skin *(X cursor)*.

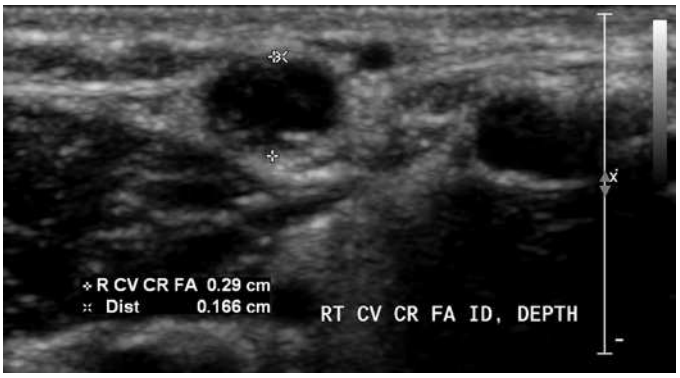

FIG. 27.55 Thick-Walled Cephalic Vein With Chronic Thrombus. This vein may not dilate normally after arteriovenous fistula (AVF) placement and should not be chosen for a potential AVF draining vein. See accompanying Video 27.25.

FIG. 27.56 Cephalic vein is quite deep from the skin surface (0.9 cm; *X cursor*), and may need to be superficialized after arteriovenous fistula creation.

Ultrasound Examination and Imaging Protocol

Upper Extremity. After assessment of the brachial and radial arteries, the inner luminal diameter of the brachial artery 2 cm proximal to the antecubital fossa, and the radial artery at the wrist are measured, along with the axillary artery diameter. Using sequential tourniquet placement and after wrist percussion of the cephalic vein region, the cephalic vein inner diameter is measured at the wrist, midforearm, and proximal forearm (approximately 4 cm from the antecubital fossa). The proximal forearm measurement is used to evaluate the length of vein available to surgically move the vein from the forearm to the brachial artery in upper arm AVF creation.

The cephalic and basilic vein diameters are measured at the antecubital fossa and mid and cranial upper arm. Distance of the anterior wall of the cephalic vein to the skin surface is measured. The axillary vein diameter is measured. The subclavian vein and IJV are assessed in the longitudinal plane with color and spectral Doppler assessment, and IJV compression is performed to assess for thrombus, stenosis, and occlusion. Subclavian and internal jugular spectral Doppler waveforms are assessed for respiratory phasicity and transmitted cardiac pulsatility.

Thigh. Once options to place AVF and grafts in the upper extremity are exhausted, the thigh graft becomes a viable option. Thigh grafts are similar to upper extremity grafts in length of time to permanent failure, with a trend toward increased loss because of infection.[147] Thigh grafts are superior to dialysis via a catheter.[148] If heavy arterial common femoral or superficial femoral arterial calcification is found at ultrasound, pelvic CT may be useful to determine the degree of atherosclerotic disease present. Careful sonographic assessment of atherosclerotic calcification and stenosis may limit immediate graft failure at surgical placement.[128] Thigh graft creation has typically been at the common femoral artery and vein (Fig. 27.57). An alternate place to anastomose the venous end of the graft is the GSV, to preserve the CFV when graft revision is necessary. However, to preserve proximal vasculature for graft revision, and potentially because of fewer infectious complications, midthigh grafts are now being increasingly placed in the mid SFA and superficial femoral vein.[149]

Technical considerations for mapping the arteries and veins of the thigh for hemodialysis graft placement are similar to mapping the upper extremity as described earlier, although a lower-frequency linear transducer may be necessary because of greater thigh size. Evaluation of the degree of arterial calcification and the presence of thrombus is carefully performed in the thigh. More central stenosis or obstruction is assessed by spectral Doppler evaluation of the CFV and common femoral artery. Distance of the vein to the skin is not measured, because typically only thigh grafts are surgically created. A tourniquet is not used in sonographic thigh graft mapping.

The common femoral artery and vein inner luminal diameters are measured, and evaluated for the degree of atherosclerotic calcification. Spectral and color Doppler evaluation of the common femoral artery and vein are performed to evaluate for more proximal stenosis or occlusion. SFA waveforms are also assessed for normalcy. The length of the GSV, which is at least 0.4 cm inner diameter, is measured from its insertion into the CFV extending distally. Inner diameter measurements of the proximal and mid superficial femoral artery and FV are obtained. Compressibility of the veins assessing for thrombus and wall thickening is performed.[128]

Arteriovenous Fistula and Graft

A surgically created hemodialysis access can have a variety of complications, and most of these can be successfully evaluated by ultrasound. Operative notes and pertinent patient history should be reviewed before sonographic evaluation of hemodialysis access. An overall ultrasound scan is performed initially to obtain an overview of the access anatomy and anastomoses. When the general layout is known, sonographic assessment is performed with duplex Doppler sonography, typically in a seated patient with his or her arm resting comfortably on a table. The caudal third of the feeding artery is assessed for stenosis, and the intraluminal diameter is measured in the transverse plane using gray-scale techniques. The feeding artery is further assessed with

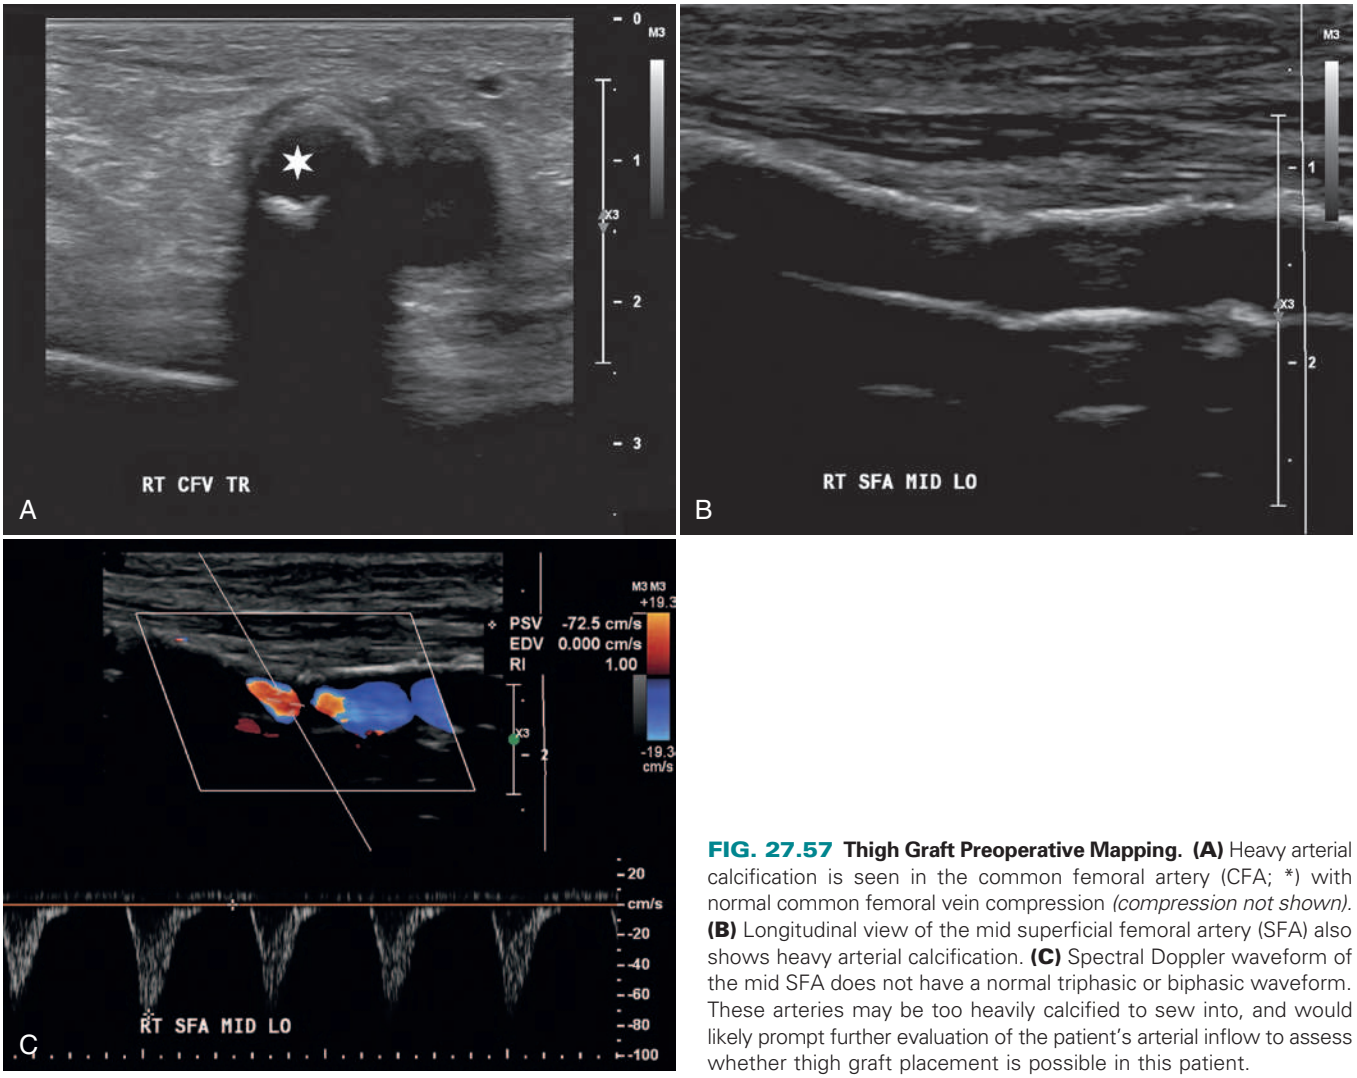

FIG. 27.57 Thigh Graft Preoperative Mapping. (A) Heavy arterial calcification is seen in the common femoral artery (CFA; *) with normal common femoral vein compression *(compression not shown).* **(B)** Longitudinal view of the mid superficial femoral artery (SFA) also shows heavy arterial calcification. **(C)** Spectral Doppler waveform of the mid SFA does not have a normal triphasic or biphasic waveform. These arteries may be too heavily calcified to sew into, and would likely prompt further evaluation of the patient's arterial inflow to assess whether thigh graft placement is possible in this patient.

color and spectral Doppler in the longitudinal plane to document normal low-resistance flow (Fig. 27.58). Measurements of PSV and EDV can be obtained in the feeding artery, and at least at the anastomosis(es). There may be multiple anastomoses in the case of a graft. The draining vein of the AVF or graft is inspected for wall thickening, stenosis, and thrombosis along its entire length.[143]

If a stenosis is seen, the highest PSV either within the stenosis or in the jet downstream from the stenosis is measured, using angle correction parallel to the jet if different from the angle with the posterior vascular wall, keeping the angle to 60 degrees or less. The PSV 2 cm upstream to the stenosis is measured, and a PSV ratio of the PSV at the stenosis divided by the upstream PSV is calculated. A longitudinal gray-scale image is obtained to document any intraluminal thrombus identified within a draining vein or graft. Duplex Doppler should be performed to confirm absence of flow, with use of the more sensitive power Doppler as needed. Description of artery and vein location with regard to the AVF and graft can be difficult. Terminology including cranial and caudal location with regard to a particular anastomosis, and upstream or downstream position, may be more useful than the conventional proximal and distal terminology.

Arteriovenous Fistula

The feeding artery luminal diameter is measured. Spectral and color Doppler evaluations of the feeding artery are performed to evaluate for arterial stenosis or occlusion. The anastomosis is assessed for visible narrowing with subsequent spectral and color Doppler evaluation. The AVF draining vein diameter is evaluated at several levels from the anastomosis to 15 cm cranial to the anastomosis. The intraluminal draining vein diameter and the depth of the vein from the skin surface are measured at several points cranial to the arteriovenous anastomosis. Access challenges may result with a depth greater than 5 to 6 mm and require superficialization.[131,150] The draining vein is interrogated for accessory branches (Fig. 27.59). Intraluminal diameter and distance from the anastomosis are recorded for each identified accessory vein within 10 to 15 cm of the anastomotic site. The flow volume rate measurements are obtained within the midportion of the draining vein of an AVF, typically at 10 cm cranial to the anastomosis. Optimal flow volume measurement is obtained

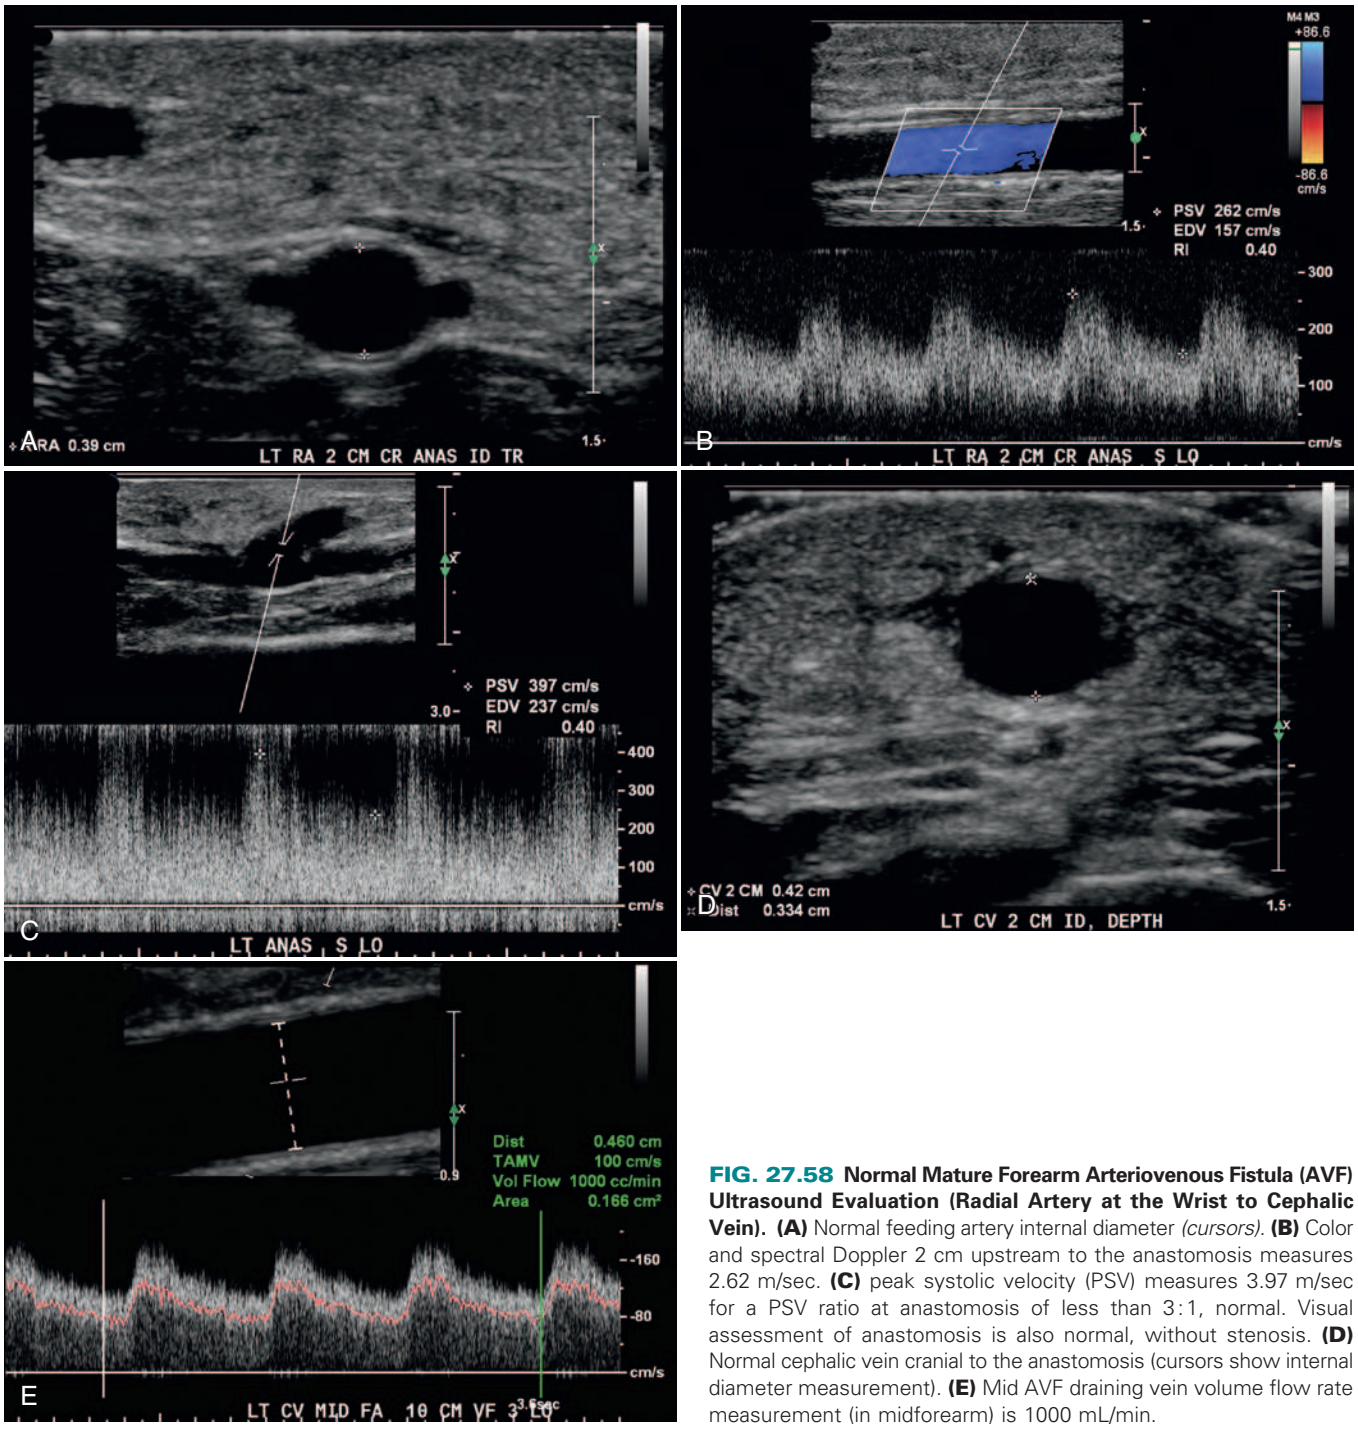

FIG. 27.58 Normal Mature Forearm Arteriovenous Fistula (AVF) Ultrasound Evaluation (Radial Artery at the Wrist to Cephalic Vein). (A) Normal feeding artery internal diameter *(cursors).* **(B)** Color and spectral Doppler 2 cm upstream to the anastomosis measures 2.62 m/sec. **(C)** peak systolic velocity (PSV) measures 3.97 m/sec for a PSV ratio at anastomosis of less than 3:1, normal. Visual assessment of anastomosis is also normal, without stenosis. **(D)** Normal cephalic vein cranial to the anastomosis (cursors show internal diameter measurement). **(E)** Mid AVF draining vein volume flow rate measurement (in midforearm) is 1000 mL/min.

in an area with parallel vessel walls, minimal vessel tortuosity, and no stenosis (Fig. 27.60).

Graft

Sonographic evaluation of the forearm or thigh graft is similar to that of the AVF. A normal graft is seen as two echogenic lines that represent strong specular reflection from polytetrafluoroethylene material. A low-resistance flow (arterialized flow) should be seen within a graft. Duplex Doppler evaluation of the feeding artery (including luminal diameter), arterial-graft anastomosis, graft (arterial side and venous side if loop graft), and venous anastomosis is performed, as well as draining vein and central vein evaluation. Flow volume is assessed within the midgraft (Fig. 27.61), and both arterial and venous limbs if a loop graft. Any points of visible narrowing are further assessed with spectral and color Doppler.

Palpable Focal Masses Near Arteriovenous Fistula and Graft

Hematoma. Avascular, hypoechoic lesions adjacent to the AVF or graft often represent postaccess or postprocedure hematomas (Fig. 27.62, Video 27.26). These collections should

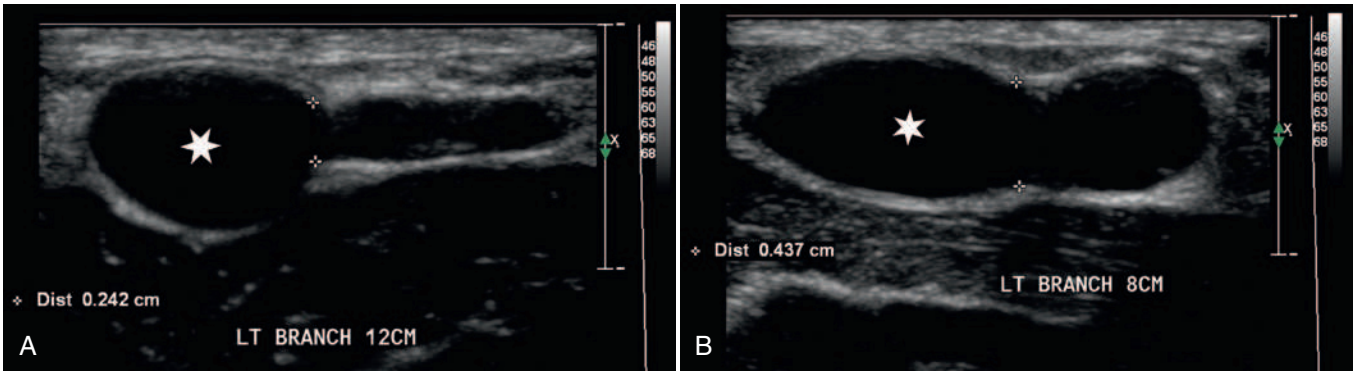

FIG. 27.59 Accessory Arteriovenous Fistula (AVF) Branch Measurement. (A) Transverse image of the AVF draining vein (*) shows a branch of 0.24 cm *(cursors)*. **(B)** Larger accessory AVF branch *(cursors)* of 0.44 cm may be large enough to sump blood away from the AVF draining vein (*).

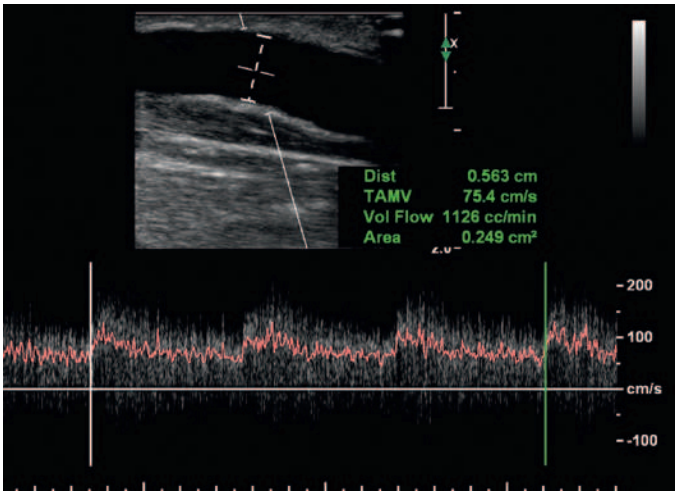

FIG. 27.60 Volume Flow in a Fairly Straight Area of an Arteriovenous Fistula (AVF) Draining Vein.

be inspected for echogenic foci or gas. Fluid collections with echogenic foci associated with shadowing suspicious for gas may represent abscess in certain clinical settings.

Aneurysm and Pseudoaneurysm. Focal or diffuse aneurysmal dilation of the AVF draining vein may occur as a result of repeated puncture (Fig. 27.63). Pseudoaneurysms may develop within a fistula or graft and often are related to suboptimal compression after cannulation. Color Doppler of a **pseudoaneurysm** reveals a circular flow pattern termed "yin-yang" (Fig. 27.64, Video 27.27). There may be "to-and-fro" flow identified in the pseudoaneurysm neck. Evaluation of the depth of the anterior wall of the pseudoaneurysm from the skin surface is important to evaluate those pseudoaneurysms in danger of imminent rupture. A unique complication of grafts is the degeneration of graft synthetic material. Irregularity of the graft wall is present, which may be associated with diffuse or focal pseudoaneurysms along the length of the graft wall (Fig. 27.65, Video 27.28).

Arteriovenous Fistula Maturation Evaluation

A 6-week postoperative AVF ultrasound is used in some clinical centers for routine evaluation of the AVF to determine its development toward usability.[130] A functioning AVF has a volume flow of at least 300 to 800 mL/min.[129,151] Robbin and colleagues showed that when an AVF had a minimum draining vein of 4 mm or larger or a blood flow rate of 500 mL/min or higher, approximately 70% of AVFs were able to be used for hemodialysis. The likelihood of fistula maturation was 95% if both criteria were met. If neither of these criteria was met, only 33% of fistulas were used for hemodialysis.[129] Sonographic criteria published by the National Kidney Foundation Kidney Disease Outcomes Quality Initiative suggestive of maturation include a draining vein greater than 6 mm diameter, blood flow rate greater than 600 mL/min, and less than 6 mm skin depth. These criteria may exclude many fistulas that could subsequently provide hemodialysis access. Active investigation is underway with larger, multicenter trials to test these criteria. Etiology of failure to mature such as anastomotic or AVF draining vein stenosis, large accessory veins, or arterial inflow stenosis can be identified and ultrasound used to triage the AVF for intervention.[131]

Arteriovenous Fistula and Graft Stenosis

AVF. Stenoses associated with AVFs are most frequently juxta-anastomotic, followed in frequency by AVF draining vein, with central venous and feeding artery stenosis less common but not infrequent. Stenoses may be clinically relevant owing to resultant flow decrease and can be associated with subsequent thrombosis. Potential sites for AVF stenosis include the feeding artery, juxta-anastomotic region, draining vein, and central veins. Early after placement, juxta-anastomotic stenoses are the most common. Later, AVF draining vein and central vein stenoses are more common, including a "cephalic arch" stenosis in which the cephalic vein enters the subclavian vein in the cephalic vein AVF. A careful directed search to common areas of stenosis is important during the sonographic examination, because stenoses may be short and therefore overlooked.

Fistula stenosis is characterized by two criteria: (1) visual narrowing of greater than 50% as assessed on gray-scale imaging, and (2) an elevated PSV ratio of the PSV at or just distal to the stenosis as compared with the PSV measured 2 cm upstream from the site of stenosis. A juxta-anastomotic stenosis is defined by a location within 2 cm of the anastomosis, encompassing both the feeding artery and the draining

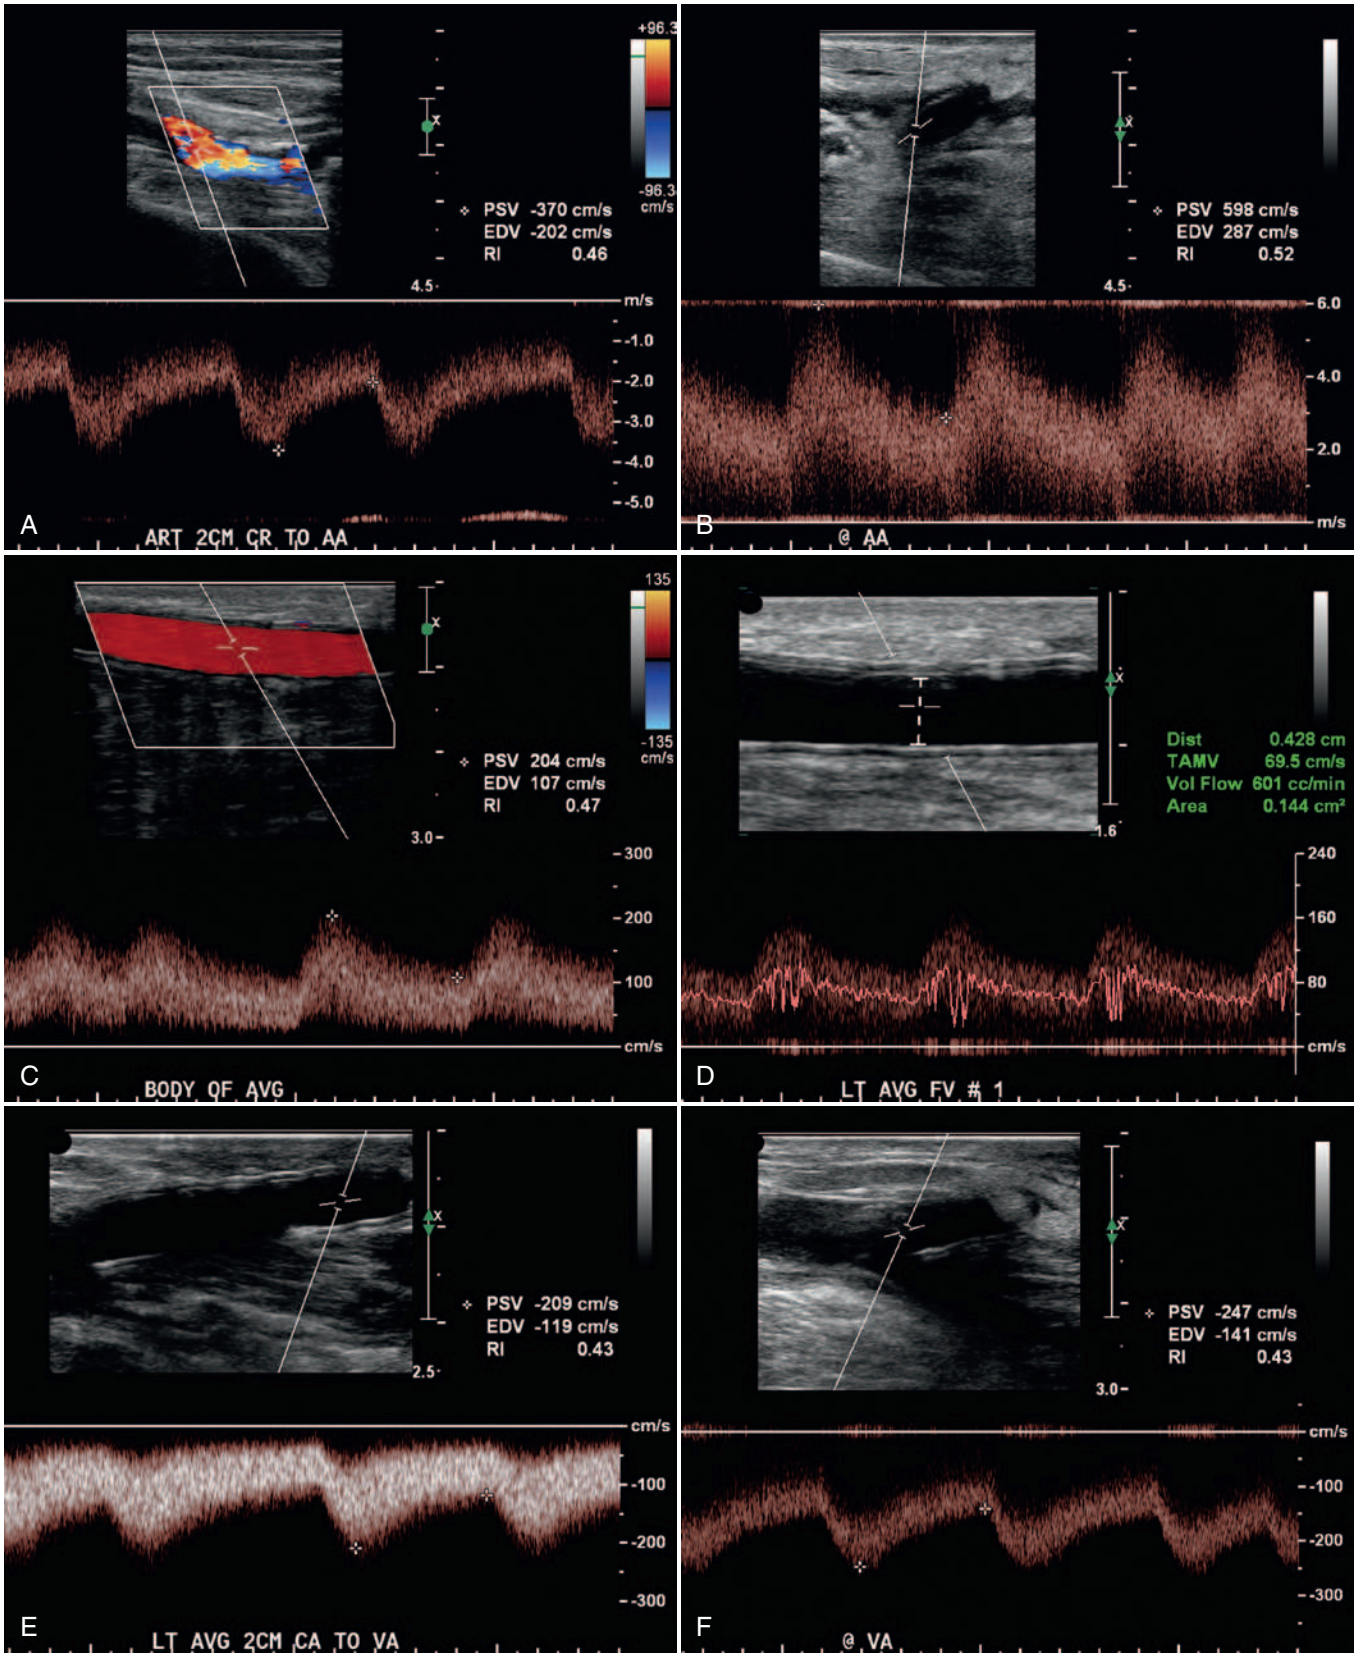

FIG. 27.61 Assessment of Upper Arm Graft (Brachial Artery to Axillary Vein Graft) With Peak Systolic Velocity (PSV) Measurement. (A) Normal color and spectral Doppler images show artery feeding the graft 2 cm cranial to the arterial anastomosis; PSV measures 3.7 m/sec. **(B)** Arterial anastomosis: PSV is 5.98 m/sec. PSV ratio is <3:1, normal, corroborating with no visual stenosis. **(C)** Midgraft body. No abnormal area of stenosis is seen. **(D)** Flow volume rate measurement of 601 mL/min in midgraft. **(E)** Within the graft, 2 cm upstream from venous anastomosis, PSV measures 2.09 m/sec. **(F)** At the venous anastomosis, PSV measures 2.47 m/sec. PSV ratio is <2:1, normal, corroborating with no visual anastomotic stenosis.

