Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

ABOUT THE EDITORS

Carol M. Rumack, MD, FACR, is Professor of Radiology and Pediatrics at the University of Colorado School of Medicine in Denver, Colorado. Her clinical practice is based at the University of Colorado Hospital. Her primary research has been in neonatal sonography of high-risk infants, particularly the brain, on which she has published and lectured widely. She is a Fellow, previous Chair of the Ultrasound Commission, past president of the American College of Radiology, and American Association for Women Radiologists, and a Fellow of both the American Institute of Ultrasound in Medicine and the Society of Radiologists in Ultrasound. She and her husband, Barry, have two children, Becky and Marc, and five grandchildren.

Deborah Levine, MD, FACR, is Professor of Radiology at Beth Israel Deaconess Medical Center, Boston, and Harvard Medical School. At Beth Israel Deaconess Medical Center she is Vice Chair of Academic Affairs of the Department of Radiology, Co-Chief of Ultrasound, and Director of Ob/Gyn Ultrasound. Her main areas of clinical and research interest are obstetric and gynecologic imaging. She is a Fellow and past Vice President of the American College of Radiology and a Fellow (and 2016-2017 President) of the Society of Radiologists in Ultrasound. She and her husband, Alex, have two children, Becky and Julie.

PREFACE

The fifth edition of *Diagnostic Ultrasound* is a major revision. Previous editions have been very well accepted as reference textbooks and have been the most commonly used reference in ultrasound education and practices worldwide. The text and references have all been updated and are now all available online. We are pleased to provide over 2500 new/revised images (with over 5800 images total) and over 380 new videos (with 480 total videos). The display of real-time ultrasound has helped to capture those abnormalities that require a sweep through the pathology to truly appreciate the lesion as well. Daily we find that cine or video clips show important areas between still images that help to make certain a diagnosis or relationships between lesions. Now we rarely need to go back to reevaluate a lesion with another scan, making patient imaging more efficient. Another new offering in this textbook is a completely online "virtual" chapter on artifacts. PowerPoint videos explain many of the artifacts that are linked to images and videos in the text.

The fifth edition was a major change for our editorial team, as we said a fond farewell to Stephanie Wilson and Bill Charboneau. Their expertise is still felt in this edition, as they have contributed chapters on gastrointestinal ultrasound (liver, biliary tree, and gastrointestinal tract, which are all some of Stephanie's passions) and thyroid and interventional ultrasound (just some of Bill's areas of expertise).

Nearly 100 outstanding new and continuing authors have contributed to this edition, and all are recognized experts in the field of ultrasound. As in prior editions, we have emphasized the use of collages to show many examples of similar anatomy and pathology. These images reflect the spectrum of sonographic changes that may occur in a given disease, instead of the most common manifestation only.

The book's format has been redesigned with key points in addition to the outline at the beginning of each chapter. There are again colored boxes to highlight the important or critical features of sonographic diagnoses. Key terms and concepts are emphasized in boldface type. To direct the readers to other research and literature of interest, comprehensive reference lists are provided.

Diagnostic Ultrasound is again divided into two volumes. Volume I consists of Parts I to III. Part I contains chapters on physics and biologic effects of ultrasound and includes descriptions of elastography and contrast agents. Part II covers abdominal sonography and includes two completely revised chapters on pelvic sonography, along with chapters on interventional procedures (including those in the thorax) and organ transplantation. Part III presents small parts imaging, including thyroid, breast, scrotum, carotid, a completely revised chapter on imaging of the extracranial vessels, and two completely revised musculoskeletal imaging chapters, as well as an updated chapter on musculoskeletal intervention.

Volume II begins with Part IV, with obstetric ultrasound, which has important updates in first-trimester scanning and screening for aneuploidy including cell-free DNA. Part V comprehensively covers pediatric sonography, including pediatric interventional sonography. Completely revised chapters on the pediatric spinal canal and pediatric kidney are replete with new images and scanning techniques.

Diagnostic Ultrasound is for practicing physicians, residents, medical students, sonographers, and others interested in understanding the vast applications of diagnostic sonography in patient care. Our goal is for *Diagnostic Ultrasound* to continue to be the most comprehensive reference book available in the sonographic literature, with a highly readable style and superb images.

Carol M. Rumack, MD, FACR
Deborah Levine, MD, FACR

ACKNOWLEDGMENTS

We wish to express our deepest appreciation and sincerest gratitude:

To all of our outstanding authors, who have contributed extensive, newly updated, and authoritative text and images and videos. We cannot thank them enough for their efforts on this project.

To Alexander Jesurum, PhD, whose outstanding efforts kept the references updated for all of our authors and who helped in author contact and communication.

To Lisa Napolitano, RDMS, who spent hours finding and cropping videos to supplement our online edition.

To Robin Carter, Executive Content Strategist at Elsevier, who has worked closely with us on this project from the very beginning of the fifth edition.

To Taylor Ball and Dan Fitzgerald at Elsevier, who kept us on track for the process of updating and copyediting the entire manuscript.

It has been an intense year for everyone, and we are very proud of this superb edition of *Diagnostic Ultrasound.*

CONTENTS

VOLUME I

PART I Physics

1 **Physics of Ultrasound,** 1
Christopher R.B. Merritt

2 **Biologic Effects and Safety,** 34
J. Brian Fowlkes and Christy K. Holland

3 **Contrast Agents for Ultrasound,** 53
Peter N. Burns

PART II Abdominal and Pelvic Sonography

4 **The Liver,** 74
Stephanie R. Wilson and Cynthia E. Withers

5 **The Spleen,** 139
Patrick M. Vos, John R. Mathieson, and Peter L. Cooperberg

6 **The Biliary Tree and Gallbladder,** 165
Korosh Khalili and Stephanie R. Wilson

7 **The Pancreas,** 210
Thomas Winter and Maryellen R.M. Sun

8 **The Gastrointestinal Tract,** 256
Stephanie R. Wilson

9 **The Kidney and Urinary Tract,** 310
Mitchell Tublin, Deborah Levine, Wendy Thurston, and Stephanie R. Wilson

10 **The Prostate and Transrectal Ultrasound,** 381
Ants Toi

11 **The Adrenal Glands,** 416
Christina Marie Chingkoe, Olga R. Brook, and Deborah Levine

12 **The Retroperitoneum,** 432
Raymond E. Bertino and Elton Mustafaraj

13 **Dynamic Ultrasound of Hernias of the Groin and Anterior Abdominal Wall,** 470
Deborah Levine, Lisa Napolitano, and A. Thomas Stavros

14 **The Peritoneum,** 504
Anthony E. Hanbidge, Korosh Khalili, and Stephanie R. Wilson

15 **The Uterus,** 528
Douglas Brown and Deborah Levine

16 **The Adnexa,** 564
Rochelle Filker Andreotti and Lori A. Deitte

17 **Ultrasound-Guided Biopsy of Chest, Abdomen, and Pelvis,** 597
Theodora A. Potretzke, Thomas D. Atwell, J. William Charboneau, and Carl Reading

18 **Organ Transplantation,** 623
Derek Muradali and Tanya Punita Chawla

PART III Small Parts, Carotid Artery, and Peripheral Vessel Sonography

19 **The Thyroid Gland,** 691
Luigi Solbiati, J. William Charboneau, Vito Cantisani, Carl Reading, and Giovanni Mauri

20 **The Parathyroid Glands,** 732
Bonnie J. Huppert and Carl Reading

21 **The Breast,** 759
Jordana Phillips, Rashmi J. Mehta, and A. Thomas Stavros

22 **The Scrotum,** 818
Daniel Sommers and Thomas Winter

23 **Overview of Musculoskeletal Ultrasound Techniques and Applications,** 856
Colm McMahon and Corrie Yablon

24 **The Shoulder,** 877
Colm McMahon and Corrie Yablon

25 **Musculoskeletal Interventions,** 898
Ronald S. Adler

26 **The Extracranial Cerebral Vessels,** 915
Edward I. Bluth, Stephen I. Johnson, and Laurie Troxclair

27 **Peripheral Vessels,** 964
Mark E. Lockhart, Heidi R. Umphrey, Therese M. Weber, and Michelle L. Robbin

VOLUME II

PART IV Obstetric and Fetal Sonography

28 **Overview of Obstetric Imaging,** 1015
Deborah Levine

29 **Bioeffects and Safety of Ultrasound in Obstetrics,** 1034
Jacques S. Abramowicz

30 **The First Trimester,** 1048
Elizabeth Lazarus and Deborah Levine

31 **Chromosomal Abnormalities,** 1088
Bryann Bromley and Beryl Benacerraf

32 **Multifetal Pregnancy,** 1115
Mary C. Frates

33 **The Fetal Face and Neck,** 1133
Ana P. Lourenco and Judy A. Estroff

34 **The Fetal Brain,** 1166
Ants Toi and Deborah Levine

35 **The Fetal Spine,** 1216
Elizabeth Asch and Eric Sauerbrei

36 **The Fetal Chest,** 1243
Dorothy Bulas

37 **The Fetal Heart,** 1270
Elizabeth R. Stamm and Julia A. Drose

38 **The Fetal Gastrointestinal Tract and Abdominal Wall,** 1304
Nir Melamed, Anne Kennedy, and Phyllis Glanc

39 **The Fetal Urogenital Tract,** 1336
Katherine W. Fong, Julia Eva Kfouri, and Kirsten L. Weind Matthews

40 **The Fetal Musculoskeletal System,** 1376
Phyllis Glanc, David Chitayat, and Sheila Unger

41 **Fetal Hydrops,** 1412
Deborah Levine

42 **Fetal Measurements: Normal and Abnormal Fetal Growth and Assessment of Fetal Well-Being,** 1443
Carol B. Benson and Peter M. Doubilet

43 **Sonographic Evaluation of the Placenta,** 1465
Thomas D. Shipp

44 **Cervical Ultrasound and Preterm Birth,** 1495
Hournaz Ghandehari and Phyllis Glanc

PART V Pediatric Sonography

45 **Neonatal and Infant Brain Imaging,** 1511
Carol M. Rumack and Amanda K. Auckland

46 **Duplex Sonography of the Neonatal and Infant Brain,** 1573
Thierry A.G.M. Huisman and Andrea Poretti

47 **Doppler Sonography of the Brain in Children,** 1591
Dorothy Bulas and Alexia Egloff

48 **The Pediatric Head and Neck,** 1628
Rupa Radhakrishnan and Beth M. Kline-Fath

49 **The Pediatric Spinal Canal,** 1672
Ilse Castro-Aragon, Deborah Levine, and Carol M. Rumack

50 **The Pediatric Chest,** 1701
Chetan Chandulal Shah and S. Bruce Greenberg

51 **The Pediatric Liver and Spleen,** 1730
Sara M. O'Hara

52 **The Pediatric Urinary Tract and Adrenal Glands,** 1775
Harriet J. Paltiel and Diane S. Babcock

53 **The Pediatric Gastrointestinal Tract,** 1833
Susan D. John and Martha Mappus Munden

54 **Pediatric Pelvic Sonography,** 1870
William L. Simpson, Jr., Humaira Chaudhry, and Henrietta Kotlus Rosenberg

55 **The Pediatric Hip and Other Musculoskeletal Ultrasound Applications,** 1920
Leslie E. Grissom and H. Theodore Harcke

56 **Pediatric Interventional Sonography,** 1942
Neil Johnson and Allison Aguado

Appendix: Ultrasound Artifacts: A Virtual Chapter
Korosh Khalili, Hojun Yu, Alexander Jesurum, and Deborah Levine
Index, I-1

VIDEO CONTENTS

4 The Liver
Stephanie R. Wilson and Cynthia E. Withers

Video 4.1 **Normal liver, sagittal sweep**
Video 4.2 **Normal liver, subcostal sweep**
Video 4.3 **Focal fat in the liver**
Video 4.4 **Geographic fatty infiltration of the liver**
Video 4.5 **CEUS of FNH with classic enhancement features**
Video 4.6 **CEUS of the flash-filling hemangioma shown in Fig. 4.47**
Video 4.7 **CEUS of focal nodular hyperplasia**
Video 4.8 **CEUS of focal nodular hyperplasia**
Video 4.9 **CEUS of hepatic adenoma in a young woman**
Video 4.10 **CEUS of small hepatocellular carcinoma**
Video 4.11 **CEUS of hepatocellular carcinoma**
Video 4.12 **Classic colorectal metastasis**
Video 4.13 **CEUS of liver metastasis**
Video 4.14 **CEUS of liver metastasis**

5 The Spleen
Patrick M. Vos, John R. Mathieson, and Peter L. Cooperberg

Video 5.1 **Normal spleen in sagittal plane**
Video 5.2 **Normal spleen in transverse plane**
Video 5.3 **Contrast study of lymphoma manifesting as a hypoechoic solitary splenic lesion**

6 The Biliary Tree and Gallbladder
Korosh Khalili and Stephanie R. Wilson

Video 6.1 **Distal common bile duct and ampulla of Vater**
Video 6.2 **Intrahepatic bile duct stones**
Video 6.3 **Distal common bile duct stone**
Video 6.4 **Choledochoduodenal fistula**
Video 6.5 **Primary sclerosing cholangitis**
Video 6.6 **Primary sclerosing cholangitis**
Video 6.7 **Cholangiocarcinoma complicating primary sclerosing cholangitis**
Video 6.8 **Cholangiocarcinoma complicating primary sclerosing cholangitis**
Video 6.9 **Cholelithiasis**
Video 6.10 **Acute cholecystitis**
Video 6.11 **Perforated cholecystitis with liver abscess**

7 The Pancreas
Thomas Winter and Maryellen R.M. Sun

Video 7.1 **Normal pancreas**
Video 7.2 **Acute pancreatitis**
Video 7.3 **Acute pancreatitis**
Video 7.4 **Chronic pancreatitis**
Video 7.5 **Chronic pancreatitis**
Video 7.6 **Pancreatic pseudocyst**
Video 7.7 **Pancreatic carcinoma**
Video 7.8 **Pancreatic carcinoma**
Video 7.9 **Intraductal papillary mucinous neoplasm**
Video 7.10 **Mucinous cystic neoplasm**

8 The Gastrointestinal Tract
Stephanie R. Wilson

Video 8.1 **An incidentally detected neuroendocrine tumor (carcinoid) of the small bowel**
Video 8.2 **Classic features of Crohn disease on a sweep through the terminal ileum**
Video 8.3 **Loss of stratification of the bowel wall layers in severe subacute inflammation of the sigmoid colon in a patient with Crohn disease**
Video 8.4 **Stricture in Crohn disease**
Video 8.5 **Color Doppler shows hyperemia in thickened bowel wall in Crohn disease**
Video 8.6 **Contrast-enhanced longitudinal image of Crohn disease**
Video 8.7 **Contrast-enhanced cross-sectional image of Crohn disease**
Video 8.8 **Severe fixation and acute angulation of the ileum with stricture and enteroenteric fistula**
Video 8.9 **Incomplete small bowel obstruction in patient with Crohn disease**
Video 8.10 **Dysfunctional and excess peristalsis**
Video 8.11 **Localized perforation with a phlegmonous inflammatory mass**
Video 8.12 **Enteroenteric fistula**
Video 8.13 **Normal appendix**
Video 8.14 **Perforated appendix**
Video 8.15 **Acute diverticulitis in second trimester of pregnancy**
Video 8.16 **Paralytic ileus**
Video 8.17 **Incomplete bowel obstruction due to an inflammatory stricture from Crohn disease seen only on endovaginal scan**

9 The Kidney and Urinary Tract
Mitchell Tublin, Deborah Levine, Wendy Thurston, and Stephanie R. Wilson

Video 9.1 **Doppler jet**
Video 9.2 **Renal cell carcinoma**
Video 9.3 **Transitional cell carcinoma of the bladder**
Video 9.4 **Bladder diverticula**

11 The Adrenal Glands
Christina Marie Chingkoe, Olga R. Brook, and Deborah Levine

Video 11.1 **Normal adrenal gland**
Video 11.2 **Adrenal adenoma**
Video 11.3 **Adrenal adenoma**
Video 11.4 **Adrenal gland with calcification**

12 The Retroperitoneum
Raymond E. Bertino and Elton Mustafaraj

Video 12.1 **Type 2 endoleak from inferior mesenteric artery–aorta**
Video 12.2 **Type 2 endoleak on enhanced computed tomography scan**
Video 12.3 **Type 3 endoleak, transverse image**
Video 12.4 **Type 3 endoleak, longitudinal image**
Video 12.5 **Aortic pseudoaneurysm (contained rupture), longitudinal image**
Video 12.6 **Restenosis of stented accessory left renal artery**
Video 12.7 **Angiogram of restenosis of stented accessory left renal artery**

Video 12.8 **Angiogram of stented accessory left renal artery restenosis after restenting**
Video 12.9 **Normal right renal artery**
Video 12.10 **Left renal artery stenosis with color bruit and aliasing throughout cardiac cycle**
Video 12.11 **Nutcracker syndrome**
Video 12.12 **Nutcracker syndrome after stent placement**
Video 12.13 **Prominent arcuate veins**
Video 12.14 **Mildly prominent arcuate veins**
Video 12.15 **Angiogram of left ovarian vein during coil placement**

13 Dynamic Ultrasound of Hernias of the Groin and Anterior Abdominal Wall
Deborah Levine, Lisa Napolitano, and A. Thomas Stavros

Video 13.1 **Fat-containing indirect inguinal hernia**
Video 13.2 **Direct inguinal hernia with intraperitoneal and preperitoneal fat**
Video 13.3 **Note bowel peristalsis in this inguinal hernia**
Video 13.4 **Large fat-containing direct inguinal hernia**
Video 13.5 **Change in hernia contents during Valsalva maneuver**
Video 13.6 **Completely reducible large wide-necked fat-containing ventral hernia**
Video 13.7 **Partially reducible indirect inguinal hernia containing fat and bowel**
Video 13.8 **Nonreducible fat-containing epigastric linea alba hernia**
Video 13.9 **Large bowel-containing indirect inguinal hernia extending into scrotum**
Video 13.10 **Fat-containing femoral hernia**
Video 13.11 **Moderate-sized fat-containing nonreducible left spigelian hernia**
Video 13.12 **Large fat- and bowel-containing incompletely reducible spigelian hernia**
Video 13.13 **Diastasis recti abdominis**
Video 13.14 **Fat-containing ventral hernia**
Video 13.15 **Small fat-containing nonreducible epigastric linea alba hernia**
Video 13.16 **Two adjacent moderate-sized fat-containing incompletely reducible epigastric linea alba hernias**
Video 13.17 **Mesh with strong shadow makes evaluation for recurrent hernia difficult**
Video 13.18 **Two adjacent moderate-sized fat-containing incisional hernias in patient after transverse rectus abdominis myocutaneous (TRAM) flap breast reconstruction**
Video 13.19 **Fat-containing incisional hernia**
Video 13.20 **Moderate-sized fat-containing reducible incisional hernia**
Video 13.21 **Moderate-sized fat-containing reducible recurrent inguinal hernia at the edge of mesh**
Video 13.22 **Pantaloon hernias**
Video 13.23 **Strangulated right femoral hernia**
Video 13.24 **Round ligament and inguinal canal (canal of Nuck) in a female with hydrocele**

14 The Peritoneum
Anthony E. Hanbidge, Korosh Khalili, and Stephanie R. Wilson

Video 14.1 **Tumor infiltration of the omentum**
Video 14.2 **Tumor implant in the pouch of Douglas**
Video 14.3 **Tumor implant in the pouch of Douglas**
Video 14.4 **Peritoneal carcinomatosis—parietal peritoneum**
Video 14.5 **Peritoneal carcinomatosis—visceral peritoneum**
Video 14.6 **Peritoneal carcinomatosis—visceral peritoneum**
Video 14.7 **Peritoneal mesothelioma**
Video 14.8 **Endometrioma in the pouch of Douglas**
Video 14.9 **Endometriotic plaque**
Video 14.10 **Endometriotic plaque**

15 The Uterus
Douglas Brown and Deborah Levine

Video 15.1 **Unicornuate uterus**
Video 15.2 **Bicornuate uterus**
Video 15.3 **Fibroid with cystic necrotic change**
Video 15.4 **Adenomyosis**
Video 15.5 **Prolapsing polyp**
Video 15.6 **Endometrial polyp**
Video 15.7 **Endometrial polyp**
Video 15.8 **Endometrial carcinoma**
Video 15.9 **Endometrial carcinoma with hematometra**
Video 15.10 **Synechia**
Video 15.11 **Low position of intrauterine device (IUD)**
Video 15.12 **Vascularized retained products of conception**
Video 15.13 **Bladder flap hematoma and sutures after cesarean section**

16 The Adnexa
Rochelle Filker Andreotti and Lori A. Deitte

Video 16.1 **Bowel peristalsis**
Video 16.2 **Hemorrhagic cyst**
Video 16.3 **Endometrioma**
Video 16.4 **Atypical endometrioma**
Video 16.5 **Deep infiltrating endometriosis**
Video 16.6 **Ovarian torsion**
Video 16.7 **Clear cell carcinoma in endometrioma**
Video 16.8 **Yolk sac tumor**
Video 16.9 **Hydrosalpinx in 70-year-old woman with adnexal cyst**
Video 16.10 **Hydrosalpinx in 35-year-old with complex left adnexal cyst**
Video 16.11 **Pelvic inflammatory disease caused by *Neisseria Gonorrhoeae***

17 Ultrasound-Guided Biopsy of Chest, Abdomen, and Pelvis
Theodora A. Potretzke, Thomas D. Atwell, J. William Charboneau, and Carl Reading

Video 17.1 **Ultrasound-guided omental core biopsy**
Video 17.2 **Ultrasound-guided liver core biopsy**
Video 17.3 **Ultrasound-guided liver mass biopsy using "freehand" technique**
Video 17.4 **Ultrasound-guided liver mass biopsy using "freehand" technique**
Video 17.5 **Power Doppler imaging improving drain conspicuity**
Video 17.6 **Transvaginal adnexal cyst local anesthesia**
Video 17.7 **Transvaginal adnexal cyst aspiration**

18 Organ Transplantation
Derek Muradali and Tanya Punita Chawla

Video 18.1 **Normal renal transplant, sagittal**
Video 18.2 **Normal renal transplant, transverse**
Video 18.3 **Arteriovenous malformation renal transplant**
Video 18.4 **Partially thrombosed pseudoaneurysm in hilum of renal transplant**
Video 18.5 **Normal pancreas transplant, sagittal**
Video 18.6 **Normal pancreas transplant, transverse**

19 The Thyroid Gland
Luigi Solbiati, J. William Charboneau, Vito Cantisani, Carl Reading, and Giovanni Mauri

Video 19.1 **Colloid cysts**
Video 19.2 **Honeycomb pattern of benign nodule**
Video 19.3 **Adenoma**
Video 19.4 **Papillary carcinoma: fine calcifications**
Video 19.5 **Papillary carcinoma: coarse and fine calcifications**
Video 19.6 **Fine-needle aspiration (FNA)**
Video 19.7 **Hashimoto thyroiditis**

20 The Parathyroid Glands
Bonnie J. Huppert and Carl Reading

Video 20.1 **Cystic and solid parathyroid adenoma**
Video 20.2 **Small parathyroid adenoma**
Video 20.3 **Multiple gland parathyroid hyperplasia**
Video 20.4 **Multiple gland parathyroid hyperplasia**
Video 20.5 **Superior parathyroid adenoma**
Video 20.6 **Superior parathyroid adenoma**
Video 20.7 **Inferior parathyroid adenoma**
Video 20.8 **Inferior parathyroid adenoma**
Video 20.9 **Ectopic superior parathyroid adenoma**
Video 20.10 **Intrathyroid parathyroid adenoma**
Video 20.11 **Intrathyroid parathyroid adenoma**
Video 20.12 **Ectopic parathyroid adenoma**
Video 20.13 **Parathyromatosis in the postoperative neck**
Video 20.14 **Parathyroid adenoma**
Video 20.15 **Small inferior parathyroid adenoma and multinodular goiter**
Video 20.16 **Small inferior parathyroid adenoma and multinodular thyroid**
Video 20.17 **Ectopic intrathyroid parathyroid adenoma biopsy**
Video 20.18 **Ectopic parathyroid adenoma biopsy**
Video 20.19 **Ethanol ablation of recurrent graft-dependent hyperparathyroidism**

21 The Breast
Jordana Phillips, Rashmi J. Mehta, and A. Thomas Stavros

Video 21.1 **Importance of light pressure for color Doppler examination**
Video 21.2 **Importance of light pressure for color Doppler examination**
Video 21.3 **Normal cyst**
Video 21.4 **Intraductal papilloma**
Video 21.5 **Percutaneous biopsy using spring-loaded biopsy device**

22 The Scrotum
Daniel Sommers and Thomas Winter

Video 22.1 **Atrophic testis with seminoma**
Video 22.2 **Epidermoid cyst**
Video 22.3 **Varicocele in patient performing a Valsalva maneuver, with gray-scale and color Doppler sonography**
Video 22.4 **Postvasectomy appearance of epididymis and vas deferens**
Video 22.5 **"Dancing sperm" postvasectomy image of scrotum**
Video 22.6 **Acute orchitis**
Video 22.7 **Inferior traumatic tunica albuginea rupture, hematoma in testis, and extrusion of seminiferous tubules**

23 Overview of Musculoskeletal Ultrasound Techniques and Applications
Colm McMahon and Corrie Yablon

Video 23.1 **Normal biceps muscle and distal tendon**
Video 23.2 **Normal Achilles tendon**
Video 23.3 **Normal finger flexor tendons—dynamic imaging**
Video 23.4 **Dynamic ulnar nerve subluxation**
Video 23.5 **Short-axis imaging of a Baker cyst**

24 The Shoulder
Colm McMahon and Corrie Yablon

Video 24.1 **Dynamic assessment for subcoracoid impingement**
Video 24.2 **Illustration of imaging the supraspinatus in long axis and the transition to infraspinatus posteriorly**
Video 24.3 **Dynamic assessment for subacromial impingement**
Video 24.4 **Dynamic imaging showing increased prominence of glenohumeral effusion on external rotation**
Video 24.5 **Short-axis imaging of the supraspinatus tendon**

25 Musculoskeletal Interventions
Ronald S. Adler

Video 25.1 **Intraarticular injection of a hip under ultrasound guidance**
Video 25.2 **Biceps tendon sheath injection using a rotator interval approach**
Video 25.3 **Aspiration of a spinoglenoid notch cyst**
Video 25.4 **Injection of calcific tendinosis**
Video 25.5 **Autologous blood injection of 50-year-old woman with lateral epicondylitis**
Video 25.6 **Depiction of Tenex procedure**
Video 25.7 **Posthydrodissection of sural nerve in a 59-year-old female patient**

26 The Extracranial Cerebral Vessels
Edward I. Bluth, Stephen I. Johnson, and Laurie Troxclair

Video 26.1 **Minimal homogeneous plaque at carotid bulb (gray-scale)**
Video 26.2 **Considerable homogenous plaque at ICA (gray-scale)**
Video 26.3 **Type 3 homogeneous plaque with less than 50% sonolucency (gray-scale)**
Video 26.4 **Type 3 homogeneous plaque with low-grade stenosis of the ICA (gray-scale)**
Video 26.5 **Calcified plaque in the CCA (gray-scale)**
Video 26.6 **Heterogeneous plaque in the left ICA (type 1) (gray-scale)**
Video 26.7 **Heterogeneous plaque (type 1) with greater than 50% sonolucency within the plaque of the left ICA (gray-scale)**
Video 26.8 **Heterogeneous plaque (type 2) in the ICA (gray-scale)**
Video 26.9 **High-grade stenosis in the proximal right ICA (color Doppler)**
Video 26.10 **Heterogeneous plaque in the ICA (color Doppler)**
Video 26.11 **Heterogeneous plaque in the left ICA (power Doppler)**
Video 26.12 **High-grade stenosis in the ICA (power Doppler)**
Video 26.13 **High-grade stenosis of the ICA (power Doppler)**
Video 26.14 **Low-grade stenosis in the ICA (color Doppler)**
Video 26.15 **Normal spectral waveform of the proximal ICA**
Video 26.16 **Normal spectral waveform of the mid ICA**
Video 26.17 **Normal spectral waveform of the distal ICA**
Video 26.18 **Normal spectral waveform of the right distal CCA**
Video 26.19 **High-grade stenosis in the ICA (power Doppler)**

Video 26.20 **High-grade stenosis in the ICA (color Doppler)**
Video 26.21 **High-grade stenosis with spectral broadening (color and spectral Doppler)**
Video 26.22 **Color and spectral Doppler of low-grade stenosis in the ICA**

27 Peripheral Vessels
Mark E. Lockhart, Heidi R. Umphrey, Therese M. Weber, and Michelle L. Robbin

Video 27.1 **Acute thrombus in the superficial femoral artery**
Video 27.2 **Occlusion of the superficial femoral artery with a large collateral exiting proximal to the occlusion**
Video 27.3 **Severe calcification of the superficial femoral artery limits ability to see within the artery lumen with gray-scale imaging**
Video 27.4 **Common femoral artery pseudoaneurysm**
Video 27.5 **Common femoral artery to common femoral vein arteriovenous fistula (AVF)**
Video 27.6 **Arterial bypass graft stenosis on grayscale and color Doppler**
Video 27.7 **Large radial artery pseudoaneurysm with rent in arterial wall**
Video 27.8 **Large radial artery pseudoaneurysm**
Video 27.9 **Subclavian steal**
Video 27.10 **Normal femoral vein compression during study to assess for deep venous thrombosis**
Video 27.11 **Acute common femoral vein (CFV) thrombus**
Video 27.12 **Nonocclusive slightly mobile thrombus within the great saphenous vein (GSV) with extension into the common femoral vein (CFV)**
Video 27.13 **Acute deep venous thrombosis in right lower extremity**
Video 27.14 **Chronic vein occlusion with collaterals**
Video 27.15 **Chronic common femoral vein (CFV) occlusion with normal antegrade flow in the femoral vein, and flow reversal in the profunda femoral vein**
Video 27.16 **Slow flow in patent, compressible vein without deep venous thrombosis, longitudinal cine clip**
Video 27.17 **Slow flow in patent, compressible vein without deep venous thrombosis, transverse cine clip**
Video 27.18 **Thrombus in one of paired femoral veins**
Video 27.19 **Normal femoral vein valve**
Video 27.20 **Normal internal jugular vein (IJV) on gray scale compression cine clip**
Video 27.21 **Acute internal jugular thrombus**
Video 27.22 **Nonocclusive thrombus in one brachial vein in the paired brachial veins**
Video 27.23 **Acute thrombus around peripherally inserted central catheter (PICC) line in the basilic vein**
Video 27.24 **Acute thrombus around peripherally inserted central catheter (PICC) line in the basilic vein**
Video 27.25 **Thick-walled cephalic vein with chronic thrombus**
Video 27.26 **Large hematoma adjacent to arteriovenous fistula (AVF)**
Video 27.27 **Small AVF basilic vein pseudoaneurysm**
Video 27.28 **Graft wall irregularity and degeneration from repeated punctures**
Video 27.29 **Graft venous anastomosis stenosis with peak systolic velocity measuring 6.1 m/sec in highest velocity portion of jet**

28 Overview of Obstetric Imaging
Deborah Levine

Video 28.1 **Normal 6-week embryo with cardiac activity**
Video 28.2 **Normal first-trimester embryo with rhombencephalon appearing as a fluid collection in the region of the head**
Video 28.3 **Sagittal view of uterus with 17-week gestational age fetus in cephalic presentation and anterior placenta**
Video 28.4 **Normal intracranial anatomy at 19 weeks' gestation**
Video 28.5 **Four-chamber view of beating fetal heart**
Video 28.6 **Scan through the heart**
Video 28.7 **Normal kidneys and lumbosacral spine**
Video 28.8 **Transverse fetal spine**
Video 28.9 **Bladder and umbilical arteries**

30 The First Trimester
Elizabeth Lazarus and Deborah Levine

Video 30.1 **Early embryonic cardiac activity**
Video 30.2 **Early pregnancy failure at 7 weeks**
Video 30.3 **Expanded amnion in nonviable pregnancy**
Video 30.4 **Ten-week demise with calcified yolk sac**
Video 30.5 **Small subchorionic hemorrhage**
Video 30.6 **Right ectopic pregnancy with adnexal mass separating from the ovary with manual pressure**
Video 30.7 **Ruptured ectopic pregnancy**
Video 30.8 **Cesarean section implantation in retroflexed uterus**
Video 30.9 **Normal rhombencephalon**
Video 30.10 **Persistent trophoblastic neoplasia**
Video 30.11 **Choriocarcinoma**

31 Chromosomal Abnormalities
Bryann Bromley and Beryl Benacerraf

Video 31.1 **Nuchal translucency**
Video 31.2 **Cystic hygroma**
Video 31.3 **Nasal bone in first trimester**
Video 31.4 **Echogenic bowel**
Video 31.5 **Amniocentesis needle being withdrawn from amniotic fluid cavity**

32 Multifetal Pregnancy
Mary C. Frates

Video 32.1 **Quintuplets, 9 weeks' gestational age**
Video 32.2 **Conjoined embryos, 7 weeks' gestational age**
Video 32.3 **Monochorionic monoamniotic twins, 26 weeks' gestational age**
Video 32.4 **Three separate placentas in a trichorionic triplet pregnancy at 13 weeks' gestational age**
Video 32.5 **Velamentous cord insertion in a twin, 34 weeks' gestational age**
Video 32.6 **Growth and fluid discrepancies in dichorionic twins, 24 weeks' gestational age**
Video 32.7 **Twin-twin transfusion syndrome, 22 weeks' gestational age**
Video 32.8 **Twin reversed arterial perfusion sequence, 16 weeks' gestational age**
Video 32.9 **Monochorionic monoamniotic twins, 12 weeks' gestational age**
Video 32.10 **Monochorionic monoamniotic twins, 28 weeks' gestational age**
Video 32.11 **Monochorionic monoamniotic conjoined twins, 35 weeks' gestational age**

33 The Fetal Face and Neck
Ana P. Lourenco and Judy A. Estroff

Video 33.1 **Left 2 complete cleft lip, cleft alveolus, and cleft palate in sagittal plane in 20-week gestational age fetus**
Video 33.2 **Left unilateral complete cleft lip, cleft alveolus, and cleft palate in axial plane in 20-week gestational age fetus**
Video 33.3 **Left unilateral complete cleft lip, cleft alveolus, and cleft palate in coronal plane in 20-week gestational age fetus**
Video 33.4 **Micrognathia at gestational age 20 weeks**

34 The Fetal Brain
Ants Toi and Deborah Levine

Video 34.1 **Normal brain, axial**
Video 34.2 **Normal brain, coronal**
Video 34.3 **Normal brain, sagittal**
Video 34.4 **Choroid plexus cysts**
Video 34.5 **Bilateral ventriculomegaly**
Video 34.6 **Chiari malformation in fetus with spinal neural tube defect**
Video 34.7 **Holoprosencephaly**
Video 34.8 **Second trimester agenesis of corpus callosum**
Video 34.9 **Agenesis of corpus callosum in coronal plane**
Video 34.10 **Agenesis of corpus callosum in sagittal plane**
Video 34.11 **Agenesis of corpus callosum in axial plane with midline cyst**
Video 34.12 **Absence of septal leaflets**

35 The Fetal Spine
Elizabeth Asch and Eric Sauerbrei

Video 35.1 **Normal transaxial spine**
Video 35.2 **Normal longitudinal spine**
Video 35.3 **Myelomeningocele**
Video 35.4 **Closed neural tube defect: transaxial**
Video 35.5 **Closed neural tube defect: longitudinal**
Video 35.6 **Sacrococcygeal teratoma**

36 The Fetal Chest
Dorothy Bulas

Video 36.1 **Congenital pulmonary adenomatoid malformation**
Video 36.2 **Small pleural effusion at 16 weeks' gestational age**
Video 36.3 **Left-sided congenital diaphragmatic hernia at 32 weeks' gestational age (transverse view)**
Video 36.4 **Left-sided congenital diaphragmatic hernia at 32 weeks' gestational age (sagittal view)**
Video 36.5 **Large left-sided congenital diaphragmatic hernia with large amount of liver in chest**
Video 36.6 **Right-sided congenital diaphragmatic hernia**

37 The Fetal Heart
Elizabeth R. Stamm and Julia A. Drose

Video 37.1 **Normal apical four-chamber view**
Video 37.2 **Normal sub-costal four-chamber view**
Video 37.3 **Normal appearance of the aorta and pulmonary artery**
Video 37.4 **Color Doppler of the aorta and pulmonary artery**
Video 37.5 **Short-axis view of the color Doppler of the ventricles and great arteries**
Video 37.6 **Three-vessel and trachea view**
Video 37.7 **Aortic arch**
Video 37.8 **Aortic arch**
Video 37.9 **Atrioventricular septal defect**
Video 37.10 **Hypoplastic left heart syndrome**
Video 37.11 **Hypoplastic right heart**
Video 37.12 **Ebstein anomaly**
Video 37.13 **Tetralogy of Fallot**

38 The Fetal Gastrointestinal Tract and Abdominal Wall
Nir Melamed, Anne Kennedy, and Phyllis Glanc

Video 38.1 **Esophageal atresia**
Video 38.2 **Gastric debris**
Video 38.3 **Gastric debris**
Video 38.4 **Duodenal atresia**
Video 38.5 **Jejunal atresia**
Video 38.6 **Duplication cyst**
Video 38.7 **Meconium peritonitis**
Video 38.8 **Echogenic bowel**
Video 38.9 **Normal gallbladder**
Video 38.10 **Annular pancreas**
Video 38.11 **Splenic cyst**
Video 38.12 **Gastroschisis**
Video 38.13 **Omphalocele**
Video 38.14 **Bladder exstrophy**
Video 38.15 **Cloacal exstrophy**

39 The Fetal Urogenital Tract
Katherine W. Fong, Julia Eva Kfouri, and Kirsten L. Weind Matthews

Video 39.1 **"Lying down" adrenal sign due to unilateral renal agenesis**
Video 39.2 **Bilateral renal agenesis**
Video 39.3 **Pelvic kidney**
Video 39.4 **Cross-fused renal ectopia**
Video 39.5 **Horseshoe kidney**
Video 39.6 **Autosomal recessive polycystic kidney disease**
Video 39.7 **Perinephric urinoma**
Video 39.8 **Primary megaureter**
Video 39.9 **Megalourethra**
Video 39.10 **Cloacal dysgenesis**
Video 39.11 **Ovarian cyst**

40 The Fetal Musculoskeletal System
Phyllis Glanc, David Chitayat, and Sheila Unger

Video 40.1 **Thanatophoric dysplasia**
Video 40.2 **Clubfeet at 21 weeks**

41 Fetal Hydrops
Deborah Levine

Video 41.1 **Fetal abdomen at 30 weeks gestational age in fetus with a small amount of ascites and polyhydramnios**
Video 41.2 **Bilateral pleural effusions, left greater than right**

CHAPTER 1

Physics of Ultrasound

Christopher R.B. Merritt

SUMMARY OF KEY POINTS

- Quality imaging requires an understanding of basic acoustic principles.
- Image interpretation requires recognition and understanding of common artifacts.
- Special modes of operation, including harmonic imaging, compounding, elastography, and Doppler, expand the capabilities of conventional gray-scale imaging.
- Knowledge of mechanical and thermal bioeffects of ultrasound is necessary for prudent use.
- High-intensity focused ultrasound has potential therapeutic applications.

THERAPEUTIC APPLICATIONS: HIGH-INTENSITY FOCUSED ULTRASOUND

All diagnostic ultrasound applications are based on the detection and display of acoustic energy reflected from interfaces within the body. These interactions provide the information needed to generate high-resolution, gray-scale images of the body, as well as display information related to blood flow. Its unique imaging attributes have made ultrasound an important and versatile medical imaging tool. However, expensive state-of-the-art instrumentation does not guarantee the production of high-quality studies of diagnostic value. Gaining maximum benefit from this complex technology requires a combination of skills, including knowledge of the physical principles that empower ultrasound with its unique diagnostic capabilities. The user must understand the fundamentals of the interactions of acoustic energy with tissue and the methods and instruments used to produce and optimize the ultrasound display. With this knowledge the user can collect the maximum information from each examination, avoiding pitfalls and errors in diagnosis that may result from the omission of information or the misinterpretation of artifacts.[1]

Ultrasound imaging and Doppler ultrasound are based on the scattering of sound energy by interfaces of materials with different properties through interactions governed by acoustic

physics. The amplitude of reflected energy is used to generate ultrasound images, and frequency shifts in the backscattered ultrasound provide information relating to moving targets such as blood. To produce, detect, and process ultrasound data, users must manage numerous variables, many under their direct control. To do this, operators must understand the methods used to generate ultrasound data and the theory and operation of the instruments that detect, display, and store the acoustic information generated in clinical examinations.

This chapter provides an overview of the fundamentals of acoustics, the physics of ultrasound imaging and flow detection, and ultrasound instrumentation with emphasis on points most relevant to clinical practice. A discussion of the therapeutic application of high-intensity focused ultrasound concludes the chapter.

BASIC ACOUSTICS

Wavelength and Frequency

Sound is the result of mechanical energy traveling through matter as a wave producing alternating **compression** and **rarefaction.** Pressure waves are propagated by limited physical displacement of the material through which the sound is being transmitted. A plot of these changes in pressure is a sinusoidal waveform (Fig. 1.1), in which the Y axis indicates the pressure at a given point and the X axis indicates time. Changes in pressure with time define the basic units of measurement for sound. The distance between corresponding points on the time-pressure curve is defined as the **wavelength** (λ), and the time (T) to complete a single cycle is called the **period.** The number of complete cycles in a unit of time is the **frequency** *(f)* of the sound. Frequency and period are inversely related. If the period (T) is expressed in seconds, $f = 1/T$, or $f = T \times sec^{-1}$. The unit of **acoustic frequency** is the **hertz** (Hz); 1 Hz = 1 cycle per second. High frequencies are expressed in kilohertz (kHz; 1 kHz = 1000 Hz) or **megahertz** (MHz; 1 MHz = 1,000,000 Hz).

In nature, acoustic frequencies span a range from less than 1 Hz to more than 100,000 Hz (100 kHz). Human hearing is limited to the lower part of this range, extending from 20 to 20,000 Hz. Ultrasound differs from audible sound only in its frequency, and it is 500 to 1000 times higher than the sound we normally hear. Sound frequencies used for diagnostic applications typically range from 2 to 15 MHz, although frequencies as high as 50 to 60 MHz are under investigation for certain specialized imaging applications. In general, the frequencies used for ultrasound imaging are higher than those used for Doppler. Regardless of the frequency, the same basic principles of acoustics apply.

Propagation of Sound

In most clinical applications of ultrasound, brief bursts or pulses of energy are transmitted into the body and propagated through tissue. Acoustic pressure waves can travel in a direction perpendicular to the direction of the particles being displaced (**transverse** waves), but in tissue and fluids, sound propagation is primarily along the direction of particle movement (**longitudinal** waves). Longitudinal waves are important in conventional ultrasound imaging and Doppler, while transverse waves are measured in shear wave elastography. The speed at which pressure waves move through tissue varies greatly and is affected by the physical properties of the tissue. **Propagation velocity** is largely determined by the **resistance** of the medium to compression, which in turn is influenced by the **density** of the medium and its **stiffness** or elasticity. Propagation velocity is increased by increasing stiffness and reduced by decreasing density. In the body, propagation velocity of longitudinal waves may be regarded as constant for a given tissue and is not affected by the frequency or wavelength of the sound. This is in contrast to transverse (shear) waves for

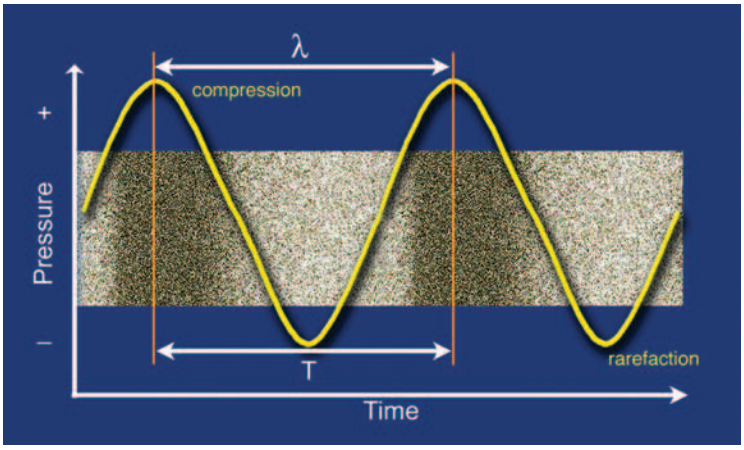

FIG. 1.1 Sound Waves. Sound is transmitted mechanically at the molecular level. In the resting state the pressure is uniform throughout the medium. Sound is propagated as a series of alternating pressure waves producing compression and rarefaction of the conducting medium. The time for a pressure wave to pass a given point is the period, *T*. The frequency of the wave is 1/T. The wavelength, λ, is the distance between corresponding points on the time-pressure curve.

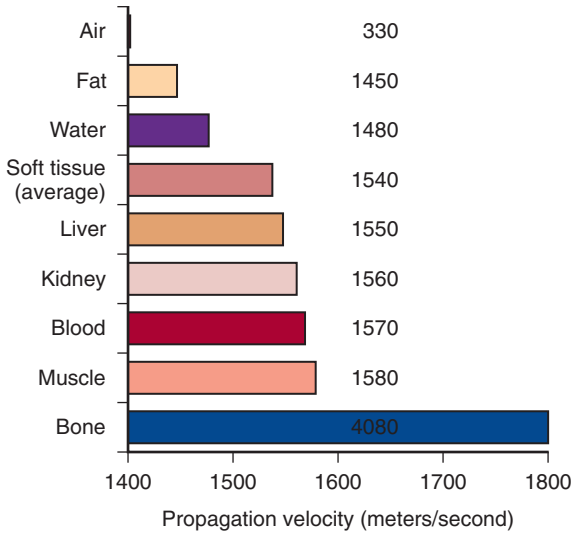

FIG. 1.2 Propagation Velocity. In the body, propagation velocity of sound is determined by the physical properties of tissue. As shown, this varies considerably. Medical ultrasound devices base their measurements on an assumed average propagation velocity of soft tissue of 1540 m/sec.

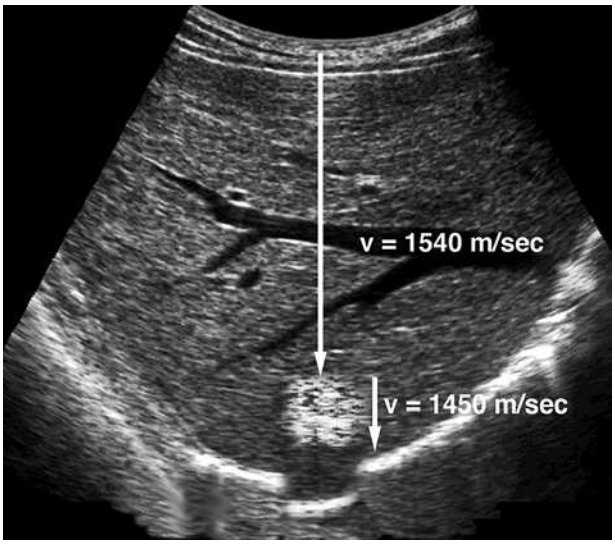

FIG. 1.3 Propagation Velocity Artifact. When sound passes through a lesion containing fat, echo return is delayed because fat has a propagation velocity of 1450 m/sec, which is less than the liver. Because the ultrasound scanner assumes that sound is being propagated at the average velocity of 1540 m/sec, the delay in echo return is interpreted as indicating a deeper target. Therefore the final image shows a **misregistration artifact** in which the diaphragm and other structures deep to the fatty lesion are shown in a deeper position than expected (simulated image).

which the velocity is determined by Young modulus, a measure of tissue stiffness or **elasticity.**

Fig. 1.2 shows typical longitudinal propagation velocities for a variety of materials. In the body the propagation velocity of sound is assumed to be 1540 meters per second (m/sec). This value is the average of measurements obtained from normal soft tissue.[2,3] Although this value represents most soft tissues, such tissues as aerated lung and fat have propagation velocities significantly less than 1540 m/sec, whereas tissues such as bone have greater velocities. Because a few normal tissues have propagation values significantly different from the average value assumed by the ultrasound scanner, the display of such tissues may be subject to measurement errors or **artifacts** (Fig. 1.3). The propagation velocity of sound (c) is related to frequency and wavelength by the following simple equation:

$$c = f\lambda$$

Thus a frequency of 5 MHz can be shown to have a wavelength of 0.308 mm in tissue: $\lambda = c/f = 1540$ m/sec $\times$ 5,000,000 $\text{sec}^{-1} =$ 0.000308 m = 0.308 mm. Wavelength is an important determinant of spatial resolution in ultrasound imaging, and selection of transducer frequency for a given application is a key user decision.

Distance Measurement

Propagation velocity is a particularly important value in clinical ultrasound and is critical in determining the distance of a reflecting interface from the transducer. Much of the information used to generate an ultrasound scan is based on the precise measurement of time and employs the principles of **echo-ranging** (Fig. 1.4). If an ultrasound pulse is transmitted into the body and the time until an echo returns is measured, it is simple to calculate the depth of the interface that generated the echo, provided the propagation velocity of sound for the tissue is known. For example, if the time from the transmission of a pulse until the return of an echo is 0.000145 seconds and the velocity of sound is 1540 m/sec, the distance that the sound has traveled must be 22.33 cm (1540 m/sec $\times$ 100 cm/m $\times$ 0.000145 sec = 22.33 cm). Because the time measured includes the time for sound to travel to the interface and then return along the same path to the transducer, the distance from the transducer to the reflecting interface is 22.33 cm/2 = 11.165 cm. By rapidly repeating this process, a two-dimensional (2-D) map of reflecting interfaces is created to form the ultrasound image. The accuracy of this measurement is therefore highly influenced by how closely the presumed velocity of sound corresponds to the true velocity in the tissue being observed (see Figs. 1.2 and 1.3), as well as by the important assumption that the sound pulse travels in a straight path to and from the reflecting interface.

Acoustic Impedance

Current diagnostic ultrasound scanners rely on the detection and display of **reflected sound** or **echoes.** Imaging based on transmission of ultrasound is also possible, but this is not used clinically at present. To produce an echo, a reflecting interface must be present. Sound passing through a totally homogeneous medium encounters no interfaces to reflect sound, and the medium appears **anechoic** or **cystic.** The junction of tissues or materials with different physical properties produces an acoustic interface. These interfaces are responsible for the reflection of variable amounts of the incident sound energy. Thus when ultrasound passes from one tissue to another or encounters a vessel wall or circulating blood cells, some of the incident sound

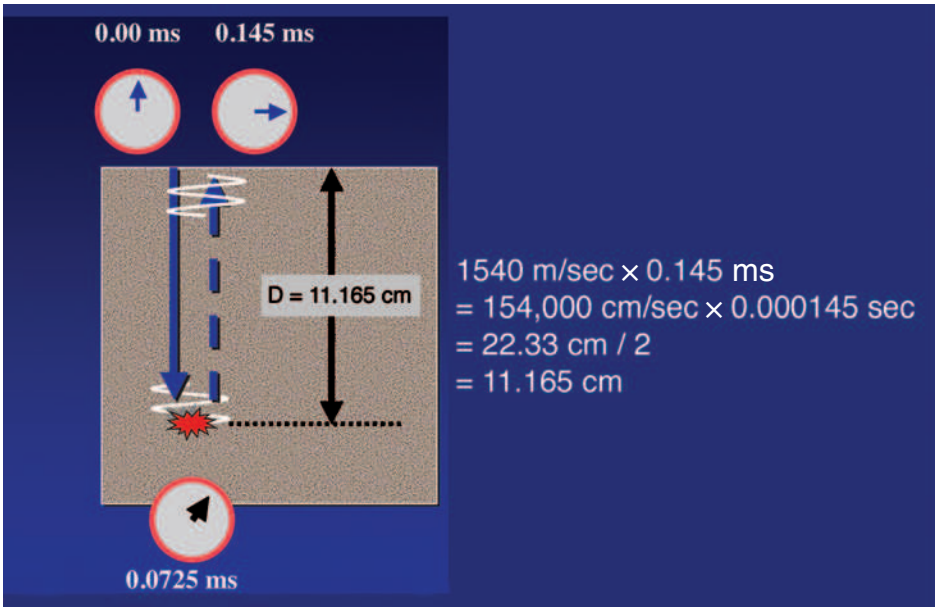

FIG. 1.4 Ultrasound Ranging. The information used to position an echo for display is based on the precise measurement of time. Here the time for an echo to travel from the transducer to the target and return to the transducer is 0.145 ms (0.000145 seconds). Multiplying the velocity of sound in tissue (1540 m/sec) by the time shows that the sound returning from the target has traveled 22.33 cm. Therefore the target lies half this distance, or 11.165 cm, from the transducer. By rapidly repeating this process, a two-dimensional map of reflecting interfaces is created to form the ultrasound image.

energy is reflected. The amount of reflection or **backscatter** is determined by the difference in the acoustic impedances of the materials forming the interface.

Acoustic impedance (Z) is determined by product of the density (ρ) of the medium propagating the sound and the propagation velocity (c) of sound in that medium ($Z = \rho c$). Interfaces with large acoustic impedance differences, such as interfaces of tissue with air or bone, reflect almost all the incident energy. Interfaces composed of substances with smaller differences in acoustic impedance, such as a muscle and fat interface, reflect only part of the incident energy, permitting the remainder to continue onward. As with propagation velocity, acoustic impedance is determined by the properties of the tissues involved and is independent of frequency.

Reflection

The way ultrasound is reflected when it strikes an acoustic interface is determined by the size and surface features of the interface (Fig. 1.5). If large and relatively smooth, the interface reflects sound much as a mirror reflects light. Such interfaces are called **specular reflectors** because they behave as "mirrors for sound." The amount of energy reflected by an acoustic interface can be expressed as a fraction of the incident energy; this is termed the **reflection coefficient** (R). If a specular reflector is perpendicular to the incident sound beam, the amount of energy reflected is determined by the following relationship:

$$R = (Z_2 - Z_1)^2 / (Z_2 + Z_1)^2$$

where Z_1 and Z_2 are the acoustic impedances of the media forming the interface.

Because ultrasound scanners only detect reflections that return to the transducer, display of specular interfaces is highly dependent on the **angle of insonation** (exposure to ultrasound waves). Specular reflectors will return echoes to the transducer only if the sound beam is perpendicular to the interface. If the interface is not at a near 90-degree angle to the sound beam, it will be reflected away from the transducer, and the echo will not be detected (see Fig. 1.5A).

Examples of Specular Reflectors

Diaphragm
Vessel wall
Wall of urine-filled bladder
Endometrial stripe

Most echoes in the body do not arise from specular reflectors but rather from much smaller interfaces within solid organs. In this case the acoustic interfaces involve structures with individual dimensions much smaller than the wavelength of the incident sound. The echoes from these interfaces are scattered in all directions. Such reflectors are called **diffuse reflectors** and account for the echoes that form the characteristic echo patterns seen in solid organs and tissues (see Fig. 1.5B). The constructive and destructive interference of sound scattered by diffuse reflectors results in the production of **ultrasound speckle,** a feature of tissue texture of sonograms of solid organs (Fig. 1.6). For some diagnostic applications, the nature of the reflecting structures creates important conflicts. For example, most vessel walls behave as specular reflectors that require insonation at a 90-degree angle for best imaging, whereas Doppler imaging requires an angle of less than 90 degrees between the sound beam and the vessel.

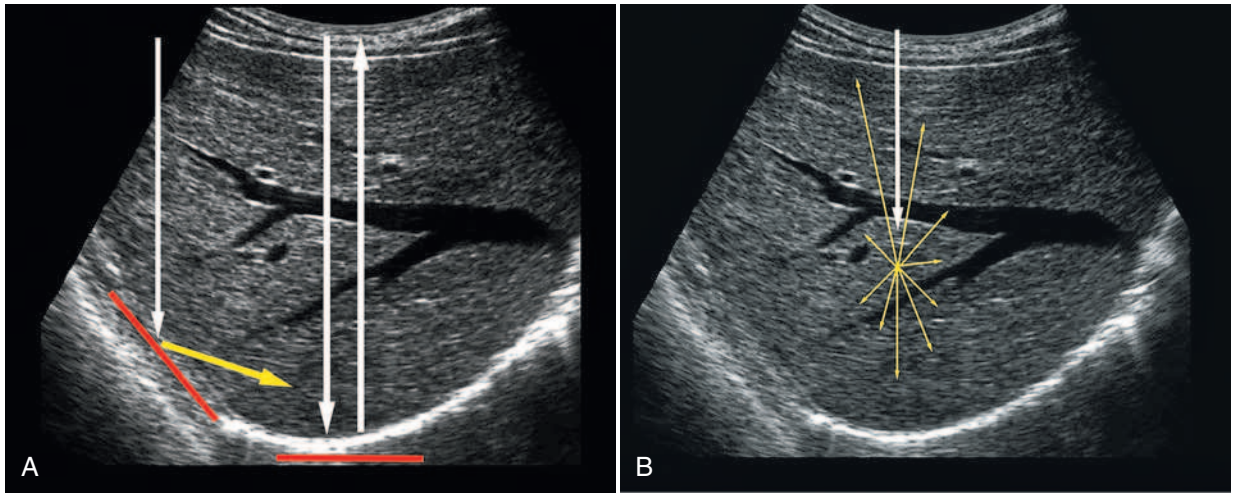

FIG. 1.5 Specular and Diffuse Reflectors. (A) Specular reflector. The diaphragm is a large and relatively smooth surface that reflects sound like a mirror reflects light. Thus sound striking the diaphragm at nearly a 90-degree angle is reflected directly back to the transducer, resulting in a strong echo. Sound striking the diaphragm obliquely is reflected away from the transducer, and an echo is not displayed *(yellow arrow).* **(B) Diffuse reflector.** In contrast to the diaphragm, the liver parenchyma consists of acoustic interfaces that are small compared to the wavelength of sound used for imaging. These interfaces scatter sound in all directions, and only a portion of the energy returns to the transducer to produce the image.

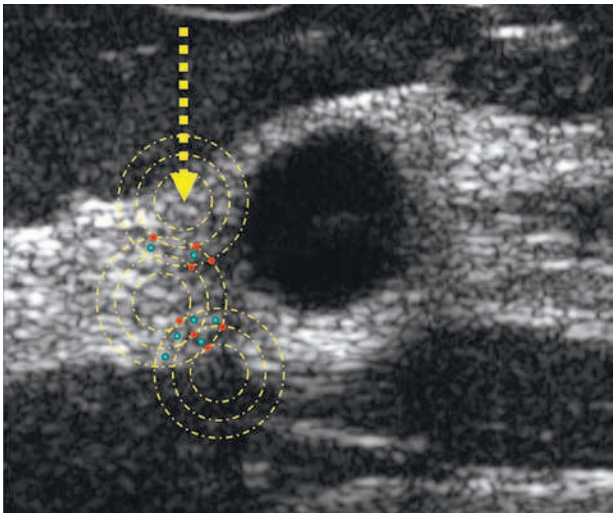

FIG. 1.6 Ultrasound Speckle. Close inspection of an ultrasound image of the breast containing a small cyst reveals it to be composed of numerous areas of varying intensity (speckle). Speckle results from the constructive *(red)* and destructive *(green)* interaction of the acoustic fields *(yellow rings)* generated by the scattering of ultrasound from small tissue reflectors. This interference pattern gives ultrasound images their characteristic grainy appearance and may reduce contrast. Ultrasound speckle is the basis of the texture displayed in ultrasound images of solid tissues.

Refraction

When sound passes from a tissue with one acoustic propagation velocity to a tissue with a higher or lower sound velocity, there is a change in the direction of the sound wave. This change in direction of propagation is called refraction and is governed by Snell law:

$$\sin\theta_1/\sin\theta_2 = c_1/c_2$$

where θ_1 is the **angle of incidence** of the sound approaching the interface, θ_2 is the **angle of refraction,** and c_1 and c_2 are the propagation velocities of sound in the media forming the interface (Fig. 1.7). Refraction is important because it is one cause of **misregistration** of a structure in an ultrasound image (Fig. 1.8). When an ultrasound scanner detects an echo, it assumes that the source of the echo is along a fixed line of sight from the transducer. If the sound has been refracted, the echo detected may be coming from a different depth or location than the image shown in the display. If this is suspected, increasing the scan angle so that it is perpendicular to the interface minimizes the artifact.

Attenuation

As the **acoustic energy** moves through a uniform medium, work is performed and energy is ultimately transferred to the transmitting medium as heat. The capacity to perform work is determined by the quantity of acoustic energy produced. **Acoustic power,** expressed in watts (W) or milliwatts (mW), describes the amount of acoustic energy produced in a unit of time. Although measurement of power provides an indication of the energy as it relates to time, it does not take into account the spatial distribution of the energy. **Intensity** (I) is used to describe the spatial distribution of power and is calculated by dividing the power by the area over which the power is distributed, as follows:

$$I\,(W/cm^2) = \text{Power}\,(W)/\text{Area}\,(cm^2)$$

The **attenuation** of sound energy as it passes through tissue is of great clinical importance because it influences the *depth* in tissue from which useful information can be obtained. This in turn affects transducer selection and a number of operator-controlled instrument settings, including time (or depth) gain compensation, power output attenuation, and system gain levels. Attenuation is measured in relative rather than absolute units. The **decibel** (dB) notation is generally used to compare different levels of ultrasound power or intensity. This value is 10 times the $\log_{10}$ of the ratio of the power or intensity values being

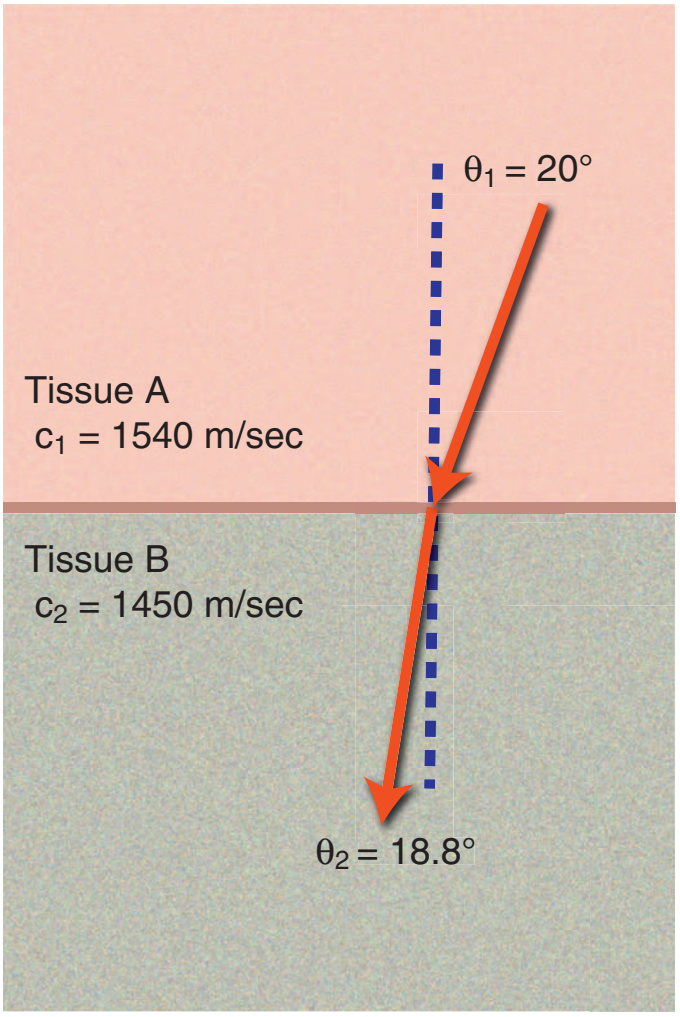

FIG. 1.7 Refraction. When sound passes from tissue A with propagation velocity (c_1) to tissue B with a different propagation velocity (c_2), there is a change in the direction of the sound wave because of refraction. The degree of change is related to the ratio of the propagating velocities of the media forming the interface ($\sin\theta_1/\sin\theta_2 = c_1/c_2$).

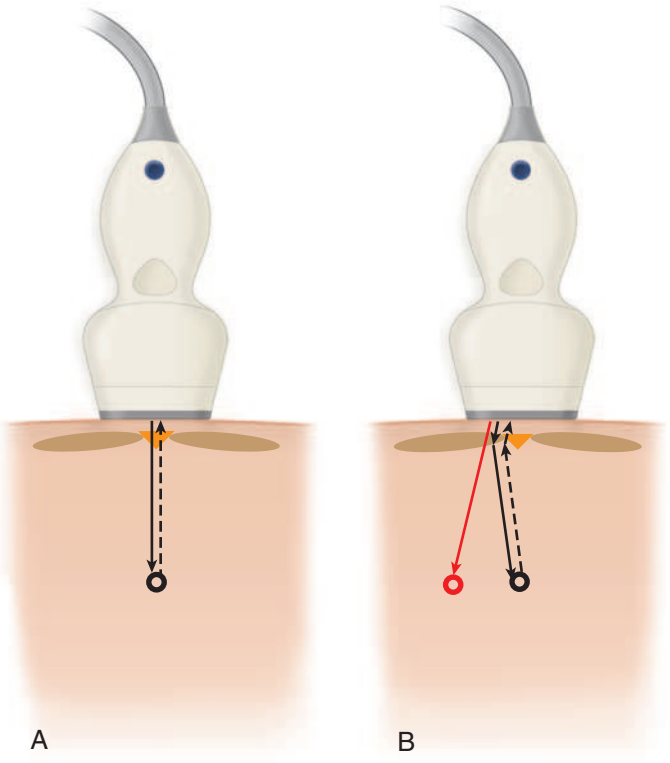
compared. For example, if the intensity measured at one point in tissues is 10 mW/cm^2 and at a deeper point is 0.01 mW/cm^2, the difference in intensity is as follows:

$$(10)(\log_{10} 0.01/10) = (10)(\log_{10} 0.001) = (10)(-\log_{10} 1000)$$
$$= (10)(-3) = -30 \text{ dB}$$

As it passes through tissue, sound loses energy, and the pressure waves decrease in amplitude as they travel farther from their source. Contributing to the attenuation of sound are the transfer of energy to tissue, resulting in heating (absorption), and the removal of energy by reflection and scattering. Attenuation is therefore the result of the combined effects of **absorption, scattering,** and **reflection.** Attenuation depends on the insonating frequency as well as the nature of the attenuating medium. High frequencies are attenuated more rapidly than lower frequencies, and transducer frequency is a major determinant of the useful depth from which information can be obtained with ultrasound. Attenuation determines the efficiency with which ultrasound



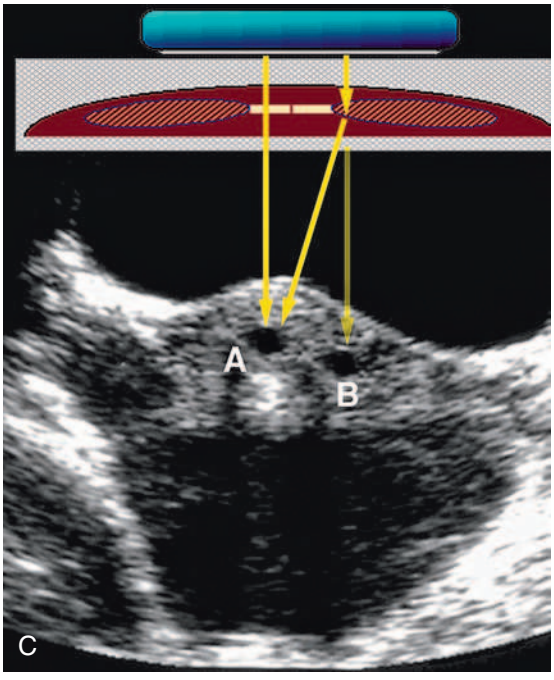


FIG. 1.8 Refraction Artifact. (A) and **(B)** Production of an artifact by refraction of sound in a transverse scan of the mid abdomen. The direct sound path properly depicts the location of the object. **(B)** A "ghost image" *(red)* produced by refraction at the edge of the rectus abdominis muscle. The transmitted and reflected sound travels along the path of the *black arrows*. The scanner assumes the returning signal is from a straight line *(red arrow)* and displays the structure at the incorrect location. **(C)** Axial transabdominal image of the uterus showing a small gestational sac *(A)* and what appears to be a second sac *(B)* due to refraction artifact.

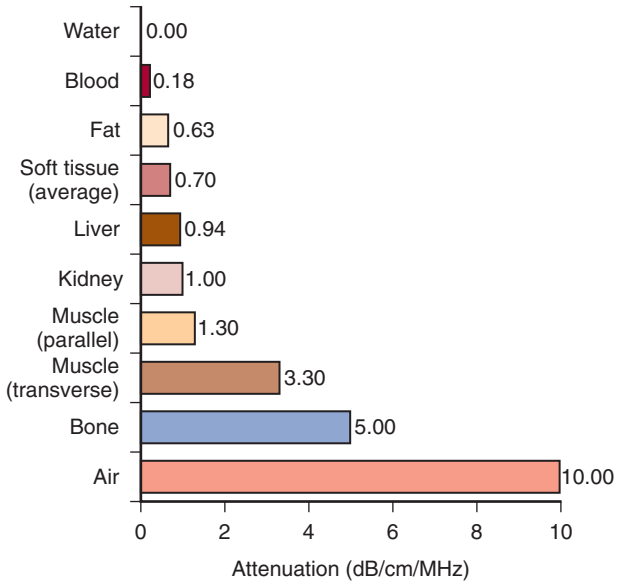

FIG. 1.9 Attenuation. As sound passes through tissue, it loses energy through the transfer of energy to tissue by heating, reflection, and scattering. Attenuation is determined by the insonating frequency and the nature of the attenuating medium. Attenuation values for normal tissues show considerable variation. Attenuation also increases in proportion to insonating frequency, resulting in less penetration at higher frequencies.

penetrates a specific tissue and varies considerably in normal tissues (Fig. 1.9).

INSTRUMENTATION

Ultrasound scanners are complex and sophisticated imaging devices, but all consist of the following basic components to perform key functions:

- Transmitter or pulser to energize the transducer
- Ultrasound transducer
- Receiver and processor to detect and amplify the backscattered energy and manipulate the reflected signals for display
- Display that presents the ultrasound image or data in a form suitable for analysis and interpretation
- Method to record or store the ultrasound image

Transmitter

Most clinical applications use pulsed ultrasound, in which brief bursts of acoustic energy are transmitted into the body. The source of these pulses, the ultrasound transducer, is energized by application of precisely timed, high-amplitude **voltage.** The maximum voltage that may be applied to the transducer is limited by federal regulations that restrict the acoustic output of diagnostic scanners. Most scanners provide a control that permits attenuation of the output voltage. Because the use of maximum output results in higher exposure of the patient to ultrasound **energy, prudent use** dictates use of the output attenuation controls to reduce power levels to the lowest levels consistent with the diagnostic problem.[4]

The transmitter also controls the rate of pulses emitted by the transducer, or the **pulse repetition frequency** (PRF). The PRF determines the time interval between ultrasound pulses and is important in determining the depth from which unambiguous data can be obtained both in imaging and Doppler modes. The ultrasound pulses must be spaced with enough time between the pulses to permit the sound to travel to the depth of interest and return before the next pulse is sent. For imaging, PRFs from 1 to 10 kHz are used, resulting in an interval of 0.1 to 1 ms between pulses. Thus a PRF of 5 kHz permits an echo to travel and return from a depth of 15.4 cm before the next pulse is sent.

Transducer

A transducer is any device that converts one form of energy to another. In ultrasound the transducer converts electric energy to mechanical energy, and vice versa. In diagnostic ultrasound systems the transducer serves two functions: (1) converting the electric energy provided by the transmitter to the acoustic pulses directed into the patient and (2) serving as the receiver of reflected echoes, converting weak pressure changes into electric signals for processing.

Ultrasound transducers use **piezoelectricity,** a principle discovered by Pierre and Jacques Curie in 1880.[5] Piezoelectric materials have the unique ability to respond to the action of an electric field by changing shape. They also have the property of generating electric potentials when compressed. Changing the polarity of a voltage applied to the transducer changes the thickness of the transducer, which expands and contracts as the polarity changes. This results in the generation of mechanical pressure waves that can be transmitted into the body. The piezoelectric effect also results in the generation of small potentials across the transducer when the transducer is struck by returning echoes. Positive pressures cause a small polarity to develop across the transducer; negative pressure during the rarefaction portion of the acoustic wave produces the opposite polarity across the transducer. These tiny polarity changes and the associated voltages are the source of all the information processed to generate an ultrasound image or Doppler display.

When stimulated by the application of a voltage difference across its thickness, the transducer vibrates. The frequency of vibration is determined by the transducer material. When the transducer is electrically stimulated, a range or **band of frequencies** results. The preferential frequency produced by a transducer is determined by the **propagation speed** of the transducer material and its thickness. In the **pulsed wave** operating modes used for most clinical ultrasound applications, the ultrasound pulses contain additional frequencies that are both higher and lower than the preferential frequency. The range of frequencies produced by a given transducer is termed its **bandwidth.** Generally, the shorter the pulse of ultrasound produced by the transducer, the greater is the bandwidth.

Most modern digital ultrasound systems employ broadbandwidth technology. **Ultrasound bandwidth** refers to the range of frequencies produced and detected by the ultrasound system. This is important because each tissue in the body has a characteristic response to ultrasound of a given frequency, and different tissues respond differently to different frequencies. The range of frequencies arising from a tissue exposed to ultrasound is referred to as the **frequency spectrum bandwidth** of the tissue, or tissue

signature. **Broad-bandwidth** technology provides a means to capture the frequency spectrum of insonated tissues, preserving acoustic information and tissue signature. Broad-bandwidth beam formers reduce speckle artifact by a process of **frequency compounding.** This is possible because speckle patterns at different frequencies are independent of one another, and combining data from multiple frequency bands (i.e., compounding) results in a reduction of speckle in the final image, leading to improved contrast resolution.

The length of an ultrasound pulse is determined by the number of alternating voltage changes applied to the transducer. For **continuous wave** (CW) ultrasound devices, a constant **alternating current** is applied to the transducer, and the alternating polarity produces a continuous ultrasound wave. For imaging, a single, brief voltage change is applied to the transducer, causing it to vibrate at its preferential frequency. Because the transducer continues to vibrate or "ring" for a short time after it is stimulated by the voltage change, the ultrasound pulse will be several cycles long. The number of cycles of sound in each pulse determines the **pulse length.** For imaging, short pulse lengths are desirable because longer pulses result in poorer axial resolution. To reduce the pulse length, **damping** materials are used in the construction of the transducer. In clinical imaging applications, very short pulses are applied to the transducer, and the transducers have highly efficient damping. This results in very short pulses of ultrasound, generally consisting of only two or three cycles of sound.

The ultrasound pulse generated by a transducer must be propagated in tissue to provide clinical information. Special transducer coatings and ultrasound coupling gels are necessary to allow efficient transfer of energy from the transducer to the body. Once in the body, the ultrasound pulses are propagated, reflected, refracted, and absorbed, in accordance with the basic acoustic principles summarized earlier.

The ultrasound pulses produced by the transducer result in a series of wavefronts that form a three-dimensional (3-D) beam of ultrasound. The features of this beam are influenced by constructive and destructive interference of the pressure waves, the curvature of the transducer, and acoustic lenses used to shape the beam. Interference of pressure waves results in an area near the transducer where the pressure amplitude varies greatly. This region is termed the **near field,** or **Fresnel zone.** Farther from the transducer, at a distance determined by the radius of the transducer and the frequency, the sound field begins to diverge, and the pressure amplitude decreases at a steady rate with increasing distance from the transducer. This region is called the **far field,** or **Fraunhofer zone.** In modern multielement transducer arrays, precise timing of the firing of elements allows correction of this divergence of the ultrasound beam and focusing at selected depths. Only reflections of pulses that return to the transducer are capable of stimulating the transducer with small pressure changes, which are converted into the voltage changes that are detected, amplified, and processed to build an image based on the echo information.

Receiver

When returning echoes strike the transducer face, minute voltages are produced across the piezoelectric elements. The receiver detects and amplifies these weak signals. The receiver also provides a means for compensating for the differences in echo strength, which result from attenuation by different tissue thickness by control of **time gain compensation** (TGC) or **depth gain compensation** (DGC).

Sound is attenuated as it passes into the body, and additional energy is removed as echoes return through tissue to the transducer. The attenuation of sound is proportional to the frequency and is constant for specific tissues. Because echoes returning from deeper tissues are weaker than those returning from more superficial structures, they must be amplified more by the receiver to produce a uniform tissue echo appearance (Fig. 1.10). This adjustment is accomplished by TGC controls that permit the user to selectively amplify the signals from deeper structures or to suppress the signals from superficial tissues, compensating for tissue attenuation. Although many newer machines provide

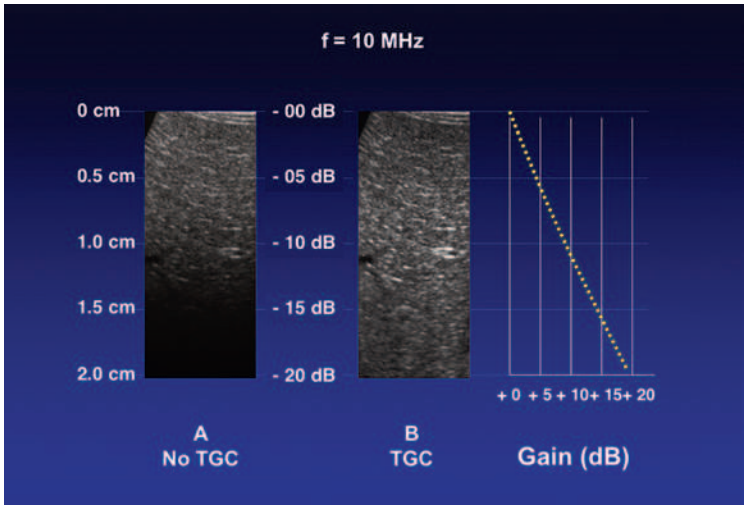

FIG. 1.10 Time Gain Compensation (TGC). Without TGC, tissue attenuation causes gradual loss of display of deeper tissues *(A)*. In this example, tissue attenuation of 1 dB/cm/MHz is simulated for a transducer of 10 MHz. At a depth of 2 cm, the intensity is –20 dB (1% of initial value). By applying increasing amplification or gain to the backscattered signal to compensate for this attenuation, a uniform intensity is restored to the tissue at all depths *(B)*.

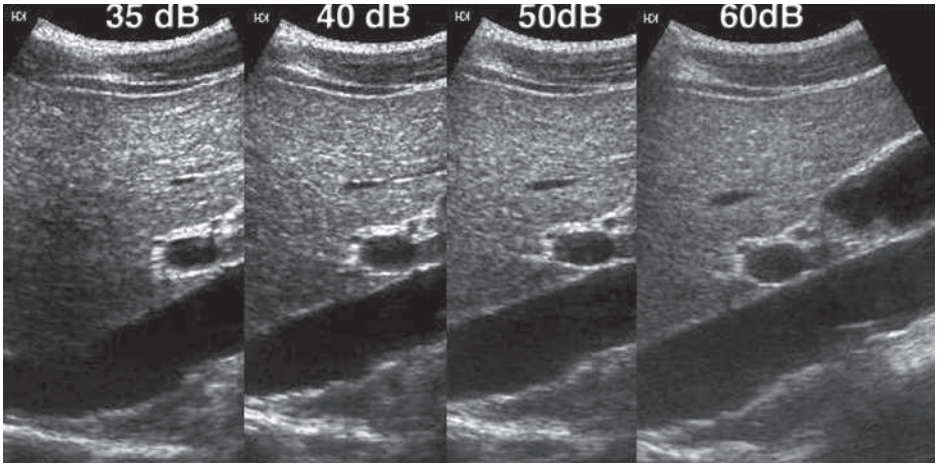

FIG. 1.11 Dynamic Range. The ultrasound receiver must compress the wide range of amplitudes returning to the transducer into a range that can be displayed to the user. Here, compression and remapping of the data to display dynamic ranges of 35, 40, 50, and 60 dB are shown. The widest dynamic range shown (60 dB) permits the best differentiation of subtle differences in echo intensity and is preferred for most imaging applications. The narrower ranges increase conspicuity of larger echo differences.

for some means of automatic TGC, the manual adjustment of this control is one of the most important user controls and may have a profound effect on the quality of the ultrasound image provided for interpretation.

Another important function of the receiver is the compression of the wide range of amplitudes returning to the transducer into a range that can be displayed to the user. The ratio of the highest to the lowest amplitudes that can be displayed may be expressed in decibels and is referred to as the **dynamic range.** In a typical clinical application, the range of reflected signals may vary by a factor of as much as $1:10^{12}$, resulting in a dynamic range of up to 120 dB. Although the amplifiers used in ultrasound machines are capable of handling this range of voltages, gray-scale displays are limited to display a signal intensity range of only 35 to 40 dB. **Compression** and **remapping** of the data are required to adapt the dynamic range of the backscattered signal intensity to the dynamic range of the display (Fig. 1.11). Compression is performed in the receiver by selective amplification of weaker signals. Additional manual postprocessing controls permit the user to map selectively the returning signal to the display. These controls affect the brightness of different echo levels in the image and therefore determine the image contrast.

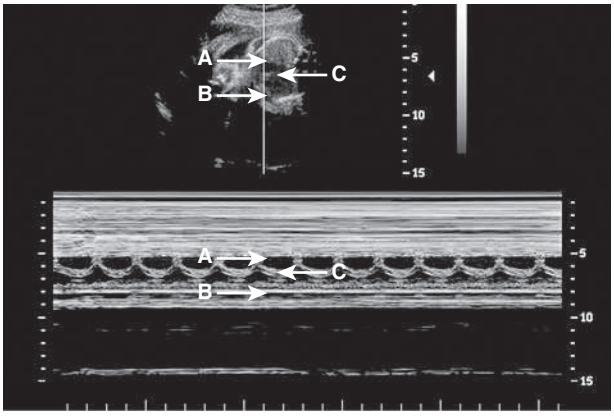

FIG. 1.12 M-Mode Display. M-mode ultrasound displays changes of echo amplitude and position with time. Display of changes in echo position is useful in the evaluation of rapidly moving structures such as cardiac valves and chamber walls. Here, the three major moving structures in the upper gray-scale image of the fetus are recorded in the corresponding M-mode image and include the near ventricular wall *(A)*, the interventricular septum *(B)*, and the far ventricular wall *(C)*. The baseline is a time scale that permits the calculation of heart rate from the M-mode data.

Image Display

Ultrasound signals may be displayed in several ways. Over the years, imaging has evolved from simple **A-mode (amplitude-mode)** and bistable display to high-resolution, real-time, gray-scale imaging. The earliest A-mode devices displayed the voltage produced across the transducer by the backscattered echo as a vertical deflection on the face of an oscilloscope. The horizontal time sweep of the oscilloscope was calibrated to indicate the distance from the transducer to the reflecting surface. In this form of display, the strength or amplitude of the reflected sound is indicated by the height of the vertical deflection displayed on the oscilloscope. With **A-mode ultrasound,** only the position and strength of a reflecting structure are recorded.

Another simple form of imaging, **M-mode (motion-mode) ultrasound,** displays echo amplitude and shows the position of moving reflectors (Fig. 1.12). M-mode imaging uses the brightness of the display to indicate the intensity of the reflected signal. The time base of the display can be adjusted to allow for varying degrees of temporal resolution, as dictated by clinical application. M-mode ultrasound is interpreted by assessing motion patterns of specific reflectors and determining anatomic relationships from characteristic patterns of motion. Currently, the major application of M-mode display is evaluation of embryonic and fetal heart rates, as well as in echocardiography, the rapid motion of cardiac valves and of cardiac chamber and vessel walls. M-mode imaging may play a future role in measurement of subtle changes in vessel wall elasticity accompanying atherogenesis.

The mainstay of imaging with ultrasound is provided by **real-time, gray-scale, B-mode display,** in which variations in display intensity or brightness are used to indicate reflected signals

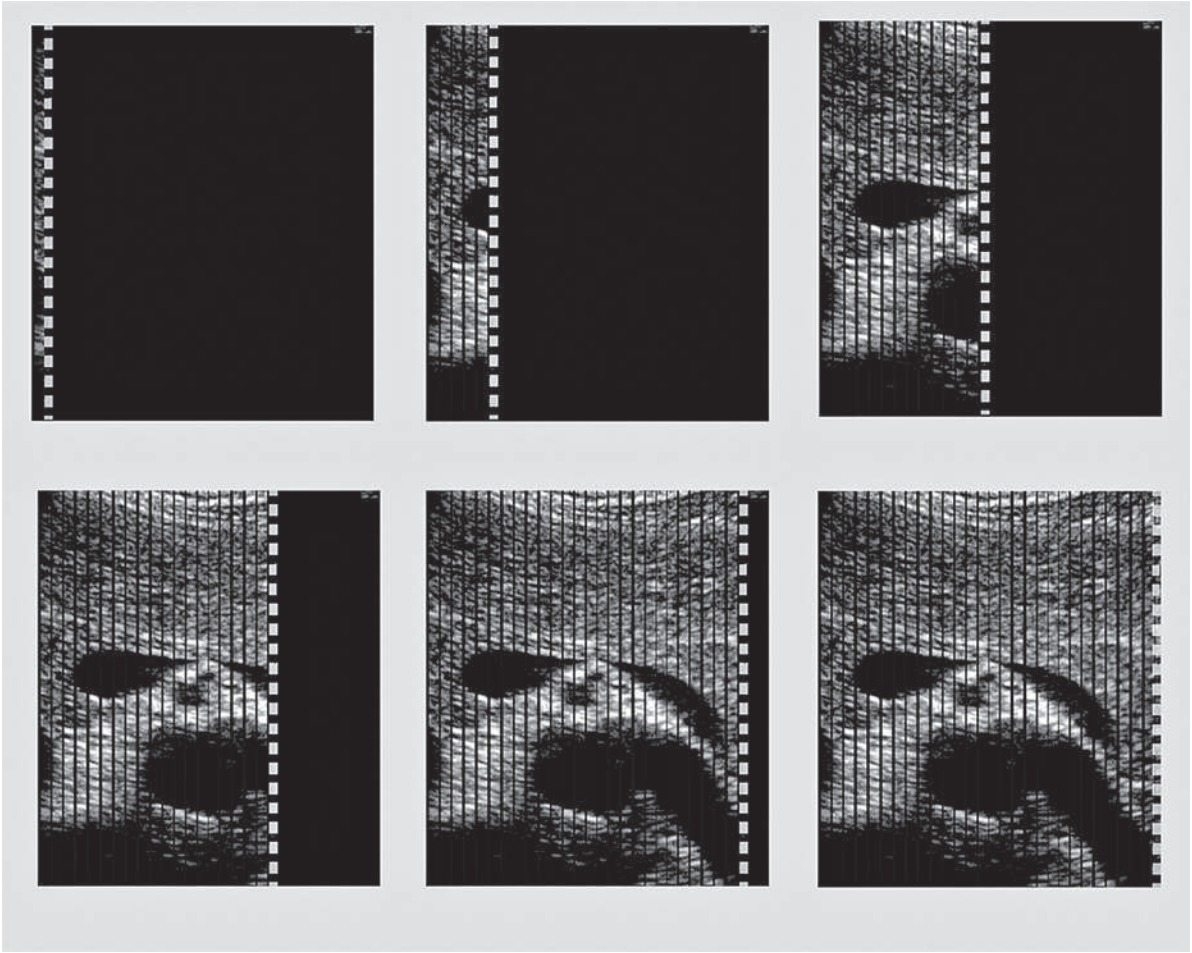

FIG. 1.13 B-Mode Imaging. A two-dimensional (2-D), real-time image is built by ultrasound pulses sent down a series of successive scan lines. Each scan line adds to the image, building a 2-D representation of echoes from the object being scanned. In real-time imaging, an entire image is created 15 to 60 times per second.

of differing amplitude. To generate a 2-D image, multiple ultrasound pulses are sent down a series of successive scan lines (Fig. 1.13), building a 2-D representation of echoes arising from the object being scanned. When an ultrasound image is displayed on a black background, signals of greatest intensity appear as white; absence of signal is shown as black; and signals of intermediate intensity appear as shades of gray. If the ultrasound beam is moved with respect to the object being examined and the position of the reflected signal is stored, the brightest portions of the resulting 2-D image indicate structures reflecting more of the transmitted sound energy back to the transducer.

In most modern instruments, digital memory is used to store values that correspond to the echo intensities originating from corresponding positions in the patient. At least 2^8, or 256, shades of gray are possible for each pixel, in accord with the amplitude of the echo being represented. The image stored in memory in this manner can then be sent to a monitor for display.

Because B-mode display relates the strength of a backscattered signal to a brightness level on the display device, it is important that the operator understand how the amplitude information in the ultrasound signal is translated into a brightness scale in the image display. Each ultrasound manufacturer offers several options for the way the dynamic range of the target is compressed for display, as well as the transfer function that assigns a given signal amplitude to a shade of gray. Although these technical details vary among machines, the way the operator uses them may greatly affect the clinical value of the final image. In general, it is desirable to display as *wide* a dynamic range as possible, to identify subtle differences in tissue echogenicity (see Fig. 1.11).

Real-time ultrasound produces the impression of motion by generating a series of individual 2-D images at rates of 15 to 60 frames per second. Real-time, 2-D, B-mode ultrasound is the major method for ultrasound imaging throughout the body and is the most common form of B-mode display. Real-time ultrasound permits assessment of both anatomy and motion. When images are acquired and displayed at rates of several times per second, the effect is dynamic, and because the image reflects the state and motion of the organ at the time it is examined, the information is regarded as being shown in real time. In cardiac applications the terms *2-D echocardiography* and *2-D echo* are used to describe real-time, B-mode imaging; in most other applications the term *real-time ultrasound* is used.

Transducers used for real-time imaging may be classified by the method used to steer the beam in rapidly generating each

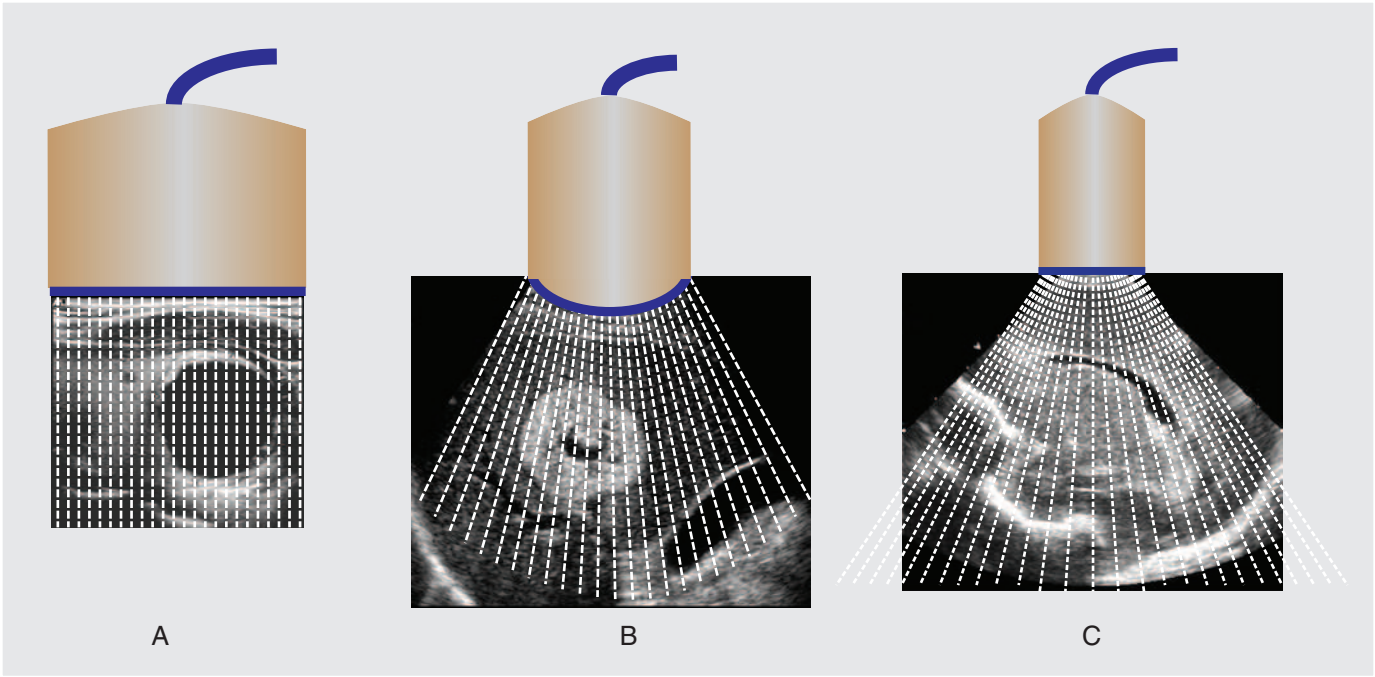

FIG. 1.14 Beam Steering. (A) Linear array. In a linear array transducer, individual elements or groups of elements are fired in sequence. This generates a series of parallel ultrasound beams, each perpendicular to the transducer face. As these beams move across the transducer face, they generate the lines of sight that combine to form the final image. Depending on the number of transducer elements and the sequence in which they are fired, focusing at selected depths from the surface can be achieved Small high-frequency linear arrays are well-suited for small parts scanning. **(B) Curved array.** A variant of the linear array, the curved array uses tranducer elements arranged in an arc, producing a pie-shaped image. These transducers are well-suited for abdominal, pelvic, and fetal examinations. **(C) Phased array.** A phased array transducer produces a sector field of view by firing multiple transducer elements in precise sequence to generate interference of acoustic wavefronts that steer the beam. The ultrasound beam that results generates a series of lines of sight at varying angles from one side of the transducer to the other, producing a sector image format. These transducers require a small contact area compared to most linear and curved arrays and are useful for scanning in areas where access is limited.

individual image, keeping in mind that as many as 30 to 60 complete images must be generated per second for real-time applications. **Beam steering** may be done through mechanical rotation or oscillation of the transducer or by electronic means (Fig. 1.14). **Electronic beam steering** is used in linear array and phased array transducers and permits a variety of image display formats. Most electronically steered transducers currently in use also provide electronic focusing that is adjustable for depth. **Mechanical beam steering** may use single-element transducers with a fixed focus or may use annular arrays of elements with electronically controlled focusing. For real-time imaging, transducers using mechanical or electronic beam steering generate displays in a rectangular or pie-shaped format. For obstetric, small parts, and peripheral vascular examinations, linear array transducers with a rectangular image format are often used. The rectangular image display has the advantage of a larger field of view near the surface but requires a large surface area for transducer contact. Sector scanners with either mechanical or electronic steering require only a small surface area for contact and are better suited for examinations in which access is limited.

Mechanical Sector Scanners

Early ultrasound scanners used transducers consisting of a single piezoelectric element. To generate real-time images with these transducers, mechanical devices were required to move the transducer in a linear or circular motion. Mechanical sector scanners using one or more single-element transducers do not allow variable focusing. This problem is overcome by using annular array transducers. Although important in the early days of real-time imaging, mechanical sector scanners with fixed-focus, single-element transducers are not presently in common use.

Arrays

Current technology uses a transducer composed of multiple elements, usually produced by precise slicing of a piece of piezoelectric material into numerous small units, each with its own electrodes. Such transducer arrays may be formed in a variety of configurations. Typically, these are linear, curved, phased, or annular arrays. High-density 2-D arrays have also been developed. By precise timing of the firing of combinations of elements in these arrays, interference of the wavefronts generated by the individual elements can be exploited to change the direction of the ultrasound beam, and this can be used to provide a steerable beam for the generation of real-time images in a linear or sector format.

Linear Arrays

Linear array transducers are used for small parts, vascular, and obstetric applications because the rectangular image format produced by these transducers is well suited for these applications.

In these transducers, individual elements are arranged in a linear fashion. By firing the transducer elements in sequence, either individually or in groups, a series of parallel pulses is generated, each forming a line of sight perpendicular to the transducer face. These individual lines of sight combine to form the image field of view (see Fig. 1.14A). Depending on the number of transducer elements and the sequence in which they are fired, focusing at selected depths from the surface can be achieved.

Curved Arrays

Linear arrays that have been shaped into convex curves produce an image that combines a relatively large surface field of view with a sector display format (see Fig. 1.14B). Curved array transducers are used for a variety of applications, the larger versions serving for general abdominal, obstetric, and transabdominal pelvic scanning. Small, high-frequency, curved array scanners are often used in transvaginal and transrectal probes and for pediatric imaging.

Phased Arrays

In contrast to mechanical sector scanners, phased array scanners have no moving parts. A sector field of view is produced by multiple transducer elements fired in precise sequence under electronic control. By controlling the time and sequence at which the individual transducer elements are fired, the resulting ultrasound wave can be steered in different directions as well as focused at different depths (see Fig. 1.14C). By rapidly steering the beam to generate a series of lines of sight at varying angles from one side of the transducer to the other, a sector image format is produced. This allows the fabrication of transducers of relatively small size but with large fields of view at depth. These transducers are particularly useful for neonatal head ultrasound, as well as for intercostal scanning, to evaluate the heart, liver, or spleen, and for examinations in other areas where access is limited.

Two-Dimensional Arrays

Transducer arrays can be formed either by slicing a rectangular piece of transducer material perpendicular to its long axis to produce a number of small rectangular elements or by creating a series of concentric elements nested within one another in a circular piece of piezoelectric material to produce an annular array. The use of multiple elements permits precise focusing. A particular advantage of 2-D array construction is that the beam can be focused in both the elevation plane and the lateral plane, and a uniform and highly focused beam can be produced (Fig. 1.15). These arrays improve spatial resolution and contrast, reduce clutter, and are well suited for the collection of data from volumes of tissue for use in 3-D processing and display. Unlike linear 2-D arrays, in which delays in the firing of the individual elements may be used to steer the beam, annular arrays do not permit beam steering and, to be used for real-time imaging, must be steered mechanically.

Transducer Selection

Practical considerations in the selection of the optimal transducer for a given application include not only the requirements for spatial resolution, but also the distance of the target object from the transducer because penetration of ultrasound diminishes as frequency increases. In general, the *highest ultrasound frequency permitting penetration to the depth of interest should be selected.* For superficial vessels and organs, such as the thyroid, breast, or testicle, lying within 1 to 3 cm of the surface, imaging frequencies of 7.5 to 15 MHz are typically used. These high frequencies are also ideal for intraoperative applications. If the region to be scanned is very superficial, such that the probe does not allow for focusing at the area of interest, a standoff pad can be utilized. For evaluation of deeper structures in the abdomen or pelvis more than 12 to 15 cm from the surface, frequencies as low as 2.25 to 3.5 MHz may be required. When maximal resolution is needed, a high-frequency transducer with excellent lateral and elevation resolution at the depth of interest is required.

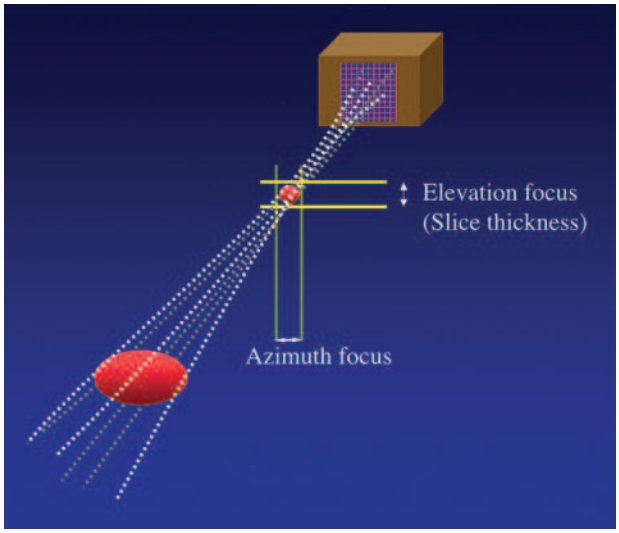

FIG. 1.15 Two-Dimensional Array. High-density, two-dimensional (2-D) arrays consist of a 2-D matrix of transducer elements, permitting acquisition of data from a volume rather than a single plane of tissue. Precise electronic control of individual elements permits adjustable focusing on both **azimuth** and elevation planes.

IMAGE DISPLAY AND STORAGE

With real-time ultrasound, user feedback is immediate and is provided by video display. The brightness and contrast of the image on this display are determined by the ambient lighting in the examination room, the brightness and contrast settings of the video monitor, the system gain setting, and the TGC adjustment. The factor most affecting image quality in many ultrasound departments is probably improper adjustment of the video display, with a lack of appreciation of the relationship between the video display settings and the appearance of hard copy or images viewed on a workstation. Because of the importance of the real-time video display in providing feedback to the user, it is essential that the display and the lighting conditions under which it is viewed are standardized and matched to the display used for interpretation. Interpretation of images and archival storage of images may be in the form of transparencies printed on film by optical or laser cameras and printers, videotape, or digital **picture**

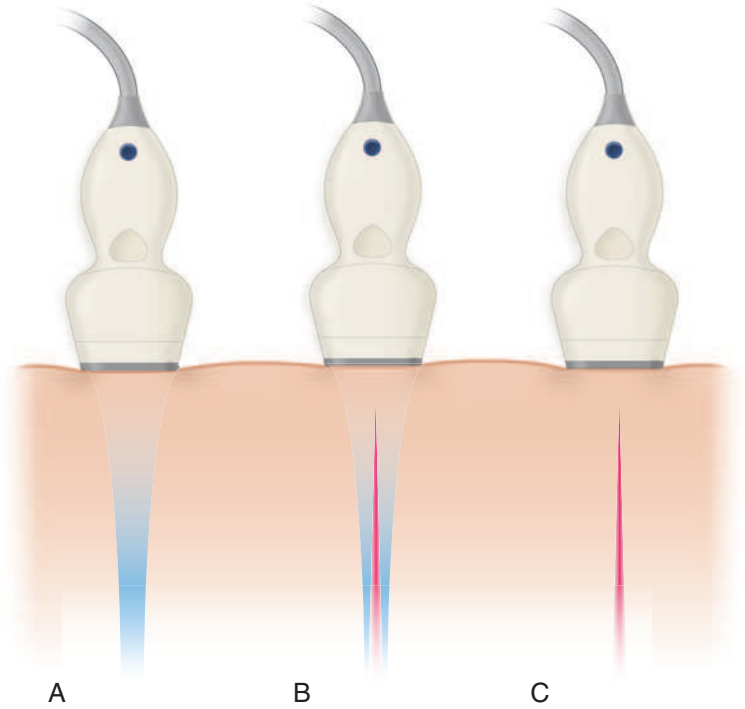

FIG. 1.16 Tissue Harmonics. As sound is propagated through tissue, the high-pressure component of the wave travels more rapidly than the rarefactional component, producing distortion of the wave and generating higher-frequency components (harmonics). **(A)** The acoustic field of the primary frequency is represented in blue. **(B)** The second harmonic (twice the primary frequency) is represented in red. **(C)** Using a broad-bandwidth transducer, the receiver can be tuned to generate an image from the harmonic frequency rather than the primary frequency. As a result, near field clutter is reduced since the harmonic only develops at depth in the tissue and the beam profile is improved, leading to better spatial resolution.

archiving and communications system (PACS). Increasingly, digital storage is being used for archiving of ultrasound images.

SPECIAL IMAGING MODES

Tissue Harmonic Imaging

Variation of the propagation velocity of sound in fat and other tissues near the transducer results in a **phase aberration** that distorts the ultrasound field, producing noise and clutter in the ultrasound image. Tissue harmonic imaging provides an approach for reducing the effects of phase aberrations.[6] Nonlinear propagation of ultrasound through tissue is associated with the more rapid propagation of the high-pressure component of the ultrasound pressure wave than its negative (rarefactional) component. This results in increasing distortion of the acoustic pulse as it travels within the tissue and causes the generation of multiples, or **harmonics,** of the transmitted frequency (Fig. 1.16).

Tissue harmonic imaging takes advantage of the generation, at depth, of these harmonics. Because the generation of harmonics requires interaction of the transmitted field with the propagating tissue, harmonic generation is not present near the transducer/skin interface, and it only becomes important some distance from the transducer. In most cases the near and far fields of the image are affected less by harmonics than by intermediate locations. Using broad-bandwidth transducers and signal filtration or coded pulses, the harmonic signals reflected from tissue interfaces can be selectively displayed. Because most imaging artifacts are caused by the interaction of the ultrasound beam with superficial structures or by aberrations at the edges of the beam profile, these artifacts are eliminated using harmonic imaging because the artifact-producing signals do not consist of sufficient energy to generate harmonic frequencies and therefore are filtered out during image formation. Images generated using tissue harmonics often exhibit reduced noise and clutter (Fig. 1.17). Because harmonic beams are narrower than the originally transmitted beams, spatial resolution is improved and side lobes are reduced.

Spatial Compounding

An important source of image degradation and loss of contrast is ultrasound **speckle.** Speckle results from the constructive and destructive interaction of the acoustic fields generated by the scattering of ultrasound from small tissue reflectors. This interference pattern gives ultrasound images their characteristic grainy appearance (see Fig. 1.6), reducing contrast (Fig. 1.18) and making the identification of subtle features more difficult. By summing images from different scanning angles through **spatial compounding** (Fig. 1.19), significant improvement in the **contrast-to-noise ratio** can be achieved (Fig. 1.20). This is because speckle is random, and the generation of an image by compounding will reduce speckle noise because only the signal is reinforced. In addition, spatial compounding may reduce artifacts that result when an ultrasound beam strikes a specular reflector at an angle

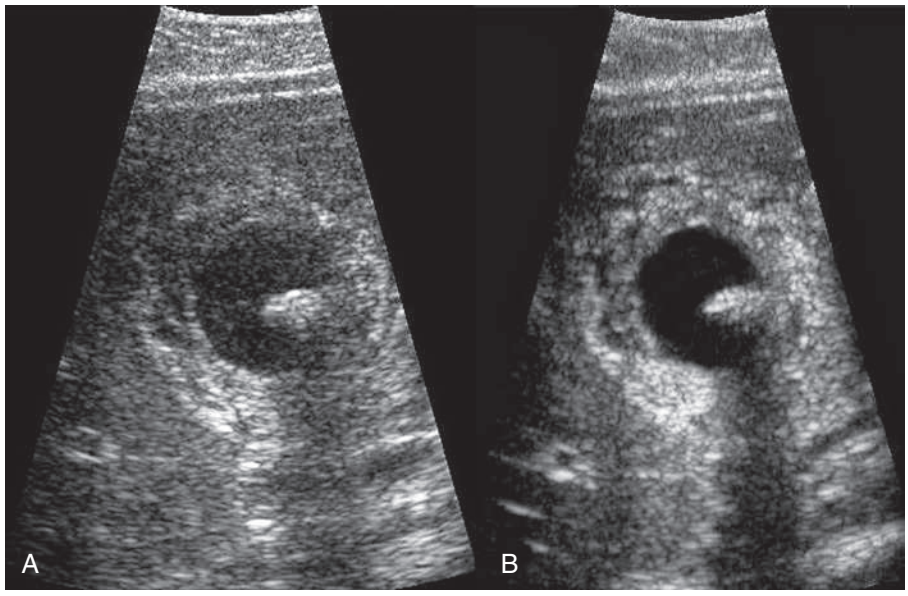

FIG. 1.17 Tissue Harmonic Imaging. (A) Conventional image and **(B) tissue harmonic image** of gallbladder of patient with acute cholecystitis. Note the reduction of noise and clutter in the tissue harmonic image. Because harmonic beams do not interact with superficial structures and are narrower than the originally transmitted beam, spatial resolution is improved and clutter and side lobes are reduced. (With permission from Merritt CR. Technology update. Radiol Clin North Am. 2001;39:385-397.[7])

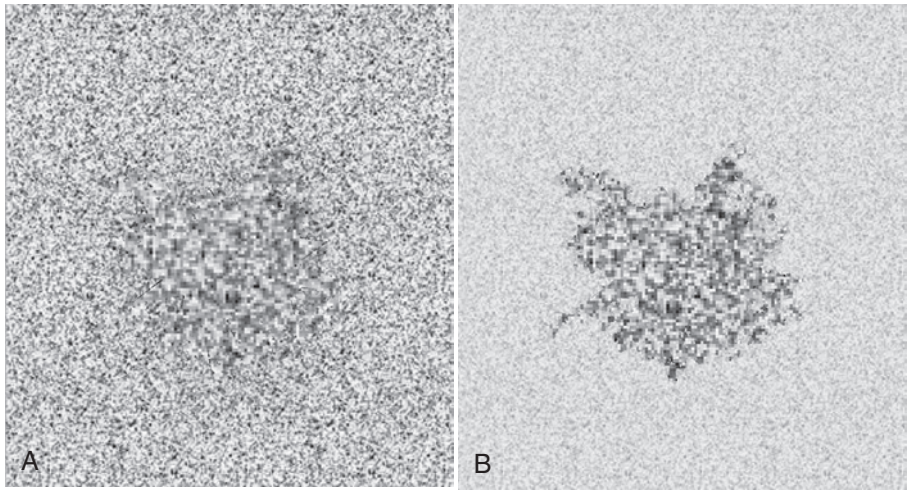

FIG. 1.18 Effect of Speckle on Contrast. (A) Speckle noise partially obscures the simulated lesion. **(B)** The speckle has been reduced, increasing contrast resolution between the lesion and the background. (With permission from Merritt CR. Technology update. Radiol Clin North Am. 2001;39:385-397.[7])

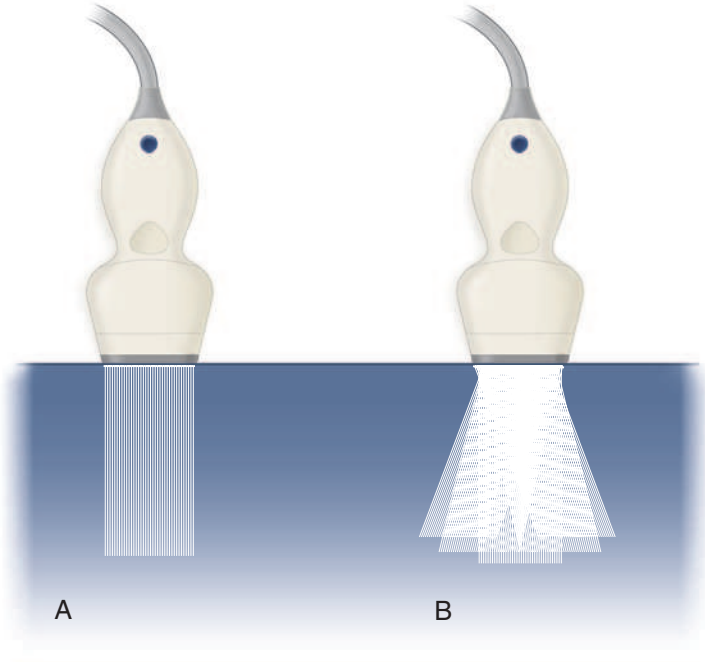

FIG. 1.19 Spatial Compounding. (A) Conventional imaging is limited to a fixed angle of incidence of ultrasound scan lines to tissue interfaces, resulting in poor definition of specular reflectors that are not perpendicular to the beam. **(B) Spatial compounding** combines images obtained by insonating the target from multiple angles. In addition to improving detection of interfaces, compounding reduces speckle noise because only the signal is reinforced; speckle is random and not reinforced. This improves contrast.

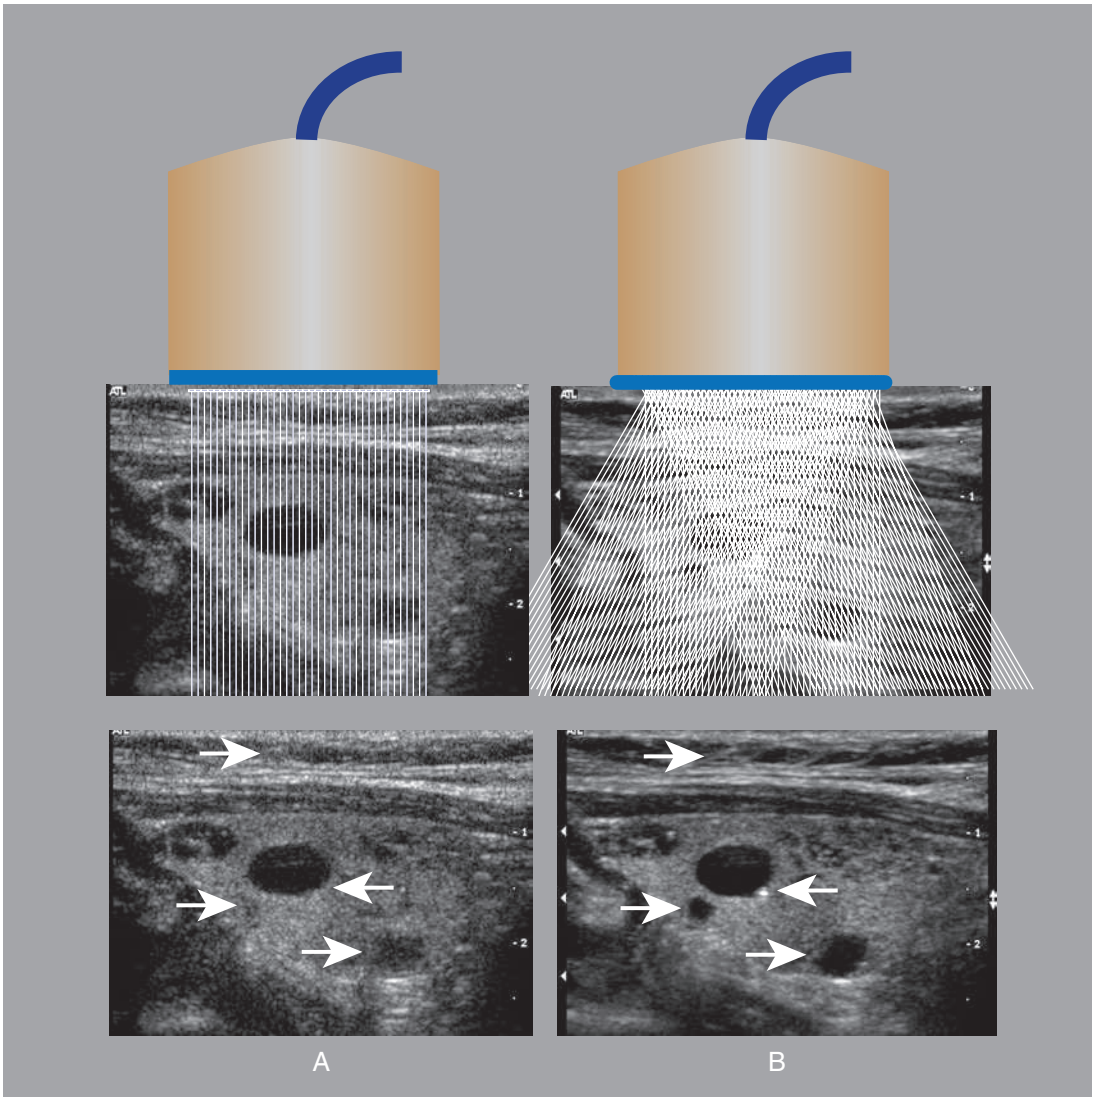

FIG. 1.20 Spatial Compounding. (A) Conventional image and **(B) compound image** of the thyroid. Note the reduced speckle as well as better definition of regions *(arrows)* such as superficial tissue as well as small cysts and calcifications.

greater or less than 90 degrees. In conventional real-time imaging, each scan line used to generate the image strikes the target at a constant, fixed angle. As a result, strong reflectors that are not perpendicular to the ultrasound beam scatter sound in directions that prevent their clear detection and display. This in turn results in poor margin definition and less distinct boundaries for cysts and other masses. Compounding has been found to reduce these artifacts. Limitations of compounding are diminished visibility of shadowing and enhancement; however, these are offset by the ability to evaluate lesions, both with and without compounding, preserving shadowing and enhancement when these features are important to diagnosis.[7]

Three-Dimensional Ultrasound

Dedicated 3-D scanners used for fetal (Fig. 1.21), gynecologic, and cardiac scanning may employ hardware-based image registration, high-density 2-D arrays, or software registration of scan planes as a tissue volume is acquired. 3-D imaging permits volume data to be viewed in multiple imaging planes and allows accurate measurement of lesion volume.

Ultrasound Elastography

Palpation is an effective method for detection of tissue abnormality based on detection of changes in tissue stiffness or elasticity and may provide the earliest indication of disease, even when conventional imaging studies are normal. Ultrasound elastography provides a noninvasive method for evaluation of tissue stiffness.[8]

Tissue contrast in conventional ultrasound imaging is based on the **bulk modulus** determined by the molecular composition of tissue, whereas elastography reflects shear properties that are determined by a higher level of tissue organization, the **strain modulus.** This higher level of tissue organization is most likely to be altered by disease. The dynamic range of the strain modulus is several orders of magnitude greater than the bulk modulus, permitting contrast resolution far exceeding conventional ultrasound imaging.[9] Elastography therefore offers the potential for a

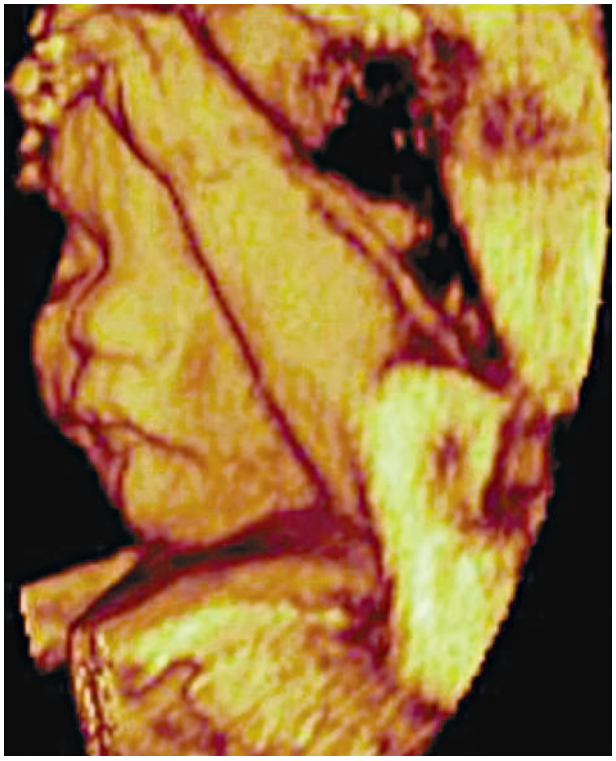

FIG. 1.21 Three-Dimensional Ultrasound Image, 24-Week Fetus. Three-dimensional ultrasound permits collection and review of data obtained from a volume of tissue in multiple imaging planes, as well as a rendering of surface features.

high degree of both sensitivity and specificity in differentiating normal and abnormal tissues.[8,10,11]

Tissue stiffness or elasticity is expressed by **Young modulus**—the ratio of compression pressure (stress) and the resulting deformation (strain)

$$E = \sigma/\varepsilon$$

where E is Young modulus expressed in Pa **(pascals),** σ is the stress, expressed in Newtons, and ε is displacement expressed in m^2.

Ultrasound-based elastography permits study of the elastic behavior of tissue through two general approaches (Fig. 1.22): strain elastography and shear wave elastography.

Strain Elastography

Strain elastography involves measurement of longitudinal tissue displacement before and after compression, usually by manual manipulation of the ultrasound transducer (see Fig. 1.22A). Speckle tracking using radiofrequency backscatter or Doppler is then used to evaluate tissue motion. Strain elastography cannot determine the Young modulus because the compression pressure (stress) cannot be measured directly. Instead, strain ratios are estimated by comparing lesion strain to surrounding normal tissues and displayed in the image in different shades of gray or through color maps (Fig. 1.23). Strain elastography provides an indication of relative stiffness of an area of interest compared to its surroundings.

Key Points of Ultrasound Elastography

- Ultrasound imaging is based on tissue bulk modulus, reflecting interactions at the molecular level.
- Changes in tissue stiffness based on the tissue shear modulus are important indications of disease.
- Ultrasound elastography provides relatative and quantitative assessment of tissue stiffness.
- Ultrasound elastography is based on tissue organization (strain modulus).
- Strain elastography provides an indication of relative tissue stiffness.
- Shear wave elastography provides a quantitative estimate of the tissue stiffness (strain modulus).

Shear Wave Elastography

Longitudinal tissue compression results in the generation of transverse shear waves[12,13] (see Fig. 1.22B). In shear wave elastography, shear waves are generated by repetitive compression produced by high-intensity pulses from the ultrasound transducer (see Fig. 1.22B). In contrast to longitudinal compressional waves that propagate very quickly in the human body (≈1540 m/sec), shear waves propagate slowly (≈1-50 m/sec). Shear waves are tracked with high frame rate images to determine their velocity. The **propagation velocity of shear waves** is directly proportional to Young modulus and provides a quantitative estimate of tissue stiffness[14,15] (Fig. 1.24).

IMAGE QUALITY

The key determinants of the quality of an ultrasound image are its spatial, contrast, and temporal resolution, as well as freedom from certain artifacts.

Spatial Resolution

The ability to differentiate two closely situated objects as distinct structures is determined by the spatial resolution of the ultrasound device. Spatial resolution must be considered in three planes, with different determinants of resolution for each. Simplest is the resolution along the axis of the ultrasound beam, or **axial resolution.** With pulsed wave ultrasound, the transducer introduces a series of brief bursts of sound into the body. Each ultrasound pulse typically consists of two or three cycles of sound. The pulse length is the product of the wavelength and the number of cycles in the pulse. Axial resolution, the maximum resolution along the beam axis, is determined by the pulse length (Fig. 1.25). Because ultrasound frequency and wavelength are inversely related, the pulse length decreases as the imaging frequency increases. Because the pulse length determines the maximum resolution along the axis of the ultrasound beam, *higher transducer frequencies provide higher image resolution.* For example, a transducer operating at 5 MHz produces sound with a wavelength of 0.308 mm. If each pulse consists of three cycles of sound, the pulse length is slightly less than 1 mm, and this becomes the maximum resolution along the beam

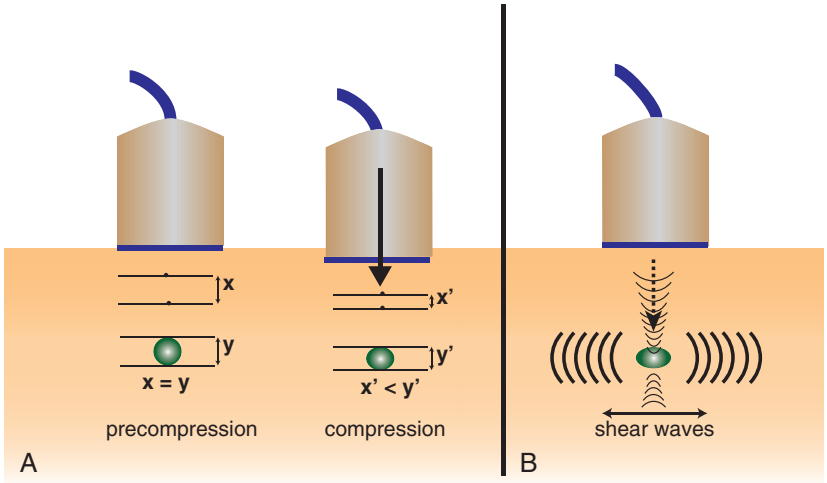

FIG. 1.22 Elastography. (A) Strain elastography (SE), and **(B) shear wave elastography (SWE).** Strain elastograms are images of tissue stiffness generated by analysis of speckle displacements before and after mechanical compression of tissue. The precompression frame is compared to a frame obtained after compression. In this example, the lesion is compressed much less than the surrounding tissue, indicating relative stiffness. SE is not quantitative and indicates only the relative hardness or softness of lesions compared to their surroundings. In SWE **(B)** high-intensity compression pulses from the transducer are focused on an area of interest, resulting in the generation of low-frequency shear waves. Speckle displacement resulting from shear (transverse) waves is tracked with multiple imaging frames in order to estimate shear wave velocity. Shear wave velocity is directly related to Young modulus, permitting a quantitative estimate of tissue stiffness.

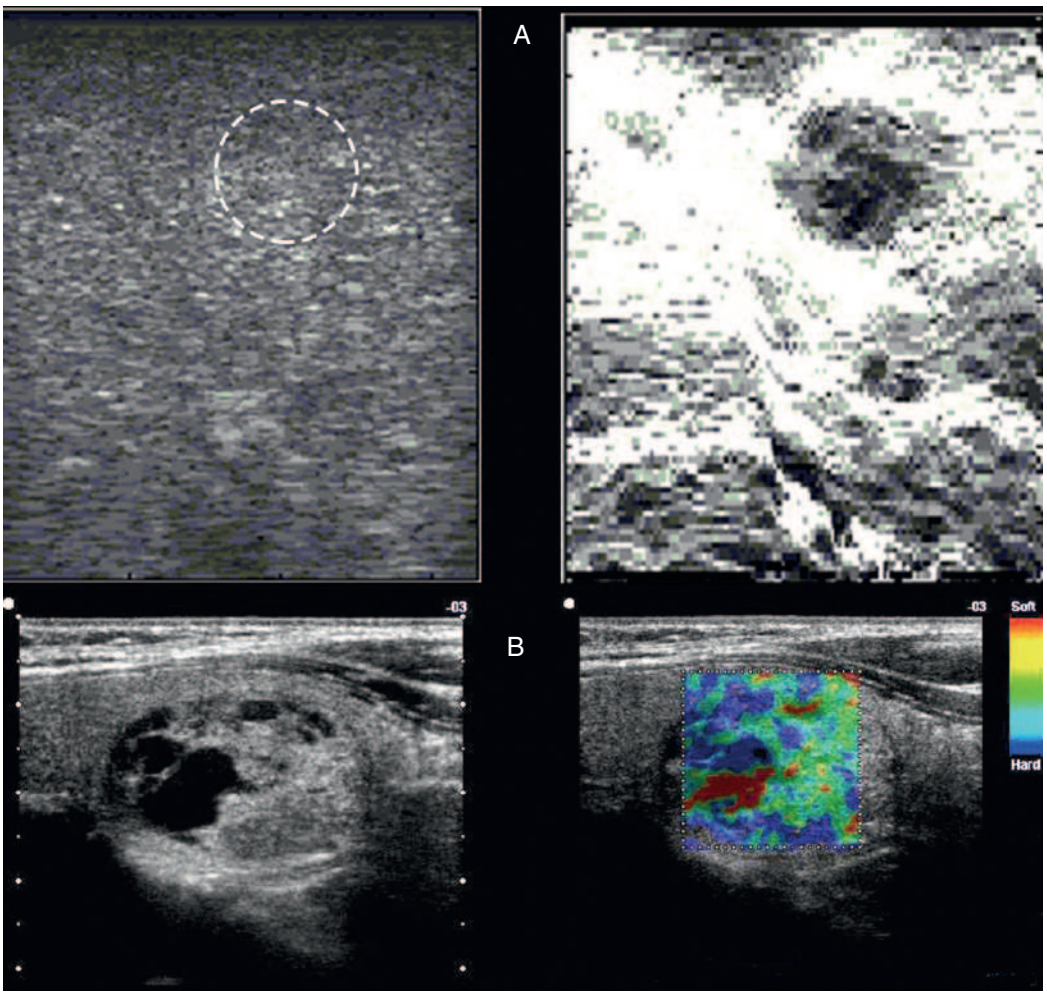

FIG. 1.23 Strain Elastograms. The upper frames **(A)** show *in vivo* images of swine liver containing a lesion produced by the injection of a small volume of absolute ethanol. In the precompression image *(left)* the lesion located within the circle is invisible. The elastogram *(right)* clearly delineates the lesion as an area of increased stiffness compared to the surrounding tissue. The lower frames **(B)** show a gray-scale image *(left)* and strain elastogram *(right)* of a mixed solid and cystic thyroid nodule. In the elastogram the color map displays relative stiffness with softer areas appearing as shades of red, orange, and yellow, and stiffer areas as dark blue. The nodule is heterogeneous with the relatively noncompressible cystic portions differentiated from more compressible surrounding tissue. (Courtesy of P. O'Kane, Thomas Jefferson University.)

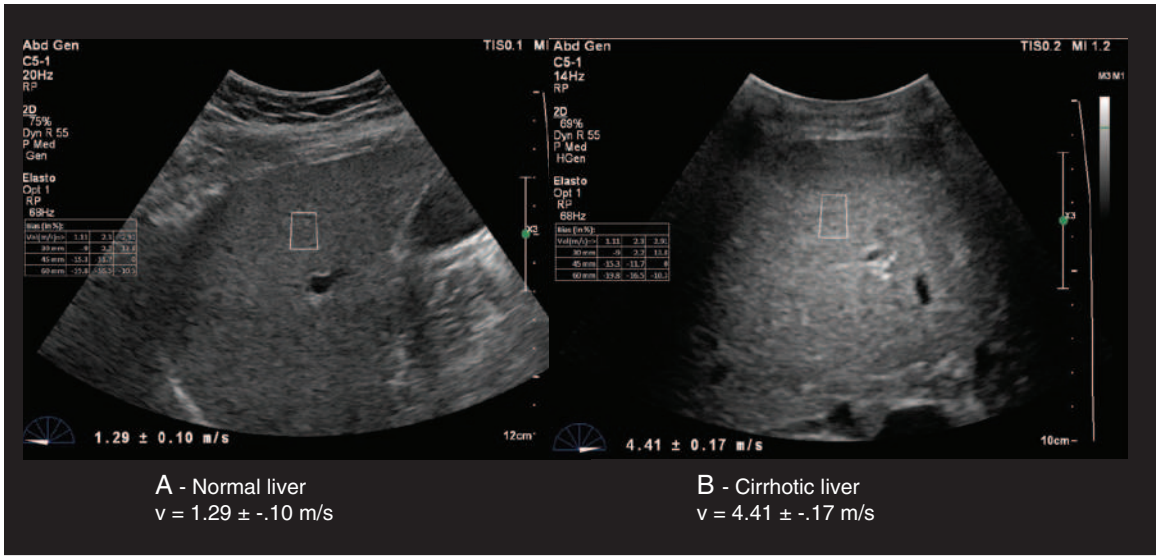

FIG. 1.24 Shear Wave Elastograms of (A) Normal and (B) Cirrhotic Liver. Shear wave velocities measured in liver tissue samples by shear wave elastography indicates a velocity of 1.29 ± 0.10 m/sec in the normal liver compared to a velocity of 4.41 ± 0.17 m/sec in the cirrhotic liver. Increased shear wave velocity is associated with increased tissue stiffness due to hepatic fibrosis. (Courtesy of P. O'Kane, Thomas Jefferson University.)

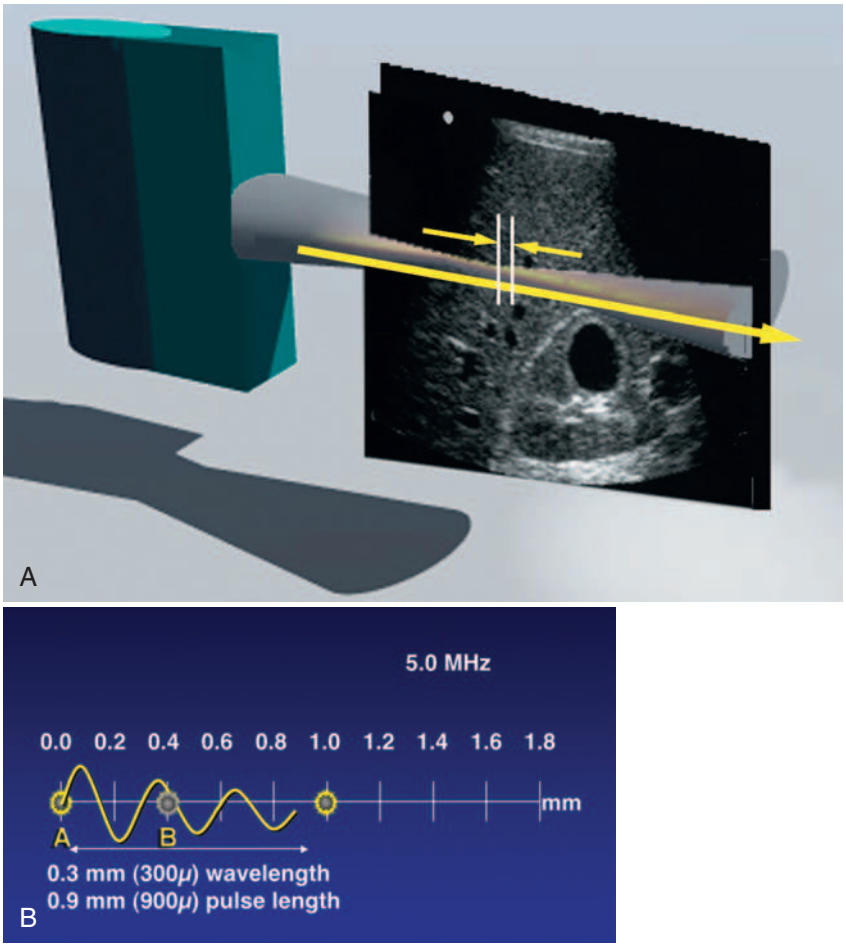

FIG. 1.25 Axial Resolution. Axial resolution is the resolution along **(A)** the beam axis and is determined by **(B)** the pulse length. The pulse length is the product of the wavelength (which decreases with increasing frequency) and the number of waves (usually two to three). Because the pulse length determines axial resolution, higher transducer frequencies provide higher image resolution. In **(B)** for example, a transducer operating at 5 MHz produces sound with a wavelength of 0.31 mm. If each pulse consists of three cycles of sound, the pulse length is slightly less than 1 mm, and objects *A* and *B,* which are 0.5 mm apart, cannot be resolved as separate structures. If the transducer frequency is increased to 15 MHz, the pulse length is less than 0.3 mm, permitting *A* and *B* to be identified as separate structures.

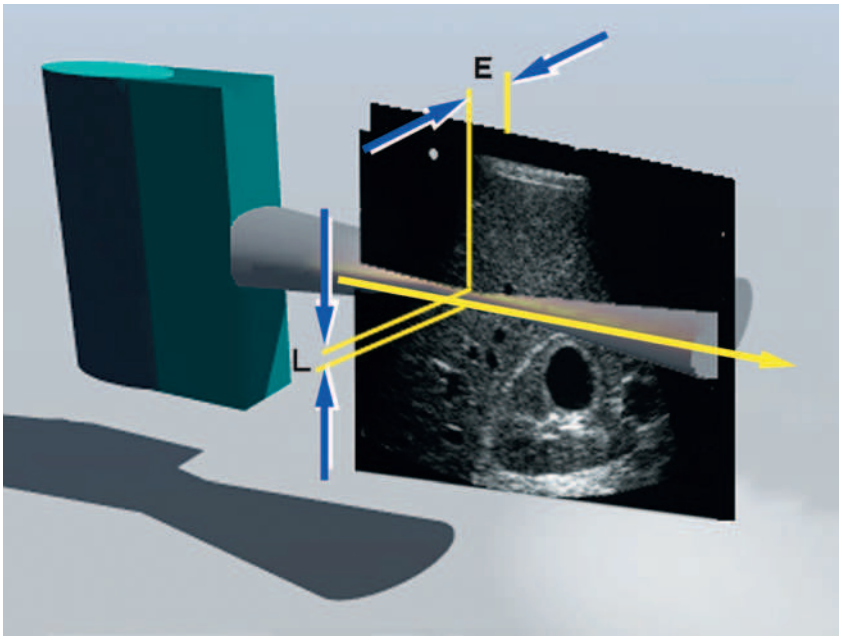

FIG. 1.26 Lateral and Elevation Resolution. Resolution in the planes perpendicular to the beam axis is an important determinant of image quality. **Lateral resolution** *(L)* is resolution in the plane perpendicular to the beam and parallel to the transducer and is determined by the width of the ultrasound beam. Lateral resolution is controlled by focusing the beam, usually by electronic phasing to alter the beam width at a selected depth of interest. Azimuth or **elevation resolution** *(E)* is determined by the slice thickness in the plane perpendicular to the beam and the transducer. Elevation resolution is controlled by the construction of the transducer. Both lateral resolution and elevation resolution are less than the axial resolution.

axis. If the transducer frequency is increased to 15 MHz, the pulse length is less than 0.4 mm, permitting resolution of smaller details.

In addition to axial resolution, resolution in the planes perpendicular to the beam axis must also be considered. **Lateral resolution** refers to resolution in the plane perpendicular to the beam and parallel to the transducer and is determined by the **width** of the ultrasound beam. Azimuth resolution, or **elevation resolution,** refers to the slice **thickness** in the plane perpendicular to the beam and to the transducer (Fig. 1.26). The width and thickness of the ultrasound beam are important determinants of image quality. Excessive beam width and thickness limit the ability to delineate small features and may obscure shadowing and enhancement from small structures, such as breast microcalcifications and small thyroid cysts. The width and thickness of the ultrasound beam determine lateral resolution and elevation resolution, respectively. Lateral and elevation resolutions are significantly poorer than the axial resolution of the beam. Lateral resolution is controlled by focusing the beam, usually by electronic phasing, to alter the beam width at a selected depth of interest. Elevation resolution is determined by the construction of the transducer and generally cannot be controlled by the user.

IMAGING PITFALLS

In ultrasound, perhaps more than in any other imaging method, the quality of the information obtained is determined by the user's ability to recognize and avoid artifacts and pitfalls. Many imaging artifacts are induced by errors in scanning technique or improper use of the instrument and therefore are preventable. Artifacts may cause misdiagnosis or may obscure important findings. Understanding artifacts is essential for correct interpretation of ultrasound examinations.

Many artifacts suggest the presence of structures not actually present. These include reverberation, refraction, and side lobes. **Reverberation artifacts** arise when the ultrasound signal reflects repeatedly between highly reflective interfaces that are usually, but not always, near the transducer (Fig. 1.27). Reverberations may also give the false impression of solid structures in areas where only fluid is present. Certain types of reverberation may be helpful because they allow the identification of a specific type of reflector, such as a surgical clip. Reverberation artifacts can usually be reduced or eliminated by changing the scanning angle or transducer placement to avoid the parallel interfaces that contribute to the artifact.

Refraction causes bending of the sound beam so that targets not along the axis of the transducer are insonated. Their reflections are then detected and displayed in the image. This may cause structures to appear in the image that actually lie outside the volume the investigator assumes is being examined (see Fig. 1.7). Similarly, side lobes may produce confusing echoes that arise from sound beams that lie outside the main ultrasound beam (Fig. 1.28). These **side lobe artifacts** are of clinical importance because they may create the impression of structures or debris in fluid-filled structures (Fig. 1.29). Side lobes may also result in errors of measurement by reducing lateral resolution. As with most other artifacts, repositioning the transducer and its focal zone or using a different transducer will usually allow the differentiation of artifactual from true echoes.

Artifacts may also remove real echoes from the display or obscure information, and important pathologic features may be missed. **Shadowing** results when there is a marked reduction in the intensity of ultrasound deep to a strong reflector or attenuator. Shadowing causes partial or complete loss of information due to attenuation of the sound by superficial structures. Another common cause of loss of image information is improper adjustment of system gain and **TGC settings.** Many low-level echoes

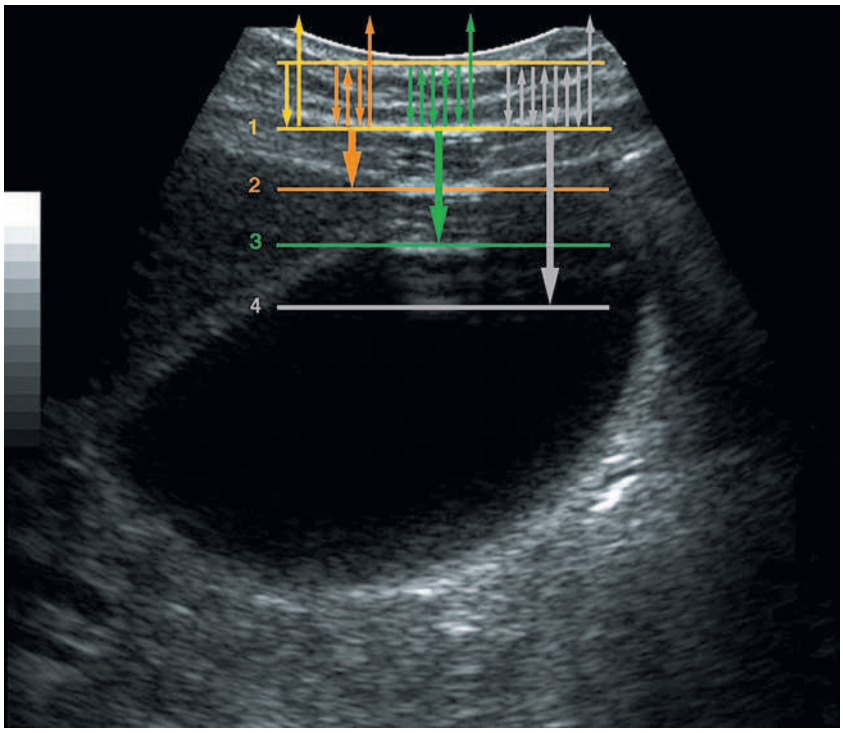

FIG. 1.27 Reverberation Artifact. Reverberation artifacts arise when the ultrasound signal reflects repeatedly between highly reflective interfaces near the transducer, resulting in delayed echo return to the transducer. This appears in the image as a series of regularly spaced echoes at increasing depth. The echo at depth *1* is produced by simple reflection from a strong interface. Echoes at levels *2, 3,* and *4* are produced by multiple reflections between this interface and the surface (simulated image).

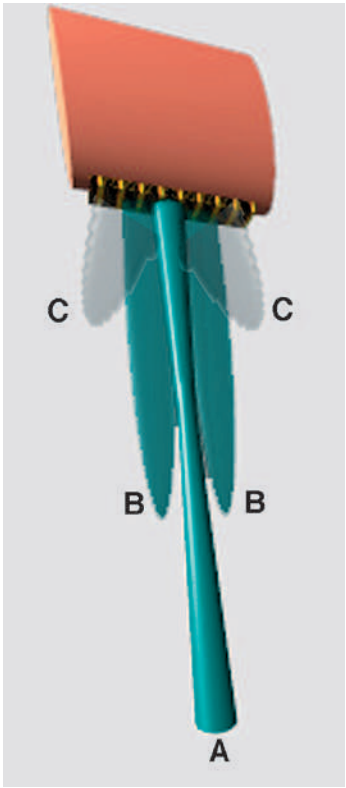

FIG. 1.28 Side Lobes. Although most of the energy generated by a transducer is emitted in a beam along the central axis of the transducer *(A),* some energy is also emitted at the periphery of the primary beam (*B* and *C*). These are called side lobes and are lower in intensity than the primary beam. Side lobes may interact with strong reflectors that lie outside of the scan plane and produce artifacts that are displayed in the ultrasound image (see also Fig. 1.29).

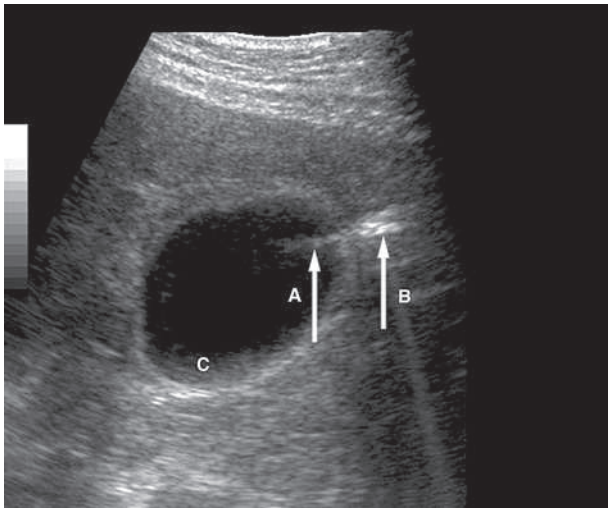

FIG. 1.29 Side Lobe Artifact. Transverse image of the gallbladder reveals a bright internal echo *(A)* that suggests a band or septum within the gallbladder. This is a side lobe artifact related to the presence of a strong out-of-plane reflector *(B)* medial to the gallbladder. The low-level echoes in the dependent portion of the gallbladder *(C)* are also artifactual and are caused by the same phenomenon. Side lobe and slice thickness artifacts are of clinical importance because they may create the impression of debris in fluid-filled structures.

are near the noise levels of the equipment, and considerable skill and experience are needed to adjust instrument settings to display the maximum information with the minimum noise. Poor scanning angles, inadequate penetration, and poor resolution may also result in loss of information. Careless selection of transducer frequency and lack of attention to the focal characteristics of

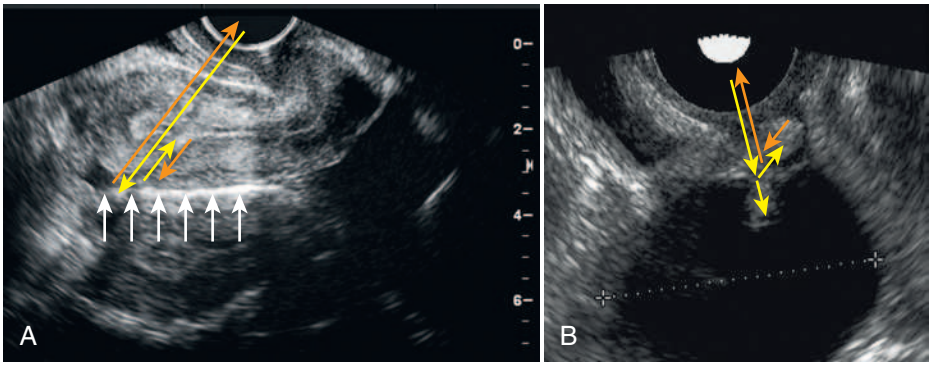

FIG. 1.30 Multipath Artifact. (A) Mirror image of the uterus is created by reflection of sound from an interface produced by gas in the rectum. **(B)** Echoes reflected from the wall of an ovarian cyst create complex echo paths that delay return of echoes to the transducer. In both examples, the longer path of the reflected sound results in the display of echoes at a greater depth than they should normally appear. In **(A)** this results in an artifactual image of the uterus appearing in the location of the rectum. In **(B)** the effect is more subtle and more likely to cause misdiagnosis because the artifact suggests a mural nodule in what is actually a simple ovarian cyst.

the beam will cause loss of clinically important information from deep, low-amplitude reflectors and small targets. Ultrasound artifacts may alter the size, shape, and position of structures. For example, a **multipath artifact** is created when the path of the returning echo is not the one expected, resulting in display of the echo at an improper location in the image (Fig. 1.30).

Shadowing and Enhancement

Although most artifacts degrade the ultrasound image and impede interpretation, two artifacts of clinical value are shadowing and enhancement. Again, shadowing results when an object (e.g., calculus) attenuates sound more rapidly than surrounding tissues. **Enhancement** occurs when an object (e.g., cyst) attenuates less than surrounding tissues. Failure of TGC applied to normal tissue to compensate properly for the attenuation of more highly attenuating (shadowing) or poorly attenuating (enhancing) structures produces the artifact (Fig. 1.31). Because attenuation increases with frequency, the effects of shadowing and enhancement are greater at higher than at lower frequencies. The conspicuity of shadowing and enhancement is reduced by excessive beam width, improper focal zone placement, and use of spatial compounding.

DOPPLER SONOGRAPHY

Conventional B-mode ultrasound imaging uses pulse-echo transmission, detection, and display techniques. Brief pulses of ultrasound energy emitted by the transducer are reflected from acoustic interfaces within the body. Precise timing allows determination of the depth from which the echo originates. When pulsed wave ultrasound is reflected from an interface, the backscattered (reflected) signal contains amplitude, phase, and frequency information (Fig. 1.32). This information permits inference of the position, nature, and motion of the interface reflecting the pulse. B-mode ultrasound imaging uses only the amplitude information in the backscattered signal to generate the image, with differences in the strength of reflectors displayed in the image in varying shades of gray. Rapidly moving targets, such as red cells in the bloodstream, produce echoes of low amplitude that are not usually displayed, resulting in a relatively anechoic pattern within the lumens of large vessels.

Although gray-scale display relies on the amplitude of the backscattered ultrasound signal, additional information is present in the returning echoes that can be used to evaluate the motion of moving targets.[16] When high-frequency sound impinges on a stationary interface, the reflected ultrasound has essentially the same frequency or wavelength as the transmitted sound. If the reflecting interface is moving with respect to the sound beam emitted from the transducer, however, there is a change in the frequency of the sound scattered by the moving object (Fig. 1.33). This change in frequency is directly proportional to the velocity of the reflecting interface relative to the transducer and is a result of the **Doppler effect.** The relationship of the returning ultrasound frequency to the velocity of the reflector is described by the Doppler equation, as follows:

$$\Delta F = (F_R - F_T) = 2 \cdot F_T \cdot v/c$$

The **Doppler frequency shift** is ΔF; F_R is the frequency of sound reflected from the moving target; F_T is the frequency of sound emitted from the transducer; v is the velocity of the target toward the transducer; and c is the velocity of sound in the medium. The Doppler frequency shift (ΔF) applies only if the target is moving directly toward or away from the transducer (Fig. 1.34A). In most clinical settings the direction of the ultrasound beam is seldom directly toward or away from the direction of flow, and the ultrasound beam usually approaches the moving target at an angle designated as the **Doppler angle** (Fig. 1.34B). In this case, ΔF is reduced in proportion to the cosine of this angle, as follows:

$$\Delta F = (F_R - F_T) = 2 \cdot F_T \cdot v \cdot \cos\theta/c$$

where θ is the angle between the axis of flow and the incident ultrasound beam. If the Doppler angle can be measured, estimation of flow velocity is possible. Accurate estimation of target velocity requires precise measurement of both the Doppler frequency shift and the angle of insonation to the direction of

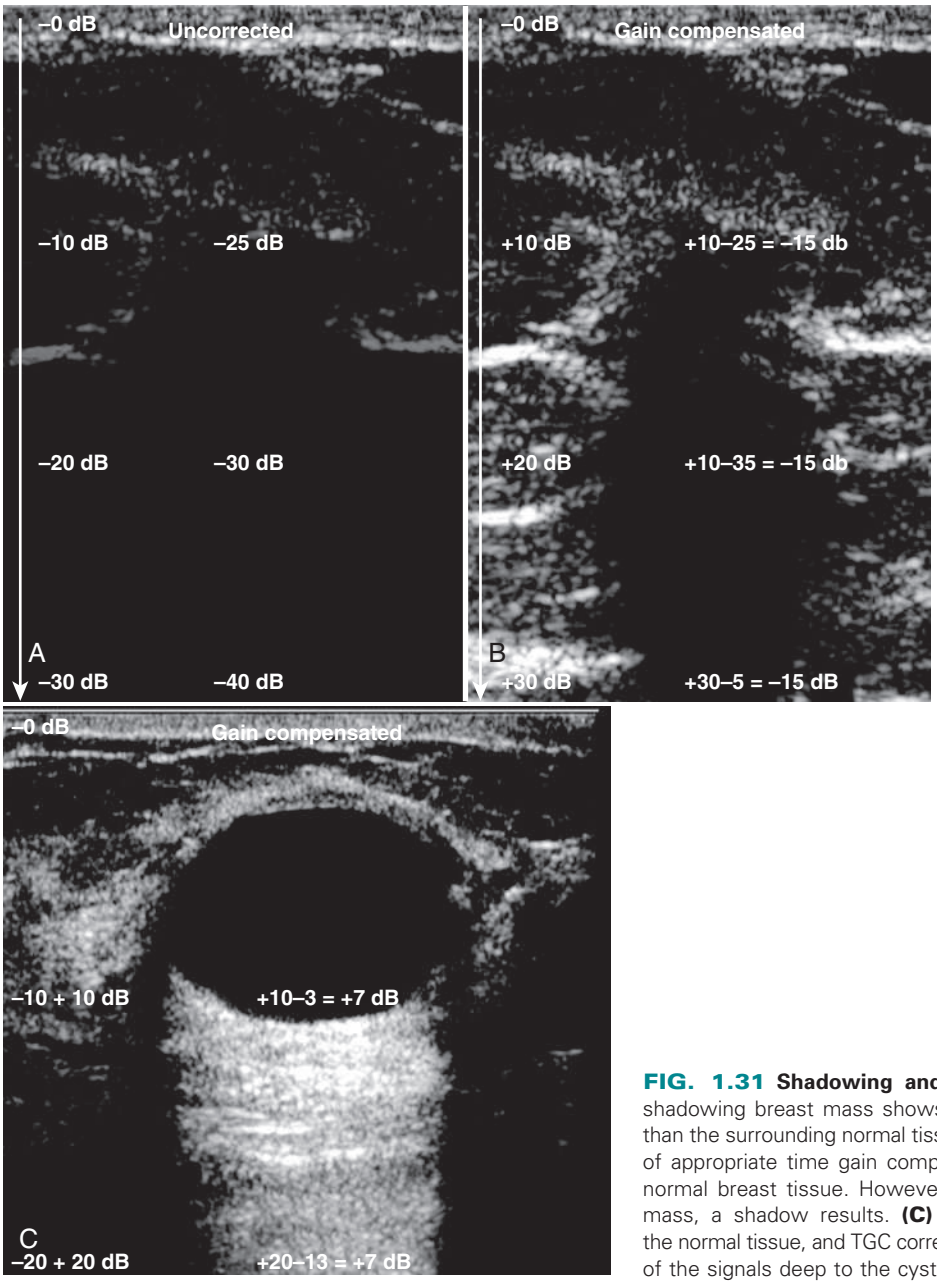

FIG. 1.31 Shadowing and Enhancement. (A) Uncorrected image of a shadowing breast mass shows that the mass attenuates 25 dB, 15 dB more than the surrounding normal tissue, which attenuates only 10 dB. **(B)** Application of appropriate time gain compensation (TGC) results in proper display of the normal breast tissue. However, because of the increased attenuation of the mass, a shadow results. **(C)** Similarly, the cyst attenuates 7 dB less than the normal tissue, and TGC correction for normal tissue results in overamplification of the signals deep to the cyst, producing enhancement of these tissues.

target movement. As the Doppler angle (θ) approaches 90 degrees, the cosine of θ approaches 0. At an **angle of 90 degrees,** there is no relative movement of the target toward or away from the transducer, and **no Doppler frequency shift** is detected (Fig. 1.35). Because the cosine of the Doppler angle changes rapidly for angles more than 60 degrees, accurate angle correction requires that Doppler measurements be made at angles of less than 60 degrees. Above 60 degrees, relatively small changes in the Doppler angle are associated with large changes in cosθ, and therefore a small error in estimation of the Doppler angle may result in a large error in the estimation of velocity. These considerations are important in using both duplex and color Doppler instruments. Optimal imaging of the vessel wall is obtained when the axis of the transducer is perpendicular to the wall, whereas maximal Doppler frequency differences are obtained when the transducer axis and the direction of flow are at a relatively small angle.

In peripheral vascular applications, it is highly desirable that measured *Doppler frequencies be corrected for the Doppler angle to provide velocity measurement.* This allows comparison of data from systems using different Doppler frequencies and eliminates error in interpretation of frequency data obtained at different Doppler angles. For abdominal applications, angle-corrected velocity measurements are encouraged, although qualitative assessments of flow are often made using only the Doppler frequency shift data.

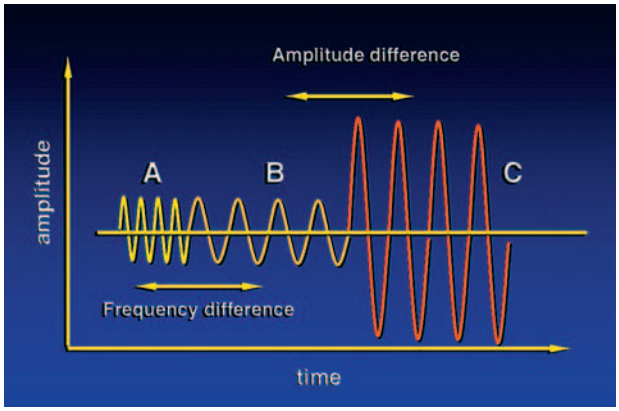

FIG. 1.32 Backscattered Information. The backscattered ultrasound signal contains amplitude, phase, and frequency information. Signals *B* and *C* differ in amplitude but have the same frequency. Amplitude differences are used to generate B-mode images. Signals *A* and *B* differ in frequency but have similar amplitudes. Such frequency differences are the basis of Doppler ultrasound.

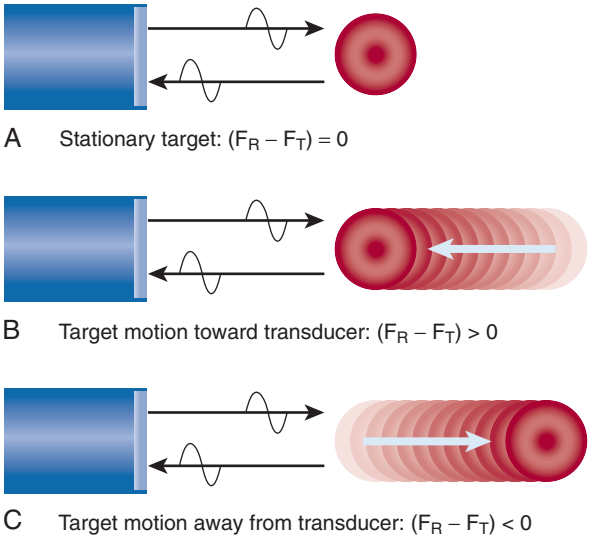

FIG. 1.33 Doppler Effect. (A) Stationary target. If the reflecting interface is stationary, the backscattered ultrasound has the same frequency or wavelength as the transmitted sound, and there is no difference in the transmitted frequency *(F_T)* and the reflected frequency *(F_R)*. **(B)** and **(C) Moving targets.** If the reflecting interface is moving with respect to the sound beam emitted from the transducer, there is a change in the frequency of the sound scattered by the moving object. When the interface moves toward the transducer **(B),** the difference in reflected and transmitted frequencies is greater than zero. When the target is moving away from the transducer **(C),** this difference is less than zero. The Doppler equation is used to relate this change in frequency to the velocity of the moving object.

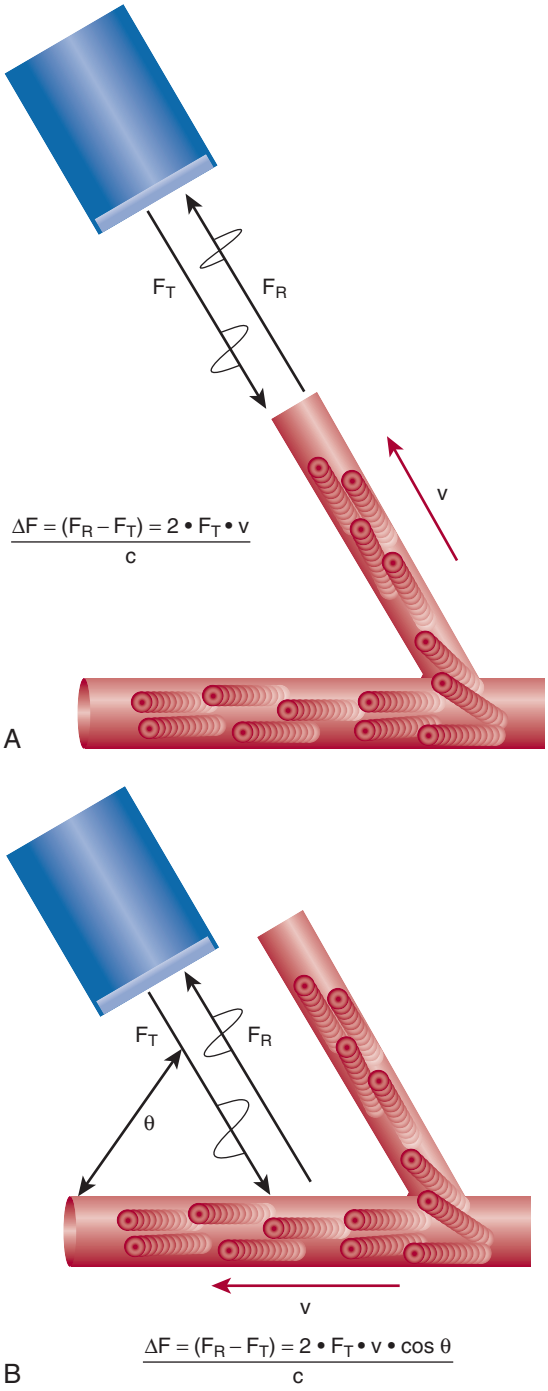

FIG. 1.34 Doppler Equations. The Doppler equation describes the relationship of the Doppler frequency shift to target velocity. **(A)** In its simplest form, it is assumed that the direction of the ultrasound beam is parallel to the direction of movement of the target. This situation is unusual in clinical practice. More often, the ultrasound impinges on the vessel at angle θ. **(B)** In this case the Doppler frequency shift detected is reduced in proportion to the cosine of θ. *ΔF,* Frequency shift; F_R, reflected frequency; F_T, transmitted frequency; *v,* velocity.

Doppler Signal Processing and Display

Several options exist for the processing of ΔF, the Doppler frequency shift, to provide useful information regarding the direction and velocity of blood. Doppler frequency shifts encountered clinically are in the audible range. This audible signal may be analyzed by ear and, with training, the operator can identify many flow characteristics. More often, the Doppler shift data are displayed in graphic form as a time-varying plot of the frequency spectrum of the returning signal. A fast Fourier transformation is used to perform the frequency analysis. The resulting Doppler frequency spectrum displays the following (Fig. 1.36):

- Variation with time of the Doppler frequencies present in the volume sampled

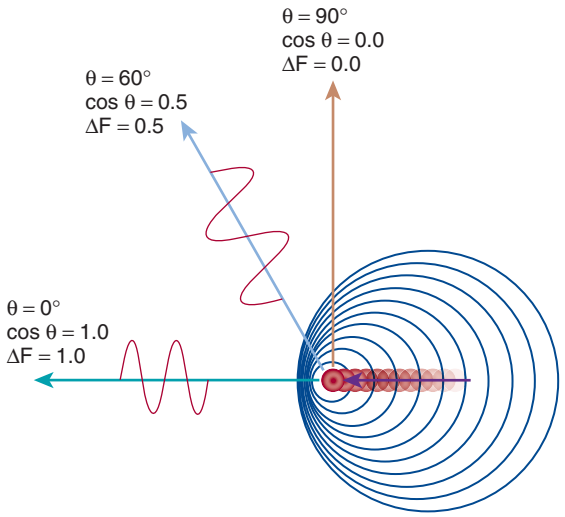

FIG. 1.35 Effect of Doppler Angle on Frequency Shift. At an angle of 60 degrees, the detected frequency shift *(ΔF)* detected by the transducer is only 50% of the shift detected at an angle of 0 degrees. At 90 degrees, there is no relative movement of the target toward or away from the transducer, and no frequency shift is detected. The detected Doppler frequency shift is reduced in proportion to the cosine of the Doppler angle. Because the cosine of the angle changes rapidly at angles above 60 degrees, the use of Doppler angles of less than 60 degrees is recommended in making velocity estimates.

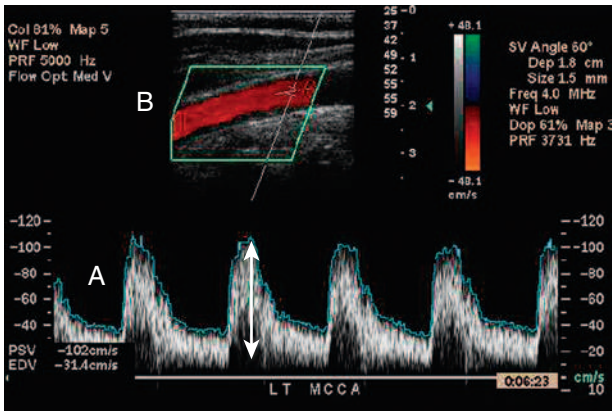

FIG. 1.36 Doppler Display. (A) Doppler frequency spectrum waveform shows changes in flow velocity and direction by vertical deflections of the waveform above and below the baseline. The width of the spectral waveform (spectral broadening) is determined by the range of frequencies present at any instant in time *(arrow)*. A brightness (gray) scale is used to indicate the amplitude of each frequency component. **(B) Color Doppler imaging.** Amplitude data from stationary targets provide the basis for the B-mode image. Signal phase provides information about the presence and direction of motion, and changes in frequency relate to the velocity of the target. Backscattered signals from red blood cells are displayed in color as a function of their motion toward or away from the transducer, and the degree of the saturation of the color is used to indicate the frequency shift from moving red cells.

- The **envelope of the spectrum,** representing the maximum frequencies present at any given point in time
- The **width of the spectrum** at any point, indicating the range of frequencies present

The amplitude of the Doppler signal is related to the number of targets moving at a given velocity. In many instruments the amplitude of each frequency component is displayed in gray scale as part of the spectrum. The presence of a large number of different frequencies at a given point in the cardiac cycle results in **spectral broadening.**

In color Doppler imaging systems, a representation of the Doppler frequency shift is displayed as a feature of the image itself (see Fig. 1.36). In addition to the detection of Doppler frequency shift data from each pixel in the image, these systems may also provide range-gated pulsed wave Doppler with spectral analysis for display of Doppler data.

Doppler Instrumentation

In contrast to A-mode, M-mode, and B-mode gray-scale ultrasonography, which display the information from tissue interfaces, Doppler ultrasound instruments are optimized to display **flow** information. The simplest Doppler devices use **continuous wave** (CW) **Doppler** rather than pulsed wave ultrasound, using two transducers that transmit and receive ultrasound continuously. The transmit and receive beams overlap in a sensitive volume at some distance from the transducer face (Fig. 1.37A). Although direction of flow can be determined with CW Doppler, these devices do not allow discrimination of motion coming from various depths, and the source of the signal being detected is difficult, if not impossible, to ascertain with certainty. Inexpensive and portable, CW Doppler instruments are used primarily at the bedside or intraoperatively to confirm the presence of flow in superficial vessels.

Because of the limitations of CW systems, most applications use range-gated, pulsed wave Doppler. Rather than a continuous wave of ultrasound emission, pulsed wave Doppler devices emit brief pulses of ultrasound energy (see Fig. 1.37B). Using pulses of sound permits use of the time interval between the transmission of a pulse and the return of the echo as a means of determining the depth from which the Doppler shift arises. The principles are similar to the echo-ranging principles used for imaging (see Fig. 1.4). In a pulsed wave Doppler system the sensitive volume from which flow data are sampled can be controlled in terms of shape, depth, and position. When pulsed wave Doppler is combined with a 2-D, real-time, B-mode imager in the form of a **duplex scanner,** the position of the Doppler sample can be precisely controlled and monitored.

In color Doppler imaging (Fig. 1.38A), frequency shift information determined from Doppler measurements is displayed as a feature of the image itself.[17] Stationary or slowly moving targets provide the basis for the B-mode image. **Signal phase** provides information about the presence and direction of motion, and changes in echo signal frequency relate to the velocity of the target. Backscattered signals from red blood cells are displayed in color as a function of their motion toward or away from the transducer, and the degree of the saturation of the color is used to indicate the relative frequency shift produced by the moving red cells.

Color Doppler flow imaging (CDFI) expands conventional duplex sonography by providing additional capabilities. The use of color saturation to display variations in Doppler shift frequency allows an estimation of relative velocity from the image alone, provided that variations in the Doppler angle are noted. The

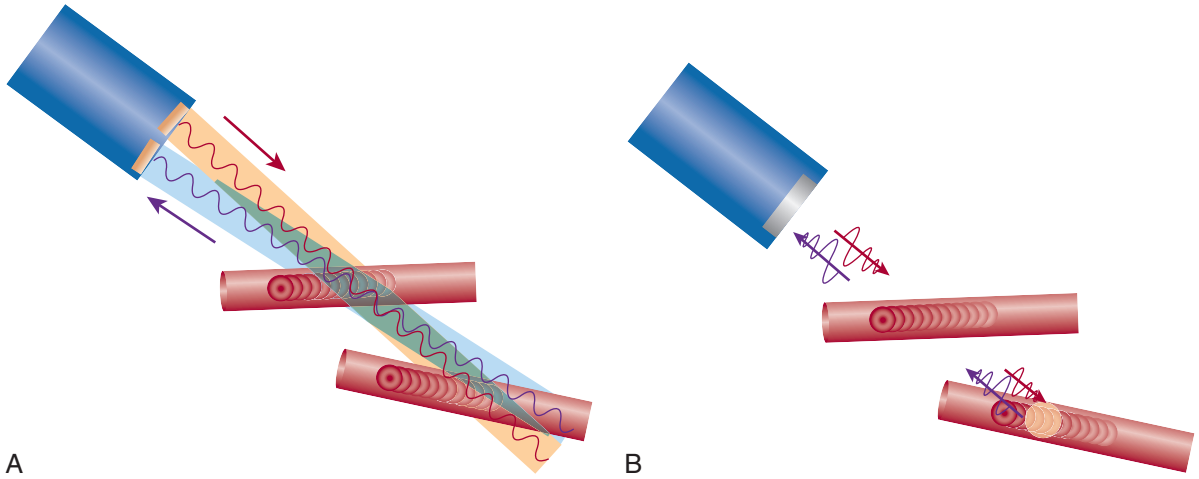

FIG. 1.37 Continuous Wave and Pulsed Wave Doppler. (A) Continuous wave (CW) Doppler uses separate transmit and receive crystals that continuously transmit and receive ultrasound. Although able to detect the presence and direction of flow, CW devices are unable to distinguish signals arising from vessels at different depths *(green-shaded area).* **(B)** Using the principle of ultrasound ranging (see Fig. 1.4), **pulsed wave Doppler** permits the sampling of flow data from selected depths by processing only the signals that return to the transducer after precisely timed intervals. The operator is able to control the position of the sample volume and, in duplex systems, to view the location from which the Doppler data are obtained.

Limitations of Color Doppler Flow Imaging
Angle dependence
Aliasing
Inability to display entire Doppler spectrum in the image
Artifacts caused by noise

Advantages of Power Doppler
No aliasing
Much less angle dependence
Noise: a homogeneous background color
Increased sensitivity for flow detection

display of flow throughout the image field allows the position and orientation of the vessel of interest to be observed at all times. The display of spatial information with respect to velocity is ideal for display of small, localized areas of turbulence within a vessel, which provide clues to stenosis or irregularity of the vessel wall caused by atheroma, trauma, or other disease. Flow within the vessel is observed at all points, and stenotic jets and focal areas of turbulence are displayed that might be overlooked with duplex instrumentation. The contrast of flow within the vessel lumen permits visualization of small vessels that are not visible when using conventional imagers and enhances the visibility of wall irregularity. CDFI aids in determination of the direction of flow and measurement of the Doppler angle.

Power Doppler

An alternative to the display of frequency information with color Doppler imaging is to use a color map that displays the integrated power of the Doppler signal instead of its mean frequency shift[18] (see Fig. 1.38B). Because frequency shift data are not displayed, there is no aliasing. The image does not provide information related to flow direction or velocity, and power Doppler imaging is much less angle dependent than frequency-based color Doppler display. In contrast to color Doppler, where noise may appear in the image as any color, power Doppler permits noise to be assigned to a homogeneous background color that does not greatly interfere with the image. This results in a significant increase in the usable dynamic range of the scanner, permitting higher effective gain settings and increased sensitivity for flow detection (Fig. 1.39).

Interpretation of the Doppler Spectrum

Doppler data components that must be evaluated both in spectral display and in color Doppler imaging include the Doppler shift frequency and amplitude, the Doppler angle, the spatial distribution of frequencies across the vessel, and the temporal variation of the signal. Because the Doppler signal itself has no anatomic significance, the examiner must interpret the Doppler signal and then determine its relevance in the context of the image.

The detection of a Doppler frequency shift indicates movement of the target, which in most applications is related to the presence of flow. The sign of the frequency shift (positive or negative) indicates the direction of flow relative to the transducer. **Vessel stenosis** is typically associated with large Doppler frequency shifts in both systole and diastole at the site of greatest narrowing, with turbulent flow in poststenotic regions. In peripheral vessels, analysis of the Doppler changes allows accurate prediction of the degree of vessel narrowing. Information related to the resistance to flow in the distal vascular tree can be obtained by analysis of changes of blood velocity with time, as shown in the **Doppler spectral display.** Doppler imaging can provide information about blood flow in both large and small vessels. Small vessel impedance is reflected in the Doppler spectral waveform of afferent vessels.

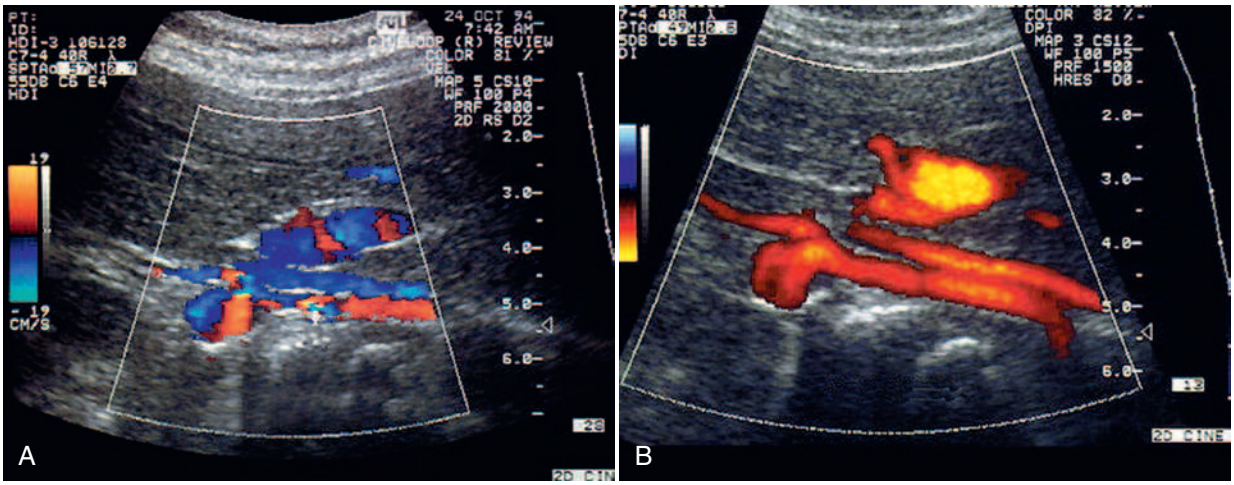

FIG. 1.38 Color Flow and Power Doppler. (A) Color flow Doppler imaging uses a color map to display information based on the detection of frequency shifts from moving targets. Noise in this form of display appears across the entire frequency spectrum and limits sensitivity. **(B) Power Doppler** uses a color map to show the distribution of the power or amplitude of the Doppler signal. Flow direction and velocity information are not provided, but noise is reduced, allowing higher gain settings and improved sensitivity for flow detection.

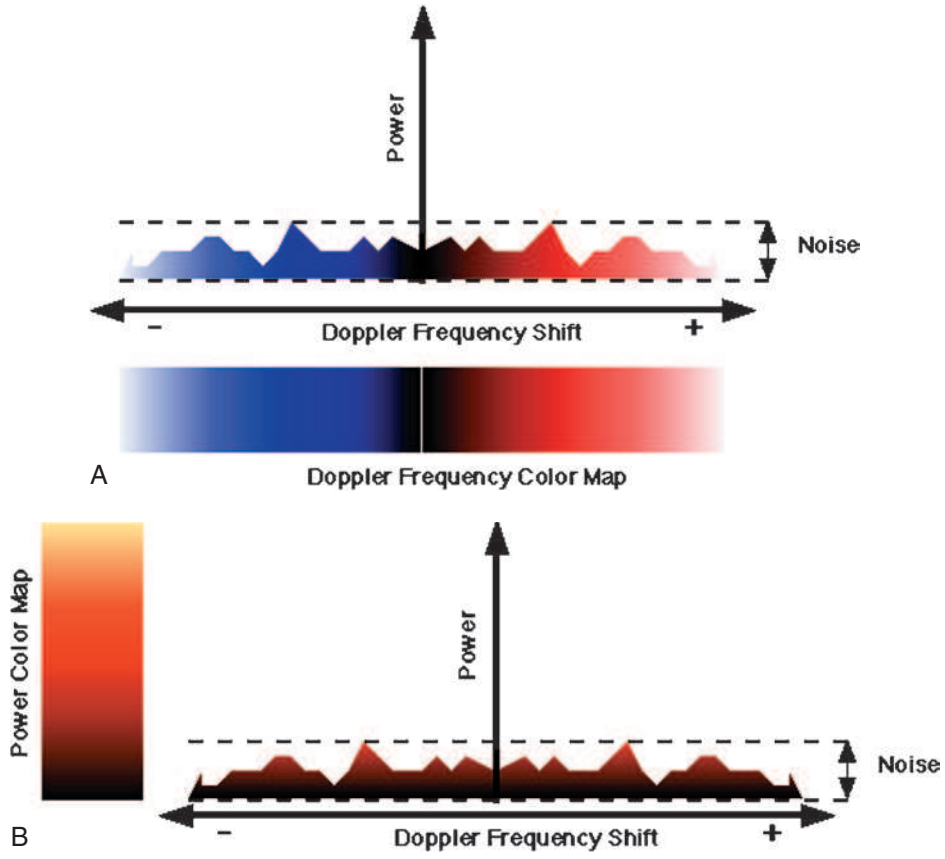

FIG. 1.39 Frequency and Power Mode Color Mapping. (A) Conventional color Doppler uses the color map to show differences in flow direction and Doppler frequency shift. Because noise appears over the entire frequency spectrum, gain levels are limited to those that do not introduce excessive noise. **(B) Power Doppler** color map, in contrast, indicates the amplitude of the Doppler signal. Because most noise is of low amplitude, it is possible to map this to colors near the background. This permits the use of high gain settings that offer significant improvements over conventional color Doppler in flow detection.

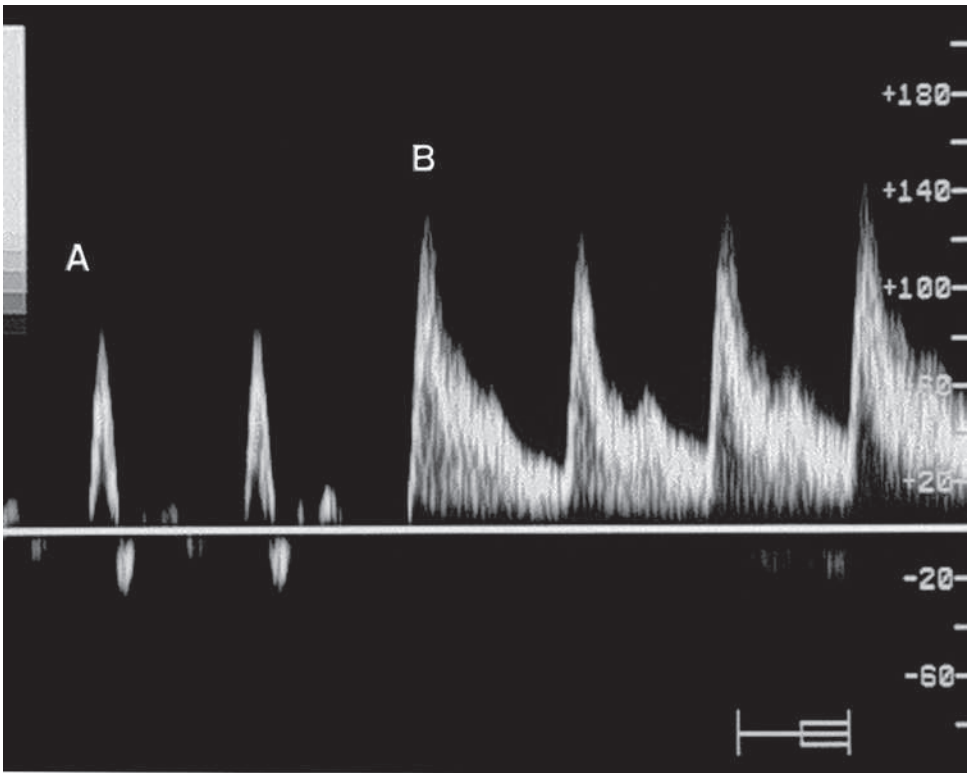

FIG. 1.40 Impedance. High-resistance waveform in brachial artery *(A),* produced by inflating forearm blood pressure cuff to a pressure above the systolic blood pressure. As a result of high peripheral resistance, there is low systolic amplitude and reversed diastolic flow. **Low-resistance waveform in peripheral vascular bed** *(B),* caused by vasodilation stimulated by the prior ischemia. Immediately after release of 3 minutes of occluding pressure, the Doppler waveform showed increased amplitude and rapid antegrade flow throughout diastole.

Fig. 1.40 provides a graphic example of the changes in the Doppler spectral waveform resulting from physiologic changes in the resistance of the vascular bed supplied by a normal brachial artery. A blood pressure cuff has been inflated to above systolic pressure to occlude the distal branches supplied by the brachial artery. This **occlusion** causes reduced systolic amplitude and cessation of diastolic flow, resulting in a waveform different than that found in the normal resting state. During the period of ischemia induced by pressure cuff occlusion of the forearm vessels, **vasodilation** has occurred. Immediately after release of the occluding pressure the Doppler waveform reflects a low-resistance peripheral vascular bed with increased systolic amplitude and rapid flow throughout diastole, typical for vasodilation.

Doppler indices include the **systolic-to-diastolic ratio** (S/D ratio), **resistive index** (RI), and **pulsatility index** (PI) (Fig. 1.41). These compare blood flow in systole and diastole, show resistance to flow in the peripheral vascular bed, and help evaluate the perfusion of tumors, renal transplants, the placenta, and other organs. With Doppler ultrasound, it is therefore possible to identify vessels, determine the direction of blood flow, evaluate narrowing or occlusion, and characterize blood flow to organs and tumors. Analysis of the Doppler shift frequency with time can be used to infer both proximal stenosis and changes in distal vascular impedance. Most work using pulsed wave Doppler imaging has emphasized the detection of stenosis, thrombosis, and flow disturbances in major peripheral arteries and veins. In these applications, measurement of peak systolic and end diastolic

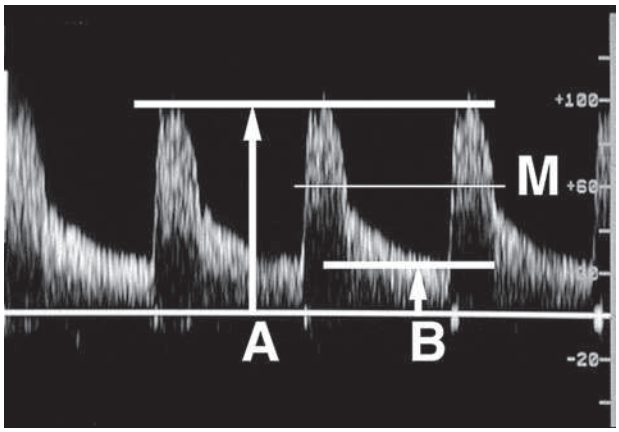

FIG. 1.41 Doppler Indices. Doppler flow indices used to characterize peripheral resistance are based on the **peak systolic frequency** or **velocity** *(A),* the **minimum** or **end diastolic frequency** or **velocity** *(B),* and the **mean frequency** or **velocity** *(M).* The most frequently used indices are the **systolic-to-diastolic ratio** (A/B); **resistive index** [(A-B)/A]; and **pulsatility index** [(A-B)/M]. In calculation of the pulsatility index, the minimum diastolic velocity or frequency is used; calculation of the systolic-to-diastolic ratio and resistive index use the end diastolic value.

frequency or velocity, analysis of the Doppler spectrum, and calculation of certain frequency or velocity ratios have been the basis of analysis. Changes in the spectral waveform measured by indices comparing flow in systole and diastole indicate the resistance of the vascular bed supplied by the vessel and the changes resulting from a variety of pathologic conditions.

Changes in Doppler indices from normal may help in the early identification of rejection of transplanted organs, parenchymal dysfunction, and malignancy. Although useful, these measurements are influenced not only by the resistance to flow in peripheral vessels, but also by heart rate, blood pressure, vessel wall length and elasticity, extrinsic organ compression, and other factors.

Interpretation of Color Doppler

Although the graphic presentation of color Doppler imaging suggests that interpretation is made easier, the complexity of the color Doppler image actually makes this a more demanding image to evaluate than the simple Doppler spectrum. Nevertheless, color Doppler imaging has important advantages over pulsed wave duplex Doppler imaging, in which flow data are obtained only from a small portion of the area being imaged. To be confident that a conventional Doppler study has achieved reasonable sensitivity and specificity in detection of flow disturbances, a methodical search and sampling of multiple sites within the field of interest must be performed. In contrast, CDFI devices permit simultaneous sampling of multiple sites and are less susceptible to this error.

Although color Doppler can indicate the presence of blood flow, misinterpretation of color Doppler images may result in important errors. Each color pixel displays a representation of the Doppler frequency shift detected at that point. The frequency shift displayed is not the peak frequency present at sampling but rather a **weighted mean frequency** that attempts to account for the range of frequencies and their relative amplitudes at sampling. Manufacturers use different methods to derive the weighted mean frequency displayed in their systems. In addition, the pulse repetition frequency (PRF) and the color map selected to display the detected range of frequencies affect the color displayed. The color assigned to each Doppler pixel is determined by the Doppler frequency shift (which in turn is determined by target velocity and Doppler angle), the PRF, and the color map selected for display; therefore the interpretation of a color Doppler image must consider each of these variables. Although most manufacturers provide on-screen indications suggesting a relationship between the color displayed and flow velocity, this is misleading because color Doppler does not show velocity and only indicates the weighted mean frequency shift measured in the vessel; without correction for the effect of the Doppler angle, velocity cannot be estimated (Fig. 1.42). Because the frequency shift at a given point is a function of velocity and the Doppler angle, depending on the frequency shift present in a given pixel and the PRF, *any* velocity may be represented by *any* color, and under certain circumstances, low-velocity flow may not be shown at all. As with spectral Doppler, **aliasing** is determined by PRF. With color Doppler, aliasing causes frequencies greater than twice the PRF to "wrap around" and to be displayed in the opposite colors of the color map. Inexperienced users tend to associate color Doppler aliasing with elevated velocity, but even low velocities may show marked aliasing if PRF is sufficiently low. As PRF is increased, aliasing of high Doppler frequency shifts is reduced; however, low-frequency shifts may be eliminated from the display, resulting in diagnostic error (Fig. 1.43).

Other Technical Considerations

Although many problems and artifacts associated with B-mode imaging (e.g., shadowing) are encountered with Doppler sonography, the detection and display of frequency information related to moving targets present additional technical considerations. It is important to understand the source of these artifacts and

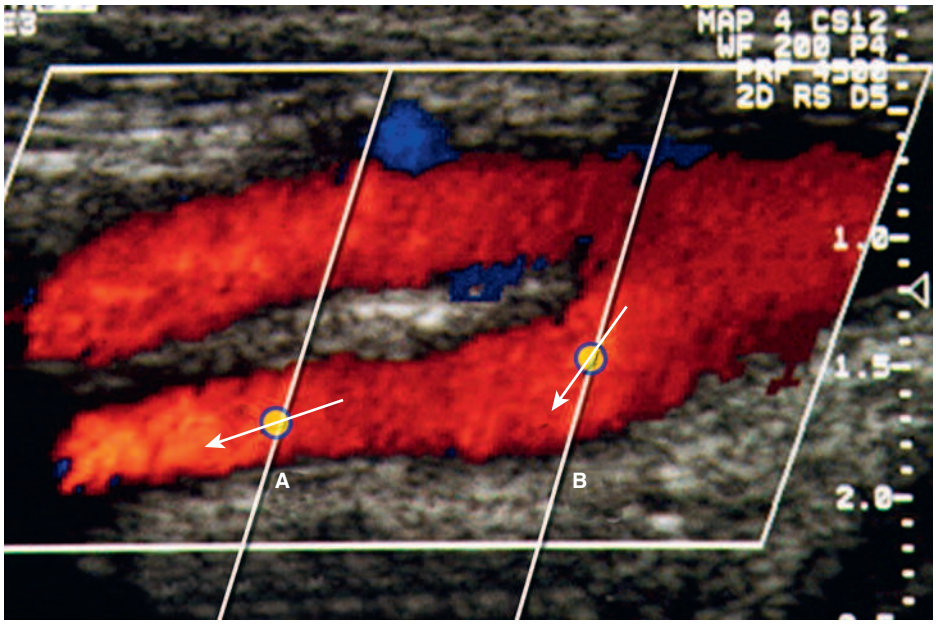

FIG. 1.42 Color Doppler. Each color pixel in a color Doppler image represents the Doppler frequency shift at that point, and it cannot be used to estimate velocity. Even though the points *A* and *B* have similar color values and therefore similar Doppler frequencies, the velocity at *A* is much higher than at *B* because of the large Doppler angle at *A* compared to *B*. The velocity represented by a given Doppler frequency increases in proportion to the Doppler angle.

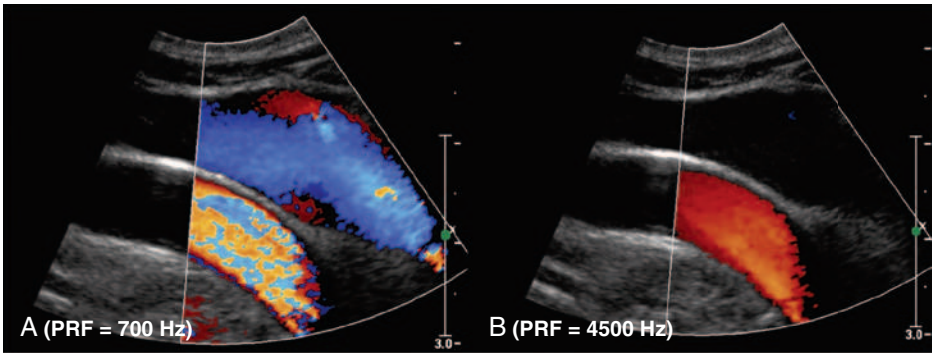

FIG. 1.43 Pulse Repetition Frequency (PRF). Depending on the color map selected, velocity of the target, Doppler angle, and PRF, a given velocity may appear as any color with color Doppler. **(A)** and **(B)** are sonograms of identical vessels. **(A)** PRF is 700 Hz, which results in aliasing of the higher Doppler frequency shifts in the carotid artery but permits the identification of relatively slow flow in the jugular vein. **(B)** PRF is 4500 Hz, eliminating aliasing in the artery but also suppressing the display of the low Doppler frequencies in the internal jugular vein.

their influence on the interpretation of the flow measurements obtained in clinical practice.

Doppler Frequency

A primary objective of the Doppler examination is the accurate measurement of characteristics of flow within a vascular structure. The moving red blood cells that serve as the primary source of the Doppler signal act as **point scatterers** of ultrasound rather than specular reflectors. This interaction results in the intensity of the scattered sound varying in proportion to the fourth power of the frequency, which is important in selecting the Doppler frequency for a given examination. As the transducer frequency increases, Doppler **sensitivity** improves, but attenuation by tissue also increases, resulting in diminished **penetration.** Careful balancing of the requirements for sensitivity and penetration is an important responsibility of the operator during a Doppler examination. Because many abdominal vessels lie several centimeters beneath the surface, Doppler frequencies in the range of 3 to 3.5 MHz are usually required to permit adequate penetration.

Wall Filters

Doppler instruments detect motion not only from blood flow but also from adjacent structures. To eliminate these low-frequency signals from the display, most instruments use **high pass filters,** or "wall" filters, which remove signals that fall below a given frequency limit. Although effective in eliminating low-frequency noise, these filters may also remove signals from low-velocity blood flow (Fig. 1.44). In certain clinical situations the measurement of these slower flow velocities is of clinical importance, and the improper selection of the wall filter may result in serious errors of interpretation. For example, low-velocity venous flow may not be detected if an improper filter is used, and low-velocity diastolic flow in certain arteries may also be eliminated from the display, resulting in errors in the calculation of Doppler indices, such as the systolic-to-diastolic ratio or resistive index. In general, the filter should be kept at the lowest practical level, usually 50 to 100 Hz.

Spectral Broadening

Spectral broadening refers to the presence of a large range of flow velocities at a given point in the pulse cycle and, by indicating turbulence, is an important criterion of high-grade vessel narrowing. Excessive system gain or changes in the dynamic range of the gray-scale display of the Doppler spectrum may suggest spectral broadening; opposite settings may mask broadening of the Doppler spectrum, causing diagnostic inaccuracy. Spectral broadening may also be produced by the selection of an excessively large sample volume or by the placement of the sample volume too near the vessel wall, where slower velocities are present (Fig. 1.45).

Aliasing

Aliasing is an artifact arising from ambiguity in the measurement of high Doppler frequency shifts. To ensure that samples originate from only a selected depth when using a pulsed wave Doppler system, it is necessary to wait for the echo from the area of interest before transmitting the next pulse. This limits the rate with which pulses can be generated, a lower PRF being required for greater depth. The PRF also determines the maximum depth from which unambiguous data can be obtained. If PRF is less than twice the maximum frequency shift produced by movement

Major Sources of Doppler Imaging Artifacts

DOPPLER FREQUENCY
Higher frequencies lead to more tissue attenuation
Wall filters remove signals from low-velocity blood flow

INCREASE IN SPECTRAL BROADENING
Excessive system gain or changes in dynamic range of the gray-scale display
Excessively large sample volume
Sample volume too near the vessel wall

INCREASE IN ALIASING
Decrease in pulse repetition frequency (PRF)
Decrease in Doppler angle
Higher Doppler frequency transducer

DOPPLER ANGLE
Relatively inaccurate above 60 degrees

SAMPLE VOLUME SIZE
Large sample volumes increase vessel wall noise

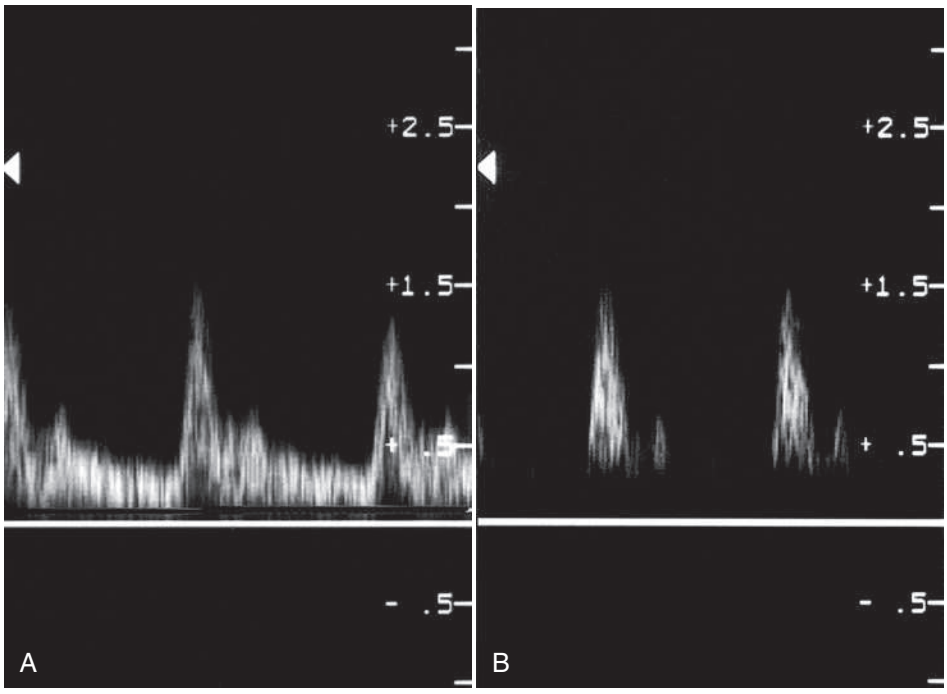

FIG. 1.44 Wall Filters. Wall filters are used to eliminate low-frequency noise from the Doppler display, but high wall filter settings may result in interpretation errors. Here the effect on the display of low-velocity flow is shown with wall filter settings of **(A)** 100 Hz and **(B)** 400 Hz. In general, wall filters should be kept at the lowest practical level, usually in the range of 50 to 100 Hz.

of the target **(Nyquist limit),** aliasing results (Fig. 1.46). When PRF is less than twice the frequency shift being detected, lower frequency shifts than are actually present are displayed. Because of the need for lower PRFs to reach deep vessels, signals from deep abdominal arteries are prone to aliasing if high velocities are present. In practice, aliasing is usually readily recognized. Aliasing can be reduced by increasing the PRF, by increasing the Doppler angle (thereby decreasing the frequency shift), or by using a lower-frequency Doppler transducer.

Doppler Angle

When making Doppler measurement of velocity, it is necessary to correct for the Doppler angle. The accuracy of a velocity estimate obtained with Doppler is only as great as the accuracy of the measurement of the Doppler angle. This is particularly true as the Doppler angle exceeds 60 degrees. In general, the **Doppler angle is best kept at 60 degrees or less** because small changes in the Doppler angle above 60 degrees result in substantial changes in the calculated velocity. Therefore measurement inaccuracies result in much greater errors in velocity estimates than do similar errors at lower Doppler angles. Angle correction is not required for the measurement of Doppler indices such as the resistive index, because these measurements are based only on the relationship of the systolic and diastolic amplitudes.

Sample Volume Size

With pulsed wave Doppler systems, the length of the Doppler sample volume can be controlled by the operator, and the width is determined by the beam profile. Analysis of Doppler signals requires that the sample volume be adjusted to exclude as much of the unwanted clutter as possible from near the vessel walls.

Doppler Gain

As with imaging, proper gain settings are essential to achieving accurate and reproducible Doppler measurements. *Excessive* Doppler gain results in noise appearing at all frequencies and may result in overestimation of velocity. Conversely, *insufficient* gain may result in underestimation of peak velocity (Fig. 1.47). A consistent approach to setting Doppler gain should be used. After placing the sample volume in the vessel, the Doppler gain should be increased to a level where noise is visible in the image, then gradually reduced to the point at which the noise first disappears completely.

OPERATING MODES: CLINICAL IMPLICATIONS

Ultrasound devices may operate in several modes, including real-time, color Doppler, spectral Doppler, and M-mode imaging. Imaging is produced in a *scanned* mode of operation. In scanned modes, pulses of ultrasound from the transducer are directed down lines of sight that are moved or steered in sequence to generate an image. This means that the number of ultrasound pulses arriving at a given point in the patient over a given interval is relatively small, and relatively little energy is deposited at any given location. In contrast, spectral Doppler imaging is an *unscanned* mode of operation in which multiple ultrasound pulses are sent in repetition along a line to collect the Doppler data. In this mode the beam is stationary, resulting in considerably greater potential for heating than in imaging modes. For imaging, PRFs are usually a few thousand hertz with very short pulses. Longer pulse durations are used with Doppler than with other imaging

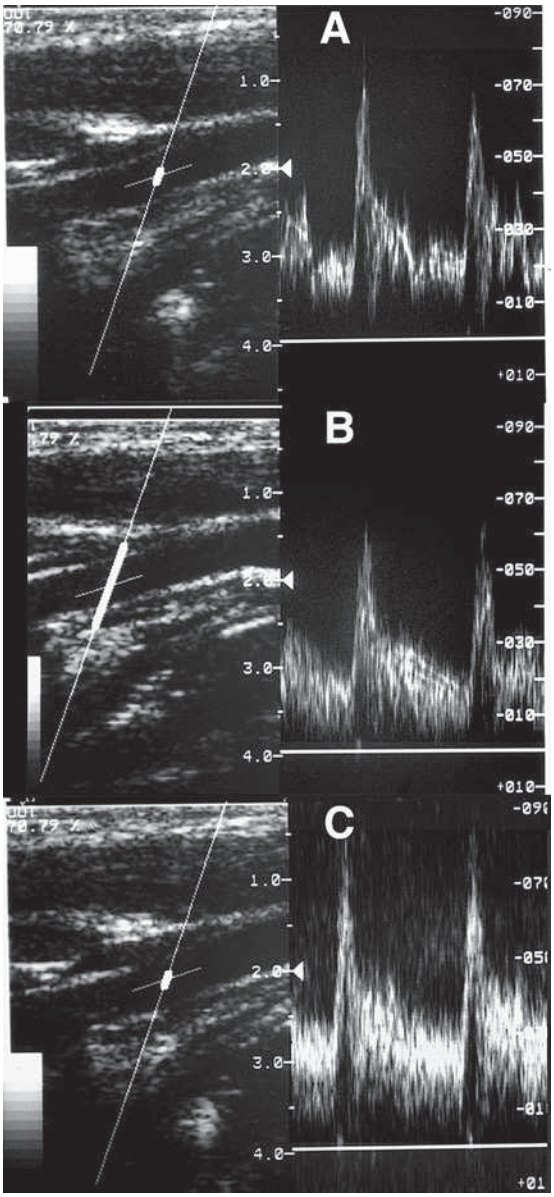

FIG. 1.45 Spectral Broadening. The range of velocities detected at a given time in the pulse cycle is reflected in the Doppler spectrum as spectral broadening. **(A) Normal spectrum.** Spectral broadening may arise from turbulent flow in association with vessel stenosis. **(B)** and **(C) Artifactual spectral broadening.** This may be produced by improper positioning of the sample volume near the vessel wall, use of **(B)** an excessively large sample volume, or **(C)** an excessive system gain.

modes. In addition, to avoid aliasing and other artifacts with Doppler imaging, it is often necessary to use higher PRFs than with other imaging applications. Longer pulse duration and higher PRF result in higher **duty factors** for Doppler modes of operation and increase the amount of energy introduced in scanning. Color Doppler, although a scanned mode, produces exposure conditions between those of real-time and Doppler imaging because color Doppler devices tend to send more pulses down each scan line and may use longer pulse durations than imaging devices. Clearly, every user needs to be aware that switching from an imaging to a Doppler mode changes the exposure conditions and the potential for biologic effects **(bioeffects).**

With current devices operating in imaging modes, concerns about bioeffects are minimal because intensities sufficient to produce measurable heating are seldom used. *With Doppler ultrasound, the potential for* ***thermal effects*** *is greater.* Preliminary measurements on commercially available instruments suggest that at least some of these instruments are capable of producing temperature rises of greater than 1°C at soft tissue/bone interfaces, if the focal zone of the transducer is held stationary. Care is therefore warranted when Doppler measurements are obtained at or near soft tissue/bone interfaces, as in the second and third trimester of pregnancy. These applications require thoughtful application of the principle of **ALARA (as low as reasonably achievable).** Under ALARA the user should use the lowest possible acoustic exposure to obtain the necessary diagnostic information.

Bioeffects and User Concerns

Although users of ultrasound need to be aware of bioeffects concerns, another key factor to consider in the safe use of ultrasound is the user. The knowledge and skill of the user are major determinants of the risk-to-benefit implications of the use of ultrasound in a specific clinical situation. For example, an unrealistic emphasis on risks may discourage an appropriate use of ultrasound, resulting in harm to the patient by preventing the acquisition of useful information or by subjecting the patient to another, more hazardous examination. The skill and experience of the individual performing and interpreting the examination are likely to have a major impact on the overall benefit of the examination. In view of the rapid growth of ultrasound and its proliferation into the hands of minimally trained clinicians, many more patients are likely to be harmed by misdiagnosis resulting from improper indications, poor examination technique, and errors in interpretation than from bioeffects. Misdiagnosis (e.g., of ectopic pregnancy) and failure to diagnose a clinically important anomaly are real dangers, and poorly trained users may be the greatest current hazard of diagnostic ultrasound.

Understanding bioeffects is essential for the prudent use of diagnostic ultrasound and is important in ensuring that the excellent risk-to-benefit performance of diagnostic ultrasound is preserved. All users of ultrasound should be prudent, understanding as fully as possible the potential risks and obvious benefits of ultrasound examinations, as well as those of alternate diagnostic methods. With this information, operators can monitor exposure conditions and implement the principle of ALARA to keep patient (and in obstetric imaging, the fetal) exposure as low as possible while fulfilling diagnostic objectives.

THERAPEUTIC APPLICATIONS: HIGH-INTENSITY FOCUSED ULTRASOUND

Although the primary medical application of ultrasound has been for diagnosis, therapeutic applications are developing rapidly, particularly the use of **high-intensity focused ultrasound** (HIFU). HIFU is based on three important capabilities of ultrasound: (1) focusing the ultrasound beam to produce highly localized energy deposition, (2) controlling the location and size of the focal zone, and (3) using intensities sufficient to destroy tissue at the focal

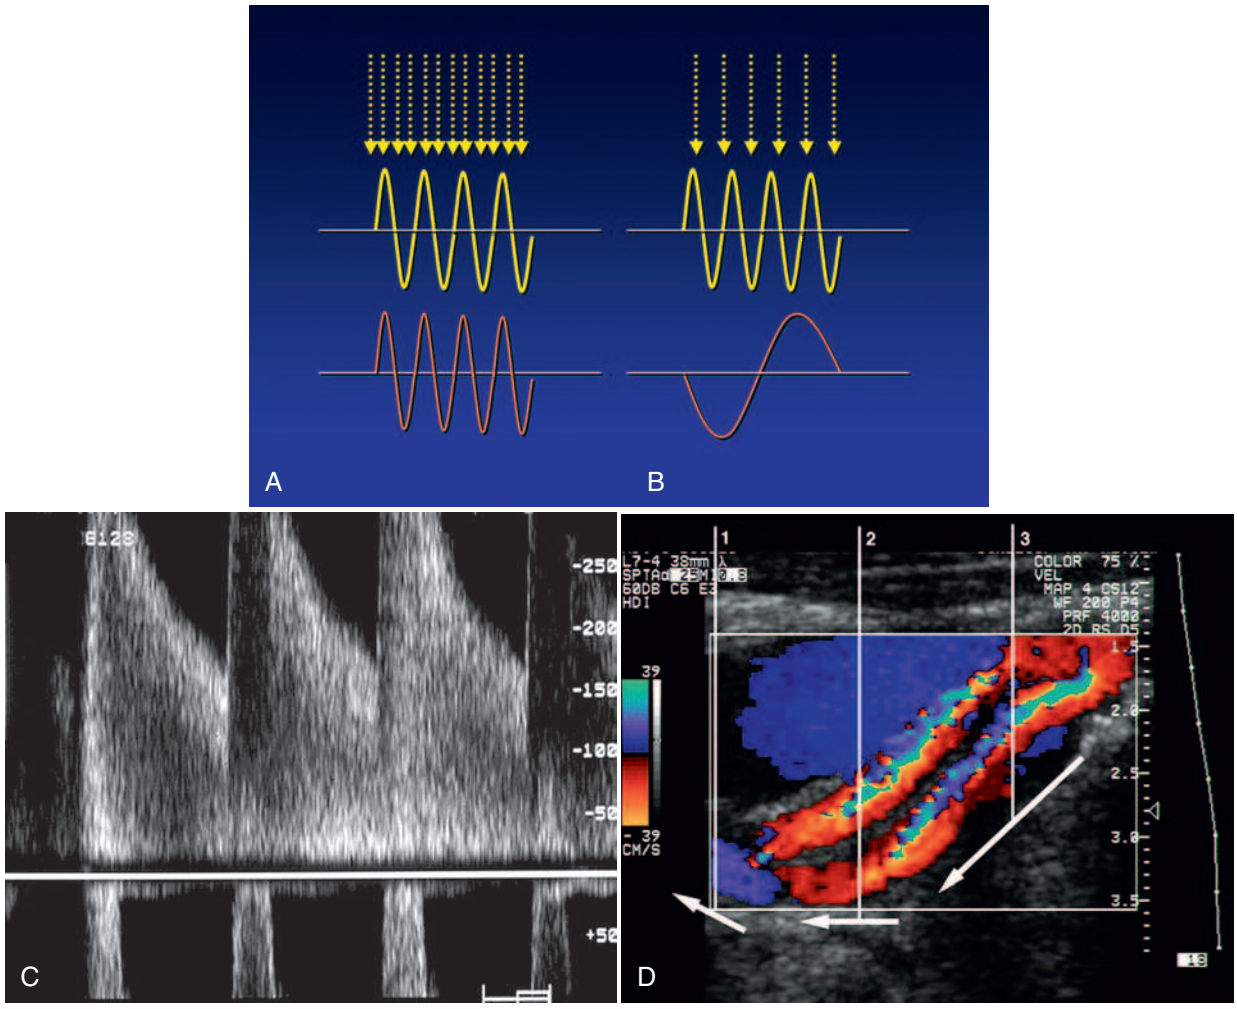

FIG. 1.46 Aliasing. Pulse repetition frequency (PRF) determines the sampling rate of a given Doppler frequency. **(A)** If PRF *(arrows)* is sufficient, the sampled waveform *(orange curve)* will accurately estimate the frequency being sampled *(yellow curve)*. **(B)** If PRF is less than half the frequency being measured, **undersampling** will result in a lower frequency shift being displayed *(orange curve)*. **(C)** In a clinical setting, **aliasing** appears in the spectral display as a "wraparound" of the higher frequencies to display below the baseline. **(D)** In color Doppler display, aliasing results in a wraparound of the frequency color map from one flow direction to the opposite direction, passing through a transition of unsaturated color. The velocity throughout the vessel is constant, but aliasing appears only in portions of the vessel because of the effect of the Doppler angle on the Doppler frequency shift. As the angle increases, the Doppler frequency shift decreases, and aliasing is no longer seen.

zone. This has led to an interest in HIFU as a means of destroying noninvasive tumor and controlling bleeding and cardiac conduction anomalies.

HIFU exploits **thermal** (heating of tissues) and **mechanical (cavitation)** bioeffect mechanisms. As ultrasound passes through tissue, attenuation occurs through scattering and absorption. Scattering of ultrasound results in the return of some of the transmitted energy to the transducer, where it is detected and used to produce an image, or Doppler display. The remaining energy is transmitted to the molecules in the acoustic field and produces heating. At the **spatial peak temporal average** (SPTA), intensities of 50 to 500 mW/cm^2 used for imaging and Doppler, heating is minimal, and no observable bioeffects related to tissue heating in humans have yet been documented with clinical devices. With higher intensities, however, tissue heating sufficient to destroy tissue may be achieved. Using HIFU at 1 to 3 MHz, focal peak intensities of 5000 to 20,000 W/cm^2 may be achieved. This energy can be delivered to a small point several millimeters in size, producing rapid temperature elevation and resulting in tissue coagulation, with little damage to adjacent tissues (Fig. 1.48). The destruction of tissue is a function of the temperature reached and the duration of the temperature elevation. In general, elevation of tissue to a temperature of 60°C for 1 second is sufficient to produce **coagulation necrosis.**

Because of its ability to produce highly localized tissue destruction, HIFU has been investigated as a tool for noninvasive or minimally invasive treatment of bleeding sites, uterine fibroids, and tumors in the prostate, liver, and breast.[19,20] As with diagnostic ultrasound, HIFU is limited by the presence of gas or bone interposed between the transducer and the target tissue. The reflection of high-energy ultrasound from strong interfaces produced by bowel gas, aerated lung, or bone may result in tissue heating along the reflected path of the sound, producing unintended tissue damage.

Major challenges with HIFU include image guidance and accurate monitoring of therapy as it is being delivered. Magnetic

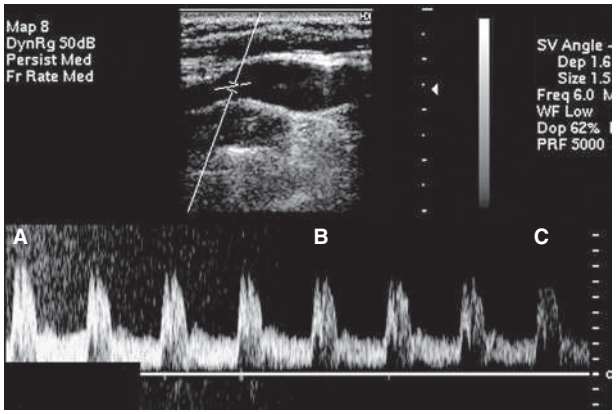

FIG. 1.47 Doppler Gain. Accurate estimation of velocity requires proper Doppler gain adjustment. **Excessive gain** will cause an overestimation of peak velocity *(A),* and **insufficient gain** will result in underestimation of velocity *(C).* To adjust gain properly, the sample volume and Doppler angle are first set at the sample site. The gain is turned up until noise appears in the background *(A),* then is gradually reduced just to the point where the background noise disappears from the image *(B). PSV,* Peak systolic velocity.

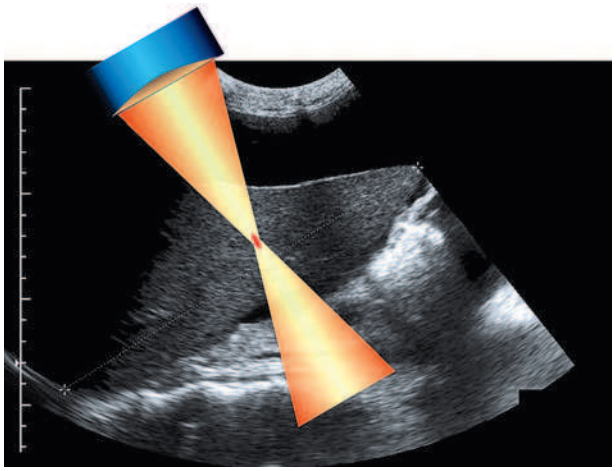

FIG. 1.48 High-Intensity Focused Ultrasound (HIFU). Local tissue destruction by heating may be achieved using HIFU delivered with focal peak intensities of several thousand W/cm^2. Tissue destruction can be confined to a small area a few millimeters in size without injury to adjacent tissues. HIFU is a promising tool for minimally invasive treatment of bleeding sites, uterine fibroids, and tumors in the prostate, liver, and breast.

resonance imaging (MRI) provides a means of monitoring temperature elevation during treatment, which is not possible with ultrasound. Guidance of therapy may be done with ultrasound or MRI, with ultrasound guidance having the advantage of verification of the acoustic window and sound path for the delivery of HIFU.

CHAPTER 2

Biologic Effects and Safety

J. Brian Fowlkes and Christy K. Holland

SUMMARY OF KEY POINTS

- Clinical ultrasound has been found to be an effective imaging modality with an excellent safety profile when used appropriately.
- Ultrasound can produce physical effects, which should be understood as part of the benefit-versus-risk assessment as with any medical procedure.
- The thermal index (TI) and mechanical index (MI) provide feedback to the user and should be minimized while obtaining the requisite medical benefit from the ultrasound examination.
- Ultrasound exposures during clinical, research, and educational examinations should be as low as reasonably achievable (ALARA).
- Users of ultrasound should be appropriately trained and familiar with the equipment operation and controls that affect ultrasound exposure.

Ultrasound has provided a wealth of knowledge in diagnostic medicine and has greatly affected medical practice, particularly in obstetrics. Millions of sonographic examinations are performed each year, and ultrasound remains one of the fastest growing imaging modalities because of its low cost, real-time interactions, portability, and apparent lack of biologic effects (bioeffects). No casual relationship has been established between clinical applications of diagnostic ultrasound and bioeffects on the patient or operator.

REGULATION OF ULTRASOUND OUTPUT

The U.S. Food and Drug Administration (FDA) regulates the maximum output of ultrasound devices to an established level. The marketing approval process requires devices to be equivalent in efficacy and output to those produced before 1976. This historic regulation of sonography has provided a safety margin for ultrasound while allowing clinically useful performance. The mechanism has restricted ultrasound exposure to levels that apparently produce few, if any, obvious bioeffects based on the epidemiologic evidence, although animal studies have shown some evidence for biologic effects.

In an effort to increase the efficacy of diagnostic ultrasound, the maximum acoustic output for some applications has increased through an additional FDA market approval process termed "510K Track 3." The vast majority of ultrasound systems currently in use were approved through this process. The Track 3 process provides the potential for better imaging performance and, as discussed later, requires that additional information be reported

to the operator regarding the relative potential for bioeffects. Therefore informed decision making is important concerning the possible adverse effects of ultrasound in relation to the desired diagnostic information. Current FDA regulations that limit the maximum output are still in place, but in the future, systems might allow sonographers and physicians the discretion to increase acoustic output beyond a level that might induce a biologic response.

Although the choices made during sonographic examinations may not be equivalent to the risk-versus-benefit decisions associated with imaging modalities using ionizing radiation, the operator will be increasingly responsible for determining the diagnostically required amount of ultrasound exposure. Thus the operator should know the potential bioeffects associated with ultrasound exposure. Patients also need to be reassured about the safety of a diagnostic ultrasound scan. The scientific community has identified some potential bioeffects from sonography, and although no causal relation has been established, it does not mean that no effects exist. Therefore it is important to understand the interaction of ultrasound with biologic systems.

PHYSICAL EFFECTS OF SOUND

The physical effects of sound can be divided into two principal groups: **thermal** and **nonthermal.** Most medical professionals recognize the thermal effects of elevated temperature on tissue, and the effects caused by ultrasound are similar to those of any localized heat source. With ultrasound, the heating mainly results from the absorption of the sound field as it propagates through tissue. However, "nonthermal" sources can generate heat as well.

Many nonthermal mechanisms for bioeffects exist. Acoustic fields can apply **radiation forces** (not ionizing radiation) on the structures within the body at both the macroscopic and the microscopic levels, resulting in exerted pressure and torque. The temporal average pressure in an acoustic field is different from the hydrostatic pressure of the fluid, and any object in the field is subject to this change in pressure. The effect is typically considered smaller than other effects because it relies on less significant factors in the formulation of the acoustic field. Acoustic fields can also cause motion of fluids. Such acoustically induced flow is called **streaming.**

Acoustic cavitation is the action of acoustic fields within a fluid to generate bubbles and cause volume pulsation or even collapse in response to the acoustic field. The result can be heat generation and associated free radical formation, microstreaming of fluid around the bubble, radiation forces generated by the scattered acoustic field from the bubble, and mechanical actions from bubble collapse. The interaction of acoustic fields with bubbles or "gas bodies" (as they are generally called) has been a significant area of bioeffects research for many years.

THERMAL EFFECTS

Ultrasound Produces Heat

As ultrasound propagates through the body, energy is lost through **attenuation.** Attenuation causes loss of penetration and the inability to image deeper tissues. Attenuation is the result of two processes, scattering and absorption. **Scattering** of the ultrasound results from the redirection of the acoustic energy by tissue encountered during propagation. With diagnostic ultrasound, some of the acoustic energy transmitted into the tissue is scattered back in the direction of the transducer, termed **backscatter,** which allows a signal to be detected and images to be made. Energy also is lost along the propagation path of the ultrasound by **absorption.** Absorption loss occurs substantially through the conversion of the ultrasound energy into heat. This heating provides a mechanism for ultrasound-induced bioeffects.

Factors Controlling Tissue Heating

The rate of temperature increase in tissues exposed to ultrasound depends on several factors, including spatial focusing, ultrasound frequency, exposure duration, and tissue type.

Spatial Focusing

Ultrasound systems use multiple techniques to concentrate or focus ultrasound energy and improve the quality of measured signals. The analogy for light is that of a magnifying glass. The glass collects all the light striking its surface and concentrates it into a small region. In sonography and acoustics in general, the term **intensity** is used to describe the spatial distribution of ultrasonic **power** (energy per unit time), where **intensity = power/area** and the **area** refers to the cross-sectional area of the ultrasound beam. Another common beam dimension is the **beam width** at a specified location of the field. If the same ultrasonic power is concentrated into a smaller area, the intensity will increase. Focusing occurs on both transmission of the ultrasound and when receiving the backscattered signals used to form the image. The transmit focusing is of importance in terms of potential biologic effects because this phenomenon controls the applied energy to the tissue. There are ultrasound imaging systems that use plane wave transmission or limited transmit focusing, which may reduce the local intensity, but all ultrasound systems must still operate under the FDA limits.

Focusing in an ultrasound system can be used to improve the spatial resolution of the images. The side effect is an increased potential for bioeffects caused by heating and cavitation. In general, the greatest heating potential is between the scanhead and the focus, but the exact position depends on the focal distance, tissue properties, and heat generated within the scanhead itself.

Returning to the magnifying glass analogy, most children learn that the secret to incineration is a steady hand. Movement distributes the power of the light beam over a larger area, thereby reducing its intensity. The same is true in ultrasound imaging. Thus imaging systems that scan a beam through tissue reduce the spatial average intensity. **Spectral Doppler** and **M-mode** ultrasound imaging maintain the ultrasound beam in a stationary position (both considered **unscanned modes**) and therefore provide no opportunity to distribute the ultrasonic power spatially, whereas **color flow Doppler, power mode Doppler,** and **B-mode** (also called **gray-scale**) ultrasound imaging require that the beam be moved to new locations **(scanned modes)** at a rate sufficient to produce the real-time nature of these imaging modes.

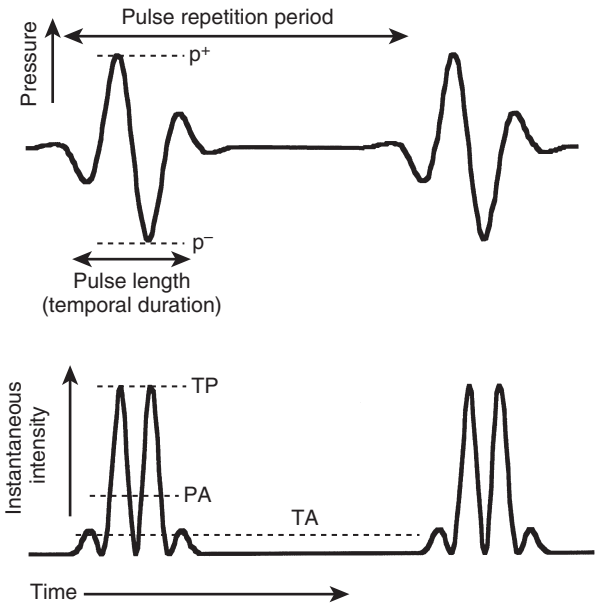

FIG. 2.1 Pressure and Intensity Parameters Measured in Medical Ultrasound. The variables are defined as follows: p^+, peak positive pressure in waveform; p^-, peak rarefactional pressure in waveform; *PA,* pulse average; *TA,* temporal average; *TP,* temporal peak.

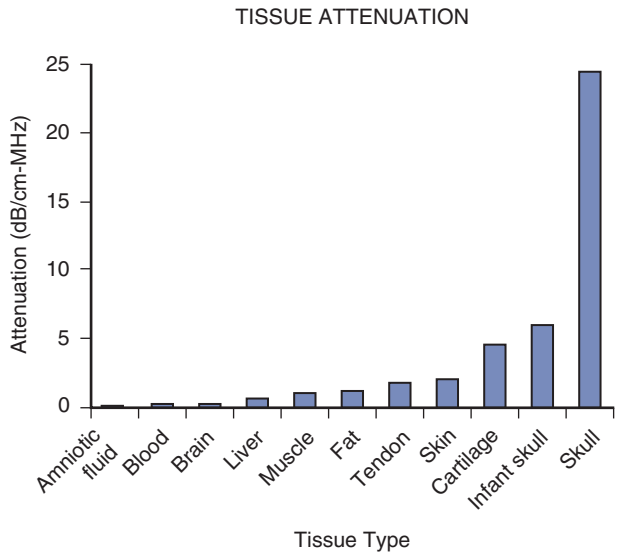

FIG. 2.2 Tissue Attenuation. Values for types of human tissue at body temperature. (Data from Duck FA, Starritt HC, Anderson SP. A survey of the acoustic output of ultrasonic Doppler equipment. Clin Phys Physiol Meas. 1987;8[1]:39-49.[47])

Temporal Considerations

The ultrasound power is the temporal rate at which ultrasound energy is produced. Therefore controlling how ultrasound is produced in time seems a reasonable method for limiting its effects.

Ultrasound can be produced in bursts rather than continuously. Ultrasound imaging systems operate on the principle of **pulse-echo,** in which a burst of ultrasound is emitted, followed by a quiescent period listening for echoes to return. This **pulsed wave** ultrasound may be swept through the image plane numerous times during an imaging sequence. On the other hand, ultrasound may be transmitted in a **continuous wave** (CW) mode, in which the ultrasound transmission is not interrupted. The **temporal peak intensity** refers to the largest intensity at any time during ultrasound exposure (Fig. 2.1). The **pulse average intensity** is the average value over the duration of the ultrasound pulse. The **temporal average intensity** is the average over the entire pulse repetition period (elapsed time between onset of ultrasound bursts). The **duty factor** is defined as the fraction of time the ultrasound field is "on." With significant time "off" between pulses (small duty factor), the temporal average value will be significantly smaller. For example, a duty factor of 10% will reduce the temporal average intensity by a factor of 10 compared with the pulse average. The time-averaged quantities are the variables most related to the potential for thermal bioeffects. Combining temporal and spatial information results in common terms such as the **spatial peak, temporal average intensity** (I_{SPTA}) and **spatial average, temporal average intensity** (I_{SATA}).

The overall duration, or **dwell time,** of the ultrasound exposure to a particular tissue is important because longer exposure of the tissue may increase the risk of bioeffects. The motion of the scanhead during an examination reduces the dwell time within a particular region of the body and can minimize the potential for bioeffects of ultrasound. Therefore performing an efficient scan, spending only the time required for diagnosis, is a simple way to reduce exposure.

Tissue Type

Numerous physical and biologic parameters control heating of tissues. Absorption is normally the dominant contributor to attenuation in soft tissue. The **attenuation coefficient** is the attenuation per unit length of sound travel and is usually given in decibels per centimeters-megahertz (dB/cm-MHz). The attenuation typically increases with increasing ultrasound frequency. The attenuation ranges from a negligible amount for fluids (e.g., amniotic fluid, blood, urine) to the highest value for bone, with some variation among different soft tissue types (Fig. 2.2).

Another important factor is the body's ability to cool tissue through blood perfusion. Well-perfused tissue will more effectively regulate its temperature by carrying away the excess heat produced by ultrasound. The exception is when heat is deposited too rapidly, as in therapeutic thermal ablation.[1]

Bone and soft tissue are two specific areas of interest based on the differences in heating phenomena. **Bone** has high attenuation of incident acoustic energy. In examinations during pregnancy, calcified bone is typically subjected to ultrasound, as in measurement of the biparietal diameter (BPD) of the skull. Fetal bone contains increasing degrees of mineralization as gestation progresses, thereby increasing risk of localized heating. Special heating situations relevant to obstetric ultrasound examinations may also occur in **soft tissue,** where overlying structures provide little attenuation of the field, such as the fluid-filled amniotic sac.

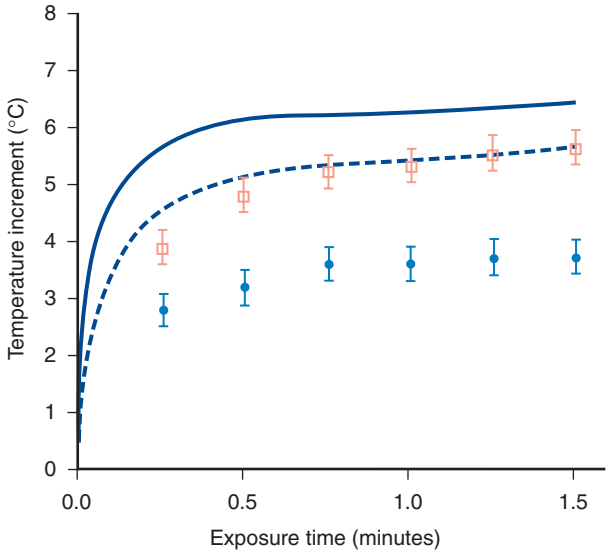

FIG. 2.3 Heating of Mouse Skull in a Focused Sound Field. For these experiments, frequency was 3.6 MHz, and temporal average focal intensity was 1.5 W/cm^2. *Solid circles,* Young (<17 wk) mice (n = 7); *open squares,* old (>6 mo) mice (n = 4); *vertical bars,* two standard errors in height; *top curves,* theoretical estimation of the temperature increases by Nyborg.[3] (With permission from Carstensen EL, Child SZ, Norton S, Nyborg W. Ultrasonic heating of the skull. J Acoust Soc Am. 1990;87[3]: 1310-1317.[2])

Bone Heating

The absorption of ultrasound at the bone surface allows for rapid deposition of energy from the field into a limited volume of tissue. The result can be a significant temperature rise. For example, Carstensen and colleagues[2] combined an analytic approach and experimental measurements of the temperature rise in mouse skull exposed to CW ultrasound to estimate the temperature increments in bone exposures. Because bone has a large absorption coefficient, the incident ultrasonic energy is assumed to be absorbed in a thin planar sheet at the bone surface. The temperature rise of mouse skull has been studied in a 3.6-MHz focused beam with a beam width of 2.75 mm (Fig. 2.3). The temporal average intensity in the focal region was 1.5 W/cm.[2] One of two models (upper curve in Fig. 2.3) in common use[3] predicts values for the temperature rise about 20% greater than that actually measured in this experiment.[2] Thus the theoretical model is conservative in nature.

Similarly for the fetal femur, Drewniak and colleagues[4] indicated that the size and calcification state of the bone contributed to the *ex vivo* heating of bone (Table 2.1). To put this in perspective and to illustrate the operator's role in controlling potential heating, consider the following scenario. By reducing the output power of an ultrasound scanner by 10 dB, the predicted temperature rise would be reduced by a factor of 10, making the increase of 3°C seen by these researchers (see Table 2.1) virtually nonexistent. **This strongly suggests the use of maximum receive gain and reduction in output power during ultrasound examinations** (see section on considerations for controlling ultrasound output). In fetal examinations an attempt should be made to maximize receive gain because this comes at no cost to the patient in terms of exposure. Distinctions are often made between bone positioned deep to the skin at the focal plane of the transducer and bone near the skin surface, as when considering transcranial applications. This distinction is discussed later with regard to the thermal index (TI).

TABLE 2.1 Fetal Femur Temperature Increments[a] at 1 W/cm^2

Gestational Age (days)	Diameter (mm)	Temperature Increments (°C)
59	0.5	0.10
78	1.2	0.69
108	3.3	2.92

[a]Temperature increments in human fetal femur exposed for 20 seconds were found to be approximately proportional to incident intensity.

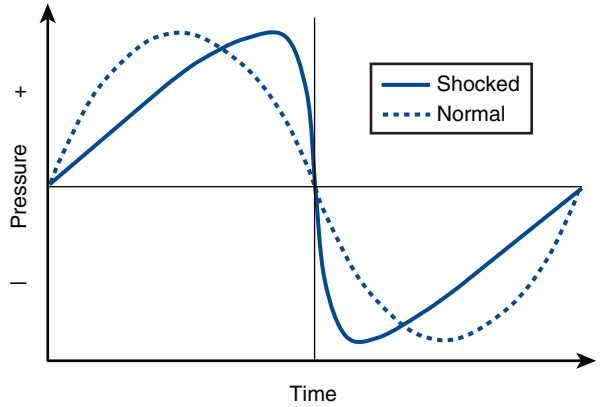

FIG. 2.4 Effect of Finite Amplitude Distortion on a Propagating Ultrasound Pulse. Note the increasing steepness in the pulse, which contains higher frequency components.

Soft Tissue Heating

Two clinical situations for ultrasound exposure in soft tissue are particularly relevant to obstetric and gynecologic applications. First, a common scenario involves **scanning through a full bladder.** The urine is a fluid with a relatively low ultrasound attenuation coefficient. The reduced attenuation allows larger acoustic amplitudes to be applied deeper within the body. Second, the propagating wave may experience **finite amplitude distortion,** resulting in energy being shifted by a nonlinear process from lower to higher frequencies. The result is a **shockwave**—a gradual wave steepening results in a waveform composed of higher frequency components (Fig. 2.4). Attenuation increases with increasing frequency; therefore the absorption of a large portion of the energy in such a wave occurs over a much shorter distance, concentrating the energy deposition in the first tissue encountered, which may include the fetus.

Ultrasound imaging systems include specific modalities that rely on nonlinear effects. In **tissue harmonic imaging,** or native harmonic imaging, the image is created using the backscatter of harmonic components induced by nonlinear propagation of the ultrasound field. This has distinct advantages in terms of reducing image artifacts and improving lateral resolution in particular. In these nonlinear imaging modes the acoustic output must be sufficiently high to produce the effect. The acoustic power currently used is still within the FDA limits, but improvements in image quality using such modes may create the need to modify or relax the regulatory restrictions. Similarly, in elasticity or shear wave imaging, the acoustic pressure may need to be increased to provide sufficient acoustic radiation force for imaging tissue stiffness. This detail will be discussed in the section on considerations for increasing acoustic output.

Transvaginal ultrasound is important to note because of the proximity of the transducer to sensitive tissues such as the ovaries. As discussed later, temperature increases near the transducer may provide a heat source at sites other than the focus of the transducer. In addition, the transducer face itself may be a significant heat source because of inefficiencies in its conversion of electric to acoustic energy. Such factors must be considered in the estimation of potential thermal effects in transvaginal ultrasound and other endocavitary applications.

Hyperthermia and Ultrasound Safety

Knowledge of the bioeffects of ultrasound heating is in part based on the experience available from other, more common forms of hyperthermia, which serve as a basis for safety criteria. Extensive data exist on the effects of short-term and extended temperature increases, or hyperthermia. Teratogenic effects from hyperthermia have been demonstrated in birds, all the common laboratory animals, farm animals, and nonhuman primates.[5] The wide range of observed bioeffects, from subcellular chemical alterations to gross congenital abnormalities and fetal death, is an indication of the effectiveness or universality of hyperthermic conditions for perturbing living systems.[6]

The National Council on Radiation Protection and Measurements (NCRP) Scientific Committee on Biological Effects of Ultrasound compiled a comprehensive list of the lowest reported thermal exposures producing teratogenic effects.[7,8] Examination of these data indicated a lower boundary for observed thermally induced bioeffects. Questions remain, however, about the relevance of this analysis of hyperthermia to the application of diagnostic ultrasound.[9] After a careful literature review, O'Brien and colleagues[10] suggested a more detailed consideration of thermal effects with regard to short-duration exposures. Fig. 2.5 shows the recommended approach to addressing the combination of temperature and duration of exposure. Note that the tolerance of shorter durations and higher temperatures suggests a substantial safety margin for diagnostic ultrasound. Regardless, it is beneficial to provide feedback to the ultrasound operator as to the relative potential for a temperature rise in a given acoustic field under conditions associated with a particular examination. This will allow an informed decision as to the exposure needed to obtain diagnostically relevant information.

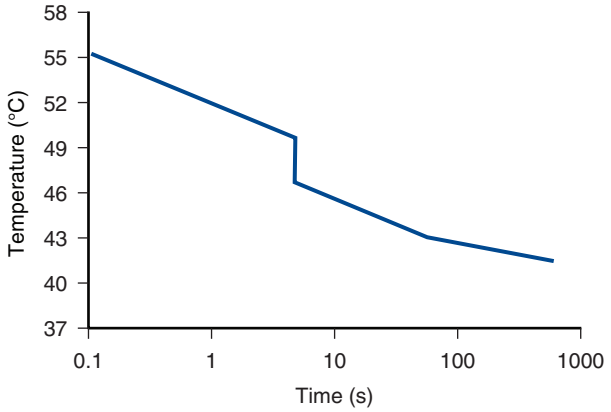

FIG. 2.5 Conservative Boundary Curve for Nonfetal Bioeffects Caused by a Thermal Mechanism. Note the increase in temperature tolerance associated with shorter durations of exposures, a modification to the earlier American Institute of Ultrasound in Medicine (AIUM) Conclusions Regarding Heat statement (March 26, 1997). The AIUM approved a revised thermal statement on April 6, 2009. For a complete description of the origins of this curve, see O'Brien and colleagues.[10] (With permission from O'Brien Jr WD, Deng CX, Harris GR, et al. The risk of exposure to diagnostic ultrasound in postnatal subjects: thermal effects. J Ultrasound Med. 2008;27[4]:517-535.[10])

Thermal Index

Based on analysis of hyperthermia data, the NCRP proposed a general statement concerning the safety of ultrasound examinations in which no temperature rise greater than 1°C is expected. In an afebrile patient within this limit, the NCRP concluded that there was no basis for expecting an adverse effect. In cases where the temperature rise might be greater, the operator should weigh the benefit against the potential risk. To assist in this decision, given the range of different imaging conditions seen in practice, a **thermal index** (TI) was approved as part of the Standard for Real-Time Display of Thermal and Mechanical Acoustical Output Indices on Diagnostic Ultrasound Equipment of the American Institute of Ultrasound in Medicine (AIUM).[11] This standard provides the operator with an indication of the relative potential risk of heating tissue, with calculations based on the imaging conditions and an on-screen display showing the TI. This standard was subsequently adopted as an international standard through the International Electrotechnical Commission (IEC).[12]

The Thermal Index

To more easily inform the physician of the operating conditions that could, in some cases, lead to a temperature elevation of 1°C, a thermal index is defined as

$$TI = \frac{W_0}{W_{deg}}$$

where W_{deg} is the ultrasonic source power (in watts) calculated as capable of producing a 1°C temperature elevation under specific conditions. W_0 is the ultrasonic source power (in watts) being used during the current exam.

Reproduced with permission of American Institute of Ultrasound in Medicine (AIUM).

The NCRP ultrasound committee introduced the TI concept.[8] The purpose of the TI is to provide an indication of the *relative* potential for increasing tissue temperature, but it is not meant to provide the *actual* temperature rise. The NCRP recommended two tissue models to aid in the calculation of the ultrasound power that could raise the temperature in tissue by 1°C: (1) a homogeneous model in which the attenuation coefficient is uniform throughout the region of interest, and (2) a fixed-attenuation model in which the minimum attenuation along the path from transducer to a distant anatomic structure is independent of the distance because of a low-attenuation fluid path (e.g., amniotic fluid).[8,13,14] Because of concern for the patient, it was recommended that "reasonable worst case" assumptions be made with respect to estimation of temperature elevations *in vivo*. The FDA, AIUM, and National Electrical Manufacturers Association (NEMA) adopted the TI as part of the output display standard. They advocate estimating the effect of attenuation in the body by reducing the acoustic power/output of the scanner (W_0) by a derating factor equal to 0.3 dB/cm-MHz for the soft tissue model.[11]

The AIUM Thermal Index Working Group considered three tissue models: (1) the homogeneous tissue or soft tissue model, (2) a tissue model with bone at the focus, and (3) a tissue model with bone at the surface, or transcranial model.[11] The TI takes on three different forms for these tissue models.

Homogeneous Tissue Model (Soft Tissue)

The assumption of homogeneity helps simplify the determination of the effects of acoustic propagation and attenuation, as well as the heat transfer characteristics of the tissue. Providing one of the most common applications for ultrasound imaging, this model applies to situations where bone is not present and can generally be used for fetal examinations during the first trimester (low calcification in bone). In the estimation of potential heating, many assumptions and compromises had to be made to calculate a single quantity that would guide the operator. Calculations of the temperature rise along the axis of a focused beam for a simple, spherically curved, single-element transducer result in two thermal peaks. The first is in the near field (between the transducer and the focus), and the second appears close to the focal region.[15,16] The **first thermal peak** occurs in a region with low ultrasound intensity and wide beam width. When the beam width is large, cooling will occur mainly because of perfusion. In the near field the magnitude of the local intensity is the chief determinant of the degree of heating. The **second thermal peak** occurs at the location of high intensity and narrow beam width at or near the focal plane. Here the cooling is dominated by conduction, and the total acoustic power is the chief determinant of the degree of heating.

Given the thermal "twin peaks" dilemma, the AIUM Thermal Index Working Group compromised in creating a TI that included contributions from both heating domains.[11] Their rationale was based on the need to minimize the acoustic measurement load for manufacturers of ultrasound systems. In addition, adjustments had to be made to compensate for effects of the large range of potential apertures. The result is a complicated series of calculations and measurements that must be performed, and to the credit of the many manufacturers, there has been considerable effort in implementing a display standard to provide user feedback. Different approaches to these calculations were considered,[10] but changes will require that the currently accepted implementation be reexamined and approved for use by the FDA and considered by the IEC.

Tissue Model With Bone at the Focus (Fetal Applications)

Applications of ultrasound in which the acoustic beam travels through soft tissue for a fixed distance and impinges on bone occur most often in obstetric scanning during the second and third trimesters. Carson and colleagues[13] recorded sonographic measurements of the maternal abdominal wall thickness in various stages of pregnancy. Based on their results, the NCRP recommended that the attenuation coefficients for the first, second, and third trimesters be 1.0, 0.75, and 0.5 dB/MHz, respectively.[7] These values represent "worst case" estimates. In addition, Siddiqi and colleagues[17] determined the average tissue attenuation coefficient for transabdominal insonification (exposure to ultrasound waves) in a patient population of nonpregnant, healthy volunteers was 2.98 dB/MHz. This value represents an average measured value and is much different from the worst-case estimates previously listed. This leads to considerable debate on how such parameters should be included in an index.

In addition, bone is a complex, hard connective tissue with a calcified collagenous intercellular structure. Its absorption coefficient for longitudinal waves is a factor of 10 greater than that for most soft tissues (see Fig. 2.2). **Shear waves** are also created in bone as sound waves strike bone at oblique incidence. The absorption coefficients for shear waves are even greater than those for longitudinal waves.[18-20]

Based on the data of Carstensen and colleagues[2] described earlier, the NCRP proposed a thermal model for bone heating. Using this model, the **Bone Thermal Index** (TIB) is estimated for conditions in which the focus of the beam is at or near bone. Again, assumptions and compromises had to be made to develop a functional TI for the case of bone exposure, as follows:

- For **unscanned mode** transducers (operating in a fixed position) with bone in the focal region, the location of the maximum temperature increase is at the surface of the bone. Therefore the TIB is calculated at the distance along the beam from the transducer where it is maximized, a worst-case assumption.
- For **scanned modes**, the **Soft Tissue Thermal Index** (TIS) is used because the temperature increase at the surface is either greater than or approximately equal to the temperature increase with bone in the focus.

Tissue Model With Bone at the Surface (Transcranial Applications)

For adult cranial applications, the same model as that with bone at the focus is used to estimate the temperature distribution in situ. However, because the bone is located at the surface, immediately after the acoustic beam enters the body, attenuation of the acoustic power output is not included.[11] In this situation the equivalent beam diameter at the surface is used to calculate the

acoustic power and derive the **Cranial Bone Thermal Index** (TIC).

Estimate of Thermal Effects

Ultrasound users should keep in mind several points when referring to the TI as a means of estimating the potential for thermal effects. First, the TI is not synonymous with temperature rise. A TI equal to 1 does not mean the temperature will rise 1°C. An increased potential for thermal effects can be expected as TI increases. Second, a high TI does not mean that bioeffects are occurring, but only that the potential exists. The thermal models employed for TI calculation may not consider factors that may reduce the actual temperature rise. However, TI should be monitored during examinations and minimized when possible. Finally, there is no consideration in the TI for the duration of the scan, so minimizing the overall examination time will reduce the potential for effects. There have been proposals suggesting the inclusion of such a dwell time effect,[21] but these have not been adopted.

Summary Statement on Thermal Effects

The AIUM statement concerning thermal effects of ultrasound includes several conclusions that can be summarized as follows[22]:

- Adult examinations resulting in a temperature rise of up to 2°C are not expected to cause bioeffects. (Many ultrasound examinations fall within these parameters.)
- A significant number of factors control heat production by diagnostic ultrasound.
- Ossified bone is a particularly important concern for ultrasound exposure.
- A labeling standard now provides information concerning potential heating in soft tissue and bone.
- Even though an FDA limit exists for fetal exposures, predicted temperature rises can exceed 2°C.
- Thermal indices are expected to track temperature increases better than any single ultrasonic field parameter.

EFFECTS OF ACOUSTIC CAVITATION

Potential Sources for Bioeffects

Knowledge concerning the interaction of ultrasound with **gas bodies** (which many term "cavitation") has significantly increased over time, although it is not as extensive as that for ultrasound thermal effects and other sources of hyperthermia. **Acoustic cavitation inception** is demarcated by a specific threshold value: the minimum acoustic pressure necessary to initiate the growth of a cavity in a fluid during the rarefaction phase of the cycle. Several parameters affect this threshold, including **initial bubble** or **cavitation nucleus size,** acoustic pulse characteristics (e.g., center frequency, pulse repetition frequency [PRF], pulse duration), ambient hydrostatic pressure, and host fluid parameters (e.g., density, viscosity, compressibility, heat conductivity, surface tension). **Inertial cavitation** refers to bubbles that undergo large variations from their equilibrium sizes in a few acoustic cycles. Specifically during contraction, the surrounding fluid inertia controls the bubble motion.[23] Large acoustic pressures are necessary to generate inertial cavitation, and the collapse of these cavities is often violent.

The AIUM Statement on Mammalian Biological Effects of Heat

APPROVED MARCH 25, 2015

1. An excessive temperature increase can result in toxic effects in mammalian systems. The biological effects observed depend on many factors, such as the exposure duration, the type of tissue exposed, its cellular proliferation rate, and its potential for regeneration. Age and stage of development are important factors when considering fetal and neonatal safety. Temperature increases of several degrees Celsius above the normal core range can occur naturally. The probability of an adverse biological effect increases with both the duration and the magnitude of the temperature rise.
2. In general, adult tissues are more tolerant of temperature increases than fetal and neonatal tissues. Therefore, higher temperatures and/or longer exposure durations would be required for thermal damage. The considerable data available on the thermal sensitivity of adult tissues support the following inferences[10]:
   a. For exposure durations up to 50 hours, there have been no significant adverse biological effects observed due to temperature increases less than or equal to 1.5°C above normal.[25]
   b. For temperature increases between 1.5°C and 6°C above normal, there have been no significant adverse biological effects observed due to temperature increases less than or equal to $6 - [\log_{10}(t/60)]/0.6$ where t is the exposure duration in seconds. For example, for temperature increases of 4°C and 6°C, the corresponding limits for the exposure durations t are 16 minutes and 1 minute, respectively.
   c. For temperature increases greater than 6°C above normal, there have been no significant adverse biological effects observed due to temperature increases less than or equal to $6 - [\log_{10}(t/60)]/0.3$ where t is the exposure duration in seconds. For example, for temperature increases of 9.6°C and 6.0°C, the corresponding limits for the exposure durations t are 5 and 60 seconds, respectively.
   d. For exposure durations less than 5 seconds, there have been no significant, adverse biological effects observed due to temperature increases less than or equal to $9 - [\log_{10}(t/60)]/0.3$ where t is the exposure duration in seconds. For example, for temperature increases of 18.3°C, 14.9°C, and 12.6°C, the corresponding limits for the exposure durations t are 0.1, 1, and 5 seconds, respectively.
3. Acoustic output from diagnostic ultrasound devices is sufficient to cause temperature elevations in fetal tissue. Although fewer data are available for fetal tissues, the following conclusions are justified[10,26]:
   a. In general, temperature elevations become progressively greater from B-mode to color Doppler to spectral Doppler applications.

The AIUM Statement on Mammalian Biological Effects of Heat[24]—cont'd

b. For identical exposure conditions, the potential for thermal bioeffects increases with the dwell time during examination.
c. For identical exposure conditions, the temperature rise near bone is significantly greater than in soft tissues, and it increases with ossification development throughout gestation. For this reason, conditions in which an acoustic beam impinges on ossifying fetal bone deserve special attention due to its close proximity to other developing tissues.
d. The current U.S. Food and Drug Administration regulatory limit for the derated spatial-peak temporal-average intensity ($I_{SPTA.3}$) is 720 mW/cm^2. For this exposure, the theoretical estimate of the maximum temperature increase in the conceptus may exceed 1.5°C.
e. Although an adverse fetal outcome is possible at any time during gestation, most severe and detectable effects of thermal exposure in animals have been observed during the period of organogenesis. For this reason, exposures during the first trimester should be restricted to the lowest outputs consistent with obtaining the necessary diagnostic information.
f. Ultrasound exposures that elevate fetal temperature by 4°C above normal for 5 minutes or more have the potential to induce severe developmental defects. Thermally induced congenital anomalies have been observed in a large variety of animal species. In current clinical practice, using commercially available equipment, it is unlikely that such thermal exposure would occur at a specific fetal anatomic site provided that the thermal index (TI) is less than 2.0 and the dwell time on that site does not exceed 4 minutes.
g. Transducer self-heating is a significant component of the temperature rise of tissues close to the transducer. This may be of significance in transvaginal scanning, but no data for the fetal temperature rise are available.

4. The temperature increase during exposure of tissues to diagnostic ultrasound fields is dependent on: (1) output characteristics of the acoustic source, such as frequency, source dimensions, scan rate, output power, pulse repetition frequency, pulse duration, transducer self-heating, exposure time, and wave shape; and (2) tissue properties, such as attenuation, absorption, speed of sound, acoustic impedance, perfusion, thermal conductivity, thermal diffusivity, anatomic structure, and the nonlinearity parameter.
5. Calculations of the maximum temperature increase resulting from ultrasound exposure are not exact because of the uncertainties and approximations associated with the thermal, acoustic, and structural characteristics of the tissues involved. However, experimental evidence shows that calculations are generally capable of predicting measured values within a factor of 2. Thus, such calculations are used to obtain safety guidelines for clinical exposures in which direct temperature measurements are not feasible. These guidelines, called thermal indices,[a] provide a real-time display of the relative probability that a diagnostic system could induce thermal injury in the exposed subject. Under most clinically relevant conditions, the soft tissue thermal index (TIS) and the bone thermal index (TIB) either overestimate or closely approximate the best available estimate of the maximum temperature increase (ΔT_{max}). For example, if TIS = 2, then $\Delta T_{max} \leq 2$°C; actual temperature increases are also dependent on dwell time.

   However, in some applications, such as fetal examinations in which the ultrasound beam passes through a layer of relatively unattenuating liquid, such as urine or amniotic fluid, the TI can underestimate ΔT_{max} by up to a factor of 2.[27,28]

[a]The thermal indices are the nondimensional ratios of attenuated acoustic power at a specific point to the attenuated acoustic power required to raise the temperature at that point in a specific tissue model by 1°C.[29]

The effect of **preexisting cavitation nuclei** may be one of the principal controlling factors in mechanical effects that result in biologic effects. The body is such an excellent filter that these nucleation sites may be found only in small numbers and at selected sites. For example, if water is filtered down to 2 µm, the cavitation threshold doubles.[30] Theoretically, the tensile strength of water that is devoid of cavitation nuclei is about 100 megapascals (MPa).[31] Various models have been suggested to explain bubble formation in animals,[32,33] and these models have been used extensively in cavitation threshold determination. One model is used in the prediction of SCUBA diving tables and may also have applicability to patients.[34] It remains to be seen how well such models will predict the nucleation of bubbles from diagnostic ultrasound in the body.

Fig. 2.6 shows a 1-MHz therapeutic ultrasound unit generating bubbles in gas-saturated water. The particular medium and ultrasound parameters were chosen to optimize the conditions for cavitation. Using CW ultrasound and many preexisting gas pockets in the water set the stage for the production of cavitation. Even though these acoustic pulses are longer than those typically used in diagnostic ultrasound, cavitation effects have also been observed with diagnostic pulses in fluids.[35] **Ultrasound contrast agents** composed

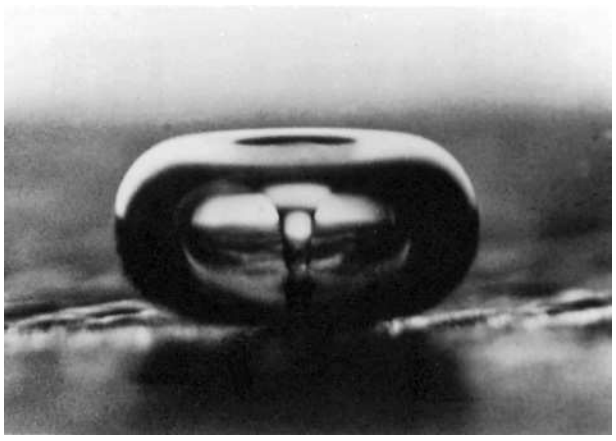

FIG. 2.8 Collapsing Bubble Near a Boundary. When cavitation is produced near boundaries, a liquid jet may form through the center of a bubble and strike the boundary surface. (Courtesy of Lawrence A. Crum.)

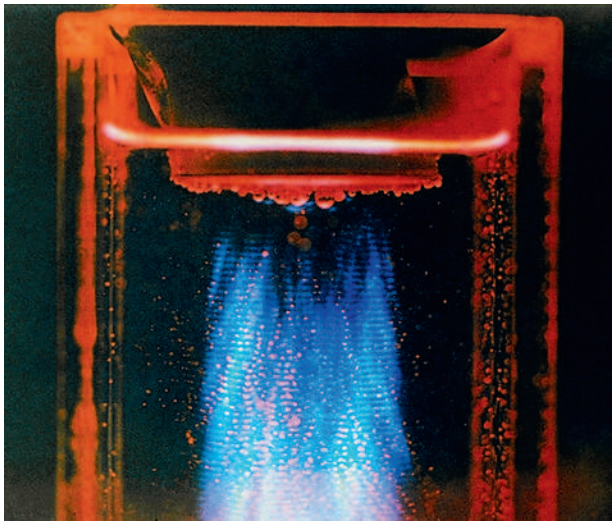

FIG. 2.7 Chemical Reaction Induced by Cavitation Producing Visible Light. The reaction is the result of free radical production. (Courtesy of National Center for Physical Acoustics, University of Mississippi.)

of stabilized gas bubbles should provide a source of cavitation nuclei, as discussed later in the section on ultrasound contrast agents.

Sonochemistry

Free radical generation and detection provide a means to observe cavitation and to gauge its strength and potential for damage. The sonochemistry of free radicals is the result of very high temperatures and pressures within the rapidly collapsing bubble. These conditions can even generate light, or **sonoluminescence.**[36] With the addition of the correct compounds, chemical luminescence can also be used for free radical detection and can be generated with short pulses similar to those used in diagnostic ultrasound.[37] Fig. 2.7 shows **chemiluminescence** generated by a therapeutic ultrasound device; the setup is backlighted (in red) to show the bubbles and experimental apparatus. The chemiluminescence emissions are the blue bands seen through the middle of the liquid sample holder. The light emitted is sufficient to be seen by simply adapting one's eyes to darkness. Electron spin resonance can also be used with molecules that trap free radicals to detect cavitation activity capable of free radical production.[38] A number of other chemical detection schemes are presently employed to detect cavitation from diagnostic devices *in vitro*.

Evidence of Cavitation From Lithotripters

It is possible to generate bubbles *in vivo* using short pulses with high amplitudes of extracorporeal shockwave lithotripsy (ESWL). The peak positive pressure for lithotripsy pulses can be as high as 50 MPa, with a rarefactional pressure of about 20 MPa. **Finite amplitude distortion** causes high frequencies to appear in high-amplitude ultrasound fields. Although ESWL pulses have significant energy at high frequencies because of finite amplitude distortion, a large portion of the energy is actually in the 100-kHz range, much lower than frequencies in diagnostic scanners. The lower frequency makes cavitation more likely. Aymé and Carstensen[39] showed that the higher frequency components in nonlinearly distorted pulses contributed little to the killing of *Drosophila* larvae.

Interestingly, evidence indicates that collapsing bubbles play a role in stone disruption.[40-42] A bubble collapsing near a surface may form a liquid jet through its center, which strikes the surface (Fig. 2.8). Placing a sheet of aluminum foil at the focus of a lithotripter generates small pinholes.[40] The impact is even sufficient to pit solid brass and aluminum plates.

At very high acoustic amplitudes, tissue can be disrupted and even emulsified using ultrasound in a process termed "histotripsy."[43-45] Peak rarefactional pressures used in this form of therapeutic ultrasound can be as high as 25 to

30 MPa, at which point gas bubbles form spontaneously in a very consistent controlled fashion that allows for therapeutic applications.

Clearly, lithotripsy and histotripsy differ greatly from diagnostic ultrasound in the acoustic power generated and are not comparable in the bioeffects produced. However, some diagnostic devices produce peak rarefactional pressures greater than 3 MPa, which is in the lower range of lithotripter outputs.[46-48] Lung damage and surface petechiae have been noted as side effects of ESWL in clinical cases.[49] Inertial cavitation was suspected as the cause, prompting several researchers to study the effects of diagnostic ultrasound exposure on the lung parenchyma.[50,51]

Bioeffects in Lung and Intestine

Lung tissue and intestinal tissue are key locations for examining for bioeffects of diagnostic ultrasound.[50] The presence of air in the alveolar spaces constitutes a significant source of gas bodies. Child and colleagues[51] measured threshold pressures for hemorrhage in mouse lung exposed to 1- to 4-MHz short-pulse diagnostic ultrasound (i.e., 10- and 1-μm pulse durations). The threshold of damage in murine lung at these frequencies was 1.4 MPa. Pathologic features of this damage included extravasation of blood cells into the alveolar spaces.[52] The authors hypothesized that cavitation, originating from gas-filled alveoli, was responsible for the damage. Their data provided the first direct evidence that clinically relevant, pulsed ultrasound exposures produce deleterious effects in mammalian tissue in the absence of significant heating. Hemorrhagic foci induced by 4-MHz pulsed Doppler ultrasound have also been reported in the monkey.[53] Damage in the monkey lung was of a significantly lesser degree than that in the mouse. In these studies it was impossible to show categorically that bubbles induced these effects because the cavitation-induced bubbles were not observed. Thresholds for petechial hemorrhage in the lung caused by ultrasound have been measured in mouse, rat, rabbit and pig.[54-56] Direct mechanical stresses associated with propagation of ultrasound in the lung were believed to contribute to the damage observed.[50,57] Thresholds for hemorrhage in the murine intestine exposed to pulsed ultrasound have also been determined.[58]

Kramer and colleagues[59] assessed cardiopulmonary function in rats exposed to pulsed ultrasound well above the acoustic output threshold of damage, at a mechanical index (MI) of 9.7. Measurements of cardiopulmonary function included arterial blood pressure, heart rate, respiratory rate, and arterial blood gases (Pco_2 and Po_2). If only one side of the rat lung was exposed, the cardiopulmonary measurements did not change significantly between baseline and postexposure values because of the functional respiratory reserve in the unexposed lobes. However, when both sides of the lung had significant ultrasound-induced lesions, the rats were unable to maintain systemic arterial pressure or resting levels of arterial Po_2.

Further studies are required to determine the relevance of these findings to humans. In general, tissues containing air (or stabilized gas) are more susceptible to damage than are tissues without gas. Also, no confirmed reports of petechial hemorrhage below an MI of 0.4 have been noted in animal studies. As recently as 2012, this threshold in lungs was confirmed in a small animal model.[60] However, it should be noted that the mechanism for pulmonary effects might not follow the functional frequency dependence embedded in the MI.[61]

Ultrasound Contrast Agents

The apparent absence of cavitation in many locations in the body can result from the lack of available cavitation nuclei. Based on evidence in the lung and intestine in mammalian models described earlier, the presence of gas bodies clearly reduces the requisite acoustic field for producing bioeffects. Many ultrasound contrast agents are composed of stabilized gas bubbles, so they could provide readily available nuclei for potential cavitation activity. This makes the investigation of bioeffects in the presence of ultrasound contrast agents an important area of research.[62-64] Studies have also shown that ultrasound exposure in the presence of contrast agents produces small vascular petechiae and endothelial damage in mammalian systems.[65-70] Acoustic emissions from activated microbubbles correlate with the degree of vascular damage.[67,68]

As a result, the AIUM has a safety statement on the bioeffects of diagnostic ultrasound with gas body contrast agents. This bioeffect may occur, but the issue remains whether it constitutes a significant physiologic risk. The safety statement is designed to make sonographers and physicians aware of the potential for bioeffects in the presence of gas contrast agents and allow them to make an informed decision based on a risk-versus-benefit assessment.

Some research also indicates the production of premature ventricular contractions (PVCs) during cardiac scanning in the presence of ultrasound contrast agents. At least one human study indicated an increase in PVCs only when ultrasound imaging was performed with a contrast agent, and not with ultrasound imaging alone or during injection of the agent without imaging.[71] Another study[72] revealed that oscillating microbubbles affect stretch activation channels[73,74] in cardiac cells, which generates membrane depolarization and triggers action potentials and thus PVCs. The importance of this bioeffect is also being debated because there is a naturally occurring rate of PVCs, and a small increase may not be considered clinically important, particularly if the patient benefits from using the agent. Additional consideration might be given to patients with specific conditions in whom additional PVCs should be avoided.

The consequences of the ultrasound contrast agent bioeffects reported thus far require more study. Although the potential exists for a bioeffect, its scale and influence on human physiology remain unclear. Contrast agents have demonstrated efficacy for specific indications, facilitating patient management.[75] In addition, clinical trials and marketing follow-up of many patients receiving ultrasound and contrast agents have reported few effects. Several publications provide evidence confirming the safety of ultrasound contrast agent use.[76-79]

The AIUM Statement on Mammalian Biological Effects in Tissues With Gas Body Contrast Agents

APPROVED MARCH 25, 2015

Presently available ultrasound contrast agents consist of suspensions of gas bodies (stabilized gaseous microbubbles). The gas bodies have the correct size for strong echogenicity with diagnostic ultrasound and also for passage through the microcirculation. Commercial agents undergo rigorous clinical testing for safety and efficacy before Food and Drug Administration approval is granted, and they have been in clinical use in the United States since 1994. Detailed information on the composition and use of these agents is included in the package inserts. In the United States, contrast agents have been approved for opacification of the left ventricular chamber and delineation of the left ventricular endocardial border. Outside the United States, additional approved indications include imaging lesions of the breast and liver, portal vein, and extracranial carotid and peripheral arteries. Many other diagnostic applications are under development or clinical testing.

Contrast agents carry some potential for nonthermal bioeffects when ultrasound interacts with the gas bodies. The mechanism for such effects is related to the physical phenomenon of acoustic cavitation. Several published reports describe adverse bioeffects in mammalian tissue *in vivo* resulting from exposure to diagnostic ultrasound with gas body contrast agents in the circulation. Induction of premature ventricular contractions by triggered contrast echocardiography in humans has been reported for a noncommercial agent and in laboratory animals for commercial agents. Microvascular leakage, killing of cardiomyocytes, and glomerular capillary hemorrhage, among other bioeffects, have been reported in animal studies. Two medical ultrasound societies have examined this potential risk of bioeffects in diagnostic ultrasound with contrast agents and provide extensive reviews of the topic: the World Federation for Ultrasound in Medicine and Biology Contrast Agent Safety Symposium[81] and the American Institute of Ultrasound in Medicine 2005 Bioeffects Consensus Conference.[62] More recently, the British Medical Ultrasound Society issued a detailed assessment of methods for the safe use of diagnostic ultrasound, including use of contrast agents.[82] Based on a review of these reports and recent literature, the Bioeffects Committee has issued the following statement.

STATEMENT ON MAMMALIAN BIOLOGICAL EFFECTS OF DIAGNOSTIC ULTRASOUND WITH GAS BODY CONTRAST AGENTS

Induction of premature ventricular contractions, microvascular leakage with petechiae, glomerular capillary hemorrhage, local cell killing, and other effects in mammalian tissue *in vivo* have been reported and independently confirmed for diagnostic ultrasound exposure with a mechanical index (MI) above about 0.4 and a gas body contrast agent present in the circulation.

Although the medical significance of such microscale bioeffects is uncertain, minimizing the potential for such effects represents prudent use of diagnostic ultrasound. In general, for imaging with contrast agents at an MI above 0.4, practitioners should use the minimal agent dose, MI, and examination time consistent with efficacious acquisition of diagnostic information. In addition, the echocardiogram should be monitored during high-MI contrast cardiac-gated perfusion echocardiography, particularly in patients with a history of myocardial infarction or unstable cardiovascular disease. Furthermore, physicians and sonographers should follow all guidance provided in the package inserts of these drugs, including precautions, warnings, and contraindications.

Considerations for Increasing Acoustic Output

Situations arise where increasing acoustic output in ultrasound imaging could provide improved performance, particularly at significant depths. The desire to increase acoustic output was the original impetus for the development of the FDA 510K Track 3 mechanism in situations in which imaging was challenging for deep tissue structures, particularly in obstetrics. Modes such as tissue harmonic imaging and elasticity and shear wave imaging may also benefit from similar considerations.

A working group of the Output Standards Subcommittee of the AIUM Technical Standards Committee examined on the potential benefits and risks of conditionally increased acoustic pressure. The resulting white paper[83] provides a rationale for a three-tiered approach for conditionally increased acoustic output that follows the model employed for elevated output in magnetic resonance imaging, and concludes with summary recommendations to facilitate clinical studies monitored by an institutional review board to investigate the benefits of an increased acoustic output in specific tissues. One of the fundamental assumptions in the MI calculation is the presence of a preexisting gas body. Based on theoretical predictions and experimentally reported cavitation thresholds for tissues that do not contain preexisting gas bodies, the working group found this assumption to be overly conservative and concluded that exceeding the recommended maximum MI given in the FDA guidance could be warranted without concern for increased risk of cavitation in these tissues. In the future, the ultrasound research community will need examine how much improvement in diagnostic ultrasound imaging might be achieved with increased acoustic output.

Mechanical Index

Calculations for cavitation prediction have yielded a trade-off between peak rarefactional pressure and frequency.[84] This

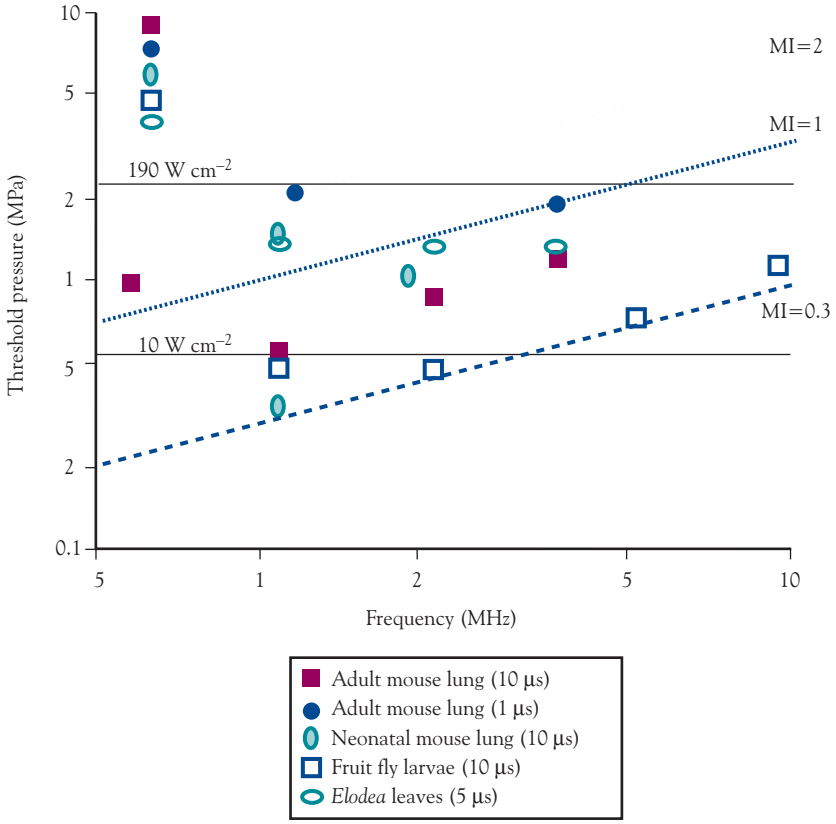

FIG. 2.9 Threshold for Bioeffects From Pulsed Ultrasound Scan Using Low Temporal Average Intensity. Data shown are the threshold for effects measured in peak rarefactional pressures (p^- in Fig. 2.1) as a function of ultrasound frequency used in the exposure. Pulse durations are shown in parentheses in the key below the graph. Also shown for reference purposes are the values for the mechanical index *(MI)* and the local spatial peak, pulse average intensity (I_{SPPA}). (With permission from American Institute of Ultrasound in Medicine. Consensus Report on Potential Bioeffects of Diagnostic Ultrasound. J Ultrasound Med. 2008;27:503-515.[22])

predicted trade-off assumes short-pulse (a few acoustic cycles) and low–duty cycle ultrasound (<1%). This relatively simple result can be used to gauge the potential for the onset of cavitation from diagnostic ultrasound. The MI was adopted by the FDA, AIUM, and NEMA as a real-time output display to estimate the potential for bubble formation *in vivo*, in analogy to the TI. As previously stated, the collapse temperature for inertial cavitation is very high. For MI, a collapse temperature of 5000 kelvins (K) was chosen based on the potential for free radical generation, and the frequency dependence of the pressure required to generate this thermal threshold takes a relatively simple form. The MI is a type of "mechanical energy index" because the square of the MI is about proportional to mechanical work that can be performed on a bubble in the acoustic rarefaction phase.

Results from several investigators have specified the MI value above which bioeffects associated with cavitation are observed in animals and insects.[22] In Fig. 2.9 the dotted lines are calculations for several MI values; all the effects appear to occur at an MI value of 0.3 or greater. In many of these cases, however, stable pockets of gas (gas bodies) are known to exist in the exposed tissues. Also, other body areas containing gas bodies might be particularly susceptible to ultrasound damage, including the intestinal lining.[85]

In response to this potential, the AIUM issued a safety statement related to the potential for bioeffects related to the interaction of ultrasound with naturally occurring nuclei.[86] Experimentation continues, and it remains to be seen if such damage occurs in human tissue.

Inherent in the formulation of the MI are the conditions only for the onset of inertial cavitation. The degree to which the threshold is exceeded, however, relates to the degree of potential bubble activity, which may correlate with the probability of a bioeffect. Note that, given present knowledge, exceeding the cavitation threshold does not mean there will be a bioeffect. Below an MI of about 0.4, the physical conditions do not favor bubble growth, even in the presence of a broad bubble nuclei distribution in the body, which is in reasonable agreement with the results of Fig. 2.9. Moreover, whereas the TI is a time-averaged measure of the interaction of ultrasound with tissue, the MI is a peak measure of this interaction. Thus there is a desirable parallel between these two measures, one thermal and one mechanical, for informing the user of the extent to which the diagnostic tool can produce undesirable changes in the body.

Summary Statement on Gas Body Bioeffects

The AIUM statements concerning bioeffects in body areas with gas bodies include several conclusions, summarized as follows[86]:

1. Current ultrasound systems can produce cavitation *in vitro* and *in vivo* and can cause blood extravasation in animal tissues.
2. The MI can gauge the likelihood for cavitation and apparently works better than other field parameters in predicting cavitation.
3. Several interesting results have been observed concerning animal models for lung damage, which indicate a potential very low threshold for damage, but the implications for human exposure have not yet been determined.
4. In the absence of gas bodies, the threshold for damage is much higher. (This is significant because ultrasound examinations may be performed predominantly in tissues with no identifiable gas bodies.)

The AIUM Statement on Mammalian Biological Effects in Tissues With Naturally Occurring Gas Bodies

APPROVED MARCH 25, 2015

Biologically significant adverse nonthermal effects have been identified in tissues containing stable bodies of gas for diagnostically relevant exposure conditions. Gas bodies occur naturally in postnatal lungs and in the folds of the intestinal mucosa. This statement concerns naturally occurring gas bodies encountered in pulmonary and abdominal ultrasound, whereas a separate statement deals with the use of gas body contrast agents.

1. The outputs of some currently available diagnostic ultrasound devices can generate levels that produce capillary hemorrhage in the lungs[60] and intestines[50] of laboratory animals.
2. Thresholds for adverse nonthermal effects associated with naturally occurring gas bodies depend on tissue characteristics and the physiologic status, including anesthesia,[87] and on physical ultrasound parameters, including attenuation by intervening tissue, exposure duration, ultrasonic output, frequency, pulse duration, and pulse repetition frequency.[50]
3. A mechanical index (MI)[a] has been formulated to assist users in evaluating the likelihood of mechanical (nonthermal) adverse biological effects for diagnostically relevant exposures, and its value is displayed on screen in accordance with output display specifications.
4. The minimum threshold value of the experimental MI (the in situ value of the peak rarefactional pressure amplitude divided by the square root of the frequency) for pulmonary capillary hemorrhage in laboratory mammals is approximately 0.4. The corresponding threshold for the intestine is MI = 1.4.
5. The implications of these observations for human exposure during thoracic or abdominal ultrasound examinations are yet to be determined.

[a]The MI is equal to the derated peak rarefactional pressure (in megapascals) at the point of the maximum derated pulse intensity integral divided by the square root of the ultrasonic center frequency (in megahertz).[12]

OUTPUT DISPLAY STANDARD

Several groups, including the FDA, AIUM, and NEMA, have developed the Standard for Real-Time Display of Thermal and Mechanical Acoustical Output Indices on Diagnostic Ultrasound Equipment, which introduces a method to provide the user with information concerning the thermal and mechanical indices. Real-time display of the MI and TI will allow a more informed decision on the potential for bioeffects during ultrasound examinations (Fig. 2.10). The standard requires dynamic updates of the indices as instrument output is modified and allows the operator to learn how controls will affect these indices. Important points to remember about this display standard include the following:

- The MI should be clearly visible on the screen (or the operator should be alerted by some other means) and should begin to appear when the instrument exceeds a value of 0.4. An exception is made for instruments incapable of exceeding index values of 1; these are not required to display the bioeffects indices such as MI.
- When the indices are required to be displayed, both indices are to be displayed at all times.
- The standard also requires that appropriate default output settings be in effect at power-up, at new patient entry, or when changing to a fetal examination. After that time the operator can adjust the instrument output as necessary to acquire clinically useful information while attempting to minimize the index values.
- As indicated previously, the bioeffects indices do not include any factors associated with the time taken to perform the scan. Efficient scanning is still an important component in limiting potential bioeffects.

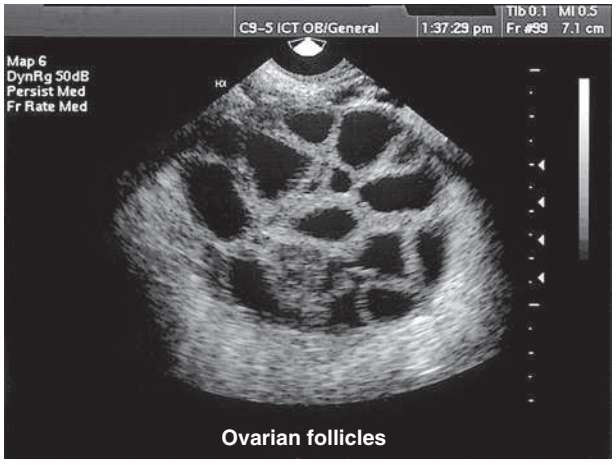

FIG. 2.10 Display of Bioeffects Indices. Typical appearance of an ultrasound scanner display showing *(right upper corner)* the thermal index in the Bone Thermal Index *(TIB)* and mechanical index *(MI)* for an endocavitary transducer.

The AIUM Safety Statements on Diagnostic Ultrasound

THE AIUM PRUDENT USE AND CLINICAL SAFETY STATEMENT[89]

Approved April 1, 2012

Diagnostic ultrasound has been in use since the late 1950s. Given its known benefits and recognized efficacy for medical diagnosis, including use during human pregnancy, the AIUM herein addresses the clinical safety of such use: No independently confirmed adverse effects caused by exposure from present diagnostic ultrasound instruments have been reported in human patients in the absence of contrast agents. Biological effects (such as localized pulmonary bleeding) have been reported in mammalian systems at diagnostically relevant exposures but the clinical significance of such effects is not yet known. Ultrasound should be used by qualified health professionals to provide medical benefit to the patient. Ultrasound exposures during examinations should be as low as reasonably achievable (ALARA).

THE AIUM PRUDENT USE IN PREGNANCY STATEMENT[90]

Approved April 1, 2012

The AIUM advocates the responsible use of diagnostic ultrasound and strongly discourages the nonmedical use of ultrasound for entertainment purposes. The use of ultrasound without a medical indication to view the fetus, obtain images of the fetus, or determine the fetal gender is inappropriate and contrary to responsible medical practice. Ultrasound should be used by qualified health professionals to provide medical benefit to the patient.

THE AIUM SAFETY IN TRAINING AND RESEARCH STATEMENT[91]

Approved April 1, 2012

Diagnostic ultrasound has been in use since the late 1950s. There are no confirmed adverse biological effects on patients resulting from this usage. Although no hazard has been identified that would preclude the prudent and conservative use of diagnostic ultrasound in education and research, experience from normal diagnostic practice may or may not be relevant to extended exposure times and altered exposure conditions. It is therefore considered appropriate to make the following recommendation: When examinations are carried out for purposes of training or research, ultrasound exposures should be as low as reasonably achievable (ALARA) within the goals of the study/training. In addition, the subject should be informed of the anticipated exposure conditions and how these compare with normal diagnostic practice. Repetitive and prolonged exposures on a single subject should be justified and consistent with prudent and conservative use.

Reproduced with permission from American Institute of Ultrasound in Medicine (AIUM). Prudent use and clinical safety. Laurel, MD: AIUM; 2012. Available from: http://www.aium.org/officialStatements/34. Approved April 1, 2012. Cited October 7, 2016[89]; American Institute of Ultrasound in Medicine (AIUM). Prudent use in pregnancy. Laurel, MD: AIUM; 2012. Available from: http://www.aium.org/officialStatements/33. Approved April 1, 2012. Cited October 7, 2016[90]; and American Institute of Ultrasound in Medicine (AIUM). Safety in training and research. Laurel, MD: AIUM; 2012. Available from: http://www.aium.org/officialStatements/36. Approved April 1, 2012. Cited October 7, 2016.[91]

In the document Medical Ultrasound Safety,[88] the AIUM suggests that the operator ask the following four questions to use the output display effectively:

1. Which index should be used for the examination being performed?
2. Are there factors present that might cause the reading to be too high or low?
3. Can the index value be reduced further even when it is already low?
4. How can the ultrasound exposure be minimized without compromising the scan's diagnostic quality?

Sonographers and physicians are being presented with real-time data on acoustic output of diagnostic scanners and are being asked not only to understand the manner in which ultrasound propagates through and interacts with tissue, but also to gauge the potential for adverse bioeffects. The output display is a tool that can be used to guide an ultrasound examination and control for potential adverse effects. The thermal and mechanical indices provide the user with more information and more responsibility in limiting output.

GENERAL AIUM SAFETY STATEMENTS

It is important to consider some official positions concerning the status of bioeffects resulting from ultrasound. Most important is the high level of confidence in the safety of ultrasound in official statements. For example, in 2012 the AIUM reiterated its earlier statement concerning the clinical use of diagnostic ultrasound, which indicated that no independently confirmed adverse effects are caused by exposure from current diagnostic equipment, and the patient benefits from prudent use outweigh the risks, if any. The AIUM also strongly discourages the nonmedical use of ultrasound during pregnancy for entertainment purposes. In commenting on the use of diagnostic ultrasound in research, the AIUM recommends that in the case of ultrasound exposure for other than direct medical benefit, the person should be informed concerning the exposure conditions and how these relate to normal exposures. For the most part, even examinations for research purposes are comparable to normal diagnostic examinations and pose no additional risk. Many research examinations can be performed in conjunction with routine examinations.

The effects based on *in vivo* animal models can be summarized by the AIUM statements on mammalian biological effects of heat,[24] in tissues with gas body contrast agents,[80] and in tissues with naturally occurring gas bodies.[86] No independently confirmed experimental evidence indicates damage in animal models below certain prescribed levels (temperature rises <2°C; MI < 0.4). The value for the MI is strict because tissues containing gas bodies exhibit damage at much lower levels than tissues devoid of gas bodies. Biologic effects have not been detected even at an MI of 4.0 in the absence of gas bodies.

EPIDEMIOLOGY

With all the potential causes for bioeffects, we must now examine the epidemiologic evidence that has been used in part to justify the apparent safety of ultrasound. In 1988 Ziskin and Petitti[92] reviewed the epidemiologic studies conducted until then and concluded, "Epidemiologic studies and surveys in widespread clinical usage over 25 years have yielded no evidence of any adverse effect from diagnostic ultrasound." However, a 2008 review[93] of the epidemiology literature conducted by an AIUM subcommittee resulted in a revised AIUM statement regarding the epidemiology of diagnostic ultrasound safety in obstetrics.[94] The earlier statements indicated that no confirmed effects associated with ultrasound exposure existed at that time. However, the distinction being made in the current AIUM statement is that although some effects may have been detected now, one cannot justify a conclusion of a causal relationship based on this evidence.

Epidemiologic studies are difficult to conduct, and data analysis and interpretation of results can be even more difficult. Several epidemiologic studies of fetal exposure to ultrasound have claimed to detect certain bioeffects and have also been criticized. Only one indication of an unspecified effect was reported in a general survey involving an estimated 1.2 million examinations in Canada.[95] However, this is an extremely low incidence, with no follow-up to determine the nature of the effect. In addition, an earlier study that included 121,000 fetal examinations reported no effect.[96] Moore and colleagues[97] reported an increased incidence of low birth weight, whereas Stark and colleagues[98] examined the same data using a different statistical treatment and found no significant increase. Scheidt and colleagues[99] noted abnormal grasp and tonic neck reflexes. These results are difficult to interpret, however, given the statistical treatment of the data. Stark and colleagues[98] detected an increased incidence of dyslexia, but the same children exhibited below-average birth weights. General problems also plague the epidemiologic studies, including the lack of clearly stated exposure conditions and gestational age, problems in statistical sampling (with both positive and negative results), and use of older scanning systems, particularly with fetal Doppler ultrasound. Dyslexia was examined as part of two randomized trials, including specific long-term follow-up that showed no statistical difference between ultrasound-exposed and control subjects.[100,101]

Ziskin and Petitti[92] also summarized the factors in evaluating epidemiologic evidence. It is important to recognize that epidemiologic evidence can be used to identify an association between exposures and biologic effects, but that this does not prove the exposure caused the bioeffect. The strength of the association is established by the statistical significance of the relationship. Hill[102] and Abramowicz and colleagues[93] have developed the following seven criteria for judging **causality:**

1. Strength of the association
2. Consistency in reproducibility and with previous, related research
3. Specificity to a particular bioeffect or exposure site
4. Classic time relationship of cause followed by effect
5. Existence of a dose response
6. Plausibility of the effect
7. Supporting evidence from laboratory studies

When considering these factors, no clear causal relationship seems to exist between an adverse biologic response and ultrasound exposure of a diagnostic nature.

Newnham and colleagues[103] reported higher intrauterine growth restriction during a study designed to determine the efficacy of ultrasound in reducing the number of neonatal days and prematurity rate. Therefore the study was not designed to detect an adverse bioeffect, but a statistically significant effect was observed as a result of subsequent data analysis. Several other deficiencies in methodology are evident in the selection and exposure of the experimental groups, but in general, some association might be inferred from the results of this well-conducted, randomized clinical trial. In a case-control study, Campbell and colleagues[104] reported a statistically significant higher rate of delayed speech in children who were insonified in utero. Evidence of association is not as strong in case-control studies as in prospective studies, and measures of delayed speech are difficult. Subsequently, Salvesen and colleagues[105] found no significant differences in delayed speech, limited vocabulary, or stuttering in a study of 1107 children exposed in utero and 1033 controls.

CONTROLLING ULTRASOUND OUTPUT

The most important issue regarding potential bioeffects involves actions the physician or sonographer can take to minimize these effects. It is essential that operators understand the risks involved in the process, but without some ability to control the output of the ultrasound system, this knowledge has limited use. Some specific methods can be used to limit ultrasound exposure while maintaining diagnostically relevant images.

Controls for the ultrasound system can be divided into direct controls and indirect controls (Table 2.2). The **direct controls** are the application types and output intensity. **Application types** are those broad system controls that allow convenient selection of a particular examination type. These often come in the form of icons that are selected by the user. These default settings help minimize the time required to optimize the imaging parameters for the myriad applications for diagnostic ultrasound. These settings should be used only as indicated (e.g., do not use the cardiac settings for a fetal examination). **Output intensity** (also called "power," "output," or "transmit") controls the overall ultrasonic power emitted by the transducer. This control will generally affect the intensity at all points in the image to varying degrees, depending on the focusing. The lowest output intensity that produces a good image should be used, to minimize the exposure intensity. Focusing of the system is controlled by the operator and can be used to improve image quality while limiting required acoustic intensity. Focusing at the correct depth can improve the image without requiring increased intensity.

The many **indirect controls** greatly affect the ultrasound exposure by dictating how the ultrasonic energy is distributed temporally and spatially. By choosing the mode of ultrasound used (e.g., B-mode, pulsed Doppler, color Doppler), the operator

TABLE 2.2 Optimum Ultrasound Output: Lowest Power Output That Creates Good Images

DIRECT CONTROLS	
Application type	Examples: fetal, cardiac
Output intensity	Power, output, transmit
Focusing	Allows increasing output intensity only at the focal zone
INDIRECT CONTROLS	
Ultrasound mode	
Unscanned modes (deposits heat in one area)	Continuous wave Doppler, spectral or pulsed Doppler, M-mode
Scanned modes	B-mode or gray-scale, color flow Doppler, power mode Doppler
Pulse repetition frequency	Increases bursts of energy per time Usually controlled by changing the maximum imaging depth in B-mode or the velocity range in Doppler modes
Pulse length	Increasing sample volume in Doppler studies
Appropriate transducer	High frequency: requires more output for depth Lower frequency: less output needed at depth
Gain controls	Time gain compensation (TGC) can improve image without more output Receiver gain increases echo amplitudes without more output

The AIUM Statement on Keepsake Fetal Imaging[107]

APPROVED APRIL 1, 2012

The AIUM advocates the responsible use of diagnostic ultrasound for all fetal imaging. The AIUM understands the growing pressures from patients for the performance of ultrasound examinations for bonding and reassurance purposes, largely driven by the improving image quality of 3-D sonography and by more widely available information about these advances. Although there is only preliminary scientific evidence that 3-D sonography has a positive impact on parental-fetal bonding, the AIUM recognizes that many parents may pursue scanning for this purpose.

Such "keepsake imaging" currently occurs in a variety of settings, including the following:

1. Images or video clips given to parents during the course of a medically indicated ultrasound examination.
2. Freestanding commercial fetal imaging sites, usually without any physician review of acquired images and with no regulation of the training of the individuals obtaining the images; these images are sometimes called "entertainment videos."
3. As added-cost visits to a medical facility (office or hospital) outside the coverage of contractual arrangements between the provider and the patient's insurance carrier.

The AIUM recommends that appropriately trained and credentialed medical professionals (licensed physicians, registered sonographers, or sonography registry candidates) who have received specialized training in fetal imaging perform all fetal ultrasound scans. These individuals have been trained to recognize medically important conditions, such as congenital anomalies, artifacts associated with ultrasound scanning that may mimic pathology, and techniques to avoid ultrasound exposure beyond what is considered safe for the fetus. Any other use of "limited medical ultrasound" may constitute practice of medicine without a license. The AIUM reemphasizes that all imaging requires proper documentation and a final report for the patient medical record signed by a physician.

Although the general use of ultrasound for medical diagnosis is considered safe, ultrasound energy has the potential to produce biological effects. Ultrasound bioeffects may result from scanning for a prolonged period, inappropriate use of color or pulsed Doppler ultrasound without a medical indication, or excessive thermal or mechanical index settings. The AIUM encourages patients to make sure that practitioners using ultrasound have received specific training in fetal imaging to ensure the best possible results.

The AIUM also believes that added cost arrangements other than those of providing patients images or copies of their medical records at cost may violate the principles of medical ethics of the American Medical Association[108-110] and the American College of Obstetricians and Gynecologists.[111] The AIUM therefore reaffirms the Prudent Use in Pregnancy Statement[90] and recommends that only scenario 1 above is consistent with the ethical principles of our professional organizations.

The market for keepsake images is driven in part by past medical approaches that have used medicolegal concerns as a reason not to provide images to patients. Sharing images with patients is unlikely to have a detrimental medicolegal impact. Although these concerns need further analysis and evaluation, we encourage sharing images with patients as appropriate when indicated obstetric ultrasound examinations are performed.[90]

controls whether the beam is scanned. Unscanned modes deposit energy along a single path and increase the potential for heating. The **pulse repetition frequency** (PRF) indicates how often the transducer is excited. Increasing the number of ultrasound bursts per second will increase the temporal average intensity. PRF is usually controlled by changing the maximum image depth in B-mode or the velocity range in Doppler modes. **Burst length** (also called "pulse length" or "pulse duration") controls the duration of on-time for each ultrasonic burst transmitted. Increasing the burst length while maintaining the same PRF will increase the temporal average intensity. The control of burst length may not be obvious. For example, in spectral Doppler ultrasound, increasing the Doppler sample volume length will increase the burst length.

The selection of the **appropriate transducer** will also limit the need for high acoustic power. Even though higher frequencies provide better spatial resolution, the attenuation of tissue increases with increasing ultrasound frequency, so penetration may be lost. Perhaps most important are the **receiver gain controls.** The receiver gain control has no effect on the amplitude of the acoustic output. Therefore before turning up the acoustic output intensity, try increasing receiver gain first. It should be noted that some system controls actually interact with the acoustic output intensity without direct control. Check to see whether the manufacturer provides separate controls for receiver gain, **time gain compensation** (TGC), and acoustic output intensity. The TGC can improve image quality without increasing the output.

There is really no substitute for a well-instructed operator. The indices and requirements of output display standards will help only those willing to use and understand them. Real-time display of the mechanical and thermal indices on diagnostic scanners will help clinicians evaluate and minimize potential risks in the use of such instrumentation. Physicians and sonographers are encouraged to learn more about how to minimize potential bioeffects.

ULTRASOUND ENTERTAINMENT VIDEOS

Of concern is the growing use of diagnostic ultrasound for the nonmedical scanning of pregnant women to provide a fetal "keepsake" video. Unfortunately, entertainment ultrasound is promoted most vigorously in the second and third trimesters, when bone calcification can increase thermal effects. Also, women with the economic means to schedule multiple ultrasound imaging sessions may be exposing both themselves and their fetuses to even greater risk if ultrasound bioeffects are shown to be additive, or just by increasing the chances for a bioeffect. If there is no clinical benefit in such entertainment ultrasound, the benefit-to-risk ratio is clearly zero. In addition, because often the ultrasound equipment used is identical to diagnostic equipment used by clinicians, the consumer may be unaware that no medical information is being generated, interpreted, or referred to her obstetrician. (It is recognized that release forms are signed to the contrary.) The FDA[106] views this as an unapproved use of a medical device and refers users to the AIUM statement regarding keepsake videos.

CHAPTER 3

Contrast Agents for Ultrasound

Peter N. Burns

SUMMARY OF KEY POINTS

- After more than 20 years of development and a somewhat hesitant start, microbubbles have finally come of age as a contrast agent for ultrasound.
- The principal requirements for an ultrasound contrast agent are that it should be easily introducible into the vascular system, be stable for the duration of the diagnostic examination, have low toxicity, and modify one or more acoustic properties of tissues that can be detected by ultrasound imaging.
- Microbubble contrast agents for ultrasound are safe, effective, and well tolerated by patients.
- Contrast-specific modes with microbubbles show real-time perfusion in organ and tumor parenchyma. The mechanical index (MI) of the transmitted pulse is the major determinant of the response of contrast bubbles to ultrasound; continuous perfusion imaging is possible only with use of low MI, which does not disrupt the bubbles.
- Future developments offer the intriguing prospects of molecular and cellular imaging, potentiated therapy, and drug and gene delivery, all with ultrasound and microbubbles.

CONCLUSION

After more than 20 years of development and a somewhat hesitant start, microbubbles have finally come of age as a contrast agent for ultrasound. In 2016 the United States was finally added to the more than 50 countries worldwide that have approved them for radiologic indications, with the Food and Drug Administration (FDA) announcing approval for their use for liver diagnosis in adults and children. Their exploitation has already opened many new areas for diagnostic ultrasound imaging and is becoming a central area for technologic advances of the modality. The bubbles themselves comprise small spheres of a gas with low solubility in blood—such as a perfluorocarbon—stabilized by a thin shell layer of a flexible, biocompatible material which is typically a lipid, although proteins and polymers are also used. The diameter of the resulting encapsulated bubble is about 3 to 5 μm, slightly smaller than a red blood cell (Fig. 3.1). Because of this size, bubbles provide a pure intravascular contrast agent (Fig. 3.2). A suspension of bubbles in water is injected into a peripheral vein in the arm or hand; a typical whole-body human dose ranges from 0.2 to 2 mL in volume and contains on the order of 10 million bubbles, roughly comparable to the number of red blood cells in a single milliliter of blood. The effect of a bolus injection is to increase the echo from blood by a factor of 500 to 1000. After about 5 minutes the gas from the bubbles has diffused into the blood and the very small mass of shell material is metabolized. By infusing the bubbles through a saline drip, a steady enhancement lasting up to 20 minutes can also be obtained.[1] Microbubble contrast agents make possible for the first time ultrasound imaging of organ and lesion perfusion

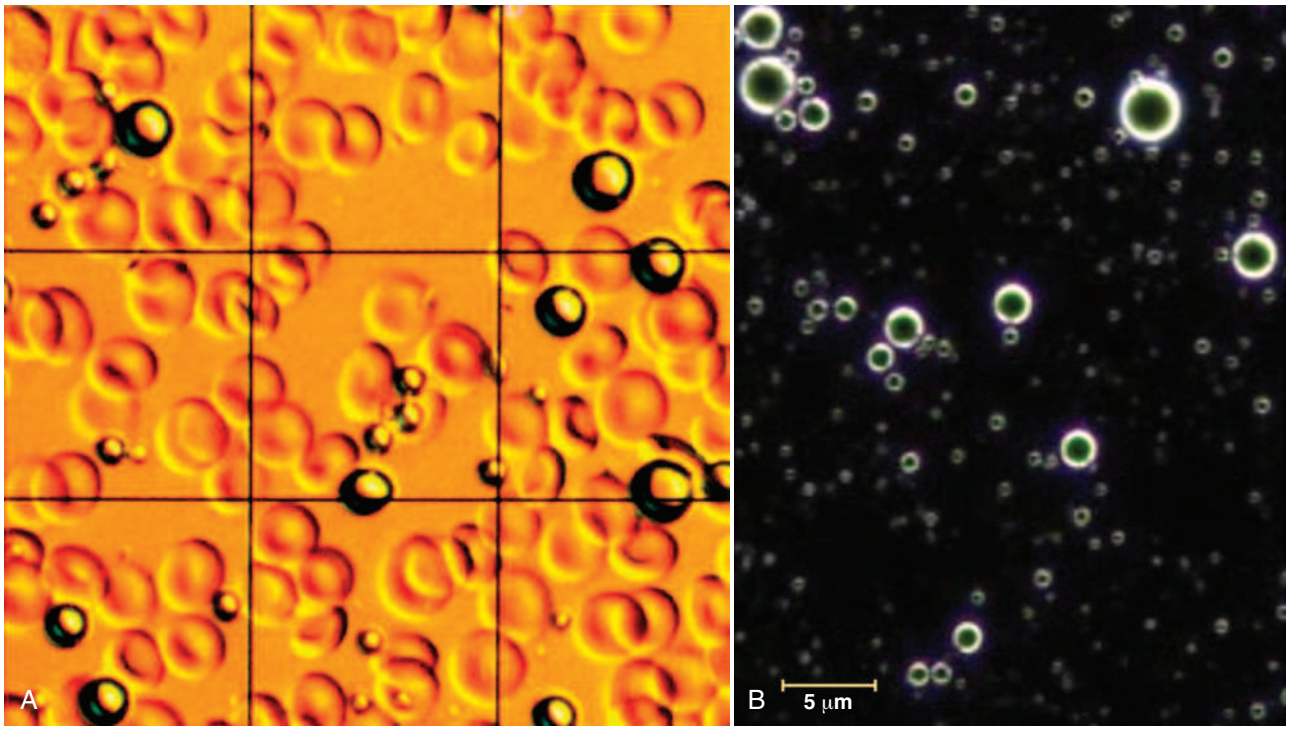

FIG. 3.1 Contrast Agents for Ultrasound. (A) Perfluoropropane bubbles with a protein shell (Optison, GE Healthcare, Milwaukee, WI), shown here against a background of red blood cells. **(B)** Lipid-coated microbubbles of perfluoropropane gas (Definity, Lantheus Medical Imaging, North Billerica, MA) are shown under a dark-field microscope.

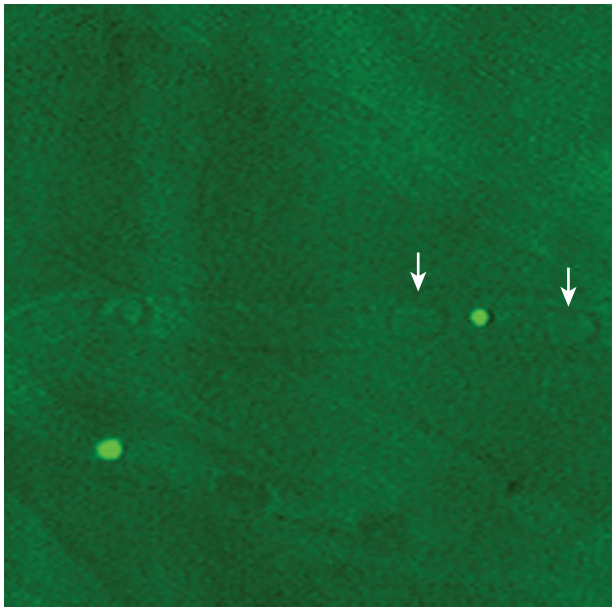

FIG. 3.2 Bubbles Are Relatively Large as Contrast Agents and Remain Within the Blood Pool. in real time. This chapter aims to provide both a tutorial and a reference for the practical use of contrast agents for these indications.

REQUIREMENTS AND TYPES

The principal requirements for an ultrasound contrast agent are that it should be easily introducible into the vascular system, be stable for the duration of the diagnostic examination, have low toxicity, and modify one or more acoustic properties of tissues that can be detected by ultrasound imaging. Although it is conceivable that applications will be found for ultrasound contrast agents that will justify their injection into arteries, the clinical context for contrast ultrasonography requires that these agents be capable of intravenous administration and intact passage through the heart and lungs. These are demanding specifications that have been met only in the past decade. The technology universally adopted is that of encapsulated bubbles of gas that are smaller than red blood cells and therefore capable of circulating freely in the pulmonary and systemic vasculature.

Contrast agents act by their presence in the vascular system, from where they are ultimately metabolized ("blood pool" agents), or by their selective uptake in tissue after a vascular phase. Of the properties of tissue that influence the ultrasound image, the most important are linear and nonlinear backscatter coefficient, attenuation, and acoustic propagation velocity.[2] Most agents enhance the echo by increasing as much as possible the backscatter of the tissue that bears them, while increasing the attenuation

in the tissue as little as possible, thus enhancing the echo from blood. More important, they change the nature of the echo from blood in a way that allows them to be imaged selectively in real time.

Blood Pool Agents

Free Gas Bubbles

Gramiak and Shah first used bubbles to enhance the blood echo in 1968.[3] They injected agitated saline into the left ventricle during an echocardiographic examination and saw strong echoes within the lumen of the aorta. It was subsequently shown that these echoes originated from free bubbles of air that came out of solution either during agitation or at the catheter tip during injection.[4] Agitated solutions of compounds such as indocyanine green and Renografin—already approved for intraarterial injection—were also used. The application of free gas as a contrast agent was confined to the heart, including evaluation of valvular insufficiency,[5] intracardiac shunts,[6] and cavity dimensions.[7] The fundamental limitation of bubbles produced in this way is that they are large, so they are effectively filtered by the lungs, and unstable, so they go back into solution on the order of a second. Apart from occasional use in the echocardiography laboratory to identify shunts, free bubbles are rarely used as a contrast agent today.

Encapsulated Air Bubbles

To overcome the natural instability of free gas bubbles, various shell coatings were developed to create a more stable particle (Table 3.1). In 1980 Carroll and colleagues[8] encapsulated nitrogen bubbles in gelatin and injected them into the femoral artery of rabbits with VX2 tumors in the thigh. Although echo enhancement of the tumor rim was identified, the large diameter of the coated bubbles (80 μm) precluded administration by an intravenous route. The challenge to produce a stable encapsulated microbubble of a comparable size to that of a red blood cell and that could survive passage through the heart and the pulmonary capillary network was first met by Feinstein and colleagues in 1984,[9] who produced microbubbles by sonication of a solution of human serum albumin and showed that it could be detected in the left side of the heart after a peripheral venous injection. This agent was subsequently developed commercially as Albunex (Mallinckrodt Medical, Inc., St. Louis, MO).

Another approach to stabilizing an air bubble is to add a lipid shell upon dissolution of a dry powder. Levovist (Schering AG, Berlin, Germany), is a dry mixture comprising 99.9% microcrystalline galactose microparticles and 0.1% palmitic acid. On dissolving in sterile water, the galactose disaggregates into microparticles, which provide an irregular surface for the adherence of microbubbles 3 to 4 μm in size. Stabilization of the microbubbles takes place as they become coated with palmitic acid, which separates the gas/liquid interface and slows their dissolution.[18] The resulting microbubbles have a median bubble diameter of about 3 μm with the 97th percentile at approximately 6 μm and are sufficiently stable for transit through the pulmonary circuit. The agent is chemically related to its predecessor Echovist (Schering), a galactose agent that forms larger bubbles and that has been used principally for visualization of nonvascular ductal structures such as the fallopian tubes.[19,20] Numerous early

TABLE 3.1 Regulatory and Marketing Status of Some Current Ultrasound Contrast Agents as of 2016

Name	Company/ Developer	Composition (Shell/Gas)	REGULATORY/MARKETING STATUS	
			Cardiology Indications	Radiology Indications
Definity	Lantheus Medical Imaging[10]	Lipid/perfluoropropane	Approved in United States, Canada	Approved in Canada, China, Australasia, Americas
SonoVue Lumason	Bracco[11]	Phospholipid/sulfur hexafluoride	Approved in European Union, Canada	Approved in 40 countries, including European Union, Canada, China, United States
Optison	GE Healthcare[12]	Sonicated albumin/ octafluoropropane	Approved in European Union, United States, Canada	Suspended development
Sonazoid	GE Healthcare and Daiichi Sankyo[13]	Lipid perfluorobutane	Clinical development	Approved in Japan, Korea, Norway Clinical development in European Union, United States

BR55	Bracco[17]	Lipopeptide VEGFR-2–targeted/perfluorocarbon		Clinical development

VEGFR, Vascular endothelial growth factor receptor.

studies with Levovist[21,22] demonstrated its capacity to traverse the pulmonary bed in sufficient concentrations to enhance both color and spectral Doppler signals, as well as gray-scale examinations using nonlinear imaging modes such as pulse inversion imaging. Levovist remains approved for use in the European Union, Canada, Japan, and numerous other countries, although not the United States. Many clinical applications of intravenous contrast were pioneered using Levovist, which has now given way to the so-called "second-generation" agents and is no longer marketed.

Second-Generation Agents

Second-generation agents were designed both to increase backscatter enhancement and to last longer in the bloodstream by taking advantage of low-solubility gases such as perfluorocarbons. These heavier gases diffuse more slowly through the bubble shell and have much lower solubility in blood. Optison (GE Healthcare, Milwaukee, WI) (see Fig. 3.1A) is a perfluoropropane-filled albumin shell with a size distribution similar to that of its predecessor, Albunex. It is currently approved for cardiology indications in the European Union, the United States, and Canada. SonoVue (Bracco, Milan, Italy) uses sulfur hexafluoride in a phospholipid shell and is available for cardiology and radiology indications in the European Union, China, and a number of other countries; it is approved in the United States under the name Lumason. Definity (Lantheus Medical Imaging, North Billerica, MA) (see Fig. 3.1B) comprises a perfluoropropane microbubble coated with a flexible bilipid shell, which also showed improved stability and high enhancement at low doses.[23] It is currently approved for cardiology and radiology indications in Canada, Australasia, and a number of Central and South American countries, and for cardiology indications in the United States. Finally, Sonazoid (Daiichi Sankyo, Tokyo, Japan and GE Healthcare, Milwaukee, WI) consists of a perfluorobutane bubble in a lipid shell[24] and is currently approved for radiology indications in countries such as Japan and Korea. It should be noted that although these bubbles are very small, they are large when compared with the molecules and particles used as contrast agents for computed tomography (CT) and magnetic resonance imaging (MRI), which diffuse through the fenestrated endothelium of blood vessels into the interstitium. Thus x-ray and magnetic resonance contrast-enhanced images frequently show an "interstitial" or "parenchymal" phase of enhancement, which may be used to identify hyperpermeable vascular structures, such as those involved with tumor angiogenesis.[25] Microbubbles, on the other hand, are of a size comparable to that of a red blood cell, so they go where a red blood cell goes (see Fig. 3.2) and, more important, do not go where a red blood cell does not go. They are clinical radiology's first pure blood pool contrast agent.

Selective Uptake Agents

An ideal blood pool agent displays the same flow dynamics as blood itself, and is ultimately metabolized from the blood pool. Agents such as Definity, SonoVue, and Optison are generally not detected outside the vascular system, and therefore come close to this ideal. Contrast preparations can be made, however, that are capable of providing ultrasound enhancement during their metabolism as well as while in the blood pool. Colloidal suspensions of liquids droplets such as perfluoroctylbromide[26] and microbubble agents with certain shell properties[24,27,28] are taken up by the reticuloendothelial system, from where they ultimately are excreted. There they may provide contrast from within the liver parenchyma, demarking the distribution of Kupffer cells.[29] Agents such as Levovist and Sonazoid provide "late-phase" enhancement in the parenchyma of the liver and spleen after having cleared from the vascular system,[30] allowing detection of Kupffer cell–poor lesions such as cancers.[31,32]

A typical dose of an ultrasound contrast agent is on the order of 10s of microliters of bubble suspension per kilogram of body weight, so a whole-body dose might be on the order of 0.1 to 1 mL. Fig. 3.3 shows the enhancement of the echo from systemic arterial blood after a peripheral venous injection of a second-generation agent. A first-pass peak occurs, followed by recirculation and washout as the agent is eliminated over the next few minutes. By infusing the bubbles through a saline drip or pump, a steady enhancement lasting up to 20 minutes can be obtained.[1] The small amount of perfluorocarbon gas goes into solution in the blood and is ultimately excreted by the lungs and liver. The trace amount of shell material is reduced to biocompatible elements that, in the case of the commonly used agents, are already present in the blood.[33]

THE NEED FOR BUBBLE-SPECIFIC IMAGING

One of the major diagnostic objectives in using an ultrasound contrast agent in a solid organ is to detect flow at the perfusion—that is, the arteriolar and capillary—level. The peak enhancement in Fig. 3.3 is more than 30 dB, corresponding to a 1000-fold increase in the power of the ultrasound echo from blood. Although this may seem impressive, it does not necessarily help ultrasound to image perfusion. The echoes from blood associated with such flow, in the hepatic sinusoids for example, exist in the midst of echoes from the surrounding solid structures of the liver parenchyma, echoes that are almost always stronger than even the contrast-enhanced blood echo. When they can be seen, blood vessels in a nonenhanced image have a low echo level, so an echo-enhancing agent actually *lowers* the contrast between blood and the surrounding tissue, making the lumen of the blood vessel less visible. Thus in order to be able to image flow in small vessels of the liver, a contrast agent is required that either enhances the blood echo to a level that is substantially higher than that of the surrounding tissue or can be used with a method for suppressing the echo from noncontrast-bearing structures. Bubble-specific imaging methods provide this capability.

Bubble Behavior and Incident Pressure

The key to understanding contrast-specific imaging modes—and the key to their successful clinical use—lies in the unique interaction between a microbubble contrast agent and the process that images it. Controlling and exploiting this interaction is central to all contrast-specific methods. Unlike tissue, microbubbles

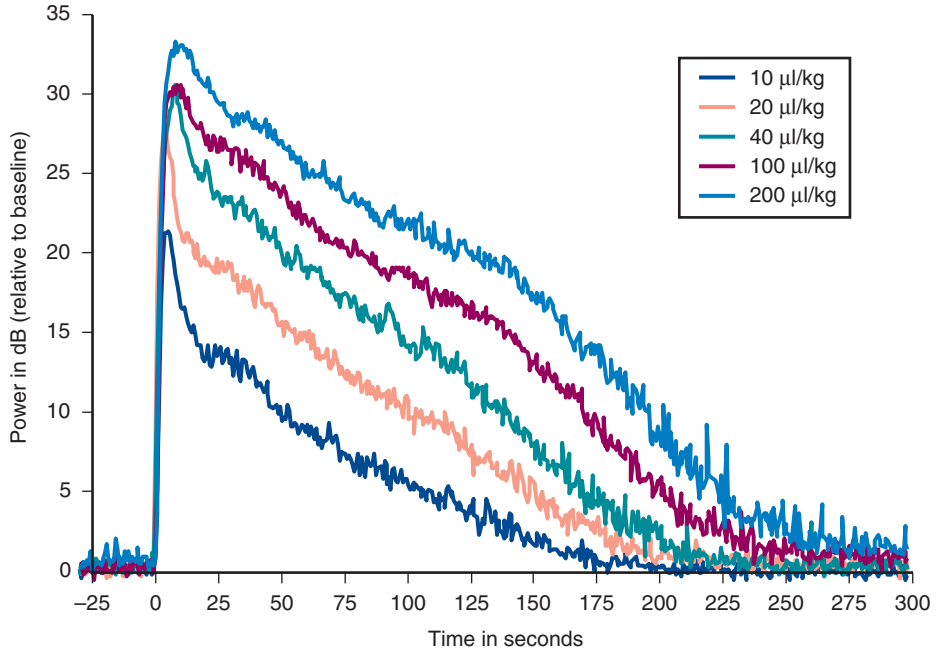

FIG. 3.3 Arterial Blood Echo Enhancement Following an Intravenous Bolus of Optison at Increasing Doses. The peak enhancement is 30 dB, corresponding to a 1000-fold increase of echo power. Note that increasing the dose by a factor of 10 does not have the same effect on the peak enhancement. Instead, it is the wash-out time that is increased.

TABLE 3.2 Three Types of Acoustic Behavior of a Typical Perfluorocarbon, Lipid-Shelled Agent in an Ultrasound Field

Peak Pressure (Approximate)	Mechanical Index (MI) at 2 MHz	Bubble Behavior	Acoustic Behavior	Application
<100 kPa	<0.07	Linear oscillation	Linear backscatter enhancement	Doppler signal enhancement
0.1-0.3 MPa	0.07-0.2	Nonlinear oscillation	Nonlinear backscatter	Real-time (low-MI) perfusion imaging
>0.5 MPa	>0.4	Disruption	Transient nonlinear echoes	Triggered perfusion or disruption-replenishment flow measurement

scatter ultrasound in a manner dependent on the amplitude of the sound to which the imaging process exposes them. The results are three broad types of bubble behavior, with three broad types of resulting echoes (Table 3.2). The types of bubble behavior depend primarily on the intensity (more precisely, the peak negative pressure and frequency) of the incident sound field produced by the scanner. At low incident pressures (corresponding to low transmit power of the scanner), the agents produce linear backscatter enhancement, resulting in an augmentation of the echo from blood. This is the behavior originally envisaged by contrast agent manufacturers. As the transmit intensity control of the scanner is increased and the negative pressure incident on a bubble goes beyond about 50 to 100 kPa, which is still below the level used in most diagnostic scans, the contrast agent backscatter begins to show nonlinear characteristics, such as the emission of harmonics. It is the detection of these that forms the basis of contrast-specific imaging modes such as harmonic and pulse inversion imaging. Finally, as the peak pressure passes about 300 kPa (or 0.3 MPa) and approaches the level emitted by a typical ultrasound imaging system in conventional B-mode imaging, bubbles produce a strong but brief echo as they are disrupted by the ultrasound beam. This behavior forms the basis of the most common way of quantifying perfusion. It should be noted that in practice, because of the different sizes present in a realistic population of bubbles[34] and the additional effect of frequency, the borders between these behaviors are not sharp. Nor will they be the same for different bubble types, the acoustic behavior of which is strongly dependent on the gas and shell properties.[35]

To reiterate, three types of behavior of bubbles in an acoustic field have been identified and depend on the amplitude and frequency of the transmitted ultrasound beam. In practice, this exposure is best monitored by means of the mechanical index (MI) displayed by the scanner. At very low MI, the bubbles act as simple but powerful echo enhancers. This is most useful for spectral Doppler enhancement but is rarely used in the

abdominal organs. At slightly higher intensities (the bottom of the range of those used diagnostically), the bubbles emit harmonics as they undergo nonlinear oscillation. These nonlinear echoes can be detected by contrast-specific imaging modes, which generally rely on trains of low-MI pulses modulated in phase and/or amplitude. Pulse inversion imaging is an example of such a method. Finally, at the higher intensity settings, comparable to those used in conventional scanning, the bubbles can be disrupted deliberately, creating a strong, transient echo. Detecting this echo with harmonic power Doppler is one of the most sensitive means available to image bubbles in very low concentrations, but it comes at the price of destroying the bubble. Because of the long replenishment periods of tissue flow, intermittent imaging using an "interval delay" in which the high-MI imaging is arrested becomes necessary. Disrupting bubbles offers a unique method for quantifying perfusion at the tissue level.

The Mechanical Index

For reasons unrelated to contrast imaging, ultrasound scanners marketed in the United States are required by the FDA to carry an on-screen label of the estimated normalized peak negative pressure to which tissue is exposed. Of course, this pressure changes according to the tissue through which the sound travels as well as the amplitude and geometry of the ultrasound beam: the higher the attenuation, the less the peak pressure in tissue will be. A scanner cannot "know" what tissue it is being used on, so the arrived-at definition of an index reflects the approximate exposure to ultrasound pressure at the focus of the beam in an average tissue. The **mechanical index** (MI) is defined as the peak rarefactional (i.e., negative) pressure divided by the square root of the ultrasound frequency. This quantity is related to the amount of mechanical work that can be performed on a bubble during a single negative half-cycle of sound[36] and is thought to give an indication of the propensity of the sound to cause cavitation in the medium. In clinical ultrasound systems, this index usually lies somewhere between 0.05 and 2.0. Although a single value is displayed for each image, in practice the actual MI varies throughout the image. In the absence of attenuation, the MI is maximal at the focus of the beam. Attenuation shifts this maximum toward the transducer. Furthermore, because it is a somewhat complex procedure to calculate the index, which is itself only an estimate of the actual quantity within the body, the indices displayed by different machines are not precisely comparable. Thus, for example, more bubble disruption might be observed at a displayed MI of 0.2 on one machine but at 0.3 with the same patient on another machine. For this reason, recommendations of machine settings for a specific examination are not transferable between manufacturers' instruments. Nonetheless, the MI is the operator's most important indication of the behavior of the contrast agent bubbles to be expected. For this reason, it is usually incorporated into the preset initial settings for a contrast imaging mode on the scanner and the **output power** adjustment brought to the operator's front line of controls. A typical initial setting of output power in a contrast mode is as low as 1% to 2% of that used in conventional imaging.

The Mechanical Index (MI)

The mechanical index (MI):

- Is defined as

$$\mathrm{MI} = \frac{P_{\mathrm{neg}}}{\sqrt{f}}$$

  where P_{neg} is the peak negative ultrasound pressure in MPa and f is the ultrasound frequency in MHz
- Reflects the normalized negative pressure to which a target (such as a bubble) is exposed in an ultrasound field
- Is defined for the focus of the ultrasound beam
- Varies with depth in the image (lessens with increasing depth)
- Varies with lateral location in the image (lessens at the sector edges)
- Is estimated differently in systems from different manufacturers

NONLINEAR ECHOES AND HARMONIC IMAGING

Two important pieces of evidence are presented by the behavior of bubbles in an acoustic field. First, the size of the echo enhancement shown in Fig. 3.3 is much larger than would be expected from such sparse scatterers of this size in blood. Second, investigations of the acoustic characteristics of early agents[37] demonstrated peaks in the spectra of attenuation and scattering that are dependent on both ultrasound frequency and the size of the microbubbles. These important observations suggest that the bubbles **resonate** in an ultrasound field. As the ultrasound wave—which consists of alternating compressions and rarefactions—propagates over the bubbles, they experience a periodic change in their radius in sympathy with the oscillations of the incident sound. Like vibrations of a string of a musical instrument, these oscillations have a natural, or resonant, frequency of oscillation at which they will both absorb and scatter ultrasound with a peculiarly high efficiency. Considering the linear oscillation of a free bubble of air in water, we can use a simple theory[2] to predict the resonant frequency of radial oscillation of a bubble 3 μm in diameter, the median diameter of a typical transpulmonary microbubble agent. As Fig. 3.4 shows, it is about 3 MHz, approximately the center frequency of ultrasound used in a typical abdominal scan. This extraordinary, and fortunate, coincidence explains why ultrasound contrast agents are so efficient and can be administered in such small quantities. It also predicts that bubbles undergoing resonant oscillation in an ultrasound field can be induced to nonlinear motion, the basis of harmonic imaging.

It has long been recognized[38] that if bubbles are "driven" by an ultrasound field at sufficiently high acoustic pressures, the oscillatory excursions of the bubble reach a point at which the alternate expansions and contractions of the bubble's size are not equal. Lord Rayleigh, the originator of the theoretical

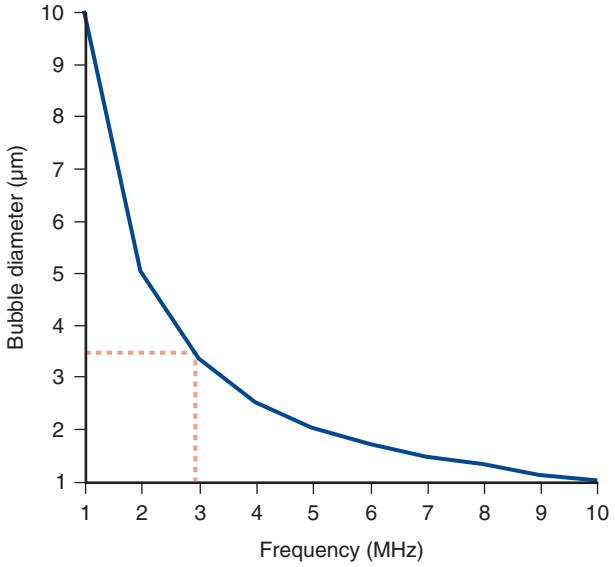

FIG. 3.4 Microbubbles Resonate in a Diagnostic Ultrasound Field. This graph shows that the resonant—or natural—frequency of oscillation of a bubble of air in an ultrasound field depends on its size. For a 3.5-μm diameter, the size needed for an intravenously injectable contrast agent, the resonant frequency is about 3 MHz.

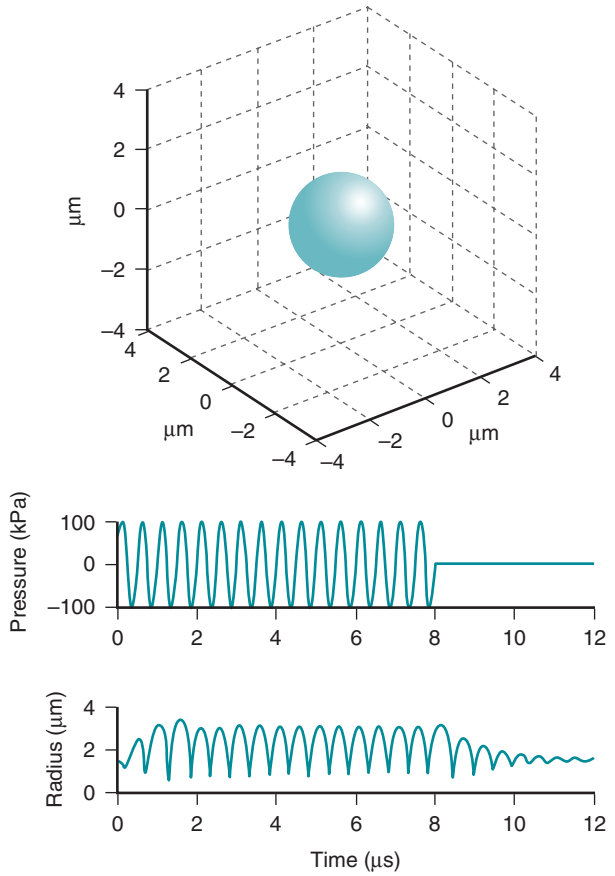

FIG. 3.5 A Microbubble in an Acoustic Field. Bubbles respond asymmetrically to diagnostic sound waves *(top graph),* stiffening when compressed by sound, yielding only small changes in radius *(bottom graph).* During the low-pressure portion of the sound wave, the bubble stiffness decreases and radius changes can be large. This asymmetric response leads to the production of harmonics in the scattered wave.

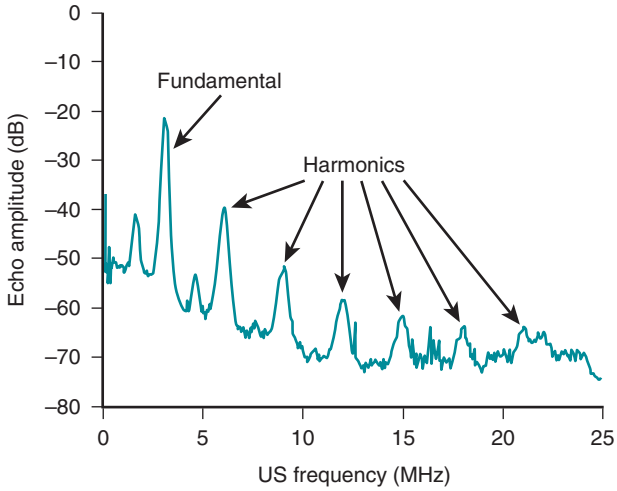

FIG. 3.6 Harmonic Emission From Optison. A sample of a contrast agent is insonated at 3 MHz and the echo analyzed for its frequency content. The largest peak of the energy in the echo is at the 3-MHz fundamental, but there are clear secondary peaks in the spectrum at 6, 9, 12, 15, and 18 MHz, as well as peaks between these harmonics (known as "ultraharmonics") and below the fundamental (known as the "subharmonic"). The second harmonic echo is about 18 dB less than that of the main, or fundamental, echo. Harmonic imaging and Doppler aim to separate and process this signal alone. (With permission from Becher H, Burns P. Handbook of contrast echocardiography: left ventricle function and myocardial perfusion. New York: Springer; 2000.[63])

understanding of sound on which ultrasound imaging is based, was first led in 1917 to investigate this by his curiosity over the creaking noises that his teakettle made as the water came to a boil.[39] The consequence of such **nonlinear** motion is that the sound emitted by the bubble, and detected by the transducer, contains harmonics, just as the resonant strings of a musical instrument, depending on how they are bowed or plucked, will produce a timbre comprising overtones (the musical term for harmonics), exact octaves above the pitch of the fundamental note. The origin of this phenomenon is the asymmetry that begins to affect bubble oscillation as the amplitude becomes large. As a bubble is compressed by the ultrasound pressure wave, it becomes stiffer and hence resists further reduction in its radius. Conversely, in the rarefaction phase of the ultrasound pulse, the bubble becomes less stiff, and therefore enlarges much more (Fig. 3.5). Fig. 3.6 shows the frequency spectrum of an echo produced by a microbubble contrast agent after exposure to a 3-MHz burst of sound. The particular agent is Optison, though most microbubble agents behave in a similar way. Ultrasound frequency is on the horizontal axis, with the relative amplitude on the vertical axis. In addition to the **fundamental echo** at 3 MHz, a series of echoes occur at whole multiples of the transmitted frequency, known as **higher harmonics.** Here, then, is one simple method to distinguish bubbles from tissue: excite them so as to produce harmonics, and detect these in preference to the fundamental echo from tissue. Key factors in the harmonic response of an agent are the incident pressure of the ultrasound field, the frequency, the size distribution of the bubbles, and the mechanical properties of the bubble capsule (a stiff capsule, for example, will dampen the oscillations and attenuate its nonlinear response).

Harmonic B-Mode Imaging

An imaging and Doppler method based on the phenomenon of harmonic emission, called "harmonic imaging,"[40] is widely available on modern ultrasound scanners. In harmonic mode, the system transmits normally at one frequency but is tuned to receive echoes preferentially at double that frequency, where the echoes from the bubbles lie. Typically, the transmit frequency lies between 1.5 and 3 MHz and the receive frequency is selected by means of a detection strategy (originally simply a radiofrequency bandpass filter whose center frequency is at the second harmonic), between 3 and 6 MHz. Harmonic imaging uses the same array transducers as conventional imaging and for most of today's ultrasound systems involves only software changes. Echoes from solid tissue, as well as red blood cells themselves, are suppressed. Real-time harmonic spectral Doppler and color Doppler modes have also been implemented in a number of commercially available systems. Clearly, an exceptional transducer bandwidth is needed to operate over such a large range of frequencies. Fortunately, much effort has been directed in recent years toward increasing the bandwidth of transducer arrays because of its important bearing on conventional imaging performance, so harmonic imaging modes do not require the additional expense of dedicated transducers.

Harmonic Spectral and Power Doppler Imaging

In harmonic images, the echo from tissue-mimicking material is reduced, but not eliminated, reversing the contrast between the agent and its surrounding environment (Fig. 3.7). The value of this effect is to increase the conspicuity of the agent when it is in blood vessels normally hidden by the strong echoes from tissue. In spectral Doppler, one would expect the suppression of the tissue echo to reduce the tissue motion or "thump" artifact that is familiar to all Doppler sonographers and limits the detection of flow in moving vessels. *In vivo* measurements from spectral Doppler show that the signal-to-noise ratio is improved by a combination of harmonic imaging and the contrast agent by as much as 35 dB.[41] Applications of this method include detection of blood flow in small vessels surrounded by tissue that is moving, such as the branches of the coronary arteries[42]; it remains a somewhat specialized technique.

In conventional color Doppler studies using a contrast agent, the increased echo signal does nothing to suppress the clutter "flash" from moving tissue, but instead adds to it a "blooming" artifact of flow signals as the receiver is overloaded with the enhanced echo from blood (Fig. 3.8). Harmonic power Doppler mode effectively overcomes this clutter problem by suppressing the signal from tissue, revealing better detail of small vessels. Combining the harmonic method with power Doppler produces an especially effective tool for the detection of flow in the small vessels of the organs of the abdomen, which may be moving with cardiac pulsation or respiration (Fig. 3.9). In a study in which flow imaged on contrast-enhanced power harmonic images was compared with histologically sized arterioles in the corresponding regions of the renal cortex,[43] it was concluded that the method is capable of demonstrating flow in vessels of less than 40-µm diameter—about 10 times smaller than the corresponding imaging resolution limit, even as the organ is moving with normal

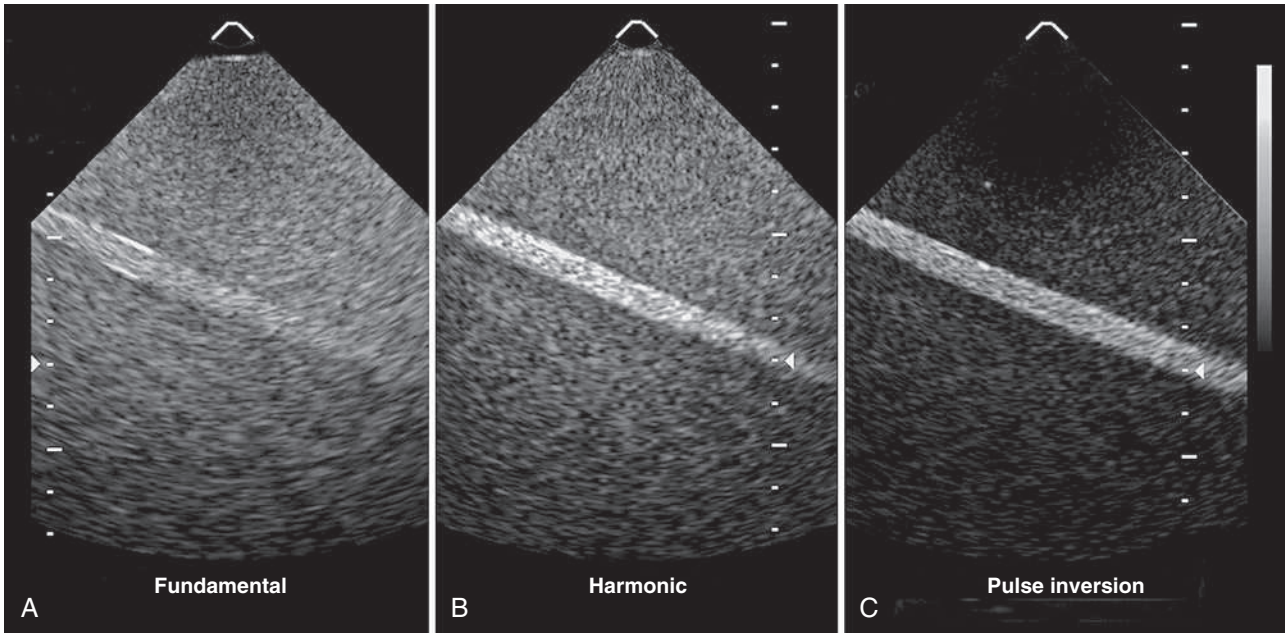

FIG. 3.7 Demonstration of Pulse Inversion Imaging. *In vitro* images of a vessel phantom containing stationary perfluorocarbon contrast agent surrounded by tissue equivalent material (Biogel and graphite). **(A)** Conventional image, mechanical index (MI) = 0.2. **(B)** Harmonic imaging, MI = 0.2, provides improved contrast between agent and tissue. **(C)** Pulse inversion imaging, MI = 0.2. By suppressing linear echoes from stationary tissue, pulse inversion imaging provides better contrast between agent and tissue than both conventional and harmonic imaging. (With permission from Becher H, Burns P. Handbook of contrast echocardiography: left ventricle function and myocardial perfusion. New York: Springer; 2000.[63])

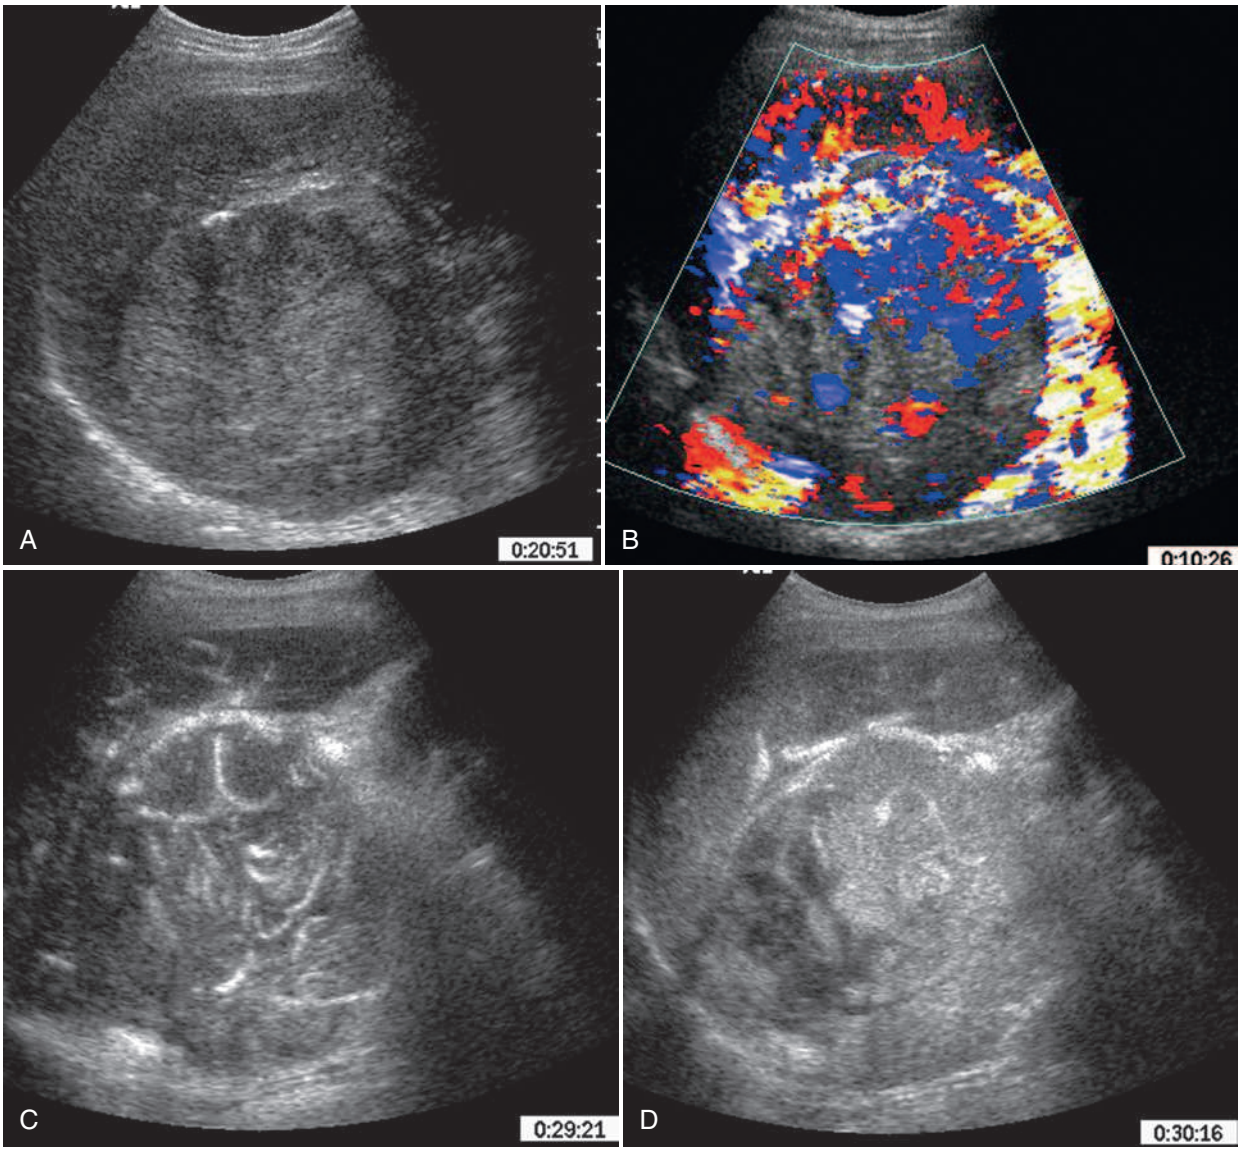

FIG. 3.8 The Need for Contrast-Specific Imaging. (A) Conventional image of liver shows a large solid mass. **(B)** Administration of contrast increases the echogenicity of blood but creates Doppler artifacts owing to blooming and tissue motion. **(C)** Contrast-specific imaging shows blood vessels not seen with Doppler. **(D)** Initiating high–mechanical index imaging after a pause reveals perfusion of the mass and a necrotic area. The lesion is a hepatocellular carcinoma. (Adapted from Burns PN, Wilson SR, Simpson DH. Pulse inversion imaging of liver blood flow: improved method for characterizing focal masses with microbubble contrast. Invest Radiol. 2000;35[1]:58-71.[53])

respiration. Using this power mode method in the heart, perfusion can be imaged in the myocardium.[44,45]

Tissue Harmonic Imaging

In second harmonic imaging, an ultrasound scanner transmits at one frequency and receives at double this frequency. The resulting improved detection of the microbubble echo is due to the peculiar behavior of a gas bubble in an ultrasound field. However, any source of a received signal at the harmonic frequency that does not come from the bubble will clearly reduce the efficacy of this method. Such unwanted signals can come from nonlinearities in the transducer or its associated electronics, and these must be tackled effectively in a good harmonic imaging system. However, tissue itself can produce harmonics that will be received by the transducer. They are developed as a wave *propagates* through tissue. Again, this is due to an asymmetry: this time, the fact that sound travels slightly faster through tissue during the compressional part of the cycle (when it is denser and hence stiffer) than during the rarefactional part. Although the effect is very small, it is sufficient to produce substantial harmonic components in the transmitted wave by the time it reaches deep tissue, so that when it is scattered by a linear target such as the myocardium, there is a harmonic component in the echo, which is detected by the scanner along with the harmonic echo from the bubble.[46] This is the reason that solid tissue is not completely dark in a typical harmonic image. The effect is to

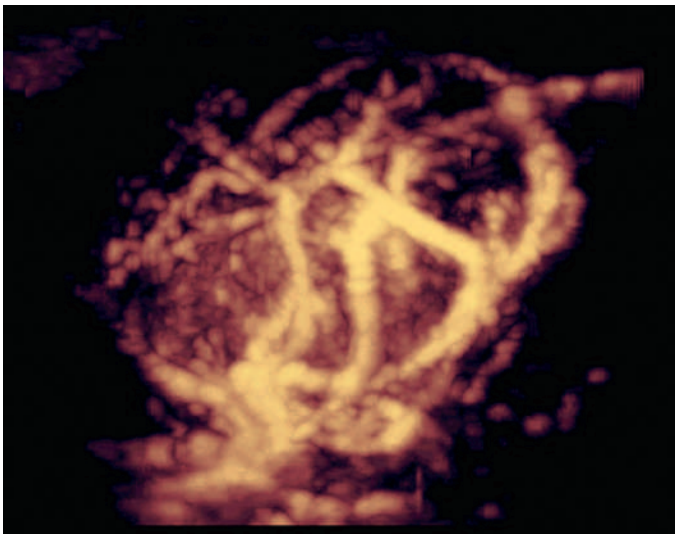

FIG. 3.9 Contrast-Specific Harmonic Imaging. Harmonic Power Doppler of a 1-cm-diameter experimental tumor (VX2 carcinoma) shows clear separation of the enhanced blood signal.

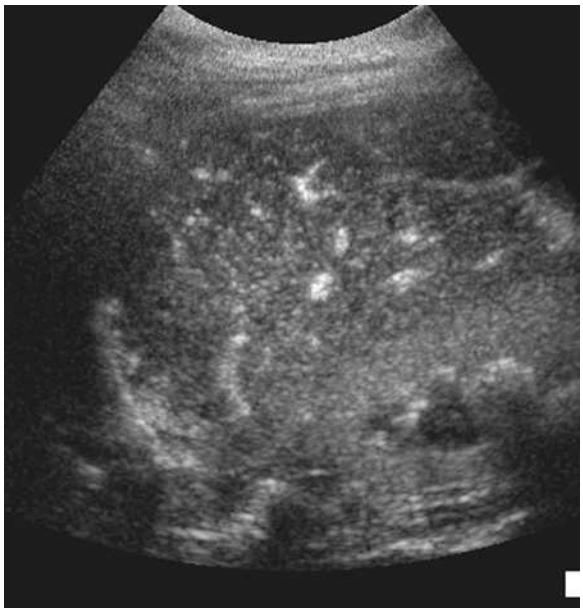

FIG. 3.10 Blood Vessel Appearance Using Harmonic B-Mode Imaging in a Patient With an Incidental Hemangioma. Note that large vessels have a punctate appearance as the high–mechanical index ultrasound disrupts the bubbles as they enter the scan plane. (With permission from Becher H, Burns P. Handbook of contrast echocardiography: left ventricle function and myocardial perfusion. New York: Springer; 2000.[63])

reduce the contrast between the bubble and tissue, rendering the problem of detecting perfusion in tissue more difficult.

Tissue harmonics, although a foe to contrast imaging, are not necessarily a bad thing. In fact, an image formed from tissue harmonics without the presence of contrast agents has so many properties that commend it over conventional imaging that it is used as the routine "default" mode in many scanner presets. Its advantages stem from the fact that tissue harmonics are developed as the beam penetrates tissue, in contrast to the conventional beam, which is generated at the transducer surface.[47,48] Artifacts that accrue from the first few centimeters of tissue, such as reverberations, are reduced by using tissue harmonic imaging. Sidelobe and other low-level interference is also suppressed, making tissue harmonic imaging the routine modality of choice in many situations, especially when visualizing fluid-filled structures.[49] Nonetheless, for contrast studies, the tissue harmonic limits the visibility of bubbles within tissue and therefore can be considered an artifact. In considering how to reduce it, it is instructive to bear in mind differences between harmonic produced by tissue propagation and by bubble echoes. First, tissue harmonics require a high peak pressure, so are only evident at high MI. Use of low-MI contrast imaging, as is most often the case, leaves only the bubble harmonics. Second, harmonics from tissue at high MI are continuous and sustained, whereas those from bubbles at high MI are transient in nature as the bubble disrupts.

Pulse Inversion Imaging

There were problems with early harmonic imaging. First, the splitting of the bandwidth of the transducer had the effect of decreasing image resolution. Second, when the received echo is weak (which from bubbles is typically the case), the overlapping region between the transmit and receive frequencies becomes a larger portion of the entire received signal, so that contrast in the harmonic image is dependent on how strong the echo is from the bubbles. In practice, this forces use of a high MI in harmonic mode, which reduces contrast more because of the tissue harmonic.[50] It also results in the transient and irreversible disruption of the bubbles.[51] As the bubbles enter the scan plane of a real-time ultrasound image, they provide an echo but then disappear. Thus vessels that lie within the scan plane are not visualized as having continuous walls in such a harmonic image, but instead have a punctate appearance (Fig. 3.10).

Pulse inversion imaging overcomes the conflict between the requirements of contrast and resolution in harmonic imaging and provides greater sensitivity, thus allowing low incident power, nondestructive, continuous imaging of microbubbles in an organ such as the liver. The method also relies on the asymmetric oscillation of an ultrasound bubble in an acoustic field, but detects "even" nonlinear components of the echo over the entire bandwidth of the transducer. In pulse inversion (also known as "phase inversion") imaging, two pulses are sent in rapid succession into the tissue. The second pulse is a mirror image of the first (Fig. 3.11): that is, it has undergone a 180-degree phase change. The scanner detects the echo from these two successive pulses and forms their sum. For ordinary tissue, which behaves in a linear manner, the sum of two inverted pulses is simply zero. For an echo with nonlinear components, such as that from a bubble, the echoes produced from these two pulses will not be simple mirror images of each other, because of the asymmetric behavior of the bubble radius with time. The result is that the sum of these two echoes is not zero. Thus a signal is detected from a bubble but not from tissue. It can be shown mathematically that this summed echo contains the nonlinear "even" harmonic components of the signal, including the second harmonic.[52] One

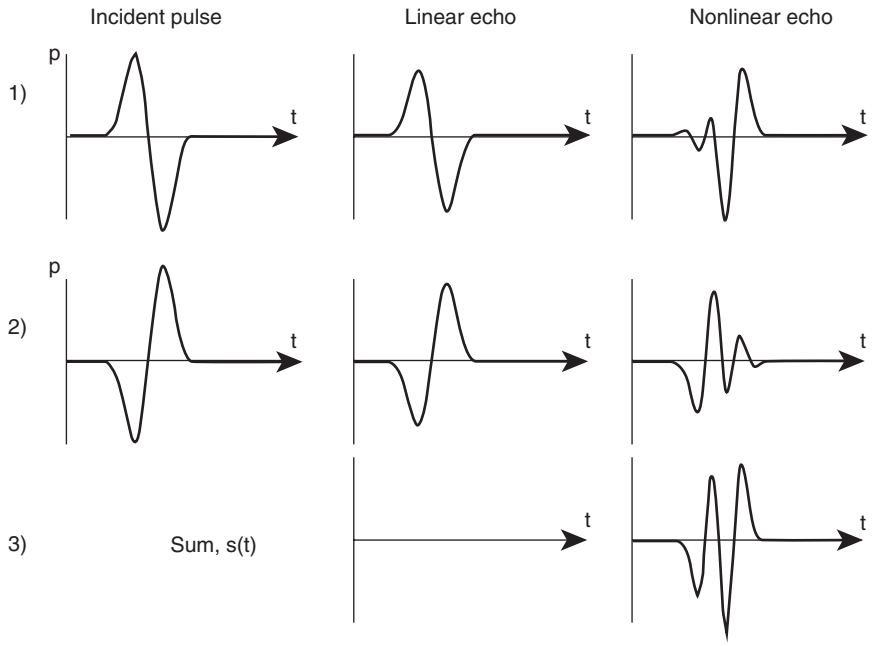

FIG. 3.11 Basic Principle of Pulse Inversion Imaging. A pulse of sound is transmitted into the body, and echoes are received from agent and tissue. A second pulse, which is an inverted copy of the first, is then transmitted in the same direction and the two resulting echoes are summed. Linear echoes from tissue are inverted copies of each other and cancel to zero. The microbubble echoes are distorted copies of each other, so the even nonlinear components of these echoes will reinforce each other when summed, producing a strong harmonic signal.

FIG. 3.12 Pulse Inversion Image of a Hypervascular Liver Mass in the Arterial Phase, Made in Real Time at Low Mechanical Index. Note that the spatial resolution of this image is comparable to that of conventional imaging, reflecting the advantage of a broad-bandwidth contrast-specific image.

advantage of pulse inversion over the filter approach to detect harmonics from bubbles is that it no longer suffers from the restriction of bandwidth. The full frequency range of sound emitted from the transducer can be detected in this way, providing a full bandwidth—that is, a high-resolution image of the echoes from bubbles.[53] Fig. 3.12 illustrates how pulse inversion imaging provides better suppression of linear echoes than harmonic imaging and is effective over the full bandwidth of the transducer, showing improvement of image resolution over harmonic mode. Because this detection method is a more efficient means of isolating the bubble echo, weaker echoes from bubbles insonated at low, nondestructive intensities can be detected. It should be noted, however, that as the MI increases, tissue harmonic renders the tissue brighter. Indeed, pulse inversion is now the preferred method used by many systems for tissue harmonic imaging. Optimal pulse inversion contrast imaging is often, then, performed at low MI. The principle of pulse inversion is the basis of many commercially named imaging modes, such as **coherent contrast imaging, ensemble harmonic imaging,** and **phase inversion imaging.**

Pulse Inversion Doppler Imaging

In spite of the improvements offered by pulse inversion over harmonic imaging for suppressing stationary tissue, the method is somewhat sensitive to echoes from moving tissue. This is because tissue motion causes linear echoes to change slightly between pulses, so that they do not cancel perfectly. Furthermore, at high MI, nonlinear propagation also causes harmonic echoes to appear in pulse inversion images, even from linear scattering structures such as the liver parenchyma. Although tissue motion artifacts can be minimized by using a short pulse repetition interval, nonlinear tissue echoes can mask the echoes from bubbles, reducing the efficacy of microbubble contrast, especially when a high MI is used. Pulse inversion Doppler seeks to address these problems by means of a generalization of the pulse inversion method.[52] This technique combines the nonlinear detection performance of pulse inversion imaging with the motion discrimination capabilities of power Doppler. Multiple transmit pulses of alternating polarity are used and Doppler signal processing techniques are applied to distinguish between bubble echoes and echoes from moving tissue and/or tissue harmonics, as desired by the operator. This method offers potential improvements in the agent-to-tissue contrast and signal-to-noise performance, although at the cost of a somewhat reduced frame rate. The most

dramatic manifestation of this method's ability to detect very weak harmonic echoes has been its demonstration of real-time perfusion imaging of the myocardium.[54] By lowering the MI to 0.1 or less, bubbles undergo stable, nonlinear oscillation, emitting continuous harmonic signals. Because of the low MI, very few bubbles are disrupted, so that imaging can take place at real-time rates. Because sustained, stable nonlinear oscillation is required for this method, perfluorocarbon gas bubbles work best.

Plane-Wave Contrast Imaging

In practice, the low frame rate that line-by-line imaging forces on pulse inversion Doppler has precluded its inclusion as a clinical scanning mode in most systems. However, line-by-line beamforming is not the only way to form an ultrasound image. It is possible to form an ultrasound image as is conventionally done by sweeping a focused beam in 100 consecutive directions, with a single, unfocused plan wave, which insonates the entire field of view with a single pulse. The echoes from each volume element of tissue are then received simultaneously on all transducer elements and processed to extract the echoes at each location in the field of view. The result is a single image, albeit of somewhat compromised quality, for a single ultrasound pulse. Thus imaging frame rates equal to the pulse repetition frequency of 5 kHz or more are possible. Although computationally demanding, the advantage of such "software beam-forming" methods are legion. One is that they provide an opportunity to send long ensembles of pulse for Doppler methods without affecting frame rate. Pulse inversion Doppler has been implemented in such systems with dramatic results, providing simultaneous perfusion, imaging, and color Doppler from a contrast injection at frame rates of 100 Hz or more.[55]

Amplitude and Phase Modulation Imaging

On receiving the echoes from a pulse inversion sequence, the receiver combines them in a way that ensures that the mirrorlike echoes from tissues combine to zero. What is left is then some combination of the nonlinear components of the bubble echo. Changing (or modulating) the pulse from one transmission to the next by flipping its phase is only one of a large number of strategies that can be employed. For example, by changing the amplitude of the pulse in consecutive transmissions and amplifying the echoes to compensate for this, linear echoes can also be cancelled out. What is left are all components of the nonlinear echoes from bubbles.[56] Precisely what nonlinear components are produced by a particular sequence of pulses can be determined mathematically and the contrast-specific imaging mode optimized for specific applications.[57] Almost all diagnostic systems now use some form of multipulse modulation processing in their contrast-specific imaging modes, variously known by such names as **power modulation pulse inversion** (PMPI) or **contrast pulse sequence** (CPS). As long as the peak negative pressure is kept low (less than about 100 kPa) so that the bubble is not disrupted by the pulses, real-time imaging of perfusion can be achieved in many organs, including the myocardium, liver, kidney, skin, prostate, and breast, even in the presence of tissue motion. Because one performance criterion that improves detection of perfusion is complete suppression of background tissue, many contrast-specific images are quite black before the contrast agent is injected, making it very hard to scan the patient. Thus side-by-side imaging, in which a simultaneous, low-MI, fundamental image is seen alongside (or superimposed on) the contrast image, has become a preferred method for hunting small lesions or guiding interventional devices such as needles or ablation probes, the echoes of which are visible in the fundamental image but suppressed in the contrast image (Fig. 3.13). Although the technology for low-MI, real-time, bubble-specific imaging in commercial ultrasound systems has stabilized over the past few years, clinical applications are still experiencing expansion, especially in tumor imaging, which in turn presents new challenges for imaging methodology.