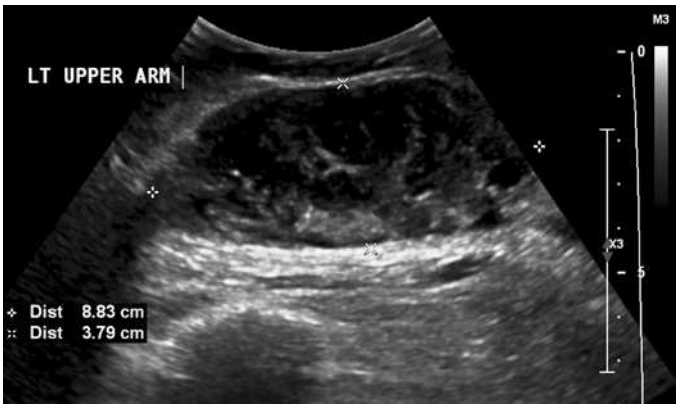

FIG. 27.62 Large Hematoma Adjacent to Arteriovenous Fistula (AVF). Gray-scale image shows hematoma *(calipers)*. No flow was seen on color or spectral Doppler *(not shown)*. See also Video 27.26 for adjacent patent AVF.

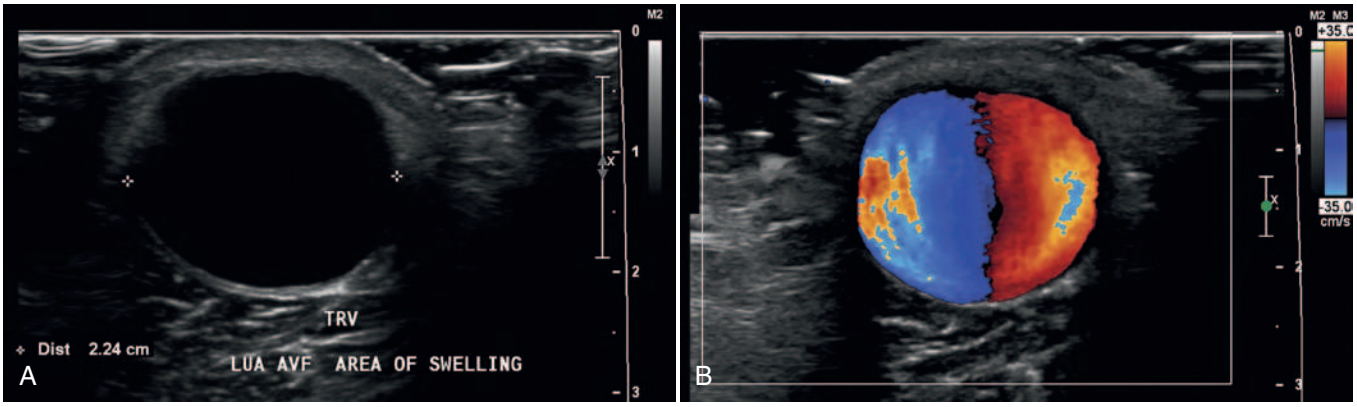

FIG. 27.63 Helical Flow in the Aneurysmal Dilation of Arteriovenous Fistula (AVF). (A) Aneurysmal dilation of the AVF draining vein in the area of palpable swelling. No pseudoaneurysm seen. **(B)** "Yin-yang" flow pattern on color Doppler due to swirling blood.

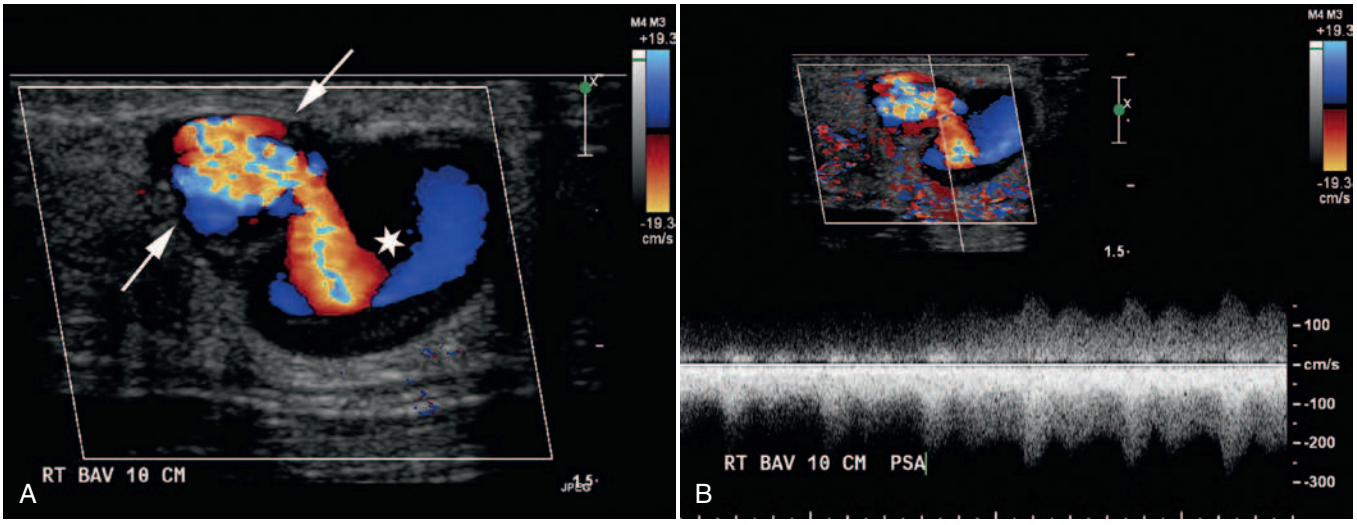

FIG. 27.64 Small Basilic Vein Pseudoaneurysm. (A) Basilic vein arteriovenous fistula (*) with pseudoaneurysm *(arrows)*. **(B)** Spectral Doppler in the pseudoaneurysm neck shows typical "to-and-fro" pattern. See also Video 27.27.

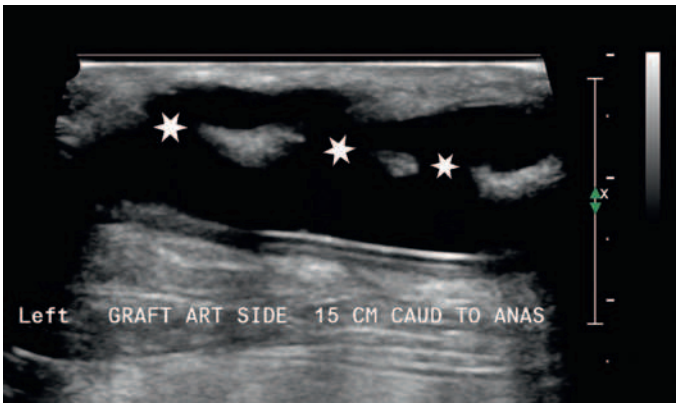

FIG. 27.65 Graft Wall Irregularity and Degeneration From Repeated Punctures. Note bright linear parallel walls posteriorly seen in polytetrafluoroethylene hemodialysis grafts. Stars (*) denote areas of degeneration. See also Video 27.28.

vein.[152,153] The juxta-anastomotic stenosis will show visible narrowing and a PSV ratio of greater than or equal to 3:1 (Fig. 27.66). A draining vein stenosis is defined by visible narrowing and a PSV ratio of 2:1 identified within the draining vein 2 cm cranial to the anastomosis[141] (Fig. 27.67). Feeding artery stenosis greater than 2 cm proximal to the anastomosis is uncommon; these are characterized by a PSV ratio of 2:1 with visible narrowing. Poststenotic waveforms show delayed systolic upstrokes that may suggest proximal arterial stenosis and prompt further direct evaluation of the feeding artery more cranially.

Graft. Graft abnormalities are similar to those described earlier for AVF, with differing diagnostic thresholds and criteria. Several studies have indicated that grafts with decreased blood flow are at increased risk for thrombosis.[141,154,155] The four sonographic criteria used to characterize graft stenosis are (1) luminal narrowing on gray-scale imaging, (2) a high-velocity jet on color Doppler, (3) a PSV ratio greater than 2:1 for the venous anastomosis or draining vein, and (4) a PSV ratio greater than 3:1 for the arterial anastomosis. The most common site of graft stenosis is the venous anastomosis. Other, less frequently used sites are the draining vein, intragraft region, arterial anastomosis, and central veins (Fig. 27.68, Video 27.29).

Arterial Steal

Arterial steal is defined as flow reversal in the native artery caudal to the anastomosis and may be asymptomatic, or associated with clinical findings such as hand pain and paresthesias that can worsen during hemodialysis.[156] In severe cases, ischemia or tissue necrosis of the fingers can occur. Sonographic evaluation may show reversal of flow in the distal artery, and rarely shows an arterial occlusion (Fig. 27.69). Brief manual compression of the graft can demonstrate a change in the reversed arterial flow, producing an antegrade high-resistance flow pattern toward the hand.[157]

It is important to note that asymptomatic flow reversal in the artery downstream from the arterial anastomosis is frequently seen, particularly in the AVF. In severe cases of arterial steal, surgical revision may be necessary.

Arm and Leg Swelling With Arteriovenous Fistula or Graft

When there is upper extremity swelling associated with an AVF or graft, the ipsilateral axillary, subclavian vein, and IJV should be included in the postoperative sonographic evaluation. Occasionally, a DVT of the brachial, axillary, or subclavian vein is the cause of arm swelling in a patient with an AVF or graft. If an upper extremity DVT is not found, spectral Doppler imaging of the IJV and subclavian vein may provide indirect evaluation of the brachiocephalic veins.

As discussed earlier in this chapter, monophasic venous waveforms of the subclavian vein and IJV suggest central venous stenosis or occlusion (Fig. 27.70). The absence of phasicity in the central veins is less specific for central venous occlusion in patients with a graft than in patients with an AVF because of the larger blood flow volume rate within grafts. Findings suggestive of central stenosis or occlusion are visible narrowing, focal turbulence, focally elevated velocity, and collaterals. If a central stenosis or occlusion is suspected, central vein assessment with magnetic resonance imaging (MRI) or venography may be useful because a central stenosis severe enough to cause arm swelling may be present despite adequate or high AVF flow.

Arteriovenous Fistula and Graft Occlusion

Access occlusion can be determined by physical examination. However, in the case of significant arm swelling or an inexperienced examiner, ultrasound evaluation may be useful. Thrombosis can be visualized within the vessel lumen on gray-scale imaging (Fig. 27.71) and confirmed by lack of color or spectral Doppler flow within the affected portion of the AVF, graft, or draining vein. Slow flow may be identified with power Doppler when nonocclusive thrombus is present. Arterial inflow will typically be high resistance flow in the occluded AVF or graft.

CONCLUSION

Ultrasound plays an important role in evaluating the peripheral vasculature. Although peripheral artery ultrasound is commonly considered for its uses in peripheral artery atherosclerotic disease, the technique can be applied in numerous clinical scenarios. For evaluation of stenosis in native or bypassed vessels, the concepts are similar, although threshold values may differ. For evaluation of aneurysm, pseudoaneurysm, or AVF, the examination can be more localized in its scope to determine the size of the abnormality by gray-scale and the use of Doppler to focus on the inflow and outflow characteristics.

For the upper and lower extremity deep venous system, ultrasound is the initial imaging modality of choice. In the occasional case where sonographic findings are equivocal or nondiagnostic, especially when there is concern for central thrombosis, correlation with MRI, CT, or catheter venography may be helpful. Ultrasound can provide an accurate, rapid, portable, low-cost, noninvasive method for screening,

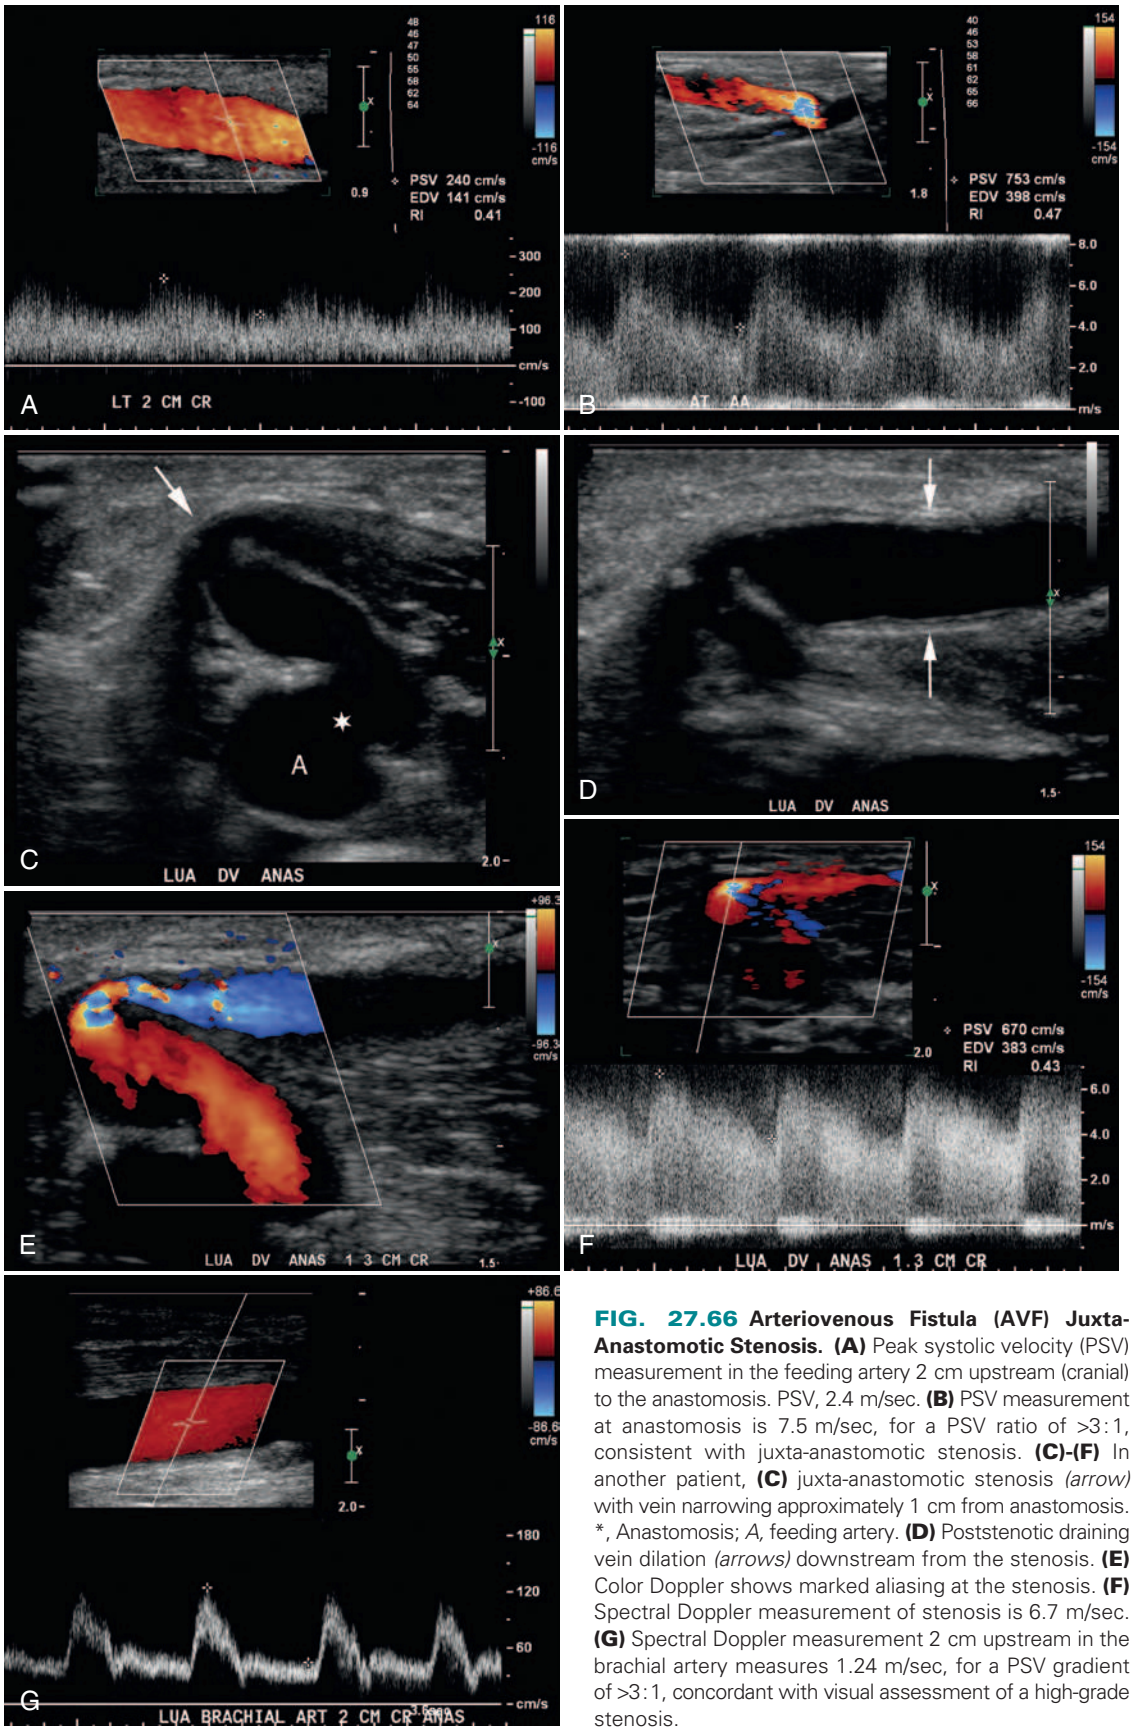

FIG. 27.66 Arteriovenous Fistula (AVF) Juxta-Anastomotic Stenosis. (A) Peak systolic velocity (PSV) measurement in the feeding artery 2 cm upstream (cranial) to the anastomosis. PSV, 2.4 m/sec. **(B)** PSV measurement at anastomosis is 7.5 m/sec, for a PSV ratio of >3:1, consistent with juxta-anastomotic stenosis. **(C)-(F)** In another patient, **(C)** juxta-anastomotic stenosis *(arrow)* with vein narrowing approximately 1 cm from anastomosis. *, Anastomosis; *A,* feeding artery. **(D)** Poststenotic draining vein dilation *(arrows)* downstream from the stenosis. **(E)** Color Doppler shows marked aliasing at the stenosis. **(F)** Spectral Doppler measurement of stenosis is 6.7 m/sec. **(G)** Spectral Doppler measurement 2 cm upstream in the brachial artery measures 1.24 m/sec, for a PSV gradient of >3:1, concordant with visual assessment of a high-grade stenosis.

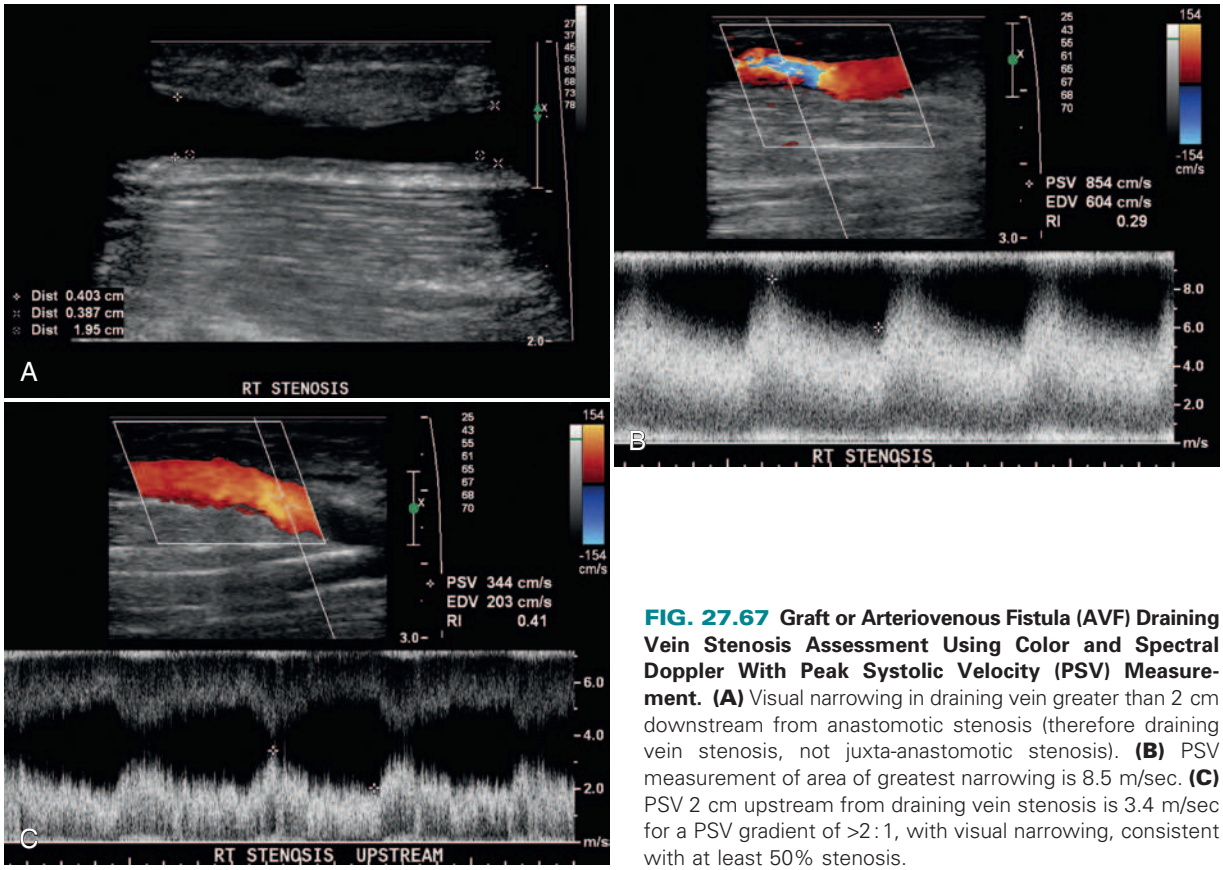

FIG. 27.67 Graft or Arteriovenous Fistula (AVF) Draining Vein Stenosis Assessment Using Color and Spectral Doppler With Peak Systolic Velocity (PSV) Measurement. (A) Visual narrowing in draining vein greater than 2 cm downstream from anastomotic stenosis (therefore draining vein stenosis, not juxta-anastomotic stenosis). **(B)** PSV measurement of area of greatest narrowing is 8.5 m/sec. **(C)** PSV 2 cm upstream from draining vein stenosis is 3.4 m/sec for a PSV gradient of >2:1, with visual narrowing, consistent with at least 50% stenosis.

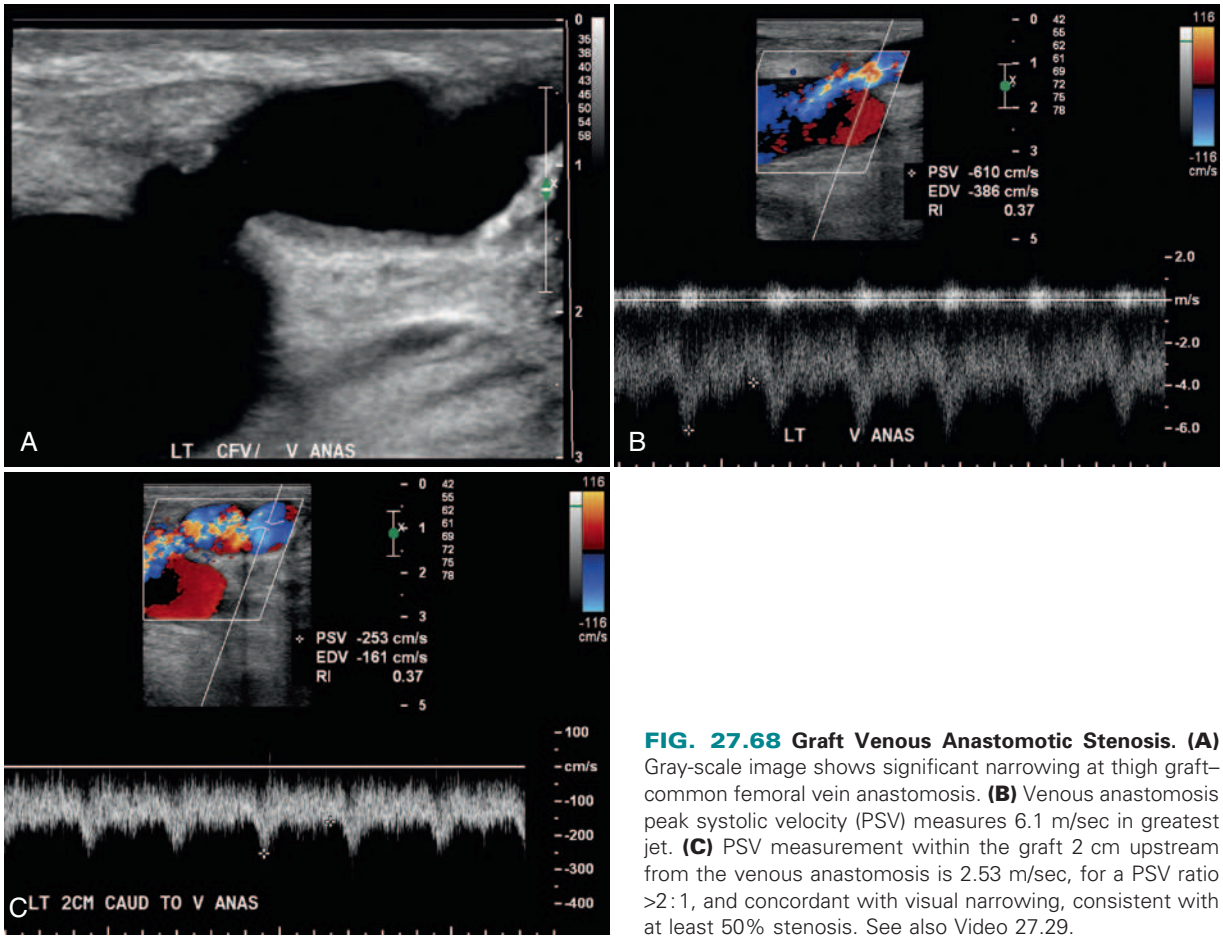

FIG. 27.68 Graft Venous Anastomotic Stenosis. (A) Gray-scale image shows significant narrowing at thigh graft–common femoral vein anastomosis. **(B)** Venous anastomosis peak systolic velocity (PSV) measures 6.1 m/sec in greatest jet. **(C)** PSV measurement within the graft 2 cm upstream from the venous anastomosis is 2.53 m/sec, for a PSV ratio >2:1, and concordant with visual narrowing, consistent with at least 50% stenosis. See also Video 27.29.

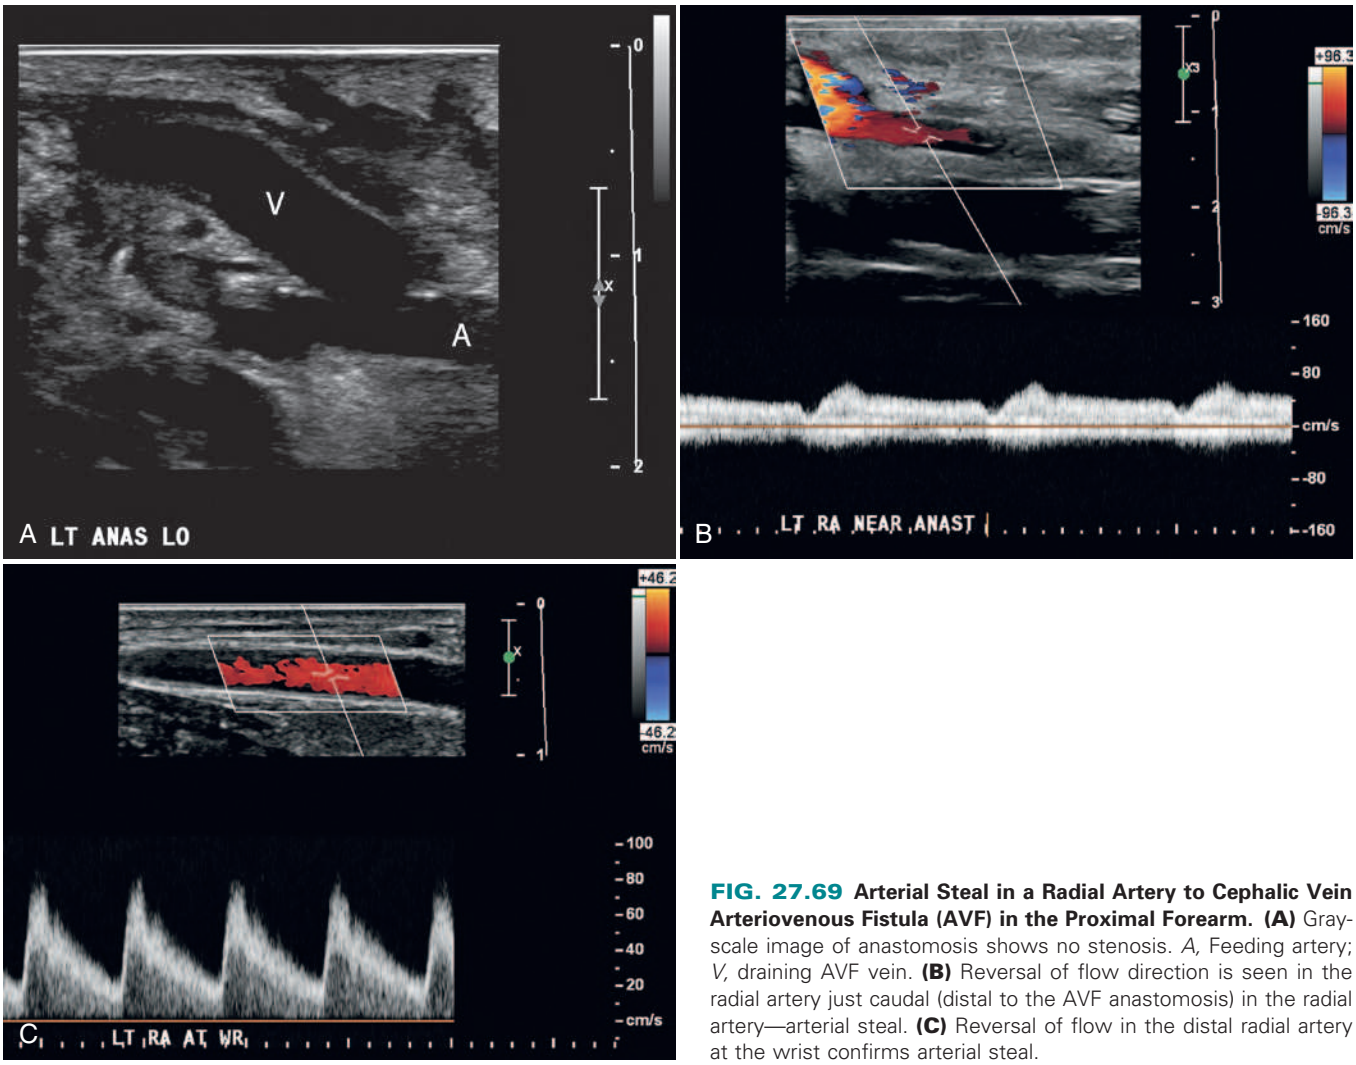

FIG. 27.69 Arterial Steal in a Radial Artery to Cephalic Vein Arteriovenous Fistula (AVF) in the Proximal Forearm. (A) Gray-scale image of anastomosis shows no stenosis. *A,* Feeding artery; *V,* draining AVF vein. **(B)** Reversal of flow direction is seen in the radial artery just caudal (distal to the AVF anastomosis) in the radial artery—arterial steal. **(C)** Reversal of flow in the distal radial artery at the wrist confirms arterial steal.

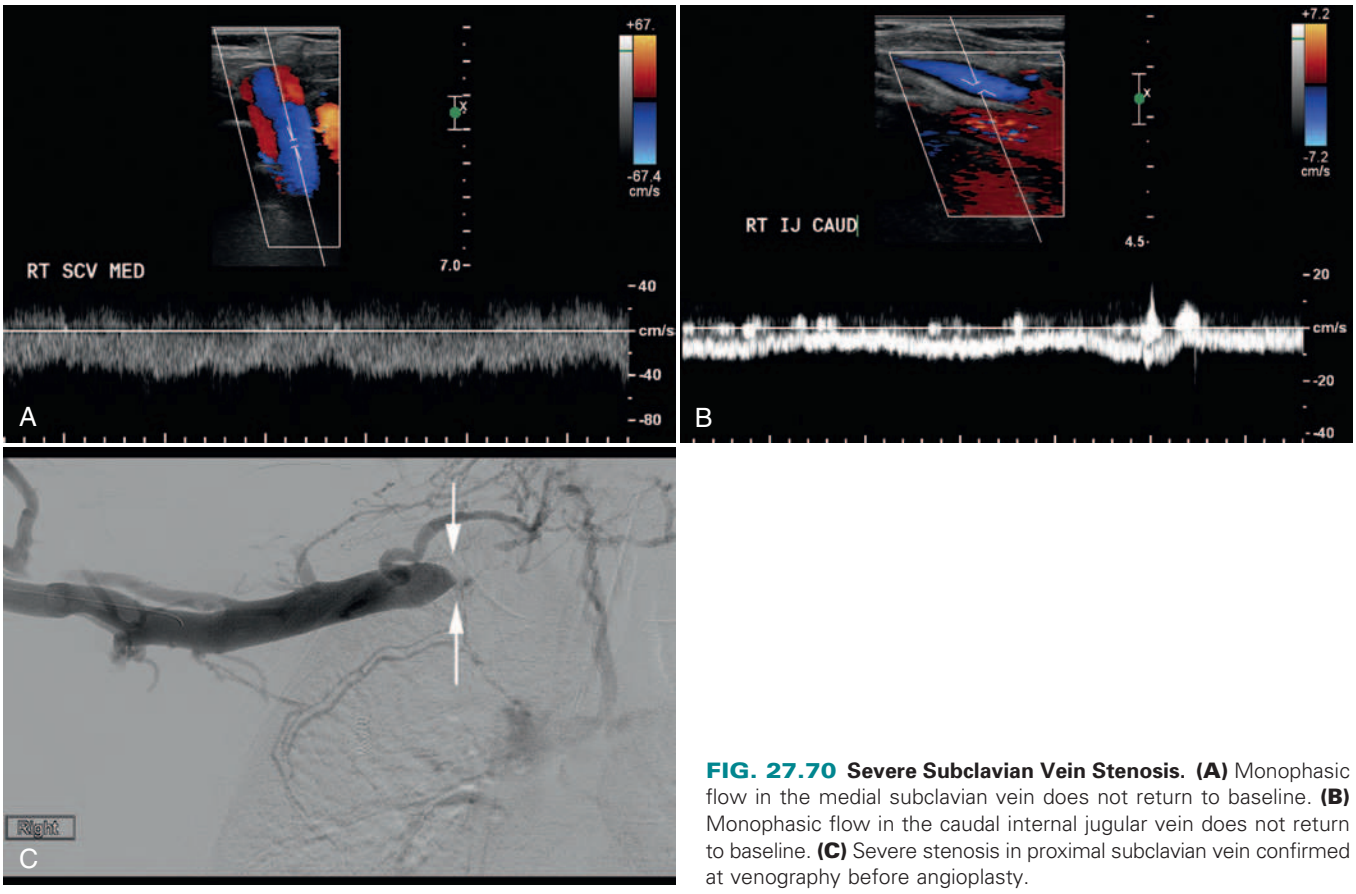

FIG. 27.70 Severe Subclavian Vein Stenosis. (A) Monophasic flow in the medial subclavian vein does not return to baseline. **(B)** Monophasic flow in the caudal internal jugular vein does not return to baseline. **(C)** Severe stenosis in proximal subclavian vein confirmed at venography before angioplasty.

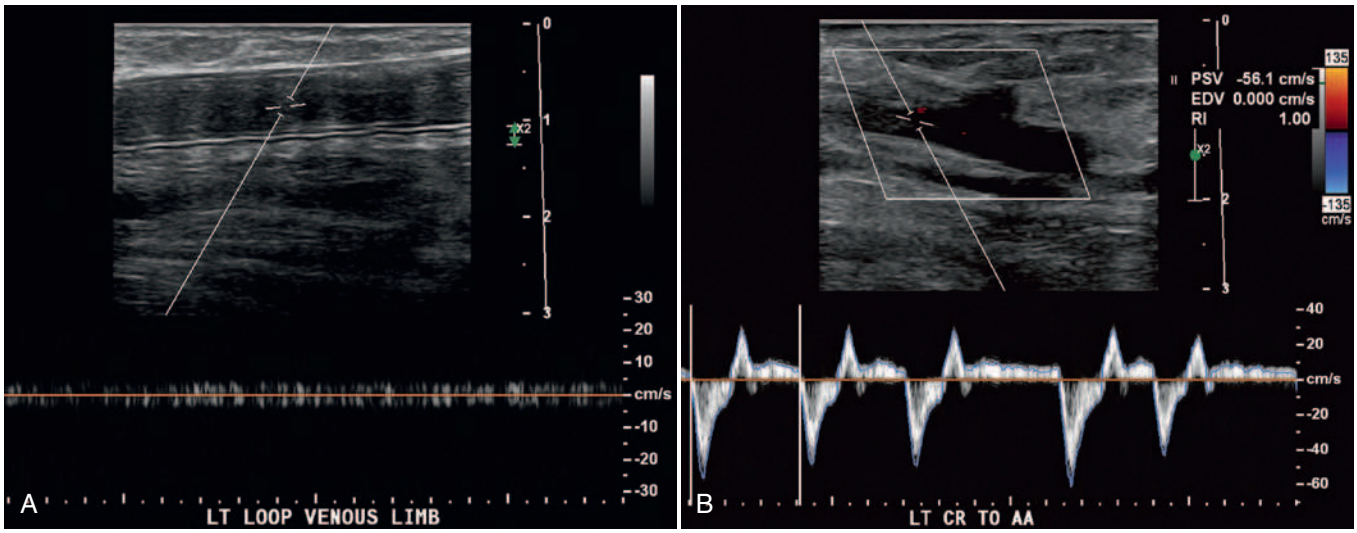

FIG. 27.71 Thrombosed Hemodialysis Graft. (A) No flow seen on spectral Doppler (no flow on color Doppler; *not shown*). **(B)** Color and spectral Doppler of artery upstream (cranial) from graft takeoff shows high-resistance waveform expected in graft thrombosis.

mapping, and surveillance of the upper and lower extremity venous system.

Preoperative ultrasound evaluation of the veins and arteries before both upper extremity and thigh hemodialysis access placement may decrease complications related to access procedures and improve overall access utility. After access placement, ultrasound is useful in the assessment of complications including stenosis, pseudoaneurysm, steal, and AVF nonmaturation.

APPENDIX

Ultrasound Artifacts: A Virtual Chapter

Korosh Khalili, Hojun Yu, Alexander Jesurum, and Deborah Levine

SUMMARY OF KEY POINTS

- Artifacts are common in ultrasound imaging.
- Knowledge of artifacts can aid in diagnosis.
- Understanding ultrasound physics allows for correction of artifacts that distort the visualized anatomy.

CHAPTER OUTLINE

ASSUMPTIONS IN GRAY-SCALE IMAGING
Velocity of Sound
Attenuation of Sound
Path of Sound
Beam Profile
PROPAGATION VELOCITY ARTIFACT
ATTENUATION ERRORS
Shadowing
Increased Through Transmission
PATH OF SOUND-RELATED ARTIFACTS
Mirror Image Artifact
Comet-Tail Artifact
Refraction
Anisotropy
Reverberation Artifact
GAS-RELATED ARTIFACTS
Reverberation Artifact
Ring-Down Artifact
Dirty Shadowing Artifact
BEAM PROFILE–RELATED ARTIFACTS
Side Lobe and Grating Lobe Artifacts
Partial Volume Averaging
DOPPLER IMAGING ARTIFACTS
Loss or Distortion of Doppler Information
Artifactual Vascular Flow
Tissue Vibration Artifact
Aliasing and Velocity Scale Errors
Spectral Broadening
Blooming Artifact
Twinkle Artifact
Acknowledgment

Almost all ultrasound images contain artifacts. Many of these artifacts go unrecognized because they are contained within (and contribute to) the background noise. However, when artifacts substantially alter the signal, they become recognizable on images. Certain artifacts distort the images and must be recognized in order to improve image quality or prevent a false diagnosis. Other artifacts add useful data and thus are important for understanding the composition, anatomy, and pathology of the image being visualized. We hope you enjoy this virtual chapter, which encompasses animated illustrations of how artifacts are produced as well as multiple examples of images and videos from the text.

ASSUMPTIONS IN GRAY-SCALE IMAGING

Several assumptions about the propagation of sound waves are made when ultrasound equipment maps echoes onto the image.[1] When one or more of these assumptions prove invalid, artifacts result.

Velocity of Sound

The speed of sound throughout the tissues is assumed to be uniform at 1540 m/sec. When the waves travel through tissues that substantially alter sound velocity, propagation velocity artifacts occur.

Attenuation of Sound

Sound waves normally become fainter—that is, their intensity decreases—as they travel through tissues. The equipment assumes that this attenuation of intensity occurs at a constant rate. If the waves travel through tissues that either do not attenuate as much or attenuate more than the adjacent tissues, attenuation errors such as increased through transmission or shadowing arise.

Path of Sound

In creating the image, the equipment assumes that the generated sound wave travels from the surface of the probe in a straight line, is reflected off a reflector only once, and returns directly back to the probe at the same angle exactly to the point from which it left the probe. If the sound waves undergo more than one reflection, then artifacts such as mirror image, reverberation,

or comet-tail occur. And if the direction of the beam or its echo is altered, refraction or anisotropy artifact may be produced.

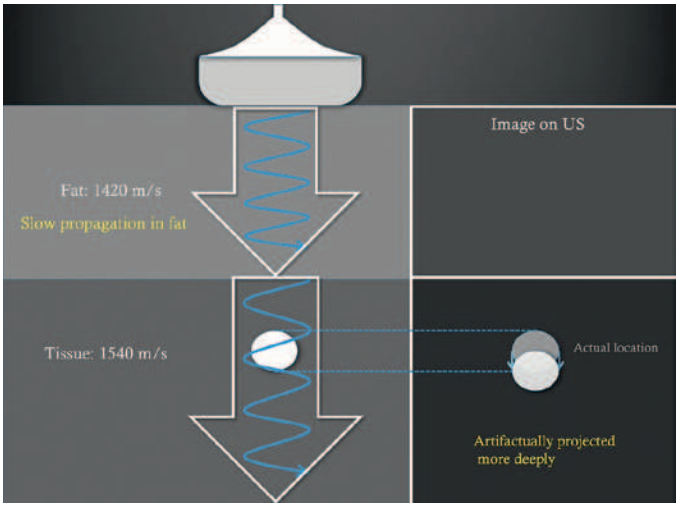
Beam Profile

An assumption is made that the sound beam generated by the transducer is a narrow line. When the beam is not sufficiency narrow in the imaging plane or in the elevation plane (i.e., along the short axis of the transducer), side lobe or grating lobe or partial volume averaging artifacts may occur.

PROPAGATION VELOCITY ARTIFACT

Ultrasound image processing assumes that the speed of sound in tissue is a constant 1540 m/sec. However, when a sufficiently large structure composed of tissue that propagates speed at a different velocity is encountered, then propagation velocity artifact can occur.[1] In the case of a fatty lesion, the slower speed of propagation (approximately 1450 m/sec) means that the echo will take longer to return to the transducer; thus the lesion is displayed deeper in the image than its true location. Some newer ultrasound machines with multibeam (spatial compounding) features and improved signal processing can minimize this artifact.

Click here to see an explanatory video of **propagation velocity artifact** (Video A.1).



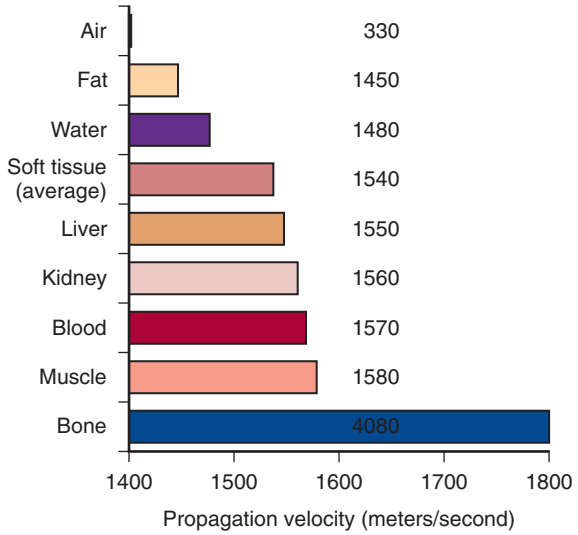


FIG. A.1 Propagation Velocity. Propagation velocity of different body tissues.[2] (See Chapter 1, Fig. 1.2.)

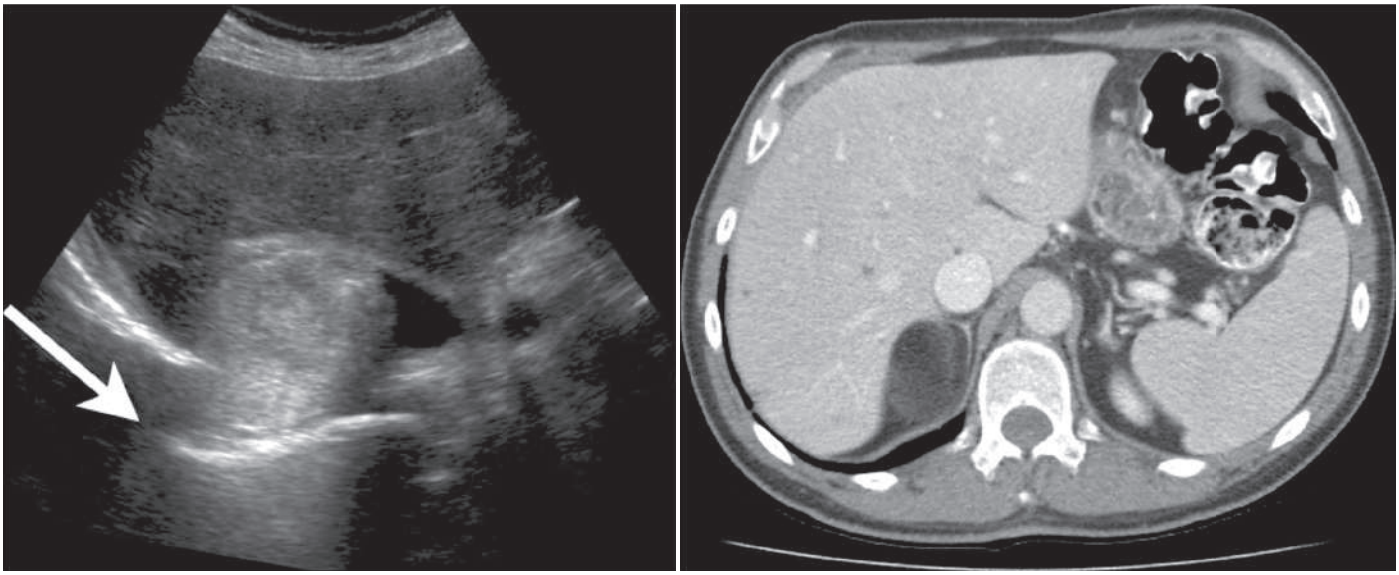

FIG. A.2 Propagation Velocity. When sound passes through a fatty mass, in this case a myelolipoma, its speed slows down to 1450 m/sec. Because the ultrasound scanner assumes that sound is being propagated at the average velocity of 1540 m/sec, the delay in echo return is interpreted as indicating a deeper target. Therefore the final image shows a **misregistration artifact** in which the diaphragm *(arrow)* is shown in a deeper position than expected in this patient with a right adrenal myelolipoma. The computed tomography image depicts the myelolipoma, confirming its fatty nature.

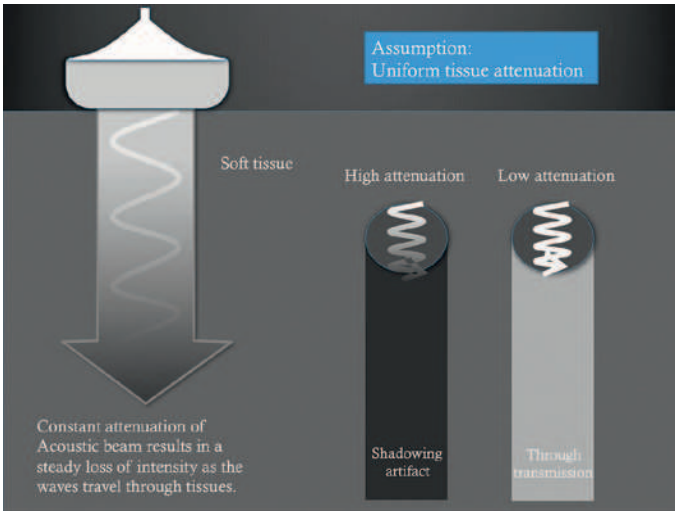
ATTENUATION ERRORS

When the ultrasound beam encounters a focal lesion that attenuates the sound to a greater or lesser extent than the surrounding tissues, the intensity of the beam deep to the lesion will be either weaker (shadowing) or stronger (increased through transmission) than in the surrounding tissues.

Click here to see an explanatory video of **attenuation-related artifacts** (Video A.2).



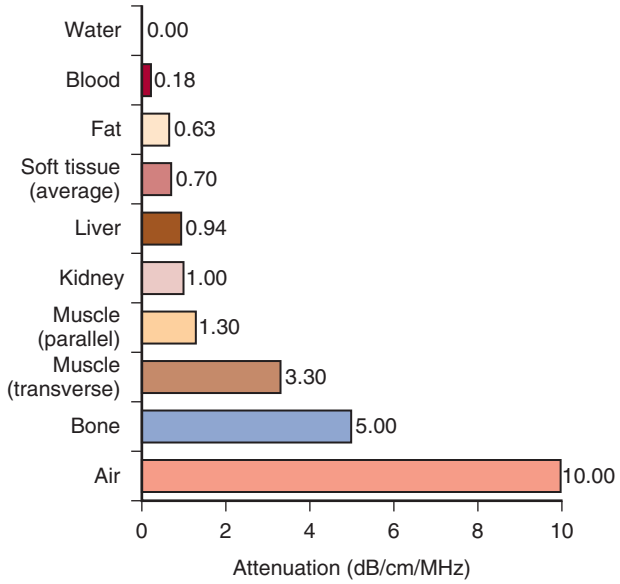


FIG. A.3 As sound passes through tissue, it loses energy through the transfer of energy to tissue by heating, reflection, and scattering. Attenuation is determined by the insonating frequency and the nature of the attenuating medium. Attenuation values for normal tissues show considerable variation. Attenuation also increases in proportion to insonating frequency, resulting in less penetration at higher frequencies.[2] (See Chapter 1, Fig. 1.9.)

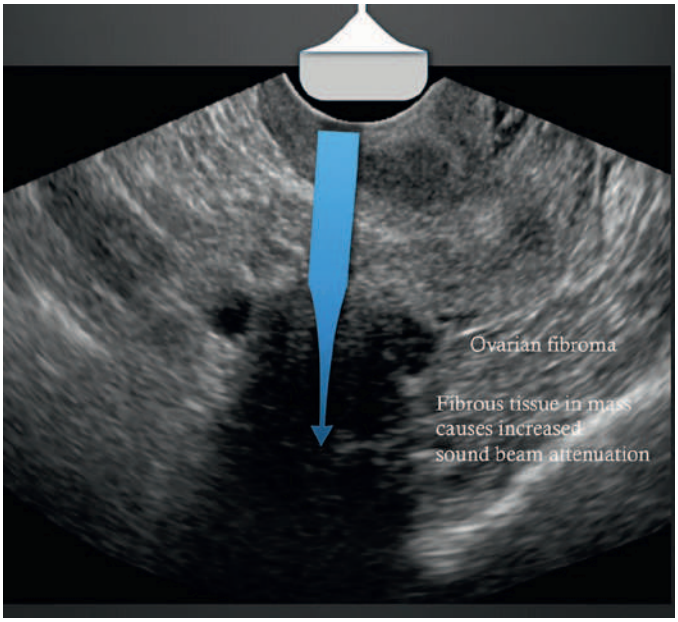
Shadowing

Shadowing results when there is a marked reduction in the intensity of the ultrasound deep to a strong reflector, attenuator, or refractor. Clean dark shadows will be seen behind calcified objects when the focal zone is at or just below the structure.

Click here to see an explanatory video of **shadowing** (Video A.3).



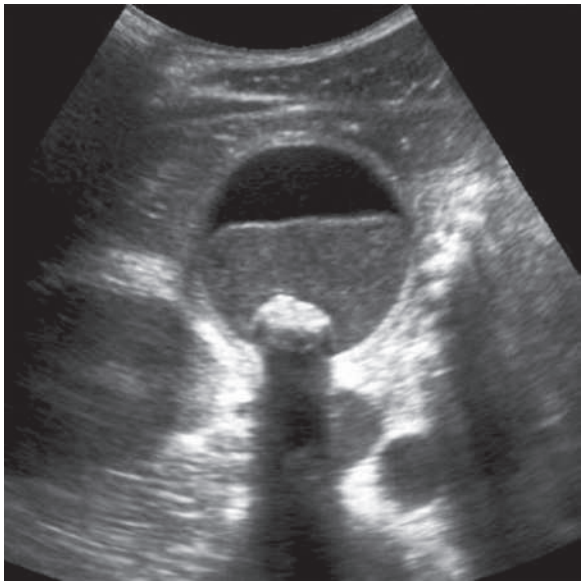


FIG. A.4 Gallstone With Shadowing. Note the dark, well-defined shadow.[3] (See Chapter 6, Fig. 6.39C.)

FIG. A.5 Shadowing From Hernia Repair Mesh.

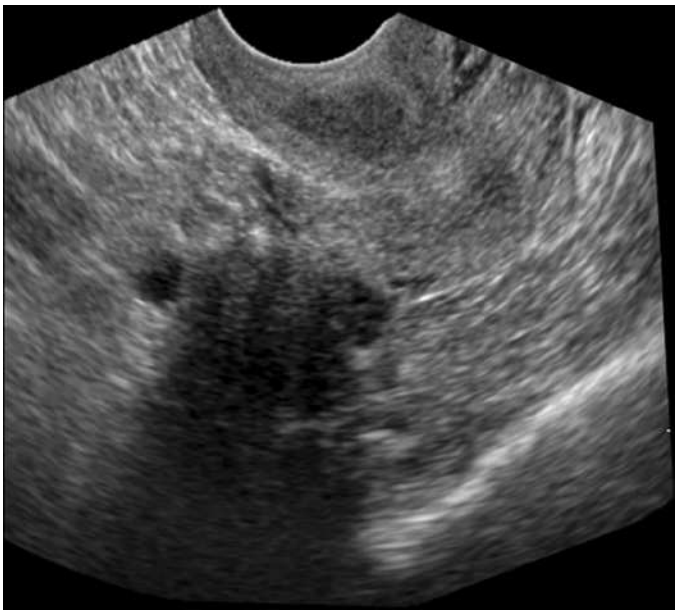

FIG. A.6 Shadowing From Ovarian Fibroma. This is a slightly less "clean" shadow since the fibroma is not as dense as a calcified stone.

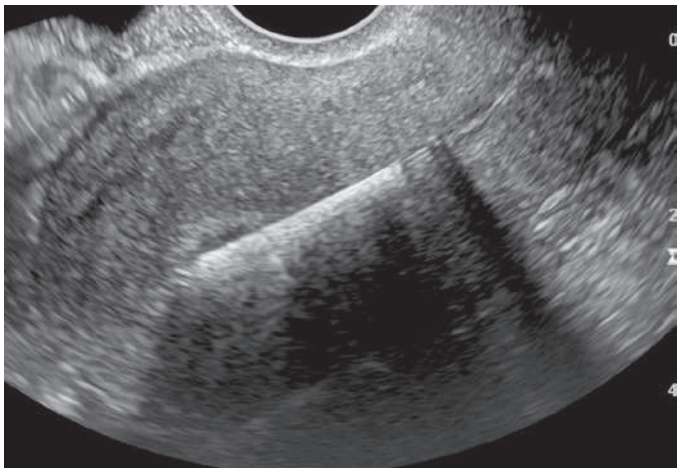

FIG. A.7 Shadowing From an Intrauterine Device.[4] (See Chapter 15, Fig. 15.25A.)

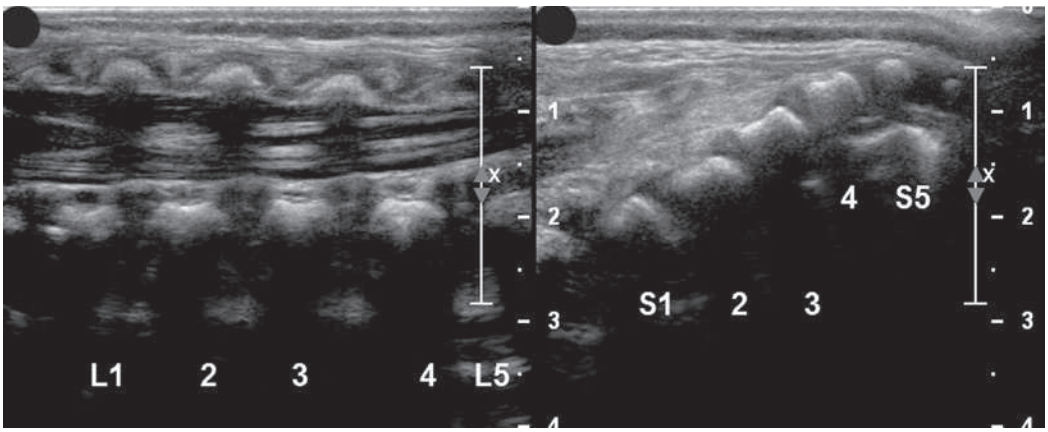

FIG. A.8 Shadowing. Coned down view of distal neonatal spine shows **shadowing** from vertebral bodies that interrupt the linear appearance of the nerve roots.[5] (See Chapter 49, Fig. 49.3.)

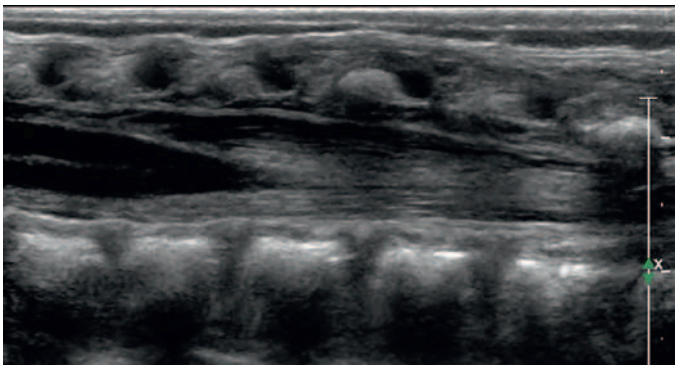
Click here to see real-time cine clip of showing in region of cauda equina (Video A.4).[5]



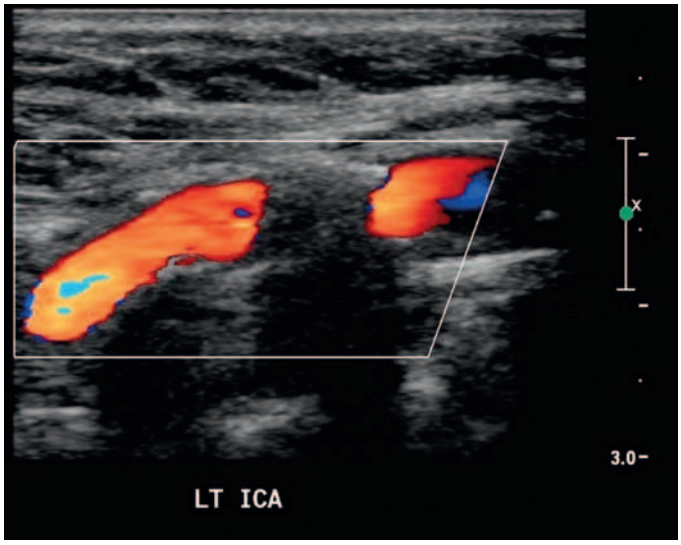


FIG. A.9 Shadowing. Shadowing from dense plaque prevents assessment of color flow in that region. Note that there must be flow present because similar color is visualized before and after the shadow.[6] (See Chapter 26, Fig. 26.8.)