Temporal Maximum Intensity Projection Imaging

One clinically striking elaboration of contrast-specific imaging exploits the fact that it is sufficiently sensitive to detect and display echoes from individual bubbles in real time. By creating the equivalent of an open-shutter photograph, in which bright objects create tracks of their own motion, the bubbles can be made to trace the morphology of the microvessels that contain them. The result, known as **temporal maximum intensity projection** (or temporal MIP) imaging can produce a detailed picture of vascular morphology lasting a few seconds or the duration of a breath hold. Usually the maximum intensity projection process is initiated after a flash, which disrupts the bubbles within the scan plane (Fig. 3.14). As new bubbles wash into the plane, their tracks are traced in an image, which is integrated over a chosen period between 100 ms to a few seconds.[58] These images can also provide dynamic information—for example, revealing whether the pattern of arterial enhancement of a liver lesion is centripetal or centrifugal.[59]

DISRUPTING BUBBLES: INTERMITTENT IMAGING

As the incident pressure to which a resonating bubble is exposed increases, so its oscillation becomes more wild, with radius increasing in some bubbles by a factor of 5 or more during the rarefaction phase of the incident sound. Just as a good soprano can shatter a wine glass by singing at its resonant frequency, so a microbubble, if driven by higher amplitude ultrasound, will sustain irreversible disruption of its shell. A physical picture of precisely what happens to a disrupted bubble is only now emerging from high-speed video studies using cameras with frame rates up to 25 million pictures per second[60,61] (Fig. 3.15). It seems certain, however, that the bubble shell disappears (not instantly, but over a period of time determined by the bubble composition) and releases free gas, which forms a highly effective acoustic scatterer, giving strong, nonlinear echoes for a brief period of time. This process was once incorrectly thought to constitute a release of energy, like a balloon bursting, and was wrongly termed "stimulated acoustic emission." Its use is twofold. First, intermittent imaging represents a very sensitive way to detect a bubble.[62]

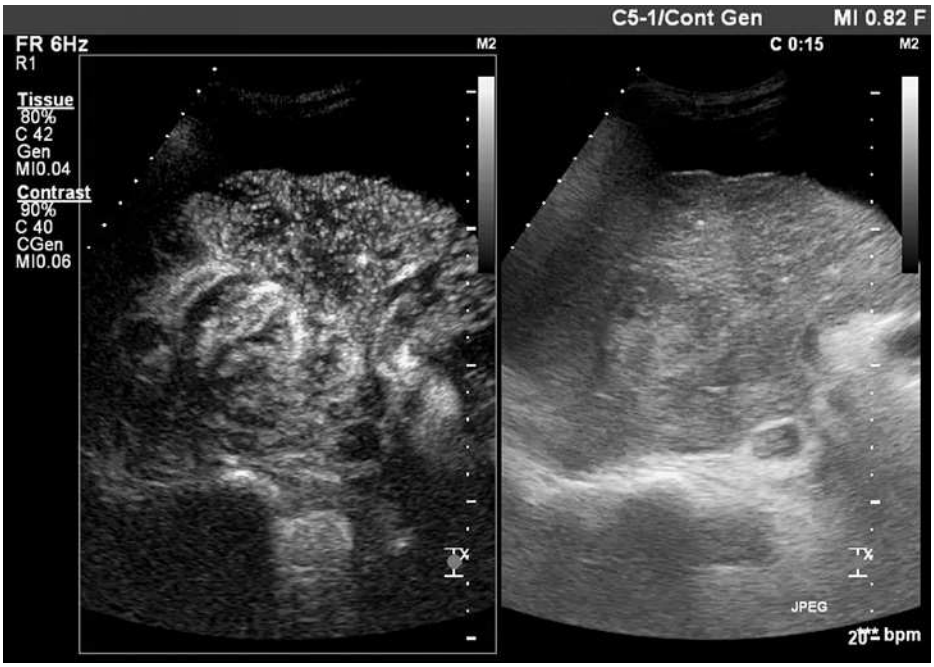

FIG. 3.13 Side-by-Side Imaging Shows a Low–Mechanical Index (MI) Real-Time Conventional Image *(Right)* at the Same Time as the Low-MI Contrast-Specific Image *(Left).* This is particularly useful for characterizing small lesions and for guiding interventional devices. The contrast mode here combines phase and amplitude modulation.

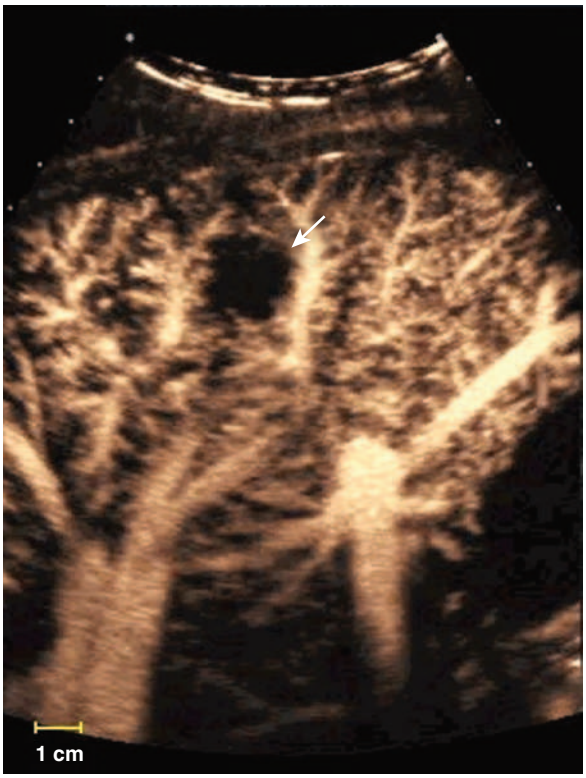

FIG. 3.14 Temporal Maximum Intensity Projection Image of Normal Liver Vasculature Shows Accumulated Enhancement in 11 Seconds After Contrast Material Arrives in Liver. Note depiction of vessel structure to fifth-order branching. Focal unenhanced region *(arrow)* is a slowly perfusing hemangioma. (Reproduced with permission from Wilson SR, Jang HJ, Kim TK, et al. Real-time temporal maximum-intensity-projection imaging of hepatic lesions with contrast-enhanced sonography. AJR Am J Roentgenol. 2008;190[3]:691-695.[58])

However, because it results in its disruption, this process cannot be performed continuously. In fact, replenishment of bubbles in a typical microvascular bed takes about 5 to 10 seconds. The technique of imaging with high MI every few seconds to display perfusion is called "triggered" or "interval delay" imaging.[63] Second, intermittent imaging by a fixed time interval can track the degree to which a region is replenished by bubbles between insonations. By demonstrating the flow rate of blood into the scan plane, intermittent imaging provides a unique method to measure tissue perfusion.

Triggered Imaging

It was discovered during the early days of harmonic imaging that by pressing the "freeze" button on a scanner for a few moments, and hence interrupting the acquisition of ultrasound images during a contrast study, it is possible to increase the effectiveness of a contrast agent. So dramatic is this effect that it was responsible for the first ultrasound images of myocardial perfusion using harmonic imaging.[64] This is a consequence of the ability of the ultrasound field, if its peak pressure is sufficiently high, to disrupt a bubble's shell and hence destroy it.[51] As the bubble is disrupted, it releases energy, thus creating a strong, transient echo that is rich in harmonics. This process is sometimes incorrectly referred to as "stimulated acoustic emission." The fact that this echo is transient in nature can be exploited for its detection. One simple method is to subtract from a disruption image a baseline image obtained either before or (more usefully) immediately after insonation. Such a method requires offline processing of stored ultrasound images, together with software that can align the ultrasound images before subtraction, and is useful only in rare circumstances.[63]

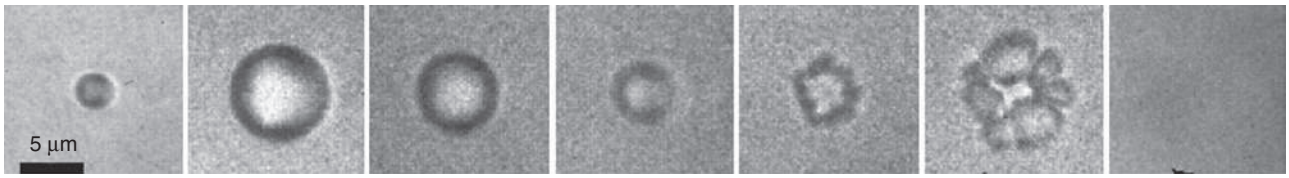

FIG. 3.15 Fragmentation of Contrast Agent Observed With a High-Speed Camera by Researchers at the University of California, Davis. The frame images are captured over 50 nanoseconds. The bubble is insonated with 2.4-MHz ultrasound with a peak negative pressure of 1.1 MPa (mechanical index [MI] ~0.7). The bubble is initially 3 µm in diameter and fragments during compression after the first expansion. Resulting bubble fragments are not seen after insonation, because they are either fully dissolved or below the optical resolution. (Courtesy of James Chomas, Paul Dayton, Kathy Ferrara, University of California, Davis CA.)

Intermittent Harmonic Power Doppler

Power Doppler imaging was developed as a way to detect the movement of targets such as red blood cells in a vessel. It works by a simple, pulse-to-pulse subtraction method,[65] in which two or more pulses are sent successively along each scan line of the image. Pairs of received echo trains are compared for each line: if they are identical, nothing is displayed, but if there is a change (owing to motion of the tissue between pulses), a color is displayed, the saturation of which is related to the amplitude of the echo that has changed. This method, although not designed for the detection of bubble disruption, is ideally suited for high-MI "disruption" imaging. The first pulse receives an echo from the bubble, and the second receives none, so the comparison yields a strong signal. In a sense, power Doppler may be thought of as a line-by-line subtraction procedure on the radiofrequency echo detected by the transducer. Interestingly, pulse inversion imaging—the most commonly used method at low MI—becomes equivalent to power Doppler if the MI is high and the bubble disrupted. Looking again at Fig. 3.11, one can easily see that if the echo from the second pulse is absent (because the bubble is gone), the sum of the two bubble echoes is the same as their difference, which is what is measured by power Doppler. The fact that the second transmitted pulse is inverted is immaterial for the bubble that has disappeared! Thus at high MI, power or pulse inversion Doppler becomes a sensitive way to detect bubbles, whether they are moving or not.

This method has been incorporated into modes specifically adapted to detect the distribution of bubbles taken up in the Kupffer cells in the postvascular phase of agents such as Levovist and Sonazoid. The transducer is slowly swept through the liver some minutes after the agent has left the vascular system; as it does so, the high-MI pulses disrupt the in situ bubbles and are detected in the image. Fig. 3.16 shows such an image, in which the defect in uptake represents the Kupffer-poor region of a cholangiocarcinoma. The preferred modes for this method are pulse inversion—which carries the attraction of high-resolution imaging but the disadvantage of a strong tissue harmonic background—or power Doppler modes known by such names as **harmonic power angio** or **agent detection imaging** (ADI). Many systems offer a low-MI "monitor" mode that can be used to give a contrast-specific or fundamental image of the liver during the scan sweep, which, when blended with the high-MI contrast mode, can be helpful to keep the scan plane aligned in the region of interest.

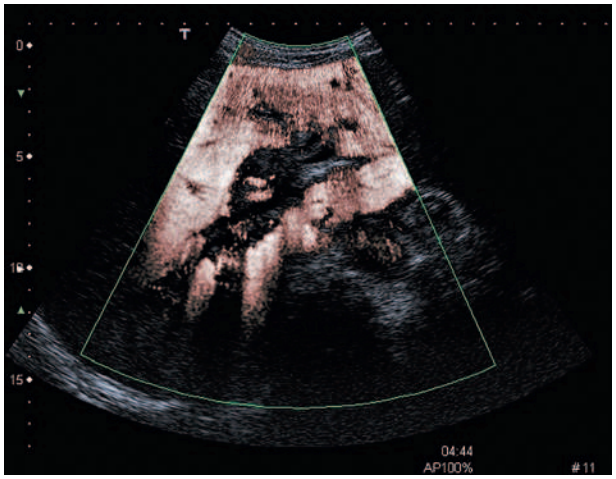

FIG. 3.16 High–Mechanical Index Power Doppler Used to Detect Levovist Bubbles by Disruption During Their Postvascular Phase in the Liver. The bubbles are detected within the Kupffer cells. The signal defect around the porta hepatis depicts a cholangiocarcinoma that was not detected in the precontrast image.

Disruption-Replenishment Imaging

By disrupting bubbles and monitoring replenishment to a region of tissue, contrast ultrasound offers a unique, noninvasive, and validated[66] method for the measurement of microvascular perfusion. In the disruption-replenishment method,[67] microbubbles are infused at a steady rate until a steady enhancement is achieved throughout the vascular system. The bubbles are then disrupted by a high-MI flash, which clears them from the scan plane (Fig. 3.17). Immediately, new bubbles begin to wash in. The rate at which they do so is related to the local flow velocity and flow rate, which can be extracted from a physical model of the process.[68] An important application for such measurement is in assessing the response of tumors and other organs to therapies that target the vasculature. In cancer therapy, a large number of new treatment strategies have been proposed that target the proliferating vasculature of a developing tumor, including drugs specifically designed to inhibit the angiogenic transformation itself.[69] Such antiangiogenic or vascular-disrupting drugs have the effect of shutting down the tumor circulation and inhibiting further growth. They do not in themselves kill cancer cells, so the tumor often responds without shrinking in size—hence the need for a functional test to determine drug response.

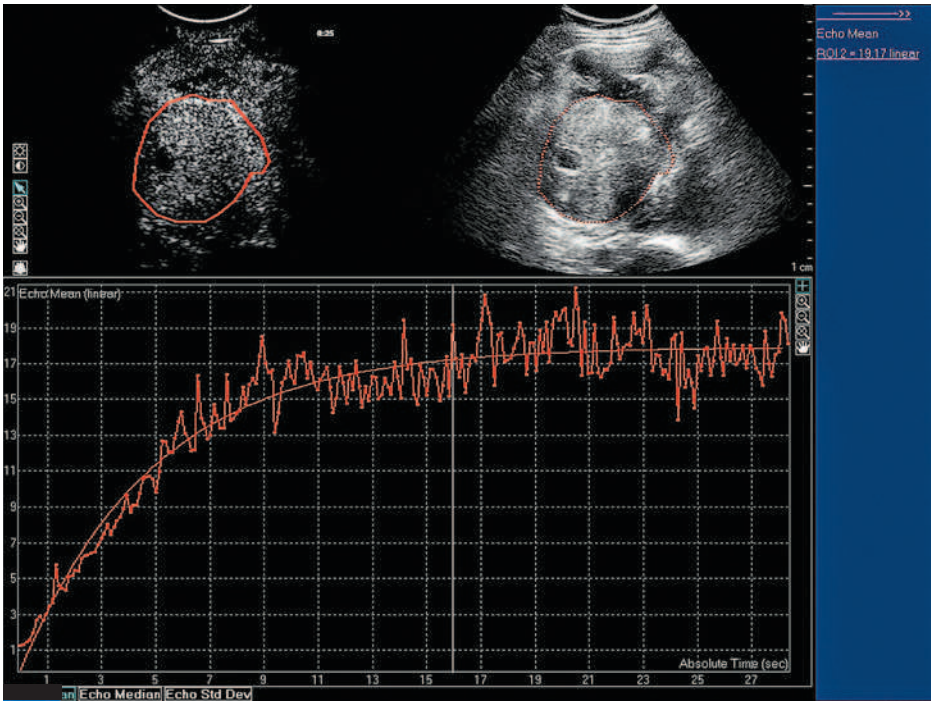

FIG. 3.17 Disruption-Replenishment Imaging Used to Quantify Flow in a Renal Cell Carcinoma in a Patient Undergoing Antiangiogenic Treatment. A side-by-side contrast image (conventional on right, simultaneous contrast-enhanced ultrasound [CEUS] on left) of a large renal cell carcinoma is made during a steady intravenous infusion of the agent Definity. Analysis software (QLAB, Philips Ultrasound, Bothell WA) measures wash-in of a region of interest from the cineloop record. The steeper the initial slope, the greater the flow rate; the higher the asymptote, the greater the vascular volume. Disruption-replenishment imaging thus allows quantitation of changes in tumor flow and relative vascular volume.

Considerable experience accumulated to date suggests that **dynamic contrast-enhanced ultrasound,** with its advantage of high sensitivity, portability, and a pure intravascular tracer, is a strong candidate for this role[70-75]; it has been incorporated into the current European guidelines for the clinical use of contrast agents.[76]

SAFETY CONSIDERATIONS AND REGULATORY STATUS

Contrast ultrasound examinations expose patients to ultrasound in a way that is identical to that of a normal ultrasound examination. Yet the use of ultrasound pulses to disrupt bubbles that sit in microscopic vessels, and the knowledge that ultrasound and bubbles can be used deliberately to penetrate cell membranes for the purpose of drug delivery and other therapies,[77] raise questions about the potential for hazard. When a bubble produces the brief echo that is associated with its disruption, it releases energy it has stored during its exposure to the ultrasound field. Can this energy damage the surrounding tissue? At higher exposure levels, ultrasound is known to produce bioeffects in tissue, the thresholds for which have been studied extensively.[78] Do these thresholds change when bubbles are present in the vasculature? Whereas the safety of ultrasound contrast agents as drugs has been established to the satisfaction of the most stringent requirements of the regulating authorities in a number of countries, it is probably fair to say that there is much to be learned about the interaction between ultrasound and tissue when bubbles are present.

The most extreme of these interactions is known as **inertial cavitation,** which refers to the rapid formation, growth, and collapse of a gas cavity in fluid as a result of ultrasound exposure. It was studied extensively before the development of microbubble contrast agents.[79] In fact, most of the mathematical models used to describe contrast microbubbles were originally developed to describe cavitation.[80] When sound waves of sufficient intensity travel through a fluid, the rarefactional half-cycle of the sound wave can actually tear the fluid apart, creating spherical cavities within the fluid. The subsequent rapid collapse of these cavities during the compressional half-cycle of the sound wave can focus large amounts of energy into a very small volume, raising the temperature at the center of the collapse to thousands of degrees Kelvin, forming free radicals and even emitting electromagnetic radiation.[81] The concern over potential cavitation-induced bioeffects in diagnostic ultrasound has led to many experimental studies, many of them assessing whether the presence of contrast microbubbles can act as cavitation seeds, potentiating bioeffects.[82-87] This work has been reviewed by ter Haar[88] and by the World Federation for Ultrasound in Medicine and Biology.[89,90] Although it has been shown that adding contrast agents to blood decreases the threshold for cavitation and related bioeffects (e.g., hemolysis,

platelet lysis), no significant effects have been reported in conditions that are comparable to the bubble concentrations and ultrasound exposure of a low-MI diagnostic clinical examination. It nonetheless remains prudent to practice an extension of the ALARA (as low as reasonably achievable) exposure principle to contrast ultrasound. The contrast ultrasound examination should expose the patient to the lowest MI, the shortest total acoustic exposure time, the lowest contrast agent dose, and the highest ultrasound frequency consistent with obtaining adequate diagnostic information.

In the meantime, at least 8 million injections of microbubble contrast for clinical diagnosis have been performed worldwide; they are very well tolerated and have an excellent safety record. In fact, postmarketing surveillance has suggested that the predominant cause of severe adverse events is anaphylactic reaction, with an estimated rate of 1 per 7000 for both the perflutren microspheres approved for cardiac indications in the United States[91] and the sulfur hexafluoride microspheres approved in Europe.[92] This rate is comparable to that of most injectable analgesics and antibiotics and lower than that for other imaging contrast agents, such as those used in CT imaging.[93] A 2006 study of more than 23,000 injections of a microbubble contrast agent for abdominal diagnosis in Europe showed no deaths and two serious adverse events, giving a serious adverse event rate of less than 1 : 10,000.[92] Although FDA approval for radiologic indications has only just occurred in the United States, there is extensive experience with ultrasound contrast in echocardiography laboratories. In 2008 Kusnetzky and colleagues reviewed more than 18,671 hospitalized patients undergoing echocardiography in an acute setting in a single center and reported no effect on mortality from the use of contrast in this group.[94] In 2008 Main and colleagues[95] analyzed registry data from 4,300,966 patients who underwent transthoracic echocardiography at rest during hospitalization, of whom 58,254 were given the contrast agent Definity. Acute crude mortality was no different between groups, but multivariate analysis revealed that in patients undergoing echocardiography, those receiving the contrast agent were 24% less likely to die within 1 day than patients not receiving contrast. The FDA has since dropped its notice of caution when using microbubble agents in patients with severe cardiopulmonary compromise.[96-98] From the accumulated knowledge of the considerable benefits of using microbubble contrast, combined with the very low incidence of adverse events associated with its administration, it is fair to conclude this technique is ready to play a major role in the practice of ultrasound diagnosis.[99] We might speculate that in offering the 2016 approval for the use of microbubble contrast in the pediatric population (children were not part of the pivotal studies included in the submission dossier), the FDA is tacitly pointing to the additional benefit that may accrue from reducing the exposure of these patients to x-rays, as well as to CT and MRI contrast agents.

THE FUTURE

Development of microbubble technology is proceeding in two complementary areas: the instruments and the bubbles. In the first, the development of three-dimensional (3-D) and fast imaging for other applications will have a substantial impact on contrast studies. Ultrafast imaging using plane waves offers the opportunity to gain quantitative flow information from large vessels, using bubble-specific vector Doppler methods, at the same time as imaging perfusion. The separation of large vessel flow from tissue perfusion is a challenge to all contrast-enhanced modalities and is likely to be solved first by ultrasound. Although 3-D contrast images have been made using mechanically swept transducers, the slow acquisition rates mean that the dynamics of enhancement—a crucial diagnostic feature—are lost. Two-dimensional matrix arrays transducers, on the other hand, offer real-time volumetric contrast imaging. In one emerging application, they allow the response of a tumor. Considering the heterogeneity of tumor perfusion, the sampling of a single plane has been shown to be unreliable; real-time 3-D imaging solves this problem, allowing very large tumors to be evaluated rapidly[75] (Fig. 3.18).

In contrast imaging, the potential for functional information yielded by the bubbles can be increased by active targeting to a specific cellular or molecular process. Thus a bubble attaches itself to the cells lining blood vessels (endothelial cells) that are involved in a disease process such as inflammation (in atherosclerosis)[100] or proliferation (in cancer).[101] This is achieved by attaching ligands to the surface of the lipid shell, such as a peptide and an antibody.[102] Antibodies to factors such as vascular cell adhesion molecule (VCAM), a marker of inflammation, and vascular endothelial growth factor (VEGF) receptor 2, a marker of vascular proliferation, have already been shown to effectively make bubbles "stick" selectively to the endothelial surface[103] (Fig. 3.19). This form of molecular imaging has potential applications in identifying the target and assessing the effectiveness of new therapies,[104] with new agents under active clinical development.[105,106] In addition, the bubbles are used as a potentiator of the therapy itself. Bubbles can concentrate and lower the threshold for thermal tissue damage in high-intensity focused ultrasound (HIFU) treatments. They can also have the effect of opening or penetrating the endothelial layer, even the blood-brain barrier,[77] allowing drugs to pass through into a region of tissue selected by the ultrasound beam. The drugs can be circulating in the bloodstream, or incorporated into the bubbles themselves. In the latter case, plasmid DNA, which cannot survive in the blood, can be carried in the bubble shell and released by acoustic disruption.[107] Oscillation of the free gas near the cell membrane allows the DNA to enter the cell. Both endothelial cells and myocytes have been successfully transfected in this potentially new form of gene therapy.[108] Finally, the barrier of the endothelium itself can be overcome by injecting liquid nanodroplets—precursors of the gas contrast agents—allowing them to diffuse into the interstitium, and then using external acoustic energy to activate them into gas bodies, which are both targeted and detectable[109] and can be used to enhance therapy.[110]

The use of bubbles as molecular and cellular probes, their targeting as a means for detection as well as drug and gene delivery, and their application as focal potentiators for minimally invasive therapies are all applications in their infancy. The coming years are likely to see an unprecedented union of ultrasound

imaging with a unique series of injectable constructs that will propel an already versatile imaging modality to the forefront of the interface between diagnosis and therapy.

CONCLUSION

Microbubble contrast agents for ultrasound are safe, effective, and well tolerated by patients. They offer a clinically approved blood pool agent unique to radiological modalities. Unlike contrast agents for other modalities, microbubbles are physically modified by the process used to image them. Understanding the behavior of bubbles while exposed to an ultrasound imaging beam is the key to performing an effective contrast ultrasound examination. The appropriate choice of a contrast-specific imaging method is based on the behavior of the agent and the requirements of the examination. The MI is the major determinant of the response of contrast bubbles to ultrasound. Low-MI harmonic and multipulse imaging offer real-time, contrast-specific methods for perfusion imaging using perfluorocarbon agents. Future developments offer the intriguing prospect of molecular and cellular imaging, potentiated therapy, and drug and gene delivery, all with ultrasound and microbubbles.

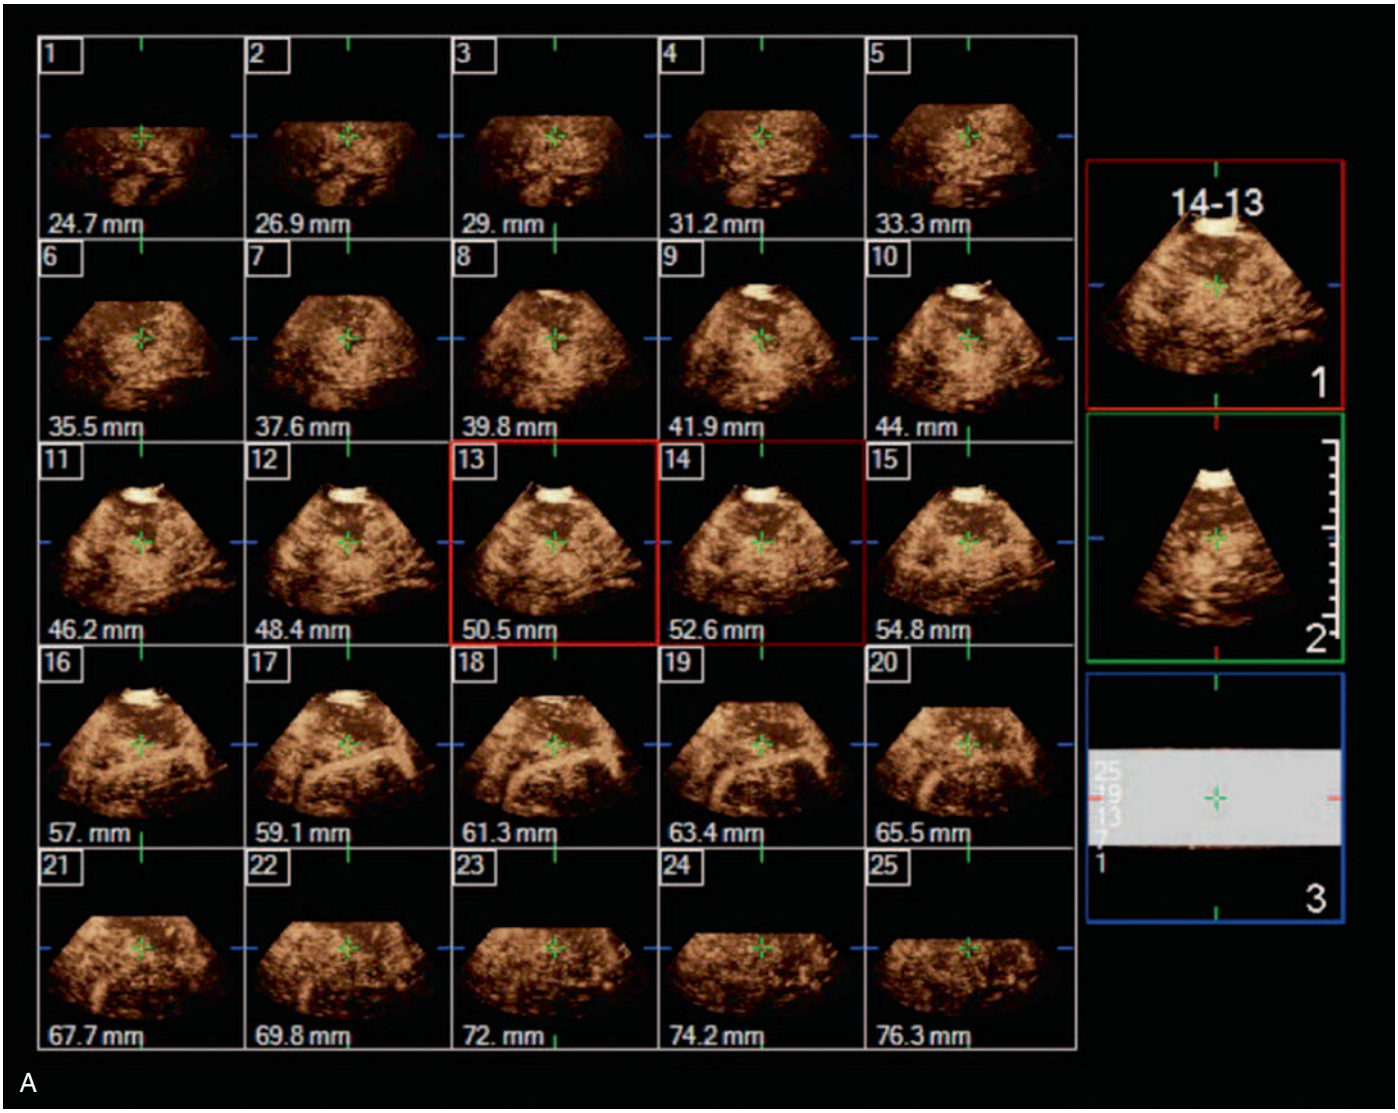

FIG. 3.18 Real-Time, Four-Dimensional Tumor Contrast Imaging Performed With a 9000-Element Ultrasound Array Transducer at a Harmonic Range of 2 to 4 MHz. Twenty-five pseudo-parallel 2.1-mm-spaced planes in a patient with renal cell carcinoma (about 5 × 5 × 8 cm) are imaged simultaneously with low–mechanical index contrast-specific imaging. **(A)** A single volume acquisition taken from a 10-Hz, 60-volume series after acoustic disruption of the microbubble agent during an intravenous infusion.

Continued

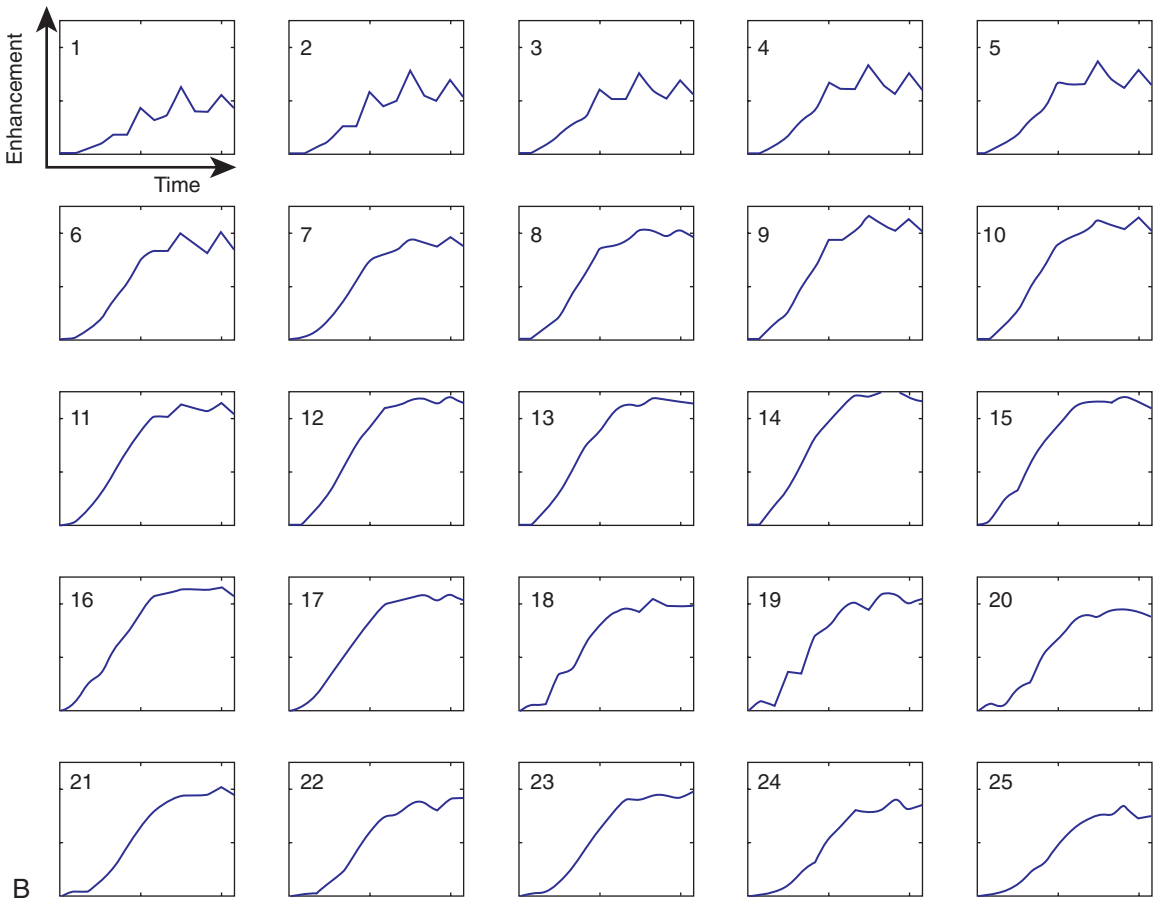

FIG. 3.18, cont'd **(B)** Time-intensity replenishment curves for each of the 25 slices, measured simultaneously. The total acquisition time is about 15 seconds; the contrast agent is Definity.

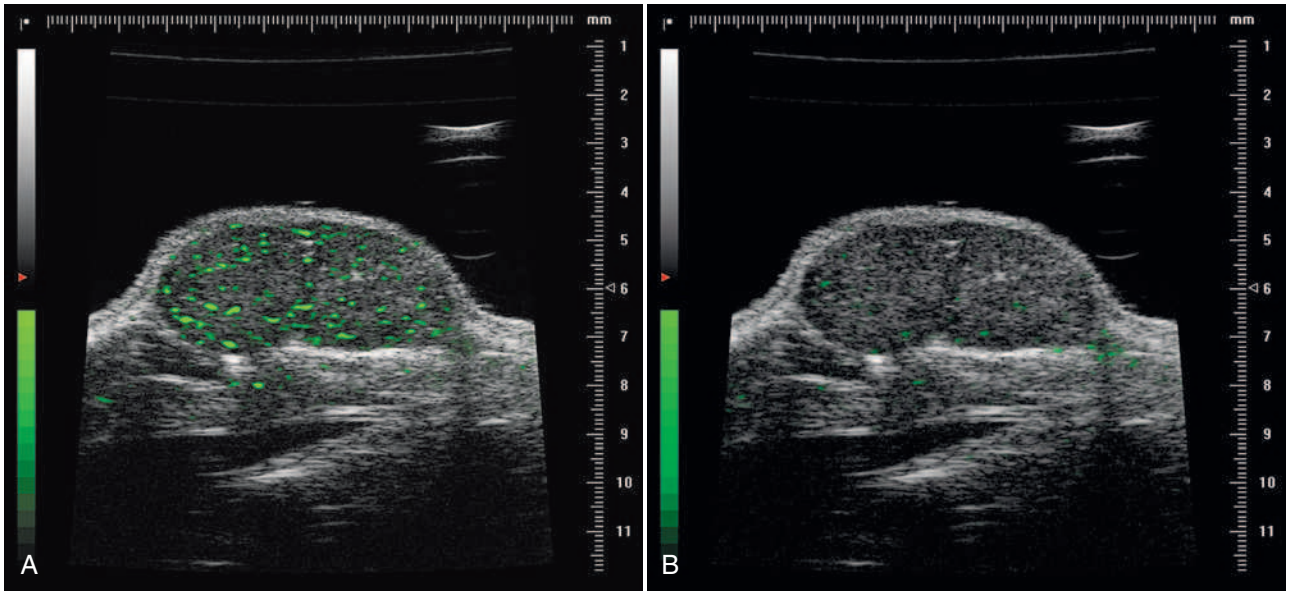

FIG. 3.19 Molecular Ultrasound Imaging of Vascular Endothelial Growth Factor Receptor 2 (VEGFR-2) With Targeted Microbubbles. Figure shows 40-MHz images of a MeWo subdermal tumor derived from human melanoma cells in a mouse after injection of VEGFR-2–targeted microbubbles. **(A)** Circulating bubbles have left the vascular system; those imaged are adhering to the receptor target. Microbubble-specific signal is shown as a green overlay. **(B)** After disruption flash, the bubble echoes disappear. The difference in bubble signal between these two images quantifies adhesion of the tracer to the target receptor. Scale units are millimeters. CHAPTER 4

The Liver

Stephanie R. Wilson and Cynthia E. Withers

SUMMARY OF KEY POINTS

- The liver is an ideal organ for sonographic evaluation based on its large size, homogeneous parenchyma, and location high in the abdomen with access provided from both a subcostal and an intercostal approach.
- Standard ultrasound with real-time gray-scale morphologic assessment and Doppler evaluation of the liver vasculature is augmented by newer techniques of contrast-enhanced ultrasound and elastography.
- Fatty liver is considered an epidemic in North America, and ultrasound is often the first test to suggest its presence and severity.
- Ultrasound performed at 6-month intervals is the recommended surveillance method for detection of nodules in the liver of those at risk for the development of hepatocellular carcinoma.
- Ultrasound is the method of choice for the guidance of interventional procedures performed on the liver, including ablation techniques in those with malignant tumors, biopsy of liver masses, and the insertion of therapeutic devices such as drainage tubes and transjugular intrahepatic portosystemic shunts.
- Intraoperative ultrasound of the liver allows for detection of previously unidentified tumors.

Acknowledgment

The liver is the largest organ in the human body, weighing approximately 1500 g in the adult. Because it is frequently involved in systemic and local disease, sonographic examination is often requested to assess hepatic abnormality.

SONOGRAPHIC TECHNIQUE

The liver is best examined with real-time sonography. Both supine and right anterior oblique positions should be used. Sagittal, transverse, coronal, and subcostal oblique views are suggested using both a standard abdominal transducer and a higher-frequency transducer. In many patients, the liver is tucked beneath the lower right ribs, so a transducer with a small scanning face, allowing an intercostal approach, is invaluable. Further, **volumetric imaging** contributes greatly to the evaluation of the liver as a single, appropriately selected acquisition may show virtually the entire liver, allowing for a rapid portrayal of liver anatomy, size, texture, and surface characteristics.[1] Therefore differentiation of the diffuse changes of cirrhosis and fatty liver from normal are enhanced by review of the videos (Videos 4.1 and 4.2) of the acquisitions as well as the multiplanar reconstructions (Fig. 4.1). Ultrasound also best demonstrates the relationship of focal liver masses to the vital vascular structures if surgical resection is contemplated.

NORMAL ANATOMY

The liver lies in the right upper quadrant of the abdomen. Functionally, it can be divided into three lobes: right, left, and caudate. The **right lobe** of the liver is separated from the left by the **main lobar fissure,** which passes through the gallbladder fossa to the **inferior vena cava** (IVC) (Fig. 4.2). The right lobe of the liver can be further divided into anterior and posterior segments by the **right intersegmental fissure.** The **left intersegmental fissure** divides the **left lobe** into medial and lateral segments. The **caudate lobe** is situated on the posterior aspect of the liver, with the IVC as its posterior border and the fissure for the ligamentum venosum as its anterior border (Fig. 4.3). The **papillary process** is the anteromedial extension of the caudate

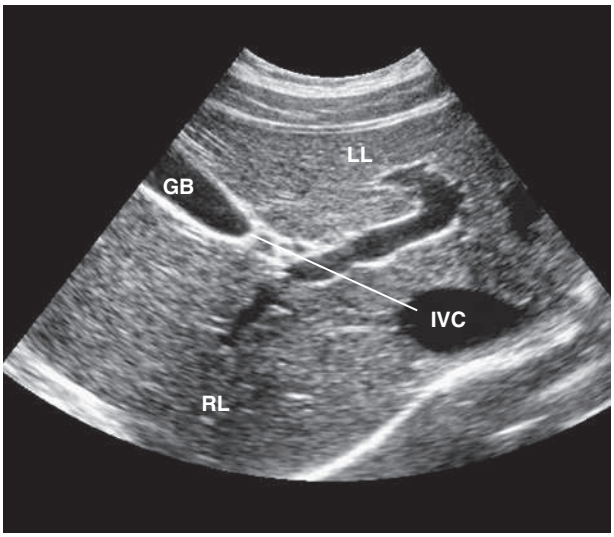

FIG. 4.2 Normal Lobar Anatomy. Right lobe of the liver *(RL)* can be separated from left lobe of the liver *(LL)* by the main lobar fissure that passes through the gallbladder fossa *(GB)* and inferior vena cava *(IVC)*.

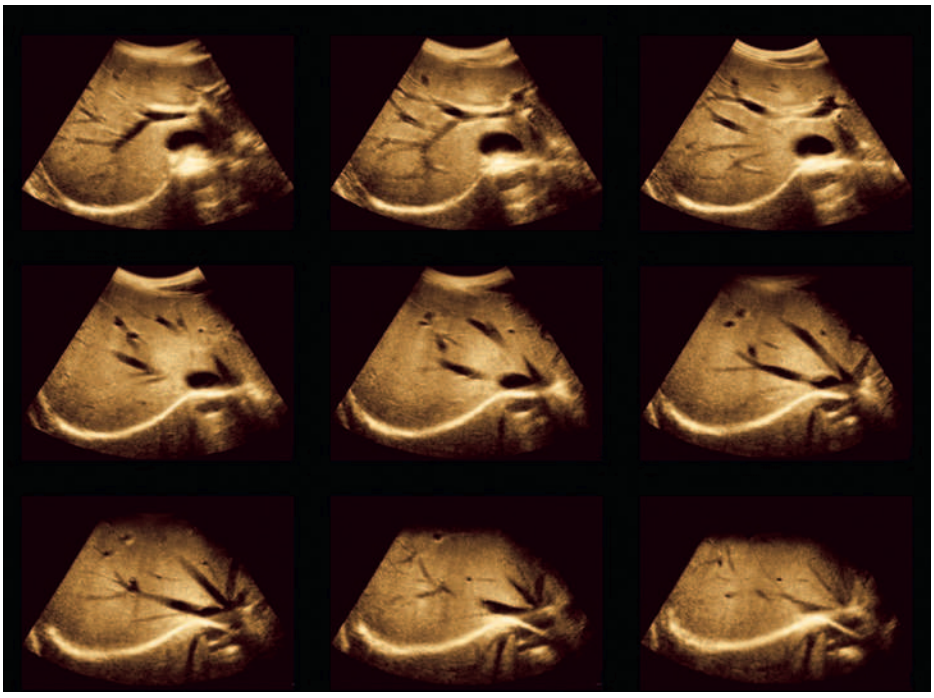

FIG. 4.1 Normal Liver. Liver shown in a nine-on-one format from a volumetric acquisition acquired in the axial plane, with the center point on the long axis of the portal veins at the porta hepatis.

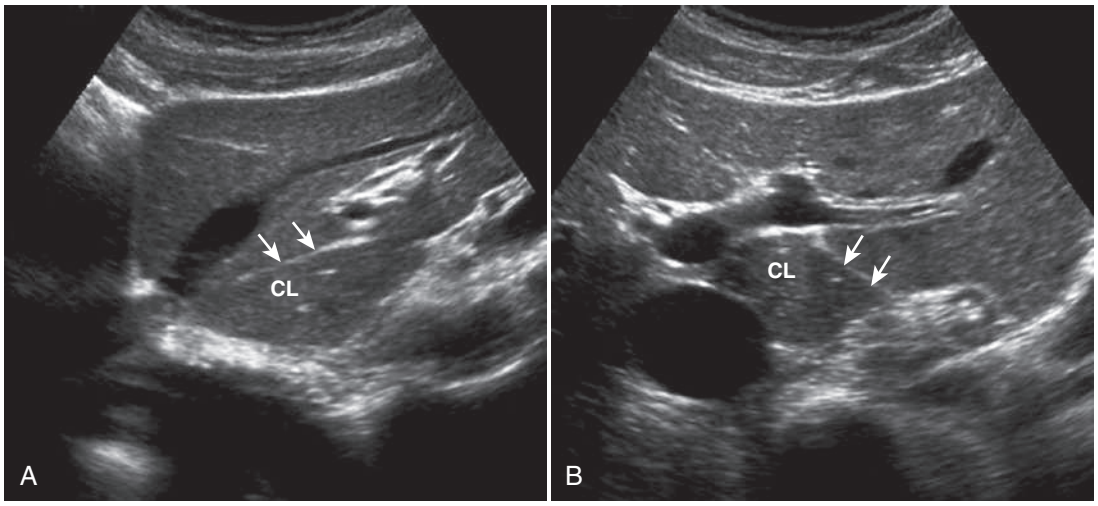

FIG. 4.3 Caudate Lobe. (A) Sagittal view and **(B)** transverse view show the caudate lobe *(CL)* separated from the left lobe by the fissure for the ligamentum venosum *(arrows)* anteriorly. Posterior is the inferior vena cava.

FIG. 4.4 Hepatic Venous Anatomy. The three hepatic veins—right *(RHV)*, middle *(MHV)*, and left *(LHV)*—are interlobar and intersegmental, separating the lobes and segments. At the level of the hepatic venous confluence with the inferior vena cava, the right hepatic vein separates the right posterior segment (segment 7) from the right anterior segment (segment 8). The left hepatic vein separates the left medial segment from the left lateral segment. The middle hepatic vein separates the right and left lobes. As shown here, the hepatic veins are best seen on a subcostal oblique view.

lobe, which may appear separate from the liver and mimic lymphadenopathy.

Understanding the vascular anatomy of the liver is essential to an appreciation of the relative positions of the hepatic segments. The major **hepatic veins** course between the lobes and segments (interlobar and intersegmental). They are ideal segmental boundaries but are visualized only when scanning the superior liver (Fig. 4.4). The **middle hepatic vein** courses within the main lobar fissure and separates the anterior segment of the right lobe from the medial segment of the left. The **right hepatic vein** runs within the right intersegmental fissure and divides the right lobe into anterior and posterior segments. In more caudal sections of the liver, the right hepatic vein is no longer identified; therefore the segmental boundary becomes a poorly defined division between the anterior and posterior branches of the right portal vein. The major branches of the right and left **portal veins** run centrally within the segments **(intrasegmental),** with the exception of the ascending portion of the left portal vein, which runs in the left intersegmental fissure. The left intersegmental fissure, which separates the medial segment of the left lobe from the lateral segment, can be divided into cranial, middle, and caudal sections. The **left hepatic vein** forms the boundary of the cranial third, the ascending branch of the left portal vein represents the middle third, and the fissure for the ligamentum teres acts as the most caudal division of the left lobe (Table 4.1).[2]

Couinaud Anatomy

Because sonography allows evaluation of liver anatomy in multiple planes, lesions can be localized to specific segments. This can aid surgical planning and follow-up of lesions over time. **Couinaud anatomy** is now the universal nomenclature for hepatic lesion localization (Table 4.2).[3] This description is based on **portal segments** and is of both **functional** and **pathologic** importance. Each segment has its own blood supply (arterial, portal venous, and hepatic venous), lymphatics, and biliary drainage. Thus the surgeon may resect a segment of a hepatic lobe, providing the vascular supply to the remaining lobe is left intact. Each segment has a branch or branches of the portal vein at its center, bounded by a hepatic vein. There are **eight segments.** The right, middle, and left hepatic veins divide the liver longitudinally into four sections. Each of these sections is further divided transversely by an imaginary plane through the right main and left main portal pedicles. **Segment I** is the caudate lobe, **segments II and III** are the left superior and inferior lateral segments, respectively, and **segment IV,** which is further divided into IVa and IVb, is

TABLE 4.1 Structures Useful for Identifying Hepatic Segments

Structure	Location	Usefulness
Right hepatic vein	Right intersegmental fissure	Divides cephalic aspect of anterior and posterior segments of right lobe
Middle hepatic vein	Main lobar fissure	Separates right and left lobes
Left hepatic vein	Left intersegmental fissure	Divides cephalic aspect of medial and lateral segments of left lobe
Right portal vein (RPV) (anterior branch)	Intrasegmental in anterior segment of right lobe	Courses centrally in anterior segment of right lobe
RPV (posterior branch)	Intrasegmental in posterior segment of right lobe	Courses centrally in posterior segment of right lobe
Left portal vein (LPV) (horizontal segment)	Anterior to caudate lobe	Separates caudate lobe posteriorly from medial segment of left lobe anteriorly
LPV (ascending segment)	Left intersegmental fissure	Divides medial from lateral segment of left lobe
Gallbladder fossa	Main lobar fissure	Separates right and left lobes
Fissure for ligamentum teres	Left intersegmental fissure	Divides caudal aspect of left lobe into medial and lateral segments
Fissure for ligamentum venosum	Left anterior margin of caudate lobe	Separates caudate lobe posteriorly from left lobe anteriorly

Modified from Marks W, Filly R, Callen P. Ultrasonic anatomy of the liver: a review with new applications. J Clin Ultrasound. 1979;7(2):137-146.[2]

TABLE 4.2 Couinaud Segments and Traditional Hepatic Anatomy

Couinaud	Traditional
Segment I	Caudate lobe
Segment II	Lateral segment left lobe (superior)
Segment III	Lateral segment left lobe (inferior)
Segment IV	Medial segment left lobe
Segment V	Anterior segment right lobe (inferior)
Segment VI	Posterior segment right lobe (inferior)
Segment VII	Posterior segment right lobe (superior)
Segment VIII	Anterior segment right lobe (superior)

the medial segment of the left lobe. The right lobe consists of **segments V and VI,** located caudal to the transverse plane, and **segments VII and VIII,** which are cephalad[4,5] (Fig. 4.5). The caudate lobe (segment I) may receive branches of both the right and the left portal vein. In contrast to the other segments, segment I has one or several hepatic veins that drain directly into the IVC.

The portal venous supply for the left lobe can be visualized using an oblique, cranially angled subxiphoid view. A "recumbent H" is formed by the main left portal vein, the ascending branch of the left portal vein, and the branches to segments II, III, and IV[6] (Fig. 4.6). Segments II and III are separated from segment IV by the left hepatic vein, as well as by the ascending branch of the left portal vein and the falciform ligament. Segment IV is separated from segments V and VIII by the middle hepatic vein and the main hepatic fissure.

The portal venous supply to the right lobe of the liver can also be seen as a recumbent H. The main right portal vein gives rise to branches that supply segments V and VI (inferiorly) and VII and VIII (superiorly). They are seen best in a sagittal or oblique sagittal plane.[6]

The oblique subxiphoid view shows the right portal vein in cross section and enables identification of the more superiorly located segment VIII (closer to confluence of hepatic veins) from segment V. Segments V and VIII are separated from segments VI and VII by the right hepatic vein.[6]

Ligaments

The liver is covered by a thin connective tissue layer called **Glisson capsule.** The capsule surrounds the entire liver and is thickest around the IVC and the porta hepatis. At the porta hepatis, the main portal vein, the proper hepatic artery, and the common bile duct are contained within investing peritoneal folds known as the **hepatoduodenal ligament** (Fig. 4.7). The **falciform ligament** conducts the umbilical vein to the liver during fetal development (Fig. 4.8). After birth, the umbilical vein atrophies, forming the **ligamentum teres** (Fig. 4.9). As the falciform ligament reaches the liver, its leaves separate. The right layer forms the upper layer of the coronary ligament; the left layer forms the upper layer of the left triangular ligament. The most lateral portion of the coronary ligament is known as the right triangular ligament (Fig. 4.10). The peritoneal layers that form the coronary ligament are widely separated, leaving an area of the liver not covered by peritoneum. This posterosuperior region is known as the **bare area** of the liver. The **ligamentum venosum** carries the obliterated ductus venosus, which until birth shunts blood from the umbilical vein to the IVC.

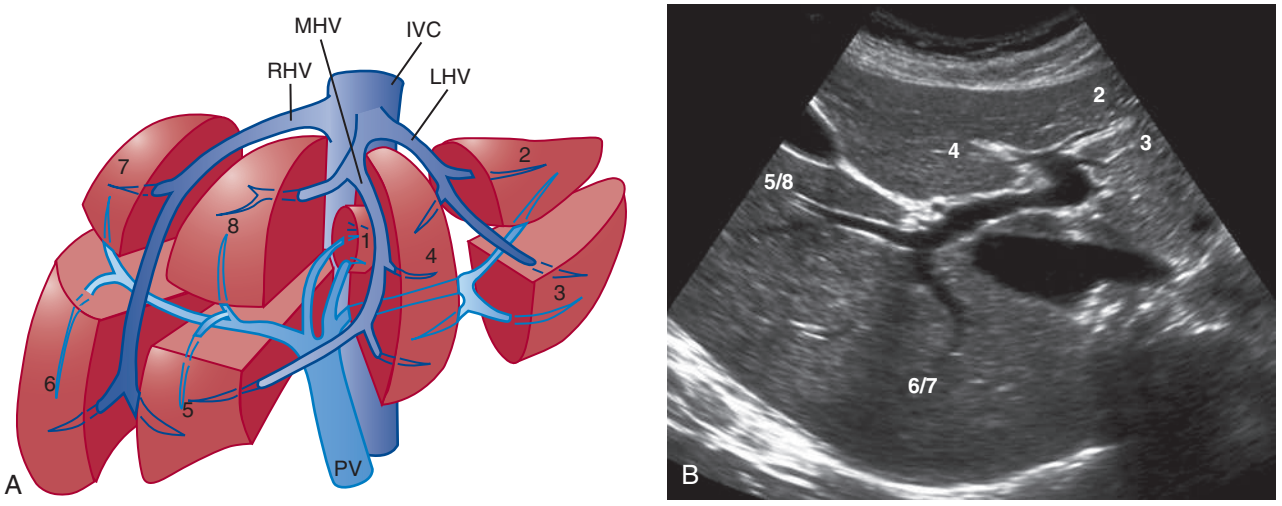

FIG. 4.5 Couinaud Functional Segmental Anatomy. (A) The liver is divided into nine segments. Blue longitudinal boundaries (right, middle, and left scissurae) are three hepatic veins. Transverse plane is defined by right main and left main portal pedicles. Segment I, caudate lobe, is situated posteriorly. **(B)** Corresponding sonogram shows the main portal vein with its right and left branches. The plane through the right and left branches is the transverse separation of the liver segments. Cephalad to this level lie segments II, IVa, VII, and VIII. Caudally located are segments III, IVb, V, and VI. *GB,* Gallbladder; *LHV,* left hepatic vein; *LPV,* left portal vein; *MHV,* middle hepatic vein; *RHV,* right hepatic vein; *RPV,* right portal vein. (With permission from Sugarbaker PH: Toward a standard of nomenclature for surgical anatomy of the liver. Neth J Surg. 1988;PO:100.[5])

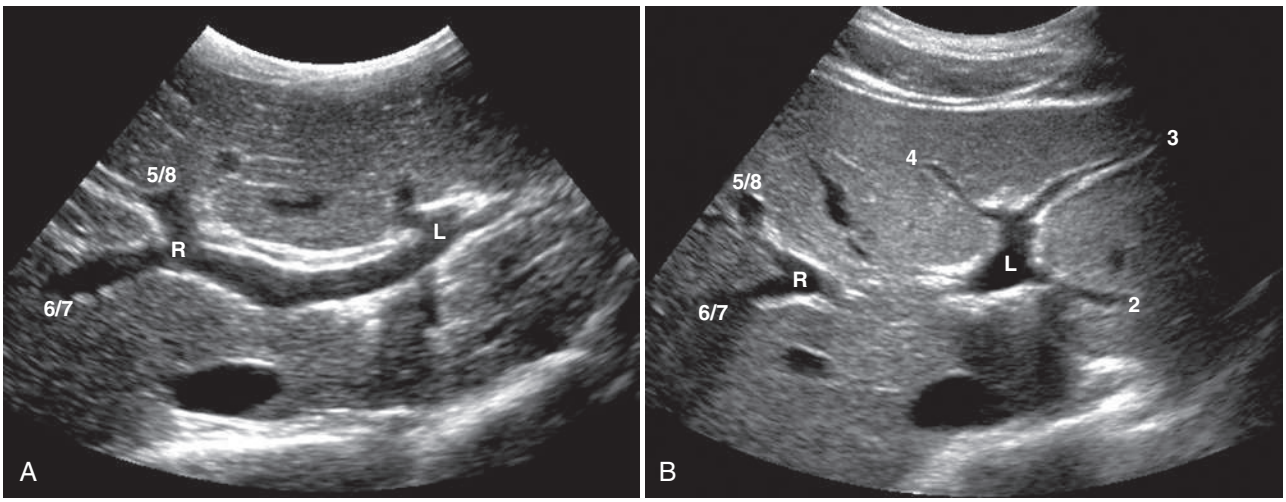

FIG. 4.6 Portal Venous Anatomy in Two Patients. (A) Best seen with a subcostal oblique view, the main portal vein is formed by the union of the right and left portal venous branches at the porta hepatis. **(B)** Segmental branches of the right and left portal veins are marked. Well seen is the recumbent-H shape of the left portal venous bifurcation, made from the ascending and horizontal left portal vein and the segmental branches to 2, 3, and 4.

Hepatic Circulation

Portal Veins

The liver receives a **dual blood supply** from both the portal vein and the hepatic artery. Although the portal vein carries incompletely oxygenated (80%) venous blood from the intestines and spleen, it supplies up to half the oxygen requirements of the hepatocytes because of its greater flow. This dual blood supply explains the low incidence of hepatic infarction.

The **portal triad** contains a branch of the portal vein, hepatic artery, and bile duct. These are contained within a connective tissue sheath that gives the portal vein an echogenic wall on sonography and that distinguishes it from the hepatic veins, which have an almost imperceptible wall. The **main portal vein** divides into right and left branches. The **right portal vein** has an anterior branch that lies centrally within the anterior segment of the right lobe and a posterior branch that lies centrally within the posterior segment of the right lobe. The **left portal vein** initially courses anterior to the caudate lobe. The ascending branch of the left portal vein then travels anteriorly in the left intersegmental fissure to divide the medial and lateral segments of the left lobe.

Arterial Circulation

The branches of the **hepatic artery** accompany the portal veins. The terminal branches of the portal vein and their accompanying hepatic arterioles and bile ducts are known as the **acinus.**

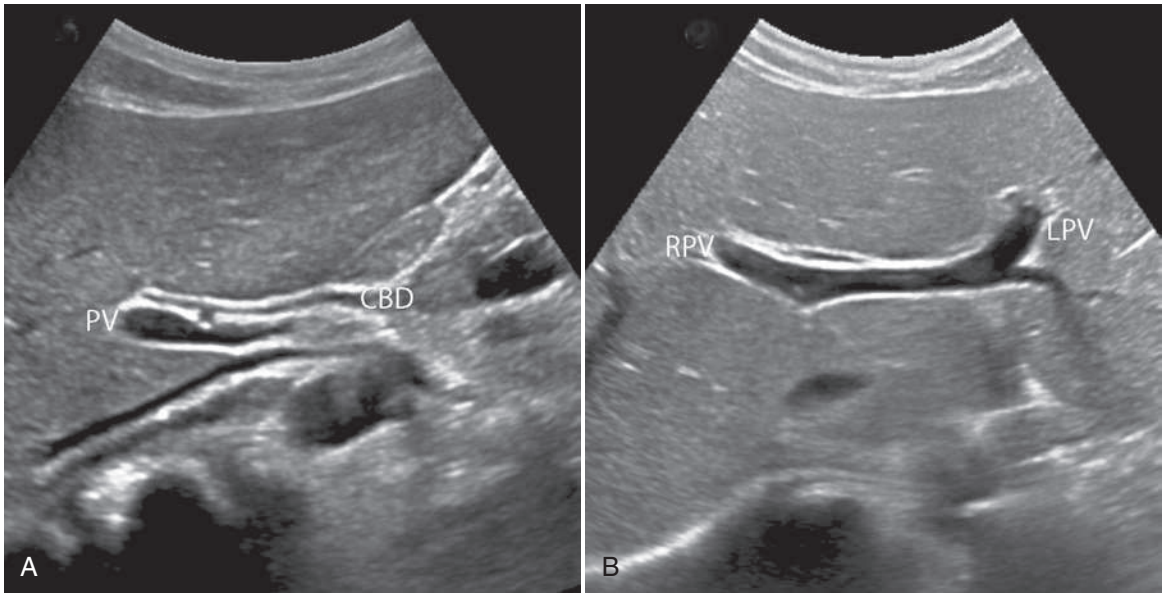

FIG. 4.7 Porta Hepatis. (A) Sagittal image of the porta hepatis shows the common bile duct *(CBD)* and main portal vein *(PV)*, which are enclosed within the hepatoduodenal ligament. **(B)** Transverse image of the porta hepatis shows the right *(RPV)* and left portal vein *(LPV)* branches.

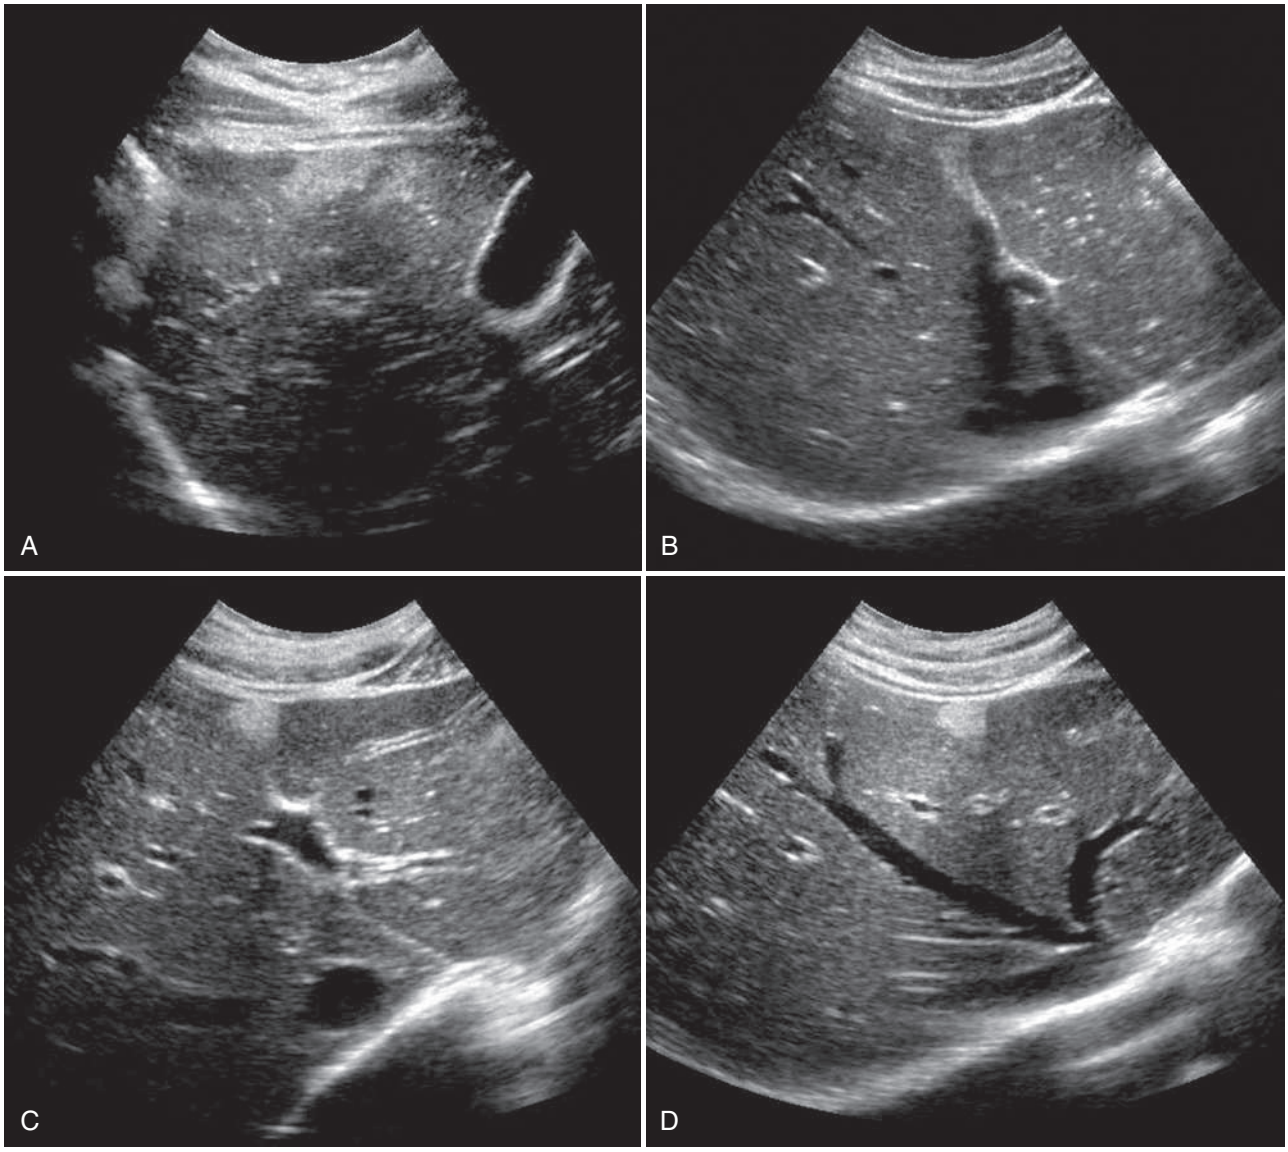

FIG. 4.8 Falciform Ligament. Contained fat helps in its localization. **(A)** Sagittal image through falciform ligament. **(B)** Subcostal oblique view of falciform ligament. **(C)** Location of the fat just anterior to the ascending branch of the left ascending portal vein branch. **(D)** Cephalad extent of the fat in the location of the ligament between the middle and the left hepatic veins.

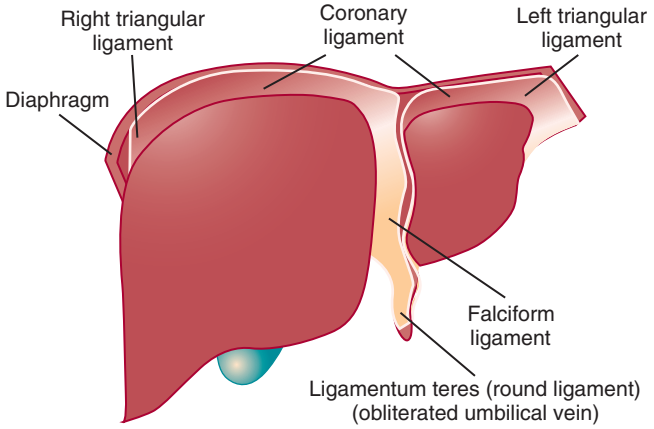

FIG. 4.9 Hepatic Ligaments. Diagram of anterior surface of the liver.

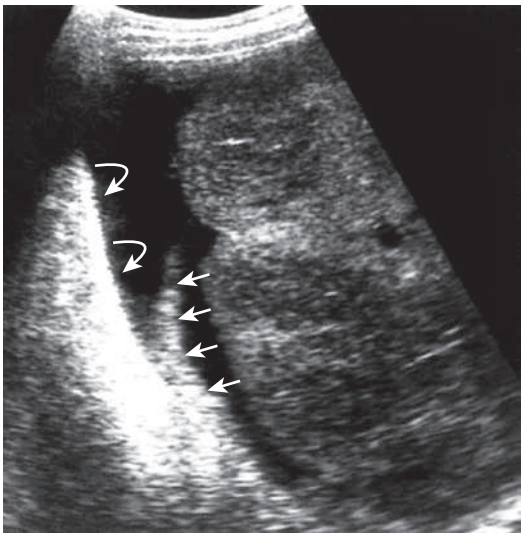

FIG. 4.10 Right Triangular Ligament. Subcostal oblique scan near dome of right hemidiaphragm *(curved arrows)*. Note lobulated contour and inhomogeneity of liver in this patient with cirrhosis. Right triangular ligament *(straight arrows)* is visualized because of ascites.

Hepatic Venous System

Blood perfuses the liver parenchyma through the sinusoids and then enters the terminal hepatic venules. These terminal branches unite to form sequentially larger veins. The hepatic veins vary in number and position. However, in the general population, there are three major veins: the right, middle, and left hepatic veins (see Fig. 4.4). All drain into the IVC and, as with the portal veins, are without valves. As discussed earlier, the right hepatic vein is usually single and runs in the right intersegmental fissure, separating the anterior and posterior segments of the right lobe. The middle hepatic vein, which courses in the main lobar fissure, forms a common trunk with the left hepatic vein in most cases. The left hepatic vein forms the most cephalad boundary between the medial and lateral segments of the left lobe.

Normal Liver Size and Echogenicity

The upper border of the liver lies approximately at the level of the fifth intercostal space at the midclavicular line. The lower border extends to or slightly below the costal margin. An accurate assessment of **liver size** is difficult with real-time ultrasound equipment because of the limited field of view. Gosink and Leymaster[7] proposed measuring the liver length in the midhepatic line. In 75% of patients with a liver length of greater than 15.5 cm, hepatomegaly is present. Niederau et al.[8] measured the liver in a longitudinal and anteroposterior diameter in both the midclavicular line and the midline and correlated these findings with gender, age, height, weight, and body surface area. They found that organ size increases with height and body surface area and decreases with age. The **mean longitudinal diameter** of the liver in the midclavicular line in this study was 10.5 cm, with standard deviation (SD) of 1.5 cm, and the mean midclavicular anteroposterior diameter was 8.1 cm (SD 1.9 cm). In most patients, measurement of the liver length suffices to measure liver size. **Riedel lobe** is a tonguelike extension of the inferior tip of the right lobe of the liver, frequently found in asthenic women.

The normal liver is homogeneous, contains fine-level echoes, and is either minimally hyperechoic or isoechoic compared to the normal renal cortex (Fig. 4.11A). The liver is hypoechoic compared to the spleen. This relationship is evident when the lateral segment of the left lobe is elongated and wraps around the spleen (Fig. 4.11B).

DEVELOPMENTAL ANOMALIES

Agenesis

Agenesis of the liver is incompatible with life. Agenesis of either right or left lobes has been reported.[9,10] In three of five reported cases of agenesis of the right lobe, the caudate lobe was also absent.[9] Compensatory hypertrophy of the remaining lobes normally occurs, and results of liver function tests (LFTs) are normal.

Anomalies of Position

In **situs inversus totalis (viscerum),** the liver is found in the left hypochondrium. In congenital **diaphragmatic hernia** or **omphalocele,** varying amounts of liver may herniate into the thorax or outside the abdominal cavity.

Accessory Fissures

Although invaginations of the dome of the diaphragm have been called "accessory fissures," these are not true fissures but rather **diaphragmatic slips.** They are a cause of pseudomasses on sonography if the liver is not carefully examined in both sagittal and transverse planes (Fig. 4.12). *True* accessory fissures are uncommon and are caused by an infolding of peritoneum. The inferior accessory hepatic fissure is a true accessory fissure that stretches inferiorly from the right portal vein to the inferior surface of the right lobe of the liver.[11]

Vascular Anomalies

The **common hepatic artery** arises from the celiac axis and divides into right and left branches at the porta hepatis. This classic textbook description of the hepatic arterial anatomy occurs

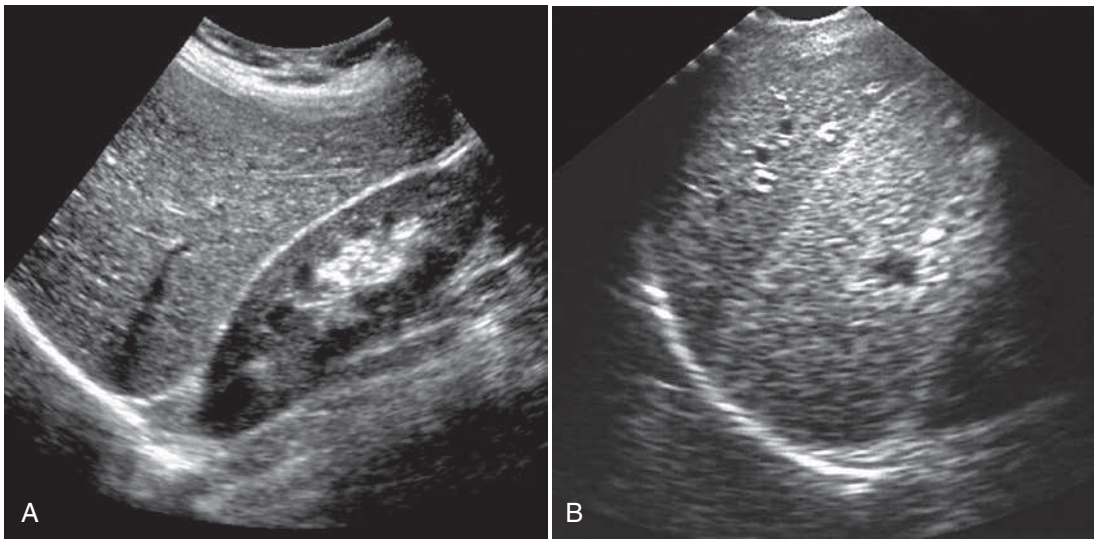

FIG. 4.11 Normal Liver Echogenicity. (A) The liver is more echogenic than the renal cortex. **(B)** The liver is less echogenic than the spleen, as seen in many thin women, whose left lobe of the liver wraps around the spleen.

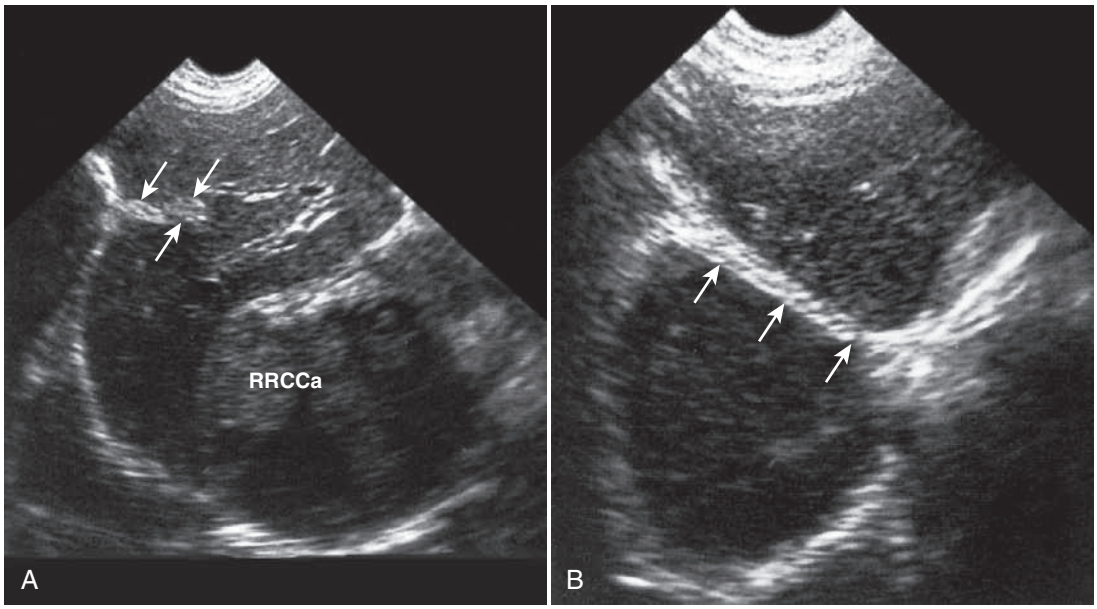

FIG. 4.12 Diaphragmatic Slip. (A) Sagittal sonogram shows echogenic mass *(arrows)* adjacent to right hemidiaphragm in this patient with right **renal cell carcinoma** *(RRCCa)*. **(B)** Subcostal oblique image reveals mass is diaphragmatic slip *(arrows)*.

in only 55% of the population. The remaining 45% have some variation of this anatomy, the main patterns of which are (1) replaced left hepatic artery originating from the left gastric artery (10%), (2) replaced right hepatic artery originating from the superior mesenteric artery (11%), and (3) replaced common hepatic artery originating from the superior mesenteric artery (2.5%).

Congenital portal vein anomalies include atresias, strictures, and obstructing valves, all of which are uncommon. Other variations of anatomy include absence of the right portal vein, with anomalies of branching from the main and left portal veins, and absence of the horizontal segment of the left portal vein.[12]

In contrast, variations in the branching of the hepatic veins and accessory hepatic veins are relatively common. The most common accessory vein drains the superoanterior segment of the right lobe (segment VIII) and is seen in approximately one-third of the population. It usually empties into the middle hepatic vein, although occasionally it joins the right hepatic vein.[13] An inferior right hepatic vein, which drains the inferoposterior portion of the liver (segment VI), is observed in 10% of individuals. This inferior right hepatic vein drains directly into the IVC and may be as large as the right hepatic vein or larger.[14] Left and right marginal veins, which drain into the left and right hepatic veins, occur in about 12% and 3% of individuals, respectively.

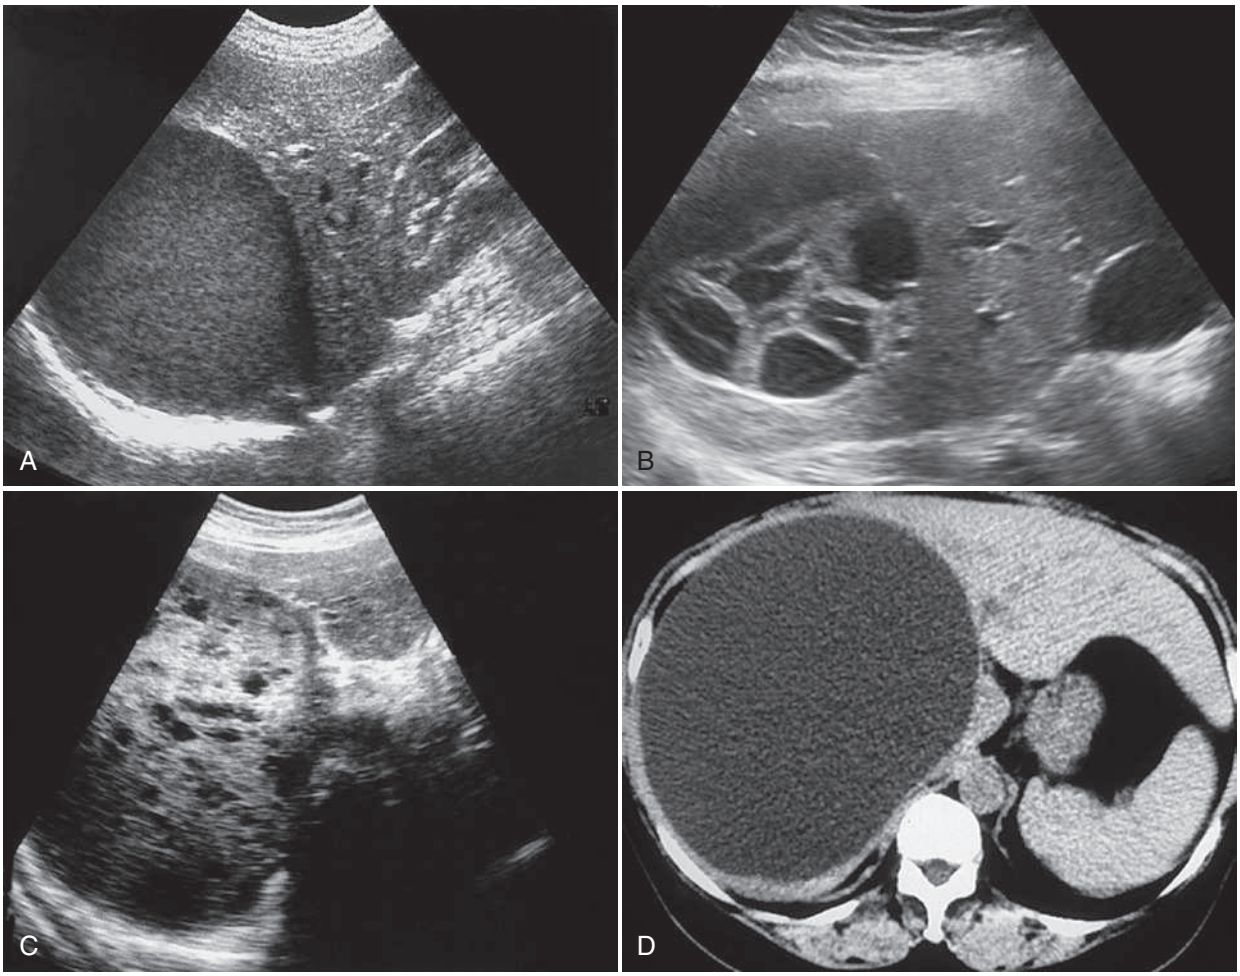

FIG. 4.13 Liver Cysts Complicated by Hemorrhage in Three Patients. **(A)** Patient presented with acute right upper quadrant pain. Ultrasound shows a thin-walled liver cyst filled with uniform low-level echogenicity consistent with blood products within the cyst. **(B)** This liver cyst shows thick internal septations (which were not vascular), consistent with organized thrombus. **(C)** and **(D)** Patient on ultrasound and on computed tomography (CT) scan. The cyst appears virtually solid on ultrasound because of organized clot, but there is enhanced through transmission. On CT, the cyst appears more homogenous.

Absence of the main hepatic veins is relatively less common, occurring in about 8% of people.[14] Awareness of the normal variations of the hepatic venous system is helpful in accurately defining the location of focal liver lesions and aids the surgeon in segmental liver resection.

CONGENITAL ABNORMALITIES

Liver Cyst

A liver cyst is defined as a fluid-filled space with an epithelial lining. Abscesses, parasitic cysts, and posttraumatic cysts therefore are not *true* cysts. The frequent presence of columnar epithelium within simple hepatic cysts suggests they have a ductal origin, although their precise cause is unclear. Their presentation at middle age is also unclear. Sonographically visualized liver cysts occur in 2.5% of the general population, increasing to 7% in the population older than 80 years.[15]

On sonographic examination, **benign hepatic cysts** are anechoic with a thin, well-demarcated wall and posterior acoustic enhancement. Occasionally, the patient may develop pain and fever secondary to cyst hemorrhage or infection. In these patients the cyst may contain internal echoes and septations (Fig. 4.13A and B), may have a thickened wall, or may appear solid (see Fig. 4.13C). Active intervention is recommended only in symptomatic patients. Although aspiration will yield fluid for evaluation, the cyst with an epithelial lining will recur. Cyst ablation with alcohol can be performed using ultrasound guidance.[16] If thick septae or nodules are seen within liver cysts, computed tomography (CT) or contrast-enhanced ultrasound is recommended because **biliary cystadenomas** and **cystic metastases** must be considered in the differential diagnosis of complex-appearing liver cysts (Fig. 4.14).

Peribiliary Cysts

Peribiliary cysts have been described in patients with severe liver disease.[17] These cysts are small, 0.2 to 2.5 cm, and are usually located centrally within the porta hepatis or at the junction of the main right and left hepatic ducts. They generally are asymptomatic but in rare cases can cause biliary obstruction.[17]

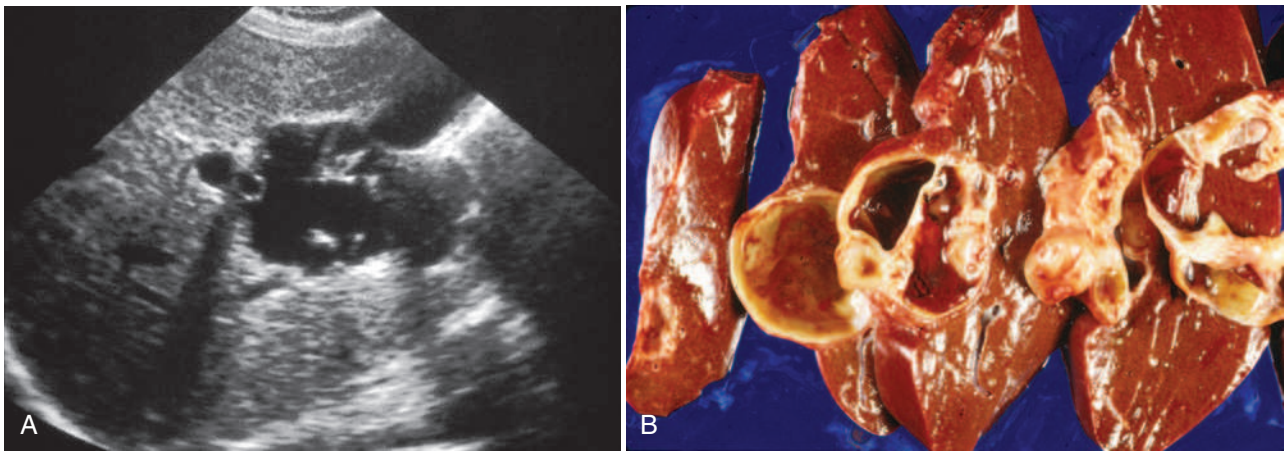

FIG. 4.14 Biliary Cystadenoma. (A) Sagittal sonogram shows irregular liver cyst with thick septa and mural nodules. **(B)** Surgical specimen.

Pathologically, peribiliary cysts are believed to represent small, obstructed periductal glands. Sonographically, they may be seen as discrete, clustered cysts or as tubular-appearing structures with thin septae, paralleling the bile ducts and portal veins.

Autosomal Dominant Polycystic Disease

Autosomal dominant polycystic kidney disease has liver cysts in 57% to 74% of patients.[18] No correlation exists between the severity of the renal disease and the extent of liver involvement. Results of LFTs are usually normal and, unlike the autosomal recessive form of polycystic kidney disease, there is no association with hepatic fibrosis or portal hypertension. Indeed, if LFT results are abnormal, complications of polycystic liver disease, such as tumor, cyst infection, and biliary obstruction, should be excluded.[18]

Biliary Hamartomas (von Meyenburg Complexes)

Bile duct hamartomas, first described by von Meyenburg in 1918, are small, focal developmental lesions of the liver composed of groups of dilated intrahepatic bile ducts set within a dense collagenous stroma.[19] These benign liver malformations are detected incidentally in 0.6% to 5.6% of autopsy series.[20]

Imaging features of von Meyenburg complexes (VMCs)[21] include single, multiple, or, most often, innumerable well-defined solid nodules usually less than 1 cm in diameter (Fig. 4.15). Nodules are usually uniformly hypoechoic[21] and less frequently hyperechoic on sonography[22,23] and hypodense on contrast-enhanced computed tomography (CECT) scan. Because of their multiplicity they can be confused with metastatic cancer. Bright echogenic foci in the liver with distal comet tail artifact without obvious mass effect are key sonographic findings (Fig. 4.16). We believe that these echogenic foci could be related to the presence of tiny cysts beyond the resolution of the ultrasound equipment. VMCs are usually isolated, insignificant observations and may occur with other congenital disorders, such as congenital hepatic fibrosis and polycystic kidney or liver disease.[20] Association of VMCs with cholangiocarcinoma has been suggested.[24]

FIG. 4.15 Von Meyenburg Complex in Cancer Patient. Sonogram shows a single, small, hypoechoic liver mass. With no other evidence of metastatic disease, a biopsy was performed and proved the benign, insignificant nature of this lesion.

INFECTIOUS DISEASES

Viral Hepatitis

Viral hepatitis is a common disease that occurs worldwide. It is responsible for millions of deaths secondary to acute hepatic necrosis or chronic hepatitis, which in turn may lead to portal hypertension, cirrhosis, and hepatocellular carcinoma (HCC). There are five distinct hepatitis viruses: hepatitis A through E. Other viruses cause hepatitis, but these are the classically characterized ones.

Hepatitis A occurs throughout the world and can be diagnosed using serosurveys with the antibody to hepatitis A virus (anti-HAV) as the marker. The primary mode of spread is the fecal-oral route. In developing countries the disease is endemic and infection occurs early in life. Hepatitis A is an acute infection leading to complete recovery or death from acute liver failure.

Hepatitis B is transmitted parenterally (e.g., blood transfusions, needle punctures) as well as by nonpercutaneous exposure through

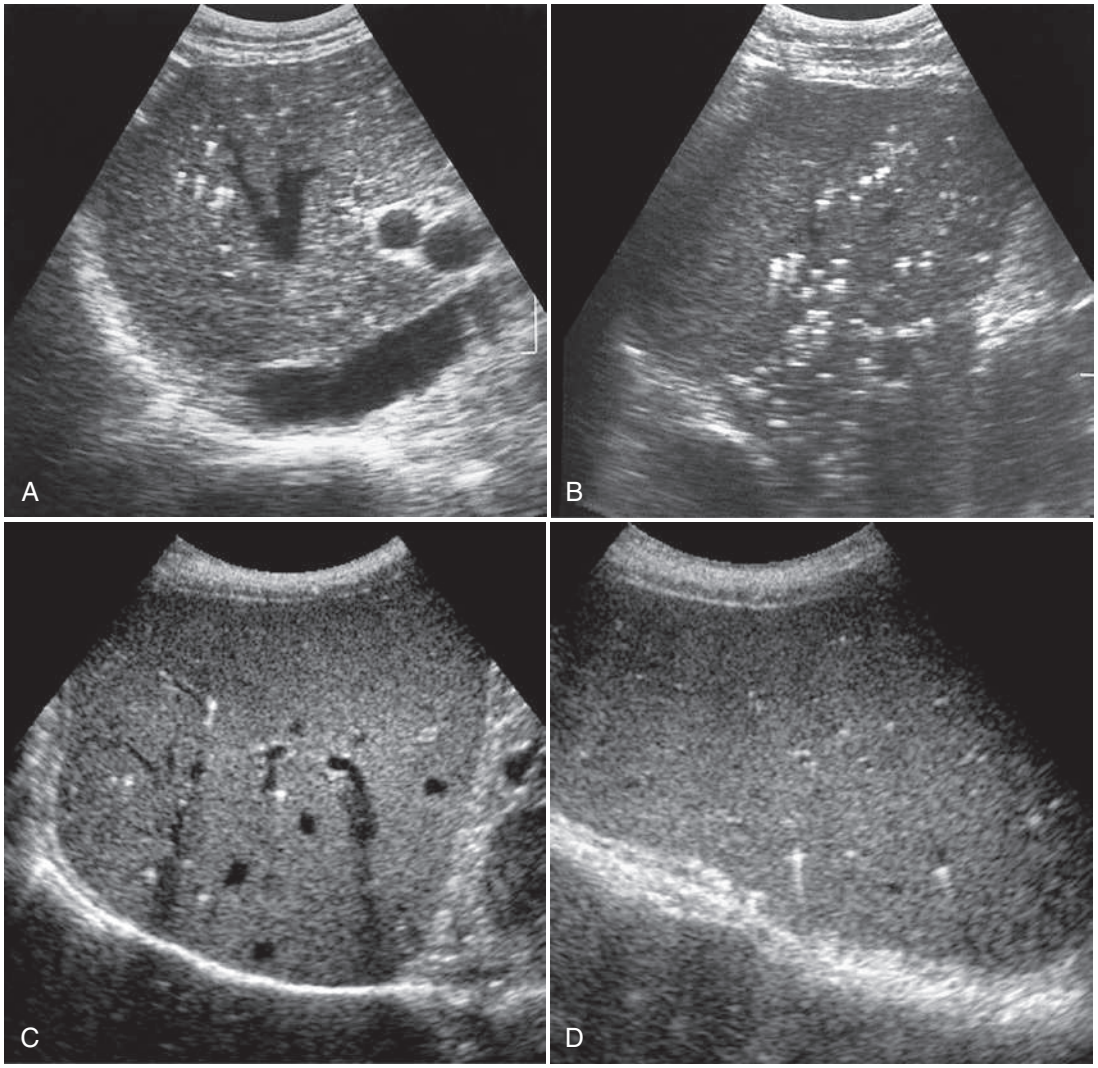

FIG. 4.16 Von Meyenburg Complex (VMC) Comet Tail Artifacts in Two Patients. **(A)** Sagittal and **(B)** transverse images of the left lobe of the liver show multiple bright echogenic foci with comet tail artifact. Biopsy showed VMC. **(C)** Sagittal and **(D)** transverse images of the right lobe in an asymptomatic patient show echogenic foci with distal comet tail artifact.

sexual contact and at birth. Hepatitis B virus (HBV), unlike HAV, has a carrier state, which is estimated worldwide at 300 million. The regions of highest carrier rates (5%-20%) are Southeast Asia, China, sub-Saharan Africa, and Greenland. The two most useful markers for acute infection are hepatitis B surface antigen (HBsAg) and antibody to hepatitis B core antigen (anti-HBc).

Hepatitis C is associated with posttransfusion hepatitis and is commonly identified in those who share needles or other equipment to inject drugs. Acutely infected patients have a much greater risk of chronic infection, with up to 85% progressing to chronic liver disease. Chronic hepatitis C virus (HCV) infection is diagnosed by the presence of antibody to HCV (anti-HCV) in the blood. Hepatitis C is a major health problem and accounts for many patients on liver transplant lists. Today, antiviral medications are changing the face of this disease with many patients having successful eradication of their virus. Unfortunately, in many of these patients the chronic liver disease has already developed and risk of developing HCC remains.

Hepatitis D, or delta hepatitis, is entirely dependent on HBV for its infectivity, requiring the HBsAg to provide an envelope coat for the hepatitis D virus (HDV). Its geographic distribution is therefore similar to that of hepatitis B. HDV is an uncommon infection in North America, occurring primarily in intravenous drug users.

Hepatitis E is similar to hepatitis A in that it is transmitted by the fecal-oral route. It is typically a self-limited disease but may persist and cause chronic hepatitis in immunocompromised patients.[25]

Clinical Manifestations

Uncomplicated **acute hepatitis** implies clinical recovery within 4 months. It is the outcome of 99% of cases of hepatitis A.

Subfulminant and fulminant **hepatic failure** follows the onset of jaundice and includes worsening jaundice, coagulopathy, and hepatic encephalopathy. Most cases of hepatic failure are caused by hepatitis B or drug toxicity and are characterized by hepatic

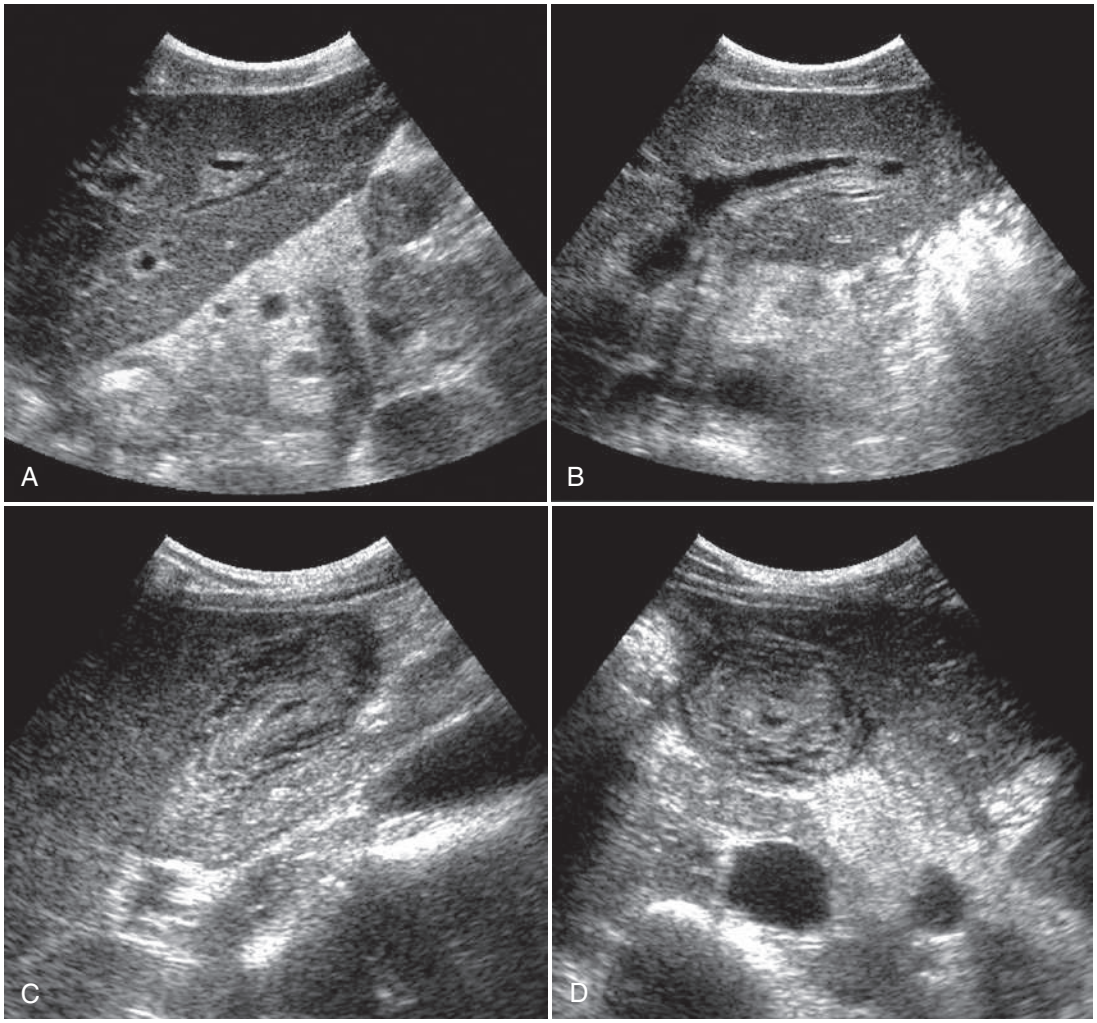

FIG. 4.17 Acute Hepatitis. (A) Sagittal and **(B)** transverse images of the left lobe of the liver show marked increased thickness and echogenicity of the soft tissue surrounding the portal vein branch, called **periportal cuffing. (C)** Sagittal and **(D)** transverse views of the gallbladder with marked mural thickening, such that the lumen is virtually obliterated. The gallbladder wall shows a multilayered appearance with extensive hypoechoic pockets of edema fluid. (With permission from Wilson SR. The liver. In Gastrointestinal disease. 6th series. Test and syllabus. Reston, VA: American College of Radiology; 2004.[26])

necrosis. Death occurs if the loss of hepatic parenchyma is greater than 40%.

Chronic hepatitis is defined as the persistence of biochemical abnormalities beyond 6 months. It has many causes other than viral, including metabolic (e.g., **Wilson disease, alpha-1 antitrypsin deficiency, hemochromatosis), autoimmune,** and **drug induced.** The prognosis and treatment of chronic hepatitis depend on the specific cause.

In acute hepatitis, there is diffuse swelling of the hepatocytes, proliferation of Kupffer cells lining the sinusoids, and infiltration of the portal areas by lymphocytes and monocytes. The sonographic features parallel the histologic findings. The liver parenchyma may have a diffusely decreased echogenicity, with accentuated brightness of the portal triads or **periportal cuffing** (Figs. 4.17 and 4.18A and B). Hepatomegaly and thickening of the gallbladder wall are associated findings (Figs. 4.17 and 4.18C and D). In most patients the liver appears normal.[26] Most cases of chronic hepatitis are also sonographically normal. When cirrhosis develops, sonography may demonstrate a coarsened echotexture and other morphologic changes of cirrhosis.

Bacterial Diseases

Pyogenic bacteria reach the liver by several routes, the most common being direct extension from the biliary tract in patients with suppurative cholangitis and cholecystitis. Other routes are through the portal venous system in patients with diverticulitis or appendicitis and through the hepatic artery in patients with osteomyelitis and subacute bacterial endocarditis. Pyogenic bacteria may also be present in the liver as a result of blunt or penetrating trauma. No cause can be found in approximately 50% of **hepatic abscesses;** the rest are mainly caused by anaerobic infection. Diagnosis of bacterial liver infection is often delayed. The most common presenting features of pyogenic liver abscess are fever, malaise, anorexia, and right upper quadrant pain. Jaundice may be present in approximately 25% of these patients.

Sonography has proved to be extremely helpful in the detection of liver abscesses. The ultrasound features of pyogenic abscesses

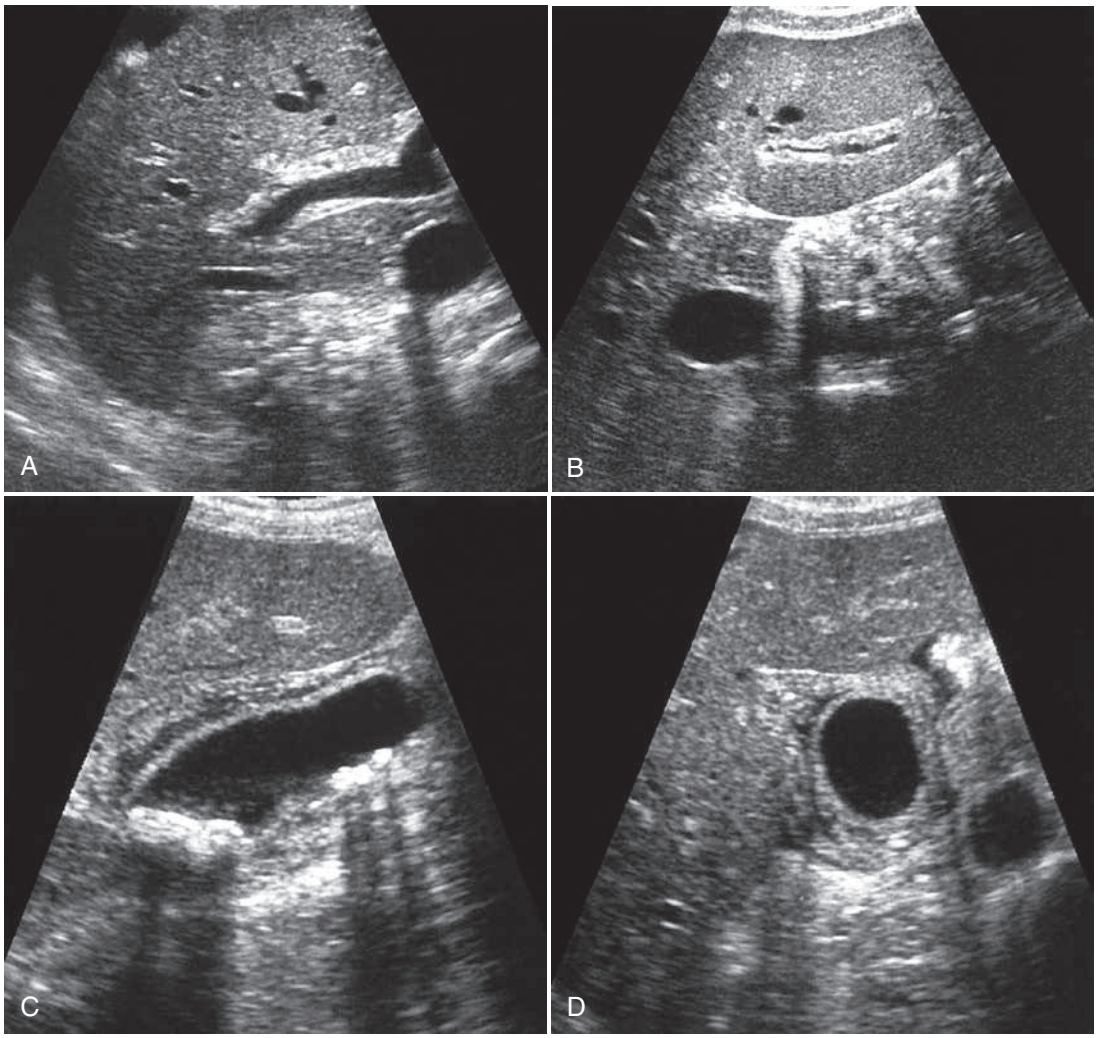

FIG. 4.18 Acute Hepatitis. Acute hepatitis in patient with fever, abnormal liver function tests, and incidental **gallstones. (A)** Transverse view of porta hepatis and **(B)** transverse view of left lobe of liver show thick, prominent echogenic bands surrounding the portal veins in the portal triads, called **periportal cuffing. (C)** Sagittal and **(D)** transverse views of the gallbladder show moderate **edema and thickening of the gallbladder wall.** The gallbladder is not large or tense, and the patient does not have acute cholecystitis. As this case illustrates, incidental cholelithiasis may be confusing.

are varied (Fig. 4.19A-F). Frankly purulent abscesses appear cystic, with the fluid ranging from echo free to highly echogenic. Regions of early suppuration may appear solid with altered echogenicity, usually hypoechoic, related to the presence of necrotic hepatocytes.[27] Occasionally, gas-producing organisms give rise to echogenic foci with a **posterior reverberation artifact** (Fig. 4.19G-I). Fluid-fluid interfaces, internal septations, and debris have all been observed. The abscess wall can vary from well defined to irregular and thick.

The differential diagnosis of pyogenic liver abscess includes amebic or echinococcal infection, simple cyst with hemorrhage, hematoma, and necrotic or cystic neoplasm. Ultrasound-guided liver aspiration is an expeditious means to confirm the diagnosis. Specimens should be sent for both aerobic and anaerobic culture. In the past, 50% of abscesses were considered sterile, probably caused by failure to transport the specimen in an oxygen-free container; thus anaerobic organisms were not identified.[28] Once the diagnosis of liver abscess is made by the identification of pus or a positive Gram stain and culture, the collection can be drained percutaneously using ultrasound or CT guidance.

Fungal Diseases: Candidiasis

The liver is frequently involved secondary to hematogenous spread of mycotic infections in other organs, most often the lungs. Patients are generally **immunocompromised,** although systemic candidiasis may occur in pregnancy or after hyperalimentation. The clinical characteristics include persistent fever in a neutropenic patient whose leukocyte count is returning to normal.[29]

The ultrasound features of **hepatic candidiasis** include the following[30]:

- "Wheel within a wheel": peripheral hypoechoic zone with inner echogenic wheel and central hypoechoic nidus. The central nidus represents focal necrosis in which fungal elements are found. This is seen early in the disease.
- Bull's-eye: 1- to 4-cm lesion with hyperechoic center and hypoechoic rim. It is present when neutrophil counts return

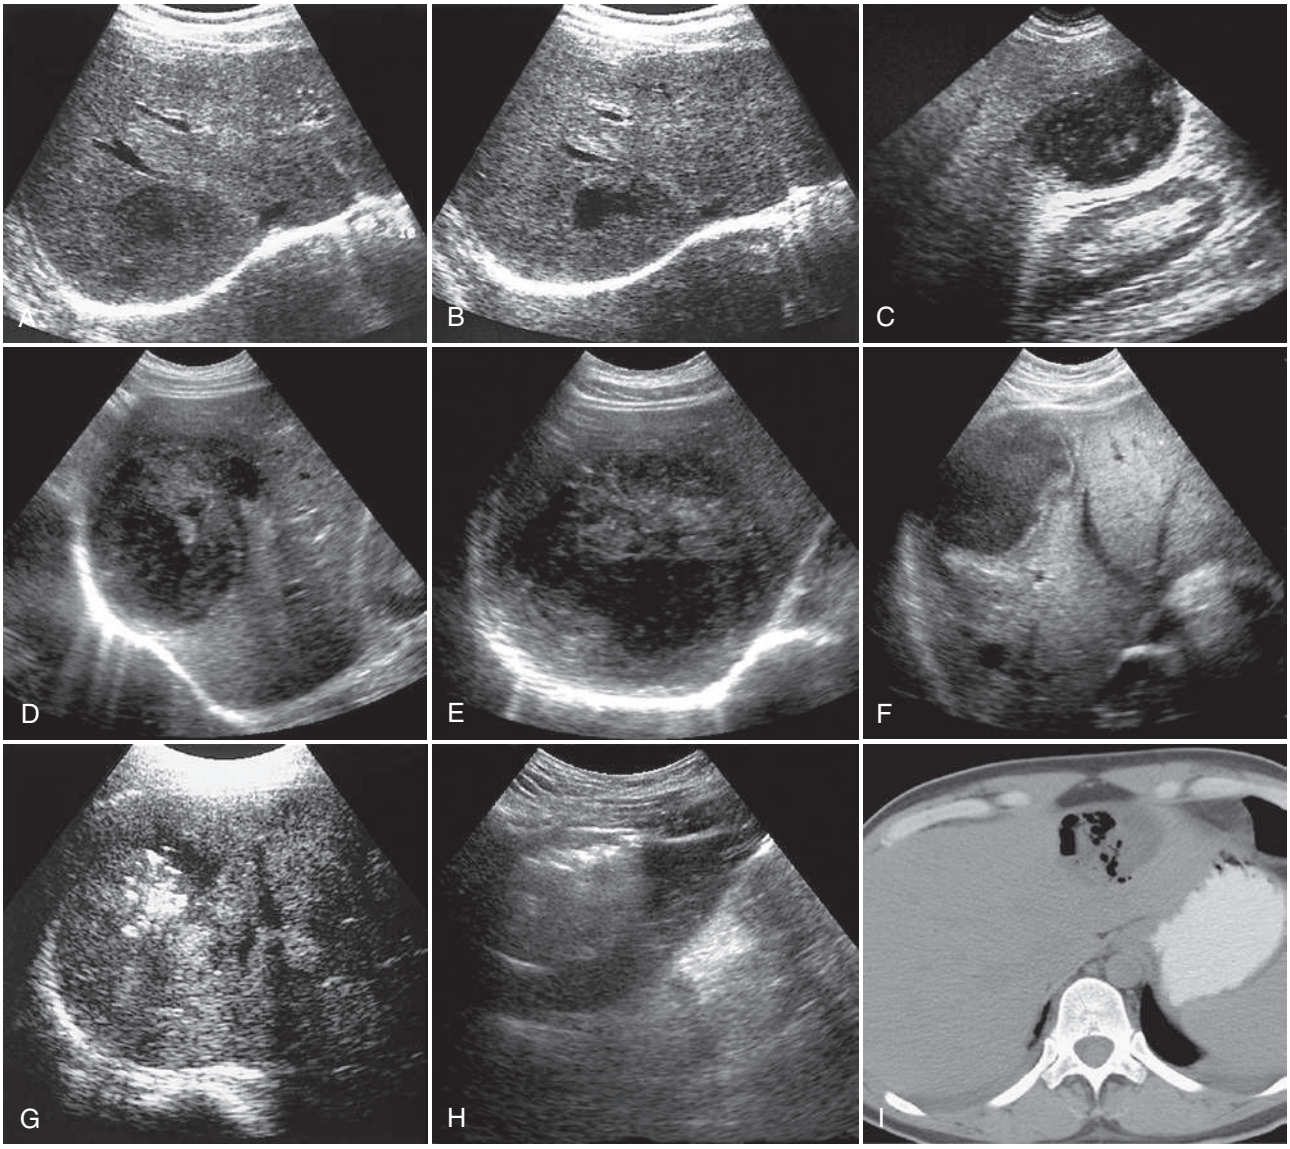

FIG. 4.19 Pyogenic Abscesses: Spectrum of Appearances. *Top row,* **Early lesions. (A)** and **(B)** Rapid evolution from phlegmon to liquefaction. **(A)** Poorly defined mass or **phlegmon** in segment 7 of the liver. **(B)** Twenty-four hours later, there is a central area of liquefaction. **(C)** Early abscess is poorly marginated and bulges the liver capsule. It is difficult to characterize this mass as solid or cystic. There was no vascularity within this or other masses. *Middle row,* **Mature abscess cavities in three patients. (D)** to **(F)** Classic mature abscess as a well-defined mass with liquefaction and internal debris. *Bottom row,* **Abscesses related to gas-forming organisms. (G)** Multiple gas bubbles are seen as innumerable bright echogenic foci within a poorly defined hypoechoic liver mass. **(H)** Sagittal image of the left lobe of the liver and **(I)** confirmatory computed tomography scan show a liver mass with extensive gas content.

to normal. The echogenic center contains inflammatory cells (Fig. 4.20).

- Uniformly hypoechoic: most common, corresponding to progressive fibrosis (Fig. 4.21A).
- Echogenic: variable calcification, representing scar formation (Fig. 4.21B).

Although percutaneous liver aspiration is helpful in obtaining the organism in pyogenic liver abscesses, it frequently yields false-negative results for the presence of *Candida* organisms.[30] This may be caused by failure to sample the central necrotic portion of the lesion, where the pseudohyphae are found.[30]

Parasitic Diseases

Amebiasis

Hepatic infection by the parasite *Entamoeba histolytica* is the most common extraintestinal manifestation of amebiasis. Transmission is by the fecal-oral route. The protozoan reaches the liver by penetrating through the colon, invading the mesenteric venules, and entering the portal vein. However, in more than one-half of patients with amebic abscesses of the liver, the colon appears normal and stool culture results are negative, thus delaying diagnosis. The most common presenting symptom is pain, which occurs in 99% of patients with amebic abscess. Approximately 15% of patients have diarrhea at diagnosis.

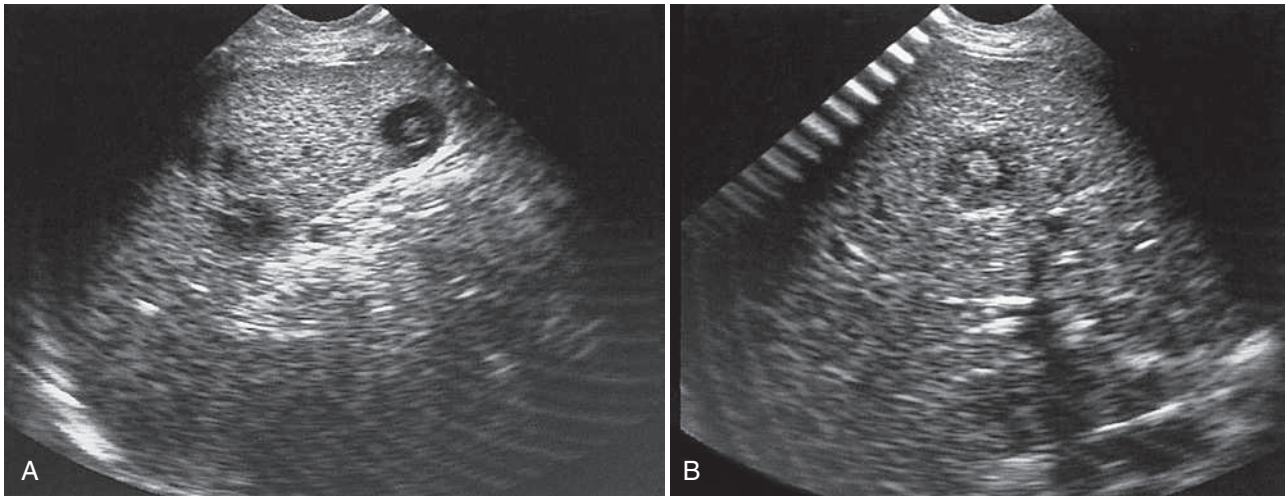

FIG. 4.20 Fungal Infection. "Bull's-eye" fungal morphology in 24-year-old man with **acute lymphoblastic leukemia** and fever. **(A)** Sagittal sonogram through the spleen shows focal hypoechoic target lesions. **(B)** The liver showed multiple masses. This magnified view shows a thick, echogenic rim and a thin, hypoechoic inner rim with a dense echogenic nidus. Biopsy revealed pseudohyphae.

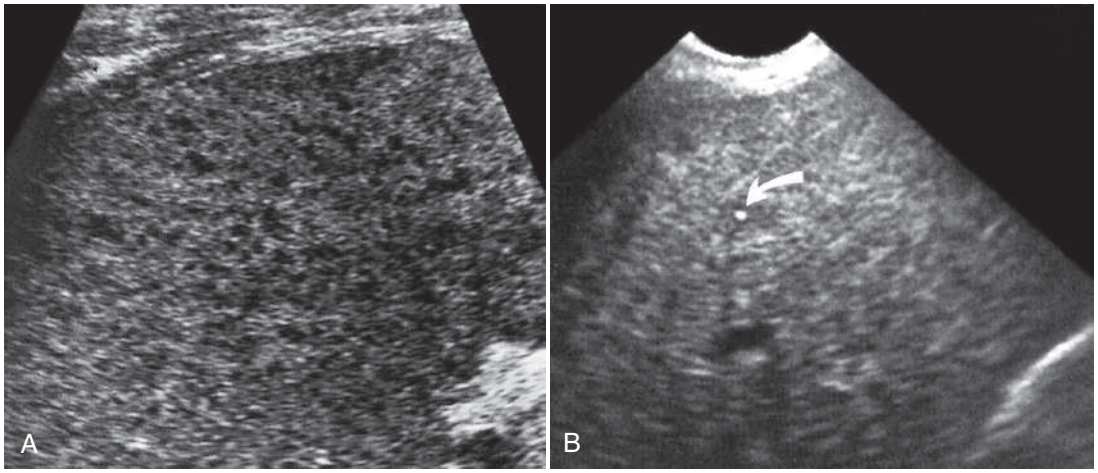

FIG. 4.21 Candidiasis. (A) Uniformly hypoechoic pattern. Multiple hypoechoic hepatic lesions are present in this young patient with acute myelogenous leukemia. **(B)** Echogenic pattern after medical therapy. Small calcified lesion *(arrow)* is visualized in another immunocompromised patient.

Sonographic features include a round or oval-shaped lesion, absence of a prominent abscess wall, hypoechogenicity compared to normal liver, fine low-level internal echoes, distal sonic enhancement, and contiguity with the diaphragm[31,32] (Fig. 4.22). All of these features, however, can be found in pyogenic abscess.

In a review of 112 amebic lesions, Ralls et al.[33] reported that two sonographic patterns were significantly more prevalent in amebic abscesses: (1) round or oval shapes in 82% versus 60% of pyogenic abscesses, and (2) hypoechoic appearance with fine internal echoes at high gain in 58% versus 36% of pyogenic abscesses. Most amebic abscesses occur in the right lobe of the liver. Diagnosis is made using a combination of the clinical features, ultrasound findings, and serologic results. The indirect hemagglutination test result is positive in more than 94% of patients.

Amebicidal drugs are effective therapy. Symptoms improve in 24 to 48 hours, and most patients are afebrile in 4 days. Those who exhibit clinical deterioration may also benefit from catheter drainage, although this is unusual. The majority of hepatic amebic abscesses disappear with adequate medical therapy.[34] The time from termination of therapy to resolution varies from 1.5 to 23 months (median, 7 months).[35] A minority of patients have residual hepatic cysts and focal regions of increased or decreased echogenicity.

Hydatid Disease

The most common cause of hydatid disease in humans is infestation by the parasite *Echinococcus granulosus,* which has a worldwide distribution. It is most prevalent in sheep- and cattle-raising countries, notably in the Middle East, Australia, and the Mediterranean. Endemic regions in the United States include the central valley in California, the lower Mississippi River Valley, Utah, and Arizona. Northern Canada is also endemic. *E. granulosus* is a tapeworm 3 to 6 mm in length that lives in the intestine

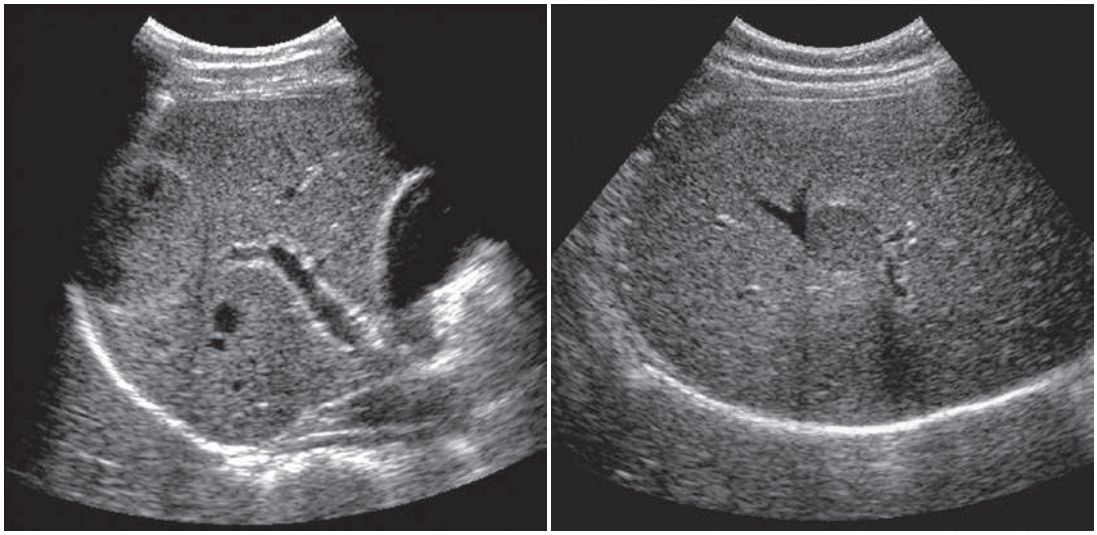

FIG. 4.22 Amebic Liver Abscess: Classic Morphology. Transverse sonograms show a well-defined oval subdiaphragmatic mass with increased through transmission. There are uniform low-level internal echoes and absence of a well-defined abscess wall.

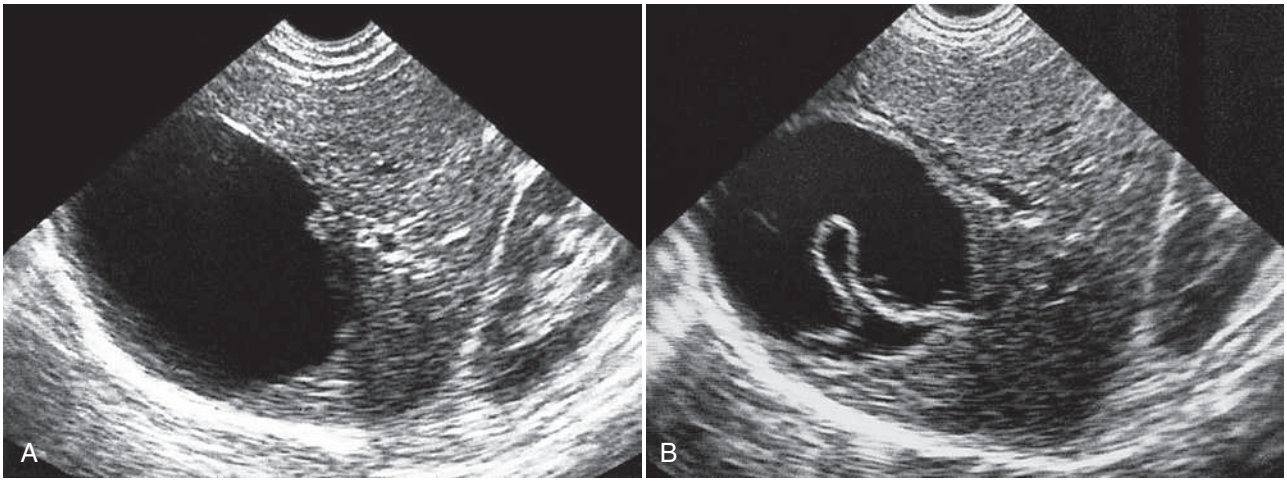

FIG. 4.23 Hydatid Cyst. (A) Baseline sonogram shows a predominately walled cyst in the right lobe with a small mural nodule and a fleck of peripheral calcium anteriorly. **(B)** Three weeks later the patient presented with right upper quadrant pain and eosinophilia. The detached endocyst is floating within the lesion.

of the definitive host, usually the dog. Its eggs are excreted in the dog's feces and swallowed by the intermediate hosts—sheep, cattle, goats, or humans. The embryos are freed in the duodenum and pass through the mucosa to reach the liver through the portal venous system. Most of the embryos remain trapped in the liver, although the lungs, kidneys, spleen, central nervous system, and bone may become secondarily involved. In the liver the right lobe is more frequently involved. The surviving embryos form slow-growing cysts. The cyst wall consists of an external membrane that is approximately 1 mm thick, which may calcify (ectocyst). The host forms a dense connective tissue capsule around the cyst (pericystia). The inner germinal layer (endocyst) gives rise to brood capsules that enlarge to form protoscolices. The brood capsules may separate from the wall and form a fine sediment called **hydatid sand.** When hydatid cysts within the organs of an herbivore are eaten, the scolices attach to the intestine and grow to adult tapeworms, thus completing the life cycle.

Several reports describe the sonographic features of hepatic hydatid disease[36-38] (Figs. 4.23 and 4.24). Lewall and McCorkell[36] proposed the following four groups for hydatid cysts:

- Simple cysts containing no internal architecture except sand
- Cysts with detached endocyst secondary to rupture (see Fig. 4.23B)
- Cysts with daughter cyst matrix (echogenic material between daughter cysts)
- Densely calcified masses

Surgery is the conventional treatment in echinococcal disease, although reports describe success with percutaneous drainage.[39-41] Although reported, anaphylaxis from hydatid cyst rupture is

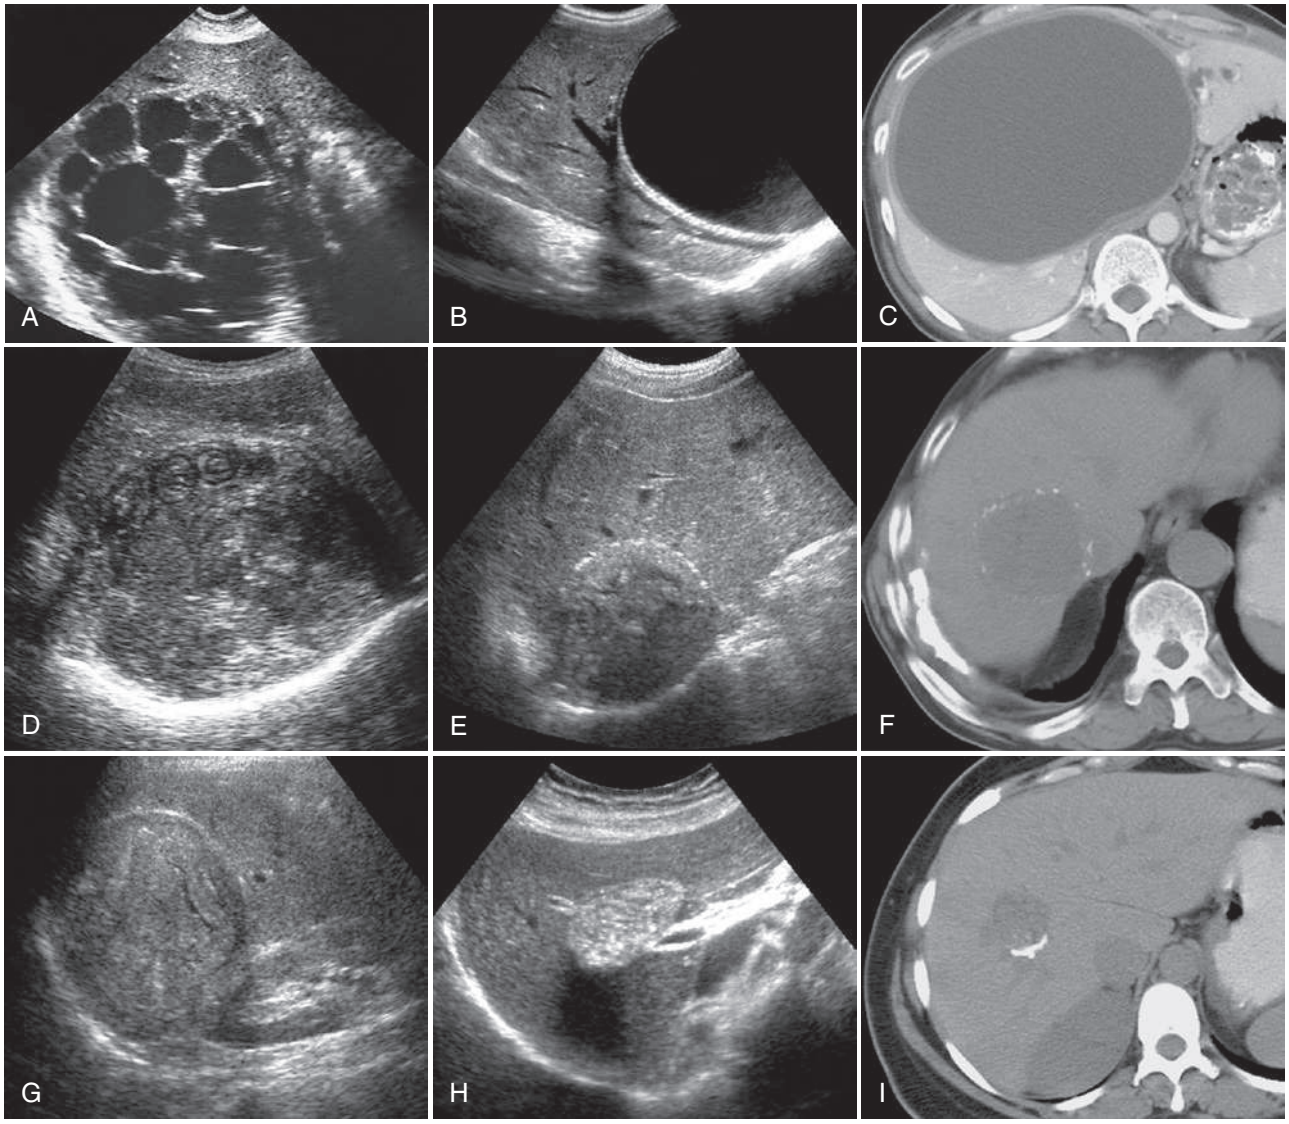

FIG. 4.24 Hydatid Liver Disease: Spectrum of Appearances. (A) Classic appearance showing a cyst containing multiple daughter cysts. **(B)** Sonogram and **(C)** confirmatory CT scan show a unilocular and simple cyst, a fairly uncommon morphology for hydatid disease. **(D)** Sonogram shows a complex mass. Anteriorly, multiple ringlike structures suggest hydatid disease. At surgery, cystic mass showed thick debris and innumerable scolices. **(E)** Sonogram and **(F)** confirmatory CT scan show an indeterminate mass with a thin rim of calcification. **(G)** Complex mass similar to that seen in **D**. There are fingerlike projections within, again suggestive of hydatid disease. **(H)** Sonogram and **(I)** confirmatory CT scan show a central liver mass with rim and internal punctate calcification.

rare. Ultrasound has been used to monitor the course of medical therapy in patients with abdominal hydatid disease.[42] A reappearance or persistence of fluid within the cavity may signify inadequate therapy and viability of the parasites.[43]

Hepatic alveolar echinococcus is a rare parasitic infestation by the larvae of *E. multilocularis.* The fox is the main host. The sonographic features include echogenic lesions, which may be single or multiple; necrotic, irregular lesions without a well-defined wall; clusters of calcification within lesions; and dilated bile ducts.[44]

Schistosomiasis

Schistosomiasis is one of the most common parasitic infections in humans, estimated to affect 200 million people worldwide. Hepatic schistosomiasis is caused by *Schistosoma mansoni, S. japonicum, S. mekongi,* and *S. intercalatum.* Hepatic involvement by *S. mansoni* is particularly severe. *S. mansoni* is prevalent in Africa, including Egypt, and South America, particularly in Venezuela and Brazil. The ova reach the liver through the portal vein and incite a chronic granulomatous reaction, first described by Symmers in 1904 as "clay-pipestem fibrosis."[45] The terminal portal vein branches become occluded, leading to presinusoidal portal hypertension, splenomegaly, varices, and ascites.

The sonographic features of schistosomiasis are widened echogenic portal tracts, sometimes reaching a thickness of 2 cm.[46,47] The porta hepatis is the region most often affected. Initially the liver size is enlarged. As the periportal fibrosis progresses, however, the liver becomes contracted, and the features of portal hypertension prevail.

FIG. 4.25 ***Pneumocystis carinii.*** Disseminated *P. carinii* infection in patient with AIDS who previously used pentamidine inhaler. Sonogram shows innumerable tiny, bright echogenic foci without shadowing throughout the liver parenchyma.

Pneumocystis carinii

Pneumocystis carinii is the most common organism causing **opportunistic infection** in patients with acquired immunodeficiency syndrome (AIDS). *Pneumocystis* pneumonia is the most common cause of life-threatening infection in patients with human immunodeficiency virus (HIV). *P. carinii* also affects patients undergoing bone marrow and organ transplantation, as well as those receiving corticosteroids or chemotherapy.[48] Extrapulmonary *P. carinii* infection was being reported with frequency in the early 1990s.[49-52] It was postulated that the use of maintenance aerosolized pentamidine achieved lower systemic levels than the intravenous form, allowing subclinical pulmonary infections and systemic dissemination of the protozoa. This treatment is now infrequently used by AIDS patients, so disseminated infection is rarely seen. Extrapulmonary *P. carinii* infection has been documented in the liver, spleen, renal cortex, thyroid gland, pancreas, and lymph nodes.

The sonographic findings of *P. carinii* involvement of the liver range from tiny, diffuse, nonshadowing echogenic foci to extensive replacement of the normal hepatic parenchyma by echogenic clumps representing dense calcification (Fig. 4.25). A similar sonographic pattern has been identified with hepatic infection by ***Mycobacterium avium-intracellulare*** and **cytomegalovirus.**[53]

DISORDERS OF METABOLISM

Fatty Liver

Fatty liver is an acquired, reversible disorder of metabolism, resulting in an accumulation of triglycerides within the hepatocytes. The most common cause likely is **obesity.** Fatty liver is recognized as a significant component of the **metabolic syndrome,** the importance of which is being increasingly recognized. Excessive alcohol intake produces a fatty liver by stimulating lipolysis, as does starvation. Other causes of fatty infiltration include poorly controlled hyperlipidemia, diabetes, excess exogenous or endogenous corticosteroids, pregnancy, total parenteral hyperalimentation, severe hepatitis, glycogen storage disease, jejunoileal bypass procedures for obesity, cystic fibrosis, congenital generalized lipodystrophy, several chemotherapeutic agents (including methotrexate), and toxins such as carbon tetrachloride and yellow phosphorus. Correction of the primary abnormality will usually reverse the process, although it is now recognized that fatty infiltration of the liver is the precursor for significant chronic disease and HCC in some patients. Fatty liver is attributed with the increasing incidence of HCC now seen in Western countries.

Sonography of fatty infiltration varies depending on the amount of fat and whether deposits are diffuse or focal[54] (Fig. 4.26). **Diffuse steatosis** may appear as follows:

- **Mild**—Minimal diffuse increase in hepatic echogenicity with normal visualization of diaphragm and intrahepatic vessel borders
- **Moderate**—Moderate diffuse increase in hepatic echogenicity with slightly impaired visualization of intrahepatic vessels and diaphragm
- **Severe**—Marked increase in echogenicity with poor penetration of posterior segment of right lobe of liver and poor or no visualization of hepatic vessels and diaphragm

Focal fatty infiltration and focal fatty sparing may mimic neoplastic involvement.[55] In **focal fatty infiltration,** regions of increased echogenicity are present within a background of normal liver parenchyma (Video 4.3). Conversely, islands of normal liver parenchyma may appear as hypoechoic masses within a dense, fatty infiltrated liver (Video 4.4). Features of **focal fatty change** include the following (Fig. 4.27):

- Focal fatty sparing and focal fatty liver most often involve the periportal region of the medial segment of the left lobe (segment IV).[56,57]
- Sparing also frequently occurs by the gallbladder fossa and along the liver margins.
- Focal subcapsular fat may occur in diabetic patients receiving insulin in peritoneal dialysate[58] (Fig. 4.27H and I).
- Lack of mass effect; hepatic vessels generally are not displaced, although traversing vessels in metastases have been reported.[59]
- Geometric margins are present, although focal fat may appear round, nodular, or interdigitated with normal tissue.[60]
- Rapid change with time; fatty infiltration may resolve as early as 6 days.

Contrast-enhanced ultrasound (CEUS) is valuable in the differentiation of fatty change from neoplasia, because all of the fatty or spared regions will appear isovascular in both the arterial and the portal venous phase of enhancement. CT and magnetic resonance imaging (MRI) can be used in distinguishing diffuse from focal fatty infiltration and in assessing for focal lesions. Radionuclide liver and spleen scintigraphic examination will yield normal results, indicating adequate numbers of Kupffer cells within the fatty regions.[54] Some postulate that these focal spared areas are caused by a regional decrease in portal blood flow, as demonstrated by CT scans during arterial portographic examinations.[61] Knowledge of typical patterns and use of CT,

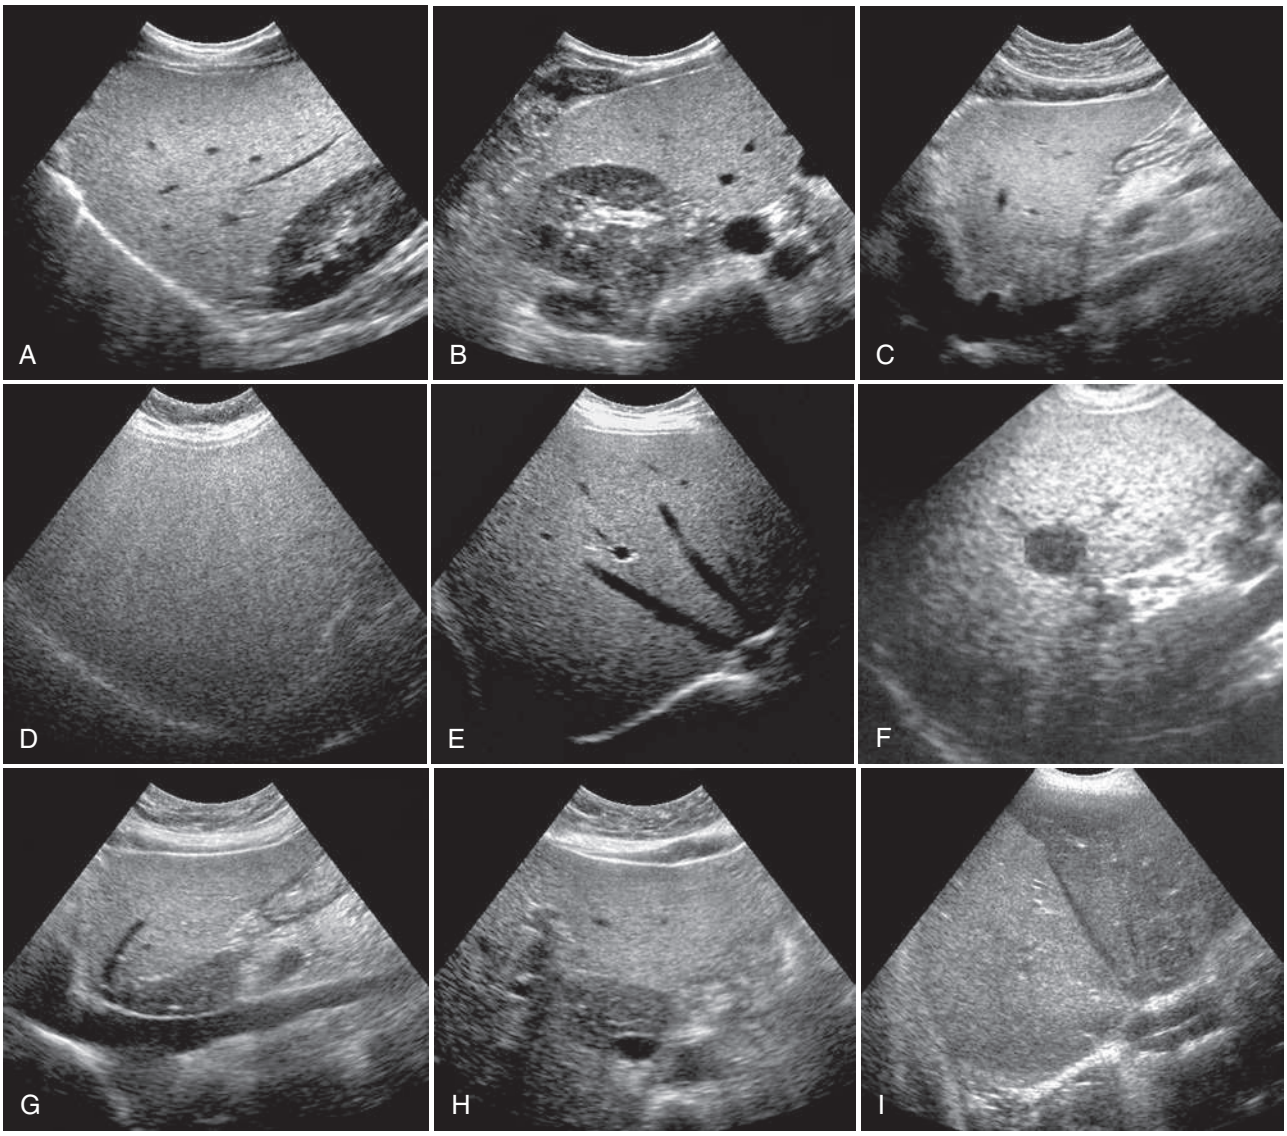

FIG. 4.26 Diffuse Fat: Spectrum of Appearances. Mild fatty infiltration: (A) sagittal right lobe, **(B)** transverse right lobe, **(C)** sagittal left lobe. The liver is diffusely bright and echogenic; sound penetration remains good. **Marked fatty infiltration: (D)** sagittal right lobe, **(E)** subcostal oblique view. The liver is enlarged and attenuating, sound penetration is poor, and the walls of the hepatic veins are not defined. **Focal fatty sparing: (F)** mimicking a hypoechoic mass; normal liver on biopsy and follow-up. **(G)** Sagittal and **(H)** transverse images show focal fatty sparing of the caudate lobe. **(I)** Geographic fatty sparing of the entire left lobe marginated by the middle hepatic vein.

CEUS, MRI, or nuclear medicine scintigraphy will avoid the necessity for biopsy in most patients with focal fatty alteration.

Glycogen Storage Disease (Glycogenosis)

Von Gierke first recognized glycogen storage disease (GSD) affecting the kidneys and liver in 1929.[62] Type 1 GSD (von Gierke disease, glucose 6-phosphatase deficiency) is manifested in the neonatal period by hepatomegaly, nephromegaly, and hypoglycemic convulsions. Because of the enzyme deficiency, large quantities of glycogen are deposited in the hepatocytes and proximal convoluted tubules of the kidney. With dietary management and supportive therapy, more patients currently survive to childhood and young adulthood. As a result, several patients have developed benign adenomas or, less often, HCC.[63]

Sonographically, type 1 GSD appears indistinguishable from other causes of diffuse fatty infiltration. Secondary hepatic adenomas are well-demarcated, solid masses of variable echogenicity. Malignant transformation can be recognized by rapid growth of the lesions, which may become more poorly defined.[63]

Cirrhosis

The World Health Organization (WHO) defines cirrhosis as a diffuse process characterized by fibrosis and the conversion of normal liver architecture into structurally abnormal nodules.[64] Three major pathologic mechanisms combine to create cirrhosis: **cell death, fibrosis,** and **regeneration.** Cirrhosis has been classified as **micronodular,** in which nodules are 0.1 to 1 cm in diameter, and **macronodular,** characterized by nodules of varying size, up to 5 cm in diameter. Alcohol consumption is the most

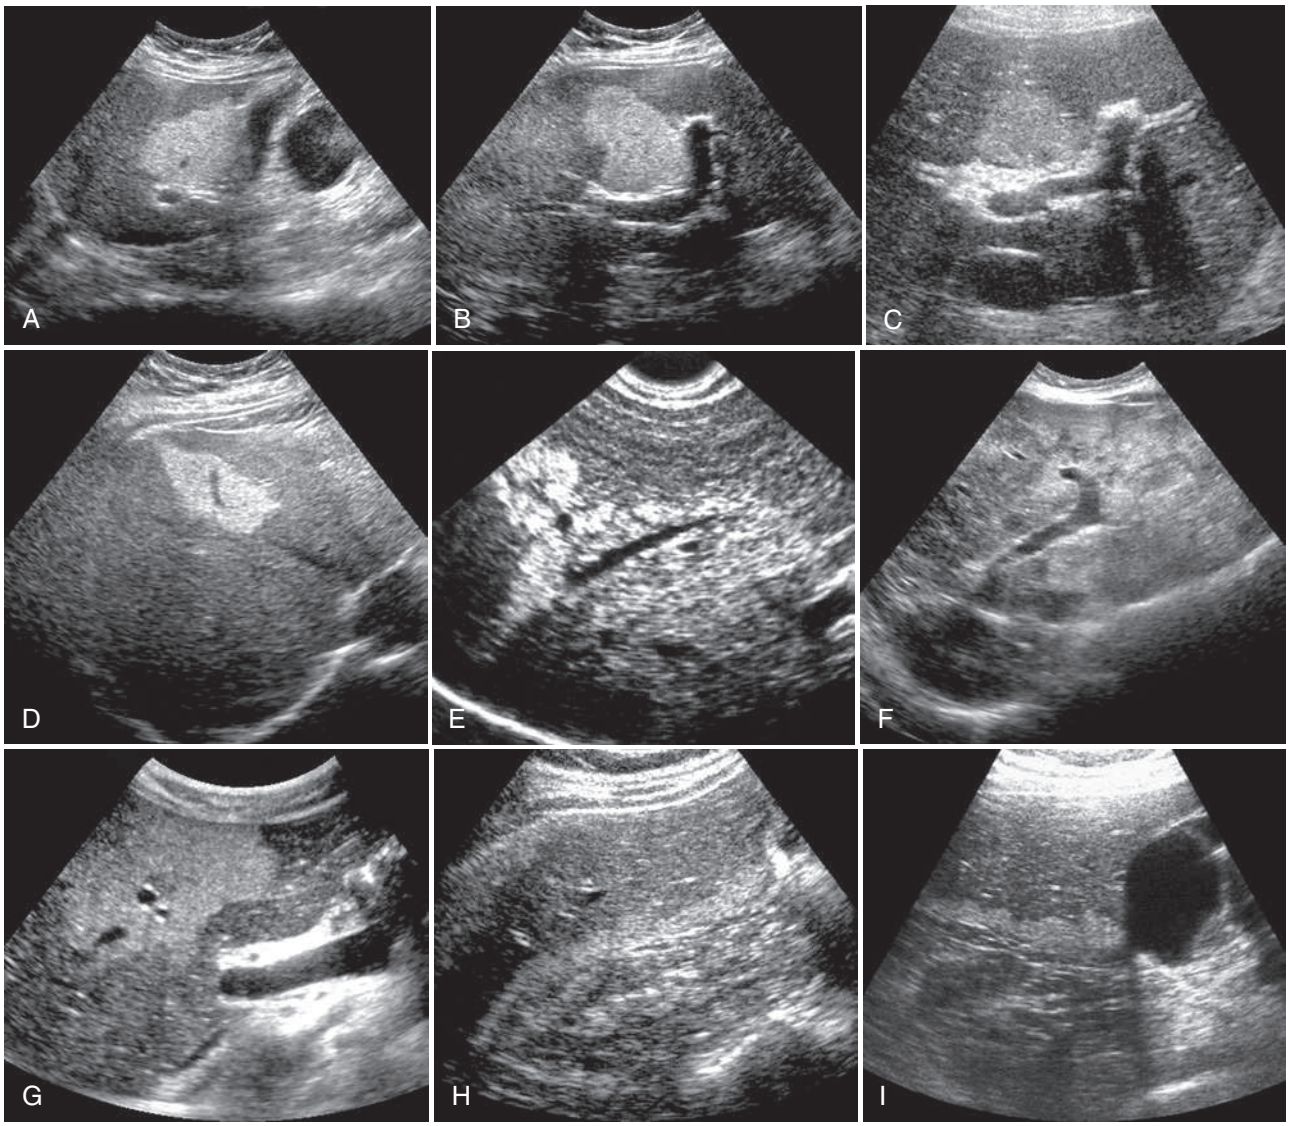

FIG. 4.27 Focal Fat: Spectrum of Appearances. (A) Sagittal and **(B)** subcostal oblique images show the most common location for **classic focal fat,** in segment 4, anterior to the portal venous bifurcation at the porta hepatis, where it is large and masslike. **(C)** Another patient showing a more common, milder form of the same fat deposition. **(D)** to **(G) Tumoral fat.** Fat deposits in all images suggest a focal liver mass. The liver vasculature is unaltered in its course at the location of the fatty masses. **(E)** Focal fat of pregnancy. **(H)** and **(I) Hepatic steatonecrosis** shown in views of the right lobe of the liver is a rare observation in diabetic patients who receive insulin in their peritoneal dialysate.

common cause of micronodular cirrhosis, and chronic viral hepatitis is the most frequent cause of the macronodular form. Patients who continue to drink may go on to end-stage liver disease, which is indistinguishable from cirrhosis of other causes. Other causes are **biliary cirrhosis** (primary and secondary), **Wilson disease, primary sclerosing cholangitis,** and **hemochromatosis.** The classic clinical presentation of cirrhosis is hepatomegaly, jaundice, and ascites. However, serious liver injury may be present without any clinical clues. In fact, only 60% of patients with cirrhosis have signs and symptoms of liver disease.

Cirrhosis has serious prognostic implications and patients may succumb to progressive liver failure and the sequelae of portal hypertension. They also have a greatly increased risk for the development of HCC. Appropriate at-risk populations, therefore, undergo surveillance ultrasound, performed at 6-month intervals in search of liver nodules above threshold size, which are then characterized as benign, indeterminate, or malignant nodules with the use of contrast-enhanced imaging techniques and enter a well-defined pathway for further evaluation and management.

Because liver biopsy is invasive, the ability to detect cirrhosis by noninvasive means, such as sonography, holds great clinical interest. The morphologic patterns associated with cirrhosis include the following (Fig. 4.28):

- **Volume redistribution.** In the early stages of cirrhosis the liver may be enlarged, whereas in advanced stages the liver is often small, with relative enlargement of the caudate lobe, left lobe, or both, compared with the right lobe. Several studies have evaluated the ratio of the caudate lobe width to the right lobe width (C/RL) as an indicator of cirrhosis. A C/RL value

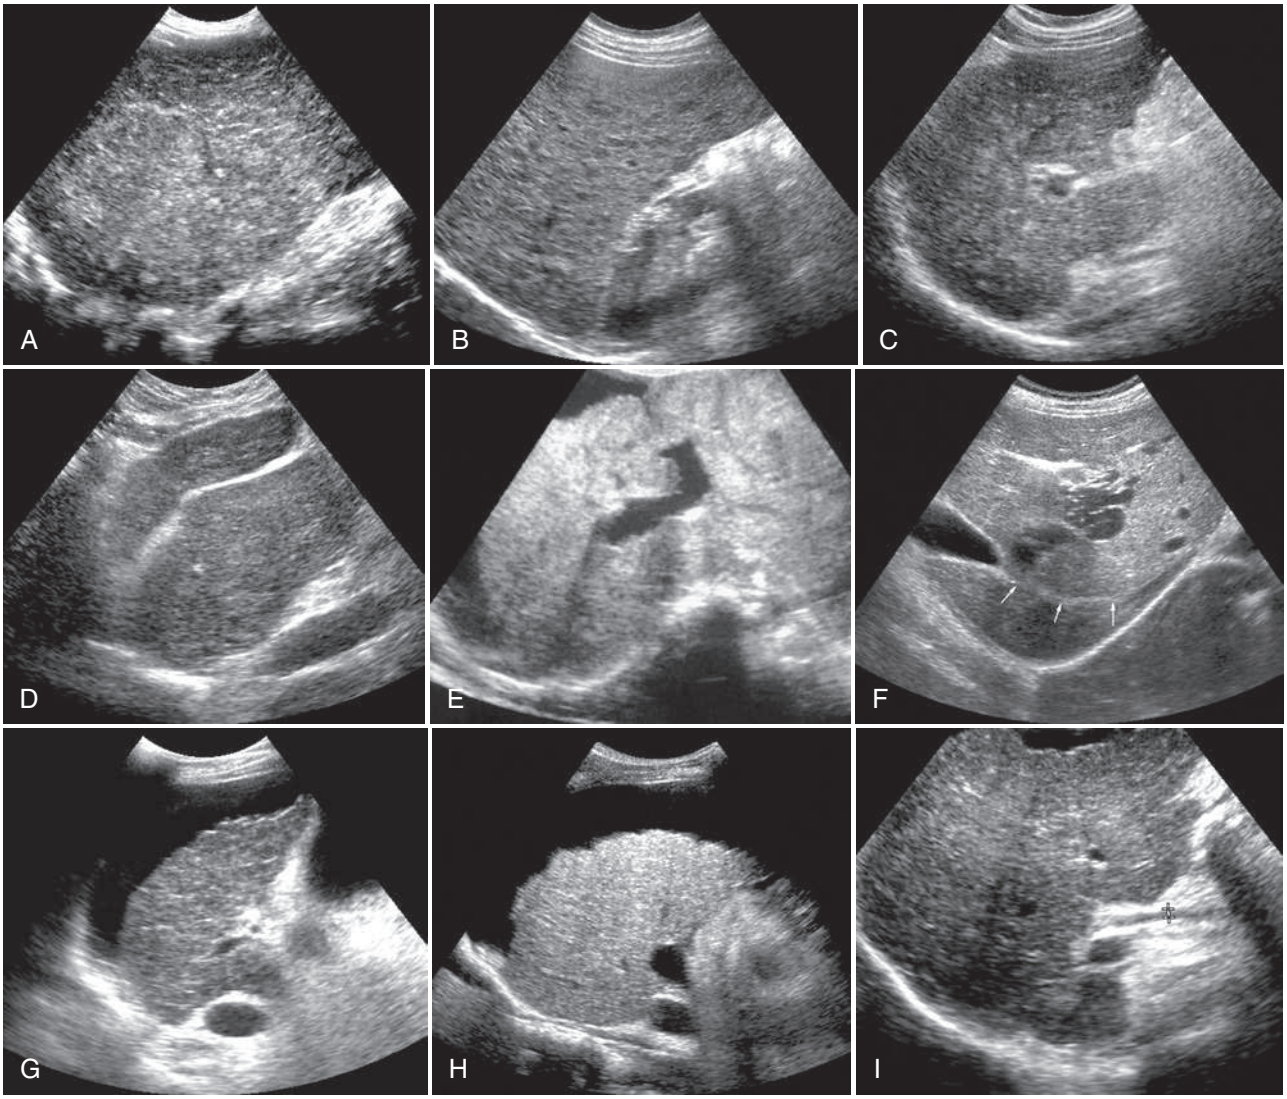

FIG. 4.28 Cirrhosis: Spectrum of Appearances. *Top row,* **Parenchymal changes. (A)** Coarse parenchyma and innumerable tiny, hyperechoic nodules. **(B)** Coarse parenchyma and innumerable tiny, hypoechoic nodules. **(C)** Coarse parenchyma and surface nodularity. *Middle row,* **Lobar redistribution. (D)** Sagittal image showing an enormous caudate lobe. **(E)** Transverse sonogram shows the right lobe is small, with enlargement of the left lateral segment. **(F)** Subcostal oblique view showing a tiny right lobe of the liver, which is separated from the large left lobe by the main lobar fissure *(arrows). Bottom row,* **Contour abnormality. (G)** and **(H)** Small, end-stage livers with surface nodularity, best appreciated in patients with ascites, as shown here. **(I)** Liver contour varies greatly, as shown here, where a large nodule protrudes from the deep liver border.

of 0.65 is considered indicative of cirrhosis. The specificity is high (100%), but the sensitivity is low (43%-84%), indicating that the C/RL ratio is a useful measurement if it is abnormal.[65] However, no patients in these studies had Budd-Chiari syndrome, which may also cause caudate lobe enlargement.

- **Coarse echotexture.** Increased echogenicity and coarse echotexture are frequent observations in diffuse liver disease. These are subjective findings, however, and may be confounded by inappropriate time gain compensation (TGC) settings and overall gain. Liver attenuation is correlated with the presence of fat, not fibrosis.[66] Cirrhotic livers without fatty infiltration had attenuation values similar to those of controls. This accounts for the relatively low accuracy in distinguishing diffuse liver disease[67] and the conflicting reports regarding attenuation values in cirrhosis.
- **Nodular surface.** Irregularity of the liver surface during routine scanning has been appreciated as a sign of cirrhosis when the appearance is gross or when ascites is present.[68] The nodularity corresponds to the presence of regenerating nodules and fibrosis.
- **Regenerating nodules.** These regenerating hepatocytes are surrounded by fibrotic septae. Because regenerating nodules have a similar architecture to the normal liver, ultrasound and CT have limited ability to detect them. Regenerating nodules tend to be isoechoic or hypoechoic with a thin, echogenic border that corresponds to fibrofatty connective tissue.[68] MRI has a greater sensitivity than both CT and ultrasound in regenerating nodule detection. Because some regenerating nodules contain iron, gradient echo sequences demonstrate these nodules as hypointense.[69]

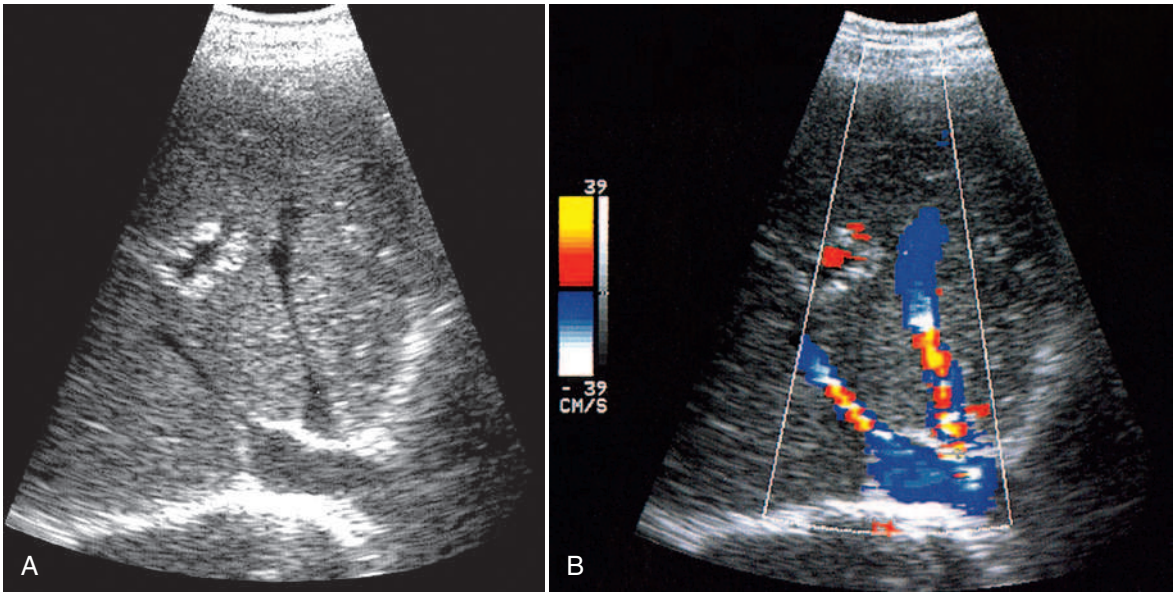

FIG. 4.29 Hepatic Vein Strictures: Cirrhosis. (A) Gray-scale image of hepatic veins shows a tapered luminal narrowing. **(B)** Color Doppler image shows appropriately directed blood flow toward the inferior vena cava. There is color aliasing from the rapid-velocity flow through the points of narrowing.

Cirrhosis: Sonographic Features

Volume redistribution
Coarse echotexture
Nodular surface
Nodules: regenerative and dysplastic
Portal hypertension: ascites, splenomegaly, and varices

- **Dysplastic nodules.** Dysplastic nodules or adenomatous hyperplastic nodules are larger than regenerating nodules (diameter of 10 mm) and are considered premalignant.[70] They contain well-differentiated hepatocytes, a portal venous blood supply, and atypical or frankly malignant cells. The portal venous blood supply can be detected with color Doppler flow imaging and distinguished from the hepatic artery–supplied HCC.[71] In a patient with cirrhosis and a liver mass, percutaneous biopsy is often performed to exclude or diagnose HCC.

Doppler Ultrasound Characteristics

The normal Doppler waveform of the hepatic veins reflects the hemodynamics of the right atrium. The waveform is triphasic: two large antegrade diastolic and systolic waves and a small retrograde wave corresponding to the atrial "kick." Because the walls of the hepatic veins are thin, disease of the hepatic parenchyma may alter their compliance. In many patients with compensated cirrhosis (no portal hypertension), the Doppler waveform is abnormal. **Two abnormal patterns** have been described: decreased amplitude of phasic oscillations with loss of reversed flow and a flattened waveform.[72,73] These abnormal patterns have also been found in patients with fatty infiltration of the liver.[72]

As cirrhosis progresses, luminal narrowing of the hepatic veins may be associated with flow alterations visible on color and spectral Doppler ultrasound. High-velocity signals through an area of narrowing produce color aliasing and turbulence (Fig. 4.29).

The hepatic artery waveform also shows altered flow dynamics in cirrhosis and chronic liver disease. Lafortune et al.[74] found an increase in the resistive index of the hepatic artery after a meal in patients with a normal liver. The vasoconstriction of the hepatic artery occurs as a normal response to the increased portal venous flow stimulated by eating (20% change). In patients with cirrhosis and chronic liver disease, the normal increase in postprandial resistive index is blunted.[75]

Elastography

Sonographic evaluation of liver morphology for the prediction of the presence and status of cirrhosis is invaluable but subjective. Furthermore, it may uncommonly be normal even with quite advanced disease. Historically, therefore, diagnosis and staging of liver cirrhosis have been performed based on invasive liver biopsy. At histology, liver fibrosis is graded from METAVIR stage F0, indicating a normal liver, through to METAVIR stage F4, indicating cirrhosis. Patients with METAVIR stage F2 are felt to have clinically important fibrosis necessitating special attention and referral to hepatology service as these patients are at risk for portal hypertension, liver failure, and development of HCC. Today, the addition of elastography provides objective, noninvasive, and repeatable evaluation of the status of liver fibrosis.[76-78] Elastography is performed with several different techniques and two of them, point shear wave elastography (SWE) and two-dimensional SWE, are integral components of high-end ultrasound systems sold today, thereby allowing for evaluation of fibrosis at the time of a routine dedicated liver ultrasound.

SWE is performed of segments VII and VIII on a supine patient under direct ultrasound visualization by obtaining multiple

samples from the generation of shear waves in the liver within a small region of interest with utilization of acoustic radiation force impulse (ARFI) imaging. Results are expressed in either kPa or meters per second, and in North America, seemingly the latter are preferred. There are published data giving the range of values for each technique and equipment used.[79] The introduction of these techniques is invaluable to reduce the requirement for liver biopsy, to allow for follow-up of patients undergoing new antiviral therapy with chronic liver disease, and to allow for preoperative assessment of those with liver cancer for optimal selection of therapy options. The current status of this technique was recently published in a special report by the Society of Radiologists in Ultrasound.[80]

VASCULAR ABNORMALITIES

Portal Hypertension

Normal portal vein pressure is 5 to 10 mm Hg (14 cm H_2O). Portal hypertension is defined by (1) wedge hepatic vein pressure or direct portal vein pressure more than 5 mm Hg greater than IVC pressure, (2) splenic vein pressure greater than 15 mm Hg, or (3) portal vein pressure (measured surgically) greater than 30 cm H_2O. Pathophysiologically, portal hypertension can be divided into presinusoidal and intrahepatic groups, depending on whether the hepatic vein wedge pressure is normal (presinusoidal) or elevated (intrahepatic).

Presinusoidal portal hypertension can be subdivided into extrahepatic and intrahepatic forms. The causes of extrahepatic presinusoidal portal hypertension include **thrombosis of the portal or splenic veins.** This should be suspected in any patient who presents with clinical signs of portal hypertension (ascites, splenomegaly, and varices) and a normal liver biopsy. Thrombosis of the portal venous system occurs in children secondary to umbilical vein catheterization, omphalitis, and neonatal sepsis. In adults the causes of portal vein thrombosis include **trauma, sepsis, HCC, pancreatic carcinoma, pancreatitis, portacaval shunts, splenectomy,** and **hypercoagulable states.** The **intrahepatic presinusoidal** causes of portal hypertension are the result of diseases affecting the portal zones of the liver, notably **schistosomiasis, primary biliary cirrhosis, congenital hepatic fibrosis,** and toxic substances, such as **polyvinyl chloride** and **methotrexate.**

Cirrhosis is the most common cause of **intrahepatic portal hypertension** and accounts for greater than 90% of all cases of portal hypertension in the West. In cirrhosis the distorted vascular channels increase resistance to portal venous blood flow and obstruct hepatic venous outflow. Diffuse metastatic liver disease also produces portal hypertension by the same mechanism. Over time, thrombotic diseases of the IVC and hepatic veins, as well as constrictive pericarditis and other causes of severe right-sided heart failure, will lead to centrilobular fibrosis, hepatic regeneration, cirrhosis, and finally portal hypertension.

Sonographic findings of portal hypertension include the **secondary signs** of splenomegaly, ascites, and portosystemic venous collaterals (Figs. 4.30 and 4.31). When the resistance to blood flow in the portal vessels exceeds the resistance to flow in the small communicating channels between the portal and systemic circulations, portosystemic collaterals form. Thus although the caliber of the portal vein initially may be increased

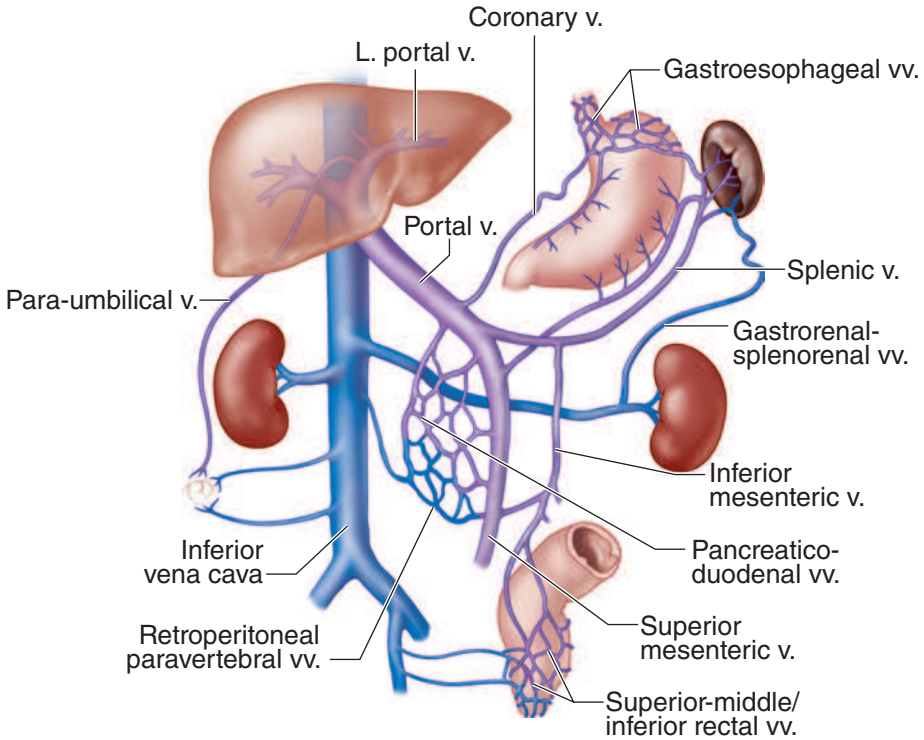

FIG. 4.30 Portal Hypertension. Major sites of portosystemic venous collaterals.

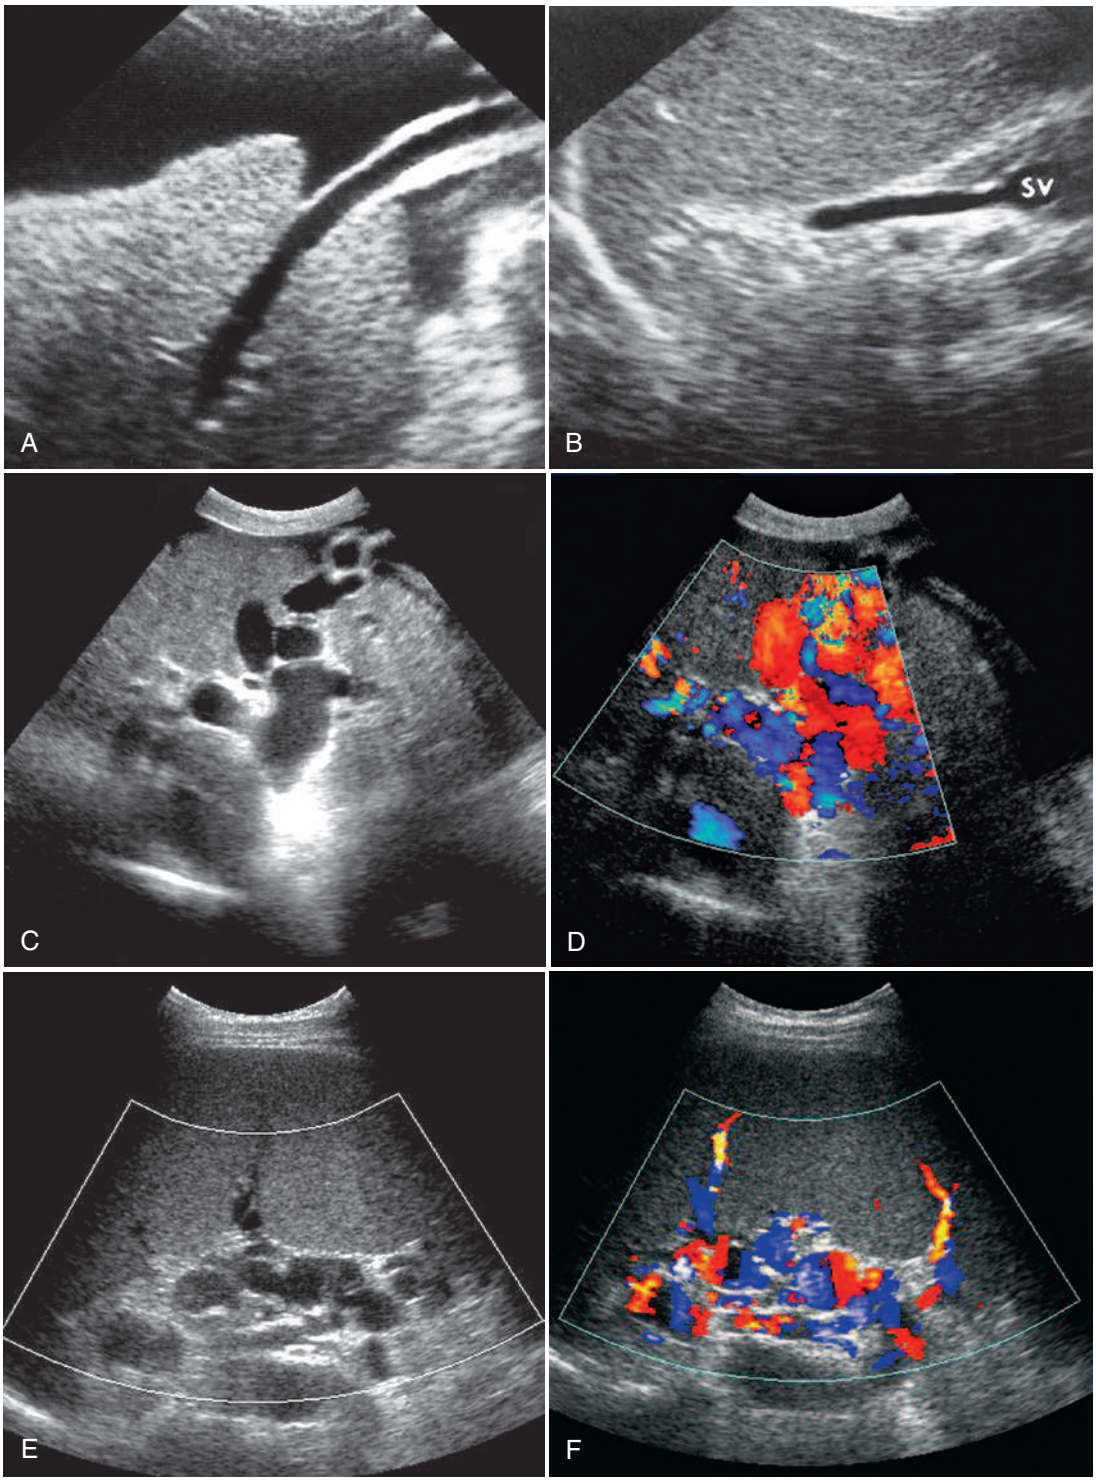

FIG. 4.31 Portal Hypertension. (A) Sagittal image of recanalized paraumbilical vein in patient with gross ascites. **(B)** Sagittal image shows enlarged coronary vein running cephalad from the splenic vein *(SV)*. **(C)** Gray-scale image and **(D)** color Doppler image show extensive varices in the distribution of the coronary vein. **(E)** Gray-scale image and **(F)** color Doppler image show splenic hilar varices.

(>1.3 cm) in portal hypertension,[81] with the development of portosystemic shunts, the portal vein caliber will decrease.[82] Five **major sites of portosystemic venous collaterals** are visualized by ultrasound[83-85] (see Fig. 4.30).

- **Gastroesophageal junction:** Between the coronary and short gastric veins and the systemic esophageal veins. These varices are of particular importance because they may lead to life-threatening or fatal hemorrhage. Dilation of the coronary vein (>0.7 cm) is associated with severe portal hypertension (portohepatic gradient >10 mm Hg)[82] (Fig. 4.31C and D).
- **Paraumbilical vein:** Runs in the falciform ligament and connects the left portal vein to the systemic epigastric veins

near the umbilicus **(Cruveilhier-Baumgarten syndrome)**[86] (Fig. 4.31A). Some studies suggest that, if the hepatofugal flow in the patent paraumbilical vein exceeds the hepatopetal flow in the portal vein, patients may be protected from developing esophageal varices.[87,88]

- **Splenorenal and gastrorenal:** Tortuous veins may be seen in the region of the splenic and left renal hilus (Fig. 4.31E and F), which represent collaterals between the splenic, coronary, and short gastric veins and the left adrenal or renal veins.
- **Intestinal:** Regions in which the gastrointestinal tract becomes retroperitoneal so that the veins of the ascending and descending colon, duodenum, pancreas, and liver may anastomose with the renal, phrenic, and lumbar veins (systemic tributaries).
- **Hemorrhoidal:** The perianal region where the superior rectal veins, which extend from the inferior mesenteric vein, anastomose with the systemic middle and inferior rectal veins.

Duplex Doppler sonography provides additional information regarding direction of portal flow. False results may occur, however, when sampling is obtained from periportal collaterals in patients with portal vein thrombosis or hepatofugal portal flow.[89] Normal portal venous flow rates vary in the same individual, increasing postprandially and during inspiration[75,90] and decreasing after exercise or in the upright position.[91] An increase of less than 20% in the diameter of the portal vein with deep inspiration indicates portal hypertension with 81% sensitivity and 100% specificity.[92]

The **normal portal vein** demonstrates an undulating **hepatopetal** (toward the liver) flow. Mean portal venous flow velocity is 15 to 18 cm/sec and varies with respiration and cardiac pulsation. As portal hypertension develops, the flow in the portal vein loses its undulatory pattern and becomes monophasic. As the severity of portal hypertension increases, flow becomes biphasic and finally **hepatofugal** (away from the liver). Intrahepatic arterial-portal venous shunting may also be seen.

Chronic liver disease is also associated with increased splanchnic blood flow. Evidence suggests that portal hypertension is partly caused by the hyperdynamic flow state of cirrhosis. Zwiebel et al.[93] found that blood flow was increased in the superior mesenteric arteries and splenic arteries of patients with cirrhosis and splenomegaly, compared with normal controls. Of interest, in patients with cirrhosis and normal-sized livers, splanchnic blood flow was not increased. Patients with isolated splenomegaly and normal livers were not included in this study.

The limitations of Doppler sonography in the evaluation of portal hypertension include the inability to determine vascular pressures and flow rates accurately. Patients with portal hypertension are often ill, with contracted livers, abundant ascites, and floating bowel, all of which create a technical challenge. In a comparison of duplex Doppler sonography with magnetic resonance angiography, MRI imaging was superior in the assessment of patency of the portal vein and surgical shunts, as well as in detection of varices.[94] However, when technically adequate, the Doppler study was accurate in the assessment of normal portal anatomy and flow direction. Duplex Doppler sonography has the added advantages of decreased cost and portability of the equipment and therefore should be used as the initial screening method for portal hypertension.

Portal Vein Thrombosis

Portal vein thrombosis has been associated with malignancy, including HCC, metastatic liver disease, carcinoma of the pancreas, and primary leiomyosarcoma of the portal vein,[95] as well as with chronic pancreatitis, hepatitis, septicemia, trauma, splenectomy, portacaval shunts, hypercoagulable states such as pregnancy and in neonates, omphalitis, umbilical vein catheterization, and acute dehydration.[96]

Sonographic findings of portal vein thrombosis include echogenic thrombus within the lumen of the vein, portal vein collaterals, expansion of the caliber of the vein, and cavernous transformation[96] (Figs. 4.32 and 4.33). **Cavernous transformation of the portal vein** refers to numerous wormlike vessels at the porta hepatis, which represent periportal collateral circulation.[97] This pattern is observed in long-standing thrombosis, requiring up to 12 months to occur, and thus is more likely to develop with benign disease.[98] **Acute thrombus** may appear relatively anechoic and thus may be overlooked unless Doppler ultrasound interrogation is performed. **Malignant thrombosis** of the portal vein has a high association with HCC and is often expansive, as is malignant occlusion from other primary or secondary disease (Fig. 4.32A and B and Fig. 4.34).

Doppler sonography is useful in distinguishing between benign and malignant portal vein thrombi in patients with cirrhosis. Both bland and malignant thrombi may demonstrate venous blood flow. Pulsatile (arterial) flow, however, has been found to be 95% specific for the diagnosis of malignant portal vein thrombosis (see Fig. 4.32). The sensitivity was only 62% because many malignant thrombi are hypovascular.[99]

Budd-Chiari Syndrome

The Budd-Chiari syndrome is a relatively rare disorder characterized by occlusion of the lumens of the hepatic veins with or without occlusion of the IVC lumen. The degree of occlusion and presence of collateral circulation predict the clinical course. Some patients die in the acute phase of liver failure. Causes of Budd-Chiari syndrome include coagulation abnormalities such as **polycythemia rubra vera, chronic leukemia, and paroxysmal nocturnal hemoglobinuria; trauma;** tumor extension from **primary HCC, renal carcinoma,** and **adrenocortical carcinoma; pregnancy; congenital abnormalities;** and **obstructing membranes.** The classic patient in North America is a young adult woman taking oral contraceptives who presents with an acute onset of ascites, right upper quadrant pain, hepatomegaly, and, to a lesser extent, splenomegaly. In some cases, no causal factor is found. The syndrome is more common in other geographic areas, including India, South Africa, and Asia.

Sonographic evaluation of the patient with Budd-Chiari syndrome includes gray-scale and Doppler features.[100-111] Ascites is invariably seen. The liver is typically large and bulbous in the acute phase (Fig. 4.35A). Hemorrhagic infarction may produce significant altered regional echogenicity. As infarcted areas become more fibrotic, echogenicity increases.[109] The caudate lobe is often

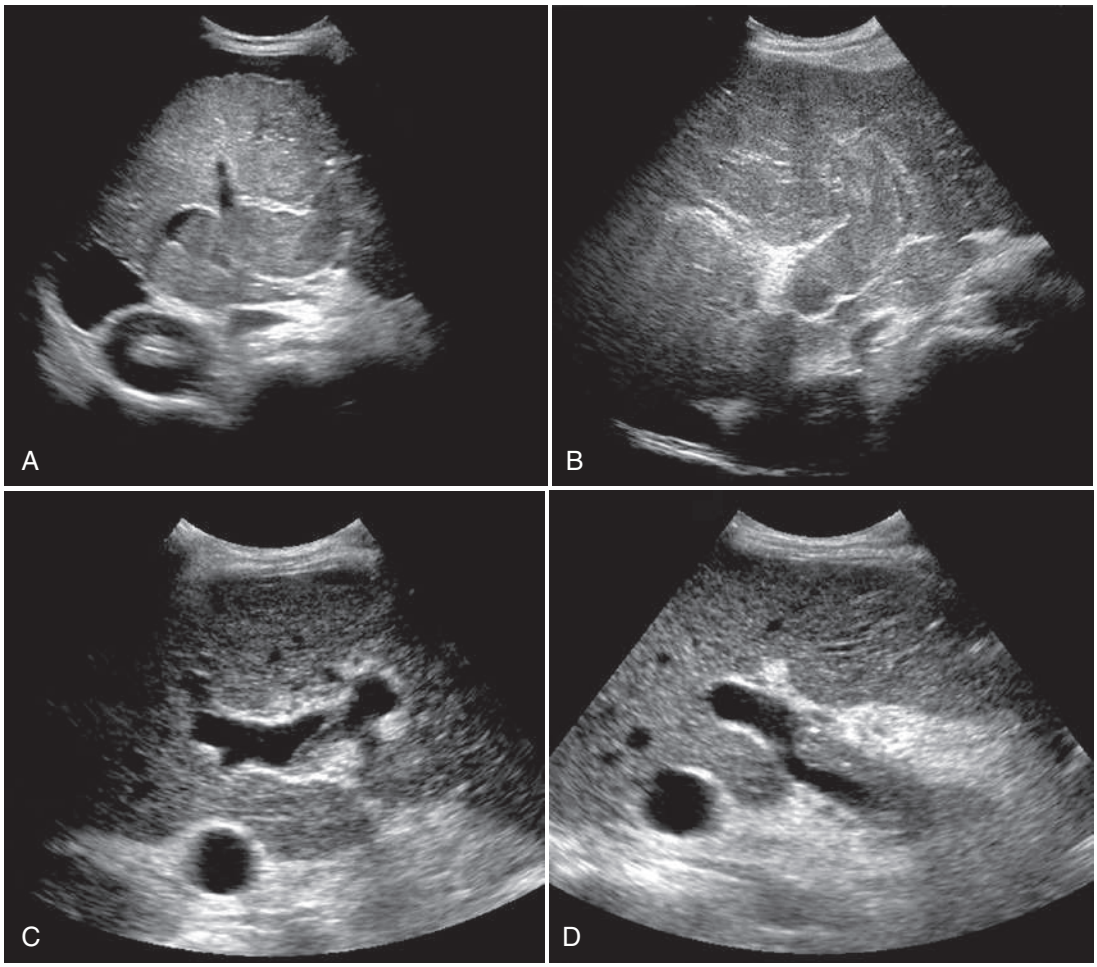

FIG. 4.32 Portal Vein Thrombosis: Benign and Malignant. Malignant thrombus: transverse views of **(A)** the vein at the porta hepatis and **(B)** left ascending left portal vein. Both are distended with occlusive thrombus. **Benign thrombus: (C)** transverse and **(D)** sagittal images of simple, bland nonocclusive thrombus in the left portal vein at the porta hepatis.

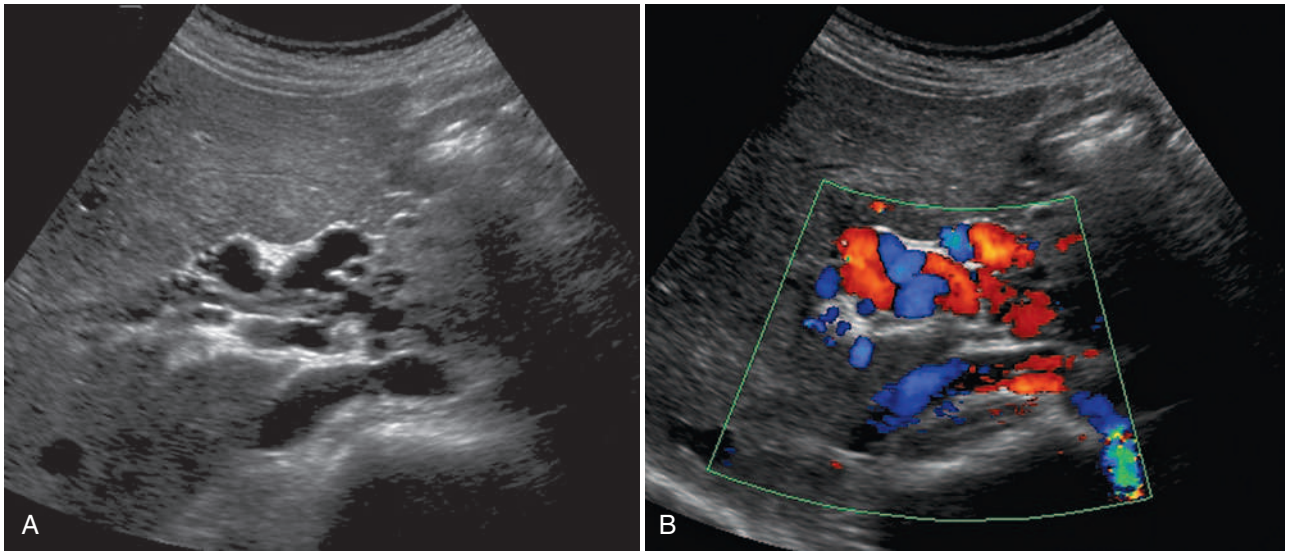

FIG. 4.33 Cavernous Transformation of Portal Vein. (A) Gray-scale image. **(B)** Color Doppler image. Numerous periportal collateral vessels are present.

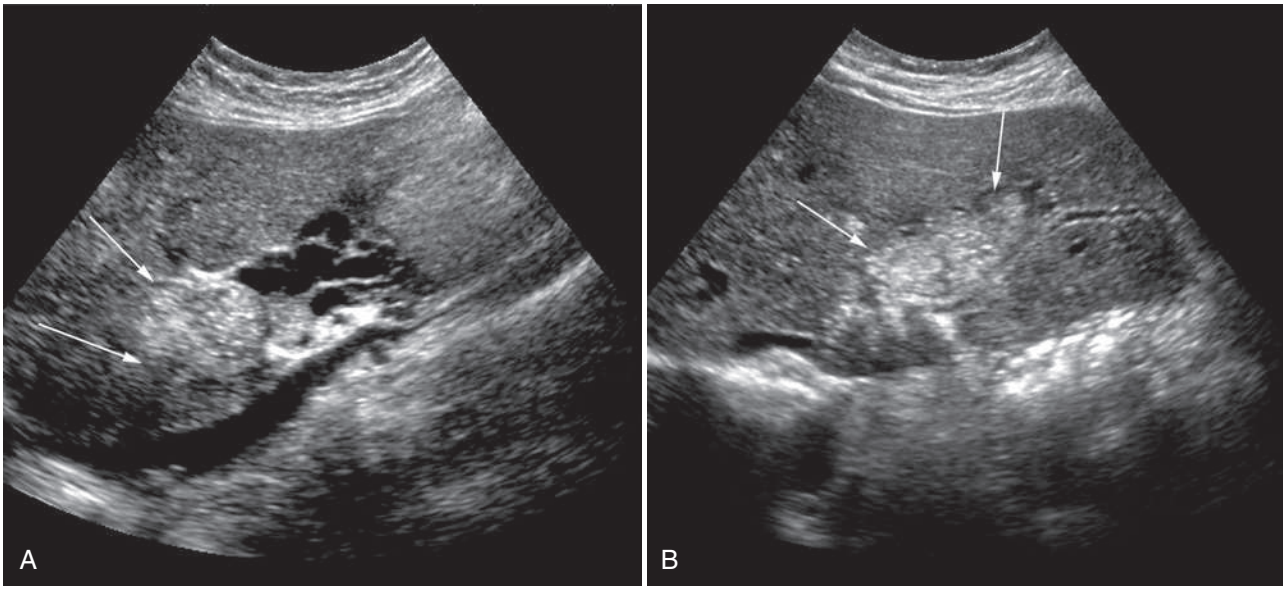

FIG. 4.34 Metastasis to the Portal Vein From Colon Cancer. (A) Sagittal view of the main portal vein at the porta hepatis and **(B)** subcostal oblique sonogram of the left ascending branch of the portal vein show the portal vein is distended and highly echogenic *(arrows)*. There is also evidence of cavernous transformation, an uncommon accompaniment of malignant portal vein occlusion.

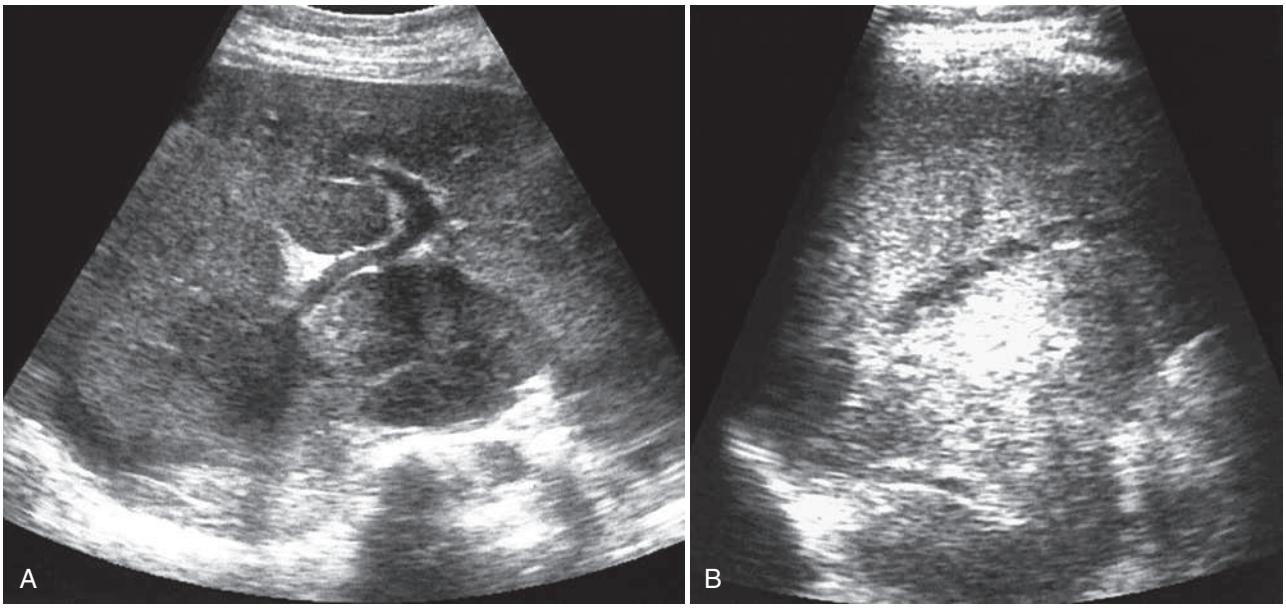

FIG. 4.35 Acute Budd-Chiari Syndrome. (A) Transverse view of liver shows a large, bulbous caudate lobe. **(B)** Sagittal view of right hepatic vein shows echoes within the vein lumen consistent with thrombosis, with absence of the vessel toward the inferior vena cava. Doppler ultrasound showed no flow in this vessel.

spared in Budd-Chiari syndrome because the emissary veins drain directly into the IVC at a lower level than the involved main hepatic veins. Increased blood flow through the caudate lobe leads to relative caudate enlargement.

Real-time scanning allows the radiologist to evaluate the IVC and hepatic veins noninvasively. Sonographic features include evidence of the **hepatic vein occlusion** (Fig. 4.35B and Fig. 4.36) and the development of **abnormal intrahepatic collaterals** (Fig. 4.37). The extent of hepatic venous involvement in Budd-Chiari syndrome includes partial or complete inability to see the hepatic veins, stenosis with proximal dilation, intraluminal echogenicity, thickened walls, thrombosis (Figs. 4.38 and 4.39), and extensive intrahepatic collaterals[107,108] (see Fig. 4.37). Membranous "webs" may be identified as echogenic or focal obliterations of the lumen.[107] Real-time ultrasonography, however, underestimates the presence of thrombosis and webs and may be inconclusive in a cirrhotic patient with hepatic veins that are difficult to image.[108] Intrahepatic collaterals, on gray-scale images, show as

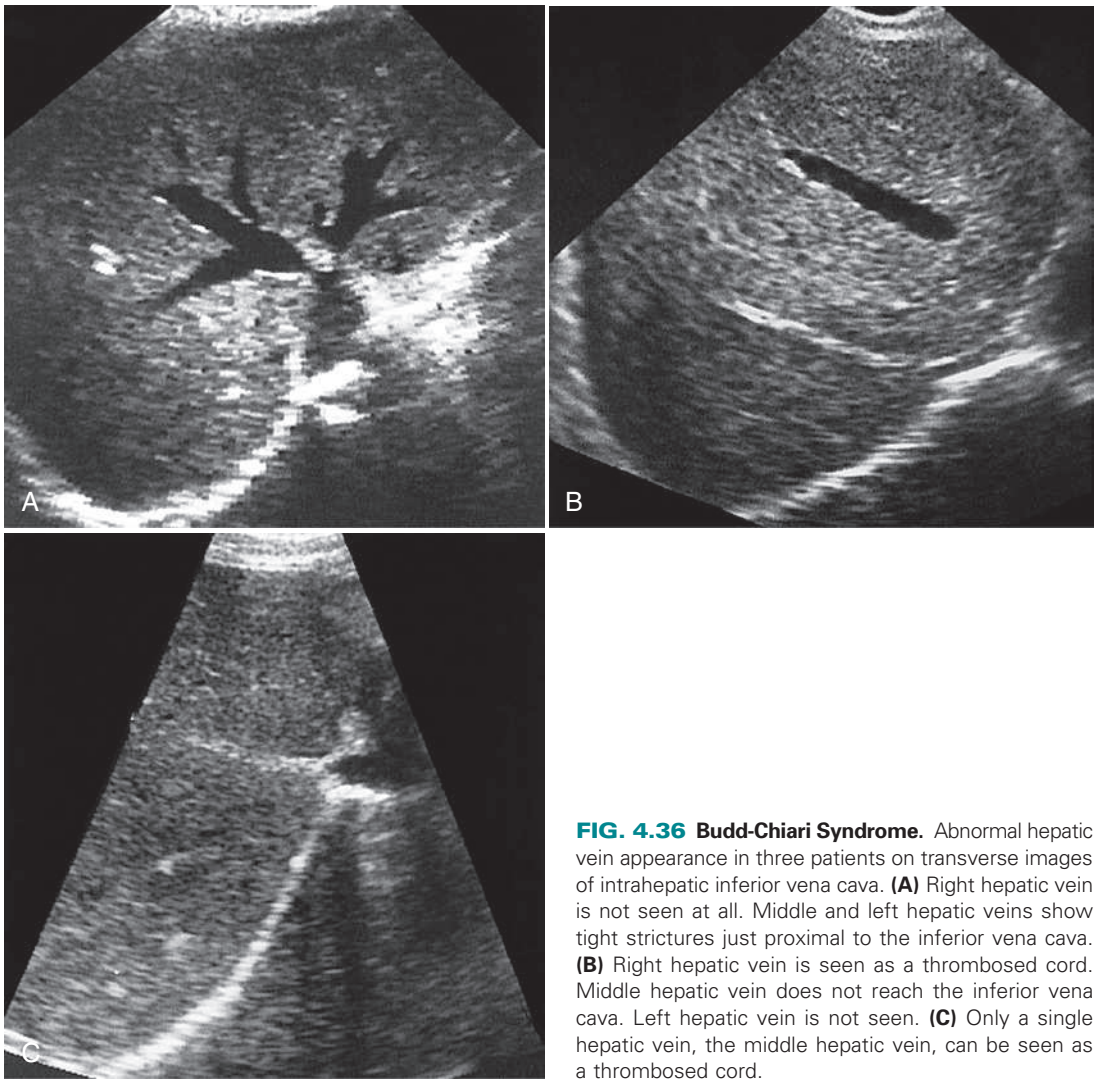

FIG. 4.36 Budd-Chiari Syndrome. Abnormal hepatic vein appearance in three patients on transverse images of intrahepatic inferior vena cava. **(A)** Right hepatic vein is not seen at all. Middle and left hepatic veins show tight strictures just proximal to the inferior vena cava. **(B)** Right hepatic vein is seen as a thrombosed cord. Middle hepatic vein does not reach the inferior vena cava. Left hepatic vein is not seen. **(C)** Only a single hepatic vein, the middle hepatic vein, can be seen as a thrombosed cord.

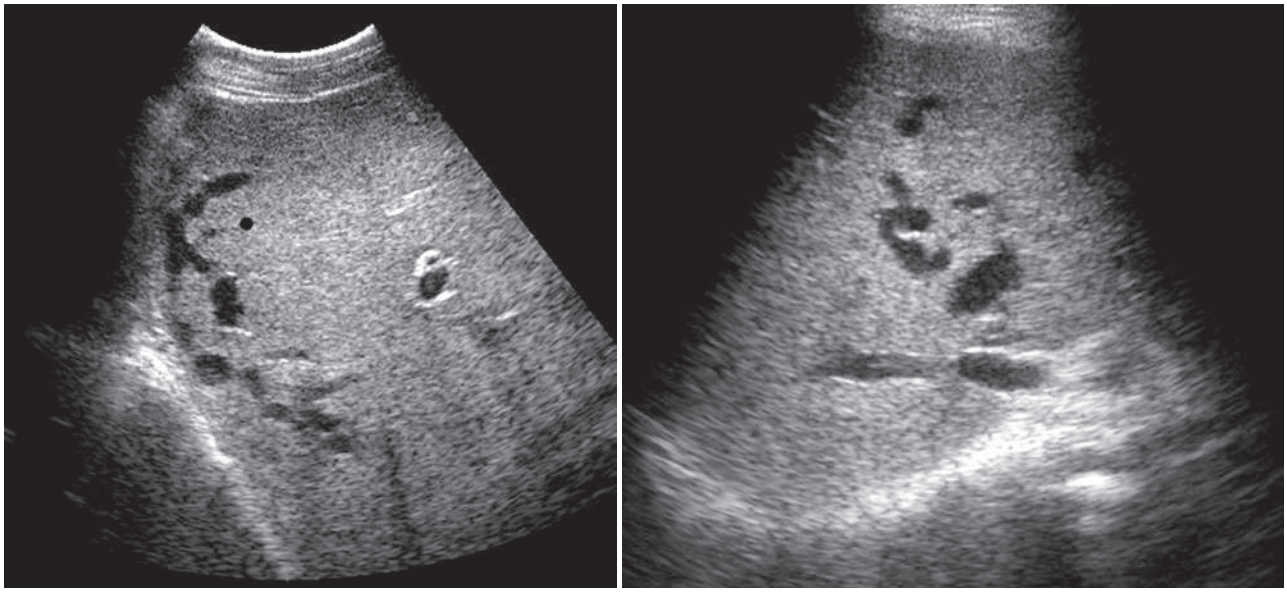

FIG. 4.37 Budd-Chiari Syndrome. Abnormal intrahepatic collaterals on gray-scale sonograms in two patients. Both images show vessels with abnormal locations and increased tortuosity compared with the normal intrahepatic vasculature.

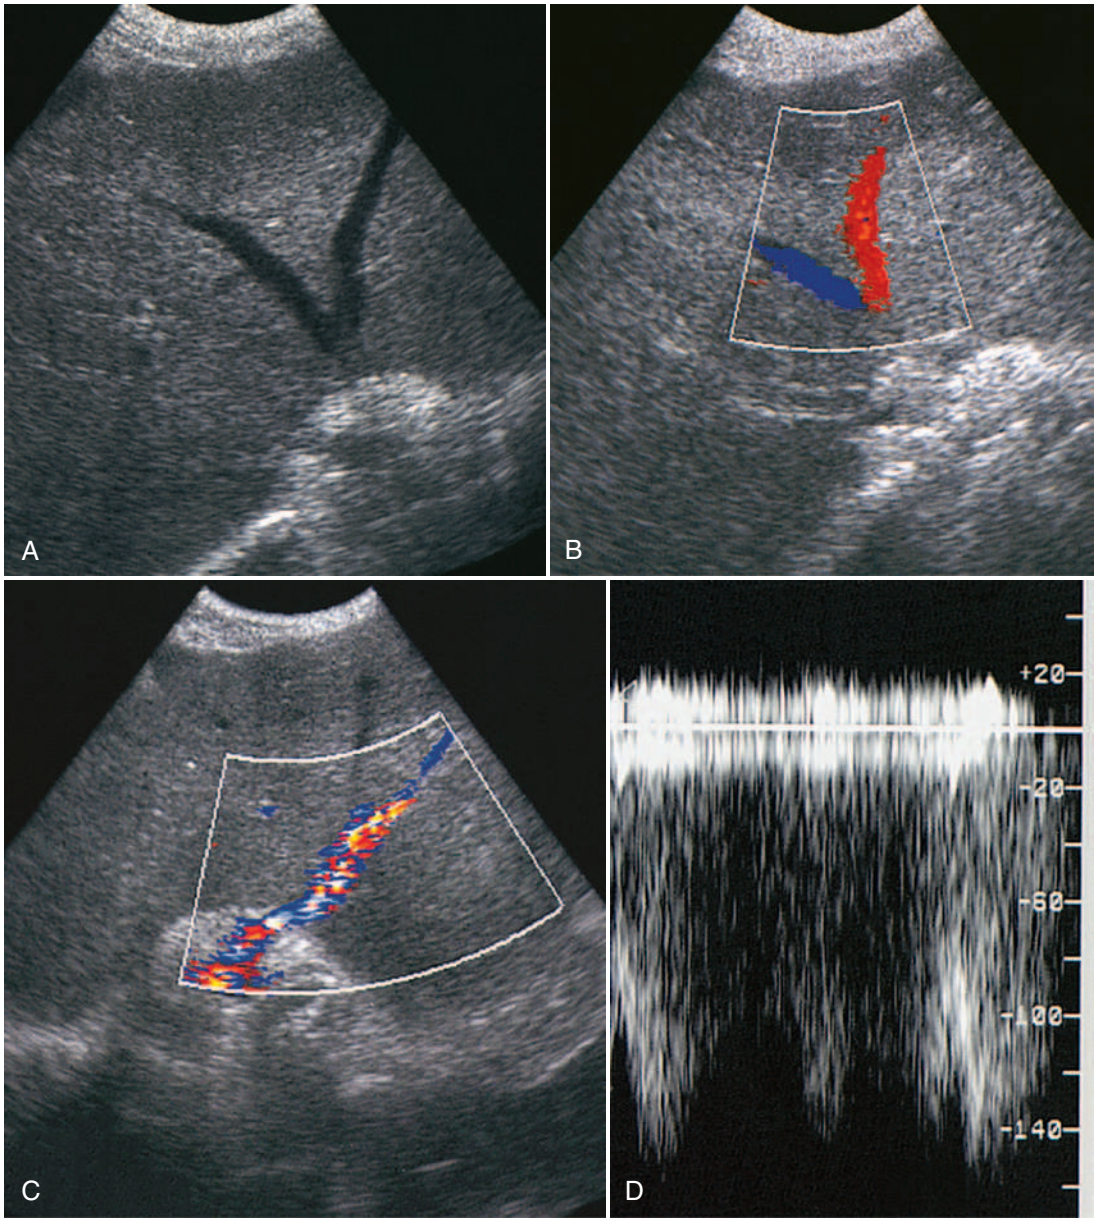

FIG. 4.38 Budd-Chiari Syndrome. (A) Gray-scale transverse image of hepatic venous confluence shows complete absence of the right hepatic vein with obliteration of the lumen of a common trunk for the middle and left hepatic veins. **(B)** Color Doppler image shows that blood flow in the middle hepatic vein *(blue)* is normally directed toward the inferior vena cava. As the trunk is obliterated, all the blood is flowing out of the left hepatic vein *(red),* which is abnormal. Other images showed anastomoses of the left hepatic vein with surface collaterals. **(C)** Color Doppler image shows an anomalous left hepatic vein with flow to the inferior vena cava (normal direction) and aliasing from a long stricture. **(D)** Spectral Doppler waveform of the anomalous left hepatic vein shows a very high abnormal velocity of approximately 140 cm/sec, confirming the tight stricture.

tubular vascular structures in an abnormal location and typically are seen extending from a hepatic vein to the liver surface, where they anastomose with systemic capsular vessels.

Duplex Doppler ultrasound and **color Doppler flow imaging** (CDFI) can help determine both the presence and the direction of hepatic venous flow in the evaluation of patients with suspected Budd-Chiari syndrome. The middle and left hepatic veins are best scanned in the transverse plane at the level of the xiphoid process. The right hepatic vein is best evaluated from a right intercostal approach.[105] The intricate pathways of blood flow out of the liver in the patient with Budd-Chiari syndrome can be mapped with documentation of hepatic venous occlusions, hepatic-systemic collaterals, hepatic venous–portal venous collaterals, and increased caliber of anomalous or accessory hepatic veins.

The normal blood flow in the IVC and hepatic veins is **phasic** in response to both the cardiac and respiratory cycles.[100] In Budd-Chiari syndrome, flow in the IVC, hepatic veins, or both, changes from phasic to **absent, reversed, turbulent,** or **continuous.**[104,112] Continuous flow has been called the **pseudoportal Doppler signal** and appears to reflect either partial IVC obstruction or extrinsic IVC compression.[103] The portal blood flow also may be affected and is characteristically either slowed or reversed.[104]

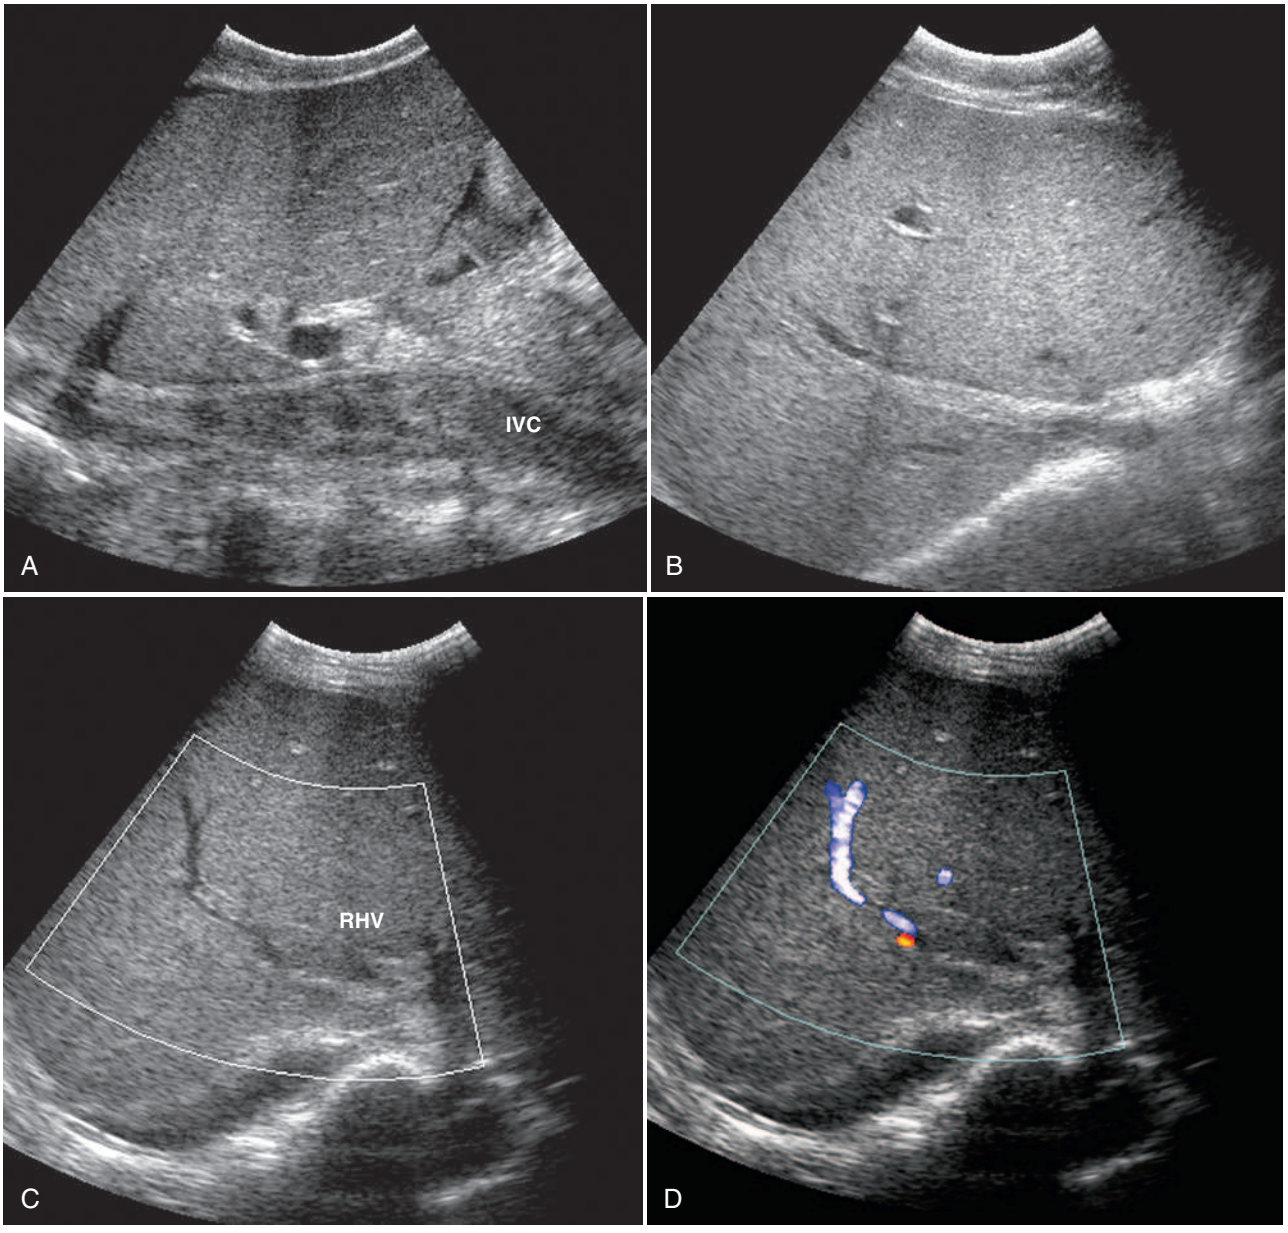

FIG. 4.39 Budd-Chiari Syndrome With Extensive Inferior Vena Cava Thrombosis. (A) Sagittal image of the inferior vena cava *(IVC)* shows that it is distended with echogenic thrombus. **(B)** Middle hepatic vein as a thrombosed cord. **(C)** Gray-scale image of right hepatic vein *(RHV)* and **(D)** color Doppler image show that anomalous right hepatic vein is distended with thrombus. There is flow in the vein proximal to the thrombus.

The use of Doppler in the patient with suspected Budd-Chiari syndrome lends strong supportive evidence to the gray-scale impression of missing, compressed, or otherwise abnormal hepatic veins and IVC.[102,112] Associated reversal of flow in the portal vein and epigastric collaterals is also optimally assessed with this technique.[112]

Hepatic veno-occlusive disease causes progressive occlusion of the small hepatic venules. The disease is endemic in Jamaica, secondary to **alkaloid toxicity** from bush tea. In North America, most cases are iatrogenic, secondary to hepatic irradiation and chemotherapy used in bone marrow transplantation.[101] Patients with hepatic veno-occlusive disease are clinically indistinguishable from those with Budd-Chiari syndrome. Duplex Doppler sonography demonstrates normal caliber, patency, and phasic forward (toward the heart) flow of the main hepatic veins and IVC.[101] Flow in the portal vein, however, may be abnormal, showing either reversed or "to and fro" flow.[101,113] In addition, the diagnosis of hepatic veno-occlusive disease may be suggested in a patient with decreased portal blood flow (compared with baseline measurement before ablative therapy).[101]

Portal Vein Aneurysm

Aneurysms of the portal vein are rare. Their origin is either congenital or acquired secondary to portal hypertension. Portal vein aneurysms have been described proximally at the junction of the superior mesenteric and splenic veins and distally involving

the portal venous radicles. The sonographic appearance is that of a vascular mass connected to the portal system with turbulent flow.

Intrahepatic Portosystemic Venous Shunts

Intrahepatic arterial-portal fistulas are well-recognized complications of large-gauge percutaneous liver biopsy and trauma. Conversely, intrahepatic portohepatic venous shunts are rare. Their cause is controversial and believed to be either congenital or related to portal hypertension.[114,115] Patients typically are middle aged and present with hepatic encephalopathy. Anatomically, portohepatic venous shunts are more common in the right lobe. Sonography demonstrates a tortuous tubular vessel or complex vascular channels, which connect a branch of the portal vein to a hepatic vein or the IVC.[114-116] The diagnosis is confirmed angiographically.

Aneurysm, Pseudoaneurysm, and Dissection

The hepatic artery is the fourth most common site of an intra-abdominal aneurysm, following the infrarenal aorta, iliac, and splenic arteries. Eighty percent of patients with a hepatic artery aneurysm experience **catastrophic rupture** into the peritoneum, biliary tree, gastrointestinal tract, or portal vein.[117] **Hepatic artery pseudoaneurysm** secondary to **chronic pancreatitis** has been described. The duplex Doppler sonographic examination revealed turbulent arterial flow within a sonolucent mass.[117] Primary dissection of the hepatic artery is rare and in most cases leads to death before diagnosis.[118] Sonography may show the intimal flap with the true and false channels.

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia, or **Osler-Weber-Rendu,** is an autosomal dominant disorder that causes arteriovenous (AV) malformations in the liver, hepatic fibrosis, and cirrhosis. Patients present with multiple telangiectasias and recurrent episodes of bleeding. Sonographic findings include a large feeding common hepatic artery up to 10 mm, multiple dilated tubular structures representing AV malformations, and large draining hepatic veins secondary to AV shunting.[119]

Peliosis Hepatis

Peliosis hepatis is a rare liver disorder characterized by blood-filled cavities ranging from less than a millimeter to many centimeters in diameter. It can be distinguished from hemangioma by the presence of portal tracts within the fibrous stroma of the blood spaces. The pathogenesis of peliosis hepatis involves rupture of the reticulin fibers that support the sinusoidal walls, secondary to cell injury or nonspecific hepatocellular necrosis. The diagnosis of peliosis can be made with certainty only by histologic examination. Most cases of peliosis affect the liver, although other solid internal organs and lymph nodes may be involved in the process as well.

Although early reports described incidental detection of peliosis hepatis at autopsy in patients with chronic wasting disorders, it has now been seen following renal and liver transplantation, in association with a multitude of drugs, especially anabolic steroids, and with an increased incidence in patients with HIV.[119] The HIV association may occur alone or as part of bacillary angiomatosis in the spectrum of opportunistic infections of AIDS.[120] Peliosis hepatis has the potential to be aggressive and lethal.

The imaging features of peliosis hepatis have been described in single case reports,[121-123] although often without adequate histologic confirmation. Angiographically, the peliotic lesions have been described as accumulations of contrast detected late in the arterial phase and becoming more distinct in the parenchymal phase.[124] On sonography, described lesions are nonspecific and have shown single or multiple masses of heterogeneous echogenicity.[119,120,125] Calcifications have been reported[125] (Fig. 4.40). Peliosis hepatis is difficult to diagnose both clinically and radiologically and must be suspected in a susceptible individual with a liver mass.

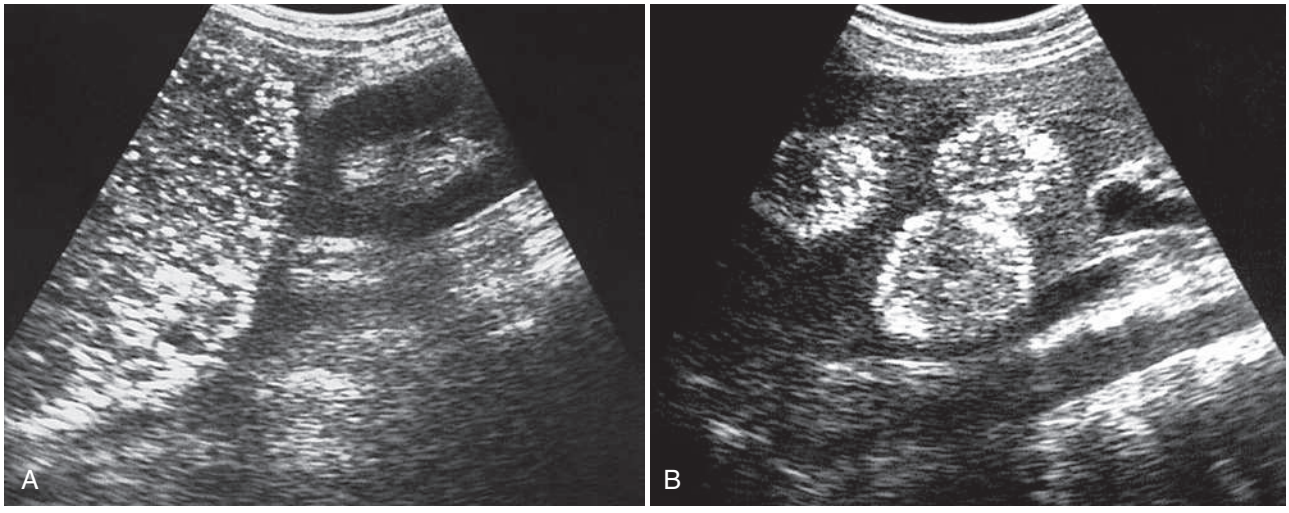

FIG. 4.40 Peliosis Hepatis. Peliosis hepatis in 34-year-old woman with deteriorating liver function necessitating transplantation. **(A)** Sagittal right lobe and **(B)** sagittal left lobe scans show multiple large liver masses with innumerable tiny punctate calcifications. (With permission from Muradali D, Wilson SR, Wanless IR, et al. Peliosis hepatis with intrahepatic calcifications. J Ultrasound Med. 1996;15[3]:257-260.[125])

HEPATIC MASSES

Focal liver masses include a variety of malignant and benign neoplasms, as well as masses with developmental, inflammatory, and traumatic causes. In cross-sectional imaging, two basic issues relate to a focal liver lesion: **characterization** of a known liver lesion (what is it?) and **detection** (is it there?). The answer to either question requires a focused examination, often adjusted according to the clinical situation.

Liver Mass Characterization

Characterization of a liver mass on conventional sonography is based on the **appearance** of the mass on gray-scale imaging and **vascular information** derived from spectral, color, and power Doppler sonography. With excellent spatial and contrast resolution, the gray-scale morphology of a mass allows for the differentiation of cystic and solid masses, and characteristic appearances may suggest the correct diagnosis without further evaluation. Often, however, definitive diagnosis is not based on gray-scale information alone, but on vascular information obtained on conventional Doppler ultrasound examination. However, conventional Doppler often fails in the evaluation of a focal liver mass, particularly in a large patient or on a small or deep liver lesion, or on a mass with inherent weak Doppler signals. Motion artifact is also highly problematic for abdominal Doppler ultrasound studies, and a left lobe liver mass close to the pulsation of the cardiac apex, for example, can limit assessment by conventional Doppler. For these reasons, conventional ultrasound is not regarded highly for characterization of focal liver masses, and a mass detected on ultrasound is historically evaluated further with CECT or MRI for definitive characterization.

Role of Microbubble Contrast Agents

Worldwide, noninvasive diagnosis of focal liver masses is achieved with CECT and MRI based on recognized enhancement patterns in the arterial and portal venous phases. These noninvasive methods of characterization have become so accurate that excisional and percutaneous biopsy for diagnosis of liver masses is now rarely performed. In recent years, however, CEUS has joined the ranks of CT and MRI in providing similar diagnostic information as well as information unique to CEUS.[126] Injection of a microbubble contrast agent to enhance the Doppler signal from blood and imaging with a specialized imaging technique such as pulse inversion sonography allow for preferential detection of the signal from the contrast agent while suppressing the signal from background tissue.

Ultrasound contrast agents currently in use are second-generation agents comprising tiny bubbles of a perfluorocarbon gas contained within a stabilizing shell. Microbubble contrast agents are blood pool agents that do not diffuse through the vascular endothelium. This is of potential importance when imaging the liver because comparable contrast agents for CT and MRI may diffuse into the interstitium of a tumor. Our personal experience with perfluorocarbon microbubble agents is largely based on the use of Definity (Lantheus Medical Imaging, Billerica, MA) and brief exposure to Optison (GE Healthcare, Milwaukee, WI).[127,128] We routinely perform CEUS for characterization of incidentally detected liver masses, those found on surveillance scans of patients at risk for HCC, and any focal mass referred by our clinicians found on outside imaging or indeterminate on CT and MRI.[129]

Microbubble contrast agents for ultrasound are unique in that they interact with the imaging process.[127] The major determinant of this interaction is the peak negative pressure of the transmitted ultrasound pulse, reflected by the **mechanical index** (MI). The bubbles show stable, nonlinear oscillation when exposed to an ultrasound field with a low MI, with the production of harmonics of the transmitted frequency, including the frequency double that of the sound emitted by the transducer, the **second harmonic.** When the MI is raised sufficiently, the bubbles undergo irreversible disruption, with the production of a brief but bright, high-intensity ultrasound signal (see Chapter 3).

Liver lesion characterization with microbubble contrast agents is based on lesional vascularity and lesional enhancement in the arterial phase (10-40 sec), portal venous phase (40-90 sec), and late phase (up to 5 minutes). **Lesional vascularity** assessment depends on continuous imaging of the agents while they are within the vascular pool. We document the presence, number, distribution, and morphology of any lesional vessels. A low MI is essential because it will preserve the contrast agent population without destruction of the bubbles in the imaging field, allowing for prolonged periods of real-time observation. The morphology of the lesional vessels is discriminatory and facilitates the diagnosis of liver lesions (Fig. 4.41).

Lesional enhancement is best determined by comparing the echogenicity of the lesion to the echogenicity of the liver at a similar depth on the same frame and requires knowledge of liver blood flow. The liver has a dual blood supply from the hepatic artery and portal vein. The liver derives a larger proportion of its blood from the portal vein, whereas most liver tumors derive their blood supply from the hepatic artery. At the initiation of the injection, the low-MI technique will cause the entire field of view (FOV) to appear virtually black, regardless of the baseline appearance of the liver and the lesion in question. In fact, a known mass may be invisible at this point. As the microbubbles arrive in the FOV, the discrete vessels in the liver and then those within a liver lesion will be visualized, followed by increasing generalized enhancement as the microvascular volume of liver and lesion fills with the contrast agent. The liver parenchyma will appear more echogenic in the arterial phase than at baseline, and even more enhanced in the portal venous phase, as a reflection of its blood flow. Vascularity and enhancement patterns of a liver lesion, by comparison, will therefore reflect the actual blood flow and hemodynamics of the lesion in question, such that a hyperarterialized mass will appear more enhanced against a less enhanced liver on an arterial phase sequence. Conversely, a hypoperfused lesion will appear as a dark or hypoechoic region within the enhanced liver on an arterial phase sequence.

Currently, evaluation of lesional enhancement is usually performed with the low-MI technique just described. However, details of vessel morphology and lesional enhancement are even more sensitively assessed using a bubble-tracking technique called **maximum-intensity projection** (MIP) imaging.[130] In this

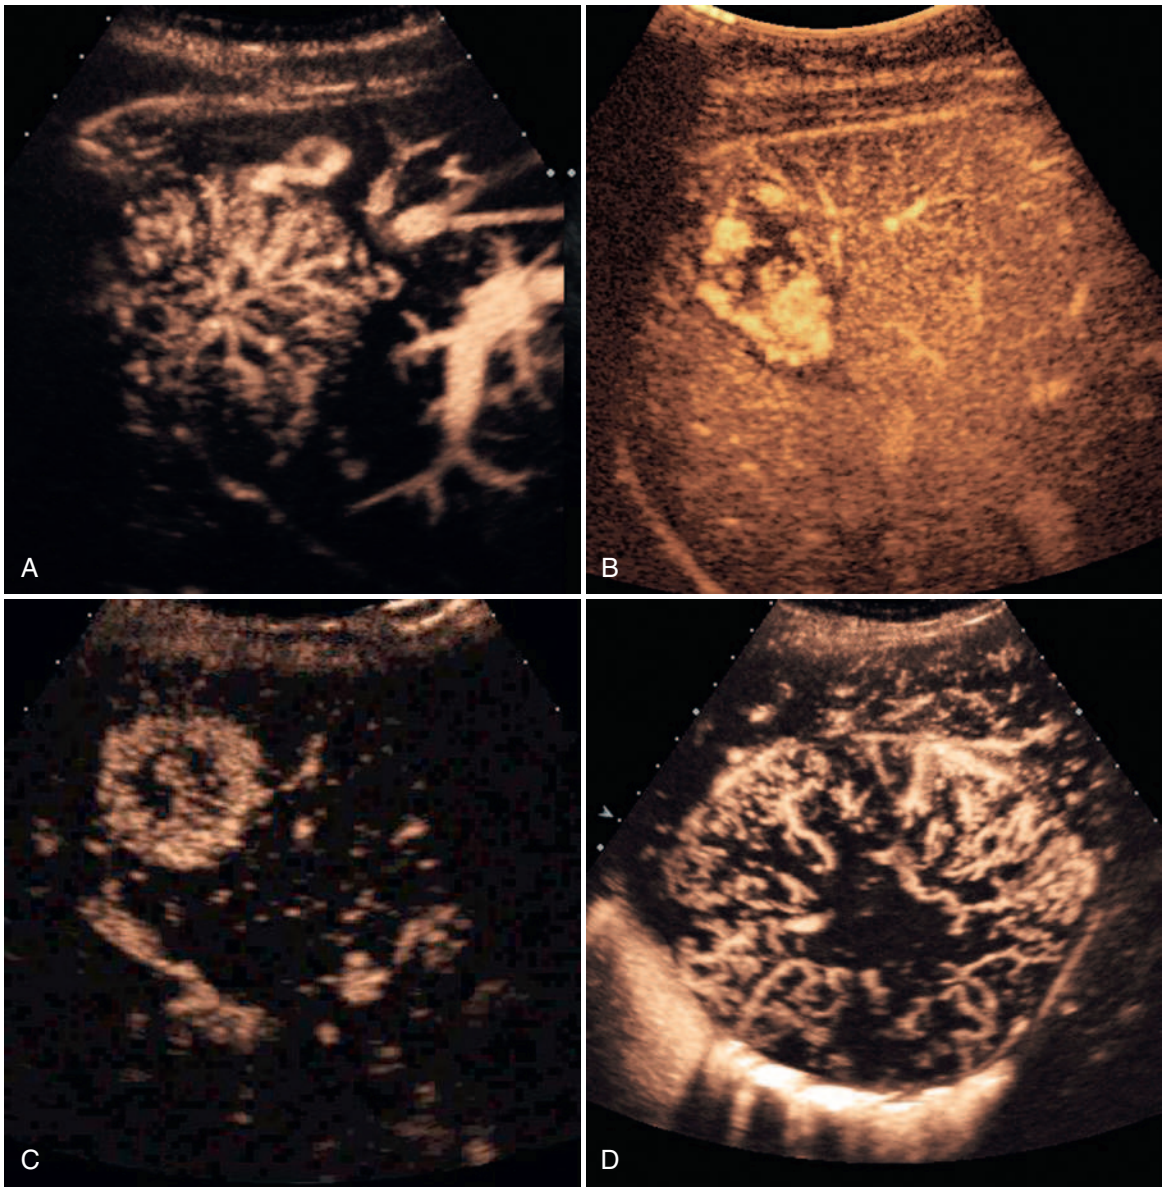

FIG. 4.41 Early Arterial Phase Vascular Morphology. Shown on real-time dynamic ultrasound, this is contributory to diagnosis of focal liver masses. **(A)** Stellate vessels are highly suggestive of **focal nodular hyperplasia. (B)** Peripheral discontinuous nodular enhancement without linear vascularity suggests **hemangioma. (C)** Rim enhancement has a high association with malignant disease, especially **metastases** and **cholangiocarcinoma. (D)** Dysmorphic tortuous vessels are suggestive of malignant tumors, in this case a **hepatocellular carcinoma.** The filling from the periphery, as here, is common for this diagnosis.

technique, performed either at wash-in of contrast or at the peak of arterial phase enhancement, a **brief high-MI exposure will destroy all the bubbles** within the FOV. Sequential frames, as the lesion and liver are reperfused, will track the bubble course providing exquisite resolution (Fig. 4.42, Videos 4.5 and 4.6).

There are established **algorithms** for the diagnosis of focal liver masses with CEUS, with similarities to CT and MRI algorithms but also important differences[131-133] (Table 4.3). Diagnosis of **benign liver masses, hemangioma,** and **focal nodular hyperplasia** (FNH) is extremely accurate showing characteristic features of enhancement in the arterial phase and **sustained enhancement** in the portal venous phase (Fig. 4.43), such that their enhancement equals or exceeds the enhancement of the adjacent liver. **Malignant tumors,** by comparison, tend to show **washout,** such that the tumor appears unenhanced in the portal venous phase of enhancement (Fig. 4.44). Exceptions to this general rule include frequent washout of benign **hepatic adenoma** and delayed or no washout of HCC. Discrimination of benign and malignant liver masses has similar high accuracy.[134]

Liver Mass Detection

Excellent spatial resolution allows small lesions to be well seen on sonography. Therefore it is not size but **echogenicity** that

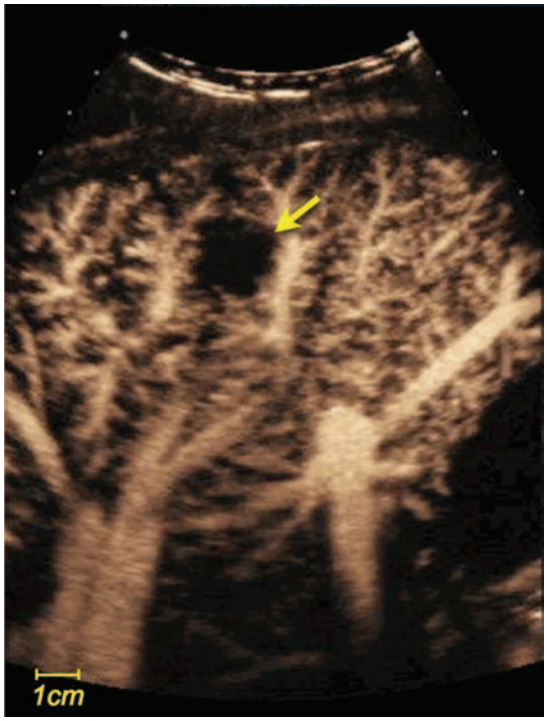

FIG. 4.42 Normal Liver Vasculature. Temporal maximum-intensity projection image shows accumulated enhancement in 11 seconds after contrast material arrives in liver. Depiction of vessel structure to fifth-order branching is evident. Focal unenhanced region *(arrow)* is slowly perfusing **hemangioma.** (With permission from Wilson S, Jang H, Kim T, et al. Real-time temporal maximum-intensity-projection imaging of hepatic lesions with contrast-enhanced sonography. AJR Am J Roentgenol. 2008;190[3]:691-695.[130])

determines lesion conspicuity on a sonogram. That is, a tiny mass of only a few millimeters will be easily seen if it is increased or decreased in echogenicity compared with the adjacent liver parenchyma. Because many metastases are either hypoechoic or hyperechoic relative to the liver, a careful examination should allow for their detection. Nonetheless, many metastatic lesions are of similar echogenicity to the background liver, making their detection difficult or impossible, even if they are of a substantial size. This occurs when the backscatter from the lesion is virtually identical to the backscatter from the liver parenchyma.

To combat this inherent problem of lack of contrast between many metastatic liver lesions and the background liver on conventional sonography, contrast-enhanced liver ultrasound is helpful (Fig. 4.45). CEUS increases the backscatter from the liver compared with the liver lesions, thereby improving their detection. This occurs rapidly following the arterial phase of enhancement and generally lasts for several minutes beginning in the portal venous and persisting for the late phase.

Of historic interest is the use of the first-generation contrast agent Levovist (Schering AG, Berlin). After clearance of the contrast agent from the vascular pool, the microbubble persisted in the liver, probably within the Kupffer cells on the basis of phagocytosis. A high-MI sweep through the liver produced bright enhancement in the distribution of the bubbles. Therefore all normal liver enhances. Liver metastases, lacking Kupffer cells, do not enhance and therefore show as black or hypoechoic holes within the enhanced parenchyma[135] (Fig. 4.45A and B). In a multicenter study conducted in Europe and Canada, more and smaller lesions were seen than on baseline scan.[136] Overall, lesion detection was equivalent to that of CT and MRI. The decibel difference between the lesions and the liver parenchyma is increased many fold because of increased backscatter from contrast agent within the normal liver tissue. Although many results were compelling, these first-generation contrast agents are no longer marketed.

Today, current requirements for improved lesion detection use a similar technique of CEUS with a **perfluorocarbon contrast agent** and low-MI scanning in both the arterial and the portal venous phase. The use of a low-MI imaging technique for lesion detection has advantages in terms of scanning because the microbubble population is preserved and timing is not so critical. Virtually all metastases will be unenhanced relative to the liver in the portal and the late phase and the liver parenchyma will remain optimally enhanced. Therefore malignant lesions tend to appear hypoechoic in the portal phase, allowing for improved lesion detection (Fig. 4.45C and D). This observation, that malignant lesions tend to be hypoechoic in the portal venous phase of perfluorocarbon liver enhancement, is helpful for both lesion detection and lesion characterization. Enhancement of benign lesions, FNH, and hemangioma generally equals or exceeds liver enhancement in the portal venous phase.

Detection of hypervascular liver masses (e.g., HCC, metastases) is also improved by scanning with perfluorocarbon agents in the arterial phase. These lesions will generally show as hyperechoic masses relative to the liver parenchyma in the arterial phase because they are predominantly supplied by hepatic arterial flow.

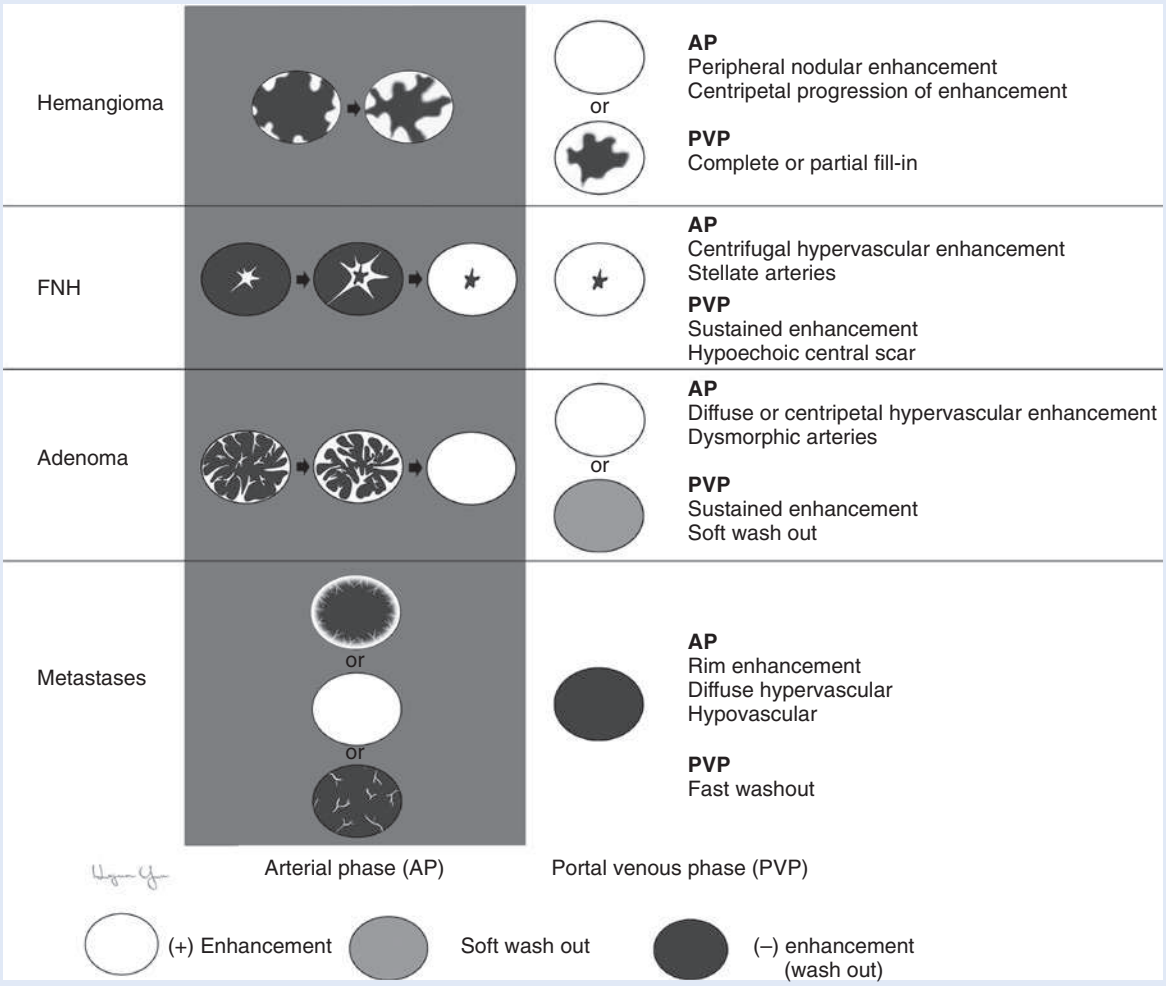
HEPATIC NEOPLASMS

Sonographic visualization of a focal liver mass may occur in a variety of clinical scenarios, ranging from incidental detection to identification in a symptomatic patient or as part of a focused search in a patient at risk for hepatic neoplasm. **Hemangiomas, FNH,** and **adenomas** are the benign neoplasms typically encountered in the liver, whereas **HCC** and **metastases** account for the majority of malignant tumors.

The role of imaging in the evaluation of an identified focal liver mass is to determine which masses are potentially clinically important, requiring confirmations of their diagnoses, and which masses are likely to be insignificant and benign, not requiring further evaluation to confirm their nature. On a sonographic study, there is considerable overlap in the appearances of focal liver masses. Once a liver mass is seen, however, the excellent contrast and spatial resolution of state-of-the-art ultrasound equipment have provided guidelines for the initial management of patients, which include recognition of the following features:

- A **hypoechoic halo** identified around an echogenic or isoechoic liver mass is an ominous sonographic sign necessitating definitive diagnosis.
- A **hypoechoic and solid liver mass** is highly likely to be significant and also requires definitive diagnosis.

TABLE 4.3 Schematic of Algorithm for Liver Mass Diagnosis on Contrast-Enhanced Ultrasound



AP, Arterial phase; *FNH,* focal nodular hyperplasia; *PVP,* portal venous phase.

- **Multiple solid liver masses** may be significant and suggest possible metastatic or multifocal malignant liver disease. However, hemangiomas are also frequently multiple.
- **Clinical history** of malignancy, chronic liver disease or hepatitis, and symptoms referable to the liver are requisite information for interpretation of a focal liver lesion.

Benign Hepatic Neoplasms

Cavernous Hemangioma

Cavernous hemangiomas are the most common benign tumors of the liver, occurring in approximately 4% of the population. They occur in all age groups but are more common in adults, particularly women, with a female-to-male ratio of approximately 5:1. Histologically, hemangiomas consist of multiple vascular channels that are lined by a single layer of endothelium and separated and supported by fibrous septa. The vascular spaces may contain thrombi.

The vast majority of hemangiomas are small, asymptomatic, and discovered incidentally. Large lesions may, in rare cases, produce symptoms of acute abdominal pain, caused by hemorrhage or thrombosis within the tumor. Thrombocytopenia, caused by sequestration and destruction of platelets within a large cavernous hemangioma **(Kasabach-Merritt syndrome),** occasionally occurs in infants and is rare in adults.

Traditional teaching suggests that once identified in the adult, hemangiomas usually have reached a stable size, rarely changing in appearance or size.[137,138] In our practice, however, we have documented substantial growth of some lesions over many years of follow-up. Hemangiomas may enlarge during pregnancy or with the administration of estrogens, suggesting the tumor is hormone dependent.

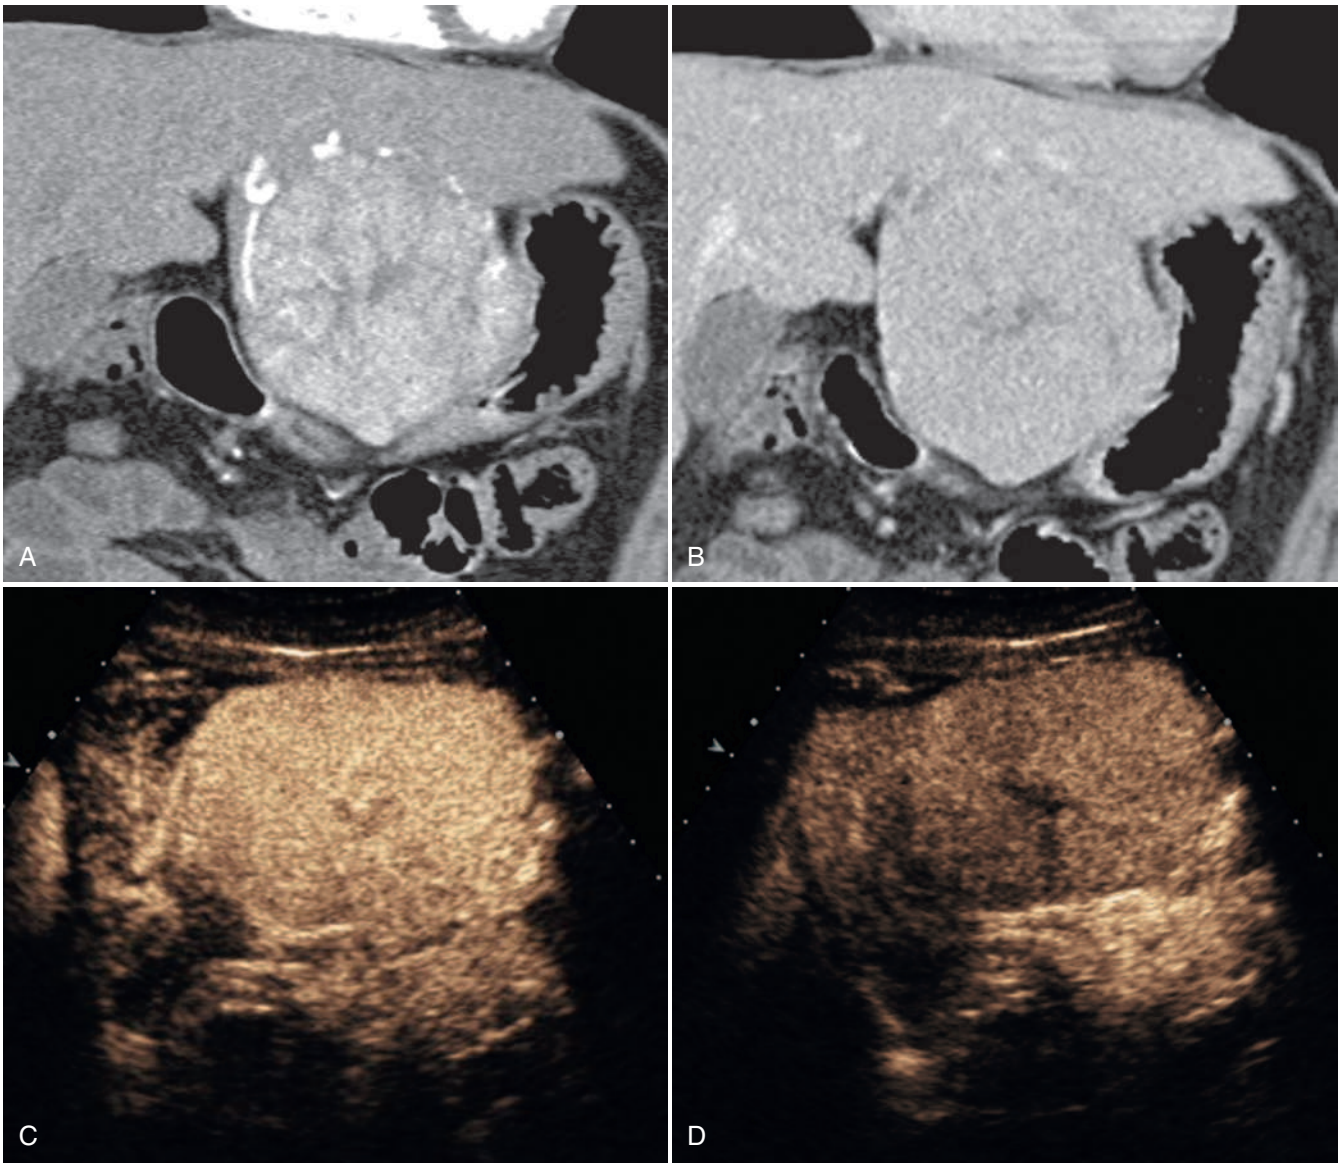

FIG. 4.43 Sustained enhancement in the portal venous phase, on contrast-enhanced ultrasound (CEUS) and contrast-enhanced computed tomography (CECT) scan, suggestive of a benign mass. **(A)** and **(C)** are arterial phase images on CT and CEUS, respectively, both showing arterial phase hyperenhancement. **(B)** and **(D)** are portal venous phase images on CT and CEUS, respectively, both showing sustained enhancement and a nonenhanced scar. This sustained enhancement is concordant on the two scans and suggests a benign tumor. This is a confirmed FNH. See also Video 4.5. (With permission from Wilson S, Greenbaum L, Goldberg B. Contrast-enhanced ultrasound: what is the evidence and what are the obstacles? AJR Am J Roentgenol. 2009;193[1]:55-60.[129])

The sonographic appearance of cavernous hemangioma varies. Typically the lesion is small (<3 cm in diameter), well defined, homogeneous, and hyperechoic[139] (Fig. 4.46A). The increased echogenicity has been related to the numerous interfaces between the walls of the cavernous sinuses and the blood within.[140] Inconsistently seen and nonspecific, posterior acoustic enhancement has been correlated with hypervascularity on angiography[141] (Fig. 4.46H). Approximately 67% to 79% of hemangiomas are hyperechoic,[142,143] of which 58% to 73% are homogeneous.[135,141] Other features include a nonhomogeneous central area containing hypoechoic portions, which may appear uniformly granular (Fig. 4.46D-F) or lacelike in character (Fig. 4.46D); an echogenic border, either a thin rim or a thick rind (Fig. 4.46E-G); and a tendency toward scalloping of the margin (Fig. 4.46B).[144] Larger lesions tend to be heterogeneous, with central hypoechoic foci corresponding to fibrous collagen scars (Fig. 4.46C), large vascular spaces, or both. A hemangioma may appear hypoechoic within the background of a fatty infiltrated liver.[145] Calcification is rare (Fig. 4.46I).

Hemangiomas are characterized by extremely slow blood flow that will not routinely be detected by either color or duplex Doppler sonography. Occasional lesions may show a low to midrange kilohertz (kHz) shift from both peripheral and central blood vessels. The ability of power Doppler ultrasound, which

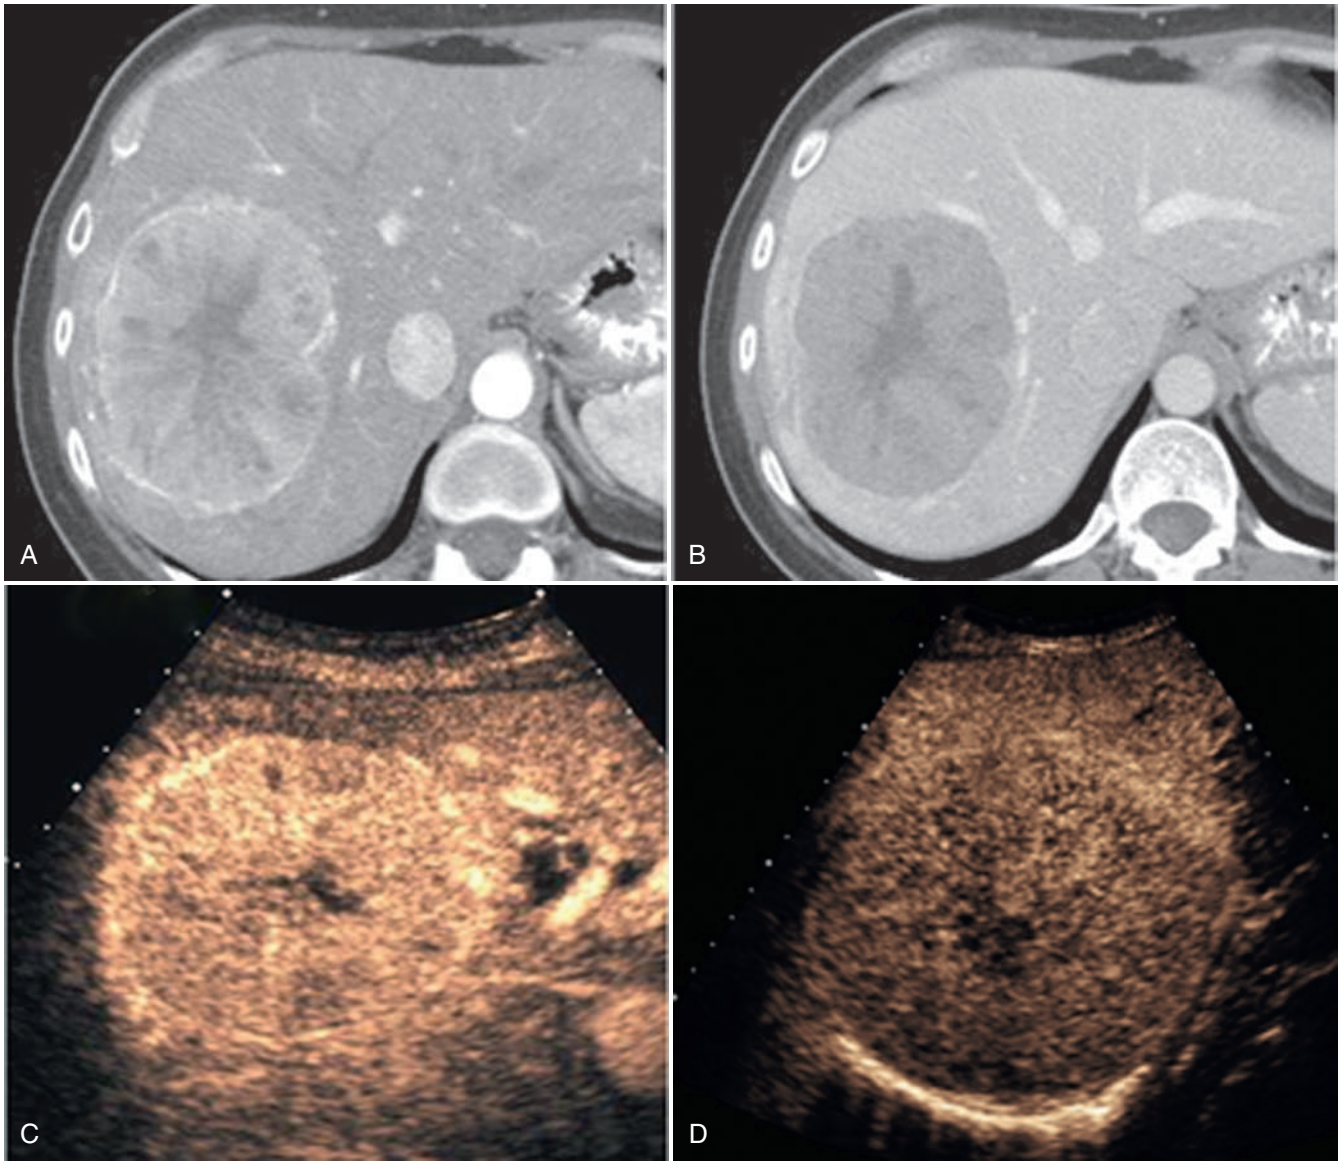

FIG. 4.44 Washout in the portal venous phase, on computed tomography (CT) and contrast-enhanced ultrasound (CEUS) is suggestive of a malignant mass in this patient with hepatocellular carcinoma. Contrast-enhanced CT scan in the **(A)** arterial phase and **(B)** portal venous phase. **(C)** and **(D)** Same mass at the same time intervals on CEUS. On each scan, there is hyperenhancement in the arterial phase and washout in the portal venous phase highly correlated with a malignant mass.

is more sensitive to slow flow, to detect signals within a hemangioma is controversial.[146]

Cavernous hemangiomas are often observed on abdominal sonograms performed for any reason, and confirmation of all visualized lesions has proved to be costly and unnecessary. Therefore it is considered acceptable practice to manage some patients conservatively without confirmation of the diagnosis. When a hyperechoic lesion typical of a cavernous hemangioma is incidentally discovered, no further examination is usually necessary, or at most, a repeat ultrasound is performed in 3 to 6 months to document lack of change.

Conversely, potentially significant lesions may mimic the morphology of a hemangioma on ultrasound and produce a single mass or multiple masses of uniform increased echogenicity. These include metastases from a colon primary or a vascular primary tumor, such as a neuroendocrine tumor and small HCCs in particular. In a prospective evaluation of 1982 patients with newly diagnosed cirrhosis, Caturelli et al.[147] found that 50% of echogenic liver lesions with morphology suggestive of hemangioma had that diagnosis, although 50% of these proved to be HCC. The authors also showed that in 1648 patients with known cirrhosis and new appearance of an echogenic hemangioma-like mass, all were HCC. These results emphasize the necessity to prove the diagnosis of all masses with this morphology in high-risk patients. Therefore in a patient with a known malignancy, an increased risk for hepatoma, abnormal results of LFTs, clinical symptoms referable to the liver, or an atypical sonographic pattern, one of the following additional imaging techniques is generally

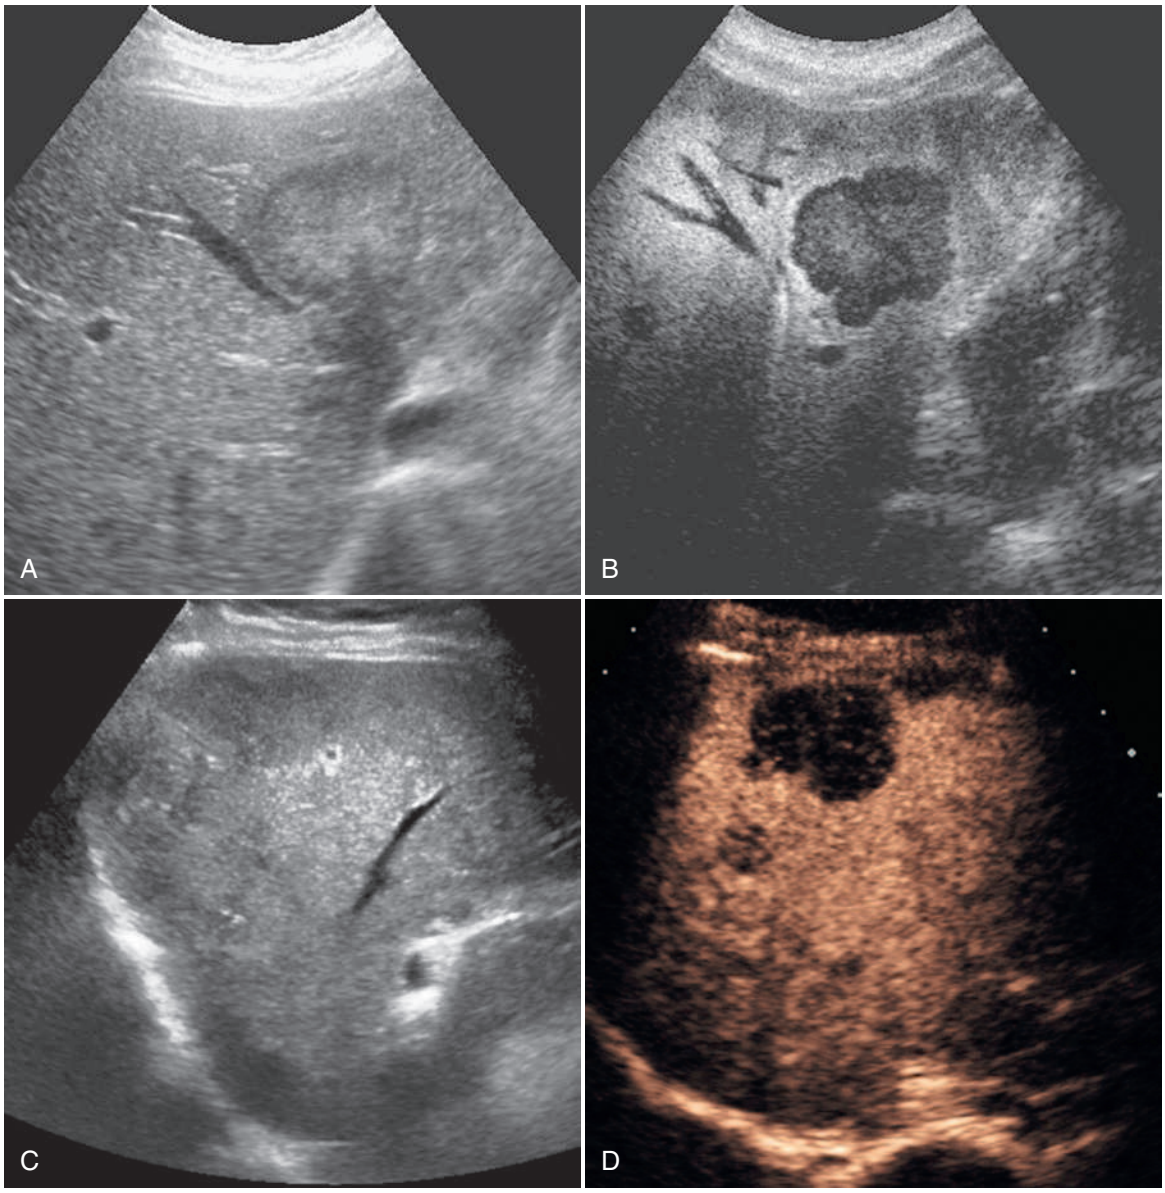

FIG. 4.45 Contrast-Enhanced Ultrasound (CEUS) Images of Increased Conspicuity of Metastases in Two Patients. (A) and **(B)** are of historic significance. **(A)** Subtle isoechoic mass in the liver. **(B)** Postvascular image with contrast agent Levovist showing increased echogenicity of the liver. The mass now appears black with increased conspicuity. **(C)** Baseline image showing a hypoechoic region in the liver without good margination raising the possibility it could be fat sparing. **(D)** CEUS performed with a perfluorocarbon contrast agent shows punched-out washout of a large metastasis, again increasing the conspicuity. Two additional small masses are shown. More and smaller metastases are detected with CEUS than on baseline.

recommended to confirm the suspicion of hemangioma: CEUS, CT, or MRI.

In the arterial phase on CEUS, hemangiomas show peripheral puddles and pools that are brighter than the adjacent enhanced liver parenchyma. There are no linear vessels. Over time, centripetal progression of the enhancement leads to complete globular fill-in, with sustained enhancement equal to or better than the liver in the portal venous phase, which may last for several minutes[148] (Fig. 4.47). This enhancement may occur rapidly or slowly and may be incomplete, even in the late portal venous phase (Video 4.6). We have diagnosed almost 100% of hemangiomas with CEUS, including those of small size, removing the necessity for confirmation with other imaging modalities.

In a small minority of patients, imaging will not allow definitive diagnosis of hemangioma. Percutaneous biopsy of hepatic hemangiomas has been safely performed.[149,150] Cronan et al.[149] performed biopsies on 15 patients (12 of whom were outpatients) using a 20-gauge needle. In all patients the histologic sample was diagnostic and was characterized by large spaces with an endothelial lining. It is recommended when sampling lesions that normal liver be interposed between the abdominal wall and the hemangioma to allow hepatic tamponade of any potential bleeding.

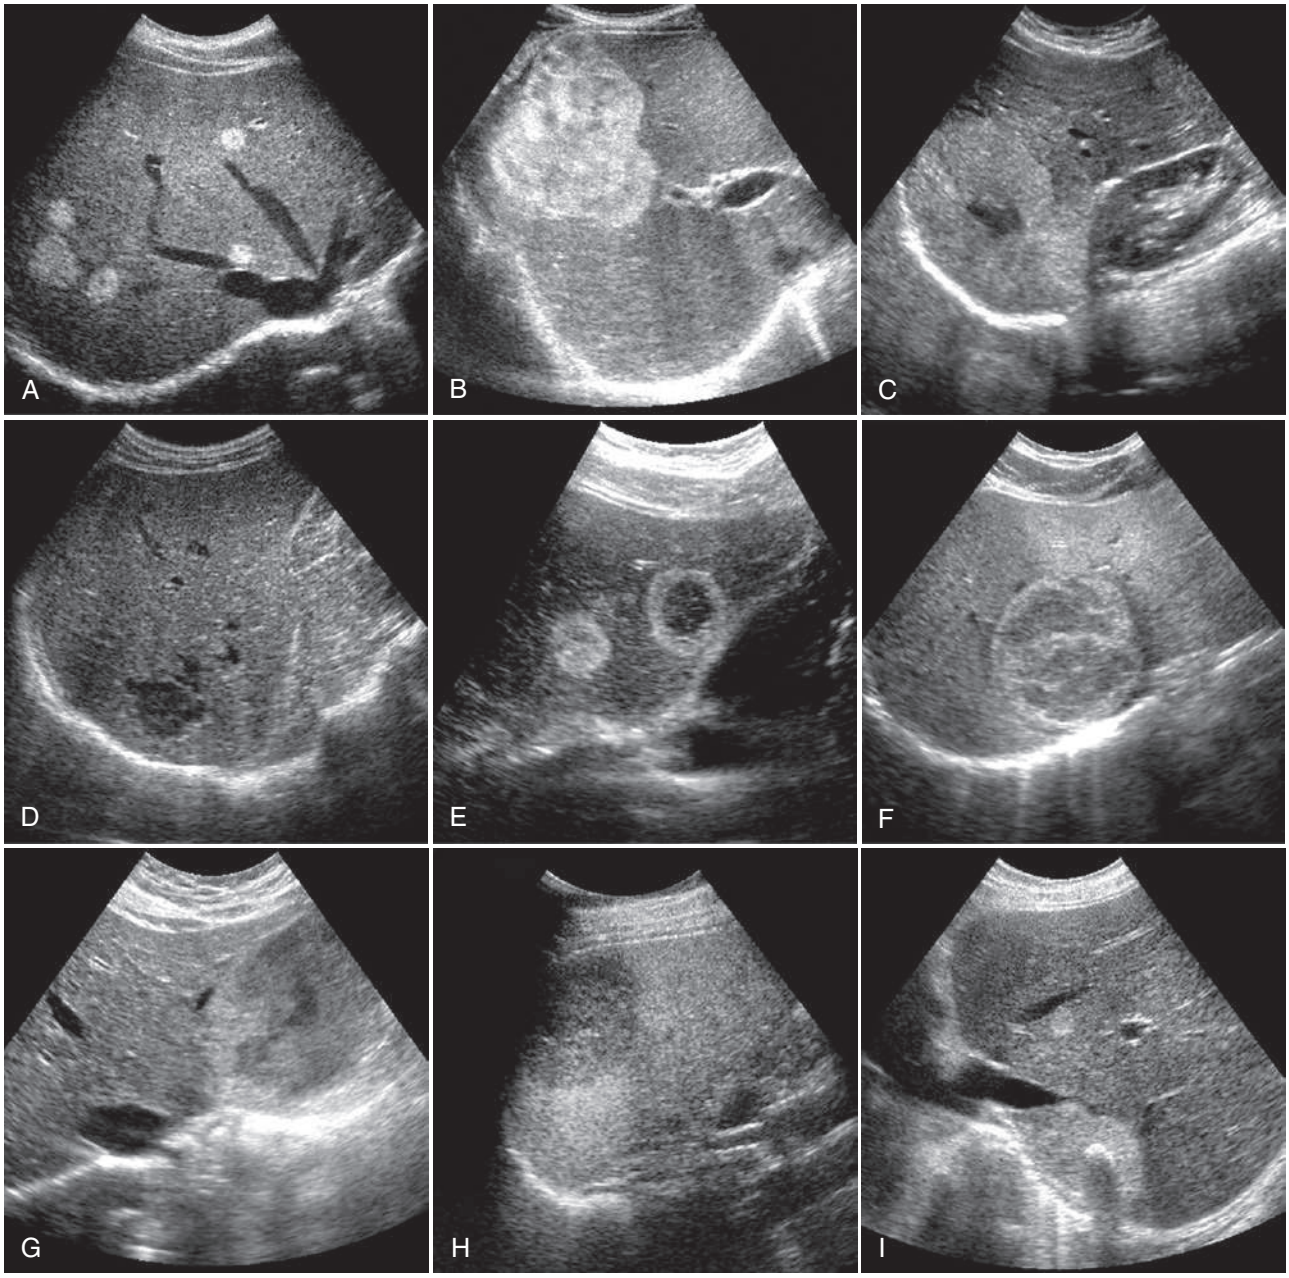

FIG. 4.46 Hemangiomas: Spectrum of Appearances. *Top row,* **Classic morphology. (A)** Multiple small echogenic masses. **(B)** Single large, lobulated echogenic mass. **(C)** Echogenic lobulated mass with a hypoechoic area centrally, probably related to central thrombosis or scarring. *Middle row,* **Atypical morphology. (D)** Atypical hemangioma. It is hypoechoic and has a thin echogenic border. **(E) Classic and atypical morphologies.** The atypical hemangioma has a thick, uniform echogenic border. **(F)** Atypical hemangioma is partially hypoechoic centrally with an irregular echogenic rim. *Bottom row,* **Infrequent observations. (G)** Exophytic hemangioma bulging from the left lateral lobe of the liver. **(H)** Hypoechoic mass with increased through transmission, a suggestive but infrequently encountered sign of hemangioma. **(I)** Central calcification in a hemangioma with distal acoustic shadowing. This is a rare ending in hemangiomas.

Sclerosis of hemangioma creates diagnostic difficulty. In our experience, these sclerotic hemangiomas mimic a malignant mass on all modalities showing frequent portal venous phase washout and lacking the classic peripheral discontinuous peripheral globules or puddles that are virtually diagnostic of hemangioma on contrast-enhanced studies. Biopsy is, therefore, frequently necessary to confirm sclerotic hemangioma.

Focal Nodular Hyperplasia

FNH is the second most common benign liver mass after hemangioma. These masses are believed to be developmental hyperplastic lesions related to an area of congenital vascular malformation, probably a preexisting arterial spider-like malformation.[151] Hormonal influences may be a factor because FNH is much more common in women than men, particularly in the

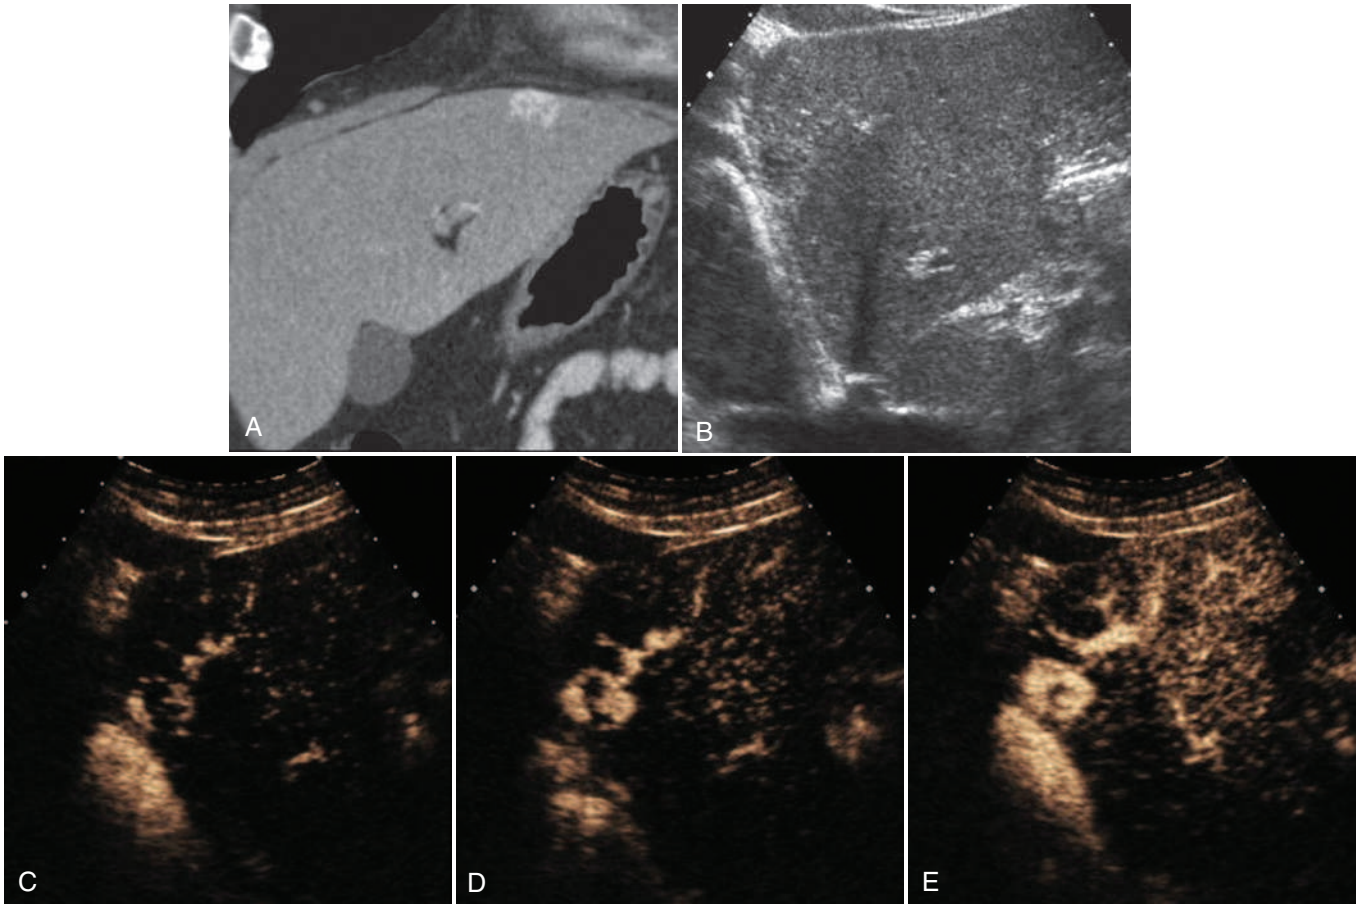

FIG. 4.47 Characterization of Hemangioma With Definity Enhancement. Resolution of an indeterminate mass on computed tomography (CT) scan is shown in a 65-year-old man with carcinoma of the esophagus. **(A)** CT scan of the thorax shows an indeterminate incidental enhanced mass in the left lobe of the liver. **(B)** Sagittal sonogram shows the mass is hypoechoic. **(C)-(E)** Frames taken between 10 and 14 seconds after the injection of contrast agent showing peripheral nodular enhancement and centripetal progression of enhancement in spite of the rapidity of lesion filling. This is a classic flash-filling hemangioma. The lesion remained enhanced to 5 minutes *(not shown)*. See also Video 4.6. (With permission from Wilson S, Burns P. Microbubble-enhanced US in body imaging: what role? Radiology. 2010;257[1]:24-39.[148])

childbearing years.[152,153] As with hemangioma, FNH is invariably an incidentally detected liver mass in an asymptomatic patient.

FNH is typically a solitary well-circumscribed mass with a central scar. Most lesions are less than 5 cm in diameter. Although usually single, multiple FNH masses have been reported. Microscopically, lesions include normal hepatocytes, Kupffer cells, biliary ducts, and the components of portal triads, although no normal portal venous structures are found. As a hyperplastic lesion, there is proliferation of normal, nonneoplastic hepatocytes that are abnormally arranged. Bile ducts and thick-walled arterial vessels are prominent, particularly in the central fibrous scar. The excellent blood supply makes hemorrhage, necrosis, and calcification rare. These lesions often produce a contour abnormality to the surface of the liver or may displace the normal blood vessels within the parenchyma.

On **sonography,** FNH is often a subtle liver mass that is difficult to differentiate in echogenicity from the adjacent liver parenchyma. Considering the histologic similarities to normal liver, this is not a surprising fact and has led to descriptions of FNH on all imaging as a "stealth lesion" that may be extremely subtle or completely hidden.[154] Subtle contour abnormalities (Fig. 4.48) and displacement of vascular structures should raise the possibility of FNH. The central scar may be seen on gray-scale sonograms as a hypoechoic, linear or stellate area within the central portion of the mass[155] (Fig. 4.48A). On occasion, the scar may appear hyperechoic. FNH may also display a range of gray-scale appearances, from hypoechoic to rarely hyperechoic.

Doppler ultrasound features of FNH are highly suggestive, in that well-developed peripheral and central blood vessels are seen. Pathologic studies in FNH describe an anomalous arterial blood vessel larger than expected for the location in the liver.[151] Our experience suggests that this feeding vessel is usually quite obvious on color Doppler imaging, although other vascular masses may appear to have unusually large feeding vessels as well.[156] The blood vessels can be seen to course within the central scar with either a linear or a stellate configuration. Spectral interrogation usually shows predominantly arterial signals centrally, with a midrange (2-4 kHz) shift.

Similar to hemangioma, FNH is consistently diagnosed with **CEUS.**[157-160] In the arterial phase, lesions are hypervascular, and highly suggestive morphologies include the presence of stellate lesional vessels, a tortuous feeding artery, and a centrifugal filling

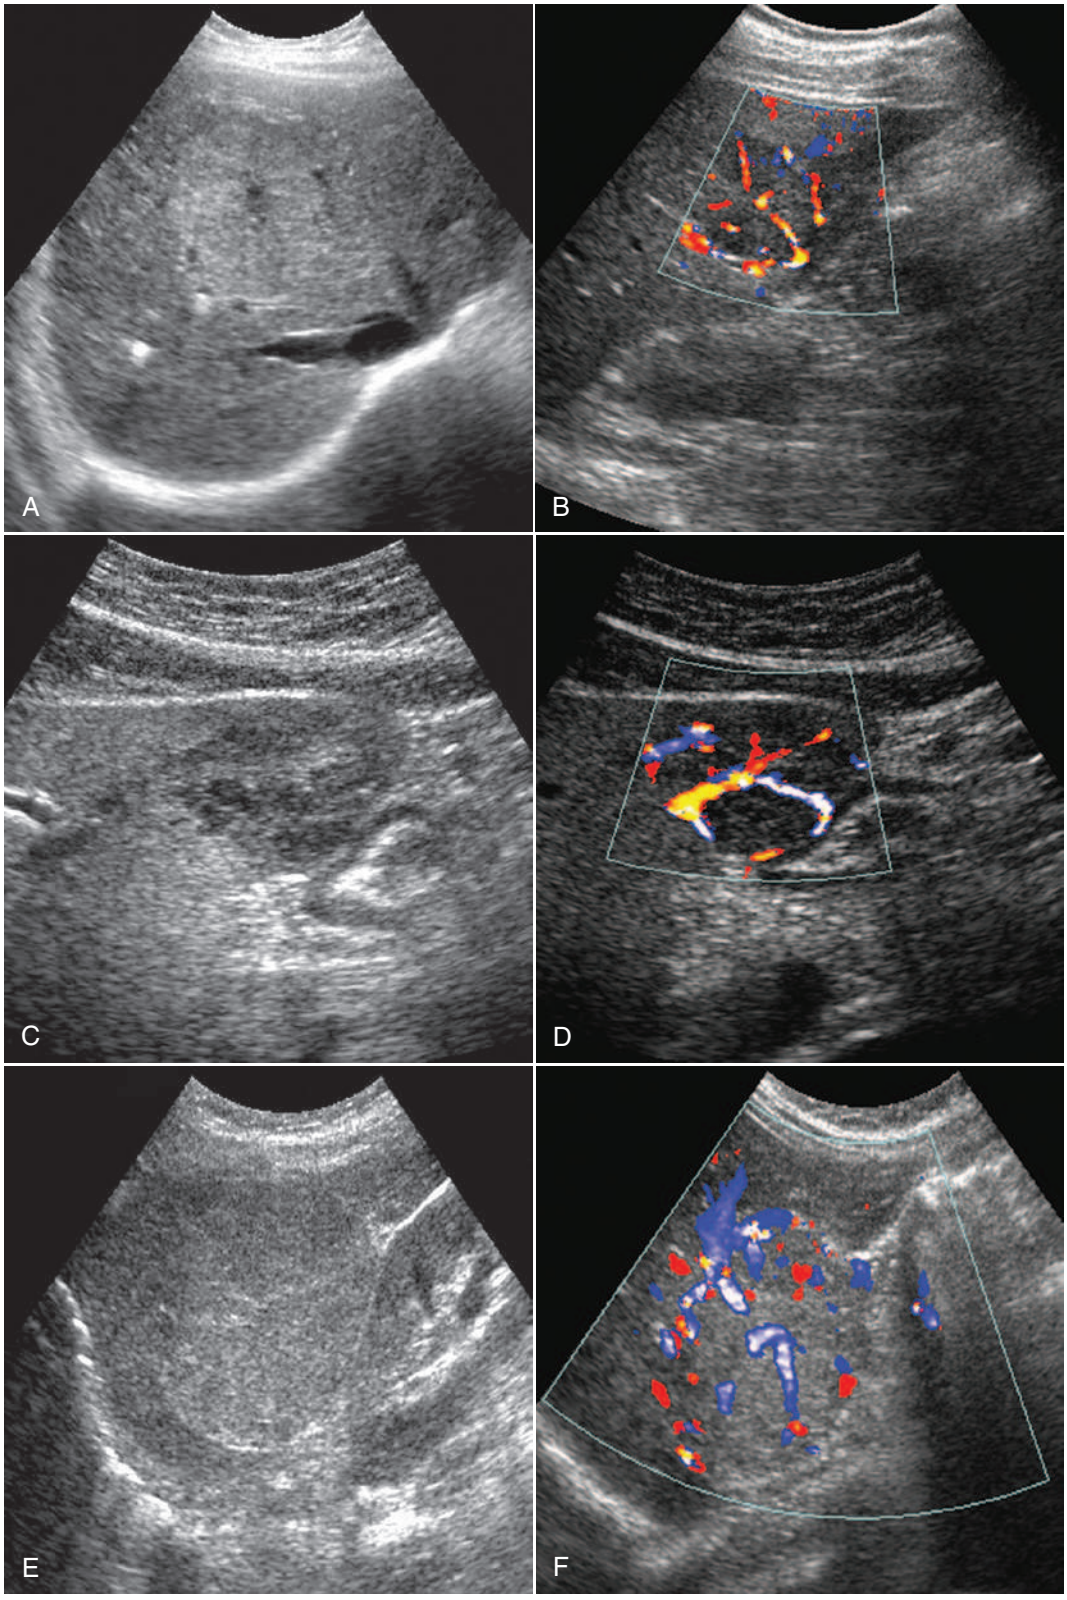

FIG. 4.48 Focal Nodular Hyperplasia (FNH) in Three Patients. Gray-scale equivalents (**A, C,** and **E**) of color Doppler images (**B, D,** and **F**). **(A)** Virtually normal image only suggests an isoechoic and subtle mass. **(B)** Doppler image shows a stellate arterial pattern and confirms the authenticity of the observation. **(C)** Fatty liver and focal hypoechoic region in the tip of segment 3. Fatty sparing was considered. **(D)** Doppler features show a hypervascular mass with a stellate appearance, the classic finding in FNH. **(E)** Contour-altering mass in the right lobe of the liver. **(F)** Doppler image again shows the central stellate vascularity suggesting FNH. This hypervascularity with stellate vasculature is usually readily observed with conventional sonography in FNH.

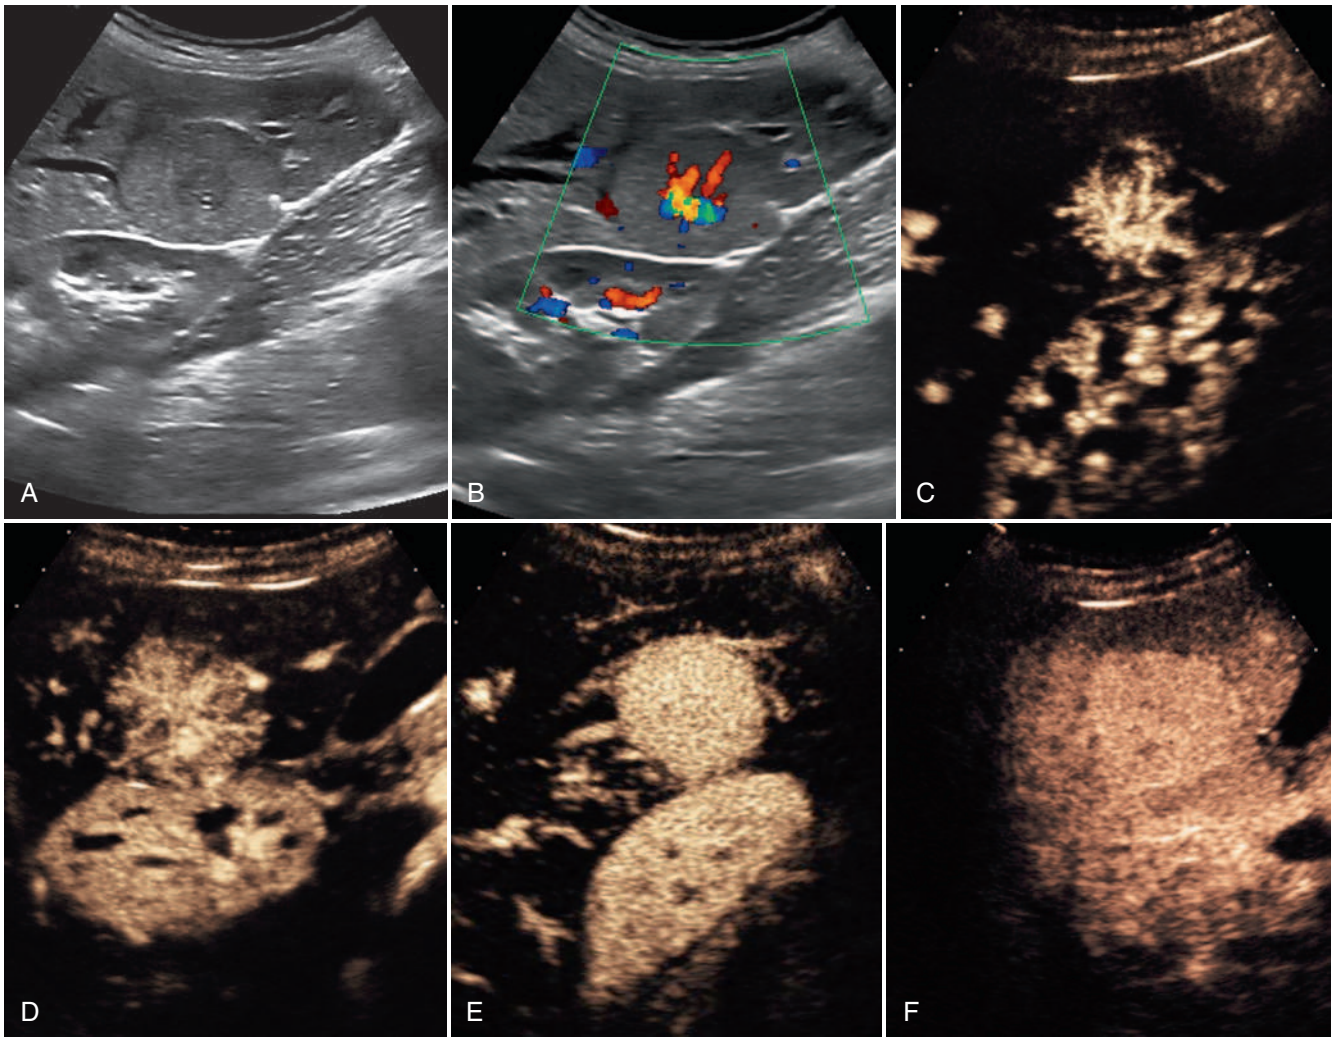

FIG. 4.49 Classic Focal Nodular Hyperplasia (FNH) on Contrast-Enhanced Ultrasound (CEUS). **(A)** Sagittal image of the liver in an asymptomatic woman shows a slightly exophytic very round isoechoic mass in the liver. **(B)** Addition of color Doppler shows strong central signal. **(C)-(E)** Sequential frames in the arterial phase show a stellate vessel morphology and centrifugal filing, from the center of the mass to its periphery. **(F)** Hypervascular mass has sustained enhancement, appearing brighter than the liver at 4 minutes, confirming the benign nature of this mass. See also Videos 4.7 and 4.8.

direction (Fig. 4.49 and Videos 4.7 and 4.8). Arterial phase enhancement is homogeneous and in excess of the adjacent liver. Portal venous enhancement is sustained such that lesion enhancement equals or exceeds that of adjacent liver with a nonenhancing scar (Video 4.5). Infrequently, FNH may show washout, which is often weak and delayed. An unenhanced scar may be seen in both arterial and portal phases. Ultrasound alone should be able to suggest the presence of these insignificant lesions without referral for further imaging.

Sulfur colloid scanning is invaluable in patients with suspect FNH because 50% of lesions will take up sulfur colloid similar to the adjacent normal liver, and another 10% will be "hot." Therefore only 40% of patients with FNH will lack confirmation of their diagnosis after performing a sulfur colloid scan.[160,161] In these patients, CECT or MRI may be performed for diagnosis.

Biopsy may be required in a minority of patients with FNH who do not have a hot or a warm lesion on sulfur colloid scanning, especially if CT or MRI features are not specific. Cytology is not confirmatory because normal hepatocytes may be found in normal liver, adenoma, and FNH. Core liver biopsy is required to show the disorganized pattern characteristic of this pathology. Because FNH rarely leads to clinical problems and does not undergo malignant transformation, conservative management is recommended.[162]

Hepatic Adenoma

Hepatic adenoma is the most important benign tumor of the liver because of its frequency and potential for complications that are life threatening, including bleeding and malignant transformation. Hepatic adenomas are much less common than FNH. However, a dramatic rise in their incidence since the 1970s clearly established a link to oral contraceptive use. As expected, therefore, hepatic adenomas are more common in women. The tumor may be asymptomatic, but often the patient or the physician feels a mass in the right upper quadrant. Pain may occur as a result of bleeding or infarction within the lesion. The most alarming manifestation is shock caused by tumor rupture and hemoperitoneum. Hepatic adenomas have also been reported

in association with GSD. In particular, the frequency of adenoma for type 1 GSD (von Gierke disease) is 40%.[163] Because of its propensity to hemorrhage and risk of malignant degeneration,[162] surgical resection is recommended. The genotyping/phenotyping of hepatic adenomas reveals three major subtypes, with the ability to predict also those with malignant potential on the basis of the tumor phenotype, with β-catenin–activated adenomas at higher risk of HCC.[164]

Pathologically, a hepatic adenoma is usually solitary, 8 to 15 cm, and well encapsulated. Microscopically, the tumor consists of normal or slightly atypical hepatocytes. Bile ducts and Kupffer cells are few or absent. Hepatic adenomas may show either calcification or fat (Figs. 4.50 and 4.51), both of which appear echogenic on sonography, making their gray-scale appearance suggestive in some cases.

Differentiation of hepatic adenomas from FNH is often not possible by their gray-scale or Doppler characteristics. Further, both have a similar demographic, occurring in young women in their childbearing years, often with a history of oral contraceptive use. Most adenomas are cold on technetium-99m sulfur colloid imaging as a result of absent or greatly decreased numbers of Kupffer cells. Isolated cases of radiocolloid uptake by the adenoma have been reported.[165] Today, MRI is a frequently used modality for the characterization of adenomas.[166]

In the typical clinical scenario, differentiation of FNH from adenoma poses a regular problem. Both masses are frequently incidentally detected in asymptomatic women, their baseline appearance at sonography is variable, and both produce a hypervascular mass in the arterial phase on contrast CT or MRI.[167] Their management are totally different. However, differentiation

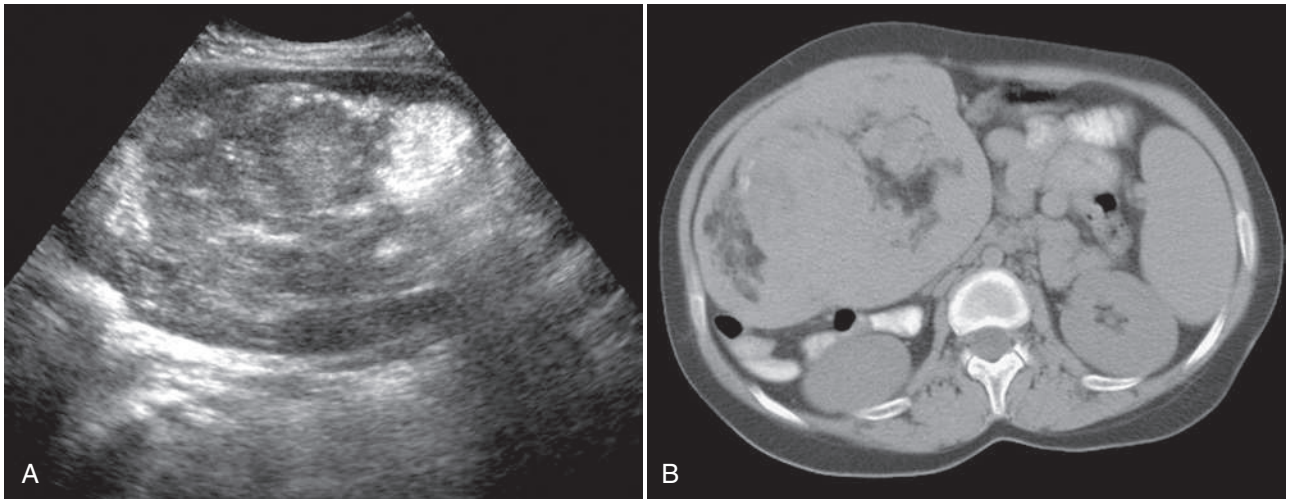

FIG. 4.50 Hepatic Adenoma. (A) Sonogram, and **(B)** confirmatory computed tomography (CT) scan, show a large exophytic liver mass in an asymptomatic young woman. The mass shows highly echogenic foci, which correspond to areas of fat and calcification on the CT scan.

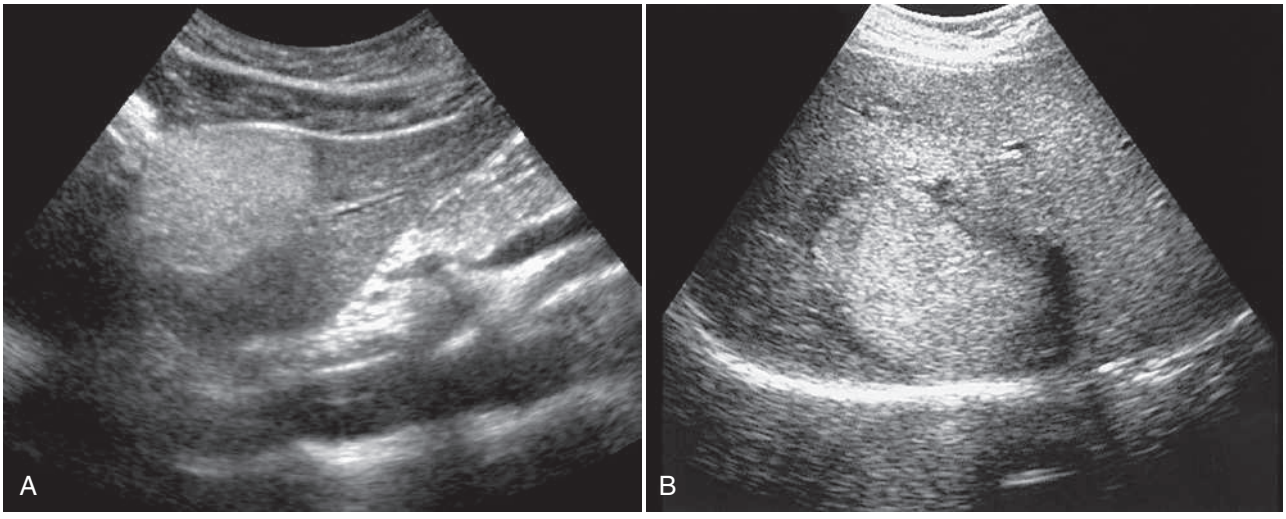

FIG. 4.51 Hepatic Adenoma: Gray-Scale Appearances in Two Patients. (A) Sagittal sonogram of the left lobe of the liver of an asymptomatic 35-year-old man shows a highly echogenic mass. It is unusual to see an adenoma in an otherwise normal man. **(B)** Oblique sonogram of a 26-year-old Chinese woman shows a highly echogenic mass with a hypoechoic halo. The hypoechoic halo was related to a surrounding zone of liver atrophy on biopsy. These highly echogenic masses show diffuse steatosis and are, therefore, HNF1a-inactivated adenomas.

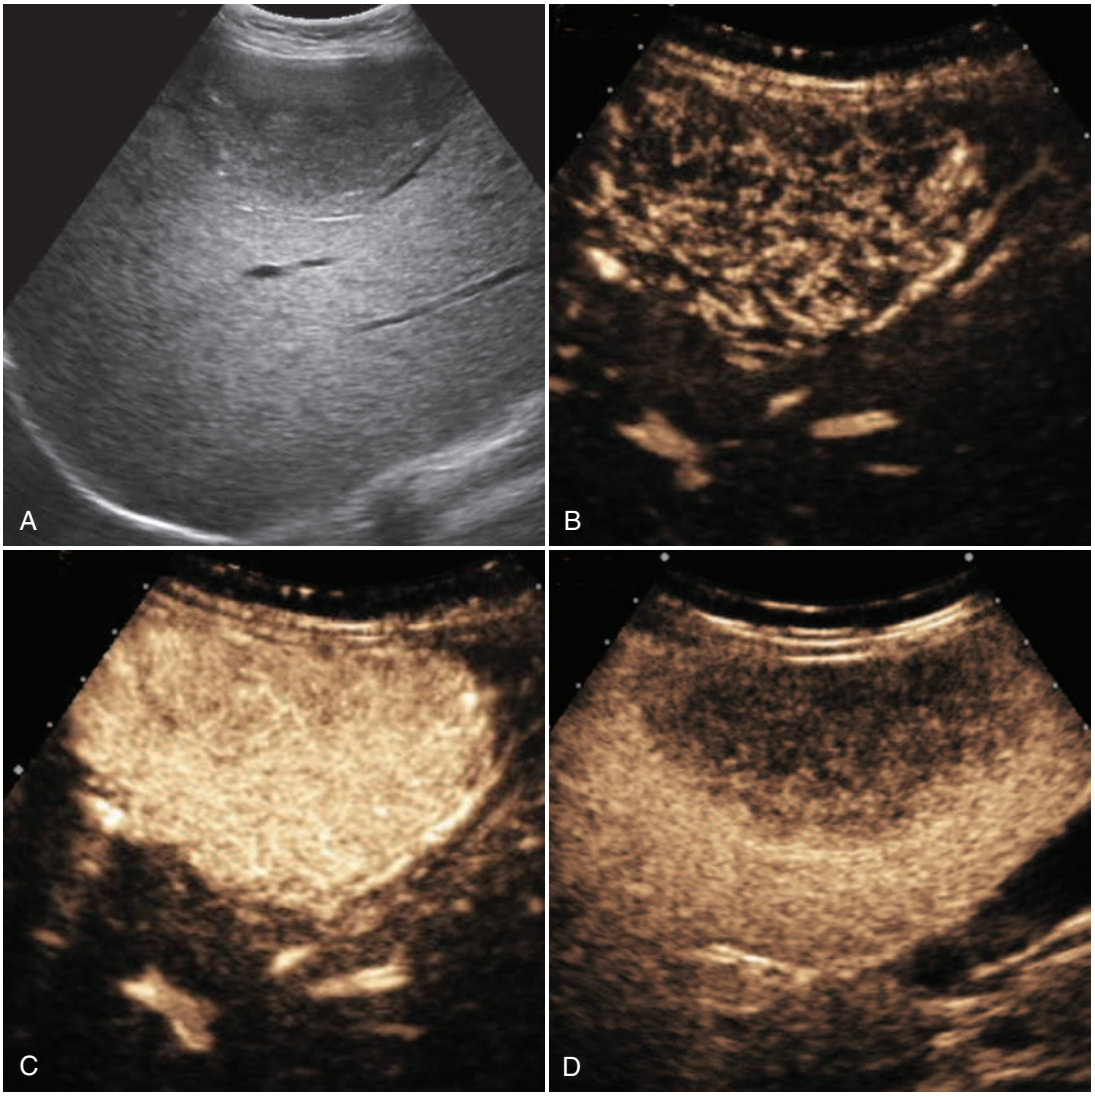

FIG. 4.52 Hepatic Adenoma: Maximum-Intensity Projection (MIP) Imaging on Contrast-Enhanced Ultrasound (CEUS). **(A)** Baseline scan on an asymptomatic 29-year-old woman with abnormal liver function tests shows a fatty liver and superficial hypoechoic focal mass. **(B)** Early arterial phase MIP image shows diffuse vascularity. **(C)** At the peak of arterial phase enhancement, the mass is hypervascular and homogeneous. **(D)** In the portal venous phase the mass shows washout, necessitating confirmation of diagnosis with biopsy. See also Video 4.9. (With permission from Wilson S, Burns P. Microbubble-enhanced US in body imaging: what role? Radiology. 2010;257[1]:24-39.[148])

is generally possible on ultrasound with CEUS (Fig. 4.52). HNF1a-inactivated adenomas are often echogenic at baseline, due to diffuse steatosis, and hypervascular in the arterial phase with no washout in the portal venous phase, consistent with a benign mass. Inflammatory adenomas are more variable on baseline imaging, from hyperechoic to isoechoic or hypoechoic, and most often show arterial phase hyperenhancement with centripetal filling and late weak washout, which are frequently described CEUS findings for this diagnosis (Video 4.9). However, the other adenomas do not show these specific features, frequently making their diagnosis a challenge.[166] Our impression also is that hepatic adenoma, although hypervascular, does not show the profuse vascularity typical of FNH (see Fig. 4.52).

In a patient with right upper quadrant pain and possible hemorrhage, a fluid component may be evident within or around the mass on ultrasound (Fig. 4.53), and free intraperitoneal blood may be seen. The sonographic changes with bleeding are variable, depending on the duration and amount of hemorrhage. In appropriate cases, it is important to perform an unenhanced CT scan of the liver before contrast injection. The hemorrhage will appear as high-density regions within the mass (Fig. 4.53C). The lesion often demonstrates rapid, transient enhancement during the arterial phase.[168]

Fatty Tumors: Hepatic Lipomas and Angiomyolipomas

Hepatic lipomas are extremely rare, and only isolated cases have been reported in the imaging literature.[169,170] There is an association between hepatic lipomas and renal angiomyolipomas and tuberous sclerosis. The lesions are asymptomatic. Ultrasound demonstrates a well-defined echogenic mass indistinguishable from a hemangioma, echogenic metastasis, or focal fat, unless the mass is large

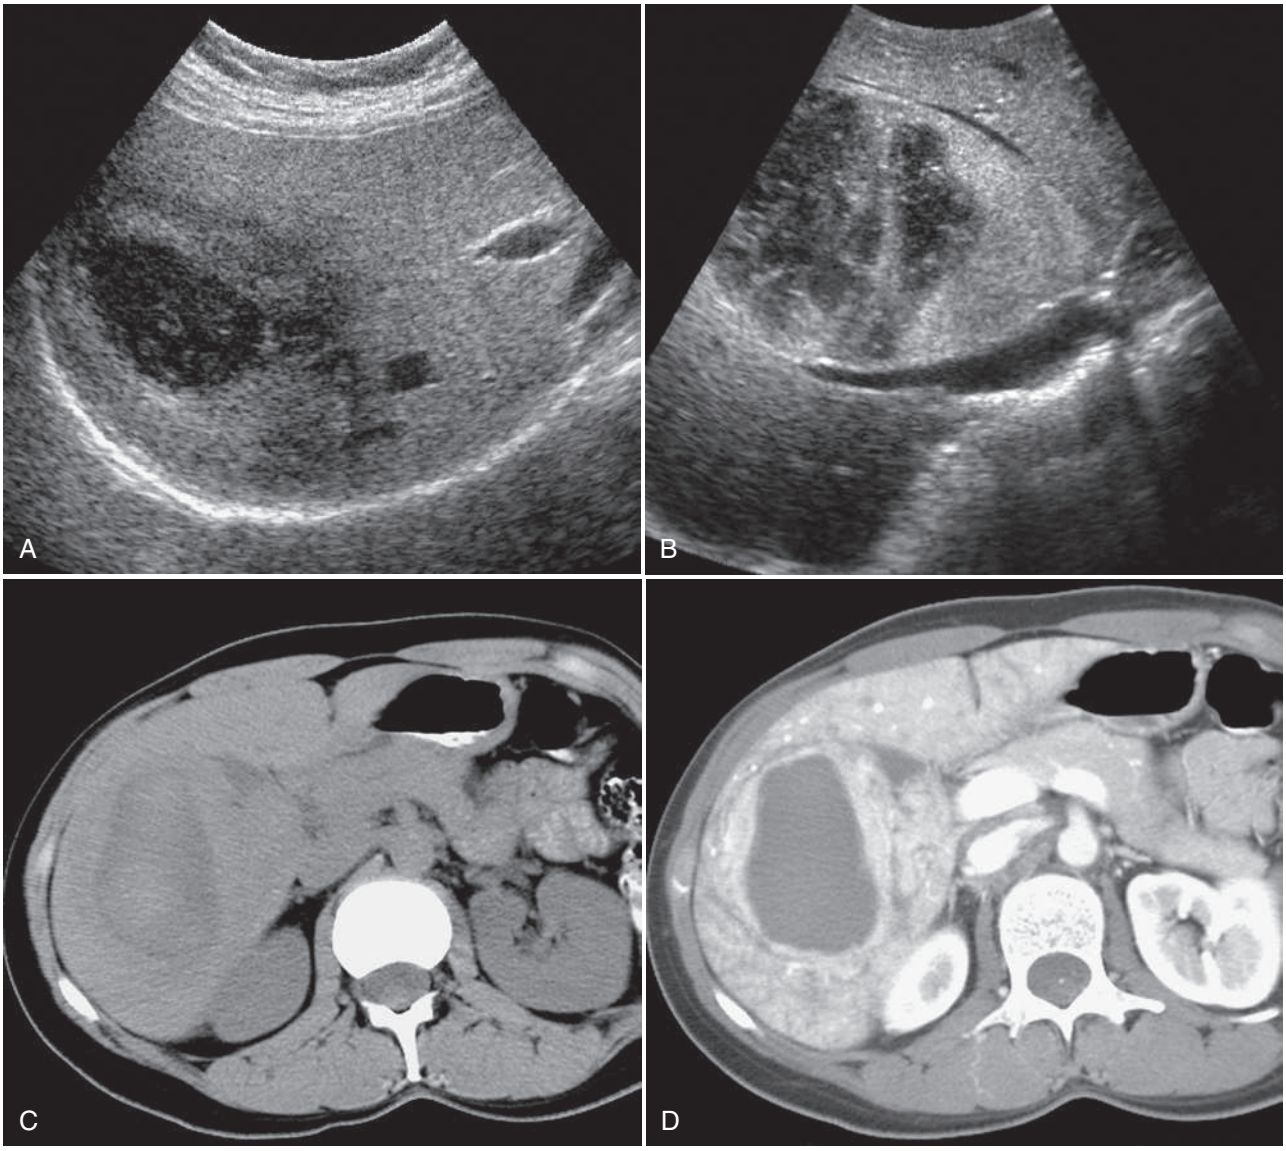

FIG. 4.53 Bleeding Hepatic Adenomas. (A) and **(B)** Sonograms of two young women presenting with acute abdominal pain from hemorrhage into hepatic adenomas. The masses are highly complex, and their appearance in a patient with pain suggests hemorrhage into a preexisting lesion. **(C)** Unenhanced and **(D)** enhanced computed tomography scans of the patient in B show the value of the unenhanced scan, which confirms the high-attenuation blood within the adenoma.

and near the diaphragm, in which case differential sound transmission through the fatty mass will produce a **discontinuous or broken diaphragm echo**[170] (Fig. 4.54A). CT or MRI can be used to confirm the fatty nature of a mass (Fig. 4.54B). Angiomyolipomas, by comparison, may also appear echogenic on sonography (Fig. 4.54C), although they may have insufficient fat to appear consistently with fatty attenuation on CT, making diagnostic confirmation more difficult without biopsy.

Malignant Hepatic Neoplasms

Hepatocellular Carcinoma

HCC is one of the most common malignant tumors, particularly in Southeast Asia, sub-Saharan Africa, Japan, Greece, and Italy. HCC occurs predominantly in men, with a male-to-female ratio of approximately 5:1. Causal factors depend on the geographic distribution. Although alcoholic cirrhosis remains a common predisposing cause for hepatoma in the West, both hepatitis C and hepatitis B are now of worldwide importance. These viral infections also account for the high incidence of HCC in sub-Saharan Africa, Southeast Asia, China, Japan, and in the Mediterranean. Of growing importance in the Western world, fatty liver with the development of steatohepatitis is increasingly important as an antecedent to the development of cirrhosis and HCC. HCC is one of the only solid tumors in North America with an increasing incidence credited almost solely to the increasing significance of nonalcoholic fatty liver disease. Aflatoxins, toxic metabolites produced by fungi in certain foods, have also been implicated in the pathogenesis of hepatomas in developing countries.

The clinical presentation of HCC is often delayed until the tumor reaches an advanced stage. Symptoms include right upper quadrant pain, weight loss, and abdominal swelling when ascites

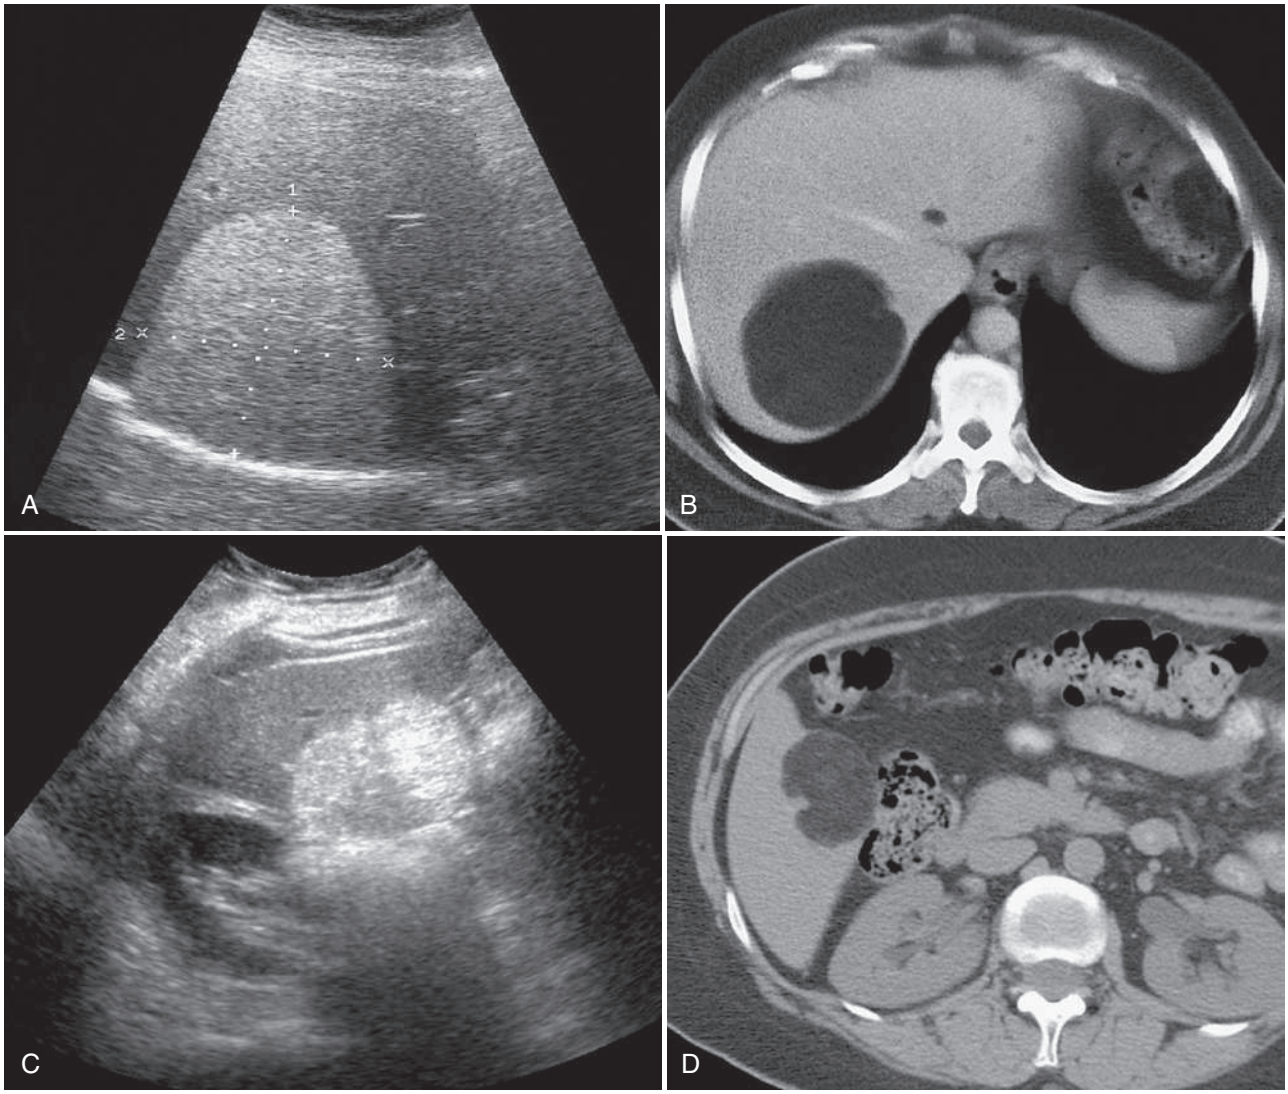

FIG. 4.54 Fatty Tumors of Liver: Lipoma and Angiomyolipoma. (A) Sonogram shows a highly echogenic, solid focal liver mass, which initially suggests a hemangioma. The **discontinuity of the diaphragm echo** caused by the altered rate of sound transmission is a clue to the correct diagnosis. **(B)** Confirmatory computed tomography scan shows the fat density of the mass, a confirmed hepatic lipoma. **(C)** and **(D)** Another highly echogenic and slightly exophytic mass in the liver, initially suggesting a hemangioma. (**A** and **B** with permission from Garant M, Reinhold C. Residents' corner. Answer to case of the month #36. Hepatic lipoma. Can Assoc Radiol J. 1996;47[2]:140-142.[242] **C** and **D** with permission from Wilson SR. The liver. In Gastrointestinal disease. 6th series. Test and syllabus. Reston Virginia: American College of Radiology; 2004.[26])

is present. Serum alpha feto-protein levels are frequently elevated. Treatments and earlier diagnosis have improved over time. Among HCC cases diagnosed from 1998 to 2007, transplant recipients experienced 84% 5-year survival. Cases with tumors less than 3 cm in size that received radiofrequency ablation had a 5-year survival rate of 53%, while cases undergoing liver resection had a 5-year survival rate of 47%. Overall the HCC survival rate from 1998 to 2007 was 18%, whereas the survival rate was 7% among cases without reported invasive surgery or local tumor destruction.[171]

Pathologically, HCC occurs in the following three forms:

- Solitary tumor
- Multiple nodules
- Diffuse infiltration

There is a propensity toward venous invasion. The portal vein is involved in 30% to 60% of cases and more often than the hepatic venous system.[172-174]

The **sonographic appearance** of HCC is variable. The masses may be hypoechoic, complex, or echogenic. Most small (<5 cm) HCCs are hypoechoic (Fig. 4.55A), corresponding histologically to a solid tumor without necrosis.[175,176] A thin, peripheral hypoechoic halo, which corresponds to a fibrous capsule, is seen most often in small HCCs.[177] With time and increasing size, the masses tend to become more complex and inhomogeneous as a result of necrosis and fibrosis (Fig. 4.55E). Calcification is uncommon.[178] Small tumors may appear diffusely hyperechoic, secondary to fatty metamorphosis or sinusoidal dilation (Fig. 4.55C), making them indistinguishable from focal fatty infiltration,

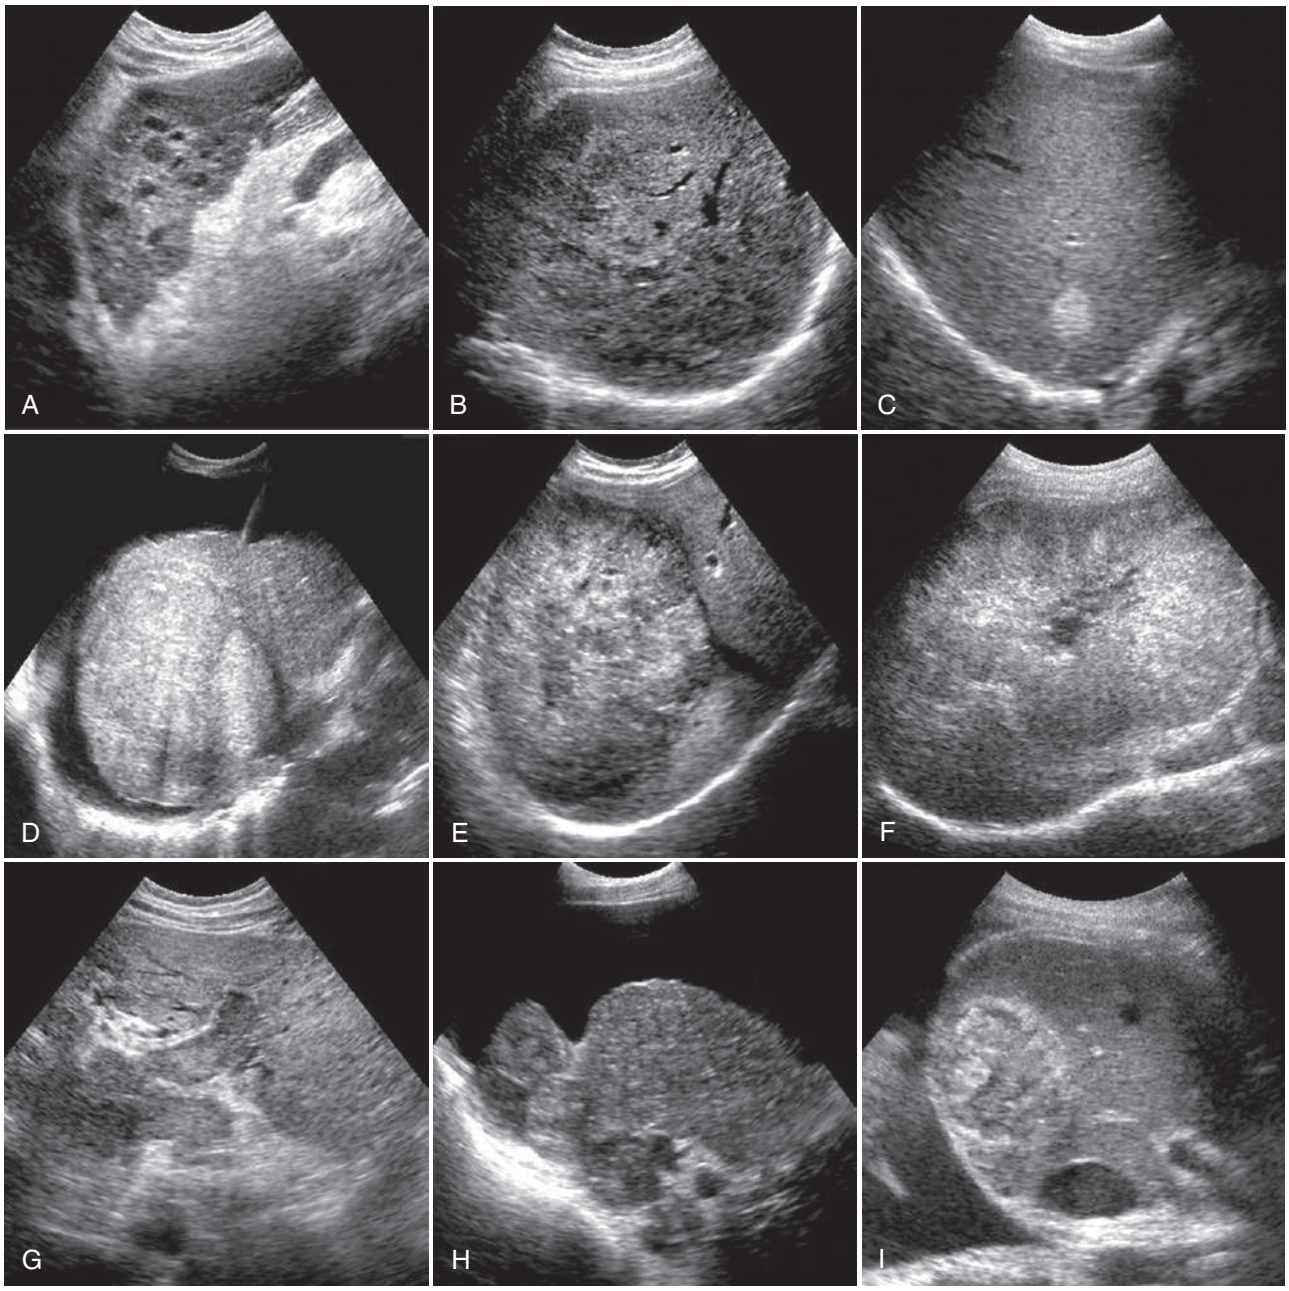

FIG. 4.55 Hepatocellular Carcinoma: Spectrum of Appearances. (A) Small, focal hypoechoic nodules. **(B)** Multifocal hypoechoic nodules, which may be difficult to differentiate from the background cirrhotic nodules. **(C)** Focal echogenic nodule mimicking hemangioma. **(D)** Large echogenic nodule in a cirrhotic liver. **(E)** Large mixed-echogenic mass. Hypoechoic regions corresponded at pathology to areas of necrosis. **(F)** Large lobulated mass with central hypoechoic region suggesting a scar. **(G)** Expansive tumor filling the portal vein is the only observation on the sonogram. **(H)** Small cirrhotic liver showing exophytic tumors. **(I)** Superficial mass of mixed echogenicity in a young patient with hepatitis B presenting with spontaneous liver rupture.

cavernous hemangiomas, and lipomas.[175,176,179] Intratumoral fat also occurs in larger masses; because it tends to be focal, it is unlikely to cause confusion in diagnosis. Patients with rare surface lesions may present with spontaneous rupture and hemoperitoneum (Fig. 4.55I).

Studies evaluating focal liver lesions with duplex Doppler and CDFI suggest HCC has characteristic high-velocity signals.[180-182] Doppler sonography is excellent for detecting neovascularity within tumor thrombi within the portal veins, diagnostic of HCC even without demonstration of the parenchymal lesion (Fig. 4.56).

CEUS is much more sensitive for the detection of lesional vascularity than is color Doppler (Table 4.4). Lesions are hypervascular (Videos 4.10 and 4.11), often showing dysmorphic vessels (Fig. 4.57) and frequently showing unenhanced regions representing either necrosis or scarring.[183,184] In the portal venous phase, lesions show washout, such that they are less enhanced than the adjacent liver (see Fig. 4.44). This washout is characteristically

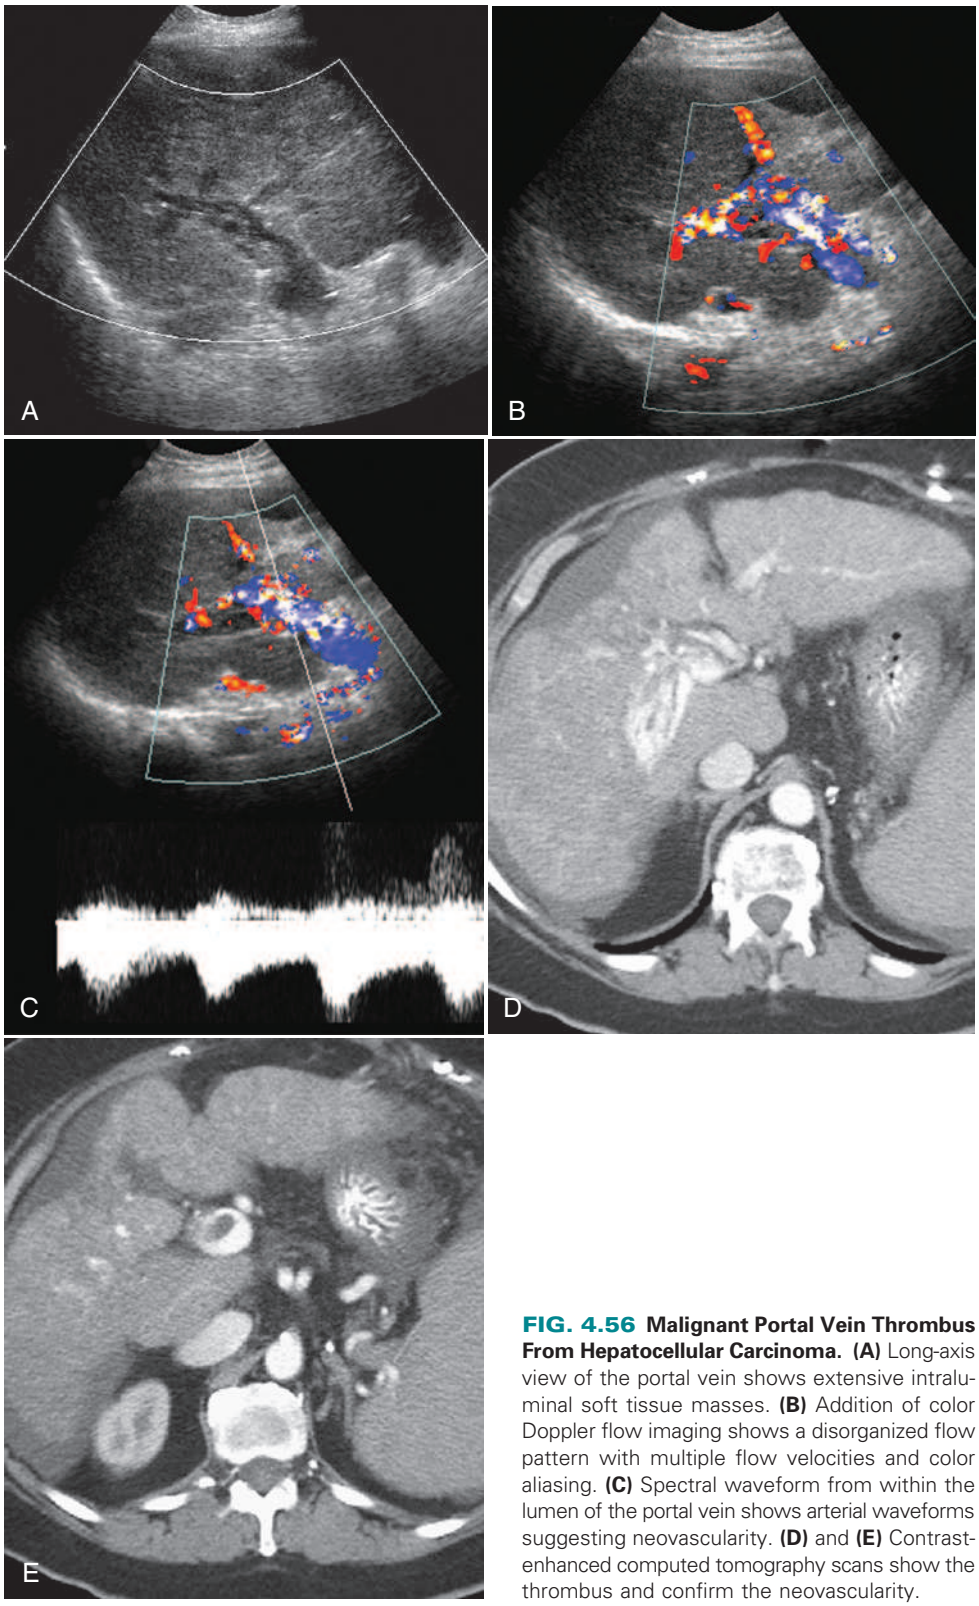

FIG. 4.56 Malignant Portal Vein Thrombus From Hepatocellular Carcinoma. (A) Long-axis view of the portal vein shows extensive intraluminal soft tissue masses. **(B)** Addition of color Doppler flow imaging shows a disorganized flow pattern with multiple flow velocities and color aliasing. **(C)** Spectral waveform from within the lumen of the portal vein shows arterial waveforms suggesting neovascularity. **(D)** and **(E)** Contrast-enhanced computed tomography scans show the thrombus and confirm the neovascularity.

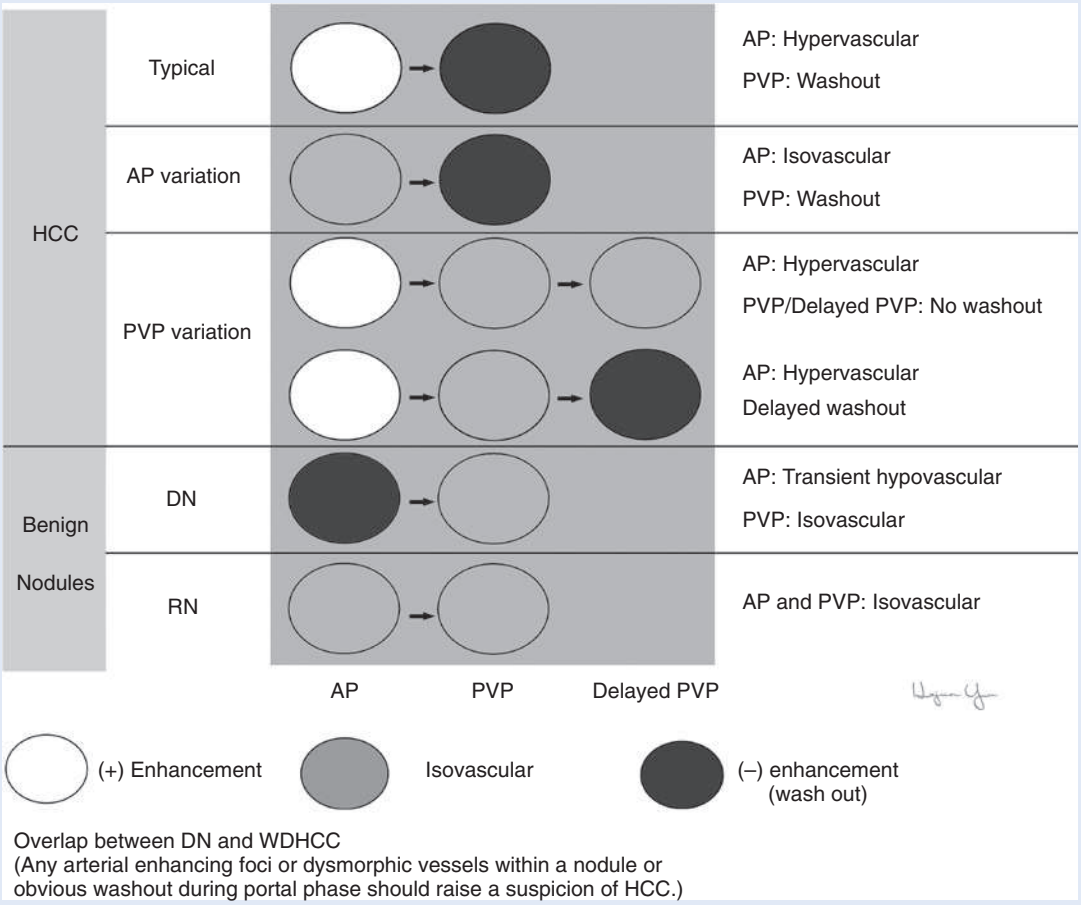
TABLE 4.4 Schematic of Algorithm for Diagnosis of Nodules in Cirrhotic Liver on Computer-Enhanced Ultrasound



AP, Arterial phase; *HCC,* hepatocellular carcinoma; *PVP,* portal venous phase; *WDHCC,* well-differentiated hepatocellular carcinoma.

slow and weak. Variations to this classic pattern are well described[184] and include arterial phase hypovascularity and delayed or no washout in the portal venous phase (Fig. 4.58). Regenerative **nodules,** by comparison, show similar arterial phase and portal venous phase vascularity and enhancement to the remainder of the cirrhotic liver. **Dysplastic nodules** may show transient arterial phase hypovascularity followed by isovascularity. Identification of this feature prompts biopsy in our institution.

Microbubble-enhanced sonography may contribute also to the detection of HCC. Sweeps of the liver in the arterial phase may detect hypervascular foci potentially representing HCC. Sweeps in the portal venous and late phases, by comparison, show HCC as hypoechoic or washout regions, again allowing for the detection of unsuspected lesions. The arterialized liver of cirrhosis, however, is problematic for several reasons. First, it shows dysmorphology of all liver vessels, in general, and the appreciation of focal increased vascularity in a small nodule is more difficult. Portal venous phase imaging is also weakened when the liver receives a greater proportion of its blood supply from the hepatic artery. Therefore washout of a specific nodule may not be as evident as in a normal liver. CT and MRI are frequently performed to screen for and evaluate HCC. The importance of CEUS for the management of small nodules detected in the surveillance for HCC is controversial and CEUS is included in some international guidelines but not others.[185] CEUS may play a pivotal role on the basis of its real-time demonstration of continuous hemodynamic changes of liver tumors, a purely intravascular contrast material, availability in patients with renal failure, excellent patient compliance, and repeatability in short intervals. CEUS is integrated into our approach for management and diagnosis of nodules in patients at high risk for HCC.

Fibrolamellar carcinoma is a histologic subtype of HCC found in younger patients (adolescents and young adults) without coexisting liver disease. The serum alpha-fetoprotein levels are usually normal. The tumors are usually solitary, 6 to 22 cm, well differentiated, and often encapsulated by fibrous tissue.[186-188] With

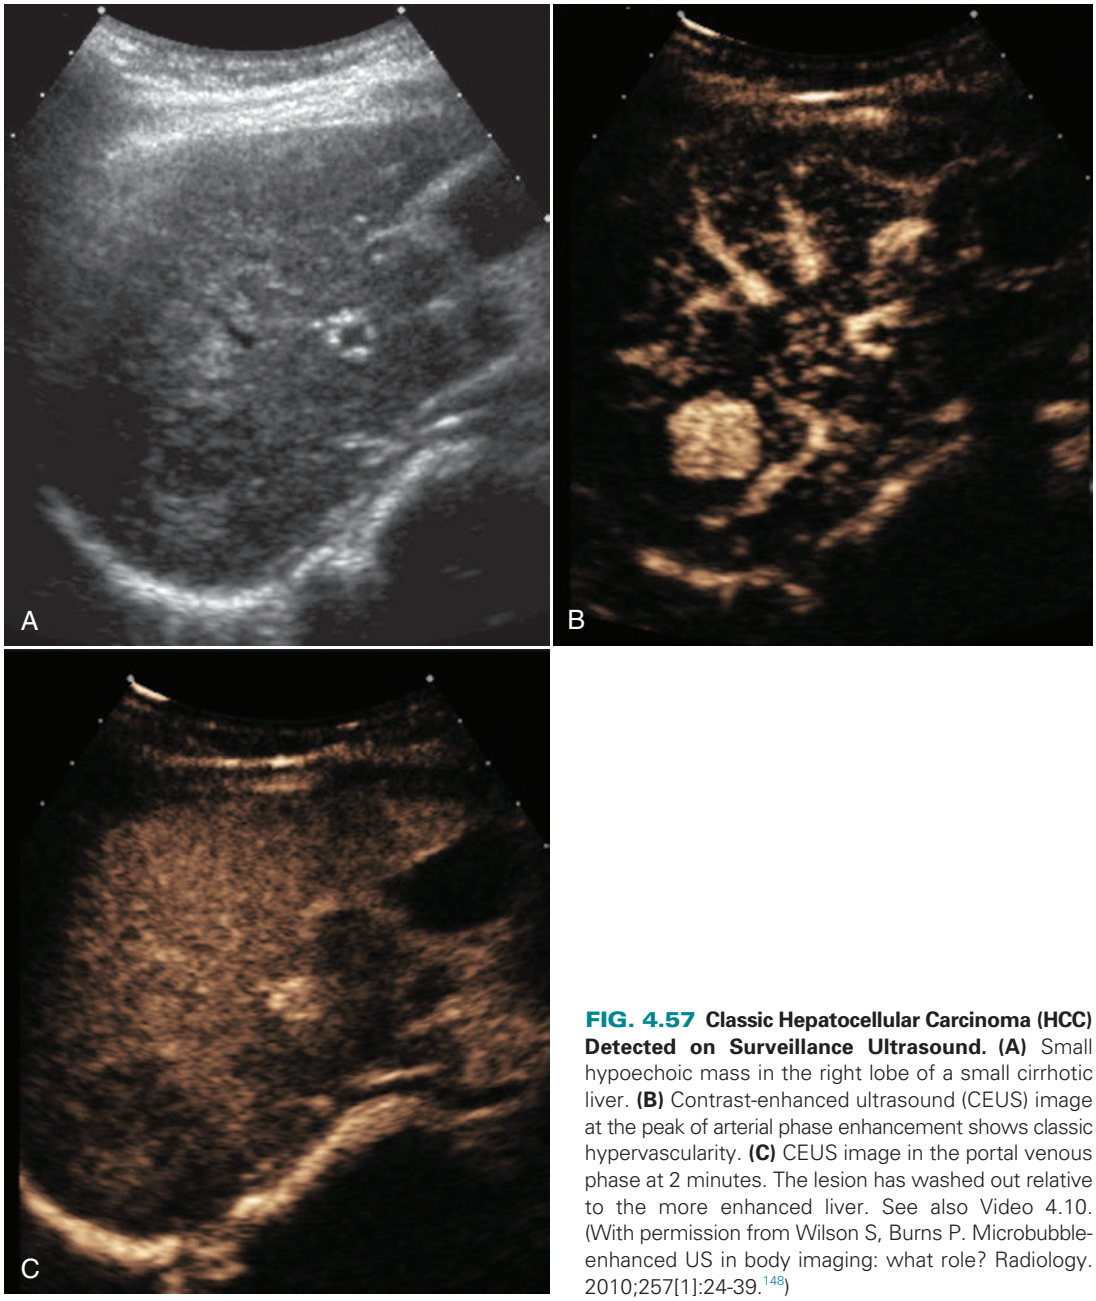

FIG. 4.57 Classic Hepatocellular Carcinoma (HCC) Detected on Surveillance Ultrasound. (A) Small hypoechoic mass in the right lobe of a small cirrhotic liver. **(B)** Contrast-enhanced ultrasound (CEUS) image at the peak of arterial phase enhancement shows classic hypervascularity. **(C)** CEUS image in the portal venous phase at 2 minutes. The lesion has washed out relative to the more enhanced liver. See also Video 4.10. (With permission from Wilson S, Burns P. Microbubble-enhanced US in body imaging: what role? Radiology. 2010;257[1]:24-39.[148])

5-year survival rates of 25% to 30%, the prognosis is generally better for fibrolamellar carcinoma than HCC.[189,190] Most patients, however, demonstrate advanced disease at diagnosis. Aggressive surgical resection of tumor is recommended at presentation as well as for recurrent disease.[187] The echogenicity of fibrolamellar carcinoma is variable. Punctate calcification and a central echogenic scar (features that are distinctly unusual in hepatomas) are more common in the fibrolamellar subtype.

Hemangiosarcoma (Angiosarcoma)

Hepatic hemangiosarcoma is an extremely rare malignant tumor. It occurs almost exclusively in adults, reaching its peak incidence in the sixth and seventh decades of life. Hemangiosarcoma is of particular interest because of its association with specific carcinogens: **thorotrast, arsenic,** and **polyvinyl chloride.** Only a few cases of hepatic hemangiosarcoma have been reported in the radiologic literature. The sonographic appearance is a large mass of mixed echogenicity.[191,192]

Hepatic Epithelioid Hemangioendothelioma

Epithelioid hemangioendothelioma (EHE) is a rare malignant tumor of vascular origin that occurs in adults. Soft tissues, lung, and liver are affected. The prognosis is variable; many patients survive longer than 5 years with or without treatment.[193] Hepatic

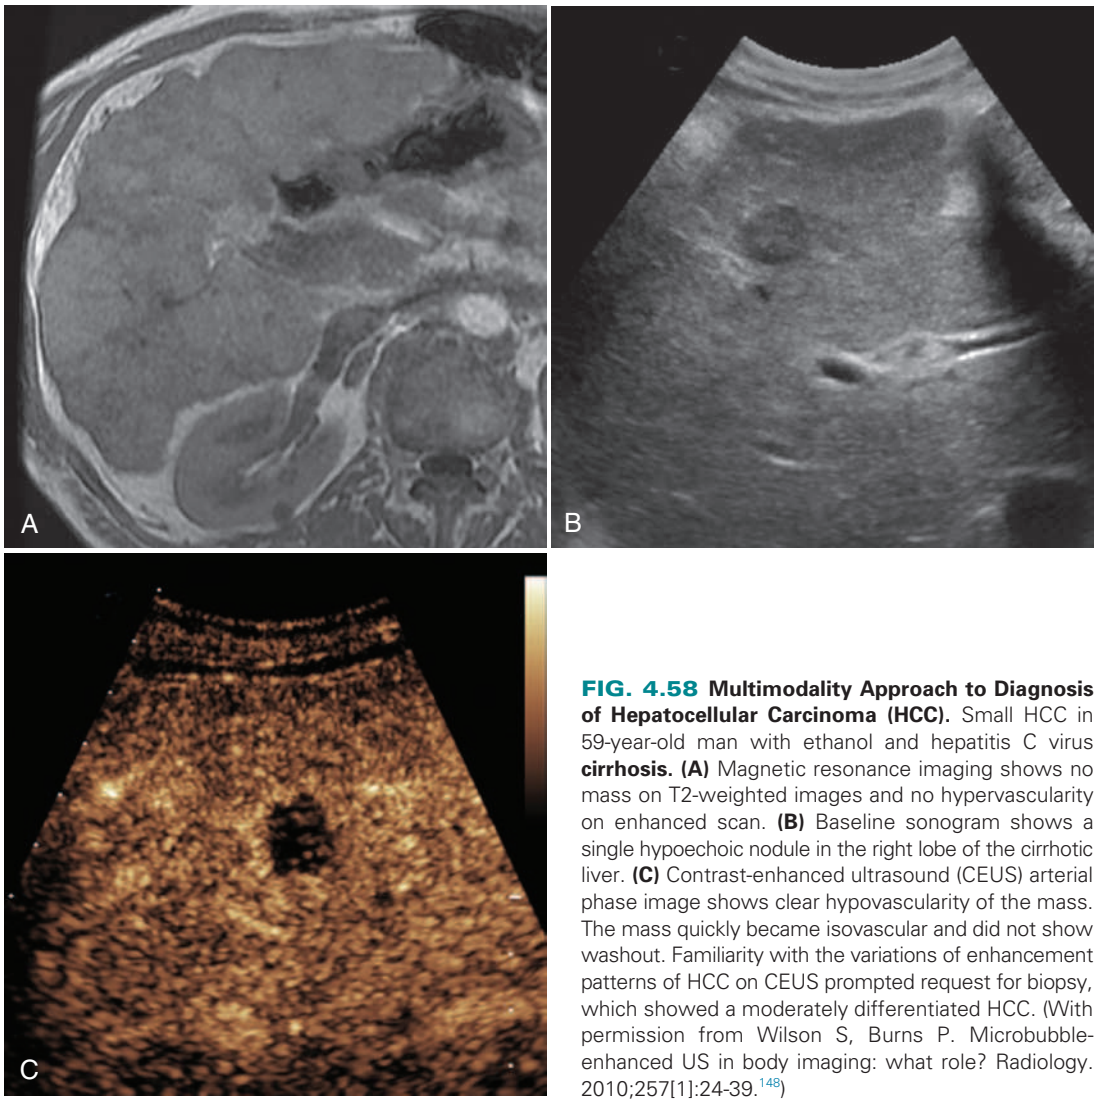

FIG. 4.58 Multimodality Approach to Diagnosis of Hepatocellular Carcinoma (HCC). Small HCC in 59-year-old man with ethanol and hepatitis C virus **cirrhosis. (A)** Magnetic resonance imaging shows no mass on T2-weighted images and no hypervascularity on enhanced scan. **(B)** Baseline sonogram shows a single hypoechoic nodule in the right lobe of the cirrhotic liver. **(C)** Contrast-enhanced ultrasound (CEUS) arterial phase image shows clear hypovascularity of the mass. The mass quickly became isovascular and did not show washout. Familiarity with the variations of enhancement patterns of HCC on CEUS prompted request for biopsy, which showed a moderately differentiated HCC. (With permission from Wilson S, Burns P. Microbubble-enhanced US in body imaging: what role? Radiology. 2010;257[1]:24-39.[148])

EHE begins as multiple hypoechoic nodules, which grow and coalesce over time, forming larger, confluent masses that tend to involve the periphery of the liver. Foci of calcification may be present.[193,194] The hepatic capsule overlying the lesions of EHE may be retracted inward, secondary to fibrosis incited by the tumor; this unusual feature is highly suggestive of the diagnosis. Importantly, peripheral postchemotherapy metastases and tumors causing biliary obstruction and segmental atrophy may have a similar appearance. The diagnosis of hepatic EHE is made by percutaneous liver biopsy and immunohistochemical staining.

Metastatic Liver Disease

In the United States, metastatic liver disease is 18 to 20 times more common than HCC. Detection of metastasis greatly alters the patient's prognosis and often the management. The incidence of hepatic metastases depends on the type of primary tumor and its stage at initial detection. At autopsy, 25% to 50% of patients dying from cancer have liver metastases. Patients with short-term survival (<1 year) after initial detection of liver metastases are those with HCC and carcinomas of the pancreas, stomach, and esophagus. Patients with longer-term survival are those with head and neck carcinomas and carcinoma of the colon. Most patients with melanoma have an extremely low incidence of hepatic metastases at diagnosis. Liver involvement at autopsy, however, may be as high as 70%.

The most common **primary tumors** resulting in liver metastases, in decreasing order of frequency, are gallbladder, colon, stomach, pancreas, breast, and lung. Most metastases to the liver are blood-borne through the hepatic artery or portal vein, but lymphatic spread of tumors from stomach, pancreas, ovary, or uterus may also occur. The portal vein provides direct access to the liver for tumor cells originating from the gastrointestinal tract and probably accounts for the high frequency of liver metastases from organs that drain into the portal circulation.

Advantages of ultrasound as a screening test for metastatic liver disease include its relative accuracy, speed, lack of ionizing radiation, and availability. Further, the multiplanar capability of ultrasound allows for excellent segmental localization of masses, with the ability to detect proximity to or involvement of the vital vascular structures. Although isolated reports describe detection of metastases on sonography in skilled hands as competitive with CT and MRI, sonography is not uniformly used as the first-line investigative technique to search for metastatic disease worldwide; CT has filled that role. Experience suggests that ultrasound without microbubble contrast agents does not compete with triphasic CT for metastasis detection.[136] Although greatly improved with the addition of contrast agents, as described earlier, we doubt CEUS will ever be widely used in routine clinical practice for the large numbers of patients who have scans for metastatic disease. Nonetheless, on a case-by-case basis, and as a problem-solving modality, CEUS may play a contributory role in the evaluation of the patient with metastatic liver disease.

On **conventional gray-scale sonography,** patients with metastatic liver disease may present with a single liver lesion (Fig. 4.59A), although more often they present with multiple focal liver masses. All metastatic lesions in a given liver may have identical sonographic morphology; however, biopsy-confirmed lesions of differing appearances may have the same underlying histologic structure. Of importance, metastases may also be present in a liver that already has an underlying diffuse or focal abnormality, most often hemangioma. Metastatic involvement of the liver may take on different forms, showing diffuse liver involvement and, in rare cases, geographic infiltration (Fig. 4.59C-F).

Knowledge of a prior or concomitant malignancy and features of disseminated malignancy at sonography are helpful in correct interpretation of sonographically detected liver masses. Although no confirmatory features of metastatic disease are seen on sonography, suggestive features include **multiple solid lesions** of varying size and a **hypoechoic halo** surrounding a liver mass. A halo around the periphery of a liver mass on sonography is an ominous sign strongly associated with malignancy, particularly metastatic disease but also HCC.

In our investigation of 214 consecutive patients with focal liver lesions, 66 had lesions that showed a hypoechoic halo; 13 had HCCs (Fig. 4.60A and B); 43 had metastases (Fig. 4.60C-F); four had FNH; and two had adenomas (see Fig. 4.51). Four lesions were unconfirmed. In 1992, Wernecke et al.[195] described the importance of the hypoechoic halo in the differentiation of malignant from benign focal hepatic lesions. Its identification has a positive and negative predictive value of 86% and 88%, respectively. Therefore we conclude that although not absolutely indicative of malignancy, a halo is seen with lesions that require further investigation and confirmation of their nature, regardless of the patient's presentation or status. Radiologic-histologic correlation of a hypoechoic halo surrounding a liver mass has revealed that, in the majority of cases, the hypoechoic rim corresponds to normal liver parenchyma, which is compressed by the rapidly expanding tumor. Less frequently, the hypoechoic rim represents proliferating malignant cells, tumor fibrosis or vascularization, or a fibrotic rim.[196-198]

The sonographic appearance of metastatic liver disease has been described as echogenic, hypoechoic, target, calcified, cystic, and diffuse. Although the ultrasound appearance is not specific for determining the origin of the metastasis, certain generalities apply (Fig. 4.61).

Echogenic metastases tend to arise from a gastrointestinal origin or from HCC (Fig. 4.61I). The more vascular the tumor is, the more likely it is that the lesion is echogenic.[180,199] Therefore metastases from **renal cell carcinoma, neuroendocrine tumors, carcinoid, choriocarcinoma,** and **islet cell carcinoma** also tend to be hyperechoic. It is this particular group of tumors that may mimic a hemangioma on sonography.

Hypoechoic metastases are generally hypovascular and may be monocellular or hypercellular without interstitial stroma. Hypoechoic lesions represent the typical pattern seen in untreated metastatic breast or lung cancer (Figs. 4.60 and 4.61), as well as **gastric, pancreatic,** and **esophageal tumors.** Lymphomatous involvement of the liver may also manifest as hypoechoic masses (Fig. 4.62). The uniform cellularity of **lymphoma** without significant background stroma is thought to be related to its hypoechoic appearance on sonography. Although at autopsy the liver is often a secondary site of involvement by Hodgkin and non-Hodgkin lymphoma, the disease tends to be diffusely infiltrative and undetected by sonography and CT.[200] The pattern of multiple hypoechoic hepatic masses is more typical of primary **non-Hodgkin lymphoma** of the liver or **lymphoma associated with AIDS.**[200,201] The lymphomatous masses may appear anechoic and septated, mimicking hepatic abscesses.

The **bull's-eye or target pattern** is characterized by a peripheral hypoechoic zone (see Fig. 4.60). The appearance is nonspecific and common, although it is frequently identified in metastases from **bronchogenic carcinoma.**[202]

Calcified metastases are distinctive by virtue of their marked echogenicity and distal acoustic shadowing (Fig. 4.61B). **Mucinous adenocarcinoma** of the colon is most frequently associated with calcified metastases. Calcium may appear as large, echogenic, and shadowing foci or, more often, shows innumerable tiny punctate echogenicities without clear shadowing. Other primary malignancies that give rise to calcified metastases are **endocrine pancreatic tumors, leiomyosarcoma, adenocarcinoma of the stomach, neuroblastoma, osteogenic sarcoma, chondrosarcoma,** and **ovarian cystadenocarcinoma and teratocarcinoma.**[203]

Cystic metastases are uncommon and generally exhibit features that distinguish them from the ubiquitous benign hepatic cyst, including mural nodules, thick walls, fluid-fluid levels, and internal septations.[204,205] Primary neoplasms with a cystic component, such as **cystadenocarcinoma of the ovary** and pancreas and **mucinous carcinoma of the colon,** may produce cystic secondary lesions, although infrequently. More often, cystic neoplasms result from extensive necrosis, seen most often in metastatic **sarcomas,** which typically have low-level echoes and a thickened, shaggy wall (Fig. 4.61H). Metastatic **neuroendocrine** and **carcinoid** tumors are typically highly echogenic and often show secondary cystic change (Fig. 4.61I). Large colorectal metastases may also rarely be necrotic, producing a predominantly cystic liver mass.

Diffuse disorganization of the hepatic parenchyma reflects **infiltrative metastatic disease** and is the most difficult to

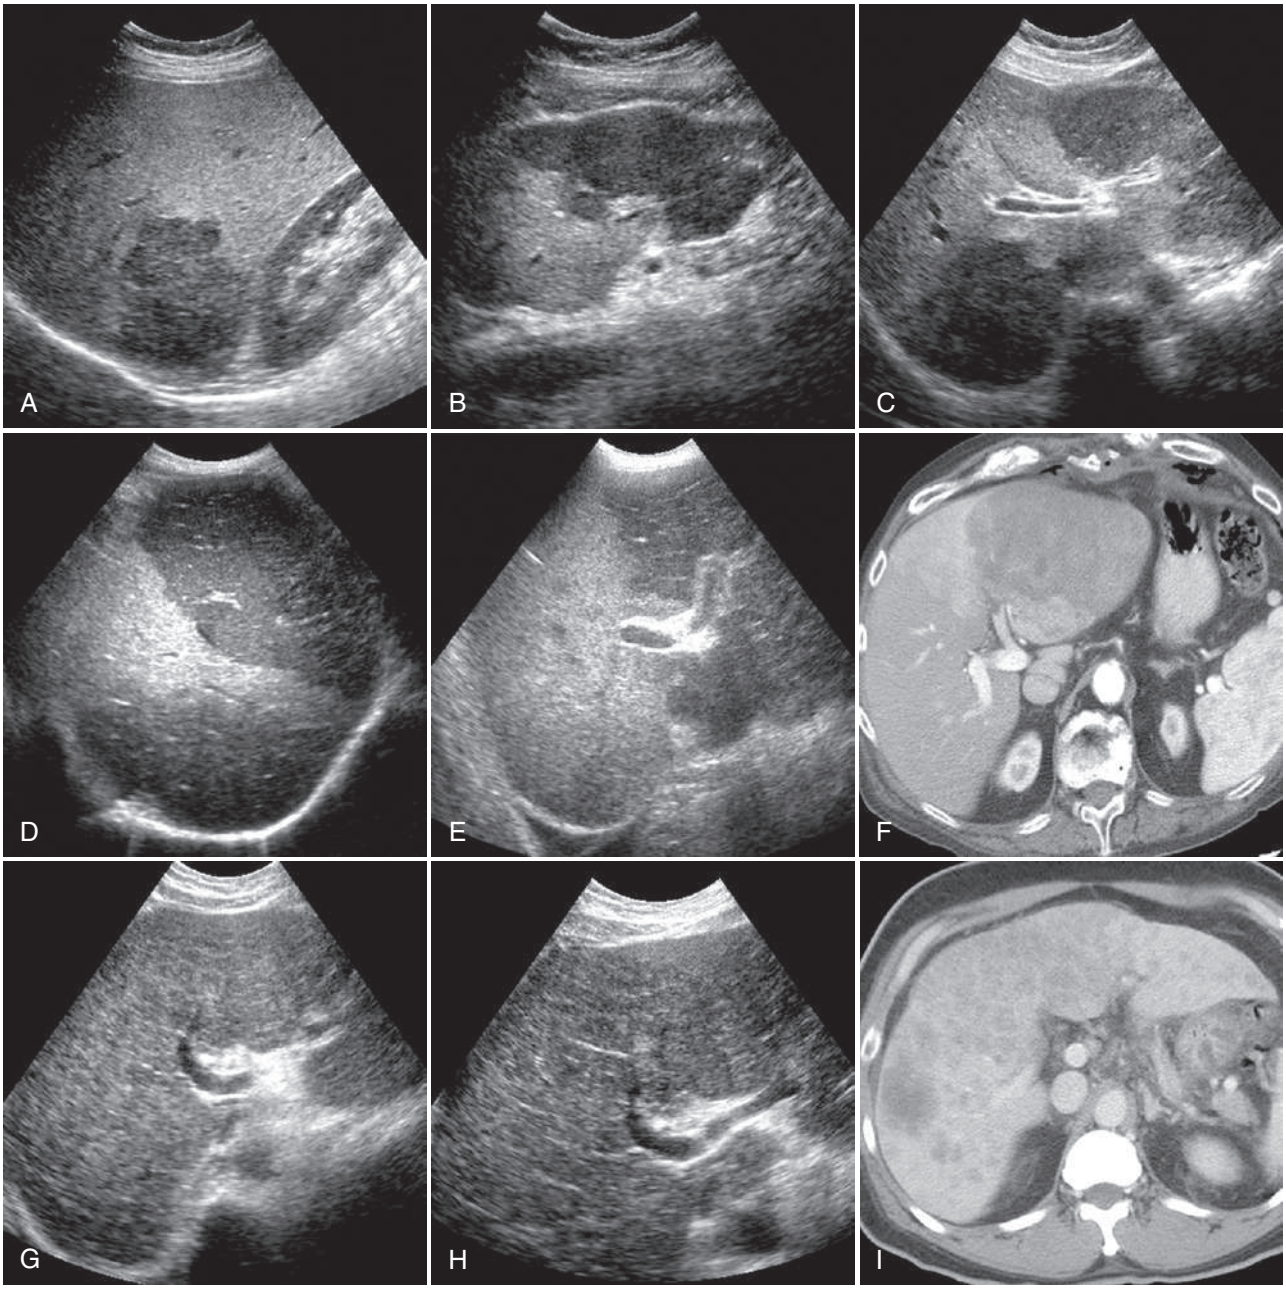

FIG. 4.59 Liver Metastases in Three Patients. *Top row,* **Focal liver masses:** most common variety and easiest to appreciate. **(A)** Sagittal image of the right lobe shows a well-defined and lobulated hypoechoic mass. **(B)** Sagittal image of the left lobe shows confluent masses in segment 3. **(C)** Transverse image shows the two focal hypoechoic masses separated by normal liver. *Middle row,* **Rare geographic pattern of metastases. (D)** and **(E)** Subcostal views show the right and left lobes of the liver. A sharp geographic or maplike border separates the normal echogenic liver from the hypoechoic tumor. The distribution and echogenicity variation suggest possible fatty change or perfusion abnormality. **(F)** Confirmatory computed tomography (CT) scan. *Bottom row,* **Diffuse tumor involvement:** often the most difficult to appreciate on ultrasound, as shown here. **(G)** Transverse sonogram; **(H)** similar view with greater magnification. Both images show a coarse liver parenchyma that is more suggestive of cirrhosis than the extensive tumor shown on **(I)** CT scan.

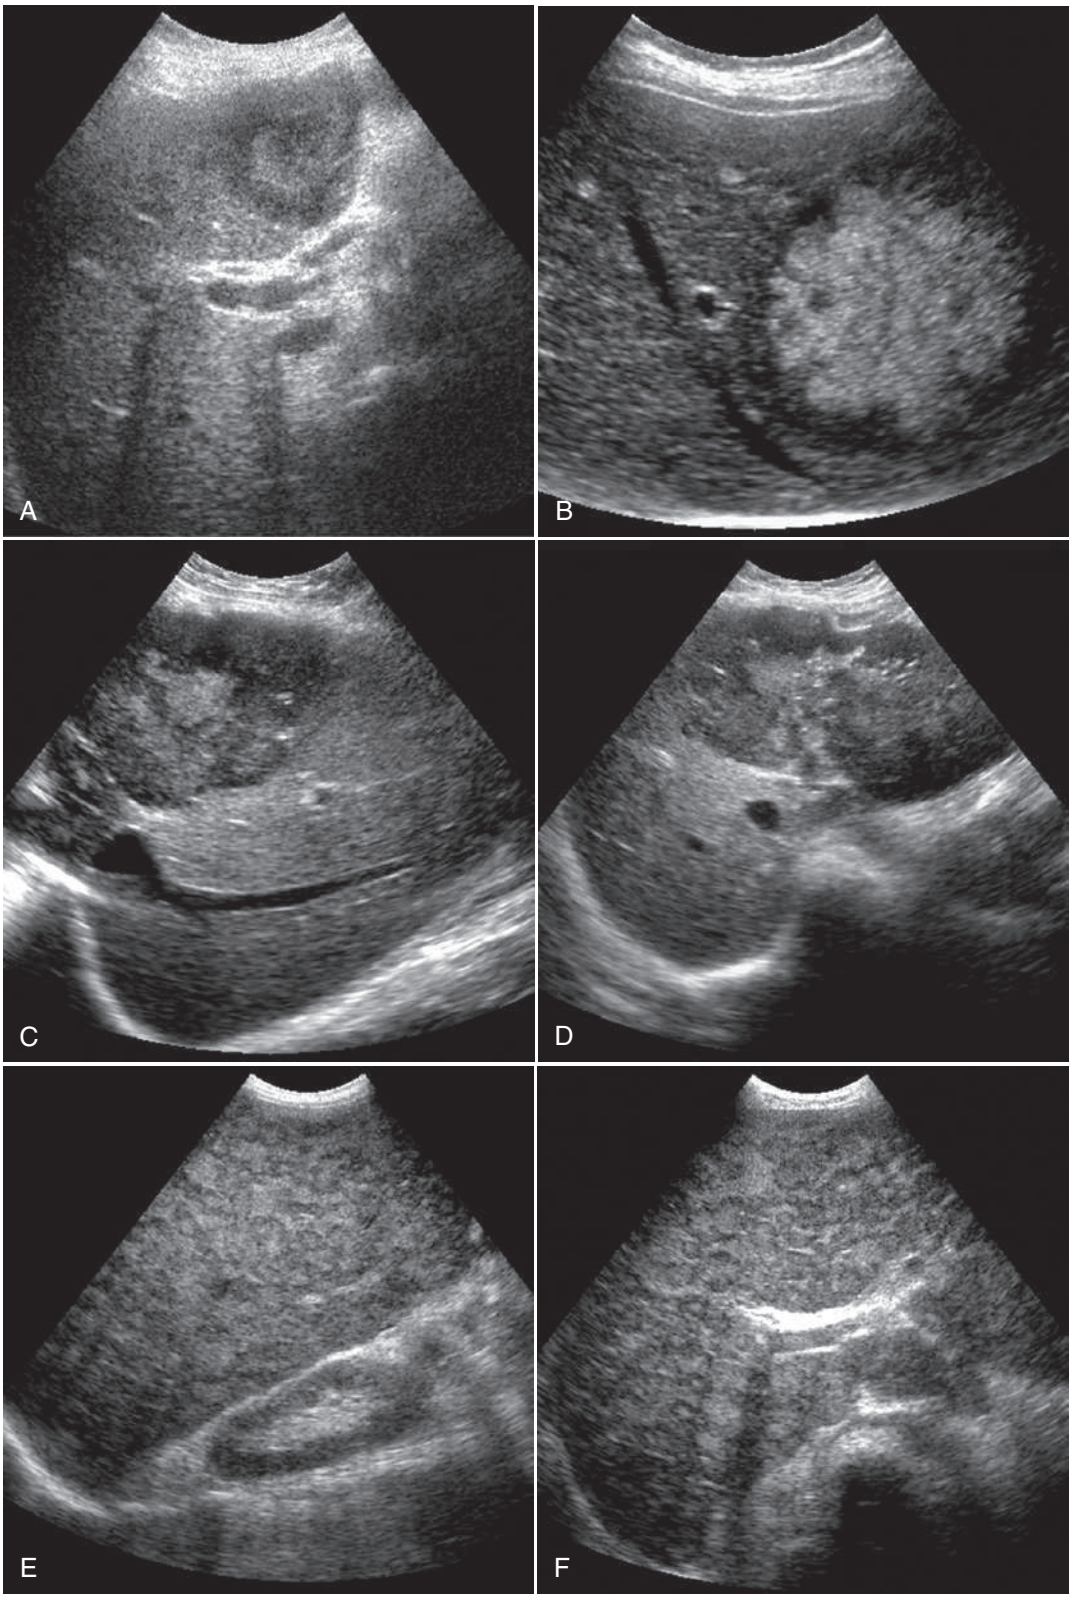

FIG. 4.60 Hypoechoic Halo in Malignant Disease. (A) and **(B) Hepatocellular carcinoma** showing as echogenic masses with a surrounding halo. **(C)** and **(D)** Sagittal and transverse images of a large solitary **breast metastasis. (E)** and **(F)** Large liver full of small masses with hypoechoic halos from **small cell carcinoma of the lung.**

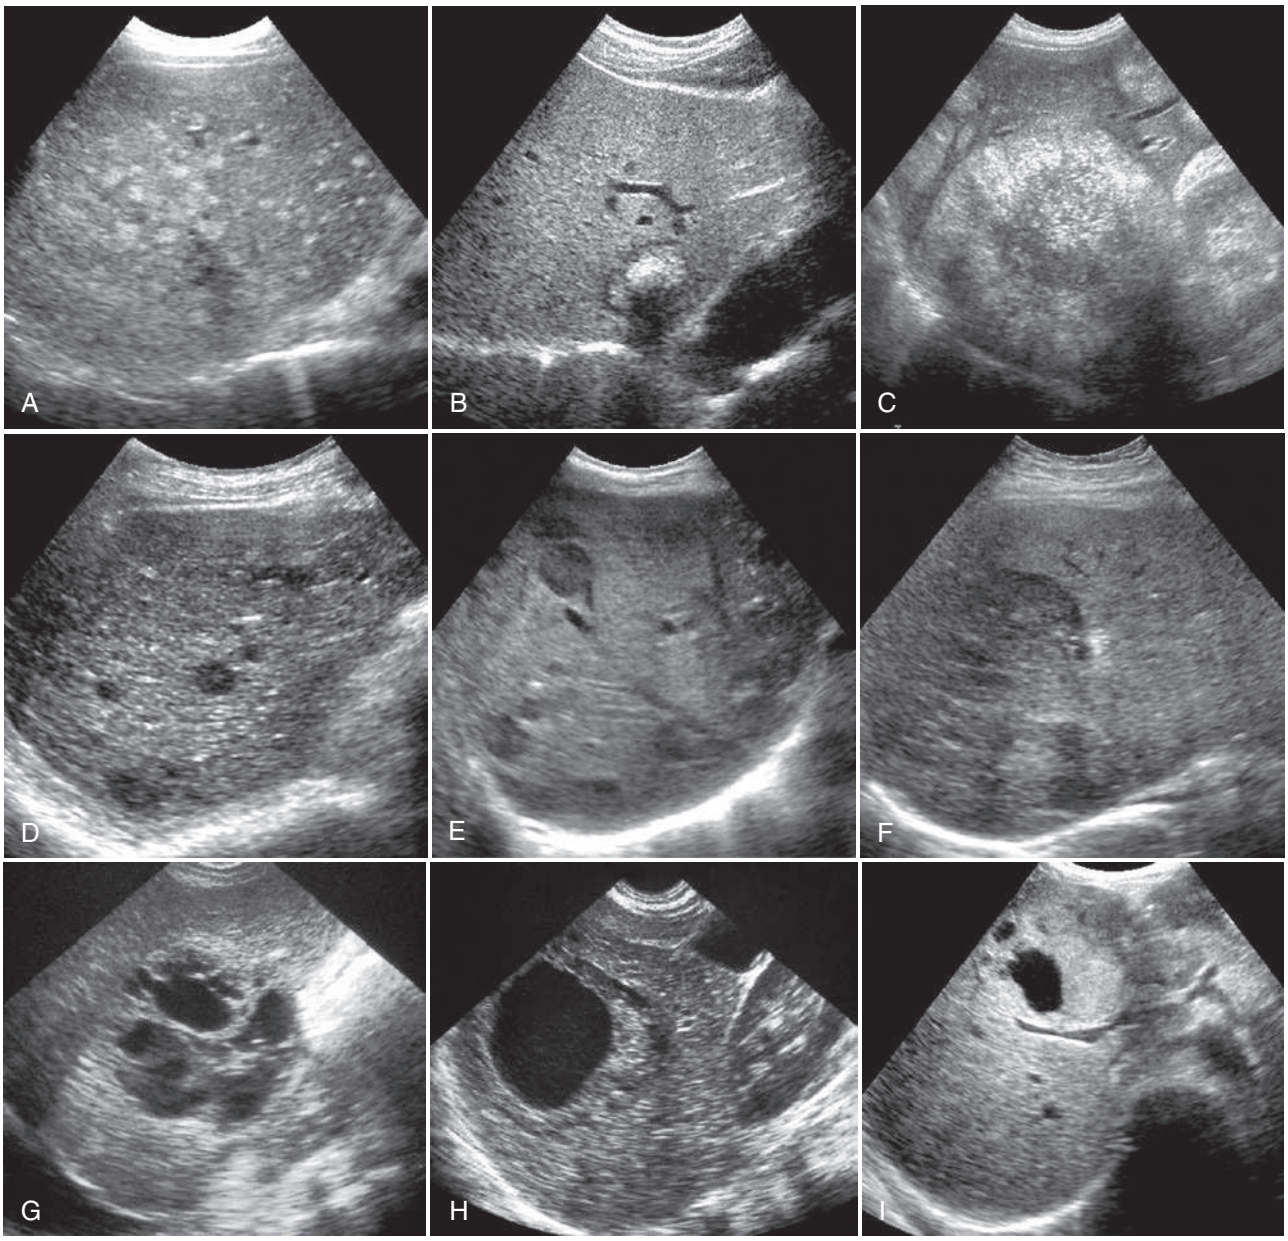

FIG. 4.61 Patterns of Metastatic Liver Disease. *Top row,* **Echogenic lesions. (A)** Multiple tiny echogenic metastases from choriocarcinoma. **(B)** Colon metastasis with clump of calcium and distal acoustic shadowing. **(C)** Large, poorly differentiated metastatic adenocarcinoma, with tiny punctate echogenicities suggesting microcalcification. *Middle row,* **Hypoechoic lesions of increasing size** from **(D)** pancreas; **(E)** lung; and **(F)** adenocarcinoma, from unknown primaries. *Bottom row,* **Cystic metastases. (G)** Rare metastatic liposarcoma from the thigh. Metastasis has a cystic growth pattern. **(H)** Metastatic sarcoma from the small bowel with necrosis, and **(I)** highly echogenic metastasis with a well-defined cystic component, highly suggestive of metastatic carcinoid or neuroendocrine tumor.

appreciate on sonography, probably because of the loss of the reference normal liver for comparison (Fig. 4.59G-I). In our experience, **breast and lung carcinomas,** as well as **malignant melanomas,** are the most common primary tumors to present this pattern. The diagnosis can be even more difficult if the patient has a fatty liver from chemotherapy. In these patients, CEUS, CT, or MRI may be helpful. Segmental and lobar tumor infiltration by secondary tumor may also be difficult to detect because it may mimic other benign conditions, such as **fatty infiltration** (Fig. 4.59D-F) or **cirrhosis** (Fig. 4.63).

CEUS plays a major role in the diagnosis and detection of metastases.[136,206] Arterial phase enhancement is variable, although most metastases, regardless of their expected enhancement, show transient hypervascularity in the arterial phase, followed by rapid washout. In the portal venous phase, metastases show washout, which tends to be complete and also rapid, beginning within

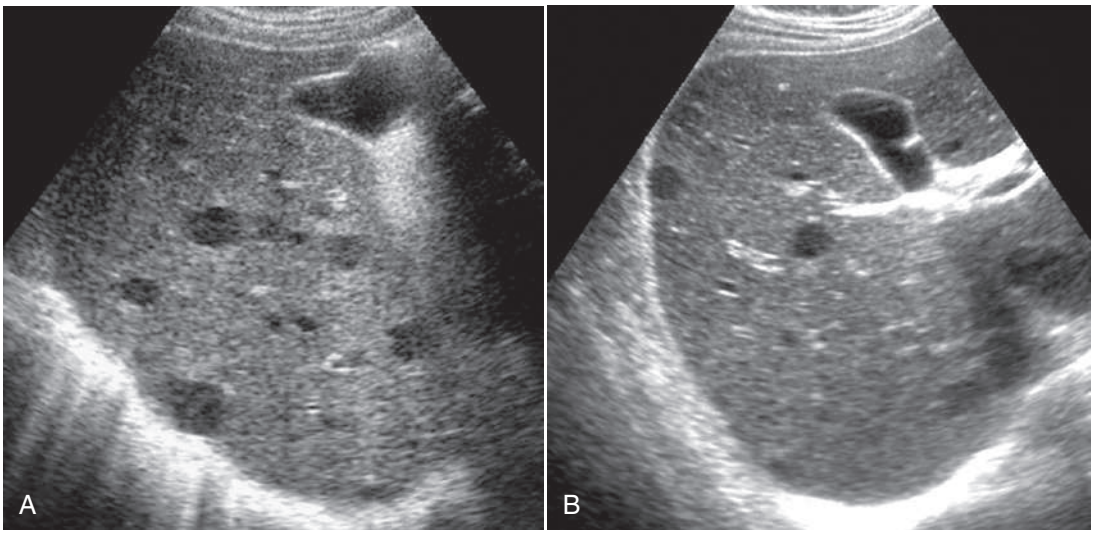

FIG. 4.62 Lymphoma of the Liver. (A) Sagittal and **(B)** transverse sonograms show small, focal hypoechoic nodules throughout the liver. Lymphoma may also involve the liver diffusely without producing a focal sonographic abnormality.

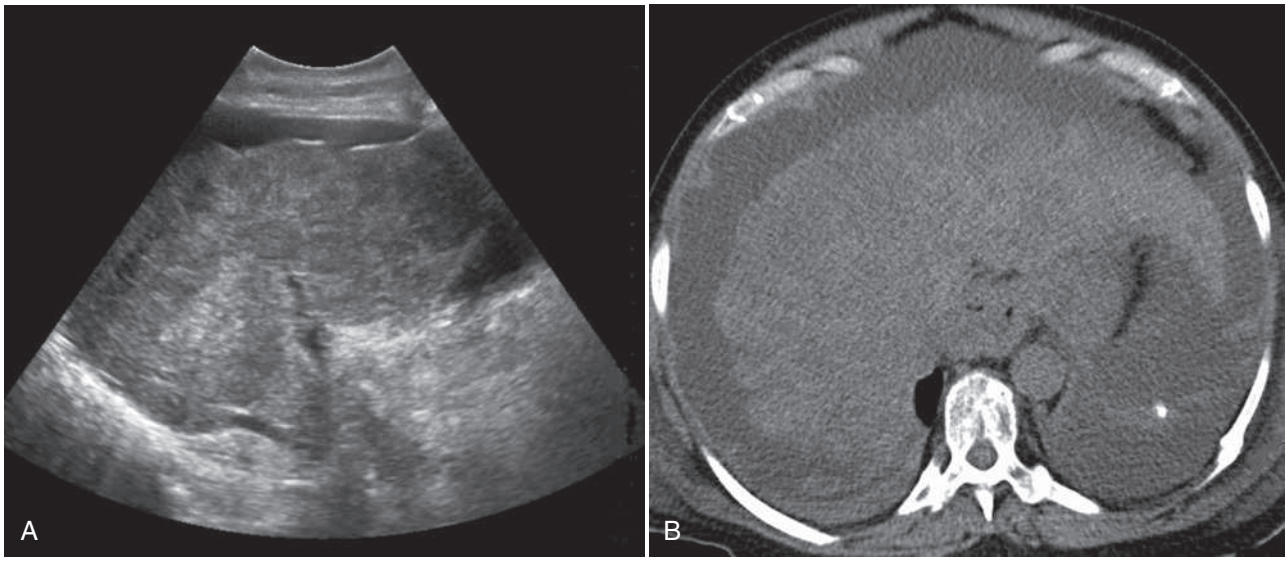

FIG. 4.63 Pseudocirrhosis in Woman With Metastatic Breast Cancer. Older woman presented to emergency department with increased abdominal girth. **(A)** Intercostal sonogram of the liver shows heterogeneous nodular parenchyma, surface nodularity, and ascites; all suggest cirrhosis. **(B)** Unenhanced computer tomography image of the liver confirms the findings, including ascites, surface nodularity, and heterogeneous parenchyma. Contrast enhancement did not suggest focal metastatic disease. At autopsy, diffuse breast metastases were found.

the arterial phase (Fig. 4.64 and Videos 4.12, 4.13, and 4.14). Therefore metastases will appear as black punched-out areas within the enhanced parenchyma. Hypovascularity and rim enhancement can also be shown.

Peripheral cholangiocarcinoma is an infrequent tumor presenting with a solitary liver mass similar to a metastasis, both on gray-scale images and CEUS. Capsular retraction may be appreciated.

Hepatic involvement by **Kaposi sarcoma,** although frequent in patients with AIDS at autopsy, is rarely diagnosed by imaging studies.[207] Sonography has demonstrated periportal infiltration and multiple small, peripheral hyperechoic nodules.[208,209]

Because of the nonspecific appearance of metastatic liver disease, **ultrasound-guided biopsy** is widely used to establish a primary tissue diagnosis. In addition, ultrasound is an excellent means to monitor the response to chemotherapy in oncology patients.

HEPATIC TRAUMA

The approach to the management of blunt hepatic injury is becoming increasingly more conservative. Surgical exploration is indicated for patients who are in shock or hemodynamically unstable. In the hemodynamically stable patient, many institutions

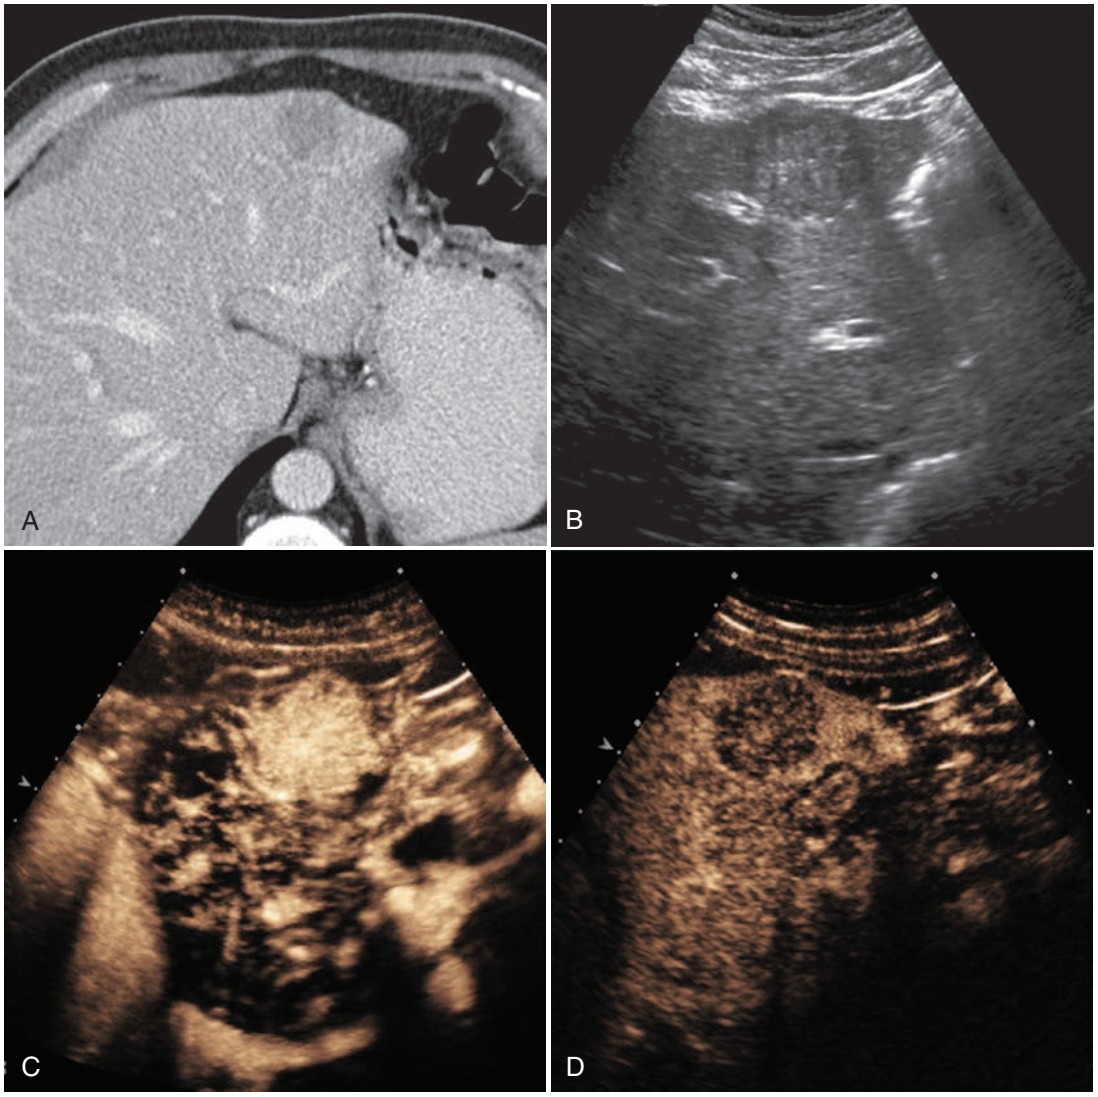

FIG. 4.64 Timing of Washout. This 49-year-old man had proven metastasis from colon cancer. **(A)** Axial computer tomography image shows a low-attenuation mass in the lateral segment of the left lobe. **(B)** Baseline sonogram shows that the mass is slightly exophytic and of mixed echogenicity. **(C)** Contrast-enhanced ultrasound arterial phase image at the peak of enhancement shows hypervascularity. **(D)** Image at 45 seconds shows clear washout of the lesion, which had begun at 28 seconds. See also Videos 4.12, 4.13, and 4.14. (With permission from Wilson S, Burns P. Microbubble-enhanced US in body imaging: what role? Radiology. 2010;257[1]:24-39.[148])

initially perform abdominal CT to assess the extent of liver trauma. Ultrasound may be used for serial monitoring of the healing pattern. In certain circumstances ultrasound can be used as a screening tool in blunt abdominal trauma (focused assessment with sonography in trauma [FAST]) by assessing for free fluid that would indicate solid organ injury.[210-214]

The predominant site of hepatic injury in blunt trauma is the right lobe, in particular the posterior segment.[215] Foley et al.[216] found that the most common type of injury was a perivascular laceration paralleling branches of the right and middle hepatic veins and the anterior and posterior branches of the right portal vein. Other findings were subcapsular, pericapsular, and isolated hematomas; liver fracture, defined as a laceration extending between two visceral surfaces; lacerations involving the left lobe; and hemoperitoneum[216] (Fig. 4.65). Hepatic infarcts are rarely identified after blunt abdominal trauma because of the dual blood supply of the liver.

VanSonnenberg et al.[217] evaluated the sonographic findings of acute trauma to the liver (<24 hours after injury or transhepatic cholangiogram) and determined that fresh hemorrhage was echogenic. Within the first week, the hepatic laceration becomes more hypoechoic and distinct as a result of resorption of devitalized tissue and ingress of interstitial fluid. After 2 to 3 weeks, the laceration becomes increasingly indistinct because of fluid resorption and filling of the spaces with granulation tissue.

Portosystemic Shunts

Surgical portosystemic shunts are performed to decompress the portal system in patients with portal hypertension. The most

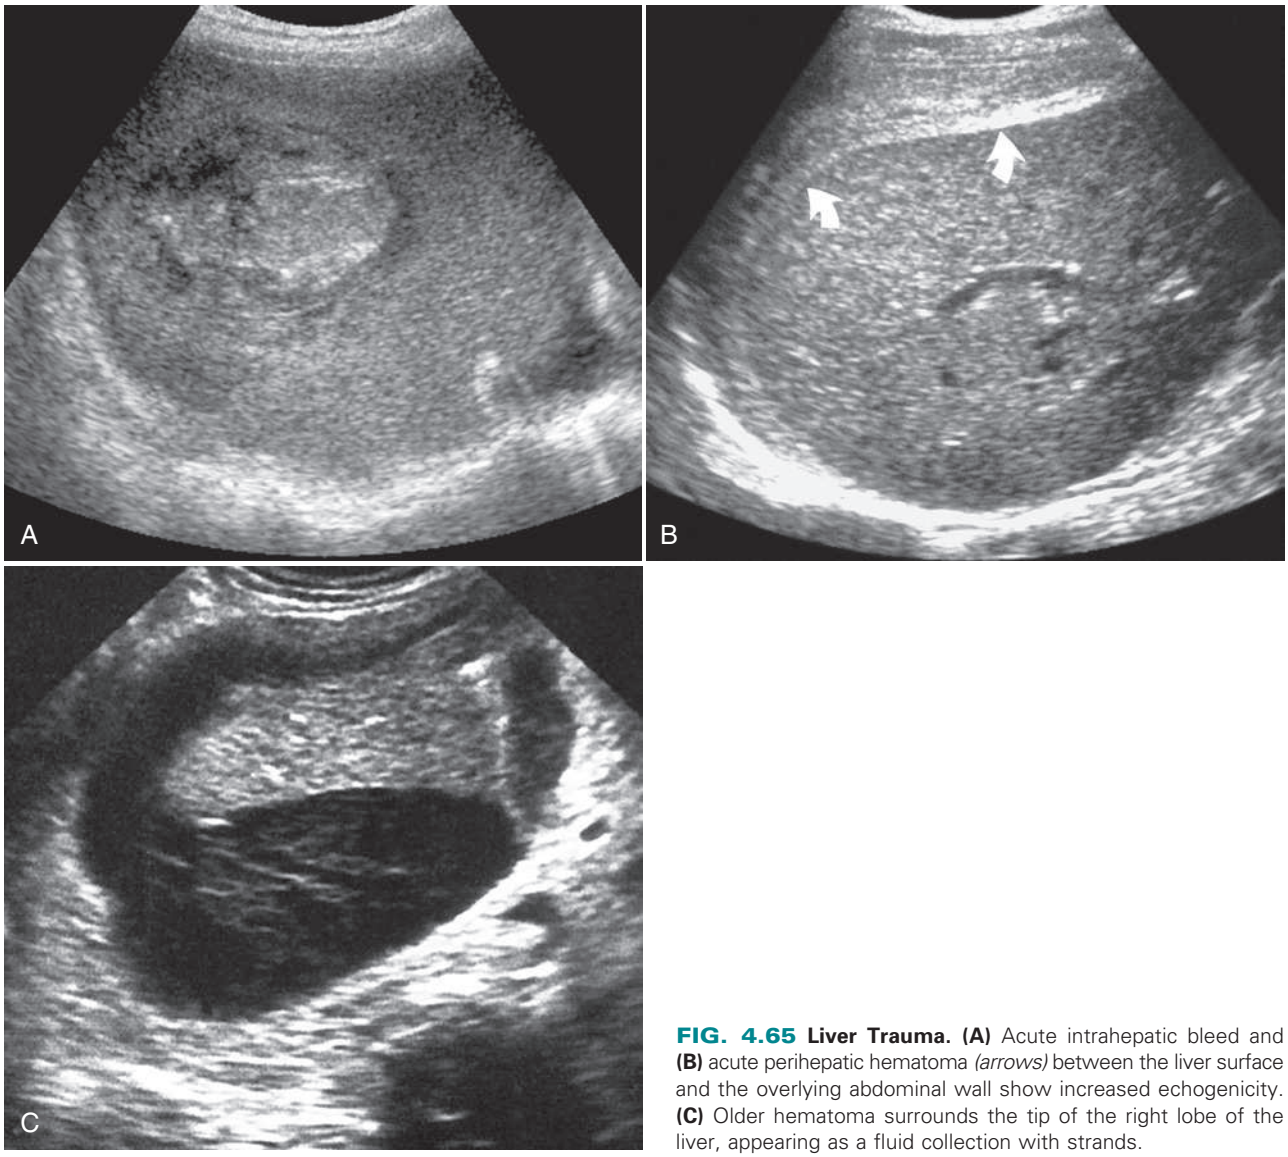

FIG. 4.65 Liver Trauma. (A) Acute intrahepatic bleed and **(B)** acute perihepatic hematoma *(arrows)* between the liver surface and the overlying abdominal wall show increased echogenicity. **(C)** Older hematoma surrounds the tip of the right lobe of the liver, appearing as a fluid collection with strands.

common surgical shunts include mesocaval, distal splenorenal (Warren shunts), mesoatrial, and portacaval. Duplex Doppler sonography and color Doppler flow imaging (CDFI) are reliable noninvasive methods of assessing shunt patency or thrombosis.[218-221] Both modalities are effective in assessing portacaval, mesoatrial, and mesocaval shunts.[218] Shunt patency is confirmed by demonstrating flow at the anastomotic site. If the anastomosis cannot be visualized, hepatofugal portal flow is an indirect sign of patency.[219,220]

Distal splenorenal communications are particularly difficult to examine with duplex Doppler sonography because overlying bowel gas and fat hinder accurate placement of the Doppler cursor.[218,222] CDFI more readily locates the splenic and renal limbs of Warren shunts. The splenic limb is best imaged from a left subcostal approach, whereas the left renal vein is optimally scanned through the left flank. Grant et al.[218] reported that color Doppler sonography correctly inferred patency or thrombosis in all 14 splenorenal communications by evaluating the flow in both limbs of the shunt.

Transjugular Intrahepatic Portosystemic Shunts

Transjugular intrahepatic portosystemic shunts **(TIPS)** are the most popular technique for relief of symptomatic portal hypertension, specifically varices with gastrointestinal bleeding, and less often, refractory ascites. Performed percutaneously with insertion of an expandable metal stent, TIPS have less morbidity and mortality than surgical shunt procedures.[223]

The technique of performing TIPS requires transjugular access to the infrahepatic IVC, with selection of the optimal hepatic vein on the basis of its angle and diameter, most often the right hepatic vein. After targeting the portal vein with either fluoroscopy or Doppler sonography, a transjugular puncture needle is passed from the hepatic vein to the intrahepatic portal vein and a shunt created. The tract is dilated to an approximate diameter of 10 mm,

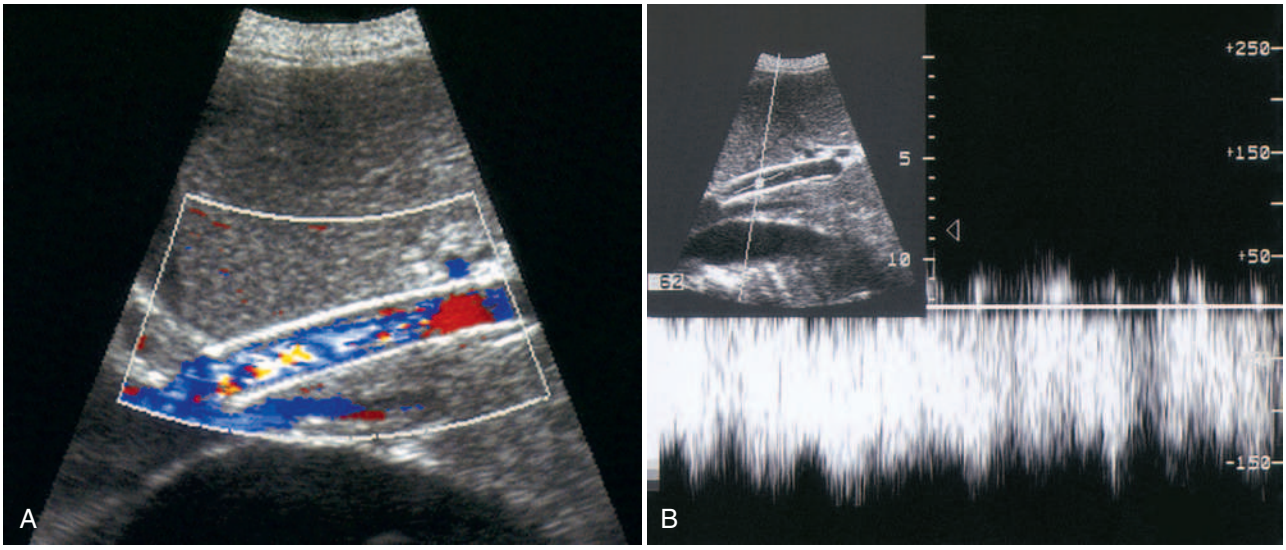

FIG. 4.66 Transjugular Intrahepatic Portosystemic Shunt (TIPS). (A) Color Doppler image of TIPS shows flow throughout the shunt appropriately directed toward the heart, with a turbulent pattern. **(B)** Angle-corrected midshunt velocity is normal at 150 cm/sec.

with monitoring of the portal pressure gradient and filling of varices on portal venography. A bridging stent is left in place.[224]

In addition to acute problems directly attributed to the procedure itself, TIPS may be complicated by stenosis or occlusion of the stent caused by hyperplasia of the pseudointimal lining. At 1 year, primary patency rates vary from 25% to 66%, with a primary assisted patency of about 83%.[225,226] Doppler sonography provides a noninvasive method for monitoring of TIPS patients because malfunction of the graft may be silent in its early phase. Scans should be performed immediately after the procedure, at 3-month intervals, and as indicated clinically.

Normal postprocedural Doppler findings include high-velocity, turbulent blood flow (mean peak systolic velocity, 135-200 cm/sec)[227] throughout the stent and hepatofugal flow in the intrahepatic portal venous branches, as the liver parenchyma drains through the shunt into the systemic circulation. Increased hepatic artery peak systolic velocity is also a normal observation, as is increased velocity in the main portal vein, because the stent serves as a low-resistance conduit, bypassing the high-resistance hepatic circulation. The reported mean main portal vein velocity in patients with patent shunts ranges from 37 to 47 cm/sec.[228-230] Hepatic artery velocities increase from 79 cm/sec preshunt to 131 cm/sec after the procedure.[227]

Sonographic evaluation should include measurement of angle-corrected stent velocities at three points along the stent and in the main portal vein, as well as evaluation of the direction of flow in the intrahepatic portal vein and in the involved hepatic vein (Figs. 4.66 and 4.67).

Sonographically detected complications include the following:

- Stent occlusion
- Stent stenosis
- Hepatic venous stenosis

Malfunction of Transjugular Intrahepatic Portosystemic Shunts: Sonographic Signs

DIRECT SIGNS

No flow, consistent with shunt thrombosis or occlusion
Peak shunt velocity: <90 or >190 cm/sec
Change in peak shunt velocity: decrease of >40 cm/sec or increase of >60 cm/sec
Main portal vein velocity <30 cm/sec
Reversal of flow in hepatic vein away from inferior vena cava, suggesting hepatic vein stenosis
Hepatopetal intrahepatic portal venous flow

SECONDARY SIGNS

Reaccumulation of ascites
Reappearance of varices
Reappearance of recanalized paraumbilical vein

Detection of these complications is related to identification of both direct abnormalities and secondary signs.[231-234] **Direct signs** include no flow, abnormal peak shunt velocity, a change in the peak shunt velocity, a low velocity in the main portal vein, reversal of hepatic vein flow, and hepatopetal intrahepatic portal venous flow. **Secondary signs** include reaccumulation of ascites and reappearance of varices and of recanalized paraumbilical vein.

PERCUTANEOUS LIVER BIOPSY

Percutaneous biopsy of malignant disease involving the liver has a sensitivity greater than 90% in most study series.[235,236]

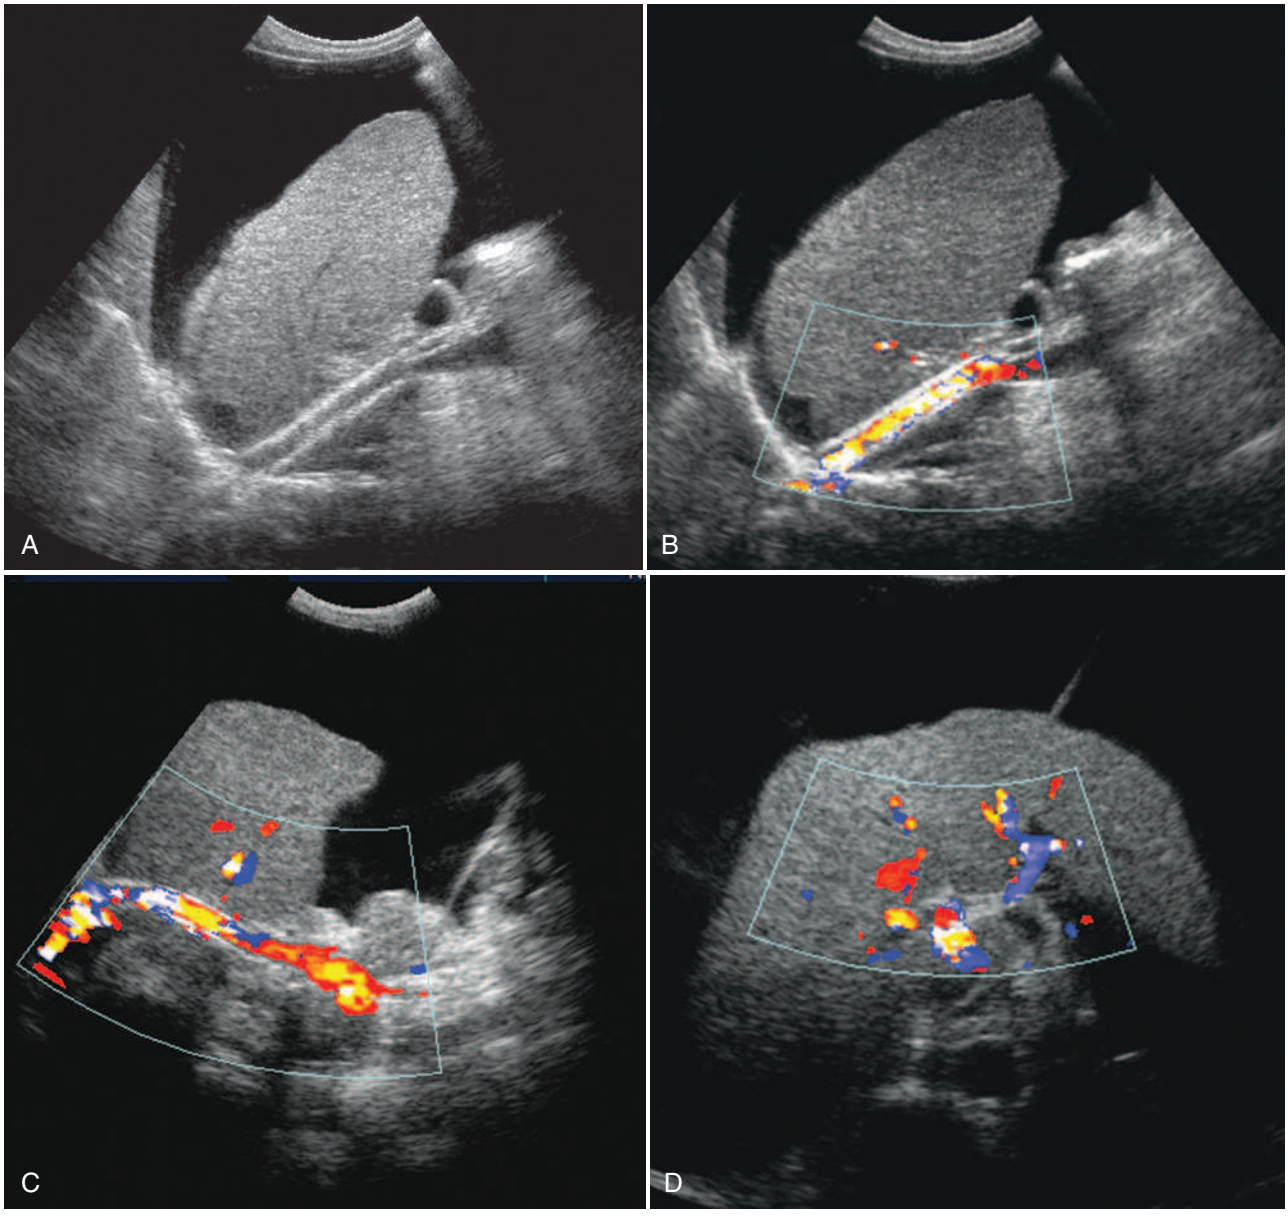

FIG. 4.67 Secondary Signs of Functional Shunt. All images show gross ascites, which suggests a dysfunctional shunt. **(A)** Gray-scale and **(B)** color Doppler images show a patent transjugular intrahepatic portosystemic shunt. Velocities throughout the shunt were about 130 cm/sec, which is normal. **(C)** Sagittal image shows that flow in the main portal vein is appropriately directed toward the shunt, appearing red. **(D)** Transverse image of the porta hepatis shows the ascending left portal venous branch is blue, flowing toward the shunt; this is also the correct direction. Therefore despite the ascites, the ultrasound evaluation does not show a dysfunctional shunt.

Relative contraindications to percutaneous biopsy are an uncorrectable bleeding diathesis, an unsafe access route, and an uncooperative patient. Ultrasound guidance allows real-time observation of the needle tip as it is advanced into the lesion. Several biopsy attachments allow continuous observation of the needle as it follows a predetermined path. Alternatively, many experienced radiologists prefer a "freehand" technique. Even small masses (2.5 cm) can undergo successful biopsy using sonographic guidance.[237] Ultrasound guidance may also be used in percutaneous aspiration and drainage of complicated fluid collections in the liver. Ultrasound-guided percutaneous ethanol injection has been used in the treatment of HCC and hepatic metastases.[238]

INTRAOPERATIVE ULTRASOUND

Intraoperative ultrasound is now an established application of ultrasound technology. The exposed liver is scanned with a sterile, 7.5-MHz transducer or one covered by a sterile sheath. Intraoperative ultrasound has been found to change the operative strategy in 31% to 49% of patients undergoing hepatic resection, either by allowing more precise resection or by indicating inoperability because of unsuspected masses or venous invasion.[239,240] Studies emphasize further improvement of surgical outcome with the addition of CEUS to intraoperative procedures.[241] Improved detection of metastases on CEUS undoubtedly accounts for this improvement.

CHAPTER 5

The Spleen

Patrick M. Vos, John R. Mathieson, and Peter L. Cooperberg

SUMMARY OF KEY POINTS

- Ultrasound can be used to diagnose or exclude splenic abnormalities, but computed tomography and/or magnetic resonance imaging may be needed in indeterminate cases.
- There is no single upper limit of normal for spleen size, since size varies with patient sex, weight, and height. Use of a strict 12-cm upper limit of normal for the spleen will lead to overdiagnosis of splenomegaly.
- The differential diagnosis of splenomegaly is long. Associated clinical and radiologic features can be helpful in assessing the cause.
- Focal splenic lesions may be benign or malignant and thus should be carefully assessed.
- Common causes of multiple splenic nodules include infection (e.g., mycobacteria, histoplasmosis), sarcoidosis, and malignancy (e.g., lymphoma, metastases).

INTERVENTIONAL PROCEDURES
PITFALLS IN INTERPRETATION

Computed tomography (CT) and/or magnetic resonance imaging (MRI) are currently the techniques of choice for the imaging evaluation of the spleen. However, ultrasound can also be very useful to diagnose or exclude splenic abnormalities and is particularly helpful in the follow-up of patients with known splenic abnormalities. Splenic lesions may be encountered in a variety of clinical settings, and the radiologist should be aware of the spectrum of processes that may involve the spleen as well as the clinical context in which they occur.[1]

The spleen and left upper quadrant (LUQ) should be routinely evaluated on all abdominal investigations, especially in patients with suspected splenomegaly, LUQ pain, or trauma. In general, the spleen can be examined by ultrasound without difficulty. Because the normal spleen is uniform in echogenicity, focal abnormalities stand out clearly. Similarly, perisplenic abnormalities and fluid collections are usually easily identified. Inadequate assessment of the spleen and surrounding structures is therefore relatively rare. Occasionally, because the spleen is located high in the LUQ, difficulties can be encountered. Shadowing from ribs, overlying bowel gas, and overlying lung can obscure visualization of the deeper structures. Expertise and persistence may be required to overcome these obstacles.

EMBRYOLOGY AND ANATOMY

The spleen arises from a mass of mesenchymal cells located between the layers of the **dorsal mesentery,** which connects the stomach to the posterior peritoneal surface over the aorta (Fig. 5.1A). These mesenchymal cells differentiate to form the **splenic pulp,** the supporting connective tissue structures, and the **splenic capsule.** The **splenic artery** penetrates the primitive spleen, and arterioles branch through the connective tissue into the splenic sinusoids.

As the embryonic stomach rotates 90 degrees on its longitudinal axis, the spleen and dorsal mesentery are carried to the left along with the greater curvature of the stomach (Fig. 5.1B). The base of the dorsal mesentery fuses with the posterior peritoneum over the left kidney, giving rise to the **splenorenal ligament.** This explains why, although the spleen is intraperitoneal, the splenic artery enters from the retroperitoneum through the splenorenal ligament (Fig. 5.1C). In most adults, a portion of the splenic capsule is firmly attached to the fused dorsal mesentery anterior to the upper left kidney, giving rise to the **bare area** of the spleen.[2] The size of the splenic bare area varies but usually involves less than half the posterior splenic surface (Fig. 5.2). This anatomic

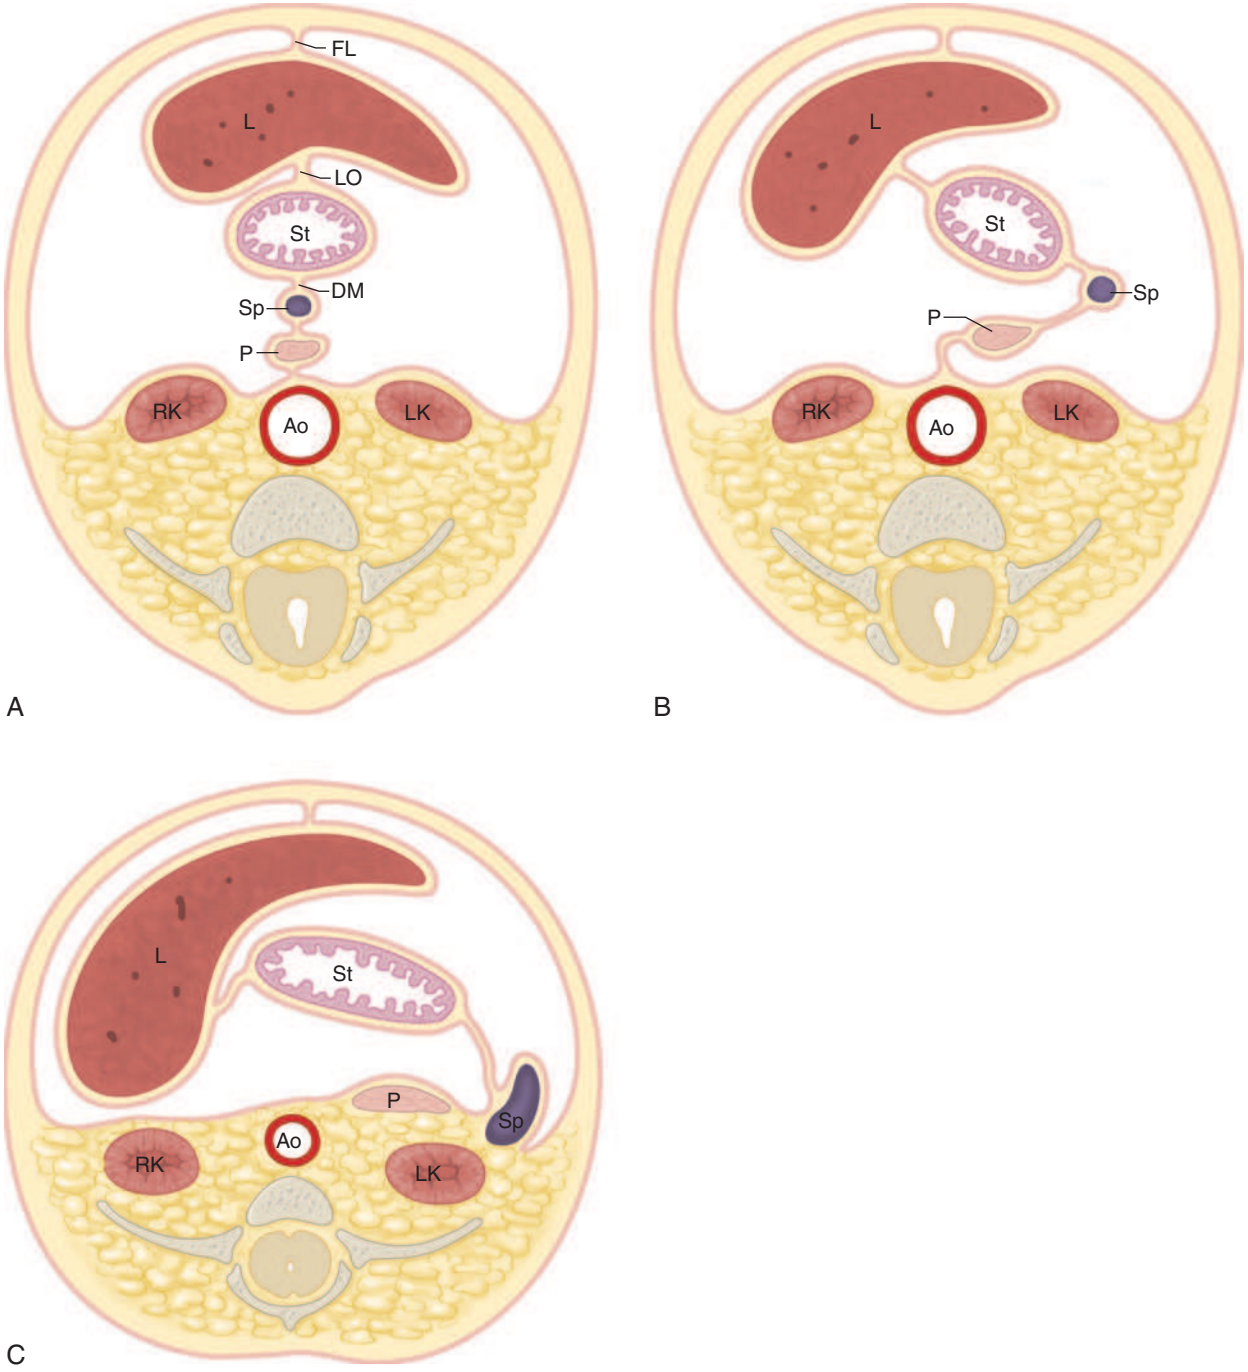

FIG. 5.1 Embryologic Development of the Spleen. Schematic axial drawings of the upper abdomen. **(A) Embryo: 4 to 5 weeks.** The mesentery anterior to the stomach *(St)* is the ventral mesentery. The ventral mesentery is divided into two portions by the liver *(L)* into the **falciform ligament** *(FL)* anteriorly and the **gastrohepatic ligament** or **lesser omentum** *(LO)* posteriorly. Posterior to the stomach is the **dorsal mesentery** *(DM)*, which contains the developing spleen *(Sp)* and pancreas *(P)*. The dorsal mesentery is divided into two portions by the spleen: the **splenogastric ligament** anteriorly and the **splenorenal ligament** posteriorly. The pancreas *(P)* has not yet become retroperitoneal and remains within the dorsal mesentery. **(B) Embryo: 8 weeks.** The stomach rotates counterclockwise, displacing the liver to the right and the spleen to the left. The portion of the dorsal mesentery containing the pancreas, splenic vessels, and spleen begins to fuse to the anterior retroperitoneal surface, giving rise to the splenogastric ligament and the "bare area" of the spleen. If fusion is incomplete, the spleen will be attached to the retroperitoneum only by a long mesentery, giving rise to a mobile or "wandering" spleen. **(C) Newborn.** Fusion of the dorsal mesentery is now complete. The pancreas is now completely retroperitoneal, and a portion of the spleen has fused with the retroperitoneum. Note the close relation of the pancreatic tail to the splenic hilum. *Ao,* Aorta; *LK,* left kidney; *RK,* right kidney.

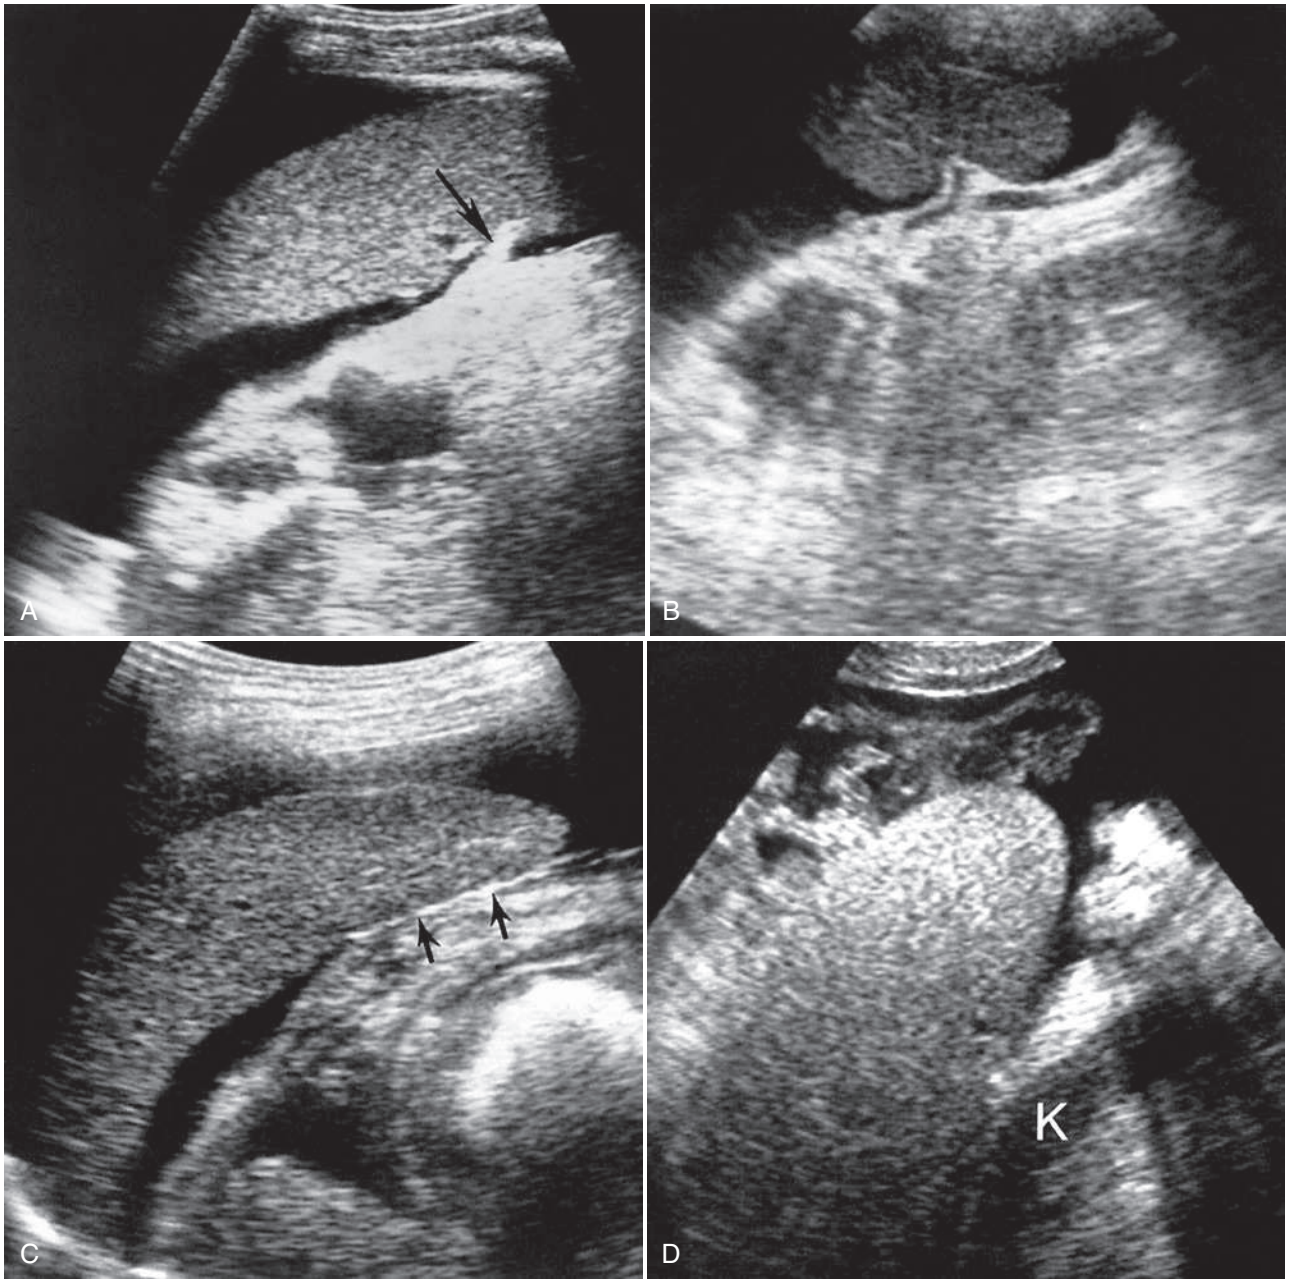

FIG. 5.2 Bare Area of the Spleen. Variability in the relationship of the spleen to the anterior retroperitoneal surface is demonstrated in patients with ascites. **(A)** This spleen has **no bare area.** The splenorenal ligament *(arrow)* is outlined on both sides by ascitic fluid. **(B)** Part of the lower pole of the spleen is fused posteriorly. **(C)** Lower pole is fused to the retroperitoneum *(arrows).* **(D)** Large proportion of this patient's spleen is fused posteriorly. Note the close relation of the spleen to the left kidney *(K).*

feature is analogous to the bare area of the liver and can be helpful in distinguishing intraperitoneal from pleural fluid collections.

The normal adult spleen is convex superolaterally, is concave inferomedially, and has a homogeneous echo pattern (Videos 5.1 and 5.2). The spleen lies between the **fundus of the stomach** and the **diaphragm,** with its long axis in the line of the left 10th rib. The diaphragmatic surface is convex and is usually situated between the 9th and 11th ribs. The visceral or inferomedial surface has gentle indentations where it comes into contact with the stomach, left kidney, pancreas, and splenic flexure. The spleen is suspended by the splenorenal ligament, which is in contact with the **posterior peritoneal wall,** the **phrenicocolic ligament,** and the **gastrosplenic ligament.** The gastrosplenic ligament is composed of the two layers of the dorsal mesentery that separate the lesser sac posteriorly from the greater sac anteriorly.

Its weight is related to the patient's age and gender; the spleen usually weighs less than 150 g on autopsy (range, 80-300 g).[3] In adults, the spleen decreases in size and weight with advancing age and is smaller in women. It also increases slightly during digestion and can vary in size according to the nutritional status of the body.

Splenic functions include phagocytosis, fetal hematopoiesis, adult lymphopoiesis, immune response, and erythrocyte storage.

The spleen may be congenitally absent. Under a variety of conditions, including surgical misadventure, the spleen also may be removed. Currently, the surgical trend is toward preservation of the spleen when possible.[4] A person can live fully without a spleen. However, particularly in childhood, the immune response may be impaired, especially to encapsulated bacteria. Overwhelming postsplenectomy **sepsis** is a long-term risk in asplenic patients, and appropriate preventive measures should be taken to minimize this risk.[5,6]

SONOGRAPHIC TECHNIQUE

All routine abdominal sonographic examinations, regardless of the indications, should include at least one **coronal view** of the spleen and the upper pole of the left kidney. The most common and easy approach to visualize the spleen (Video 5.1) is to maintain the patient in the supine position and place the transducer in the coronal plane of section posteriorly in one of the lower left intercostal spaces. The patient can then be examined in various degrees of inspiration to maximize the window to the spleen. Deep inspiration introduces air into the lung in the lateral costophrenic angle and may obscure visualization. A modest inspiration depresses the central portion of the left hemidiaphragm and spleen inferiorly so that they can be visualized. The plane of section should then be swept posteriorly and anteriorly to view the entire volume of the spleen. We generally find that a thorough examination in the **coronal plane** of section is highly accurate for excluding any lesion within or around the spleen and for documenting the spleen's approximate size.

If an abnormality is discovered within or around the spleen, other planes of section should be used. An **oblique plane** of section along the intercostal space can avoid rib shadowing (Fig. 5.3). In some patients with narrow intercostal spaces, however, intercostal scanning can be difficult. A **transverse plane** from a lateral, usually intercostal, approach may help to localize a lesion within the spleen anteriorly or posteriorly.

If the spleen is not enlarged and is not surrounded by a large mass, scanning from an anterior position—as one would for imaging the liver—is not helpful because of the interposition of gas within the stomach and the splenic flexure of the colon. However, if the patient has a relatively large liver, or spleen, the spleen may be visualized from an anterior approach (Fig. 5.4). If there is free intraperitoneal fluid around the spleen or a left pleural effusion, the spleen may be better visualized from an anterolateral approach. Often, it is beneficial to have the patient roll onto the right side as much as 45 degrees, or even 90 degrees, so that a more posterior approach can be used to visualize the spleen. The spleen may also rotate to the right, making it easier to visualize.

Generally, the same curvilinear transducers and technical settings are used for examination of the spleen as for the other abdominal organs. A high-frequency linear array transducer can be used for more detail. Techniques such as harmonic and compound imaging are used to improve image quality and detect subtle lesions. Color Doppler may also be useful for solitary lesions (Fig. 5.5).[7]

The use of contrast-enhanced ultrasound (CEUS) is increasing in both research and clinical settings. Multiple reports have recently described CEUS of the spleen (Video 5.3) and its characterization of splenic lesions.[8,9] However, its role in general practice has not yet been confirmed.

SONOGRAPHIC APPEARANCE

The shape of the normal spleen is variable. The spleen consists of **two components** joined at the hilum: a **superomedial** component and an **inferolateral** component. More superiorly, on transverse scanning, the spleen has a typical fat, "inverted comma"

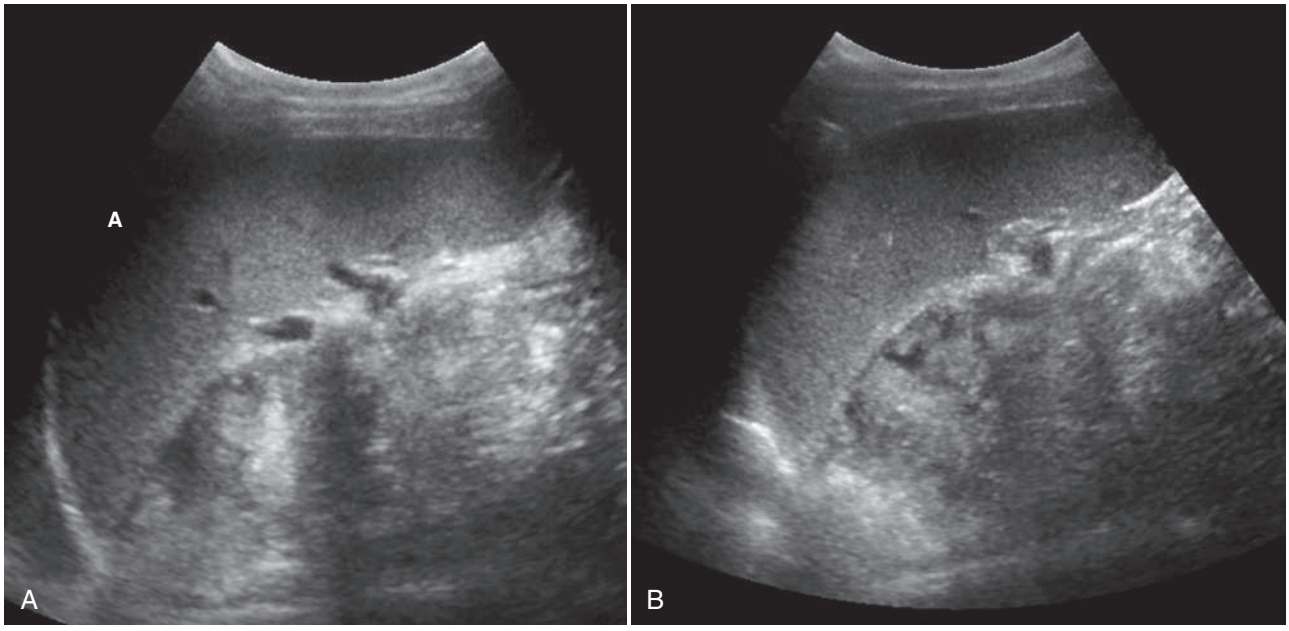

FIG. 5.3 Importance of Scan Plane. (A) Coronal ultrasound scan shows part of the spleen obscured by air in the lung. **(B)** Improved visualization of the spleen on coronal oblique scan aligned with the 10th interspace between the ribs.

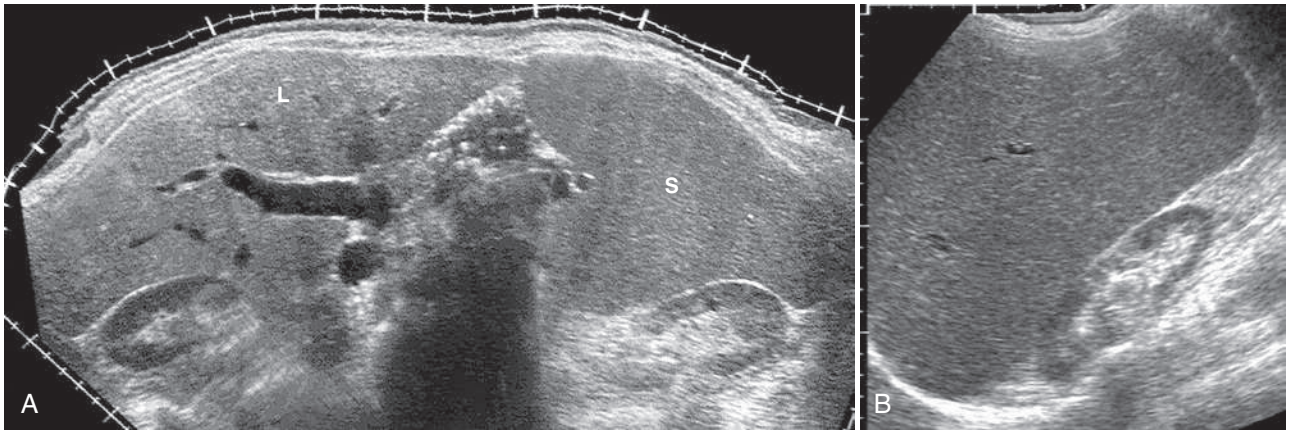

FIG. 5.4 Splenomegaly. (A) Transverse and **(B)** coronal extended–field of view images demonstrate marked splenic *(S)* enlargement. *L,* Liver.

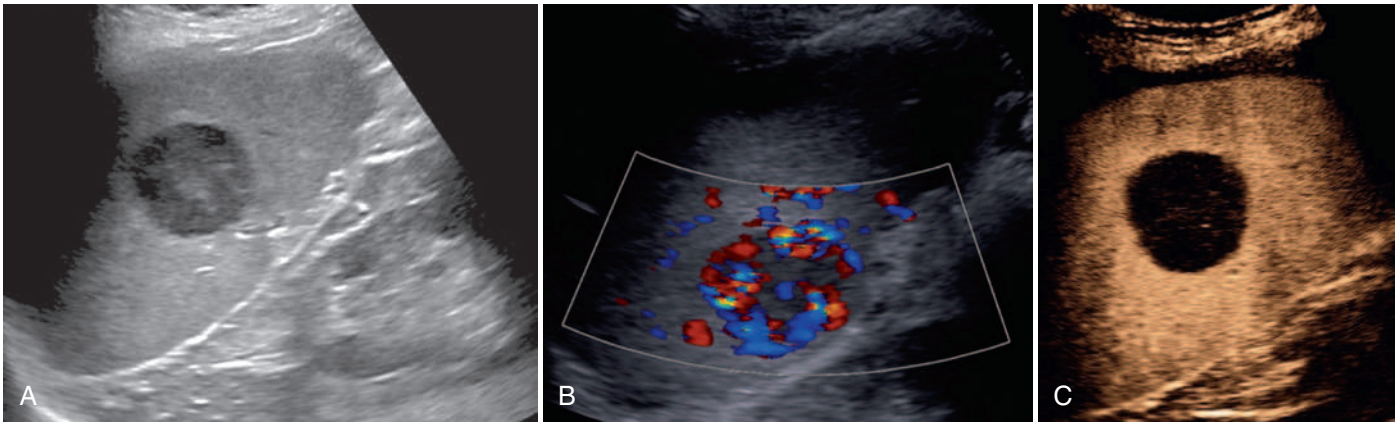

FIG. 5.5 Lymphoma Manifesting as a Hypoechoic Solitary Splenic Lesion. (A) Sagittal image shows a well-defined hypoechoic lesion. **(B)** Color Doppler shows peripheral flow within the lesion. **(C)** Delayed image from contrast-enhanced sonogram shows filling from the periphery. (Courtesy of Stephanie Wilson, MD.) See also Video 5.3.

shape, with a thin component extending anteriorly and another component extending medially, either superior to or adjacent to the upper pole of the kidney. This component (superomedial) can be seen to indent the gastric fundus on plain films of the abdomen or cross sectional imaging. As the scan plane moves inferiorly, only the inferior component of the spleen is seen. This component (inferolateral) can be outlined by a thin rim of fat above the splenic flexure. It may extend inferiorly to the costal margin and present clinically as a palpable spleen. However, either the superomedial or the inferolateral component can enlarge independently, without enlargement of the other component.

It is important to recognize the **normal structures** that are related to the spleen. The diaphragm cradles the spleen posteriorly, superiorly, and laterally. The left liver lobe may extend into the LUQ superior and lateral to the spleen (Fig. 5.6). The fundus of the stomach and lesser sac are medial and anterior to the splenic hilum. The gastric fundus may contain gas or fluid, which should not be confused with a fluid collection. The tail of the pancreas lies posterior to the stomach and lesser sac. It approaches the hilum of the spleen, closely related to the splenic artery and vein. Consequently, the spleen can be used as a "window" to evaluate the pancreatic tail area. The left kidney generally lies inferior and medial to the spleen. A useful landmark in identifying the spleen and splenic hilum is the **splenic vein,** which generally can be demonstrated without difficulty.

The normal splenic **parenchyma** is homogeneous. The liver is generally considered to be more echogenic than the spleen, but in fact the echogenicity of the parenchyma is higher in the spleen than in the liver. Using a dual-image setting, the operator may compare the echogenicity of these two organs. The impression that the liver has greater echogenicity results from its large number of reflective vessels.

As in measuring other body structures, it is helpful to have measurements that establish the **upper limits of normal.** The size of a normal spleen depends on gender, age, and body height. The range of the "normal sized" adult spleen, combined with its complex three-dimensional shape, makes it difficult to establish a normal range of sonographic measurements. Ideally, the clinician would assess splenic **volume** or **weight.** Techniques have been developed to measure serial sections of the spleen by planimetry and then compute the volume of the spleen by adding the values for each section.[10] However, these techniques are cumbersome and not popular. The most frequently used method is "eyeballing" the size (Fig. 5.7; see also Fig. 5.4). Unfortunately, this method

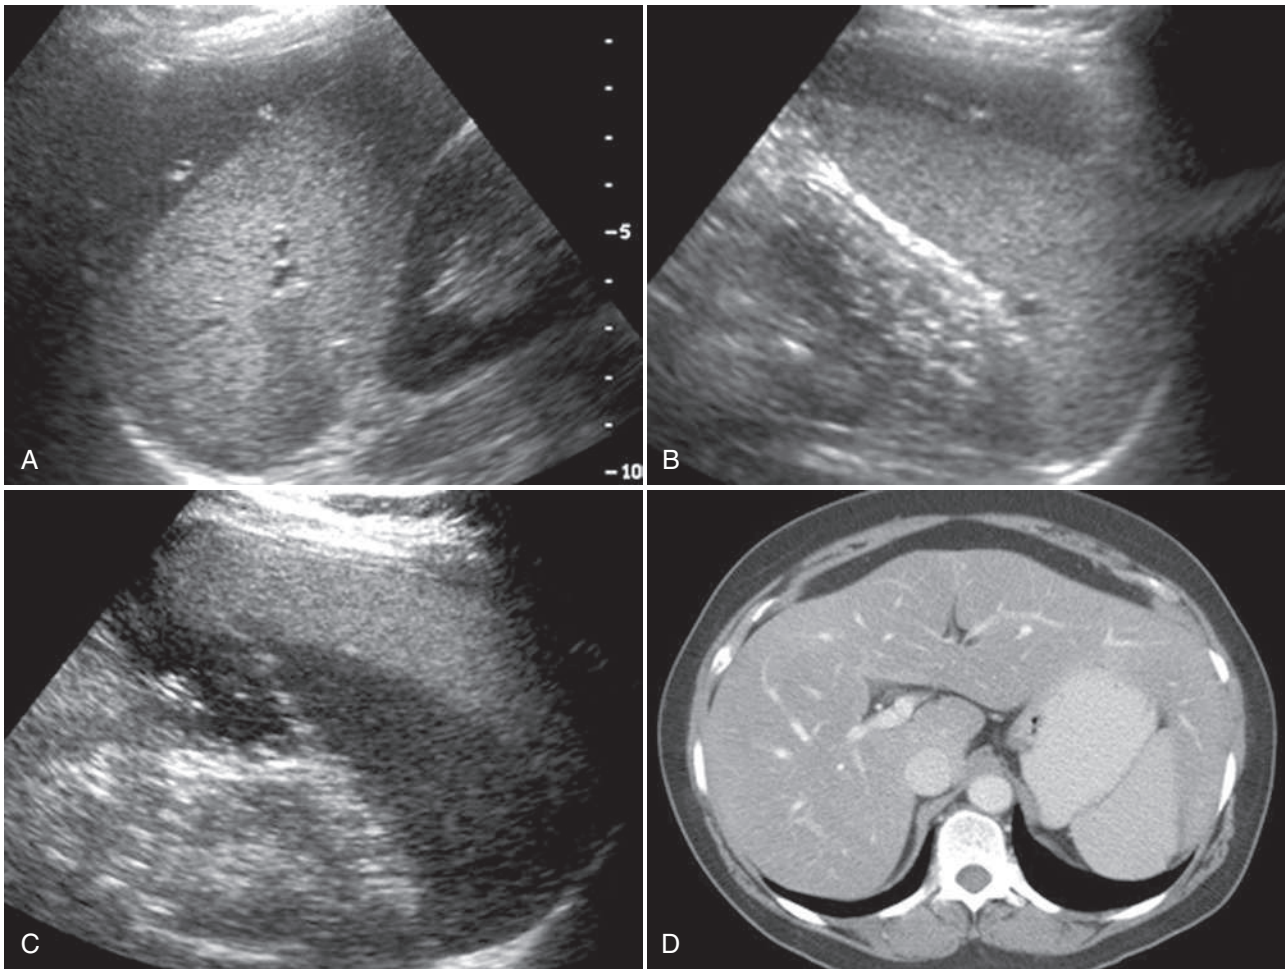

FIG. 5.6 Relationship of Spleen With Surrounding Structures. Left liver lobe extends into the left upper quadrant superior to the spleen. **(A)** Coronal and **(B)** transverse sonograms demonstrate the left liver lobe superior to the spleen. The liver is hypoechoic compared with the spleen. **(C)** and **(D)** Liver extends over spleen in a different patient with a fatty liver. **(C)** Transverse sonogram shows an echogenic liver and a relatively hypoechoic spleen. **(D)** Axial computed tomography image shows the left liver lobe draping around the spleen.

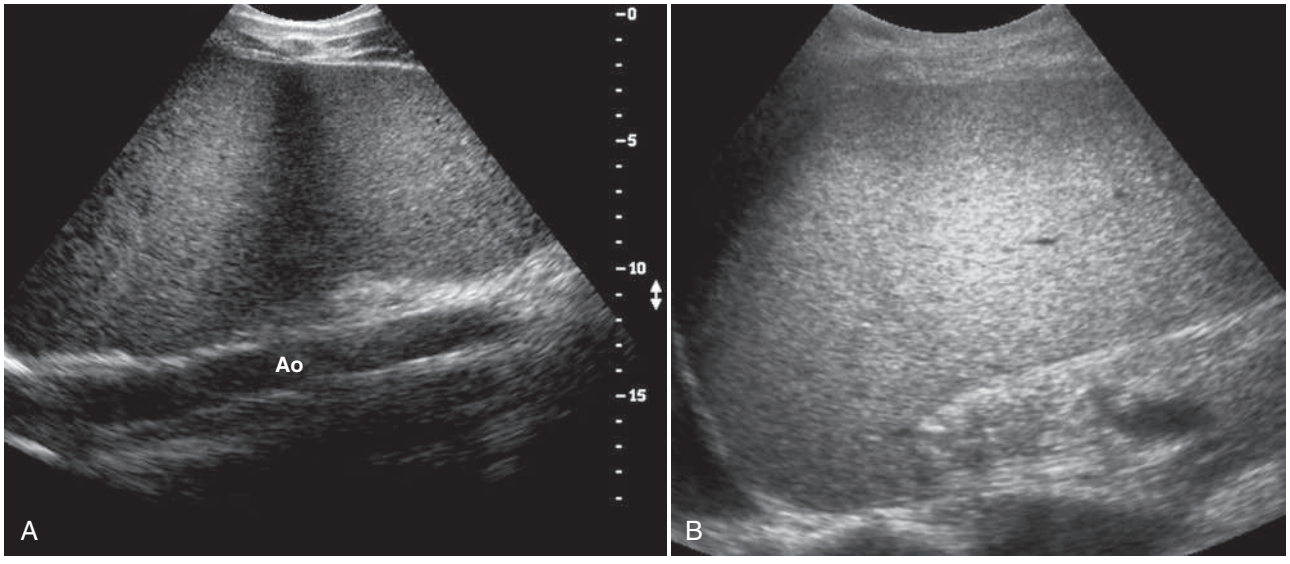

FIG. 5.7 Splenomegaly in Two Patients. (A) Coronal ultrasound scan shows an enlarged spleen with margins beyond the sector format. Midportion is partially obscured by a rib shadow. **(B)** Increased echogenicity of a large spleen. *Ao,* Aorta.

of assessment requires considerably more experience than is necessary for other imaging techniques and is relatively inaccurate. Various clinicians have used different methods to measure splenic size. The length of the spleen measured on a coronal or coronal oblique view that includes the hilum is the most common technique[11,12] (Fig. 5.8). This view can be obtained during deep inspiration or quiet breathing. Importantly, this method correlates well with the splenic volume, particularly when performed with the patient in the **right lateral decubitus** position.[12]

Multiple studies have tried to establish nomograms of spleen size. In a study of 703 normal adults, the **length** of the spleen was less than 11 cm, the **width** (breadth) less than 7 cm, and the **thickness** less than 5 cm in 95% of patients.[13] Rosenberg et al.[11] established an upper limit of normal splenic length of 12 cm for girls and 13 cm for boys (≥15 years). Hosey et al.[14] demonstrated a mean splenic length of 10.65 cm. In this study, men also had larger spleens than women. Spielmann et al.[15] showed that the length of the spleen correlates with height and established nomograms for tall, healthy athletes. In women taller than 5 feet (ft), 6 inches (168 cm), the mean splenic length of 10 cm increased by 0.1 cm for each 1-inch incremental increase in height. In men taller than 6 ft (180 cm), the mean splenic length of 11 cm increased by 0.2 cm for each 1-inch incremental increase in height. Upper limits of normal in splenic length were 14 cm in women 6 ft, 6 inches (198 cm) tall and 16.3 cm in men 7 ft (213 cm) tall. Chow et al. assessed 1230 healthy volunteers and found that spleen length and volume were significantly and independently associated with sex, body height, and weight, with men and taller and heavier individuals having longer and larger spleens. The spleen length of 20 of 324 women (6%) and 234 of 906 men (26%) exceeded a strict upper limit of normal of 12 cm.[16]

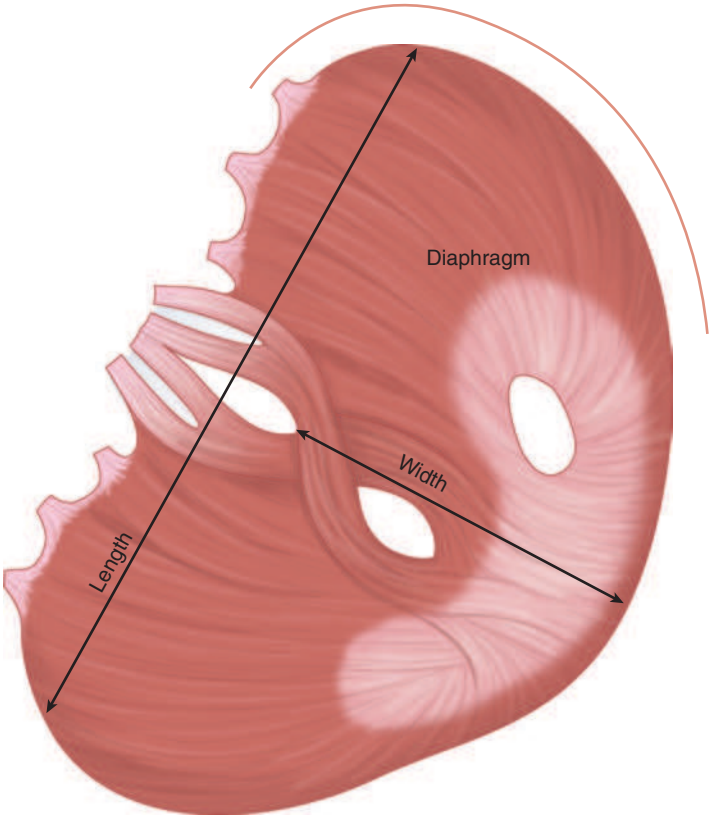

FIG. 5.8 Splenic Measurement. Diagram shows sonographic approach to measuring splenic length and width. Splenic size is best measured by obtaining a coronal view that includes the hilum.

PATHOLOGIC CONDITIONS

Splenomegaly

The differential diagnosis of splenomegaly is exceedingly long. It includes infection (e.g., mononucleosis, tuberculosis, malaria), hematologic disorders (myelofibrosis, lymphoma, leukemia),[17] congestion (portal hypertension, portal/splenic vein thrombosis, congestive heart failure), inflammation (sarcoidosis), neoplasia (hemangioma, metastases), and infiltration (e.g., Gaucher disease)[18] (Table 5.1).

Frequency and causes of splenomegaly vary between developing and developed countries and even between hospitals in the same region.[19] Sonography is very helpful in determining the degree of enlargement. In "borderline" splenomegaly, however, diagnosis can be difficult.

The spleen is capable of growing to an enormous size. It can extend inferiorly into the left iliac fossa, and it can cross the midline and appear as a mass inferior to the left lobe of the liver on longitudinal section. The degree of splenomegaly is generally not a reliable tool in providing a more concise differential diagnosis. The differential diagnosis of **massive splenomegaly,** defined as a spleen size greater than 18 cm, is less extensive and includes hematologic disorders and infections[18] (see Table 5.1). Sonographic assessment of the splenic architecture is used to differentiate between focal lesions (single or multiple) causing splenomegaly and diffuse splenomegaly.

The most common finding is diffuse enlargement; in these patients, imaging is typically not helpful in providing a specific diagnosis. When the spleen enlarges, it can become more echogenic, but the clinician cannot differentiate between the different types of splenomegaly on the basis of its echogenicity (see Fig. 5.7B). In experimental studies researchers have tried to quantify the degree of fibrosis in liver and spleen using the echotexture characteristics, but no clinical applications have yet been established.[20] More promising is the use of splenic elastography in patients with portal hypertension. Studies have shown that use of elastography in patients at risk for cirrhosis can lead to improved triage of patients with respect to degree of liver fibrosis[21,22] as well as esophageal varices and bleeding.[23]

Associated clinical and radiologic features can be helpful in establishing a differential diagnosis. Liver disease and evidence of portal venous collaterals can establish **portal hypertension** as the cause of splenomegaly (Fig. 5.9). Focal lesions, multiorgan involvement, and lymphadenopathy may indicate **lymphoma.**

However, in many patients, extensive radiologic and laboratory investigations will fail to yield a diagnosis. In these cases of "isolated" splenomegaly, the risks of serious underlying disease must be balanced against the risks of further invasive

TABLE 5.1 Causes of Splenomegaly

Splenomegaly (<18 cm)	Massive Splenomegaly (>18 cm)

Langerhans cell histiocytosis	

Data from Abramson JS, Chatterji M, Rahemtullah A. Case records of the Massachusetts General Hospital. Case 39-2008. A 51-year-old woman with splenomegaly and anemia. N Engl J Med. 2008;359(25):2707-2718[17]; Pozo AL, Godfrey EM, Bowles KM. Splenomegaly: investigation, diagnosis and management. Blood Rev. 2009;23(3):105-111.[18]

investigations, such as diagnostic splenic biopsy or splenectomy.[17] In selected cases, ultrasound-guided splenic biopsy of focal abnormalities can be helpful in establishing a diagnosis, with an acceptable complication rate and high accuracy.[24,25]

Complications of splenomegaly include **hypersplenism** and **spontaneous splenic rupture.** Spontaneous splenic rupture typically occurs in patients with an enlarged spleen after minimal trauma or insignificant events such as coughing.[26,27]

Focal Abnormalities

Ultrasound can be helpful in finding and characterizing focal splenic lesions. However, because of the overlap in the appearance of splenic lesions, it is often not possible to make a specific diagnosis based on the sonographic findings alone. Splenic lesions can be solitary or multiple, diffuse, and infiltrative. Focal lesions can be cystic, complex cystic, or solid. Further, lesions can be categorized according to size as **micronodular** (<1 cm), **nodular** (1-3 cm), or **focal** (>3 cm) masses.[28] Knowledge of past medical history, clinical presentation, and sonographic findings is required to provide an appropriate differential diagnosis and guide further management.[29] Ultimately, percutaneous biopsy or splenectomy may be required to obtain a definitive diagnosis.

Types of Splenic Cysts

- Congenital cysts
- Pseudocysts
- Hydatid (echinococcal) cysts
- Pancreatic pseudocysts
- Endothelial-lined cysts
  - Lymphangiomas
  - Cystic hemangiomas
- Peliosis
- Cystic metastasis[a]
- Abscess[a]
- Hematoma[a]

[a]Not true cysts.

Splenic Cysts

Splenic cysts, as with cysts elsewhere in the body, appear as anechoic lesions with posterior acoustic enhancement. Simple cysts are round to ovoid in shape and have a thin, sharply defined wall. **Complex cysts** do not meet these criteria and may demonstrate septations, thick walls, calcifications, solid components, or internal echoes. Occasionally, cysts can grow to a very large size, becoming predominantly **exophytic.** It may then be difficult to appreciate their splenic origin (Fig. 5.10).

The most common splenic cystic lesions are primary congenital cysts, pseudocysts, and hydatid cysts. Uncommon splenic cystic lesions include pancreatic pseudocysts, lymphangiomas, hemangiomas, peliosis, hamartomas, angiosarcomas, and cystic metastases.[30] Other lesions that can mimic cysts on ultrasound are **abscesses, lymphoma, necrotic metastases,** and **hematomas.**[31]

In the developed world, most splenic cysts are asymptomatic incidental findings discovered during routine imaging and generally represent congenital cysts or pseudocysts. These cysts may cause symptoms when large or when present with complications such as internal hemorrhage, infection, or rupture. **Primary congenital cysts,** also called **epidermoid cysts** or **true cysts,** are characterized by the presence of an epithelial lining on pathologic examination.[32] Thought to arise from embryonic rests of primitive mesothelial cells within the spleen, typical epidermoid cysts present as well-defined, thin-walled anechoic lesions that do not change over time (Fig. 5.11A). **Pseudocysts,** also known as **false cysts,** have no cellular lining and are presumably secondary to trauma, infarct, or infection.[33] These cysts are more often

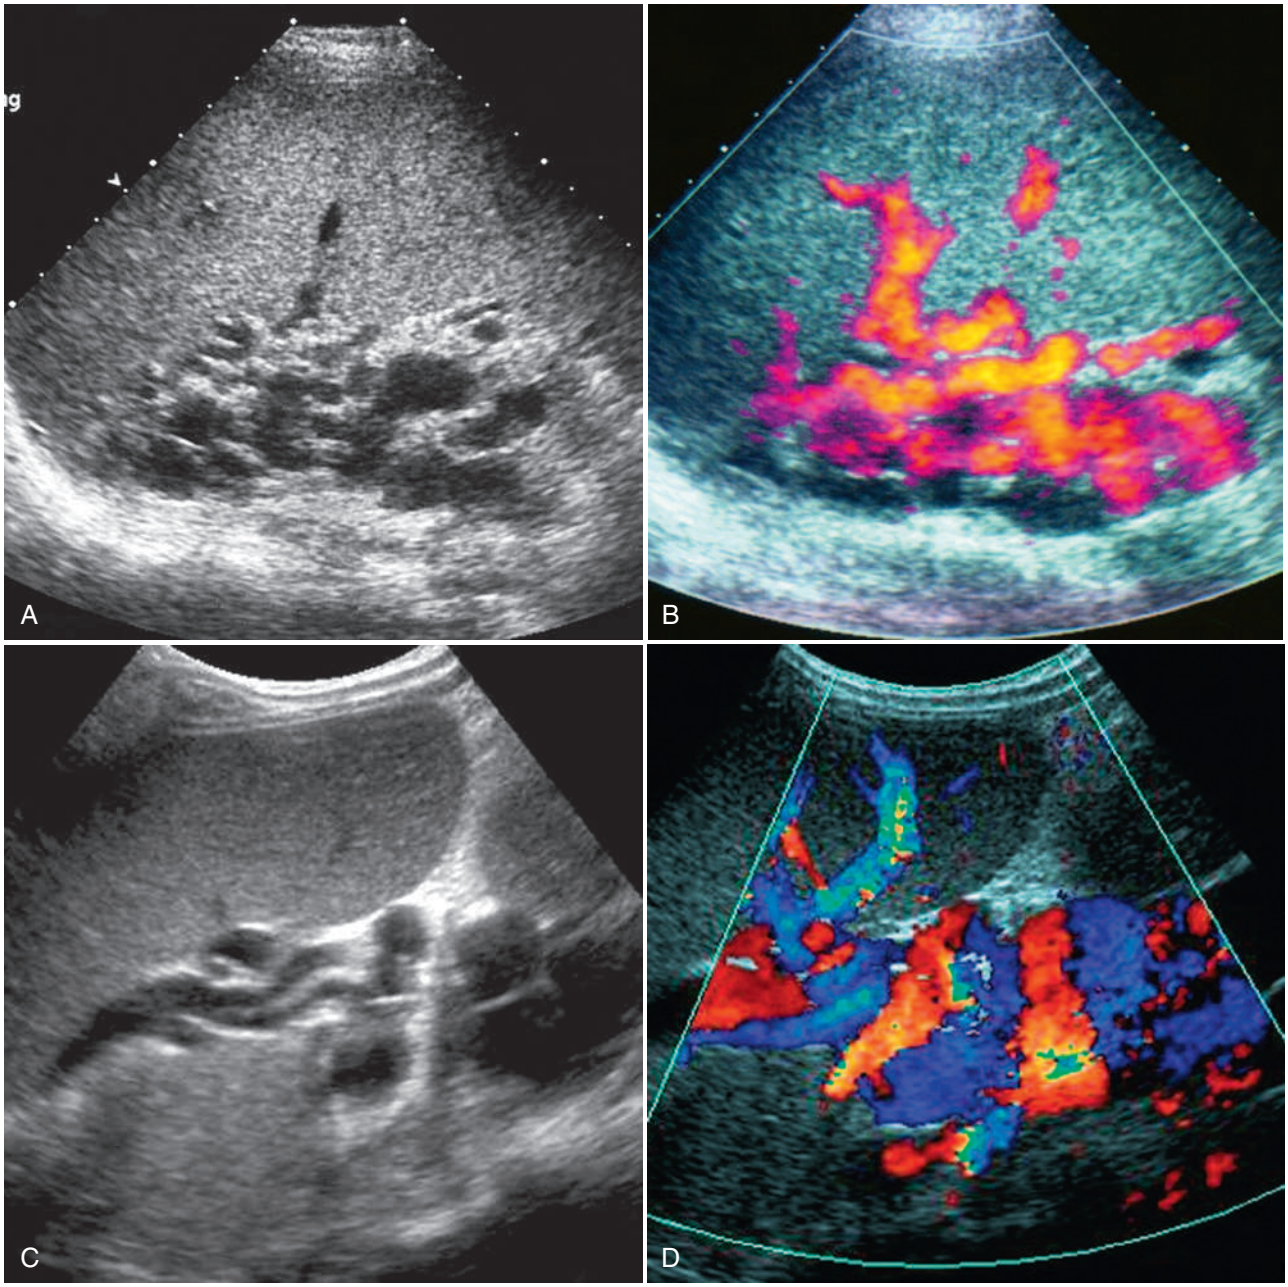

FIG. 5.9 Varices in Patients With Portal Hypertension. (A) Coronal gray-scale and **(B)** power Doppler images show splenomegaly and tortuous varices medial to the spleen. **(C)** and **(D)** Varices medial and inferior to the spleen representing a splenorenal shunt.

complex, with wall calcifications and internal echoes (Fig. 5.11B). However, differentiation between both types of cysts is usually not possible because there is considerable overlap both on imaging and on pathologic examination[34] (Fig. 5.11C). Furthermore, a history of significant trauma or infection is rarely established in patients with a pseudocyst. Both types of cysts can be complex, with wall calcifications or increased echogenicity of the fluid caused by cholesterol crystals, inflammatory debris, or hemorrhage[35] (Fig. 5.12; see also Fig. 5.10).

Hydatid (or **echinococcal**) **disease** is the most common cause of splenic cysts in endemic areas. Isolated splenic involvement without liver and peritoneal disease is rare.[36] The appearance of a hydatid cyst depends on the stage of the disease and varies from simple to complex, with or without daughter cysts (Fig. 5.13). The diagnosis is made by combining the appropriate history, geographic background, serologic testing, and imaging appearances.[37,38] Percutaneous fine-needle aspiration can be diagnostic, provided the pathologist has been alerted to search for the scolices.

Pseudocysts related to **pancreatitis** in or adjacent to the spleen are usually diagnosed by the associated features of pancreatitis.[39] Splenic **peliosis** is very rare and characterized by multiple blood-filled cystic spaces, sometimes involving the entire spleen.[40] On ultrasound, these lesions appear as multiple indistinct hypoechoic lesions. The lesions may be hyperechoic if thrombosis is present.

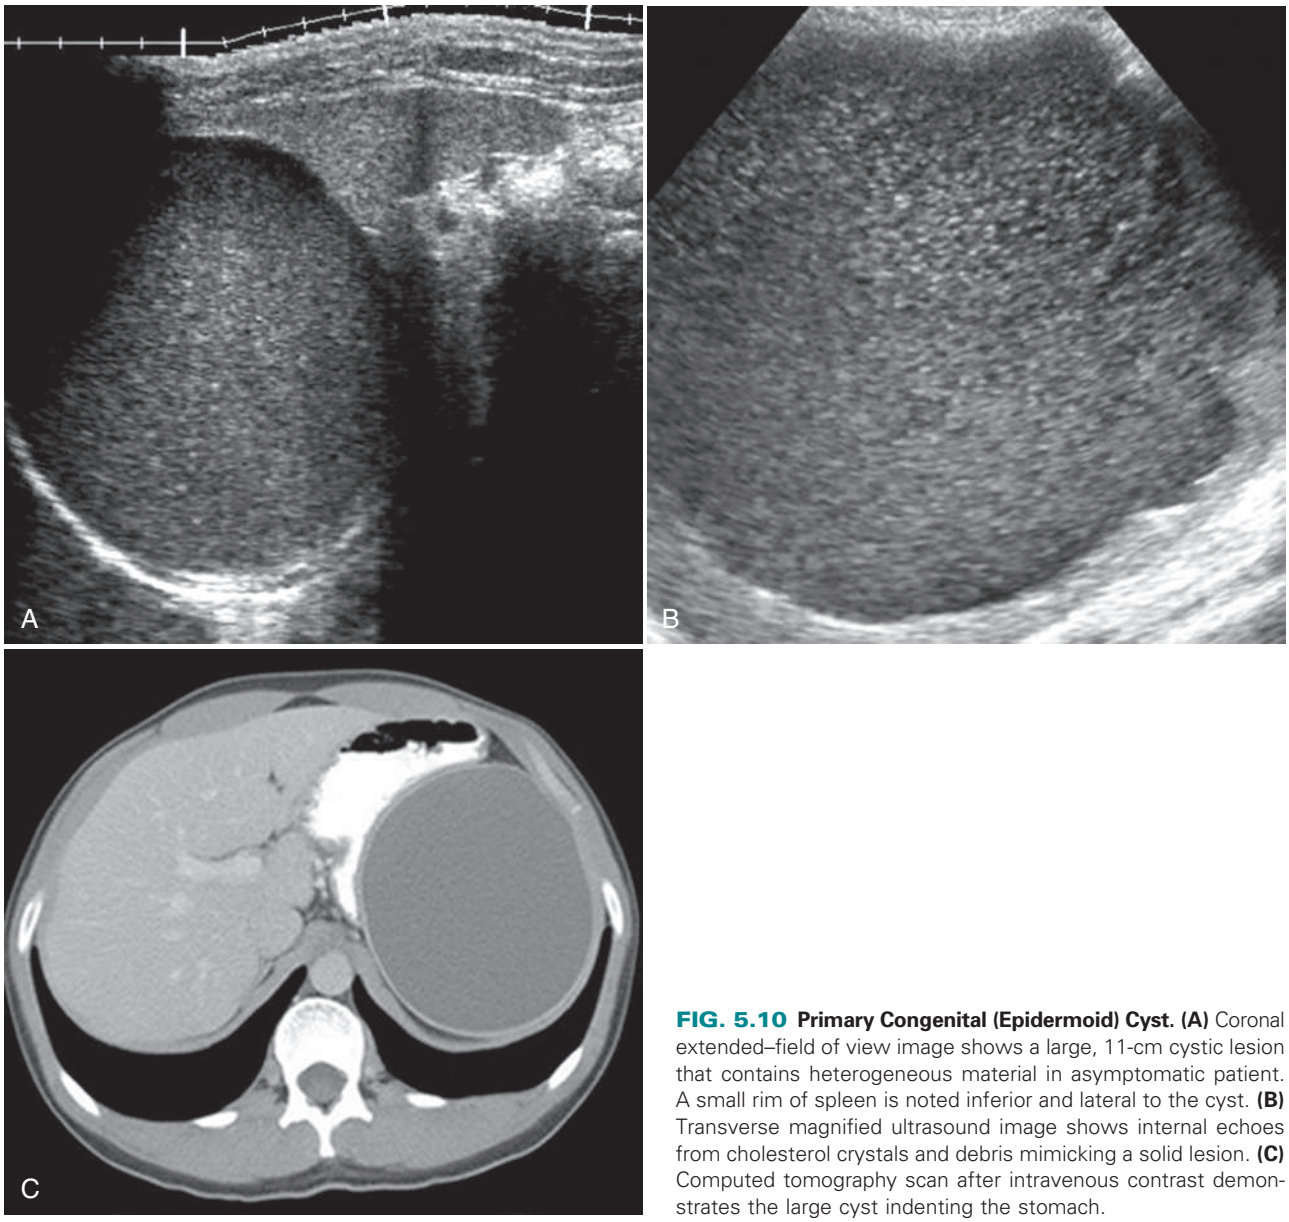

FIG. 5.10 Primary Congenital (Epidermoid) Cyst. (A) Coronal extended–field of view image shows a large, 11-cm cystic lesion that contains heterogeneous material in asymptomatic patient. A small rim of spleen is noted inferior and lateral to the cyst. **(B)** Transverse magnified ultrasound image shows internal echoes from cholesterol crystals and debris mimicking a solid lesion. **(C)** Computed tomography scan after intravenous contrast demonstrates the large cyst indenting the stomach.

Endothelial-lined cysts include lymphangiomas and cystic hemangiomas.[41,42] **Lymphangiomas** have been described as multiple cysts of varying size, ranging from a few millimeters to several centimeters, divided by thin septa.[43] **Hemangiomas** with cystic spaces of variable size have been reported.

Cystic metastases to the spleen are typically seen in patients with widespread metastatic disease, such as ovarian or colon carcinoma. Occasionally, necrotic metastases mimic a cystic lesion.

The most common causes of **splenic abscess** are endocarditis, septicemia, and trauma.[44] Splenic pyogenic abscesses may have an appearance similar to that of simple cysts, but the diagnosis is typically made in conjunction with the clinical findings. The presence of gas indicates an infectious cause. Gas may cause a confusing picture if only a small, curvilinear or punctate hyperechoic focus is seen. The presence of a reverberation artifact (dirty shadowing) indicates the presence of gas (Fig. 5.14). However, the sonographic findings of a pyogenic abscess are variable, and in indeterminate cases, aspiration is useful for diagnosis.[45] Percutaneous catheter drainage can be used as a safe and successful treatment option.[46]

Nodular Splenic Lesions

Nodular lesions are often multiple and can be subdivided into micronodular (<1 cm) and nodular (1-3 cm). If splenic nodules are present in a patient with a known diagnosis such as lymphoma, tuberculosis, or sarcoidosis, these nodules likely represent the same disease. However, if no diagnosis has been established and the splenic nodules are an isolated finding, the diagnosis is rarely made on the imaging features alone. The most common causes of splenic nodules include infection (e.g., **mycobacteria, histoplasmosis**), **sarcoidosis,** and malignancy (e.g., **lymphoma,** metastases). Other, less common causes of splenic nodular lesions with similar imaging findings include **Gamna-Gandy bodies,**

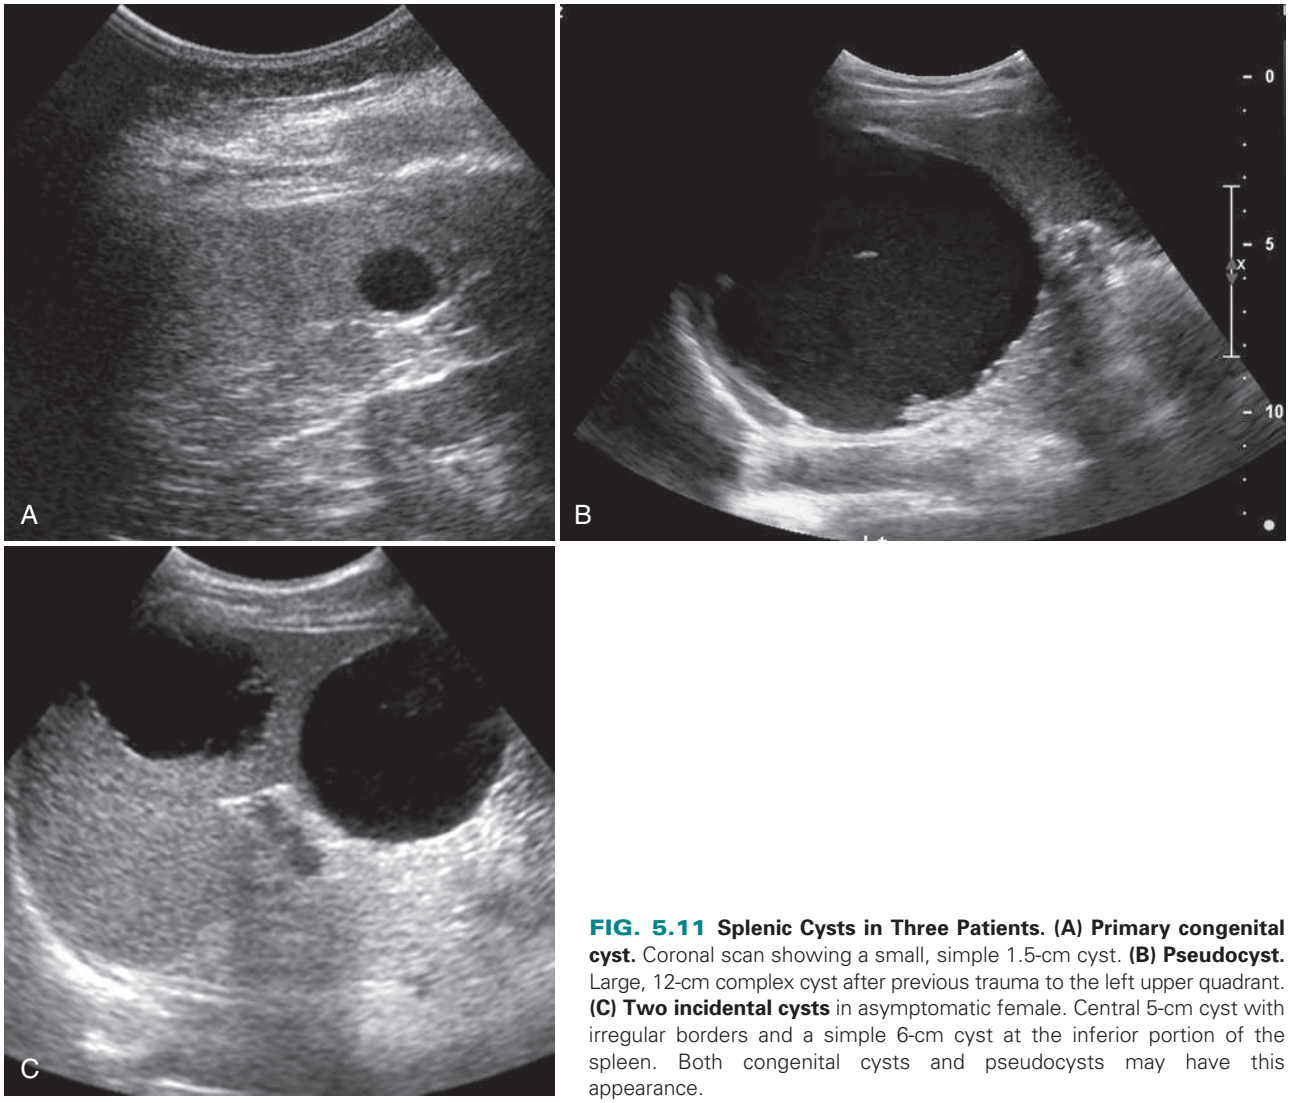

FIG. 5.11 Splenic Cysts in Three Patients. (A) Primary congenital cyst. Coronal scan showing a small, simple 1.5-cm cyst. **(B) Pseudocyst.** Large, 12-cm complex cyst after previous trauma to the left upper quadrant. **(C) Two incidental cysts** in asymptomatic female. Central 5-cm cyst with irregular borders and a simple 6-cm cyst at the inferior portion of the spleen. Both congenital cysts and pseudocysts may have this appearance.

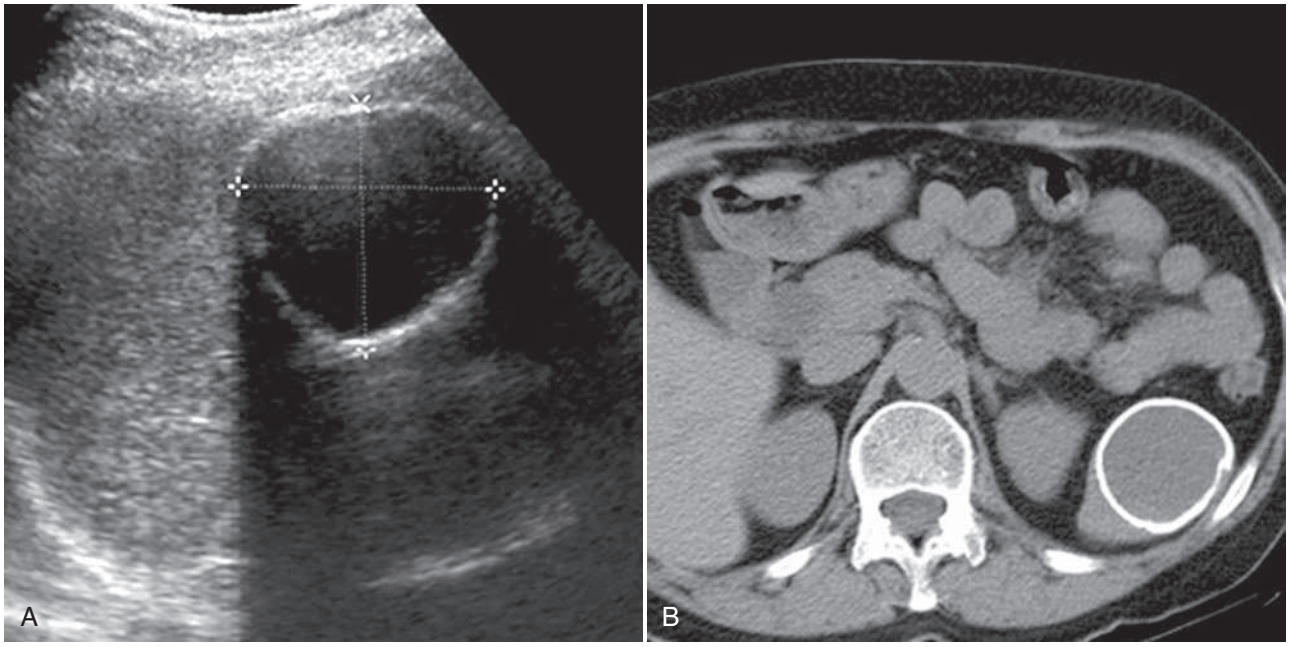

FIG. 5.12 Calcified Splenic Cyst. (A) Coronal image shows the cyst with calcified wall (calipers). Note the shadowing from the near wall. **(B)** Noncontrast-enhanced computed tomography image demonstrates the wall calcification. Congenital cysts, pseudocysts, and "burned out" hydatid cysts may have similar appearance.

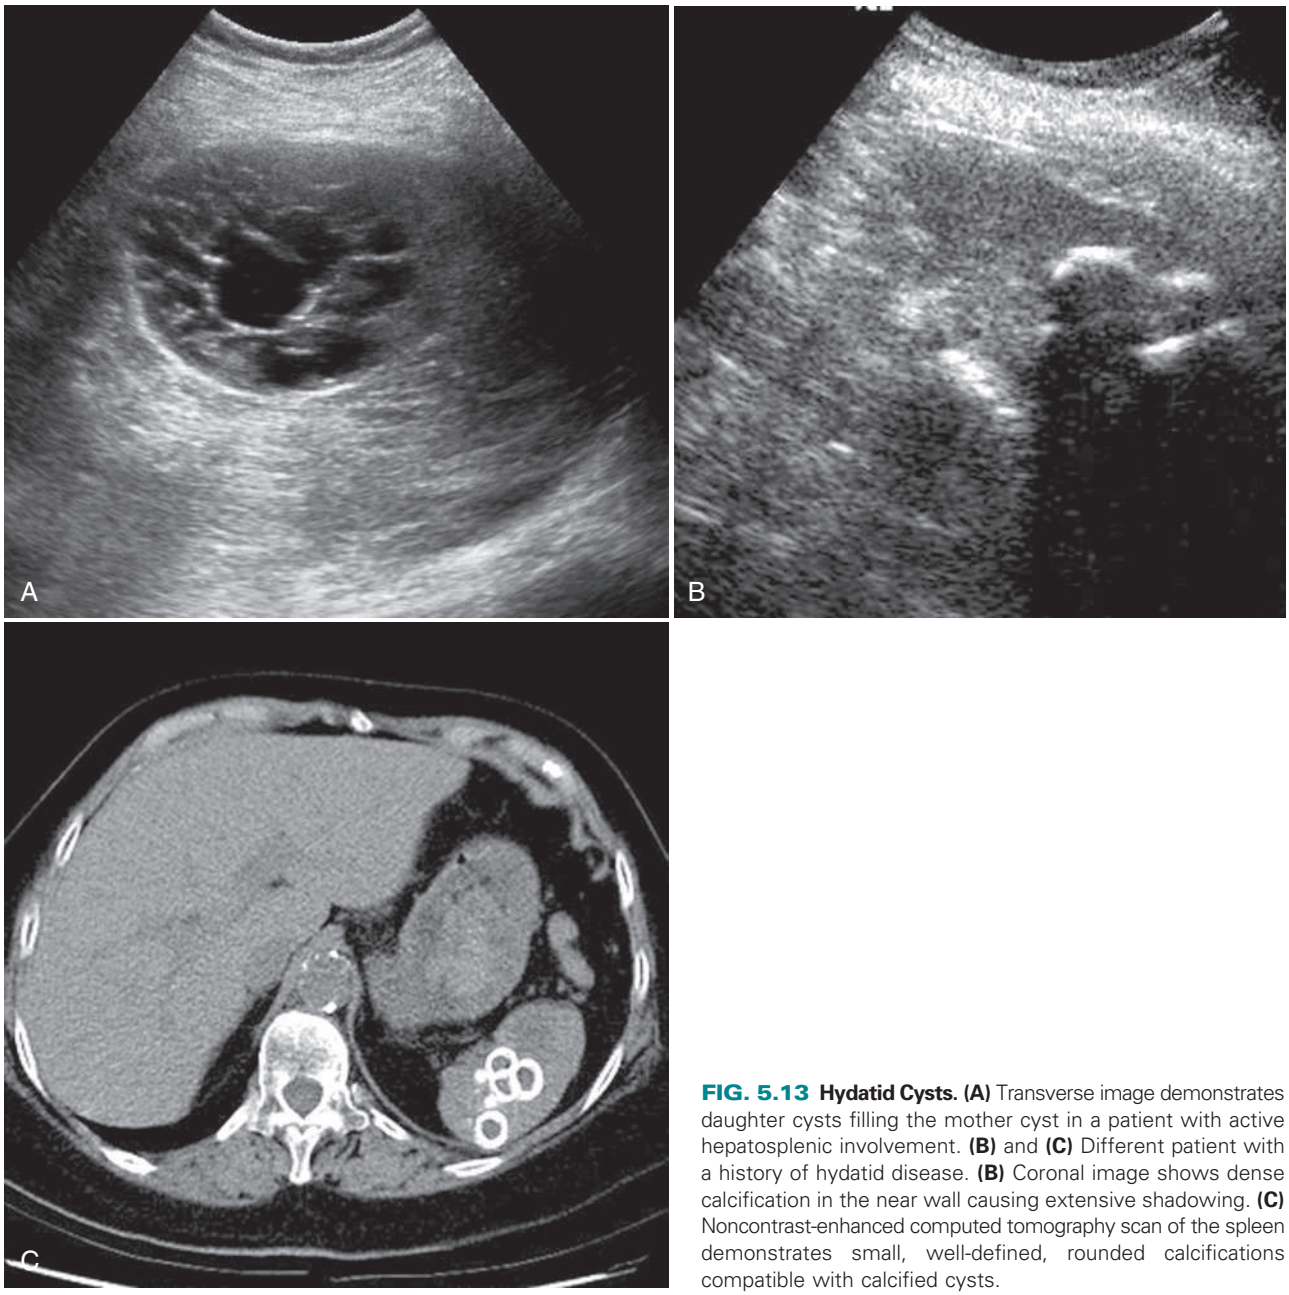

FIG. 5.13 Hydatid Cysts. (A) Transverse image demonstrates daughter cysts filling the mother cyst in a patient with active hepatosplenic involvement. **(B)** and **(C)** Different patient with a history of hydatid disease. **(B)** Coronal image shows dense calcification in the near wall causing extensive shadowing. **(C)** Noncontrast-enhanced computed tomography scan of the spleen demonstrates small, well-defined, rounded calcifications compatible with calcified cysts.

Pneumocystis jiroveci (formerly known as *P. carinii* pneumonia) and **cat-scratch disease.**[47-49]

Active **tuberculosis** involving the spleen is typically seen in miliary dissemination and can occur with both tuberculosis and atypical mycobacterial infections. The typical sonographic findings are multiple hypoechoic nodules 0.2 to 1 cm in size (Fig. 5.15). Sometimes the nodules are hyperechoic or present as larger, echo-poor or cystic lesions representing tuberculous abscesses (Figs. 5.16 and 5.17).

When the nodules or granulomas heal, they can be become calcified and appear as small, scattered, discrete, bright echogenic lesions with posterior shadowing in an otherwise normal spleen (Fig. 5.18). These probably are the most frequently encountered nodular splenic lesions. Splenic artery calcifications are also common and should not be confused with a granuloma (Fig. 5.19).

Microabscesses are typically seen in immunocompromised patients with generalized infections. They often coexist in the liver and spleen and are similar in appearance. Microabscesses usually present as multiple hypoechoic nodules (Fig. 5.20A). In **hepatosplenic candidiasis** the two most common sonographic patterns are hypoechoic nodules and hyperechoic foci 2 to 5 mm in size, occasionally containing central calcification. Two other sonographic patterns have also been described. In the **wheels-within-wheels** appearance the outer hypoechoic "wheel" is thought to represent a ring of fibrosis surrounding the inner echogenic "wheel" of inflammatory cells and a central hypoechoic, necrotic area.[50] The **bull's-eye** appearance consists of echogenic

FIG. 5.14 Splenic Abscess. FIG. 5.15 Tuberculosis (TB) in Two Patients. (A) Coronal sonogram shows calcified granulomas with shadowing in the superior aspect of the spleen and echo-poor lesions *(arrowheads)* in the midportion resulting from reactivated TB. **(B)** Transverse and **(C)** coronal extended–field of view images in a young AIDS patient with active **miliary TB.** Numerous tiny hypoechoic nodules are present throughout the enlarged spleen.

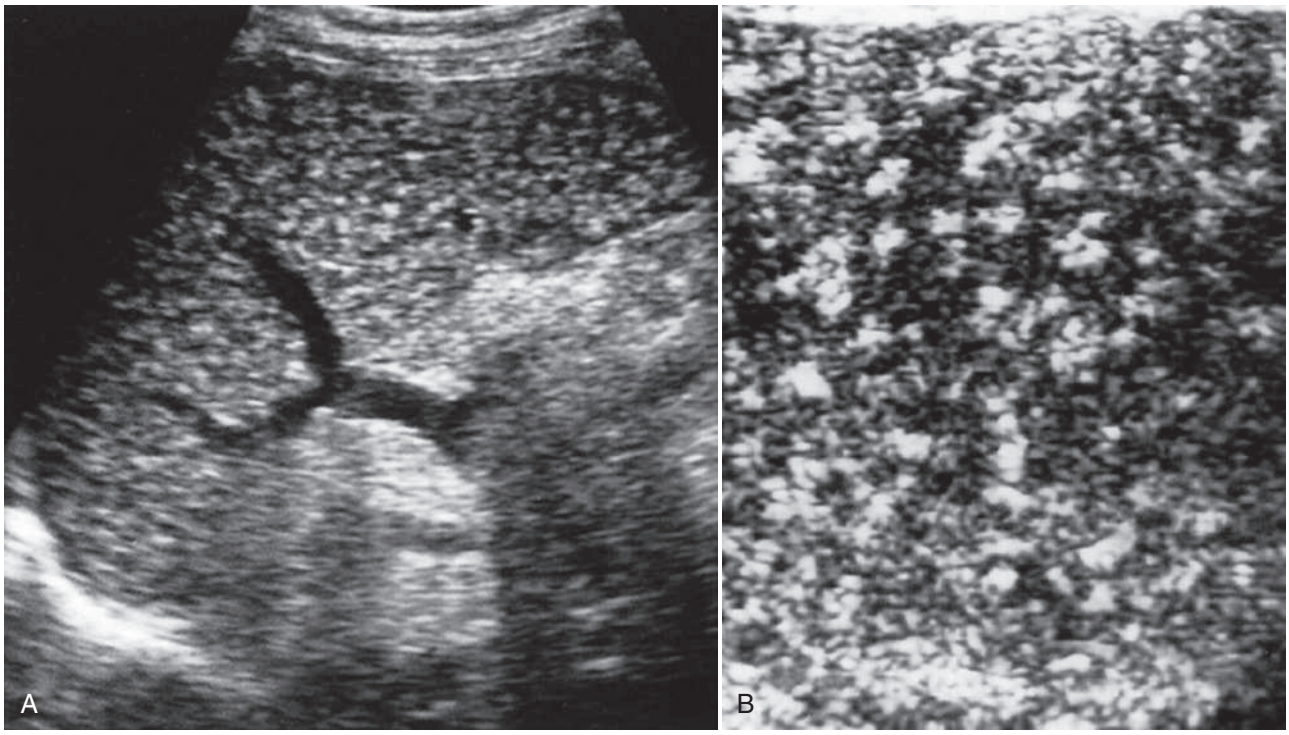

FIG. 5.16 Miliary Tuberculosis of the Spleen. (A) Coronal and **(B)** high-resolution linear array ultrasound images show multiple tiny echogenic foci of tuberculous granulomata in this patient with active tuberculosis.

FIG. 5.17 Atypical Tuberculosis of the Spleen in AIDS Patient. Tiny echogenic foci throughout the spleen. Isolated foci were also identified in the liver and kidneys. Several core biopsies through the liver confirmed these to be *Mycobacterium avium-intracellulare* granulomas. Disseminated *Pneumocystis jiroveci,* formerly *P. carinii* pneumonia (PCP), can also appear in this way.

inflammatory cells in the center surrounded by a hypoechoic fibrotic outer rim[51] (Fig. 5.20B).

Lymphoma and **metastatic disease** can also present with a small, diffuse nodular pattern, especially Hodgkin disease and low-grade non-Hodgkin lymphoma[52] (Fig. 5.21A).

Malignancies. The spleen is frequently involved in patients with **lymphoma.** Patients with lymphomatous involvement of the spleen often present with associated abdominal lymphadenopathy and constitutional symptoms. In **Hodgkin disease,** splenic enlargement occurs in 30% to 40% of patients, but in one-third of these patients there is no lymphomatous involvement of the spleen at histopathology. Conversely, one-third of patients with Hodgkin disease and splenic involvement have a normal-sized spleen. In **non-Hodgkin lymphoma** the spleen is involved in 40% of patients during the course of their disease. **Four**

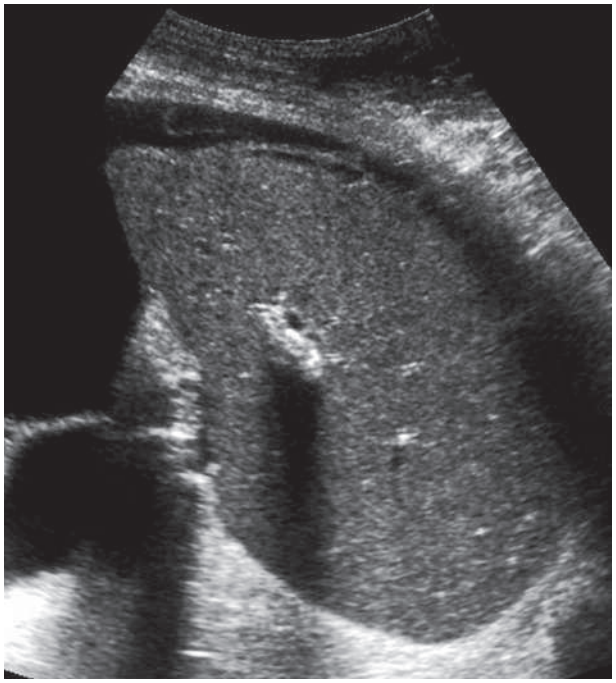

FIG. 5.19 Splenic Artery Calcifications. Central splenic artery calcifications in a patient on peritoneal dialysis.

sonographic patterns of lymphomatous involvement of the spleen have been described,[53] corresponding with the pathologic findings: (1) diffuse involvement, typically an enlarged spleen with a normal echotexture or patchy inhomogeneity; (2) focal small (<3 cm) hypoechoic nodular lesions; (3) focal large (>3 cm) nodular lesions; and (4) bulky solid mass lesions (Fig. 5.21). Focal lesions in lymphoma are typically hypoechoic and hypovascular.[31] Occasionally, after central necrosis with subsequent liquefaction, lesions may present as anechoic cysts or mimic an abscess.[54] Hyperechoic lesions are uncommon.

Primary splenic malignancies include primary lymphoma, angiosarcoma, and hemangiopericytoma. **Isolated (primary) lymphoma** of the spleen is rare and is encountered in less than 1% of all patients with lymphoma. It typically represents Hodgkin disease.[52] **Angiosarcoma** is a rare primary malignant vascular neoplasm of the spleen with a very poor prognosis. Sonographic findings include a heterogeneous echotexture, complex mass or masses, and splenomegaly (Fig. 5.22). Increased Doppler flow may be seen in the solid components of the tumor.[55,56] **Hemangiopericytoma** is a very rare tumor that may arise in the spleen with variable malignant potential. On ultrasound, it may appear as a hypoechoic vascular mass distinct from the surrounding splenic parenchyma.[40]

Metastases to the spleen are relatively rare and generally occur as a late phenomenon. They are typically seen in patients with widespread metastatic disease rather than as a presenting feature.[57] Isolated metastases to the spleen are very uncommon. Splenic metastases are relatively frequent in **malignant melanoma** but can be encountered in any metastatic disease, including carcinoma of the lung, breast, ovary, stomach, or colon and in Kaposi sarcoma.[58] Metastases are usually hypoechoic but may be echogenic, heterogeneous, or even cystic[1] (Fig. 5.23).

Benign Lesions. **Hemangioma** is the most common primary benign neoplasm of the spleen; incidence ranges from 0.3% to 14% in autopsy series.[59] Hemangiomas are usually isolated phenomena but can be part of a generalized condition, such as hemangiomatosis or Klippel-Trenaunay-Weber syndrome.[60,61] The lesions often have a well-defined echogenic appearance similar to the typical appearance of hemangiomas in the liver, but this appearance is seen much less frequently in the spleen than in the liver (Fig. 5.24). Lesions of mixed echogenicity, with cystic spaces of variable sizes and foci of calcification, have also been reported.[41,59]

Other benign tumors of the spleen are rare and include hamartomas, littoral cell angioma, sclerosing angiomatoid nodular transformation (SANT), and inflammatory pseudotumor. **Hamartomas** are typically well-defined, homogeneous, isoechoic to mildly hypoechoic or hyperechoic lesions[62] (Fig. 5.25). Hamartomas may contain cystic areas or coarse calcifications, and

some demonstrate increased vascularity on color Doppler imaging.[63] The sonographic appearance of **littoral cell angioma** is variable and includes reports of hypoechoic and hyperechoic focal lesions as well as a diffuse mottled pattern without discrete lesions[40,64] (Fig. 5.26). Sclerosing angiomatoid nodular transformation is a rare benign vascular lesion of the spleen. Appearance on ultrasound has been described as heterogeneous hypoechoic.[65] These may grow, and thus be difficult to distinguish from more concerning lesions, and thus may need biopsy for diagnosis. **Inflammatory pseudotumors** usually present as a well-defined hypoechoic mass.[66]

Splenic infarction is one of the more common causes of focal splenic lesions and may mimic a mass on ultrasound. If a typical peripheral, wedge-shaped, hypoechoic lesion is noted, splenic

infarction should be the first diagnostic consideration[67,68] (Figs. 5.27 and 5.28). However, the sonographic appearance of splenic infarcts varies and includes multinodular or masslike changes with irregular margins.[69] The temporal evolution of the ultrasound appearance of splenic infarctions has shown that the echogenicity of the lesion is related to the age of the infarction. Infarctions are hypoechoic in early stages and progress to hyperechoic lesions when fibrosis develops over time.[70,71]

Other Abnormalities

Sickle Cell Disease

Sickle cell disease almost always affects the spleen. The most common splenic complications are autosplenectomy, acute sequestration, hypersplenism, massive infarction, and abscess. In homozygous **sickle cell disease**, multiple infarcts generally result in a small, fibrotic spleen and complete loss of function **(autosplenectomy).** Although promising new therapies are being developed, many homozygous sickle cell patients become **asplenic** in late childhood or early adulthood. This results in a small spleen, often difficult to visualize, with a diffuse echogenic appearance. Patients with heterozygous sickle cell disease often present with **splenomegaly** and may demonstrate the sequelae of **infarction.**[72,73] In some patients, areas of preserved splenic tissue are present in an otherwise small and fibrotic spleen, and these should not be mistaken for an abscess or mass.

Acute splenic sequestration is a life-threatening complication of sickle cell disease and typically occurs in infants and children with homozygous sickle cell disease. It represents sudden trapping of blood in the spleen, resulting in splenic enlargement. On ultrasound, the spleen is larger than expected and heterogeneous with multiple hypoechoic areas.[72] It is important to recognize that in homozygous sickle cell patients, an apparently normal-sized spleen may actually indicate splenomegaly.

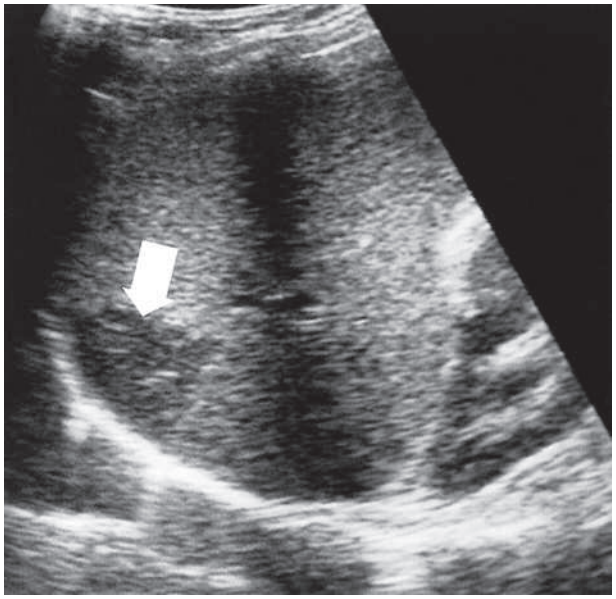

FIG. 5.27 Splenic Infarct. Triangular hypoechoic infarct *(arrow)* in the superior aspect of the spleen extends to the splenic capsule.

Gaucher Disease

In Gaucher disease, splenomegaly occurs almost universally, and approximately one-third of patients have multiple splenic nodules. These nodules frequently are well-defined hypoechoic lesions, but they may also be irregular, hyperechoic, or of mixed echogenicity[74,75] (Fig. 5.29). Pathologically, these nodules represent focal areas of Gaucher cells associated with fibrosis and infarction. In rare cases, the entire spleen may be involved, with ultrasound showing a diffuse heterogeneous spleen.

Gamna-Gandy Bodies

Gamna-Gandy bodies (Gamna nodules) are fibrosiderotic nodules that result from organized focal hemorrhagic infarcts, typically seen in congestive splenomegaly and sickle cell disease. Gamna-Gandy bodies appear as multiple punctate hyperechoic foci on ultrasound but are usually better seen on MRI.[76]

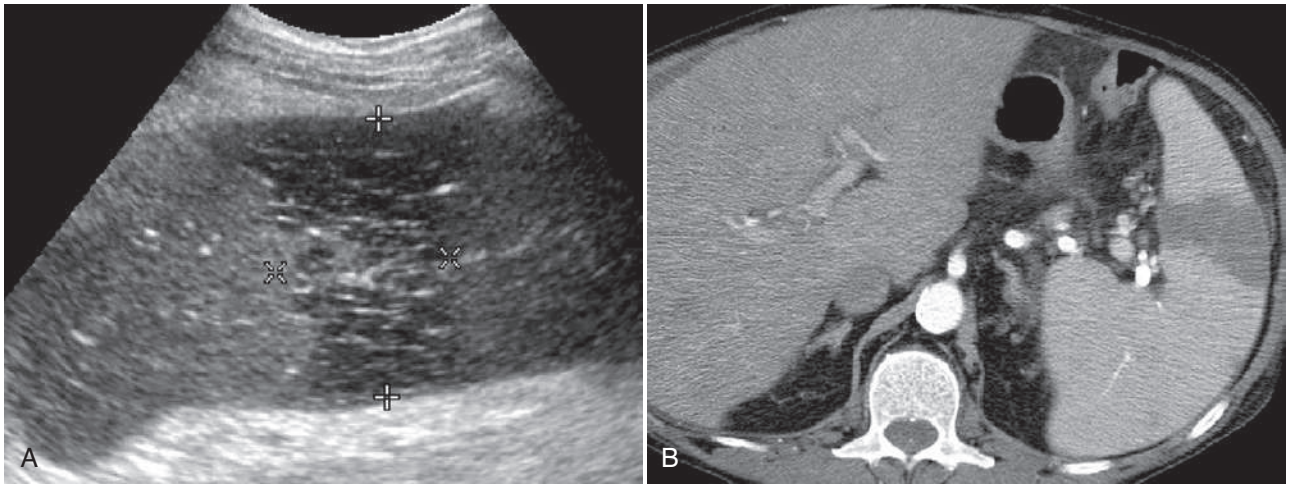

FIG. 5.28 Splenic Infarct. (A) Coronal image shows a well-defined hypoechoic central area reaching the splenic capsule medial and lateral in a patient with splenomegaly receiving peritoneal dialysis. **(B)** Corresponding computed tomography scan after intravenous contrast demonstrates the wedge-shaped nonenhancing area in keeping with an infarct.

Splenic Trauma

The spleen is the most frequently injured visceral organ in patients with blunt abdominal trauma. The spectrum of splenic injuries ranges from contusion to a completely shattered spleen. The severity of the splenic injury can be scored using the American Association for the Surgery of Trauma **Organ Injury Scoring Scale.**[77] Treatment options depend on hemodynamic and clinical criteria and include conservative management with or without embolization and surgery.[4]

Ultrasound can be very helpful and highly accurate in the diagnosis of splenic injury. However, CT has proved particularly useful in this area because the severity of splenic injury is better assessed and other abdominal injuries can be identified in one examination.[78] In addition, traumatic splenic vascular injuries (e.g., active bleeding, pseudoaneurysms, arteriovenous fistulas) are difficult to detect with ultrasound.[79] However, splenic injury is not always clinically apparent and **spontaneous splenic rupture** or **pathologic splenic rupture** can occur after negligible trauma or insignificant events such as coughing.[26] This is typically seen in patients with a pathologically enlarged spleen caused by the altered consistency and splenic extension below the rib cage.

Advantages of ultrasound are that it is fast, portable, and easily integrated into the resuscitation of patients with trauma without delaying therapeutic measures.[80] In addition, if the patient is hemodynamically unstable, obtaining a CT scan may not be feasible.[81] Therefore ultrasound examinations performed in the emergency department after blunt abdominal trauma should not only focus on free intraabdominal fluid but also evaluate the solid organs. Further, now that nonsurgical management is preferred, ultrasound is helpful for numerous follow-up examinations. CEUS may also be used to increase the sensitivity of ultrasound for parenchymal injury.[82]

When the spleen is involved in blunt abdominal trauma, two outcomes are possible. If the capsule remains intact, the result may be an **intraparenchymal** or **subcapsular hematoma** (Fig. 5.30). If the capsule ruptures, a focal or free intraperitoneal hematoma may result. With capsular rupture, it might be possible to demonstrate fluid surrounding the spleen in the LUQ. Although blood often spreads within the peritoneal cavity and can be found in the pelvis or in the Morison pouch, on some occasions it becomes walled off in the LUQ (Fig. 5.31).

It is important to consider the timing of the sonographic examination relative to the trauma. Immediately after the traumatic incident, the hematoma is liquid and can easily be differentiated from splenic parenchyma. After the blood clots, and for the subsequent 24 to 48 hours, the echogenicity of the perisplenic hematoma may closely resemble the echogenicity of normal splenic parenchyma and may mimic splenomegaly. Subsequently, the blood re-liquefies and the diagnosis becomes easy again. In splenic injuries, there are often focal areas of inhomogeneity within the spleen, but these can be subtle (Fig. 5.32).

There is no clear consensus as to whether imaging follow-up is clinically useful.[83] If follow-up is performed, the clinician may see the subcapsular hematoma differentiated from the pericapsular, organized hematoma by the capsule itself (see Fig. 5.30B). The splenic capsule is very thin and frequently not visualized separately from adjacent fluid. In these cases the shape of the fluid collection can provide an important clue to the location of the hematoma. If the collection is crescentic and conforms to the contour of the spleen, the hematoma is likely subcapsular. Irregularly shaped collections are seen more with perisplenic hematomas.

Perisplenic fluid may persist for weeks or even months after splenic injury. Although there may actually be a condition of delayed rupture of the spleen, it is possible that all ruptures of the spleen occurred at the time of injury and were walled off initially.[84] Delayed rupture may be only the extension of blood into the peritoneal cavity after liquefaction of a perisplenic hematoma.

Aside from splenic capsule rupture, there may be internal damage to the spleen with an intact splenic capsule. This can result in intraparenchymal or subcapsular hematoma of the spleen, which initially appears only as an inhomogeneous area in the otherwise uniform splenic parenchyma. Subsequently, the hematoma may resolve, and repeat scans may show cystic change at the site of the original injury.

Sonographically, a perisplenic hematoma can closely mimic a perisplenic abscess. A hematoma can also become infected and transform into a left subphrenic abscess.[44] If the distinction cannot be made clinically, fine-needle aspiration can differentiate between a hematoma and an abscess.

CONGENITAL ANOMALIES

Accessory spleens, also known as **splenunculi,** are common normal variants found in up to 30% of autopsies. They are typically located near the splenic hilum and have similar echogenicity as the normal spleen. Splenunculi may be confused with enlarged lymph nodes around the spleen or with masses in the tail of the pancreas. When the spleen enlarges, the accessory spleens may also enlarge. **Ectopic accessory spleens** described in various locations, including the pancreas and scrotum, are typically confused with abnormal masses or, in rare cases, can undergo torsion and cause acute abdominal pain.[85,86] The vast majority

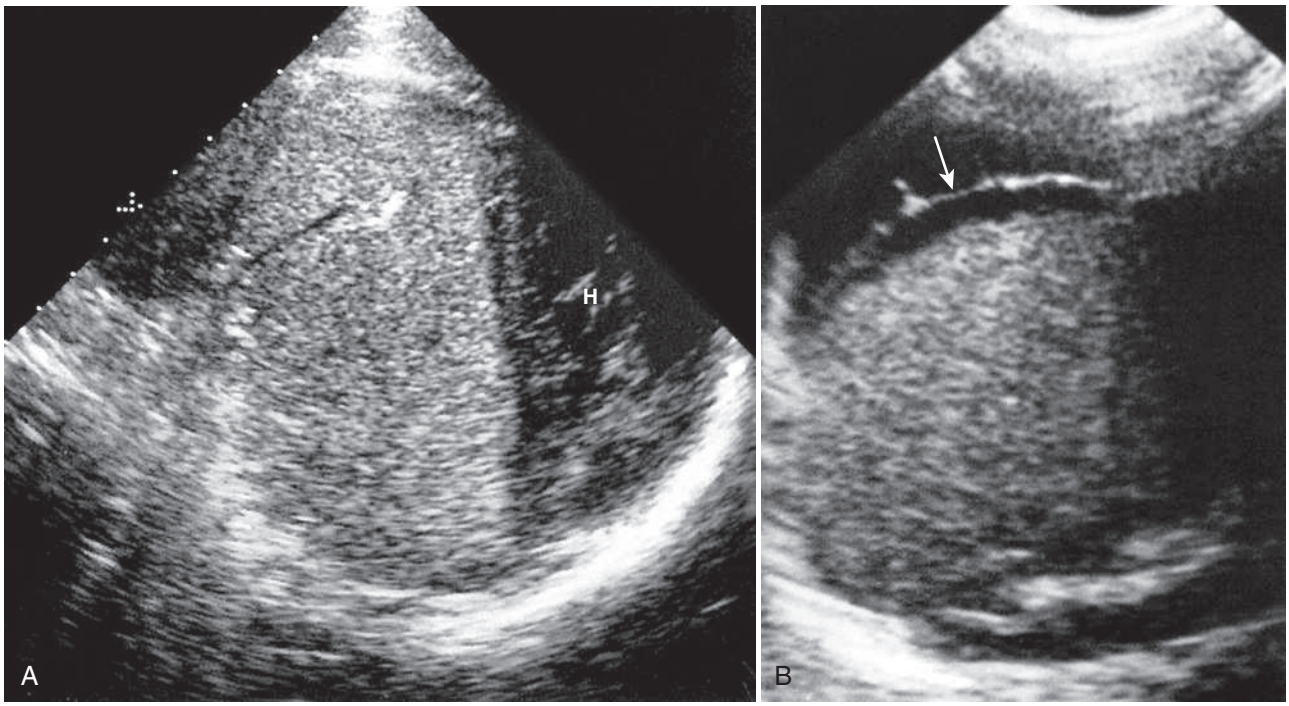

FIG. 5.30 Subcapsular Hematoma. (A) Transverse scan shows a fluid- and debris-filled crescentic hematoma *(H)* in the lateral aspect of the spleen. **(B)** Thin, brightly echogenic crescentic line *(arrow)* represents the splenic capsule.

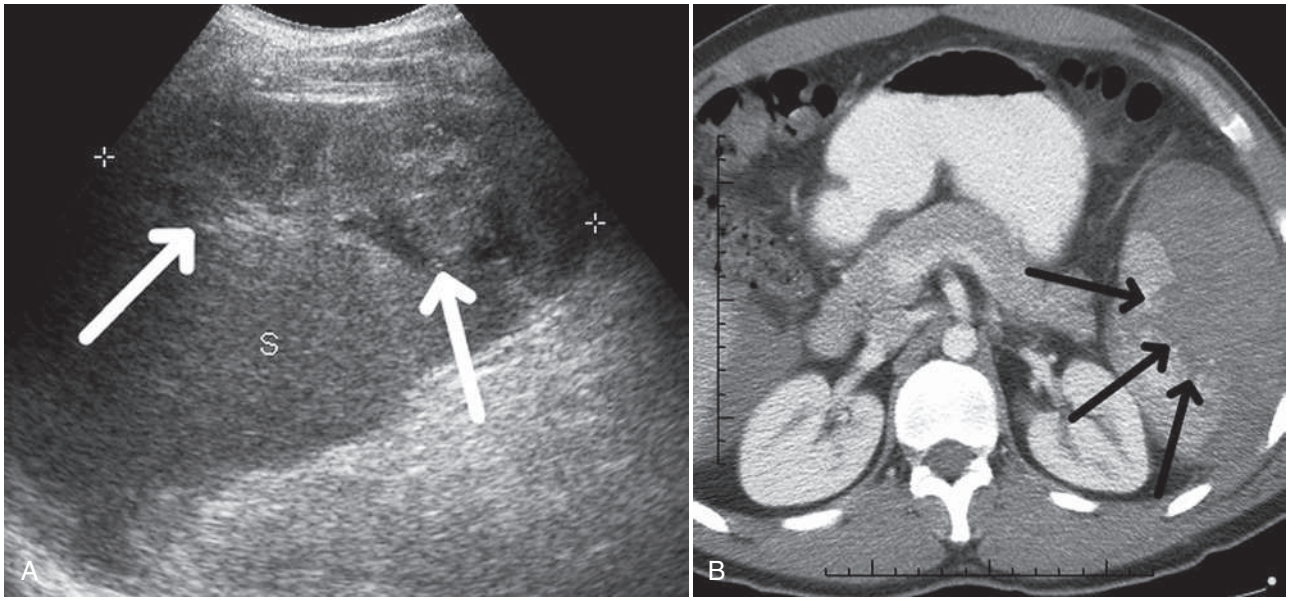

FIG. 5.31 Perisplenic Hematoma. (A) Coronal scan shows a hematoma *(arrows)* lateral to the spleen *(S)*. **(B)** Corresponding contrast-enhanced computed tomography image shows the splenic laceration *(arrows)* and large, perisplenic hematoma. Free fluid is also seen in the right upper abdomen.

of accessory spleens, however, are easy to recognize sonographically as small, rounded masses, usually less than 5 cm in diameter, with the same echogenicity as the spleen (Fig. 5.33). CT, MRI, or, in challenging cases, scintigraphy with technetium-labeled heat-damaged red blood cells, can confirm the diagnosis.[87]

A "**wandering spleen**" (or **mobile** spleen) can be found in unusual locations and may be mistaken for a mass (Fig. 5.34). It is caused by absence or extreme laxity of the supporting ligaments and a long, mobile mesentery (see Fig. 5.1B). The mobile spleen may undergo torsion, resulting in acute or chronic abdominal pain.[88,89] If the diagnosis of a wandering spleen is made in a patient with acute abdominal pain, the diagnosis of torsion is supported by color flow Doppler imaging showing absence of blood flow.[90]

The other two major congenital splenic anomalies are the asplenia and polysplenia syndromes. These conditions are best understood if viewed as part of the spectrum of **visceral heterotaxy.** A normal arrangement of asymmetrical body parts is

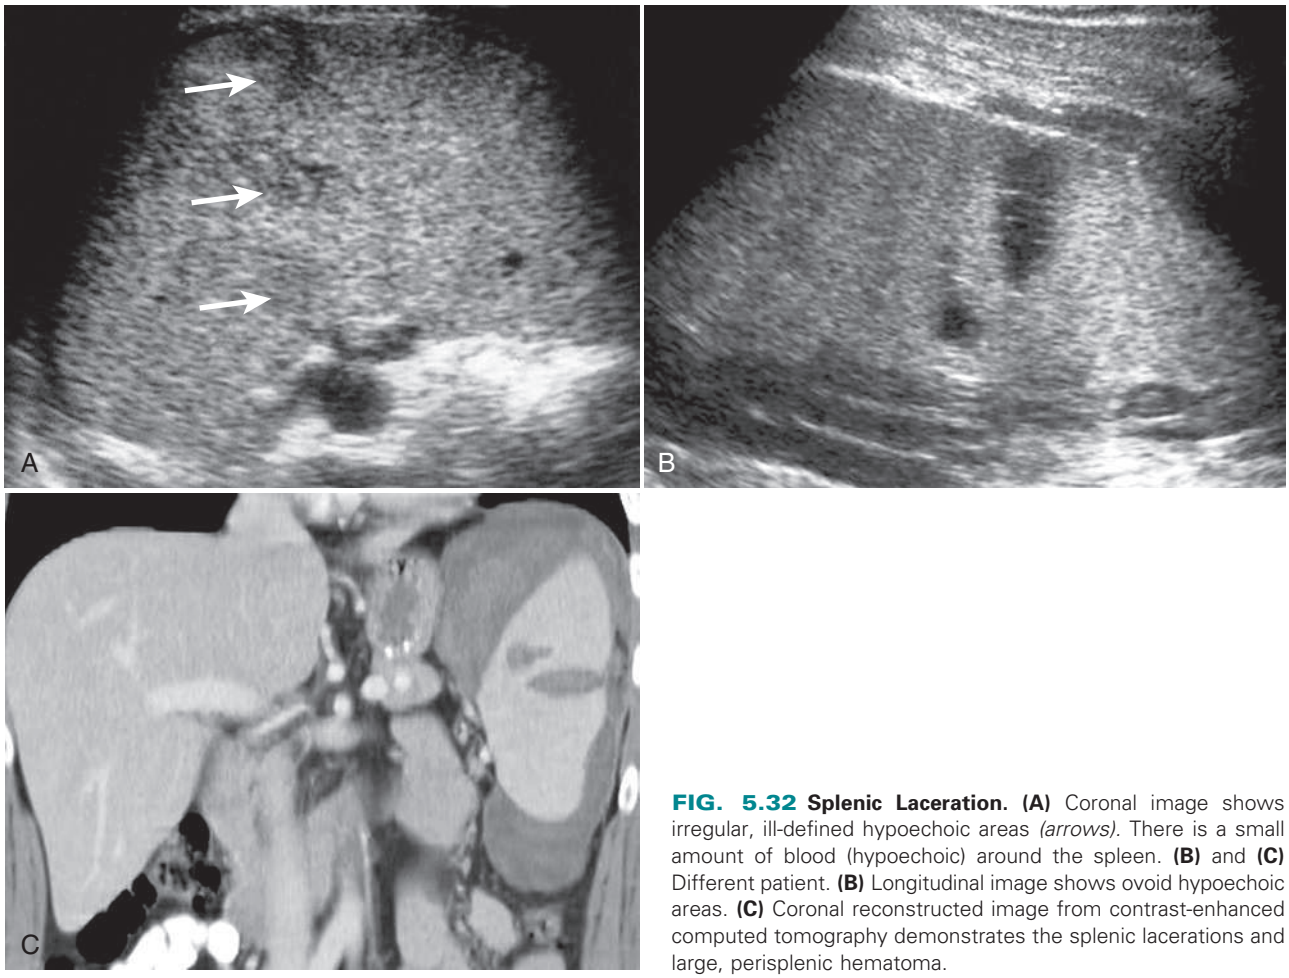

FIG. 5.32 Splenic Laceration. (A) Coronal image shows irregular, ill-defined hypoechoic areas *(arrows)*. There is a small amount of blood (hypoechoic) around the spleen. **(B)** and **(C)** Different patient. **(B)** Longitudinal image shows ovoid hypoechoic areas. **(C)** Coronal reconstructed image from contrast-enhanced computed tomography demonstrates the splenic lacerations and large, perisplenic hematoma.

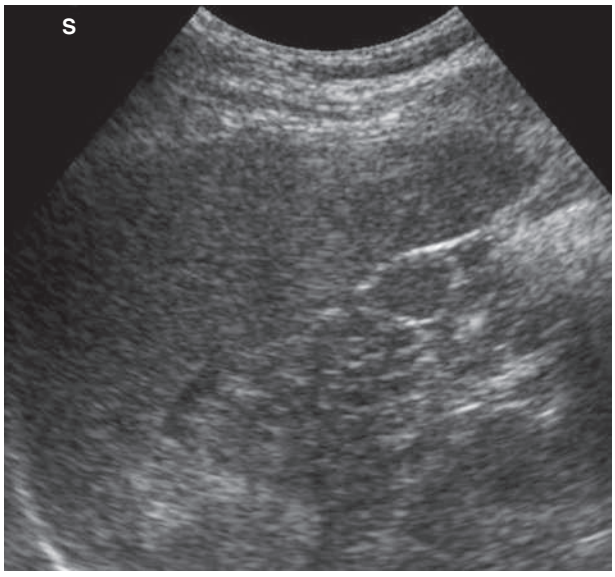

FIG. 5.33 Accessory Spleen. Coronal sonogram shows an accessory spleen adjacent to the inferior medial portion of the spleen.

known as situs solitus. The mirror image condition is called situs inversus. Between these two extremes is a wide spectrum of abnormalities called situs ambiguus. Splenic abnormalities in patients with visceral heterotaxy consist of polysplenia and asplenia. Interestingly, patients with **polysplenia** have **bilateral left-sidedness,** or a dominance of left-sided over right-sided body structures. They may have two morphologically left lungs, left-sided azygous continuation of an interrupted inferior vena cava, biliary atresia, absence of the gallbladder, gastrointestinal malrotation, and frequently cardiovascular abnormalities. Conversely, patients with **asplenia** may have **bilateral right-sidedness.** They may have two morphologically right lungs, midline location of the liver, reversed position of the abdominal aorta and inferior vena cava, anomalous pulmonary venous return, and **horseshoe kidneys.** The wide range of possible anomalies accounts for the variety of presenting symptoms, but absence of the spleen itself causes impairment of the immune response, and such patients can present with serious infections, such as sepsis and bacterial meningitis.[6]

Polysplenia must be differentiated from **posttraumatic splenosis.**[91] Splenosis is an acquired condition defined as autotransplantation of viable splenic tissue throughout different anatomic compartments of the body. It occurs after traumatic or iatrogenic rupture of the spleen.[92] Nuclear medicine imaging,

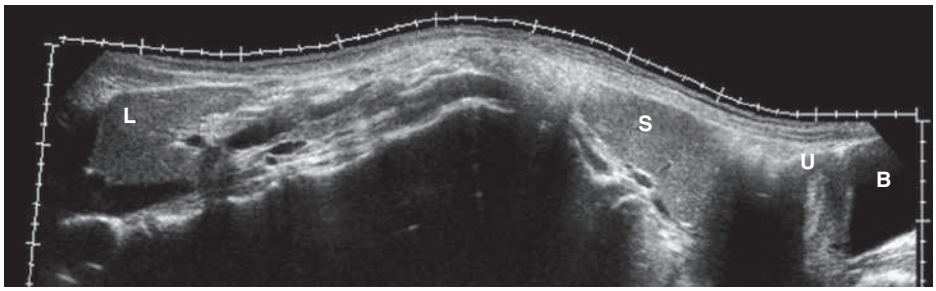

FIG. 5.34 Wandering Spleen. Sagittal extended–field of view image of midline abdomen in asymptomatic young woman. *B,* Bladder; *L,* liver, *S,* spleen; *U,* uterus.

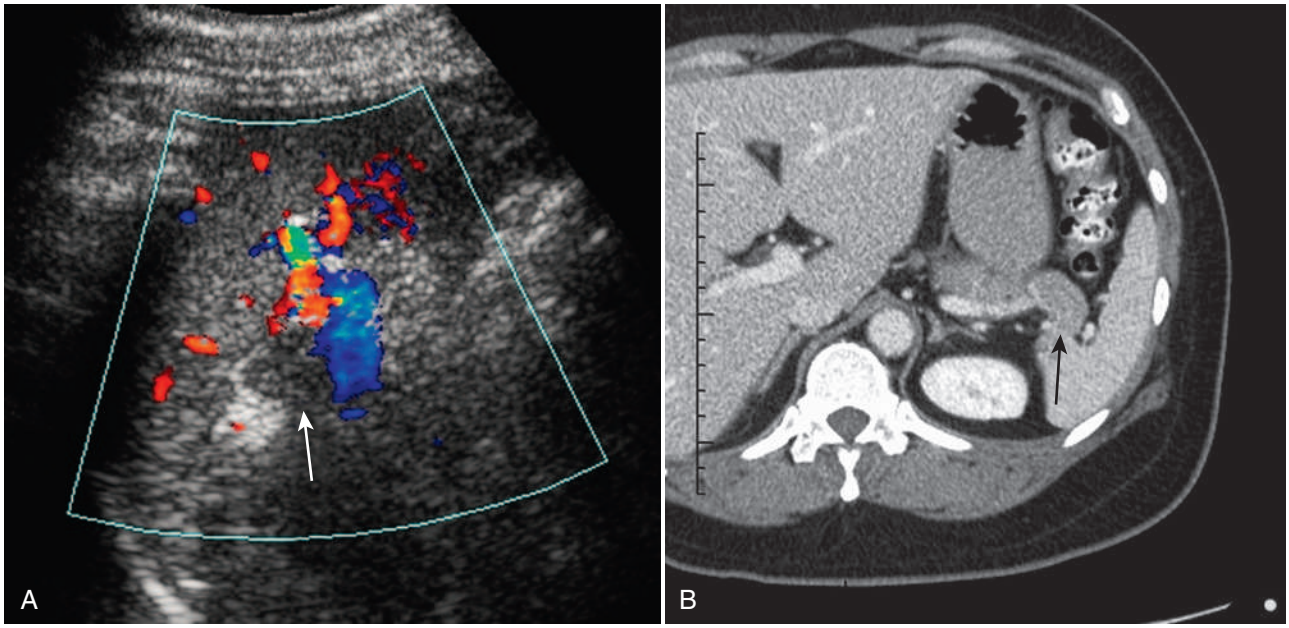

FIG. 5.35 Pancreatic Tail Simulating Mass. (A) Sonogram shows 2-cm lesion adjacent to the splenic hilum *(arrow).* **(B)** Computed tomography scan shows that "lesion" is the normal pancreatic tail *(arrow).*

with technetium-labeled heat-damaged red blood cells, is the most sensitive study for both posttraumatic splenosis and congenital polysplenia. Accessory spleens as small as 1 cm can be demonstrated by this method.[87]

INTERVENTIONAL PROCEDURES

Multiple reports and case series have described percutaneous splenic interventions.[93,94] Although typically described in smaller series, safety and success rates are similar to those performed elsewhere in the abdomen.[95]

Ultrasound-guided splenic biopsy can help establish a diagnosis with a low rate of complication rates and a high diagnostic yield.[24] Fine-needle and core-needle biopsies have been performed successfully to diagnose focal abnormalities, including abscesses, sarcoidosis, primary splenic malignancies, metastases, and lymphoma.[96,97]

In patients with abscesses, cysts, hematomas, and infected necrotic tumors, percutaneous catheter drainage is often successful.[46] Even radiofrequency ablation (RFA) procedures involving the spleen have been reported.[98]

Despite these reports, however, many interventional radiologists remain reluctant to perform splenic interventions. The main concern has been fear of **bleeding** caused by the highly vascular nature of the organ. However, clinicians should take into consideration that a successful image-guided percutaneous procedure could prevent the need for splenectomy.[95]

PITFALLS IN INTERPRETATION

Sonographers must be wary of several ultrasound pitfalls when scanning the LUQ and spleen. The first is the crescentic, echo-poor area superior to the spleen, which can be caused by the left lobe of the liver in thin individuals[99-102] (see Fig. 5.6). The left liver lobe can mimic the appearance of a subcapsular hematoma or a subphrenic abscess. Observing the liver sliding over the more echogenic spleen during quiet respiration can lead to the correct diagnosis. Hepatic and portal veins may help to identify this structure as the liver.

The tail of the pancreas may simulate a mass adjacent to the hilum of the spleen (Fig. 5.35). This is particularly true if the plane of section is aimed along the long axis of the pancreatic

tail. Identifying the splenic artery and vein may be helpful in confirming the normal tail of the pancreas.

Similarly, the fundus of the stomach may nestle in the hilum of the spleen. An oblique plane during scanning may pass through the spleen and include the hilum, with an echogenic portion of the stomach simulating an intrasplenic lesion. In some patients, this is just the fat around the stomach. Occasionally, fluid in the fundus of the stomach can simulate a perisplenic fluid collection. This can usually be resolved by scanning transversely or by letting the patient drink some water during the scan.

An occasional anatomic variant can occur if the inferior portion of the spleen is located posterolateral to the upper pole of the left kidney. This variant has been called the **retrorenal spleen.** Awareness of its existence can prevent the misdiagnosis of an abnormal mass. If visualized sonographically, it should be avoided in any interventional procedure performed on the left kidney.[103]

It can be very difficult to determine the site of origin of large, LUQ masses arising from the spleen, left adrenal gland, left kidney, tail of the pancreas, stomach, or retroperitoneum. Differential motion observed during shallow respiration may be helpful. Additionally, the identification of the splenic vein entering the splenic hilum can be definitive. CT or MRI should be used to clarify challenging cases.

CHAPTER 6

The Biliary Tree and Gallbladder

Korosh Khalili and Stephanie R. Wilson

SUMMARY OF KEY POINTS

- Ultrasound should be the first imaging modality used in the evaluation of the patients with potential disease of the biliary tree.
- Awareness of various scanning techniques and use of harmonic and compound imaging improve visualization of various diseases affecting the biliary tree.
- Stones in the intrahepatic and extrahepatic biliary tree can be easily overlooked; familiarity with their appearance and a high index of suspicious improve their detection.
- Cholecystitis is a common disease with variable degrees of severity. A high index of suspicion and sensitivity, particularly to distention and hyperemia of the gallbladder, allows for improved detection.
- The clinical presentation of the patient, particularly pain and signs of inflammation, helps in differentiating the common inflammatory conditions of the biliary tree and gallbladder from the rarer malignancies which they may mimic.

Patterns of Tumor Spread
Sonographic Appearance

Sonographic evaluation of the biliary tract is one of the most appropriate and efficacious uses of the ultrasound examination. The cystic nature of both the gallbladder and the bile ducts, particularly when dilated, provides an inherently high-contrast resolution in comparison to the adjacent tissues. The excellent spatial resolution of sonography, and the acoustic window provided by the liver allow for a high-quality examination in most patients. Currently, sonography remains the imaging modality of choice for the detection of gallstones, assessment of acute right upper quadrant (RUQ) pain, and initial evaluation of the patient with jaundice or elevated liver function tests. In conjunction with magnetic resonance imaging (MRI), magnetic resonance cholangiopanreatography (MRCP), and contrast-enhanced computed tomography (CT), sonography also plays a key role in the multimodality evaluation of more complex biliary problems, such as the diagnosis and staging of hilar cholangiocarcinoma. The recent development of contrast-enhanced sonography for detection of hepatic masses further broadens this role. From the smallest ultrasound departments operating in remote geographic areas to the largest tertiary institutions, no other anatomic location in the body is better studied with sonography than the biliary tract.

THE BILIARY TREE

Anatomy and Normal Variants

An understanding of the normal location of the bile ducts and common anatomic variations is important in staging malignancies and directing intervention. In biliary terminology, *proximal* denotes the portion of the biliary tree that is in relative proximity to the liver and hepatocytes, whereas *distal* refers to the caudal end closer to the bowel. The term *branching order* applies to the level of division of the bile ducts starting from the **common hepatic duct** (CHD); first-order branches are the right and left hepatic ducts, second-order branches are their respective divisions (also known as secondary biliary *radicles*), and so on. *Central* specifies proximity to the porta hepatis, whereas *peripheral* refers to the higher-order branches of the intrahepatic biliary tree extending well into the hepatic parenchyma. Knowledge of **Couinaud functional anatomy** of the liver is also vital in description of the intrahepatic biliary abnormalities (see Chapter 4).

The *intrahepatic ducts* are not in a fixed relation to the portal veins within the portal triads and can be anterior or posterior to the vein or even tortuous about the vein.[1] The right and left hepatic ducts, that is, the first-order branches of the CHD, are routinely seen on sonography, and normal second-order branches may be visualized[2] (Fig. 6.1). Spectral and color Doppler ultrasound are often needed to distinguish hepatic arteries from ducts, though ducts tend to be straight whereas arteries are tortuous. In our experience, visualization of third-order or higher-order branches is often an abnormal finding and requires a search for the cause of dilation. Most of the right and left hepatic ducts are

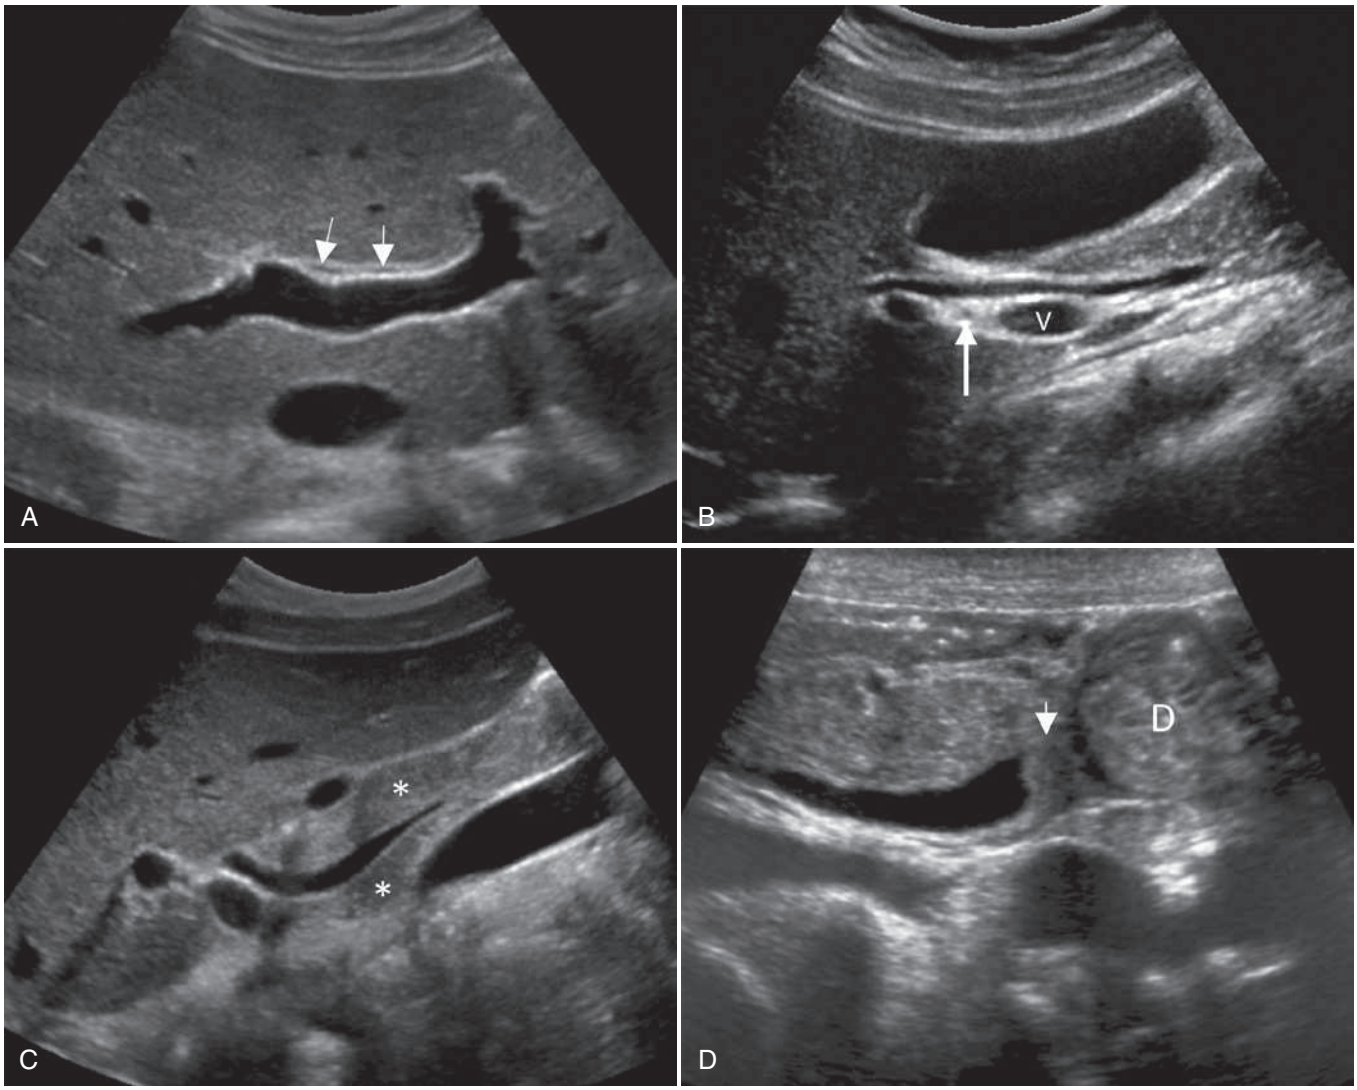

FIG. 6.1 Normal Bile Ducts. (A) Right and left hepatic ducts *(short arrows)* are normally seen lying anterior to the portal veins. **(B)** Common hepatic/common bile ducts of normal caliber in sagittal view lying in the typical position anterior to the portal vein *(V)* and hepatic artery *(arrow)*. **(C)** Mid and distal common bile duct in longitudinal view. Note the pancreas (*), the cranial margin of which demarcates the transition between the suprapancreatic and intrapancreatic segments. **(D)** Distal common bile duct and the ampulla of Vater *(short arrow)* are shown running posterior to the pancreatic head and inserting into the duodenum *(D)*. See also Video 6.1.

extrahepatic and, along with the CHD, form the hilar or central portion of the biliary tree at the porta hepatis. This is the most common location for cholangiocarcinoma. The normal diameter of the first-order and higher-order branches of the CHD has been suggested to be 2 mm or less, and no more than 40% of the diameter of the adjacent portal vein.[2]

The most common **biliary branching pattern** occurs in 56% to 58% of the population[3,4] (Figs. 6.2 and 6.3). On the right side, the right hepatic duct forms from the right anterior and right posterior branches, draining the anterior (segments 5 and 8) and posterior (segments 6 and 7) segments of the right lobe, respectively. On the left side, segment 2 and 3 branches join to the left of the falciform ligament to form the left hepatic duct. This duct becomes extrahepatic in location as it extends to the right of the falciform ligament, where it is joined by ducts of segments 4 and 1.

The key to understanding the common normal variants of biliary branching lies in the variability of the site of insertion of the **right posterior duct** (RPD) (segments 6 and 7). The RPD often extends centrally toward the porta hepatis in a cranial direction. It passes superior and posterior to the **right anterior duct** (RAD) and then turns caudally, joining the RAD to form the short right hepatic duct (see Fig. 6.2). Three other common sites of insertion of the RPD account for the majority of the **biliary anatomic variations.** If the RPD extends more to the left than usual, it can join the junction of the right and left hepatic ducts ("trifurcation pattern"; ≈8% of normal variants) or the left hepatic duct (≈13%) (Fig. 6.4). If the RPD extends in a caudal-medial direction instead, it can join the CHD or common bile duct (CBD) directly (≈5%). Anomalous drainage of various segmental hepatic ducts directly into the CHDs is less common.

The **normal caliber** of the CHD/CBD in patients without history of biliary disease is up to 6 mm in most studies[5] (see Fig. 6.1). Controversy surrounds whether there is a normal widening of the duct with increasing age.[6] Similarly, studies on an association between cholecystectomy and a large-caliber CBD are inconclusive. Although diameters of up to 10 mm have been recorded in an asymptomatic normal population, the great majority of the diameters are under 7 mm. Therefore a ductal diameter of 7 mm or greater should prompt further investigations, such as correlation with serum levels of cholestatic liver enzymes.

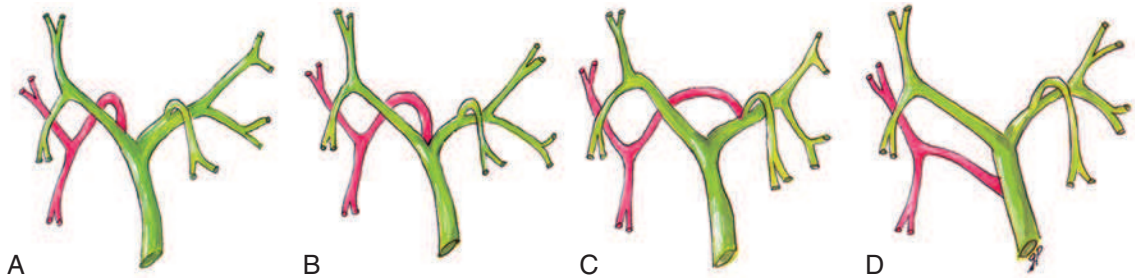

FIG. 6.2 Common Variants of Bile Duct Branching. Right posterior duct (RPD) is in red. **(A)** RPD joins the right anterior duct in 56% to 58% of the population. **(B)** Trifurcation pattern, 8%. **(C)** RPD joins the left hepatic duct, 13%. **(D)** RPD joins the common hepatic or common bile duct directly, 5%.

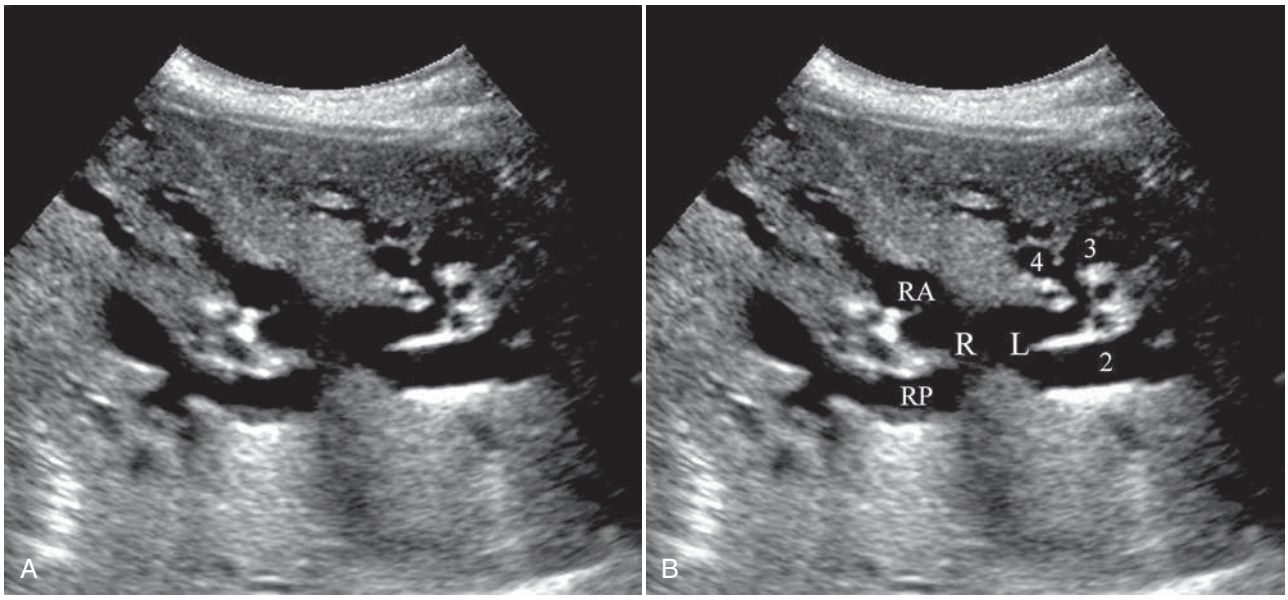

FIG. 6.3 Typical Ductal Branching Order. Intrahepatic biliary tree is dilated because of an obstructed common bile duct (not shown). **(A)** and **(B)** Subcostal oblique views foreshorten the right *(R)* and left *(L)* hepatic ducts. *RA,* Right anterior duct; *RP,* right posterior duct; *2,* segment 2 duct; *3,* segment 3 duct; *4,* segment 4 duct.

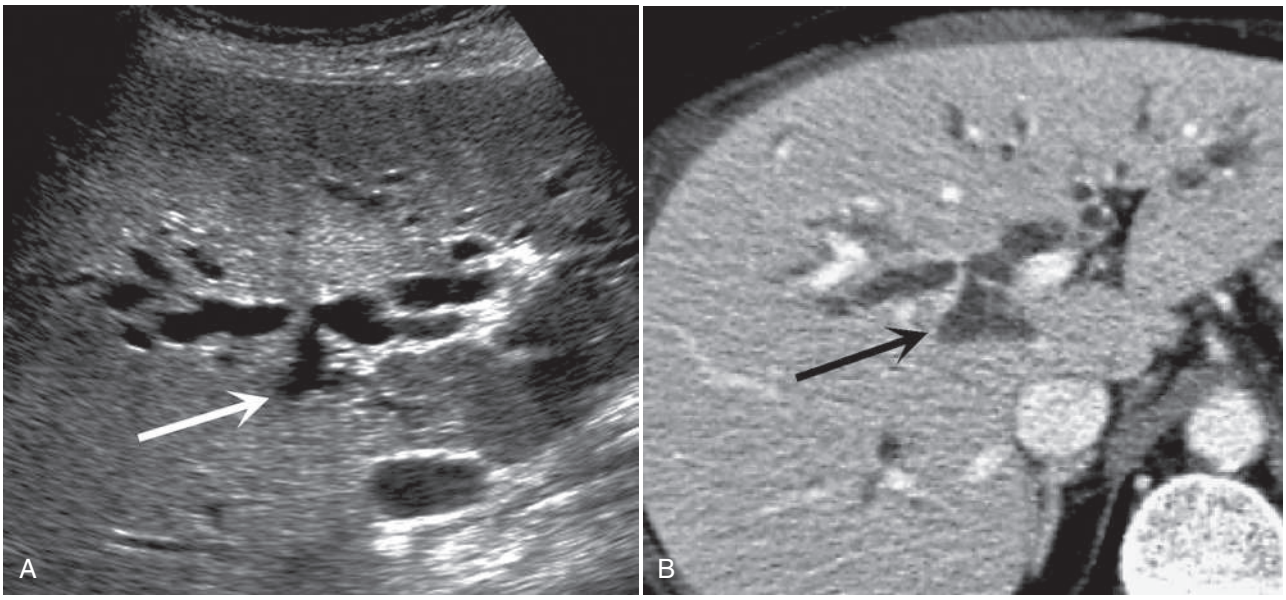

FIG. 6.4 Aberrant Right Posterior Duct. (A) Transverse image obtained cranial to the porta hepatis depicts the aberrant right posterior duct *(arrow)* inserting into the left hepatic duct. This is the most common anomaly of the biliary tree. **(B)** Corresponding enhanced computed tomography image shows the same anomaly.

The site of insertion of the **cystic duct** into the bile duct is quite variable. The cystic duct may join the bile duct along its lateral, posterior, or medial border. It may also run a parallel course to the duct and insert into the lower one-third of the duct, close to the ampulla of Vater.[7] The **common bile duct** is commonly divided into three segments: the suprapancreatic, retropancreatic, and interstitial/ampullary components. It extends caudally within the hepatoduodenal ligament, lying anterior to the portal vein and to the right of the hepatic artery. It then passes posterior to the first portion of the duodenum and the head of the pancreas, sometimes embedded in the latter. The superior margin of the pancreatic head demarcates the transition between the suprapancreatic and retropancreatic segments of the CBD. It ends in the ampulla of Vater, which is occasionally identified on transabdominal ultrasound with the use of high-frequency linear transducers (see Fig. 6.1D, Video 6.1).

Sonographic Technique

Our technique for assessment of the intrahepatic ducts includes a routine scan, as would be performed for liver evaluation, including both sagittal and transverse scans. In addition, we perform a *focused scan* to assess the porta hepatis, recognizing that its orientation requires an oblique plane to show the length of the right and left hepatic ducts in a single image. For this we utilize a subcostal oblique view with the left edge of the transducer more cephalad than the right edge. The face of the transducer is directed toward the right shoulder. With a full suspended inspiration, a sweep of the transducer from the shoulder to the umbilical region will show the middle hepatic vein, then the long axis of the right and left hepatic ducts at the porta hepatis, followed by the common duct in cross section. By rotating the transducer 90 degrees to this plane, a second suspended inspiration will allow for a long-axis view of the CHD and CBD at the porta hepatis. The visualization of the distal CBD can be a challenge because of overlying duodenal or transverse colonic gas. If the gallbladder is distended, it is often an excellent window through which the distal CBD and pancreatic head can be visualized. With the patient in supine or left lateral decubitus position, the probe may be placed on the gallbladder and angled slightly to the left toward the pancreatic head. Protrusion of the abdomen or examination of the patient in standing upright position also allows the intervening colon to migrate caudally and improves visibility of the pancreatic head.

Harmonic imaging and spatial compound imaging allow for improved contrast between the ducts and adjacent tissues, leading to improved visualization of the duct, its luminal contents, and wall[8] (Fig. 6.5). Furthermore, the conspicuity of stones and their posterior acoustic shadowing is increased. Spatial compounding, while diminishing posterior shadowing, also results in improved contrast to speckle ratio and better depicts intraductal and periductal structures. We advocate routine use of harmonic and compound imaging in the assessment of the biliary tree. Specific scanning techniques for assessment of choledocholithiasis and cholangiocarcinoma are discussed in the appropriate sections.

Choledochal Cysts

Choledochal cysts represent a heterogeneous group of congenital diseases that may manifest as focal or diffuse cystic dilation of the biliary tree. These cysts occur most often in East Asian populations; the incidence in Japan is 1 in 13,000 versus 1 in 100,000 in Western populations.[9,10] The female-to-male ratio is 3:1 to 4:1.

Although most patients present early in life, about 20% of choledochal cysts are encountered in adulthood, when sonography is performed for symptoms of gallstone disease.[11] The most widely used classification system divides choledochal cysts into **five types**[12] (Figs. 6.6 and 6.7). **Type I** choledochal cysts, a fusiform dilation of the CBD, are the most common (80%) and, along

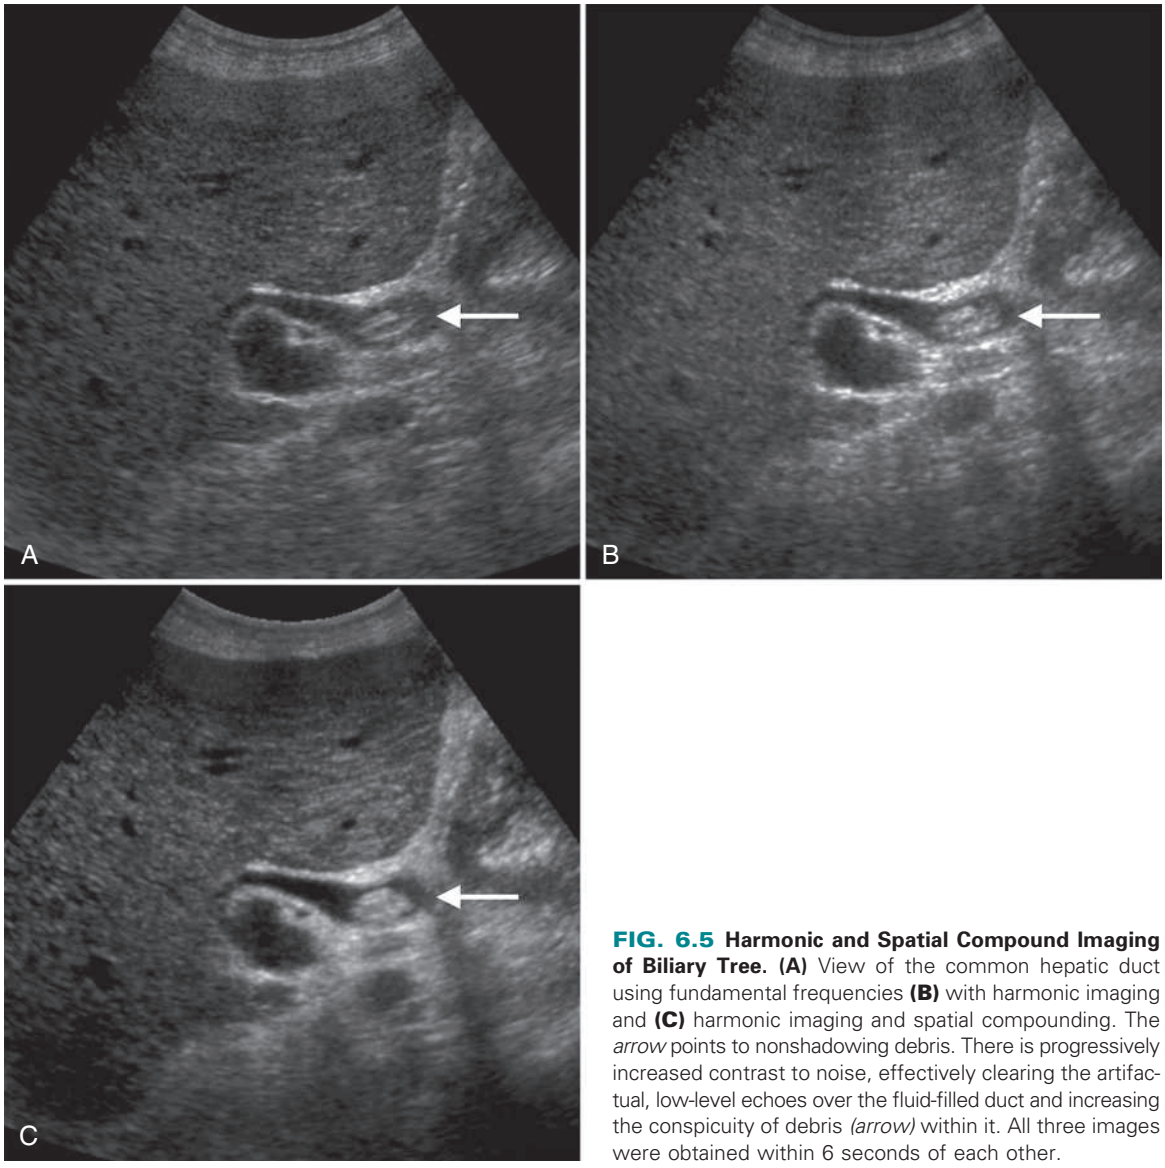

FIG. 6.5 Harmonic and Spatial Compound Imaging of Biliary Tree. (A) View of the common hepatic duct using fundamental frequencies **(B)** with harmonic imaging and **(C)** harmonic imaging and spatial compounding. The *arrow* points to nonshadowing debris. There is progressively increased contrast to noise, effectively clearing the artifactual, low-level echoes over the fluid-filled duct and increasing the conspicuity of debris *(arrow)* within it. All three images were obtained within 6 seconds of each other.

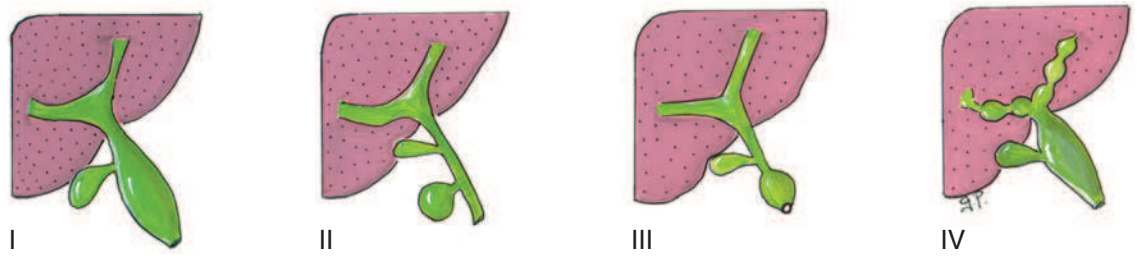

FIG. 6.6 Todani Classification System for Choledochal Cysts. Type I cyst: diffuse dilation of the extrahepatic bile duct; this is the most common type (80%). **Type II cyst:** true diverticulum of the bile duct; very rare. **Type III cyst:** also called choledochocele; diffuse dilation of the very distal (intraduodenal) common bile duct. **Type IV cyst:** multifocal dilations of the intrahepatic and extrahepatic bile ducts. **Type V cyst,** Caroli disease, is omitted because it is not a true choledochal cyst. (With permission from Todani T, Watanabe Y, Narusue M, et al. Congenital bile duct cysts: classification, operative procedures, and review of thirty-seven cases including cancer arising from choledochal cyst. Am J Surg. 1977;134:263-269.[12])

with type IVa, are associated with an abnormally long common channel (>20 mm) between the distal bile duct and the pancreatic duct. This long common channel could allow for reflux of pancreatic juices into the CBD, causing dilation, but this remains controversial.[9,13] **Type II** cysts are true diverticula of the bile ducts and are very rare. **Type III** cysts, the "choledochoceles," are confined to the intraduodenal portion of the CBD. **Type IVa** cysts are multiple intrahepatic and extrahepatic biliary dilations, whereas **type IVb** cysts are confined to the extrahepatic biliary tree. Caroli disease has been classified as a **type V** cyst, but it

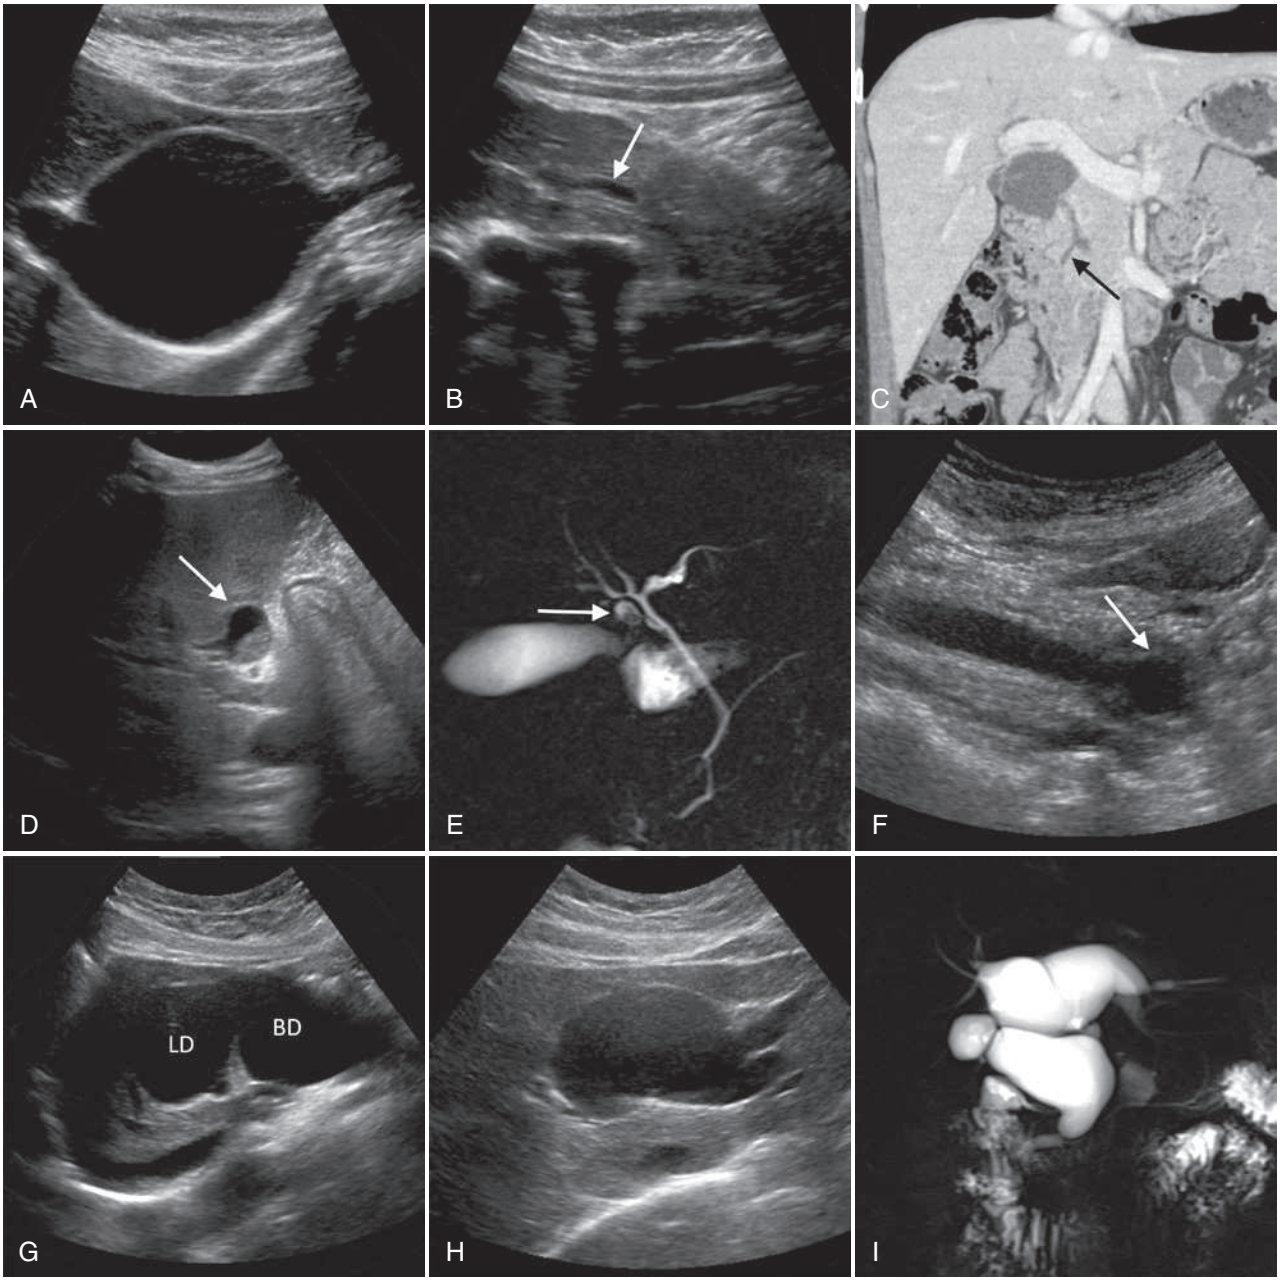

FIG. 6.7 Choledochal Cysts. (A)-(C) Type I. Fusiform dilation of the common bile duct (CBD) is seen, but no obstructive lesion is noted. This is the most common type of choledochal cyst. **(B)** Careful examination of the distal CBD using high-frequency linear transducer reveals a long common channel *(arrow)* between the CBD and pancreatic duct. **(C)** Coronal computed tomography image confirms the presence of long common channel *(arrow)*. **(D)** and **(E) Type II.** A large diverticulum *(arrow)* is shown in **(D)** arising from the common hepatic duct at the portal hepatis and containing mobile debris. **(E)** Thick-slab magnetic resonance cholangiopanreatography (MRCP) confirms the same. **(F) Type III.** Fusiform dilation of the distal CBD *(arrow)* is demonstrated protruding into the duodenum. **(G)-(I)**. **Type IV. (G)** Sagittal view of the liver shows a markedly dilated bile duct (BD) and left hepatic duct (LD). **(H)** Transverse view of the left lobe of the liver depicts marked enlargement of the left hepatic duct with dilated branches. **(I)** Thick-slab MRCP shows both intrahepatic and extrahepatic involvement.

has a different embryonic origin and is not a true choledochal cyst.[10]

On sonography, a cystic structure is identified that may contain internal sludge, stones, or even solid neoplasm. In some cases the cyst is large enough that its connection to the bile duct is not immediately recognized. Use of various scanning windows and angles allows for demonstration of the relationship of the lesion to the biliary tract, differentiating it from pancreatic pseudocysts or enteric duplication cysts. Biliary scintigraphy, MRCP, and endoscopic retrograde cholangiopancreatography (ERCP) have been used to delineate further the structure of choledochal cysts. ERCP is necessary to ensure that the dilation is not a result of distal neoplasm, especially in the case of type I choledochal cysts (see Fig. 6.7). Because there is a risk of cholangiocarcinoma with all choledochal cysts, surgical resection is advocated.

Caroli Disease

Caroli disease is a rare congenital disease of the intrahepatic biliary tree that results from malformation of the **ductal plates,** the primordial cells that give rise to the intrahepatic bile ducts. There are two types of Caroli disease: the simple, classic form and the second, more common form, which occurs with **congenital hepatic fibrosis.**[14] The second form has also been called **Caroli syndrome.** Caroli disease has been associated with cystic renal disease, most often renal tubular ectasia **(medullary sponge kidneys).** However, both forms may also be seen in patients with autosomal recessive polycystic kidney disease. Caroli disease affects men and women equally, and more than 80% of patients present before the age of 30 years.[15]

Caroli disease leads to *saccular dilation* or, less often, *fusiform dilation* of the intrahepatic biliary tree, resulting in biliary stasis, stone formation, and bouts of cholangitis and sepsis (Fig. 6.8). The disease most often affects the intrahepatic biliary tree diffusely, but it may be focal. The dilated ducts contain stones and sludge. Unlike recurrent pyogenic cholangitis, the ductal contents do not form a cast of the dilated system and thus are more easily identified as ductal contents.[16] Also, small portal vein branches surrounded by dilated bile ducts and *bridging echogenic septa* traversing the dilated ducts have been described on ultrasound. These correspond to persistent embryonic ductal structures.[17] If associated with congenital hepatic fibrosis, findings of altered hepatic architecture and portal hypertension are also present. **Cholangiocarcinoma** develops in 7% of patients with Caroli disease.[15]

Overview of Biliary Tree Obstruction

Elevation of cholestatic liver parameters, which may appear clinically as jaundice, is a frequent indication for sonographic examination of the abdomen. The major objective in performing these scans is to determine if the patient has obstruction of the bile ducts, as opposed to a hepatocellular or biliary ductular disease. Sonography is highly sensitive in the detection of dilation of the biliary tree and is therefore an excellent modality for

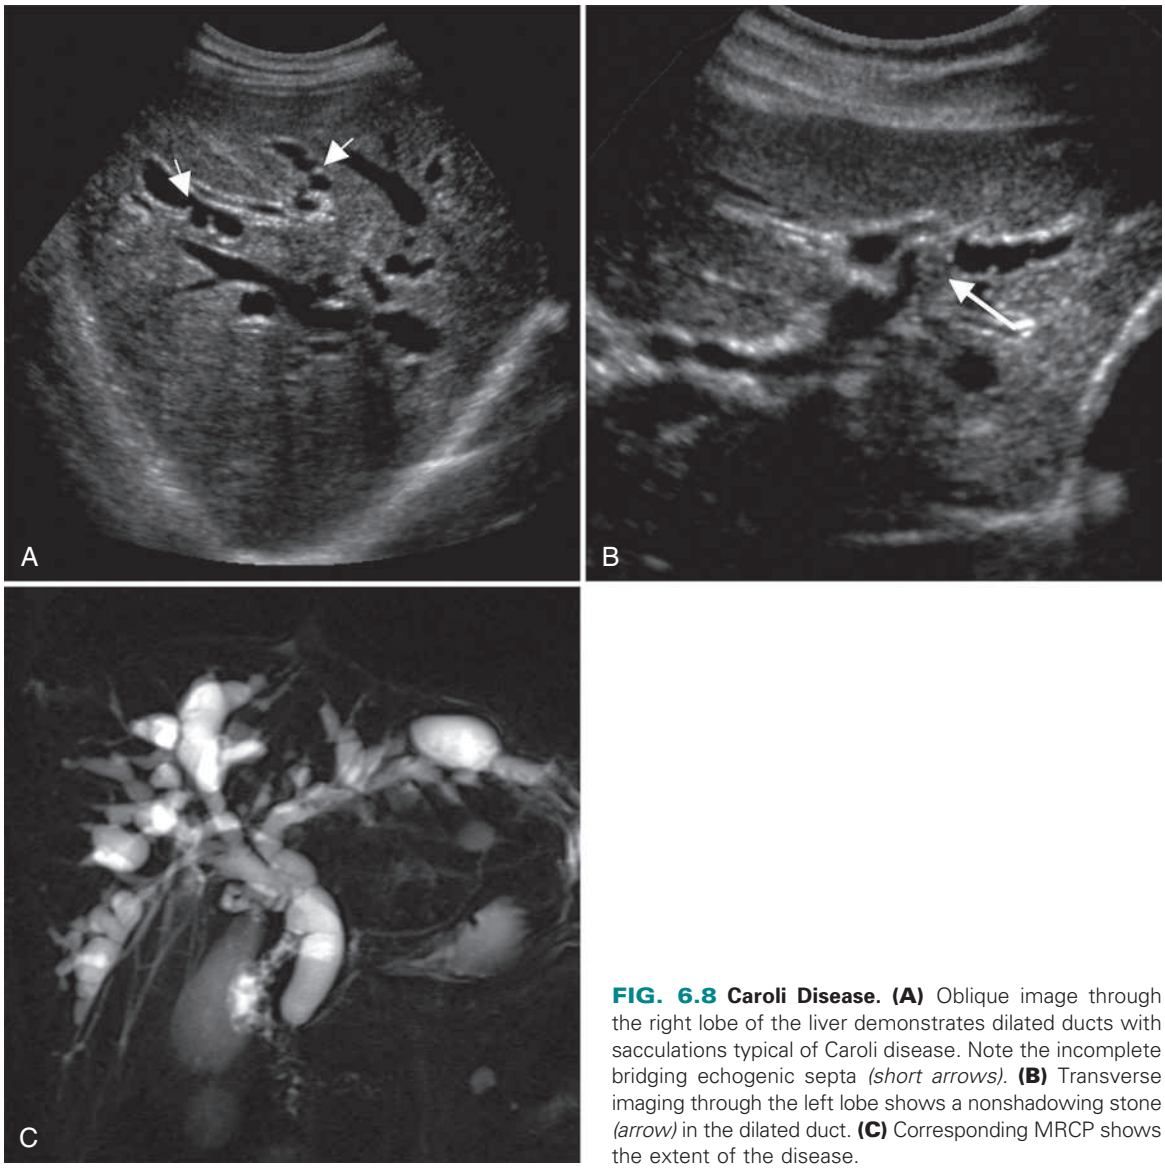

FIG. 6.8 Caroli Disease. (A) Oblique image through the right lobe of the liver demonstrates dilated ducts with sacculations typical of Caroli disease. Note the incomplete bridging echogenic septa *(short arrows).* **(B)** Transverse imaging through the left lobe shows a nonshadowing stone *(arrow)* in the dilated duct. **(C)** Corresponding MRCP shows the extent of the disease.

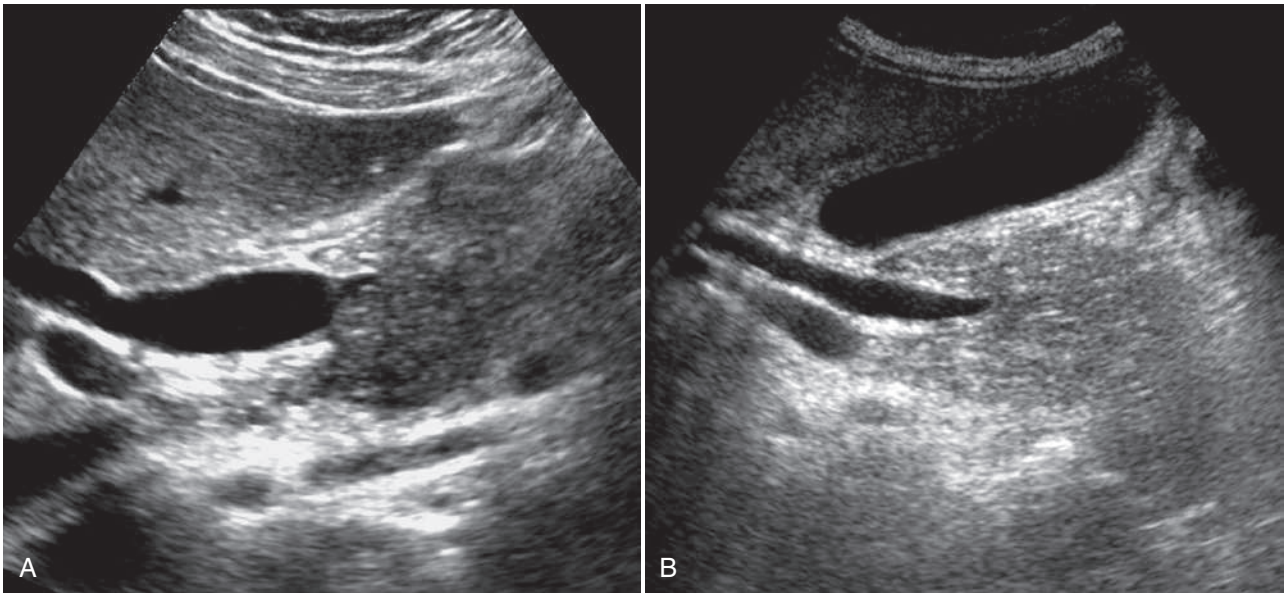

FIG. 6.9 Common Bile Duct Obstruction Caused by Extrinsic Factors. (A) Pancreatic adenocarcinoma. Short transition zone with shouldering, large duct caliber, along with an obstructive mass are typical findings in malignant obstruction. **(B) Pancreatitis.** Elongated tapering of the duct suggests a benign cause. Note mild sympathetic **gallbladder wall thickening** caused by adjacent inflammation.

Causes of Biliary Obstruction

BENIGN MISCELLANEOUS
Choledocholithiasis[a]
Hemobilia[a]
Congenital biliary diseases
  Caroli disease[a]
  Choledochal cysts
Cholangitis
  Infectious
Acute pyogenic cholangitis[a]
Biliary parasites[a]
Recurrent pyogenic cholangitis[a]
HIV cholangiopathy
  Sclerosing cholangitis

NEOPLASMS
Cholangiocarcinoma
Gallbladder carcinoma
Locally invasive tumors (esp. pancreatic adenocarcinoma)
Ampullary tumors
Metastases

EXTRINSIC COMPRESSION
Mirizzi syndrome[a]
Pancreatitis
Adenopathy

[a]Denotes causes of painful jaundice.

initiation of the imaging investigation (Fig. 6.9). These scans should be performed with knowledge of the patient's clinical condition, especially whether the patient has painless jaundice or has painful jaundice, as seen with acute obstruction or infection affecting the biliary tree.

Acute biliary obstruction in the absence of infection may present with RUQ pain and a predominant transaminitis suggesting **acute hepatitis** rather than cholestasis.[18,19] Early on, the bile ducts may only be minimally dilated, with imaging findings of a nonspecific hepatitis manifest by edema in the portal triads (echogenic periportal thickening) and fluid accumulation in the gallbladder wall. Therefore in patients with unexplained acute hepatitis, the distal biliary tree should always be examined carefully for choledocholithiasis even if the bile ducts do not appear significantly dilated.

The ultrasound examination should focus on answering the following three questions:

1. Are the bile ducts or gallbladder dilated?
2. If dilated, to what level?
3. What is the cause of the obstruction?

Choledocholithiasis

Choledocholithiasis is classified into primary and secondary forms. **Primary choledocholithiasis** denotes de novo formation of stones, often made of calcium bilirubinate **(pigment stones)** within the ducts. The etiologic factors are often related to diseases causing strictures or dilation of the bile ducts, leading to stasis, as follows:

- Sclerosing cholangitis
- Caroli disease
- Parasitic infections of the liver (e.g., *Clonorchis, Fasciola, Ascaris*)[20]
- Chronic hemolytic diseases, such as sickle cell disease
- Prior biliary surgery, such as biliary-enteric anastomoses

Migration of stones from the gallbladder into the CBD constitutes **secondary choledocholithiasis.** Whereas primary choledocholithiasis is relatively rare outside endemic regions (East Asia), secondary choledocholithiasis is quite common, representing the worldwide distribution of gallstone disease. Bile duct stones are found in 8% to 18% of patients with symptomatic gallstones.[21]

Intrahepatic Stones

Harmonic and compound imaging have improved the ability to find small stones within the intrahepatic bile ducts, especially with dilated ducts. Visualization of small intrahepatic stones is quite difficult on MRCP and other biliary imaging modalities; because of the intrinsic high contrast of stones on ultrasound, it is often the first modality to detect intrahepatic stones.

The appearance of stones depends on their size and texture (Fig. 6.10, Video 6.2). Most stones are highly echogenic with posterior acoustic shadowing, although small (<5 mm) or soft pigment stones (especially in the patient with recurrent pyogenic cholangitis) may not show shadowing. When the affected ducts are filled with stones, the individual stones may not be appreciated; instead, a bright, echogenic linear structure with posterior shadowing is seen. Stones should always be suspected if discrete or linear echogenicities with or without shadowing are seen in the region of the portal triads, paralleling the course of the portal veins within the liver. Harmonic imaging improves both the contrast resolution and the detection of the acoustic shadow and is therefore recommended for routine assessment of the biliary tree.[22]

Common Bile Duct Stones

The majority of stones in the CBD are in the distal duct close to or at the ampulla of Vater. Therefore sonographic evaluation should include assessment of the entire duct, focusing on the periampullary region. Unfortunately, this region is often the most

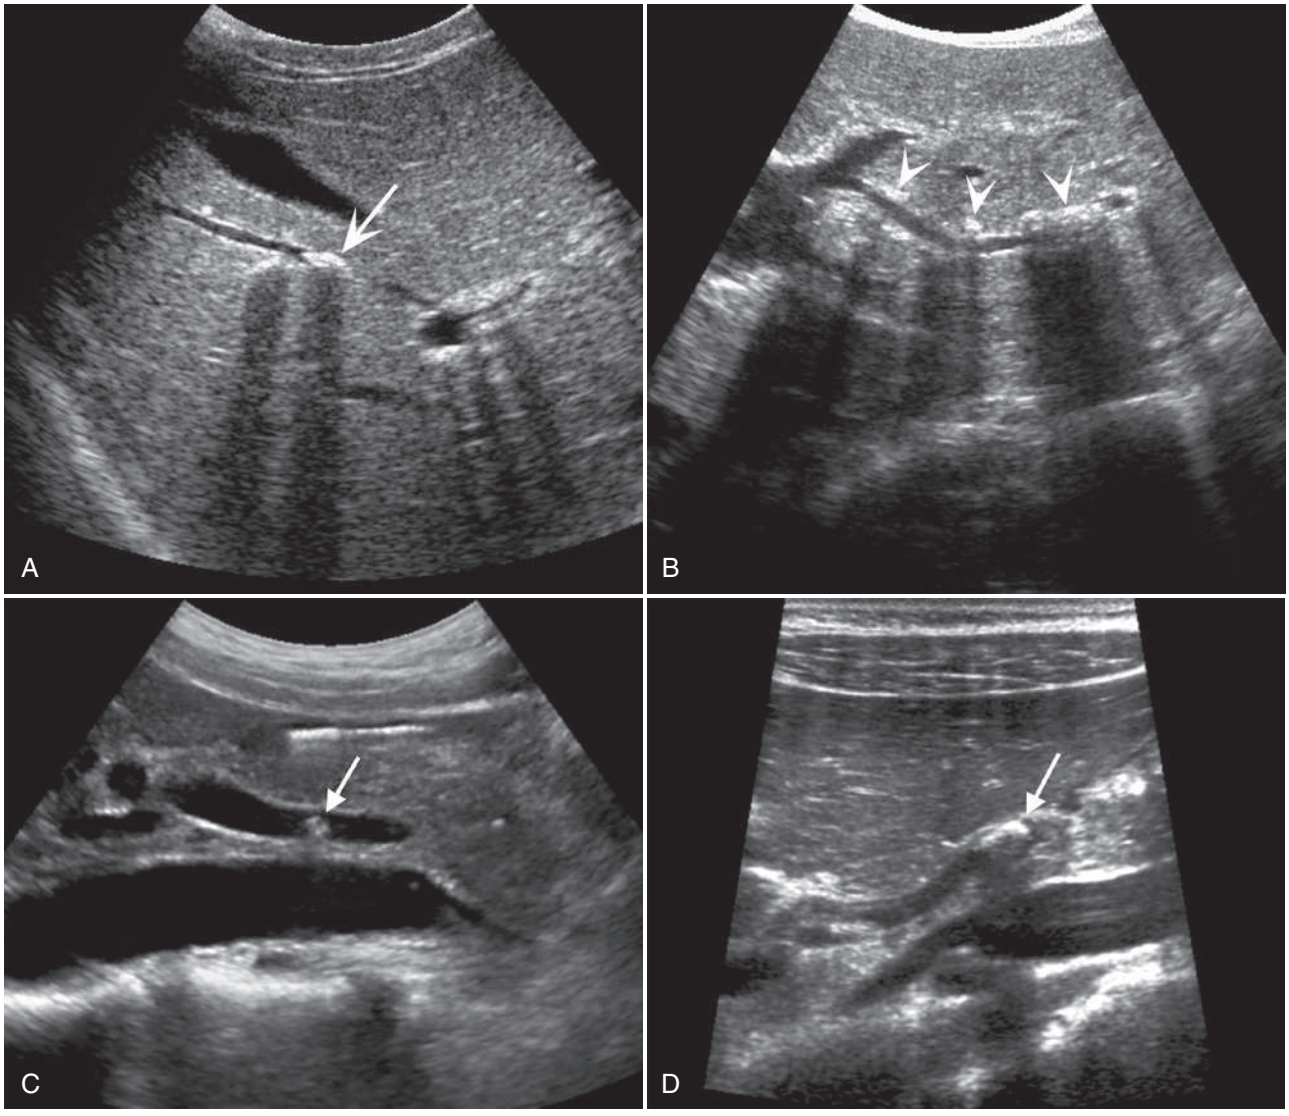

FIG. 6.10 Choledocholithiasis. (A) Intrahepatic stones. Small stones *(arrow)* are seen in the right lobe causing acoustic shadowing. Note the dilated duct proximal to the larger stone. **(B) Multiple stone clusters** *(arrowheads)* in the left lobe appearing as echogenic linear structures with shadowing. Both patients (in **A** and **B**) had **cystic fibrosis. (C)** and **(D) Common bile duct (CBD) stones. (C)** Small stone *(arrow)* may not show shadowing. **(D)** Distal stone *(arrow)* with posterior acoustic shadowing. See also Videos 6.2 and 6.3.

difficult area to visualize because it may be hidden by bowel gas, making detection of distal CBD stones difficult. Maneuvers to improve assessment include the following:

- **Changes in patient position.** The CBD may be examined in supine, left lateral decubitus, and standing positions. The change in the relative position of adjacent organs and bowel gas may allow improved visualization of the distal duct.
- **Choice of sonographic window.** The subcostal view is most useful for the assessment of the porta hepatis and proximal CBD. An epigastric view is best for the distal CBD.
- **Use of compression sonography.** Physically compressing the epigastrium may collapse the superficial bowel and displace the bowel gas that is blocking the view.
- **Detailed assessment of the distal CBD.** The distal intrapancreatic CBD is often best visualized with the probe focused on the pancreatic head in the **transverse** plane. Once the dilated CBD is identified, a slight rocking of the transducer to just "peek" at the point of caliber change will often allow a glimpse of a stone impacted in the distal duct, which is otherwise hidden from sonographic view. Similarly, a **sagittal** view focused on the pancreatic head should show the dilated CBD on the dorsal aspect of the head. Again, slight manipulation of the transducer, focusing on the point of caliber change, is best to see a solitary stone impacted in the distal duct. If the gallbladder is distended, it may be used as an acoustic window through which the distal CBD and ampulla may be visible.

The classic appearance of CBD stones is a rounded echogenic lesion with **posterior acoustic shadowing** (see Fig. 6.10, Video 6.3). Importantly, no fluid rim will be seen around an impacted distal CBD stone because it is compressed against the duct wall. The lateral margins of the stone are therefore not seen, decreasing the conspicuity of the stone, versus a stone seen in the gallbladder or proximal duct, where it is likely to be surrounded by bile. Small stones may lack good acoustic shadows and appear only as a reproducible bright, linear echogenicity, either straight or curved. Awareness of this subtle appearance of CBD stones definitely improves their detection.

Pitfalls in the diagnosis of choledocholithiasis include blood clot **(hemobilia), papillary tumors,** and occasionally **biliary sludge;** none of these will shadow. **Surgical clips** in the porta hepatis, mostly from previous cholecystectomy, appear as linear echogenic foci with shadowing.[23] The short length, the relatively high degree of echogenicity, the lack of ductal dilation, and the absence of the gallbladder should allow differentiation of surgical clips from stones.

Mirizzi Syndrome

Mirizzi syndrome is a clinical syndrome of jaundice with pain and fever resulting from obstruction of the CHD caused by a stone impacted in the cystic duct. It occurs most often when the cystic duct and CHD run a parallel course. The stone is often impacted in the distal cystic duct, and the accompanying inflammation and edema result in the obstruction of the adjacent CHD. The obstruction of the cystic duct causes recurrent bouts of cholecystitis, and the impacted stone may erode into the CHD, resulting in a **cholecystocholedochal fistula** and biliary obstruction.[24] Identification of the fistula complication (called **Mirizzi type II**) is important because the treatment requires surgical repair of the fistula. **Acute cholecystitis, cholangitis,** and even **pancreatitis** may occur.[25]

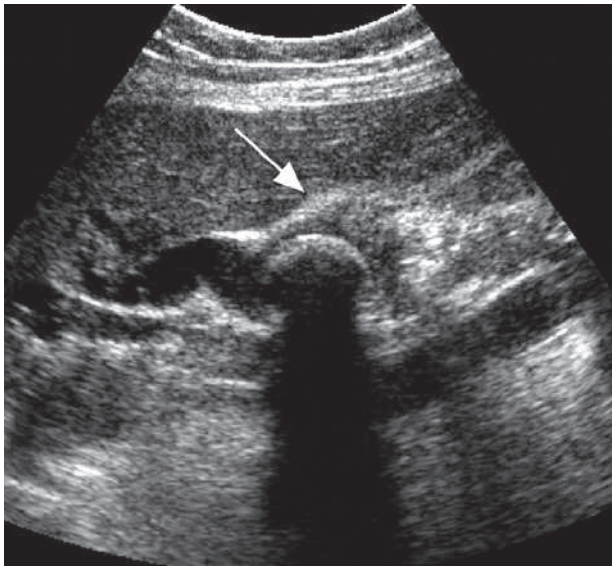

FIG. 6.11 Mirizzi Syndrome. Mirizzi syndrome in a patient with abdominal pain and jaundice. Sagittal sonogram shows a dilated common bile duct obstructed by a large stone impacted in the distal cystic duct. This appearance may be mistaken for a common bile duct stone. There is thickening of the wall of the cystic duct *(arrow)*.

Mirizzi syndrome should be considered on sonography when biliary obstruction with dilation of the biliary ducts to the CHD level is seen with acute or chronic cholecystitis. Thus the gallbladder has features of acute cholecystitis but may or may not be distended.[2] A stone impacted in the cystic duct with surrounding edema at the level of the obstruction is confirmatory (Fig. 6.11).

Hemobilia

Iatrogenic biliary trauma, mostly caused by percutaneous biliary procedures or liver biopsies, accounts for approximately 65% of all causes of hemobilia. Other causes include **cholangitis** or **cholecystitis** (10%), vascular malformations or aneurysms (7%), abdominal **trauma** (6%), and malignancies, especially **hepatocellular carcinoma** and **cholangiocarcinoma** (7%).[26] Pain, gastrointestinal bleeding, and biochemical jaundice are the usual complaints at presentation. Apart from the blood loss, which occasionally is severe, complications are rare and include cholecystitis, cholangitis, and **pancreatitis.**

The appearance of blood within the biliary tree is similar to blood clots encountered elsewhere (Fig. 6.12). Most often, the clot is echogenic or of mixed echogenicity, and retractile, conforming to the shape of the duct. Occasionally, hemobilia may appear tubular with a central hypoechoic area. Acute hemorrhage will appear as fluid with low-level internal echoes. Blood clots may be mobile. Extension into the gallbladder is common. The clinical history is often essential to the diagnosis.

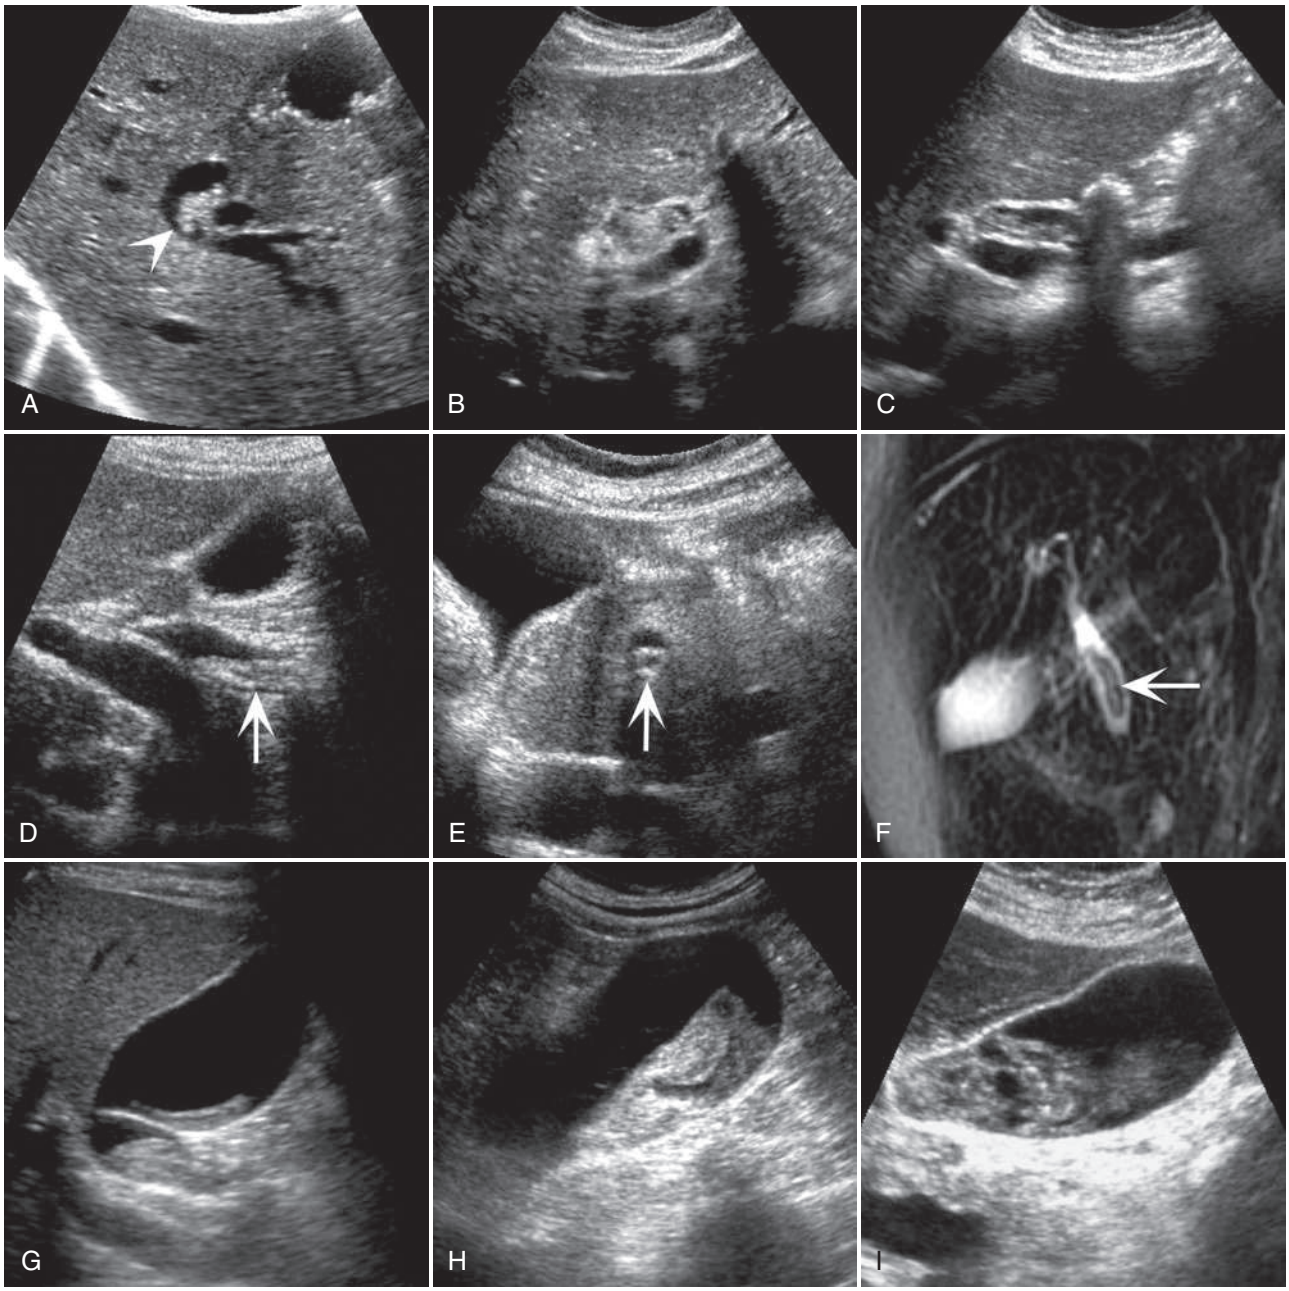

FIG. 6.12 Hemobilia: Spectrum on Sonography. (A) Echogenic blood clot *(arrowhead)* within a dilated duct, after insertion of biliary drainage catheter. Biliary obstruction was caused by pancreatic tumor. **(B)** and **(C)** Echogenic clot in the common hepatic duct in two patients after liver biopsy. **(D)** and **(E)** Spontaneous hemobilia in patient receiving anticoagulation therapy. Note the tubular appearance of the clot *(arrow)* with central hypoechoic lumen. **(F)** Corresponding MRCP image depicts the same. **(G)-(I)** Blood in gallbladder in three different patients. All patients developed pain after liver biopsy. **(H)** Note the angled edge typical of blood clot.

Pneumobilia

Air within the biliary tree usually results from previous biliary intervention, biliary-enteric anastomoses, or CBD stents. In the acute abdomen, pneumobilia may be caused primarily by three entities. **Emphysematous cholecystitis** may lead to pneumobilia; its risk factors and findings are discussed under "Acute Cholecystitis." Inflammation caused by an impacted stone in the CBD may cause erosion of the duct wall, leading to **choledochoduodenal fistula.** The third entity, prolonged acute cholecystitis, may lead to erosion into an adjacent loop of bowel, most frequently the duodenum or transverse colon, called **cholecystenteric fistula.** Stones may then pass from the gallbladder into the bowel and can cause a gastric outlet or small bowel obstruction called **gallstone ileus.**

Air in the bile ducts has a characteristic appearance. Bright, echogenic linear structures following the portal triads are seen, more often in a nondependent position (Fig. 6.13). Posterior **"dirty" shadowing, reverberation,** and **ring-down artifacts** are seen with large quantities of air. Movement of the air bubbles, best seen just after changing the patient's position, is diagnostic.

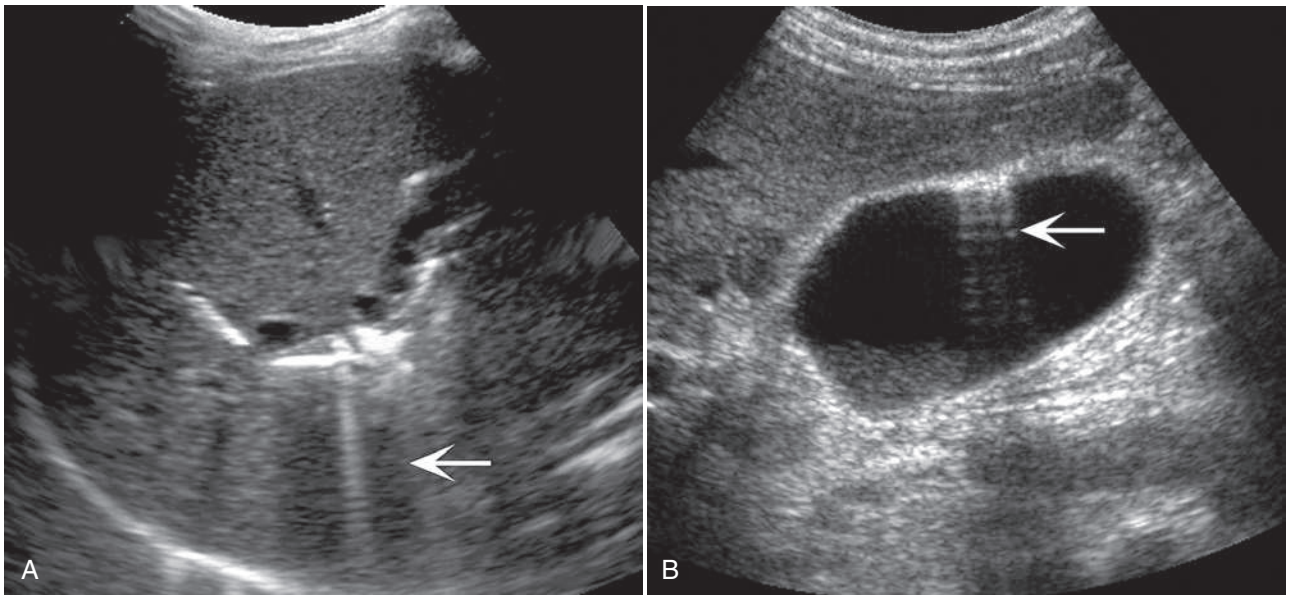

FIG. 6.13 Pneumobilia. (A) Extensive air within the central ducts manifests as linear echogenic structures paralleling the portal veins. Note the dirty shadowing *(arrow)* and ring-down artifact. **(B)** Air in the gallbladder. Pneumobilia often extends into the gallbladder. Note the ring-down artifact *(arrow).*

Extensive arterial calcifications, seen especially in diabetic patients, can mimic pneumobilia.

Biliary Tree Infection

Acute (Bacterial, Ascending) Cholangitis

Antecedent **biliary obstruction** is an essential component of bacterial cholangitis, associated in 85% of cases with CBD stones.[27] Other causes of obstruction include biliary stricture as a result of trauma or surgery, congenital abnormalities such as choledochal cysts, and partially obstructive tumors. Intrinsic or extrinsic neoplasms causing complete biliary obstruction rarely cause pyogenic cholangitis before biliary intervention.[19] The clinical presentation is usually that of (1) fever (≈90%), (2) RUQ pain (≈70%), and (3) jaundice (≈60%), the classical **Charcot triad.** There is leukocytosis, or at least a left shift, and elevated levels of serum alkaline phosphatase and bilirubin in the great majority of patients. Often, mild serum hepatic transaminitis is present, but occasionally, levels above 1000 are seen early in the disease because of a sudden increase in intrabiliary pressures.[19] The bile is most often infected by gram-negative enteric bacteria, which are often retrieved in blood cultures.

Acute cholangitis is a medical emergency. Sonography is advocated as the first imaging modality to determine the cause and level of obstruction and to exclude other diseases, such as cholecystitis, acute hepatitis, and Mirizzi syndrome. Sonography is more accurate than CT and more practical than MRI, endoscopic ultrasound, and ERCP in the initial assessment of patients with potential acute biliary disease.[28]

The **sonographic findings** of bacterial cholangitis include the following (Fig. 6.14):

- Dilation of the biliary tree
- Choledocholithiasis and possibly sludge
- Bile duct wall thickening
- Hepatic abscesses

Dilation of the biliary tree, when present, can be diagnosed by sonography. A CBD diameter greater than 6 mm is considered abnormal in most patients. *Subtle dilation* of the intrahepatic biliary tree is a frequently overlooked finding that should be specifically sought. This includes use of subcostal oblique scanning of the porta hepatis to assess the caliber of the right and left hepatic ducts, as well as evaluation of the CBD, which may measure normal but still show a somewhat "tense" or distended morphology. Dilation of the biliary tree is seen in 75% of patients. The obstructive stone is usually lodged in the distal CBD but may be mobile, causing intermittent obstruction. Air is rarely seen within the ducts; thus its presence suggests a **choledochoenteric fistula** in the absence of previous biliary manipulation (Fig. 6.15, Video 6.4). Circumferential thickening of the bile duct wall, similar to other causes of cholangitis, may be present and may extend to the gallbladder. Multiple small hepatic abscesses—sometimes grouped in a lobe or segment of the liver—may be seen but tend to become visible on sonography when they have undergone liquefaction and are a late finding.

Liver Flukes

Fascioliasis. *Fasciola hepatica* infection is unevenly endemic in many regions of the world, including Asia, Europe, Northern Africa, and South America (mainly Peru and Bolivia).[29] Infection is caused by consumption of water or raw vegetables contaminated with the larvae (metacercariae) of the *F. hepatica* fluke. The infection has two stages: the acute phase, lasting 3 to 5 months, and the chronic phase, which may last several years to over a decade. The acute phase corresponds to the migration of the

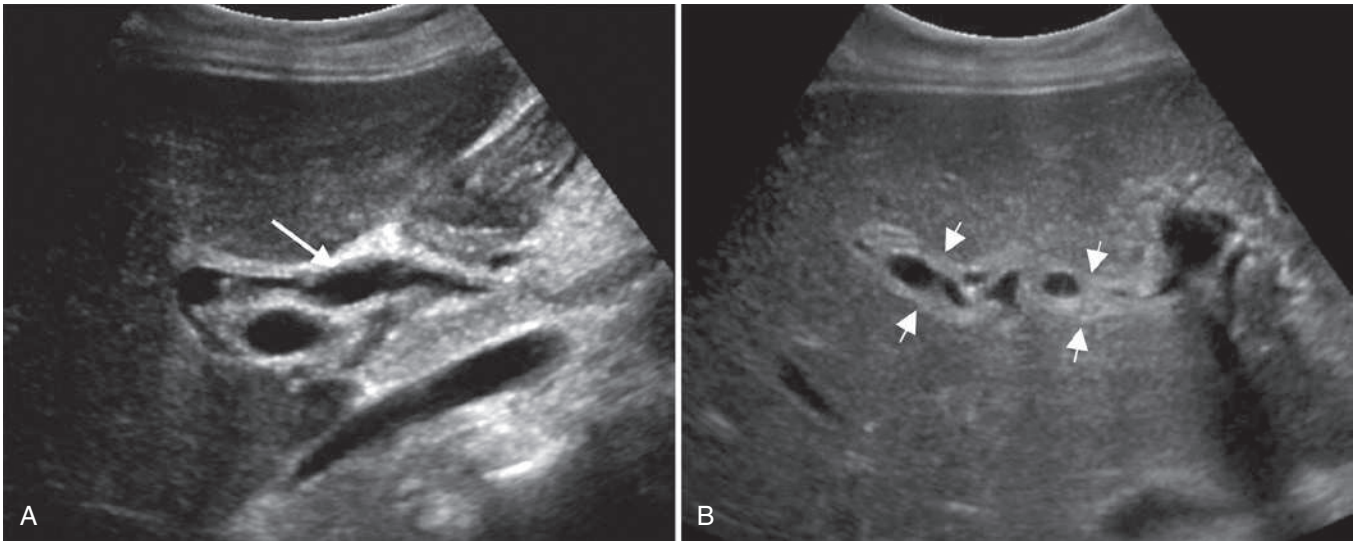

FIG. 6.14 Acute Bacterial Cholangitis. (A) Bile duct wall thickening *(arrow)* in a dilated duct. **(B)** Extensive periportal edema manifest by echogenic thickening of periportal tissues *(short arrows)*.

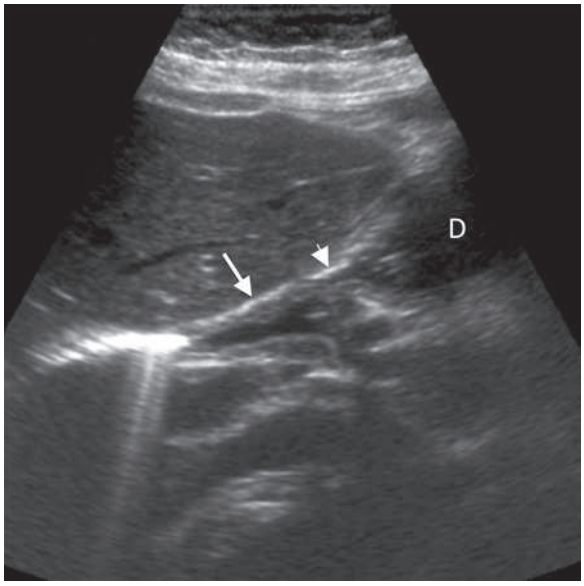

FIG. 6.15 Choledochoduodenal Fistula. Gas within the common bile duct *(arrow)* and marked mucosal thickening caused by inflammation. The fistulous tract *(short arrow)* extends from the duodenal bulb *(D)*. See also Video 6.4.

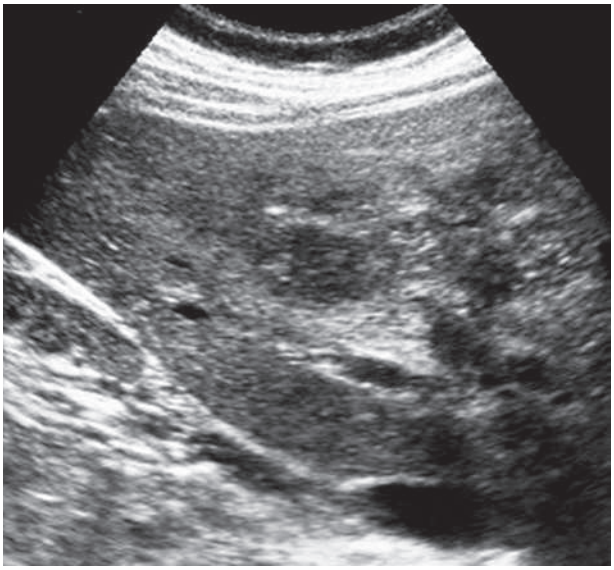

FIG. 6.16 *Fasciola Hepatica* Infection, Acute (Parenchymal) Phase. Oblique image through the right lobe shows poorly defined hypoechoic lesions in the liver parenchyma. Patients often present with fever and pain. (Courtesy of Dr. Adnan Kabaalioglu, Akdeniz University Hospital, Antalya, Turkey.)

immature larvae through the bowel wall, peritoneal cavity, and liver capsule, into the liver parenchyma. Patients may present with acute RUQ pain, hepatomegaly, and prolonged fevers. The final destination of the larvae is the biliary tree, where the parasite matures and produces eggs, indicating the chronic phase of infection. The mature *Fasciola* is the largest of the liver flukes (20-40 mm in length), is flat in shape (1 mm thin), and can be directly seen within the bile ducts. Symptoms then relate to biliary obstruction with intermittent jaundice, fevers, and intrahepatic abscesses. One-half of the patients are asymptomatic in the chronic phase.[29]

The **imaging appearance** of fascioliasis depends on the phase of infection. In the acute phase, sonography demonstrates nonspecific findings of hepatomegaly, hilar adenopathy, and hypoechoic or mixed echogenicity lesions[30,31] (Fig. 6.16). The hepatic lesions are often multiple, confluent, subcapsular, and ill-defined and are present in approximately 90% of patients.[31] The specific finding of the migratory tract of the larvae, manifest by small cystlike clusters in serpiginous tracts in the periphery of the liver are better imaged with CT or MRI.[32] Serial examination may show slowly evolving disease with progressive central migration of lesions and periportal tracking representing lymphangiectasia in the portal triads.[33] Sonography is more specific in the **chronic ductal phase** of the disease, depicting ductal dilation and the flukes in the ducts and gallbladder as flat, sometimes moving, material (Fig. 6.17). However, the most

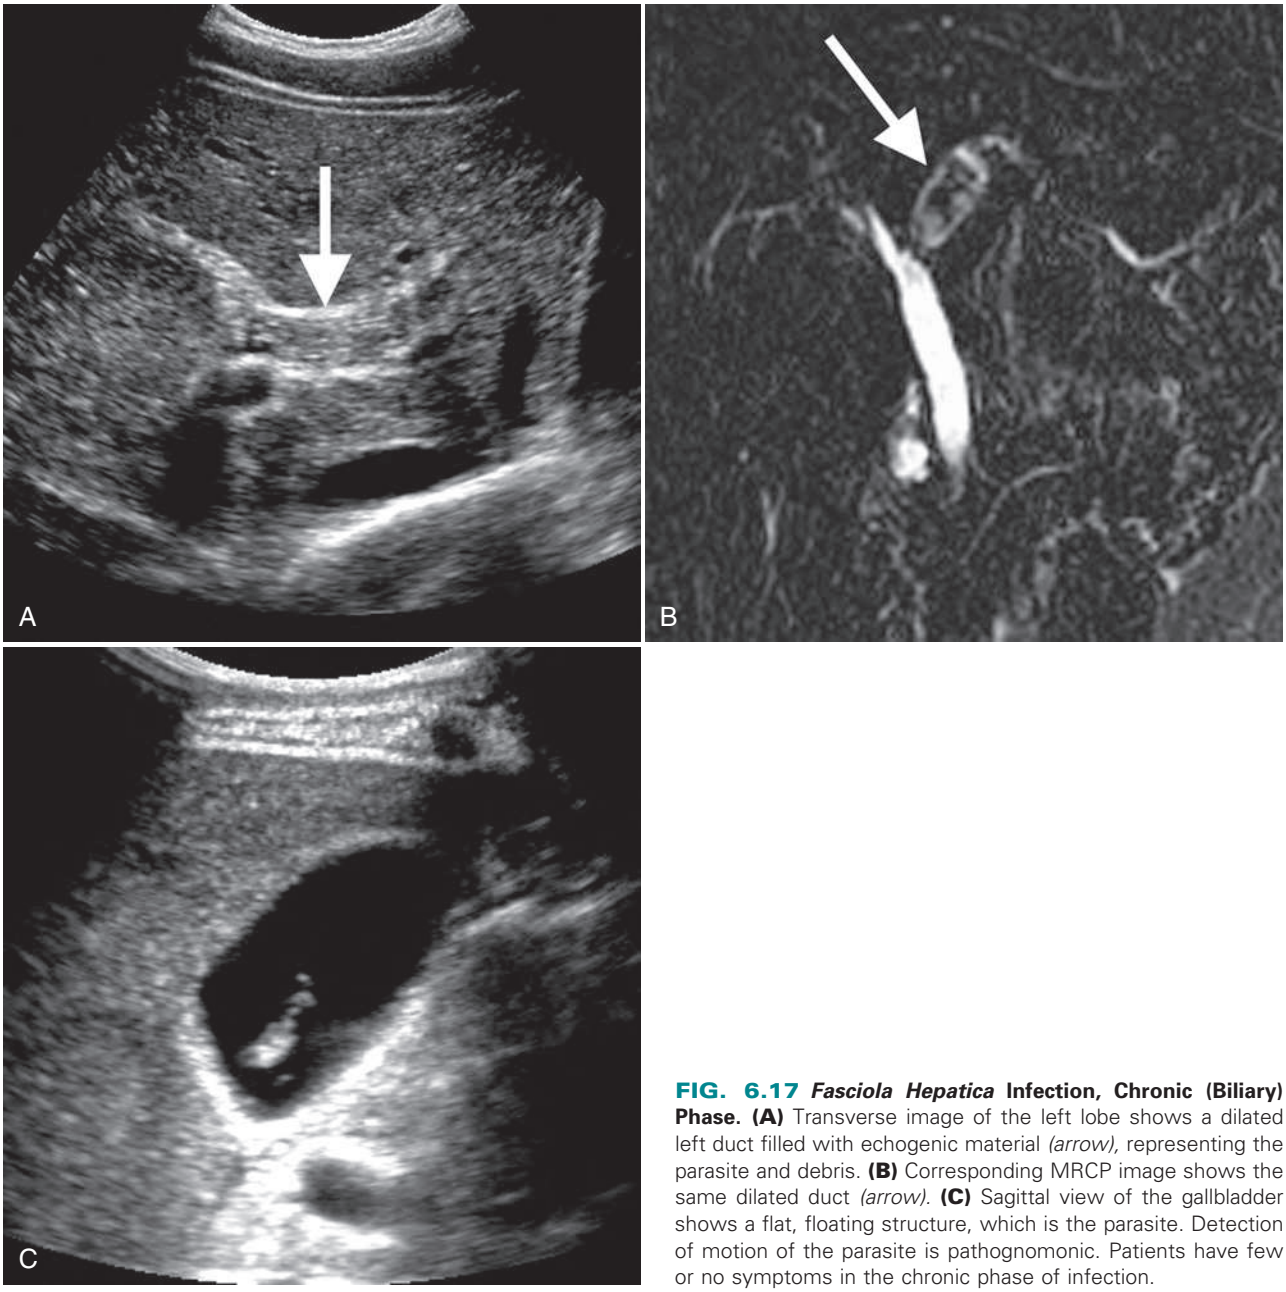

FIG. 6.17 *Fasciola Hepatica* Infection, Chronic (Biliary) Phase. (A) Transverse image of the left lobe shows a dilated left duct filled with echogenic material *(arrow),* representing the parasite and debris. **(B)** Corresponding MRCP image shows the same dilated duct *(arrow).* **(C)** Sagittal view of the gallbladder shows a flat, floating structure, which is the parasite. Detection of motion of the parasite is pathognomonic. Patients have few or no symptoms in the chronic phase of infection.

common findings are gallbladder and bile duct wall thickening.[34] The living flukes within the gallbladder were present in 37% of patients in a series of 87 patients.[31]

Clonorchiasis and Opisthorchiasis. *Clonorchis sinensis* (endemic in East and Southeast Asia), *Opisthorchis viverrini* (endemic in Cambodia, Laos, Thailand, and Vietnam) and *Opisthorchis felineus* (endemic in Central Asia, Russia, and Ukraine) are similar in morphology and life cycle but vary in their geographic distribution.[29] The infection is acquired by ingestion of raw fish (carp) contaminated by the larvae (metacercariae), which migrate through the ampulla of Vater, up the bile duct, then mature and live within the small and medium-sized intrahepatic bile ducts. The mature flukes are smaller than *F. hepatica,* measuring 8 to 15 mm. The acute phase of infection tends to be asymptomatic for *C. sinensis* and *O. viverrini.* The infestation may last for many years or decades.[29]

Ultrasound imaging of *C. sinensis* and *O. viverrini* infestation shows similar findings, which are present in moderate and severe infestation.[35] The principal abnormality is the diffuse dilation of the peripheral intrahepatic bile ducts, often with normal or minimally dilated central and extrahepatic ducts (Fig. 6.18). The peripheral dilation results from the predilection of the fluke for these ducts. Active infection is suggested by increased periportal echoes (likely representing edema) and floating echogenic foci in the gallbladder, representing the flukes or debris.[35] The biliary dilation may persist even after treatment. Chronic infection by these flukes has been directly linked to **cholangiocarcinoma** and is postulated as a cause of recurrent pyogenic cholangitis.

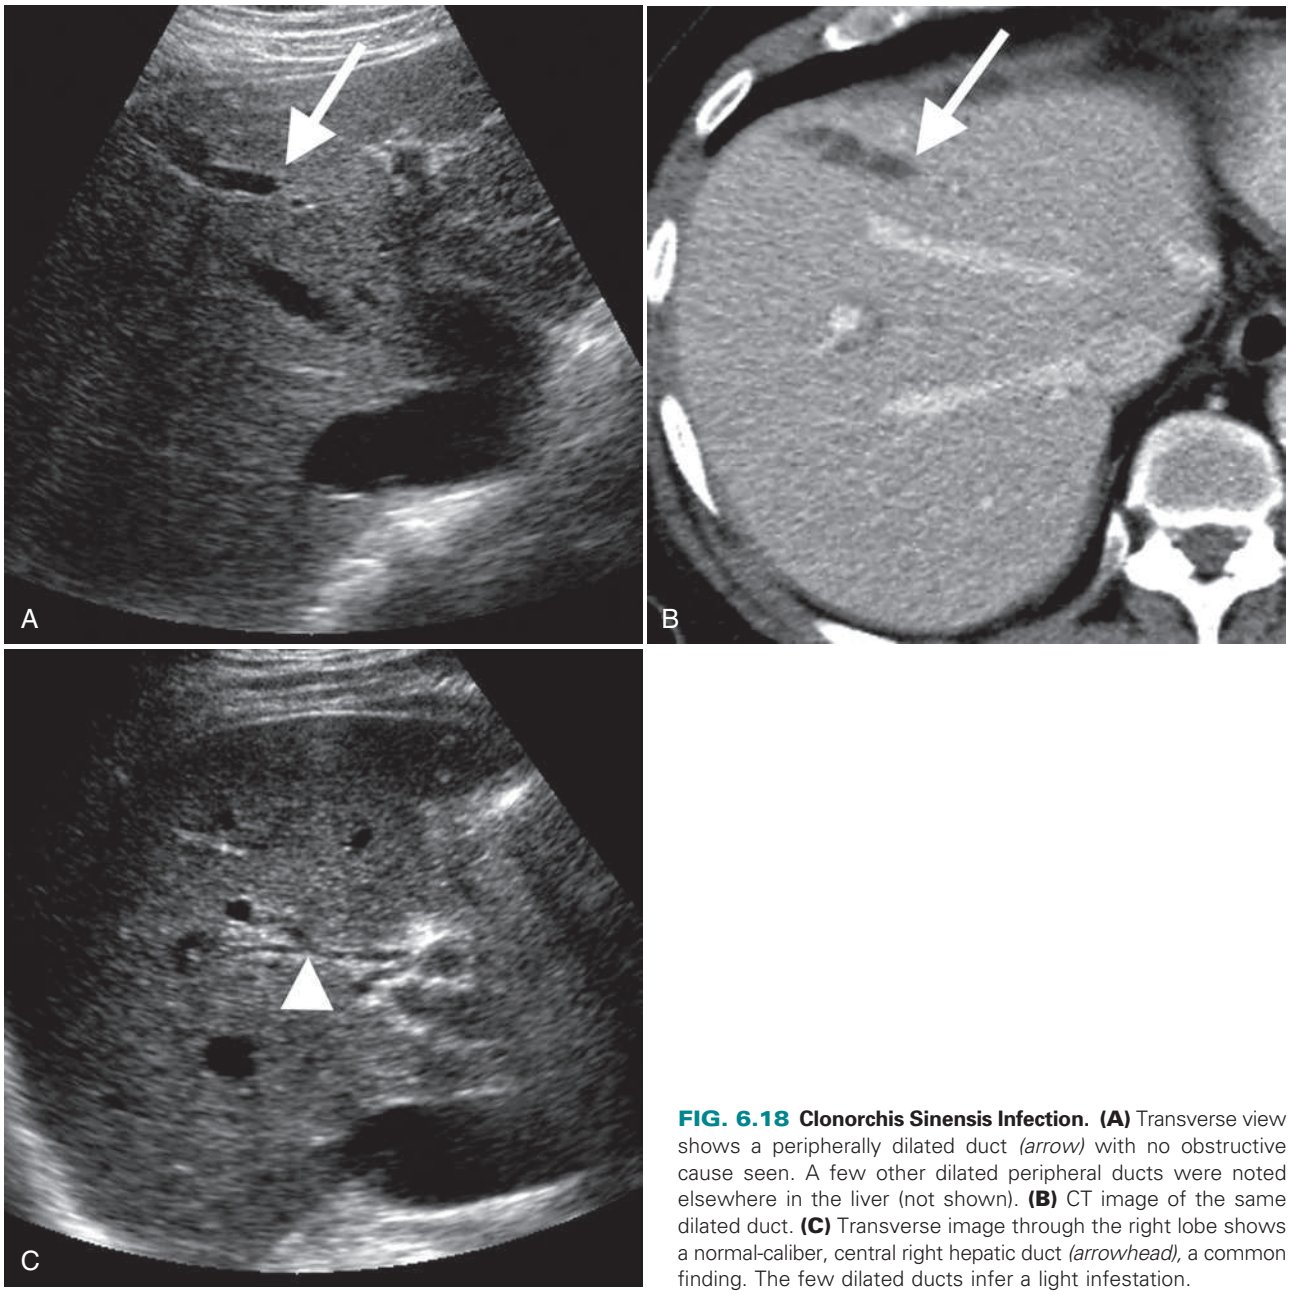

FIG. 6.18 Clonorchis Sinensis Infection. (A) Transverse view shows a peripherally dilated duct *(arrow)* with no obstructive cause seen. A few other dilated peripheral ducts were noted elsewhere in the liver (not shown). **(B)** CT image of the same dilated duct. **(C)** Transverse image through the right lobe shows a normal-caliber, central right hepatic duct *(arrowhead),* a common finding. The few dilated ducts infer a light infestation.

The imaging of *O. felineus* infestation has not been systematically described.

Recurrent Pyogenic Cholangitis

Recurrent pyogenic cholangitis has been known by other names, including **hepatolithiasis** and (now obsolete) **Oriental cholangiohepatitis.** It is a disease characterized by chronic biliary obstruction, stasis, and stone formation, leading to recurrent episodes of acute pyogenic cholangitis. Its incidence is highest in Southeast and East Asia. It is rare and sporadic in other populations. Although liver fluke infections (especially *C. sinensis*), malnutrition, and portal bacteremia have all been implicated, the cause of recurrent pyogenic cholangitis remains unknown.[36] Any segment of the liver may be affected, but the lateral segment of the left lobe is most often involved. Acute complications of the disease, most importantly sepsis, may be fatal and may need urgent percutaneous biliary decompression or surgery. The chronic stasis and inflammation eventually lead to severe atrophy of the affected segment. Biliary cirrhosis and cholangiocarcinoma are long-term complications. The treatment of hepatolithiasis lies in repeated biliary dilation and stone removal.[37]

Ultrasound is often used for both screening and monitoring of recurrent pyogenic cholangitis.[19] The typical **appearance on sonography** is dilated ducts filled with sludge and stones, confined to one or more segments of the liver (Figs. 6.19 and 6.20). Patients may also have multiple echogenic masses in the liver, and recognizing that these, in fact, lie within extremely dilated ducts requires care. When dilated ducts are identified, their

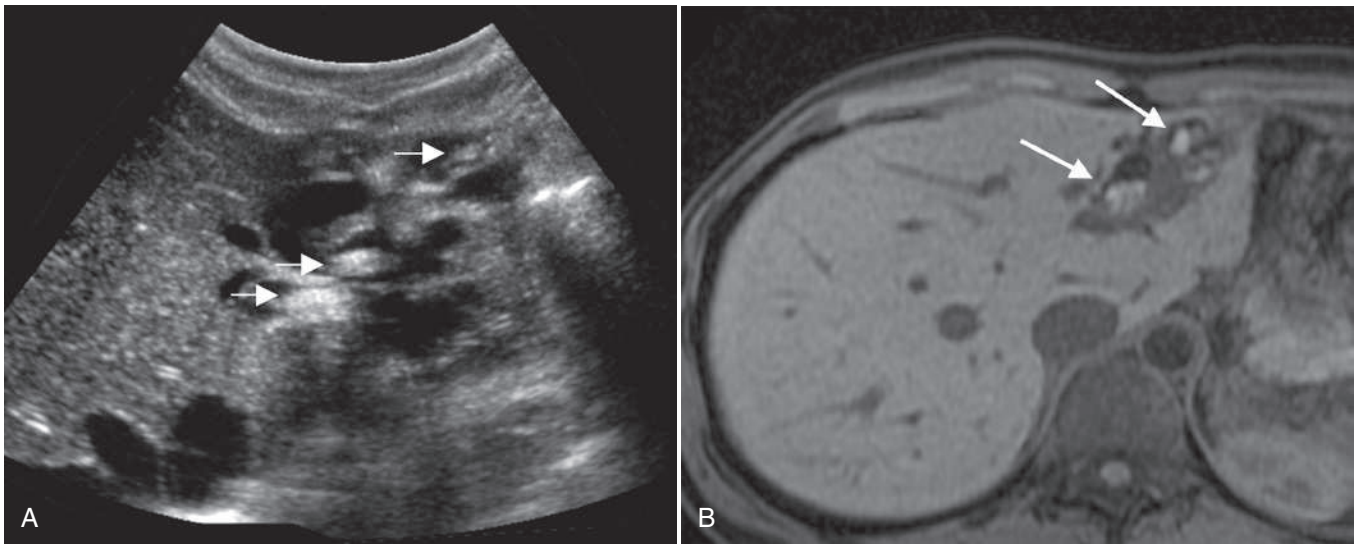

FIG. 6.19 Segmental Recurrent Pyogenic Cholangitis. (A) Transverse sonogram and **(B)** T1-weighted MRI scan depict severe atrophy of segment 3 around dilated, stone-filled ducts *(arrows).*

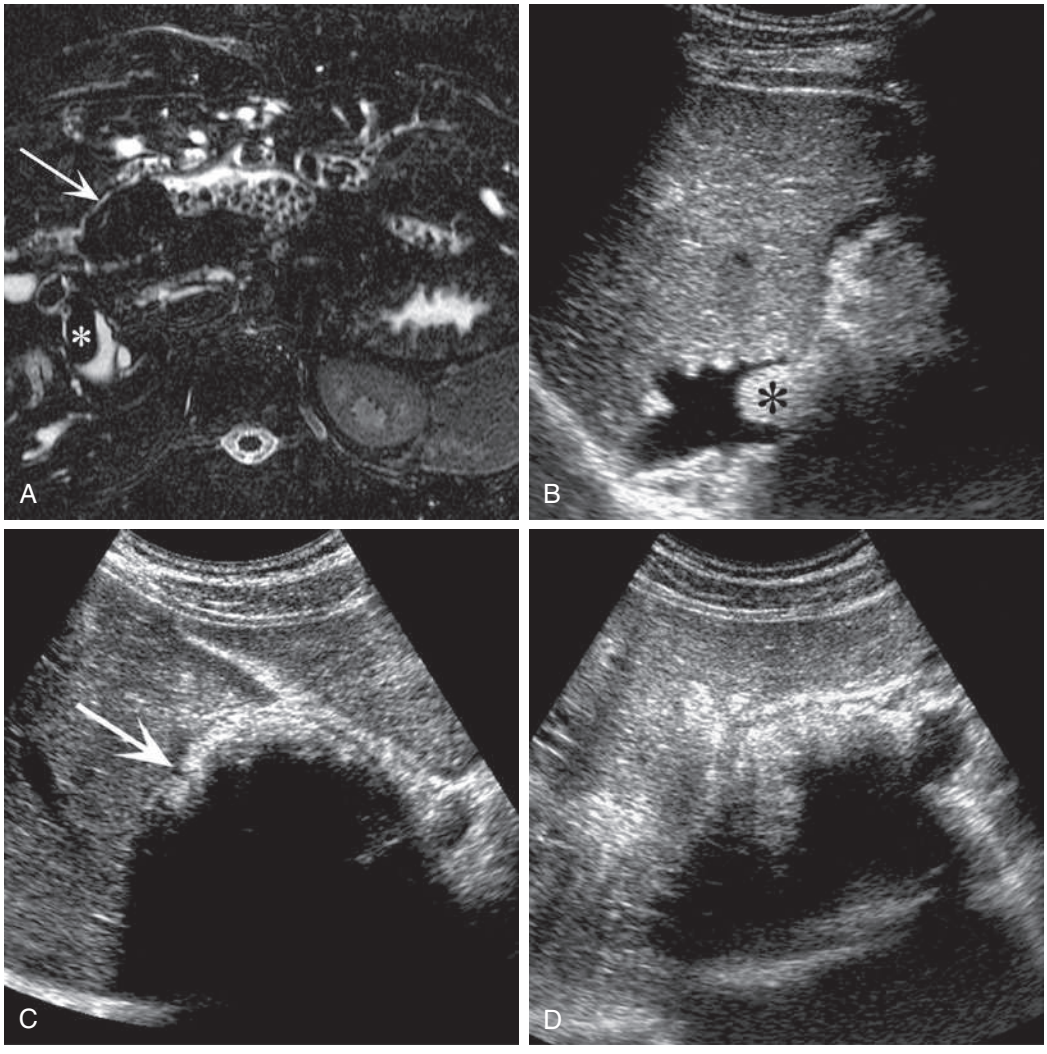

FIG. 6.20 Recurrent Pyogenic Cholangitis. (A) Transverse MRCP view through the liver demonstrates greatly dilated biliary tree filled with stones. **(B)** Transverse ultrasound image of the right lobe shows a large stone (*) in the dilated right posterior duct, corresponding to abnormality on MRCP view. **(C)** Huge stone in the central duct *(arrow)* with marked posterior acoustic shadowing. **(D)** Multiple small stones in the left lobe, which appear as a masslike, echogenic conglomerate on the sonogram. This is the most common appearance of recurrent pyogenic cholangitis, especially when accompanied by atrophy of the hepatic parenchyma.

contents may be hypoechoic or echogenic, and the stones may not show shadowing. With severe atrophy of the affected segment, minimal liver parenchyma may be present, and the crowded, stone-filled ducts may appear as a single, heterogeneous mass.

Ascariasis

Ascaris lumbricoides is a parasitic roundworm estimated to infect up to one-quarter of the world's population. It uses a **fecal-oral route** of transmission and is most common in children, presumably because of their lower hygiene.[38] The worm is generally 20 to 30 cm long and up to 6 mm in diameter. It is active within the small bowel and may enter the biliary tree retrogradely through the ampulla of Vater, causing acute biliary obstruction. Generally, infected patients are asymptomatic but may present with biliary colic, cholangitis, acalculous cholecystitis, or pancreatitis.

The **appearance** of biliary ascariasis on sonography depends on the number of worms within the bile ducts at the time of the study. Most often, a single worm is identified that appears as a tube or as parallel echogenic lines within the bile ducts. The appearance is similar to a biliary stent, which should be excluded on clinical history. On the transverse view, the rounded worm surrounded by the duct wall gives a target appearance. The worm may be folded on itself or may occupy any portion of the ductal system, including far into the liver parenchyma, close to the capsule, or within the gallbladder. Movement of the worm during the scan facilitates the diagnosis. When infestation is heavy, multiple worms may lie adjacent to each other within a distended duct, resembling spaghetti. Occasionally, the worms may appear as an amorphous, echogenic filling defect, making the diagnosis more difficult.[38]

HIV Cholangiopathy

Also known as acquired immunodeficiency syndrome **(AIDS) cholangitis,** human immunodeficiency virus (HIV) cholangiopathy is an inflammatory process affecting the biliary tree in the advanced stages of HIV infection. It is most often caused by an opportunistic infection and therefore occurs in patients with CD4 counts of less than 100. Patients present with severe RUQ pain or epigastric pain, a nonicteric cholestatic picture, and greatly elevated serum alkaline phosphatase with a normal bilirubin level. In most patients a pathogen is recovered, usually ***Cryptosporidium*** or, less often, **cytomegalovirus.**[39]

Sonography has been advocated as the first imaging test for assessment of HIV cholangiopathy (Fig. 6.21). A negative scan

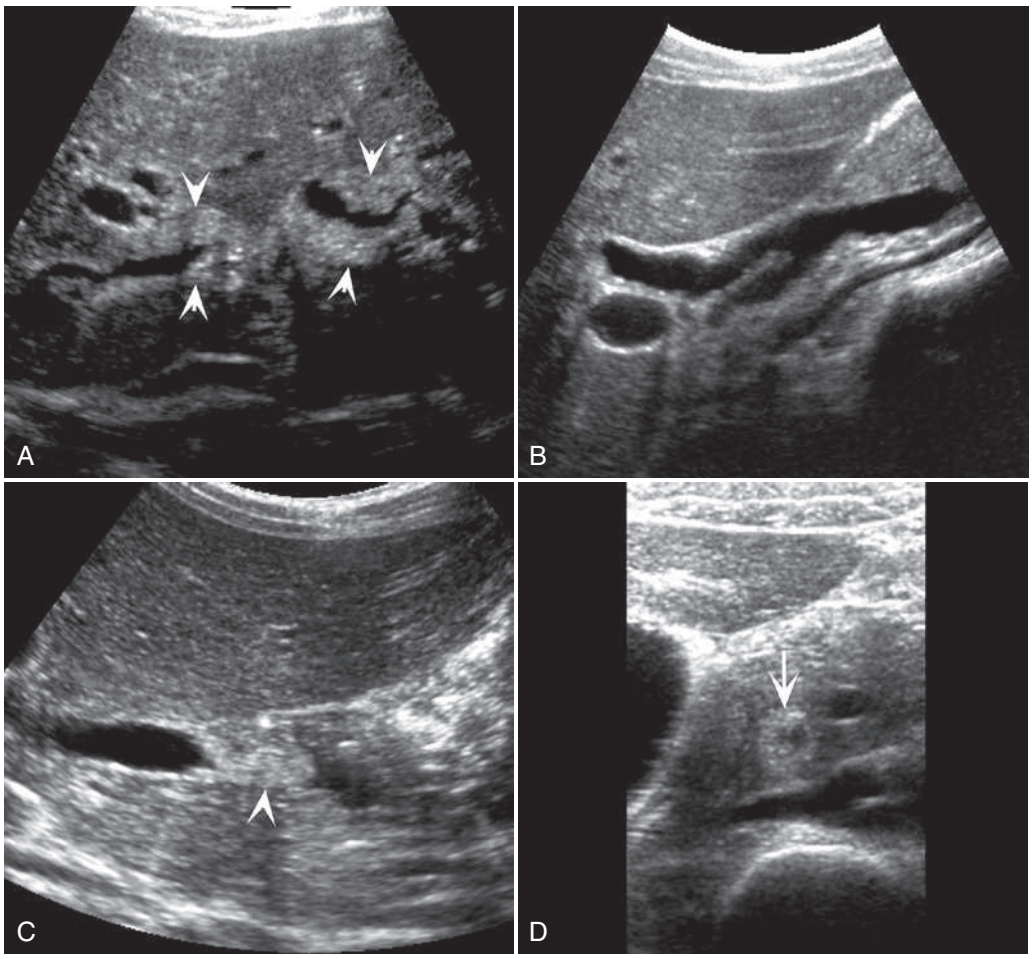

FIG. 6.21 HIV Cholangiopathy. (A) Intrahepatic biliary tree. Note the thick rind of echogenic tissue *(arrowheads)* surrounding the central portal triads and causing irregular narrowing of the bile ducts. **(B)** Common bile duct (CBD) is dilated, and its wall is minimally irregular. **(C)** Papillary stenosis. The dilated CBD abruptly tapers in an echogenic, inflamed ampulla *(arrowhead).* **(D)** Transverse view of ampulla *(arrow),* which is enlarged and echogenic, viewed in the caudal aspect of pancreatic head.

effectively rules out the disease. The findings include the following:

- Bile duct wall thickening of the intrahepatic and extrahepatic biliary tree.
- Focal strictures and dilations identical to those of primary sclerosing cholangitis.
- Dilation of the CBD caused by an inflamed and stenosed papilla of Vater (papillary stenosis). The inflamed papilla itself may be seen as an echogenic nodule protruding into the distal duct.[40]
- Diffuse gallbladder wall thickening.[41]

Immune-Related Diseases of the Biliary Tree

Primary Biliary Cirrhosis and Autoimmune Cholangitis

Primary biliary cirrhosis and autoimmune cholangitis (also called **autoimmune cholangiopathy**) affect biliary ductules that are too small to resolve by imaging. Only gross changes in the liver architecture resulting from biliary cirrhosis are detected. **Biliary cirrhosis,** resulting from any cause of chronic diffuse biliary obstruction, appears as diffusely enlarged liver unless the liver disease is end-stage.

Primary Sclerosing Cholangitis

Sclerosing cholangitis is a chronic inflammatory disease process affecting the biliary tree. If the cause of the disease is unknown, the term *primary sclerosing cholangitis* is used.

Primary sclerosing cholangitis is a chronic disease affecting the entire biliary tree. The process involves a fibrosing inflammation of the small and large bile ducts, leading to biliary strictures and cholestasis and eventually biliary cirrhosis, portal hypertension, and hepatic failure.[42,43] It occurs more frequently in men, with median age of 39 years at diagnosis.[38] About 80% of the patients have concomitant **inflammatory bowel disease,** typically **ulcerative colitis,** but this association occurs less often in a non-Western population. It may also occur with other autoimmune disorders.[36]

Most patients diagnosed with primary sclerosing cholangitis are asymptomatic. Ultrasound is a key component of the multimodality assessment of patients with this disease. The high spatial resolution of ultrasound allows for detection of minute early changes that can be missed with MRCP. Sonographic findings include irregular, circumferential bile duct wall thickening of varying degree, encroaching on and narrowing the lumen (Fig. 6.22, Videos 6.5 and 6.6). Focal strictures and dilations of the bile ducts ensue. The extrahepatic disease is more easily visible. A high degree of suspicion and careful examination of the portal triads in all hepatic segments is required to detect intrahepatic ductal involvement. **Irregularity of the thickened bile duct mucosa** is a key feature that should be sought. An earlier study suggested false normal appearance of the intrahepatic bile ducts in 25% of patients.[39] The gallbladder and cystic duct are involved in 15% to 20% of patients.[40] **Choledocholithiasis,** once thought to exclude the disease, is now recognized as a complication and is more frequently seen in symptomatic patients.[41] They are most often nonshadowing (Fig. 6.22D). The stones are easily overlooked and should be specifically sought especially with patients with deteriorating cholestatic liver enzymes. Patients with primary sclerosing cholangitis also have hepatic findings of biliary cirrhosis, namely hepatomegaly, and enlarged periportal lymph nodes. In advanced cases, findings of cirrhosis are present, often with diffuse atrophy of the liver but occasionally manifest as peripheral atrophy with central hypertrophy of the liver.[44]

Cholangiocarcinoma develops in 7% to 30% of patients with primary sclerosing cholangitis and is particularly a difficult diagnosis to make in this setting.[43] Rapid progression of the disease or development of a visible mass is a clue to this complication (Fig. 6.23, Videos 6.7 and 6.8). Hepatic transplantation is required in the latter stages of the disease. Unfortunately, the disease may recur in the transplanted organ in 1% to 20% of patients.[45]

IgG4-Related Cholangitis

Immunoglobulin G subtype 4 (IgG4)–related cholangitis is the biliary manifestation of **IgG4-related disease** or **multifocal systemic fibrosclerosis.** The exact cause of the disease is unknown but is associated with elevation of serum immunoglobulin G and specifically IgG subtype 4 levels in a majority of patients. In the abdomen, the most commonly affected organ is the pancreas, resulting in **autoimmune pancreatitis,** followed by the biliary tree and gallbladder, the kidneys **(interstitial nephritis),** and the retroperitoneum **(retroperitoneal fibrosis).**[46] A history of salivary or lacrimal gland disease is also common. The disease predominates in older patients and is more common in males. Unlike primary sclerosing cholangitis, the disease tends to be **steroid responsive.** IgG4-related cholangitis affects both large and small ducts. There is a lymphoplasmacytic infiltrate about the ducts with associated fibrosis causing strictures; if untreated it can lead to cirrhosis. Given the similarity in imaging appearance to primary sclerosing cholangitis, until recently it has been mistaken for this disease.

Several features help the differentiation or at least direct the referring clinicians to further investigations. In IgG4-related disease, the patient is usually older and the disease may spontaneously resolve or improve. Bile duct wall thickening can be much

IgG4-related sclerosing cholangitis
AIDS cholangiopathy
Bile duct neoplasm[a]
Biliary tract surgery, trauma
Choledocholithiasis
Congenital abnormalities of biliary tract
Ischemic stricturing of bile ducts
Toxic strictures related to intraarterial infusion of floxuridine
Posttreatment for hydatid cyst

[a]Primary sclerosing cholangitis not previously established.
Modified from Narayanan Menon KV, Wiesner RH. Etiology and natural history of primary sclerosing cholangitis. *J Hepatobiliary Pancreat Surg.* 1999;6(4):343-351.[43]

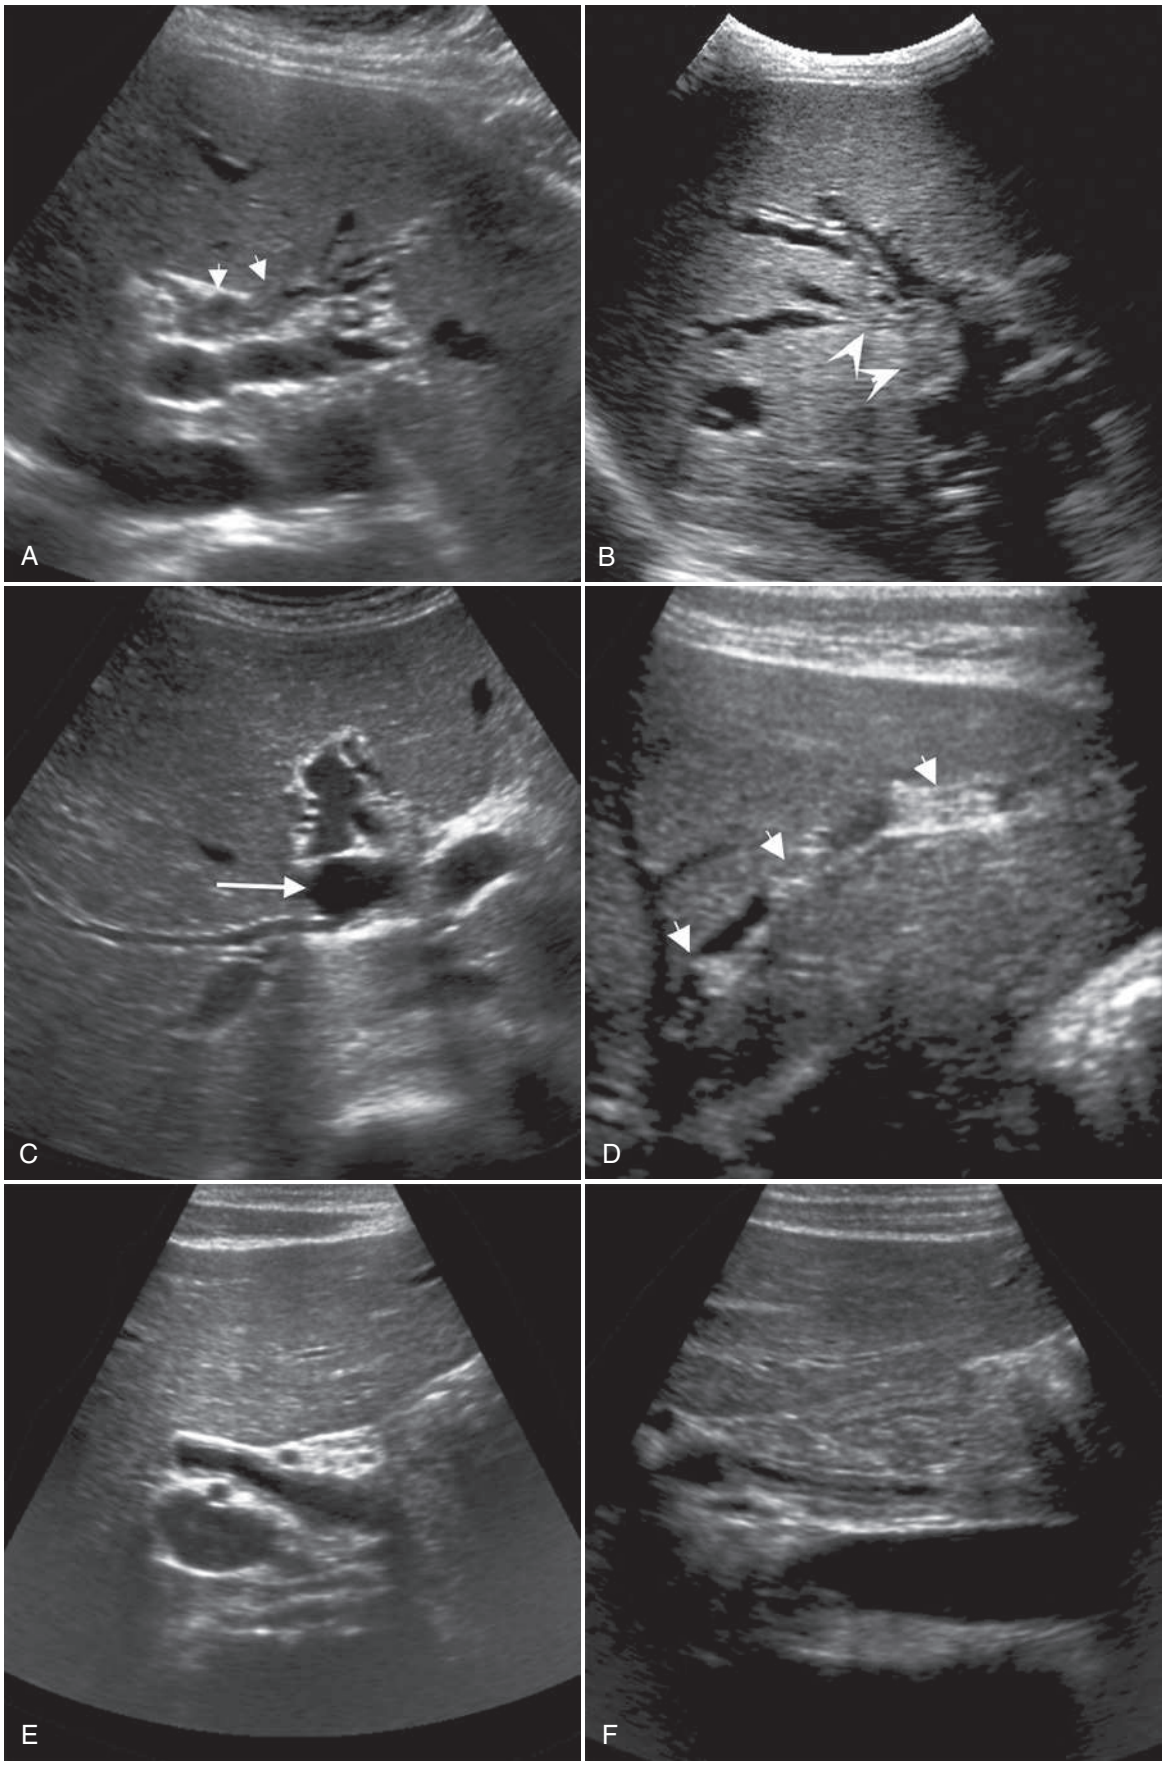

FIG. 6.22 Primary Sclerosing Cholangitis. (A) Isoechoic inflammatory tissue causing obliteration of right and left hepatic ducts *(short arrows)* with proximal dilation. **(B)** Dilated intrahepatic ducts "rat-tail" as they extend centrally toward the hepatic hilum. Note the hypoechoic ductal/periductal tissue obstructing the central ducts *(arrowheads).* **(C)** Saccular diverticula *(arrow)* of the duct are occasionally seen presumably due to distal obstruction. **(D)** Intraductal stones *(short arrows)* are seen, which often do not shadow. **(E)** and **(F)** Common bile duct wall thickening of moderate and severe degrees, respectively. Note the extremely narrowed, anechoic central lumen with a finely serrated appearance. See also Videos 6.5 and 6.6.

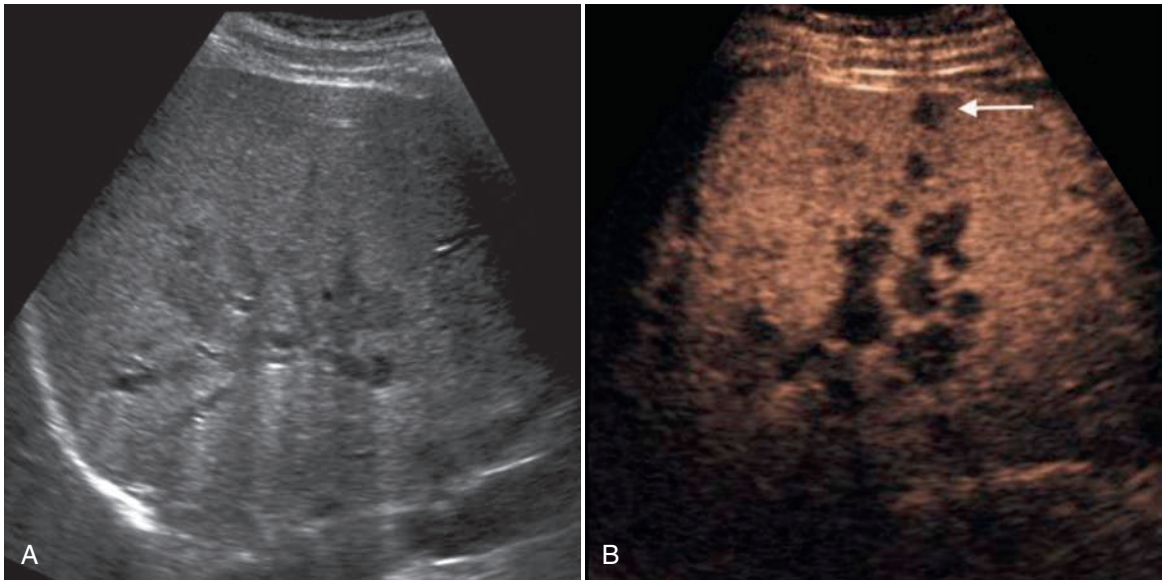

FIG. 6.23 Cholangiocarcinoma in Primary Sclerosing Cholangitis. (A) An infiltrative mass is seen centered on dilated ducts. **(B)** Contrast-enhanced ultrasound in the venous phase improves the visualization of the tumor margins and extent, including a satellite subcapsular focus not visible on the gray-scale scan. See also Videos 6.7 and 6.8.

more pronounced than in primary sclerosing cholangitis (single wall thickness > 3 mm) and can appear masslike (Fig. 6.24).[47] Strictures are longer and continuous as opposed to skip disease in primary sclerosing cholangitis, but mucosal irregularity, which is an important feature of primary sclerosing cholangitis, is difficult to appreciate. Many patients with IgG4-related cholangitis have involvement of other organs, which can be searched for during the scan; pancreatic involvement virtually makes the diagnosis. Many of the changes improve within weeks of commencement of steroid therapy.

Cholangiocarcinoma

Cholangiocarcinoma is an uncommon neoplasm that may arise from any portion of the biliary tree. Its incidence varies geographically and is highest in populations with known risk factors. Overall incidence ranges from 1 or 2 per 100,000 population in the United States, 2 to 6 in other Western countries, 5.5 in Japan, and up to 130 per 100,000 in northeastern Thailand, where the liver fluke *Opisthorchis viverrini* is endemic.[48,49] The frequency of cholangiocarcinoma increases with age, with the peak incidence in the eighth decade. Most cholangiocarcinomas are sporadic, but several risk factors exist, usually related to chronic biliary stasis and inflammation. **Primary sclerosing cholangitis** is the most common risk factor for cholangiocarcinoma in the Western world; the lifetime risk of developing a clinically detectable cholangiocarcinoma in these patients is about 10%.[50] The most common risk factors in other populations are **recurrent biliary infections** and **stone disease.**

Cholangiocarcinomas are classified based on the anatomic location: **intrahepatic,** also called peripheral (≈10%); **hilar,** also called **Klatskin** (≈60%); and **distal** (≈30%).[51] Approximately 90% of cholangiocarcinomas are **adenocarcinomas,** with squamous carcinomas the next most common subtype.[52] Macroscopically, cholangiocarcinomas are divided into three subtypes: sclerosing, nodular, and papillary; the first two subtypes frequently occur together. **Nodular-sclerosing tumors,** the most common subtype, appear as a firm mass surrounding and narrowing the affected duct, with a nodular intraductal component. Most hilar cholangiocarcinomas are of the nodular-sclerosing variety. These tumors incite a prominent desmoplastic reaction and demonstrate a periductal, perineural, and lymphatic pattern of spread along the ducts, as well as subendothelial spread within the ducts. **Papillary cholangiocarcinomas** represent approximately 10% of these tumors and are most common in the distal CBD. Patients present with an intraductal polypoid mass that expands, rather than constricts, the duct.[51,53,54]

The overall prognosis for cholangiocarcinoma is poor. In a large, single-center series, the 5-year survival rate for patients with intrahepatic, hilar, and distal cholangiocarcinoma was 23%, 6%, and 24%, respectively, and improved to only 44%, 11%, and 28% in patients who underwent resection.[55]

Intrahepatic Cholangiocarcinoma

Intrahepatic cholangiocarcinoma, also called **peripheral cholangiocarcinoma,** are the least common location for cholangiocarcinomas, but they represent the second most common primary malignancy of the liver. They arise from the second-order or higher-order branches of the biliary tree within the liver parenchyma, and their histologic origin is different than that of extrahepatic ducts. The incidence of intrahepatic cholangiocarcinomas has been increasing in part because of the increase in numbers of patients with liver cirrhosis and long-term hepatitis C infection.[56] Hepatitis B also has recently been identified as a risk factor.[57] These tumors are associated with a poor prognosis because the mass is often unresectable.[58,59]

The most common manifestation of intrahepatic cholangiocarcinoma is a large hepatic mass. The sonographic appearance is often that of a hypovascular solid mass with heterogeneous

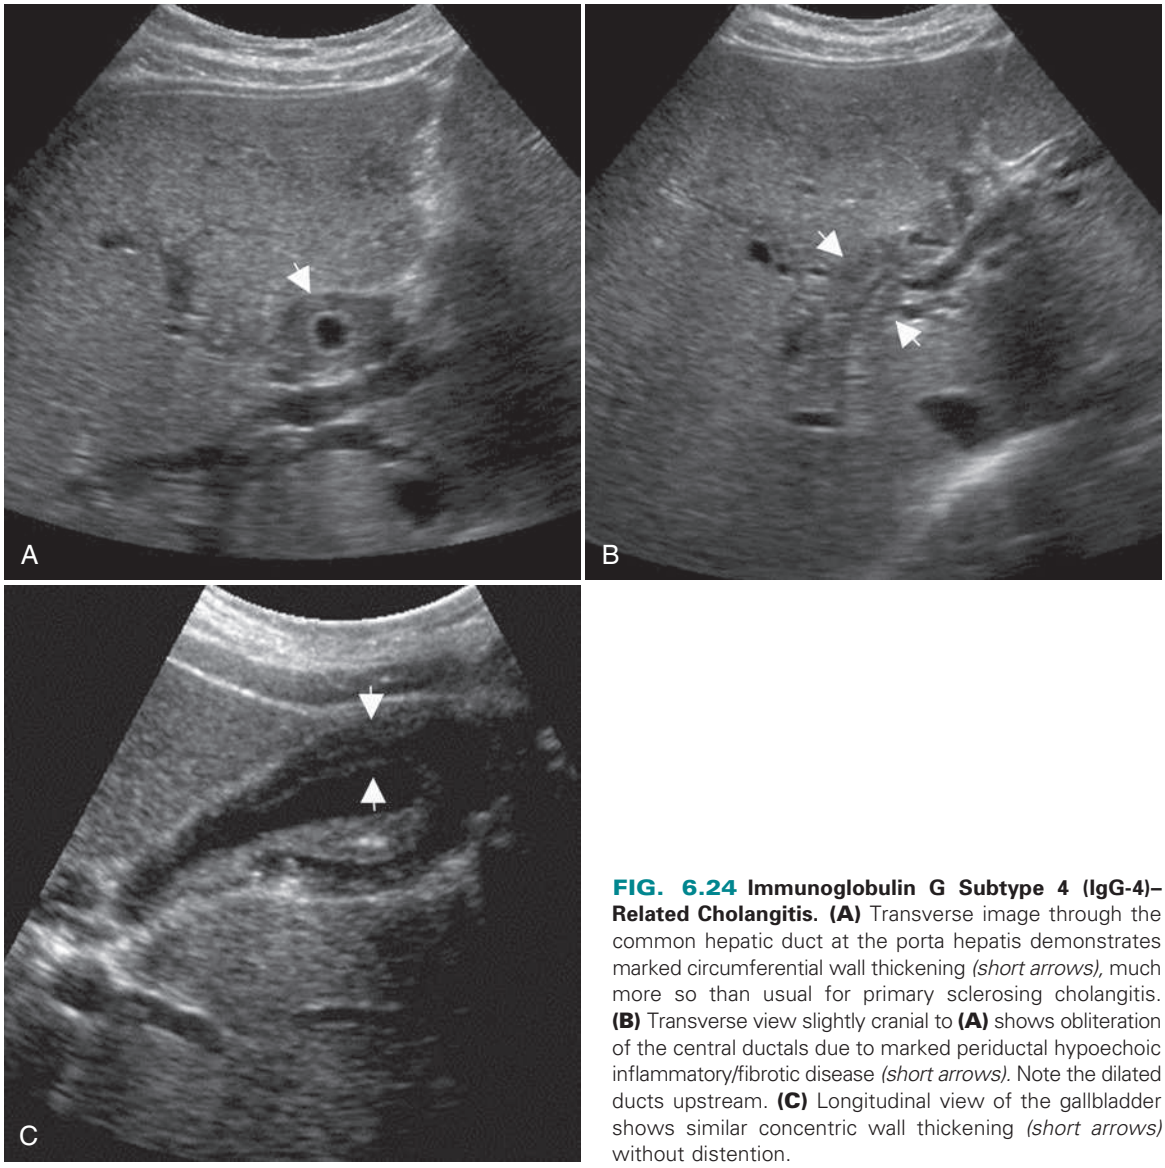

FIG. 6.24 Immunoglobulin G Subtype 4 (IgG-4)–Related Cholangitis. (A) Transverse image through the common hepatic duct at the porta hepatis demonstrates marked circumferential wall thickening *(short arrows),* much more so than usual for primary sclerosing cholangitis. **(B)** Transverse view slightly cranial to **(A)** shows obliteration of the central ductals due to marked periductal hypoechoic inflammatory/fibrotic disease *(short arrows).* Note the dilated ducts upstream. **(C)** Longitudinal view of the gallbladder shows similar concentric wall thickening *(short arrows)* without distention.

echotexture, and it may appear hypoechoic, isoechoic, or hyperechoic (Fig. 6.25). A clue to the differentiation from **hepatocellular carcinoma** is a much higher incidence of **ductal obstruction,** reportedly occurring in 31% of patients with intrahepatic cholangiocarcinoma and only 2% of those with hepatocellular carcinoma.[60,61] Contrast-enhanced ultrasound also provides differentiating features (see Chapter 4 for further discussion). However, a solitary metastasis to the liver may cause intrahepatic ductal obstruction and therefore may be difficult to distinguish.[62]

A more unusual manifestation of intrahepatic cholangiocarcinoma is a purely intraductal mass, called **intraductal intrahepatic cholangiocarcinoma.** These polypoid masses distend the affected ducts, often third-order or fourth-order branches, spreading within the duct and filling it with **mucin.** These tumors have a much better prognosis and are thought to be histologically separate from other intrahepatic cholangiocarcinomas, resembling papillary tumors of the extrahepatic bile ducts.[59,63] The most common appearance of the intraductal intrahepatic cholangiocarcinoma is one or more polypoid masses confined to the bile ducts. Abundant mucin production, manifest sonographically with a subtle layered appearance, can greatly distend the affected lobar and distal ducts (Fig. 6.26). Occasionally a focal mass is not evident as the disease diffusely affects the bile ducts, as a result of **biliary papillomatosis,** a rare condition in which there is diffuse papillary adenoma formation throughout the biliary tree.[64] A less common form may present as a solid mass within a cystic structure, representing tumor within an extremely distended duct that does not communicate with the biliary tree (Fig. 6.27).

Hilar Cholangiocarcinoma

The correct identification and staging of hilar cholangiocarcinoma are challenging with all imaging modalities because of the tumor's **desmoplastic** nature (causing fibrous tissue formation), its peribiliary and subendothelial patterns of growth, and the

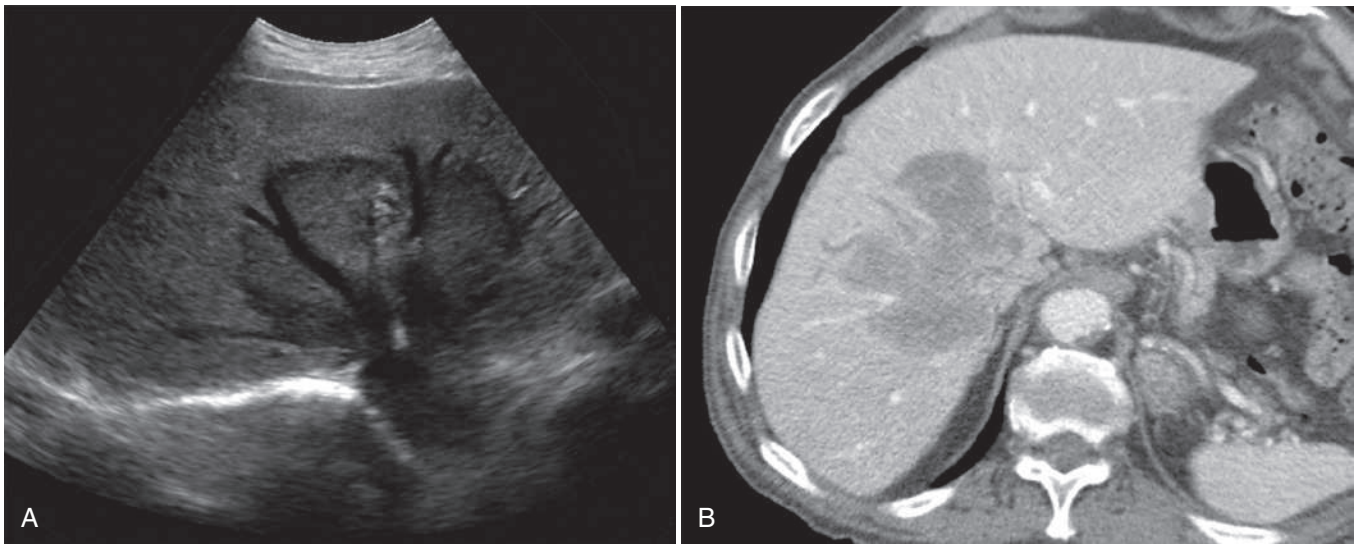

FIG. 6.25 Peripheral Cholangiocarcinoma. (A) Ultrasound and **(B)** CT images depict a solid mass encasing but not obliterating the right and middle hepatic veins, a finding suggestive of peripheral cholangiocarcinoma.

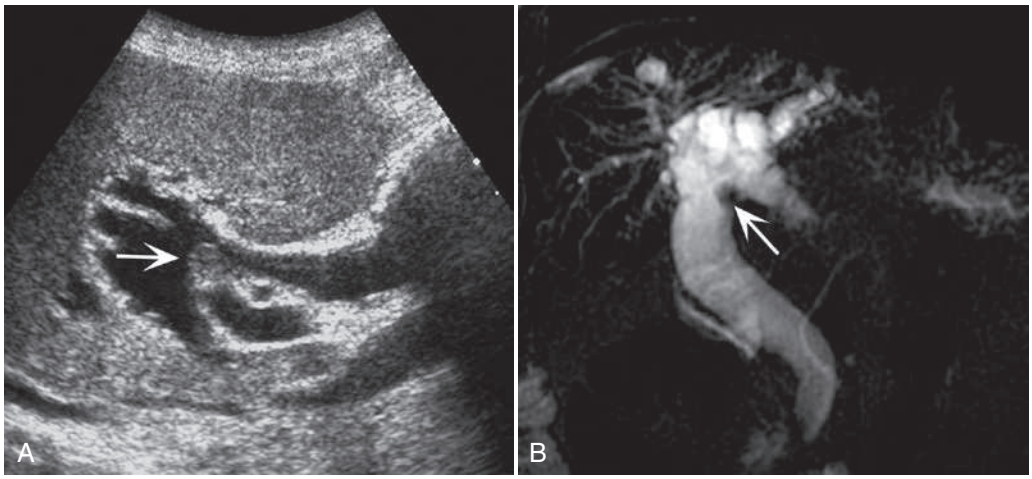

FIG. 6.26 Intraductal Papillary, Mucin-Producing Tumor of Bile Ducts. (A) Ultrasound and **(B)** MRCP images show papillary tumor arising from the common hepatic duct *(arrow)* and causing diffuse ductal dilation due to excessive mucin production.

complex anatomy of the porta hepatis, with structures lying just outside the liver and surrounded by connective tissue. Ultrasound plays an important role in both detection and staging of hilar cholangiocarcinomas because it is often the first modality used in assessment of these tumors. Furthermore, ultrasound is often performed before any biliary manipulation and stent placement. Because biliary intervention often obscures the intraductal disease and causes secondary bile duct thickening, sonography may be the only cross-sectional modality to assess the unmanipulated ducts. Most patients with hilar cholangiocarcinoma present for a sonographic evaluation with jaundice, pruritus, and elevated cholestatic liver parameters, or with vague symptoms and elevated serum alkaline phosphatase or γ-glutamyl transpeptidase levels.

Patterns of Tumor Growth. Hilar cholangiocarcinomas often begin in either the right or the left bile duct and extend both proximally into higher-order branches and distally into the CHD and contralateral bile ducts. The spread of tumor may be subendothelial, or within the peribiliary connective tissue, leading to obstruction or irregular ductal narrowing. The tumors also extend outside the ducts to involve adjacent portal vein and arteries. Chronic obstruction, especially if accompanied with portal vein involvement, leads to atrophy of the involved lobe. Nodal disease often begins in the porta hepatis and within the hepatoduodenal ligaments (local nodes) and extends to celiac, superior mesenteric, peripancreatic, and posterior pancreatoduodenal stations (distant nodes).[65] Metastases are usually to the liver and peritoneal surfaces.

Treatment and Staging. Curative treatment of cholangiocarcinoma requires surgical resection; the vast majority of patients with unresectable disease die within 12 months of diagnosis.[51] The current surgical approach to patients with hilar cholangiocarcinoma is resection of the involved lobe with extensive hilar dissection to remove tumor extending to the contralateral lobe (extended lobectomy). A biliary-enteric anastomosis is created to allow bile drainage. Currently, no widely used staging systems

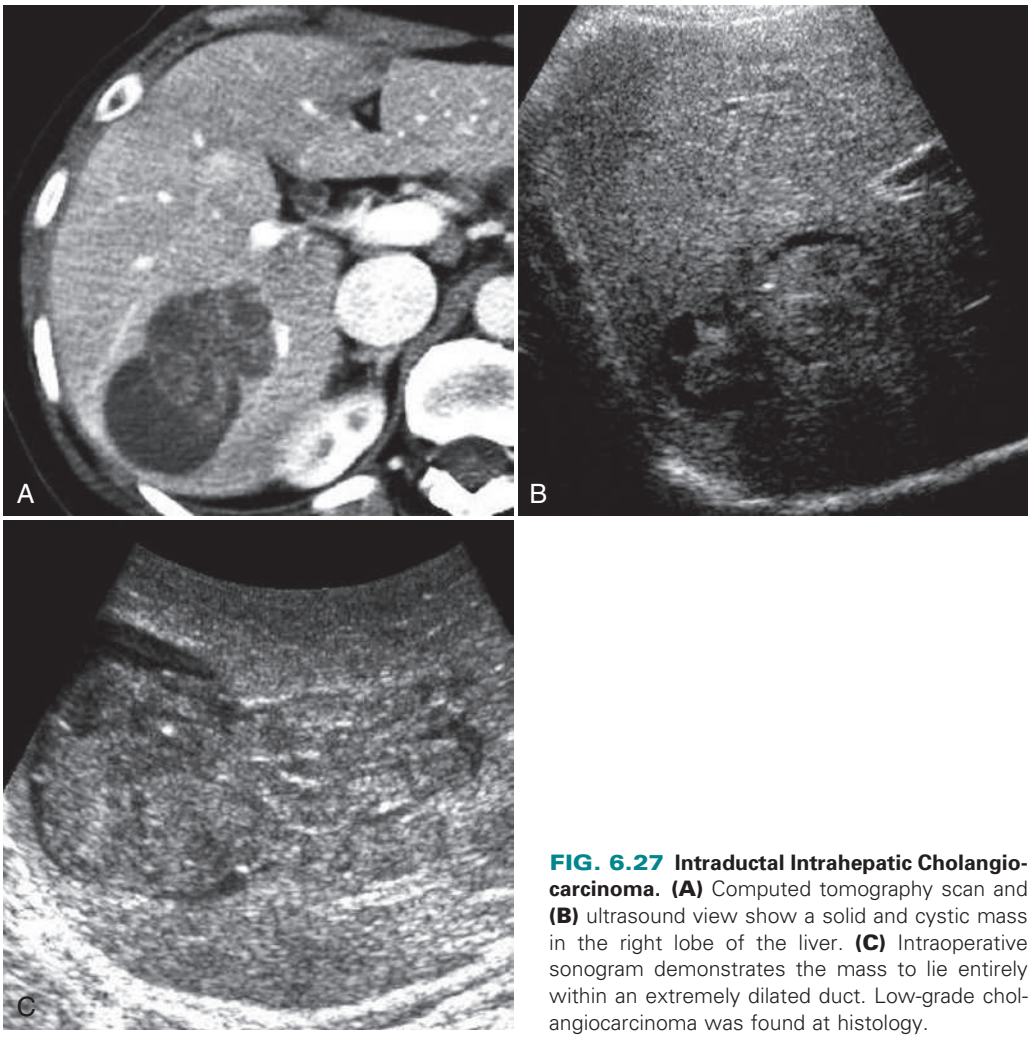

FIG. 6.27 Intraductal Intrahepatic Cholangiocarcinoma. (A) Computed tomography scan and **(B)** ultrasound view show a solid and cystic mass in the right lobe of the liver. **(C)** Intraoperative sonogram demonstrates the mass to lie entirely within an extremely dilated duct. Low-grade cholangiocarcinoma was found at histology.

accurately stratify patients based on surgical resectability. However, Jarnagin et al.[65] proposed a system that allows for preoperative staging of hilar cholangiocarcinoma. Because a lobectomy is performed, the remaining liver parenchyma, its portal vein, hepatic artery, and at least some proximal length of its lobar bile duct (first-order branch of CHD) should ideally be free of disease. The main portal vein and proper hepatic artery should also ideally be disease free. The remaining liver should not have undergone significant atrophy because it may not be able to maintain hepatic function. Although regional nodes may be removed en bloc with the tumor, distant nodal disease precludes resection. Advancements in surgical techniques now allow biliary-enteric anastomoses using second-order ducts and vessel resection with reconstruction; therefore criteria for resectability vary according to the age of the patient and local surgical preference.[66]

Assessment by Conventional and Doppler Sonography. An accurate assessment of hilar cholangiocarcinoma requires diligent, hands-on involvement by the responsible physician. The use of various views and patient positions as well as familiarity with biliary anatomy and common variants significantly improves sonographic performance. Once dilated intrahepatic ducts have been detected, the following parameters should be assessed:

- Level of the obstruction
- Presence of a mass
- Lobar atrophy

Criteria for Unresectable Hilar Cholangiocarcinoma

Hepatic duct involvement up to secondary biliary radicles bilaterally
Encasement or occlusion of the main portal vein proximal to its bifurcation
Atrophy of one hepatic lobe with encasement of contralateral portal vein branch
Atrophy of one hepatic lobe with contralateral involvement of secondary biliary radicles
Distant metastases (peritoneum, liver, and lung)

With permission from Jarnagin WR. Cholangiocarcinoma of the extrahepatic bile ducts. *Semin Surg Oncol.* 2000;19(2):156-176.[51]

- Patency of main, right, and left portal veins
- Encasement of hepatic artery
- Local and distant adenopathy
- Presence of metastases

Dilation of the higher-order intrahepatic bile ducts with nonunion of the right and left ducts is the classic appearance of hilar cholangiocarcinomas[62] (Figs. 6.28 and 6.29). When encountered, dilated ducts should be followed centrally toward the hepatic hilum to determine which order of branching (segmental ducts and higher or right/left hepatic ducts) is involved with tumor. Tumor extension into segmental ducts bilaterally precludes resection.

The obstructing tumor is not always visualized by sonography. Rates of sonographic detection of masses range from 21% to 87%, with more recent studies showing higher rates.[67-69] When a mass is not directly visualized, its presence can be inferred based on the level of obstruction, although this often underestimates the tumor extent.[70] **Lobar atrophy** leads to crowding of the dilated bile ducts and, if long-standing, a shift in the axis of the liver caused by hypertrophy of the contralateral side. The atrophy of the lobe is often accompanied by obliteration of its portal vein and precludes its resection. **Differences in lobar echogenicity,** caused by the varying degree of ductal and vascular obstruction between the two lobes, is an uncommon finding (Fig. 6.30).

The main, right, and left **portal veins** should all be examined with both gray-scale and color Doppler sonography. Narrowing of the right or left portal veins leads to compensatory increased flow in the accompanying hepatic artery; when prominent arterial signal is noted on color Doppler, the portal venous flow should be carefully examined (see Fig. 6.30). Tumor encasing, narrowing, or obliterating the main portal vein or the proper hepatic artery renders the tumor unresectable, unless en bloc resection of the vessels is contemplated. Detection of the extrahepatic tumor infiltration and early peritoneal metastases is difficult with sonography, and CT or MRI is recommended as an adjunct for preoperative assessment.

Assessment by Contrast-Enhanced Sonography. The role of contrast is in the assessment of the liver-invasive component of cholangiocarcinoma, and the differentiation of intraductal enhancing tumor from sludge and debris within the duct. Both the liver-specific phase of enhancement in agents that are retained by the reticuloendothelial system and the venous/delayed phase in agents that remain purely within the intravascular space are useful in this regard. Depending on the agent, the delayed or liver-specific phase of enhancement significantly increases the contrast difference between the liver parenchyma and invasive tumors that show washout or lack uptake. Therefore the invasive component of cholangiocarcinoma—not seen in a significant minority of patients—becomes visible in most, if not all, cases[70] (see Fig. 6.23; Fig. 6.31, Videos 6.7 and 6.8). This improved visibility allows for improved performance of sonography in the staging of hilar cholangiocarcinomas.[70]

Distal Cholangiocarcinoma

Distal cholangiocarcinomas are clinically indistinguishable from the hilar forms, with progressive jaundice seen in 75% to 90% of patients.[51] Although the nodular-sclerosing subtype still predominates, polypoid masses are seen more frequently. Surgical resection is the most effective therapy, so a careful search for spread that would preclude resection is vital. The tumor may locally extend cranially within the ducts, even involving the cystic and right and left hepatic ducts; therefore the superior extent of the tumor must be clearly defined. The tumor may also extend beyond the duct walls. Patients may present with a distal obstructive mass with identical appearance to pancreatic adenocarcinoma. The status of the adjacent vascular structures must be determined, including portal and superior mesenteric veins and common hepatic artery. Spread to **lymph nodes** adjacent to the tumor is common. Spread to more distant nodes, such as celiac, superior mesenteric, and periportal regions may preclude resection.[51] Surgical approach to a distal cholangiocarcinoma is a pancreaticoduodenectomy.

On sonography the distal cholangiocarcinoma has a variable appearance. A **polypoid tumor** appears as a duct-expanding, well-defined intraductal mass, often with no internal vascularity (Fig. 6.32). The **nodular-sclerosing tumor** causes focal irregular ductal constriction and duct wall thickening. In more advanced disease the tumor appears as a hypoechoic, hypovascular mass with poorly defined margins invading adjacent structures.

Metastases to Biliary Tree

Metastases to the biliary tree mimic the varied appearance of cholangiocarcinoma, affecting both the intrahepatic and extrahepatic ducts (Fig. 6.33). The history of past or concurrent malignancy along with multiple lesions should suggest metastases. In our experience the breast, colon, and skin (melanoma) constitute the primary sites of malignancy.

THE GALLBLADDER

Anatomy and Normal Variants

The gallbladder is a pear-shaped organ lying in the inferior margin of the liver, between the right and left lobes (Fig. 6.34). The middle hepatic vein lies in the same anatomic plane and may be used to help find the **gallbladder fossa.** The **interlobar fissure,** the third structure separating the two hepatic lobes, extends from the origin of the right portal vein to the gallbladder fossa. This fissure has been seen in up to 70% of hepatic ultrasound studies[71] and may also be used as a landmark for the gallbladder fossa. The gallbladder is divided into the fundus, body, and neck; the fundus is the most anterior, and often inferior, segment. In the region of the gallbladder neck, there may be an infundibulum, called the **Hartmann pouch,** which is a common location for impaction of gallstones.[11]

The gallbladder derives as an outpouching from the embryonic biliary tree. The proximal portion of the pouch forms the cystic duct, and the distal portion forms the gallbladder. Within the cystic duct (and sometimes the gallbladder neck) are small mucosal folds called the **spiral valves of Heister;** these are occasionally identified on sonography. During its initial development, the gallbladder lies in an intrahepatic position, but as it

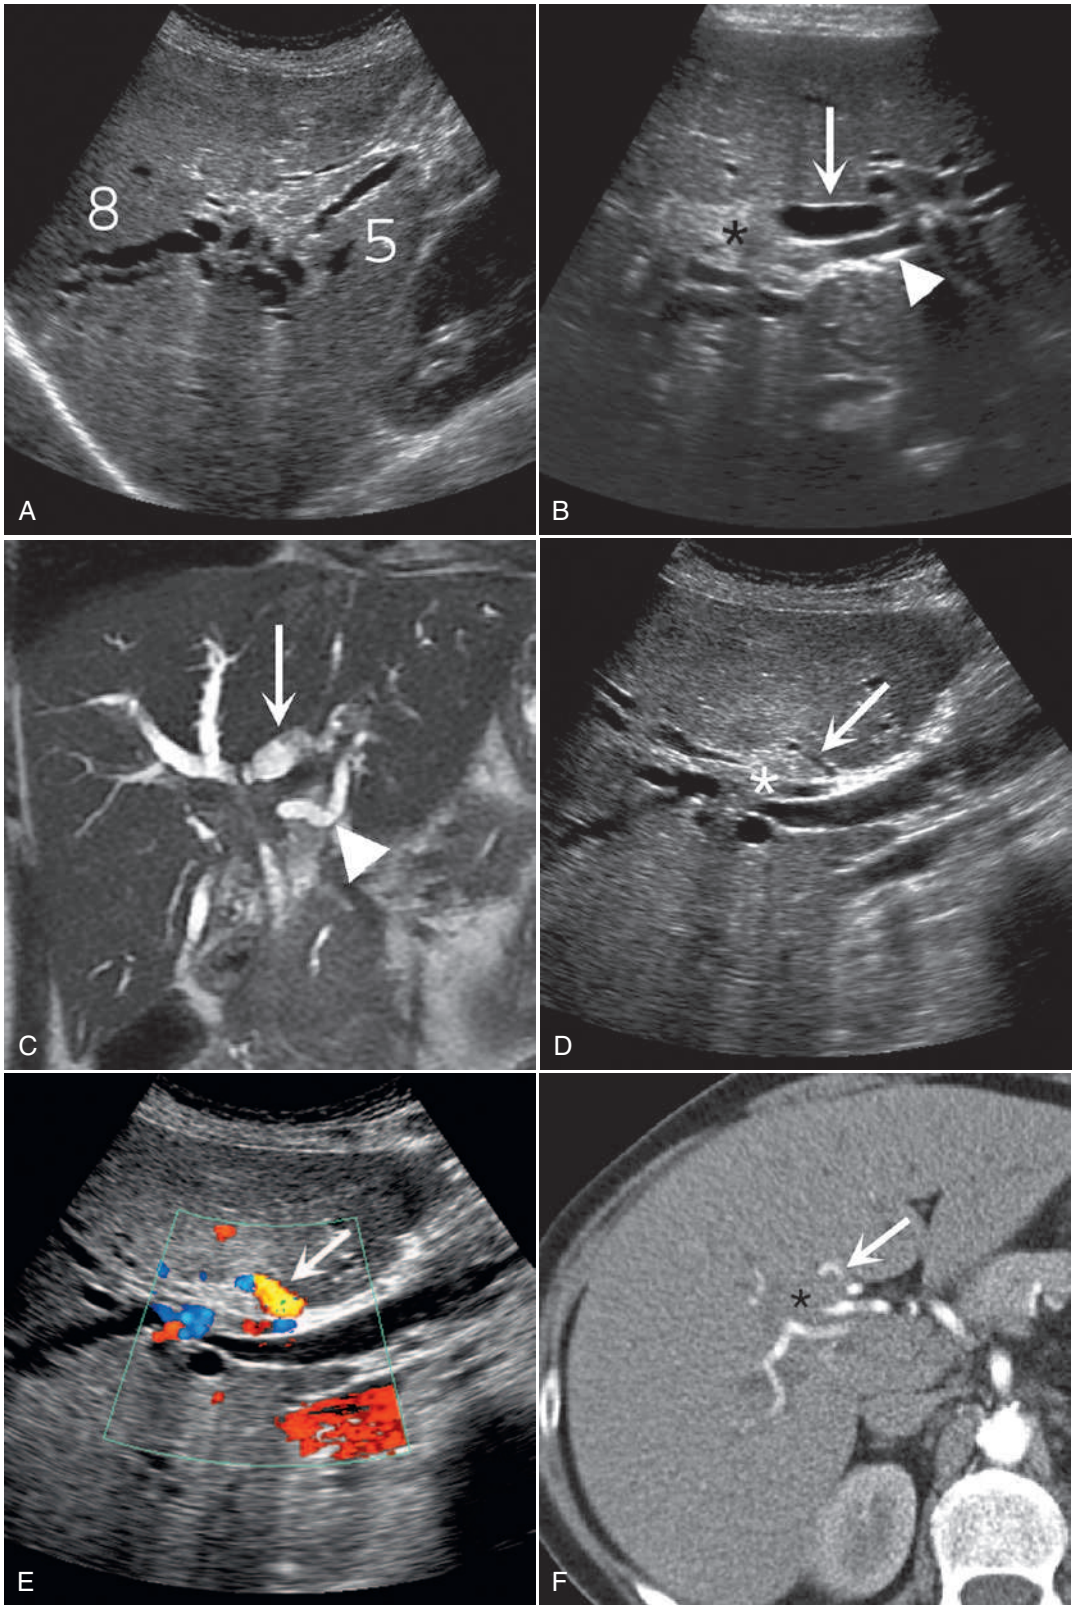

FIG. 6.28 Resectable Hilar Cholangiocarcinoma. (A) Sagittal image of the right lobe shows an invasive central echogenic tumor with segmental dilation of the ducts of segments 8 and 5, indicating second-order branch involvement. **(B)** Transverse view of the central left lobe shows the tumor (*) obstructing the distal left hepatic duct *(arrow)* and an aberrant segment 4 duct *(arrowhead)*. **(C)** Coronal T2-weighted MRI confirms the ultrasound findings of the central tumor obstructing the left hepatic *(arrow)* and aberrant segment 4 ducts *(arrowhead)*. **(D)** Transverse image of the porta hepatis depicts the tumor (*) narrowing the right portal vein and displacing branches of the right hepatic artery *(arrow)*. **(E)** Doppler image (same plane as **D**) confirms the right hepatic artery involvement. **(F)** Corresponding CT image in the arterial phase also shows intimate contact of tumor (*) with right hepatic artery branches *(arrow)*. The tumor did not extend deep into the left lobe, and the main and left hepatic arteries and portal vein were not involved; therefore the patient underwent an extended right-sided hepatectomy.

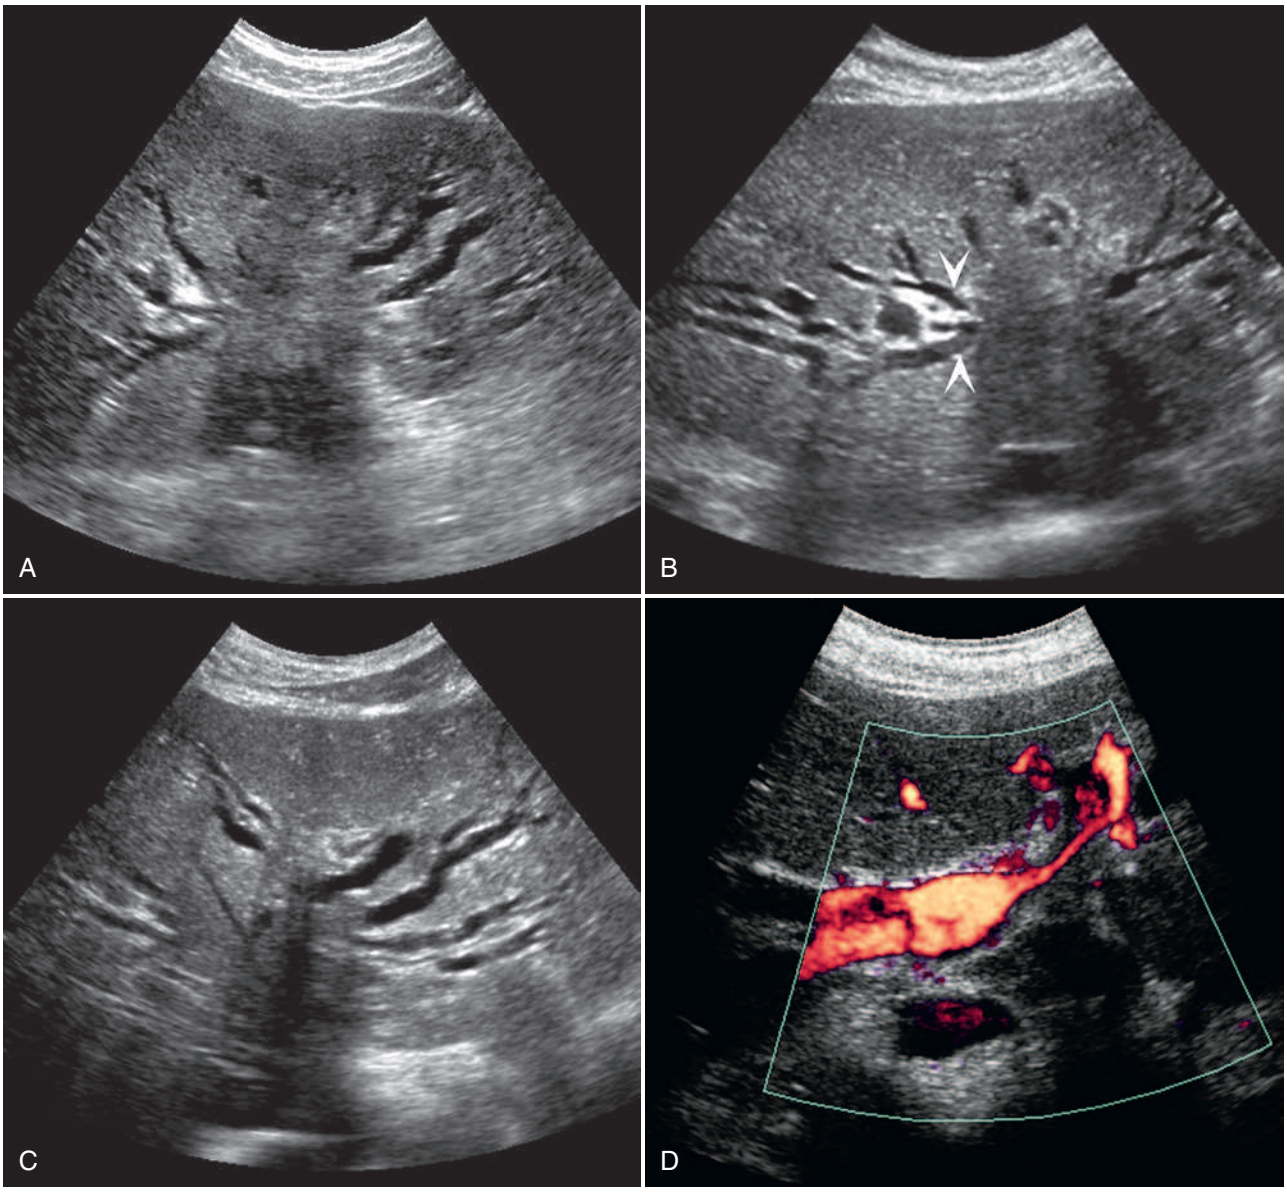

FIG. 6.29 Unresectable Hilar Cholangiocarcinoma. (A) Dilated right-sided and left-sided intrahepatic ducts with nonunion centrally, as seen here, are hallmarks of hilar cholangiocarcinoma. Determination of the level of obstruction is key in assessing resectability. **(B)** In right lobe view, the right anterior and posterior ducts *(arrowheads)* approach each other but never join to form the right hepatic duct. **(C)** In left lobe view, second-order and third-order branches end abruptly, blocked by tumor. Because the tumor completely involves the first-order branches (right and left hepatic ducts) bilaterally, it is unresectable. **(D)** Tumor also encases and narrows the left portal vein.

migrates to the surface of the liver, it acquires a peritoneal covering (part of liver capsule) typically covering 50% to 70% of its surface.[11] The remainder of the gallbladder surface is covered with adventitial tissue that merges with connective tissue in contiguity with the liver. In generalized edematous processes or local inflammation, this potential space between the gallbladder and liver is a common area for edema. Failure to migrate may lead to an **intrahepatic gallbladder** (or partially intrahepatic), a rare but important finding that may preclude laparoscopic surgery[72] (Fig. 6.35). Conversely, the gallbladder may become fully enveloped in visceral peritoneum, hanging from a mesentery that extends from the liver. This leads to increased mobility of the gallbladder and appears to be a risk factor in the rare development of **torsion (volvulus) of the gallbladder.**[73]

Failure to identify the gallbladder on sonographic examination most often results from a previous cholecystectomy. Occasionally, chronic cholecystitis leading to a collapsed and fibrosed gallbladder makes its detection difficult. At times a collapsed gallbladder filled with stones (wall-echo-shadow, see Fig. 6.36B) will be mistaken for bowel gas. **Agenesis of the gallbladder** is rare, occurring in up to 0.09% of the population.[74] Although most often incidental, dilation of the bile duct and choledocholithiasis may occur with gallbladder agenesis, leading to attempted cholecystectomy in some patients. In most cases the cystic duct

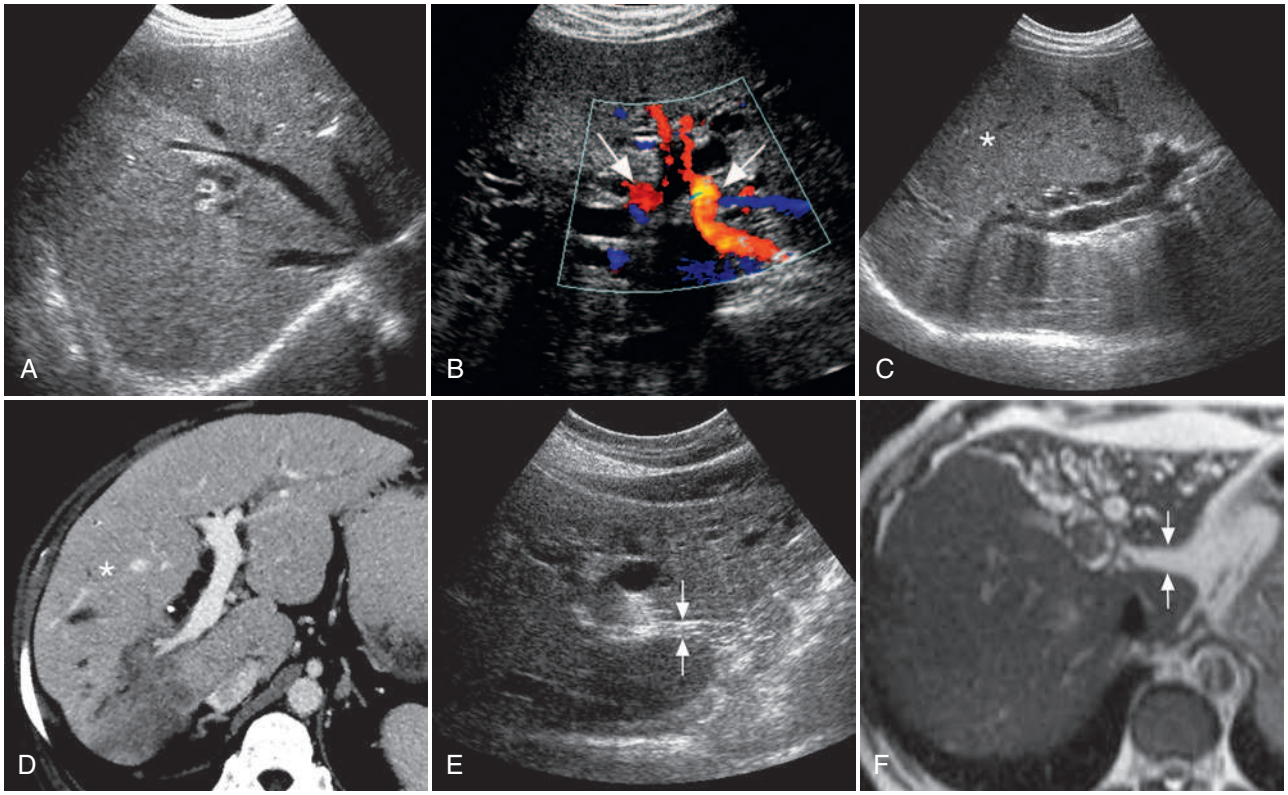

FIG. 6.30 Secondary Findings in Hilar Cholangiocarcinoma. (A) Difference in lobar echogenicity. The right lobe of the liver is demarcated from the left by its increased echogenicity. The right biliary system was obstructed by tumor centrally. **(B) Compensatory increased flow in hepatic arteries.** Enlarged hepatic arterial branches *(arrows)* on either side of the ascending branch of the left portal vein are clearly seen, whereas no flow is noted in the portal vein. This finding suggests severe stenosis or obstruction of the portal vein. **(C)** and **(D) Lobar atrophy.** Marked atrophy of the right lobe with compensatory hypertrophy of the left lobe (*). Enlarged medial segment of the left lobe. **(E)** and **(F) Lobar atrophy.** Marked atrophy of the left lobe of the liver. Besides the small size, widening of the fissure for ligamentum venosum *(arrows)* and concave liver margins are secondary clues. **(F)** Axial SSFSE T2-weighted MRI shows the same.

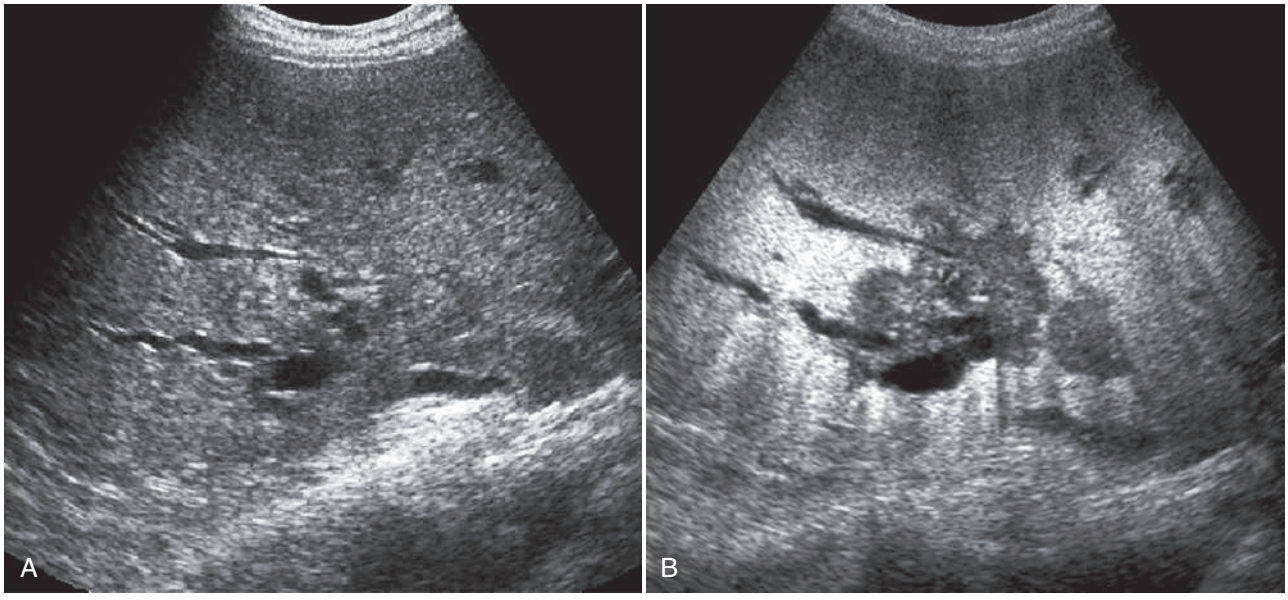

FIG. 6.31 Cholangiocarcinoma: Conventional Versus Contrast Evaluation. (A) Routine gray-scale image demonstrates dilated ducts terminating abruptly. The tumor is not visible. **(B)** Contrast-enhanced image obtained in the postvascular phase clearly depicts the margins of the unenhancing tumor.

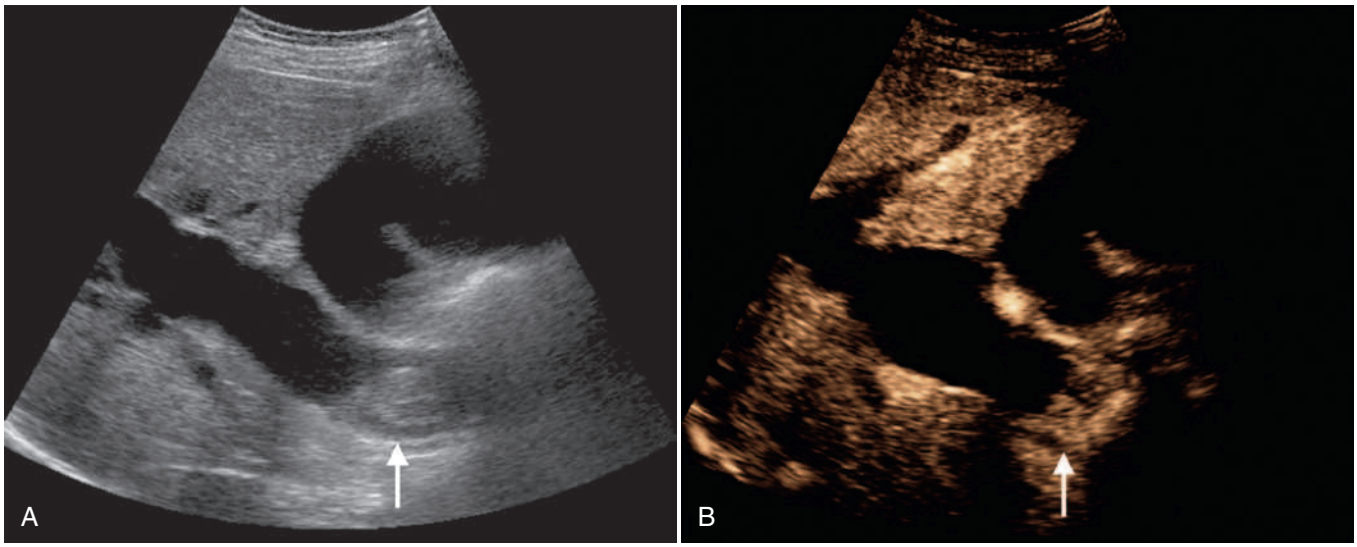

FIG. 6.32 Distal Cholangiocarcinoma. (A) Polypoid solid intraductal mass *(arrow)* within the distal common bile duct, causing ductal obstruction. **(B)** Corresponding contrast-enhanced image demonstrates internal enhancement *(arrow),* proving a vascularized tumor.

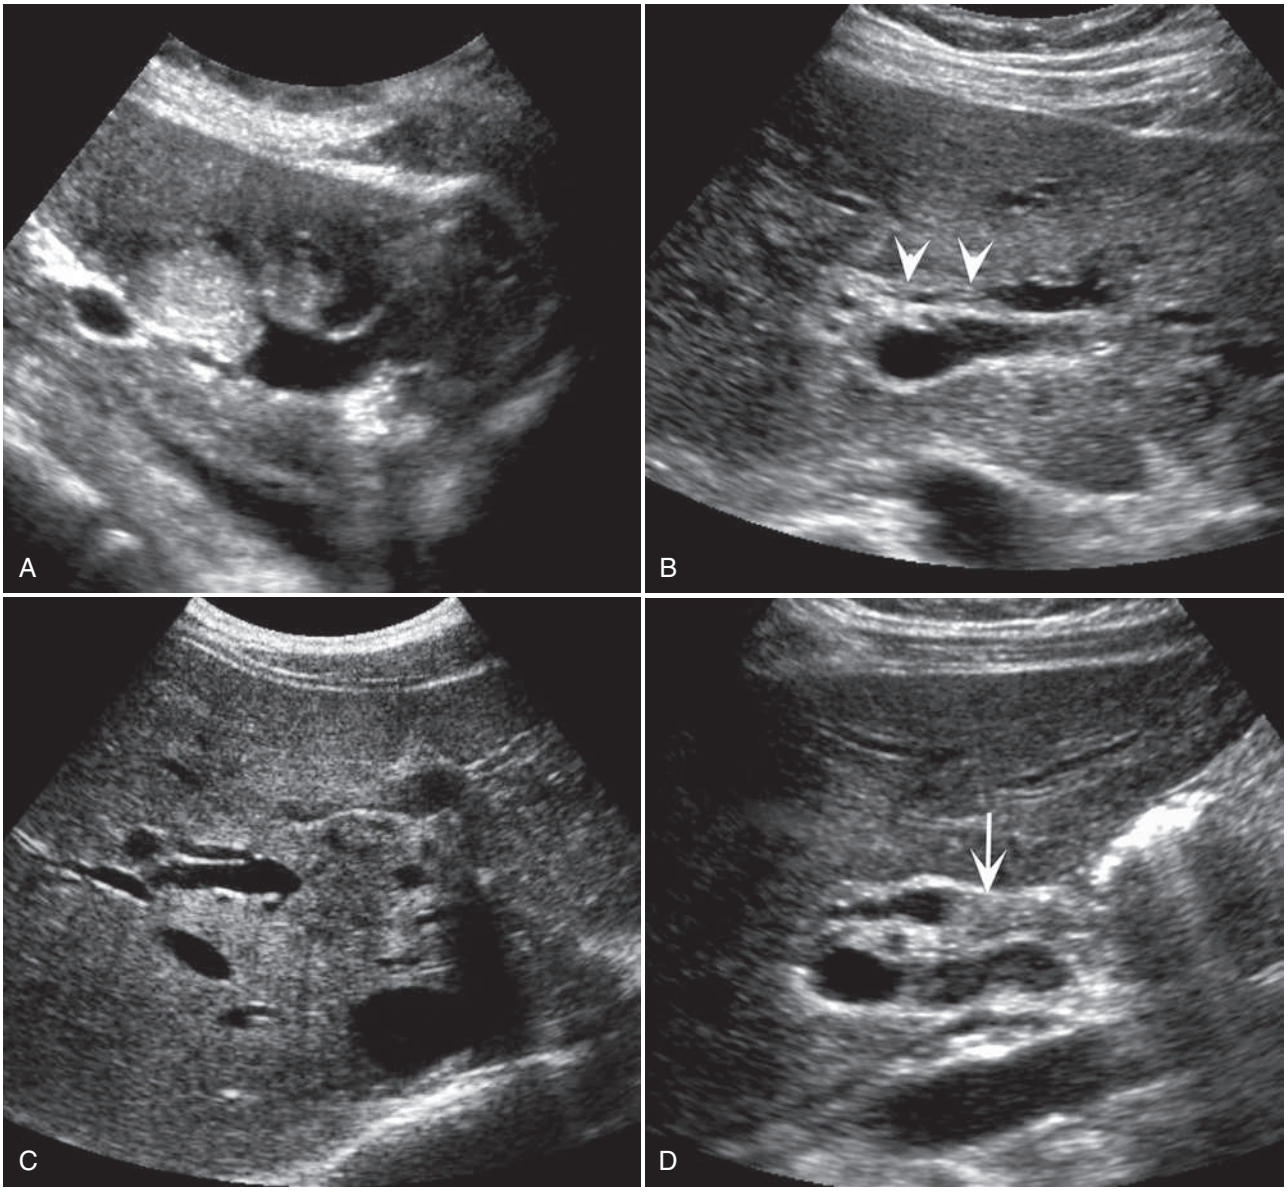

FIG. 6.33 Metastases to the Biliary Tree: Spectrum of Appearances. (A) Entirely intraductal echogenic mass obstructing left lobe of liver. **(B)** Periductal/duct wall infiltration *(arrowheads)* with obliteration of the left hepatic duct. **(C)** Poorly defined hilar tumor with ductal obstruction. **(D)** Echogenic intraductal tumor *(arrow)* within the extrahepatic ducts. In all cases, tumor mimics cholangiocarcinoma. The diagnosis in all four images was metastatic breast carcinoma.

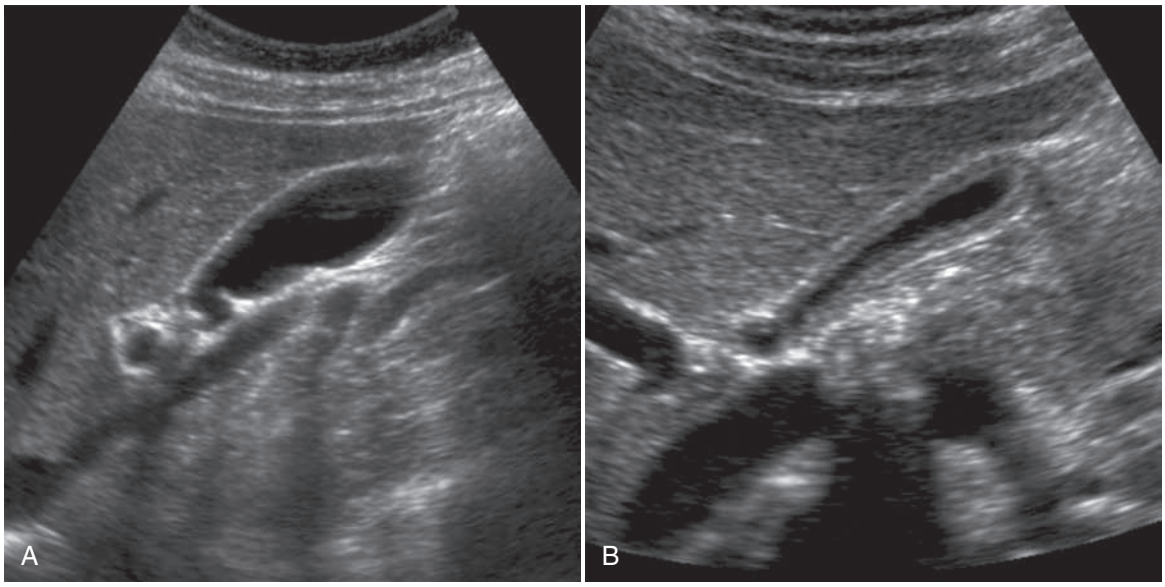

FIG. 6.34 Normal Gallbladder. (A) Distended (fasting). **(B)** Contracted (postprandial).

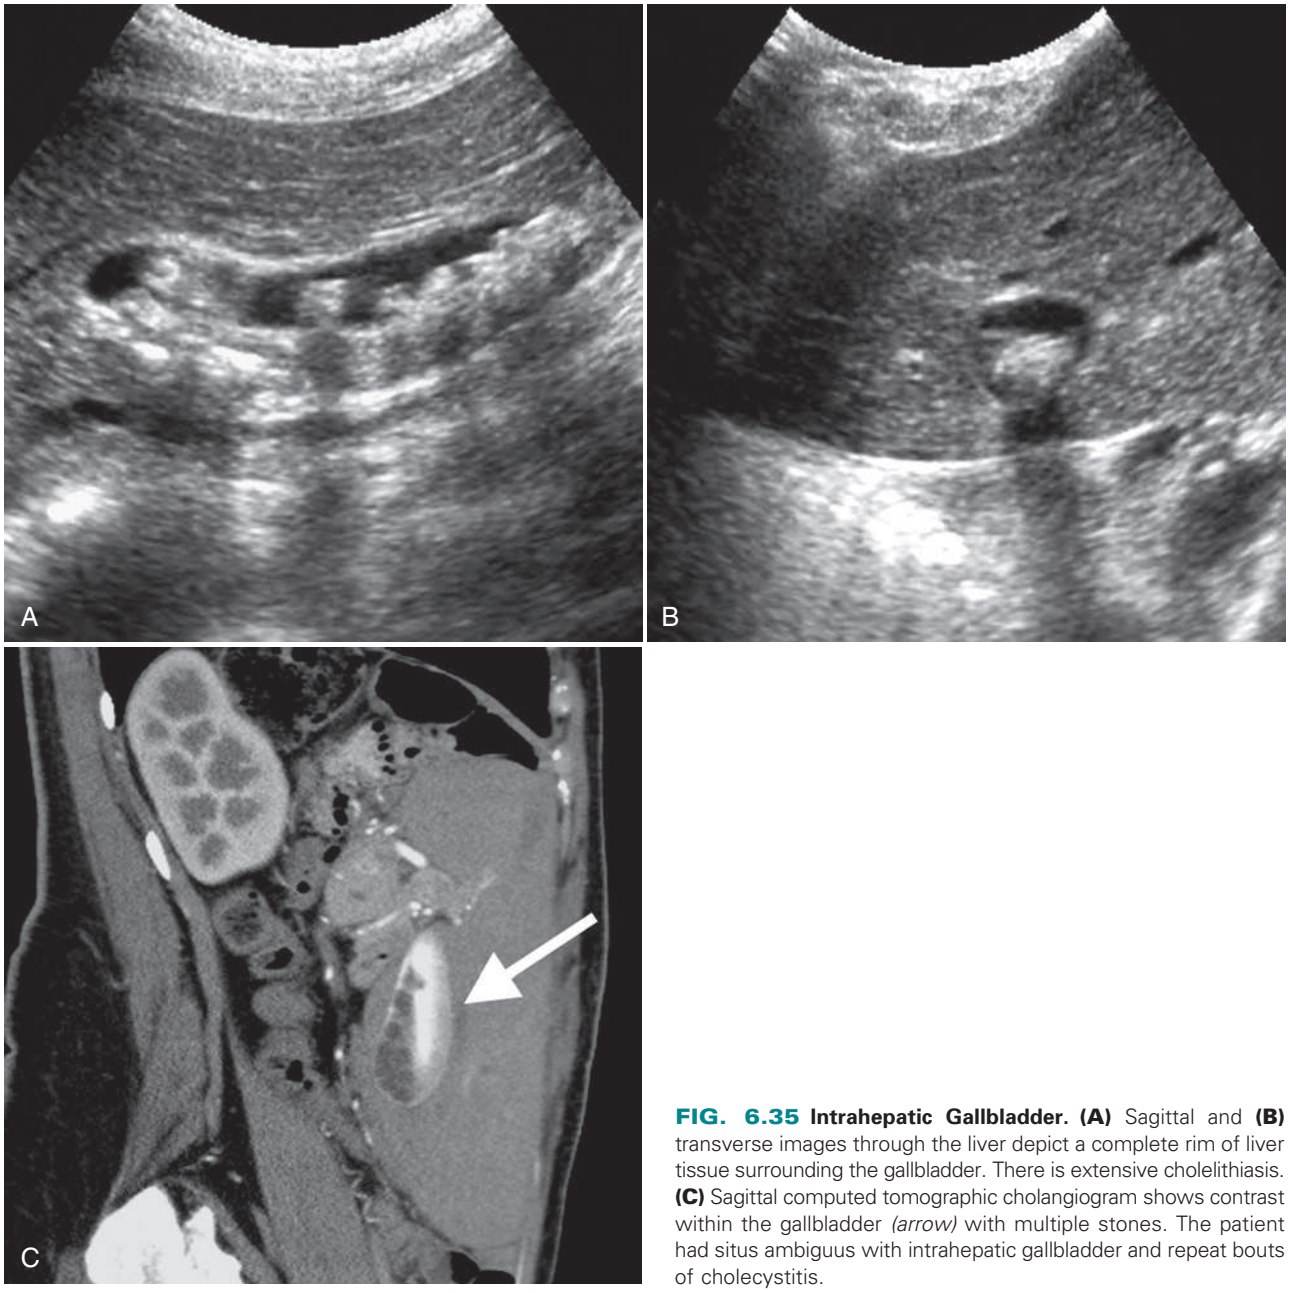

FIG. 6.35 Intrahepatic Gallbladder. (A) Sagittal and **(B)** transverse images through the liver depict a complete rim of liver tissue surrounding the gallbladder. There is extensive cholelithiasis. **(C)** Sagittal computed tomographic cholangiogram shows contrast within the gallbladder *(arrow)* with multiple stones. The patient had situs ambiguus with intrahepatic gallbladder and repeat bouts of cholecystitis.

Causes of Sonographic Nonvisualization of Gallbladder

Previous cholecystectomy
Physiologic contraction
Fibrosed gallbladder duct—chronic cholecystitis
Air-filled gallbladder or emphysematous cholecystitis
Tumefactive sludge
Agenesis of gallbladder
Ectopic location

is also absent. The lack of visualization of the gallbladder on sonography in symptomatic patients warrants CT or MRCP to avoid an unnecessary surgical procedure. The gallbladder may also lie in **ectopic** positions, including suprahepatic, suprarenal, within the anterior abdominal wall, or in the falciform ligament.[11]

The gallbladder may fold unto itself, the body onto the neck, or the fundus onto the body. The latter is called a **phrygian cap** and has no clinical importance. A **septate gallbladder** is composed of two or more intercommunicating compartments divided by thin septa.[11] This is distinguished from the hourglass gallbladder (see "Adenomyomatosis"), which has thick septa separating the components. **Duplication of the gallbladder** often occurs with duplication of the cystic duct and may be diagnosed prenatally. Variations of the cystic duct are discussed in the section on anatomy of the biliary tree.

The gallbladder derives its blood supply from the **cystic artery,** which arises from the right hepatic artery, or less often from the gastroduodenal artery. In acute cholecystitis an enlarged, prominent cystic artery may be identified on sonography.

Sonographic Technique

Evaluation of the gallbladder is usually performed with routine sagittal and transverse sonograms. If the gallbladder is not visualized, however, maneuvers to evaluate the gallbladder fossa are essential to avoid missing gallbladder disease. This is done primarily with subcostal oblique sonograms, performed with the left edge of the transducer more cephalad than the right edge. The face of the transducer is directed toward the right shoulder. A sweep from cephalad to caudad shows the middle hepatic vein superiorly and the gallbladder fossa inferiorly in a single plane. They form the anatomic boundary separating the right and left liver lobes. The fossa runs from the anterior surface of the right portal vein obliquely to the surface of the liver. It may have a variable appearance, mainly influenced by the state of the gallbladder, and after gallbladder removal the fossa appears as an echogenic line as a result of the remaining connective tissues.

Ingestion of food, particularly fatty food, stimulates the gallbladder to contract. The contracted gallbladder appears thick walled and may obscure luminal or wall abnormalities. Therefore the examination of the gallbladder should be performed after a minimum of 4 hours of fasting.

Gallstone Disease

Gallstone disease is common worldwide. The prevalence of gallstones is highest in the European and North American populations (≈10%) and lowest in the East Asian (≈4%) and sub-Saharan African (2%-5%) populations.[75] Common risk factors are age, female gender (but not in Asian populations), fecundity, obesity, diabetes, and pregnancy. Although most patients are asymptomatic, about one in five develops a complication, often biliary colic. The risk of acute cholecystitis or other serious complications of gallstones in patients with a history of biliary colic is about 1% to 2% per year.[76]

Sonography is highly sensitive in the **detection of stones** within the gallbladder. The varying size and number of stones within the gallbladder lead to a variable appearance on sonography (Fig. 6.36, Video 6.9). The large difference in the acoustic impedance of stones and adjacent bile makes them highly reflective, which results in an echogenic appearance with strong posterior acoustic shadowing. Small stones (<5 mm) may not show shadowing but will still appear echogenic. **Mobility** is a key feature of stones, allowing differentiation from polyps or other entities. Various maneuvers may be used to demonstrate mobility of a stone; scanning with the patient in the right or left lateral decubitus or upright standing position may allow the stone to roll within the gallbladder.

Multiple stones may appear as one large stone, producing uniform acoustic shadowing. When the gallbladder is filled with small stones or a single giant stone, the gallbladder fossa will appear as an echogenic line with posterior shadowing. This can be differentiated from air or calcification in the gallbladder wall by analysis of the echoes. With stones the gallbladder *wall* is first visualized in the near field, followed by the bright *echo* of the stone, followed by the acoustic *shadowing,* called the **wall-echo-shadow complex** (Fig. 6.36B). When air or calcification is present, the normal gallbladder wall is not seen, and only the bright echo and the posterior dirty shadowing are seen.

Milk of calcium bile, also known as **limey bile,** is a rare condition in which the gallbladder becomes filled with a pasty, semisolid substance of mainly calcium carbonate.[77] It is often associated with gallbladder stasis and in rare cases may cause acute cholecystitis or migrate into the bile ducts. The appearance on sonography is highly echogenic material with posterior acoustic shadowing, forming a bile calcium level on various patient positions (Fig. 6.37).

Biliary Sludge

Biliary sludge, also known as **biliary sand** or **microlithiasis,** is defined as a mixture of particulate matter and bile that occurs when solutes in bile precipitate. Its existence was first recognized with the advent of sonography. The exact prevalence of sludge is unknown in the general population because most studies have examined high-risk populations. The predisposing factors in development of sludge are pregnancy, rapid weight loss, prolonged fasting, critical illness, long-term total parenteral nutrition, ceftriaxone or prolonged octreotide therapy, and bone marrow transplantation. In one study, over a 3-year period, about 50% of cases resolved spontaneously, 20% persisted asymptomatically, 5% to 15% developed gallstones, and 10% to

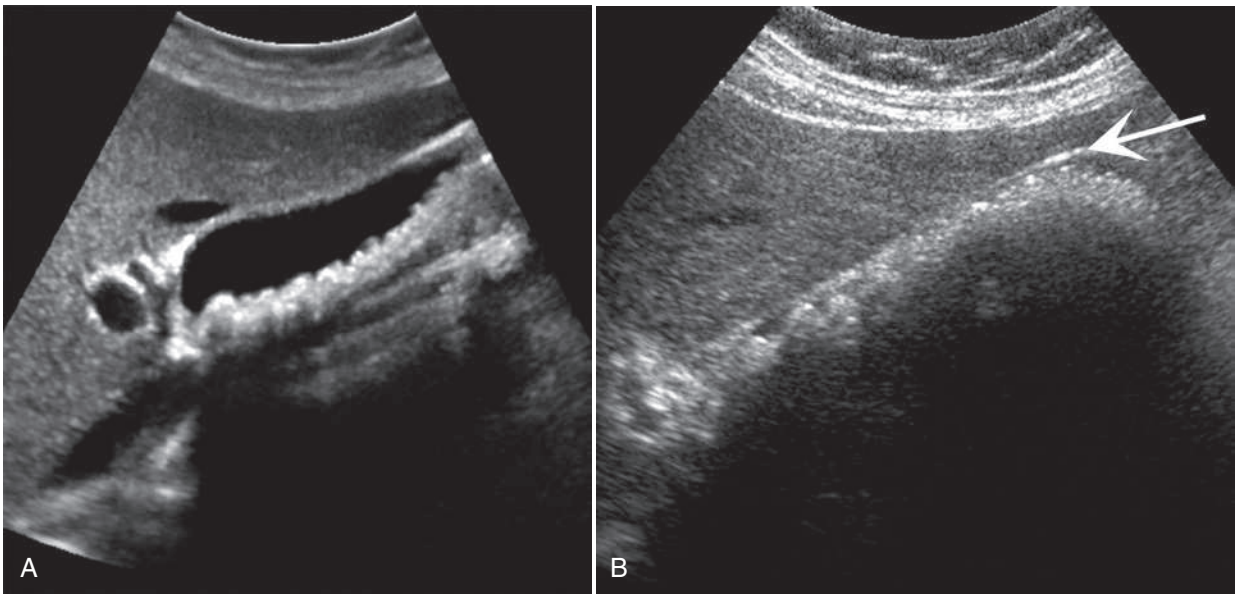

FIG. 6.36 Gallstones. (A) Sagittal image shows multiple dependent stones appearing as echogenic foci with posterior acoustic shadowing. **(B)** "Wall-echo-shadow complex" in a gallbladder filled with stones. Gallbladder wall *(arrow)* is thin. See also Video 6.9.