Edge shadowing is caused by excessive refraction and commonly occurs from the edges vessels, cystic structures, and bones.

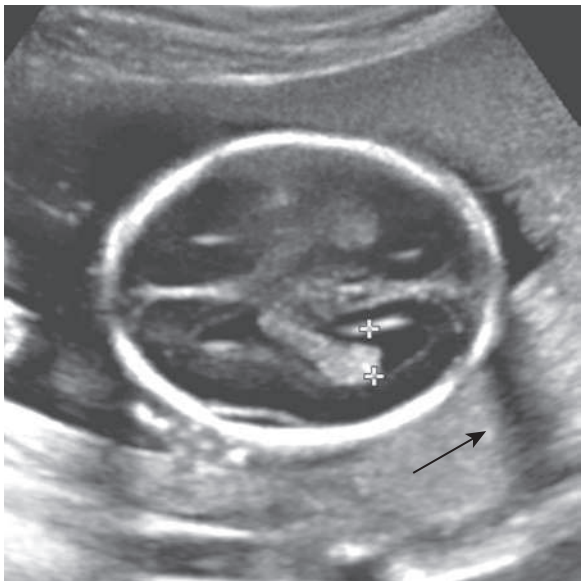

FIG. A.10 Edge Shadowing. Note the **edge shadowing** artifact behind the posterior aspect of the fetal skull. The beam bends at curved surface and loses intensity, producing a shadow *(arrow)*.[7] (See Chapter 34, Fig. 34.3.)

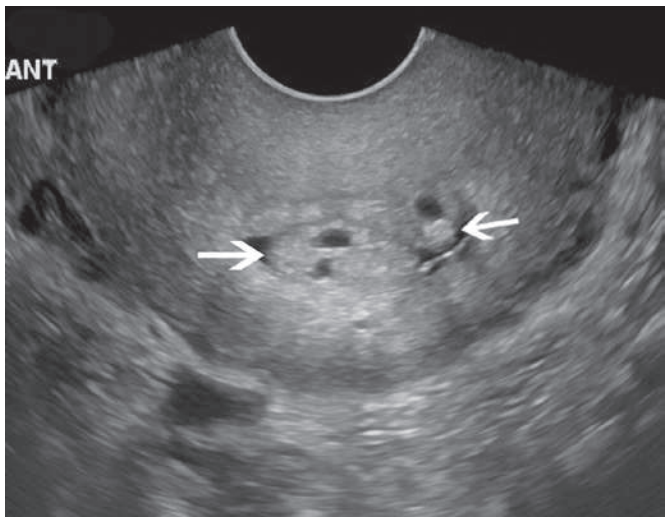

FIG. A.11 Edge Shadowing 2. Endometrial polyp shows both **through transmission** behind the cystic spaces and **edge shadowing** at the margins of the cysts.[4] (See Chapter 15, Fig. 15.14B.)

Increased Through Transmission

Increased through transmission occurs when an object (such as a cyst) attenuates the sound waves less than the surrounding tissues.

Click here to an explanatory video of **increased through transmission** (Video A.5).

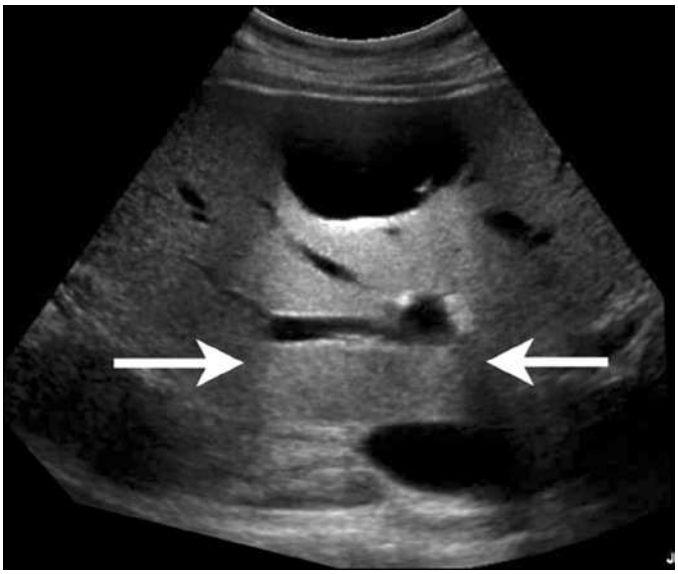

FIG. A.13 Increased Through Transmission. The hepatic parenchyma distal to the cysts is falsely displayed as increased in echogenicity *(arrows)* secondary to increased through-transmission artifact.

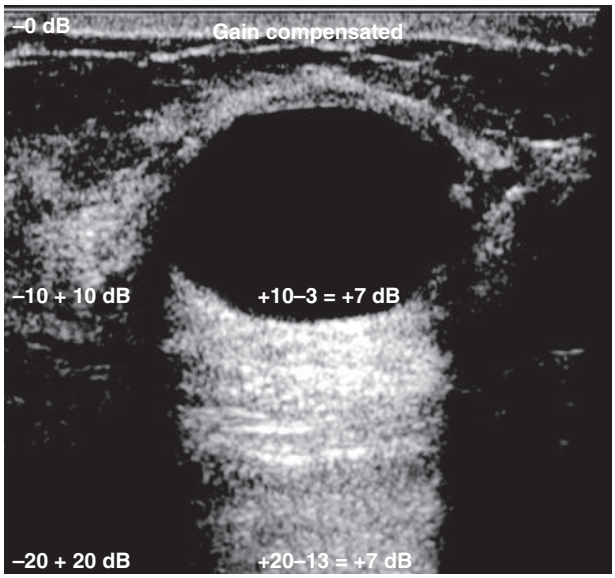

FIG. A.12 Increased Through Transmission. The cyst attenuates 7 dB less than the normal tissue, and time gain curve correction for normal tissue results in overamplification of the signals deep to the cyst, producing **increased through transmission** of these tissues.[2] (See Chapter 1, Fig. 1.31C.)

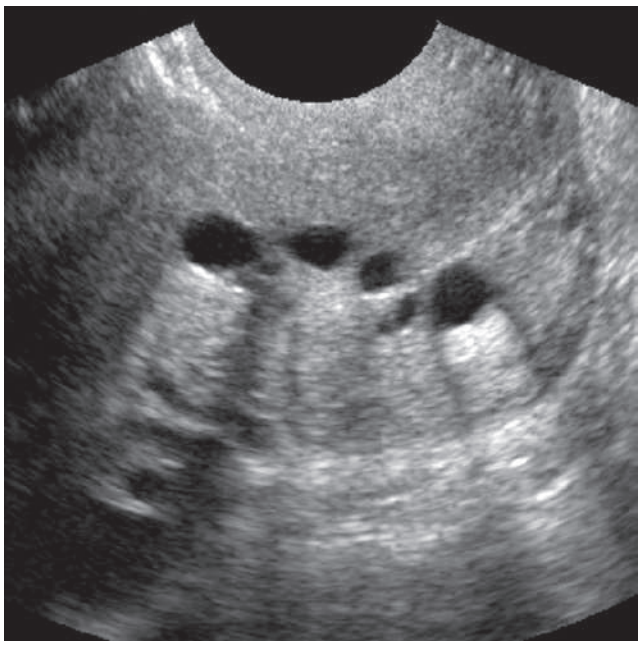

FIG. A.14 Increased Through Transmission. Nabothian cysts show both **increased through transmission** behind the cysts and **edge shadowing** at the margins of the cysts.[4] (See Chapter 15, Fig. 15.7C.)

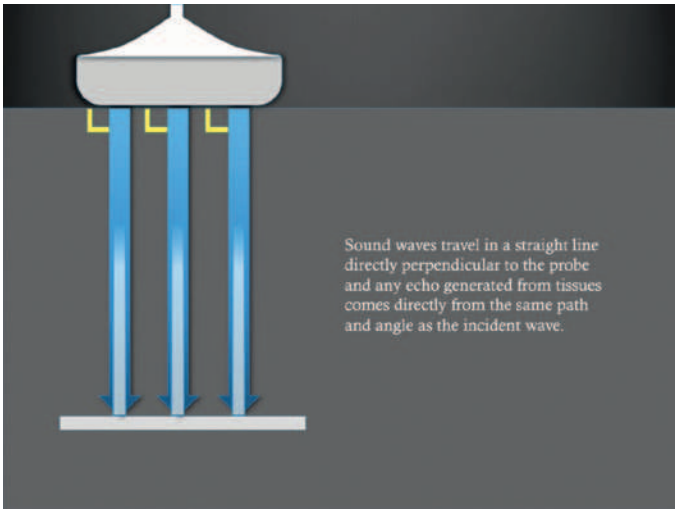
PATH OF SOUND-RELATED ARTIFACTS

In mapping a returning echo onto the generated image, an assumption is made that it originated from the same part of the transducer from which it was produced. Also, an assumption is made that the echo is the result of a single reflection. The depth of the reflector is calculated based on the time it took for the sound wave to travel from the transducer to the reflector and back, assuming a single reflection. When these assumptions do not hold, various types of artifacts occur.

Click here to see an explanatory video of **path of sound assumption** (Video A.6).



Mirror Image Artifact

A mirror image artifact is created when the primary beam encounters a highly reflective surface that acts like a mirror. The reflected echoes then encounter other reflectors and bounce back onto the mirror before being directed to the transducer. The result is artifactually inverted projection of the reflectors deeper to the surface of the mirror. The image is displayed deeper because of the longer path of the reflected sound. If the mirror image artifact causes confusion, it can be decreased or eliminated by moving the transducer to center it on the region of interest and/or placing the focal zone at the level of interest in the real structure.

Click here to see an explanatory video of **mirror image artifact** (Video A.7).

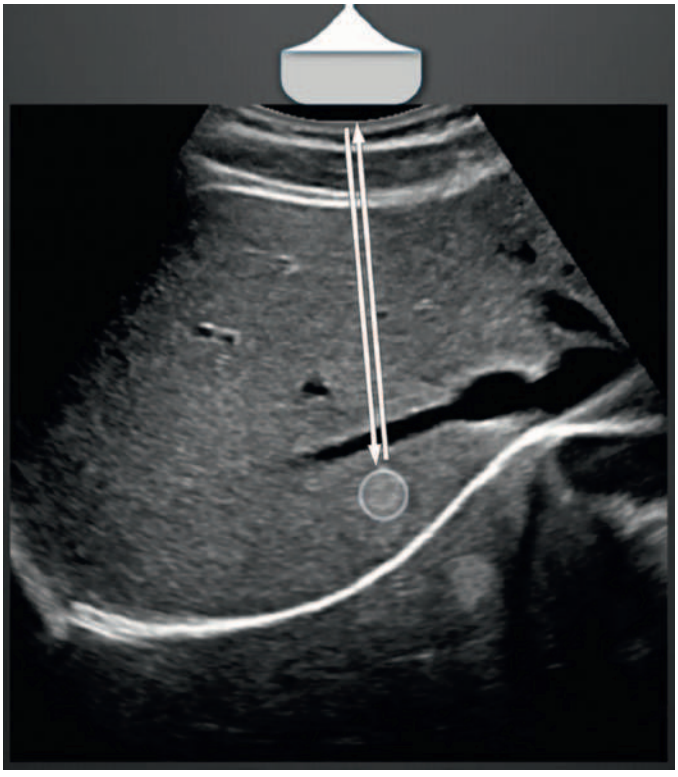


FIG. A.15 Mirror Image. Picture of reflection in water—similar to mirror image artifact.

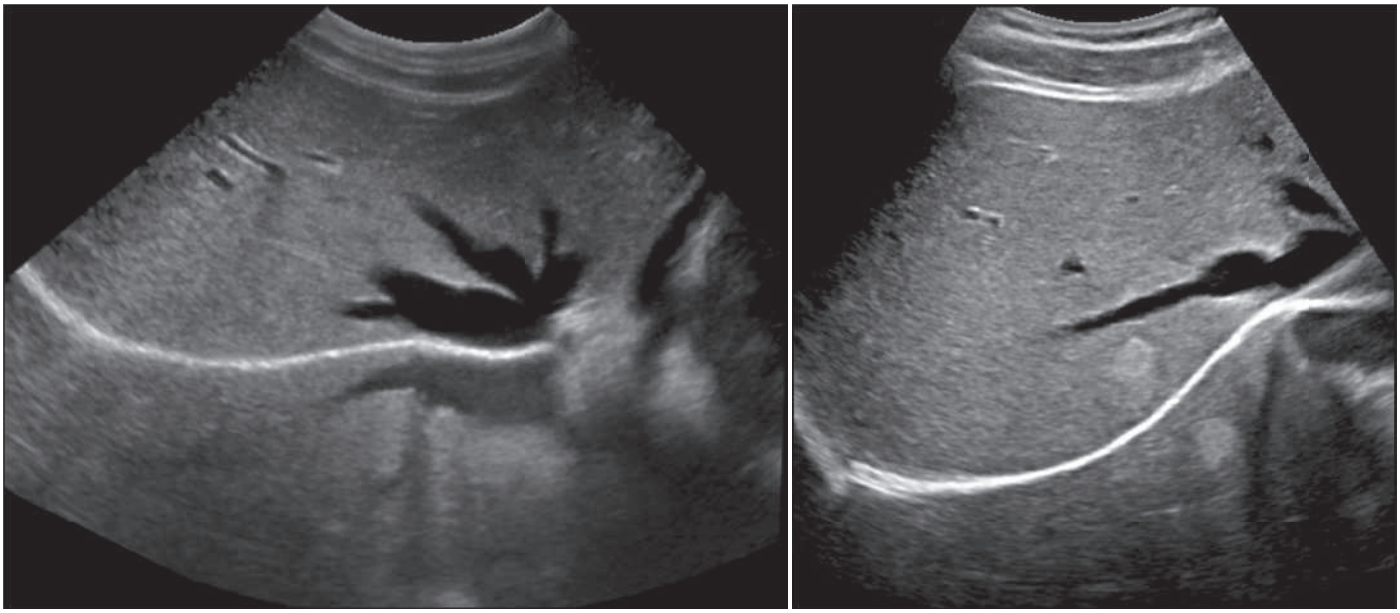

FIG. A.16 Mirror Image Artifact. Soft tissue–gas interfaces, such as the diaphragm, are excellent reflectors of the sound beam owing to the large difference in the acoustic impedance between the two materials. Therefore hepatic structures are frequently seen mirrored beyond the diaphragm onto the lungs. These two figures show liver parenchyma, hepatic veins in part A, and a hepatic hemangioma in part B all inversely projected onto lung.

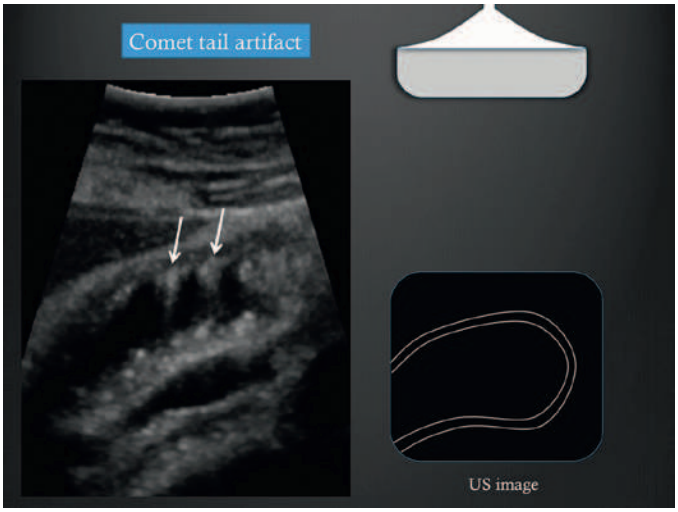
Comet-Tail Artifact

Comet-tail artifact is a type of reverberation artifact.[8] The repetitive reflections occur within very small structures, such as tiny cysts in the case of von Meyenburg complexes and tiny crypts in the wall of the gallbladder in the case of adenomyomatosis. Accordingly, the reverberated echoes may not be individually visible. The tapered, comet-tail appearance is due to the decreasing amplitude of each reverberation as a result of beam attenuation.

Click here to see the explanatory video of **comet-tail artifact** in adenomyomatosis (Video A.8).



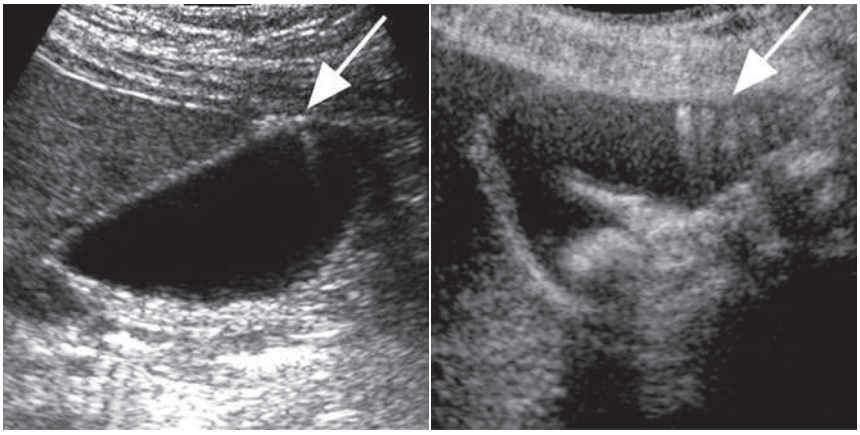


FIG. A.17 Comet-Tail Artifact in Association With Adenomyomatosis. This is felt to be due to cholesterol crystals within the prominent Rokitansky-Aschoff sinuses.[3] (See Chapter 6, Fig. 6.45.)

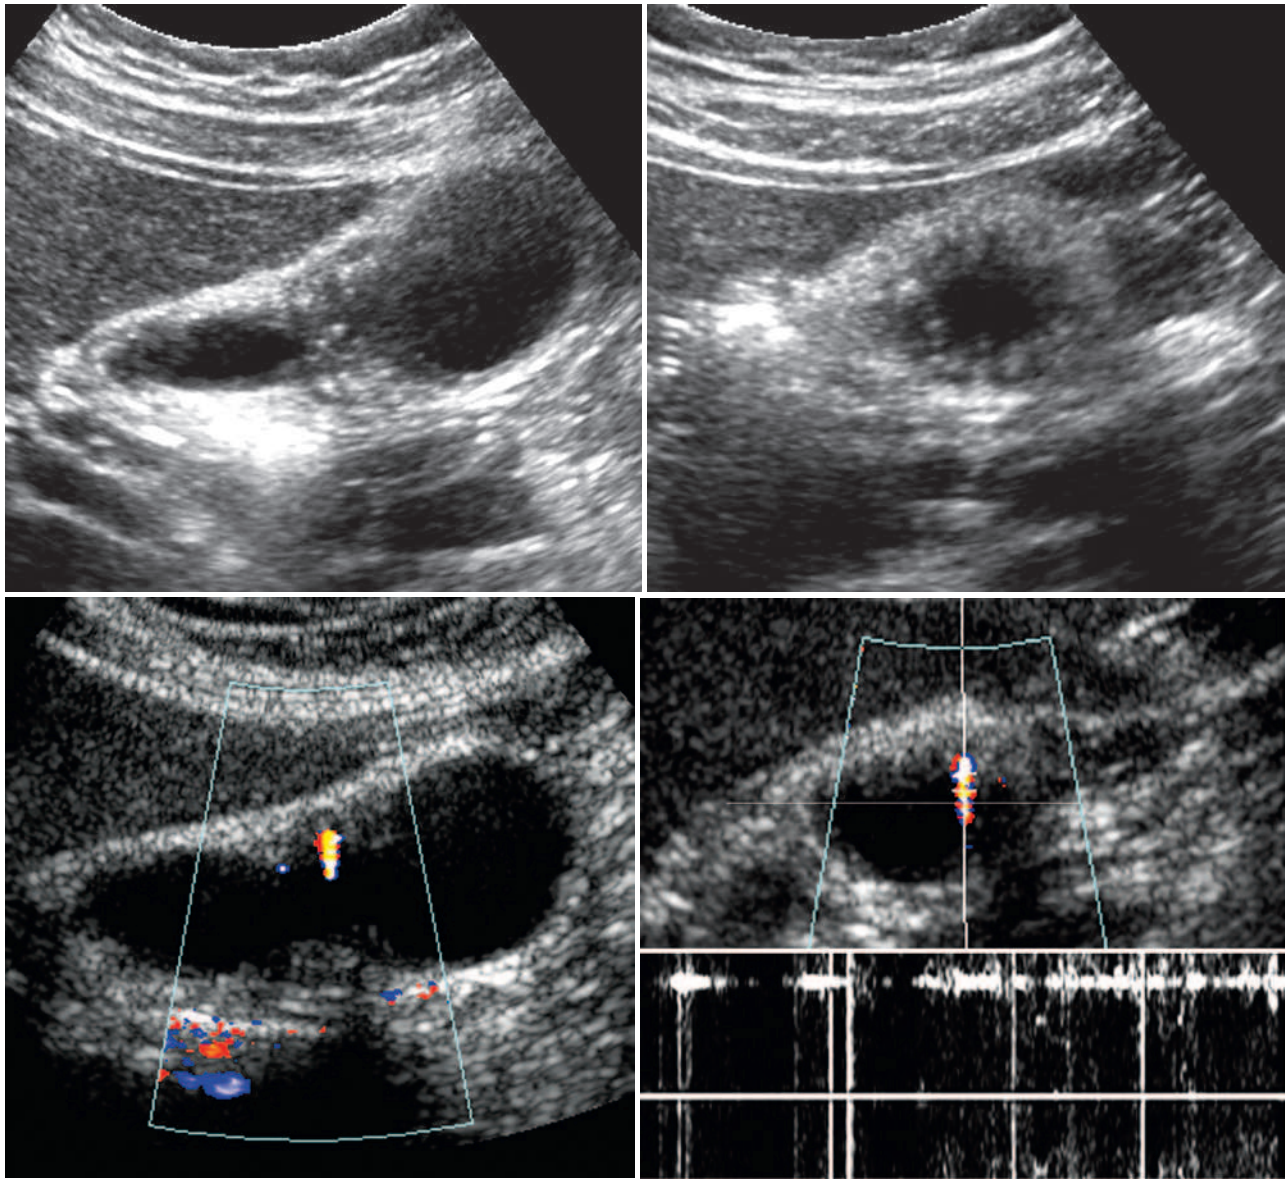

FIG. A.18 Comet-Tail Artifact. On color and spectral Doppler this can look like a twinkle artifact, but it is a color representation of the comet-tail. (See section on color Doppler artifacts for description of the twinkling.[3]) (See Chapter 6, Fig. 6.46.)

FIG. A.19 Adenomyomatosis and Comet-Tail Artifact.

FIG. A.21 Colloid Cyst in Thyroid Gland With Characteristic Comet-Tail Artifact *(Arrow).*[10] (See Chapter 19, Fig. 19.10A.)

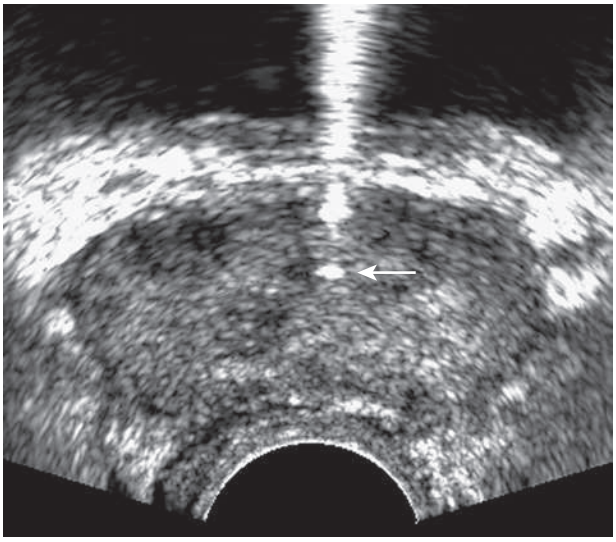

FIG. A.22 Strong Comet-Tail Artifact Due to Fiducial Marker in Patient With Prostate Cancer.[11] (See Chapter 10, Fig. 10.13.)

Refraction

As sound moves between tissues with different propagation velocities, such as from muscle to fat, it changes its direction at their interface as a result of refraction. The physical properties of refraction are explained by Snell's law, as demonstrated in Figs. A.23[12] and A.24. The change in the direction of the sound waves results in violation of the assumption made by the ultrasound equipment that the incident and reflected waves travel in a straight line. Therefore, with refraction, structures insonated by the bent path of sound waves are artifactually translated to appear as if the sound waves had traveled along a straight path. If refraction is suspected, it can be minimized by increasing the scan angle so that sound waves travel perpendicular to the interface.

Click here to see an explanatory video of **refraction** from the anterior abdominal wall (Video A.10).

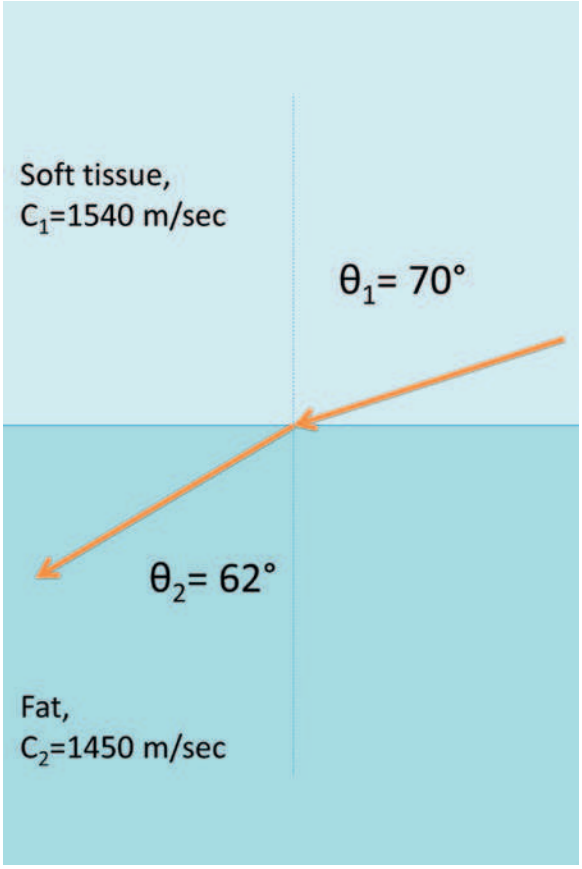

FIG. A.23 Refraction. Refraction can be due to tissues with different propagation velocities. When sound passes from soft tissue with propagation velocity (C_1) of 1540 m/sec to fat with a propagation velocity (C_2) of 1450 m/sec, there is a change in the direction of the sound wave because of refraction. The degree of change is related to the ratio of the propagating velocities of the media forming the interface ($\sin\theta_1/\sin\theta_2 = C_1/C_2$)[2]. Note that when the incident angle is changed to zero degrees—that is, the incident beam is perpendicular to the interface ($\theta_1 = 0°$)—the artifact disappears.

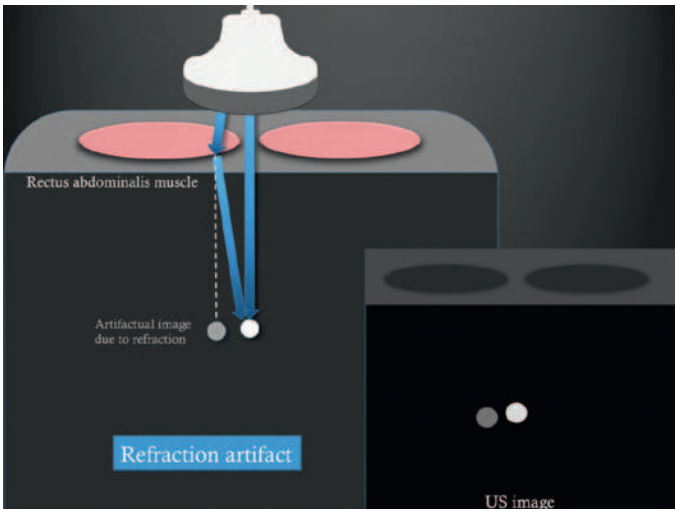

FIG. A.24 Refraction. Image of a straw in water. Refraction has occurred owing to the difference between air and water, causing an offset in the appearance of the straw. Note also how the straw appears larger in the water because of distortion of the image.

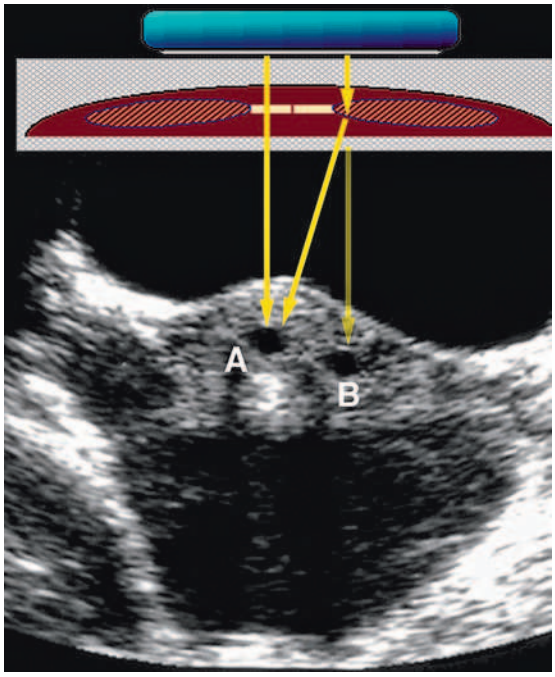

FIG. A.25 Refraction. This figure shows what appears to be a second gestational sac due to refraction artifact. This is sometimes called **"ghosting."**[2] (See Chapter 1, Fig. 1.8.)

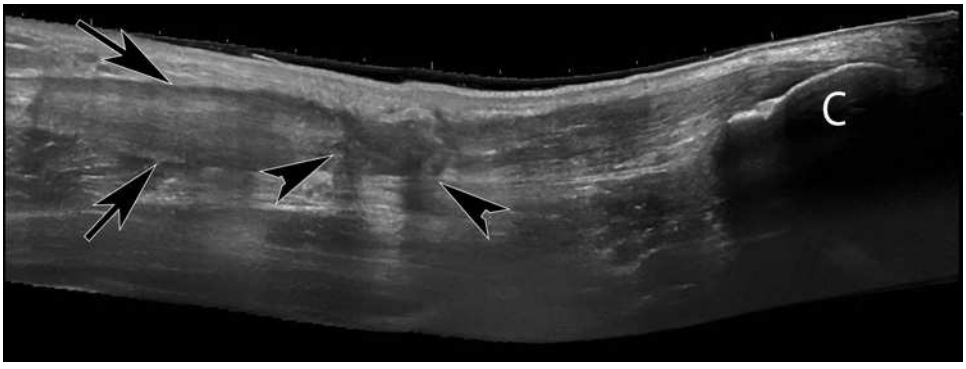

FIG. A.26 Refraction. A panoramic view of the Achilles tendon demonstrates a rupture within the midportion of the tendon. The proximal aspect of the tendon is chronically thickened and hypoechoic *(arrows)*. **Refraction artifact** *(arrowheads)* is caused by the interfaces between the ruptured tendon edges and hemorrhage. *C,* Calcaneus.[13] (See Chapter 23, Fig. 23.11.)