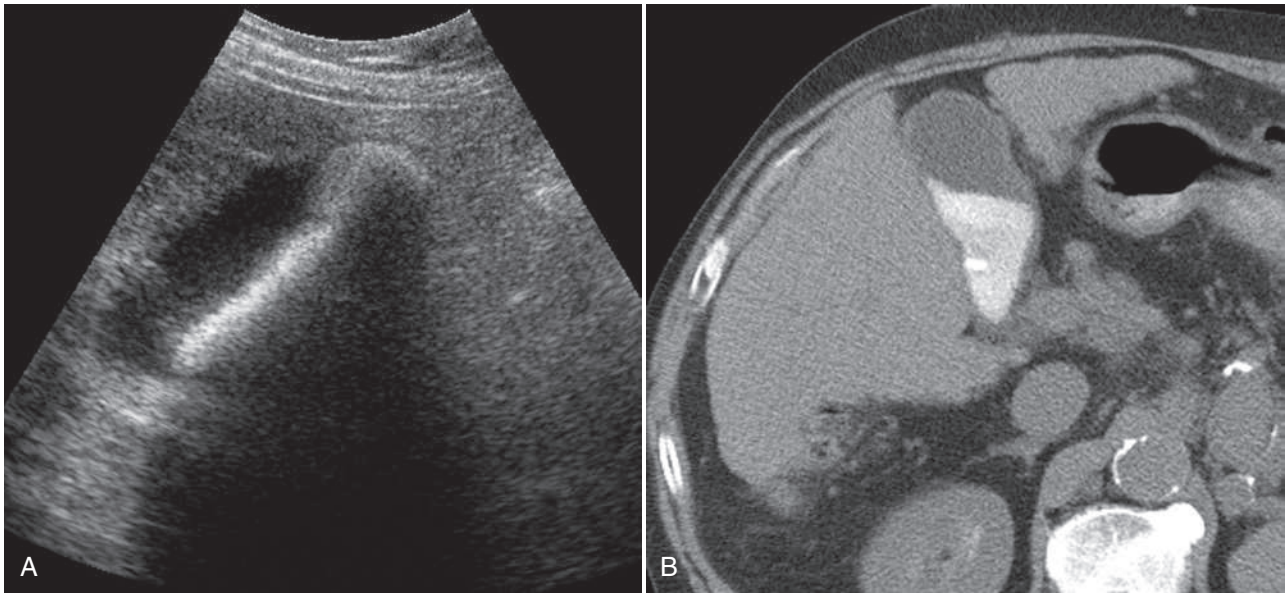

FIG. 6.37 Milk of Calcium Bile. (A) Sonogram and **(B)** corresponding CT scan show a bile calcium level.

15% became symptomatic.[78] The complications of biliary sludge are stone formation, **biliary colic, acalculous cholecystitis,** and **pancreatitis.**

The sonographic appearance of sludge is that of amorphous, low-level echoes within the gallbladder in a dependent position, with no acoustic shadowing. With a change in patient position, sludge may slowly resettle in the most dependent location. In fasting, critically ill patients, sludge may be present in large quantities and completely fill the gallbladder. Sludge that mimics polypoid tumors is called **tumefactive sludge** (Fig. 6.38). Lack of internal vascularity, potential mobility of the sludge, and a normal gallbladder wall are all clues to the presence of sludge. When doubts persist, lack of contrast enhancement on ultrasound, CT, or MRI allows conservative management. Occasionally, sludge has the same echotexture as the liver, camouflaging the gallbladder; called **hepatization** of the gallbladder, this may be easily recognized by identifying the normal gallbladder wall, and lack of Doppler flow within the sludge.

Acute Cholecystitis

Acute cholecystitis is a relatively common disease, accounting for 5% of the patients arriving to the emergency department with abdominal pain and 3% to 9% of hospital admissions.[79] It is caused by gallstones in more than 90% of patients.[80] Impaction of the stones in the cystic duct or the gallbladder neck results in obstruction, with luminal distention, ischemia, superinfection,

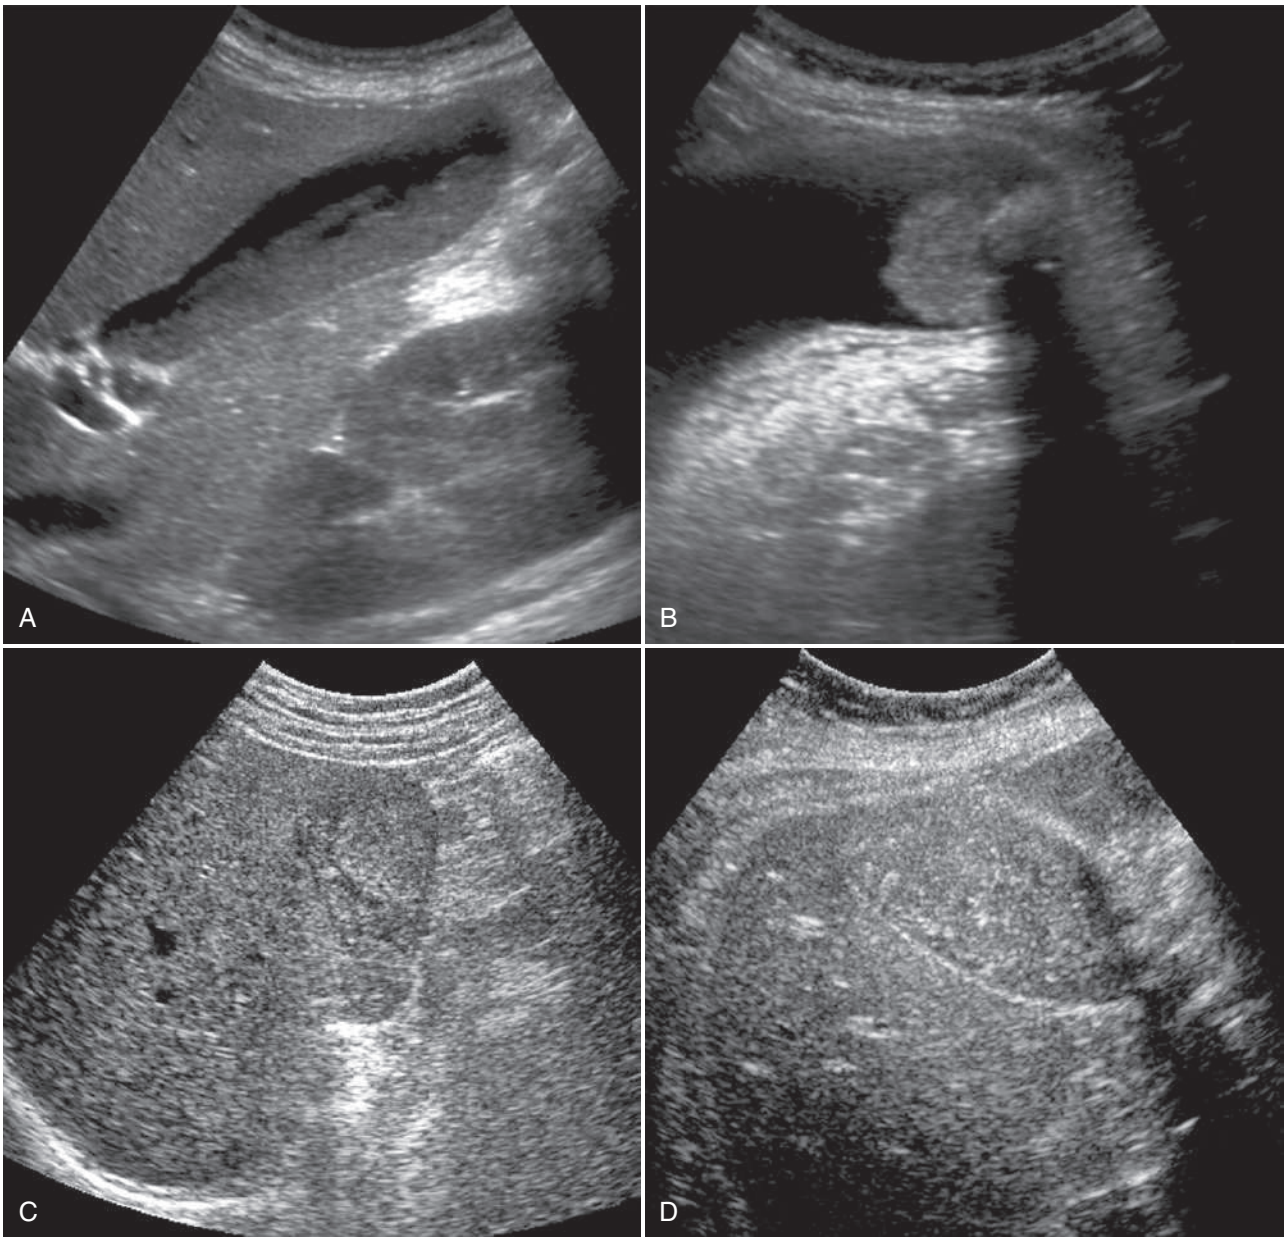

FIG. 6.38 Tumefactive Sludge in Three Patients. (A) Sagittal sonogram shows gallbladder filled with tumorlike sludge. **(B)** Transverse image shows a polypoid appearance of sludge on the dependent gallbladder wall, with an embedded stone (note shadowing). **(C)** Sagittal and **(D)** subcostal oblique sonograms of the same patient show "hepatization" of the gallbladder, with internal echoes mimicking the normal liver parenchyma. In all three patients the gallbladder wall was normal. There was no vascularity detected from the tumefactive sludge.

and eventually necrosis of the gallbladder. In the under-50 age group, women are affected three times more often than men, although incidence of acute cholecystitis is similar in older age groups.[76] However, cholecystitis tends to be more severe in men.[81] Clinically, patients experience prolonged, constant RUQ or epigastric pain associated with RUQ tenderness. Fever, leukocytosis, and increased serum alkaline phosphatase and bilirubin levels may be present.

Sonography is currently the most practical and accurate method to diagnose acute cholecystitis (Figs. 6.39 and 6.40, Video 6.10). When adjusted for verification bias, sensitivity and specificity of ultrasound are approximately 88% and 80%, respectively.[82] Cholescintigraphy uses ionizing radiation, cannot be performed at the bedside, and also has a significant false-positive rate. Although less accurate than sonography in the diagnosis of acute cholecystitis, CT may be useful for depiction of complications.[83] Sonographic findings include the following[84] (Table 6.1):

- Thickening of the gallbladder wall (>3 mm)
- Distention of the gallbladder lumen (diameter > 4 cm)
- Gallstones
- Impacted stone in cystic duct or gallbladder neck
- Pericholecystic fluid collections
- Positive sonographic Murphy sign
- Hyperemic gallbladder wall on Doppler interrogation

TABLE 6.1 Acute Calculous Cholecystitis: Pathologic-Sonographic Correlation

Pathophysiology	Sonographic Appearance
Obstruction of cystic duct or neck of gallbladder	Stones in gallbladder, possibly in neck or cystic duct
Continued secretions	Gallbladder distention
Inflammatory cell infiltration	Thickening of gallbladder wall
and	Gallbladder wall often striated with pockets of edema fluid
Gallbladder wall edema	Positive sonographic Murphy sign (>90%)
Hypervascularity	Hyperemia of gallbladder wall
Gallbladder stasis with bacterial overgrowth by 72 hours	Biliary sludge
Empyema of gallbladder	Heterogeneous luminal contents of variable echogenicity with layering
Increased pressure in gallbladder lumen and wall	Sloughed membranes; hypovascularity
Gangrene	Loss of Murphy sign
Perforation	Loss of gourd shape; collection in or adjacent to gallbladder fossa

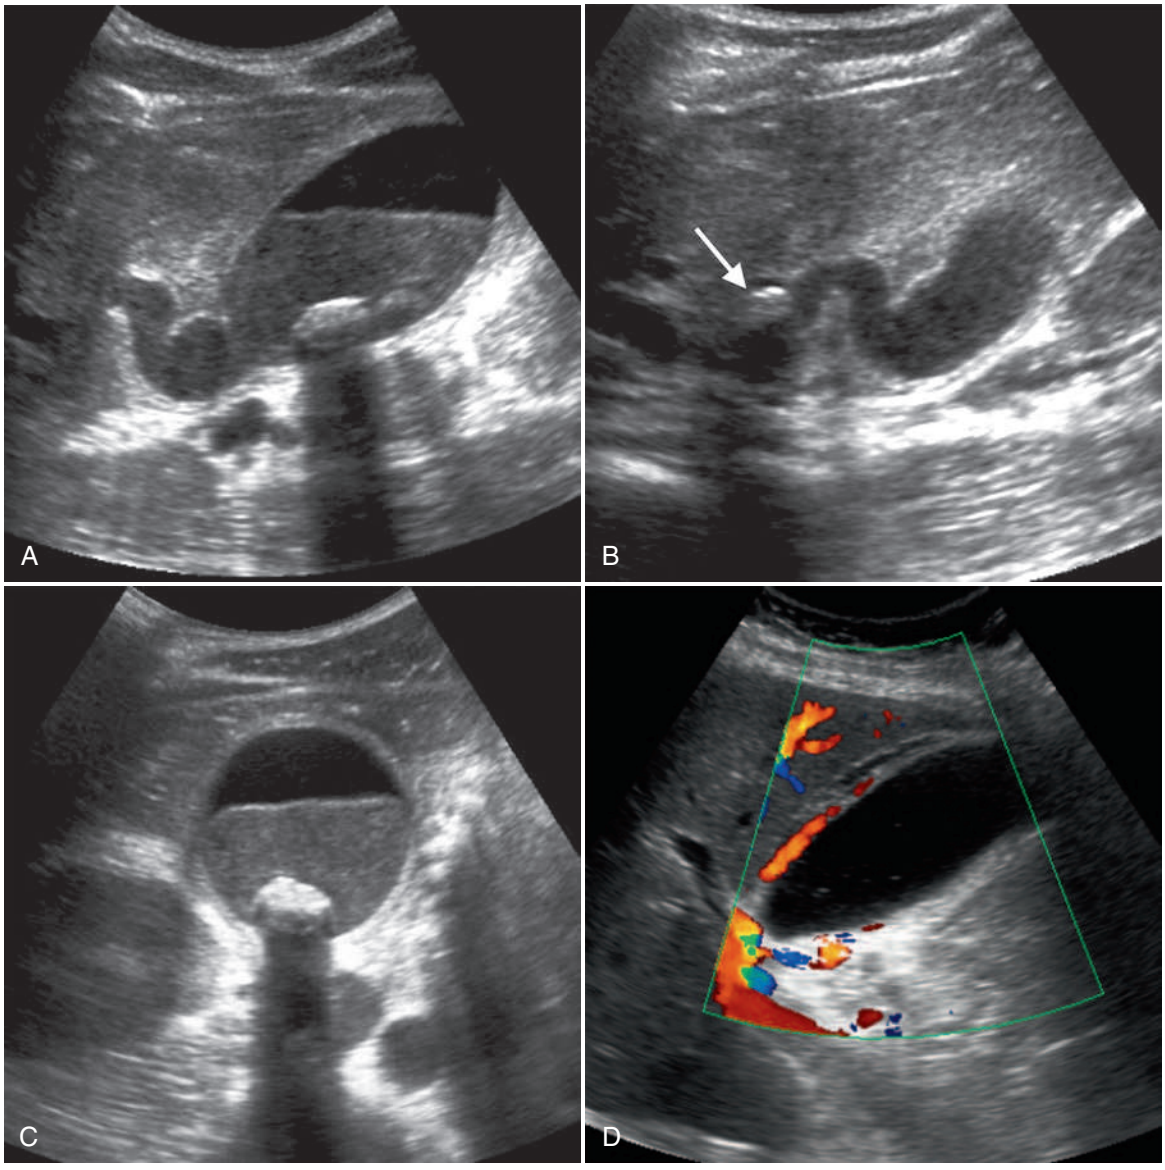

FIG. 6.39 Acute Cholecystitis. Classic acute cholecystitis in a young man. **(A)** Sagittal images show a tense distended gallbladder, wall thickening, fluid-debris level, and a nonobstructive stone with posterior acoustic shadowing. **(B)** Further scrutiny of the distended cystic duct reveals the obstructive stone *(arrow)*. **(C)** Transverse image through the gallbladder shows the gallbladder forming a near perfect circle, due to internal increased pressure. **(D)** Sagittal Doppler image shows a prominent cystic artery and hyperemia in the wall of the gallbladder as well as the adjacent liver.

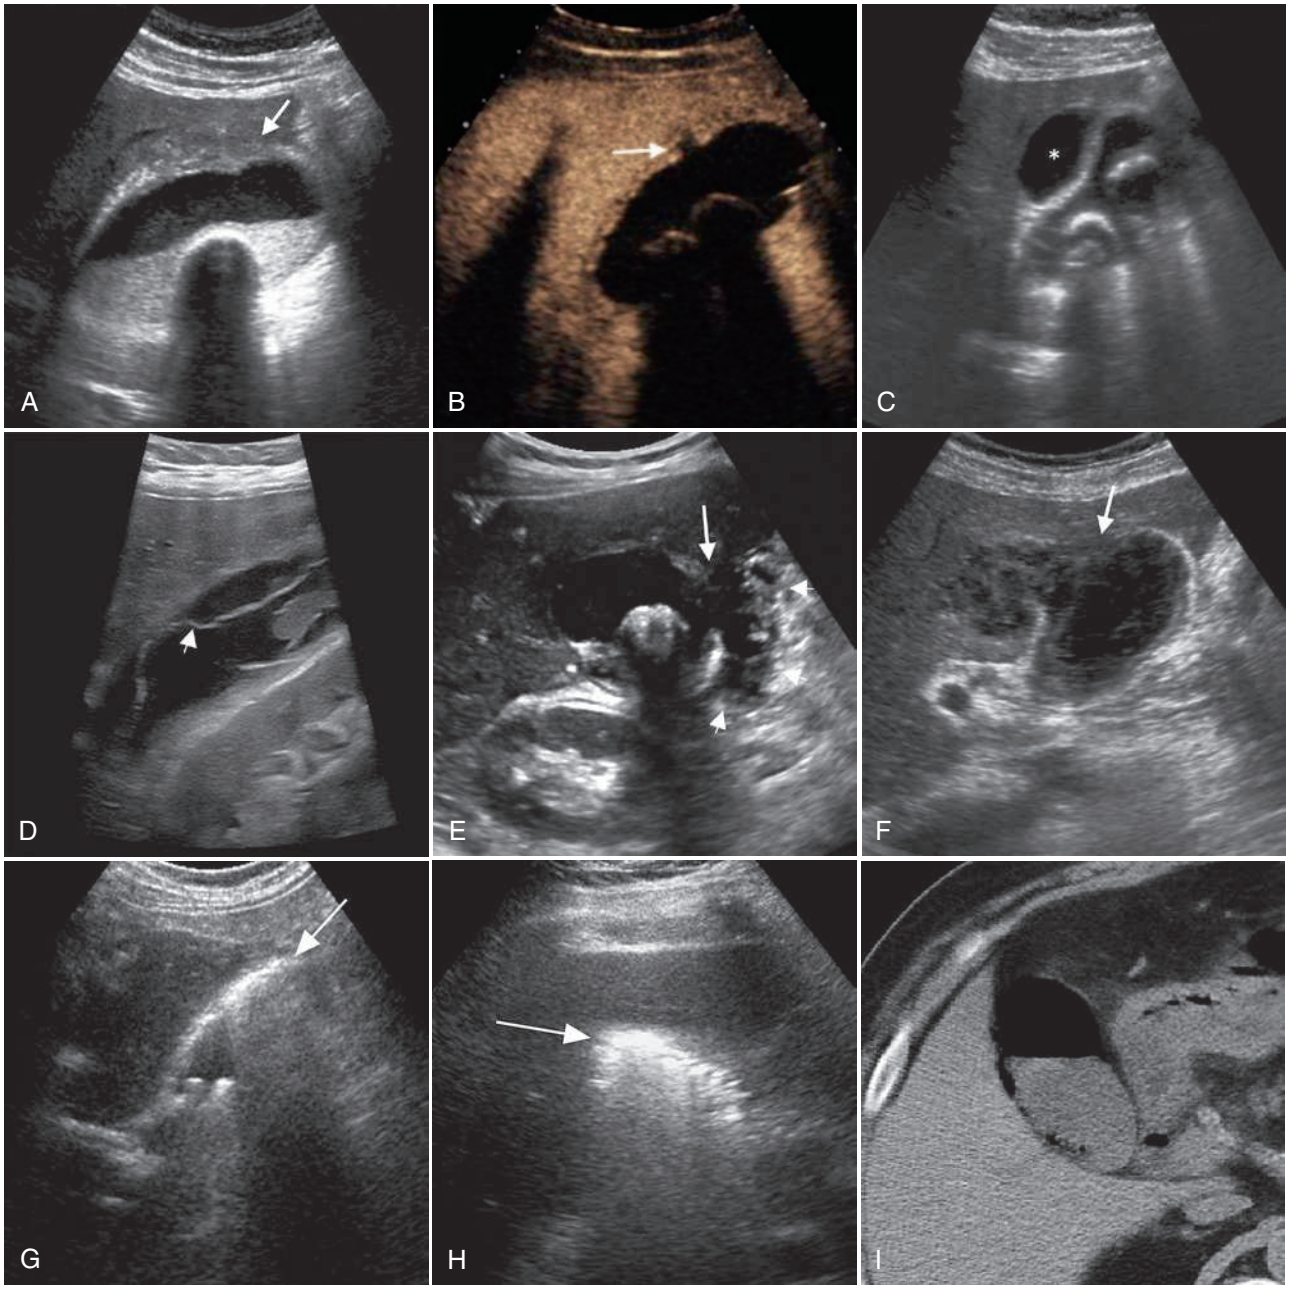

FIG. 6.40 Acute Cholecystitis: Complications. (A)-(C) Early perforation and sequelae. (A) The gallbladder is tense with thickened walls and sludge and a stone. There is poor definition of its near wall *(arrow)* with adjacent heterogeneity of the hepatic parenchyma. **(B)** Contrast-enhanced scan demonstrates a defect *(arrow)* in the gallbladder wall. The patient was treated with antibiotics. **(C)** Three-month follow-up scan in the now asymptomatic patient shows a localized fluid collection (*) between the wall of the gallbladder and liver parenchyma. **(D) Gangrenous cholecystitis.** Sloughed membranes *(short arrow)* appear as linear intraluminal echoes. **(E) Perforation,** shown as disruption of the gallbladder wall *(arrow)* with a subhepatic abscess *(short arrows)*. **(F) Perforation into the liver.** There is a large defect *(arrow)* in the wall of the gallbladder with an adjacent hepatic abscess. See also Video 6.11. **(G)-(I) Emphysematous cholecystitis. (G)** Sagittal sonogram of the gallbladder with a focus of intraluminal air appearing as a bright echogenic focus *(arrow)* with dirty shadowing. **(H)** Gallbladder that is filled with air *(arrow)*. The gallbladder is not actually visualized, and knowledge of the location of the gallbladder fossa is essential to avoid mistaking this for bowel gas. **(I)** Corresponding CT scan shows air in the gallbladder wall and lumen.

Gallbladder wall thickening has many causes. The appearance of the gallbladder wall in acute cholecystitis is nonspecific, but marked thickening of the wall with visible stratification, as seen in generalized edematous states, is usually not present (Fig. 6.41). Multiple focal, noncontiguous, hypoechoic pockets of edema fluid within the thickened wall are typically observed. The inflamed gallbladder is often significantly distended, unless its wall is perforated. Gallstones, including the obstructing stone, and sludge are usually identified. A thin rim of fluid, representing edema, is often seen around much of the organ.

A sonographic **Murphy sign** is maximal tenderness over the gallbladder when the probe is used to compress the RUQ. It is

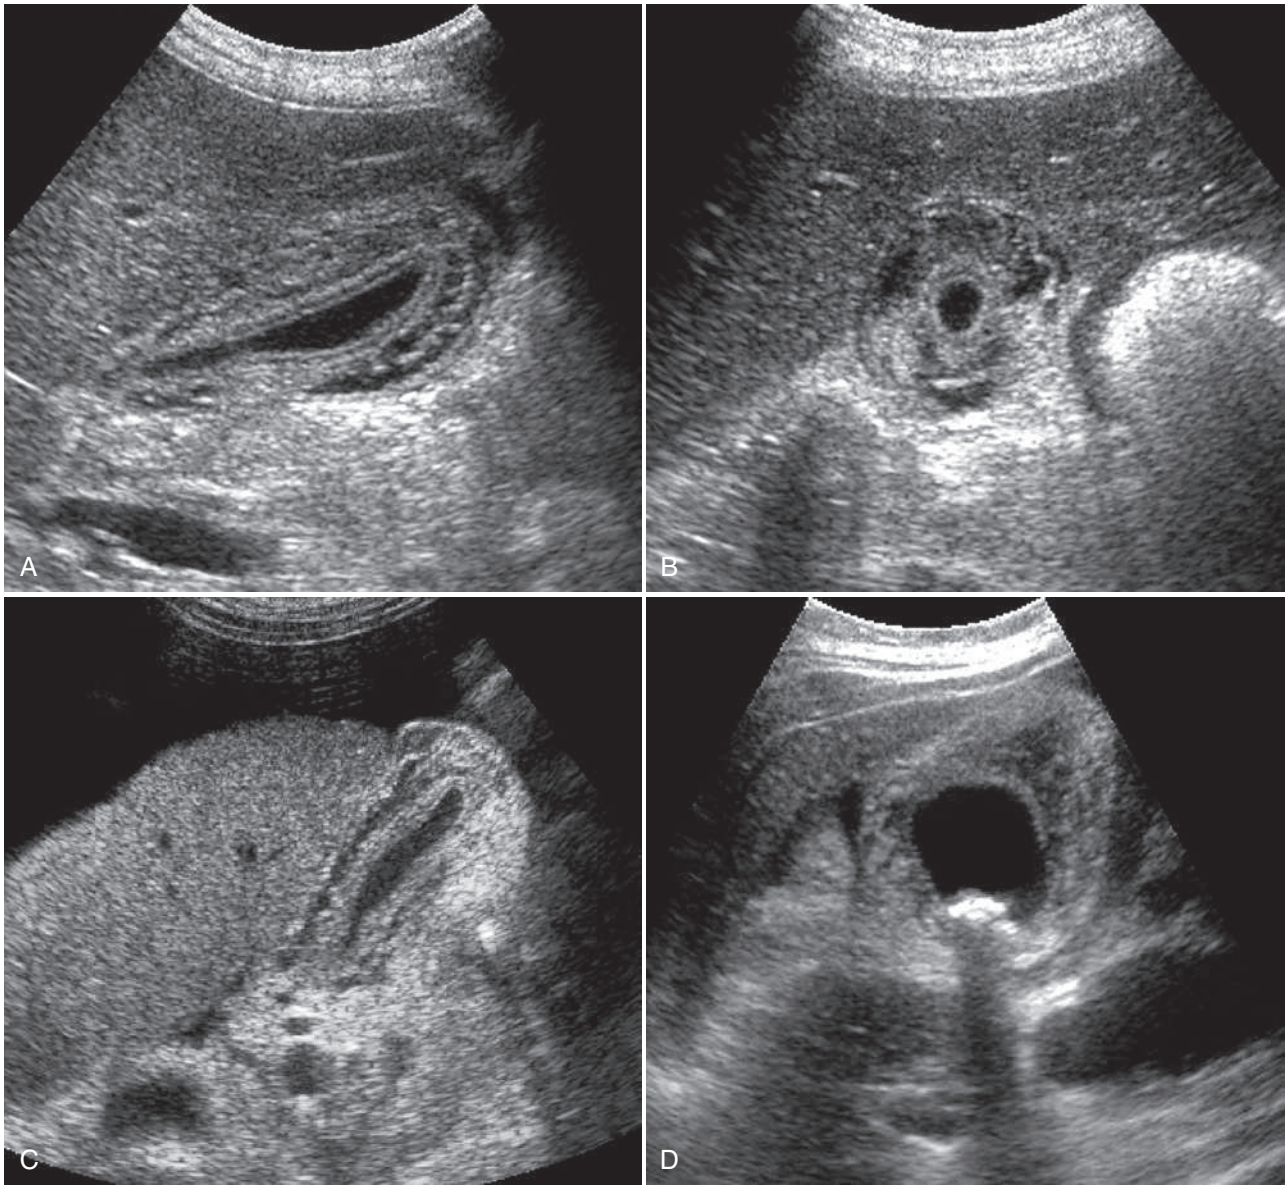

FIG. 6.41 Systemic Causes of Gallbladder Wall Edema. (A) Sagittal and **(B)** transverse images of patient with **hypoalbuminemia** show marked thickening of the gallbladder wall with a small lumen. **(C)** Sagittal image of the gallbladder in a patient with **cirrhosis** demonstrating similar changes to those in **(A)** and **(B)**. Note nodular liver ascites. **(D)** Patient with **congestive heart failure,** small amount of ascites, no pain, and negative Murphy sign has marked gallbladder wall thickening and incidental gallstones.

often better elicited with deep inspiration, which displaces the gallbladder fundus below the costal margin, allowing for direct compression. Sonographic Murphy sign may be absent in older patients, if analgesics were taken before the study, or when prolonged inflammation has led to gangrenous cholecystitis. **Hyperemia** in the gallbladder wall and the adjacent liver and a **prominent cystic artery** are relatively specific findings in acute cholecystitis (see Fig. 6.39D). Power Doppler has been shown to be superior to color Doppler in detecting such hyperemia.[85] Hyperemia is only qualitatively assessed, however, and motion artifact somewhat limits the utility of power Doppler. The latest generation of sonography equipment has highly sensitive Doppler techniques, and detection of flow in the cystic artery of a normal gallbladder is common. In our experience this limits the qualitative assessment of gallbladder wall hyperemia. We rely heavily on the morphologic changes in the gallbladder for the diagnosis of acute cholecystitis but find Doppler ultrasound quite useful in equivocal cases.

Although none of the signs just described is pathognomonic of acute cholecystitis, the combination of multiple findings should lead to the correct diagnosis. Some patients with acute cholecystitis may not show classic findings, making diagnosis challenging. This occurs in patients with mild inflammation but occurs more often in patients hospitalized for other reasons, not receiving an oral diet, and unable to communicate symptoms. A distended gallbladder in these patients should trigger a high index of suspicion, and careful RUQ scanning is recommended. **Perforated duodenal ulcer, acute hepatitis, pancreatitis, colitis**

Causes of Gallbladder Wall Thickening

GENERALIZED EDEMATOUS STATES
Congestive heart failure
Renal failure
End-stage cirrhosis
Hypoalbuminemia

INFLAMMATORY CONDITIONS
Primary
- Acute cholecystitis
- Cholangitis
- Chronic cholecystitis

Secondary
- Acute hepatitis
- Perforated duodenal ulcer
- Pancreatitis
- Diverticulitis/colitis

NEOPLASTIC CONDITIONS
Gallbladder adenocarcinoma
Metastases

MISCELLANEOUS
Adenomyomatosis
Mural varicosities

or **diverticulitis,** and even **pyelonephritis** can demonstrate a Murphy sign and **sympathetic gallbladder wall thickening** (Fig. 6.42). Absence of a distended gallbladder and gallstones is often a clue to the nonbiliary origin of the cholecystic process.

Gangrenous Cholecystitis

When acute cholecystitis is especially severe or prolonged, the gallbladder may undergo necrosis. Sonographic findings of gangrenous cholecystitis include nonlayering bands of echogenic tissue within the lumen representing sloughed membranes and blood (see Fig. 6.40D). The gallbladder wall also becomes irregular, with small collections within the wall that may represent abscesses or hemorrhage.[76] Murphy sign is absent in two-thirds of patients,[86] presumably because of necrosis of the nerve supply to the gallbladder. **Hemorrhagic cholecystitis** represents a rare gangrenous process marked by bleeding within the gallbladder wall and lumen. The clinical symptoms are indistinguishable from gangrenous cholecystitis, and only occasionally does the patient experience a gastrointestinal bleed.

Perforated Gallbladder

Perforation of the gallbladder occurs in 5% to 10% of patients with acute cholecystitis, generally in cases of prolonged inflammation.[76] The focus of perforation, seen as a small defect or rent in the wall of the gallbladder, is often visible (see Fig. 6.40, Video 6.11). Clues to perforation are the deflation of the gallbladder, with loss of its normal gourdlike shape, and a focal **pericholecystic fluid collection.** The latter is often a small fluid collection around the wall defect, unlike the thin rim of fluid around the entire organ in uncomplicated cholecystitis.[87] The collection may have internal strands typical of abscesses elsewhere (see Fig. 6.40E). Perforation of the gallbladder may extend into the adjacent liver parenchyma, forming an abscess collection. The presence of a cystic liver lesion around the gallbladder fossa should suggest a pericholecystic abscess.

Emphysematous Cholecystitis

Emphysematous cholecystitis represents less than 1% of all cases of acute cholecystitis, but it is rapidly progressive and fatal in approximately 15% of patients. Emphysematous cholecystitis differs from acute cholecystitis in several ways. It is three to seven times more common in men than women; about one-half of patients have **diabetes;** and one-third to one-half have no gallstones.[76,88] The gas is produced by gas-forming bacteria, presumably after an ischemic event affecting the gallbladder.[88] These patients have a much higher incidence of gallbladder perforation than those with typical acute cholecystitis, and urgent surgical treatment is advocated for all patients.

The appearance of emphysematous cholecystitis on sonography depends on the amount of gas present (see Fig. 6.40G-I). The gas is often within both the lumen and the wall of the gallbladder. Small amounts of gas appear as echogenic lines, with posterior dirty shadowing, reverberation, or ring-down artifact. Large amounts of gas can be more difficult to appreciate. The absence of a normal gallbladder is a clue. A bright, echogenic line with posterior dirty shadowing is seen within the entire gallbladder fossa. Movement of gas bubbles is a helpful finding and may be precipitated by compression of the gallbladder fossa. Pneumobilia may also be seen.[88]

Acalculous Cholecystitis

Acalculous cholecystitis may occur in patients with no risk factors but is more common in critically ill patients, who thus have a worse prognosis. Risk factors include major surgery, severe trauma, sepsis, total parenteral nutrition, diabetes, atherosclerotic disease, and HIV infection.[80] In nonhospitalized patients, it is more common in older male patients with atherosclerotic disease,[89] who have a much better prognosis.

The diagnosis of acalculous cholecystitis can be difficult because gallbladder distention, wall thickening, internal sludge, and pericholecystic fluid may all be present in critically ill patients without cholecystitis.[90] Patients may be obtunded or receiving analgesics, reducing the sensitivity of Murphy sign. The combination of findings suggests the diagnosis; the more signs present, the greater is the likelihood of cholecystitis.[91] Nevertheless, cholescintigraphy or percutaneous sampling of the luminal contents should be used more liberally to assist in the diagnosis.

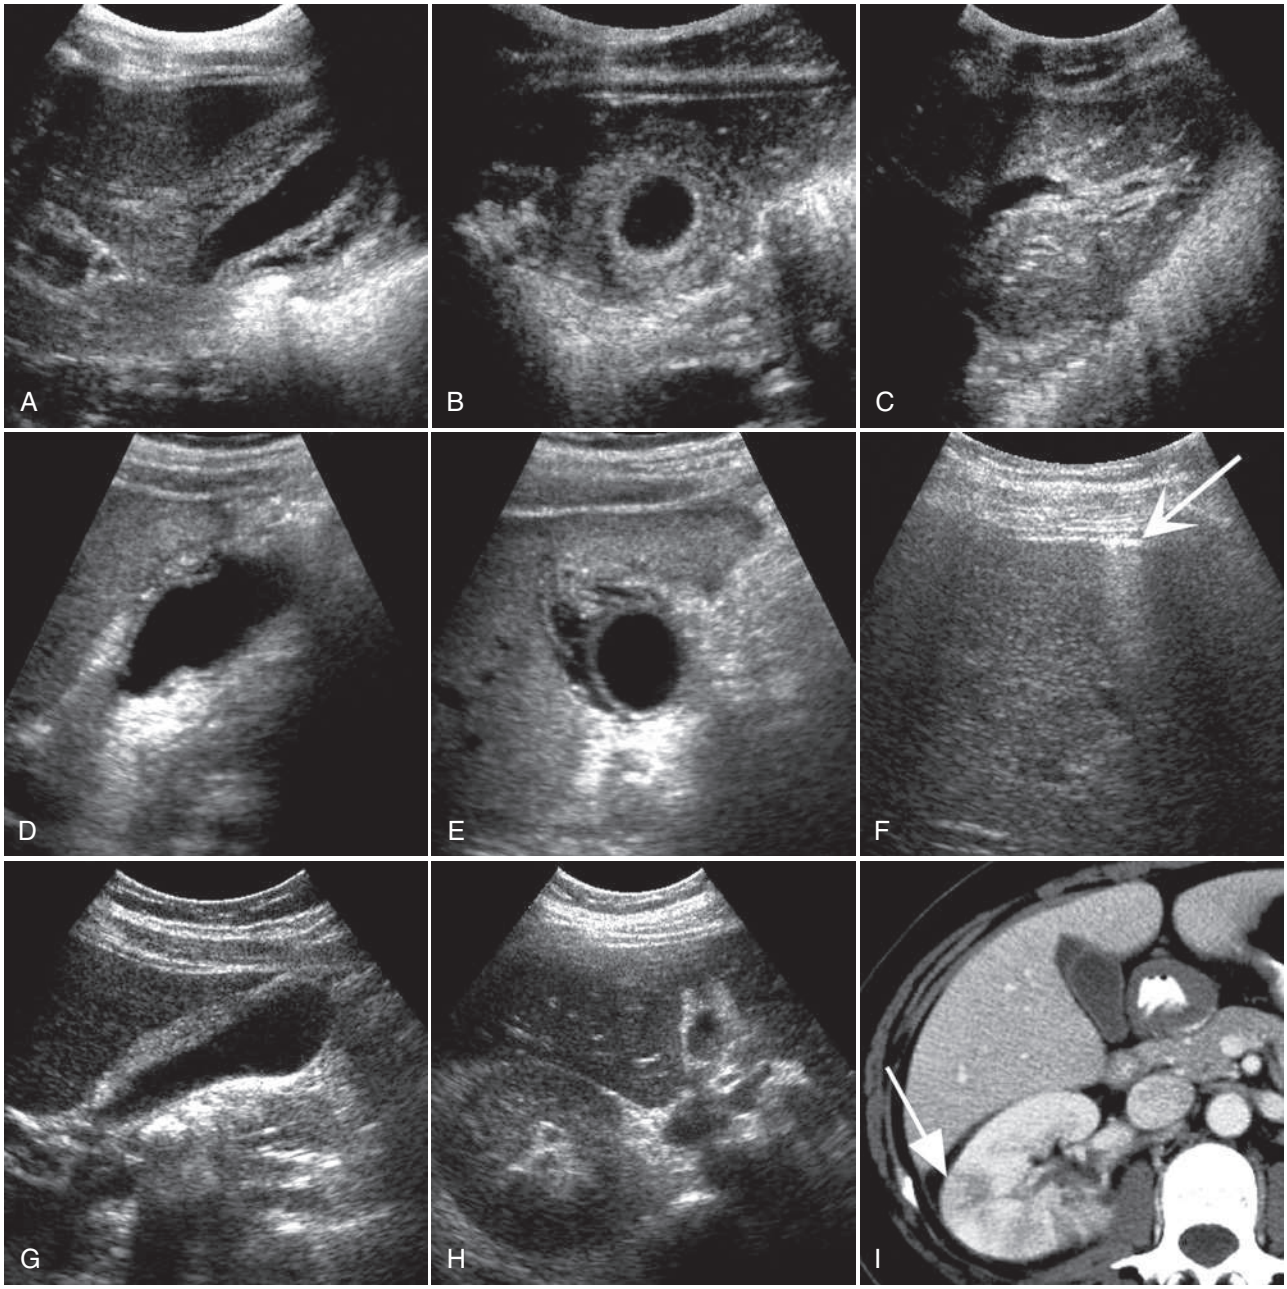

FIG. 6.42 Sympathetic Thickening of the Gallbladder Wall in Three Patients With Positive Sonographic Murphy Sign. (A)-(C) Acute hepatitis. (A) and **(B)** Views of the gallbladder show marked circumferential thickening of the gallbladder wall. The lumen is not distended. **(C)** Left lobe of the liver shows periportal cuffing. **(D)-(F) Perforation of a duodenal ulcer. (G)** and **(H)** Asymmetrical thickening of the gallbladder wall. **(I)** CT scan shows striated nephrogram *(arrow)*. (**D-F** courtesy of Dr. A.E. Hanbidge, University of Toronto.)

Torsion (Volvulus) of Gallbladder

Gallbladder torsion is a rare, acute entity. Patients have symptoms of acute cholecystitis. Volvulus is often seen in older women and may be related to a mobile gallbladder with a long suspensory mesentery. The hallmarks on imaging are a massively distended and inflamed gallbladder lying in an unusual horizontal position, with its long axis oriented in a left-to-right direction. A twist of the cystic artery and cystic duct may be visible. If the torsion is greater than 180 degrees, gangrene of the gallbladder ensues; otherwise, obstruction of the cystic duct and acute cholecystitis occur. In either case, treatment is usually surgical.[92]

Chronic Cholecystitis

Chronic cholecystitis is associated with the mere presence of gallstones; therefore patients are usually asymptomatic and have mild disease. Chronic cholecystitis has the same incidence and risk factors as gallstone disease. More advanced cases involve wall thickening and fibrosis, appearing on sonographic

examination as a thick-walled gallbladder with gallstones. Differentiation from acute cholecystitis is made by the absence of other signs, namely, gallbladder distention, Murphy sign, and hyperemia in the wall.[93] Bouts of acute cholecystitis may complicate chronic cholecystitis.

Xanthogranulomatous cholecystitis is a rare form of chronic cholecystitis in which collections of lipid-laden macrophages occur within grayish yellow nodules or streaks in the gallbladder wall. In addition to gallstones, hypoechoic nodules or bands within the thickened wall, representing the lipid-laden xanthogranulomatous nodules, may suggest the diagnosis.[94]

Porcelain Gallbladder

Calcification of the gallbladder wall is termed *porcelain gallbladder.* Its cause is unknown, but it occurs in association with gallstone disease and may represent a form of chronic cholecystitis. This rare entity is seen in up to 0.8% of cholecystectomy specimens, with a female predominance and most often found in the sixth decade of life.[95] Two large studies disputed a high incidence of gallbladder carcinoma in porcelain gallbladder, suggesting the coincidental occurrence of the two entities in up to 7% of patients.[96,97] Nevertheless, prophylactic resection is advised.[94]

The degree and pattern of calcification determine the sonographic appearance (Fig. 6.43). When the entire gallbladder wall is thickly calcified, a hyperechoic semilunar line with dense posterior acoustic shadowing is noted. Mild calcification appears as an echogenic line with variable degrees of posterior acoustic shadowing. The luminal contents may be visible. Interrupted clumps of calcium appear as echogenic foci with posterior shadowing.[76] Differential diagnosis includes gallstones and emphysematous cholecystitis. Because the calcifications occur in the wall of the gallbladder, the wall-echo-shadow complex is absent (see "Gallstone Disease").

Adenomyomatosis (Adenomatous Hyperplasia)

Gallbladder adenomyomatosis is a benign condition caused by exaggeration of the normal invaginations of the luminal epithelium **(Rokitansky-Aschoff sinuses)** with associated smooth muscle proliferation (Fig. 6.44). The affected areas demonstrate thickening of the gallbladder wall with internal cystic spaces, the key to the radiologic diagnosis. The great majority of adenomyomatoses are asymptomatic.[98]

Adenomyomatosis may be **focal** or **diffuse.** The most common appearance on sonography is tiny, echogenic foci in the gallbladder wall that create **comet-tail artifacts,** presumably caused by either the cystic space itself or the internal debris (Fig. 6.45). Prominent masslike focal areas of adenomyomatosis, called **adenomyomas,** are the next most common manifestation. Careful evaluation of the adenomyoma, sometimes requiring higher frequency or linear probes, can show several features that are diagnostic of the entity and allow for differentiation from neoplasm. The most diagnostic finding, although not the most common, is the presence of cystic spaces. Echogenic foci with comet-tail or "twinkling" artifact on Doppler examination are also typical. Focal adenomyomatosis is most common in the gallbladder fundus, less often narrowing the midportion of the organ, called **hourglass gallbladder** (Fig. 6.46).

Fundal adenomyomas are often folded onto the body of the gallbladder and can occasionally be mistaken for a pericholecystic or even a hepatic mass. The entire gland wall may be involved, causing collapse of the lumen. The absence of the cystic spaces, echogenic foci, or twinkling artifact or the presence of internal vascularity should prompt further investigation to differentiate from neoplasm. MRI or MRCP allows for improved specificity, with the presence of cystic spaces within the thickened wall leading to the diagnosis.[99]

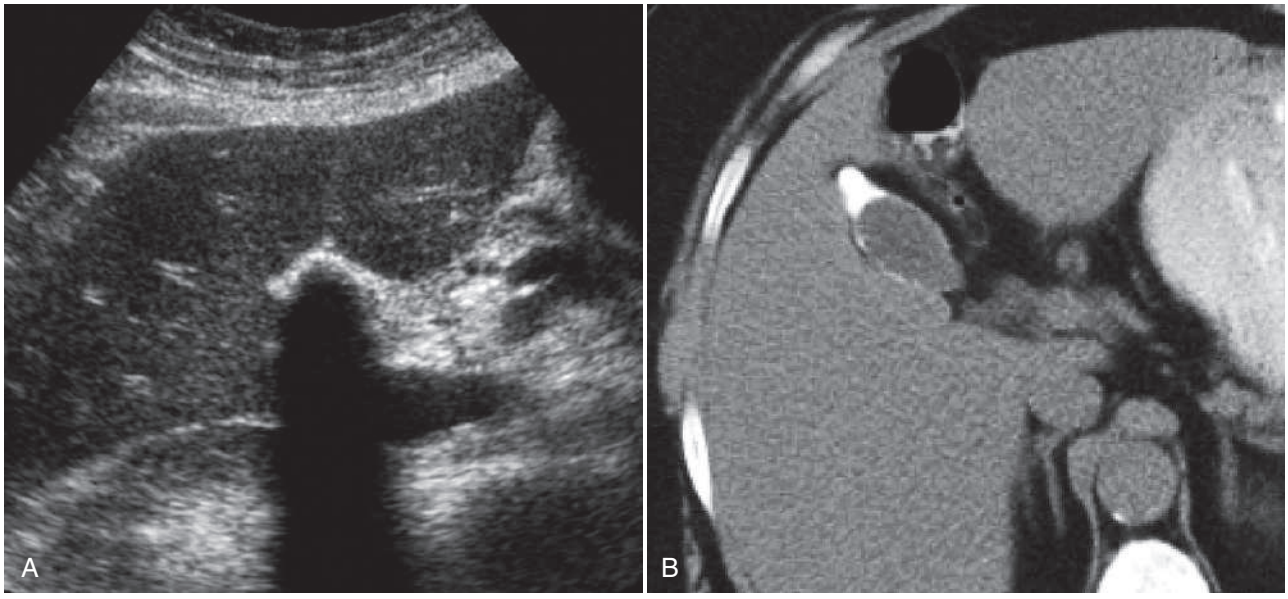

FIG. 6.43 Porcelain Gallbladder. (A) Sonogram. **(B)** Corresponding CT scan. On ultrasound, this appearance could be mistaken for a stone within the gallbladder lumen. There is, however, no gallbladder wall superficial to the echogenic focus.

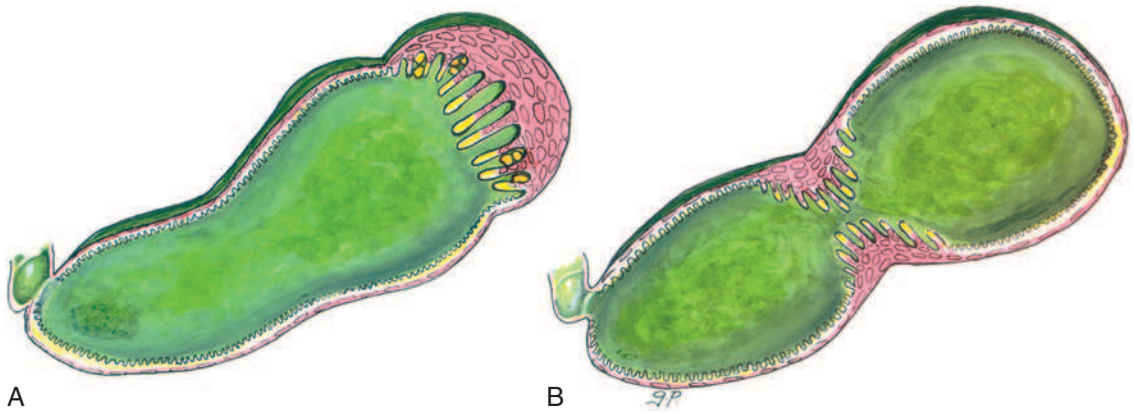

FIG. 6.44 Segmental Adenomyomatosis. (A) Fundal adenomyoma. **(B)** Hourglass adenomyomatosis. In both cases, note the constricted contour of the gallbladder and thickening of the wall with hypertrophy of the smooth muscle. On sonography, the exaggerated Rokitansky-Aschoff sinuses may appear as cystic spaces or as echogenic foci with comet-tail artifact, possibly caused by cholesterol crystals (depicted here as *yellow particles*) lodged in them.

Polypoid Masses of Gallbladder

Differentiation of benign and malignant polyps is essential because benign masses are common and malignant polyps require early intervention to improve outcome. Current evidence suggests that risk of malignancy in polyps less than 6 mm in size is negligible and they require no further follow-up.[100-102] More recent data suggest that gallbladder adenomas form a small fraction of 6- to 10-mm polyps and because they may have a risk of malignant transformation, imaging follow-up is recommended.[101,103] Whether such practice, based on retrospective surgical series, is justified through a cost-benefit analysis remains unknown, especially in a Western population where gallbladder cancer is rare.[104] Malignancy has been documented in 37% to 88% of resected polyps greater than 10 mm and therefore resection of these larger polyps is advised.[105]

Apart from size, research from both endoscopic and high-resolution ultrasound has identified additional features that help differentiate nonneoplastic from neoplastic polyps. The presence of hypoechoic foci centrally within the polyp has been shown to be a significant predictor of neoplastic polyps with sensitivity/specificity of 85%/67% on high-resolution transabdominal ultrasound and 91%/89% on endoscopic ultrasound.[106,107] Also the presence of a central vessel within the polyp (vascular core) and hypoechoic appearance are suggestive of a neoplastic polyp.

Cholesterol Polyps

Approximately one-half of all polypoid gallbladder lesions are cholesterol polyps. These represent the focal form of gallbladder **cholesterolosis,** a common nonneoplastic condition of unknown origin. Cholesterolosis results in accumulation of lipids within macrophages. The diffuse form, commonly known as **"strawberry gallbladder,"** is not visible on imaging. Cholesterolosis has the same risk factors as gallstone disease, but the two conditions rarely coexist.[98] Cholesterol polyps usually are 2 to 10 mm, although lesions up to 20 mm have been described.[105] On pathologic series, one-fifth are solitary, but the mean number of polyps is eight.[98]

Common Polypoid Masses of the Gallbladder

Cholesterol polyps[a] (50%-60%)
Inflammatory polyps[a] (5%-10%)
Adenoma[a] (<5%)
Focal adenomyomatosis
Gallbladder adenocarcinoma
Metastases (especially melanoma)

[a]Data from Bilhartz LE. Acalculous cholecystitis, cholesterolosis, adenomyomatosis, and polyps of the gallbladder. In: Feldman M, et al., editors. Sleisenger and Fordtran's gastrointestinal and liver disease. 7th ed. New York: Elsevier Science; 2002. pp. 1123-1125.[98]

The sonographic appearance of cholesterol polyps is multiple ovoid, nonshadowing lesions attached to the gallbladder wall (Fig. 6.47). Unlike small, nonshadowing stones, polyps are not mobile. Larger lesions may contain a fine pattern of echogenic foci.[108]

Adenomas, Adenomyomas, and Inflammatory Polyps

Adenomas are true benign neoplasms of the gallbladder, with a premalignant potential much lower than for colonic adenomas. Adenomas represent less than 5% of gallbladder polyps and occur as solitary lesions. They have a propensity to occur in patients with primary sclerosing cholangitis and polyposis syndromes.[109] Adenomas are usually pedunculated, and larger lesions may contain foci of malignant transformation.[98] Adenomas tend to be homogeneously hyperechoic but become more heterogeneous as they increase in size[105] (Fig. 6.48). Thickening of the gallbladder wall adjacent to an adenoma should suggest malignancy. Central hypoechoic foci, representing central vessels or microscopic cysts are quite suggestive.[107] On occasion, an **adenomyoma** may appear as a sessile, polypoid gallbladder lesion. Imaging features, especially hyperechoic foci with or without comet-tail artifact and microcysts, should allow differentiation.[106] **Inflammatory**

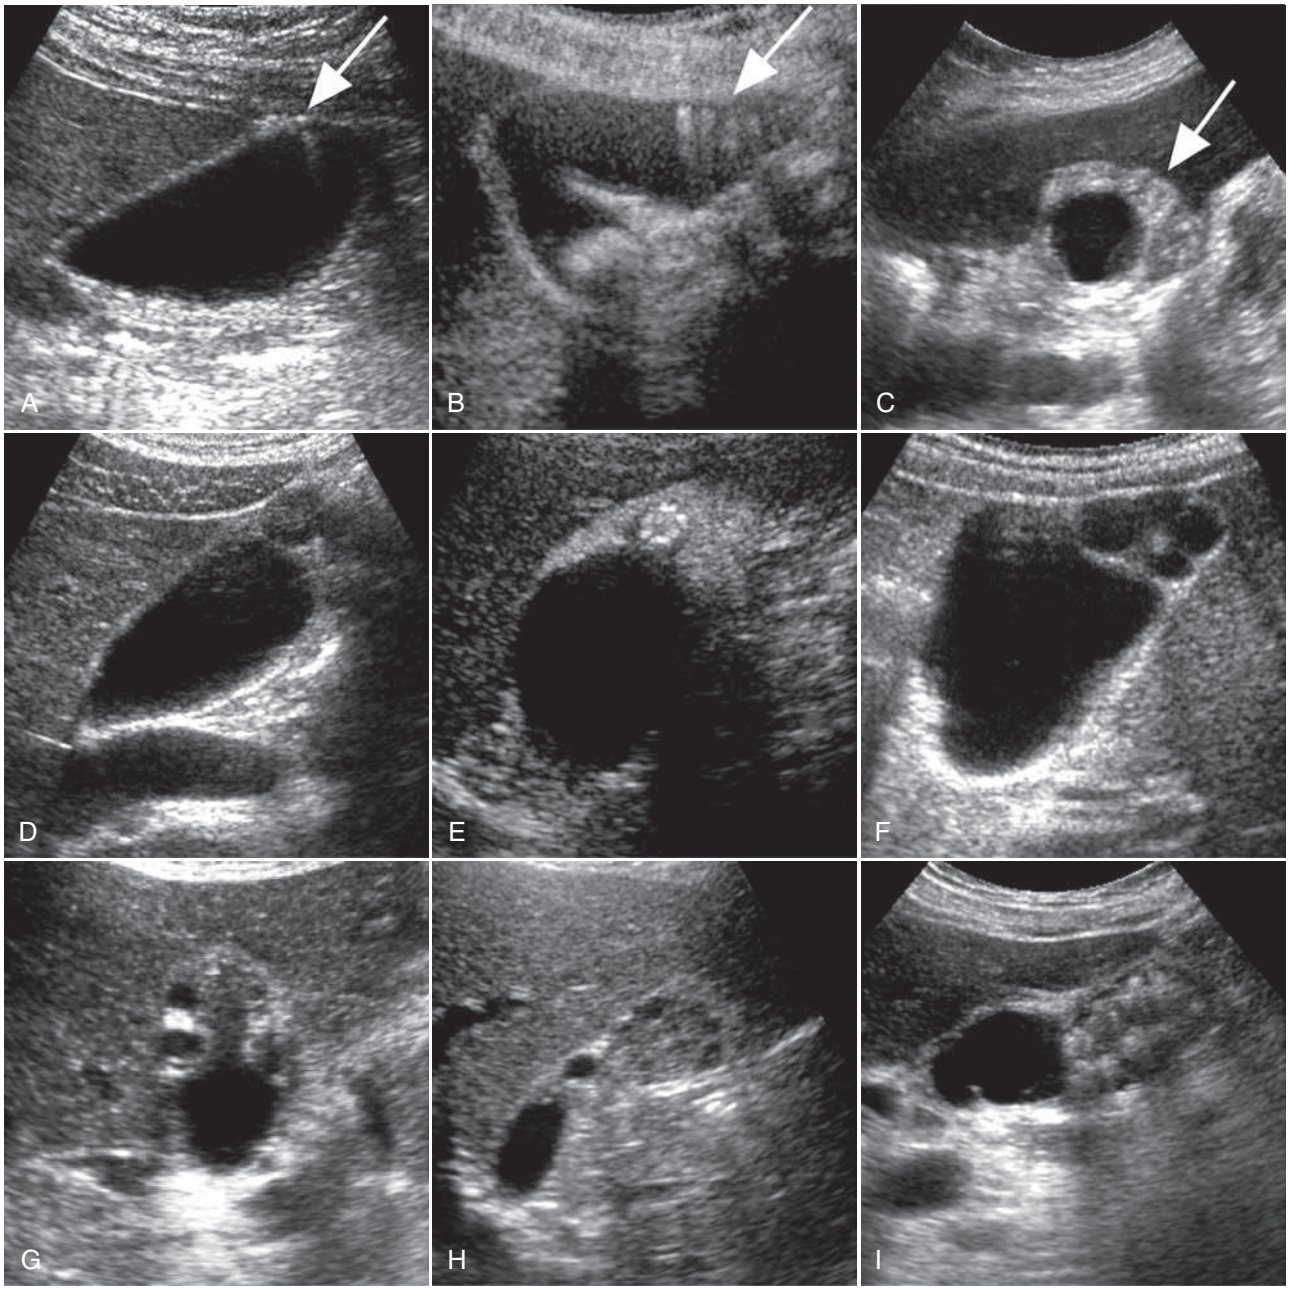

FIG. 6.45 Adenomyomatosis: Spectrum of Appearances. (A)-(C) Focal adenomyomatosis, the most common manifestation. **(A)** Small focal area of thickening of the anterior fundal wall *(arrow)* with a bright echogenic focus with a distal comet-tail artifact. **(B)** Multiple bright foci *(arrow)* with distal artifacts. **(C)** Highly echogenic focal thickening of the gallbladder wall *(arrow)*. Increased echogenicity is unusual for a malignant tumor that is more likely to appear hypoechoic. **(D)-(F) Fundal adenomyomas. (D)** Adenomyoma appears hypoechoic and masslike. **(E)** Caplike area with multiple tiny, highly echogenic foci that suggest multiple crystals in the Rokitansky-Aschoff sinuses. **(F)** Multiple cystic spaces within the adenomyoma. **(G)-(I) Segmental adenomyomatosis. (G)** and **(H)** Masslike areas obliterating the gallbladder lumen. Multiple cystic spaces suggest the correct diagnosis. **(I)** Multiple echogenic foci suggest crystals in the Rokitansky-Aschoff sinuses.

polyps of the gallbladder constitute 5% to 10% of gallbladder polyps and are multiple in one-half of the cases.[98] Inflammatory polyps tend to occur in the background of gallstone disease and chronic cholecystitis.[110] The sonographic appearance of these lesions has not been systematically studied.

Malignancies

Primary gallbladder adenocarcinomas may appear as a polypoid mass. Melanoma is reported to be the cause of 50% to 60% of metastases to the gallbladder. These appear as hyperechoic, broad-based polypoid lesions, potentially multiple and usually more than 10 mm in diameter.[111] But in our experience, the most common metastases to the gallbladder are from signet ring cell adenocarcinomas, particularly from gastric primaries. However, these are not polypoid but rather diffusely infiltrative in nature, causing contraction of the gallbladder with a hyperemic wall. In a series of 20 pathologically proven gallbladder metastases, bowel adenocarcinomas accounted for 60% of

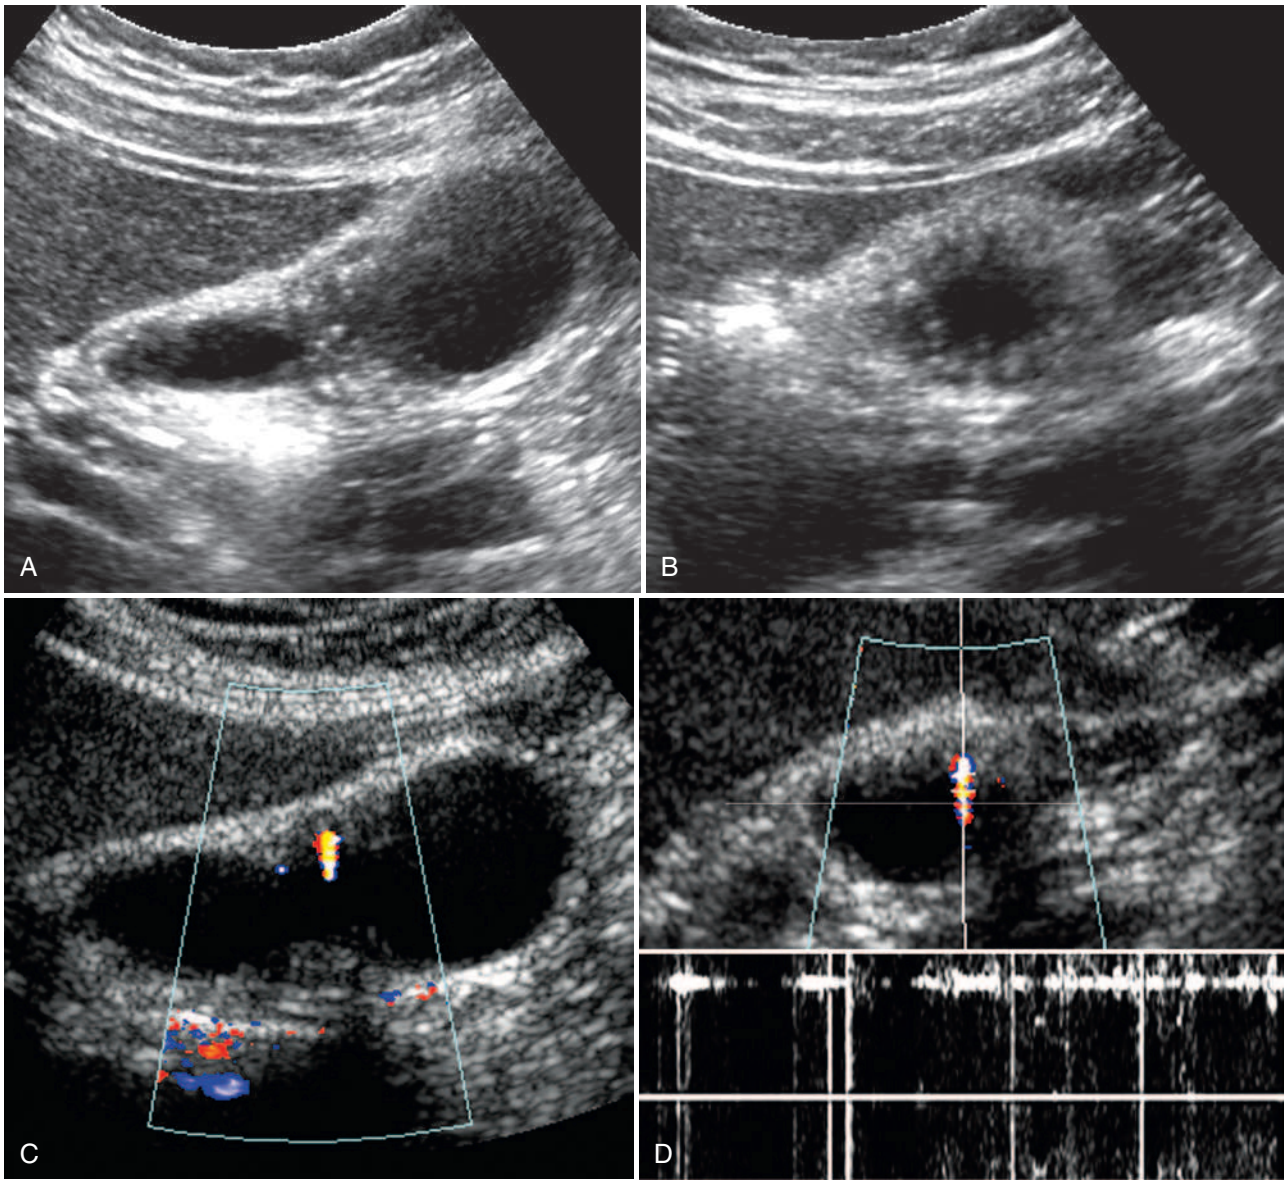

FIG. 6.46 Hourglass Adenomyoma. (A) Sagittal and **(B)** transverse sonograms show thickening of the gallbladder wall, creating an hourglass configuration. At the point of wall thickening, there are innumerable bright echogenic foci with comet-tail artifact, suggesting cholesterol crystals in Rokitansky-Aschoff sinuses. **(C)** and **(D)** Color and spectral Doppler show "twinkling" artifact without real vascularity, supportive of the correct diagnosis.

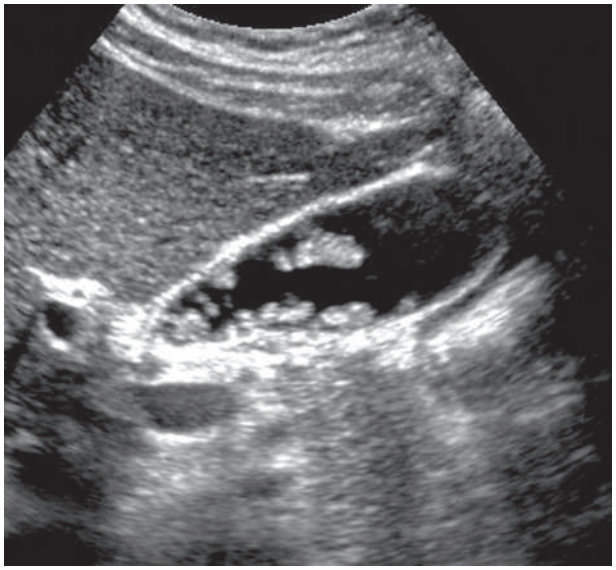

FIG. 6.47 Gallbladder Polyps. Small size (≤10 mm) and multiple tumors are features most suggestive of a benign lesion.

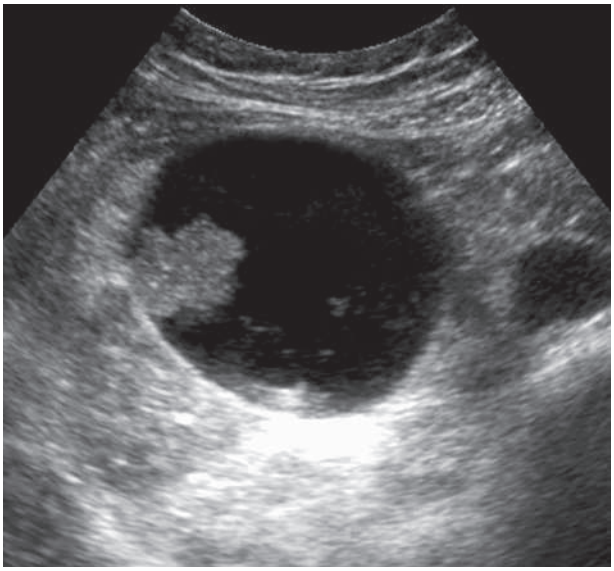

FIG. 6.48 Gallbladder Adenoma. Transverse image through the gallbladder shows a polypoid lesion found incidentally in a patient with mild acute cholecystitis. The lesion was a tubulovillous adenoma on resection.

the primary sites.[112] Advanced hepatocellular carcinoma can directly invade the gallbladder fossa and extend through the gallbladder wall to appear as a luminal mass. The large hepatic component of the mass and its hypervascular nature assist in the diagnosis.

Gallbladder Carcinoma

Gallbladder carcinoma is an uncommon malignancy occurring mainly in the older population, with a 3:1 female-to-male ratio. High incidence of gallbladder cancer is reported along the Pacific coast of South America and in East and South Asian countries.[113] In a majority of cases, carcinoma is associated with gallstones. Chronic gallstone disease and resultant dysplasia have been cited as a causative factor.[114] More recently, pancreaticobiliary maljunction (long common channel between the pancreatic and the bile duct that extends outside of the duodenal wall) and chronic ***Salmonella typhi*** carrier state have been implicated as risk factors.[113,115] About 98% of gallbladder carcinomas are

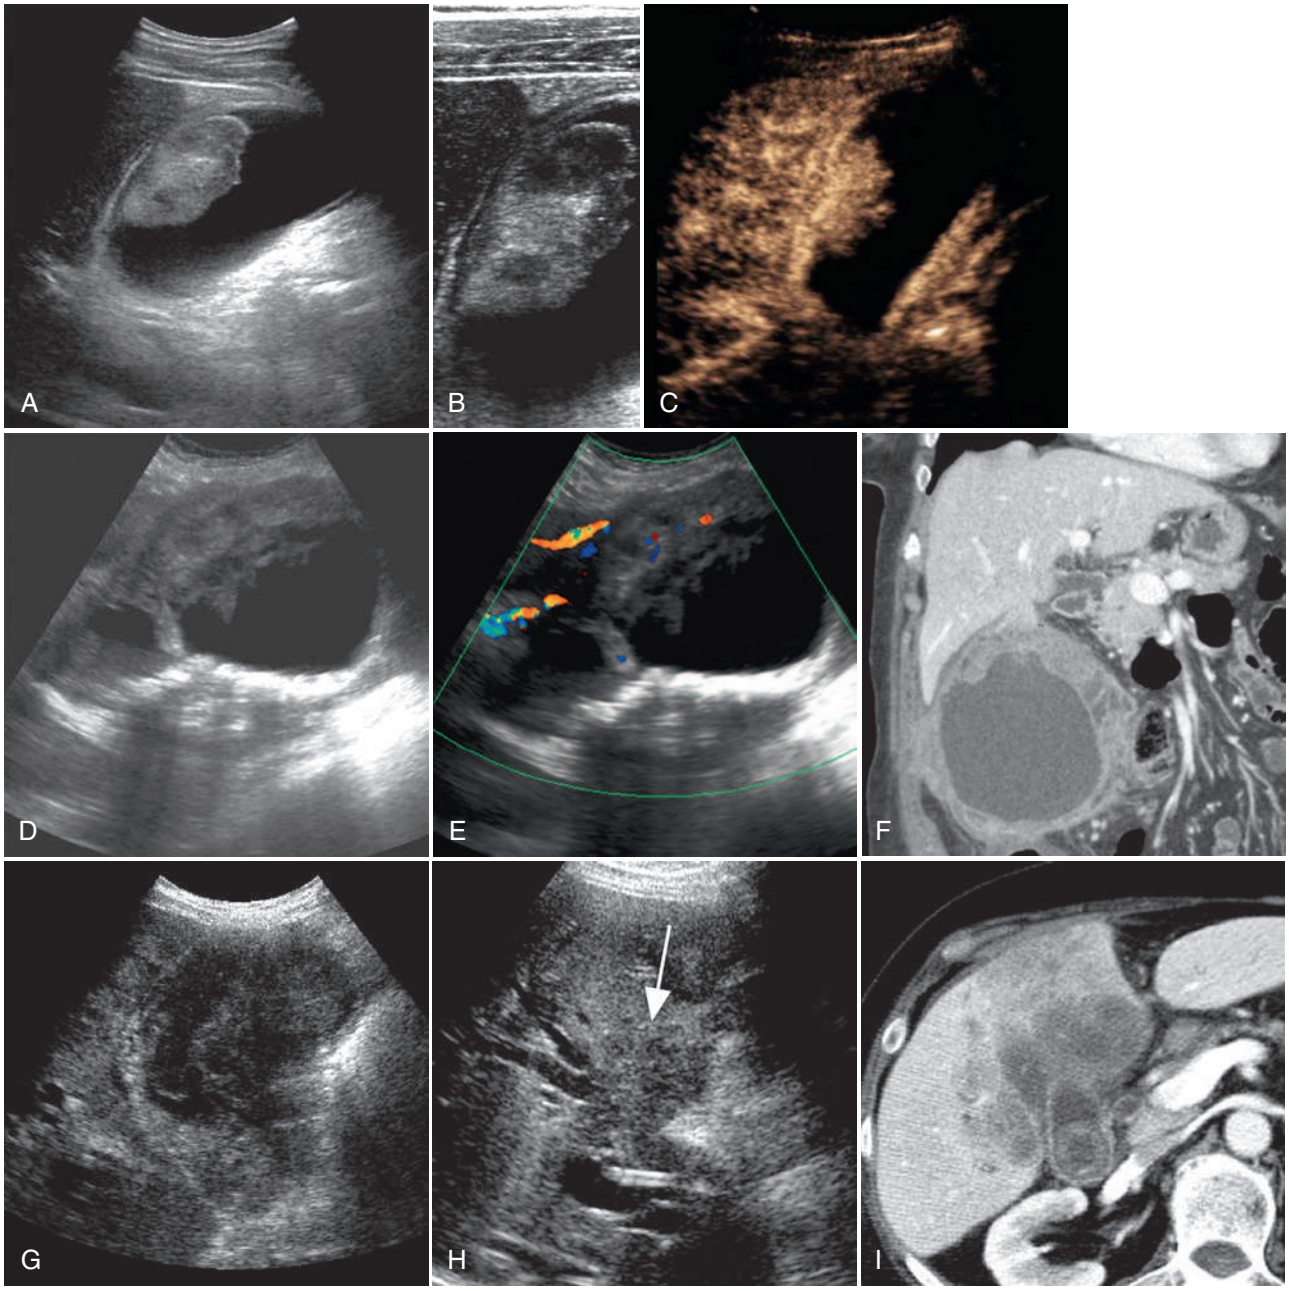

FIG. 6.49 Gallbladder Cancer: Spectrum of Appearances. (A) and **(B) Polypoid mass. (A)** A large polypoid mass. **(B)** Examination with high-frequency linear probe shows no invasion beyond the gallbladder wall. **(C)** Contrast-enhanced examination confirms the solid vascular nature of the mass and rules out hepatic extension. **(D)-(F) Wall thickening. (D)** and **(E)** Extensive asymmetrical, heterogeneous wall thickening in a markedly enlarged gallbladder with abnormal flow on Doppler assessment. **(F)** Corresponding CT scan. **(G)-(I) Invasive gallbladder cancer. (G)** and **(H)** Huge mass replacing the gallbladder fossa and invading the liver. **(H)** Biliary obstruction caused by the invasive mass *(arrow).* **(I)** Corresponding CT scan.

adenocarcinomas, with squamous cell carcinoma and metastases accounting for the rest. The following three patterns of disease have been described:

- Mass arising in the gallbladder fossa, obliterating the gallbladder and invading the adjacent liver (most common pattern)
- Focal or diffuse, irregular wall thickening
- Intraluminal polypoid mass

Patterns of Tumor Spread

Because the gallbladder wall is quite thin, without a muscularis mucosa and little connective tissue to separate it from the liver parenchyma, contiguous hepatic invasion is the most common pattern of spread. Gallbladder tumors also extend along the cystic duct into the porta hepatis, where they mimic hilar cholangiocarcinomas. Tumor extension into bile ducts or encasement of the portal vein or hepatic artery may ensue. Direct invasion into adjacent loops of bowel, especially the duodenum or colon, may also occur. A resultant **cholecystenteric fistula** and inflammation may be mistaken for a benign abscess collection. Metastases to the peritoneum are a common finding.

Lymphatic spread is also a common feature of gallbladder carcinoma and may occur in the absence of invasion of adjacent organs.[116] The first nodes to be affected are in the hilar region. Adenopathy may then extend either down the hepatoduodenal ligament, to affect peripancreatic and mesenteric nodes, or across the gastrohepatic ligament to celiac nodal stations.

Surgical resection is the only chance of cure; however, reported resection rates range from 10% to 30%.[116] If the tumor is not confined to the mucosa, an extended cholecystectomy, involving resection of 3- to 5-cm rim of liver adjacent to the gallbladder fossa, or a formal right hepatectomy is required. Regional lymph nodes of the cystic bile ducts and CBDs are also removed. Noncontiguous hepatic or peritoneal metastases, celiac or peripancreatic nodal disease, or encasement of the main portal vein or hepatic artery should be carefully sought because they render the patient unresectable.

Sonographic Appearance

The appearance on sonography varies depending on the **pattern** of carcinoma (Fig. 6.49). When masses replacing the normal gallbladder fossa are small, it may be difficult to appreciate them because they may blend into the liver. The absence of a normal-appearing gallbladder with no history of cholecystectomy should raise suspicion. A clue to the diagnosis is the common presence of an immobile stone that is engrossed by the tumor, the "trapped stone." On Doppler interrogation the mass may demonstrate internal arterial and venous flow. Diffuse, malignant thickening of the wall differs from other causes in that the wall is irregular with loss of the normal mural layers. Polypoid intraluminal masses are differentiated from nonneoplastic abnormalities by immobility of the mass, larger size (>1 cm), and prominent internal vascularity. Gallbladder carcinomas may produce large quantities of *mucin,* which distends the gallbladder.

Contrast-enhanced ultrasound has been reported to be a useful tool in differentiating benign from malignant gallbladder disease. In one study, the disruption of the wall of the gallbladder as detected by contrast-enhanced ultrasound was reported as a having a sensitivity of 85% and specificity of 100% in diagnosing gallbladder cancer.[117]

Sonography performs very well in locally staging gallbladder carcinoma. Bach et al.[118] reported 94% sensitivity and 63% accuracy for prediction of resectability compared with surgical findings. More recently, high-resolution ultrasound of gallbladder cancer using higher frequency probes (5-12 MHz) has shown excellent performance in differentiating T1 from higher tumor stages.[106] However, sonography is often difficult in patients with unresectable disease because of limited detection of noncontiguous hepatic, lymph node, and especially peritoneal metastases. A CT scan is recommended to improve detection of metastatic gallbladder disease.

CHAPTER 7

The Pancreas

Thomas Winter and Maryellen R.M. Sun

SUMMARY OF KEY POINTS

- Knowledge of a few key scanning techniques will optimize imaging of the entire pancreas.
- Understanding of the embryologic development, normal anatomy, and anatomic variants of the pancreas aids in detection and characterization of disease.
- Ultrasound plays an important role in assessment of acute and chronic pancreatitis, allowing for detection of gallstones, bile duct dilation, and guiding aspiration and drainage when needed.
- Computed tomography is the imaging modality of choice for staging pancreatic cancer, but ultrasound can be used to detect, characterize, and stage solid pancreatic neoplasms.
- Cystic pancreatic lesions are common, and it is important to understand the benign and malignant features of these lesions.

CHAPTER OUTLINE

ANATOMY AND SONOGRAPHIC TECHNIQUE
Pancreatic Body
Pancreatic Head
Pancreatic Tail
Pancreatic Parenchyma
Fatty Pancreas
Embryology and Pancreatic Duct
Imaging Anatomic Variants
Peripancreatic Structures
ACUTE PANCREATITIS
Approach to Imaging
Ultrasound Findings
Complications
Acute Fluid Collections
Pseudocysts
Necrosis and Abscess
Treatment
Vascular Complications
CHRONIC PANCREATITIS
Approach to Imaging
Ultrasound Findings
Pseudocysts
Portal and Splenic Vein Thrombosis
Masses Associated With Chronic Pancreatitis
PANCREATIC NEOPLASMS
Periampullary Neoplasm
Pancreatic Carcinoma
Detection of Pancreatic Cancer
Ultrasound Findings
Resectability Imaging
Color Doppler Ultrasound
CYSTIC PANCREATIC LESIONS
Simple Pancreatic Cysts
Cystic Neoplasms
Serous Cystic Neoplasm
Intraductal Papillary Mucinous Neoplasm
Mucinous Cystic Neoplasm
Solid-Pseudopapillary Tumor
Rare Cystic Tumors
OTHER PANCREATIC MASSES
Endocrine Tumors
Unusual and Rare Neoplasms
Lipoma
Metastatic Tumors

Acknowledgment

Pancreatic sonography can be an efficient and valuable tool in many common diseases, such as pancreatitis and pancreatic neoplasm. Sonography is often the first test used in patients with jaundice or abdominal pain. However, sonography is "technically dependent" and necessitates understanding techniques to optimize pancreatic sonography. Knowledge of sonographic findings in common (and less common) pancreatic diseases is crucial to obtaining good imaging and clinical outcomes in these patients.

ANATOMY AND SONOGRAPHIC TECHNIQUE

Patient preparation is important in pancreatic sonography. An 8-hour fast before the study (usually overnight) is recommended, but we allow our patients to drink water and take medicines orally.

The three key regions of the pancreas are the head, body, and tail. The visualization of each requires knowledge of pancreatic anatomy, appropriate patient positioning, and often the use of multiple transducers. The pancreas lies obliquely in the anterior pararenal space of the **retroperitoneum,** with the head caudal to the body and tail. The pancreas is draped over the **spine and aorta;** thus the neck and body are more superficial than the head and tail. The more caudal position of the head often leads to the technical error of not visualizing the entire head on "transverse" scans. This can be avoided by understanding the anatomy and by visualizing the normal uncinate process behind the gastrocolic trunk on images of the pancreatic head (Fig. 7.1). Knowledge of a few key scanning techniques will optimize imaging of the entire pancreas.

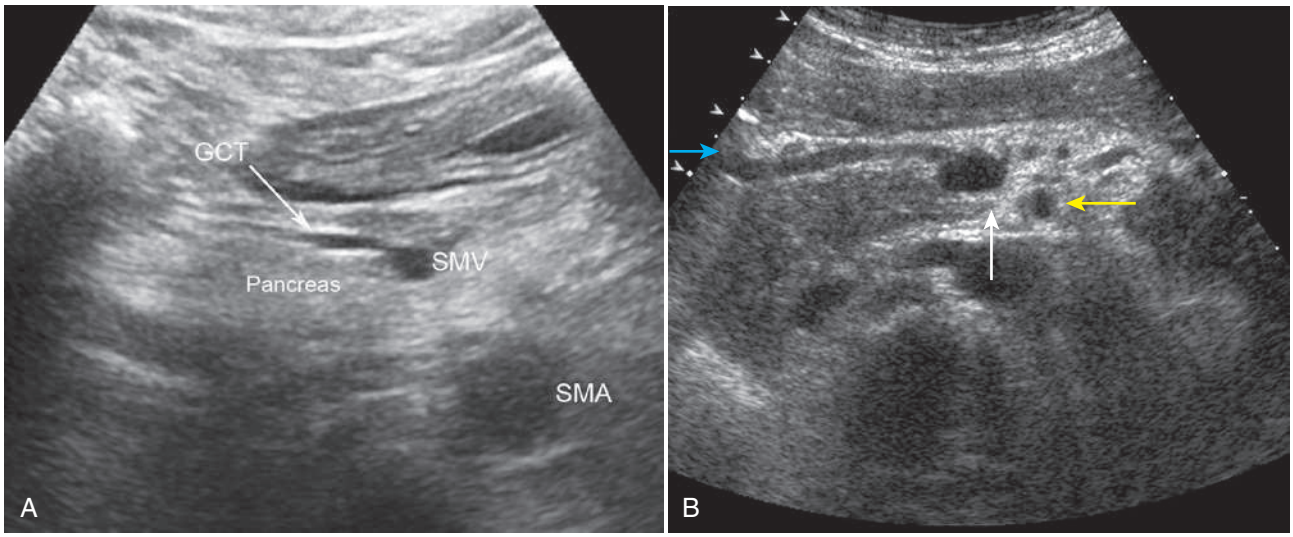

FIG. 7.1 Normal Pancreatic Head and Gastrocolic Trunk. (A) Transverse image of the pancreatic head and its ventral landmark, the gastrocolic venous trunk *(GCT).* The caudal uncinate *(Pancreas)* is dorsal to the GCT. **(B)** In another patient, note the triangular point of the uncinate that points medially *(white arrow)* behind the SMV and nearly reaches the SMA *(yellow arrow).* GCT *(blue arrow)* enters the SMV. *SMA,* Superior mesenteric artery; *SMV,* superior mesenteric vein.

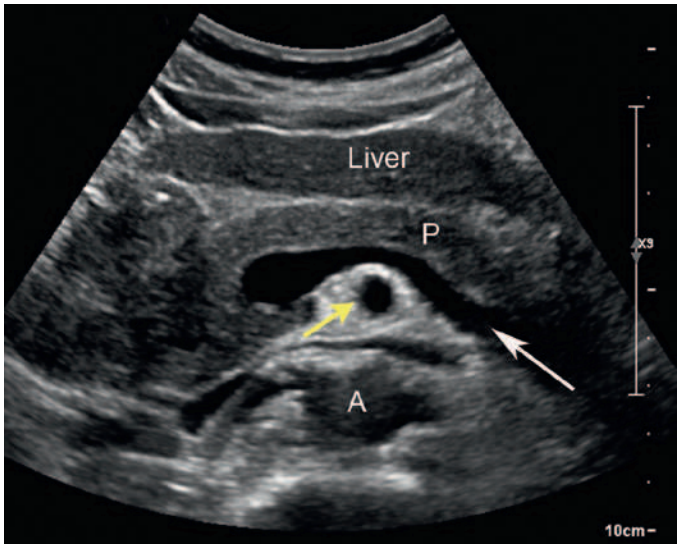

FIG. 7.2 Normal Pancreatic Body and Landmarks. Transverse image of the pancreatic body and its dorsal landmark, the splenic vein *(white arrow)* and portosplenic confluence. Note the normal parenchymal echogenicity, similar to that of the liver echogenicity. The superior mesenteric artery *(yellow arrow)* is surrounded by a collar of fat. *A,* Aorta; *P,* pancreas. See also Video 7.1.

Pancreatic Body

Compression scanning with a "large footprint," curved linear transducer is the key technique in visualizing the body of the pancreas. Compression displaces gas and fluid from the overlying stomach and duodenum and places the transducer closer to the pancreas itself. The key vascular landmarks for the body of the pancreas are the **splenic vein,** its confluence with the **superior mesenteric vein** (SMV), and the **superior mesenteric artery** (SMA) (Fig. 7.2, Video 7.1). Some call the region between the body and head of the pancreas the "neck," generally referring to the part of the pancreatic body ventral to the SMA-SMV and portosplenic confluence (Fig. 7.3).

Start scanning with the patient supine. Initially, scan the patient in quiet respiration. Breath holding may cause the patient to contract the abdominal muscles, preventing good compression. Images obtained in various degrees of held inspiration or, less often, expiration may facilitate pancreatic visualization. In inspiration the liver may be a useful sonographic window. In some patients a high-riding transverse colon may prevent good visualization of the pancreatic body. Unlike the stomach and duodenum, the contents of which are generally compressible, the colon often contains stool, which contains suspended gas. Stool cannot be compressed and is therefore an impediment to pancreatic sonography. In these patients, scanning caudal to the transverse colon and angling cephalic behind the colon may be useful. The left lateral decubitus position may also be useful, especially to see the left part of the body and more central tail. Position the transducer to the right of the midline and angle "down the barrel" (longitudinal axis) of the pancreatic body and tail (Fig. 7.4).

Other potentially useful techniques include scanning during a Valsalva maneuver and scanning after oral water or contrast administration,[1-3] sometimes combined with scanning while the patient is standing or sitting, using the fluid-filled stomach as a window.

Pancreatic Head

The head is the key pancreatic structure; common bile duct stones, periampullary neoplasms, and pancreatic/extrahepatic duct obstructions occur here. Failure to adequately visualize the pancreatic head is a common but usually avoidable technical failure. Supine compression imaging is useful but rarely allows demonstration of the periampullary region. Vascular landmarks for the pancreatic head are the **inferior vena cava** (IVC) dorsally, the SMA and SMV medially, and the **gastroduodenal artery**

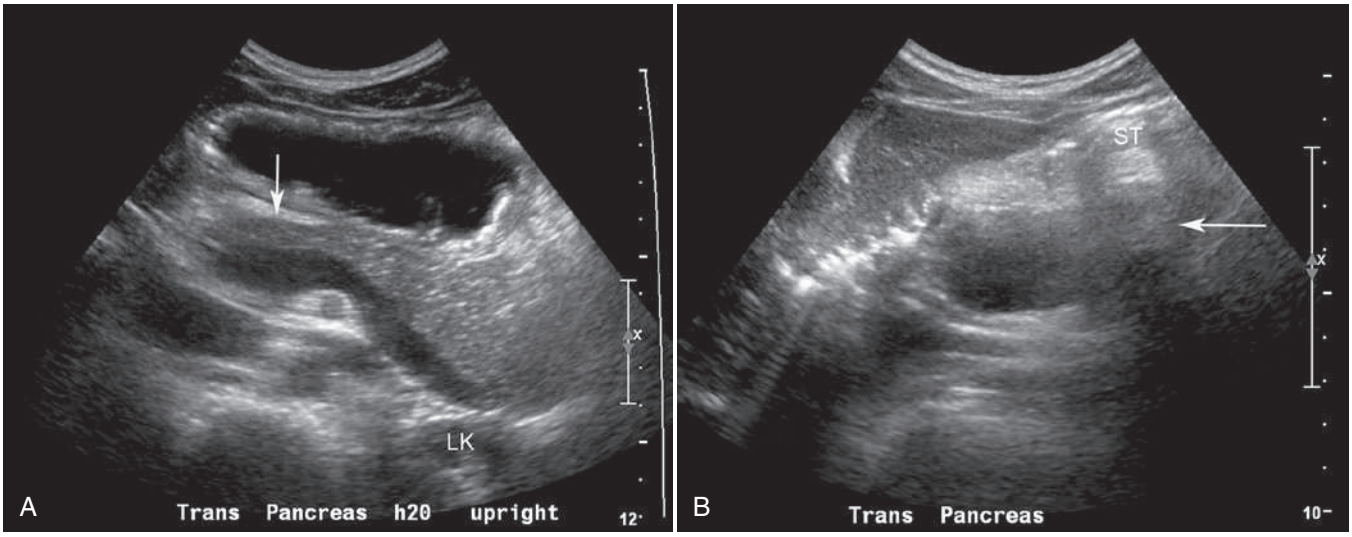

FIG. 7.3 Normal Pancreatic Neck and Body. (A) Transverse image of pancreatic body. The "neck" of the pancreas *(arrow)* is that part of the body ventral to the superior mesenteric artery and portosplenic confluence. **(B)** Role of technique in sonographic visualization of the pancreas. Transverse image of region of pancreas shows poor visualization of the gland *(arrow);* water was administered orally and patient placed in the upright position to achieve the image shown in **(A)**. *LK,* Left kidney*; ST,* stomach.

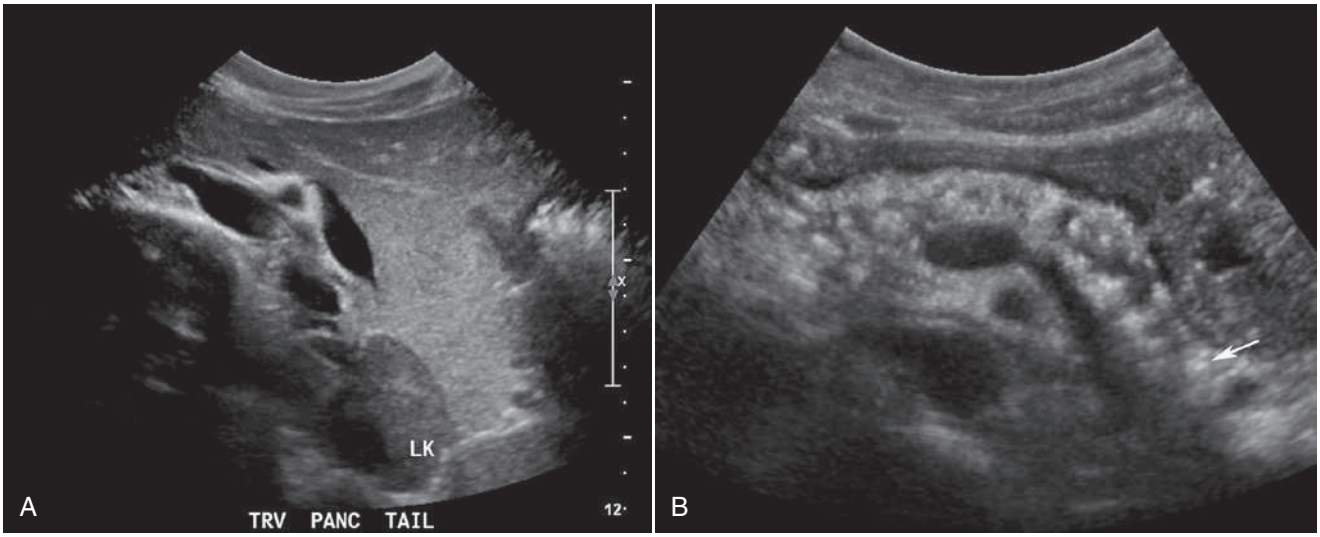

FIG. 7.4 Pancreatic Body and Tail. (A) Transverse image of the pancreatic body and tail obtained by positioning the transducer to the right of the midline and angling back toward the left. **(B)** In another patient with **chronic pancreatitis,** the transverse view shows the dilated pancreatic duct with scattered calcifications extending to the end of the duct in the pancreatic tail *(arrow). LK,* Left kidney.

(GDA) and the **pancreaticoduodenal arcade** anterolaterally (Fig. 7.5). The pancreatic head is usually directly ventral to the IVC. Cephalic to the pancreas, the IVC is adjacent to the portal vein; this location is the entrance into the lesser peritoneal sac, the **epiploic foramen (foramen of Winslow).**

The **uncinate process** (or uncinate) is a portion of the caudal pancreatic head that wraps around behind the SMA and SMV, ending in a point oriented medially. The uncinate process is medial and dorsal to the SMA and SMV (Fig. 7.6; see also Fig. 7.1B). The GDA is a landmark for the ventrolateral pancreatic head; the GDA courses between the pancreas and the second portion of the duodenum (Fig. 7.7).

Another useful vascular landmark for the pancreatic head and uncinate process is the **gastrocolic trunk** (GCT). Several splanchnic veins variably join to form the GCT. These often include the right or middle colic vein, right gastroepiploic vein, and pancreaticoduodenal veins. The GCT enters the right side of the SMV just anterior to the pancreatic head, thus serving as a ventral landmark for the uncinate process[4] (see Fig. 7.1).

The left lateral decubitus position is best to see the pancreas adjacent to the duodenum. In the left lateral decubitus position, scan in inspiration, and use the gallbladder or liver to either side of the gallbladder to view the rightmost portion of the pancreas

and the ampullary portion of the pancreatic and bile ducts (Fig. 7.8). It is best to be explicit when describing locations within the pancreas (e.g., mass within the tail of the pancreas) rather than using the terms *proximal* and *distal* because these terms are ambiguous when applied to the pancreas and may mean different things to different people.[5]

Pancreatic Tail

It is rarely necessary or helpful for the patient to drink water before the head or body of the pancreas is scanned. The **water-filled stomach,** however, may provide an excellent window for visualizing the pancreatic tail, the most difficult portion of the pancreas to visualize sonographically. To see the tail, place the patient in a right anterior oblique position and scan through the water-filled stomach (Fig. 7.9). Another helpful way to see the region of the pancreatic tail is coronal imaging through the spleen and left kidney, with the patient in a right lateral decubitus position (Fig. 7.10). Color Doppler sonography can reveal the splenic artery and vein, facilitating identification of the tail. Scanning through the spleen and left kidney, although not always revealing the normal pancreatic tail itself, may show abnormalities in the region of the tail (e.g., pseudocysts, masses) that are not visible on other views. The view through the left kidney and spleen should be routine in all pancreatic sonograms.

Pancreatic Parenchyma

The sonographic appearance of the normal pancreas varies widely in parenchymal echogenicity and texture, shape, and size. The

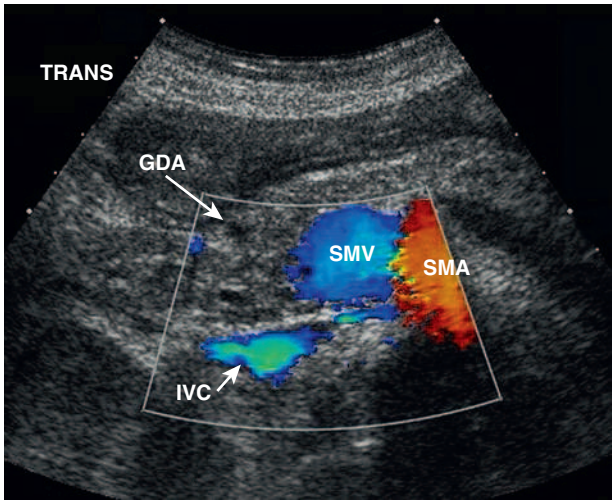

FIG. 7.5 Normal Pancreatic Head and Vascular Landmarks. Transverse sonogram shows vascular landmarks for the pancreatic head: inferior vena cava *(IVC)* dorsally, superior mesenteric artery *(SMA)* and superior mesenteric vein *(SMV)* medially, and gastroduodenal artery *(GDA)*.

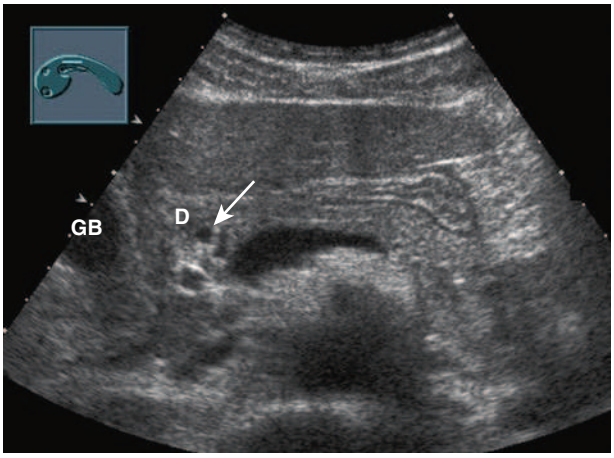

FIG. 7.7 Normal Gallbladder, Duodenum, and Pancreatic Head. Transverse sonogram shows the gastroduodenal artery (GDA) *(arrow)* as a landmark for the ventrolateral pancreatic head. The GDA courses between the pancreas and the second portion of the duodenum *(D)*. The gallbladder *(GB)* is lateral to the duodenum. The image shows the cephalic portion of the pancreatic head.

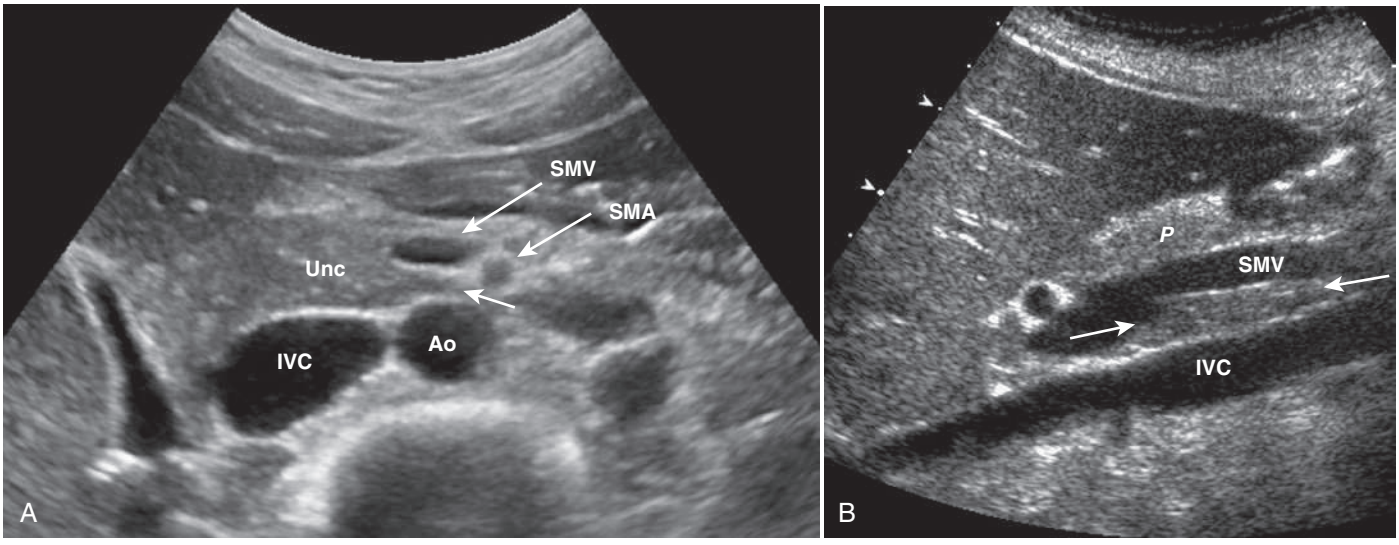

FIG. 7.6 Normal Uncinate Process. (A) Transverse sonogram showing the uncinate process *(Unc)*, the part of the pancreatic head dorsal to the superior mesenteric vein *(SMV)* and superior mesenteric artery *(SMA)*. Note the pointed medial tip of the uncinate *(small arrow)* (see also Fig. 7.1B). **(B)** Longitudinal sonogram in another patient shows the uncinate process *(arrows)* dorsal to the SMV and ventral to the inferior vena cava *(IVC)*. The neck/body of the pancreas *(P)* is ventral to the SMV. *Ao,* Aorta; *IVC,* inferior vena cava.

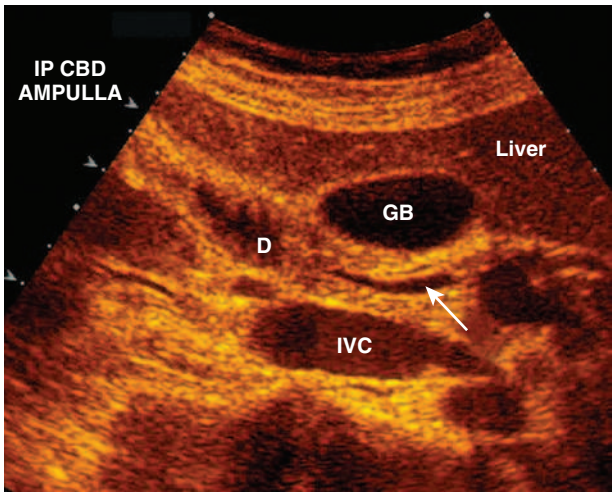

FIG. 7.8 Normal Ampullary Area and Bile Duct. Sonographic scan through the gallbladder *(GB)* and liver, with the patient in the left lateral decubitus position, to visualize the ampullary region shows the normal distal bile duct *(arrow)* as it passes through the pancreatic head and enters the duodenum through the major papilla. *D,* Duodenum; *IP CBD,* intrapancreatic common bile duct.

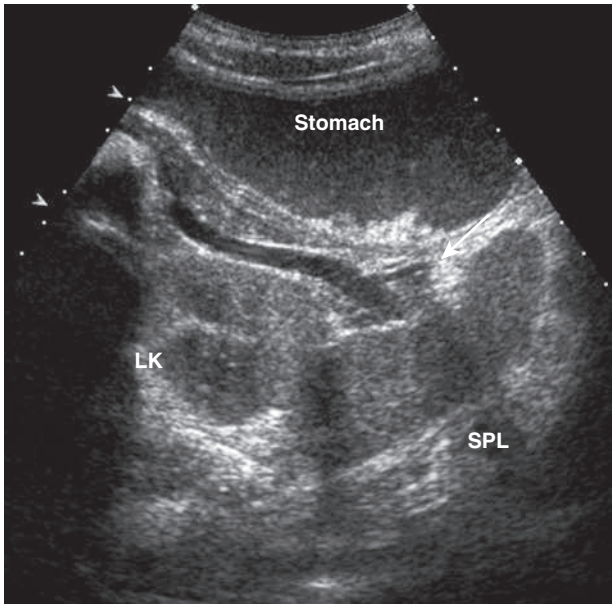

FIG. 7.9 Normal Pancreatic Body and Tail. Transverse image of the pancreatic body and tail, surrounding the splenic vein, seen through the fluid-filled stomach, with patient in a right anterior oblique position. *LK,* Left kidney; *SPL,* spleen.

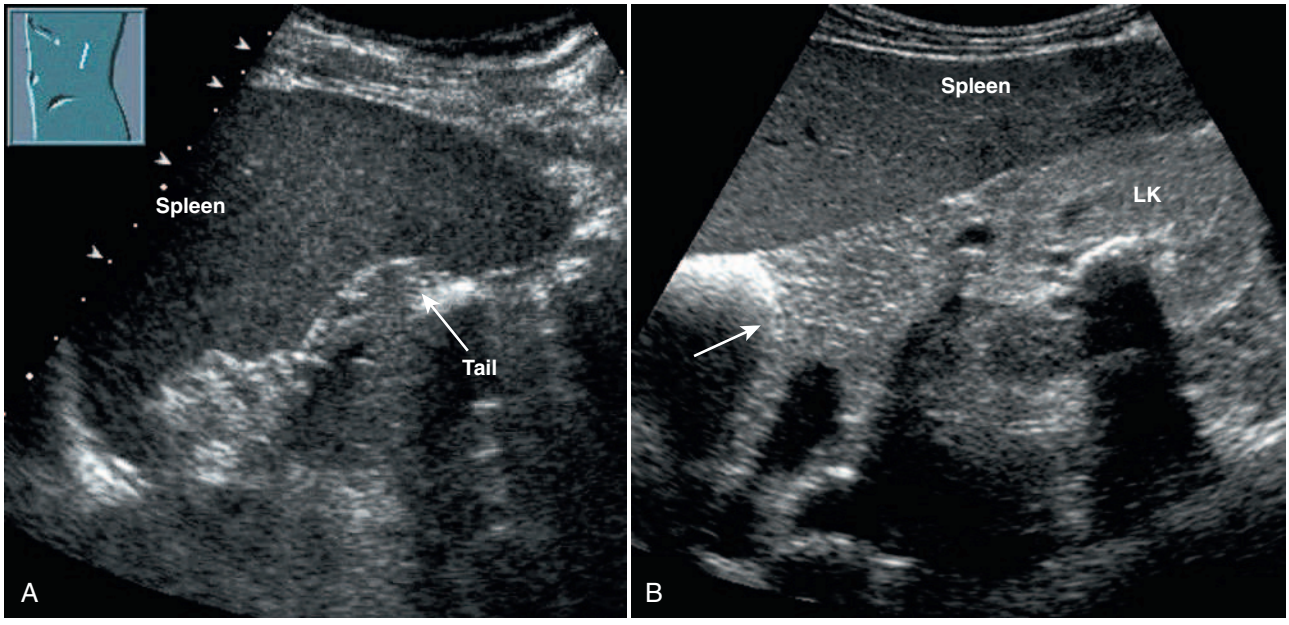

FIG. 7.10 Normal Pancreatic Tail. Pancreatic tail seen through the spleen, with patient in right lateral decubitus position. **(A)** Longitudinal coronal image shows the normal pancreatic tail *(arrow)* through the spleen. **(B)** Transverse image of the normal pancreatic tail *(arrow)*. Note large stone in the left kidney *(LK)* with a conspicuous acoustic shadow.

pancreatic parenchyma is usually isoechoic or hyperechoic compared with the hepatic parenchyma (Fig. 7.11; see also Figs. 7.2 and 7.3). Evidence indicates that pancreatic echogenicity increases with age.[6]

The parenchymal **texture** varies widely from homogeneous to a lobular internal architecture (Fig. 7.12). Pancreatic **size** varies considerably from individual to individual. Guerra et al.[7] found that the size of the head of the pancreas ranged from 6 to 28 mm (17.7 ± 4.2 mm), body size from 4 to 23 mm (10.1 ± 3.8 mm), and tail size from 5 to 28 mm (16.4 ± 4.2 mm). Men and women had comparable pancreatic size. The size of the pancreas diminishes with age.[7,8]

The **shape** of the pancreas can also vary considerably.[9] Variations in the shape of the pancreatic head are the most troublesome

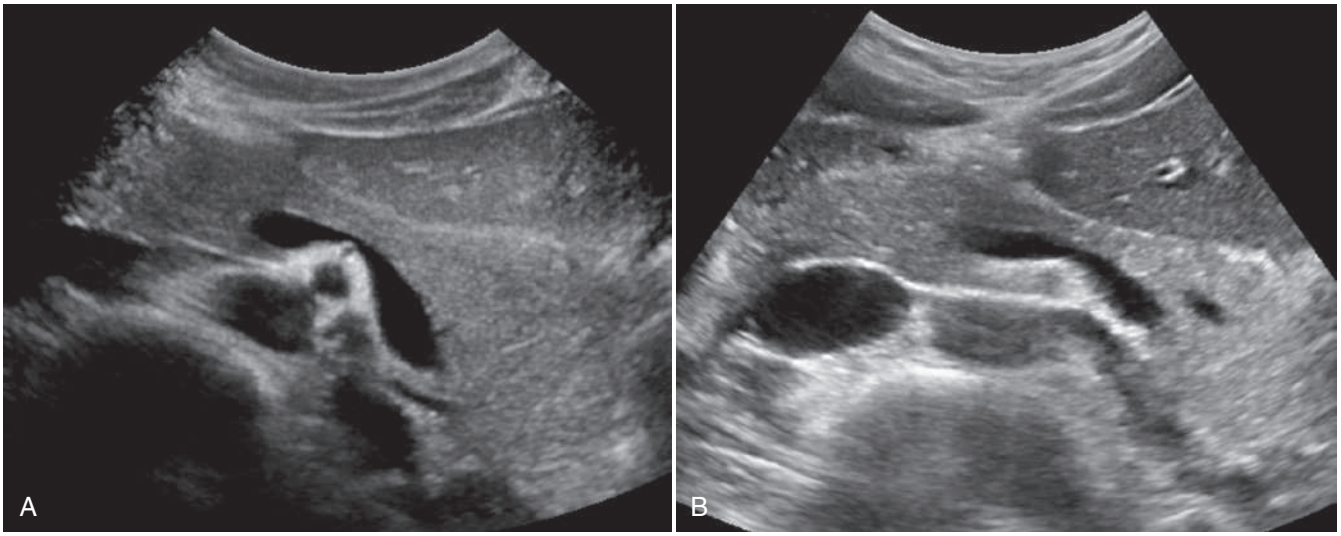

FIG. 7.11 Normal Pancreatic Parenchymal Echogenicity. (A) Transverse sonogram showing pancreas has echogenicity similar to that of the liver. **(B)** Transverse sonographic image of another patient, showing pancreas with a much more echogenic appearance.

because they can simulate a pancreatic head mass, a **pseudomass.** Typically, these bulges extend to the right of the GDA and superior pancreaticoduodenal artery (Fig. 7.13). Another common pseudomass is a bulge on the anterior body, often seen where the left lobe of the liver touches the pancreas. Pseudomasses have texture and echogenicity identical to normal pancreas, allowing differentiation from true pancreatic mass lesions. When high-quality images of the pancreas cannot be obtained because of technical difficulties, however, it may be difficult to differentiate a pseudomass from a true neoplasm of the pancreas. In these cases, comparison to appearance on prior exam or correlation with computed tomography (CT) or magnetic resonance imaging (MRI) may be needed for further assessment.

Fatty Pancreas

Because the pancreatic parenchyma can be very echogenic normally, it may be difficult or impossible to diagnose fatty infiltration with sonography. Although the fatty pancreas has been described as being more echogenic than the normal pancreas,[10] this is difficult to judge (see Fig. 7.12). The pancreas can appear sonographically normal with complete fatty replacement[11] (Fig. 7.14). CT is sensitive in diagnosing fatty replacement, whereas ultrasound is unreliable. Severe fatty replacement of the pancreatic parenchyma can occur with **cystic fibrosis, diabetes, obesity,** and occasionally, old age and **Shwachman-Diamond syndrome.** Shwachman-Diamond syndrome is a rare congenital genetic disorder characterized by pancreatic insufficiency, bone marrow dysfunction, and skeletal abnormalities.[12]

An interesting pseudomass can be caused by a relatively hypoechoic pancreatic head or uncinate process (ventral pancreas) compared with the dorsal pancreas (Fig. 7.15). Some evidence suggests that this phenomenon is related to relative fatty sparing in that part of the gland.[13-15] Based on a large prospective study, Coulier[16] found that "hypoechoic ventral embryologic cephalic pancreas" is never found before age 25 and is most common in middle-aged women with a "moderately echoic pancreas."

Embryology and Pancreatic Duct

The embryologic precursors of the adult pancreas develop as two outpouchings ("buds"), called the **dorsal (cranial) pancreatic anlage** and **ventral (caudal) pancreatic anlage.** These embryonic buds arise from opposite sides of the junction of the primitive foregut and midgut (Fig. 7.16). The two pancreatic anlagen (primordia) rotate to be in proximity, typically fusing at 6 to 8 weeks of gestation.[17] The dorsal (cranial) pancreatic bud becomes the body and tail of the pancreas. The ventral (caudal) bud becomes the pancreatic head and uncinate process, ending up in a position caudal to the body and tail. The ventral bud is also the embryologic origin of the gallbladder, bile duct, and liver. The bile duct and pancreatic head sharing a common origin explains the usual fusion (60%-80%) of the pancreatic and bile duct in the ampulla and their common entry into the duodenum through the major papilla.

The pancreatic duct is crucial to the **exocrine function** of the pancreas, conveying the pancreatic digestive secretions to the duodenum. Most adults have a single, **main pancreatic duct** that originates when portions of the two ducts from each pancreatic anlage fuse. The main pancreatic duct empties into the duodenum via the major papilla, usually after merging with the common bile duct in the ampulla. In 20% to 40% of individuals the ducts do not join—only the bile duct enters the duodenum through the major papilla.[18] The pancreatic duct enters separately, usually near the bile duct.

The duct in the body and tail (from the dorsal pancreatic anlage) fuses with the duct in the head (from the ventral pancreatic anlage) to form the main pancreatic duct. A portion of the duct from the body and tail, the **accessory duct** (Fig. 7.17), often persists (≈50% in autopsy series) and enters the duodenum

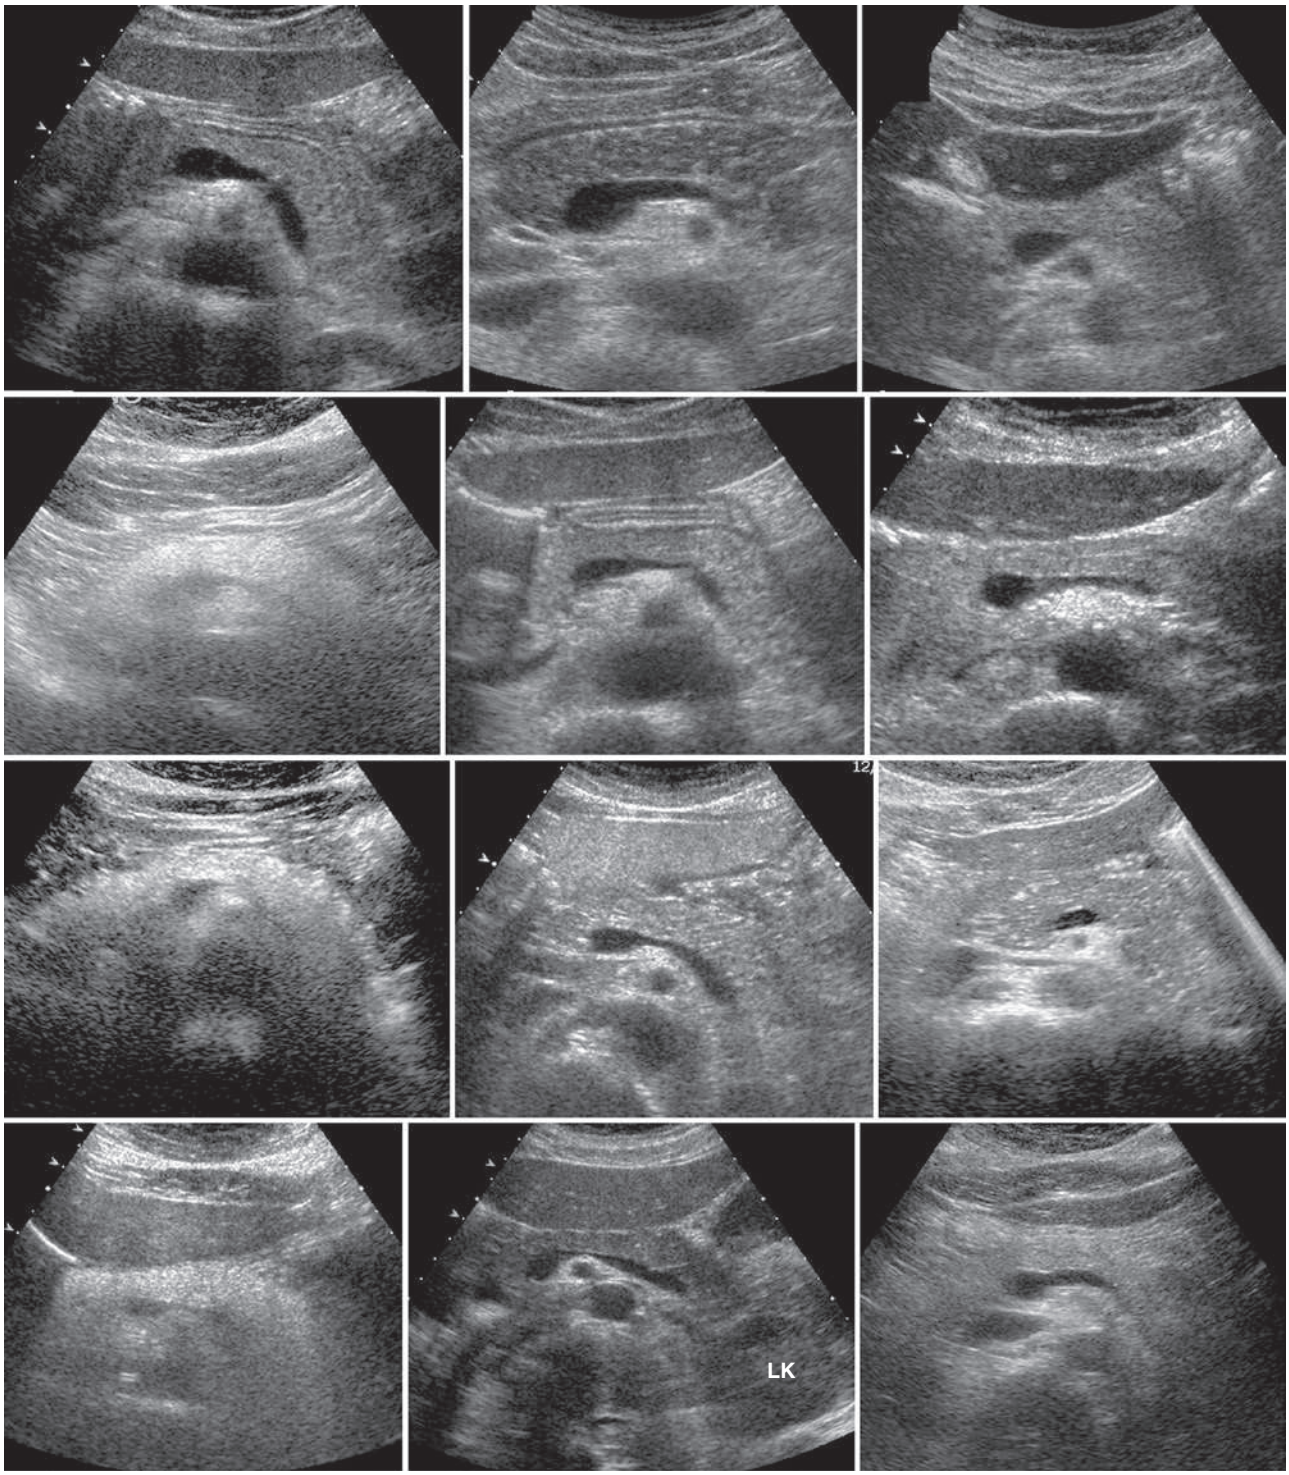

FIG. 7.12 Normal Pancreatic Parenchymal Echogenicity. Transverse sonograms in 12 normal patients demonstrate the various patterns of normal pancreatic parenchyma. Echogenicity, texture, and size vary considerably. *LK,* Left kidney.

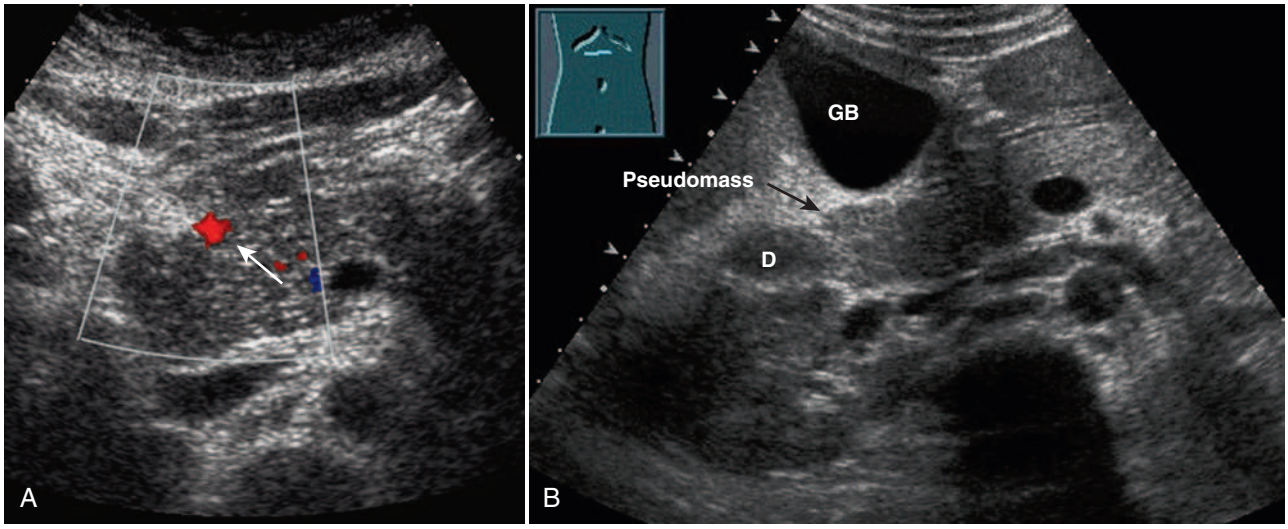

FIG. 7.13 Normal Anatomic Variations: Pancreatic Head Pseudomass. Variations in shape of the pancreatic head include bulges to the right of gastroduodenal artery. **(A)** Transverse image of a pseudomass that extends to the right of the gastroduodenal artery *(arrow)*. **(B)** Transverse image of another pseudomass. *D,* Duodenum.

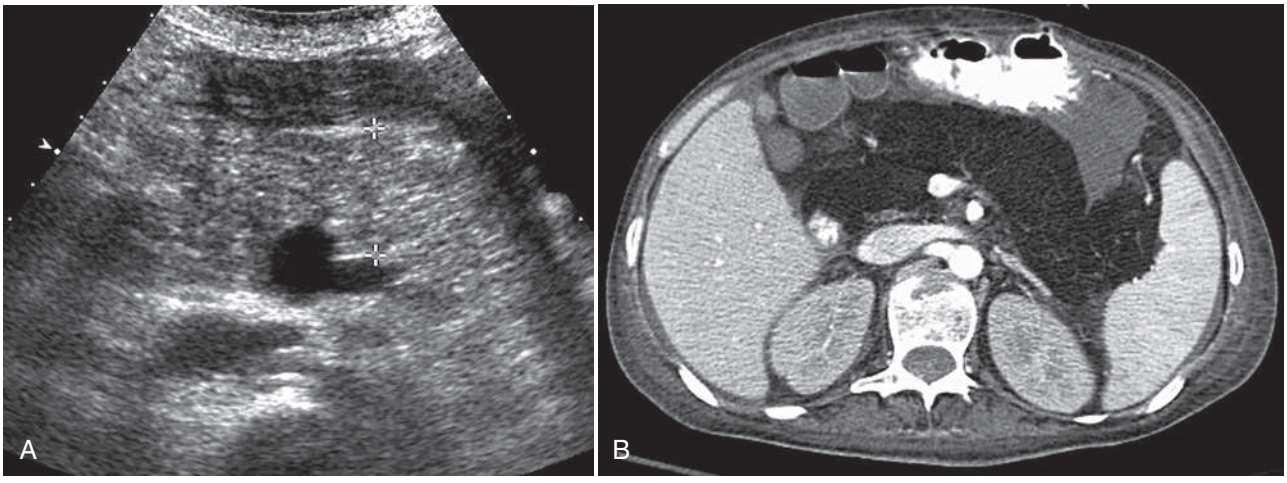

FIG. 7.14 Fatty Infiltration of Pancreas. (A) In this transverse image, the appearance and echogenicity of the pancreas (calipers) do not differ substantially from many normal glands. **(B)** Computed tomography scan shows diffuse fatty infiltration. (Courtesy of Drs. Vinay Duddlewar and Jabi Shiriki.)

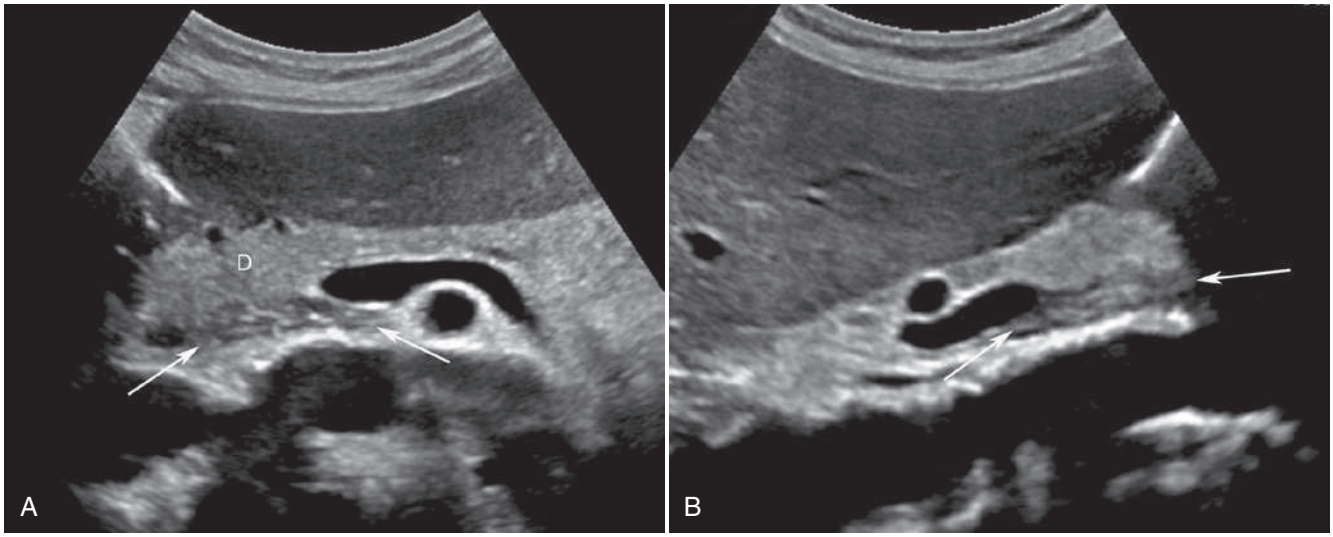

FIG. 7.15 Hypoechoic Ventral Pancreas. (A) Transverse sonogram of pancreatic head. Note the hypoechoic uncinate *(arrows),* likely related to less fatty change than present in the dorsal component *(D)*. **(B)** Longitudinal sonogram of pancreas. The more posterior uncinate *(arrows)* is lower in echogenicity than the remainder of the pancreas.

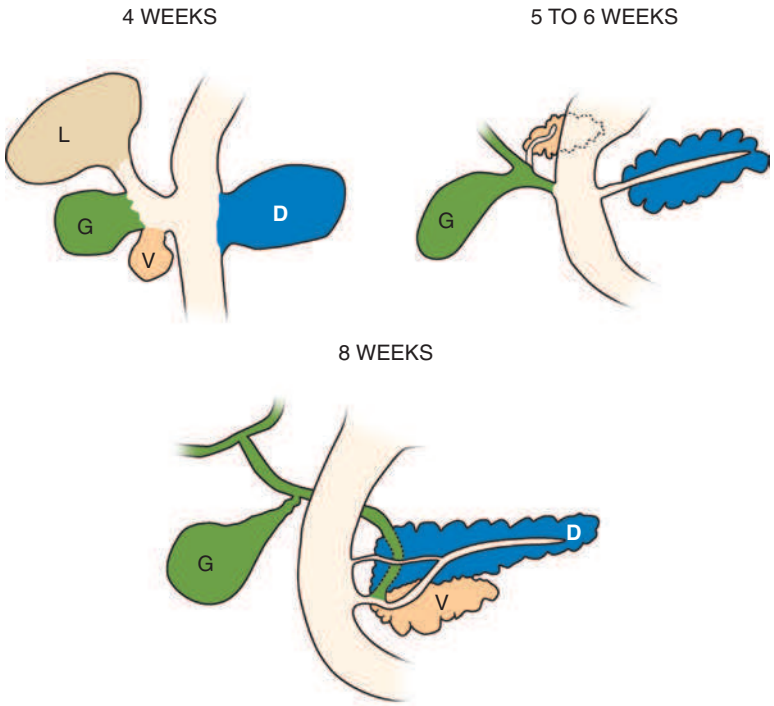

FIG. 7.16 Embryologic Development of Pancreas. At 4 weeks the embryologic precursors of the adult pancreas develop as two outpouchings ("buds"), called the dorsal *(D, blue)* and ventral *(V, brown)* pancreatic **anlage.** The ventral bud is also the embryologic origin of the gallbladder *(G)*, bile duct, and liver *(L)*. The embryonic pancreatic buds arise from opposite sides of the junction of the primitive foregut and midgut. **At 5 to 6 weeks** the two pancreatic anlagen rotate into proximity. **At 6 to 8 weeks** the anlagen typically fuse. The dorsal pancreatic bud becomes the body and tail of the pancreas.

through the minor papilla.[19] The minor duodenal papilla is several centimeters proximal to the major papilla.

Usually, only an insignificant amount of the pancreatic secretions drain through the accessory duct. An exception occurs when the accessory duct is the only duct entering the duodenum; the duct from the pancreatic head empties into the dorsal duct, not the duodenum (Fig. 7.18A). This anatomic variant is found in 10% of individuals who have an accessory duct. Another exception is **pancreatic divisum,** in which the ventral and dorsal pancreatic ducts do not fuse (Fig. 7.18B). This results in most of the pancreatic secretions (those secreted by dorsal pancreas) entering the duodenum through the accessory duct via the minor papilla.

The descriptive terminology of the pancreatic ducts is confusing. It is most clear to use the functional description shown in Fig. 7.17B, that is, the main pancreatic duct and accessory duct. Most authors use the terms *accessory duct* and the **duct of Santorini** synonymously. Some define the duct of Santorini as the entire dorsal duct, including the accessory duct. The main pancreatic duct is sometimes called the **duct of Wirsung,** whereas others reserve that name for the ventral duct only.

In normal individuals the pancreatic duct diameter is usually 3 mm or less. Hadidi[20] found that the mean duct diameter was 3 mm in the head, 2.1 mm in the body, and 1.6 mm in the tail. The diameter of the duct can vary significantly. In fasting individuals, the duct is often seen as a linear structure in the pancreatic body (Fig. 7.19). The diameter increases with age, although 3 mm is still an appropriate upper limit of normal in older patients.[6] Using a 2.5-mm upper limit of normal, Wachsberg[21] showed that inspiration could increase duct size to exceed that limit in 12% of patients without pancreatic disease. **Secretin injection** increases duct size, presumably because of increased pancreatic secretion,[22] which likely explains the observation that pancreatic duct size may increase postprandially in some normal individuals.[8]

Imaging Anatomic Variants

Transabdominal ultrasound plays little role in the diagnosis of anatomic variants of the pancreas, which are generally discovered and evaluated with CT, endoscopic retrograde cholangiopancreatography (ERCP), and magnetic resonance cholangiopancreatography (MRCP).[17,23] Endoscopic ultrasound has been found to be useful in diagnosing pancreas divisum, especially in patients with unexplained pancreatitis.[24] Congenital variants of the pancreas are common, occurring in about 10% of the population. Variants include **pancreas divisum, annular pancreas,** and **partial agenesis.** Most pancreatic variants are of no clinical significance and are found incidentally with imaging, at surgery, or on autopsy. Pancreas divisum, the most common variant, may predispose to **pancreatitis,** although the literature is unclear about this association.[25] The vast majority of patients (95%) with divisum do not develop pancreatitis.[26]

Peripancreatic Structures

The **intraperitoneal stomach** is generally located immediately ventral to the retroperitoneal pancreatic body, with the collapsed potential space of the lesser peritoneal sac between the two organs

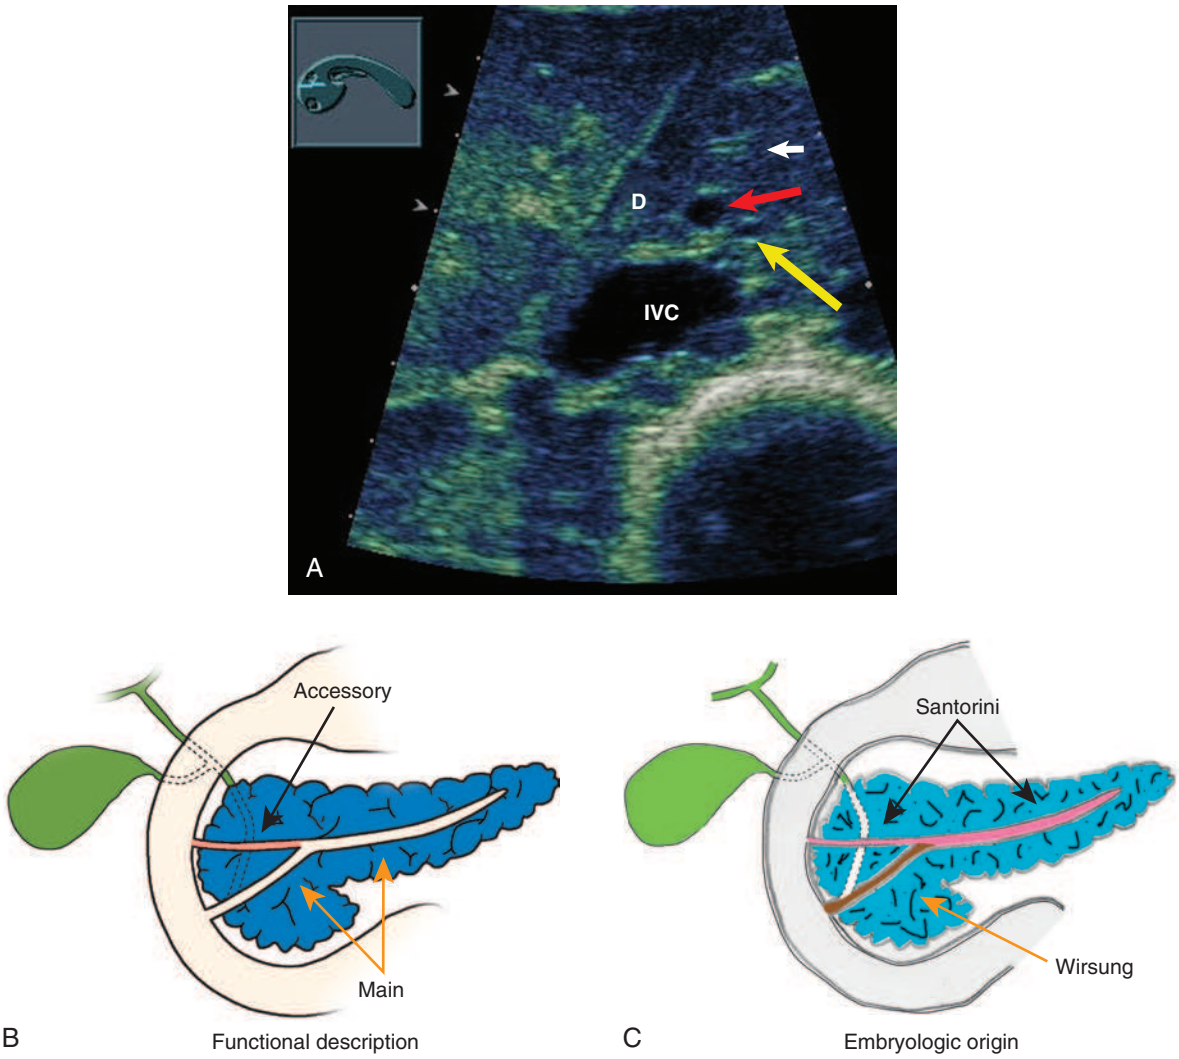

FIG. 7.17 Pancreatic Ductal Anatomy. (A) Pancreatic head. Transverse sonogram shows the accessory pancreatic duct *(white arrow).* The main pancreatic duct *(yellow arrow)* is seen dorsal and medial to the common bile duct *(red arrow). D,* Duodenum; *IVC,* inferior vena cava. **(B) Pancreatic ductal system, functional description.** Accessory duct is shown in tan *(black arrow)* and the main duct in white *(orange arrows).* The accessory duct persists in only a minority of individuals. **(C) Pancreatic ductal system, embryologic origin.** Dorsal component of main adult duct and the accessory duct (*black arrows,* duct of Santorini, *pink*) both originate from the dorsal anlage. Ventral component of main duct (*orange arrow,* duct of Wirsung, *brown*) in pancreatic head arises from the ventral anlage and usually fuses with main duct from pancreatic body (dorsal anlage).

(Fig. 7.20). This explains why fluid in the stomach can sometimes be helpful in sonographic visualization of the pancreas. The **lesser peritoneal sac** is situated between the lesser omentum, greater omentum, and the stomach anteriorly and the parietal peritoneum and transverse mesocolon posteriorly (Fig. 7.21).

The **antrum** and **duodenal bulb** are intraperitoneal structures, whereas the **duodenal sweep** (second and third parts of duodenum) is retroperitoneal and hugs the pancreatic head. The third portion of the duodenum is a useful landmark, defining the caudal aspect of the pancreatic head. The transverse colon and hepatic flexure often overlie the pancreas, sometimes obscuring direct visualization.

The **transverse mesocolon** arises from the anterior pancreas and duodenum, formed by the parietal peritoneum that invests the pancreas and duodenum. The transverse mesocolon invests the transverse colon and forms part of the posterior limits of the lesser peritoneal sac.

The tail of the pancreas lies within the splenorenal ligament and contacts the left kidney, left colic (splenic) flexure, and the hilum of the spleen posteriorly. Thus a portion of the pancreatic tail is intraperitoneal and somewhat mobile.

ACUTE PANCREATITIS

Acute pancreatitis is defined by the International Symposium on Acute Pancreatitis (Atlanta, 1992) as "an acute inflammatory process of the pancreas with variable involvement of other regional tissues or remote organ systems associated with raised pancreatic enzyme levels in blood and/or urine."[27] More than 300,000 patients are admitted to US hospitals annually with acute pancreatitis.[28] It is difficult to determine the prevalence of acute pancreatitis because mild pancreatitis is often missed. The annual incidence of acute pancreatitis has been reported as 5 to 35 per 100,000 population.[29]

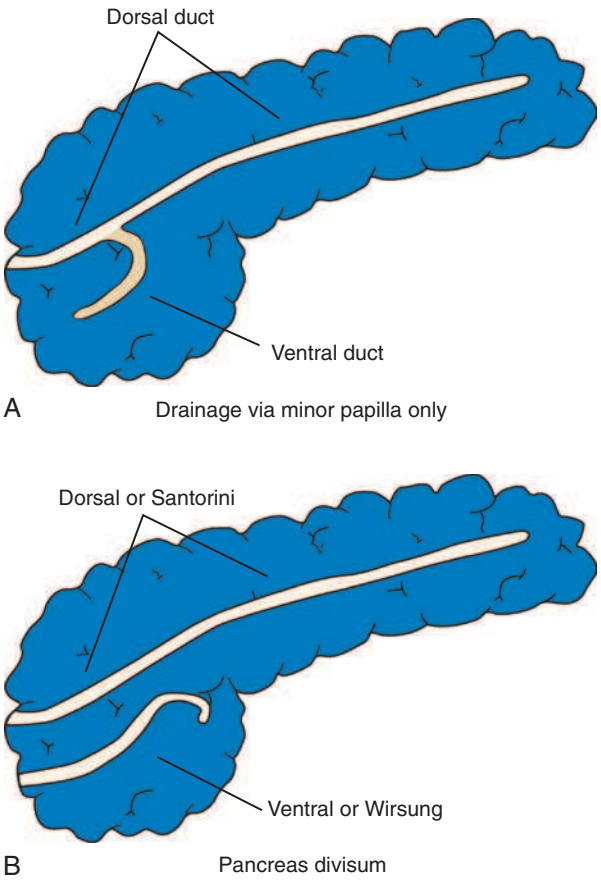

FIG. 7.18 Pancreatic Ductal Variants With Secretions Entering Duodenum via Minor Papilla. (A) Minor papilla only. Ventral duct from pancreatic head empties into the dorsal duct instead of the duodenum. **(B) Pancreas divisum** lacks formation of the main adult duct because the ducts from each pancreatic anlage did not fuse. The duct from the dorsal anlage remains separate from the main duct in the head. This anatomic variant is present in 5% to 10% of the population.

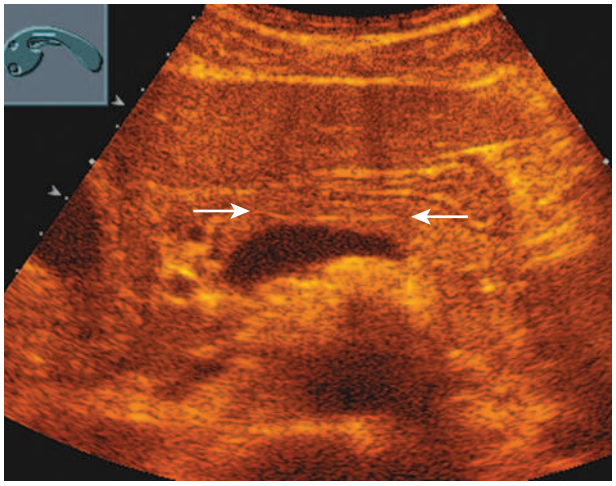

FIG. 7.19 Normal Pancreatic Duct. Transverse image of the pancreas shows the appearance of the pancreatic duct as a linear, collapsed structure in the body *(arrows)*.

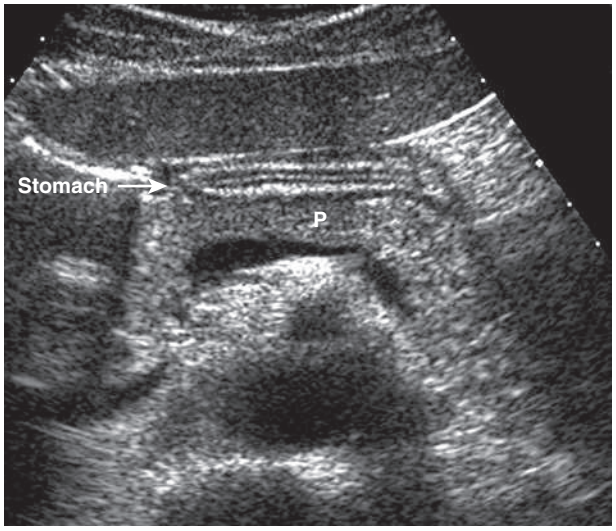

FIG. 7.20 Potential Space of Lesser Peritoneal Sac. Transverse image demonstrates the potential space of the lesser peritoneal sac between the stomach *(arrow)* and pancreas *(P)*.

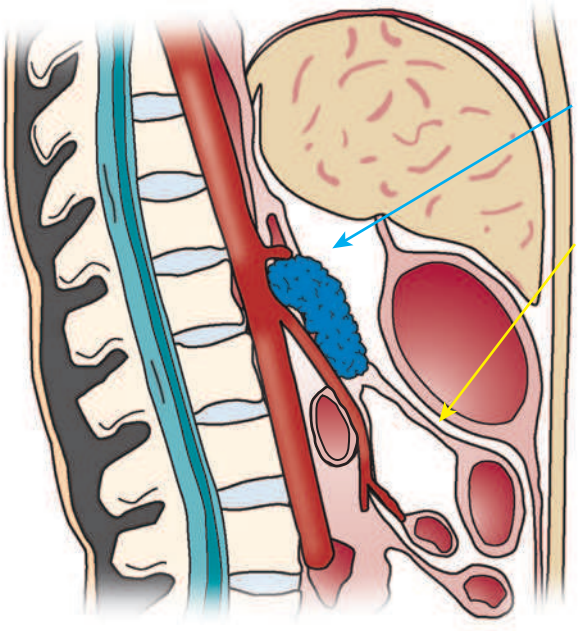

FIG. 7.21 Peritoneal Reflections and Transverse Mesocolon. Transverse mesocolon *(yellow arrow)* arises from the anterior pancreas and duodenum, formed by the parietal peritoneum that invests the pancreas and duodenum. The transverse mesocolon invests the transverse colon and forms part of the posterior limits of the lesser peritoneal sac *(blue arrow)*.

The clinical spectrum of acute pancreatitis ranges from a benign, self-limited disorder (75% of patients) to severe pancreatitis that may be fulminant and quickly cause death from multiorgan failure.[30] Mild acute pancreatitis generally resolves spontaneously with supportive management. Acute interstitial/edematous pancreatitis results in an enlarged and congested gland without appreciable necrosis or hemorrhage.[31] Banks and Freeman[32] found that the overall mortality of pancreatitis is approximately 5%. Mortality in the first 2 weeks usually results from organ failure, and after that, from infection. Mortality was

3% in patients with nonnecrotic (interstitial) pancreatitis and 17% for those with necrotizing pancreatitis. The same review noted 30% mortality with infected necrosis versus 12% for uninfected necrosis. Organ failure is even more skewed; there was no mortality with no organ failure, 3% with single-organ failure, and 47% mortality with multiorgan failure.[32]

The causes of acute pancreatitis are numerous and diverse. One problem in evaluating and treating acute pancreatitis has been the lack of a universally accepted classification system. The International Symposium on Acute Pancreatitis (Atlanta, 1992) attempted to address these problems by proposing a classification system that is clinically oriented.[33] With better understanding of the disease, improved imaging options, and myriad new treatments, the Atlanta classification of acute pancreatitis was updated and revised.[28,34,35] The predominant causes of acute pancreatitis are gallstones and alcohol abuse, accounting for about 80% of all cases[36] (Table 7.1).

All patients, including known alcoholics, who present with their first episode of acute pancreatitis should have sonography to evaluate the biliary tree for **gallstones.**[37] Evaluation of the biliary tree is crucial in patients with acute pancreatitis because cholecystectomy with removal of common duct stones prevents recurrence of acute pancreatitis,[38] which can be fatal. Gallstones affect about 15% of the US population,[39] but prevalence varies widely by ethnicity. After a careful search of the gallbladder for stones, the bile duct should be evaluated for choledocholithiasis and obstruction. Reports vary, but the prevalence of **common duct stones** in patients with symptomatic gallstones is likely 10% to 20%. If the ducts are not dilated sonographically, however, the prevalence of common duct stones is probably about 5%.[40] With careful technique, ultrasound can identify common duct stones with a sensitivity of approximately 75% in expert hands.[41,42]

When biliary dilation or choledocholithiasis is present sonographically, a stone may be impacted in the distal common duct. It seems reasonable to assume that urgent intervention to relieve the obstruction is necessary in these patients. There is conflicting evidence, however, whether patients benefit from intervention in the acute setting.[43-47] Acosta et al.[48] reported results from a prospective randomized clinical trial of patients with biliary pancreatitis that showed better outcomes with decompression of the duct within 48 hours from the onset of symptoms. It made no difference if the decompression was spontaneous or from surgical treatment or ERCP.

How gallstones cause acute pancreatitis is unknown, although it is somehow related to passage of stones into and through the common duct. Gallstones cause 30% to 50% of acute pancreatitis attacks, whereas only 3% to 7% of patients with gallstones develop pancreatitis.[38] Another important cause of acute pancreatitis is **biliary sludge (microlithiasis).** These cases comprise most of what was previously characterized as **"idiopathic" pancreatitis.**[49] The myriad other causes of acute pancreatitis include neoplasm,[50,51] infection, pancreas divisum, toxins, drugs, and genetic, traumatic, and iatrogenic (endoscopy, postoperative) factors.[36] From 5% to 7% of patients with pancreaticobiliary tumors, benign or malignant, present with acute pancreatitis.[47]

TABLE 7.1 Causes of Acute Pancreatitis

Cause	Acute Pancreatitis Cases
Gallstones	40%
Alcoholism	40%
Idiopathic	10%
Other	10%

Approach to Imaging

Abdominal sonography and contrast-enhanced computed tomography (CECT) are the two most useful imaging modalities in patients with acute pancreatitis. Other useful, but usually secondary diagnostic and therapeutic studies include MRI, MRCP, ERCP, and endoscopic ultrasound. The choice of modality depends on the clinical situation. Ultrasound should be performed to detect gallstones and bile duct obstruction in all patients in whom biliary acute pancreatitis is possible. CECT is indicated early in the clinical course of patients with severe pancreatitis, mainly to diagnose pancreatic necrosis.[52] Pancreatic necrosis is considered significant when more than 30% of the gland is affected or an area larger than 3 cm is present. Patients with pancreatic necrosis must be observed closely for clinical deterioration and treated with prophylactic antibiotics.[53-55] Sharma and Howden[56] found that antibiotic prophylaxis significantly reduced sepsis by 21% and mortality by 12% compared with no prophylaxis. CT is also the most accurate examination when seeking delayed complications of acute pancreatitis.

MRCP is an accurate means of detecting stones in the gallbladder and bile ducts of patients with acute pancreatitis.[36,57] Abdominal MRI can provide information similar to CECT, including the diagnosis of pancreatic necrosis.[58,59] Because of expense, MRCP and MRI are often reserved for patients in whom CT or ultrasound does not provide adequate information to

Imaging in Acute Pancreatitis

ROLE OF ULTRASOUND

Detect gallstones as a cause of acute pancreatitis
Detect bile duct dilation and obstruction
Diagnose unsuspected acute pancreatitis or confirm diagnosis of acute pancreatitis
Guide aspiration and drainage

ROLE OF COMPUTED TOMOGRAPHY

Detect pancreatic necrosis (patients with suspected severe pancreatitis)
Detect complications of acute pancreatitis
Diagnose unsuspected acute pancreatitis or confirm diagnosis of acute pancreatitis
Diagnose conditions mimicking acute pancreatitis, including gastrointestinal ischemia, ulceration, or perforation and ruptured abdominal aortic aneurysm
Guide aspiration and drainage

guide management and for those who have a contraindication to CECT.

Endoscopic ultrasound is more sensitive than abdominal ultrasound for the detection of common bile duct stones and can be useful in suspected gallstone pancreatitis.[60] Endoscopic ultrasound is also valuable in diagnosing microlithiasis and pancreas divisum.[61]

Because of its complications (including pancreatitis) and expense, ERCP, formerly both a diagnostic and a therapeutic modality, is now usually reserved for therapy.[62] Sometimes coupled with endoscopic sphincterotomy and stone removal, ERCP is a valuable therapeutic modality in choledocholithiasis with jaundice, dilated common bile duct, acute pancreatitis, or cholangitis.[63]

Ultrasound Findings

Evaluation of the gallbladder and bile ducts is the focus of most sonographic examinations performed in patients with acute pancreatitis. Nevertheless, understanding pancreatic and extrapancreatic abnormalities associated with acute pancreatitis is important. The combined use of serum amylase and serum lipase yields sensitivity and specificity of 90% to 95% in diagnosing acute pancreatitis,[64] but mild cases may be missed. In mild acute pancreatitis the patient may present for diagnosis after transient elevated amylase and lipase levels have resolved; thus no serologic indicators of pancreatitis may be present.[65] In these patients the diagnosis of mild acute pancreatitis is clinical. On the other hand, the diagnosis may be missed in patients with severe pancreatitis because pain is absent or masked by other, more severe symptoms. Analyzing fatal pancreatitis between 1980 and 1985, Lankisch et al.[66] reported that 30% of cases were not diagnosed until autopsy.

After a careful search of the gallbladder and bile duct for **stones,** the entire pancreas should be scanned. After scanning the pancreas, peripancreatic pathology should be sought in the lesser sac, anterior pararenal spaces, and transverse mesocolon.

The reported prevalence of sonographic abnormality in acute pancreatitis varies from 33% to 92%. In a retrospective evaluation of patients with acute pancreatitis, using a defined scanning protocol to look for pancreatitis-associated findings, Finstad et al.[37] found that sonography revealed abnormalities in 45 of 48 patients (92%) (Table 7.2).

TABLE 7.2 Sonographic Abnormalities in Patients With Acute Pancreatitis

Abnormality	No. of Patients (48 Total)	Prevalence
Peripancreatic inflammation	29	60%
Heterogeneous parenchyma	27	56%
Decreased gland echogenicity	21	44%
Indistinct ventral margin	16	33%
Pancreas enlarged[a]	13	27%
Focal intrapancreatic echo change	11	23%
Peripancreatic fluid collections	10	21%
Focal mass	8[b]	17%
Perivascular inflammation	5	10%
Pancreatic duct dilation	2	4%
Venous thrombosis	2	4%

[a]Anteroposterior dimension was ≥23 mm at superior mesenteric artery.
[b]Five of eight were hypoechoic.
Modified from Finstad TA, Tchelepi H, Ralls PW. Sonography of acute pancreatitis: prevalence of findings and pictorial essay. Ultrasound Q. 2005;21(2):95-104.[37]

Pancreatic echogenicity typically decreases in patients who have acute pancreatitis because of interstitial edema. In some patients, echogenicity is normal. In rare cases, echogenicity may increase, possibly because of hemorrhage, necrosis, or fat saponification. Cotton et al.[67] noted that, compared with the liver, the pancreatic echogenicity was increased in 16% of normal individuals and 32% of patients with acute pancreatitis. Finstad et al.[37] found no acute pancreatitis patients with globally increased echogenicity, although focal areas of increased echogenicity and inhomogeneity did occur.

Enlargement of the pancreas is almost universal in acute pancreatitis. Unfortunately, enlargement may be difficult to judge, because pancreatic size before the onset of pancreatitis is usually unknown and varies widely. In 1995 Guerra et al.[7] found that the thickness of the body of the normal pancreas in 261 adults was 10.1 mm (±3.8 mm; range, 4-23 mm). In 2005, Finstad et al.[37] in his series of patients with acute pancreatitis found that the mean anteroposterior measurement of the pancreatic body at the SMA level was 21.1 mm (±6.4 mm; range, 12-45 mm), almost twice the average found in normal individuals by Guerra et al. It seems reasonable, therefore, to use **22 mm** (mean plus 3 standard deviations) as the upper limit of normal pancreatic thickness, understanding that this is likely to be an insensitive parameter for diagnosing acute pancreatitis (Fig. 7.22).

The classic finding of **decreased gland echogenicity** is present in only 44% of patients. In addition, when there is fatty infiltration of the liver, the normal pancreas may appear hypoechoic, a pattern called **"pseudopancreatitis"** (Fig. 7.23). Pancreatic heterogeneity is a subjective but common finding, present in more than 50% of patients (Fig. 7.24). Focal hypoechoic regions are noted in some patients (Fig. 7.25).

The least subjective, most common, and thus most useful finding is **pancreatitis-associated inflammation** (Fig. 7.26; see also Figs. 7.22 and 7.24). Extrapancreatic inflammatory changes may be detected even when the pancreatic contour is normal and the pancreas is not obviously enlarged. Pancreatic inflammation is typically hypoechoic or anechoic (Fig. 7.27) and conforms to a known retroperitoneal or peritoneal space (Video 7.2). It may be difficult or impossible to distinguish inflammation from fluid (Fig. 7.28). In contrast to inflammation, fluid collections

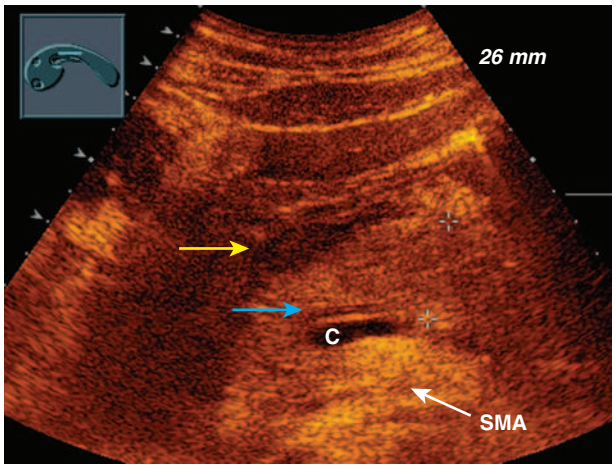

FIG. 7.22 Enlarged Pancreas, Acute Pancreatitis With Inflammation. Transverse image of the pancreas shows 26-mm anteroposterior dimension (calipers) at the level of the superior mesenteric artery *(SMA)*. Note the acute inflammation ventral to the pancreas *(yellow arrow)* and ventral to *(blue arrow)* the splenic vein–superior mesenteric vein confluence *(C)*.

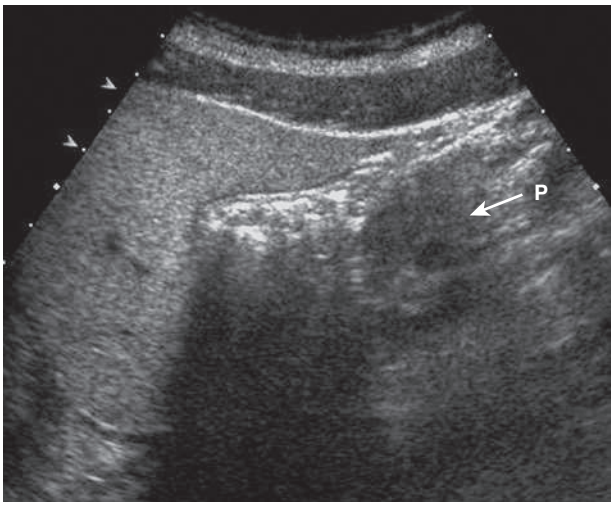

FIG. 7.23 Pseudopancreatitis. Longitudinal image of pancreas *(P)* and liver shows that the fatty liver is more echogenic than the normal pancreas, simulating a hypoechoic pancreas.

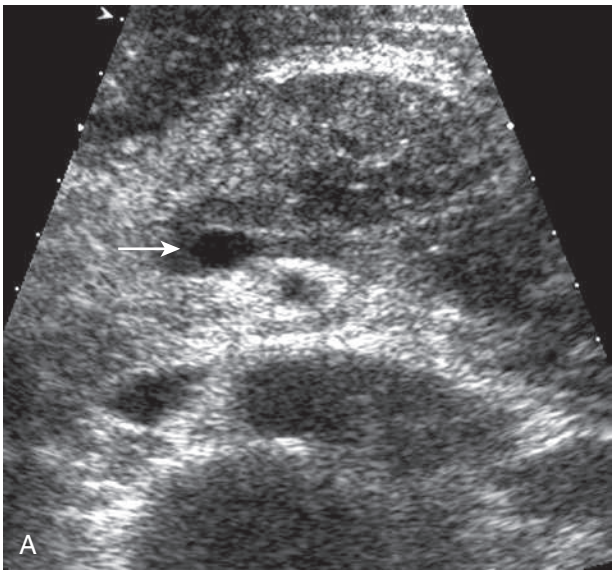

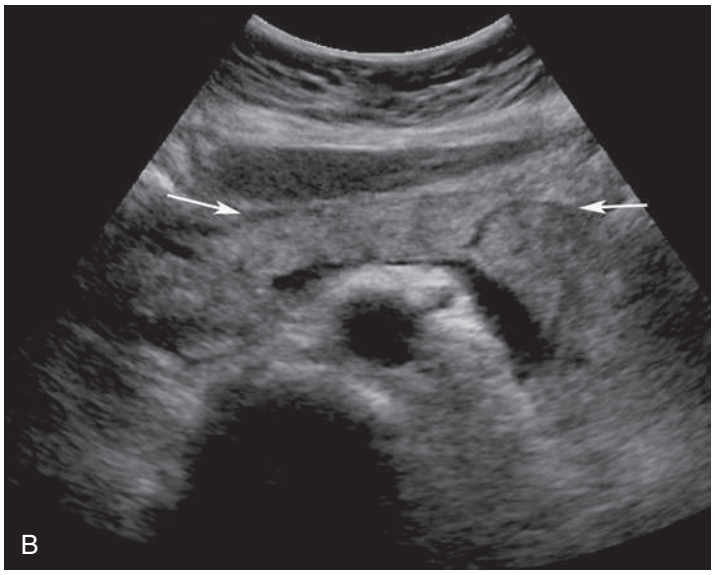

FIG. 7.24 Heterogeneous Pancreas, Acute Pancreatitis. (A) Transverse image shows that heterogeneity can be a subtle, subjective finding. Arrow indicates the perivascular inflammation and splenic vein–superior mesenteric vein clot. **(B)** Transverse sonogram in a different patient shows heterogeneous pancreatic echotexture with trace areas of peripancreatic fluid about the gland and interspersed between parenchymal lobules *(arrows)*. **(C)** Transverse contrast-enhanced computed tomography (CT) image of the same patient in **(B)** shows corresponding CT appearance of heterogeneous gland with peripancreatic fluid.

often have convex margins, are thicker and more localized, may cause a mass effect, and sometimes have through transmission of sound (Fig. 7.29, Video 7.3).

Inflammation is most often seen ventral and adjacent to the pancreas in the **prepancreatic retroperitoneum** (see Figs. 7.22, 7.26, and 7.28), the right and left anterior pararenal spaces, the perirenal spaces, and the transverse mesocolon. The **anterior pararenal spaces** are best seen through a coronal flank approach (Fig. 7.30). The patient is scanned while in a decubitus position with the transducer angled to achieve a sagittal scan plane through the flank. Areas of inflammation within the anterior pararenal space are often seen immediately adjacent to the echogenic fat within the **perirenal space.** Acute pancreatic inflammation within the anterior pararenal space occasionally outlines **Gerota fascia.** An inflammatory mass (formerly called a **phlegmon,** although this term has been abandoned in the newest Atlanta classification[28]) may be present (Fig. 7.31; see also Fig. 7.28). The **transverse mesocolon** region can be seen well in most patients on longitudinal scans. Inflammation can extend caudal to the pancreas and behind the stomach (Fig. 7.32; see also Fig. 7.21) and may reach the transverse colon. The transverse colon itself may be difficult to identify; in the transverse plane it lays directly ventral

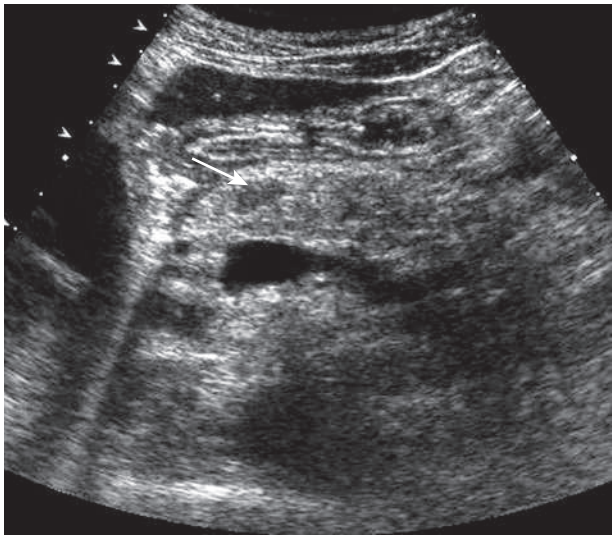

FIG. 7.25 Focal Hypoechoic Area, Acute Pancreatitis. Transverse image shows heterogeneous pancreas with focal hypoechoic area *(arrow).*

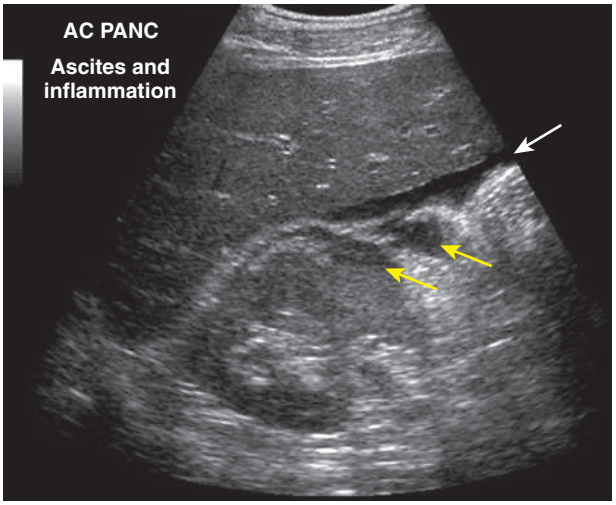

FIG. 7.27 Inflammation and Ascitic Fluid, Acute Pancreatitis. Transverse image of right upper quadrant shows acute inflammation in the anterior pararenal (retroperitoneal) space and the perirenal space *(yellow arrows).* Ascites is present in the adjacent subhepatic space *(white arrow).* See also Video 7.2.

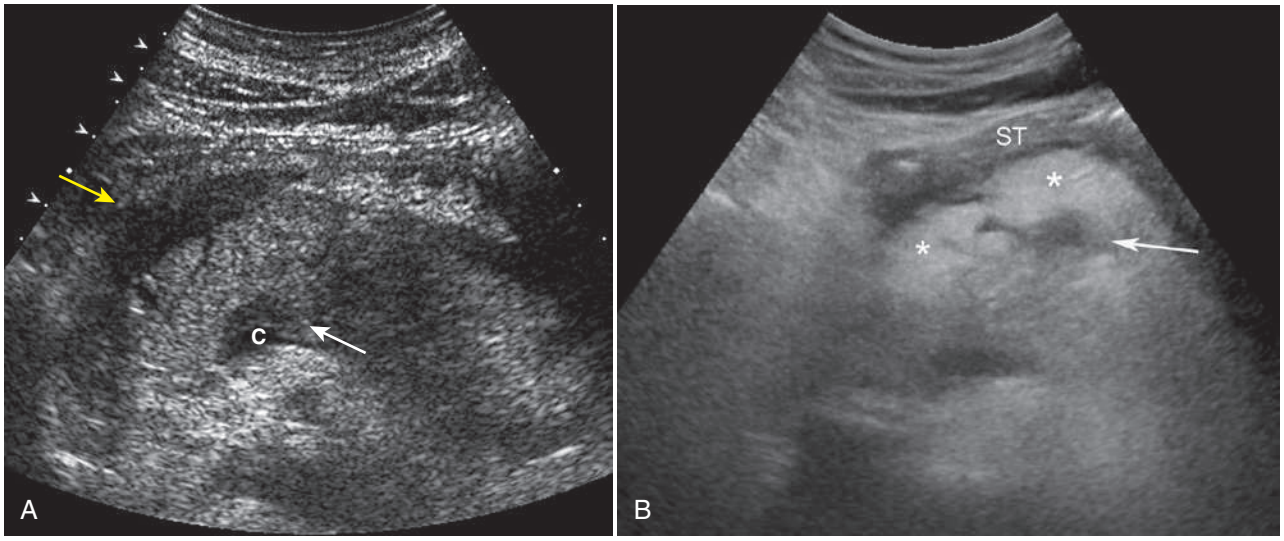

FIG. 7.26 Inflammation From Acute Pancreatitis. (A) Transverse image shows acute inflammation ventral to the pancreas *(yellow arrow)* and ventral to *(white arrow)* the splenic vein–superior mesenteric vein confluence *(C).* The pancreas is enlarged and heterogeneous. **(B)** Transverse image shows acute inflammation ventral to the pancreas, displacing the stomach *(ST)* anteriorly. There is an echogenic appearance of the peripancreatic fat (*) and interspersed small fluid collection *(arrow).*

(anterior) to the head and uncinate process of the pancreas. Spread of inflammation along perivascular spaces, especially the splenic vein and splenoportal confluence, is characteristic of acute pancreatitis (Figs. 7.33, 7.34, and 7.35; see also Figs. 7.22, 7.24, and 7.26). This perivascular inflammation may explain why some patients develop thrombosis of the portal veins (Figs. 7.36 and 7.37; see also Fig. 7.34). Occasionally, retroperitoneal findings similar to those seen in acute pancreatitis can be seen in patients with ascites, perhaps because of a "leaky" peritoneum.

Complications

Complications of acute pancreatitis can be classified as systemic complications (those related to organ failure) and local complications.[34,68]

Local Complications of Acute Pancreatitis

Acute fluid collections
Pseudocysts
Pancreatic abscess
Necrosis
Infected necrosis
Hemorrhage
Venous thrombosis
Pseudoaneurysms

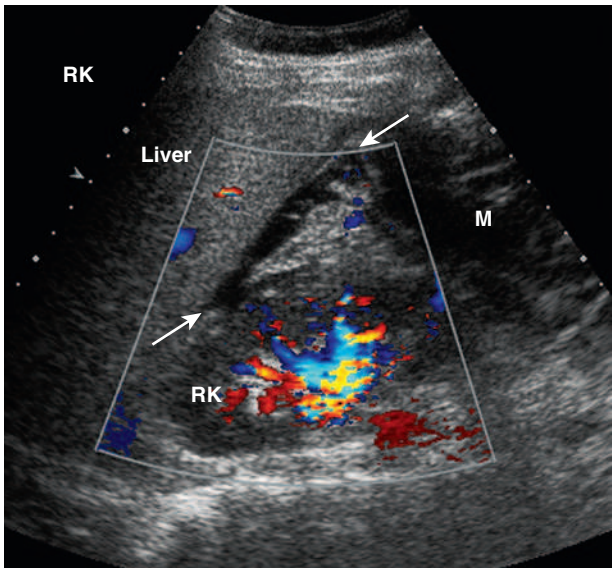

FIG. 7.28 Inflammation Simulates Free Fluid. Longitudinal image of right upper quadrant shows that the acute inflammation *(arrows)* in the anterior pararenal (retroperitoneal) space simulates free fluid and might be mistaken for ascites. Note the retroperitoneal inflammatory mass *(M)*. *RK,* Right kidney.

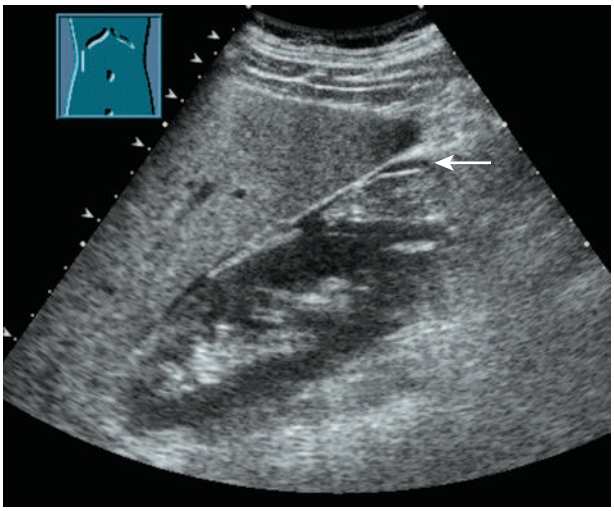

FIG. 7.30 Inflammation in Right Anterior Pararenal and Perirenal Spaces. Longitudinal coronal image of right upper quadrant, with decubitus position facilitating visualization of the pararenal and perirenal spaces. The inflammation partially outlines the perirenal space *(arrow),* which is contained by **Gerota fascia.**

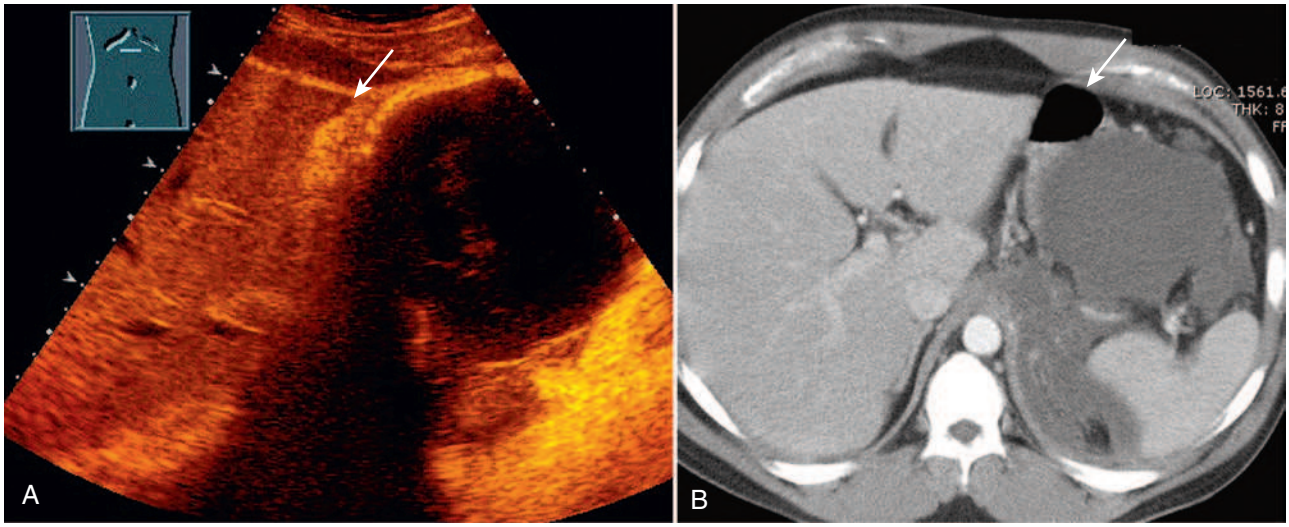

FIG. 7.29 Pancreatitis-Associated Fluid Collection. (A) Transverse sonogram and **(B)** computed tomography image of a "lesser sac" fluid collection. Such collections are actually in the prepancreatic retroperitoneum. Note the displaced stomach *(arrows)*. See also Video 7.3.

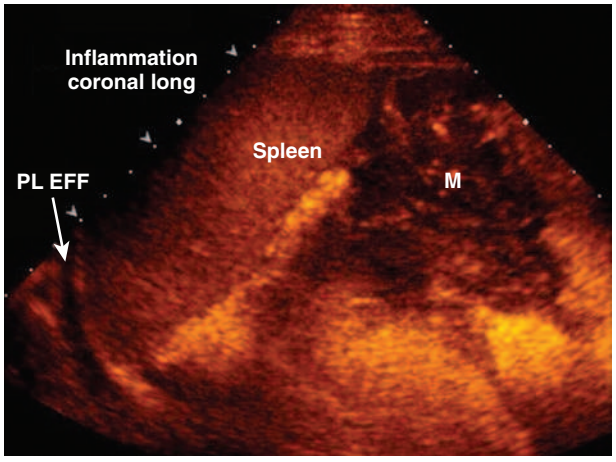

FIG. 7.31 Inflammatory Mass in Left Anterior Pararenal Space. Longitudinal coronal image of left upper quadrant shows retroperitoneal inflammatory mass *(M)*. Such masses were formerly called "phlegmons" before this term was proscribed by the 1992 International Symposium on Acute Pancreatitis (Atlanta). *PL EFF,* Left pleural effusion.

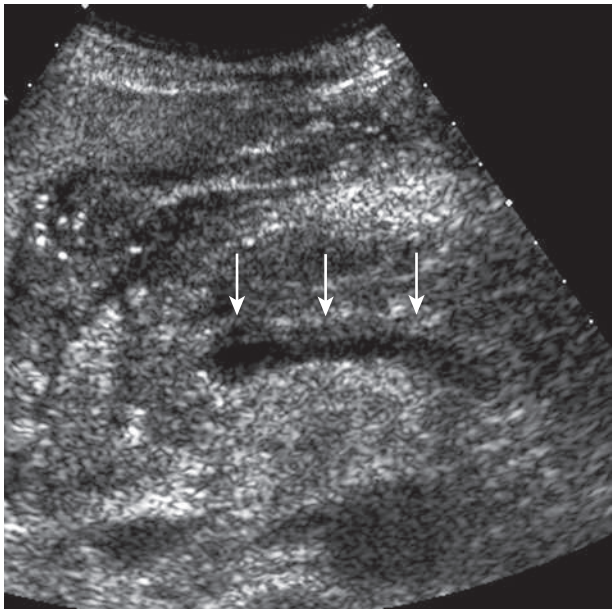

FIG. 7.33 Perivascular Inflammation. Transverse image of the pancreatic body shows hypoechoic inflammation *(arrows)* around the splenic vein.

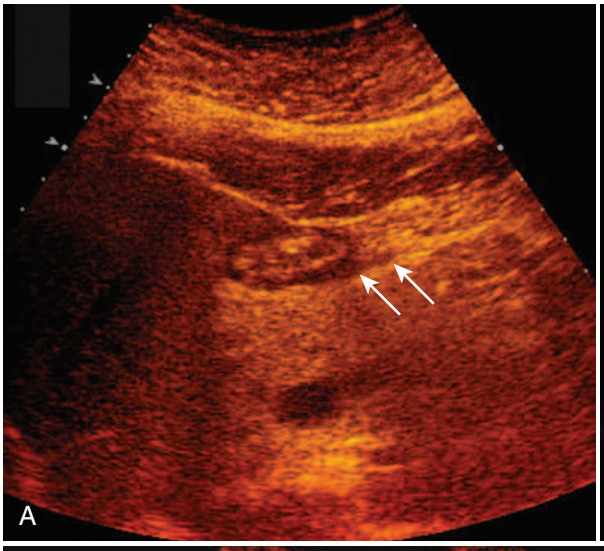

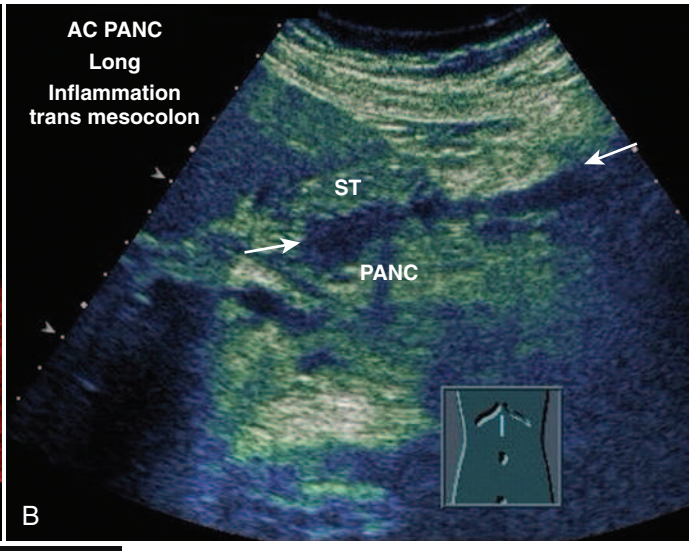

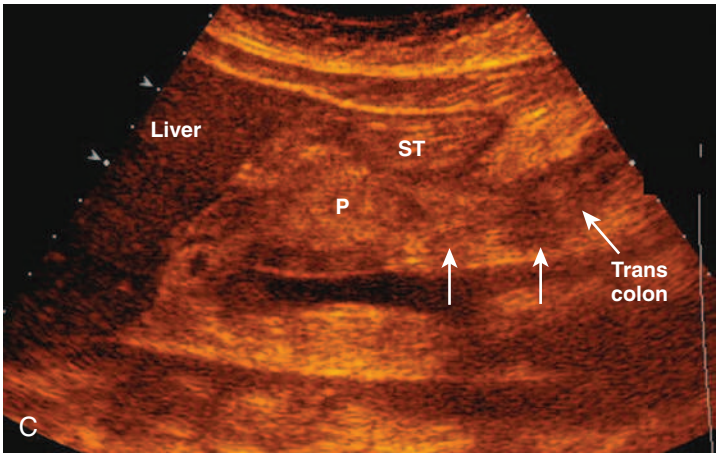

FIG. 7.32 Inflammation in Transverse Mesocolon. Longitudinal images. **(A)** Subtle, relatively minor inflammation *(arrows)*. **(B)** More significant inflammation *(arrows)*. **(C)** Transverse colon, which may be difficult to visualize; mesocolon inflammation is more diffuse *(arrows)*. *P,* Pancreas; *PANC,* pancreas; *ST,* stomach.

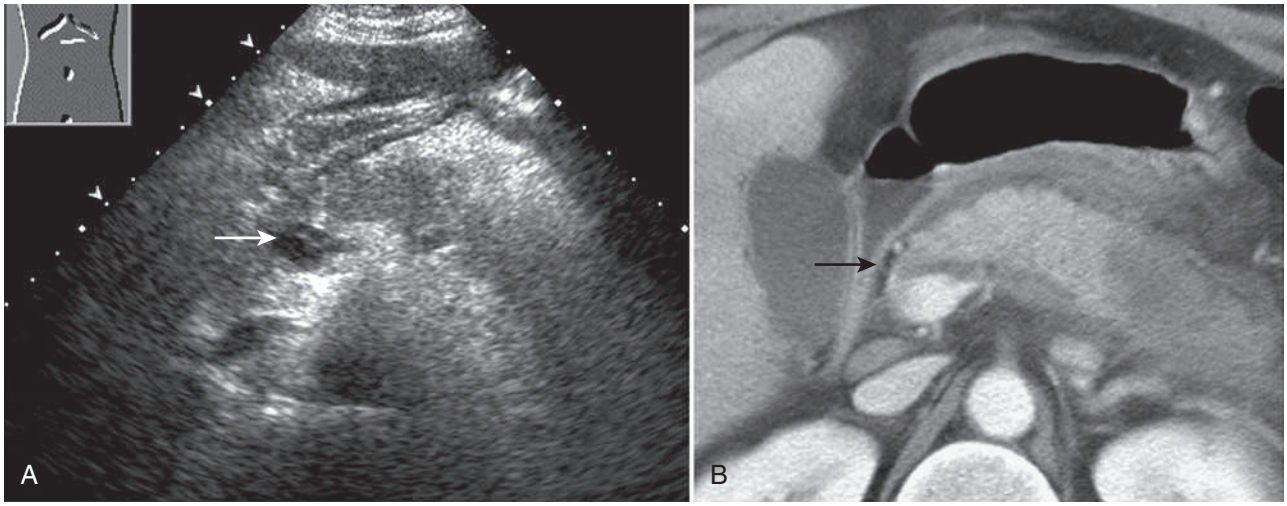

FIG. 7.34 Pancreatitis Causes Perivascular Inflammation. (A) Transverse sonogram and **(B)** computed tomography (CT) image of the pancreas show obvious evidence of perivascular inflammation *(arrows),* hypoechoic on sonogram and low density on CT.

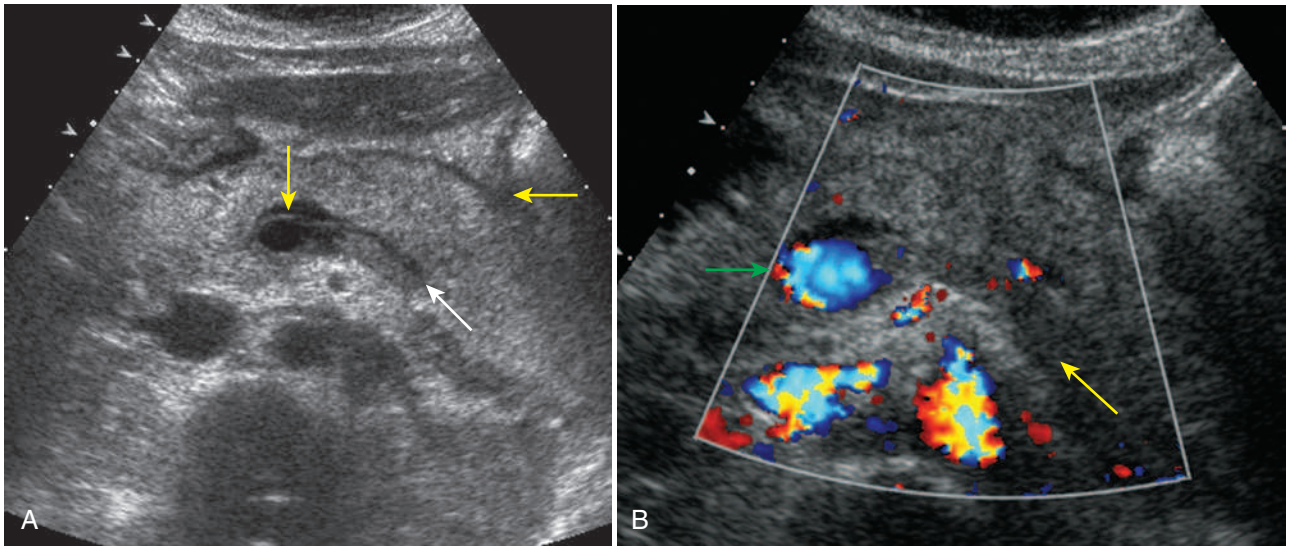

FIG. 7.35 Perivascular Inflammation and Clot Caused by Pancreatitis. (A) Transverse sonogram of pancreas shows the confluence free of thrombus, but clot in the splenic vein *(white arrow).* Note the obvious signs of perivascular and peripancreatic inflammation *(yellow arrows).* **(B)** Transverse color Doppler sonogram confirms splenic vein clot *(yellow arrow)* and the open confluence *(green arrow).*

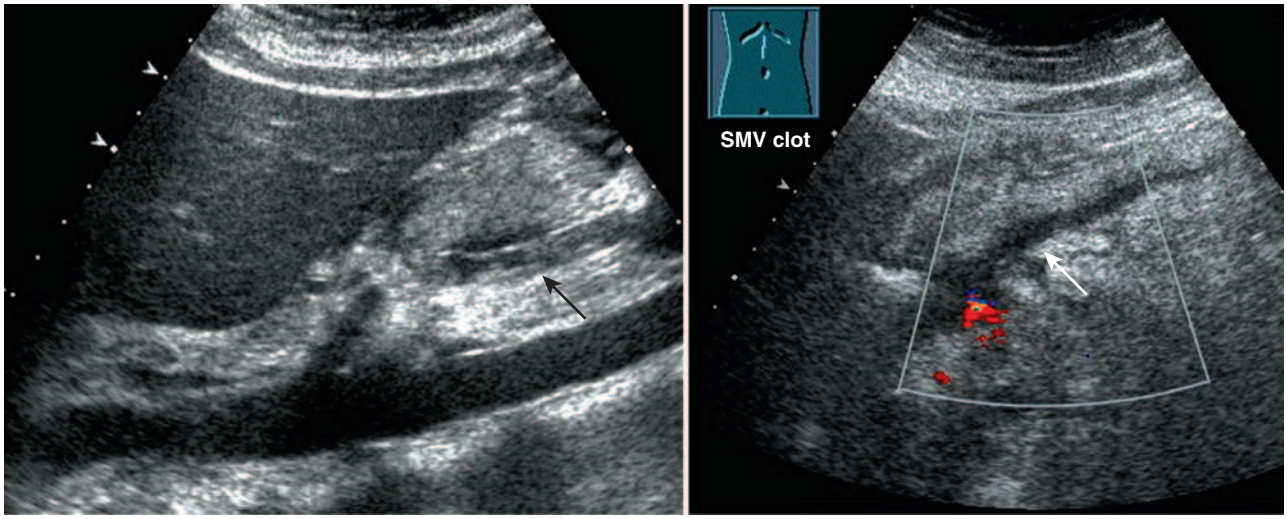

FIG. 7.36 Superior Mesenteric Vein Clot. Longitudinal sonograms show clot in the superior mesenteric vein (SMV) *(arrows)* in two patients with acute pancreatitis.

Acute Fluid Collections

Pancreatitis-associated fluid collections represent a spectrum of disease and thus can be problematic to classify (Figs. 7.38 and 7.39; see also Fig. 7.29). Fluid collections, when they contain debris or necrosis or may be infected, cannot always be categorized. Approximately 40% of patients with acute pancreatitis develop acute fluid collections.[69,70] About half of these appear to resolve spontaneously,[69] with almost 70% resolving in patients with nonnecrotizing pancreatitis.[70] Thus drainage or other intervention in acute collections is inappropriate, unless a rare superinfection occurs. The Atlanta Classification suggests that the differentiation between acute fluid collection and **pseudocyst** should be made after 4 weeks from the onset of disease.[27,34] Others suggest that a fluid collection that persists for 6 weeks can be considered a pseudocyst. The 6-week definition is based on classic surgical management; the pseudocyst wall requires 6 weeks to "mature" to the point where it can be drained surgically.[71]

Pseudocysts

Pancreatic pseudocysts are a well-known complication of acute and chronic pancreatitis. Pseudocysts comprise 75%[72] to 90%[73] of all cystic lesions of the pancreas. The "wall" of pancreatic pseudocysts consists of fibrous and granulation tissue. Thus unlike true cysts or cystic neoplasms, pseudocysts do not have an epithelial lining. Pseudocysts are more common in patients with chronic than acute pancreatitis. Pseudocyst prevalence ranges from 5% to 16% in patients with acute pancreatitis. In chronic pancreatitis, prevalence varies from 20% to 40%, with the highest rates in alcohol-related chronic pancreatitis.[74] On occasion, pseudocysts can be caused by trauma (Fig. 7.40).

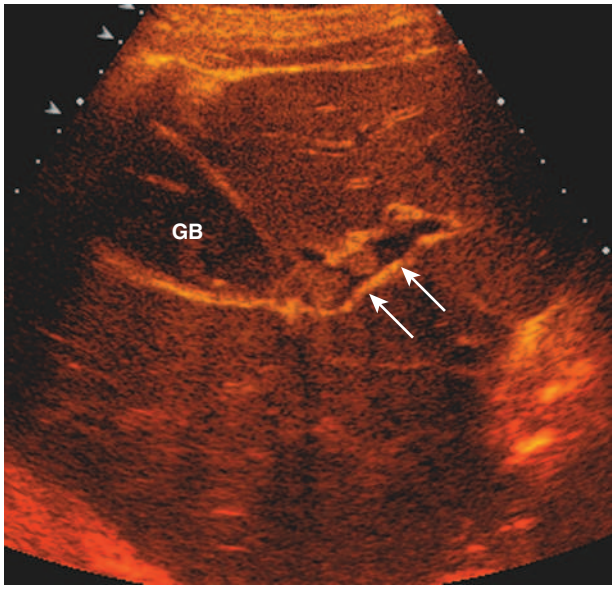

FIG. 7.37 Left Portal Vein Clot. Transverse sonogram shows clot in the left portal vein *(arrows)* caused by pancreatitis. *GB,* Gallbladder.

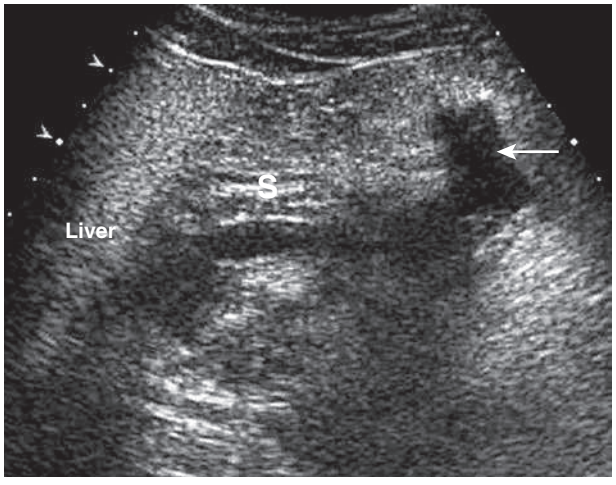

FIG. 7.38 Acute Fluid Collection. Longitudinal image shows inflammation and an acute fluid collection *(arrow)* in the transverse mesocolon. *S,* Stomach.

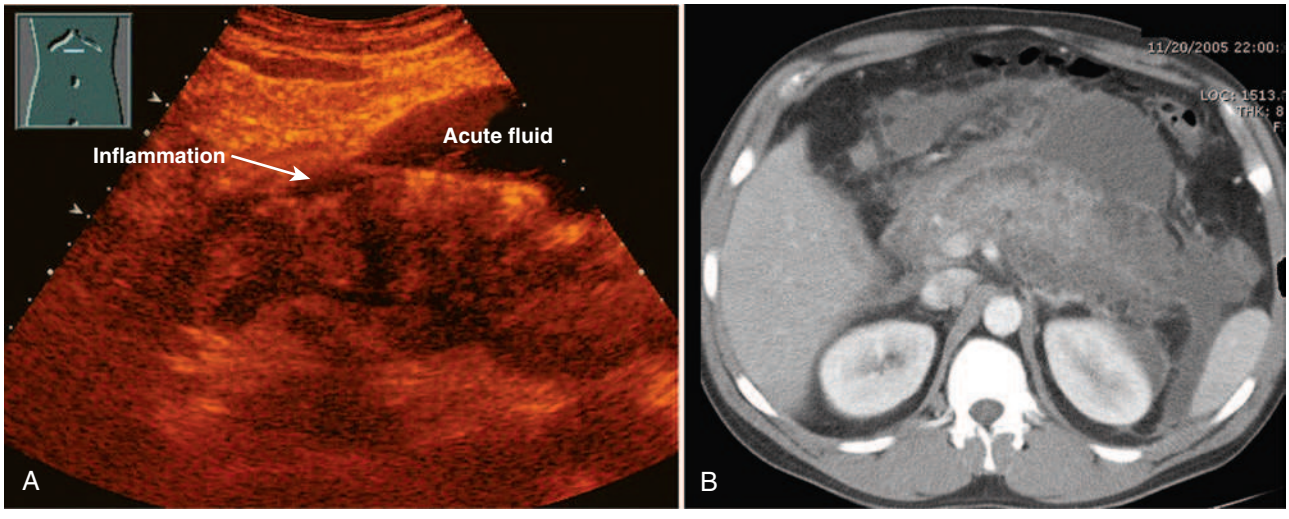

FIG. 7.39 Pancreatitis-Associated Fluid Collection. (A) Transverse sonogram and **(B)** CT image show enlarged and heterogeneous pancreas, with prominent peripancreatic inflammation *(arrow)* and an acute fluid collection that later resolved spontaneously.

The most important issue in diagnosing pseudocysts on images is avoiding confusion with cystic neoplasm, a mistake that can lead to adverse clinical outcomes.[75] Unfortunately, this distinction may be difficult. The major criterion for diagnosing a pseudocyst is a clinical history or imaging evidence of acute or chronic pancreatitis. Failing this, differentiating a pseudocyst from cystic pancreatic lesions becomes problematic. The sonographic findings in pseudocysts are variable. Pseudocysts can range in appearance from almost purely cystic to collections with considerable mural irregularity, septations, and internal echogenicity because of debris (Fig. 7.41) from necrosis, hemorrhage (see Fig. 7.40), or infection. Successful differentiation of cystic neoplasm from pseudocyst thus depends on a high degree of suspicion for possible cystic neoplasm and understanding findings strongly suggestive of "the usual suspects": **serous cystic neoplasm (microcystic adenoma), mucinous cystic neoplasm, solid-pseudopapillary tumor,** and **intraductal papillary mucinous neoplasm.**[76] Characterization of cystic neoplasms by CT or MRI is unreliable, even when the reviewers' diagnostic certainty was 90% or more.[77]

Conservative management of pseudocysts is appropriate unless complications occur. As noted, many pseudocysts resolve spontaneously. Persistent uncomplicated pseudocysts require no intervention and can be safely observed.[78,79] Indications for drainage of a pseudocyst include abdominal pain, usually related to growth of (or hemorrhage into) the pseudocyst, biliary obstruction (Fig. 7.41), and gastrointestinal (usually duodenal) obstruction.[80] Internal or external fistula formation can result in pancreatic ascites or pleural effusion.[81] Inflammation from pancreatitis can digest and dissect through tissue plane boundaries. For example, pseudocysts and inflammatory masses can present in the neck[81,82] or the groin[83] (Fig. 7.42).

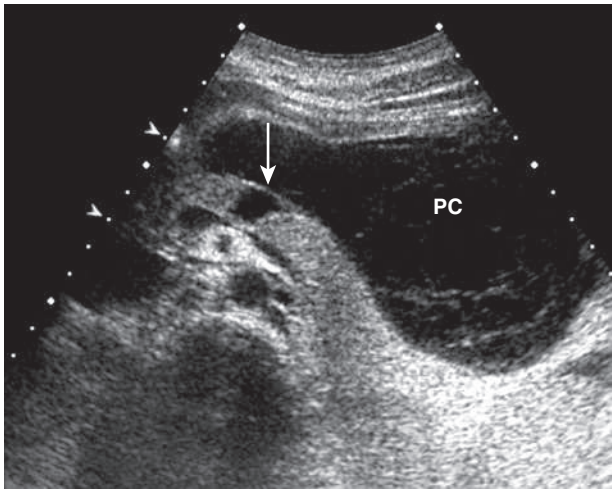

FIG. 7.40 Pancreatic Fracture and Associated Pseudocyst. Transverse sonogram shows the fracture/laceration *(arrow)* of the pancreatic body. A pseudocyst *(PC)* has developed ventral to the pancreas. Trauma is an uncommon cause of pancreatic pseudocysts. (Courtesy of Stephanie Wilson, MD.)

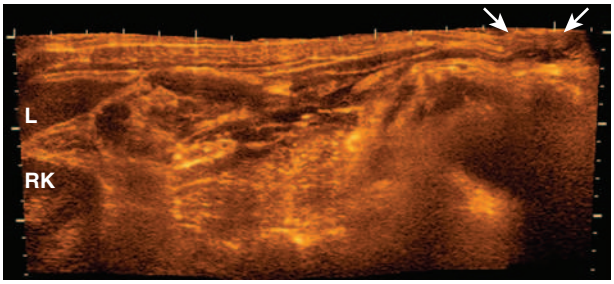

FIG. 7.42 Inflammation From Pancreatitis Causing Groin Mass. Longitudinal extended field of view sonogram from right upper quadrant to right groin. An inflammatory mass *(arrows)* is caudal to the inguinal ligament. Extensive spread of acute inflammation is common in acute pancreatitis. *L,* Liver; *RK,* right kidney.

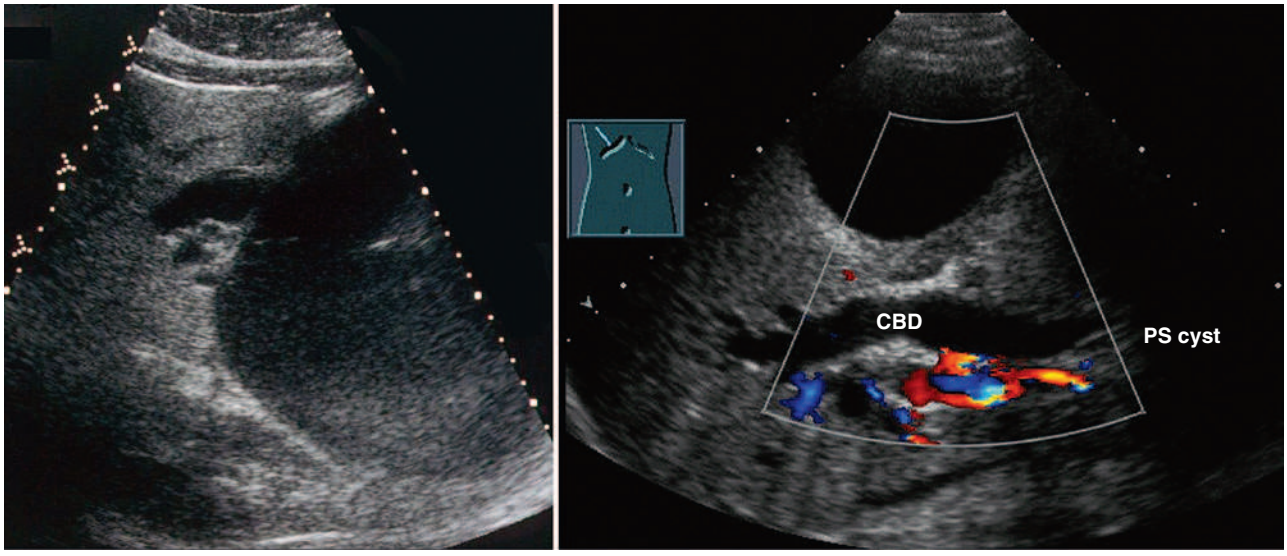

FIG. 7.41 Pseudocysts Causing Biliary Obstruction. Longitudinal oblique sonograms in two different patients demonstrate common bile duct *(CBD)* dilation from obstruction. Biliary obstruction is an indication for pseudocyst *(PS cyst)* drainage.

Necrosis and Abscess

Significant pancreatic necrosis has been defined by the Atlanta Classification system as nonenhanced pancreatic parenchyma greater than 3 cm or involving more than 30% of the area of the pancreas on CECT.[27,28] These patients are at greater risk than patients without necrosis and are treated with prophylactic antibiotics and observed closely. Necrosis cannot be definitively diagnosed by ultrasound, although ultrasound contrast agents may change that situation.

The original Atlanta Classification terminology describing significant infection associated with pancreatitis was somewhat confusing. *Pancreatic abscess* was reserved for infected fluid collections, essentially pseudocysts that become infected. **Infected pancreatic necrosis,** a much more serious condition, can also result in pus-filled collections, which might also be called *abscesses* in other clinical settings. Thus it is best to think of **two distinct types of acute pancreatitis–associated abscess,** as follows:

1. The original Atlanta Classification pancreatic abscess, an infected fluid collection/pseudocyst, which has minimal necrosis. The revised Atlanta classification has dropped the term *pancreatic abscess* because of confusion over its meaning.[34]
2. Infected necrosis with a fluid collection, which arises from infection of necrotic pancreatic tissue.

Treatment

The major approaches to the treatment of pseudocysts include surgery, percutaneous image-guided drainage and endoscopic-guided drainage. Andrén-Sandberg et al.[71] state:

> *There are no randomized studies for the management protocols for pancreatic pseudocysts. … First of all, it is important to differentiate acute from chronic pseudocysts for management, but at the same time not miss cystic neoplasias. Conservative treatment should always be considered the first option (pseudocysts should not be treated just because they are there).*

It is difficult to determine the best method to treat pseudocysts. The cause of pancreatitis, communication of the pancreatic duct with the pseudocyst, and local technical expertise must be considered when choosing a treatment method. Although the data are unclear, **percutaneous drainage** of pseudocysts likely is overall less successful than surgical or endoscopic drainage.[84] Nevertheless, percutaneous drainage can be used as a first option with other techniques reserved for percutaneous drainage failures. In the large subset of patients with normal duct anatomy and no communication of the pseudocyst with the pancreatic duct, percutaneous drainage is successful in more than 80%. On the other hand, percutaneous drainage failed in 77% to 91% of patients who had duct obstruction or strictures.[80] Therefore ERCP,[85] and in some cases MRCP,[58,74] may be useful in the selection of treatment technique.

Infected fluid collections without significant necrosis may often be best treated by percutaneous drainage.[85] Percutaneous drainage can also be used in **infected necrosis,** for which it is curative in some patients[86] and is a useful temporizing technique in others.[84] Although management of infection in pancreatitis is evolving,[27] therapy for infected pancreatic necrosis remains surgical debridement.

Vascular Complications

Vascular complications occur in both acute and chronic pancreatitis. **Pseudoaneurysms** and **venous thrombosis** are the most important vascular complications. Most cases of clinically insignificant hemorrhagic pancreatitis are related to venous and small vessel disease, whereas potentially fatal hemorrhage is usually related to enzymatic digestion or pseudoaneurysm of major vessels, including the splenic, gastroduodenal (Fig. 7.43), and superior pancreaticoduodenal arteries. The prevalence of hemorrhage in patients with a pseudocyst is 5%, but with an up to 40% rate of mortality.[87] Vascular erosion can produce a sudden, painful expansion of the cyst or gastrointestinal bleeding caused by bleeding into the pancreatic duct ("hemosuccus pancreaticus").[88] Thrombosis of the portal venous system may occur in both acute and chronic pancreatitis[68]; **splenic vein thrombosis** is most common (Fig. 7.44). Agarwal et al.[89] reported a 22% prevalence of splenic vein thrombosis in patients with chronic pancreatitis. Bernades et al.[90] reported the prevalence of **portal vein thrombosis** as 5.6% (15/266). Splenic vein thrombosis may result in upper gastrointestinal bleeding from gastric varices; this condition is called **"sinistral" (left-sided) portal hypertension.**

CHRONIC PANCREATITIS

The prevalence of chronic pancreatitis ranges from 3.5 to 10 per 100,000 in the population. Chronic pancreatitis is characterized by intermittent pancreatic inflammation with progressive, irreversible damage to the gland. The key histologic features are fibrosis,

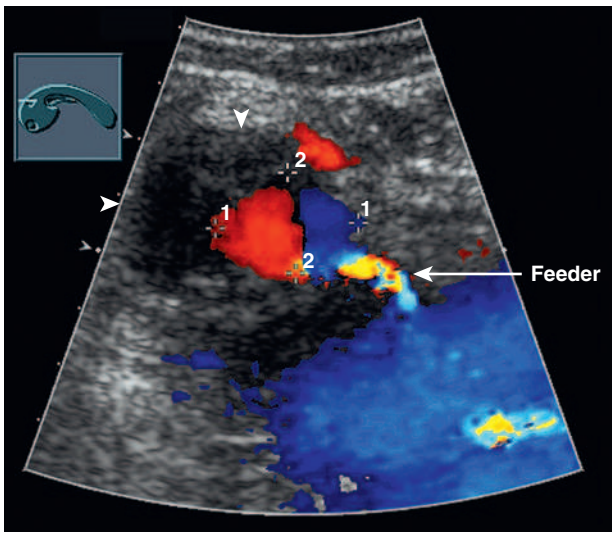

FIG. 7.43 Pancreatic Pseudoaneurysm. Transverse color Doppler sonogram shows acute pancreatitis–associated pseudoaneurysm arising from the gastroduodenal artery. The clotted portion of the pseudoaneurysm *(arrowheads)* is noted. Calipers denote the patent portion of the pseudoaneurysm. Pseudoaneurysm is a rare complication of pancreatitis, much less common than venous thrombosis. Notice the "yin and yang" *(red/blue)* color Doppler appearance representing the blood swirling in the lesion.

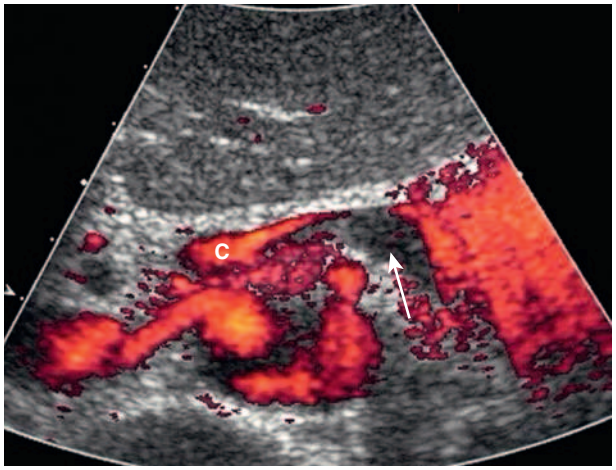

FIG. 7.44 Splenic Vein Clot. Transverse power Doppler image shows partial splenic vein clot *(arrow)* caused by chronic pancreatitis. *C,* Confluence of splenic and superior mesenteric veins.

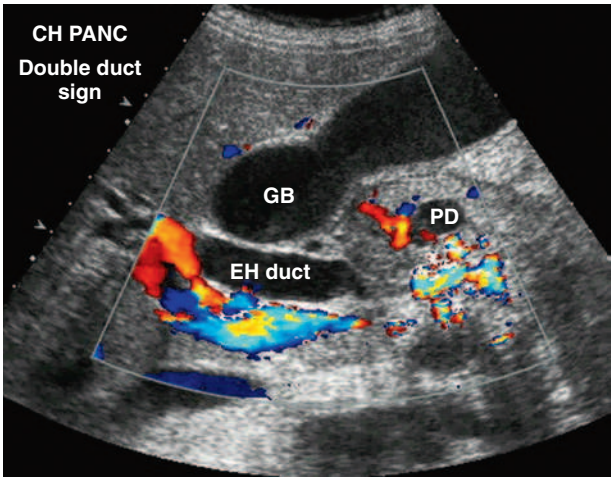

FIG. 7.45 "Double-Duct" Sign. Longitudinal oblique image shows dilation from obstruction of the pancreatic duct *(PD)* and extrahepatic bile duct *(EH).* Chronic pancreatitis often causes the double-duct sign. *GB,* Gallbladder.

acinar atrophy, chronic inflammation, and distorted and blocked ducts.[91] Chronic pancreatitis ultimately leads to permanent structural change and deficient endocrine and exocrine function. Some lasting morphologic changes include alterations in parenchymal texture, glandular atrophy, glandular enlargement, focal masses, dilation and beading of the pancreatic duct (often with intraductal calcifications), and pseudocysts.

Alcoholism is the predominant cause of chronic pancreatitis (70%-90% in Western countries).[92] Other causes include pancreatic duct obstruction caused by strictures, hypertriglyceridemia, hypercalcemia, autoimmune pancreatitis, tropical pancreatitis, and other genetic mutations.[93]

Chronic pancreatitis is characterized clinically by pain, malabsorption, and diabetes. Treatment of uncomplicated chronic pancreatitis is usually conservative, with the major aim to improve the patient's quality of life by alleviating pain and mitigating malabsorption and diabetes. Surgical and endoscopic interventions are reserved for complications such as pseudocysts, abscesses, and malignancy.[91] Obstruction and thrombosis of the portal veins may occur (see Fig. 7.37). Chronic pancreatitis may also lead to obstruction of the pancreatic and bile ducts, sometimes resulting in the "double-duct" sign (Fig. 7.45). In settings with a high prevalence of alcoholism, the double-duct sign is caused by chronic pancreatitis more often than by periampullary neoplasm.[94] The frequency of common bile duct obstruction in patients hospitalized for chronic pancreatitis ranges from 3% to 23% (mean, 6%). The frequency of duodenal obstruction is about 1.2% in hospitalized patients.[95] All of these findings occur in various combinations and with differing frequency.[8]

Approach to Imaging

The imaging diagnosis of chronic pancreatitis depends on detecting the structural changes associated with advanced disease. Unfortunately, these changes are rarely present in early disease, decreasing imaging sensitivity. Consequently, imaging is not very useful in patients with early chronic pancreatitis. Furthermore, morphologic changes do not correlate well with endocrine or exocrine function.[96]

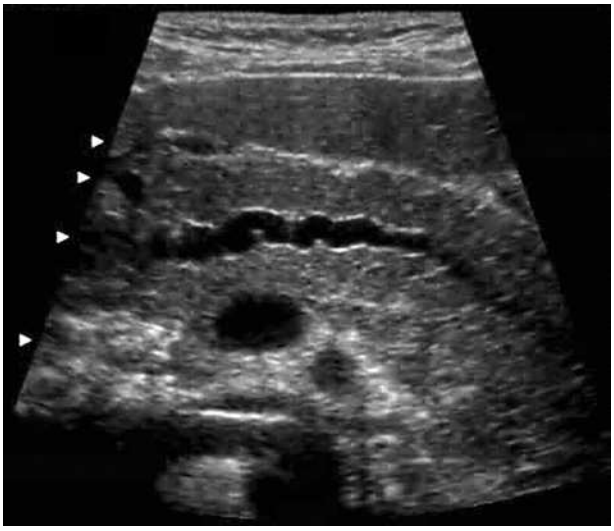

FIG. 7.46 Dilation of Pancreatic Duct. Transverse sonogram of the pancreatic body shows a beaded, dilated pancreatic duct, resulting from chronic pancreatitis.

Despite the common belief that it is diagnostically inferior overall to CECT, MRCP, and endoscopic ultrasound,[97-99] ultrasound is often recommended as the first diagnostic test.[91] Bolondi et al.[8] stated that ultrasound diagnosis of chronic pancreatitis remains difficult because of "the polymorphism of anatomic changes and the relatively high incidence of false-negative results in early stages of the disease."

Ultrasound Findings

Sonography can be effective in diagnosing chronic pancreatitis, but other tests are generally required if intervention is contemplated. The hallmark of chronic pancreatitis is **ductal dilation** (Fig. 7.46) and **calcifications,** which can be in the branch ducts (Fig. 7.47), main duct (Fig. 7.48), or both (Video 7.4). When these findings are present in a patient with pain and a history of alcoholism, the diagnosis of chronic pancreatitis is secure.

FIG. 7.47 Dilated Pancreatic Duct and Branch Duct Calcifications. Ductal calcification is a hallmark of chronic pancreatitis. Transverse sonogram shows many branch duct stones.

CT is superior to sonography in detecting calcifications and ductal dilation. Calcifications are often made much more conspicuous on ultrasound images by looking for the **color comet-tail artifact,** also known as the "twinkling artifact"[99,100] (Fig. 7.49; see also Fig. 7.48B and Video 7.5).

Areas of increased and decreased echogenicity are related to the effects of patchy fibrosis. These focal areas of altered echogenicity are often subjective and difficult to appreciate.

Pseudocysts

Pseudocysts are more common in patients with chronic (20%-40%) than with acute (5%-16%) pancreatitis (Figs. 7.50 and 7.51, Video 7.6).[74] Pseudocysts may present with various shapes, contain necrotic debris (Fig. 7.52), hemorrhage (≈5%)[72] (Fig. 7.53), or even have a completely solid pattern.[8]

Portal and Splenic Vein Thrombosis

Thrombosis of the portal venous system can occur in chronic pancreatitis because of (1) intimal injury from recurrent acute

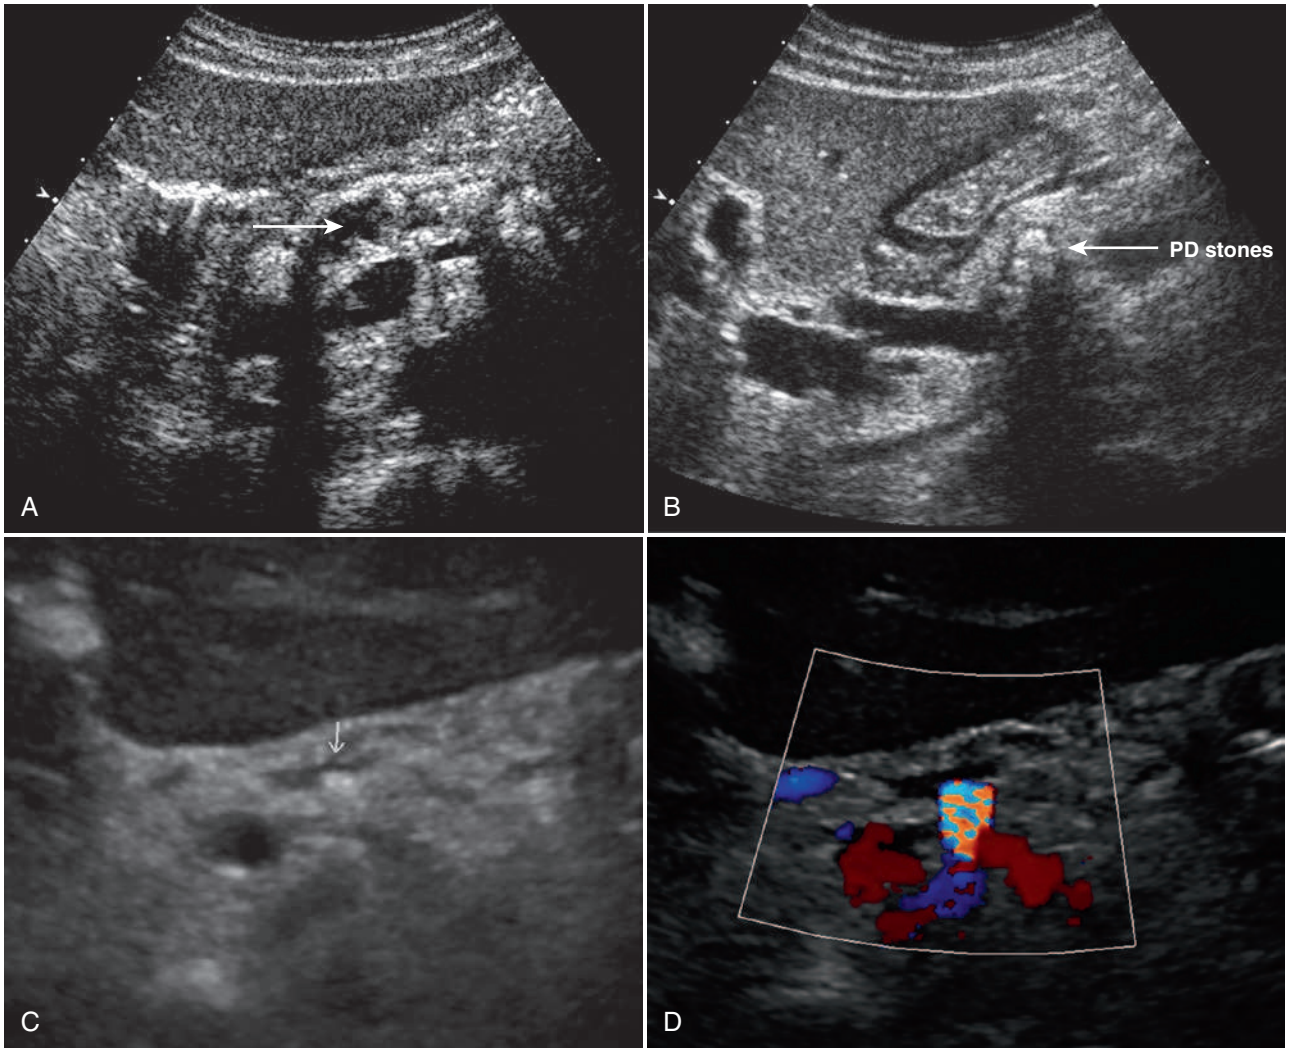

FIG. 7.48 Dilated Pancreatic Duct and Intraductal Stone. (A) Transverse and **(B)** longitudinal sonograms show chronic pancreatitis with dilation of the pancreatic duct *(PD)* and multiple stones in the main duct *(arrow)*. Branch duct stones are manifest as almost confluent, echogenic parenchymal foci. **(C)** Transverse gray-scale and **(D)** color Doppler sonograms show chronic pancreatitis with dilation of the pancreatic duct and stone in the main duct *(arrow)*. **(D)** Color comet-tail (aka "twinkle") artifact at color Doppler imaging can increase stone conspicuity. See also Video 7.4.

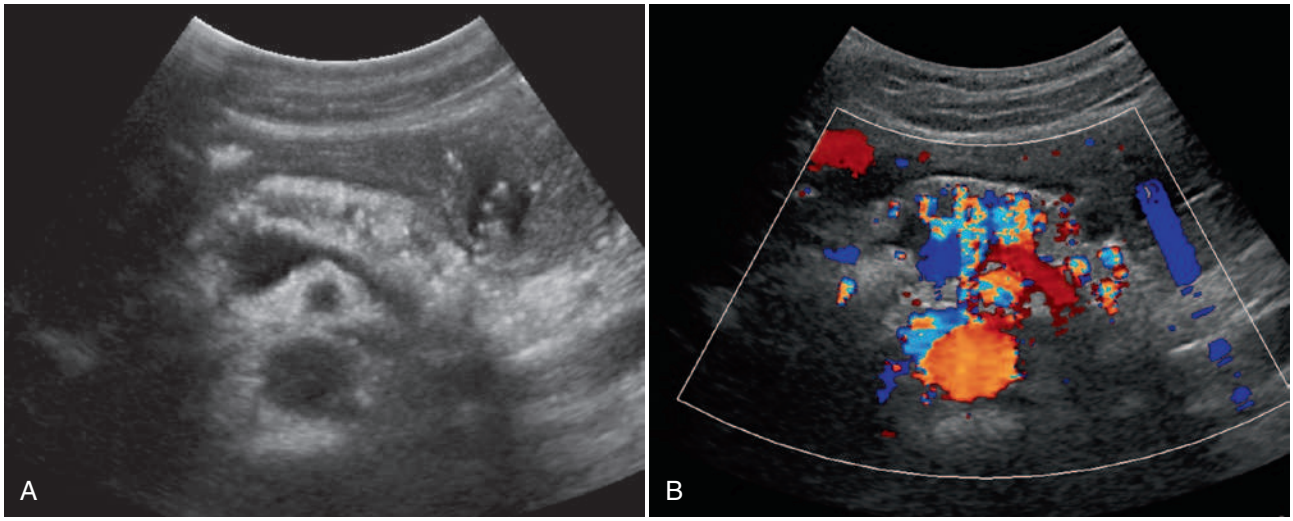

FIG. 7.49 Calcifications in Chronic Pancreatitis Highlighted by Color Comet-Tail Artifact. (A) Transverse gray-scale and **(B)** color Doppler sonograms show that color comet-tail artifact makes the extensive pancreatic calcification much more conspicuous. See also Video 7.5.

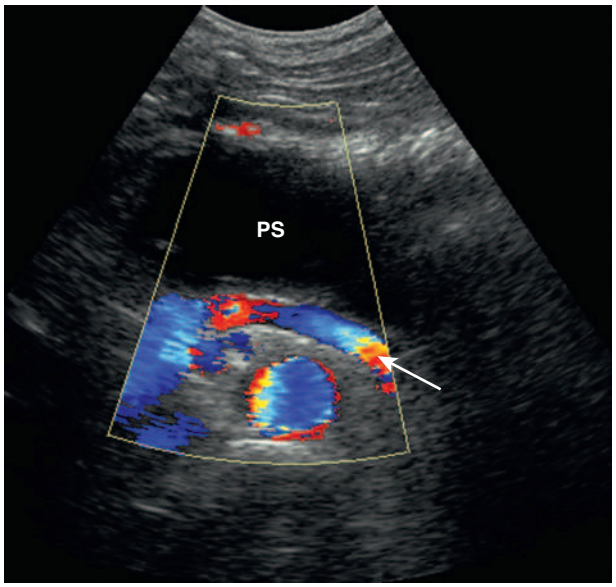

FIG. 7.50 Pseudocyst in Pancreatic Body in Patient With Chronic Pancreatitis. This pseudocyst *(PS)* is almost free of internal debris. The flow reversal in the splenic vein *(arrow)* is related to cirrhotic portal hypertension. See also Video 7.6.

inflammation, (2) chronic fibrosis and inflammation, or (3) compression by either a pseudocyst or an enlarged pancreas.[101] **Splenic vein thrombosis** is relatively common in patients with chronic pancreatitis (5%[102]–40%[101]) (see Fig. 7.44). **Portal vein thrombosis** occurs less frequently. Bernades et al.[90] reported the prevalence of splenoportal vein obstruction as 13%, with the splenic vein obstructed in 8%, portal vein in 4%, and SMV in 1%.

Pancreatitis-associated thrombus in the splenic or portal vein often results in collaterals different from those in portal hypertension from liver disease. Rather than conveying blood away from the diseased liver, these collaterals conduct blood *toward* the liver, bypassing the clot. Splenic vein thrombosis will often result in **left-sided** ("sinistral") **portal hypertension** (Fig. 7.54). This can result in isolated gastric varices, which can cause life-threatening gastrointestinal bleeding. The hepatopetal pathway to bypass the splenic vein clot (Fig. 7.55) includes short gastric collaterals that lead to the **gastric mural varices** (Fig. 7.56), then flow toward the liver in the coronary vein. It may be difficult or impossible to detect splenic vein clot or even the splenic vein itself. Therefore the diagnosis of splenic vein clot may depend on detection of collaterals, such as short gastric varices or an enlarged coronary vein.[103] When the main portal vein is clotted, blood flows to the liver around the clot. If the portal vein clot persists, these hepatopetal collaterals may enlarge, resulting in cavernous transformation of the portal vein. **Gallbladder wall varices** were present in 30% of patients with portal vein thrombosis in one study[104] (Fig. 7.57). These can be successfully diagnosed with color Doppler[105] or gray-scale[106] imaging.

Masses Associated With Chronic Pancreatitis

Focal pancreatic masses occur in approximately 30% of patients who have chronic pancreatitis. Carcinoma- and pancreatitis-related masses are usually easy to differentiate clinically and by imaging (Fig. 7.58). In some patients, however, the distinction may be difficult[107] (Fig. 7.59). Pancreatitis-associated masses are found in a surprisingly large percentage of patients having surgery for suspected pancreatic malignancy (5%-18.4%).[108] In one series, 10.6% (47 patients) of 442 patients undergoing **pancreaticoduodenectomy (Whipple resection)** had benign disease.[109] Of these 47 patients, 40 (85%) were resected because of a suspected malignancy.

The presence of calcification within a mass makes the diagnosis of chronic pancreatitis likely (Fig. 7.60). Only 4% to 6% of ductal adenocarcinomas have calcifications.[110,111] The pattern of calcification in patients with ductal adenocarcinoma is different from

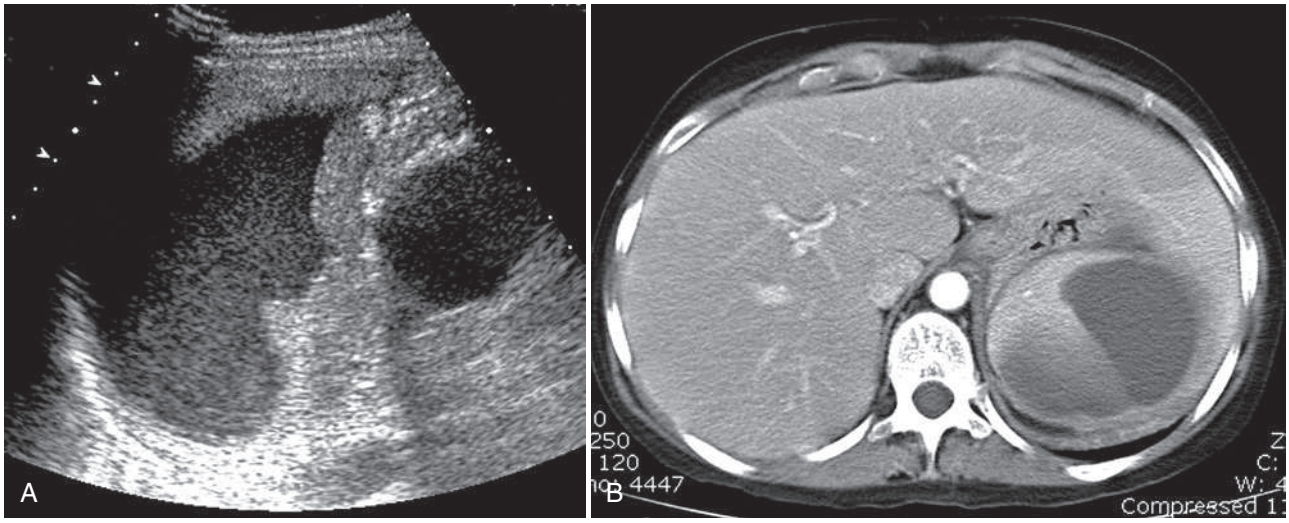

FIG. 7.51 Hemorrhagic Pseudocyst in Pancreatic Tail. (A) Complex, debris-filled pseudocyst seen through pancreatic tail in patient with chronic pancreatitis. **(B)** Computed tomography scan shows debris in the pseudocyst.

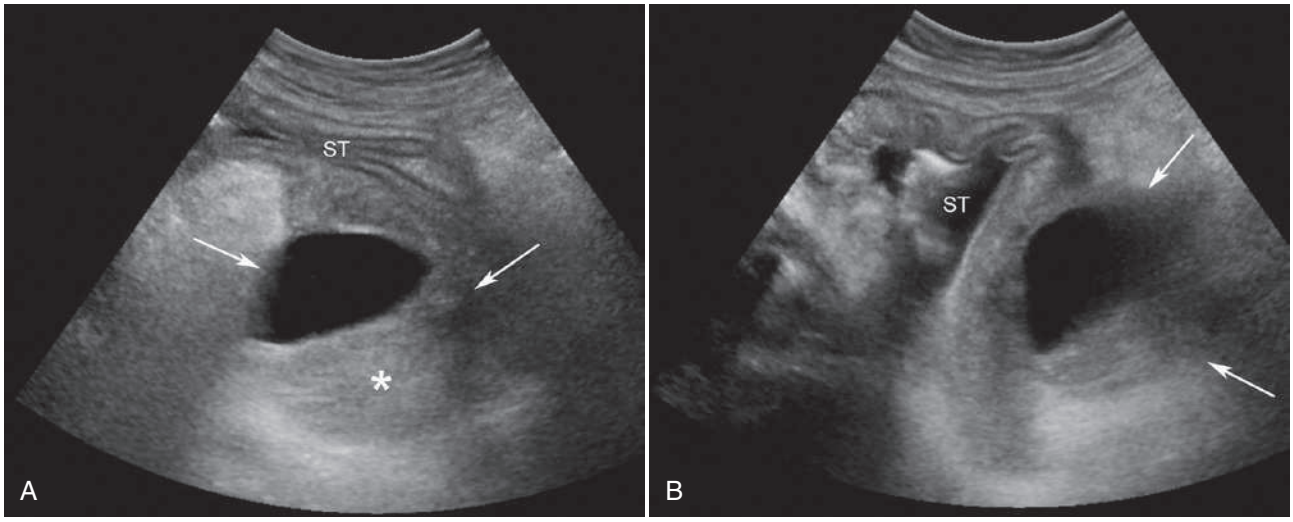

FIG. 7.52 Debris-Containing Pseudocyst. (A) Transverse sonogram shows a well-organized collection *(arrows)* abutting the stomach *(ST)* with internal debris (*) and a fluid-debris level. **(B)** Sagittal sonogram demonstrates the debris-containing pseudocyst *(arrows)* abutting the greater curvature of the stomach. The gastric wall is thickened as a result of reactive inflammatory changes.

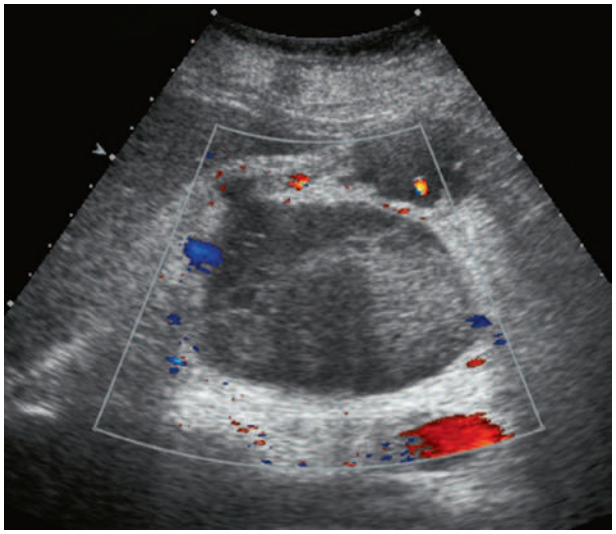

FIG. 7.53 Hemorrhagic Pseudocyst in Pancreatic Body. Chronic pancreatitis–associated debris-filled pseudocyst; it may be difficult or impossible to distinguish a hemorrhagic pseudocyst from a debris-filled nonhemorrhagic pseudocyst.

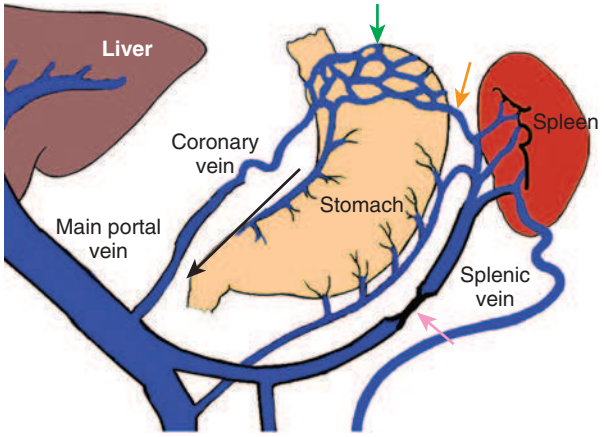

FIG. 7.54 Splenic Vein Clot With Left-Sided ("Sinistral") Portal Hypertension. This can result in isolated gastric varices *(green arrow),* which can cause life-threatening gastrointestinal bleeding. The hepatopetal pathway to bypass the splenic vein clot *(purple arrow)* includes short gastric collaterals *(orange arrow). Long black arrow* indicates direction of blood flow.

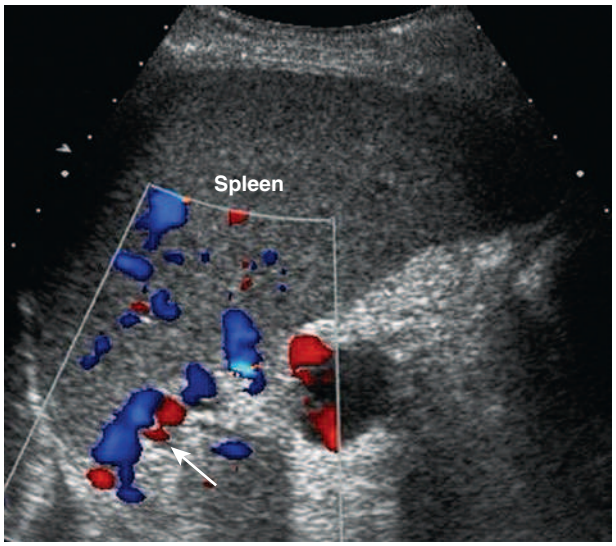

FIG. 7.55 Short Gastric Collaterals From Splenic Vein Clot. Longitudinal coronal color Doppler sonogram in a patient with left-sided (sinistral) portal hypertension shows blood in the short gastric venous collaterals *(arrow)* flowing away from the splenic hilum.

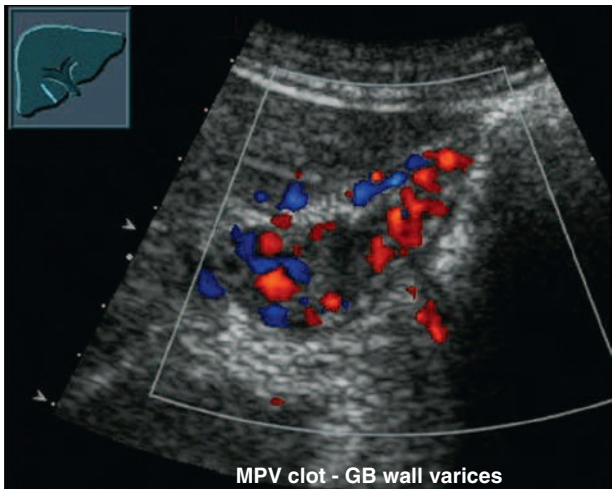

FIG. 7.57 Gallbladder Wall Varices and Clot. Oblique color Doppler sonogram shows main portal vein (MPV) clot engenders hepatopetal collaterals, including cavernous transformation of the portal vein and, in some patients, gallbladder (GB) wall varices.

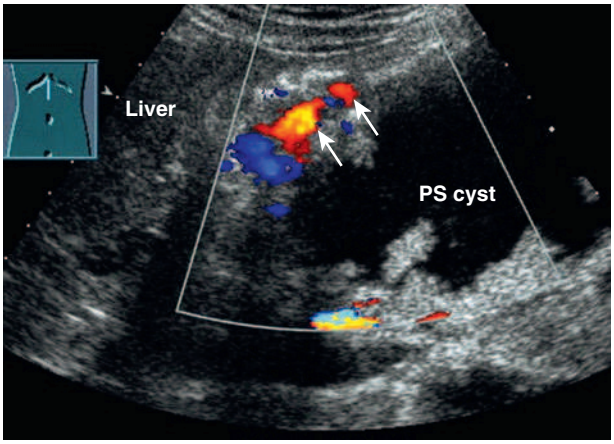

FIG. 7.56 Gastric Mural Varices. Longitudinal color Doppler sonogram in a patient with left-sided portal hypertension. The actual gastric mural varices *(arrows)* are visualized, unusual in these patients. The pseudocyst *(PS cyst)* that caused the splenic vein clot is compressing the stomach.

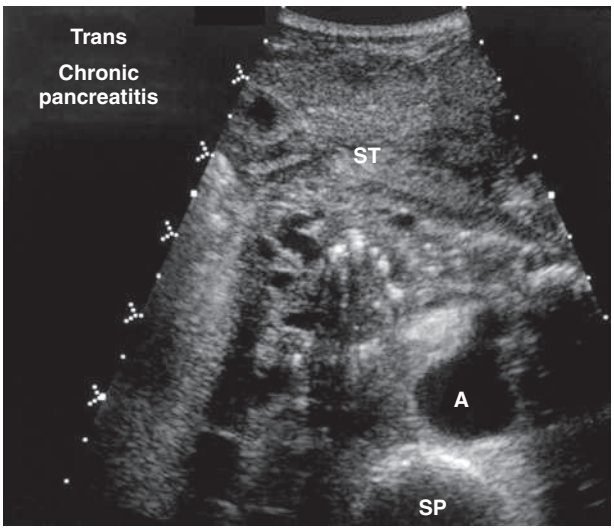

FIG. 7.58 Chronic Pancreatitis–Associated Mass, With Calcification and Dilated Ducts. Transverse sonogram of pancreatic head. When classic findings such as ductal dilation and multiple calcifications are present, the diagnosis of chronic pancreatitis is clear. *A,* Aorta; *SP,* spine; *ST,* stomach.

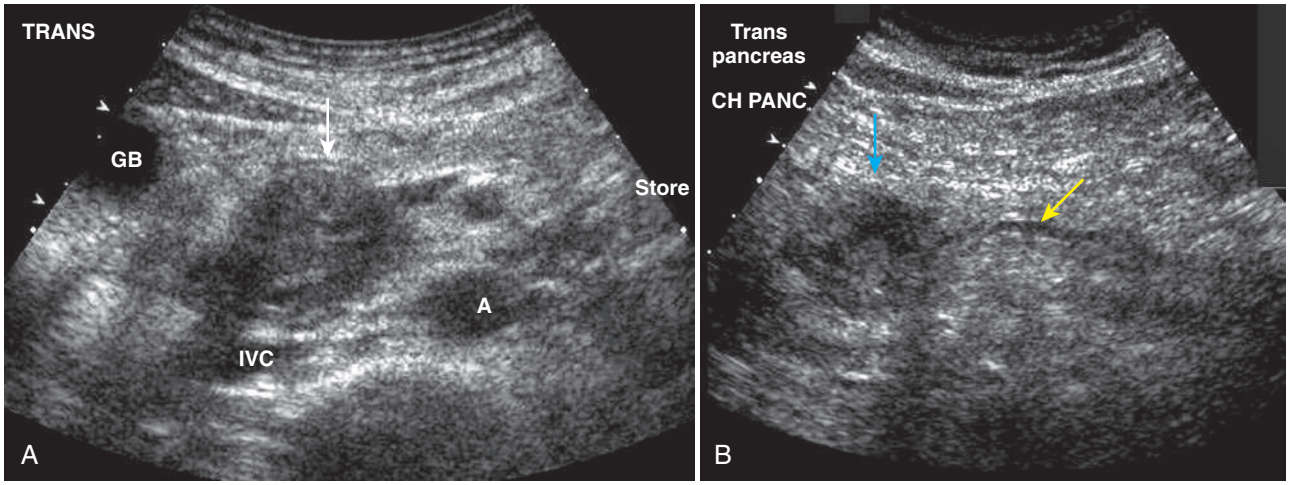

FIG. 7.59 Chronic Pancreatitis–Associated Masses in Pancreatic Head Simulating Carcinoma. Two different patients. **(A)** Transverse sonogram reveals a mass *(arrow)* that lacks calcification and other features of chronic pancreatitis, simulating a malignant mass. **(B)** Transverse sonogram reveals a mass *(blue arrow)* that simulates a malignancy; *yellow arrow,* pancreatic duct. *A,* Aorta; *GB,* gallbladder; *IVC,* inferior vena cava.

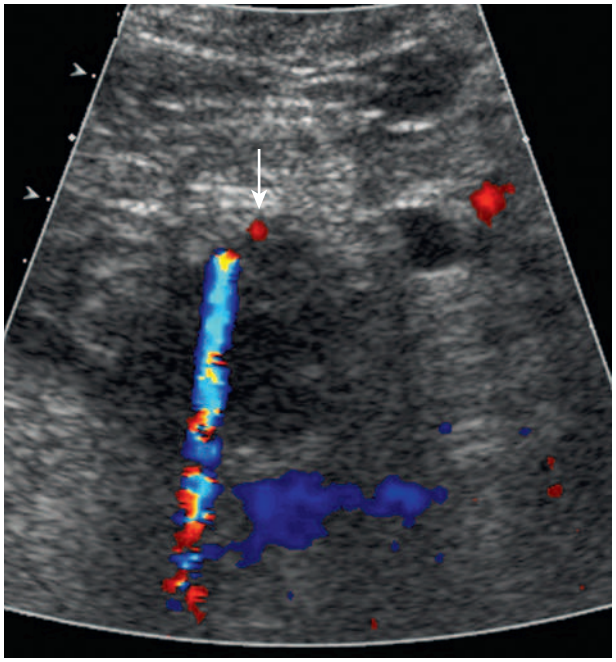

FIG. 7.60 Mass With Color Comet-Tail Artifact From Calcification. Transverse sonogram reveals a mass *(arrow)*. Calcification, revealed by a prominent color comet-tail artifact, indicates a likely diagnosis of chronic pancreatitis.

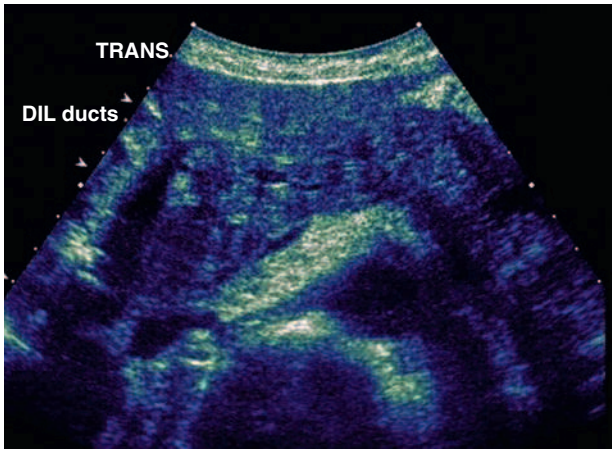

FIG. 7.61 Many Small, Dilated Ducts. Transverse sonogram shows multiple dilated branch ducts in the pancreatic head, more typical of chronic pancreatitis and rarely found in pancreatic cancer.

that of patients with the usual chronic pancreatitis. In chronic pancreatitis calcifications are multiple and ductal. In carcinoma there are generally only one or a few coarse calcifications, usually unrelated to dilated ducts. Hyperechoic masses, even without discrete calcifications, are usually (but not always) related to chronic pancreatitis. An uncalcified isoechoic or hypoechoic mass occurring in a patient without clinical or imaging evidence of chronic pancreatitis is nonspecific. In this case, other imaging or biopsy is indicated to differentiate carcinoma from chronic pancreatitis. As noted, the double-duct sign is nonspecific, occurring in both pancreatitis and pancreatic carcinoma. Finding multiple dilated branch ducts in the pancreatic head is more typical of chronic pancreatitis and is rarely found in pancreatic cancer (Fig. 7.61). Pseudocysts are common in chronic pancreatitis (20%-40%)[74] and rare in carcinoma,[112] but they occur in both conditions. So-called obstructive pseudocysts that occur with carcinoma usually are peripheral to body or tail lesions. Pancreatitis-associated pseudocysts occur anywhere in the gland, usually arising in areas of necrosis.

Autoimmune pancreatitis is a masslike imitator of pancreatic carcinoma[113] (Figs. 7.62 and 7.63). Autoimmune pancreatitis accounts for many cases previously classified as "idiopathic pancreatitis," comprising perhaps 4% to 6% of all patients diagnosed with chronic pancreatitis. The autoimmune pancreatitis terminology is confusing; synonyms include **chronic sclerosing pancreatitis, lymphoplasmacytic sclerosing pancreatitis,** and **tumefactive chronic pancreatitis.**[114] About 2% of pancreatic masses resected for suspected malignancy are found instead to be autoimmune pancreatitis.[115] Although benign masses from the usual causes of chronic pancreatitis are more common, autoimmune pancreatitis masses are much more likely to be confused for carcinoma.[116] In one series, 13 of 19 (68%) masses caused by the usual types of chronic pancreatitis were resected for a clinical suspicion of malignancy, whereas all 11 (100%) of autoimmune pancreatitis–related masses were thought to be malignant preoperatively.[109]

Anecdotal experience suggests that when a definite pancreatic mass is seen sonographically but not imaged on CT, chronic pancreatitis is the likely cause of the mass. Another slightly confounding fact is that patients with chronic pancreatitis have an increased lifetime risk of developing pancreatic carcinoma (4%)[117] compared with the general population (1%-2%).[118]

PANCREATIC NEOPLASMS

Periampullary Neoplasm

Periampullary neoplasms are difficult to differentiate from one another and are generally managed identically—by **pancreaticoduodenectomy (Whipple resection). Jaundice** is the most common presenting feature of these tumors (85%).[119] Tumors in this group include **pancreatic ductal adenocarcinoma** (about two-thirds of periampullary neoplasms), **ampullary carcinoma** (15%-25%), **duodenal carcinoma** (10%), and distal **cholangiocarcinoma** (10%).[119] Survival rates are best for patients with duodenal and ampullary carcinoma, but only in comparison to the poor survival rates for those with cholangiocarcinoma and especially pancreatic cancer.

Image evaluation of these tumors is basically the same as that described later for pancreatic ductal adenocarcinoma. The approach varies depending on the clinical presentation and local expertise. Most agree, however, with Ross and Bismar,[119] that "the relative availability, economy, and usefulness of the results make transabdominal ultrasound a common initial imaging study for patients with suspected obstructive jaundice."

Pancreatic Carcinoma

Pancreatic ductal adenocarcinoma is the most common primary pancreatic neoplasm, accounting for 85% to 95% of all pancreatic

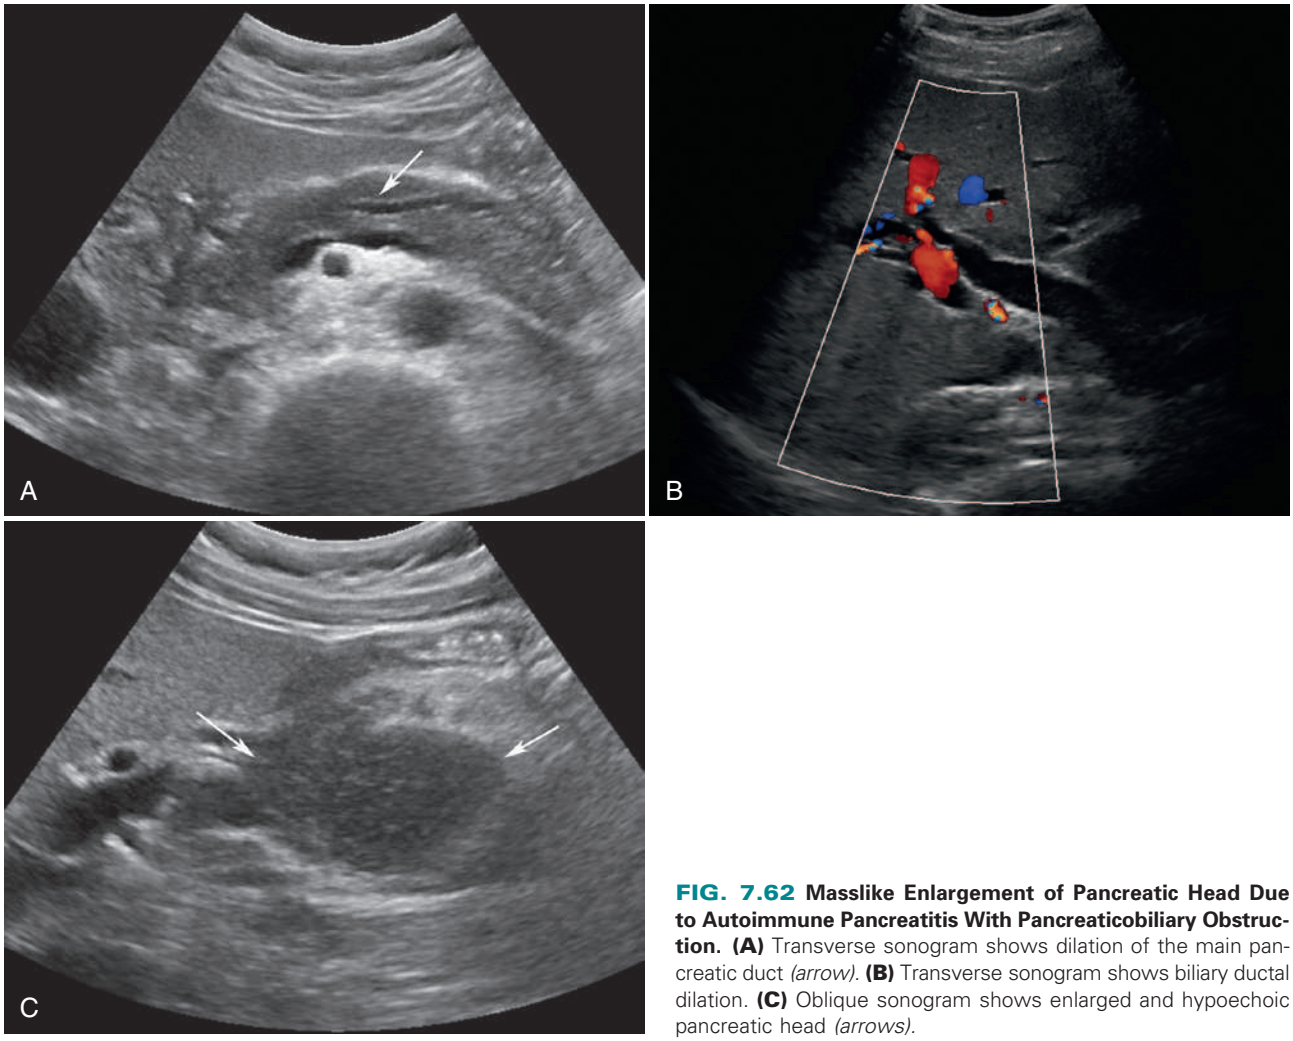

FIG. 7.62 Masslike Enlargement of Pancreatic Head Due to Autoimmune Pancreatitis With Pancreaticobiliary Obstruction. (A) Transverse sonogram shows dilation of the main pancreatic duct *(arrow)*. **(B)** Transverse sonogram shows biliary ductal dilation. **(C)** Oblique sonogram shows enlarged and hypoechoic pancreatic head *(arrows)*.

malignancies.[120,121] Ductal adenocarcinoma has a slight male predominance, most frequently affecting patients 60 to 80 years of age. The prevalence of pancreatic carcinoma tripled during the mid-20th century. The mortality rate for patients with pancreatic cancer has continued to decline since 1975 in men and has leveled off in women after increasing from 1975 to 1984.[122] Pancreatic cancer represents only 2% of all cancers but is the fourth most common cause of cancer death in the United States. Overall 5-year survival is poor: 2% to 5%. Risk factors include tobacco smoking (twice the risk as for nonsmokers), obesity, chronic pancreatitis, diabetes, cirrhosis, and use of smokeless tobacco. A family history of pancreatic cancer also increases risk.[123] Rare syndromes associated with increased risk include Peutz-Jeghers syndrome.[124]

The selection of imaging techniques in patients with pancreatic cancer requires a rational approach based on grim realities about the disease. Although sophisticated imaging of candidates for resection consumes much time and effort, it is crucial to remember that only a few patients have potentially resectable disease at initial diagnosis. These are the patients who can potentially benefit from sophisticated "resectability" studies. Further, even for that small minority who can be resected with a hope for cure, the

Pancreatic Cancer Imaging: Three Key Concepts

1. The vast majority of patients with pancreatic cancer can be classified as "unresectable for cure," based on the initial ultrasound or CT.
2. Only 10% to 20% of patients require sophisticated "resectability" studies, whether done with CT, MRI, or ultrasound (transabdominal or endoscopic).
3. The survival statistics for patients with pancreatic cancer have been exaggerated in the literature. The usefulness of surgery is questionable in this malignancy.

prognosis is poor. Most patients with newly diagnosed pancreatic carcinoma have advanced unresectable disease at initial diagnosis. In most studies from major oncology centers, only 10% to 20% of the patients are eligible for curative surgery at diagnosis.[125,126] The initial routine imaging study, whether ultrasound or CT, can usually detect advanced disease.[127]

Although the diagnosis of periampullary tumors and safety of the Whipple procedure have improved over the decades, prognosis for patients with pancreatic cancer remains poor. In a meta-analysis of virtually the entire surgical literature on resection of pancreatic cancer, Gudjonsson[128] found significant errors and exaggerations in the reporting of survival figures, and that the overall survival rate actually was less than 0.4%. The best overall survival rate in detailed surgical studies is only 3.6%, and for a nonsurgical study, 1.7%. In another report, Gudjonsson[129] stated,

> *Resections for pancreatic cancer have been performed for 65 years, with approximately 20,000 reported. A number of authors claim a 5-year survival rate of 30% to 58%. Review of the literature reveals only about 1,200 5-year survivors; however, 10 times as many individual resected survivors have been reported (in various countries), and nonresected survivors are overlooked. This high survival percentage is obtained by reducing the subset on which calculations are based and by using methods such as the Kaplan-Meier method, which produces higher figures as increasing numbers of patients are lost to follow-up. After adjustments, hardly more than 350 resected survivors could be found. Revision of statistical methods is urgently needed.*

Conlon et al.[126] reported that 5-year survival does not equal cure. In their series of 118 resected patients, median survival was 14.3 months. Twelve patients survived 5 years after surgery (10.2% of resected patients), but 5 of these 12 patients died of pancreatic cancer in the sixth postoperative year. At the time of the report, 6 patients were alive and without evidence of disease at a median follow-up of 101 months (range, 82-133 months). In periampullary tumors other than ductal adenocarcinoma, 5-year survival rate is higher, for example, 9% versus 36% in the study by Wade et al.[130] Despite these grim facts, most surgeons favor an aggressive approach, as expressed by Farnell et al.[131]:

> *Significant progress has been made in diagnosis, preoperative staging, and safety of surgery; however, long-term survival after resection is unusual, and cure is rare. That said, the authors maintain their aggressive posture regarding this disease, recognizing that resection offers the only potential for cure.*

Because of prevailing surgical opinion, radiologists will continue to be asked to do studies to assess the potential resectability of pancreatic cancer in the 10% to 20% of patients in whom the initial study does not show advanced disease.

Detection of Pancreatic Cancer

Sonography and CT are the primary tools used to detect focal pancreatic disease, especially pancreatic carcinoma and periampullary neoplasms. Sonography often detects pancreatic carcinoma because it is the method of choice to screen patients with jaundice[132] and is frequently used to assess patients with pain. There are few recent US studies of ultrasound in pancreatic carcinoma. Nonetheless, sonography clearly is effective in detecting pancreatic carcinoma,[127,133,134] with a sensitivity of 72% to 98%.[68] **Multidetector computed tomography** (MDCT) has a reported sensitivity of 86% to 97% for all pancreatic tumors.[132] CT is less operator dependent than ultrasound, which, along with CT's higher reimbursement, likely accounts for most radiologists' preference for CT in tumor detection. Sonography may be useful to characterize abnormalities noted on CT, such as determining whether a lesion is cystic or solid. MRI, MRCP, ERCP, and endoscopic ultrasound are all comparably sensitive to CT, but reserved for problem solving or special circumstances.[120]

Ultrasound Findings

From 60% to 70% of pancreatic cancers originate from the pancreatic head, 25% to 35% are in the body and tail, and 3% to 5% are diffuse[110,121] (Fig. 7.64). This distribution explains in part the good detection rates of cancer, because the head and body are more easily seen sonographically than the tail. The hallmark of periampullary pancreatic cancer is the double-duct sign, with both bile duct dilation (Fig. 7.65) and pancreatic duct dilation (Fig. 7.66). Pancreatic ductal adenocarcinoma may cause considerable desmoplastic reaction, so even a mass that appears eccentric can cause ductal obstruction (Fig. 7.67). If a mass in the pancreatic head region is found and there is no ductal dilation, lesions other than pancreatic ductal adenocarcinoma should be sought.

Reviewing findings in 62 patients with pancreatic carcinoma, Yassa et al.[110] found that tumors were ovoid or spherical in 37 patients (60%) and irregular in 25 (40%). Forty tumors (65%) deformed the shape of the gland, whereas six lesions (10%) caused no glandular contour abnormality and were visualized only because tumor echogenicity differed from that of the normal pancreas. Thirty-four tumors (55%) were homogeneously hypoechoic compared with the normal pancreas, 25 (40%) had heterogeneous echotexture (Fig. 7.68), 2 (3%) were homogeneously hyperechoic, and 1 (2%) was isoechoic. Many of the heterogeneous tumors were predominantly hypoechoic with areas of varied echogenicity. **Calcifications** were noted in 4 patients (6%) and **small, intratumoral cystic areas** in 9 patients (15%) (Fig. 7.69, Video 7.7). **Postobstructive pseudocysts** were found in 4 patients (6%) (Fig. 7.70). Such pseudocysts may be caused by obstructive

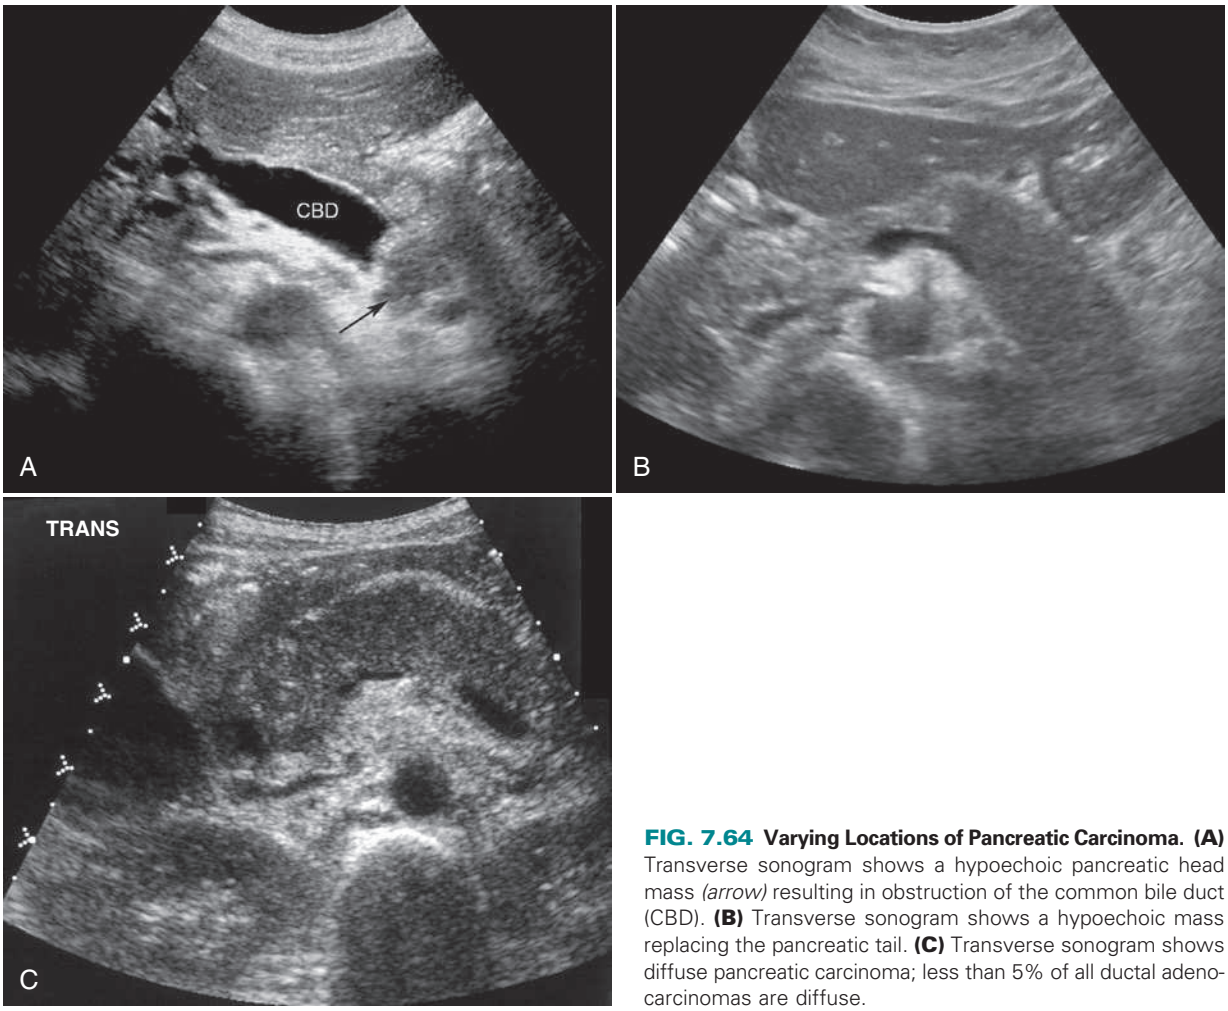

FIG. 7.64 Varying Locations of Pancreatic Carcinoma. (A) Transverse sonogram shows a hypoechoic pancreatic head mass *(arrow)* resulting in obstruction of the common bile duct (CBD). **(B)** Transverse sonogram shows a hypoechoic mass replacing the pancreatic tail. **(C)** Transverse sonogram shows diffuse pancreatic carcinoma; less than 5% of all ductal adenocarcinomas are diffuse.

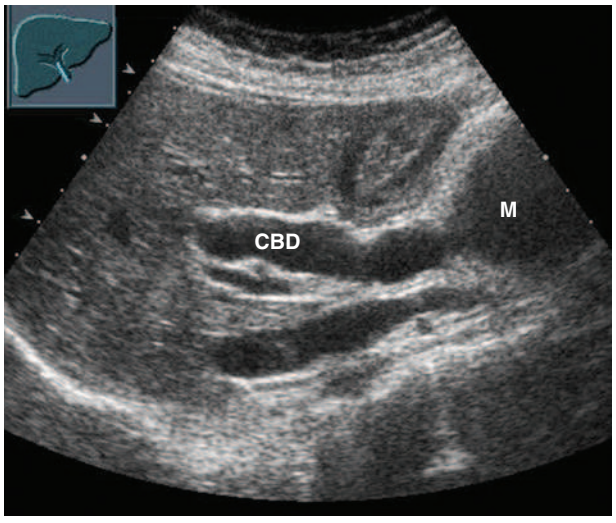

FIG. 7.65 Large Pancreatic Carcinoma. Longitudinal oblique sonogram shows large, hypoechoic mass *(M)* obstructing the extrahepatic common bile duct *(CBD)*.

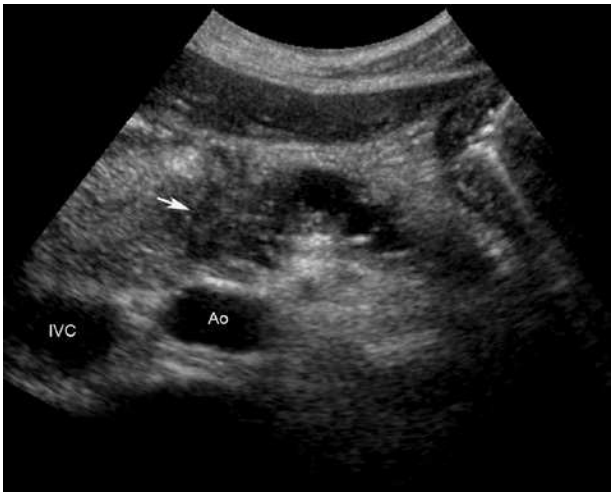

FIG. 7.66 Pancreatic Carcinoma. Transverse sonogram shows hypoechoic mass *(arrow)* obstructing the pancreatic duct. Note the "beaded" pattern of the dilated, obstructed duct. *Ao,* Aorta; *IVC,* inferior vena cava.

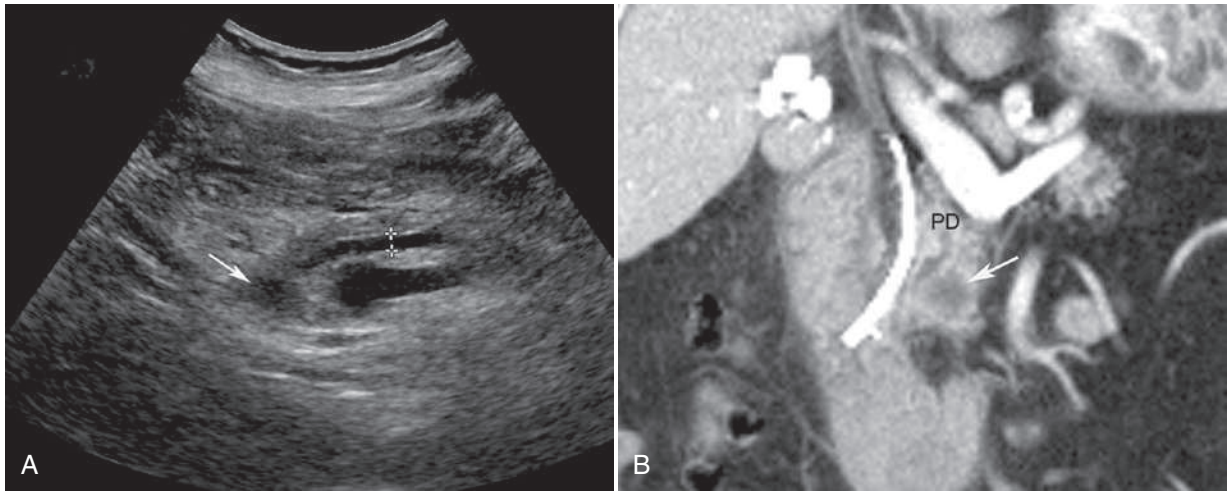

FIG. 7.67 Eccentric Pancreatic Ductal Adenocarcinoma. (A) Transverse sonogram shows that pancreatic carcinoma may cause considerable fibrosis (desmoplastic reaction) and obstruct adjacent ducts. Thus even this uncinate process mass *(arrow),* which appears somewhat distant from the dilated pancreatic duct (calipers) and common bile duct (CBD), can cause ductal obstruction. **(B)** Coronal contrast-enhanced computed tomography confirms that the uncinate process mass *(arrow)* is eccentric to the obstructed pancreatic duct *(PD)*. CBD obstruction has been relieved by stenting.

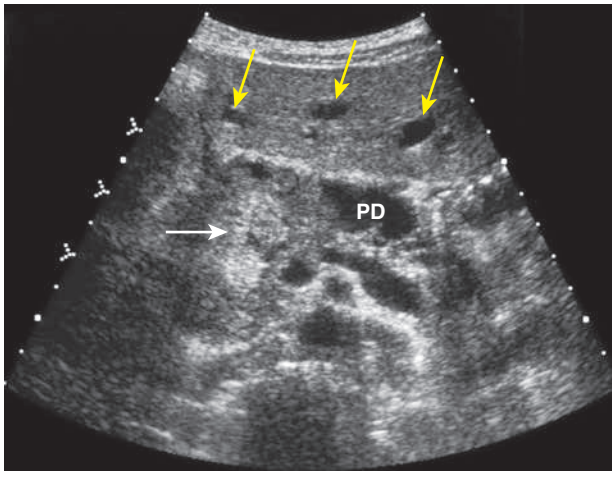

FIG. 7.68 Heterogeneous, Mainly Echogenic Pancreatic Carcinoma. Transverse sonogram shows tumor obstructing the extrahepatic bile duct. Increased echogenicity *(white arrow)* is unusual in pancreatic ductal adenocarcinoma. This heterogeneous cancer causes a double-duct sign with pancreatic duct dilation *(PD)*. The intrahepatic duct dilation is manifest as dilated minor ducts *(yellow arrows)*.

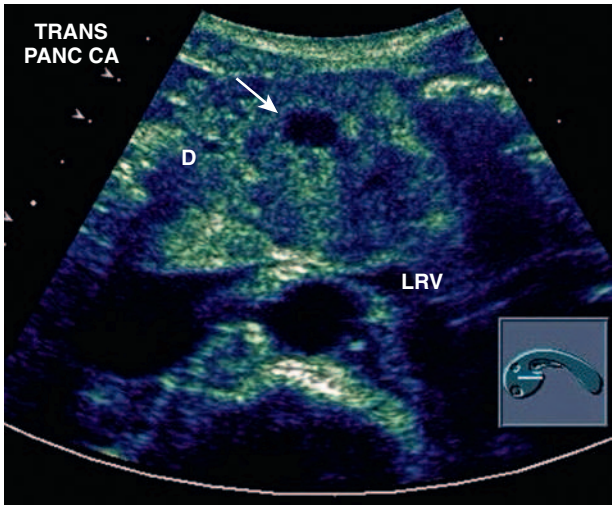

FIG. 7.69 Cystic Area in Pancreatic Ductal Adenocarcinoma. Transverse sonogram shows a complex mass in the pancreatic head. Small, intratumoral cystic areas *(arrow)* are present in about 10% to 15% of pancreatic cancers. These cysts can be seen in chronic pancreatitis as well, rendering this feature unhelpful in differentiating the two conditions. *D,* Duodenum; *LRV,* left renal vein. See also Video 7.7.

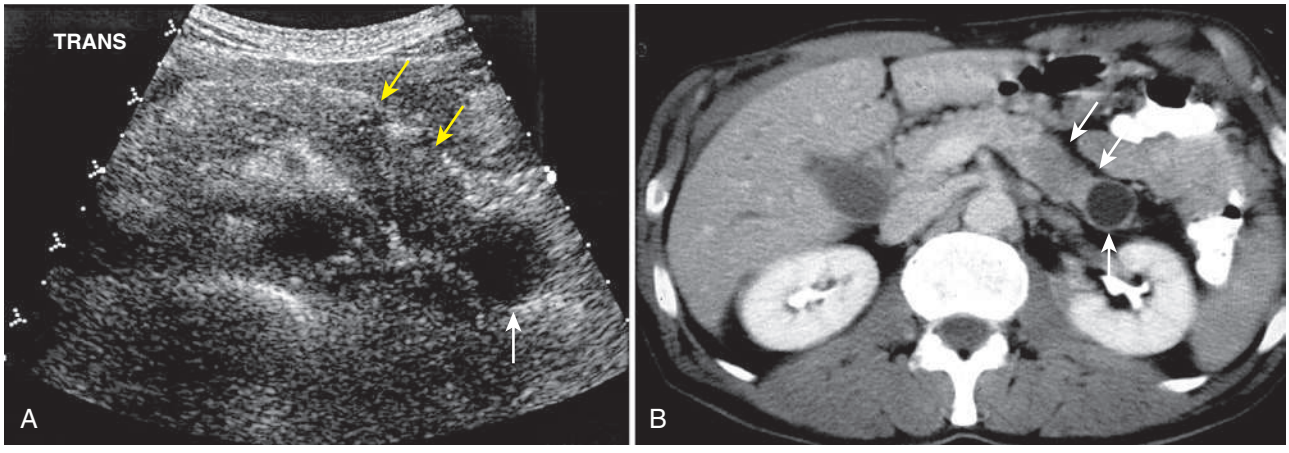

FIG. 7.70 Pancreatic Ductal Adenocarcinoma Causing "Obstructive Pseudocyst." (A) Transverse sonogram reveals a subtle cancer in the body of the pancreas *(yellow arrows)* with a pseudocyst peripheral to the mass *(white arrow)*. **(B)** Computed tomography image at a similar level shows identical findings.

pancreatitis.[135] **Glandular atrophy** may occur from obstruction caused by a tumor. This atrophy is more easily appreciated with CT than ultrasound. It is important to remember that masses caused by chronic pancreatitis can closely simulate periampullary cancers. Very few carcinomas have internal flow that can be imaged on color Doppler.

Resectability Imaging

As the safety of pancreaticoduodenectomy (Whipple procedure) improves, some surgeons have become more aggressive. Also, with advances in surgery, many pancreatic cancers are technically resectable. Unfortunately, the technical ability to resect does not equate to improved outcome (compared to no resection).

Findings that suggest unresectability for cure include tumor larger than 2 cm, extracapsular extension, **vascular invasion** (arterial or venous, although some literature suggests that portal vein resection with jump grafts may have a survival benefit), lymphadenopathy, and metastatic disease. Image findings of unresectability are reliable. Only rarely can such a tumor be resected for cure at surgery. Conversely, many tumors believed resectable because of their imaging appearance are discovered to be unresectable at surgery. Unfortunately, even "resectable" patients with local disease have a 5-year survival rate of only 10%[126] to 20%.[122]

As noted, only a small percentage of patients who have no evidence of advanced disease on initial imaging studies (10%-20%) require sophisticated resectability studies, whether done with transabdominal ultrasound, CT, MRI, positron emission tomography, or endoscopic ultrasound.[136-139] The usefulness of three-dimensional–reconstructed thin-section MDCT evaluation of pancreatic tumors,[140,141] is unmistakable. MDCT has clear advantages over ultrasound for duodenal and retroperitoneal invasion, as well as for detection of malignant lymph nodes. It is unclear, however, how many resectability CT scans would be needed if resectability sonograms were done first. Sonography, especially with color Doppler, can be effective in detecting patients who are unresectable for cure.[134,142-145] Data from Ralls et al. shows a predictive value of 100% for unresectability.[143] In the prediction of resectability, however, 40% of patients thought to be potentially resectable based on color Doppler ultrasound interpretation were found unresectable at surgery. Given these facts, it seems best to use less invasive ultrasound to screen the subgroup of patients needing resectability studies, reserving MDCT for those with no sonographic signs of advanced disease.[146]

Color Doppler Ultrasound

Ralls et al. have developed a technique to assess the resectability of pancreatic tumors using color Doppler sonography.[143] Images are obtained with a large-footprint, curved linear array transducer, using compression technique and color Doppler sonography to evaluate the relationship of the tumor mass to critical vessels, including the main portal vein, SMV (Fig. 7.71), splenic vein, left renal vein, and IVC. Arteries evaluated include the aorta, celiac axis (Fig. 7.72), splenic and common hepatic arteries, and SMA (Fig. 7.73, Video 7.8). Vessels that are touched or occluded by tumor are categorized according to a **pancreatic color Doppler score** (Table 7.3). Other factors affecting resectability (metastasis, enlarged nodes) are recorded.

Color Doppler flow sonography can correctly predict unresectability in 80% or more of pancreatic carcinoma patients. Most of these patients would then require less CT and subsequent imaging evaluation, thus decreasing expense and the need to use more invasive tests. A Polish study found that the diagnostic accuracy of routine, color, and power Doppler and 3-D ultrasound was comparable to that of helical CT in detecting and staging pancreatic carcinoma.[127] The use of ultrasound contrast agents shows some promise to improve the sonographic evaluation of pancreatic tumors,[147] but this is currently an investigational technique.

Pancreatic Cancer Imaging: Suggested Approach

Color Doppler ultrasound should be used to screen patients for resectability of pancreatic cancer.
MDCT or other examinations may then be used in patients with no sonographic evidence of advanced disease.

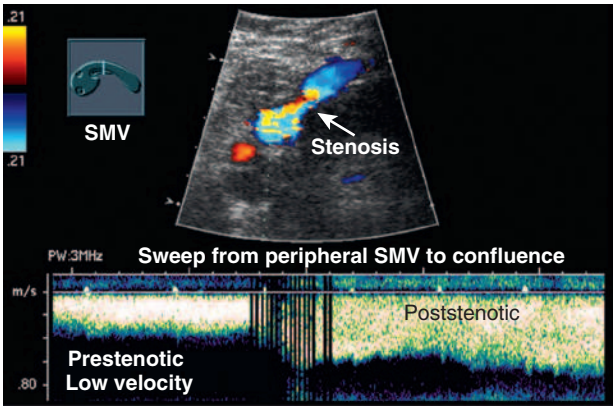

FIG. 7.71 Pancreatic Ductal Adenocarcinoma Narrowing Superior Mesenteric Vein (SMV). Longitudinal oblique spectral Doppler sample volume was swept from the prestenotic lower-velocity region to the poststenotic area (high velocity). Color Doppler image reveals the area of stenosis *(arrow)*.

TABLE 7.3 Pancreatic Color Doppler Score

Score	Description
0	Tumor *does not touch* a vessel.
1	Tumor touches, 1%-24% around the vessel circumference.
2	Tumor touches, 25%-49% around the vessel circumference.
3	Tumor touches, 50%-99% around the vessel circumference.
4	Tumor encased, 100% around the vessel circumference.
5	Vessel invaded or occluded.

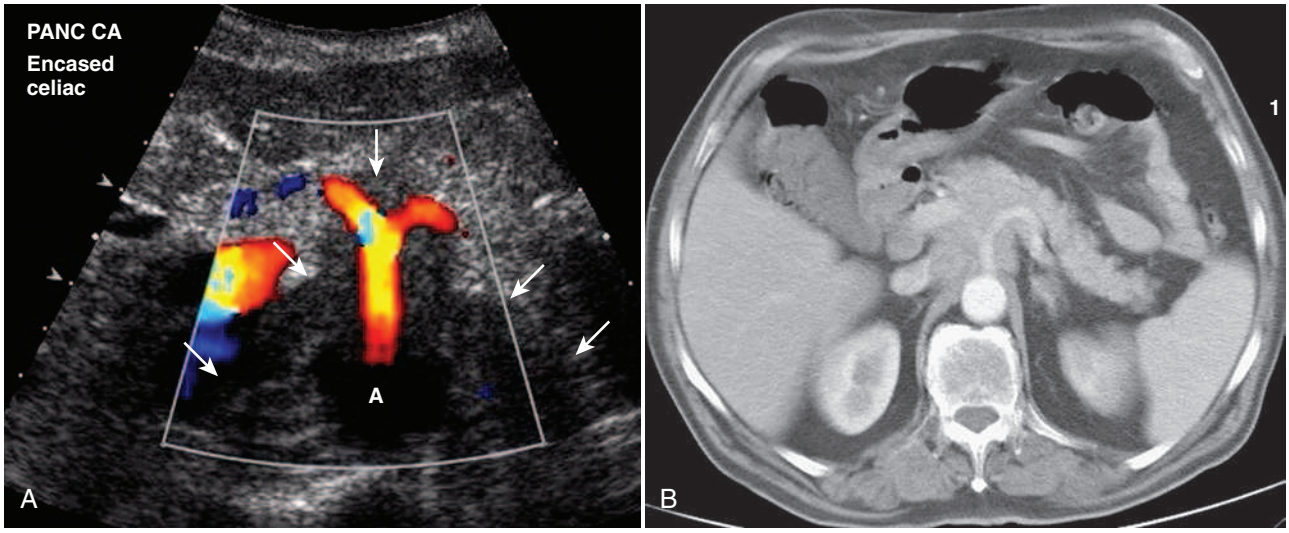

FIG. 7.72 Pancreatic Ductal Adenocarcinoma Encasing Celiac Axis and Aorta. (A) Transverse color Doppler sonogram shows a hypoechoic mass *(arrows)* that encases the aorta *(A)* and celiac axis. **(B)** Computed tomography image at a similar level shows the same findings. This lesion is clearly unresectable for cure.

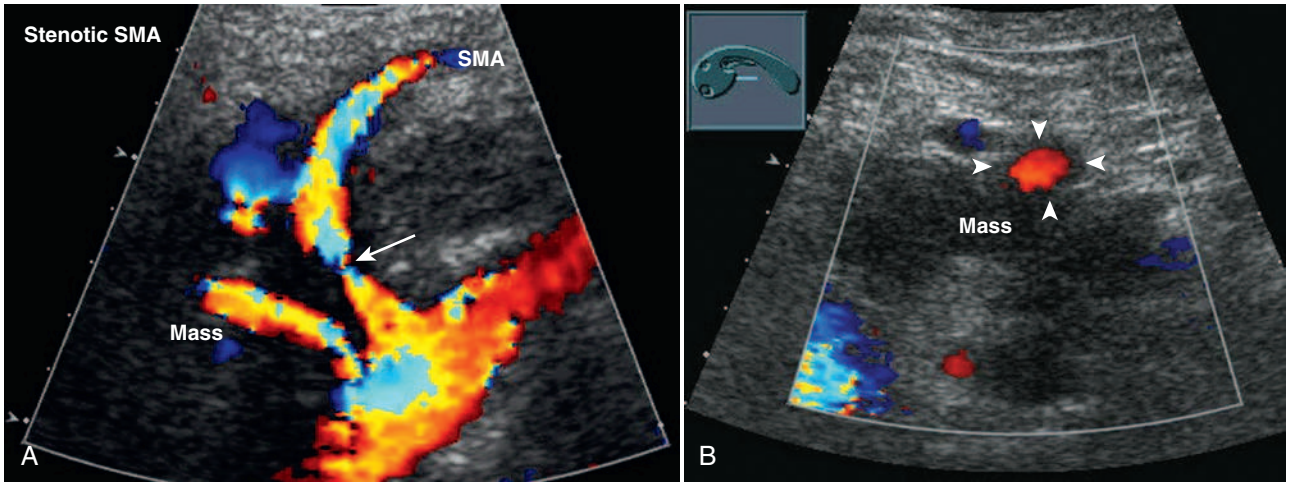

FIG. 7.73 Pancreatic Ductal Adenocarcinoma Encasing Superior Mesenteric Artery (SMA). (A) Longitudinal color Doppler sonogram shows that hypoechoic mass, which also encases the celiac axis, narrows the SMA *(arrow)*. **(B)** Transverse color Doppler sonogram in a different patient demonstrates much more subtle encasement *(arrowheads)*. Ductal adenocarcinoma narrows and occludes veins much more frequently than arteries. This narrowing is equivalent to classic angiographic encasement. See also Video 7.8.

CYSTIC PANCREATIC LESIONS

Understanding cystic pancreatic lesions is increasingly important because improved imaging techniques result in the detection of progressively more of these lesions, often as incidental findings.[72,148,149] New concepts and pathologic definitions of cystic neoplasms, especially mucinous and intraductal papillary forms, have altered the approach to diagnosis and management of these lesions.

Although the number of cystic lesions of the pancreas detected is increasing because of improved imaging techniques,[148,149] pancreatic pseudocyst remains the most common, accounting for 75% or more of all cystic lesions.[72] A careful history must be obtained to rule out previous acute or chronic pancreatitis, so as to minimize the chance of confusing a pseudocyst with other cystic masses. Nonpseudocyst lesions include simple cysts and cystic neoplasms. Although certain image features may be helpful, the differential diagnosis of cystic lesions, especially when small, is unreliable by CT or MRI. Visser et al.[77] found that, even when their diagnostic certainty was 90% or greater, characterization was unreliable.

Fortunately, it appears reasonably safe to follow unilocular pancreatic cystic lesions with a diameter 3 cm or less[72] (Fig. 7.74). Sahani et al.[150] reported that 35 of 36 unilocular pancreatic cystic lesions 3 cm or less were benign. Internal septations were associated with borderline or in situ malignancy in 10 of 50 cases (20%). Other surgeons believe that resection of these lesions is a better approach.[73,151] The usefulness of tumor markers and cyst fluid cytology is debated.[73,152-154] Most agree that high-risk patients and features should be managed more aggressively,

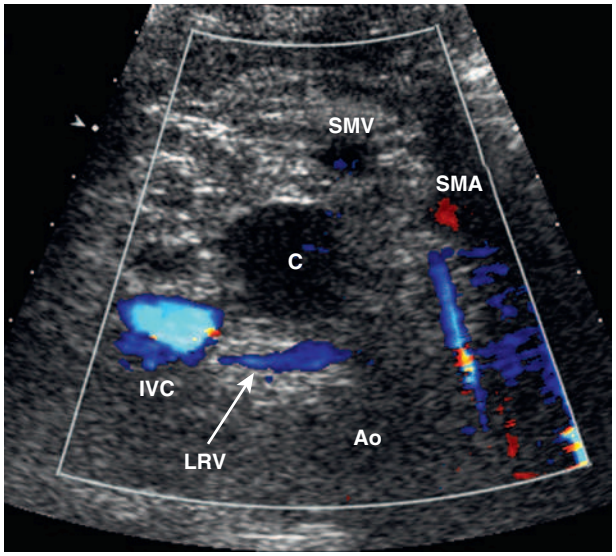

FIG. 7.74 Benign Pancreatic Cyst (Presumed). Transverse color Doppler sonogram shows 2-cm cyst discovered incidentally on abdominal sonogram and followed for 4 years without a change in size. It is generally safe to follow small completely simple pancreatic cysts (please see text). *Ao,* Aorta; *C,* cyst; *IVC,* inferior vena cava; *LRV,* left renal vein; *SMA,* superior mesenteric artery; *SMV,* superior mesenteric vein.

High-Risk Features of Cystic Pancreatic Lesions

Symptomatic patients
Growth on serial examinations
Diameter > 3 cm
Internal soft tissue
Mural or septal thickening

including symptomatic patients, growth of the cyst on serial studies, tumor greater than 3 cm in diameter, internal soft tissue, and mural or septal thickening. Multiple societies have proposed algorithms to follow incidentally detected pancreatic cysts,[155] but there is a great deal of uncertainty in this process,[156,157] and future assessment may rely on novel tumor markers and molecular analysis rather than cross-sectional imaging morphology.[158] Data from 2015 suggest that pancreatic cysts found incidentally by using CT or MRI may be associated with increased mortality for patients younger than 65 years and an overall increased risk of pancreatic adenocarcinoma.[159]

Simple Pancreatic Cysts

Simple pancreatic cysts are rare in the general population, with a prevalence of 0.2%[160] to 1.2%.[151] These low percentages may underestimate true prevalence because imaging[161] and autopsy[162] studies have recorded a substantially higher prevalence, about 20% and 24.3%, respectively. Our experience suggests that the lower prevalence rates are closer to the actual experience in clinical imaging. Detecting a simple pancreatic cyst should raise suspicion of an inherited disease that has a high prevalence of cysts, such as **autosomal dominant polycystic kidney disease** (ADPKD)[163] or **von Hippel–Lindau** (VHL) **disease.**[164] Multiple pancreatic cysts can also occur in individuals with **cystic fibrosis.**[165]

Multiple pancreatic cysts are more common in VHL disease than in ADPKD. Prevalence of pancreatic cysts in patients with VHL ranges from 50% to 90%, making pancreatic cysts the most common type of lesion in VHL disease.[164] Thus multiple simple pancreatic cysts should suggest the diagnosis of VHL (Fig. 7.75). In addition to simple cysts, other pancreatic lesions associated with VHL include serous cystic neoplasm and pancreatic endocrine tumors, with a slightly increased risk of ductal adenocarcinoma.[164]

TABLE 7.4 Estimated Prevalence of Cystic Pancreatic Lesions[a]

Rank	Neoplasm
1	Intraductal papillary mucinous neoplasm
2	Serous cystic neoplasm (microcystic adenoma)
3	Mucinous cystic neoplasm
4	Solid-pseudopapillary tumor
5	Other cystic tumors

[a]Subjective estimate based on the authors' experience.

Cystic Neoplasms

Cystic tumors of the pancreas account for about 10% of cystic pancreatic lesions. Although most solid tumors are ductal adenocarcinomas with a poor prognosis, cystic tumors are usually either benign lesions or low-grade malignancies. Malignant cystic tumors account for about 1% of all pancreatic malignancies.[73] Mucinous tumors such as intraductal papillary mucinous neoplasm and mucinous cystic neoplasm are often malignant. The risk of malignancy is greater in older individuals. Reliable prevalence data are difficult to find[166] but are estimated in Table 7.4.

Serous Cystic Neoplasm

Serous cystic neoplasm, previously known as **microcystic adenoma,** is typically a benign tumor, although a few invasive, malignant examples have been reported.[73,166] Serous cystic neoplasm occurs more frequently in women and is most often found in the pancreatic head.[154] These lesions are composed of myriad tiny cysts, generally too small to be individually resolved sonographically (Fig. 7.76). The multiple reflective interfaces caused by the walls of the tiny cysts leads to an echogenic appearance, analogous to that of autosomal recessive polycystic kidney disease. Through transmission is usual. Larger cysts (1-3 cm in diameter) often are present at the periphery of the lesion. A radially oriented, fibrous pattern occurs in a minority of patients,[149] and a central calcification is often present (30%-50%) (Fig. 7.77). Small lesions (<2 cm) may appear identical to simple cysts. This pattern is common in the **serous oligocystic adenoma** variant.[154]

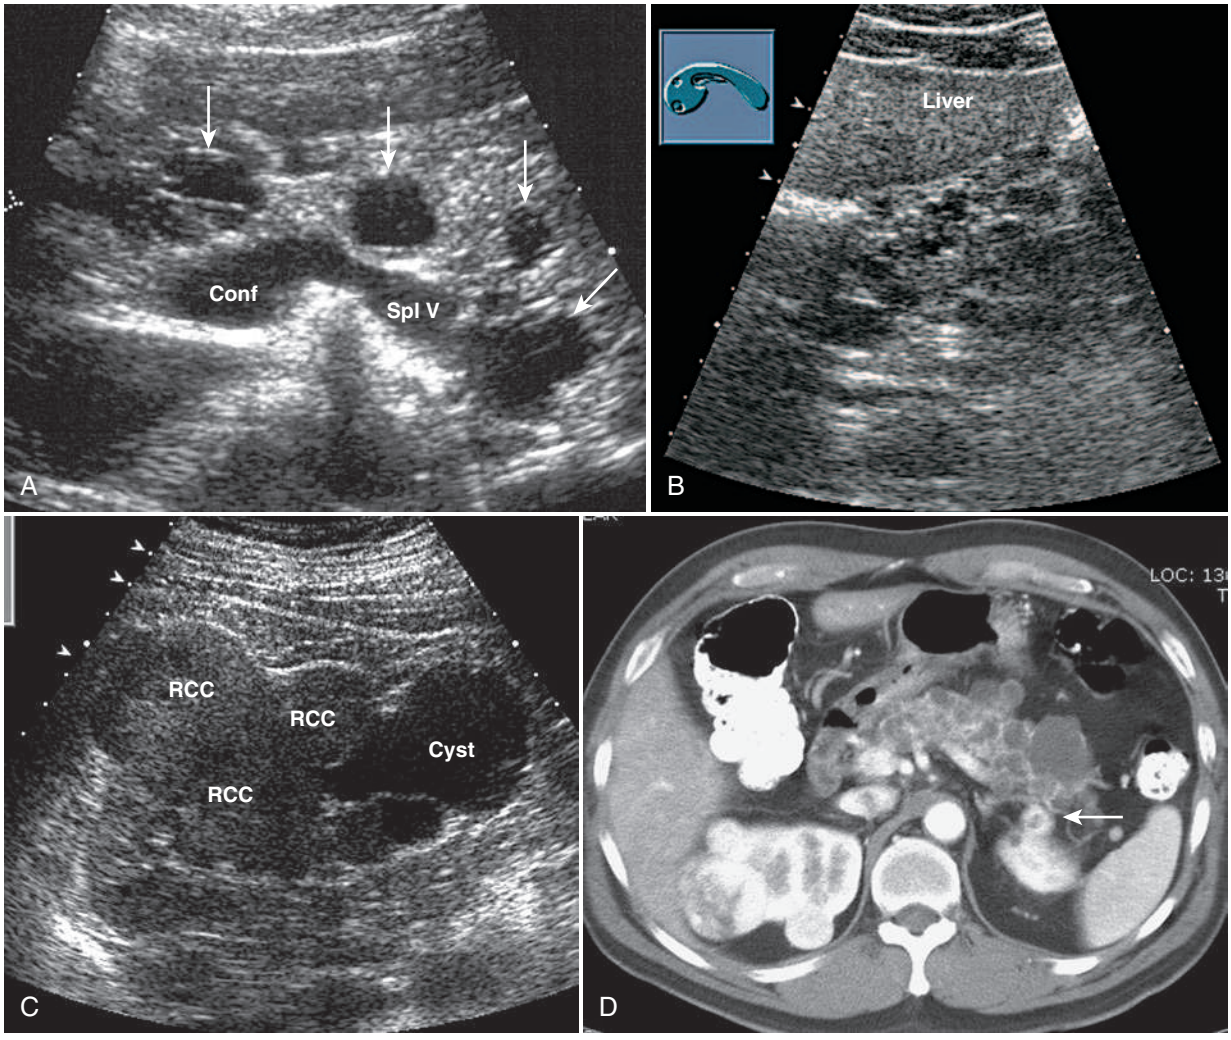

FIG. 7.75 Von Hippel–Lindau (VHL) Disease With Multiple Pancreatic Cysts. (A) Transverse sonogram shows multiple simple pancreatic cysts *(arrows).* **(B)-(D)** Another patient. **(B)** Transverse sonogram of pancreas shows multiple pancreatic cysts, suggesting the diagnosis of von Hippel–Lindau disease. **(C)** Longitudinal sonogram of the right kidney shows associated VHL lesions: multiple renal cell carcinomas *(RCC)* and a large renal cyst. **(D)** Computed tomography image at a similar level shows myriad pancreatic cysts and some of the right-sided RCCs. A small, left-sided RCC is noted *(arrow). Conf,* Confluence; *Spl V,* splenic vein.

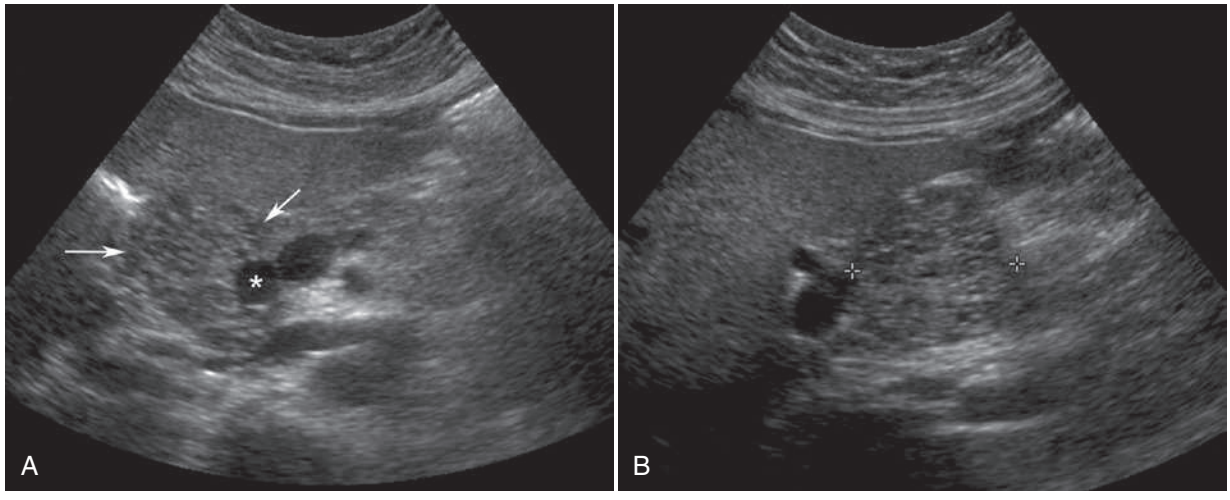

FIG. 7.76 Serous Cystic Neoplasm. (A) Transverse sonogram shows classic serous cystic neoplasm findings, with many tiny cysts resulting in an echogenic and nearly solid appearance *(arrows);* a larger cystic component is seen at the periphery of the lesion (*). Note lack of pancreatic duct dilation. **(B)** Sagittal sonogram shows classic serous cystic neoplasm findings, including many tiny cysts. No normal pancreas is shown.

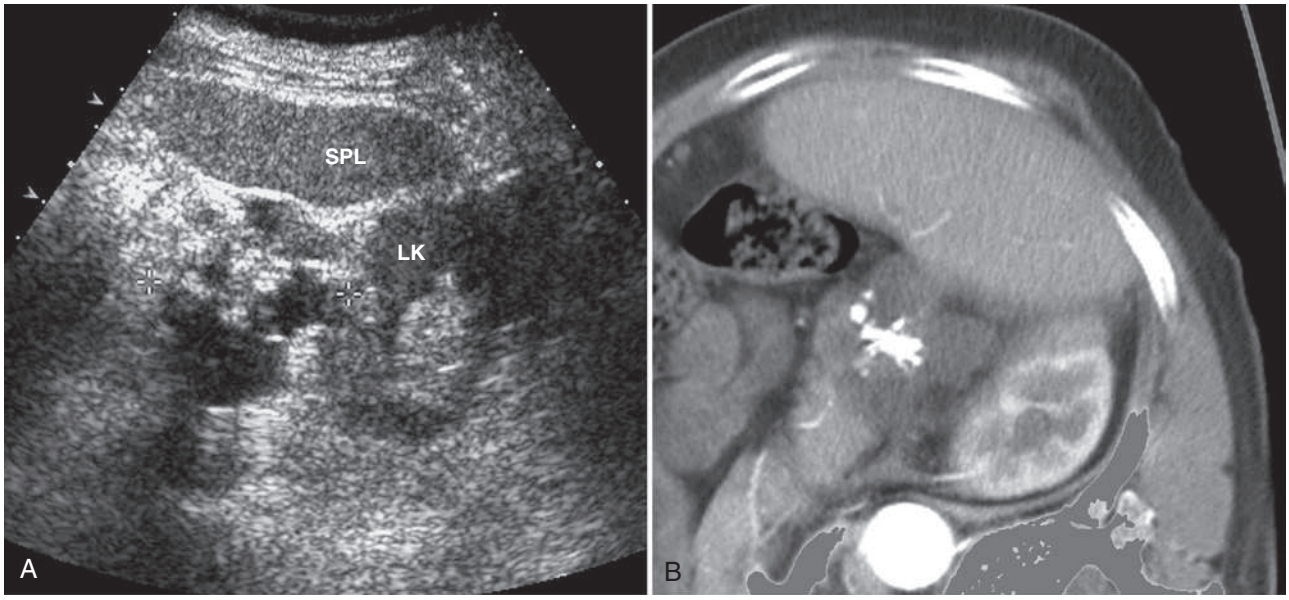

FIG. 7.77 Serous Cystic Neoplasm. (A) Transverse sonogram shows lesion through the spleen *(SPL)* and left kidney *(LK)*. Calcifications and some larger peripheral cysts are noted. **(B)** Computed tomography image, rotated and cropped to match the ultrasound image, shows the dense calcifications.

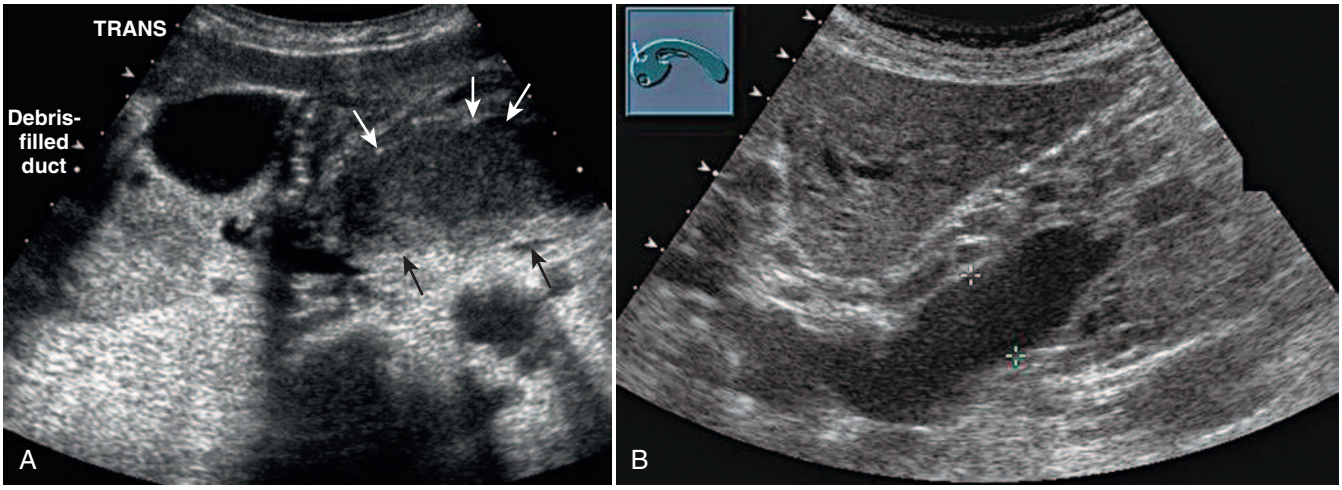

FIG. 7.78 Intraductal Papillary Mucinous Neoplasm (IPMN). (A) Transverse sonogram shows massively dilated main pancreatic duct *(white and black arrows)* filled with mucin, characteristic of main duct IPMN. **(B)** Another patient in whom a longitudinal oblique sonogram shows IPMN causing massive bile duct obstruction. Both benign and malignant IPMNs can cause bile duct obstruction. See also Video 7.9.

Intraductal Papillary Mucinous Neoplasm

Intraductal papillary mucinous neoplasm (IPMN) was unreported before 1982[167]; other names include **intraductal papillary mucinous tumor, intraductal mucin-hypersecreting neoplasm,** and **ductectatic mucinous neoplasm.**[154] Unlike mucinous cystic neoplasm, IMPN arises from the pancreatic ducts, usually in the head of the pancreas. IMPN occurs in an older population than mucinous cystic neoplasm and affects men and women equally.

Mucin is secreted into the ducts, causing prominent dilation (Fig. 7.78, Video 7.9) and sometimes mucin extrusion from the ampulla of Vater.[166] IPMN often presents as acute pancreatitis. Both benign and malignant lesions can cause bile duct obstruction[168] (Fig. 7.79). IPMN ranges from a benign to an overtly malignant lesion. Invasive adenocarcinoma is seen in approximately 30% of resected cases. Invasive or in situ carcinomas are likely present in about 70% of patients.[149] The overall 5-year survival rate for patients with a resected IPMN is higher than 70%.[166] Controversy surrounds the evolving management of these patients. Some believe that asymptomatic patients or those with lesions of branch duct origin can be observed or treated with segmental pancreatectomy.[169]

The hallmark of IPMN on ultrasound is **ductal dilation** (Fig. 7.80; see also Fig. 7.78). Findings include lobulated multicystic dilation of the branch ducts, diffuse dilation of the main pancreatic duct, and intraductal papillary tumors.[170] Because mucin has a

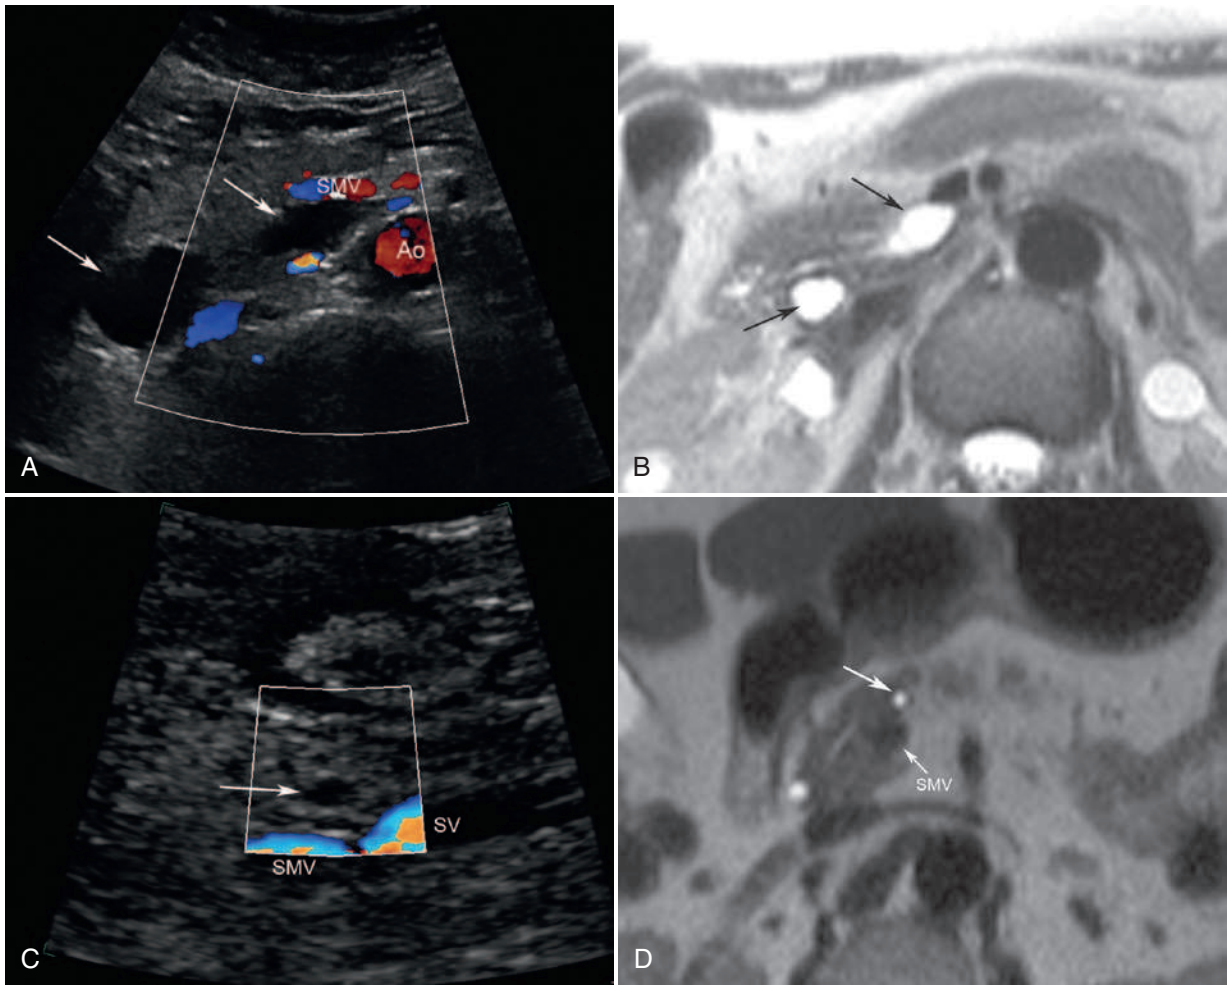

FIG. 7.79 Side Branch Intraductal Papillary Mucinous Neoplasm (IPMN). (A) Transverse image of pancreatic head and neck shows two cystic lesions *(arrows)* corresponding to side branch IPMN. **(B)** Transverse T2-weighted single-shot fast spin echo (SSFSE) magnetic resonance (MR) image of side branch IPMN lesions *(arrows)* shown in **(A)**. **(C)** In another patient, transverse sonographic image depicts a smaller side branch IPMN *(arrow)* in pancreatic body. **(D)** Corresponding axial T2-weighted SSFSE MR image shows same IPMN *(arrow). Ao,* Aorta; *SMV,* superior mesenteric vein; *SV,* splenic vein.

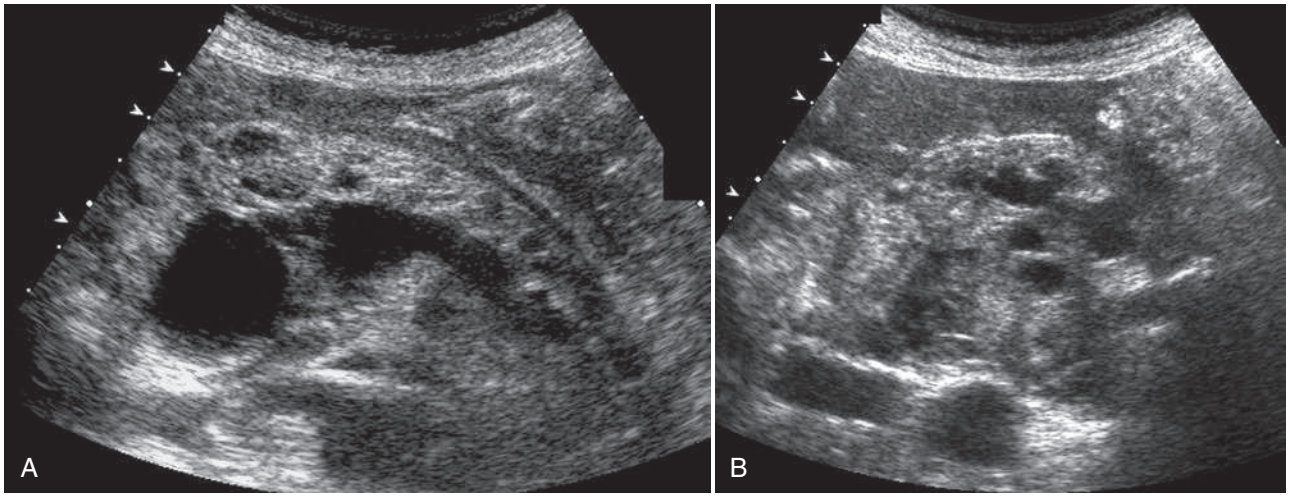

FIG. 7.80 Intraductal Papillary Mucinous Neoplasm (IPMN). IPMN with main and branch duct involvement. **(A)** Transverse sonogram shows lobulated dilation of the branch ducts and diffuse dilation of the main pancreatic duct. **(B)** Transverse sonogram of pancreatic head and proximal body shows dilation of branch ducts in the enlarged head.

sonographic appearance that may be similar to debris or sludge, the degree and extent of ductal dilation may be more difficult to appreciate on ultrasound than on CT or MRI. Calcification is rare.

Mucinous Cystic Neoplasm

Mucinous cystic neoplasms arise as de novo cystic tumors, unlike IPMNs, which arise from the pancreatic ducts. Mucinous cystic neoplasms occur most often in the pancreatic body or tail but may occur anywhere in the gland.[169] They may be unilocular and simulate a simple cyst but generally have up to six internal loculations. Internal septations may be thin or thick, and may be papillary; internal debris is common (Fig. 7.81, Video 7.10). Calcifications, usually linear and peripheral, occur in about 15% to 20% of lesions. Mucinous cystic neoplasm is found in perimenopausal women as thick-walled multilocular cystic masses, usually in the tail of the pancreas.[166]

Mucinous cystic neoplasm is the lesion most likely to be confused with pseudocyst because of their similar appearance in some cases. Mucinous cystic neoplasm shares histologic and prognostic similarities with mucinous ovarian cystic tumors. Because of the newer pathologic definition that requires the

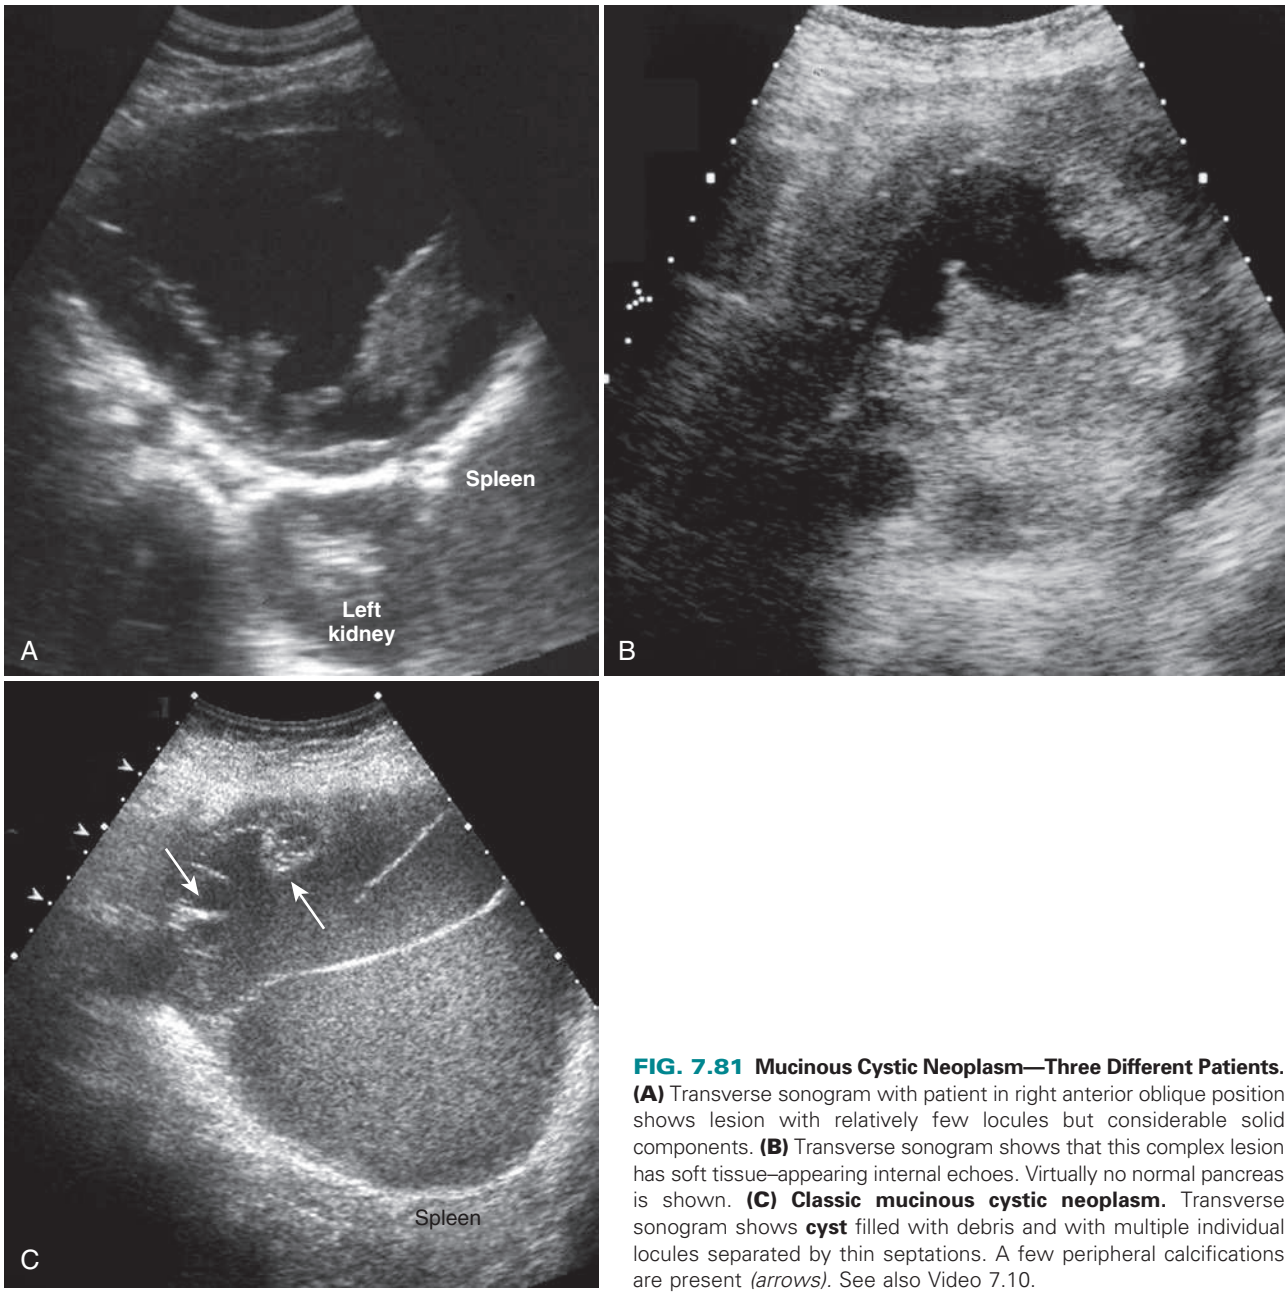

FIG. 7.81 Mucinous Cystic Neoplasm—Three Different Patients. **(A)** Transverse sonogram with patient in right anterior oblique position shows lesion with relatively few locules but considerable solid components. **(B)** Transverse sonogram shows that this complex lesion has soft tissue–appearing internal echoes. Virtually no normal pancreas is shown. **(C) Classic mucinous cystic neoplasm.** Transverse sonogram shows **cyst** filled with debris and with multiple individual locules separated by thin septations. A few peripheral calcifications are present *(arrows)*. See also Video 7.10.

presence of ovarian stroma in mucinous cystic neoplasm, these tumors are now rarely diagnosed in men.[166,171] Mucinous tumors, previously classified as mucinous cystic neoplasms in men, would likely now be considered IPMNs. Mucinous cystic neoplasms may be benign, may have "low malignant potential," or may be overtly malignant. Thus these tumors are generally managed as malignant lesions.

Solid-Pseudopapillary Tumor

Solid-pseudopapillary tumor is the most recent name advocated by the World Health Organization[172,173] and is found most frequently in young female patients. Previous names include **solid and cystic tumor, solid and papillary epithelial neoplasm, papillary-cystic neoplasm, papillary cystic epithelial neoplasm, papillary cystic tumor,** and **Frantz tumor.** About 15% of solid-pseudopapillary tumors are malignant. The likelihood of malignancy increases with patient age.[154] Resection is generally curative.

Solid-pseudopapillary tumors occur most often in the tail of the pancreas. They are usually round, encapsulated masses[174] with variable amounts of necrotic, cystic-appearing areas and soft tissue foci (Fig. 7.82). The cavities in solid-pseudopapillary tumors are not "true" cysts but rather necrotic regions containing blood and debris.[166] Central and rim calcifications have been reported in 29% of patients.[154] Buetow et al.[175] described 31 cases studied with ultrasound, CT, and MRI and noted variable echotexture; anechoic and hypoechoic areas were seen centrally. Through transmission was seen in all cases in which internal cystic areas were grossly depicted, regardless of the echotexture.

FIG. 7.82 Large Solid-Pseudopapillary Tumor. Transverse sonogram shows a large lesion in the pancreatic tail, the most common location for these tumors.

Rare Cystic Pancreatic Tumors

Acinar cell cystadenocarcinoma
Cystic choriocarcinoma
Cystic lymphangioma
Cystic teratoma
Cystic pancreatic endocrine tumor
Metastases

Rare Cystic Tumors

Virtually any imaginable histology has been reported as a "necrotic" or "cystic" lesion of the pancreas.[165,176-178] In general, there is no characteristic ultrasound appearance for these rare tumors.

OTHER PANCREATIC MASSES

Endocrine Tumors

Pancreatic endocrine tumors are a small but important group of pancreatic neoplasms, previously called **islet cell tumors** or **neuroendocrine tumors;** the current suggested terminology is **gastroenteropancreatic neuroendocrine tumors (GEP-NETs).**[179] Formerly thought to arise from pancreatic islets, these tumors are now believed to originate from neuroendocrine stem cells in the duct epithelium.[180] These tumors are rare, with an annual incidence of approximately 5 cases per million.[181] Pancreatic endocrine tumors constitute 1% to 5% of pancreatic neoplasms.[182] The two different presentations depend on whether there is endocrine hyperfunction.[183] **Hyperfunctioning** lesions, about 90% of pancreatic endocrine tumors tend to present clinically when the tumor is small. The endocrine manifestations cause clinical symptoms before the tumor grows enough to cause problems because of its size, invasion, or metastasis.

Insulinomas and **gastrinomas** are the most common hyperfunctioning pancreatic endocrine tumors (about 80% of all pancreatic endocrine tumors); others are rare (Table 7.5).

Hyperfunctioning pancreatic endocrine tumors tend to be small, 1- to 3-cm (see Fig. 7.83), round or oval, hypoechoic masses with smooth margins and, with the exception of insulinoma, malignant. When a hyperfunctioning pancreatic endocrine tumor is suspected, preoperative localization is appropriate. Choice of modality depends on institutional preference and includes transabdominal ultrasound, CT, or endoscopic ultrasound.[184] MDCT is superior to sonography in detecting small endocrine tumors,[185] but sometimes ultrasound shows lesions that are occult on CT. It is difficult to image pancreatic endocrine tumors with conventional transabdominal sonography; they are usually small when the patient presents with hormonal abnormalities. Sensitivity of detection with ultrasound varies. Detection rates for insulinomas range from 9%[186] to 65%.[184] The sensitivity of ultrasound in the detection of gastrinoma is only 20% to 30%.[187] Sonographically, most **hyperfunctioning** pancreatic endocrine tumors are small. Serotonin-secreting pancreatic endocrine tumors may be associated with marked dilation of the pancreatic duct.[188,189] Intraoperative sonography is the most sensitive and accurate means of evaluating these neoplasms[184] (Fig. 7.83).

Nonhyperfunctioning tumors cause no endocrine-related symptoms. Therefore these tumors must be larger to present

TABLE 7.5 Pancreatic Endocrine Tumors (PETs)

Tumor Type	Located in Pancreas	Size	All PETs
	Hyperfunctioning		
Insulinoma	90%-100%	2-3 cm	45%

All tumors		>5 cm	10%

VIP, Vasoactive intestinal polypeptide.

FIG. 7.83 Insulinoma on Intraoperative Ultrasound. This 10-mm lesion was discovered because of hyperinsulinism. (Courtesy of Dr. Hisham Tchelepi.)

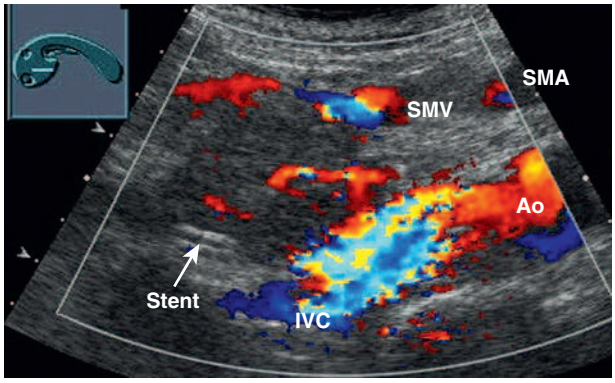

FIG. 7.84 Pancreatic Endocrine Tumor, Nonhyperfunctioning. Longitudinal oblique color Doppler sonogram shows 5-cm, hypoechoic malignant tumor large enough to cause bile duct obstruction, requiring stenting. Internal color flow is typical with pancreatic endocrine tumors. *Ao,* Aorta; *IVC,* interior vena cava; *SMA,* superior mesenteric artery; *SMV,* superior mesenteric vein.

clinically—because of pain,[185] mass effect, or, if malignant, invasion and metastasis[119] (Fig. 7.84). Incidental detection of smaller, nonhyperfunctioning tumors is becoming more frequent (Fig. 7.85). These tumors are usually well defined and round or oval. They generally appear hypoechoic compared to the normal parenchyma. These tumors may have cystic changes and calcification.[187] The larger, nonhyperfunctioning pancreatic endocrine tumors may be difficult to differentiate from the more common pancreatic ductal adenocarcinoma. Sonographic findings that suggest the diagnosis are (1) prominent internal color flow (rare in carcinoma), (2) lack of biliary or pancreatic ductal dilation in a pancreatic head lesion, and (3) lack of progression or metastasis on serial imaging.

Unusual and Rare Neoplasms

On ultrasound, many histologic variants of pancreatic ductal adenocarcinoma are indistinguishable from tumors with the usual histologic features. These include **adenosquamous cell carcinoma, anaplastic carcinoma,** and **pleomorphic giant cell carcinoma. Acinar cell carcinoma** and pleomorphic giant cell carcinoma, although often indistinguishable from ductal adenocarcinoma, may be larger and may exhibit central necrosis. Primary **pancreatic lymphoma** is prohibitively rare, although adenopathy or diffuse involvement from more generalized disease occurs with some frequency.[120] Other rare pancreatic tumors include connective tissue–origin tumors (sarcomas), **pancreaticoblastomas, dysontogenetic cysts,** and metastases.[190,191]

Lipoma

In contrast to the usual echogenic appearance of fat and fatty lesions, pancreatic lipomas are usually **hypoechoic**[192,193] (Fig. 7.86). Other lipomas may have a mixed appearance, with a variable amount of internal echoes, or they may appear hyperechoic. The cause of hypoechoic fat is not known but may involve the number

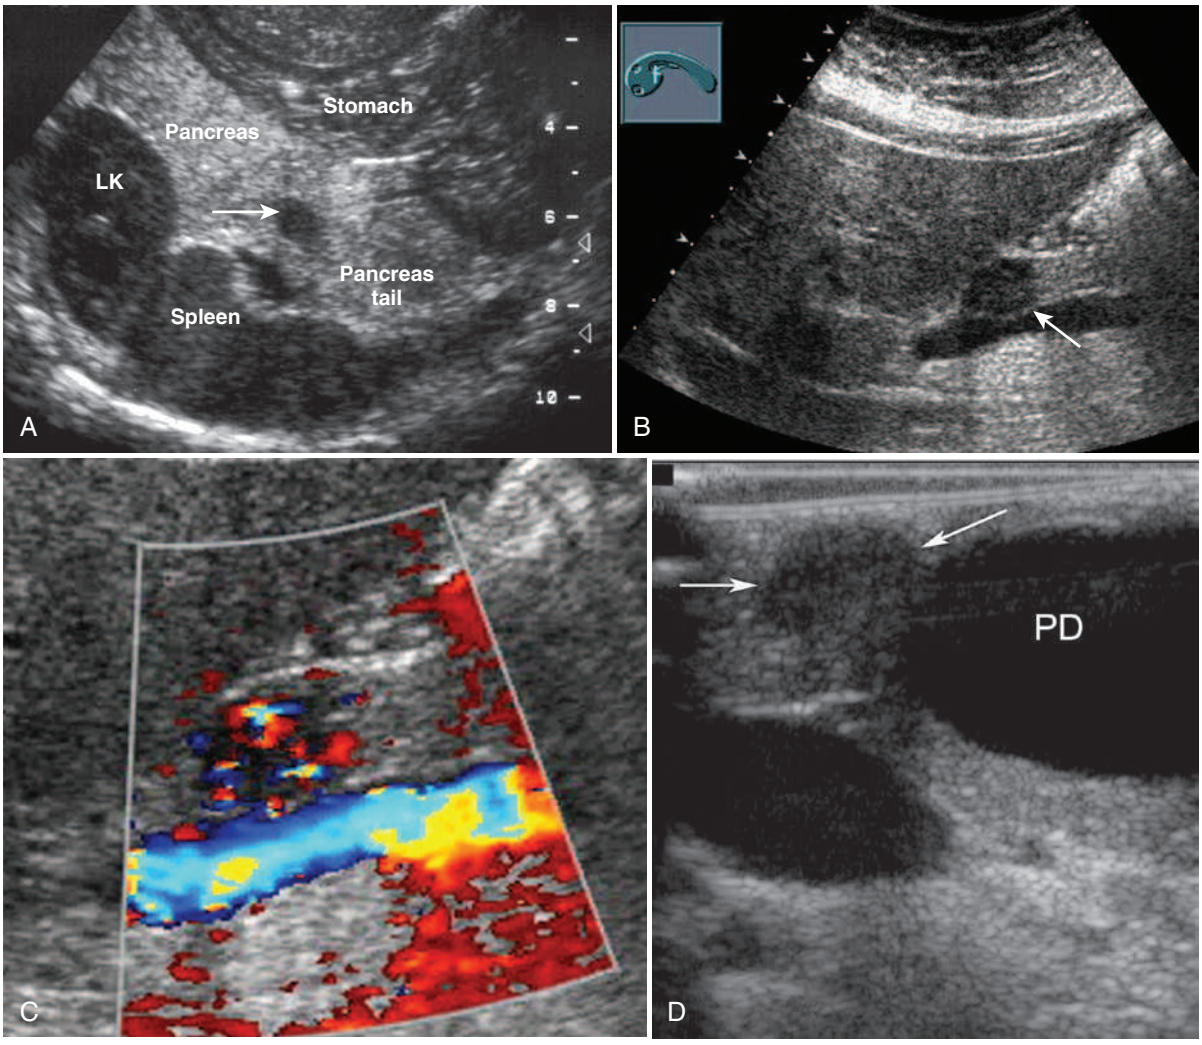

FIG. 7.85 Small, Nonhyperfunctioning Pancreatic Endocrine Tumors. (A) Transverse sonogram shows 9-mm hypoechoic nonhyperfunctioning pancreatic endocrine tumor *(arrow)* discovered incidentally during an abdominal ultrasound. The pancreatic tail was removed. **(B)** and **(C)** In another patient, gray-scale **(B)** and color Doppler **(C)** sonograms show 2-cm hypervascular pancreatic endocrine tumor indenting the superior mesenteric artery *(arrow).* **(D)** In another patient, **intraoperative ultrasound shows a** 9-mm lesion *(arrows)* that was discovered incidentally. Marked dilation of the pancreatic duct is noted and can be a hallmark of serotonin-secreting pancreatic endocrine tumors. Intraoperative ultrasound is considered essential in many institutions for the surgical management of pancreatic endocrine tumors. *PD,* Pancreatic duct.

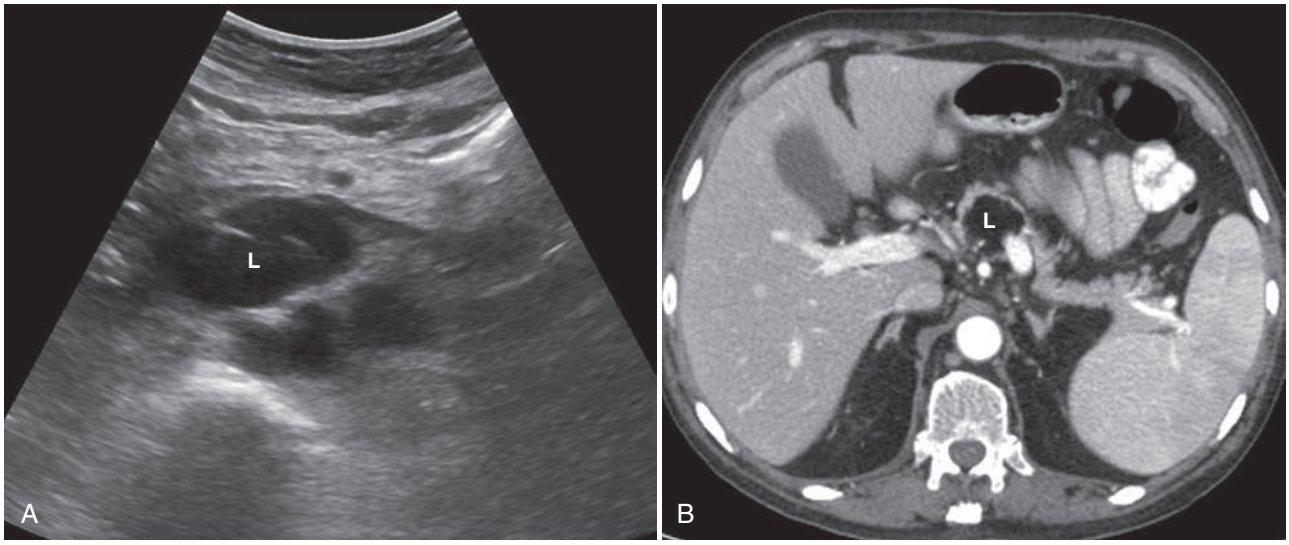

FIG. 7.86 Pancreatic Lipoma. (A) Transverse sonogram of almost anechoic pancreatic lipoma *(L).* In contrast to the usual echogenic appearance of fat and fatty lesions, pancreatic lipomas are usually hypoechoic. **(B)** Computed tomography image confirms the fatty nature of the lesion. (Courtesy of Dr. Vinay Duddlewar.)

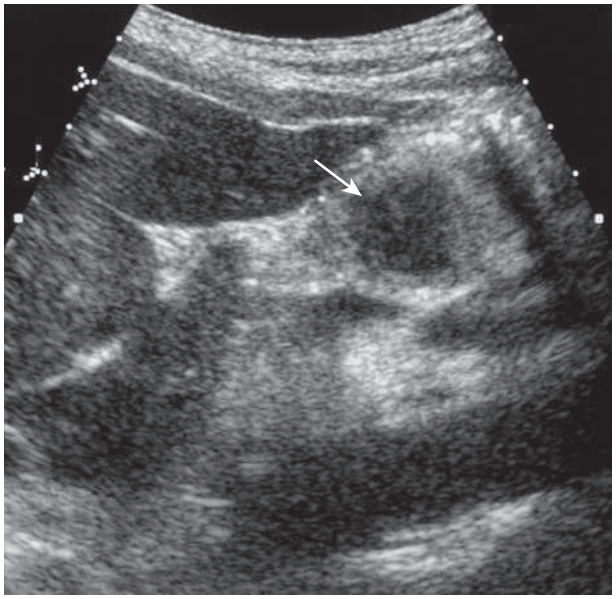

FIG. 7.87 Lung Carcinoma Metastasis to Pancreas. Longitudinal sonogram shows typical hypoechoic metastasis *(arrow)*. Pancreatic metastases are the most common pancreatic neoplasm in autopsy series but are rarely found clinically because they generally occur late with widespread metastatic disease.

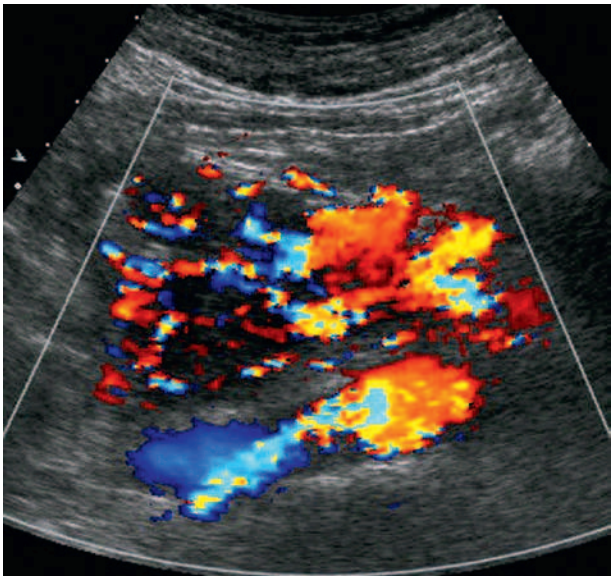

FIG. 7.88 Renal Cell Carcinoma Metastasis to Pancreas. Longitudinal color Doppler sonogram shows hypervascular metastasis. Differentiation from a hypervascular pancreatic endocrine tumor may be difficult in these cases.

of blood vessels, amount and thickness of connective tissue stroma, number of fibrous septae that separate fat lobules, and amount of water content in the fat.[192,194]

Metastatic Tumors

In autopsy series, metastasis is the most common pancreatic neoplasm, found about four times as often as pancreatic cancer.[191] Clinical discovery of metastasis was rare until the advent of modern imaging.[195] Pancreatic metastases are rarely clinically significant because they generally occur late in patients with widespread metastatic disease. Primary tumors that most often metastasize to the pancreas include **renal cell carcinoma, breast carcinoma, lung carcinoma** (Fig. 7.87), **melanoma, colon carcinoma,** and **stomach carcinoma.**[120,191,195]

With metastasis to the pancreas, there may be a long interval between initial diagnosis of the primary lesion and discovery of the metastasis. This is especially true of renal cell carcinoma and, to a lesser degree, melanoma. Klein et al.[195] found that the mean delay between discovery of the primary renal cell carcinoma and metastasis was 10 years; the longest interval was more than 24 years. A classic scenario is the discovery of a hypervascular mass (or masses) in the pancreas of a patient who had a remote, presumably cured renal cell carcinoma (Fig. 7.88). Differential diagnosis from a hypervascular pancreatic endocrine tumor may be difficult in such cases.

CONTRAST-ENHANCED ULTRASOUND

Contrast-enhanced ultrasound (CEUS) shows promise as a technique that will be beneficial in both endoscopic ultrasound and transabdominal ultrasound of the pancreas. Historically, CEUS was best considered an experimental technique.[98,196] However, more recent data suggest that CEUS may become much more routine.[197-199] Fan states, "CEUS has obvious superiority over conventional US in the general diagnostic accuracy of solid pancreatic lesions and in the diagnostic consistency among doctors. The performances of CEUS are similar to that of CECT in the diagnosis of pancreatic carcinoma and focal pancreatitis."[200] CEUS might be helpful in diagnosing pancreatic necrosis in patients with severe acute pancreatitis.[147]

Acknowledgment

The authors would like to acknowledge Dr. Philip Ralls, the prior author of this chapter. His supreme dedication and passion for quality ultrasound practice and education in all areas was exemplary, and his images and text form the backbone of this updated version.

CHAPTER 8

The Gastrointestinal Tract

Stephanie R. Wilson

SUMMARY OF KEY POINTS

- High-resolution ultrasound allows for excellent depiction of the bowel, including the normal multilayered appearance of the bowel wall and many pathologic features.
- Ultrasound is a safe, objective, and accurate method for measuring the severity of inflammatory activity in inflammatory bowel disease, an essential requirement considering the young population most often affected by this chronic and often debilitating disease.
- Contrast-enhanced ultrasound is an objective biomarker that may accurately evaluate disease activity in those with bowel wall inflammation.
- Elastography measures bowel wall stiffness, increasing in those with chronic disease, helping to differentiate patients amenable to medical therapy from those requiring surgical intervention.
- Transrectal ultrasound (TRUS) is an excellent noninvasive and well-tolerated procedure for staging of rectal tumors.
- Transvaginal ultrasound increases accuracy of bowel ultrasound in many women as pathologic features located deep in the pelvis may only be visible with this technique.
- Transperineal scan allows for accurate depiction of perianal inflammatory masses without necessity of performing often painful scans with endoanal or endorectal placement of the transducer.

Acknowledgment

Gastrointestinal (GI) tract sonography is frequently frustrating and always challenging. Gas content within the gut lumen can make visibility difficult or even impossible; intraluminal fluid may mimic cystic masses; and fecal material can create a variety of artifacts and pseudotumors. Nevertheless, normal gut has a reproducible pattern, or gut signature, and a variety of gut diseases create recognizable sonographic abnormalities. Therefore ultrasound may play a valuable role in the evaluation of patients in a variety of clinical situations, including suspicion of acute conditions of the GI tract, especially appendicitis and diverticulitis.

Recent years have shown growing interest in the use of ultrasound for surveillance of patients with inflammatory bowel disease. Further, endosonography, performed with high-frequency transducers in the gut lumen, is an increasingly popular technique for assessing the esophagus, stomach, and rectum.

ANATOMY AND SONOGRAPHIC TECHNIQUE

The Gut Signature

The gut is a continuous hollow tube with **four concentric layers** (Fig. 8.1). From the lumen outward, these layers are (1) mucosa, which consists of an epithelial lining, loose connective tissue (or lamina propria), and muscularis mucosa; (2) submucosa; (3) muscularis propria, with inner circular and outer longitudinal fibers; and (4) serosa or adventitia. These histologic layers correspond with the sonographic appearance[1-3] (Table 8.1) and are referred to as the **gut signature,** where up to **five layers** may be visualized (Fig. 8.2).

The sonographic layers appear alternately echogenic and hypoechoic; the first, third, and fifth layers are echogenic, and the second and fourth layers are hypoechoic. This relationship of the histologic layering with the sonographic layering is best remembered by recognition that the muscular components of the gut wall—the muscularis mucosa and the muscularis propria—constitute the hypoechoic layers on sonography.

On routine sonograms, the gut signature may vary from a "bull's-eye" in cross section, with an echogenic central area and a hypoechoic rim, to full depiction of the five sonographic layers. The quality of the scan and the resolution of the transducer determine the degree of layer differentiation. Ultrasound is superior to both computed tomography (CT) and magnetic resonance imaging (MRI) for resolution of the gut wall layers. The normal gut wall is uniform and compliant, with an average thickness of 3 mm if distended and 5 mm if not. Other morphologic features that allow recognition of specific portions of the gut include the gastric rugae (in the stomach), valvulae conniventes (plicae circulares in the small intestines), and haustra (in the colon) (Fig. 8.3).

Real-time sonography allows assessment of the content and diameter of the GI lumen and the motility of the gut. Hypersecretion, mechanical obstruction, and ileus are implicated when gut fluid is excessive. **Peristalsis** is normally seen in the small bowel and stomach. Activity may be increased with mechanical obstruction and inflammatory enteritides. Decreased activity is seen with paralytic ileus and in the end stages of mechanical bowel obstruction.

TABLE 8.1 Gut Signature: Histologic-Sonographic Correlation

Histology	Sonography
Superficial mucosa/interface (epithelium and lamina propria)	Echogenic
Muscularis mucosa	Hypoechoic
Submucosa	Echogenic
Muscularis propria (inner circular and outer longitudinal fibers)	Hypoechoic
Serosa/interface	Echogenic

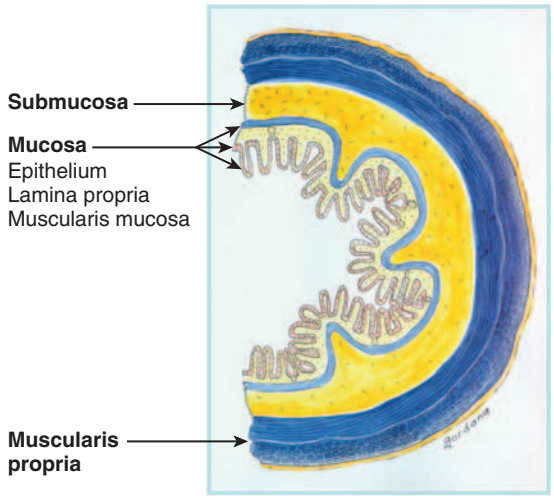

FIG. 8.1 Schematic Depiction of the Histologic Layers of the Gut Wall.

Gut Wall Pathology

Evaluation of thickened gut on sonography is far superior to the evaluation of normal gut for two important reasons. Thick gut, particularly if associated with abnormality of the perienteric soft tissues, creates a mass effect, which is easily seen on sonography. In addition, thickened gut is frequently relatively gasless, improving its sonographic evaluation. Gut wall pathology creates characteristic sonographic patterns (Fig. 8.4). The most familiar, the **target pattern,** was first described by Lutz and Petzoldt[4] in 1976 and later by Bluth et al.,[5] who referred to the pattern as a "**pseudokidney,**" noting that a pathologically significant lesion was found in more than 90% of patients with this pattern. In both descriptions the hypoechoic external rim corresponds to thickened gut wall, whereas the echogenic center relates to residual gut lumen or mucosal ulceration.

Identification of thickened gut on sonographic examination may be related to a variety of diseases. Diagnostic possibilities are predicted by determining the (1) extent and location of disease, (2) preservation or destruction of wall layering, and (3) concentricity or eccentricity of wall involvement. Benignancy is favored by long segment involvement with concentric thickening and wall layer preservation. The classic benign pathology showing gut wall thickening is **Crohn disease.** Malignancy is favored by short segment involvement with eccentric disease and wall layer destruction. The classic malignant pathology showing gut wall thickening is **adenocarcinoma of the stomach or colon.** These are guidelines rather than rules, because chronically thickened gut in Crohn disease may show layer destruction related to fibrotic and subacute inflammatory change, and infiltrative adenocarcinoma may show some wall layer preservation. Lymphadenopathy and hyperemia of the thickened gut wall

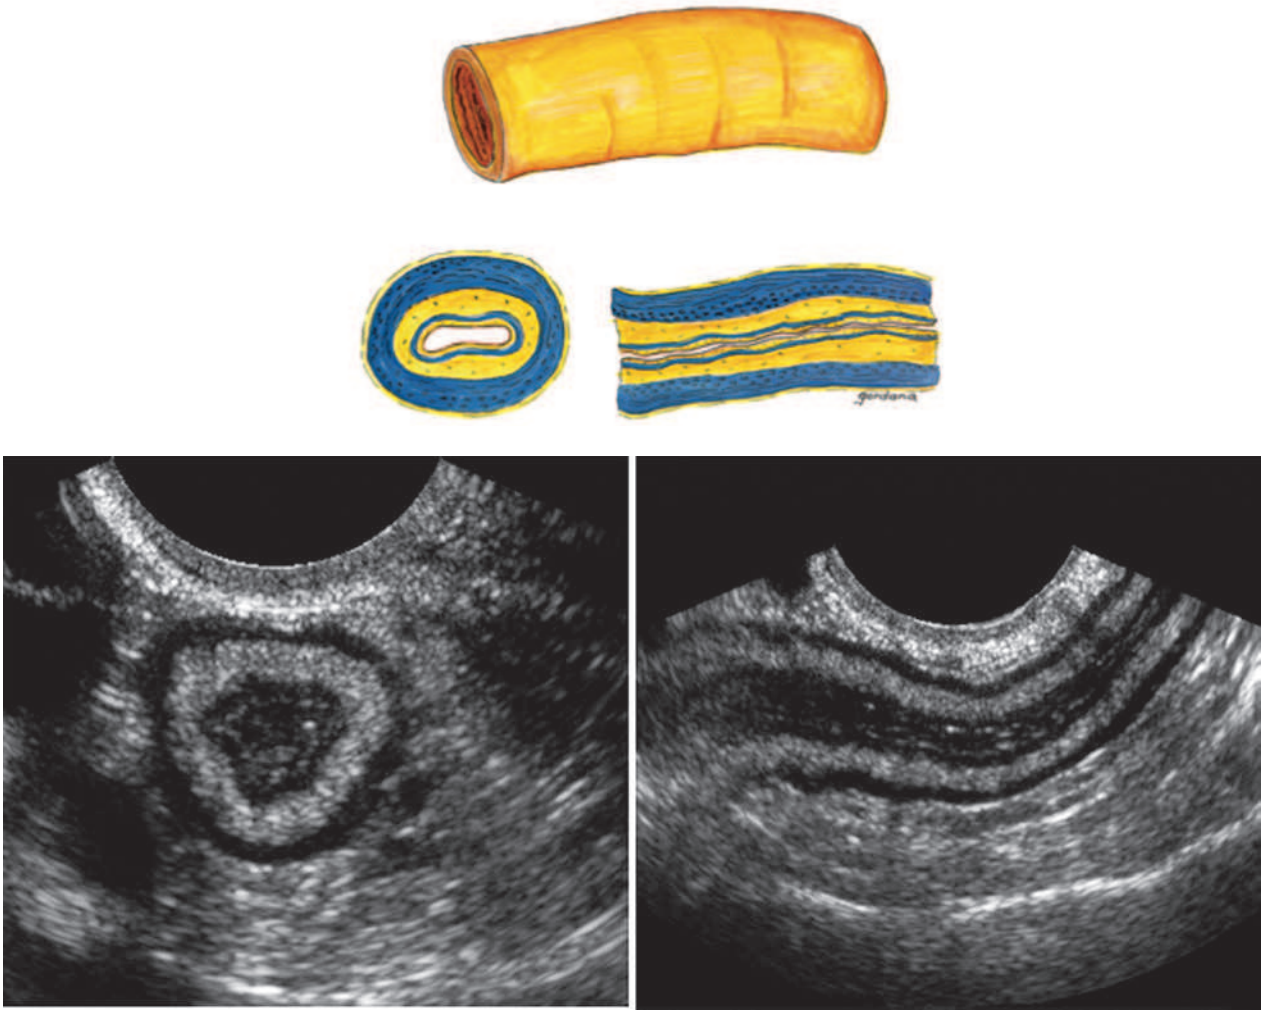

FIG. 8.2 Gut Signature in a Patient With Mild Gut Thickening Caused by Crohn Disease. The muscle layers are hypoechoic. The submucosa and superficial mucosa layers are hyperechoic. There is a small amount of fluid and air in the gut lumen.

may be seen in association with both malignant and benign gut wall thickening.

Gut wall masses, as distinguished from thickened gut wall, may be intraluminal, mural, or exophytic, all with or without ulceration. Intraluminal gut masses and mucosal masses have a variable appearance on sonography but are frequently hidden by gas or luminal content. In contrast, gut pathology creating an exophytic mass (without or with mucosal involvement or ulceration) may form masses that are more readily visualized. These may be difficult to assign to a GI tract origin if typical gut signatures, targets, or pseudokidneys are not seen on sonographic examination. Consequently, intraperitoneal masses of varying morphology, which do not clearly arise from the solid abdominal viscera or the lymph nodes, should be considered to have a potential gut origin.

Imaging Technique

Routine sonograms are best performed when the patient has fasted. A real-time survey of the entire abdomen is performed with a 3.5- to 5-MHz transducer, and any obvious masses or gut signatures are observed. The pelvis is scanned before and after the bladder is emptied because the full bladder facilitates visualization of pathologic conditions in some patients and displaces abdominal bowel loops in others. A routine gut evaluation should include assessment of all of the small bowel and the colon. In women, **transvaginal sonography** is invaluable for evaluation of the portions of the gut within the true pelvis, particularly the rectum, sigmoid colon, and, in some patients, the ileum. Further, oral fluid and a Fleet enema may improve localization and diagnosis of intraluminal or intramural gastric masses and rectal masses, respectively. Still images in long-axis and cross-sectional views as well as cine sweeps to show pathologic features allow for optimal review.