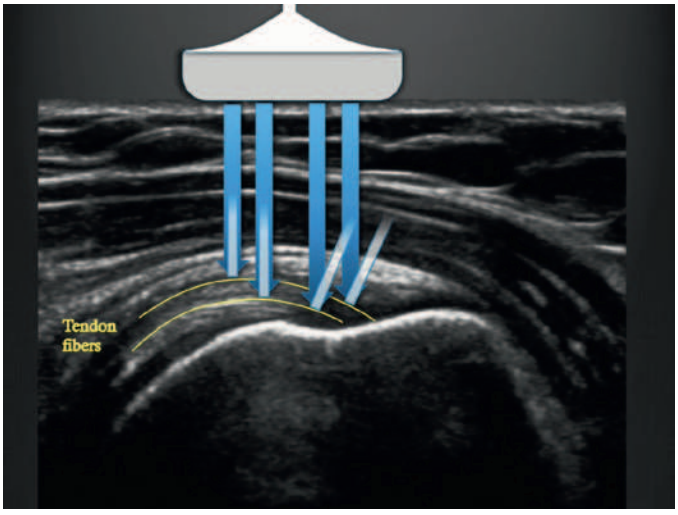
Anisotropy

Anisotropy is an artifact caused by structures that are composed of bundles of highly reflective fibers running parallel to each other, such as tendons and ligaments. If the sound beam hits the tendon or ligament fibers perpendicular to their length, it is reflected directly back, resulting in an echogenic appearance. But if the angle of insonation is not perpendicular to the tendon fibers, the beam is reflected away from the transducer, leading to the generation of an image with artifactual hypoechogenicity within the tendon.

Click here to see an explanatory video of **anisotropy** (Video A.11).



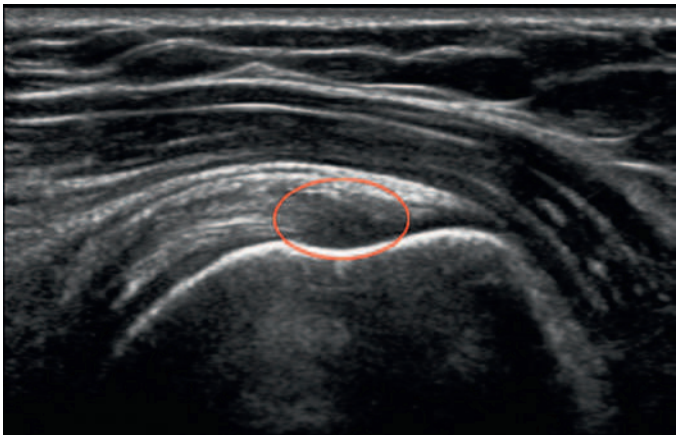


FIG. A.27 Anisotropy. The insertion of supraspinatus tendon artifactually appears hypoechoic due to anisotropy.

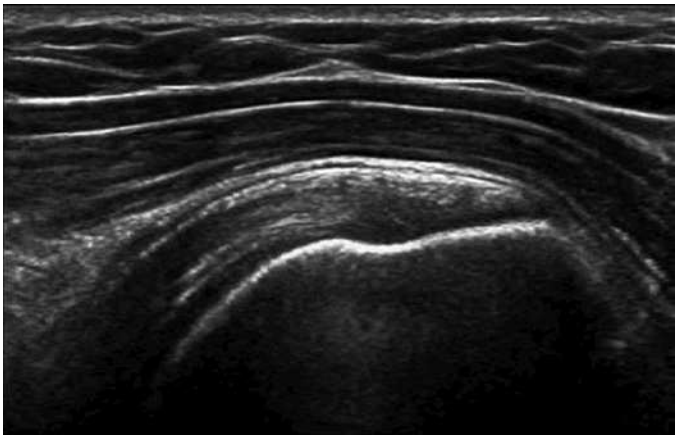
Click here for video of real-time scanning of **anisotropy** at supraspinatus insertion (Video A.12).



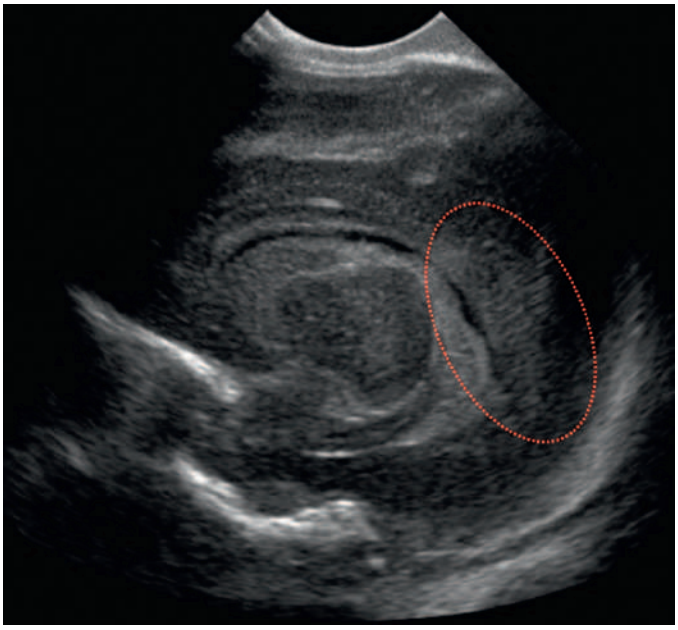


FIG. A.28 Anisotropy. The peritrigonal region of the white matter *(ellipse)* appears relatively echogenic, also called "peritrigonal blush." This **anisotropic effect** artifact occurs because in the trigone region, the parallel white matter fibers run perpendicular to the incident sound beam, causing increased reflection.[14] The artifact is visible only in the region of the trigone when the anterior fontanelle is used as a scanning window.

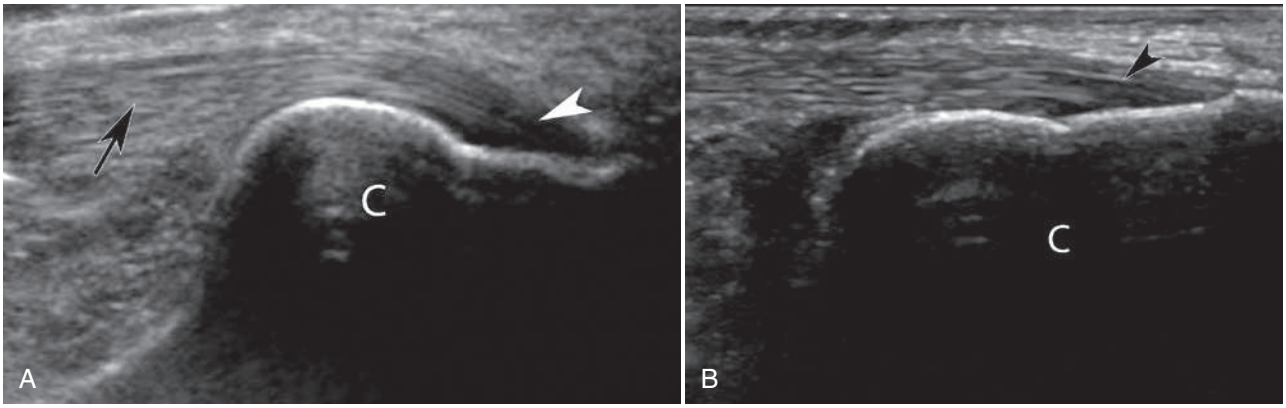

FIG. A.29 Anisotropy. (A) In this long-axis scan of the Achilles insertion on the calcaneus, the proximal portion of the imaged tendon demonstrates a normal fibrillar appearance *(arrow),* whereas the distal tendon insertion is hypoechoic *(arrowhead). (B)* When the transducer is angled 90 degrees to the distal tendon insertion, the tendon then becomes fibrillar and is normal in appearance *(arrowhead). C,* Calcaneus.[13] (See Chapter 23, Fig. 23.8.)

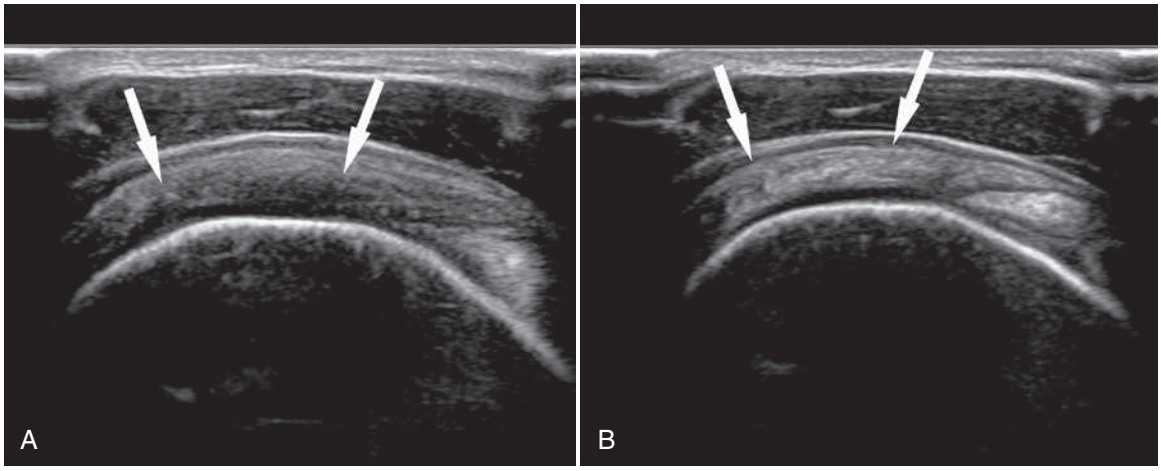

FIG. A.30 Anisotropy. Short-axis images of the supraspinatus tendon. **(A)** Artifactual hypoechogenicity of the supraspinatus tendon *(arrows)* may simulate tendinosis or tear. **(B)** Correction of angle of insonation to be perpendicular to the tendon permits visualization of the normal intact tendon.[15] (See Chapter 24, Fig. 24.30.)

Reverberation Artifact

Reverberation artifact occurs when a strong reflector runs perpendicular to the direction of the beam (i.e., parallel to the probe surface), usually close to the skin surface.[1] The sound waves may then get partially "trapped" between the reflector and skin, reverberating back and forth and causing the appearance of multiple regular lines when some of the waves eventually reach the probe. Often the reflectors are the skin and subcutaneous fascia (see Fig. A.31). Reverberation artifact is angle dependent, so moving the transducer slightly will cause a decrease in or elimination of the artifact. Reverberation can be helpful during biopsies, to see a needle. If it is distracting, try changing the angle of insonation, using a different window, or decreasing the gain.

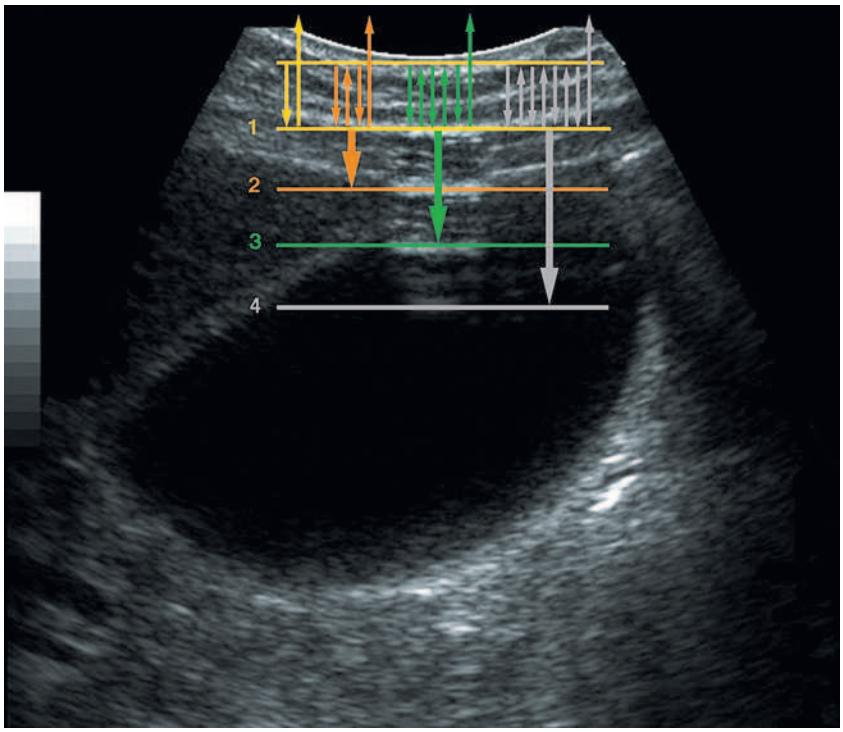

FIG. A.31 Reverberation Artifact. Reverberation artifacts arise when the ultrasound signal reflects repeatedly between highly reflective interfaces near the transducer, resulting in delayed echo return to the transducer. This appears in the image as a series of regularly spaced echoes at increasing depth.[2] (See Chapter 1, Fig. 1.27.)

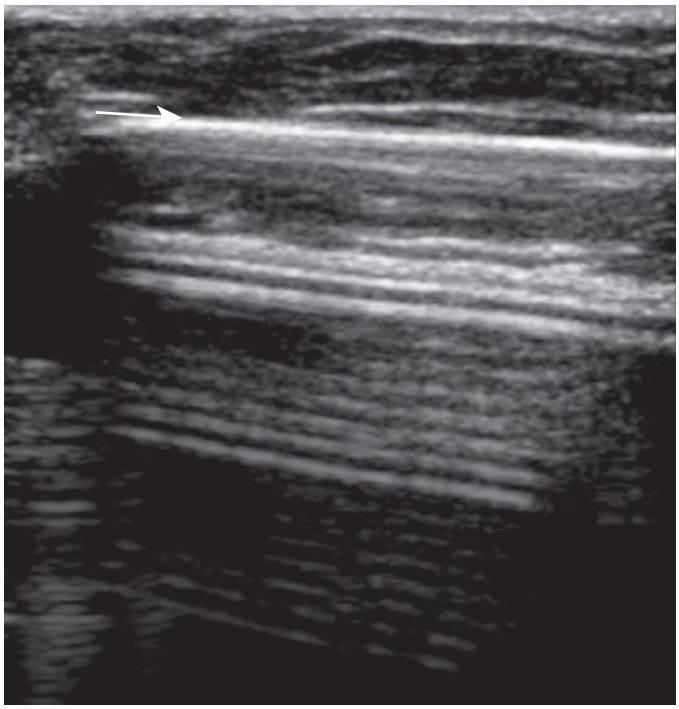

FIG. A.32 Mirror Image and Reverberation Artifacts Behind a Pacemaker. The highly reflective and mirrorlike surface of the pacemaker *(arrow)* results in repeated bouncing of sound wave among the probe surface, pacemaker, and skin.

For reverberation due to gas, see next section.

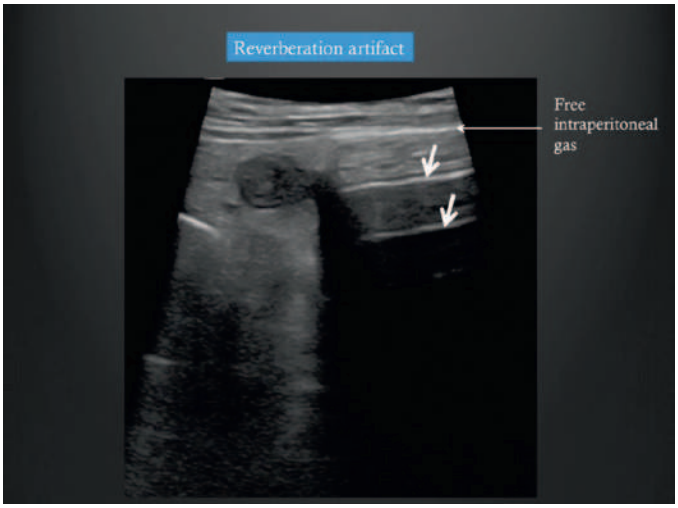
GAS-RELATED ARTIFACTS

Several physical properties of gases lead to unique artifacts in ultrasound that help identify gas but also may hinder visualization of other organs. These properties include the very dissimilar acoustic impedance of gas compared with soft tissues, making them highly reflective surfaces. The varied and ever-changing shape of gas in the body, including foam, leads to variability of its appearance even in the same field. The very low density of gases makes them quite compressible, and they can undergo resonant oscillation in response to sound waves, leading to amplification of echoes. These properties result in three distinct artifacts, which can be present at the same time: **reverberation, ring-down,** and **dirty shadowing.**[16]

Reverberation Artifact

The physical pressure of the probe on the soft tissues, such as the abdominal wall, flattens their shape in the near field, making them perpendicular to the surface of the probe and the incident sound beam. Because gases conform to the shape of their containers, they too will form a linear and perpendicular interface to the incident sound beam, especially when in the form of a large bubble. The highly reflective gas interface will act like a mirror, resulting in reverberation artifacts.

Click here to see an explanatory video of **reverberation artifact due to gas** (Video A.13).



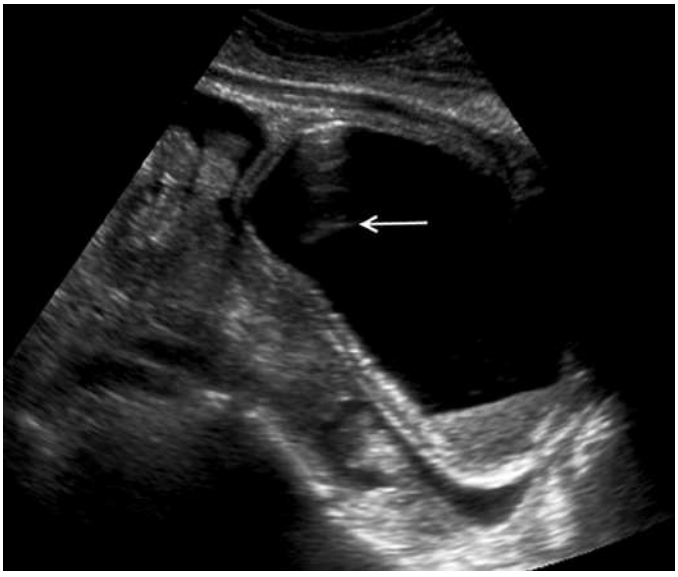


FIG. A.33 Reverberation Artifact. Small amount of gas within the bladder is recognizable by the reverberation artifact *(arrow)*.

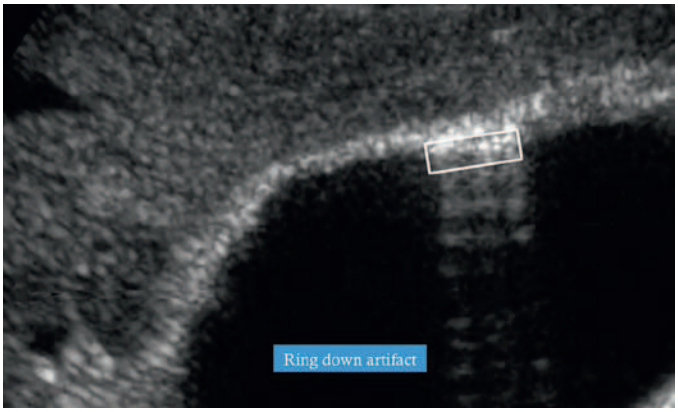
Ring-Down Artifact

Ring-down artifact occurs when the ultrasound waves cause oscillation within fluid trapped by a tetrahedron of gas bubbles.[17] These oscillations create a continuous sound wave that is transmitted back to the transducer. What will be seen is a line or series of parallel bands extending posterior to a gas collection. Although this has the appearance of reverberation artifact, it actually has a different mechanism.

Click here to see an explanatory video of **ring-down artifact** (Video A.14).



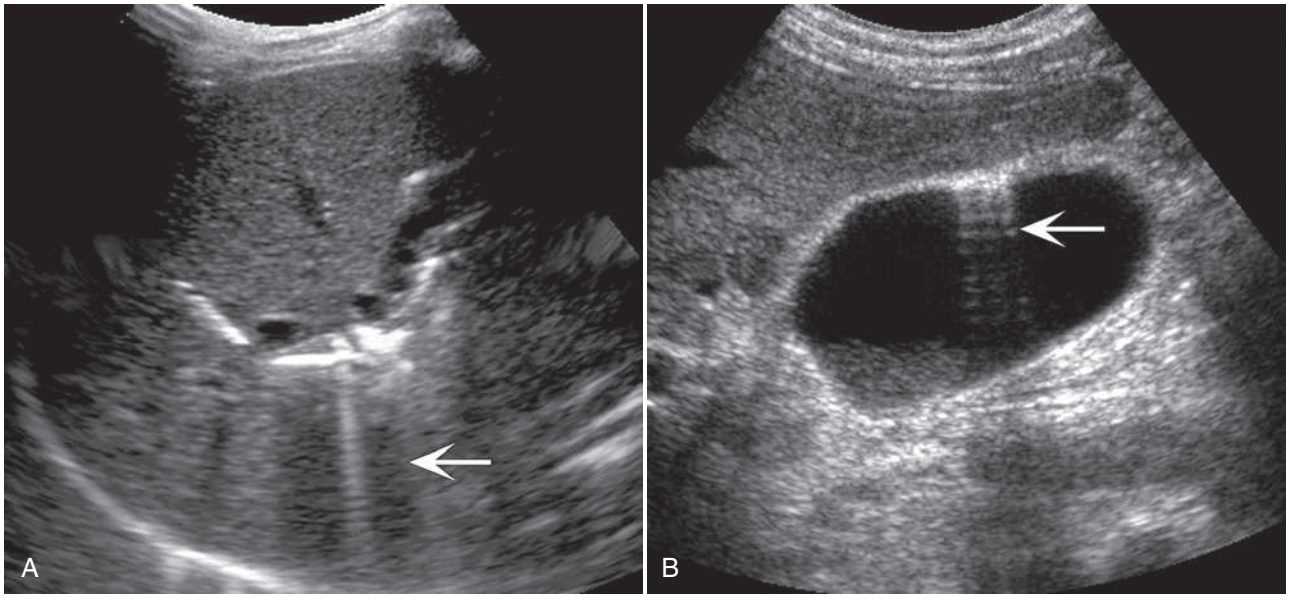


FIG. A.34 Ring-Down Artifact. Pneumobilia causing **ring-down artifact** in the biliary tree **(A)** and gallbladder **(B).**[3] (See Chapter 6, Fig. 6.13.)

Click here to see a video clip of **ring-down artifact** in peripheral ducts of the liver (Video A.15).

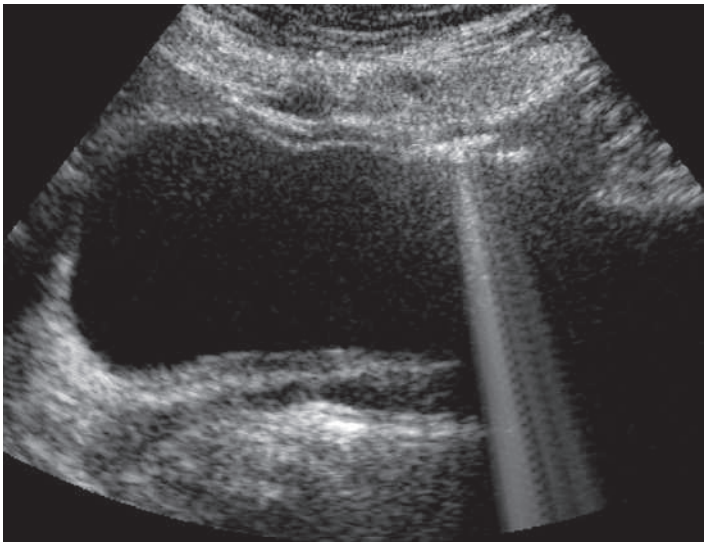

FIG. A.35 Ring-Down Artifact. Iatrogenic air in the bladder introduced at cystoscopy appears as a nondependent bright region with **ring-down artifact.**[18] (See Chapter 9, Fig. 9.36.)

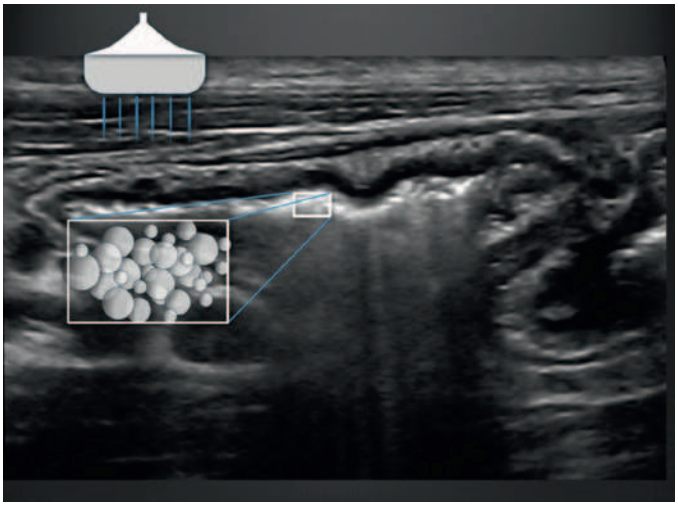
Dirty Shadowing Artifact

Dirty shadowing results from a combination of reflection, reverberation, and ring-down artifacts arising from multiple variably sized bubbles in foam.[16]

Click here to see an explanatory video of **dirty shadowing** artifact (Video A.16).



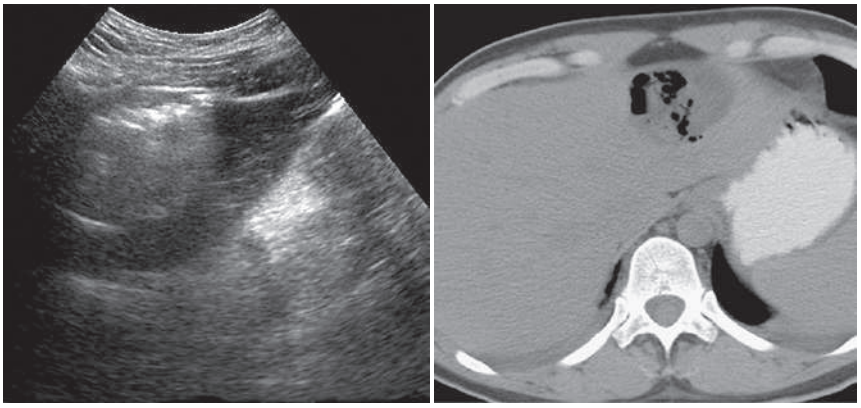


FIG. A.36 Dirty Shadowing. Sonographic image of the liver shows gas in liver mass with reverberation artifact filling the cavity. See comparison computed tomography scan.[9] (See Fig. 4.19.)

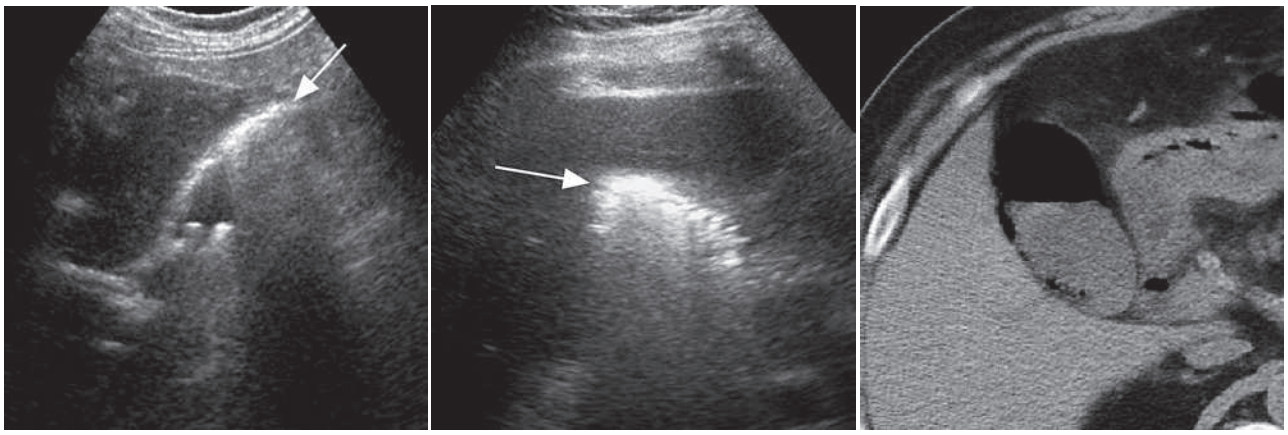

FIG. A.37 Dirty Shadowing Posterior to Emphysematous Cholecystitis.[3] (See Chapter 6, Fig. 6.40.)

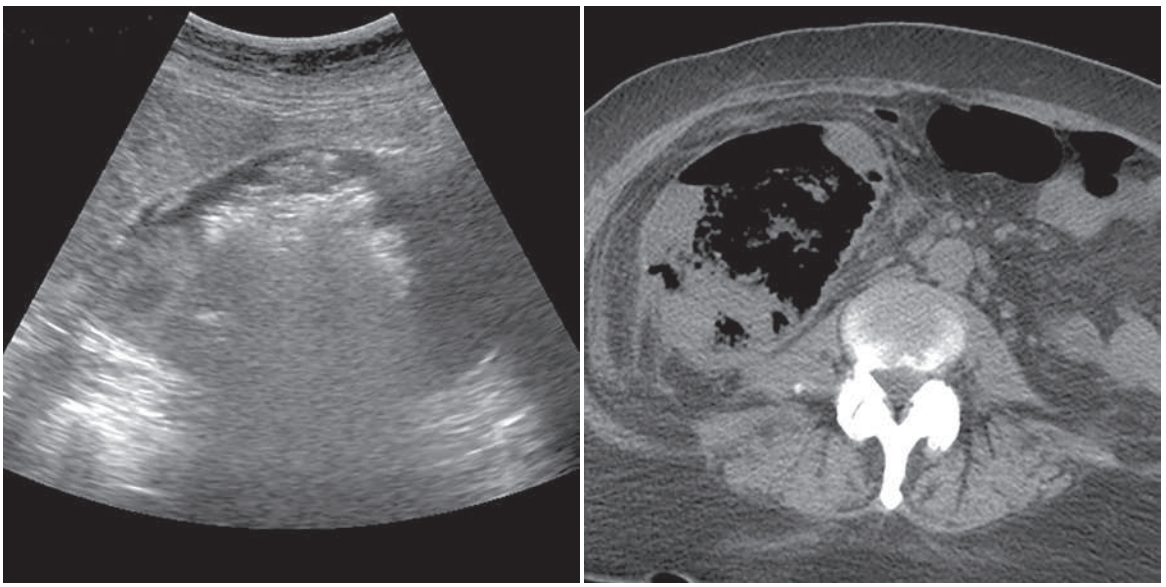

FIG. A.38 Dirty Shadowing in the Kidney Due to Emphysematous Pyelonephritis.[18] (See Chapter 9, Fig. 9.22.)