Areas of interest then receive detailed analysis, including **compression sonography**[6] (Fig. 8.5). Although this technique was initially described using high-frequency linear probes, 5- to 9-MHz convex probes and some sector probes work extremely well. The critical factor is a transducer with a short focal zone,

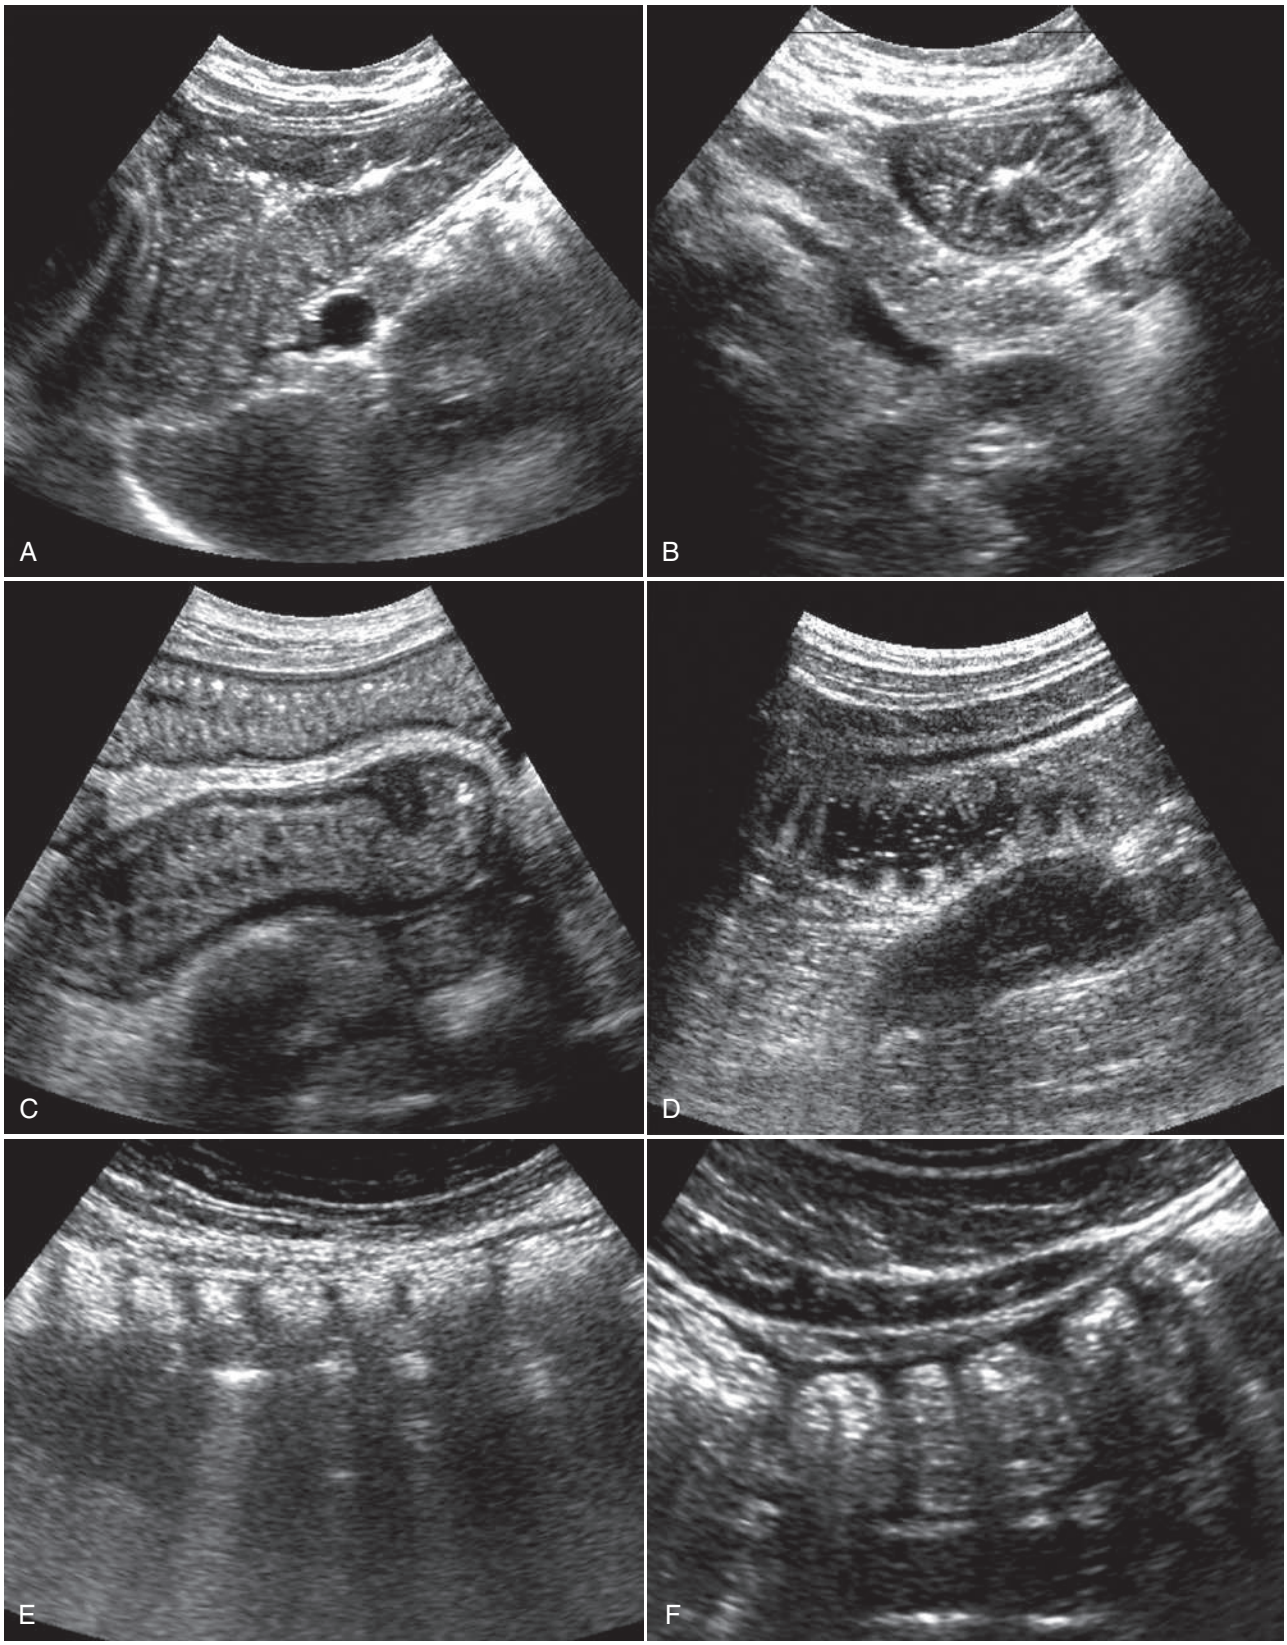

FIG. 8.3 Gut Recognition. **(A)** Sagittal and **(B)** cross-sectional views of the stomach show normal gastric rugae. The collapsed stomach shows variable wall thickness. **(C)** and **(D)** Valvulae conniventes (plicae circulares) of the small bowel. These are more easily seen when **(C)** there is fluid in the lumen of the bowel or **(D)** the valvulae are edematous. **(E)** and **(F)** Variations in the appearance of the colonic haustrations in two normal persons.

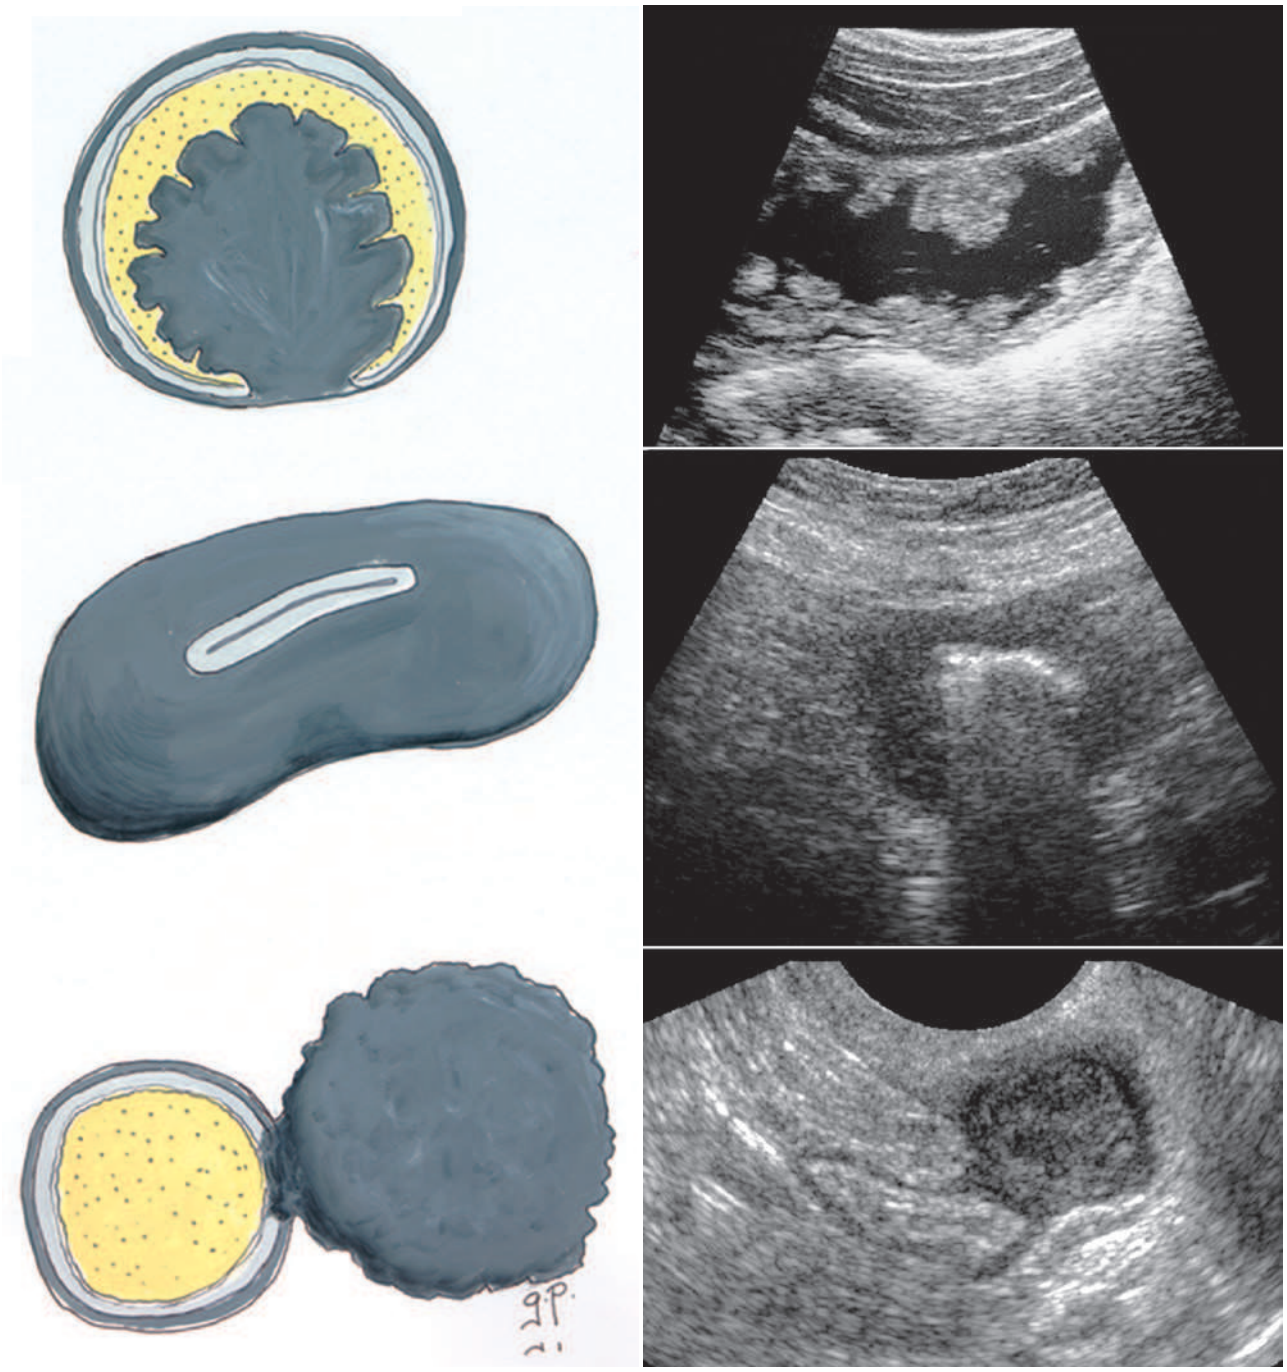

FIG. 8.4 Gut Wall Pathology. Schematic of sonographic appearances with sonographic equivalents. *Top,* **Intraluminal mass.** Inflammatory pseudopolyp on sonogram. *Middle,* **Pseudokidney sign,** with symmetrical wall thickening and wall layer destruction. Carcinoma of the colon on sonogram. *Bottom,* **Exophytic mass.** Serosal seed on visceral peritoneum of the gut on sonogram. (With permission from Wilson SR. The bowel wall looks thickened: what does that mean? In: Cooperberg PL, editor. RSNA categorical course syllabus. Chicago: RSNA; 2002. pp. 219-228.[1])

allowing optimal resolution of structures close to the skin. Slow, graded pressure is applied. Normal gut will be compressed and gas pockets displaced away from the region of interest. In contrast, thickened abnormal loops of bowel and obstructed noncompressible loops will remain unchanged. Patients with peritoneal irritation or local tenderness will usually tolerate the slow, gentle increase in pressure of compression sonography, whereas they show a marked painful response if rapid, uneven scanning is performed.

Doppler Evaluation of Gut Wall

Normal gut shows little signal on conventional color Doppler because interrogation is difficult in a normal and mobile bowel loop. Both **neoplasia** and **inflammatory disease** show increased vascularity compared with the normal gut wall (Fig. 8.6), whereas ischemic and edematous gut tends to be relatively hypovascular. The addition of color and spectral Doppler ultrasound evaluation to the study of the gut wall provides supportive evidence that gut wall thickening is caused by either ischemic or inflammatory

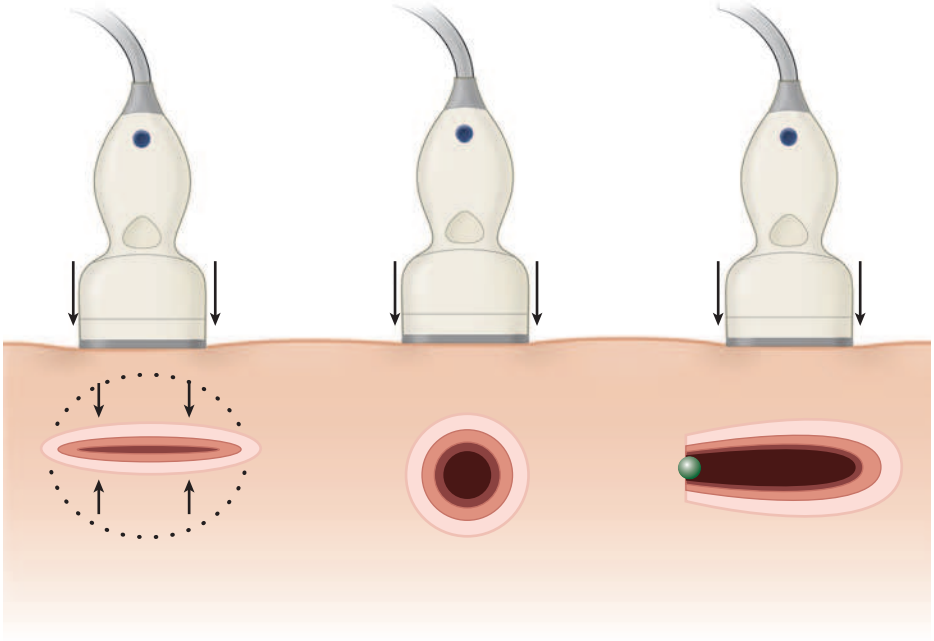

FIG. 8.5 Schematic of Compression Sonography. *Left,* Normal gut is compressed. *Middle,* Abnormally thickened gut, or *right,* an obstructed loop, such as that seen in acute appendicitis, will be noncompressible.

change in the patient with acute abdominal pain. Teefey et al.[7] examined 35 patients and found absent or barely visible blood flow on color Doppler and absence of arterial signal to be suggestive of ischemia. In contrast, readily detected color Doppler flow was consistent with inflammation.

Contrast-Enhanced Ultrasound and Elastography of the Bowel

Two exciting new applications of ultrasound of the bowel include contrast-enhanced ultrasound (CEUS) and elastography. The former provides objective repeatable measures of mural blood flow, which may change in response to inflammation and neoplasia, and the latter measures bowel wall stiffness.[9] Although these investigations are still in their infancy, their additional benefit over routine gray-scale ultrasound with Doppler is evident. Their great contribution to the evaluation of those with inflammatory bowel disease will be discussed in that section. CEUS is also useful in the assessment of mass lesions to determine the presence of vascularity analogous to the role of contrast enhancement on CT or MRI scan.

GASTROINTESTINAL TRACT NEOPLASMS

The role of sonography in the evaluation of GI tract neoplasms is similar to that of CT. Visualization is limited in cases of early mucosal lesions or with small intramural nodules, whereas tumors growing to produce an exophytic mass, a thickened segment of gut, or a sizable intraluminal mass are more easily detected (Fig. 8.7, Video 8.1). Sonograms are frequently performed early in the diagnostic workup of patients with GI tract tumors, often before their initial identification. Vague abdominal symptomatology, abdominal pain, a palpable abdominal mass, and anemia are common indications for these scans. Appreciation of the typical morphologies associated with GI tract neoplasia may lead to accurate recognition, localization, and even staging of disease, with the opportunity for directing appropriate further investigation, including sonography-guided aspiration biopsy.

Adenocarcinoma

Adenocarcinoma is the most common malignant tumor of the GI tract. Grossly, it has variable growth patterns (see Fig. 8.7), including infiltrative, polypoid, fungating, and ulcerated tumors. Most GI tract mucosal cancers are not visualized on sonography. However, large masses, either intraluminal or exophytic, and annular tumors create sonographic abnormalities.[10,11] Tumors of variable length may thicken the gut wall in either a concentric symmetrical or an asymmetrical pattern. A target or pseudokidney morphology may be created (see Fig. 8.4). Air in mucosal ulcerations typically produces linear echogenic foci, often with ring-down artifact, within the bulk of the mass. Tumors are usually, but not invariably, hypoechoic. Annular lesions may produce gut obstruction with dilation, hyperperistalsis, and increased luminal fluid of the gut proximal to the tumor site.[11] Evidence of direct invasion, regional lymph node enlargement, and liver metastases should be sought.

Adenocarcinoma accounts for 80% of all malignant gastric neoplasms, where infiltration may be superficial or transmural, the latter creating a linitis plastica, or "leather bottle," stomach. Adenocarcinoma occurs much less frequently in the small bowel than in the stomach or large bowel. It accounts for approximately

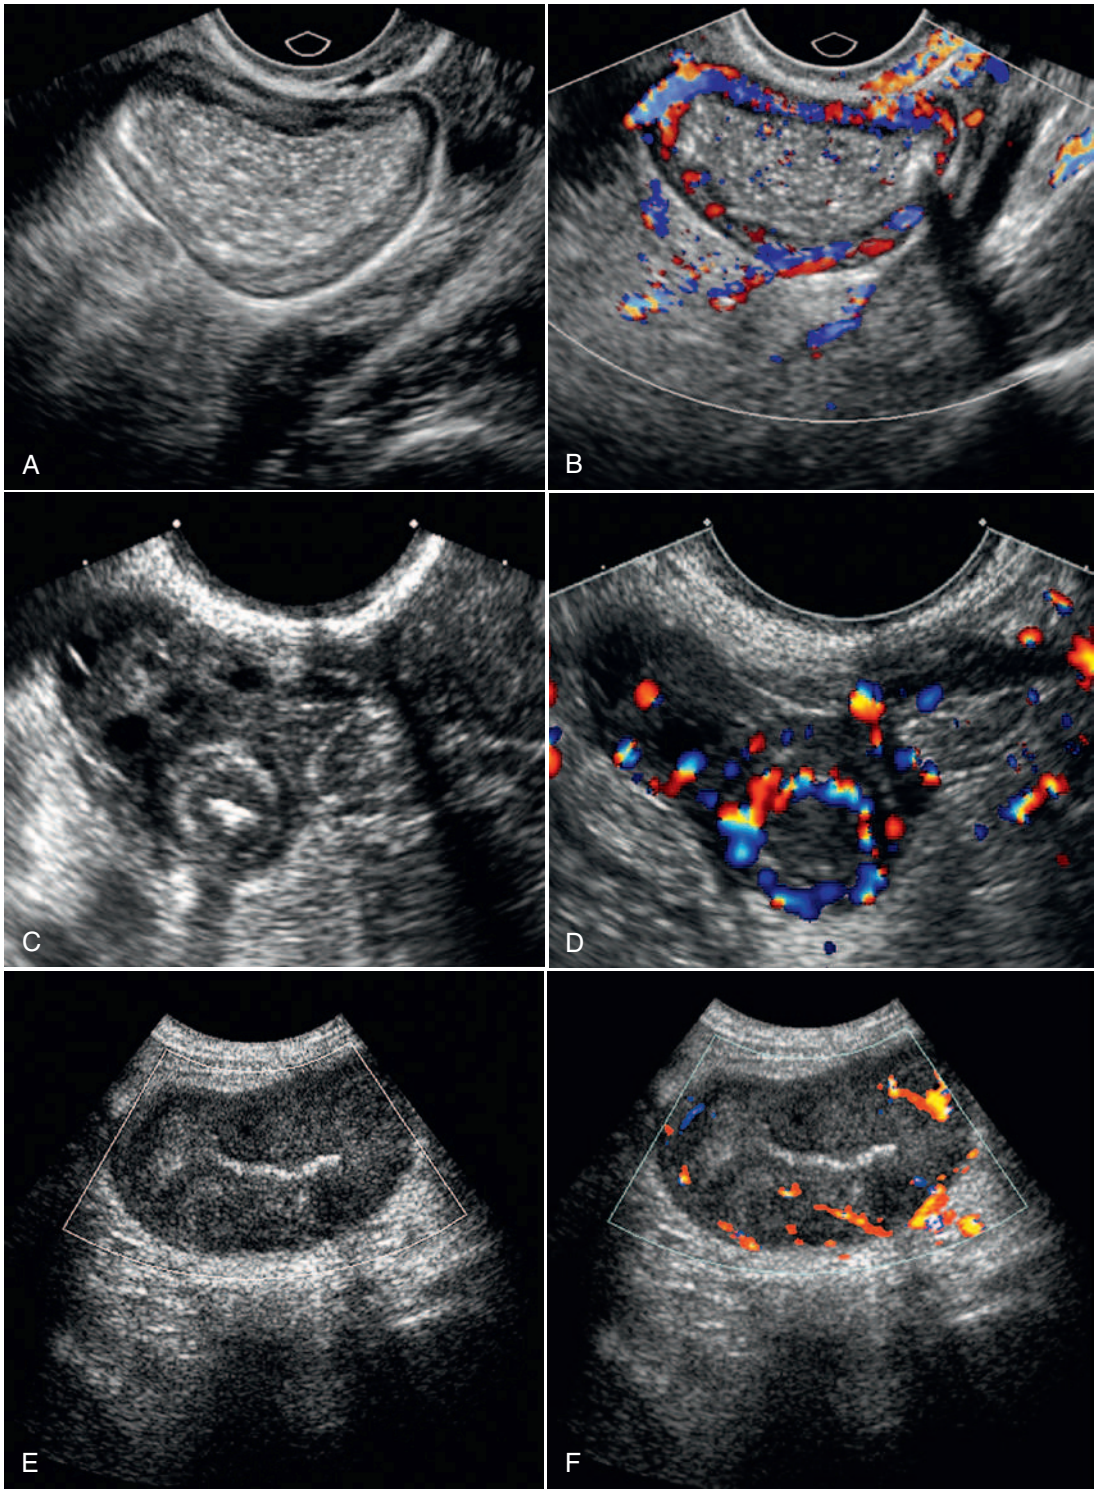

FIG. 8.6 Contribution of Doppler to Gut Assessment in Three Patients. (A) and **(B)** Cross-sectional images of the ileum proximal to an inflammatory stricture in **Crohn disease.** The lumen is distended with fluid. The wall is slightly thick. **(B)** Color Doppler image shows marked hyperemia of the gut wall as a reflection of its inflammation. **(C)** and **(D)** Transvaginal views in a young woman with right lower quadrant pain show the appendix as a round, tubular structure adjacent to the ovary. **(D)** Color Doppler image shows that appendix is hyperemic, consistent with inflammation. **(E)** and **(F)** Transverse images of the ascending colon show wall thickening with total layer destruction related to **invasive colon carcinoma.** Neoplastic tumors of the gut invariably show vascularity as here.

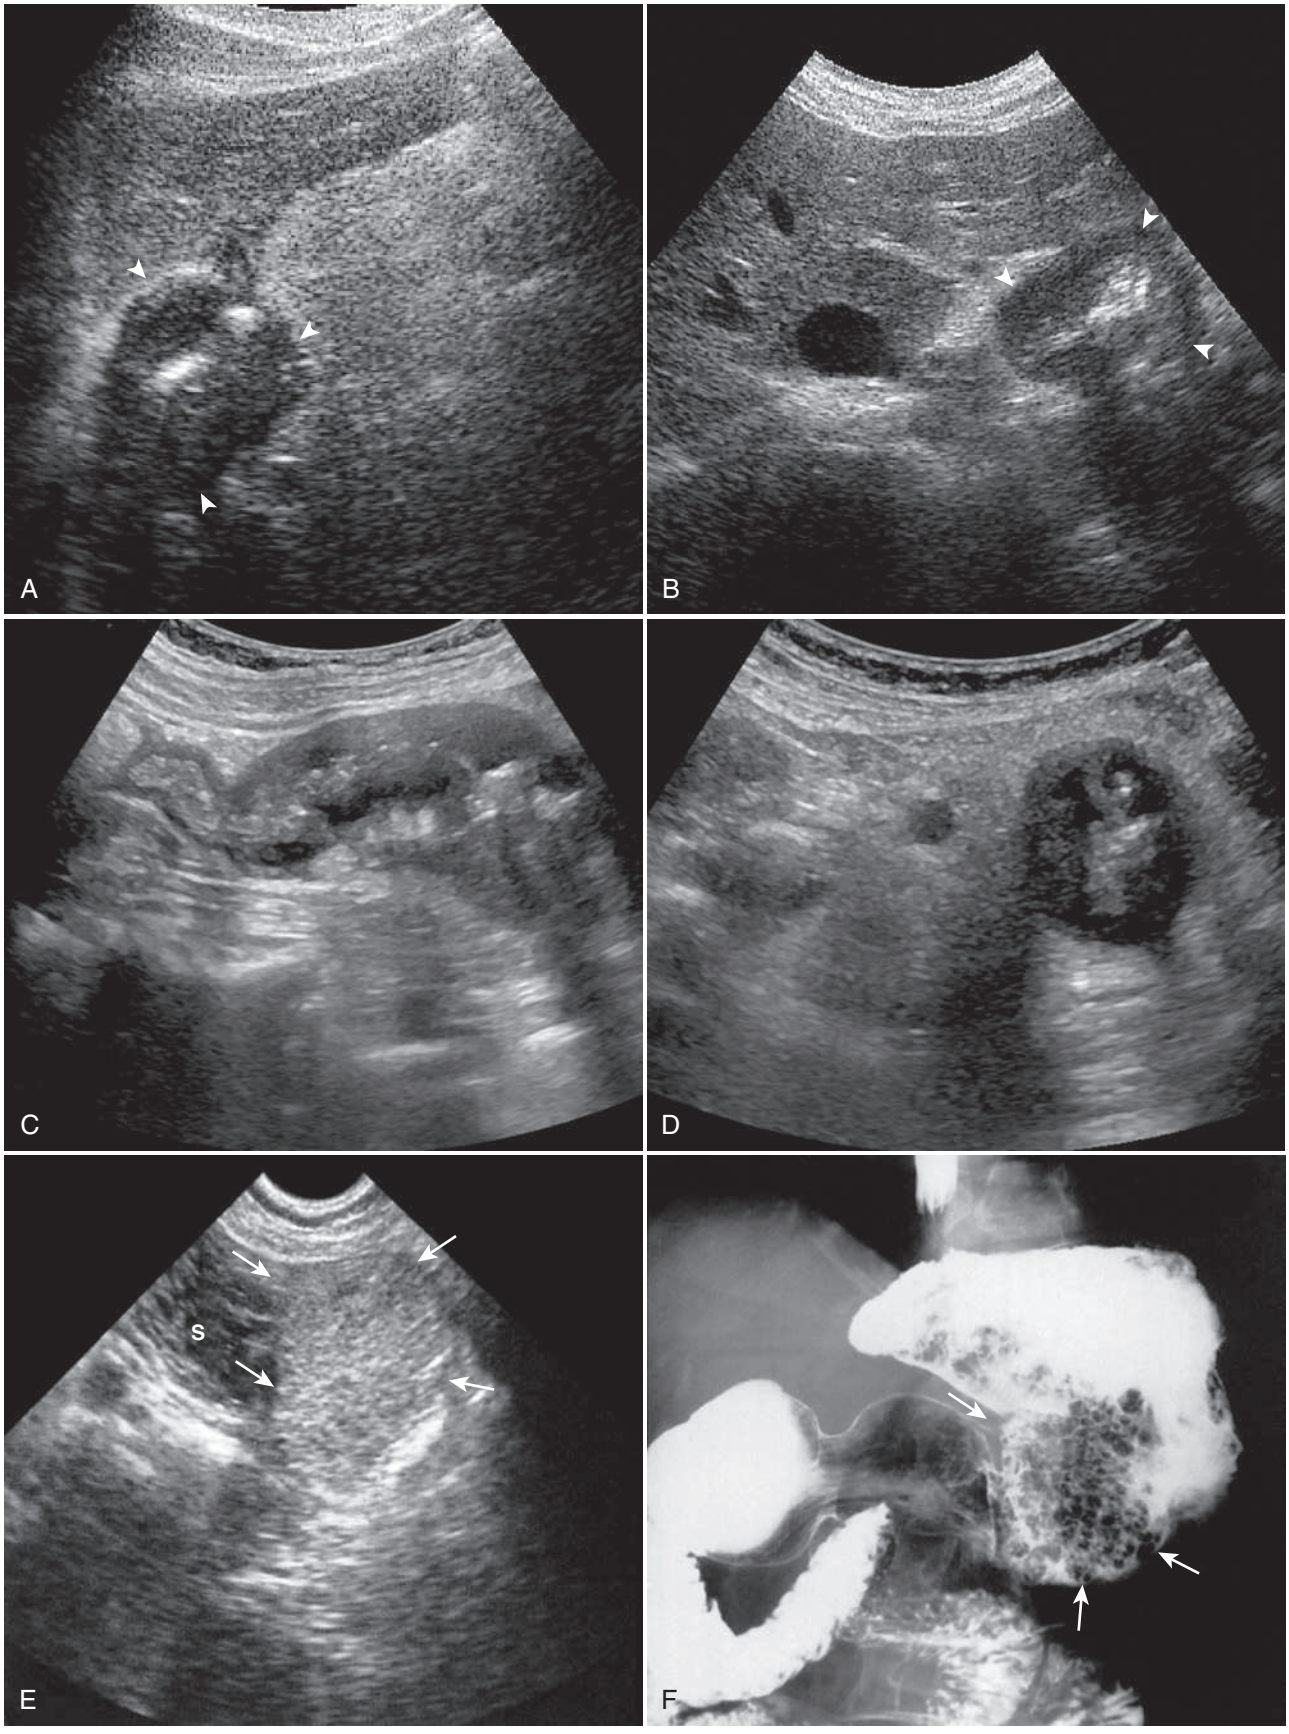

FIG. 8.7 Adenocarcinoma of the Gut in Three Patients. (A) and **(B) Cancer at gastroesophageal junction. (A)** Sagittal and **(B)** transverse sonograms of the upper abdomen show a pseudokidney *(arrowheads)* adjacent to the left lobe of the liver. **(C)** and **(D) Carcinoma of descending colon. (C)** Long-axis image of the colon shows an abrupt transition from normal to thickened bowel. **(D)** An axial image shows a hypoechoic, circumferential mass with an "apple core" appearance. There is echogenic infiltrated fat and an enlarged hypoechoic lymph node adjacent to the tumor. **(E)** and **(F) Intraluminal villous adenocarcinoma of stomach. (E)** Transverse sonogram after fluid ingestion shows a relatively well-defined, inhomogeneous, echogenic mass *(arrows)* within body of stomach. Fluid is in the stomach lumen *(S)*. **(F)** Confirmatory barium swallow shows the villous tumor *(arrows)*. See also Video 8.1.

50% of the small bowel tumors found, 90% of them arising in either the proximal jejunum (Fig. 8.8A and B) or the duodenum. Crohn disease is associated with a significantly increased incidence of adenocarcinoma that usually develops in the ileum. Small bowel adenocarcinomas are generally annular in gross morphology, frequently with ulceration. **Colon carcinoma** is very common and accounts for virtually all malignant colorectal neoplasms. Colorectal adenocarcinoma grows with two major gross morphologic patterns: **polypoid intraluminal tumors,** which are most prevalent in the cecum and ascending colon, and **annular constricting lesions** (see Fig. 8.7C and D), which are most common in the descending and sigmoid colon. In rare cases, infiltrative tumors similar to those seen in the stomach may occur in the colon (Fig. 8.8C and D).

Gastrointestinal Stromal Tumors

Of the mesenchymal tumors affecting the gut, those of smooth muscle origin are the most common and account for about 1% of all GI tract neoplasms. These gastrointestinal stromal tumors (GISTs) are found most often in the stomach and the small bowel. Colonic tumors are the least common and occur most often in the rectum. Although GISTs may be found as an incidental observation at surgery, sonography, or autopsy, these vascular tumors frequently become very large and may undergo ulceration, degeneration, necrosis, and hemorrhage.[12]

On sonography, smooth muscle (stromal) tumors typically produce round mass lesions of varying size and echogenicity, often with central cystic areas[13] related to hemorrhage or necrosis (Fig. 8.9). Their gut origin is not always easily determined, but if ulceration is present, pockets of gas in an ulcer crater may suggest their origin. Smooth muscle tumors of gut origin should be considered in the differential diagnosis of incidentally noted, indeterminate abdominal masses in asymptomatic patients, particularly if they show central cystic or necrotic change (Fig. 8.9E and F). These tumors are very amenable to sonographic-guided aspiration biopsy.

Lymphoma

The gut may be involved with lymphoma in two basic forms: as widespread dissemination in stage III or IV lymphoma of any

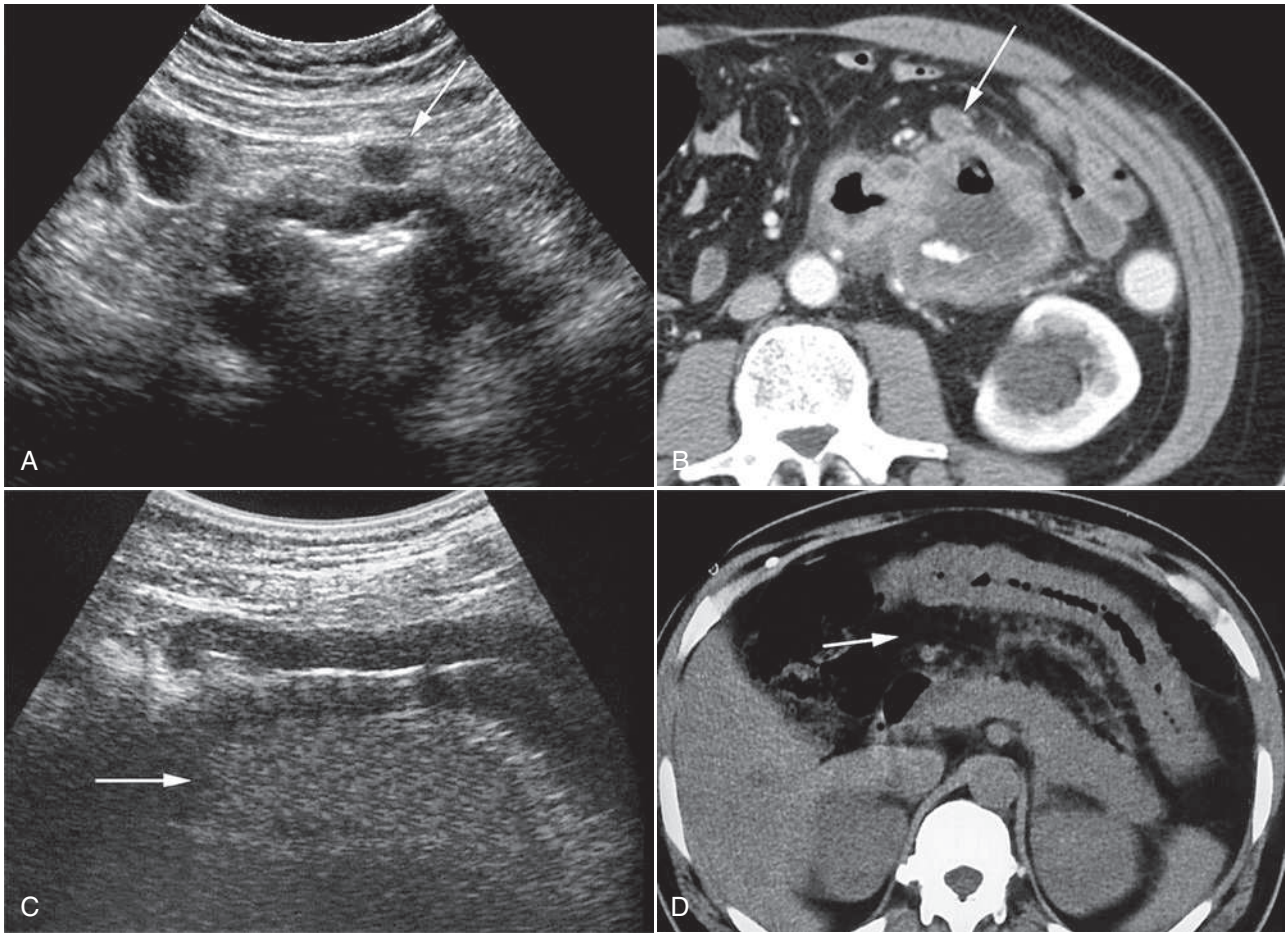

FIG. 8.8 Adenocarcinoma of Bowel: Sonographic-CT Correlation. (A) Sonogram and **(B)** CT scan show large, necrotic, left upper quadrant mass at the ligament of Treitz with enlargement of the perienteric lymph nodes *(arrow)* in a 60-year-old man who presented with abdominal discomfort and blood loss. **(C)** and **(D)** Infiltrative carcinoma of transverse colon in a 42-year-old man who presented to the emergency department with acute abdominal pain. **(C)** Transverse sonogram of the epigastrium shows a featureless segment of thick gut with total loss of wall layering in the location of the transverse colon. Deep to the gut is a diffuse echogenic mass effect *(arrow)* suggesting infiltrated or inflamed fat. **(D)** Confirmatory CT scan. The infiltrated fat is black and streaky on the CT image. Neoplasia was not suspected on the basis of either imaging test or at surgery.

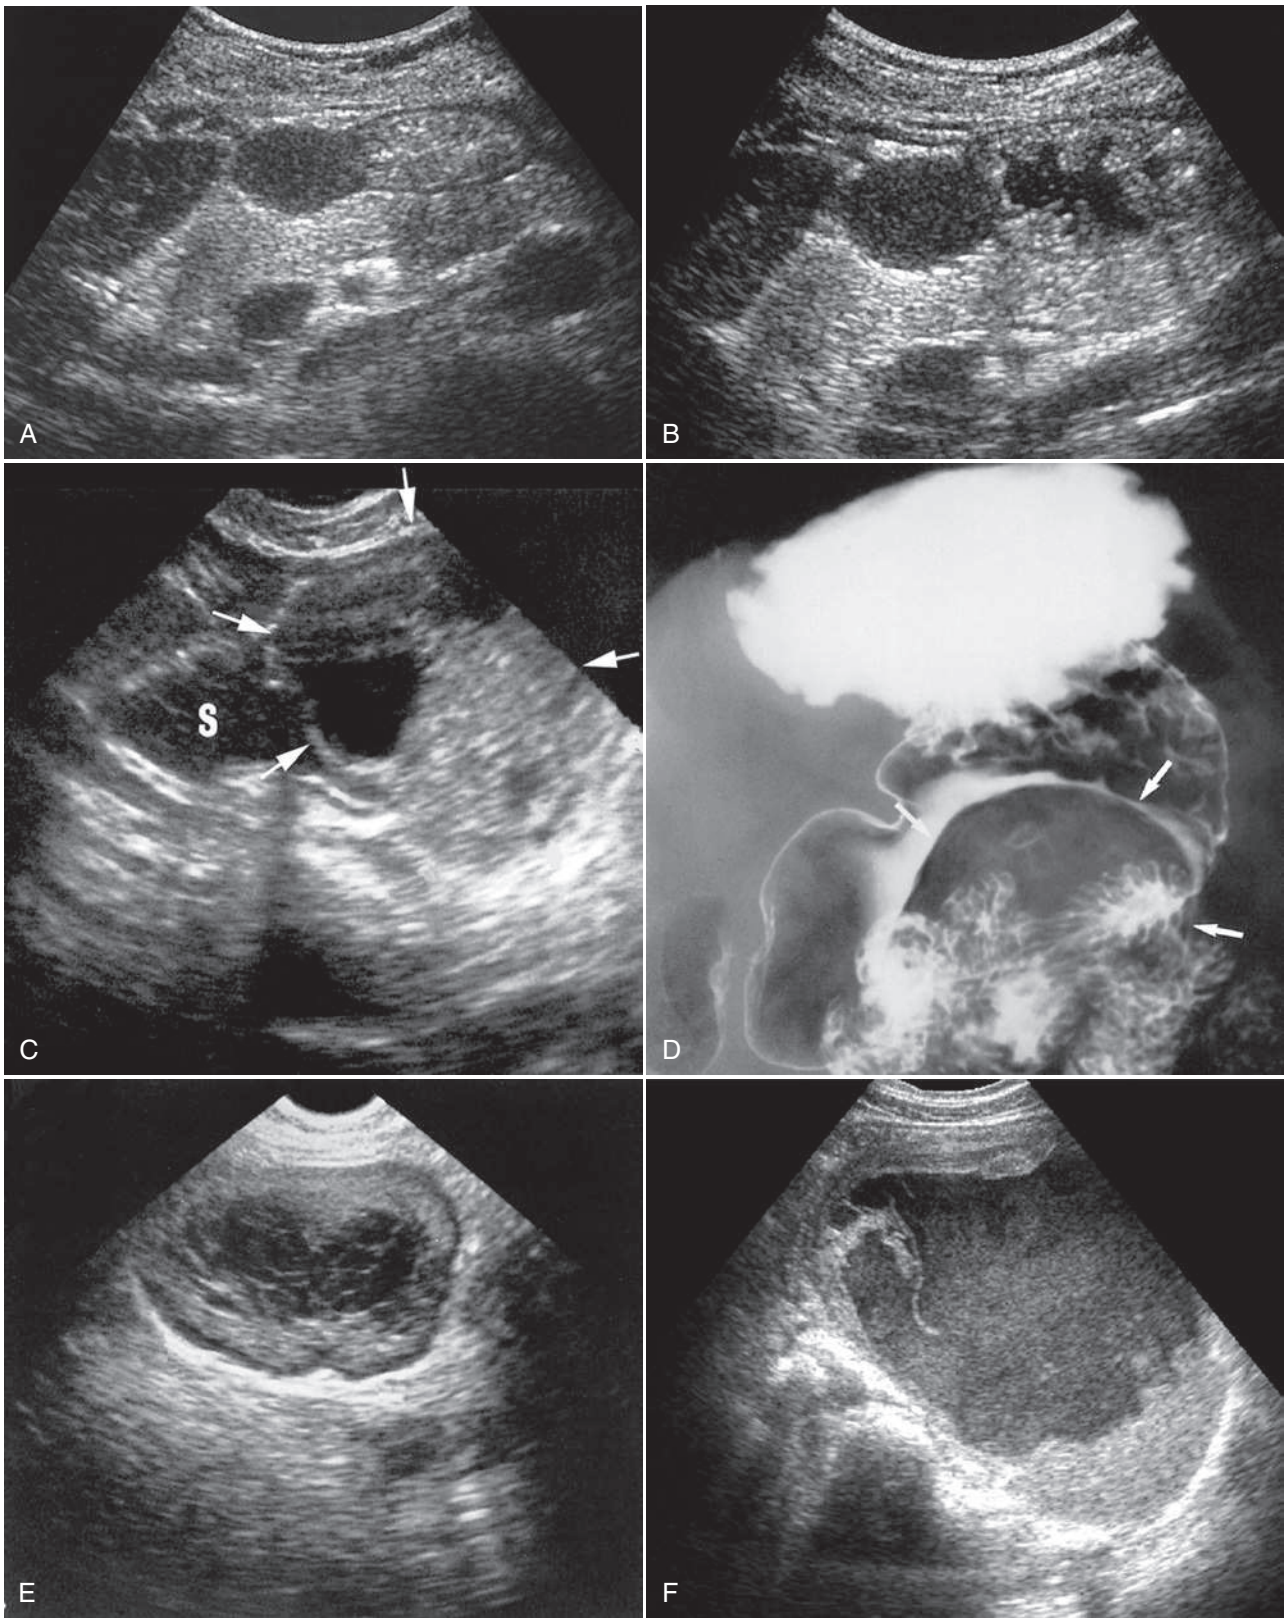

FIG. 8.9 Gastrointestinal Stromal Tumors (GISTs) in Four Patients. (A) and **(B)** Exophytic gut mass, a **gastric leiomyoma. (A)** Transverse sonogram of epigastrium shows the normal gastric gut signature and the focal exophytic mass. **(B)** After water ingestion, the lumen contains fluid that appears hypoechoic. The solid mass is clearly seen. **(C)** and **(D) Gastric leiomyosarcoma. (C)** Transverse sonogram after fluid ingestion shows a complex, smooth intramural mass *(arrows)* projecting into the fluid-filled stomach lumen *(S)*. **(D)** Confirmatory barium swallow shows the intramural tumor *(arrows)*. **(E)** and **(F)** Two patients with a large, upper abdominal, complex, and necrotic-appearing mass on sonography. Although the gut origin of the masses is not evident on the images, the correct diagnosis of GIST was suggested based on the appearance. The jejunum is the origin of the tumor in **(E)** and the stomach in **(F)**.

cell type or, more often, as primary lymphoma of the GI tract, which is virtually always a **non-Hodgkin lymphoma.** Primary tumors constitute only 2% to 4% of all GI tract malignant tumors[12] but account for 20% of those found in the small bowel. Three predominant growth patterns are observed: nodular or polypoid, carcinoma-like ulcerations, and infiltrating tumor masses that frequently invade the adjacent mesentery and lymph nodes.

Small, submucosal nodules may be easily overlooked on sonography. However, many patients have large, easily visible, very hypoechoic, ulcerated masses in the stomach or small bowel[14,15] (Fig. 8.10). Long, linear, high-amplitude echoes with **ring-down artifacts,** indicating gas in the residual lumen or ulcerations, and aneurysmal dilation of the bowel lumen are common observations. This particular pathologic state has been recognized as one of the more frequent presentations of patients with acquired immunodeficiency syndrome **(AIDS)–related lymphoma.** Regional lymph node enlargement may be visualized, although generalized lymph node abnormality is uncommon.

Metastases

Malignant melanoma and primary tumors of the lung and breast are the tumors most likely to have secondary involvement of the GI tract[16] (Fig. 8.11). In order of frequency, the stomach, small bowel, and colon are involved. On sonography, small submucosal nodules that tend to ulcerate are rarely seen, whereas large, diffusely infiltrative tumors with large ulcerations are common, particularly in the small bowel where they create hypoechoic, well-defined masses that often have bright, specular echoes with ring-down artifacts in areas of ulceration.

Secondary neoplasm affecting the omentum and peritoneum may cause **ascites** (which may be particulate ascites), tiny or confluent superficial secondary nodules on the gut surface, or extensive **omental cakes** that virtually engulf the involved gut loops[17] (Fig. 8.12). Metastases to the peritoneum most often arise from primary tumors in the ovary or the gut. A **drop metastasis** in the pelvic pouch of Douglas shows as a small, solid, peritoneal nodule without obvious origin from the pelvic viscera.

INFLAMMATORY BOWEL DISEASE: CROHN DISEASE

Inflammatory bowel disease (IBD) comprises Crohn disease and ulcerative colitis. **Ulcerative colitis** is a mucosal inflammation of the colon and often shows little in the way of gross morphologic

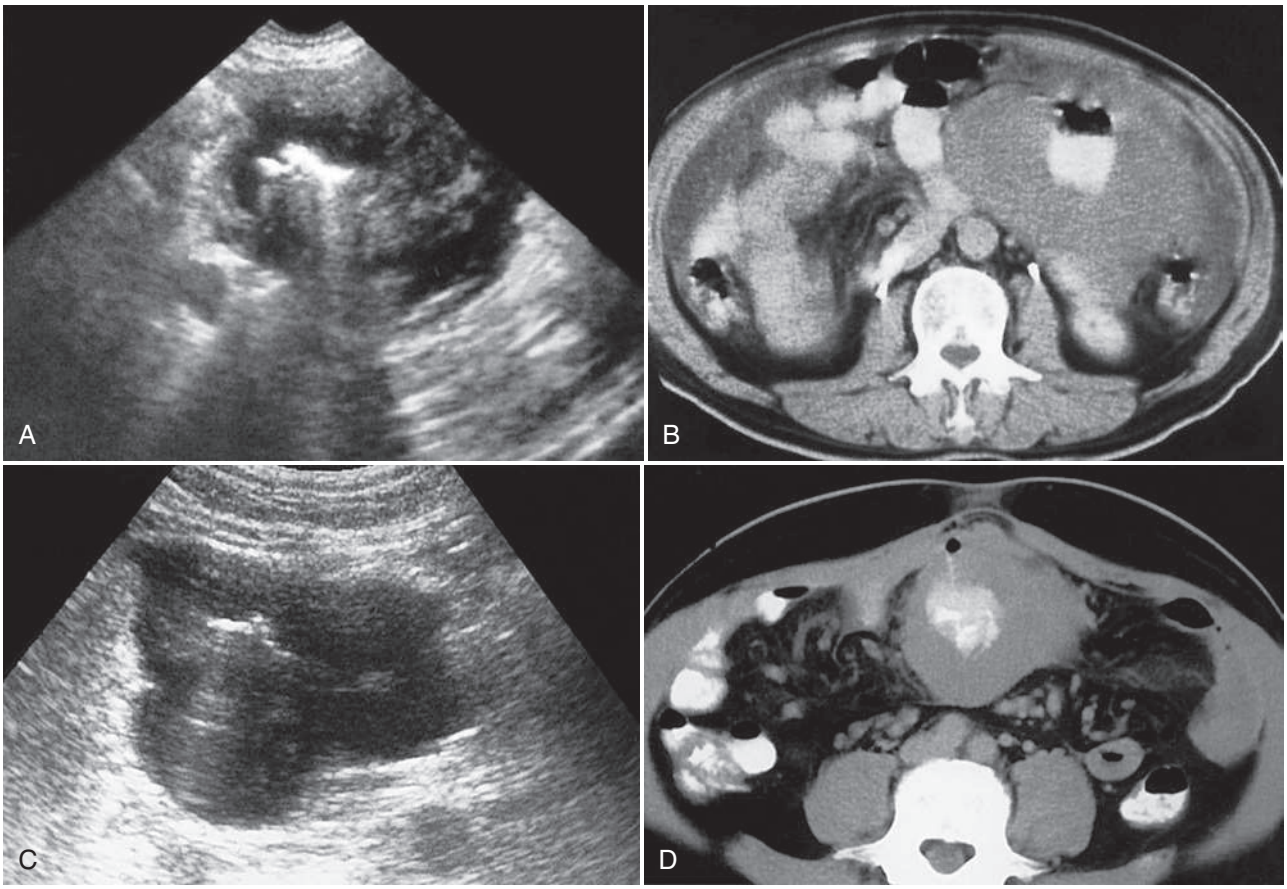

FIG. 8.10 Small Bowel Lymphoma in Two Patients. (A) Transverse left sonogram shows a hypoechoic round mass lesion. Central echogenicity with ring-down gas artifact suggests its gut origin. **(B)** Correlative CT scan shows large, soft tissue mass with corresponding residual gut lumen. **(C)** Sonogram in AIDs patient shows a focal midabdominal, hypoechoic mass with no wall layer definition, which is classic for gut lymphoma. The luminal gas appears as central bright echogenicity with dirty shadowing. **(D)** Correlative CT scan.

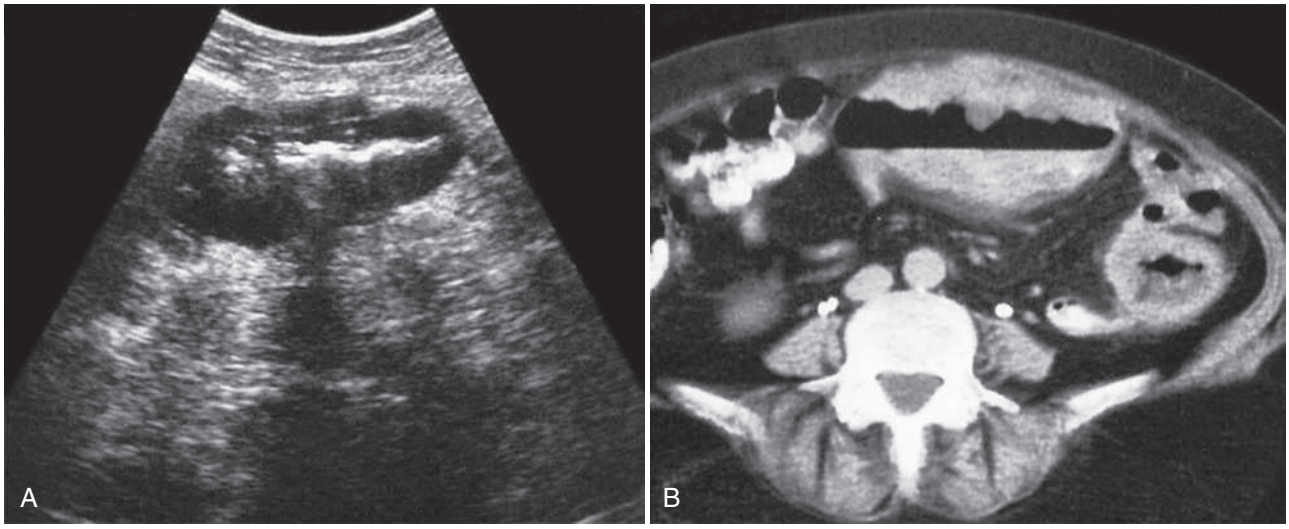

FIG. 8.11 Metastatic Malignant Melanoma to Small Bowel. (A) Transverse paraumbilical sonogram shows well-defined, hypoechoic mass with central irregular echogenicity with gas artifact suggesting gut origin. **(B)** Confirmatory CT scan.

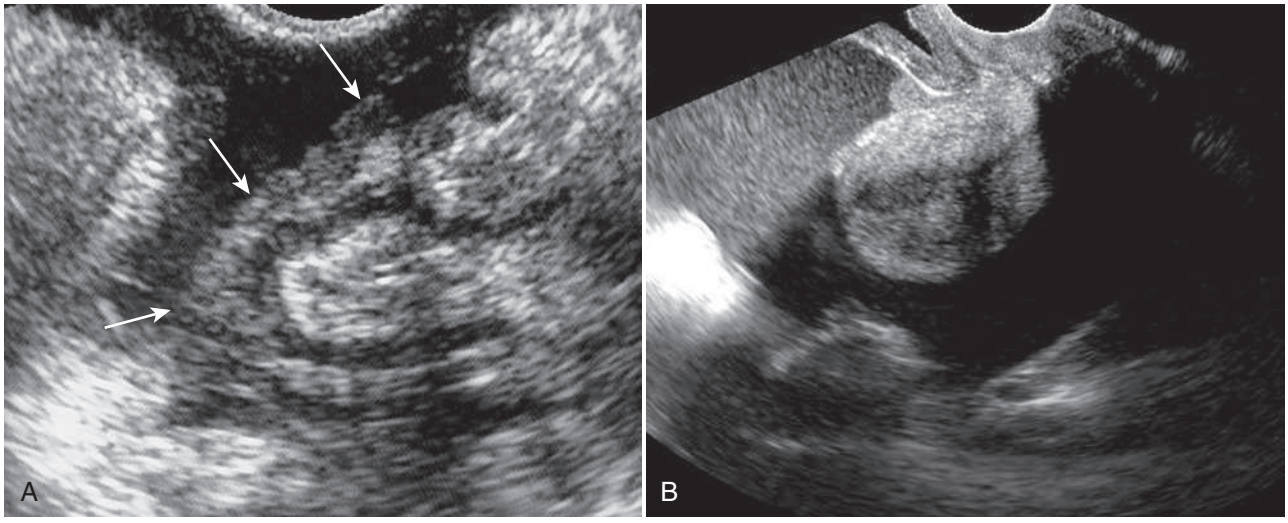

FIG. 8.12 Peritoneal Metastases in Two Patients. (A) Transvaginal image shows ascites and visceral peritoneal plaque on the surface of the small bowel loop *(arrows)* from metastatic ovarian cancer. **(B)** Transvaginal scan of peritoneal drop metastasis from stomach primary shows grossly particulate ascites. There is a small peritoneal implant in the vesicouterine angle.

change except with acute disease. Further, the involved colon is readily evaluated with colonoscopy and also with all cross-sectional imaging, making its assessment relatively straightforward. **Crohn disease,** by comparison, is a chronic transmural. The peak age of onset is early in life, between the ages of 15 and 40 years, thus affecting patients during their most productive years. The natural course of the disease includes alternating periods of active inflammation and remission with a strong tendency to complicate over time, with the development of penetrating and/or fibrostenotic lesions. As a result, surgical intervention rates have been high. Historically, Crohn disease was managed according to patient symptomatology. It is recognized, however, that neither inflammatory markers nor symptoms are an accurate reflection of the state of the disease. Today, therefore, there is a dramatic shift in approach with an effort to treat to the target of mucosal healing on endoscopy, including the use of aggressive biologic therapy and the increasing popularity of early introduction of anti–tumor necrosis factor-α (anti-TNFα). These management changes necessitate frequent monitoring of all patients because repeated endoscopic performance is poorly tolerated, expensive, and not without risk. Therefore safe, objective, noninvasive, and accurate methods for measuring the severity of inflammatory activity are vital.

Imaging plays a major role in the diagnosis of disease,[18] in the detection of recurrence, and in the recognition of complications, which may be associated with a silent clinical course. Surveillance imaging and monitoring response to therapy (which may be both expensive and toxic) is of prime importance. In a meta-analysis comparing different modalities for diagnosis of IBD, mean sensitivity estimates for the diagnosis on a per-patient

basis were high and not significantly different for ultrasound (89.7%), MRI (93.0%), and CT (84.3%).[19] Therefore in this era of cost and radiation awareness, ultrasound is rising in importance for imaging of IBD.[20] Sonography is our routine evaluation technique for initial disease diagnosis, the detection of recurrence,[21] the determination of the extent, complications[22] and activity of disease, and in the assessment of response to treatment.

Although any portion of the gut may be involved, Crohn disease most commonly affects the terminal ileum and the colon. This transmural, granulomatous inflammatory process affects all layers of the gut wall and also the perienteric soft tissues. Grossly, the gut wall may become very thick and rigid with secondary luminal narrowing. Discrete or continuous ulcers and deep fissures are characteristic, frequently leading to fistula formation. Mesenteric lymph node enlargement and matting of involved loops are common. The mesentery may be markedly thickened and fatty, creeping over the edges of the gut to the antimesenteric border. The classic features of Crohn disease—wall thickening, inflammatory fat, lymphadenopathy, and hyperemia—reflect these gross morphologic changes. Complications of Crohn disease include **stricture, incomplete bowel obstruction, perforation, fistulas, and inflammatory masses.**[21]

The immediate objectives of a sonogram on a patient with known or suspected IBD, therefore, include documentation of the distribution and the extent of the disease, as well as the disease activity. A global assessment is made on ultrasound grading all of the classic features from 0, not present; through 1, mild; 2, moderate; and 3, showing severe change[23] (Table 8.2). Utilization of such a scoring system allows for consistency of performance and reproducibility of results. It also facilitates comparisons for monitoring response to therapy.

TABLE 8.2 Ultrasound Global Assessment Showing Crohn Disease Activity Scores on Gray-Scale Ultrasound and Color Doppler Imaging

Gray-Scale Ultrasound Features of Activity	Classification			
	INACTIVE	MILD	MODERATE	SEVERE
Wall thickness (mm)	<4.0	4.0-6.0	6.1-8.0	>8.1
Inflammatory fat	• Absent • Perienteric region resembles normal mesenteric fat	• Masslike • Slightly echogenic • Of less area than the bowel on axial view	• Masslike • More echogenic • Equal area to the bowel on axial view	• Masslike • Significantly echogenic • Of greater area than the bowel on axial view
Color Doppler imaging (CDI) Mural blood flow	• Absent	• Small regions of color without the vessel	• Medium-length segments of color vessels in the bowel wall	• Circumferential or continuous depiction of vessels in the bowel wall with or without mesenteric vessels
Ultrasound global assessment	• No signs of active disease	• Mild wall thickness • Minimal inflammatory fat • Present but not minimal signal on CDI • Wall layer preservation	• Moderate wall thickness • Moderate inflammatory fat • Moderate signal on CDI • ± Wall layer preservation[a]	• Moderate to severely thickened bowel wall • Abundant inflammatory fat • Long continuous mural blood vessels on CDI • ± Wall layer preservation[a] • Spiculation of serosal border[a]

[a]Loss of wall layering and serosal spiculation both suggest increasing disease severity.

Classic Features

Gut Wall Thickening

Gut wall thickening is the most frequently observed abnormality in patients with Crohn disease and varies in proportion to disease severity. Its identification comprises the basis for initial disease detection, for detection of recurrence,[24] and for determining the extent of disease. In a meta-analysis on the accuracy of sonography in detecting Crohn disease, Fraquelli et al.[25] showed sensitivity and specificity of 88% and 93%, respectively, when a bowel wall thickness threshold greater than 3 mm was used, and 75% and 97% with a threshold greater than 4 mm.

Gut wall thickening in Crohn disease is most frequently concentric and may be marked.[26,27] Wall echogenicity varies depending on the degree of inflammatory infiltration and fibrosis. Stratification with retention of the gut layers is typical (Fig. 8.13A and B; also see Fig. 8.2, Videos 8.2 and 8.3). A target or pseudokidney appearance is possible in acute disease or long-standing fibrotic or subacute inflammatory disease as the gut wall layering is progressively lost (Fig. 8.13C and D). Long-standing and often burnt-out disease may also show wall thickening with fat deposition in the submucosa, which appears as increased echogenicity of this layer (Fig. 8.13E and F). Actively involved gut typically appears rigid and fixed, with decreased or absent peristalsis (Video 8.4). Involvement of the serosal border of the bowel may result in **spiculation** of the border of the bowel (Fig. 8.14). Skip areas are frequent. Involved segments vary in length from a few millimeters to many centimeters. Bowel wall thickening may be caused by acute inflammatory change or related to chronic fibrosis and smooth muscle hypertrophy.

Inflammatory Fat

Mesenteric edema and inflammation of the mesenteric fat are also characteristic of Crohn disease, producing a mass in the mesentery adjacent to the diseased gut that may creep over the border of the abnormal gut or completely engulf it, the so-called **creeping fat.** Fat creeping onto the margins of the involved gut creates a uniform echogenic halo around the mesenteric border of the gut, with a thyroidlike appearance in cross section (Fig. 8.15). It may become more heterogeneous and even hypoechoic in long-standing disease. Creeping fat is the most common cause of gut loop separation seen on GI contrast studies.[21] It is also the most striking and detectable abnormality on sonography of patients with perienteric inflammatory processes. Therefore detection of creeping fat should lead to a detailed evaluation of the regional gut.

Lymphadenopathy

Tender and enlarged mesenteric and perienteric nodes are common features of the active phase of inflammation with Crohn disease (Fig. 8.16). Lymphadenopathy may persist in the inactive phase. The nodes appear as focal hypoechoic masses circumferentially surrounding the gut and in the expected location of the mesenteric attachment. Nodes are frequently quite round, are of moderate size, and typically lose the normal linear echogenic streak from the nodal hilum. Similar to the gut, the lymph nodes show hyperemia as a reflection of their inflammation.

Hyperemia

Mesenteric vascularization and neoangiogenesis are recognized components of the inflammatory process, and evaluation of blood flow is a useful tool for monitoring inflammatory activity and response to therapy. Disease activity correlates with hyperemia, as seen on **color Doppler evaluation**[28] (Fig. 8.17, Video 8.5). Although subjective, this addition of color Doppler to gray-scale sonography can provide valuable supportive evidence of inflammatory change in the gut and adjacent inflamed fat[21] (see Fig. 8.6B, D, and F). However, color Doppler shows blood flow in major blood vessels with relatively fast-moving blood and does not show blood flow at the perfusion level. To overcome this limitation of activity assessment, there has been increasing interest over recent years in the use of CEUS of the bowel, performed with the injection of microbubble contrast agents. Using ultrasound quantitative techniques, CEUS allows for objective measurement of blood flow at the perfusion level as a reflection of activity. On observation, we look for transmural enhancement of the bowel wall and also a "comb sign," reflective of blood flow within the mesenteric vasculature (Fig. 8.18, Videos 8.6 and 8.7). Generation of time intensity curves allows for measurement of the peak enhancement and the area under the curve. Studies have shown a direct correlation between the level of bowel wall enhancement and active inflammatory disease, as assessed on colonoscopy.[29,30] Further, Ripollés et al.[29] show that CEUS measurements perform better than wall thickness in prediction of disease severity at colonoscopy. In our own laboratory, we have integrated the objective measurements of blood flow on CEUS with the baseline gray-scale assessments of wall thickness and inflammatory fat to improve the objectivity of activity assessments on ultrasound.[23]

Mucosal Abnormalities

Although endoscopy remains the major tool for evaluating mucosal and luminal abnormality, ultrasound may on occasion show luminal polypoid masses, such as inflammatory polyps, and deep ulcerations with pockets of echogenic air projecting within the gut wall. Ultrasound may also show intramural sinus tracts with air dissecting within the layers of the bowel wall (Fig. 8.19), as a complication of both Crohn disease and diverticulitis.

Conglomerate Masses

Conglomerate masses may be related to clumps of matted bowel, inflamed edematous mesentery, increased fat deposition in the mesentery, or, infrequently, mesenteric lymphadenopathy. Involved loops may demonstrate angulation and fixation resulting from retraction of the thickened fibrotic mesentery.

COMPLICATIONS

Strictures

Strictures are the most common complication of Crohn disease requiring surgical intervention. These are due to rigid narrowing of the gut lumen, contributed to by mural inflammation, fibrosis, and smooth muscle hypertrophy. The luminal surfaces of involved

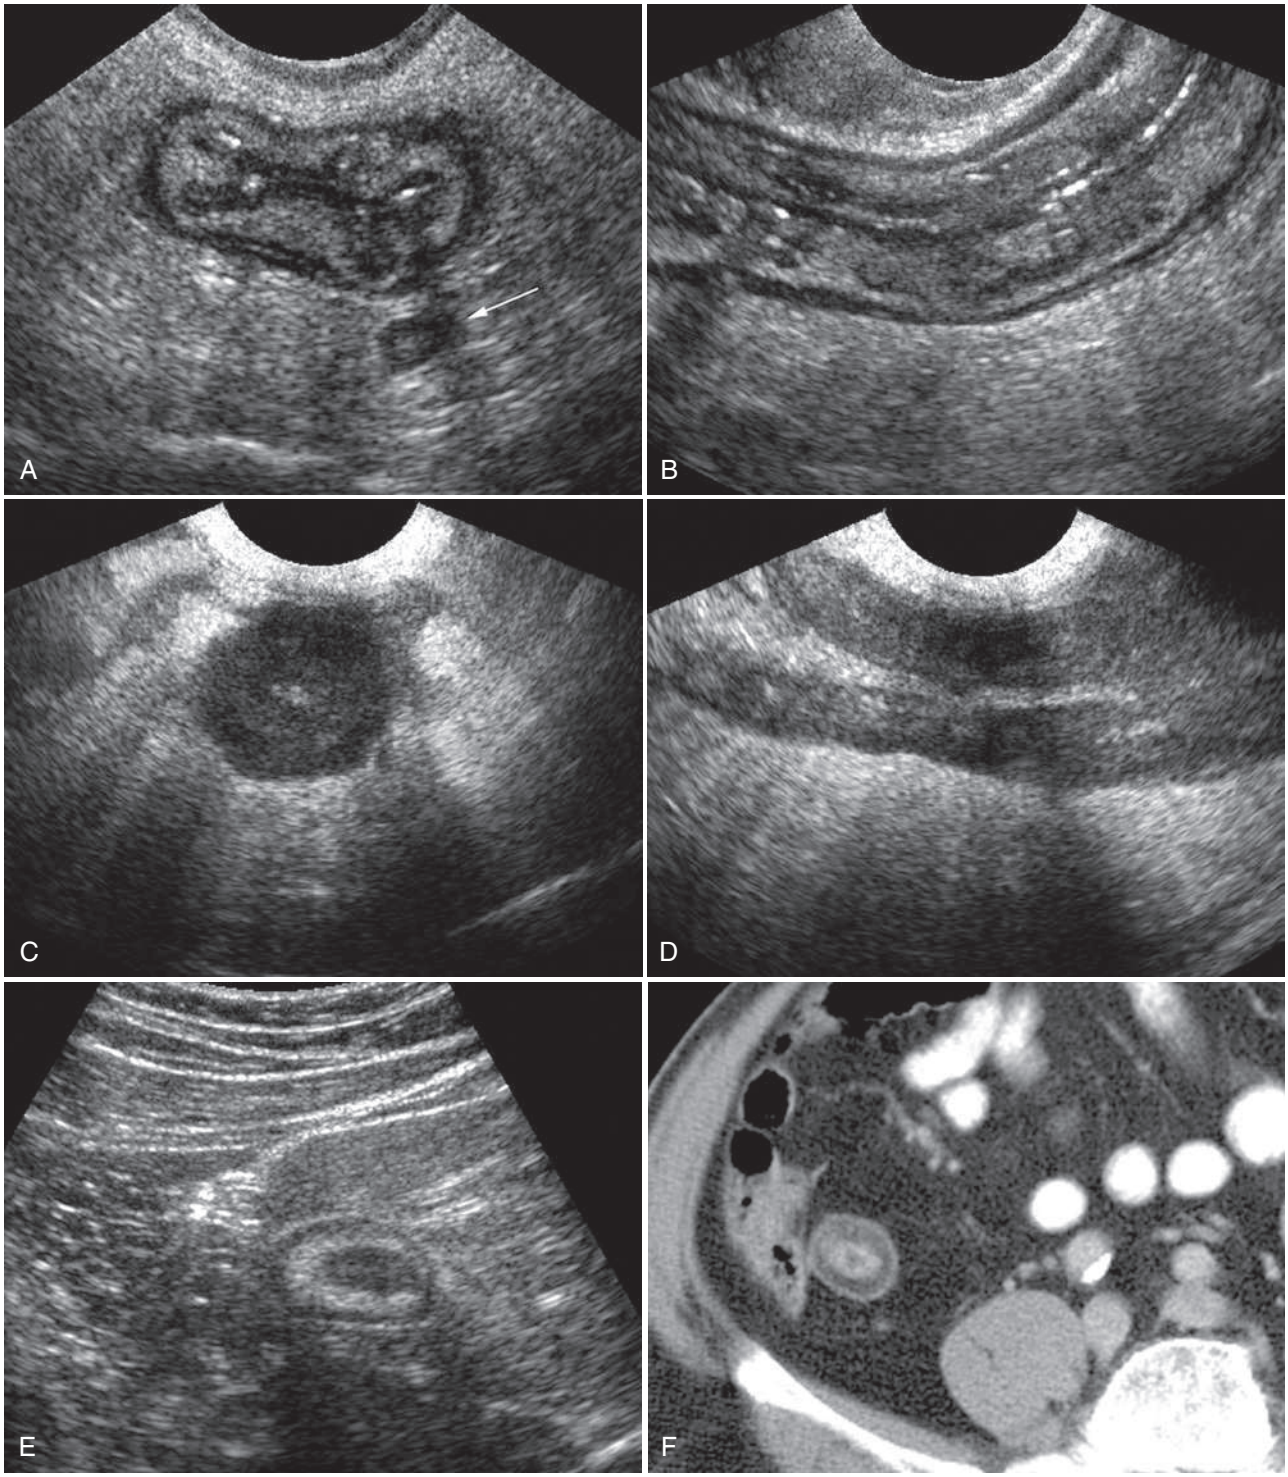

FIG. 8.13 Gut Wall Thickening in Three Patients With Crohn Disease. (A) Cross-sectional and **(B)** sagittal views showing the typical thickening in active disease with wall layer retention; *arrow,* lymph node. **(C)** Cross-sectional and **(D)** sagittal views show complete loss of wall layering, as seen with active disease. **(E)** Sonogram and **(F)** corresponding CT image of the terminal ileum in a patient with burnt-out disease and fatty deposition in the submucosa, which appears echogenic on the sonogram. See also Videos 8.2 and 8.3. (**C** and **D** with permission from Wilson SR. The bowel wall looks thickened: what does that mean? In: Cooperberg PL, editor. RSNA categorical course syllabus. Chicago: RSNA; 2002. pp. 219-228.[1])

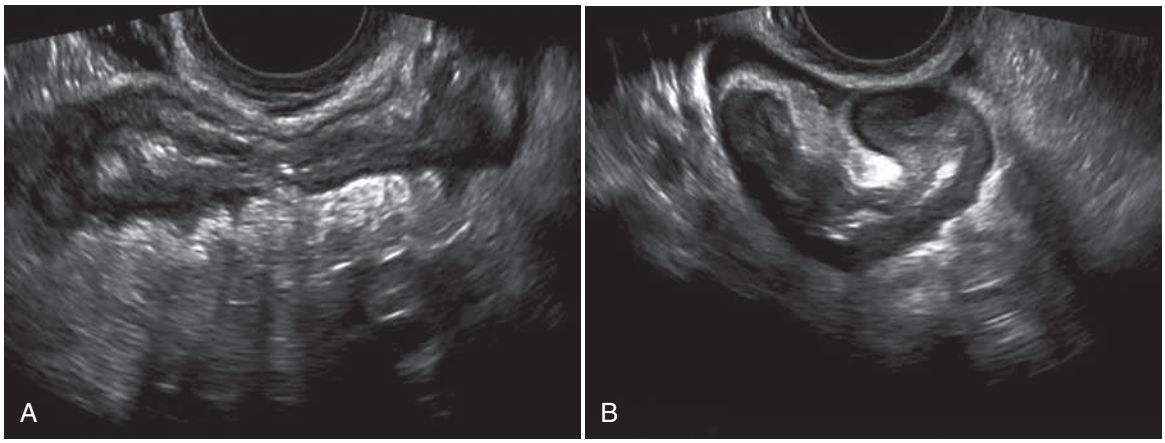

FIG. 8.14 Concerning Features for Severe Disease and Complication on Bowel Ultrasound in Two Patients. (A) A long-axis view of the terminal ileum shows bowel wall thickening and abundant surrounding echogenic inflammatory fat. The serosal margin of the bowel shows spiculation. **(B)** A long-axis view of the terminal ileum shows a hypoechoic bowel with loss of wall layering. There is a fixed acute angulation as well as spiculation of the serosal margin. Both the spiculation and fixed angulation have an association with stricture and perforation.

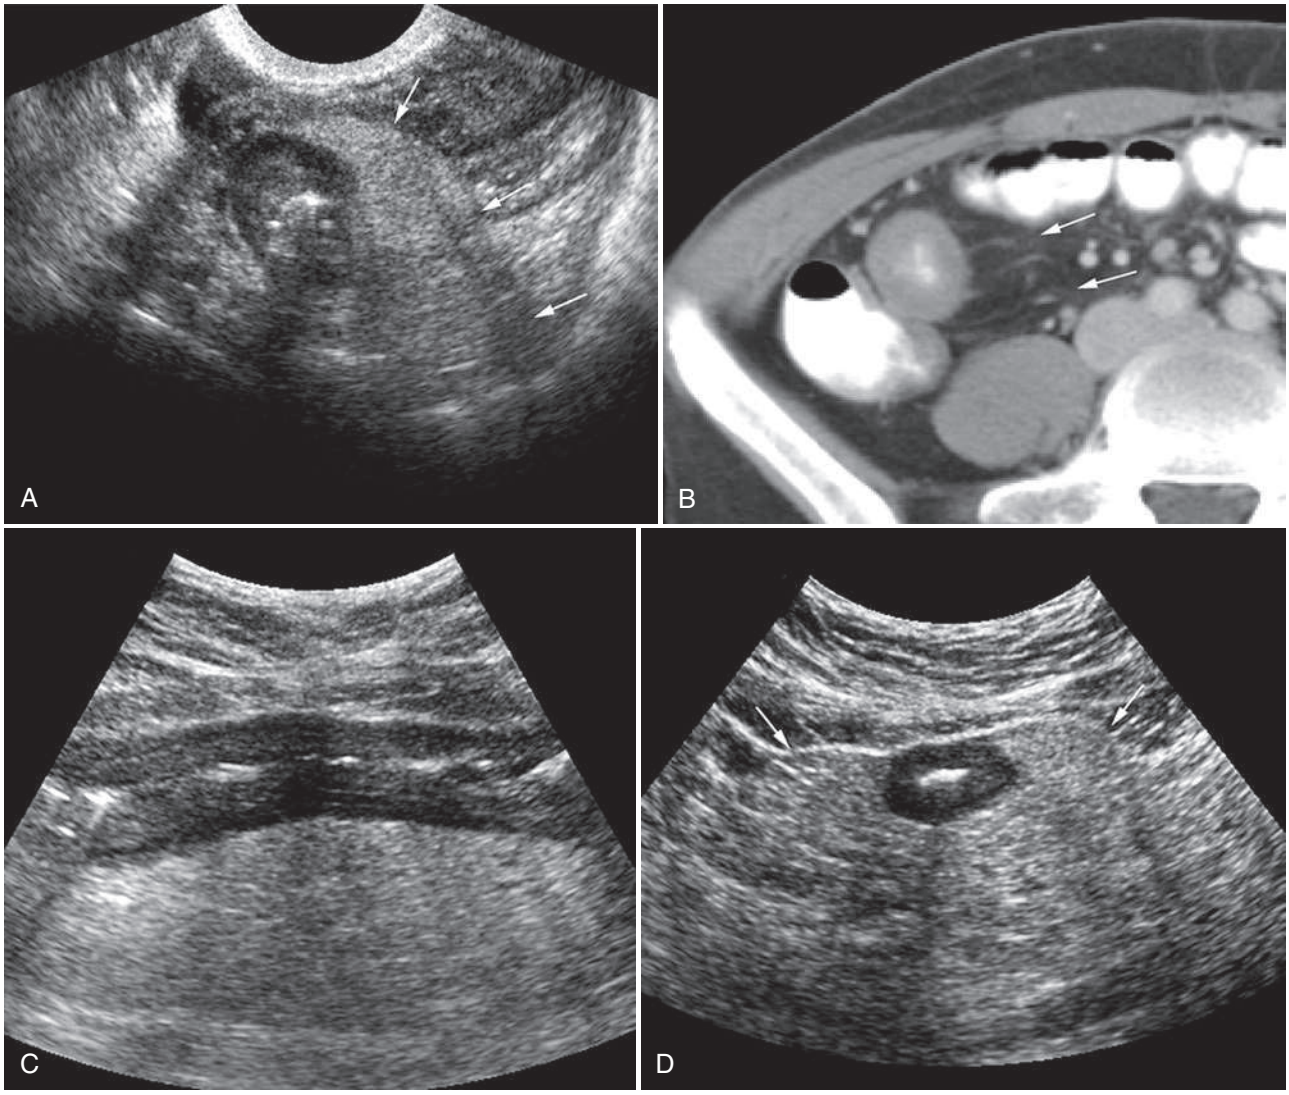

FIG. 8.15 Creeping Fat in Two Patients With Crohn Disease. (A) Cross-sectional view of terminal ileum shows a hyperechoic mass effect *(arrows)* along the medial border of the gut representing creeping fat. **(B)** Confirmatory CT scan shows both the thick wall of the terminal ileum and the streaky fat *(arrows)*. In another patient, **(C)** long-axis and **(D)** cross-sectional images of the sigmoid colon show gut wall thickening and surrounding echogenic inflammatory fat *(arrows)*.

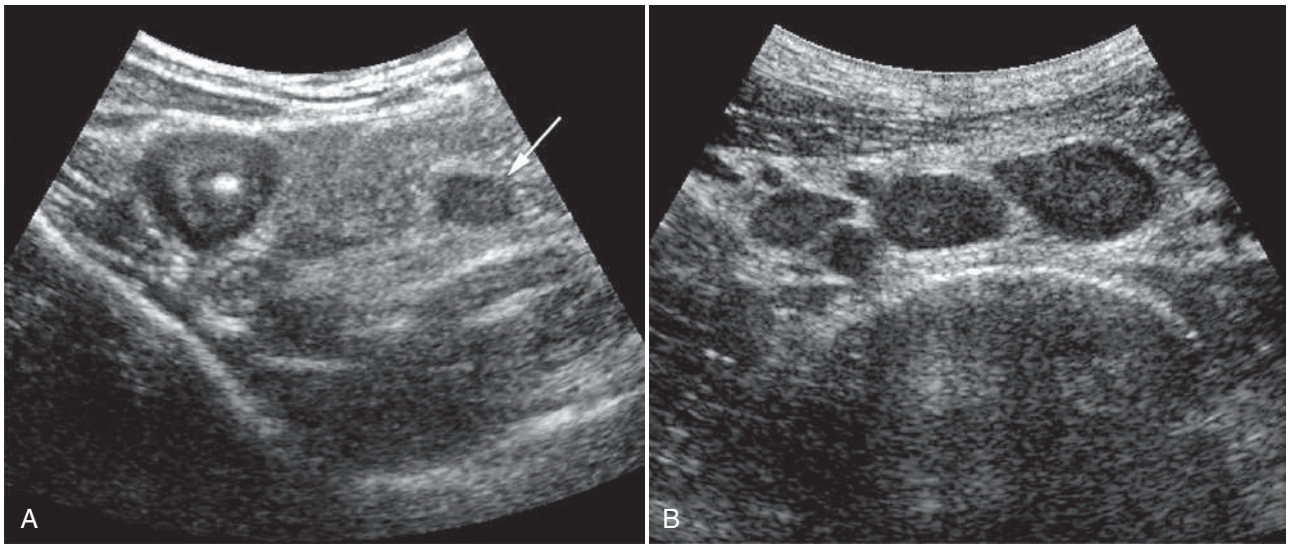

FIG. 8.16 Lymphadenopathy in Two Patients With Crohn Disease. (A) Transverse image in the right lower quadrant shows a thick terminal ileum in cross section. There is inflamed fat in the location of the mesentery. A mesenteric node *(arrow)* shows as a small, solid, hypoechoic mass within the fat. **(B)** Multiple mesenteric nodes of varying size show as hypoechoic soft tissue masses within the mesentery, optimally shown in an oblique plane between the region of the ileocecal valve and the aortic bifurcation.

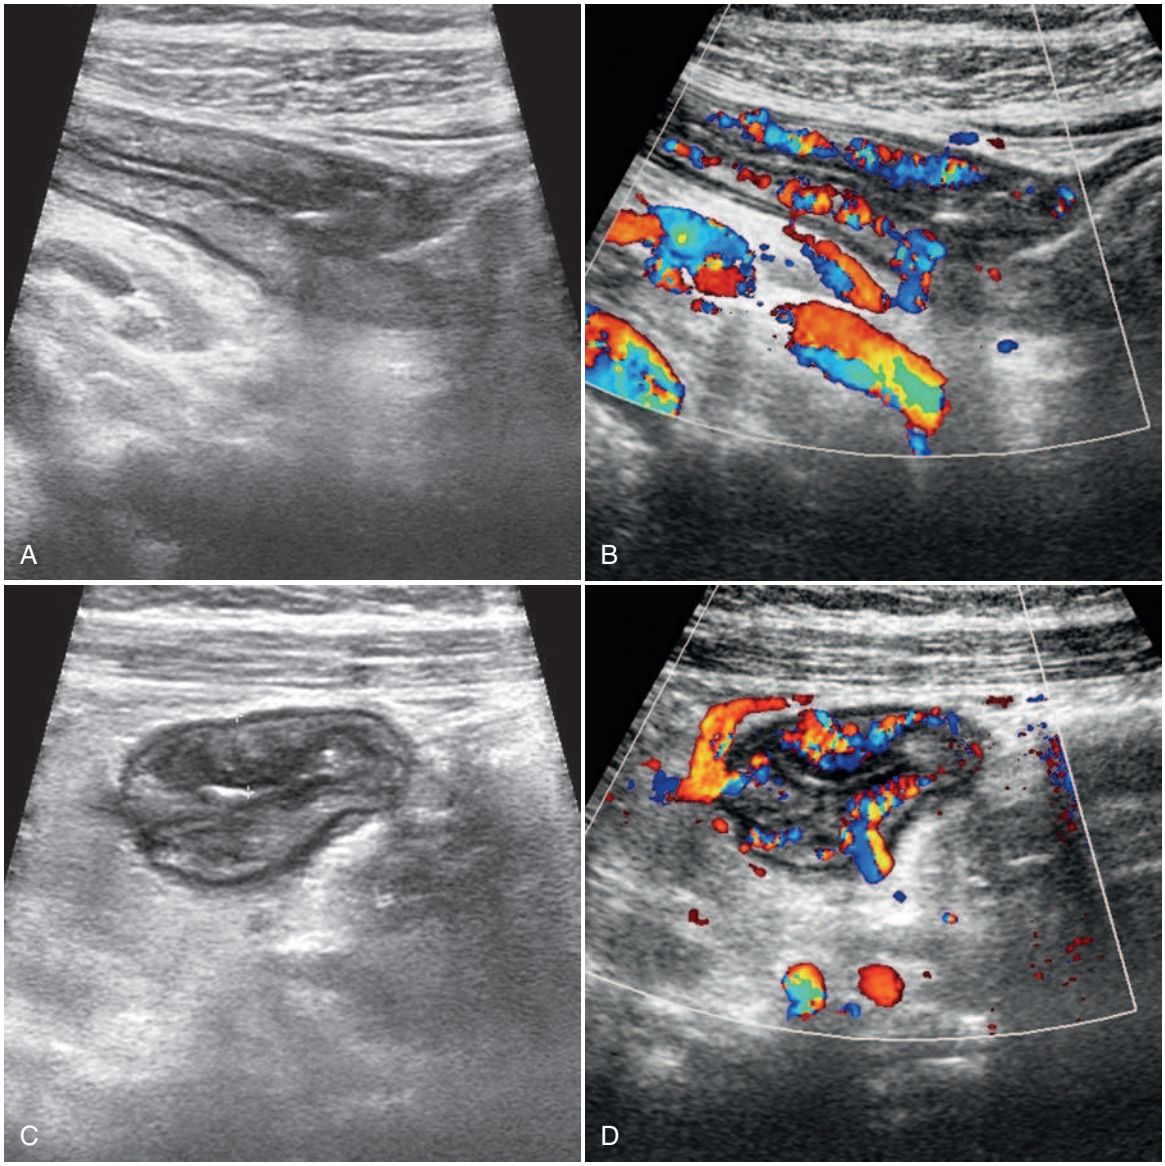

FIG. 8.17 Classic Features of Active Crohn Disease. Gray-scale **(A, C)** and color Doppler **(B, D)** images of the terminal ileum show moderate wall thickening (7 mm), moderate inflammatory fat, and moderate hyperemia on color Doppler imaging. See also Videos 8.4 and 8.5.

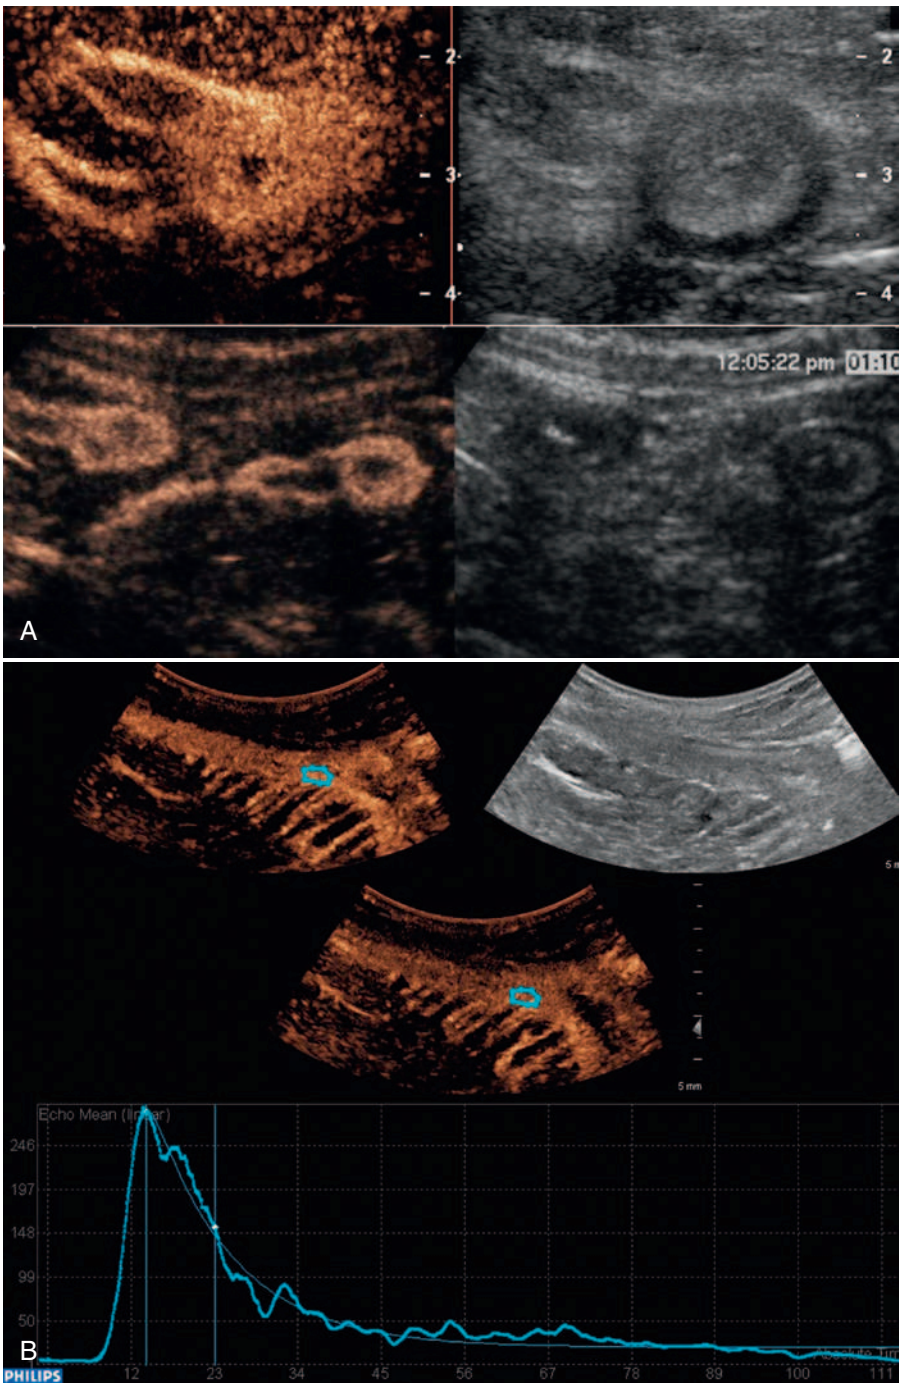

FIG. 8.18 Contrast-Enhanced Ultrasound of the Bowel in Crohn Disease, Subjective and Objective. **(A)** Two images of contrast-enhanced bowel, axial view, show the comblike vessels from vascularization of the mesentery and the transmural enhancement of the bowel wall. The adjacent images on the right are low mean intensity poor detail gray-scale, used for reference. **(B)** Images are in long axis. A region of interest in the bowel wall and a subsequent objective time intensity curve allow measurement of the peak enhancement and area under the curve. At the bottom is the time intensity curve that allows for quantification of the enhancement parameters. See also Videos 8.6 and 8.7. (**A** with permission from Wilson S. Evaluation of the small intestine by ultrasonography. In: Gourtsoyiannis N, editor. Radiologic imaging of the small intestine. Heidelberg: Springer-Verlag; 2002. pp. 73-86.[18])

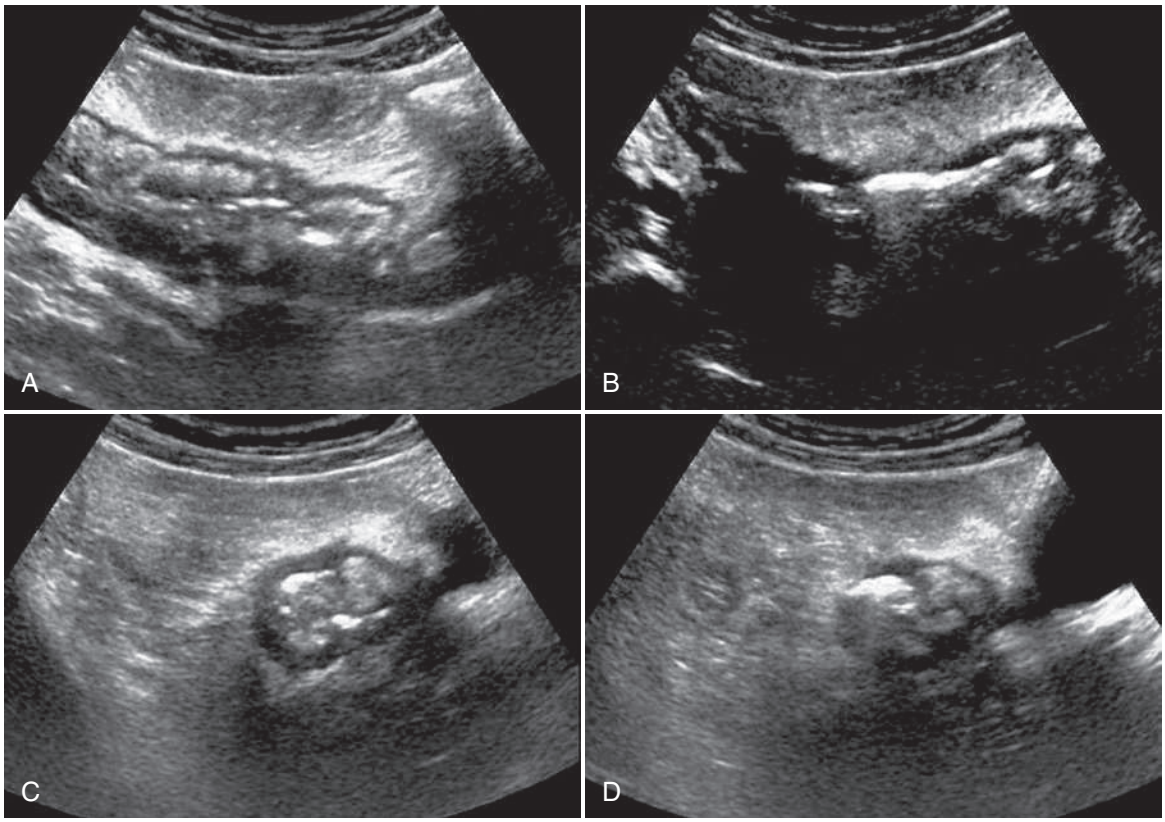

FIG. 8.19 Intramural Sinus Tract in Active Crohn Disease of the Neoterminal Ileum. (A) and **(B)** Long-axis views of the terminal ileum show wall thickening and surrounding abundant inflammatory fat. The luminal surfaces are in apposition and are central within the thickened loop. **(B)** Bright echogenic line running parallel to the serosa, an intramural sinus tract filled with air. **(C)** and **(D)** Axial images show two bright echogenic linear streaks suggesting air dissected within the layers of the bowel, deep to the echogenic submucosal layer.

segments of gut most often appear to be in fixed constant apposition, with the lumen appearing as a linear echogenic central area within a thickened gut loop (Fig. 8.20). This is in contrast to thickened sections, where the luminal diameter may be maintained (Fig. 8.21). Fixed acute angulations are frequent associations with advanced strictures (Video 8.8). Incomplete mechanical obstruction may be inferred if dilated, hyperperistaltic segments are seen proximal to a stricture (Fig. 8.21C and D, Videos 8.9 and 8.10). Peristaltic waves from the obstructed gut, proximal to a narrowed segment, may produce visible movement through the strictured segment. Less often, involved segments of gut show luminal dilation with sacculation, as well as narrowing, and the retained lumen is of variable caliber. Concretions and bezoars may develop in gut between strictured segments.

Parente et al.[31] showed that bowel ultrasound is an accurate technique for detecting small bowel strictures, especially in patients with severe disease who are candidates for surgery.

Management of strictures in Crohn disease is challenging. Differentiating between patients who have a predominantly inflammatory versus a mainly fibrotic component of their stricture is imperative to improve selection between medical therapy and surgery. Investigations using only gray-scale ultrasound features are frequently inconclusive.

However, bowel ultrasound has been shown to detect fibrosis using a variety of elastographic techniques. Shear wave elastography uses acoustic radiation force impulse technology to assess elastic properties of tissue through an acoustic ultrasound force that propagates a shear wave through tissue. Measurements of the velocity in meters per second (m/sec) of this shear wave traversing through the tissue are made. Shear wave elastography provides an objective and reproducible quantitative measurement of tissue stiffness.[32] Early investigations assessing fibrosis in animal models with elastography show some promising results.[33] Our recent experience combines both CEUS and point shear wave elastography. Our results suggest CEUS parameters reflect inflammation and elastography values reflect the chronic features of fibrosis and smooth muscle hypertrophy, improving greatly our contributions to patient management.[34]

Incomplete Mechanical Bowel Obstruction

Obstructive symptoms of bloating abdominal pain and abdominal distention are frequently associated with stricture in IBD. On sonography, distended prestenotic loops of bowel are fluid distended and show dysfunctional and excess peristalsis (see Fig. 8.21C and D, Videos 8.9 and 8.10).

Localized Perforation

Although free perforation of the bowel is rare in Crohn disease, localized perforation with phlegmonous masses contained within the surrounding perienteric inflammatory fat is common

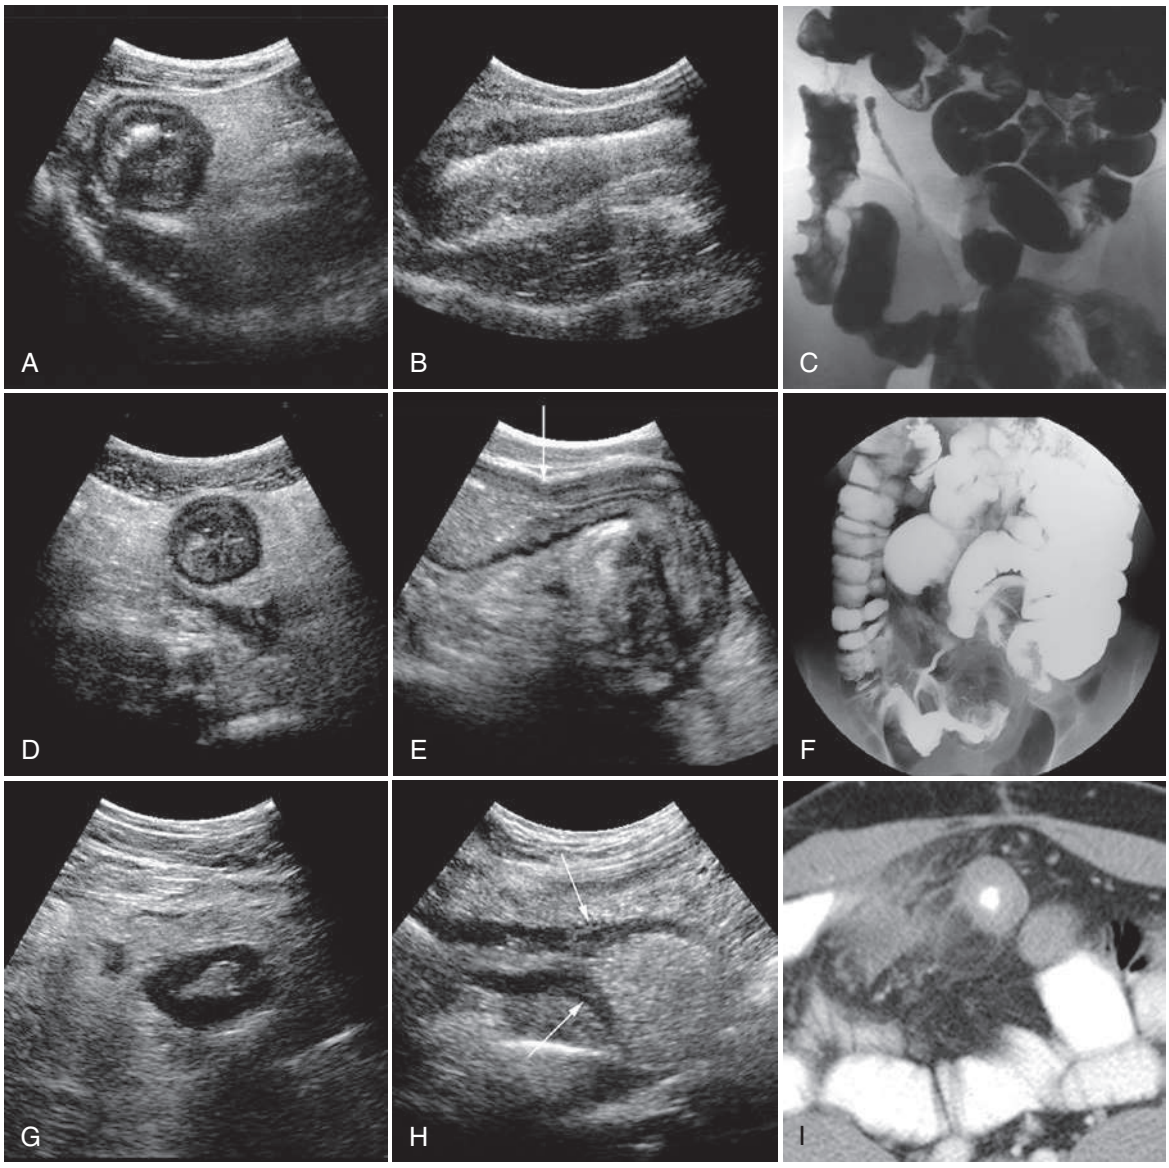

FIG. 8.20 Strictures in Three Patients With Crohn Disease. **(A)** An axial view of the terminal ileum shows wall thickening and surrounding inflammatory fat. **(B)** The long-axis image shows long segment thickening with luminal apposition. **(C)** Confirmatory fluoroscopic image from a small bowel enema shows the long, tight stricture in the ileum. **(D)** and **(E)** Sonograms of the terminal ileum show an abrupt transition in the caliber of the gut *(arrow).* The gut proximal to the arrow is dilated and fluid filled. The distal gut has a stricture, confirmed on **(F)**, the small bowel enema. **(G)** Short-axis image through the stricture shows the thickened wall and surrounding inflamed fat. **(H)** Long-axis image of the neoterminal ileum shows a thickened, featureless wall with a caliber alteration *(arrows).* **(I)** Confirmatory CT scan.

(Fig. 8.22, Video 8.11). Spiking of the border of acutely inflamed gut is characteristic (see Fig. 8.14). On occasion, an air-containing tract may be identified, traversing the bowel wall into the perienteric fat. Phlegmonous masses should alert the sonographer to possible underlying localized perforation.

Inflammatory Masses

Inflammatory masses involving the fibrofatty mesentery are the most common complication of Crohn disease, although the development of abscesses with drainable pus occurs infrequently. Before the stage of liquefaction, phlegmonous change may be noted as poorly defined, hypoechoic areas without fluid content interdigitating into the surrounding inflamed fat (Figs. 8.23A and B and 8.24A). Abscess formation results in a complex or fluid-filled mass (Figs. 8.23G-I and 8.24B). Gas content within an abscess is helpful in suggesting an abscess, but this gas content is also a potential source of sonographic error, particularly if large quantities are present. Abscesses may be intraperitoneal or extraperitoneal or may be in remote locations such as the liver, abdominal wall (Fig. 8.23H and I), and psoas muscles. An excellent application of CEUS is in the characterization of inflammatory masses related to the bowel in a variety of clinical situations. The differentiation of phlegmonous inflammatory masses, without drainable pus, from those with liquid content

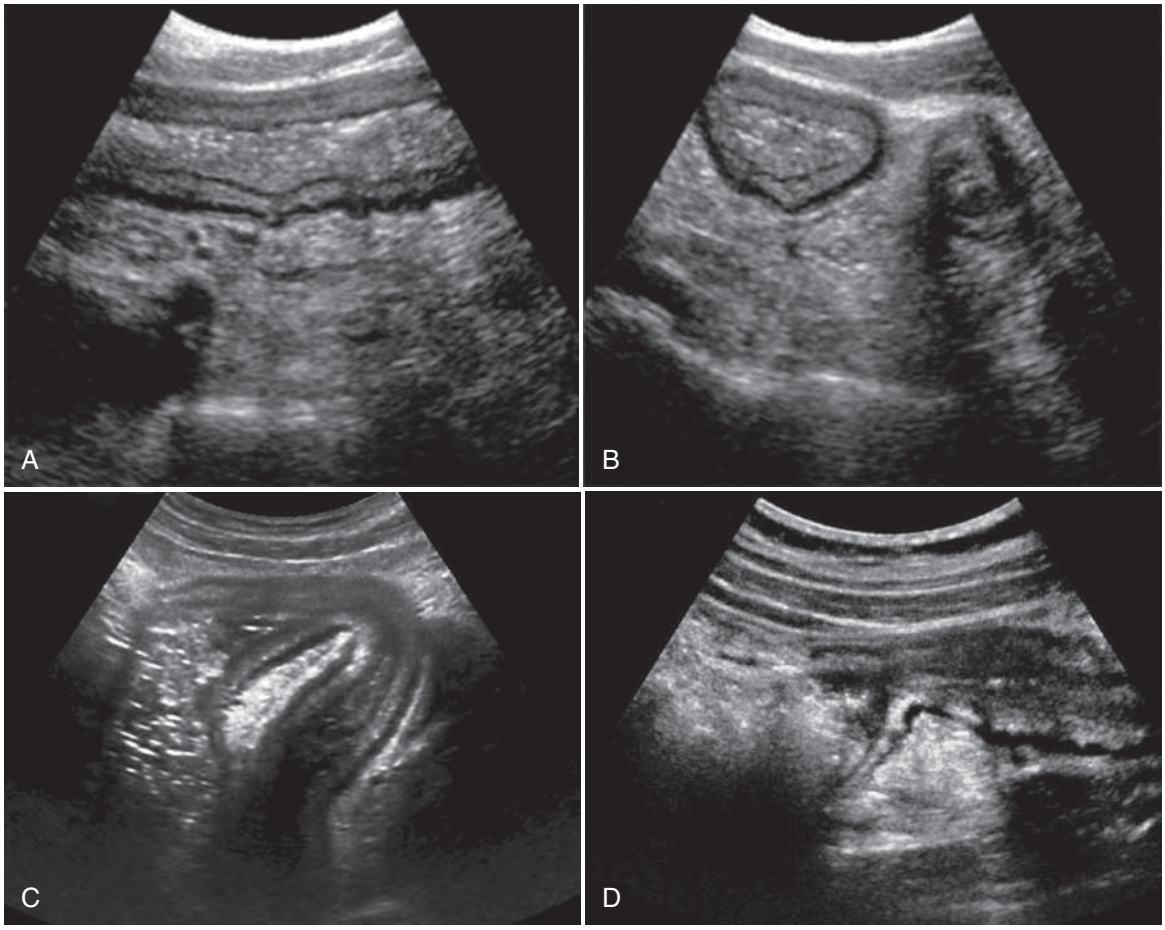

FIG. 8.21 Bowel Proximal to a Stricture in Three Patients. (A) and **(B)** Images of the small bowel slightly proximal to a stricture show a fluid-distended lumen and moderate mural wall thickening. **(C)** and **(D)** Two patients with prestenotic fluid-distended bowel and a stricture distal with an obvious transition point. See also Videos 4.9 and and 4.10.

is frequently a challenge.[35] The addition of CEUS will quickly and effectively differentiate these masses as phlegmons are invariably hypervascular, whereas all fluid-containing abscesses are completely avascular on CEUS (Fig. 8.25)

Fistula Formation

This characteristic penetrating complication of Crohn disease occurs most often at the proximal end of a thickened, strictured segment of bowel. Although mucosal ulcerations are not well assessed on sonography, deep fissures in the gut wall or intramural sinus tracts appear as echogenic linear areas penetrating deeply into the wall beyond the margin of the gut lumen (see Fig. 8.22, Video 8.11). With fistula formation, linear bands of varying echogenicity can be seen extending from segments of abnormal gut to the skin (Fig. 8.26C), bladder (Figs. 8.26B and 8.27D), vagina, or other abnormal loops (Video 8.12). If there is gas or movement in the fistula during the sonographic study, the fistula will usually appear bright or echogenic, with or without ring-down artifact related to air in the tract. Conversely, if the tract is empty or partially closed, the fistula may appear as a hypoechoic or hypoechoic tract. Palpation of the abdomen during the examination may produce movement of fluid or air through the fistula, assisting in its identification.

Perianal Inflammatory Disease

Perianal inflammation is a frequent and debilitating complication of Crohn disease and its presence at initial diagnosis is a poor prognostic indicator. Highly complex, transsphincteric tracts may extend to involve the deep tissues of the buttocks (Fig. 8.28), perineum, scrotum (men), and labia and vagina (women). Unlike commonly encountered perianal fistulas based on the cryptoglandular theory, fistulas in Crohn disease have no predilection for the location of the internal openings and are highly complex. In patients of either gender, we have found **transperineal scanning** to be the most comfortable and often most informative technique, performed alone or in combination with transrectal ultrasound.[36] Further, in women, transvaginal scan contributes greatly to our assessment of rectal and perirectal disease. It is also ideal for showing enterovesical, enterovaginal, and rectovaginal fistulas.[37] Rectal involvement in Crohn disease is characterized by (1) thickening of the rectal wall with wall layer preservation, (2) inflammation of the perirectal fat, and (3) enlargement of the perirectal lymph nodes.

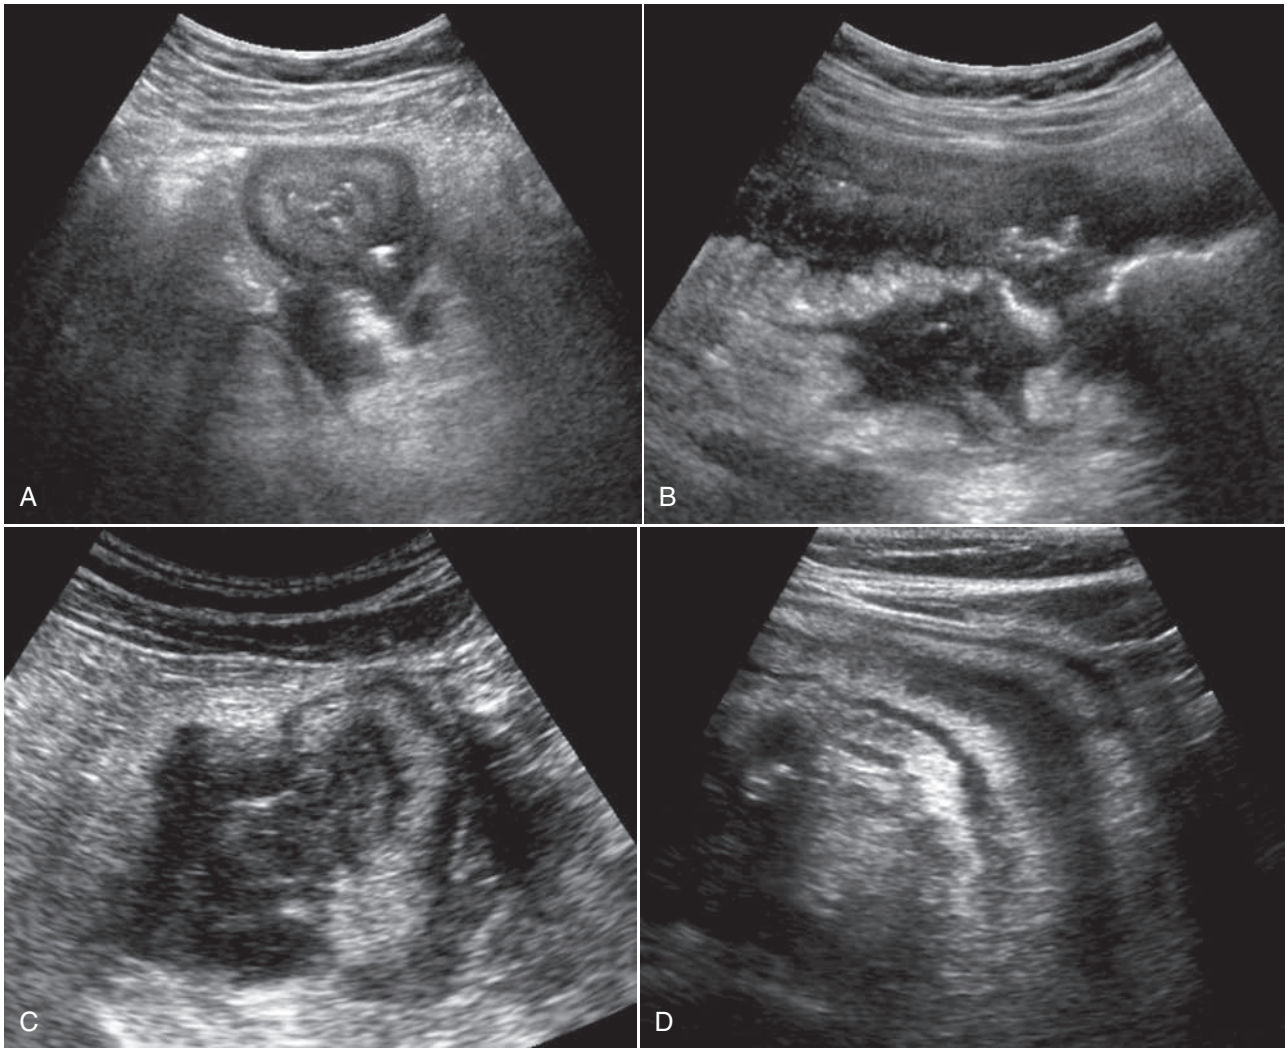

FIG. 8.22 Localized Perforation With Phlegmon. Two young women with acute flare of Crohn disease symptoms. **(A)** and **(B)** First patient. **(A)** Cross-sectional and **(B)** long-axis images of the bowel show wall thickening and a deep hypoechoic mass with fingerlike projections into the surrounding perienteric fat, suggesting phlegmon. Also, on **(A)**, air appears as a bright focus extending beyond the lumen of the bowel into the bowel wall, suggesting localized perforation. **(C)** and **(D)** Second patient. **(C)** Cross-sectional image of the ileum shows a large area of disruption of the bowel wall, an adjacent hypoechoic phlegmon, and an air tract from localized perforation. **(D)** Long-axis image of loop of ileum shows that the wall is uniformly thickened with layer preservation. The phlegmon is on the margin of the bowel and not shown in the longitudinal view. See also Video 8.11.

ACUTE ABDOMEN

Sonography is a valuable imaging tool in patients with specific suspected acute GI abnormalities such as acute appendicitis or acute diverticulitis.[38] However, its contribution to the assessment of patients with possible GI tract disease is less certain. Seibert et al.[39] emphasized the value of ultrasound in assessing the patient with a distended and gasless abdomen and detecting ascites, unsuspected masses, and abnormally dilated, fluid-filled loops of small bowel. In my experience, sonography has been helpful not only in the gasless abdomen but also in a variety of other situations. The real-time aspect of sonographic study allows for direct patient–sonographer/physician interaction, with confirmation of palpable masses and focal points of tenderness. The doctrine "scan where it hurts" is invaluable and has led sonographers to describe the value of the sonographic equivalent to clinical examination with such descriptors as a sonographic Murphy sign or sonographic McBurney sign. Similar to the radiographic approach to plain film interpretation, a systematic approach is essential in the sonographic assessment of the abdomen in a patient with an acute abdomen of uncertain origin.

The abdominal ultrasound evaluation should include visible gas and fluid (to determine their luminal or extraluminal location), the perienteric soft tissues, and the GI tract itself. Identification of gas in a location where it is not usually found is a clue to many important diagnoses. The gas itself may appear as a bright, echogenic focus, but the identification of the artifacts associated with the gas pockets usually leads to their detection. These include both ring-down artifact and "dirty" shadowing. Extraluminal gas may be intraperitoneal (**Free intraperitoneal**

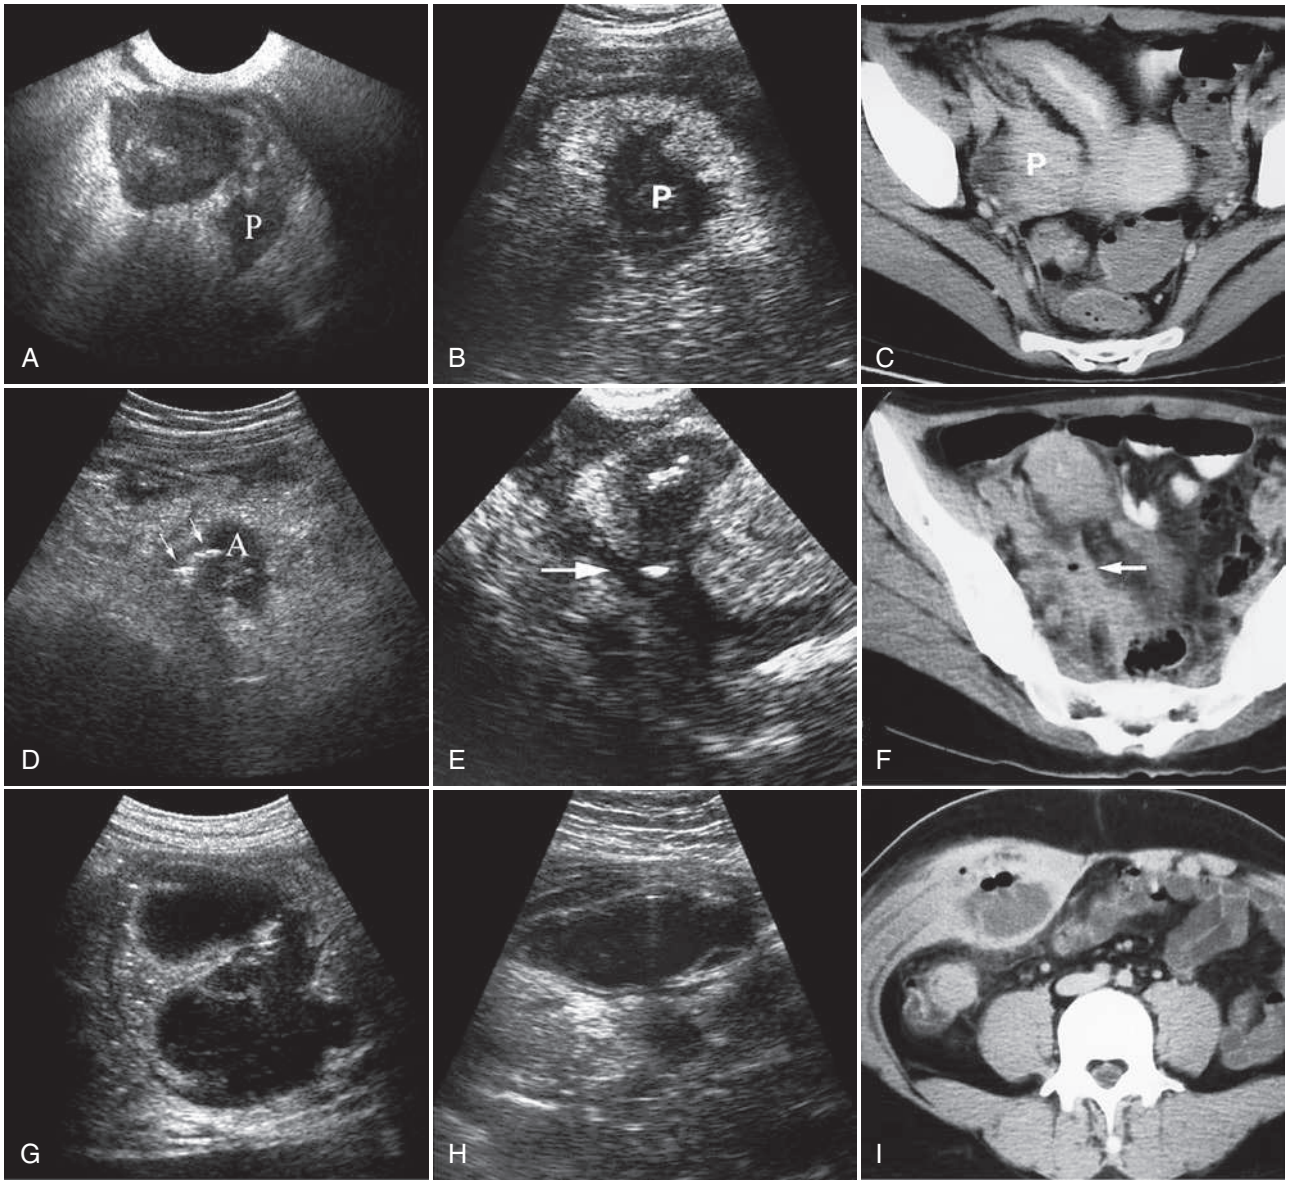

FIG. 8.23 Inflammatory Masses in Crohn Disease. *Top row,* **Phlegmons** *(P).* **(A)** Loop of thick sigmoid colon is seen in cross section. Adjacent to the margin is a poorly defined, hypoechoic zone within extensive inflamed fat. **(B)** Transverse sonogram in the right lower quadrant shows a thick terminal ileum superficially. Within the extensive inflamed fat is a poorly defined, hypoechoic zone representing the phlegmon. **(C)** Confirmatory CT scan. *Middle row,* **Inflammatory masses,** with air but no drainable pus. **(D)** Transverse image of the right lower quadrant shows abundant inflamed fat. Centrally, there is a small fluid collection or abscess *(A)* with small, echogenic shadowing foci *(arrows)* caused by air bubbles. **(E)** Cross-sectional sonogram through the terminal ileum shows gut thickening, echogenic inflamed fat, and a poorly defined, focal hypoechoic area deep to the gut. Bubbles of gas outside the gut are seen as bright, echogenic foci *(arrow)* on sonography. **(F)** Confirmatory CT scan. *Bottom row,* **Drainable abscesses. (G)** Large, interloop fluid collection. **(H)** Sonogram and **(I)** confirmatory CT scan show a superficial fluid collection with small gas bubbles in the anterior abdominal wall. (**B, E, F, H,** and **I** with permission from Sarrazin J, Wilson SR. Manifestations of Crohn disease at US. Radiographics. 1996;16[3]:499-520.[21])

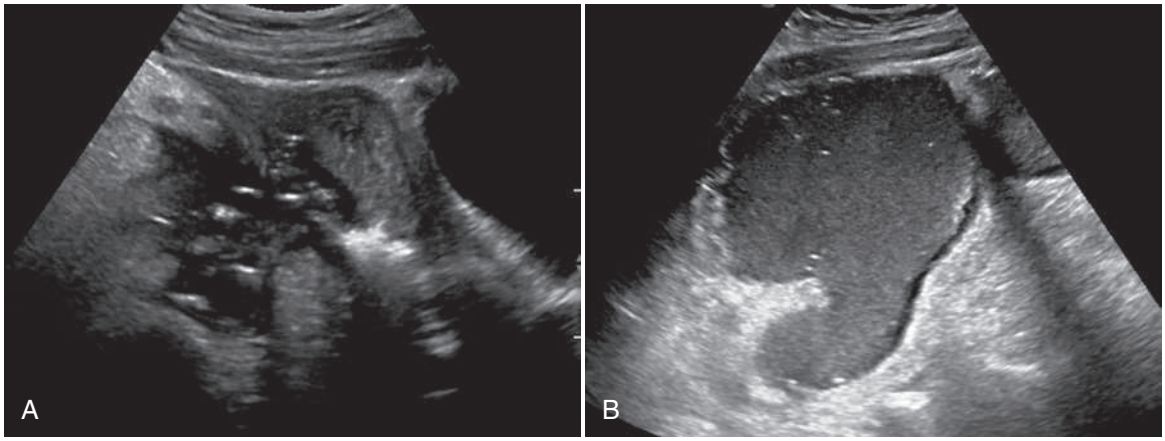

FIG. 8.24 Inflammatory Masses on Sonography. (A) Classic phlegmon with no drainable pus. The mass is hypoechoic and interdigtitates with the surrounding inflammatory fat. There are bright foci of extraluminal air within. **(B)** Classic abscess—a well-defined mass with uniform low-level echoes within related to the presence of pus.

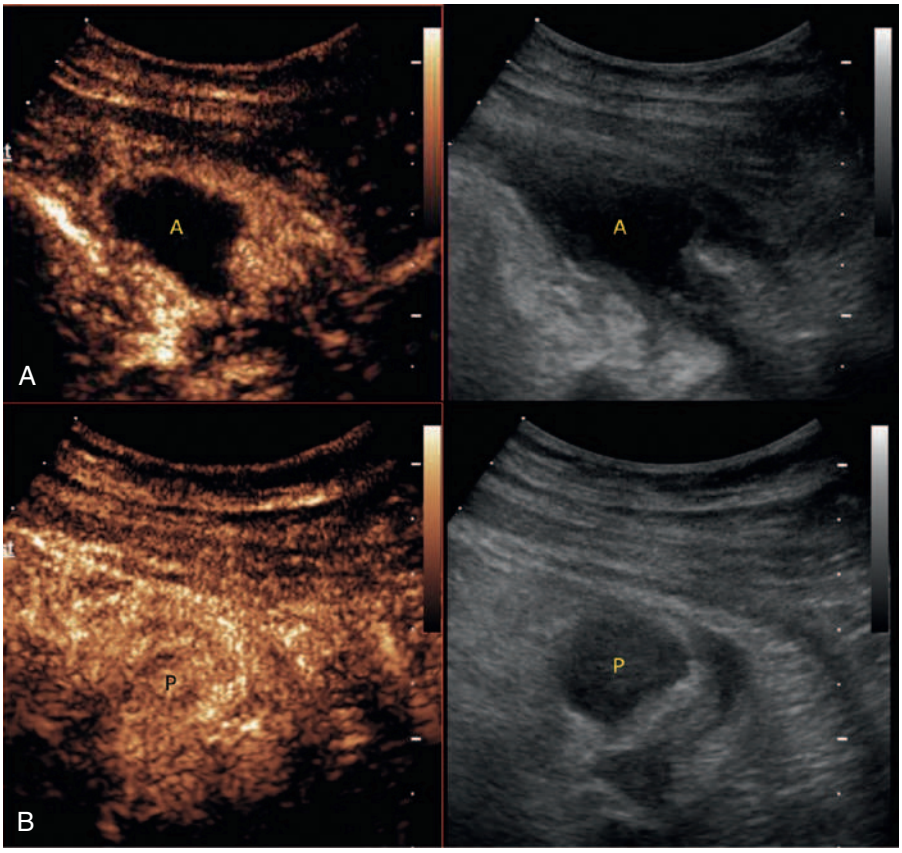

FIG. 8.25 Use of Contrast-Enhanced Ultrasound (CEUS) to Distinguish Between Abscess and Phlegmon; Exams in Two Patients. Both examinations include a contrast-enhanced image *(left)* and low-resolution gray-scale image *(right)*. **(A)** Hypoechoic mass on baseline is completely avascular on CEUS diagnostic for a fluid-containing abscess *(A)*. **(B)** Hypoechoic mass is uniformly vascular on CEUS, diagnostic for a hypervascular inflammatory mass, a phlegmon. Heidelberg: Springer-Verlag; 2002. pp. 73-86.[18])

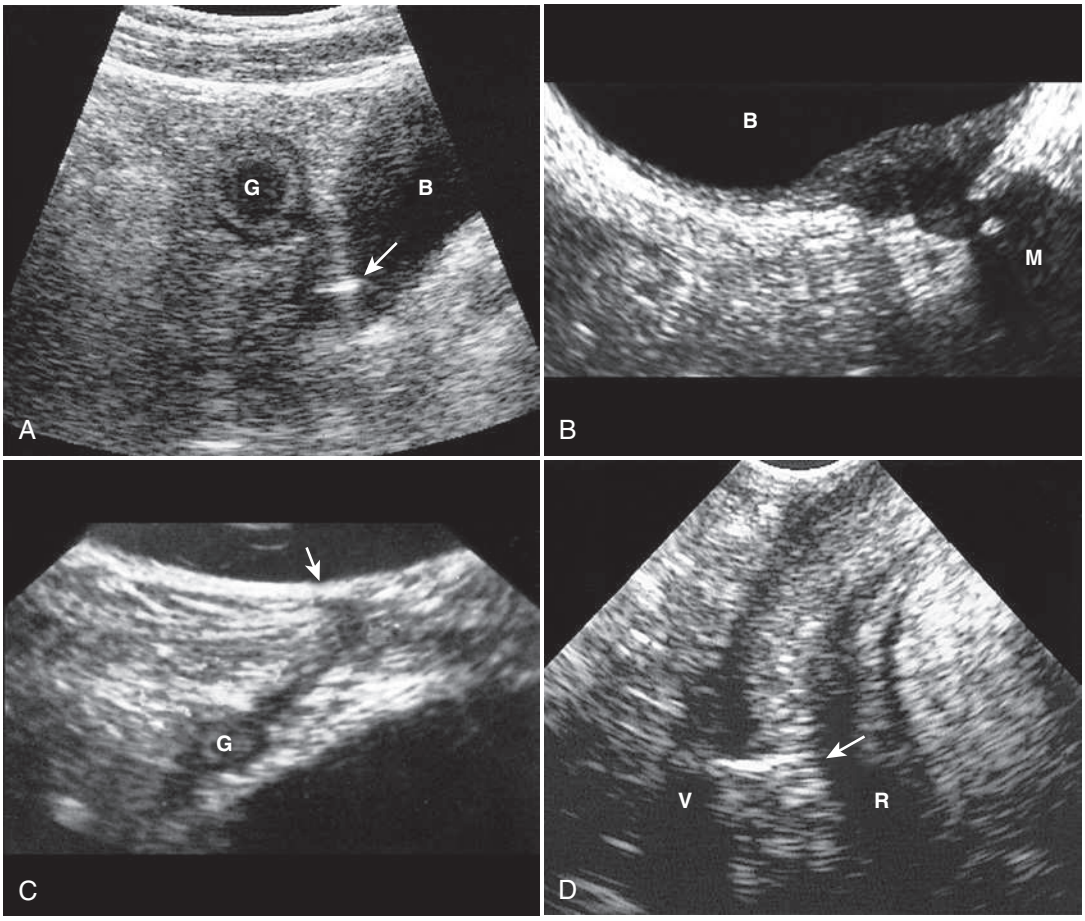

FIG. 8.26 Fistulas in Patients With Crohn Disease. (A) and **(B) Enterovesical fistulas. (A)** Tract between the abnormal gut *(G)* and the bladder *(B)*. An air bubble within shows as a bright, echogenic focus *(arrow)*. **(B)** Hypoechoic tract connects an inflammatory mass *(M)* to the bladder *(B)*. **(C) Enterocutaneous fistula.** Hypoechoic tract runs from a loop of abnormal gut *(G)* to the skin surface *(arrow)*. **(D) Rectovaginal fistula** on transvaginal sonogram appears as a bright, air-containing tract *(arrow)* coursing from the rectum *(R)* to the vagina *(V)*. See also Video 8.12 for **enteroenteric fistula.**

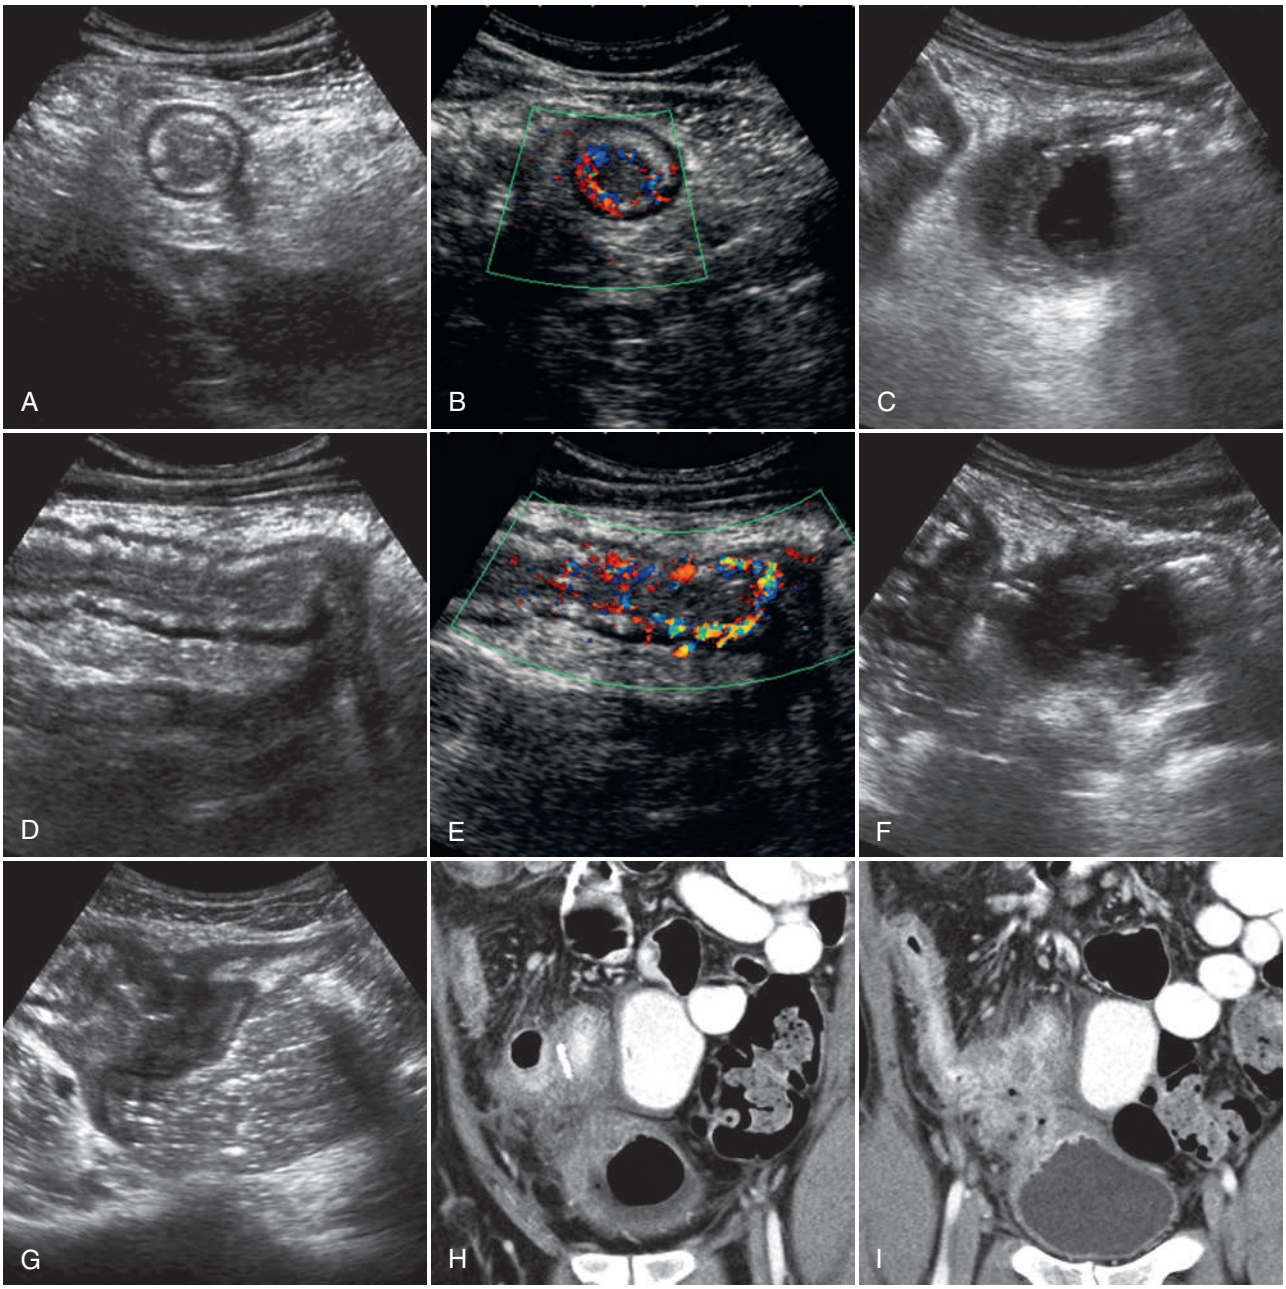

FIG. 8.27 Enterovesical Fistula in Crohn Disease. (A) and **(B)** Cross-sectional images of the terminal ileum show wall thickening and hyperemia. **(C)** Air in the bladder appears as nondependent bright echoes with dirty shadowing. **(D)** and **(E)** Long-axis views of the ileum show the hyperemia and the constant luminal apposition, consistent with stricture. **(F)** Bladder with the luminal air and an air-containing tract from the bladder to the adjacent bowel. **(G)** Dilated, fluid-filled bowel proximal to the thickening, suggesting incomplete mechanical bowel obstruction. **(H)** and **(I)** Coronal CT images confirm the bladder air and an inflammatory mass related to the bladder dome.

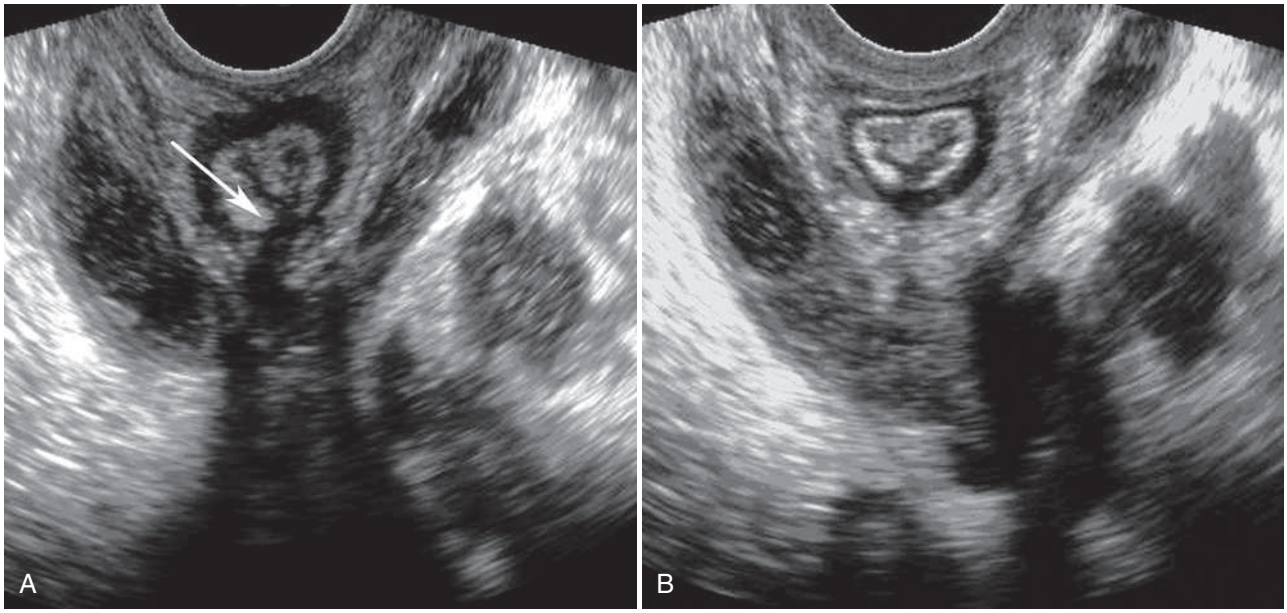

FIG. 8.28 Perianal Inflammatory Crohn Disease. (A) Axial image of the anal canal shows an internal opening *(arrow)* posteriorly at 6 o'clock. A transsphincteric fistula runs to a large, horseshoe-shaped posterior abscess more optimally shown in **(B)**, which also shows deeper collections in the left buttock.

air) or retroperitoneal, and its presence should suggest either hollow viscus perforation or infection with gas-forming organisms[40] (Fig. 8.29). Nonluminal gas may be easily overlooked, particularly if the collection is large. Gas in the wall of the GI tract, **pneumatosis intestinalis,** with or without gas in the portal veins, raises the possibility of ischemic gut.

The likelihood of gas artifacts between the abdominal wall and the underlying liver to be related to free intraperitoneal gas was well described by Lee et al.[40] In my group's work, we have found that the peritoneal stripe appears as a bright, continuous, echogenic line, and that air adjacent to the peritoneal stripe produces enhancement of this layer, because the gas has a higher acoustic impedance to sound waves than does the peritoneum itself. Careful peritoneal assessment is best done with a 5-MHz probe or even a 7.5-MHz probe, with the focal zone set at the expected level of the peritoneum. In a clinical situation, enhancement of the peritoneal stripe is a highly specific but insensitive sign to detect pneumoperitoneum.[41]

Loculated **fluid collections** can mimic portions of the GI tract. Left upper quadrant and pelvic collections suggestive of the stomach and rectum may be clarified by adding fluid orally and rectally. Assessing peristaltic activity and wall morphology also helps in distinguishing luminal from extraluminal collections. Interloop and flank collections are aperistaltic and tend to correspond in contour to the adjacent abdominal wall or intestinal loops, frequently forming acute angles, which are rarely seen with intraluminal fluid.

The appearance of the **perienteric soft tissues** is frequently the first and most obvious clue to abdominal pathology on abdominal sonograms. Inflammation of the perienteric fat shows as a hyperechoic mass effect (see Fig. 8.15), often without the usual appearance of normal gut and its contained small pockets of gas. Neoplastic infiltration of the perienteric fat is often

indistinguishable from inflammatory infiltration on ultrasound (see Fig. 8.8C and D).

Mesenteric adenopathy is another manifestation of both inflammatory and neoplastic processes of the gut that should be specifically sought when performing abdominal sonography. As elsewhere, lymph nodes tend to change in size and shape when replaced by abnormal tissue. A normal, oval or flattened lymph node with a normal linear hilar echo becomes increasingly round and hypoechoic with either inflammatory or neoplastic replacement. In contrast to the sonographic appearance of loops of gut, mesenteric lymph nodes typically appear as focal, discrete hypoechoic masses of varying size (see Fig. 8.16). Their identification on sonography suggests enlargement because they are not usually seen on routine examinations. In the presence of mesenteric adenopathy, abnormal masses related to or causing a GI tract abnormality should also be sought; these most often are neoplastic or inflammatory in origin.

Right Lower Quadrant Pain

Acute Appendicitis

Acute appendicitis is the most common explanation for the "acute abdomen presentation" to an emergency department. Patients typically have right lower quadrant (RLQ) pain, tenderness, and leukocytosis. A mass may also be palpable. The patient with a classic presentation may have an appendectomy without preoperative imaging. This approach often becomes complicated when a normal appendix is removed in a patient with symptoms caused by other factors. On the other hand, surgery may be delayed in some patients with acute appendicitis if the presentation is atypical. This approach may lead to perforation before the surgery, making it a complicated and difficult procedure, often followed by abscess formation. In older clinical literature before routine cross-sectional imaging was available, laparotomy resulted in removal of normal, noninflamed appendices in 16% to 47% of cases (mean, 26%).[42,43] Also, perforation occurred in up to 35%

of patients.[44] It is a balance between this negative laparotomy rate and the perforation rate at surgery that motivates cross-sectional imaging before initiating treatment for the patient with acute RLQ pain. For a patient with suspected appendicitis, the sonographic objectives are to identify the patient with acute appendicitis, to identify the patient without acute appendicitis, and, in this latter population, to identify an alternate explanation for the RLQ pain.

Symptoms of appendicitis, RLQ pain, and elevated white blood cell count overlap with a variety of other GI conditions, including **typhlitis, mesenteric adenitis, Crohn disease,** right-sided **diverticulitis, segmental infarction of the omentum,** and, in women, acute gynecologic conditions such as **ruptured or torsion of an adnexal cyst** or **pelvic inflammatory disease.**[45] Urologic disease, especially stone-related and right-sided segmental omental infarction, may also mimic acute appendicitis. Addressing the value of sonography in establishing an alternative diagnosis in patients with suspected acute appendicitis, Gaensler et al.[46] found that 70% of patients with another diagnosis had abnormalities visualized on the sonogram. From a retrospective review of 462 patients with suspected appendicitis who underwent appendectomy, Bendeck et al.[47] found that women in particular benefit most from preoperative imaging, with a statistically significant, lower negative appendectomy rate than women with no preoperative imaging.

Both CT and ultrasound provide sensitive and accurate diagnosis of appendicitis. The choice of imaging modality is determined somewhat by local expertise.[48] Some institutions also screen patients on the basis of their weight, sending thin patients for ultrasound and reserving CT for larger patients. These considerations aside, we recommend **sonographic evaluation of all women (and children)**—with the addition of transvaginal scan for all patients whose pain is still not explained after completion of a traditional suprapubic pelvic sonogram.

The pathophysiology of acute appendicitis likely involves obstruction of the appendiceal lumen, with 35% of cases demonstrating a fecalith.[49] Mucosal secretions continue, increasing the intraluminal pressure and compromising venous return. The mucosa becomes hypoxic and ulcerates. Bacterial infection ensues, eventually with gangrene and perforation. A walled-off abscess is more common than free peritoneal contamination.

Acute appendicitis begins with transient, visceral, or referred crampy pain in the periumbilical area associated with nausea and vomiting. Coincident with inflammation of the serosa of the appendix, the pain shifts to the RLQ and may be associated with physical signs of peritoneal irritation. Both clinical and experimental data support the belief that some patients have repeated attacks of appendicitis.[50,51]

In 1986 Puylaert[6] described the value of **graded compression sonography** in the evaluation of 60 consecutive patients suspected of having acute appendicitis. Puylaert's initial reports of success in diagnosing acute appendicitis depended solely on visualization of the abnormal appendix, a blind-ended, noncompressible, aperistaltic tube arising from the tip of the cecum with a gut signature (Fig. 8.30). However, other investigators reported seeing normal appendices on a sonogram.[52,53] The normal appendix is compressible, with a wall thickness of 3 mm or less[54] (Fig. 8.31, Video 8.13). Jeffrey et al.[55] concluded that size can differentiate the normal from the acutely inflamed appendix. Threshold levels for the diameter of the appendix, above which acute appendicitis is highly likely, have been set at either 6 mm or 7 mm, with a resultant change in sensitivity and specificity. Sonographic visualization of an appendix with an **appendicolith,** regardless of appendiceal diameter, should also be regarded as a positive test. Rettenbacher et al.[56] added assessment of appendiceal **morphology** in confirming suspicion of appendicitis. A round or partly round appendix had a high correlation with acute appendicitis, whereas an ovoid appendix did not. Color Doppler is also contributory, showing hyperemia in the appendiceal wall in the acutely inflamed appendix.

Lee et al.[57] described visualization of the appendix in 485 of 570 patients (85%) using graded compression sonography alone. Use of a posterior manual compression technique allowed for identification of the appendix in an additional 57 of the remaining 85 patients, increasing the percentage of identified appendices to 95%.

The appendix positioned in the true pelvis may show subtle evidence of inflammation on a suprapubic scan because the pathology may be deep in the pelvic cavity. In our experience, this occurs most often in women, possibly related to a more capacious pelvis, and the clinical presentation is frequently that of pelvic inflammatory disease. This particular disease is optimally studied with transvaginal placement of the ultrasound probe because the appendix is often intimately related to either the uterus or the ovaries. The origin of such an appendix from the base of the cecum may be impossible to determine on transvaginal sonography, and compression with the ultrasound probe is often not feasible. Nonetheless, the identification of the blind-ended tip of the appendix with an increased diameter, luminal distention, and inflammation of the surrounding fat is obvious (Fig. 8.32). If rupture of a pelvic appendix has occurred before the sonogram, the identification of a **pelvic abscess** without identification of the appendix itself may produce an equivocal result as to the source of the pelvic inflammatory problem.

Although the sensitivity of sonography for the diagnosis of appendicitis decreases with **perforation,** features associated with

Circumferential loss of submucosal layer of the appendix

its occurrence include loculated pericecal fluid, phlegmon or abscess, prominent pericecal or periappendiceal fat, and circumferential loss of the submucosal layer of the appendix[58] (Fig. 8.33, Video 8.14). False-positive diagnosis for acute appendicitis may occur if a normal appendix or a thickened terminal ileum is mistaken for an inflamed appendix.

Crohn Appendicitis

Patients with Crohn disease may have acute appendicitis caused by IBD involvement of the appendix, in contrast to acute suppurative appendicitis. The wall of the appendix typically is extremely thickened and hyperemic with wall layer preservation, and the luminal surfaces are often in apposition[59] (Fig. 8.34). This appearance contrasts with that in suppurative appendicitis, where luminal distention is the expectation and wall thickening is moderate at best.

Crohn appendicitis is a self-limited process,[60,61] and treatment may be conservative if the appropriate diagnosis can be established with noninvasive techniques. In a small number of the patients for whom we have suggested this diagnosis, follow-up sonograms have shown resolution of the sonographic findings with no disease progression. Patients with Crohn disease who present with Crohn appendicitis account for about 10% of total presentations. This patient population typically has a more benign course. If the appendix is removed surgically in the mistaken belief that the patient has acute suppurative appendicitis, recurrence or progression of Crohn disease is rare.

Right-Sided Diverticulitis

Acute inflammation of a right-sided diverticulum is distinct from the more common diverticulitis that is encountered in the left hemicolon. These diverticula occur more often in women than in men and have a predilection for Asian populations. Most patients are young adults. Right-sided diverticula are usually solitary and are congenital in origin. They are **true** diverticula and therefore have all layers of the gut wall. Their inflammation is associated with RLQ pain, tenderness, and leukocytosis, with a mistaken diagnosis of appendicitis in virtually all cases.

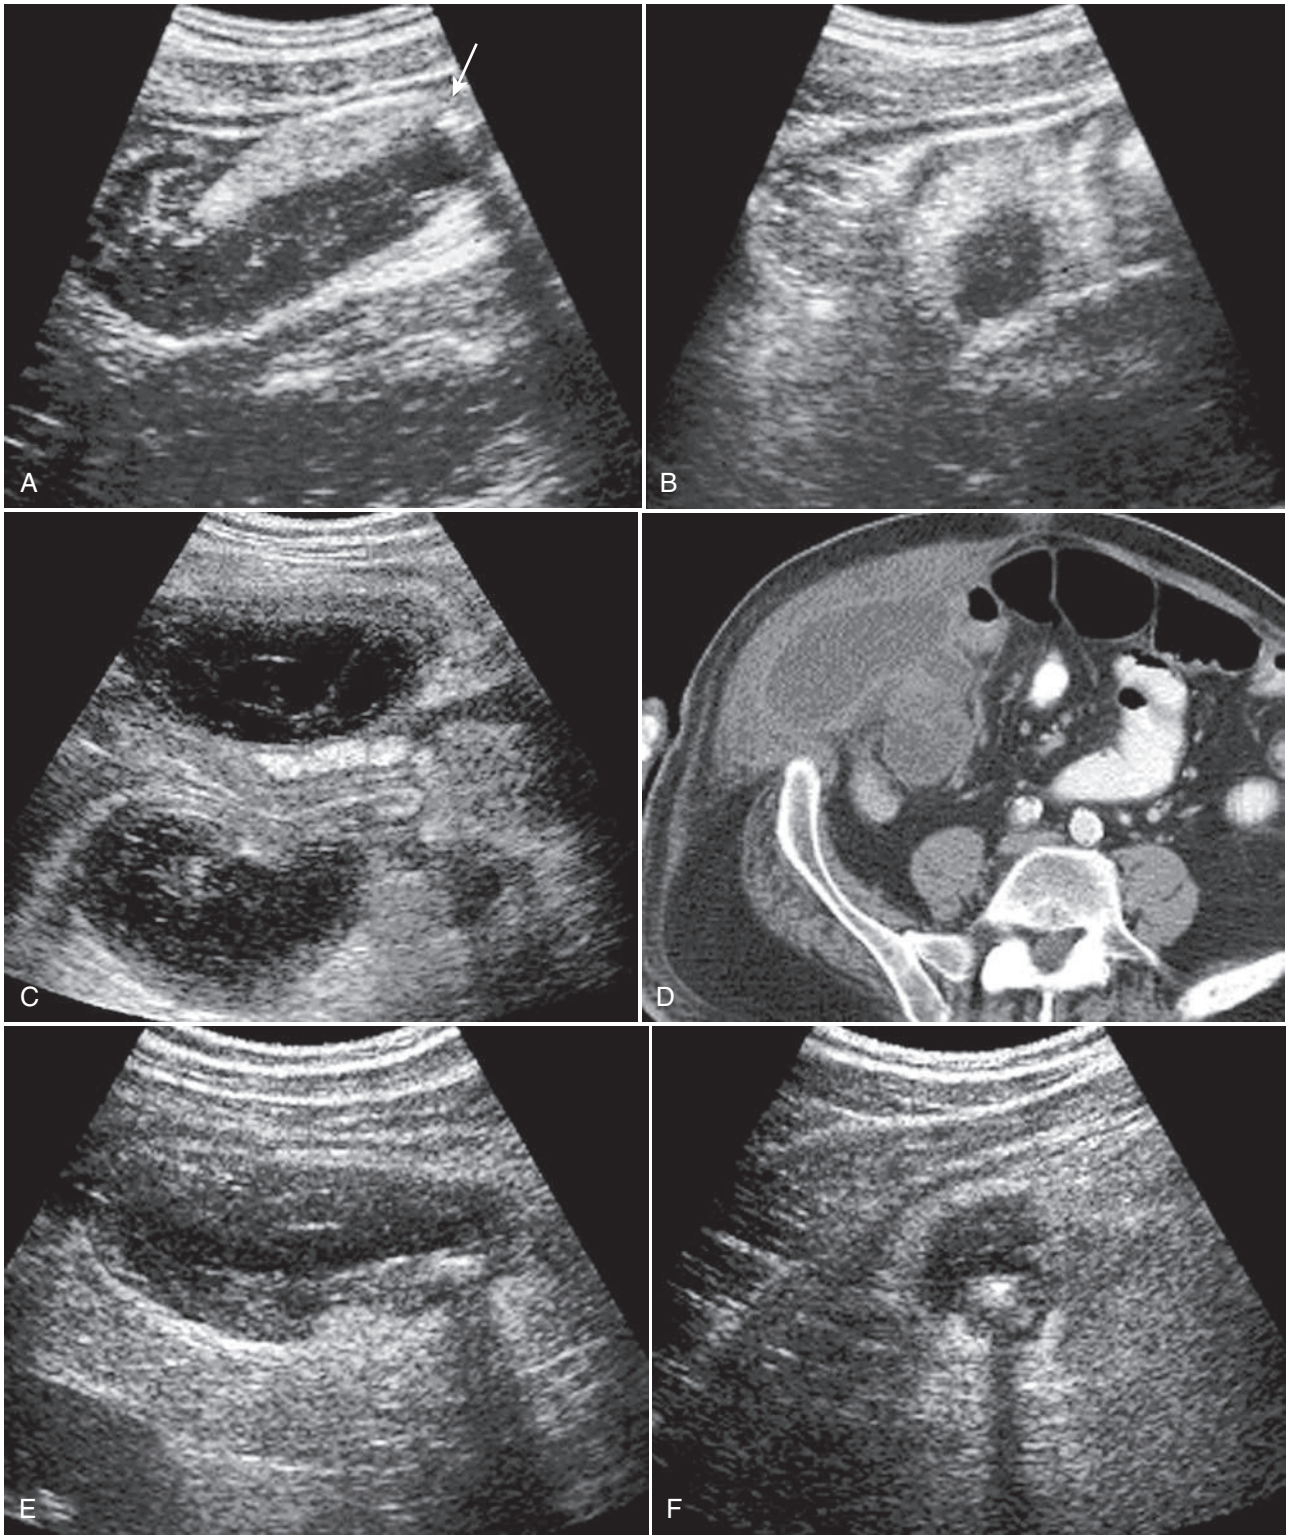

FIG. 8.33 Perforation of Appendix in Three Patients. (A) Long-axis image and **(B)** cross-sectional image show the blind-ended appendix. There is loss of definition of the wall layers, and the appendix is surrounded by an echogenic mass effect representing inflamed fat in the mesoappendix. **(A)** Arrow points to a bubble of extraluminal gas at the tip of the appendix; tip perforation was confirmed at surgery. **(C)** Sonogram and **(D)** CT scan show a **periappendiceal abscess.** The decompressed appendix is seen centrally on the sonogram. **(E)** Long-axis and **(F)** transverse images in the right lower quadrant show an abscess with an escaped **appendicolith** with acoustic shadowing. The appendix is no longer visible. See also Video 8.14. (**C** with permission from Birnbaum B, Wilson S. Appendicitis at the millennium. Radiology. 2000;215[2]:337-348.[48])

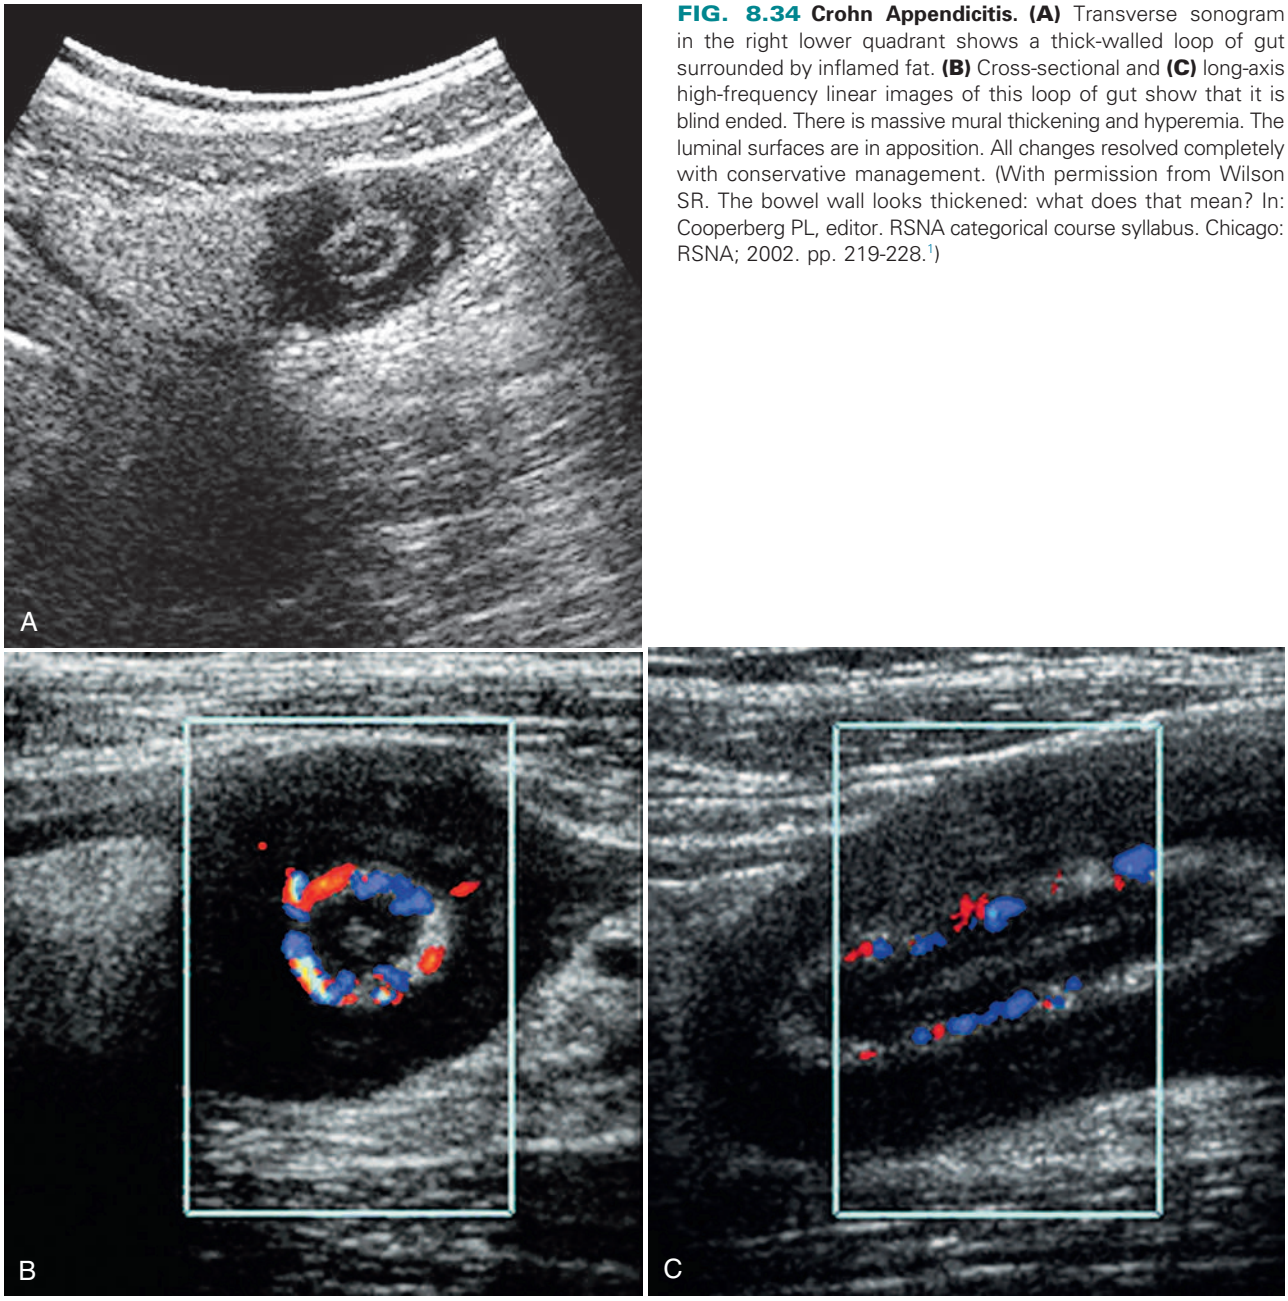

FIG. 8.34 Crohn Appendicitis. (A) Transverse sonogram in the right lower quadrant shows a thick-walled loop of gut surrounded by inflamed fat. **(B)** Cross-sectional and **(C)** long-axis high-frequency linear images of this loop of gut show that it is blind ended. There is massive mural thickening and hyperemia. The luminal surfaces are in apposition. All changes resolved completely with conservative management. (With permission from Wilson SR. The bowel wall looks thickened: what does that mean? In: Cooperberg PL, editor. RSNA categorical course syllabus. Chicago: RSNA; 2002. pp. 219-228.[1])

On sonography, acute diverticulitis is associated with inflammation of the pericolonic fat. The diverticula may be located in the cecum or the adjacent ascending colon. When inflamed, they may have one of two appearances.[62] Most often, the diverticulum may show as a pouch or saclike structure arising from the colonic wall[63] (Fig. 8.35). Wall layers are continued into the wall of the congenital diverticulum. Hyperemia of the diverticulum and the inflamed fat is typical. If a fecalith is present within the diverticulum, it may show as a bright, echogenic focus located within or beyond a segment of thickened colonic wall. Occasionally, the culprit diverticulum is not evident and the only observations are those of inflamed fat and focal thickening of the colonic wall. In the appropriate clinical milieu, this is highly suspicious for acute diverticulitis. Treatment of acute diverticulitis is conservative and not surgical, emphasizing the importance of preoperative imaging in patients with RLQ pain attributed to this condition.

Acute Typhlitis

Immunocompromised patients are most often affected with acute typhlitis. Although infrequent today in North America, AIDS patients previously accounted for the overwhelming majority of cases of acute typhlitis seen since 1990. **Cytomegalovirus** (CMV) and ***Cryptosporidium*** are the pathogens isolated most often in

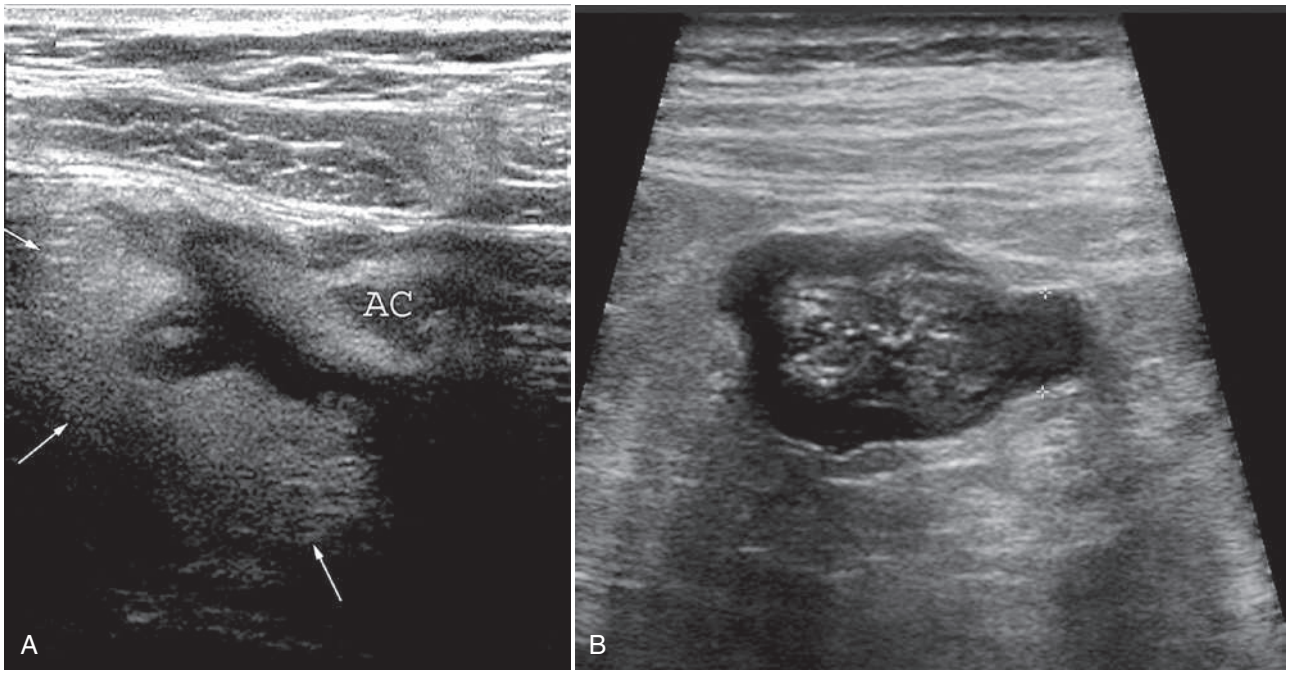

FIG. 8.35 Right-Sided Diverticulitis in Two Patients. Transverse sonograms through the ascending colon *(AC)* show a hypoechoic pouchlike projection, representing the inflamed diverticulum, which arises from **(A)** the lateral wall of the gut and **(B)** the medial border of the gut. Both are surrounded by inflamed fat *(arrows)*.

patients with typhlitis and **colitis,** although other organisms have been implicated. Sonographic study most often shows striking concentric, uniform thickening of the colon wall, usually localized to the cecum and the adjacent ascending colon[64] (Fig. 8.36). The colon wall may be several times the normal thickness, reflecting inflammatory infiltration throughout the gut wall.[65,66] Acute abdominal catastrophe in patients with AIDS is usually a complication of CMV colitis with deep ulceration and may result in hemorrhage, perforation, and peritonitis.[67] **Tuberculous colitis** may similarly affect the right colon and is frequently associated with **lymphadenopathy** (particularly involving the mesenteric and omental nodes), **splenomegaly,** intrasplenic masses, ascites, and peritoneal masses, all of which may be assessed using sonography.

Mesenteric Adenitis With Terminal Ileitis

Mesenteric adenitis, in association with acute terminal ileitis, is the most frequent GI cause of misdiagnosis of acute appendicitis. Patients typically have RLQ pain and tenderness. On the sonographic examination, enlarged mesenteric lymph nodes and mural thickening of the terminal ileum are noted. *Yersinia enterocolitica* and *Campylobacter jejuni* are the most common causative agents.[68,69]

Right-Sided Segmental Omental Infarction

Right-sided segmental infarction of the omentum is a rare condition invariably mistaken clinically for acute appendicitis.[70] Of unknown origin, it is postulated to occur with an anomalous and fragile blood supply to the right lower omentum, making it susceptible to painful infarction. Patients experience RLQ pain and tenderness and are diagnosed clinically with acute appendicitis. On sonography, a plaque or cakelike area of increased echogenicity, suggesting inflamed or infiltrated fat, is seen superficially in the right flank with adherence to the peritoneum[70] (Fig. 8.37). No underlying gut abnormality is shown. Because segmental infarction is a self-limited process, its correct diagnosis will prevent unnecessary surgery. CT scan is confirmatory, showing streaky fat in a masslike configuration in the right side of the omentum.

Left Lower Quadrant Pain

The sonographic evaluation of the patient with left lower quadrant (LLQ) pain is less problematic than that of the patient with pain on the right side as acute diverticulitis is the explanation for the overwhelming majority of cases for which a valid explanation for the pain is found. The diagnostic features of **acute diverticulitis** are also less variable than those for acute appendicitis, making a suspicion of diverticulitis a good indication for the use of sonographic examination.

Acute Diverticulitis

Diverticula of the colon are usually acquired deformities and are found most frequently in Western urban populations.[71] The incidence of diverticula increases with age,[72] affecting approximately half the population by the ninth decade. Muscular dysfunction and hypertrophy are constant associated features. Diverticula are usually multiple, and their most common location is the sigmoid and left colon. Both acute diverticulitis and **spastic diverticulosis** may be associated with a classic triad of presentation: LLQ pain, fever, and leukocytosis. Diverticula may also be

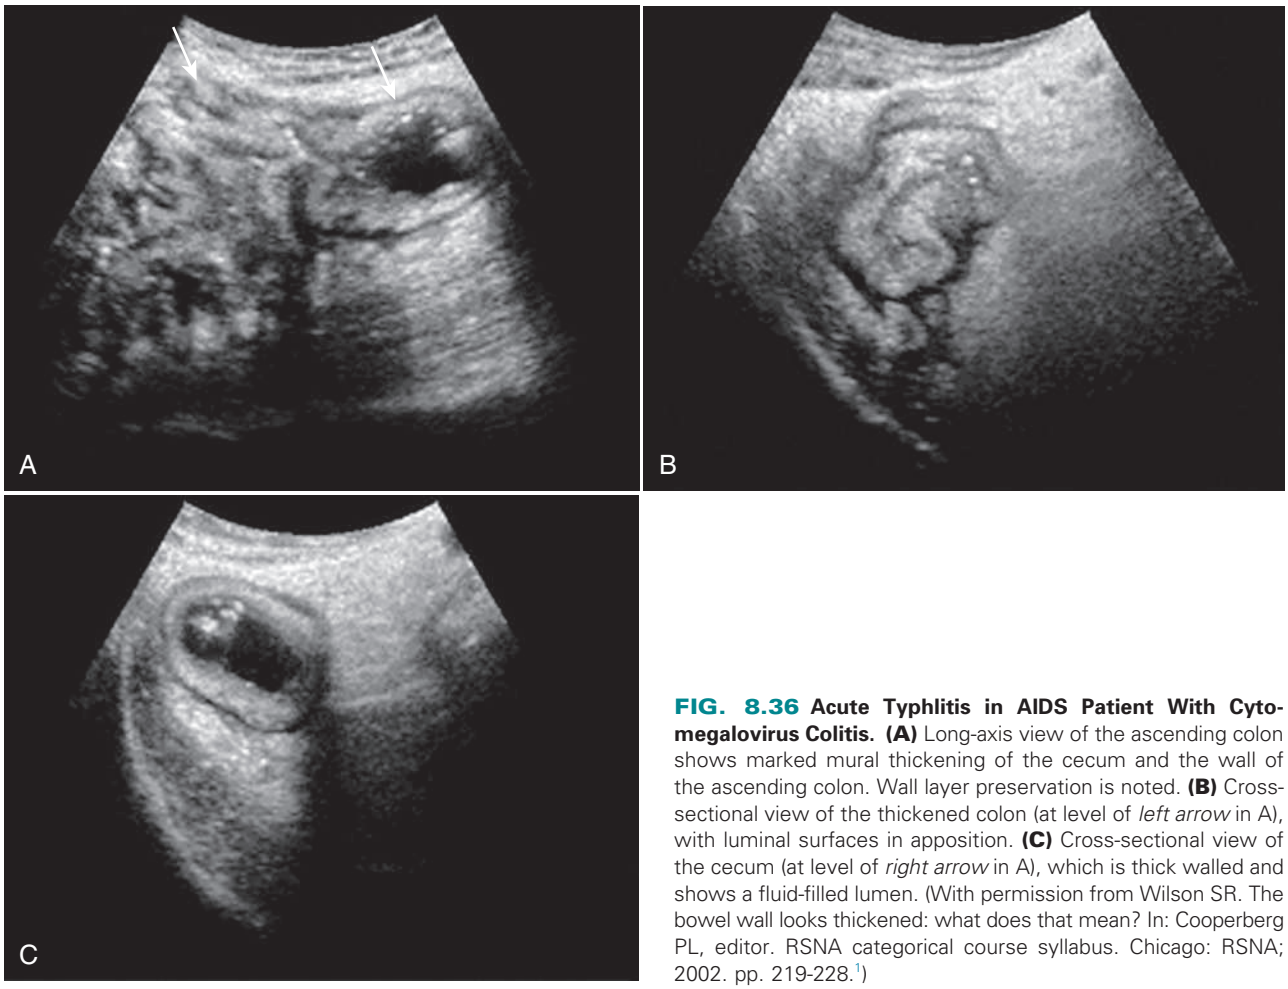

FIG. 8.36 Acute Typhlitis in AIDS Patient With Cytomegalovirus Colitis. (A) Long-axis view of the ascending colon shows marked mural thickening of the cecum and the wall of the ascending colon. Wall layer preservation is noted. **(B)** Cross-sectional view of the thickened colon (at level of *left arrow* in A), with luminal surfaces in apposition. **(C)** Cross-sectional view of the cecum (at level of *right arrow* in A), which is thick walled and shows a fluid-filled lumen. (With permission from Wilson SR. The bowel wall looks thickened: what does that mean? In: Cooperberg PL, editor. RSNA categorical course syllabus. Chicago: RSNA; 2002. pp. 219-228.[1])

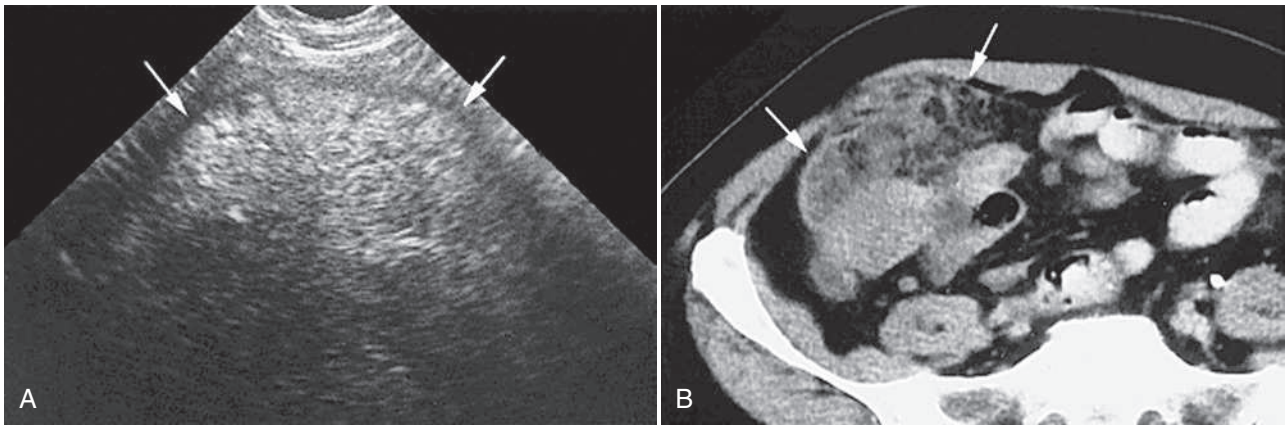

FIG. 8.37 Acute Omental Infarction. (A) Sonogram shows a large, tender mass in the right lower quadrant (RLQ; *arrows*) in older man with acute RLQ pain. The mass is uniformly echogenic and attenuating, with an ultrasound appearance suggesting inflamed fat. **(B)** Confirmatory CT scan shows the heterogeneous superficial fatty mass.

found singly and in the right colon, where no association with muscular hypertrophy or dysfunction has been established.

Inspissated fecal material is believed to incite the initial inflammation in the apex of the diverticulum leading to acute diverticulitis.[73] Spread to the peridiverticular tissues and microperforation or macroperforation may follow. Localized abscess formation occurs more often than peritonitis. Fistula formation, with communication to the bladder, vagina, skin, or other bowel loops, is present in a minority of cases. Surgical specimens demonstrate shortening and thickening of the involved segment of colon, associated with muscular hypertrophy. The peridiverticular inflammatory response may be minimal or extensive.

Sonography appears to be of value in early assessment of patients thought to have acute diverticulitis.[74,75] Classic features include segmental thickened gut and inflamed diverticula and inflamed perienteric fat. A negative scan combined with a low clinical suspicion is usually a good indication to stop investigation. However, a negative scan in a patient with a highly suggestive clinical picture justifies a CT scan. Similarly, demonstration of extensive pericolonic inflammatory changes on the sonogram may be appropriately followed by CT scan to define better the nature and extent of the pericolonic disease before surgery or other intervention.

Because diverticula and smooth muscle hypertrophy of the colon are so prevalent, it seems likely that they would be frequently seen on routine sonography, but this is not the usual experience. However, with the development of acute diverticulitis, both the inflamed diverticulum and the thickened colon become evident. Presumably, the impacted fecalith, with or without microabscess formation, accentuates the diverticulum, whereas smooth muscle spasm, inflammation, and edema accentuate the gut wall thickening. Identification of diverticula on the sonogram strongly indicates diverticulitis.[76]

Diverticula are arranged in parallel rows along the margins of the teniae coli, so careful technique is required to make their identification. After demonstration of a thickened loop of gut, the long axis of the loop should be determined (Fig. 8.38). Slight tilting of the transducer to the margins of the loop will increase visualization of the diverticula, because they may be on the lateral and medial edges of the loop rather than directly anterior or posterior (Fig. 8.39). Cross-sectional views are then obtained along the entire length of the thickened gut. Abnormalities must be confirmed on both views. Errors related to overlapping gut loops, in particular, can be virtually eliminated with this careful technique. Identification of diverticula on sonography is correlated highly with inflammation, because it is unusual to show the diverticula in the absence of inflammation (Fig. 8.40).

Failure to identify gas-containing abscesses or interloop abscesses is the major source of error when using sonography to evaluate patients with suspected diverticulitis. The meticulous technique of following involved thickened segments of colon in long-axis and transverse section will help detect even small amounts of extraluminal gas.

Sonographic features of diverticulitis include segmental concentric thickening of the gut wall that is frequently strikingly hypoechoic, reflecting the predominant thickening in the muscle layer; inflamed diverticula, seen as bright, echogenic foci with acoustic shadowing or ring-down artifact within or beyond the thickened gut wall; acute inflammatory changes in the pericolonic fat, seen as poorly defined hyperechoic zones without obvious gas or fluid content (Fig. 8.41, Video 8.15); and abscess formation, seen as loculated fluid collections in an intramural, pericolonic, or remote location. With the development of extraluminal inflammatory masses, the diverticulum may no longer be identified on sonography, presumably being incorporated into the inflammatory process. Therefore demonstration of a thickened segment of colon with an adjacent inflammatory mass may be consistent with diverticulitis, but also with neoplastic or other inflammatory disease. Intramural sinus tracts appear as high-amplitude, linear echoes, often with ring-down artifact, within the gut wall. Typically, the tracts are deep, between the muscularis propria and the serosa. Fistulas appear as linear tracts that extend from the involved segment of gut to the bladder, vagina, or adjacent loops. Their echogenicity depends on their content, usually gas or fluid. Thickening of the mesentery and inflamed mesenteric fat may also be seen (Fig. 8.41).

The sonographic and clinical features of diverticulitis are more specific than those of acute appendicitis, and errors of diagnosis occur less often. However, **torsion of appendices epiploicae** (omentales) may produce a sonographic appearance so closely resembling acute diverticulitis that differentiation may be difficult.[76] The inflamed or infarcted fat of the appendix shows as shadowing of increased echogenicity related to the margin of the colon, mimicking an inflamed diverticulum. However, regional perienteric inflammatory change is usually minimal, with fewer systemic symptoms. The noninflamed colonic appendices epiploicae are not visible, except with ascites, where they are seen as uniformly spaced, echogenic foci along the margins of the colon.

Sonography of Diverticulitis

GUT
Segmental concentric thickening of wall
- Hypoechoic reflecting muscular hypertrophy

INFLAMED DIVERTICULA
Echogenic foci within or beyond gut wall
Intramural sinus tracts
- High-amplitude linear echoes within gut wall
- Acoustic shadowing or ring-down artifact

PERIENTERIC SOFT TISSUE
Inflammation of pericolonic fat
- Hyperechoic mass effect

Thickening of the mesentery
Abscess formation
- Loculated fluid collection
- Often with gas component

Fistulas
- Linear tracts from gut to bladder, vagina, or adjacent loops
- Hypoechoic or hyperechoic

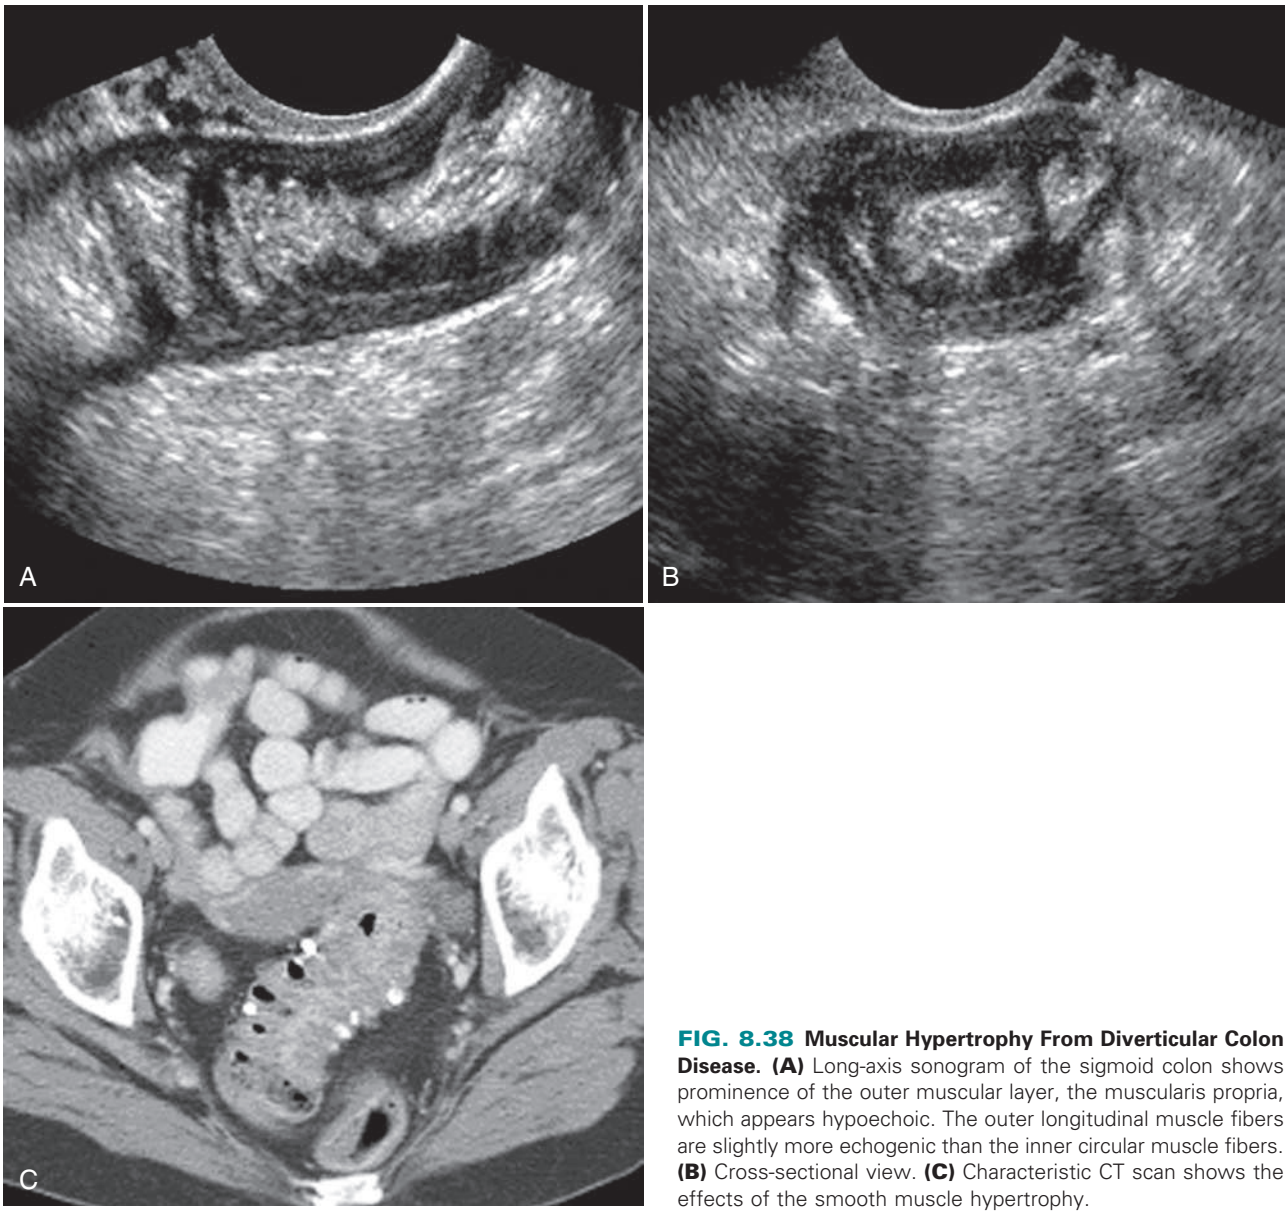

FIG. 8.38 Muscular Hypertrophy From Diverticular Colon Disease. (A) Long-axis sonogram of the sigmoid colon shows prominence of the outer muscular layer, the muscularis propria, which appears hypoechoic. The outer longitudinal muscle fibers are slightly more echogenic than the inner circular muscle fibers. **(B)** Cross-sectional view. **(C)** Characteristic CT scan shows the effects of the smooth muscle hypertrophy.

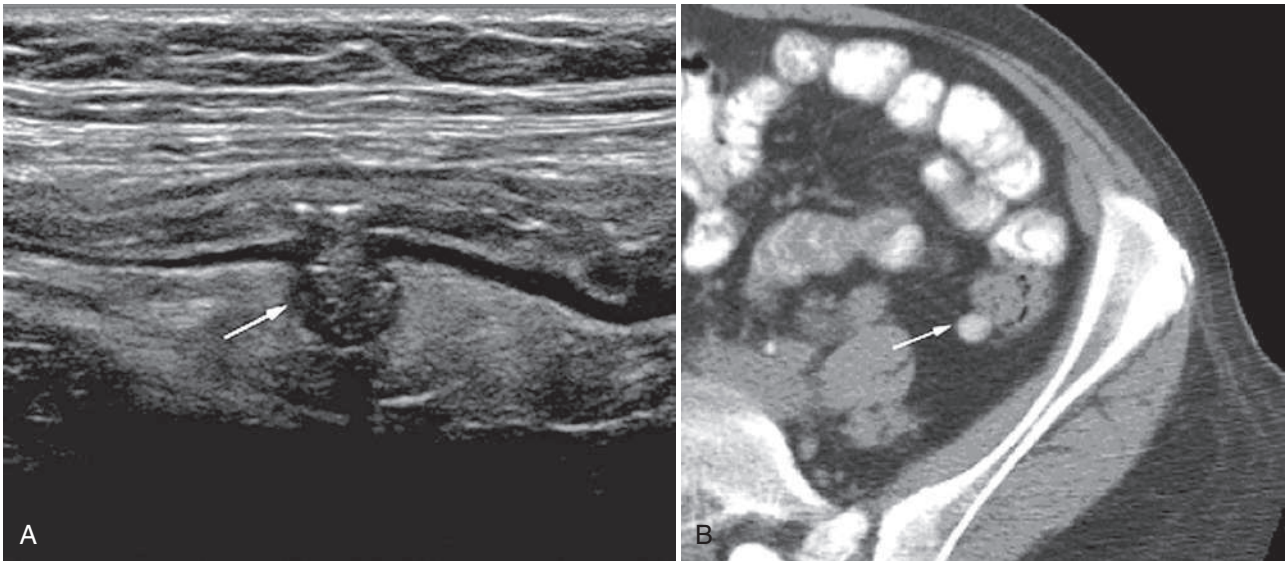

FIG. 8.39 Diverticulum of Colon. (A) Long-axis sonogram and **(B)** correlative CT scan show a small pouch *(arrows)* arising from the wall of the descending colon. There is mild inflammatory change in the perienteric fat.

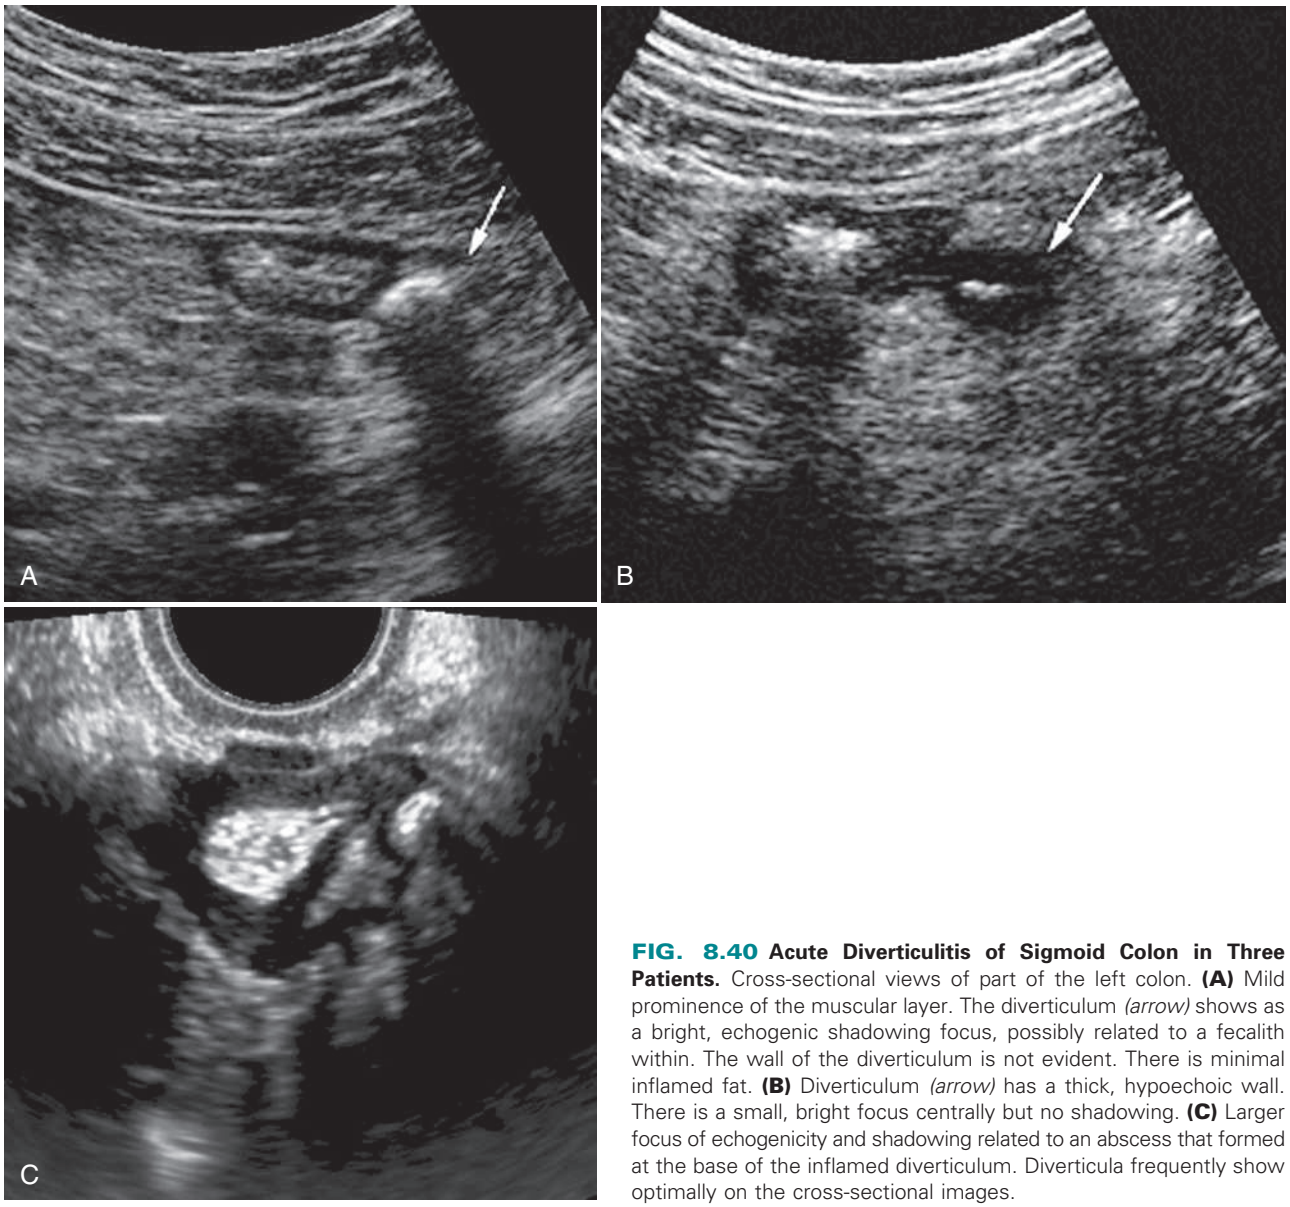

FIG. 8.40 Acute Diverticulitis of Sigmoid Colon in Three Patients. Cross-sectional views of part of the left colon. **(A)** Mild prominence of the muscular layer. The diverticulum *(arrow)* shows as a bright, echogenic shadowing focus, possibly related to a fecalith within. The wall of the diverticulum is not evident. There is minimal inflamed fat. **(B)** Diverticulum *(arrow)* has a thick, hypoechoic wall. There is a small, bright focus centrally but no shadowing. **(C)** Larger focus of echogenicity and shadowing related to an abscess that formed at the base of the inflamed diverticulum. Diverticula frequently show optimally on the cross-sectional images.

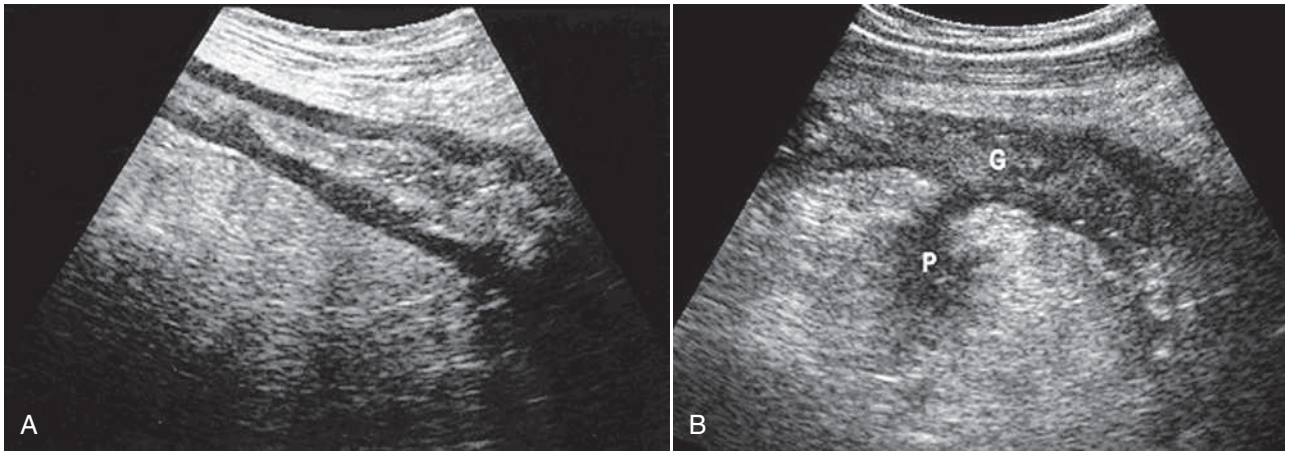

FIG. 8.41 Pericolonic Changes With Diverticulitis in Two Patients. (A) Long-axis view of descending colon shows a long segment of thickened gut with prominent muscularis propria. Edema of the perienteric fat is striking and shows as a homogeneous echogenic mass effect deep to the gut. **(B)** Similarly inflamed fat; phlegmonous change *(P)* shows as a hypoechoic zone centrally within the fat. *G,* Gut. See also Video 8.15.

OTHER ABNORMALITIES

Occlusion of the GI tract lumen producing obstruction may be either **mechanical,** where an actual physical impediment to the progression of the luminal content exists, or **functional,** where paralysis of the intestinal musculature impedes progression (paralytic ileus).

Mechanical Bowel Obstruction

Mechanical bowel obstruction (MBO) is characterized by (1) dilation of the GI tract proximal to the site of luminal occlusion, (2) accumulation of large quantities of fluid and gas, and (3) hyperperistalsis as the gut attempts to pass the luminal content beyond the obstruction. If the process is prolonged, exhaustion and overdistention of the bowel loops may occur, with a secondary decrease in peristaltic activity. There are three broad categories of mechanical obstruction: **obturation obstruction,** related to blockage of the lumen by material in the lumen; **intrinsic abnormalities of the gut wall,** associated with luminal narrowing; and **extrinsic bowel lesions,** including adhesions. **Strangulation** obstruction develops when the circulation of the obstructed intestinal loop becomes impaired.

Sonography in patients with suspected MBO is frequently unhelpful as **adhesions,** the most common cause of intestinal obstruction, are not visible on the sonogram. Also, the presence of abundant **gas** in the intestinal tract, characteristic of most patients with obstruction, frequently produces sonograms of nondiagnostic quality. However, in the minority of patients with MBO who do not have significant gaseous distention, sonography may be helpful. In a prospective study of 48 patients, Meiser and Meissner[77] found that ultrasound was positive in 25% of patients with a "normal" plain film. Ultrasound alone allowed complete diagnosis of the cause of obstruction in 6 patients in a retrospective study of sonography on 26 patients with known colonic obstruction; it also correctly predicted the location of colonic obstruction in 22 cases (85%) and the cause of the obstruction in 21 cases (81%).[11] Of 13 patients ultimately confirmed to have adenocarcinoma, 5 had a mass on sonography, 5 had segmental thickening, and 11 others showed a target sign of intussusception.

Sonographic study of potential MBO should include assessment of the following:

- GI tract **caliber** from the stomach to the rectum, noting any point at which the caliber alters (Fig. 8.42).
- **Content** of any dilated loops, with special attention to their fluid and gaseous nature (Fig. 8.43; see also Videos 8.9, 8.10, and 8.16).
- **Peristaltic activity** within the dilated loops, which is typically greatly exaggerated and abnormal, frequently producing a to-and-fro motion of the luminal content. With strangulation, peristalsis may decrease or cease.
- **Site of obstruction** for *luminal* (large gallstones, bezoars,[78] foreign bodies, intussusception, occasional polypoid tumors), *intrinsic* (segmental gut wall thickening and stricture formation from Crohn disease, annular carcinomas), and *extrinsic* (abscesses, endometriomas) abnormality as a cause of the obstruction (Video 8.16).
- **Location of gut loops,** noting any abnormal position. Obstruction associated with external hernias is ideal for sonographic detection in that dilated loops of gut may be traced to a portion of the gut with normal caliber but abnormal location (Fig. 8.44). Spigelian and inguinal hernias are the types most frequently seen on sonograms.

Unique sonographic features are seen in the following:

Closed-loop obstruction occurs if the bowel lumen is occluded at two points along its length, a serious condition that facilitates strangulation and necrosis. As the obstructed loop is closed off from the more proximal portion of the GI tract, little or no gas is present within the obstructed segments, which may become dilated and fluid filled. Consequently, the abdominal radiograph may be unremarkable (Fig. 8.45A), and sonography may be most helpful by showing the dilated involved segments (Fig. 8.45B) and often the normal-caliber bowel distal to the point of obstruction. The features of closed-loop obstruction are well described on ultrasound and include dilated small bowel, a C- or U-shaped bowel loop (Fig. 8.45C), a whirl sign, and two adjacent collapsed loops.[79,80] This last important observation is difficult to observe on ultrasound, in contrast to CT scan. However, we have correctly suspected closed-loop obstruction in many patients on the basis of virtually normal plain films, small bowel dilation, and a U- or C-shaped bowel loop, especially if there is gut wall thickening or pneumatosis intestinalis suggesting gut infarction.

Afferent loop obstruction is an uncommon complication of subtotal gastrectomy, with Billroth II gastrojejunostomy, that may occur by twisting at the anastomosis, internal hernias, or anastomotic stricture. Again, a gasless, dilated loop may be readily recognized on sonography in a location consistent with the enteroenteric anastomosis coursing from the right upper quadrant across the midline. Its detection, location, and shape should allow for correct sonographic diagnosis of afferent loop obstruction.[81]

Intussusception, invagination of a bowel segment (the intussusceptum) into the next distal segment (the intussuscipiens), is seen on sonography of the abdomen most often as a transient and infrequent occurrence. However, it is a relatively infrequent cause of MBO in the adult, usually associated with a tumor as a lead point. In our experience, this is often a lipoma that appears as a highly echogenic, intraluminal mass related to its fat content. A sonographic appearance of multiple concentric rings, related to the invaginating layers of the telescoped bowel and seen in cross section, is virtually pathognomonic[82] (Fig. 8.46A). Occasionally, only a target appearance may be seen.[83,84] The longitudinal appearance suggesting a "hay fork"[84] is not as reliably detected. In both projections, the mesenteric fat invaginating with the intussusceptum will show as an eccentric area of increased echogenicity. A lipoma, as a lead point, similarly shows as a focus of increased echogenicity (Fig. 8.46B and C).

Midgut malrotation predisposes to MBO and infarction. It is infrequently encountered in adults. A sonographic abnormality related to the superior mesenteric vessels suggests malrotation.[85] On transverse sonograms, the superior mesenteric vein is seen on the left ventral aspect of the superior mesenteric artery, a reversal of the normal relationship.

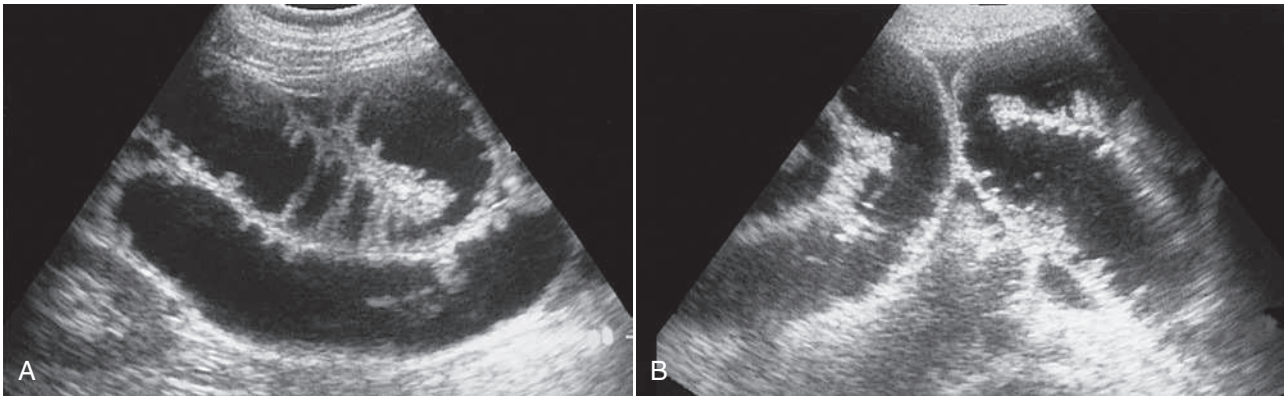

FIG. 8.42 Mechanical Small Bowel Obstruction. (A) Sagittal image of right flank shows multiple, adjacent, long loops of dilated, fluid-filled small bowel with the classic morphology for a distal mechanical small bowel obstruction. **(B)** Transverse image in the left lower quadrant confirms the multiplicity of dilated loops involved in the process. A small amount of ascites is seen between the dilated loops.

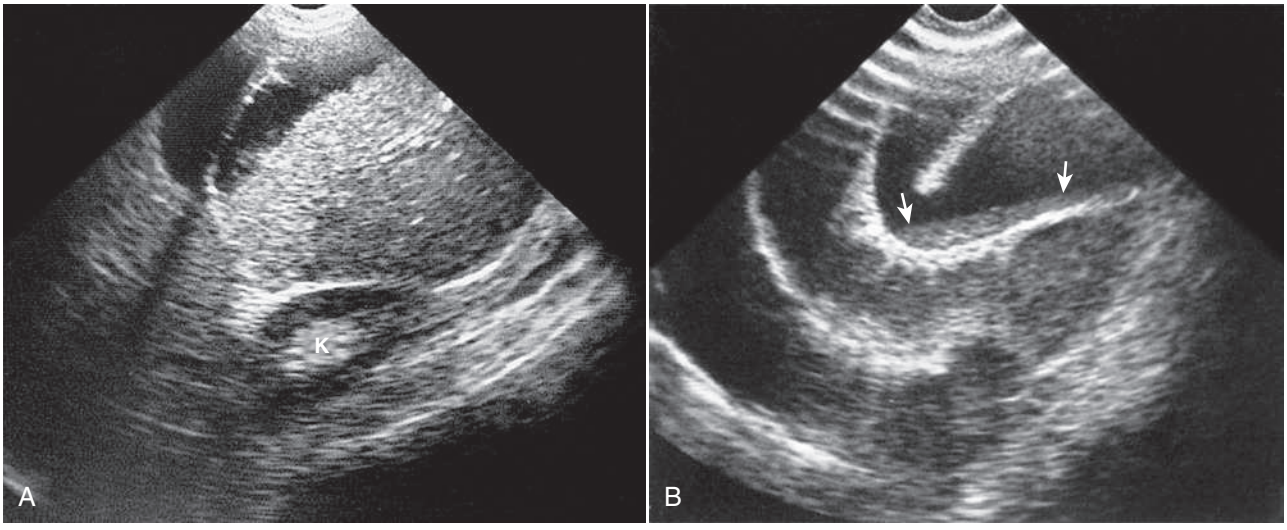

FIG. 8.43 Dilated Hypoperistaltic Segments. (A) Sagittal sonogram in the right flank of a patient with a Crohn stricture shows gross dilation of the ascending colon. A long, fluid-sediment level is seen as a reflection of the hypoperistalsis of this segment of obstructed gut. **(B)** Sagittal sonogram in a patient with paralytic ileus shows extensive small bowel dilation. Loops are fluid filled and quiet with fluid-fluid level *(arrowheads)*. See also Video 8.16. *K,* Kidney. (**A** with permission from Sarrazin J, Wilson SR. Manifestations of Crohn disease at US. Radiographics. 1996;16[3]:499-520.[21])

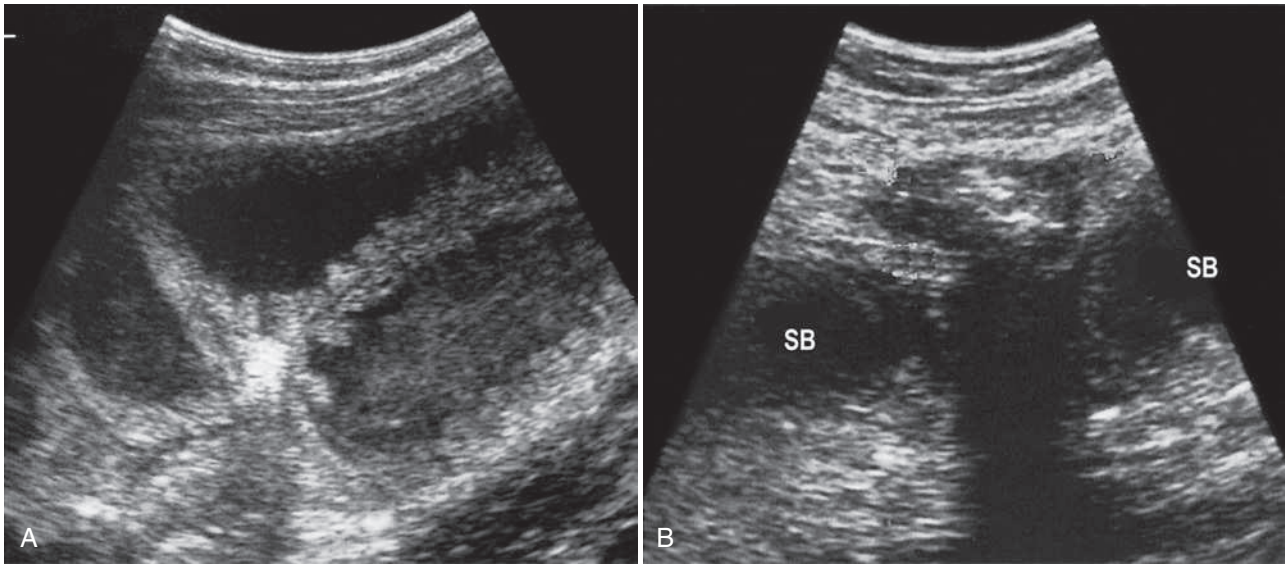

FIG. 8.44 Mechanical Small Bowel Obstruction: Ventral Hernia. (A) Sonogram shows dilated fluid-filled loops of small bowel with edematous valvulae conniventes. **(B)** Transverse paraumbilical sonogram shows normal-caliber gut lying in abnormal superficial location between two dilated loops of small bowel *(SB)*.

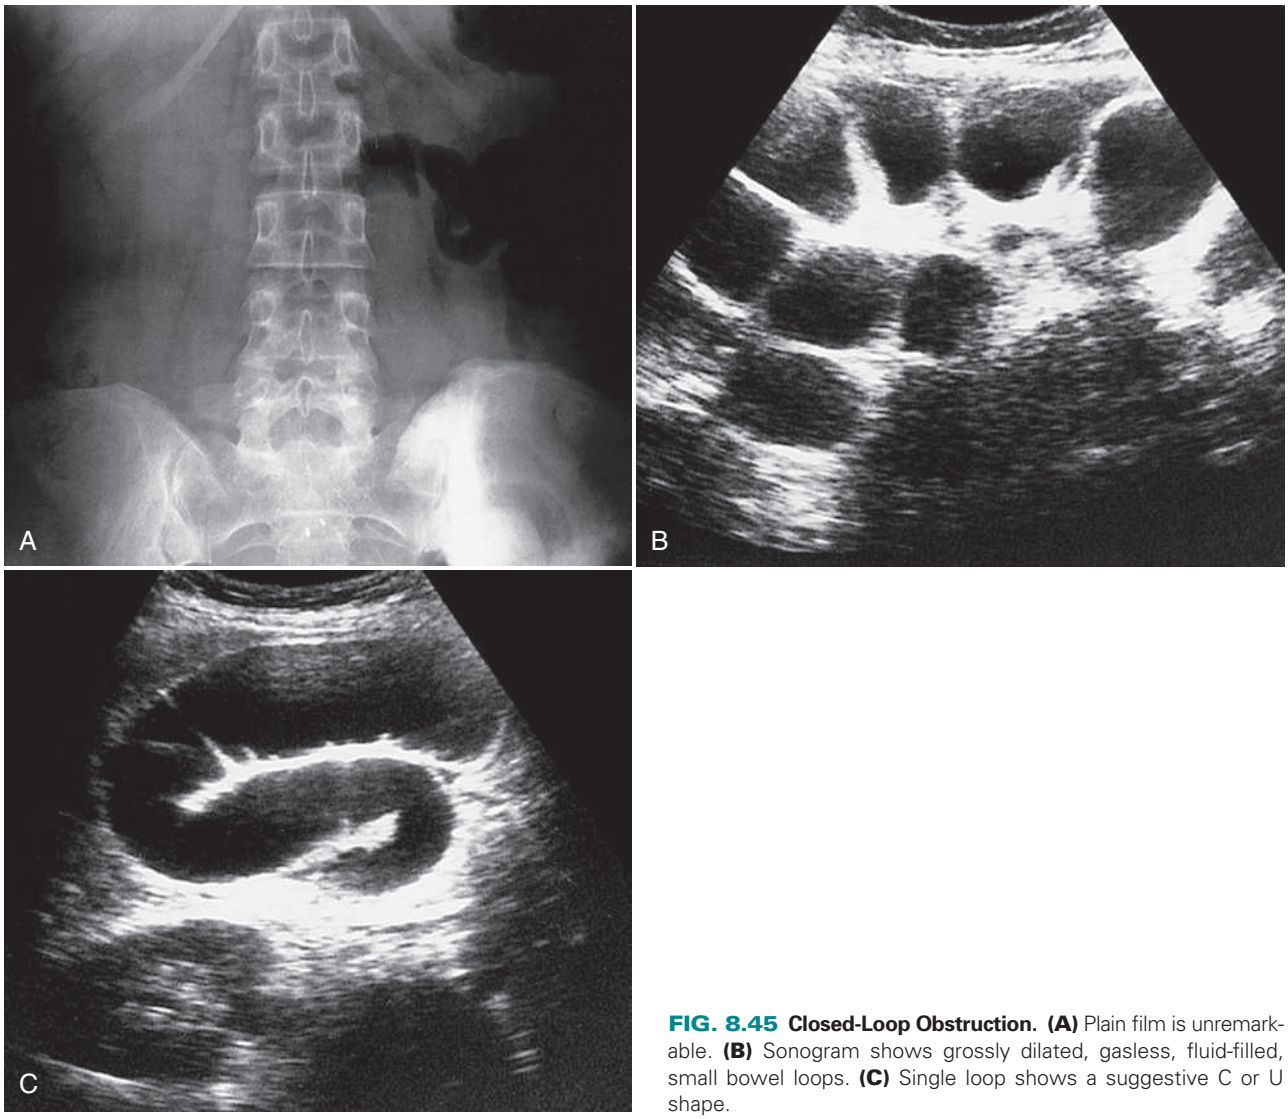

FIG. 8.45 Closed-Loop Obstruction. (A) Plain film is unremarkable. **(B)** Sonogram shows grossly dilated, gasless, fluid-filled, small bowel loops. **(C)** Single loop shows a suggestive C or U shape.

Paralytic Ileus

Paralytic ileus is a type of bowel obstruction related to adynamic function of the bowel wall. Paralysis of the intestinal musculature, in response to general or local insult, may impede the progression of luminal contents. Although the lumen remains patent, no progression occurs. Sonography is usually of little value because these patients characteristically have poor-quality sonograms resulting from large quantities of gas in the intestinal tract. However, on rare occasions, the sonogram may demonstrate dilated, fluid-filled, very quiet, or aperistaltic loops of intestine. A fluid-fluid level in a dilated loop is characteristic of paralytic ileus, reflecting lack of movement of the intestinal contents (see Fig. 8.43).

Gut Edema

Patients with **acute vasculitis** of various causes may present with acute abdominal pain and ascites, with massive edema of the small bowel wall seen as the major abnormality on imaging. Hypoalbuminemia, congestive heart failure, and spontaneous venous thrombosis may also show diffuse edema of the gut wall. Prominent, thickened, hypoechoic valvulae conniventes (Fig. 8.47) and gastric rugae are relatively easy to recognize on the sonographic study, which should also include Doppler evaluation of the mesenteric and portal veins.

Gastrointestinal Tract Infections

Although fluid-filled, actively peristaltic gut may be seen with infectious viral or bacterial gastroenteritis, most affected patients do not demonstrate a sonographic abnormality. However, some pathogens, notably *Yersinia enterocolitica, Mycobacterium tuberculosis,* and *Campylobacter jejuni,* produce highly suggestive sonographic abnormalities in the ileocecal area, as described earlier. Certain high-risk populations, such as those with AIDS and neutropenia,[64] appear to be susceptible to **acute typhlitis** and **colitis,** which also have a highly suggestive sonographic appearance.

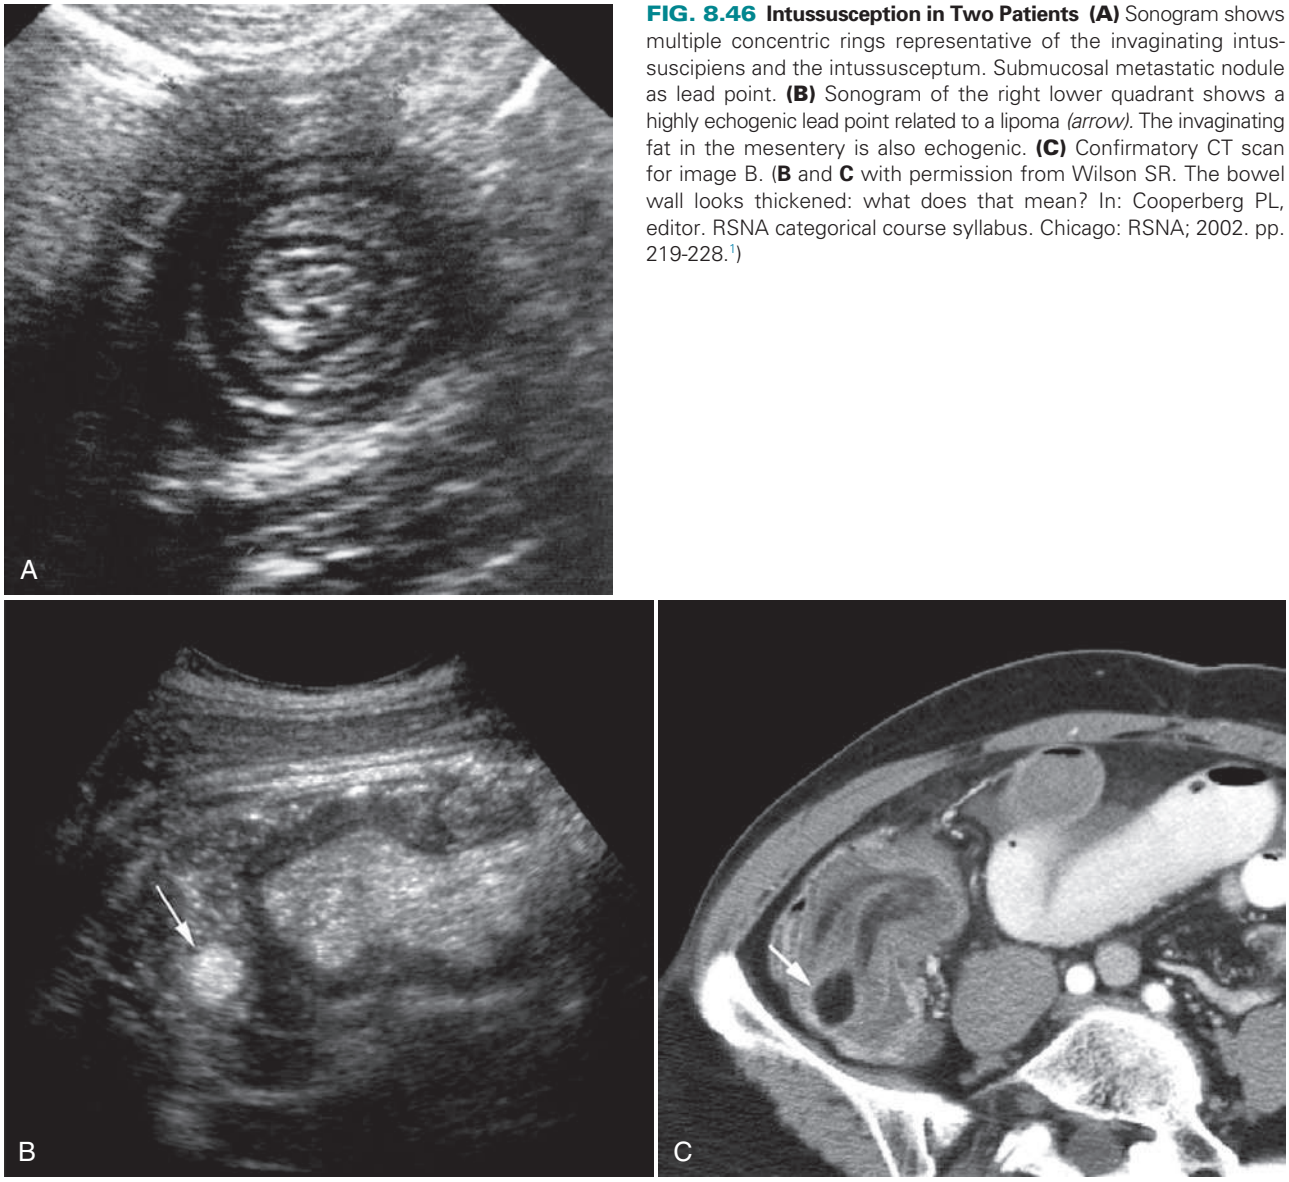

FIG. 8.46 Intussusception in Two Patients (A) Sonogram shows multiple concentric rings representative of the invaginating intussuscipiens and the intussusceptum. Submucosal metastatic nodule as lead point. **(B)** Sonogram of the right lower quadrant shows a highly echogenic lead point related to a lipoma *(arrow).* The invaginating fat in the mesentery is also echogenic. **(C)** Confirmatory CT scan for image B. (**B** and **C** with permission from Wilson SR. The bowel wall looks thickened: what does that mean? In: Cooperberg PL, editor. RSNA categorical course syllabus. Chicago: RSNA; 2002. pp. 219-228.[1])

AIDS Patients

Today, effective antiviral medications for HIV infection have drastically changed the outlook for those living with AIDS in the Western world. Nonetheless, patients with AIDS are at increased risk for development of both GI tract neoplasia, especially lymphoma (see Fig. 8.10C and D), and unusual opportunistic infections, most often *Candida* esophagitis and CMV colitis[65,66] (see Fig. 8.36).

Pseudomembranous Colitis

Pseudomembranous colitis is a necrotizing inflammatory bowel condition that may occur as a response to a heterogeneous group of insults. At present, antibiotic therapy with effects from the toxin of *Clostridium difficile,* a normal inhabitant of the GI tract, is most often implicated. Watery diarrhea is the most common symptom and usually occurs during antibiotic therapy but may be quite remotely associated, occurring up to 6 weeks later. Endoscopic demonstration of pseudomembranous exudative plaques on the mucosal surface of the gut and culture of the enterotoxin of *C. difficile* are diagnostic. Superficial ulceration of the mucosa is associated with inflammatory infiltration of the lamina propria and the submucosa, which may be thickened to many times the normal size.[86]

Sonography is frequently performed before pseudomembranous colitis is diagnosed, often based on a history of fever, abdominal pain, and watery diarrhea. Sonographic features have only rarely been described[87,88] but are suggestive of pseudomembranous colitis. Usually the entire colon is involved in a process that may produce striking thickening of the colon wall. Exaggerated haustral markings and a nonhomogeneous thickened submucosa, with virtual apposition of the mucosal surfaces of the thickened walls, are characteristic[63] (Fig. 8.48).

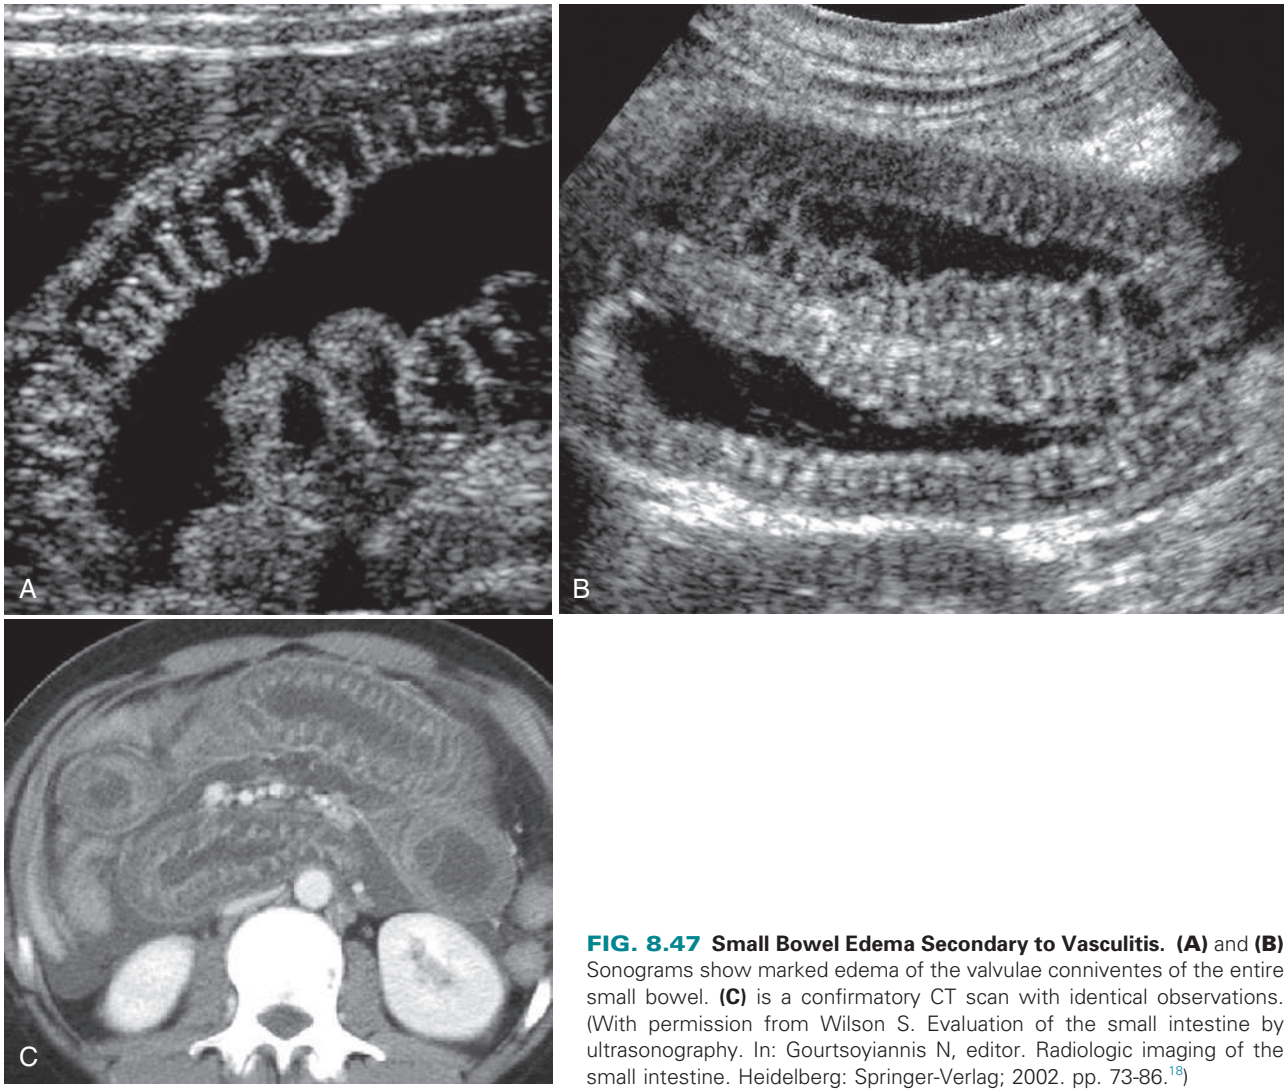

FIG. 8.47 Small Bowel Edema Secondary to Vasculitis. (A) and **(B)** Sonograms show marked edema of the valvulae conniventes of the entire small bowel. **(C)** is a confirmatory CT scan with identical observations. (With permission from Wilson S. Evaluation of the small intestine by ultrasonography. In: Gourtsoyiannis N, editor. Radiologic imaging of the small intestine. Heidelberg: Springer-Verlag; 2002. pp. 73-86.[18])

Pseudomembranous colitis should be suspected in any patient with diffuse colonic wall thickening but without a previous history of IBD. Because the history of concurrent or prior antibiotic therapy is not always given, direct questioning of the patient is frequently helpful.

Congenital Cysts

Duplication cysts, characterized by the presence of the normal layers of the gut wall, can occur in any portion of the GI tract. These cysts may be visualized on sonogram, either routine or endoscopic, and should be considered as diagnostic possibilities whenever unexplained abdominal cysts are seen. **Tailgut cysts** are variants of abdominal cysts that are seen in the presacral region and are related to the rectum (Fig. 8.49).

Ischemic Bowel Disease

Ischemic bowel disease most often affects the colon and is most prevalent in older persons with arteriosclerosis. In younger patients, it may complicate cardiac arrhythmia, vasculitis, coagulopathy, embolism, shock, or sepsis.[12] Sonographic features of ischemic bowel disease have been poorly described, although gut wall thickening may be encountered. Pneumatosis intestinalis may complicate gut ischemia with a characteristic sonographic appearance.

Pneumatosis Intestinalis

Pneumatosis intestinalis is a relatively rare condition in which intramural pockets of gas are found throughout the GI tract. It has been associated with a wide variety of underlying conditions, including chronic obstructive pulmonary disease, collagen vascular disease, IBD, traumatic endoscopy, and post–jejunoileal bypass. In many situations, affected patients are asymptomatic and the observation is incidental. However, its demonstration is of great clinical significance when necrotizing enterocolitis or ischemic bowel disease is present. Both conditions are associated with mucosal necrosis in which gas from the lumen passes to the gut wall.

Sonographic description of pneumatosis intestinalis is limited to isolated case reports. High-amplitude echoes may be demonstrated in the gut wall, with typical air artifact or shadowing[89,90]

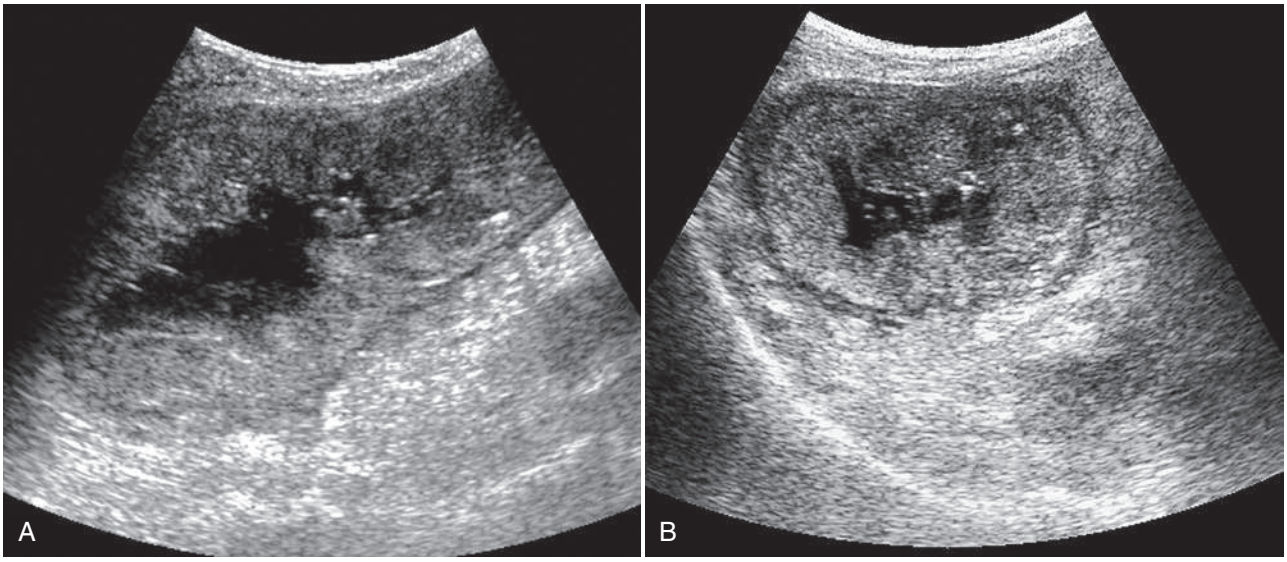

FIG. 8.48 Pseudomembranous Colitis. (A) Long-axis view and **(B)** cross-sectional view of the ascending colon show striking mural thickening of the gut wall. (With permission from O'Malley M, Wilson S. US of gastrointestinal tract abnormalities with CT correlation. Radiographics. 2003;23[1]:59-72.[63])

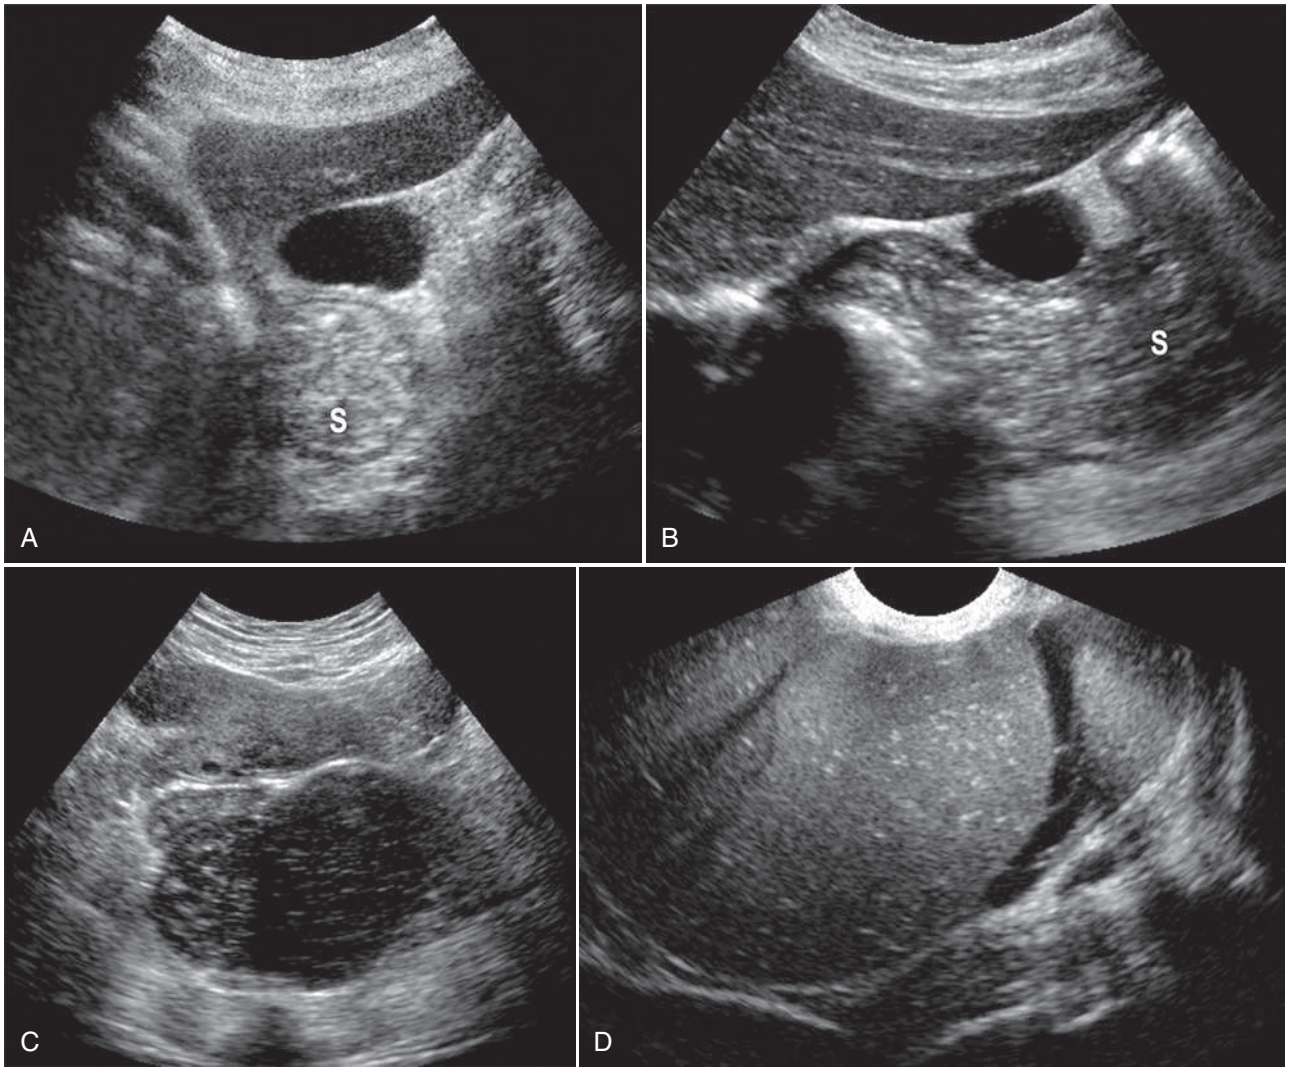

FIG. 8.49 Congenital Cysts. (A) Sagittal and **(B)** transverse sonograms in the epigastrium show an incidental gastric duplication cyst adjacent to the lesser curve of the stomach *(S)*. **(C)** Suprapubic and **(D)** transvaginal pelvic scans show a complex, presacral pelvic mass, an incidental tailgut cyst.

(Fig. 8.50). Gut wall thickening may be noted if the pneumatosis is associated with underlying IBD. If gut ischemia is suspected, careful evaluation of the liver is recommended to look for evidence of portal venous air.

Mucocele of Appendix

Mucocele of the appendix is relatively uncommon, occurring in 0.25% of 43,000 appendectomy specimens in one series. Many patients with this condition are asymptomatic. A mass may be palpated in approximately 50% of cases. **Benign** and **malignant** varieties occur in a ratio of approximately 10:1.[91] In the benign form the appendiceal lumen is obstructed by either inflammatory scarring or fecaliths. The glandular mucosa in the isolated segment continues to secrete sterile mucus. The neoplastic variety of mucocele is associated with primary mucous **cystadenoma** or **cystadenocarcinoma** of the appendix. Although the gross morphology of the appendix may be similar in the benign and malignant varieties, the malignant form is often associated with pseudomyxoma peritonei if rupture occurs.[92]

On sonography, **mucoceles** typically produce large, hypoechoic, well-defined RLQ cystic masses with variable internal echogenicity, wall thickness, and wall calcification (Fig. 8.51). The internal contents often show a laminated or whorled appearance. These masses are frequently retrocecal and may be mobile.

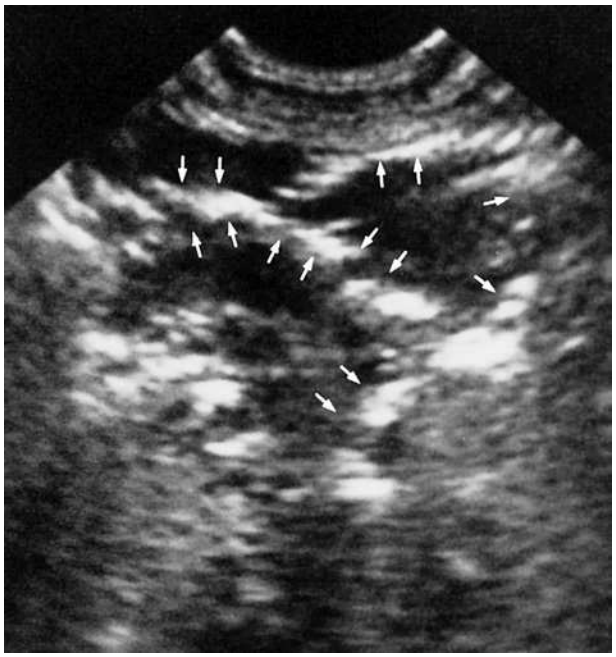

FIG. 8.50 Pneumatosis Intestinalis. Sonogram shows three loops of gut with bright, high-amplitude echoes *(arrows)* originating within the gut wall.

Gastrointestinal Tract Hematoma

Blunt abdominal trauma, complicated by duodenal hematoma and rectal trauma, either sexual or iatrogenic after rectal biopsy, are the major causes of local hematomas seen on sonography. Hematoma is usually localized to the submucosa. Larger or more diffuse hematomas may complicate anticoagulation therapy or bleeding disorders associated with leukemia. If hematomas are large, diffuse gut wall thickening may be seen on sonograms.

Peptic Ulcer

Peptic ulcer, a defect in the epithelium to the depth of the submucosa, may be seen in either **gastric** or **duodenal** locations. Although rarely visualized, peptic ulcer has a fairly characteristic sonographic appearance. A gas-filled ulcer crater is seen as a bright, echogenic focus with ring-down artifact, either in a focal area of wall thickening or beyond the wall, depending on the depth of penetration (Fig. 8.52). **Edema** in the acute phase and **fibrosis** in the chronic phase may produce localized wall thickening and deformity.

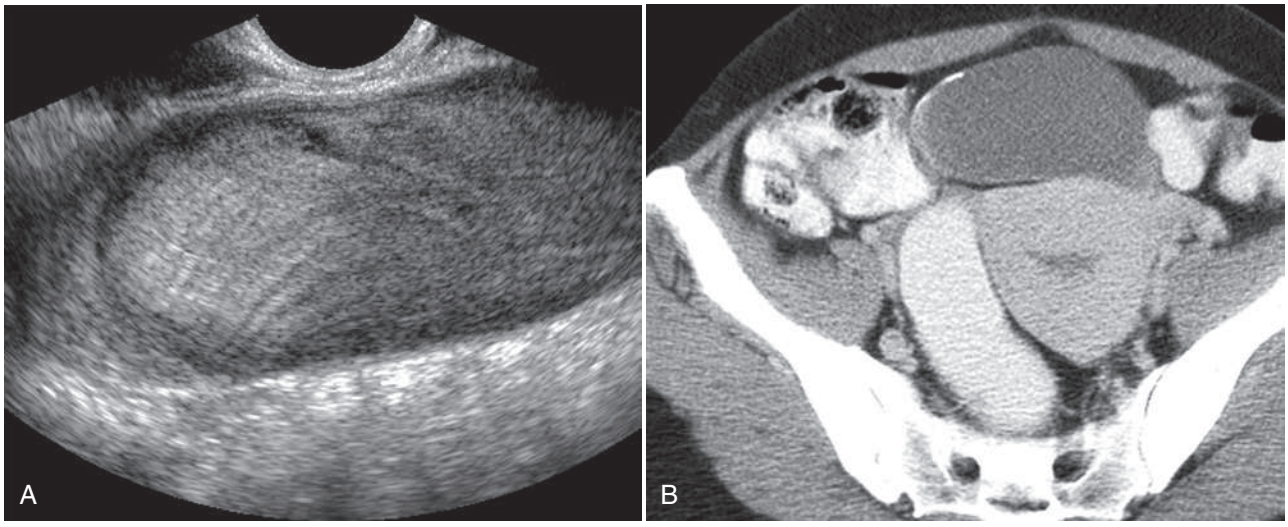

FIG. 8.51 Mucocele of the Appendix. (A) Sonogram and **(B)** CT scan show a large, mucus-filled appendix as an incidental observation. The whorled appearance on the sonogram is characteristic. There is a fleck of calcification in the wall on the CT scan.

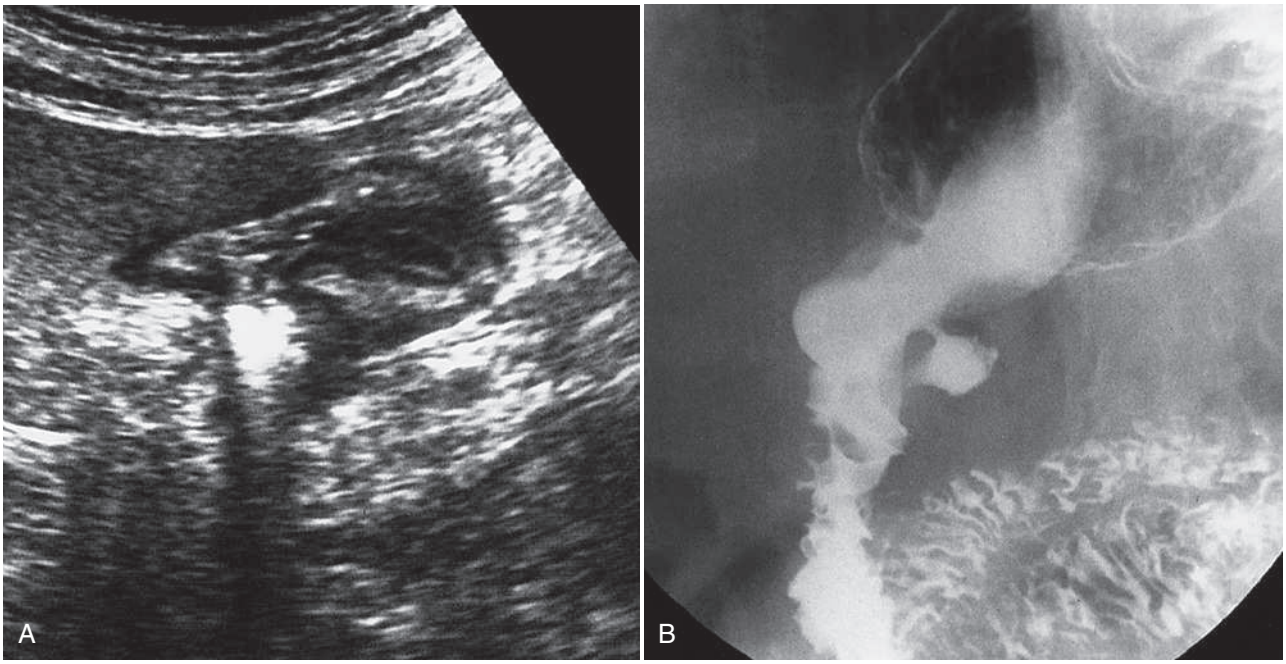

FIG. 8.52 Peptic Ulcer. (A) Cross-sectional sonogram of the stomach shows a hypoechoic eccentric mass with a bright, central echogenic focus representing air in the ulcer crater. **(B)** Confirmatory scan with barium swallow.

Bezoars

Bezoars are masses of foreign material or food, typically found in the stomach after surgery for peptic ulcer disease **(phytobezoars)** or after ingestion of indigestible organic substances such as hair **(trichobezoars).** These masses may produce shadowing intraluminal densities on the sonogram and have been documented as a rare cause of small bowel obstruction.[78] They may also form in the small bowel in association with chronic stasis.

Intraluminal Foreign Bodies

Large foreign bodies, including bottles, candles, sexual vibrators, contraband, tools, and food, may be identified in the GI tract, particularly in the rectum and sigmoid colon, where they produce fairly sharp, distinct specular echoes with sharp, acoustic shadows. Their recognition is enhanced by suspicion of their presence.

Celiac Disease

Undiagnosed adult patients with celiac disease are encountered infrequently in general ultrasound departments. Nonetheless, I have occasionally seen patients in whom sonography is the first test to suggest the correct diagnosis. Sonographic observations include abnormal fluid-filled small intestine with moderate dilation of the involved loops. Abnormal morphology is observed, which Dietrich et al.[93] describe as a reduction in Kerckring plicae circulares (valvulae conniventes) with loss of density and uniformity. Peristalsis is increased above normal. An increase in the caliber of the superior mesenteric artery and portal vein may also be seen.[94]

Cystic Fibrosis

Aggressive treatment of the pulmonary problems of cystic fibrosis (CF) increases the likelihood of encountering adult patients in a general ultrasound department that performs abdominal sonography. Thickening of the gut wall, particularly of the right hemicolon and to a lesser extent the left colon and small bowel, may be seen in association with infiltration of both the pericolonic and the mesenteric fat.[95] These may often be incidental observations without significant associated symptomatology. In advanced CF, a fibrosing colonopathy with stricture may be seen.[96,97] The culture of *C. difficile* is also documented in some patients with CF and colon wall thickening, without the accompanying symptoms of abdominal pain and diarrhea.[98] However, positive stool culture is not the rule in CF patients with detectable colon wall thickening.

ENDOSONOGRAPHY

Endoscopic sonography, performed with high-frequency transducers in the lumen of the gut, allows for detection of mucosal abnormality, delineation of the layers of the gut wall, and definition of the surrounding soft tissues to a depth of 8 to 10 cm from the transducer crystal. Thus tumors hidden below normal mucosa, tumor penetration into the layers of the gut wall, and tumor involvement of surrounding vital structures or lymph nodes may be well evaluated. Staging of previously identified mucosal tumors is one of the major applications of endosonographic technique.

Upper Gastrointestinal Tract

Rotating, high-frequency transducers, using 7.5-MHz crystals fitted into a fiberoptic endoscope, are most suitable for endosonography of the esophagus, stomach, and duodenum. Light sedation of the patient is usually required. The patient is placed in the left lateral decubitus position and the endoscope inserted to the desired location. Intraluminal gas is aspirated, and a balloon covering the transducer crystal is inflated with deaerated water. Localization is determined from the distance of insertion from

the teeth and identification of anatomic landmarks, such as the spleen, liver, pancreas, and gallbladder. Rotation and deflection of the transducer tip allow scanning of visualized lesions in different planes.[99]

Identification, localization, and characterization of benign masses are possible with endosonography. **Varices** are seen as compressible hypoechoic or cystic masses deep to the submucosa or in the outer layers of the esophagus, gastroesophageal junction, or gastric fundus.[100] Benign tumors such as **fibromas** or **leiomyomas** are well-defined, solid masses without mucosal involvement that can be localized to the layer of the wall from which they arise, usually the submucosa and the muscularis propria, respectively. Peptic ulcer typically produces marked thickening of all layers of the gastric wall, with a demonstrated ulcer crater. Ménétrier disease produces thickening of the mucosal folds.

Staging of **esophageal carcinoma** involves assessment of depth of tumor invasion and evaluation of involvement of the local lymph nodes and adjacent vital structures.[101] Constricting lesions that do not allow passage of the endoscope may produce technically unsatisfactory or incomplete examinations.

Gastric lymphoma is typically very hypoechoic; its invasion is along the gastric wall or horizontal, and involvement of extramural structures and lymph nodes is less than with gastric carcinoma. Thus, localized mucosal ulceration with extensive infiltration of the deeper layers suggests lymphoma, which may also grow with a polypoid pattern or as a diffuse infiltration without ulceration.[102] **Gastric carcinoma,** in contrast, arises from the gastric mucosa, is usually more echogenic, tends to invade vertically or through the gastric wall, and frequently involves the perigastric lymph nodes at diagnosis.

Rectum: Tumor Staging of Rectal Carcinoma

Transrectal (endorectal) sonography is an established modality for the staging of rectal carcinoma.[103-105] Its resolution of the layers of the rectum surpasses the performance of both CT and MRI. Although a variety of pathologic conditions may be assessed with endorectal sonography, the staging of previously detected rectal carcinoma is its major role. Patients are scanned in the left lateral decubitus position following a cleansing enema. Both axial and sagittal images are obtained. A variety of rigid intrarectal probes are commercially available, using a range of transducer technologies with phased array, mechanical sector, and rotating crystals.

Further, we have also been routinely evaluating women with rectal carcinoma using a transvaginal probe placed in the vagina after a Fleet enema. This technique is excellent, especially for larger tumors, because the rectovaginal septum, the tumor, and the lymph nodes in the mesorectum are more optimally seen.[106]

Tumors are staged according to the Astler-Coller modification[107] of the Dukes Classification, or more simply with the **primary tumor** component of the Union Internationale Contre le Cancer (UICC) **TNM classification,**[108] where **T** represents the primary tumor, **N** the nodal involvement, and **M** the distant metastases (Fig. 8.53).

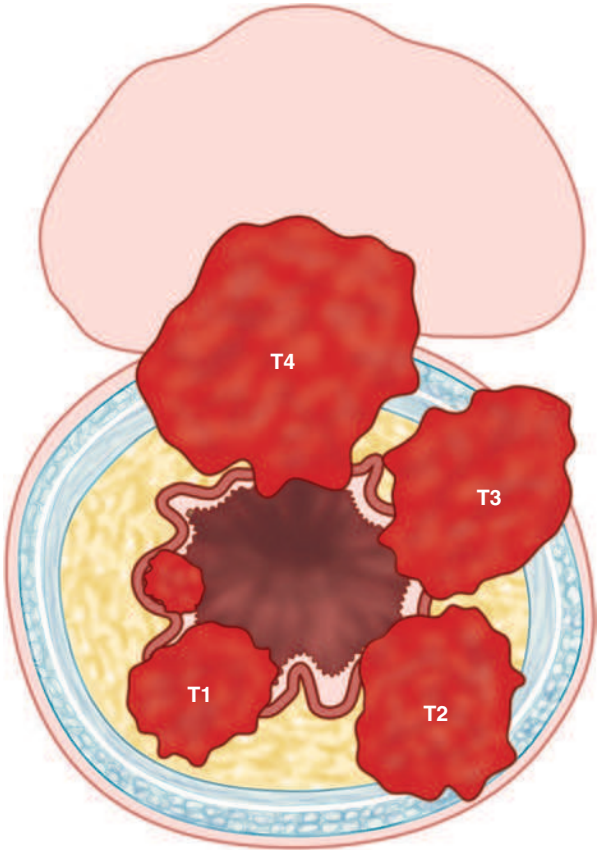

FIG. 8.53 Schematic of Tumor (T) Component of TNM Staging of Rectal Cancer on Sonography. Tumors *(red)* exhibit progressively deeper invasion beginning at 10 o'clock, where T superficial noninvasive lesion involves only superficial layers of intestinal wall. At 7 o'clock, T1 lesion invades submucosa *(yellow)*. At 5 o'clock, T2 lesion invades muscularis propria *(blue)*. At 2 o'clock, T3 lesion exhibits full-thickness invasion through layers of rectal wall, with invasion of surrounding perirectal fat. In directly anterior aspect (12 o'clock), T4 lesion exhibits invasion of prostate gland.

Rectal carcinoma arises from the mucosal surface of the gut. Tumors appear as relatively hypoechoic masses that may distort the rectal lumen. Invasion of the deeper layers, the submucosa, the muscularis propria, and the perirectal fat produces discontinuity of these layers on the sonogram (Fig. 8.54). Superficial ulceration or crevices that allow small bubbles of gas to be trapped deep to the crystal surface may demonstrate ring-down artifact and shadowing, with loss of layer definition deep to the ulceration. Lymph nodes appear as round or oval, hypoechoic masses in the perirectal fat (Fig. 8.54C). Color Doppler is an excellent addition to transrectal probes, showing the extent of tumors on the basis of their hypervascularity (Fig. 8.55) Infrequently, actual deposits may be shown within enlarged nodes. Therefore definitive staging requires pathologic assessment of both the tumor and the regional nodes.

Limitations of rectal sonography include the following: inability to identify microscopic tumor invasion, to image stenotic tumors, and to image tumors greater than 15 cm from the anal verge. It is also limited for distinguishing nodes involved with tumor from those with reactive change and to identify normal-sized nodes with microscopic tumor invasion.

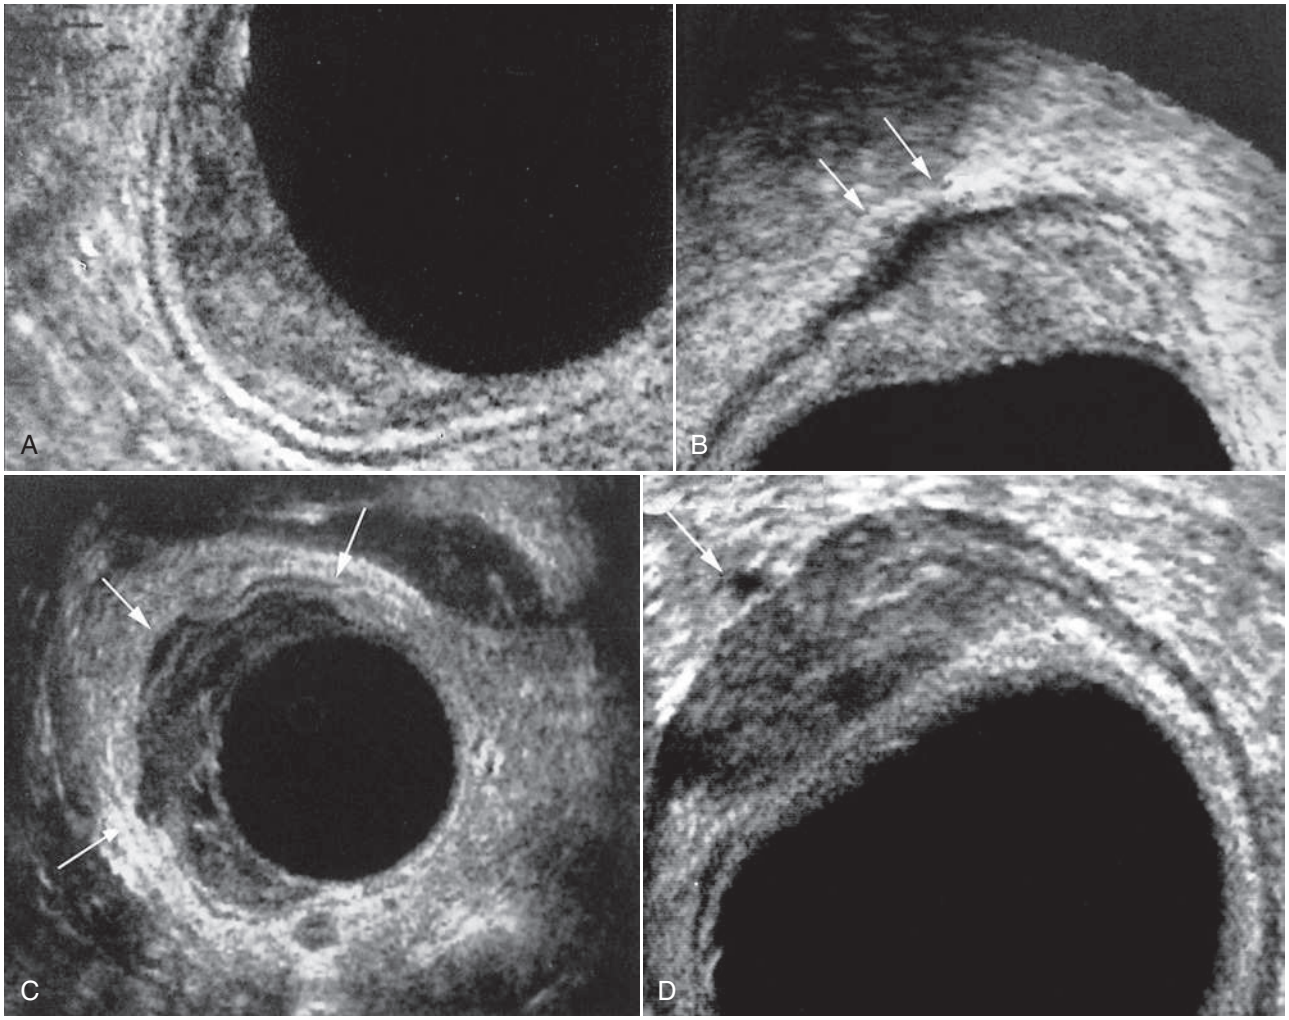

FIG. 8.54 Rectal Tumors Seen at Transrectal Sonography. (A) Rectal carcinoma: T1. Hypoechoic mass between 6 o'clock and 8 o'clock is noted. The submucosa (the echogenic line) and the muscularis propria (the external hypoechoic line) are intact. **(B) Rectal carcinoma: T2.** Tumor is seen anteriorly. The muscularis propria *(arrows)* is the hypoechoic line that is thickened and nodular, consistent with tumor involvement. **(C) Rectal carcinoma: T3.** A large tumor involves the entire right lateral wall of the rectum. Invasion of the perirectal fat *(arrows)* is noted in several locations. A large node is seen at the 6 o'clock position; smaller nodes are seen at 5 o'clock and 8 o'clock. **(D) Metastatic prostate carcinoma to rectal wall.** Hypoechoic mass is seen between 10 o'clock and 1 o'clock. It involves the deep layers of the rectal wall and not the rectal mucosa. There is a small lymph node *(arrow).* (With permission from Berton F, Gola G, Wilson S. Perspective on the role of transrectal and transvaginal sonography of tumors of the rectum and anal canal. AJR Am J Roentgenol. 2008;190[6]:1495-1504.[106])

Recurrent rectal cancer after local resection is usually extraluminal, involving the resection margin secondarily. Serial transrectal sonography may be used in conjunction with serum carcinoembryonic antigen levels to detect these recurrences. A pericolic hypoechoic mass or local thickening of the rectal wall, in either deep or superficial layers, is taken as evidence of recurrence. Previous radiation treatment may produce a diffuse thickening of the entire rectal wall, usually of moderate or high echogenicity, with an appearance that is usually easily differentiated from the focal hypoechoic appearance of recurrent cancer. Sonographic-guided biopsy of a detected abnormality facilitates histologic differentiation of recurrence from postoperative, inflammatory, or postradiation change.

Prostatic carcinoma may invade the rectum directly, or more remote tumors may involve the rectum, usually as a result of seeding to the posterior peritoneal pouch. Because these tumors initially involve the deeper layers of the rectal wall, with mucosal involvement occurring as the disease progresses, their sonographic appearance is distinct from that of primary rectal carcinoma (see Fig. 8.54D).

Benign mesenchymal tumors, especially of smooth muscle origin, are uncommon in the rectum. When seen, their sonographic features are the same as elsewhere (Fig. 8.56). **Mucous retention cysts,** resulting from obstruction of mucous glands, produce cystic masses of varying size that are located deep in the rectal wall.

Anal Canal

Cancer of the anal canal is a very rare tumor that is well shown on anal sonography (Fig. 8.57).

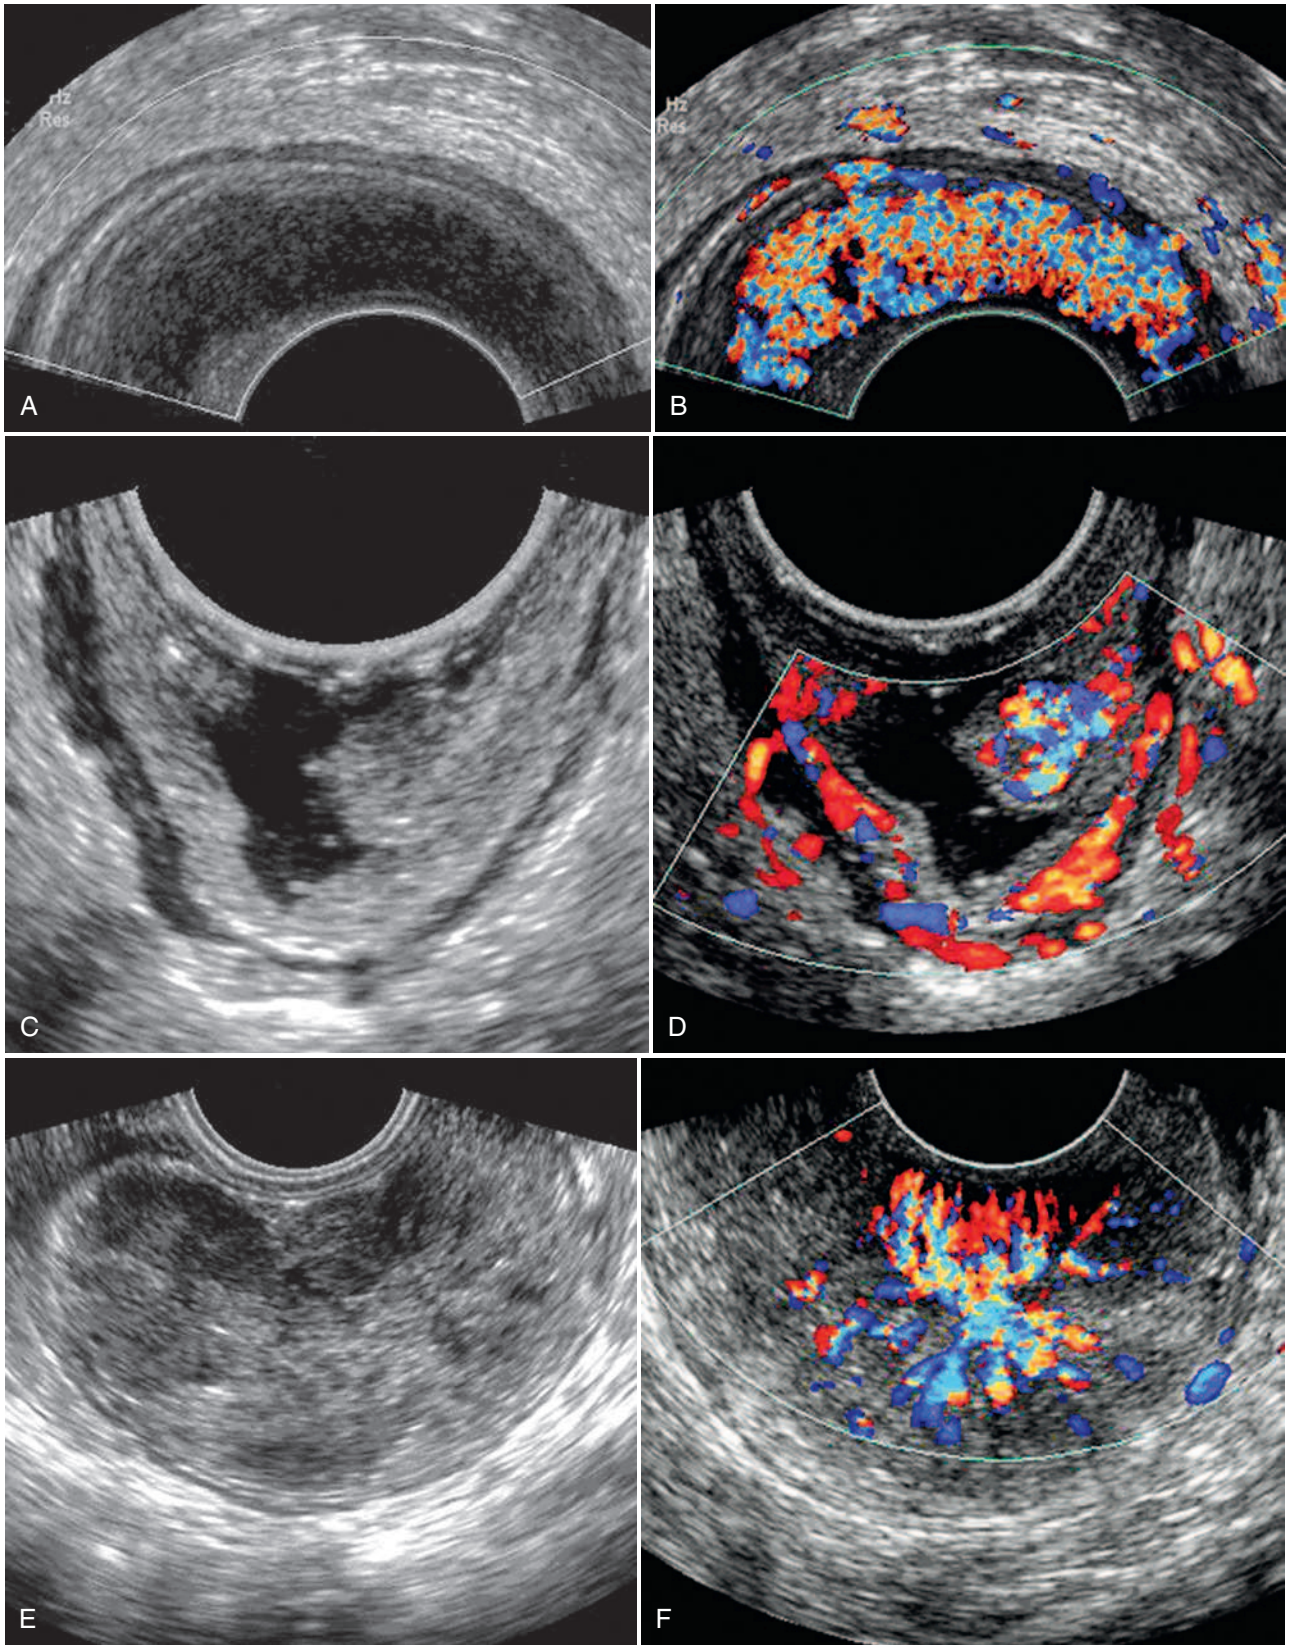

FIG. 8.55 Contribution of Color Doppler at Transrectal Sonography to Staging and Diagnosis of Rectal Cancer. (A) and **(B) T2 rectal cancer** in 58-year-old man. **(A)** Axial image shows hypoechoic tumor. Destruction of submucosa is evident with involvement of muscularis propria on right side of image. **(B)** Color Doppler shows typical hypervascularity. Color demarcates tumor from normal rectal wall on left side of image. **(C)** and **(D)** Small **rectal adenocarcinoma** originating in adenomatous polyp in 55-year-old man. **(C)** Axial image shows an isoechoic polypoid mass with a broad base surrounded by fluid within the rectal lumen. Mass involves the submucosal layer only. **(D)** Color Doppler image shows profuse vascularity and vascular stalk of the polypoid mass. **(E)** and **(F)** tubulovillous adenoma in 58-year-old woman. **(E)** Axial transvaginal image shows a mixed-echogenic mass that seems to fill the lumen of the rectum. **(F)** Color Doppler frequently shows this type of stellate, branching vascularity in tubulovillous tumors. (With permission from Berton F, Gola G, Wilson S. Perspective on the role of transrectal and transvaginal sonography of tumors of the rectum and anal canal. AJR Am J Roentgenol. 2008;190[6]:1495-1504.[106])

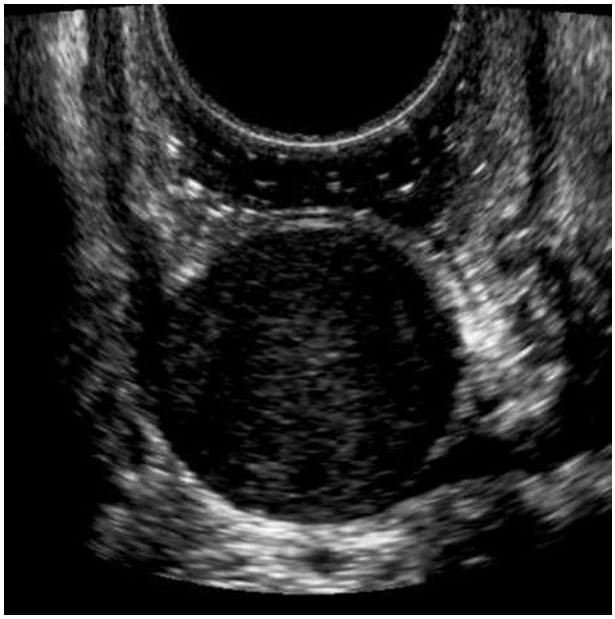

FIG. 8.56 Gastrointestinal Stromal Tumor (GIST) of Rectum. Transrectal sonographic image shows solid, well-defined, round mass arising from muscularis propria layer in 59-year-old woman with asymptomatic palpable mass found at routine physical examination. Tumor is growing with submucosal pattern, and mucosal surface bulges into fluid-filled lumen.

FIG. 8.57 Cancer of Anal Canal. (A) Long-axis image and **(B)** cross-sectional image show a hypoechoic tumor disrupting the normal planes of the anal canal. **(C)** Sonogram shows the vascularity of the tumor. (With permission from Berton F, Gola G, Wilson S. Perspective on the role of transrectal and transvaginal sonography of tumors of the rectum and anal canal. AJR Am J Roentgenol. 2008;190[6]:1495-1504.[106])

Fecal Incontinence

Anal endosonography, performed with the addition of a hard cone attachment to a radial 7.5-MHz probe, allows accurate assessment of the anal canal, including the internal and external sphincters.[109] Performed primarily for assessment of fecal incontinence, this test shows the integrity of the sphincters with documentation of the degree and size of muscle defects. We do not use this technique any longer, preferring instead assessment of the sphincter and perianal soft tissues with a combination of transvaginal and transperineal scan.[37,110-113]

Young women, following traumatic obstetric delivery, are most often afflicted with fecal incontinence. The internal anal sphincter, in continuity with the muscularis propria of the rectum above, is seen as a thick circular hypoechoic or hypoechoic ring just deep to the convoluted mucosal echoes (Fig. 8.58). The external anal sphincter, in contrast, is less well defined and more echogenic, appearing gray on the ultrasound examination, and in continuity with fibers from the puborectalis sling. Traumatic disruption of the muscle layers will show as defects in the continuity of the normal muscle texture, most often anterior (Fig. 8.59). Post-traumatic scarring may be associated with a change of shape of the anal canal from round to oval.

Perianal Inflammatory Disease

Perianal inflammatory disease is seen in two distinct patient populations: (1) those with **Crohn disease** who develop perianal inflammation as part of their disease and (2) those who develop a **perianal abscess** or **perianal fistula** as a spontaneous event. The first group is described earlier in the section on Crohn disease. In other patients, perianal infection arises in small,

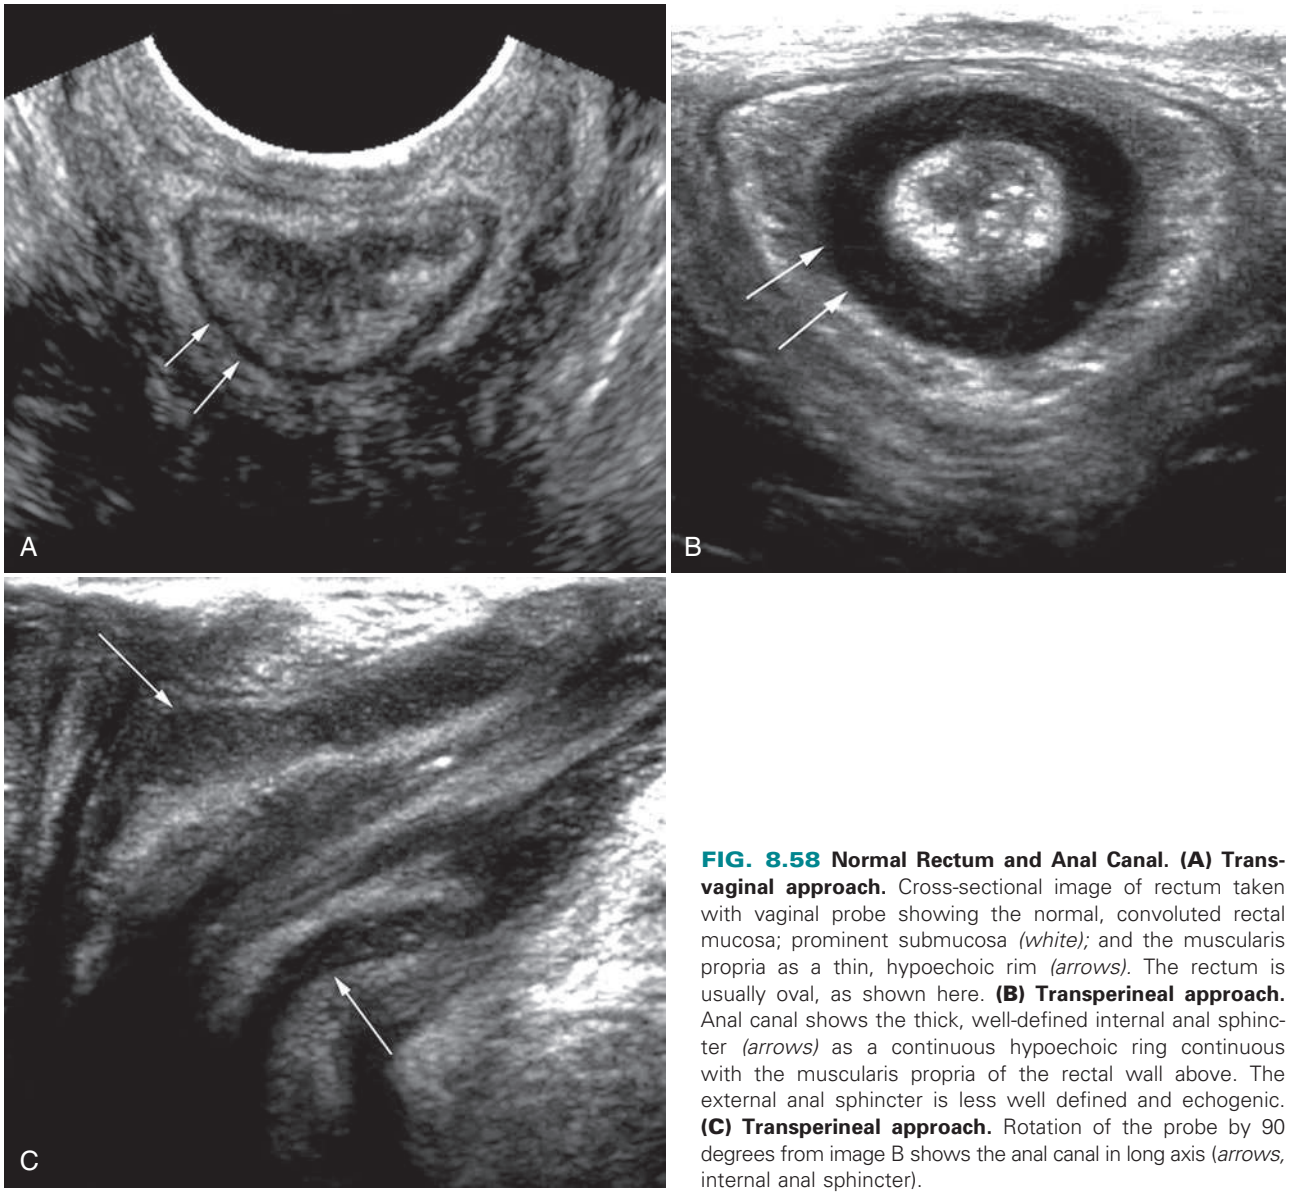

FIG. 8.58 Normal Rectum and Anal Canal. (A) Transvaginal approach. Cross-sectional image of rectum taken with vaginal probe showing the normal, convoluted rectal mucosa; prominent submucosa *(white);* and the muscularis propria as a thin, hypoechoic rim *(arrows).* The rectum is usually oval, as shown here. **(B) Transperineal approach.** Anal canal shows the thick, well-defined internal anal sphincter *(arrows)* as a continuous hypoechoic ring continuous with the muscularis propria of the rectal wall above. The external anal sphincter is less well defined and echogenic. **(C) Transperineal approach.** Rotation of the probe by 90 degrees from image B shows the anal canal in long axis (*arrows,* internal anal sphincter).

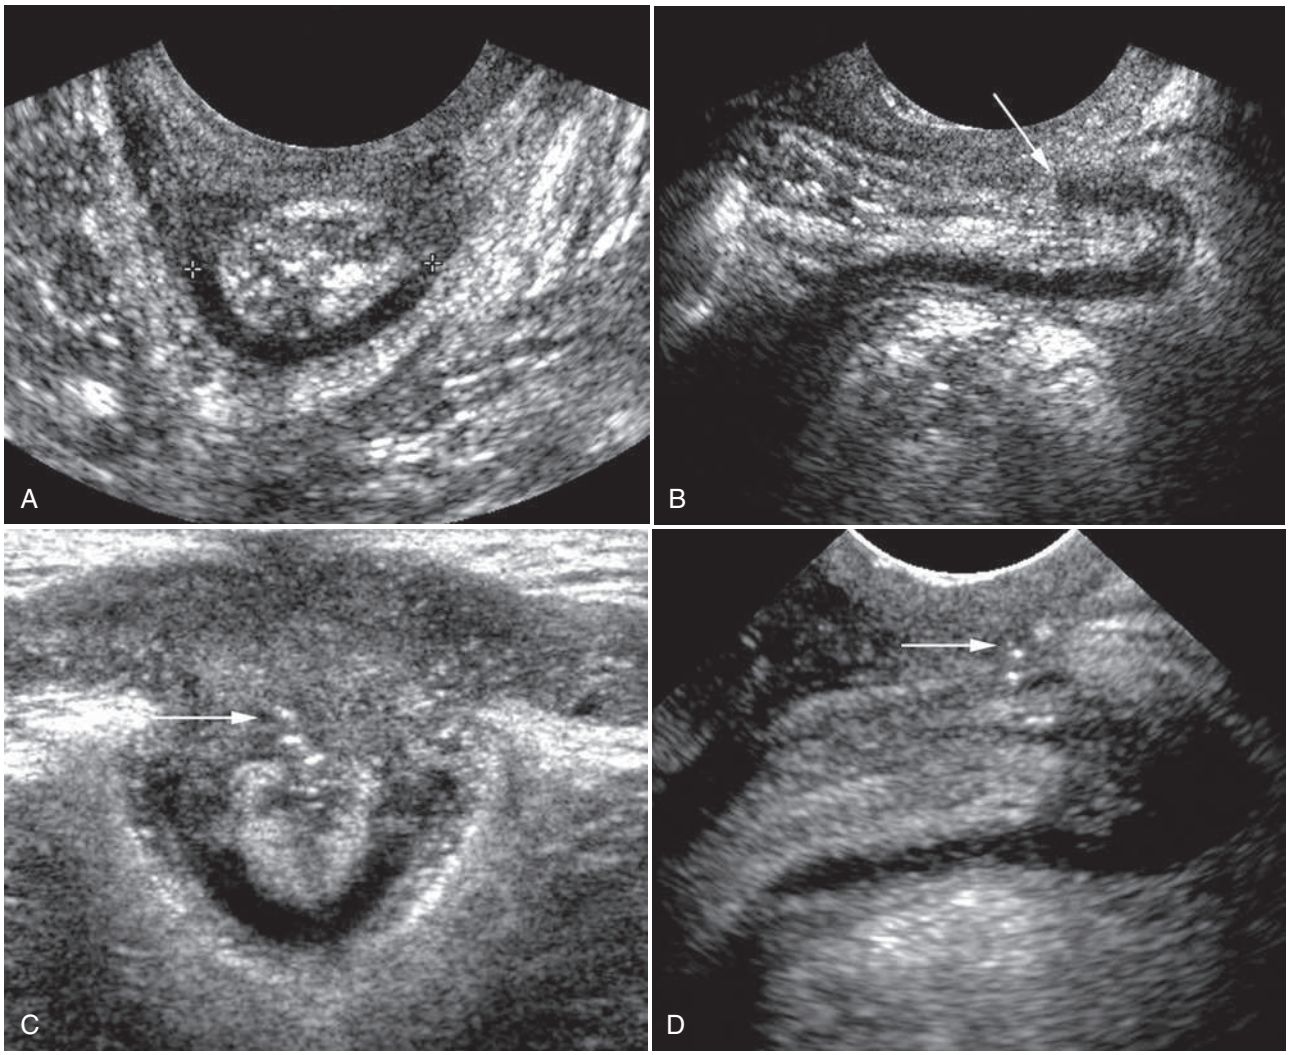

FIG. 8.59 Traumatic Disruption of Anal Sphincter in Two Patients. (A) Cross-sectional and **(B)** long-axis views of the anal canal from a transvaginal approach show disruption of the sphincter anteriorly from 9 to 3 o'clock. The arrow on the sagittal image shows the cephalad extent of the internal anal sphincter. **(C)** Cross-sectional and **(D)** long-axis views of the anal canal show full-thickness disruption of the anterior anal canal between 11 and 1 o'clock. The arrow in each image shows air bubbles within an anovaginal fistula.

intersphincteric anal glands predominantly located at the dentate line. This occurs most frequently in young adult men. Documentation of fluid collections and the relationship of inflammatory tracts to the sphincter mechanism are important for surgical treatment. We prefer transvaginal sonography (Video 8.17) in conjunction with transperineal sonography in women and transperineal sonography in men for evaluation of this problem.

Scans are performed with curved and high-frequency linear probes placed firmly on the skin of the perineum between the introitus and the anal canal in women and between the scrotum and the anal canal in men.[111] Firm pressure on the transducer is required to afford good visualization of the anal canal. We begin the procedure with the transducer in the transverse plane relative to the body. The transducer should be directed cephalad and anterior to the plane of the anal canal, then angled slowly through the plane of the anal canal, which will show it in cross section from the anorectal junction to the external anal opening. Rotation of the transducer by 90 degrees will allow for imaging in the longitudinal plane. Tracts and collections in the perineum, buttocks, scrotum, and labia can also be assessed and followed in a retrograde direction to their connection with the anal canal.

Sonography of Perianal Inflammatory Disease

Internal opening in the anal canal or rectum
Tracts and their relationship to anal sphincter
External openings
Fluid collections

Perianal inflammatory tracts and masses are classified according to Parks et al.[114] Their classification provides an anatomic description of fistulous tracts, which acts as a guide to operative

treatment. The four main subtypes are **intersphincteric** (between internal and external sphincter), **transsphincteric** (crossing both internal and external anal sphincter into ischiorectal or ischioanal fossa), **suprasphincteric,** and **extrasphincteric.** In each patient, we also document the internal opening and the external openings, as possible. Tracts show on the ultrasound scan as hypoechoic linear areas or fluid-containing tubular areas, depending on their size and activity (Fig. 8.60). As with fistulas elsewhere, air bubbles within the tract show as bright, echogenic foci that may move during the scan, helping with their identification. In our initial experience with 54 patients with perianal inflammatory masses, sonographic findings were confirmed in 22 of 26 patients (85%) who underwent surgical treatment for their disease.

Acknowledgment

The author would like to acknowledge Gordana Popovich for her artwork.

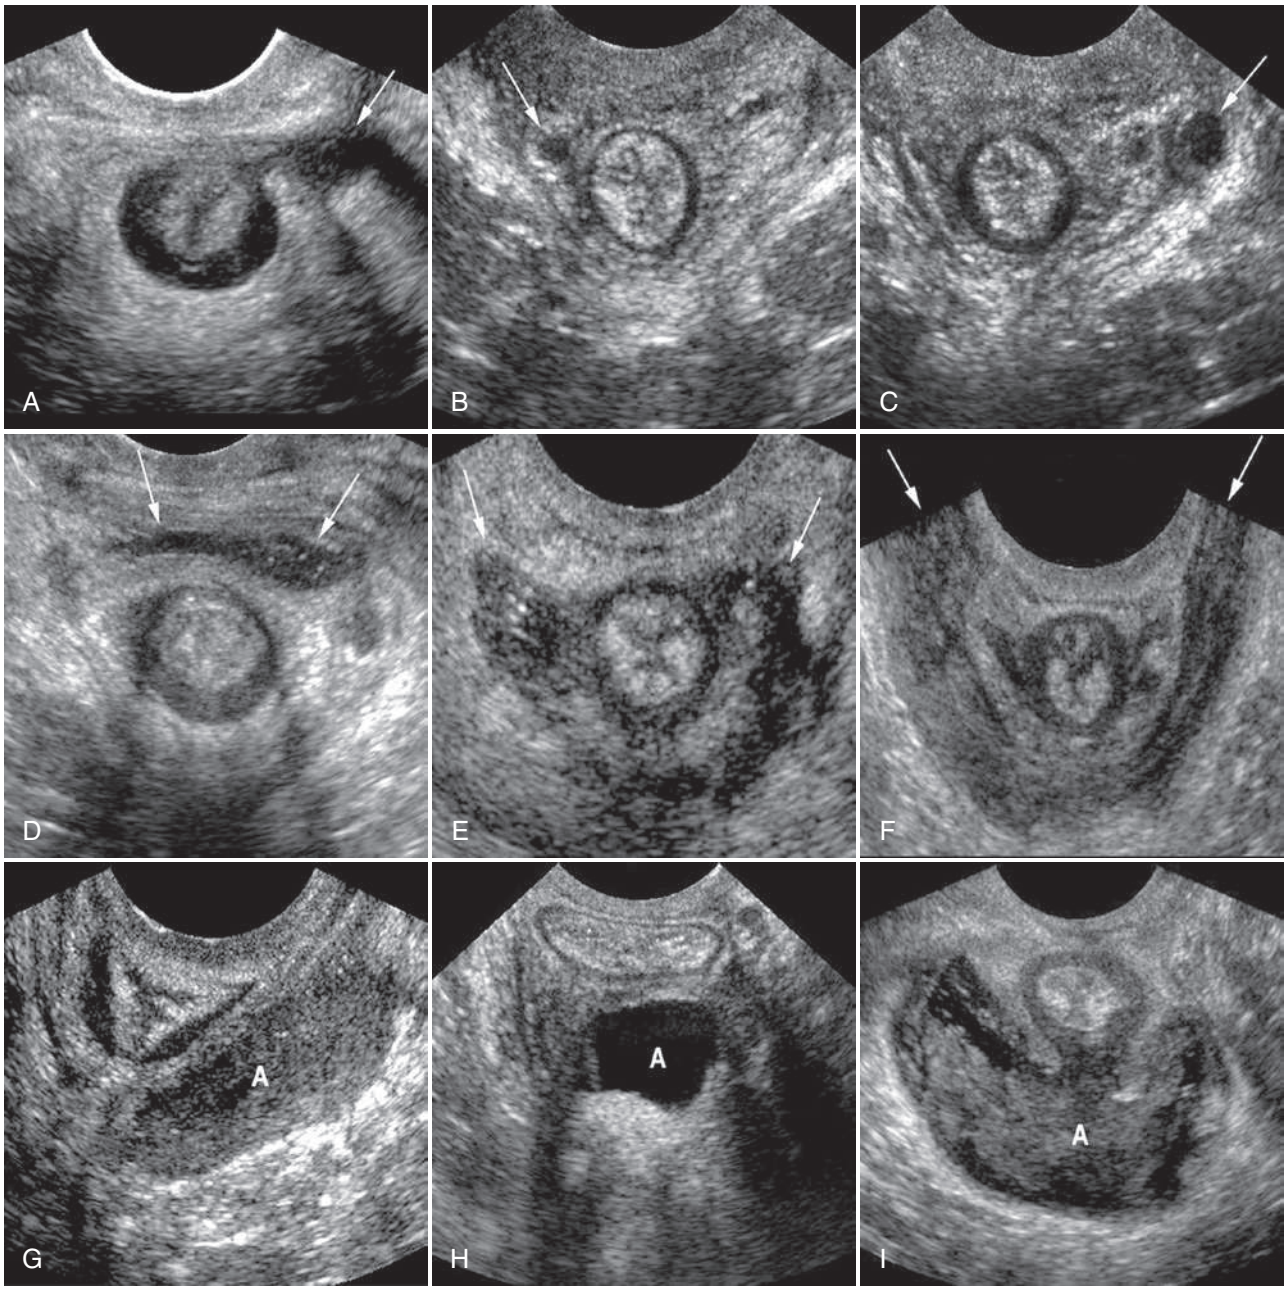

FIG. 8.60 Perianal Inflammatory Disease in Nine Patients. *Top row,* **Simple inflammatory openings and tracts** *(arrows).* Cross-sectional images of the anal canal show internal opening at 1 o'clock with **(A)** transsphincteric tract running to a small collection; **(B)** intersphincteric tract; **(C)** larger extrasphincteric tract. *Middle row,* **More complex tracts** *(arrows).* **(D)** Anterior extrasphincteric tract shows fluid within. **(E)** Bilateral, complex, intersphincteric tracts and collections show bright, echogenic foci representing extraluminal air. **(F)** Boomerang, or horseshoe, tract surrounds the anal canal posteriorly and laterally. There are internal openings at 2, 4, and 9 o'clock. *Bottom row,* **Perianal abscesses** *(A).* **(G)** Abscess on left posterolateral aspect of the anal canal is particle filled. **(H)** Large, posterior abscess is complex, with a dependent debris level. **(I)** Large, posterior abscess shows a large internal opening posteriorly at 6 o'clock.

CHAPTER 9

The Kidney and Urinary Tract

Mitchell Tublin, Deborah Levine, Wendy Thurston, and Stephanie R. Wilson

SUMMARY OF KEY POINTS

- Renal ultrasound is the screening modality of choice for the initial evaluation of renal insufficiency. Relevant imaging markers include parenchymal echogenicity, renal length, and collecting system dilatation.
- The primary role for ultrasound in the evaluation of renal masses is to differentiate between cystic and solid lesions, although an appropriate differential diagnosis may be given based on clinical history and cyst complexity.
- Echogenic renal masses are problematic, and although several discriminatory features have been proposed, renal computed tomography or magnetic resonance imaging is typically employed for larger lesions to differentiate between renal cell carcinoma and angiomyolipoma.
- The role of ultrasound in the evaluation of hematuria continues to evolve. Ultrasound is an effective screening modality for typical "urologic" causes of hematuria (namely, renal calculi) in younger patients.
- Focal and diffuse bladder wall thickening at ultrasound is nonspecific and may be caused by a variety of infectious, inflammatory reactions or neoplastic processes. Urine analysis, clinical history, and potentially cystoscopy are typically performed after thickening is identified at sonography.

CHAPTER OUTLINE

CONCLUSION
Acknowledgment

The prime function of the kidney is excretion of metabolic waste products. The kidneys do this by converting more than 1700 liters of blood per day into 1 liter of highly concentrated urine.[1] The kidney is an endocrine organ that secretes many hormones, including erythropoietin, renin, and prostaglandins. The kidneys also function to maintain homeostasis by regulating water-salt and acid-base balance. The renal collecting system, ureters, and urethra function as conduits, and the bladder serves as a reservoir for urinary excretion.

EMBRYOLOGY

Development of the Kidneys and Ureter

Three sets of kidneys develop in human embryos: the pronephros, mesonephros, and metanephros (definitive or permanent kidney).[2] The **pronephroi** appear early in the fourth embryologic week and are rudimentary and nonfunctioning. The **mesonephroi** form late in the fourth week and function as interim kidneys until the developing metanephroi begin to function (ninth week). The **metanephroi** (permanent kidneys) develop from two sources: the **ureteric bud** and **metanephrogenic blastema.**[2] The ureteric bud forms the ureter, renal pelvis, calices, and collecting ducts, interacting with and penetrating the metanephrogenic blastema. This interaction is necessary to initiate ureteric bud branching and differentiation of nephrons within the blastema (Fig. 9.1). Initially, the permanent kidneys are found in the pelvis. With fetal growth, the kidneys come to lie in the upper retroperitoneum. With ascent, the kidneys rotate medially 90 degrees so that the renal pelvis is directed anteromedially. The kidneys are in their adult location and position by the ninth gestational week. As the kidneys ascend, they derive their blood supply from nearby vessels; adult blood supply is from the abdominal aorta.

Development of the Bladder

In the seventh gestational week the urorectal septum fuses with the cloacal membrane, dividing it into a ventral **urogenital sinus** and a **dorsal rectum.** The bladder develops from the urogenital sinus. Initially, the bladder is continuous with the allantois, which eventually becomes a fibrous cord called the **urachus,** the adult median umbilical ligament. As the bladder enlarges, the distal portion of the mesonephric ducts is incorporated as connective tissue into the bladder trigone. At the same time, the ureters come to open separately into the bladder.[2] In infants and children the bladder is an abdominal organ; it is not until after puberty that it becomes a true pelvic structure[2] (Fig. 9.2).

Development of the Urethra

The epithelium of most of the male urethra and the entire female urethra is derived from the endoderm of the urogenital sinus. The urethral connective tissue and smooth muscle form from adjacent splanchnic mesenchyme.[2]

ANATOMY

Kidney

In the adult, each kidney measures approximately 11 cm long, 2.5 cm thick, and 5 cm wide and weighs 120 to 170 grams.[3] Emamian et al.[4] demonstrated that the parenchymal volume of the right kidney is smaller than that of the left kidney, possibly because of a relatively larger potential space for left renal growth (growth of right kidney inhibited by liver) or relatively increased left renal blood flow (left renal artery typically shorter than right renal artery). Renal length correlates best with body height, and renal size decreases with advancing age because of parenchymal reduction.

The left kidney usually lies 1 to 2 cm higher than the right kidney.[3] The kidneys are mobile and will move depending on body position. In the supine position, the superior pole of the left kidney is at the level of the 12th thoracic vertebra, and the inferior pole is at the level of the third lumbar vertebra.

The **normal adult kidney** is bean shaped with a smooth, convex contour anteriorly, posteriorly, and laterally. Medially,

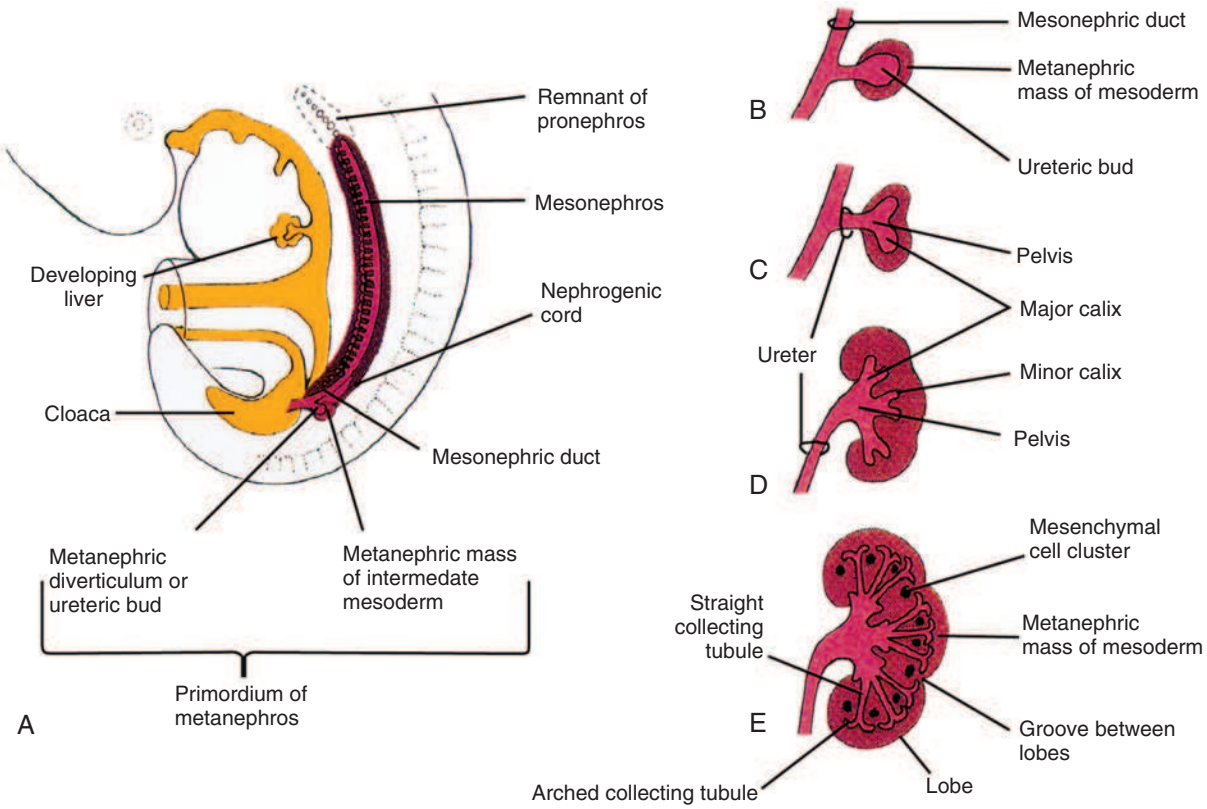

FIG. 9.1 Embryology of the Kidney and Ureter. (A) Lateral view of a 5-week embryo shows the three embryologic kidneys. **(B)-(E)** Successive stages of development of the ureteric bud (fifth to eighth week) into the ureter, pelvis, calices, and collecting tubules. FIG. 9.2 Embryology of the Bladder and Urethra. Diagrams show division of the cloaca into the urogenital sinus and rectum; absorption of the mesonephric ducts; development of the urinary bladder, urethra, and urachus; and change in location of the ureters. **(A)** and **(B)** Five-week embryo. **(C)-(H)** Seven- to 12-week embryo. (**A, C, E,** and **G,** female; **B, D, F,** and **H,** male.) (With permission from The urogenital system. In: Moore KL, Persaud TVN, editors. The developing human: clinically oriented embryology. 5th ed. Philadelphia: Saunders; 1993. pp. 265-303.[2])

the surface is concave; the medial surface is known as the **renal hilum.** The renal hilum is continuous with a central cavity called the **renal sinus.** Within the renal sinus are the major branches of the renal artery, major tributaries of the renal vein, and the collecting system.[3] The remainder of the renal sinus is packed with fat. The collecting system (renal pelvis) lies posterior to the renal vessels in the renal hilum (Fig. 9.3).

Renal parenchyma is composed of cortex and medullary pyramids. The **renal medullary pyramids** are hypoechoic relative to the renal cortex and can be identified in most normal adults (Fig. 9.4). Normal **renal cortex** is typically less echogenic than adjacent liver and spleen. Platt et al.[5] found that 72% of 153 patients with renal cortical echogenicity equal to that of the liver had normal renal function. Greater renal echogenicity than liver echogenicity showed a specificity and a positive predictive value for abnormal renal function of 96% and 67%, respectively. However, the sensitivity of this ultrasound criterion was poor (20%).

During normal development, two parenchymal masses called **ranunculi** partially fuse. **Parenchymal junctional defects** occur at the site of fusion and must not be confused with pathologic processes (e.g., renal scar, angiomyolipoma). The junctional parenchymal defect is most often located anteriorly and superiorly, typically at the junction of the upper and middle thirds of the kidney, and can be traced medially and inferiorly into the renal sinus. Usually, it is oriented more horizontally than vertically and therefore it is best appreciated on sagittal scans[6] (Fig. 9.5). Junctional cortical defects are more often shown within the right kidney, although left junctional cortical defects may be detected with favorable acoustic windows.

A **hypertrophied column of Bertin** (HCB) is a normal variant; it represents unresorbed polar parenchyma from one or both of the two subkidneys that fuse to form the normal kidney.[7] Sonographic features that may aid in the demarcation of HCB include indentation of the renal sinus laterally and a border formed by the junctional parenchymal defect. Hypertrophied columns are usually located at the junction of the upper and middle thirds of the kidney and contain renal cortex that is continuous with the adjacent renal cortex of the same subkidney.

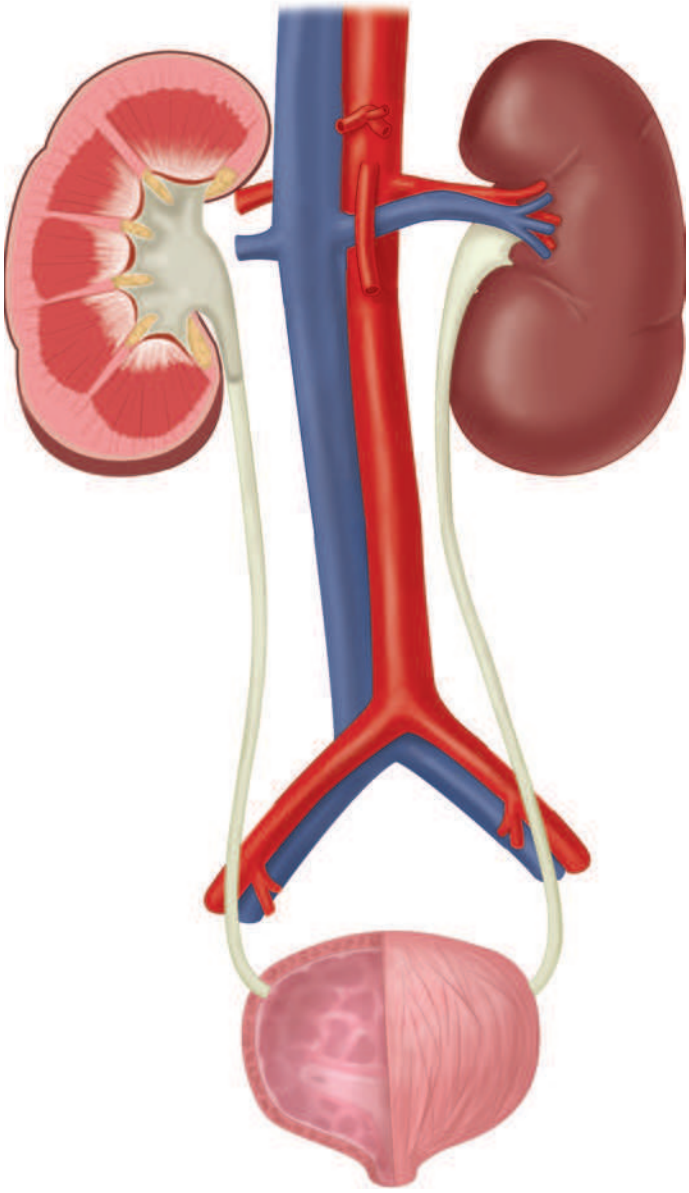

FIG. 9.3 Anatomy of the Kidney, Ureter, and Bladder.

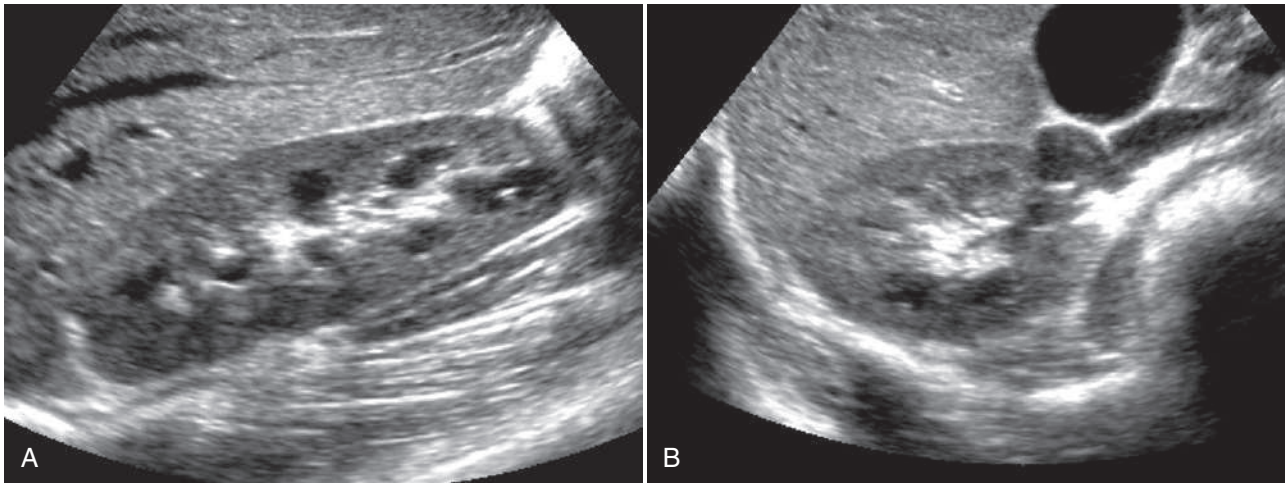

FIG. 9.4 Normal Kidney. (A) Sagittal and **(B)** transverse sonograms of normal anatomy with corticomedullary differentiation show relatively hypoechoic medullary pyramids, with cortex slightly less echogenic than the liver and spleen.

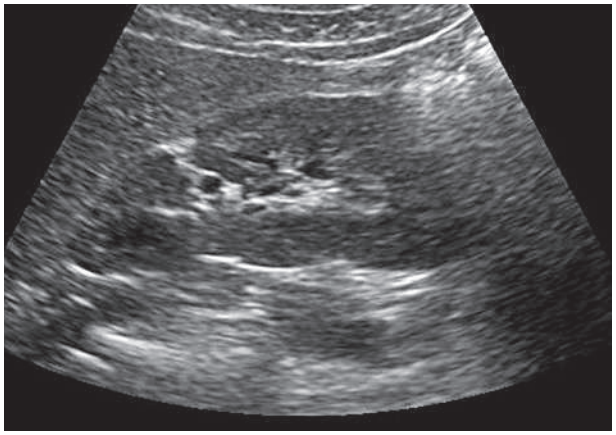

FIG. 9.5 Anterior Junction Line. Sagittal sonogram demonstrates an echogenic line that extends from the renal sinus to perinephric fat. The defect is typically located at the junction of the upper and middle thirds of the kidney, as in this example.

Sonographic Criteria for Hypertrophied Column of Bertin

Indentation of renal sinus laterally
Bordered by junctional parenchymal defect
Location at junction of upper and middle thirds
Continuous with adjacent renal cortex
Similar color flow to surrounding parenchyma
Contains renal pyramids
Less than 3 cm in size

Columns contain renal pyramids and usually measure less than 3 cm[7,8] (Fig. 9.6). The echogenicity of HCB and adjacent renal cortex depend on the scan plane. Alterations in tissue orientation produce different acoustic reflectivity.[7] The echoes of the HCB are brighter than those of adjacent renal cortex when seen en face[7] (Fig. 9.6). It may be difficult to differentiate a small, hypovascular tumor from an HCB; however, demonstration of arcuate arteries by color Doppler ultrasound indicates an HCB rather than a tumor. Occasionally, contrast-enhanced computed tomography (CT) may be necessary to differentiate between an HCB and a non–border-deforming renal lesion.

The kidney has a thin, fibrous **capsule.** The capsule is surrounded by perirenal fat. Perirenal fat is encased anteriorly by **Gerota fascia** and posteriorly by **Zuckerkandl fascia.**[9] The right perirenal space opens superiorly at the bare area of the liver, and both perirenal spaces communicate with the pelvic peritoneal space.[10] Right and left perirenal spaces communicate with each other across the midline at the level of the third to fifth lumbar vertebrae.[10]

Ureter

The ureter is a long (30-34 cm), mucosal-lined conduit that delivers urine from the renal pelvis to the bladder. Each ureter varies in diameter from 2 to 8 mm.[3] As it enters the pelvis, the ureter passes anterior to the common/external iliac artery. The ureter has an oblique course through the bladder wall (see Fig. 9.3).

Bladder

The bladder is positioned in the pelvis, inferior and anterior to the peritoneal cavity and posterior to the pubic bones.[3] Superiorly, the peritoneum is reflected over the anterior aspect of the bladder. Within the bladder, the ureteric and urethral orifices demarcate an area known as the **trigone;** the urethral orifice also marks the **bladder neck.** The bladder neck and trigone remain constant in shape and position; however, the remainder of the bladder will change shape and position depending on the volume of urine within it. Deep to the peritoneum covering the bladder is a loose, connective tissue layer of subserosa that forms the adventitial layer of the bladder wall. Adjacent to the adventitia are three muscle layers: the outer (longitudinal), middle (circular), and internal longitudinal layers. Adjacent to the muscle, the innermost layer of the bladder is composed of mucosa. The bladder wall should be smooth and of uniform thickness. The wall thickness depends on the degree of bladder distention.

SONOGRAPHIC TECHNIQUE

The ability to visualize organs of the genitourinary tract by ultrasound depends on the patient's body habitus, operator experience, and scanner platform. High-frequency probes should be used for patients with a favorable body habitus. Harmonic imaging is often useful for difficult-to-scan patients (e.g., obese patients). Compound imaging and speckle reduction may increase lesion conspicuity and decrease artifacts.

Kidney

The kidneys should be assessed in the transverse and coronal plane. Optimal patient positioning varies; supine and lateral decubitus positions often suffice, although oblique and occasionally prone positioning may be necessary (e.g., obese patients). Usually, a combination of subcostal and intercostal approaches is required to evaluate the kidneys fully; the upper pole of the left kidney may be particularly difficult to image without a combination of approaches. When the collecting system is dilated, additional images should be taken to assess for the level of obstruction, any obstructing lesion, and appearance of the kidneys after voiding (see "Hydronephrosis").

Ureter

The proximal ureter is best visualized using a coronal oblique view with the kidney as an acoustic window. The ureter is followed to the bladder, maintaining the same approach. A nondilated ureter may be impossible to visualize because of overlying bowel gas. Transverse scanning of the retroperitoneum often demonstrates a dilated ureter, which can then be followed caudally with both transverse and sagittal imaging. In women, a dilated distal ureter is well seen with transvaginal scanning.

Bladder and Urethra

The **bladder** is best evaluated when it is moderately filled; an overfilled bladder causes patient discomfort. The bladder should be scanned in the transverse and sagittal planes. To better visualize the bladder wall in women, transvaginal scanning may be helpful. If the nature of a large, fluid-filled mass in the pelvis is uncertain,

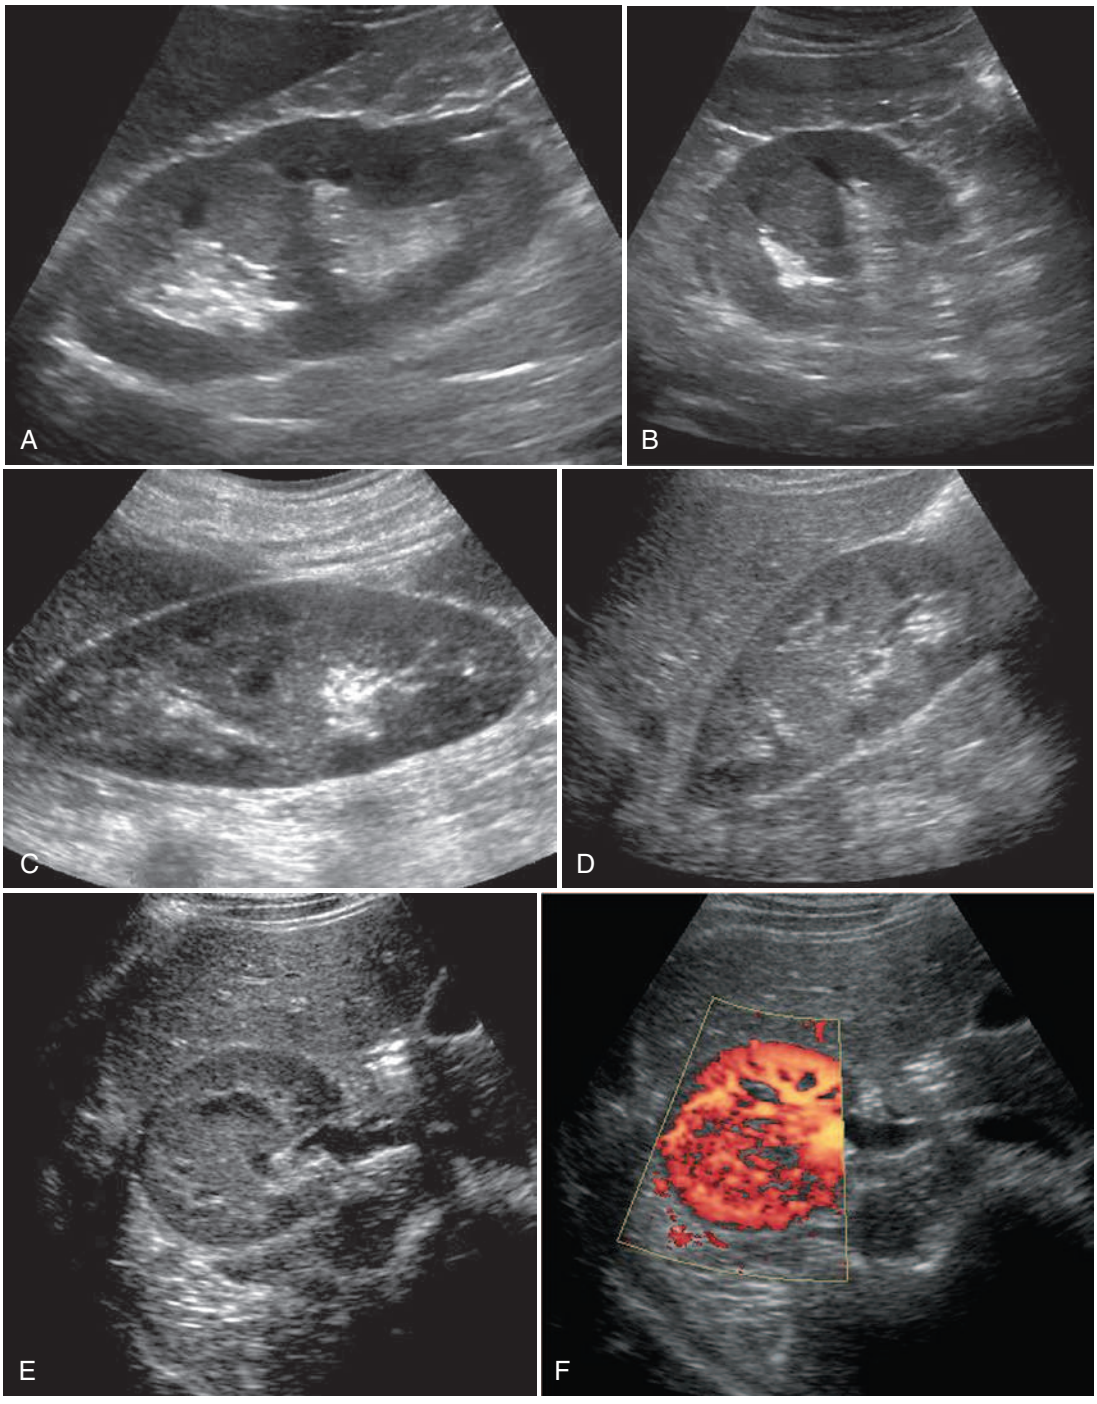

FIG. 9.6 Hypertrophied Column of Bertin. (A) Sagittal and **(B)** transverse sonograms show classic appearance of the column of Bertin. **(C)** Medullary pyramids can be seen within the hypertrophied column of Bertin. **(D)** Echogenicity of the column may vary based on orientation. **(E)** Transverse sonogram and **(F)** corresponding power Doppler image confirm a hypertrophied column.

voiding or insertion of a Foley catheter will clarify the location and appearance of the bladder relative to the fluid-filled mass.

Incomplete bladder emptying can be due to prostate enlargement, neurogenic bladder, or pelvic floor weakness. Bladder stones and infection are important complications. Initial assessment includes assessment of the kidneys and ureter for dilatation, as well as calculation of both a prevoid and postvoid residual. We typically calculate bladder volume by taking the three orthogonal measurements and multiplying by .6 (this is different from most organs, which multiply by .52). This slightly larger value is because the shape of the bladder is more of a cuboidal shape than a prolate ellipse.

The **urethra** in a woman can be scanned with transvaginal, transperineal, or translabial sonography[11] (Fig. 9.7). The posterior or the prostatic urethra in men is best visualized with transrectal probes (Fig. 9.8).

HYDRONEPHROSIS

The term *hydronephrosis* refers to dilatation of the collecting system. Obstruction is often present, but this is not always the case. There are many causes of a dilated renal collecting system, and ultrasound is the initial imaging modality of choice for the majority of these assessments (except as discussed in the previous section where noncontrast-enhanced CT may be used in the initial assessment of acute renal colic). Initial sonographic evaluation should include an assessment of the degree of dilatation, appearance of surrounding renal parenchyma, assessment for level of obstruction and any obstructing lesion. Numerous grading systems for the assessment of the degree of hydronephrosis have been proposed following Ellenbogen and colleagues' original article on the topic.[12] None has been readily adopted, however, and most radiologists continue to use descriptive terminology such as *mild, moderate,* and *severe.*[13]

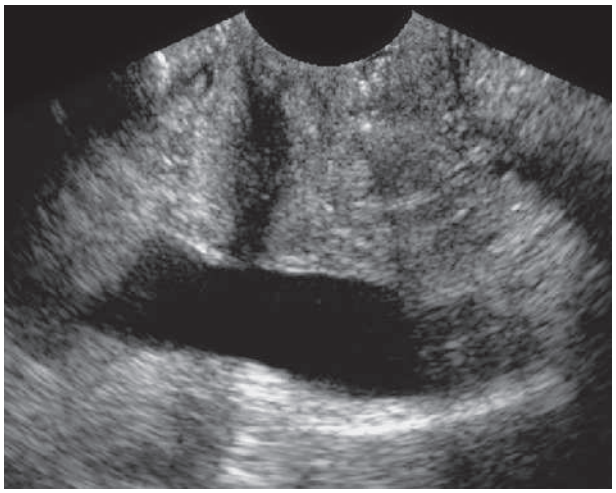

FIG. 9.7 Translabial Ultrasound of Female Urethra. Sagittal sonogram shows the tubular hypoechoic urethra extending from the bladder to the skin surface.

A practical pearl for the ultrasound evaluation of hydronephrosis is to assess the degree of dilatation before and after bladder voiding. Hydronephrosis that persists after voiding suggests an anatomic obstruction. If collecting system dilatation diminishes postvoiding, then one might consider nonobstructive pelvicaliectasis (i.e., vesicoureteral reflux). Most obstructing lesions are located within the pelvis (fibroids, prostatic hypertrophy, ovarian tumor, bladder tumor) and thus are obvious on sonographic evaluation. When the pelvis is normal, the length of the ureter should be assessed for dilatation and/or obstructing lesion. In pregnancy, it is helpful to have the patient lie in the decubitus position with the symptomatic side up to allow for the weight of the uterus to move off of the ureter.

Over time the obstructed kidney will initially become enlarged. Later, renal damage may occur with parenchymal atrophy and blunting of calices.

In pregnancy, the urinary tract frequently is dilated. Smooth muscle relaxation occurs as a result of elevated hormone levels. Mass effect on the ureter may be caused by the enlarged uterus. Because of the location of the ureters, the right ureter is frequently more dilated than the left ureter. Physiologic dilatation of the urinary tract in pregnancy is suggested when the distal ureters taper at the sacral promontory. Pregnant patients are also at increased risk for urinary tract infections (UTIs), which can complicate the assessment. In addition, stone disease can occur and this needs to be distinguished from the physiologic dilatation associated with pregnancy.

In acute hydronephrosis of pregnancy, patients may present with severe flank or lower abdominal pain radiating to the groin due to ureteric obstruction. The obstruction usually occurs at the level of the pelvic brim. Symptoms may improve with change in posture with the patient in the lateral decubitus position, symptomatic side up. In extreme cases, ureteral stunting may be required. When severe overdistention syndrome occurs, rupture of the urinary tract may occur, which can be identified as fluid collection around the periphery of the kidney by ultrasound.

Causes of Hydronephrosis

Genitourinary Obstruction	Comments
Renal/ureteral stone	Look for stone in common sites of obstruction: ureterovesical junction and ureteropelvic junction
Transitional cell carcinoma	Hematuria
Sloughed papilla	
Blood clot	Hematuria
Posterior urethral valves	Bilateral, pediatric diagnosis
Ureterocele	May be orthotopic or heterotopic If heterotopic, look for renal duplication abnormality
Ureteropelvic junction obstruction	Extrarenal pelvis may be dilated out of proportion to calices
Ureteral stricture (prior infection, surgery, radiation)	History aids in diagnosis
Neurogenic bladder	Check for postvoid residual
Extrinsic Obstruction	
Retrocaval ureter	May need CT for diagnosis
Prostatic hypertrophy	Enlarged prostate impinges on bladder
Tumor (fibroid, ovarian carcinoma, lymphoma)	Abnormal mass seen in pelvis
Lymphadenopathy	Abnormal mass seen in pelvis
Retroperitoneal fibrosis	Mass encasing the aorta CT may be needed for diagnosis
Aneurysm	Should be obvious on Doppler assessment of vessels
Endometriosis	Mass typically seen in pelvis
Pregnancy	Ureter dilated to pelvic brim
Nonobstructive	
Vesicoureteral reflux	Cortical scarring, typically in upper poles
Congenital megacalices	May be unilateral or bilateral If associated with congenital megaureter, both dilated ureter and calices will be present May need contrast-enhanced CT for diagnosis
Prior obstruction	Prior severe dilatation may not return to normal
Infection	Signs and symptoms of infection
High flow states (diabetes insipidus, psychogenic polydipsia)	Typically mild dilatation
Distended bladder	Returns to normal after bladder emptying

PITFALLS IN ASSESSMENT OF OBSTRUCTION

Although obstruction typically causes dilatation, early in the process the renal collecting system may not dilate. In cases of renal failure, a poorly functioning kidney may not make sufficient urine to demonstrate dilatation. In addition, in cases of severe obstruction, pelvocaliceal rupture may lead to decompression of the collecting system with a perinephric hematoma/urinoma. Hydronephrosis (a condition in which dilated calices communicate with central collecting system) should be distinguished from multiple parapelvic cysts (which do not communicate).

CONGENITAL ANOMALIES

Anomalies Related to Renal Growth

Hypoplasia

Renal hypoplasia is a renal parenchymal anomaly in which there are too few nephrons. Renal function depends on the mass of the kidney. True hypoplasia is a rare anomaly. Many patients with **unilateral** hypoplasia are asymptomatic; the condition is typically an incidental finding. Patients with **bilateral** hypoplasia often have renal insufficiency. Hypoplasia is believed to result from the ureteral bud making contact with the most caudal portion of the metanephrogenic blastema. This can occur with delayed development of the ureteric bud or from delayed contact of the bud with the cranially migrating blastema. Hypoplasia is established when fewer but otherwise histologically normal renal lobules are identified.[14] At ultrasound, the kidney is small but otherwise appears normal.

Fetal Lobation

Fetal lobation is usually present until 4 or 5 years of age; however, persistent lobation is seen in 51% of adult kidneys.[15] There is infolding of the cortex without loss of cortical parenchyma. At ultrasound, sharp clefts are shown overlying the columns of Bertin.[16]

Compensatory Hypertrophy

Compensatory hypertrophy may be diffuse or focal. It occurs when existing healthy nephrons enlarge to allow healthy renal parenchyma to perform more work. The diffuse form is seen

with contralateral nephrectomy, **renal agenesis, renal hypoplasia, renal atrophy,** and **renal dysplasia.** Diffuse compensatory hypertrophy is suggested at ultrasound when an enlarged but otherwise normal-appearing kidney is identified. The focal form is seen when residual islands of normal tissue enlarge in an otherwise diseased kidney; focal compensatory hypertrophy may be particularly prominent in the setting of **reflux nephropathy.** Large areas of nodular but normal renal tissue identified between scars may mimic a solid renal mass.[5]

Anomalies Related to Ascent of Kidney

Ectopia

Failure of the kidney to ascend during embryologic development results in a **pelvic kidney;** prevalence is 1 in 724 pediatric autopsies.[16] These kidneys are often small and abnormally rotated. Fifty percent of pelvic kidneys have decreased function.[16] The ureters are often short; poor drainage and collecting system dilatation predispose pelvic kidneys to infection and stone formation. The blood supply is often complex; multiple arteries may be derived from regional arteries (typically, internal iliac or common iliac). If the kidney ascends too high, it may pass through the foramen of Bochdalek and become a true **thoracic kidney;** this is usually of no clinical significance. A search for a pelvic kidney should be performed if the kidney is not identified within renal fossae (Fig. 9.9). If the kidney has ascended too high, ultrasound is helpful to determine if the diaphragm is intact.

Crossed Renal Ectopia

In crossed renal ectopia, both kidneys are found on the same side. In 85% to 90% of cases, the ectopic kidney will be fused to the other kidney **(crossed-fused ectopia).** The upper pole of the ectopic kidney is usually fused to the lower pole of the other kidney, although fusion may occur anywhere. The incidence is 1 in 1000 to 1 in 1500 at autopsy.[15] Fusion of metanephrogenic blastema does not allow proper rotation or ascent; thus both kidneys are more caudally located, although the ureterovesical junctions (UVJs) are located normally. At sonography, both kidneys are on the same side and are typically fused (Fig. 9.10). In patients with renal colic, knowing that the UVJs are in the normal location is particularly important, since bilateral ureters need to be assessed.

Horseshoe Kidney

The incidence of horseshoe kidneys in the general population is 0.01% to 0.25%. Horseshoe kidneys occur when metanephrogenic blastema fuse prior to ascent; fusion is usually at the lower poles (95%). Typically, the isthmus is composed of functioning renal tissue, although rarely it is made up of fibrous tissue. The horseshoe kidney sits anterior to the abdominal great vessels and derives its blood supply from the aorta and other regional vessels, such as inferior mesenteric, common iliac, internal iliac, and external iliac arteries. Abnormal rotation of renal pelves often results in **ureteropelvic junction (UPJ) obstruction;** the horseshoe kidney is thus predisposed to infection and stone formation. Additional associated anomalies include **vesicoureteral reflux, collecting system duplication, renal dysplasia, retrocaval ureter, supernumerary kidney, anorectal malformation, esophageal atresia, rectovaginal fistula, omphalocele,** and cardiovascular and skeletal abnormalities.

At sonography, horseshoe kidneys are usually lower than normal and the lower poles project medially. Transverse imaging of the retroperitoneum will demonstrate the renal isthmus crossing the midline anterior to abdominal great vessels (Fig. 9.11). Hydronephrosis (pyelocaliectasis) and collecting system calculi may be evident.

Anomalies Related to Ureteral Bud

Renal Agenesis

Renal agenesis may be unilateral or bilateral. **Bilateral** renal agenesis is a rare anomaly that is incompatible with life. The prevalence rate of bilateral agenesis at autopsies is 0.04%. The condition has a 3:1 male predominance.[15] **Unilateral** renal

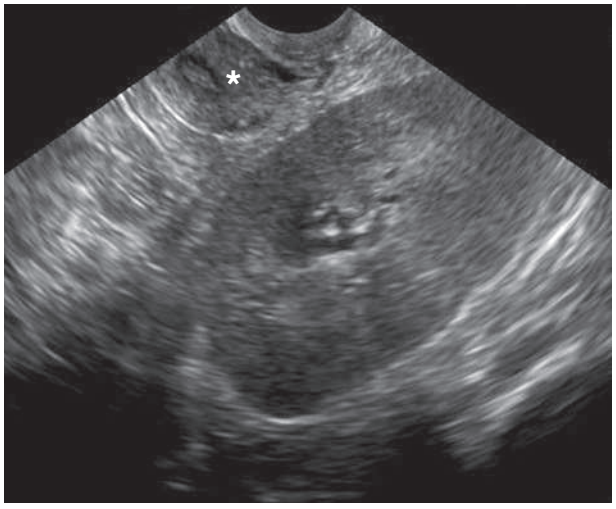

FIG. 9.9 Pelvic Kidney. Transverse sonogram demonstrates a left pelvic kidney posterior to the uterus (*).

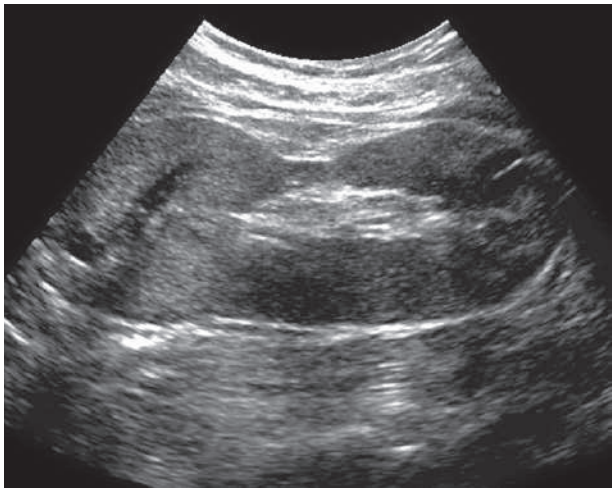

FIG. 9.10 Cross-Fused Ectopia. Sagittal sonogram demonstrates two kidneys fused to each other.

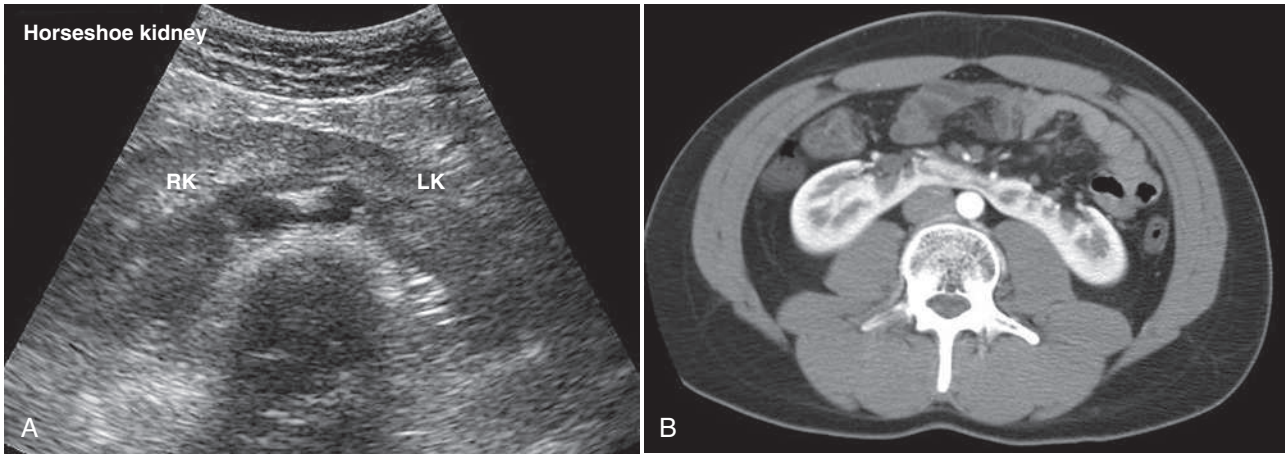

FIG. 9.11 Horseshoe Kidney. (A) Transverse sonogram shows the isthmus crossing anterior to the retroperitoneal great vessels, with the renal parenchyma of each limb of the horseshoe draping over the spine. **(B)** Confirmatory contrast-enhanced CT examination. *LK,* Left kidney; *RK,* right kidney.

agenesis is usually an incidental finding; the contralateral kidney of these patients may be quite large secondary to compensatory hypertrophy. Renal agenesis occurs when there is (1) absence of the metanephrogenic blastema, (2) absence of ureteral bud development, or (3) absence of interaction and penetration of the ureteral bud with the metanephrogenic blastema. Renal agenesis is associated with genital tract anomalies, which are often cystic pelvic masses in both men and women. Other associated anomalies include skeletal abnormalities, **anorectal malformations,** and **cryptorchidism.**

At ultrasound, although the kidney is absent, a normal adrenal gland is usually found. The adrenal gland will be absent in 8% to 17% of patients with renal agenesis.[16] It may be difficult to differentiate between renal agenesis and a small, hypoplastic or dysplastic kidney. With all these conditions, the contralateral kidney will be enlarged as a result of compensatory hypertrophy. Usually, the colon falls into the empty renal bed. Care should be taken not to confuse a loop of gut with a normal kidney.

Supernumerary Kidney

Supernumerary kidney is an exceedingly rare anomaly. The supernumerary kidney is usually smaller than normal and can be found above, below, in front of, or behind the normal kidney. The supernumerary kidney often has only a few calices and a single infundibulum. The formation of a supernumerary kidney is likely caused by the same mechanism that gives rise to a duplex collecting system.[15] Two ureteric buds reach the metanephrogenic blastema, which then divides, or alternatively, there are initially two blastema. On sonography, an extra kidney will be found.

Duplex Collecting System and Ureterocele

Duplex collecting system is the most common congenital anomaly of the urinary tract, with an incidence of 0.5% to 10% of live births.[15] The degree of duplication is variable. Duplication is complete when there are two separate collecting systems and two separate ureters, each with their own ureteral orifice. Duplication is incomplete when the ureters join and enter the bladder through a single ureteral orifice. Ureteropelvic duplication arises when two ureteral buds form and join with the metanephrogenic blastema or when there is division of a single ureteral bud early in embryogenesis. Normally during embryologic development, the ureteral orifice migrates superiorly and laterally to become part of the bladder trigone. With complete duplication, the ureter from the lower pole of the kidney migrates to assume its normal location, whereas the ureter draining the superior pole of the kidney migrates abnormally to a more medial and inferior ureteral orifice. Patients have an increased incidence of UPJ obstruction and uterus didelphys.[16]

In complete duplication, the ureter draining the lower pole has a more perpendicular course through the bladder wall, making it more prone to reflux. The ectopic ureter from the upper pole is prone to obstruction, reflux, or both (Fig. 9.12). Obstruction can result in cystic dilatation of the intramural portion of the ureter, giving rise to a ureterocele. **Ureteroceles** may be unilateral or bilateral and may occur in normal, duplicated, or ectopic ureters. Ureteroceles may result in ureteral obstruction and give rise to recurrent or persistent UTIs. If large, they may block the contralateral ureteral orifice and the urethral orifice at the bladder neck. Treatment of these symptomatic ureteroceles is surgical. However, most ureteroceles are transient, incidental, and clinically insignificant.

At ultrasound, a duplex collecting system is seen as two central echogenic renal sinuses with intervening, bridging renal parenchyma. Unfortunately, this sign is insensitive and is only seen in 17% of duplex kidneys.[17] Hydronephrosis of the upper-pole moiety and visualization of two distinct collecting systems and ureters are diagnostic. The bladder should always be carefully evaluated for the presence of a ureterocele. A ureterocele will appear as a round, cystlike structure within the bladder (Fig. 9.13). Occasionally, it may be large enough to occupy the entire bladder and will cause obstruction of the bladder neck. In female patients, transvaginal sonography can be helpful to identify small ureteroceles[18] (Fig. 9.14). These ureteroceles may be transient. Madeb et al.[19] demonstrated that transvaginal sonography with color Doppler and spectral analysis can provide additional information about flow dynamics, eliminating the need for invasive procedures.

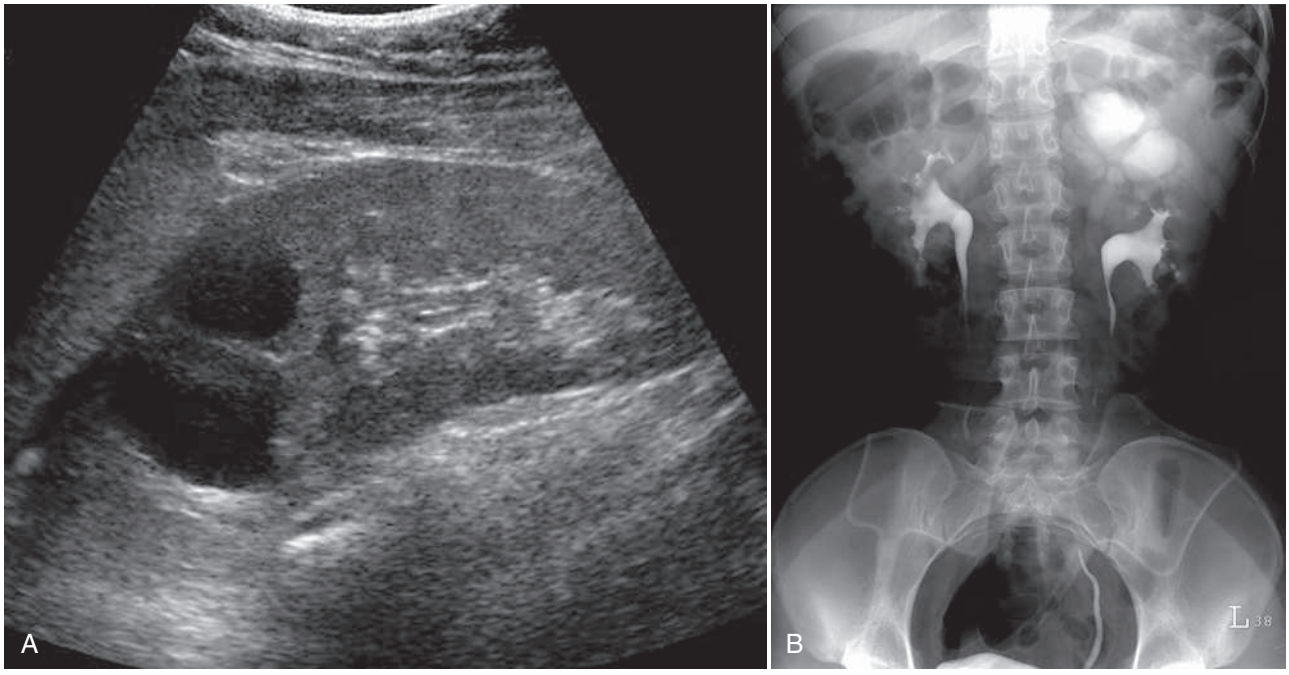

FIG. 9.12 Duplex Collecting System. (A) Sagittal sonogram shows an upper-pole cystic mass. Note collecting system dilatation and cortical thinning. **(B)** Delayed intravenous urogram shows duplicated left collecting system and dilated upper-pole moiety.

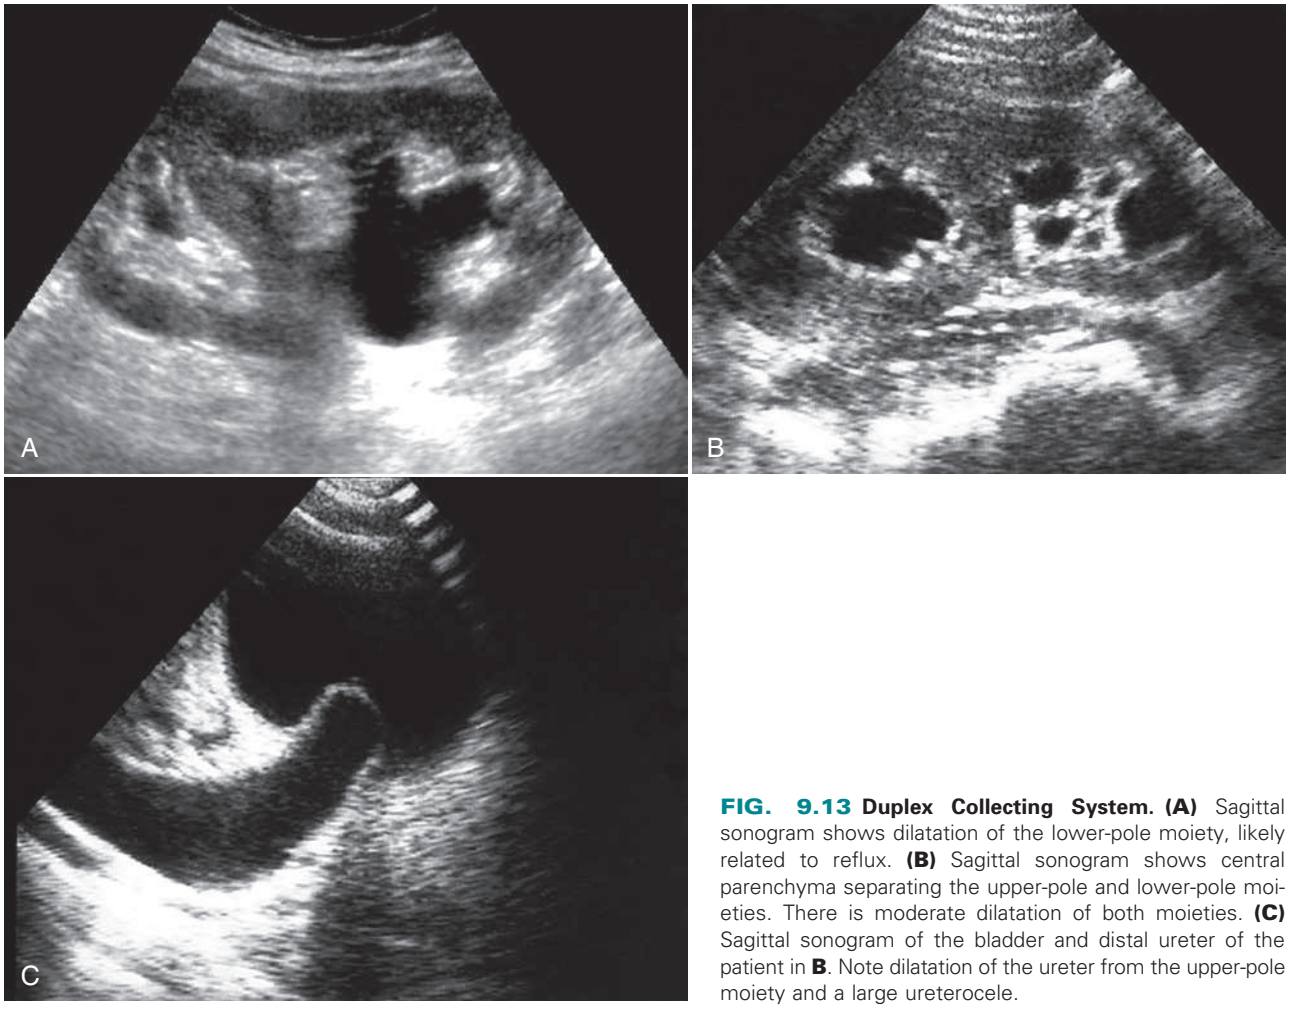

FIG. 9.13 Duplex Collecting System. (A) Sagittal sonogram shows dilatation of the lower-pole moiety, likely related to reflux. **(B)** Sagittal sonogram shows central parenchyma separating the upper-pole and lower-pole moieties. There is moderate dilatation of both moieties. **(C)** Sagittal sonogram of the bladder and distal ureter of the patient in **B**. Note dilatation of the ureter from the upper-pole moiety and a large ureterocele.

Ureteropelvic Junction Obstruction

UPJ obstruction is a common anomaly with a 2:1 male predominance. The left kidney is affected twice as frequently as the right kidney. UPJ obstruction is bilateral in 10% to 30% of cases.[20] Most adult patients present with chronic, vague, back or flank pain. Symptomatic patients and those with complications, including superimposed infection, stones, or impaired renal function, should be treated. Patients have an increased incidence of contralateral multicystic dysplastic kidney and renal agenesis. Most idiopathic UPJ obstructions are thought to be functional rather than anatomic.[20] Histologic evaluation of affected specimens has demonstrated excessive collagen between muscle bundles, deficient or absent muscle, and excessive longitudinal muscle.[20] Occasionally, intrinsic valves, true luminal stenosis, and aberrant arteries are the cause of obstruction. At ultrasound, hydronephrosis is present to the level of the UPJ (Fig. 9.15). Marked ballooning of the renal pelvis is often shown, and if long-standing, there will be associated renal parenchymal atrophy. The caliber of the ureter, on the other hand, is normal. Careful evaluation of the contralateral kidney should be performed to exclude associated anomalies.

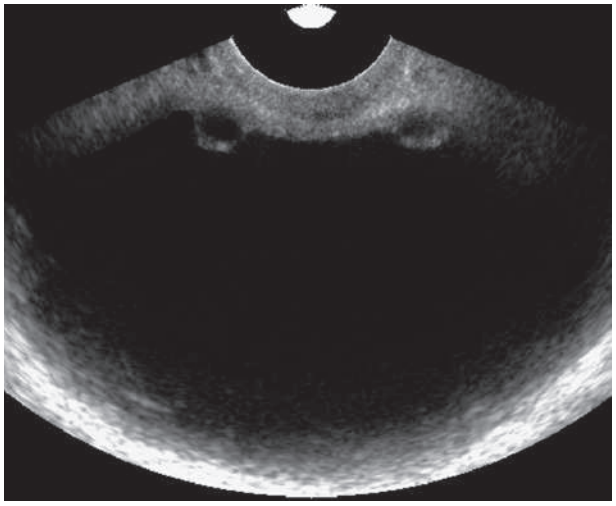

FIG. 9.14 Small Bilateral Ureteroceles. Transverse transvaginal sonogram demonstrates two small cystic structures related to the bladder wall. With the probe in the vagina, the bladder trigone and the ureteric orifices are shown in the near field of the transducer.

Congenital Megacalices

Congenital megacalices refer to typically unilateral, nonobstructive enlargement of the calices. It is nonprogressive; overlying parenchyma and renal function are maintained. Infection and stone formation are increased because of caliceal enlargement. The exact pathogenesis is speculative; the most common association is with primary megaureter.[21] At ultrasound, numerous enlarged clubbed calices are shown. Papillary impressions are absent, and cortical thickness is maintained.

Congenital Megaureter

Megaureter (congenital megaureter, megaloureter) results in functional ureteric obstruction. The most distal segment of ureter is aperistaltic: focal ureteral lack of peristalsis results in a wide spectrum of findings, from insignificant distal ureterectasis to progressive hydronephrosis/hydroureter. As with UPJ obstructions, men are affected more often, and the left ureter is typically involved.[20] Bilateral involvement has been demonstrated in 8% to 50% of patients. The classic finding at ultrasound is **fusiform dilatation** of the distal third of the ureter (Fig. 9.16). Depending on the severity, associated pyelocaliectasis may or may not be present. Calculi may form just proximal to the adynamic segment.

Anomalies Related to Vascular Development

Aberrant Vessels

As it ascends during embryologic development, the kidney derives its blood supply from successively higher levels of the aorta.

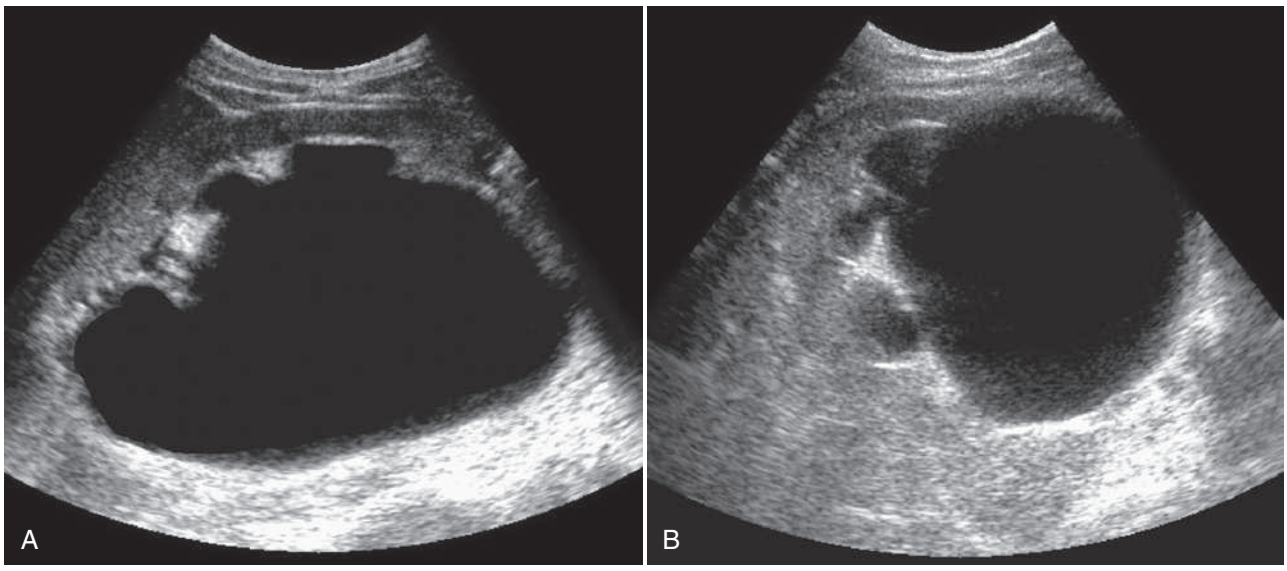

FIG. 9.15 Ureteropelvic Junction Obstruction. (A) Sagittal and **(B)** transverse sonograms demonstrate marked ballooning of the renal pelvis with associated proximal caliectasis.

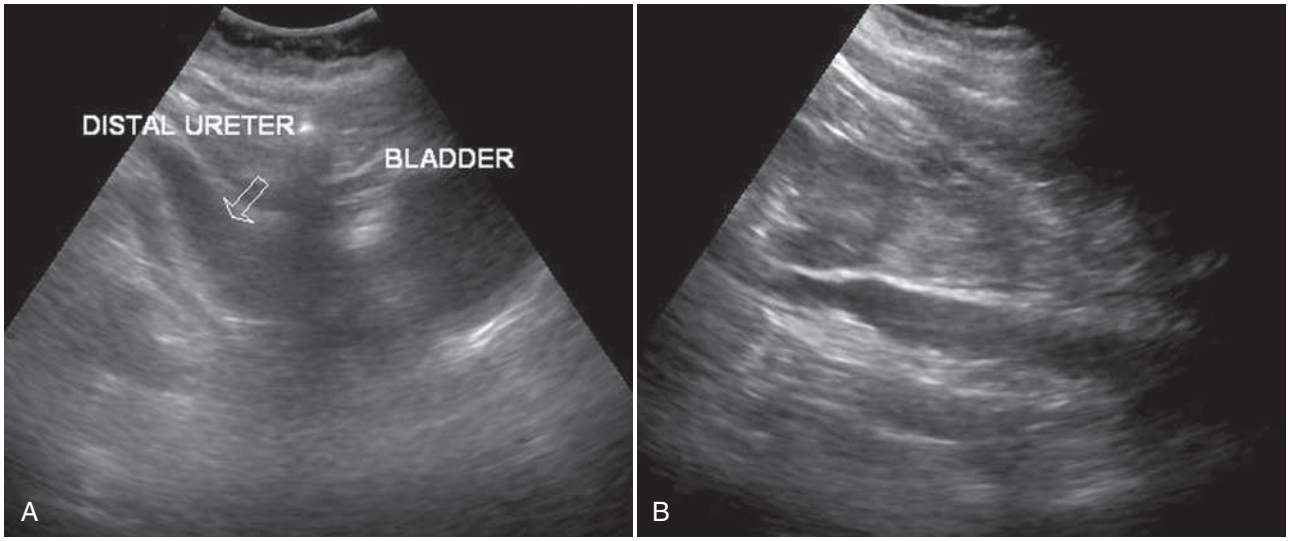

FIG. 9.16 Congenital Megaureter. (A) Sagittal sonogram shows marked dilatation of the distal ureter up to the ureterovesical junction. **(B)** Sagittal sonogram shows moderate midregion ureterectasis.

Aberrant renal arteries will be present if the vascular supply from the lower levels of the aorta persists. Aberrant vessels can compress the ureter anywhere along its course. Color Doppler ultrasound may be useful to identify obstructing vessels crossing at the UPJ.

Retrocaval Ureter

Retrocaval ureter is a rare but well-recognized congenital anomaly with a 3:1 male predominance. Most patients present with pain in the second to fourth decade of life. Normally, the infrarenal inferior vena cava (IVC) develops from the **supracardinal vein;** if it develops from the **subcardinal vein,** the ureter will pass posterior to the IVC. The ureter then passes medially and anteriorly between the aorta and IVC to cross the right iliac vessels. It then enters the pelvis and bladder in a normal manner. Sonography shows collecting system and proximal ureteral dilatation. In easy-to-scan patients the compressed retrocaval ureter may be identified.

Anomalies Related to Bladder Development

Bladder Agenesis

Bladder agenesis is a rare anomaly. Most infants with bladder agenesis are stillborn; virtually all surviving infants are female.[22] Many associated anomalies are often present. At ultrasound, the bladder is absent.

Bladder Duplication

Bladder duplication is divided into three types, as follows[16]:

Type 1: A complete or incomplete peritoneal fold separates the two bladders.

Type 2: An internal septum divides the bladder. The septum may be complete or incomplete and may be oriented in a sagittal or coronal plane. There may be multiple septa.

Type 3: A transverse band of muscle divides the bladder into two unequal cavities.

Bladder Exstrophy

Bladder exstrophy occurs in 1 in 30,000 live births, with a 2:1 male predominance.[16] Failure in development of the mesoderm below the umbilicus leads to absence of the lower abdominal and anterior bladder wall. There is a high incidence of associated musculoskeletal, gastrointestinal, and genital tract anomalies. These patients have an increased (200-fold) incidence of bladder carcinoma (adenocarcinoma in 90%).[16]

Urachal Anomalies

Normally, the urachus closes in the last half of fetal life.[16] The four types of congenital urachal anomalies, in order of frequency, are as follows[16,23,24] (Fig. 9.17):

1. Patent urachus (50%)
2. Urachal cyst (30%)
3. Urachal sinus (15%)
4. Urachal diverticulum (5%)

Urachal anomalies have a 2:1 predominance in males. A **patent urachus** is usually associated with urethral obstruction and serves as a protective mechanism to allow normal fetal development. A **urachal cyst** forms if the urachus closes at the umbilical and bladder ends but remains patent in between. The cyst is usually situated in the lower third of the urachus. There is an increased incidence of adenocarcinoma. At ultrasound, a midline cyst with or without internal echoes is seen superior to the bladder. A **urachal sinus** forms when the urachus closes at the bladder end but remains patent at the umbilicus. A **urachal diverticulum** forms if the urachus closes at the umbilical end but remains patent at the bladder. Urachal diverticula are usually incidentally found. There is an increased incidence of carcinoma and stone formation.

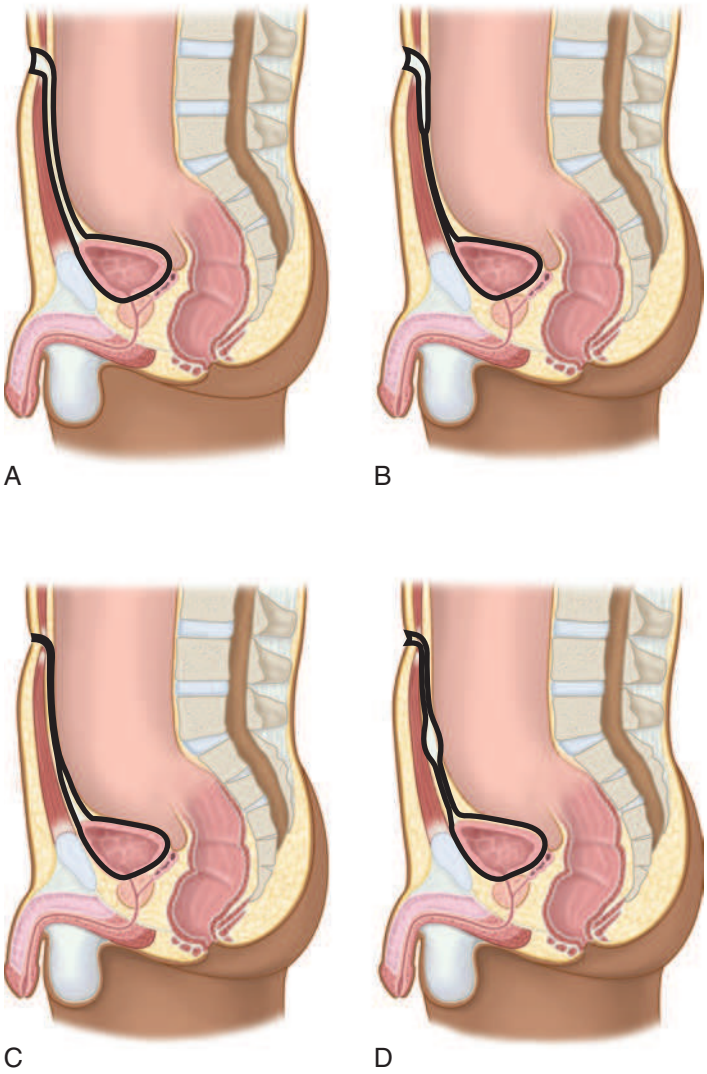

FIG. 9.17 Congenital Urachal Anomalies. (A) Patent urachus extends from the bladder to the umbilicus. **(B)** Urachal sinus. **(C)** Urachal diverticulum. **(D)** Urachal cyst.

Anomalies Related to Urethral Development: Diverticula

The majority of urethral diverticula are acquired secondary to injury or infection, although congenital diverticula occur rarely. Most urethral diverticula in women form as a result of infection of the periurethral glands; some may be related to childbirth. Most diverticula are found in the midurethra and are bilateral. Often, a fluctuant anterior vaginal mass is felt. Stones may develop because of urinary stasis. Transvaginal or translabial scanning may demonstrate a simple or complex cystic structure communicating with the urethra through a thin neck (Fig. 9.18).

GENITOURINARY INFECTIONS

Pyelonephritis

Acute Pyelonephritis

Acute pyelonephritis is a tubulointerstitial inflammation of the kidney. Two routes may lead to inflammation: ascending infection (85%; e.g., *Escherichia coli*) and hematogenous seeding (15%; e.g., *Staphylococcus aureus*). Women age 15 to 35 years are most often affected[25]; 2% of pregnant women will develop acute pyelonephritis.[26] Most adults present with flank pain and fever and can be diagnosed clinically with the aid of laboratory studies (bacteriuria, pyuria, and leukocytosis). With appropriate antibiotics, both clinical and laboratory findings show rapid improvement. Imaging is necessary only when symptoms and laboratory abnormalities persist: imaging is useful to identify potential causes of insufficiently treated infection, including renal and perirenal abscesses, calculi, and urinary obstruction. The Society of Uroradiology proposed using acute **pyelonephritis** to describe acutely infected kidneys, eliminating the need for terms such as bacterial nephritis, lobar nephronia, renal cellulitis, lobar nephritis, renal phlegmon, and renal carbuncle.[27]

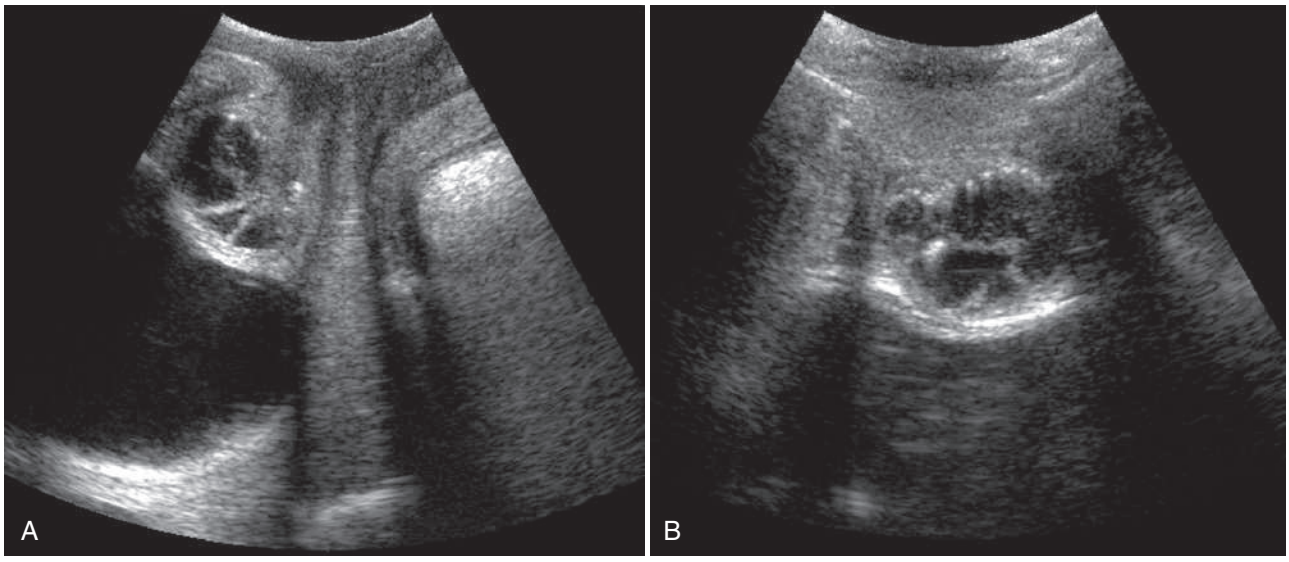

FIG. 9.18 Urethral Diverticulum in Young Woman With Palpable Vaginal Mass. (A) Sagittal and **(B)** transverse translabial sonograms show a complex cystic mass adjacent to the anterior urethra.

At **ultrasound,** the majority of kidneys with acute pyelonephritis appear normal. However, ultrasound findings of pyelonephritis include (Fig. 9.19) renal enlargement, compression of the renal sinus, decreased echogenicity (secondary to edema) or increased echogenicity (potentially from hemorrhage), loss of corticomedullary differentiation, poorly marginated mass(es), gas within the renal parenchyma,[26,27] and focal or diffuse absence of color Doppler perfusion corresponding to the swollen inflamed areas.

If the pyelonephritis is **focal,** the poorly marginated masses may be echogenic, hypoechoic, or of mixed echogenicity. **Echogenic masses** may be the most common appearance of focal pyelonephritis.[28]

Sonography, including power Doppler, is less sensitive than CT, magnetic resonance imaging (MRI), or technetium-99m single-photon emission computed tomography (^{99m}Tc-DMSA SPECT) renal cortical scintigraphy for demonstrating changes of acute pyelonephritis. However, ultrasound is more accessible and less expensive and thus an excellent screening modality for monitoring and follow-up of complications,[29] as well as in the assessment of pregnant patients with acute pyelonephritis because of its lack of ionizing radiation.[26,27]

A unique renal infection known as **alkaline-encrusted pyelitis** has been described in **renal transplants** and native kidneys of

Acute Pyelonephritis on Sonography

Renal enlargement
Compression of renal sinus
Abnormal echotexture (either increased or decreased)
Loss of corticomedullary differentiation
Poorly marginated mass(es)
Gas within renal parenchyma
Focal or diffuse absence of color Doppler perfusion corresponding to the swollen inflamed areas

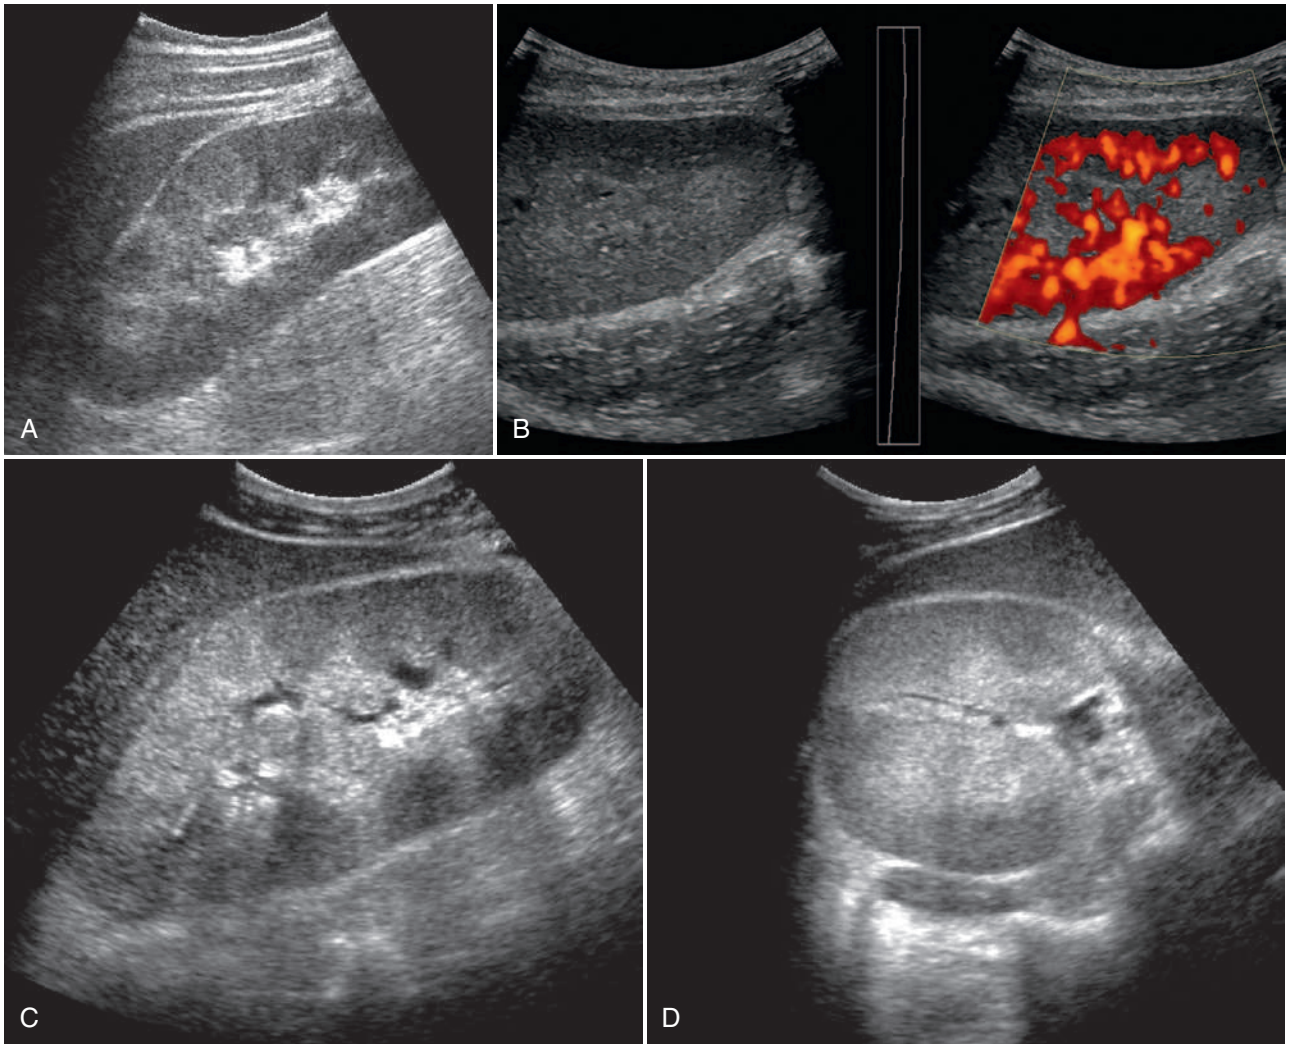

FIG. 9.19 Acute Pyelonephritis in Three Patients. (A) Subtle focal increased echogenic areas are seen in the anterior cortex of the right kidney. **(B)** Power Doppler perfusion defect in lower pole of kidney of patient with documented *E. coli* pyelonephritis. Note normal corresponding gray-scale image. **(C)** Sagittal and **(D)** transverse sonograms in a third patient show a swollen and edematous kidney with focal altered echogenicity and loss of corticomedullary differentiation. The renal sinus fat is attenuated by swollen parenchyma.

debilitated and immunocompromised patients.[30] This entity is most frequently caused by *Corynebacterium urealyticum,* a urea-splitting microorganism. Urothelial stone encrustation develops in the kidney and bladder. If the kidney is affected, the patient may present with hematuria, stone passage, or an ammonium odor to the urine. Dysuria and suprapubic pain are the most common clinical signs if the bladder is involved. Treatment is with antibiotics and local acidification of the urine. On sonography, alkaline-encrusted pyelitis is suggested if thickened, calcified urothelium is identified.[30] The calcification can be thin and smooth or thick and irregular. Care should be taken to distinguish urothelial calcification from layering of collecting system calculi.[30]

Renal and Perinephric Abscess

Untreated or inadequately treated acute pyelonephritis may lead to parenchymal necrosis and abscess formation. Patients at increased risk for **renal abscesses** include those with diabetes, compromised immunity, chronic debilitating diseases, urinary tract obstruction, infected renal calculi, and intravenous drug abuse.[26,31] Renal abscesses tend to be solitary and may spontaneously decompress into the collecting system or perinephric space. **Perinephric abscesses,** also a complication of **pyonephrosis,** may result from direct extension of peritoneal or retroperitoneal infection or interventions.[24] Small abscesses are treated conservatively with antibiotics, whereas larger abscesses often require percutaneous drainage and, if drainage is unsuccessful, surgery.

At ultrasound, renal abscesses appear as round, thick-walled, hypoechoic complex masses with through transmission (Fig. 9.20). Internal mobile debris and septations may be seen. Occasionally, "dirty shadowing" may be noted posterior to gas within the abscess. The differential diagnosis includes (1) hemorrhagic or infected cysts, (2) parasitic cysts, (3) multiloculated cysts, and (4) cystic neoplasms. Although not as accurate as CT in determining the presence and extent of perinephric abscess extension,[26] sonography is an excellent modality for following conservatively treated patients with abscesses to document resolution.

Pyonephrosis

Pyonephrosis implies purulent material in an obstructed collecting system. Depending on the level of obstruction, any portion of the collecting system, including the ureter, can be affected. Early diagnosis and treatment are crucial to prevent development of bacteremia and life-threatening septic shock. The mortality rates of bacteremia and septic shock are 25% and 50%, respectively[32]; 15% of patients are asymptomatic at presentation.[33] In the young adult, UPJ obstruction and calculi are the most frequent cause of pyonephrosis, whereas malignant ureteral obstruction is typically the predisposing factor in older patients.[26] Pyonephrosis is suggested when ultrasound shows mobile collecting system debris (with or without a fluid-debris level), collecting system gas, and stones (Fig. 9.21).

Emphysematous Pyelonephritis

Emphysematous pyelonephritis (EPN) is an uncommon, life-threatening infection of the renal parenchyma characterized by gas formation.[34] Most patients are women (2:1) and diabetic (90%), with a mean age of 55 years. In diabetic patients, EPN tends to occur in nonobstructed collecting systems; the reverse is true in nondiabetic patients. Bilateral disease occurs in 5% to 10% of EPN patients. *Escherichia coli* is the offending organism in 62% to 70% of cases; *Klebsiella* (9%), *Pseudomonas* (2%) *Proteus, Aerobacter,* and *Candida* are additional causative organisms.[26,31] At presentation, most patients are extremely ill with fever, flank pain, hyperglycemia, acidosis, dehydration, and electrolyte imbalance[35]; 18% present only with fever of unknown origin.[36]

Wan et al.[37] retrospectively studied 38 patients with EPN and identified two types of disease: **EPN1,** characterized by parenchymal destruction and streaky or mottled gas, and **EPN2,**

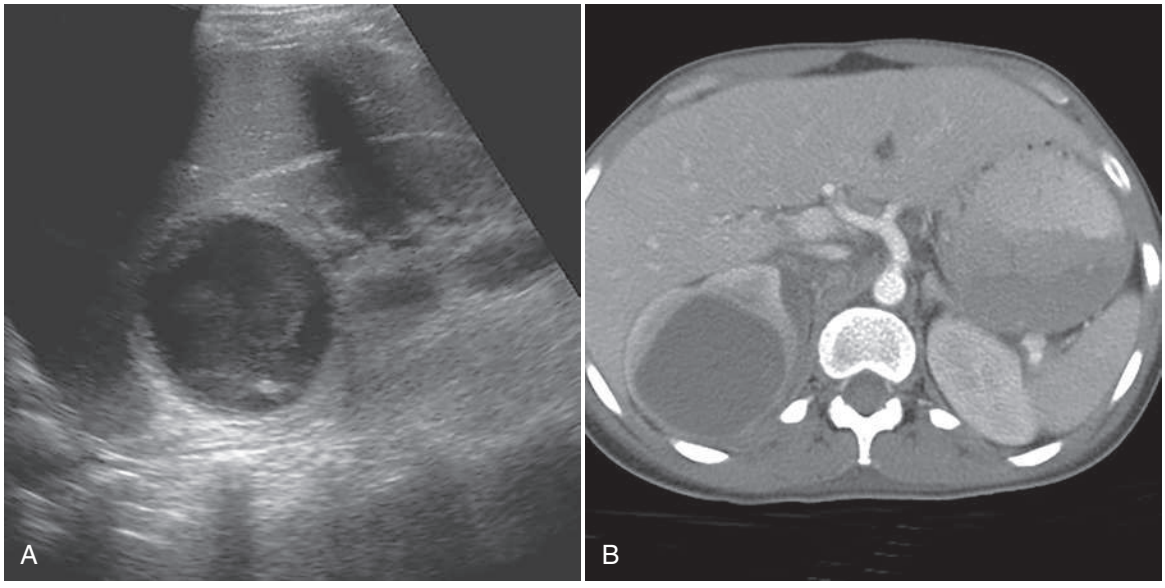

FIG. 9.20 Renal Abscess. (A) Sagittal ultrasound shows a complex cystic upper-pole lesion containing layering low level echoes. **(B)** Corresponding contrast-enhanced CT exam shows a large right upper-pole cystic lesion with a thick rind. The patient was successfully treated with ultrasound guided drain placement and antibiotics.

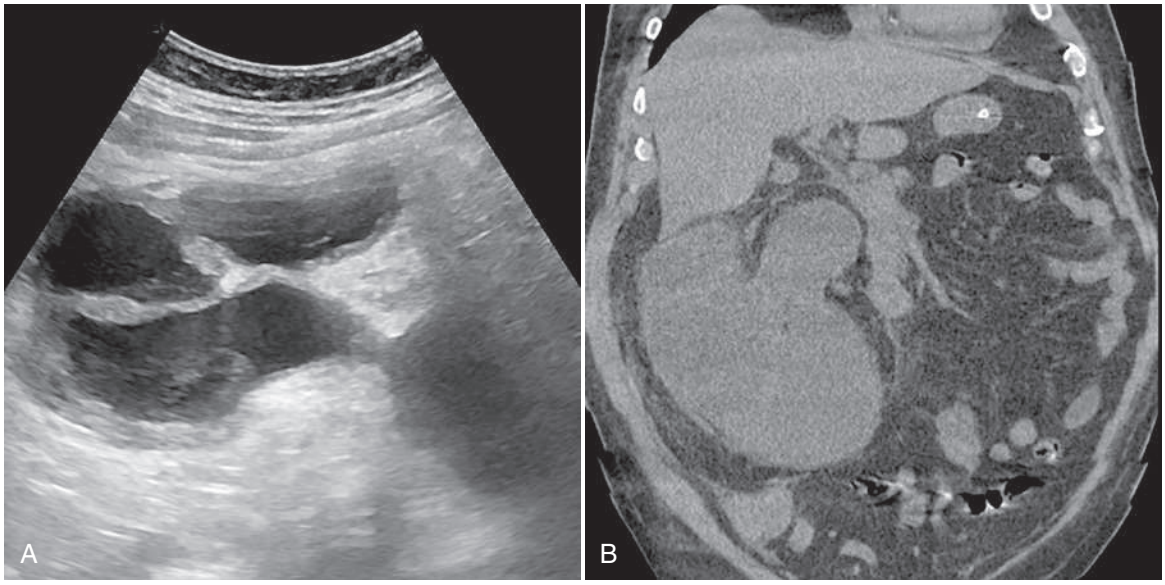

FIG. 9.21 Pyonephrosis. (A) Sagittal ultrasound of an older male with *Proteus mirabilis* sepsis shows a deformed, chronically hydronephrotic kidney, with layering collecting system echoes. **(B)** Corresponding noncontrast-enhanced CT shows a large right hydronephrotic sac and perinephric infiltration. Clinical history and imaging findings prompted successful, emergent drainage.

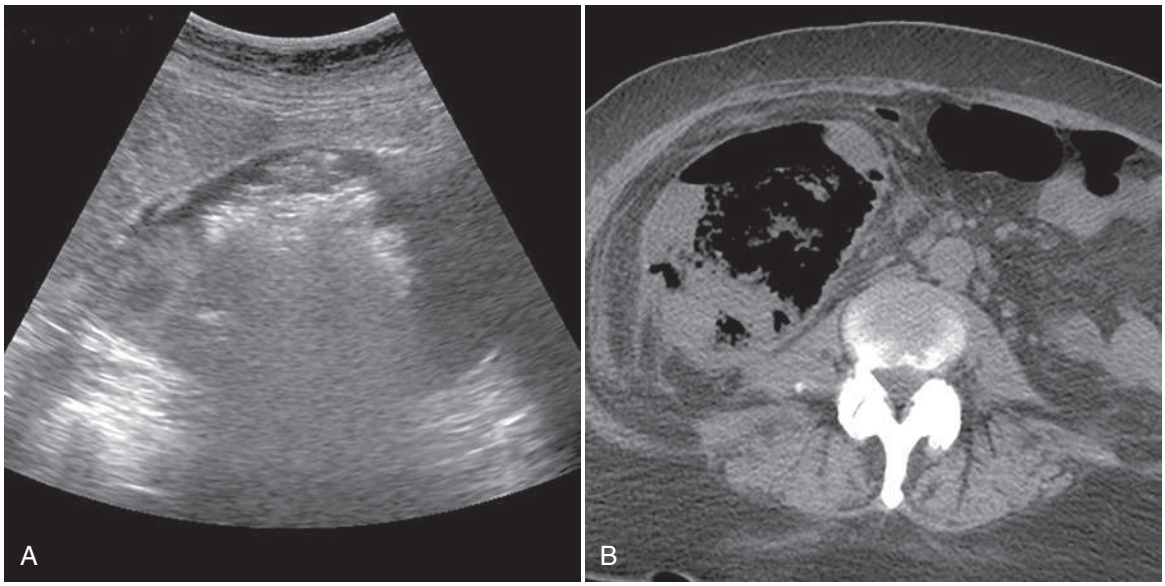

FIG. 9.22 Emphysematous Pyelonephritis Type 1 (EPN1). (A) Sagittal sonogram of right renal fossa shows extensive shadowing gas occupying most of the right kidney. **(B)** Corresponding noncontrast-enhanced CT demonstrates diffuse parenchymal destruction of the right kidney with extensive mottled gas. Nephrectomy was eventually performed in this septic, diabetic patient. Caution must be exercised to avoid missing EPN1 altogether on ultrasound. Failure to see a kidney in a septic patient should prompt alternative cross-sectional imaging.

characterized as renal or perirenal fluid collections, with bubbly or loculated gas or with gas in the collecting system. Mortality rates for EPN1 and EPN2 were 69% and 18%, respectively. The authors postulated that the different clinical outcomes of EPN1 and EPN2 result from the patient's immune status and the vascular supply of the affected kidney. Emergency nephrectomy is the treatment of choice for EPN1, whereas percutaneous drainage is recommended for EPN2. CT is the preferred method to image patients with EPN, to determine the location and extent of renal and perirenal gas. Sonographic evaluation of EPN1 or EPN2 may be difficult because dirty shadowing from parenchymal gas will obscure deeper structures; shadowing might also prompt an erroneous interpretation of renal calculi or bowel gas[38] (Fig. 9.22).

Emphysematous Pyelitis

Emphysematous pyelitis refers to gas localized within the urinary collecting system.[34] This disease entity is seen most often in women with diabetes or obstructing stone disease; a mortality rate of 20% has been reported. It is important to exclude iatrogenic causes of gas within the collecting system. At ultrasound, nondependent linear echogenic lines with dirty distal posterior

acoustic shadowing, indicative of gas are seen within the collecting system (Fig. 9.23). As with EPN, CT is often required to identify emphysematous pyelitis because dirty acoustic shadowing from gas at ultrasound may obscure the exact extent of renal and perirenal disease.

Chronic Pyelonephritis

Chronic pyelonephritis is an interstitial nephritis often associated with vesicoureteric reflux. **Reflux nephropathy** is believed to cause 10% to 30% of all cases of **end-stage renal disease** (ESRD)[39] (Fig. 9.24). Chronic pyelonephritis usually begins in childhood and is more common in women. The renal changes may be unilateral or bilateral but usually are asymmetric. Reflux into the collecting tubules occurs when the papillary duct orifices are incompetent. This reflux occurs more often in compound papillae, which are typically found at the poles of the kidneys. Cortical scarring therefore tends to occur over polar calices. There is associated papillary retraction with caliceal clubbing. At ultrasound, a dilated blunt calix is seen, associated with overlying **cortical scar** or **cortical atrophy**[40] (Fig. 9.25). These changes may be multicentric and bilateral. If the disease is unilateral, there may be compensatory hypertrophy of the contralateral kidney. If the disease is multicentric, compensatory hypertrophy of normal intervening parenchyma may create an island of normal tissue simulating a tumor.

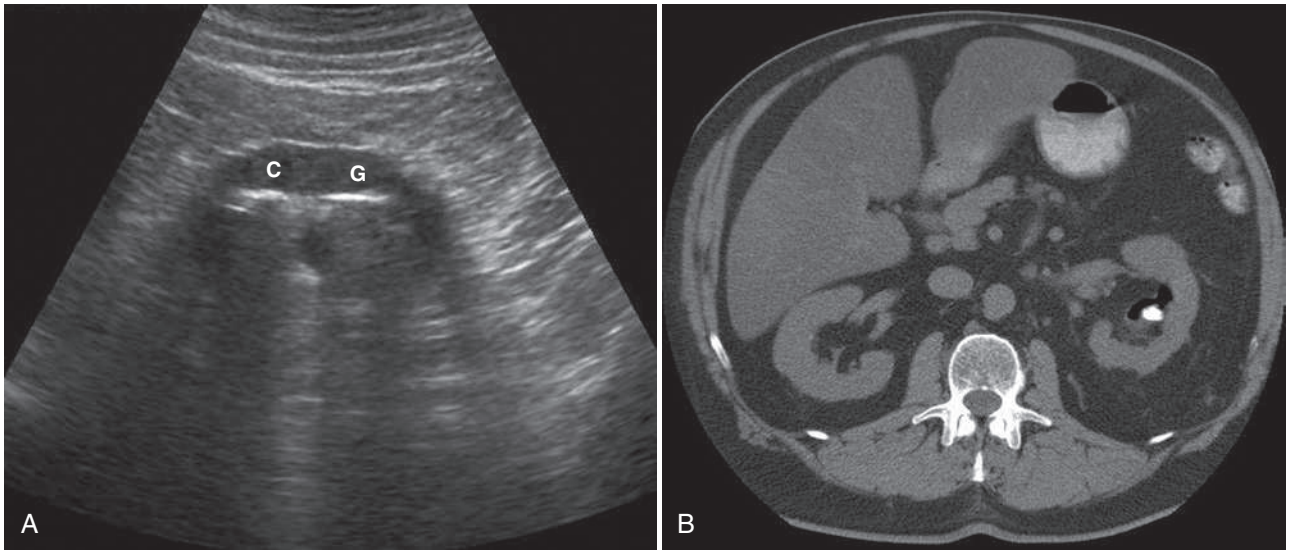

FIG. 9.23 Emphysematous Pyelitis. (A) Transverse sonogram of left kidney shows "clean" shadowing posterior to a renal calculus *(C)* and "dirty" shadowing posterior to nondependent collecting system gas *(G)*. **(B)** Confirmatory unenhanced CT image shows both a calculus and gas within the left collecting system.

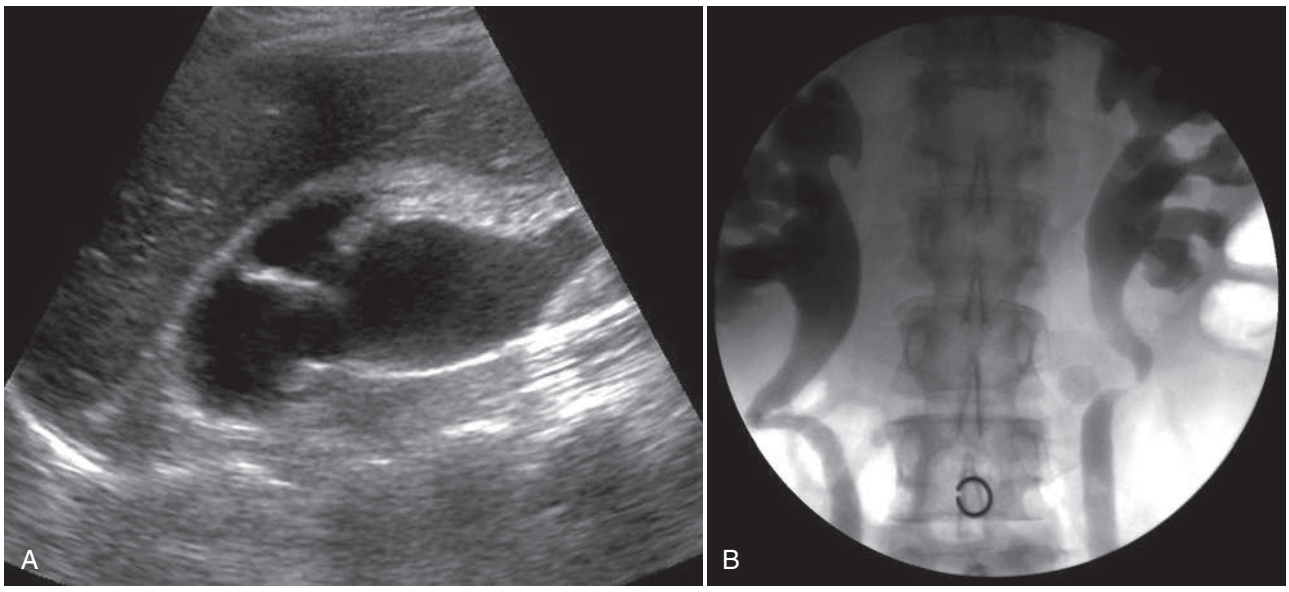

FIG. 9.24 Reflux Nephropathy: Renal Transplantation Evaluation. (A) Sagittal sonogram shows marked right hydronephrosis and absence of overlying cortex. **(B)** Cystogram confirms massive bilateral ureteral reflux.

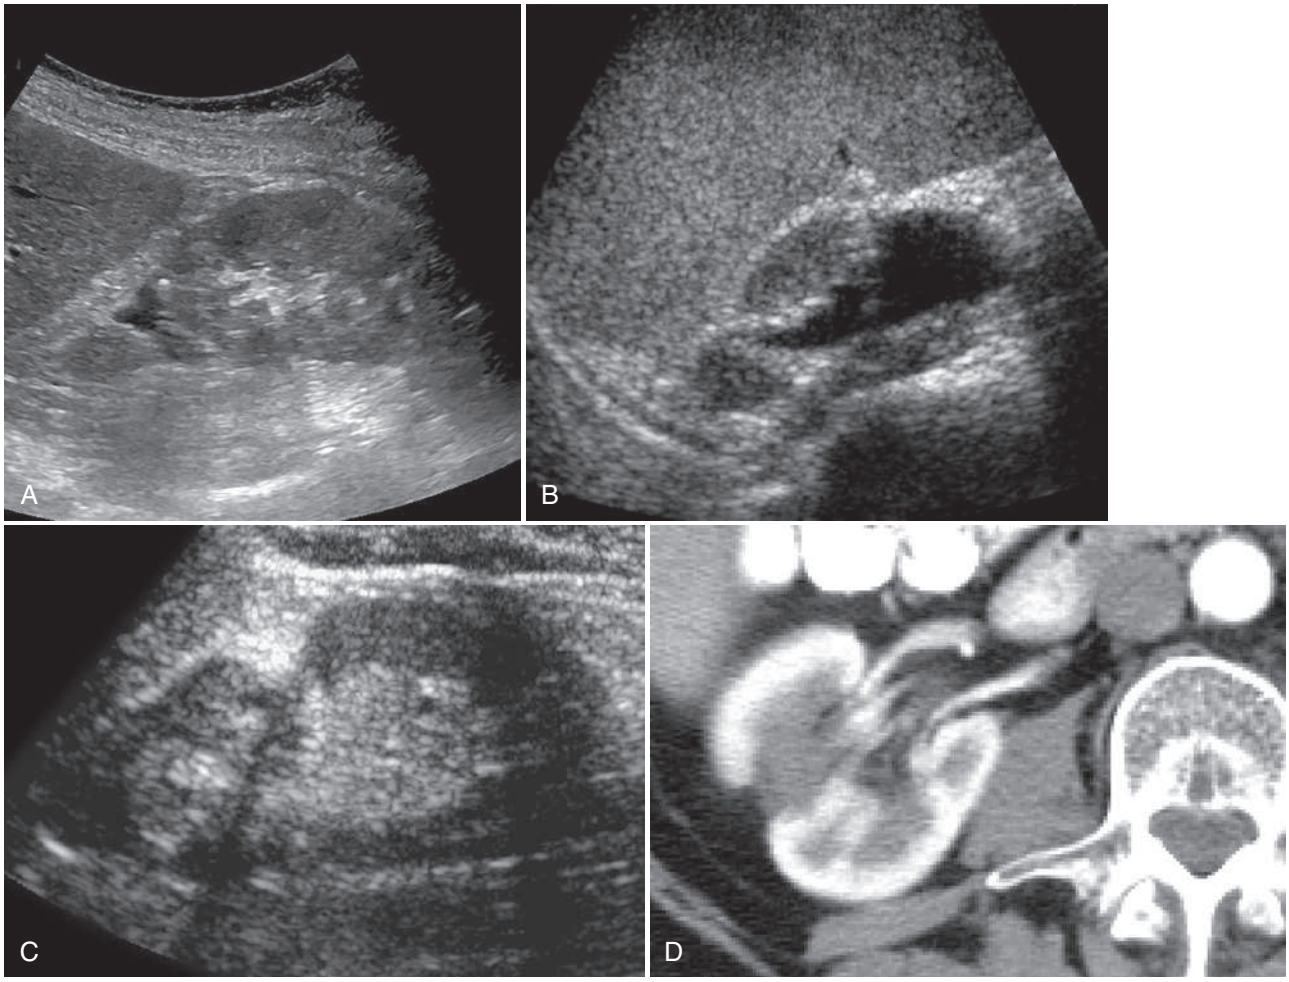

FIG. 9.25 Chronic Pyelonephritis. (A) Sagittal sonogram of a patient with a history of vesicoureteral reflux shows upper-pole atrophy and severe cortical loss overlying a deformed, dilated calyx. **(B)** Sagittal sonogram shows an atrophic kidney with scarring and dilatation of the collecting system caused by reflux. **(C)** Sagittal sonogram shows an echogenic wedge-shaped scar in the midpole of the kidney. **(D)** Confirmatory CT scan.

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis (XGP) is a chronic, suppurative renal infection in which destroyed renal parenchyma is replaced with lipid-laden macrophages. XGP is typically unilateral and may be diffuse, segmental, or focal. XGP is typically associated with nephrolithiasis (70%) and obstructive nephropathy.[41-43] The disease most commonly occurs in middle-aged women and diabetic patients.[43] Presenting signs are nonspecific: pain, mass, weight loss, and UTI (*Proteus* or *E. coli*).[41] The diffusely involved kidney is usually nonfunctional. Ultrasound findings of diffuse XGP include renal enlargement, maintenance of a reniform shape, and lack of corticomedullary differentiation. Multiple hypoechoic areas correspond to dilated calices or inflammatory parenchymal masses.[41] Through transmission is variable and depends on the degree of liquefaction of the parenchymal masses. Occasionally, the large, complex cystic masses may mimic pyonephrosis. A **staghorn calculus** will result in extensive shadowing from the central renal sinus (Fig. 9.26). Perinephric extension may occur, but this is often best appreciated with CT. **Diffuse** XGP has no specific sonographic features but is suggested when parenchymal thinning, hydronephrosis, stones, debris in a dilated collecting system, and perinephric fluid collections are present.[44] **Segmental** XGP will be seen as one or more hypoechoic masses, often associated with a single calyx.[41,45] An obstructing calculus may be seen near the papilla. **Focal** XGP arises in the renal cortex and does not communicate with the renal pelvis. It cannot be distinguished sonographically from tumor or abscess.[41]

Papillary Necrosis

Causative factors implicated in the ischemia that leads to papillary necrosis include analgesic abuse, diabetes, UTI, renal vein thrombosis, prolonged hypotension, urinary tract obstruction, dehydration, sickle cell anemia, and hemophilia.[46] Initially, the papilla swells (Fig. 9.27); then a communication with the caliceal system occurs. The central aspect of the papilla cavitates and may slough. With papillary cavitation, ultrasound shows cystic collections within the medullary pyramids. If the papilla sloughs, the affected adjacent calyx will be clubbed. The sloughed papilla can be seen in the collecting system as an echogenic nonshadowing structure. If the sloughed papilla calcifies, distal acoustic shadowing simulating medullary nephrocalcinosis will be seen.[47]

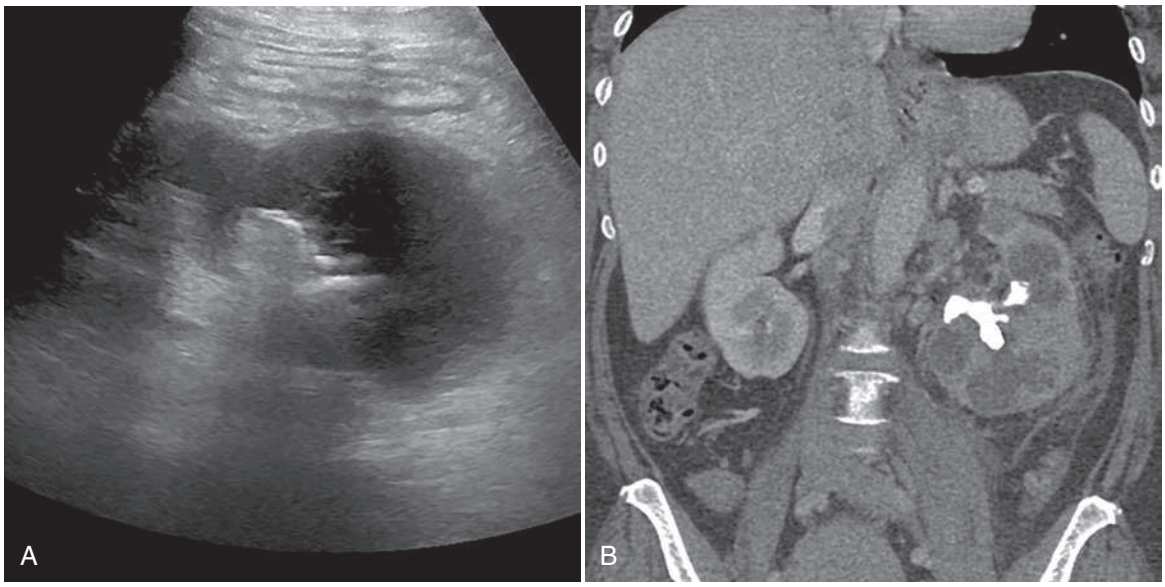

FIG. 9.26 Xanthogranulomatous Pyelonephritis. (A) Sagittal sonogram shows an enlarged hypoechoic kidney and a large showing staghorn calculus. **(B)** Corresponding contrast-enhanced CT demonstrates a diffusely enlarged left kidney, multiple intrarenal abscesses, and a large, central obstructing calculus.

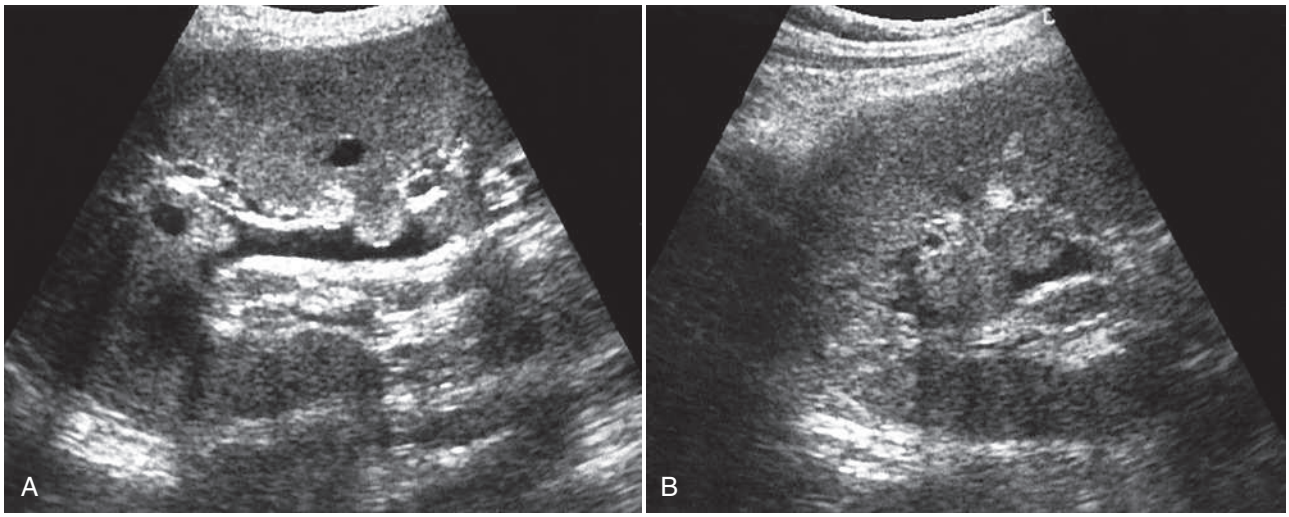

FIG. 9.27 Papillary Necrosis. (A) Sagittal and **(B)** transverse sonograms show swollen bulbous papillae.

Sonographic Findings of Papillary Necrosis

Swollen pyramids
Papillary cavitation
Adjacent clubbed calix
Sloughed papilla in collecting system that can calcify and simulate a stone
Sloughed papilla may cause obstruction

Hydronephrosis may develop if the sloughed papilla obstructs the ureter.

Tuberculosis

Urinary tract tuberculosis (TB) occurs with hematogenous seeding of the kidney by *Mycobacterium tuberculosis* from an extraurinary source (typically lung). Urinary tract TB usually manifests 5 to 10 years after the initial pulmonary infection. Chest radiographs may be normal (35%-50% of patients) or may show active TB (10%) or inactive healed TB (40%-55%). Most patients present with lower urinary tract signs and symptoms that include frequency, dysuria, nocturia, urgency, and gross or microscopic hematuria, whereas 10% to 20% of patients are asymptomatic.[48] Urinalysis findings include sterile pyuria, microscopic hematuria, and acidic pH. TB is definitively diagnosed with acid-fast bacilli urine cultures; however, this usually requires 6 to 8 weeks for growth.

Although both kidneys are seeded initially, clinical manifestations of urinary tract TB are typically unilateral. The early or acute changes include development of multiple small bilateral tuberculomas. Das et al.[49] found that the most frequently encountered sonographic abnormality was **focal renal lesions**

(Fig. 9.28). Small focal lesions (5-15 mm) were echogenic or were hypoechoic with an echogenic rim. Larger, mixed-echogenicity focal lesions (>15 mm) were poorly defined. Bilateral disease was noted in 30% of patients. Most tuberculomas will heal spontaneously or after antituberculous therapy. At some later date (perhaps years later), one or more of the tubercles may enlarge. With enlargement, cavitation and communication with the collecting system will occur. The resultant pathologic changes resemble papillary necrosis; papillary involvement is noted when a sonolucent linear tract is shown extending from the involved calix into the papilla. Soft tissue caliceal masses representing sloughed papilla may be seen. After rupture into the collecting system, *M. tuberculosis* bacilluria develops and allows the spread of the renal infection to other parts of the urinary tract. Spasm or edema in the region of the UVJ may occur, giving rise to hydronephrosis and hydroureter. Ureteric linear ulcers may also occur, typically within the distal ureter. Bladder involvement is seen in 33% of patients with genitourinary tract TB.[49] Early bladder manifestations include mucosal edema and ulceration. Early clinical symptoms (dysuria and frequency) are also nonspecific. If edema occurs at the bladder trigone, ureteric obstruction may occur. At ultrasound, early bladder involvement will appear as focal or diffuse wall thickening; the thickening can be quite extensive (Fig. 9.29).

The later or more chronic changes of genitourinary tract TB include fibrotic strictures, extensive cavitation, calcification, mass lesions, perinephric abscesses, and fistulas.[48] The chronic changes, in particular those related to fibrotic strictures, result in functional renal damage. Strictures may occur anywhere in the intrarenal collecting system and ureter. The obstruction then results in proximal collecting system dilatation and pressure atrophy of the renal parenchyma. With time, calcification in the areas of caseation or sloughed papilla may occur. If renal infection ruptures into the perinephric space, an abscess may develop. Perinephric abscesses may ultimately result in fistulas to adjacent viscera. The hallmark of chronic, upper tract renal TB is a small, nonfunctional, calcified kidney, the **"putty" kidney.** In the bladder, chronic infection and fibrosis result in a thickened, small-capacity bladder.[48] Speckled or curvilinear calcification of the bladder wall may rarely occur.[50]

Most cases of genitourinary tract TB can be diagnosed with a combination of intravenous/retrograde urography, ultrasound, CT, and CT urography.[51] Premkumar et al.[52] demonstrated in 14 patients with advanced urinary tract TB that detailed morphologic information and functional renal status are best assessed with CT and urography. Das et al.[53] reported that ultrasound-guided, fine-needle aspiration (1) may be diagnostic in patients with negative urine cultures and (2) may confirm a diagnosis of upper genitourinary tract TB in those patients with suspicious lesions and positive cultures.

Fungal Infections

Patients with a history of diabetes mellitus, chronic indwelling catheters, malignancy, hematopoietic disorders, chronic antibiotic or steroid therapy, transplantation, and intravenous drug abuse are at risk for developing fungal infections of the urinary tract.[54]

Candida Albicans

Candida albicans is the most common fungal agent that affects the urinary tract. Renal parenchymal involvement, typically manifested by small parenchymal abscesses, occurs in the context of diffuse systemic involvement. The abscesses may calcify over

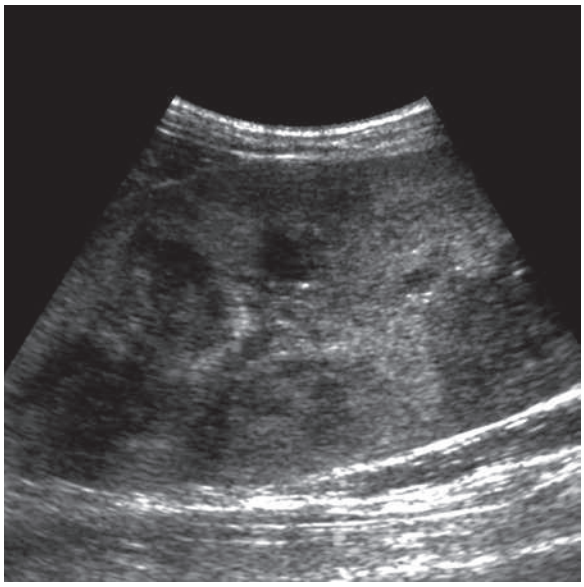

FIG. 9.28 Progressive Renal Tuberculosis. Sagittal sonogram shows small, irregular hypoechoic medullary lesions. Areas of cavitation ultimately connect to the collecting system. (With permission from Wasnik AP. Tuberculosis, urinary tract. In: Kamaya A, Wong-You-Cheong J, editors. Diagnostic ultrasound: abdomen and pelvis. Philadelphia: Elsevier; 2016. pp. 490-493.[51])

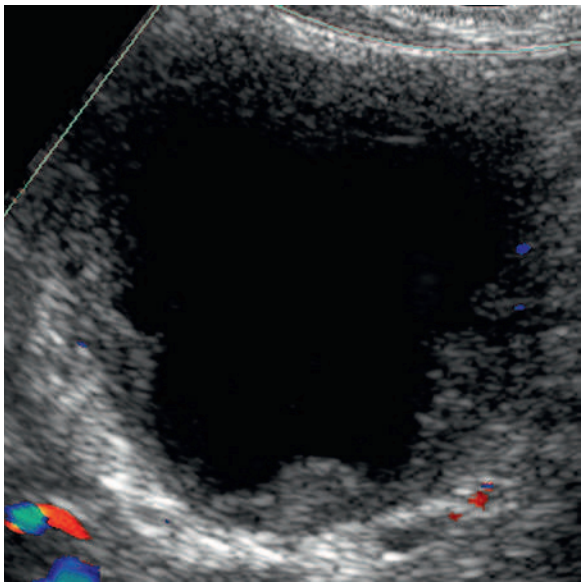

FIG. 9.29 Urinary Bladder Tuberculosis. Transverse sonogram shows irregular mucosal thickening, particularly at the ureteric orifice—a characteristic feature of early bladder tuberculosis. (With permission from Wasnik AP. Tuberculosis, urinary tract. In: Kamaya A, Wong-You-Cheong J, editors. Diagnostic ultrasound: abdomen and pelvis. Philadelphia: Elsevier; 2016. pp. 490-493.[51])

time.[55] Extension into the perinephric space is also possible. Invasion of the collecting system ultimately results in fungus balls. Collecting system **mycetomas** may be differentiated from blood clots, radiolucent stones, transitional cell tumors, sloughed papillae, fibroepithelial polyps, cholesteatomas, and leukoplakia based on clinical history and urine cultures.[56-58] On sonography, **candidal microabscesses** are typically small, hypoechoic cortical lesions; the appearance is similar to other bacterial abscesses. **Fungus balls** appear as echogenic, nonshadowing soft tissue masses within the collecting system[59] (Fig. 9.30). Fungus balls are mobile and may cause obstruction and hydronephrosis.

Parasitic Infections

A wide variety of parasitic infections are common in developing countries. Sonographers should be particularly familiar with schistosomiasis and echinococcal (hydatid) disease.

Schistosomiasis

Schistosoma haematobium is the most common agent to affect the urinary tract. The worms enter the human host by penetrating the skin. They are then carried via the portal venous system to the liver, where they mature into their adult form. *S. haematobium* likely enters the perivesical venous plexus from the hemorrhoidal plexus.[60] The female worm then deposits eggs into the venules of the bladder wall and ureter. Granuloma formation and obliterative endarteritis occur. Serologic tests demonstrating ova allow diagnosis. Hematuria is the most frequent complaint.[60]

At sonography, the kidneys are normal until late in the disease. Pseudotubercles develop in the ureter and bladder, and the urothelium becomes thickened (Fig. 9.31).[61] Over time the pseudotubercles calcify; the calcification may be fine, granular and linear, or thick and irregular. If repeated infections occur, the bladder will become small and fibrotic. Bladder stasis results in an increased incidence of ureteral and bladder calculi.[60] Patients with chronic disease also have an increased incidence of squamous cell carcinoma.[60]

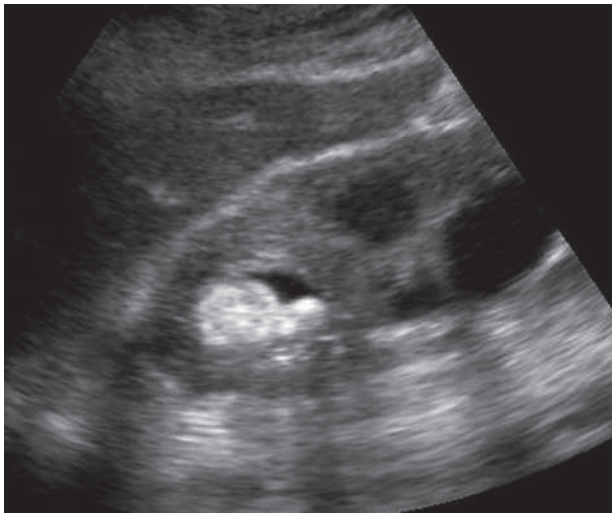

FIG. 9.30 Fungus Ball. Sagittal sonogram shows an echogenic soft tissue mass within a dilated upper-pole cortex.

Echinococcal (Hydatid) Disease

The two major types of hydatid disease that affect the urinary tract are caused by *Echinococcus multilocularis* and the more common *Echinococcus granulosus.* Renal hydatid disease is found in 2% to 5% of patients with hydatid disease,[60] is usually solitary, and typically involves the renal poles.[62] Hydatid cysts may occur along the ureter or within the bladder. Each hydatid cyst consists of three layers: the pericyst, ectocyst, and endocyst. Echinococcal disease is often silent until the cyst grows large enough to rupture or compress adjacent structures.

The ultrasound manifestation of early hydatid disease is an **anechoic cyst.** Mural nodularity suggests scolices. When **daughter cysts** are present, a multiloculated cystic mass will be seen (Fig. 9.32). The membranes from the endocyst may detach and precipitate to the bottom of the hydatid fluid to become "hydatid sand."[63] Varying patterns of calcification occur, ranging from eggshell to dense reticular calcification. Ring-shaped calcifications inside a larger, calcified lesion suggest calcified daughter cysts.[60,63] A specific ultrasound diagnosis is difficult without an appropriate clinical history. However, several features may suggest hydatid disease, including floating membranes, daughter cysts, and thick, double-contour cyst walls.[64]

Acquired Immunodeficiency Syndrome

The disease course and imaging manifestations of human immunodeficiency virus (HIV) infection, acquired immunodeficiency syndrome (AIDS), and HIV-associated nephropathy have rapidly evolved largely because of advances in the care of HIV-positive patients. Highly active antiretroviral therapy (HAART) has resulted in a decreased incidence of opportunistic infections and improved survival.

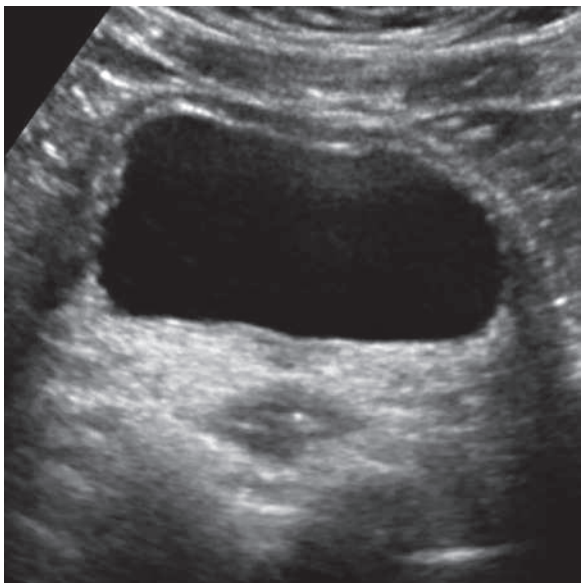

FIG. 9.31 Bladder Schistosomiasis. Transverse sonogram shows mild bladder wall thickening and linear anterior wall echogenicity due to early calcification. (With permission from Wasnik AP. Schistosomiasis, bladder. In: Kamaya A, Wong-You-Cheong J, editors. Diagnostic ultrasound: abdomen and pelvis. Philadelphia: Elsevier; 2016. pp. 548-549.[61])

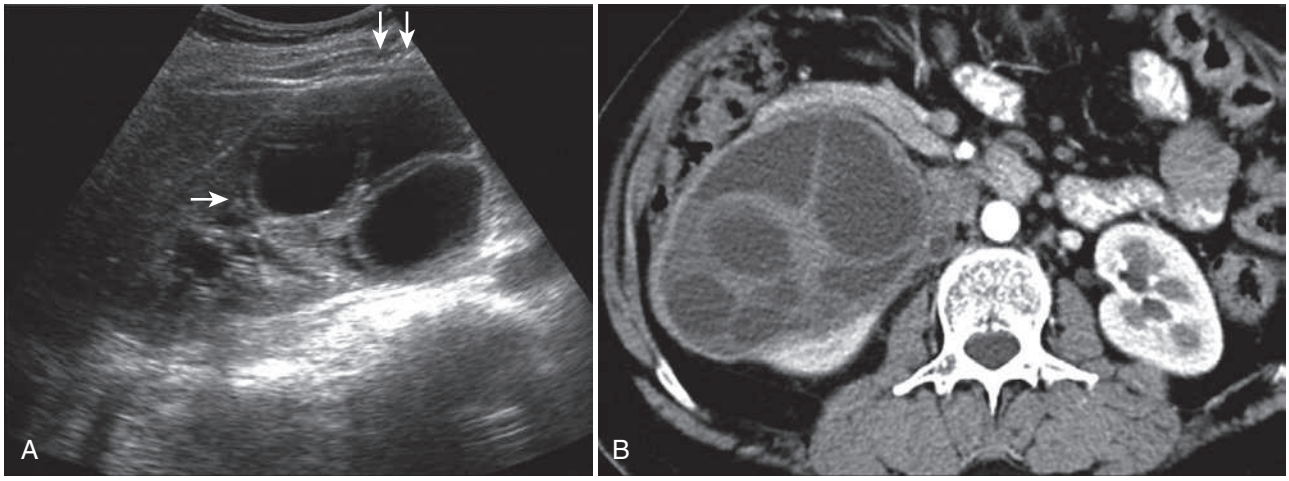

FIG. 9.32 Renal Hydatid Cyst. (A) Sagittal sonogram shows a complex multiloculated lower-pole cystic mass *(arrows).* **(B)** Contrast-enhanced CT shows multiple confluent daughter cysts. (Courtesy of Drs. Vikram Dogra and Suleman Merchant.)

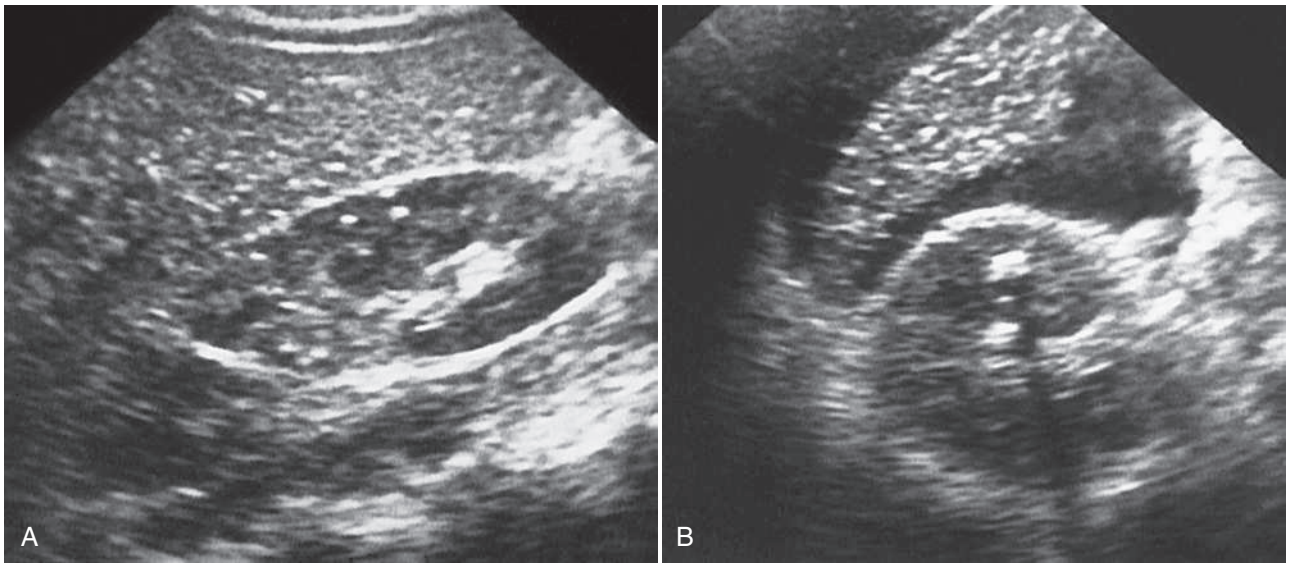

FIG. 9.33 Proven *Pneumocystis* Nephropathy in a Patient With AIDS. (A) Sagittal and **(B)** transverse sonograms show multiple scattered echogenic foci within the renal parenchyma. Some foci demonstrate the distal acoustic shadowing of calcification. Similar findings are seen in the liver. (With permission from Spouge AR, Wilson S, Gopinath N, et al. Extrapulmonary Pneumocystis carinii in a patient with AIDS: sonographic findings. AJR Am J Roentgenol. 1990;155:76-78.[66])

Early literature noted the increased incidence of opportunistic genitourinary infections (cytomegalovirus [CMV], *Candida albicans, Cryptococcus, Pneumocystis jiroveci* [formerly *P. carinii*], *Mycobacterium avium-intracellulare, Mucormycosis*) and tumors (lymphoma, Kaposi sarcoma) in these immunocompromised patients.[65] The appearance of these infections is often nonspecific (and now rare), but diffuse visceral/renal calcifications suggest disseminated *P. jiroveci*, CMV, or *M. avium-intracellulare* infections[66-68] (Fig. 9.33). The genitourinary infections that now occur in these patients, including pyelonephritis, renal abscesses, and cystitis, are similar to those seen in non–HIV-infected individuals.

Use of HAART has also changed the spectrum of chronic renal diseases seen in HIV-positive patients. The incidence of ESRD in HIV patients decreased initially after the institution of HAART; however, the increased prevalence of HIV in the US population has resulted in an increased number of patients with **HIV-associated nephropathy** (HIVAN).[69] In HIV-positive patients, HIVAN is the most common cause of chronic kidney disease; black patients are at particular risk. The histologic hallmark of HIVAN is focal segmental glomerulosclerosis. Nephropathy in HIV-positive patients may also be caused by HIV immune complex disease and HIV thrombotic microangiopathy. Adverse renal effects of various drugs also complicate the diagnosis of chronic renal failure.[70] However, other disease processes not directly associated with HIV infection (e.g., hypertension, diabetic nephropathy, interstitial nephritis) may result in ESRD in patients successfully treated with HAART.[71] Definitive diagnosis of HIVAN is usually made after renal biopsy. Renal sonography is useful in these patients to exclude obstruction

and determine renal size. Early reports also suggested that **greatly increased renal echogenicity** is a fairly specific finding of HIVAN (and **heroin nephropathy**)[65,72,73] (Fig. 9.34). Other features in HIV-positive patients with renal insufficiency include globular-appearing kidneys, decreased corticomedullary differentiation, decreased renal sinus fat, and parenchymal heterogeneity.[74]

Cystitis

Infectious Cystitis

Women are at increased risk for cystitis because of colonization of the short female urethra by rectal flora. Bladder outlet obstruction or prostatitis results in cystitis in men. The most common pathogen is *E. coli*.[75] Mucosal edema and decreased bladder capacity are common. Findings may be more prominent at the trigone and bladder neck. Patients will present with bladder irritability and hematuria. The most common finding at sonography is diffuse bladder wall thickening. If cystitis is focal, **pseudopolyps** may form, which are impossible to differentiate from tumor[76] (Fig. 9.35A).

Malacoplakia

Malacoplakia is a rare granulomatous infection with a predilection for the urinary bladder. The disease is seen more often in women (4:1), with a peak incidence in the sixth decade.[77] The pathogenesis of malacoplakia is not known; however, an association with **diabetes mellitus, alcoholic liver disease, mycobacterial infections, sarcoidosis,** and **transplantation** suggests an altered immune response.[78] Patients may present with hematuria and symptoms of bladder irritability. At sonography, single or multiple mucosal-based masses ranging from 0.5 to 3.0 cm are seen, typically at the bladder base. Malacoplakia may be locally invasive[77] (Fig. 9.35B).

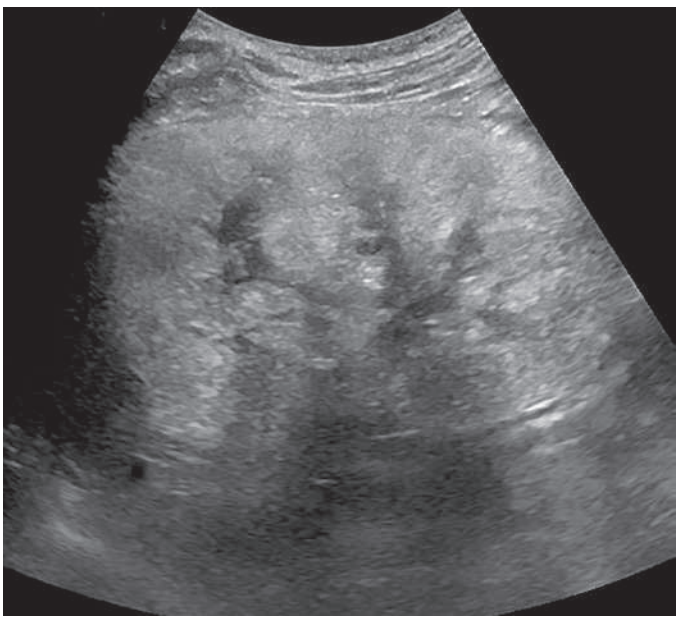

FIG. 9.34 HIV-Associated Nephropathy (HIVAN). Sagittal sonogram shows an enlarged, markedly echogenic kidney. Biopsy confirmed focal segmental glomerulosclerosis.

Emphysematous Cystitis

Emphysematous cystitis occurs most often in female patients and those with diabetes. Patients present with symptoms of cystitis and occasionally have pneumaturia.[75] The most common offending organism is *E. coli*. Both intraluminal and intramural gas are present. In these severely ill patients, the urothelium is ulcerated and necrotic and may slough completely. Emphysematous cystitis is suggested at sonography when echogenic foci within the bladder wall are associated with ring-down artifact or dirty shadowing[79] (Fig. 9.36A and B). Gas may be seen in the bladder lumen as well. The bladder wall is usually thickened and echogenic.[34] A lack of bladder wall thickening may be a helpful sonographic feature to distinguish the gas of emphysematous cystitis from gas introduced by catheterization (Fig. 9.36C).

Chronic Cystitis

Chronic inflammation of the bladder may be caused by various agents. Although the histology may also vary, the imaging manifestations, including a small, thickened bladder, are nonspecific. Chronic cystitis may result in invagination of solid "nests" of urothelium into the lamina propria **(Brunn epithelial nests),** which may result in morphologic changes that mimic neoplasia.[80] If the central portion of a Brunn nest degenerates, a cyst results **(cystitis cystica).** If chronic irritation persists, the Brunn nests may develop into glandular structures **(cystitis glandularis).** These may be precursors of adenocarcinoma.[75] Cystitis cystica and cystitis glandularis may be manifested at ultrasound as bladder wall cysts or solid papillary masses (see Fig. 9.35C). Because the appearance of these conditions on imaging can be mistaken for malignancy, cystoscopy with biopsy is necessary for diagnostic confirmation.

FISTULAS, STONES (CALCULI), AND CALCIFICATION

Bladder Fistulas

Bladder fistulas can be congenital or acquired. Causes of acquired fistulas include trauma, inflammation, radiation, and neoplasm. Fistula from the bladder to the vagina, gut, skin, uterus, and the ureter may occur. **Vesicovaginal fistulas** are most often related to gynecologic or urologic surgery, bladder carcinoma, and carcinoma of the cervix. **Vesicoenteric** fistulas typically occur as a complication of **diverticulitis** or **Crohn disease. Vesicocutaneous** fistulas result from surgery or trauma. **Vesicouterine** fistulas are a rare complication of cesarean section. **Vesicoureteral** fistulas are also rare and usually occur after hysterectomy.[81]

All these fistulas are difficult to identify directly by sonography because the tracts are often thin and short. Occasionally, linear bands of varying echogenicity may be seen.[82,83] If the bladder communicates with gut, vagina, or skin, an abnormal collection of gas may be seen in the bladder lumen. At ultrasound, this appears as a nondependent linear echogenic focus with distal dirty shadowing. Palpation of the abdomen during scanning may cause gas to percolate through the fistula, enhancing its detection[83] (Fig. 9.36D). For depicting often short vesicovaginal fistulas, color Doppler sonographic flow jets may be shown with diluted microbubble contrast agents in the bladder.[84]

Renal Calculi

Renal stones are common, with a reported prevalence of 12% in the general population.[85] Stone disease increases with advancing age, and white men are most often affected. From 60% to 80% of calculi are composed of calcium.[86] Multiple predisposing conditions, including **dehydration, urinary stasis, hyperuricemia, hyperparathyroidism,** and **hypercalciuria,** may result in renal calculi, but no cause is identified in most patients. **Caliceal**

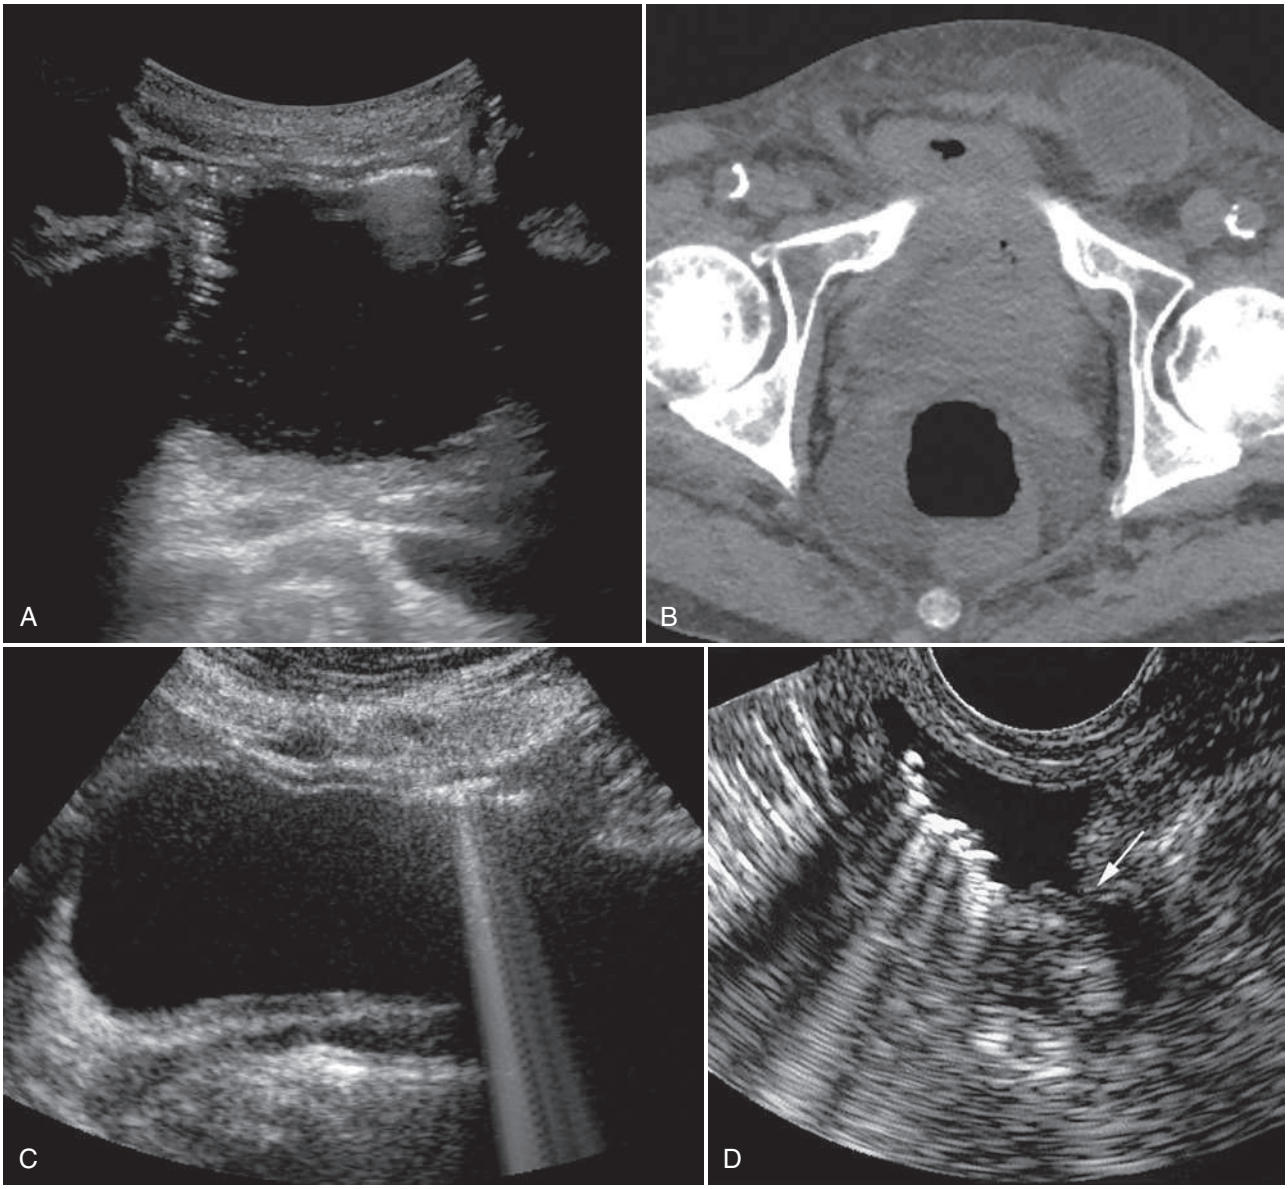

FIG. 9.36 Gas Within the Bladder; Emphysematous Cystitis. (A) Transverse sonogram shows intraluminal gas along left anterior bladder wall. calculi that are nonobstructing are usually asymptomatic. Patients with small caliceal calculi may have gross or microscopic hematuria and may have colic symptoms despite the lack of imaging findings suggestive of obstruction.[87] A calculus that migrates and causes infundibular or UPJ obstruction often results in clinical signs and symptoms of flank pain. If a stone passes into the ureter, the calculus may lodge in three areas of ureteric narrowing: just past the UPJ; where the ureter crosses the iliac vessels; and at the UVJ. The very small diameter of the UVJ (1-5 mm) accounts for the large percentage of calculi that lodge within the distal ureter.[86] Approximately 80% of stones smaller than 5 mm will pass spontaneously.

Renal calculi can be detected using many different imaging modalities, including plain films, tomography, intravenous urography, ultrasound, and unenhanced CT. Sensitivities of 12% to 96% for the ultrasound detection of calculi have been reported. This wide discrepancy is a result of differing definitions (renal or ureteral), composition, and sizes of calculi.[88] Stones greater than 5 mm were detected with 100% sensitivity by ultrasound. Ultrasound with or without plain radiography competes favorably with unenhanced CT in select patients with ureteral colic.[89-91] The sensitivity of ultrasound detection of urinary calculi in patients with acute flank pain is 77% to 93%.[92-94] The 2016 European Association of Urology guidelines for diagnosis and

treatment of urolithiasis list ultrasound as the primary diagnostic imaging tool.[95]

However, noncontrast-enhanced low-dose CT has higher sensitivity (95%) and specificity (97%) for urolithiasis than does ultrasound.[96] Thus many centers use low-dose CT, particularly in patients in whom ureteral stones are suspected or patients whose initial screening ultrasound examination is negative or equivocal but clinical suspicion remains elevated.

Operator technique clearly impacts the ability of ultrasound to depict renal calculi. On sonography, renal calculi are seen as echogenic foci with sharp, distal acoustic shadowing (Fig. 9.37). Even in favorable locations, however, small urinary tract calculi may be difficult to detect if they have a weak posterior acoustic shadow. The trade-off between tissue penetration and resolution should be considered when selecting probe frequency, with appropriate focal zones applied to maximize signature shadowing. Harmonic imaging should also be routinely used, particularly in obese patients. The application of color Doppler may also improve the detection of small, minimally shadowing calculi.[97] Lee et al.[98] demonstrated that most urinary tract stones (83%) show color and power Doppler sonographic **twinkling artifacts,** although the artifact at least partially depends on stone composition[99] (Fig. 9.38). The relevance of this adjunct technique in the screening of patients with potential urinary colic has been questioned, however. In a recent retrospective study, Dillman et al. demonstrated a high (51%) false positive rate for the twinkle artifact when using noncontrast-enhanced CT as a reference standard.[100]

Several features that mimic renal calculi at ultrasound can result in false positive examination results, including **intrarenal gas** (see Fig. 9.23), **renal artery** *calcification* (Fig. 9.39), calcified **sloughed papilla,** calcified **transitional cell tumor, alkaline-encrusted pyelitis, and encrusted ureteral stents.** Although the ultrasound evaluation of the secondary manifestation of an obstructing ureteral calculus—collecting system dilatation—is usually straightforward, pitfalls include (1) evaluation before hydronephrosis develops, leading to a false negative result, and (2) mistaking parapelvic cysts and nonobstructive pyelocaliectasis as hydronephrosis.[101]

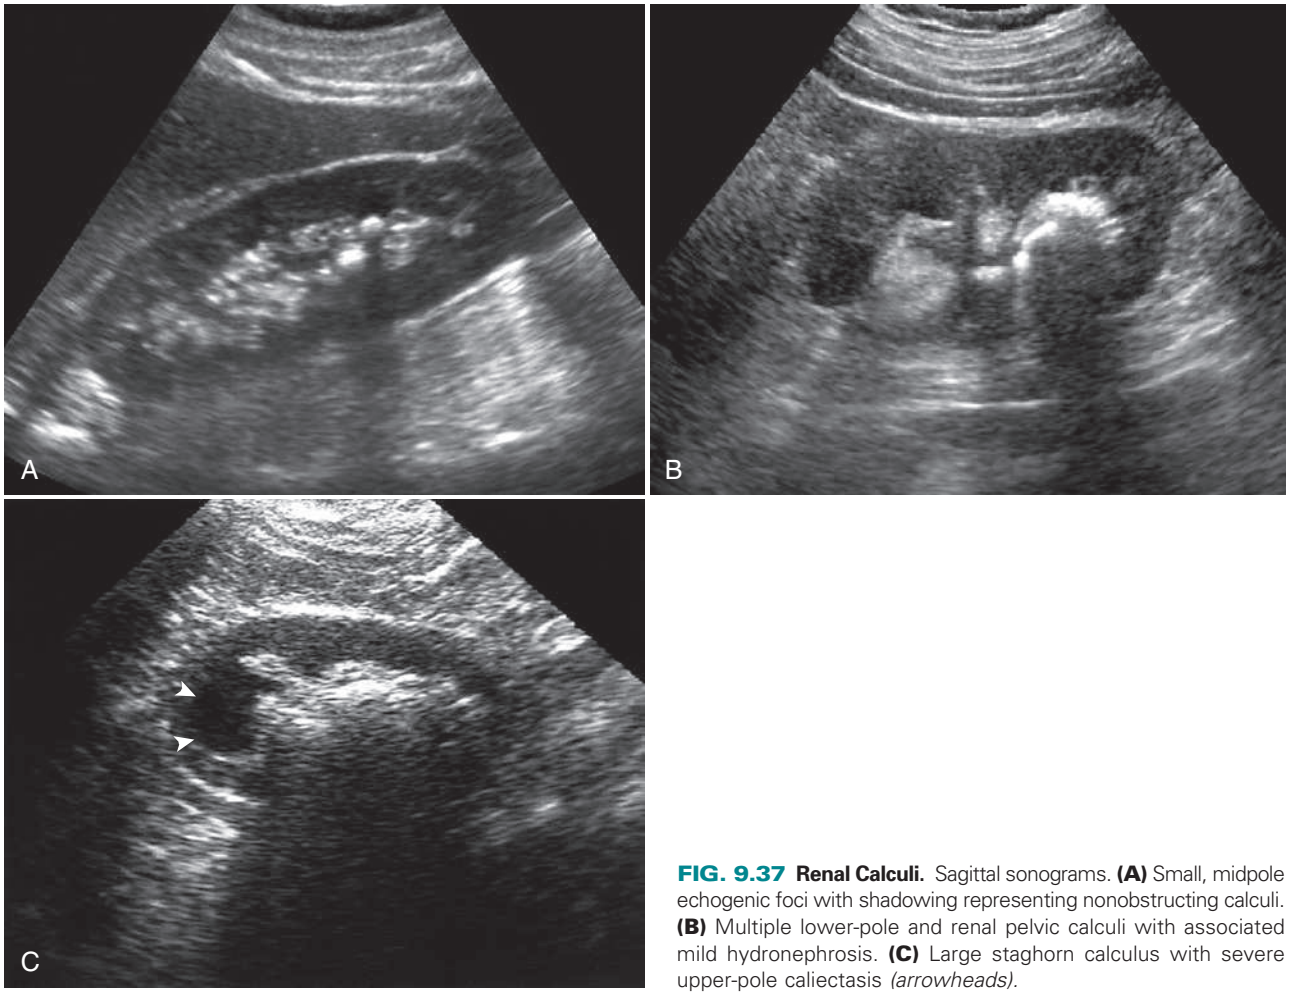

FIG. 9.37 Renal Calculi. Sagittal sonograms. **(A)** Small, midpole echogenic foci with shadowing representing nonobstructing calculi. **(B)** Multiple lower-pole and renal pelvic calculi with associated mild hydronephrosis. **(C)** Large staghorn calculus with severe upper-pole caliectasis *(arrowheads).*

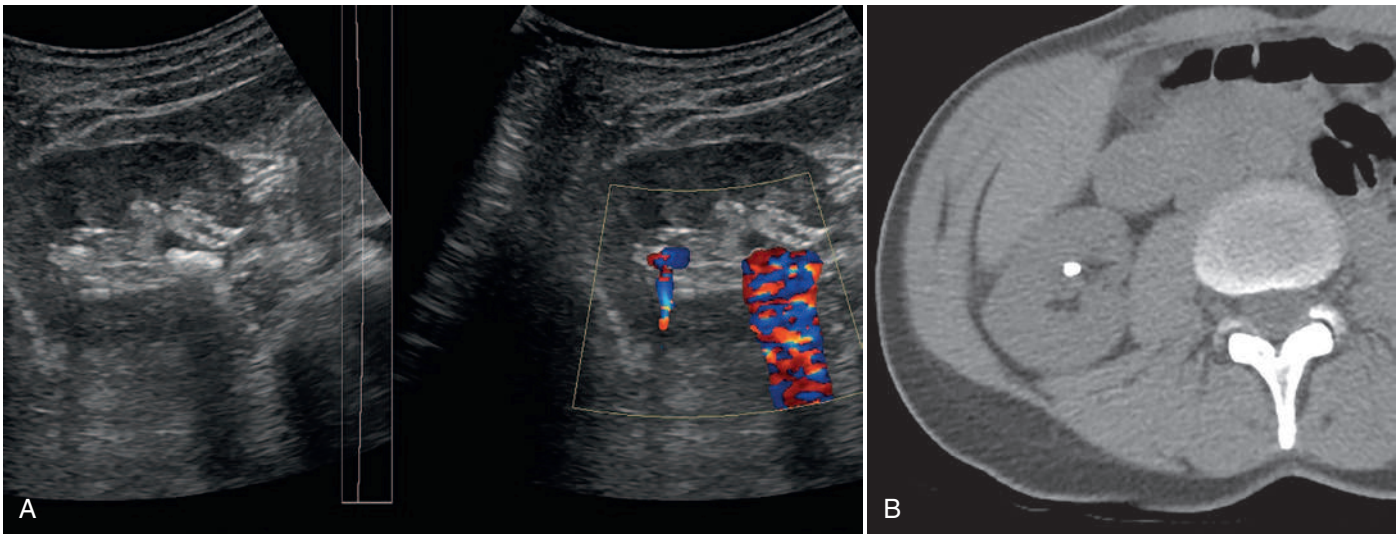

FIG. 9.38 Twinkle Artifacts Indicating Renal Calculi. (A) Transverse sonogram and simultaneous Doppler image show shadowing calculi, posterior shadowing, and color Doppler twinkle artifact. **(B)** A follow-up CT shows the larger calculus. The color Doppler twinkle artifact may sometimes aid in detection of small calculi, although often no corresponding calculi are shown on noncontrast-enhanced CT. The reason for this discrepancy is not clear, although it may be due to relatively large (5-mm) collimation typically used for the CT evaluation of calculi.

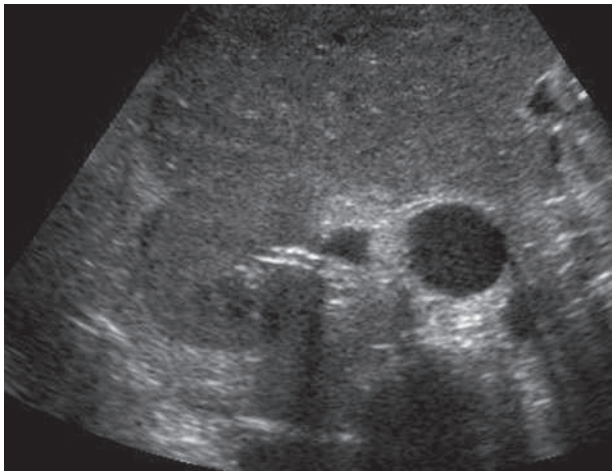

FIG. 9.39 Sonographic Feature Mimicking Renal Calculus. Transverse sonogram shows a linear distal renal artery calcification.

Entities That Mimic Renal Calculi

Intrarenal gas
Renal artery calcification
Calcified sloughed papilla
Calcified transitional cell tumor
Alkaline-encrusted pyelitis
Encrusted calcification of ureteric stent

Ureteral Calculi

The search for ureteral calculi may be particularly difficult at sonography because of overlying bowel gas and the deep retroperitoneal location of the ureter (Fig. 9.40). However, **transvaginal** or **transperineal** scanning aid in detection of distal ureteral calculi that are not seen with a transabdominal suprapubic approach.[83,102,103]

When the ureter is dilated, the distal 3 cm will be seen as a tubular hypoechoic structure entering the bladder obliquely. A stone will be identified as an echogenic focus with sharp, distal acoustic shadowing within the ureteric lumen (Fig. 9.41). There may be associated mucosal edema at the bladder trigone. Transabdominal evaluation of the ureteral orifices for jets is helpful to assess for obstruction (Video 9.1).[104] At gray-scale ultrasound, a stream of low-level echoes can be seen entering the bladder from the ureteral orifice. The jet is likely shown at ultrasound because of both motion and a density difference between the jet and urine in the bladder.[105] Good hydration before the study maximizes the density difference between ureteral and bladder urine and aids in jet visualization.[106]

In addition to gray-scale evaluation, Doppler ultrasound improves detection of ureteric jets. **Color Doppler** allows for simultaneous visualization of both ureteral orifices[104] (Fig. 9.42). Depending on the state of hydration, jet frequency may vary from less than one per minute to continuous flow; however, jets should be symmetric in a healthy individual. Patients with high-grade ureteral obstruction will have either a completely absent jet or a continuous, low-level jet on the symptomatic side. Patients with low-grade obstruction may or may not have **asymmetric jets.**[104] Semiqualitative assessment of relative jet frequency from the affected side[107] may improve diagnostic accuracy, but this technique has not been widely adopted. Thus centers that evaluate ureteral jets with color Doppler use the technique as an adjunct for assessing ureteric obstruction and the possibility of spontaneous ureteral stone passage.

Initial studies suggested that the addition of renal **duplex Doppler** to the gray-scale ultrasound examination would allow diagnosis of both acute and chronic urinary tract obstruction.[108] Several studies indicated that the complex hemodynamics that occur with unrelieved obstruction can be semiquantitatively assessed by measuring intrarenal arterial resistive indices (RI =

peak systolic velocity–end diastolic velocity/peak systolic velocity). It is believed that with obstruction, renal pelvic wall tension increases, initially resulting in a short period of prostaglandin-mediated vasodilation.[109] With prolonged obstruction, many hormones, including **renin-angiotensin, kallikrein-kinin,** and **prostaglandin-thromboxane,** reduce vasodilation and produce diffuse vasoconstriction. Geavlete et al.[110] found that if there was an intravesical ureteric jet on the renal colic side associated with arcuate or intralobar RI values of 0.7 or less and difference between renal RI values of 0.06 or less, spontaneous passage of the stone occurred in 71% of cases. Platt et al.[108] used a threshold RI greater than 0.70 to indicate obstruction, noting a difference in RI of 0.08 to 0.1 when comparing the patients' obstructed and non-obstructed kidneys. Initial reports advocating the Doppler assessment of renal obstructive physiology were tempered by a series of less promising studies.[101,109] The RI is largely dependent on tissue/vascular compliance (diminished compliance results in elevated RI, and vice versa) and driving pulse pressures, and thus is not uniformly affected by obstruction.[111-114]

Bladder Calculi

Bladder calculi most often result from either stone migration from the kidney or bladder stasis. Urinary stasis is usually related to a **bladder outlet obstruction, cystocele, neurogenic bladder,**

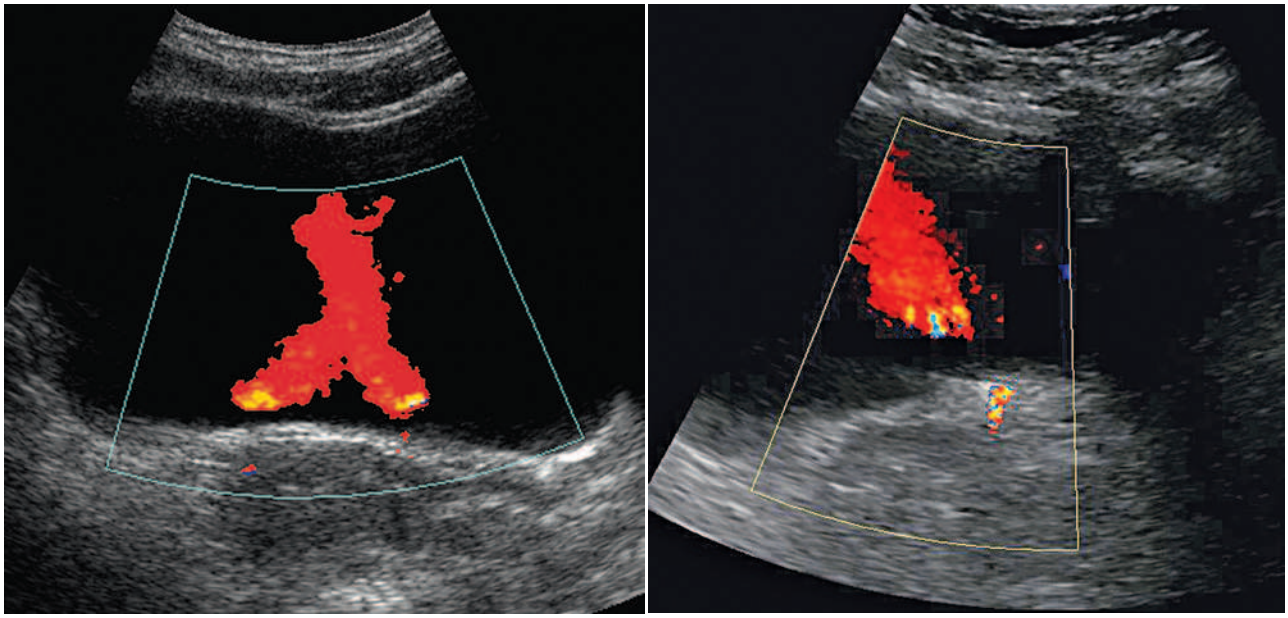

FIG. 9.42 Color Doppler Evaluation of Ureteral Colic. or a **foreign body in the bladder.** Bladder calculi may be asymptomatic. If symptomatic, patients will complain of bladder pain or foul-smelling urine with or without hematuria. At sonography, a mobile, echogenic mass with distal acoustic shadowing will be seen (Fig. 9.43). If the stone is large, edema of the ureteral orifices and thickening of the bladder wall may be visualized. Occasionally, stones can adhere to the bladder wall because of adjacent inflammation; these calculi are known as **"hanging" bladder stones.**

Nephrocalcinosis

Nephrocalcinosis refers to renal parenchymal calcification. The calcification may be dystrophic or metastatic. With **dystrophic calcification,** there is deposition of calcium in devitalized (ischemic or necrotic) tissue.[115] This type of parenchymal calcification occurs in tumors, abscesses, and hematomas. **Metastatic nephrocalcinosis** occurs most often with hypercalcemic states caused by **hyperparathyroidism, renal tubular acidosis,** and **renal failure.** Metastatic nephrocalcinosis can be further categorized by the location of calcium deposition as cortical or medullary. Causes of **cortical nephrocalcinosis** include **acute cortical necrosis, chronic glomerulonephritis, chronic hypercalcemic states, ethylene glycol poisoning, sickle cell disease,** and **renal transplant rejection.** Causes of **medullary nephrocalcinosis** include **hyperparathyroidism (40%), renal tubular acidosis (20%), medullary sponge kidney, bone metastases, chronic pyelonephritis, Cushing syndrome, hyperthyroidism, malignancy, renal papillary necrosis, sarcoidosis, sickle cell disease, vitamin D excess,** and **Wilson disease.**[115]

The Anderson-Carr-Randall theory of stone progression postulates that the concentration of calcium is high in the fluid around the renal tubules. The calcium is removed by lymphatics, and if the amount exceeds lymphatic capacity, deposits of calcium in the fornical tips and margins of the medulla will result. The ultrasound manifestation of early medullary calcification are nonshadowing echogenic rims surrounding medullary pyramids.[116] However, increased medullary echogenicity can also be caused by medullary sponge kidney[117] (Fig. 9.44); it can be a normal transient finding in neonates.[118] Further calcium deposition results in acoustic shadowing (Fig. 9.45). The calcifications may perforate the calix and form a nidus for further stone growth.[119]

Although the physiology of cortical nephrocalcinosis differs from that of medullary nephrocalcinosis, its ultrasound

manifestations are similar; early cortical calcification may be suggested by increased cortical echogenicity. With progressive calcification, a continuous, shadowing calcified rim develops.

GENITOURINARY TUMORS

Renal Cell Carcinoma

Renal cell carcinoma (RCC) accounts for approximately 3% of all adult malignancies and 86% of all primary malignant renal parenchymal tumors.[120] There is a 2:1 male predominance, and peak age is 50 to 70 years. The cause is unknown, although weak associations with smoking,[121] chemical exposure, asbestosis, obesity, and hypertension have been shown. The vast majority of RCCs are sporadic, but an estimated 4% occur in the context of inherited syndromes.[122,123] These "inherited" RCCs occur at an earlier age, are multifocal and bilateral, and affect men and women equally.[122] **Von Hippel–Lindau (VHL) disease** is the best known inherited RCC syndrome; 24% to 45% of patients who have VHL disease will develop RCC. Most of these lesions are multicentric and bilateral and are clear cell carcinomas.[124-126] Other inherited renal cancer syndromes include **hereditary papillary renal cancer, Birt-Hogg-Dubé syndrome, hereditary leiomyoma RCC, familial renal oncocytoma, hereditary nonpolyposis colon cancer,** and **medullary RCC.** An increased incidence of RCC in patients with **tuberous sclerosis** has also been reported.[123] Another important but nonsyndromic risk factor for RCC is the **acquired cystic kidney disease** that occurs in patients receiving long-term hemodialysis or peritoneal dialysis. The RCCs in these patients are small and hypovascular and tend to be relatively less aggressive.[127,128]

Histologic subtypes of RCC include **clear cell** (70%-75%), **papillary** (15%), **chromophobe** (5%), **oncocytic** (2%-3%), and **collecting duct** or **medullary** (<1%) tumors. Patients with papillary, chromophobe, and oncocytic tumors have a much better prognosis than those with clear cell and collecting duct tumors. Attempts have been made to differentiate histologic subtypes at imaging, largely based on enhanced-CT kinetics, but overlapping patterns have precluded attempts at preoperative imaging classification. However, potentially relevant features may be shown at ultrasound; for example, lack of necrosis and the presence of calcification appear to be associated with a better prognosis (papillary and chromophobe subtypes).[129]

Before the advent of cross-sectional imaging, most patients with RCC presented with advanced metastatic disease. In a 1971 series the **classic diagnostic triad** of flank pain, gross hematuria, and palpable renal mass was seen in 4% to 9% of patients at presentation.[130] Systemic symptoms (e.g., anorexia, weight loss) are common with advanced disease. Manifestations reported secondary to hormone production include **erythrocytosis (erythropoietin), hypercalcemia (parathormone, vitamin D metabolites, prostaglandins), hypokalemia (adrenocorticotropic hormone [ACTH]), galactorrhea (prolactin), hypertension (renin), and gynecomastia (gonadotropin).** RCC metastases to virtually every organ in the body have been described.

Sagittal sonogram demonstrates increased echogenicity in a rimlike pattern around all medullary pyramids and several punctate, shadowing calculi. **(B)** Sagittal sonogram shows extensive medullary calcification in a patient with renal tubular acidosis.

Imaging and Treatment Approaches

Before the advent of CT, renal tumors less than 3 cm represented 5% of lesions, whereas now these small lesions represent 9% to 38% of all renal tumors.[131] Jamis-Dow et al.[132] found that CT was more sensitive than ultrasound for the detection of small renal masses (<1.5 cm) and that both ultrasound and CT could equally characterize a mass larger than 1 cm. They also demonstrated that a combination of ultrasound and CT allowed accurate characterization of a lesion larger than 1.0 cm in 95% of cases. With the advent of helical CT, respiratory misregistration and partial volume averaging are minimal; thus nephrographic-phase helical CT scans enable better lesion detection and characterization and typically is sufficient for diagnosis.[133-136]

A particular role of MRI is in the characterization of high-attenuation renal masses.[137] Most centers, however, still reserve renal MRI for patients with (1) an allergy to iodinated contrast, (2) CT-indeterminate renal masses, or (3) extent of vascular involvement inadequately determined by ultrasound and CT. Previously, renal MRI was also performed to assess lesional enhancement in patients with renal insufficiency. However, recognition of the central role of gadolinium in the development of nephrogenic systemic fibrosis highlighted the potential risks in these patients.[138] Thus ultrasound has again assumed a preeminent role for mass characterization in patients with renal insufficiency at risk for nephropathy after iodinated contrast exposure at CT or for nephrogenic systemic fibrosis after gadolinium exposure at MRI.

Contrast-enhanced ultrasound (CEUS) also holds promise for assessment of renal lesions. Quaia et al. compared sonography without contrast material versus CEUS and CT for the characterization of 40 complex cystic renal masses and found that the diagnostic accuracy of CEUS (80%-83%) was better than that of nonconstrast sonography (30%) and CT (63%-75%) for all readers.[139] In another European study of 143 lesions, CEUS was shown to predict malignancy with 97% sensitivity, 45% specificity, and 90% accuracy. CEUS was superior to CT in the staging and characterization of RCC, as well as in the subgroup of patients with cystic lesions.[140]

The increased detection of small, incidental lesions and better understanding of the natural history of these tumors have led to less aggressive approaches to RCCs. The traditional surgical approach, radical nephrectomy, is now usually reserved for larger, central lesions. The greater likelihood of small, benign, solid lesions in older patients[141] and the limited metastatic potential of small (<3 cm) lesions[142] have prompted a "watchful waiting" approach, particularly in older or ill patients.[143] Nephron-sparing surgery (open/laparoscopic partial nephrectomy, laparoscopic cryoablation, percutaneous radiofrequency ablation/cryoablation) may be offered to younger patients or older patients unwilling or unable to undergo imaging surveillance (Fig. 9.46). Primary/secondary efficacy and long-term survival rates with these techniques are likely comparable to those resulting from traditional nephrectomy.[144] Gervais et al.[145] found that radiofrequency ablation of exophytic RCCs up to 5 cm in size can be performed successfully. Tumors with a component in the renal sinus are more difficult to treat. Retrospective studies have suggested that cryoablation may be the preferred ablation modality in this setting[146] although a recent large meta-analysis has indicated little difference in complication rates between techniques.[147]

Sonographic Appearance

Most RCCs are solid. Tumors may be hypoechoic, isoechoic, or hyperechoic (Fig. 9.47, Video 9.2). An early ultrasound series reported that the majority of RCCs are isoechoic (86%), whereas the minority is hypoechoic (10%) or echogenic (4%).[148] Later series noted the ultrasound appearance of the smaller RCCs that are now often depicted with cross-sectional imaging. These smaller RCCs (<3 cm) are often echogenic compared with surrounding

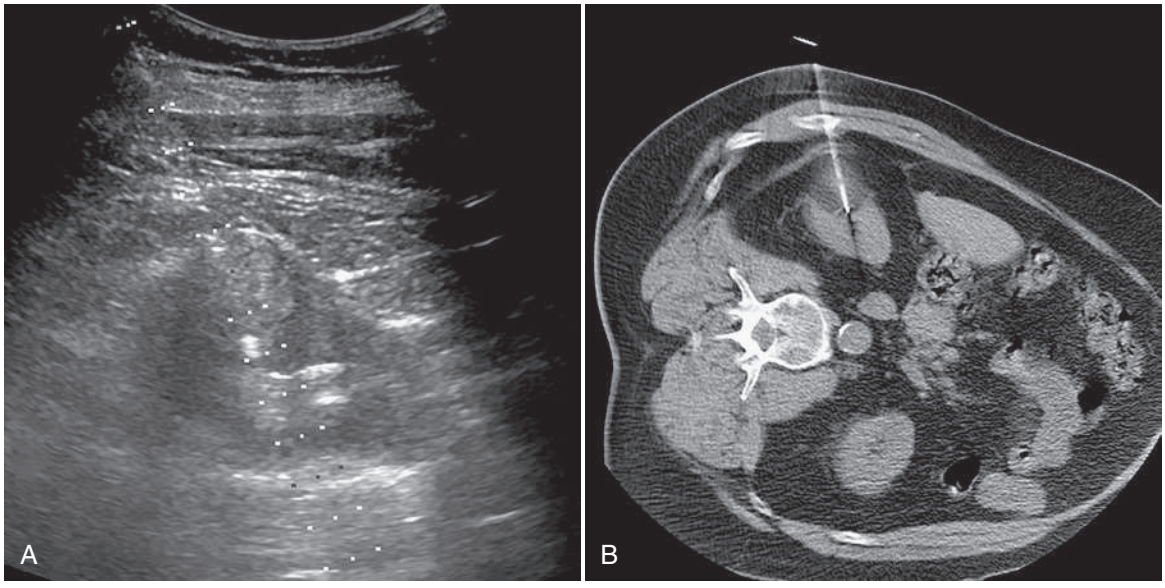

FIG. 9.46. Ultrasound-Guided Cryoablation of Renal Cell Carcinoma. (A) Transverse sonogram shows placement of a cryoablation probe within the posterior aspect of a small (<3 cm) echogenic renal cell carcinoma. A prior ultrasound-guided biopsy had confirmed clear cell carcinoma. **(B)** Corresponding noncontrast-enhanced CT shows the ablation zone as a low attenuation "ice-ball." Ultrasound may facilitate renal biopsy and probe placement, although the ablation is monitored under CT.

See also Video 9.2.

renal parenchyma; Forman et al.[149] found that 77% of smaller RCCs were echogenic, and Yamashita et al.[150,151] reported 61% as echogenic.

The small, echogenic RCC may be difficult to differentiate from a benign angiomyolipoma (AML) at ultrasound. Yamashita et al.[151] emphasized the overlap in RCC/AML imaging appearance. A thin, hypoechoic rim, thought to be a pseudocapsule at histology, was reported in 84% of RCCs and no AMLs. Weak shadowing posterior to AMLs and hypoechoic halos or cystic spaces in RCCs were also thought to be characteristic features.[152] Nonetheless, although increased echogenicity of a solid renal lesion has high sensitivity for AML (99%), it is not specific. If a lesion is of a size that would lead to a change in management, echogenic renal lesions should be further assessed with either MRI or CT.[153]

The exact pathologic basis for the hyperechoic appearance of RCC is not understood, but increased echogenicity has been reported in RCCs with papillary, tubular, or microcystic architecture and in tumors with minute calcification, necrosis, cystic degeneration, or fibrosis.[131] Macroscopic calcification are identified in 8% to 18% of RCCs. This calcification may be punctate, curvilinear, diffuse (rare), central, or peripheral.[154-158] Daniel et al.[157] showed that central calcification was associated with a malignant tumor in 87% of cases. When posterior rim shadowing or diffuse calcification make it impossible to characterize a renal lesion by ultrasound, CT is needed to identify additional features of malignancy (e.g., enhancement of associated soft tissue mass).[159]

Papillary tumors account for 15% of all RCCs.[129,160] The papillary type is characterized by slower growth, a lower stage at presentation, and a better prognosis.[161] Papillary tumors also tend to be hypoechoic or isoechoic, although no consistent sonographic pattern exists, because some may also be hyperechoic.[160]

From 5% to 7% of all RCCs are **cystic** tumors.[162] Four histologic growth patterns within cystic RCCs have been described: multilocular, unilocular, necrotic (cystic necrosis), and tumors originating in a simple cyst[163] (Figs. 9.48 and 9.49). Recognition of subtypes have clinical significance because the multilocular and unilocular subtypes are less aggressive.[162] At sonography, **multilocular** cystic RCC appears as a cystic mass with internal septations. These septations may be thick (>2 mm), nodular, and may contain calcification (see Fig. 9.47). The characteristic ultrasound appearance of a **unilocular** cystic RCC is a debris-filled mass with thick, irregular walls that may be calcified. The appearance of **necrotic** RCCs depends on the degree of tumor necrosis. Tumors originating in a **simple cyst** are rare (excluding VHL patients). At ultrasound, a mural tumor nodule will be found at the base of a simple cyst. A combined approach with helical CT and ultrasound allows accurate characterization of the internal nature of most cystic renal lesions.[164]

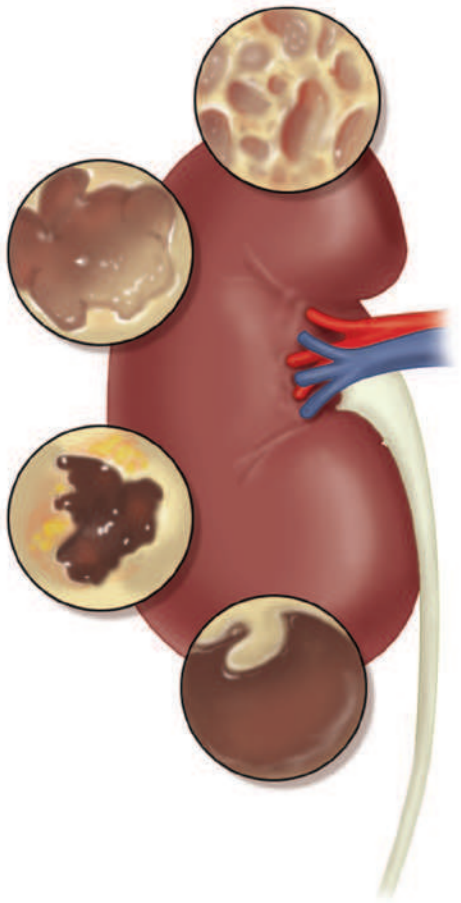

FIG. 9.48 Cystic Growth Patterns of Renal Cell Carcinoma. *Upper pole,* Multilocular; *upper lateral,* unilocular; *lower lateral,* cystic necrosis; *lower pole,* origin in the wall of a simple cyst. (With permission from Yamashita Y, Watanabe O, Miyazaki H, et al. Cystic renal cell carcinoma. Acta Radiol. 1994;35:19-24.[162])

The use of **Doppler ultrasound**[165] for detection of tumor vascularity has been reported. Most malignant renal tumors (70%-83%) have Doppler shift frequency of 2.5 kHz.[165-169] Similar changes may be noted with inflammatory masses; however, patients with renal infection should be clinically apparent. Unfortunately, the absence of high-frequency Doppler shift does not exclude malignancy.[168] Confirmation of blood flow within malignant solid and cystic renal tumors has also been performed with microbubble contrast agents and low–mechanical index pulse inversion sonography. Criteria for neovascularity used with CT or MRI for mass characterization—septal and nodular enhancement—can also be used with stable, second-generation ultrasound contrast agents[170,171] (Fig. 9.50). However, lack of US Food and Drug Administration approval, reimbursement issues, and logistics associated with technologist/radiologist-intensive, contrast-enhanced sonography protocols have hindered widespread adoption of this technique.

Biopsy and Prognosis

Recent pathologic and biopsy series of small (<3 cm), solid enhancing renal masses have shown that a surprising number of these lesions are benign (i.e., **AML, oncocytoma, metanephric adenoma**). Moreover, image-directed needle biopsy (aspiration or core) has been shown to be a relatively safe and usually conclusive procedure.[172-176] Further advances in immunohistology and greater acceptance of percutaneous ablation techniques

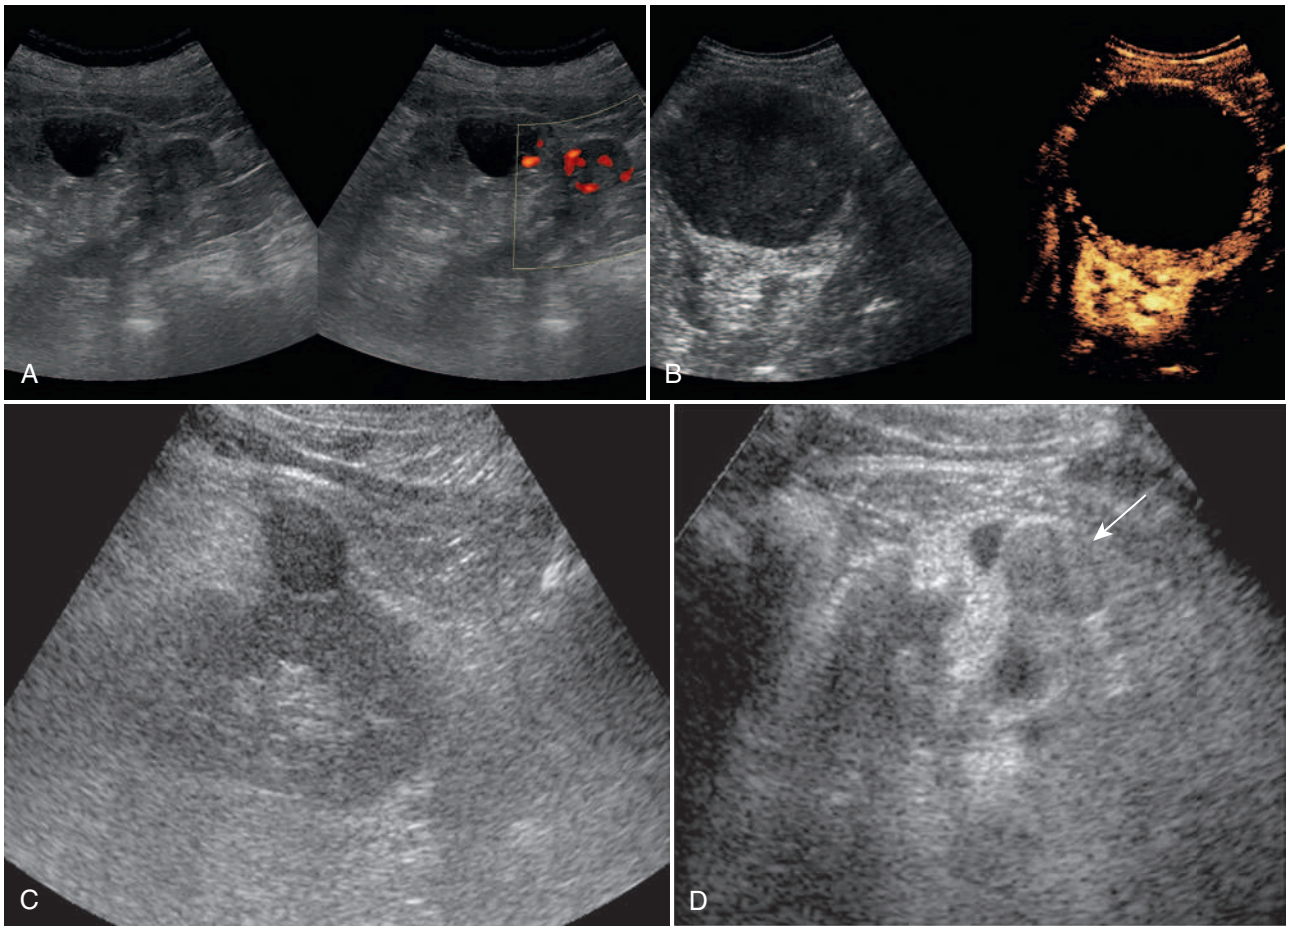

FIG. 9.50 Value of Color Doppler and Microbubble-Enhanced Sonography for Determining Vascularity of a Renal Mass. (A) Sagittal sonogram shows an isoechoic lower-pole mass and an adjacent cyst; the simultaneous power Doppler image shows flow within the mass (biopsy confirmed renal cell carcinoma). **(B)** Sonogram of a patient with renal failure shows a large complex cyst containing low-level echoes. The simultaneous microbubble enhanced image shows no enhancement of the center of the mass, but it confirms enhancement of the nodular, thick wall of a cystic renal cell carcinoma. **(C)** Baseline transverse sonogram of exophytic hypoechoic midpole renal mass. **(D)** Nephrographic phase image shows enhancement of both normal kidney and relatively hypovascular renal cell carcinoma *(arrow)*. (**C** and **D** courtesy of Ed Grant, MD.)

continue to increase the role of imaging-directed, particularly ultrasound-guided, renal mass biopsy[177] (Fig. 9.51).

For patients with imaging findings (or biopsy results) definitive for RCC, the **stage at diagnosis** directly impacts prognosis. The Robson staging classification for RCC is the following:

I: Tumor confined within renal capsule
II: Tumor invasion of perinephric fat
III: Tumor involvement of regional lymph nodes or venous structures
IV: Invasion of adjacent organs or distant metastases

Five-year survival rates for patients with Robson stages I, II, III, and IV are 67%, 51%, 33.5%, and 13.5%, respectively.[178] Patients with stage I and stage II disease are treated surgically (partial or radical nephrectomy). Patients with stage III disease, with extensive metastatic lymphadenopathy, are often treated palliatively. Patients with stage III disease and tumor thrombus are treated with radical nephrectomy and thrombectomy. Patients with stage IV disease usually receive palliative treatment only,[179] although greater understanding of the molecular biology of RCC has led to clinical trials of novel, small-molecule-targeted inhibitors and monoclonal antibodies.[180]

Pitfalls in Interpretation

Ultrasound is inferior to CT and MRI for staging RCC. Unfortunately, obesity and overlying bowel gas often make it difficult to assess for lymphadenopathy or vascular involvement. In thin patients and in those with minimal bowel gas, however, the renal veins and retroperitoneum can be well assessed with ultrasound. Sonography is excellent for assessment of the intrahepatic IVC and for determination of the cephalad extent of venous tumor thrombus with RCC (Fig. 9.52). Habboub et al.[181] found the accuracy of detecting renal vein and IVC involvement at sonography was 64% and 93%, respectively. The addition of color Doppler sonography improved accuracy for diagnosing both renal vein and IVC thrombus to 87% and 100%, respectively. It is crucial to determine the location and extent of vascular tumor thrombus to plan the surgical approach.

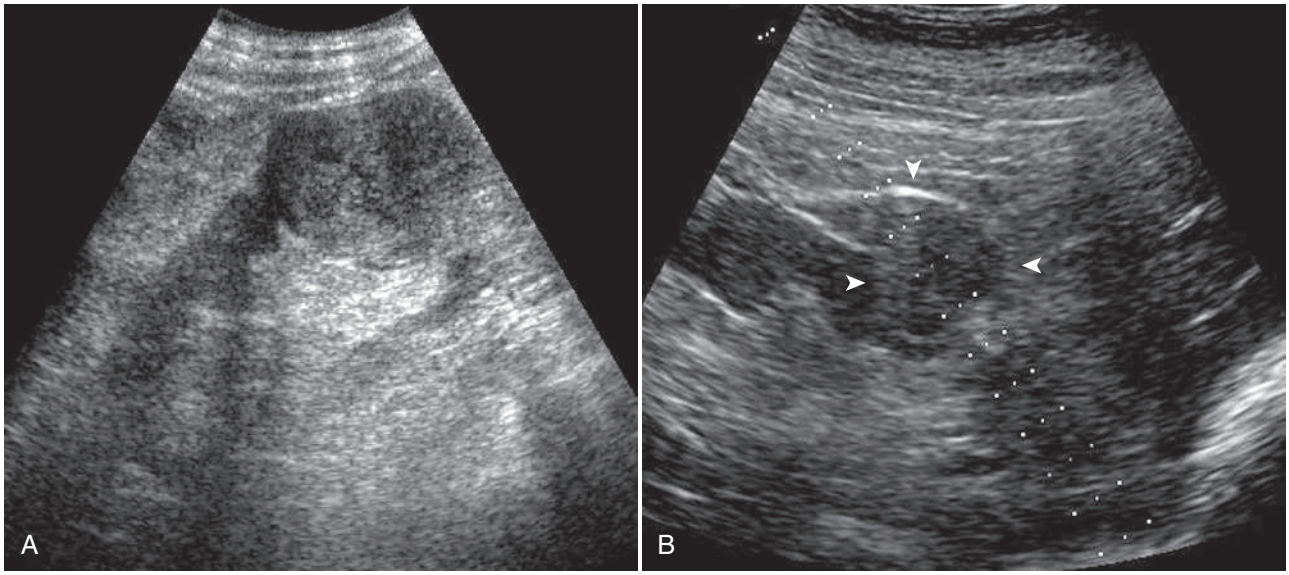

FIG. 9.51 Renal Oncocytoma. (A) Sagittal sonogram shows a large, isoechoic, partially exophytic renal mass that cannot be differentiated from renal cell carcinoma. **(B)** Ultrasound-guided biopsy of an isoechoic renal lesion *(arrowheads)* in another patient, performed before possible cryoablation, confirms an oncocytoma.

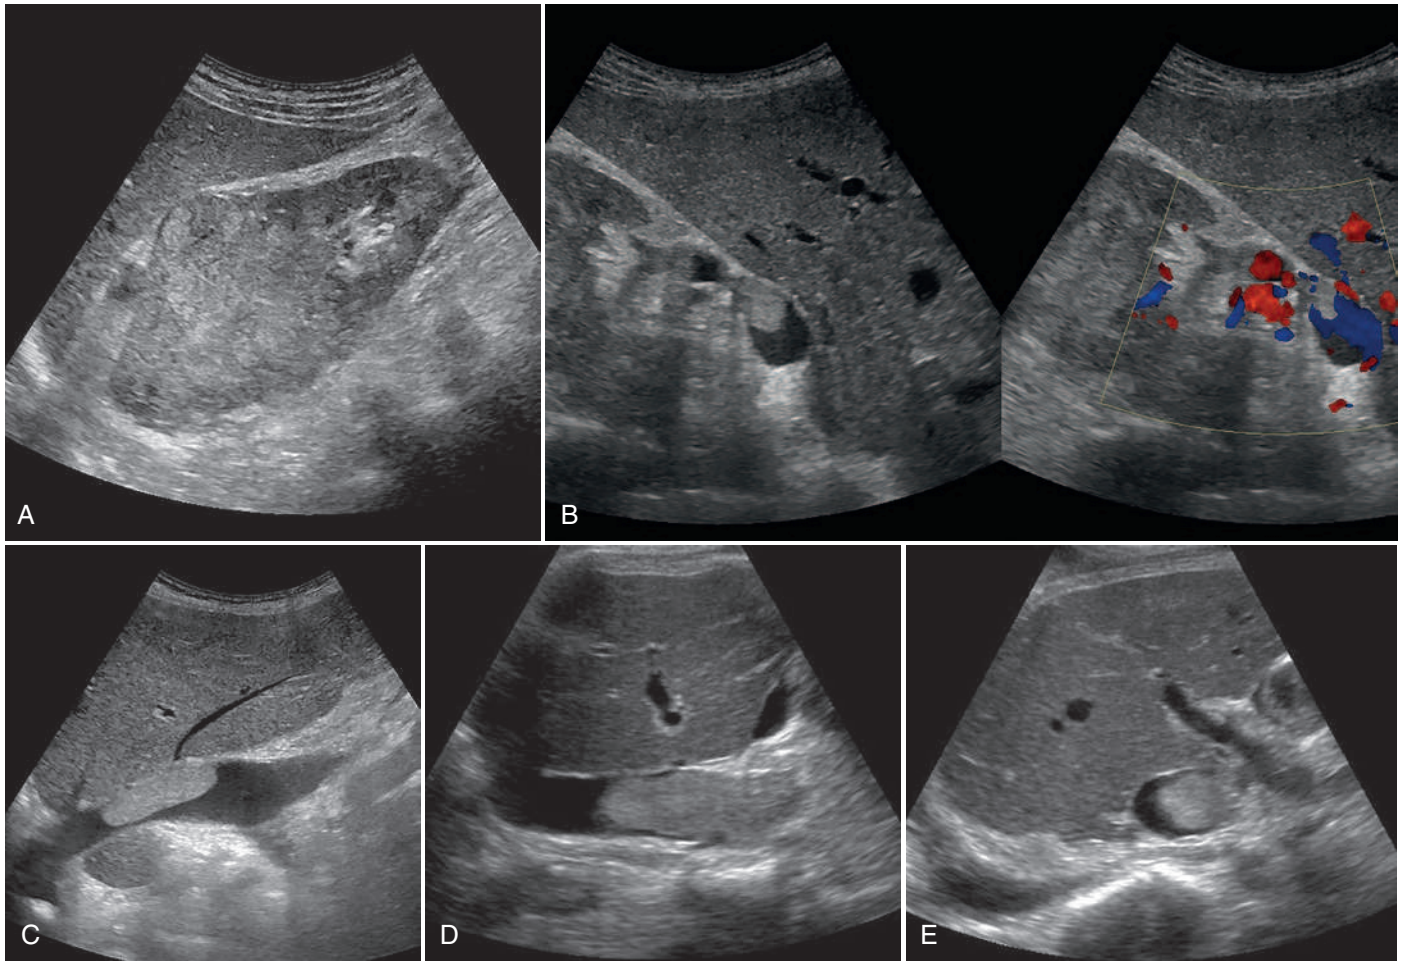

FIG. 9.52 Venous Thrombosis With Renal Cell Carcinoma. (A) Sagittal sonogram shows a huge infiltrating right upper-pole renal cell carcinoma. **(B)** Transverse ultrasound and simultaneous color Doppler image shows nonocclusive but expansile malignant thrombus within right renal vein and inferior vena cava (IVC). **(C)** Sagittal ultrasound of the same patient shows echogenic, nonocclusive thrombus within suprarenal IVC. Clot extends to 1 cm below the hepatic venous confluence. **(D)** Sagittal sonogram in another patient shows expansile, malignant thrombus within retrohepatic IVC. **(E)** Transverse sonogram in the same patient in D showing partially adherent malignant thrombus in the IVC.

Transitional Cell Carcinoma

Transitional cell carcinoma (TCC) of the renal pelvis accounts for 7% of all primary renal tumors.[182] **Renal** TCC is two to three times more common than **ureteral** neoplasms. **Bladder** TCC, because of its large surface area, is 50 times more common than renal pelvic TCC.[183] The multifocal and bilateral nature of TCC requires accurate diagnosis and staging to allow appropriate surgical planning. Yousem et al.[184] reviewed 645 cases of TCC of the bladder, ureter, and kidney and found that 3.9% of patients with bladder cancer developed an upper tract lesion (mean, within 61 months); 13% of patients with ureteral TCC and 11% of those with renal TCC developed **metachronous tumors** (mean, within 28 and 22 months, respectively). **Synchronous TCC** was present in 2% of patients with bladder TCC, 39% with ureteral TCC, and 24% with renal TCC. Upper tract disease surveillance may be performed by retrograde pyelography, urine cytology, CT urography, and/or magnetic resonance urography.[185]

TCCs may be papillary or nonpapillary. **Papillary** TCCs are exophytic polypoid lesions attached to the mucosa by a stalk. This type of tumor tends to be lower grade at presentation; polypoid TCC typically infiltrates slowly and metastasizes late in the disease. **Nonpapillary,** sessile TCCs present as nodular or flat tumors; the mucosal thickening that is a hallmark of sessile TCC may be difficult to depict even at CT. These tumors are usually high grade and infiltrating.[183]

Renal Tumors

Transitional cell tumors of the kidney are more common in men than women (4:1). Renal TCC is typically seen in older patients; the mean age at diagnosis is 65 years.[183] About 75% of patients with renal pelvic tumors present with gross or microscopic hematuria; 25% have flank pain. Renal TCC is discovered incidentally in less than 5% of patients.[183]

Unfortunately, the sonographic assessment of the **renal sinus** poses unique problems and is a challenge to evaluate for pathologic processes because of its variable appearance. Fat within the renal sinus can appear as a hypoechoic mass and can simulate a solid TCC (Fig. 9.53). In uncertain cases, confirmation with CT

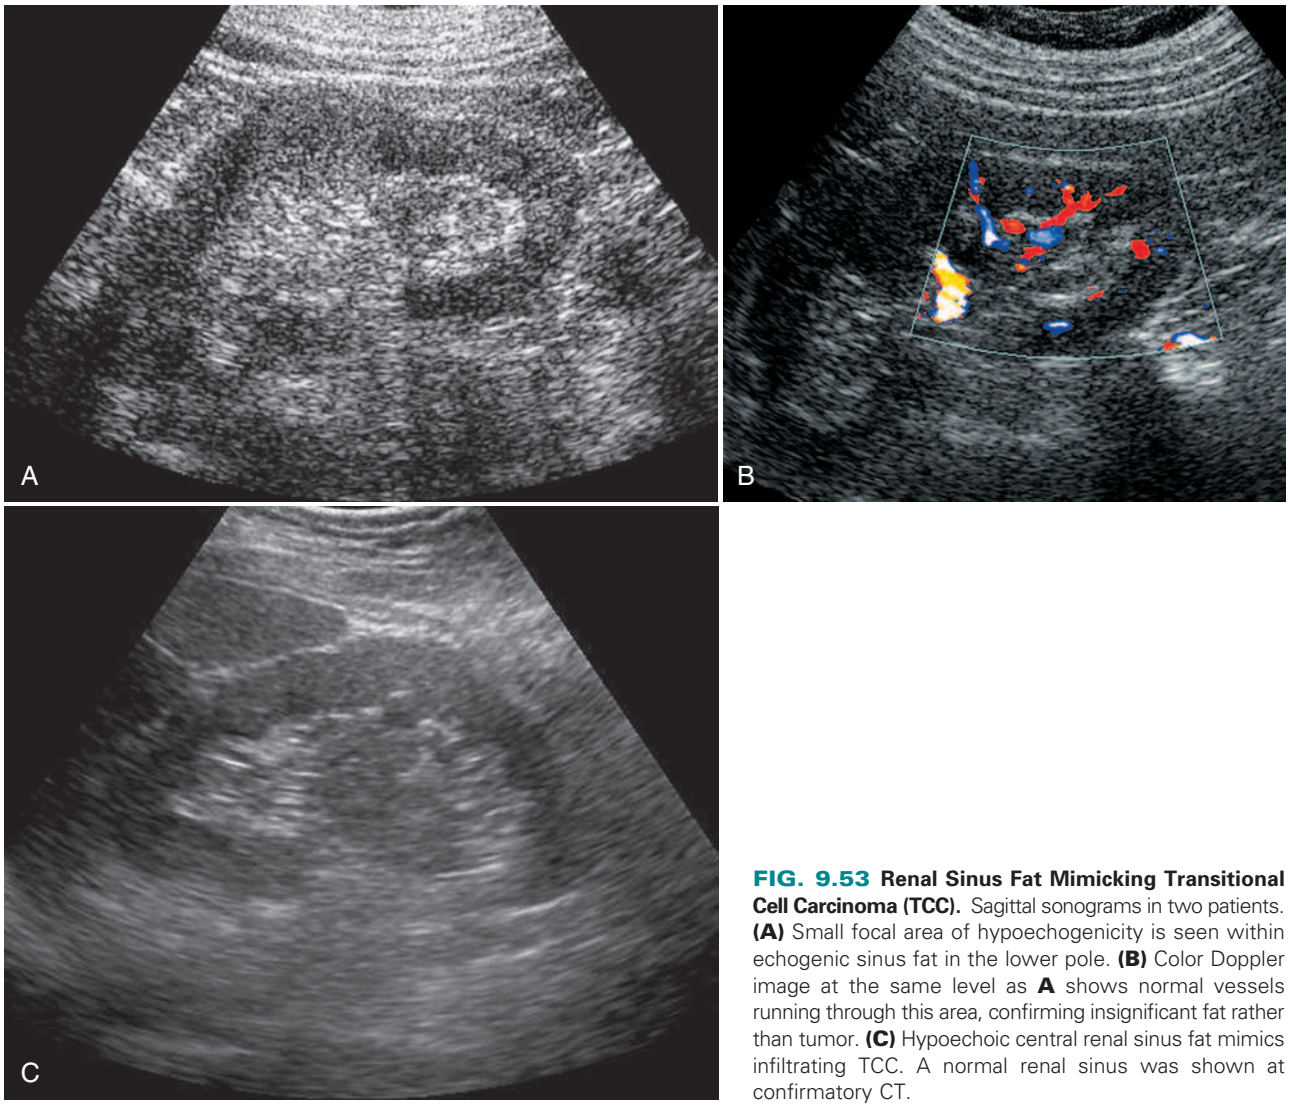

FIG. 9.53 Renal Sinus Fat Mimicking Transitional Cell Carcinoma (TCC). Sagittal sonograms in two patients. **(A)** Small focal area of hypoechogenicity is seen within echogenic sinus fat in the lower pole. **(B)** Color Doppler image at the same level as **A** shows normal vessels running through this area, confirming insignificant fat rather than tumor. **(C)** Hypoechoic central renal sinus fat mimics infiltrating TCC. A normal renal sinus was shown at confirmatory CT.

urography is recommended to exclude neoplasm, particularly in patients with hematuria (Fig. 9.54).

The sonographic appearance of renal TCC is variable and depends on the morphology of the lesion (papillary, nonpapillary, or infiltrative), location, size, and the presence or absence of hydronephrosis (Fig. 9.55). Small, nonobstructing tumors may be impossible to visualize at ultrasound. With growth, **papillary tumors** will be seen as discrete, solid, central, hypoechoic renal sinus masses with or without associated proximal caliectasis (Fig. 9.56). The differential diagnosis includes **blood clots, sloughed papillae, and fungus balls.**

Tumor infiltration within the renal pelvis or renal parenchyma may be subtle. Findings suggestive of infiltrating TCC are distortion and enlargement of the kidney and maintenance of an overall reniform shape (Fig. 9.56). Sessile lesions are particularly difficult to image directly by ultrasound, but the secondary finding of an obstructing lesion (caliectasis, pelviectasis) is usually easily depicted. A small subset of both sessile and papillary TCCs may have dystrophic calcifications, which makes it difficult to differentiate tumor from a sloughed, calcified papilla.[186] TCC rarely invades the renal vein.[187]

Ureteral Tumors

TCC of the ureter accounts for 1% to 6% of all upper urinary tract cancers.[183,188] Men are affected more often than women (3:1). As with renal TCC, ureteral lesions are usually identified in older patients; peak prevalence of ureteral TCC is between the fifth and seventh decades.[183] The majority of tumors are found in the lower third of the ureter (70%-75%).[183,188] About 60% of ureteral TCCs are papillary and 40% nonpapillary.[183] The most common symptoms are hematuria, frequency, dysuria, and pain.[188] The traditional imaging modalities of choice for evaluation of ureteral TCC have included intravenous urography or retrograde pyelography, but the advantages of multidetector CT urography (ability to detect and stage even small urothelial lesions) have been documented.[189,190] At sonography, hydronephrosis and hydroureter are seen, and occasionally a solid ureteral mass may be shown.[188]

Bladder Tumors

TCC of the bladder is a common malignant tumor. Bladder TCCs occur more often in men (3:1), with a peak incidence in

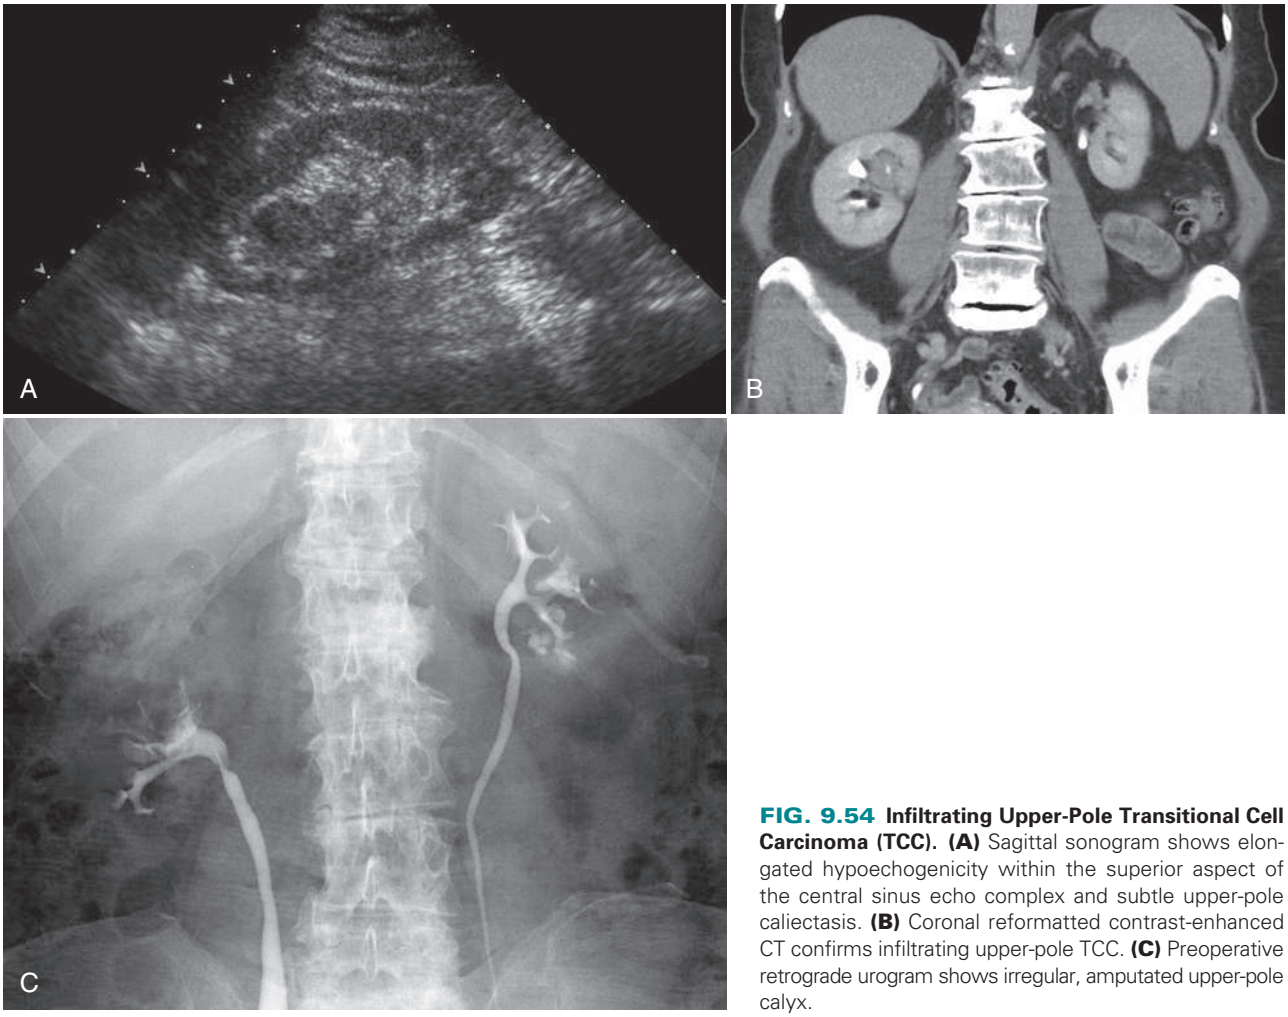

FIG. 9.54 Infiltrating Upper-Pole Transitional Cell Carcinoma (TCC). (A) Sagittal sonogram shows elongated hypoechogenicity within the superior aspect of the central sinus echo complex and subtle upper-pole caliectasis. **(B)** Coronal reformatted contrast-enhanced CT confirms infiltrating upper-pole TCC. **(C)** Preoperative retrograde urogram shows irregular, amputated upper-pole calyx.

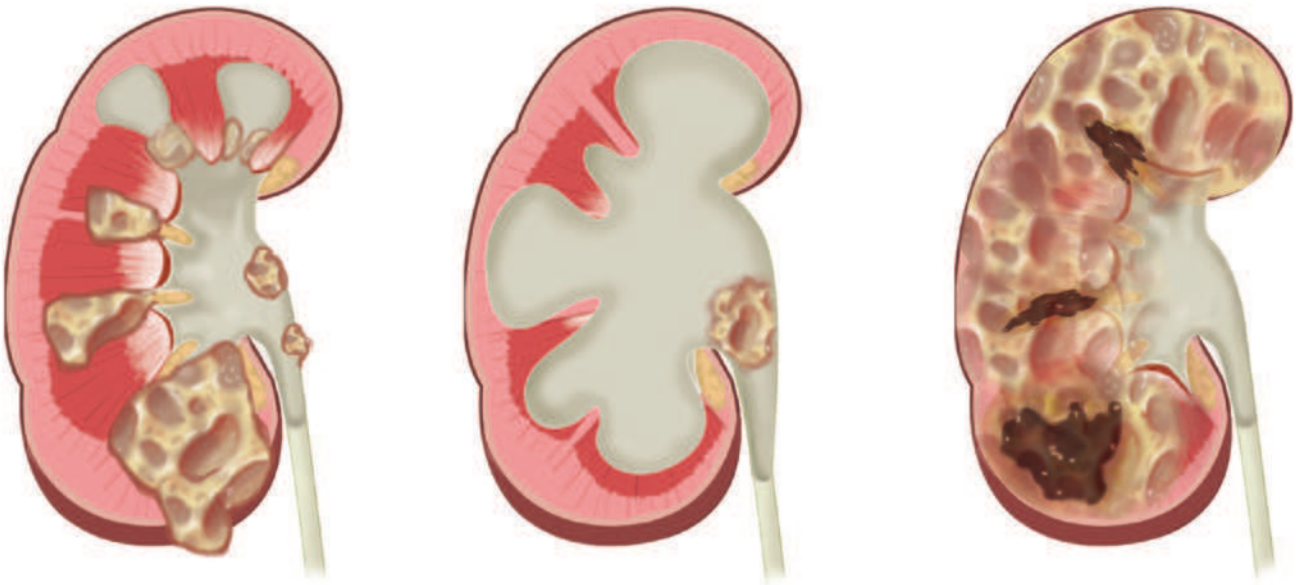

FIG. 9.55 **Morphologic Growth Patterns of Renal Transitional Cell Carcinoma.**

the sixth and seventh decades. They occur most frequently at the trigone and along the lateral and posterior walls of the bladder. Approximately 70% of bladder cancers are superficial; the remaining 30% are invasive. Patients typically present with hematuria, although they may also complain of frequency, dysuria, and suprapubic pain. Sonographic detection of **polypoid bladder tumors** is excellent (≥95%).[191] The appearance is that of a nonmobile focal mass or of urothelial thickening (Fig. 9.57, Video 9.3). Ultrasound appearances are nonspecific, however, and the differential diagnosis is extensive, including cystitis, wall thickening caused by **bladder outlet obstruction, postradiation/postoperative change,** adherent **blood clot,** invasive **prostate carcinoma, lymphoma, metastasis, endometriosis,** and **neurofibromatosis.** Some papillary bladder tumors may also calcify. Cystoscopy and biopsy are necessary for diagnosis. Both transvaginal and transrectal ultrasound may also be used to assess a bladder wall mass if suprapubic visualization is compromised.

Transitional cell (and squamous cell) carcinomas may also arise within **urinary bladder diverticula.** Many diverticula have narrow necks, making them inaccessible for cystoscopic examination, so imaging plays an important role in the detection of these tumors. The periureteric and posterolateral wall locations of most bladder diverticula allow for adequate sonographic visualization.[192] At ultrasound, diverticular tumors are moderately echogenic, nonshadowing masses. Although ultrasound is good for tumor detection, staging is still best performed clinically in combination with CT or MRI.[193]

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is rare but is the second most common malignant urothelial tumor after TCC. SCC accounts for 6% to 15% of renal pelvic tumors and 5% to 8% of all bladder tumors.[194,195] Chronic infection, irritation, and stones lead to **squamous metaplasia** and **leukoplakia** of the urothelium. Leukoplakia is thought to be premalignant. SCC tends to be a solid, flat, infiltrating lesion with extensive ulceration. Distant metastases are usually present at diagnosis. As with other infiltrating renal lesions, renal SCC appears at sonography as a diffusely enlarged kidney that has maintained its reniform shape. Normal renal echotexture is destroyed, and often a stone (47%-58%)[194] will be present. It thus may be impossible to differentiate renal SCC from **XGP**. Often, perinephric tumor extension and metastases are present. Ureteral SCC is rare; hydronephroureterectasis proximal to the tumor mass will be apparent. Occasionally, the lesion is seen as a poorly defined, irregular, solid mass. Associated stones are often present. Bladder SCCs tend to be large, solid, and infiltrating. SCCs may also arise within bladder diverticula.[192] Ultrasound may be an effective modality for detecting pedunculated bladder SCC, but CT or MRI are more appropriate modalities for detecting perivesical invasion, regional adenopathy, and distant metastases.

Adenocarcinoma

Adenocarcinoma of the renal pelvis, ureter, and bladder is rare. Almost all patients with adenocarcinoma of the renal pelvis have a history of chronic UTI,[196] and two-thirds have a stone, typically a **staghorn calculus.** Clinicians must be careful to differentiate adenocarcinoma of the bladder from adenocarcinoma of the rectum, uterus, or prostate that has invaded the bladder. The prognosis is poor. At sonography, a renal pelvic, ureteric, or bladder mass is seen, occasionally with calcification. An associated stone is often present.

Oncocytoma

Oncocytes are large, epithelial cells. The characteristic granular eosinophilic cytoplasm in these cells results from extensive cytoplasmic mitochondria. Oncocytomas may occur in the parathyroid glands, thyroid, adrenal glands, salivary glands, and

kidneys. Oncocytomas account for 3% to 7% of all renal tumors.[197,198] They occur more often in men (1.7:1), with a peak incidence in the sixth and seventh decades.[199] Most patients are asymptomatic.[197] Oncocytomas vary in size and may be multicentric (5%-10%) or bilateral (3%). Bilateral tumors are seen particularly in hereditary syndromes **(Birt-Hogg-Dubé, hereditary oncocytosis).**[198,200] Hemorrhage and calcification are uncommon. These tumors histologically may have a benign or a more malignant appearance. Differentiation between oncocytomas and chromophobe RCCs may be difficult,[201] and hybrid lesions consisting of both oncocytic and chromophobe RCC elements have been reported (see Fig. 9.51).

Not surprisingly, oncocytoma and RCC cannot be differentiated by imaging. Davidson et al.[202] demonstrated that CT homogeneity and a central stellate "scar" are poor predictors in differentiating oncocytomas from RCCs. In earlier surgical series, oncocytomas represented about 5% of all tumors originally diagnosed as RCC on imaging.[203] A higher percentage of benign oncocytomas will likely be documented in future series of smaller, incidental lesions sampled before nephron-sparing procedures.

There is no distinctive ultrasound appearance of oncocytomas. These lesions may be homogeneous or heterogeneous with a distinct or poorly demarcated wall.[204] A central scar, central necrosis, or calcification may be seen, although these features

may also be identified with RCC (see Fig. 9.51). The lack of specificity of imaging features of oncocytomas typically prompts surgical resection, although as mentioned previously, recent improvements in immunohistochemistry may prompt imaging surveillance for patients with biopsy results consistent with benign oncocytomas.

Angiomyolipoma

AMLs are benign renal tumors composed of varying proportions of adipose tissue, smooth muscle cells, and blood vessels. AMLs may occur sporadically or may be found in patients with **tuberous sclerosis.** In patients without stigmata of tuberous sclerosis, AMLs are typically unilateral and discovered in middle-aged women. Up to 50% of patients with AMLs will have clinical stigmata of tuberous sclerosis (mental retardation, epilepsy, facial sebaceous adenomas), and up to 80% of patients with tuberous sclerosis will have one or more AMLs.[205] AMLs associated with tuberous sclerosis are usually small, multiple, bilateral tumors, with no gender predilection. **Sporadic** AMLs are histologically identical to those associated with tuberous sclerosis. It is unusual for small tumors (<4 cm)[206] to be symptomatic; with growth, however, these tumors may hemorrhage, with symptoms such as hematuria, flank pain, and palpable flank mass.

At sonography, the echo pattern of AMLs depends on the proportions of fat, smooth muscle, vascular elements, and hemorrhage. These tumors may be located within renal parenchyma or may be exophytic (Fig. 9.58). If muscle, hemorrhage, or vascular elements predominate, the tumor may be hypoechoic. Siegel et al.[152] showed that the multiple fat and nonfat interfaces in the more typical AMLs, along with the large acoustic impedance differences at these interfaces, causes scattering and attenuation of sound waves. This histology leads to the classic ultrasound

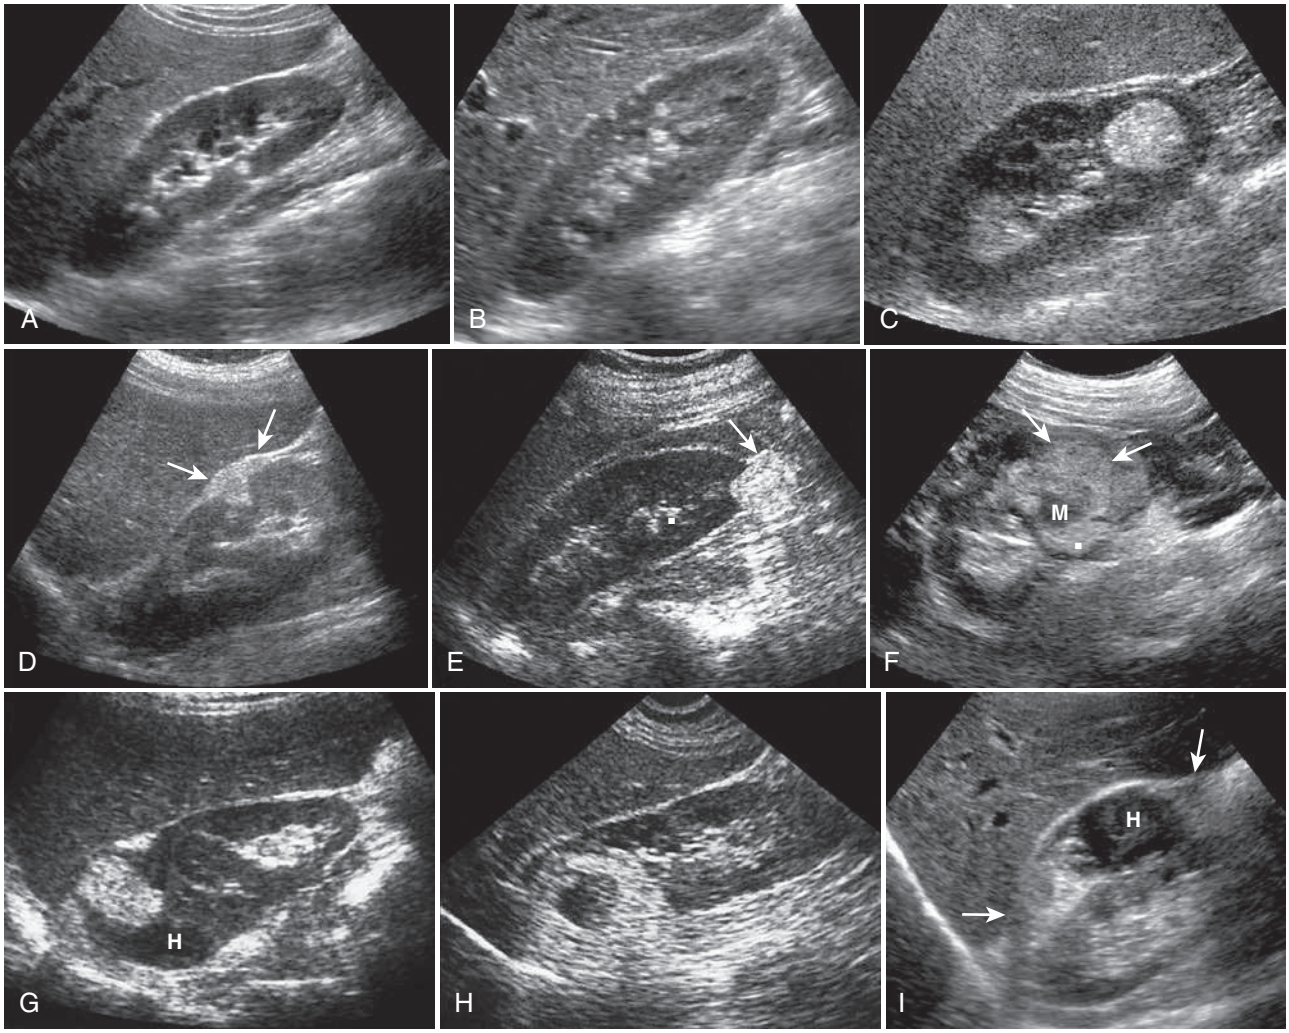

FIG. 9.58 Imaging Spectrum of Angiomyolipomas (AMLs). (A) Classic small hyperechoic intraparenchymal tumor. **(B)** Multiple small echogenic foci in the anterior cortex of the midpole. **(C)** Solitary, large, highly echogenic mass in the lower pole. **(D)** Exophytic echogenic mass involves the cortex and the perirenal space *(arrows)*. The flat appearance suggests a compliant soft tumor. **(E)** Large exophytic lower-pole echogenic mass *(arrow)*. The echogenicity of the mass may be very similar to the perirenal fat. **(F)** Large, complex intrarenal mass *(arrows)* is mildly echogenic and has a hypoechoic component representing myomatous elements *(M)*. **(G)-(I)** Hemorrhagic AMLs. **(G)** Exophytic ruptured upper-pole AML with a perirenal hematoma *(H)*. **(H)** Echogenic mass with central hypoechoic hemorrhage. **(I)** Large, predominantly exophytic AML. The kidney below the mass appears normal. The mass *(arrows)* shows increased echogenicity from the fat in the AML and a large hypoechoic hemorrhage *(H)*.

appearance of an AML: an echogenic lesion with shadowing. As mentioned earlier, although several distinguishing features have been suggested, there is significant imaging overlap between classic AMLs and small, echogenic RCCs. Involvement of regional lymph nodes and extension of AMLs into the IVC have also been described.[207] Further, it may be difficult to differentiate a large, exophytic AML from a large, retroperitoneal **liposarcoma** (Fig. 9.59). Helpful features that may allow differentiation from liposarcomas include (1) a defect in the renal parenchyma where the tumor originates and (2) the presence of enlarged vessels and other associated AMLs.[208] The blood vessels in an AML lack normal elastic tissue and are prone to aneurysm formation and hemorrhage.[209] Color flow Doppler sonography appears to be the best imaging modality to detect an intratumoral pseudoaneurysm in a hemorrhagic AML.[210]

Small, asymptomatic AMLs may be followed for growth; if large, symptomatic, or hemorrhaged, surgery is often performed.

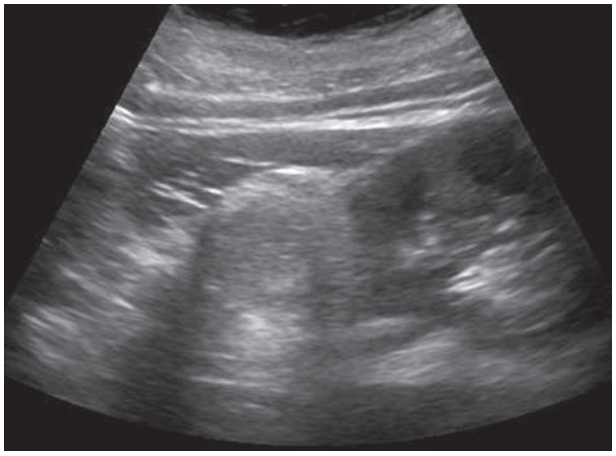

FIG. 9.59 Exophytic Angiomyolipoma. Sagittal sonogram shows a large, exophytic, echogenic angiomyolipoma.

If possible, renal-sparing surgery is preferable, because these tumors are benign or may be multiple. Embolization may also be used to treat actively bleeding AMLs.[211]

Lymphoma

Kidney

The kidney does not contain lymphoid tissue. Thus lymphomatous involvement of the kidney occurs from either hematogenous dissemination or contiguous extension of retroperitoneal disease. Renal involvement occurs more often in the setting of non-Hodgkin lymphoma than Hodgkin lymphoma. By the time renal disease is evident, disseminated disease is usually apparent. Urinary tract symptoms are uncommon. Occasionally, flank pain, a flank mass, or hematuria may occur. Nonetheless, at autopsy, renal involvement is found in one-third of lymphoma patients,[212] and bilateral renal disease is more common than unilateral disease. Isolated renal disease may be seen in patients undergoing treatment.

The sonographic appearance of **renal lymphoma** depends on the pattern of involvement. **Focal parenchymal involvement** may appear as solitary or multiple nodules. These masses appear homogeneous and hypoechoic or anechoic (Fig. 9.60). They may simulate cysts; however, increased through transmission is absent.[213,214] As with other infiltrating renal tumors, **infiltrating lymphoma** is manifested by maintenance of a reniform shape despite disruption of renal architecture. The kidney may be enlarged (Fig. 9.61). Tumor may invade the renal sinus and destroy the echogenic, central echo complex.[215] **Direct invasion** of the kidney by large retroperitoneal **lymph node masses** may occur with associated vascular and ureteral encasement. Large, retroperitoneal, hypoechoic conglomerate adenopathy may extend into the renal pelvis and cause hydronephrosis. The absence of renal venous invasion, despite extensive retroperitoneal and renal

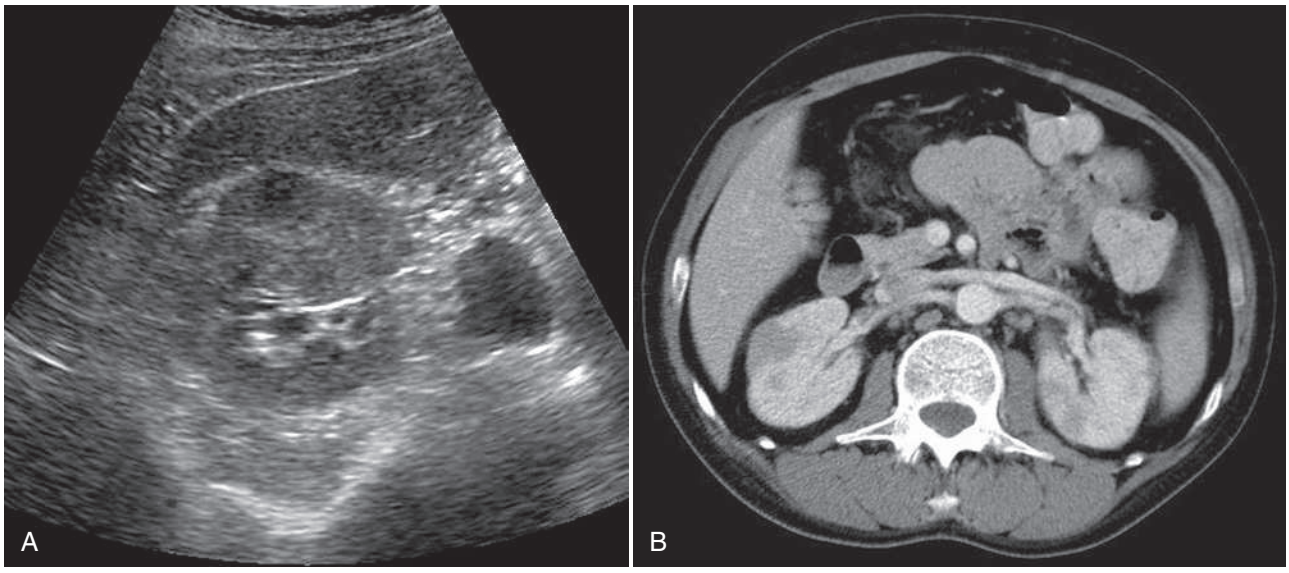

FIG. 9.60 Renal Lymphoma. (A) Transverse sonogram shows a subtle right midpole contour deformity and vague hypoechoic lesion. **(B)** Contrast-enhanced CT confirms mildly border-deforming renal lesion and shows contralateral lesions.

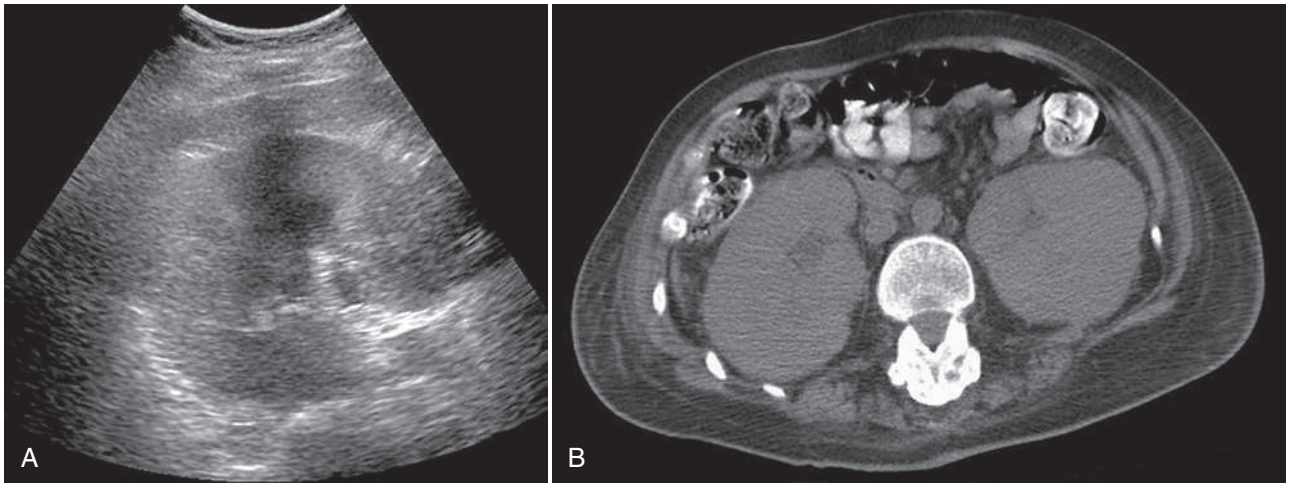

FIG. 9.61 Renal Lymphoma. (A) Transverse sonogram shows enlarged, echogenic globular kidney. **(B)** Noncontrast-enhanced CT shows marked bilateral renomegaly.

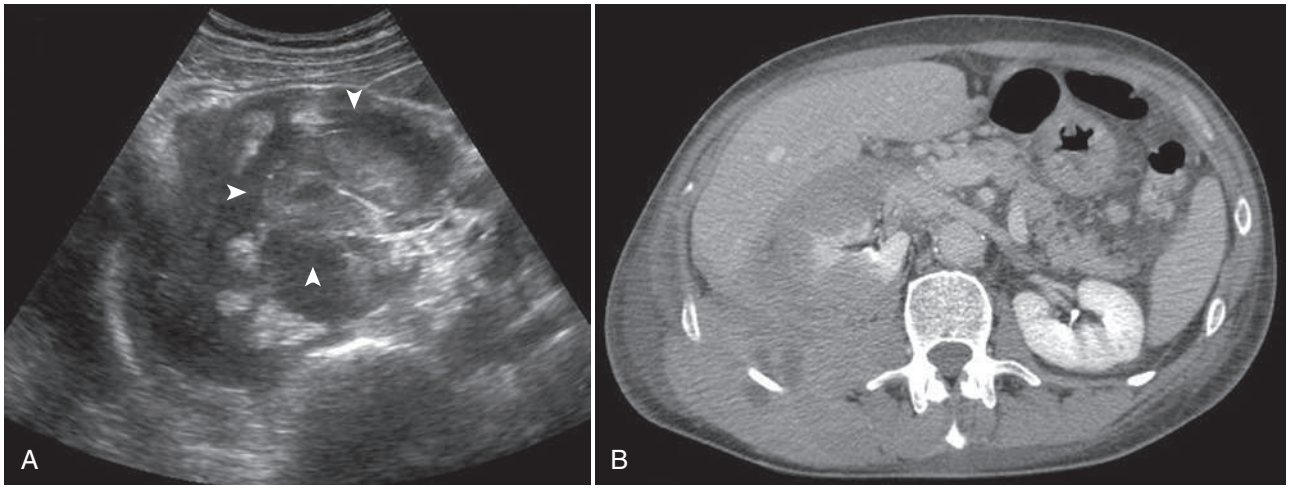

FIG. 9.62 Perirenal Burkitt Lymphoma. (A) Transverse sonogram shows extensive, poorly defined perirenal tumor. The kidney *(arrowheads)* is compressed and invaded by tumor. **(B)** Contrast-enhanced CT shows bulky perirenal tumor. Tumor involves both the kidney and the overlying flank musculature.

Sonographic Appearance of Renal Lymphoma

Focal parenchymal involvement
Diffuse infiltration
Invasion from retroperitoneal mass
Perirenal involvement

sinus tumor, may help in differentiating renal lymphoma from RCC. Rarely, **perirenal predominant tumor** may be depicted at ultrasound as a surrounding hypoechoic perirenal mass or rind. Tumor may be confused with hematoma or extramedullary hematopoiesis[216,217] (Fig. 9.62).

Ureter

The ureter may be either encased or displaced by surrounding retroperitoneal lymphoma. Ureteral displacement by periureteral tumor is more common; actual invasion of the ureteral wall occurs in only one-third of cases.[188] The result is usually dilatation of the intrarenal collecting system and ureter to the level of the retroperitoneal mass. This is usually easily appreciated on sonography.

Bladder

Primary bladder lymphoma arises from lymphoid follicles in the submucosa. Submucosal tumor usually infiltrates the other layers of the bladder wall.[218] Most patients with primary bladder lymphoma are 40 to 60 years of age, and women are affected more than men. At sonography, a bladder wall mass is seen. If the mass is large, ulceration may occur (Fig. 9.63).

Leukemia

Leukemic involvement of the kidney may be **diffuse** or **focal.** In autopsy series, renal leukemic infiltration was reported in 65% of patients.[219] Despite this, renal leukemia is difficult to identify at ultrasound. The classic appearance of **renal leukemia** at ultrasound is **bilateral renal enlargement.** However, 15% of patients with leukemia will have nonspecific renomegaly without

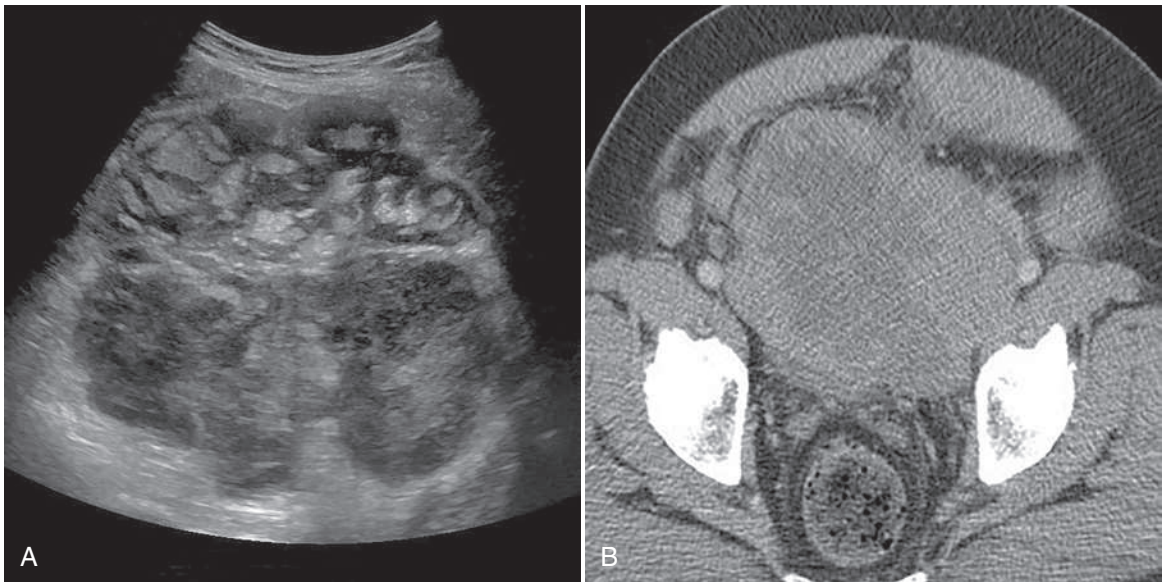

FIG. 9.63 Diffuse B-Cell Bladder Lymphoma. (A) Transverse sonogram shows a large irregular mass that replaces the bladder. **(B)** Corresponding contrast-enhanced CT shows a bulky mass that occupies the entire bladder lumen. (Courtesy of R. Brooke Jeffrey, MD.)

leukemic infiltration.[220] Renal leukemia may also be manifested as a coarsened renal echo pattern with distortion of the central sinus echo complex.[221] Alternatively, the kidneys may be diffusely echogenic. Focal masses may be single or multiple.[222] These patients are prone to renal, subcapsular, and perinephric hemorrhage.

Metastases

Kidney

Renal metastases are typically clinically occult, but autopsy series done before cross-sectional imaging documented an incidence of 2% to 20%.[223] The true prevalence of renal metastases in the era of cross-sectional imaging is unknown, but the prevalence of subclinical, imaging-apparent renal involvement is likely greater than estimated by gross autopsy.

Spread to the kidneys is by a hematogenous route. The most **common primary tumors** giving rise to renal metastases are (1) lung carcinoma, (2) breast carcinoma, and (3) RCC of the contralateral kidney.[120] Other tumors that may produce renal metastases include colon, stomach, cervix, ovary, pancreas, and prostate.[120] Renal metastatic spread may manifest as a solitary mass, multiple masses, or a diffusely infiltrating mass that enlarges the kidney. Choyke et al.[224] evaluated 27 patients with renal metastases and found that metastases are usually multifocal; however, large, solitary tumors may occur that are otherwise indistinguishable from primary RCC. Also, a new renal lesion in a patient with advanced cancer is more likely a metastatic than a primary tumor. If a single renal lesion is discovered synchronously in a patient with a known primary tumor, or with a tumor in remission with no evidence of other metastases, renal biopsy is necessary to differentiate a primary RCC from a renal metastasis.

Contrast-enhanced CT is the best radiographic technique for detecting renal metastasis, although ultrasound is almost as sensitive.[224] At sonography, the appearance depends on the **pattern of involvement.** A solitary metastasis will be seen as a solid mass indistinguishable from RCC; this often occurs with colon carcinoma.[224] Central necrosis, hemorrhage, and calcification may be evident. Multiple metastases usually appear as small, poorly marginated, hypoechoic masses. Involvement of the perinephric space is possible, particularly with malignant melanoma and lung cancer.[224] Infiltrating renal metastases are particularly subtle at ultrasound; as with other infiltrating processes, the only manifestation at sonography may be an enlarged, but still reniform, kidney (Fig. 9.64).

Ureter

Ureteral metastases are rare; evidence of diffuse metastases elsewhere is seen in 90% of cases.[225] Metastatic disease to the ureter occurs by hematogenous or lymphatic dissemination. Tumors that may secondarily involve the ureter include melanoma, bladder, colon, breast, stomach, lung, prostate, kidney, and cervical lesions. Three types of ureteral involvement occur: (1) infiltration of the periureteral soft tissues, (2) transmural involvement of the ureteral wall, and (3) submucosal nodules. With the first two types, imaging may demonstrate strictures with or without an associated mass. Intraluminal lesions may be shown with the third type.[188] At sonography, the site of tumor involvement may be seen if a mass is present. Usually, however, the only manifestation of ureteral involvement is secondary hydronephrosis.

Bladder

Although rare, metastases to the bladder may occur with malignant melanoma, lung, gastric, or breast cancer. The appearance

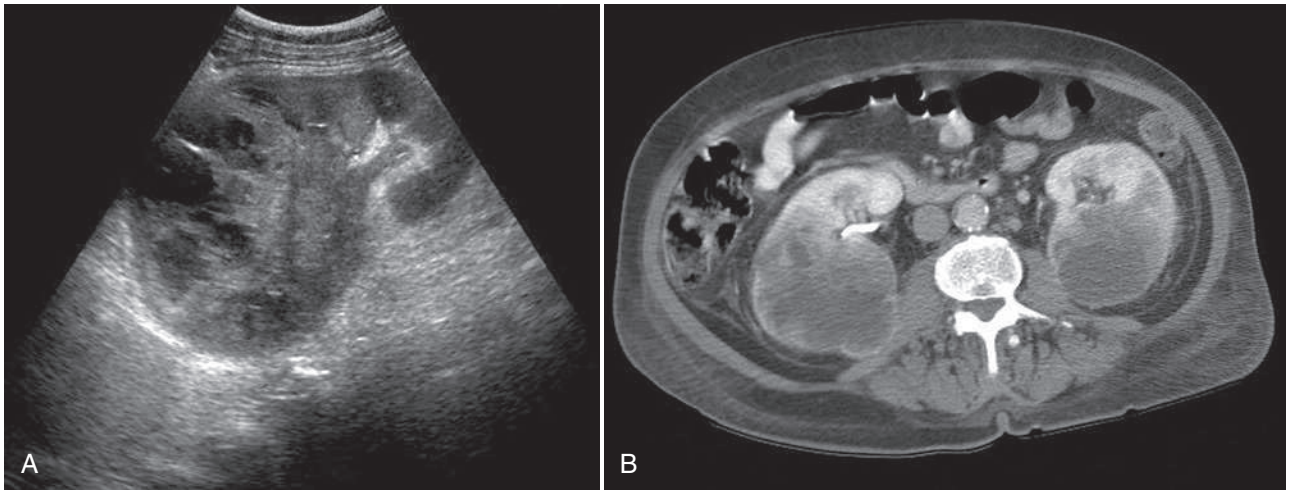

FIG. 9.64 Renal Metastases (Lung Primary). (A) Sagittal sonogram shows infiltrating, mixed-echogenicity tumor throughout the upper pole of the kidney. **(B)** Contrast-enhanced CT demonstrates bilateral infiltrating metastases.

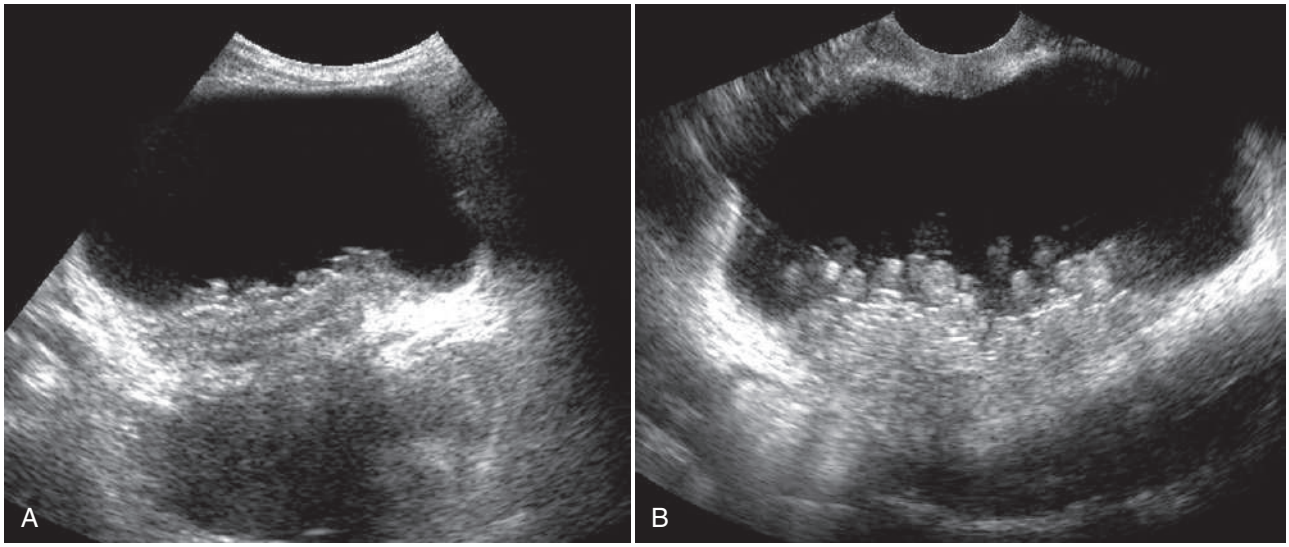

FIG. 9.65 Bladder Metastasis From Gastric Adenocarcinoma. (A) Transverse suprapubic sonogram shows a papillary solid intraluminal mass with obvious bladder wall involvement. **(B)** Confirmatory transvaginal scan shows the papillary nature of the tumor to better advantage.

at ultrasound is nonspecific; a solid mass may be seen in the bladder wall (Fig. 9.65).

Urachal Adenocarcinoma

The urachus measures 3 to 10 cm in length and represents the obliterated remnant of the allantois. It is lined by transitional epithelium. The urachal remnant is divided into supravesical, intramural, and intramucosal portions. Urachal neoplasms are rare, usually arising in the upper part of the intramural portion of the urachal remnant or in the lower part of the extravesical portion of the bladder.[226] Urachal cancers represent 0.01% of all adult cancers, 0.17% to 0.34% of all bladder cancers, and 20% to 39% of all primary bladder adenocarcinomas.[227] About 75% of urachal cancers occur in men.[228] Most tumors arise at the bladder dome at the vesicourachal junction. Urachal tumors have a poor prognosis and tend to invade the anterior abdominal wall. Most patients present with hematuria, although other common symptoms include frequency, dysuria, and mucosuria.[228] At sonography, a bladder dome mass is seen, often calcified (50%-70%). The mass may be solid, cystic, or complex cystic-solid. Tumor extension into the perivesical fat, space of Retzius, and the abdominal wall is common. Local recurrence after resection is common.

Rare Neoplasms

Kidney

Juxtaglomerular tumors are rare benign tumors that more frequently affect women. **Renin secretion** by these lesions results in **hypertension.** At sonography, they are usually small, solid, and hyperechoic.[229] Excision will alleviate the hypertension. **Leiomyomas** are benign tumors that arise from the renal capsule. They are usually discovered incidentally but may grow large enough to become clinically evident. On sonography, a solid,

well-defined peripheral mass is seen. **Carcinoid tumor** is a rare renal tumor that tends to be solid, with peripheral or central calcification.[230] Other benign tumors that have been described include **lipomas** and **hemangiomas.**

Renal sarcomas are aggressive tumors that account for approximately 1% of all malignant renal tumors. **Leiomyosarcoma** is the most common, representing 58% of all renal sarcomas. **Hemangiopericytoma** represents 20%. At sonography, these tumors cannot be distinguished from RCC. **Liposarcoma** accounts for 20% of all renal sarcomas. Depending on the amount of mature fat present, these tumors can be quite hyperechoic and indistinguishable from AMLs. Less common sarcomas include **rhabdomyosarcoma, fibrosarcoma,** and **osteogenic sarcoma. Wilms tumor** may rarely occur in adults and cannot be differentiated radiologically from RCC.

Bladder

Mesenchymal bladder tumors also are rare, accounting for about 1% of all bladder tumors. **Leiomyoma** is the most common benign bladder tumor. Most leiomyomas arise from the submucosa near the bladder trigone.[231] These tumors may show intravesical (63%), intramural (7%), or extravesical (30%) growth.[231] At sonography, a well-defined, round or oval, solid mass will be seen. Cystic degeneration may occur. **Neurofibromas** of the bladder may be seen as an isolated finding or may occur with diffuse systemic disease. These tumors are similar to leiomyomas at ultrasound. **Cavernous hemangiomas** are most often found in the dome and posterolateral bladder wall.[232] At sonography, two types have been described: (1) a round, well-defined, solid, hyperechoic, intraluminal mass that is highly vascular on color Doppler ultrasound and (2) diffuse wall thickening with multiple hypoechoic spaces and calcification.[232] Bladder **pheochromocytomas** are rare; they account for only 1% of all pheochromocytomas.[231] Patients may have symptoms that include headaches, sweating, and tachycardia related to bladder distention or voiding. Pheochromocytomas arise in the submucosa and may be found anywhere in the bladder, but usually at the dome. At ultrasound, a well-defined, solid, intramural bladder wall mass will be seen (Fig. 9.66). Malignant mesenchymal bladder tumors are rare; the most common are **leiomyosarcomas** and **rhabdomyosarcomas.** At sonography, a large, infiltrative mass is seen.

RENAL CYSTIC DISEASE

Cortical Cysts

Simple renal cysts are benign and fluid filled. Although their exact pathogenesis is unknown, they likely originate from distal convoluted or collecting ducts.[233] Incidence of simple cysts increases with advancing age, and they are found in at least

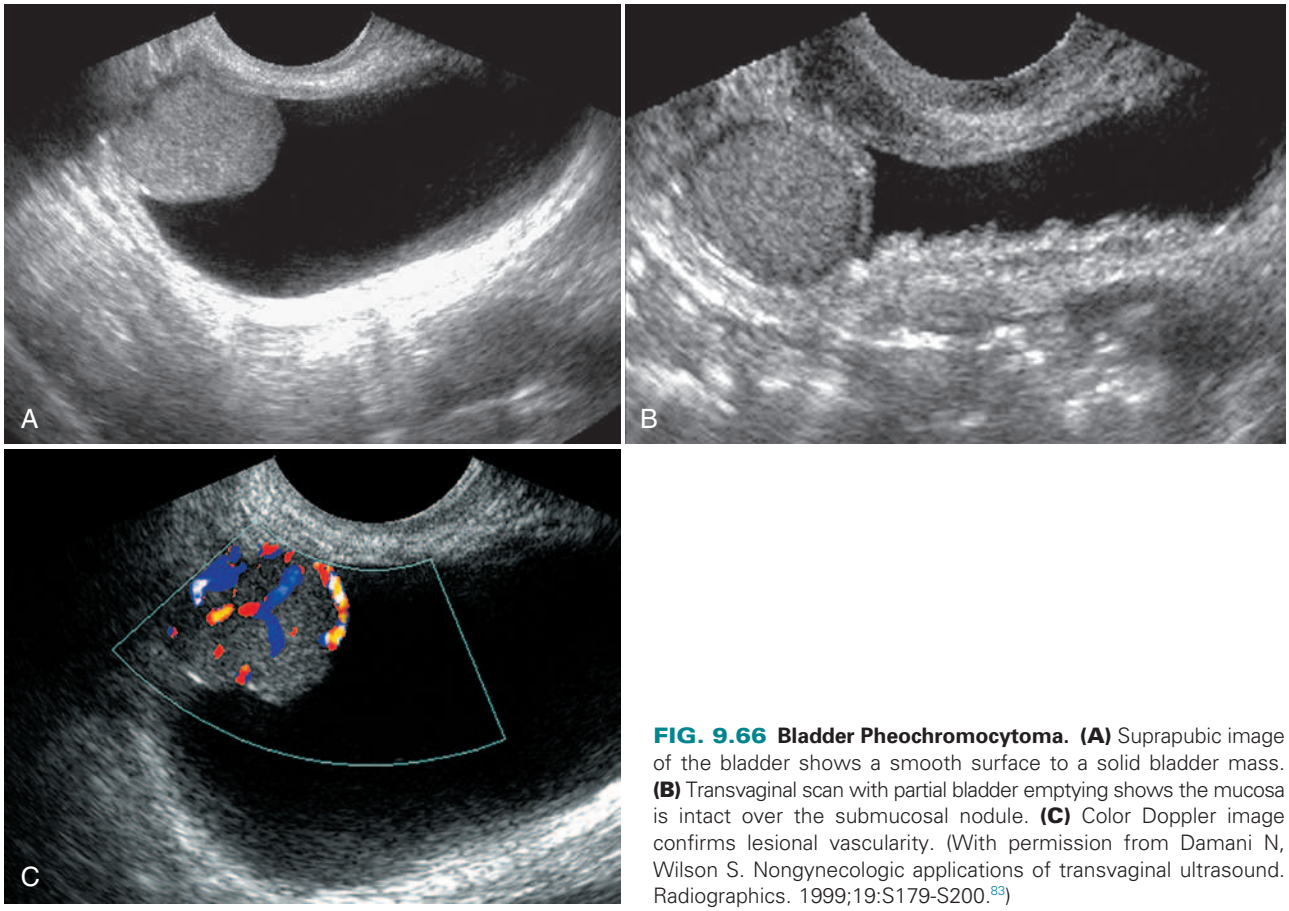

FIG. 9.66 Bladder Pheochromocytoma. (A) Suprapubic image of the bladder shows a smooth surface to a solid bladder mass. **(B)** Transvaginal scan with partial bladder emptying shows the mucosa is intact over the submucosal nodule. **(C)** Color Doppler image confirms lesional vascularity. (With permission from Damani N, Wilson S. Nongynecologic applications of transvaginal ultrasound. Radiographics. 1999;19:S179-S200.[83])

33% of persons over age 60.[234] Most cysts are asymptomatic. Patients with large cysts, however, may present with flank pain or hematuria. A cyst is confidently characterized at sonography when it (1) is anechoic; (2) has a sharply defined, imperceptible back wall; (3) is round or ovoid; and (4) enhances sound transmission.

If all these sonographic criteria are met, further evaluation or follow-up of the cyst is not required (Fig. 9.67). If a renal cyst is large and symptomatic, cyst puncture, aspiration, and sclerosis using a variety of agents may be performed. Several simple cysts may be found in both kidneys, and rarely, several simple cysts may involve only one kidney or a localized portion of one kidney.

Complex renal cysts do not meet the strict criteria of a simple renal cyst and include cysts containing internal echoes, septations, calcifications, perceptible defined walls, and mural nodularity (Fig. 9.68). Depending on the degree of abnormality, most complex renal cysts require further imaging with CT or magnetic resonance.

Internal echoes within a cyst are usually the result of hemorrhage or infection. Approximately 6% of cysts are complicated by hemorrhage.[235] Infection of a cyst may occur by hematogenous seeding, by vesicoureteric reflux, or as a complication of cyst puncture or surgical manipulation. A thickened cyst wall and a debris-fluid or gas-fluid level suggest an infected cyst. Cysts that are thought to be hemorrhagic at ultrasound (i.e., cysts that contain low-level echoes but otherwise fulfill criteria for a benign cyst) may be followed with serial ultrasound. Infected cysts require aspiration and drainage for diagnosis and treatment.

Septations may be seen within a renal cyst and are often the result of hemorrhage, infection, or percutaneous aspiration. Occasionally, two adjacent cysts may appear as a large, septated cyst. If septa are thin or barely perceptible, smooth, and attach to the cyst wall without thickened elements, a benign cyst can be diagnosed[236] (Fig. 9.68B-D). Complex cysts with irregular, thickened (>1 cm) septa, or with septa that have solid elements

Approach to Complex Renal Cyst Discovered on Sonography

INTERNAL ECHOES

Follow up with ultrasound if no other features of malignancy are present

Perform CT or MRI if associated features of malignancy are present (perceptible thickened wall, multiple or thick septations, or extensive septal calcification)

SEPTATIONS

Follow up with ultrasound if septations are few and thin (≤1 mm)

Perform CT or MRI if there is septal irregularity and nodularity, multiple complex septations, or solid elements at septal wall attachment

CALCIFICATION

Follow up with ultrasound if there is a small amount of calcium or milk of calcium without an associated soft tissue mass

Perform CT if thick, irregular, or amorphous calcification is found

Perform CT if calcification obscures adequate sonographic visualization

PERCEPTIBLE DEFINED WALL OR MURAL NODULARITY

If presumed malignant, perform CT/MRI

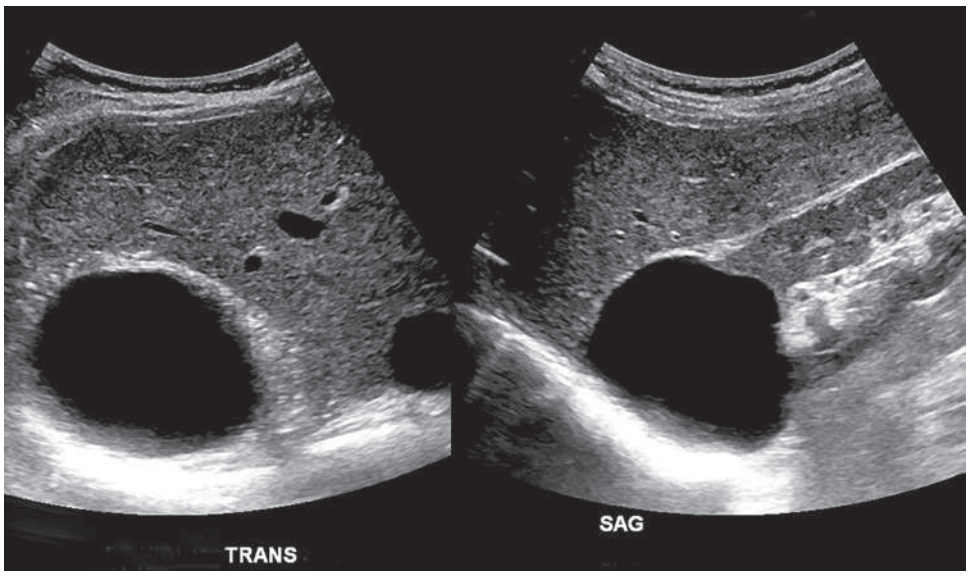

FIG. 9.67. Renal Cyst. Transverse and sagittal images show classic features of a renal cyst: a smooth, imperceptible wall, an echo-free center, and posterior acoustic enhancement caused by increased through transmission.

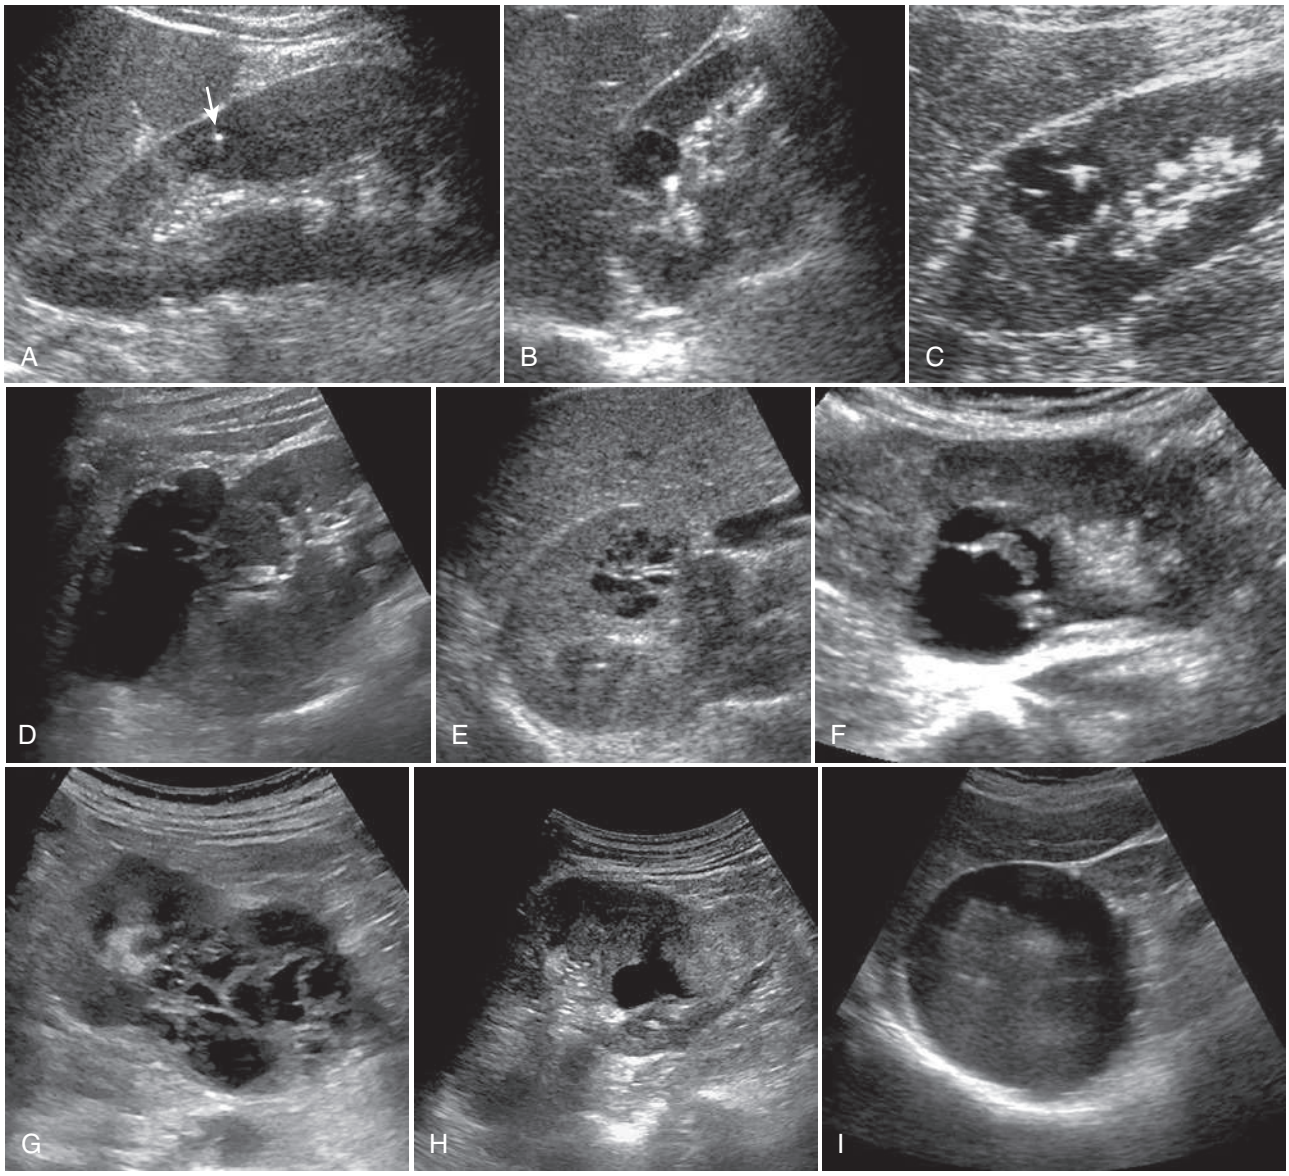

FIG. 9.68 Complex Renal Cysts. (A) Tiny renal cyst *(arrow)* in the anterior cortex is not resolved. A bright echogenic focus with ring-down artifact is the only visible abnormality. **(B)** Discernible cyst shows a bright echogenic focus with ring-down artifact. This echogenicity does not represent calcification. **(C)** Complex benign cyst with a few thin septations. Ring-down artifact originates from the septations and the cyst wall. **(D)** Complex cyst containing several thin septations. Septation was imperceptible at follow-up MRI. Septation is accentuated at ultrasound, and Bosniak classification is ultimately made based on features at MRI or CT. **(E)** Cyst shows numerous internal thick and thin septations. **(F)** Complex cyst shows thick nodular septations. **(G)** Cyst containing thick, nodular septations. Lack of enhancement of septations at CT suggested a Bosniak category 3 lesion, although a decrease in size of the mass at short follow-up imaging confirmed a hemorrhagic cyst. **(H)** Cyst with large solid component post trauma. Real-time color Doppler examination confirmed that the solid component was mobile and avascular. Intracystic clot resolved at follow-up sonography. **(I)** Large hemorrhagic cyst shows extensive internal debris within an otherwise simple-appearing cyst.

at the wall attachment, should be viewed with concern (Fig. 9.68E-G). Cyst aspiration is not indicated in these multiseptated cystic lesions.[236] Ultrasound is often better than CT in defining the internal characteristics of a cystic lesion.

Calcification of renal cysts may be fine and linear or amorphous and thick. Thin wall or septal calcification suggests a complicated cyst rather than malignancy, if all other features of a benign cyst are shown at ultrasound, with no associated soft tissue mass enhancement at CT.[237] Thick, irregular, amorphous calcification is more worrisome, however, and should prompt additional assessment with CT.[237] On the other hand, layering milk of calcium within a cyst is a benign finding. Mimicking cyst wall calcification, the bright, echogenic foci with ring-down artifact are frequently seen in septa and cyst walls at ultrasound (Fig. 9.68A-C). These foci are of no consequence, and no corresponding calcification is shown at CT. Thickened walls or mural nodularity typically excludes a diagnosis of a benign cyst (Fig. 9.68E-H) although ultimate management is based on corresponding features at CT/MRI and, in the appropriate clinical context (e.g., fever, leukocytosis or trauma), imaging follow-up.

The assessment of the **malignant potential** of renal cysts based on complexity at imaging was the basis of the classification introduced in 1991 by Bosniak.[238] Many sonographers attempt to classify cyst complexity using Bosniak terminology. It should be emphasized, however, that Bosniak criteria are primarily based on contrast-enhanced cross-sectional imaging. Malignancy risk assessment may be flawed, however, if the sonographer arbitrarily uses ultrasound features of more complex lesions to assign Bosniak grades. Minimally complex (Bosniak 2) lesions at CT can have a much more malignant appearance at ultrasound.

The **Bosniak category 1 cystic lesion** has all the benign features of a simple cyst. The **Bosniak category 2 cystic lesion** is more complicated and may have thin septa and calcification. On CT, a high-attenuation (proteinaceous or hemorrhagic, with an attenuation of less than 60 Hounsfield units [HU] that enhances less than 10 HU after contrast administration) may often appear as a simple cyst at ultrasound. High levels of protein with cyst fluid may appear at ultrasound as low-level echoes, an appearance that might erroneously suggest a solid lesion. In addition, thin septations within a Bosniak type 2 cyst at CT will often appear much more ominous at ultrasound. The risk of malignancy in a cystic lesion classified as **Bosniak 2F** (by CT) is estimated at 5%.[239]

The **Bosniak category 3 cystic lesion** is indeterminate at CT. Thick, irregular septations, calcifications, and wall nodularity increase the risk of malignancy. As indicated earlier, imaging follow-up is done in the appropriate clinical setting, as when a renal abscess is suspected in a patient with fever, leukocytosis, and pyuria, or in older patients with comorbidities. Other lesions in this category include highly complex hemorrhagic cysts, **multilocular cystic nephroma,** localized cystic disease, and cystic RCC. CT enhancement of septa, mural nodules, and solid components within highly complex cysts significantly increases the risk of malignancy in the **Bosniak category 4 cystic lesion.**

Ultrasound has played a largely adjunct role in risk stratification of more complex renal cystic lesions because it does not readily demonstrate renal tumor neovascularity. Wall or septal enhancement that is obvious at CT may be rarely depicted at ultrasound as focally increased color or power Doppler flow (see Fig. 9.49). However, microbubble contrast agents may increase the importance of ultrasound in renal mass characterization (see Fig. 9.50). Renal lesion enhancement using continuous, low–mechanical index pulse inversion imaging (or an equivalent) may mimic the enhancement shown at contrast-enhanced CT or MRI.[170,240] The ability of CEUS to show neovascularity may be particularly relevant for patients with renal insufficiency and may assist in assessing adequacy of ablation.[241]

Parapelvic Cysts

Parapelvic cysts do not communicate with the collecting system. They may originate from lymphatics or embryologic rests.[242] Most are asymptomatic, although in rare cases parapelvic cysts may cause hematuria, hypertension, or hydronephrosis; may become infected; or may bleed.[243] At sonography, parapelvic cysts appear as well-defined, anechoic, renal sinus masses (Fig. 9.69). If they have hemorrhaged, internal echoes will be seen in the cysts. It may be difficult to differentiate multiple parapelvic cysts from hydronephrosis (Fig. 9.69). Optimized technique and real-time examination usually suffice to distinguish between multiple noncommunicating, haphazard parapelvic cysts and the communicating, dilated calices and renal pelvis that are the hallmark of hydronephrosis. In rare instances where differentiation is not possible with sonography, MRI or CT can be helpful.

Medullary Cysts

Medullary Sponge Kidney

Medullary sponge kidney is described as dilated, ectatic collecting tubules. It may be focal or diffuse. The cause is unknown. The incidence of medullary sponge kidney in the general population is not known, but it is found in up to 12% of patients with renal calculi.[218,244] Associations with **hemihypertrophy, Ehlers-Danlos syndrome, congenital hypertrophic pyloric stenosis, hyperparathyroidism, Caroli disease,** and **autosomal recessive polycystic disease** have been reported.[218] Uncomplicated medullary sponge kidney is usually not associated with symptoms; with stone formation, however, renal colic, hematuria, dysuria, and flank pain may occur.[245] The onset of symptomatic medullary sponge kidney is usually in the third or fourth decade of life.[218]

Tubular ectasia may be difficult to impossible to recognize at ultrasound (see Fig. 9.44). When **nephrocalcinosis** is present, multiple echogenic shadowing foci are seen localized to the medullary pyramids (see Fig. 9.45). Erosion of a calcification into the collecting system can result in obstruction.

Medullary Cystic Disease

Familial juvenile nephronophthisis and medullary cystic disease are both characterized by small cysts at the corticomedullary junction and medulla. The kidneys are small or normal sized. **Tubulointerstitial fibrosis** is a hallmark of both entities.[246] Juvenile nephronophthisis is an autosomal recessive condition. Patients present with polyuria, salt wasting, and ultimately ESRD. **Medullary cystic disease,** on the other hand, is an autosomal dominant condition. Patients with this disease present in the third or fourth decade of life with similar renal symptoms as nephronophthisis.[247] At sonography, small echogenic kidneys with medullary cysts (0.1-1.0 cm) are seen.

Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease (ARPKD) is divided into four types—perinatal, neonatal, infantile, and juvenile—depending on the patient's age at the onset of clinical manifestations. ARPKD is characterized pathologically as a spectrum of dilated renal collecting tubules, hepatic cysts, and periportal fibrosis. Younger patients present predominantly with renal insufficiency. Hepatic involvement is typically dominant in older patients with ARPKD. ARPKD occurs in 1:6000 to 1:14,000 live births. Patients with perinatal disease have massively enlarged kidneys, hypoplastic lungs, and oligohydramnios. Death usually results from pulmonary hypoplasia and renal failure. Older children will present with manifestations of portal hypertension. Renal sonographic features of ARPKD include a lack of corticomedullary differentiation and massively enlarged echogenic kidneys (Fig. 9.70). Occasionally, macroscopic cysts will be noted.

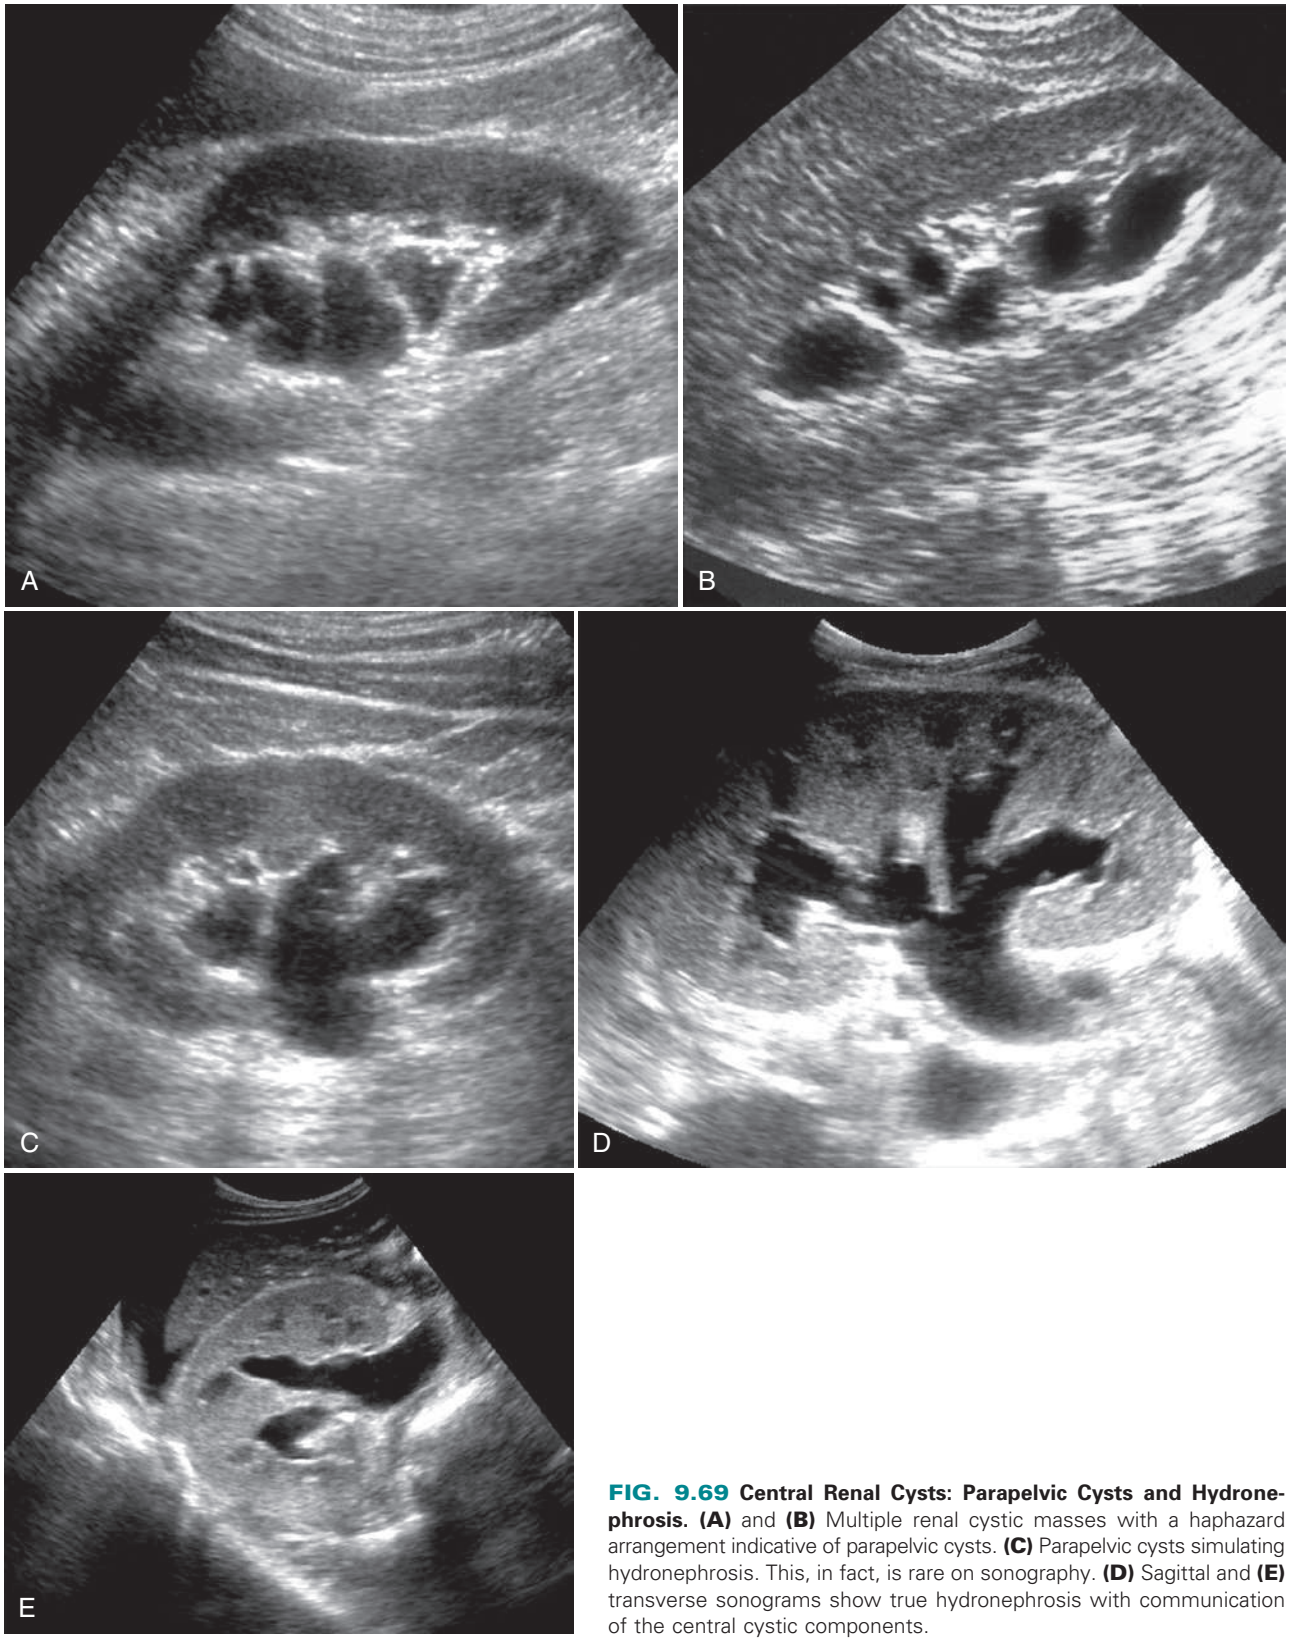

FIG. 9.69 Central Renal Cysts: Parapelvic Cysts and Hydronephrosis. (A) and **(B)** Multiple renal cystic masses with a haphazard arrangement indicative of parapelvic cysts. **(C)** Parapelvic cysts simulating hydronephrosis. This, in fact, is rare on sonography. **(D)** Sagittal and **(E)** transverse sonograms show true hydronephrosis with communication of the central cystic components.

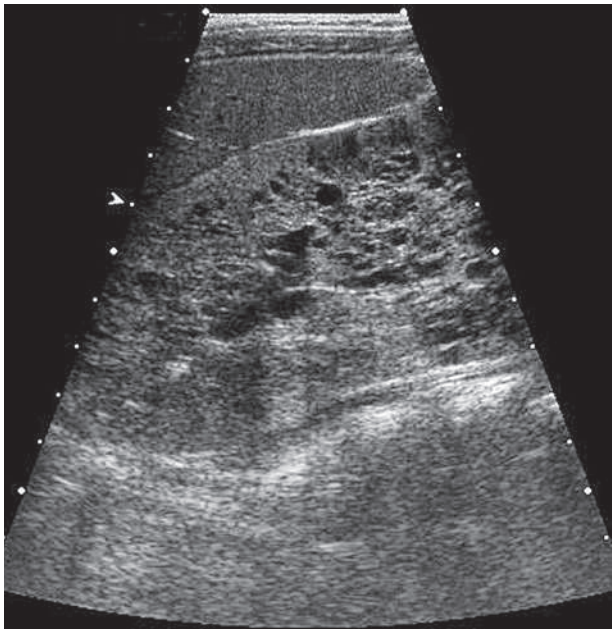

FIG. 9.70 Autosomal Recessive Polycystic Kidney Disease. Two-year-old patient with renal insufficiency. Sagittal sonogram shows marked renal enlargement and innumerable microcysts.

Autosomal dominant polycystic kidney disease (ADPKD) results in a large number of bilateral cortical and medullary renal cysts. The cysts vary in size and are often asymmetric. ADPKD is the most common hereditary renal disorder and has no gender predilection. Its incidence is 1:500 to 1:1000, and ADPKD accounts for 10% to 15% of patients receiving dialysis. Up to 50% of patients have no family history. Seemingly sporadic involvement is caused by variable expression and spontaneous mutations. Signs and symptoms of palpable masses, pain, hypertension, hematuria, and UTI usually do not develop until the fourth or fifth decade. Renal failure develops in 50% of patients and is usually present by age 60.[248] Complications of ADPKD include infection, hemorrhage, stone formation, cyst rupture, and obstruction. Stone formation tends to occur in patients with more and larger cysts.[249] Associated anomalies include liver cysts (30%-60%); pancreatic cysts (10%); splenic cysts (5%); cysts in thyroid, ovary, endometrium, seminal vesicles, lung, brain, pituitary gland, breast, and epididymis; cerebral berry aneurysms (18%-40%); abdominal aortic aneurysm; cardiac lesions; and colonic diverticula. Patients with ADPKD who are not receiving dialysis do not have an increased incidence of RCC.[248]

Ultrasound is used for screening families of patients with ADPKD, as well as for routine follow-up. At sonography, the kidneys are enlarged and replaced by multiple bilateral, asymmetric cysts of varying size (Fig. 9.71). Cysts complicated by hemorrhage or infection have thick walls, internal echoes, and/or fluid-debris levels. Dystrophic calcification within cyst walls or stones may be seen as echogenic foci with sharp, distal acoustic shadowing.

Renal cysts in patients younger than 30 years are rare. Ravine et al.[250] modified the criteria of Bear et al.[251] and reported that patients age 30 or younger with a family history of ADPKD require two renal cysts (unilateral or bilateral) to have the diagnosis of ADPKD disease. For patients age 30 to 59, two cysts in each kidney are required, and for those age 60 or older, four cysts in each kidney are needed. These criteria were modified to account for the relatively later onset of disease in patients with type 2 polycystic kidney disease, but fewer than two renal cysts in at-risk individuals older than age 40 was still sufficient to exclude the disease.[252]

Multicystic Dysplastic Kidney

Multicystic dysplastic kidney (MCDK) is a nonhereditary developmental anomaly also known as **renal dysplasia, renal dysgenesis,** and **multicystic kidney.** The kidney is small, malformed, and composed of multiple cysts with little, if any, normal renal parenchyma. The kidney functions poorly if at all. The dysplastic change is usually unilateral and involves the entire kidney, although rarely it may be bilateral, segmental, or focal. If bilateral, involving the entirety of both kidneys, it is incompatible with life. Men and women are equally affected, as are both sides. Up to 30% of patients have a contralateral UPJ obstruction. The exact pathogenesis is obscure. However, 90% of cases are associated with some form of urinary tract obstruction during embryogenesis. The severity of the malformation and the age of the patient at diagnosis account for the varying manifestations of MCKD, from a large, multicystic mass present at birth to a kidney with smaller cysts that are asymptomatic and not discovered until adulthood.

Ultrasound findings of MCKD include (1) multiple noncommunicating cysts of varying size, (2) absence of normal parenchyma and normal renal sinus, and (3) focal echogenic areas representing primitive mesenchyma or tiny cysts[253] (Fig. 9.72). In adults a small, cystic renal fossa mass is seen, and cyst wall calcification is appreciated as echogenic foci with shadowing. Calcification may be so extensive that ultrasound visualization is impossible, and CT is required to make the diagnosis. Segmental disease is usually seen in duplex kidneys, and if the cysts are tiny, the mass may appear solid and echogenic.

Lithium Nephropathy

Known complications of chronic lithium administration include nephrogenic diabetes insipidus (polyuria-polydipsia syndrome) and/or chronic renal disease. Diabetes insipidus develops in up to 40% of patients on chronic lithium therapy, and is typically reversible. On the other hand, a smaller subset of patients may develop chronic focal interstitial nephritis that is manifested by a progressive, permanent defect in urine concentrating ability and chronic renal insufficiency. The diagnosis is typically made based on clinical criteria, but biopsy findings include tubulointerstitial fibrosis, tubular dilatation, and microcysts.[254]

The histopathology of chronic lithium nephrotoxicity is manifested at ultrasound by numerous microcysts and punctate echogenic foci. These foci are thought to be microcysts rather than nonshadowing calcification[255] (Fig. 9.73).

Multilocular Cystic Nephroma

Multilocular cystic nephroma (MLCN) is an uncommon benign cystic neoplasm composed of multiple noncommunicating cysts

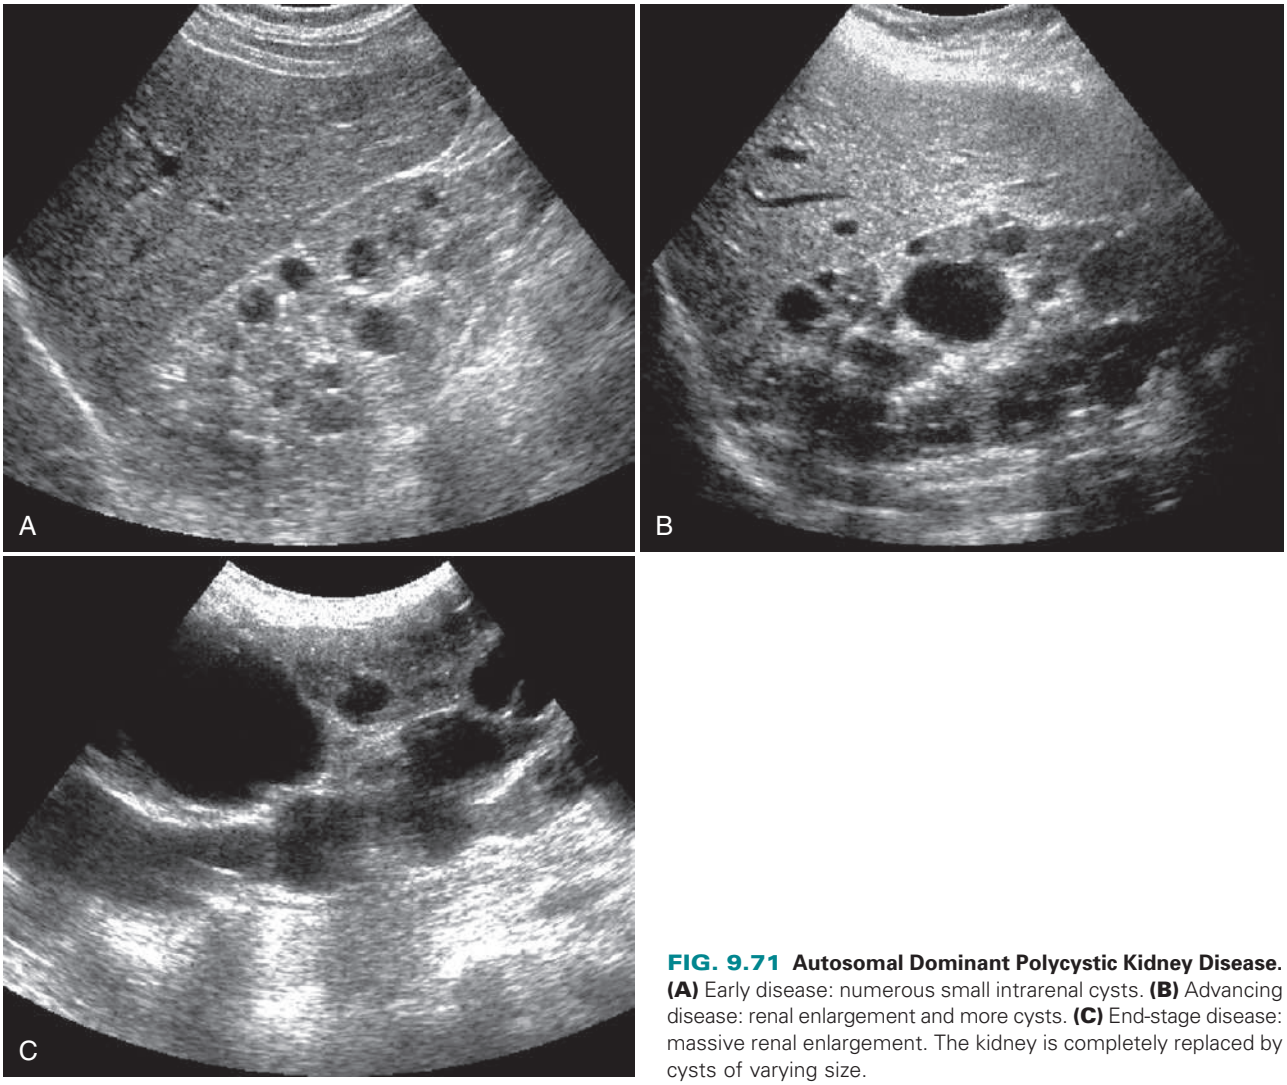

FIG. 9.71 Autosomal Dominant Polycystic Kidney Disease. **(A)** Early disease: numerous small intrarenal cysts. **(B)** Advancing disease: renal enlargement and more cysts. **(C)** End-stage disease: massive renal enlargement. The kidney is completely replaced by cysts of varying size.

FIG. 9.72 Multicystic Dysplastic Kidney. Small, malformed kidney containing multiple cysts. (Courtesy of Deborah Rubens, MD.)

contained within a well-defined capsule. Occasionally, sarcomatous stroma is present, making this a more malignant lesion. MLCN has no predilection for side, and occasionally, bilateral tumors are seen. These tumors are found in male patients less than 4 years of age and in female patients age 4 to 20 or 40 to 60 years.[256]

Most children present with an abdominal mass. Adults may be asymptomatic or may present with abdominal pain, hematuria, hypertension, or UTI.

The ultrasound appearance of MLCN is variable and depends on the number and size of the locules. With multiple large locules, noncommunicating cysts will be seen within a well-defined mass (Fig. 9.74). If the locules are tiny, a more solid-appearing nonspecific echogenic mass will be present. Calcification of the capsule and septa is uncommon. With either appearance, it is impossible with imaging to differentiate MLCN from cystic RCC.

Localized Cystic Disease

Localized cystic disease is a rare, benign, nonhereditary entity that may mimic MLCN. In localized cystic disease, multiple closely opposed cysts occupy either a portion of kidney or an entire kidney—thus the previous description of "unilateral polycystic disease."[257] At ultrasound, localized cystic disease appears a conglomerate mass of multiple cysts of varying size separated by normal or atrophic renal parenchyma (Fig. 9.75). The lack of cysts within other organs (or the contralateral kidney) and the absence of an appropriate family history prompt the

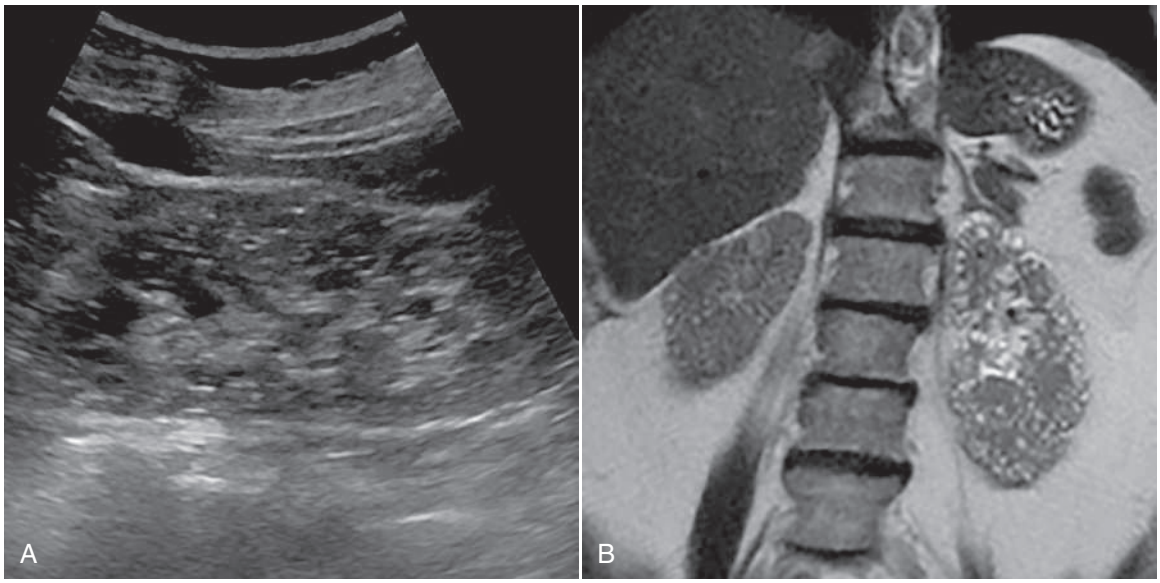

FIG. 9.73 Chronic Lithium Nephropathy. (A) Sagittal sonogram of a patient on long-term maintenance lithium therapy with a history of mild renal insufficiency and diabetes insipidus shows innumerable microcysts and punctate nonshadowing echogenic foci. **(B)** Corresponding T2-weighted MRI in the same patient confirms innumerable microcysts.

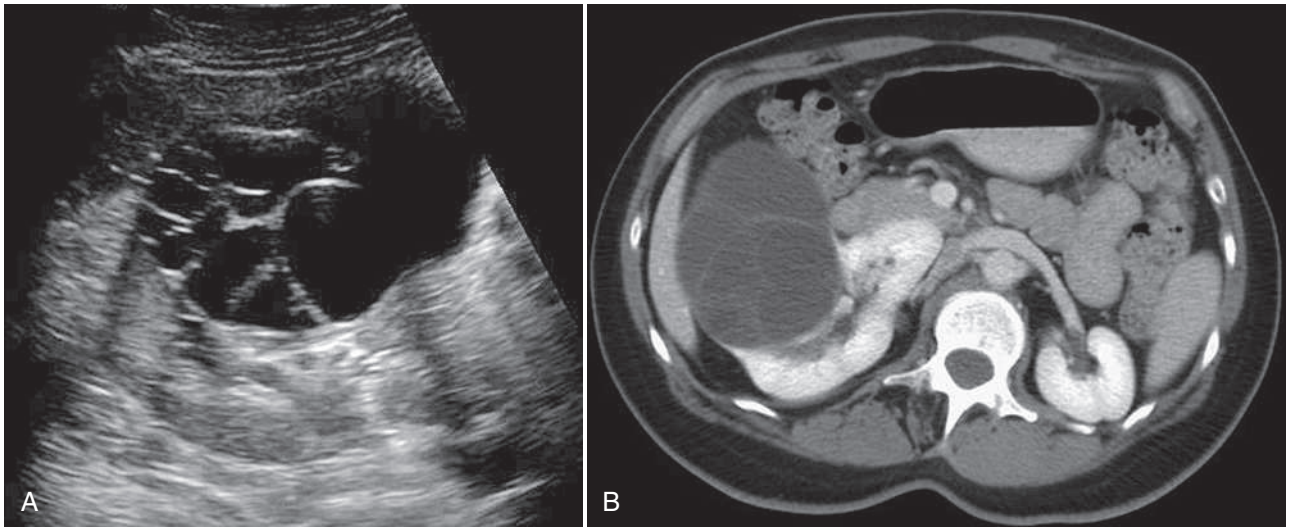

FIG. 9.74 Multilocular Cystic Nephroma. (A) Transverse sonogram demonstrates a multiseptated, exophytic, complex cystic mass with noncommunicating locules. **(B)** Confirmatory contrast-enhanced CT.

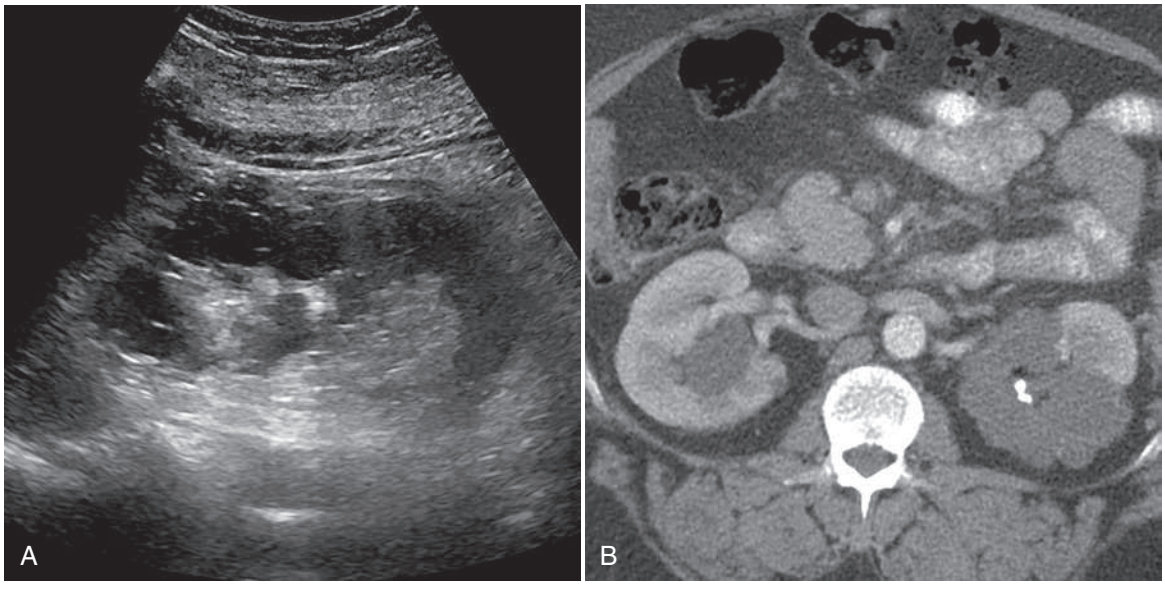

FIG. 9.75. Localized Cystic Disease. (A) Sagittal sonogram shows multiple, closely opposed cysts throughout upper pole of kidney. **(B)** Corresponding contrast-enhanced CT shows that the upper pole of the left kidney is replaced by innumerable cysts.

ultrasound diagnosis of localized cystic disease, although CT or MRI confirmation is typically needed. In addition, CT (or MRI) better shows the thick, fibrous, encapsulating capsule characteristic of MLCN.[258]

Neoplasm-Associated Renal Cystic Disease

Acquired Cystic Kidney Disease

Acquired cystic kidney disease (ACKD) occurs in the native kidneys of patients with **renal failure** undergoing either hemodialysis or peritoneal dialysis. ACKD affects 40% to 90% of these patients, depending on the duration of dialysis.[127,128,247,259] RCC occurs in 4% to 10% of patients with ACKD.[259] The pathogenesis of ACKD is speculative. Epithelial hyperplasia caused by tubular obstruction resulting from toxic substances plays some role in the development of both cysts and tumors.[259] On histology, multiple small cysts (0.5-3 cm) involving both renal cortex and medulla are found. Hemorrhage into cysts is common. Ultrasound, CT, and MRI are useful in the evaluation and follow-up of patients with ACKD and its complications.[127,128,260] ACKD and tumor development persist even after successful renal transplantation. ACKD and tumors may develop in renal allografts during dialysis therapy.[261]

At sonography, finding three to five cysts in each kidney in a patient with chronic renal failure is diagnostic.[261] The cysts are usually small, as are the kidneys, which typically are quite echogenic (Fig. 9.76). Internal echoes are seen in cysts that have hemorrhaged. Tumors are solid or cystic with mural nodules.

Von Hippel–Lindau Disease

VHL disease is transmitted as an autosomal dominant gene with variable expression and moderate penetrance. Its incidence is 1:35,000.[248] The predominant significant abnormalities include **retinal angiomatosis,** central nervous system **hemangioblastomas, pheochromocytomas,** and **renal cell carcinoma** (40%). RCC in VHL patients usually is multifocal (75%-90%) and bilateral (75%). These patients are often offered nephron-sparing surgery. In addition, renal cysts, the most common finding in VHL disease, are found in 76% of patients.[262] Cysts range from 0.5 to 3.0 cm in size and are mostly cortical based. Ultrasound may be used as an initial screening test for VHL disease. However, CT or MRI is better for detection of the small, multifocal, bilateral tumors found in VHL disease and are the preferred modalities for surveillance after nephron-sparing surgery (Fig. 9.77).

Tuberous Sclerosis

Tuberous sclerosis is an autosomal dominant syndrome characterized by mental retardation, seizures, and adenoma sebaceum. Many cases also result from spontaneous mutation. The incidence ranges from 1:9000 to 1:170,000.[263] Associated renal lesions include cysts, AML, and RCC (1%-2%).[248] The renal cysts vary in size from microscopic to 3 cm. At sonography, if only cysts are present, it may be difficult to differentiate tuberous sclerosis from ADPKD. The presence of cysts and multiple AMLs suggests

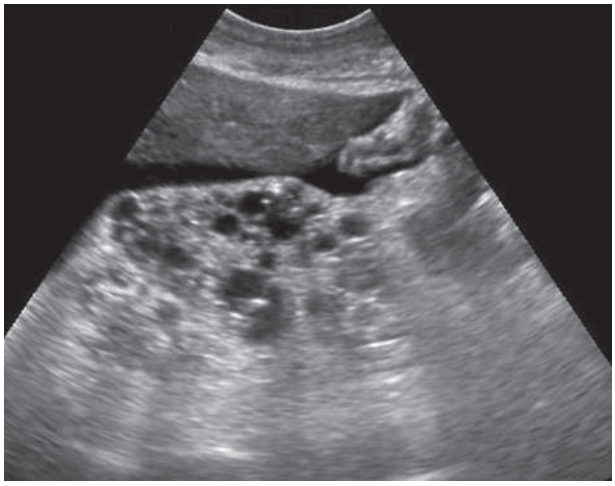

FIG. 9.76 Acquired Cystic Kidney Disease. Sagittal sonogram demonstrates an echogenic small kidney containing multiple cysts. A small amount of intraperitoneal dialysate fluid is seen.

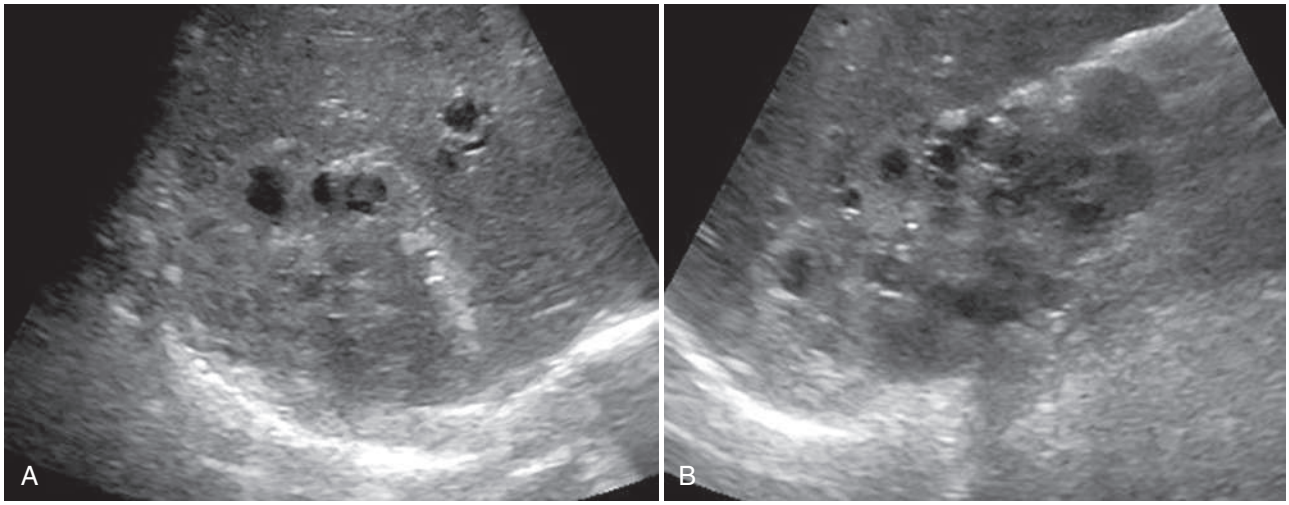

FIG. 9.77 Von Hippel–Lindau Disease. (A) Transverse and **(B)** sagittal sonograms show multiple small, complex cystic lesions.

tuberous sclerosis (Fig. 9.78). Periodic CT screening is recommended to assess for AML growth and tumor development.

TRAUMA

Renal Injuries

Traumatic injury to the kidney may be blunt or penetrating. Most forms of **blunt** trauma to the kidney are relatively minor and heal without treatment. **Penetrating** injuries are usually the result of gunshot or stab wounds. Kidneys with cysts, tumors, and hydronephrosis are more prone to injury. Renal injuries are classified into the following four categories[264]:

I: Minor injury (75%-85%): contusions, subcapsular hematoma, small cortical infarct and lacerations that do not extend into the collecting system

II: Major injury (10%): renal lacerations that extend into the collecting system and segmental renal infarct

III: Catastrophic injury (5%): vascular pedicle injury and shattered kidney

IV: Uteropelvic junction avulsion

Category I lesions are treated conservatively, whereas category III and IV lesions require urgent surgery. Category II lesions are treated conservatively or surgically depending on severity.[264,265]

CT is regarded as the premier imaging modality for the evaluation of suspected renal trauma.[264] Because renal trauma is frequently accompanied by injuries to other organs, CT has the advantage of multiorgan imaging. Theoretically, sonography has the capability of evaluating traumatized kidneys; in reality, technical limitations usually hinder an adequate examination. Sonography does not provide information regarding renal function and is probably best used in the follow-up of patients with known renal parenchymal trauma. **Renal hematomas** may be hypoechoic, hyperechoic, or heterogeneous. **Lacerations** are seen as linear defects that may extend through the kidney if a fracture is present (Fig. 9.79). Associated **perirenal collections** consisting of blood and urine will be present if the kidney is fractured. **Subcapsular hemorrhage** can be seen as a perirenal fluid collection that flattens the underlying renal contour (Fig. 9.80). A **shattered kidney** consists of multiple fragments of disorganized tissue with associated hemorrhage and urine collection in the renal bed. Color

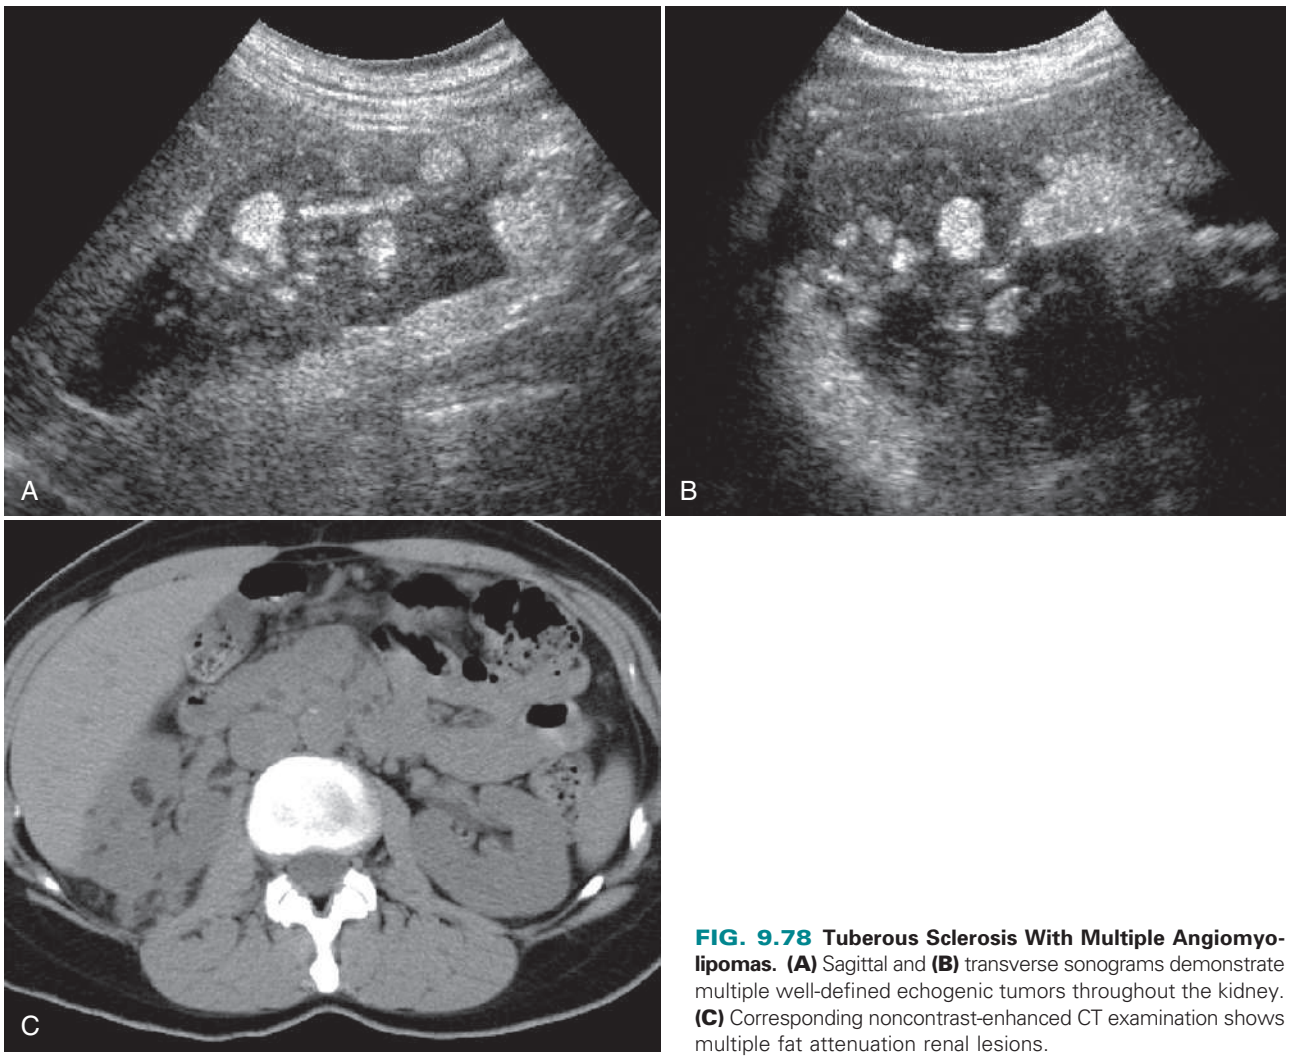

FIG. 9.78 Tuberous Sclerosis With Multiple Angiomyolipomas. (A) Sagittal and **(B)** transverse sonograms demonstrate multiple well-defined echogenic tumors throughout the kidney. **(C)** Corresponding noncontrast-enhanced CT examination shows multiple fat attenuation renal lesions.

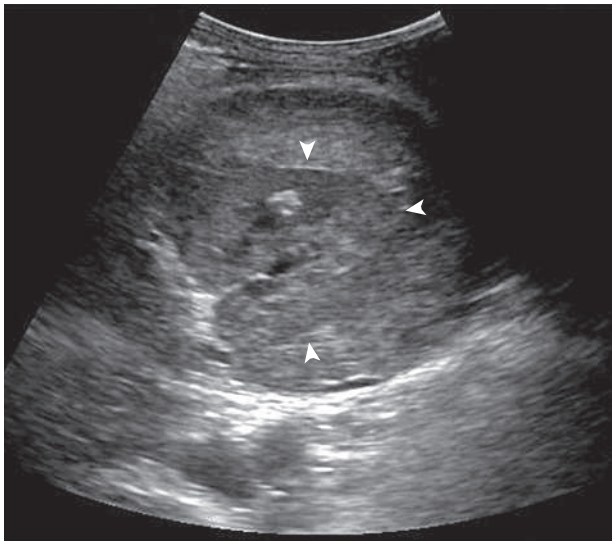

FIG. 9.80 Subcapsular Hematoma After Renal Biopsy. Note compression of kidney *(arrowheads)* by large, hyperechoic subcapsular hematoma.

Doppler sonography may be helpful in the assessment of **vascular pedicle injuries.** As use of CEUS becomes more prevalent, there may be a role for CEUS in the initial bedside assessment and follow-up of renal injuries in critically ill patients.[266,267]

Ureteral Injuries

Traumatic injury of the ureter is most often a complication of either gynecologic (70%) or urologic (30%) surgery.[268] Blunt and penetrating injuries are much less common. Sonography is not useful in the assessment of these injuries, except to detect sizable fluid collections and hydronephrosis.

Bladder Injuries

Bladder injury may be the result of blunt, penetrating, or iatrogenic trauma. Bladder injury may result in extraperitoneal or intraperitoneal rupture, or a combination. Sonography is usually not helpful in the assessment of these injuries, except to identify large fluid collections or free intraperitoneal fluid.

VASCULAR ABNORMALITIES

Renal Vascular Doppler Sonography

The number and size of arteries supplying a kidney are quite variable. Duplex and color Doppler imaging are able to demonstrate both normal and abnormal renal blood flow. Normal flow within the renal artery and its branches has a "low resistance" perfusion pattern, with continuous forward blood flow during diastole. Several Doppler parameters have been used to describe changes in Doppler arterial spectra that may accompany renal disease. The most common parameter is the RI. Keogan et al.[269] recommend averaging a number of RI measurements in a kidney before a single representative average is reported. Most sonographers consider an RI of 0.7 to be the upper threshold of normal in adults, although renal RIs greater than 0.7 may be seen in children younger than 4 years of age and in older patients, despite normal renal function.[270-272] Mostbeck et al.[273] also showed how the RI varies with heart rate and can range from 0.57 ± 0.06 (pulse, 120/min) to 0.70 ± 0.06 (pulse, 70/min).

Despite this variability, early literature indicated the potential of Doppler for improving the sonographic assessment of **renal dysfunction.** Changes in intrarenal spectra (quantified using RI) were associated with acute or chronic urinary obstruction, several intrinsic native renal diseases, renal transplant rejection, and renal vascular disease. Less favorable results in follow-up studies and discouraging clinical experience prompted most radiologists to abandon the RI. Studies show that the RI varies as a result of **driving pulse pressures,** which explains Mostbeck's observation of rate-dependent changes in RIs, as well as changes in vascular/interstitial compliance.[112-114]

Renal Artery Occlusion and Infarction

Renal artery occlusion may be caused by either emboli or in situ thrombosis. The degree of renal insult depends on the size and location of the occluded vessel. If the main renal artery is occluded, the entire kidney will be affected, whereas segmental infarction and focal infarction occur with peripherally located vascular occlusion. The acutely infarcted kidney is often normal appearing at gray-scale sonography. However, no flow within the kidney is shown at duplex and color/power Doppler examination (Fig. 9.81). Segmental or focal infarction may appear as a wedge-shaped mass indistinguishable from acute pyelonephritis. With time, an echogenic mass[274] or scar may form. With chronic occlusion, a small, scarred, end-stage kidney will be seen.

Arteriovenous Fistula and Malformation

Abnormal arteriovenous communications can be acquired (75%) or congenital (25%). **Acquired** lesions are usually iatrogenic, although spontaneous abnormal arteriovenous communications may occur with eroding tumors. Most acquired lesions consist of a single, dominant feeding artery and a single, dominant draining vein. **Congenital** malformations consist of a tangle of

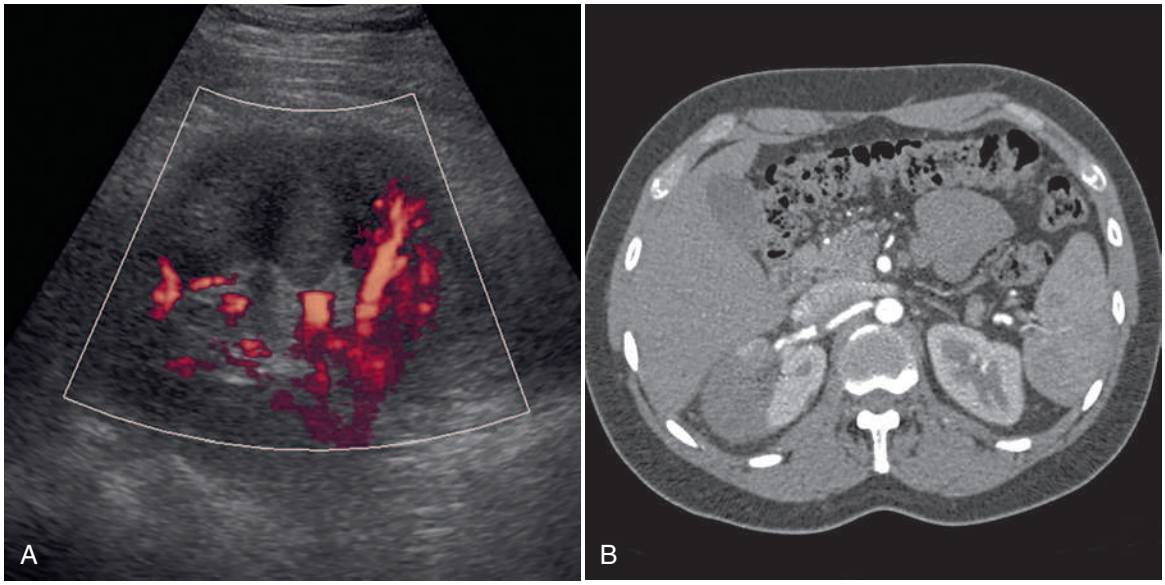

FIG. 9.81. Renal Infarct. (A) Transverse power Doppler sonogram shows an avascular slightly echogenic "lesion." **(B)** Corresponding CT angiogram shows an acute right upper-pole renal infarct and focal clot within mid right renal artery. (Courtesy of William Middleton, MD. Mallinckrodt Institute of Radiology, St. Louis Missouri.)

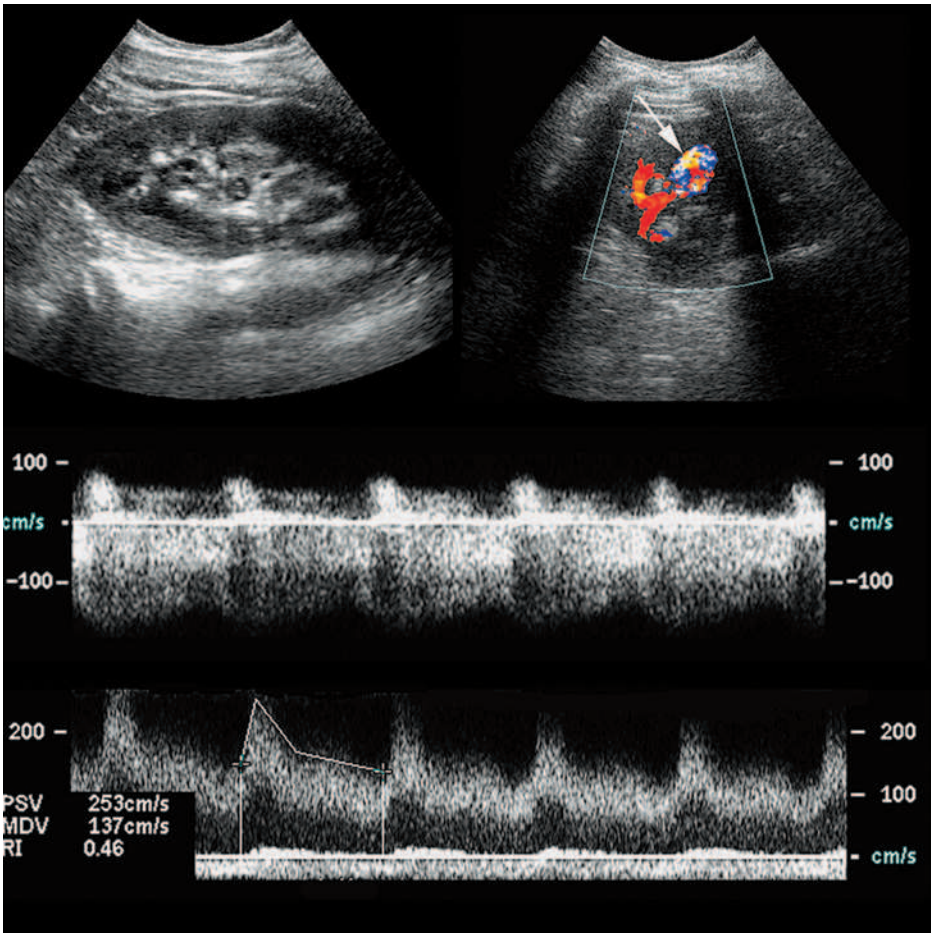

FIG. 9.82 Renal Arteriovenous Malformation (AVM). Top: *Left image,* Normal sagittal sonogram of the kidney. *Right image,* Focus of color aliasing *(arrow).* **Middle:** Spectral waveform shows a high-velocity draining vein. **Bottom:** Spectral wave form shows an arterial signal from within the AVM. Note high-velocity, low "resistance" flow (RI = 0.46).

small, abnormal vessels. Gray-scale sonography may reveal no abnormality. The addition of duplex and color Doppler imaging has been helpful in defining these lesions.[275] Duplex Doppler demonstrates increased flow velocity, a decreased RI (0.3-0.4), and turbulent diastolic flow in the arterial limb. Arterial pulsations in the draining vein are also observed. Spectral broadening is present. Color Doppler sonography may demonstrate a tangle of tortuous vessels with multiple colors, indicative of the haphazard orientation and turbulent flow within the malformation (Fig. 9.82).

Renal Artery Stenosis

Hypertension may be **primary** (95%-99%) or **secondary** (1%-5%). The vast majority of patients with secondary hypertension have renovascular disease. **Renovascular disease** is most frequently caused by **atherosclerosis** (66%), and the majority of the remaining cases largely result from **fibromuscular dysplasia.**[276] Many different imaging techniques have been used in an effort to detect patients with renovascular hypertension. These include intravenous and intraarterial digital subtraction angiography, captopril renal scintigraphy, duplex and color Doppler ultrasound, CT angiography, and magnetic resonance angiography.

Numerous studies and clinical experience in ultrasound laboratories have suggested the utility of **Doppler ultrasound** as an initial screening examination for renal vascular hypertension. The screening approach may involve (1) detection of abnormal Doppler signals at or just distal to the stenosis or (2) detection of abnormal Doppler signals in the intrarenal vasculature. Typical direct criteria for hemodynamically significant stenosis (>60%-70%) include a focal peak systolic velocity of higher than 200 cm/sec, poststenotic turbulence, and a renal artery to aortic ratio of greater than 3.5.[277]

Evaluation of the main renal arteries in their entirety is usually not possible with ultrasound. It is estimated that the main renal arteries are not seen in up to 42% of patients.[278] In addition, 14% to 24% of patients have accessory renal arteries that are usually not detected sonographically. Therefore, evaluation of the main renal arteries as a screening approach for renal artery stenosis often fails, particularly in difficult-to-scan patients. The second approach is to interrogate the intrarenal vasculature. Normally, there is a steep upstroke in systole with a second small peak in early systole. A **tardus-parvus waveform** downstream from a stenosis refers to a slowed systolic acceleration with low amplitude of the systolic peak (Fig. 9.83). To evaluate the delayed upstroke, two measurements are taken:

- **Acceleration time:** time from start of systole to peak systole
- **Acceleration index:** slope of the systolic upstroke

An acceleration time greater than 0.07 second and a slope of systolic upstroke less than 3 m/sec^2 are suggested as thresholds to assess for renal artery stenosis.[278] Simple recognition of the change in pattern may be adequate[279] (Fig. 9.84). Pharmacologic manipulation with **captopril**[280] can enhance the waveform abnormalities in patients with renal artery stenosis. The use of intravascular contrast agents increases the technical success rate for the evaluation of renal artery stenosis.[281] They may also play a role in the assessment and follow-up of patients undergoing renal artery angioplasty and stent placement.[282]

Despite abundant literature indicating the promise of either direct or indirect Doppler approaches, both techniques can be tedious in hard-to-scan patients. Widely varying reported sensitivities and specifities for both approaches for the detection of "significant" renal arterial stenosis have also called into question

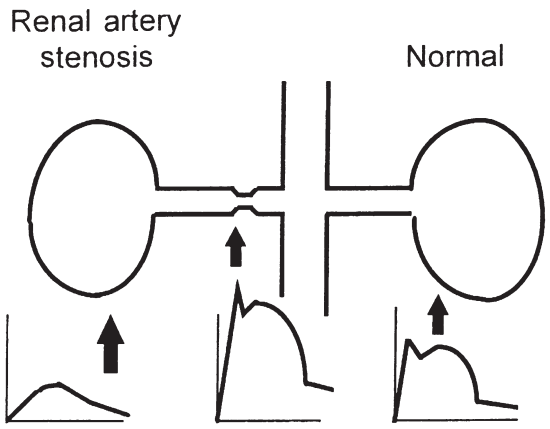

FIG. 9.83 Schematic Diagram of Renal Artery Doppler Tracings. *Right side,* Tracing from a normal renal artery. Note early systolic peak. *Middle,* Tracing shows high-velocity flow measured at the stenosis. *Left side,* Tracing shows the dampened tardus-parvus waveform downstream from the stenosis. (With permission from Mitty HA, Shapiro RS, Parsons RB, Silberzweig JE. Renovascular hypertension. Radiol Clin North Am. 1996;34:1017-1036.[278])

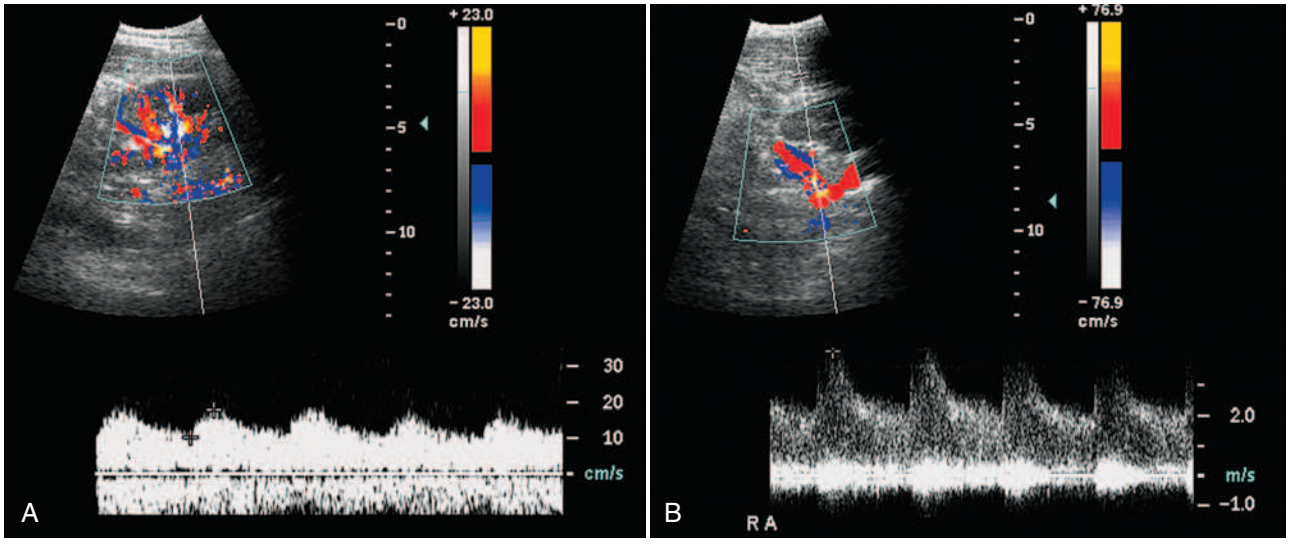

FIG. 9.84 Renal Artery Stenosis. (A) Intrarenal spectral waveform shows a tardus-parvus signal with a prolonged acceleration time and low resistive index (RI). **(B)** Waveform at the origin of the renal artery from the aorta shows a high peak velocity of 410 cm/sec with an RI of 0.43.

the potential of Doppler as a primary screening modality. Moreover, several recent trials showing no benefit of revascularization/stenting over conservative, pharmacologic antihypertensive management of renal arterial stenosis may impact screening algorithms in the future.[283,284]

Renal Artery Aneurysm

Renal artery aneurysms are saccular or fusiform dilatations of the renal artery or one of its branches. The incidence of renal artery aneurysm is 0.09% to 0.3%.[285] The cause may be congenital, inflammatory, traumatic, atherosclerotic, or related to fibromuscular disease. If the aneurysm is large (>2.5 cm), noncalcified, or associated with pregnancy, the possibility of rupture increases and treatment is recommended. At gray-scale sonography, a cystic mass may be seen. The addition of duplex and color Doppler imaging will readily demonstrate arterial flow within the cystic mass (Fig. 9.85).

Renal Vein Thrombosis

Renal vein thrombosis (RVT) usually results from an underlying abnormality of the kidney, dehydration, or hypercoagulability. Tumors of the kidney and left adrenal gland may grow into the veins, resulting in RVT. Extrinsic compression related to tumors, **retroperitoneal fibrosis, pancreatitis,** and **trauma** cause RVT by attenuating the vessel and slowing flow. In adults the most common cause of RVT is **membranous glomerulonephritis;** 50% of patients with this disease will have RVT. If thrombosis is acute, the patient may have flank pain and hematuria. Venous collaterals develop with more chronic occlusion; patients with chronic RVT thus are often asymptomatic.

The sonographic features of acute RVT are nonspecific and include an enlarged, edematous, hypoechoic kidney with loss of normal corticomedullary differentiation.[286,287] Occasionally, thrombus will be seen within the renal vein (Fig. 9.86), but acutely, it may be anechoic and difficult to visualize. The use of duplex and color Doppler ultrasound can help; however, the inability to detect flow within renal veins does not necessarily indicate RVT. Extremely slow flow often will not be detected in difficult-to-scan patients despite optimized technique. Absent or reversed end diastolic flow in the intraparenchymal native renal arteries is a secondary sign of RVT. Platt et al.[288] evaluated 20 native kidneys in 12 patients with clinical findings suggestive of acute RVT. They found that normal arterial Doppler studies should not prevent further workup if RVT is suspected (2 in 4 with normal Doppler had RVT), and that absent or reversed diastolic signals should not be considered specific for RVT (2 in 10 with absent or reversed diastolic flow had RVT). If findings are equivocal, MRI should be performed. Chronic RVT usually results in a small, end-stage, echogenic kidney.

Ovarian Vein Thrombosis

Ovarian vein thrombosis is most commonly seen in postpartum women, but it may also be seen as a result of pelvic inflammatory disease, Crohn disease, or after gynecologic surgery. The right side is affected more often than the left. Gray-scale, duplex, and color Doppler sonography may reveal a long, tubular structure filled with thrombus extending from the region of the renal vein to deep within the pelvis. Patients are usually treated with anticoagulation and antibiotics.

MEDICAL GENITOURINARY DISEASES

Patients presenting with elevated creatinine levels are often sent to the ultrasound department for an initial screening test. The purpose is to rule out an underlying mechanical obstruction. If

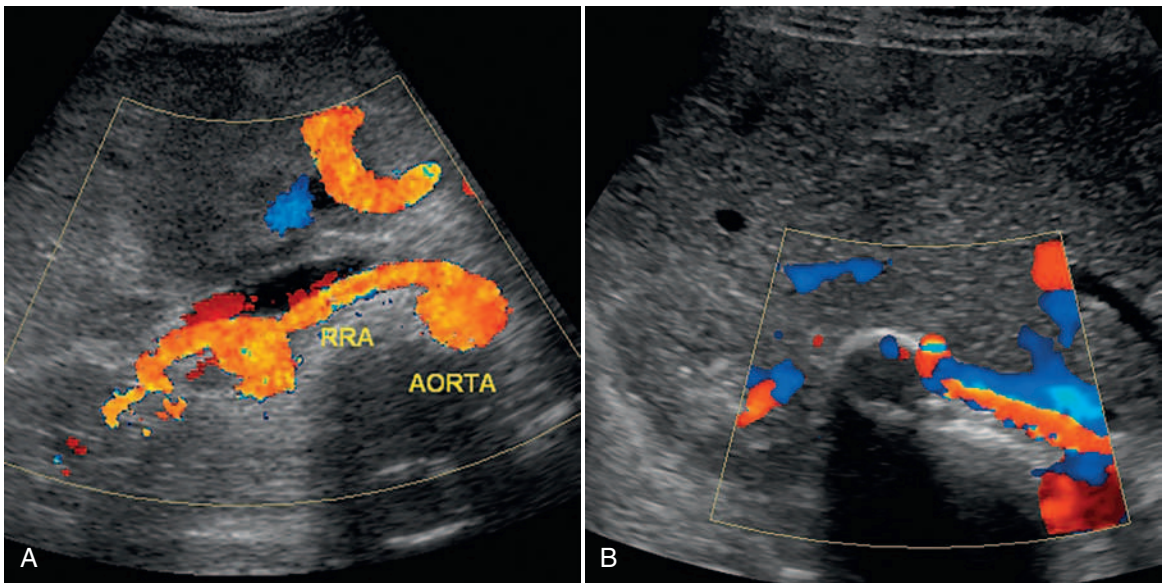

FIG. 9.85 Renal Artery Aneurysm. (A) Color Doppler ultrasound image shows a distal right renal artery aneurysm. **(B)** Color Doppler of another patient shows a peripherally calcified but thrombosed distal right renal artery (RRA) aneurysm.

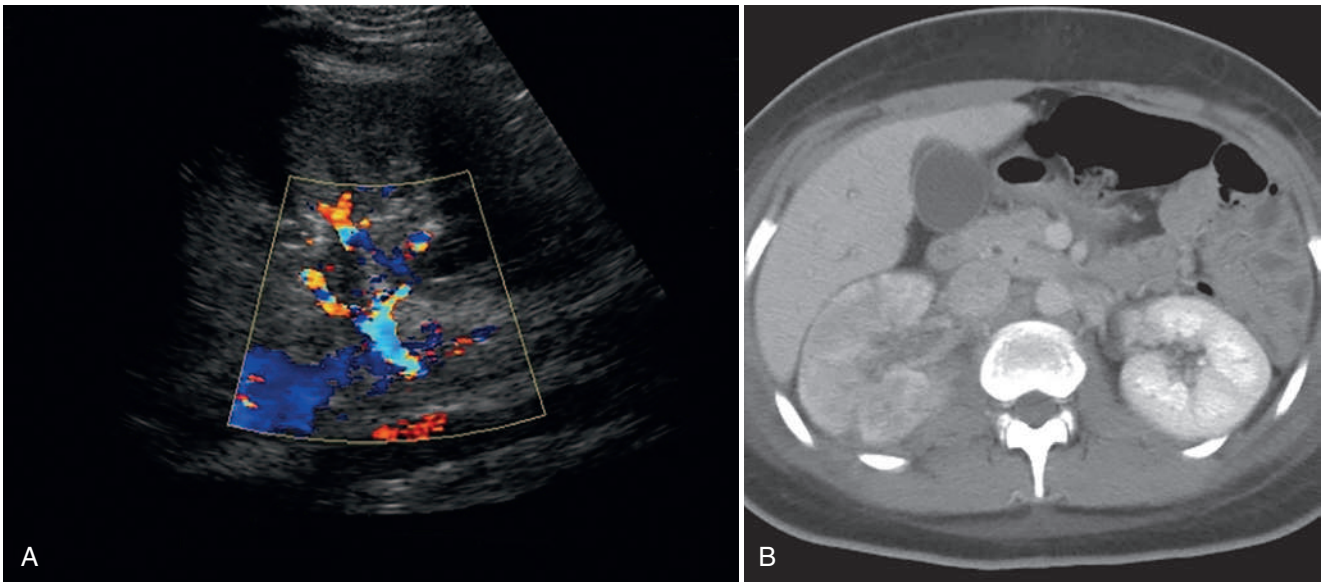

FIG. 9.86 Renal Vein Thrombosis. (A) Color Doppler image shows an echogenic right kidney and nonocclusive right renal vein thrombus extending into inferior vena cava. **(B)** Corresponding contrast-enhanced CT shows an enlarged right kidney, a delayed right nephrogram, and a right renal vein thrombus. (Courtesy of Shweta Bhatt, MD.)

obstruction is not found, this often indicates a renal parenchymal abnormality—thus the terms ***medical renal disease*** or ***renal parenchymal disease.*** The acutely injured kidney may be hyperechoic, echogenic, or normal appearing at ultrasound; a thin rim of perirenal fluid is often shown in the acute setting.[289,290] The chronically diseased kidney is small and echogenic (Fig. 9.87). Unfortunately, it is usually impossible to distinguish between the numerous causes of intrinsic renal disease based on the appearance of the kidney at ultrasound, although renal size is a clinically relevant parameter used to distinguish between acute and chronic processes. Thus percutaneous biopsy is often necessary when clinical features and history are inconclusive.

Acute Tubular Necrosis

Acute tubular necrosis (ATN) is the most common cause of acute reversible renal failure and is related to deposition of cellular debris within the renal collecting tubules. Both ischemic and toxic insults will cause tubular damage. Initiating factors include hypotension, dehydration, drugs, heavy metals, and solvent exposure. The sonographic appearance of ATN depends on the underlying cause. With ATN caused by hypotension, kidneys may appear normal, whereas drugs, metals, and solvents will cause enlarged, echogenic kidneys. Prerenal disease and ATN account for 75% of all patients presenting with acute renal failure.

Acute Cortical Necrosis

Acute cortical necrosis (ACN) is a rare cause of acute renal failure resulting from ischemic necrosis of the cortex with sparing of the medullary pyramids. The outermost aspect of cortex remains viable as a result of capsular blood supply. ACN occurs in association with sepsis, burns, severe dehydration, snakebite, and pregnancy complicated by **placental abruption** or **septic abortion.** The exact cause is uncertain, although it is likely related to a transient episode of intrarenal vasospasm, intravascular thrombosis, or glomerular capillary endothelial damage. At sonography, the renal cortex is initially hypoechoic[291] (Fig. 9.88). With time (mean, 2 months), both kidneys atrophy and the cortex may calcify.

Glomerulonephritis

Necrosis and mesangial proliferation of the glomerulus are the hallmarks of **acute glomerulonephritis.** Systemic diseases that also have acute glomerulonephritis as a feature include **polyarteritis nodosa, systemic lupus erythematosus, Wegener granulomatosis, Goodpasture syndrome, thrombocytopenic purpura,** and **hemolytic uremic syndrome.** Patients often present with hematuria, hypertension, and azotemia. At sonography, both kidneys are affected; the size of the kidneys may be normal, but renomegaly is often encountered. The echo pattern of the cortex is altered; renal cortex may be normal, echogenic, or hypoechoic, but the medulla is spared (see Fig. 9.87). With treatment, the kidneys may revert to a normal size and echogenicity. **Chronic glomerulonephritis** occurs with unabated acute disease over weeks to months following an acute episode. Profound, global, symmetrical parenchymal loss occurs. The calices and papillae are normal, and the amount of peripelvic fat increases. Small, smooth, echogenic kidneys are seen, with prominence of the central echo complex.

Acute Interstitial Nephritis

Acute interstitial nephritis is an acute hypersensitivity reaction of the kidney most often related to drugs. Penicillin, methicillin, rifampin, sulfa drugs, nonsteroidal antiinflammatory drugs, cimetidine, furosemide, and thiazides have been implicated. Usually, renal failure will resolve with cessation of drug therapy. At sonography, enlarged echogenic kidneys are noted.

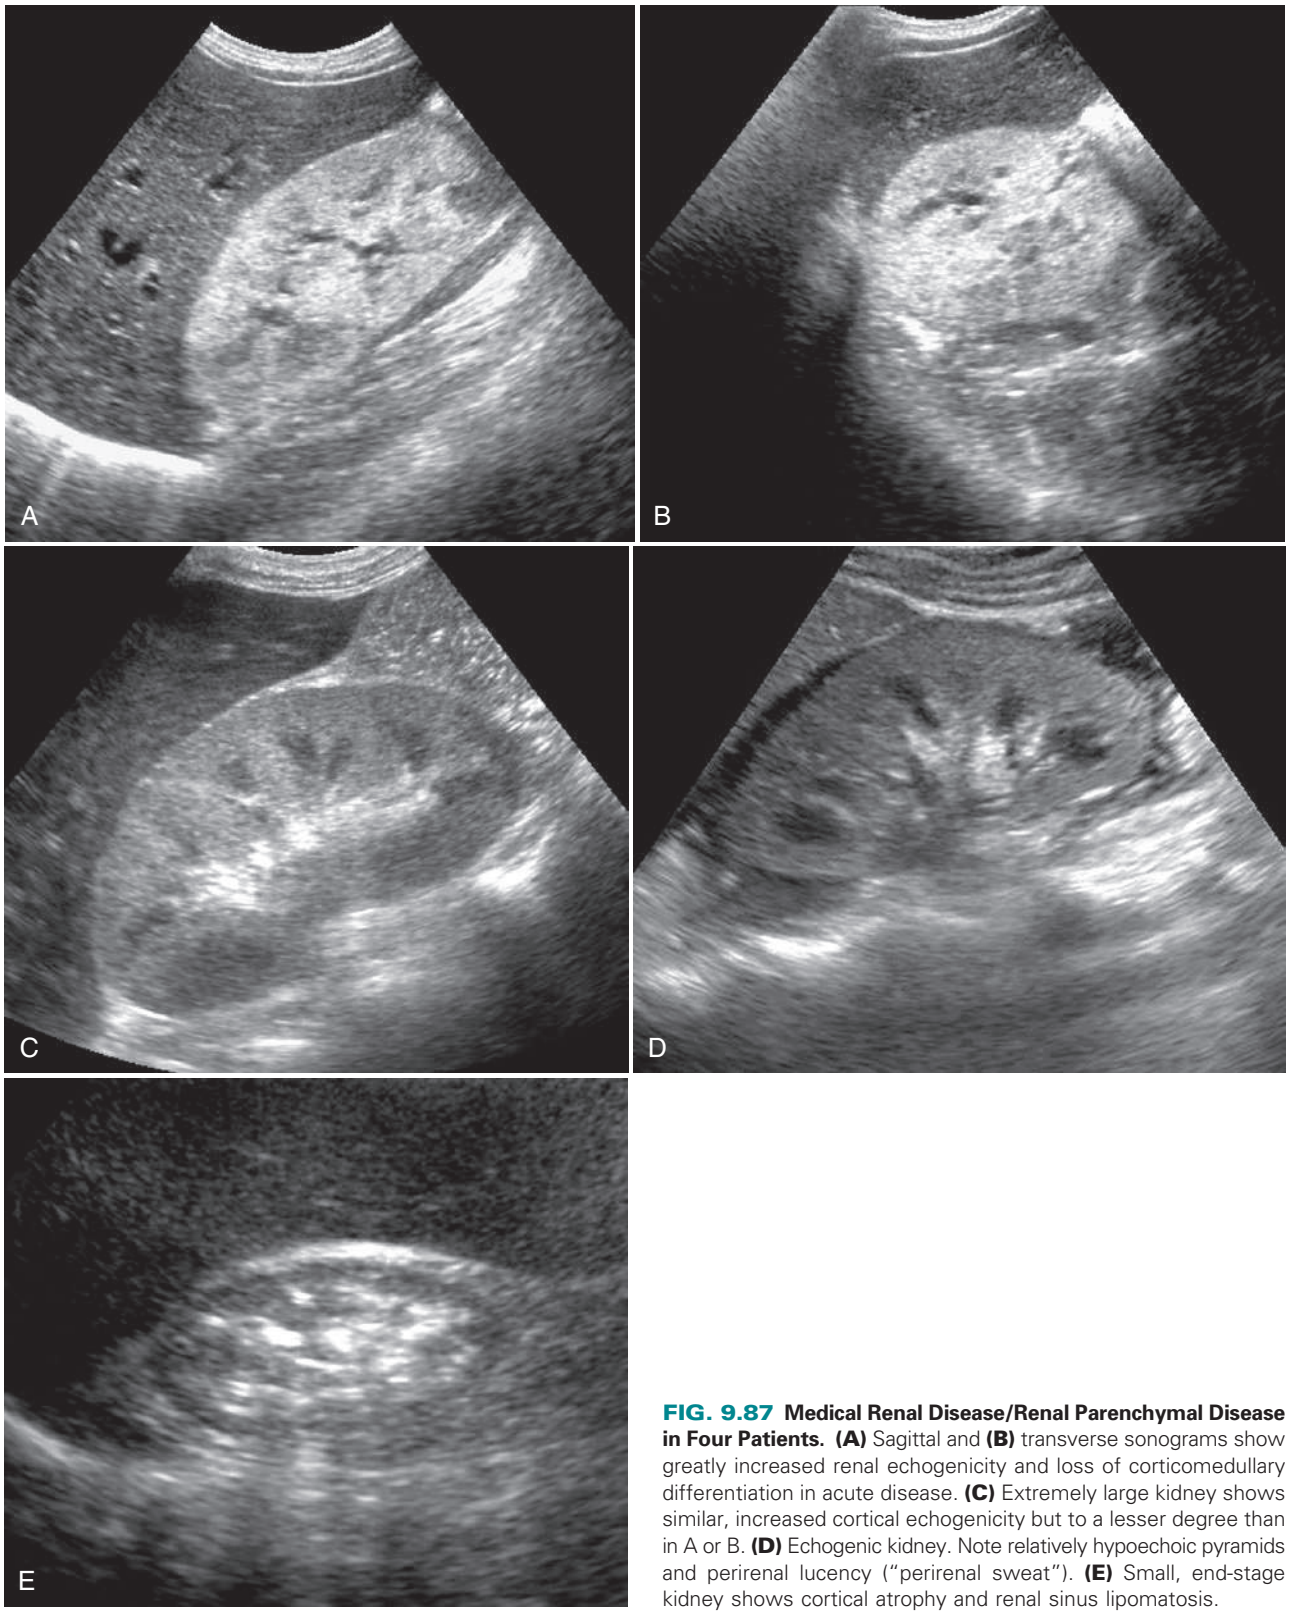

FIG. 9.87 Medical Renal Disease/Renal Parenchymal Disease in Four Patients. (A) Sagittal and **(B)** transverse sonograms show greatly increased renal echogenicity and loss of corticomedullary differentiation in acute disease. **(C)** Extremely large kidney shows similar, increased cortical echogenicity but to a lesser degree than in A or B. **(D)** Echogenic kidney. Note relatively hypoechoic pyramids and perirenal lucency ("perirenal sweat"). **(E)** Small, end-stage kidney shows cortical atrophy and renal sinus lipomatosis.

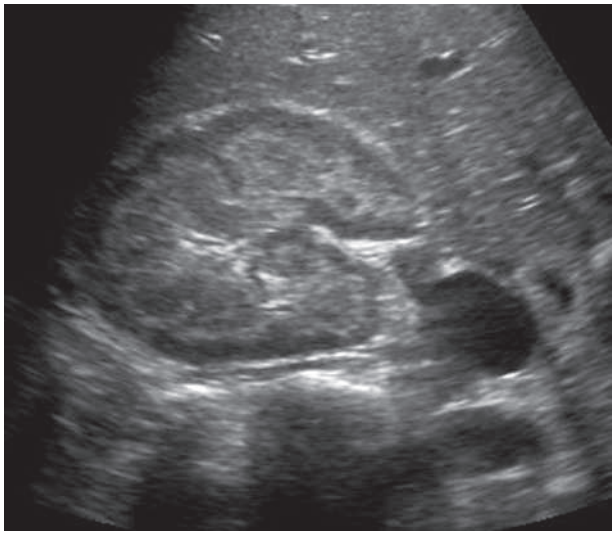

FIG. 9.88 Acute Cortical Necrosis. Transverse sonogram shows a rim of cortical hypoechogenicity.

FIG. 9.89 Bladder Endometrioma. Transvaginal scan demonstrates cystic components in a mural mass that are typical for an endometrioma. (With permission from Damani N, Wilson S. Nongynecologic applications of transvaginal ultrasound. Radiographics. 1999;19:S179-S200.[83])

Diabetes Mellitus

Diabetes mellitus is the most common cause of **chronic renal failure.** Diabetic nephropathy is believed to be related to glomerular hyperfiltration. Renal hypertrophy occurs. With time, diffuse intercapillary glomerulosclerosis develops, causing a progressive decrease in renal size. At sonography, the kidneys are initially enlarged but, with time and progressive renal insufficiency, the kidneys decrease in size and increase in cortical echogenicity, and corticomedullary junctions are preserved. With end-stage disease, the kidneys become smaller and more echogenic, and the medulla becomes as echogenic as the cortex.[292]

Amyloidosis

Amyloidosis may be primary or secondary and usually is a systemic disease; 10% to 20% of cases are localized to one organ system.[293] Patients with amyloidosis often present with renal failure. Patients with primary disease are more often men, with a mean age of 60 years. Causes of secondary amyloidosis include **multiple myeloma** (10%-15%), **rheumatoid arthritis** (20%-25%), **tuberculosis** (50%), **familial Mediterranean fever** (26%-40%), **RCC,** and **Hodgkin disease.**[293] During the acute phase, the kidneys are be symmetrically enlarged. With disease progression, the kidneys shrink; cortical atrophy and increased echogenicity are shown at ultrasound. Focal renal masses, amorphous calcification, a central renal pelvic mass that may be a hemorrhage or amyloid deposit, and perirenal soft tissue masses may be seen. Similarly, involvement of the ureter and bladder may be localized or diffuse. Wall thickening or masses with or without calcification may be demonstrated. The diagnosis is made with biopsy.

Endometriosis

Endometriosis occurs when endometrial tissue is found outside the uterus in women during the reproductive years. Patients typically present with pain, infertility, dysmenorrhea, and dyspareunia. Approximately 1% of women with pelvic endometriosis will have urinary tract involvement, most frequently in the bladder. Patients with bladder endometriosis will present with hematuria. Bladder endometriosis may be focal or diffuse. Less often the ureter and rarely the kidney are affected. At sonography, patients with bladder endometriosis may present with a mural or intraluminal cyst or a complex or solid lesion. Diagnosis is usually made cystoscopically with biopsy (Fig. 9.89).

Interstitial Cystitis

Interstitial cystitis is a chronic inflammation of the bladder wall of unknown origin. It usually affects middle-aged women and has been associated with other systemic diseases, including systemic lupus erythematosus, rheumatoid arthritis, and polyarteritis.[75] Irritative voiding symptoms predominate, and hematuria (30%) may occur.[294] At sonography, a small-capacity, thick-walled bladder is seen (Fig. 9.90). Ureteric obstruction may be present. In some cases it is impossible to differentiate interstitial cystitis from diffuse TCC of the bladder; patients should have cystoscopy with biopsy for confirmation.

NEUROGENIC BLADDER

Voiding is a well-coordinated neurologic process controlled by areas within the cerebral cortex. These areas control the detrusor muscle of the bladder as well as both the internal and the external urethral sphincter. For simplicity, lesions causing neurogenic bladder are divided into those causing either detrusor **areflexia** (a lower motor neuron lesion) or detrusor **hyperreflexia** (lesions above the sacral reflux arc).

At sonography, detrusor areflexia results in a smooth, large-capacity, thin-walled bladder. The bladder may extend high into the abdomen (Fig. 9.91A). Detrusor hyperreflexia produces a thick-walled, vertical, trabeculated bladder, often with associated upper tract dilatation (Fig. 9.91B and C). A large, postvoid residual will be seen.[295] If neurogenic bladder dysfunction is not properly

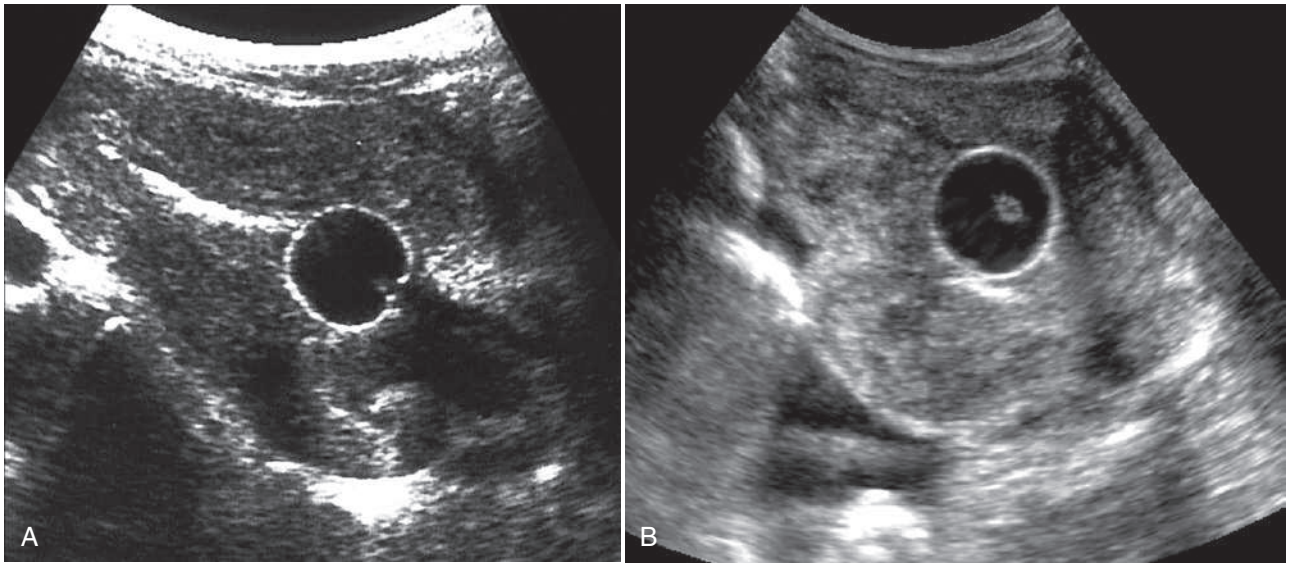

FIG. 9.90 Diffuse Bladder Wall Thickening. Two patients presenting with urinary retention. **(A)** Interstitial cystitis. **(B)** Diffuse transitional cell carcinoma in second patient. Both sonograms show marked circumferential bladder wall thickening after Foley catheterization. Cystoscopy and biopsy are required for differentiation.

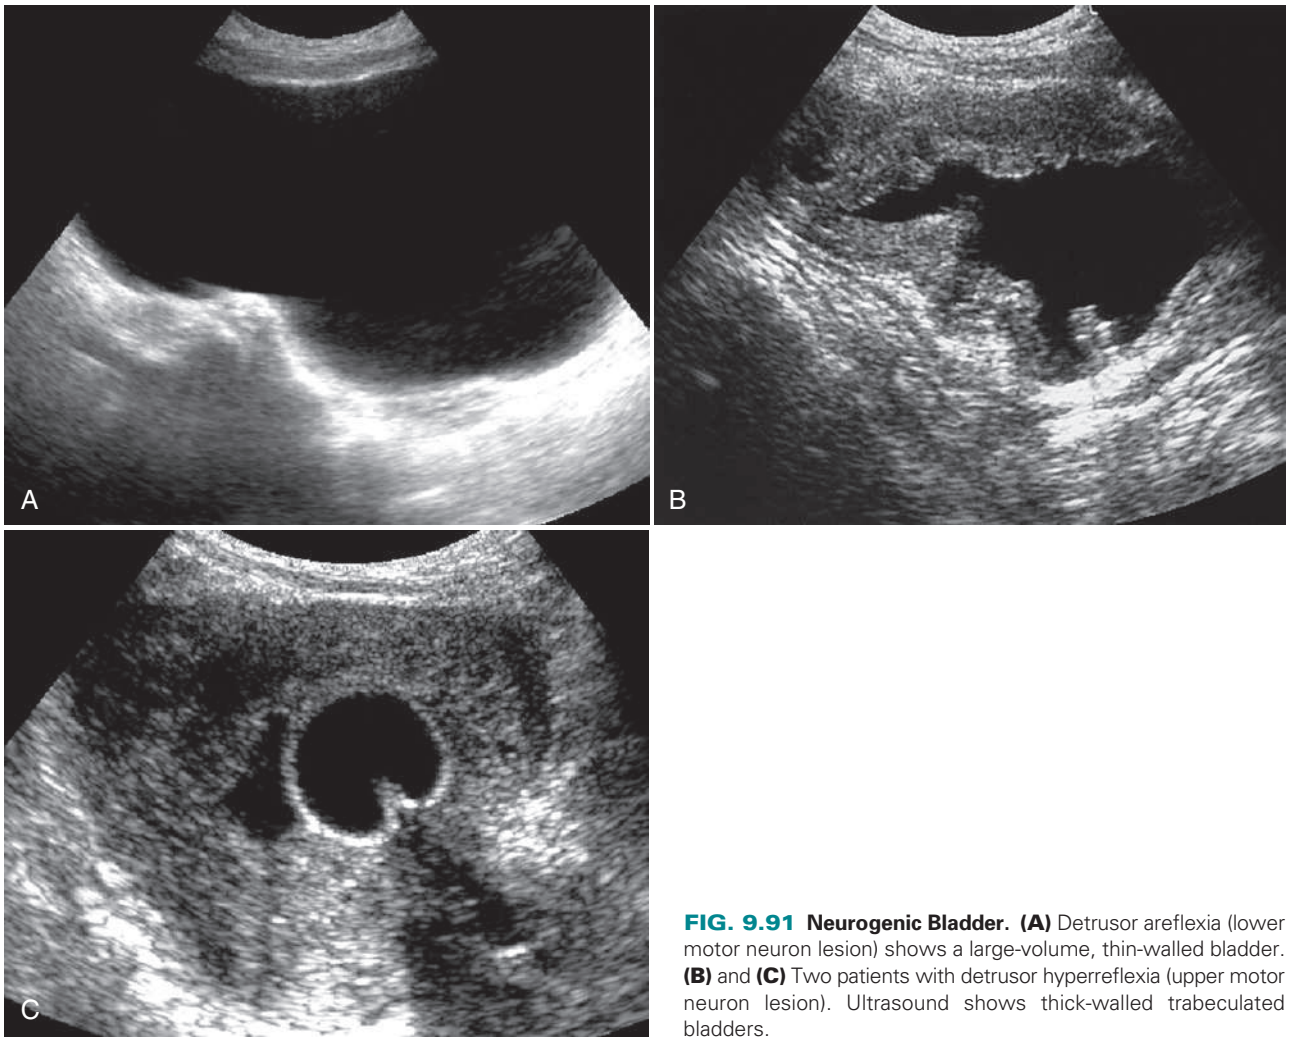

FIG. 9.91 Neurogenic Bladder. (A) Detrusor areflexia (lower motor neuron lesion) shows a large-volume, thin-walled bladder. **(B)** and **(C)** Two patients with detrusor hyperreflexia (upper motor neuron lesion). Ultrasound shows thick-walled trabeculated bladders.

diagnosed and treated, rapid deterioration of renal function may occur.

BLADDER DIVERTICULA

Bladder diverticula may be congenital or acquired. Congenital diverticula are known as **Hutch diverticula** and are located near the ureteral orifice. Most acquired diverticula result from bladder outlet obstruction. Bladder mucosa herniates through weak areas in the wall that are typically located posterolaterally near the ureteral orifices. The diverticular neck may be narrow or wide. It is the narrow-neck diverticula that lead to urinary stasis and give rise to complications, including infection, stones, tumors, and ureteral obstruction. Tumors arising in a diverticulum have a poorer prognosis than tumors arising within the bladder. Diverticula are composed only of mucosa and submucosa, without the muscularis layer present. Tumors therefore grow and invade much more quickly into the surrounding perivesical fat.

At sonography, diverticula appear as an outpouching sac from the bladder. The internal echogenicity of the diverticulum varies depending on its contents. The neck is often easily appreciated (Fig. 9.92, Video 9.4). Urine may be seen flowing into and out of the diverticulum.

POSTSURGICAL EVALUATION

Nephrectomy

Vascularized retroperitoneal fat is often placed with partial nephrectomy defects. The fat may simulate a renal mass at both CT and ultrasound. At sonography, the mass may be hyperechoic or isoechoic.[296,297] Surgical history correlation and an awareness

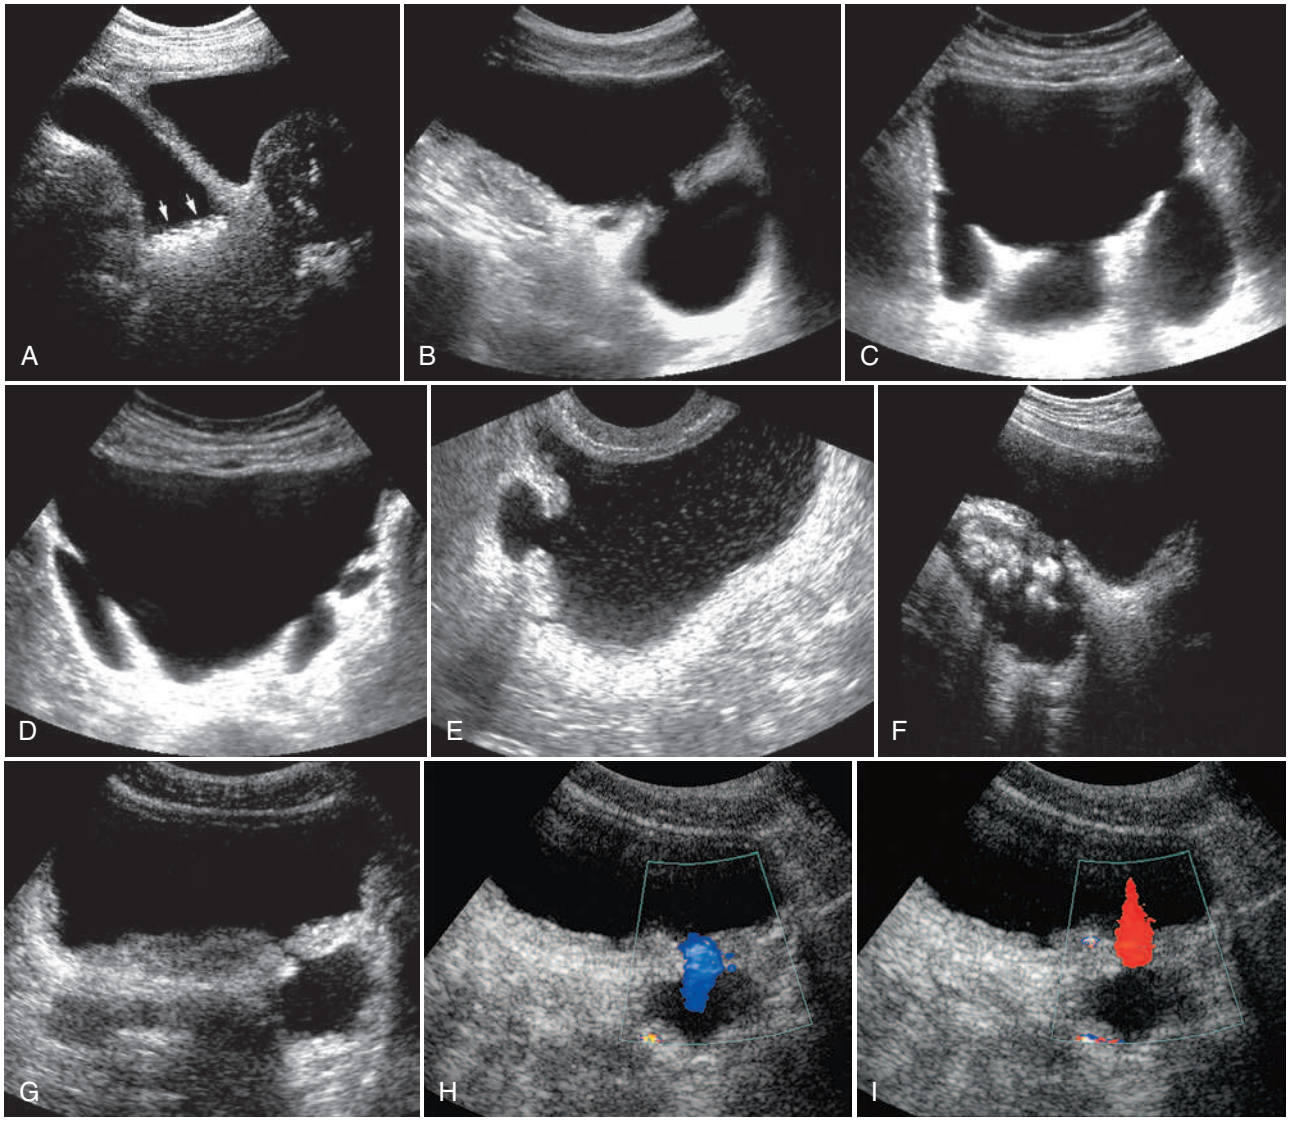

FIG. 9.92 Bladder Diverticula: Imaging Spectrum. (A) Large bladder diverticulum containing multiple calculi *(arrows)*. **(B)** Posterolateral Hutch diverticulum. **(C)** Multiple wide-neck diverticula. **(D)** Multiple diverticula of varying size. **(E)** Transvaginal sonogram shows an unusual diverticulum in a woman, with debris in the bladder lumen. **(F)** Large transitional cell carcinoma with extensive calcification fills the diverticulum. **(G)-(I)** Patient with a narrow-neck diverticulum. **(H)** and **(I)** Urine flow into and out of the diverticulum. See also Video 9.4.

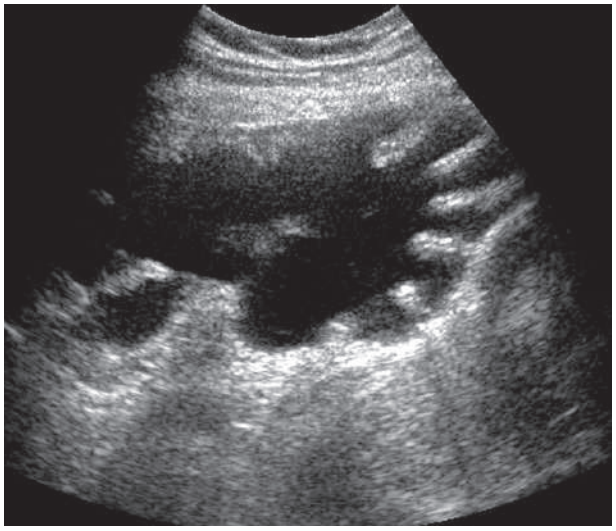

FIG. 9.93 Ileal Conduit (Urinary Diversion). Ultrasound image of the conduit may show gut wall signature and variable filling.

of this potential mimic should obviate additional, unnecessary imaging evaluation.

Urinary Diversion

Urinary diversions, or **ileal conduits,** are constructed for patients with nonfunctioning bladders or for postcystectomy patients. A portion of bowel is used to create a pouch that can mimic normal bladder function. The pouch may attach to the abdominal wall (cutaneous pouch) or urethra (orthotopic pouch). Postoperative complications are similar for both and include urine extravasation, reflux, fistula formation, abscess, urinoma, hematoma, deep vein thrombosis, ileus, and small bowel obstruction. The role of sonography is for detecting complications rather than for evaluating the pouch itself. If the pouch is urine filled, sonographic assessment is possible (Fig. 9.93). Often, thickened or irregularly shaped bowel wall, pseudomasses, intraluminal mucus collections, and intussuscepted bowel segments can be seen.[298] Stone formation in a pouch may occur.

CONCLUSION

Sonography plays a central role in the evaluation of renal, ureteral, and bladder anatomy and disease processes. The ability of ultrasound to identify and characterize genitourinary disease is an ongoing imaging success story.

Acknowledgment

The authors would like to thank Dr. Jenny Tomashpolskaya for her wonderful illustrations.

CHAPTER 10

The Prostate and Transrectal Ultrasound

Ants Toi

SUMMARY OF KEY POINTS

- Prostate cancer is a significant health problem and its management is changing rapidly.
- Currently, transrectal ultrasound (TRUS) with biopsy is the primary modality to diagnose prostate cancer.
- New modalities including multiparametric magnetic resonance imaging and biomarkers are being introduced for prostate cancer assessment.
- Understanding of prostate cancer has evolved with recognition of aggressive and indolent forms, which are managed differently.
- Screening for prostate cancer has become controversial, and population screening is being replaced by focused "smart screening."
- TRUS has applications in assessment of nonmalignant prostate conditions and assessment of nonprostate abnormalities within the field of view of the transrectal probe.

CONCLUSIONS

In the early 1980s **transrectal ultrasound** (TRUS) of the prostate was believed to be the pivotal imaging test of the prostate for benign conditions (e.g., benign hyperplasia, obstructive infertility) and for cancer evaluation, including screening, diagnosis, biopsy, staging, and monitoring of response to therapy. With experience and emergence of new techniques such as multiparametric magnetic resonance imaging (mpMRI), the uses, strengths, and limitations of TRUS and other newer prostate imaging modalities such as elastography, contrast-enhanced ultrasound (CEUS) including targeted microbubbles, and scintigraphy have become better defined.[1-6] Most current referrals for TRUS relate to prostate cancer evaluation, biopsy, and guidance of therapeutic procedures. TRUS was initially considered a primary screening test for prostate cancer. This role has now been replaced by prostate-specific antigen (PSA) and digital rectal examination (DRE).[7,8] Currently the understanding of prostate cancer is undergoing rapid changes in every aspect including screening, serum and urine tests, diagnosis, management, pathology, staging, and therapy. New

approaches are being proposed almost monthly. There is even discussion that the most commonly detected low-grade Gleason score 3 + 3 = 6 cancer may not behave as a significant malignancy that needs active and immediate treatment.[9,10] mpMRI is assuming an increasing role for detection of clinically significant prostate cancer, biopsy guidance, staging, and guidance of therapy. Its availability, applications, and interpretation are evolving rapidly. Additional modalities including new biomarkers, scintigraphic imaging, positron emission tomography (PET)–computed tomography (CT) and PET–magnetic resonance imaging (MRI), and labeled metabolic tracers are being introduced.[6]

Occasional patient referrals for prostate examination relate to urinary dysfunction, infertility, pelvic pain, and prostatitis. TRUS guidance has also proven useful to assess and perform biopsy on any accessible lesion in the pelvis in both men and women.[1,11]

ANATOMY

Zonal Anatomy

Original textbook anatomic descriptions of the prostate referred to **lobar anatomy,** describing anterior, posterior, lateral, and median lobes; this designation has not been useful in identification and evaluation of carcinoma of the prostate.[3,12] Detailed anatomic dissections of the prostate reveal **zonal anatomy** in which the prostate is divided into the four glandular zones surrounding the prostatic urethra (Fig. 10.1):

- Peripheral zone
- Transition zone
- Central zone
- Anterior fibromuscular zone

These zones have differing embryologic origins and disease susceptibilities. In the normal young gland, sonography can rarely identify these zones separately unless a pathologic condition is present (Figs. 10.2 and 10.3). At sonography it is helpful to consider the prostate as having a peripheral or outer gland (peripheral zone plus central zone) and inner gland (transition zone plus anterior fibromuscular stroma plus internal urethral sphincter).[3,13-15]

The prostate does not have a true anatomic capsule, but it is surrounded by an outer fibromuscular band that is visible as a clear line demarking the prostate from the surrounding fat but that becomes blurred at the posterolateral margins at sites of entry of the neurovascular bundles.[3,16]

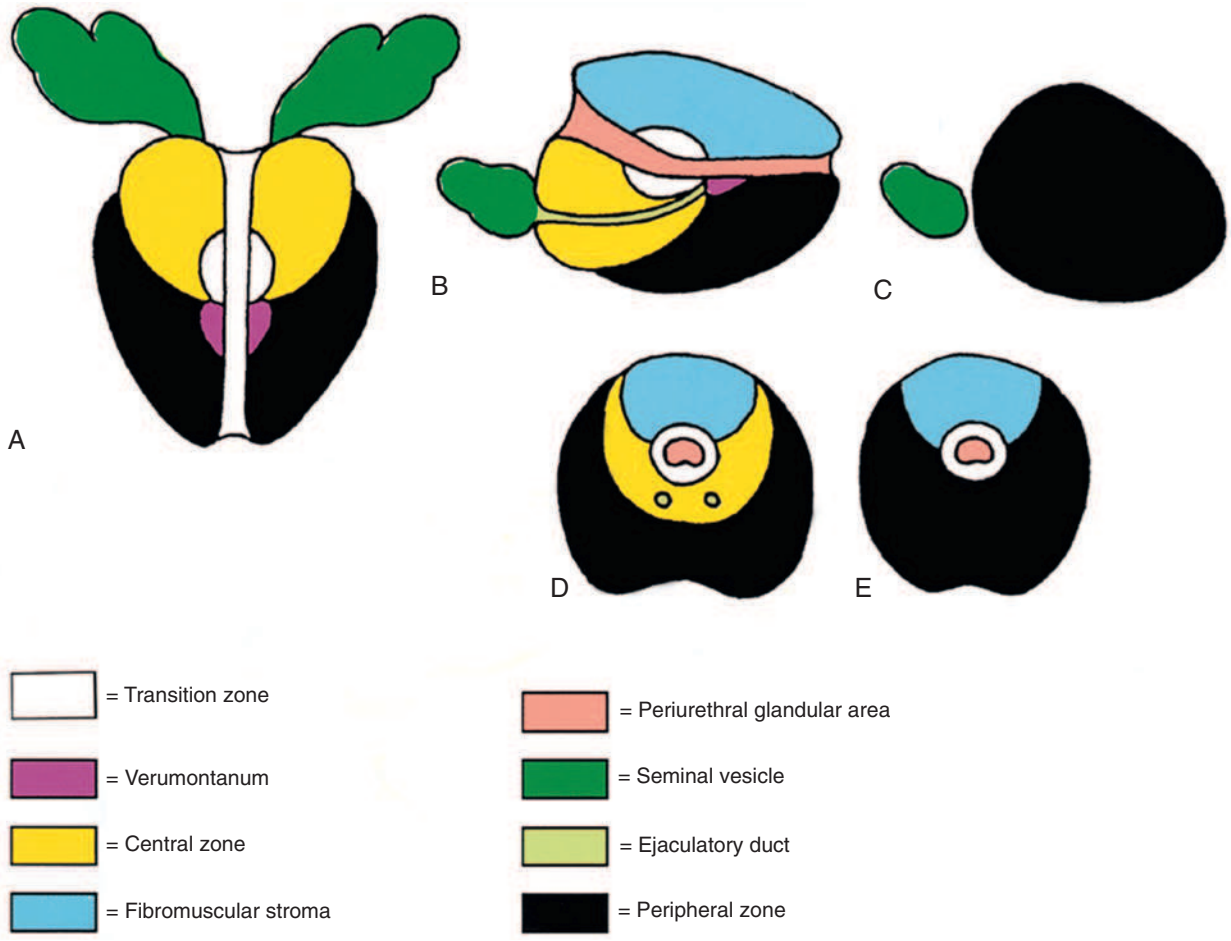

FIG. 10.1 Diagram of Prostate Zonal Anatomy. This is the anatomy in a young man because the transition zone *(white areas)* is small. The transition zone will undergo marked enlargement in older men with benign prostatic hyperplasia. **(A)** Coronal section at midprostate level. **(B)** Sagittal midline section. **(C)** Parasagittal section. **(D)** Axial section through base. **(E)** Axial section through apex.

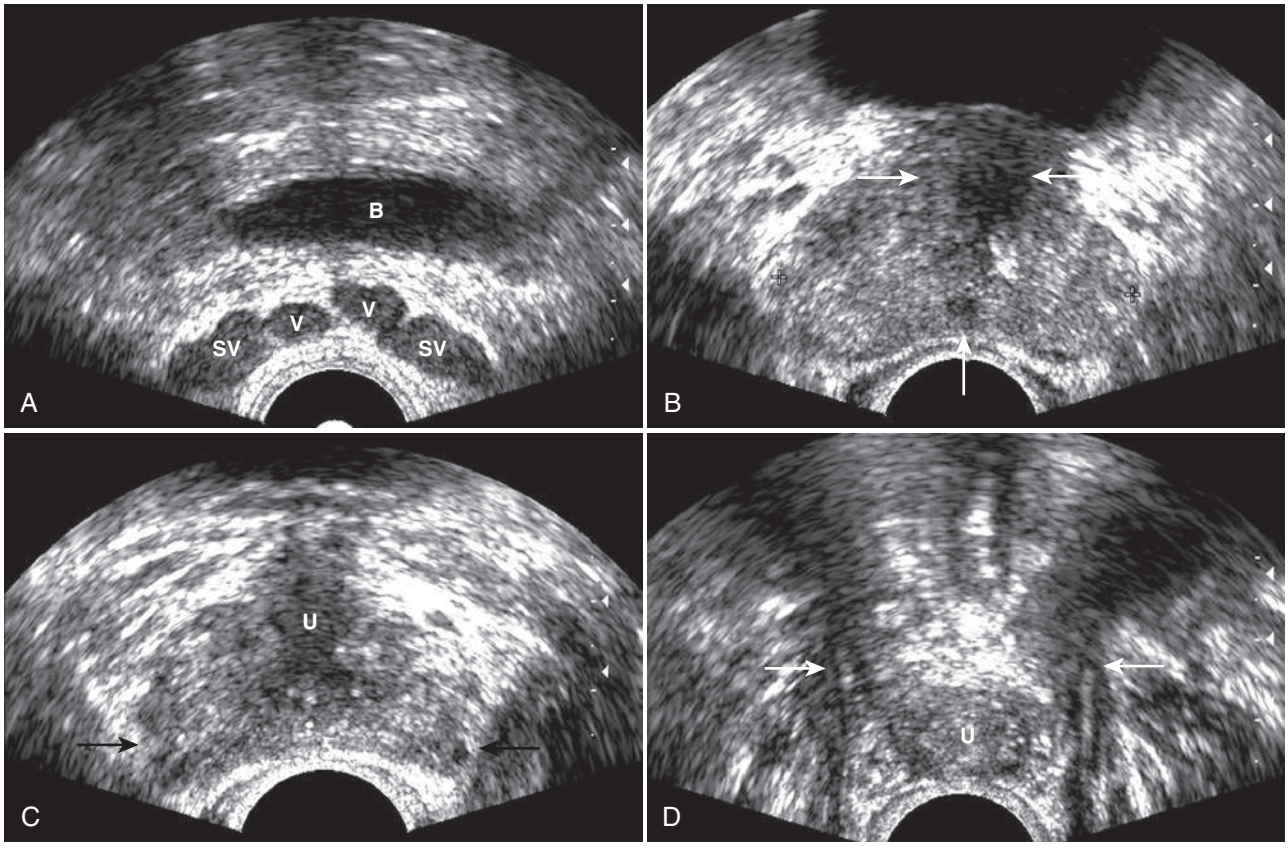

FIG. 10.2 Axial Sonograms of Prostate. (A) Transverse image above base shows the seminal vesicles *(SV)* and vas deferens *(V)*. **(B)** Axial scan at midgland level. Note the normal hypoechoic muscular internal urethral sphincter *(horizontal arrows)* and the ejaculatory ducts *(vertical arrow)*. **(C)** Axial scan at lower third of prostate shows hypoechoic urethra *(U)*. Most of the visible gland at this level is peripheral zone. Note the irregular outline at the posterolateral aspects *(arrows),* resulting from the entrance of the neurovascular bundles. **(D)** Axial scan just below apex of prostate shows cross section of distal urethra *(U)*. Pelvic sling muscles are visible *(arrows). B,* Bladder.

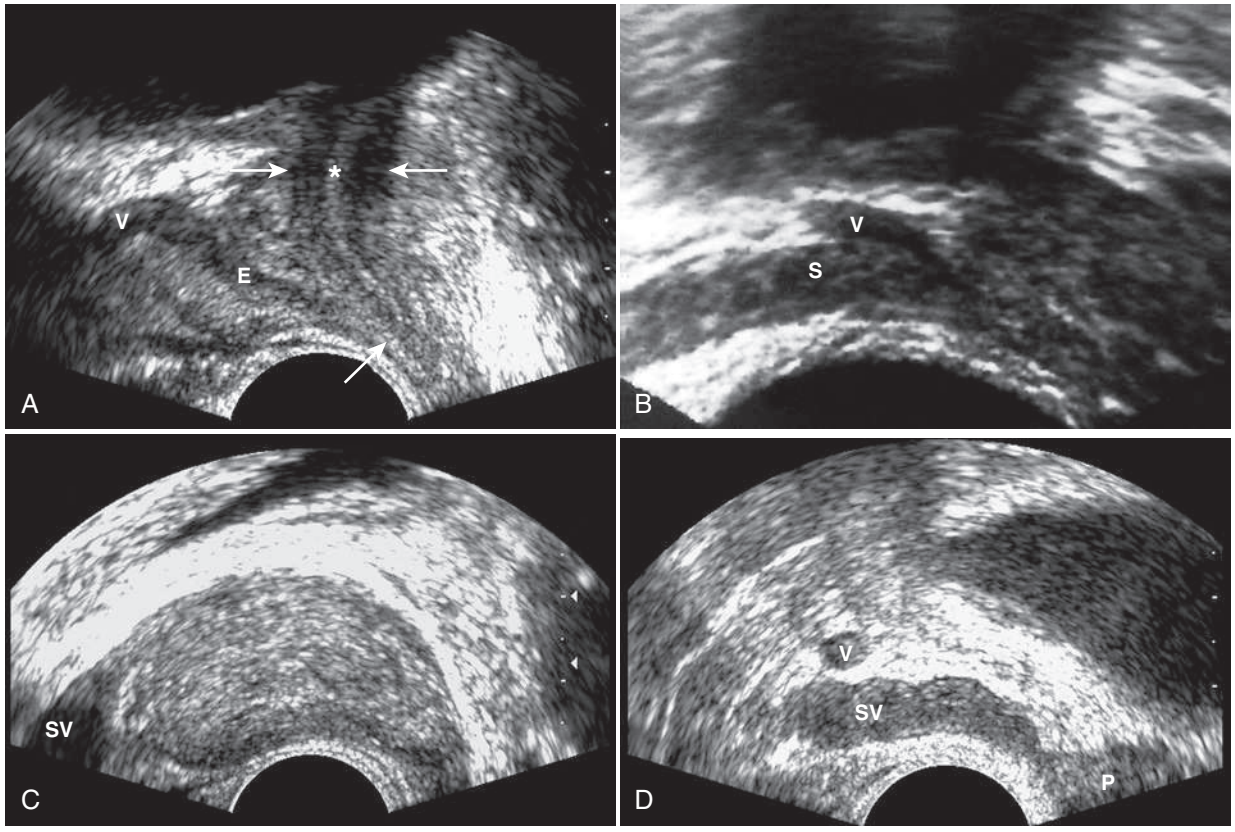

FIG. 10.3 Sagittal Views of Prostate. (A) Midsagittal view shows internal urethral sphincter *(white arrows),* which contains the echogenic collapsed urethra (*). The ejaculatory ducts *(E)* course from the vas deferens *(V)* to the verumontanum *(oblique arrow)*. **(B)** Midsagittal view at base shows the vas deferens *(V)* and adjacent seminal vesicles *(S)* as they enter the prostate. **(C)** Parasagittal view shows the lateral prostate, which is homogeneous and isoechoic and composed almost totally of peripheral zone tissue. **(D)** Parasagittal view above the prostate shows the normal seminal vesicles *(SV)* and vas deferens *(V)* in cross section above the prostate *(P). SV,* Seminal vesicle.

The **peripheral zone,** the largest of the glandular zones, arises from the urogenital sinus and in a young man before the onset of **benign prostatic hyperplasia** (BPH) contains approximately 70% of the prostatic glandular tissue and is the site for about 70% of prostate cancers.[17,18] It is separated from the **transition zone** and central zone by the **surgical capsule,** a hypoechoic line that is rendered hyperechoic by the frequent accumulation of corpora amylacea or calcifications along it. Traditionally, urologists at the time of suprapubic or transurethral prostate resection believed that they dissected to this line, which demarked hypertrophied periurethral glands from posterior lobe—hence "surgical" capsule. The peripheral zone occupies the posterior, lateral, and apical regions of the prostate, extending anteriorly around the margins, like an egg cup holding the "egg" of the central gland (Fig. 10.4A).

The young **transition zone** contains about 5% of the prostatic glandular tissue. It is visible as two small glandular areas positioned like saddlebags adjacent to the proximal urethral sphincter, which is a muscular tube up to 2 cm in diameter. It is the site of origin of most BPH and about 20% of prostate cancers.[17,19]

The **central zone** along with the seminal vesicles (SVs) arises from the wolffian ducts. It constitutes approximately 25% of the glandular tissue and is wedged at the prostate base between the peripheral and transition zones. The ducts of the vas deferens (VD) and SVs enter the base of the prostate at the central zone, where they are renamed the **ejaculatory ducts** and pass through it en route to the **verumontanum.** The central zone is relatively resistant to disease processes and is the site of only about 5% of prostate cancer.[17-19]

At the base of the prostate at the bladder neck is the thick, muscular, continence-providing, **internal urethral sphincter.** Its substantial homogeneous muscle content can make it appear hypoechoic. It contains periurethral glands that often contain calcifications.[12,13,19]

Vascular and Neural Structures

The prostate is supplied by the prostaticovesical arteries, which arise from the internal iliac arteries on each side and give rise to the prostatic artery and inferior vesical artery. The **prostatic artery** gives rise to the urethral and capsular arteries. The **inferior vesical artery** supplies the bladder base, SVs, and ureter. The urethral artery supplies about one-third of the prostate, and the capsular branches supply the remainder.[20]

On Doppler ultrasound the prostate is mildly to moderately vascular. The neurovascular bundles are visible at the posterolateral angles (Fig. 10.5). The capsular and urethral arteries are easily seen, and branches to the inner gland and peripheral zone are visible in a somewhat radial pattern with the periurethral vessels as the axle. A dense cluster of vessels is often seen capping the base of the prostate, and care must be taken not to mistake these for tumor vascularity.[20]

Nerve supply to the prostate has been clarified.[15,21,22] Parasympathetic supply is through the S2-S4 sacral roots, and sympathetic supply is through the hypogastric nerve. These combine in the pelvic plexus just above and lateral to the prostate and give rise to about 6 to 16 small branches that supply the SVs, prostate, levator ani, and corpora cavernosa. The cavernosal branches are responsible for erections. The nerves and blood vessels travel together as the neurovascular bundle in the Denonvilliers (rectoprostatic) fascia at the posterolateral aspect of the prostate, where the vessels are visible with color flow Doppler ultrasound. These nerves are vulnerable to injury during surgery, radiotherapy, and other interventions and are avoided at nerve-sparing prostatectomy to preserve potency.[15,21,22]

SONOGRAPHIC APPEARANCE

Images are oriented using the standards for abdominal sonography and other cross-sectional imaging modalities. The images are displayed as though one were standing at the feet of a supine patient and looking headward. The rectum is at the bottom of the screen; the right prostate is on the left of the screen. On sagittal views, the base (head end) is on the left side.

On axial ultrasound, above the prostatic base, the **seminal vesicles** are paired, relatively hypoechoic, multiseptated structures cephalad to the base of the prostate normally measuring about 1 cm diameter (see Fig. 10.2A). The adjacent vasa deferentia are visible as uniform muscular tubes measuring about 6 mm in diameter coursing from the internal inguinal ring to lie beside the SVs and enter the midbase of the prostate, where they become the **ejaculatory ducts,** which connect to the **verumontanum** (seminal colliculus).

In the axial plane, the urethra between the bladder neck and verumontanum and its surrounding smooth muscle, the internal sphincter, can be a quite conspicuous hypoechoic structure measuring 2 cm in diameter that can mimic the appearance of a transurethral resection defect (see Figs. 10.2B and 10.3A). Those unfamiliar with transrectal and pelvic ultrasound may mistake the sphincter for hypoechoic tumor. The muscular sphincter ends at the verumontanum, which forms a small bulge pointed anteriorly, often with a small, conspicuous calcification at its apex, giving it an Eiffel Tower appearance.

The inner transition zone is separated from the peripheral zone by the usually hypoechoic surgical capsule (see Fig. 10.4A). This line is less visible in young men but becomes conspicuous as BPH enlarges the transition zone (see Figs. 10.2B and 10.4A). The peripheral zone has a uniform, homogeneous texture and is slightly more echogenic than the transition zone. Peripheral zone echogenicity is defined as **isoechoic** and taken as the standard for prostate echogenicity and other areas of the gland are compared to its echogenicity. Laterally, the peripheral zone curves anteriorly to enclose the transition zone. This upward curved part was named the "anterior horns" by Babaian from Texas because it resembled the horns of a steer. Prominent veins of Batson venous plexus are visible in the periprostatic fat, sometimes containing calcified shadowing phleboliths.[12]

On midsagittal view the muscular internal urethral sphincter extends from the bladder to the verumontanum, sometimes surrounded by corpora amylacea in the periurethral glands (see Fig. 10.3A). The anterior fibromuscular zone is an inconspicuous area anterior to the internal sphincter. At the verumontanum the distal urethra angles slightly anteriorly and ultimately exits the apex of the prostate just before it enters the urogenital

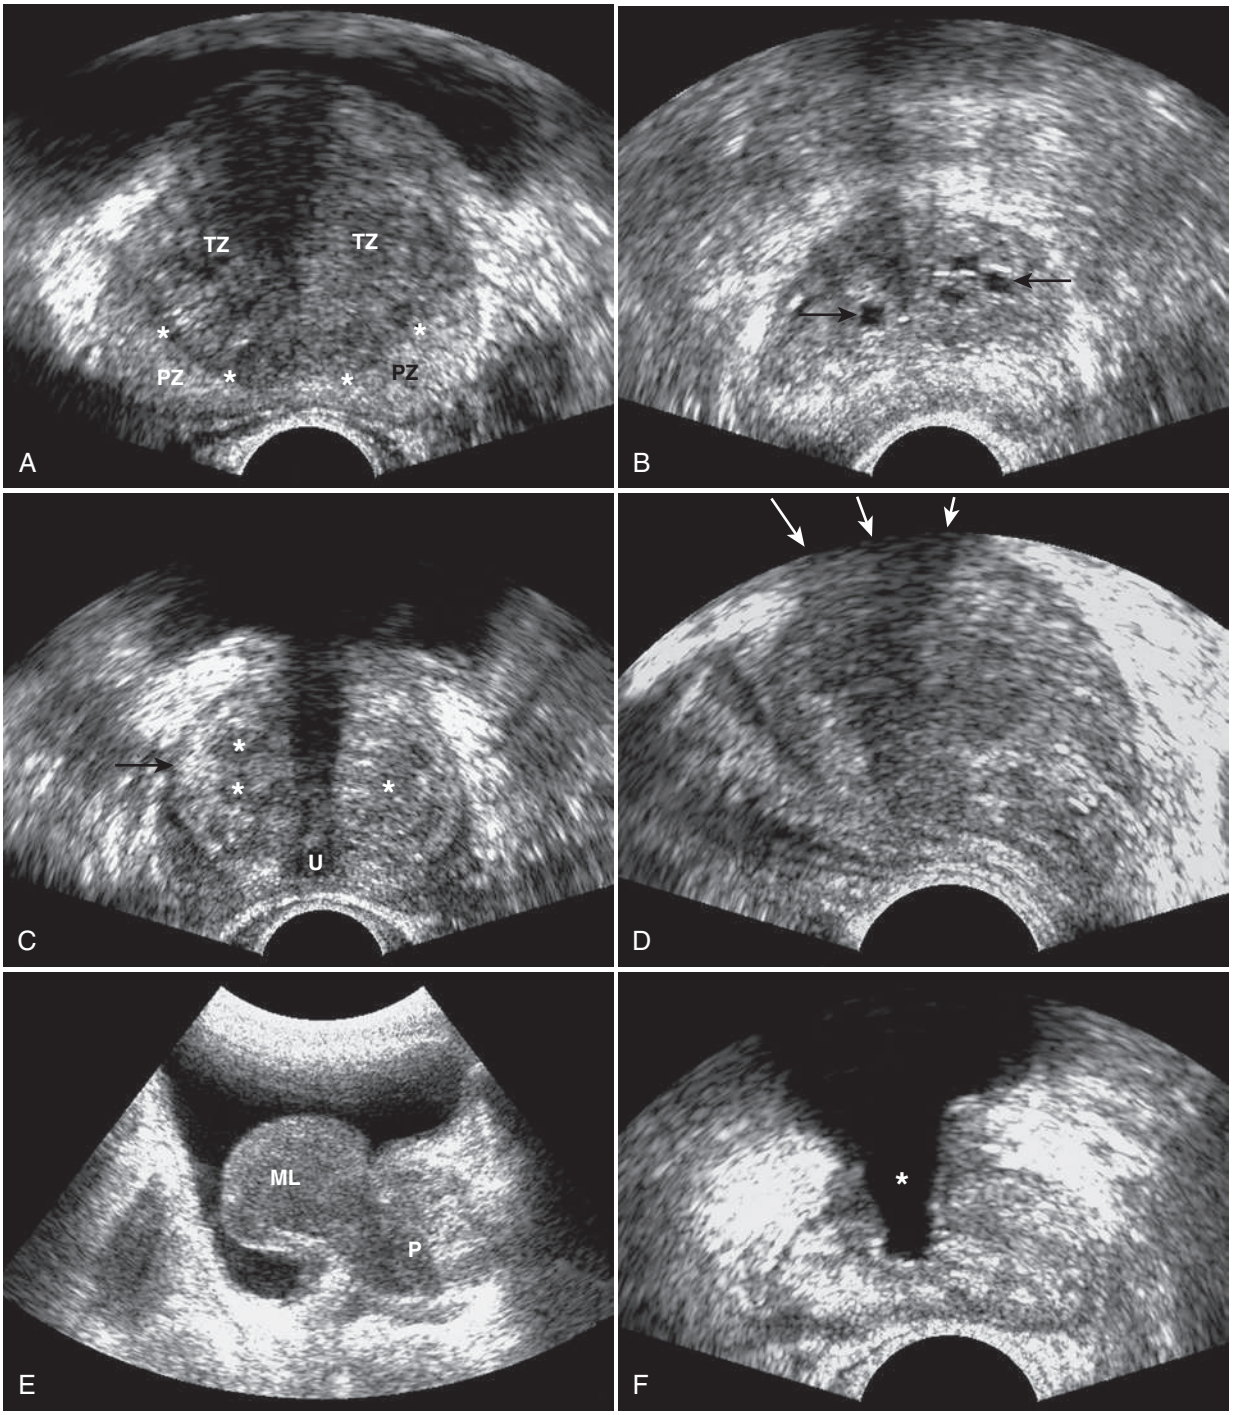

FIG. 10.4 Benign Prostatic Hyperplasia (BPH). (A) Axial view shows the greatly enlarged, slightly hypoechoic transition zone *(TZ)*, which compresses the more echogenic peripheral zone *(PZ)*. Their interface is the surgical capsule (*). The region inside the surgical capsule (transition zone) is also called the "inner gland" and the region outside the surgical capsule, the "outer gland," which is composed of peripheral zone plus central zone. (Peripheral zone is the "egg cup" holding the "egg" of the central gland.) **(B)** Benign degenerative cysts in the transition zone *(arrows)*. These have no clinical significance. The transition zone can become acoustically very heterogeneous, making cancer diagnosis difficult. **(C)** Heterogeneous nature of hyperplasia in the transition zone. Both hyperechoic *(black arrow)* and hypoechoic (*) areas are present. *U,* Urethra. **(D)** Sagittal view shows pitfall in transrectal ultrasound (TRUS) of BPH. If the field of view is not deep enough *(arrows),* prominent median lobe enlargement may be cut off and may escape detection. **(E)** Transvesical midsagittal scan shows obvious massive enlargement of the median lobe *(ML)* protruding into the bladder. Evaluation for symptoms of prostatism is better done transvesically than transrectally with TRUS. *P,* Prostate. **(F)** Axial view of typical transurethral resection of prostate (TURP) surgical defect (*).

diaphragm, which is the external urethral sphincter. In the midplane the ejaculatory ducts (see Fig. 10.3A) are visible as hypoechoic tracts extending from the VD at the base to the centrally located verumontanum.

Parasagittally with hyperplasia, the anterior hyperplastic transition zone can be seen separated from the posteriorly situated peripheral zone by the surgical capsule. The VD and SVs are visible above the base. Still more laterally, the transition zone ends, leaving only the part of the peripheral zone curving anteriorly at the sides of the gland (anterior horns).[12]

Histologically, the prostate does not have a true membranous capsule but is surrounded by condensed connective tissue through which the vessels and nerves course. On transverse and sagittal imaging, the border appears sharply defined except at the posterolateral margins where the neurovascular bundle enters the prostate and makes the margin look ragged. This can hinder determination of extracapsular extension by tumors[3,16] (see Fig. 10.2C).

EQUIPMENT AND TECHNIQUE

Most modern ultrasound machines can be equipped with **transrectal probes** and biopsy guides suitable for examination of the prostate and rectum. It is advantageous to use the thinnest probe to negotiate "tight" anal sphincters. End-fire probes (Fig. 10.6) are suitable for most biopsy applications and allow for multiplanar imaging in transverse and axial projections. They are well suited for biopsy guidance, allowing easy access to all prostate regions including the apex and anterior gland. The current

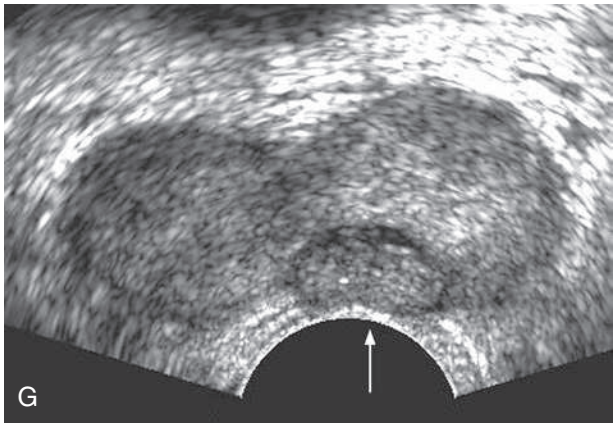

FIG. 10.4 cont'd (G) Benign peripheral zone hyperplastic nodule. Transverse image shows prominent isoechoic posterior nodule that bulges the capsule and has a well-defined hypoechoic rim *(arrow)*. It resembles BPH nodules, which are normally seen in the transition zone, but it is located in the peripheral zone. At palpation these feel hard and can be mistaken for cancer. Biopsy is needed for reassurance to confirm their benign nature. *P,* Prostate; *U,* urethra.

FIG. 10.6 Typical End-Fire Ultrasound Probe for Transrectal and Intracavitary Work. Active element is at tip of probe, and needle in guide fires parallel to probe (end-fire). In clinical use the probe and guide would be covered by protective sheaths.

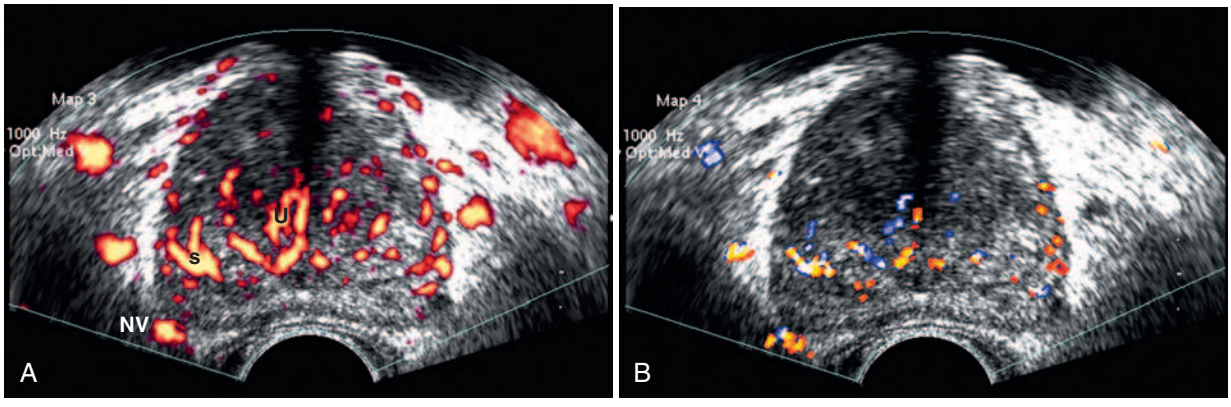

FIG. 10.5 Normal Doppler Ultrasound Anatomy in Patient With Moderate Benign Prostatic Hyperplasia (BPH). (A) Axial view with power Doppler ultrasound shows the urethral vessels *(U)*, some vessels along the surgical capsule *(S)*, and the neurovascular bundle *(NV)* on one side. This is an average degree of vascularity. Note the large vessels, mostly veins, outside the prostate. Care must be taken when biopsy is performed outside the prostate to avoid injury to these vessels. **(B)** Color Doppler flow imaging is more difficult to interpret owing to different colors related to flow direction.

trends emphasize high central frequency (8-10 MHz) and broad bandwidth. This increases spatial resolution but may decrease lesion conspicuity. Probes with a center frequency of about 5 MHz appear to provide a good balance between resolution and tissue/cancer contrast.[23]

Probes should be covered with sheaths or condoms during the examination and sterilized between patients, following manufacturers' recommendations. Linear probes help with transperineal techniques.[24]

In general, **rectal cleansing** is done before the scan. A self-administered rectal enema is preferred, but laxatives can be used. Some believe enemas decrease infectious complications of biopsy.[25,26] A **digital rectal examination** before probe insertion is performed to ensure that there are no rectal abnormalities to interfere with safe probe insertion and to correlate images with palpable abnormalities. The patient usually lies in a **left lateral decubitus** position for the scan. Some examiners prefer a lithotomy position, particularly if the examination is done in conjunction with other urologic procedures or transperineal interventions. With use of adequate lubrication, the probe is gently inserted into the rectum. To decrease discomfort, viscous lidocaine (Xylocaine) gel can be used as the lubricant in patients with tight sphincters or anal pathology such as fissures or inflamed hemorrhoids.

A **systematic approach** works best for examination and helps ensure that the whole gland is assessed. Typically the prostate is scanned and appropriate images are taken, first in gray scale starting in the transverse plane, from the SVs and proceeding to the apex, and then in the sagittal plane, from right to left lobe. Subsequently the scan is repeated with Doppler flow ultrasound imaging in the transverse plane to evaluate vascularity and vascular symmetry.

Measurements are taken as follows: maximal transverse width (W; right to left), anteroposterior plane (AP; anterior midline to rectal surface), length (L; maximal head to foot). **Prostate volume** is usually calculated with the "oblate spheroid" formula: volume = $0.5236 \times (W \times AP \times L)$. Volume measurement is only moderately repeatable to within 10%. Prostate volume can be converted to **prostate weight** because the specific gravity of prostate tissue is about 1; thus 1 cc (mL) is equivalent to 1 g.

Color or power Doppler ultrasound is used routinely when searching for cancer. Vessel density is more easily evaluated with **power Doppler,** which portrays color more evenly and is three to five times more sensitive than the color Doppler. Cancer detection is increased by about 5% to 10% with use of power Doppler, and vascular lesions have a slightly higher Gleason score (5.9% vs. 6.9%).[27,28] Overall it is still felt that although vascular density as shown by Doppler increases cancer detection, its absence is not sensitive enough to avoid systematic biopsy. Increased vascularity is not specific and can be seen with hypertrophy or inflammation, as well as cancer.[27,28] Spectral Doppler indices (such as resistive index [RI], pulsatility index [PI], and peak systolic velocity) vary with patient age and cannot differentiate between cancer and benign prostate conditions.[29] A pitfall of Doppler ultrasound is the normal, high vascular density seen capping the base of the left and right lobes, which should not be mistaken for enhanced vascularity seen with tumors.

BENIGN CONDITIONS

Normal Variants

Benign ductal ectasia is seen in older men who develop atrophy and dilation of peripheral prostatic ducts and has no clinical significance. The ducts appear as single or grouped, 1- to 2-mm-diameter tubular structures in the peripheral zone radiating from the capsule toward the urethra. Clusters of these can form hypoechoic areas that could be mistaken as prostate cancer (Fig. 10.7).

Prostatic calcifications and **corpora amylacea** are normal findings visible as bright echogenic foci or clumps consisting of proteinaceous debris in dilated prostatic ducts, most often in periurethral glands and along the surgical capsule. When densely clustered they can attenuate sound and block anterior visibility, and on Doppler they create a prominent "twinkle" artifact (see Fig. 10.7D). Subclinical infections, inflammation, and atrophy may contribute to their formation. Corpora amylacea have no clinical significance and are not usually palpable even if dense or clumped. Peripheral zone calcifications should not be accepted as a cause for palpable firmness or nodules. Patients with palpable abnormality need further evaluation, frequently with biopsy.

Benign Prostatic Hyperplasia

Prostate enlargement with **benign prostatic hypertrophy** (BPH) is a common cause of **lower urinary tract symptoms** (LUTS) in older men and affects about 50% of men older than 60 years and over 90% older than 70. The cause of BPH is unclear but is probably related to hormonal changes with aging and results in hypertrophy and hyperplasia of the fibrous, muscular, and glandular elements, primarily affecting the transition and periurethral zones.[1,19]

Lower urinary tract symptoms, also called **prostatism** and **bladder outlet obstruction,** can relate to increases in prostate size and muscular tone, both causing urethral constriction. Symptoms include frequency, nocturia, weak stream, hesitancy, intermittence, incomplete emptying, and urgency and are quantified using the American Urological Association (AUA) symptom index.[19,30] Many men have a misguided concern about prostate size. The issue is *urinary obstruction,* not prostate size. Prostate size correlates poorly with urinary obstruction. Urinary dysfunction is multifactorial and can also arise from abnormalities of the central nervous system, spine, bladder, prostate, and urethra. Patients with urinary dysfunction need evaluation of all these systems, not just the prostate. Ultrasound investigation of the patient with symptoms of prostatism is best done transvesically to assess prostate size, identify median lobe enlargement, and evaluate bladder volume and postvoid residual, bladder wall character, trabeculation, diverticula, tumors, and calculi, and the kidneys and ureters should be evaluated for hydronephrosis and masses. TRUS plays only a small role but helps if there is a clinical concern for prostate cancer (BPH is one cause for PSA

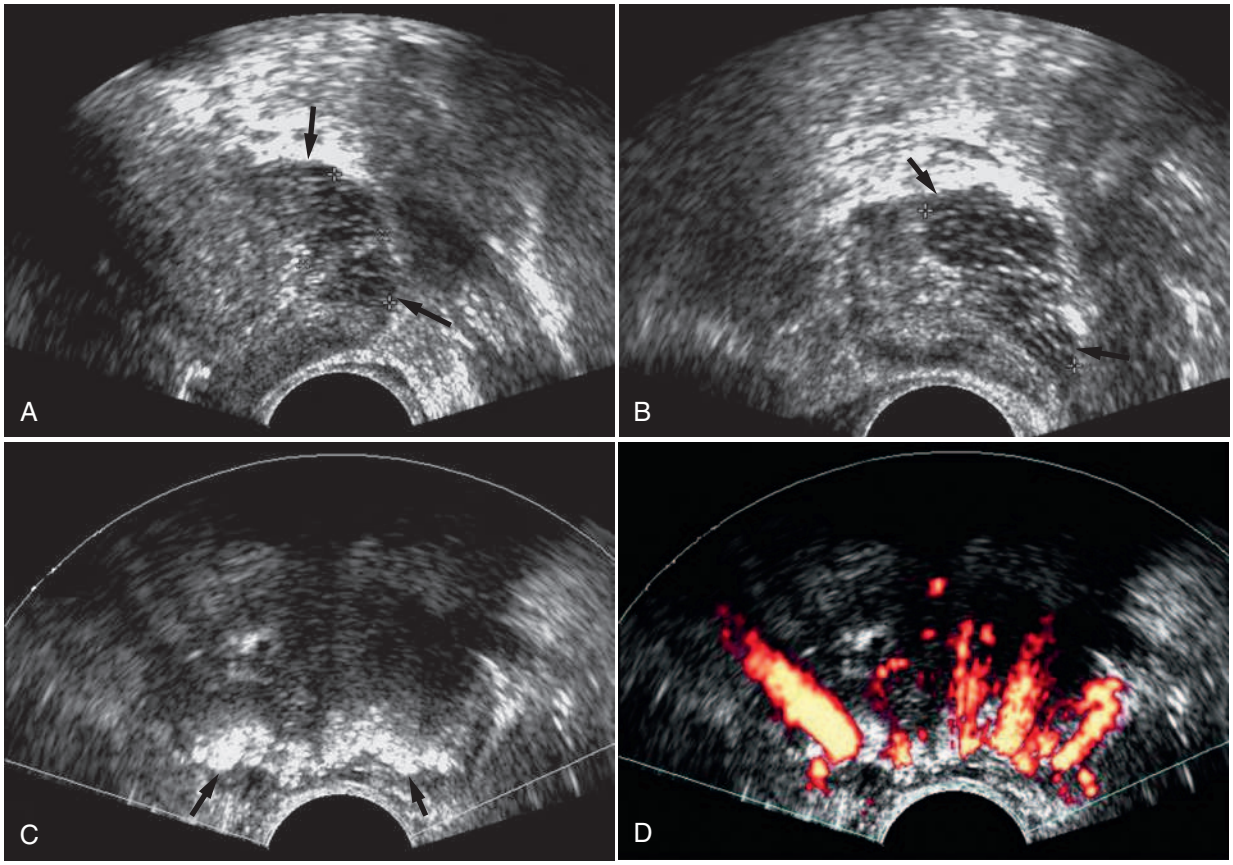

FIG. 10.7 Normal Anatomic Variants. (A) Axial view with benign glandular ectasia *(arrows)* visible as a peripheral hypoechoic area containing multiple radially oriented tubes. This hypoechoic appearance should not be mistaken for cancer. **(B)** Parasagittal view of benign ectatic glands *(arrows)*. **(C)** Axial view shows extensive echogenic material, both calcifications and corpora amylacea *(arrows),* along the surgical capsule and peripheral zone. This has no clinical significance and usually is not palpable. It hinders ultrasonic visibility. **(D)** Doppler examination of same patient shows the extensive Doppler noise artifact caused by the calcifications. Virtually all the visible color is artifactual.

elevation) or there is need for precise gland volume determination to plan surgical or medical treatment.[19]

The appearance of BPH is heterogeneous and depends on underlying histopathologic changes. This heterogeneity hinders cancer detection for both TRUS and mpMRI. Typically there is enlargement of the inner gland **(transition zone)** with hypoechoic, isoechoic, or hyperechoic nodules.[31] The specific echo pattern depends on the admixture of glandular, stromal, and muscular elements and nodules, which may be fibroblastic, fibromuscular, muscular, adenomatous, or fibroadenomatous. Hyperplasia of the periurethral glandular elements results in "median lobe" enlargement manifesting as a bulge into the urinary bladder (see Fig. 10.4E). Calcifications and **degenerative or retention cysts** are common.[31] Benign BPH nodules tend to have distinct margins, whereas transition zone cancer usually manifests as a diffuse, poorly marginated, usually hypoechoic nodule that may cause an asymmetrical bulge of the adjacent anterior contour similar to findings on mpMRI.[32]

Because of the distortion of the gland in patients with BPH, some hyperplastic nodules may bulge into the peripheral zone when they actually originate in the transition zone. Hypoechoic, well-circumscribed transition zone nodules are virtually always benign.[33] Although BPH nodules are generally confined to the transition zone, on occasion they can form entirely within the **peripheral zone,** appearing as an isoechoic nodule with a well-circumscribed halo and often containing a small degenerative cyst and frequently create a prominent bulge at the capsule. They are similar in appearance to BPH nodules seen in the transition zone on TRUS and mpMRI (see Fig. 10.4G). Because these benign, peripheral zone nodules are palpable as a firm or hard, cancer-like nodule, they should undergo biopsy to confirm their benign nature and obviate continuing concern.[34,35]

After exclusion of other systemic causes of the symptoms, such as neurologic disease, diabetes, and local urinary conditions, treatment focuses on the prostate. **Transurethral resection of the prostate** (TURP) is considered the standard of care for many patients, but other treatments can include watchful waiting, medical therapy, minimally invasive therapies, open surgery, and laser therapy.[19,36]

TURP initially leaves a large basal surgical defect that rapidly contracts as the gland collapses into the defect, often surprising unwary urologists who may think they have removed considerably more tissue than the visible defect suggests (see Fig. 10.4F).

Chronic Prostatitis/Chronic Pelvic Pain Syndrome

Understanding of the condition called "prostatitis" has changed over the years. It is not merely "infection in the prostate." Rather, prostatitis refers to a **chronic pain syndrome** in which, surprisingly, infection, inflammation, and even involvement of the prostate are not always present. It is commonly termed **chronic prostatitis/chronic pelvic pain syndrome** (CP/CPPS).[37,38] Prostatitis and pelvic pain complaints encompass many clinical syndromes and can severely affect the quality of life of many men who have chronic pain, sexual dysfunction, and LUTS. Patients and physicians are often frustrated because diagnosis and treatments can be time-consuming and ineffective. The impact of prostatitis on quality of life has been likened to the morbidity of myocardial infarction, angina, or Crohn disease. Interestingly, men with CP/CPPS also have an increased incidence of cardiovascular disease, neurologic disease, sinusitis, anxiety or depression, and sexual dysfunction. Prostatitis can elevate PSA and on mpMRI can mimic cancer, leading to potential unneeded cancer investigations.[32] An estimated 9% to 13% of all men in the 40- to 50-year-old age group are affected. About 25% of visits to urologists are related to prostatitis symptoms. In men younger than 50 years, CP/CPPS is the leading cause of visits to a urologist, and in men older than 50, it is the third most common cause, after BPH and cancer. The lack of public awareness of this condition likely relates to men's general reluctance to discuss "personal" concerns.[37,39]

A consensus group at the National Institutes of Health produced a Chronic Prostatitis Symptom Index (NIH-CPSI) and diagnostic flowcharts to help in diagnosis and characterization of symptom severity.[38,39]

I. Acute bacterial prostatitis
II. Chronic bacterial prostatitis
III. CP/CPPS
    A. Inflammatory
    B. Noninflammatory
IV. Asymptomatic inflammatory prostatitis

Acute bacterial prostatitis is the least common form of prostatitis, seen in about 2 of 10,000 office visits, and 5% to 10% of cases become chronic. Patients have symptoms of acute urinary or systemic infection usually caused by infection with gram-negative organisms such as *Escherichia coli*. TRUS is generally of little use in acute prostatitis and can be very painful. About half of these men have findings including edema, prostate enlargement, increased blood flow, venous engorgement, hypoechoic peripheral halo, and altered patchy echo changes that can be decreased, increased, or both. TRUS and mpMRI findings can mimic neoplasia[40] (Fig. 10.8). The diagnosis is mainly clinical. Symptoms should subside promptly with antibiotic therapy, but treatment is continued for 4 to 6 weeks. If symptoms do not subside quickly, abscess formation should be considered. **Abscesses** occur in 0.5% to 2.5% of patients with acute bacterial prostatitis and are more common in those with underlying diabetes mellitus or immunosuppression (including human immunodeficiency virus [HIV] infection) and after catheterization or instrumentation (see Fig. 10.8E). In such patients, TRUS should be promptly performed for diagnosis. Small abscesses may not need drainage, but larger abscesses over about 1.5 cm in diameter can be easily drained transrectally or transperineally using TRUS guidance, or they can be unroofed at cystoscopy. Experience has shown that simple transrectal aspiration can be effective without need for a drainage catheter. Abscesses have resolved even after a single drainage, but repeat aspiration is easily performed if needed.[40]

Chronic bacterial prostatitis is also uncommon. Patients are typically afebrile but have recurrent episodes of bacterial urinary infection–like symptoms. Most have no ultrasound findings, but during acute episodes this condition may appear similar to acute prostatitis on TRUS and mpMRI. In general, urine cultures are negative but some have gram-negative organisms, most often *E. coli*. Empirically, about half of patients with chronic bacterial prostatitis respond to 6- to 12-week courses of antimicrobial therapy.[40]

Chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) is the most common form of prostatic inflammation. These men have lower genitourinary pain with variable voiding and sexual dysfunction but no evidence of bacterial infection or other cause of pain. CP/CPPS accounts for about 90% of cases and affects about 2 per 100 men. It is the most difficult to understand and treat. CP/CPPS is classified into two types: **inflammatory type** (diagnosed by seeing leukocytes in prostate secretions, urine, or semen) and **noninflammatory type** (no evidence of inflammation; also called **prostatodynia**). The cause is unknown, and the CP/CPPS name takes into account that the prostate may not be the sole source of discomfort. The symptoms, however, are identical to those of true prostate infection. Neurologic factors, psychological factors, stress, and genetic predisposition have been implicated, as well as association with other conditions such as fibromyalgia, irritable bowel syndrome, and chronic fatigue syndrome. No cause is identified in the majority of men with CP/CPPS. Patients may respond to antibiotics, alpha blockers, nonsteroidal antiinflammatory drugs (NSAIDs), and analgesics, which are often used in multimodal fashion.[38,41] In most cases the prostate appears normal on ultrasound. Some sonograms show nonspecific findings such as peripheral hypoechoic areas, calcifications, venous congestion, increased arterial flow, bladder neck thickening, hypoechoic prostatic rim, and periurethral hypogenicity, and on TRUS and mpMRI the findings can mimic neoplasia.[32,38]

Asymptomatic inflammatory prostatitis is diagnosed in men who have no history of genitourinary pain complaints but who are shown to have inflammatory changes at histology. Often biopsy is done because of PSA elevations that are common with prostate inflammation, even with asymptomatic inflammation.[40]

Diagnostic protocols have attempted to differentiate among the various types of prostatitis using history, physical examination, and urine or other cultures.[38,39] An issue for TRUS and biopsy is that many of these men have chronically elevated but often fluctuating PSA levels, even in excess of 10 ng/mL, and the often-multiple inflammatory areas can mimic cancer on ultrasound and mpMRI, leading to biopsy to exclude cancer[32] (see Fig. 10.8).

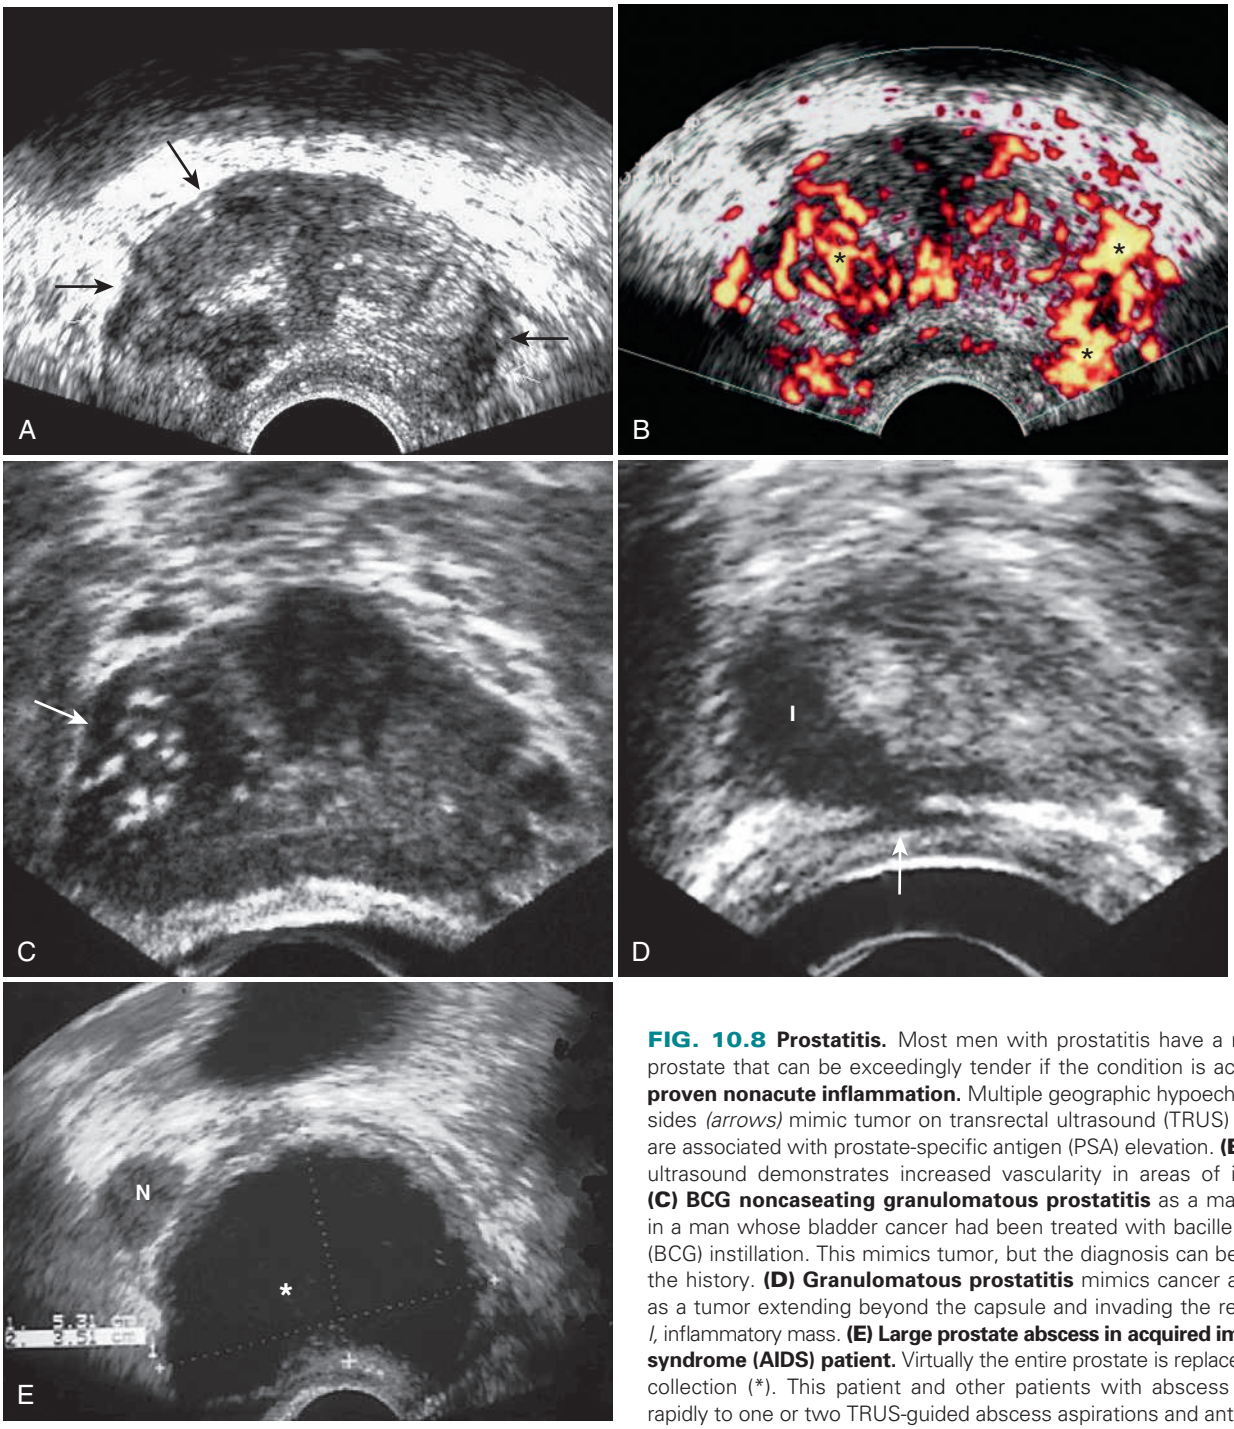

FIG. 10.8 Prostatitis. Most men with prostatitis have a normal-appearing prostate that can be exceedingly tender if the condition is acute. **(A) Biopsy-proven nonacute inflammation.** Multiple geographic hypoechoic areas on both sides *(arrows)* mimic tumor on transrectal ultrasound (TRUS) and Doppler and are associated with prostate-specific antigen (PSA) elevation. **(B)** Power Doppler ultrasound demonstrates increased vascularity in areas of inflammation (*). **(C) BCG noncaseating granulomatous prostatitis** as a mass lesion *(arrow)* in a man whose bladder cancer had been treated with bacille Calmette-Guérin (BCG) instillation. This mimics tumor, but the diagnosis can be suspected from the history. **(D) Granulomatous prostatitis** mimics cancer and here appears as a tumor extending beyond the capsule and invading the rectal wall *(arrow); I,* inflammatory mass. **(E) Large prostate abscess in acquired immunodeficiency syndrome (AIDS) patient.** Virtually the entire prostate is replaced by the abscess collection (*). This patient and other patients with abscess have responded rapidly to one or two TRUS-guided abscess aspirations and antibiotics. *N,* Node.