BEAM PROFILE–RELATED ARTIFACTS

Frequently echoes are seen within what should be an anechoic structure. This can occur as a result of side lobe or grating lobe artifacts in which information from the side of the image projects centrally, or because of partial volume averaging (owing to the thickness of the ultrasound beam (resolution in the Z plane).

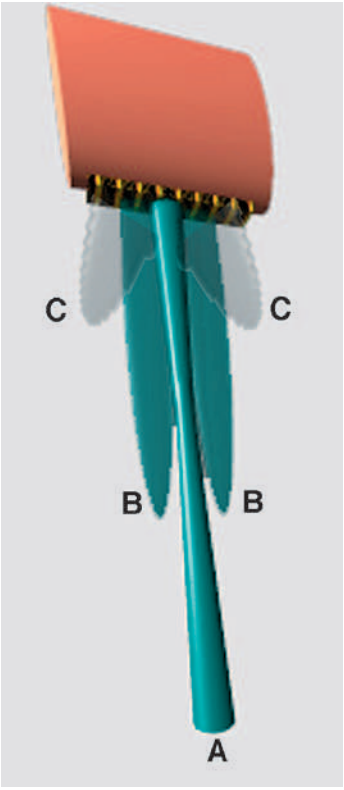

FIG. A.39 The ultrasound beam is not a narrow straight line but has a complex profile that varies depending on the type and shape of the transducer. Although most of the energy generated by a transducer is emitted in a beam along the central axis of the transducer *(A)*, some energy is also emitted at the periphery of the primary beam (*B* and *C*). These are called "side lobes" *(B)* or "grating lobes" *(C)* and are lower in intensity than the primary beam. Side lobes or grating lobes may interact with strong reflectors that lie outside of the scan plane and produce artifacts that are displayed in the ultrasound image.[2] They are more evident when the misplaced echoes overlap an expected anechoic structure. (See Chapter 1, Fig. 1.28.)

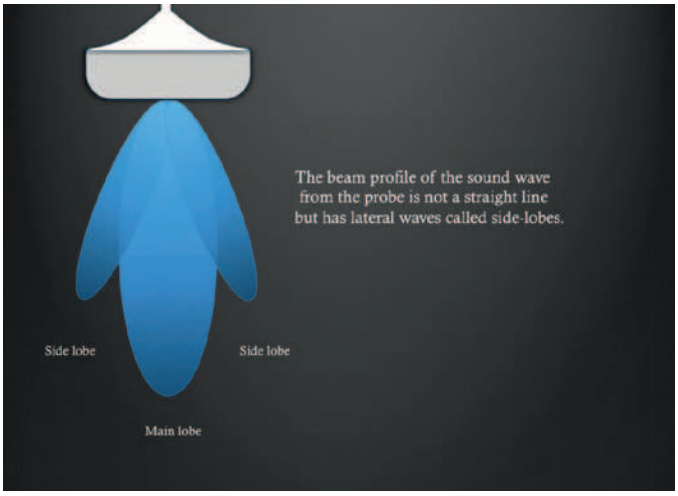
Side Lobe and Grating Lobe Artifacts

Click here to see an explanatory video of **side lobe artifact** (Video A.17).



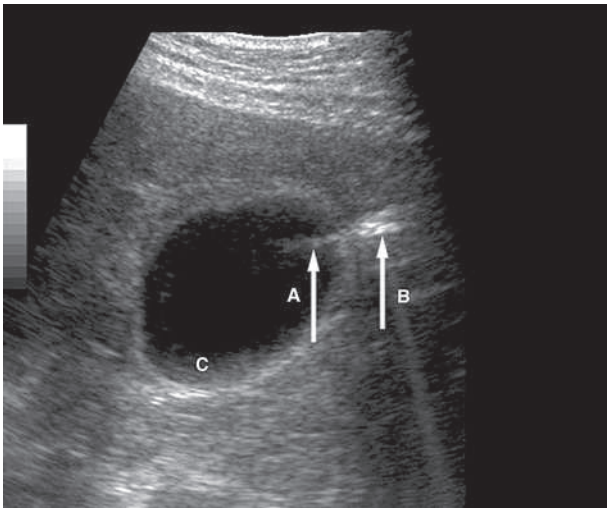


FIG. A.40 Side or Grating Lobe 1. Transverse image of the gallbladder reveals a bright internal echo *(A)* that suggests a band or septum within the gallbladder. This is a side lobe artifact related to the presence of a strong out-of-plane reflector *(B)* medial to the gallbladder. The low-level echoes in the dependent portion of the gallbladder *(C)* are also artifactual and are caused by the same phenomenon. Side lobe and slice thickness artifacts are of clinical importance because they may create the impression of debris in fluid-filled structures.[2] (See Chapter 1, Fig. 1.29.)

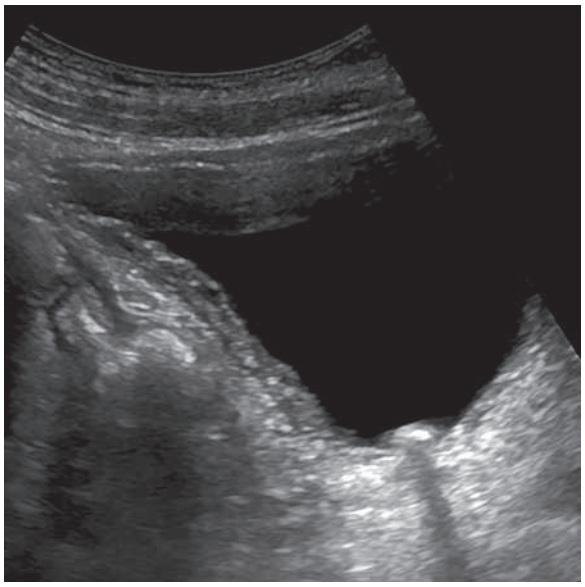

FIG. A.41 Side or Grating Lobe. In this patient with a ureterovesical junction stone there are echoes seen in the nondependent portion of the bladder. These are due to **grating lobe artifact,** wherein off-axis signal projects into the field of view.[18] Note also the **shadowing** behind the bladder stone.[18] (See Chapter 9, Fig. 9.43.)

Partial Volume Averaging

The ultrasound beam not only has a complex shape in the imaging plane but also has a real profile in the third dimension, called the "elevation plane" or "Z plane." The ultrasound image appears as a flat two-dimensional image, but the brightness of each pixel is representative of the average sum of all the echoes received within the thickness of the beam in the elevation plane. This results in echoes being projected in structures that should be anechoic.

Click here to see an explanatory video of **partial volume averaging** (Video A.18).

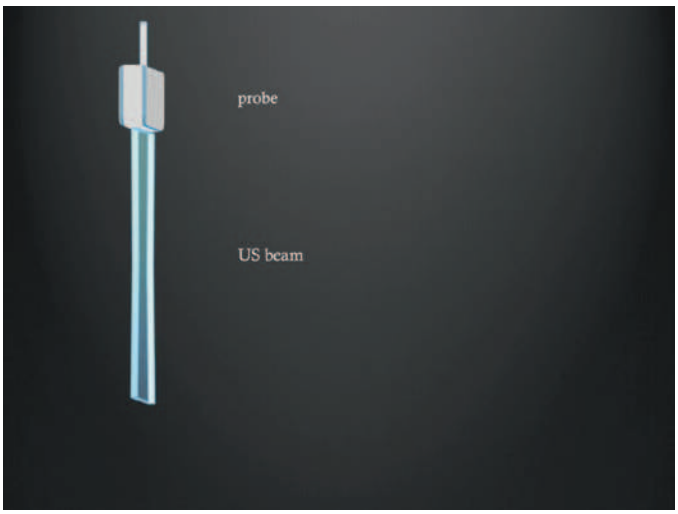

FIG. A.42 Partial Volume Averaging. The bladder wall is indistinct in region of this image. It is unclear if there are masses or if this is due to **grating lobe artifact** or **partial volume artifact** or both. Moving the patient or transducer to avoid bowel gas and putting the focal zone in the region in question should aid in evaluation. For the area closer to the patient's anterior abdominal wall, a higher-frequency transducer might be helpful.[18] (See Chapter 9, Fig. 9.57.)

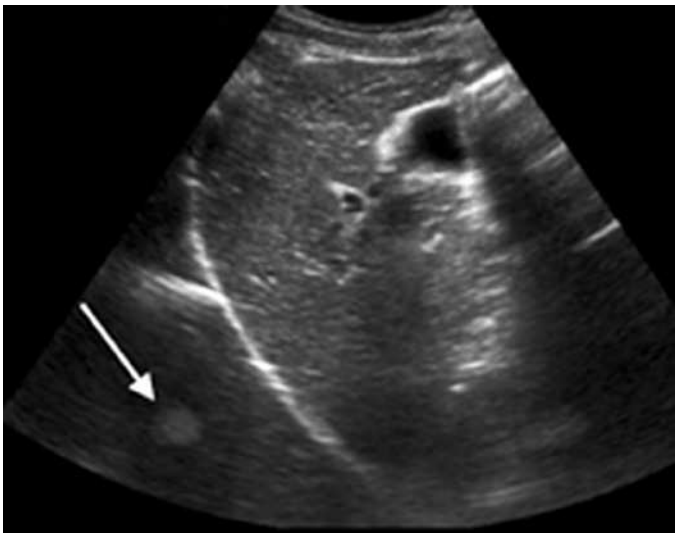

FIG. A.43 Partial Volume Averaging. A radiofrequency ablation zone present in the liver just outside the scanning plane is depicted onto the lungs through both partial volume averaging and mirror image artifacts.

DOPPLER IMAGING ARTIFACTS

The appearance of color Doppler signal is affected by several variables including color-write priority, gray-scale gain, and pulse repetition frequency. If the color gain is too low, flow might not be visualized. If the gain is too high, artifactual flow may be seen in adjacent soft tissues, and thrombus within the vessel might be missed.

Loss or Distortion of Doppler Information

Incorrect gain, wall-filter, and velocity scale can all lead to loss or distortion of Doppler signal. A rule of thumb for gain adjustment in Doppler imaging is to turn up the color gain until noise is encountered and then back off just until the noise clears from the image. In estimating frequency, the rule of thumb is to use a Doppler angle less than 60 degrees (but not 0). Wall filters eliminate low-frequency noise, but a high setting can lead to loss of signal. In general, wall filters should be kept at the lowest practical level, typically in the range of 50 to 100 Hz.

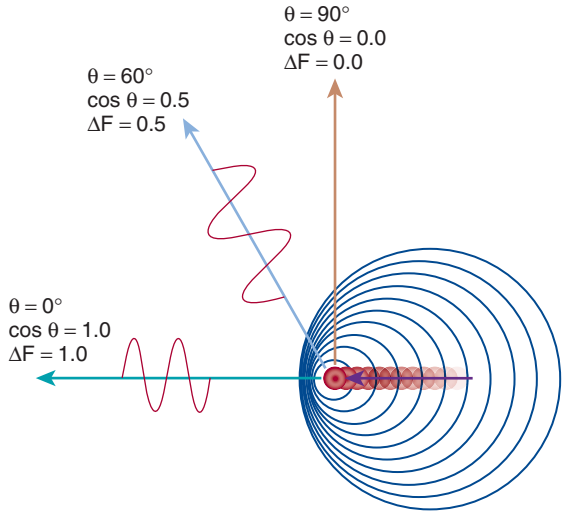

FIG. A.44 Effect of Doppler Angle on Frequency Shift. At an angle of 60 degrees, the detected frequency shift detected by the transducer is only 50% of the shift detected at an angle of 0 degrees. At 90 degrees, there is no relative movement of the target toward or away from the transducer, and no frequency shift is detected. The detected Doppler frequency shift is reduced in proportion to the cosine of the Doppler angle. Because the cosine of the angle changes rapidly at angles above 60 degrees, the use of Doppler angles of less than 60 degrees is recommended in making velocity estimates.[2] (See Chapter 1, Fig. 1.35.)

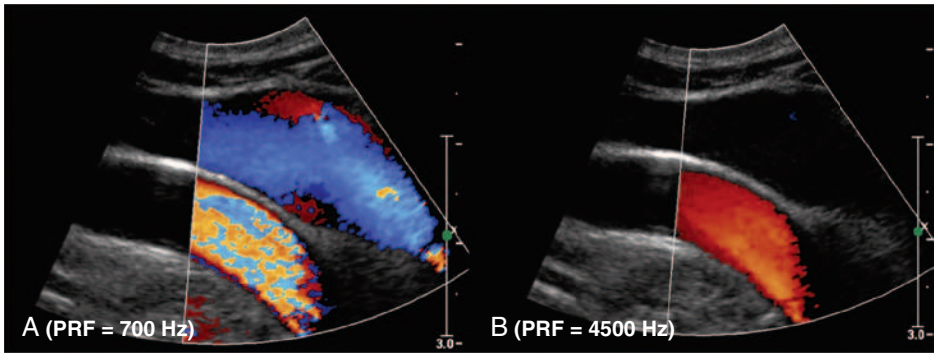

FIG. A.45 Artifactual Lack of Flow. Color Doppler image of a carotid artery and jugular vein. In **(A),** the pulse repetition frequency *(PRF)* is 700 Hz and there is aliasing in the carotid artery, but slow flow in the jugular vein is seen. In **(B),** the PRF is 4500 Hz, eliminating aliasing in the artery but also suppressing the display of the low Doppler frequencies in the internal jugular vein.[2] (See Chapter 1, Fig. 1.43.)

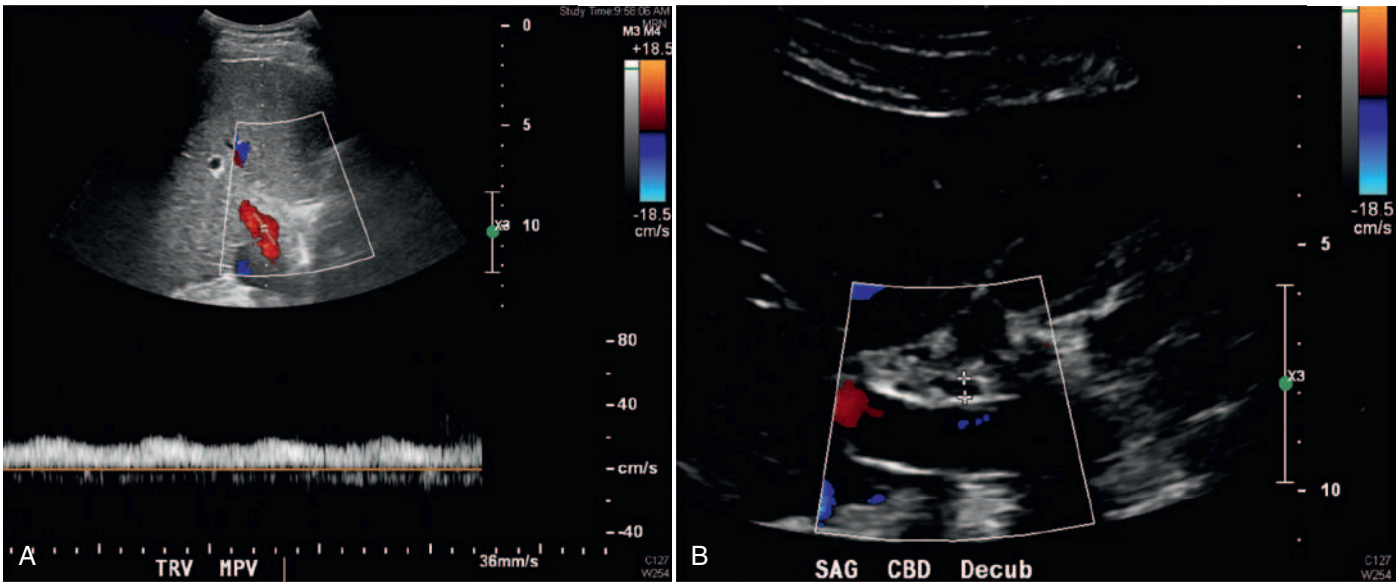

FIG. A.46 Artifactual Lack of Flow. (A) Color Doppler image shows flow in the portal vein. **(B)** When a color image is taken to assess the common duct, no flow is visible in the portal vein. Note the difference in overall gain in image **B.**

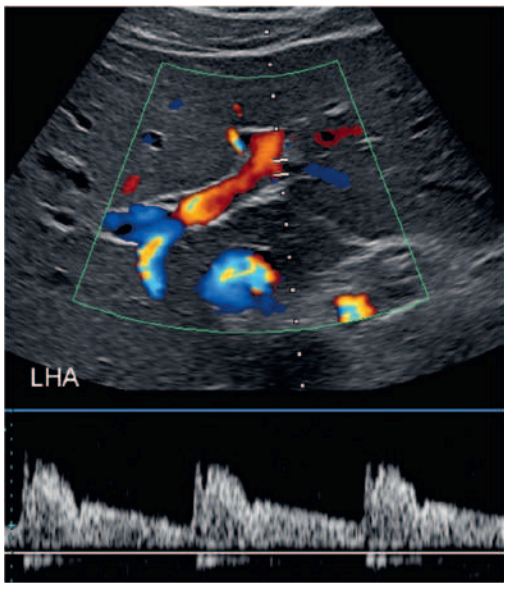

FIG. A.47 Color Direction. Shown in color is a portion of the portal venous system. Note how the flow direction appears to change in the region of branching, but this is merely a result of the orientation of flow with respect to the mid transducer. Note the aliasing in the posterior branch of the right portal vein. This is due to the curve of the vein and change in Doppler angle.[19] (See Chapter 51, Fig. 51.22.)

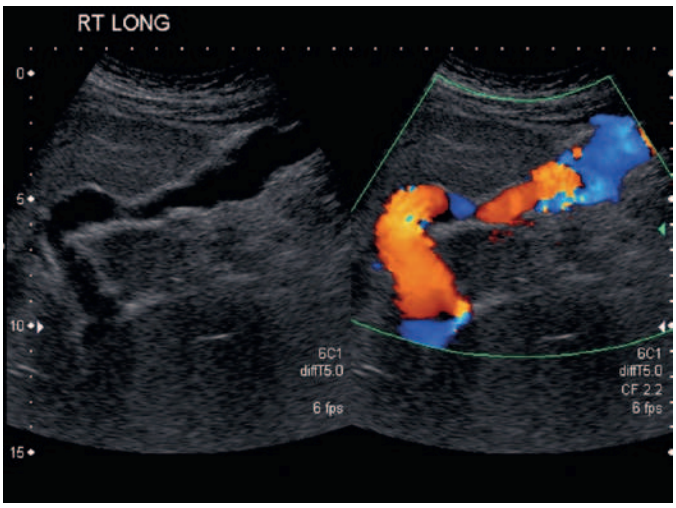

FIG. A.48 Color Direction as Shown in Recanalized Umbilical Vein. Flow on color Doppler will sometimes appear to change direction, but the flow needs to be assessed with respect to the transducer in order to determine if it is in the appropriate direction or not. In this example, transverse paramedian gray-scale and color Doppler sonograms show left lobe of liver in a child with cirrhosis and portal hypertension.[19] The recanalized umbilical vein is always flowing in relatively the same direction out of the liver, but at times, due to tortuosity, appears to change flow direction. Note that the flow changes from red (toward the transducer) to blue (away from the midpoint of the transducer), but at each interface there is a black region where the Doppler angle is 90. (See Chapter 51, Fig. 51.28.)

Artifactual Vascular Flow

The Doppler effect (shift) is not specific to vascular flow and occurs with movement of any reflector toward or away from the ultrasound beam. Fluid or solid tissue motion can mimic vascular flow. Transmitted pulsations, especially close to the heart or major arteries, can therefore result in artifactual appearance of flow within thrombosed veins or avascular areas. Artifactual vascular flow can also be visualized if the color gain is too high or the color-write priority is too high.

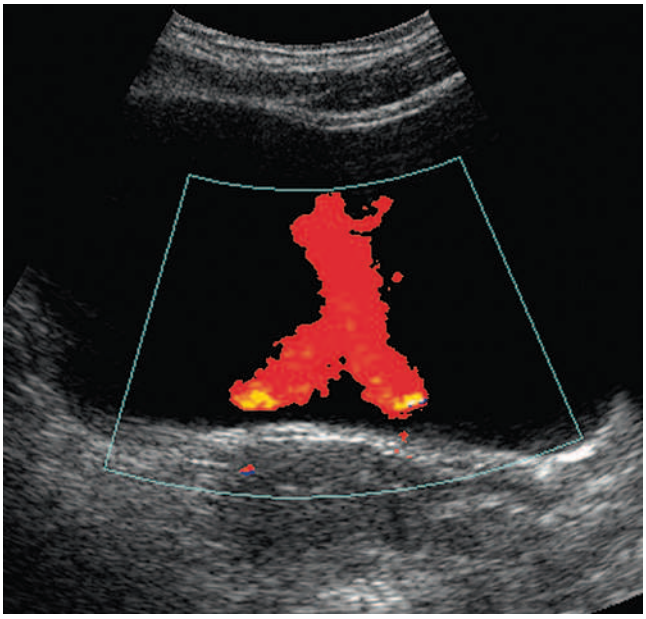

FIG. A.49 Artifactual Vascular Flow. Color Doppler jets in the bladder use color motion to indicate that there is flow from each ureteral orifice.[18] (See Chapter 9, Fig. 9.42A.)

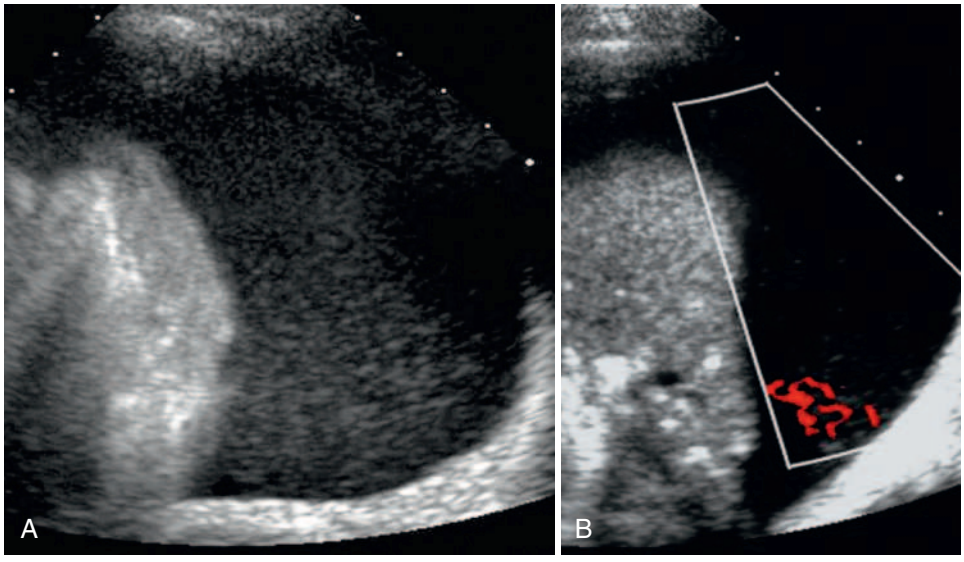

FIG. A.50 Artifactual Vascular Flow. Color flow Doppler signal in pleural fluid with debris. **(A)** Gray-scale sonogram shows left pleural fluid with much debris. **(B)** Color flow Doppler signal.[20] (See Chapter 50, Fig. 50.14.)

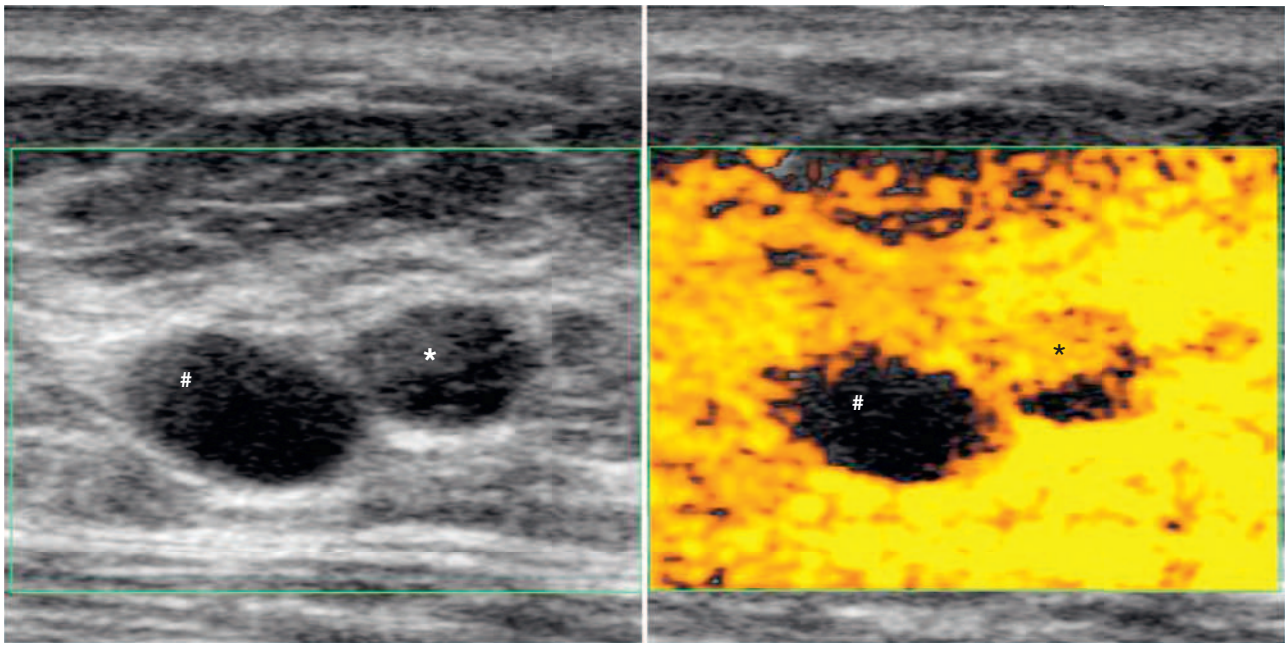

FIG. A.51 Artifactual Vascular Flow. Power Doppler ultrasound **vocal fremitus** can be used to distinguish a mural nodule from a fat-fluid level. The lipid layer is not attached to the cyst wall, so the fremitus artifact will not pass through it. On the other hand, true papillary lesions that are attached to the cyst wall will vibrate and transmit the fremitus artifact on power Doppler; having the patient hum in a deep voice creates a color artifact on power Doppler ultrasound.[21] (See Chapter 21, Fig. 21.26.)

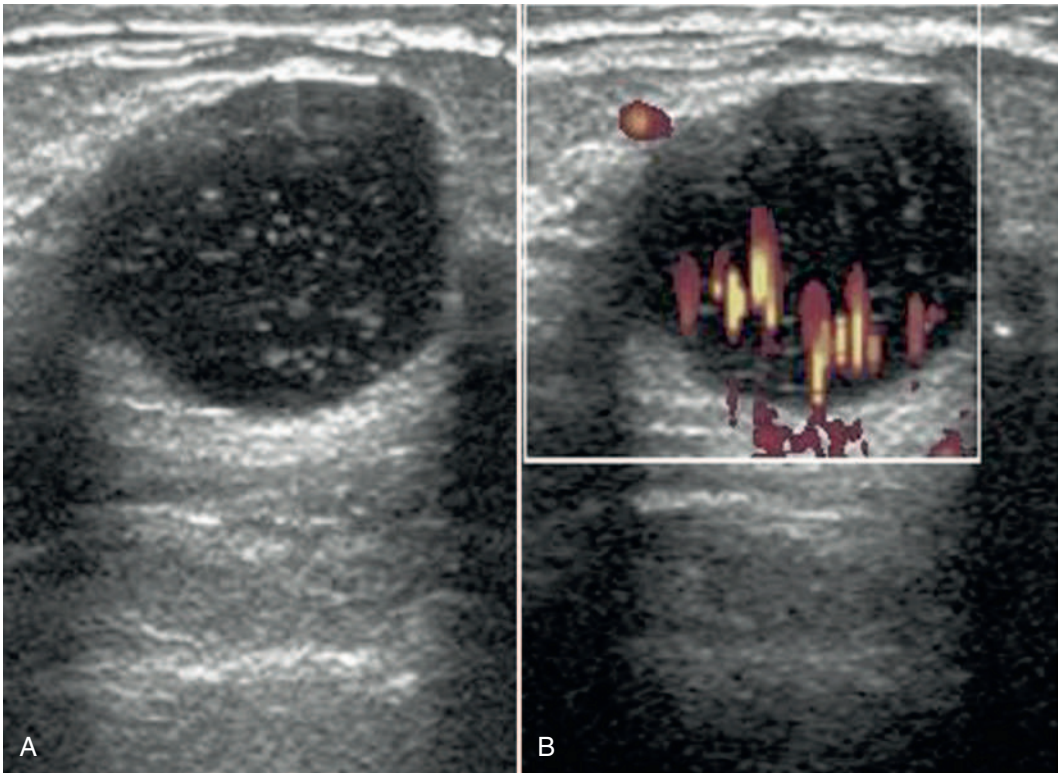

FIG. A.52 Color Streaking Artifact. (A) This complicated cyst contains floating punctate echoes that move posteriorly while being scanned, creating a scintillating appearance on gray-scale sonography. **(B)** Power Doppler ultrasound pushes the echoes posteriorly faster and with more energy than does the gray-scale beam. The echoes move fast enough that color persistence creates the appearance of **"color streaking"** artifact.[21] (See Chapter 21, Fig. 21.21.)

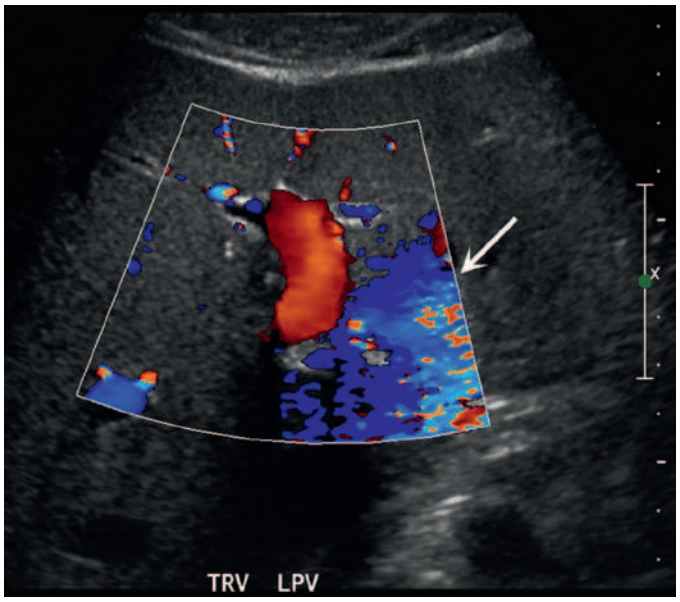

FIG. A.53 Flash Artifact From Pulsation. In this image of the left portal vein, note how transmitted pulsation from the heart causes artifactual flow in the adjacent liver owing to motion.

Tissue Vibration Artifact

Tissue vibration artifact consists of color pixels erroneously placed in the adjacent soft tissue by the ultrasound scanner because of the transmitted vibration from a region of marked turbulence. It is commonly seen with shunts, tight stenoses of large arteries, and especially arteriovenous fistulas. If tissue vibration artifact is seen, a search should be made for an arteriovenous fistula.

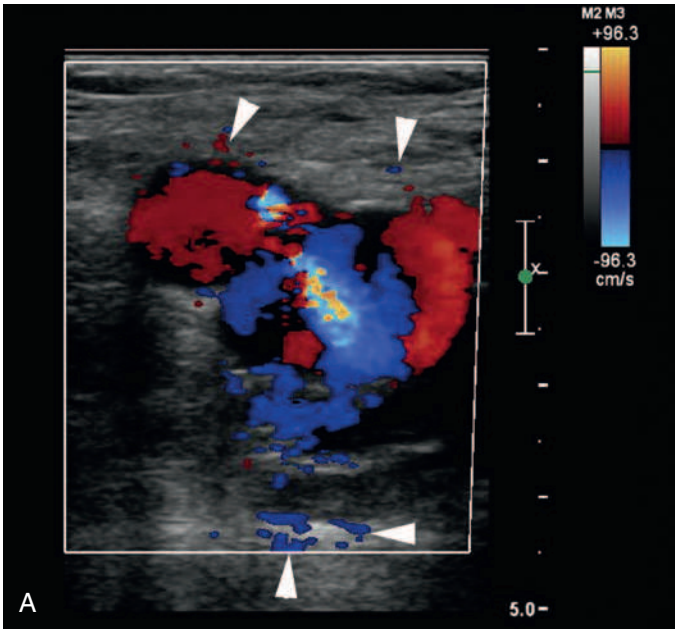

FIG. A.54 Tissue Vibration Artifact From Common Femoral Artery to Common Femoral Vein Arteriovenous Fistula. Turbulent flow through the fistula may affect surrounding tissues, causing a tissue vibration artifact, which may be the first clue that an arteriovenous fistula (AVF) is present. **Common femoral artery to common femoral vein AVF. (A)** Color Doppler shows common femoral artery to common femoral vein AVF. Note the adjacent tissue vibration artifact *(arrowheads)*. (See Chapter 27, Fig. 27.14.)

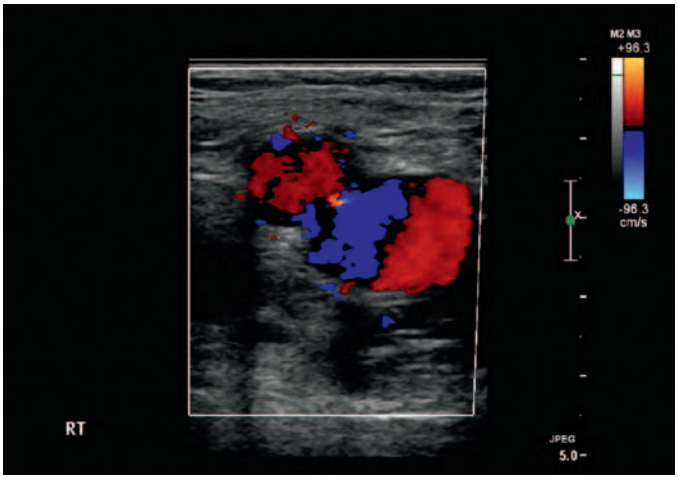
Click here to see the video of **tissue vibration** (Video A.19).



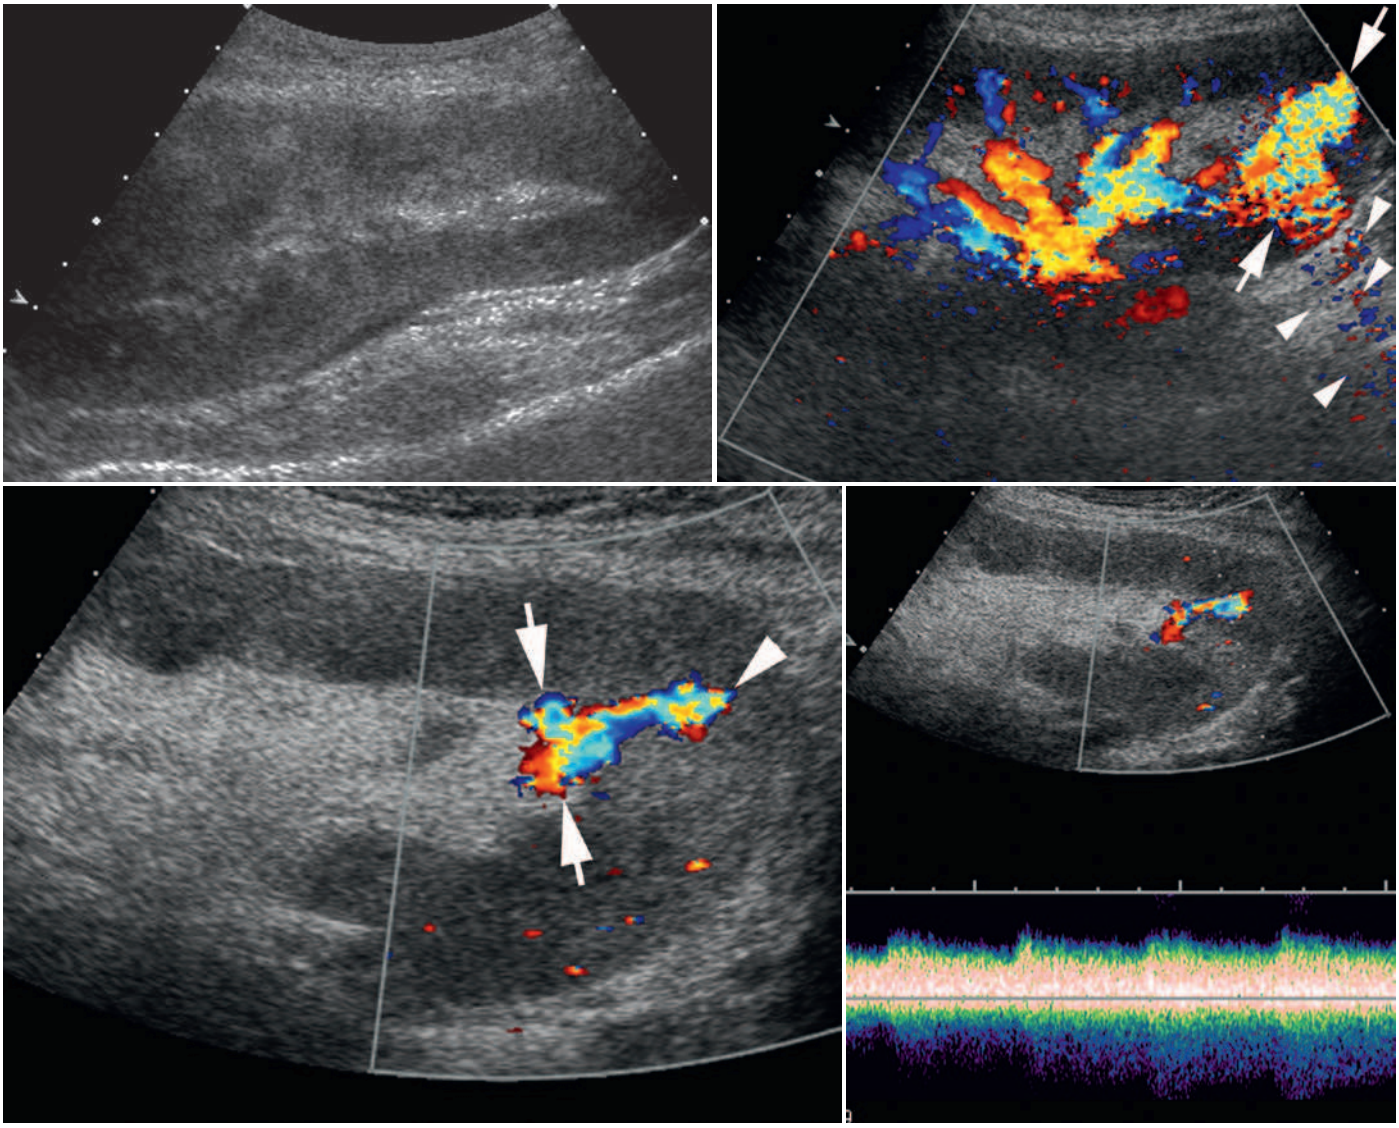


FIG. A.55 Tissue Vibration Artifact. Postbiopsy arteriovenous fistula. Color Doppler image shows markedly increased lower-pole blood flow *(arrows)* with adjacent soft tissue color artifact related to tissue vibration *(arrowheads)*.[22] (See Chapter 52, Fig. 52.49.)

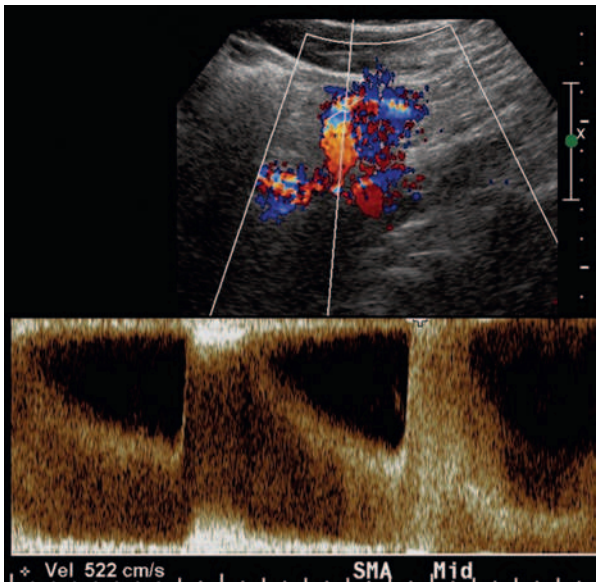

FIG. A.56 Tissue Vibration Artifact. Spectral waveform at site of superior mesenteric artery stenosis shows very high systolic velocity, and diastolic velocities of greater than 500 cm/sec. Color portion of the image shows **color bruit** consisting of color outside the vessel near the stenosis site. Color bruit is believed to be caused by tissue vibration.[23] (See Chapter 12, Fig. 12.27A.)

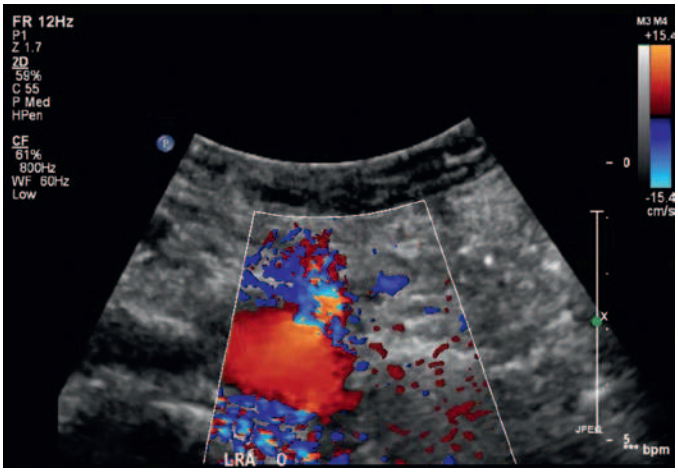
Click for video showing **tissue vibration artifact** in patient with **stenotic superior mesenteric artery with color bruit** (Video A.20). (See also Video 12.11.)



Aliasing and Velocity Scale Errors

Aliasing is an artifact due to undersampling of Doppler signal, resulting in incorrect estimation of flow velocity. To measure the Doppler frequency shift appropriately by pulsed Doppler, at least two samples from the cycle are required (Nyquist limit). If the pulse repetition frequency is less than twice the maximum frequency shift produced by movement of the target, aliasing results. The Doppler signal wraps around either the spectrum (spectral Doppler) or the color scale (color Doppler). The most common methods for correcting for aliasing are to shift the baseline down or up, or increase the pulse repetition frequency (or velocity scale). A lower-frequency transducer can also be used to help in correcting for aliasing. As angulation approaches 90 degrees, directional ambiguity can occur, suggesting bidirectional flow. Errors in Doppler angle correction can also lead to misleading assessments of flow velocity.

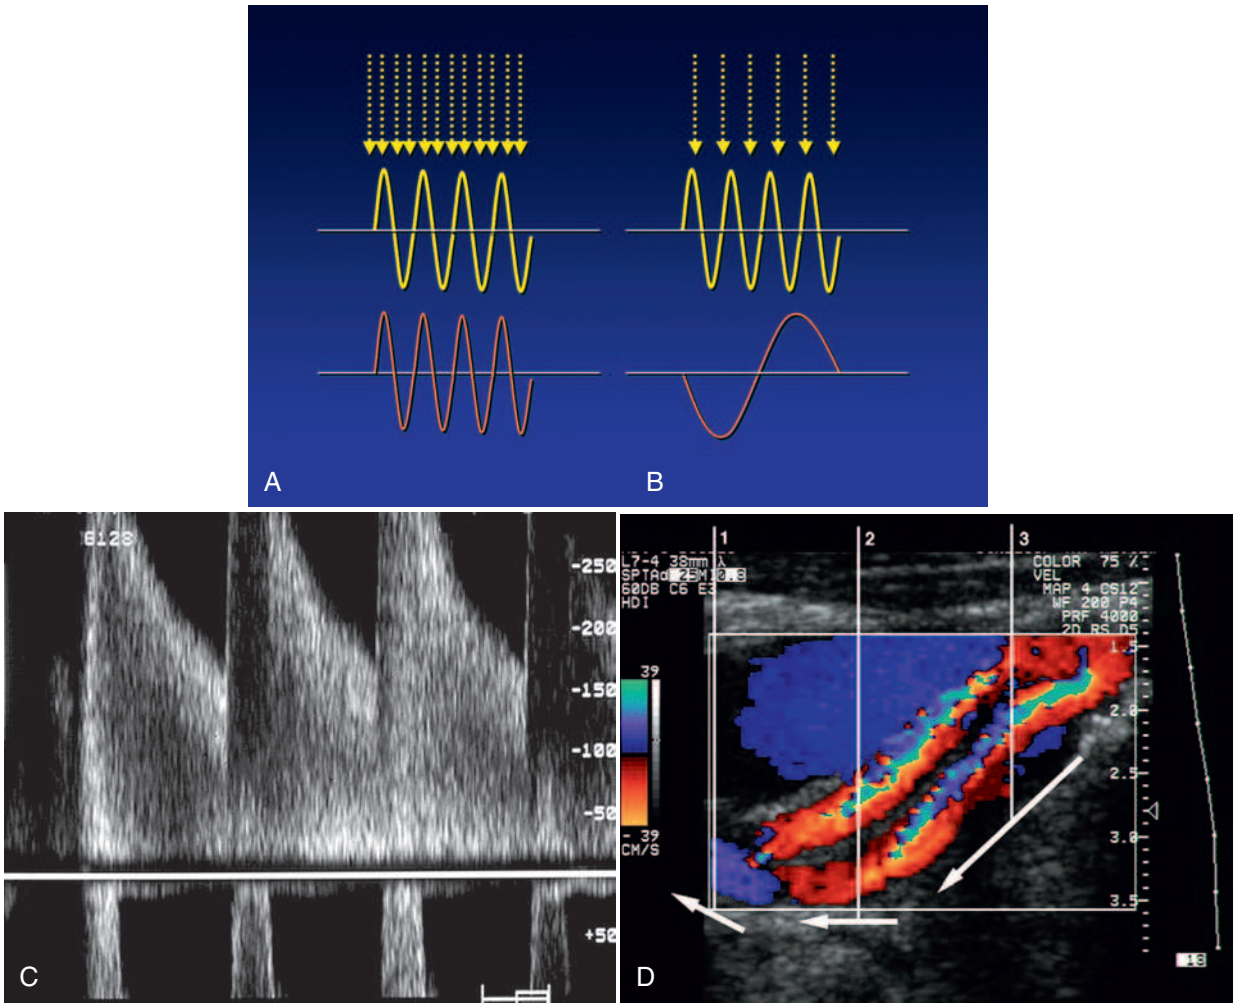


FIG. A.57 Aliasing. Pulse repetition frequency (PRF) determines the sampling rate of a given Doppler frequency. **(A)** If PRF *(arrows)* is sufficient, the sampled waveform *(orange curve)* will accurately estimate the frequency being sampled *(yellow curve)*. **(B)** If PRF is less than half the frequency being measured, **undersampling** will result in a lower-frequency shift being displayed *(orange curve)*. **(C) Aliasing** appears in the spectral display as a "wraparound" of the higher frequencies to display below the baseline. **(D)** In color Doppler display, aliasing results in a wraparound of the frequency color map from one flow direction to the opposite direction.[2] Unlike a true direction of flow change, with aliasing there will be no transition of unsaturated color. (See Chapter 1, Fig. 1.46.)

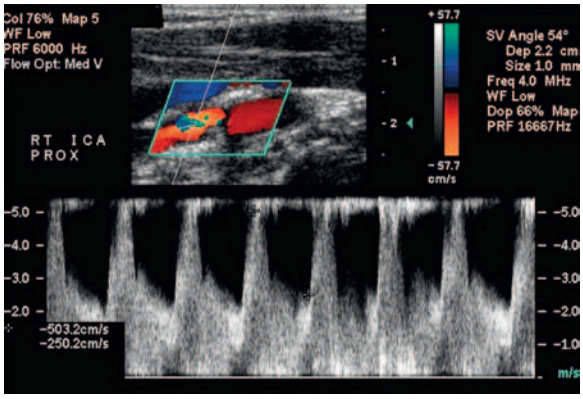

FIG. A.58 Aliasing. Note that aliasing prevents precise calculation of the maximum systolic velocity. However, because it is greater than 500 cm/sec, the precise number is not needed. The aliasing in the image allows for easier identification of the region of highest velocity for placement of the spectral Doppler gate.[6] (See Chapter 26, Fig. 26.20.)

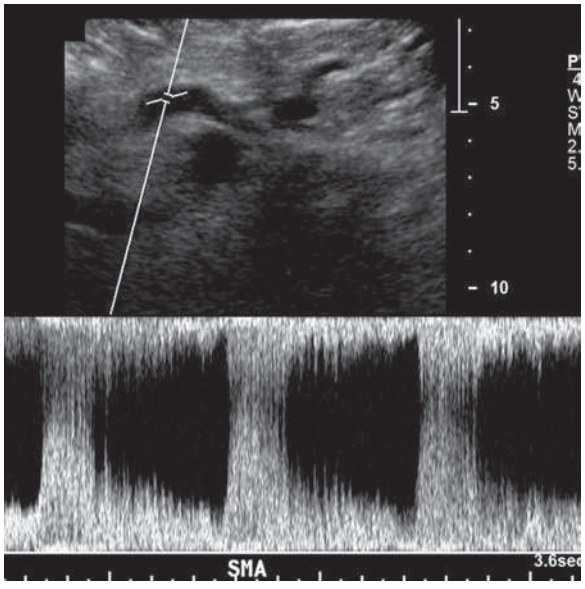

FIG. A.59 Aliasing in Superior Mesenteric Artery (*SMA*) Due to High-Velocity Flow.[23] (See Chapter 12, Fig. 12.28.)

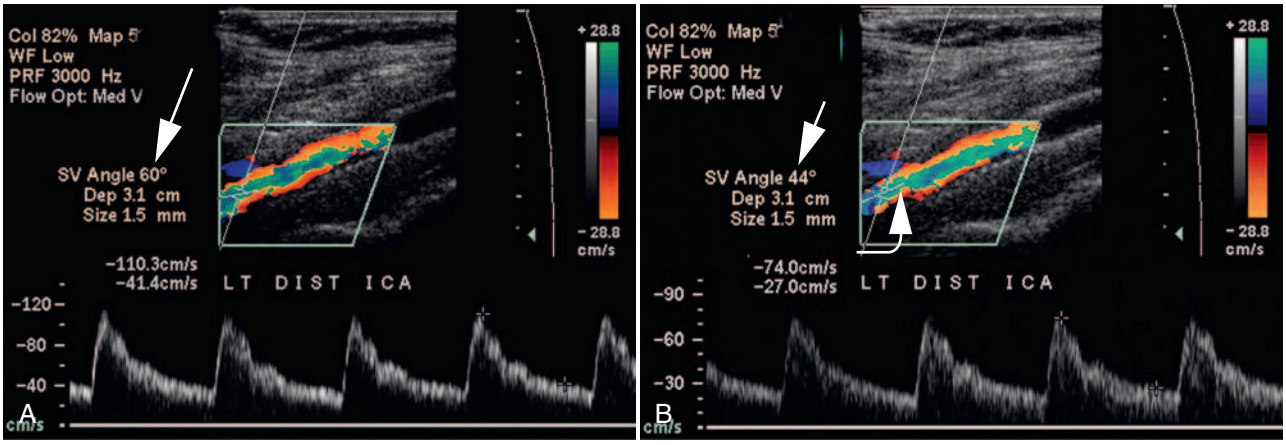

FIG. A.60 Aliasing Due to Doppler Angle Theta Changes. (A) Velocity obtained in the distal internal carotid artery with angle theta of 60 degrees is higher than that obtained at 44 degrees *(arrow)*. **(B)** However, the sample angle does not parallel the vessel wall at 60 degrees. Note central color aliasing in the region of highest velocity *(curved arrow)*.[6] (See Chapter 26, Fig. 26.16.)

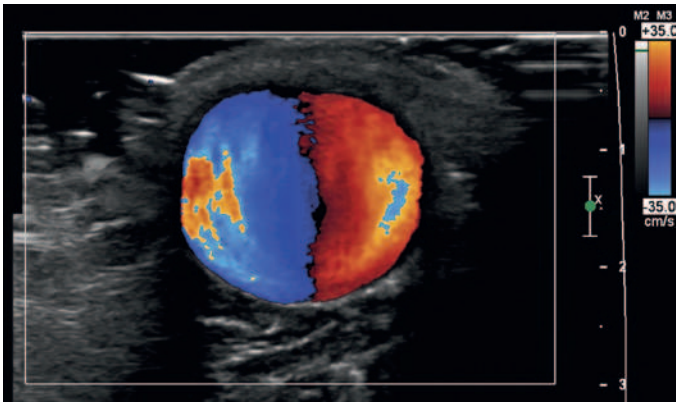

FIG. A.61 Aliasing in Pseudoaneurysm. Note the swirling flow in a pseudoaneurysm, resulting in a yin-yang appearance.[24] At the midline border of red and blue, there is a black line where the Doppler angle is 90 degrees. Here the flow is perpendicular to the sound beam, and so it is not detected. At 3 and 9 o'clock positions, there is aliasing within the blue and red areas. Here the Doppler angle is zero degrees with the flow directly toward and away from the transducer, thus appearing with maximal velocity. As the velocity exceeds the selected 35-cm/sec Doppler velocity range, aliasing results with artifactual opposite direction color signal. (See Chapter 27, Fig. 27.63.)

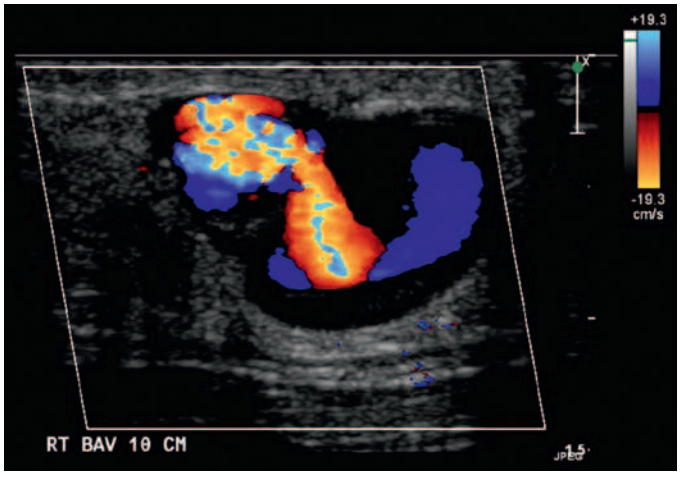
Click here to see the pseudoaneurysm video clip showing even more dramatic aliasing in the femoral artery (Video A.21).[24] (See also Chapter 27, Video 27.5.)



Spectral Broadening

Spectral broadening occurs when there are multiple different velocities of flow within a vessel. This can be a sign of stenosis. However, artifactual spectral broadening can occur owing to improper positioning of the sample volume near the vessel wall, use of an excessively large sample volume, or excessive system gain.

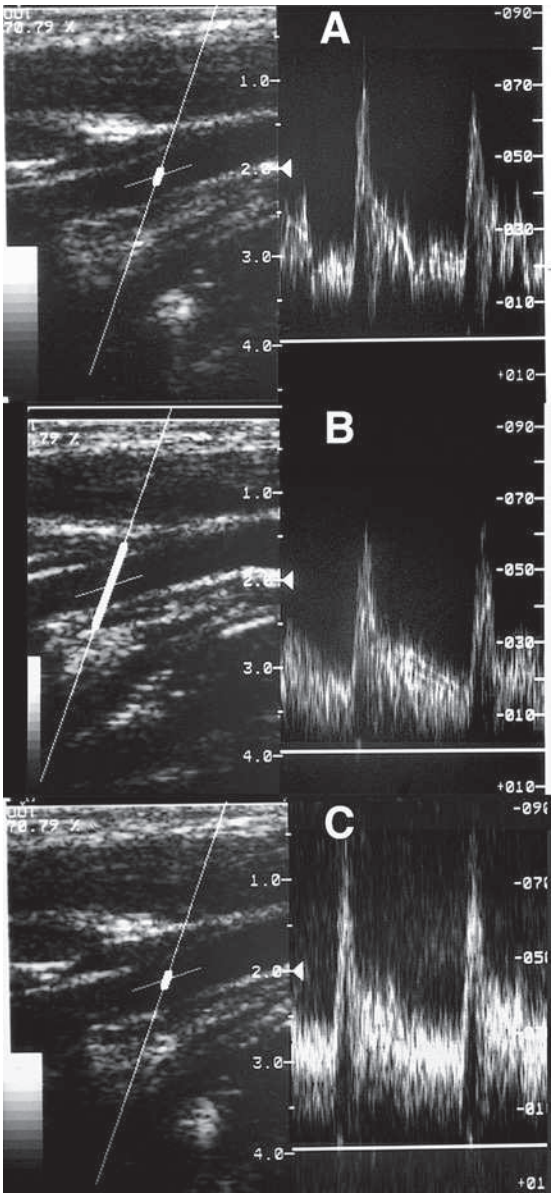


FIG. A.62 Spectral Broadening. The range of velocities detected at a given time in the pulse cycle is reflected in the Doppler spectrum as spectral broadening. **(A) Normal spectrum.** Spectral broadening may arise from turbulent flow in association with vessel stenosis. **(B** and **C) Artifactual spectral broadening** may be produced by improper positioning of the sample volume near the vessel wall, use of an excessively large **sample volume (B), or excessive system gain (C).**[2] (See Chapter 1, Fig. 1.45.)

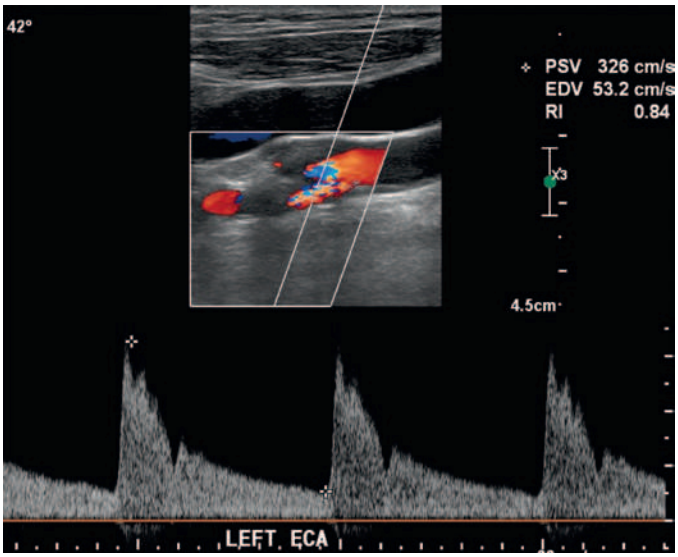

FIG. A.63 Spectral Broadening. True spectral broadening due to ECA stenosis.[6] (See Chapter 26, Fig. 26.18.)

Blooming Artifact

Blooming artifact occurs when color reaches beyond the vessel wall, making the vessels look larger than expected. It is gain dependent in that lowering the gain will decrease blooming. It is also wall filter and color-overwrite dependent, in that increasing the wall filter will decrease the artifact.

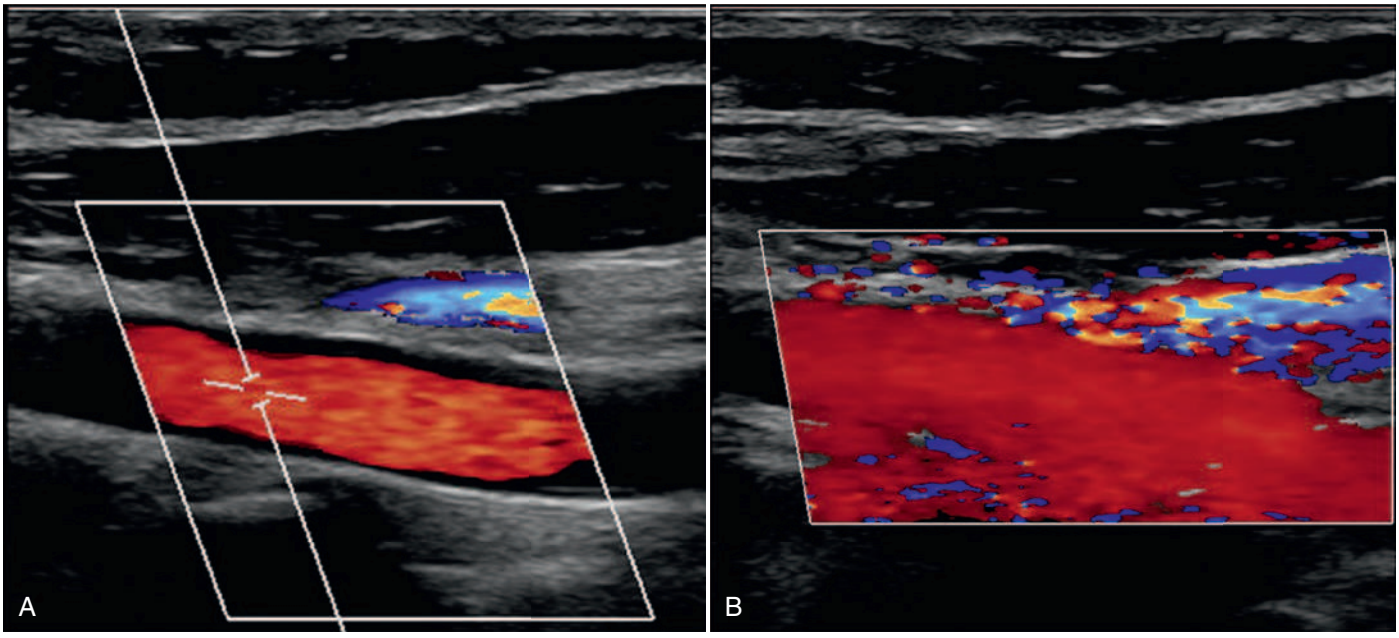

FIG. A.64 Blooming Artifact. Two images of the same carotid artery. In **(A)** the gain and wall filter are appropriate to show the flow centrally in the vessel. In **(B)** the gain and wall filter have been changed (in a manner beyond what would be used in clinical imaging) to demonstrate how these can make the vessel "bloom" and appear larger.