Other infectious or inflammatory conditions affecting the prostate do not fit easily into these groups. These include conditions such as malacoplakia, eosinophilic prostatitis, cytomegalovirus (CMV) prostatitis, and granulomatous prostatitis. **Granulomatous prostatitis** is usually idiopathic but can follow prior instrumentation and may be caused by bacteria (e.g., tuberculosis, brucellosis, syphilis), fungi (e.g., coccidioidomycosis, blastomycosis, histoplasmosis, cryptococcosis), and parasites (e.g., schistosomiasis). Most cases in North America are caused by bacille Calmette-Guérin (BCG). BCG is commonly instilled into the bladder to treat transitional cell carcinoma. It leaks into the prostate, where it can cause granulomatous inflammation. Granulomatous prostatitis mimics cancer on DRE, TRUS, and mpMRI and elevates PSA level. A history of BCG instillation can be reassuring, but biopsy generally is needed to exclude cancer.[1,38]

Prostate Cysts

Prostate cysts are common and have been grouped into six categories: (1) parenchymal cysts, (2) isolated medial cysts (utricle

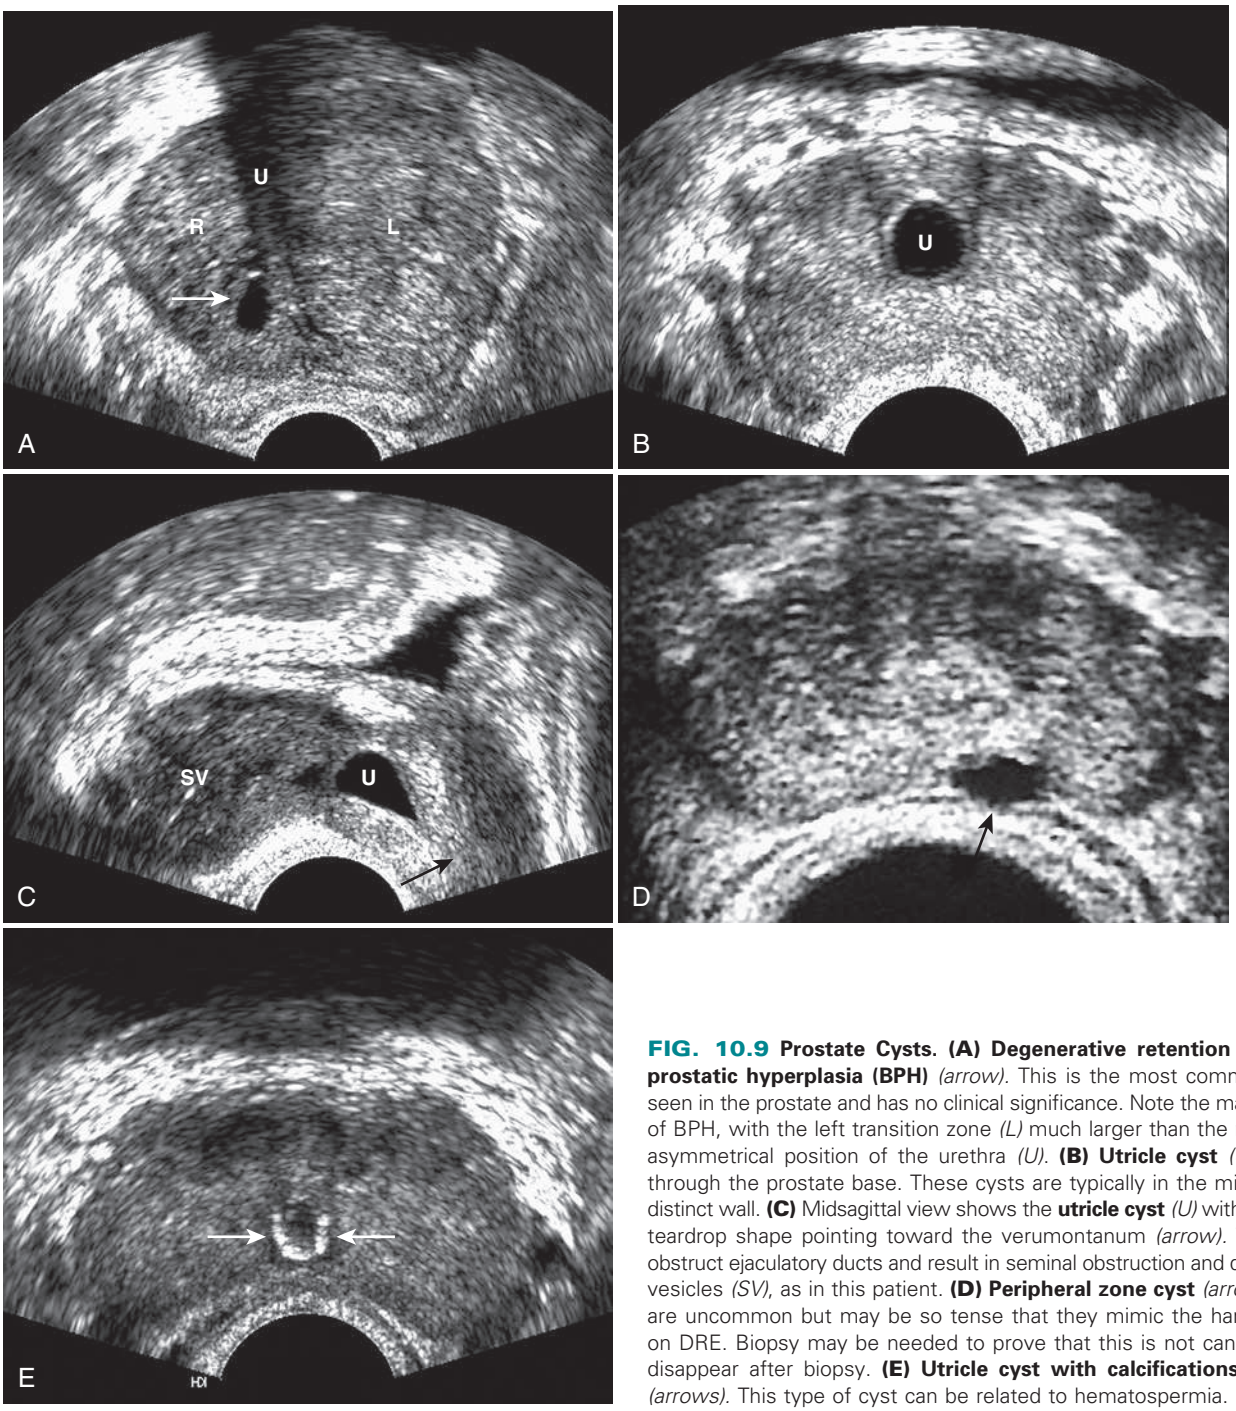

FIG. 10.9 Prostate Cysts. (A) Degenerative retention cyst of benign prostatic hyperplasia (BPH) *(arrow).* This is the most common type of cyst seen in the prostate and has no clinical significance. Note the marked asymmetry of BPH, with the left transition zone *(L)* much larger than the right *(R)*, and the asymmetrical position of the urethra *(U).* **(B) Utricle cyst** *(U)* on axial view through the prostate base. These cysts are typically in the midline and have a distinct wall. **(C)** Midsagittal view shows the **utricle cyst** *(U)* with its characteristic teardrop shape pointing toward the verumontanum *(arrow).* These cysts can obstruct ejaculatory ducts and result in seminal obstruction and dilation of seminal vesicles *(SV),* as in this patient. **(D) Peripheral zone cyst** *(arrow).* These cysts are uncommon but may be so tense that they mimic the hardness of cancer on DRE. Biopsy may be needed to prove that this is not cancer. These cysts disappear after biopsy. **(E) Utricle cyst with calcifications along its wall** *(arrows).* This type of cyst can be related to hematospermia.

and müllerian), (3) ejaculatory duct cysts, (4) abscesses, (5) cystic tumors, and (6) cysts related to parasitic disease (schistosomiasis, hydatid disease).[42,43] By far, the most common cysts are **parenchymal degenerative cysts** in hyperplastic nodules in the transition zone. These have no clinical significance but on occasion can become large enough to contribute to urinary or ejaculatory obstruction. Typically, these are seen as unilocular or thinly septated multilocular cysts in a typical BPH nodule in the transition zone (see Fig. 10.9A). Some patients develop atrophic dilation of prostate ducts, which appear as 1- to 2-mm-diameter clusters of radially oriented tubules or cysts in the peripheral zone. These have no significance (see Fig. 10.9A,B).

Retention cysts are focal cysts typically smaller than 1 cm at the surface of the prostate and result from duct obstruction. They can be very tense and become palpable as a hard prostate nodule mimicking cancer on DRE but on ultrasound appear as a typical cyst. They have no significance, but if they are palpable, aspiration helps confirm their benign nature and avoids future clinical concern when a hard "nodule" is again palpated at that site (see Fig. 10.9D).

Congenital cysts of the prostate occur in or close to the midline and are related to the wolffian (mesonephric or pronephric [archinephric]) ducts or müllerian (paramesonephric) ducts[44] (Fig. 10.9B–C). Most men with congenital cystic lesions in the prostate and SV are asymptomatic, but occasional symptoms arise if the cysts become large or infected.

Congenital abnormalities are common in and around the prostate and SVs.[42] The müllerian tubercle gives rise to the prostatic utricle, a small, midline blind pouch situated near the summit of the verumontanum. Prostatic **utricle cysts** are caused by dilation of the prostatic utricle. Utricle cysts rarely contain spermatozoa but can be associated with genitourinary anomalies including unilateral renal agenesis, hypospadias, and undescended testis. Utricle cysts are always in the midline and are usually small but occasionally can enlarge to several centimeters in diameter (see Fig. 10.9B–C). **Müllerian duct cysts** may arise from remnants of the paramesonephric duct. Müllerian duct cysts are usually small and usually midline but may extend lateral to the midline and enlarge to extend above the prostate. They have no other associations and never contain spermatozoa. As with utricle cysts, they have a teardrop shape pointing toward the verumontanum, a thick visible wall, and occasional mural or contained calcifications. In practice, utricle and müllerian cysts appear similar and their differentiation is not important. When large, both may obstruct ejaculatory ducts or develop calcifications (see Fig. 10.9E) and become painful or infected and rarely may develop tumors.[43,44]

Ejaculatory duct cysts are usually small and probably represent cystic dilation of the ejaculatory duct, possibly as a result of obstruction. Alternatively, they may be diverticula of the duct. They tend to be fusiform in shape and are typically pointed at both ends. Ejaculatory duct cysts contain spermatozoa when aspirated. They can be associated with infertility and may be seen in patients with a low sperm count. Some may cause perineal pain.[43,44]

Other disorders that mimic prostate cysts include SV cysts, ectopic ureterocele, **Cowper duct cysts** (in urogenital diaphragm below apex of prostate), and bladder diverticula.

Prostate abscesses are cystlike cavities with thick, irregular walls and debris containing fluid and resemble abscesses seen elsewhere (see Fig. 10.8E). Coliform organisms such as *E. coli* are the most common cause. Predisposing conditions include diabetes, instrumentation, and immunodeficiency. Transrectal aspiration or TURP drainage can be an effective treatment in addition to antimicrobial therapy.[42-44] Cysts caused by parasites are rare in Western countries and can result from schistosomiasis (bilharziasis) or hydatid (echinococcal) disease.[42,43]

Cystic neoplasms are rare, but cystadenoma and cystadenocarcinoma have been described.[42,43]

Seminal Vesicles and Vas Deferens

The **seminal vesicles** and **vas deferens** develop from the mesonephric duct and are associated with renal and ureteric development. Developmental anomalies of the SV/VD are often associated with renal and ureteric abnormalities. Normal SVs measure about 1 × 5 cm, and VD, about 6 mm. The SVs function to produce and secrete seminal fluid and not to store sperm. The vasa deferentia drain via the ejaculatory ducts through the prostate into the verumontanum. Primary pathology of the SV and VD is being increasingly detected with use of TRUS and MRI.[45,46]

Hypoplasia or agenesis of the SV occurs surprisingly commonly. It may be unilateral or bilateral and can be associated with agenesis or ectopia of the VD and ipsilateral kidney. Patients with **cystic fibrosis** commonly have bilateral agenesis of the SV and VD but normal kidneys.[45,46]

Seminal vesicle cysts are rare and usually solitary (Fig. 10.10C). Most are asymptomatic. The cysts can enlarge and become symptomatic and can be aspirated with TRUS guidance. They may be associated with ipsilateral renal anomalies, including renal agenesis, because the SVs are derivatives of the wolffian (mesonephric) ducts, which also give rise to the ureter and VD. Congenital SV cyst and absence of the ipsilateral kidney is known as Zinner syndrome. Other associations include adult polycystic disease, hemivertebra, and ipsilateral absence of testis. The SV is a common site of ectopic insertion of the ureter.[44,46,47]

Calcification of the SV and VD can occur with diabetes or infection. **Diabetic** calcification tends to involve the walls and resembles "tram tracks" on x-ray films, whereas **infectious or inflammatory** calcification is luminal and segmental and may be associated with SV calcifications. In endemic areas, tuberculosis and schistosomiasis should be considered.[45,46]

On occasion, a 1-cm-diameter eggshell calcification is seen in the SV. These calcifications are asymptomatic and likely related to inflammation.

Malignancy in the SV is most commonly secondary to carcinoma of the prostate, bladder, or rectum and appears as a mass involving the SV. If SV involvement is suspected at time of prostate TRUS biopsy, then additional cores can be taken from the SV and may alter treatment plans. Primary neoplasms of the SV are very rare and include benign cystadenomas, leiomyoma, fibromas, and others and malignant lesions such as adenocarcinoma. Tumor mimics such as amyloid deposits are increasingly becoming recognized.[45,47]

INFERTILITY AND TRANSRECTAL ULTRASOUND

Infertility is defined as failure to achieve pregnancy after 1 year of regular unprotected intercourse and affects about 15% of couples. Male factors are solely responsible in about 20% of couples and contributory in another 30% to 40%. When present, male infertility is usually but not always detected by abnormal semen analysis. The AUA and the European Association of Urology have defined "best practice" policies for investigating male infertility, and both partners should be evaluated simultaneously.[48,49] The **goals of male evaluation** include the following:

1. Identification of potentially correctable conditions
2. Identification of irreversible conditions for which alternative treatments (e.g., donor insemination) or adoption may be used, preventing ineffective therapies
3. Detection of health-threatening conditions underlying infertility

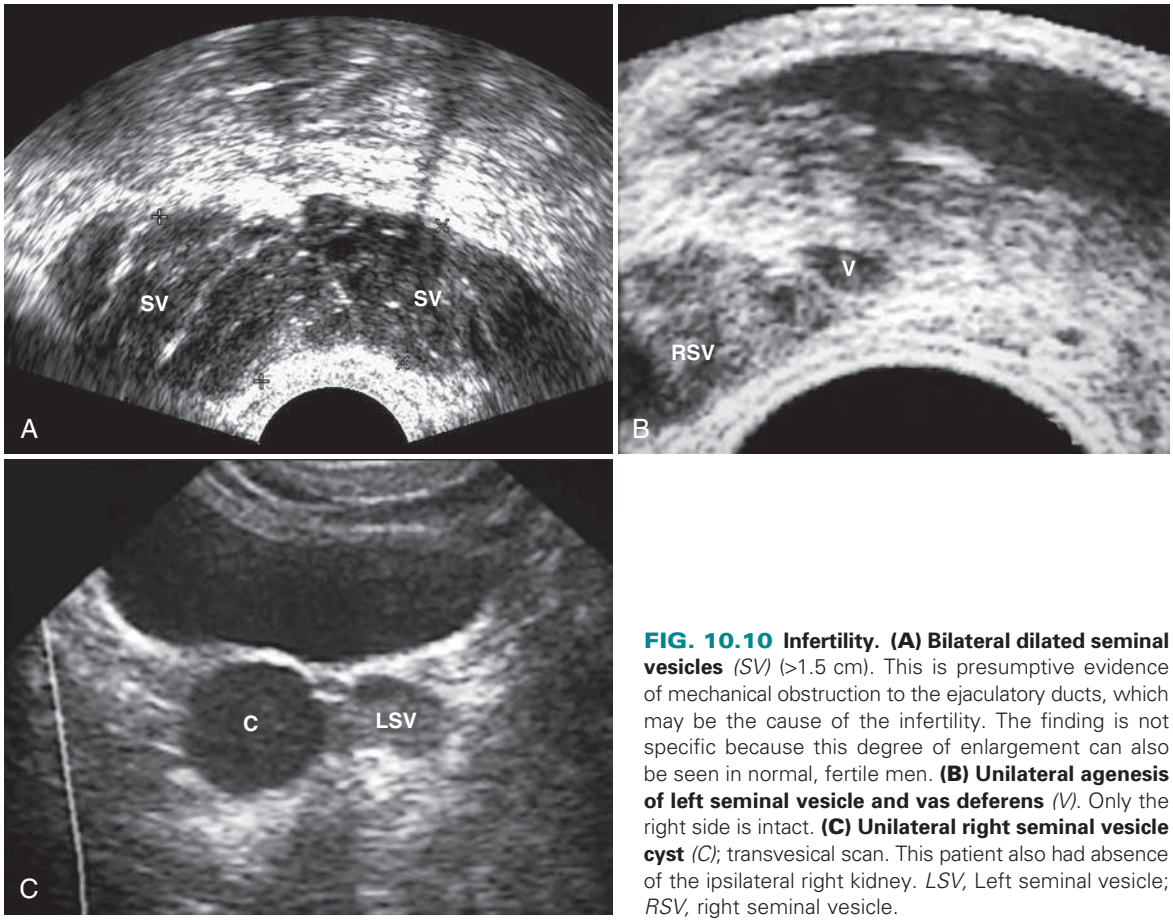

FIG. 10.10 Infertility. (A) Bilateral dilated seminal vesicles *(SV)* (>1.5 cm). This is presumptive evidence of mechanical obstruction to the ejaculatory ducts, which may be the cause of the infertility. The finding is not specific because this degree of enlargement can also be seen in normal, fertile men. **(B) Unilateral agenesis of left seminal vesicle and vas deferens** *(V)*. Only the right side is intact. **(C) Unilateral right seminal vesicle cyst** *(C)*; transvesical scan. This patient also had absence of the ipsilateral right kidney. *LSV,* Left seminal vesicle; *RSV,* right seminal vesicle.

4. Detection of genetic abnormalities (e.g., cystic fibrosis) that may affect the health of children if affected sperm are harvested or used for assisted reproductive techniques.

Male factors can be categorized as pretesticular, testicular, and posttesticular. **Pretesticular factors** include conditions such as faulty reproductive behavior and genetic abnormalities (e.g., *CFTR* gene of cystic fibrosis, Y chromosome microdeletions). **Testicular factors** include congenital and acquired intrinsic disorders of spermatogenesis (e.g., infections, trauma, and treated cryptorchidism) that, except for varicocele, are generally irreversible. Also tumors and testicular microlithiasis are more common in infertile men. **Posttesticular causes** of **azoospermia** (no sperm in ejaculate) and **oligospermia** (low numbers of sperm in ejaculate) generally relate to obstructive issues and are found in about 40% of infertile men, although only 1% to 5% have **ejaculatory duct obstructions** that are amenable to surgical therapies such as prostate cyst unroofing or **transurethral resection of ejaculatory ducts.**[50] This excludes vasectomy reversal, which is successful in 70% to 95% of patients and results in achievement of pregnancy in 30% to 70% of couples. In 100 consecutive azoospermic men, the causes of azoospermia were genetic abnormalities, 27%; diseases or external influence (orchitis, radiotherapy, infections, surgery, trauma), 22%; corrected cryptorchidism, 27%; and unexplained, 22%.[51] This illustrates the broad spectrum of disorders apart from ejaculatory duct obstructions that relate to azoospermia and that are part of the investigation of infertile men.[48,49]

Imaging investigations—ultrasound and MRI—are used to evaluate for abnormalities and focus on the scrotum and testes, prostate, and seminal ducts and occasionally the developmentally related urinary tract.[50,52,53]

The **role of TRUS** and increasingly MRI is to identify anatomically correctable ejaculatory duct obstructions and anomalies in men who are azoospermic or oligospermic and who have VD on palpation. Obstructions can result from calculi in the vas, müllerian or wolffian duct cysts, postsurgical or inflammatory scars, calculi, or atresia of the ejaculatory ducts (see Fig. 10.10). Note that the presence or absence of the VD is diagnosed clinically by palpation of the spermatic cord and not through imaging. Vasography has been used to demonstrate obstruction, but this generally has been discontinued because of the risk of injury to the VD. On occasion, TRUS can be used to inject SVs with ultrasound or x-ray contrast agents to demonstrate patency of the ejaculatory ducts or to retrieve sperm from the SVs for assisted reproduction.[50,52,53]

There are no specific symptoms associated with **ejaculatory duct obstruction.** The diagnosis is suggested in infertile males with azoospermia or oligospermia who have low ejaculate volume, normal secondary sex characteristics and testes, pain during or after ejaculation or orgasm, or history of prostatitis. The relative frequencies of TRUS findings in infertile men with low-volume azoospermia are as follows: normal appearance (25%); bilateral absence of VD (34%); bilateral occlusion of the VD, SVs, and ejaculatory ducts by calcification or fibrosis (16%); unilateral

absence of the VD (11%); obstructing cysts of the SVs, vas ejaculatory ducts, or prostate (9%); and ductal obstruction due to calculi (4%). All these symptoms and findings are also seen in normal, fertile men but are more common in men with obstructive infertility.[50]

The treatment of suspected distal ejaculatory obstruction consists of transurethral resection of the ejaculatory duct, unroofing of the ducts, or draining of obstructing cysts and results in symptom improvement in 50% to 100% and pregnancies in 20% to 30%.[50]

Absence of the vas deferens is a clinical diagnosis made by palpating the spermatic cord. Congenital bilateral absence of the vas deferens (CBAVD) is found in almost all men with cystic fibrosis gene mutations *(CFTR)* whether they are symptomatic or not. It affects about 1% of infertile men and accounts for 4% to 17% of azoospermia and is commonly associated with SV abnormalities. There is a low association with renal anomalies. However, 44% to 60% of men with autosomal dominant polycystic kidney disease also have bilateral VD agenesis. In contrast, men with unilateral absence of the vas are less likely to have cystic fibrosis but more likely to have ipsilateral abnormalities of wolffian duct derivatives including the kidneys.[45,49,53]

HEMATOSPERMIA

Hematospermia is the macroscopic presence of blood in the semen. In most cases it is a benign, self-limiting condition that typically resolves spontaneously over a few weeks. It affects about 1 in 5000 men, peaks between 30 and 40 years of age, and causes significant anxiety among men and their partners who fear cancer or sexually transmitted disease and loss of sexual function. The differential diagnosis is extensive, but most cases are **iatrogenic** (following interventions such as biopsy or cystoscopy), **infectious,** or **inflammatory** and can be effectively treated with minimal investigation and simple reassurance. Malignant tumors, mainly prostate, testis, and SV, are an uncommon cause of hematospermia and are found in only 3.5% of cases, predominantly in men over age 40 years.[54,55]

Hematospermia

COMMON CAUSES
Idiopathic (about 15%)
Sexually transmitted diseases
Trauma (including iatrogenic and self-inflicted)
Prostatic diseases (prostatitis, benign prostatic hyperplasia (BPH), calculi, tuberculosis, schistosomiasis, prostate cancer)
Testis or epididymis (infection, trauma)
Systemic diseases (bleeding disorders, liver disease, severe hypertension)

UNCOMMON CAUSES
Seminal vesicle disorders (carcinoma, calculi)
Prostate cysts (ejaculatory, müllerian, especially with calculi)
Urethra (abnormal vessels, polyps)
Testis tumor
Systemic disorders (amyloidosis)

The primary aim of investigation is to allay anxiety, because the great majority of hematospermia cases, especially in younger men and after single episodes, are highly unlikely to be associated with sinister pathology. In addition to history and physical examination, most patients initially undergo evaluation for sexually transmitted diseases, urinalysis, and urine culture. Men older than 40 should also be assessed for malignancy, especially prostate cancer, even though this is an uncommon cause.

Imaging may be helpful in unexplained or persistent cases. TRUS shows findings in 74% to 95% of men with persistent hematospermia including prostate calcifications, ejaculatory duct calculi, dilated ejaculatory ducts, BPH, dilated SVs, SV calcifications, ejaculatory duct cysts, and prostatitis (see Figs. 10.9E and 10.10A). Color Doppler ultrasound may be able to depict the rare vascular malformation. In practice, it can be difficult to establish that the TRUS finding is responsible for hematospermia because similar findings are often seen in asymptomatic men. MRI can be helpful in persistent cases because it is able to detect bleeding sites that are not apparent on ultrasound, especially bleeding into the SVs.[45,54-56]

Treatment beyond reassurance is not needed in most patients with hematospermia. Alternatively, therapy is directed to any discovered causes and can include antimicrobial therapy, cyst unroofing or aspiration, and systemic therapy for hypertension and bleeding diathesis. Urologic consultation is suggested if the bleeding is persistent and in men older than 40 years who have increased risk of cancer.[54,55]

PROSTATE CANCER

Prostate cancer is a significant health problem for men and their partners. In the United States it is the most common male cancer; in 2016 it was estimated to affect 181,000 men (21% of all male cancers), and after lung cancer, the second most common cause of cancer deaths (26,000 men or 8% of cancer deaths).[57,58] It is important for those evaluating prostate cancer with imaging studies such as TRUS and mpMRI to be aware of and follow the very rapid changes in screening, diagnosis, management, and even pathologic definitions of what constitutes significant aggressive cancer.[9,10,59] Prostate cancer is a difficult problem filled with uncertainties and dilemmas for men, their partners, and physicians. Effective treatments exist but have side effects that substantially alter quality of life, and there is risk of overdiagnosis and overtreatment.[58,60-63]

Unlike some other cancers, not every prostate cancer progresses rapidly and inevitably to metastases and death. There is a large burden of indolent disease that would not benefit from radical therapy, which must be differentiated from aggressive progressive disease. Prostate cancer mainly affects men older than 50 and thus competes with comorbidities as a cause of death.[64] At autopsy, significant grade (Gleason score of 7 or higher) cancer was found in 32% of men who died from other causes.[65] Prostate cancer has a long course, not uncommonly taking about 10 years from asymptomatic diagnosis to cause-specific death. This makes it difficult to determine if screening and treatment protocols are effective, because trials take more than 10 years during which diagnostic and therapeutic changes could make study results irrelevant.[58,63,66,67]

To complicate matters further, no consensus has emerged for the optimal treatment of **clinically localized disease,** which has become the most common presentation in the United States (91% of cases) since the advent of PSA screening in 1991.[68]

Epidemiology

Prostate adenocarcinoma is the most frequently diagnosed cancer in men, two to three times more than lung and colorectal cancer. It is a disease seen primarily in men older than 50. It is the fourth most common male malignancy worldwide. The rates are highest in Scandinavia and North America, especially in African Americans (272 per 100,000), and lowest in China (1.9 per 100,000), but rates are increasing in those countries.[19,69] Genetics and environment, including a fatty diet, play roles in prostate cancer incidence. The risk doubles with a single affected relative and is even higher with multiple affected relatives. The incidence and stage at diagnosis have been decreasing since the early 1990s, partly because of the introduction of PSA screening.[70,71] More than 95% of primary malignant tumors of the prostate are adenocarcinomas. Rarely other primary neoplasms are found, including prostate transitional cell carcinoma, sarcomas, lymphomas, and neuroendocrine tumors.[72] The prostate can be secondarily affected by tumors of regional structures, including the bladder and rectum.

It has been reported that 24-year median follow-up of clinically localized prostate cancer and showed that cause-specific mortality increases with Gleason score and age at diagnosis. With Gleason score of 6 or lower, comorbidities are a more likely cause of mortality, but with higher scores cancer-related death is likely, especially in the 50- to 64-year age group, in which cause-specific mortality approaches 80% to 90% at 15 to 20 years.[64] Of interest, most pathologists currently do not report Gleason score below 6 as cancer, and there is discussion that perhaps even Gleason 3 + 3 = 6 does not represent aggressive life-threatening cancer that needs immediate radical therapy.[9,10,59,73]

Prostate Cancer: Key Facts

Most common cancer diagnosed in men
The second leading cause of cancer deaths in men (after lung cancer)
The fourth most common male malignancy worldwide
Many and varied treatments that are personalized to patient situation
Treatments are associated with quality-of-life issues
Many men have low-grade tumors that may not need treatment or affect longevity

Prostate-Specific Antigen and Variants

PSA is the most commonly used tumor marker to detect prostate cancer and follow patients after therapy.[74,75] PSA is a normally occurring enzyme in the kallikrein family driven by androgen and secreted by the epithelial cells of prostate ducts and functions to liquefy the ejaculate. The prostate epithelium is the main source of PSA and only trace amounts are found in other tissues in men and women. Intact tissues allow only small amounts to leak into the blood where it is partly unbound (free) and partly bound to proteins such as alpha-1-antichymotrypsin. Serum PSA levels are a nonspecific indication of prostate abnormality or irritation that allows excess leakage of this normal enzyme into the blood. Free PSA is composed of three isoforms: pro-PSA, BPH-associated PSA, and intact free PSA. **Elevated total PSA levels** can occur with cancer but also are variably seen with benign conditions including BPH and inflammation and after ejaculation, prostate manipulation, biopsy, and cystoscopy. In general, DRE and TRUS without biopsy do not elevate PSA significantly, but it is prudent to draw the blood before disturbing the prostate. PSA levels can be artificially reduced by a factor of 2 with antiandrogenic medications such as finasteride (Proscar) and dutasteride (Avodart). Unpredictably reduced levels are found with herbal medications such as palmetto and PC SPEC. With cancer the proportion of bound PSA increases resulting and can decrease the ratio of free to total PSA **(percent free PSA, %fPSA).**[75]

Although PSA is accepted as a prostate cancer marker, there are issues with its use. It is organ specific but not cancer specific, and levels overlap in benign conditions and cancer. Also, not all cancer elevates PSA and cancer can be found in 6.6% of men with low PSA (<0.5 ng/mL). The discriminatory level is uncertain. Initially 4 ng/mL was considered the threshold for consideration of biopsy, but this has decreased to as low as 2.6 ng/mL. It is generally agreed that unexplained PSA over 10 ng/mL is an indication for biopsy and has a positive predictive value (PPV) of about 80%. Biopsy of men in the problematic 4- to 10-ng/mL range finds cancer in about 40%. This highlights the problem with PSA testing: PSA of 4 ng/mL has a sensitivity of about 79% but a low specificity of 59%. The low specificity means that many men without significant cancer would be subjected to the risks of biopsy and overdiagnosis and overtreatment. These issues have led to controversy in the use of PSA for screening.[58,76] However, screening aside, PSA remains the optimal tool to follow men for recurrence after curative therapy.

Several approaches have been considered to try to improve both sensitivity and especially specificity so that in the 2.6- to 10-ng/mL gray area initial and repeat biopsy are performed only in men at risk for significant aggressive cancer and can be avoided in men at low risk or at risk for just indolent cancer. Most urologists feel that their clinical acumen, which takes into consideration PSA, family history, patient clinical status and history, prior biopsy results, and discussion with the patient, remains the mainstay of determining need for both initial and repeat biopsy. Although PSA and its variants remain the dominant test, there is a rapidly increasing catalog of additional blood, urine, and tissue tests that may be taken into consideration and may provide supporting information regarding diagnosis, prognosis, and need for enhanced therapy.[74,75,77]

With cancer the proportion of bound PSA increases, resulting in a decrease in the ratio of free to total PSA **(percent free PSA, %fPSA).**[75] Using a ratio of 25%, Catalona and colleagues detected 95% of cancers and avoided 20% of biopsies.[78] There is no general agreement on cut points, which range from about 15% to 25% (or ratio 0.15-0.25). The instability of fPSA (free PSA) after phlebotomy unfortunately has limited its use for general screening.[75]

PSA density (PSAd) is the ratio of PSA to prostate volume. This test assumes prostate cancer makes more PSA than benign

tissue and tries to allow for elevated PSA in men with enlarged glands due to BPH. Cut points range from 0.12 to 0.15. This test is less often used to determine need for biopsy but commonly used as one of the risk criteria for entering men into active surveillance programs.[10,75,79,80]

PSA velocity evaluates rate of increase of PSA over time. It assumes that PSA rises faster with cancer and requires at least three PSA determinations over 18 months showing a rise over 0.75 ng/mL per year.[81] This test is less often used currently but may have a role in active surveillance.[10,82]

Role of Prostate-Specific Antigen (PSA)

PSA and digital rectal examination today are the standard of care for initial prostate cancer screening
PSA level is associated directly with the tumor burden of prostate cancer
Not all cancers produce PSA
20% to 40% of men with clinically significant cancer will have a "normal" PSA level
PSA may be elevated by nonmalignant conditions
PSA variants are used to improve screening accuracy
- PSA density
- PSA velocity
- Free/total PSA ratio

Used during active surveillance, to evaluate for progression and reclassification
Used after active therapy, to follow patients for recurrence
Can be combined with other biomarkers to improve sensitivity and specificity

Alternate Prostate Cancer Biomarkers

PSA remains the most commonly used biomarker, but numerous other biomarkers are being developed to overcome the limitations of PSA to indicate need for initial and repeat biopsy, to help distinguish between indolent and aggressive tumors, to help select appropriate therapy, and to follow patients after therapy. Biomarkers can be evaluated in blood, other body fluids, urine, or tissues. Some have been approved for use and others remain investigational. In general, their role is supportive to clinical acumen and initial PSA use. In many instances their incremental value has not yet been established. Also, multiparametric risk nomograms and mpMRI are increasingly being used.[74,75,77,83]

PCA3 score uses noncoding RNA in urine and is approved for use. PCA3 is not found in normal prostate tissue but is expressed in 95% of prostate cancers. It is recommended as a test to help determine need for repeat biopsy with elevated PSA. A cut point of 35 has been recommended, which would yield optimal balance between sensitivity (47%) and specificity (72%) while missing 21% of high-grade tumors.[74,75,77,83-85]

Prostate Health Index (PHI) is approved for men 50 years or older in the PSA 4- to 10-ng/mL range and negative DRE findings. It combines several isoforms of PSA. It is used to help support need for biopsy in the PSA 4 to 10 range.[74,75,77,84,85]

4Kscore is currently not a US Food and Drug Administration (FDA)–approved test. It uses four different PSA forms and an algorithm including age, DRE findings, and prior biopsy status to predict a risk score for finding aggressive cancer in a future biopsy.[74,75,77]

TMPRSS2:ERG is currently not an FDA-approved test. It is a urine test for pathologic fusion of *TMPRSS2* and *ERG* genes that is found in 50% of prostate cancer specimens. It has a low sensitivity but high specificity for predicting prostate cancer at biopsy.[74,75,77]

On biopsy samples, tissues near cancer show altered field or "halo" effects that can be evaluated on biopsy samples and can manifest as changes in genes **(Oncotype DX test)** or tissue methylation **(ConfirmMDx test).** A negative biopsy result in a patient with positive tissue markers suggests that a nearby cancer was missed and can help determine need for repeat biopsy.[74,75,77]

Increasingly the concept of combining these tests and other tests including mpMRI and clinical parameters in the form of "risk calculators" is proving useful. The more popular risk calculators in current use are the ERSPC-RC, PCTP-RC, and UCSF-CAPRA calculators, which can be found online or downloaded to smartphones (http://www.prostatecancer-riskcalculator.com/seven-prostate-cancer-risk-calculators; http://deb.uthscsa.edu/URORiskCalc/Pages/uroriskcalc.jsp; https://urology.ucsf.edu/research/cancer/prostate-cancer-risk-assessment-and-the-ucsf-capra-score).[86,87]

Screening

Early stage prostate cancer is curable but rarely symptomatic. The presence of symptoms suggests advanced disease with little likelihood of cure. This would suggest that screening is reasonable to detect asymptomatic disease while it is still curable. The goal of any cancer screening, including prostate, is the early identification of cancer or precancerous lesions before symptoms develop and at a point when treatment improves outcomes. The World Health Organization (WHO) has proposed criteria that should be met before population screening is offered. The condition should be an important health problem with a known natural history; have agreed-on treatment that is acceptable, available, and effective; have a recognizable latent stage to allow time for screening; and have a screening test that is acceptable and effective and has a reasonable cost.[88] Many of these conditions are met for prostate cancer, but issues remain that have introduced controversy into screening.[60]

TRUS is not used as a primary screening modality in screening for prostate cancer. TRUS has sensitivity of 30% to 67% and specificity of 52% to 61%, compared with mpMRI sensitivity of 72% to 90% and specificity of 55% to 79%.[89] It is hoped that CEUS and ultrasound elastography will improve ultrasound accuracy. There is increasing discussion of use of hybrid or multiparametric imaging to improve detection and characterization.[4,6,90-92] Most techniques are qualitative and not quantitative, and operator skills remain paramount. This results in variabilities in accuracy and performance characteristics that are apparent in the literature for cancer detection.

The current recommended screening tests are PSA and DRE followed by confirmatory diagnostic transrectal biopsy.[7] The added value of TRUS for cancer detection at screening over PSA plus DRE is about 5%.[93] Diagnosis requires tissue to be obtained by biopsy. Currently this is most efficiently and effectively done

with TRUS guidance. MRI in-bore biopsy and MRI-TRUS fusion biopsies are being introduced but currently are less practical and limited by access and costs. Cancer detection by mpMRI is imperfect, and currently systematic biopsy cannot be avoided if the MRI is negative.

Prostate cancer mortality has decreased since 1990 and there has been a 75% reduction in the proportion of advanced disease at diagnosis. This is attributed to opportunistic PSA screening rather than new and improved therapies.[94] However, there are concerns regarding generalized population screening. On one hand, prostate cancer remains an important cause of morbidity and mortality. On the other hand, prostate cancer affects older men and typically has a 10-year course. Men of this age have competing causes of mortality, so men with cancer often die with, and not from, their cancer. PSA screening has limited sensitivity and specificity. The diagnostic transrectal biopsy is not infallible and has risks. There is a large background of low-volume low-grade (Gleason 6) cancer that is not likely to need active therapy. This raises concerns regarding overdiagnosis and overtreatment because therapy (surgery, radiation, hormones) is not without risk and has significant side effects affecting quality of life.

Several studies have evaluated the role of screening and therapy for prostate cancer; some have shown benefit but others have not, possibly because of study design limitations.[95,96] The major quoted screening studies are the ERSPC (European Randomized Study of Screening for Prostate Cancer)[97] and the US study PLCO (Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial).[98] The ERSPC first consented and then randomized men into a screening arm offered PSA testing every 4 years and a control arm. Biopsy was offered for PSA above 3 ng/mL. At 13 years, the screened arm showed a 29% decrease in mortality. To prevent one cancer death, the number needed to invite for screening was 781 and number needed to detect was 27. The Göteborg subset of this study used a more real-world approach that first randomized men to be invited to screening and then obtained consents. Biopsy was recommended for PSA above 2.5 ng/mL. At 14 years, the investigators reported that the relative risk for dying from cancer decreased to 0.44, with number needed to screen of 293 and number needed to treat of 12.[97,99]

The PLCO randomized men to annual PSA and DRE or usual care groups. Biopsy indication was PSA above 4 ng/mL or palpable nodule. At 13 years there was no significant difference in mortality. Subsequent analysis showed that about 90% of the control arm had undergone PSA screening either before or during the study. True comparison was not possible because both screen and control arms in effect were screened with PSA.[58,95,98]

Considering these and other studies, in 2012 the US Preventive Services Task Force (USPSTF) issued a D recommendation against prostate cancer screening (no net benefit or harms outweigh benefits).[96] Notwithstanding decreasing prostate cancer mortality since introduction of PSA screening, the USPSTF concluded that any screening benefits were outweighed by the seeming lack of overall benefit as shown especially in the PLCO study, the risks of overdiagnosis and overtreatment, the risks of biopsy and therapy, the large proportion of indolent disease that is unlikely to be symptomatic, and competing mortality in older men. This recommendation is strongly contested by many who believe that it will decrease detection of prostate cancer while still treatable and result in increasing morbidity and mortality; this appears to be happening.[58,100,101] Also, urologic groups are promoting "smart screening" that focuses screening on those most likely to benefit and only after shared decision making; to avoid harms of active therapy, they recommend active surveillance of men with seemingly indolent cancer (low-volume Gleason 6, also called IDLE [indolent lesions of epithelial origin]). In general, in men without risk factors, screening is recommended starting at about age 50 years, is repeated at 1- to 4-year intervals, and is stopped at about 70 years or with life expectancy below 10 years. A low (<1.0 ng/mL) baseline PSA between 40 and 49 years of age is associated with low cancer risk and can be used to further lengthen intervals between testing. Before biopsy, the PSA should be repeated to allow normal fluctuations from producing a false-positive result. Antibiotics should not be given to asymptomatic patients to lower PSA to test if there is an asymptomatic infection causing the PSA elevation. In high-risk groups such as those with a first-degree relative with prostate cancer or African-American men, screening should start at about age 40. The new biomarkers, mpMRI, and risk calculators could further be used to increase specificity of screening tests and need for biopsy or therapy.[58,73,88,95,102]

Clinical Staging and Histologic Grading

Staging relates to extent of disease spread; **grading** relates to histologic appearance of aggressiveness. **Clinical staging** of prostate adenocarcinoma uses pretreatment parameters to estimate extent of tumor, determine treatment options, and predict prognosis by using DRE; PSA; biopsy characteristics; imaging including TRUS, CT, isotope scan, and mpMRI; and nomograms such as the Partin tables, which combine multiple characteristics such as PSA, clinical stage, and Gleason score (Fig. 10.11, Table 10.1).[103] **Pathologic staging** requires histologic evaluation of

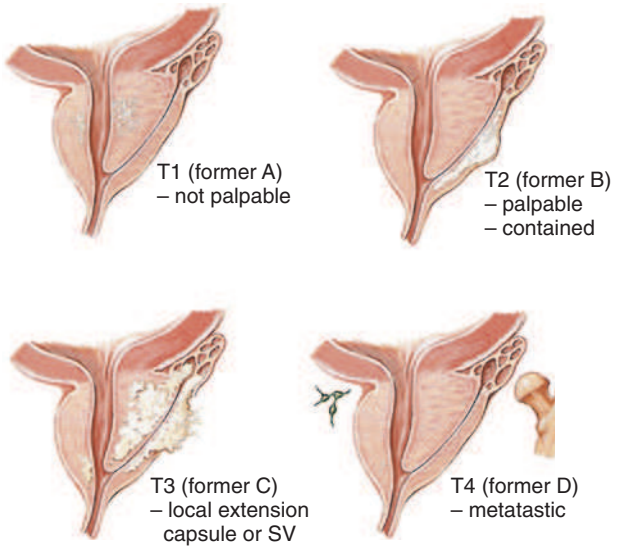

FIG. 10.11 Contemporary prostate cancer staging using the tumor-nodes-metastasis (TNM) classification. *SV,* Seminal vesicle.

TABLE 10.1 Staging of Prostate Cancer, 2010

Stage	Description	Comments
CLINICAL STAGING (cT__)		
cTX	**Primary tumor cannot be assessed**	
cT0	**No evidence of primary tumor**	Describes cancer on biopsy but no cancer is found at radical prostatectomy, possibly because of microfocal cancer that is not included in prostatectomy histologic sections. This occurs in about 0.4% of cases and in general has a good prognosis.
cT1	**Clinically inapparent tumor that is not palpable nor visible by imaging**	Describes tumors that are not palpable or visible on TRUS or mpMRI, possibly because of size, soft consistency, or anterior location. These may be found on TURP, where about 6% of men will have <5% of positive chips. Prognosis is variable and about 10%-26% may have subsequent progression especially when many chips are involved.
cT1a	Tumor incidental histologic finding in ≤5% of tissue resected	
cT1b	Tumor incidental histologic finding in >5% of tissue resected	
cT1c	Tumor identified by needle biopsy	Describes men with impalpable disease who have positive needle biopsy (e.g., after screening showed elevated PSA).
cT2	**Tumor confined within prostate**	Describes palpable organ-confined tumors. Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is included in T2.
cT2a	Tumor involves ≤½ of one lobe	cT2a and cT2b tumors involve only one lobe and cT2c both lobes. However, pathologic examination suggests this distinction is arbitrary because most tumors are multifocal and present in both lobes, and prognosis also depends on tumor volume and grade and not just findings of palpation and ultrasound.
cT2b	Tumor involves >½ of one lobe but not both lobes	
cT2c	Tumor involves both lobes	
cT3	**Tumor extends through the prostate capsule**	Describes tumors with extracapsular extension, a poor prognostic factor. Pathologically it manifests as cancer in adjacent fat, neurovascular bundles, anterior muscle, or bladder neck or invading seminal vesicles. Seminal vesicle invasion may occur via extension along ejaculatory ducts, direct invasion from prostate, or rarely discontinuous metastasis.
cT3a	Extracapsular extension (unilateral or bilateral)	
T3b	Tumor invades seminal vesicle(s)	
T4	**Tumor is fixed or invades adjacent structures other than seminal vesicles such as external sphincter rectum, bladder, levator muscles, and/or pelvic wall**	
PATHOLOGIC STAGING (pT)		
pT2	**Organ confined**	
pT2a	Unilateral, one-half of one side or less	
pT2b	Unilateral, involving more than one-half of side but not both sides	
pT2c	Bilateral disease	
pT3	**Extraprostatic extension**	
pT3a	Extraprostatic extension or microscopic invasion of bladder neck	
pT3b	Seminal vesicle invasion	
pT4	**Invasion of rectum, levator muscles, and/or pelvic wall**	
Regional Lymph Nodes (N)		Based on clinical and/or pathologic assessment
NX	Regional lymph nodes were not assessed	
N0	No regional lymph node metastasis	
N1	Metastasis in regional lymph nodes(s)	
Distant Metastasis (M)		Distant nodes are deemed metastases
M0	No distant metastasis	
M1	Distant metastasis	
M1a	Nonregional lymph node(s)	
M1b	Bone(s)	
M1c	Other sites with or without bone disease	

mpMRI, Multiparametric magnetic resonance imaging; *PSA,* prostate-specific antigen; *TRUS,* transrectal ultrasound; *TURP,* transurethral resection of the prostate.

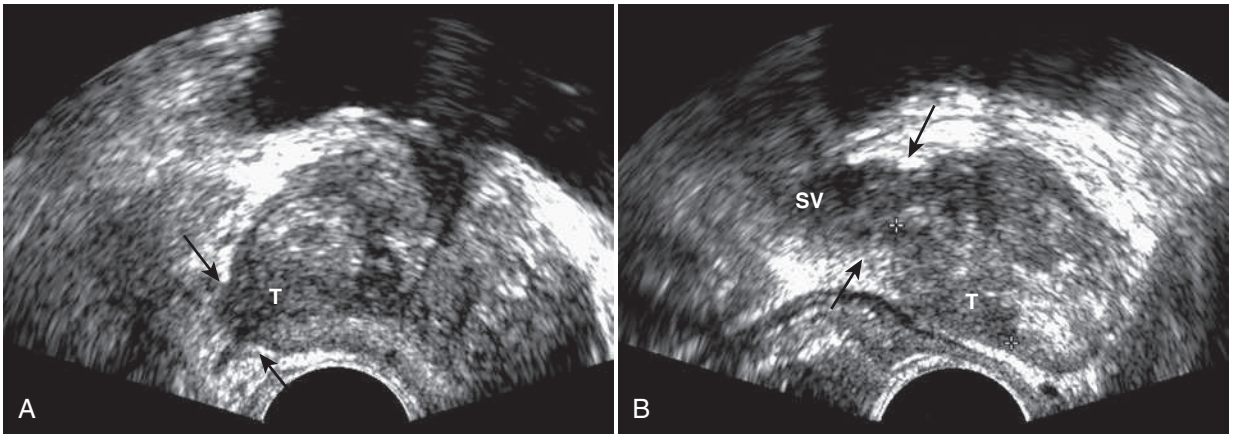

FIG. 10.12 Staging of Extensive Prostate Cancer. (A) Stage T3A cancer (T) has extended outside the prostate at the neurovascular bundle *(arrows)*. Note how difficult it is to differentiate tumor extension from the normal irregularity caused by the neurovascular bundle. **(B) Stage T3C** (parasagittal view) cancer (T) extending *(arrows)* into the seminal vesicles (SV).

prostate, SVs, and lymph nodes and is more accurate for prognosis. Clinical staging (designated as cT_) is important for deciding management but is less accurate than histologic evaluation (designated as pathologic stage pT_) of the prostate and surrounding tissues because DRE and imaging modalities have limitations in predicting extraprostatic extension and 60% to 90% of tumors are multifocal. Compared with pathologic evaluation, clinical understaging occurs in about 40% to 60% and overstaging in about 5%.

Staging with imaging is used selectively in high-risk groups using isotope bone scans, CT, and mpMRI. When the risk of extraprostatic disease is low, consideration is given to avoidance of these tests to reduce radiation exposure and costs. It is estimated that in the current PSA era over 90% of cases are localized, obviating need for routine staging by CT, MRI, or bone scan at initial diagnosis. Recommendations for staging by imaging differ among organizations. In general, bone scans are recommended for men with PSA above 10 to 20 ng/mL, Gleason score of 8 or higher, or symptoms. Soft tissue imaging with CT, MRI, or PET-CT is recommended for cT3 or cT4 cancers, nomogram risks of extensive disease exceeding 10%, and men with symptoms.[104,105]

Neither of the current imaging modalities, MRI or TRUS, is completely accurate in predicting extracapsular extent (ECE) or SV involvement, but they are superior to clinical assessment.[106] MRI appears superior to TRUS because TRUS is operator dependent. In experienced hands MRI performance characteristics are sensitivity, 65%; specificity, 73%; PPV, 88%; and negative predictive value (NPV), 38%. SV invasion gauged by altered shape and signal has sensitivity of 83% and specificity of 99%. Detection of node involvement is typically not possible with TRUS but is similar for CT and MRI, with sensitivity of 7%, specificity of 100%, PPV of 85%, and NPV of 100%. However a normal CT or MRI scan does not exclude nodal involvement.[90]

TRUS findings suggesting ECE are similar to MRI findings and include capsule bulge or distortion, asymmetry of neurovascular bundle, and obliteration of rectoprostatic angle. SV invasion is suggested by visible extension into or a mass in the SV (Fig. 10.12). In very experienced hands TRUS was shown to be as accurate as MRI for determining ECE (area under curve for TRUS of 0.81 vs. MRI, 0.71)[107] and superior to nomograms that predict stage.[108] However, experience and equipment appear to be important, and overall reported TRUS accuracy in determining ECE ranges as follows: sensitivity, 12% to 90%; specificity, 46% to 91%; PPV, 46% to 85%; NPV, 38%; and SV invasion sensitivity, 9% to 60%, and specificity, 82% to 100%.[109] Because imaging has limitations for preoperative staging, many physicians rely on their clinical acumen or use multifactorial staging nomograms (e.g., Kattan, Partin) that make use of DRE, PSA, Gleason score, and other variables.[6,106,110,111] However, experienced physicians have found meticulous TRUS to be more accurate than DRE and tables for staging[108] (see Fig. 10.12).

Remember also that although 95% of malignant prostate tumors are adenocarcinomas, the remaining 5% are unusual tumors of many cell types that do not elevate PSA. These frequently affect younger patients in whom the initial symptoms are those of metastatic disease including urinary dysfunction and skeletal pain. At imaging they mimic locally extensive and metastatic prostate cancer.[72,112]

Histologic grading describing the microscopic pathologic spectrum of prostate adenocarcinoma was devised by Dr. Donald Gleason in the 1960s and updated in 2014. It uses five progressive histologic patterns of gland disorganization to assign a **Gleason pattern** 1 through 5, which correlates with tumor aggression. Most prostate cancers are heterogeneous and display several patterns. The two most prevalent patterns are added to give a score (e.g., primary pattern 4 and secondary pattern 3 give a **Gleason score** of 4 + 3 = 7/10). Recently patterns 1 and 2 and scores of 5 or lower were eliminated, so currently scores range from 6 to 10.[59,73,113]

Recently Gleason score 3 + 3 = 6, specifically pattern 3, has come under discussion as to its malignant and aggressive potential and clinical importance. In the current PSA era Gleason 6 is the most commonly diagnosed score at biopsy and accounts for about 49% of cases. Although Gleason 3 + 3 = 6 demonstrates many visible characteristics of malignancy including local invasion and molecular and genetic markers, its clinical behavior

appears indolent. Some have suggested that Gleason 6 be renamed IDLE (indolent lesions of epithelial origin). However, finding only Gleason 6 cancer at biopsy may undergrade about 22% of men in whom sampling missed coexistent higher pattern cancer and in whom higher grades are found subsequently at radical prostatectomy. In these cases, prognosis relates to the higher initially undetected grade. It is recommended that men initially found to have Gleason 3 + 3 = 6 cancer undergo a follow-up confirmatory and more extensive biopsy before they are included in active surveillance programs to try to ensure that no higher grade cancer is present. mpMRI is proving useful for additional lesion targeting before repeat biopsy, but to date a negative mpMRI scan should not be used to avoid confirmatory biopsy or avoid systematic biopsy in addition to sampling of MRI targets.[59,73,114,115]

The high frequency of Gleason 6 cancer and the perceived "moderately severe" level of cancer that the term "grade 6/10" conveys to patients during discussion has led to difficulties in counseling patients who are not aware that 6/10 is actually very low risk and likely indolent disease. As a result, patients may request inappropriate radical therapies leading to overtreatment and its attendant risks and side effects with little benefit. A workaround has been to continue to use the Gleason scoring (6-10) but assign tumor grades from 1 to 5: 3 + 3 = grade 1; 3 + 4 = grade 2; 4 + 3 = grade 3; 4 + 4 = grade 4; 9 or 10 = grade 5. This would assign Gleason 6 the lowest grade 1 during discussions and hopefully provide sufficient psychological reassurance to patients to consider active surveillance and avoid immediate radical therapy.[9,73,115]

Therapy

Many treatment options are available depending on grade, stage, patient choices, and risk strata. There are many guidelines for determining risk levels.[116] Two commonly used ones are Epstein and D'Amico. The Epstein risk score predicts risk of clinically insignificant tumors, defined as less than 0.5 mL volume at prostatectomy. It is based on biopsy characteristics and defines low risk as Gleason 6 or lower, fewer than three positive cores, and less than 50% involvement of any core.[117] The D'Amico score predicts risk of biochemical failure after radiation therapy. It defines cancers as low risk (clinical stage T1c or T2a, PSA ≤10 ng/mL, or Gleason 6), intermediate risk (T2b, PSA 10-20 ng/mL, or Gleason 7), and high risk (T2c, PSA > 20 ng/mL, or Gleason 8-10).[118] Nomograms may further be used to help with patient decisions. The Kattan nomogram estimates survival when managed without curative intent.[110,119] The UCSF-CAPRA score estimates recurrence risk after radical prostatectomy.[120] To date, there is no consensus regarding optimal treatment for the most common, clinically localized cancer. Treatments are personalized after shared decision making with the patient and taking into consideration life expectancy, overall health, tumor characteristics, and the risks and benefits of the various therapies.[61,121,122] Treatment options include established therapies such as radical prostatectomy and radiotherapy (escalated-dose conformal external beam radiotherapy, brachytherapy with radioactive seed implants). Men with advanced disease can undergo watchful waiting or palliative therapy.[19,61,121]

Focal therapy is still an investigational treatment seeking to provide cure to focal intraprostatic lesions while avoiding the incontinence and impotence complications of treating the whole gland with surgery or radiation. It is being considered for men with an unequivocal solitary focal low-grade index lesion that is defined as the largest lesion and presumed to be the most aggressive. Small low-volume Gleason satellites do not seem to matter and are felt to need no treatment. It is an appealing approach in young patients with Gleason 6 or 7 cancer with a low proportion of grade 4 and volume greater than 1.3 mL proven by mpMRI-fusion biopsy or transperineal template biopsy. Early results have shown good "trifecta" outcomes (continent, potent, no evidence of disease) in 84%, which is higher than obtained with whole-gland active therapy. Several novel focal tissue ablating methods are used with TRUS or MRI guidance to kill tissue by heating, cooling, radiation, electroporation, and focal vascular occlusion. High-intensity focused ultrasound (HIFU) focally heats tissue. Cryotherapy freezes tissue. Electroporation uses low-energy direct current to disrupt cell membranes. Vascular-targeted photodynamic therapy (VTP) uses a novel systemically injected agent, TOOKAD, which when focally activated by laser causes local vascular occlusion and secondary tissue anoxic destruction.[10,123]

Cancer control by the established surgical and radiation therapies in low-risk patients with organ-confined disease exceeds 90% at 10 years but falls rapidly with higher grade and more extensive disease. All the treatments have varying degrees of side effects that can significantly affect quality of life, including incontinence, erectile dysfunction, and urethral strictures, in addition to the usual surgical concerns. Patients may select a specific treatment depending on local expertise and the expected complications. High cure rates and long-term survival have made quality of life and side effects important issues when considering treatment.[63,66,121]

Radical prostatectomy is the "reference standard" of therapy and has a disease-free survival advantage over expectant management.[124] Cure rates in men with low-grade cancer exceed 90% but decrease with advanced grades and stages. For example, when nodes are involved at radical prostatectomy, 10-year survival falls to about 15%. An attempt is made to avoid injury to the neurovascular bundle, if safe for cancer control, to avoid erectile and continence problems (nerve-sparing prostatectomy). In skilled hands, continence is about 90% and erectile function is preserved in 50% to 90%, depending on patient age. Alternatives to the classic open retropubic prostatectomy are laparoscopic surgery and robotic surgery, which have similar outcomes in experienced hands, although postoperative recovery is faster.[121,122]

The two general approaches for radiotherapy are external beam and implanted radioactive seeds (brachytherapy). Conformal escalated-dose **external beam radiotherapy** uses image guidance, usually CT, to confine and conform the beam tightly to the prostate. This allows an increasing or escalating target dose while minimizing collateral damage to adjacent organs. Tight field planning is aided by fiducial (reference) markers placed into the prostate under TRUS guidance to improve planning and to allow higher doses (escalated dose) that can be precisely confined

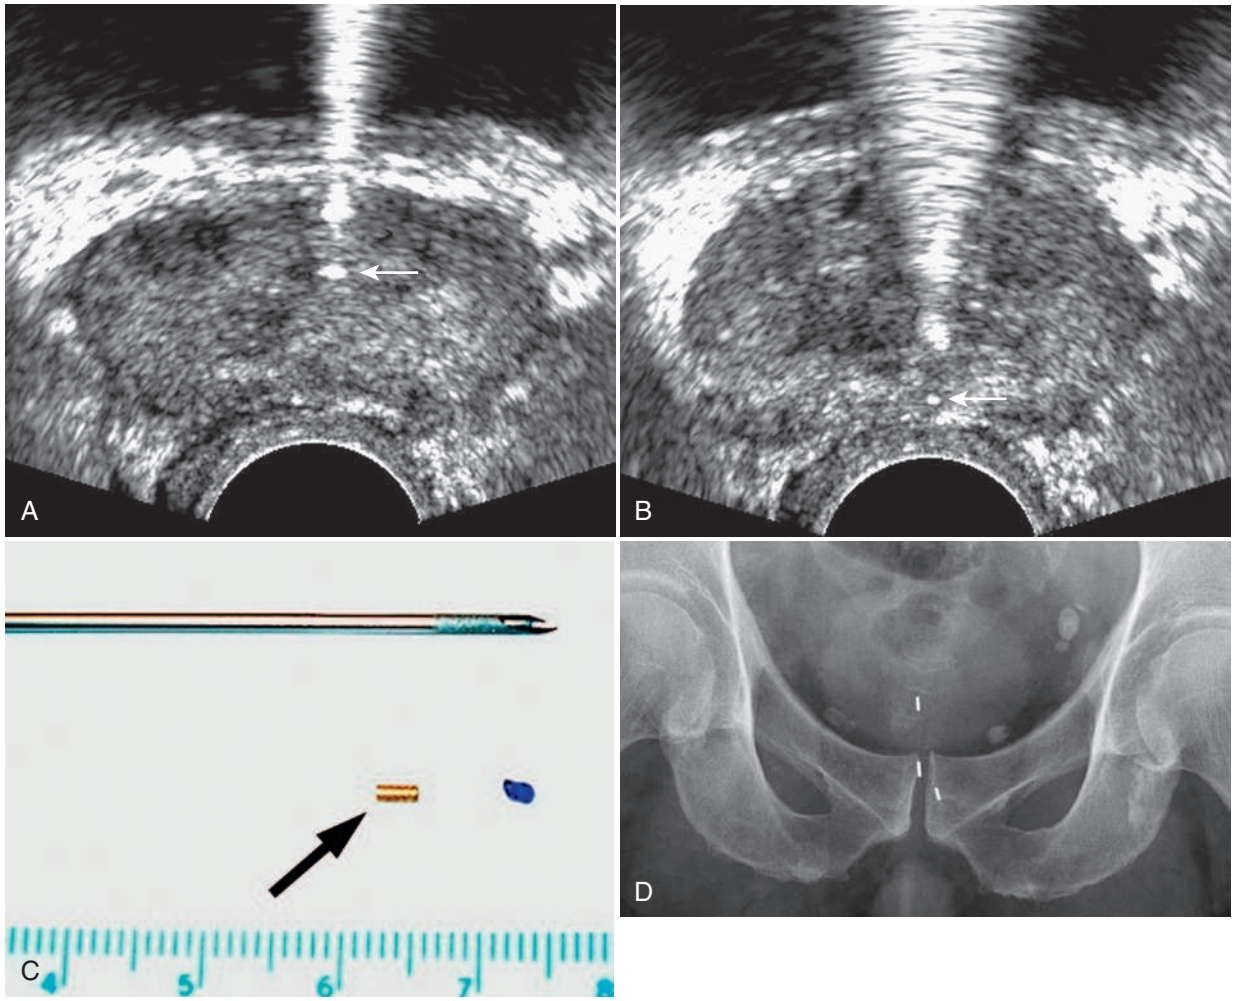

FIG. 10.13 Ultrasound-Guided Radiotherapy. Fiducial marker seeds inserted with transrectal ultrasound (TRUS) guidance and used to guide escalated-dose external beam radiotherapy. **(A)** Transverse image shows basal seed *(arrow)* with characteristic comet-tail reverberation artifact. **(B)** Rectal surface seed *(arrow)*. **(C)** Fiducial (marker or reference) gold seed, which is inserted into the prostate to precisely guide escalated-dose conformal radiotherapy *(arrow)*. The smaller seed is a bone wax plug used to keep the seed in the needle before placement. **(D)** Pelvic x-ray film shows the three marker seeds in place.

(conformed) to the prostate to lessen collateral damage to adjacent organs (Fig. 10.13). Five-year freedom from biochemical recurrence (no PSA rise) is 70% to 85%. Erectile function is preserved in about 50% and continence in 80% of patients, but long-standing rectal irritation may occur.[61,66,121]

Brachytherapy involves intraoperative placement of radioactive seeds, usually iodine-125, into the prostate using TRUS guidance and a perineal template (Fig. 10.14). Direct radioactive seed placement into the prostate allows higher local radiation doses. The technique is restricted to low-risk patients with PSA less than 10 ng/mL, Gleason score of 6 or less, and gland volume less than 50 mL. Erectile function is preserved in about 50% and continence in about 80% of patients, although urinary stricture and bowel irritation are common.[66]

Two new treatment strategies, watchful waiting and active surveillance, are being introduced to delay invasive therapy and its side effects and avoid possible overtreatment. **Watchful waiting** is used in men who have asymptomatic cancer but are unlikely to benefit from therapy because of comorbid conditions. They are monitored until they become symptomatic and then receive symptomatic palliative care, usually with hormones.

Active surveillance (active monitoring with curative intent) is an increasingly popular "PSA era phenomenon" that is almost unique to prostate cancer and seeks to avoid overtreatment. It recognizes that many men with low-risk cancer will never suffer from the cancer and are 10 times more likely to die from other causes such as cardiovascular disease. It also takes into consideration the apparent indolent behavior of Gleason grade 3 lesions (Gleason score 3 + 3 = 6), which do not appear to metastasize or cause death. There is no general consensus on optimal protocols and there are very many published guidelines for inclusion criteria, monitoring, and criteria for triggering of definitive therapy. It is suggested that pure Gleason 3 + 3 = 6 disease and tumor volumes of up to 1.3 mL (diameter about 1.4 cm) may behave in a benign manner, and patients could be offered surveillance.[115,116,123]

Strict criteria are suggested to define suitable low-risk patients, typically including PSA below 10 ng/mL, Gleason score of 6 or lower, stage T1c or T2a, less than 50% of length of any biopsy

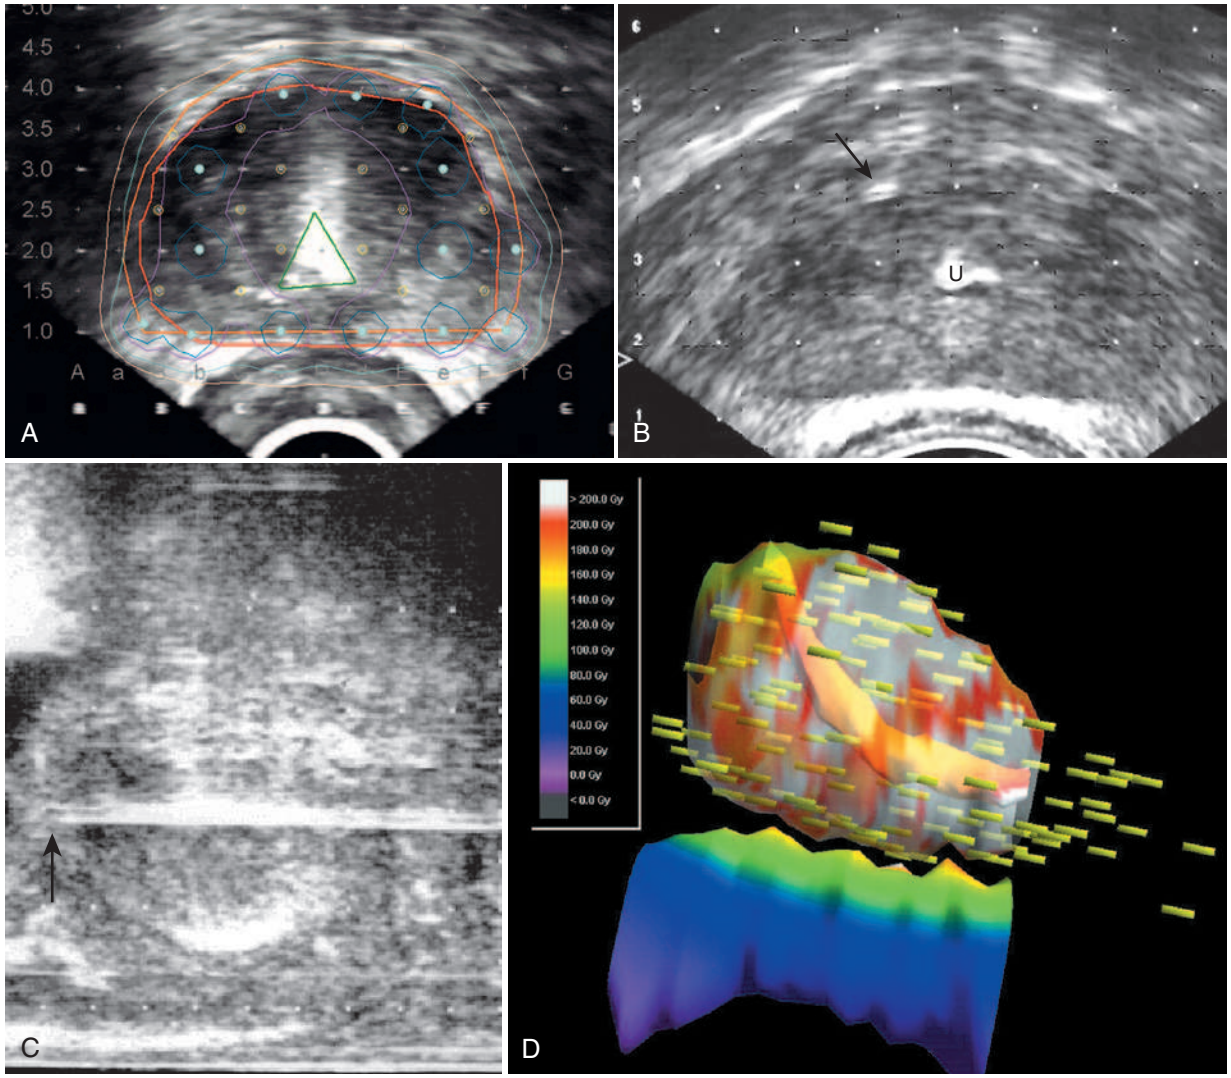

FIG. 10.14 Ultrasound-Guided Brachytherapy. Transrectal ultrasound (TRUS) used to plane and guide brachytherapy (radioactive seed implantation) using a special stepping device and perineal needle template. This same template can be used to guide transperineal saturation biopsy. **(A)** One of multiple transverse prostate images used to plan seed sites *(dots)* and determine radiation isodose dose curves *(colored lines).* Urethral dose is avoided *(white central area inside the green triangle).* Note the grid markers at the bottom *(A, a, b … G)* and on the left side *(1.0, 1.5, 2.0 … 4.5)* and the grid dots superimposed on the field. **(B)** TRUS-guided seed placement in the operating room; *U,* urethra. Transverse image shows the guiding grid dots and the tip of one inserting needle as a hamburger-like echo *(arrow).* **(C)** Sagittal image shows brachytherapy needle inserted to base of prost ate *(arrow)* to insert a row of seeds. **(D)** Postprocedural CT reconstruction shows the position of the seeds *(green)* and that the entire prostate is receiving a high *(white)* radiation dose. core, fewer than three positive biopsy cores, and life expectancy of over 10 years. In general, after initial diagnosis of low-risk disease and a confirming biopsy and if patients agree, they are actively monitored with combinations of PSA, PSA kinetics, PSA density, DRE, TRUS, repeat biopsy, and the new biomarkers to detect signs of progression resulting in reclassification, which triggers therapy. Use of mpMRI to specifically allow targeting of high-risk areas at repeat biopsy is emerging, but currently the effectiveness of the mpMRI approach has not been established.[125]

Significant progression and reclassification that triggers treatment is variably defined by a rapid rise in PSA (doubling time < 2 years) and increase in tumor grade or volume. Using this approach and with 14-year follow-up, Klotz has reported that 1.5% of men showed progression and 30% of men requested active therapy; cancer-specific mortality was only 5%, and in the interval 10 times as many men died of unrelated causes and were never symptomatic and avoided prostate cancer treatment and attendant complications. Other groups have shorter follow-up but have reported similar results.[115,116,123]

Progression of known or treated disease is monitored with PSA because it provides an easier and more objective indicator of total tumor burden and neoplastic activity than TRUS or mpMRI.[2,4,89]

Sonographic Appearance of Prostate Cancer

Gray-Scale Ultrasound

About 30% to 50% of prostate cancers are visible on TRUS, but detection varies depending on operator experience and equipment. The classic appearance of cancer is that of a **hypoechoic nodule** typically located in the **peripheral zone** abutting the capsule that cannot be attributed to benign causes[3,126,127] (Figs. 10.15, 10.16, and 10.17). The corollary to this is that about half of cancers are not visible on TRUS. Normal appearances on TRUS do not imply the absence of cancer and should not delay systematic biopsy if there is clinical suspicion of cancer.

Previously the sonographic appearance of prostate cancer was extensively debated. Early investigators incorrectly thought that most prostate cancers were hyperechoic. In 1985 Lee and colleagues[126] first convincingly demonstrated the **hypoechoic** appearance of cancer. Others subsequently confirmed that a substantial portion but not all peripheral zone cancers are hypoechoic to some extent.[127,128] The pathologic basis of the hypoechogenicity is the replacement of normal loose glandular tissue by a packed homogeneous mass of tumor cells with fewer reflecting interfaces and thus fewer echoes. Tumors that grow by infiltration or have a strongly glandular structure will preserve tissue interfaces and echogenicity and thus appear isoechoic.[127]

When attempting to correlate the echogenicity of neoplasms with the amount of stromal fibrosis, it was found that hypoechoic lesions had less stromal fibrosis than did their more echogenic counterparts. Also, hypoechoic lesions tended to be more aggressive than isoechoic lesions. Tumor size plays a role in visibility. Shinohara and colleagues reported 88% detection of tumors over 20 mm, 19% of tumors 4 to 10 mm, and none under 4 mm.[129]

Hyperechoic cancer has been described but occurs infrequently. Uncommon histologic types of cancer, including the cribriform pattern and comedonecrosis with focal calcifications, can be focally **echogenic.** The calcifications associated with comedonecrosis are tiny and act as crystals that are highly echogenic, more so than dystrophic calcifications. On scanning they are conspicuous and appear to twinkle, giving a "starry sky" appearance[127] (see Fig. 10.17C).

About 30% of prostate cancers are difficult or impossible to detect with TRUS because they are **isoechoic** and do not contrast

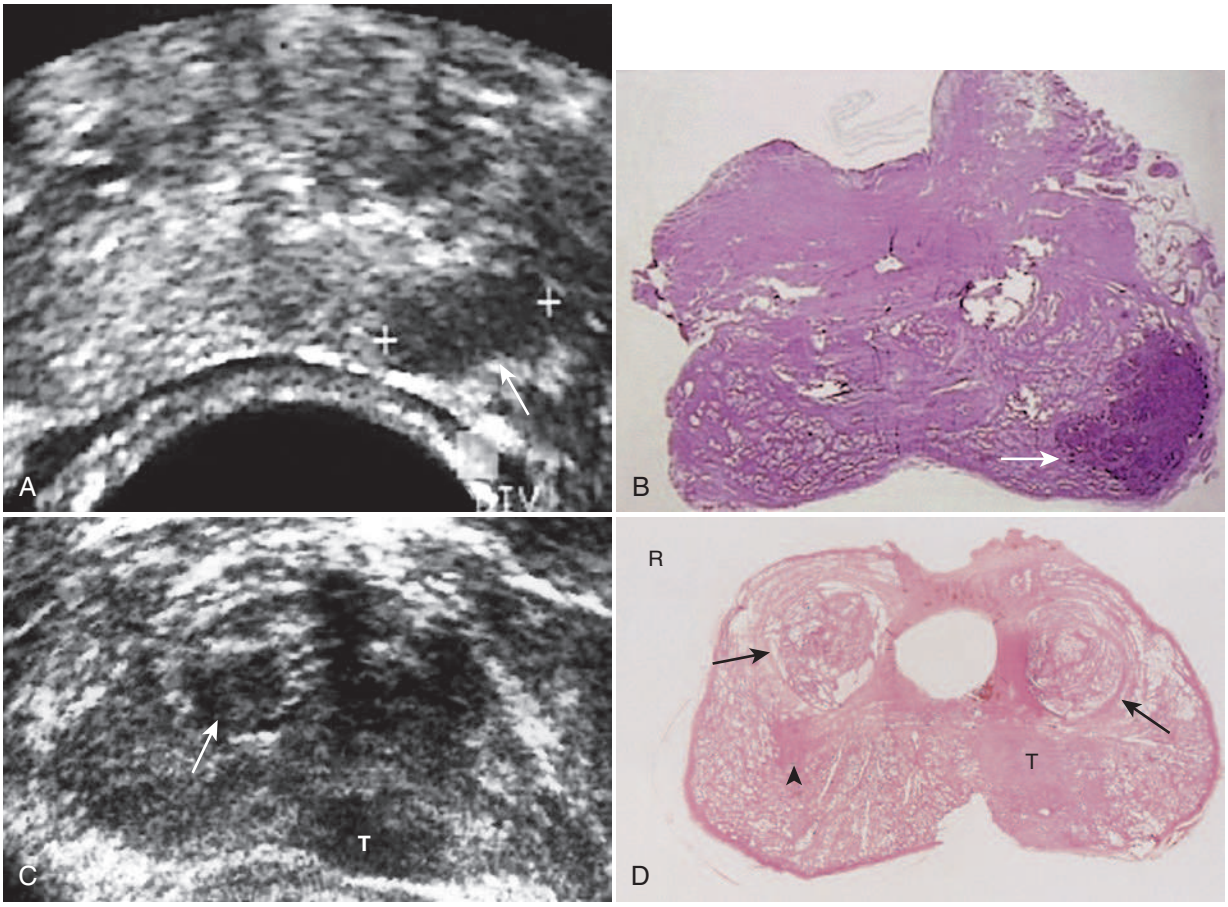

FIG. 10.15 Prostate Cancer: Typical Appearances. (A) Hypoechoic nodule in peripheral zone along the capsule that cannot be attributed to benign causes *(arrow).* **(B)** Pathology section of **A** shows the homogeneous solid cellular mass of tumor tissue *(arrow),* which reflects sound poorly compared with the adjacent prostate, which has the multiple glandular interfaces. **(C) Typical hypoechoic peripheral zone cancer nodule** *(T).* Note also the well-circumscribed hypoechoic benign prostatic hyperplasia (BPH) nodule in the right transition zone *(arrow).* **(D)** Section of (C) for correlation shows the homogeneous tumor mass *(T).* There is a second small lesion on the right side *(arrowhead).* Also note the bilateral BPH nodules *(arrows).*

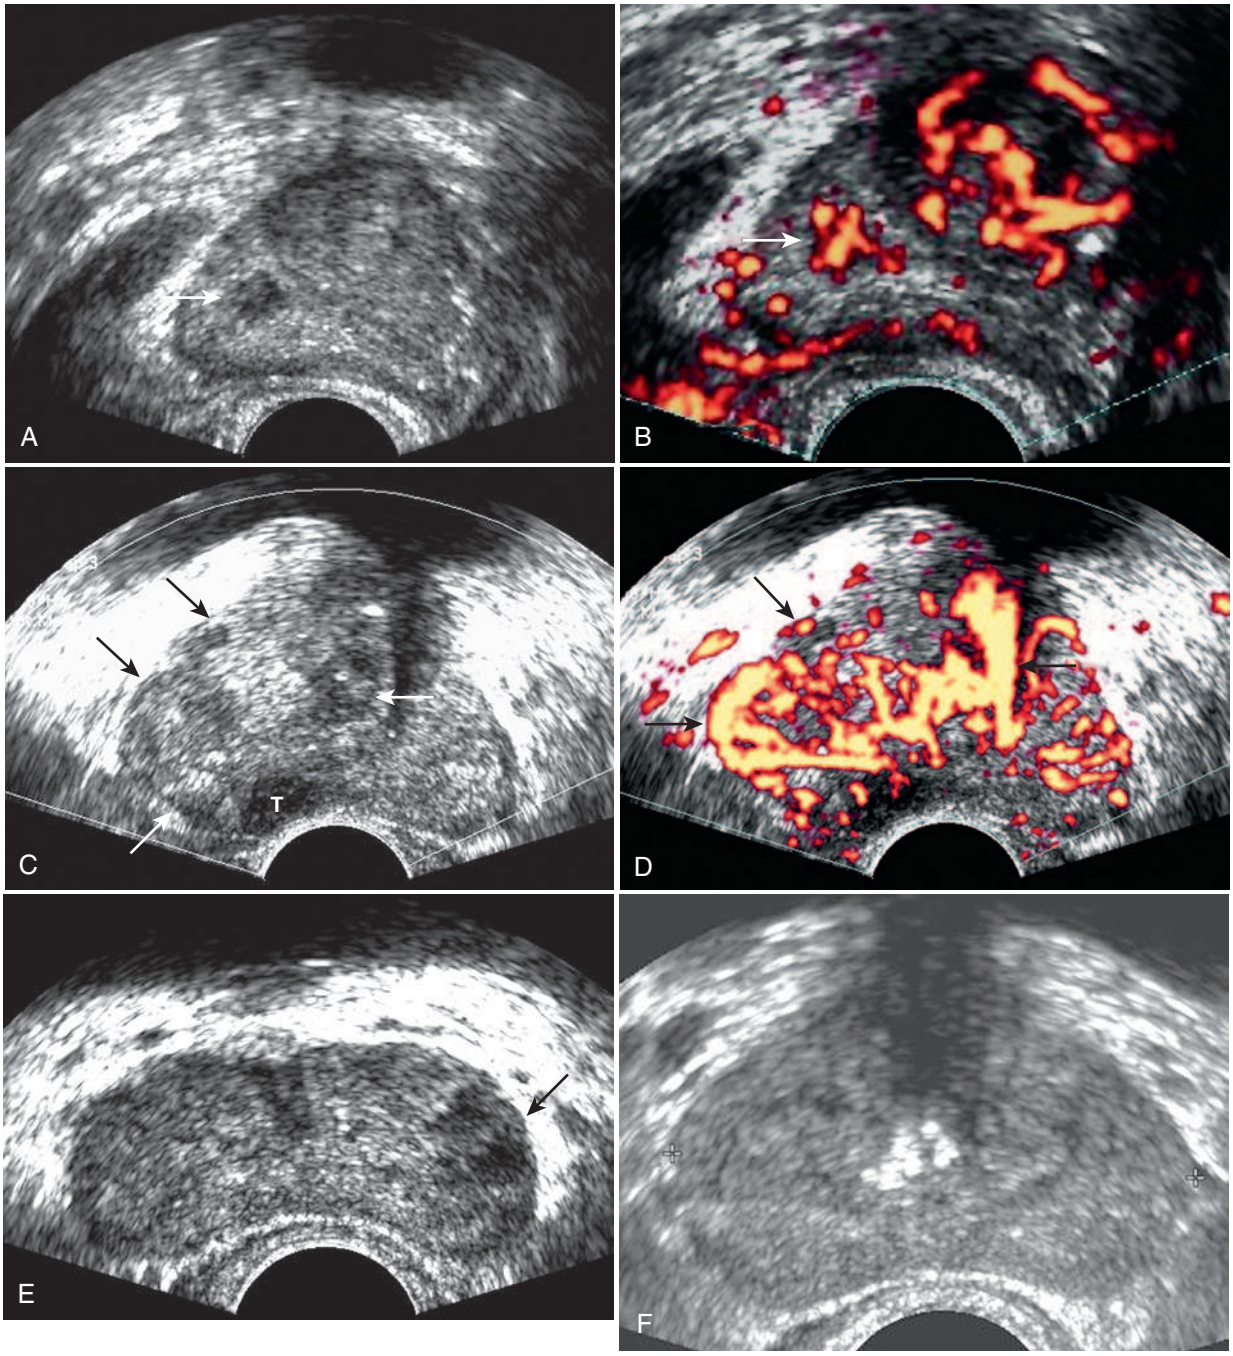

FIG. 10.16 Prostate Cancer: Less Common Appearances. (A) Small hypoechoic lesion entirely inside the peripheral zone *(arrow)* proved to be cancer. Digital rectal examination (DRE) findings were negative, but prostate-specific antigen (PSA) was slightly elevated. **(B)** Power Doppler scan of **A** shows increased vascularity *(arrow)* in region of the nodule. **(C)** Small "tip of the iceberg" lesion visible posteriorly in the right lobe *(T)*. Cancer is filling virtually the entire right lobe *(white and black arrows)*. Most of this tumor is isoechoic and thus not visible on gray-scale imaging. Remember that prostate cancer is typically multifocal and larger than the lesion seen on transrectal ultrasound (TRUS). **(D)** Power Doppler scan shows large abnormal area of hypervascularity involving not only the small peripheral hypoechoic lesion, but also most of the transition zone *(arrows);* PSA, 265 ng/mL; Gleason score, 7/10. **(E)** Multifocal cancer involving both right and left lobes: one hypoechoic, the other isoechoic. DRE findings were negative; PSA, 4.5 ng/mL with a 14% free/total ratio. In the left lobe there is a suspicious area anteriorly *(arrow)*. The right lobe appears very normal and free of lesions. At biopsy, both lobes had Gleason 6/10 cancer. **(F)** Isoechoic significant cancer not visible on ultrasound. DRE and TRUS findings were negative. PSA of 10.7 ng/mL led to biopsy, which showed bilateral Gleason 7 cancer.

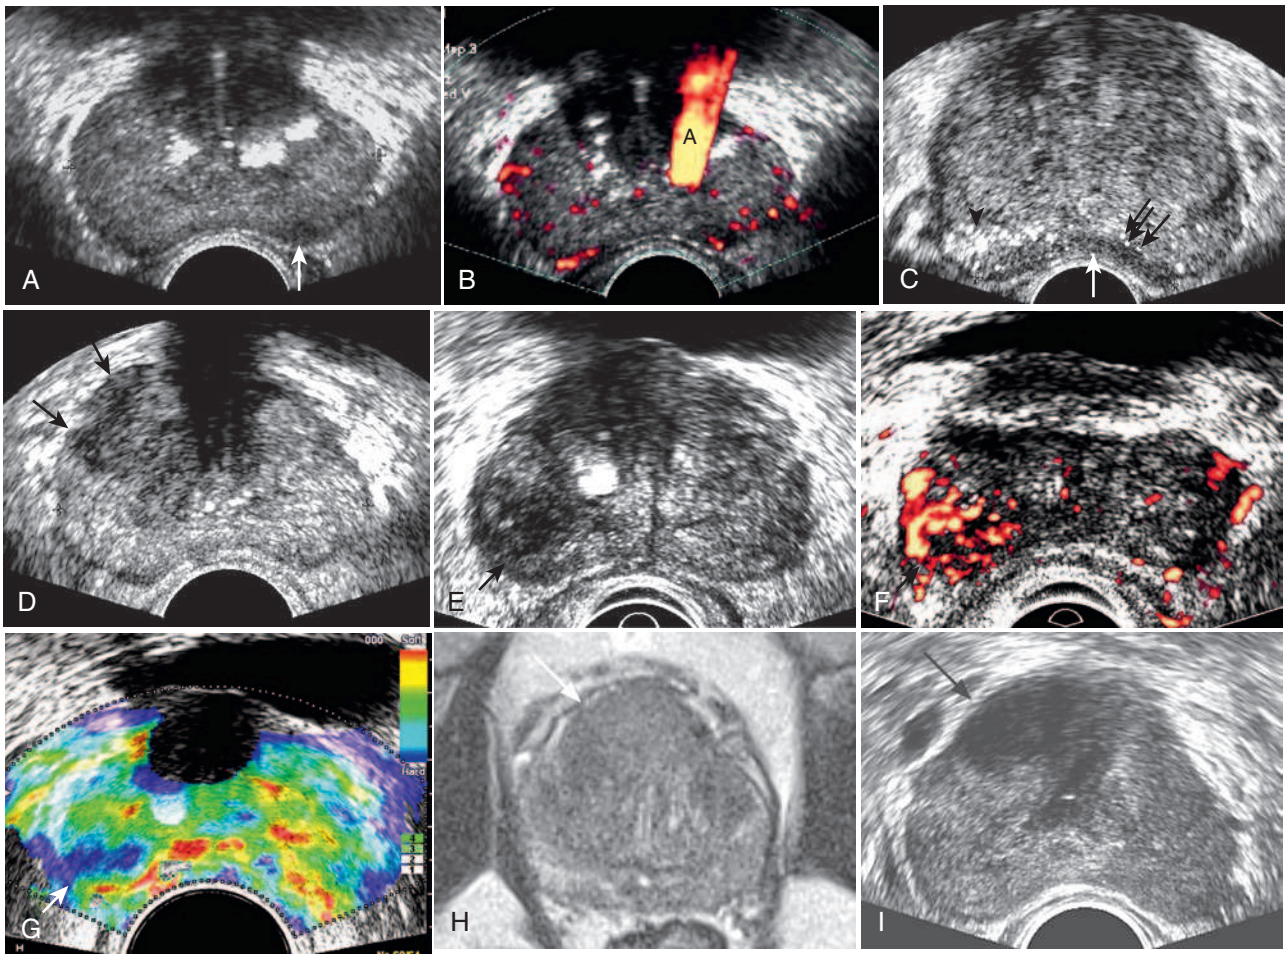

FIG. 10.17 Prostate Cancer: Other Appearances. (A) Almost isoechoic, impalpable **nonvascular cancer.** Digital rectal examination (DRE) findings were normal; prostate-specific antigen (PSA), 6.08 ng/mL with 12% free/total ratio. Transrectal ultrasound (TRUS) is only mildly suspicious for cancer at left *(arrow).* Biopsy showed isoechoic ultrasonically undetectable, Gleason 7/10 cancer in the right side involving 25% of the tissue. On the left, where there is a visible lesion *(arrow),* the biopsy was only 15% cancer. This highlights the need to do both systematic and targeted biopsy. **(B)** Power Doppler shows almost no detectable signal despite **extensive bilateral cancer.** Only about 80% of cancers demonstrate increased vascularity. The strong Doppler color signal anteriorly is all artifactual *(A),* from calcification. **(C) Extensive cancer** with "starry sky" appearance caused by comedonecrosis in the tumor. The malignant nodule extends across the entire peripheral zone *(between cursors).* On the right, the calcified clumps are normal corpora amylacea *(arrowhead).* On the left, the densities have a different character: small, more scattered, round, and very echogenic, and will "twinkle" on probe movement *(arrows).* These are highly suggestive of comedonecrosis in tumor. **(D)** Isolated **transition zone cancer** visible as an amorphous hypoechoic bulge of the right anterior transition zone *(arrows).* DRE was negative. Biopsy to investigate PSA of 12.0 ng/mL showed Gleason 6/10 cancer. **(E)** Typical hypoechoic **peripheral zone lesion.** Biopsy showed Gleason 8/10 cancer *(arrow).* **(F) Power Doppler** scan shows enhanced vascularity in lesion *(arrow).* **(G) Elastography** of same lesion *(arrow)* in **(F)** shows blue color in lesion, implying stiff tissue. **(H)** T2-weighted magnetic resonance imaging (T2W MRI) scan shows suspicious "charcoal" texture lesion bulging capsule in the right anterior fibromuscular zone *(arrow).* Prior systematic biopsy findings were not unexpectedly negative because only the posterior 2 cm of the prostate would be sampled. **(I)** Corresponding TRUS shows the same lesion. Such lesions are often missed on TRUS because attention and biopsy are confined to the posterior peripheral zone and because the procedure is performed by operators who use TRUS only to guide systematic biopsy without first evaluating the gland.

with the surrounding prostate gland (see Figs. 10.16C and 10.17A). When present, an isoechoic tumor can be detected only if secondary signs are appreciated, including glandular asymmetry, capsular bulging, and areas of attenuation. This is often true of transition zone cancer[127,130] (see Figs. 10.16E and 10.17D, H, and I).

When the tumor replaces the entire peripheral zone, it often is **less echogenic** than the inner gland, which is a reversal of the normal sonographic relation. When the entire gland is replaced with tumor on a BPH background, the gland may be diffusely inhomogeneous (see Fig. 10.17B).

Only about half of **hypoechoic** areas are cancer.[131] Other benign causes of hypoechoic areas seen in the prostate include normal internal sphincter muscle, hyperplasia, prostatitis, hematoma, vessels, benign glandular ectasia, and cysts.[2,91,127]

Fortunately, 70% of prostate cancers arise in the homogeneous **peripheral zone** where the homogeneous background makes

them easier to detect. About 20% are in the **transition zone,** where detection is hindered by the heterogeneous and variably vascular background of hyperplasia. Clues to transition zone cancer are the identification of a poorly marginated hypoechoic area that appears different from other BPH nodules and the focal loss of surgical capsule and asymmetrical bulge of the contour.[132]

Tumors in the **anterior midline** fibromuscular area anterior to the urethra are difficult to detect because this area is far from the probe and obstructed by the urethra; these tumors often become very large before being detected. These have also been called PEATs **(prostate evasive anterior tumors).** Biopsy of these tumors can be difficult. The typical systematic transition zone biopsy may miss them because of their far anterior and midline location and the desire to avoid the urethra during biopsy. Just remembering to look in this area at TRUS examination and using mpMRI are helpful in detection of these anterior tumors[133] (see Fig. 10.17H–I).

Some suggest that systematic biopsy without scanning or looking for lesions is adequate for cancer detection. We feel it remains important to search for suspicious areas at TRUS. Biopsy of suspicious lesions doubles the likelihood of cancer detection (58% vs. 31%), shows greater percent of core involvement (50% vs. 10%), and doubles the likelihood of Gleason score of 7 or higher (69% vs. 28%).[87,134,135]

New ultra-high-frequency (29 MHz) probes are under evaluation. With such high resolution, it appears that additional appearances and tissue characteristics may become helpful to discriminate between benign and cancerous tissue that are different from the hypoechoic nodule seen with lower resolution. With high frequency, benign areas tend to show ducts or a "Swiss cheese" appearance and malignant areas appear more isoechoic and may have a heterogeneous mottled appearance with microcalcifications, shadowing regions, and subtle capsular irregularity. A scoring system called PRI-MUS (prostate risk identification using micro-ultrasound) has been proposed; this can be helpful in predicting presence and grade of cancer.[136]

Transrectal Ultrasound (TRUS) Findings Suspicious for Prostate Cancer

Hypoechoic nodule not attributable to benign causes
Often in peripheral zone
Nodule with vascularity
Nodule and capsule bulge
Capsule bulge
Capsule irregularity
Focal hypervascularity
Loss of surgical capsule definition

Color Flow and Power Doppler Imaging

Doppler imaging has been evaluated for detection of neovascularity associated with cancer. This approach is especially attractive to find isoechoic cancer because pathologic examinations show cancers have increased neovascular density. Malignant neovascularity vessel diameter ranges from about 0.01 to 0.05 mm. However, Doppler ultrasound is limited to detecting flow in vessels about 10 times larger, with diameter greater than 0.1 mm. As a result, increased flow may not be apparent until lesions have grown enough to generally increase blood flow[91,137] (see Fig. 10.16B and D). Both color Doppler flow imaging and the more sensitive power Doppler can be used. I prefer power Doppler, which is more sensitive to flow detection, gives a more uniform display of vascular density, and produces images that are more stable with different equipment settings[133,137] (see Fig. 10.5). Flow inside a lesion is more specific than peripheral flow. Overall, Doppler increases cancer detection by about 5% to 17% over gray-scale imaging.[130,137,138] Suspicious hypoechoic nodules that are also vascular tend to have larger tumor volume and higher Gleason score.[139]

Doppler imaging has pitfalls. Not all cancers are vascular, and the absence of vascularity should not prevent systematic biopsy or biopsy of a suspicious nodule. Vascularity may be increased with nonmalignant conditions such as inflammation (see Fig. 10.8B). There is no increased benefit for color flow Doppler in the transition zone because BPH nodules can range from hypovascular to hypervascular.[6,139] The capsule of the prostate is very vascular, especially at the base and apex, and this can mimic neovascularity to the uninitiated operator. Prostate calcifications and corpora amylacea cause considerable Doppler twinkle artifact and may prevent diagnostic studies (see Fig. 10.7D).

Contrast-Enhanced Ultrasound

Tumor-associated neovascularity consists of small disorganized vessels of 10 to 100 μm diameter, which are below the usual Doppler resolution limit of about 100 to 1000 μm (0.1-1.0 mm). Microbubble contrast agents have been developed that act as intravascular contrast agents and allow imaging of contrast-enhanced vessels down to 50 to 100 μm. Apart from visual inspection of increased vascular intensity, several other parameters can be assessed, including bolus arrival time, time to peak intensity, wash in–wash out curves. 5α-Reductase inhibitors have been used to suppress normal vascularity and increase conspicuity of neovascularity. Additional developments are underway to attach ligands to the microbubbles that bind to specific tissue or tumor targets and can be used to enhance lesion delectability or, more important, to target delivery of therapeutic agents.[2-4,91]

Sensitivity and specificity of CEUS for cancer detection are about 70% and 74%. CEUS requires experienced operators and currently there is inadequate standardization of agents, imaging techniques, and diagnostic criteria. It can assist in detection of cancer but as yet cannot replace systematic biopsy.[2,91,140]

Three-Dimensional Ultrasound and Transrectal Ultrasound–Magnetic Resonance Imaging Fusion

Because three-dimensional (3-D) depends on two-dimensional (2-D) scanning, in general there is no improvement in cancer detection, but there may be slight improvement in cancer staging.[137] There may be a role for 3-D imaging in accurate volume determinations when precise volumes are needed to monitor changes in gland size. The Urostation (Koelis, France) MRI-TRUS fusion biopsy platform uses 3-D imaging to co-register MRI and

TRUS images and records areas where biopsy specimens have been taken.[91] Increasingly, mpMRI and MRI-TRUS fusion biopsy are proving helpful in complex cases such as in patients with multiple negative extensive biopsies but rising PSA.

Elastography

Tumors are about 5 to 28 times stiffer than normal prostate. Elastography of the prostate assumes that stiff areas such as tumors with increased cellularity allow less internal movement. The amount of movement is presented as a color-coded map from blue (stiff) to red (elastic) (see Fig. 10.17G). In strain elastography, force is applied by probe motion, a technique that is very operator dependent and does not allow quantification. In shear wave elastography, the probe is held still and strain is provided by sound waves, which allow better standardization and direct measurement of Young's modulus.

Meta-analysis of elastography reports sensitivity of 71% to 82% and specificity of 60% to 90%. Cancer detection increases with lesion size and Gleason score. However, elastography does not evaluate the gland uniformly. Performance is better in the peripheral zone, which is adjacent to the probe, especially the apex and midgland, and is less accurate at the base, anterior gland, and transition zone. The technique remains operator dependent. Although it can assist in lesion localization, it does not allow avoidance of systematic biopsy. False-positive results are seen with chronic inflammation and atrophy. Experience has shown that elastography is subjective and has a long learning curve and that images are difficult to reproduce.[4,6,91,141]

ULTRASOUND-GUIDED BIOPSY

Biopsy should be offered to men who would benefit from tissue diagnosis following informed consent and after shared decision making. Most men are initially identified by PSA over 2.5 to 4 ng/mL and/or palpable nodule. Other factors taken into consideration with regard to biopsy include comorbidities, risk calculators, results of imaging and biomarker tests, and patient preferences. But the final decision is individual, relying on the physician's acumen and patient's wishes. Indications differ between initial and subsequent biopsies.[26,142,143]

Preparation for Biopsy

Typically, TRUS biopsy is performed in an ambulatory setting. Appropriate clinical information should be available to know why the biopsy is needed and to allow for its safe performance. This includes results of DRE, PSA, and other relevant tests including imaging, prior biopsy results, relevant medications, and comorbidities. Risk factors that can alter risks of infection or bleeding should be identified so they can be appropriately managed. Informed consent should be obtained.

Antibiotic Prophylaxis

Transrectal biopsy requires antibiotic prophylaxis to minimize risk of infection and sepsis. Specific antibiotic choices can be found by consulting regional urologic association guidelines and infectious disease specialists and taking into account local and regional antibiotic resistance patterns. For low-risk patients most guidelines recommend fluoroquinolone (ciprofloxacin) or a cephalosporin. Minimal coverage should start 1 hour before the procedure and last for 24 hours; some are more comfortable with 3-day courses, although this additional coverage is debated as being unnecessary and possibly contributing to antibiotic resistance. Patients at increased risk of infection may benefit from supplemental antibiotics such as aminoglycosides or ceftriaxone. Risk factors include recent urinary infections, recent antibiotic use, recent instrumentation or catheter, international travel especially to southeast Asia, hospital exposure (both patients and workers), and immunotherapy. Endocarditis prophylaxis for patients with valvular heart disease is no longer recommended.[144] Use of rectal swab stool culture to individualize antibiotic choices has been suggested and may decrease infections. Although there are concerns about the logistics of implementing this approach for every patient, it may be helpful in high-risk patients and those with prior complications. For complex cases, infectious disease consultation may helpful. Most prostate biopsies are done transrectally (Fig. 10.18), but some suggest that transperineal biopsy should be reintroduced to decrease infection risk because of the increasing prevalence of cephalosporin-resistant *E. coli*.[145]

Postbiopsy sepsis can occur acutely after biopsy, and its seriousness may not be initially appreciated by the patient or his physician. I find it useful to emphasize to the patient the potential seriousness of infection and the need for prompt medical attention and provide patients with a letter to their physicians stating that postbiopsy sepsis should be managed promptly with blood and urine cultures and intravenous broad-spectrum antibiotics.[146-148]

Bowel Preparation

Laxatives or a cleansing enema is helpful to clean the rectum to improve visibility. Some believe that an enema decreases infection risk, but this has not been confirmed. Povidone-iodine enemas and suppositories have been suggested to decrease infections, but this has not been confirmed.[26,148]

Analgesia

Analgesia is important to decrease discomfort of the procedure. Periprostatic nerve block with 1% lidocaine is standard. In general, 5 mL is injected into the neurovascular bundle on each side (10 mL total) at the base in the fatty triangle between the prostate and SV. Some suggest additional injections at the apex and sides of the prostate, but we have not found these to provide improved analgesia. Analgesic gel may be helpful if the anus is tight or sensitive. Some have found oral medications, including acetaminophen and combinations, to be helpful. In rare cases conscious sedation may be needed.[26,149,150]

Anticoagulation

Aspirin and NSAIDs do not need to be discontinued and are associated with clinically insignificant bleeding. Antiplatelet drugs such as clopidogrel (Plavix) should be discontinued for 5 to 10 days before the biopsy. More potent anticoagulants should be discontinued, but only after consultation with the prescribing physician to ensure patient safety. Bridging anticoagulation with

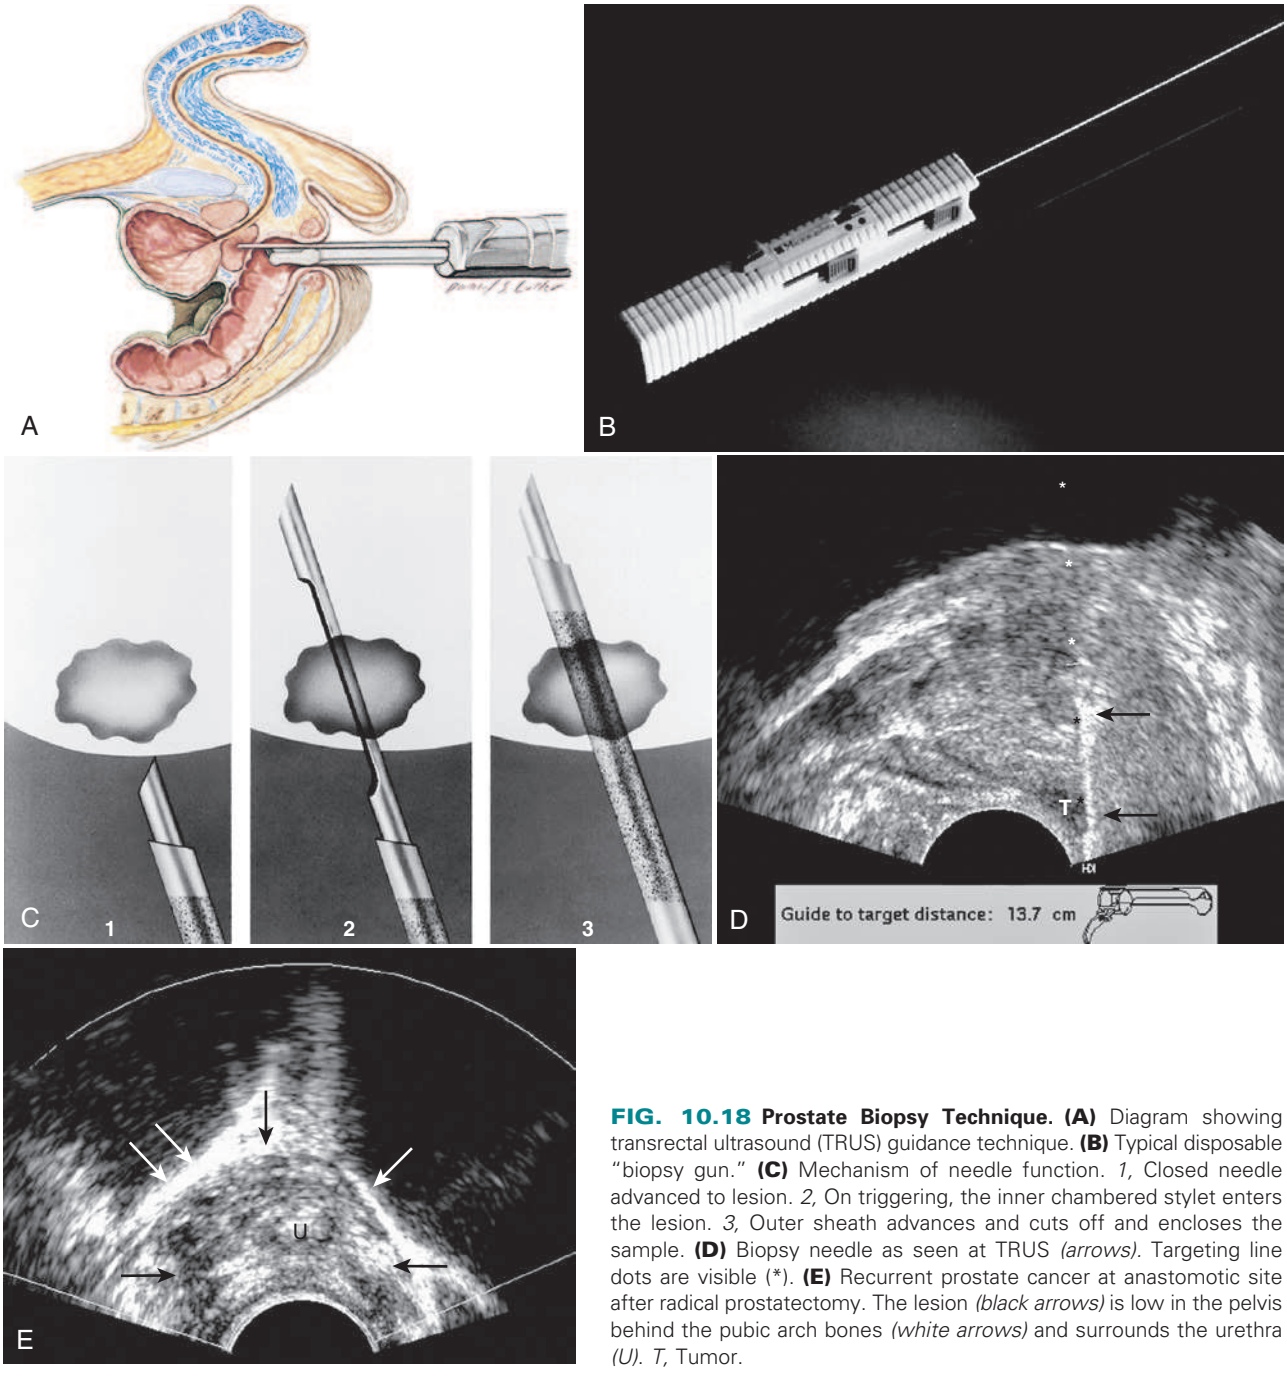

FIG. 10.18 Prostate Biopsy Technique. (A) Diagram showing transrectal ultrasound (TRUS) guidance technique. **(B)** Typical disposable "biopsy gun." **(C)** Mechanism of needle function. *1,* Closed needle advanced to lesion. *2,* On triggering, the inner chambered stylet enters the lesion. *3,* Outer sheath advances and cuts off and encloses the sample. **(D)** Biopsy needle as seen at TRUS *(arrows).* Targeting line dots are visible (*). **(E)** Recurrent prostate cancer at anastomotic site after radical prostatectomy. The lesion *(black arrows)* is low in the pelvis behind the pubic arch bones *(white arrows)* and surrounds the urethra *(U). T,* Tumor.

short-acting heparin may be needed. Warfarin should be discontinued for 5 days, and international normalized ratio (INR) should be confirmed to be 2 or lower. The newer oral anticoagulants such as dabigatran should be withheld for 3 days and coagulation testing is not needed. In general, anticoagulants can be restarted after 24 hours. Coagulation specialists should be consulted if patients have other bleeding disorders.[26,151,152]

Technique

The patient lies in the decubitus position. A DRE is performed before probe insertion to palpate the prostate, to confirm that probe insertion is safe, and to relax the sphincter. We insert the probe with needle guide attached at the outset to save time and examine the prostate with the guide in place. The decision to perform the biopsy has already been made, so only target details need to be clarified. A variety of probes and guides are available. Ching and colleagues have suggested that end-fire probes and guides provide better sampling than side-fire devices.[24] End-fire probes, unlike side-fire probes, allow easy sampling of all parts of the prostate including the apex and far anterior transition zone. Electronic guidelines direct the needle path (see Fig. 10.18D).

Local anesthetic can be injected as soon as the probe is inserted and before the gland is examined, to allow the agent to have

additional time to act. After injection, prostate measurements are made and the SVs and prostate are examined in a standardized manner. Suspicious areas are imaged and noted for targeted biopsy.

Biopsy is best done by a single operator who controls both the probe and the gun and takes samples as appropriate for the situation. The **automatic biopsy gun** with 18-gauge needles is standard and has remarkable patient acceptance and safety. With the gun cocked, the needle is "parked" in the guide, ensuring that the tip is safely inside the guide. The probe and contained needle are moved to the target using the targeting line. With end-fire probes, better samples are obtained if the prostate is compressed during the biopsy. A simple, swift motion advances the gun and needle tip to the surface of the lesion. Once in position, the device is triggered and the needle advances approximately 2 to 3 cm to cut the tissue core and trap it in the beveled chamber of the inner needle. We sample suspicious areas first in case the patient cannot tolerate the entire procedure, and finish with systematic sampling. Biopsy through the urethra, internal urethral sphincter, and ejaculatory ducts is avoided. When the biopsy is finished, the probe is removed and the site is palpated for hematomas. After the biopsy, we keep the patient for an hour to allow observation and recovery, the first 20 minutes lying down and the remainder seated. This helps in management of late onset of vasovagal complications.

Side Effects and Complications

Minor side effects that do not require treatment are common. These include bleeding in the urine (50%) and stool (30%) and hematospermia (50%). Minor bleeding in the urine and stool generally lasts only a few days but can continue for several weeks. The ejaculate may remain discolored for many months. Transient erectile dysfunction is uncommon (<1%), but it is not clear if this is psychological as a result of concerns related to biopsy or physiologic.[25,143,148]

About 1% to 5% of patients have a hypotensive vasovagal-like reaction after biopsy, which can occur up to 60 minutes after the procedure. It is characterized by pallor, sweating, nausea and vomiting, bradycardia of 50 to 60 beats/min, and hypotension. Most men recover spontaneously and rapidly after being placed in Trendelenburg head-down position. We keep patients in the clinic for an hour after the biopsy to avoid problems with these delayed vasovagal hypotensive reactions.

Significant biopsy complications requiring physician intervention or hospitalization are relatively uncommon, but incidence of hospital admissions for any reason within 30 days of biopsy is about 4.8% to 6.9% regardless of the mode of guidance, needle size, or approach and is probably not related to number of biopsy cores. These complications include minor transient fever (5%-7%), sepsis necessitating hospitalization (1%-3%), large hematoma (uncommon), transient symptoms of obstruction (6%-25%), urinary retention necessitating catheterization (0.2%-2.6%), and significant rectal bleeding (1%). Immediate visible rectal bleeding usually responds to 2 to 5 minutes of finger or probe pressure. With the use of prophylactic antibiotics, the incidence of septic complications requiring therapy is about 1% to 2%. Hospitalizations after biopsy are mainly (about 70%) due to infections with antibiotic resistant *E. coli*. These infections have been increasing owing to increased prevalence of ciprofloxacin resistance and are more common in patients at risk. Sepsis can rapidly progress to septic shock. Patients should be advised to seek help promptly if they start feeling feverish or unwell. Tumor seeding is virtually unknown.[25,143,147,148]

Biopsy should never be taken lightly. Some patients have required prolonged hospitalization, and there are rare reports of spinal infections and patients dying from biopsy-related complications.

Indications and Sampling

Biopsy is performed in patients suspected to have significant cancer in whom the results would alter clinical management. Currently for the first biopsy the AUA recommends only TRUS guidance without preceding mpMRI.[153]

The **number of samples and locations** used in prostate biopsy have been controversial. Initially it was thought that only suspicious areas should be sampled. It was quickly discovered, however, that only about 50% of hypoechoic areas contained cancer, and that significant cancer also could be present in normal-appearing areas of the prostate.[131,154] This led to "targeted plus systematic" biopsy. Currently if no lesion is seen, then obtaining 10 to 12 systematic cores is felt to be appropriate on the initial visit (Fig. 10.19). This balances the likelihood of detecting significant cancer while minimizing overdetection of insignificant disease, but also acknowledges that about 20% to 30% of significant cancer could be missed. Further increase in number of systematic cores above 12 to 14 or use of saturation biopsy is felt to be not beneficial, nor does it appear to decrease detection-positive rate at subsequent biopsies. Additional cores should be obtained from suspicious areas that lie outside the systematic pattern.

Indications for Prostate Biopsy

INITIAL BIOPSY

Whenever tissue diagnosis would alter management
Abnormal findings on digital rectal examination
Unexplained PSA elevation
Abnormal findings on transrectal ultrasound
Excessive PSA velocity
Positive chips at transurethral resection of prostate
Metastatic adenocarcinoma when primary is not evident
Approved research

REPEAT BIOPSY

Initial biopsy is negative but there is continued clinical suspicion
Initial suspicious histology (high-volume HG-PIN, ASAP, microscopic cancer)
PSA level greater than 10 ng/mL or rising
Follow-up of men under active surveillance
Evaluation for recurrence after therapy
Approved research

ASAP, Atypical small acinar proliferation; *HG-PIN,* high-grade prostate intraepithelial neoplasia; *PSA,* prostate-specific antigen.

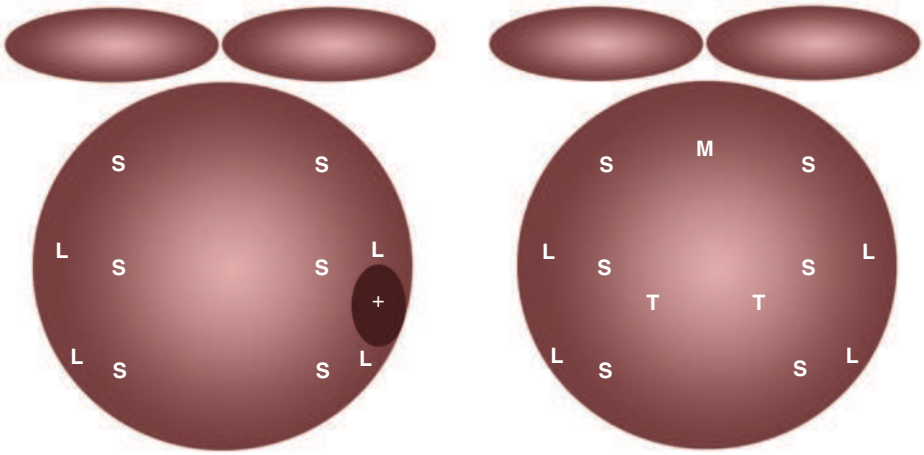

FIG. 10.19 Biopsy Sites as Viewed en Face From Posterior Aspect of Prostate. Left image shows the standard 10 prostate biopsy sites. Additional samples are taken of any lesion that is evident outside the systematic pattern (+). Right image shows a typical extended pattern of biopsies, in this case a 13-core pattern. In addition to the sextant sites *(S)*, samples are taken from the lateral peripheral zones *(L)*, deep in the anterior transition zone *(T)*, and from the peripheral zone in the midline *(M)* at the base, cephalad to the verumontanum. *L*, lateral or "anterior horn"; *S*, sextant.

Systematic samples are obtained from the peripheral zone at the base, middle, and apex of the gland both medially and laterally from each lobe.[25,26,135,142,143] Some term this patterned approach as "random biopsy" or "blind biopsy." It is neither random nor blind, but rather sampling follows a specific systematic pattern along with a search for suspicious targets. It is important that the lateral samples include the "anterior horns" (part of peripheral zone that curves anteriorly around the sides of the transition zone) and the apical peripheral zone. Others have found that both medial and lateral samples are equally important, and that it remains important to search for hypoechoic nodules.[153,155] This approach should result in an overall 30% to 60% positive biopsy rate, and about a 60% or higher yield for lesions that are suspicious at ultrasound.[135] Although TRUS biopsy is the established and currently recommended procedure for the *initial* biopsy because of its simplicity and cost-effectiveness, there is emerging enthusiasm to consider mpMRI before the first biopsy.[156,157] Optimistic reports from a highly experienced luminary center in biopsy-naïve patients showed overall cancer detection with TRUS of 57%, with 37% being low grade. In contrast, mpMRI in bore biopsy yielded 70% cancer, of which only 6% was low grade. By relying on mpMRI findings, these researchers estimated a decrease in biopsy rate of 51% and an 81% decrease in low-risk cancer detection. Nonetheless, follow-up of negative biopsy was still recommended.[158] Reviews of published reports find little difference between TRUS and MRI for initial biopsy and suggest that, currently, systematic TRUS biopsy may suffice for first biopsy and that there is still need for research and training before restricting biopsy only to mpMRI targets because systematic TRUS biopsy detects significant cancer in about 12% of men with negative mpMRI findings.[159]

About 20% to 30% of men with initial negative biopsy have cancer that was missed. The box lists indications for repeat or additional biopsy. Following negative initial biopsy, some have suggested that after four negative repeat sessions the yield is only 4%, but others find a continued cancer yield of about 15% on each repeat.

Timing of the repeat biopsy varies with clinical indications and pathologic findings at initial biopsy. In low-risk cancer patients opting for active surveillance, an initial confirmatory repeat is suggested in 3 to 18 months and then follow-up as per local protocols. Atypical small acinar proliferation (ASAP) is found in about 4% (1%-23%) of biopsies. Many pathologists believe that ASAP is a minute cancer focus and may represent either a tiny tumor or possibly a few cells from the margin of a larger adjacent tumor. Repeat biopsy is recommended in 3 to 6 months and yields cancer in about 40%. Multifocal high-grade prostate intraepithelial neoplasia (HG-PIN) is found in about 5% (0%-25%). It is a histologic abnormality found in association with cancer but not necessarily leading to cancer. With multifocal HG-PIN, repeat biopsy is suggested in 1 year and cancer yield is about 40%. Repeat biopsy is not recommended for unifocal HG-PIN unless clinical findings are worrisome.[26,142,143]

There is no generally accepted protocol for sample sites at repeat biopsy, but most recommend repeating the systematic 12-core biopsy and adding about four additional transition zone cores (see Fig. 10.19, right).

Most of the cancers will be found in the original systematic sites with only a small contribution from the added transition zone and midline.[114] It is important at repeat to especially evaluate the anterior fibromuscular area, a common site for large missed cancers[133] (see Fig. 10.17H–I). Most would not consider transperineal template biopsy with multiple cores for simple repeat but would consider it for special situations such as staging for focal therapy.[26,142,143,160]

mpMRI-TRUS Fusion Biopsy

mpMRI is emerging for lesion localization before biopsy, especially repeat biopsy. At *initial* biopsy both mpMRI targeted and systematic 12-core approaches have similar cancer detection rates. Targeted

mpMRI approaches require fewer cores to detect significant cancer and avoid detection of many clinically insignificant cancers, but still miss some significant cancer. At time of repeat biopsy following prior negative biopsy, MRI guidance increases overall cancer detection by about 1.62 times over systematic biopsy and should be considered before repeat biopsy.[159-161] mpMRI is especially helpful to search sites that are typically not sampled at systematic 12-core biopsy including the transition zone and anterior fibromuscular area (see Fig. 10.17H–I) Currently there are caveats to mpMRI use, including need for high-quality MRI or expert readers, use of standardized PI-RADS 2 reporting formats, definitions of what constitutes "significant cancer," costs, and access, but developments are occurring rapidly in all these areas.[160,162]

There are several general methods of MRI guidance: cognitive, MRI-TRUS fusion, and in-bore biopsy.[163,164] With **cognitive guidance** the operator reviews the MRI and uses this knowledge to target the same areas at TRUS biopsy. This is the easiest and likely most used approach currently. With **MRI-TRUS fusion** biopsy, the MRI images and targets are co-registered and fused to TRUS images. Biopsy is performed with one of several available tracking and co-registration devices and is slightly more sensitive in detection of significant cancer than the cognitive approach.[161,162,165] With **in-bore** biopsy, the biopsy is carried out in the MRI gantry.

Transperineal Biopsy and Template Biopsy

Transperineal biopsy is considered for two separate reasons: to decrease infections and to provide accurate cancer characterization and mapping for focal therapy and active surveillance. Both can use freehand approaches or use the same template that is used in brachyradiotherapy (see Fig. 10.14). Chang and colleagues have suggested that transperineal biopsy provides more sterile access to the prostate and avoids concerns of increasing antibiotic resistance and sepsis.[145,166]

Before considering active surveillance or focal therapy, some have expressed concern that sampling by conventional biopsy is inadequate to detect and map significant disease. In these cases **transperineal template mapping** or saturation biopsy under general anesthesia is performed, taking samples using the brachytherapy template, which allows 40 to 70 evenly distributed cores taken 5 mm apart (see Fig. 10.19). Compared with conventional TRUS biopsy, cancer detection increases to about 70% from 20% to 40%. Complications are similar to those of TRUS biopsy, but transient urinary retention is seen in up to 39%.[166]

Biopsy After Radical Prostatectomy

Radical prostatectomy should reduce PSA to virtually undetectable levels. Recurrent disease is suspected if the PSA starts rising. In this situation, many urologists just arrange for radiotherapy of the prostate bed and pelvis and do not rely on biopsy. If histologic proof is needed before therapy, TRUS with biopsy can be used to evaluate the anastomotic site and look for local lymphadenopathy and pelvic masses (see Fig. 10.18E). If requested, in such cases we obtain two samples from either side of the anastomosis and perform biopsy of any other abnormal masses and any SV remnants. mpMRI can help identify suspicious areas. Care must be taken not to mistake large pelvic vessels for masses; this can be avoided by using Doppler before biopsy (Fig. 10.20).

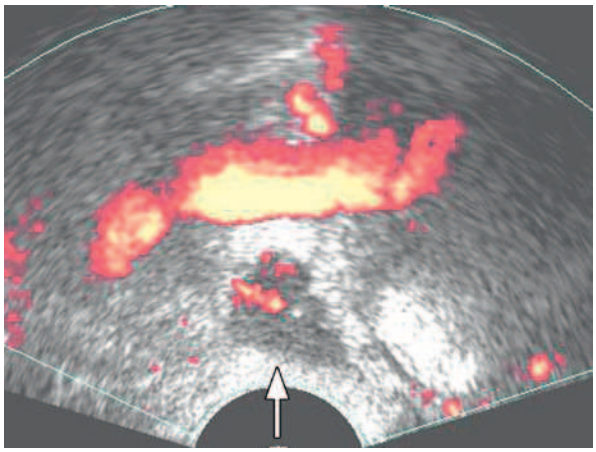

FIG. 10.20 Other Transrectal Ultrasound (TRUS) Applications: Pelvic Mass. Woman with perirectal mass *(arrow)* shown to be recurrent colon cancer by TRUS-guided biopsy. Note the large adjacent vessel. When biopsy is performed outside the prostate, Doppler helps avoid injury to vessels. The transrectal technique is useful for biopsy of any pelvic mass in men or women that can be accessed by the probe.

Biopsy in Men With Absent Anus

Men who have had their anus closed by abdominoperineal resection are difficult to manage when their PSA becomes elevated. Prostate visibility is restricted through both the transabdominal and the transperineal approach. Transperineal ultrasound–guided biopsy with local anesthesia is moderately successful in obtaining prostate tissue. It is helpful to precede the biopsy with mpMRI, which may locate suspicious areas that cannot be seen with ultrasound. Antibiotic prophylaxis and coagulation management is the same as with TRUS biopsy. We scan the patient in the decubitus position just as with regular transrectal biopsy, use the same transrectal probe because of its small size, push it firmly against the perineum, and proceed as with a transrectal biopsy using local skin cleansing. Others scan using the lithotomy position. A Foley catheter with inflated balloon and some fluid in the bladder can help to identify the prostate and to avoid urethral injury. About 20 mL of 1% lidocaine is needed for perineal anesthesia. Both lobes are systematically sampled and extra cores are taken from suspicious regions.[167] Cancer yield is about 30%; others report it as high as 40% to 82%. If ultrasound visibility is very restricted owing to perineal distortion by surgery, then an alternative approach using mpMRI for initial lesion detection followed by CT transsciatic biopsy or in-bore MRI-guided biopsy could be considered.

OTHER APPLICATIONS OF TRANSRECTAL ULTRASOUND AND BIOPSY IN MEN AND WOMEN

In both men and women the transrectal route is useful to evaluate and perform biopsy on any pelvic mass or structure that is within range of the probe and needle. TRUS also provides high-resolution pelvic access in girls and women when transvaginal ultrasound is not possible (see Fig. 10.20).

A few caveats exist. Because of the large vessels in the pelvis, it is important to use Doppler ultrasound to investigate any area where biopsy is contemplated. Remember that pelvic kidneys may mimic pathologic masses. Also, anterior meningoceles may mimic masses behind the rectum and should not be entered because of the risk of infection.

We have performed abscess drainage and biopsies of numerous masses, including ovarian masses, recurrent masses after diverse primary tumor surgery, periureteric masses, bladder masses, and pericolic masses, in both men and women. All these procedures have the same preparation and protocol as the basic prostate biopsy.[11]

In addition, the distal ureters and ureterovesical junctions are readily accessible to evaluation for distal ureteric obstructing lesions, including calculi.

CONCLUSIONS

TRUS has revolutionized prostate assessment and biopsy. TRUS-guided biopsy is currently the standard for prostate biopsy. Concepts regarding all aspects of prostate cancer are rapidly changing and there is rapid emergence of new biomarkers, therapies, and imaging modalities including mpMRI, all of which will facilitate assessment and management of men with prostate cancer.

Transrectal probes provide access to all regional structures in men and women, and TRUS can also help with their management.

CHAPTER 11

The Adrenal Glands

Christina Marie Chingkoe, Olga R. Brook, and Deborah Levine

SUMMARY KEY POINTS

- The adrenal glands are responsible for maintaining homeostasis and regulating hormonal production and secretion within the body.
- The adrenal cortex is comprised of the zona glomerulosa, fasciculata, and reticularis, which are responsible for aldosterone, glucocorticoid, and androgen regulation, respectively. The adrenal medulla regulates catecholamines.
- Sonographic visualization of the right adrenal gland is best through a transverse oblique and coronal view, using the liver as an acoustic window. Sonographic visualization of the left adrenal gland is best along the posterior axillary line through an oblique coronal view, using either the spleen or the left kidney as an acoustic window.
- Adrenal lesions can be localized via dynamic scanning: adrenal glands are fixed relative to the great vessels and move independently from the kidneys during deep inspiration and upright positioning.
- Benign adrenal masses include adenomas (which may be functional or nonfunctional), myelolipomas, pheochromocytomas, cysts, hemorrhage, and postinfectious calcifications.
- Malignant adrenal masses include adrenocortical carcinoma, metastases (most often from lung or breast primary), and lymphoma.
- Ultrasound guidance can be used for percutaneous or transhepatic biopsies, as well as for interventions including radiofrequency, cryotherapy, or chemical ablation.

Acknowledgments

The adrenal glands are the smallest paired organs in the abdomen, measuring approximately 4 to 6 cm in length, 2 to 3 cm in width, and 0.2 to 0.6 cm in thickness, equivalent to 4 g.[1,2] In spite of their size, the adrenal glands are responsible for maintaining homeostasis and regulating hormonal production and secretion within the body. The mainstay of adrenal gland imaging is computed tomography (CT) because of its wide availability, ease of anatomic visibility, and ability for lesion characterization. However, adrenal lesions can be identified during sonographic evaluation of the abdomen, and because abdominal sonography is a common examination, these lesions are relatively frequently found on sonography. It is therefore important for the radiologist to have a thorough understanding of the role that ultrasound can play in adrenal gland imaging, including the diagnosis and management of lesions.

ANATOMY AND PHYSIOLOGY

The adrenal glands are located in the perirenal space, superior to the kidneys, at the level of the 11th or 12th thoracic rib, lateral to the first lumbar vertebra. The adrenal glands are comprised of a **superoanteromedial ridge,** an often larger and more superiorly located medial limb, as well as a smaller more inferiorly located lateral limb. Although the shape of the adrenal glands can vary, the thickness of the limbs, particularly the lateral limbs, remain relatively constant and therefore are the most useful

indicators of **gland hypertrophy.**[2] They are supplied by the suprarenal arteries comprised of the superior suprarenal artery, which arises from the inferior phrenic artery; the middle suprarenal artery, arising from the abdominal aorta; and the inferior suprarenal artery, arising from the main renal artery. They are drained by the suprarenal veins, which empty into the inferior vena cava on the right and the left renal vein or the left inferior phrenic vein on the left side (Figs. 11.1 and 11.2).

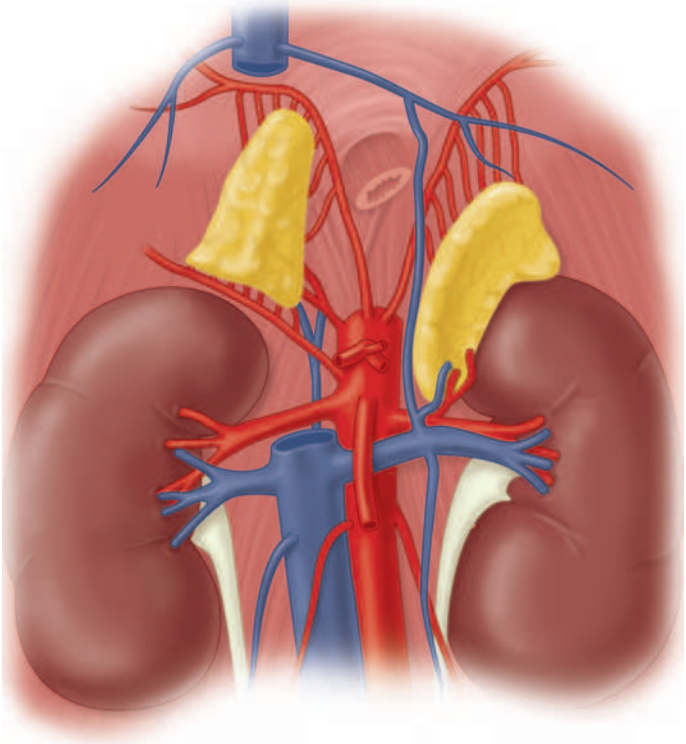

FIG. 11.1 Anatomy and Blood Supply of the Adrenal Glands.

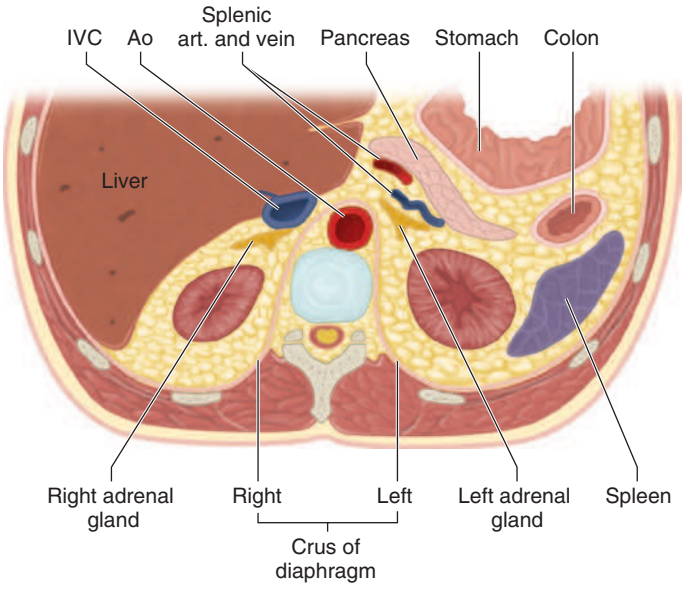

FIG. 11.2 Cross-Sectional Anatomy of the Adrenal Glands. *Ao,* Aorta; *art.,* artery; *IVC,* inferior vena cava.

The adrenal glands can be divided into the cortex and medulla, with each part derived from different embryologic origins, thereby accounting for differences in function. The **adrenal cortex** originates from mesenchymal cells of the posterior abdominal peritoneal lining. Between the sixth and eighth week of gestation, the mesenchymal cells proliferate, invaginate into the retroperitoneum, and then further proliferate, forming three distinct layers within the cortex: the zona glomerulosa, zona fasciculata, and zona reticularis from peripheral to central, respectively. The **zona glomerulosa** is responsible for aldosterone production and secretion, which subsequently influences sodium retention at the level of the renal tubules to regulate intravascular fluid volume and pressure. The **zona fasciculata** secretes glucocorticosteroids, including cortisol, to regulate stress and inflammatory responses. **The zona reticularis** is involved in androgen secretion and regulation. The adrenal cortex in a nonstressed adult secretes about 20 mg of cortisol daily and with stressful stimuli may increase secretion up to 150 to 200 mg/day. The physiologic importance of the adrenal androgens is not known. In excess, androgens may cause hirsutism or virilization in females and precocious pseudopuberty in males.[3]

The **adrenal medulla** originates from neuroectodermal cells, which become enveloped by the adrenal cortex during the seventh week of gestation, and differentiate into chromaffin cells.[4] These are responsible for the synthesis and secretion of the catecholamines epinephrine and norepinephrine, to regulate the body's sympathetic responses. These hormones play an important role in the response to actual or anticipated stress but are not essential to life.[3]

SONOGRAPHIC IMAGING AND SCANNING TECHNIQUE

Sonography remains widely used in abdominal imaging, and normal adrenal glands can be visualized with careful scanning. However, sonographic visualization of the adrenal glands can be difficult, given their location deep to the ribs and on the left side, posterior to stomach. Marchal et al. reported that the normal right and left adrenal glands were visualized by high-resolution real-time sonography in 92% and 71% of patients, respectively.[5] Cortex and medulla were differentiated in 13% of patients. However, Günther et al. studied 60 healthy subjects with high-resolution real-time sonography and identified adrenal glands in only one thin female.[6] In newborn infants, real-time high-frequency scanning identified the right and left adrenal glands in 97% and 83% of patients, respectively.[7] In a study of 882 patients and 991 adrenal masses, Fan et al. noted the sensitivity, specificity, and accuracy of ultrasound diagnoses of benign versus malignant adrenal masses to be 89%, 99%, and 93%, respectively, with a positive predictive value of 90.9% and a negative predictive value of 94.2%.[8]

With the introduction of high-resolution, real-time sector scanners, the adrenal glands have become easier to examine. Ideally, the patient should fast for 6 to 8 hours before the examination to reduce the amount of intervening bowel gas.

The key to the identification of the adrenals is to remember they lie anterior to the upper pole of the kidneys. The right

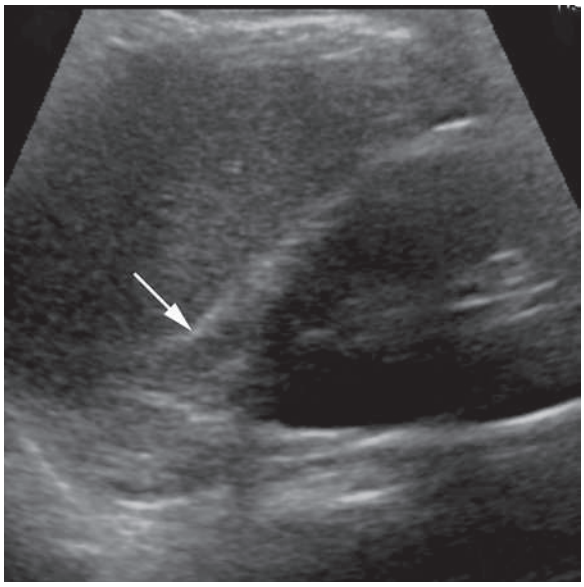

FIG. 11.3 Normal Adult Right Adrenal Gland. Sagittal sonogram shows the adrenal gland as a hypoechoic structure *(arrow)* between the liver and right kidney. See also Video 11.1.

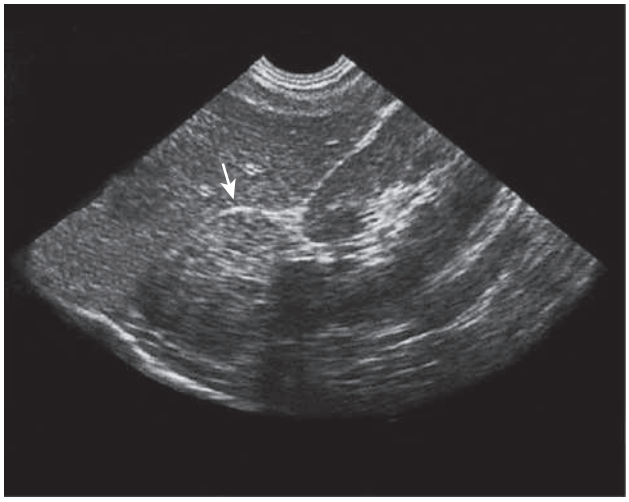

FIG. 11.4 Retroperitoneal Fat Stripe Displacement. Sagittal sonogram shows anterior displacement of the retroperitoneal fat stripe *(arrow)* by right adrenal cortical cancer.

adrenal gland is best seen through a transverse oblique and coronal view, using the liver as an acoustic window. The key to the identification of the right adrenal gland is the posterior location relative to the inferior vena cava (IVC). It is medial to the porta hepatis on scanning the right flank. The left adrenal gland is best seen along the posterior axillary line on an oblique coronal view, using either the spleen or the left kidney as an acoustic window.[9]

Normal sonographic appearance of the adrenal gland includes an inverted V or Y shape. Given its anatomic orientation, the entire gland is very difficult to visualize on a single plane. Furthermore, the adrenal gland is overall more echogenic relative to the background retroperitoneal fat, with the adrenal medulla depicted as a more distinctly linear echogenic component of the gland. The echogenic linear medulla is most prominent in the fetus and newborn. Oppenheimer et al. proposed that the increased medullary echogenicity in newborn infants is caused by increased collagen around the central vessels and haphazard orientation of its cell population, resulting in multiple reflective interfaces[7] (Fig. 11.3, Video 11.1).

The small size of the adrenal glands, in tandem with patient factors that limit visibility such as body habitus, result in several pitfalls for proper sonographic visualization. Normal anatomic structures can be mistaken for adrenal masses. On the right side these include lymph nodes, small bowel loops, and prominent native or collateral vasculature. On the left side, these include splenules, lobulated splenic margins, gastric fundus, small bowel loops, pancreatic parenchymal lobulations, and lymph nodes, as well as prominent native or collateral vasculature. Additionally, lesions arising from the liver, kidneys, or pancreas can also be mistaken for adrenal masses. Anterior displacement of the retroperitoneal fat reflection is a good indication of a primary adrenal lesion[8] (Fig. 11.4). Additionally, dynamic sonographic scanning demonstrating separation of the adrenal glands from the kidneys during deep inspiration and upright positioning is a useful troubleshooting technique as the adrenal glands are anchored with the perirenal fascia by fibrous tissue and are therefore fixed in position relative to the great vessels compared to the kidneys.

	Pancreatic tail mass	Thickened diaphragmatic crus
	Gastric fundus	

BENIGN ADRENAL MASSES

Adrenal Adenomas

Adrenal adenomas are the most commonly encountered adrenal lesion, representing 60% to 80% of all adrenal masses. Autopsy studies have documented that adrenal adenomas are seen in 3% to 9% of the population.[2,10,11] Adenomas are often less than 3 cm in size and can therefore be difficult to see on sonography. Magnetic resonance imaging (MRI) and CT have improved sensitivity and specificity in diagnosing adenomas, particularly with characterization of microscopic fat content and washout characteristics, respectively. The presence of abundant intracellular lipid on imaging studies sufficiently excludes malignancy in all incidentally found adrenal lesions[12] (Fig. 11.5, Videos 11.2 and 11.3). Because adrenal lesions are so commonly present, in patients with no known malignancy these lesions are almost always benign. Even in patients with a known malignancy, an incidentally found adrenal lesion is more likely to be an adenoma than metastatic disease.[13]

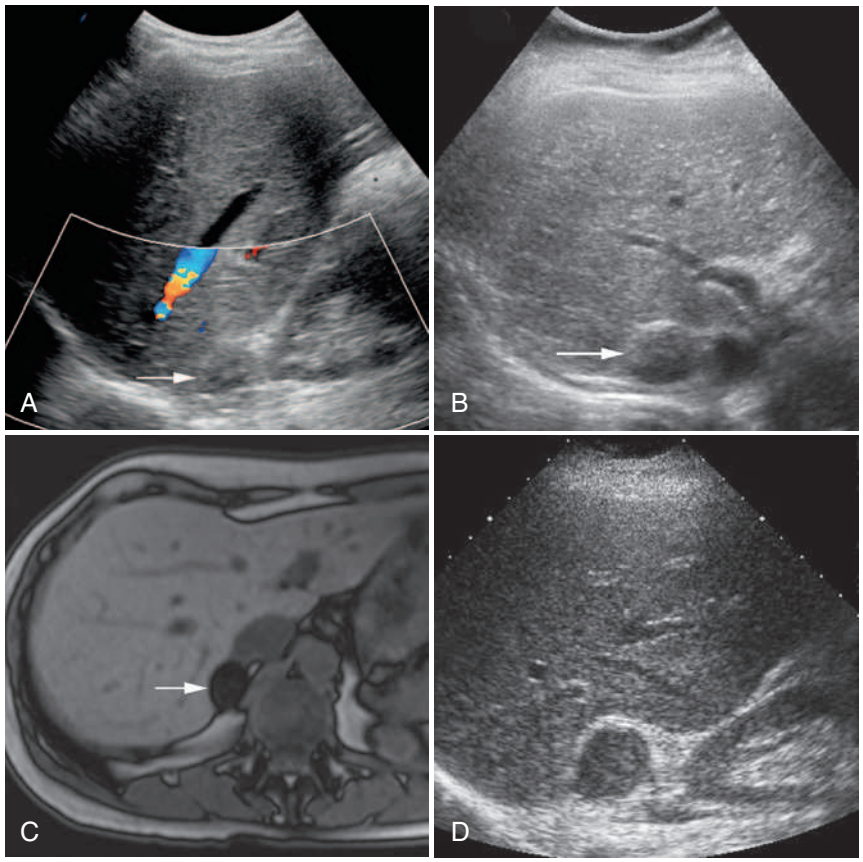

FIG. 11.5 Adrenal Adenoma. (A) Sagittal and **(B)** transverse sonograms show a hyperechoic right adrenal mass *(arrow)* between the liver and upper pole of the right kidney. **(C)** MRI demonstrates diffuse loss of signal on out-of-phase imaging confirming the presence of intravoxel fat and the diagnosis of adenoma *(arrow)*. See also Videos 11.2 and 11.3. **(D)** In another patient, sagittal sonogram shows a small solid right adrenal mass.

Nonfunctioning adenomas are more common than functioning adenomas and are often larger in size by the time of diagnosis as patients are asymptomatic. MRI evaluation to determine intracellular lipid content or contrast-enhanced CT to ascertain physiologic washout characteristics is helpful in characterizing adenomas.

Although adenomas can grow, progressive or rapid interval increase in size may suggest underlying malignancy or collision tumor, where a malignant lesion arises within an adenoma.[14] In this context, further imaging and possibly histologic evaluation is warranted. 18-Fluorodeoxyglucose positron emission tomography (^{18}FDG-PET) CT has been found to be useful in differentiating a collision tumor from an adenoma.[15]

Functioning adrenal adenomas are often diagnosed earlier, and with a smaller size, than nonfunctioning adenomas given the clinical manifestations of the tumor. For example, **Cushing syndrome** occurs with excessive glucocorticoid levels. Clinical symptoms include increased weight gain, fat redistribution with increased abdominal fat, characteristic buffalo hump and moon facies, and decreased fat deposition in the extremities. Cushing syndrome is most often encountered secondarily in the setting of chronic steroid use. Primary Cushing syndrome caused by hyperfunctioning adrenal lesions account for about 15% to 20% of cases, with adenomas, adenomas within a myelolipoma, adenomas of uncertain malignant potential, and adrenal carcinomas accounting for 92% of cases.[16] Unilateral disease is most common and 70% of cases occur as a result of adrenal hyperplasia.[17] In contradistinction, **Cushing disease** is hypercortisolism secondary to a primary adrenocorticotropic hormone (ACTH)–producing pituitary tumor. The two can be differentiated via biochemical analysis. An autonomously cortisol secreting adrenal lesion would yield low serum ACTH as well as elevated plasma cortisol unsuppressed by low dose dexamethasone test.[18]

Conn syndrome results from oversecretion of aldosterone.[19] Primary aldosteronism can result from adrenal adenoma (70%), adrenal hyperplasia (30%), and, in rare cases, adrenal carcinoma.[20] Clinical manifestations include **hypertension** and **hypokalemia.** Patients with hyperaldosteronism from an adenoma typically are female, whereas those with hyperaldosteronism from hyperplasia are usually male.[21,22] These tumors tend to be small (<2 cm). Biochemically, elevated urine and serum aldosterone levels, hypokalemia, hypernatremia, and elevated bicarbonate and low plasma pH levels are found. A suppressed renin level indicates primary hyperaldosteronism.

Adrenal vein sampling can be performed to determine whether there is hypersecretion from the adrenal gland. **Laparoscopic adrenalectomy** and **radiofrequency ablation** are the treatments for hyperfunctioning adenomas.[23,24]

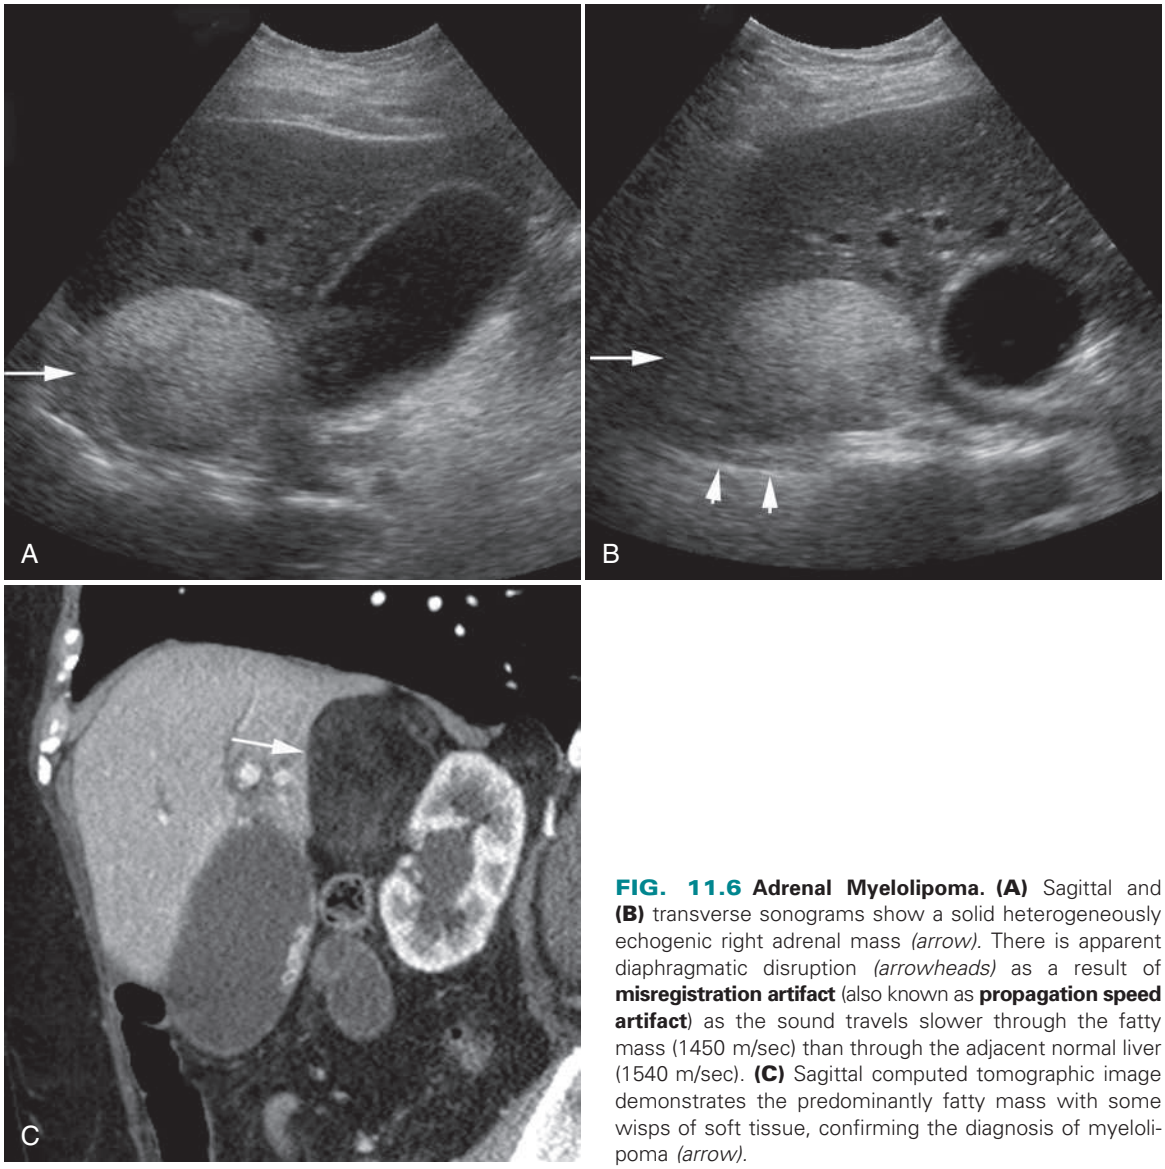

FIG. 11.6 Adrenal Myelolipoma. (A) Sagittal and **(B)** transverse sonograms show a solid heterogeneously echogenic right adrenal mass *(arrow)*. There is apparent diaphragmatic disruption *(arrowheads)* as a result of **misregistration artifact** (also known as **propagation speed artifact**) as the sound travels slower through the fatty mass (1450 m/sec) than through the adjacent normal liver (1540 m/sec). **(C)** Sagittal computed tomographic image demonstrates the predominantly fatty mass with some wisps of soft tissue, confirming the diagnosis of myelolipoma *(arrow)*.

Sonographic Features

Sonographic features for adenomas can be nonspecific but commonly appear as small homogeneously hypoechoic masses with well-defined borders and no substantial demonstrable vascularity. Nonfunctional adenomas are often larger and can have heterogeneous features such as cystic necrosis, hemorrhage, and sometimes calcification that make them difficult to distinguish from malignant lesions.

Myelolipomas

Myelolipomas are rare benign tumors classically containing mature adipose and hematopoietic tissue, with an estimated prevalence of 0.08% to 0.4%.[12] They have been histologically compared to angiomyolipomas of the kidneys and therefore exhibit similar imaging characteristics, being well-defined and diffusely echogenic. Their etiology and pathogenesis are unknown, although these lesions are thought to arise in the zona fasciculata of the adrenal cortex. Men and women are equally affected, with tumors most often occurring in the fifth or sixth decade of life. Differential considerations include other fat-containing masses within the retroperitoneum (Fig. 11.6).

Fat-Containing Suprarenal Masses

Adrenal myelolipoma
Exophytic renal angiomyolipoma
Lipoma
Retroperitoneal liposarcoma
Retroperitoneal teratoma
Pheochromocytoma (rare)

Sonographic Features

Macroscopic fat within myelolipomas can be appreciated as homogeneous, highly echogenic components with associated acoustic shadowing. When small, they may be difficult to

differentiate from the adjacent echogenic retroperitoneal fat. **Propagation speed artifact** (also called **misregistration artifact,** see Chapter 1, Fig. 1.3) results from decreased sound velocity through fatty masses. **Apparent diaphragmatic disruption,** originally described by Richman et al. with an adrenal myelolipoma, can result from this velocity change.[25] The presence of this artifact is good evidence as to the fatty nature of a mass. Musante et al. found this artifact only when tumors were larger than 4 cm.[26] Additionally, in their study of 13 patients, only 11 cases demonstrated echogenic components, of which 5 were homogeneous and 6 were heterogeneous.[26] Lesions with greater proportions of myeloid tissue can appear more heterogeneous with isoechoic or hypoechoic components. The heterogeneity may also be caused by internal hemorrhage, which is common. Focal areas of calcification may be seen. In these cases, CT or MRI can be useful in discerning the presence of macroscopic fat.

Pheochromocytomas

Pheochromocytomas are functional neuroendocrine tumors of the adrenal medulla with associated catecholamine hypersecretion. As such, clinical symptoms include refractory hypertension, palpitations, flushing, diarrhea, and weight loss. The incidence of pheochromocytoma has been described in up to 5% of incidentally found adrenal lesions and can be seen in 0.6% of patients with unexplained hypertension.[12] Of these, 10% can be bilateral.

Pheochromocytomas are associated with many **neuroectodermal disorders,** including tuberous sclerosis, neurofibromatosis, von Hippel–Lindau disease, and **multiple endocrine neoplasia** IIa (50%) and IIb (90%).[27] In such cases, bilateral involvement can be seen in up to 80% of cases.[28]

Multiple endocrine neoplasia (MEN) is a familial disease that is categorized into three types:

- **MEN I** affects pancreatic islets, the adrenal cortex, and pituitary and parathyroid glands.
- **MEN IIa** (Sipple syndrome) includes medullary thyroid carcinoma, parathyroid hyperplasia, and pheochromocytoma.
- **MEN IIb** (III) includes all features of IIa, with marfanoid facies, mucosal neuromas, and gastrointestinal ganglioneuromatosis.

Inherited as an **autosomal dominant** trait, MEN II is believed to be caused by a genetic defect in the neural crest.[29] Pheochromocytomas in MEN syndromes are typically in the adrenal gland, usually bilateral (65%), multicentric within the gland, more often malignant, and frequently asymptomatic.[30] Patients diagnosed with MEN II should be screened biochemically and with imaging on a routine basis because they will eventually develop bilateral adrenal pheochromocytomas.

As imaging findings can be variable, correlation with elevated serum or urine metanephrines and increased activity on **^{123}I-metaiodobenzulguanidine (MIBG)** studies is useful for more definitive diagnosis.[31] Although pheochromocytomas are most commonly benign, malignant degeneration has been described in approximately 9% of cases.[8,32] Metastatic involvement of lymph nodes, liver, lung, and bone has been described.

Sonographic Features

Pheochromocytomas appear as heterogeneous lesions that can vary in size but are often larger than adenomas, with a mean of 5.9 ± 3.2 cm in a study evaluating 161 cases.[8] Pheochromocytomas can be solid, mixed solid and cystic, or cystic. Many have well-defined capsules or rim and avid vascularity on Doppler interrogation. Raja et al. studied the sonographic appearance of 20 pheochromocytomas and found 9 (45%) appeared solid and heterogeneous, 7 (35%) appeared solid and homogeneous, and 4 (20%) were predominantly cystic with a peripheral rim.[33] There may also be fluid-fluid levels within the cystic components due to underlying necrosis or hemorrhage. In some cases, lipid degeneration of pheochromocytomas has also been described, and macroscopic or microscopic lipid can be identified[12] (Fig. 11.7).

Adrenal Cysts

Adrenal cysts are uncommon, accounting for approximately 6% of incidentally detected adrenal lesions.[4] Causes are variable and include pseudocysts, endothelial cysts, epithelial cysts, and parasitic cysts.[34] The origin of cystic lesions is quite variable among different studies because of variations in patient demographics. In a retrospective review of adrenal cystic lesions in New York over a 20-year period, Sebastiano et al. found 31 lesions of which 39% were pseudocysts, 6% endothelial cysts, and 55% epithelial or neuroectogenic cysts.[35] A study by Erickson et al. from Mayo Clinic evaluated 41 lesions over a 25-year period and found 78% pseudocysts, 19% endothelial cysts, and 2% epithelial cysts.[36] Generally pseudocysts are the most commonly occurring cystic lesion described in surgery, whereas endothelial cysts are more commonly encountered in autopsy series (up to 45%).[36,37]

Histologically, **pseudocysts** are characterized as having fibrous walls with no endothelial or epithelial component. They most often occur secondary to hemorrhage. **Endothelial cysts** include lymphangiomatous cysts in 42% and hemangiomatous cysts in 3% of cases.[34] **Epithelial cysts** are congenital and include glandular retention cysts, mesothelial cysts, and cystic adenomas.[38] **Parasitic cysts** have been most commonly described with echinococcal infection.[39] In these cases, the appearance can vary depending on the stage of disease and may present as simple cysts, septated cysts, cysts with daughter cysts, cysts with solid nodules, or calcification.

Cysts with complex features are indeterminate and percutaneous aspiration may be indicated for definitive characterization to exclude cystic or necrotic malignancies. Traditionally, lesions with clear aspirates were often followed while those with bloody aspirates were deemed indeterminate and underwent surgical excision. Currently, the decision for surgery depends more on the size of the lesion and overall complexity of its features.[40]

Sonographic Features

On imaging, simple adrenal cysts appear homogeneously anechoic with through transmission with thin nonenhancing walls and absent septa (Fig. 11.8). Superimposed hemorrhage can occur within the cysts resulting in echogenic contents with sedimentation or fluid-fluid level, septa, or calcification. Complex features

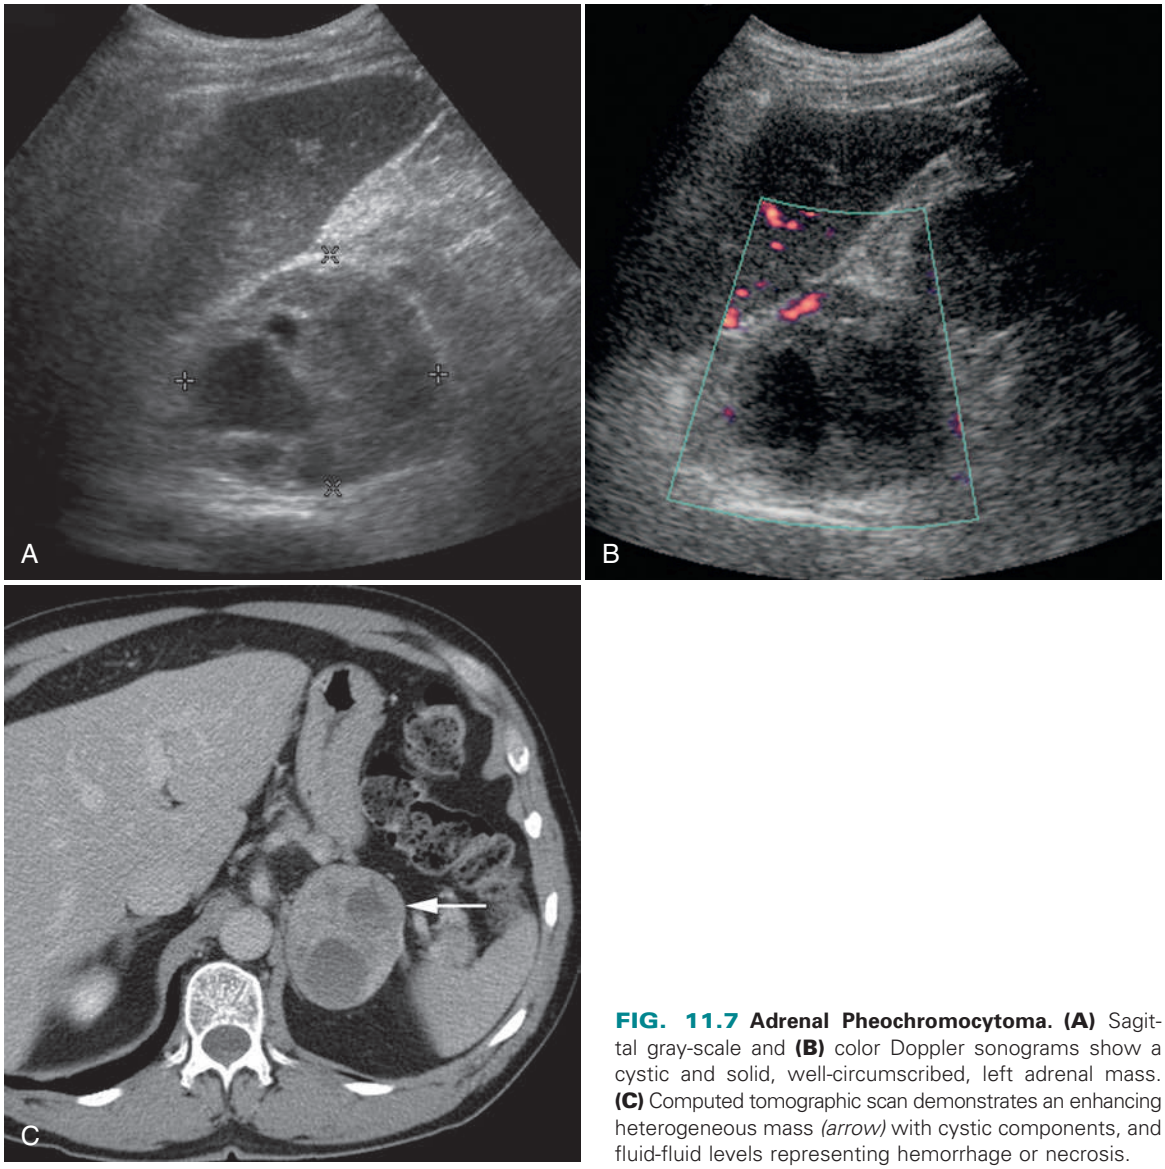

FIG. 11.7 Adrenal Pheochromocytoma. (A) Sagittal gray-scale and **(B)** color Doppler sonograms show a cystic and solid, well-circumscribed, left adrenal mass. **(C)** Computed tomographic scan demonstrates an enhancing heterogeneous mass *(arrow)* with cystic components, and fluid-fluid levels representing hemorrhage or necrosis.

of cystic lesions include thickened wall or septations, or internal vascularity.

Cystic Adrenal Lesions

Pseudocyst
Endothelial cyst
Epithelial cyst
Infection (echinococcus, abscess)
Necrotic neoplasm
Cystic pheochromocytoma
Lymphangioma
Adrenal hemorrhage

Adrenal Hemorrhage

Adrenal hemorrhage is bilateral in 20% of cases. This is most commonly associated with anticoagulation use, trauma, postoperative status from surgery, postprocedure after adrenal venography, sepsis, or burns. In rare cases, spontaneous adrenal hemorrhage has been associated with meningococcal septicemia known as **Waterhouse-Friderichsen syndrome.** In the context of trauma, adrenal hemorrhage often suggests traumatic injury to other solid abdominal organs. Bilateral adrenal hemorrhage predisposes for adrenal insufficiency.[41] Adrenal hemorrhage can sometimes be associated with an underlying lesion, which can be difficult to ascertain in the acute setting. An underlying lesion may be suspected in cases of intralesional enhancement on MRI or metabolic activity on ^{18}FDG-PET CT.[40]

Sonographic Features

In the acute setting, adrenal hemorrhage can appear solid and diffusely or heterogeneously echogenic. The hemorrhage becomes progressively heterogeneous in echogenicity with time, and chronic hematomas can have central cystic components. Calcification can also occur in the chronic setting. Adrenal hemorrhage is avascular on Doppler interrogation.[42] (Fig. 11.9).

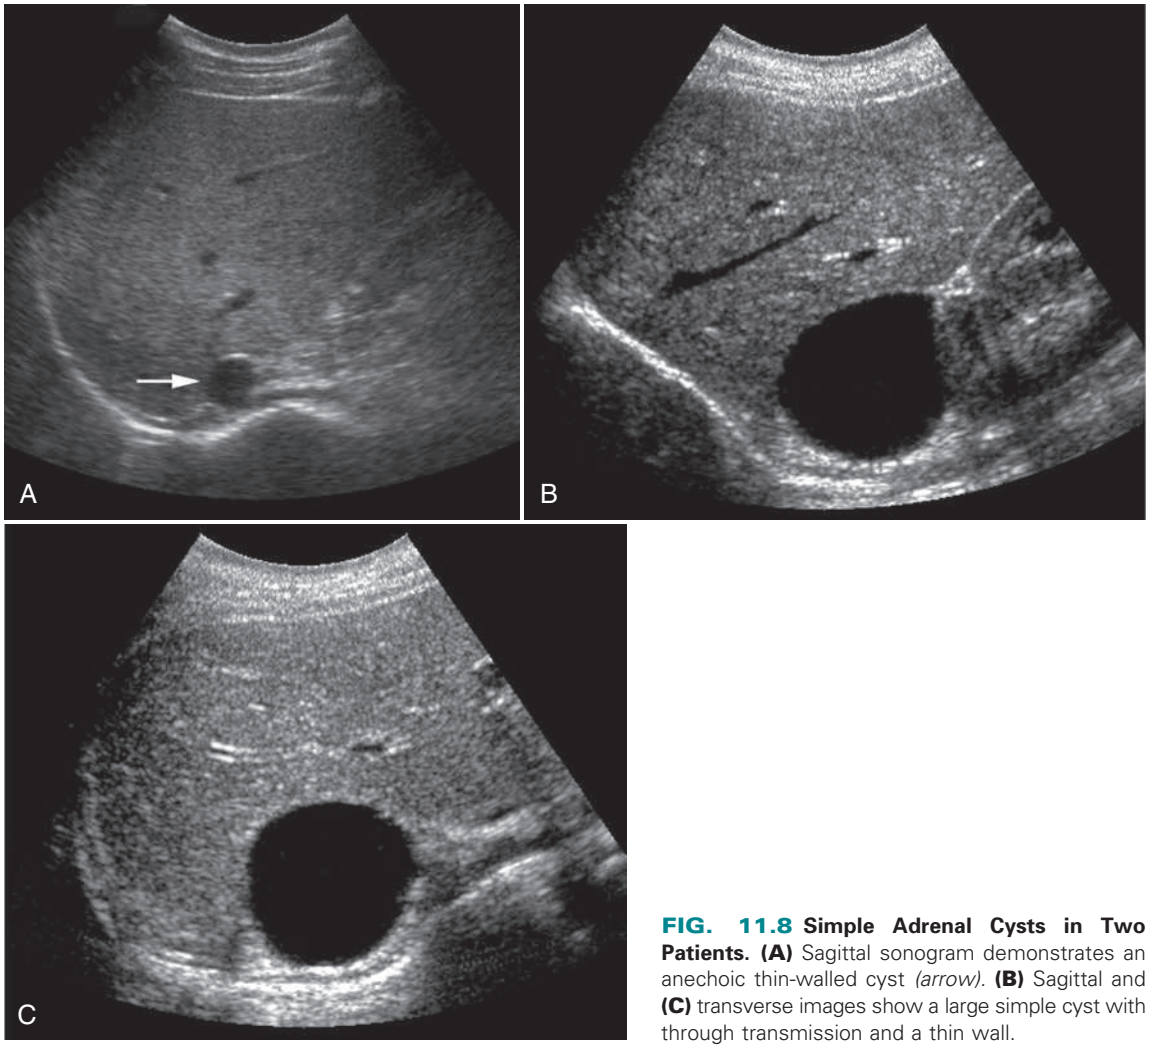

FIG. 11.8 Simple Adrenal Cysts in Two Patients. (A) Sagittal sonogram demonstrates an anechoic thin-walled cyst *(arrow)*. **(B)** Sagittal and **(C)** transverse images show a large simple cyst with through transmission and a thin wall.

Infectious and Inflammatory Masses

Tuberculosis, histoplasmosis, blastomycosis, paracoccidiomycosis, meningococcal, echinococcal, cytomegalovirus (CMV), herpesvirus, and *Pneumocystis* infections are the most common infectious diseases of the adrenal gland.[27,41,42]

Tuberculosis of the adrenal gland has been noted to be one of the most common causes of adrenal insufficiency worldwide.[43] Chest radiographs and sputum cultures may be negative even in cases of positive adrenal tuberculous infection. Tuberculosis and **histoplasmosis** are the two most common causes of adrenal calcification in the adult population.[44] In the setting of disseminated fungal infection, histoplasmosis and **paracoccidiomycosis** are most commonly seen, where up to 80% have adrenal involvement based on autopsy series.[45-47]

Echinococcal infection of the adrenal gland rarely occurs in isolation and is more often seen in the presence of widespread multiorgan echinococcal infection.[47,48]

Immunosuppression resulting from acquired immunodeficiency syndrome (AIDS), transplantation, or other causes increases these patients' risk for infectious involvement of the adrenal gland. Common organisms include fungi (histoplasmosis), mycobacteria, CMV, herpesvirus, *Pneumocystis carinii (jiroveci)*, human immunodeficiency virus (HIV), and toxoplasmosis.[41] Grizzle[42] described focal or diffuse damage of the glands by CMV in 70% of AIDS patients who died. In a study involving 74 AIDS patients, Pulakhandam et al. found that up to 50% had CMV infection at autopsy, of which 84% had adrenal involvement.[49]

Bacterial adrenal abscesses are found more frequently in neonates and are relatively uncommon in adults.[50,51] In the neonate, hematogenous seeding of normal glands or those affected by hemorrhage can result in abscess formation.[52]

Sonographic Features

Sonographic features are indistinguishable among these infections, and diagnosis is based on the patient's geographic profile, occupational exposure, and laboratory testing. Acute adrenal involvement in granulomatous infections can lead to enlargement of the gland, with nodular contours and hypervascularity. Superimposed areas of necrosis and hemorrhage can also be seen in cases of caseous necrosis. In the chronic setting, gland atrophy and calcifications can be present, which appear as coarse echogenic foci with acoustic shadowing.[19,20] (Fig. 11.10, Video 11.4).

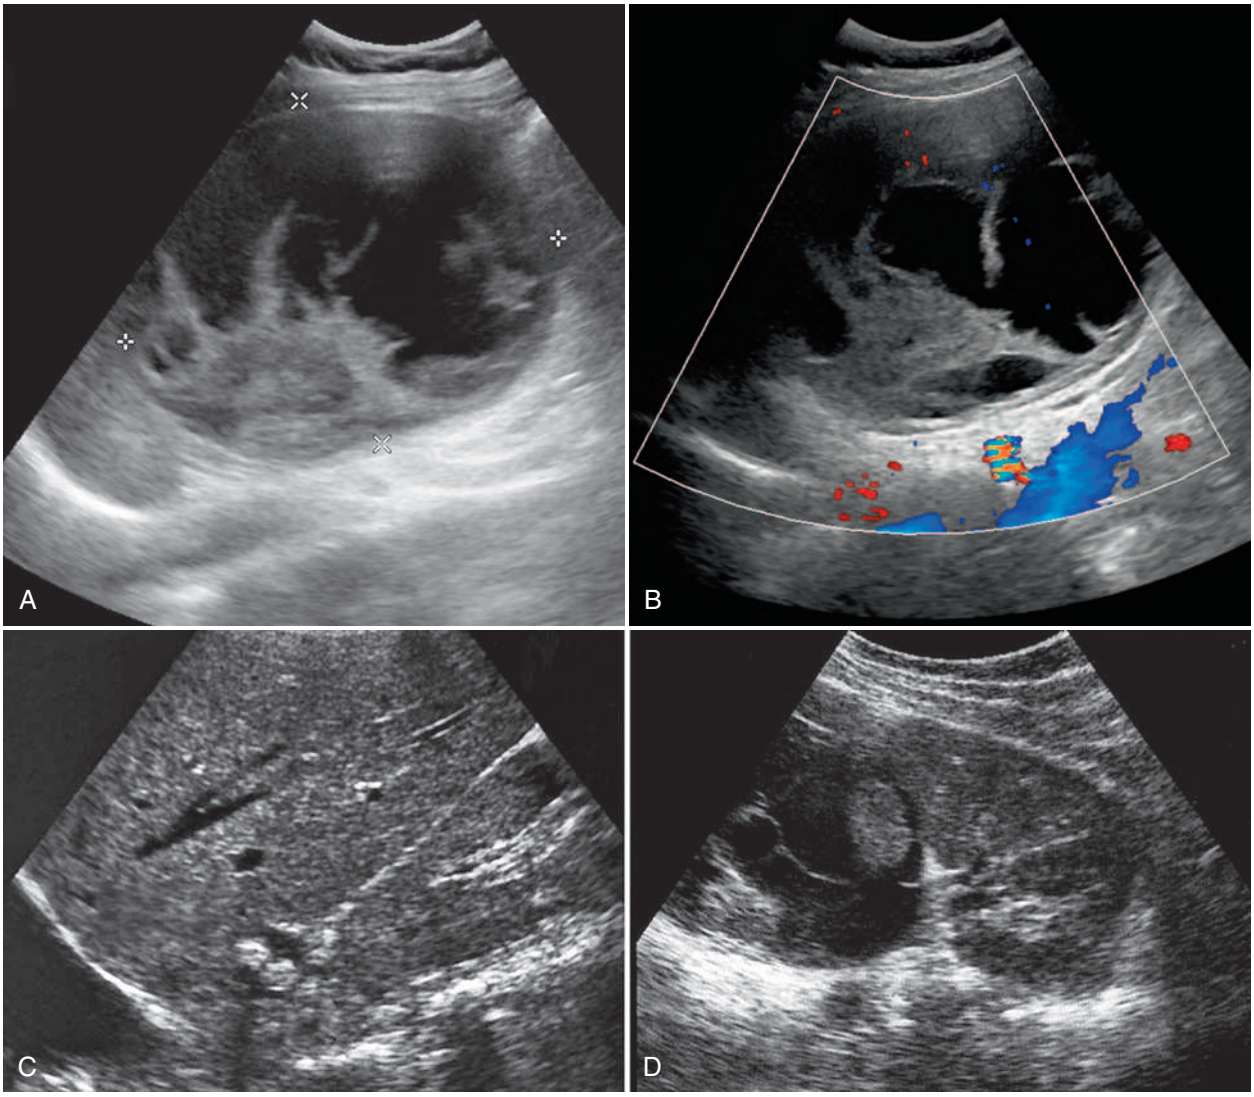

FIG. 11.9 Spontaneous Adrenal Hemorrhage. (A) Sagittal gray-scale and **(B)** color Doppler sonograms demonstrate a heterogeneous cystic left adrenal mass with irregular appearing clot and no demonstrable vascularity. On magnetic resonance imaging (not shown) this was compatible with hemorrhage without underlying lesion. **(C)** Chronic adrenal hemorrhage. Sagittal sonogram shows two echogenic foci representing clotted blood in an enlarged right adrenal gland. **(D)** Acute hemorrhage. Sagittal sonogram shows a large complex mass displacing the left kidney inferiorly and anteriorly.

Echinococcal infection of the adrenal gland manifests similarly to echinococcal disease seen elsewhere and is most often characterized by cysts with varying amounts of septation, secondary cysts, and calcification.[47,48] CMV infection of the adrenal glands appears as hypoechoic masses that may be heterogeneous and may contain gas if abscess formation occurs. Adrenal abscesses typically appear as complex, avascular cystic masses.

MALIGNANT ADRENAL MASSES

Adrenocortical Carcinomas

Adrenocortical carcinomas are rare primary malignant adrenal tumors with an estimated prevalence of 1 to 2 million worldwide. There is a bimodal age distribution with peak incidence occurring in children younger than 5 years or in adults in their fourth to

Causes of Adrenal Calcification

See also Video 11.4. **(C)** In a different patient, sagittal sonogram shows a partially calcified adrenal mass with acoustic shadowing. (**C** courtesy of Dr. Mitchell Tublin.)

fifth decade of life.[44,51] Increased prevalence has been reported in patients with particular familial neoplastic syndromes, including **familial adenomatous polyposis, Beckwith-Wiedemann syndrome,** and **Li-Fraumeni syndrome,** Carney syndrome, MEN I, as well as mutations involving the *p53* tumor suppressor gene.[45,51] Adrenocortical carcinomas are hyperfunctioning in 55% to 78% of cases, manifesting with Cushing syndrome, virilization or precocious puberty, feminization in males, primary hyperaldosteronism, or combined hormonal excess in 33%, 35%, 10%, 2.5%, and 3% of cases, respectively.[46] Functioning adrenocortical carcinomas are often diagnosed at an earlier stage because of their clinical symptomatology and can therefore measure less than 6 cm in size. Nonfunctioning adrenocortical carcinomas are large, with 81% to 90% measuring over 6 cm at the time of diagnosis (Fig. 11.11).[47] Because of their later presentation, nonfunctional carcinomas tend to be more aggressive, and hepatic metastases and tumor thrombus within the adrenal vein or IVC may be present at the time of initial presentation. The presence of metastases and tumor thrombus confers poorer prognosis. Management of adrenocorticocarcinoma requires a thorough imaging and biochemical workup to assess for tumor resectability.[48] The mainstay of treatment is surgery; however, despite resection, prognosis is often poor with estimated 5-year survival rates of 16% to 38% and estimated recurrence rates at 85%.[47]

Sonographic Features

Adrenocortical carcinomas (Figs. 11.11 and 11.12) are often large heterogeneous masses with areas of cystic necrosis, hemorrhage, and calcification, as well as demonstrable vascularity or prominent supplying vessel. Lobulated borders are common. The adjacent veins should be examined to assess for venous tumor extension.

Metastases

Adrenal metastases are the most common malignant lesions of the adrenal gland and the second most common adrenal lesion

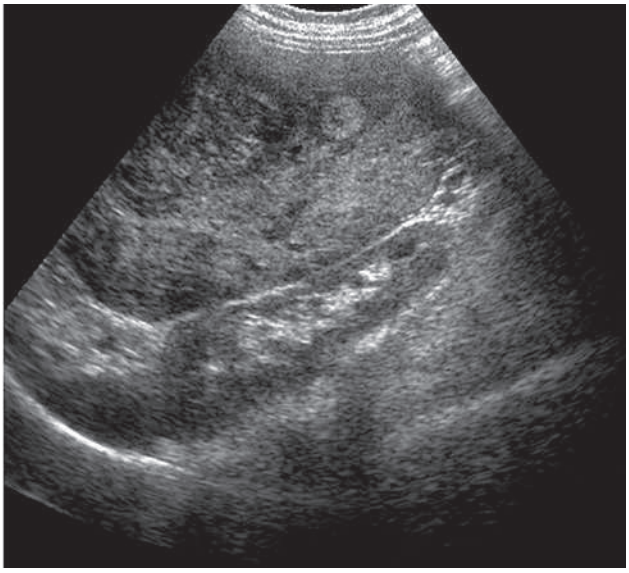

FIG. 11.11 Large Adrenocortical Carcinoma. Sagittal sonogram of the left flank shows a large heterogeneous solid mass anterior to the left kidney.

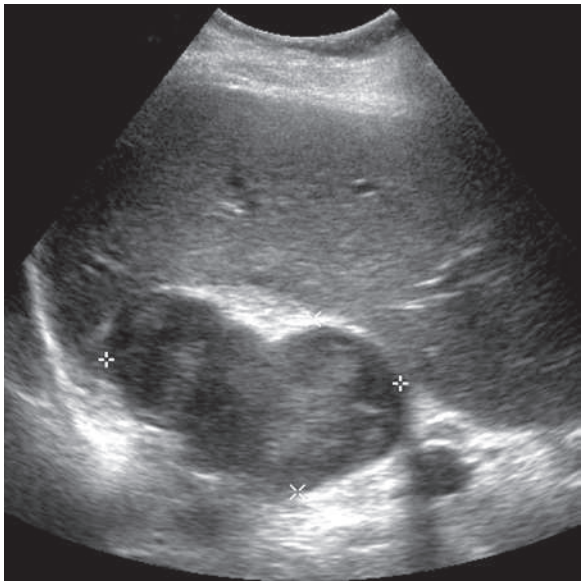

FIG. 11.12 Adrenocortical Carcinoma. Transverse sonogram shows a heterogeneous large lobulated right adrenal mass *(calipers).*

after adenomas.[53] In an autopsy series involving 464 patients with adrenal metastases over a 30-year period, Lam and Lo found that 90% of the lesions were carcinoma, of which 56% were adenocarcinomas. The most common primary tumor site was the lung at 35%.[51] Adrenal metastases can also be secondary to malignancies of breast, hepatocellular, thyroid, renal, pancreatic, gastrointestinal, or melanoma origins. Direct invasion of the adrenal gland can also be seen in some cases of renal cell and hepatocellular carcinomas. In these cases, the aggressive tumors disrupt fascial planes and invade the adrenal gland.

Sonographic Features

Metastatic lesions are variable in size, often with ill-defined borders and inhomogeneously hypoechoic features (Fig. 11.13). Bilateral lesions are seen in 40% of cases and often occur in patients with metastatic disease elsewhere. Many metastatic lesions are large, greater than 4 cm in size, with irregular shape and features of cystic necrosis. In some cases, metastases can appear small and homogeneously hypoechoic and thus be mistaken for benign adenomas on sonography. Therefore when adrenal lesions are identified in patients with known malignancy, further CT or MRI characterization should be pursued to determine if the lesion meets the criteria for an adenoma.[54] In cases of direct invasion of the adrenal gland by adjacent primary malignancy, it may be difficult to distinguish the adrenal gland from the primary tumor on ultrasound (Fig. 11.14).

Lymphoma

Adrenal involvement in lymphoma is most commonly seen as secondary involvement from lymphomatous disease elsewhere, with an estimated prevalence of 5% and up to 35% in autopsy cases.[53,55] Primary adrenal lymphoma is rare, with fewer than 200 cases reported in literature.[56,57] Primary adrenal lymphoma is most commonly seen in older men, with a mean age of 65 years.[47] Non-Hodgkin lymphoma is more common than Hodgkin lymphoma, of which the diffuse large B-cell subtype is most common.[58] The most common clinical manifestation of adrenal lymphoma is **adrenal insufficiency,** which can be seen in up to two-thirds of cases. Patients can also present with hypoglycemia, hyponatremia, or **Addisonian crisis.**[59] Some patients may also have nonspecific symptoms of pain and fever. Hepatosplenomegaly, lymphadenopathy, and bone marrow involvement are

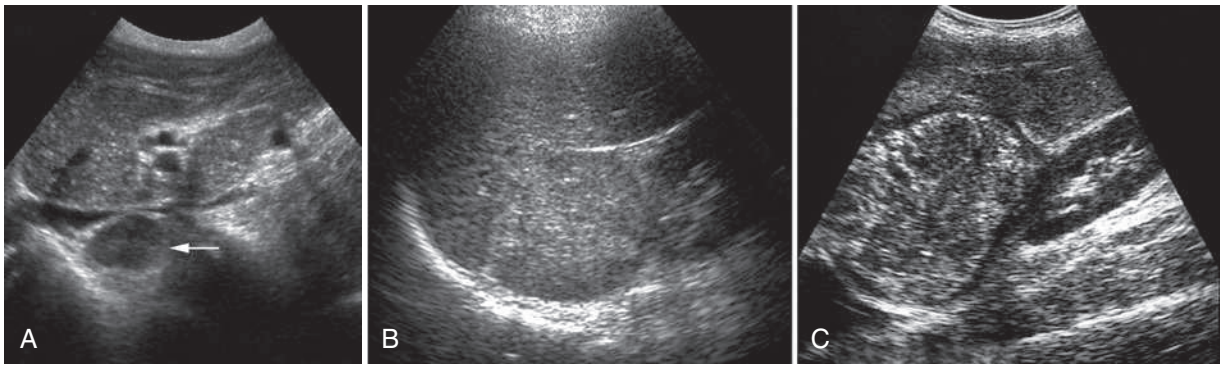

FIG. 11.13 Adrenal Metastasis in Three Different Patients. (A)-(C) Sagittal sonograms show heterogenous adrenal mass.

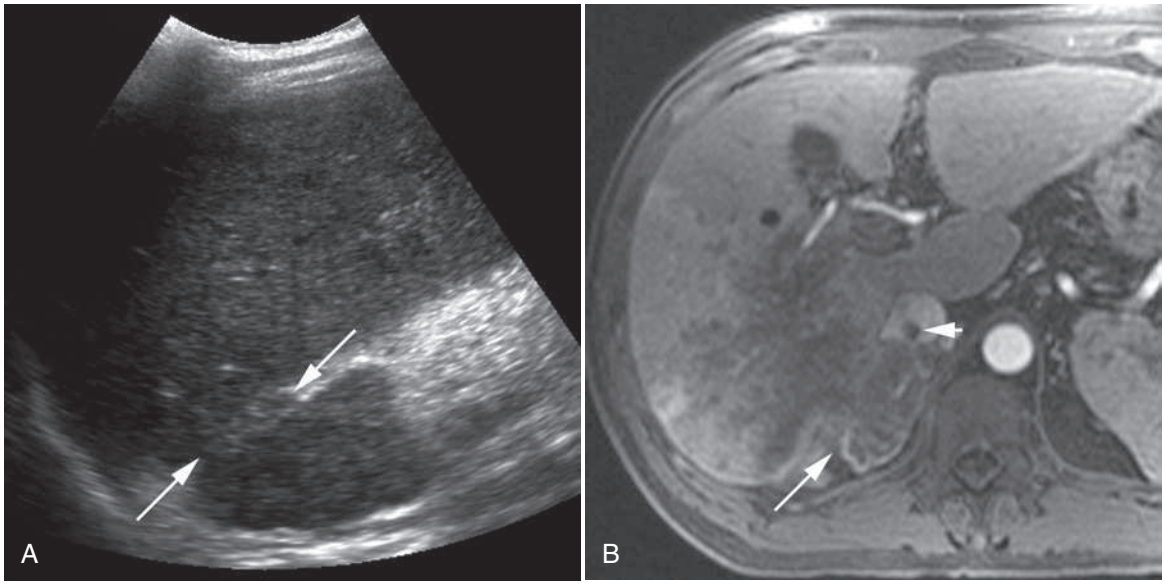

FIG. 11.14 Direct Invasion of the Right Adrenal Gland by Hepatocellular Carcinoma. (A) Sagittal sonogram demonstrates a large mass with ill-defined borders extending to the suprarenal space, resulting in loss of the normal fat plane *(arrows)*. **(B)** MRI of the same patient demonstrates invasion of the right adrenal gland by the primary hepatic tumor *(arrows)*. A small thrombus is also seen in the inferior vena cava *(arrowhead)*.

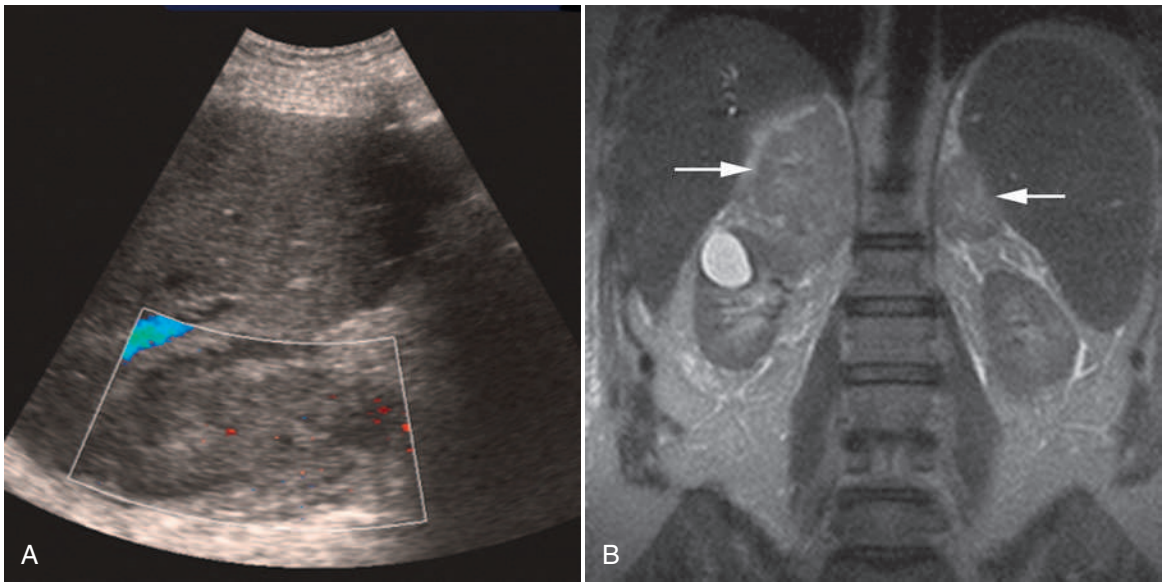

FIG. 11.15 Adrenal Lymphoma. (A) Sagittal color Doppler sonogram shows a solid, fairly homogeneous right adrenal mass with no demonstrable vascularity. **(B)** Coronal MRI of the same patient demonstrates bilateral adrenal masses *(arrows)*. Note also splenomegaly.

uncommon in primary adrenal lymphoma but are seen more often in secondary adrenal lymphoma.[56] In secondary adrenal lymphoma, concomitant lymphomatous involvement of the kidneys, retroperitoneum, and adjacent vessels can be seen. Treatment includes chemotherapy or radiation therapy, often with poor prognosis because of disease extent. In particular, rituximab-containing chemotherapeutic agents are preferred.

Sonographic Features

Lymphomatous deposits within the adrenal gland are often large and homogeneously very hypoechoic with little internal architecture. In some cases, lesions have mixed heterogeneous echogenicity or targetoid morphology and can develop cystic necrosis or hemorrhage. Bilateral lesions are seen in 50% to 70% of cases[1,8,56] (Fig. 11.15).

RARE ADRENAL MASSES

Ganglioneuromas are rare benign masses of Schwann cells, ganglion cells, and nerve fibers from the retroperitoneal sympathetic chain coursing along the adrenal glands.[60,61] These tumors are most commonly incidentally found in children and young adults and can be large in size. On ultrasound, they appear as large heterogeneous masses with variable vascularity. Calcification

can also be present in about 20% of cases. Resection confers good prognosis with low recurrence rates.

Neuroblastomas are malignant cells that arise from the sympathetic chain in the retroperitoneum or adrenal gland and are sometimes referred to as the malignant form of **ganglioneuromas.** Although they are the most common extracranial malignancy in infants and the pediatric population, they are extremely rare in the adult population and can occur in the adrenals or elsewhere in the abdomen and pelvis.[62] In the adrenal gland, they classically appear as heterogeneous masses often with calcification and hemorrhage. Adults often present with stage IV incurable disease.[62]

Other rare adrenal masses include hemangioma, lymphangioma, plasmacytoma, oncocytoma, neurilemoma, teratoma, and angiosarcoma.

MANAGEMENT OF ADRENAL LESIONS

Adrenal incidentalomas are defined as incidentally found adrenal lesions measuring over 1 cm.[63] The incidence is reported to be up to 5% in the general population and up to 7% in adults older than 70 years.[64,65] Approximately 90% of these lesions are benign in patients with no underlying malignancy. However, in the cancer population, the incidence of malignant adrenal lesions can be as high as 26% to 75%.[65,66] Both benign and malignant lesions can exhibit hormonal function; therefore it is integral to evaluate incidental lesions for underlying function and malignancy.

The initial workup for patients with an adrenal incidentaloma includes (1) 1 mg dexamethasone overnight suppression test with serum cortisol; (2) a plasma fractionated metanephrine, which is preferred over a urinary fractionated metanephrine or both; and (3) serum aldosterone, plasma renin activity, and serum potassium. These are evaluated for subclinical manifestations of Cushing syndrome, pheochromocytoma, and hyperaldosteronism, respectively.

The American College of Radiology white paper on the incidentally discovered adrenal mass outlines the recommended imaging algorithm.[13] Of note, ultrasound is not considered appropriate in definitively characterizing adrenal lesions. For patients with no history of malignancy with lesions 1 to 4 cm, initial evaluation is performed with noncontrast-enhanced CT. A mass of any size with typical features of an adenoma or myelolipoma does not require further imaging or workup. If the lesion has nondiagnostic features, then a 1-year follow-up with unenhanced CT or unenhanced MRI is recommended to reassess for size change. If the lesion is stable in size after 1 year, then it can be deemed benign with no additional imaging or workup. An enlarging lesion may warrant biopsy or resection. Masses that measure greater than 4 cm are initially evaluated with a contrast-enhanced CT or contrast-enhanced MRI. Resection should be considered if the lesion does not have typical features of an adenoma, myelolipoma, hemorrhage, or simple cyst.

In patients with known malignancy, adrenal lesions smaller than 4 cm are initially evaluated with noncontrast-enhanced CT. A mass larger than 4 cm should undergo biopsy or ^{18}FDG-PET CT to diagnose metastases.[65,67] Although pheochromocytoma is rare in cases of incidentally found lesions, it is prudent to exclude this with urinary or plasma catecholamine levels or a glucagon stimulation test before a biopsy is pursued.

Laparoscopic adrenalectomy is often recommended for smaller lesions measuring up to 1.2 cm but also in many tumors larger than 4 cm with the exception of adrenocortical carcinomas. Adrenocortical carcinomas require open adrenalectomy to obtain clear resection margins because these tumors respond poorly to adjuvant therapy.[67] Image-guided ablation is also increasingly useful in the management of small lesions and in the management of patients who are poor candidates for surgery.[24]

INTERVENTIONS

Ultrasound-Guided Biopsy and Interventions

Adrenal lesions that are easily visualized on ultrasound can be amenable for ultrasound-guided biopsy, drainage, or ablation. Adrenal biopsies and drainages are predominantly performed under CT guidance because of improved visibility, but larger lesions can also be performed guided by ultrasound. On the right side, a transhepatic approach is preferred to avoid the pleural space (Fig. 11.16). On the left side, posterior, lateral, and anterior approaches have been described. Generally, a posterior approach is preferred over an anterior approach to decrease the risk for pancreatitis. Welch et al.[68] reviewed their 10-year experience with adrenal biopsy, which included 277 percutaneous biopsies in 270 patients. Sensitivity was 81%, specificity 99%, and accuracy 90%. Positive predictive value was 99%, and negative predictive value was 80%. Complication rate was 2.8%. Potential complications of percutaneous adrenal biopsy depend on the approach and include hematoma (0.05%-2.5%), pneumothorax (most common), pancreatitis (6%), sepsis, and needle tract seeding.[69,70] Needle biopsy of a pheochromocytoma may precipitate a hypertensive crisis and should be avoided.[71]

A variety of techniques have been described for adrenal **ablation,** including radiofrequency, cryotherapy, chemical ablation with acetic acid, or ethanol via a percutaneous approach with a 19- to 22-gauge needle.[72] Alternatively, ablation can be performed via accessing the ipsilateral adrenal artery. Complications include hypertensive crisis, pain, and adrenal insufficiency, particularly if more than 90% of the adrenal tissue is destroyed.

Endoscopic Ultrasound

Endoscopic ultrasound is being used with greater frequency; an **echoendoscope** is inserted via the alimentary tract to visualize surrounding organs. The right adrenal gland tends to be difficult to visualize endoscopically because of the retrocaval location of the gland. The right adrenal gland is best visualized with the endoscopic ultrasound probe in the longitudinal position in the duodenum oriented toward the greater curvature of the stomach. It is estimated that approximately 30% of glands are identified[73] (Fig. 11.17). The left adrenal gland is more easily identified, best with a linear echoendoscope within the stomach aimed between the descending aorta and celiac trunk. The adrenal glands appear as seagull-shaped organs posterior to the pancreatic body that

come into view with a clockwise rotation of the probe. Martinez et al. performed endoscopic fine-needle aspiration of the adrenal glands in 94 patients with sensitivity, specificity, accuracy, positive predictive value, and negative predictive value at 86%, 97%, 92%, 96%, and 89% for malignant lesions, and 97%, 86%, 92%, 89%, 96% for benign lesions, respectively.[73] In 24 patients with endoscopic ultrasound-guided fine-needle aspiration of the adrenal glands, Jhala et al. reported that adequate cellularity was obtained from all patients, with no significant complications.[74] Similarly, Puri et al. performed endoscopic ultrasound-guided fine-needle aspiration in 21 consecutive patients and found no significant adverse events in cases where conventional imaging modalities were deemed unsuccessful.[75]

Intraoperative Ultrasound

Intraoperative ultrasound can be performed in cases of partial adrenalectomy to ensure clear resection margins or for improved localization of an underlying lesion. This is especially valuable in cases of adrenal sparing surgery, where a laparoscopic ultrasound probe can be used to identify multiple lesions within the adrenal gland, as well as to decipher the plane between the lesion and the native gland.[76]

Acknowledgments

The authors thank Lisa Napolitano, Dr. Trevor Morrison, and Dr. Tyler Berzin for their assistance in image collection The authors also acknowledge authors of this chapter in the fourth edition of this text, Drs. AR Ahuja, W Thurston, and SR Wilson, since their text formed the backbone of this revised chapter.

CHAPTER 12

The Retroperitoneum

Raymond E. Bertino and Elton Mustafaraj

SUMMARY OF KEY POINTS

- If an abdominal aortic aneurysm progresses to rupture, survival is very unlikely. If discovered before rupture, survival is highly likely.
- Most aneurysms are fusiform, which makes them readily diagnosable with ultrasound. Clinicians must also be aware of related entities that are more difficult to diagnose with ultrasound, including eccentric aneurysms, pseudoaneurysms, and penetrating ulcers.
- Ultrasound is *not* an appropriate method for the diagnosis of vascular emergencies in the abdomen. Particularly, it is not appropriate in the settings of possible ruptured abdominal aortic aneurysm and of acute mesenteric ischemia.
- In less acute situations, ultrasound has a strong role in the diagnosis of aortic aneurysm, renal artery stenosis, and chronic mesenteric ischemia. It also has a role in surveillance of aneurysms to assess growth and in treated aneurysms to assess for endoleaks.
- Ultrasound also has a role in the diagnosis of abdominal venous abnormalities. Clinicians should particularly be aware of the diagnoses of nutcracker syndrome and pelvic congestion syndrome, conditions that are probably underdiagnosed.

CONCLUSION

ATHEROSCLEROSIS

Atherosclerosis causes more deaths than any other disease in the Western world.[1] It is the main cause of cardiovascular diseases, including heart disease, cerebrovascular accident (stroke), hypertension, and peripheral vascular disease. It is a primary contributor to several other conditions, such as heart failure, arrhythmias (including atrial fibrillation), and cardiomyopathy. Cardiovascular disease has been the leading cause of death in the United States every year since 1900 except during the 1918 flu epidemic.[2]

There has been significant recent improvement. In 2013 cardiovascular disease was listed as the underlying cause for 800,937 deaths, a 28.8% drop from 2003.[2] In 2013 coronary heart

disease, when considered separately from other cardiovascular diseases, was still by far the single leading cause of death (370,213 deaths) in the United States.[2] Stroke, when considered separately from other cardiovascular diseases, was the underlying cause for 128,978 deaths in 2013.[2] By 2013, stroke had dropped to become the fifth leading cause of death, ranking behind heart disease, cancer, chronic lower respiratory diseases, and unintentional injuries in that order.[2]

Atherosclerosis is a complex process. Current understanding of its pathogenesis views atherosclerosis as a chronic inflammatory response triggered by injury to the endothelium. The endothelial injury results in increased permeability of the intima, allowing accumulation of low-density lipoprotein into the arterial wall. Inflammation results and plaque is produced, consisting of lipids, smooth muscle cells, fibrous tissue, macrophages, and calcium within the arterial wall.[1] Hemorrhage may also be present within the plaque. Atherosclerotic plaque can cause decreased blood flow to target organs by narrowing the arterial lumen, which can result in ischemic signs and symptoms such as claudication and erectile dysfunction (aortoiliac disease), hypertension and renal insufficiency (renal artery disease), and mesenteric ischemia (mesenteric artery disease).

Although there is controversy, many researchers believe that the processes inherent in atherosclerosis contribute to aneurysm formation.[3] Other, less common causes of aneurysms include cystic medial necrosis, trauma, and infection.[1]

ABDOMINAL AORTIC ANEURYSM

The abdominal aorta slowly tapers from the diaphragmatic hiatus to the aortic bifurcation (Fig. 12.1). Most of the tapering occurs in the proximal abdominal aorta as its largest branches (celiac, superior mesenteric, and renal arteries) arise. The normal size of the supraceliac abdominal aorta ranges from 2.5 to 2.7 cm in men and 2.1 to 2.3 cm in women. The normal diameter of the infrarenal aorta ranges from 2.0 to 2.4 cm in men and 1.7 to 2.2 cm in women.[4]

FIG. 12.1 Abdominal Aorta Anatomy. The abdominal aorta tapers from the aortic hiatus to the aortic bifurcation. The greatest tapering occurs as the aorta gives off its largest branches: the celiac, superior mesenteric, and renal arteries.

Mortality

Abdominal aortic aneurysm (AAA) is a common disease in the older population. Annually, 40,000 patients undergo elective repair in the United States.[5] AAA rupture is a catastrophic event. Many patients with ruptured aneurysms die before reaching a hospital. Of those admitted with rupture, many do not survive to go to surgery. For those with ruptured AAA that make it to surgery, the operative mortality rate is decreasing. Statistics from 2010 show an operative mortality rate of 33.4% for open procedures, a decrease of 10.1% from 2000.[5] When endovascular repair is used, the mortality rate is even lower—19.8% in 2010.[5] The overall mortality rate of a ruptured AAA is reported as being 85% to 90%,[6] largely because many patients with aortic rupture never make it to the operating room. Mortality for those undergoing elective repair in 2010 was 0.9% for endovascular repair and 4.8% for those undergoing open repair.[5] These facts suggest that the majority of deaths from AAA ruptures are preventable.

Much research has been conducted on reducing the number of deaths caused by AAAs. Ultrasound screening has proved to be a cost-effective step. Medical therapies may reduce the rate of growth of AAAs once they are detected. For large aneurysms, open or endovascular repair is much safer when done electively than emergently. With this knowledge, the AAA mortality rate can be greatly reduced.

Definition

There are many definitions of an arterial **aneurysm.**[7] A general definition is an increase in the diameter of an artery of at least 50% compared to the normal diameter of that artery.[4] For example, if a patient has an aorta that measures 2.2 cm in diameter, the aorta would be classified as aneurysmal at 3.3 cm. This definition can be difficult to apply to an abdominal aorta because it may not be clear what constitutes the normal aortic diameter in a specific patient.

The majority of AAAs are infrarenal. The most practical and common definition of infrarenal AAA specifies that an aneurysm is present when the infrarenal aorta has a diameter of 3.0 cm or greater. Aortas can also be referred to as **subaneurysmal** when they measure between 2.5 and 2.9 cm.[8] Subaneurysmal aortas have about a 50% chance of developing into a true aneurysm at 5 years.[9]

The definition that an AAA is present if the infrarenal aorta measures 3.0 cm or greater works well in most situations. However, the definition can be insufficient, particularly in small patients. It should be remembered that an aorta measuring 2.5 cm in diameter is properly called aneurysmal in a patient who has a more proximal aortic diameter measuring 1.6 cm.

Aneurysms that involve the renal arteries or the suprarenal aorta are less common and often occur with an aneurysmal thoracic aorta. AAAs that occur at or above the renal arteries are included in the Crawford classification of thoracoabdominal

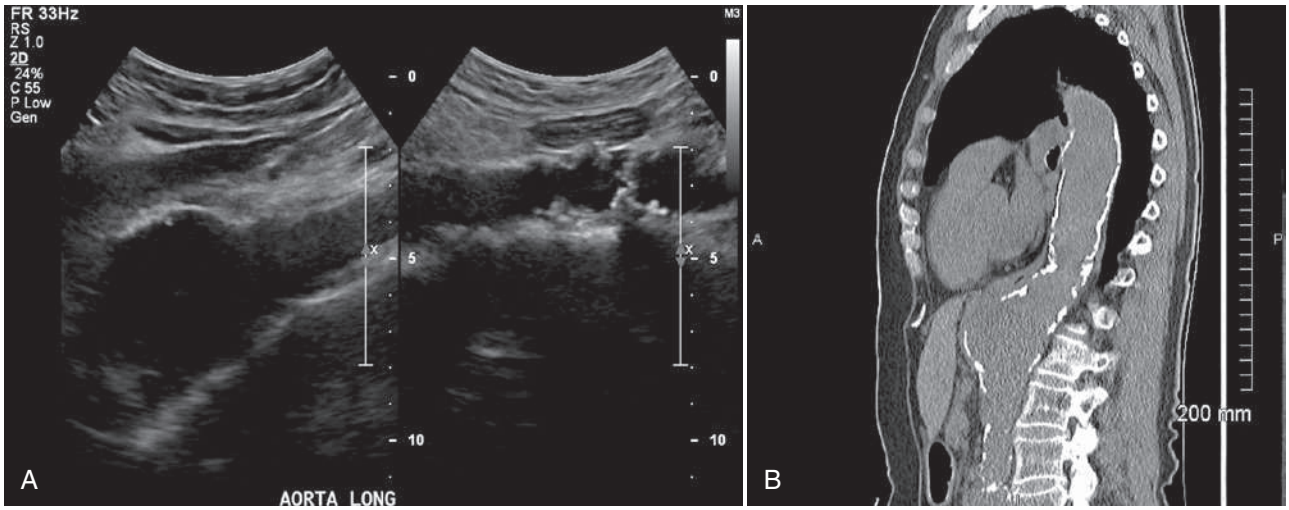

FIG. 12.2 Isolated Aneurysms of the Suprarenal Abdominal Aorta Are Rare. Most suprarenal abdominal aorta aneurysms (AAAs) also involve the thoracic aorta above the diaphragm. Isolated suprarenal AAAs are included in the Crawford classification of thoracoabdominal aneurysms. **(A)** Longitudinal ultrasound image shows isolated suprarenal AAA measuring 5.5 cm. **(B)** Sagittal reformatted CT demonstrates the isolated suprarenal AAA.

aneurysms[10] (Fig. 12.2). In the literature, unless otherwise specified, the term "abdominal aortic aneurysm" usually is used to mean "infrarenal abdominal aortic aneurysm."

Pathophysiology

Arteries have three layers: intima, media, and adventitia. The **intima,** the inner layer, is composed of the endothelium and the internal elastic lamina, along with scant intervening tissue. The intima is the main layer involved in the formation of atherosclerotic plaques. The **adventitia,** the outer layer, consists of connective tissue and carries nerves and the vasa vasorum.[1]

The **media** supplies much of the strength of the aorta and consists of elastin, collagen, smooth muscle cells, and extracellular matrix proteins. AAA formation is a disease largely involving the media and also the adventitia.[11,12] The aorta is an elastic artery and the aortic media has high elastin content.[1] With AAA, there is a significant decrease in elastin and collagen content in the media and adventitia.[11] Destruction of elastin is mediated by enzymes such as **matrix metalloproteinases** (MMPs). Medications may be able to reduce the rate of elastin destruction, either by suppression of the MMPs or inhibiting other biochemical pathways.[13] Statins and doxycycline are known inhibitors of MMP enzymes. Good evidence, however, is lacking regarding what may be the best medical therapy to help reduce the rate of AAA growth.[14]

Natural History and Medical Therapy

AAA is a disease of older persons. AAAs rarely occur before age 50 and affect men four times more often than women. The risk of developing an AAA also increases with smoking and with a family history of AAA in a first-degree relative. Other factors that increase risk are a history of peripheral vascular disease, cardiovascular disease, and hypertension.[15] AAAs typically increase in diameter at a rate of 1.7 to 2.6 mm per year. This rate of growth increases as the AAA becomes larger.[15] The rate of growth is faster in women.[16,17]

As the size of the AAA increases, the risk of rupture increases. Rupture is rare when the AAA is less than 4.0 cm in diameter, with near 0% risk per year. The rate of rupture increases to 1% when the AAA is 4 to 4.9 cm, 1.0% to 11 % for AAAs 5.0 to 5.9 cm in diameter, 10% to 22% for AAAs 6.0 to 6.9 cm, and 30% to 33% for aneurysms larger than 7 cm.[18] Although data for larger aneurysms are conflicting, when the diameter is greater than 6.0 cm, clearly the risk of rupture is significantly higher than for smaller aneurysms.[19,20] Other risk factors for rupture include current smoking and chronic obstructive pulmonary disease. In addition, the rupture rate for women is four times that of men.[21] Rupture in women occurs in smaller aneurysms, although the exact amount of increased risk is not well quantified. Because smaller AAAs in women have a risk similar to larger ones in men, elective treatment in women should occur at a smaller aneurysm size than in men.[17,18] Recommendations about how much smaller vary from 3 mm to greater than 5 mm.[22]

Current medical therapy is limited in its ability to prevent the growth of an AAA. Rate of aneurysm growth is increased in smokers and may be decreased in diabetics. Medications including statins and doxycycline have been suggested as possibly reducing the rate of aneurysm growth.[23-25] To date, none of the current strategies for reducing rate of growth through medications has been shown to be very effective.[14,26]

Screening

Recent Studies

The malady of AAA meets the 10 World Health Organization criteria for the institution of screening programs.[27] Research has been extensive, particularly in Europe, on the effectiveness and cost-effectiveness of ultrasound screening for AAA.

A meta-analysis commissioned by the US Preventive Services Task Force (USPSTF) combined analyses from four studies, including European studies. The analysts concluded that "for men age 65 to 75, an invitation to attend AAA screening reduces

AAA-related mortality." Based on these results, in 2005 the USPSTF published a recommendation for one-time screening for men aged 65 to 75 who had ever smoked.[28] In 2014 the USPSTF issued an update reiterating this recommendation.[29] The task force also recommended selective screening based on risk factors for men aged 65 to 75 who had never smoked. The risk factors they referenced were older age, positive smoking history, first-degree relative with AAA, history of other vascular aneurysm, coronary artery disease, cerebrovascular disease, atherosclerosis, hypercholesterolemia, obesity, and hypertension. The USPSTF believed the evidence to support screening for AAA in women smokers was inconclusive and consequently made no specific recommendation about such screening. The USPSTF recommended against routine screening for women who had never smoked.

The Screening Abdominal Aortic Aneurysms Very Efficiently **(SAAAVE) Act** was passed by the US Congress and signed on February 8, 2006. Since January 1, 2007, Medicare has covered a one-time, ultrasound screening to check for AAA in qualified patients. Qualified patients are men with a history of smoking (i.e., those who have smoked more than 100 cigarettes total during their lives) and men and women with a family history of AAA in a first-degree relative. To be covered, patients must undergo the AAA screening study as part of the Welcome to Medicare Physical Exam and complete the screening within the first 6 months of Medicare eligibility. Analysis of data from the first 2 years after the SAAVE Act was passed indicates that a minority (<20%) of the Medicare population that was eligible for AAA screening underwent screening. The impact of the SAAVE Act on the rate of AAA screening during those first 2 years was described as modest.[30]

Across the world, a few countries currently have nationwide screening programs although several others have begun pilot studies. National screening has been implemented in Sweden, in all member nations of the United Kingdom (England, Scotland, Wales, and Northern Ireland), and in the United States. Sweden has achieved an impressive attendance rate of 85% of those eligible for its screening program.[8]

Ultrasound Approach

Screening for AAA must have high sensitivity. It is mandatory that the entire infrarenal abdominal aorta be examined. The screening ultrasound has one of three results: positive, negative, or indeterminate.[31] The number of expected indeterminate exams should be very low, much less than 5%.

There are currently two paradigms for ultrasound in the screening of AAAs. The first is embodied in the current guidelines issued by the American College of Radiology (ACR) and involves obtaining a full set of documentation images on every patient.[31] When the screening examination is positive for AAA, the recommended images are adequate to document aneurysm size accurately. The screening examination thus also serves as the first diagnostic exam. This type of screening exam is not very different from a full "diagnostic" examination and is probably the most common type in radiology departments.

The second paradigm is used by several mobile companies offering aneurysm screening to the general population. These for-profit programs are prepaid by the individuals requesting screening; profit is based on doing a high volume of cases within a short time, keeping cost to a minimum. It is unclear whether adequate quality control mechanisms are in place for these exams, which often have only two possible results: positive and negative. Positive exams do not result in extension of the study to be diagnostic. Instead, a positive exam results in a recommendation to the patient to have a diagnostic evaluation. This allows the provider to save time and reduce cost.

The decreased cost of this type of examination offers a potential benefit. If the low cost of this type of service could be widely reproduced, and if the issue of quality control were addressed, screening that is both accurate and cost-effective could become available for a wider segment of the population.

Unfortunately, at least some of the programs make recommendations to their customers that cannot be supported by the literature such as the concept of needing to screen for AAA on a yearly basis. Screening on a yearly basis certainly will increase the number of patients using the service and increase profit but hardly seems to represent an disinterested attempt to improve health care.[32] Atherosclerotic aneurysm formation is a very slow process and there is absolutely no need for yearly screening for someone without an aneurysm. There are some who would question whether a second screening is ever needed if the first screening was performed at age 65 or later. Certainly, once a first well-performed screen is negative there is no justification for rescreening except perhaps after many years.

Surveillance

Once an AAA is discovered, the patient moves from screening to a **surveillance** program in which the aneurysm size is periodically checked. Because an AAA tends to grow more rapidly as its size increases, there is general agreement that a smaller aneurysm needs to be checked less frequently than a larger one. Otherwise, however, consensus is lacking on frequency of sonographic surveillance. Recommendations for assessing aneurysms less than 4.0 cm in diameter range from 1 to 3 years.[33] For the U.K. Small Aneurysm Trial, Brady et al.[34] concluded that surveillance could be performed at intervals of 36, 24, 12, and 3 months for aneurysms of 35, 40, 45, and 50 mm, respectively. Following this schedule, the risk of the AAA size on recheck being greater than 55 mm would be less than 1%. Achieving a 5% rate would require even less frequent surveillance. Society for Vascular Surgery practice guidelines recommend surveillance at 36, 12, and 6 months for aneurysms between 3.0 and 3.4 cm, between 3.5 and 3.9 cm, and between 4.0 and 5.4 cm, respectively. They also recommend surveillance every 5 years for aortas between 2.6 and 2.9 cm in size.[35] It has been suggested that aortic aneurysms may need even less frequent surveillance than what is cited above.[36]

Up until several years ago, we scanned most aneurysms yearly. Our aneurysm clinic now follows AAAs sonographically every 2 years when the aneurysm is less than 40 mm, every year for aneurysms 40 to 44 mm, and every 6 months once the aneurysm reaches 45 mm.

Surveillance of aneurysms lends itself well to being followed by a database. Our interventional radiology–run aneurysm clinic started a database in 2003 to follow AAAs.[37] Patients with known

AAAs of any size are entered into the database. Patients are seen once in our interventional radiology clinic so that they can meet the physicians and advanced practice nurses involved and can be informed about their disease, its treatment, and how their aneurysm is to be followed. The clinic orders all subsequent aortic ultrasounds and monitors all results. After that first visit, all communication is by phone and by mail. The database is monitored periodically to make sure patients keep their appointments. When the aneurysm reaches 5.0 cm in greatest diameter, patients again begin to be seen regularly in the clinic.

Sonographic Technique

Pertinent history should be obtained when doing surveillance on a known aneurysm. Questions of interest are whether the patient has back and/or abdominal pain or tenderness. These symptoms can be experienced by patients who have inflammatory aneurysms. In the absence of an inflammatory aneurysm, these symptoms are considered an indication for aneurysm repair.

The following principles apply both to screening examinations and studies for surveillance. Evaluation of the entire infrarenal aorta is necessary. Identifying the aortic bifurcation guarantees that one has seen far enough distally. By identifying the celiac, superior mesenteric, or renal arteries or the aortic hiatus of the diaphragm, sonographers can guarantee that the proximal examination has been carried high enough. Images should be obtained in both transverse and longitudinal planes. The goal is to find the maximum diameter of the aorta, measured from outer edge of the wall to outer edge of the opposite wall. Measurements should be taken perpendicular to the axis of the lumen of the aorta. To guarantee that the measurement is perpendicular, longitudinal images are usually best for obtaining the most accurate measurements (Fig. 12.3). The measurement includes both the front and the back walls.

Most infrarenal aneurysms are fusiform in shape with a relatively circular cross section. With a fusiform aneurysm, measurement of its size taken from any longitudinal plane through the aorta will be the same (Fig. 12.4). The walls of the aorta are generally well seen with longitudinal imaging because they are parallel to the face of the transducer, resulting in a strong echo from the walls. Transverse imaging is particularly important to identify the small proportion of aneurysms that are eccentric. If the aneurysm is eccentric, the measurement must be taken in the plane of the aneurysm's eccentricity to find the largest diameter of the aneurysm (Figs. 12.5 and 12.6).

We routinely image patients from two windows: the anterior abdominal midline (sagittal plane), which allows imaging of the maximum length of the abdominal aorta, and the left flank (near the coronal plane), with the patient in the right lateral

FIG. 12.3 Measuring Abdominal Aorta Aneurysms (AAAs). AAA measurements from longitudinal images are usually the most accurate and are taken perpendicular to the lumen. The measurement includes both the front and the back walls.

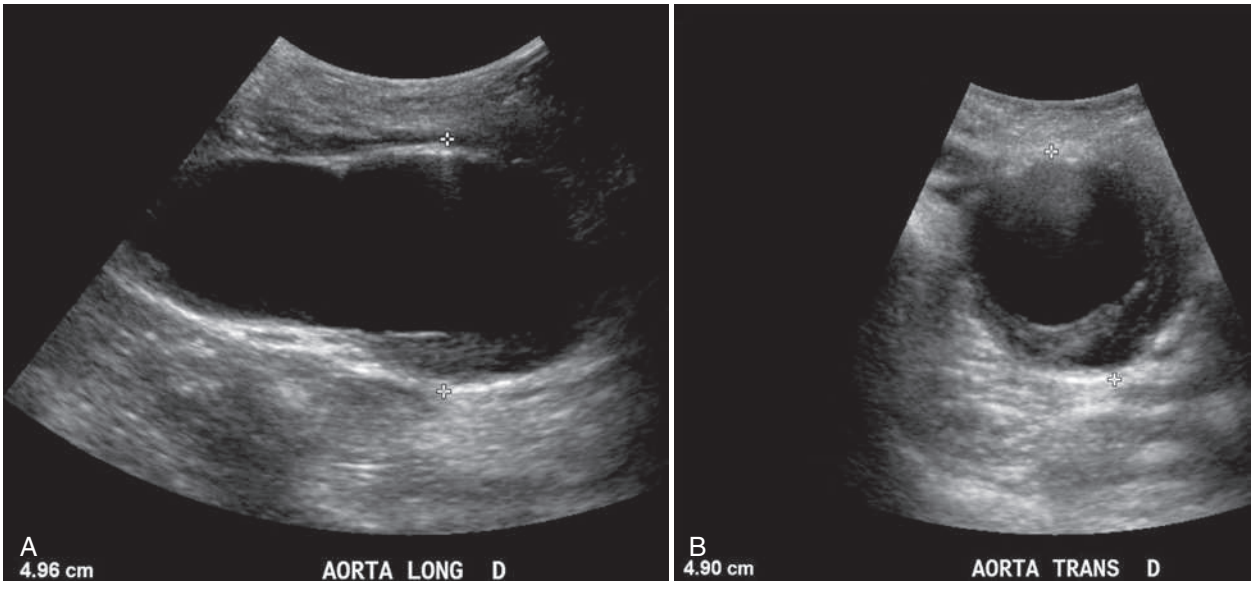

FIG. 12.4 Most Abdominal Aortic Aneurysms (AAAs) Are Fusiform. When fusiform, the AAA is circular in cross section. **(A)** Longitudinal and **(B)** transverse gray-scale sonograms show measurement of the AAA.

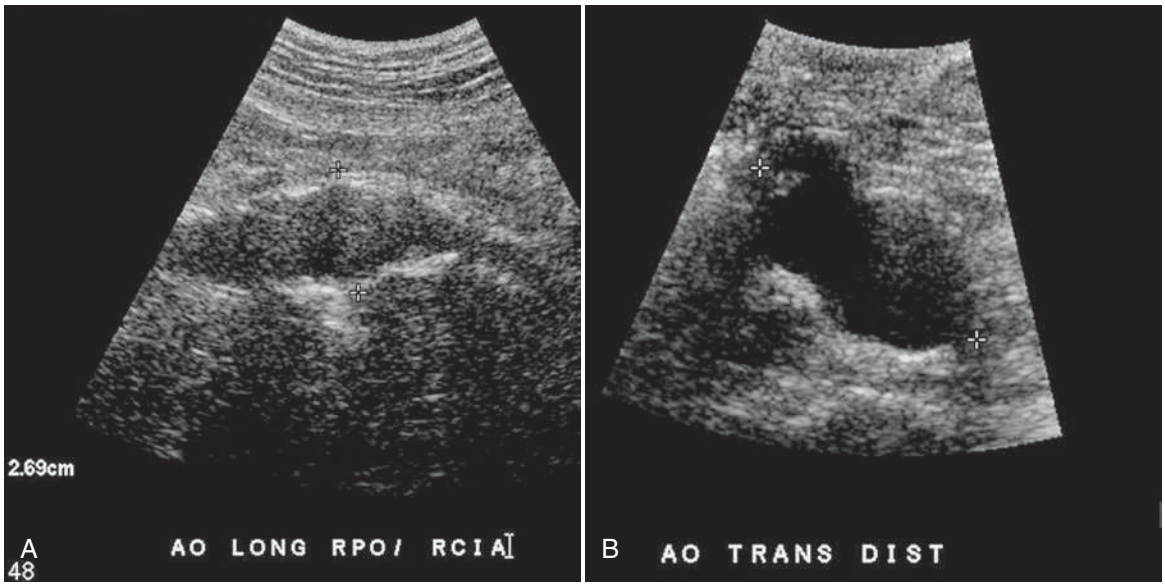

FIG. 12.5 Aorta With Saccular Aneurysm. (A) Viewed in the longitudinal plane, the aorta appears normal. **(B)** Transverse imaging of the aorta is required to reliably detect a saccular aneurysm. Unless a longitudinal image can be obtained in the plane of the greatest diameter of a saccular aneurysm, transverse imaging must be used to measure the greatest diameter.

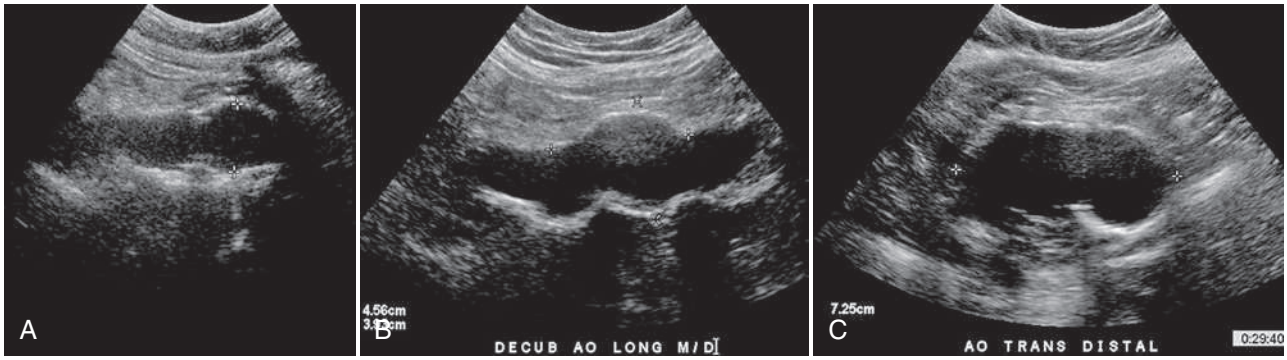

FIG. 12.6 Small Aortic Aneurysm Just Reaching 3.0 cm. (A) Longitudinal scan. Note that the abdominal aortic aneurysm was incorrectly measured from inner wall to inner wall (*calipers,* 2.9 cm) instead of the correct method, which is outer wall to outer wall. **(B)** The patient was lost to follow-up of the aneurysm. He returned 6 years later with a 6-week history of abdominal and back pain. The aneurysm was incidentally rediscovered during the course of abdominal ultrasound. On longitudinal imaging, the aneurysm had increased in size (4.6 cm). **(C)** Transverse view shows that the aortic lumen is actually larger and now is eccentric, with a largest diameter of 7.3 cm. In retrospect, the patient's 6-week history of abdominal and back pain probably had been from the contained perforation of the aneurysm.

decubitus position. The middle and distal abdominal aorta are often better seen in this position, particularly in obese patients. The proximal common iliac arteries may also be better seen in this position.

We obtain longitudinal and transverse cine loops from an anterior window and from a left lateral window. The longitudinal cine loops allow for easy remeasurement of the aorta by the reviewing physician. The transverse cine loops allow the reviewing physician to determine whether there is eccentricity of the aneurysm.

Computed Tomography

Computed tomography (CT) has a limited role in AAA screening and surveillance but should be used in any of the following situations:

1. The patient is so obese or otherwise difficult to image that whether the aneurysm may be eccentric cannot be determined with reasonable certainty on initial scanning. Once the aneurysm is shown to be fusiform, performing most of the further surveillance with ultrasound is reasonable.
2. The aneurysm is known to be eccentric, and the area of eccentricity is not optimally seen with ultrasound.
3. The patient is acutely symptomatic (including emergency room patients).
4. Portions of the iliac arteries that are known to be aneurysmal are not well seen.
5. The AAA is suspected to be an inflammatory AAA (described later) and has not yet been imaged with CT.
6. The aneurysm is suspected of having reached a size at which treatment planning is needed.

FIG. 12.7 False-Positive Abdominal Aortic Aneurysm. The deep cursor has been placed on the echo caused by the anterior edge of lumbar vertebral body, posterior to the aorta. Mistaking the anterior lumbar spine for the posterior wall of the aorta may cause a false-positive exam, particularly if visualization is poor because of obesity. Transverse imaging can usually detect the error. Longitudinal imaging in the coronal plane also helps avoid this error.

False-Positive/False-Negative Results

Screening for aortic aneurysm should be highly accurate. Nonetheless, we have encountered two sets of circumstances where it is possible to have a false-positive study. The first can happen when the aorta at the diaphragmatic hiatus measures 3.0 cm or greater and is mistakenly called "aneurysmal." The normal size of the supraceliac aorta is 2.1 to 2.7 cm.[4] Based on a definition of aneurysm that requires the diameter to be 1.5 times or more the normal diameter, a small aorta would not become aneurysmal until it reached approximately 3.2 cm in diameter, whereas the larger supraceliac aorta would not be aneurysmal even at 4.0 cm.

The second circumstance where we have seen several false-positive studies is when the spine is mistaken for the posterior wall of the aorta. This is particularly likely to occur when visualization is poor, as in a very obese patient. The true posterior wall of the aorta may then be difficult to determine. Usually, transverse imaging or imaging from the left flank will help define the true posterior wall to help determine if an aneurysm is present (Fig. 12.7).

False-negative studies may occur if visualization of the infrarenal aorta is incomplete. If the entire infrarenal aorta is well seen in longitudinal imaging, the diagnostician can exclude the presence of a fusiform aneurysm, the most common type of AAA. However, if the entire infrarenal aorta is not well seen in the transverse plane, an eccentric aneurysm is not excluded (see Figs. 12.5 and 12.6).

Ultrasound Versus Computed Tomography for Evaluation of Rupture

As previously mentioned, **rupture** of aortic aneurysms is catastrophic, usually resulting in the patient's death. Although it played a role in the rapid diagnosis of ruptured AAAs in the emergency room 30 years ago,[38] ultrasound no longer has such a place at most institutions. The near ubiquitousness of high-speed multidetector CT scanners has made CT diagnosis extremely rapid. CT has a number of other advantages in comparison to ultrasound. CT, even without intravenous contrast, is diagnostic of AAA in all cases, is highly diagnostic of retroperitoneal bleeding associated with aneurysm rupture, and is not operator dependent.

Because of these factors, obtaining a formal ultrasound in patients with an emergent need for diagnosis in most settings is unwise. If the patient has a ruptured AAA, time is of the essence, and the patient needs the most complete information that can be obtained in a reliable way. Performing ultrasound risks wasting precious minutes that may be the difference between patient survival and death (Fig. 12.8).

Treatment Planning

Treatment of large AAAs involves either open surgical repair or **endovascular aortic repair** (EVAR). Endovascular repair involved the placement of an **endoluminal graft** (also known as a **stent graft**) to create a new channel for blood flow through the aneurysm isolating the aneurysmal sac.

Computed tomography angiography (CTA) is the most appropriate imaging method for AAA treatment planning. In the setting of open repair, CTA accurately assesses the degree to which the iliac arteries may be involved with the aneurysm. In addition, evaluation of the mesenteric arteries is of value to determine whether reimplantation of the inferior mesenteric artery (IMA) is needed. For EVAR, the distance of the renal arteries from the top of the aneurysm and the presence and location of accessory renal arteries are important. Knowledge of the three-dimensional anatomy of the aneurysm and size and configuration of the iliac arteries is critical.

Postoperative Ultrasound Assessment

After open surgical repair of an aortic aneurysm, imaging surveillance generally is not performed. Imaging is used to assess **postoperative complications,** including thrombosis, infection, stenosis (graft kink, neointimal hyperplasia, atherosclerosis), and **anastomotic pseudoaneurysm.** Ultrasound may play a role in the diagnosis of any of these complications. Another complication is **aortoenteric fistula,** generally to the third portion of the duodenum, which is potentially catastrophic and presents most often with upper gastrointestinal bleeding. Ultrasound has no role to play in the diagnosis of aortoenteric fistula.

Ultrasound has a larger, potentially much larger, role to play after repair of AAAs with EVAR. Current recommendations include lifelong imaging surveillance for endoleaks and graft migration in patients who have undergone EVAR for AAA.[39] An **endoleak** is an area of the AAA that has been excluded by the stent graft that nonetheless continues to have blood flow. There are four types of endoleaks, categorized by four different sources of blood flowing into the aneurysmal sac (Fig. 12.9). Egress of blood from the sac is usually through patent aortic branches in all types of endoleak.

With a **type 1 leak,** one of the ends of the stent graft is not tightly apposed to the arterial wall, allowing blood to enter the aneurysmal sac (Fig. 12.10). A **type 2 leak** is caused by retrograde

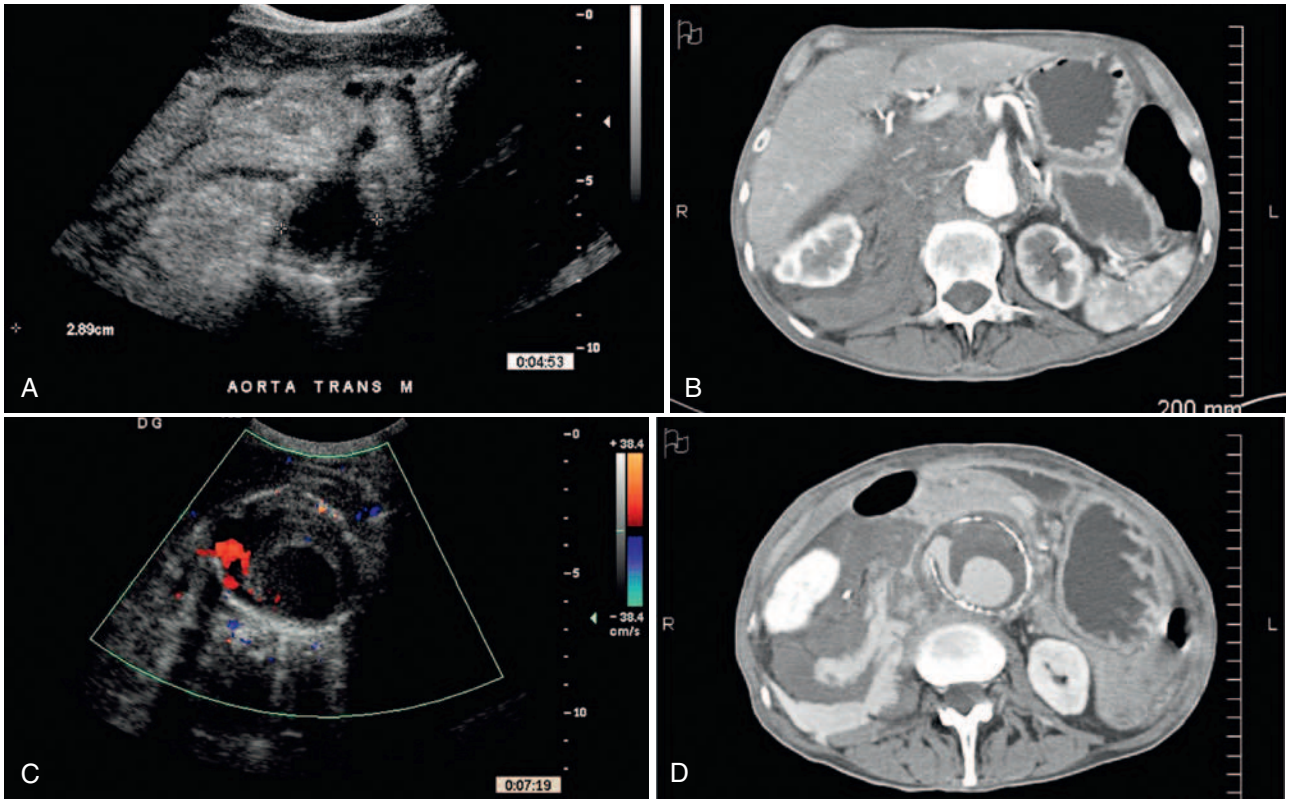

FIG. 12.8 Ruptured Abdominal Aortic Aneurysm (AAA). The use of both **(A)** ultrasound and **(B)** computed tomography (CT) in suspected rupture of AAA should be avoided because of the addition of time for the workup. (In this case 45 minutes elapsed between the ultrasound and CT.) CT is preferred in this setting because it can usually be done expeditiously and more reliably answers the pertinent questions. **(C)** Transverse ultrasound and **(D)** contrast-enhanced CT show the same AAA visualized at the site of rupture. The patient did not survive.

flow into the aneurysm sac through an aortic branch, usually the IMA or a lumbar artery (Fig. 12.11, Videos 12.1 and 12.2). In a **type 3 leak,** there is disruption of the integrity of the stent graft, caused by a fabric tear or a separation of component parts of the modular stent graft (Fig. 12.12, Videos 12.3 and 12.4). A **type 4 leak** is caused by porosity of the stent graft fabric with blood actually going through the pores in the fabric. This is seen only early after placement and is self-correcting. The term **endotension** refers to an aneurysm sac that stays pressurized in the presence of a stent graft. This is sometimes referred to as a type 5 endoleak. Its presence is inferred by continued growth in the aneurysm sac size in the absence of detecting another type of leak.[40,41]

With an endoleak, a treated aneurysm may continue to grow and eventually rupture. Endoleaks occur in approximately one-third of AAAs treated with stent grafts.[42] Types 1 and 3 endoleaks require immediate treatment when diagnosed. Type 4 endoleaks are generally seen only during placement of the stent graft and are self-limited, requiring no treatment. More judgment is involved in the care of type 2 leaks. Small leaks may be watched over time to see if they resolve and whether expansion of the aneurysm occurs.[42,43]

Because of the possibility of endoleaks, AAAs treated with stent grafts undergo routine imaging surveillance. Imaging most often includes yearly, contrast-enhanced, multiphase CT examinations. This regular imaging greatly increases cost and exposes patients to contrast and substantial radiation. Color duplex Doppler sonography alone can be used to visualize endoleaks. Several studies suggest that standard color duplex Doppler ultrasound may be the preferred method of surveillance.[44,45] Studies comparing contrast-enhanced duplex with standard color duplex have found the addition of contrast improves the quality of the study. Several studies suggest that contrast-enhanced ultrasound is at least as sensitive as CT for the detection of endoleaks.[46-48] The issue is still a topic of research,[49] although with more experience, contrast-enhanced ultrasound likely will play a significant role in AAA endoluminal graft surveillance.

As already mentioned, surveillance for graft migration is also necessary after EVAR. In those undergoing surveillance for endoleak with color duplex Doppler sonography, plain radiography can be used to assess for graft migration.

OTHER ENTITIES CAUSING ABDOMINAL AORTIC DILATION

Inflammatory Abdominal Aortic Aneurysm

Inflammatory AAAs constitute as much as 5% or more of all AAAs.[50] According to some investigators, inflammatory AAA is likely related to retroperitoneal fibrosis (see later discussion),

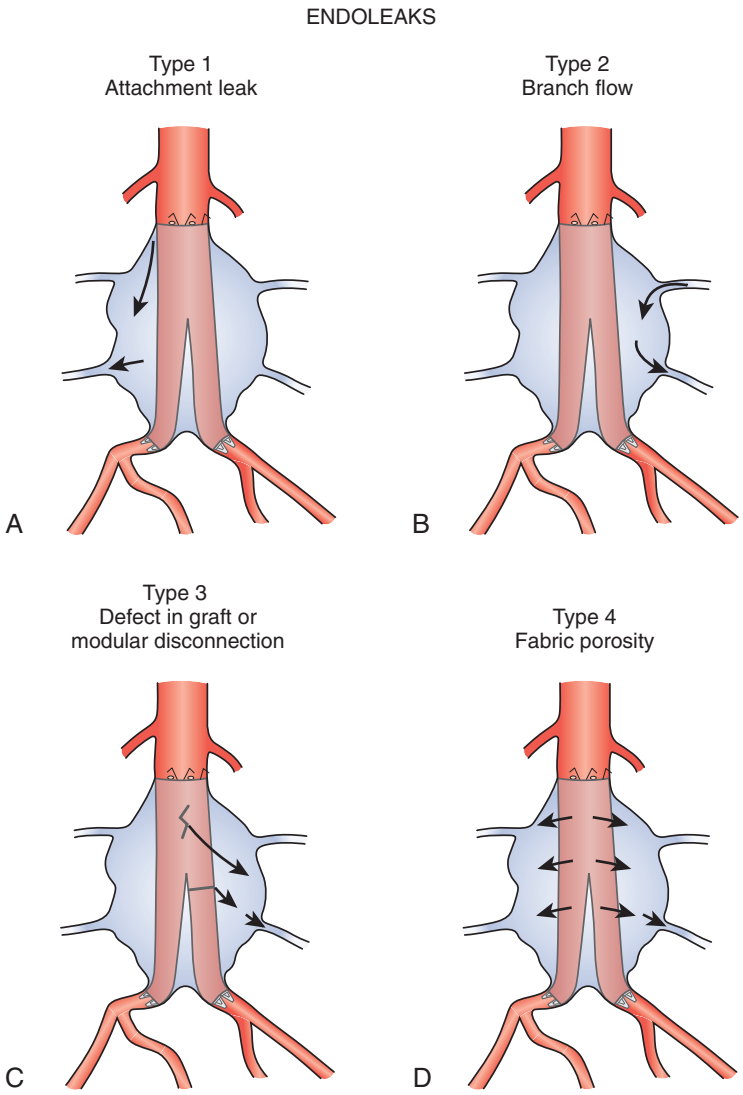

FIG. 12.9 Endoleaks of Abdominal Aortic Aneurysm After Endovascular Aneurysm Repair. (A) Type 1 leak (attachment leak). Blood continues to enter the aneurysm sac at one of the three ends of the bifurcated stent graft, the points where the stent graft should be tightly affixed to the arterial wall. Egress, as with all endoleaks, is through branches of the aorta that remain patent. Treatment of type 1 leaks is indicated. **(B) Type 2 leak (branch artery leak).** Blood enters the aneurysm sac through a patent branch artery. This type of leak can be self-limited and may be just observed. Treatment is indicated if the aneurysm enlarges. **(C) Type 3 leak (loss of integrity of stent graft).** Either the modules of the stent graft have become separated or a rent has formed in the fabric of the stent graft. Blood enters the sac from the stent graft lumen through the site of loss of stent graft integrity. Treatment is indicated. **(D) Type 4 leak (fabric porosity).** Blood enters the sac from the stent graft lumen through intact cloth of the stent graft. This is self-limited and present only at surgery. The pores of the fabric quickly become occluded by blood products.

with both included as part of a classification referred to as **chronic periaortitis.**[50-52] The newly discovered entity of **immunoglobulin G4 (IgG4)–related periaortitis** and periarteritis likely is also part of this complex.[53]

Inflammatory AAAs are recognized by extremely thickened aortic wall and surrounding fibrosis that tends to spare the posterior wall (Fig. 12.13). As in retroperitoneal fibrosis, the inflammation may involve the ureters, causing obstruction. Inflammatory AAAs are less prone to rupture than other AAAs but are more prone to producing symptoms such as back pain. Antiinflammatory drugs, including steroids and methotrexate, have been used to treat the inflammation.[50-52] With surgical or endovascular treatment, the inflammation surrounding many AAAs resolves (Fig. 12.14).[54] Sonographically, inflammatory AAAs may be recognized by a rind of tissue surrounding the aorta. Needle biopsy is usually necessary to confirm the diagnosis and to exclude the small chance that the mass instead is due to neoplasm, particularly lymphoma.

Arteriomegaly and Aortic Ectasia

Arteriomegaly is diffuse arterial dilation involving several arteries, each with an increased diameter of at least 50% compared with the normal diameter. **Ectasia** refers to diffuse or focal dilation that is less than 50% increased in diameter.[4]

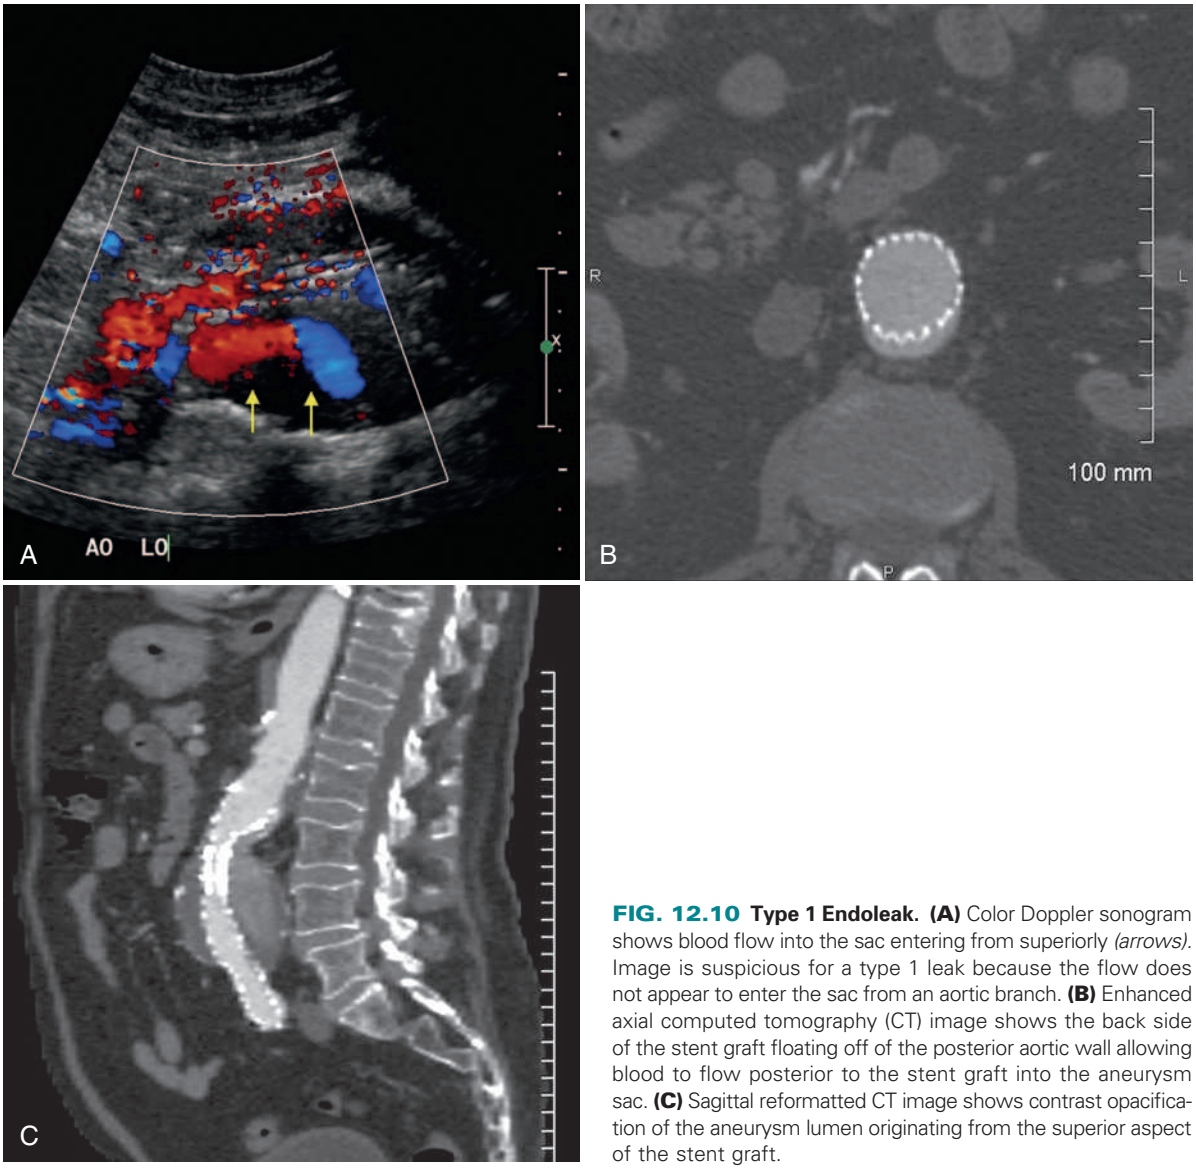

FIG. 12.10 Type 1 Endoleak. (A) Color Doppler sonogram shows blood flow into the sac entering from superiorly *(arrows)*. Image is suspicious for a type 1 leak because the flow does not appear to enter the sac from an aortic branch. **(B)** Enhanced axial computed tomography (CT) image shows the back side of the stent graft floating off of the posterior aortic wall allowing blood to flow posterior to the stent graft into the aneurysm sac. **(C)** Sagittal reformatted CT image shows contrast opacification of the aneurysm lumen originating from the superior aspect of the stent graft.

Penetrating Ulcer

Penetrating ulcer has been recognized for approximately 30 years.[55] It is believed to result when an atherosclerotic ulceration penetrates the media, allowing an intramural hematoma to form.[56] This outpouching into the media may progress, developing into a saccular aneurysm. Penetrating ulcers occur more frequently in the thoracic aorta but are also seen in the abdominal aorta[57,58] (Fig. 12.15).

Pseudoaneurysm

A true aneurysm is a dilation of an artery that is contained by all three layers of the arterial wall. In contrast, a **pseudoaneurysm** is a dilation that may be confined by only two layers, only one layer, or only adjacent soft tissue. In the abdominal aorta, a pseudoaneurysm is most likely to occur as a late surgical complication of aortic aneurysm repair or of other arterial surgery, almost always at sites of anastomosis. It can also be the result of incomplete rupture of a penetrating ulcer or aneurysm (Video 12.5). Sonographically, the appearance often is similar to a true aneurysm. With the proper findings, the diagnosis of pseudoaneurysm versus true aneurysm is made largely based on the clinical setting (e.g., previous trauma or aneurysm repair).

STENOTIC DISEASE OF THE ABDOMINAL AORTA

Stenosis or occlusion of the abdominal aorta can be congenital or caused by atherosclerosis, vasculitis (arteritis), trauma, or embolus. Dissection may also result in stenosis. **Midaortic syndrome** is a rare congenital stenosis that is also called **abdominal coarctation.**

Symptoms of aortic stenosis or occlusion include intermittent claudication and impotence. These symptoms, along with the finding of decreased femoral pulses, are called **Leriche syndrome,** although the term often is used more broadly to refer to all the

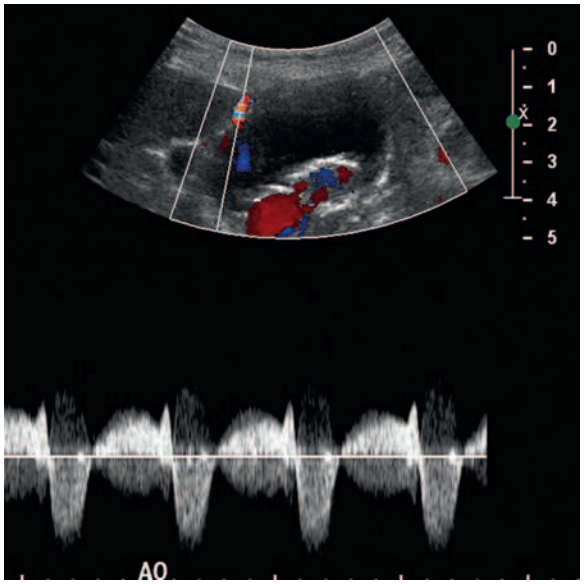

FIG. 12.11 Type 2 Endoleak. To-and-fro flow in the inferior mesenteric artery filling a small patent space in the aneurysm sac. See also Videos 12.1 and 12.2.

signs and symptoms that may result from aortic occlusive disease or even the occlusion itself. In the great majority of patients with aortic stenosis or occlusion, the disease is caused by atherosclerosis. However, certain clinical settings suggest other causes.

With embolic disease, a dramatic abrupt onset of symptoms is the best historical evidence of the nature of the event. The patient can often relate exactly what he or she was doing when the symptoms started, even if the event was weeks in the past (e.g., "I had just gotten up from cutting roses …"). The rapidity with which the patient seeks treatment depends on the severity of the reduction in blood flow. Embolus to any artery must be viewed as a very serious and signal event. The majority of emboli to the abdominal aorta come from the heart. Having an arterial embolism of any type is similar to having a pulmonary embolism; having one puts the patient at risk for having more. If the origin of the embolus is cardiac, the next one that forms may go to some less favorable place, such as the cerebral circulation, resulting in stroke, or to the mesenteric circulation, resulting in intestinal infarction. The workup of any patient identified as having an embolus should be expeditious, and anticoagulation

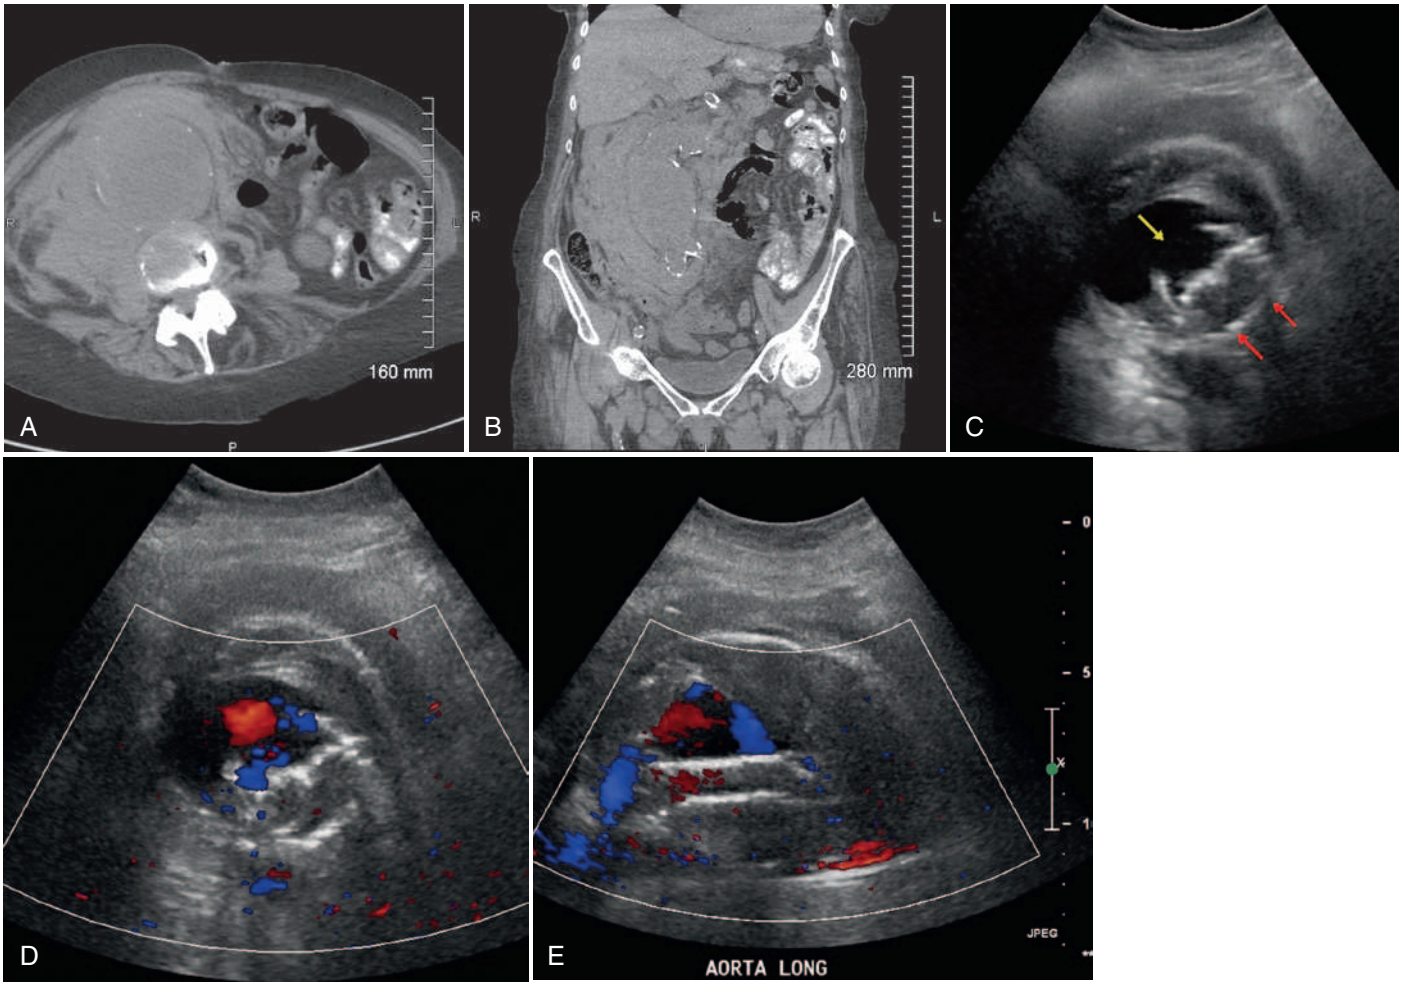

FIG. 12.12 Type 3 Endoleak. (A) Axial and **(B)** coronal computed tomography images show a ruptured abdominal aortic aneurysm. The patient had emergent endovascular aortic repair (EVAR) using disparate components in an attempt to fashion a workable endograft. **(C)** Axial gray-scale and **(D)** color Doppler images one day post EVAR show a gap *(yellow arrow)* between the tubular portion of the stent graft and the bifurcated portion *(red arrows)*. Blood flow visible throughout the gap. **(E)** Longitudinal image shows flow into the sac that appears to arise from the graft and not from an aortic branch artery. See also Videos 12.3 and 12.4.

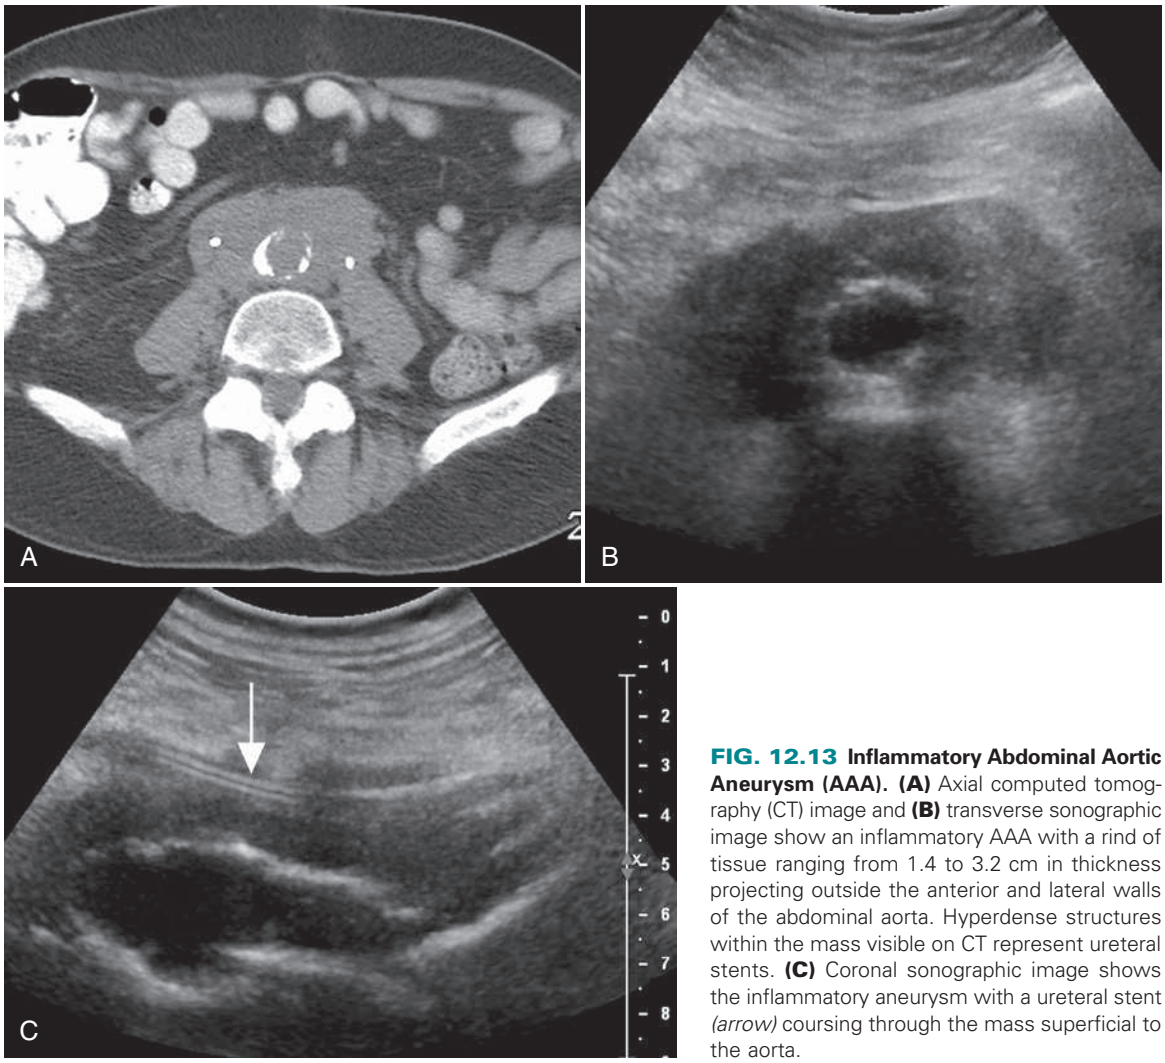

FIG. 12.13 Inflammatory Abdominal Aortic Aneurysm (AAA). (A) Axial computed tomography (CT) image and **(B)** transverse sonographic image show an inflammatory AAA with a rind of tissue ranging from 1.4 to 3.2 cm in thickness projecting outside the anterior and lateral walls of the abdominal aorta. Hyperdense structures within the mass visible on CT represent ureteral stents. **(C)** Coronal sonographic image shows the inflammatory aneurysm with a ureteral stent *(arrow)* coursing through the mass superficial to the aorta.

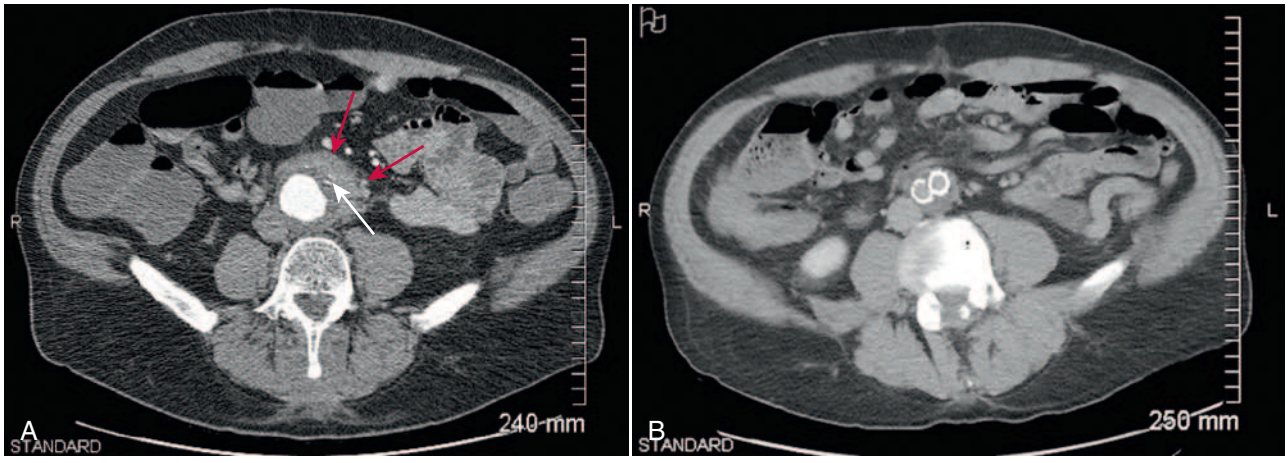

FIG. 12.14 Inflammatory Abdominal Aortic Aneurysm (AAA) Before and After Treatment. (A) Computed tomography (CT) scan of inflammatory AAA, which has maximal diameter of 4.9 cm. Note calcification *(white arrow)* indicating the aortic wall. Inflammatory tissue is present outside the aorta *(red arrows)*. Patient was symptomatic and was treated with an endoluminal graft shortly after this scan. **(B)** CT scan 2 years later shows that aortic size is smaller. Inflammatory mass has disappeared.

FIG. 12.15 Penetrating Ulcer. (A) Longitudinal image shows an outpouching of the aorta with an otherwise relatively normal abdominal aorta. **(B)** Computed tomography image at level of outpouching. The rest of the aorta was not dilated and had no more than minimal atherosclerosis. **(C)** and **(D)** Angiography images before and after placement of a stent graft.

is usually in order, certainly until the source is determined and addressed.

Takayasu arteritis is a cause of aortic stenosis and is of particular note because it may occur in younger patients. It can affect the abdominal aorta or its branches.[59] Takayasu arteritis can present with symptoms resulting from aortic stenosis or branch vessel stenosis.

Posttraumatic aortic stenosis can occur in patients of any age, including younger patients. The initial aortic injury results from a forceful, nonpenetrating injury to the abdomen.[60] The resulting intimal injury can cause subintimal fibrosis, which can result in stenosis. Trauma can also result in more acute aortic injuries, including intimal tears, pseudoaneurysm formation, and aortic rupture.[61]

Isolated dissection of the abdominal aorta is rare. Involvement of the abdominal aorta more frequently results from extension of thoracic dissection, which can result in obstruction of the abdominal aorta or branch arteries.

In most cases of suspected aortic stenosis, we prefer to evaluate the aorta with CTA instead of sonography. Peripheral vascular disease is first confirmed in the patient by obtaining ankle brachial indices before and after exercise with or without arterial duplex sonography of the lower extremities. The next step in the workup is to obtain a map of the arteries supplying blood flow to the lower extremities to direct treatment. Maps of the arterial tree are more easily and reliably obtained either by CTA or by conventional catheter angiography than with sonography.

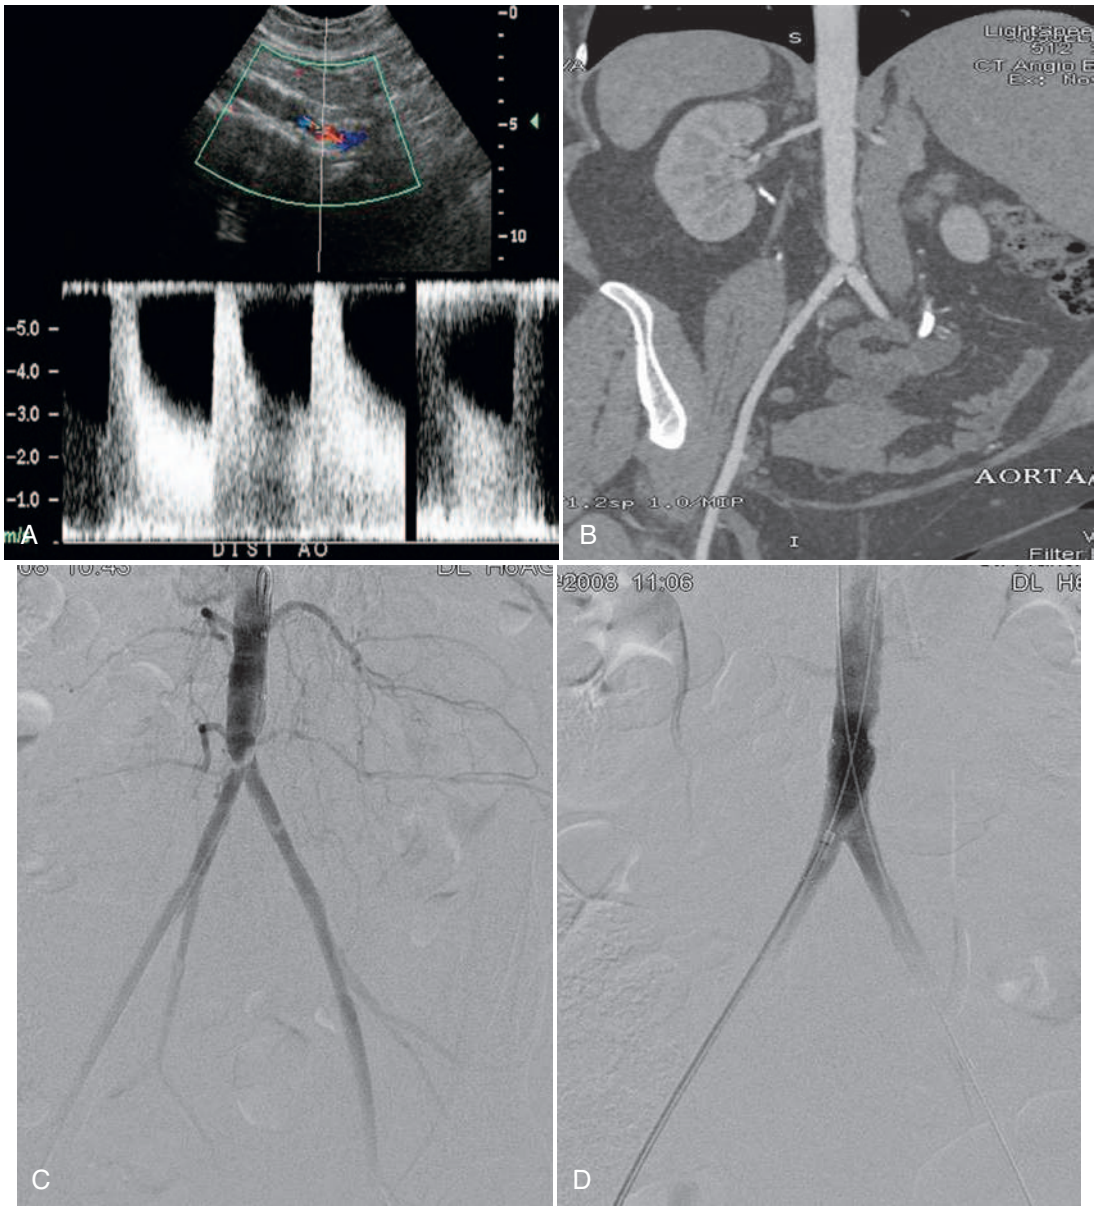

FIG. 12.16 Stenotic Aortic Bifurcation. (A) Duplex Doppler sonogram shows velocity of greater than 500 cm/sec at stenosis at the aortic bifurcation. Proximal to the stenosis, the aortic velocity varied from 35 to 50 cm/sec. Note the stenosis has an extremely high diastolic velocity of about 250 cm/sec. **(B)** Computed tomographic angiography shows very focal stenosis of the abdominal aorta at its bifurcation. **(C)** Angiography shows severe stenosis. **(D)** Stenosis treated with "kissing" stents with good result.

However, situations still arise in which aortic or iliac duplex Doppler sonography is indicated to assess for stenotic disease (Fig. 12.16). Several windows are necessary to complete an entire examination of the aorta and iliac arteries. Maintaining a proper Doppler angle of 60 degrees or less can be difficult.

DISEASES OF ABDOMINAL AORTA BRANCHES

Renal Arteries

Anatomy

The renal arteries usually arise distal to the **superior mesenteric artery** but can originate as far distally as the common iliac arteries. The main renal arteries are the only large lateral branches of the abdominal aorta.

When seen in cross section, viewing the aorta as if it were the face of a clock, the right renal artery arises from the aorta between the 9 and 11 o'clock positions. It then courses posterior to the inferior vena cava. The left renal artery most commonly arises between the 3 and 4 o'clock locations. The left renal artery typically arises directly posterior to the left renal vein.[62]

In most cases, a single renal artery supplies each kidney. In 30% of kidneys, however, one or both kidneys are supplied by two or more arteries.[63] When there are two renal arteries, the smaller artery is an **accessory artery.** Accessory arteries most often arise within 1 to 2 cm of the main renal artery. However, they may arise anywhere from the SMA to, in rare cases, as far distal as the common iliac arteries. Some accessory arteries do

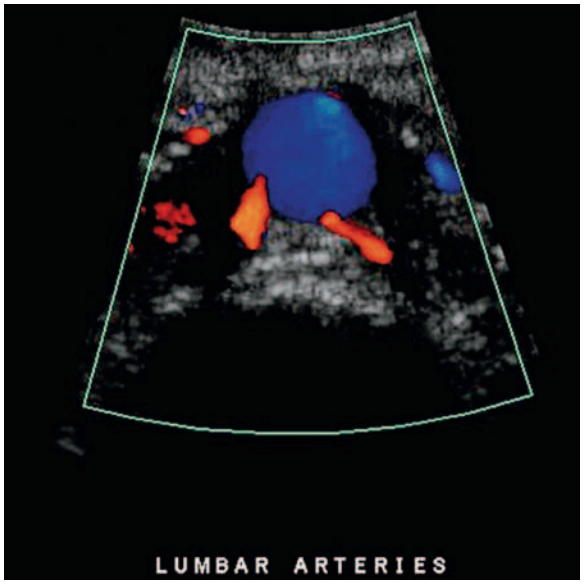

FIG. 12.17 Lumbar Arteries. Color Doppler sonogram of one set of the paired lumbar arteries shows their typical posterior origins.

not enter the kidney at the hilum and instead enter the kidney at one of the poles. These accessory arteries are referred to as **polar arteries.**

Other arteries that can occasionally be confused for an accessory renal artery are the lumbar arteries. Occasionally seen near the abdominal aorta, lumbar arteries are small and arise more posteriorly than accessory renal arteries (Fig. 12.17). Lumbar arteries can be properly identified by their very-high-resistance waveform, similar to that of an extremity artery of a person at rest. Lumbar arteries can sometimes be identified by their course as they hug the vertebral body, coursing sharply posteriorly along the lateral vertebral bodies.

In renal anomalies such as crossed-fused ectopia or horseshoe kidney (see Chapter 9), the arterial supply is highly variable, making thorough duplex evaluation of the arteries challenging.[64,65]

Renal Artery Stenosis and Renovascular Hypertension

Recent data from the US Department of Health and Human Services indicates that 32.6% of the population age 20 and older either have hypertension or are being treated for hypertension.[2] More than 90% of cases do not have a clear cause.[66] A minority of cases are caused by decreased arterial blood supply to the kidneys, activating the renin-angiotensin system that, through a complex series of events, results in elevated blood pressure. This mechanism causes only 1% to 5% of hypertension, but with the high prevalence of hypertension, the number of patients with renovascular hypertension is high.[67] Screening for renovascular hypertension is most appropriate in the presence of certain clinical features.

Treatment recommendations for renovascular hypertension caused by renal artery stenosis are in flux. Until recently, endovascular stenting constituted the standard of care. Recent studies, however, have failed to show a benefit to renal artery stent placement when compared with optimal medical management.[68] There has been reasoned criticism of these studies.[69] Nevertheless, as a result of these studies, the volume of renal artery stenting at our institution and others has substantially decreased. Which patients should receive endovascular treatment remains a topic of discussion. One proposed paradigm is that patients with known renal artery stenosis who have good blood pressure control and stable renal function achieved with medical management no longer should be treated with renal artery stenting. Endovascular treatment is reserved for those who fail medical management or whose cases have certain high-risk clinical features.[70-72]

Many radiologic tests are available to assess for renal artery stenosis, including conventional angiography, CTA, magnetic resonance angiography (MRA), captopril scintigraphy, and renal artery duplex Doppler sonography. Opinions differ regarding the most advantageous strategy for using these tests.[67,73] The advantages of renal artery duplex Doppler sonography include low cost and the ability to achieve diagnostic information in most patients, regardless of the degree of renal function. Many articles support the use of renal artery duplex Doppler in the diagnostic evaluation of renovascular hypertension.[74-76]

To be a good first-line test, renal artery duplex Doppler sonography must have high sensitivity and accuracy. Utility is greatest when there is proper clinical screening of patients for the test so that the pretest probability is higher than that of the hypertensive population as a whole. Performing the test must also be practical for ultrasound laboratories. There is a learning curve and while technologists are on the learning curve, the exam may suffer from inaccuracy or be unusually prolonged. The exam is probably best done in facilities where it is practical to periodically monitor results versus the results of conventional angiography, CTA, or MRA. Such monitoring is valuable for advancing on the learning curve and in raising the confidence in the examination. Once technologists are proficient in the examination, it can be performed fairly rapidly.

Clinical Findings in Patients With Hypertension That Increase Probability of Renovascular Cause (Renal Artery Stenosis)

- History of peripheral vascular disease, cerebrovascular disease, or coronary artery disease
- Recent onset of hypertension
- Refractory hypertension (not responsive with at least three medications)
- Malignant hypertension (with papilledema) or accelerated (without papilledema but usually with fundus changes)
- Abdominal or flank bruit
- Elevated creatinine and/or cholesterol levels (even higher suspicion if creatinine levels increase after treatment with angiotensin-converting enzyme inhibitor)
- Unexplained congestive heart failure or acute pulmonary edema

Data from Safian RD, Textor SC. Renal-artery stenosis. N Engl J Med. 2001;344(6):431-442[77]; Krijnen P, van Jaarsveld BC, Steyerberg EW, et al. A clinical prediction rule for renal artery stenosis. Ann Intern Med. 1998;129(9):705-711.[78]

Feasibility of the examination in obese patients is also a concern. A few years after starting our duplex Doppler sonography program, we studied a total of 100 consecutive main renal arteries (50 patients), recording the body mass index (BMI) of each patient (unpublished data, 2002, Saint Francis Medical Center, Peoria, Ill). Of the 100 arteries, 20 were in obese patients (BMI ≥ 30) and 4 in extremely obese patients (BMI ≥ 40), 30 arteries were in overweight patients (BMI ≥ 25), and 46 were in patients of normal weight. We were able to complete a technically adequate examination in 96 of the 100 arteries. Of the 4 arteries with failed studies, 3 were in overweight patients, and 1 was in a patient of normal weight. All 24 arteries of the obese or morbidly obese patients were successfully studied.

Our technologists routinely score the quality of the duplex sonography of each renal artery on a 5-point scale. All examinations graded 2 or higher are considered diagnostically adequate; the entire extrarenal portion of the artery has been successfully interrogated. Our mean Duplex quality score was from 4 to 4.6 in all the categories. Our experience shows that renal duplex Doppler sonography can be completed successfully in most obese patients.

Causes of Renal Artery Stenosis. The most common causes of renal artery stenosis in adults are atherosclerosis and fibromuscular dysplasia.[77] Atherosclerotic disease most often occurs in the proximal third of the artery, often at the origin of the artery.[77] Percutaneous transluminal angioplasty alone has had mixed results in the treatment of atherosclerotic disease. In lesions that are at the origin of the artery, there tends to be strong elastic recoil that allows the balloon to be inflated fully but causes the artery to revert quickly to its stenotic state on deflation of the balloon. The development of stents has changed the situation by allowing the artery to be scaffolded. After stenting, there remains a risk of restenosis secondary to neointimal hyperplasia.[74,79] **Restenosis** is seen in 10% to 20% of patients between 6 and 12 months after stenting[80,81] and is yet higher for patients followed for longer than 1 year (Videos 12.6, 12.7, and 12.8). Because of the relatively low cost, lack of iodinated contrast, and high accuracy, renal artery duplex Doppler sonography is an ideal method to use when following stented arteries.

Fibromuscular dysplasia (FMD) is the second most common cause of renovascular hypertension and typically occurs in women aged 20 to 50 years. Multiple pathologic subtypes are seen; the most common FMD in the renal arteries is medial fibroplasia.[82,83] FMD lesions most often occur in the distal two-thirds of the renal artery and often have an angiographic appearance suggestive of a thin, fibrous web. The classic appearance on angiography is the "string of pearls," caused by multiple dysplastic regions in a row with short areas of poststenotic dilation immediately distal to each stenosis (Fig. 12.18). FMD often responds well to simple percutaneous transluminal angioplasty. A single treatment often is effective in controlling blood pressure and is enduring.[84] Stent placement is rarely needed for FMD.

Another cause of impaired blood flow to the kidney that may result in renovascular hypertension is **dissection.** If the dissection extends to the renal artery, the raised intimal flap in the aorta may partially or completely occlude the renal artery orifice. Alternatively, if the dissection extends into the renal artery, the raised intima may cause stenosis or occlusion within the artery itself. Endovascular treatment is frequently successful either by stenting of the narrowed artery or by fenestration of the dissected intima[85] (Fig. 12.19).

FIG. 12.18 Fibromuscular Dysplasia: Angiography. Note the "string of beads" appearance, most often in the distal two-thirds of the renal artery.

Embolus can result in abruptly impaired blood flow to some or all of a kidney. The patient frequently complains of flank pain. Diagnosis often is delayed, resulting in irreversible damage to the kidney involved. The kidney can tolerate only a brief episode of warm ischemia.[86] Revascularization of the kidney is unlikely to result in full return of function if it is delayed more than 90 minutes.[87]

Vasculitis is an uncommon cause of renal artery stenosis in adults. The vasculitides that are most likely to cause stenosis of large vessels are **Takayasu arteritis** and **giant cell arteritis.**[88]

Renal artery stenosis can also occur in children; FMD is the most common cause. **Neurofibromatosis** and **vasculitis** can also cause renal artery stenosis in children.[89] **Midaortic syndrome,** which is a hypoplasia of the abdominal aorta, can also result in reduced renal blood flow. **Aortic coarctation** most commonly is discovered in other ways but, if not recognized, also will cause renovascular hypertension (Fig. 12.20).

Renal Artery Duplex Doppler Sonography

When performing renal artery duplex Doppler sonography, it is critical to interrogate the entire extrarenal portion of the artery. The examination is not adequate unless the entire extrarenal portion of the main renal artery is seen and interrogated by Doppler every 2 to 3 mm. Accessory arteries and large, early extrarenal branches of the main renal artery are also similarly assessed. Even then, stenoses in accessory arteries or branch renal arteries may be missed. Fortunately, nonvisualization of branch arteries or accessories is unlikely to affect patient management.[90,91]

Visualization of the renal artery is the key to successful ultrasound interrogation (Video 12.9). At our institution, patients are prepared by eating a bland, low-fiber diet the day before and taking nothing by mouth (NPO) after midnight the night before. We ask them to avoid caffeine, smoking, and dairy products. The sonographic examination is more likely to be successful with a prepped patient.

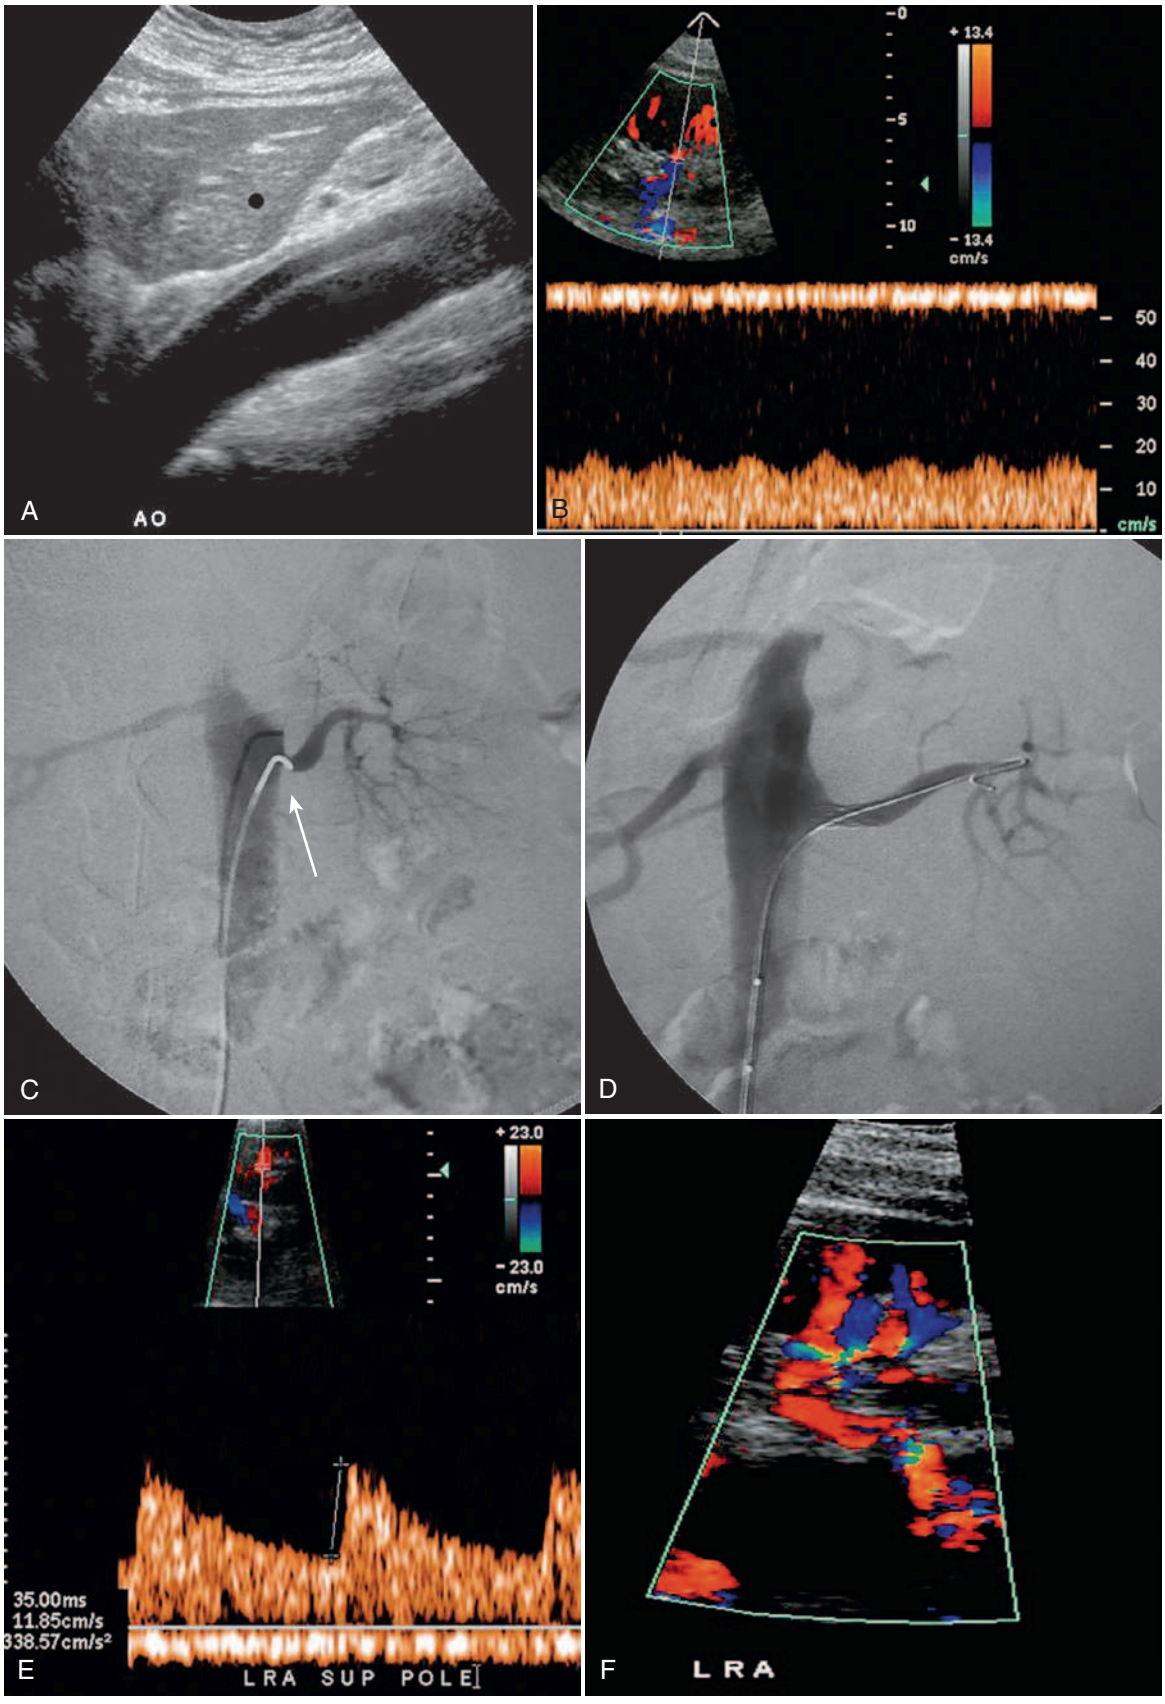

FIG. 12.19 Aortic Dissection With Raised Intima in Lumen of Aorta. (A) Ultrasound of the proximal abdominal aorta *(Ao)* in 30-year-old cocaine user. **(B)** Duplex Doppler sonogram shows highly abnormal intrarenal waveforms from left kidney. Also, it is very difficult to see the main left renal artery with color Doppler. The systolic rise time is 190 msec and acceleration is 34 cm/sec^2. **(C)** Selective injection of the left renal artery at angiography. Angiography shows moderate stenosis at origin of the left renal artery *(arrow)*. **(D)** After stenting of left renal artery, angiography shows origin is widely patent. **(E)** Greatly improved intrarenal waveforms in left renal artery after stenting. Note that systolic rise time is 35 msec and acceleration is 339 cm/sec^2. **(F)** Left renal artery is easy to see with color duplex Doppler after stenting because of increased flow.

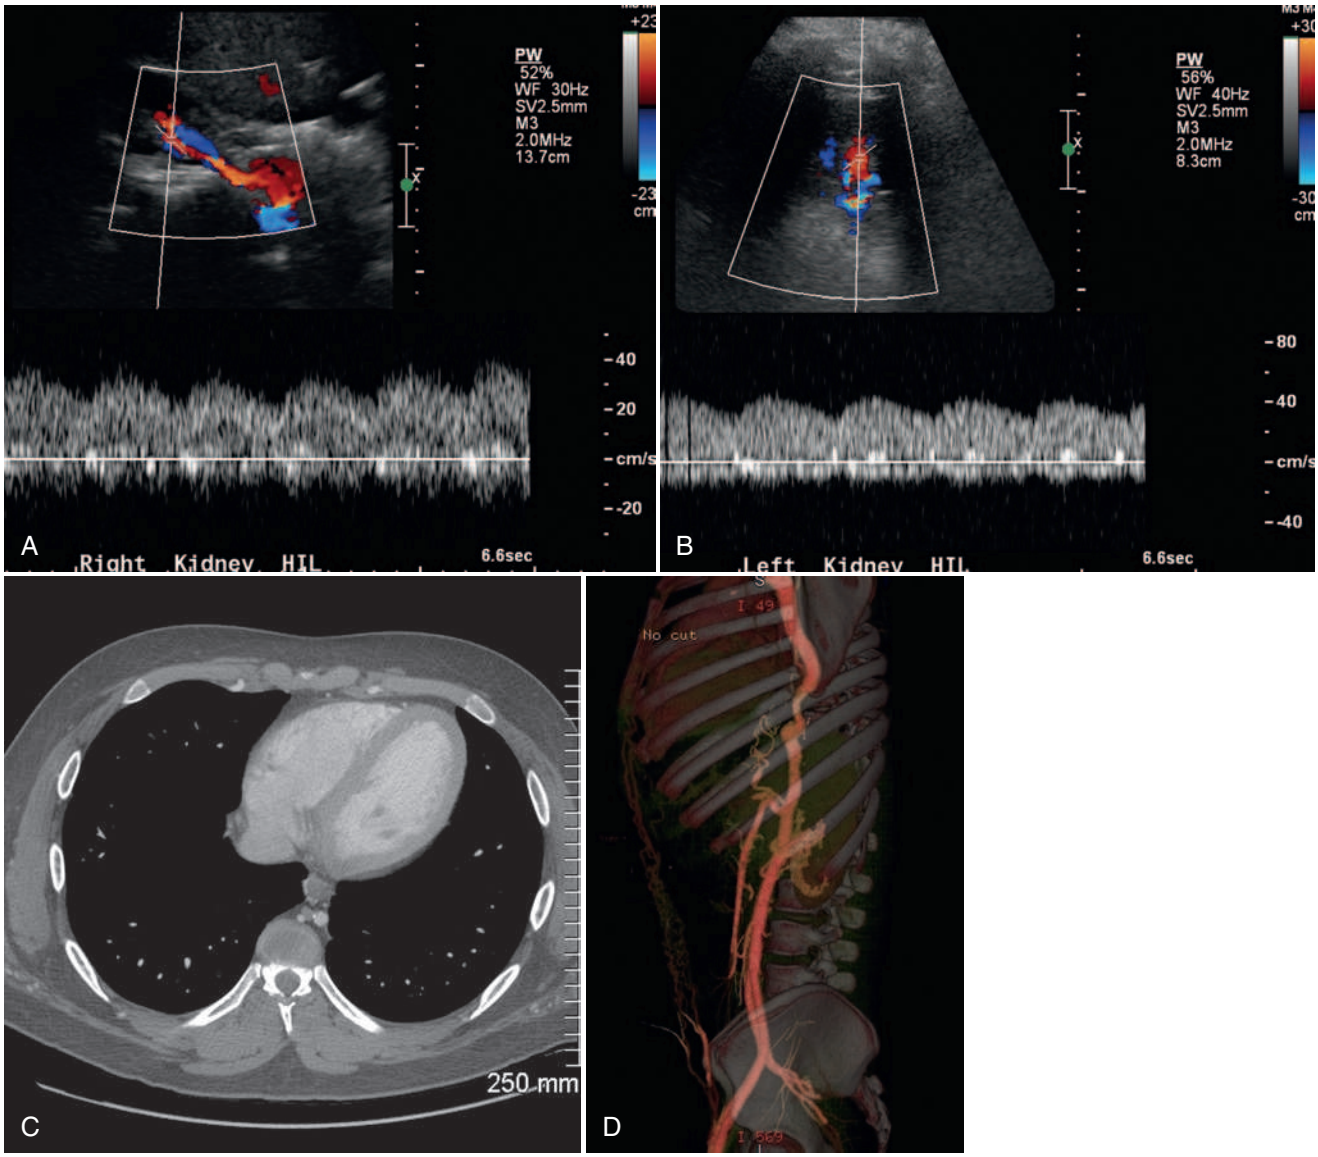

FIG. 12.20 Descending Thoracic Aortic Coarctation. (A) and **(B)** Renal duplex ultrasound of a 15-year-old football lineman presenting with hypertension. Waveforms from the right and left renal arteries. Waveforms bilaterally have low velocity, low resistance, and a rounded peak, all indications of a poststenotic waveform. No renal artery stenosis was seen. Waveforms suggested a more proximal aortic stenosis and are what might be expected with thoracic coarctation. **(C)** Axial computed tomography (CT) scan shows a severely narrowed thoracic aorta. **(D)** 3D CT reconstruction shows severe narrowing of the descending thoracic aorta.

Color Doppler sonography is usually necessary for visualization of the entire extrarenal portion of the artery. In rare cases, however, the right renal artery can be seen better without color Doppler, using the liver as a window. Color Doppler sometimes makes the site of stenosis obvious because of a color bruit or increased diastolic velocity, causing a portion of the artery to remain filled with color throughout the cardiac cycle. At our facility, we typically set the color scale relatively low to increase our ability to see the artery. The entire length of the artery often is more readily seen with this setting.

We set the wall filter to the lowest setting allowed by the manufacturer. If the renal artery is not well seen, color gain is increased. The very highest color sensitivity is achieved by increasing gain to the point where color artifact starts to fill the image and then slightly backing off the gain to remove the artifact. When necessary, power output is increased to aid visualization. We set the ensemble packet size (this setting is controlled in varying ways on different machines) to the highest size possible to increase sensitivity of flow detection. Maintaining an adequate frame rate (>10 frames/sec) is important. We keep the frame rate adequate by making the color window as narrow as reasonably possible. We also decrease the line density of the image and the sector width of the transducer. Our pictures of the renal artery often are not "pretty" because of the aliasing and the high color gain. Our goal, however, is to see the artery. With these settings, we can see the entire extrarenal portion of the artery in almost all patients, regardless of size.

We generally use a 5-1 curvilinear transducer. With thin patients, interrogation from the anterior midline is likely to be successful. At our facility, however, the flank approach is most

often used; it has a higher probability of seeing the entire renal artery in obese patients. Also, achieving an acceptable Doppler angle of less than 60 degrees is easier from the flank. Breath holding is often used, although it does not work well in many patients, either because the patient is dyspneic, or because of a slow but steady cephalad drift of the kidneys, which occurs in some patients despite breath holding. Even without breath holding, the examination often is successful.

When possible, we avoid examining patients who are in heart failure, who have acute dyspnea, who have acutely decreased mobility, or who are on ventilators. All these patients have a reduced ability to accomplish the breath holding. Renal duplex Doppler sonograms generally are not emergent. The examination will likely become much easier, more successful, and more highly accurate once the patient's condition improves.

Performance of the renal artery duplex Doppler study mainly relies on obtaining accurate velocities throughout the main renal artery. However, measurement of the resistive index (RI) is also important. Treatment of renal artery stenosis is less likely to be effective in reducing blood pressure when the segmental artery RI is high (≥0.80), probably because of irreversible damage to the small blood vessels in kidneys with a high RI.[92]

Attention to **intrarenal waveforms** is also of some importance. A highly abnormal waveform can be a valuable indicator of stenosis. A delayed systolic peak (tardus, i.e., "tardy") and velocities that are greatly decreased (parvus, i.e., "puny") can be a strong sign of a more proximal stenosis. The intrarenal waveform can be analyzed quantitatively by calculating the systolic rise time and the acceleration (Fig. 12.21). Although we calculate these parameters, a qualitative assessment of the appearance of the waveform usually serves just as well. We rely on a **tardus-parvus waveform** to make the diagnosis only when the finding is pronounced (compare Fig. 12.19B and E; see also Fig. 12.20A and B).

Finally, because of the regular occurrence of renal lesions or abnormalities that affect patient care, we believe that ultrasound of the kidneys should be considered when renal artery duplex Doppler ultrasound is performed, unless the patient has had recent (<1 or 2 years) cross-sectional imaging. Incidental findings in our ultrasound department have included xanthogranulomatous pyelonephritis, adrenal tumors, hydronephrosis, and several renal cell carcinomas.[93]

Doppler Interpretation. There are many proposed guidelines for Doppler interpretation. Proposed parameters to assess for stenosis include the **peak systolic velocity** (PSV), **renal aortic ratio** (RAR; defined as highest systolic velocity in renal artery divided by aortic systolic velocity, with aortic velocity measured at or above SMA origin),[94] **acceleration time, acceleration index, renal interlobar ratio,**[95,96] and **renal-renal ratio.**[95,97,98] An influential article suggested a combination of RAR of 3.5 or greater *or* PSV of 200 or greater as the criterion for renal artery stenosis of more than 60%.[75] We use a variation of these criteria, using the same RAR as the study but a higher PSV of 350.

False-Positive/False-Negative Results. To obtain the highest accuracy, it is important to avoid relying solely on the numerical data obtained. When a high velocity is seen or when the renal aortic ratio is high, the interpreting radiologist must also actively look for secondary signs of stenosis, such as a characteristic harsh audible signal at the site of stenosis, increased diastolic flow, color bruit, color aliasing, and poststenotic turbulence (Fig. 12.22, Video 12.10). Without ancillary findings, the interpreter must consider the possibility that the high velocity or high RAR represents a false-positive result.

False-negative findings are a risk primarily when visualization is marginal and the entire artery has not been adequately evaluated. In perhaps 5% to 10% of patients, accurate diagnosis cannot be made because of inadequate visualization of one or both arteries.

The examination is challenging to the uninitiated operator, but establishment of a renal artery duplex Doppler program can be rewarding. Because of the lower cost versus other diagnostic tests, Doppler ultrasound lowers the threshold for the diagnosis of renovascular hypertension. Hurdles mainly relate to the learning curve and the initial investment of time. Starting a program is more feasible in a large center where demand will likely be higher than in a smaller facility. Once the program is mature, the study is financially viable and can result in improved patient care.

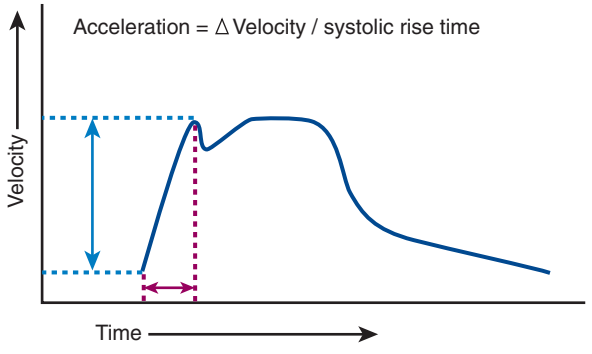

FIG. 12.21 Renal Artery Systolic Waveform. Normal waveform. In early systole there is a rapid acceleration of blood in the renal artery. The systolic rise time *(purple arrow)* is the time expended during this rapid acceleration. The acceleration is the change in velocity during the systolic rise *(blue arrow)* divided by the systolic rise time.

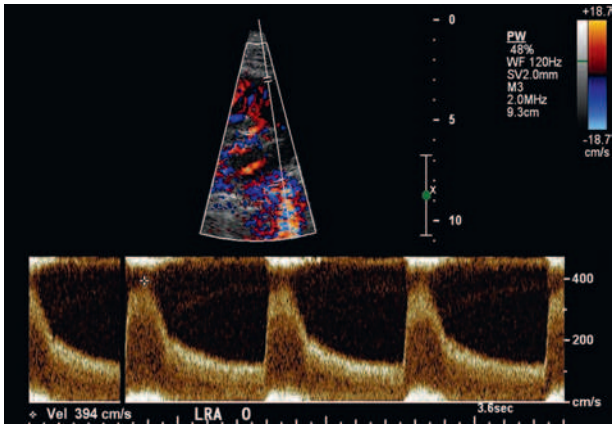

FIG. 12.22 Secondary Signs of Stenosis. Increased diastolic flow, as seen here, can help confirm the presence of renal artery stenosis. Other secondary signs include color bruit, poststenotic turbulence, and a tardus-parvus waveform. See also Video 12.10.

Renal Artery Aneurysm

Renal artery aneurysms are uncommon and may be saccular or fusiform. They can be seen with atherosclerosis or FMD. They are more reliably seen and followed with CT than with ultrasound. Most renal artery aneurysms do not result in significant morbidity or mortality.[99] They grow slowly; a recent study showed a growth rate of 0.16 mm/year.[100] Treatment should be considered if the aneurysm is greater than 2.0 cm. Treatment is indicated if the aneurysm is believed to be causing symptoms (e.g., hematuria, pain, hypertension) or if the patient is a woman of childbearing age who anticipates becoming pregnant.[100-102] The patient and family must be made aware of a renal aneurysm to be alert to symptoms so that diagnosis and treatment can be expedited. Currently, no well-accepted guidelines address how often renal artery aneurysms should be imaged.

Mesenteric Arteries

Anatomy

Three arteries constitute the main sources of arterial blood flow to the gastrointestinal tract: celiac, superior mesenteric, and inferior mesenteric. The **celiac artery** arises anteriorly from the abdominal aorta at the level of the aortic hiatus of the diaphragm. The celiac artery supplies blood to the spleen, pancreas, liver, stomach, and proximal duodenum. The standard branching pattern of the celiac artery is into the splenic and common hepatic arteries, which are easily identified. The third branch of the celiac artery is the left gastric, which is much less frequently seen with sonography. The common hepatic artery branches into the proper hepatic artery and the gastroduodenal artery; the latter is important as a conduit for collateral blood flow to the celiac circulatory territory when the celiac artery is highly stenosed or occluded.

The **superior mesenteric artery** (SMA) typically arises from the anterior aorta approximately 1 cm below the celiac artery origin. The SMA supplies blood to the pancreas, distal duodenum, jejunum, ileum, and proximal colon as far distal as the splenic flexure. In about 20% of people, the SMA supplies some of the hepatic blood flow through a replaced or accessory right hepatic artery. Other important branches of the SMA include the inferior pancreaticoduodenal artery (IPDA) and the middle colic artery. The IPDA and its branches form an arcade of blood vessels around the head of the pancreas with the gastroduodenal artery.[103,104] In celiac arterial occlusion, the IPDA-gastroduodenal arcade often becomes the primary route for blood to reach the celiac circulation (Fig. 12.23). In cases of SMA occlusion, blood often flows in the opposite direction through the arcade, supplying the occluded SMA with blood from the celiac artery.

The **inferior mesenteric artery** supplies the descending colon, sigmoid colon, and superior rectum. The IMA arises from the anterior aorta slightly to the left of midline, approximately two-thirds the distance between the renal artery origins and the aortic bifurcation. When the aorta is viewed transversely, the IMA arises at approximately the 1 o'clock position. Viewed longitudinally, the appearance is similar to that of the SMA, except the IMA is significantly smaller and always courses inferiorly to the left of the aorta. After 1 to 2 cm, the IMA bifurcates into a superior hemorrhoidal artery that runs caudally slightly to the left of midline and into a left colic artery that runs laterally to the descending colon. The left colic artery immediately divides into ascending and descending branches. The superior hemorrhoidal artery gives off sigmoid branches as it courses inferiorly to the rectum (Fig. 12.24).

Connections between the SMA and IMA occur in the region of the splenic flexure. The IMA can supply blood to the SMA when the proximal SMA is occluded. Blood then flows from the IMA through the marginal artery of Drummond or through the sometimes present and more direct arc of Riolan to the middle colic artery and then into the SMA. The middle colic artery is an anterior branch of the SMA and is generally identified sonographically only in cases of SMA occlusion when it becomes a source of collateral supply and has increased flow.

Mesenteric Ischemia

Acute Ischemia. **Acute mesenteric ischemia** occurs when there is an abrupt reduction of arterial flow to the intestines. The most common cause is cardiac embolus. Acute mesenteric ischemia also may be caused by aortic dissection. Less often, abrupt reduction of arterial flow results from SMA thrombosis, decreased cardiac output without any obstruction of the arterial tree, or thrombosis of the superior mesenteric vein.[105] Only a single artery needs to be compromised acutely to cause mesenteric ischemia, most often the SMA. Patients present with an abrupt onset of severe abdominal pain, nausea and vomiting, and diarrhea. Later in the course, they may develop "currant jelly" stools from intestinal bleeding and mucosal sloughing.

Acute mesenteric ischemia is a medical emergency. Mortality is high, at least 50%.[106] The wide differences in reported mortality likely relates to the rapidity of diagnosis. Patient survival depends on quick and accurate diagnosis and treatment. In most cases, ultrasound has no role in the diagnosis of acute mesenteric ischemia.[107] These patients can be of any size and often have a large amount of gas in the bowel that compromises sonographic diagnosis. In most cases, the clinician simply cannot risk wasting time by initiating the diagnostic workup with mesenteric duplex Doppler sonography. CTA or angiography is the test of choice.[108] ACR Appropriateness Criteria state that ultrasound "is not recommended for initial evaluation of patients with suspected acute mesenteric ischemia because timing of the diagnosis is very critical."[109]

Chronic Ischemia. Duplex Doppler sonography has a more central role in the diagnosis of **chronic mesenteric ischemia.** Chronic ischemia is usually the result of atherosclerosis slowly occluding the arteries that supply the intestines. Because the buildup of plaque is slow, collateral circulation has an opportunity to develop and supply some of the needed blood flow to the intestines. Mesenteric artery stenosis is relatively common, reported in 17.5% of the independent-living older population. Most patients with severe narrowing of one or more of the arteries supplying the intestines have no symptoms and need no treatment.[108] These patients maintain adequate blood flow to the gut through collateral circulation. The collateral blood flow usually

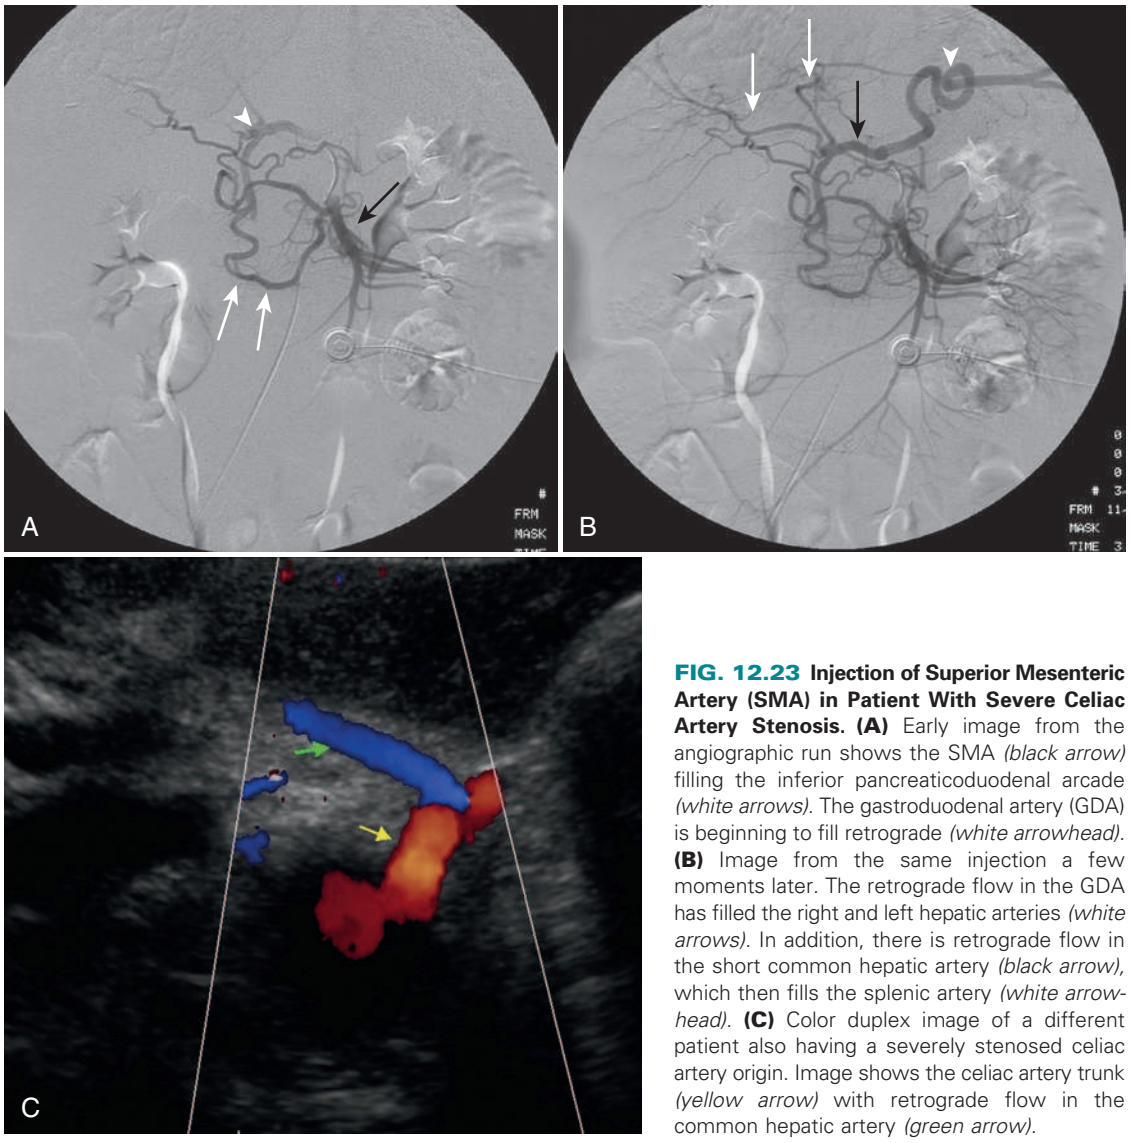

FIG. 12.23 Injection of Superior Mesenteric Artery (SMA) in Patient With Severe Celiac Artery Stenosis. (A) Early image from the angiographic run shows the SMA *(black arrow)* filling the inferior pancreaticoduodenal arcade *(white arrows)*. The gastroduodenal artery (GDA) is beginning to fill retrograde *(white arrowhead)*. **(B)** Image from the same injection a few moments later. The retrograde flow in the GDA has filled the right and left hepatic arteries *(white arrows)*. In addition, there is retrograde flow in the short common hepatic artery *(black arrow)*, which then fills the splenic artery *(white arrowhead)*. **(C)** Color duplex image of a different patient also having a severely stenosed celiac artery origin. Image shows the celiac artery trunk *(yellow arrow)* with retrograde flow in the common hepatic artery *(green arrow)*.

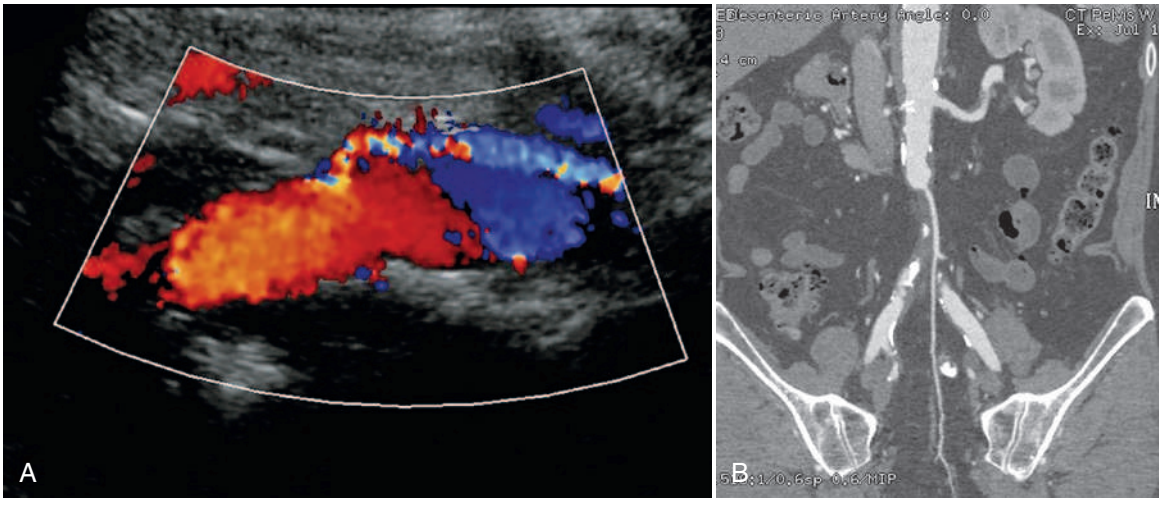

FIG. 12.24 Inferior Mesenteric Artery (IMA) Has Similar Appearance to Superior Mesenteric Artery When Scanned Longitudinally. (A) Color Doppler longitudinal sonogram. **(B)** Curved reformatted computed tomography image of the IMA.

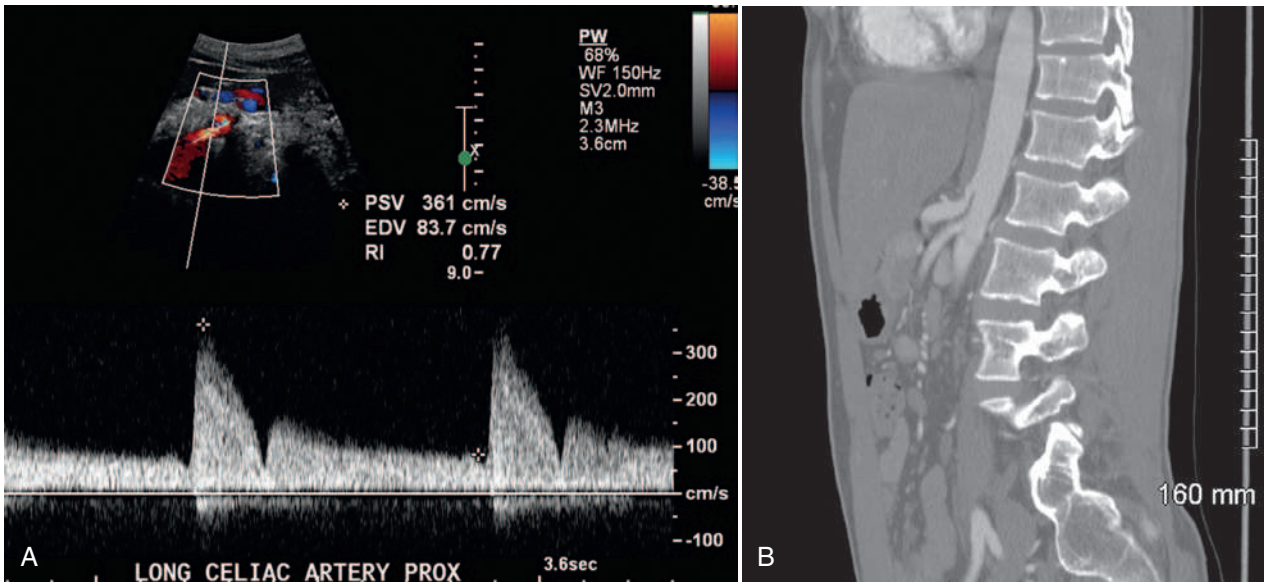

FIG. 12.25 Median Arcuate Ligament Syndrome. Male, 37 years old, with history of severe abdominal pain for more than 20 years. **(A)** Duplex exam shows elevated velocity in the celiac artery of 361 cm/sec. **(B)** Computed tomography angiography sagittal reconstruction image shows the characteristic narrowing of the celiac artery caused by the median arcuate ligament. Patient had immediate and enduring relief of symptoms after surgery to release the median arcuate ligament.

must be impaired before the patient becomes symptomatic. In most cases, two of the three arteries that supply mesenteric blood flow (celiac artery, SMA, IMA) must be severely diseased before a patient experiences chronic mesenteric ischemia, but even many patients with multiple-artery disease are not symptomatic.[108] Again, the clinician must remember that, although uncommon, significant mesenteric ischemia can result from the narrowing of one artery, particularly the SMA.[110]

The onset of chronic ischemia is insidious, with the classic patient experiencing weight loss and postprandial pain. Atypical features in the history are common and often include complaints of "indigestion." Patients with chronic ischemia frequently are very thin, which facilitates ultrasound.

Vasculitis, most often **Takayasu arteritis,** can also lead to mesenteric ischemia. Although typically the symptoms are chronic, involvement of the mesenteric arteries can be rapidly progressive and result in bowel infarction.[111]

Median Arcuate Ligament Syndrome

Most commonly, patients with symptomatic mesenteric ischemia have at least two of the mesenteric arteries narrowed or completely occluded. Patients with the median arcuate ligament syndrome have narrowing only of the celiac artery.

The **median arcuate ligament** of the diaphragm is close to the celiac artery. This ligament is a band of fibrous tissue that crosses the aorta, usually above the origin of the celiac artery, although the crossing can be below. Deformity and narrowing of the celiac artery caused by the median arcuate ligament are fairly common angiographic findings on lateral aortography. One study reported that 24% of aortograms performed for unrelated reasons showed celiac artery stenosis of at least 50% caused by the median arcuate ligament.[112]

In **median arcuate ligament syndrome,** patients with only narrowing of the celiac artery experience significant postprandial pain that results in avoidance of eating and weight loss. The syndrome is poorly understood, but the pain is believed to be possibly related to ischemia.[113,114] Other investigators support a neurogenic cause.[115] Some patients respond dramatically to surgery and become symptom free.[113-116] Surgical decision making in these patients is very important to help decide those who are likely to benefit from surgery. Surgery consists of dividing the median arcuate ligament and may include celiac artery revascularization (Fig. 12.25).

Mesenteric Artery Duplex Doppler Sonography

Mesenteric artery duplex Doppler ultrasound is most often performed with the patient fasting. Most studies assessing the addition of a postprandial study conclude that it is not of value.[117-119]

Blood flow to the intestines in the fasting state is relatively low. Normal waveforms in the SMA and IMA are high resistance. When the patient eats, blood is shunted to the intestines, and the SMA has a lower-resistance waveform. The celiac artery supplies the liver and spleen, which have a higher need for flow than the intestines when the patient is fasting. Accordingly, the celiac artery has lower resistance than the SMA or IMA when interrogated with the patient fasting.

Because chronic mesenteric ischemia can be fatal, it is critical that the examination be performed and interpreted in a way that guarantees very high sensitivity. The majority of stenoses that result in chronic mesenteric ischemia are within the first 1 to 2 cm of the origin of the celiac artery, SMA, and IMA. It is possible, although rare, to have a branch artery occlusion that results in chronic mesenteric ischemia. Ultrasound is not a reliable

technique for screening for these more distal stenoses or occlusions.

The evaluation of the celiac artery starts at its origin and proceeds to its bifurcation into the splenic and common hepatic arteries. As with all duplex Doppler studies, the sample volume is advanced slowly through the celiac artery with waveforms viewed every 2 to 3 mm and any abnormal sites documented with an image. A standard set of waveforms from the proximal, middle, and distal celiac artery is also obtained.

In patients with very severe celiac stenosis or occlusion, the celiac artery often receives its blood supply from the SMA through the pancreaticoduodenal arcade. The blood flow in the gastroduodenal artery reverses, carrying the blood from the arcade back to the common hepatic artery. Blood flow then arrives at the liver through the proper hepatic artery. To arrive at the spleen, blood flow from the gastroduodenal artery flows retrograde in the common hepatic artery to reach the splenic artery. Assessment of blood flow direction in the common hepatic artery should be part of the sonographic examination of the celiac artery to detect cases in which this collateral flow is present (see Fig. 12.23).

The evaluation of the SMA starts at the origin and is carried distally with viewing of waveforms every 2 to 3 mm, documenting waveforms in the proximal, middle, and distal artery. The examination can be performed with or without breath holding. However, without breath holding, motion of the sample volume with respect to the celiac artery and SMA often occurs. With the patient breathing, the sonographer may believe a waveform is being obtained from the SMA when in fact the celiac artery is being sampled or vice versa. Care should be exercised when not using breath holding to guarantee that the proper vessel is being evaluated. The SMA exam is also challenging because of the very sharp turn it makes proximally. The turn creates problems with accurate angle correction, and great care with the Doppler angle is important.

The IMA has only a short trunk before it branches into the left colic, sigmoidal, and superior hemorrhoidal arteries. In many, perhaps most, patients the IMA is readily found, being the only anterior branch of the abdominal aorta below the level of the renal arteries. Its identification can be impeded by patient size and bowel gas and by the fact that it not as large of an artery as the celiac artery or SMA. The IMA requires Doppler interrogation only for 2 to 3 cm.

Finally, special maneuvers must be used when celiac artery stenosis caused by the median arcuate ligament is suspected. The traditional test is to remeasure flow velocity in the artery when the patient takes a deep inspiration. We have found this test to be inconsistent. Reexamination of the artery with the patient standing may be superior in its ability to show normalization of velocities in the celiac artery in the setting of compression by the median arcuate ligament.[120] Our experience supports that remeasurement with the patient standing is greatly superior compared with deep inspiration at normalizing blood flow in a compressed celiac artery (Fig. 12.26).

Mesenteric Artery Duplex Interpretation. Probably the most widely accepted duplex criteria state that PSVs greater than 275 cm/sec in the SMA and 200 cm/sec in the celiac artery are indicative of stenosis of greater than 70% in these arteries.[121] These criteria are the ones suggested in the ACR Appropriateness Criteria.[109] A more recent article suggests higher cutoffs of 295 cm/sec in the SMA and 240 cm/sec in the celiac artery as being indicative of greater than 50% stenosis.[122] Other investigators have found diastolic velocities to be a more accurate indicator. One group found an end diastolic velocity (EDV) greater than 45 cm/sec with a PSV greater than 300 cm/sec to be an accurate indicator of SMA stenosis greater than 50%.[123] Another group found EDV greater than 70 cm/sec to be highly accurate for diagnosing SMA stenosis of more than 50%, with an EDV greater than 100 cm/sec needed to diagnose celiac artery stenosis of over 50%.[124]

In our laboratory, we have found the criteria using systolic velocities (but not diastolic) to be highly sensitive but to result in a substantial number of false-positive studies. Because of the high sensitivity, we are confident that for a high-quality examination that does not show systolic velocities higher than those stated above (200 cm/sec in the celiac artery; 275 cm/sec in the SMA), the diagnosis of chronic mesenteric ischemia is excluded. When velocities reach one of the thresholds given above, we look for secondary features that support the diagnosis of significant stenosis before we become confident that the stenosis is real. These secondary features include an increased diastolic velocity and the presence of significant poststenotic turbulence (Fig. 12.27). Color bruit is also supportive of severe stenosis. In the absence of secondary findings, the radiologist must consider the possibility of a false-positive result. In this setting, we have a low threshold to recommend either CTA or MRA to assist in the diagnosis (Fig. 12.28).

There have been no widely accepted duplex Doppler criteria for what constitutes significant stenosis of the IMA. Therefore evaluation for severe stenosis must be based on qualitative more than on quantitative data. High systolic velocity in the presence of high diastolic velocity and poststenotic turbulence is indicative of severe stenosis. A PSV greater than 200 cm/sec in the IMA may be an accurate indicator of severe stenosis.[125] Stenosis of the IMA may be an important contributor to the development of mesenteric ischemia. We have seen and treated many patients with mesenteric ischemia in whom a stenotic IMA was the sole blood supply to the gut.

Treatment of chronic mesenteric ischemia can be surgical or endoluminal. Rates of restenosis with endoluminal treatment are high, and thus, posttreatment surveillance is important. As with all arteries treated with stents, restenosis is usually caused by intimal hyperplasia, which is common within bare-metal stents but even more common at the end of the stent (Fig. 12.29). There is suggestion that covered stents may have a lower restenosis rate in the mesenteric arteries.[126]

Posttreatment duplex surveillance is confounded by Doppler velocities often remaining high in stented SMAs.[127,128] Some speculate that this velocity elevation may be caused by a change in the elastic properties of the arterial wall induced by its incorporation of the stent.

The goal of stenting often is not to restore normal flow, but only to restore enough flow to make the patient asymptomatic. Those arteries treated with stenting often supply collateral flow

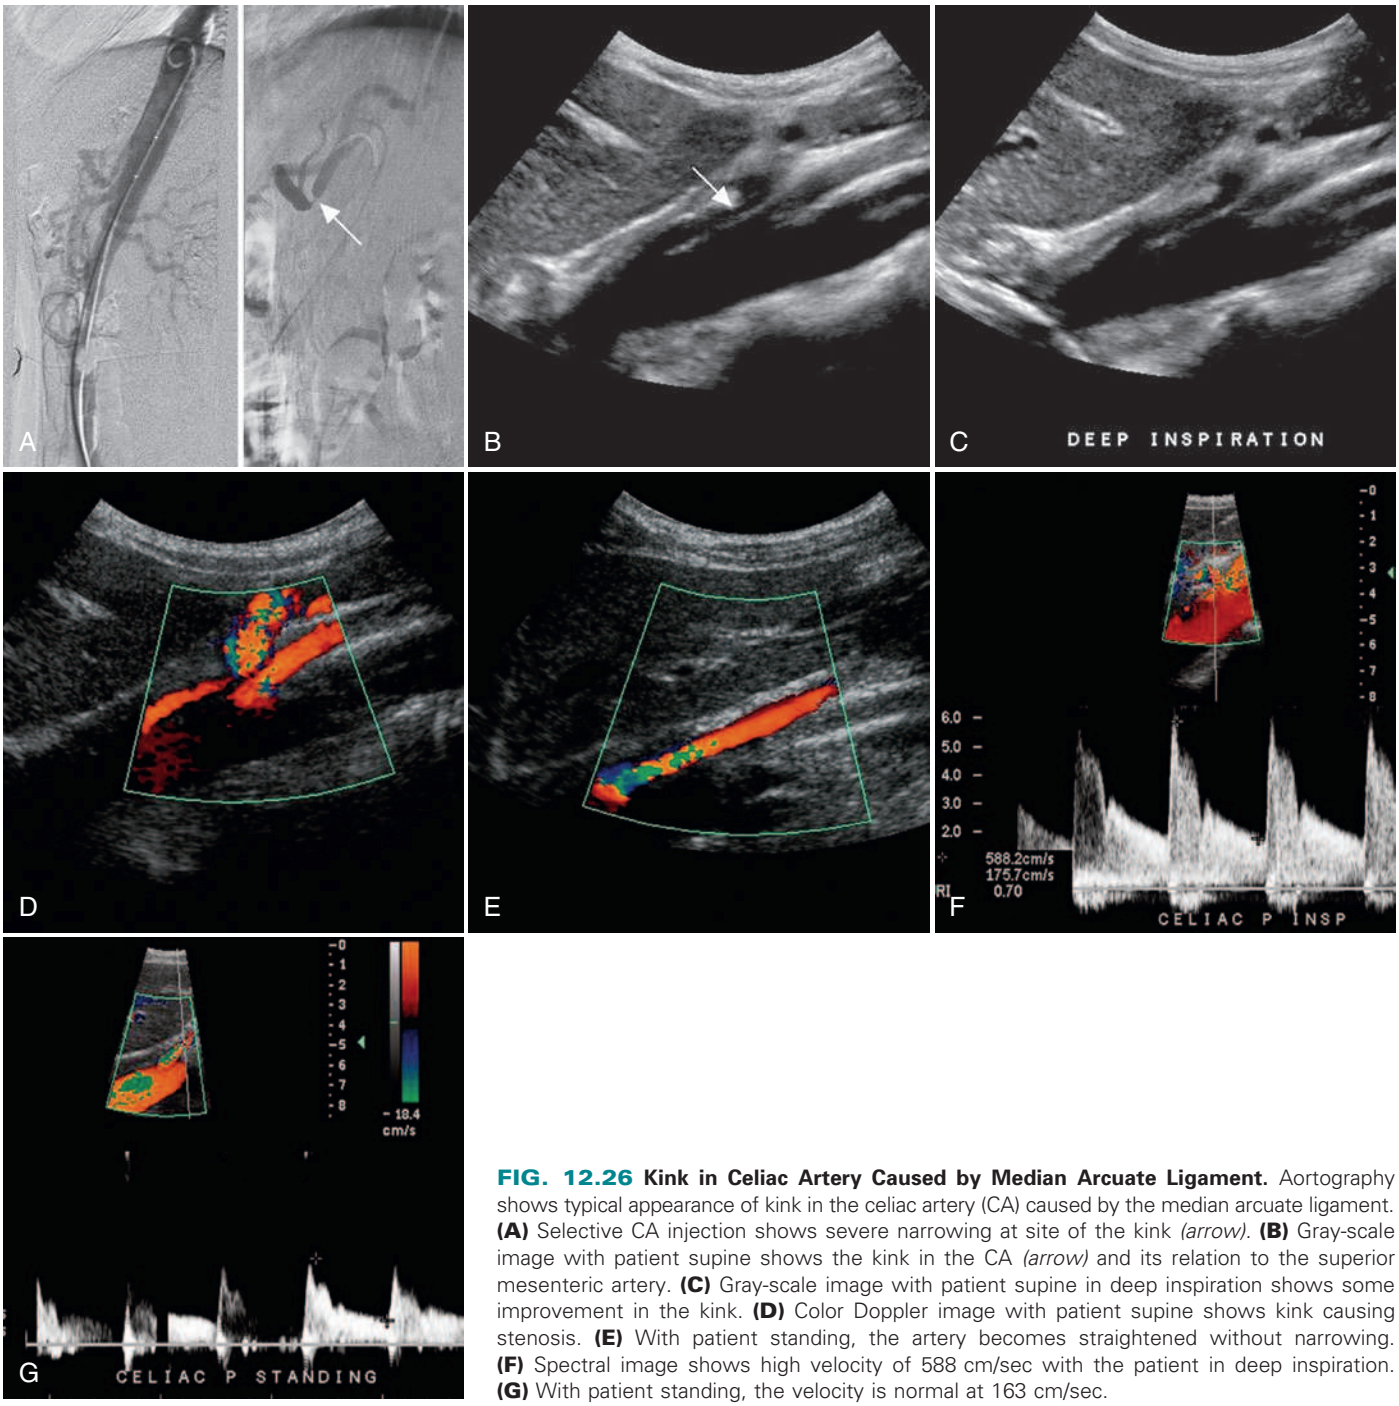

FIG. 12.26 Kink in Celiac Artery Caused by Median Arcuate Ligament. Aortography shows typical appearance of kink in the celiac artery (CA) caused by the median arcuate ligament. **(A)** Selective CA injection shows severe narrowing at site of the kink *(arrow)*. **(B)** Gray-scale image with patient supine shows the kink in the CA *(arrow)* and its relation to the superior mesenteric artery. **(C)** Gray-scale image with patient supine in deep inspiration shows some improvement in the kink. **(D)** Color Doppler image with patient supine shows kink causing stenosis. **(E)** With patient standing, the artery becomes straightened without narrowing. **(F)** Spectral image shows high velocity of 588 cm/sec with the patient in deep inspiration. **(G)** With patient standing, the velocity is normal at 163 cm/sec.

to any untreated arteries that remain stenotic or occluded (e.g., an SMA stent placed in a patient who has an occluded celiac artery). The stented arteries often have increased flow throughout their course. This results in velocities that are uniformly elevated throughout the artery. We have found this result not only in the SMA but also in the other mesenteric arteries (Fig. 12.30). Treatment decisions after stenting must be made in the context of the entire clinical picture and not on the basis of velocities alone. If the patient is entirely asymptomatic, treatment will generally not be undertaken regardless of the results of mesenteric artery duplex scanning.

Iliac Veins and Inferior Vena Cava

As with veins throughout the body, the range of pathology occurring in the iliac veins and inferior vena cava (IVC) is narrow. Thrombosis of the iliac veins and IVC is probably the most common pathology, but is much less common than lower extremity venous thrombosis.

Often, the iliac veins and the infrarenal IVC are not well evaluated directly with ultrasound. Therefore ultrasound exams are infrequently done with the intent of doing a primary evaluation of the entire IVC and iliac veins. The main exception is infants,

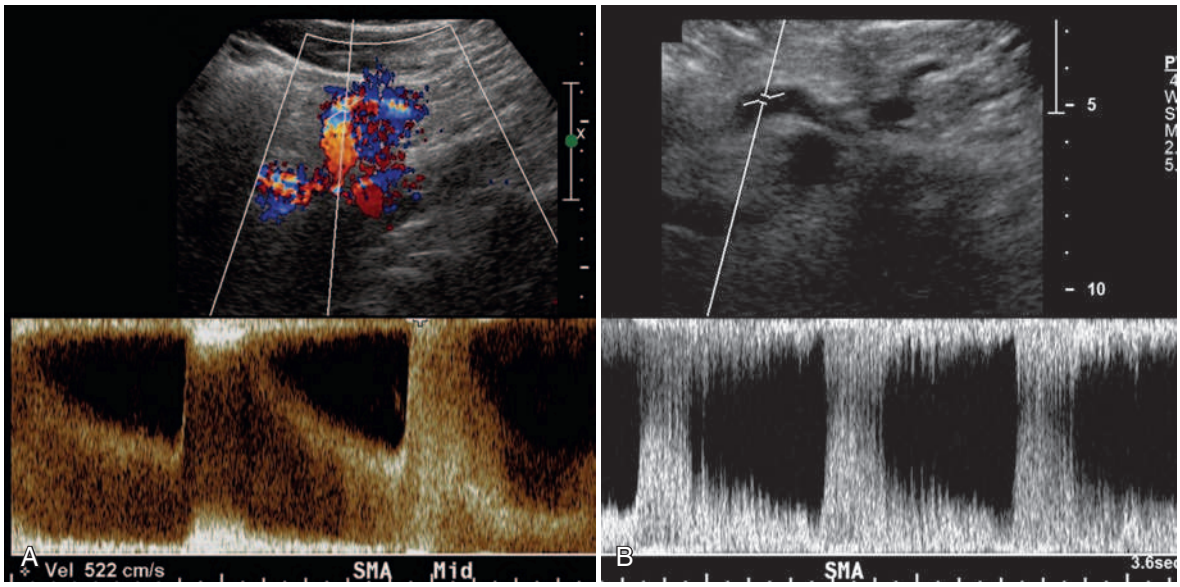

FIG. 12.27 Poststenotic Turbulence. (A) Spectral waveform at site of stenosis shows very high diastolic velocities of greater than 500 cm/sec. Color portion of the image shows color bruit consisting of color outside the vessel near the stenosis site. Color bruit is believed to be caused by tissue vibration. **(B)** Spectral waveform shows the typical "spike hairdo" waveform caused by poststenotic turbulence. There is mirror-image artifact. Because of the very high velocities, the baseline of the waveform has been placed at the bottom, causing the "flow below the baseline" to appear at the top of the tracing. Flow below the baseline is also typical of turbulence.

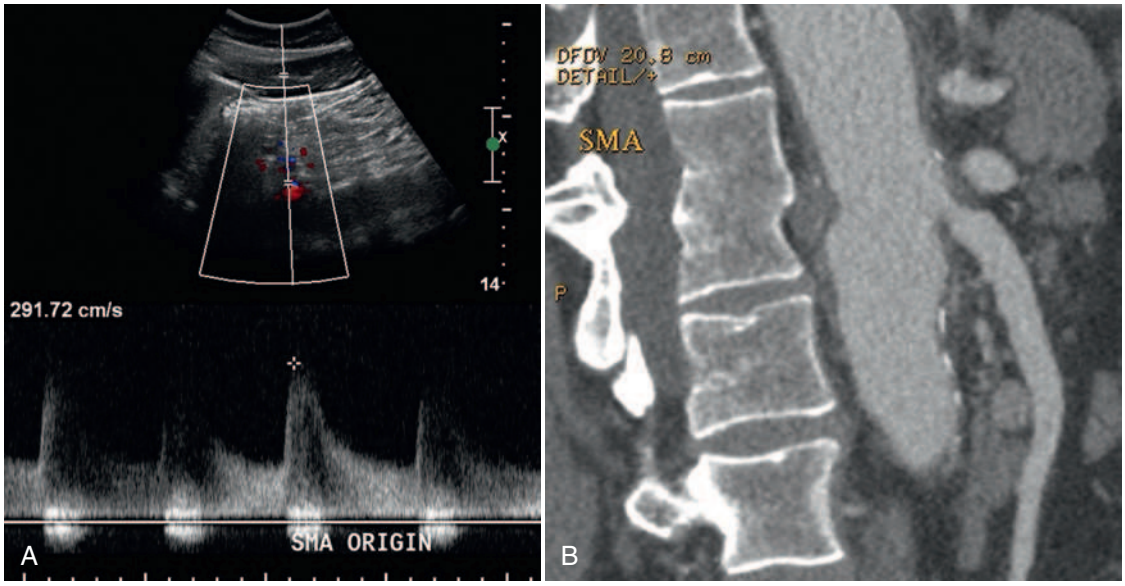

FIG. 12.28 Takayasu Arteritis. Patient, 34 years old, with blood pressure discrepancy between the right and left arms. Subsequent workup showed occlusion of the left subclavian artery and severe stenosis of the right renal artery origin. Two years later, the arteritis flared and the patient developed severe stenosis of the celiac artery and the superior mesenteric artery *(SMA)*. **(A)** Mesenteric duplex shows elevation of both systolic and diastolic velocities. **(B)** Curved reformatted computed tomography image shows moderate narrowing of the SMA origin. Note the wall thickening of the SMA at its origin caused by mural inflammation. The patient was treated medically.

in whom IVC evaluation with ultrasound has a better opportunity to provide good diagnostic information.

Anatomy

The IVC can be divided into several segments. The most proximal (i.e., central) segment is the suprahepatic (posthepatic), which is short and intrathoracic. In adults this segment is approximately 2.5 cm in length and has the hepatic veins as tributaries. The next segment is intrahepatic, with accessory hepatic and caudate veins as tributaries. The next segment is the infrahepatic/suprarenal, which has the renal veins as tributaries. The last segment is infrarenal, which is the longest segment and has the right gonadal vein as a tributary. Proceeding distally, the IVC divides into the common iliac veins. The left common iliac vein

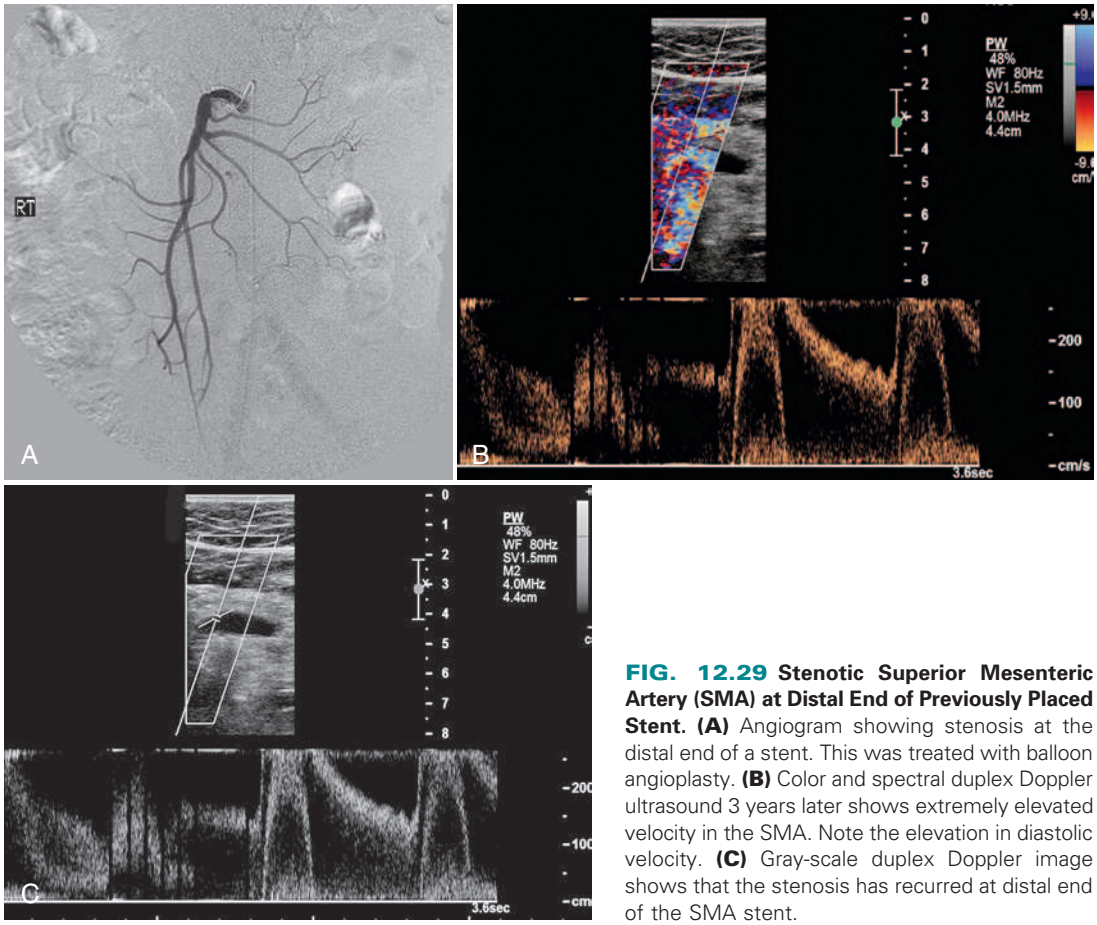

FIG. 12.29 Stenotic Superior Mesenteric Artery (SMA) at Distal End of Previously Placed Stent. (A) Angiogram showing stenosis at the distal end of a stent. This was treated with balloon angioplasty. **(B)** Color and spectral duplex Doppler ultrasound 3 years later shows extremely elevated velocity in the SMA. Note the elevation in diastolic velocity. **(C)** Gray-scale duplex Doppler image shows that the stenosis has recurred at distal end of the SMA stent.

passes between the right common iliac artery and the spine, where it can become compressed producing May-Thurner physiology (called **May-Thurner syndrome** when it results in thrombosis). The common iliac veins have major tributaries of the internal and external iliac veins.

Anatomic Variants

There are three major variations of IVC anatomy, the most common a **duplicated IVC.** The duplication is of the infrarenal portion of the IVC, with incidence of approximately 2% (Fig. 12.31A). Most often, the IVC's left channel enters the left renal vein. The suprarenal IVC has normal anatomy. The second most common anomaly is a **left IVC** (0.5%; Fig. 12.31B), which also usually drains into the left renal vein. As with a duplicated IVC, anatomy above the level of the renal veins is normal. With both these anomalies, the anomalous left-sided segment may cross the aorta below the level of the left renal vein. Also, the anomalous segment may cross either anterior or posterior to the aorta.[129]

The third major anomaly is **azygous continuation of the IVC.** The infrarenal IVC flows superiorly into the hemiazygos or azygos veins. The IVC does not course through the liver in this setting; there is no intrahepatic IVC. The hepatic veins drain normally into the short suprahepatic (posthepatic) IVC, which enters the right atrium. Incidence of azygous continuation is approximately 0.6%.[129]

Regarding IVC tributaries, there are variations in the anatomy of the hepatic veins, left renal vein, and gonadal veins. The hepatic veins have numerous variations important in preprocedural planning of liver resection or transplantation.[130] The most common variation is the presence of an **accessory right hepatic vein.**[131]

The **left renal vein** usually passes in front of the abdominal aorta to join the IVC. It also can be **circumaortic** (up to 8.7%),[129] where the left renal vein has two branches, one passing behind the aorta and the other anterior to the aorta. Less often, it is **retroaortic** (up to 2.4%), where a single left renal vein passes behind the aorta. In both cases, the portion of the left renal vein passing behind the aorta most frequently descends a short distance toward the pelvis as it passes behind the aorta.[129]

The **right gonadal vein** joins the IVC just below the level of the right renal vein or at the right renal vein in 90% of cases. In the remaining 10%, it joins the right renal vein. When IVC anatomy is standard, the **left gonadal vein** almost always drains into the left renal vein. In a duplicated or left IVC, the left gonadal vein most often drains into the left-sided IVC.[132]

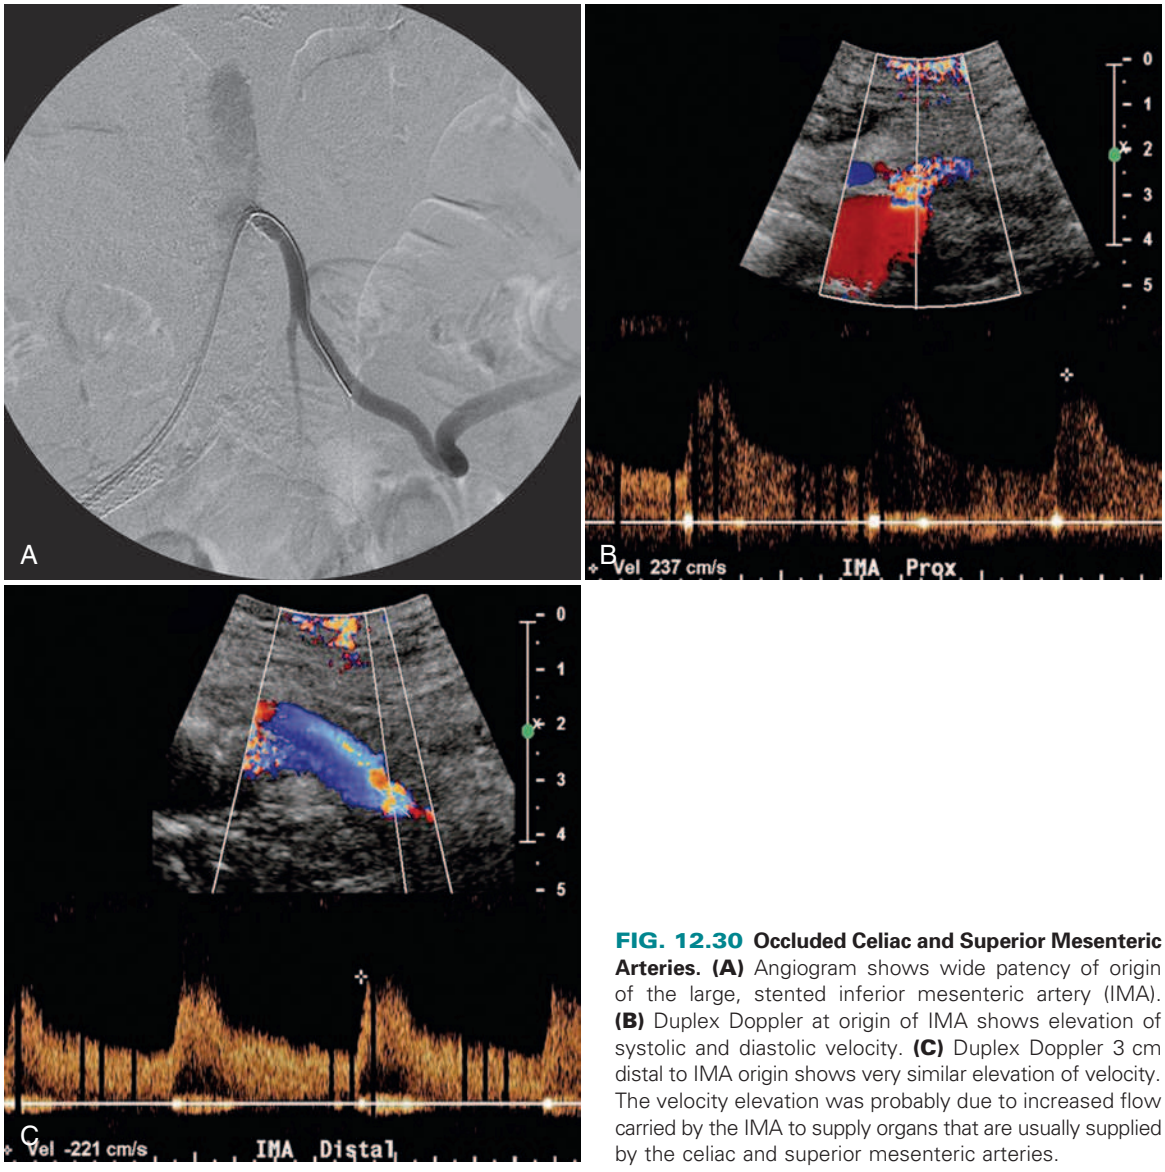

FIG. 12.30 Occluded Celiac and Superior Mesenteric Arteries. (A) Angiogram shows wide patency of origin of the large, stented inferior mesenteric artery (IMA). **(B)** Duplex Doppler at origin of IMA shows elevation of systolic and diastolic velocity. **(C)** Duplex Doppler 3 cm distal to IMA origin shows very similar elevation of velocity. The velocity elevation was probably due to increased flow carried by the IMA to supply organs that are usually supplied by the celiac and superior mesenteric arteries.

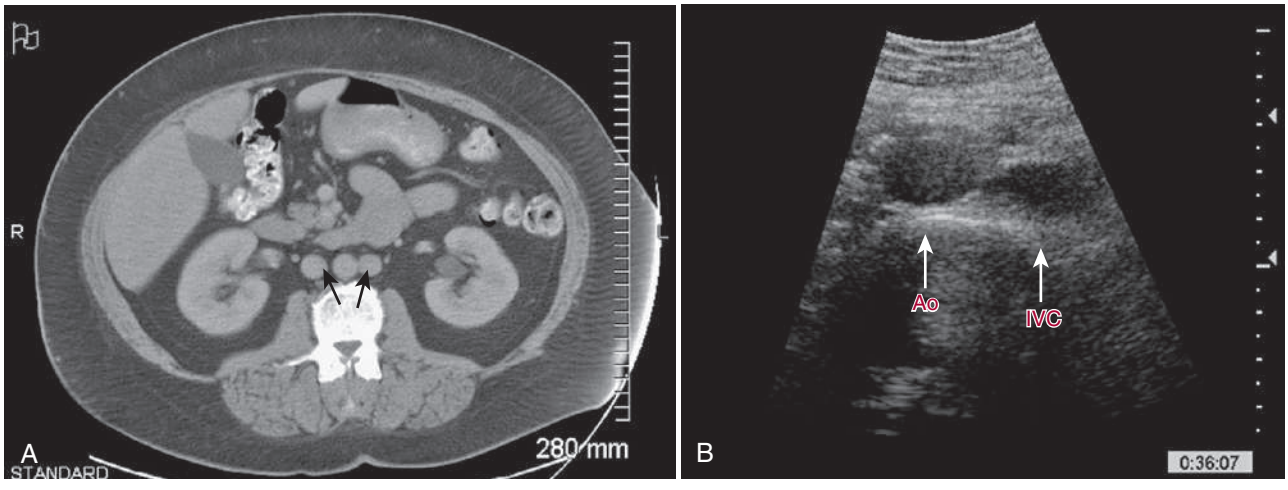

FIG. 12.31 Inferior Vena Cava (IVC) Anomalies. (A) Computed tomography image of duplicated IVC *(black arrows),* the most common anomaly of the IVC. The left IVC joined the left renal vein. The IVC above the level of the renal veins was in the normal location. **(B)** Ultrasound of another IVC anomaly, a left IVC running to the left of the aorta *(Ao)*. The left IVC joins the left renal vein.