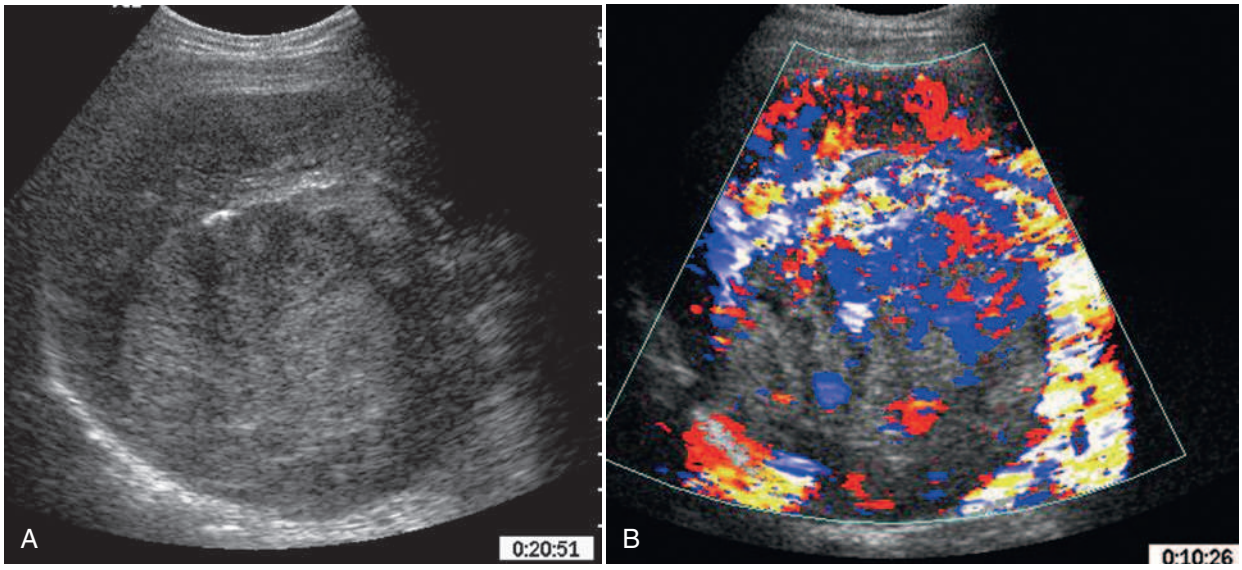

FIG. A.65 Blooming artifact due to use of contrast and tissue motion. **(A)** Use of contrast material creates color Doppler artifacts owing to blooming and tissue motion. **(B)** Contrast-specific imaging shows blood vessels not seen with Doppler.[25] (See Chapter 3, Fig. 3.7.)

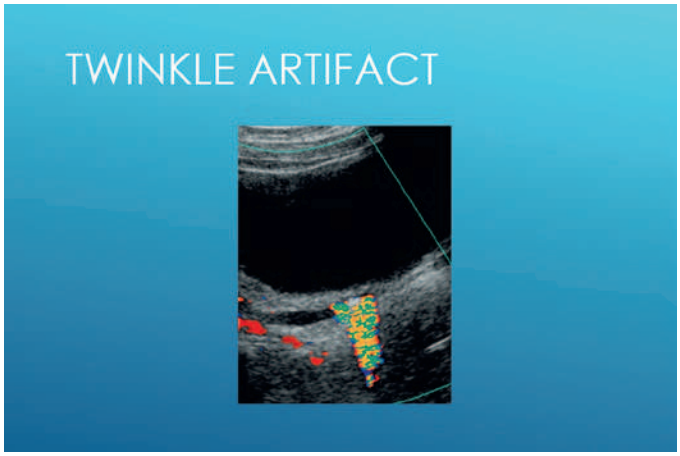
Twinkle Artifact

Twinkle artifact is the artifactual depiction of color signal on crystalline materials in the body. It appears as discrete foci of alternating colors with or without an associated color comet-tail artifact. The appearance of twinkle artifact is highly dependent on machine settings and is likely generated by a narrow-band, intrinsic machine noise called "phase (or clock) jitter." This, along with a strongly reflecting, rough surface such as a renal stone, results in a high-amplitude, broadband signal appearing as random motion on color Doppler sonography. The twinkle artifact is quite useful clinically because it can aid in the detection of small stones, calcifications, and other crystalline material within the body.

View the PowerPoint illustration of **twinkle artifact** here (Video A.22).



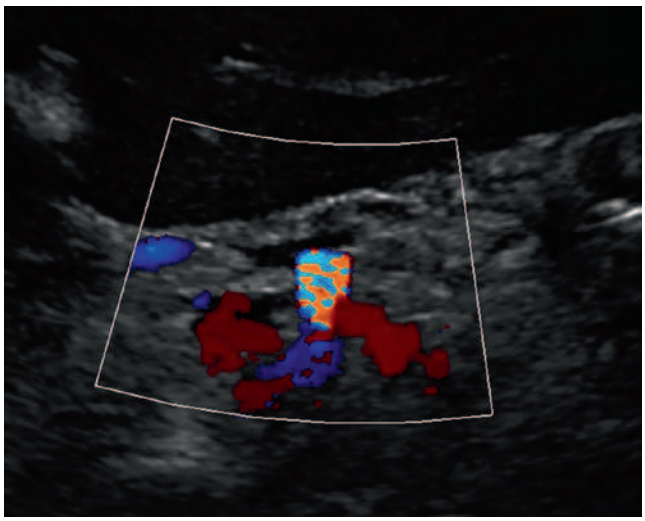


FIG. A.66 Twinkle Artifact Posterior to Pancreatic Duct Stone.[26] (See Chapter 7, Fig. 7.48D.)

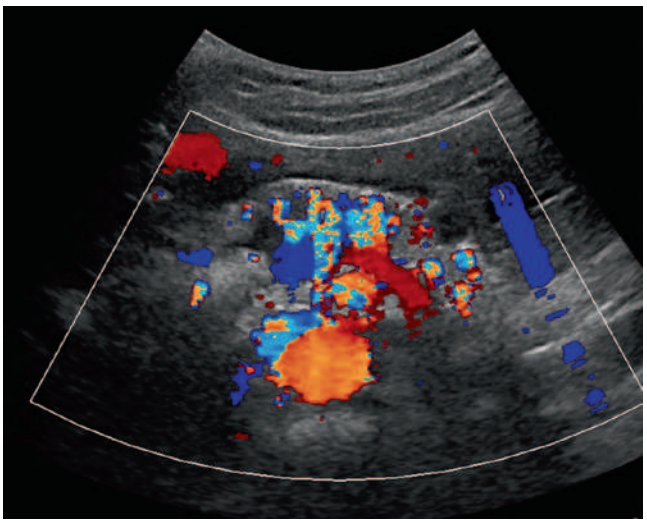

FIG. A.67 Calcifications in Chronic Pancreatitis With Twinkle Artifact.[26] (See Chapter 7, Fig. 7.49B.)

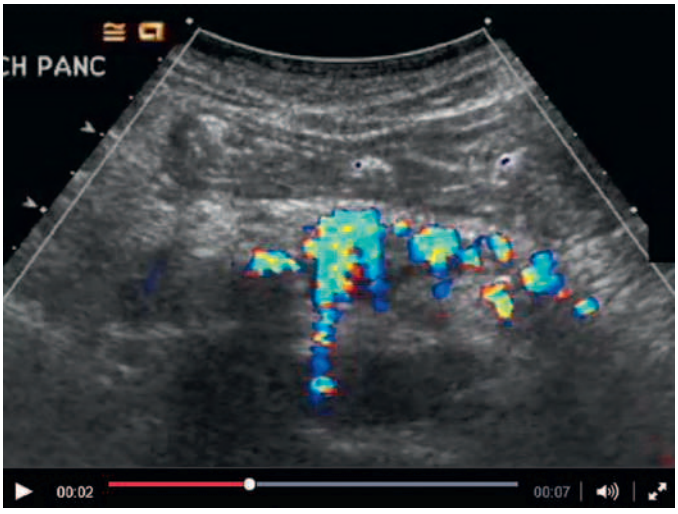
Click here for associated cine clip (Video A.23).[26] (See also Chapter 7, Video 7.5.)



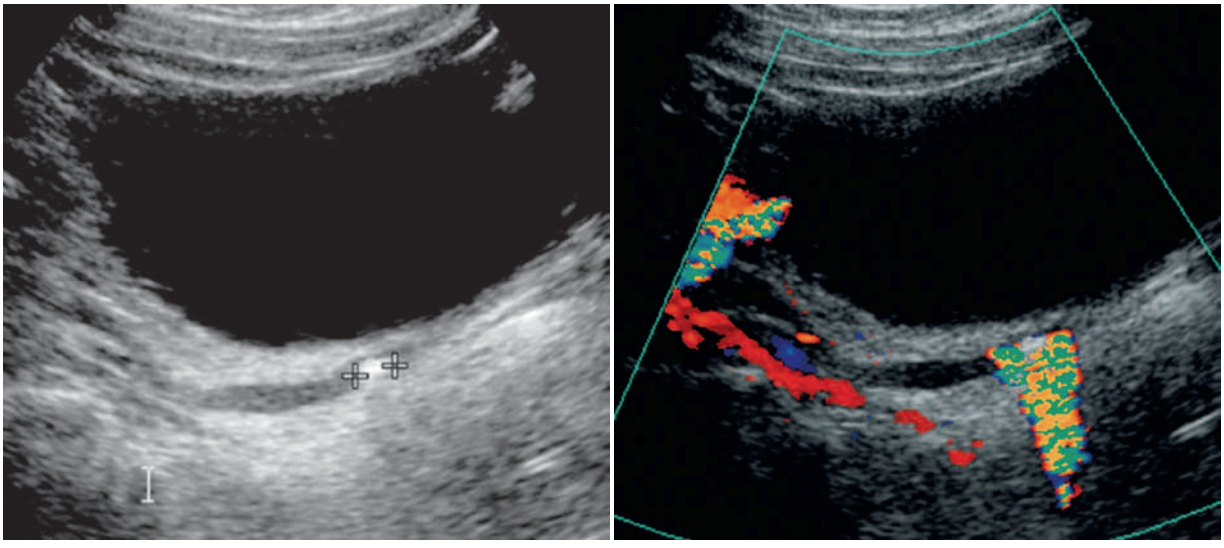


FIG. A.68 Twinkle Behind Distal Ureterovesical Junction Stone.[27] (See Chapter 54, Fig. 54.61.)

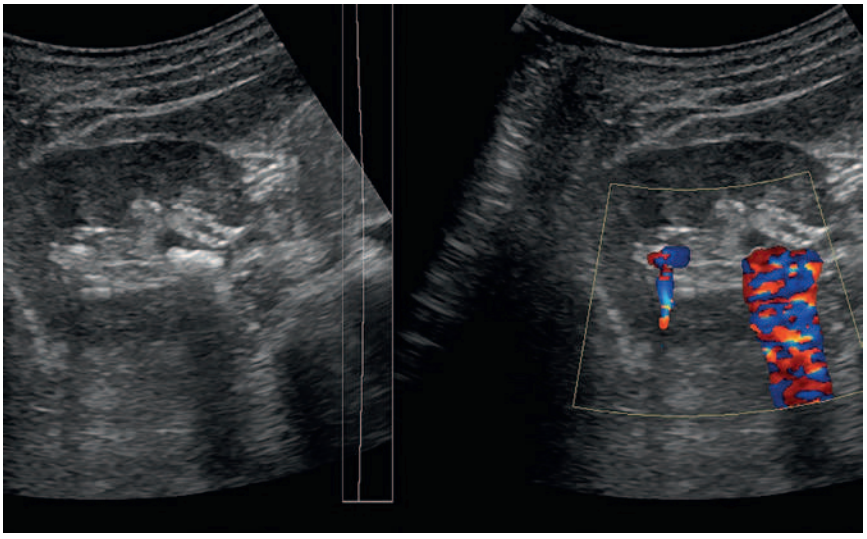

FIG. A.69 Twinkle Behind a Kidney Stone.[18] (See Chapter 9, Fig. 9.38.)

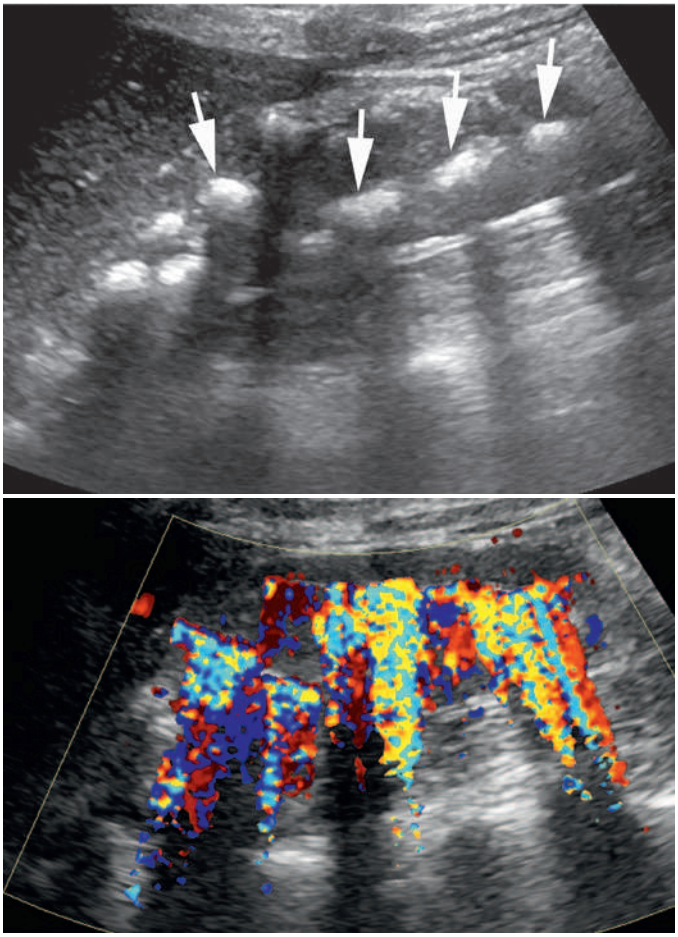

FIG. A.70 Twinkle Behind Multiple Kidney Stones.[22] (See Chapter 52, Fig. 52.37.)

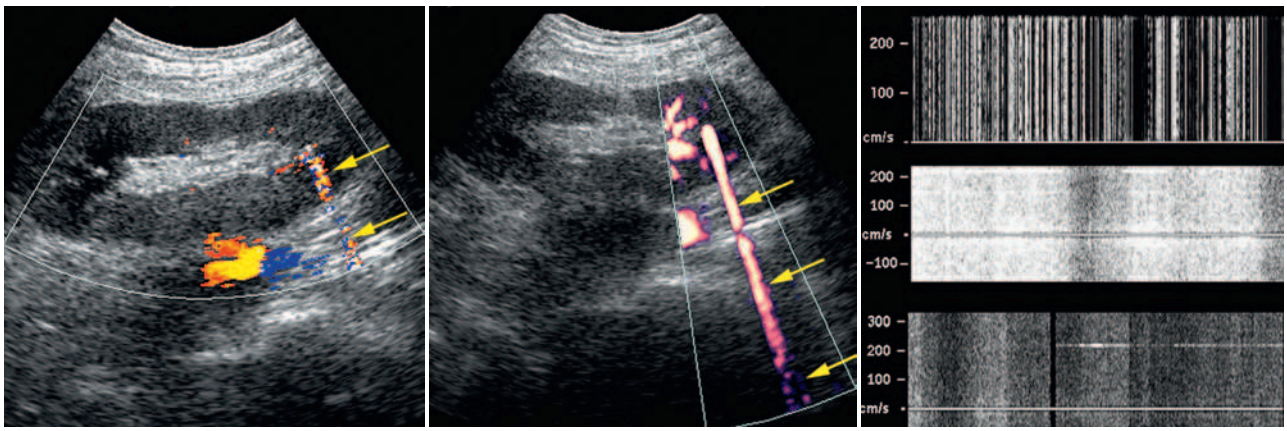

FIG. A.71 Appearances of Twinkle Artifact on Color, Power, and Pulsed Wave Doppler. Note how the spectral Doppler tracing of a twinkle artifact shows lines going through the tracing, which allow distinction from true blood flow.[28] (See Chapter 18, Fig. 18.52.)

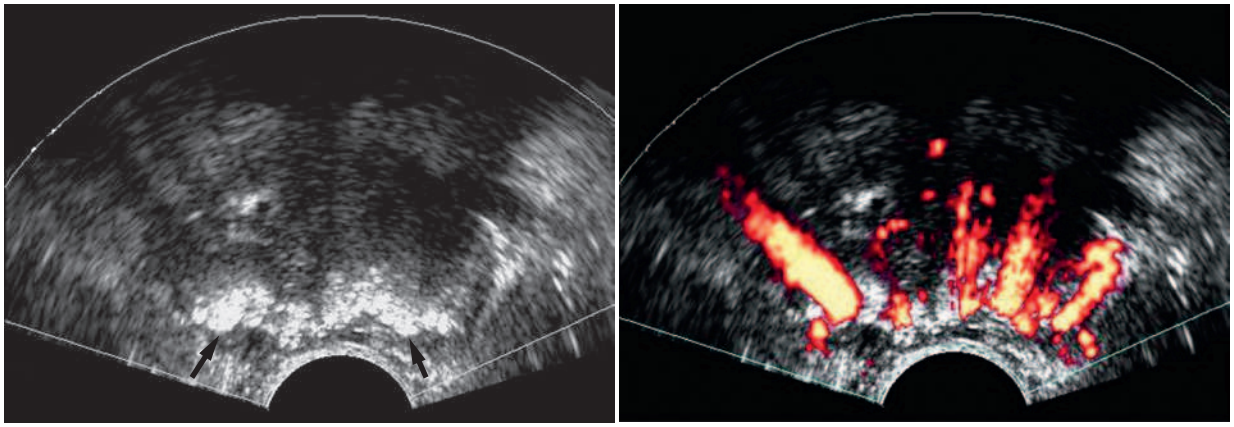

FIG. A.72 Power Doppler Image of Twinkle Behind Prostatic Calcifications.[11] (See Chapter 10, Fig. 10.7.)

Acknowledgment

Most of the images in this virtual chapter were obtained from chapters in the fifth edition of Diagnostic Ultrasound. We thank the authors for the use of their work.

Calcar avis, neonatal/infant, development of, 1523*f*, 1524
Calcarine fissure, neonatal/infant, development of, 1520–1521, 1524
Calcific bursitis, 891
Calcific tendinitis
injections for, 909, 911*f*
of supraspinatus tendon, 891–892, 892*f*
Calcification(s). *See also* Nephrocalcinosis
abdominal, meconium peritonitis and, 1313, 1314*f*
of adrenal glands, 423, 425*f*
causes of, 424*b*
in breast sonography, 793–794, 795*f*
chronic DVT indicated by, 984, 987*f*
in chronic pancreatitis masses, 233–236, 236*f*
cystic meconium peritonitis with, 1842–1843, 1846*f*
DCIS and, 793, 795*f*
dystrophic, 339
pediatric urinary tract and, 1799
eggshell, breast cysts and, 779, 780*f*
of endometrium, 533, 534*f*
of gallbladder, 202, 202*f*
intracranial, fetal, 1195*f*, 1203, 1204*f*
liver, fetal, 1316–1318, 1317*f*, 1318*b*
of meconium periorchitis, focal, 1904, 1904*f*
of myometrium, 531–533, 533*f*–534*f*
ovarian, focal, 566–568
of prostate, 387, 388*f*
psammomatous, in peritoneal nodule, 510–511, 513*f*
of radial arteries, evaluation for, 998, 998*f*
renal artery, 336
of renal cysts, 358, 358*f*
of renal parenchyma, 339–340, 340*f*
scrotal, 833–834, 833*b*, 834*f*
of seminal vesicles, 392
splenic, 150, 153*f*
pediatric, 1769
of superficial femoral artery, 968, 970*f*
of tendons, 859–861
of thyroid cysts, 695
in thyroid nodules
diagnostic significance of, 713–714
in papillary carcinoma, 699, 702*f*
of urinary tract, pediatric, 1798–1801
cortical nephrocalcinosis and, 1798, 1798*b*, 1798*f*
dystrophic, 1799
medullary nephrocalcinosis and, 1798–1799, 1799*f*
renal vein thrombosis and, 1799, 1800*f*
urinary stasis and, 1799, 1800*f*
urolithiasis and, 1799–1801, 1799*f*
in uterine fibroids, 539*f*, 540, 540*b*
of vas deferens, 392
yolk sac, 1067, 1068*f*
Calcified metastases, of liver, 125, 128*f*
Calcimimetics, for secondary hyperparathyroidism, 734
Calcitonin, secretion of, in medullary carcinoma of thyroid, 701
Calcium bile, milk of, 194, 195*f*
Calcium hydroxyapatite, in calcific tendinitis, 909
Calculus(i)
bladder, 338–339, 339*f*
pediatric, 1908
caliceal, 334–335
Calculus(i) *(Continued)*
liver transplantation complications with, 629, 632*f*
renal, 334–336, 336*f*–337*f*

  neonatal/infant, development of, 1524
Cerebellum
  Blake pouch and, 1189
  Dandy-Walker malformation in, 1190, 1190*f*
  embryology of, 1167
  fetal, sonographic view of, 1024*f*
  hypoplasia of, 1190
  mega-cisterna magna and, 1192, 1193*f*
  neonatal/infant, in coronal imaging, 1514–1515, 1514*f*
  rhombencephalosynapsis in, 1192
  ventral induction errors in, 1189–1192
  vermis hypoplasia or dysplasia in, 1190–1192, 1192*f*
Cerebral artery. *See* Anterior cerebral artery; Middle cerebral artery; Posterior cerebral artery
Cerebral blood flow, neonatal/infant
  arterial, velocities in, range of, 1576, 1577*t*
  velocity of, determination of, 1576, 1576*f*
  venous, velocities in, range of, 1578, 1578*f*, 1578*t*
Cerebral blood vessels, extracranial, 917*f*. *See also* Internal jugular vein; Vertebral artery
  IJV as, 955–956
  vertebral artery as, 950–955
Cerebral cavernous malformation, in venous malformations of neck, 1657
Cerebral cortex. *See also* Cortical development malformations, fetal brain and
  development of, 1167
  malformations of, 1193–1203
Cerebral edema
  neonatal/infant, 1550–1556
    diffuse, 1553–1555, 1554*f*–1555*f*
    duplex Doppler studies of brain and, 1580
  pediatric, TCD sonography in, 1614, 1617*f*
Cerebral hemisphere, neonatal/infant, in sagittal imaging, 1517, 1517*f*
Cerebral infarction, neonatal/infant, 1550–1556
  focal, 1555–1556, 1556*b*, 1556*f*
  luxury perfusion and, 1580–1581, 1584*f*
Cerebral palsy
  pediatric, neurogenic bladder in, 1907
  periventricular leukomalacia and, 1550
Cerebral peduncles, 1518
  as transtemporal approach landmark, 1592, 1593*f*
Cerebral sinovenous thrombosis, 1547–1548
Cerebrohepatorenal syndrome
  cortical malformations in, 1196
  subependymal cysts from, 1566
Cerebroplacental ratio, MCA and, 1458, 1460*f*
Cerebrospinal fluid, hydrocephalus and production and circulation of, 1538–1541
Cerebrovascular accident, 915–916. *See also* Stroke
Cerebrovascular disease, SCD indicators for, 1598, 1599*b*
  MCA and, 1600*f*, 1604*f*–1605*f*
  ophthalmic artery flow as, 1599*f*
  stroke and, 1601*f*–1603*f*
Cervical aortic arch, 1658
Cervical canal, dilation of, spontaneous PTB and, 1503
Cervical carcinoma, iliac veins and, 461*f*
Cervical cerclage, for cervical incompetence, 1505–1507, 1506*f*
Cervical ectopia cordis, 1295
Cervical ectopic pregnancy, 1073–1074, 1074*f*
Cervical ectopic thymus, 1723
Cervical fascia, pediatric. *See also* Infrahyoid space, pediatric; Suprahyoid space, pediatric
  deep layers of, 1628, 1629*f*
    infrahyoid space in, 1628–1629, 1640–1650
    suprahyoid space in, 1628–1629
Cervical kyphosis, in campomelic dysplasia, 1381–1382
Cervical lymph node(s)
  parathyroid adenomas confused with, 745
  pediatric, inflammatory disease of, 1658–1663, 1661*f*–1663*f*
  percutaneous needle biopsies for, 717–718, 718*f*
Cervical teratoma
  fetal, 1159, 1161*f*
  pediatric, 1654, 1654*f*
Cervicothoracic vertebrae, campomelic dysplasia and, 1395
Cervix, 528–530
  abnormalities of, 541–544, 543*f*
    management protocols for, 1507, 1507*f*–1508*f*
    transvaginal ultrasound findings on, 1503*b*
  assessment of, 1503–1507
    for asymptomatic patients, 1503–1505
    in cervical incompetence and cervical cerclage, 1505–1507, 1506*f*
    fetal therapy and, 1505
    in general obstetric population screening, 1503–1504
    in high-risk obstetric population screening, 1504–1505
    in multiple gestations, 1504–1505
    in pervious cervical surgery, 1505
    in polyhydramnios, 1505
    in preterm premature rupture of membranes, 1505
    in prior PTB, 1504

Cervix *(Continued)*
for symptomatic patients, 1505–1507
in uterocervical anomalies, 1505
carcinoma of, 542, 543*f*
hematometra in, 547*f*, 549
duplicated, 538
dynamic changes in, spontaneous PTB and, 1501–1503, 1503*f*
ectopic pregnancy implantation in, 1073–1074, 1074*f*
funneling of, in spontaneous PTB prediction, 1501, 1502*f*
incompetence of, 1495–1496
cervical cerclage and, 1505–1507, 1506*f*
vaginal pessary and, 1507
length of, 1499–1500, 1499*f*
in prediction of spontaneous preterm birth, 1500–1501, 1501*t*
short, 1500–1501, 1500*f*, 1501*t*
nabothian cysts of, 533, 535*f*
in pregnancy, on second-trimester scan, 1021*f*
pseudomass in, 533, 536*f*
short, 1500–1501, 1500*f*, 1501*t*
shortening of, progressive, spontaneous PTB and, 1501
sonography of, 1496–1501
technical limitations and pitfalls of, 1498–1499, 1498*b*, 1499*f*
transabdominal approach to, 1496–1497, 1496*f*
transperineal/translabial approach to, 1497, 1497*f*
transvaginal approach to, 1497–1498, 1497*f*–1498*f*
surgery on, prior, cervical assessment and, 1505
trauma to, carotid artery damage from, 946, 948*f*
Cesarean section(s)
hematomas and
bladder flap, 556–557, 557*f*
subfascial, 556–557, 557*f*
pediatric pregnancy and, 1884
postpartum findings on, 556–557, 557*f*–558*f*
scars from, 557, 558*f*
ectopic pregnancy implantation and, 1073, 1075*f*
CEUS. *See* Contrast-enhanced ultrasound
CF. *See* Cystic fibrosis
CHAOS. *See* Congenital high airway obstruction
Charcot triad, in acute cholangitis, 176
CHARGE syndrome, coloboma in, 1143
CHD. *See* Congenital heart disease
Chemical peritonitis, 514
Chemical ventriculitis, in intraventricular hemorrhage, 1545–1547
Chemiluminescence, 42, 42*f*
Chest, fetal. *See also* Congenital diaphragmatic hernia; Congenital pulmonary airway malformation; Lung(s)
bronchogenic cysts in, 1255–1256, 1255*f*, 1255*t*
CHAOS and, 1253–1255, 1254*f*
congenital diaphragmatic hernia in, 1258–1264
development of structures in, 1243–1245
neurenteric cyst in, 1256
normal sonographic features of, 1244–1245, 1244*f*
pericardial effusion in, 1258, 1258*f*
pleural effusion in, 1256–1258, 1257*f*
pleuropulmonary blastoma and, 1252–1253
pulmonary development in, 1243
pulmonary hypoplasia and, 1245–1246
pulmonary lymphangiectasia and, 1258, 1259*f*
Chest, pediatric. *See also* Pneumonia, pediatric
atelectasis and, 1714, 1716*f*
bronchopulmonary foregut malformations and, 1716, 1718*f*
CPAM and, 1715–1716, 1717*f*
diaphragm disorders of, 1716, 1718*f*–1720*f*
empyema in, sonographic signs of, 1702–1711, 1707*f*
lung abscess in, 1711, 1713*f*
lung parenchyma and, 1711–1716
lymphatic malformations and, 1723
mediastinal masses in, 1723–1724
abnormal thymus location mimicking, 1723
anterior, 1723–1724
lymphadenopathy and, 1724
posterior, 1724
thymic index and, 1723, 1724*t*, 1725*f*, 1726*t*
parapneumonic collections in, 1710–1711
pleural effusions in, sonographic signs of, 1702–1711, 1704*f*–1708*f*
pleural fluid in, sonographic signs of, 1709, 1709*b*, 1709*f*–1710*f*
rib fractures in, 1727
sonography of
CT compared to, 1709, 1710*f*–1711*f*
indications for, 1701, 1702*b*
pitfalls in, 1709–1710, 1712*f*
technique for, 1701–1702, 1703*f*–1704*f*
ultrasound-guided interventional procedures in, 1724–1726, 1726*f*–1727*f*
vascular disorders of, 1716–1723
thrombosis, 1716–1721, 1721*f*–1723*f*
wall of, lesion of, ultrasound-guided biopsy of, 1724–1725
Chiari malformation(s)
I, 1526
II, 1190
banana sign in, 1183–1185, 1184*f*, 1221, 1228, 1230–1232
corpus callosum agenesis in, 1526, 1528*f*
lemon sign in, 1183–1185, 1184*f*, 1221, 1232–1233
myelomeningoceles with no, 1526, 1529*f*
normal sonographic appearance of fetal, 1168–1169
open spina bifida and fetal, 1183, 1184*f*
open spinal dysraphism with, pediatric, 1681–1682
sonographic findings in, 1526, 1526*b*, 1527*f*–1528*f*
in spina bifida screening, 1221, 1228
VM with, 1177
III, 1526
neonatal/infant neural tube closure disorders and, 1526, 1526*b*, 1527*f*–1529*f*
Chiba needles, 1948
Child life specialists, 1776–1781
Childhood malignancies, obstetric sonography and, 1041
Chlamydia trachomatis, 846, 1633–1634
Chlamydial perihepatitis, PID and, 1887
Chloroma
masseter muscle, 1641*f*
pediatric, neck, 1667*f*
Chocolate cysts, 574–575
Cholangiocarcinoma, 171
biliary tree and, 184–188
characterization of, with microbubble contrast agents, 106*f*
distal, 188, 192*f*
fluke infections and, 178–179
hilar, 185–188
CEUS assessment of, 188, 191*f*
criteria for unresectable, 187*b*
Cholangiocarcinoma *(Continued)*
Doppler ultrasound assessment for, 187–188, 189*f*–191*f*
treatment and staging for, 186–187
tumor growth patterns in, 186
intrahepatic, 184–185, 186*f*
intraductal, 185, 186*f*–187*f*
peripheral, 129
Cholangiography, transhepatic, 614–615
Cholangiohepatitis, Oriental, 179
Cholangiopathy
autoimmune, 182
HIV, 181–182, 181*f*