Thrombosis

The iliac veins and IVC are large veins with high-volume flow. They are less prone to primary thrombosis than are deep veins of the extremities. Perhaps the most common scenario to result in IVC thrombosis is when clot embolizes into an IVC filter. Isolated iliac vein thrombosis is uncommon, occurring in 1.6% of cases of lower extremity deep venous thrombosis.[133]

Iliac thrombus most often results from extension of lower extremity venous thrombosis. Extrinsic compression of the IVC or iliac veins, as in May-Thurner physiology or a gravid uterus, may also result in thrombosis. Iliac vein thrombosis in adults is infrequently directly seen sonographically because of lack of an adequate window. Most often, the possibility of iliac thrombosis can only be inferred sonographically.

Sonographic clues to iliac vein thrombosis are found in the common femoral veins. When thrombus in the common femoral vein extends as far proximally as can be seen, it is easy to infer possible extension into the iliac veins. More subtle cases involve continuous, low, or absent flow in an open (nonthrombosed) common femoral vein. Common femoral vein waveforms generally show respiratory phasicity or cardiac phasicity, or both. When **phasicity** is not clearly seen, as in continuous, low, or absent flow, it suggests obstruction to flow more proximally (Fig. 12.32). Before ordering other tests to look for more proximal obstruction, it is worthwhile to perform a few maneuvers to eliminate nonpathologic causes of lack of phasicity. First, have the patient remove underwear if it is tight. Second, sonographically check the fullness of the bladder. If moderately or greatly distended, the patient should be asked to empty the bladder. Third, if the patient is in the second or third trimester of pregnancy, check the waveforms in posterior oblique or decubitus positions. If the compression is caused by the gravid uterus compressing the veins, these maneuvers will often allow the waveform to return to normal, showing that there is no fixed blockage of the veins (Fig. 12.33).

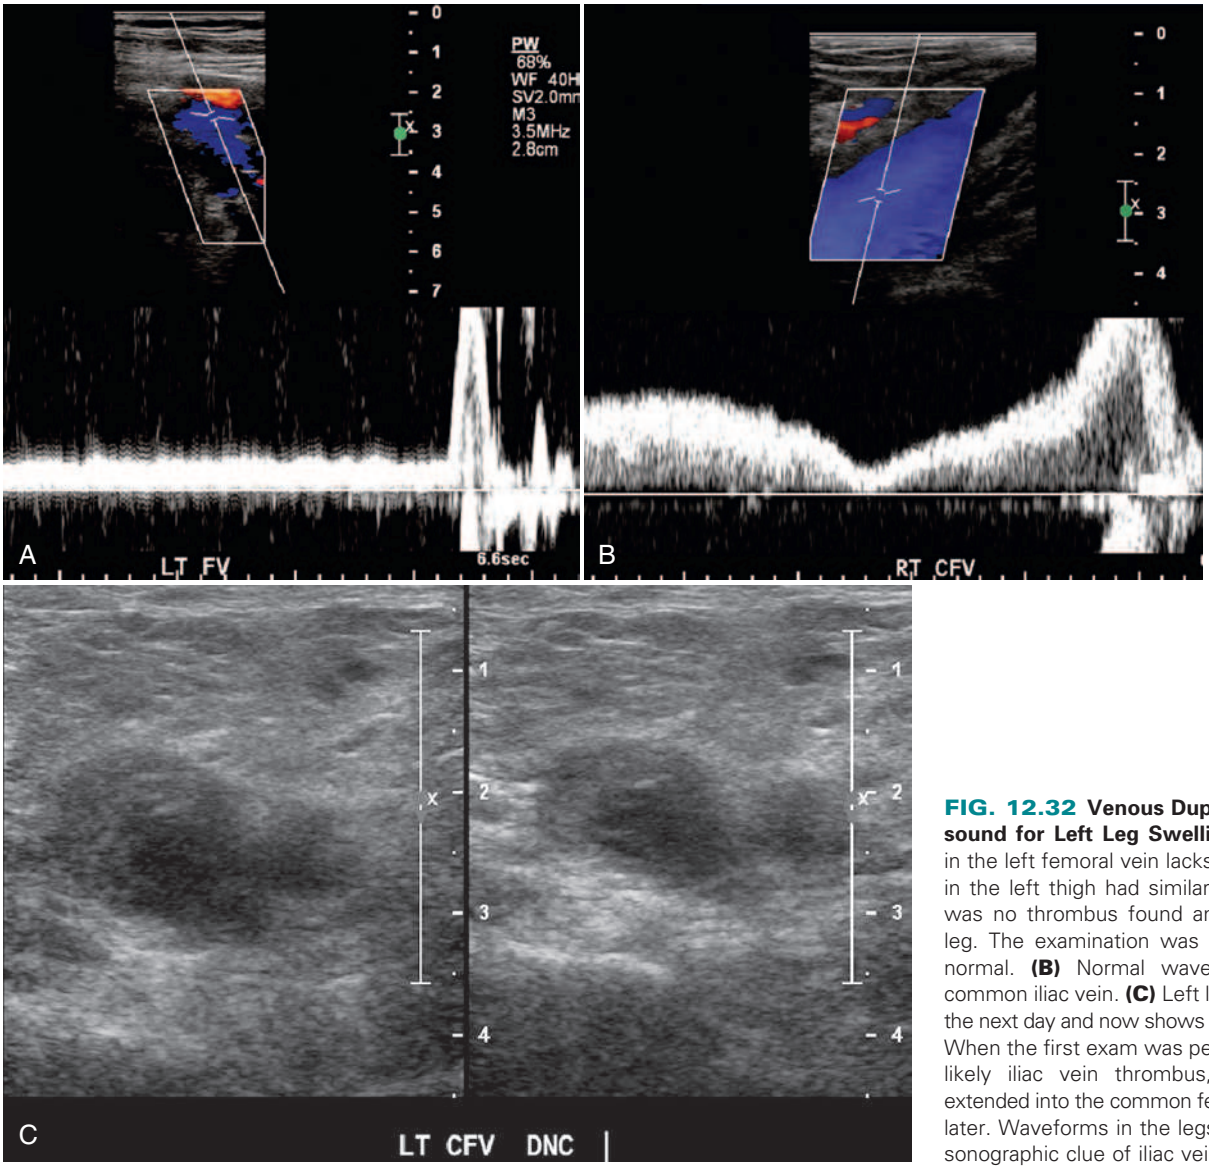

FIG. 12.32 Venous Duplex Doppler Ultrasound for Left Leg Swelling. (A) Waveform in the left femoral vein lacks phasicity. All veins in the left thigh had similar waveforms. There was no thrombus found anywhere in the left leg. The examination was mistakenly read as normal. **(B)** Normal waveform in the right common iliac vein. **(C)** Left leg was reexamined the next day and now shows extensive thrombus. When the first exam was performed, there was likely iliac vein thrombus, which then had extended into the common femoral vein 24 hours later. Waveforms in the legs are often the only sonographic clue of iliac vein thrombosis.

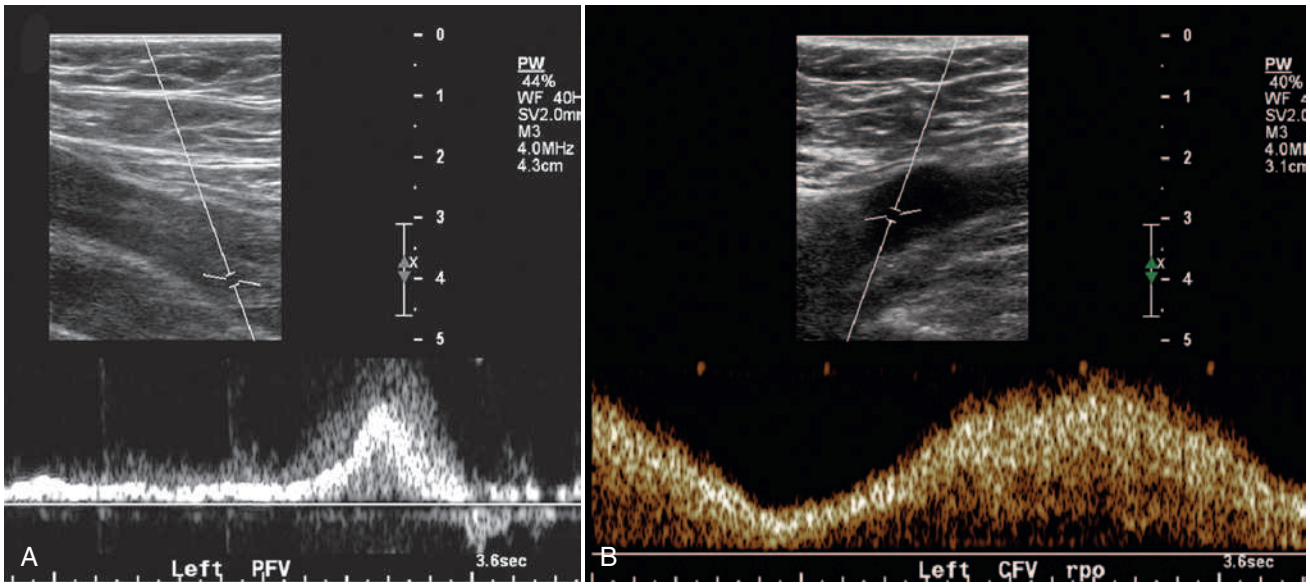

FIG. 12.33 Patient in Third Trimester of Pregnancy With Leg Swelling. (A) Waveform in the left profunda femoral vein with patient supine shows decreased phasicity. All veins in the left thigh had a similar waveform. The only variation seen in flow is when an augmentation (calf or thigh squeeze) was performed, causing a brief increase in flow. **(B)** Patient turned into right posterior oblique position. Turning has moved the gravid uterus off of the left iliac veins. Flow in the left common femoral vein shows normal respiratory phasicity.

If these maneuvers are not successful at restoring a normal waveform, there may be an obstruction proximal to the common femoral vein(s). If unilateral, there is likely to be iliac vein obstruction. If bilateral, the obstruction may be of the iliac veins bilaterally or of the IVC. In our experience the lack of common femoral vein phasicity is more likely to be a false-positive finding if it is bilateral rather than unilateral.

In the setting of absent common femoral vein phasicity, more proximal obstruction may be caused by acute or chronic thrombosis, May-Thurner physiology, or extrinsic compression of the vein by a benign or malignant mass or fluid collection. When lack of phasicity is found, other imaging studies may be performed to evaluate possible causes. This is particularly important if the patient has clinical findings suggestive of a more proximal obstruction. We typically use contrast-enhanced CT (Fig. 12.34) and, in pregnancy, MRI. Pelvic venography is another option.

In infants, particularly those with femoral venous catheters, scanning of the IVC can be valuable in assessing for thrombosis. The intrahepatic IVC is generally well seen. Thrombus can often be seen in gray scale and confirmed with color and spectral Doppler ultrasound. The infrahepatic IVC is more difficult to see but often can be adequately assessed using a far lateral approach obtaining coronal images using either kidney as a window.

Nutcracker Syndrome

Nutcracker phenomenon is described as extrinsic compression of the left renal vein resulting in mesoaortic (medial) segment narrowing and hilar (lateral) segment dilation of the vein (Videos 12.11 and 12.12).[134] **Nutcracker syndrome** refers to the associated clinical symptoms (flank pain, abdominal pain, hematuria, and/or proteinuria) when associated with the anatomic and hemodynamic findings of nutcracker phenomenon.[134] The syndrome can be divided into anterior (compression of the left renal vein between the aorta and SMA) and posterior (compression of a retroaortic left renal vein between the aorta and vertebral column) categories. Posterior nutcracker syndrome is rare, likely because the incidence of retroaortic left renal vein is only 0.5% to 3.7%.[135]

The overall prevalence of nutcracker syndrome is unknown, and diagnostic and treatment criteria are not well established. Proposed diagnostic steps in suspected cases include laboratory tests to evaluate for the cause of hematuria, ultrasound with sonography, CTA or MRA of the abdomen, and venography with renocaval pressure gradient measurements.[136] Peak velocity ratios and anterior-posterior diameter ratios greater than 5 between the mesoaortic and hilar segments of the left renal vein have been proposed as ultrasound diagnostic criteria.[137] However, the examiner needs to consider cases of long-standing nutcracker phenomenon where well-developed collateral vessels may decrease the blood flow through the narrowed portion of the left renal vein. Color Doppler should be used in these instances to evaluate for blood flow in collateral vessels.[138] CTA or MRA evaluation shows an acute angle origin of the SMA from the aorta, reported 54 degrees ± 5 degrees.[139] The distance between the SMA and anterior wall of the aorta in nutcracker phenomenon has been reported as 3 mm (normal, 5-6 mm).[139] Venography and renocaval pullback pressure gradient is an invasive evaluation but considered by most as the reference standard.[140] The pressure difference between the IVC and left renal vein normally is less than 1 mm Hg.[141] In patients with nutcracker phenomenon, the pressure gradient is 3.0 mm Hg or greater, consistent with left renal vein hypertension.[134] However, we have seen more than one patient with nutcracker syndrome who did not have a significant gradient

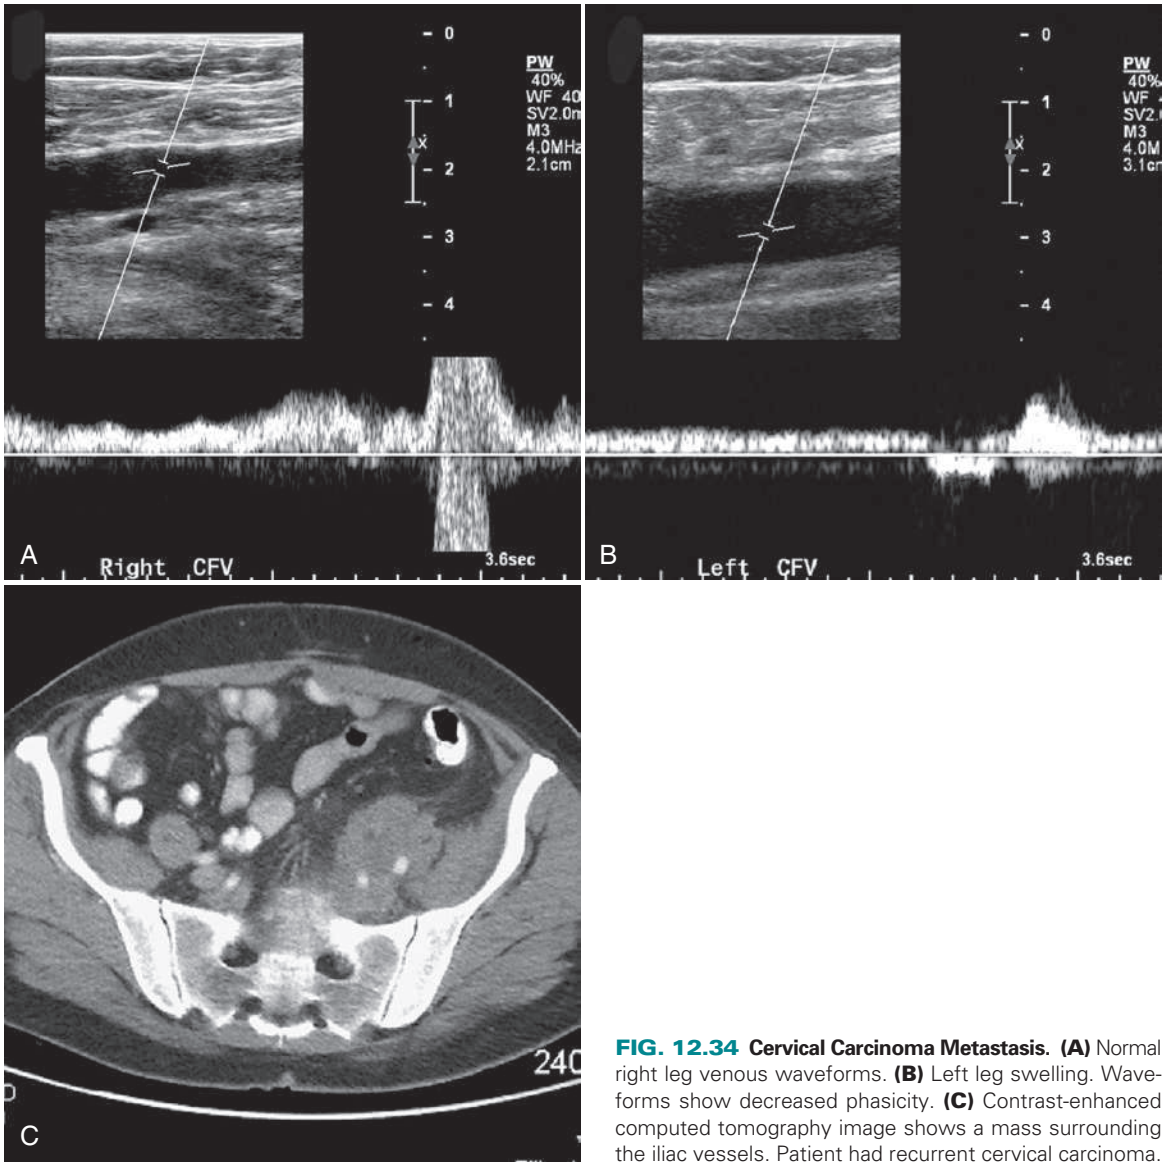

FIG. 12.34 Cervical Carcinoma Metastasis. (A) Normal right leg venous waveforms. **(B)** Left leg swelling. Waveforms show decreased phasicity. **(C)** Contrast-enhanced computed tomography image shows a mass surrounding the iliac vessels. Patient had recurrent cervical carcinoma.

on pressure measurement and yet became symptom free after a stent was placed in the left renal vein.

Just as diagnosis criteria for nutcracker syndrome are not well established and controversial, so are the treatment options. Surgical options include left renal vein transposition, renal venous bypass, auto transplantation of the kidney, and SMA transposition.[140] More recent studies, however, suggest that endovascular stenting should be considered as the primary treatment option because of its minimal invasive nature and successful outcomes (Fig. 12.35).[142]

Pelvic Congestion Syndrome

Pelvic congestion syndrome can present with vague chronic pelvic pain, usually of longer than 6 months duration.[143] The correct diagnosis is often delayed because of broad differential diagnoses for pelvic pain in women. The pain is related to pelvic and ovarian varicosities, which develop from chronic venous reflux or venous outflow obstruction of the pelvic veins.[144] Multiparity is an important risk factor. Multiple pregnancies result in increased venous distention and valve incompetence that leads to chronic venous reflux.[143,145] Nutcracker phenomenon, described earlier, also is a risk factor for development of pelvic congestion syndrome.

Ultrasound findings include dilated ovarian veins of more than 6 mm in diameter with reversed caudal flow, pelvic varicocele (>5 mm in diameter), and dilated arcuate veins (>5 mm in diameter) crossing the myometrium between pelvic varicoceles (Videos 12.13 and 12.14).[146,147] Examining the patient in the standing position should be considered because the pelvic veins may collapse when supine.[144] CT and MRI findings include four or more dilated parauterine veins (>4 mm in diameter) and ovarian vein diameter greater than 8 mm.[148] Time-resolved MRA demonstrates retrograde flow in the ovarian veins.[149] When clinical history is suggestive, venography is considered the reference

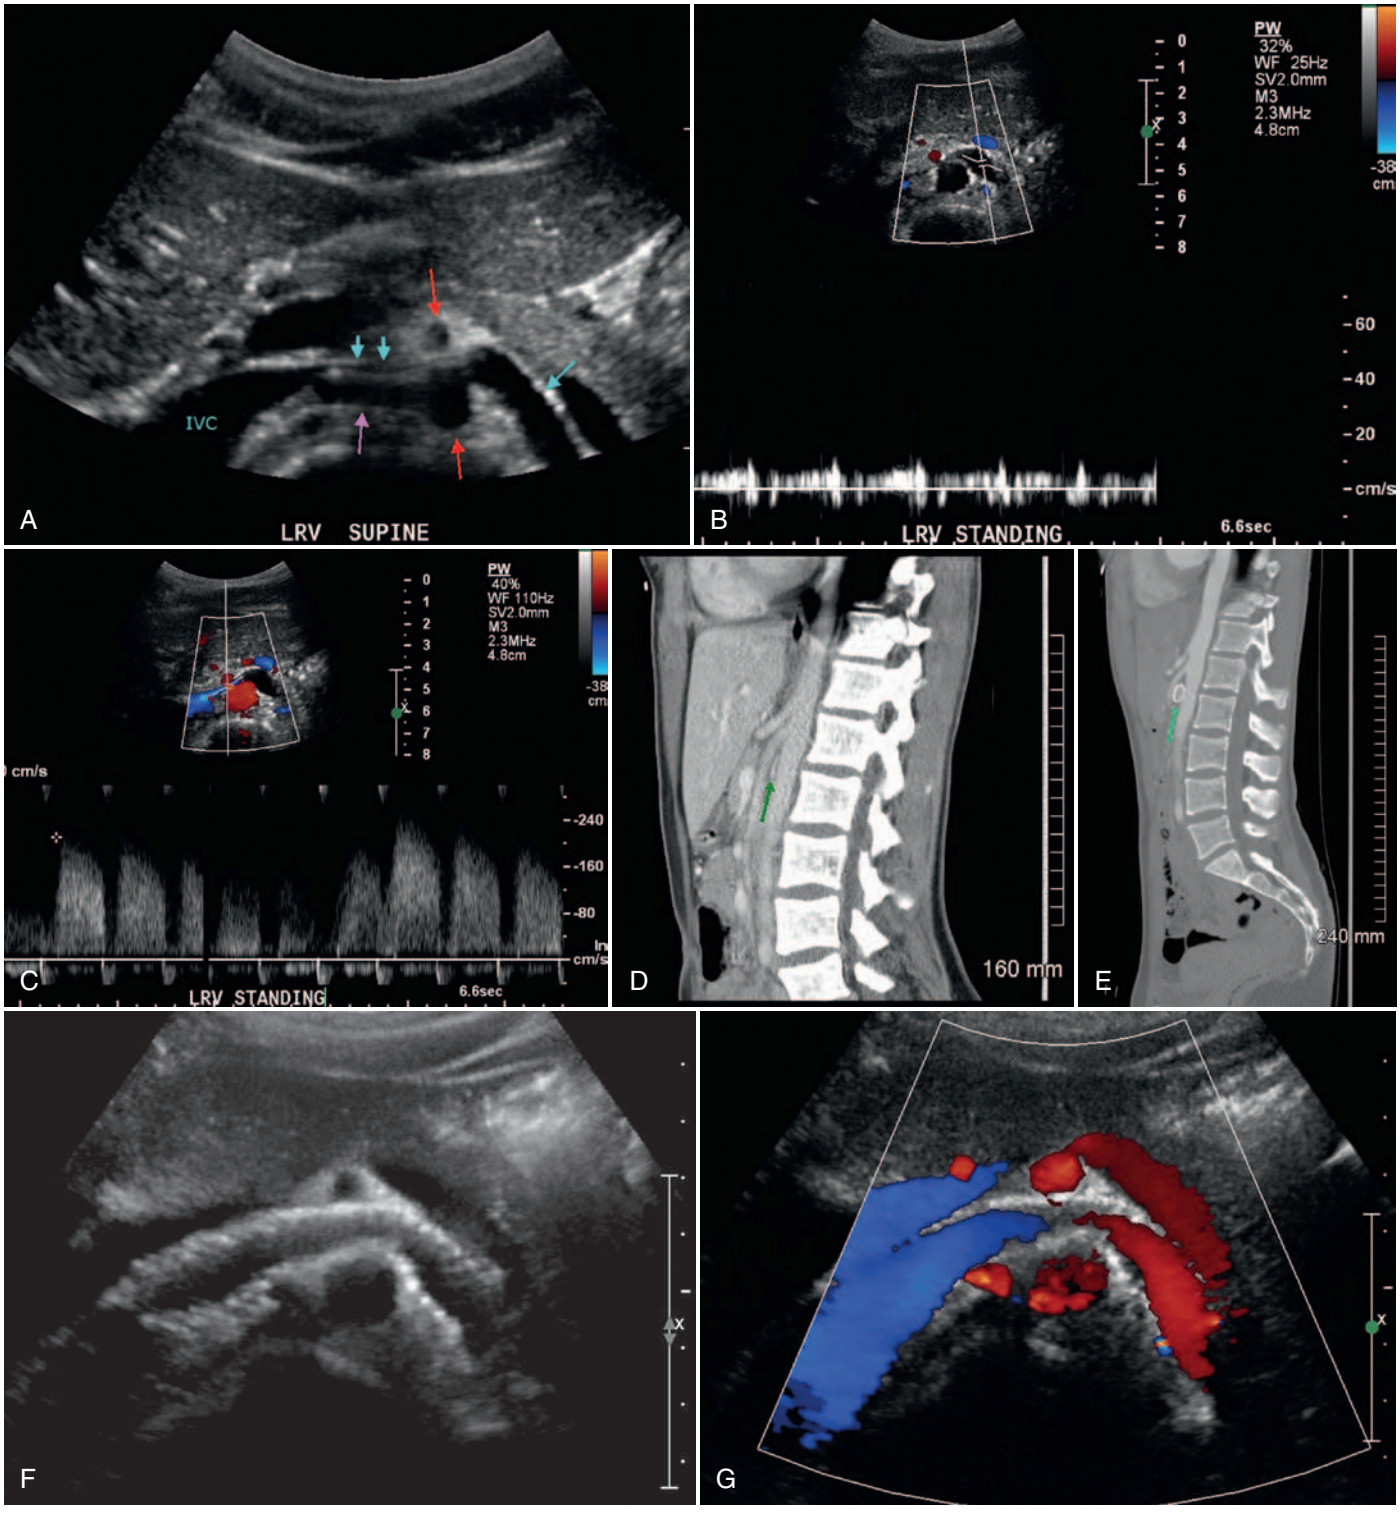

FIG. 12.35 Nutcracker Syndrome. Female, 17 years old, with left abdominal pain. **(A)** Transverse ultrasound image in the abdomen shows an enlarged left renal vein (LRV) *(blue arrow)* just before it crosses between the superior mesenteric artery (SMA) and aorta *(red arrows).* The LRV is narrowed and barely visible *(blue short arrows)* anterior to the right renal artery *(pink arrow).* **(B)** Duplex image of LRV shows slow flow in the dilated portion of the vein. **(C)** Duplex of the stenotic portion of the vein shows increased flow velocity of 210 cm/sec. **(D)** Sagittal reformatted computed tomography angiography shows that the LRV looks like a slit *(green arrow)* where it crosses between the aorta and the SMA. **(E)** Sagittal reformatted images after stent placement shows that the anterior-posterior diameter of the LRV is improved *(green arrow).* **(F)** Transverse gray-scale image shows the stent in the LRV. **(G)** Color duplex shows uniform flow in the stent. Spectral Doppler (not shown) demonstrated normal velocities throughout.

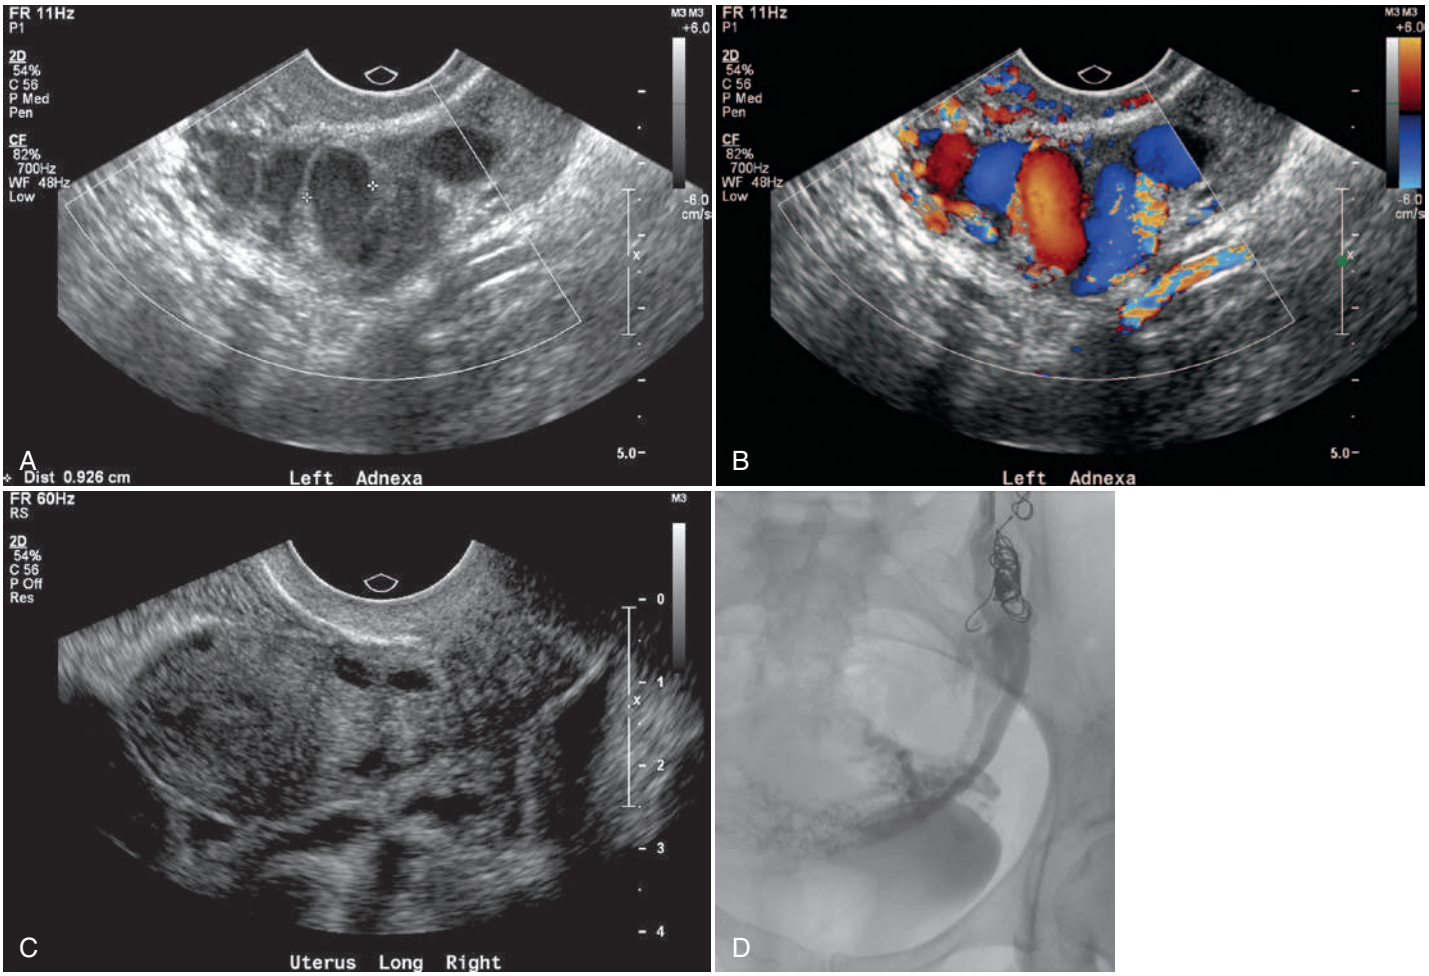

FIG. 12.36 Pelvic Congestion Syndrome. (A) Pelvic transvaginal gray-scale and **(B)** color Doppler images of dilated left ovarian veins with the largest vein measuring 9 mm in diameter. **(C)** Sagittal transvaginal image shows dilated uterine arcuate veins. These connect the left ovarian vein with the right. **(D)** Pelvic venography in a different patient performed during ovarian vein embolization. Numerous collateral veins arise from the left ovarian vein and cross the pelvis. These would be expected to connect to the right ovarian vein. See also Video 12.15.

standard.[148,150] Venographic findings include an enlarged left ovarian vein, retrograde flow of contrast into the left ovarian vein, and delayed clearance of contrast.[145,150] Medical management includes treatment with medroxyprogesterone acetate or goserelin acetate (gonadotropin-releasing hormone agonist).[151] Transcatheter embolization of the ovarian veins may be performed as a primary treatment or in patients with failed medical management. It results in clinical improvement in 60% to 100% of the patients[150] (Fig. 12.36 and Video 12.15).

Budd-Chiari Syndrome

Budd-Chiari syndrome is a rare condition caused by obstruction to outflow of the hepatic veins. In Caucasians the condition is often related to hypercoagulability. In Asians, membranous obstruction of the IVC is the most common cause.[152] When there is isolated stenosis of the IVC, percutaneous transluminal angioplasty with or without stent placement is often successful. Transjugular intrahepatic portosystemic shunt (TIPS) placement is often effective for hepatic vein obstruction.[153]

Budd-Chiari syndrome has many intrahepatic manifestations.[154,155] IVC manifestations are visible sonographically and include an IVC web just above the hepatic veins,[152] narrowing of the intrahepatic IVC caused by swelling of the liver, and IVC thrombosis.[153]

Inferior Vena Cava Neoplasms

Neoplasm of the IVC is rare and most often occurs in the setting of extension of solid organ tumors extending through their venous drainage to enter the IVC. This phenomenon is seen when renal cell carcinoma extends through the renal veins into the IVC. The same phenomenon can occur with hepatocellular and adrenocortical carcinoma extending through the hepatic and adrenal veins into the IVC.

Primary neoplasms of the IVC are even rarer. Leiomyosarcoma can occur at other sites in the systemic veins as well, but most often it arises in the IVC.

Ultrasound is not the primary method of imaging these tumors. When findings of IVC tumor involvement are seen

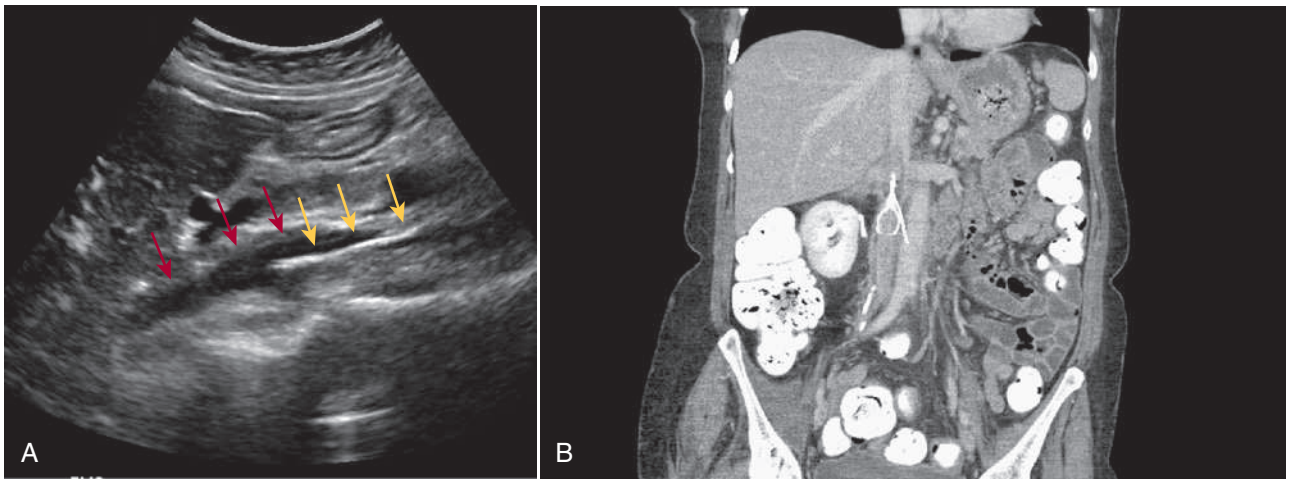

FIG. 12.37 Inferior Vena Cava (IVC) Filters. (A) IVC filters can be very difficult to see. Bright linear echoes *(yellow arrows)* indicate a tine of the filter within the IVC *(red arrows)*. This image represents an unusually good visualization of a filter. **(B)** Coronal reconstruction of computed tomography shows the location and form of the filter. (Courtesy of Anthony Hanbidge, MD.)

sonographically, cross-sectional imaging with CT or MRI should generally be recommended to determine the full extent of the abnormality.

Other Inferior Vena Cava Findings

Dilation of the IVC and hepatic vein orifices is seen in patients with congestive heart failure.[156]

Placement of **IVC filters** has become more common. In our experience, they are inconsistently seen. When seen, filters appear as an echogenic foreign body in the IVC. It is rarely possible to determine more about the filter than its presence and approximate location (Fig. 12.37). The IVC may become sclerotic in patients with long-standing filters, in whom it may be possible to see an absence of the IVC along with retroperitoneal collateral veins. The legs of the filters can also penetrate the wall of the IVC. This finding is fairly common on CT and most often is an incidental finding, although complications may result.[157] IVC penetration may be able to be observed sonographically as an echogenic foreign body extending outside of the IVC.

NONVASCULAR DISEASES OF THE RETROPERITONEUM

Excepting specific organs covered in other chapters, ultrasound is not the primary modality used in defining nonvascular problems in the retroperitoneum. When the abnormalities described next are seen sonographically, further cross-sectional imaging with CT or MRI often is needed to define the abnormality completely.

Solid Masses

Probably the most common solid mass is lymphadenopathy (enlarged lymph nodes). Causes of nodal enlargement can be benign or malignant (e.g., infection, lymphoma), but in all cases, malignancy must be excluded. Lymph nodes are most commonly hypoechoic. The identification of a structure as a probable lymph node is often by location in a paraaortic or paracaval region or in the mesentery.

Metastatic disease is another cause of solid masses in the retroperitoneum. Metastasis most frequently occurs to lymph nodes but can be seen in other sites. Often, it is impossible to tell with certainty whether the mass is nodal or is centered in some other type of tissue (Fig. 12.38).

Primary malignancies in the retroperitoneum are rare. The most common malignant retroperitoneal tumor is lymphoma.[158] The next most common are sarcomas: liposarcoma, leiomyosarcoma, and fibrous histiocytoma. These tumors generally undergo surgical resection and have a relatively high rate of recurrence.[159]

Benign masses also occur in the retroperitoneum, including **fibromas, schwannomas, neurofibromas,** and **lipomas. Extraadrenal paragangliomas** (extraadrenal **pheochromocytomas**) are usually benign but can be malignant.[160] The distinction between benign and malignant retroperitoneal masses cannot generally be made sonographically, and the finding of an unexpected mass in the retroperitoneum should generally prompt further evaluation with CT or MRI.

Fluid collections may also be seen in the retroperitoneum, including hematoma, urinoma, lymphocele, abscess, and pancreatic pseudocyst. If well seen and when indicated, sonography in conjunction with fluoroscopy is often the best way to drain these collections.

Retroperitoneal Fibrosis

As mentioned previously, retroperitoneal fibrosis is often grouped with inflammatory AAA in the disease process called **chronic periaortitis.** Retroperitoneal fibrosis can be seen as a mass usually surrounding the aorta and the common iliac arteries. It can involve adjacent structures, most often the ureters, resulting in displacement of the ureters and often in obstruction. When related to AAA, retroperitoneal fibrosis often regresses with repair of the AAA.

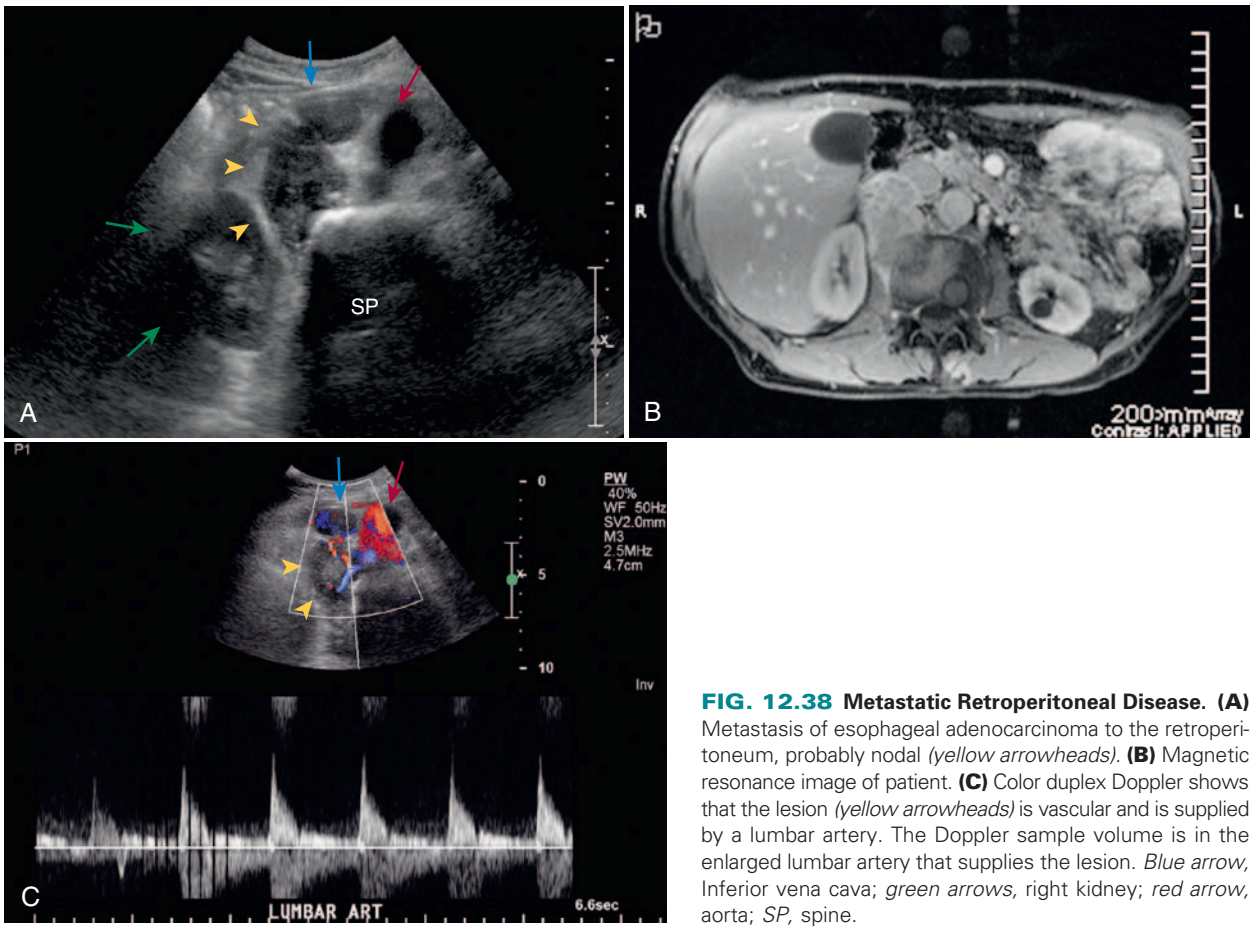

FIG. 12.38 Metastatic Retroperitoneal Disease. (A) Metastasis of esophageal adenocarcinoma to the retroperitoneum, probably nodal *(yellow arrowheads).* **(B)** Magnetic resonance image of patient. **(C)** Color duplex Doppler shows that the lesion *(yellow arrowheads)* is vascular and is supplied by a lumbar artery. The Doppler sample volume is in the enlarged lumbar artery that supplies the lesion. *Blue arrow,* Inferior vena cava; *green arrows,* right kidney; *red arrow,* aorta; *SP,* spine.

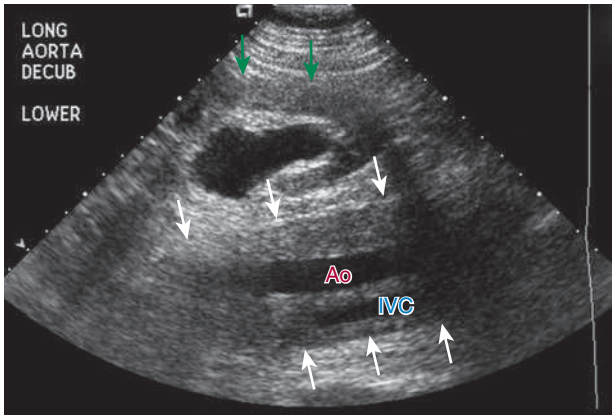

FIG. 12.39 Chronic Periaortitis. Coronal ultrasound image of chronic periaortitis with no abdominal aortic aneurysm (retroperitoneal fibrosis) *(white arrows)* surrounding the aorta *(Ao).* Inferior vena cava *(IVC)* is also faintly visible, surrounded by the mass. Left kidney *(green arrows)* is hydronephrotic because of entrapment of the left ureter by the periaortic mass. (Courtesy of Carl Reading, MD.)

In retroperitoneal fibrosis, ultrasound shows a mass encasing the abdominal aorta (Fig. 12.39). The back wall of the aorta is usually spared. A periaortic mass seen to separate the aorta from the spine suggests that the cause is instead malignant.[161] Ultrasound is not sensitive for detection of retroperitoneal fibrosis,[162] although it is sensitive for detection of AAA, which may be present. Sonography is also sensitive for the detection of ureteral obstruction and hydronephrosis, the most common complication.

CONCLUSION

Ultrasound often is used for targeted evaluation of solid organs and blood vessels in the retroperitoneum. Solid organ evaluation is covered in other chapters. For diseases of blood vessels of the retroperitoneum, ultrasound is generally an excellent diagnostic method and often the first modality used in diagnosis. For several reasons ultrasound is not a primary method for imaging the connective tissue regions of the retroperitoneum. To perform a thorough diagnostic examination when scanning the retroperitoneal organs and blood vessels, the clinician must have a clear concept of all retroperitoneal findings that may be encountered so that the best patient care can be provided.

CHAPTER 13

Dynamic Ultrasound of Hernias of the Groin and Anterior Abdominal Wall

Deborah Levine, Lisa Napolitano, and A. Thomas Stavros

SUMMARY OF KEY POINTS

- Dynamic ultrasound is the key examination for assessing the groin or anterior abdominal wall pain. Dynamic components of the examination include Valsalva and compression maneuvers and scanning in both supine and upright positions. Dynamic sonography enables clinicians to determine hernia type, size, contents, reducibility, and tenderness.
- Evaluation of groin pain in athletes is frequently more complex than in nonathletes because of associated tendinosis and osteitis pubis. Adding magnetic resonance imaging to dynamic ultrasound is usually necessary to identify underlying pathologic processes and to decide the best combination of surgical and nonsurgical treatments.
- Patients with one hernia frequently have multiple hernias, so in any patient in whom a hernia is sonographically demonstrable, the examination should be continued, looking for other types of ipsilateral and contralateral groin or anterior abdominal hernias. Even when no additional hernias are found, it is important to the surgeon to specifically mention in the report that a complete search of both groin areas was made and no additional hernias were found.
- Strangulation is the most dreaded complication of groin hernias. Gray-scale findings of strangulation—hyperechoic fat, isoechoic thickening of the hernia sac, fluid within the sac, and thickening of the walls of bowel loops—are all more sensitive for strangulation than is Doppler ultrasound.
- Recurrent pain after herniorrhaphy is a relatively common problem. Dynamic sonography can be helpful in assessing both acute and chronic recurrences of groin pain. Most hernia repairs now use mesh. The key to sonographic identification of recurrent hernias is to assess the edges of the mesh with dynamic maneuvers, because recurrent hernias arise from the edges of the mesh.
- Many pathologic processes, both rare and nonspecific, can simulate hernia, but cysts or hydroceles of the processus vaginalis (or canal of Nuck) and round ligament varices are relatively common and have virtually pathognomonic sonographic appearances.

Hernia Complications
Entities That Simulate Groin Hernias
Entities That Simulate Anterior Abdominal Wall Hernias
SUMMARY

Patients with groin pain may have a variety of conditions including, but not limited to, hip abnormalities, tendonitis, lymphadenopathy, or hernia.[1] Groin pain is a common presenting symptom in adult patients. Herniorrhaphy is the most common surgical procedure in the United States, with more than 800,000 operations performed annually.[2] An estimated 2.3 million inpatient abdominal hernia repairs were performed from 2001 to 2010, of which an estimated 567,000 were performed emergently. A general increase in the rate of total emergent hernias was observed from 16.0 to 19.2 emergent hernia repairs per 100,000

person-years in 2001 and 2010, respectively.[3] The lifetime risk of inguinal hernia requiring repair is high, estimated at 27.2% for men and 2.6% for women.[4] Over 90% of these procedures are performed on male infants younger than 1 year,[4] and thus these numbers do not reflect the incidence in adults.

Large hernias typically cause an obvious lump or bulge and are often diagnosed clinically and infrequently require imaging[5] (except to evaluate the contralateral side preoperatively). On the other hand, patients with hernias with pain but without a lump or bulge are more often referred for diagnostic imaging. Computed tomography (CT) and magnetic resonance imaging (MRI) have been used to identify and describe hernias (Fig. 13.1). However, real-time ultrasound has advantages over other imaging modalities: the ability to scan the patient in both upright and supine positions, to use **dynamic maneuvers** such as Valsalva and compression, and to document motion in real time (Fig. 13.2). Positioning and dynamic maneuvers affect the operator's ability to diagnose a hernia, alter its size and contents, and evaluate its reducibility. Sonography also enables the user to assess tenderness and clinical importance of a hernia. Thus ultrasound is the imaging modality of choice for assessment of inguinal masses and inguinal pain.[6,7]

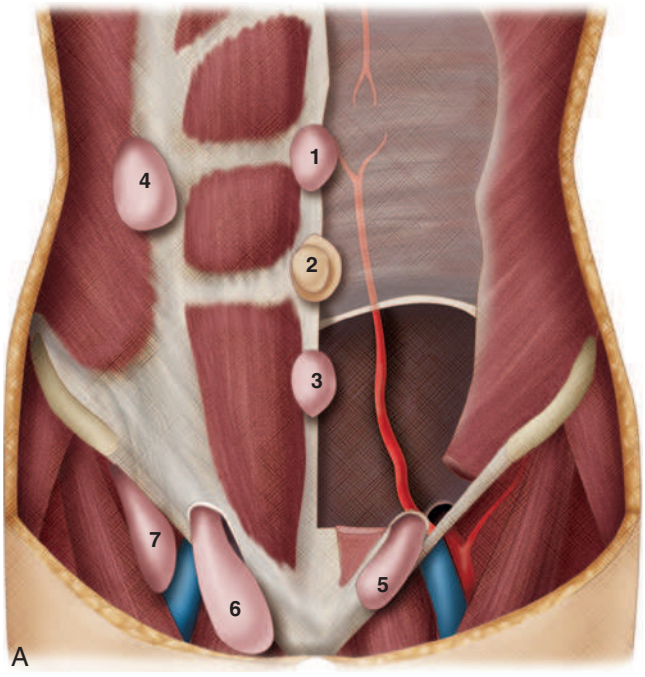

FIG. 13.1 Types of Hernias. (A) Diagram of the anterior abdominal wall, depicting site of abdominal wall hernias. *1,* **Supraumbilical hernia.** *2,* **Umbilical hernia.** *3,* **Infraumbilical hernia.** *4,* **Spigelian hernia.** *5,* **Erect inguinal hernia.** *6,* **Indirect inguinal hernia.** *7,* **Femoral hernia. (B) Indirect inguinal hernias on computed tomography (CT).** Abdominal CT scan shows bilateral fat-containing indirect inguinal hernias *(arrows).* (**A** with permission from Granja M, Rivero O, Aguirre D. Abdominal wall hernias. In: Sahani DV, Samir AE, editors. Abdominal imaging. 2nd ed. Philadelphia: Elsevier; 2017:1014-1025.[43])

The most common definition of the groin is that it is the region of the ilioinguinal crease at the junction of the abdomen and the thigh and the adjacent areas immediately above and below. In the strictest sense, the only "groin hernias" are **inguinal (direct or indirect).** However, **spigelian** and **femoral** hernias lie so close to the inguinal area that they are considered to be groin hernias as well.

Hernias occur in areas of natural weakness—in areas where vessels penetrate the abdominal wall (femoral and spigelian), where fetal migration of testis, spermatic cord, or round ligament have occurred (**indirect** inguinal), and through broad flat tendons called "aponeuroses" (**direct** inguinal). Hernias do not occur through the belly of abdominal wall muscles unless they have been surgically incised or otherwise injured.

TECHNICAL REQUIREMENTS

A high-frequency (≥12 MHz) 50-mm-long transducer is optimal in the majority of patients. In obese patients a lower-frequency transducer may be necessary, usually a 7- to 9-MHz curved array. Use of a 50-mm transducer is important because its larger field of view (FOV) allows better identification of landmarks, especially in patients who have diastasis of aponeuroses. When long-footprint linear transducers are not available, use of a trapezoidal or virtual convex display can be helpful. In some cases, extended-FOV modes can be helpful, particularly in indirect inguinal hernias that extend into the scrotum and long incisional hernias. It is important to be able to store and review video loops in order to capture dynamic events critical to diagnosis. Color and power Doppler ultrasound features show the degree of vascularity associated with inflammatory processes and solid masses and the viability of the herniated bowel loops.[8]

THE REPORT FOR DYNAMIC ULTRASOUND OF GROIN HERNIAS

It is important to use correct terminology in reporting the results of a dynamic groin ultrasound examination. In addition to the indication, the report should contain the following elements: (1) the examination name; (2) the specific dynamic components of the examination; (3) the side examined; (4) presence or absence of a hernia; (5) hernia size; (6) hernia contents; (7) reducibility of the hernia; and (8) whether the hernia is tender or nontender. Tenderness is important in determining whether a hernia is more likely to be incidental or clinically significant. This is particularly important when a hernia is found as an incidental finding in a patient who is asymptomatic.

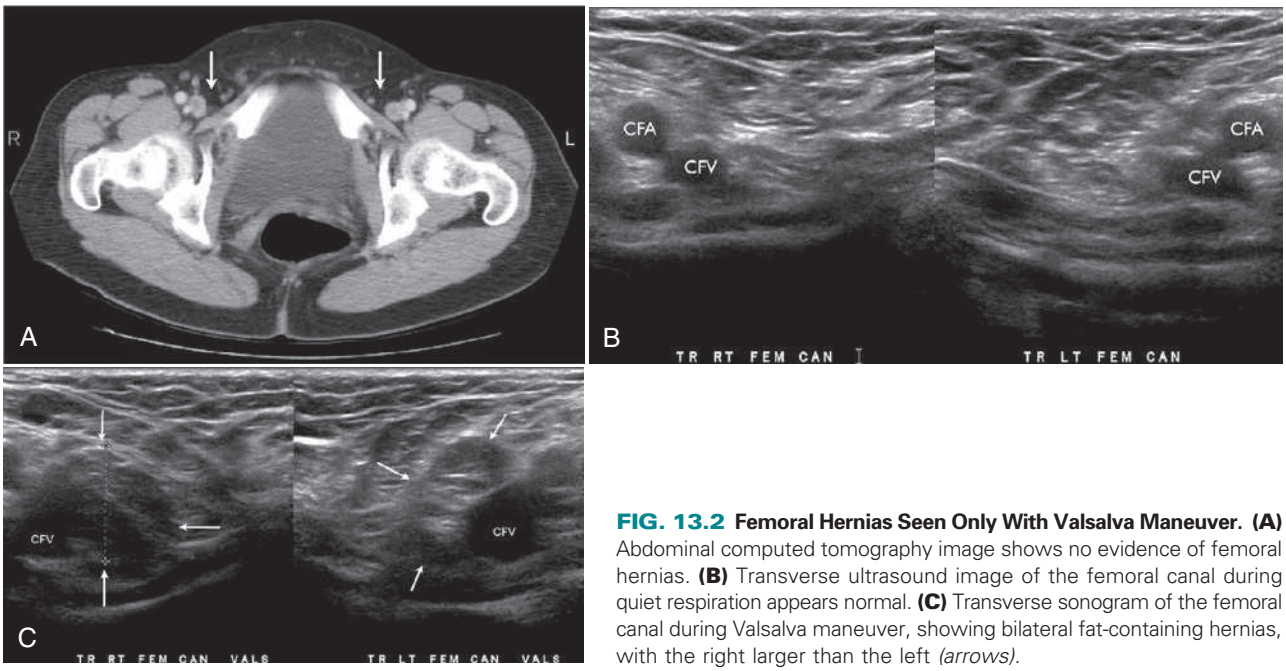

FIG. 13.2 Femoral Hernias Seen Only With Valsalva Maneuver. (A) Abdominal computed tomography image shows no evidence of femoral hernias. **(B)** Transverse ultrasound image of the femoral canal during quiet respiration appears normal. **(C)** Transverse sonogram of the femoral canal during Valsalva maneuver, showing bilateral fat-containing hernias, with the right larger than the left *(arrows).*

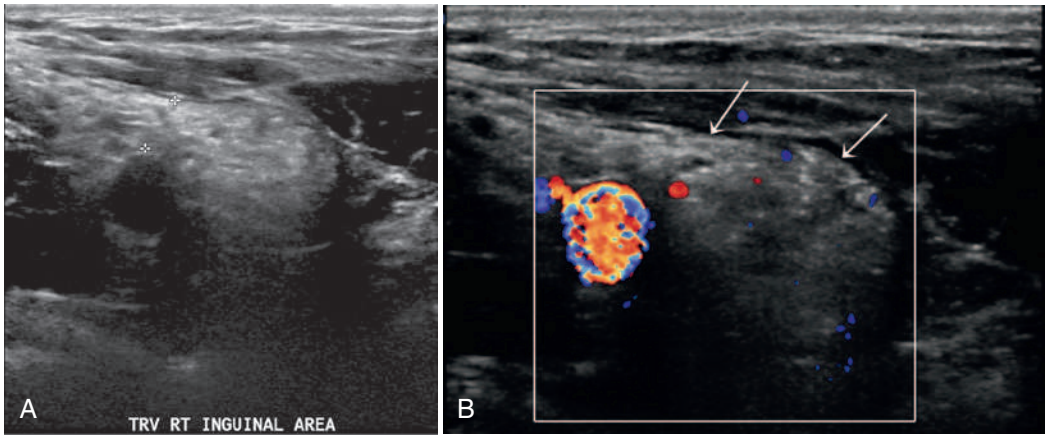

FIG. 13.3 Indirect Inguinal Hernia. A 25-year-old man with right inguinal pain and a fat-containing indirect hernia. **(A)** Transverse sonogram shows a hernia *(calipers)* in the right inguinal region. **(B)** Color Doppler image shows that the hernia *(arrows)* is lateral to the vessels. Only fat was seen in the hernia sac. See also Video 13.1.

When a hernia has been described in the report, we also report about our search for additional types of ipsilateral or contralateral groin hernias. In a patient with an inguinal hernia, presence of an ipsilateral femoral or spigelian hernia may necessitate use of a larger piece of mesh. Presence of a contralateral hernia may lead to bilateral rather than unilateral repair. Children in particular are often found to have bilateral inguinal hernias.[9]

HERNIA CONTENTS

Hernias are composed of a sac, the parts of which are described as the neck, the body and fundus, and the hernia contents. The inguinal hernia sac consists of peritoneum, which protrudes through the abdominal defect or "hernial orifice" and envelopes the hernial contents. The neck of the sac is situated at the defect. Hernias with a narrow or rigid neck are more likely to obstruct and strangulate. The body is the widest part of the hernia sac, and the fundus is the portion furthest away from the defect. Viscera most likely to enter a hernia sac are those normally situated in the region of the defect and those that are mobile—for example, the omentum and small bowel.

Most sonographically detected hernias do not contain bowel. In fact, most hernias contain only fat (Fig. 13.3, Video 13.1). The origin of the fat may be **intraperitoneal** (mesenteric or omental), **preperitoneal,** or, in rare instances, both (Video 13.2). Hernias that contain intraperitoneal fat may contain bowel later and thus may be a greater risk than those that contain only preperitoneal fat. Some hernias contain free fluid of intraperitoneal origin (Fig. 13.4). Hernias that contain bowel are considered higher risk because strangulation may lead to infarction of bowel (Fig. 13.5, Video 13.3). Large hernias that are the most likely to contain bowel are easier to detect clinically and less

FIG. 13.4 Fluid-Containing Incarcerated Direct Inguinal Hernia. Long-axis image of a fluid-containing femoral hernia that caused pain and swelling.

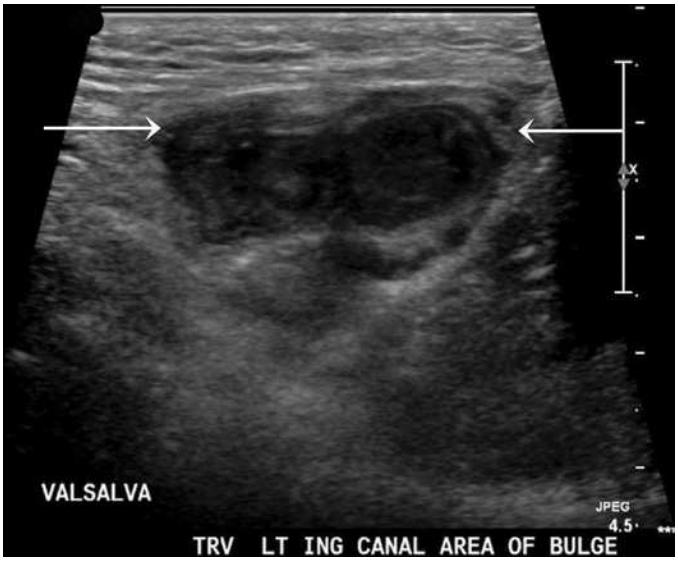

FIG. 13.5 Bowel-Containing Inguinal Hernia. Short-axis view of the inguinal canal shows an indirect inguinal hernia that contains bowel. See also Video 13.3 showing peristalsis.

often require sonographic imaging for diagnosis. Hernias can contain small bowel, colon, or appendix. The Amyand hernia is a rare inguinal hernia (about 1% of inguinal hernias, <1% of appendicitis cases) that contains the appendix[10,11] (Fig. 13.6). Other, much less common hernia contents include ovaries and/or "bladder ears."

DYNAMIC MANEUVERS

The dynamic maneuvers that are the key to ultrasound's ability to depict and evaluate hernias include watching the region during quiet breathing, the Valsalva maneuver, the compression maneuver, and upright positioning. Dynamic maneuvers are useful because many hernias spontaneously reduce when the patient is supine and breathing quietly.[8] Hernias that contain only fat are almost isoechoic with surrounding tissues and therefore relatively inconspicuous. Watching the groin region during quiet breathing allows for visualization of bowel peristalsis. Assessment with color Doppler allows for assessment of bowel perfusion (implying viability). Dynamic maneuvers can cause the fat within a hernia to move, making the hernia contents more conspicuous. The direction of movement can be helpful, because movement of surrounding tissues is almost always in the anteroposterior (AP) direction, whereas hernia contents often move horizontally or obliquely during compression maneuvers (Video 13.4). Hernia contents may change with dynamic maneuvers. Finally, reducibility and tenderness can be assessed.

The **Valsalva maneuver** is most useful when the patient is supine. It forces hernia contents anteriorly, and often horizontally in an inferomedial direction (Fig. 13.7), and at times elicits pain. Some hernias become visible only during the Valsalva maneuver (see Fig. 13.2). In other cases, hernia sacs that can be seen in quiet respiration elongate and widen during the Valsalva maneuver. Hernias that appear to contain only fat during quiet respiration may be shown to contain bowel during the Valsalva maneuver (Video 13.5). In general, hernia sacs should become larger with the Valsalva maneuver. If they stay the same size, this is worrisome for incarceration.

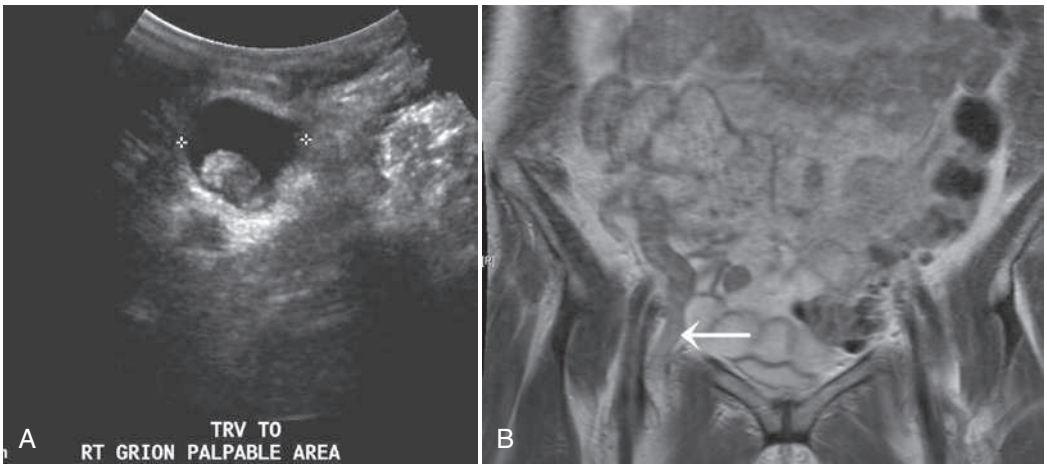

FIG. 13.6 Amyand Hernia. (A) Right lower quadrant sonogram shows a complex cyst in the region of patient's pain. **(B)** Magnetic resonance image shows the appendix *(arrow)* extending into the hernia.

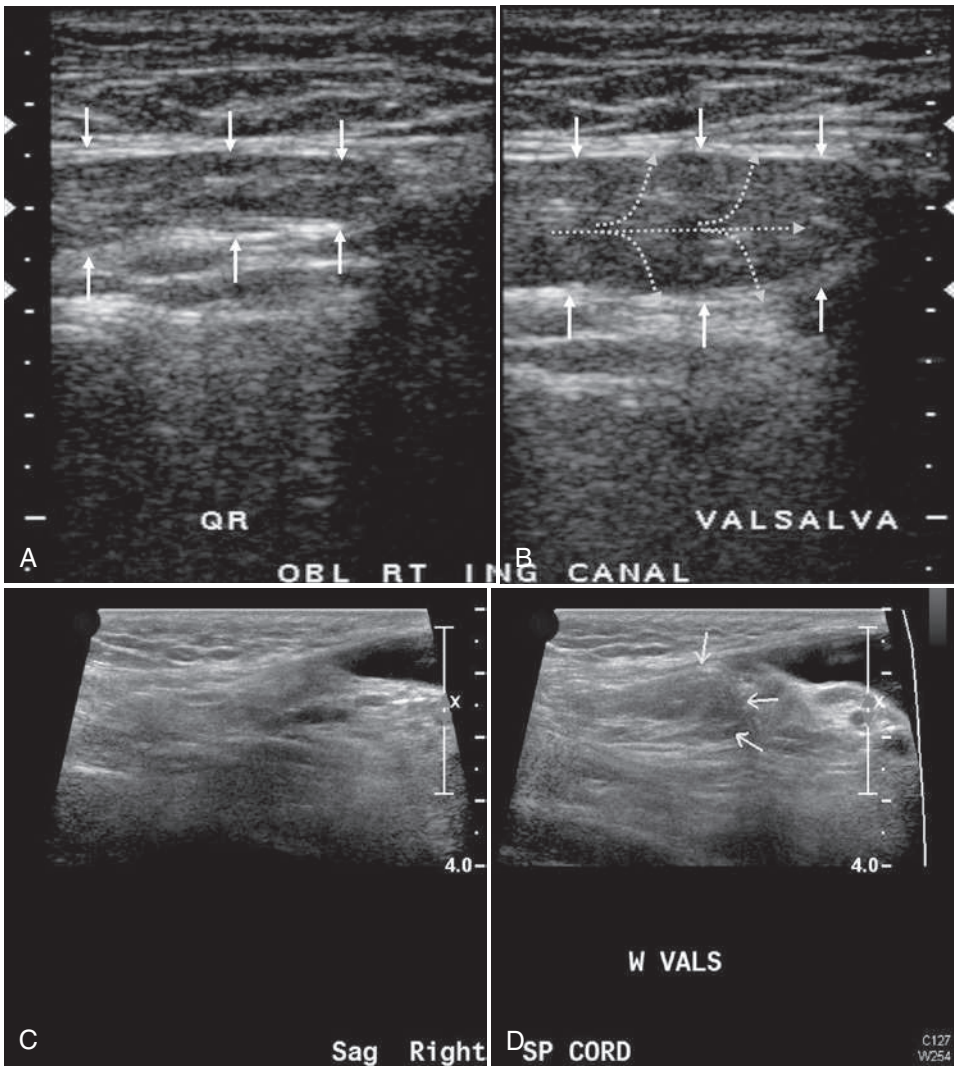

FIG. 13.7 Value of Valsalva Maneuver. Indirect Inguinal Hernias. (A) and **(B)** Split-screen long-axis views of a fat-containing indirect inguinal hernia during quiet respiration and Valsalva maneuvers. The left image shows the hernia during quiet respiration *(arrows)*. The right image, obtained during a Valsalva maneuver, shows the hernia contents being forced distally in a horizontal direction within the inguinal canal *(arrows and dotted arrows)*. **(C)** and **(D)** Split-screen views in another patient show the more obvious hernia with Valsalva maneuver.

The **compression maneuver** is essential to assess reducibility and tenderness in patients who have sonographically detectable hernias, regardless of whether the patient is upright or supine. Compression maneuvers are also useful in supine patients in whom the Valsalva maneuver is ineffective. Compression helps assess **reducibility** of a hernia. Hernias may be completely reducible (Video 13.6), partially reducible (Video 13.7), or nonreducible (Video 13.8). The shape of hernias correlates with reducibility. A hernia with a broad fundus and narrow neck is likely to be nonreducible, whereas a hernia with a broad neck compared with the fundus is more likely to be reducible (Fig. 13.8). Assessing tenderness is very important because dynamic sonography is so sensitive that it can detect many asymptomatic and clinically unimportant hernias. Furthermore, in some patients the pain is caused by other etiologies.

Upright positioning is essential in all patients being sonographically evaluated for groin hernia. Many patients are symptomatic only in the upright position, or they are more symptomatic in the upright position. Fluid is often best demonstrated with the patient in the upright position. It may take minutes for the free fluid to "puddle" in the inferior end of the hernia sac once the patient has been standing. Therefore delayed imaging in the upright position may be helpful in demonstrating **peritoneal fluid.** Other hernias contain bowel only in the upright position. Some hernias are either only visible in the upright position[6] or are much better demonstrated in the upright position (direct inguinal and femoral). The reducibility of a hernia may vary between supine and upright position, so it is important to assess reducibility in both positions. In most patients, groin hernias are more reducible in the supine than in the upright position, whereas in others the opposite is true.

KEY SONOGRAPHIC LANDMARKS

Ultrasound shows characteristic features of groin hernias that lie above the inguinal ligament. Four types of hernias occur

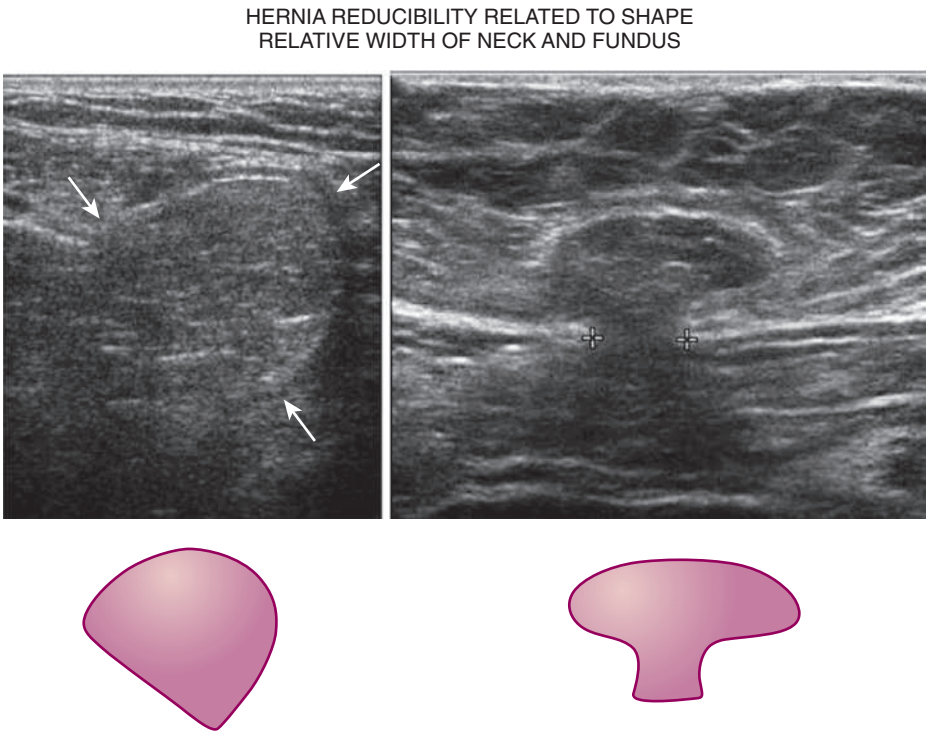

FIG. 13.8 Typical Hernia Shapes. *Left,* Direct inguinal hernia shows a wide neck in comparison to the fundus. This hernia shape correlates with complete reducibility. *Right,* Linea alba hernia shows a very narrow neck in comparison to the fundal width. This hernia shape correlates with nonreducibility and increased risk of strangulation.

within the broader definition of the groin: indirect inguinal, direct inguinal, spigelian, and femoral. The key landmark in distinguishing among the first three types is the **inferior epigastric artery** (IEA). This artery arises from the external iliac artery and then courses superomedially, crossing the spigelian fascia and the semilunar line, eventually coursing along the midposterior aspect of the rectus abdominis muscle. The IEA can be identified sonographically in all patients along the midposterior surface of the rectus abdominis muscle at a level about halfway between the umbilicus and pubic symphysis while scanning in a transverse plane (Fig. 13.9). The IEA lies anterior to the peritoneum and thus is never obscured by bowel gas. Once identified in the transverse plane, the IEA can be traced inferiorly and laterally to its origin from the external iliac artery. There are four main types of inguinal hernias (Table 13.1, Fig. 13.10).

Once the origin of the IEA is identified, the transducer should be rotated into an axis that is parallel to the inguinal ligament, which courses obliquely from superolaterally to inferomedially. The patient should be scanned in long axis parallel to the inguinal ligament and short axis perpendicular to the inguinal ligament.

INGUINAL AND INGUINAL REGION HERNIAS

Inguinal hernias can be classified as direct or indirect. The terms **direct** and **indirect** refer to how hernias appear during open surgical repairs. **Direct inguinal hernias** protrude into the surgically opened inguinal canal "directly" from posteriorly. **Indirect inguinal hernias,** on the other hand, enter the surgically opened inguinal canal "indirectly" from a superolateral direction after passing through the internal inguinal ring (deep inguinal ring). From a sonographic point of view, "direct" and "indirect" are potentially confusing. It would be less confusing to characterize them as internal inguinal ring (indirect) hernia and nonring (direct) hernia. In a retrospective review of ultrasound examinations of 172 groins in 151 patients, 119 hernias were diagnosed in 107 patients, 60% were indirect inguinal hernias, 19% were direct inguinal hernias, 18% were femoral hernias, and 3% were combined hernias (direct and indirect inguinal hernia). Ninety-two percent contained fat and 30% contained bowel.[12] The overall rates of sensitivity and specificity of ultrasound for diagnosing the presence of groin hernia were 96% and 96% (increasing to 98% and 100% after 2011), and determination of type of hernia was 96% accurate (increasing to 98% after 2011).[12] In a prospective study of 118 patient with a clinical diagnosis of groin hernia, ultrasound was found to be 100% sensitive and specific for the diagnosis of hernia, with distinction between direct and indirect inguinal hernias having sensitivities of 86% and 97%, respectively.[13] Clearly, experience and technique are important factors in achieving high accuracy.

Strength of the transversalis fascia is altered in many patients with inguinal hernias. It is felt that collagen structure and metalloproteinase activity are different in patients with hernias than in the general population, thus putting the transversalis fascia, owing to its location with high pressure with little additional support, at risk for stretching, tearing, and failure.[14-19] Thus patients

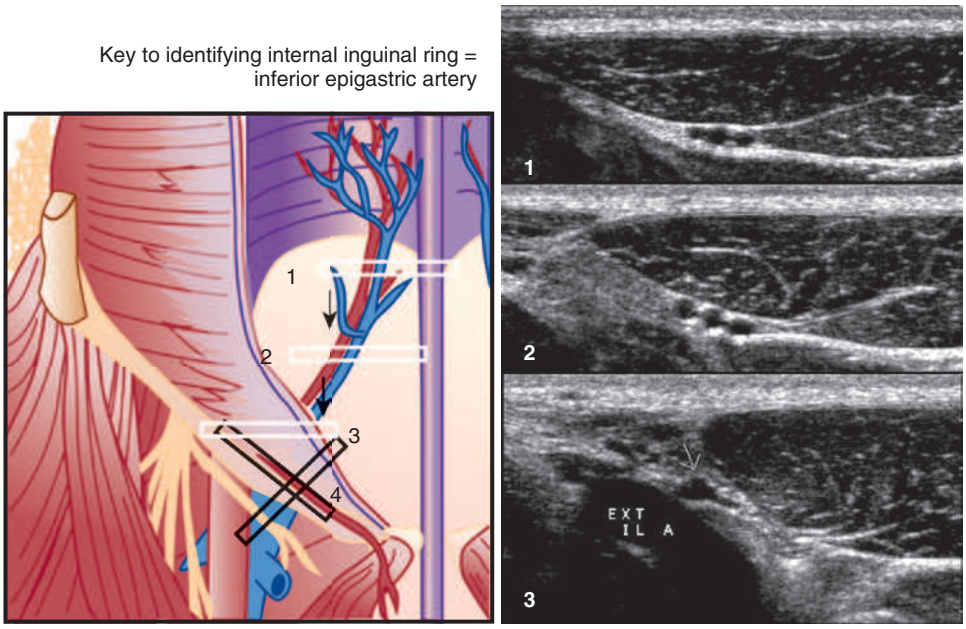

FIG. 13.9 Inferior Epigastric Vessels (IEVs) Are Main Landmarks for Evaluating Inguinal Area. Image 1 was obtained in a transverse plane about halfway between the umbilicus and the pubic symphysis. The inferior epigastric artery and its paired veins lie along the midlateral posterior surface of the rectus abdominis muscle. Image 2 was obtained several centimeters inferiorly, and the IEVs lie more laterally. Image 3 was obtained at a level where the IEVs *(arrow)* lie at the edge of the rectus muscle. This is the level at which most spigelian hernias occur. Once the origin of the inferior epigastric artery is identified, the transducer should be rotated into planes that are parallel (see line 4 on the drawing) and perpendicular (see image 3) to the inguinal canal—long-axis and short-axis views.

TABLE 13.1 Types of Inguinal Hernias

Hernia Type	Key Findings	Classic Teaching Point
Indirect inguinal	Herniated structures enter the inguinal canal lateral to the epigastric artery and superior to the inguinal ligament, and extend for a variable distance through the inguinal canal.	Most common groin hernia. Extension into scrotum or labia majora is almost always due to indirect hernia.
Direct inguinal	Arise from conjoined tendon, inferior and medial to inferior epigastric artery. Herniation at the inferior aspect of **Hesselbach triangle.**	Associated with increased abdominal pressure (ascites, obesity, pregnancy), older age, and weak musculature
Spigelian	Arise through the spigelian fascia just lateral to where it is penetrated by the internal epigastric artery. The transverse abdominis tendon is always torn. In most cases the internal oblique aponeurosis is also torn.	Sonography shows a complex mass within the anterolateral aspect of the abdominal wall, which may contain fluid- or gas-filled loops of bowel.
Femoral	Within the femoral canal, inferior to the inguinal ligament.	This type of hernia has a relatively high association with incarceration.

with known disorders of tissue strength, including Ehlers-Danlos, Marfan, and Hurler-Hunter syndromes, polycystic kidney disease, and osteogenesis imperfecta, are at increased risk for inguinal hernia.[14,19-21]

Indirect Inguinal Hernias

The characteristic finding of an indirect inguinal hernia is abnormal movement of intraabdominal contents (fat, bowel, or both) through the deep inguinal ring and through the inguinal canal. In the short axis, the indirect inguinal hernia can be seen moving into and out of the plane adjacent to the spermatic cord (in males).[1,8,22,23]

Indirect inguinal hernias are the most common type of groin hernia, being five times more common than direct hernias.[24] In boys, the indirect inguinal hernia is the result of a congenital defect of a patent processus vaginalis. In adults, an indirect hernia is acquired as a result of weakness and dilation of the internal inguinal ring.[25,26] Indirect hernias represent a persistence of a patent **process vaginalis.** In males the testis descends from the abdominal cavity into the scrotum, which can result in delayed

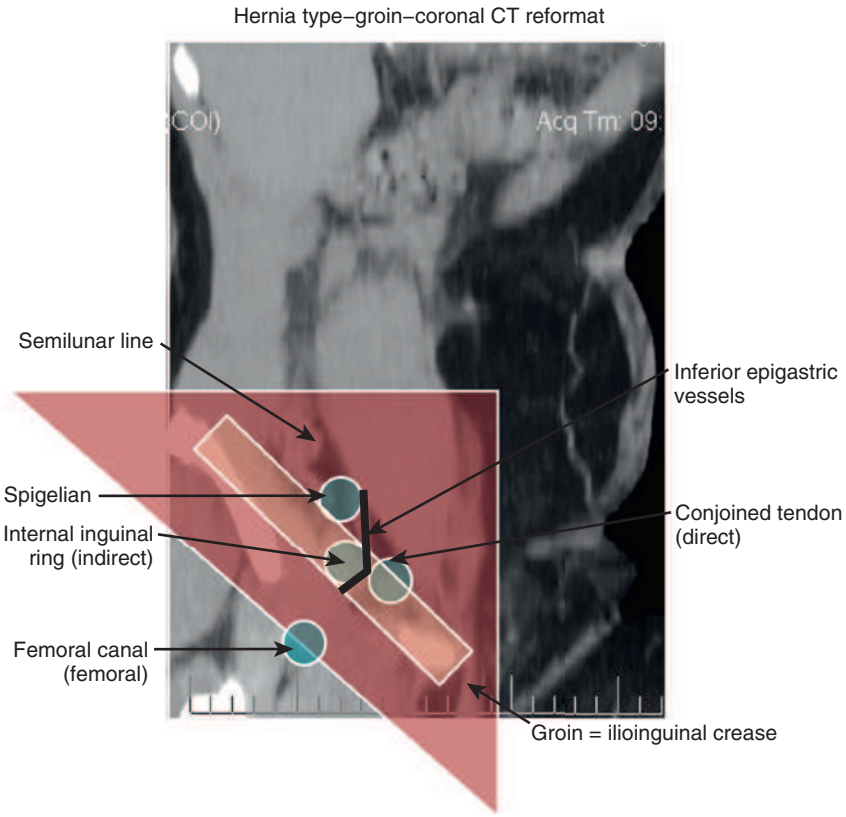

FIG. 13.10 Locations of Four Types of "Groin" Hernias. Abdominal and pelvic computed tomography *(CT)* image, reformatted in coronal plane. **Indirect inguinal hernias** arise within the internal or deep inguinal ring, which lies in the crotch between the external iliac artery and the proximal inferior epigastric artery. **Direct inguinal hernias** arise through the "conjoined tendon," which lies inferior and medial to the origin of the inferior epigastric artery. **Spigelian hernias** arise through the spigelian fascia just lateral to the inferior epigastric artery, where it reaches the lateral margin of the rectus muscle. **Femoral hernias** lie within the femoral canal, inferior to the inguinal canal and inguinal ligament.

or incomplete closure of the inguinal canal. Thus indirect inguinal hernias are more common in males. However, delayed or incomplete closure of the **canal of Nuck** can occur in females. The neck of an indirect inguinal hernia is the segment that lies within the internal inguinal ring, and the fundus lies within the inguinal canal (Fig. 13.11). The neck (internal inguinal ring) lies just superior and lateral to the IEA's origin and tends to be oriented in an AP direction, whereas the fundus (inguinal canal) is oriented horizontally and courses inferiorly and medially, passing superficial to the IEA's origin The fundus of an indirect inguinal hernia lies anterior and lateral to the **spermatic cord** in males and the **round ligament** in females (Fig. 13.12). In the short axis, the internal inguinal ring and the neck of the indirect inguinal hernia lie between the external iliac artery along its lateral side and the IEA along its medial side.

In the long axis, indirect inguinal hernias can have two appearances: sliding and nonsliding. The **sliding type** of indirect inguinal hernia has a relatively wide neck compared with the fundus, with loss of the angle between the neck and fundus. It is usually reducible and is more likely to contain bowel and other intraperitoneal contents. The **nonsliding type** has a relatively narrower neck compared with the fundus and maintains the almost 90-degree angle between the neck and fundus (Fig. 13.13). Nonsliding hernias usually contain only properitoneal fat and are nonreducible, and may be misclassified as "spermatic cord lipoma" or "inguinal canal lipoma" at surgery. True spermatic

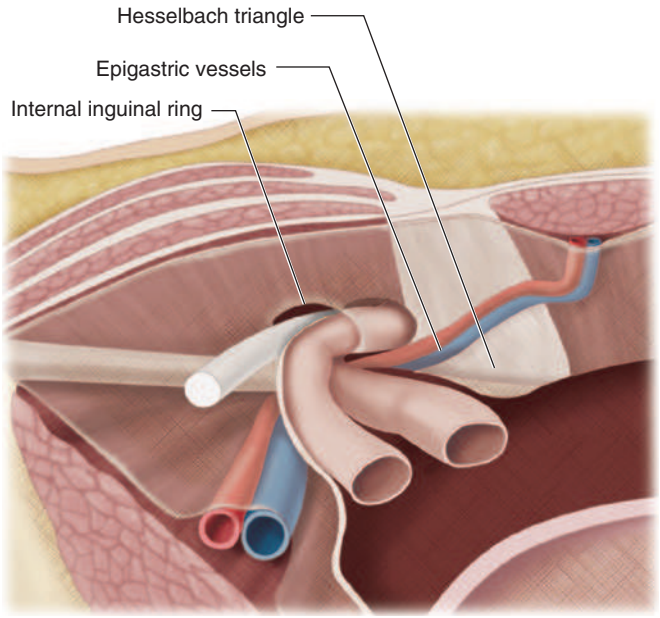

FIG. 13.11 Indirect Inguinal Hernia. Diagram of the deep aspect of the anterior abdominal wall depicting a left indirect inguinal hernia. The hernia sac protrudes through the internal inguinal ring, located lateral to the epigastric vessels. Note the Hesselbach triangle, located medial and inferior to the epigastric vessels. (Reproduced with permission from Granja M, Rivero O, Aguirre D. Abdominal wall hernias. In: Sahani DV, Samir AE, editors. Abdominal imaging. 2nd ed. Philadelphia: Elsevier; 2017:1014-1025.[43])

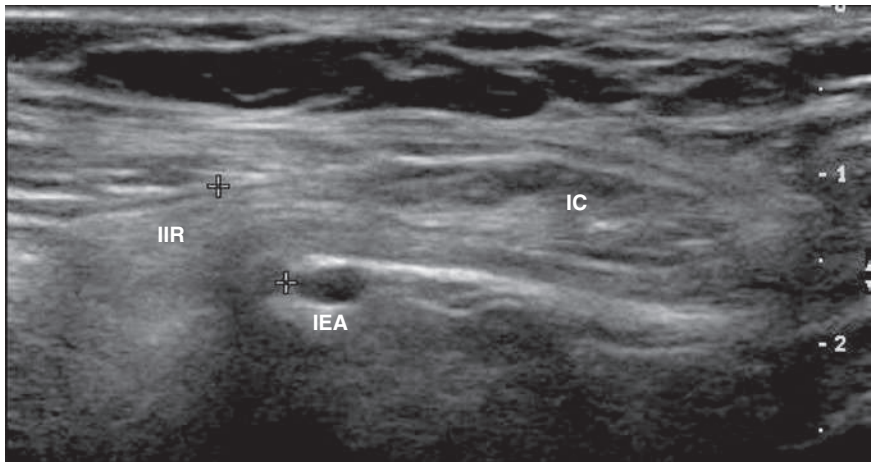

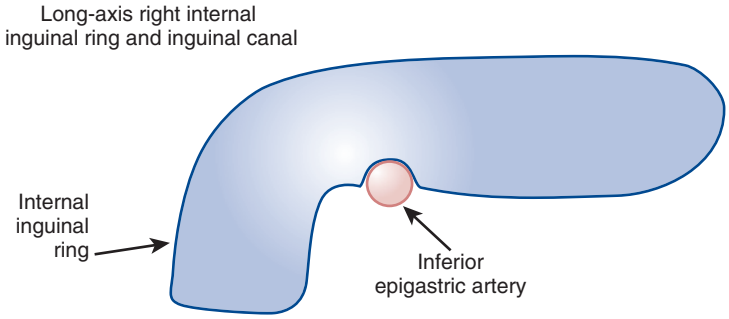

FIG. 13.12 Indirect Inguinal Hernia. Long-axis view shows that neck of the hernia lies in the internal inguinal ring *(IIR),* which lies superior and lateral to the proximal inferior epigastric artery *(IEA).* Hernia sac then courses horizontally in an inferomedial direction within the inguinal canal *(IC).* Indirect inguinal hernias always pass superficial to the IEA.

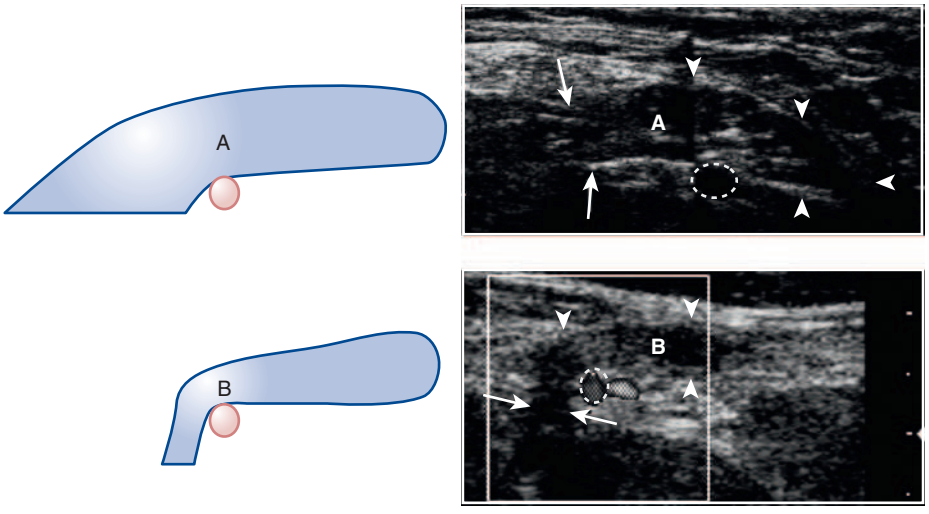

FIG. 13.13 Indirect Inguinal Hernias: Two Types. (A) Sliding type. The neck *(arrows)* is as wide as or wider than the fundus *(arrowheads),* with loss of the angle between the internal inguinal ring and inguinal canal. Sliding hernias usually contain intraperitoneal contents and are reducible. **(B) Nonsliding type.** The neck *(arrows)* is narrow in comparison to the fundus *(arrowheads),* and the nearly 90-degree angle between the internal inguinal ring and inguinal canal is preserved. Nonsliding hernias usually contain only properitoneal fat and are nonreducible. They have often been misclassified as "lipomas" of the inguinal canal or spermatic cord. *Circle,* inferior epigastric artery.

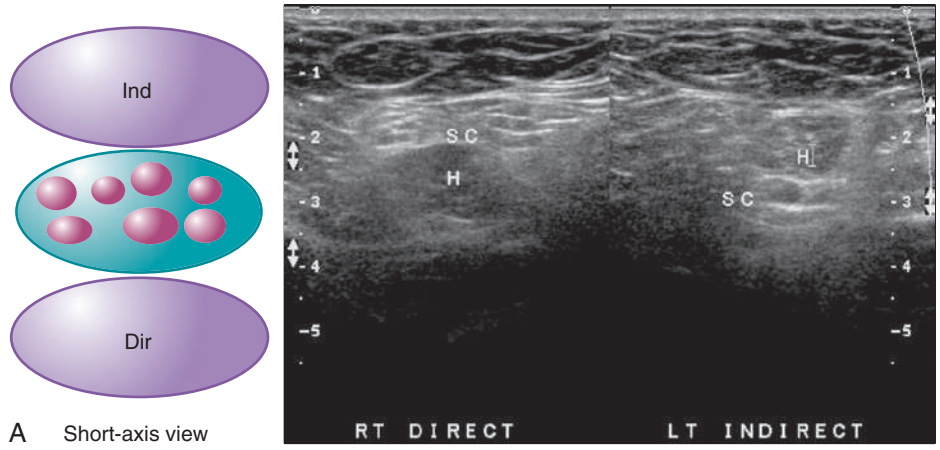
cord lipomas can occur, but are rare. Nonsliding indirect inguinal hernias are more difficult to diagnose sonographically than sliding types because (1) they tend to be smaller; (2) they contain only fat, which is almost isoechoic with surrounding tissues; and (3) their nonreducibility minimizes motion of contents during dynamic maneuvers. In the short axis, the sliding type of direct inguinal hernia can be diagnosed at either the level of the internal inguinal ring or the level of the inguinal canal. However, the nonsliding type can be diagnosed only at the level of the inguinal canal, where it is widest.

In some cases, it can be difficult to demonstrate the relationship of the hernia neck to the inferior epigastric vessels. In such cases, it is helpful to assess the relationship of the hernia sac to the spermatic cord. In males, indirect inguinal hernias tend to lie



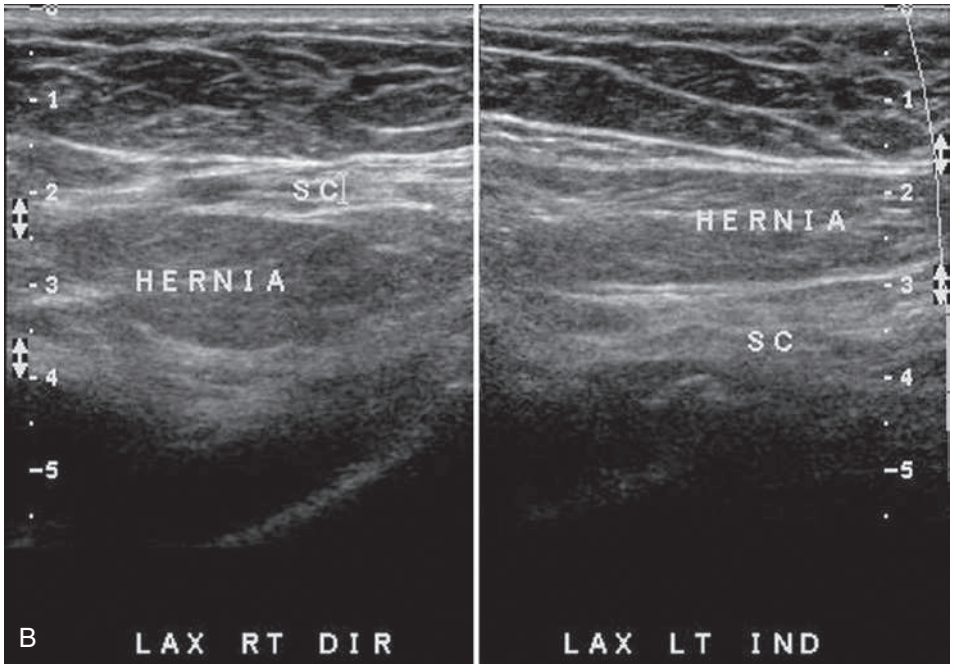


FIG. 13.14 Hernia Sacs Relative to Spermatic Cord. (A) Direct *(Dir)* and indirect *(Ind)* hernia sacs relative to the spermatic cord *(SC). Left,* Drawing shows that indirect inguinal hernia sac tends to lie anterior to spermatic cord, whereas direct inguinal hernia sac lies posterior to the cord. *Center,* Short-axis view shows fat-containing direct inguinal hernia *(H)* posterior and medial to the spermatic cord *(SC). Right,* Short-axis view shows fat-containing indirect inguinal hernia *(H)* lying anterior and lateral to the spermatic cord *(SC).* **(B)** Long-axis views of right direct and left indirect inguinal hernias in the same patient. *Left,* Image shows the right direct inguinal hernia sac lying posterior to the spermatic cord *(SC). Right,* Image shows the left indirect inguinal hernia sac lying anterior to the spermatic cord *(SC).*

along the anterolateral aspect of the spermatic cord, whereas direct inguinal hernia sacs tend to lie posteromedial to the cord (Fig. 13.14). In females, indirect inguinal hernias lie anterior to the round ligament (Fig. 13.15). Large indirect inguinal hernias can flatten and splay the spermatic cord (Figs. 13.16 and 13.17), causing pain that radiates into the scrotum. Indirect inguinal hernias are much more likely than direct inguinal hernias to extend into the scrotum or labium majus (Fig. 13.18, Video 13.9).

Direct Inguinal Hernias

The characteristic finding of a direct inguinal hernia is focal intraabdominal tissue moving anteriorly through the Hesselbach triangle.[1,8,22,23] On ultrasound, this tissue of variable echogenicity will move characteristically in a posterior-to-anterior direction.[1]

Direct inguinal hernias are the second most common type of groin hernia and are acquired. The incidence increases with age, as this type of hernia results from a weakening of the tranversalis fascia in the Hesselbach triangle.[27] The Hesselbach triangle is anatomically bounded inferiorly by the inguinal ligament, medially by the lateral margin of the rectus abdominis, and superolaterally by the IEA.

Direct hernias arise in two ways: either a passing through a defect in the "conjoined tendon" (Fig. 13.19) or by greatly stretching the tendon into the inguinal canal (Fig. 13.20). During open hernia repair, direct inguinal hernias protrude "directly" into the opened inguinal canal from a posterior direction. Indirect

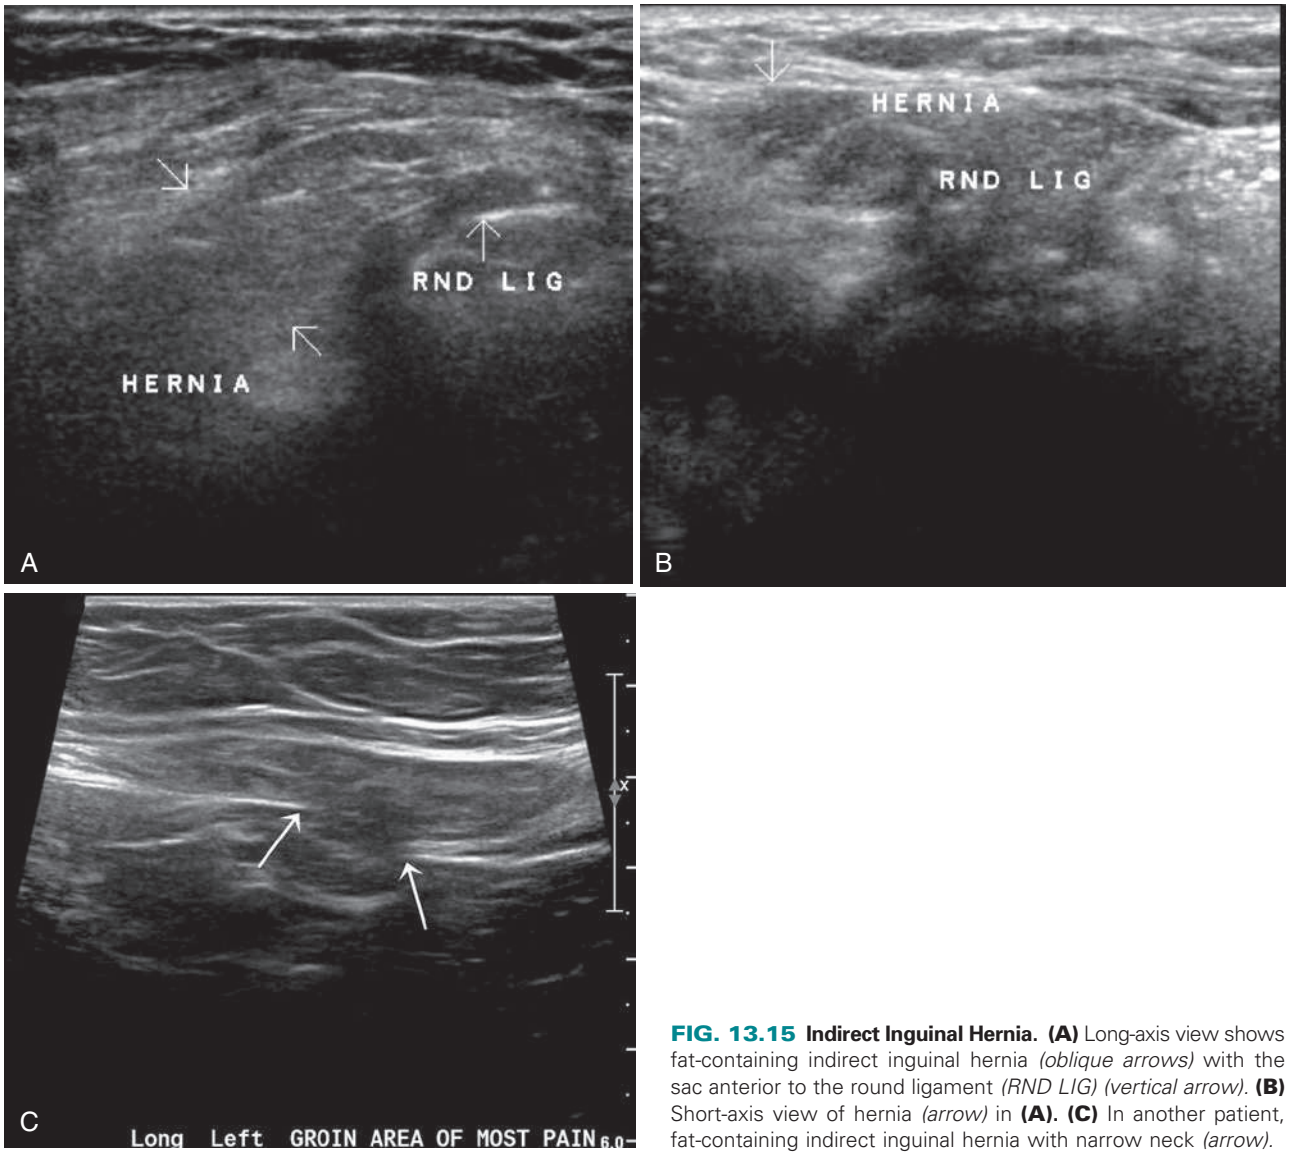

FIG. 13.15 Indirect Inguinal Hernia. (A) Long-axis view shows fat-containing indirect inguinal hernia *(oblique arrows)* with the sac anterior to the round ligament *(RND LIG) (vertical arrow)*. **(B)** Short-axis view of hernia *(arrow)* in **(A). (C)** In another patient, fat-containing indirect inguinal hernia with narrow neck *(arrow)*.

inguinal hernias, on the other hand, extend into the opened inguinal canal "indirectly" from a superior and lateral direction. The conjoined tendon area, and thus the neck of a direct inguinal hernia, arises inferior and medial to the inferior epigastric vessels (Fig. 13.21).

The neck of direct inguinal hernias is typically wider than the fundus. This makes incarceration and strangulation of direct hernias rare. Most small to medium direct inguinal hernias are completely reducible, but large direct inguinal hernias may be incompletely reducible, especially in the upright position. Most direct inguinal hernias spontaneously reduce completely in the supine position during quiet respiration, and therefore they are visible only during Valsalva maneuvers or in the upright position.

The **conjoined tendon** consists of the aponeuroses of the internal oblique and transverse abdominis muscles and the underlying transversalis (transverse) fascia. It is located inferior to the lower edge of the external oblique aponeurosis. In most patients the aponeuroses of the internal oblique and transverse abdominis muscles are not closely adherent to each other; the aponeurosis of the transverse abdominis is separated from the underlying transversalis fascia and peritoneum by a variable layer of preperitoneal fat; and the conjoined tendon is not well defined (Fig. 13.22).

Thinning and anterior bulging of the conjoined tendon **(conjoined tendon insufficiency)** is a precursor to development of direct inguinal hernias. In males the anterior bulging displaces and rotates the spermatic cord laterally. The thinning and bulging of the conjoined tendon push the aponeuroses of the internal oblique and transverse abdominis muscles closer together, making the conjoined tendon appear to be a more discrete structure than when the patient is in the supine position and in quiet respiration (Figs. 13.23 and 13.24). As the thinning and bulging progress, a **tear** can form within the tendon, leading to the formation of a direct inguinal hernia. Smaller direct inguinal hernias extend anteriorly into the floor of the inguinal canal, but larger

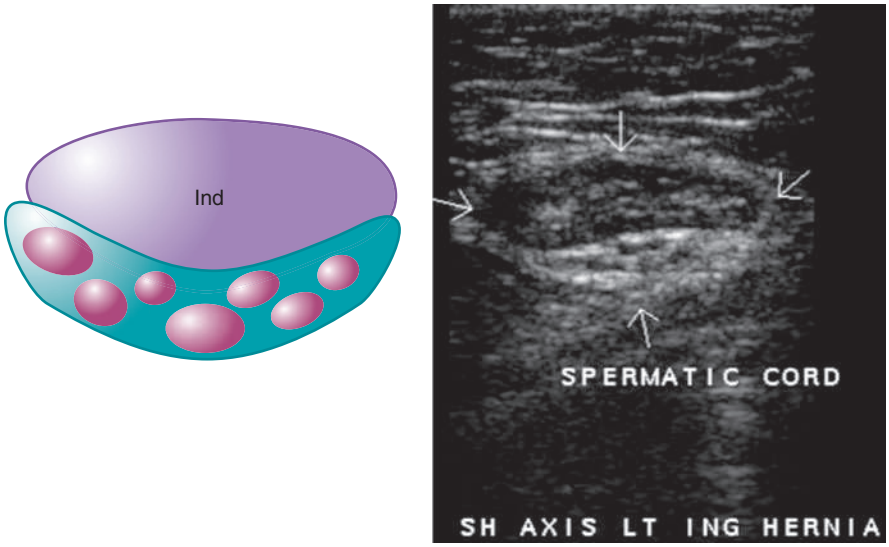

FIG. 13.16 Indirect *(Ind)* Inguinal Hernia. (A) Drawing and **(B)** sonogram. Short-axis view shows indirect inguinal hernia displacing and compressing the hyperechoic spermatic cord posteriorly.

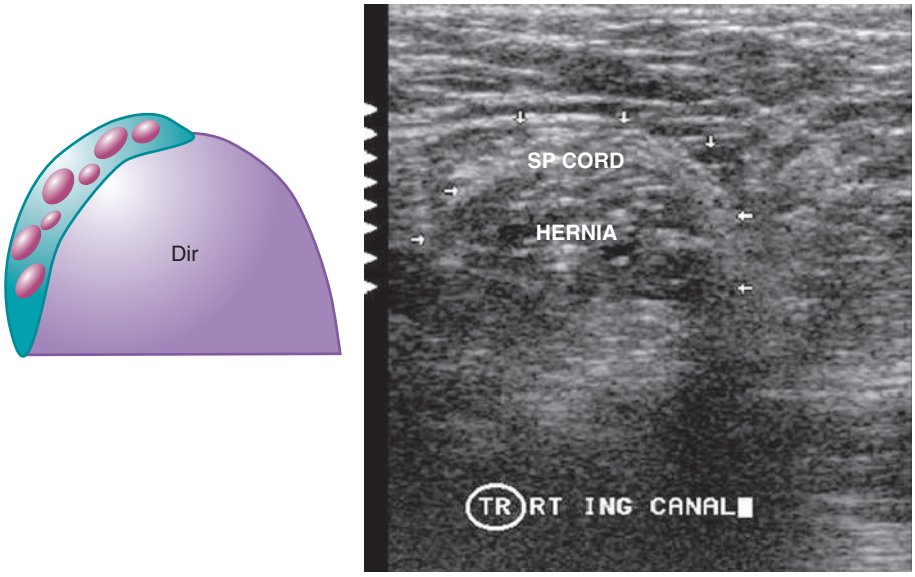

FIG. 13.17 Direct *(Dir)* Inguinal Hernia. Short-axis view shows direct inguinal hernia displacing and compressing the hyperechoic spermatic cord *(SP CORD)* anteriorly and laterally. See also Video 13.10.

hernias turn inferomedially, extending distally within the canal. Factors associated with conjoined tendon insufficiency progression to frank direct inguinal hernia include increased intraabdominal pressure (obesity, pregnancy, ascites, coughing, straining) and generalized connective tissue weakness. Because these underlying causes affect both sides, direct inguinal hernias are frequently bilateral, although often asymmetric in size and symptoms (Fig. 13.25). Direct inguinal hernia and its precursor, posterior inguinal wall insufficiency, are a common problem for athletes (see Sports Hernias).

Femoral Hernias

The characteristic finding of a femoral hernia is abnormal intraabdominal contents moving in an inferior direction through the femoral canal.[1,8] Femoral hernias have been described as having a sonographic appearance of a hypoechoic sac with speckled internal echoes. When examining during the Valsalva maneuver, a femoral hernia passes deep to the inguinal ligament, expands the femoral canal, displacing the normal canal fat, and effaces the femoral vein.[28]

Femoral hernias are less common than inguinal hernias and are difficult to diagnose clinically unless strangulated. Unlike inguinal hernias, femoral hernias are more common in women than in men.[8,24] Ultrasound has high accuracy (96.9%) for diagnosis of nonpalpable femoral hernias in patients with symptoms.[29] It is thought that the increased intrapelvic pressure that occurs during the third trimester of pregnancy, together with the hormone-induced softening of tissues, predisposes to the development of femoral hernias. They are twice as common on the right as on the left side.[30]

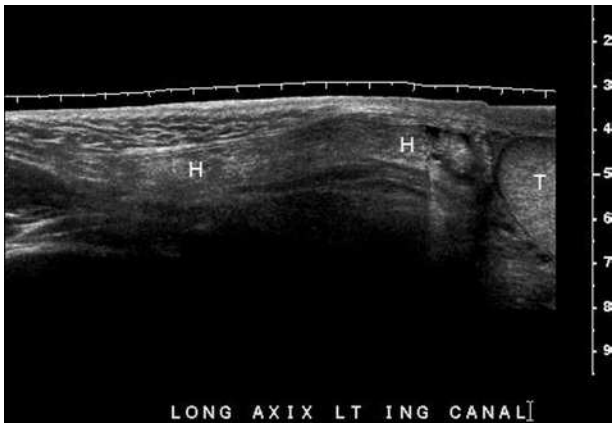

FIG. 13.18 Indirect Inguinal Hernia. Long-axis extended–field-of-view (FOV) image shows extremely large, indirect inguinal hernia *(H)* extending down the entire length of the inguinal canal into the scrotum. *T,* Testis. See also Video 13.9.

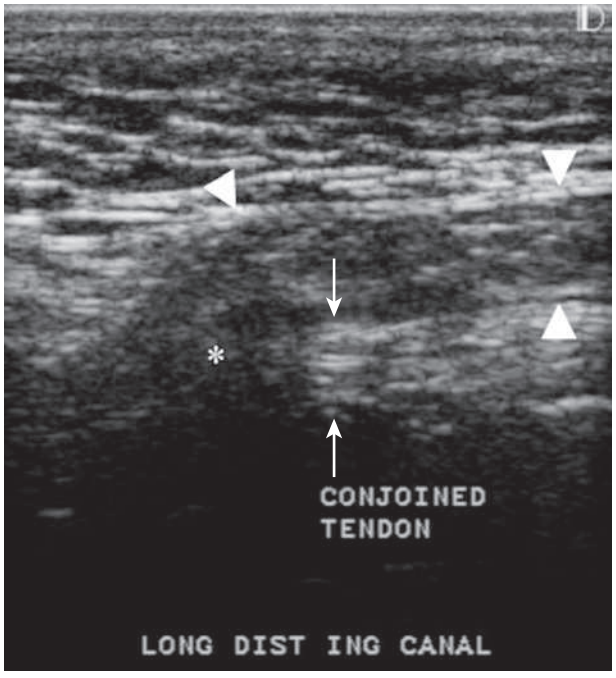

FIG. 13.19 Direct Inguinal Hernia. Long-axis view shows fat-containing direct inguinal hernia passing through an acute tear (*) in the conjoined tendon *(arrows)* and extending down the inguinal canal *(arrowheads).*

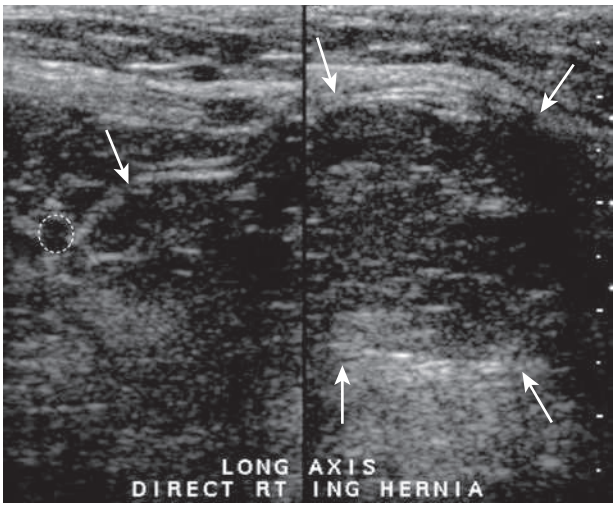

FIG. 13.20 Direct Inguinal Hernia. Long-axis view of large, direct inguinal hernia shows the thinned and stretched conjoined tendon and underlying transversalis fascia and peritoneum *(arrows)* forming the hernia sac. Note that the neck of direct inguinal hernias arises inferior and medial to the inferior epigastric artery *(circle).*

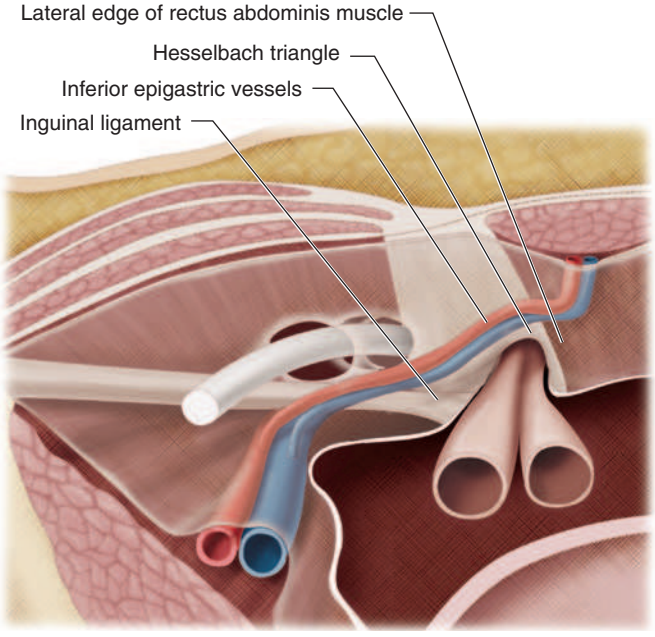

FIG. 13.21 Direct Inguinal Hernia. Diagram of the deep aspect of the anterior abdominal wall depicting a left direct inguinal hernia. The hernia sac protrudes through the Hesselbach triangle, which is bounded by the inferior epigastric vessels, lateral edge of the rectus abdominis muscle, and inguinal ligament. (With permission from Granja M, Rivero O, Aguirre D. Abdominal wall hernias. In: Sahani DV, Samir AE, editors. Abdominal imaging. 2nd ed. Philadelphia: Elsevier; 2017:1014-1025.[43])

Femoral hernias arise within the femoral canal inferior to the inguinal canal and ilioinguinal crease. The **femoral canal** lies just medial to the **common femoral vein** (CFV) and just superior to the **saphenofemoral junction** (Fig. 13.26, Video 13.10). The most common location for femoral hernias is medial to the CFV, but a few lie anterior to the common femoral vessels (Figs. 13.27 and 13.28). Most femoral hernias that lie anterior to the CFV arise medially and then extend anteriorly. It is rare for a femoral hernia to actually arise anteriorly **(Teale hernia)** (Fig. 13.29). Although femoral hernias reportedly can lie posterior or lateral to the CFV, we have never seen one in either of these locations. A femoral hernia tends to have a narrow neck in comparison to the width of its fundus, a shape that predisposes the femoral hernia to strangulation. Because of the narrowness of the femoral ring (the opening that forms the neck of a femoral hernia), it is more likely than an inguinal hernia to become incarcerated and strangulated[24,31] (Fig. 13.30). Femoral hernia contents vary, and most contain only fat. Femoral hernias that contain bowel are almost always nonreducible and frequently are strangulated.

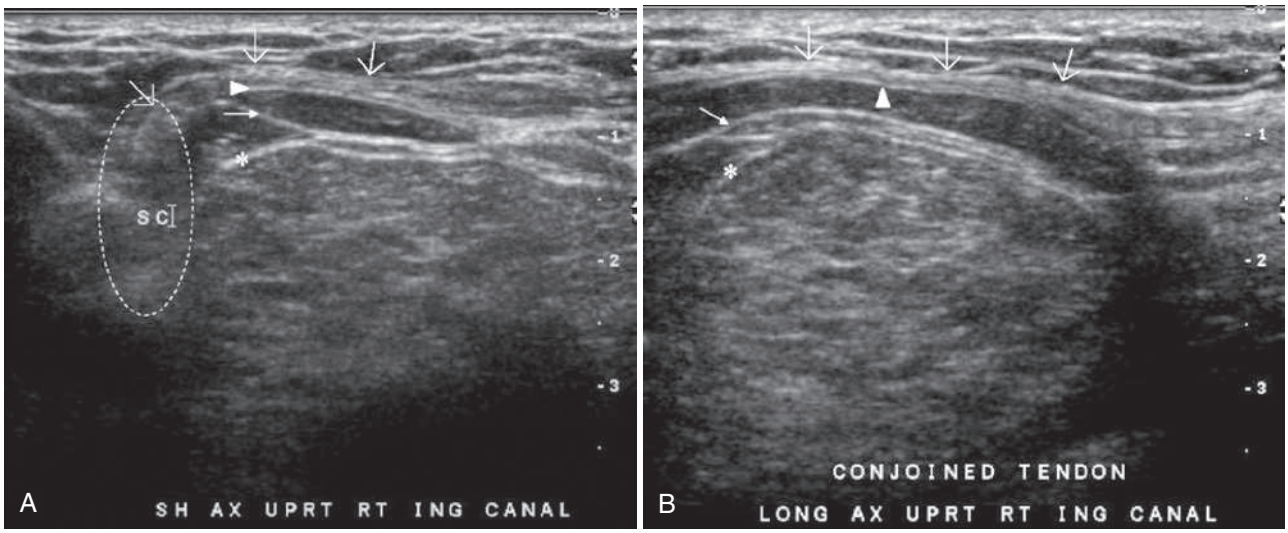

FIG. 13.22 Direct Inguinal Hernia. (A) Short-axis view of direct inguinal hernia shows a thinned and bulging conjoined tendon, consisting of the internal oblique aponeurosis *(superficial arrows)* and transverse abdominis aponeurosis *(arrowhead),* and underlying transversalis fascia *(horizontal arrow)* and peritoneum (*). *SC* and *oval dotted lines* indicate spermatic cord. **(B)** Long-axis view shows the conjoined tendon *(among three vertical arrows and arrowhead),* underlying transversalis fascia *(oblique arrow),* and peritoneum (*).

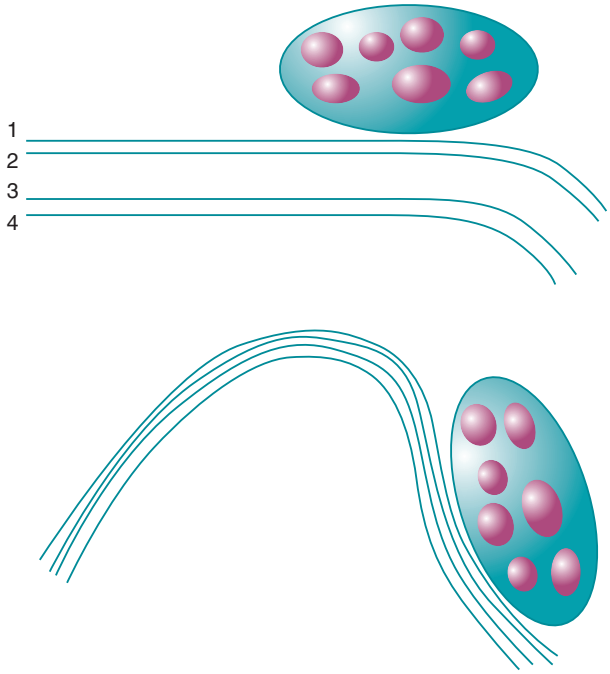

FIG. 13.23 Conjoined Tendon: Two Views. *Upper illustration,* Relationship of the conjoined tendon to the spermatic cord in quiet respiration in the supine position. The layers are separated by loose connective tissues or fat. *Lower illustration,* Bulging of the conjoined tendon during Valsalva maneuver or in the upright position. The layers tend to be pushed together and are more difficult to distinguish from one another. When the aponeuroses of the internal oblique *(1)* and transverse abdominis *(2)* muscles are pushed together, the conjoined tendon appears as a more discrete structure. *3,* Transversalis fascia; *4,* peritoneum. The anterior bulging of the conjoined tendon pushes the spermatic cord laterally and rotates it from a "wider-than-tall" orientation to a "taller-than-wider" orientation.

The femoral canal lies deeper than the inguinal canal and may be more difficult to assess with a high-frequency linear array transducer. Small and even moderate-sized femoral hernias frequently reduce completely in the supine position during quiet respiration and are most readily demonstrated during the Valsalva maneuver or in the upright position during compression maneuvers. Femoral hernias are often bilateral (see Fig. 13.2C).

Spigelian Hernias

Spigelian hernias are usually considered anterior abdominal wall hernias rather than groin hernias. They can occur anywhere along the course of the **spigelian fascia,** the complex aponeurotic tendon that lies between the oblique muscles laterally and the rectus muscles medially. However, almost all spigelian hernias occur at the inferior end of the **semicircular line,** inferior to the arcuate line, where the posterior rectus sheath is absent, and where the spigelian fascia is penetrated and weakened by the inferior epigastric vessels (Fig. 13.31). In many patients, this location is within 2 cm of the internal inguinal ring. Furthermore, when symptomatic, the pain caused by spigelian hernias can be difficult to distinguish from that caused by indirect inguinal hernias. Therefore we are including spigelian hernias in our discussion of groin hernias, because sonographic diagnosis of these patients is possible when they are referred for lower quandrant pain.[32]

Spigelian hernias are associated with conditions that increase intraabdominal pressure.[33,34] The spigelian fascia is composed of several different layers of loosely apposed aponeurotic tendons. From external to internal lie the aponeuroses of the external oblique, internal oblique, and transverse abdominis muscles. Internal to the aponeuroses lie the transversalis fascia and peritoneum. In spigelian hernias the transverse abdominis tendon

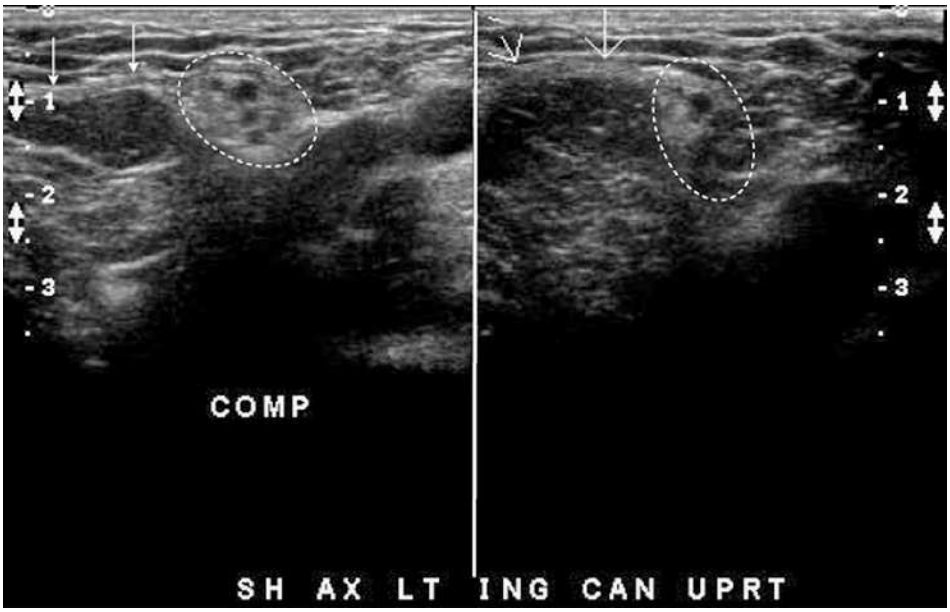

FIG. 13.24 Conjoined Tendon: Two More Views. *Left image,* Relationship of the conjoined tendon *(arrows)* to the spermatic cord *(dashed oval)* in quiet respiration in the supine position. The conjoined tendon lies posterior to the spermatic cord. *Right image,* Valsalva maneuver results in anterior bulging of the conjoined tendon, which now protrudes anterior to the spermatic cord and pushes and rotates the cord laterally.

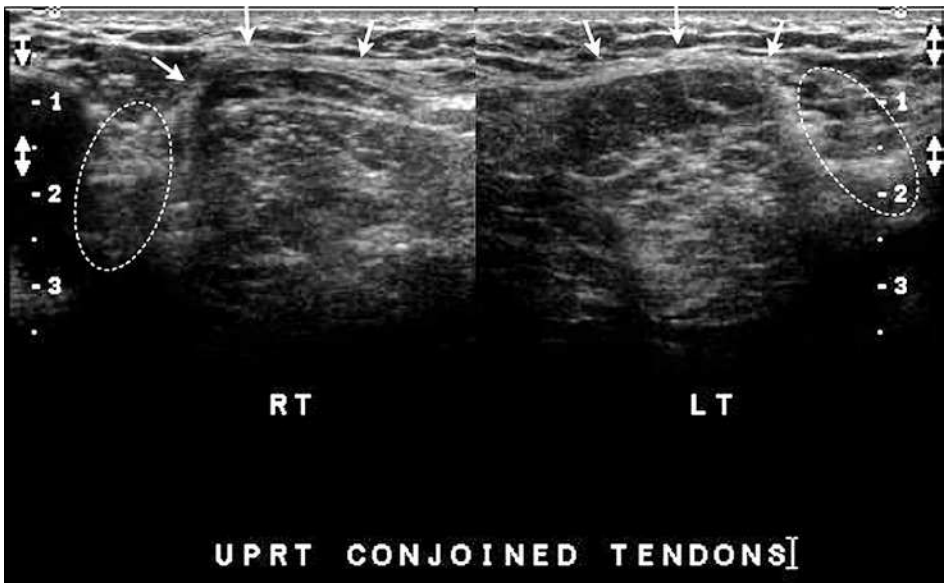

FIG. 13.25 Bilateral Inguinal Hernias. Short-axis views show bilateral fat-containing direct inguinal hernias, which are common. Markings are the same as in Fig. 13.24.

is always torn. In most cases the internal oblique aponeurosis is also torn (Fig. 13.32). The external oblique tendon is always intact and usually forces the hernia sac to extend either medially over the anterior aspect of the rectus abdominis muscle or laterally over the external oblique muscle, forcing it into the shape of an anvil or mushroom (Figs. 13.33 and 13.34). As with femoral hernias, spigelian hernias have narrow necks and broad fundi (Video 13.11 and Video 13.12), making them at least partially nonreducible and predisposing them to strangulation (Fig. 13.35). Because spigelian hernias pass through multiple layers of tendons, projections of the hernia may also extend intraparietally between the multiple layers of lateral muscles (either between the transverse abdominis and internal oblique muscles or between the internal and external oblique muscles). In some cases the spigelian fascia, like the linea alba, can become diastatic and widen. Extended-FOV modes may be helpful in demonstrating the anatomy in such cases (see Figs. 13.32 and 13.33). Sonography shows a complex mass within the anterolateral aspect of the abdominal wall, which may contain fluid or gas-filled loops of bowel.[35]

Sports Hernias

Sports hernia is a common cause of groin and pubic pain among elite and professional athletes. In a review of chronic groin pain in athletes, sports hernia was found in 50%.[36] Sports hernia, also

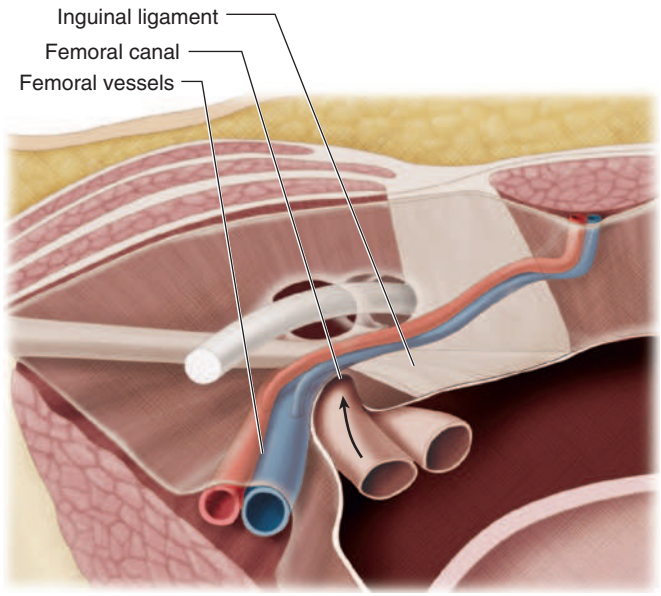

FIG. 13.26 Femoral Hernia. Diagram of the deep aspect of the anterior abdominal wall depicting a left femoral hernia. The hernia sac protrudes through the femoral canal *(arrow)* medial to the femoral vessels and inferior to the inguinal ligament.

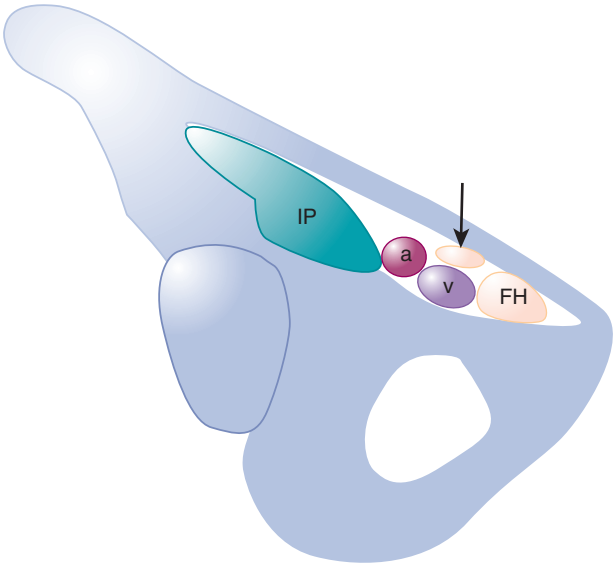

FIG. 13.27 Femoral Hernia: Relationship to Femoral Vessels. Short-axis view shows that most femoral hernias arise medial to the common femoral vein (CFV) and can extend anterior to the CFV as they enlarge. A few small femoral hernias (Teale hernias) may arise anterior to the CFV *(arrow). a,* Common femoral artery; *FH* and *arrow,* most common femoral hernia locations; *IP,* iliopsoas muscles; *v,* CFV.

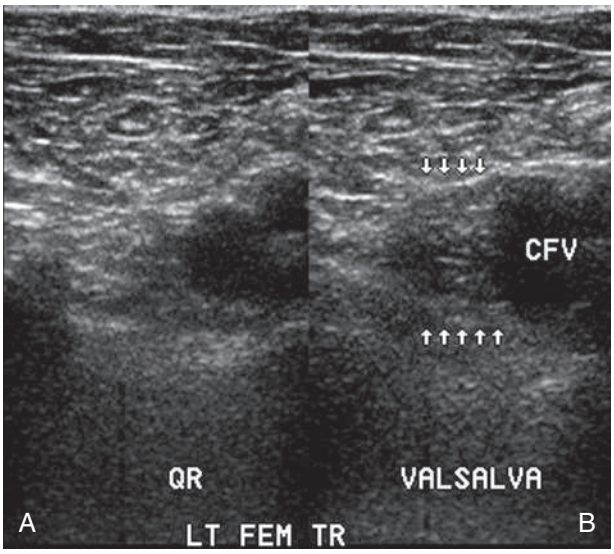

FIG. 13.28 Femoral Hernia on Valsalva Maneuver. (A) No evidence of a femoral hernia during quiet respiration. **(B)** During a Valsalva maneuver, a fat-containing femoral hernia *(arrows)* appears medial to the common femoral vein *(CFV).*

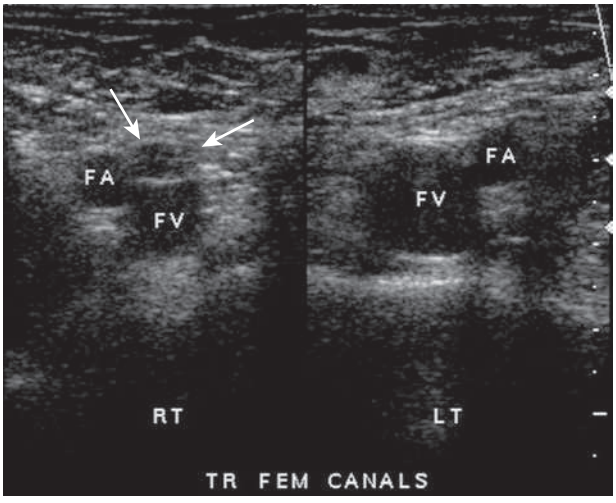

FIG. 13.29 Teale Femoral Hernia. Small, Teale type of right femoral hernia lying anterior to the common femoral vein *(FV),* but with no femoral hernia on the left. *FA,* Femoral artery.

called "sportsman's hernia" and "athletic pubalgia," is complex because it occurs in an area where many tendons come together and are difficult to separate from one another, and where weakness in one tendon may lead to failure of another or to instability of the pubic symphysis. Also, multiple abnormalities often contribute to pain. Surgery may help some of the underlying causes, but not others.

Sports hernias most often occur in elite athletes whose sport involves cutting, pivoting, kicking, and sharp turns, such as soccer, ice hockey, or football.[37] "Sports pubalgia" can be especially debilitating for elite and professional athletes, causing long periods of disability, and can be career threatening. Sports hernias are much more common in men than in women because of differences in the insertion of the rectus muscles into the pubis, but the incidence is increasing in women.

The type of hernia most often associated with groin pain in athletes is the **direct inguinal hernia** or its precursor, "posterior inguinal wall deficiency" (conjoined tendon insufficiency). In many athletes with groin pain, however, the hernia is not the only, or even the main, cause of pain. Dynamic ultrasound is the best modality for demonstrating groin hernias associated

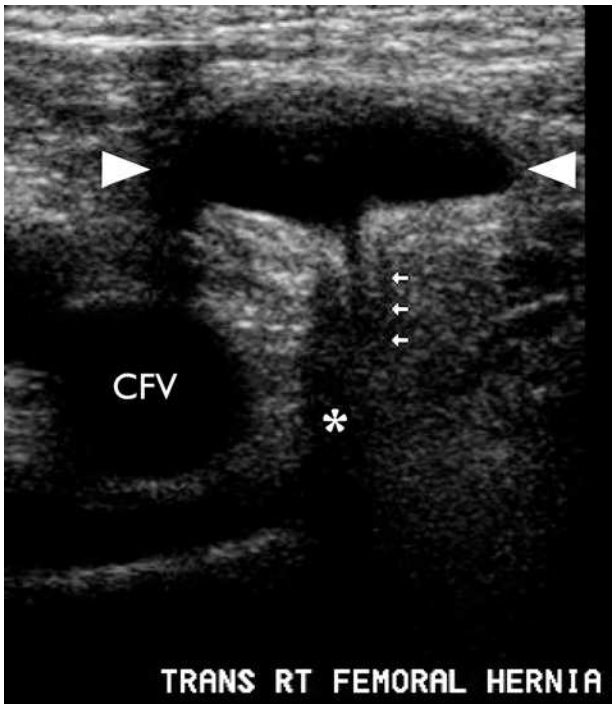

FIG. 13.30 Nonreducible Femoral Hernia. Short-axis view shows large, nonreducible femoral hernia that arises within the femoral canal (*) medial to the common femoral vein *(CFV)*. The long, narrow neck *(arrows)* extends directly anteriorly, and the large fundus *(arrowheads)* filled with peritoneal fluid causes this hernia to be at extremely high risk for strangulation.

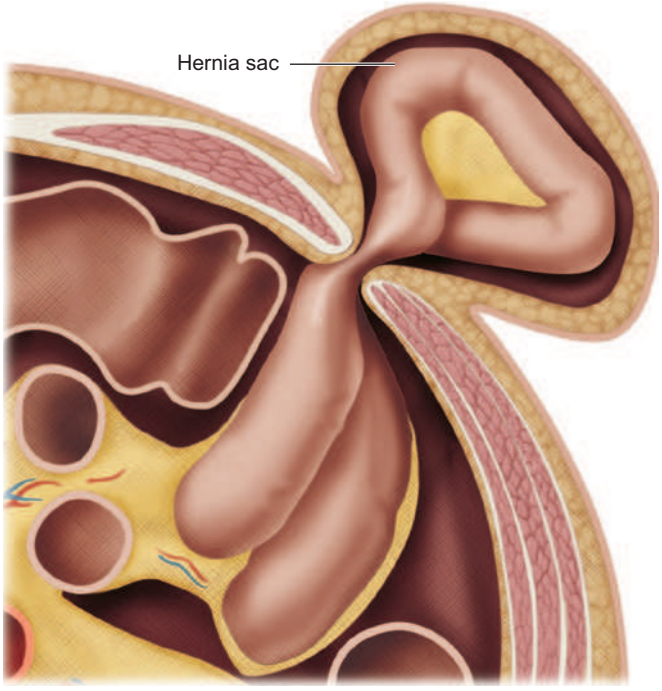

FIG. 13.31 Spigelian Hernia. Diagrammatic axial view of the abdomen at the level of the umbilicus depicting a complete Spigelian hernia. The hernia sac protrudes through the linea semilunaris. In complete spigelian hernias the hernia sac protrudes through the complete thickness of the wall musculature. (With permission from Granja M, Rivero O, Aguirre D. Abdominal wall hernias. In: Sahani DV, Samir AE, editors. Abdominal imaging. 2nd ed. Philadelphia: Elsevier; 2017:1014-1025.[43])

with sports pubalgia.[38] In a study of 1450 athletes in a sports medicine clinic who had long-standing pubalgia but no clear evidence of hernia, 580 (40%) were felt to have "sport hernia." In 573 patients, ultrasound examination detected some protrusion of the posterior wall with normal or minimally dilated inguinal rings; 498 of them coincided with areas affected by pain. Compared with findings of laparoscopy, ultrasound had a sensitivity of 95.42% and a specificity of 100%.[38]

The underlying pathology is usually **tendinosis** (degenerative change in tendons without signs of inflammation) of either the adductor longus origin or the rectus abdominis insertion. The tendons of these two muscles interdigitate, making them inseparable from each other as they insert onto the pubis. Tendinosis of one tendon usually leads to tendinosis of the other, and eventually to instability of the pubic symphysis and **osteitis pubis.** Tendinosis of the rectus abdominis muscle can also lead to microtears in which the aponeuroses of the internal oblique and transverse abdominis muscles (components of conjoined tendon) insert onto the rectus sheath, causing them to bulge anteriorly into the inguinal canal (posterior inguinal wall insufficiency or conjoined tendon insufficiency) and also leading to dilation of the external (superficial) inguinal ring. The thinned and bulged conjoined tendon pushes the spermatic cord laterally, rotates it, and compresses it. Because of the effects on the spermatic cord, the resulting pain often radiates into the scrotum.

Posterior inguinal wall insufficiency is usually bilateral, even though symptoms may be only unilateral. In the short axis, posterior inguinal wall insufficiency appears indistinguishable from direct inguinal hernia (see Figs. 13.23 and 13.24). In the long axis, however, posterior inguinal wall insufficiency and direct inguinal hernia have different shapes. The posterior wall insufficiency is semicircular, whereas the direct inguinal hernia protrudes inferiorly within the inguinal canal in a fingerlike projection (Fig. 13.36). At the level of the proximal inguinal canal, insufficiency and hernia can be distinguished only in the long axis, appearing identical in the short axis. More distally within the inguinal canal, however, the distinction can be made in the short axis. The direct inguinal hernia sac will be seen posterior to the spermatic cord (see Fig. 13.14), whereas in posterior inguinal wall insufficiency, the inguinal canal will appear normal.

Posterior inguinal wall insufficiency can progress to direct inguinal hernia in two ways: the conjoined tendon can tear completely, or the tendon can become so thinned and stretched that it is pushed inferomedially into the distal inguinal canal. Both complications arise inferior and medial to the origin of the inferior epigastric vessels. In patients with acute tendon tears, the neck is small, and the hernia sac appears thin (transversalis fascia and peritoneum) (Fig. 13.37). In severe stretching of the conjoined tendon, however, the neck is wide, and the hernia sac appears thicker (aponeuroses of internal oblique and transverse abdominis muscles as well as transversalis fascia and peritoneum) (see Figs. 13.20 and 13.36).

Because there is usually some degree of **tendinosis** or **osteitis pubis,** even when a direct inguinal hernia or posterior inguinal wall insufficiency is present, simply assessing sonographically for hernia is often insufficient for the workup of these patients.

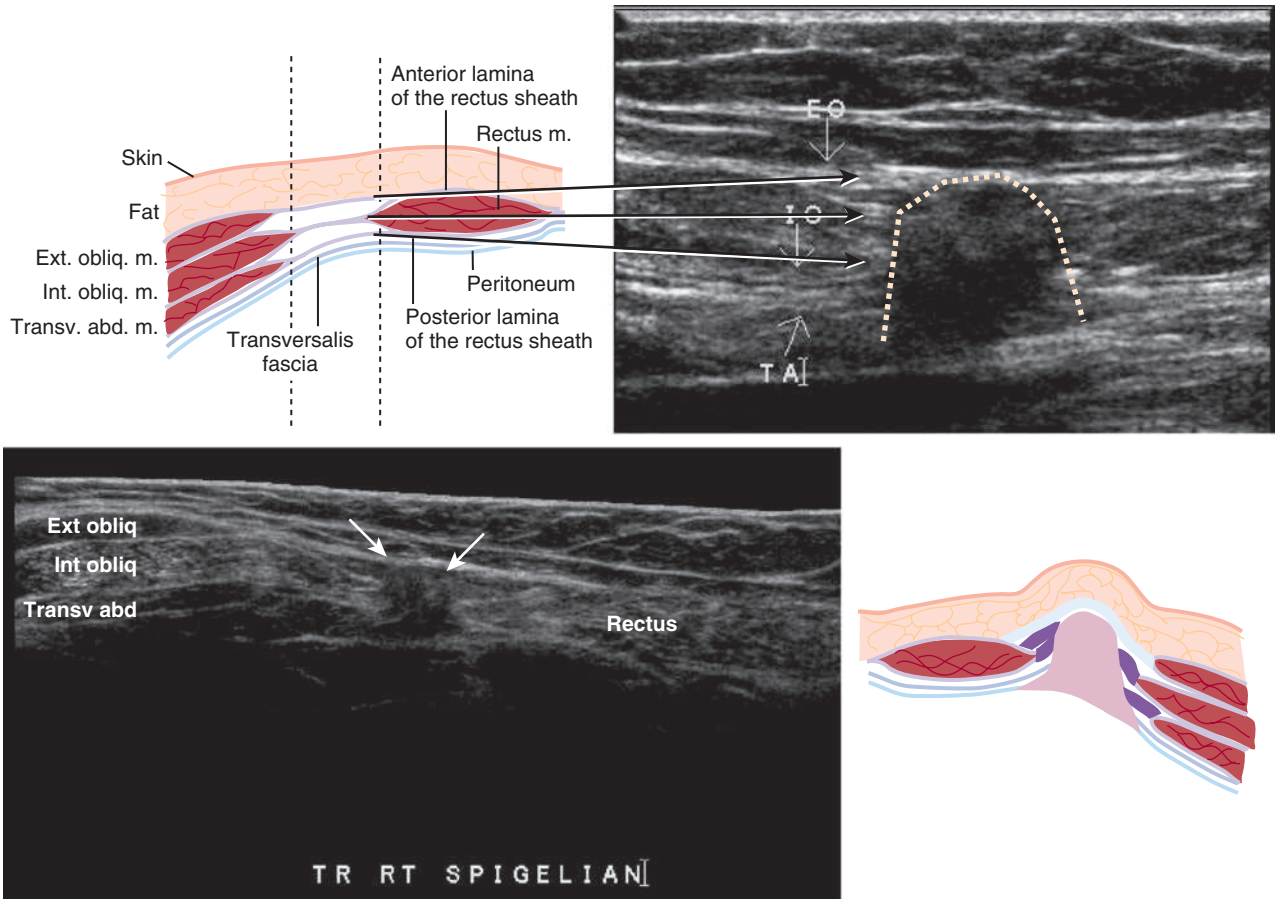

FIG. 13.32 Spigelian Hernia: Torn Aponeuroses. Small, spigelian hernia in which the aponeuroses of both the transverse abdominis *(TA)* and internal oblique *(IO)* muscles are torn, but in which the external oblique *(EO)* aponeurosis, as usual, is intact. This is the most common pattern of aponeurosis defects in spigelian hernias.

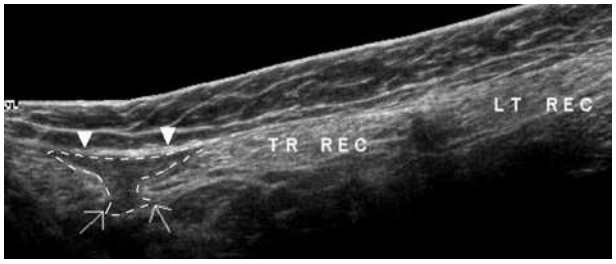

FIG. 13.33 Spigelian Hernia: "Mushroom" Shape. Transverse extended–field-of-view sonogram shows small, nonreducible, fat-containing right spigelian hernia. Because the external oblique aponeurosis is not torn, it forces the hernia sac to extend medially over the anterior surface of the right rectus muscle and laterally over the anterior aspect of the right external oblique muscle. This results in a mushroom or anvil shape, which correlates with nonreducibility and an increased risk of strangulation.

FIG. 13.34 Spigelian Hernia: Typical Shape. Nonreducible left spigelian hernia contains bowel and has a narrow neck and broad fundus, the typical shape for spigelian hernias.

Ultrasound can show tendinosis in the rectus and adductor tendons in some cases (Fig. 13.38), but not as reliably as MRI, which can also demonstrate osteitis pubis and findings such as the secondary cleft. In a patient with other pathology, only repairing an inguinal hernia or posterior wall deficiency may not cure the patient's groin pain. Thus optimal imaging workup of athletes with groin pain usually requires both dynamic ultrasound of the groin and MRI.[37,39] In patients with inguinal hernia or inguinal wall insufficiency, both surgical repair of the hernia and surgical or medical treatment of the associated tendinosis and pubic symphysis instability may be necessary.

Laparoscopic repair of sports hernia via either transabdominal preperitoneal or extraperitoneal approach has a high success

rate and earlier recovery of full sports activity compared with open surgery or conservative management.[40-42]

ABDOMINAL WALL OR VENTRAL HERNIAS

Ventral hernias are hernias through the anterior and lateral abdominal wall (excluding inguinal hernias). Midline hernias include umbilical, paraumbilical, epigastric, and hypogastric. Included in our discussion of abdominal wall hernias are incisional hernias, although these of course can occur where any incision has been made. Spigelian hernias are discussed earlier with inguinal region hernias, but when located above the groin, they are also considered in this group of ventral hernias. After adhesions, abdominal wall hernias are the second leading cause of small bowel obstruction and account for 10% to 15% of all small bowel obstructions.[43,44] However, as these authors point out, the presence of a hernia does not imply that it is the source of the obstruction. To establish the hernia as the obstructing point, one must make an effort to demonstrate the dilated loop leading into the hernia sac and a collapsed loop exiting from the point.[44] These hernias have increased in incidence over time,[45] perhaps related to our aging population and comorbidities such as obesity.

FIG. 13.35 Strangulated Spigelian Hernia. Transverse extended–field-of-view image shows strangulated left spigelian hernia containing large bowel and fat *(arrows)*. Note the hyperechoic texture of the edematous strangulated contents.

Linea Alba Hernias

Linea alba hernias are anterior abdominal wall hernias that protrude through the linea alba. Those that occur superior to the umbilicus are called **epigastric hernias,** and those that occur inferior to the umbilicus are called **hypogastric hernias.** Hypogastric hernias are much less common than epigastric hernias because the linea alba is much narrower and shorter inferior to

B

FIG. 13.36 Inguinal Wall Insufficiency Versus Direct Inguinal Hernia. Long-axis views show different appearance of posterior inguinal wall insufficiency and direct inguinal hernia. **(A)** Insufficiency of the posterior inguinal wall *(long arrows)*. *Short arrow* is inferior epigastric artery. **(B)** Frank direct inguinal hernia extends distally within the inguinal canal in a fingerlike projection *(long arrows)* posterior to the spermatic cord. At the level of the proximal inguinal canal, the distinction is possible only on long-axis views, because insufficiency and frank hernia appear identical on short-axis views obtained proximally. *Short arrow* is inferior epigastric artery.

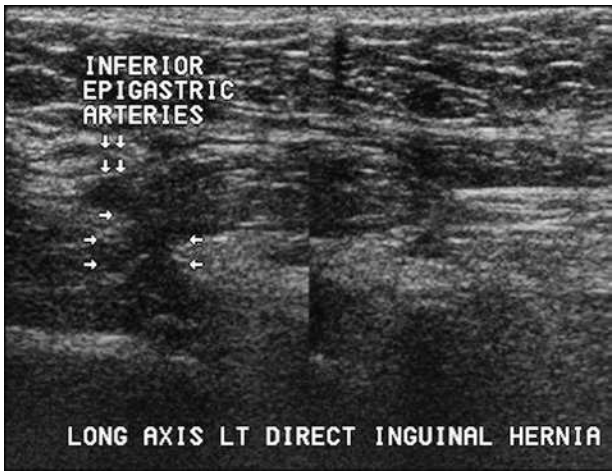

FIG. 13.37 Acute Tear of Conjoined Tendon *(Arrows).* Note that the neck is small in comparison to the fundus in this long-axis view. This is an unusual configuration for a direct inguinal hernia.

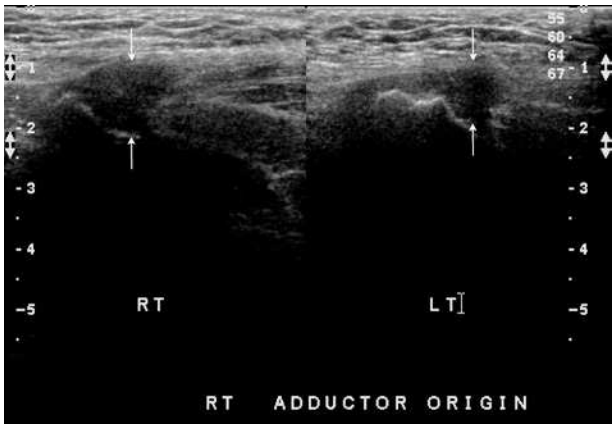

FIG. 13.38 Bilateral Tendinosis of Adductor Longus Tendons. Note that the edema and thickening of the tendon *(arrows)* is greater on the symptomatic right side than on the contralateral left side. The tendinosis in patients with athletic punbalgia is usually bilateral, but asymmetric.

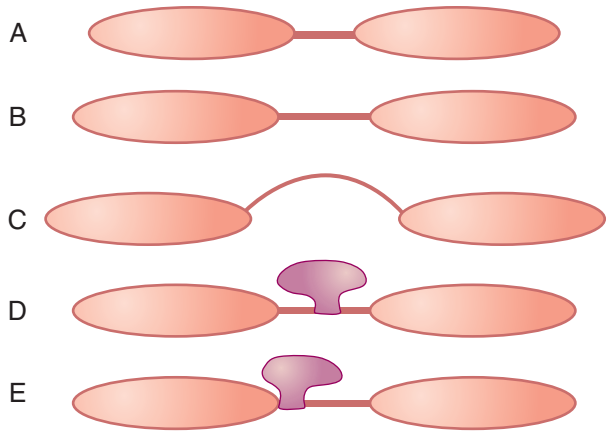

FIG. 13.39 Linea Alba Between Rectus Abdominis Muscles: Spectrum of Appearances. Transverse views. **(A)** Normal, thick linea alba. **(B)** Thinner but wider linea alba, possibly resulting from fewer decussations of rectus sheath fibers or representing diastasis recti when the patient is in the supine position in quiet respiration. **(C)** Marked thinning and bulging of the linea alba that occurs in diastasis recti during a Valsalva maneuver or in the upright position. **(D)** Typical small, epigastric linea alba hernia with its neck near the midline of the linea alba. **(E)** Small linea alba hernia with neck occurring eccentrically near the right edge of the linea alba. Note that linea alba hernias typically have narrow necks and broad fundi in the transverse view, a shape that correlates with nonreducibility and increased risk of strangulation.

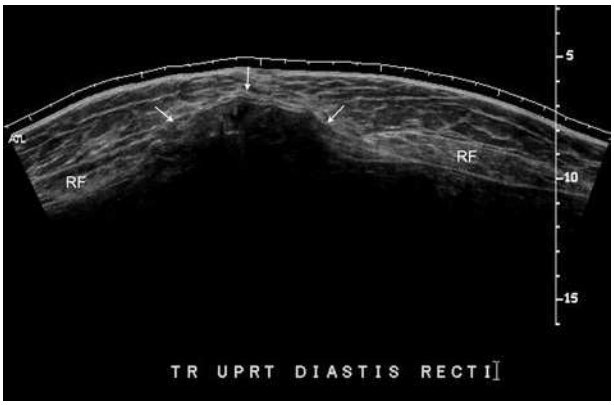

FIG. 13.40 Linea Alba–Diastasis Recti. Extended–field-of-view image obtained upright in the transverse plane shows marked widening, thinning, and bulging of the linea alba–diastasis recti abdominis.

the umbilicus than superior to the umbilicus. These are usually related to diastasis of the rectus abdominis muscles.

The **linea alba** is a thick layer of aponeurosis that separates the rectus abdominis muscles. It is formed by fusion and interlacing of fibers of the anterior and posterior sheaths of the right and left rectus muscles. Unlike the "conjoined tendon" and semilunar line, in which there are multiple thin layers of thin, loosely associated aponeuroses that do not form a discrete, well-defined structure, the linea alba is single, thick, well defined, extremely hyperechoic, and easily seen on ultrasound in most patients (Fig. 13.39A). However, the degree of decussation of fibers from the right and left sides varies. Most patients have three layers of interlaced fibers, but a minority of patients show only a single layer of interlaced fibers. In the latter group the linea alba is weaker and more predisposed to stretching (diastasis recti abdominis) and tearing (epigastric linea alba hernia).

Any cause of prolonged increased intraabdominal pressure can predispose toward weakening of the linea alba, including pregnancy, morbid obesity, and ascites. The first step is often **diastasis recti abdominis,** thinning and stretching of the linea alba that is most apparent during straining or in the upright position. The stretching of the linea alba pulls the decussated fibers apart, decreasing their interlacing, weakening the tendon, and predisposing to **epigastric herniation.**

In patients with diastasis, the linea alba is thinner and wider than normal. When the patient is supine and in quiet respiration, the associated anterior bulging of the tendon is not evident (see Fig. 13.39B). However, having the patient perform a Valsalva maneuver or raise the head off the pillow while lying supine, or having the patient stand, will make the anterior bulging visible (see Fig. 13.39C; Fig. 13.40, Video 13.13). In patients with diastasis recti abdominis, the anterior bulging extends along the entire craniocaudal length of the epigastric segment of the linea alba. In patients with epigastric hernia, any bulging will be more

localized along the craniocaudal axis. Although diastasis usually does not, epigastric hernias often do cause tenderness.

Epigastric linea alba hernias are easier to diagnose than are groin hernias as long as they are scanned with the proper transducer and the sonographer or physician is actually visually inspecting the linea alba. Epigastric hernias are usually superficial enough in location that they are best shown with 10- to 12-MHz linear array transducers. With these transducers, the defect through the linea alba is usually quite conspicuous because it is either isoechoic or hypoechoic compared with the extremely hyperechoic linea alba. The defect is usually very near the midline, but it may occur eccentrically toward the right or left side of the linea alba (see Fig. 13.39D-E; Figs. 13.41 and 13.42, Video 13.14). The most frequent reason for missing an epigastric linea alba hernia is that the examination for abdominal pain was performed with the standard 3-MHz curved linear array transducer, focused too deep in the elevation axis to identify any structures except large hernias in obese patients. The clinician must have an index of suspicion to use the appropriate transducer.

Although clinically detected epigastric hernias tend to be quite large and often contain bowel and other intraperitoneal contents, sonographically detected epigastric hernias are usually small to moderate-sized and contain only preperitoneal fat (Video 13.15). In hernias that contain only preperitoneal fat, the underlying peritoneal membrane and transversalis fascia are intact and the hernia cannot be seen or repaired laparoscopically. Epigastric hernias always have a very narrow neck in comparison to the size of the fundus and thus are usually not reducible and are at increased risk for strangulation, even when small. Some epigastric hernias that contain only preperitoneal fat are so small that it is difficult to believe that herniation is the cause of pain (Fig. 13.43). These hernias are not palpable, and patients typically have pain, which more likely results from the tear or tendinosis of the linea alba than from herniation of a tiny amount of properitoneal fat.

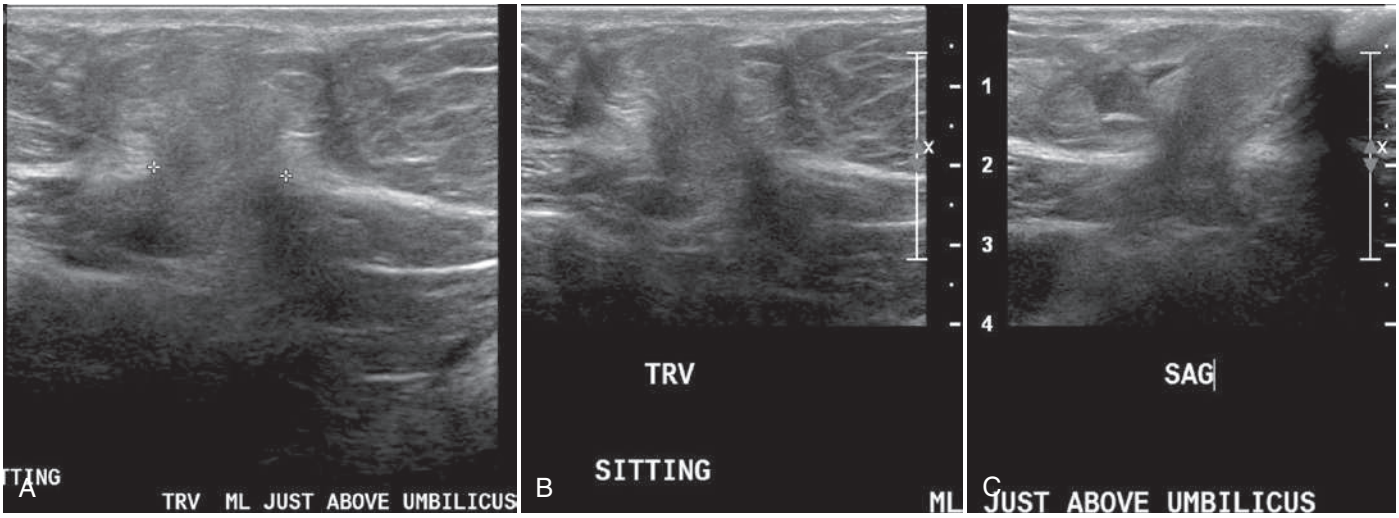

FIG. 13.41 Epigastric Linea Alba Hernia. Mesenteric fat protrudes through a 1-cm defect *(calipers)* in the linea alba at midline just above the umbilicus. Images were obtained in the transverse supine **(A),** transverse with patient sitting **(B),** and sagittal with patient sitting **(C).** Note the change in the appearance of the hernia defect with change in patient position.

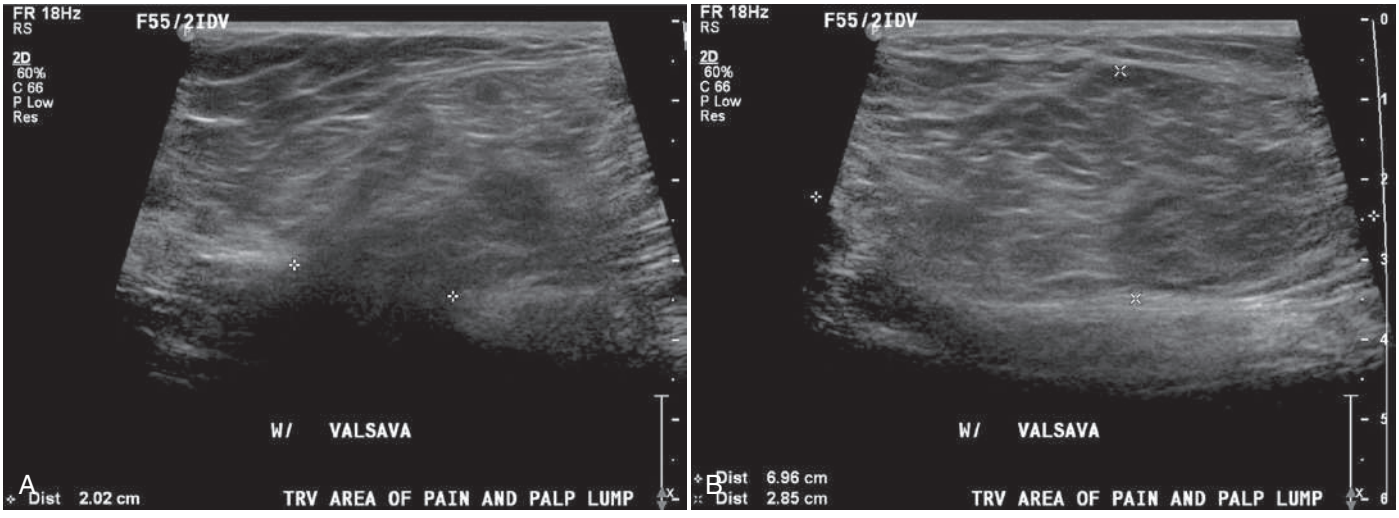

FIG. 13.42 Large Ventral Hernia. Large fat-containing hernia is visible just left of midline. **(A)** and **(B)** Transverse images show the hernia in the region of patient's pain in palpable abnormality. See also Video 13.14.

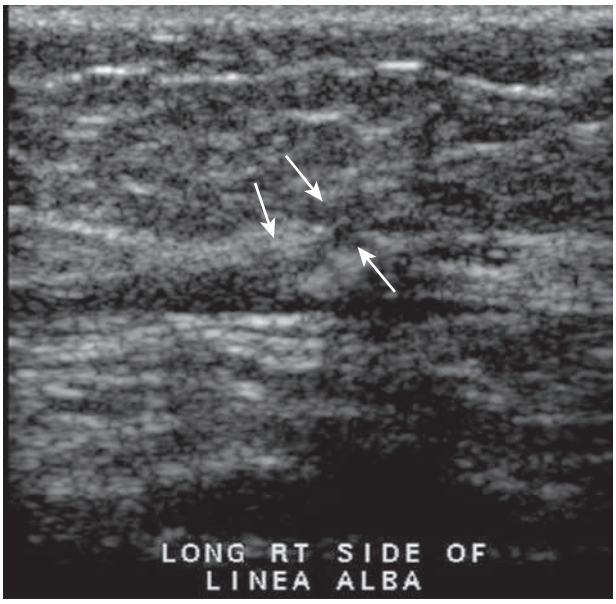

FIG. 13.43 Linea Alba Tear. Tiny tear of the linea alba *(arrows)* caused pain but was not palpable. Such tears are relatively common in patients with preexisting diastasis recti abdominis.

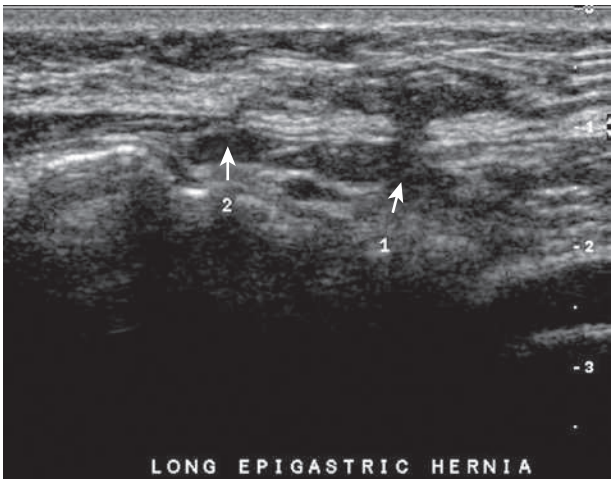

FIG. 13.44 Two Epigastric Hernias. Longitudinal view shows a small, fat-containing, nonreducible, epigastric linea alba hernia inferiorly and a tiny tear superiorly. This patient had three other small hernias more superiorly. Multiple epigastric linea alba hernias are common enough that the entire length of the linea alba should be investigated in any patient with an identified epigastric hernia. See also Video 13.16.

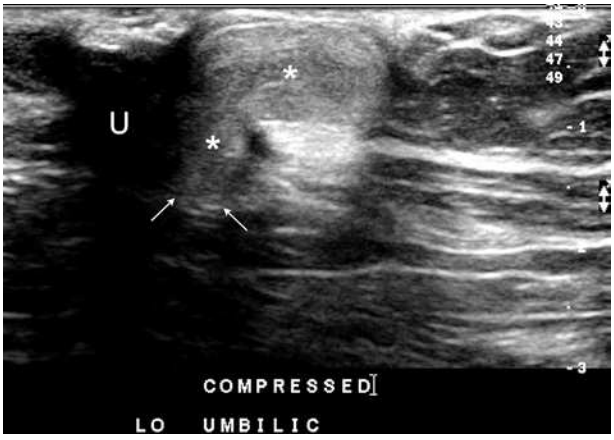

FIG. 13.45 Hypogastric Linea Alba Hernia. Longitudinal view shows a moderate-sized, fat-containing, periumbilical hypogastric linea alba hernia (*) immediately inferior to the umbilicus *(U)*. Note that neck of the hernia *(arrows)* is very narrow and that the edematous strangulated fat is hyperechoic in comparison to the surrounding subcutaneous fat.

Simply identifying diastasis in a patient with epigastric midline pain is insufficient. The linea alba in the area of pain and along its entire epigastric segment must be examined for hernias, because patients with diastasis are at increased risk for multiple epigastric hernias. It is important to assess the entire length of the linea alba in any patient in whom one epigastric linea alba hernia is found. Most hernias contain only properitoneal fat, so they cannot be seen laparoscopically and must be repaired externally. If surgeons do not know that multiple hernias are present, they may use too small a piece of mesh to repair all the hernias. It is our experience that "recurrent" epigastric hernias are more likely to be secondary hernias that were not recognized and repaired, rather than true recurrences (Fig. 13.44, Video 13.16 and Video 13.17).

The much less common **hypogastric linea alba hernia** usually lies within a few centimeters of the umbilicus. Inferior to this area, the rectus muscles are more closely apposed or even fused. As with epigastric hernias, hypogastric linea alba hernias have narrow necks, usually are small to moderate-sized, contain only preperitoneal fat, are usually not reducible, and are prone to strangulation (Fig. 13.45).

Umbilical Hernias

Umbilical hernias occur through a widened **umbilical ring.** In newborns, they result from delayed return to the abdomen of bowel loops that lie in the base of the umbilical cord in the first trimester. In many cases, umbilical hernias in newborns will regress spontaneously by 3 or 4 years of age. Those that do not regress by age 4 are usually repaired.

Umbilical hernias can, however, develop at any time during life. Any cause of chronically increased intraabdominal pressure or connective tissue weakness can lead to dilation of the umbilical ring and formation of an umbilical hernia. Umbilical hernias contain intraperitoneal contents, but smaller umbilical hernias usually contain only intraperitoneal fat (Fig. 13.46). We are asked to evaluate umbilical hernias sonographically much less frequently than we are asked to evaluate patients for groin pain, because the diagnosis of umbilical hernia is usually obvious clinically. The role of ultrasound is usually limited to evaluating for umbilical pain in patients who are so morbidly obese that an umbilical hernia cannot be detected clinically, or to assess for strangulation. In obese patients the umbilicus courses obliquely from deep superiorly to superficial inferiorly (Fig. 13.47). Thus the umbilical ring may be much more superiorly located than is suspected from the location of the umbilicus in obese patients. Untreated umbilical hernias tend to increase in size over time. They are usually reducible but may become nonreducible and can also

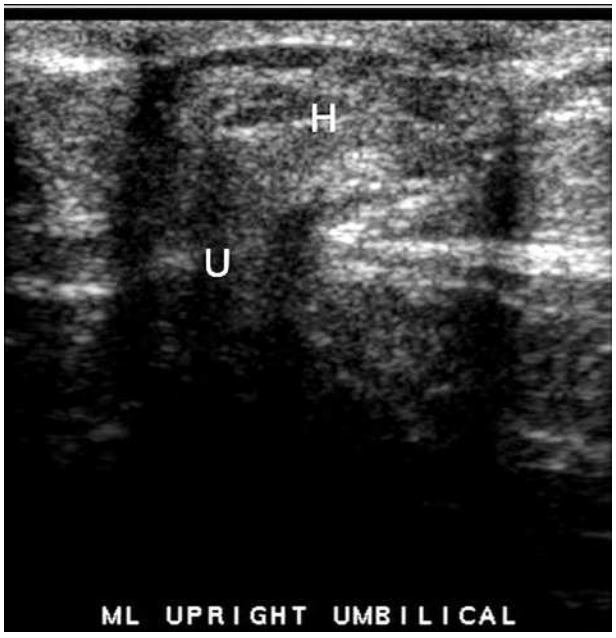

FIG. 13.46 Umbilical Hernia. Longitudinal view shows moderate-sized, fat- and bowel-containing umbilical hernia *(H)*. Umbilical hernias pass through dilated umbilical rings *(U)*.

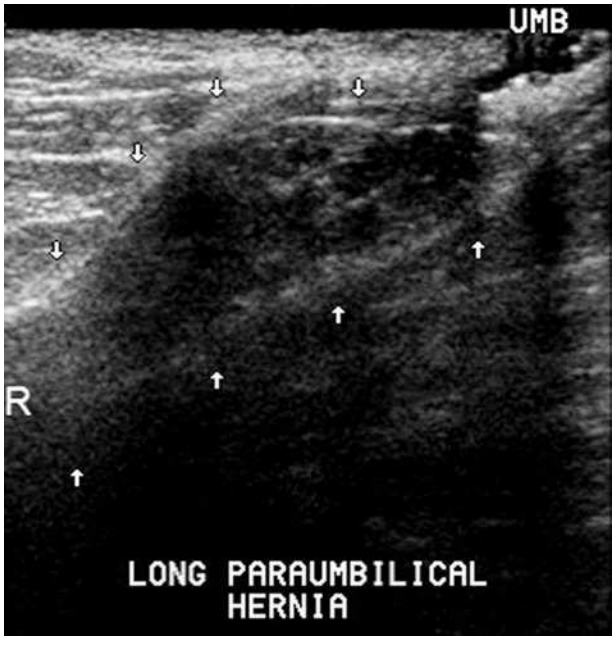

FIG. 13.47 Umbilical Hernia. Longitudinal view of moderate-sized, fat-containing umbilical hernia *(arrows)* in a morbidly obese patient with umbilical pain. The hernia was not clinically apparent. In such obese patients the umbilicus lies several centimeters inferior to the umbilical ring. Thus one must investigate superior to the umbilicus to identify small to moderate hernias.

become strangulated. Clinically, it may be difficult to distinguish between acute omphalitis and a strangulated small umbilical hernia. Both can cause pain and redness in the umbilical area. Sonography, however, can readily make the distinction (Figs. 13.48 and 13.49).

FIG. 13.48 Small, Nonreducible, Strangulated Umbilical Hernia. Note in this transverse view that the edematous strangulated fat within the hernias is hyperechoic compared with the surrounding subcutaneous fat.

The sonographic evaluation of umbilical hernias is similar to that for any hernia. Dynamic maneuvers are used, with identification of type, size, contents, reducibility, and tenderness.

Paraumbilical or Periumbilical Hernias

A "paraumbilical" hernia is not really a distinct type of hernia. It is usually either an epigastric or a hypogastric **linea alba** hernia that lies very close to the umbilicus. **Periumbilical** linea alba hernias, whether epigastric or hypogastric, are particularly likely to become strangulated (see Fig. 13.45, Fig. 13.50).

Incisional Hernias

Incisional hernias are a complication in 4% to 28% of patients undergoing open abdominal surgery, with the majority of articles quoting about 10% in patients undergoing major abdominal operations.[46-49] However, the rates of incisional hernias are associated with the type of surgery, older age, and obesity, and repair of incisional hernias has become the most common hernia repair procedure. Incisional hernias can occur in any area along the anterior abdominal wall where an incision is made, including laparoscopy ports and stomal sites. The herniation can result from thinning and stretching of the scar or from a tear in a segment of the scar. Whether the scar is stretched or torn affects the shape of the hernia, its reducibility, and its risk of strangulation. Incisional hernias resulting from **thinning and stretching** of the scar have wide necks and are reducible, whereas those resulting from **tears** in the scar are more likely to have narrow necks and to be nonreducible (Fig. 13.51, Video 13.18). Incisional hernias can occur where natural hernias cannot, through the bellies of muscles that have been incised. Incisional hernias can occur through very small scars (e.g., laparoscopy ports) (Video 13.19 and Video 13.20). Obese patients who have undergone transverse rectus abdominis myocutaneous (TRAM) flap breast reconstruction surgery are particularly likely to have one or more incisional hernias (see Video 13.18). In a study comparing

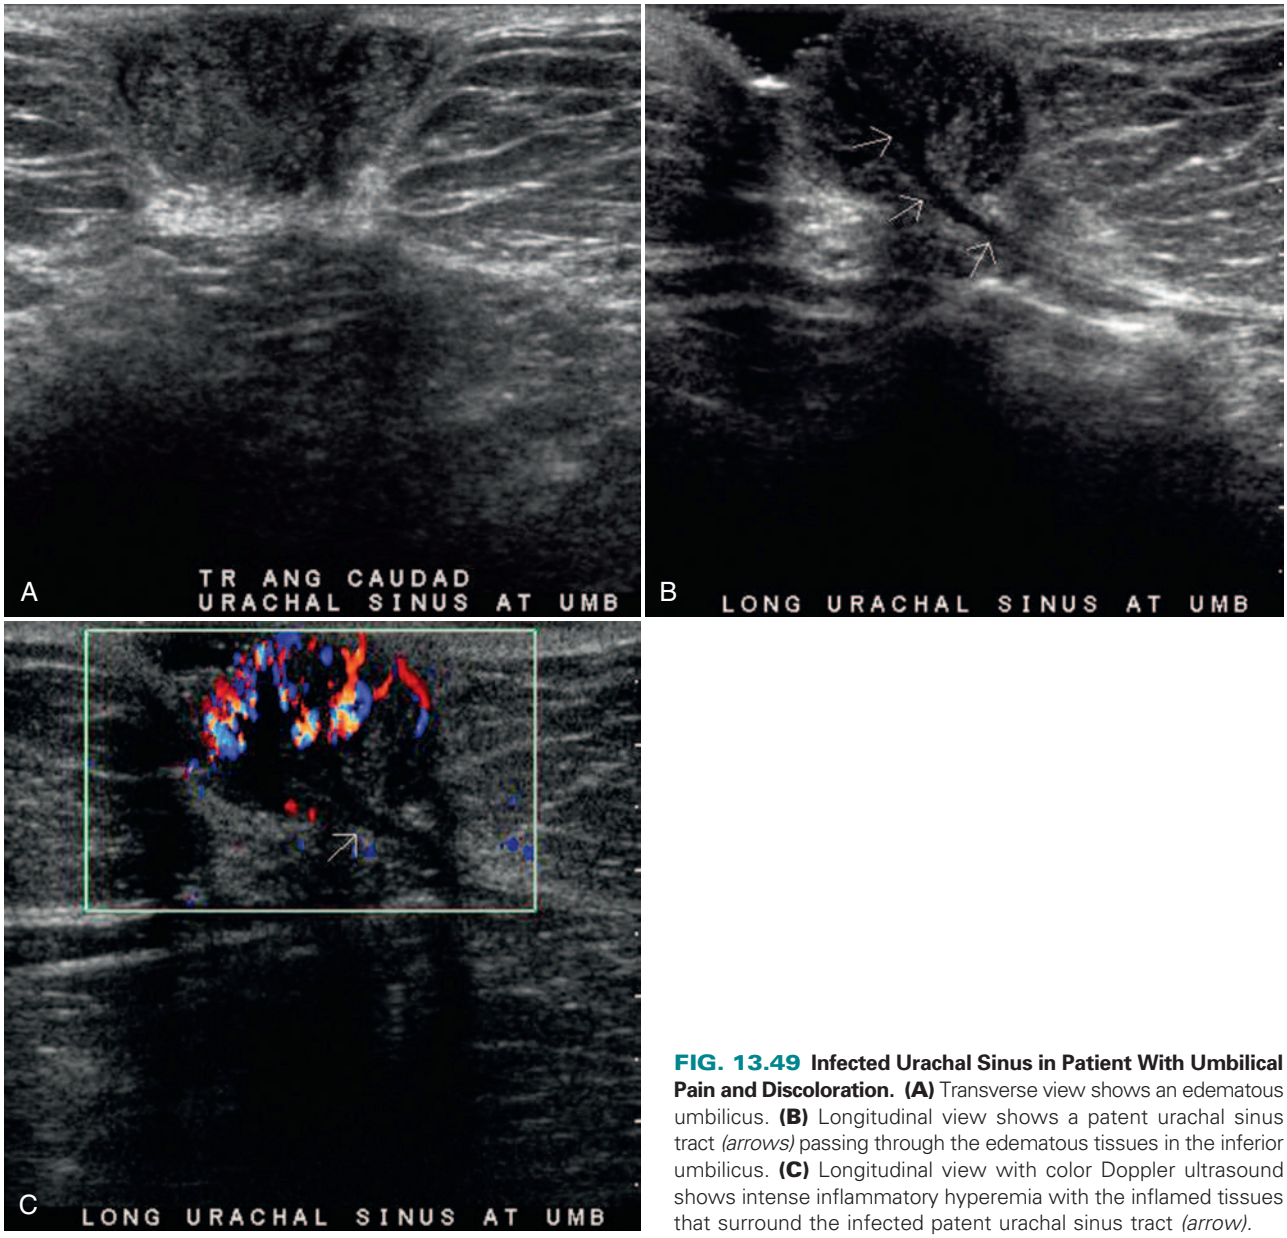

FIG. 13.49 Infected Urachal Sinus in Patient With Umbilical Pain and Discoloration. (A) Transverse view shows an edematous umbilicus. **(B)** Longitudinal view shows a patent urachal sinus tract *(arrows)* passing through the edematous tissues in the inferior umbilicus. **(C)** Longitudinal view with color Doppler ultrasound shows intense inflammatory hyperemia with the inflamed tissues that surround the infected patent urachal sinus tract *(arrow)*.

dynamic ultrasound versus CT in the assessment of suspected incisional hernias, of 109 patients, 102 and 107 had incisional hernia noted on CT and ultrasound, respectively. The measurements of the hernias were similar comparing the techniques.[50] Repair of the hernia can be by either laparoscopic or open repair.[51] In a retrospective study of ventral wall hernias, the main indication was pain in 78%, and 10% had an acute presentation with incarceration or strangulation.[52] Mesh repair is being increasingly performed because it seems to be associated with fewer recurrences.[53]

Multiple Hernias

Patients who have one type of hernia are more likely to have additional hernias. These patients are more likely to have contralateral hernias of the same type, and they are more likely to have either ipsilateral or contralateral hernias of different types. There are several reasons for this. First, **bilateralism** may be caused by timing of closure of fetal canals, and delayed closure for any reason is likely to affect both sides simultaneously. Second, underlying factors that lead to formation of hernias can affect all sites simultaneously. Factors that increase the risk of hernias include any cause of chronically increased intraabdominal pressure, as well as repetitive stress. Pregnancies, morbid obesity, and ascites can increase intraabdominal pressure long enough to lead to development of hernias. Certain professions lead to repetitive stress injuries. Sedentary lifestyle, nutritional deficiencies, and hereditary factors can result in weak connective tissues.

In a patient with unilateral groin pain but no demonstrable hernia on that side during dynamic ultrasound, the study can be stopped after examining the symptomatic side. However, in

any patient in whom one type of groin hernia is found during the dynamic ultrasound examination, the clinician must look for the other three types of ipsilateral groin hernias. Femoral and indirect inguinal hernias can occur together (Fig. 13.52). In addition, direct and indirect inguinal hernias can occur on the same side. On long-axis views, the necks of the hernias resemble pant legs straddling the inferior epigastric vessels, explaining why the combination of the two hernias has been termed a **pantaloon hernia** (Fig. 13.53, Video 13.22). The contralateral groin is evaluated as well. This is especially important in patients who will undergo laparoscopic hernia repairs, because surgeons are more likely to perform bilateral repairs using a laparoscopic approach than when performing external herniorrhaphy. Direct inguinal hernias and femoral hernias are most likely to be bilateral. Multiple linea alba and incisional hernias are also relatively common.

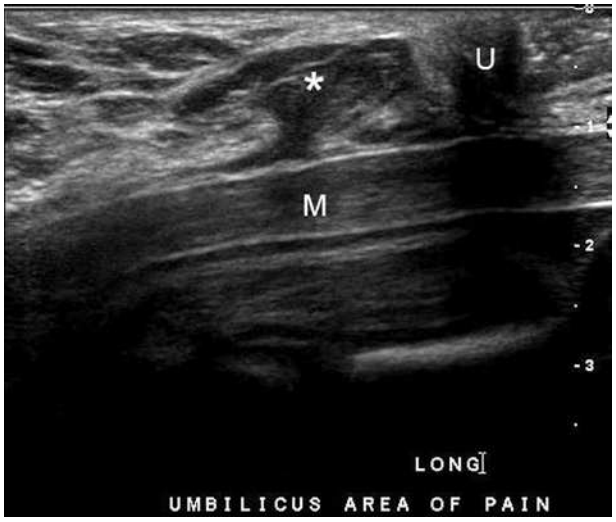

FIG. 13.50 Small Periumbilical Hernia. Patient had periumbilical pain during the third trimester of pregnancy. Longitudinal view shows a fat-containing, nonreducible epigastric linea alba hernia (*). The increased intraabdominal pressure, together with the softening of ligaments that occurs in the late third trimester, predisposes to all types of hernias. *U,* Umbilicus; *M,* myometrium of gravid uterus.

ADDITIONAL ISSUES REGARDING HERNIAS

Recurrent Groin Hernias

Hernia repair can be performed by direct anterior incision of the inguinal canal or laparoscopically. Hernia repairs performed decades ago were done without mesh. Originally, fascia was pulled up to reinforce the inguinal area, but this tended to widen the femoral canal and led to "recurrent" femoral hernias. "Tension-free" external repairs using proline mesh were developed to prevent this. Recent data suggest that results of laparoscopic repairs equal those of external repairs. Laparoscopic repairs have the advantage of allowing bilateral repair, but require general anesthesia. External repairs are generally limited to one side, but can be done with regional anesthesia. Most hernia repairs now are "tension free" and employ mesh. Mesh can be used with both external and laparoscopic repairs.

Unfortunately, recurrent or residual groin pain after herniorrhaphy is relatively common. Recurrent hernia is not the only cause of residual or recurrent groin pain after herniorrhaphy, and dynamic sonography is an integral part of the evaluation of other causes in patients with acute or chronic postherniorrhaphy pain.

In the acute phase, **residual pain** unchanged from preoperative pain is rare and usually the result of an unsuccessful hernia repair. The original hernia persists and can be demonstrated sonographically. More often, acute pain is caused by entities other than recurrent hernia, including incisional pain or pain caused by acute **hematomas** (Fig. 13.54A) or **seromas** (Fig. 13.54B), and sometimes pain radiating into the scrotum as the result of spermatic cord compression by a seroma, a hematoma,

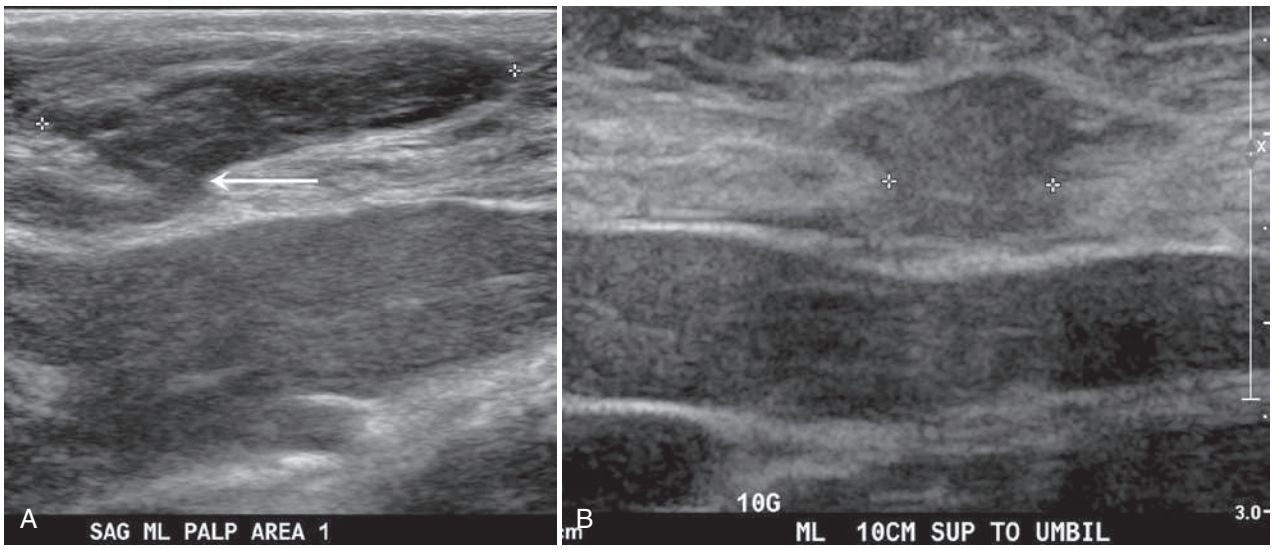

FIG. 13.51 Incisional Hernia. (A) and **(B)** Two patients with fat-containing incisional hernias. **(A)** *Arrow* shows the narrow neck of a fat containing incisional hernia, while *calipers* show the extent of the fat within the hernia. The narrow neck increases the risk of strangulation. **(B)** In another fat containing incisional hernia the neck is much wider *(calipers)*. See also Video 13.19 and Video 13.20.

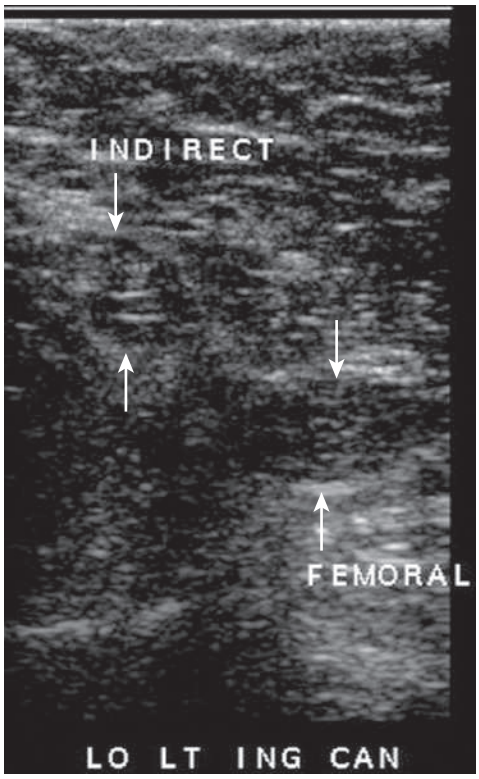

FIG. 13.52 Two Hernias. Longitudinal image of indirect inguinal and femoral hernias.

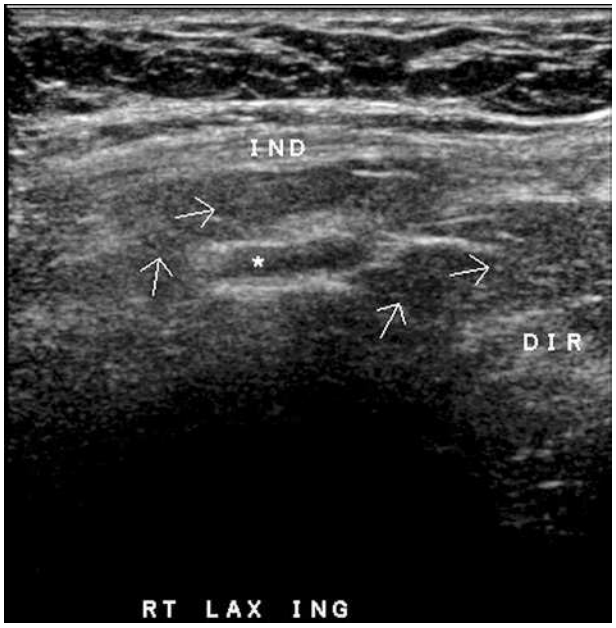

FIG. 13.53 Pantaloon Hernia. Long-axis view of right inguinal area shows both direct *(DIR)* and indirect *(IND)* inguinal hernias with the inferior epigastric vessels (*) between them, a pantaloon hernia. The necks of the direct and indirect inguinal hernia resemble pant legs straddling the inferior epigastric vessels.

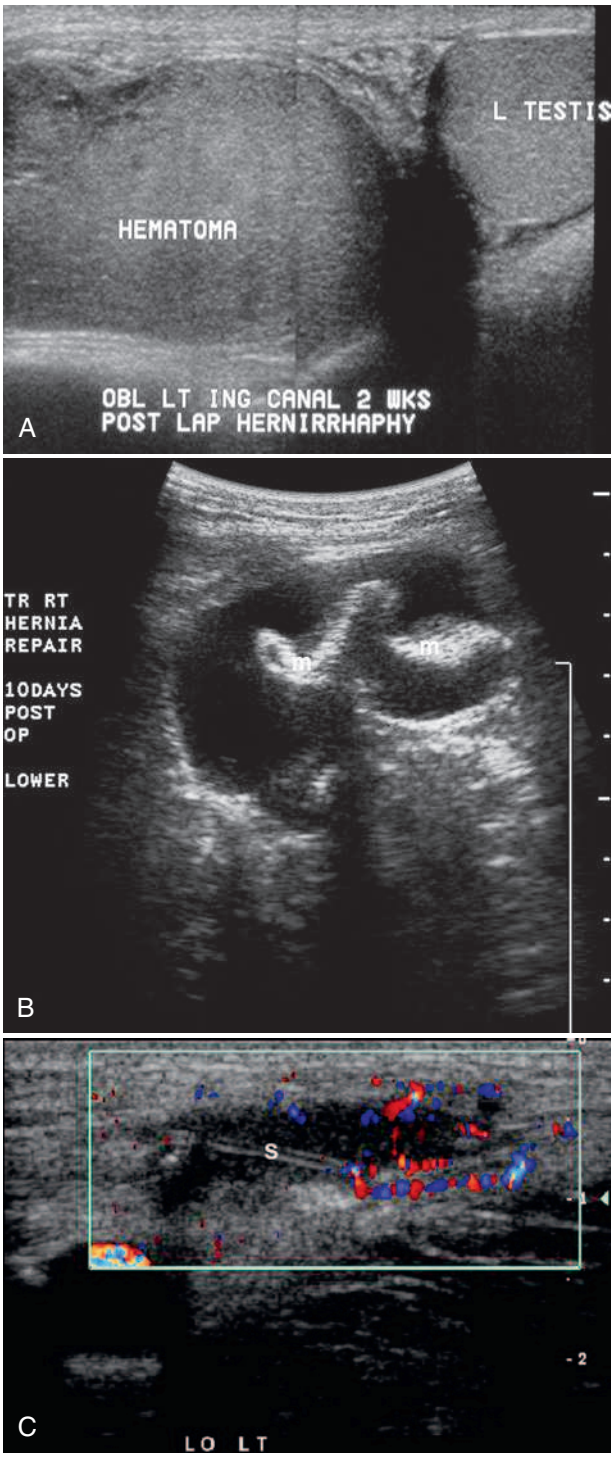

FIG. 13.54 Complications After Hernia Surgery in Patients With Pain and Swelling After Hernia Repair. (A) Hematoma. **(B)** Seroma. **(C)** Stitch abscess.

the mesh, or a repair that makes the internal inguinal ring too tight. In such cases it is important to assess the ipsilateral scrotum and testis with gray-scale imaging and Doppler ultrasound, because cord compression of any etiology can lead to **testicular infarction.** Doppler ultrasound evidence of testicular ischemia may indicate the need for emergency decompression by either evacuating an inguinal canal hematoma or seroma or

loosening the repaired internal inguinal ring. Inguinal canal hematomas or seromas that do not compress the spermatic cord or cause testicular ischemia, on the other hand, can usually be managed conservatively. Postherniorrhaphy hematomas or seromas can become secondarily infected and evolve into abscesses. **Stitch granulomas** or **stitch abscesses** can cause pain (see Fig. 13.54C).

Late recurring pain also has a variety of causes, but recurrent hernia becomes a greater concern, particularly when the pain is similar in type to that present before surgery. Late pain etiology includes recurrent hernia, seroma, hematoma, abscess, traction on the edges of the mesh, immune reaction to the mesh, spiral clips, compression of the spermatic cord, and fibrosis and scarring of the ilioinguinal nerve. Again, dynamic sonography is essential in evaluating such patients, although it is more difficult than in patients not previously repaired.

In patients who underwent herniorrhaphy without mesh, the recurrent hernia is usually of the same type as the original. However, it is not unusual, even after tension-free repairs, to find a "recurrent" femoral hernia. In such cases, especially after external repair, the femoral hernia may have been present before the repair, but subclinical and unrecognized. This is a major reason why it is important to look for *all* types of groin hernias during dynamic sonography. In our experience, "recurrent" femoral hernias are less common after tension-free repairs that employ mesh, because they usually employ a piece of mesh large enough to cover the conjoined tendon, internal inguinal ring, femoral canal, and spigelian area.

In patients whose hernias were repaired with mesh, it is not possible to determine sonographically whether a recurrent inguinal hernia is direct or indirect. It is only possible to determine that it is a *recurrent* inguinal hernia. The key to finding recurrent hernias in patients who have mesh in place is to identify the mesh and then assess for herniations along the edges of the mesh with dynamic maneuvers. In patients being evaluated for recurrent hernia, the most useful dynamic maneuver is usually the compression maneuver with the patient in the upright position.

Because many types of mesh are available, the appearance varies greatly (Fig. 13.55). In ideal cases, we can actually see the texture of the mesh. In most cases, however, the mesh can be seen only as an echogenic line of variable thickness with variable shadowing or as an area of variable shadowing. Some newer types of mesh are thin and much more difficult to identify sonographically. Normal mesh can have folds and can be rolled at the edges, and it normally bulges mildly outwardly in the upright position and during Valsalva maneuvers. Patient history is rarely helpful because patients are unaware of the type of mesh used.

However, every effort should be made to identify the mesh, because recurrent hernias do not occur through the center but rather at the *edges* of the mesh. Most recurrent hernias occur along the **inferomedial edge** of the mesh (Fig. 13.56; Video 13.21), but it is still important to identify the mesh and then assess the entire periphery of the mesh, because hernias can occur along any edge of the mesh. Herniation from the edge of the mesh likely occurs because the affected edge has "pulled loose" (Fig. 13.57).

The edges of the mesh can be anchored to surrounding connective tissues with sutures, surgical clips, or special spiral clips. The sutures and clips hold the mesh in place for about the first 6 weeks after surgery. After this, fibrosis forms and generally holds the mesh in place. It is during the first 6 postoperative weeks, before the mesh has fibrosed to the anterior abdominal wall, that mesh is most likely to pull loose from its anchors. In our experience, this is most likely to occur after laparoscopic repairs—not because the repair has been defective or because laparoscopic repair is less effective, but because the patient feels "too well, too soon" after the minimally invasive repair and resumes activities that put the repair at risk within the first 6 weeks. Some patients may complain of a tearing sensation during some movement, followed by the onset of recurrent inguinal pain, but in most patients the onset is more insidious.

A chronic hematoma or seroma can cause chronic pain, and its evacuation can relieve the pain. Therefore searching for a hematoma or seroma is a standard part of the postherniorrhaphy sonogram. Some patients can develop an allergic or hypersensitivity reaction to the mesh, with a thin seroma localized to the mesh surface.

When sonography demonstrates no hernia, hematoma, or seroma, it is important to assess the mesh for tenderness. In many cases without sonographically demonstrable pathology, the mesh is tender for a variety of reasons. First, the mesh may compress the spermatic cord; compressing the mesh will cause pain that radiates into the scrotum. Second, the mesh may be placing traction on the fibrosis that holds its edges in place; this is especially common in patients with significant weight gain since surgery. The mesh usually bulges anteriorly in such cases. In other cases, the fibrosis that holds the mesh in place has entrapped nerves, notably the **ilioinguinal nerve.**

The **spiral clips** used to anchor the mesh require special mention. Because these can become tender and a source of postherniorrhaphy pain, spiral clips are now seldom used. However, their past popularity means many patients have them. Spiral clips have a characteristic radiographic and sonographic appearance (Fig. 13.58). In some postherniorrhaphy patients with no other sonographically demonstrable pathology, the only finding is focal tenderness directly over the offending clip. Surgical removal of the clip will relieve the pain and tenderness and typically will not adversely affect the soundness of the repair, because the edge of the mesh will be held firmly in place by fibrosis, even after the clip is removed.

Hernia Complications

Hernia complications include incarceration, obstruction, and strangulation. **Incarcerated hernias** are simply hernias that are nonreducible. **Obstructed hernias** contain incarcerated bowel loops that have become mechanically obstructed. **Strangulated hernias** contain incarcerated contents with compromised vascularity. Not all strangulated hernias contain bowel loops; even preperitoneal fat can become strangulated. Most incarcerated hernias are neither obstructed nor strangulated, but all obstructed and strangulated hernias are also incarcerated. Only incarcerated hernias that are also obstructed or strangulated are surgical emergencies. Even strangulated hernias that contain only

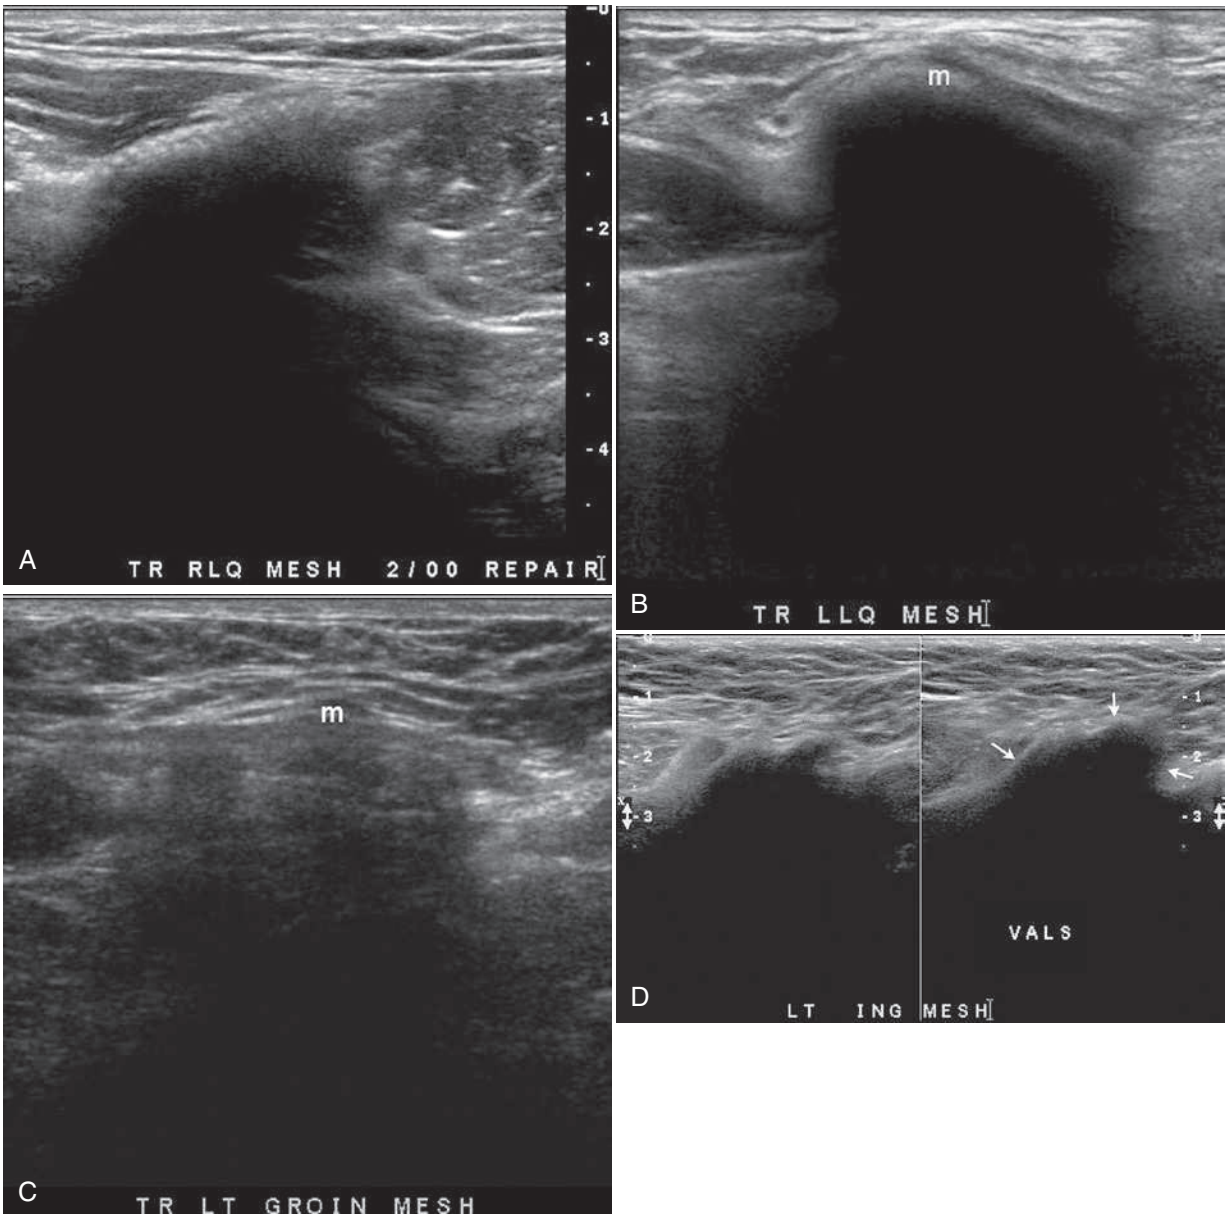

FIG. 13.55 Mesh After Hernia Repair. (A) Normal mesh. The mesh used in this hernia repair is thick and echogenic, and individual fibers within the mesh are visible. It casts a strong acoustic shadow. The mesh can be well seen in only a small percentage of cases. **(B) Herniorrhaphy mesh with strong shadow.** Mesh typically appears thick and echogenic and casts a strong acoustic shadow, but individual fibers within the mesh *(m)* are not visible sonographically. **(C) Herniorrhaphy mesh with weak shadow.** Thin, poorly defined mesh casts only a weak acoustic shadow. Such mesh can be identified only with high-frequency transducers, optimal technique, and careful search. **(D) Wrinkled herniorrhaphy mesh.** Mesh can bulge during the Valsalva maneuver or when the patient is scanned in the upright position; this may be normal. These split-screen images show wrinkled mesh in the supine position in quiet respiration *(left image)* and bulging with straightening of some of the wrinkles in the upright position *(right image)*.

preperitoneal fat may not be emergencies. It is the presence of bowel loops within strangulated hernias that makes them emergent. Instead of incarcerated, we use the term **nonreducible** because the referring clinician is less likely to confuse it with strangulation.

The **shape** of hernias affects their reducibility and their likelihood of becoming obstructed or strangulated in the future. The hernia type affects its shape. Hernias that have relatively **broad necks** in comparison to their fundi are usually completely reducible and rarely become obstructed or strangulated. Groin hernias that typically have broad necks and infrequently strangulate are direct inguinal hernias and some indirect inguinal hernias. Hernias that have relatively **narrow necks** in comparison to their fundi are more likely to be nonreducible, to become obstructed, and to strangulate. Hernia types that typically have narrow necks and are at high risk for strangulation include femoral (Video 13.23), spigelian (see Figs. 13.33 and 13.35), linea alba (see Fig. 13.45; Fig. 13.59), umbilical, and some indirect inguinal hernias.

Although **vascular compromise** is the hallmark of strangulation, Doppler ultrasound is not the most sensitive modality for

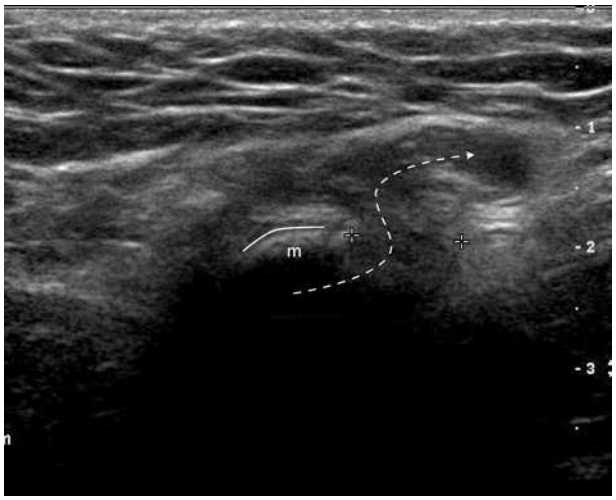

FIG. 13.56 Recurrent Inguinal Hernia. Short-axis view shows small, fat-containing, reducible *(dotted line)* hernia arising from inferomedial edge of the mesh *(m),* where recurrent inguinal hernias most often arise. See also Video 13.21.

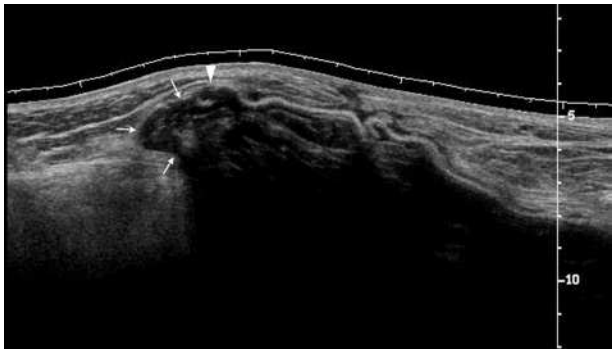

FIG. 13.57 Detached Mesh With Hernia. Transverse extended–field-of-view image shows that a large piece of mesh used to repair a large ventral hernia has become detached along its right edge *(arrowhead),* allowing a recurrent hernia to protrude from under the detached edge *(arrows).*

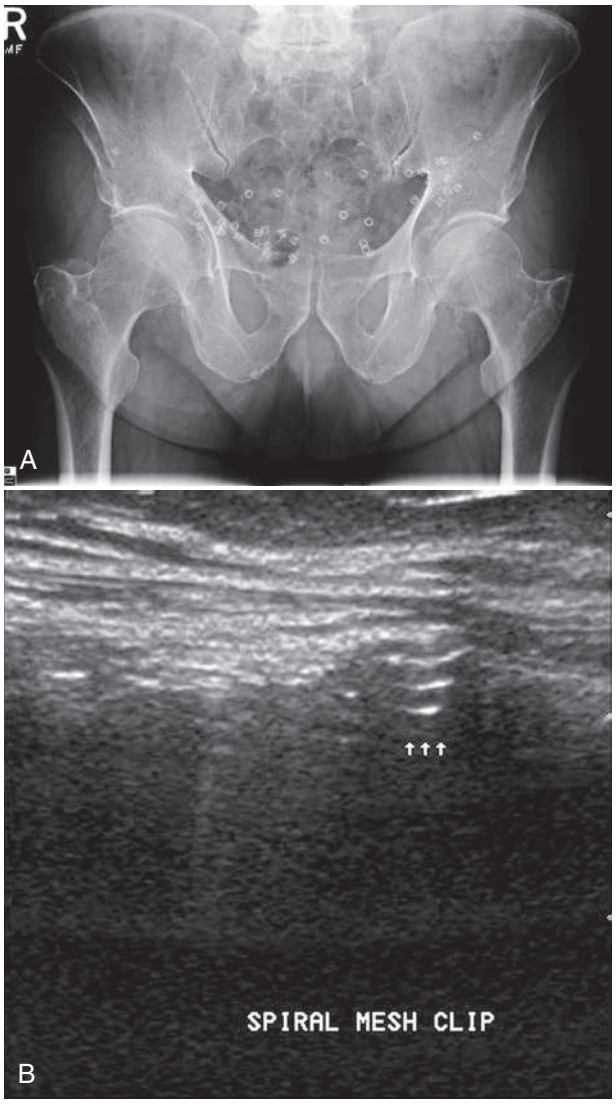

FIG. 13.58 Spiral Clips. (A) Anteroposterior radiograph of the pelvis shows spiral clips in both inguinal areas from bilateral inguinal herniorrhaphies. **(B)** Characteristic sonographic appearance of a spiral clip *(arrows).*

demonstrating signs of strangulation. Gray-scale sonography, however, is sensitive. Doppler ultrasound shows arterial flow within hernias with some success (Fig. 13.60), but often is not sensitive enough to demonstrate venous flow and cannot show lymphatic flow at all. Lymphatic and venous vessel walls are very thin and easily compressed within by the tissues surrounding the neck of the hernia. Arteries, on the other hand, are relatively thick walled and incompressible and in general are not compressed by the surrounding tissues. Thus in strangulated hernias the lymphatics and veins become obstructed long before arterial flow decreases. Blood can still supply the strangulated hernia long after venous and lymphatic outflow stops. The continued inflow in the presence of obstructed outflow (1) increases intravascular pressure, (2) causes increased transudation and exudation of fluid into the extracellular spaces, and (3) changes the gray-scale appearance of the hernia even when Doppler ultrasound can still detect arterial inflow. When both arterial and venous flow are seen in an otherwise unremarkable ventral hernia, emergency surgery may not be indicated.[54] However, in a study by Rettenbacher, the absence of blood flow in the contents of a hernia could not be taken as a sign of incarceration because most incarcerated hernias in his series (78%) had detectable blood flow on color Doppler sonography.[34]

In a retrospective study of sonographically examined hernias (predominately after indeterminate surgical physical examination) 149 abdominal wall hernias (in 131 patients) were found and underwent surgery (Table 13.2). The most sensitive findings of incarceration were free fluid in the hernia sac, bowel wall thickening in the hernia, fluid in the herniated bowel loop, and dilated bowel loops in the abdomen.[34] All 23 incarcerated abdominal wall hernias were correctly interpreted preoperatively as incarcerated by the investigating radiologists, whereas 2 of 126 nonincarcerated hernias were considered incarcerated and were therefore falsely positive for incarceration on sonography.[34]

Strangulation of the hernia, which implies compromise of blood flow, has additional findings including the following:

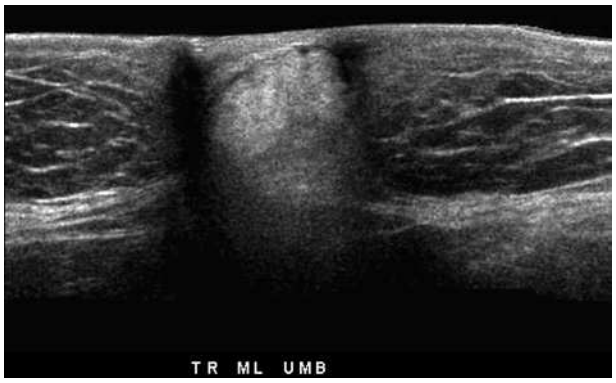

FIG. 13.59 Linea Alba Strangulated Hernia. Long-axis extended–field-of-view sonogram shows strangulated hypogastric linea alba hernia. The hallmark of strangulation is **hyperechogenicity** of the fat with the hernia.

- Hyperechoic fat (see Fig. 13.59)
- Isoechoic thickening of the normally thin and echogenic hernia sac (Fig. 13.61, see Video 13.23)
- Fluid within the sac (see Fig. 13.61, Video 13.23)
- Thickening of bowel wall in bowel-containing hernias (Fig. 13.62)

In most strangulated hernias, more than one of these gray-scale findings are present, even when Doppler ultrasound demonstrates normal flow within the hernia contents. Care should be taken in equating fluid within the hernia sac with strangulation; nonstrangulated hernias that contain intraperitoneal contents can contain peritoneal fluid, especially in female patients.

Entities That Simulate Groin Hernias

A wide spectrum of space-occupying lesions in the groin can simulate hernias of the groin (Fig. 13.63). **Cysts** or **hydroceles** of the inguinal canal can occur in both males and females. In males these localized fluid collections can occur when the segment of the processus vaginalis peritonei within the inguinal canal

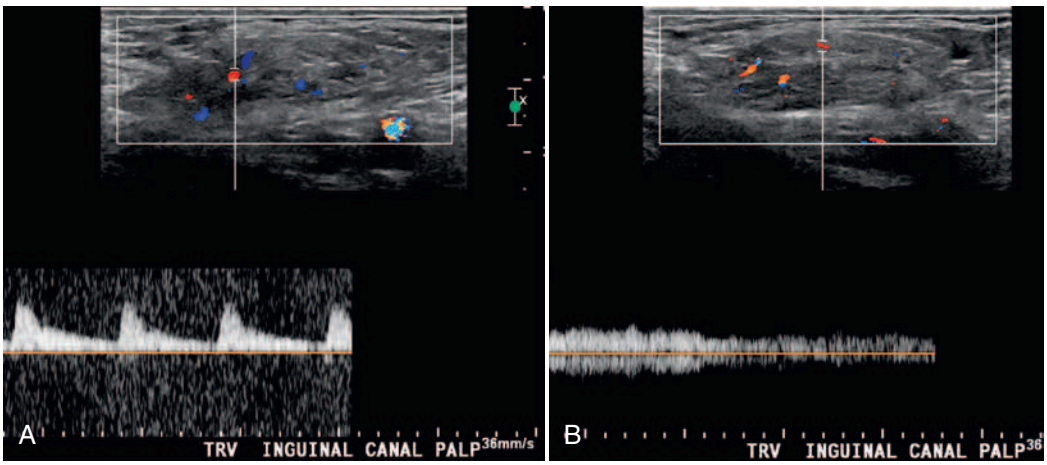

FIG. 13.60 Color and pulsed Doppler shows **(A)** arterial and **(B)** venous flow in fat-containing inguinal hernia.

TABLE 13.2 Findings of Hernia Strangulation

Sonographic Finding	Percent Incarcerated (N = 23)	Percent Not Incarcerated (N = 126)
Contents of hernia		
Fat only	n = 6	n = 54
Fat and bowel	n = 4	n = 47
Bowel only	n = 13	n = 16
Urinary bladder		n = 3
Free fluid in the hernia sac	91% (21/23)	3% (4/126)
Bowel wall thickening in the hernia (≥4 mm)	88% (15/17)	0% (0/63)
Fluid in the herniated bowel loop	82% (14/17)	3% (2/63)
Dilated loops of bowel in abdomen	65% (11/17)	0 (0/63)
Absence of blood flow in the hernia	22% (5/23)	25% (31/126)
Absence of peristalsis within hernia	76% (13/17)	38% (24/63)

Modified from Rettenbacher T, Hollerweger A, Macheiner P, et al. Abdominal wall hernias: cross-sectional imaging signs of incarceration determined with sonography. AJR Am J Roentgenol. 2001;177(5):1061-1066.[34]

FIG. 13.61 Strangulated Femoral Hernia. Short-axis view shows strangulated left femoral hernia that shows two additional gray-scale findings of strangulation: transudative or exudative fluid and isoechoic thickening of the hernia sac wall. See also Video 13.23.

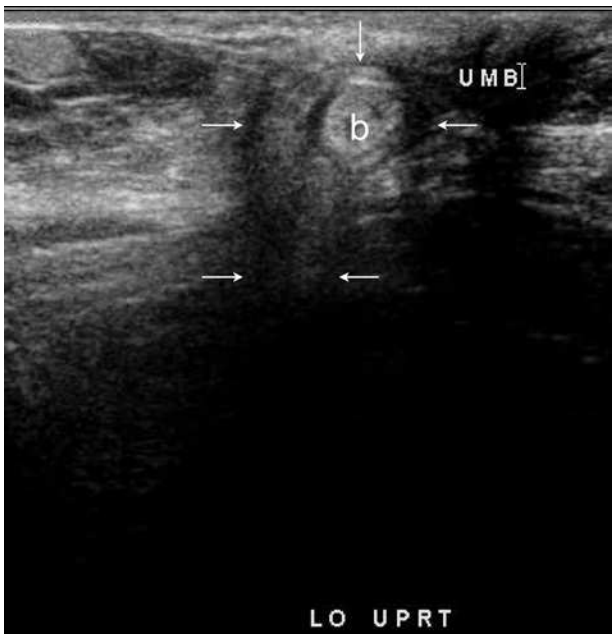

FIG. 13.62 Strangulated Periumbilical Epigastric Linea Alba Hernia. The fat is hyperechoic, the sac wall is isoechoic and thickened, and a small bowel loop *(b)* has a thickened wall and is aperistaltic. The hernia sac is outlined by *arrows*.

does not fuse while segments proximal and distal to it do fuse. This leads to accumulation of fluid within the unfused segment of processus vaginalis and forms a localized process hydrocele. In males these occur within the inguinal canal next to the spermatic cord and can compress the cord. In females the unfused processus vaginalis is called the canal of Nuck, so this localized cyst or hydrocele is termed a **cyst** or **hydrocele of the canal of Nuck** (see Fig. 13.63A; Video 13.24). Hydroceles are usually unilocular and fixed in position within the canal, but can become lobulated and septated as they enlarge.

Hematomas and inflammation may occur in the inguinal regional in proximity to the round ligament and can give rise to cysts and leiomyomas. Unlike inguinal canal hydroceles, which are fixed in position, **round ligament cysts** can be mobile and can move back and forth between the abdominal cavity and the inguinal canal. The round ligament contains smooth muscle fibers from which **leiomyomas** can arise. **Round ligament varices** develop as collateral pathways for uterine venous drainage during pregnancy. They are usually asymptomatic and incidental, but in some patients can cause a tender, palpable, inguinal or labial abnormality that can mimic a hernia[55] (see Fig. 13.63B). They usually resolve spontaneously and completely after delivery, but in a few patients can persist and cause inguinal pain and swelling months or years after the last pregnancy. They are relatively inapparent with the patient in the supine position, but become larger and have faster flow in the upright position. Occasionally, round ligament variceal **thrombosis** occurs spontaneously, most often in the postpartum period when collateral uterine flow through them regresses. **Endometriomas** can occur along the course of the round ligament within the inguinal canal (see Fig. 13.63C). They often have a history of cyclic variation in size and tenderness.

The most common benign tumor of the inguinal region is a lipoma.[6] Most so-called inguinal canal lipomas are not true lipomas, but rather **nonsliding-type indirect inguinal hernias** that contain only properitoneal fat. However, true **lipomas** can occur anywhere along the length of the inguinal canal and into the scrotum or labium majus (see Fig. 13.63D-E).

Other benign tumors of the groin include leiomyomas, dermoid cysts, epidermoid cysts, and lymphangiomas.

Other entities that can occur in the inguinal region include desmoids, sarcomas, hematomas, seromas, undescended testes, and metastatic peritoneal implants.[6]

Inguinal lymphadenopathy, common femoral or external iliac artery aneurysms and pseudoaneurysms, iliopsoas bursae, and sebaceous cysts can all occur within the groin, but *outside* the inguinal canal. In addition, pain from intraabdominal inflammatory processes can simulate groin pain; acute appendicitis and acute diverticulitis can cause pain near the groin.

Entities That Simulate Anterior Abdominal Wall Hernias

Subcutaneous or intramuscular lipomas have a sonographic appearance identical to those of the inguinal canal or labium. In patients being evaluated for incisional hernias, **exuberant scars** and **fat necrosis** resulting from previous surgeries can clinically simulate an anterior abdominal wall incisional hernia. **Hematomas** of the rectus abdominis (Fig. 13.64A) or oblique muscles can cause pain and swelling that simulate anterior abdominal wall hernia. The patient usually (but not always) has a history of significant acute trauma.

Anterior abdominal wall desmoids are usually sporadic. They arise from the fibrous elements of the anterior abdominal

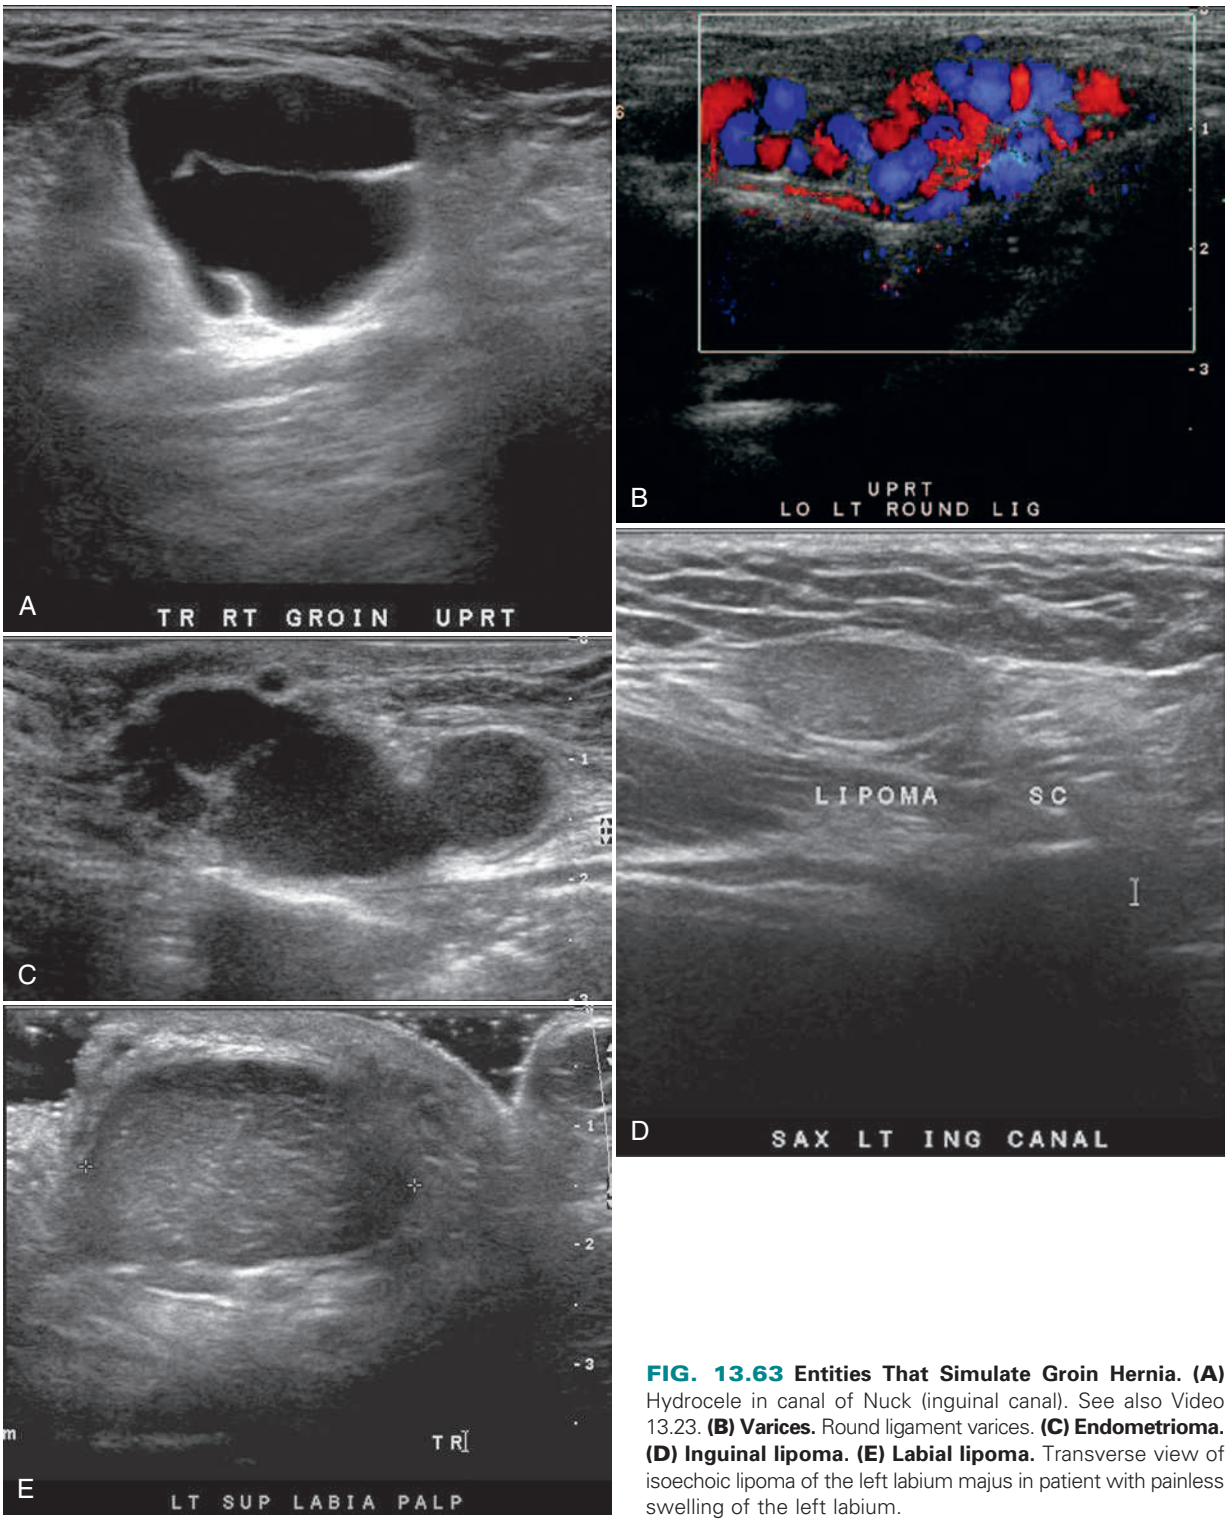

FIG. 13.63 Entities That Simulate Groin Hernia. (A) Hydrocele in canal of Nuck (inguinal canal). See also Video 13.23. **(B) Varices.** Round ligament varices. **(C) Endometrioma. (D) Inguinal lipoma. (E) Labial lipoma.** Transverse view of isoechoic lipoma of the left labium majus in patient with painless swelling of the left labium.

wall aponeuroses or muscle sheaths. Desmoids are locally invasive and tend to recur if not excised widely enough, but do not metastasize distantly. Sonographically, desmoids are solid nodules or masses that are irregular in shape and have some internal vascularity (see Figs. 13.64B). Desmoids are difficult to distinguish from sarcomas, except for slightly less blood flow on color or power Doppler ultrasound. If not excised, desmoids grow progressively. Benign and malignant connective tissue tumors of the anterior abdominal wall such as **fibromas** (see Fig. 13.64C) and **fibrosarcomas** (see Fig. 13.64D) can simulate anterior abdominal wall hernias.

SUMMARY

Dynamic ultrasound is the key examination for assessing groin or anterior abdominal wall pain. Dynamic components of the

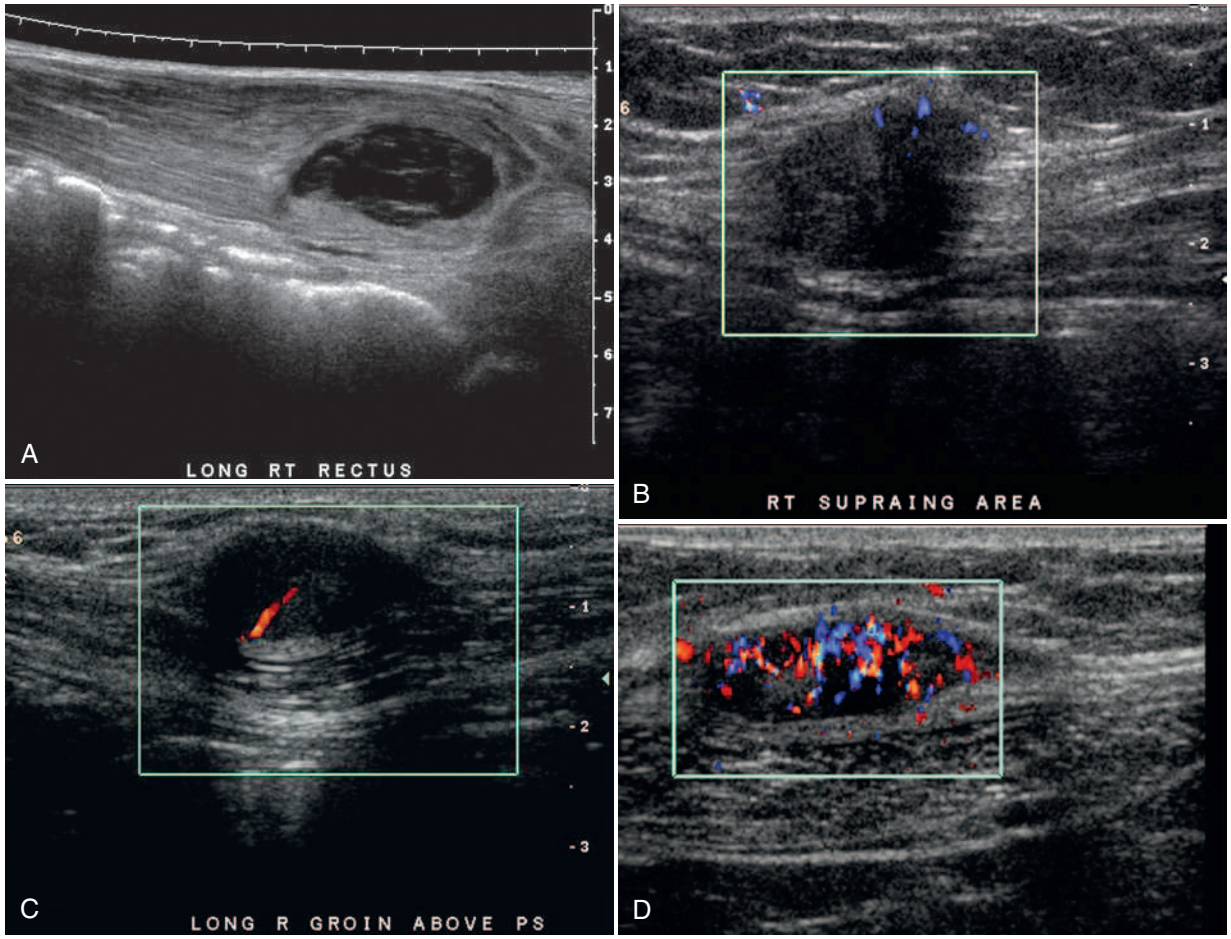

FIG. 13.64 Entities That Simulate Anterior Abdominal Wall Hernia. (A) Muscle tear with hematoma. **(B) Desmoid tumor.** Anterior abdominal wall desmoid tumor has a small amount of peripheral blood flow. **(C) Fibroma.** Long-axis view of a benign fibroma of the anterior rectus sheath of the inferior right rectus abdominis muscle that caused a nontender swelling near the right groin. Note that there is minimal internal vascularity. **(D) Fibrosarcoma.** Transverse view of a fibrosarcoma of the anterior sheath of the left rectus abdominis muscle that manifested as a painless lump. It is similar in appearance to the fibroma shown in **(C)** but is much more vascular.

examination include Valsalva and compression maneuvers and scanning in both supine and upright positions. Dynamic sonography enables clinicians to determine hernia type, size, contents, reducibility, and tenderness.

Evaluation of groin pain in athletes is frequently more complex than in nonathletes because of associated tendinosis and osteitis pubis. Adding MRI to dynamic ultrasound is usually necessary to identify underlying pathologic processes and decide the best combination of surgical and nonsurgical treatments.

Patients with one hernia frequently have multiple hernias, so in any patient in whom a hernia is sonographically demonstrable, the examination should be continued, looking for other types of ipsilateral and contralateral groin or anterior abdominal hernias. Even when no additional hernias are found, it is important to the surgeon to specifically mention in the report that a complete search of both groin areas was made and no additional hernias were found.

Strangulation is the most dreaded complication of groin hernias. Gray-scale findings of strangulation—hyperechoic fat, isoechoic thickening of the hernia sac, fluid within the sac, and thickening of the walls of bowel loops—are all more sensitive for strangulation than is Doppler ultrasound.

Recurrent pain after herniorrhaphy is a relatively common problem. Dynamic sonography can be helpful in assessing both acute and chronic recurrences of groin pain. Most hernia repairs now use mesh. The key to sonographic identification of recurrent hernias is to assess the edges of the mesh with dynamic maneuvers, because recurrent hernias arise from the edges of the mesh.

Many pathologic processes can simulate hernia, both rare and nonspecific, but cysts or hydroceles of the processus vaginalis (or canal of Nuck) and round ligament varices are relatively common and have virtually pathognomonic sonographic appearances.

CHAPTER 14

The Peritoneum

Anthony E. Hanbidge, Korosh Khalili, and Stephanie R. Wilson

SUMMARY OF KEY POINTS

- Ultrasound has a role in peritoneal imaging.
- Success is dependent on operator awareness and thorough technique.
- Inclusion of transvaginal scan in women will greatly improve accuracy.
- Ultrasound is excellent for detecting and characterizing peritoneal fluid.
- Ultrasound is very useful for detecting and characterizing neoplastic and inflammatory peritoneal disease.
- Ultrasound is often the modality of choice to guide paracentesis and biopsy of peritoneal masses.

PNEUMOPERITONEUM
CONCLUSION

Ultrasound of the abdomen and pelvis has become an extension of the physical examination when evaluating patients with abdominal symptoms and signs. It is accurate, safe, readily available, portable, and relatively inexpensive. Evaluations have traditionally focused on assessing the solid viscera, the gallbladder, and bile ducts. Frequently, images of only these organs are recorded, and the peritoneal cavity is often neglected or subjected to cursory evaluation. The general belief is that ultrasound is not particularly helpful at imaging the peritoneum because of technical limitations, such as poor visibility and interference from bowel gas. There is also unfamiliarity with the common sonographic features encountered with peritoneal disease, as reflected by extensive literature on ultrasound of the liver, gallbladder, bile ducts, pancreas, spleen, kidneys, bladder, and reproductive organs but little on sonographic evaluation of the peritoneum and peritoneal cavity. As a result, teaching of optimal sonographic technique to evaluate these areas is minimal.

If peritoneal disease is a clinical concern, computed tomography (CT)[1,2] or magnetic resonance imaging (MRI)[3-5] is generally used to investigate. We believe that ultrasound can also be sensitive and specific in this regard.[6] To be successful, however, two criteria must be met: (1) the operator must be aware of the potential involvement of the peritoneum and peritoneal cavity with a disease process, and (2) these areas must receive a thorough sonographic assessment.

PERITONEUM, OMENTUM, AND MESENTERY

The **peritoneum** is a serous membrane lined with epithelial cells. It is divided into the parietal and visceral peritoneum. The **parietal peritoneum** lines the anterior and posterior walls of the abdominal cavity and is visible with ultrasound as a thin, smooth, echogenic line in the deepest layer of the anterior abdominal wall. Bowel loops can usually be seen deep to the parietal peritoneum, moving independent of it with respiration. The **visceral peritoneum,** on the other hand, covers the intraabdominal organs and is not visible with ultrasound in its normal state. The potential space between these two layers is known as the **peritoneal cavity,** which usually contains a small volume of fluid that acts as a lubricant.[7,8]

The **small bowel mesentery** is a specialized, fan-shaped, peritoneal fold extending from the second lumbar vertebra to the right iliac fossa. It connects the jejunum and ileum to the posterior abdominal wall. It is composed of a double layer of peritoneum, blood vessels, nerves, lacteals (lymphatic capillaries in villi), lymph nodes, and a variable amount of fat. Normal bowel mesentery is best assessed with ultrasound in the presence of **ascites;** it appears as freely floating, smooth leaves separated by fluid, directed toward the center of the abdomen, away from small bowel loops (Fig. 14.1). In the absence of ascites, the mesentery is more difficult to appreciate but has been described as a series of elongated, aperistaltic structures separated from each other by specular echoes, best appreciated in the left lower quadrant.[9] It is frequently difficult to localize a disease process to the mesentery, and the relationship to other anatomic landmarks may be helpful. For example, lymphoma may be correctly localized to the mesentery if a mass is seen that encases the mesenteric vessels.

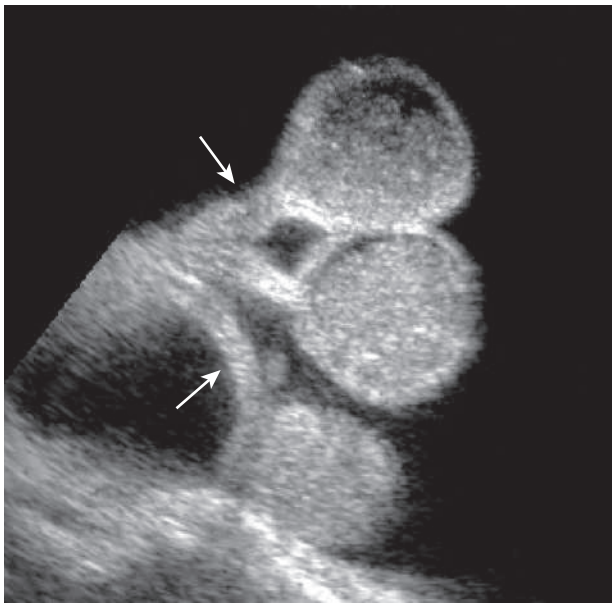

FIG. 14.1 Normal Mesentery With Gross Ascites. Oblique sagittal ultrasound image of the midabdomen shows the normal small bowel mesenteric leaves *(arrows)* outlined by fluid.

The **omenta** are also specialized peritoneal folds. They are composed of a double layer of peritoneum, blood vessels, lymphatics, and a variable amount of fat. The **lesser omentum** connects the lesser curvature of the stomach and proximal duodenum with the liver. The **greater omentum** descends from the greater curvature of the stomach, anterior to the abdominal contents, often as low as the pelvis, then reflects back on itself to form a four-layered structure that ascends and separates to enclose the transverse colon. A potential space exists between the two layers of the greater omentum, which is continuous with the lesser sac.

In the normal state, the omenta may be extremely difficult or impossible to distinguish with ultrasound. In the presence of ascites, the free inferior edge of the normal **greater omentum** may be visible floating in the fluid with variable thickness, depending on the fat content. In patients with disease the greater omentum may become infiltrated, thickened, and nodular (Fig. 14.2, Video 14.1). Its superficial location allows for careful sonographic evaluation with high-frequency transducers, and disease processes may often be correctly identified and localized to the greater omentum even in the absence of ascites.

SONOGRAPHIC TECHNIQUE

Sonographic assessment of the peritoneum requires the motivation to evaluate, as far as possible, the parietal and visceral peritoneum, mesentery, omentum, and peritoneal cavity. The initial survey of the peritoneum and peritoneal cavity is performed with a standard-frequency, 3.5-MHz or 5-MHz transducer (Fig. 14.3A).

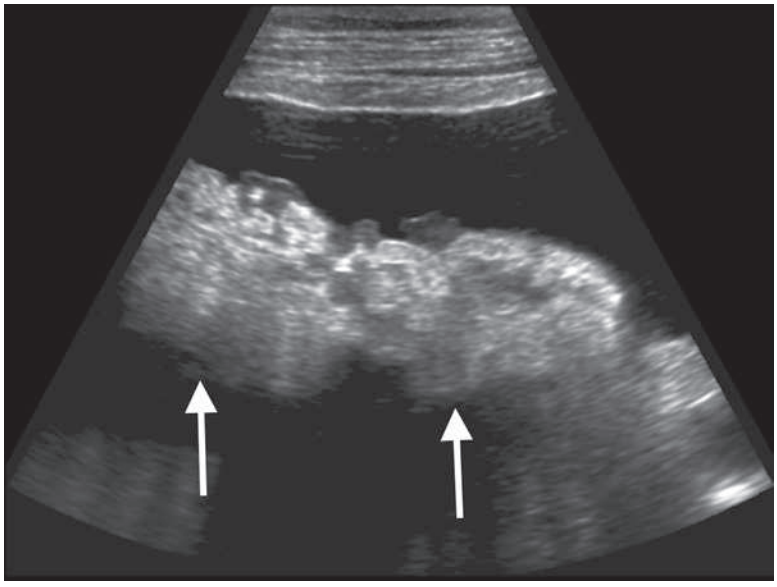

FIG. 14.2 Tumor Infiltration of the Omentum. Sagittal ultrasound image of the midabdomen shows thickening and hypoechoic nodularity of the omentum *(arrows)* immediately posterior to free fluid deep to the anterior abdominal wall. See also Video 14.1.

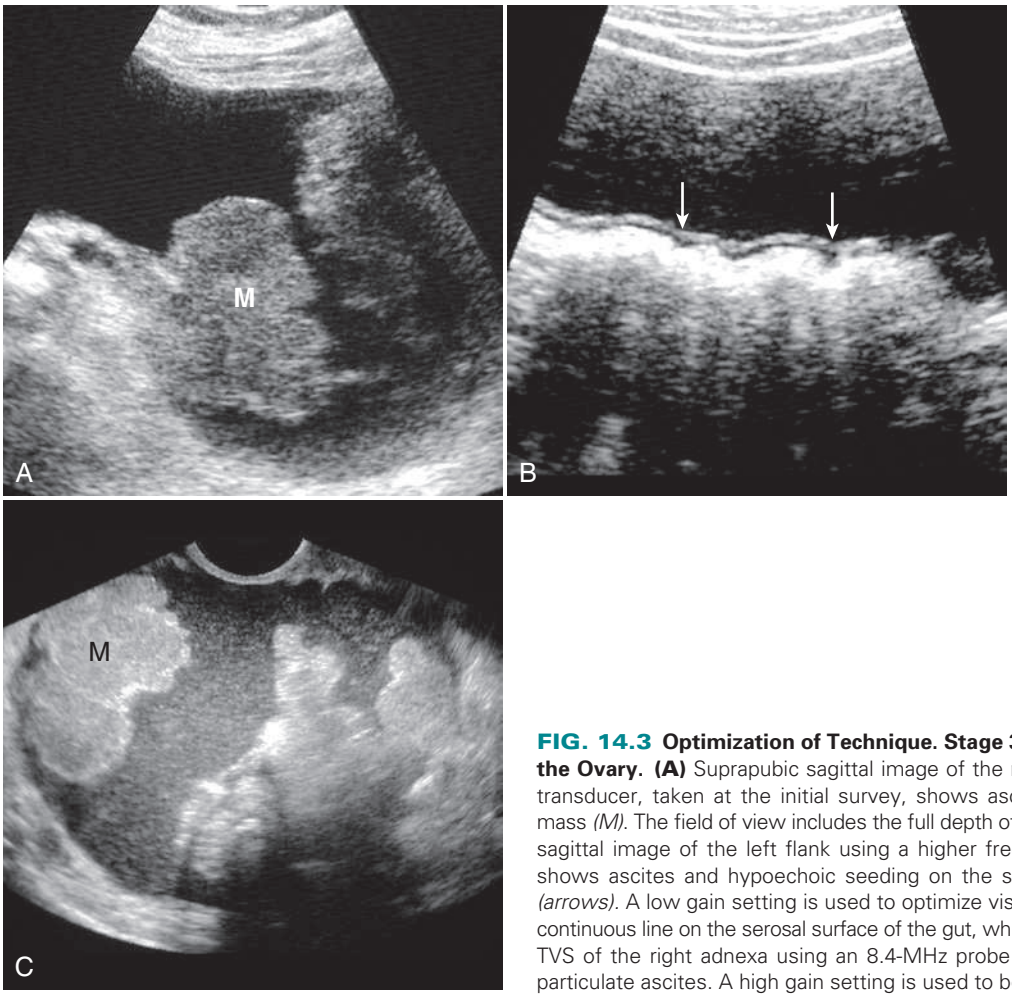

FIG. 14.3 Optimization of Technique. Stage 3 Papillary Serous Adenocarcinoma of the Ovary. (A) Suprapubic sagittal image of the right adnexa using a 5.2-MHz curvilinear transducer, taken at the initial survey, shows ascites and a solid, lobulated, hypoechoic mass *(M)*. The field of view includes the full depth of the peritoneal cavity. **(B)** Transabdominal sagittal image of the left flank using a higher frequency, 7.4-MHz, curvilinear transducer shows ascites and hypoechoic seeding on the serosal surface of the descending colon *(arrows)*. A low gain setting is used to optimize visualization of the seeding, seen as a thin, continuous line on the serosal surface of the gut, which contains shadowing air. **(C)** Transverse TVS of the right adnexa using an 8.4-MHz probe shows the right adnexal mass *(M)* and particulate ascites. A high gain setting is used to better characterize the particulate ascites.

The **field of view** (FOV) is set to include the full depth of the peritoneal cavity, but no more; this adds perspective to the image. The **focal zone** is continually adjusted to evaluate in detail different depths within the FOV. The **power** and **gain** settings are also adjusted using a high gain setting to characterize free fluid as anechoic or particulate and a low gain setting to visualize hypoechoic nodules or masses optimally. Once the initial survey is complete, higher-frequency transducers are used to more carefully evaluate and characterize abnormalities in the near field (Fig. 14.3B).

When scanning transabdominally, graded compression is used to displace bowel gas. Determination of the site of origin of a peritoneal process may be aided by several techniques. Palpation of an abnormal mass, either with the transducer or with the free hand, will determine both the compliance and the mobility of a mass. Masses arising from the parietal peritoneum are often fixed, whereas masses arising from the visceral peritoneum may be mobile. This distinction may also be demonstrated by changing the patient's position or with changes in respiration. For example, in the right upper quadrant, a lesion in the near field is likely to be located on the parietal peritoneum if the liver moves independent of it with respiration.

A **transvaginal sonography (TVS)** examination is critical for all female patients at risk for or with suspected peritoneal disease (Fig. 14.3C). The pelvic pouch of Douglas is a common site of involvement, particularly in carcinomatosis and acute conditions. This technique allows exquisite assessment of both the parietal and the visceral pelvic peritoneum.[10,11] In addition to assessing the uterus and ovaries, the probe should be directed to the pouch of Douglas, by elevating the examining hand (Fig. 14.4), and to both pelvic side-walls. A dynamic assessment is often helpful to help establish the origin of a nodule or mass (Videos 14.2 and 14.3). The TVS may also facilitate improved visualization of pelvic bowel loops and the urinary bladder.

Ultrasound is an accurate, fast, and efficient means of guiding interventions involving the peritoneum and peritoneal cavity and is frequently the modality of choice to guide diagnostic and therapeutic paracentesis and biopsy of peritoneal masses.[12]

ASCITES

One of the earliest uses of sonography in the abdomen and pelvis involved the detection of ascites.[13] Normally, 50 to 75 mL of free fluid is present in the peritoneal cavity, acting as a lubricant. Ascites occurs with excess accumulation of peritoneal fluid. Ascites can be classified as **transudate** or **exudate** depending on the protein content. In North America, cirrhosis, peritoneal carcinomatosis, congestive heart failure, and tuberculosis account

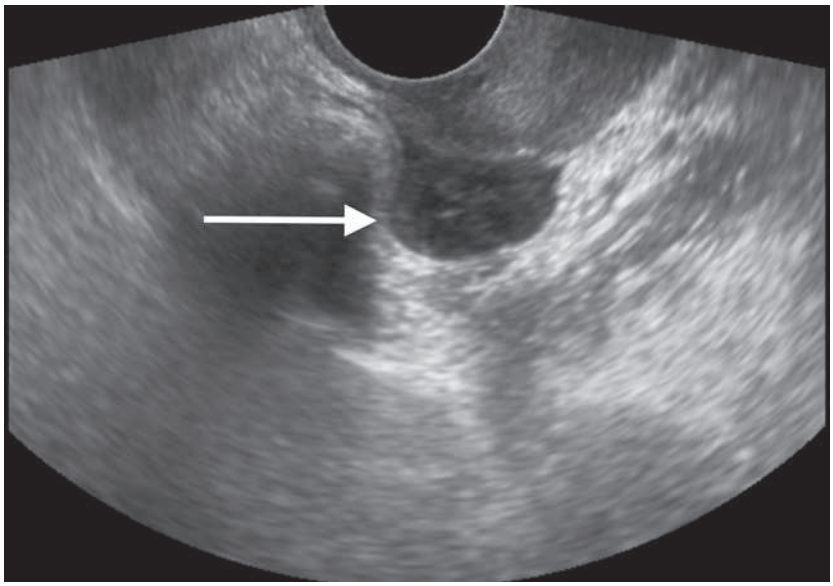

FIG. 14.4 Tumor Implant in the Pouch of Douglas. Oblique transverse TVS shows a small solid hypoechoic nodule *(arrow)* in the pouch of Douglas. See also Videos 14.2 and 14.3.

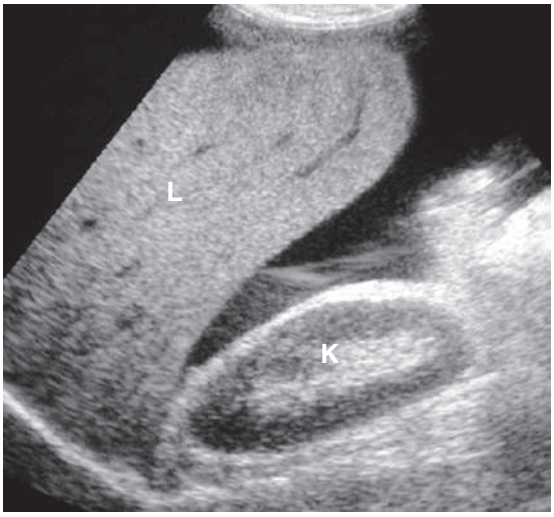

FIG. 14.5 Cirrhosis of the Liver With Portal Hypertension. Sagittal ultrasound image of the right upper quadrant readily demonstrates a large amount of ascites surrounding an enlarged, bulbous, fatty liver *(L)*. *K,* Right kidney.

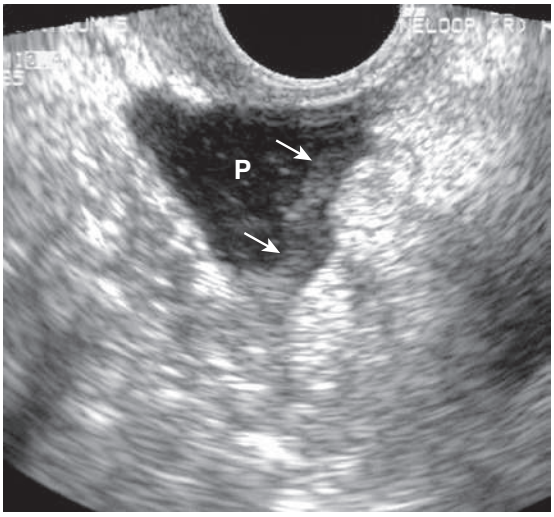

FIG. 14.6 Grade 2/3 Ovarian Mucinous Cystadenocarcinoma. Transverse TVS of the right adnexa shows a small amount of particulate free fluid *(P)* and serosal seeding *(arrows)* on loops of bowel in the pelvis. This was visible only on the TVS.

for 90% of all cases of ascites. Accumulations of blood, urine, chyle, bile, or pancreatic juice are more unusual causes.

Ascites can be detected with physical examination when the volume reaches 500 mL. Transabdominal ultrasound can readily detect large volumes of ascites (Fig. 14.5). TVS is more sensitive in this regard, and volumes of free fluid as small as 0.8 mL can be demonstrated with the transvaginal probe[14] (Fig. 14.6). With the patient lying supine, free fluid tends to accumulate in the paracolic gutters and pelvis,[15] particularly the superior end of the right paracolic gutter and Morison pouch. These areas should therefore be carefully assessed when ascites is suspected. Ultrasound is also accurate at quantifying[16] and localizing ascites and may be used to guide both diagnostic and therapeutic paracentesis.

In addition to its excellent capability to quantify ascites, ultrasound can also characterize ascites as anechoic or particulate. This may be helpful in determining the source because **particulate ascites** suggests the presence of blood, pus, or neoplastic cells in the fluid. The observation of particulate ascites should prompt a more detailed assessment of the peritoneum with ultrasound,[17,18] further imaging with CT/MRI, and diagnostic paracentesis.

Hemoperitoneum has many causes, including trauma, ruptured aneurysm, ruptured ectopic pregnancy, ruptured liver mass (e.g., adenoma, hepatoma), and postsurgical bleeding. Spontaneous hemorrhage may occur in patients receiving anticoagulants. The appearance of acute blood is varied, including anechoic or particulate free fluid (Fig. 14.7). A fluid-debris level may develop if the patient has maintained a stable position for

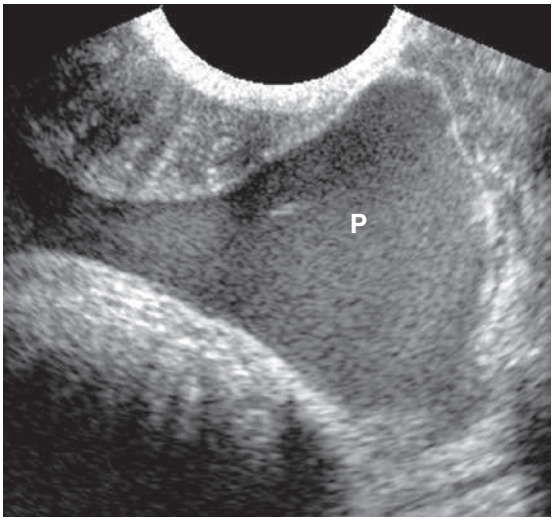

FIG. 14.7 Hemoperitoneum in Ruptured Ectopic Pregnancy. Oblique transverse TVS of the left adnexa shows particulate free fluid *(P)*.

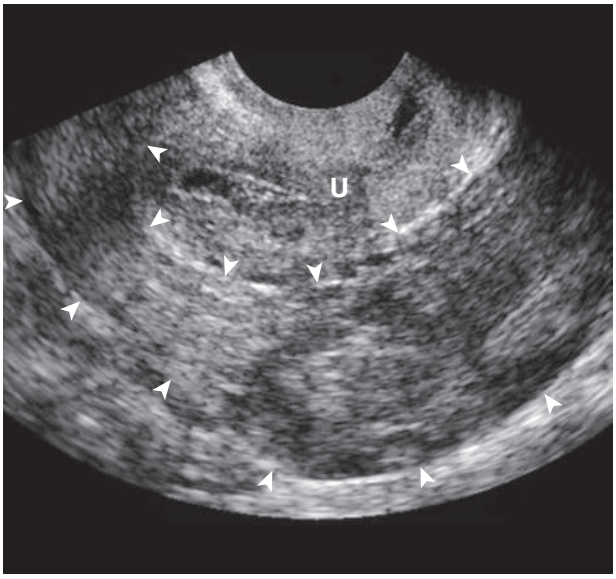

FIG. 14.9 Pelvic Hematoma 2 Days After Surgery in Female Patient Taking Anticoagulants. Sagittal TVS image shows the uterus *(U)*, with fluid in the endometrial canal, surrounded by a large, hypoechoic heterogeneous hematoma *(arrowheads)*.

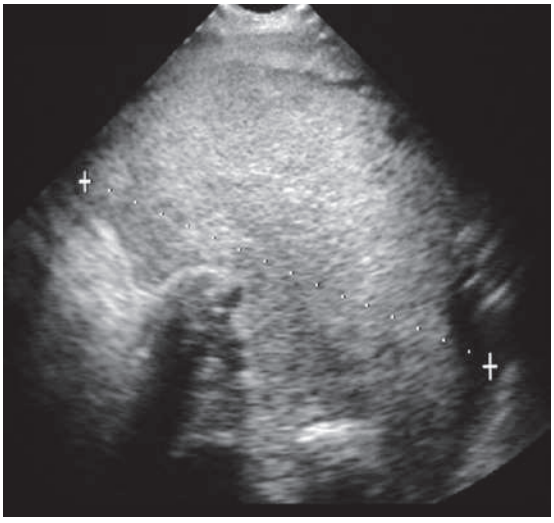

FIG. 14.8 Blood Clot. Acute blood clot secondary to rupture of a pseudoaneurysm at the hepatic artery anastomosis after liver transplantation. Sagittal ultrasound image of the left lower quadrant shows a solid, heterogeneous mass *(calipers)*.

a time. Massive hemorrhage often results in a large, echogenic mass that may become more heterogeneous as lysis occurs over time (Figs. 14.8 and 14.9).

Focused abdominal sonography for trauma (FAST) has become an accepted screening modality for intraabdominal injuries in the traumatized patient.[19-23] The primary focus of this limited study is to detect free intraperitoneal fluid with ultrasound in the trauma center. Fluid detected in this setting strongly suggests significant intraabdominal injury requiring urgent laparotomy. FAST has replaced peritoneal lavage in many centers.

Chylous ascites is an unusual condition in which lymph accumulates within the peritoneal cavity. The causes are varied, including **trauma, surgery, lymphangioma, lymphoma, intestinal lymphangiectasia,** and **cystic hygroma.** Sonography may show particulate ascites or a fluid-fluid level because of layering of the lymphatic fluid.[24,25]

It is sometimes difficult to decide if fluid visualized in the peritoneal cavity is free or loculated. Altering the patient's position may be helpful to establish if the fluid moves under the force of gravity. For example, free fluid in the right paracolic gutter with the patient lying supine may move from this location if the patient lies in a left lateral decubitus position. The morphology of the fluid collection may also be helpful. **Free fluid** tends to conform to the surrounding organs and will frequently exhibit acute angles when in contact with surrounding structures such as bowel loops. **Loculated fluid,** on the other hand, tends to have rounded margins and show mass effect, frequently displacing surrounding structures from their usual location. Loculated fluid collections can occur anywhere in the abdomen and pelvis. Characterization of fluid and the demonstration of complexity of localized or generalized peritoneal fluid collections are strengths of ultrasound, and ultrasound is superior to CT scan in this regard (Fig. 14.10).

PERITONEAL INCLUSION CYSTS (BENIGN ENCYSTED FLUID)

The fluid produced by active ovaries in premenopausal patients is usually absorbed by the peritoneum. This balance can be upset by disease processes involving the pelvis, such as previous surgery, trauma, **pelvic inflammatory disease, inflammatory bowel disease,** or **endometriosis.** In these patients the fluid produced by the ovaries may not be absorbed but may become trapped by adhesions. Over time, an inclusion cyst forms that frequently encases the ovary and may cause pelvic pain and pressure. Inclusion cysts vary in size and complexity and may be relatively simple or may contain internal echoes and septations.[26-28] They often cause confusion when imaging is performed and may be

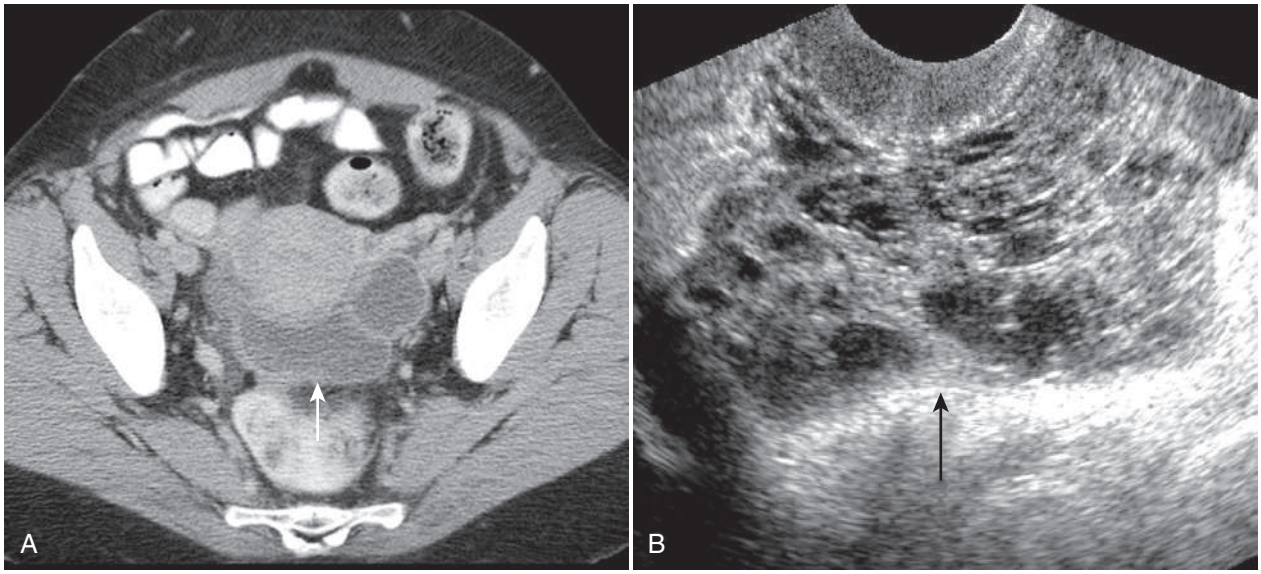

FIG. 14.10 Fibrinous Peritonitis. (A) Axial, contrast-enhanced pelvic CT scan shows loculated fluid in the pouch of Douglas and left adnexa with an enhancing rim *(arrow)*. **(B)** Transverse TVS shows the high degree of complexity of this fluid *(arrow)* to much better advantage.

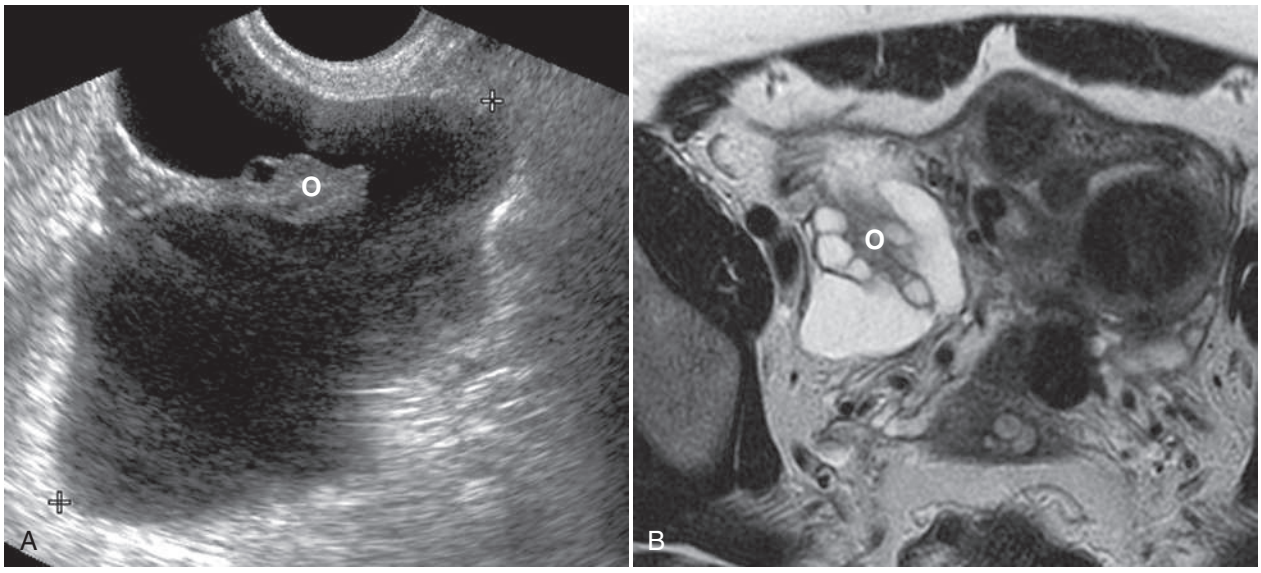

FIG. 14.11 Peritoneal Inclusion Cyst. (A) Transverse TVS of the right adnexa. **(B)** Axial T2-weighted MRI through the midpelvis. Both images show the normal right ovary *(O)* surrounded by encysted fluid, conforming to the contours of the peritoneal cavity. (Reproduced from Wilson SR. Pseudomyxoma peritonei. In: Cohen HL, editor. Gastrointestinal disease, test and syllabus. Reston, VA: American College of Radiology; 2004. pp. 73-84.[28])

misinterpreted as representing ovarian cysts, parovarian cysts, hydrosalpinges, or even ovarian cancer. The key to the correct diagnosis is to suspect this condition based on the patient's profile, then demonstrate a normal ovary, either within or on the margin of the inclusion cyst, most often with TVS (Fig. 14.11). Complex peritoneal inclusion cysts are also known as multicystic **mesotheliomas.**[29]

MESENTERIC CYSTS

Mesenteric cysts are rare intraabdominal masses often discovered incidentally at imaging. However, they may present clinically with abdominal distention because of their size, or acutely with pain because of a complication such as hemorrhage, rupture, or torsion. Mesenteric cysts are most often of lymphatic **(lymphangioma)** or mesothelial origin but may also be of enteric **(enteric duplication cyst)** or urogenital origin. **Dermoid cysts** and **pseudocysts** (infectious, inflammatory, or traumatic) are seen as well.[30,31] Mesenteric cysts vary in size from less than 1 cm to greater than 25 cm, filling the entire peritoneal cavity. They may be entirely simple to highly complex with extensive internal septations, as sometimes seen with lymphangiomas[32,33] (Fig. 14.12). Smaller mesenteric cysts are frequently mobile, changing location with palpation or with changes in the patient's position.

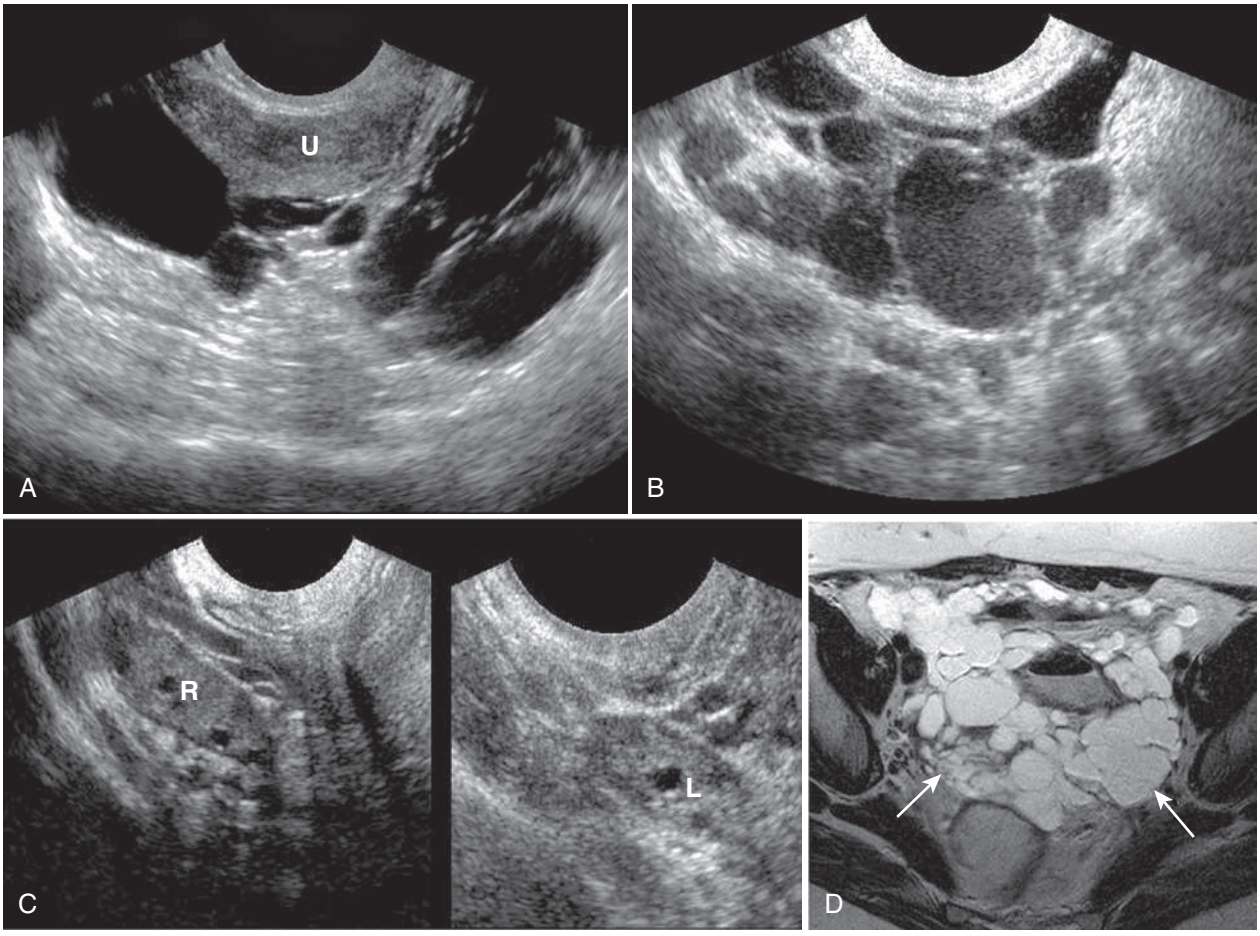

FIG. 14.12 Pelvic Lymphangioma in Asymptomatic Woman. (A) Transverse TVS shows the normal uterus *(U)* in cross section, surrounded by innumerable cysts with thin septations. There is no nodularity. Real-time examination suggested that these cysts were soft and compliant. **(B)** TVS lateral to the uterus shows that the cystic changes are extensive. Their distribution and extent do not suggest an ovarian origin. **(C)** Two TVS images show a normal right *(R)* and a normal left *(L)* ovary. This excludes the ovaries as a source of the pathology. **(D)** Axial T2-weighted MRI confirms the extensive intraperitoneal thin-walled cystic masses *(arrows)*. (Reproduced from Wilson SR. Pseudomyxoma peritonei. In: Cohen HL, editor. Gastrointestinal disease, test and syllabus. Reston, VA: American College of Radiology; 2004. pp. 73-84.[28])

Asymptomatic cysts are frequently managed conservatively, particularly if simple or with the typical appearance of a lymphangioma. Surgery is usually reserved to alleviate pressure symptoms or to address acute complications.

PERITONEAL TUMORS

Tumors involving the peritoneum are often encountered with ultrasound and are generally malignant. **Metastatic tumors** are much more common than **primary peritoneal tumors.** The ovary is the primary site of disease in the vast majority of female patients. Other sites of primary disease with a propensity to spread to the peritoneum include the **stomach, colon, breast, pancreas, kidney, bladder, uterus,** and **skin (melanoma).**

Peritoneal Carcinomatosis

Peritoneal carcinomatosis is the term used to describe diffuse involvement of the peritoneum with metastatic disease. Carcinomatous seeding involving the parietal peritoneum (Fig. 14.13, Fig. 14.14A, Video 14.4) or visceral peritoneum (Figs. 14.14B and 14.15, Videos 14.5 and 14.6) may produce discrete hypoechoic nodules, irregular masses, or hypoechoic rind-like thickening

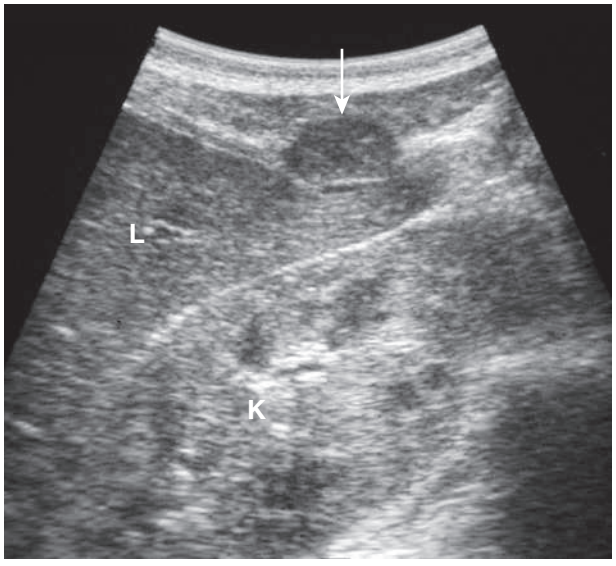

FIG. 14.13 Parietal Peritoneal Metastasis From Squamous Cell Carcinoma of the Lung. Sagittal image of the right upper quadrant shows a hypoechoic nodule *(arrow)* anterior to the liver *(L)*. With respiration, the liver moved freely and independent of the nodule, which stayed stationary, correctly suggesting its location on the parietal peritoneum. *K,* Kidney. See also Video 14.4.

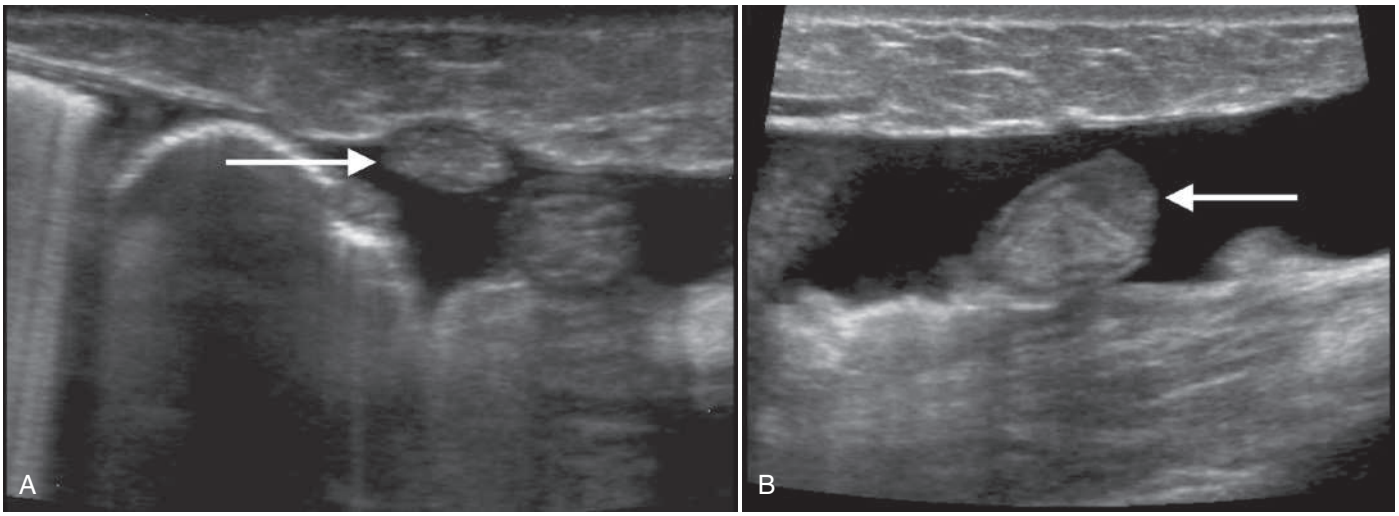

FIG. 14.14 Peritoneal Carcinomatosis. (A) Oblique sagittal ultrasound image of the midabdomen shows free fluid in the peritoneal cavity and a mildly hypoechoic nodular tumor implant involving the parietal peritoneum *(arrow)* immediately deep to the anterior abdominal wall. **(B)** Oblique sagittal ultrasound image of the midabdomen shows free fluid in the peritoneal cavity and a hypoechoic nodular tumor implant involving the visceral peritoneum *(arrow)* on the serosal surface of a small bowel loop. See also Videos 14.5 and 14.6.

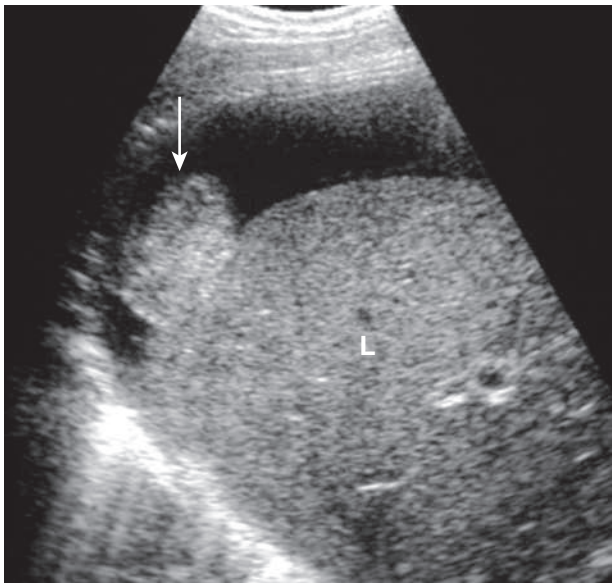

FIG. 14.15 Visceral Peritoneal Metastasis From Adenocarcinoma of the Colon. Oblique sagittal image of the right upper quadrant shows an echogenic nodule *(arrow)* on the surface of the liver *(L)*, surrounded by ascites. With respiration, the nodule moved in concert with the liver, correctly suggesting its location on the visceral peritoneum.

of the peritoneum.[18] Ascites is common and may be the only finding. The **pouch of Douglas, greater omentum, Morison pouch,** and the right subphrenic space are common sites,[34] and therefore any sonographic evaluation of the peritoneum for metastatic disease should include careful and detailed assessment of these areas (Fig. 14.16). The **parietal peritoneal line** is often preserved on sonography with small seeds but is often lost as the lesion increases in size. Growth of a lesion is usually inward, toward the peritoneal cavity, but growth outward with invasion of the abdominal wall can occur (Fig. 14.17). If **psammomatous calcification** occurs within a peritoneal nodule, it appears echogenic with ultrasound, and if the calcification is dense, it may demonstrate posterior acoustic shadowing (Fig. 14.18).

Peritoneal carcinomatosis can be detected with ultrasound in the absence of ascites (Figs. 14.19 and 14.20), but its presence greatly enhances the detection of peritoneal lesions. Nodules as small as 2 to 3 mm may be seen on the parietal and visceral peritoneum with the transvaginal probe (Fig. 14.21). The detection of omental involvement is also enhanced by ascites. Infiltration of the omentum leads to an "omental cake,"[35] which may float freely in the ascitic fluid (Fig. 14.22). Alternatively, the omentum may be adherent to the parietal peritoneum in the near field (Fig. 14.23), or it may be deeper in the peritoneal cavity, adherent to the visceral peritoneum and surrounding small bowel loops (Fig. 14.24). **Thickening of the mesentery, mesenteric nodules,** and **lymphadenopathy** are other possible features of carcinomatosis.

After the full extent of peritoneal involvement has been documented with ultrasound, a careful search should be made for the primary lesion within the abdomen and pelvis, if not already identified. This search should not be limited to the solid organs, gallbladder, and bile ducts and should include the stomach and bowel.

Primary Tumors of Peritoneum

Primary tumors of the peritoneum are rare and include **primary peritoneal serous papillary carcinoma, malignant mesothelioma,** and **lymphoma.** Primary peritoneal serous papillary carcinoma is a multicentric peritoneal tumor that is morphologically identical to **ovarian serous papillary carcinoma** of equivalent grade but that can spare or minimally invade the ovaries.[36] Women with primary peritoneal serous papillary carcinoma are more likely to present with ascites than women with ovarian serous papillary carcinoma and have a worse 3-year survival rate.[37]

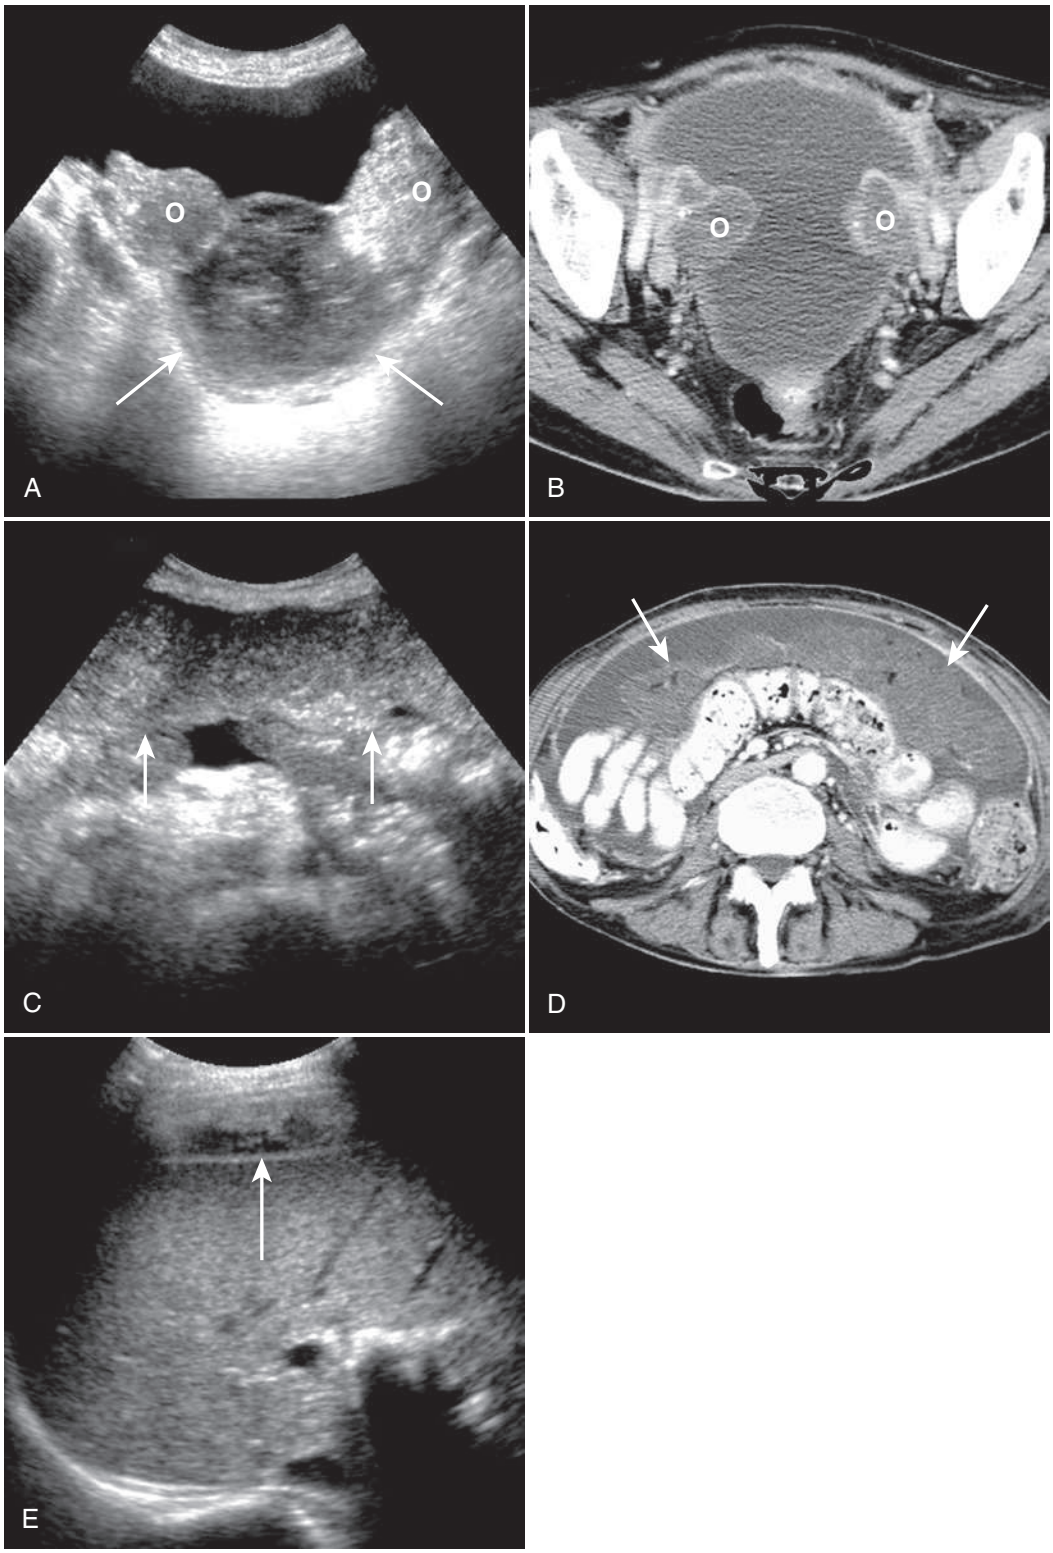

FIG. 14.16 Peritoneal Carcinomatosis From Mucinous Adenocarcinoma, Presumably of Gastrointestinal Origin. (A) Transverse transabdominal pelvic sonogram and **(B)** CT scan at the same level show ascites and bilateral ovarian solid masses *(O)* suggestive of Krukenberg tumors. The marked complexity of the fluid with particles and septations is better appreciated on the ultrasound scan (*arrows* in A). **(C)** Transverse midabdominal ultrasound image and **(D)** corresponding CT scan show a thick "omental cake" *(arrows)* displacing bowel loops posteriorly in the peritoneal cavity. Free fluid is also visualized. **(E)** Oblique ultrasound image in the right upper quadrant shows a rim of complex, mixed-echogenic material overlying and indenting the convexity of the liver *(arrow)*. There is echogenic nodularity on the parietal peritoneum of the diaphragm. This did not move with the liver on respiration, confirming its origin from the parietal peritoneum. (Reproduced from Wilson SR. Pseudomyxoma peritonei. In: Cohen HL, editor. Gastrointestinal disease, test and syllabus. Reston, VA: American College of Radiology 2004. pp. 73-84.[28])

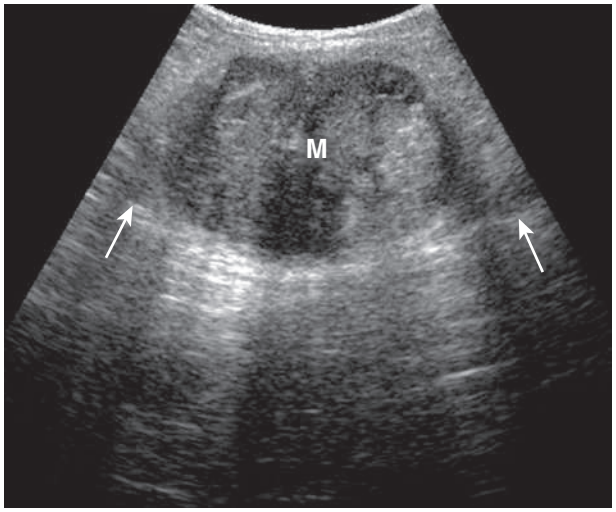

FIG. 14.17 Abdominal Wall Seed in Patient With Known Peritoneal Carcinomatosis. Transverse ultrasound image of the midabdomen shows a hypoechoic solid mass *(M)* in the anterior abdominal wall, superficial to the parietal peritoneum *(arrows)*.

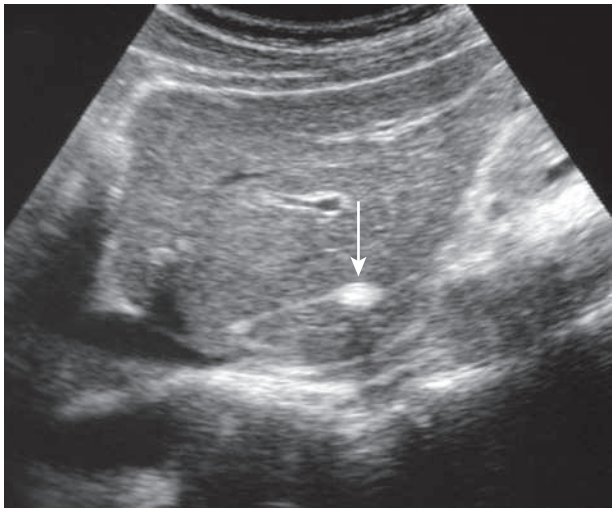

FIG. 14.18 Well-Differentiated Stage 3 Papillary Serous Ovarian Cancer. Sagittal ultrasound image through the liver shows a calcified implant *(arrow)* in the ligamentum venosum, with posterior acoustic shadowing.

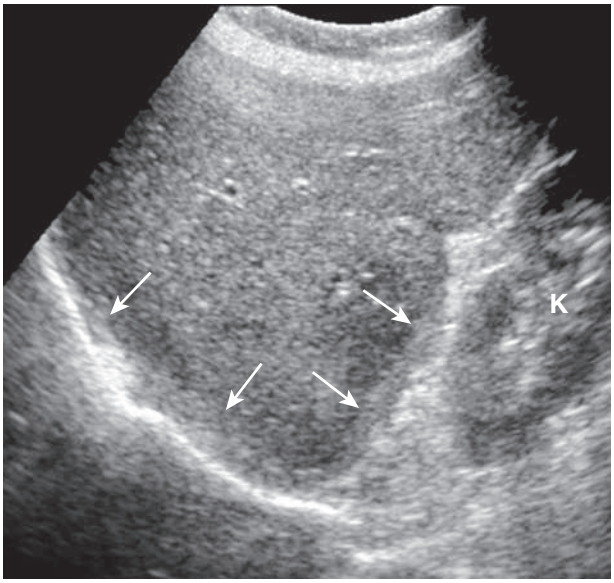

FIG. 14.19 Stage 3 Papillary Serous Ovarian Cancer Without Ascites. Sagittal ultrasound image in the right upper quadrant shows a subtle, thin, echogenic "rind" of seeding *(arrows)* on the surface of the liver, extending into the Morison pouch. *K,* Kidney.

Imaging may demonstrate the typical features of peritoneal carcinomatosis, but no obvious primary site[38-42] (Fig. 14.25). The ovaries are generally normal in size but may be enlarged by surface involvement.

Primary peritoneal mesothelioma accounts for 10% to 30% of all cases of malignant mesothelioma[1,2,29,43] and is most common in middle-aged men. The tumor proves invariably fatal, and as with mesothelioma of the pleura, there is an association with asbestos exposure. Up to 65% of chest radiographs show evidence of asbestos exposure at diagnosis. In this condition the parietal and visceral peritoneums are diffusely thickened or are extensively involved by tumor plaques or nodules (Fig. 14.26, Video 14.7). These plaques and nodules may aggregate to form discrete masses. The viscera may be encased or invaded by tumor. Ascites is a common finding and is seen in up to 90% of cases.[44] As with peritoneal carcinomatosis, the nodules and plaques are often hypoechoic in peritoneal mesothelioma (Fig. 14.27). Pleural effusions and pleural plaques may also be appreciated with ultrasound. The solid organs should be evaluated for direct invasion or metastases. Ultrasound-guided biopsy can be performed to confirm the diagnosis.[45] Generally, core biopsies from a number of locations are required because of difficulty sometimes encountered in establishing the diagnosis of peritoneal mesothelioma.

Primary lymphoma of the peritoneum is extremely rare and is the non-Hodgkin variety.[2,46] There is an increased incidence in patients with acquired immunodeficiency syndrome (AIDS).[47] Again, features include diffuse peritoneal seeding, often with more focal masses. Lymphomatous masses may be extremely hypoechoic and can be mistaken for fluid collections with cursory assessment (Fig. 14.28).

Pseudomyxoma Peritonei

Pseudomyxoma peritonei is a rare, often fatal intraabdominal disease characterized by dissecting gelatinous ascites and multifocal peritoneal implants of columnar epithelium that secrete copious globules of extracellular mucin.[48] Controversy surrounds the origin of pseudomyxoma peritonei. Some studies suggest synchronous ovarian and appendiceal tumors in 90% of patients,[49] whereas most now believe that the condition almost always originates from a perforated appendiceal epithelial tumor.[50] The disease process tends to remain localized to the peritoneal cavity, and extraperitoneal spread is rare. Pseudomyxoma peritonei encompasses benign, borderline, and malignant mucinous neoplasms, resulting in a variable and poorly predictable prognosis. The overall 5-year survival is 40% to 50%, depending on cell type.[51]

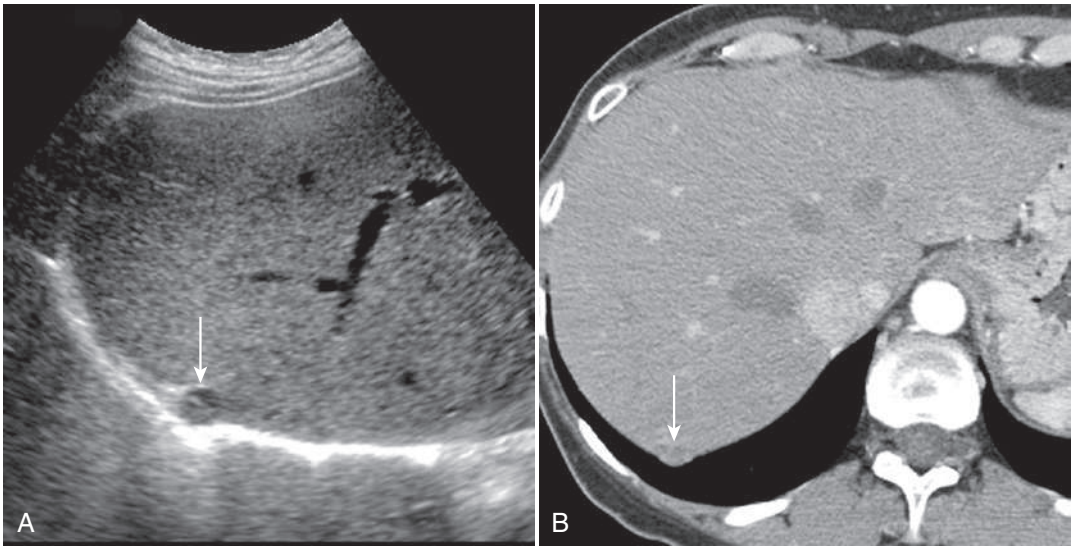

FIG. 14.20 Peritoneal Implant Without Ascites. (A) Transverse ultrasound image and **(B)** axial CT image of the right upper quadrant show a small peritoneal implant *(arrow)* overlying segment 7 of the liver. Note that the implant is better appreciated on the ultrasound image.

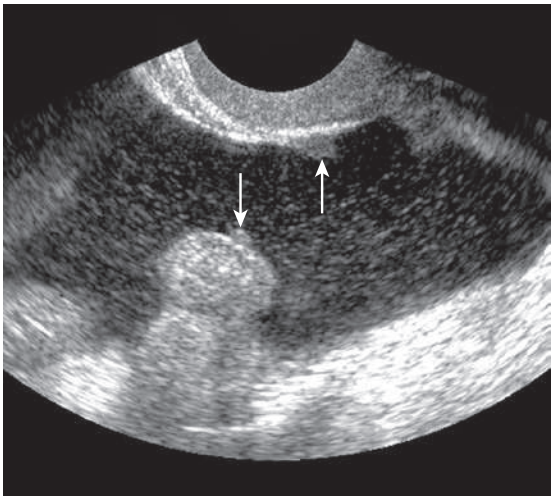

FIG. 14.21 Peritoneal Carcinomatosis From Ovarian Cancer. Oblique sagittal TVS shows small (<5 mm), parietal (near-field), and visceral (far-field) peritoneal implants *(arrows),* surrounded by particulate ascites.

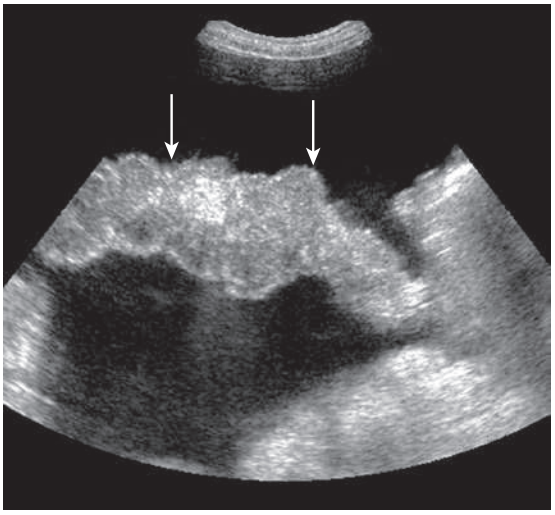

FIG. 14.22 Free-Floating "Omental Cake." Sagittal ultrasound image of the lower midline abdomen shows an omental cake *(arrows)* floating freely in the ascitic fluid. Note the free edge of the abnormal greater omentum inferiorly.

Patients with pseudomyxoma peritonei present with abdominal pain and distention. Ultimately, the bowel becomes encased with mucinous material, and bowel obstruction may occur. Repeated surgical intervention to remove the accumulated mucinous material remains the treatment of choice.[52] Perioperative intraperitoneal chemotherapy may add additional benefit.[53] Because patients present with abdominal symptoms, the diagnosis is frequently made preoperatively by ultrasound or CT.[54] Sonography frequently shows complex ascites reflecting the gelatinous nature of the fluid. The echogenic foci within the fluid are nonmobile, and the bowel loops, instead of floating freely, are displaced centrally and posteriorly by the surrounding mass, giving a characteristic "starburst" appearance[55] (Fig. 14.29). Scalloping of the liver is another typical feature of pseudomyxoma peritonei.[56] Ultrasound may be helpful to guide paracentesis in these patients because less viscous areas may be identified, with a greater likelihood of successful aspiration.

INFLAMMATORY DISEASE OF PERITONEUM

Peritonitis is defined as diffuse inflammation of the parietal and visceral peritoneum, with both infectious and noninfectious causes.[3] Infectious causes include bacteria (including tuberculosis), viruses, fungi, and parasites. Noninfectious causes are less common and include **chemical peritonitis** (secondary to gastric or pancreatic juice or bile), **granulomatous peritonitis** (secondary to foreign bodies such as talc), and **sclerosing peritonitis** associated with **continuous ambulatory peritoneal dialysis.**

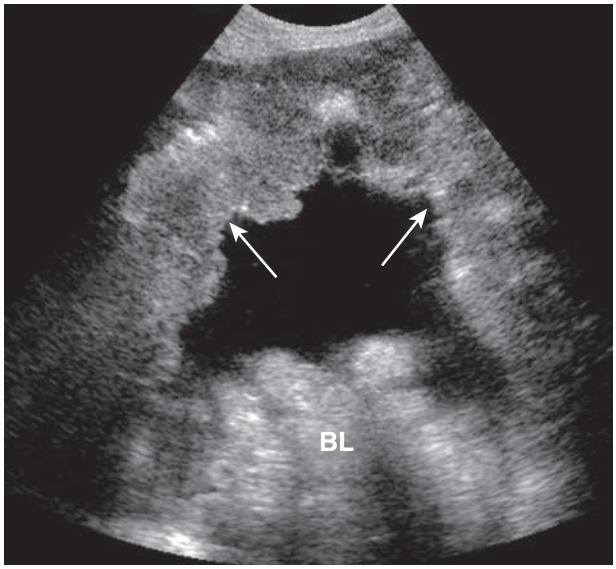

FIG. 14.23 Omental Cake Adherent to Parietal Peritoneum. Transverse ultrasound image of the midabdomen shows an omental cake *(arrows)* in the near field, adherent to the parietal peritoneum. Small bowel loops *(BL)* are visible in the far field, outlined by ascites.

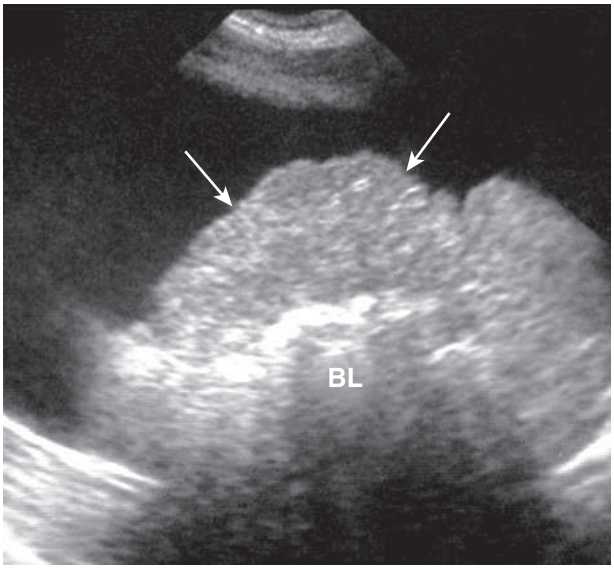

FIG. 14.24 Omental Cake Adherent to Visceral Peritoneum. Transverse ultrasound image of the midabdomen shows a thick omental cake *(arrows)* adherent to the visceral peritoneum and encasing gas-filled small bowel loops *(BL)*.

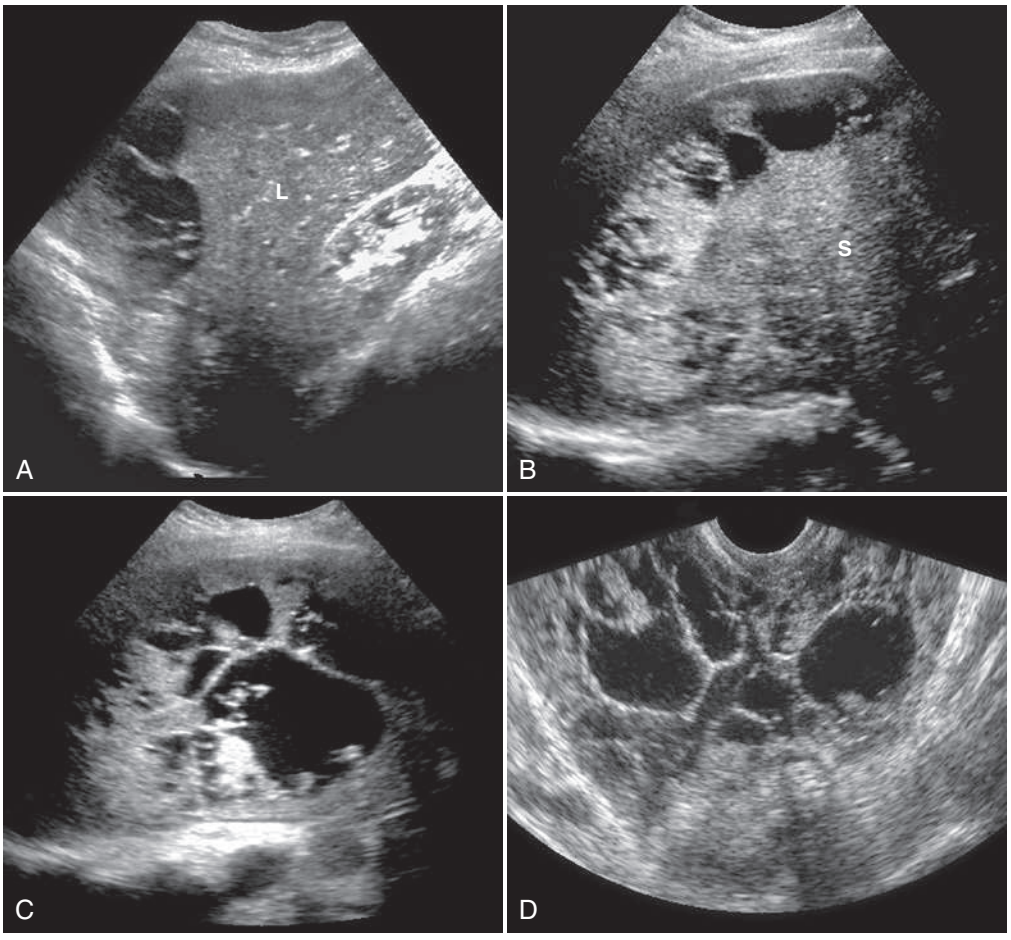

FIG. 14.25 Primary Peritoneal Serous Papillary Carcinoma. (A) Sagittal ultrasound image shows a highly complex peritoneal mass between the right hemidiaphragm and the liver *(L)*. The liver border is scalloped. **(B)** Sagittal ultrasound image in the left upper quadrant shows a similar complex peritoneal mass over the convexity of the spleen *(S)*. **(C)** Midabdominal image shows a complex peritoneal cystic and solid mass of enormous size. **(D)** TVS image taken in the pouch of Douglas shows no normal tissue. The entire pouch is filled with a complex cystic and solid tumor. (Reproduced from Wilson SR. Pseudomyxoma peritonei. In: Cohen HL, editor. Gastrointestinal disease, test and syllabus. Reston, VA: American College of Radiology; 2004. pp. 73-84.[28])

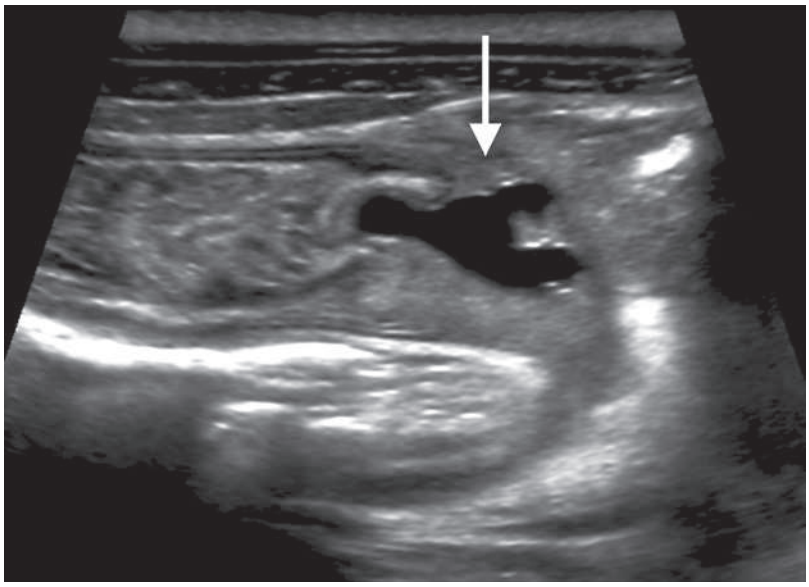

FIG. 14.26 Peritoneal Mesothelioma. Sagittal ultrasound image of the midabdomen shows hypoechoic thickening of the visceral peritoneum with a pocket of loculated fluid *(arrow)* separating small bowel loops. See also Video 14.7.

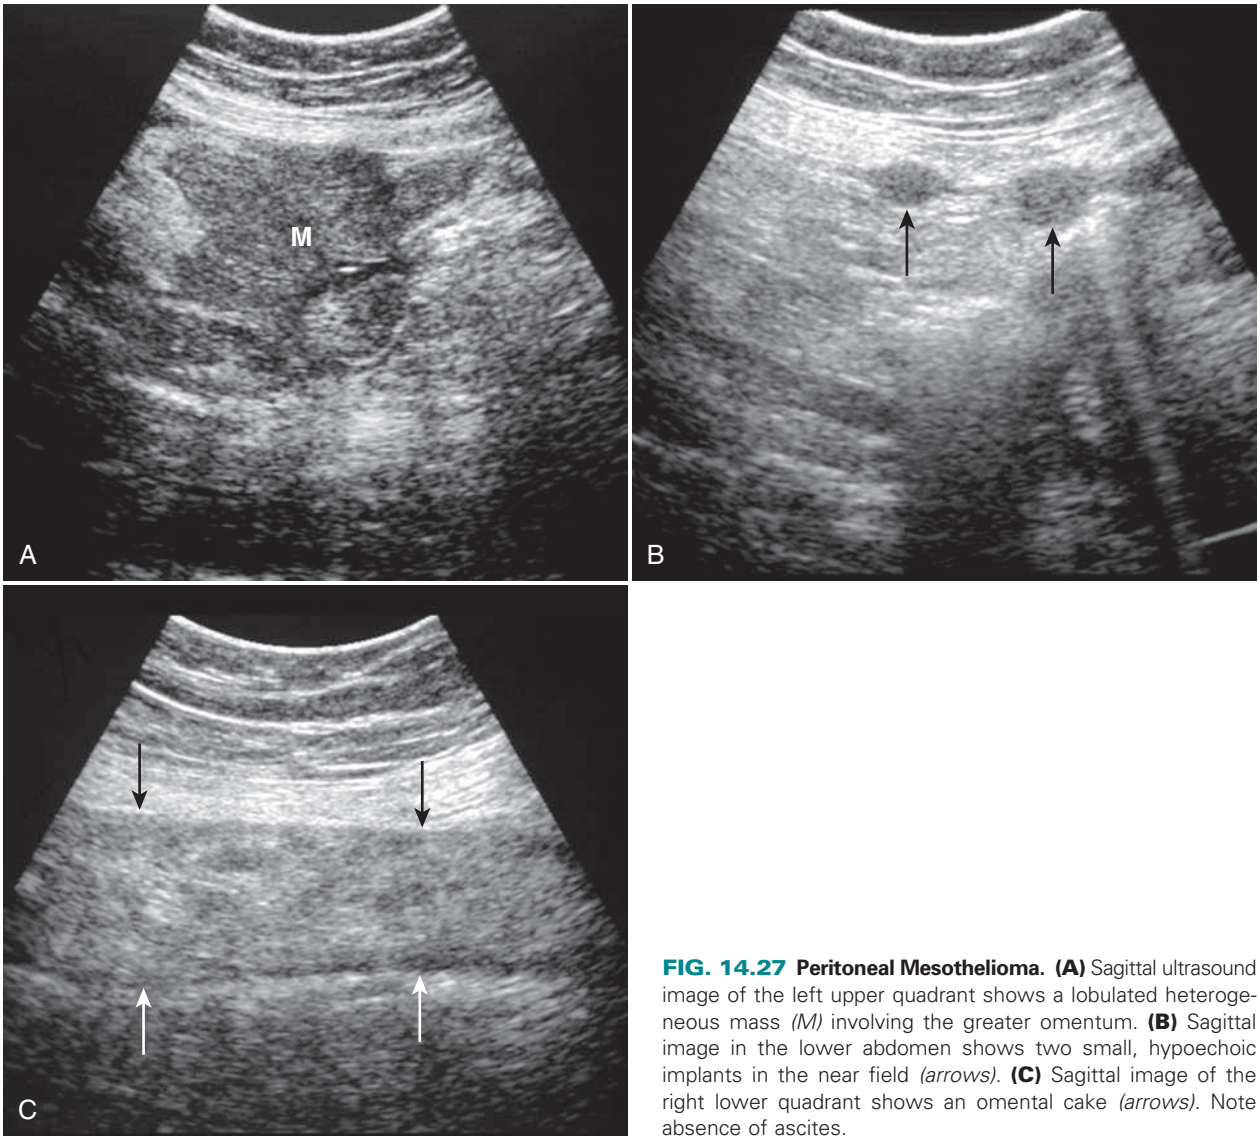

FIG. 14.27 Peritoneal Mesothelioma. (A) Sagittal ultrasound image of the left upper quadrant shows a lobulated heterogeneous mass *(M)* involving the greater omentum. **(B)** Sagittal image in the lower abdomen shows two small, hypoechoic implants in the near field *(arrows)*. **(C)** Sagittal image of the right lower quadrant shows an omental cake *(arrows)*. Note absence of ascites.

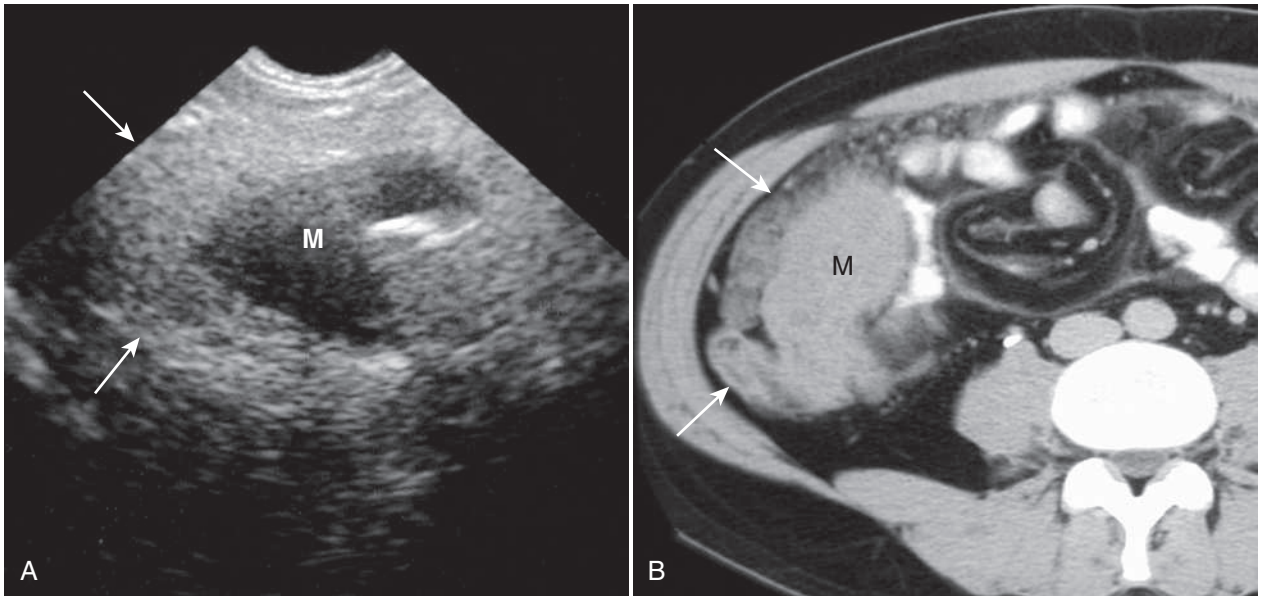

FIG. 14.28 Non-Hodgkin Lymphoma of the Peritoneum. (A) Transverse ultrasound image and **(B)** axial CT image of the right lower quadrant show a mass *(M)* displacing bowel loops medially. Infiltrated fat *(arrows)* is seen lateral to the mass as echogenic mass effect on the sonogram.

Most cases of **infective peritonitis** are **bacterial, secondary to complications** of disease processes involving intraabdominal organs. Common causes include bowel necrosis secondary to ischemia, perforated appendicitis, perforated diverticulitis, perforated duodenal ulcer, inflammatory bowel disease, and postoperative leaks. Culture of the exudate generally reveals a mixed flora in this setting, with gram-negative bacilli and anaerobes predominating.

Primary or **spontaneous bacterial peritonitis** occurs much less often, predominantly in association with cirrhosis and nephrotic syndrome. The clinical findings are often subtle, and correct diagnosis requires a high index of suspicion. Spontaneous bacterial peritonitis should be considered in any cirrhotic patient with ascites, fever, and an unexplained clinical deterioration. Culture of the ascitic fluid will characteristically reveal a single organism, usually *Escherichia coli.*

The sonographic appearance of infective peritonitis varies but may include particulate ascites (Fig. 14.30A), loculated ascites, or ascitic fluid containing septations (Fig. 14.31), debris, or gas.[57] Diffuse thickening of the parietal and visceral peritoneum (Fig. 14.30B), mesentery, and omentum may also be observed, and heterogeneous exudate may be seen interposed between bowel loops.

Peritonitis secondary to viruses, fungi, or parasites is rare and usually occurs in immunocompromised patients (Fig. 14.32) or patients on continuous ambulatory peritoneal dialysis. **Echinococcal disease** may involve the peritoneum.[58] A hepatic or splenic cyst may rupture, resulting in diffuse seeding of the peritoneal cavity. Ultrasound may reveal one or more of the typical appearances of hydatid cysts, including daughter cysts, the sonographic "water lily" sign, or multiple, closely folded echogenic membranes within the cyst cavity.

Abscess

Abscesses may occur at the site of a localized perforation or may result from delayed treatment of peritonitis, in which case they often develop in dependent areas of the abdomen and pelvis. The subphrenic or subhepatic spaces and the pouch of Douglas are common locations. Ultrasound is often limited in detecting intraabdominal abscesses, particularly in postoperative patients. These patients are less mobile because of their recent surgery and frequently have open wounds and dressings, limiting access for the ultrasound probe. In addition, visibility is often limited by extensive bowel gas, a result of paralytic ileus. In this setting, it may prove extremely difficult to distinguish between a dilated, aperistaltic, fluid-filled or gas-filled bowel loop and an extraluminal abscess collection.

Recognized features of intraabdominal abscesses include round or oval fluid collections with well-defined and irregular walls. They usually contain internal debris and septations (Figs.14.33 and 14.34) and occasionally small pockets of gas that appear as echogenic foci with ultrasound, often with posterior reverberation artifact. The presence of gas within a collection is virtually diagnostic of infection.[59] Ultrasound-guided or CT-guided percutaneous drainage is generally the treatment of choice, and follow-up sonographic examinations are helpful at assessing response to therapeutic intervention.

Tuberculous Peritonitis

Tuberculosis (TB) is still prevalent in developing countries, with a recent resurgence in the developed world, particularly among **AIDS** patients and immigrant populations.[60] Other groups at risk include patients with **alcoholism** and **cirrhosis.** Of all non-AIDS patients with TB, extrapulmonary disease occurs in only

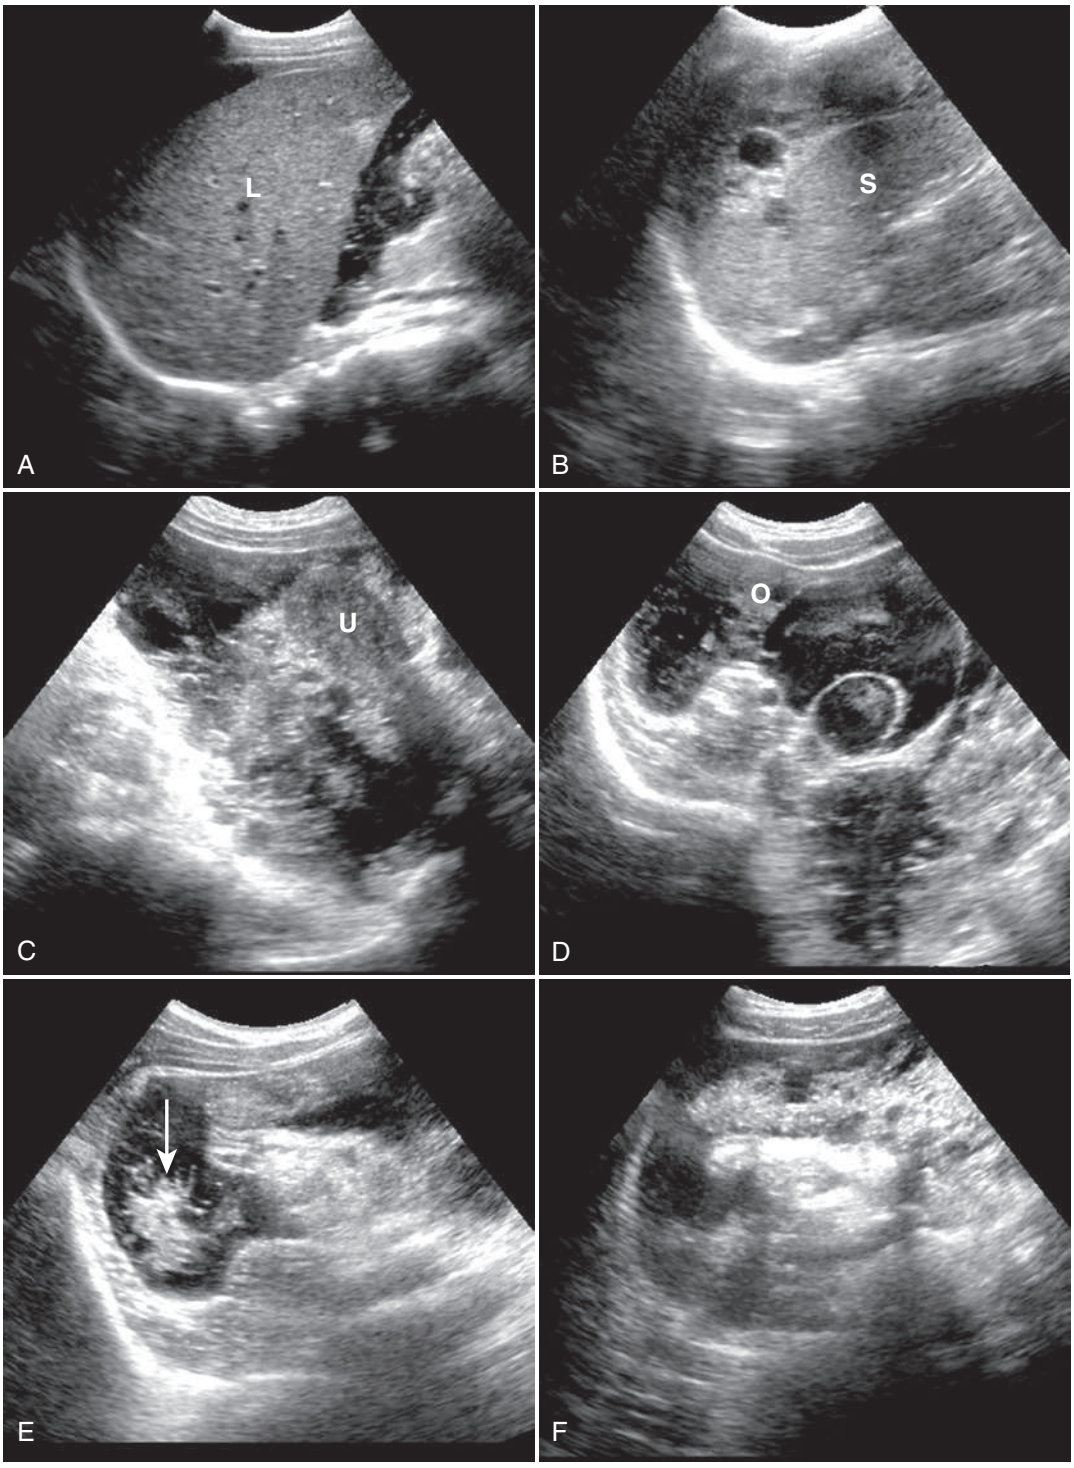

FIG. 14.29 Pseudomyxoma Peritonei. (A) Sagittal ultrasound image of the right upper quadrant shows complex fluid surrounding the liver *(L)* shows very mild and subtle scalloping of the deep border of the liver. **(B)** Sagittal ultrasound image of the left upper quadrant shows the spleen *(S)* surrounded by highly complex and echogenic fluid. The echogenic components of the fluid do not move with gravity. There is an indentation on the convexity of the spleen where the peritoneal process appears to invaginate the splenic parenchyma. **(C)** Sagittal transabdominal pelvic sonogram shows a normal anteverted uterus *(U)*. The pouch of Douglas is filled with highly complex fluid. **(D)** Oblique sagittal ultrasound image of the right abdomen at the pelvic brim shows a thin-walled intraperitoneal cyst with intracystic septations. This is not within the normal appearing right ovary *(O)*. The normal left ovary was seen elsewhere. **(E)** Transverse image in the right paracolic gutter shows a "starburst" within the fluid *(arrow)*. This is associated, in our experience, with the presence of mucin in the peritoneal cavity. **(F)** Highly echogenic plaque-like structure anteriorly represents a very thick and abnormal omentum, an "omental cake." There are hypoechoic nodules within the cake that are highly suggestive of tumor deposits. (Reproduced from Wilson SR. Pseudomyxoma peritonei. In: Cohen HL, editor. Gastrointestinal disease, test and syllabus. Reston, VA: American College of Radiology; 2004. pp. 73-84.[28])

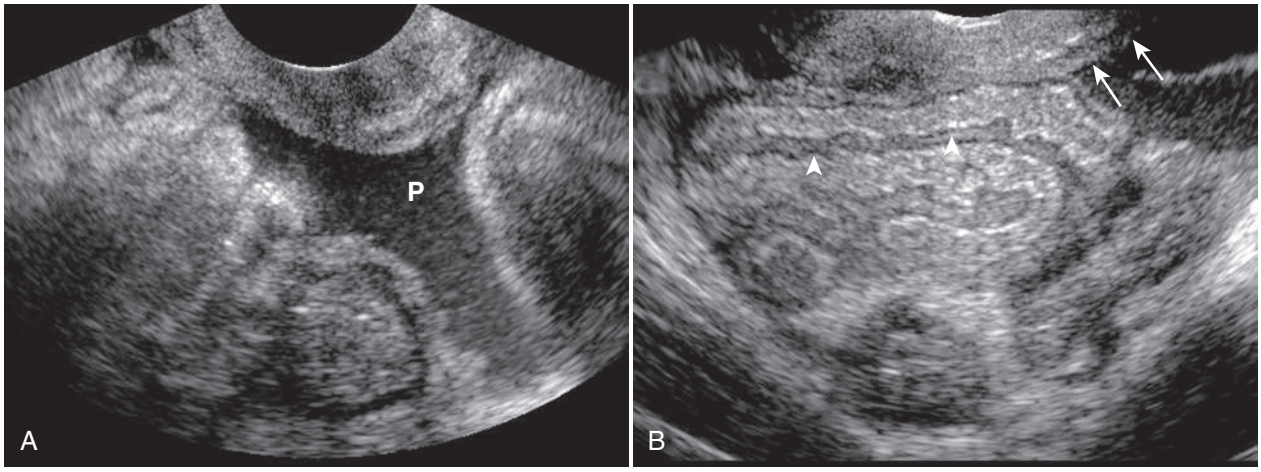

FIG. 14.30 Suppurative Peritonitis. (A) Transverse TVS of the pouch of Douglas shows particulate free fluid (P). **(B)** Transverse TVS more anteriorly in the pelvis shows diffuse thickening of both the parietal *(arrows)* and the visceral *(arrowheads)* peritoneum. An S-shaped small bowel loop is seen meandering through the thickened visceral peritoneum.

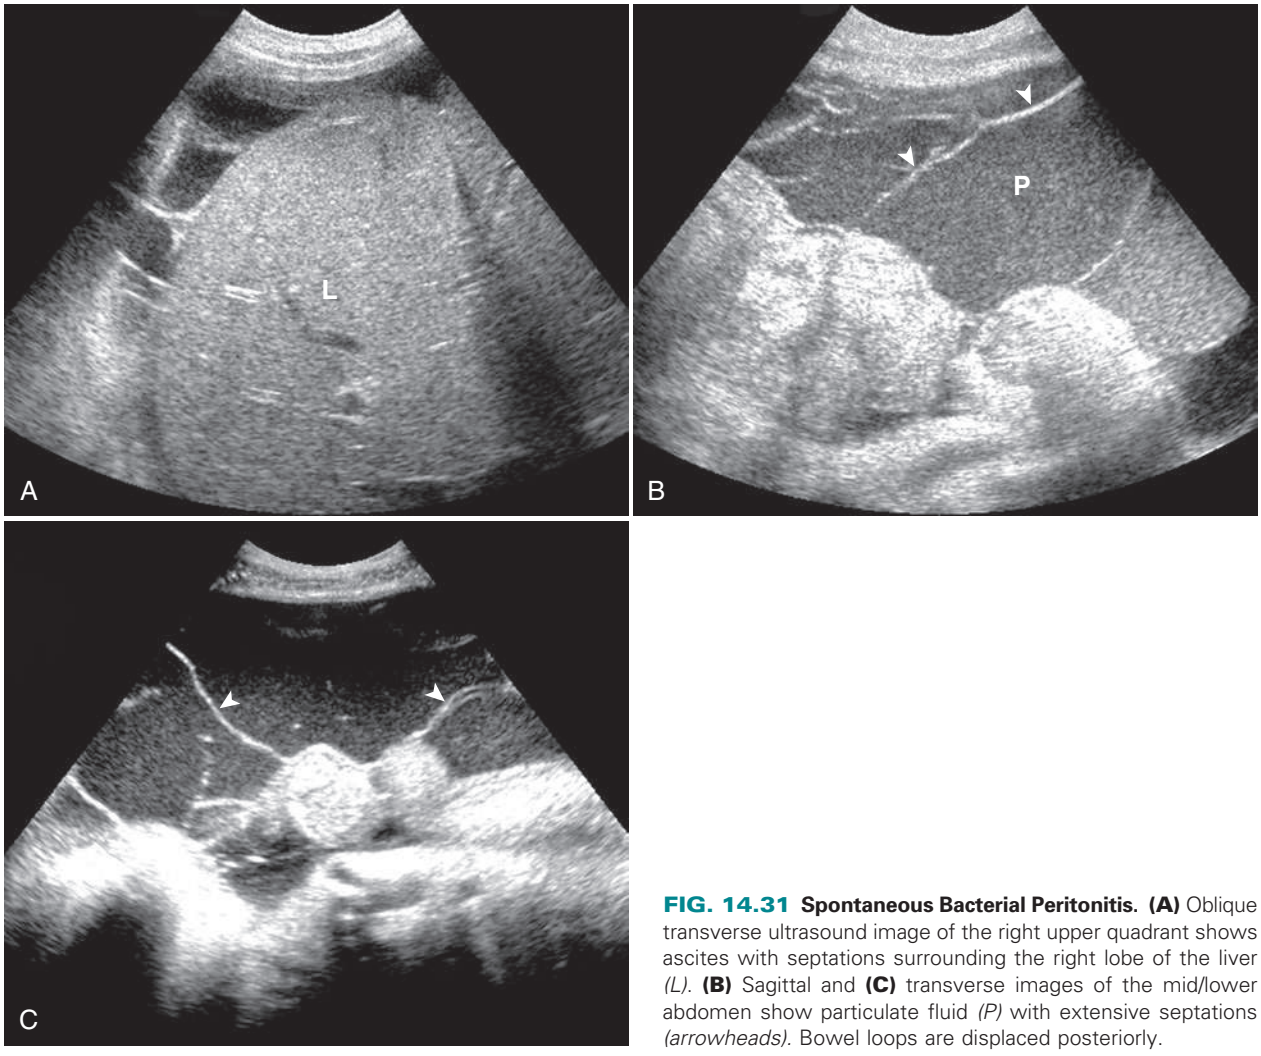

FIG. 14.31 Spontaneous Bacterial Peritonitis. (A) Oblique transverse ultrasound image of the right upper quadrant shows ascites with septations surrounding the right lobe of the liver *(L)*. **(B)** Sagittal and **(C)** transverse images of the mid/lower abdomen show particulate fluid *(P)* with extensive septations *(arrowheads)*. Bowel loops are displaced posteriorly.

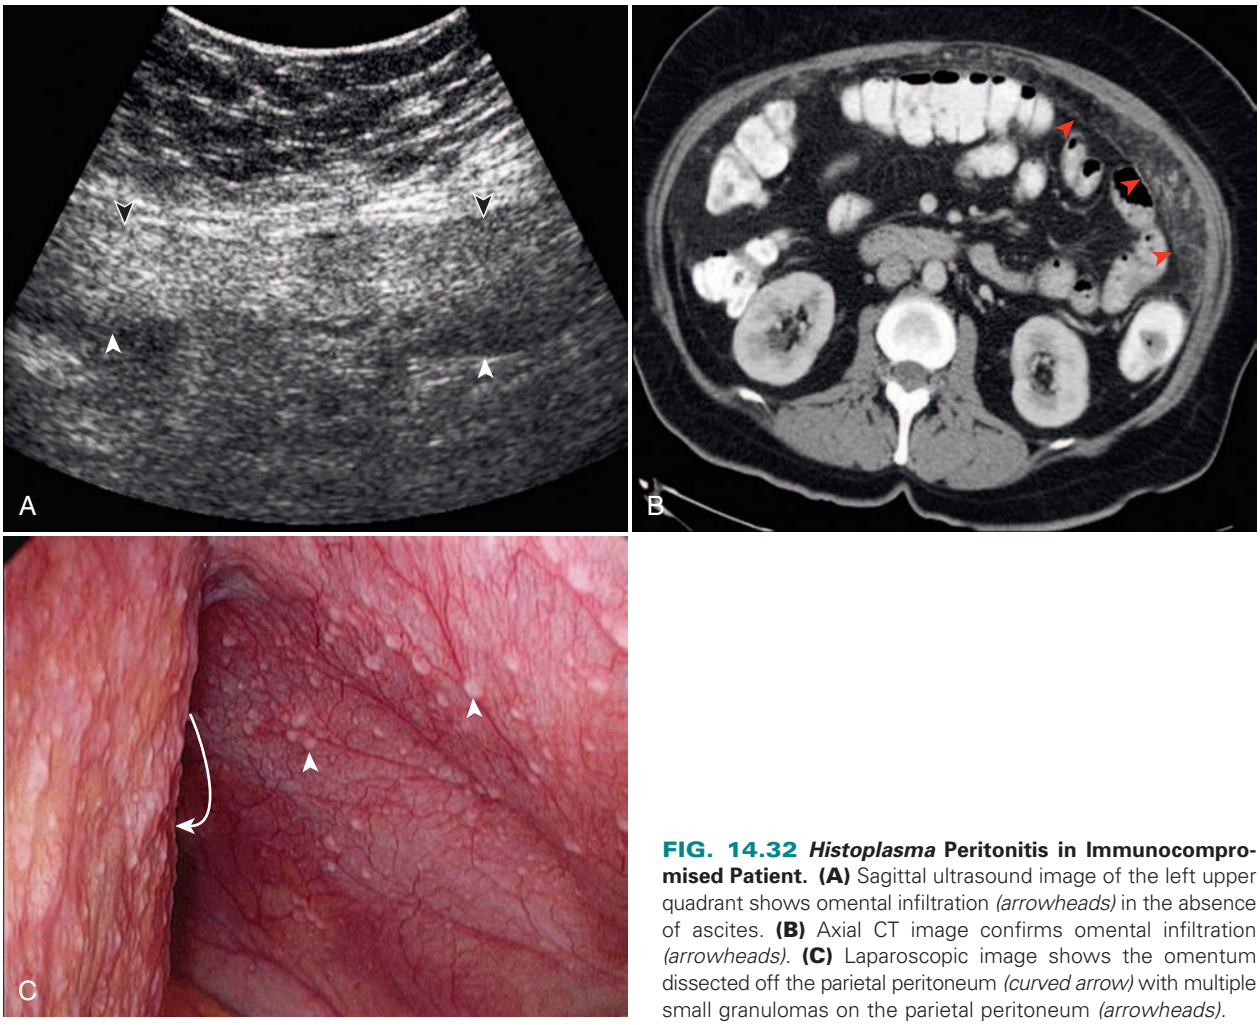

FIG. 14.32 *Histoplasma* Peritonitis in Immunocompromised Patient. (A) Sagittal ultrasound image of the left upper quadrant shows omental infiltration *(arrowheads)* in the absence of ascites. **(B)** Axial CT image confirms omental infiltration *(arrowheads)*. **(C)** Laparoscopic image shows the omentum dissected off the parietal peritoneum *(curved arrow)* with multiple small granulomas on the parietal peritoneum *(arrowheads)*.

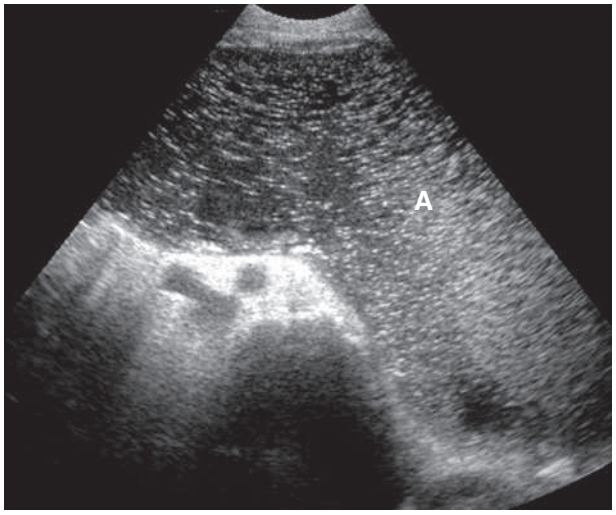

FIG. 14.33 Abscess. Transverse ultrasound image of the midabdomen shows a large abscess collection *(A)*.

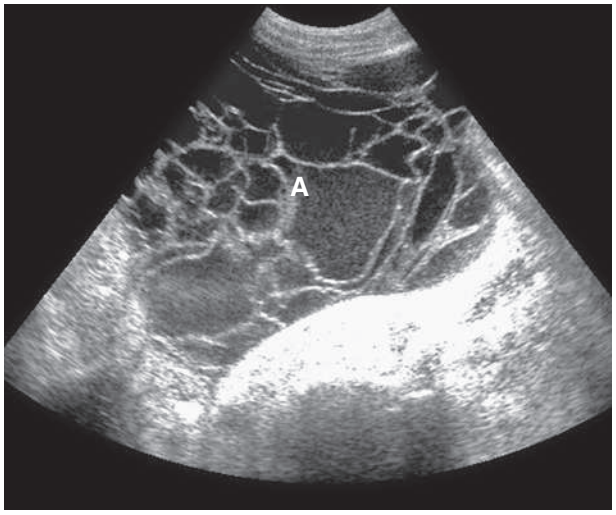

FIG. 14.34 Abscess. Sagittal ultrasound image of the right lower quadrant shows a large abscess collection with internal septations *(A)*.

10% to 15%; this increases to more than 50% in AIDS patients.[61] The peritoneum is a common site of extrapulmonary involvement,[62] but the chest radiograph will show evidence of pulmonary TB in only 14% of these patients. Therefore a high index of suspicion, particularly in high-risk groups, and knowledge of the common sonographic features allow for earlier diagnosis of this potentially curable disease, thus reducing morbidity and mortality.

There are no pathognomonic sonographic features for **TB peritonitis** but, in the proper clinical setting, a diffuse peritoneal process may strongly suggest the diagnosis. Ascites is frequently present and may be free or loculated. It may be anechoic or more frequently particulate and may contain fine, mobile strands composed of fibrin. These strands may produce a latticelike pattern. Irregular and nodular hypoechoic thickening of the peritoneum, mesentery, and omentum is another feature (Fig. 14.35).[63] Associated **lymphadenopathy** in the mesentery and retroperitoneum is a common feature and is more common than in peritoneal carcinomatosis.[64-66] The nodes may be discrete or conglomerate because of periadenitis. Caseation may give rise to a hypoechoic center within the node, although a similar appearance can be seen with metastatic lymph nodes undergoing necrosis. Echogenic nodes caused by fat deposition may suggest the diagnosis of TB. Sonographic assessment of the solid viscera may show involvement, particularly hypoechoic masses in the spleen. Ultrasound helps guide diagnostic paracentesis in TB peritonitis and may also guide fine-needle aspiration of enlarged nodes.[67] Sonography can also readily document response to treatment.

Sclerosing Peritonitis

Sclerosing peritonitis is a major complication of **continuous ambulatory peritoneal dialysis** and is characterized by the formation of a connective tissue membrane covering the peritoneum and eventually encasing and strangulating bowel loops.[68,69] Patients initially complain of abdominal pain and loss of ultrafiltration. Ultimately, bowel obstruction occurs. Surgery is often difficult in these patients, and the prognosis is poor. Early diagnosis of sclerosing peritonitis may be important in reducing mortality.

Ultrasound is extremely helpful in the diagnosis.[70] Increased peristalsis in multiple bowel loops is one of the earliest findings in sclerosing peritonitis. Ascites, both free and loculated, is common. With time, the fluid becomes more complex with **stranding** (Fig. 14.36). Bowel loops become matted together and are tethered to the posterior abdominal wall by a characteristic enveloping membrane. This membrane can be seen with ultrasound as a uniformly echogenic layer measuring 1 to 4 mm in thickness.

LOCALIZED INFLAMMATORY PROCESS OF PERITONEAL CAVITY

The CT appearance and significance of inflamed peritoneal fat are familiar to sonographers. If ultrasound is to be successful at investigating patients with abdominal symptoms, the sonographic appearance of inflamed fat must become just as familiar.

Inflamed perienteric fat appears as an echogenic "mass effect," with ultrasound frequently displacing bowel loops out of the scanning plane. Compression sonography may greatly enhance the detection of focally inflamed fat, and gentle palpation with the transducer over this area will frequently show that it is the site of the patient's maximal tenderness. Frequently, an associated underlying abnormality, such as an abnormal bowel segment, can be identified with ultrasound[71] (Fig. 14.37). **Appendicitis** and **diverticulitis** are the most common acute processes giving rise to focally inflamed fat. Other possibilities include inflammatory bowel disease, pancreatitis, and complicated acute cholecystitis. Progression to phlegmon typically shows development of a hypoechoic region within the echogenic fat without fluid content (Fig. 14.38). If untreated, this may progress to abscess formation. Color Doppler imaging frequently shows increased blood flow in the area of inflammation.[72]

RIGHT-SIDED SEGMENTAL OMENTAL INFARCTION

Right-sided segmental omental infarction is a rare clinical entity that usually presents with right-sided abdominal pain and is often mistaken for appendicitis. It is important to make the correct diagnosis because the condition is self-limiting and resolves spontaneously with supportive measures. Omental infarction occurs in all age groups and is thought to result from an embryologic variant in the blood supply to the right inferior portion of the omentum, leaving it prone to infarction. Precipitating factors include straining and eating a large meal.

Ultrasound reveals an echogenic, ovoid, or cakelike mass in the right midabdomen at the site of the patient's tenderness[73,74] (Fig. 14.39). Careful assessment will reveal no underlying bowel abnormality. The typical location of right-sided omental infarction is anterolateral to the hepatic flexure of the colon, and it corresponds to a circumscribed fatty mass on CT, with areas of stranding. The mass often adheres to the parietal peritoneum, with bowel moving deep to it on respiration.

ENDOMETRIOSIS

Endometriosis is a common condition affecting predominantly premenopausal women and occurs when functional endometrium is located outside of the uterus. Patients may be asymptomatic but frequently present with pelvic pain, dyspareunia, or infertility. The ovaries and suspensory ligaments of the uterus are the sites most often affected, but endometriotic implants can involve the bowel, urinary bladder, peritoneum, chest, or soft tissues.[75]

Sonographic evaluation is often normal in patients with endometriosis. If **endometriomas** are present, TVS is very sensitive at detecting and characterizing the masses, often showing the typical "chocolate" cysts with uniform, low-level internal echoes (Fig. 14.40, Video 14.8). There may be associated complex free fluid with stranding. Occasionally, tiny echogenic foci may be identified along the pelvic peritoneal surfaces. These foci are not specific for endometriosis and may also be seen with serous papillary ovarian neoplasms. Clinical correlation is essential,

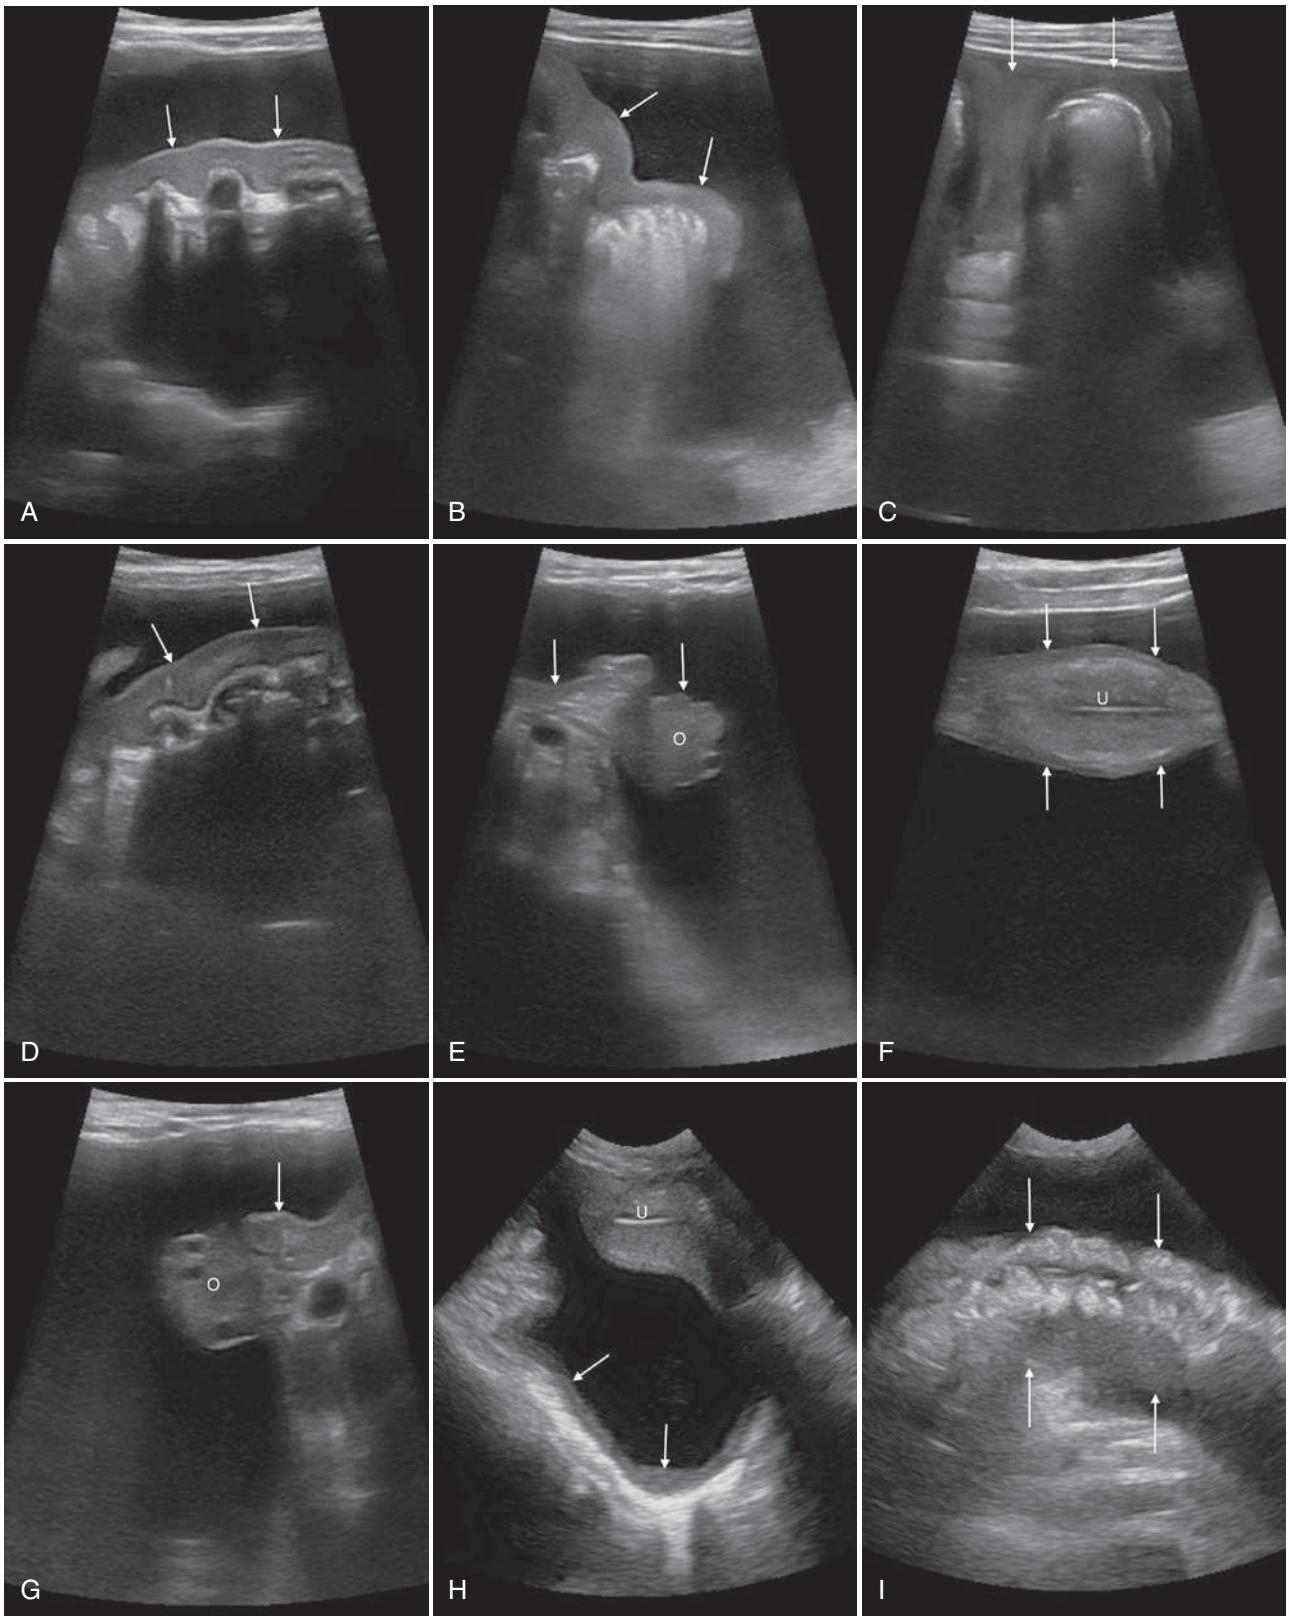

FIG. 14.35 Tuberculous Peritonitis. (A)-(D) Ultrasound images show a large volume of free fluid and striking smooth, hypoechoic, plaque-like thickening of the visceral peritoneum *(arrows)*. **(E)-(G)** Transverse ultrasound images of the pelvis show a large volume of free fluid surrounding the uterus *(U)* and ovaries *(O)*. Note smooth hypoechoic thickening of the peritoneum *(arrows)*. **(H)** Sagittal ultrasound image of the midpelvis with a large field of view shows the uterus *(U)*, a large volume of free fluid and hypoechoic thickening of the parietal peritoneum *(arrows)*. **(I)** Sagittal ultrasound image of the midabdomen shows a markedly thickened and heterogeneous omentum *(arrows)* and free fluid.

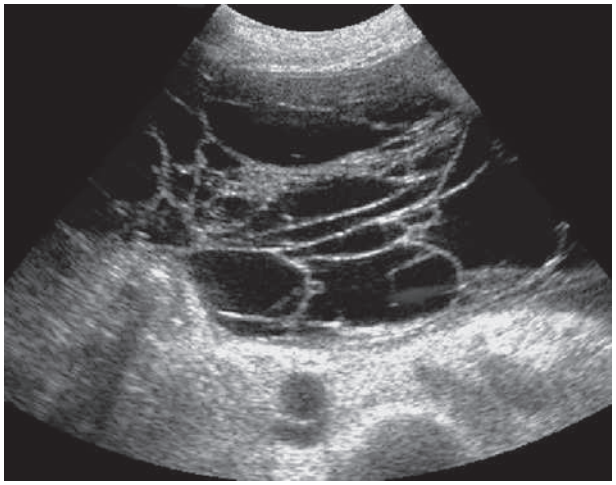

FIG. 14.36 Sclerosing Peritonitis. Transverse ultrasound image of the midabdomen shows extensive, complex, septated ascites.

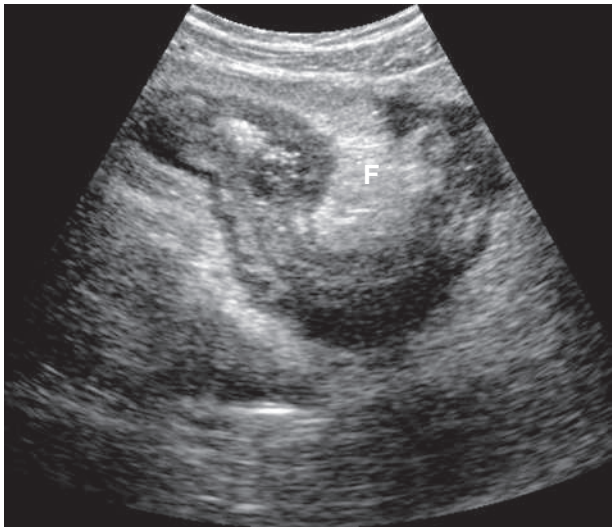

FIG. 14.37 Inflamed Fat. Transverse ultrasound image of the right lower quadrant shows echogenic inflamed fat *(F)* associated with a long segment of thickened terminal ileum in patient with Crohn disease.
